Biologists have documented trade-offs between the size of eggs or seeds that an individual makes and the number of offspring it can produce, between rapid growth and long life span, and between bright coloration and tendency to attract predators. The message of this research is simple: Because selection acts on many traits at once, every adaptation is a compromise.

Historical Constraints In addition to being constrained by genetic correlations, lack of genetic variation, and fitness trade-offs, adaptations are constrained by history. The reason is simple: All traits have evolved from previously existing traits.

Natural selection acts on structures that originally had a very different function. For example, the tiny incus, malleus, and stapes bones found in your middle ear evolved from bones that were part of the jaw and jaw support in the ancestors of mammals. These bones now function in transmitting and amplifying sound from your outer ear to your inner ear. Biologists routinely interpret these bones as adaptations that improve your ability to hear airborne sounds. But are the bones a "perfect" solution to the problem of transmitting sound from the outside of the ear to the inside? The answer is no. They are the best solution possible, given an important historical constraint. Other vertebrates have different structures involved in transmitting sound to the ear. In at least some cases, those structures may be more efficient than our incus, malleus, and stapes.

To summarize, not all traits are adaptive, and even adaptive traits are constrained by genetic and historical factors. In addition, natural selection is not the only process that causes evolutionary change. Three other processes—genetic drift, gene flow, and mutation—change allele frequencies over time (see Chapter 26). Compared with natural selection, these processes have very different consequences. You can see the Big Picture of how natural selection relates to other evolutionary processes on pages 526–527.

CHAPTER 25 REVIEW

If you understand . . .

25.1 The Evolution of Evolutionary Thought

- Plato, Aristotle, and the Bible's book of Genesis consider species as unchanging types. This view is called typological thinking.
- Lamarck proposed a theory of evolution—that species are not static but change through time. He proposed that evolution occurs by the inheritance of acquired characteristics.
- Darwin and Wallace proposed that evolution occurs by natural selection. This was the beginning of population thinking, whereby variation among individuals is the key to understanding evolution.

✔ **You should be able to compare and contrast typological thinking and population thinking.**

25.2 The Pattern of Evolution: Have Species Changed, and Are They Related?

- Data on **(1)** the age of the Earth and the fact of extinction; **(2)** the resemblance of modern to fossil forms; **(3)** transitional features in fossils; **(4)** the presence of vestigial traits; and **(5)** change in contemporary populations show that species change through time.
- Data on **(1)** the geographic proximity of closely related species; **(2)** the existence of structural, developmental, and genetic homologies; and **(3)** the contemporary formation of new species support the consensus that species are related by common ancestry.
- Evidence for evolution is internally consistent, meaning that data from several independent sources are mutually reinforcing.

✔ **You should be able to cite examples in support of the statement that species have changed through time and are related by common ancestry.**

25.3 The Process of Evolution: How Does Natural Selection Work?

- Darwin developed four postulates that outline the process of evolution by natural selection. These postulates can be summarized by the following statement: Heritable variation leads to differential reproductive success.
- Alleles or traits that increase the reproductive success of an individual are said to increase the individual's fitness. A trait that leads to higher fitness, relative to individuals without the trait, is an adaptation. If a particular allele increases fitness and leads to adaptation, the allele will increase in frequency in the population.

✔ **You should be able to explain the difference between the biological and everyday English definitions of fitness.**

25.4 Evolution in Action: Recent Research on Natural Selection

- Selection by drugs on the TB bacterium and changes in the size and shape of finch beaks in the Galápagos as a result of seed availability are well-studied examples of evolution by natural selection.
- Both examples demonstrate that evolution can be observed and measured. Evolution by natural selection has been confirmed by a wide variety of studies and has long been considered to be the central organizing principle of biology.

✔ **You should be able to predict how changes in *Mycobacterium tuberculosis* populations would be explained under special creation and under evolution by inheritance of acquired characters.**

25.5 Common Misconceptions about Natural Selection and Adaptation

- Natural selection acts on individuals, but evolutionary change occurs in populations. Nonheritable changes that occur in individuals are not adaptations and do not result in evolution.
- Evolution is not goal directed and does not lead to perfection. There is no such thing as a higher or lower organism.
- Organisms do not act for the good of the species.
- Not all traits are adaptive, and even adaptive traits are limited by genetic and historical constraints.

✔ **You should be able to discuss how adaptations such as the large brains of *Homo sapiens* and the ability of falcons to fly very fast are constrained.**

TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. How can biological fitness be estimated?
   a. Document how long different individuals in a population survive.
   b. Count the number of healthy, fertile offspring produced by different individuals in a population.
   c. Determine which individuals are strongest.
   d. Determine which phenotype is the most common one in a given population.
2. True or false? Some traits are considered vestigial because they existed long ago.
3. What is an adaptation?
   a. a trait that improves the fitness of its bearer, compared with individuals without the trait
   b. a trait that changes in response to environmental influences within the individual's lifetime
   c. an ancestral trait—one that was modified to form the trait observed today
   d. the ability to produce offspring
4. Why does the presence of extinct forms and transitional features in the fossil record support the pattern component of the theory of evolution by natural selection?
   a. It supports the hypothesis that individuals change over time.
   b. It supports the hypothesis that weaker species are eliminated by natural selection.
   c. It supports the hypothesis that species evolve to become more complex and better adapted over time.
   d. It supports the hypothesis that species change over time.
5. Traits that are derived from a common ancestor, like the bones of human arms and bird wings, are said to be _____.
6. According to data presented in this chapter, which of the following statements is correct?
   a. When individuals change in response to challenges from the environment, their altered traits are passed on to offspring.
   b. Species are created independently of each other and do not change over time.
   c. Populations—not individuals—change when natural selection occurs.
   d. The traits of populations become more perfect over time.

TEST YOUR UNDERSTANDING

Answers are available in Appendix A

7. Some biologists summarize evolution by natural selection with the phrase "mutation proposes, selection disposes." Mutation is a process that creates heritable variation. Explain what the phrase means.

8. Explain how artificial selection differs from natural selection.

9. Why don't the biggest and strongest individuals in a population always produce the most offspring?
a. The biggest and strongest individuals always have higher fitness.
b. In some environments, being big and strong lowers fitness.
c. Sometimes the biggest and strongest individuals may choose to have fewer offspring.
d. Sometimes the number of offspring is not related to fitness.

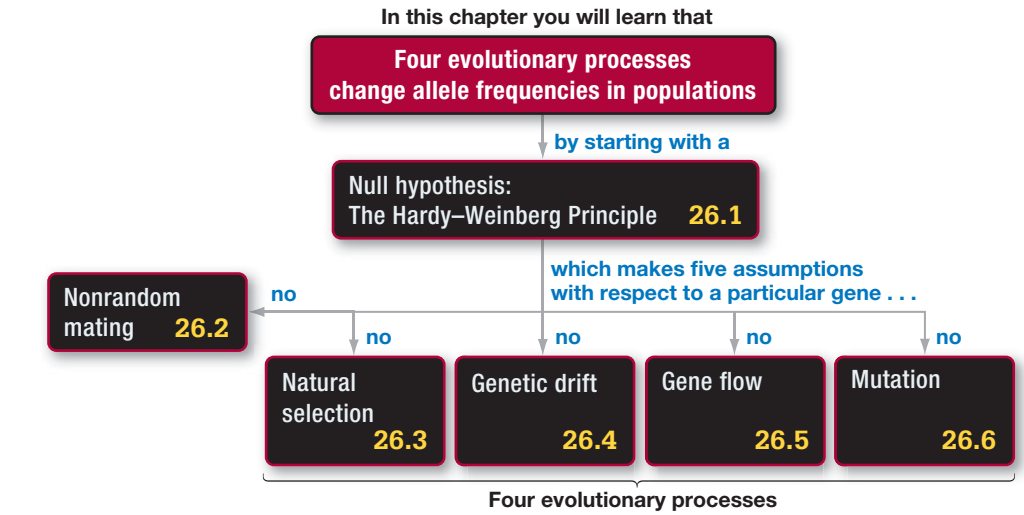
10. **QUANTITATIVE** The graphs in Figure 25.16 show that the average beak depth of medium ground finches increased after the drought. However, more finches had deep beaks before the drought than after. Explain this seeming contradiction by calculating the percent of finches that survived the drought.

11. Review the section on the evolution of drug resistance in *Mycobacterium tuberculosis*.
- What evidence do researchers have that a drug-resistant strain evolved in the patient analyzed in their study, and wasn't instead transmitted from another infected individual?
- If the antibiotic rifampin were banned, would the mutant *rpoB* gene have lower or higher fitness in the new environment? Would strains carrying the mutation continue to increase in frequency in *M. tuberculosis* populations?

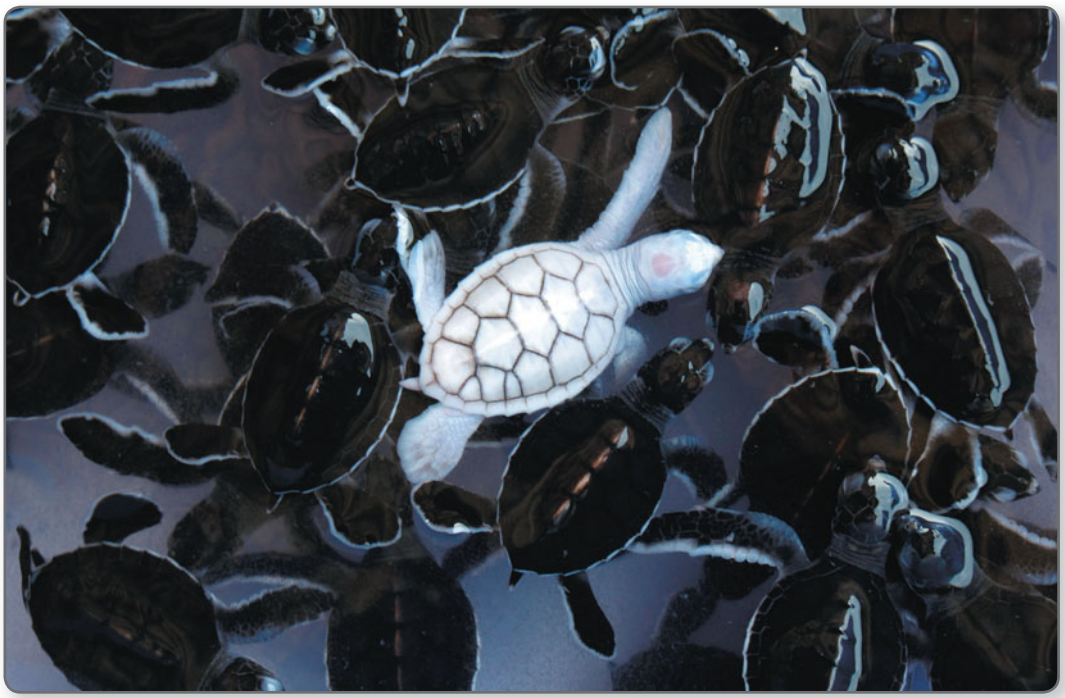
12. Describe how Darwin's four postulates would apply to a population of rabbits sharing a meadow with foxes.

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A



13. Scientists have observed white deer mice living on coastal beaches in Florida and brown deer mice living in nearby forests. Compare and contrast how the theory of evolution by natural selection, special creation, and evolution by inheritance of acquired characters might explain this observation.



14. The average height of humans in industrialized nations has increased steadily for the past 100 years. This trait has clearly changed over time. Most physicians and human geneticists hypothesize that the change is due to better nutrition and a reduced incidence of disease. Has human height evolved?
a. Yes, because average height has changed over time.
b. No, because changes in height due to nutrition and reduced incidence of disease are not heritable.
c. Yes, because height is a heritable trait.
d. No, because height is not a heritable trait.

15. Scientists hypothesize that humans and chimpanzees diverged from a common ancestor that lived in Africa about 6–7 million years ago. What evidence would support this hypothesis?

16. The geneticist James Crow wrote that successful scientific theories have the following characteristics: (1) They explain otherwise puzzling observations; (2) they provide connections between otherwise disparate observations; (3) they make predictions that can be tested; and (4) they are heuristic, meaning that they open up new avenues of theory and experimentation. Crow added two other elements of scientific theories that he considered important on a personal, emotional level: (5) They should be elegant, in the sense of being simple and powerful; and (6) they should have an element of surprise. How well does the theory of evolution by natural selection fulfill these six criteria?

26 Evolutionary Processes

This albino sea turtle carries rare alleles that prevent pigment formation. The frequency of these alleles changes in the sea turtle population over time due to the evolutionary processes discussed in this chapter.

Since evolution is one of the five key attributes of life, understanding evolutionary processes is essential to understanding living things. How did the diversity of organisms around us (including us) come to be?

It turns out that natural selection (see Chapter 25) is only one of four processes that can shift allele frequencies in populations over time, causing evolution:

1. ***Natural selection*** increases the frequency of certain alleles—the ones that contribute to reproductive success in a particular environment. Natural selection is the only one of the four processes that leads to adaptation.
2. ***Genetic drift*** causes allele frequencies to change randomly. In some cases, drift may cause alleles that decrease fitness to increase in frequency.

BIG PICTURE

This chapter is part of the Big Picture. See how on pages 526–527.

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

3. ***Gene flow*** occurs when individuals leave one population, join another, and breed. Allele frequencies may change when gene flow occurs, because arriving individuals introduce alleles to their new population and departing individuals remove alleles from their old population.

4. ***Mutation*** modifies allele frequencies by continually introducing new alleles. The alleles created by mutation may be beneficial or deleterious (detrimental) or have no effect on fitness.

This chapter has two fundamental messages: Natural selection is not the only agent responsible for evolution, and each of the four evolutionary processes has different consequences for genetic variation and fitness.

The first few decades of the 1900s were pivotal for the study of evolutionary processes. Biologists began to apply Mendelian genetics (Chapter 14) to Darwinian evolution (Chapter 25), resulting in an era known as the Modern Synthesis. Evolutionary biologists, mathematicians, and geneticists collaborated to make huge leaps in *quantifying* evolution. One product of this era was a model called the **Hardy–Weinberg principle,** which serves as a mathematical null hypothesis for the study of evolutionary processes. Let's examine the logic of this model and then consider each of the four evolutionary processes in turn.

26.1 Analyzing Change in Allele Frequencies: The Hardy–Weinberg Principle

In 1908, a British mathematician, G. H. Hardy, and a German doctor, Wilhelm Weinberg, each published a major result independently. At the time, it was commonly believed that changes in allele frequency occur simply as a result of sexual reproduction—meiosis followed by the random fusion of gametes (eggs and sperm) to form offspring. Some biologists claimed that dominant alleles inevitably increase in frequency when gametes combine at random. Others predicted that two alleles of the same gene inevitably reach a frequency of 0.5.

To test these hypotheses, Hardy and Weinberg analyzed the frequencies of alleles when many individuals in a population mate and produce offspring. Instead of thinking about the consequences of a mating between two parents with a specific pair of genotypes (as you did with Punnett squares in Chapter 14), Hardy and Weinberg wanted to know what happened in an entire population when *all* of the individuals—and thus all possible genotypes—bred.

Like Darwin, Hardy and Weinberg were engaged in population thinking. A **population** is a group of individuals from the same species that live in the same area at the same time and can interbreed—and that vary in the traits they possess (Chapter 25).

The Gene Pool Concept

To analyze the consequences of matings among all of the individuals in a population, Hardy and Weinberg invented a novel approach: They imagined that all of the alleles from all the gametes produced in each generation go into a single group called the **gene pool** and then combine at random to form offspring. Something similar to this happens in species like clams and sea stars, which release their gametes into the water where the gametes mix randomly before combining to form zygotes.

To determine which genotypes would be present in the next generation and in what frequencies, Hardy and Weinberg calculated what happens when two gametes are plucked at random out of the gene pool, many times, and each of these gamete pairs then combines to form offspring. These calculations predict the genotypes of the offspring that would be produced, as well as the frequency of each genotype.

Quantitative Methods 26.1 walks through Hardy's and Weinberg's calculations by focusing on just one gene with two alleles, A_1 and A_2. The letter p is used to symbolize the frequency of A_1 alleles in the gene pool, and q is used to symbolize the frequency of A_2 alleles in the same gene pool. **FIGURE 26.1** illustrates the same calculations a little differently. The figure uses a Punnett square to predict the outcome of random mating—meaning, random combinations of all gametes in a population. (Recall that in Chapter 14 you used Punnett squares to predict the outcome of a mating between two individuals.) The outcome of this analysis is the same as in Quantitative Methods 26.1.

The resulting Hardy–Weinberg principle makes two fundamental claims:

1. If the frequencies of alleles A_1 and A_2 in a population are given by p and q, then the frequencies of genotypes A_1A_1,

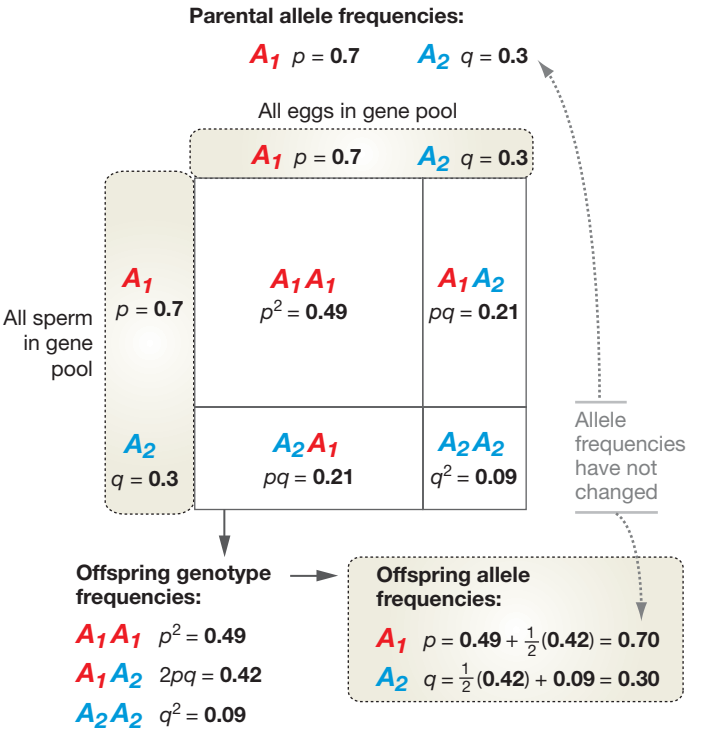


FIGURE 26.1 A Punnett Square Illustrates the Hardy–Weinberg Principle.

QUANTITATIVE METHODS 26.1 Deriving the Hardy–Weinberg Principle

Hardy and Weinberg began by analyzing the simplest situation possible—where just two alleles of a particular gene exist in a population. Let's call these alleles A_1 and A_2. The letter p is used to symbolize the frequency of A_1 alleles in the gene pool and q is used to symbolize the frequency of A_2 alleles in the same gene pool. Because there are only two alleles, the two frequencies must add up to 1:

$$p + q = 1$$

Now follow the steps in **FIGURE 26.2**:

Parental Allele Frequencies

Although p and q can have any value between 0 and 1, let's suppose that the initial frequency of A_1 is 0.7 and that of A_2 is 0.3. In this gene pool, 70 percent of the gametes carry A_1 and 30 percent carry A_2.

Offspring Genotype Frequencies

Each time a gamete is involved in forming an offspring, there is a 70 percent chance that it carries A_1 and a 30 percent chance that it carries A_2. In general, there is a p chance that it carries A_1 and a q chance that it carries A_2.

Because only two alleles are present, three genotypes are possible in the offspring generation: A_1A_1, A_1A_2, and A_2A_2. What will the frequency of these three genotypes be? According to the logic of Hardy's and Weinberg's result:

- Frequency of the A_1A_1 genotype: p^2
- Frequency of the A_1A_2 genotype: $2pq$
- Frequency of the A_2A_2 genotype: q^2

The genotype frequencies in the offspring generation must add up to 1, which means that:

$$p^2 + 2pq + q^2 = 1$$

In this numerical example:

$$0.49 + 0.42 + 0.09 = 1$$

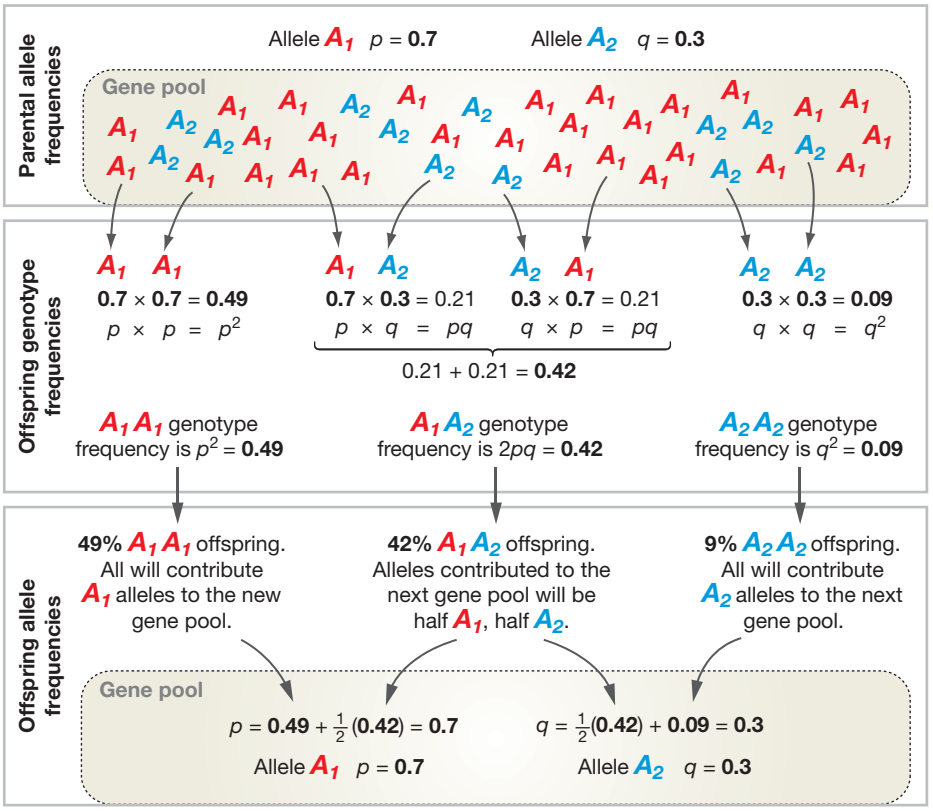

FIGURE 26.2 Deriving the Hardy–Weinberg Principle. To understand the logic behind calculating the frequency of A_1A_2 genotypes, see **BioSkills 5** in Appendix B.

Offspring Allele Frequencies

The easiest way to calculate the allele frequencies in the offspring is to imagine that they form gametes that go into a gene pool. All of the gametes from A_1A_1 individuals carry A_1, so 49 percent (p^2) of the gametes in the gene pool will carry A_1. But half of the gametes from A_1A_2 will also carry A_1, so an additional ½(0.42) = 0.21 (this is ½ × $2pq$ = pq) gametes in the gene pool will carry A_1, for a total of 0.49 + 0.21 = 0.70 or $p^2 + pq = p(p + q) = p$. Use the same logic to figure out the frequency of A_2.

In this example, the frequency of allele A_1 in the offspring generation is still 0.7 and the frequency of allele A_2 is still 0.3. Thus, the frequency of allele A_1 is still p and the frequency of allele A_2 is still q.

No change in allele frequency occurred. Even if A_1 is dominant to A_2, it does not increase in frequency. And there is no trend toward both alleles reaching a frequency of 0.5. This result is called the Hardy–Weinberg principle.

✔**QUANTITATIVE** **If you understand these calculations, you should be able to: (1) calculate the frequencies of the three offspring genotypes if $p = 0.6$ and $q = 0.4$ in the parental gene pool; (2) use your answer to calculate the allele frequencies in the offspring gene pool; (3) determine whether evolution occurred.**

A_1A_2, and A_2A_2 will be given by p^2, $2pq$, and q^2, respectively, for generation after generation. That is:

Allele frequencies: $p + q = 1$

Genotype frequencies: $p^2 + 2pq + q^2 = 1$

2. When alleles are transmitted via meiosis and random combinations of gametes, their frequencies do not change over time. For evolution to occur, some other factor or factors must come into play.

What are these other factors?

The Hardy–Weinberg Model Makes Important Assumptions

The Hardy–Weinberg model is based on important assumptions about how populations and alleles behave. These assumptions helped to define the four processes of evolution that can be acting on the population. In addition, the model assumes that mating is random with respect to the gene in question. Here are the five assumptions that must be met:

1. ***Random mating*** This condition was enforced by picking gametes from the gene pool at random. Individuals were not allowed to *choose* a mate.
2. ***No natural selection*** The model assumed that *all* members of the parental generation survived and contributed equal numbers of gametes to the gene pool, no matter what their genotype.
3. ***No genetic drift (random allele frequency changes)*** The model assumed that alleles were picked in their exact frequencies p and q, and not at some different values caused by chance—that is, the model behaved as though the population was infinitely large. For example, allele A_1 did not "get lucky" and get drawn more than 70 percent of the time.
4. ***No gene flow*** No new alleles were added by immigration or lost through emigration. As a result, all of the alleles in the offspring population came from the original population's gene pool.
5. ***No mutation*** The model didn't consider that new A_1s or A_2s or other, new alleles might be introduced into the gene pool.

The Hardy–Weinberg principle tells us what to expect if selection, genetic drift, gene flow, and mutation are not affecting a gene, *and* if mating is random with respect to that gene. Under these conditions, the genotypes A_1A_1, A_1A_2, and A_2A_2 should be in the Hardy–Weinberg proportions p^2, $2pq$, and q^2, respectively, and no evolution will occur.

How Does the Hardy–Weinberg Principle Serve as a Null Hypothesis?

Recall that a null hypothesis predicts there are no differences among the treatment groups in an experiment (see Chapter 1). Biologists often want to test whether nonrandom mating is occurring, natural selection is acting on a particular gene, or one of the other evolutionary processes is at work. In addressing questions like these, the Hardy–Weinberg principle functions as a null hypothesis.

Given a set of allele frequencies, the Hardy–Weinberg principle predicts what genotype frequencies will occur when mating is random with respect to that gene, and when natural selection, genetic drift, gene flow, and mutation are not affecting the gene. If biologists observe genotype frequencies that do not conform to the Hardy–Weinberg prediction, it means that something interesting is going on: Either nonrandom mating is occurring (which changes genotype frequencies but not allele frequencies), or allele frequencies are changing for some reason. Further research is then needed to determine which of the five Hardy–Weinberg conditions is being violated.

Let's consider two examples to illustrate how the Hardy–Weinberg principle is used as a null hypothesis: MN blood types and *HLA* genes, both in humans.

Case Study 1: Are MN Blood Types in Humans in Hardy–Weinberg Proportions? One of the first genes that geneticists could analyze in natural populations was the MN blood group of humans. Most human populations have two alleles, designated *M* and *N*, at this gene.

Because the *MN* gene codes for a protein found on the surface of red blood cells—the *M* allele codes for the M version, and the *N* allele codes for the N version—researchers could determine whether individuals are *MM, MN*, or *NN* by treating blood samples with antibodies to each protein (this technique was first introduced in Chapter 11). The *M* and *N* alleles are codominant—meaning that heterozygotes have both M and N versions of the protein on their red blood cells.

To estimate the frequency of each genotype in a population, geneticists obtain data from a large number of individuals and then divide the number of individuals with each genotype by the total number of individuals in the sample.

TABLE 26.1 shows *MN* genotype frequencies for populations from throughout the world and illustrates how observed genotype frequencies are compared with the genotype frequencies expected if the Hardy–Weinberg principle holds. The analysis is based on the following steps:

Step 1 Estimate genotype frequencies by observation—in this case, by testing many blood samples for the *M* and *N* alleles. These frequencies are given in the rows labeled "observed" in Table 26.1.

Step 2 Calculate observed allele frequencies from the observed genotype frequencies. In this case, the frequency of the *M* allele is the frequency of *MM* homozygotes plus half the frequency of *MN* heterozygotes; the frequency of the *N* allele is the frequency of *NN* homozygotes plus half the frequency of *MN* heterozygotes. (You can review the logic behind this calculation in Quantitative Methods 26.1.)

Step 3 Use the observed allele frequencies to calculate the genotypes expected according to the Hardy–Weinberg principle. Under the null hypothesis of random mating and no evolution, the expected genotype frequencies are $p^2 : 2pq : q^2$.

Step 4 Compare the observed and expected values. Researchers use statistical tests to determine whether the differences between the observed and expected genotype frequencies are small enough to be due to chance or large enough to reject the null hypothesis of no evolution and random mating.

Although using statistical testing is beyond the scope of this text (see **BioSkills 4** in Appendix B for a brief introduction to the topic), you should be able to inspect the numbers and comment on them. In these populations, for example, the observed and expected *MN* genotype frequencies are almost identical. (A statistical test shows that the small differences observed are probably due to chance.) For every population surveyed, genotypes

TABLE 26.1 The MN Blood Group of Humans: Observed and Expected Genotype Frequencies

The expected genotype frequencies are calculated from the observed allele frequencies, using the Hardy–Weinberg principle.

		Genotype Frequencies			Allele Frequencies	
Population and Location	**Data Type**	***MM***	***MN***	***NN***	***M***	***N***
Inuit (Greenland)	Observed	0.835	0.156	0.009	0.913	0.087
	Expected	0.834	0.159	0.008		
Native Americans (U.S.)	Observed	0.600	0.351	0.049	0.776	0.224
	Expected	0.602	0.348	0.050

✔**EXERCISE** Fill in the values for observed allele frequencies and expected genotype frequencies for the Ainu people of Japan.

at the *MN* gene are in Hardy–Weinberg proportions. As a result, biologists conclude that the assumptions of the Hardy–Weinberg model are valid for this locus.

The results imply that when these data were collected, the *M* and *N* alleles in these populations were not being affected by the four evolutionary processes and that mating was random with respect to this gene—meaning that humans were not choosing mates based on their *MN* genotype.

Before moving on, however, it is important to note that a study such as this does not mean that the *MN* gene has never been subject to nonrandom mating, or has never been under selection or genetic drift. Even if selection has been very strong for many generations, one generation of random mating and no evolution will result in genotype frequencies that conform to Hardy–Weinberg expectations.

Case Study 2: Are *HLA* Genes in Humans in Hardy–Weinberg Equilibrium? Geneticist Therese Markow and colleagues collected data on the genotypes of 122 individuals from the Havasupai tribe native to Arizona. These biologists were studying two genes that are important in the functioning of the human immune system. More specifically, the genes that they analyzed code for proteins that help immune system cells recognize and destroy invading bacteria and viruses.

Previous work had shown that different alleles exist at both the *HLA-A* and *HLA-B* genes, and that the alleles at each gene code for proteins that recognize proteins from slightly different disease-causing organisms. Like the *M* and *N* alleles, *HLA* alleles are codominant.

As a result, the research group hypothesized that individuals who are heterozygous at one or both of these genes may have a strong fitness advantage. The logic is that heterozygous people possess a wider variety of HLA proteins, so their immune systems can recognize and destroy more types of bacteria and viruses. They should be healthier and have more offspring than homozygous people do.

To test this hypothesis, Markow and her colleagues used their data on observed genotype frequencies to determine the frequency of each allele present. When they used these allele frequencies to calculate the expected number of each genotype according to the Hardy–Weinberg principle, they found the observed and expected values reported in **TABLE 26.2**.

When you inspect these data, notice that there are many more heterozygotes and many fewer homozygotes than expected under Hardy–Weinberg conditions. Statistical tests show it is extremely unlikely that the difference between the observed and expected numbers could occur purely by chance.

These results supported the team's prediction and indicated that one of the assumptions behind the Hardy–Weinberg

TABLE 26.2 *HLA* Genes of Humans: Observed and Expected Genotypes

The expected numbers of homozygous and heterozygous genotypes are calculated from observed allele frequencies, according to the Hardy–Weinberg principle.

		Genotype Counts ($n = 122$)	
Gene	**Data Type**	**Homozygotes**	**Heterozygotes**
HLA-A	Observed	38	84
	Expected	48	74
HLA-B	Observed	21	101
	Expected	30	92

DATA: Markow, T., P. H. Hedrick, K. Zuerlein, et al. 1993. *Journal of Human Genetics* 53: 943–952, Table 3.

principle was being violated. But which assumption? The researchers argued that mutation, gene flow, and drift are negligible in this case and offered two explanations for their data:

1. ***Mating may not be random with respect to the HLA genotype.*** Specifically, people may subconsciously prefer mates with *HLA* genotypes unlike their own and thus produce an excess of heterozygous offspring. This hypothesis is plausible. For example, experiments have shown that college students can distinguish each others' genotypes at genes related to *HLA* on the basis of body odor. Individuals in this study were more attracted to the smell of genotypes unlike their own. If this is true among the Havasupai, then nonrandom mating would lead to an excess of heterozygotes compared with the proportion expected under the Hardy–Weinberg principle.
2. ***Heterozygous individuals may have higher fitness.*** This hypothesis is supported by data collected by a different research team, who studied the Hutterite people living in South Dakota. In the Hutterite population, married women who have the same *HLA*-related alleles as their husbands have more trouble getting pregnant and experience higher rates of spontaneous abortion than do women with *HLA*-related alleles different from those of their husbands. The data suggest that homozygous fetuses have lower fitness than do fetuses heterozygous at these genes. If this were true among the Havasupai, selection would lead to an excess of heterozygotes relative to Hardy–Weinberg expectations.

Which explanation is correct? It is possible that both are. Using the Hardy–Weinberg principle as a null hypothesis allowed biologists to detect an interesting pattern in a natural population. Research continues on the question of why the pattern exists.

Now let's consider each of the processes that can violate the Hardy–Weinberg assumptions—and thus influence evolution.

check your understanding

CYU

If you understand that . . .

- The Hardy–Weinberg principle functions as a null hypothesis when researchers test whether nonrandom mating or evolution is occurring at a particular gene.

✔ **QUANTITATIVE You should be able to . . .**

Analyze whether a gene suspected of causing hypertension in humans is in Hardy–Weinberg proportions. In one study, the observed genotype frequencies were A_1A_1 0.574; A_1A_2 0.339; A_2A_2 0.087. (Note: The sample size in this study was so large that a difference of 3 percent or more in any of the observed versus expected frequencies indicated a statistically significant difference—meaning, a difference that was not due to chance.)

Answers are available in Appendix A.

26.2 Nonrandom Mating

In the Hardy–Weinberg model, gametes were picked from the gene pool at random and paired to create offspring genotypes. In nature, however, matings between individuals may not be random with respect to the gene in question. Even in species like clams that simply broadcast their gametes into the surrounding water, gametes from individuals that live close to each other are more likely to combine than gametes from individuals that live farther apart.

The most intensively studied form of nonrandom mating is called **inbreeding,** the mating between relatives. Since relatives share a recent common ancestor, individuals that inbreed are likely to share alleles they inherited from their common ancestor.

How Does Inbreeding Affect Allele Frequencies and Genotype Frequencies?

To understand how inbreeding affects populations, let's follow the fate of alleles and genotypes when inbreeding occurs. As before, focus on a single locus with two alleles, A_1 and A_2, and suppose that these alleles initially have equal frequencies of 0.5.

Now imagine that the gametes produced by individuals in the population don't go into a gene pool. Instead, individuals self-fertilize. Many flowering plants, for example, contain both male and female organs and routinely self-pollinate. Self-fertilization, or selfing, is the most extreme form of inbreeding.

As **FIGURE 26.3a** shows, homozygous parents that self-fertilize produce all homozygous offspring. Heterozygous parents, in contrast, produce homozygous and heterozygous offspring in a 1:2:1 ratio.

FIGURE 26.3b shows the outcome for the population as a whole. In this figure, the width of the boxes represents the frequency of the three genotypes, which start out at the Hardy–Weinberg ratio of $p^2:2pq:q^2$. Notice that the homozygous proportion of the population increases with each generation, while the heterozygous proportion is halved. At the end of the four generations illustrated, heterozygotes are rare. The same outcomes occur more slowly with less extreme forms of inbreeding.

This simple exercise demonstrates two fundamental points about inbreeding:

1. Inbreeding increases homozygosity. In essence, inbreeding takes alleles from heterozygotes and puts them into homozygotes.
2. Inbreeding itself does not cause evolution, because allele frequencies do not change in the population as a whole.

Nonrandom mating changes only genotype frequencies, not allele frequencies, so is not an evolutionary process itself. ✔ **If you understand this concept, you should be able to predict how observed genotype frequencies and allele frequencies should differ from those expected under the Hardy–Weinberg principle when inbreeding is occurring.**

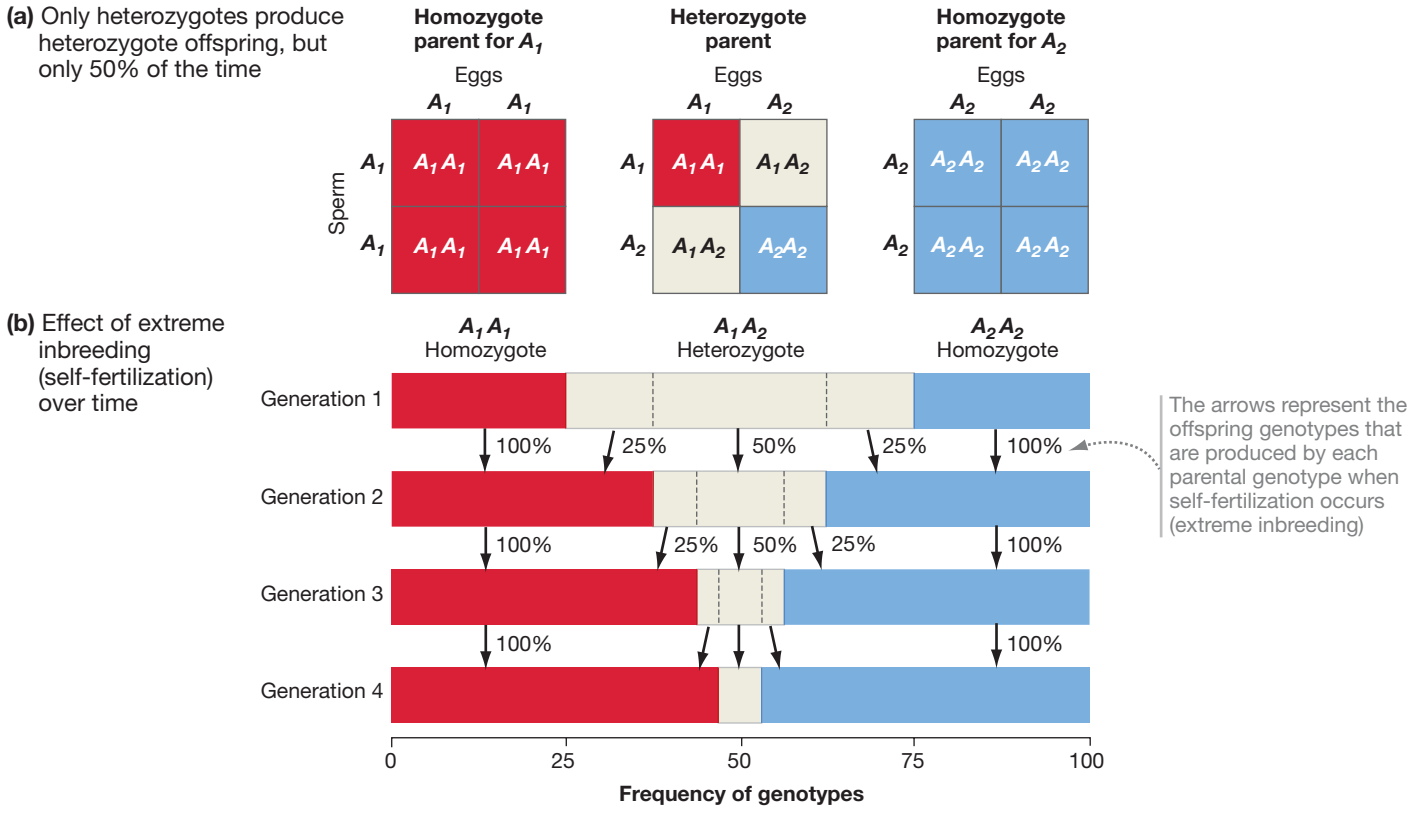

FIGURE 26.3 Inbreeding Increases Homozygosity and Decreases Heterozygosity. (a) Heterozygous parents produce homozygous and heterozygous offspring in a 1:2:1 ratio. **(b)** The width of the boxes corresponds to the frequency of each genotype.

How Does Inbreeding Influence Evolution?

The trickiest point to grasp about inbreeding is that even though it does not cause evolution directly—because it does not change allele frequencies—it can speed the rate of evolutionary change. More specifically, it increases the rate at which natural selection eliminates recessive **deleterious** alleles—alleles that lower fitness—from a population.

Consider **inbreeding depression**—the decline in average fitness that takes place when homozygosity increases and heterozygosity decreases in a population. Inbreeding depression results from two causes:

1. ***Many recessive alleles represent loss-of-function mutations.*** Because these alleles are usually rare, there are normally very few homozygous recessive individuals in a population. Instead, most loss-of-function alleles exist in heterozygous individuals. The alleles have little or no effect when they occur in heterozygotes, because one normal allele usually produces enough functional protein to support a normal phenotype. But inbreeding increases the frequency of homozygous recessive individuals. Loss-of-function mutations are usually deleterious or even lethal when they are homozygous—they are quickly eliminated by selection.
2. ***Many genes—especially those involved in fighting disease—are under intense selection for heterozygote advantage, a selection process that favors genetic diversity.*** If an individual is homozygous at these genes, then fitness declines.

The upshot here is that the offspring of inbred matings are expected to have lower fitness than the offspring of outcrossed matings. This prediction has been verified in a wide variety of species. **FIGURE 26.4** shows results from recent efforts to reduce illness in a small population of endangered Florida panthers by introducing females from Texas. Note that the two sets of data points compare the fitnesses of offspring from non-inbred

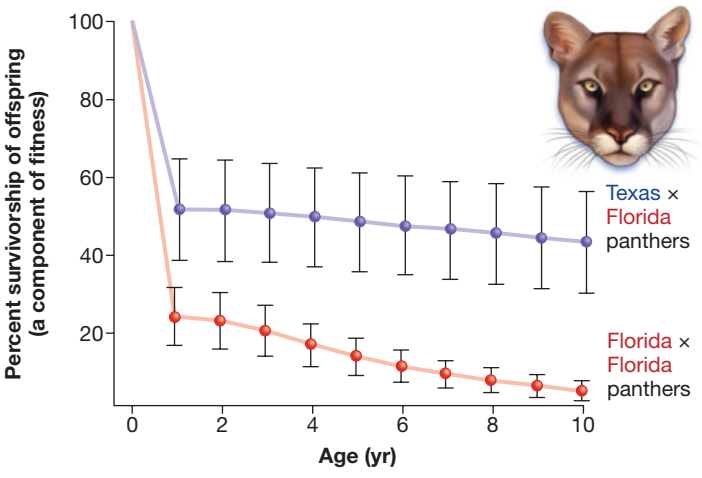

FIGURE 26.4 Inbreeding Depression Occurs in Florida Panthers. Inbreeding depression is the fitness difference between non-inbred and inbred individuals.

DATA: Johnson, W. E., E. P. Onorato, M. E. Roelke, et al. 2010. *Science* 329: 1641–1645.

Texas × Florida matings and inbred Florida × Florida matings. Inbreeding depression is represented by the vertical distance between data points at each age.

Several studies show similar results on inbreeding depression in human populations around the world. Children of first-cousin marriages consistently have a higher mortality rate than children of marriages between nonrelatives. Because inbreeding has such deleterious consequences in humans, it is not surprising that many human societies have laws forbidding marriages between individuals who are related as first cousins or closer.

In insects, vertebrates, and many other animals where inbreeding is uncommon, females often don't mate at random but actively choose certain males, and/or males compete among themselves to secure mates. This form of nonrandom mating is fundamentally different from inbreeding because it *does* lead to changes in allele frequencies in the population, and thus is a form of natural selection—called **sexual selection.** According to the Hardy–Weinberg assumptions, sexual selection violates the "no natural selection" hypothesis, as discussed in the next section.

26.3 Natural Selection

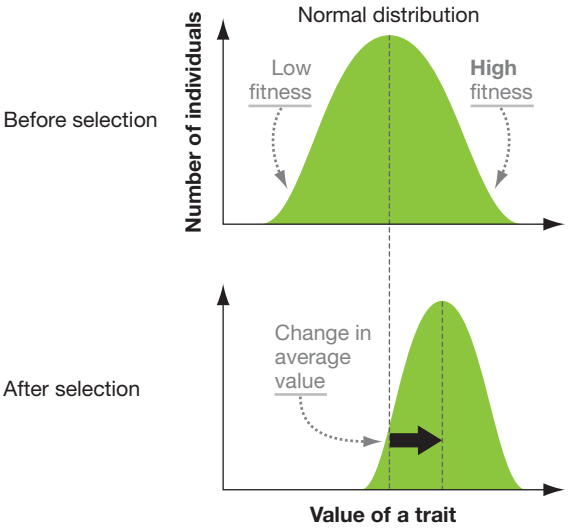
Evolution by natural selection occurs when heritable variation leads to differential success in survival and reproduction (see Chapter 25). Stated another way, natural selection occurs when individuals with certain phenotypes produce more surviving offspring than individuals with other phenotypes do. If certain alleles are associated with the favored phenotypes, they increase in frequency while other alleles decrease in frequency. The result is evolution—a violation of the assumptions of the Hardy–Weinberg model.

How Does Selection Affect Genetic Variation?

When biologists analyze the consequences of selection, they often focus on **genetic variation**—the number and relative frequency of alleles that are present in a particular population. The reason is simple: Lack of genetic variation in a population is usually a bad thing.

To understand why this is so, recall that selection can occur only if heritable variation exists in a population (Chapter 25). If genetic variation is low and the environment changes—perhaps due to the emergence of a new disease-causing virus, a rapid change in climate, or a reduction in the availability of a particular food source—no alleles that have high fitness under the new conditions are likely to be present. As a result, the average fitness of the population will decline. If the environmental change is severe enough, the population may even be faced with extinction.

Natural selection occurs in a wide variety of patterns, or modes, each with different consequences to genetic variation:



- *Directional selection* changes the average value of a trait.
- *Stabilizing selection* reduces variation in a trait.
- *Disruptive selection* increases variation in a trait.
- *Balancing selection* maintains variation in a trait.

Let's take a closer look at each of these four modes in turn.

Mode 1: Directional Selection When **directional selection** occurs, the average phenotype of a population changes in one direction.

To get a sense of how directional selection affects genetic variation, look at the top graph in **FIGURE 26.5a**, which plots the value of a trait on the *x*-axis and the number of individuals with a particular value of that trait on the *y*-axis. (In a graph like this, the *y*-axis could also plot the frequency of individuals with a

(a) Directional selection changes the average value of a trait.

(b) For example, directional selection caused average body size to increase in a cliff swallow population.

FIGURE 26.5 Directional Selection. When directional selection acts on traits that have a normal distribution, individuals at one end of the distribution experience poor reproductive success.

DATA: Brown, C. R., and M. B. Brown. 1998. *Evolution* 52: 1461–1475.

particular trait value—see **BioSkills 3** in Appendix B.) Note that the trait in question is determined by multiple genes, so it has a bell-shaped, normal distribution in this hypothetical population (Chapter 14).

The second graph in the figure shows what happens when directional selection acts on this trait. Directional selection tends to reduce the genetic diversity of populations. If directional selection continues over time, the favored alleles will eventually approach a frequency of 1.0 while disadvantageous alleles will approach a frequency of 0.0, a clear violation of the assumptions of the Hardy–Weinberg model. Alleles that reach a frequency of 1.0 are said to be fixed; those that reach a frequency of 0.0 are said to be lost. When disadvantageous alleles decline in frequency, **purifying selection** is said to occur.

Now consider data from real organisms in the wild. In 1996 a population of cliff swallows native to the Great Plains of North America endured a six-day period of exceptionally cold, rainy weather. Cliff swallows feed by catching mosquitoes and other insects in flight. Insects disappeared during this cold snap, however, and the biologists recovered the bodies of 1853 swallows that died of starvation.

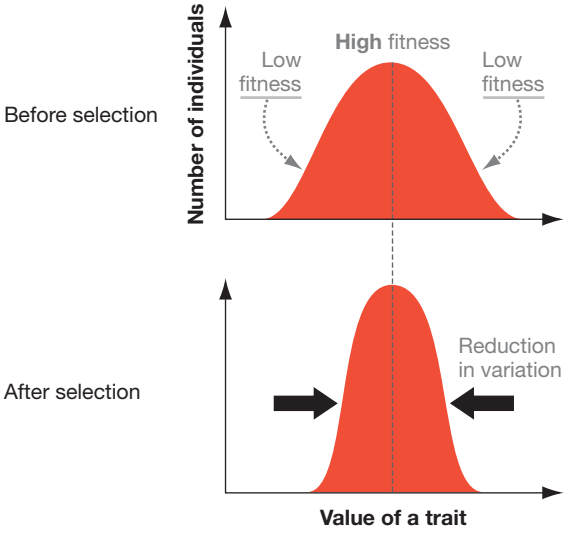
As soon as the weather improved, the researchers caught and measured the body size of 1027 survivors from the same population. As the histograms in **FIGURE 26.5b** show, survivors were much larger on average than the birds that died.

Directional selection, favoring large body size, had occurred. To explain this observation, the investigators suggested that larger birds survived because they had larger fat stores and did not get as cold as the smaller birds. As a result, the larger birds were less likely to die of exposure to cold and more likely to avoid starvation until the weather warmed up and insects were again available.

If variation in swallow body size was heritable, and if this type of directional selection continued, then alleles that contribute to small body size would quickly decline in frequency in the cliff swallow population.

As it turned out in this case, directional selection was short-lived because the severe weather event was temporary. In other cases, directional selection can be more persistent, such as the directional selection that occurs during global climate change.

Mode 2: Stabilizing Selection



When cliff swallows were exposed to cold weather, selection greatly reduced one extreme in the range of phenotypes and resulted in a directional change in the average characteristics of the population. But selection can also reduce both extremes in a population, as illustrated in **FIGURE 26.6a**. This mode of selection is called **stabilizing selection.** It has two important consequences: There is no change in the average value of a trait over time, and genetic variation in the population is reduced.

FIGURE 26.6b shows a classical data set in humans that illustrates stabilizing selection. Biologists who analyzed birth weights and mortality in 13,730 babies born in British hospitals in the 1940s found that babies of average size (slightly over 7 pounds) survived best. Mortality was high for very small babies and very large babies. This is persuasive evidence that birth weight was under strong stabilizing selection in this population. Alleles associated with high birth weight or low birth weight were subject to purifying selection, and alleles associated with intermediate birth weight increased in frequency.

Mode 3: Disruptive Selection

Disruptive selection has the opposite effect of stabilizing selection. Instead of favoring phenotypes near the average value and eliminating extreme phenotypes, it eliminates phenotypes near the average value and favors

(a) Stabilizing selection reduces the amount of variation in a trait.

(b) For example, very small and very large babies are the most likely to die, leaving a narrower distribution of birthweights.

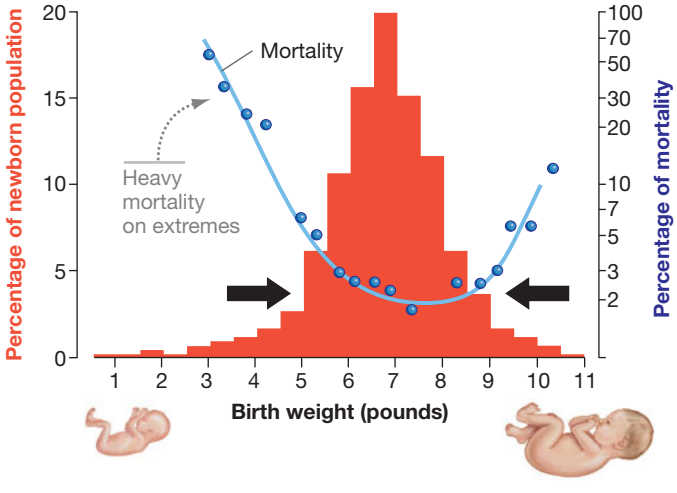


FIGURE 26.6 Stabilizing Selection. When stabilizing selection acts on normally distributed traits, individuals with extreme phenotypes experience poor reproductive success.

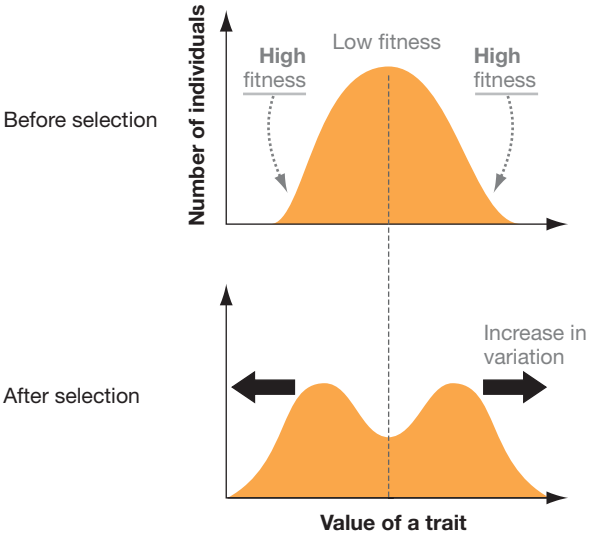
DATA: Karn, M. N., H. Lang-Brown, J. J. MacKenzie, et al. 1951. *Annals of Eugenics* 15: 306–322.

extreme phenotypes (**FIGURE 26.7a**). When disruptive selection occurs, the overall amount of genetic variation in the population is maintained.



Recent research has shown that disruptive selection is responsible for the striking distribution of bills of black-bellied seedcrackers (**FIGURE 26.7b**). The data plotted in the graph show that individuals with either short or very long beaks survive best and that birds with intermediate phenotypes are at a disadvantage.

In this case, the agent that causes natural selection is food. At a study site in south-central Cameroon, West Africa, a researcher found that only two sizes of seed are available to the seedcrackers: large and small. Birds with small beaks crack and eat small seeds efficiently. Birds with large beaks handle large seeds efficiently. But birds with intermediate beaks have trouble with both, so alleles associated with medium-sized beaks are subject to purifying selection. Disruptive selection maintains high overall variation in this population.

Disruptive selection is important because it sometimes plays a part in speciation, or the formation of new species. If small-beaked seedcrackers began mating with other small-beaked individuals, their offspring would tend to be small-beaked and would feed on small seeds. Similarly, if large-beaked individuals chose only other large-beaked individuals as mates, they would tend to produce large-beaked offspring that would feed on large seeds.

In this way, selection would result in two distinct populations. Under some conditions, the populations may eventually form two new species. (See Chapter 27 for a detailed discussion of the process of species formation, which is based on disruptive selection and other mechanisms.)

(a) Disruptive selection increases the amount of variation in a trait.

(b) For example, only juvenile black-bellied seedcrackers that had short or extremely long beaks survived long enough to breed.

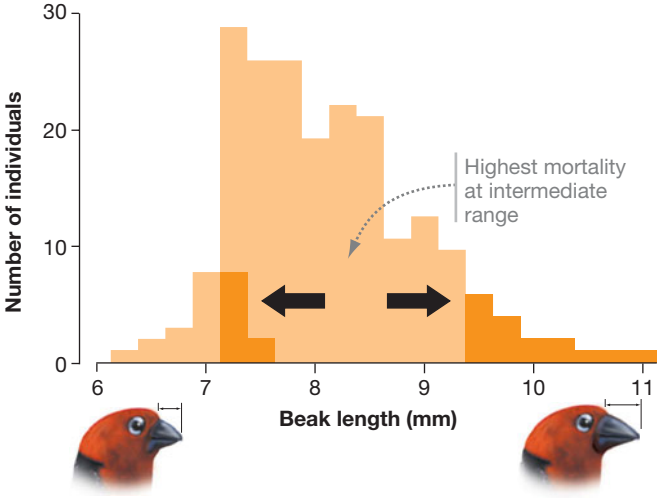


FIGURE 26.7 Disruptive Selection. When disruptive selection occurs on traits with a normal distribution, individuals with extreme phenotypes experience high reproductive success.

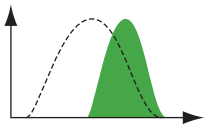

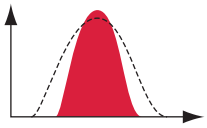

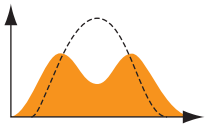

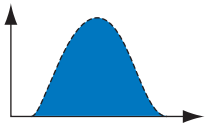

DATA: Smith, T. B. 1987. *Nature* 329: 717–719.

Mode 4: Balancing Selection Directional selection, stabilizing selection, and disruptive selection describe how natural selection can act on one polygenic trait in a single generation or episode. Another mode of selection, called **balancing selection,** occurs when no single allele has a distinct advantage. Instead, there is a balance among several alleles in terms of their fitness and frequency. Balancing selection occurs when:

1. Heterozygous individuals have higher fitness than homozygous individuals do, a pattern called **heterozygote advantage**. This pattern of selection is one explanation for the data in Table 26.2, where heterozygotes for the *HLA* genes have a fitness advantage compared to homozygotes. The consequence of this pattern is that genetic variation is maintained in populations.
2. The environment varies over time or in different geographic areas occupied by a population—meaning that certain alleles are favored by selection at different times or in different places. As a result, overall genetic variation in the population is maintained or increased.
3. Certain alleles are favored when they are rare, but not when they are common—a pattern known as **frequency-dependent selection.** For example, rare alleles responsible for coloration in guppies are favored because predators learn to recognize common color patterns. Alleles for common colors get eliminated; alleles for rare colors increase in frequency. As a result, overall genetic variation in the population is maintained or increased.

TABLE 26.3 summarizes the four modes of natural selection. No matter how natural selection occurs, though, its most fundamental attribute is the same: It increases fitness and leads to adaptation. Natural selection results in allele frequencies that deviate from those predicted by the Hardy–Weinberg principle because selection favors certain alleles over others. ✔ **If you understand this concept, you should be able to predict how genotype frequencies differ from Hardy–Weinberg proportions under directional selection.**

SUMMARY TABLE 26.3 Modes of Selection

Mode of Selection	Effect on Phenotype	Effect on Genetic Variation
Directional selection 	Favors one extreme phenotype, causing the average phenotype in the population to change in one direction.	Genetic variation is reduced.
Stabilizing selection 	Favors phenotypes near the middle of the range of phenotypic variation, maintaining average phenotype.	Genetic variation is reduced.
Disruptive selection 	Favors extreme phenotypes at both ends of the range of phenotypic variation.	Genetic variation is increased.
Balancing selection 	No single phenotype is favored in all populations of a species at all times.	Genetic variation is maintained.

Sexual Selection

Darwin was the first to recognize that selection based on success in courtship is a mechanism of evolutionary change. Although he introduced the idea of sexual selection in *On the Origin of Species* in 1859, it was not until 12 years later that he detailed his views on sexual selection in *The Descent of Man, and Selection in Relation to Sex*.

Darwin was initially perplexed by seemingly nonadaptive traits such as the extravagantly long and iridescent trains of peacocks. Why was it adaptive for the peacock to spend energy producing a structure that would increase the peacock's vulnerability to predation? Darwin concluded that the peacock's train is adaptive because it helps the peacock to attract mates, thereby increasing its reproductive success.

The peacock example demonstrates mate choice, sometimes referred to as ***inter*sexual selection**—the selection of an individual of one gender for mating by an individual of the other gender. Darwin also recognized that individuals sometimes compete with one another to obtain mates. This form of selection *within* a gender is referred to as ***intra*sexual selection.**

Theory: The Fundamental Asymmetry of Sex Why would the extravagant trains of peacocks occur in the males but not the peahens? A. J. Bateman addressed this question in the 1940s, followed by Robert Trivers three decades later. The Bateman–Trivers theory contains an observed pattern and a hypothesized process:

- ***Pattern*** Sexual selection usually acts on males much more strongly than on females. Traits that attract members of the opposite sex are much more highly elaborated in males.
- ***Process*** The energetic cost of creating a large egg is enormous, whereas a sperm contains few energetic resources. That is, "eggs are expensive, but sperm are cheap."

In most species, females invest much more in their offspring than do males. This phenomenon is called the fundamental asymmetry of sex. It is characteristic of almost all sexual species and has two important consequences:

1. Because eggs are large and energetically expensive, females produce relatively few young over the course of a lifetime. A female's fitness is limited not by her ability to find a mate but primarily by her ability to gain the resources needed to produce more eggs and healthier young.
2. Sperm are so energetically inexpensive to produce that a male can father an almost limitless number of offspring. Thus, a male's fitness is limited not by the ability to acquire the resources needed to produce sperm but by the number of females he can mate with.

The Bateman–Trivers theory of sexual selection makes strong predictions:

- If females invest a great deal in each offspring, then they should protect that investment by being choosy about their mates. Conversely, if males invest little in each offspring, then they should be willing to mate with almost any female.
- If there are an equal number of males and females in the population, and if males are trying to mate with any female possible, then males will compete with each other for mates.
- If male fitness is limited by access to mates, then any allele that increases a male's attractiveness to females or success in male–male competition should increase rapidly in the population, violating the assumptions of Hardy–Weinberg. Thus, sexual selection should act more strongly on males than on females.

Do data from experimental or observational studies agree with these predictions? Let's consider each of them in turn.

Female Choice for "Good Alleles" If females are choosy about which males they mate with, what criteria do females use to make their choice? Recent experiments have shown that in several bird species, females prefer to mate with males that are well fed and in good health. These experiments were motivated by three key observations:

1. In many bird species, the existence of colorful feathers or a colorful beak is due to the presence of the red and yellow pigments called carotenoids.
2. Carotenoids protect tissues and stimulate the immune system to fight disease more effectively.
3. Animals usually cannot synthesize their own carotenoids, but plants can. To obtain carotenoids, animals have to eat carotenoid-rich plant tissues.

These observations suggest that the healthiest and best-nourished birds in a population have the most colorful beaks and feathers. Sick birds have dull coloration because they are using all of their carotenoids to stimulate their immune system. Poorly fed birds have dull coloration because they have few carotenoids available. By choosing a colorful male as the father of her offspring, a female is likely to have offspring with alleles that will help the offspring fight disease effectively and feed efficiently.

To test the hypothesis that females prefer colorful males, a team of researchers experimented with zebra finches (**FIGURE 26.8a**). They identified pairs of brothers and randomly assigned one brother to the treatment group and one brother to the control group. They fed the treatment group a diet that was heavily supplemented with carotenoids, and they fed the control group a diet that was similar in every way except for the additional carotenoids.

As predicted, the males eating the carotenoid-supplemented diet developed more colorful beaks than did the males fed the carotenoid-poor diet. When given a choice of perching with either of the two brothers, 9 out of the 10 females tested preferred the more-colorful male (**FIGURE 26.8b**). These results support the hypothesis that females of this species are choosy about their mates and that they prefer to mate with healthy, well-fed males.

Enough experiments have been done on other bird species to support a general conclusion: Colorful beaks and feathers, along with songs and dances and other types of courtship displays, carry the message "I'm healthy and well fed because I have good alleles. Mate with me."

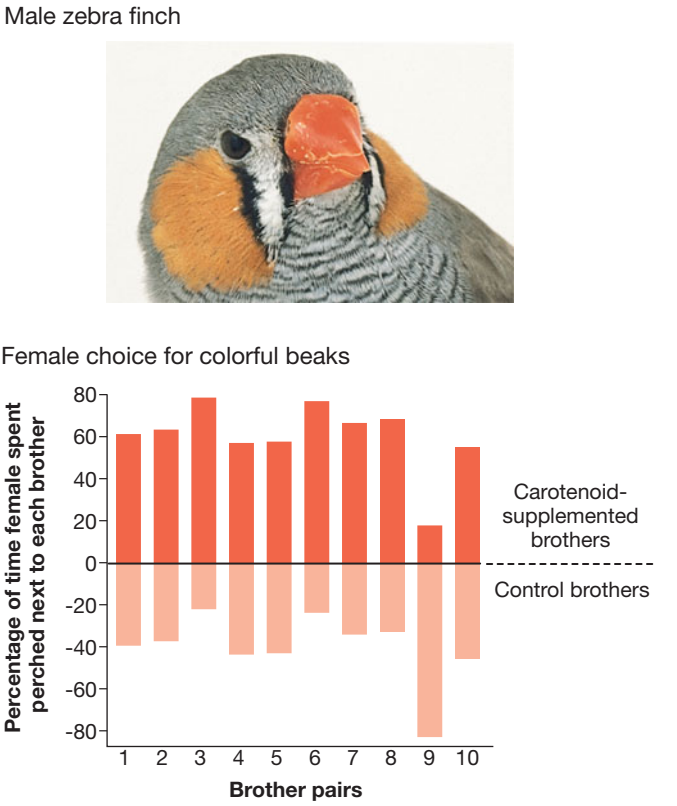

FIGURE 26.8 Female Zebra Finches Prefer Males with Colorful Beaks.

DATA: Blount, J. D., N. B. Metcalf, T. R. Birkhead, et al. 2003. *Science* 300: 125–127.

Female Choice for Paternal Care Choosing "good alleles" is not the entire story in sexual selection via female choice. In many species, females prefer to mate with males that care for young or that provide the resources required to produce eggs.

Brown kiwi females make an enormous initial investment in their offspring—their eggs routinely represent over 15 percent of the mother's total body weight (**FIGURE 26.9**)—but choose to mate with males that take over all of the incubation and other care of the offspring. It is common to find that female fish prefer to mate with males that protect a nest site and care for the eggs until they hatch. In humans and many species of birds, males provide food, protection, and other resources for rearing young.

To summarize, females may choose mates on the basis of **(1)** physical characteristics that signal male genetic quality, **(2)** resources or parental care provided by males, or **(3)** both. In some species, however, females do not have the luxury of choosing a male. Instead, competition among males is the primary cause of sexual selection.

Male–Male Competition As an example of research on how males compete for mates, consider data from a long-term study of a northern elephant seal population breeding on Año Nuevo Island, off the coast of California.

Elephant seals feed mostly on marine fish, squid, and octopus, and spend most of the year in the water. But when females are ready to mate and give birth, they haul themselves out of the water onto land. Females prefer to give birth on islands, where newborn pups are protected from terrestrial and marine predators. Because elephant seals have flippers that are ill-suited for walking, females can haul themselves out of the water only on the few beaches that have gentle slopes. As a result, large numbers of females congregate in tiny areas to breed.

FIGURE 26.9 In Many Species, Females Make a Large Investment in Each Offspring. X-ray of a female kiwi, ready to lay an egg.

Male elephant seals establish territories on breeding beaches by fighting (**FIGURE 26.10a**). A **territory** is an area that is actively defended and that provides exclusive or semi-exclusive use by the owner. Males that win battles with other males monopolize matings with the females residing in their territories. Males that lose battles are relegated to territories with fewer females or are excluded from the beach. Fights are essentially slugging contests and are usually won by the larger male. The males stand face to face, bite each other, and land blows with their heads.

Based on these observations, it is not surprising that male northern elephant seals frequently weigh 2700 kg (5940 lbs) and are over four times more massive, on average, than females. The logic here runs as follows:

- Males that dominate beaches with large congregations of females father large numbers of offspring. Males that lose fights father few or no offspring.
- The alleles of dominant males rapidly increase in frequency in the population.
- If the ability to win fights and produce offspring is determined primarily by body size, then alleles for large body size have a significant fitness advantage, leading to the evolution of large male size. The fitness advantage is due to sexual selection, and the consequence is directional selection on large body size.

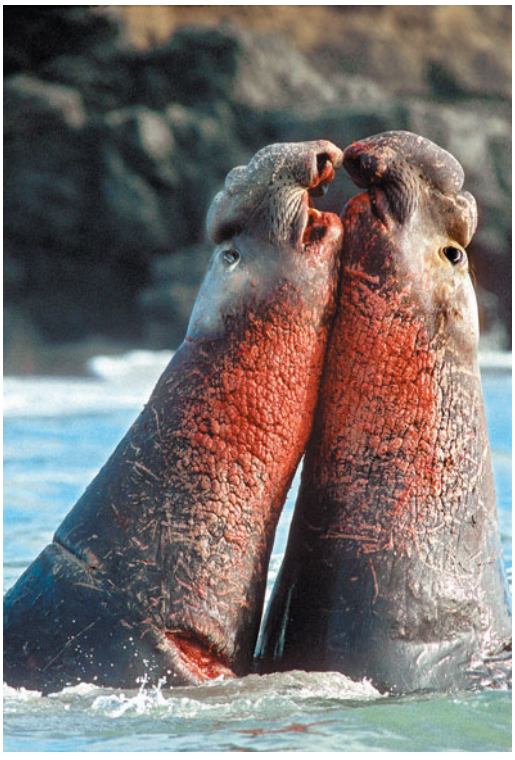

FIGURE 26.10b provides evidence for intense sexual selection in males. Biologists have marked many of the individuals in the seal population on Año Nuevo to track the lifetime reproductive success of a large number of individuals. The *x*-axis indicates fitness, plotted as the number of offspring produced over a lifetime. The *y*-axis indicates the percentage of males in the population that achieved each category of offspring production (0, 1–10, and so on). As the data show, in this population a few males father a large number of offspring, while most males father few or none.

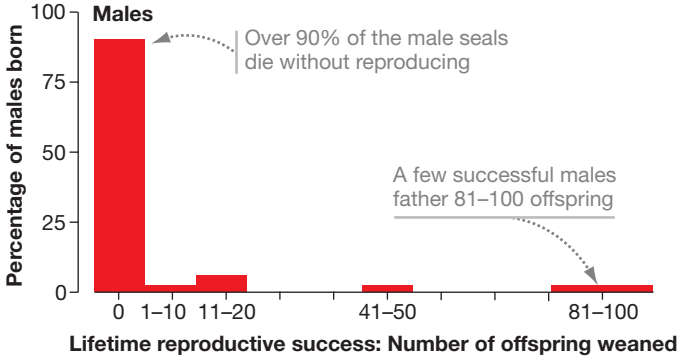
Among females, variation in reproductive success is also high, but it is much lower than in males (**FIGURE 26.10c**). In this species, most sexual selection appears to be driven more by male–male competition than by female choice.



Sexual Dimorphism Results from Sexual Selection In elephant seals and most other animals studied, most females that survive to adulthood get a mate. In contrast, many males do not. Because sexual selection tends to be much more intense in males than females, males tend to have many more traits that function only in courtship or male–male competition. Stated another way, sexually selected traits often differ sharply between the sexes.

Sexual dimorphism (literally, "two-forms") refers to any trait that differs between males and females. Such traits range from weapons that males use to fight over females, such as antlers and

(a) Males compete for the opportunity to mate with females.

(b) Variation in reproductive success is high in males.

(c) Variation in reproductive success is relatively low in females.

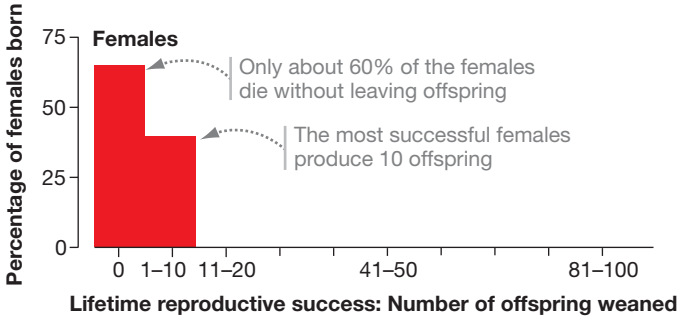


FIGURE 26.10 Intense Sexual Selection in Male Elephant Seals. The histograms show that variation in lifetime reproductive success is higher in **(b)** male northern elephant seals than it is in **(c)** females.

DATA: Le Boeuf, B. J., and R. S. Peterson. 1969. *Science* 163: 91–93.

horns (**FIGURE 26.11a**), to the elaborate ornamentation and behavior used in courtship displays (**FIGURE 26.11b**). Humans are sexually dimorphic in size, distribution of body hair, and many other traits.

✔ **If you understand sexual selection, you should be able to (1) define the fundamental asymmetry of sex, and (2) explain why males are usually the sex with exaggerated traits used in courtship.**

Take-Home Messages Female choice and male–male competition illustrate how selection can favor certain phenotypes in a population. The adaptive alleles responsible for these phenotypes increase in frequency over time. Thus, evolution occurs and the assumptions of the Hardy–Weinberg model are violated.

Sexual selection is just one type of natural selection. All the other types, sometimes referred to collectively as **ecological (or environmental) selection,** favor traits that enable organisms to do things other than obtain mates—such as survive in their physical and biological environments. Different agents of natural selection can act on organisms simultaneously, sometimes favoring the same traits, other times resulting in fitness trade-offs (Chapter 25). For example, sexual selection may favor long trains in peacocks, while ecological selection may favor shorter trains that make the peacocks less vulnerable to predators. The relative importance of different agents of selection can change over time and in space.

Natural selection is the only evolutionary process that results in adaptation, but it is not the only evolutionary process that violates the Hardy–Weinberg assumptions. Let's consider what happens when random changes in allele frequency occur.

(a) Red deer males use weaponry to compete for mates.

(b) Male raggiana birds of paradise display for females.

FIGURE 26.11 Sexually Selected Traits Are Used to Compete for Mates. Males often have exaggerated traits that they use in fighting or courtship. In many species, females lack these traits.

26.4 Genetic Drift

Genetic drift is defined as any change in allele frequencies in a population that is due to chance. The process is aptly named, because it causes allele frequencies to drift up and down randomly over time. When drift occurs, allele frequencies change due to blind luck—what is known in statistics as **sampling error.** Sampling error occurs when the allele frequencies of a chosen subset of a population (the sample) are different from those in the total population, by chance. Drift occurs in every population, in every generation, but especially in small populations.

Simulation Studies of Genetic Drift

To understand why genetic drift occurs, imagine a couple marooned on a deserted island. Suppose that at gene A, the wife's genotype is A_TA_H and the husband is also A_TA_H. In this population, the two alleles are each at a frequency of 0.5.

Now suppose that the couple produce five children over their lifetime. Half of the eggs produced by the wife carry allele A_T and half carry allele A_H. Likewise, half of the sperm produced by the husband carry allele A_T and half carry allele A_H. To simulate which sperm and which egg happen to combine to produce each of the five offspring, you can flip a coin for each sperm and each egg, where tails represents allele A_T and heads represents allele A_H.

The following coin flips were done by a pair of students in a recent biology class:

	Sperm	Egg	Genotype
First offspring	A_H	A_H	A_HA_H
Second offspring	A_T	A_T	A_TA_T
Third offspring	A_T	A_H	A_HA_T
Fourth offspring	A_H	A_H	A_HA_H
Fifth offspring	A_T	A_H	A_HA_T

When the parents die, there are a total of 10 alleles in the population. But note that the allele frequencies have changed. In this generation, six of the 10 alleles (60 percent) are A_H; four of the 10

alleles (40 percent) are A_T. Evolution—a change in allele frequencies in a population—occurred due to genetic drift.

Instead of each allele being sampled in exactly its original frequency when offspring formed, as the Hardy–Weinberg principle assumes, a chance sampling error occurred. Allele A_H "got lucky," and allele A_T was "unlucky."

Computer Simulations **FIGURE 26.12** shows what happens when a computer simulates the same process of random combinations in gametes over time. The program that generated the graphs combines the alleles in a gene pool at random to create an offspring generation, calculates the allele frequencies in the offspring generation, and uses those allele frequencies to create a new gene pool.

In this example, the process was continued for 100 generations. The *x*-axis on each graph plots time in generations; the *y*-axis plots the frequency of one of the two alleles present at the *A* gene in a hypothetical population.

The top graph shows eight replicates of this process with a population size of 4; the bottom graph shows eight replicates with a population of 400. Notice (**1**) the striking differences between the effects of drift in the small versus large population and (**2**) the consequences for genetic variation when alleles drift to fixation or loss.

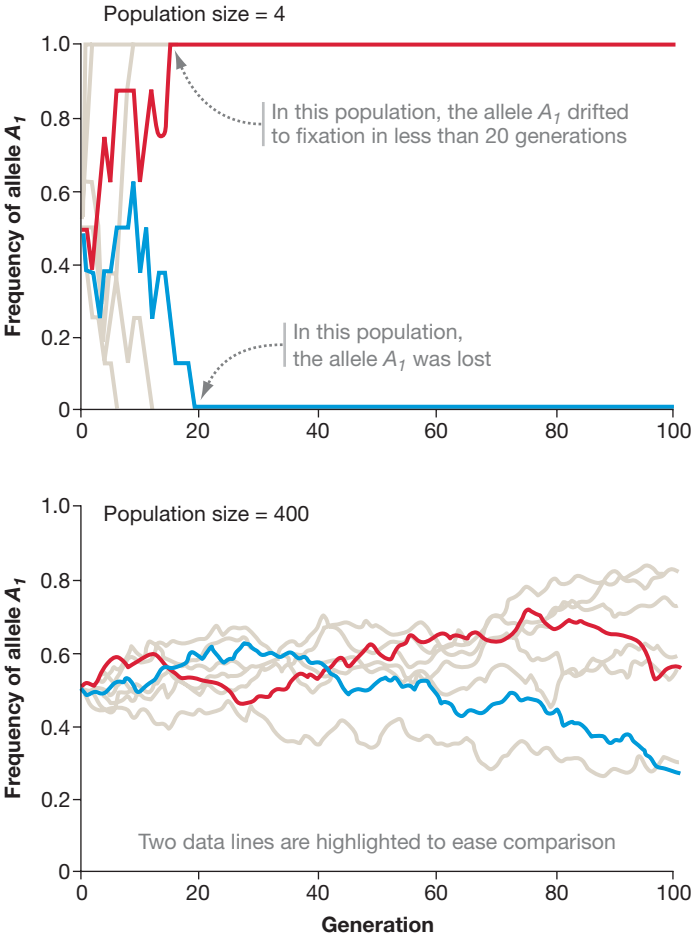

FIGURE 26.12 Genetic Drift Is More Pronounced in Small Populations than in Large Populations.

✔**EXERCISE** Draw a graph predicting what these simulation results would look like for a population size of 4000.

Given enough time, drift can be an important factor even in large populations. For example, alleles containing silent mutations, usually in the third position of a codon, do not change the gene product (Chapter 16). As a result, most of these alleles have little or no effect on the phenotype. Yet these alleles routinely drift to high frequency or even fixation over time.

✔ **If you understand genetic drift, you should be able to examine the MN blood group genotype frequencies in Table 26.1 and describe how drift could explain differences in genotype frequencies among populations.** Note that there are no data indicating a selective advantage for different MN genotypes in different environments.

Key Points About Genetic Drift These simulated matings illustrate three important points about genetic drift:

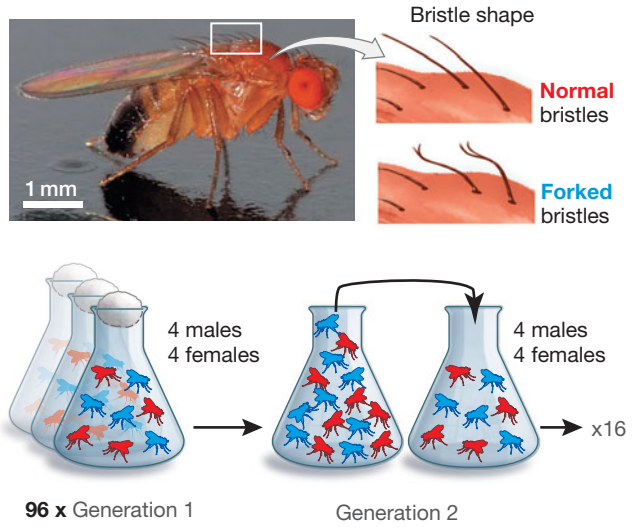
1. Genetic drift is random with respect to fitness. The changes in allele frequency that it produces are not adaptive.
2. Genetic drift is most pronounced in small populations. In the computer simulation, allele frequencies changed much less in the large population than in the small population. And if the couple on the deserted island had produced 50 children instead of five, allele frequencies in the next generation almost certainly would have been much closer to 0.5.
3. Over time, genetic drift can lead to the random loss or fixation of alleles. In the computer simulation with a population of 4, it took at most 20 generations for one allele to be fixed or lost. When random loss or fixation occurs, genetic variation in the population declines.

The importance of drift in small populations is a particular concern for conservation biologists because many populations are being drastically reduced in size by habitat destruction and other human activities. Small populations that occupy nature reserves or zoos are particularly susceptible to genetic drift. If drift leads to a loss of genetic diversity, it could darken the already bleak outlook for some endangered species.

Experimental Studies of Genetic Drift

Research on genetic drift began in the 1930s and 1940s with theoretical work that used mathematical models to predict the effect of genetic drift on allele frequencies and genetic variation. In the mid-1950s, Warwick Kerr and Sewall Wright did an experiment to determine how drift works in practice.

Kerr and Wright started with a large laboratory population of fruit flies that contained a **genetic marker**—a specific allele that causes a distinctive phenotype. In this case, the marker was the morphology of bristles. Fruit flies have bristles on their bodies that can be either straight or bent. This difference in bristle phenotype depends on a single gene. Kerr and Wright's lab population contained just two alleles—normal (straight) and "forked" (bent), designated as A_N and A_F respectively. Since the trait is



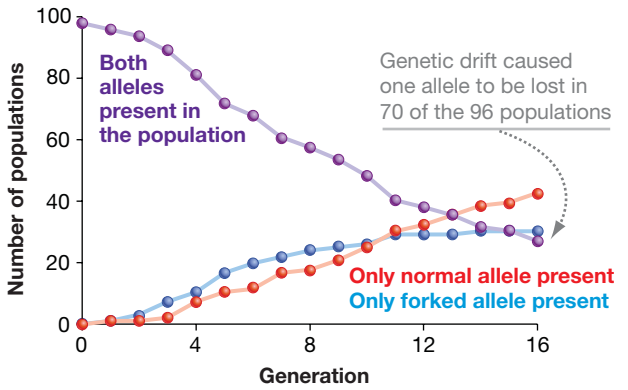
RESEARCH

QUESTION: Does genetic drift in lab populations work as predicted by mathematical models?

HYPOTHESIS: Genetic drift causes alleles to be fixed or lost over time.

NULL HYPOTHESIS: Allele frequencies do not change; they stay in Hardy–Weinberg proportions.

EXPERIMENTAL SETUP:



PREDICTION: The number of fruit fly populations with fixed or lost alleles will increase over time. The number of populations with both alleles will decrease.

PREDICTION OF NULL HYPOTHESIS: Both alleles will remain present in all fruit fly populations for all generations.

RESULTS:

Genetic drift reduced allelic diversity in most populations:

CONCLUSION: Genetic drift occurs in laboratory populations as predicted by mathematical models.

sex-linked, males have only one allele (see Chapter 14). In females, the forked allele is recessive to the normal allele, but Kerr and Wright were able to distinguish homozygous females (A_NA_N) from heterozygotes (A_NA_F).

Kerr and Wright studied drift in these alleles as shown in the experimental setup in **FIGURE 26.13**:

Step 1 The researchers set up 96 small populations in their lab, each consisting of four adult females and four adult males of the fruit fly *Drosophila melanogaster*. They chose individual flies to begin these experimental populations so that the frequency of the normal and forked alleles in each of the 96 starting populations was 0.5. The two alleles do not affect the fitness of flies in the lab environment, so Kerr and Wright could be confident that if changes in the frequency of normal and forked phenotypes occurred, they would not be due to natural selection.

Step 2 After these first-generation adults bred, Kerr and Wright reared their offspring. In the offspring (F_1) generation, they randomly chose four males and four females—meaning that they simply grabbed individuals without caring whether their bristles were normal or forked—from each of the 96 offspring populations and allowed them to breed and produce the next generation.

Step 3 They repeated this procedure until all 96 populations had undergone a total of 16 generations. They then counted the number of populations that had both alleles still present, only the normal allele present, or only the forked allele present.

During the entire course of the experiment, no migration from one population to another occurred. Previous studies had shown that mutations from normal to forked bristles (and forked to normal) are rare. Thus, the only evolutionary process operating during the experiment was genetic drift. It was as if random accidents claimed the lives of all but eight individuals in each generation, so that only eight bred.

Their result? After 16 generations, both alleles were still present in only 26 of the 96 populations—significantly less than the full 96 expected by Hardy–Weinberg proportions. Forked bristles were found on all of the individuals in 29 of the experimental populations. Due to drift, the forked allele had been fixed in these 29 populations and the normal allele had been lost. In 41 other populations, however, the opposite was true: All individuals had normal bristles. In these populations, the forked allele had been lost due to chance.

The message of the study is startling: In 73 percent of the experimental populations (70 out of the 96), genetic drift had reduced allelic diversity at this gene to zero.

FIGURE 26.13 An Experiment on the Effects of Genetic Drift in Small Populations.

SOURCE: Kerr, W. E., and S. Wright. 1954. Experimental studies of the distribution of gene frequencies in very small populations of *Drosophila melanogaster*: I. Forked. *Evolution* 8: 172–177.

✔**QUESTION** Why do you think the researchers decided to start each generation with only eight individuals?

As predicted, genetic drift decreased genetic variation within populations and increased genetic differences between populations. Is drift important in natural populations as well?

What Causes Genetic Drift in Natural Populations?

The random sampling process that takes place during fertilization occurs in every population in every generation in every species that reproduces sexually. Similarly, accidents that remove individuals at random occur in every population in every generation.

It is important to realize, though, that because drift is caused by sampling error, it can occur by *any* process or event that involves sampling—not just the sampling of gametes that occurs during fertilization or the loss of unlucky individuals due to accidents. Let's consider two special cases of genetic drift, called founder effects and bottlenecks.

Founder Effects on the Green Iguanas of Anguilla When a group of individuals immigrates to a new geographic area and establishes a new population, a founder event is said to occur. If the new population is small enough, the allele frequencies in the new population are almost guaranteed to be different from those in the source population—due to sampling error. A change in allele frequencies that occurs when a new population is established is called a **founder effect** (**FIGURE 26.14a**).

In 1995, fishermen on the island of Anguilla in the Caribbean witnessed a founder event involving green iguanas. A few weeks after two major hurricanes swept through the region, a large raft composed of downed logs tangled with other debris floated onto a beach on Anguilla. The fishermen noticed green iguanas on the raft and several onshore. Because green iguanas had not previously been found on Anguilla, the fishermen notified biologists. The researchers were able to document that at least 15 individuals had arrived; two years later, they were able to confirm that at least some of the individuals were breeding. A new population had formed.

During this founder event, it is extremely unlikely that allele frequencies in the new Anguilla population of green iguanas exactly matched those of the source population, which was thought to be on the islands of Guadeloupe.

Colonization events like these have been the major source of populations that occupy islands all over the world, as well as island-like habitats such as mountain meadows, caves, and ponds. Each time a founder event occurs, a founder effect is likely to accompany it, changing allele frequencies through genetic drift.

Genetic Bottleneck on Pingelap Atoll If a large population experiences a sudden reduction in size, a population bottleneck is said to occur. The term comes from the metaphor of a few individuals of a population fitting through the narrow neck of a bottle, by chance. Disease outbreaks, natural catastrophes such as floods or fires or storms, or other events can cause population bottlenecks.

Genetic bottlenecks follow population bottlenecks, just as founder effects follow founder events. A **genetic bottleneck** is a sudden reduction in the number of alleles in a population (**FIGURE 26.14b**). Genetic drift occurs during genetic bottlenecks and causes a change in allele frequencies.

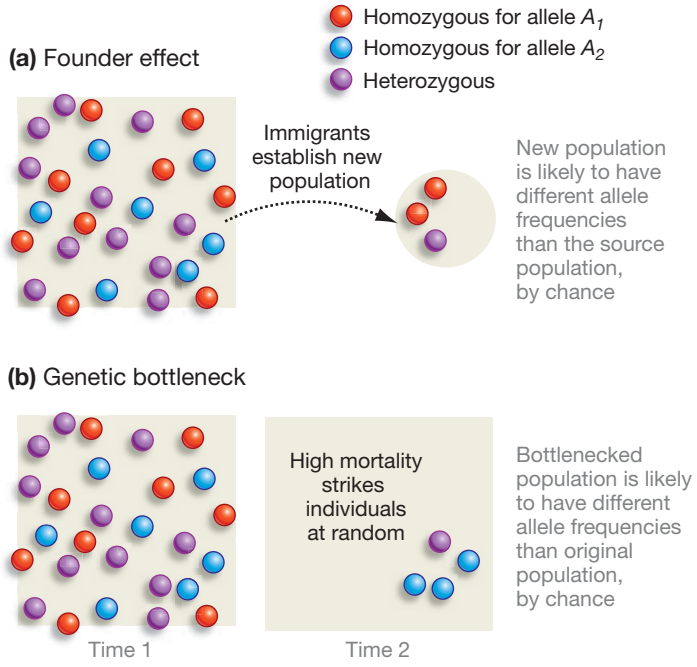


FIGURE 26.14 Two Causes of Genetic Drift in Natural Populations. The smaller the new population, the higher the likelihood that genetic drift will result in differences in allele frequencies as well as in loss of alleles.

✔**QUANTITATIVE** The original population in **(a)** consists of 9 A_1A_1, 11 A_1A_2, and 7 A_2A_2 individuals (this hypothetical population is very small for simplicity). Compare the frequencies of the A_1 allele in the original and new populations.

For an example from a natural population, consider the humans who occupy Pingelap Atoll in the South Pacific. On this island, only about 20 people out of a population of several thousand managed to survive the effects of a typhoon and a subsequent famine that occurred around 1775. The survivors apparently included at least one individual who carried a loss-of-function allele at a gene called *CNGB3*, which codes for a protein involved in color vision.

The *CNGB3* allele is recessive, and when it is homozygous it causes a serious vision deficit called achromatopsia. People with this condition have poor vision and are either totally or almost totally color-blind. The condition is extremely rare in most populations, and the frequency of the *CNGB3* allele is estimated to be under 1.0 percent.

In the population that survived the Pingelap Atoll disaster, however, the loss-of-function allele was at a frequency of about 1/40, or 2.5 percent. If the allele was at the typical frequency of 1.0 percent or less before the population bottleneck, then a large frequency change occurred during the bottleneck, due to drift.

In today's population on Pingelap Atoll, over 1 in 20 people are afflicted with achromatopsia, and the allele that causes the affliction is at a frequency of well over 20 percent. Because the loss-of-function allele is extremely unlikely to be favored by

directional selection or heterozygote advantage, researchers hypothesize that the frequency of the allele in this small population has continued to increase over the past 230 years due to drift.

check your understanding

If you understand that . . .

- Genetic drift occurs whenever allele frequencies change due to chance.
- Drift violates the Hardy–Weinberg assumptions and occurs during many different types of events, including random fusion of gametes at fertilization, founder events, and population bottlenecks.

You should be able to . . .

1. Explain why genetic drift leads to a random loss or fixation of alleles.
2. Explain why genetic drift is particularly important as an evolutionary force in small populations.

Answers are available in Appendix A.

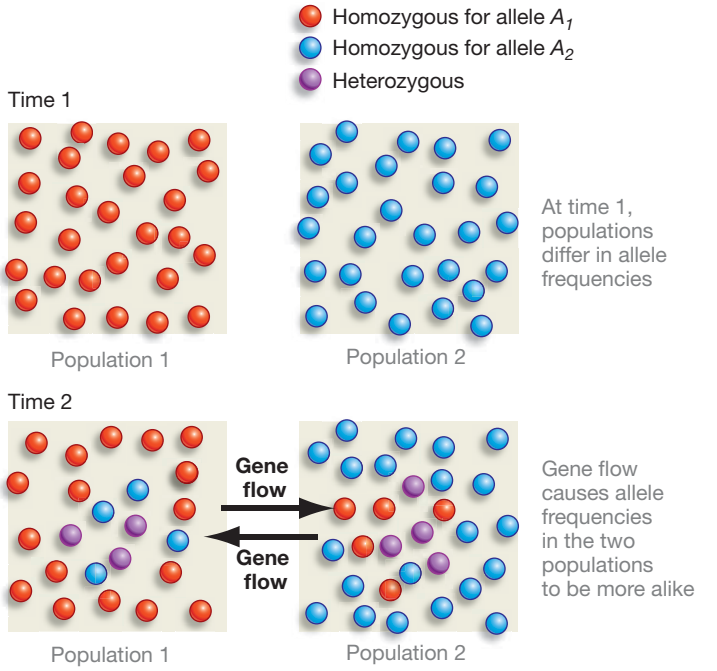

FIGURE 26.15 Gene Flow Makes Allele Frequencies More Similar between Populations. Gene flow can occur in one or both directions. If gene flow continues and no selection occurs, allele frequencies will eventually be identical.

26.5 Gene Flow

When an individual leaves one population, joins another, and breeds, **gene flow** is said to occur—the movement of alleles between populations. Note that while allele flow might be a more apt description, gene flow is the term that evolutionary biologists traditionally use. Also note that while organisms can *emigrate* from a source population or *immigrate* to a new population, the movement of their alleles is called gene flow.

As an evolutionary process, gene flow usually has one outcome: It equalizes allele frequencies between the source population and the recipient population. When alleles move from one population to another, the populations tend to become more alike. To capture this point, biologists say that gene flow homogenizes allele frequencies among populations (**FIGURE 26.15**).

Measuring Gene Flow between Populations

The presence or absence of gene flow has particularly important implications for the conservation of threatened and endangered species. Numerous studies have documented the decline of gene flow between wild populations that have been isolated from one another—for example, by habitat fragmentation. Many studies have also documented the effects of gene flow between wild populations and captive populations.

For example, the captive breeding of fish is increasing around the world as wild populations are being depleted. In some cases, wild fish are used to start captive populations, which are then kept isolated in "farms" until they go to market—except when they escape. In other cases, captive-bred fish are purposefully released into the wild in an effort to supplement the size of wild populations. What are the effects of gene flow between captive-bred populations and wild populations?

A team of biologists recently studied steelhead trout (*Oncorhynchus mykiss*) in the Hood River of Oregon to answer this question (**FIGURE 26.16a**). Some of the trout in the Hood River are wild, while others were raised in a hatchery and released to supplement the diminishing wild population. The researchers were able to catch, sample, and release all of the steelhead trout in the Hood River each year for three years by trapping them in a dam near the mouth of the river as the fish traveled upstream to their wintering streams.

The researchers extracted DNA from tissue samples and calculated genotypes using eight microsatellite alleles (see Chapter 21) to determine whether the parents of each fish were wild or captive-bred. The team then compared the reproductive fitness—the number of surviving adult offspring—of the trout in three groups:

1. Individuals with two wild parents (Wild × Wild)
2. Individuals with one wild parent and one captive-bred parent (Wild × Captive)
3. Individuals with two captive-bred parents (Captive × Captive)

The graph in **FIGURE 26.16b** shows the fitness results for female steelhead trout. Individuals with one or two captive-bred parents are assigned a value from 0 to 1 relative to the fitness of trout with two wild parents (fitness = 1). Individuals with one captive-bred parent have 16 percent lower fitness than wild trout on average, while individuals with two captive-bred parents have significantly lower fitness, 38 percent lower than wild-bred trout,

(a) Wild steelhead trout populations are declining

(b) Captive-bred trout reduce the fitness of wild populations

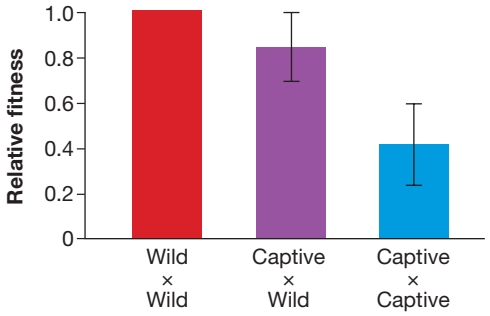

FIGURE 26.16 Gene Flow Reduces Fitness in a Population of Steelhead Trout. In this study, the fitness of female steelhead trout with one or two captive-bred parents is shown relative to females with two wild parents. Data for males are comparable (not shown).
DATA: Araki, H., B. Cooper, and M. S. Blouin. 2009. *Biology Letters* 5(5): 621–624.

on average. The researchers observed similar results for males (not shown).

These data demonstrate that gene flow is occurring from the captive-bred population to the wild population and is causing a reduction in fitness in that population. Related research on farmed Atlantic salmon in Ireland demonstrated that farmed salmon produce smaller eggs, spawn at different times, and have different predator-avoidance behaviors than wild salmon. When farmed salmon were introduced into wild populations, the reproductive success of the wild population decreased.

The conclusion of these studies on steelhead trout and Atlantic salmon is that gene flow between captive-bred and wild populations reduces fitness in the wild populations. As a result, efforts to augment wild populations with captive-bred fish may ultimately result in a *decline* in population size—contrary to the intentions of fisheries biologists.

Gene Flow Is Random with Respect to Fitness

It is not true, though, that gene flow always reduces fitness in the receiving population. If a population has lost alleles due to genetic drift, then the arrival of new alleles via gene flow should increase genetic diversity. If increased genetic diversity results in better resistance to infections by bacteria or viruses or other parasites, for example, gene flow would increase the average fitness of individuals. This was the result when gene flow was used to aid an endangered population of the Florida panther (see Figures 26.4 and 57.14).

Gene flow is random with respect to fitness—the arrival or departure of alleles can increase or decrease average fitness, depending on the situation. But in every case, movement of alleles between populations tends to reduce their genetic differences.

This latter generalization is particularly important in our own species right now. Large numbers of people from Africa, the Middle East, Mexico, Central America, and Asia are immigrating to the countries of the European Union and the United States. Because individuals from different cultural and ethnic groups are intermarrying and having offspring, allele frequencies are becoming more similar across human populations.

26.6 Mutation

To appreciate the role of mutation as an evolutionary force, let's return to one of the central questions that biologists ask about an evolutionary process: How does it affect genetic variation in a population? Recall that:

- Natural selection often favors certain alleles and leads to a decrease in overall genetic variation.
- Genetic drift tends to decrease genetic diversity over time, as alleles are randomly lost or fixed.
- Gene flow increases genetic diversity in a recipient population if new alleles arrive with immigrating individuals. But gene flow may decrease genetic variation in the source population if alleles leave with emigrating individuals.

If most of the evolutionary processes lead to a loss of genetic diversity over time, what restores it? In sexually reproducing organisms, independent assortment and recombination (crossing over) are major sources of genetic diversity (see Chapter 13). But these processes create new combinations of existing alleles. Where do entirely new alleles come from? The answer to this question is **mutation.**

Mutations can occur in a number of ways (Chapters 16 and 21):

- ***Point mutations*** If a change in nucleotide sequence occurs in a stretch of DNA that codes for a protein, the new allele may result in a polypeptide with a novel amino acid sequence. If the mutation occurs in a stretch of DNA that codes for regulatory RNA, the new allele may result in a change in regulation of the expression of other alleles.
- ***Chromosome-level mutations*** One consequence of chromosome mutation is gene duplication, which increases the number of copies of a gene. If duplicated genes diversify via point mutations, they can lose their function or create new alleles.
- ***Lateral gene transfer (also known as horizontal gene transfer)*** New studies suggest that the transfer of genes from one

species to another, rather than from parent to offspring, might be a more important source of genetic variation than previously realized (Chapter 21).

Because errors and chromosome damage are inevitable, mutation constantly introduces new alleles into populations in every generation. Mutation is an evolutionary process that increases genetic diversity in populations.

Even though it consistently leads to an increase in genetic diversity in a population, mutation is random with respect to the affected allele's impact on the fitness of the individual. Changes in the makeup of chromosomes or in specific DNA sequences do not occur in ways that tend to increase fitness or decrease fitness. Mutation just happens.

But because most organisms are well adapted to their current habitat, random changes in genes usually result in products that do not work as well as the alleles that currently exist. Stated another way, most mutations in sequences that code for a functional protein or RNA result in deleterious alleles, which lower fitness. Deleterious alleles tend to be eliminated by purifying selection.

On rare occasions, however, mutation in these types of sequences produces a **beneficial** allele—an allele that allows individuals to produce more offspring. Beneficial alleles should increase in frequency in the population due to natural selection.

Because mutation produces new alleles, it can in principle change the frequencies of alleles through time. But does mutation *alone* occur often enough to make it an important factor in changing allele frequencies? The short answer is no.

Mutation as an Evolutionary Process

To understand why mutation is not a significant mechanism of evolutionary change by itself, consider that the highest mutation rates that have been recorded at individual genes in humans are on the order of 1 mutation in every 10,000 gametes produced by an individual. This rate means that for every 10,000 alleles produced, on average one will have a mutation at the gene in question.

When two gametes combine to form an offspring, then, at most about 1 in every 5000 offspring will carry a mutation at a particular gene. Now suppose that 195,000 humans live in a population, that 5000 offspring are born one year, and that at the end of that year, the population numbers 200,000. Humans are diploid, so in a population this size there are, in total, 400,000 copies of each gene. Only one of them is a new allele created by mutation, however. Over the course of a year, the allele frequency change introduced by mutation is 1/400,000, or 0.0000025 (2.5×10^{-6}). At this rate, it would take 4000 years for mutation to produce a change in allele frequency of 1 percent.

These calculations support the conclusion that mutation does little on its own to change allele frequencies. Although mutation can be a significant evolutionary process in bacteria and archaea, which have extremely short generation times, mutation in eukaryotes rarely causes a change from the genotype frequencies expected under the Hardy–Weinberg principle. As an evolutionary process, mutation is slow compared with selection, genetic drift, and gene flow.

However, mutation can have a very large effect on evolution when *combined* with genetic drift, gene flow, and selection. Let's consider two examples.

Experimental Studies of Mutation

Consider a lab experiment designed by Richard Lenski and colleagues to evaluate the role that mutation plays over many generations.

Experimental Evolution Lenski's group focused on *Escherichia coli*, a bacterium that is a common resident of the human intestine. To begin, they set up a large series of populations, each founded with a single cell, and allowed them to replicate for over four years—about 10,000 generations. The strain of *E. coli* used in the experiment is completely asexual and reproduces by cell division. Thus, mutation was the only source of genetic variation in these populations.

The biologists saved a sample of cells from each population at regular intervals during the experiment and stored them in a freezer. Because frozen *E. coli* cells resume growth when they are thawed, the frozen cells serve as an archive of individuals from different generations.

Were cells from the older and newer generations of each population different? Lenski's group used competition experiments to address this question. They grew cells from two different generations on the same plate and compared their growth rates. The populations of cells that were more numerous had grown the fastest, meaning that they were better adapted to the experimental environment.

In this way the researchers could measure the fitness of descendant populations relative to ancestral populations. Relative fitness values greater than 1 meant that recent-generation cells outnumbered older-generation cells following the competition.

Fitness Increased in Fits and Starts The data from the competition experiments are graphed in **FIGURE 26.17**. Notice that relative fitness increased dramatically—almost 30 percent—over time. But notice also that fitness increased in fits and starts. This pattern is emphasized by the solid line on the graph, which represents a mathematical function fitted to the data points.

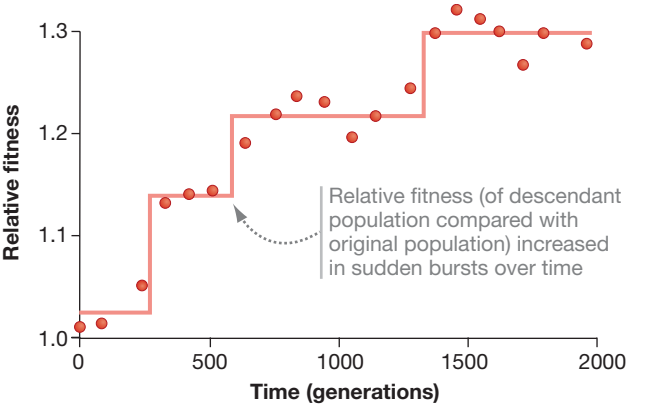

FIGURE 26.17 Evidence of Mutation in Lab Populations of *E. coli*.
DATA: Elena, S. F., V. S. Cooper, and F. E. Lenski. 1996. *Science* 272: 1802–1804.

What caused this stair-step pattern? Lenski's group hypothesized that genetic drift was relatively unimportant in this experiment because population sizes were so large. Instead, they proposed that each jump was caused by a novel mutation that conferred a fitness benefit under selection. Their interpretation was that cells that happened to have the beneficial mutation grew rapidly and came to dominate the population.

After a beneficial mutation occurred, the fitness of the population stabilized—sometimes for hundreds of generations—until another random but beneficial mutation occurred and produced another jump in fitness. These results demonstrate the combined effects of mutation and natural selection.

Studies of Mutation in Natural Populations

Lenski's experiment demonstrates the effect of cumulative mutations in laboratory populations. Now consider a recent study showing how several forms of mutation have combined with natural selection to create color variations, or polymorphisms, in pea aphids.

Lateral Gene Transfer Pea aphids (*Acyrthosiphon pisum*) are small insects that feed on plant sap. They occur in two colors in the wild, red and green, and both colors coexist within populations (**FIGURE 26.18a**). The two phenotypes are maintained in the population due to frequency-dependent selection—ladybird beetles are more likely to prey on red aphids, whereas parasitoid wasps are more likely to lay their eggs in green aphids. The balancing selection on both colors preserves genetic variation in the populations.

The color of aphids is determined by carotenoid pigments, the same group of pigments that give zebra finches their bright orange beaks. Finches and other animals get their carotenoid pigments from the food they eat, mostly from plants.

But there is a twist. Pea aphids do *not* acquire their carotenoids from the plant sap they eat. So where do the pigments come from? Researchers recently examined several bacteria associated with pea aphids and concluded that the carotenoids did not originate from these symbionts either. Instead, other researchers found that the aphids are generating their *own* carotenoids—the first animals ever discovered to have this ability.

If the ancestors of aphids did not have the genes that code for the necessary enzymes for carotenoid biosynthesis, how did the pea aphids obtain this pathway? The answer is by mutation, more specifically by lateral gene transfer—from the genome of a fungal symbiont to the genome of a recent ancestor of the pea aphids. This result was surprising—clear evidence of lateral gene transfer from one eukaryote to another.

Gene Duplication Lateral gene transfer is only part of the mutation story in pea aphids. Carotenoids are a family of molecules with similar pigment and a number of intermediate forms. Two types of enzymes are primarily responsible for the biosynthesis of these molecules in both pea aphids and their fungal ancestor.

A comparison of aphid and fungal genome sequences suggests that after the fungal genes for these two types of enzymes

(a) Red–green color polymorphism in pea aphids

(b) Origin of genes for carotenoid synthesis enzymes in aphids

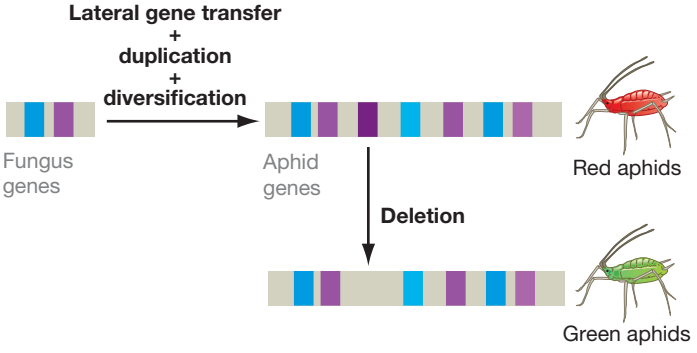

FIGURE 26.18 Evidence of Mutation in Pea Aphids.

were transferred to aphids, they underwent further mutations—duplications, sequence diversification by point mutations, and deletion. As a result, red pea aphids have the enzymes necessary to synthesize yellow, green, and red carotenoid pigments, while green pea aphids have the enzymes necessary to synthesize only the yellow and green ones (**FIGURE 26.18b**). The deletion of a gene in the green aphid genome illustrates an important point: Sometimes a loss-of-function mutation can be adaptive. In this case, being green helps aphids to avoid predation by ladybird beetles.

Take-Home Messages

The research on mutations in *E. coli* populations in the lab and the origin of color polymorphism in pea aphids reinforces three fundamental messages about the role of mutation in evolution.

1. Mutation is the ultimate source of genetic variation. Crossing over and independent assortment shuffle existing alleles into new combinations, but only mutation creates new alleles. Mutations just happen—organisms cannot create mutations because they "want" or "need" them.
2. If mutation did not occur, evolution would eventually stop. Recall that natural selection and genetic drift tend to eliminate alleles. Without mutation, eventually there would be no variation for selection and drift to act on.

SUMMARY TABLE 26.4 Evolutionary Processes

	Definition/Description	Effect on Genetic Variation	Effect on Average Fitness
Natural selection	Certain alleles are favored	Can maintain, increase, or reduce genetic variation	Can produce adaptation, increasing fitness
Genetic drift	Random changes in allele frequencies; most important in small populations	Tends to reduce genetic variation via loss or fixation of alleles	Random with respect to fitness; usually reduces average fitness
Gene flow	Movement of alleles between populations; reduces differences between populations	May increase genetic variation by introducing new alleles; may decrease it by removing alleles	Random with respect to fitness; may increase or decrease average fitness by introducing high- or low-fitness alleles
Mutation	Production of new alleles	Increases genetic variation by introducing new alleles	Random with respect to fitness; most mutations in coding sequences lower fitness

3. Mutation *alone* is usually inconsequential in changing allele frequencies at a particular gene. However, when considered across the genome and when combined with natural selection, genetic drift, and gene flow, mutation becomes an important evolutionary process.

TABLE 26.4 summarizes these points and similar conclusions about the four evolutionary processes. Each of the four evolutionary processes has different consequences for allele frequencies, all of them violating Hardy–Weinberg predictions. These processes interact to create new species—that is, new branches on the tree of life (Chapter 27). The ultimate result is biological diversity (Chapter 28 and Unit 6). You can see how nonrandom mating and the four evolutionary processes fit into the Big Picture of Evolution on pages 526–527.

CHAPTER 26 REVIEW

For media, go to MasteringBiology

If you understand . . .

26.1 Analyzing Change in Allele Frequencies: The Hardy–Weinberg Principle

- The Hardy–Weinberg principle played an important role in the synthesis of Mendelian genetics and Darwinian evolution.
- The Hardy–Weinberg principle can serve as a null hypothesis in evolutionary studies because it predicts what genotype and allele frequencies are expected to be if mating is random with respect to the gene in question and if none of the four evolutionary processes is operating on that gene.

✔ **QUANTITATIVE** You should be able to write out the Hardy–Weinberg equations for allele and genotype frequencies and calculate the genotype frequencies expected if the frequency of A_1 is 0.2.

26.2 Nonrandom Mating

- Nonrandom mating changes only genotype frequencies, not allele frequencies, so is not an evolutionary process itself.
- Inbreeding, or mating among relatives, is a form of nonrandom mating. It leads to an increase in homozygosity and a decrease in heterozygosity.
- Inbreeding can accelerate natural selection and can cause inbreeding depression.

✔ You should be able to predict how extensive inbreeding during the 1700s and 1800s affected the royal families of Europe.

26.3 Natural Selection

- Natural selection is the only evolutionary process that produces adaptation.
- Directional selection favors phenotypes at one end of a distribution. It decreases allelic diversity in populations.
- Stabilizing selection eliminates phenotypes with extreme characteristics. It decreases allelic diversity in populations.
- Disruptive selection favors extreme phenotypes and thus maintains genetic variation in populations. Disruptive selection sometimes leads to the formation of new species.
- Balancing selection occurs when no single phenotype is favored; there is a balance among alleles in terms of fitness and frequency. Balancing selection preserves genetic variation.
- Sexual selection is a type of natural selection that leads to the evolution of traits that help individuals attract mates. It usually has a stronger effect on males than on females.

✔ You should be able to explain why natural selection violates the Hardy–Weinberg principle.

26.4 Genetic Drift

- Genetic drift causes random changes in allele frequencies.
- Genetic drift is particularly important in small populations, and it tends to reduce overall genetic diversity.
- Genetic drift can result from random fusion of gametes at fertilization, founder events, and population bottlenecks.

✔ **You should be able to suggest how genetic drift could be important to the management of endangered species.**

26.5 Gene Flow

- Gene flow equalizes allele frequencies between populations.
- Gene flow can introduce alleles from one population to another when individuals migrate among populations.
- The introduced alleles may have a beneficial, neutral, or deleterious effect.

✔ **You should be able to suggest how gene flow could be important to the management of endangered species.**

26.6 Mutation

- Mutation is the only evolutionary process that creates new alleles. They may be beneficial, neutral, or deleterious.
- Mutation occurs too infrequently to be a major cause of change in allele frequency alone, but it is important when combined with natural selection, genetic drift, and gene flow.

✔ **You should be able to suggest how mutation could be important to the management of endangered species.**

TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. In what sense is the Hardy–Weinberg principle a null hypothesis?
2. Why isn't inbreeding considered an evolutionary process?
   a. It does not change genotype frequencies.
   b. It does not change allele frequencies.
   c. It does not occur often enough to be important in evolution.
   d. It does not violate the assumptions of the Hardy–Weinberg principle.
3. Why is genetic drift aptly named?
   a. It causes allele frequencies to drift up or down randomly.
   b. It occurs when alleles from one population drift into another.
   c. It occurs when mutations drift into a genome.
   d. It occurs when populations drift into new habitats.
4. What does it mean when an allele reaches "fixation"?
   a. It is eliminated from the population.
   b. It has a frequency of 1.0.
   c. It is dominant to all other alleles.
   d. It is adaptive.
5. True or false? Gene flow can either increase or decrease the average fitness of a population.
6. Mutation is the ultimate source of genetic variability. Why is this statement correct?
   a. DNA polymerase (the enzyme that copies DNA) is remarkably accurate.
   b. "Mutation proposes and selection disposes."
   c. Mutation is the only source of new alleles.
   d. Mutation occurs in response to natural selection. It generates the alleles that are required for a population to adapt to a particular habitat.

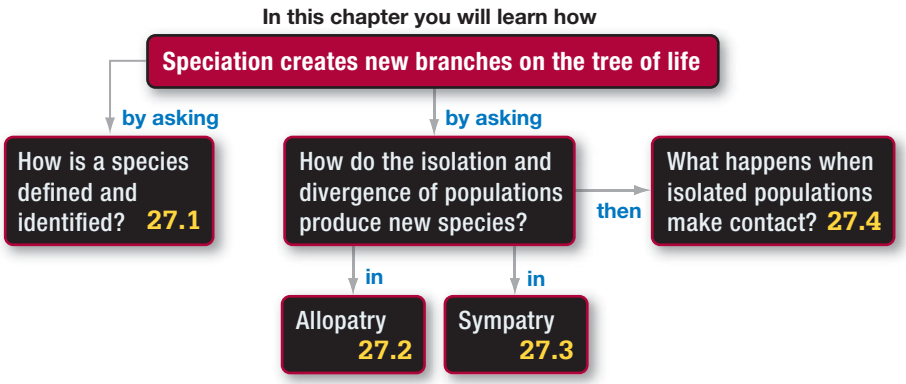
TEST YOUR UNDERSTANDING

Answers are available in Appendix A

7. **QUANTITATIVE** In a population of 2500, how many babies would you expect to have cystic fibrosis, a homozygous recessive condition, if the frequency of the dominant allele is 0.9 and the population is at Hardy–Weinberg equilibrium?
   a. $0.9 \times 2500 = 2025$
   b. $2 \times 0.9 \times 0.1 \times 2500 = 800$
   c. $0.9 \times 0.1 \times 2500 = 400$
   d. $0.1 \times 0.1 \times 2500 = 25$
8. Suggest why inbreeding could cause recessive deleterious alleles for cystic fibrosis to be "purged" from a population.
9. Determine what is incorrect in the following statement: Red aphids mutated their genes so that they could be green and avoid predation by ladybird beetles.
10. Why does sexual selection often lead to sexual dimorphism?
11. Consider an allele that increases reproductive success in elephant seal males versus an allele that increases reproductive success in females. Which allele will increase in frequency faster, and why?
12. Draw a small concept map (**BioSkills 15**) showing how selection, genetic drift, gene flow, and mutation relate to genetic variation.

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A



13. **QUANTITATIVE** In humans, albinism is caused by loss-of-function mutations in genes involved in the synthesis of melanin, the dark pigment in skin. Only people homozygous for a loss-of-function allele (genotype *aa*) have the albino phenotype. In Americans of northern European ancestry, albino individuals are present at a frequency of about 1 in 10,000 (or 0.0001). Assuming that genotypes are in Hardy–Weinberg proportions, what is the frequency of Caucasians in the United States who carry an allele for albinism?

14. A group of researchers presented artificial calls of the male cricket *Teleogryllus commodus* to female crickets in the lab to measure selection for male calls. They used artificial calls so that they could vary properties such as length of the pause between calls and number of trills in each call. When positive selection was plotted as a function of call characteristics, the shapes of the selection curves started low, peaked in the middle, and ended low. What kind of selection is occurring?
a. sexual selection
b. balancing selection
c. sexual selection and stabilizing selection
d. sexual selection and balancing selection

15. Suppose you were studying several species of human. In one, males never lifted a finger to help females raise children. In another, males provided just as much parental care as females except for actually carrying the baby during pregnancy. How does the fundamental asymmetry of sex compare in the two species? How would you expect sexual dimorphism to compare between the two species?

16. You are a conservation biologist charged with creating a recovery plan for an endangered species of turtle. The turtle's habitat has been fragmented by suburbanization and highway construction into small, isolated, but protected areas. Some evidence indicates that certain turtle populations are adapted to typical freshwater marshes, whereas others are adapted to acidic wetlands or salty habitats. Further, some turtle populations number less than 25 breeding adults, making genetic drift and inbreeding a major concern. In creating a recovery plan, the tools at your disposal are captive breeding, the capture and transfer of adults to create gene flow, or the creation of habitat corridors between wetlands to make migration possible. How would you use gene flow to help this species?

27 Speciation

New sunflower species have formed recently in southwestern North America. This chapter explains how.

Although Darwin called his masterwork *On the Origin of Species by Means of Natural Selection*, he actually had little to say about how new species arise. Instead, his data and analyses focused on the process of natural selection and the changes that occur *within* populations over time.

Recall that there are four evolutionary processes—natural selection, genetic drift, mutation, and gene flow—and that gene flow makes allele frequencies more similar among populations (see Chapter 26). If gene flow ends, allele frequencies in isolated populations are free to diverge—meaning that the populations begin to evolve independently of each other. For example, when a new mutation creates an allele that changes the phenotype of individuals in one population, there is no longer any way for that allele to appear in the other population. If mutation, selection, and genetic drift cause isolated populations to diverge sufficiently, distinct types, or species, form—that is, the process of speciation takes place.

BIG PICTURE

This chapter is part of the Big Picture. See how on pages 526–527.

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

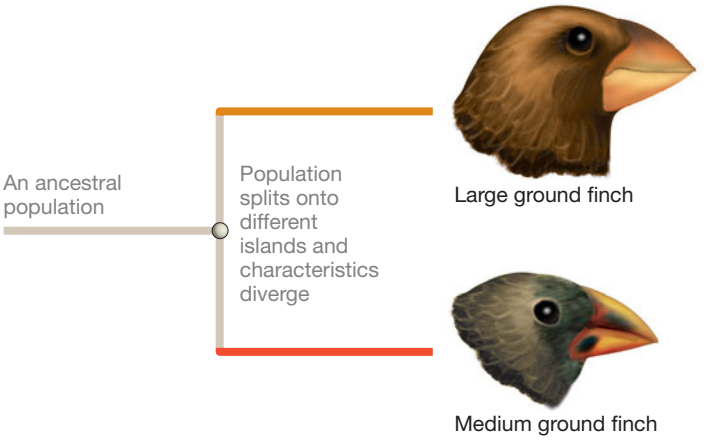


FIGURE 27.1 Speciation Creates Evolutionarily Independent Populations. The large ground finch and medium ground finch are derived from the same ancestral population. This ancestral population split into two populations isolated by lack of gene flow. Because the populations began evolving independently, over time they acquired the distinctive characteristics observed today.

In essence, speciation results from *genetic isolation* and *genetic divergence*. Genetic isolation results from lack of gene flow, and genetic divergence occurs because selection, genetic drift, and mutation proceed independently in the isolated populations.

Speciation is a splitting event that creates two or more distinct species from a single ancestral species (**FIGURE 27.1**). When speciation is complete, a new branch has been added to the tree of life. Thus, the study of speciation is critical to understanding how life evolved and has many practical implications for the preservation of biodiversity on Earth (see Chapter 57). You can see how speciation fits into the Big Picture of Evolution on pages 526–527.

Let's begin by considering the *pattern* component of studying speciation—how can we define and identify species? Then let's explore the *process* of speciation—how do new species form?

27.1 How Are Species Defined and Identified?

If your friend were to tell you that she was planning to study polar bears and grizzly bears during her summer research project, you would immediately recognize these animals as distinct species. Polar bears and grizzly bears are distinguishable from one another in appearance, behavior, habitat use, and other traits. But what if your friend was going to compare elephants that live in the forests and savannas of Africa? Are these elephants the same species or two different species?

Evolutionary biologists have been wrangling with the definition of species for decades—how can you reliably distinguish two or more species of bears, elephants, or bacteria in the field or fossil record? Although there is no single, universal answer, scientists do agree there is a distinction between the *definition* of species in general and the criteria that can be used to *identify* species in particular cases.

In general, a **species** is defined as an evolutionarily independent population or group of populations. Of the many criteria that can be used to identify species, the three most common ones are **(1)** the biological species concept, **(2)** the morphospecies concept, and **(3)** the phylogenetic species concept.

The Biological Species Concept

According to the **biological species concept,** the main criterion for identifying species is reproductive isolation. This is a logical yardstick because no gene flow occurs between populations that are reproductively isolated from each other. Specifically, if two different populations do not interbreed in nature, or if they fail to produce viable and fertile offspring when matings take place, then they are considered distinct species. The influential evolutionary biologist Ernst Mayr strongly promoted the biological species concept because the criterion of reproductive isolation enables clear evidence of evolutionary independence.

Reproductive isolation can result from a wide variety of events and processes. To organize the various mechanisms that stop gene flow between populations, biologists distinguish between:

- **prezygotic** (literally, "before-zygote") **isolation,** which prevents individuals of different species from mating; and
- **postzygotic** ("after-zygote") **isolation,** in which the offspring of matings between members of different species do not survive or reproduce.

TABLE 27.1 outlines some of the more important mechanisms of prezygotic and postzygotic isolation.

Although the biological species concept has a strong theoretical foundation, it has disadvantages. The criterion of reproductive isolation cannot be evaluated in fossils or in species that reproduce asexually. What's more, the concept is difficult to apply when closely related populations do not happen to overlap with each other geographically. In this case, biologists are left to guess whether interbreeding and gene flow would occur if the populations happened to come into contact.

Further, reproductive isolation can sometimes be a complex gradient rather than an all-or-nothing scenario. For example, if a male lion and female tiger produce a rare "liger" that survives and reproduces in captivity (the ranges of these cats do not overlap in nature), are lions and tigers necessarily the same species?

The Morphospecies Concept

How do biologists identify species when the criterion of reproductive isolation cannot be applied? Under the **morphospecies** ("form-species") **concept,** researchers identify evolutionarily independent lineages by differences in size, shape, or other morphological features. The logic behind the morphospecies concept is that distinguishing features are most likely to arise if populations are independent and isolated from gene flow.

The morphospecies concept is compelling simply because it is so widely applicable. It is a useful criterion when biologists have no data on the extent of gene flow, and it is equally applicable to sexual, asexual, or fossil species. Its disadvantages

TABLE 27.1 Mechanisms of Reproductive Isolation

	Process	Example
Prezygotic Isolation		
Temporal	Populations are isolated because they breed at different times.	Bishop pines and Monterey pines release their pollen at different times of the year.
Habitat	Populations are isolated because they breed in different habitats.	Parasites that begin to exploit new host species are isolated from their original population.
Behavioral	Populations do not interbreed because their courtship displays differ.	To attract male fireflies, female fireflies give a species-specific sequence of flashes.
Gametic barrier	Matings fail because eggs and sperm are incompatible.	In sea urchins, a protein called bindin allows sperm to penetrate eggs. Differences in the amino acid sequence of bindin cause matings to fail between closely related populations.
Mechanical	Matings fail because male and female reproductive structures are incompatible.	In alpine skypilots (a flowering plant), the length of the floral tube varies. Bees can pollinate in populations with short tubes, but only hummingbirds can pollinate in populations with long tubes.
Postzygotic Isolation		
Hybrid viability	Hybrid offspring do not develop normally and die as embryos.	When ring-necked doves mate with rock doves, less than 6 percent of eggs hatch.
Hybrid sterility	Hybrid offspring mature but are sterile as adults.	Eastern meadowlarks and western meadowlarks are almost identical morphologically, but their hybrid offspring are usually infertile.

are that **(1)** it may lead to the naming of two or more species when there is only one **polymorphic species** with differing phenotypes, such as the spotted and black morphs of jaguars; **(2)** it cannot identify **cryptic species,** which differ in traits other than morphology, such as the meadowlarks in Table 27.1; and **(3)** the morphological features used to distinguish species are subjective. In the worst case, different researchers working on the same populations disagree on the characters that distinguish species, such as when paleontologists disagree on the identity of an extinct human species based on measurements of fossil bone fragments.

The Phylogenetic Species Concept

The **phylogenetic species concept** identifies species based on the evolutionary history of populations. The reasoning behind the phylogenetic species concept begins with Darwin's theory that all species are related by common ancestry. In modern terms, all species form a monophyletic ("one-tribe") group—the tree of life.

A **monophyletic group,** also called a **clade** or **lineage,** consists of an ancestral population, all of its descendants, and *only* those descendants. On any given evolutionary tree, there are many monophyletic groups (**FIGURE 27.2a**).

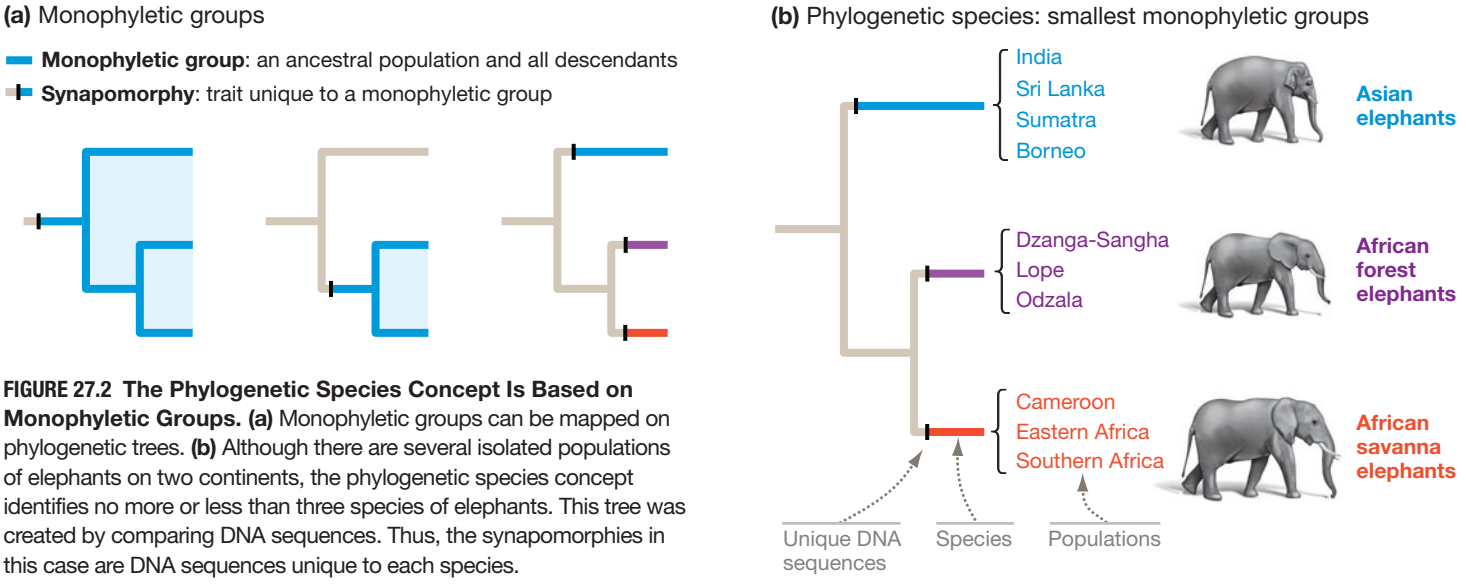

FIGURE 27.2 The Phylogenetic Species Concept Is Based on Monophyletic Groups. (a) Monophyletic groups can be mapped on phylogenetic trees. **(b)** Although there are several isolated populations of elephants on two continents, the phylogenetic species concept identifies no more or less than three species of elephants. This tree was created by comparing DNA sequences. Thus, the synapomorphies in this case are DNA sequences unique to each species.

Monophyletic groups, in turn, are identified by traits called synapomorphies ("unique-forms"). A **synapomorphy** is a trait that is found in certain groups of organisms and their common ancestor, but is missing in more distant ancestors. Fur and lactation, for example, are synapomorphies that identify mammals as a monophyletic group.

Synapomorphies are homologous traits that can be identified at the genetic, developmental, or structural level. In many cases, researchers use DNA sequence data to identify synapomorphies and estimate phylogenetic trees. (Chapter 28 explores the data and logic that biologists use to reconstruct phylogenies, and **BioSkills** 7 in Appendix B reviews how to read phylogenetic trees.)

Under the phylogenetic species concept, species are defined as the smallest monophyletic groups on the tree of life. Phylogenetic species are made up of populations that share one or more synapomorphies.

The tree in **FIGURE 27.2b,** for example, is based on DNA sequence data from an array of elephant populations. Each of the populations is not distinctive enough to represent separate branches. The phylogenetic species on the tree are labeled Asian elephants, African forest elephants, and African savanna elephants. These are the smallest monophyletic groups on the tree.

The names at some of the tips on this tree (Cameroon, Eastern Africa, Southern Africa, etc.) represent populations within species. These populations may be separated geographically, but their characteristics are so similar that they do not form independent branches on the tree. They are simply part of the same monophyletic group containing other populations.

The phylogenetic species concept has two distinct advantages: **(1)** It can be applied to any population (fossil, asexual, or sexual), and **(2)** it is logical because different species have different synapomorphies only if they are isolated from gene flow and have evolved independently. The approach has a distinct disadvantage, however: Carefully estimated phylogenies are available only for a tiny (though growing) subset of populations on the tree of life.

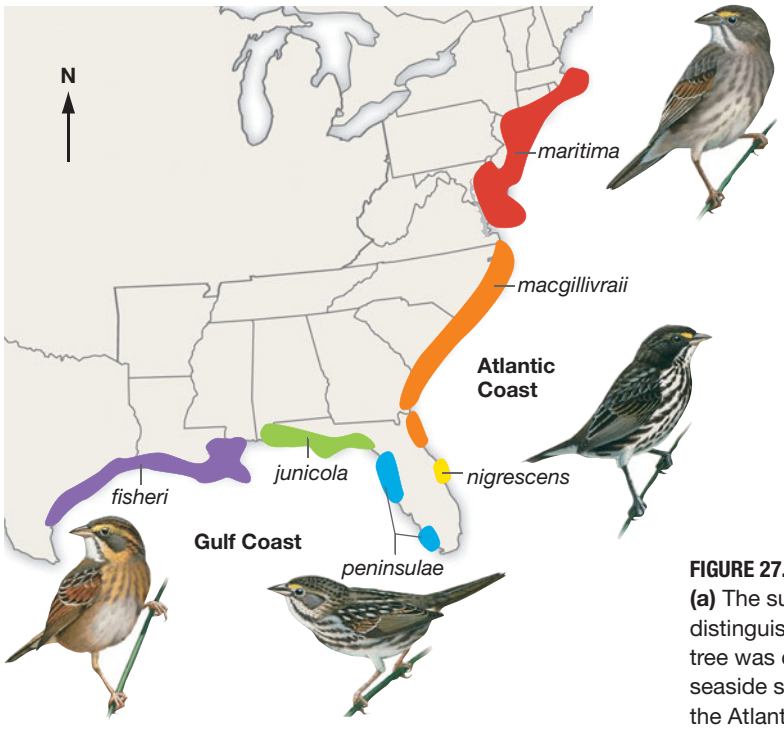
Critics of the phylogenetic species concept also point out that it would probably lead to recognition of many more species than either the morphospecies or biological species concepts. Proponents counter that, far from being a disadvantage, the recognition of increased numbers of species might better reflect the extent of life's diversity.

The three major species concepts are summarized in **TABLE 27.2**. In practice, researchers use a combination of species concepts to identify evolutionarily independent populations in nature. Conflicts have occurred, however, as in the case of the dusky seaside sparrow.

Species Definitions in Action: The Case of the Dusky Seaside Sparrow

Seaside sparrows live in salt marshes along the Atlantic and Gulf Coasts of the United States. The scientific name of this species is *Ammodramus maritimus*. Recall that scientific names consist of a genus name followed by a species name (Chapter 1).

Using the morphospecies and biological species concepts, researchers had traditionally named six seaside sparrow "subspecies" (**FIGURE 27.3a**). **Subspecies** are populations that live in discrete geographic areas and have distinguishing features, such as coloration or calls, but are not considered distinct enough to be called separate species. For example, *A. m. nigrescens* (*nigrescens* indicates the subspecies name) lives on the Atlantic Coast of Florida, while *A. m. peninsulae* lives on the Gulf Coast of Florida. These subspecies can interbreed if the geographical barriers to their isolation are removed.



By the late 1960s, biologists began to be concerned about the future of some seaside sparrow subspecies because their habitats were increasingly threatened by agriculture and ocean-front housing. Further, since the seaside sparrow subspecies are physically isolated from one another, and because young seaside sparrows tend to breed near where they hatched, little or no gene flow occurs among populations.

A subspecies called the dusky seaside sparrow (*A. m. nigrescens*) was in particular trouble; by 1980 only six individuals from this population remained. All were males. At this point government and private conservation agencies sprang into action under the Endangered Species Act, a law whose goal is to prevent the extinction of species and, as in this case, subspecies.

SUMMARY TABLE 27.2 Three Most Common Species Concepts

	Criterion for Identifying Populations as Species	Advantages	Disadvantages
Biological species	Reproductive isolation between populations (they don't breed and don't produce viable, fertile offspring)	Reproductive isolation = evolutionary independence	Not applicable to asexual or fossil species; difficult to assess if populations do not overlap geographically.
Morphospecies	Morphologically distinct populations	Widely applicable	Subjective (researchers often disagree about how much or what kinds of morphological distinction indicate speciation); misidentifies polymorphic species; misses cryptic species.
Phylogenetic species	Smallest monophyletic group on phylogenetic tree	Widely applicable; based on testable criteria	Relatively few well-estimated phylogenies are currently available.

(a) Each subspecies of seaside sparrow has a restricted range.

(b) The six subspecies form two monophyletic groups when DNA sequences are compared.

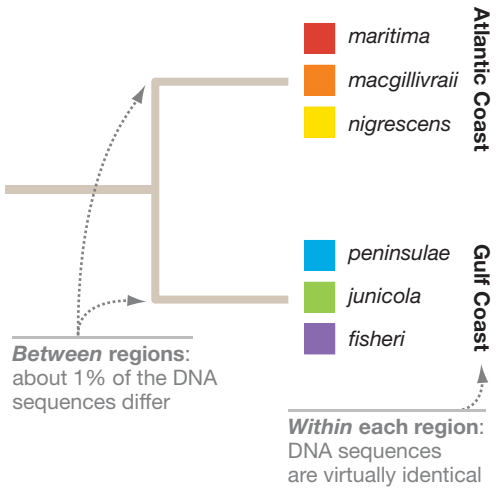


FIGURE 27.3 Seaside Sparrows Form Two Monophyletic Groups. **(a)** The subspecies of seaside sparrows named on this map are distinguished by their distinctive coloration and songs. **(b)** This phylogenetic tree was constructed by comparing DNA sequences. The tree shows that seaside sparrows represent two distinct monophyletic groups, one native to the Atlantic Coast and the other native to the Gulf Coast.

To launch the rescue program, the remaining male dusky seaside sparrows were taken into captivity and bred with females from the nearby subspecies, *A. m. peninsulae*. Officials planned to use these hybrid offspring as breeding stock for a reintroduction program. The goal was to preserve as much genetic diversity as possible by reestablishing a healthy population of dusky-like birds.

The plan was thrown into turmoil, however, when a different group of biologists estimated the phylogeny of the seaside sparrows by comparing gene sequences. The tree in **FIGURE 27.3b** shows that seaside sparrows represent just two distinct monophyletic groups: one native to the Atlantic Coast and the other native to the Gulf Coast. Under the phylogenetic species concept, the dusky sparrow is part of the same monophyletic group that includes the other Atlantic Coast sparrows.

Officials had unwittingly crossed the dusky males, *A. m. nigrescens* from the Atlantic Coast, with females from the Gulf Coast lineage—a population that may have been geographically isolated from dusky sparrows for more than 250,000 years. Because the goal of the conservation effort was to preserve existing genetic diversity, this was the wrong population to use.

The researchers who did the phylogenetic analysis maintained that the biological and morphospecies concepts had misled a well-intentioned conservation program. Under the phylogenetic species concept, they claimed that officials should have allowed the dusky sparrow to go extinct and then concentrated their efforts on preserving one or more populations from each coast. In this way, the two monophyletic groups of sparrows—and the most genetic diversity—would be preserved.

Under the morphospecies concept, however, officials did the right thing by attempting to preserve all subspecies. They argue that dusky seaside sparrows had distinctive heritable traits, like coloration and songs, that are better "watered down" by cross-breeding than lost completely.

When it comes to conservation, life-and-death decisions like these are crucial. Now our task is to consider a fundamental question about process: How do isolation and divergence produce the event called speciation?

If you understand that . . .

- Species are evolutionarily independent because no gene flow occurs between them and other species.
- Biologists use an array of criteria to identify evolutionarily independent groups.

✓ You should be able to . . .

1. Explain why the criteria invoked by the biological species, morphospecies, and phylogenetic species concepts allow biologists to identify evolutionarily independent groups.
2. Describe the disadvantages of the biological species, morphospecies, and phylogenetic species concepts.

Answers are available in Appendix A.

27.2 Isolation and Divergence in Allopatry

Speciation begins when gene flow between populations is reduced or eliminated, causing genetic isolation. Genetic isolation happens routinely when populations become geographically separated. Populations that are geographically separated are said to be in **allopatry** ("different-homeland"). Thus, speciation that begins with geographic isolation is known as **allopatric speciation.**

Geographic isolation, in turn, occurs in one of two ways: dispersal or **vicariance,** the physical splitting of a habitat. As **FIGURE 27.4a** illustrates, a population can disperse to a new habitat, colonize it, and found a new population. Alternatively, a new geographic barrier can split a population into two or more subgroups that are physically isolated from each other (**FIGURE 27.4b**).

The case studies that follow address two questions: First, how do dispersal and vicariance events occur? Answering this question takes us into the field of **biogeography**—the study of how species and populations are distributed geographically (see Chapter 52). And second, once populations are physically isolated, how do mutation, genetic drift, and selection produce divergence?

Allopatric Speciation by Dispersal

Peter Grant and Rosemary Grant had the good fortune to witness a colonization event while working in the Galápagos Islands off the coast of South America. The Grants have been studying finches on the island of Daphne Major since 1971 (Chapter 25).

In 1973 the Grants began to observe a yearly migration of large ground finches from their home island to Daphne Major for a few months between breeding seasons. Finally, in 1982, thirteen colonists stayed on Daphne Major throughout the breeding season, and five of them produced offspring. These colonists represented a new population, allopatric with their migrant source population, because the two populations bred and nested on different islands.

Could this dispersal event lead to speciation? To evaluate this question, the Grants caught, weighed, and measured most of the parents and offspring produced on Daphne Major over the succeeding 12 years. When they compared these data with measurements of large ground finches in the migrant population, they discovered that the average beak size in the colonist population was much larger.

Two evolutionary processes could be responsible for the change in beak size:

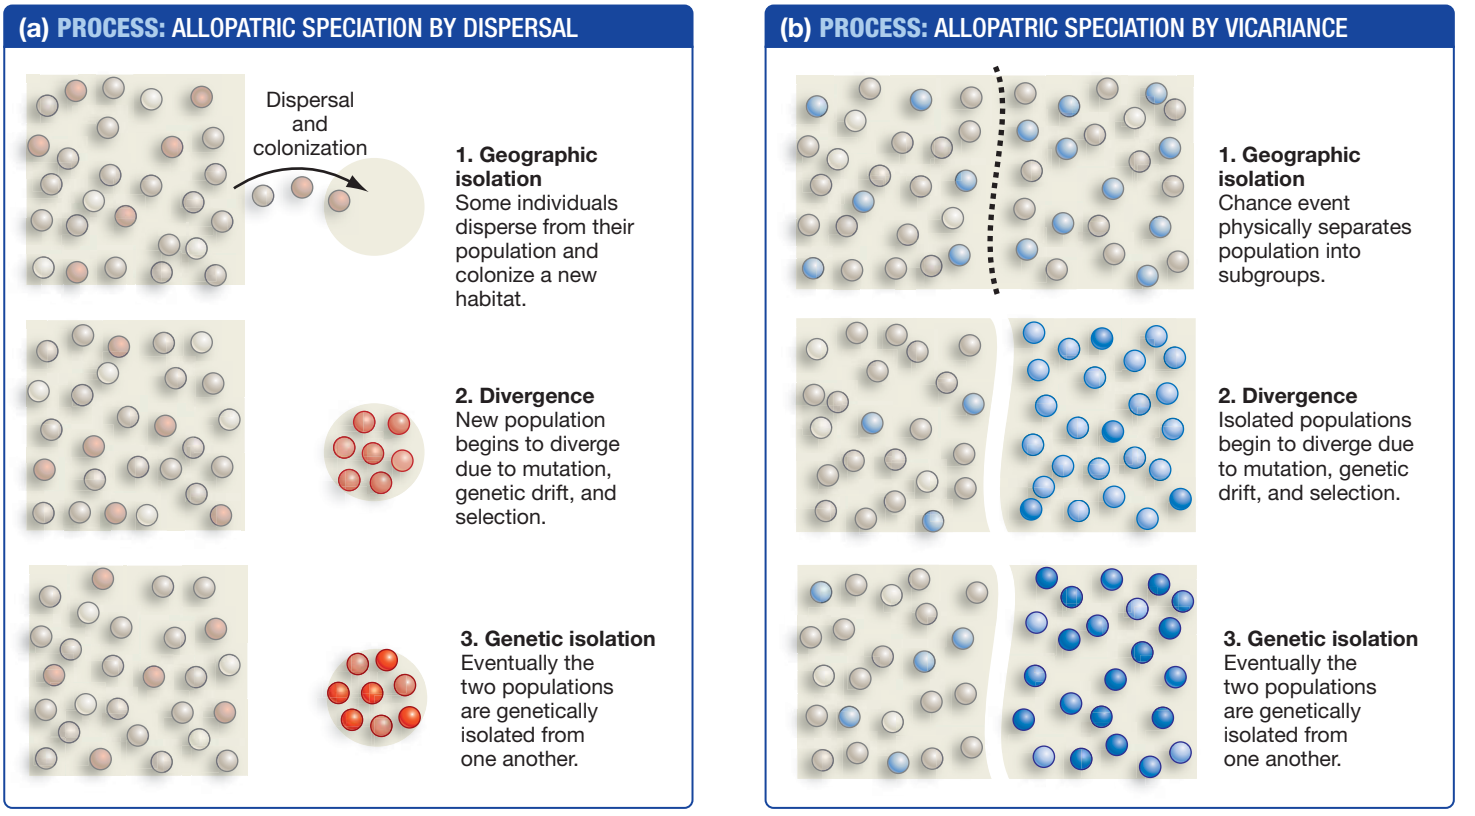

FIGURE 27.4 Allopatric Speciation Begins via Dispersal or Vicariance. (a) When dispersal occurs, colonists establish a new population in a novel location. **(b)** In vicariance, a widespread population becomes fragmented into isolated subgroups. Different colors represent genetic variation.

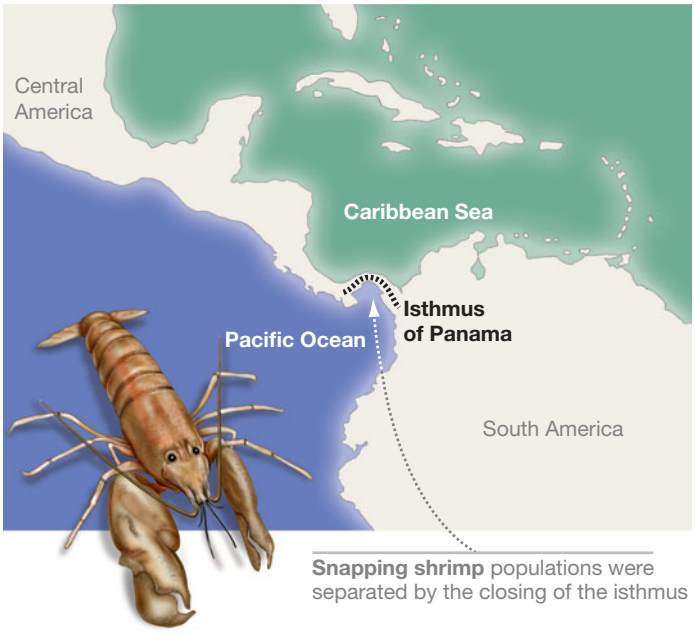
✔**QUESTION** A continuous salt marsh once existed across what is now central Florida, but it was disrupted by geologic events. How does this discovery support the phylogenetic species concept in seaside sparrows (see Figure 27.3)?

1. Genetic drift produced a colonizing population that happened to have particularly large beaks relative to the migrant population. This is an example of the founder effect (Chapter 26).
2. Natural selection in the new environment could favor alleles associated with large beaks.

The Grants concluded from their detailed observations that both genetic drift and natural selection were at play.

The new population of large ground finches is not yet considered a separate species from the migrant population, because some gene flow continues to occur—such as when a new migrant joins the colonist population. Given enough time, however, the populations may continue to diverge. Dispersal and colonization, followed by genetic drift and natural selection, is thought to be responsible for speciation in Galápagos finches and many other island groups.



Allopatric Speciation by Vicariance

If a new physical barrier such as a mountain range or river splits the geographic range of a species, vicariance has taken place. Such changes are commonplace on Earth due to continental drift (Chapter 28), climate fluctuations, and many other factors (see Chapter 52). For example, geologists estimate that the Isthmus of Panama closed about 3 million years ago, forming a land bridge between North and South America. This vicariance event split the Caribbean and Pacific populations of many marine species, including snapping shrimp (**FIGURE 27.5a**).

A phylogenetic tree of the snapping shrimp shows that many of the species found on either side of the isthmus are **sister species**—meaning that they are each other's closest relative (**FIGURE 27.5b**). This is exactly the pattern predicted if the populations of many species were split in two: the populations on either side of the isthmus subsequently diverged to form distinct species.

To summarize, geographic isolation of populations via dispersal or vicariance produces genetic isolation due to the interruption of gene flow—the first requirement of speciation. When genetic isolation is accompanied by genetic divergence due to mutation, selection, and genetic drift, speciation results.

(a) Vicariance event: The closing of the Isthmus of Panama

(b) Result: Pairs of sister species straddling the isthmus

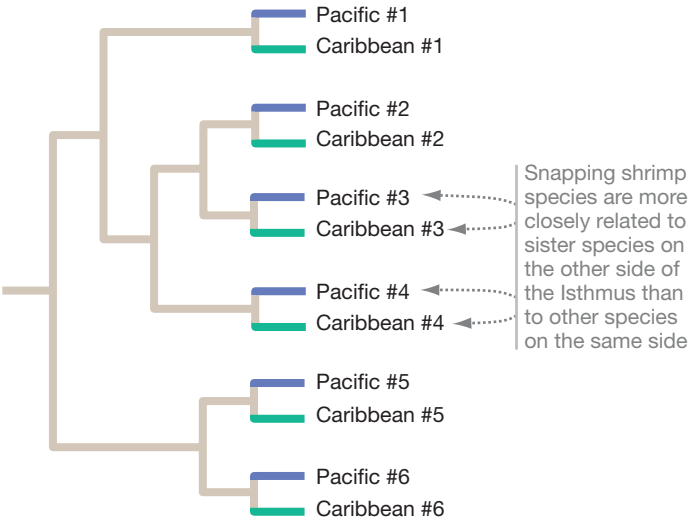


FIGURE 27.5 Evidence for Speciation by Vicariance in Snapping Shrimp. (a) The Isthmus of Panama separated the Caribbean Sea from the Pacific Ocean about 3 million years ago. **(b)** The most logical interpretation of this phylogenetic tree is that 6 species of snapping shrimp split into 12 species when the Isthmus of Panama formed.

27.3 Isolation and Divergence in Sympatry

When populations or species live in the same geographic area, or at least close enough to one another to make interbreeding possible, biologists say that they live in **sympatry** ("together-homeland"). Traditionally, evolutionary biologists such as Ernst Mayr predicted that speciation could not occur among sympatric populations because gene flow would easily overwhelm any differences among populations created by genetic drift and natural selection.

But recently, a number of studies have countered this prediction. **Sympatric speciation**—speciation that occurs even though populations live within the same geographical area (see **FIGURE 27.6** on page 496)—can indeed occur, and serves as a source of new branches on the tree of life. How does it work?

Two types of events can initiate the process of sympatric speciation: **(1)** external events, such as disruptive selection for extreme phenotypes based on different ecological niches (see Chapter 26 for a review of disruptive selection), and **(2)** internal events, such as chromosomal mutations. Let's consider each one in turn.

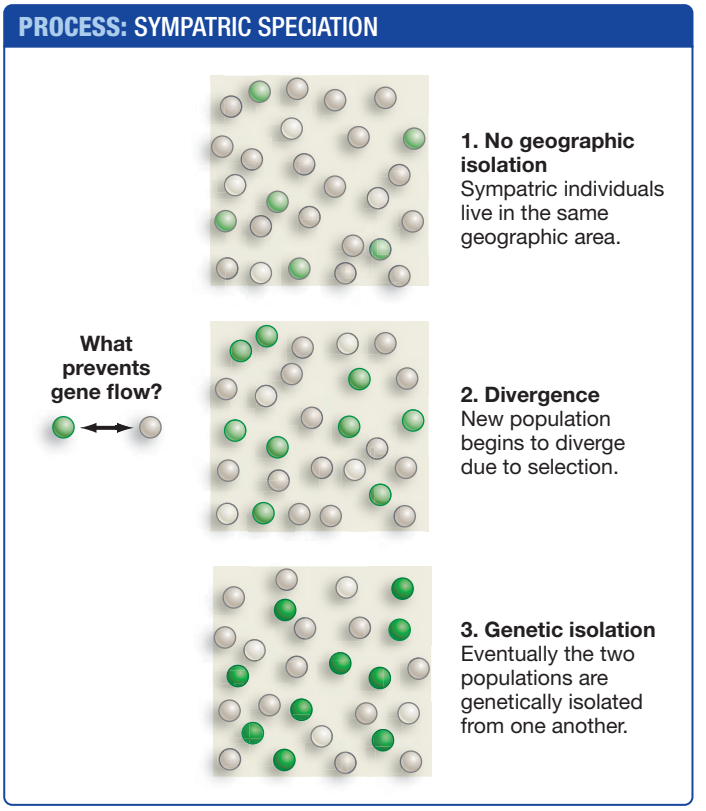

FIGURE 27.6 Sympatric Speciation Has Long Perplexed Researchers. Recent studies have documented several mechanisms that reduce gene flow and result in sympatric speciation. Different colors represent genetic variation.

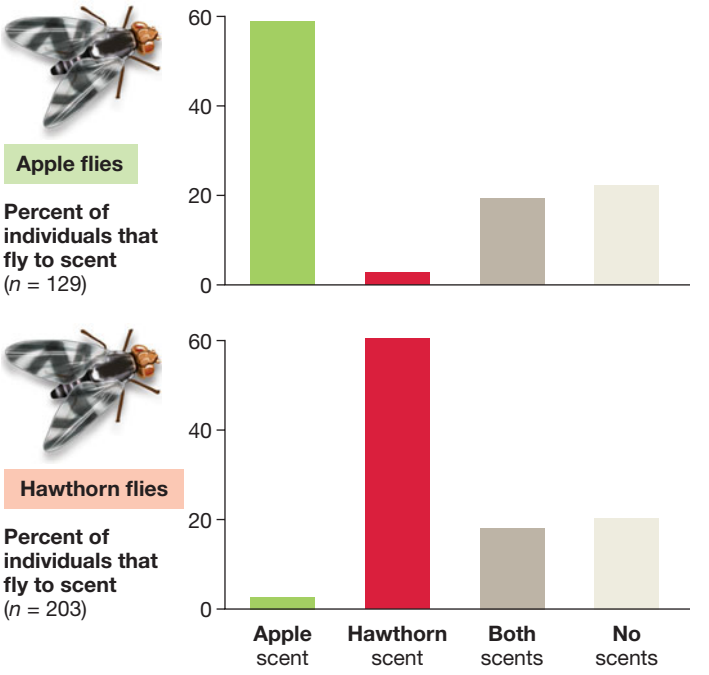

FIGURE 27.7 Disruptive Selection on Fruit Preference in Flies. Each fly was tested with four types of scent, one at a time, in a lab setting.

DATA: Dambroski, H. R., C. Linn Jr., S. H. Berlocher, et al. 2005. *Evolution* 59: 1953–1964.

✔**QUESTION** Apple maggot flies mate on their food plants. How is this behavior relevant to the population's divergence from hawthorn flies?

Sympatric Speciation by Disruptive Selection

Biologists use the term **niche** (pronounced *nitch*) to describe the range of ecological resources that a species can use and the range of conditions that it can tolerate (see Chapter 55). A key realization in the study of sympatric speciation was that even though sympatric populations are not geographically isolated, they may become reproductively isolated by adapting to different ecological niches via disruptive selection.

For example, apple maggot flies rely on apples to complete their life cycle—apples are an important part of their niche. Male and female apple maggot flies usually court and mate on apple fruits. The female then lays a fertilized egg inside the fruit, which will be the food source for the growing larva. After the fruit drops off the tree, the larva burrows into the ground and pupates—meaning that it secretes a protective case and undergoes metamorphosis (see Chapter 33). The new adult then emerges the following spring, starting the cycle anew.

Apple trees were introduced to North America from Europe less than 300 years ago, however. Where did apple maggot flies come from? Did they arrive with the apple trees?

Evolutionary biologist Jeffrey Feder and colleagues have been researching this mystery in a long-term study of apple maggot flies and their closest relatives. Phylogenetic trees, estimated from synapomorphies in DNA sequence data, indicate that apple maggot flies are very closely related to hawthorn maggot flies, which are native to North America. These data suggest that apple maggot flies originated from hawthorn maggot flies following the introduction of apples. Hawthorn flies lay their eggs in hawthorn fruits and apple flies lay their eggs in apples, even though hawthorn trees and apple trees often grow almost side by side. Do the apple flies and hawthorn flies interbreed?

By following marked individuals in the field, Feder's team determined that only about 6 percent of the matings observed are between apple flies and hawthorn flies. The data in **FIGURE 27.7** show why. The bars on the graphs indicate the percentage of apple flies (top) or hawthorn flies (bottom) that land on a surface containing scents from apple, hawthorn, both apple and hawthorn, or neither apple nor hawthorn, in laboratory tests. Notice that

- Apple flies respond most strongly to apple scents; hawthorn flies respond most strongly to hawthorn scents.
- In both types of flies, there is no difference in the response to a mix of both scents and no scent at all.
- Apple flies *avoid* hawthorn scent, and hawthorn flies *avoid* apple scent.

Other experiments have established that **(1)** a fly's ability to discriminate scents has a genetic basis—meaning that apple flies and hawthorn flies have different alleles associated with attraction to fruit; **(2)** specific odor receptor cells are responsible for the difference in scent response; and **(3)** hybrid individuals do not orient to fruit scents as well as their parents.

The upshot is that although apple flies and hawthorn flies live in the same geographic area, prezygotic reproductive isolation is occurring as a result of natural selection for adaptations to two different niches. Apple flies mate on apples (avoiding hawthorn fruits) and hawthorn flies mate on hawthorn fruits (avoiding apples). Hybrid flies have lower fitness due to their reduced success in finding fruits and thus mates, an indication that disruptive selection is occurring (see Chapter 26).

Although they are not yet separate species on the basis of the biological, morphological, or phylogenetic species concepts, apple flies and hawthorn flies are diverging. They are currently in the process of becoming distinct species.

Follow-up studies have shown that the genetic divergence of apple flies and hawthorn flies is not limited to a few alleles associated with attraction to fruit. The divergence of their genomes is widespread—remarkable, given the short time since they began to diverge.

✔ **If you understand the sympatric speciation process occurring in these flies, you should be able to hypothesize why natural selection would favor divergence based on the observation that apple fruits drop about 3–4 weeks earlier in the fall than hawthorn fruits.**

Although the apple maggot fly's story might seem localized and specific, the events may be common. Biologists currently estimate that over 3 million insect species exist. Most of these species are associated with specific host plants, and thus they occupy specific niches. Based on the data from apple maggot flies, it is reasonable to hypothesize that switching host plants has been a major trigger for speciation throughout the course of insect evolution. Further, speciation itself can trigger more speciation. Researchers have described a species of parasitic wasp that specializes on apple maggot flies.

Sympatric Speciation by Polyploidization

Based on the theory and data reviewed thus far, it is clear that gene flow, genetic drift, and natural selection play important roles in speciation. Can the fourth evolutionary process—mutation—influence speciation as well?

Even though mutation is the ultimate source of genetic variation in populations, it is an inefficient mechanism of evolutionary change on its own—the rate of mutation tends to be low (Chapter 26). Natural selection and genetic drift are usually responsible for amplifying the effects of mutations.

One particular type of mutation, though, turns out to be extremely important in speciation—especially in plants. **Polyploidy** occurs when an error in meiosis or mitosis results in a doubling of the chromosome number—a massive mutation. There are two types of polyploids:

1. **Autopolyploid** ("same-many-form") individuals are produced when a mutation results in a doubling of chromosome number and the chromosomes all come from the same species (**FIGURE 27.8a**).

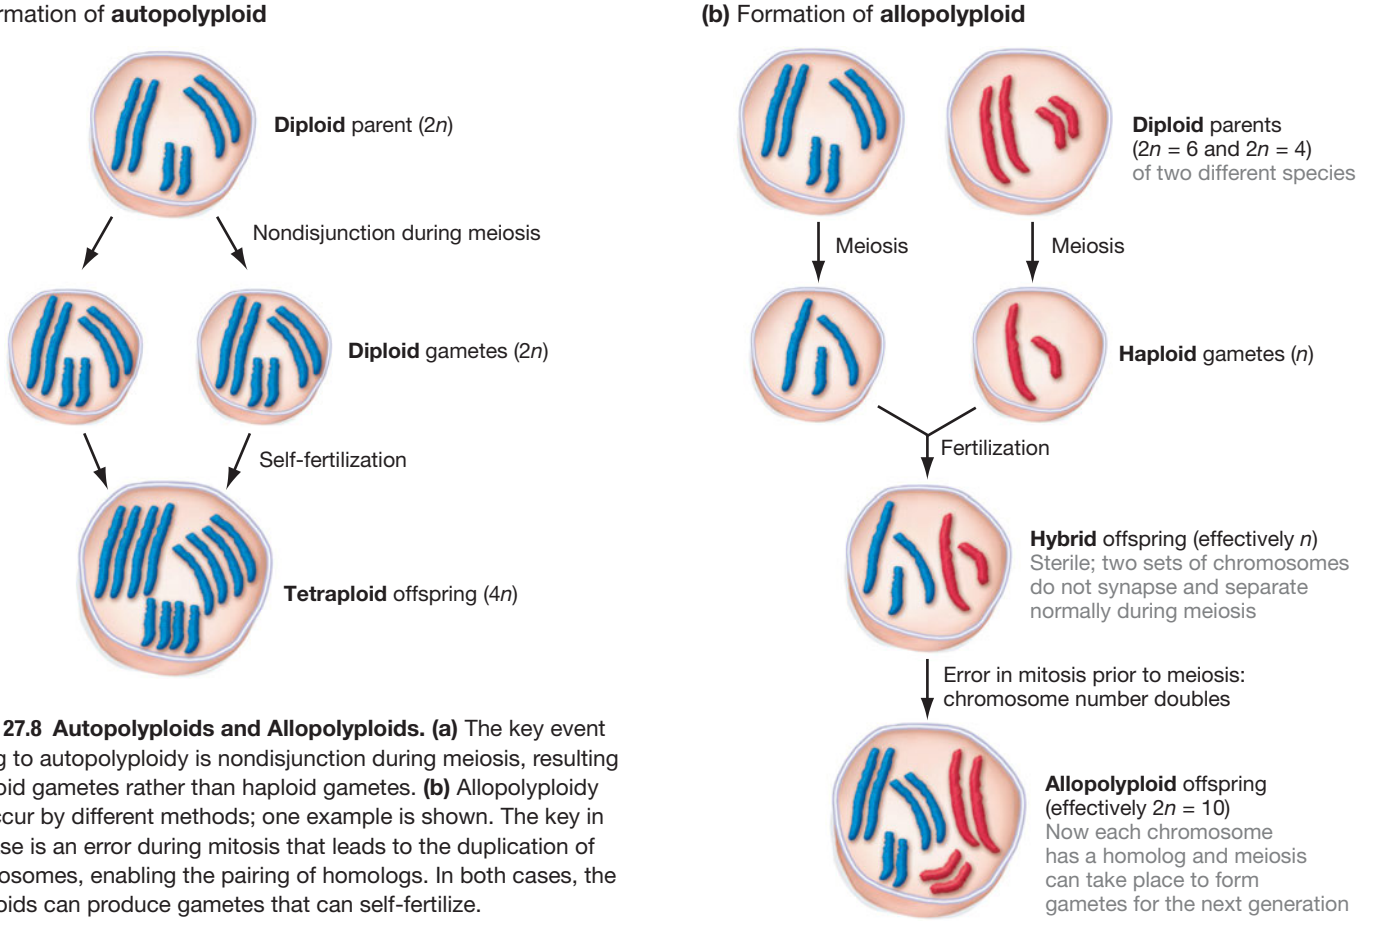

FIGURE 27.8 Autopolyploids and Allopolyploids. (a) The key event leading to autopolyploidy is nondisjunction during meiosis, resulting in diploid gametes rather than haploid gametes. **(b)** Allopolyploidy can occur by different methods; one example is shown. The key in this case is an error during mitosis that leads to the duplication of chromosomes, enabling the pairing of homologs. In both cases, the polyploids can produce gametes that can self-fertilize.

2. **Allopolyploid** ("different-many-form") individuals are created when parents that belong to different species mate and produce an offspring with two different sets of chromosomes (**FIGURE 27.8b**).

How can these two types of polyploidy lead to speciation? Let's consider a specific example of each.

Autopolyploidy Autopolyploidy is thought to be much less common than allopolyploidy. One example is the maidenhair fern, native to woodlands across North America.

Biologists initially set out to do a routine survey of allelic diversity in a population of these ferns. By chance, they stumbled upon individuals that could produce offspring that were tetraploid ($4n$) rather than diploid—that is, polyploid mutants within a normal population.

To follow up on the observation, researchers studied the parents of the mutant individuals. The parents turned out to have a defect in meiosis that caused nondisjunction of chromosomes (introduced in Chapter 13). Instead of producing normal, haploid cells as a result of meiosis, the mutant individuals produced diploid cells. These diploid cells eventually led to the production of diploid gametes (see Figure 27.8a). Because maidenhair ferns can self-fertilize, the diploid gametes could combine to form tetraploid offspring.

How could this event lead to speciation? The tetraploid offspring can self-fertilize or mate with their tetraploid parent or each other, but not with other diploids in the population. Consider what happens when that tetraploid individual mates with a diploid individual (**FIGURE 27.9**).

- During meiosis, tetraploid individuals produce diploid gametes, and diploid individuals produce haploid gametes. These gametes unite to form a triploid ($3n$) zygote.
- Even if this offspring develops normally and reaches sexual maturity, its three homologous chromosomes cannot synapse and separate correctly during meiosis. Thus, the chromosomes are distributed to daughter cells unevenly.
- Because almost all of its gametes contain an uneven number of chromosomes, the triploid individual is virtually sterile.

Polyploid individuals are reproductively isolated from the original diploid population and thus evolutionarily independent, because breeding between diploids and tetraploids generally results in sterile offspring. Thus, according to the biological species concept, speciation occurs in a single generation—instantaneous in evolutionary terms.

✔ If you understand how autopolyploidy works, you should be able to create a scenario explaining how the process gave rise to a tetraploid grape with extra-large fruit, from a diploid population with smaller fruit. (You've probably seen both types of fruit in the supermarket.)

Allopolyploidy As Figure 27.8b illustrates, new polyploid species may be created when two species hybridize. The drawing shows a hybrid offspring forming from a mating between two diploid species. Because the offspring has chromosomes that do not pair normally during meiosis, it is sterile. But if a mutation occurs during mitosis that doubles the chromosome number in this individual before meiosis, then each chromosome gains a homolog and meiosis can proceed normally.

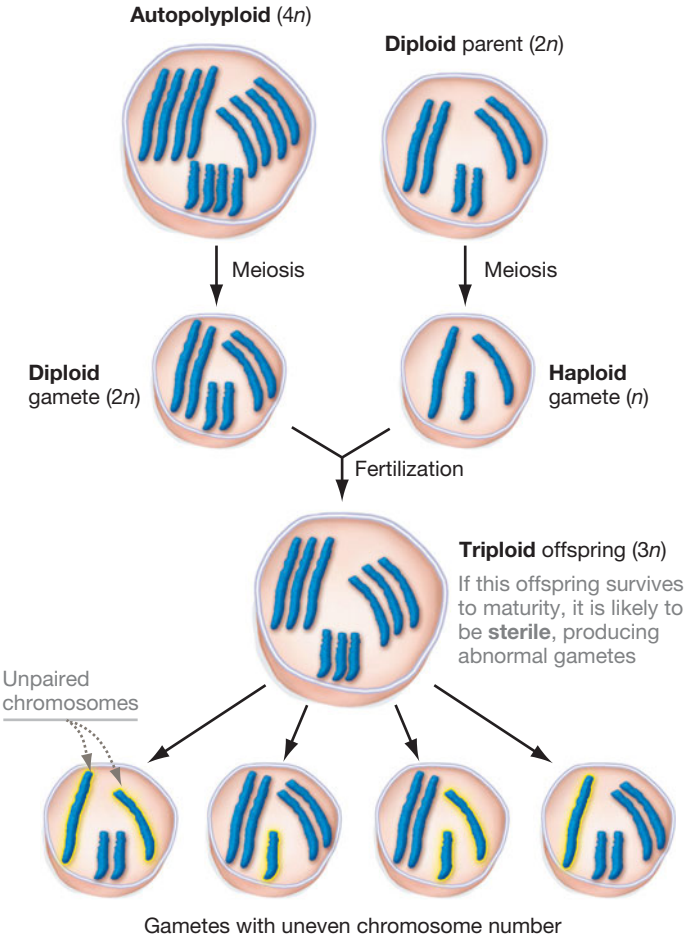

FIGURE 27.9 Polyploidy Can Lead to Reproductive Isolation. The mating diagrammed here illustrates why tetraploid individuals are reproductively isolated from diploid individuals.

Notice that the allopolyploid offspring in Figure 27.8b appears diploid in the sense that it has two copies of each chromosome ($2n = 10$). However, it is functionally polyploid because it has two copies each of *two sets* of chromosomes (indicated by blue and red). In terms of genetic information, this offspring has four copies of genes that are common to both parent species, instead of just two.

Exactly this chain of events occurred after three European species of weedy plants in the genus *Tragopogon* were introduced to western North America in the early 1900s. In 1950 a botanist described the first of two new allopolyploid species (**FIGURE 27.10**). Based on an analysis of chromosomes, both were clearly the descendants of matings between the introduced diploids.

Follow-up work by plant geneticists Pam and Doug Soltis has shown that at least one of the new allopolyploid species is expanding its geographic range and outcompeting its parental species. Further, this polyploidization event has occurred multiple times between the same parent species. The Soltises raise an

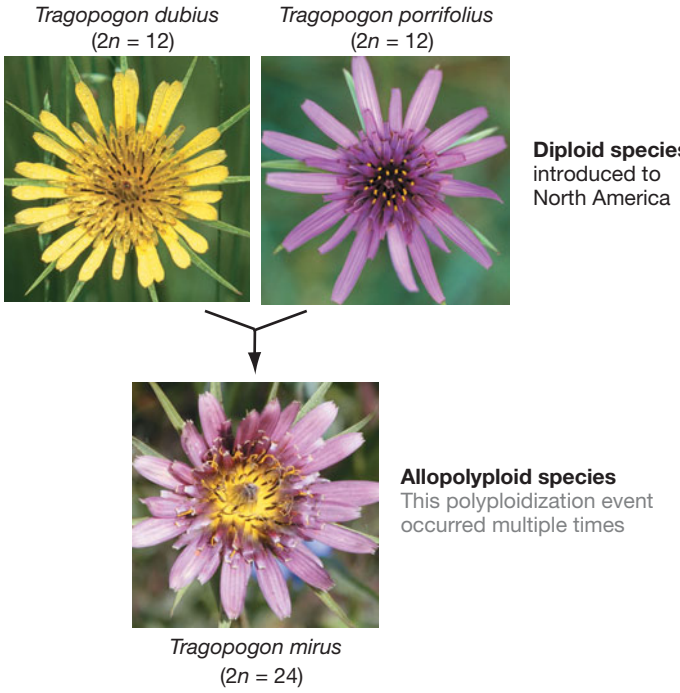

FIGURE 27.10 Allopolyploids Can Form New Species.

interesting question: Should the resulting polyploid populations be considered the same or different daughter species?

✔ **If you understand how allopolyploidy works, you should be able to create a scenario explaining how a cross between a tetraploid population called Emmer wheat and a wild, diploid wheat gave rise to the hexaploid bread wheat grown throughout the world today.**

Why Is Speciation by Polyploidy so Common in Plants? The claim that speciation by polyploidization has been particularly important in plants is backed by the observation that many diploid species have close relatives that are polyploid. Why have polyploids been so successful? The Soltises have addressed this question by examining the genetic implications of polyploidy:

1. Polyploids have higher levels of heterozygosity than their diploid relatives.
2. Polyploids can tolerate higher levels of self-fertilization because they are not as affected by inbreeding depression as their diploid relatives. (See Chapter 26 to review inbreeding.)
3. Genes on duplicated chromosomes can diverge independently, increasing genetic variation in the population.

Genetic variation is a prerequisite for evolution (Chapter 26). Thus, the high genetic diversity of polyploids has enabled a rapid diversification of plant species.

To summarize, speciation by polyploidization is driven by chromosome-level mutations and occurs in sympatry. Compared to the gradual process of speciation by geographic isolation or by disruptive selection in sympatry, speciation by polyploidization is virtually instantaneous. It is fast, sympatric, and common.

Give an example of an event that can lead to the genetic isolation of populations, and explain why selection, drift, and mutation would cause the populations to diverge.

Answers are available in Appendix A.

27.4 What Happens When Isolated Populations Come into Contact?

Suppose two populations that have been isolated come into contact again. If divergence has taken place and if divergence has affected when, where, or how individuals in the populations mate, then interbreeding is unlikely to take place. In cases such as this, prezygotic isolation exists. When it does, mating between the populations is rare, gene flow is minimal, and the populations continue to diverge.

But what if prezygotic isolation does not exist, and the populations begin interbreeding? The simplest outcome is that the populations fuse over time, as gene flow erases any distinctions between them. Several other possibilities exist, however. Let's explore three of them: reinforcement, hybrid zones, and speciation by hybridization.

Reinforcement

If two populations have diverged extensively and are distinct genetically, it is reasonable to expect that their hybrid offspring will have lower fitness than their parents. This phenomenon has been observed in many cases, such as in the apple maggot fly example. If two populations are well adapted to different habitats, then hybrid offspring will not be well adapted to either habitat. If the two populations have diverged enough genetically, hybrid offspring also may fail to develop normally or may be infertile (see postzygotic isolation in Table 27.1).

When postzygotic isolation occurs, there should be strong selection against interbreeding because hybrid offspring represent a wasted effort on the part of parents—especially for females, due to their typically higher investment in offspring. Individuals that do not interbreed, because of different courtship ritual or pollination system or other form of prezygotic isolation, should be favored because they produce more viable offspring.

Natural selection for traits that isolate populations in this way is called **reinforcement.** The name is descriptive because the selected traits reinforce differences that evolved while the populations were isolated from one another.

Some of the best data on reinforcement come from laboratory studies of closely related fruit fly species in the genus *Drosophila*. Evolutionary biologists Jerry Coyne and Allen Orr analyzed a large series of experiments that tested whether members of closely related fly species are willing to mate with one another. They found an interesting pattern:

- If closely related species are sympatric—meaning that they live in the same area—individuals from the two species are seldom willing to mate with one another.
- If the species are allopatric—meaning that they live in different areas—then individuals from the two species are often willing to mate with one another.

The pattern is logical because natural selection can act to reduce mating between species only if their ranges overlap. Thus, it is reasonable to find that sympatric species exhibit prezygotic isolation but that allopatric species do not. There is a long-standing debate, however, over just how important reinforcement is in other species.

Hybrid Zones

Hybrid offspring are not always dysfunctional. In some cases they are capable of mating and producing viable offspring that have features that are intermediate between those of the two parental populations. When this is the case, hybrid zones can form. A **hybrid zone** is a geographic area where interbreeding occurs and hybrid offspring are common.

Depending on the fitness of hybrid offspring and the extent of breeding between parental species, hybrid zones can be narrow or wide, and long or short lived. As an example of how researchers analyze the dynamics of hybrid zones, let's consider recent work on two bird species.

Townsend's warblers and hermit warblers live in the coniferous forests of North America's Pacific Northwest. In western Washington State, where their ranges overlap, the two species hybridize extensively. As the drawings in **FIGURE 27.11** show, hybrid offspring have characteristics that are intermediate relative to the two parental species.

To explore the dynamics of this hybrid zone, ornithologist Sievert Rohwer teamed up with population geneticist Eldredge Bermingham and others to examine gene sequences in the mitochondrial DNA (mtDNA) of a large number of Townsend's, hermit, and hybrid warblers collected from forests throughout the region. The team found that each of the parental species has certain species-specific mtDNA sequences. This result allowed the researchers to infer how hybridization was occurring.

To grasp the reasoning here, it is critical to realize that mtDNA is maternally inherited in most animals and plants. If a hybrid individual has Townsend's mtDNA, its mother had to be a Townsend's warbler while its father had to be a hermit warbler. In this way, identifying mtDNA types allowed the research team to infer whether Townsend's females were mating with hermit males, or vice versa, or both.

Their data presented a clear pattern: Most hybrids form when Townsend's males mate with hermit warbler females.

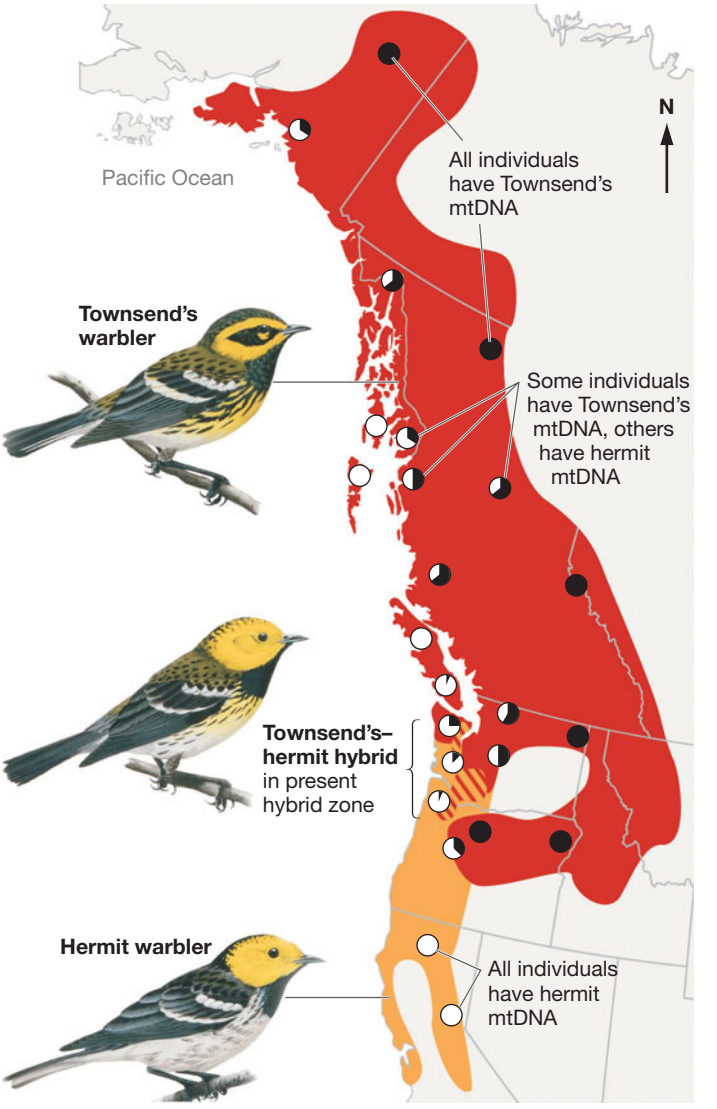

FIGURE 27.11 Analyzing a Hybrid Zone. When Townsend's warblers and hermit warblers hybridize, the offspring have intermediate characteristics. The current ranges of Townsend's warblers (in red) and hermit warblers (in orange) are shown in the map. The small pie charts show the percentage of individuals with Townsend's warbler mtDNA (in black) and hermit warbler mtDNA (in white).
DATA: Rohwer, S., E. Bermingham, and C. Wood. 2001. *Evolution* 55: 405–422.

Rohwer followed up on this result with experiments showing that Townsend's males are extremely aggressive in establishing territories and that they readily attack hermit warbler males. The data suggest that Townsend's males invade hermit territories, drive off the hermit males, and mate with hermit females.

The team also found something completely unexpected. When they analyzed the distribution of mtDNA types along the Pacific Coast and in the northern Rocky Mountains, they discovered that many Townsend's warblers actually had hermit mtDNA. Figure 27.11 shows that in some regions—such as the larger islands off the coast of British Columbia—*all* of the warblers had hermit mtDNA (indicated on the map by white pie charts), even though they looked like full-blooded Townsend's warblers (indicated on the map by the red distribution).

How could this be? To explain the result, the team hypothesized that hermit warblers were once found as far north as Alaska and that Townsend's warblers have gradually taken over their range. Their logic is that repeated mating with Townsend's warblers over time made the hybrid offspring look more and more like Townsend's, even while maternally inherited mtDNA kept the genetic record of the original hybridization event intact.

If this hypothesis is correct, then the hybrid zone should continue moving south. If it does so, hermit warblers may eventually become extinct. In some cases, however, hybridization does not lead to extinction but rather leads to the opposite—the creation of new species.

New Species through Hybridization

If two species interbreed and produce hybrid offspring that can not only survive and reproduce but also possess a unique combination of traits that happen to be adaptive in their particular environment, a new species may result. How would you identify such a species in nature?

Evolutionary biologist Loren Rieseberg and colleagues recently examined the relationships of three sunflower species native to the Southwest: *Helianthus annuus* and *H. petiolaris* are known to hybridize in regions where their ranges overlap, and *H. anomalus* resembles these hybrids (see photo at the start of this chapter). How are these species related?

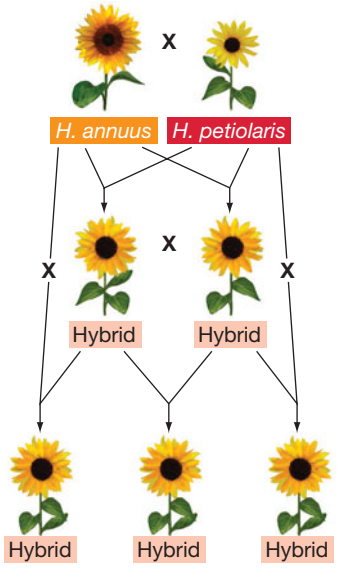
DNA sequencing studies have shown that some gene regions in *H. anomalus* are remarkably similar to those found in *H. annuus*, while other *H. anomalus* gene sequences are almost identical to those found in *H. petiolaris*. Based on these data, Rieseberg hypothesized that *H. anomalus* originated in hybridization between *H. annuus* and *H. petiolaris*. All three species have the same number of chromosomes, so neither allopolyploidy nor autopolyploidy was involved. Instead, the chromosomes of *H. annuus* and *H. petiolaris* must be similar enough that they can synapse and undergo normal meiosis in hybrid offspring.

The specific hypothesis here is that *H. annuus* and *H. petiolaris* were isolated and diverged as separate species, and later began interbreeding. The hybrid offspring created a third, new species that had unique combinations of alleles from each parental species and therefore different characteristics. This hypothesis is supported by the observation that *H. anomalus* grows in much drier habitats than either of the parental species—suggesting that a unique combination of alleles allowed *H. anomalus* to thrive in dry habitats.

Rieseberg and his colleagues set out to test the hybridization hypothesis by trying to re-create the speciation event experimentally (**FIGURE 27.12**).

Step 1 They mated individuals from the two parental species and raised the offspring in a greenhouse.

Step 2 When these hybrid individuals were mature, the researchers either mated the plants to other hybrid individuals or "backcrossed" them to individuals from one of the parental species.



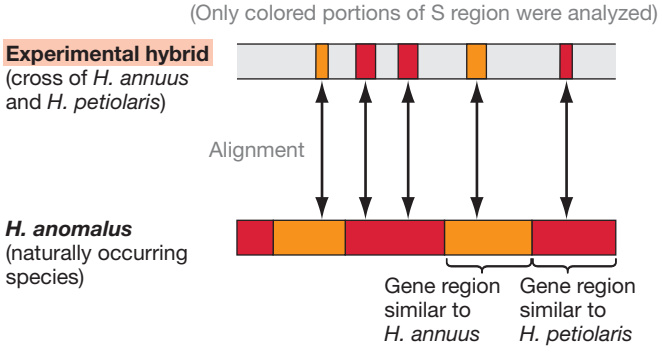
RESEARCH

QUESTION: Can new species arise by hybridization between existing species?

HYPOTHESIS: *Helianthus anomalus* originated by hybridization between *H. annuus* and *H. petiolaris.*

NULL HYPOTHESIS: *Helianthus anomalus* did not originate by hybridization between *H. annuus* and *H. petiolaris.*

EXPERIMENTAL SETUP:



PREDICTION: Experimental hybrids will have the same mix of *H. annuus* and *H. petiolaris* genes as natural *H. anomalus*.

PREDICTION OF NULL HYPOTHESIS: Experimental hybrids will not have the same mix of *H. annuus* and *H. petiolaris* genes as natural *H. anomalus.*

RESULTS:

DNA comparison of a chromosomal region called S:

CONCLUSION: New species may arise via hybridization between existing species.

FIGURE 27.12 Experimental Evidence That New Species Can Originate in Hybridization Events.

✔**QUESTION** Why it is valid to use experiments with living organisms—like this one—to infer what happened during historical speciation events?

SUMMARY TABLE 27.3 Possible Outcomes of Secondary Contact between Populations

	Process	Example
Fusion of the populations	The two populations freely interbreed.	Occurs whenever populations of the same species come into contact.
Reinforcement of divergence	If hybrid offspring have low fitness, natural selection favors the evolution of traits that prevent interbreeding between the populations.	Appears to be common in fruit fly species that occupy the same geographic areas.
Hybrid zone formation	Hybridization occurs in a well-defined geographic area. This area may move over time or be stable.	Many stable hybrid zones have been described; the hybrid zone between hermit and Townsend's warblers appears to have moved over time.
Extinction of one population	If one population or species is a better competitor for shared resources, then the poorer competitor may be driven to extinction.	Townsend's warblers may be driving hermit warblers to extinction.
Creation of new species	If the combination of genes in hybrid offspring allows them to occupy distinct habitats or use novel resources, they may form a new species.	Hybridization between sunflowers gave rise to a new species with unique characteristics.

Step 3 This breeding program continued for four more generations before the experiment ended. Ultimately, the experimental lines were backcrossed twice, and they were mated to other hybrid offspring three times.

The goal of these crosses was to simulate matings that might have occurred naturally.

The experimental hybrids looked like the natural hybrid species, but did they resemble them genetically? To answer this question, Rieseberg's team constructed genetic maps of each population, using a large series of genetic markers (see Chapter 20). Because each parental population had many unique markers in its genomes, the research team hoped to identify which genes found in the experimental hybrids came from which parental species.

Some of their data are diagrammed in the "Results" section of Figure 27.12. The bottom bar in the illustration represents a region called S in the genome of the naturally occurring species *Helianthus anomalus*. As the legend indicates, this region contains three sections of sequences that are also found in *H. petiolaris* (indicated with the color red) and two that are also found in *H. annuus* (indicated with the color orange). The top bar shows the composition of this same region in the genome of the experimental hybrid lines.

The key observation here is that the genetic composition of the synthesized hybrids matches that of the naturally occurring hybrid species. In effect, the researchers succeeded in re-creating a speciation event. Their results provide strong support for the hybridization hypothesis for the origin of *H. anomalus*. ✔ **If you understand this experiment, you should be able to suggest one result that would have caused the researchers to reject the hybridization hypothesis.**

Secondary contact of two populations can produce a dynamic range of possible outcomes: fusion of the populations, reinforcement of divergence, founding of stable hybrid zones, extinction of one population, or the creation of new species. **TABLE 27.3** summarizes the outcomes of secondary contact.

The study of speciation provides an essential link between the processes of evolution (Chapters 25 and 26) and the tree of life (Chapter 28 and Unit 6). Research on speciation is accelerating, in part due to availability of new genetic and phylogenetic tools, and in part due to the study of human impacts on biodiversity (see Chapter 57). Although human activities usually result in the extinction of species, they can also result in the creation of new species. Humans are changing the shape of the tree of life.

If you understand . . .

27.1 How Are Species Defined and Identified?

- A species is defined as an evolutionarily independent population or group of populations. Researchers use several criteria to identify whether populations represent distinct species.
- The biological species concept uses reproductive isolation as a criterion to identify species.
- The morphospecies concept identifies species using distinctive morphological traits.
- The phylogenetic species concept identifies species as the smallest monophyletic groups on the tree of life.

✔ **You should be able to explain whether human populations would be considered separate species under the biological species, morphospecies, and phylogenetic species concepts.**

27.2 Isolation and Divergence in Allopatry

- Speciation is a splitting event in which one lineage gives rise to two or more independent descendant lineages.
- Speciation occurs when populations of the same species become genetically isolated by lack of gene flow and then diverge from each other due to selection, genetic drift, and mutation.
- Allopatric speciation occurs when populations diverge in geographic isolation.
- Geographic isolation occurs through dispersal, when small groups of individuals colonize a new habitat, or through vicariance, when a large, continuous population becomes fragmented into isolated habitats.

✔ **You should be able to design an experiment that would, given enough time, result in the production of two species from a single ancestral population.**

27.3 Isolation and Divergence in Sympatry

- Sympatric speciation occurs when populations diverge genetically despite living in the same geographic area.
- Sympatric speciation can occur when disruptive selection favors individuals that breed in different ecological niches.
- Mutations that produce polyploidy can trigger rapid speciation in sympatry because they lead to reproductive isolation between diploid and tetraploid populations.

✔ **You should be able to evaluate whether your experiment on speciation (see previous exercise under 27.2) represents a case of dispersal, vicariance, different habitat use, or polyploidy.**

27.4 What Happens When Isolated Populations Come into Contact?

- If gene flow occurs, populations that have diverged may fuse into a single species.
- If prezygotic isolation exists, populations that come back into contact will probably continue to diverge.
- Secondary contact can lead to reinforcement—the evolution of mechanisms that prevent hybridization.
- Gene flow between different species can lead to the formation of hybrid zones that move over time or are stable.
- In some cases, hybridization between species can create new species with unique combinations of traits.

✔ **You should be able to predict how a hybrid zone will change over time when hybrid offspring have higher fitness than the parental populations.**

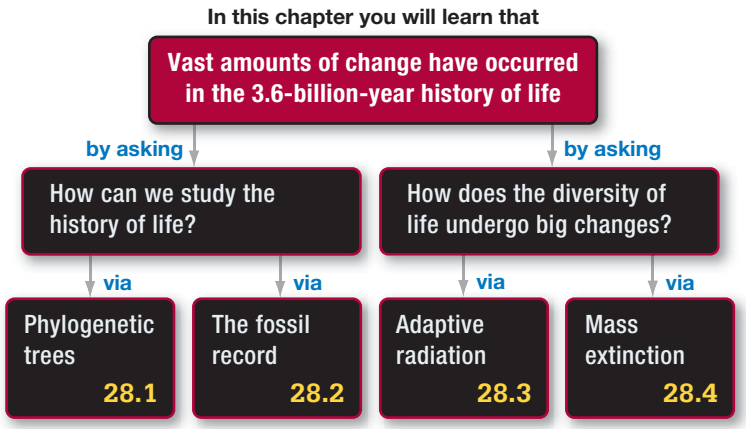
TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. What distinguishes a morphospecies?
   a. It has distinctive characteristics, such as size, shape, or coloration.
   b. It represents a distinct twig in a phylogeny of populations.
   c. It is reproductively isolated from other species.
   d. It is a fossil from a distinct time in Earth history.
2. Which of the following describes vicariance?
   a. Small populations coalesce into one large population.
   b. A population is fragmented into isolated subpopulations.
   c. Individuals colonize a novel habitat.
   d. Individuals disperse and found a new population.
3. Why are genetic isolation and genetic divergence occurring in apple maggot flies, even though populations occupy the same geographic area?
   a. Different populations feed and mate on different types of fruit.
   b. One population is tetraploid; others are diploid.
   c. The introduction of a nonnative host plant caused vicariance.
   d. Responses to scents have changed due to disruptive selection.
4. The biological species concept can be applied only to which of the following groups?
   a. bird species living today
   b. dinosaurs and bird species living today
   c. dinosaurs
   d. bacteria
5. Why is "reinforcement" an appropriate name for the concept that natural selection should favor divergence and genetic isolation if populations experience postzygotic isolation?
   a. Selection should reinforce high fitness for hybrid offspring.
   b. Selection should reinforce the fact that the diverging populations are "good species" under the morphological species concept.
   c. Hybrid offspring do not develop at all or are sterile when mature because selection reinforces only the success of purebred species.
   d. The selected traits reinforce differences that evolved while the populations were isolated from one another.
6. True or False? Gene flow increases the divergence of populations.

TEST YOUR UNDERSTANDING

Answers are available in Appendix A



7. Which studies in this chapter represent direct observation of speciation? Which are indirect studies of historical speciation events?
8. When the ranges of two different species meet, a stable "hybrid zone" occupied by hybrid individuals may form. How is this possible?
   a. Hybrid individuals may have intermediate characteristics that are advantageous in a given region.
   b. Hybrid individuals are always allopolyploid and are thus unable to mate with either of the original species.
   c. Hybrid individuals may have reduced fitness and thus be strongly selected against.
   d. One species has a selective advantage, so as hybridization continues, the other species will go extinct.
9. In the case of the seaside sparrow, how did the species identified by the biological species concept, the morphospecies concept, and the phylogenetic species concept conflict?
10. Explain how isolation and divergence are occurring in apple maggot flies. Of the four evolutionary processes (mutation, gene flow, genetic drift, and selection), which two are most important in causing this event?
11. A large amount of gene flow is now occurring among human populations due to intermarriage among people from different ethnic groups and regions of the world. Is this phenomenon increasing or decreasing racial differences in our species? Explain.
12. **QUANTITATIVE** If one species ($2n = 10$) crosses with another species ($2n = 18$), producing an allopolyploid offspring, what is the ploidy of the offspring?
    a. $2n = 10$
    b. $2n = 18$
    c. $2n = 18 + 10 = 28$
    d. $4n = 36 + 20 = 56$

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A

13. Unlike animal gametes, plant reproductive cells do not differentiate until late in life. Why are plants much more likely than animals to produce diploid gametes and polyploid offspring?
    a. Cells that do not divide for long periods accumulate mutations.
    b. Cells that differentiate later in life undergo many rounds of mitosis, so are more likely to accumulate mutations.
    c. Cells that differentiate later in life undergo many rounds of meiosis, so are more likely to accumulate mutations.
    d. Undifferentiated cells are more prone to mutations than differentiated cells.
14. Sexual selection is a type of natural selection that favors individuals with traits that increase their ability to obtain mates, such as female choice for bright orange beaks in zebra finches. Propose a scenario where sexual selection could contribute to divergence in sympatric speciation.
15. A friend says that apple maggot flies prefer apple fruit scents because they need to, in order to survive. Another agrees and adds that the flies acquire the ability to distinguish the apple scents by spending time on the fruit, and that's why their offspring prefer apples. What's wrong with these statements?
16. All over the world, natural habitats are being fragmented into tiny islands as suburbs, ranches, and farms expand, and roads are built to connect them. Explain why this fragmentation process could lead to extinction. Then explain how it could lead to speciation.

28 Phylogenies and the History of Life

A fossilized trilobite. The last trilobites disappeared during a mass extinction event analyzed in Section 28.4.

This chapter is about time and change. More specifically, it's about vast amounts of time and profound change in organisms. Both of these topics can be difficult for humans to grasp. Our lifetimes are measured in decades, and our knowledge of history is usually measured in centuries or millennia. But this chapter analyzes events that occurred over millions and even billions of years.

It takes practice to get comfortable analyzing the profound changes that occur in organisms over deep time. To help you get started, the chapter begins by introducing the two major analytical tools that biologists use to reconstruct the history of life: phylogenetic trees and the fossil record. The remaining two sections explore evolutionary episodes called adaptive radiations and mass extinctions, which can cause major changes to the tree of life. The Big Picture of Evolution on pages 526–527 shows how the tree of life relates to speciation (Chapter 27) and the four evolutionary processes (Chapters 25 and 26).

BIG PICTURE

This chapter is part of the Big Picture. See how on pages 526–527.

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

28.1 Tools for Studying History: Phylogenetic Trees

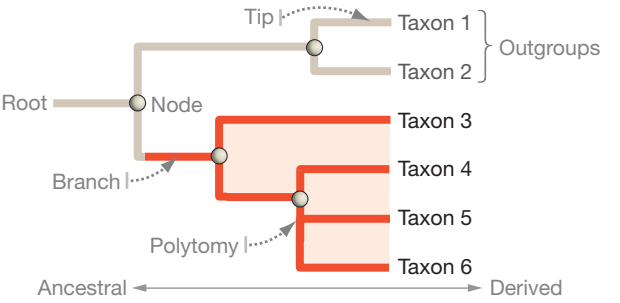
The evolutionary history of a group of organisms is called its **phylogeny.** A **phylogenetic tree** is a graphical summary of this history, showing the ancestor–descendant relationships among populations, species, or higher taxa, and clarifying who is related to whom. The **tree of life** is the most universal of all phylogenetic trees, depicting the evolutionary relationships among all living organisms on Earth (see Chapter 1). Phylogenetic trees have revolutionized the study of evolution and many related fields. For example:

- Phylogenetic trees can be used in taxonomy to define species (Chapter 27).
- Phylogenetic trees provide evidence for the endosymbiosis theory—that mitochondria and chloroplasts originated as free-living bacteria (Chapter 30).
- Phylogenetic trees can be used to examine how the HIV virus jumped from other primates to humans (Chapter 36).
- Phylogenetic trees can aid in identifying species that are a priority for conservation (Chapter 57).

Phylogenetic trees are extremely effective at summarizing data and testing hypotheses. However, they are unusual diagrams—it can take practice to interpret them correctly.

Take a moment to review the parts of a phylogenetic tree in **TABLE 28.1**. Notice that the tree in this table, like all the trees used in this text, is rooted, which means that the **branches** on the left are more ancient, or ancestral, while the ones on the right are most recent, or derived. Notice also that the **nodes** (forks) represent *hypothetical* common ancestors—the taxa themselves are always located on the branch **tips,** never within the tree. That is, none of the taxa are presumed to be ancestors of others, even if some of the taxa are extinct.

Let's practice reading phylogenetic trees by focusing on how biologists go about building them.



How Do Biologists Estimate Phylogenies?

Like any other pattern or measurement in nature, from the average height of a person in a particular human population to the speed of a passing flock of geese, the historical relationships among species cannot be known with absolute certainty. In addition, humans have not been around to observe most evolutionary events directly. Thus, the relationships depicted in phylogenetic trees must be *estimated* from the best available data.

Creating the Data Matrix The first step in inferring evolutionary relationships is to decide which populations, species, or higher taxa to compare and which characteristics to use—usually morphological or genetic characteristics, or both. For example, to reconstruct relationships among fossil species of humans (there were many; see Chapter 35), scientists analyze aspects of tooth, jaw, and skull structure, since this is often the only sort of evidence available. To reconstruct relationships among contemporary human populations, investigators usually compare the sequences of bases in a particular gene.

SUMMARY TABLE 28.1 Anatomy of a Phylogenetic Tree

Graphical Symbols and Definitions

Branch Represents a population through time

Node (fork) A point within the tree where a branch splits into two or more branches

Outgroup A taxon that diverged prior to the taxa that are the focus of the study; helps to root the tree

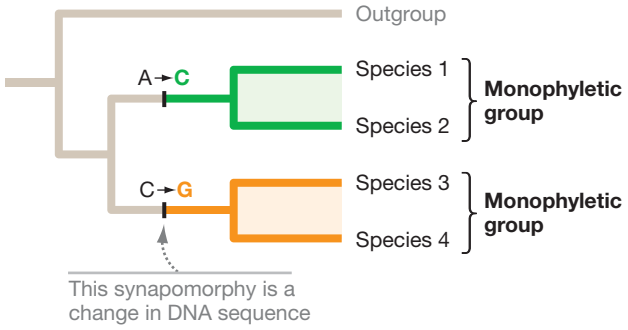
Root The most ancestral branch in the tree

Polytomy A node that depicts an ancestral branch dividing into three or more (rather than two) descendant branches; usually indicates that insufficient data were available to resolve which taxa are more closely related

Tip (terminal node) Endpoint of a branch; represents a living or extinct group of genes, species, families, phyla, or other taxa

Consider the simple case of estimating a phylogenetic tree for four closely related species using a short DNA sequence as the character set, where a **character** is any genetic, morphological, physiological, or behavioral characteristic to be studied. The data matrix for this group is shown in **FIGURE 28.1a**. The sequence consists of six characters (nucleotides 1, 2, 3, 4, 5, and 6), each with four possible character states: A, T, C, and G.

Notice that a fifth species is included in the matrix as an **outgroup**—a species that is closely related to the group being studied, but not part of it. Outgroups are used to establish the polarity of each trait—that is, whether a character state is ancestral or derived. An **ancestral trait** is a characteristic that existed in an ancestor; a **derived trait** is one that is a modified form of the ancestral trait, found in a descendant. Derived traits originate via mutation, selection, and genetic drift (see Chapter 26).



It's important to recognize that ancestral and derived traits are relative. If you are comparing mammals with the fossil forms called mammal-like reptiles, then fur and lactation are derived traits. But if you are comparing whales and humans, then fur and lactation are ancestral traits. In the example in Figure 28.1a, the ancestral DNA sequence is estimated to be AAA GCT based on the outgroup; any nucleotides that differ from those in this sequence are considered derived. Since outgroup lineages can

(a) Data matrix

DNA nucleotide sequence

1	2	3	4	5	6	
A	A	A	G	C	T	Outgroup
A	A	C	G	C	T	Species 1
A	A	C	G	C	T	Species 2
A	A	A	G	G	T	Species 3
A	A	A	G	G	T	Species 4

(b) Phylogenetic tree inferred from the data

(c) One of many alternate trees

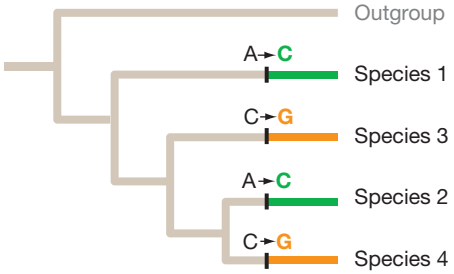


FIGURE 28.1 Constructing a Phylogenetic Tree. Cladistic analysis **(a)** begins with a data matrix and **(b)** builds trees based on the principle that closely related species are likely to share derived traits, called synapomorphies. **(c)** The tree that best fits the data must be selected from many alternate trees (only one shown here).

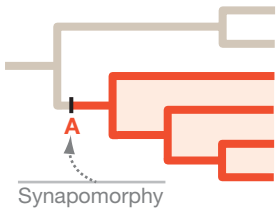
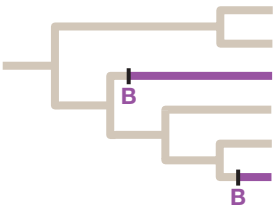
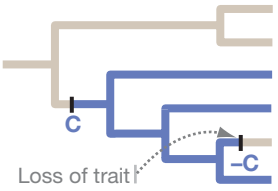






✔ **EXERCISE** Draw another alternate tree for the same data set.

evolve too, multiple outgroups are often used to estimate ancestral character states (for simplicity, only one is used here).

Using the Data Matrix to Estimate a Tree The most commonly used method of inferring phylogenetic trees, called cladistics, was introduced by German biologist Willi Hennig in the 1960s. The **cladistic approach** is based on the principle that relationships among species can be reconstructed by identifying shared derived characters—synapomorphies (introduced in Chapter 27).

A **synapomorphy** is a trait found in two or more taxa that is present in their most recent common ancestor but is missing in more distant ancestors. Synapomorphies allow biologists to recognize monophyletic groups—also called **clades** or **lineages.** A **monophyletic group** is an evolutionary unit that includes an ancestral population and all of its descendants, but no others.

SUMMARY TABLE 28.2 Mapping Traits and Groups on Trees

Graphical Symbol	Definition
	Homology Similarity in organisms due to common ancestry (trait **A** is homologous among the red branches)
	**Monophyletic group** An evolutionary unit that includes an ancestral population and all of its descendants but no others (also called a lineage, or clade)
	Synapomorphy A shared, *derived* trait (trait **A** occurs *only* in the red branches)
	Homoplasy Similarity in organisms due to reasons other than common ancestry (trait **B** arose twice independently)
	**Polyphyletic group** An unnatural group (shown in purple) that does not include the most recent common ancestor (see segmented animals in Chapter 33)
	**Paraphyletic group** A group (shown in blue) that includes an ancestral population and some of its descendents, but not all (see dicots in Chapter 31, and fish and reptiles in Chapter 35)

See **TABLE 28.2** for a comparison of monophyletic groups and two types of non-monophyletic groups.

In the case of the character set in Figure 28.1a, species 1 and 2 can be recognized as a monophyletic group based on their shared, derived trait, a C in the third position of the DNA sequence. Similarly, species 3 and 4 can be recognized as a different monophyletic group based on their shared, derived trait, a G in the fifth position of the sequence. This logic is summarized by the tree in **FIGURE 28.1b**.

In this example, it is relatively easy to infer a tree that represents the data set in a logical way. In common practice, there are several possible complications to resolve. For example:

- Traits can be similar in two species not because those traits were present in a common ancestor, but because similar traits evolved independently in two different lineages. For example, the A ⟶ C changes in DNA sequence at nucleotide 3 may have arisen separately in species 1 and 2 rather than once in their common ancestor (**FIGURE 28.1c**).
- Sometimes a reversal in a change occurs, such as an A ⟶ C transition in a nucleotide in one branch followed by a C ⟶ A

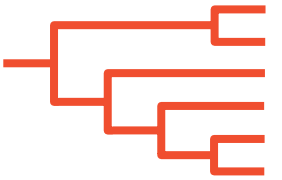
change in the same nucleotide in a subsequent branch, thus creating the appearance that no change occurred.

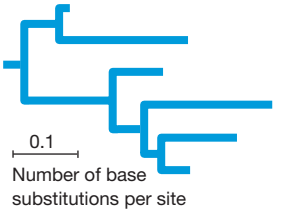
- Sometimes the species forms a monophyletic group one way according to one trait in the matrix and a different way according to a different trait in the matrix (as would occur if species 1 and 3 had a unique base change at position 1).
- The example in Figure 28.1 shows a small number of species with a small number of traits. The larger the number of species and traits added to the matrix, the greater the number of possible trees and character combinations. There are 15 possible trees for a phylogeny of 4 taxa but over 100,000 trees for a phylogeny of 8 taxa.

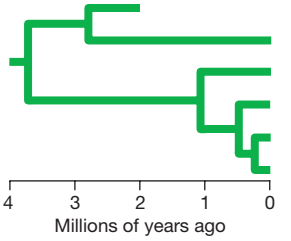
How can researchers identify the tree with the best fit to the data? And how can they avoid an erroneous conclusion? Biologists often invoke the logical principle of **parsimony** to address these questions. Under parsimony, the most likely explanation or pattern is the one that implies the least amount of change.

To implement a parsimony analysis, biologists use computer programs that compare the branching patterns that are theoretically possible in a phylogenetic tree and count the number of changes in DNA sequences required to produce each pattern. For example, the tree in Figure 28.1b requires two changes in base sequence; the tree in Figure 28.1c requires four.

Since independent evolution of traits should be rare compared with similarity due to shared descent, the tree that implies the fewest overall evolutionary changes is hypothesized to be the one that most accurately reflects what really happened during evolution. If the branching pattern in Figure 28.1b is the most parsimonious of all possible trees, then biologists conclude that it is the most likely representation of actual phylogeny based on the data in hand.







There are methods other than parsimony to find the tree with the best fit to the data, each guided by different assumptions. However, all the methods are similar in serving as "filters" to identify optimal trees out of a pool of hundreds, thousands, or millions of possible trees. Some researchers use multiple methods to gain more confidence in their results.

It's important to recognize that the trees created using cladistic analysis (called cladograms) focus on branching *patterns*—the branch *lengths* themselves are arbitrary. Some analyses produce trees whose branch lengths represent genetic distance or time since divergence. You can identify these trees by the presence of scale bars (see **TABLE 28.3**). (If you feel that you need more practice interpreting phylogenetic trees, you can turn to **BioSkills 7** in Appendix B at any time.)

How Can Biologists Distinguish Homology from Homoplasy?

The cladistic approach is a powerful method of estimating phylogenies because it is based on one of the central concepts in evolutionary biology—homology (see Table 28.2). **Homology** (literally, "same-source") occurs when traits are similar due to shared ancestry; in contrast, **homoplasy** ("same-form") occurs when traits are similar for reasons other than common ancestry.

SUMMARY TABLE 28.3 Branch Lengths in Phylogenetic Trees

Graphical Symbol	Meaning of Branch Lengths
	Branch lengths are *arbitrary*. Emphasis is on the branching *pattern*, which estimates evolutionary relationships among populations. This is the type of tree used in this book.
	Horizontal branch lengths show the extent of *genetic difference* among populations. A scale bar is included.
	Horizontal branch lengths show the extent of *evolutionary time* between nodes. A scale bar is included.

A common cause of homoplasy is convergent evolution. **Convergent evolution** occurs when natural selection favors similar solutions to the problems posed by a similar way of making a living in different species. Since species have many characteristics, some may be homologous with characteristics in other species, while others may be convergent. Let's consider how to distinguish homology and homoplasy.

Are *Hox* Genes in Fruit Flies and Humans Homologous or Convergent? Consider the *Hox* genes of insects and vertebrates (introduced in Chapter 22). Even though insects and vertebrates last shared a common ancestor some 600–700 million years ago, biologists argue that their *Hox* genes are derived from the same ancestral sequences—that is, they are homologous. Several lines of evidence support this hypothesis:

- Groups of *Hox* genes are organized on chromosomes in a similar way. **FIGURE 28.2** shows that *Hox* genes in both insects and vertebrates are found in gene clusters, and similar genes are often found in the same order on the chromosome. Genes with these characteristics are called gene families (Chapter 21). The organization of the gene families is nearly identical among insect and vertebrate species.
- All *Hox* genes share a 180-base-pair sequence called the homeobox. The portion of a protein encoded by the homeobox (introduced in Chapter 22) is almost identical in insects and vertebrates and has a similar function. It binds to DNA and regulates the expression of other genes.

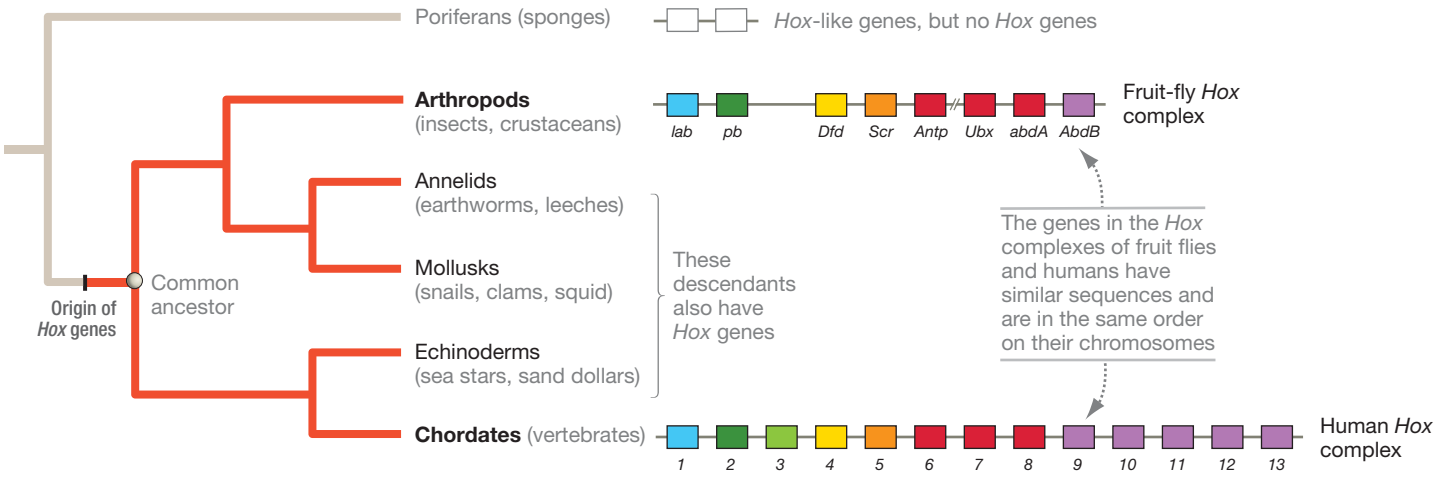


FIGURE 28.2 Homology: Similarities Are Inherited from a Common Ancestor. All animals except sponges have *Hox* complexes that are similar to those illustrated for fruit flies and humans. (Human *Hox* genes occur in four clusters but are summarized here in one for simplicity.)

- The products of the *Hox* genes have similar functions (see Chapter 22): identifying the locations of cells in embryos. They are also expressed in similar patterns in time and space.

Further, if traits found in distantly related lineages are similar due to common ancestry, then similar traits should be found in many intervening lineages on the tree of life—because all of the species in question inherited the trait from the same common ancestor. Indeed, all other lineages of animals that branched off between insects and mammals have similar *Hox* genes. Sponges serve as an outgroup to the clade since they appear to have split off before *Hox* genes arose.

The internal consistency of the genetic, developmental, and phylogenetic data provide strong evidence that *Hox* genes in fruit flies and humans are homologous.

Are Streamlined Bodies in Dolphins and Ichthyosaurs Homologous or Convergent? The extinct aquatic reptiles called ichthyosaurs were strikingly similar to modern dolphins (**FIGURE 28.3**). Both are large marine predators with streamlined bodies and large dorsal fins. Are these characteristics homologous in dolphins and ichthyosaurs?

Figure 28.3 shows a phylogenetic tree based on skeletal characters, such as the number and placement of openings in the skull (since ichthyosaurs are known only from their fossilized skeletons). This analysis shows that dolphins occur within the mammal clade, whereas ichthyosaurs are most closely related to lizards. Notice that the sister groups to dolphins and ichthyosaurs—that is, the most closely related branches on the tree—do not possess streamlined bodies, flippers, and fins.

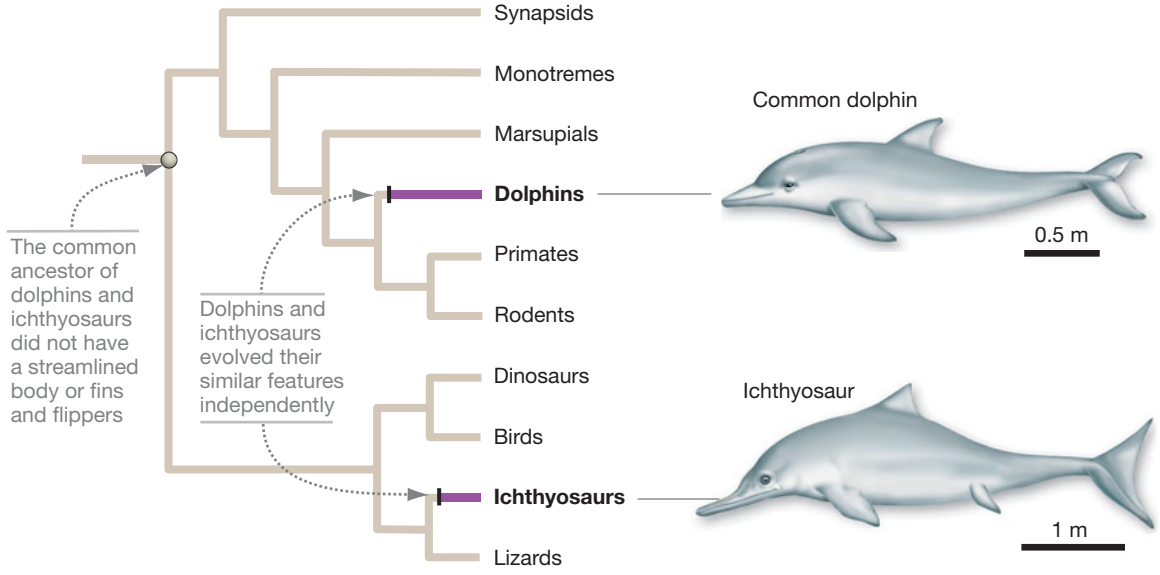

FIGURE 28.3 Homoplasy: Traits Are Similar but Not Inherited from a Common Ancestor. Dolphins and ichthyosaurs look similar but are not closely related.

Based on these data, it is logical to argue that the similarities between ichthyosaurs and dolphins result from convergent evolution. The convergent traits do not occur in the common ancestor of the similar species. Streamlined bodies, flippers, and dorsal fins are adaptations that help *any* aquatic species—whether it is a reptile or a mammal—chase down fish in open water.

Whale Evolution: A Case Study

Let's apply what you've learned about phylogenetic trees and the concept of homology to an interesting evolutionary case study: the origin of a unique clade of mammals, the whales. Scientists since Darwin have puzzled over the rightful place of whales (including dolphins) on the tree of life. Data from the fossil record support the hypothesis that whales evolved from terrestrial mammals. More specifically, hippos, which are semiaquatic, appear to be the closest living relative of today's whales. How can phylogenetic trees be used to test this claim?

Data Set 1: A Phylogeny Based on Morphological Traits Hippos, along with cows, deer, pigs, and camels, are artiodactyls. Members of this mammal group have hooves and an even number of toes. They also share another feature: the unusual pulley shape of an ankle bone called the astragalus. Along with having a unique foot morphology, the shape of the astragalus is a synapomorphy that identifies the artiodactyls as a monophyletic group. Members of the outgroup, perissodactyls (including horses and rhinos), do not possess a pulley-shaped astragalus.

These data support the tree shown in **FIGURE 28.4a**. Notice that whales do not have an astragalus (indeed, no ankles at all) and are shown as an outgroup to the artiodactyls on this tree based on other morphological characteristics. It is logical to map the gain of the pulley-shaped astragalus in the ancestral population, marked by a black bar in Figure 28.4a, because all descendants of that ancestor have the trait, but members of the outgroup do not.

Data Set 2: A Phylogeny Based on DNA Sequence Data When researchers began comparing DNA sequences of artiodactyls and other species of mammals, however, the data showed that whales share many similarities with hippos. These results supported the tree shown in **FIGURE 28.4b**.

Here, it is still logical to map the evolution of the pulley-shaped astragalus at the same ancestor as in Figure 28.4a. But to recognize that the trait had to have been lost in an ancestor of today's whales—which do not have a pulley-shaped astragalus—the tree contains another black bar mapping the trait loss.

The tree supported by the DNA data conflicts with the tree supported by morphological data because it implies that the pulley-shaped astragalus evolved in artiodactyls and then was lost during whale evolution. These two changes (a gain *and* a loss of the astragalus) are less parsimonious than just one change (a gain only).

Data Set 3: Transposable Elements The conflict between the two phylogenies was resolved when researchers analyzed the distribution of the parasitic DNA sequences called **SINEs (short interspersed nuclear elements),** which occasionally insert themselves into the genomes of mammals. (SINEs are transposable elements, similar to the LINEs introduced in Chapter 21.) SINEs provide convincing evidence of relationships because the chance of the same SINE inserting itself in exactly the same place in the genomes of two species is astronomically small.

As the data in **FIGURE 28.4c** show, whales and hippos share several types of SINEs (4, 5, 6, and 7) that are not found in other groups. Other SINEs are present in some artiodactyls but not in others. Camels have no SINEs at all.

To explain these data, biologists hypothesize that no SINEs were present in the population that is ancestral to all of the species in the study. Then, after the branching event that led to the split between the camels and all the other artiodactyls, different SINEs inserted themselves into the genomes of descendant populations.

If this hypothesis is correct, then the presence of a particular SINE represents a derived character. Because whales and hippos share four of these unique derived characters, it is logical to conclude that these animals are closely related.

✔ **If you understand this concept, you should be able to explain why SINEs numbered 4–7 are synapomorphies that identify whales and hippos as a monophyletic group, and why the similarity in these SINEs is unlikely to represent homoplasy.**

Conclusion: Whales Are Closely Related to Hippos If a phylogenetic tree were estimated based on the SINE data, it would have the same branching pattern as the one shown in Figure 28.4b. (To convince yourself, try the exercise in the figure caption). Thus, most biologists accept the phylogeny shown in Figure 28.4b as the most accurate estimate of whale evolutionary history. According to this phylogeny, whales are artiodactyls and share a relatively recent common ancestor with hippos. This observation inspired the hypothesis that both whales and dolphins are descended from a population of artiodactyls that spent most of their time feeding in shallow water, much as hippos do today.

In 2001, the discovery of fossil artiodactyls supported this hypothesis in spectacular fashion. These fossil species were clearly related to whales—they have an unusual ear bone found only in whales—and yet had a pulley-shaped astragalus.

The combination of DNA sequence data and data from the fossil record has clarified how a particularly interesting group of mammals evolved. What else do fossils have to say?

Whales and hippos share four *unique* SINEs (4, 5, 6, and 7)

FIGURE 28.4 Where Do Whales Belong on the Tree of Life?

DATA for (c): Nikaido, M., A. P. Rooney, and N. Okada. 1999. *Proceedings of the National Academy of Sciences, USA* 96: 10261–10266.

✔**EXERCISE** Map the origin of the following groups of SINEs on the tree in part (b): Group (4, 5, 6, 7) identifies hippos and whales as part of a monophyletic group; (8, 11, 14, 15, 17) identifies deer and cows as part of a monophyletic group; (10, 12, 13) identifies hippos, whales, deer, and cows as part of a monophyletic group. What two species does SINEs group (19, 20) identify as part of a monophyletic group?

28.2 Tools for Studying History: The Fossil Record

Phylogenetic analyses are powerful ways to infer the order in which events occurred during evolution and to understand how particular groups of species are related. But only the fossil record provides *direct* evidence about what organisms that lived in the past looked like, where they lived, and when they existed.

A **fossil** is a piece of physical evidence from an organism that lived in the past. The **fossil record** is the total collection of fossils that have been found throughout the world. The fossil record is housed in thousands of private and public collections.

Let's review how fossils form, analyze the strengths and weaknesses of the fossil record, and then summarize major events that have taken place in life's approximately 3.5-billion-year history.

How Do Fossils Form?

Most of the processes that form fossils begin when part or all of an organism is buried in ash, sand, mud, or some other type of sediment. For example, imagine that leaves, pollen, seeds,

branches, or entire trees fall onto a muddy swamp, where they are buried by soil and debris before they decay. Once burial occurs, several things can happen.

- If decomposition does not occur, the organic remains can be preserved intact—like the fossil pollen in **FIGURE 28.5a**.
- If sediments accumulate on top of the material and become cemented into rocks such as mudstone or shale, the sediments' weight can compress the organic material below into a thin, carbonaceous film. This happened to the leaf in **FIGURE 28.5b**.
- If the remains decompose *after* they are buried—as did the branch in **FIGURE 28.5c**—the hole that remains can fill with dissolved minerals and create an accurate **cast** of the remains.
- If the remains rot extremely slowly, dissolved minerals can gradually infiltrate the interior of the cells and harden into stone, forming a permineralized fossil, such as petrified wood (**FIGURE 28.5d**).

After many centuries have passed, fossils can be exposed at the surface by erosion, a road cut, quarrying, or other processes. If researchers find a fossil, they can prepare it for study by painstakingly clearing away the surrounding rock.

If the species represented is new, researchers describe its morphology in a scientific publication, name the species, estimate the fossil's age based on dates assigned to nearby rock layers, and add the specimen to a collection so that it is available for study by other researchers. It is now part of the fossil record.

This scenario is based on conditions that are ideal for fossilization: The trees fell into an environment where decomposition was slow and burial was rapid. In most habitats the opposite situation occurs—decomposition is rapid and burial is slow. In reality, then, fossilization is an extremely rare event.

To appreciate this point, consider that there are 10 specimens of the first bird-like dinosaur to appear in the fossil record, *Archaeopteryx*. If you accept an estimate that crow-sized birds native to wetland habitats would have a population size of around 10,000 and a life span of 10 years, and if you accept the current estimate that the species existed for about 2 million years, then you can calculate that about 2 billion *Archaeopteryx* lived. But as far as researchers currently know, only 1 out of every 200,000,000 individuals were fossilized and discovered. For this species, the odds of becoming part of the fossil record were almost 40 times worse than your odds are of winning the grand prize in a state lottery.

Limitations of the Fossil Record

Before looking at how the fossil record is used to answer questions about the history of life, it is essential to review the nature of this archive and recognize several features.

Habitat Bias Because burial in sediments is so crucial to fossilization, there is a strong habitat bias in the database. Organisms that live in areas where sediments are actively being deposited—including beaches, mudflats, and swamps—are much more likely to form fossils than are organisms that live in other habitats.

Within these habitats, burrowing organisms such as clams are already underground—pre-buried—at death and are therefore much more likely to fossilize. Organisms that live aboveground in dry forests, grasslands, and deserts are much less likely to fossilize.

Taxonomic and Tissue Bias Slow decay is almost always essential to fossilization, so organisms with hard parts such as bones or shells are most likely to leave fossil evidence. This requirement introduces a strong taxonomic bias into the record. Clams, snails, and other organisms with hard parts have a much higher tendency to be preserved than do worms.

A similar bias exists for tissues within organisms. For instance, pollen grains are encased in a tough outer coat that resists decay, so they fossilize much more readily than do flowers. Shark teeth are abundant in the fossil record, but shark skeletal elements, which are made of cartilage, are almost nonexistent.

Temporal Bias Recent fossils are much more common than ancient fossils. This causes a temporal bias in the fossil record. The reason is straightforward—the older a fossil is, the longer it has been exposed to potentially destructive forces.

Older fossils usually occur in sedimentary rock layers deep below newer layers (see Chapter 25). These fossils are more vulnerable to crushing, heating, melting, and distortion by various chemical and physical processes. Older fossils are also more likely to be subducted further into the Earth's interior by the sliding and collision of Earth's tectonic plates. The fossils that survive these destructive forces will be discovered by scientists only if the

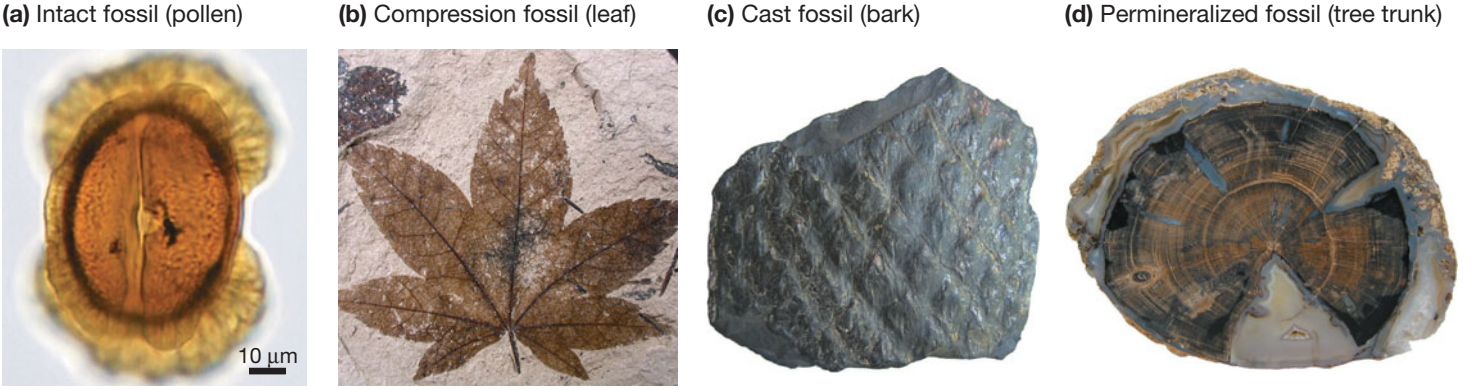

FIGURE 28.5 Fossils Are Formed in Several Ways. Different preservation processes give rise to different types of fossils.

deep layers of sedimentary rock they occupy are exposed to the surface by erosion (such as in the Grand Canyon) or by uplift.

Abundance Bias The fossil record has an abundance bias; it is weighted toward common species. Organisms that are abundant, widespread, and/or present on Earth for long periods of time leave evidence much more often than do species that are rare, local, or ephemeral.

To summarize, the fossil database represents a highly nonrandom sample of the past. **Paleontologists**—scientists who study fossils—recognize that they are limited to asking questions about tiny and scattered segments on the tree of life. ✔ **If you understand the biases of the fossil record, you should be able to predict at least two ways that paleontologists could be misled by their observations of fossils.**

And yet, as this chapter shows, the fossil record is a scientific treasure trove. Analyzing fossils is the only way scientists have of examining the physical appearance of extinct forms and inferring how they lived. The fossil record is like an ancient library, filled with volumes that give us glimpses of what life was like millions of years before humans appeared.

Life's Time Line

It is very difficult to date the origin of life precisely. Our best estimate is that the Earth started to form about 4.6 billion years ago, and that life began before 3.5 billion years ago—probably in the warm, hydrothermal vents at the bottom of the ocean (see Chapter 2). To organize the tremendous sweep of time between then and now, researchers divide Earth history into segments called eons, eras, and periods.

Originally, geologists used distinctive rock formations or fossilized organisms to identify the boundaries between named time intervals. Later, researchers were able to use radiometric dating to assign absolute dates—expressed as years before the present—to events in the fossil record. Radiometric dating is based on the well-studied decay rates of certain radioactive isotopes (see Chapter 25). By dating rocks near fossils, researchers can also assign an absolute age to many of the species in the fossil record.

To summarize the history of life, researchers create time lines that record key "evolutionary firsts"—the appearance of important new lineages or innovations. It's important to recognize, though, that the times assigned to these first appearances underestimate when lineages appeared and events occurred. The reason is simple: A particular species or lineage can exist for millions of years before leaving fossil evidence. The fossil record and efforts to date fossils are constantly improving, so time lines are always a work in progress.

Precambrian The interval between the formation of Earth about 4.6 billion years ago and the appearance of most animal groups about 542 million years ago (abbreviated mya) is called the **Precambrian** (**FIGURE 28.6**); it is divided into the Hadean, Archaean, and Proterozoic eons.

FIGURE 28.7 Major Events of the Phanerozoic Eon (at left). The Phanerozoic began with the initial diversification of animals, continued with the evolution and early diversification of land plants and fungi, and includes the subsequent movement of animals to land. A total of five mass extinctions occurred during the eon.

Here are the important things to know about the Precambrian:

- Life was exclusively unicellular for most of Earth's history.
- Oxygen was virtually absent from the oceans and atmosphere for almost 2 billion years after the origin of life. Photosynthetic bacteria were responsible for the creation of the oxygen atmosphere (see Chapter 29).

Phanerozoic Eon The interval between 542 mya and the present is called the Phanerozoic eon and is divided into three eras (**FIGURE 28.7**). Each of these eras is further divided into intervals called periods, which are themselves divided into epochs.

1. The **Paleozoic** ("ancient life") **era** begins with the appearance of most major animal lineages and ends with the obliteration of almost all multicellular life-forms at the end of the Permian period. The Paleozoic includes the origin and initial diversification of the animals, land plants, and fungi, as well as the appearance of land animals.
2. The **Mesozoic** ("middle life") **era** begins with the end-Permian extinction events and ends with the extinction of the dinosaurs (except birds) and other groups at the boundary between the Cretaceous period and Paleogene period. In terrestrial environments of the Mesozoic, gymnosperms were the most dominant plants and dinosaurs were the most dominant vertebrates.
3. The **Cenozoic** ("recent life") **era** is divided into the Paleogene, Neogene, and Quaternary periods. On land, angiosperms were the most dominant plants and mammals were the largest vertebrates.

At the top of Figure 28.7 you can see that the periods of the Cenozoic are divided into epochs, and that we are presently in the Holocene epoch. However, many scientists have called for the delineation of a new epoch—the Anthropocene ("new human epoch")—to reflect the dramatic physical, chemical, and biological changes that humans are causing on Earth, especially since the industrial revolution. Much discussion will take place before any official change is made.

Changes in the Oceans and Continents The changes in environments and life-forms that are recorded in Figures 28.6 and 28.7 took place in the context of radical changes in climate and in the extent and location of Earth's oceans and continents. Earth's crust is broken into enormous plates that are in constant motion, driven by heat rising from the planet's core.

FIGURE 28.8 summarizes the most recent data on how the positions of the continents and oceans have changed through time,

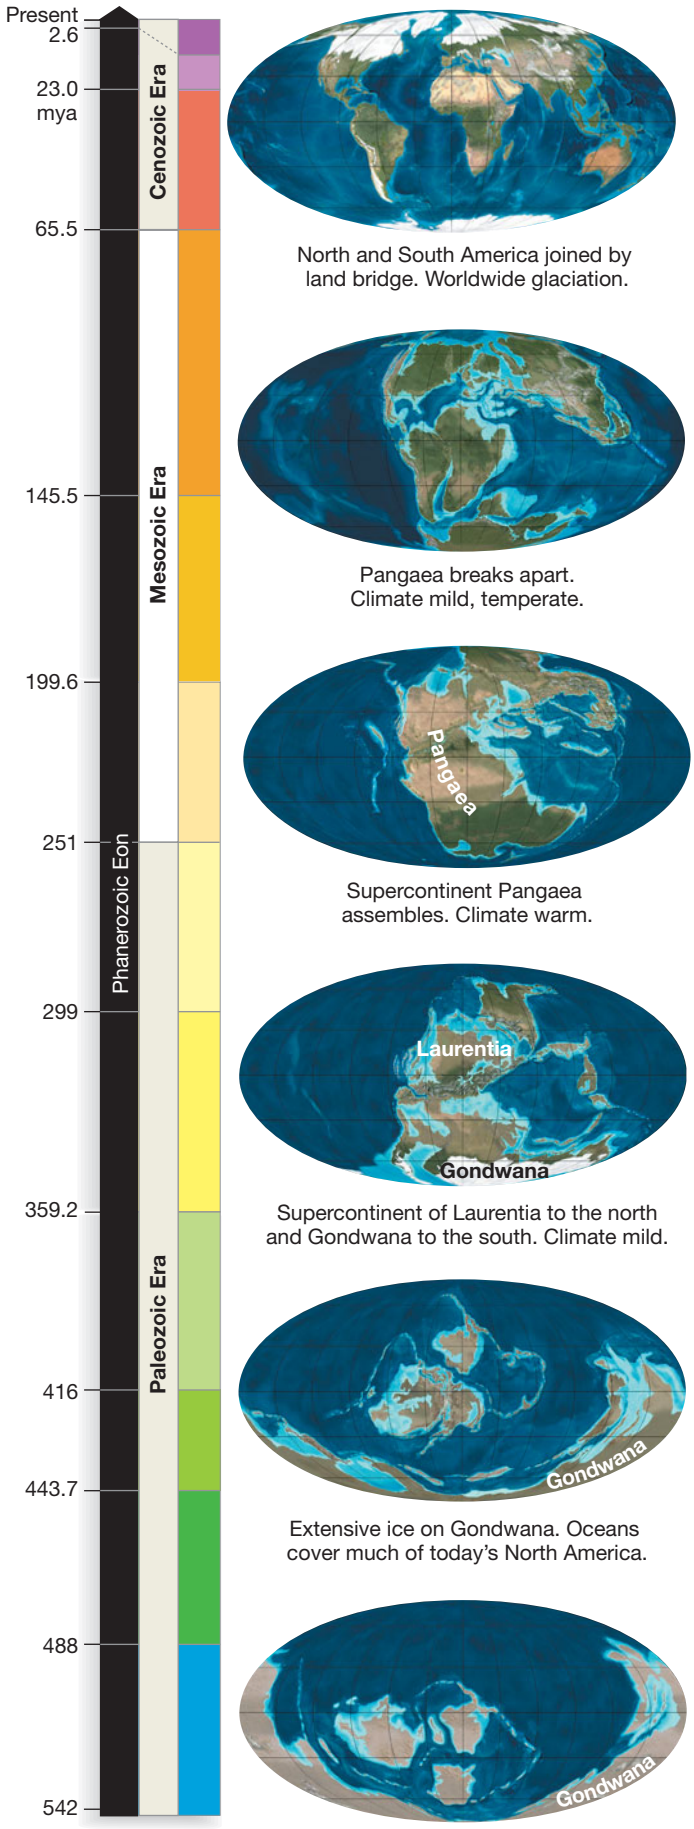

FIGURE 28.8 Continental Positions during the Phanerozoic (at right). Dramatic changes in the extent and position of the continents took place during the Phanerozoic. These changes affected the total amount of land area, the relative amounts of land in the tropics versus northern latitudes, and the nature of ocean currents.

starting at the beginning of the Phanerozoic Eon. The figure also includes notes on the prevailing climate. Over the past 542 million years alone, terrestrial and marine landforms and climates have changed radically.

Taken together, the fundamental message in time-line data is a story of constant change. The changes are well documented, but the sweep of time involved is still difficult for the human mind to comprehend. If the history of the Earth were scaled to fit in one calendar year, our species, *Homo sapiens*, would not appear until one hour before the stroke of midnight on December 31st.

28.3 Adaptive Radiation

When biologists consider the history of life, two of the most compelling types of evolutionary events to study are **(1)** periods when species originate and diversify rapidly, and **(2)** periods when species go extinct rapidly. Let's focus on dramatic events that create biological diversity first; the chapter's concluding section analyzes how that diversity gets wiped out.

When a single lineage rapidly produces *many* descendant species with a wide range of adaptive forms, biologists say that an **adaptive radiation** has occurred. Adaptive radiations are noteworthy because they cause dramatic changes to the tree of life. They can be observed as a sudden appearance of related, diverse species in the fossil record and also by phylogenetic analysis.

FIGURE 28.9 provides an example: the Hawaiian silverswords. The 30 species in this lineage evolved from a species of tarweed, native to California, that colonized the islands about 5 million years ago. This is an example of allopatric speciation by dispersal (see Chapter 27). Compared to speciation rates in other groups, this rate is extremely rapid. Further, today's silverswords vary from mosslike mats to vines and rosettes. They live in habitats ranging from lush rain forests to austere lava flows.

The Hawaiian silverswords fulfill the three hallmarks of an adaptive radiation: **(1)** they are a monophyletic group, **(2)** they speciated rapidly, and **(3)** they diversified ecologically—meaning, in terms of the resources they use and the habitats they occupy.

Biologists use the term niche to describe the range of resources that a species can use and the range of conditions that it can tolerate (see Chapter 27). Silverswords occupy a wide array of niches.

Why Do Adaptive Radiations Occur?

Adaptive radiations are a major pattern in the history of life. But why do some lineages diversify rapidly, while others do not?

Two general mechanisms can trigger adaptive radiations: new resources, and new ways to exploit resources. Let's consider each in turn.

Ecological Opportunity Ecological opportunity—meaning the availability of new or novel types of resources—has driven a wide array of adaptive radiations. For example, biologists explain the diversification of silverswords by hypothesizing that few other flowering plant species were present on the Hawaiian Islands 5 million years ago. With few competitors, the descendants of the colonizing tarweed were able to grow in a wide range of habitats. Over time—by the processes of mutation, genetic drift, and natural selection (discussed in Chapter 26)—some became specialized for growth in different niches.

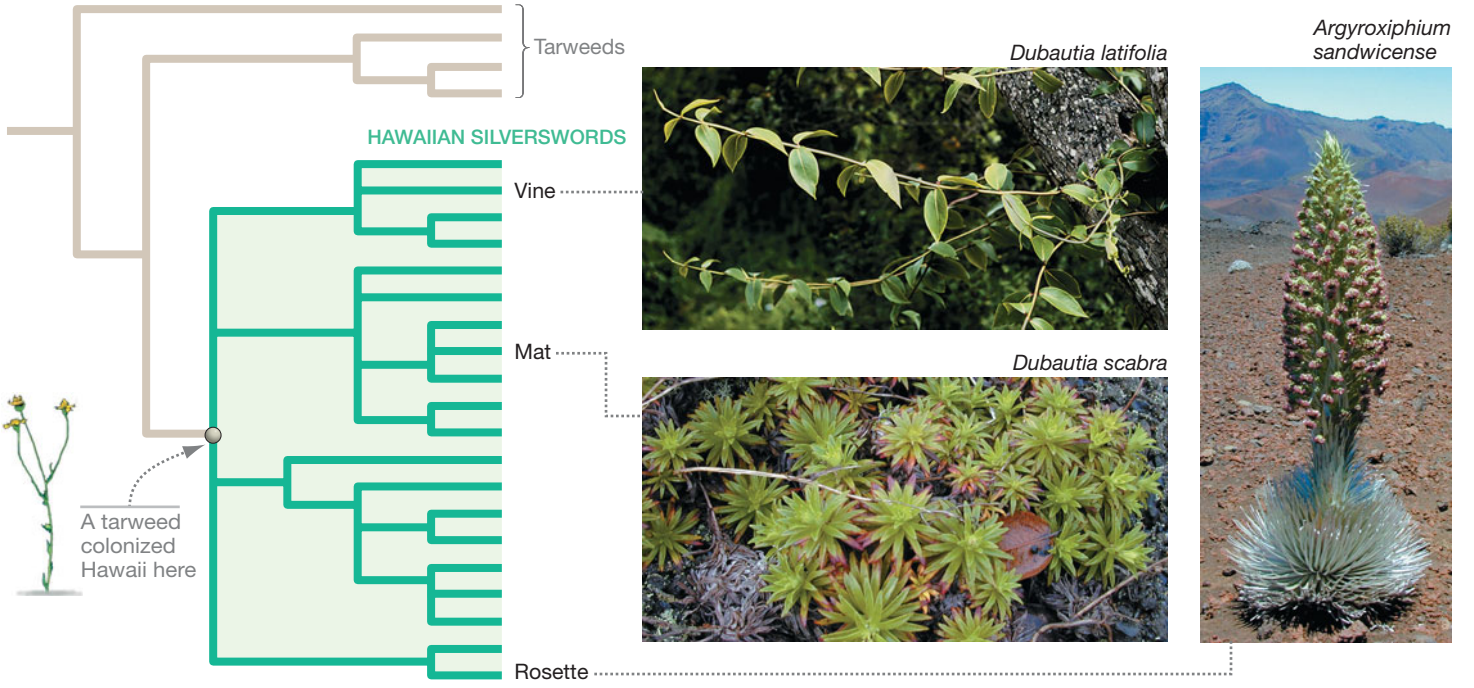

FIGURE 28.9 An Adaptive Radiation. This tree shows a subset of the Hawaiian silverswords, illustrating the extent of morphological divergence.

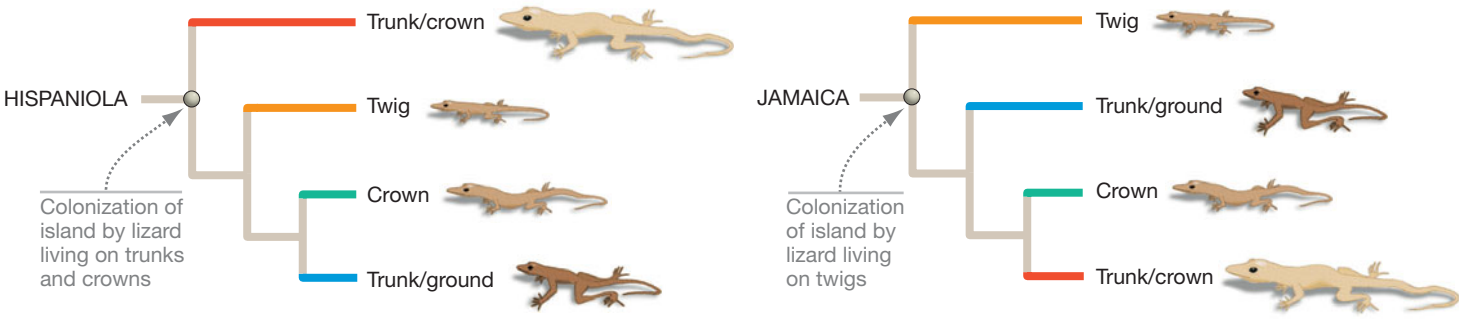
(a) Short-legged lizard species spend most of their time on the twigs of trees and bushes.



(b) Long-legged lizard species live on tree trunks and the ground.

FIGURE 28.10 Adaptive Radiations of *Anolis* Lizards. (a, b) Species of *Anolis* lizards vary in leg length and tail length. **(c)** Evolutionary relationships among lizard species on the islands of Hispaniola and Jamaica. The initial colonist species was different on these islands, but in terms of how they look and where they live, a similar suite of four species evolved.

(c) The same adaptive radiation of *Anolis* has occurred on different islands, starting from different types of colonists.

The same type of ecological opportunity was hypothesized to explain the adaptive radiation of *Anolis* lizards on islands in the Caribbean. The lineage includes 150 species. They thrive in a wide array of habitats and have diverse body sizes and shapes. And in most cases, a lizard's size and shape are correlated with the habitat it occupies. For example:

- Species that live on tree twigs have short legs and tails that allow them to move efficiently on narrow surfaces (**FIGURE 28.10a**).
- Species that spend most of their time clinging to broad tree trunks or running along the ground have long legs and tails, making them fast and agile on broad surfaces (**FIGURE 28.10b**).

Most islands in the Caribbean have a distinct suite of lizard species. And in most cases, each island has a species that lives only in the twigs, on the ground, or in other distinctive habitats. The classical explanation for this pattern was that a mini-radiation occurred on each island: An original colonizing group encountered no competitors, and diversified in a way that led to efficient use of the available resources by a group of descendant species.

To test this hypothesis rigorously, Jonathan Losos and his colleagues estimated the phylogeny of *Anolis* from DNA sequence data. The results supported a key claim of the ecological opportunity hypothesis: The lizards on each island were monophyletic.

The critical data, though, are shown in **FIGURE 28.10c**. These phylogenetic trees, for species found on two different islands, are typical. The key observation is that the original colonist on each island was specialized for a different niche. The initial species on Hispaniola lived on the trunks and crowns of trees, while the original colonist on Jamaica occupied twigs.

From different evolutionary starting points, then, an adaptive radiation filled the same niches on both islands. This is exactly what the ecological opportunity hypothesis predicts. In *Anolis* lizards in the Caribbean, a series of mini-radiations were triggered when colonists arrived on an island that had food, space, and other resources, but lacked competitors. ✔ **If you understand this concept, you should be able to generate a hypothesis to explain why tarweeds in California and *Anolis* lizards on the mainland are not particularly species-rich or ecologically diverse.**

Morphological Innovation The evolution of a key morphological trait—one that allowed descendants to live in new areas, exploit new sources of food, or move in new ways—triggered many of the important diversification events in the history of life. For example:

- *Flowers* are a unique reproductive structure that helped trigger the diversification of angiosperms (flowering plants). Because flowers are particularly efficient at attracting pollinators, the evolution of the flower made angiosperms more efficient in reproduction. Today angiosperms are far and away the most species-rich lineage of land plants. Over 250,000 species are known.
- *Feathers and wings* gave some dinosaurs the ability to fly. Feathers originally evolved for display or insulation; later they were used in gliding and in powered flight. Today the lineage called birds contains about 10,000 species, whose representatives live in virtually every habitat on the planet.

In each case, the evolution of new morphological features is hypothesized to have supported rapid speciation and ecological divergence.

The Cambrian Explosion

Almost all life-forms were unicellular for almost 3 *billion* years after the origin of life. The exceptions were several lineages of small multicellular algae, which show up in the fossil record about 1 billion years ago. Then, the first animals—early sponges—appear, perhaps as early as 635 million years ago.

In a relatively short time, creatures with shells, exoskeletons, internal skeletons, legs, heads, tails, eyes, antennae, jaw-like mandibles, segmented bodies, muscles, and brains had evolved. It was arguably the most spectacular period of evolutionary change in the history of life. Because much of it occurred during the Cambrian period, this adaptive radiation of animals is called the **Cambrian explosion.**

All organisms were small for 3 billion years; then life got big, in just 50 million years—1/60th of the total time life had existed. Before asking how this happened, let's explore the fossilized evidence for what happened.

The Doushantuo, Ediacaran, and Early Cambrian Fossils The Cambrian explosion is documented by three major fossil assemblages that record the state of animal life near the beginning of the Cambrian. As **FIGURE 28.11a** indicates, the species collected from each of these intervals are referred to respectively as the Doushantuo fossils (named after the Doushantuo formation in China), Ediacaran fossils (named after the Ediacara Hills, Australia), and Cambrian fossils (from the Burgess Shale in Canada, the Chengjiang region of China, and several other sites around the world).

Each fossil assemblage records a distinctive **fauna**—or collection of animal species:

- *Doushantuo microfossils* include tiny sponges and corals, less than 1 mm across. These creatures—the first animals on Earth—probably made their living by filtering organic debris from the water.
- *Ediacaran faunas* include sponges, jellyfish, and comb jellies as well as fossilized burrows, tracks, and other traces from unidentified animals. None of these organisms have shells, limbs, heads, or feeding appendages (**FIGURE 28.11b, bottom**). Ediacaran animals likely filtered or absorbed organic material as they burrowed in sediments, sat immobile on the seafloor, or floated in the water.
- *Cambrian faunas* are among the most sensational additions ever made to the fossil record. Sponges, jellyfish, and comb jellies are abundant in these rocks, but so are several worm-like creatures and arthropods (**FIGURE 28.11b, top**), in addition to mollusks, echinoderms, and virtually all the other major animal lineages (see Chapter 33). This list includes our own lineage—the chordates—represented by early vertebrate fossils with streamlined, fishlike bodies and a skull made of cartilage (**FIGURE 28.12**). A tremendous increase in the size and morphological complexity of animals occurred, accompanied by diversification in how they made a living. Species in these faunas swam, burrowed, walked, ran, slithered, clung, or floated; there were predators, scavengers, filter feeders, and grazers. The diversification filled many of the ecological niches found in marine habitats today.

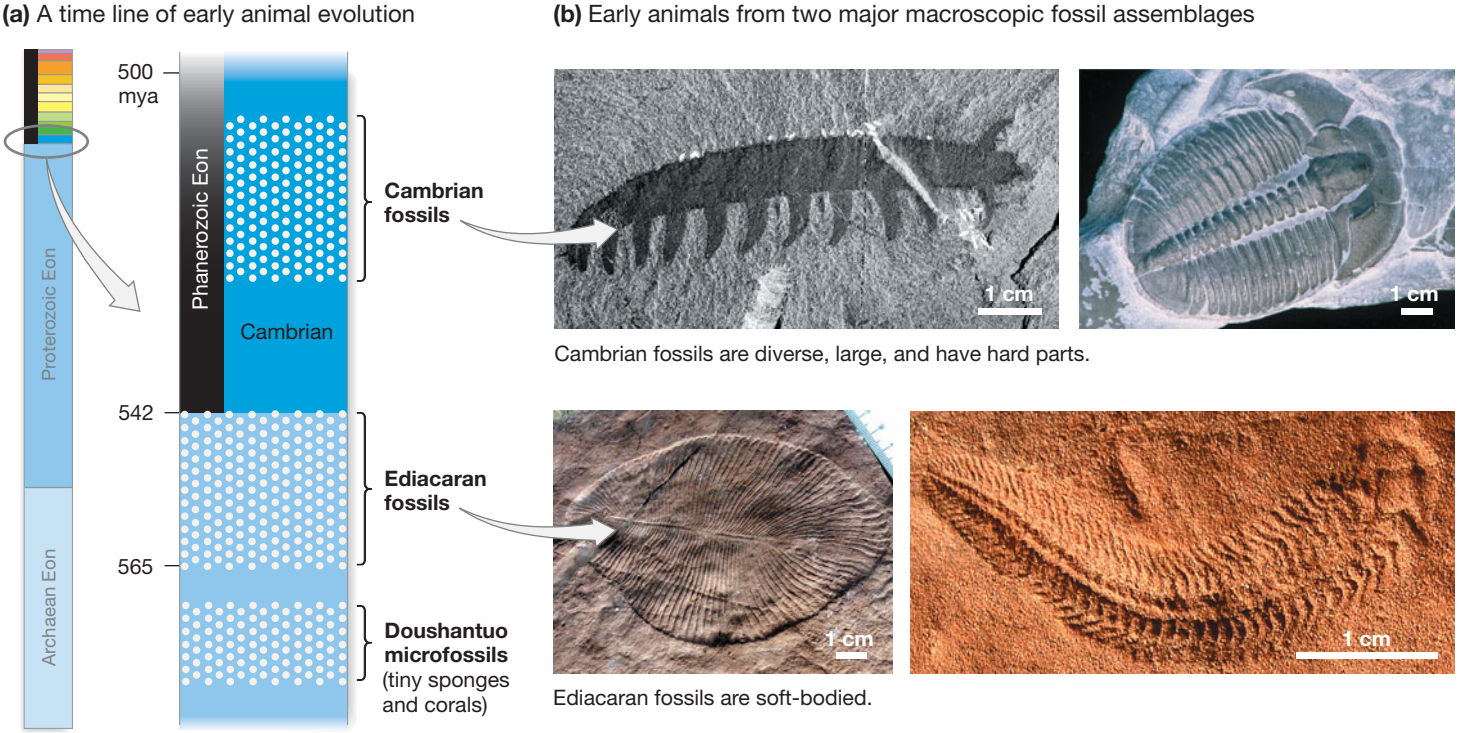


FIGURE 28.11 Fossils Document the Cambrian Explosion. The origin of animals and their diversification during the Cambrian explosion is documented by three major fossil assemblages, two of them represented by macroscopic fossils.

FIGURE 28.12 Life in the Cambrian. This artist's interpretation of animal diversity during the Cambrian is based on fossils found in the Chengjiang formation of China. Chengjiang is famous for its unique fossils of fishlike early vertebrates.

What Triggered the Cambrian Explosion? The Doushantuo, Ediacaran, and Cambrian faunas document what happened during the Cambrian explosion. Now the question is: *How* did all this speciation, morphological change, and ecological diversification come about?

To answer this question, biologists point to an array of data sets and hypotheses:

- ***Higher oxygen levels*** By analyzing the composition of rocks formed during the Proterozoic, geologists have established that oxygen levels gradually rose in the atmosphere and ocean. Increased oxygen levels make aerobic respiration more efficient (see Chapter 9); increased aerobic respiration is required to support larger bodies and more active movements. Some biologists suggest that oxygen levels reached a critical threshold at the start of the Cambrian explosion, making the evolution of big, mobile animals possible.
- ***The evolution of predation*** Before the Cambrian explosion, animals made their living by eating organic material that settled on the seafloor or filtering cells and debris from the water. But Cambrian fossils include shelled animals with holes in the shells—evidence that a predator drilled through and ate the animal inside. When predators evolved, they exerted selection pressure for shells, hard exoskeletons, rapid movement, and other adaptations for prey to defend themselves. This selection would drive morphological divergence.
- ***New niches beget more new niches*** The vast majority of Doushantuo and Ediacaran animals lived on the ocean floor—in what biologists call benthic habitats. Once animals could move off this substrate, they could exploit algae and other resources that were available above the ocean floor. The presence of animals at an array of depths created selection pressure for the evolution of species that could eat them. In this way, the ability to exploit new niches created new niches, driving speciation and ecological diversification.
- ***New genes, new bodies*** *Hox* genes play a key role in organizing the development of the body in diverse animals by signaling where cells are in the embryo (Chapter 22). **FIGURE 28.13** summarizes the *Hox* genes found in some major animal

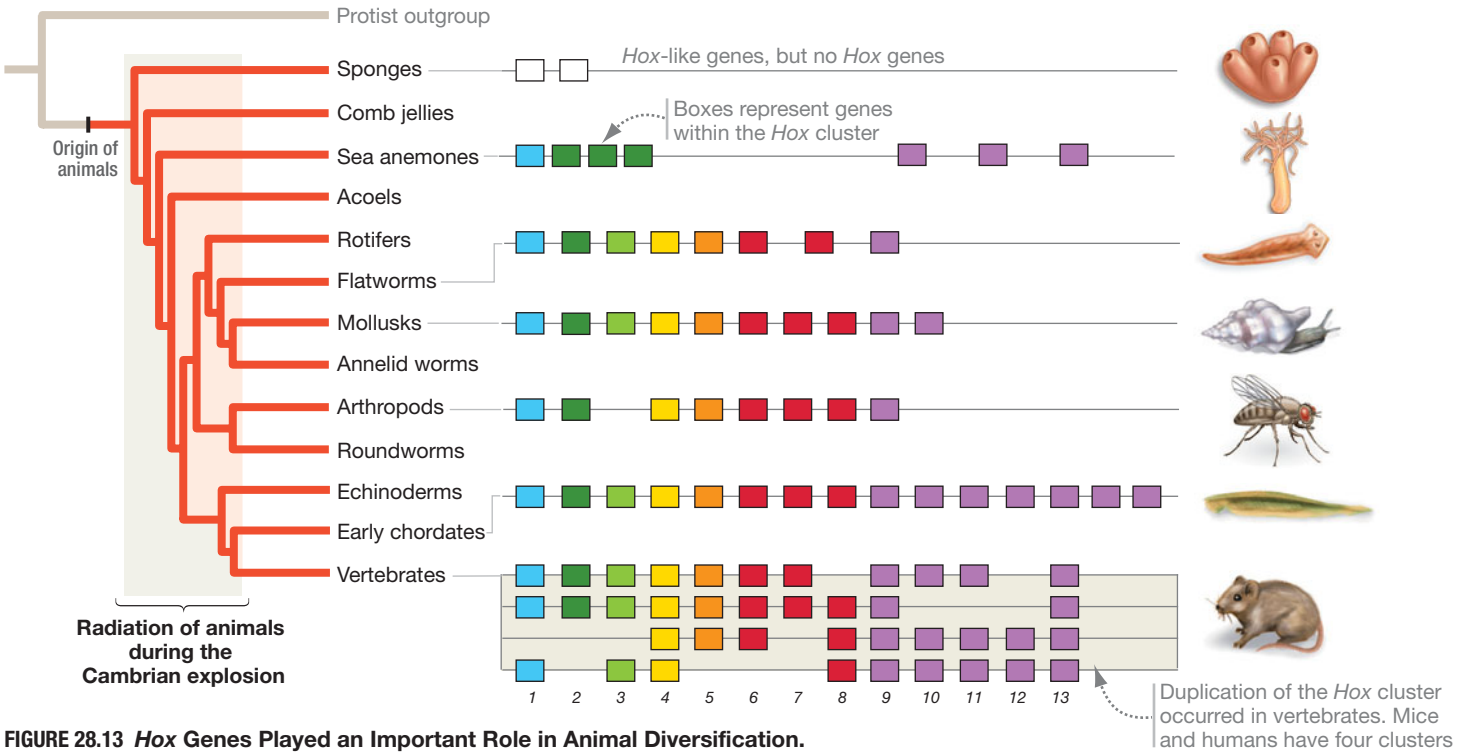

FIGURE 28.13 *Hox* Genes Played an Important Role in Animal Diversification.

groups. The key observation is that the earliest animals in the fossil record had few or no *Hox* genes; most groups that appeared later have more. The idea here is that gene duplication and diversification increased the number of *Hox* genes in animals and made it possible for larger, more complex bodies to evolve.

It's important to recognize that most or all of these hypotheses could be correct. They are not mutually exclusive. If increased oxygen levels made larger bodies and more rapid movement possible, then animals could move into new habitats off the seafloor and become large enough to eat smaller animals. Selection would favor individuals with mutations in *Hox* genes and other DNA sequences that make the development of a large, complex body possible.

About 100 million years after the Cambrian explosion, a similar adaptive radiation occurred after the first plants—the descendants of green algae—adapted to life on land. In the span of about 56 million years, an array of growth forms and most major lineages of plants appear in the fossil record. This "Devonian explosion" resulted from the morphological innovations that allowed green plants to thrive on land, coupled with the ecological opportunity provided by an environment awash in sunlight (Chapter 31).

Adaptive radiations occur when species originate and diversify rapidly. Now let's consider how dramatic events can *wipe out* diversity.

check your understanding

C Y U

If you understand that . . .

- Adaptive radiations are triggered by ecological opportunity and morphological innovation.

✓ You should be able to . . .

Explain the role of ecological opportunity and morphological innovation in the Cambrian explosion.

Answers are available in Appendix A.

28.4 Mass Extinction

A **mass extinction** refers to the rapid extinction of a large number of lineages scattered throughout the tree of life. More specifically, a mass extinction occurs when at least 60 percent of the species present are wiped out within 1 million years.

Mass extinction events are evolutionary hurricanes. They buffet the tree of life, snapping twigs and breaking branches. They are catastrophic episodes that wipe out huge numbers of species and lineages in a short time, giving the tree of life a drastic pruning. They are the polar opposite of adaptive radiation.

Before analyzing two of the best-studied mass extinctions in the fossil record, let's step back and ask how they differ from normal extinction events.

How Do Mass Extinctions Differ from Background Extinctions?

Background extinction refers to the lower, average rate of extinction observed when a mass extinction is not occurring. Although there is no hard-and-fast rule for distinguishing between background and mass extinction rates, paleontologists traditionally recognize and study five historic mass extinction events. **FIGURE 28.14**, for example, plots the percentage of plant and animal lineages called families that died out during each stage in the geologic time scale since the Cambrian explosion. Five spikes in the graph—denoting a large number of extinctions within a short time—are drawn in red. These are referred to as "The Big Five."

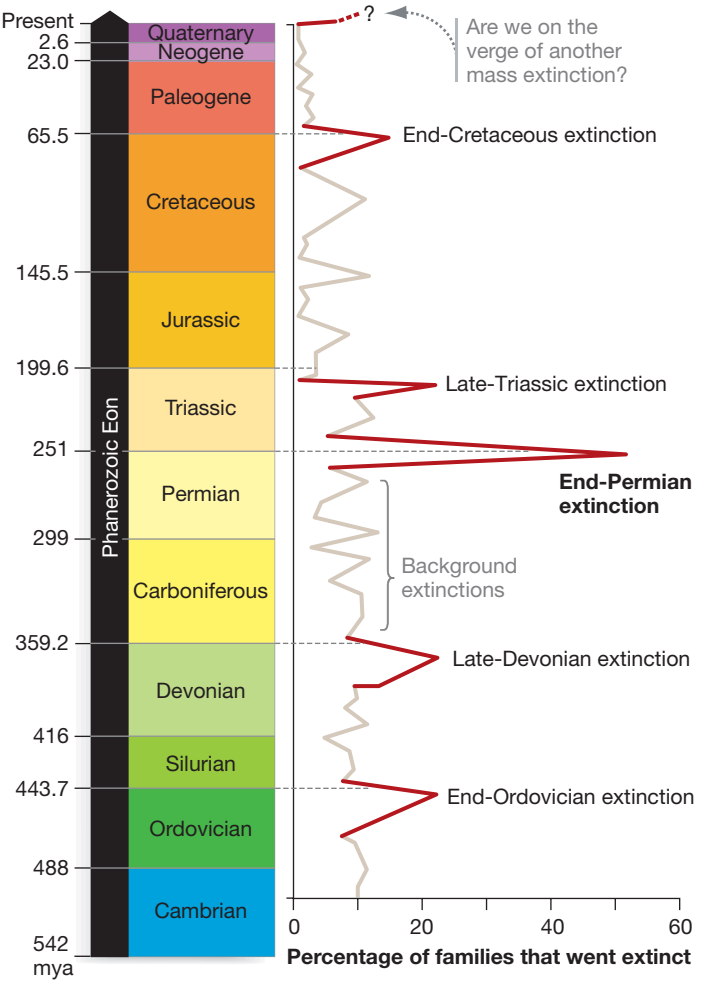

FIGURE 28.14 The Big Five Mass Extinction Events. This graph shows the percentage of lineages called families that went extinct over each interval in the fossil record since the Cambrian explosion. Over 50 percent of families and 90 percent of species went extinct during the end-Permian extinction.

DATA: Benton, M. J., 1995. *Science* 268: 52–58.

✓**QUANTITATIVE** Which extinction event ended the era of the dinosaurs 65 million years ago? About what percentage of families went extinct?

Biologists are interested in distinguishing between background and mass extinctions because these events have contrasting causes and effects.

- *Background extinctions* are thought to occur when normal environmental change, emerging disease, predation pressure, or competition with other species reduces certain populations to zero.
- *Mass extinctions* result from extraordinary, sudden, and temporary changes in the environment. During a mass extinction, species do not die out because individuals are poorly adapted to normal or gradually changing environmental conditions. Rather, species die out from exposure to exceptionally harsh, short-term conditions—such as huge volcanic eruptions or catastrophic sea-level changes.

To drive these points home, consider a mass extinction event that nearly uprooted the tree of life entirely. The end-Permian extinction, which occurred about 251 million years ago, came close to ending multicellular life on Earth.

The End-Permian Extinction

The end-Permian has been called the Mother of Mass Extinctions. To appreciate the scale of the event, imagine that while walking along a seashore, you identified 100 different species of algae and animals living on the beach and in tide pools and the shallow water offshore. Now imagine that you snapped your fingers, and 90 of those species disappeared forever. Only 10 species are left. An area that was teeming with diverse forms of life would look barren.

This is what happened, all over the world, during the end-Permian extinction. The event was a catastrophe of almost unimaginable proportions. On a personal level, it would be like nine of your ten best friends dying.

Although biologists have long appreciated the scale of the end-Permian extinction, research on its causes is ongoing. Consider the following:

- Flood basalts are outpourings of molten rock that flow across Earth's surface. The largest flood basalts on Earth, called the Siberian traps, occurred during the end-Permian. They added enormous quantities of heat, CO_2, and sulfur dioxide to the atmosphere.
- High levels of atmospheric CO_2 trapped heat, causing intense global warming, the stratification of the oceans, and reaction of deep-ocean sulfur dioxide with water to form sulfuric acid, which is toxic to most organisms.
- Rocks that formed during the interval indicate that the oceans became completely or largely anoxic—meaning that they lacked oxygen. These conditions are fatal to organisms that rely on aerobic respiration.
- There is convincing evidence that sea level dropped dramatically during the extinction event, reducing the amount of habitat available for marine organisms.
- Terrestrial animals may have been restricted to small patches of low-elevation habitats, due to low oxygen concentrations and high CO_2 levels in the atmosphere.

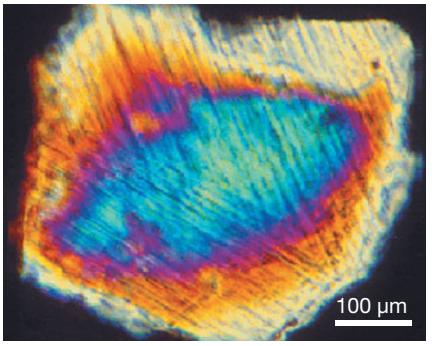
In short, both marine and terrestrial environments deteriorated dramatically for organisms that depend on oxygen to live. A prominent researcher has captured this point by naming the suite of killing mechanisms the "world went to hell hypothesis."

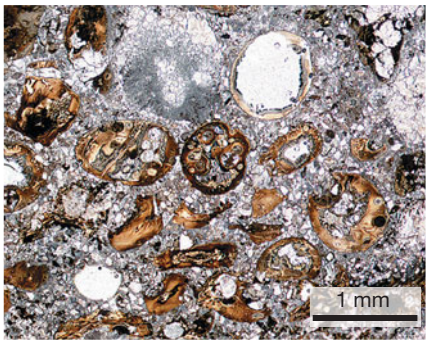
What biologists don't understand is *why* the environment changed so radically, and so quickly. For example, no one has yet been able to establish a convincing connection between the eruption of the Siberian traps and the other, more global, environmental changes that occurred.

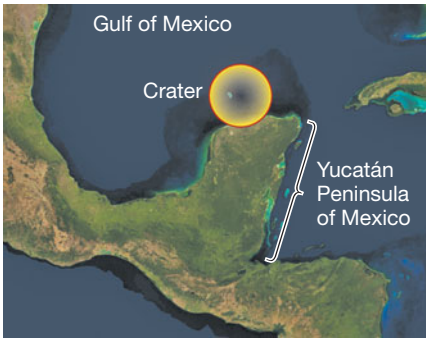
The cause of the end-Permian extinction may be the most important unsolved question in research on the history of life, aside from the origin of life itself (see Chapter 2). The cause of the dinosaur's demise, in contrast, is settled.

What Killed the Dinosaurs?

The end-Cretaceous extinction of 65 million years ago is as satisfying a murder mystery as you could hope for, but the butler didn't do it. The **impact hypothesis** for the extinction of the dinosaurs, first put forth in the early 1970s by father-and-son team Luis and Walter Alvarez, proposed that an asteroid struck Earth and snuffed out an estimated 60–80 percent of the multicellular species alive.







Evidence for the Impact Hypothesis The impact hypothesis was intensely controversial at first. As researchers set out to test its predictions, however, support began to grow (**TABLE 28.4**):

- Worldwide, sedimentary rocks that formed at the Cretaceous–Paleogene (K–P) boundary were found to contain extremely high quantities of the element iridium. Iridium is vanishingly rare in Earth rocks, but it is an abundant component of asteroids and meteorites.
- Shocked quartz and microtektites are minerals that are found only at documented meteorite impact sites. In Haiti and an array of other locations, both shocked quartz and microtektites have been discovered in abundance in rock layers dated to 65 million years ago.
- A crater larger than New Jersey was found just off the northwest coast of Mexico's Yucatán peninsula. Microtektites are abundant in sediments from the crater's walls, and the crater dates to the K–P boundary.

Taken together, these data provided conclusive evidence in favor of the impact hypothesis. Researchers agree that the mystery is solved.

Nature of the Impact The shape of the Yucatán crater and the distribution of shocked quartz and microtektites dated to 65 mya indicates that the asteroid hit Earth at an angle and splashed material over much of southeastern North America. Based on

SUMMARY TABLE 28.4 Evidence for the Impact Hypothesis

Type of Evidence	Explanation
	**Spike of iridium in 65-million-year-old rocks worldwide** Iridium is very rare on Earth but abundant in asteroids and meteors
	**Spike of shocked quartz in 65-million-year-old rocks worldwide** Shocked quartz forms only under extremely high pressures created from events like impacts (not from volcanoes)
	**Spike of microtektites in 65-million-year-old rocks in Gulf of Mexico** These glass droplets form only under extremely high temperatures and pressures as rock is splashed, molten, from an impact site
	**Huge, 65-million-year-old crater discovered off coast of Mexico** The crater is 180 kilometers in diameter (absolutely massive), so an impact of this size would have far-reaching effects

currently available data, astronomers and paleontologists estimate that the asteroid was about 10 km across.

To get a sense of the event's scale, consider that Mt. Everest is about 10 km above sea level and that planes cruise at an altitude of about 10 km. Imagine Earth being hit by a rock the size of Mt. Everest, or a rock that would fill the space between you and a jet in the sky.

According to both computer models and geologic data, the consequences of the K–P asteroid strike were nothing short of devastating.

- A tremendous fireball of hot gas would have spread from the impact site; large soot and ash deposits in sediments dated to 65 million years ago testify to catastrophic wildfires, worldwide.
- The largest tsunami in the last 3.5 billion years would have disrupted ocean sediments and circulation patterns.
- The impact site itself is underlain by a sulfate-containing rock called anhydrite. The SO_4^{2-} released by the impact would have reacted with water in the atmosphere to form sulfuric acid, triggering extensive acid rain.
- Massive quantities of dust, ash, and soot would have blocked the Sun for long periods, leading to rapid global cooling and a crash in plant productivity.

Selectivity of the Extinctions The asteroid impact did not kill indiscriminately. Perhaps by chance, certain lineages escaped virtually unscathed while others vanished. Among vertebrates, for example, most dinosaurs (except birds), pterosaurs (flying reptiles), and all of the large-bodied marine reptiles (mosasaurs and plesiosaurs) expired; birds, mammals, crocodilians, amphibians, and turtles survived.

Why? Answering this question has sparked intense debate. For years the leading hypothesis was that the K–P extinction event was size selective. The logic here was that the extended darkness and cold would affect large organisms disproportionately, because they require more food than do small organisms. But extensive data on the survival and extinction of marine clams and snails have shown no hint of size selectivity, and small-bodied dinosaurs (except for birds) perished along with large-bodied forms.

One hypothesis currently being tested is that organisms that were capable of inactivity for long periods—by hibernating or resting as long-lived seeds or spores—were able to survive the catastrophe. Also, recent data show selectivity according to habitat; organisms in the open oceans suffered higher extinction rates than those in coastal waters. The reason for selectivity of the extinctions is still unsolved.

Recovery from the Extinction After the K–P extinction, fern fronds and fern spores dominate the plant fossil record from North America and Australia. These data suggest that extensive stands of ferns replaced diverse assemblages of cone-bearing and flowering plants after the impact. The fundamental message here is that terrestrial ecosystems around the world were radically simplified by the extinction event. In marine environments, some invertebrate groups do not exhibit typical levels of species diversity in the fossil record until 4–8 million years past the K–P boundary. Recovery was slow.

The organisms present in the Paleogene were markedly different from those of the preceding period. The lineage called

Mammalia had begun to diversify before the K–P extinction, during a period of rapid diversification of flowering plants. But early mammals were mostly rat-sized predators and scavengers in the heyday of the dinosaurs. It wasn't until after the dinosaurs became extinct that each of the major lineages of mammals diversified into the orders we recognize today—from bats to bears, and pigs to primates—and average body size increased exponentially. Why? A major branch on the tree of life had disappeared. With competitors removed from many ecological niches, mammals flourished.

The change in the terrestrial vertebrate fauna was not due to a competitive superiority conferred by adaptations such as fur and lactation. Rather, it was due to a chance event: a once-in-a-billion-years collision with a massive rock from outer space.

The Sixth Mass Extinction?

Are mass extinctions events of the distant past? Not likely. Many scientists now propose that life on Earth is on the verge of the sixth mass extinction, precipitated by human impacts such as habitat loss, pollution, overfishing, invasive species, and climate change. Could human activities really cause such dire consequences as massive as those caused by an asteroid impact?

There is mounting evidence that the answer to this question is yes. The exponential increase of human populations, combined with our hunger for resources, has put the diversity of life as we know it at risk.

Unit 6 explores the diversity of life itself. Then Unit 9 examines how human actions are rapidly pruning branches from the tree of life during your lifetime.

CHAPTER 28 REVIEW

For media, go to MasteringBiology

If you understand . . .

28.1 Tools for Studying History: Phylogenetic Trees

- Phylogenetic trees show the evolutionary history of a group of organisms—who is most closely related to whom. They have revolutionized the study of evolution and many related fields.
- Phylogenetic trees are usually estimated by analyzing shared, derived characters (synapomorphies) that identify monophyletic groups.
- Researchers often use the principle of parsimony to decide which of the many possible trees is most likely to reflect actual evolutionary history. Parsimony assumes that the most likely explanation or pattern is the one that implies the least amount of change.
- Homology occurs when traits are shared due to common ancestry. Homoplasy occurs when traits are similar due to reasons other than common ancestry, such as convergent evolution.

✔ **You should be able to explain why upright posture and bipedalism (walking on two legs) is a synapomorphy that defines a monophyletic group called hominins, which includes humans.**

28.2 Tools for Studying History: The Fossil Record

- The fossil record is the only direct source of data about what extinct organisms looked like and where they lived.
- The fossil record is biased: Common, recent, and abundant species that burrow and that have hard parts are most likely to be present in the record.
- During the Precambrian, which started with the formation of the Earth 4.6 billion years ago and ended with the origin of most animals about 542 million years ago, life was almost exclusively unicellular.
- Oxygen was virtually absent from the oceans and atmosphere for almost 2 billion years after the origin of life. The oxygen atmosphere was generated by photosynthetic bacteria.
- During the Phanerozoic, which began about 542 million years ago and continues to the present, animals originated and diversified first in the ocean and then on land. Land plants and fungi also originated and diversified.
- If the history of the Earth were scaled to fit in one calendar year, our species, *Homo sapiens*, would not appear until one hour before the stroke of midnight on December 31st.

✔ **You should be able to explain why some paleontologists use snail fossils rather than other types of fossils to estimate how biodiversity has changed over time.**

28.3 Adaptive Radiation

- Adaptive radiations occur when a single lineage rapidly produces many descendant species with a wide range of adaptive forms.
- Adaptive radiations can be triggered by ecological opportunity, such as the availability of unoccupied niches on an island, or morphological innovations, such as flowers and wings.
- The Cambrian explosion was one of the most spectacular adaptive radiations of all time, producing virtually all of the major animal lineages existing today. During this event, the size and morphological complexity of animals increased tremendously, and animals diversified in how they made a living.

✔ **You should be able to explain why the evolution of animals that could swim free of benthic habitats—such as fishlike early vertebrates—created an ecological opportunity.**

28.4 Mass Extinction

- Mass extinctions are short-term environmental catastrophes that eliminate most of the species alive. Mass extinctions have altered the course of evolutionary history at least five times.
- Mass extinctions such as the end-Permian and end-Cretaceous prune the tree of life more or less randomly and have marked the end of several branches within prominent lineages and the subsequent rise of new branches.
- After the devastation of a mass extinction, the fossil record indicates that it can take 10–15 million years for ecosystems to recover their former levels of diversity.
- A mass extinction may presently be under way due to the drastic effects of humans on the Earth in recent history.

✔ **You should be able to evaluate this statement: Environmental changes caused by humans are eliminating species that are poorly adapted to their natural environment.**

TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. Choose the best definition of a fossil.
   a. any trace of an organism that has been converted into rock
   b. a bone, tooth, shell, or other hard part of an organism that has been preserved
   c. any trace of an organism that lived in the past
   d. the process that leads to preservation of any body part from an organism that lived in the past
2. What is the difference between a branch and a node on a phylogenetic tree?
   a. A branch is a population through time; a node is where a population splits into two independent populations.
   b. A branch represents a common ancestor; a node is a species.
   c. A branch is a lineage; a node is any named taxonomic group.
   d. A branch is a population through time; a node is the common ancestor of all species or lineages present on a particular tree.
3. Which of the following best characterizes an adaptive radiation?
   a. Speciation occurs extremely rapidly, and descendant populations occupy a large geographic area.
   b. A single lineage diversifies rapidly, and descendant populations occupy many habitats and ecological roles.
   c. Natural selection is particularly intense, because disruptive selection occurs.
   d. Species recover after a mass extinction.
4. True or false? The dinosaurs (other than birds) went extinct during the asteroid impact at the K–P boundary because they were poorly adapted to their ecological niches.
5. Which of the following is an example of homoplasy?
   a. hair in humans and fur in mice
   b. astragalus ankle bones in hippos and deer
   c. *Hox* genes in humans and flies
   d. streamlined bodies in dolphins and ichthyosaurs
6. True or false? Monophyletic groups are identified by shared, derived traits.

TEST YOUR UNDERSTANDING

Answers are available in Appendix A

7. The text claims that the fossil record is biased in several ways. What are these biases? If the database is biased, is it still an effective tool to use in studying the diversification of life? Why or why not?
8. The initial diversification of animals took place over some 50 million years, mostly during the Cambrian period. Propose an analogy from everyday life to illustrate the significance of this event.
9. Why is parsimony a useful tool for assessing which phylogenetic tree is most accurate? Why was parsimony misleading in the case of the astragalus during the evolution of artiodactyls?
10. Give an example of an adaptive radiation that occurred after a colonization event and another that occurred after a key innovation. In each case, provide a hypothesis to explain why the adaptive radiation occurred.
11. **QUANTITATIVE** The end-Permian extinction was devastating. If each student in your graduating class represented a different species during the Permian and there were 1880 students in your graduating class, about how many students would make it to graduation?
12. **BioSkills 7** in Appendix B recommends a "one-snip test" to identify monophyletic groups—meaning that if you cut any branch on a tree, everything that "falls off" is a monophyletic group. Why is this valid?
    a. Monophyletic groups are nested on a tree—meaning that they are hierarchical.
    b. Monophyletic groups can also be called clades or lineages.
    c. Species are the smallest monophyletic groups on the tree of life.
    d. One snip gets an ancestor and all of its descendants.

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A

13. Suppose that the dying wish of a famous eccentric was that his remains be fossilized. His family has come to you for expert advice. What method would you recommend as most likely to maximize the chances that his wish will be fulfilled?

a. Place the corpse in an environment where decomposition is rapid (such as a forest).

b. Place the corpse in an environment where decomposition is slow (such as a swamp or bog).

c. Bury only the bones, since soft parts don't fossilize well.

d. Place the corpse in an environment where plenty of oxygen is available.

14. Use the data matrix below to draft at least three alternate phylogenetic trees. Label the outgroup. Indicate which tree is most parsimonious, and explain why. How could you change your analysis to increase your confidence that the tree represents true evolutionary relationships?

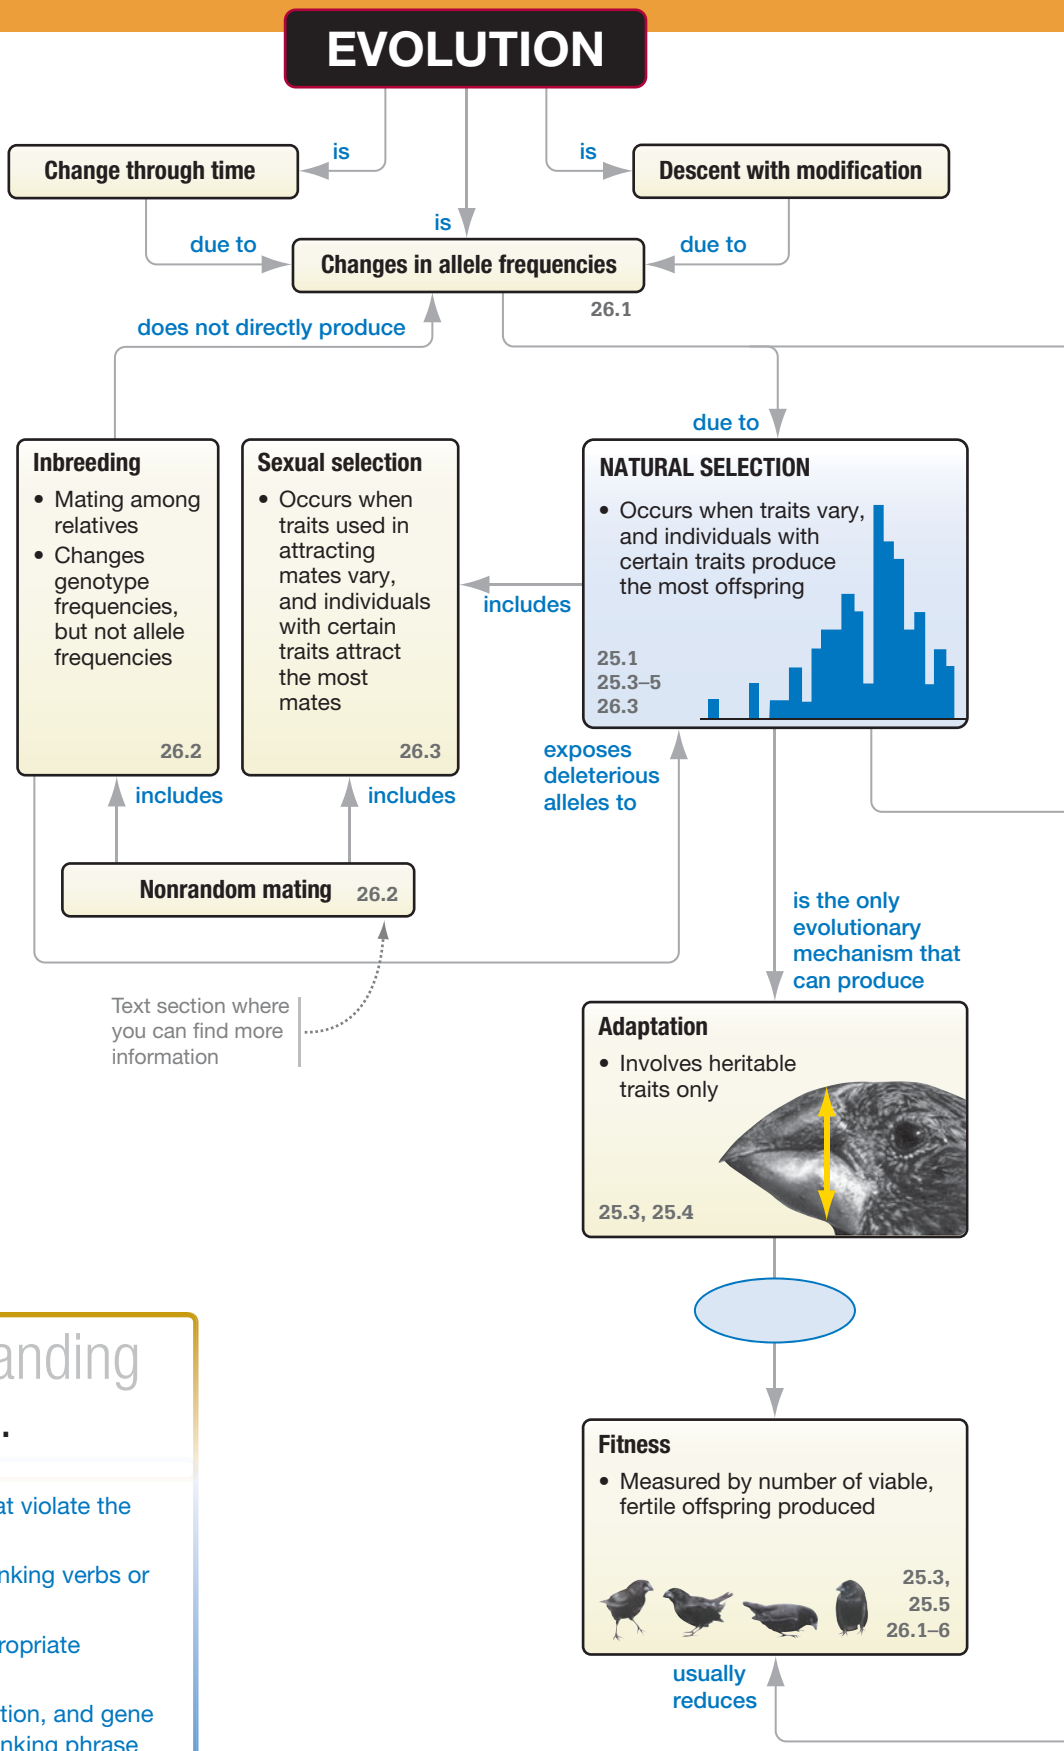
	Presence or Absence of *Hox* Genes*				
	Hox1	*Hox2*	*Hox3*	*Hox4*	*Hox12*
Mouse	**1**	**1**	**1**	**1**	**1**
Snail	**1**	**1**	**1**	**1**	0
Fly	**1**	**1**	**1**	**1**	0
Sea anemone	**1**	**1**	0	0	0
Sponge	0	0	0	0	0

*1 = gene present; 0 = gene absent.

15. Some researchers contend that the end-Permian extinction event was caused by an impact with a large extraterrestrial object. Describe three forms of evidence that you would like to see before you accept this hypothesis.

16. One of the "triggers" proposed for the Cambrian explosion is a dramatic rise in oxygen concentrations that occurred in the oceans about 800 mya. (Review material in Chapter 9 on how oxygen compares with other atoms or compounds as an electron acceptor during cellular respiration; look near the end of Section 9.6, where aerobic and anaerobic respiration are compared.) Make a small concept map outlining the logic behind the "oxygen-trigger" hypothesis for the Cambrian explosion. (See **BioSkills 15** in Appendix B if you need help making concept maps.)

BIG PICTURE



The Big Picture

Geneticist and evolutionary biologist Theodosius Dobzhansky said that "Nothing in biology makes sense except in the light of evolution." Use this concept map to study how ideas introduced in Unit 5 fit together.

The key is to connect the four evolutionary processes that work at the level of populations—natural selection, genetic drift, mutation, and gene flow—to processes, events, and outcomes at higher levels of organization: speciation, adaptive radiation, mass extinction, and the tree of life.

It's all about changes in allele frequencies. Over time, small changes that occur between populations lead to large changes that distinguish major lineages on the tree of life.

Note that each box in the concept map indicates the chapter and section where you can go for review. Also, be sure to do the blue exercises in the Check Your Understanding box below.

28.3

29 Bacteria and Archaea

Although this hot spring looks devoid of life, it is actually teeming with billions of bacterial and archaeal cells.

Bacteria and Archaea (usually pronounced *ar-KEE-ah*) form two of the three largest branches on the tree of life (**FIGURE 29.1**). The third major branch, or domain, consists of eukaryotes and is called the Eukarya. Virtually all members of the Bacteria and Archaea domains are unicellular, and all are prokaryotic—meaning that they lack a membrane-bound nucleus.

Although their relatively simple morphology makes bacteria and archaea appear similar to the untrained eye, in some ways they are strikingly different at the molecular level (**TABLE 29.1**). Organisms in the Bacteria and Archaea domains are distinguished by the types of molecules that make up their plasma membranes and cell walls:

- **Bacteria** have a unique compound called peptidoglycan in their cell walls (see Chapter 5).

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

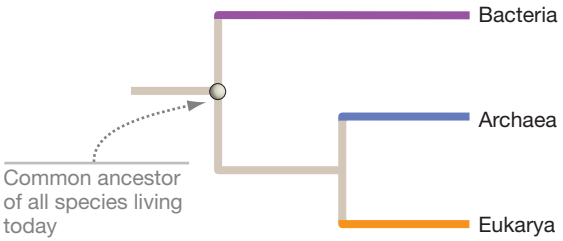

FIGURE 29.1 Bacteria, Archaea, and Eukarya Are the Three Domains of Life. Archaea are more closely related to eukaryotes than they are to bacteria.

✔**QUESTION** Was the common ancestor of all species living today prokaryotic or eukaryotic? Explain your reasoning.

- **Archaea** have unique phospholipids in their plasma membranes—the hydrocarbon tails of the phospholipids are made from isoprene (see Chapter 6).

If you were unicellular, bacteria and archaea would look as different to you as mammals and fish.

In addition, the machinery that bacteria and archaea use to process genetic information is strikingly different. More specifically, the DNA polymerases, RNA polymerases, transcription-initiation proteins, and ribosomes found in Archaea and Eukarya are distinct from those found in Bacteria and similar to each other. These differences have practical consequences: Antibiotics that poison bacterial ribosomes do not affect the ribosomes of archaea or eukaryotes. If all ribosomes were identical, these antibiotics would kill you along with the bacterial species that was supposed to be targeted.

As an introductory biology student, you may know less about bacteria and archaea than about any other group on the tree of life. Before taking this course, it's likely that you'd never even heard of the Archaea. You might be surprised to find out that biologists suspect that the first eukaryotic cells may have formed as a result of a symbiotic event between these two groups of prokaryotes. Notice in Table 29.1 that cells in the domain Eukarya share some features with both Bacteria and Archaea. Studying these shared features has helped biologists understand the early evolution of life on Earth.

This chapter's goal is to convince you that even though bacteria and archaea are tiny, they have an enormous impact on you and the planet in general. By the time you finish reading the chapter, you should understand why a researcher summed up the bacteria and archaea by claiming, "They run this joint."

29.1 Why Do Biologists Study Bacteria and Archaea?

Biologists study bacteria and archaea for the same reasons they study any organisms. First, they are intrinsically fascinating. Discoveries such as finding bacterial cells living a kilometer underground or in 95°C hot springs keep biologists awake at night, staring at the ceiling. They can't wait to get into the lab in the morning and figure out how those cells stay alive.

SUMMARY TABLE 29.1 Characteristics of Bacteria, Archaea, and Eukarya

	Bacteria	Archaea	Eukarya
DNA enclosed by a nuclear envelope? (see Chapter 7)	No	No	Yes
Circular chromosome present?	Yes (but linear in some species)	Yes	No (linear)
Organelles enclosed by membranes present? (see Chapter 7)	No	No	Yes
Rotating flagella present? (see Chapter 7)	Yes	Yes	No (flagella and cilia undulate)
Multicellular species?	No (with some exceptions)	No	Yes
Plasma membrane lipids composed of glycerol bonded to unbranched fatty acids by ester linkages? (see Chapter 6)	Yes	No (branched lipids bonded by ether linkages)	Yes
Cell walls, when present, contain peptidoglycan? (see Chapter 5)	Yes	No	No
RNA polymerase composed of >10 subunits?	No (only 5 subunits)	Yes	Yes
Translation initiated with methionine? (see Chapter 17)	No (initiated with *N*-formylmethionine; *f*-met)	Yes	Yes

✔**EXERCISE** Using the data in this table, add labeled marks to Figure 29.1 indicating where the following traits evolved: peptidoglycan in cell wall, archaeal-type plasma membrane, archaeal- and eukaryotic-type translation initiation, and nuclear envelope.

Second, there are practical benefits to understanding the species that share the planet with us. Understanding bacteria and archaea is particularly important—in terms of both understanding life on Earth and improving human health and welfare.

Biological Impact

The lineages in the domains Bacteria and Archaea are ancient, diverse, abundant, and ubiquitous. The oldest fossils of any type found to date are 3.5-billion-year-old carbon-rich deposits derived from bacteria. Because eukaryotes do not appear in the fossil record until 1.75 billion years ago, biologists infer that prokaryotes were the only form of life on Earth for at least 1.7 billion years.

Just how many bacteria and archaea are alive today? Although a mere 5000 species have been formally named and described to date, it is virtually certain that millions exist. Consider that over 1000 species of prokaryotes are living in your large intestine right now, and another 700 species are living in your mouth. Well-known microbiologist Norman Pace points out that there may be tens of millions of different insect species but notes, "If we squeeze out any one of these insects and examine its contents under the microscope, we find hundreds or thousands of distinct microbial species." Most of these **microbes** (microscopic organisms) are bacteria or archaea. Virtually all are unnamed and undescribed. If you want to discover and name new species, then study bacteria or archaea.

Abundance Besides recognizing how diverse bacteria and archaea are in terms of numbers of species, it's critical to appreciate their abundance.

- The approximately 10^{13} (10 trillion) cells in your body are outnumbered ten to one by the bacterial and archaeal cells living on and in you. You are a walking, talking habitat—one that is teeming with bacteria and archaea.
- A mere teaspoon of good-quality soil contains *billions* of microbial cells, most of which are bacteria and archaea.
- In sheer numbers, species in a lineage of marine archaea may be the most successful organisms on Earth. Biologists routinely find these cells at concentrations of over 10,000 individuals per milliliter in most of the world's oceans. At these concentrations, one liter of seawater contains a population equivalent to that of the largest human cities. Yet this lineage was not described until the early 1990s.
- Recent research has found enormous numbers of bacterial and especially archaeal cells in rocks and sediments as much as 1600 meters underneath the world's oceans. Although recently discovered, the bacteria and archaea living under the ocean may make up 10 percent of the world's total mass of living material.
- Biologists estimate the total number of individual bacteria and archaea alive today at over 5×10^{30}. If they were lined up end to end, these cells would make a chain longer than the Milky Way galaxy. They contain 50 percent of all the carbon and 90 percent of all the nitrogen and phosphorus found in organisms.

In terms of the total volume of living material on our planet, bacteria and archaea are dominant life-forms.

Habitat Diversity Bacteria and archaea are found almost everywhere. They live in environments as unusual as oxygen-free mud, hot springs, and salt flats. In seawater they are found from the surface to depths of 10,000 meters (m), and at temperatures over 120°C (well above water's boiling point) near submarine volcanoes.

Although there are far more prokaryotes than eukaryotes, much more is known about eukaryotic diversity than about prokaryotic diversity. Researchers who study prokaryotic diversity are exploring one of the most wide-open frontiers in all of science. So little is known about the extent of these domains that recent collecting expeditions have turned up entirely new **phyla** (singular: **phylum**). These are names given to major lineages within each domain. To a biologist, this achievement is equivalent to the sudden discovery of a new group of eukaryotes as distinctive as flowering plants or animals with backbones.

The physical world has been explored and mapped, and many of the larger plants and animals are named. But in **microbiology**—the study of organisms that can be seen only with the aid of a microscope—this is an age of exploration and discovery.

Some Microbes Thrive in Extreme Environments

Bacteria or archaea that live in high-salt, high-temperature, low-temperature, or high-pressure habitats are **extremophiles** ("extreme-lovers"). Studying them has been extraordinarily fruitful for understanding the tree of life, developing industrial applications, and exploring the structure and function of enzymes.

As an example of these habitats, consider hydrothermal vents at the bottom of the ocean, where water as hot as 300°C emerges and mixes with 4°C seawater. At locations like these, archaea are abundant forms of life.

Researchers recently discovered an archaeon that grows so close to these hydrothermal vents that its surroundings are at 121°C—a record for life at high temperature. This organism can live and grow in water that is heated past its boiling point (100°C) and at pressures that would instantly destroy a human. Since high temperature breaks non-covalent bonds holding macromolecules together, extreme heat usually denatures proteins, makes membranes leaky, and separates the strands of the DNA double helix. Biologists are intrigued by how these unusual archaeal cells can thrive under such extreme conditions.

Other discovered bacteria and archaea can grow

- at a pH less than 1.0;
- at temperatures of 0°C under Antarctic ice;
- in water that is virtually saturated with salt (**FIGURE 29.2**).

Extremophiles have become a hot area of research. The genomes of a wide array of extremophiles have been sequenced, and expeditions regularly seek to characterize new species. Why?

- ***Origin of life*** Based on models of conditions that prevailed early in Earth's history, it appears likely that the first forms of life lived at high temperature and pressure in environments

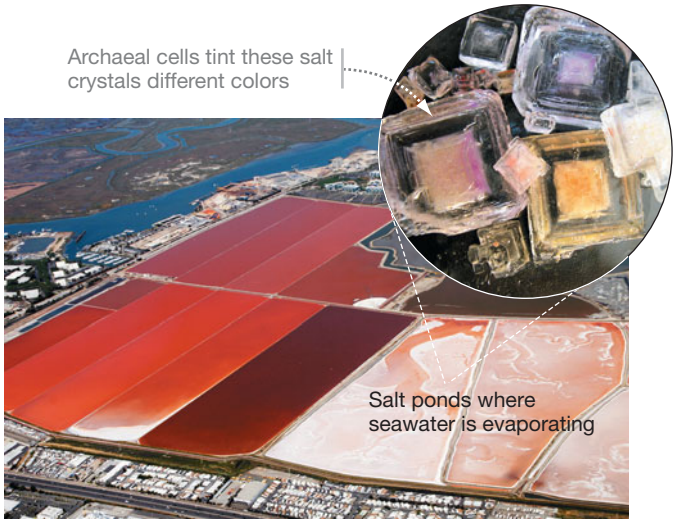

FIGURE 29.2 Some Archaeal Cells Live in High-Salt Habitats. The evaporating water is colored red by these photosynthetic cells.

that lacked oxygen—conditions that humans would call extreme. Thus, understanding extremophiles may help explain how life on Earth began.

- ***Extraterrestrial life?*** In a similar vein, many astrobiologists ("space-biologists") use extremophiles as model organisms in the search for extraterrestrial life. The idea is that if bacteria and archaea can thrive in extreme habitats on Earth, cells might possibly be found in similar environments on other planets or moons of planets.
- ***Commercial applications*** Because enzymes that function at extreme temperatures and pressures are useful in many industrial processes, extremophiles are of commercial interest as well. Recall that *Taq* polymerase—a DNA polymerase that is stable up to 95°C—is used to run the polymerase chain reaction (PCR) in research and commercial settings (see Chapter 20). This enzyme was isolated from a bacterium called *Thermus aquaticus* ("hot water"), which was discovered in a hot spring in Yellowstone National Park.

Bacteria and archaea may be small, but they thrive in an amazing range of conditions.

Medical Importance

The first paper documenting that an archaeon was associated with a human disease—a dental condition called periodontitis—was published in 2004. But biologists have been studying disease-causing bacteria for over a century.

Of the thousands of bacterial species living in and on your body, only a tiny fraction can disrupt normal body functions enough to cause illness. Bacteria that cause disease are said to be **pathogenic** (literally, "disease-producing"). Pathogenic bacteria have been responsible for some of the most devastating epidemics in human history.

TABLE 29.2 lists some of the bacteria that cause illness in humans. Here are the important things to note:

- Pathogenic forms come from several different lineages in the domain Bacteria.

TABLE 29.2 Some Bacteria That Cause Illness in Humans

Lineage	Species	Tissues Affected	Disease
Firmicutes	*Clostridium tetani*	Wounds, nervous system	Tetanus
	Staphylococcus aureus	Skin, urogenital canal	Acne, boils, impetigo, toxic shock syndrome
	Streptococcus pneumoniae	Respiratory tract	Pneumonia
	Streptococcus pyogenes	Respiratory tract	Strep throat, scarlet fever
Spirochaetes	*Borrelia burgdorferi*	Skin and nerves	Lyme disease
	Treponema pallidum	Urogenital canal	Syphilis
Actinobacteria	*Mycobacterium tuberculosis*	Respiratory tract	Tuberculosis
	Mycobacterium leprae	Skin and nerves	Leprosy
	Propionibacterium acnes	Skin	Acne
Chlamydiales	*Chlamydia trachomatis*	Urogenital canal	Genital tract infection
ε-Proteobacteria	*Helicobacter pylori*	Stomach	Ulcer
β-Proteobacteria	*Neisseria gonorrhoeae*	Urogenital canal	Gonorrhea
γ-Proteobacteria	*Haemophilus influenzae*	Ear canal, nervous system	Ear infections, meningitis
	Pseudomonas aeruginosa	Urogenital canal, eyes, ear canal, lungs	Infections of eye, ear, urinary tract, lungs
	Salmonella enterica	Gastrointestinal tract	Food poisoning
	Yersinia pestis	Lymph and blood	Plague

- Pathogenic bacteria tend to affect tissues at the entry points to the body, such as wounds or pores in the skin, the respiratory and gastrointestinal tracts, and the urogenital canal.

Koch's Postulates Robert Koch was the first person to establish a link between a particular species of bacterium and a specific disease. When Koch began his work on the nature of disease in the late 1800s, microscopists had confirmed the existence of the particle-like organisms people now call bacteria, and Louis Pasteur had shown that bacteria and other microorganisms are responsible for spoiling milk, wine, broth, and other foods. Koch hypothesized that bacteria might also be responsible for causing infectious diseases, which spread by being passed from an infected individual to an uninfected individual.

Koch set out to test this hypothesis by identifying the organism that causes anthrax. Anthrax is a disease of cattle and other grazing mammals that can result in fatal blood poisoning. The disease also occurs infrequently in humans and mice.

To establish a causative link between a specific microbe and a specific disease, Koch proposed that four criteria had to be met:

1. The microbe must be present in individuals suffering from the disease and absent from healthy individuals. By careful microscopy, Koch was able to show that the bacterium *Bacillus anthracis* was always present in the blood of cattle suffering from anthrax, but absent from healthy individuals.
2. The organism must be isolated and grown in a pure culture away from the host organism. Koch was able to grow pure colonies of *B. anthracis* in glass dishes on a nutrient medium, using gelatin as a substrate.
3. If organisms from the pure culture are injected into a healthy experimental animal, the disease symptoms should appear. Koch demonstrated this crucial causative link in mice injected with *B. anthracis*. The symptoms of anthrax infection appeared and then the infected mice died.
4. The organism should be isolated from the diseased experimental animal, again grown in pure culture, and demonstrated by its size, shape, and color to be the same as the original organism. Koch did this by purifying *B. anthracis* from the blood of diseased experimental mice.

These criteria, now called **Koch's postulates,** are still used to confirm a causative link between new diseases and a suspected infectious agent. Microbiologists now recognize that many bacteria cannot be grown in culture, so they use other means of detection for those organisms.

The Germ Theory Koch's experimental results were the first test of the **germ theory of disease.**

- The pattern component of this theory is that certain diseases are infectious—meaning that they can be passed from person to person.
- The process responsible for this pattern is the transmission and growth of certain bacteria and viruses.

Viruses are acellular particles that parasitize cells (see Chapter 36).

The germ theory of disease laid the foundation for modern medicine. Initially its greatest impact was on sanitation—efforts to prevent transmission of pathogenic bacteria. During the American Civil War, for example, records indicate that more soldiers died of bacterial infections contracted from drinking water contaminated with human feces than from wounds in battle. Also during that conflict it was common for surgeons to sharpen their scalpels on their shoe leather, after walking in horse manure.

Fortunately, improvements in sanitation and nutrition have caused dramatic reductions in mortality rates due to infectious diseases in the industrialized countries.

What Makes Some Bacterial Cells Pathogenic? Virulence, or the ability to cause disease, is a heritable trait that varies among individuals in a population. Most *Escherichia coli*, for example, are harmless inhabitants of the gastrointestinal tract of humans and other mammals. But some *E. coli* cells cause potentially fatal food poisoning.

What makes some cells of the same species pathogenic, while others are harmless? Biologists have answered this question for *E. coli* by sequencing the entire genome of a harmless lab strain and the pathogenic strain called O157:H7, which is harmful to humans. The genome of the pathogenic strain is slightly larger because it has acquired virulence genes, including one coding for a protein **toxin.** After entering a host cell, this toxin binds to ribosomes and inhibits protein synthesis, killing the host cells. Because of key differences between the ribosomes of bacteria and eukaryotic cells, only host-cell protein synthesis is blocked by the toxin. Cells lining the blood vessels near the host's intestinal epithelium are most affected by the toxin, and the resulting damage leads to bloody diarrhea and possible death. If sanitation is poor, the pathogenic bacteria are likely to infect many new hosts.

Similar types of studies are identifying the genes responsible for virulence in a wide array of pathogenic bacteria.

The Past, Present, and Future of Antibiotics **Antibiotics** are molecules that kill bacteria or stop them from growing. They are produced naturally by a wide array of soil-dwelling bacteria and fungi. In these environments, antibiotics are hypothesized to help cells reduce competition for nutrients and other resources.

The discovery of antibiotics in 1928, their development over subsequent decades, and widespread use starting in the late 1940s gave physicians effective tools to combat many bacterial infections.

Unfortunately, extensive use of antibiotics in the late twentieth century in clinics and animal feed led to the evolution of drug-resistant strains of pathogenic bacteria (see Chapter 25). One study found that there are now soil-dwelling bacteria in natural environments that—far from being killed by antibiotics—actually use them as food.

Coping with antibiotic resistance in pathogenic bacteria has become a great challenge of modern medicine. Some researchers even claim that humans may be entering the "post-antibiotic era" in medicine.

New research indicates that bacteria have another advantage: They usually grow as **biofilms,** dense bacterial colonies enmeshed

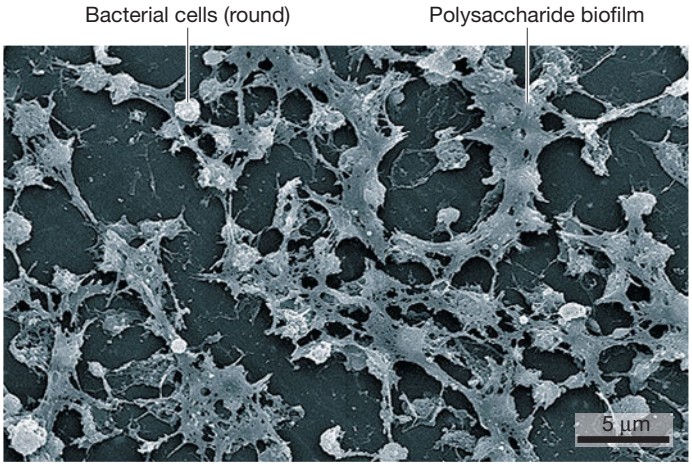

FIGURE 29.3 Biofilm Growing Inside a Catheter. This micrograph shows *Staphylococcus aureus* cells growing inside a catheter—a tube inserted into a body so that fluids can be withdrawn or injected. Bacterial communities that secrete polysaccharides and adhere to surfaces are sometimes more resistant to antibiotics.

FIGURE 29.4 Bacteria and Archaea Can Play a Role in Cleaning Up Pollution. These clean-up workers are spraying nitrogenous nutrients to encourage bacterial and archaeal growth following the 1989 *Exxon Valdez* oil spill in Alaska.

in a polysaccharide-rich matrix that helps shield the bacteria from antibiotics. Antibiotic-resistant biofilms on medical devices such as catheters are a growing problem in hospitals (**FIGURE 29.3**).

Role in Bioremediation

Bacteria are often in the news because of their dire medical effects. However, only a tiny proportion of bacteria and archaea actually cause disease in humans or other organisms. In the vast majority of cases, bacteria and archaea either have no direct impact on humans or are beneficial. For example, microbes play an important role in wastewater treatment efforts, and researchers are using bacteria and archaea to clean up sites polluted with organic solvents—an effort called **bioremediation.**

Throughout the industrialized world, some of the most serious pollutants in soils, rivers, and ponds consist of organic compounds that were originally used as solvents or fuels but leaked or were spilled into the environment. Most of these compounds are highly hydrophobic. Because they do not dissolve in water, they tend to accumulate in sediments. If the compounds are subsequently ingested by burrowing worms or clams or other organisms, they can be passed along to fish, insects, humans, birds, and other species.

At moderate to high concentrations, these pollutants are toxic to eukaryotes. Petroleum from oil spills and compounds that contain ring structures and chlorine atoms, such as the family of compounds called dioxins, are particularly notorious because of their toxicity to humans.

Fortunately, naturally existing populations of bacteria and archaea can grow in spills and degrade the toxins. This growth can be enhanced using two complementary bioremediation strategies:

1. ***Fertilizing contaminated sites to encourage the growth of existing bacteria and archaea that degrade toxic compounds.*** After several oil spills, researchers added nitrogen to affected sites as a fertilizer (**FIGURE 29.4**). Dramatic increases occurred in the growth of bacteria and archaea that use hydrocarbons in cellular respiration, probably because the cells used the added nitrogen to synthesize enzymes and other key compounds. In at least some cases, the fertilized shorelines cleaned up much faster than unfertilized sites.
2. ***"Seeding," or adding, specific species of bacteria and archaea to contaminated sites.*** Seeding shows promise of alleviating pollution in some situations. For example, researchers have recently discovered bacteria that are able to render certain chlorinated, ring-containing compounds harmless. Instead of being poisoned by the pollutants, these bacteria use the chlorinated compounds as electron acceptors during cellular respiration. In at least some cases, the byproduct is dechlorinated and nontoxic to humans and other eukaryotes.

To follow up on these discoveries, researchers are now growing the bacteria in quantity, to test the hypothesis that seeding can speed the rate of decomposition in contaminated sediments. Initial reports suggest that seeding may help clean up at least some polluted sites.

29.2 How Do Biologists Study Bacteria and Archaea?

Biologists' understanding of the domains Bacteria and Archaea is advancing more rapidly right now than at any time during the past 100 years—and perhaps faster than our understanding of any other lineages on the tree of life.

As an introduction to the domains Bacteria and Archaea, let's examine a few of the techniques that biologists use to answer questions about them. Some of these research strategies have been used since bacteria were first discovered; some were invented less than 10 years ago.

Using Enrichment Cultures

Which species of bacteria and archaea are present at a particular location, and what do they use as food? To answer questions like these, biologists rely heavily on their ability to culture organisms in the lab. Of the 5000 species of bacteria and archaea described to date, almost all were discovered when they were isolated from natural habitats and grown under controlled conditions in the laboratory.

One classical technique for isolating new types of bacteria and archaea is called **enrichment culture.** Enrichment cultures are based on establishing a specified set of growing conditions—temperature, lighting, substrate, types of available food, and so on. Cells that thrive under the specified conditions increase in numbers enough to be isolated and studied in detail.

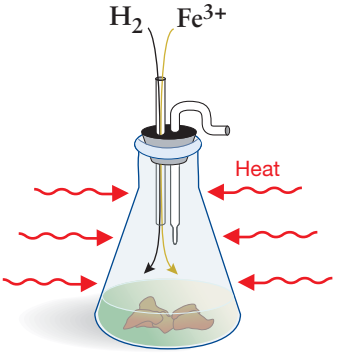
To appreciate how this strategy works in practice, consider research on bacteria that live deep below Earth's surface. One study began with samples of rock and fluid from drilling operations in Virginia and Colorado. The samples came from sedimentary rocks at depths ranging from 860 to 2800 meters below the surface, where temperatures are between 42°C and 85°C. The questions posed in the study were simple: Is anything alive down there? If so, what do the organisms use to fuel cellular respiration?

The research team hypothesized that if organisms were living deep below the surface of the Earth, the cells might use hydrogen molecules (H_2) as an electron donor and the ferric ion (Fe^{3+}) as an electron acceptor (**FIGURE 29.5**). Recall that most eukaryotes use sugars as electron donors and use oxygen as an electron acceptor during cellular respiration (see Chapter 9). Fe^{3+} is the oxidized form of iron, and it is abundant in the rocks the biologists collected from great depths. It exists at great depths below the surface in the form of ferric oxyhydroxide, $Fe(OH)_3$. The researchers predicted that if an organism in the samples reduced the ferric ions during cellular respiration, then a black, oxidized, and magnetic mineral called magnetite (Fe_3O_4) would start appearing in the cultures as a by-product of cellular respiration.

What did their enrichment cultures produce? In some cultures, a black compound began to appear within a week. A variety of tests confirmed that the black substance was indeed magnetite. As the "Results" section of Figure 29.5 shows, microscopy revealed the organisms themselves—previously undiscovered bacteria. Because they grow only when incubated at 45°C–75°C, these organisms are considered **thermophiles** ("heat-lovers"). The discovery was spectacular—it was one of the first studies demonstrating that Earth's crust is teeming with organisms to depths of over a mile below the surface. Enrichment culture continues to be a productive way to isolate and characterize new species of bacteria and archaea.

Using Metagenomics

Researchers estimate that of all the bacteria and archaea living today, less than 1 percent have been grown in culture. To augment research based on enrichment cultures, researchers are



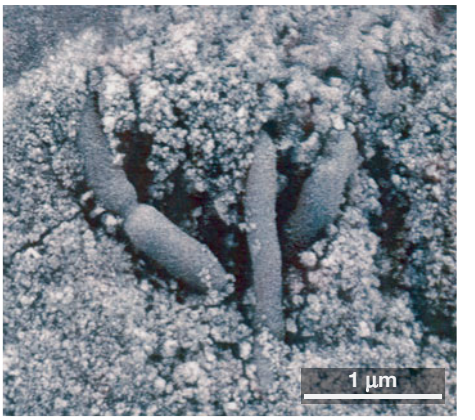
RESEARCH

QUESTION: Can bacteria live a mile below Earth's surface?

HYPOTHESIS: Bacteria are capable of cellular respiration deep below Earth's surface by using H_2 as an electron donor and Fe^{3+} as an electron acceptor.

NULL HYPOTHESIS: Bacteria from this environment are not capable of using H_2 as an electron donor and Fe^{3+} as an electron acceptor.

EXPERIMENTAL SETUP:



1. Prepare enrichment culture abundant in H_2 and Fe^{3+}; raise temperatures above 45°C.

2. Add rock and fluid samples extracted from drilling operations at depths of about 1000 m below Earth's surface.

PREDICTION: Black, magnetic grains of magnetite (Fe_3O_4) will accumulate because Fe^{3+} is reduced by growing cells and shed as a waste product. Cells will be visible.

PREDICTION OF NULL HYPOTHESIS: No magnetite will appear. No cells will grow.

RESULTS: Cells are visible, and magnetite is detectable.

CONCLUSION: At least one bacterial species that can live deep below Earth's surface grew in this enrichment culture. Different culture conditions might result in the enrichment of different species present in the same sample.

FIGURE 29.5 Enrichment Cultures Isolate Large Populations of Cells That Grow under Specific Conditions.

✔**QUESTION** Suppose no organisms had grown in this culture. Explain why the lack of growth would be either strong or weak evidence on the question of whether organisms live a mile below the Earth's surface.

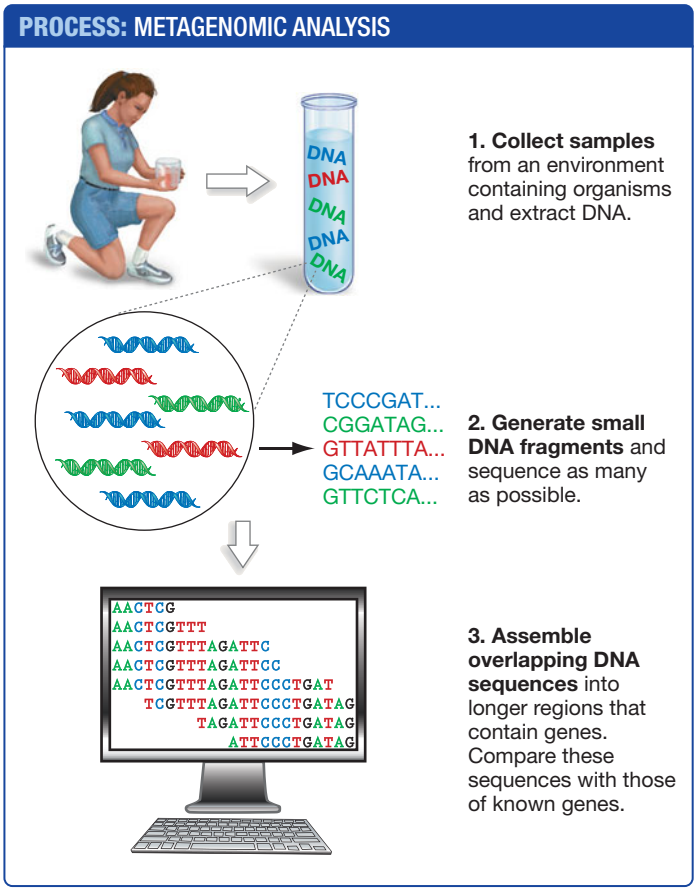

FIGURE 29.6 Metagenomics Allows Researchers to Identify Species That Have Never Been Seen. Metagenomic analysis is used to generate DNA sequences from an environmental sample. That information can then be used to identify novel species and investigate biological processes.

employing a technique called **metagenomics** or **environmental sequencing** (see Chapter 21). Metagenomics is employed in part to document the presence of bacteria and archaea in an environmental sample that cannot be grown in culture. It is based on extracting and sequencing much of the DNA from a sample and then identifying species and biochemical pathways by comparing the DNA sequences with those of known genes. **FIGURE 29.6** outlines the steps performed in a metagenomics study.

Metagenomic analysis allows biologists to rapidly identify and characterize organisms that have never been seen. The technique has revealed huge new branches on the tree of life and produced revolutionary data on the habitats where bacteria and archaea are found.

In one recent study biologists extracted DNA from 125 human fecal samples and generated over 500 billion base pairs of sequence, over 150 times more than the entire human genome. The results they obtained are fascinating:

- In total, the samples contained about 1000 different species of bacteria. Some species were found in most of the samples while others were found in only a few of the humans sampled;
- the vast majority of bacterial species identified were from three phyla: Bacteroidetes, Firmicutes, and Actinobacteria;
- the identified bacterial genes that were shared by all of the human subjects suggest that bacteria play important roles in human physiology, including digestion of complex carbohydrates and synthesis of essential amino acids and vitamins.

Results like these make it clear that humans harbor a diverse ecosystem of symbiotic bacteria. Some bacteria may make us sick, but we depend on many others to stay healthy.

In combination with **direct sequencing**—a technique based on isolating and sequencing a specific gene from organisms found in a particular habitat—metagenomics is revolutionizing biologists' understanding of bacterial and archaeal diversity.

Evaluating Molecular Phylogenies

To put data from enrichment culture and metagenomic studies into context, biologists depend on the accurate placement of species on phylogenetic trees. Recall that phylogenetic trees illustrate the evolutionary relationships among species and lineages (see Chapter 1, Chapter 28, and **BioSkills 7** in Appendix B). They are a pictorial summary of which species are more closely or distantly related to others.

Some of the most useful phylogenetic trees for the Bacteria and the Archaea have been based on studies of the RNA molecules found in the small subunit of ribosomes, or what biologists call 16S and 18S RNA. (See Chapter 17 for more information on the structure and function of ribosomes.) In the late 1960s Carl Woese and colleagues began a massive effort to determine and compare the base sequences of 16S and 18S RNA molecules from a wide array of species. The result of their analysis was the **tree of life,** illustrated in Figure 29.1.

check your understanding

If you understand that . . .

- Enrichment cultures isolate cells that grow in response to specific conditions. They create an abundant sample of bacteria that thrive under particular conditions, allowing further study.
- Metagenomics is based on isolating DNA from samples taken directly from the environment, generating random DNA fragments for sequencing, and then analyzing the DNA sequences to identify the organisms and genes present.

✔ You should be able to . . .

1. Design an enrichment culture that would isolate species that could be used to clean up oil spills.
2. Outline a study designed to identify the bacterial and archaeal species present in a soil sample near the biology building on your campus.

Answers are available in Appendix A.

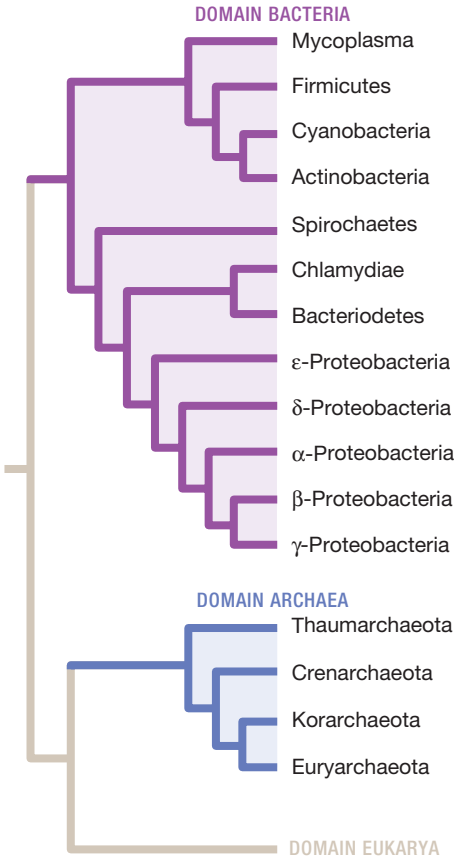

FIGURE 29.7 Phylogeny of Some Major Lineages in Bacteria and Archaea.

Woese's tree is now considered a classic result. Before its publication, biologists thought that the major division among organisms was between prokaryotes and eukaryotes. But based on data from ribosomal RNA molecules, the major divisions of life-forms are actually the Bacteria, Archaea, and Eukarya. Tracing the early evolutionary history of these domains is extremely difficult since the events distinguishing the lineages took place so long ago. In addition, lateral gene transfer (described in Chapter 21) has blurred the boundaries of the domains. However, recent studies suggest that Eukarya may have formed from a symbiosis between an archaeal cell and a bacterial cell. Traits of both lineages are found within Eukarya (see Chapter 30).

More recent analyses of morphological and molecular characteristics have succeeded in identifying a large series of monophyletic groups within the domains. Recall that a **monophyletic group** consists of an ancestral population and all of its descendants (see Chapter 28). Monophyletic groups can also be called clades or lineages.

The phylogenetic tree in **FIGURE 29.7** summarizes recent results but is still considered highly provisional. Work on molecular phylogenies continues at a brisk pace. Section 29.4 explores some of these lineages in detail, but for now let's turn to the question of how all this diversification took place.

29.3 What Themes Occur in the Diversification of Bacteria and Archaea?

At first, the diversity of bacteria and archaea can seem almost overwhelming. To make sense of the variation among lineages and species, biologists focus on two themes in diversification: morphology and metabolism. Regarding metabolism, the key question is which molecules are used as food. Bacteria and archaea are capable of living in a wide array of environments because they vary in cell structure and in how they make a living.

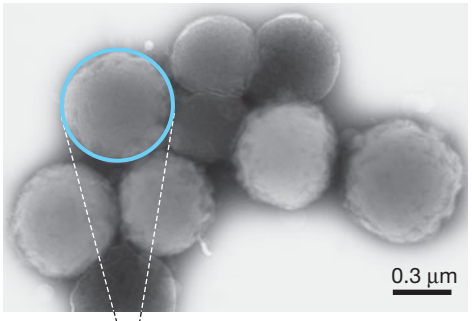
Morphological Diversity

Because we humans are so large, it is hard for us to appreciate the morphological diversity that exists among bacteria and archaea. To us, they all look small and similar. But at the scale of a bacterium or archaean, different species are wildly diverse in morphology.

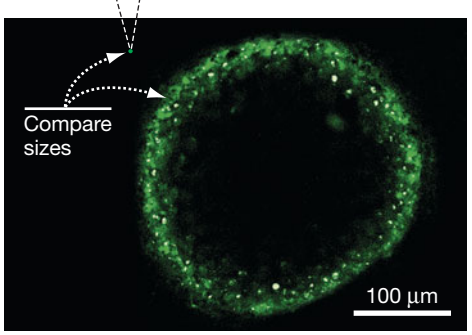
Size, Shape, and Motility To appreciate how diverse these organisms are in terms of morphology, consider bacteria alone:

- ***Size*** Bacterial cells range in size from the smallest of all free-living cells—bacteria called mycoplasmas with volumes as small as 0.15 μm^3—to the largest bacterium known, *Thiomargarita namibiensis*, which has volumes as large as 200×10^6 μm^3. Over a billion *Mycoplasma* cells could fit inside an individual *T. namibiensis* (**FIGURE 29.8a**).
- ***Shape*** Bacterial cells range in shape from filaments, spheres, rods, and chains to spirals (**FIGURE 29.8b**).
- ***Motility*** Many bacterial cells are motile; their swimming movements are powered by rotating flagella. Depending on the direction of rotation, cells either swim ahead or tumble, which allows them to change direction. Gliding movement, which enables cells to creep along a surface, also occurs in several groups, though the molecular mechanism responsible for this form of motility is still unknown (**FIGURE 29.8c**).

Cell-Wall Composition For single-celled organisms, the composition of the plasma membrane and cell wall are particularly important. The introduction to this chapter highlights the dramatic differences between the plasma membranes and cell walls of bacteria versus archaea.



Within bacteria having cell walls, biologists distinguish two general types of wall using a dyeing system called the **Gram stain.** As **FIGURE 29.9a** shows, Gram-positive cells look purple but Gram-negative cells look pink.

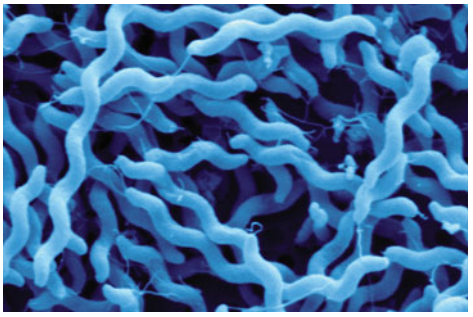


At the molecular level, most cells that are **Gram-positive** have a plasma membrane surrounded by a cell wall with extensive peptidoglycan (**FIGURE 29.9b**). You might recall that peptidoglycan is a complex substance composed of carbohydrate strands that are cross-linked by short chains of amino acids (see Chapter 5). Most cells that are **Gram-negative,** in contrast, have a plasma

(a) Size varies.

Most bacteria are about 1 μm in diameter, but some are much larger.

Smallest (*Mycoplasma mycoides*)

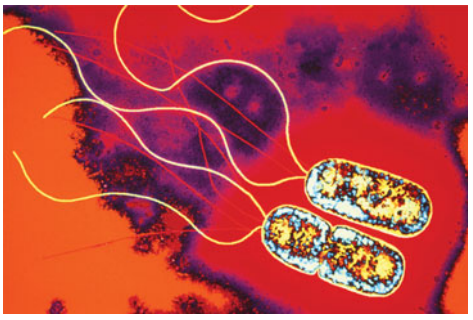


Largest (*Thiomargarita namibiensis*)

(b) Shape varies...

... from rods to spheres to spirals. In some species, cells adhere to form chains.

Rods, chains of spheres (compost bacteria)



Spirals (*Campylobacter jejuni*)

(c) Motility varies.

Some bacteria are nonmotile, but swimming and gliding are common.

Swimming (*Pseudomonas aeruginosa*)

Gliding (*Oscillatoria limosa*)

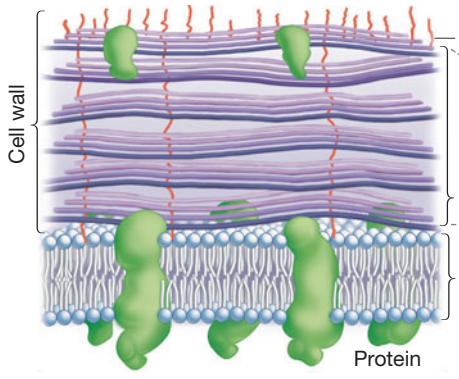
membrane surrounded by a cell wall that has two components—a thin gelatinous layer containing peptidoglycan and an outer phospholipid bilayer (**FIGURE 29.9c**).



Analyzing cell cultures with the Gram stain can be an important preliminary step in treating bacterial infections. Because they contain so much peptidoglycan, Gram-positive cells may respond to treatment by penicillin-like drugs that disrupt peptidoglycan synthesis. Gram-negative cells, in contrast, are more likely to be affected by erythromycin or other types of drugs that poison bacterial ribosomes.

To summarize, members of the Bacteria and the Archaea are remarkably diverse in their overall size, shape, and motility as well as in the composition of their cell walls and plasma membranes. But when asked to name the innovations that were most responsible for the diversification of these two domains, biologists do not point to their morphological diversity. Instead, they

(a) Gram-positive cells stain more than Gram-negative cells.

(b) Gram-positive cell wall

(c) Gram-negative cell wall

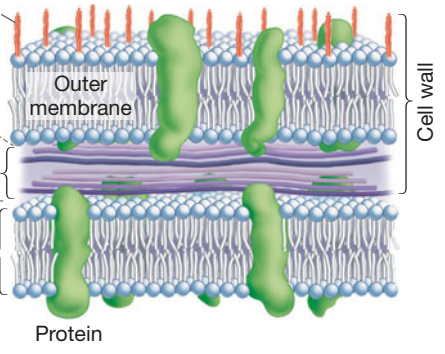


FIGURE 29.9 Gram Staining Distinguishes Two Types of Cell Walls in Bacteria. Cells with extensive peptidoglycan retain a large amount of stain and look purple; others retain little stain and look pink, as can be seen in part (a).

point to metabolic diversity—variation in the chemical reactions that go on inside these cells.

Metabolic Diversity

The most important thing to remember about bacteria and archaea is how diverse they are in the types of compounds they can use as food. Bacteria and archaea are the masters of metabolism. Taken together, they can subsist on almost anything—from hydrogen molecules to crude oil. Bacteria and archaea look small and relatively simple to us in their morphology, but their biochemical capabilities are dazzling.

Just how varied are bacteria and archaea when it comes to making a living? To appreciate the answer, recall that all organisms have two fundamental nutritional needs—acquiring chemical energy in the form of adenosine triphosphate (ATP) and obtaining molecules with carbon–carbon bonds that can be used as building blocks for the synthesis of fatty acids, proteins, DNA, RNA, and other large, complex compounds required by the cell.

Bacteria and archaea produce ATP in three ways:

1. **Phototrophs** ("light-feeders") use light energy to excite electrons. ATP is produced by photophosphorylation (see Chapter 10).
2. **Chemoorganotrophs** oxidize organic molecules with high potential energy, such as sugars. ATP may be produced by cellular respiration—with sugars serving as electron donors—or via fermentation pathways (see Chapter 9).
3. **Chemolithotrophs** ("rock-feeders") oxidize inorganic molecules with high potential energy, such as ammonia (NH_3) or methane (CH_4). ATP is produced by cellular respiration, and inorganic compounds serve as the electron donor.

Bacteria and archaea fulfill their second nutritional need—obtaining building-block compounds with carbon–carbon bonds—in two ways:

1. By synthesizing their own compounds from simple starting materials such as CO_2 and CH_4. Organisms that manufacture their own building-block compounds are termed **autotrophs** ("self-feeders").
2. By absorbing ready-to-use organic compounds from their environment. Organisms that acquire building-block compounds from other organisms are called **heterotrophs** ("other-feeders").

Because there are three distinct ways of producing ATP and two general mechanisms for obtaining carbon, there are a total of six methods for producing ATP and obtaining carbon. The names that biologists use for organisms that employ these six "feeding strategies" are given in **TABLE 29.3**.

Of the six possible ways of producing ATP and obtaining carbon, just two are observed among eukaryotes. But bacteria and archaea do them all. In addition, certain species can switch among modes of living, depending on environmental conditions. In their metabolism, eukaryotes are simple compared with bacteria and archaea. ✔ **If you understand the essence of metabolic diversity in bacteria and archaea, you should be able to match the six example species described in TABLE 29.4 to the appropriate category in Table 29.3.**

What makes this remarkable diversity possible? Bacteria and archaea have evolved dozens of variations on the basic processes of respiration and photosynthesis (see Chapters 9 and 10). They use compounds with high potential energy to produce ATP via cellular respiration (electron transport chains) or fermentation, they use light to produce high-energy electrons, and they reduce carbon from CO_2 or other sources to produce sugars or other building-block molecules with carbon–carbon bonds.

The story of bacteria and archaea can be boiled down to two sentences: The basic chemistry required for photosynthesis, cellular respiration, and fermentation originated in these lineages. Then the evolution of variations on each of these processes allowed prokaryotes to diversify into millions of species that occupy diverse habitats. Let's take a closer look.

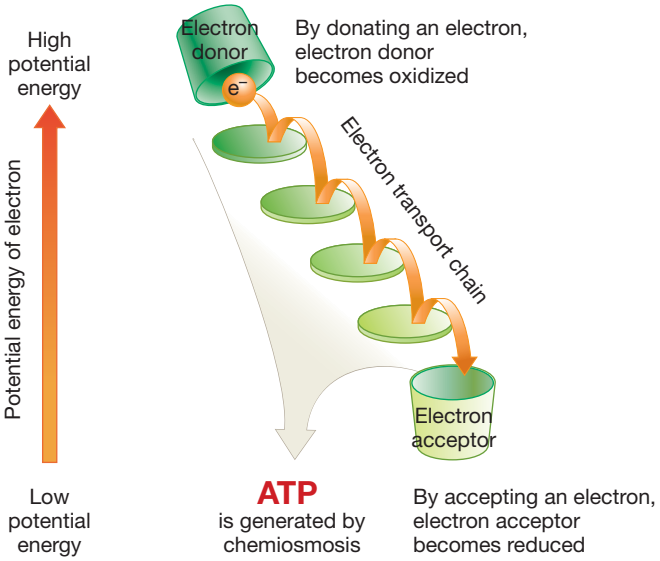
Producing ATP Through Cellular Respiration: Variation in Electron Donors and Acceptors

Millions of bacterial, archaeal, and eukaryotic species—including animals and some plants—are chemoorganotrophs. These organisms obtain the energy required to make ATP by breaking down organic compounds such as sugars, starch, or fatty acids.

SUMMARY TABLE 29.3 Six General Methods for Obtaining Energy and Carbon–Carbon Bonds

		Source of C–C Bonds (for synthesis of complex organic compounds)	
		Autotrophs: self-synthesized from CO_2, CH_4, or other simple molecules	**Heterotrophs:** from molecules produced by other organisms
Source of Energy (for synthesis of ATP)	**Phototrophs:** from sunlight	photoautotrophs	photoheterotrophs
	Chemoorganotrophs: from organic molecules	chemoorganoautotrophs	chemoorganoheterotrophs
	Chemolithotrophs: from inorganic molecules	chemolitho[auto]trophs	chemolithotrophic heterotrophs

TABLE 29.4 Six Examples of Metabolic Diversity



Example	How ATP Is Produced	How Building-Block Molecules Are Synthesized
Cyanobacteria	via oxygenic photosynthesis	from CO_2 via the Calvin cycle
Clostridium aceticum	via fermentation of glucose	from CO_2 via reactions called the acetyl-CoA pathway
Ammonia-oxidizing archaea (e.g., *Nitrosopumilus* sp.)	via cellular respiration, using ammonia (NH_3) as an electron donor	from CO_2 via the Calvin cycle
Helicobacteria	via anoxygenic photosynthesis	absorb carbon-containing building-block molecules from the environment
Escherichia coli	via fermentation of organic compounds or cellular respiration, using organic compounds as electron donors	absorb carbon-containing building-block molecules from the environment
Beggiatoa	via cellular respiration, using hydrogen sulfide (H_2S) as an electron donor	absorb carbon-containing building-block molecules from the environment

Cellular enzymes can strip electrons from organic molecules that have high potential energy and then transfer these high-energy electrons to the electron carriers NADH and $FADH_2$ (see Chapter 9). These compounds feed electrons to an electron transport chain (ETC), where electrons are stepped down from a high-energy state to a low-energy state (**FIGURE 29.10a**). In eukaryotic cells the ETC is located in the highly folded inner mitochondrial membrane. In bacteria and archaea, this membrane is the plasma membrane.

The energy that is released allows components of the ETC to generate a proton gradient across the plasma membrane (**FIGURE 29.10b**). The resulting flow of protons back through the enzyme ATP synthase results in the production of ATP, via the process called chemiosmosis.

The essence of this process, called **cellular respiration,** is that a molecule with high potential energy serves as an original electron donor and is oxidized, while a molecule with low potential energy serves as a final electron acceptor and becomes reduced. The potential energy difference between the electron donor and electron acceptor is eventually transformed into chemical energy in the form of ATP or is used for other processes (see Chapter 9).

(a) Model of Electron Transport Chain (ETC)

(b) ETC generates proton gradient across plasma membrane.

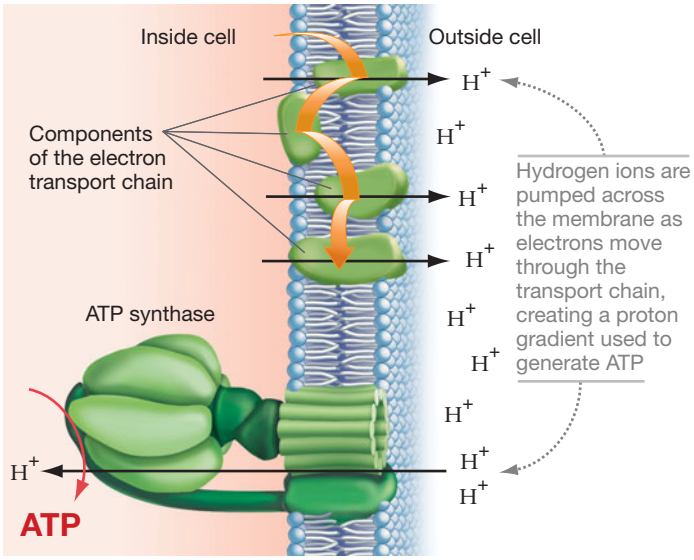


FIGURE 29.10 Cellular Respiration Is Based on Electron Transport Chains. Protons may diffuse away from the cell but a gradient will still form.

✔**EXERCISE** In part (a), add the chemical formula for a specific electron donor, electron acceptor, and reduced by-product for a species of bacteria or archaea. Then write in the electron donor, electron acceptor, and reduced by-product observed in humans.

Most eukaryotes carry out aerobic respiration:

- Organic compounds with high potential energy—often glucose—serve as the original electron donor. When cellular respiration is complete, glucose is completely oxidized to CO_2, which is given off as a by-product.
- Oxygen is the final electron acceptor, and water is also produced as a by-product.

Many bacteria and archaea also rely on these molecules.

It is common, however, to find bacteria and archaea that employ an electron donor other than sugars and an electron acceptor other than oxygen during cellular respiration. These species produce by-products other than carbon dioxide and water (**TABLE 29.5**):

- Molecules with high potential energy serve as electron donors. The substances used as electron donors range from hydrogen molecules (H_2) and hydrogen sulfide (H_2S) to ammonia (NH_3) and methane (CH_4).
- Compounds with relatively low potential energy—including sulfate (SO_4^{2-}), nitrate (NO_3^-), carbon dioxide (CO_2), or ferric ions (Fe^{3+})—act as electron acceptors.

It is only a slight exaggeration to claim that researchers have found bacterial and archaeal species that can use almost any compound with relatively high potential energy as an electron donor and almost any compound with relatively low potential energy as an electron acceptor.

Because the electron donors and electron acceptors used by bacteria and archaea are so diverse, one of the first questions biologists ask about a species is whether it undergoes cellular respiration—and if so, how. The best way to answer this question is through the enrichment culture technique introduced in Section 29.2. Recall that in an enrichment culture, researchers supply specific electron donors and electron acceptors in the medium and try to isolate cells that can use those compounds to support growth.

The remarkable metabolic diversity of bacteria and archaea explains why they play such a key role in cleaning up some types of pollution. Species that use organic solvents or petroleum-based fuels as electron donors or electron acceptors may excrete waste products that are less toxic than the original compounds.

Producing ATP via Fermentation: Variation in Substrates One strategy for making ATP that does not involve electron transport chains is called **fermentation** (see Chapter 9). In fermentation, no outside electron acceptor is used.

Because fermentation is a much less efficient way to make ATP compared with cellular respiration, in many species it occurs as an alternative metabolic strategy when no electron acceptors are available to make cellular respiration possible. In other species, fermentation does not occur at all. But in many bacteria and archaea, fermentation is the only way that cells make ATP.

Although some eukaryotic organisms can ferment glucose to ethanol or lactic acid (see Chapter 9), some bacteria and archaea are capable of using other organic compounds as the starting point for fermentation. Bacteria and archaea that produce ATP via fermentation are still classified as organotrophs, but they are much more diverse in the substrates used. For example:

- The bacterium *Clostridium aceticum* can ferment ethanol, acetate, and fatty acids as well as glucose.
- Other species of *Clostridium* ferment complex carbohydrates (including cellulose or starch), proteins, purines, or amino acids. Species that ferment amino acids produce by-products with names such as cadaverine and putrescine. These molecules are responsible for the odor of rotting flesh.
- Other bacteria can ferment lactose, a prominent component of milk. In some species this fermentation has two end products: propionic acid and CO_2. Propionic acid is responsible for the taste of Swiss cheese; the CO_2 produced during fermentation creates the holes in cheese.
- Many bacterial species in the human digestive tract ferment complex carbohydrates in our diet. The human cells then absorb the by-products and extract even more energy from them using O_2 as the final electron acceptor.

The diversity of enzymatic pathways observed in bacterial and archaeal fermentations extends the metabolic repertoire of these organisms. The diversity of substrates that are fermented also

TABLE 29.5 Some Electron Donors and Acceptors Used by Bacteria and Archaea

Electron Donor	By-Product from Electron Donor	Electron Acceptor	By-Product from Electron Acceptor	Category*
Sugars	CO_2	O_2	H_2O	Organotrophs
H_2 or organic compounds	H_2O or CO	SO_4^{2-}	H_2S or S^{2-}	Sulfate reducers
H_2	H_2O	CO_2	CH_4	Methanogens
CH_4	CO_2	O_2	H_2O	Methanotrophs
H_2S or S^{2-}	SO_4^{2-}	O_2	H_2O	Sulfur bacteria
Organic compounds	CO_2	Fe^{3+}	Fe^{2+}	Iron reducers
NH_3	NO_2^-	O_2	H_2O	Ammonia oxidizers
Organic compounds	CO_2	NO_3^-	N_2O, NO, or N_2	Nitrate reducers

*The name biologists use to identify species that use a particular metabolic strategy.

supports the claim that as a group, bacteria and archaea can use virtually any molecule with relatively high potential energy as a source of high-energy electrons for producing ATP.

Producing ATP via Photosynthesis: Variation in Electron Sources and Pigments Instead of using molecules as a source of high-energy electrons, phototrophs pursue a radically different strategy: **photosynthesis.** Among bacteria and archaea, photosynthesis can happen in three different ways:

1. Light activates a pigment called bacteriorhodopsin, which uses the absorbed energy to transport protons across the plasma membrane and out of the cell. The resulting flow of protons back into the cell drives the synthesis of ATP via chemiosmosis (see Chapter 9).
2. A recently discovered bacterium that lives near hydrothermal vents on the ocean floor performs photosynthesis not by absorbing light, but by absorbing geothermal radiation.
3. Pigments that absorb light raise electrons to high-energy states. As these electrons are stepped down to lower energy states by electron transport chains, the energy released is used to generate ATP.

An important feature of this last mode of photosynthesis is that the process requires a source of electrons (see Chapter 10). Recall that in cyanobacteria and plants, the required electrons come from water. When these organisms "split" water molecules apart to obtain electrons, they generate oxygen as a by-product. Species that use water as a source of electrons for photosynthesis are said to complete **oxygenic** ("oxygen-producing") photosynthesis.

In contrast, many phototrophic bacteria use a molecule other than water as the source of electrons. In some cases, the electron donor is hydrogen sulfide (H_2S); a few species can use the ion known as ferrous iron (Fe^{2+}). Instead of producing oxygen as a by-product of photosynthesis, these cells produce elemental sulfur (S) or the ferric ion (Fe^{3+}). This type of photosynthesis is said to be **anoxygenic** ("no oxygen-producing").

The photosynthetic pigments found in plants are chlorophylls *a* and *b* (see Chapter 10). Cyanobacteria have these two pigments. But researchers have isolated seven additional chlorophylls from different lineages of bacterial phototrophs. Each lineage has one or more of these distinctive chlorophylls, and each type of chlorophyll absorbs light best at a different wavelength.

✔ **If you understand that different photosynthetic bacteria contain different kinds of light-absorbing pigments, you should be able to explain how several different photosynthetic species can live in the same habitat without competing for light.**

Obtaining Building-Block Compounds: Variation in Pathways for Fixing Carbon In addition to acquiring energy, organisms must obtain building-block molecules that contain carbon–carbon bonds. Organisms use two mechanisms to procure usable carbon—either making their own or getting it from other organisms (see Chapters 9 and 10). Autotrophs make their own building-block compounds; heterotrophs consume them.

In many autotrophs, including cyanobacteria and plants, the enzymes of the Calvin cycle transform carbon dioxide (CO_2) into organic molecules that can be used in synthesizing cell material. The carbon atom in CO_2 is reduced during the process and is said to be "fixed." Animals and fungi, in contrast, obtain carbon from living plants or animals, or by absorbing the organic compounds released as dead tissues decay.

Bacteria and archaea pursue these same two strategies. Some interesting twists occur among bacterial and archaeal autotrophs, however. Not all of them use the Calvin cycle to make building-block molecules, and not all start with CO_2 as a source of carbon atoms. For example, consider these biochemical pathways:

- Some proteobacteria are called **methanotrophs** ("methane-eaters") because they use methane (CH_4) as their carbon source. (They also use CH_4 as an electron donor in cellular respiration.) Methanotrophs process CH_4 into more complex organic compounds via one of two enzymatic pathways, depending on the species.
- Some bacteria can use carbon monoxide (CO) or methanol (CH_3OH) as a starting material.

These observations drive home an important message from this chapter: Compared with eukaryotes, the metabolic capabilities of bacteria and archaea are remarkably complex and diverse.

Ecological Diversity and Global Impacts

The metabolic diversity observed among bacteria and archaea explains why these organisms can thrive in such a wide array of habitats.

- The array of electron donors, electron acceptors, and fermentation substrates exploited by bacteria and archaea allows the heterotrophic species to live just about anywhere.
- The evolution of three distinct types of photosynthesis—based on bacteriorhodopsin, geothermal energy, or pigments that donate high-energy electrons to ETCs—extends the types of habitats that can support phototrophs.

The complex chemistry that these cells carry out, combined with their numerical abundance, has made them potent forces for global change throughout Earth's history. Bacteria and archaea have altered the chemical composition of the oceans, atmosphere, and terrestrial environments for billions of years. They continue to do so today.

The Oxygen Revolution Today, oxygen represents almost 21 percent of the molecules in Earth's atmosphere. But researchers who study the composition of the atmosphere are virtually certain that no free molecular oxygen (O_2) existed for the first 2.3 billion years of Earth's existence. This conclusion is based on two observations:

1. There was no plausible source of oxygen at the time the planet formed.
2. Chemical analysis of the oldest Earth rocks suggests that they formed in the absence of atmospheric oxygen.

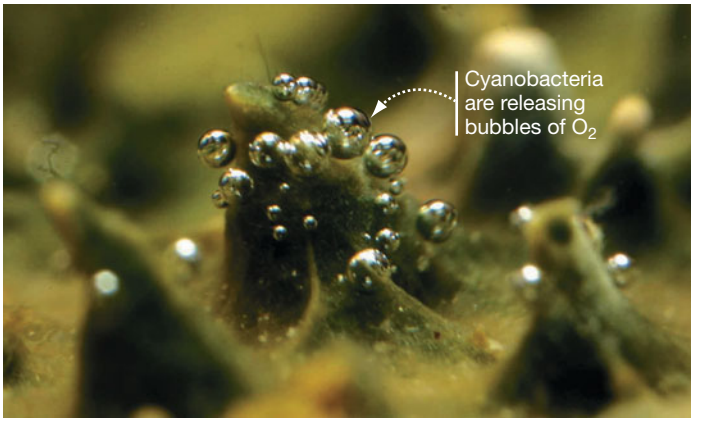

FIGURE 29.11 Cyanobacteria Were the First Organisms to Perform Oxygenic Photosynthesis.

Early in Earth's history, the atmosphere was dominated by nitrogen and carbon dioxide. Where did the oxygen we breathe come from? The answer is cyanobacteria.

Cyanobacteria is a lineage of photosynthetic bacteria. According to the fossil record, species of cyanobacteria first became numerous in the oceans about 2.7–2.5 billion years ago. Their appearance was momentous because cyanobacteria were the first organisms to perform oxygenic ("oxygen-producing") photosynthesis (**FIGURE 29.11**).

The fossil record and geologic record indicate that oxygen concentrations in the oceans and atmosphere began to increase 2.3–2.1 billion years ago. Once oxygen was common in the oceans, cells could begin to use it as the final electron acceptor during cellular respiration. **Aerobic** respiration was now a possibility. Before that, organisms had to use compounds other than oxygen as a final electron acceptor—only **anaerobic** respiration was possible. (Aerobic and anaerobic respiration are introduced in Chapter 9.)

The evolution of aerobic respiration was a crucial event in the history of life. Because oxygen is extremely electronegative, it is an efficient electron acceptor. Much more energy is released as electrons move through electron transport chains with oxygen as the ultimate acceptor than is released with other substances as the electron acceptor.

To drive this point home, study the graph in **FIGURE 29.12**. Notice that the vertical axis plots free energy changes; the graph shows the energy released when glucose is oxidized with iron, nitrate, or oxygen as the final electron acceptor. Once oxygen was available, then, cells could produce much more ATP for each electron donated by NADH or $FADH_2$. As a result, the rate of energy production rose dramatically.

To summarize, data indicate that cyanobacteria were responsible for a fundamental change in Earth's atmosphere—a high concentration of oxygen. Never before, or since, have organisms done so much to alter the nature of our planet.

Nitrogen Fixation and the Nitrogen Cycle In many environments, fertilizing forests or grasslands with nitrogen results in increased growth. Researchers infer from these results that plant growth is often limited by the availability of nitrogen.

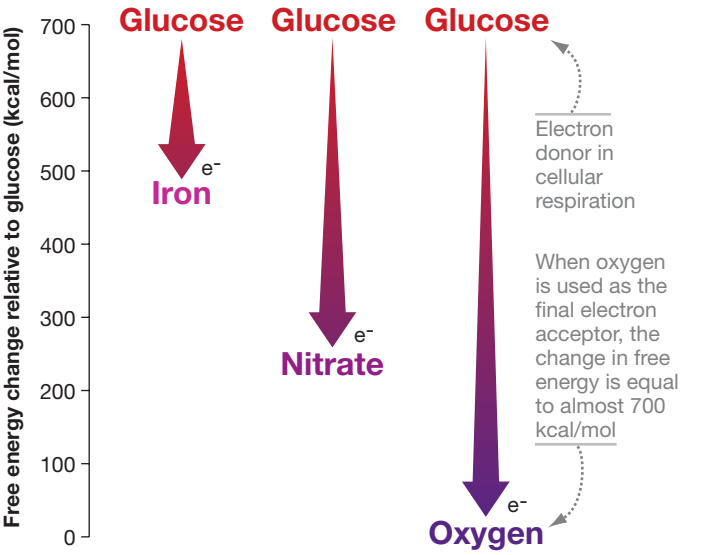

FIGURE 29.12 Cellular Respiration Can Produce More Energy When Oxygen Is the Final Electron Acceptor. More potential energy in glucose can be released when oxygen is the final acceptor compared to other molecules or ions.

DATA: Wilson, D. F., M. Erecińska, and P. L. Dutton. 1974. *Annual Review of Biophysics and Bioengineering 3*: 203–230; Tables 1 and 3.

✔**QUESTION** Which organisms grow faster—those using aerobic respiration or those using anaerobic respiration? Explain your reasoning.

Organisms must have nitrogen to synthesize proteins and nucleic acids. Although molecular nitrogen (N_2) is extremely abundant in the atmosphere, most organisms cannot use it because of the strong triple bond linking the nitrogen atoms. To incorporate nitrogen atoms into amino acids and nucleotides, all eukaryotes and many bacteria and archaea have to obtain N in a form such as ammonia (NH_3) or nitrate (NO_3^-).

Certain bacteria and archaea are the only species that are capable of converting molecular nitrogen to ammonia. The steps in the process, called **nitrogen fixation,** are highly endergonic reduction-oxidation (redox) reactions (see Chapter 9). The key enzyme that catalyzes the reaction—nitrogenase—is found only in selected bacterial and archaeal lineages. Many of these organisms are free living, but some form important relationships with plants:

- Some species of cyanobacteria live in association with a water fern that grows in rice paddies and helps fertilize the plants.
- In terrestrial environments, nitrogen-fixing bacteria live in close association with plants—often taking up residence in special root structures called nodules (see Chapter 39).

Why is nitrogenase not found in all organisms? The answer lies in an interesting property of the enzyme. When exposed to O_2, nitrogenase is irreversibly poisoned and is degraded. The only organisms with the nitrogenase gene are those that live in anaerobic habitats or are able to protect the enzyme from O_2.

Nitrogen fixation is only the beginning of the story, however. A quick glance back at Table 29.5 should convince you that bacteria and archaea use a wide array of nitrogen-containing

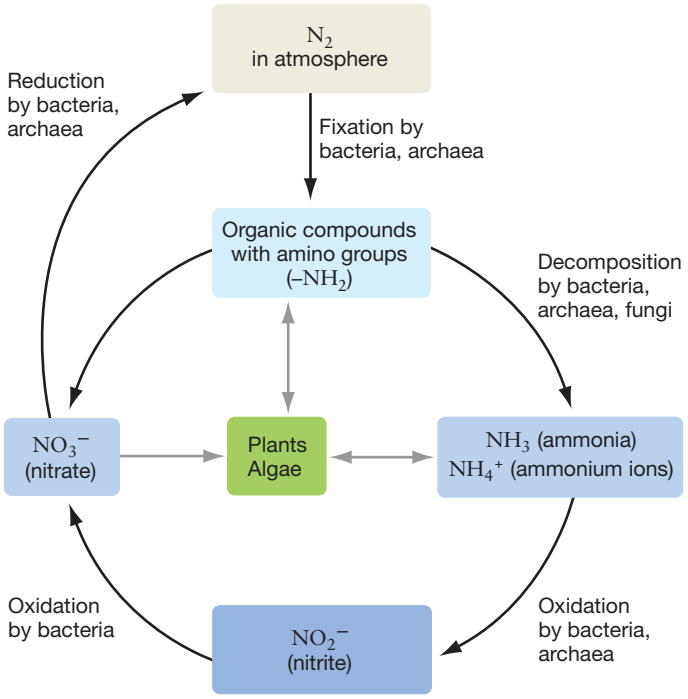

FIGURE 29.13 Bacteria and Archaea Drive the Movement of Nitrogen Atoms through Ecosystems. Nitrogen atoms cycle in different molecular forms.

✔**EXERCISE** Add arrows and labels to indicate that animals ingest amino groups from plants or other animals and release amino groups or ammonia.

compounds as electron donors and electron acceptors during cellular respiration.

To understand why this is important, consider that the nitrite (NO_2^-) produced by some bacteria as a by-product of respiration does not build up in the environment. Instead, other species of bacteria and archaea use it as an electron donor, and it is oxidized to molecular nitrate (NO_3^-). Nitrate, in turn, is reduced to molecular nitrogen (N_2) by yet another suite of bacterial and archaeal species. In this way, bacteria and archaea are responsible for driving the movement of nitrogen atoms through ecosystems around the globe in a process called the **nitrogen cycle** (**FIGURE 29.13**).

Similar types of interactions occur with molecules that contain phosphorus, sulfur, and carbon. In this way, bacteria and archaea play a key role in the cycling of nitrogen and other nutrients. ✔ **If you understand the role of bacteria and archaea in the nitrogen cycle, you should be able to provide a plausible explanation of what the composition of the atmosphere and what the nitrogen cycle might be like if bacteria and archaea did not exist.**

Nitrate Pollution Most crop plants—including corn, rice, and wheat—do not live in association with nitrogen-fixing bacteria. To increase yields of these crops, farmers use fertilizers that are high in nitrogen. In parts of the world, massive additions of nitrogen in the form of ammonia are causing serious pollution problems.

FIGURE 29.14 shows why. When ammonia is added to a cornfield—in midwestern North America, for example—much of

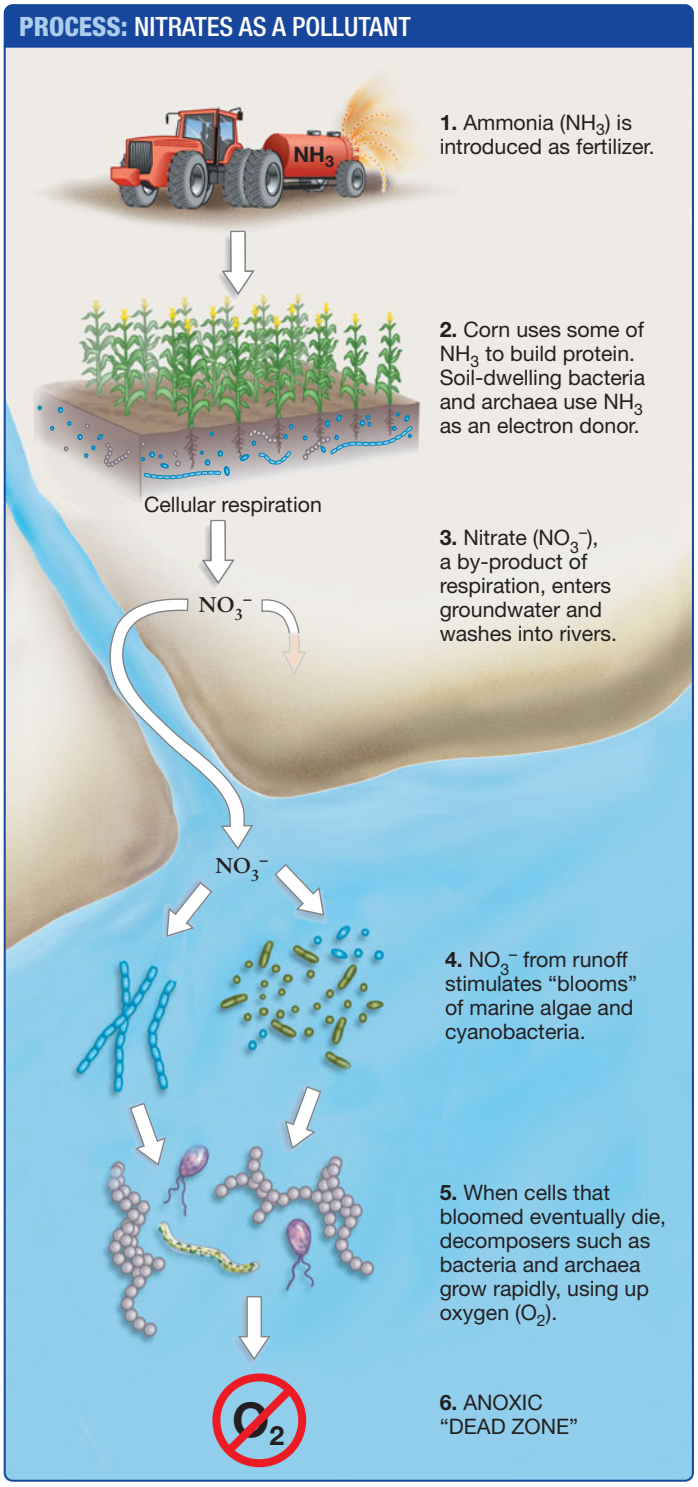

FIGURE 29.14 Nitrates Act as a Pollutant in Aquatic Ecosystems.

it never reaches the growing corn plants. Instead, bacteria and archaea in the soil use a significant fraction of the ammonia as food. Microbes that use ammonia as an electron donor to fuel cellular respiration release nitrite (NO_2^-) as a waste product. Other microbes use nitrite as an electron donor and release nitrate (NO_3^-). Nitrate molecules are extremely soluble in water and tend to be washed out of soils into groundwater or streams.

From there they eventually reach the ocean, where they can cause pollution.

To understand why nitrates can pollute the oceans, consider the Gulf of Mexico:

1. Nitrates carried by the Mississippi River are used as a nutrient by cyanobacteria and algae that live in the Gulf.
2. These cells explode in numbers in response.
3. When they die and sink to the bottom of the Gulf, bacteria and archaea and other decomposers use them as food.
4. The decomposers use so much oxygen as an electron acceptor in cellular respiration that oxygen levels in the sediments and even in Gulf waters decline.

Nitrate pollution has been so severe that large areas in the Gulf of Mexico are anoxic (lacking in oxygen). The oxygen-free "dead zone" in the Gulf of Mexico is devoid of fish, shrimp, and other organisms that require oxygen.

Lately, the dead zone has encompassed about 22,000 square kilometers (km^2)—roughly the size of New Jersey. Similar problem spots are cropping up in other parts of the world. Virtually every link in the chain of events leading to nitrate pollution involves bacteria and archaea.

The general message of this section is simple: Bacteria and Archaea may be small in size, but because of their abundance, ubiquity, and ability to do sophisticated chemistry, they have an enormous influence on the global environment.

check your understanding

CUY

If you understand that . . .

- As a group, Bacteria and Archaea can use a wide array of electron donors and acceptors in cellular respiration and a diverse set of compounds in fermentation, perform anoxygenic as well as oxygenic photosynthesis, and fix carbon from several different sources via a variety of pathways.

✓ You should be able to . . .

Defend the claim that the metabolism of bacteria and archaea is much more sophisticated than that of eukaryotes.

Answers are available in Appendix A.

29.4 Key Lineages of Bacteria and Archaea

In the decades since the phylogenetic tree identifying the three domains of life was first published, dozens of studies have confirmed the result. It is now well established that all organisms alive today belong to one of the three domains, and that archaea and eukaryotes are more closely related to each other than either group is to bacteria.

Although the relationships among the major lineages within Bacteria and Archaea are still uncertain in some cases, many of the lineages themselves are well studied. Let's survey the attributes of species from selected major lineages within the Bacteria and Archaea, with an emphasis on themes explored earlier in the chapter: their morphological and metabolic diversity, their impacts on humans, and their importance to other species and to the environment.

Bacteria

The name *bacteria* comes from the Greek root *bacter*, meaning "rod" or "staff." The name was inspired by the first bacteria to be seen under a microscope, which were rod shaped. But as the following descriptions indicate, bacterial cells come in a wide variety of shapes.

Biologists who study bacterial diversity currently recognize at least 21 lineages, or phyla, within the domain. Some of these lineages were recognized by distinctive morphological characteristics and others by phylogenetic analyses of gene sequence data. The lineages reviewed here are just a sampling of bacterial diversity.

- Bacteria > Firmicutes
- Bacteria > Cyanobacteria
- Bacteria > Actinobacteria
- Bacteria > Spirochaetes (Spirochetes)
- Bacteria > Chlamydiae
- Bacteria > Proteobacteria

Archaea

The name *archaea* comes from the Greek root *archae*, for "ancient." The name was inspired by the hypothesis that this is a particularly ancient group, which turned out to be incorrect. Also incorrect was the initial hypothesis that archaeans are restricted to hot springs, salt ponds, and other extreme habitats. Archaea live in virtually every habitat known.

Recent phylogenies based on DNA sequence data indicate that the domain is composed of at least four major phyla, called the Thaumarchaeota, Crenarchaeota, Euryarchaeota, and Korarchaeota. The Korarchaeota are known only from direct sequencing studies. They have never been grown in culture, and almost nothing is known about them.

- Archaea > Thaumarchaeota
- Archaea > Crenarchaeota
- Archaea > Euryarchaeota

Bacteria > Firmicutes

The Firmicutes have also been called "low-GC Gram positives" because their cell walls react positively to the Gram stain and because their DNA contains a relatively low percentage of guanine and cytosine (G and C). In some species, G and C represent less than 25 percent of the bases present. There are over 1100 species. ✔ **You should be able to mark the origin of the Gram-positive cell wall on Figure 29.7.**

Morphological diversity Most are rod shaped or spherical. Some of the spherical species form chains or tetrads (groups of four cells). A few form a durable resting stage called a spore. One subgroup synthesizes a cell wall made of cellulose.

Metabolic diversity Some species can fix nitrogen; some perform anoxygenic photosynthesis. Others make all of their ATP via various fermentation pathways; still others perform cellular respiration, using hydrogen gas (H_2) as an electron donor.

Human and ecological impacts Recent metagenomic studies have shown that members of this lineage are extremely common in the human gut. Species in this group also cause a variety of diseases, including anthrax, botulism, tetanus, walking pneumonia, boils, gangrene, and strep throat. *Bacillus thuringiensis* produces a toxin that is one of the most important insecticides currently used in farming. Species in the lactic acid bacteria group are used to ferment milk products into yogurt or cheese (**FIGURE 29.15**).

Lactobacillus bulgaricus (rods) and *Streptococcus thermophilus*

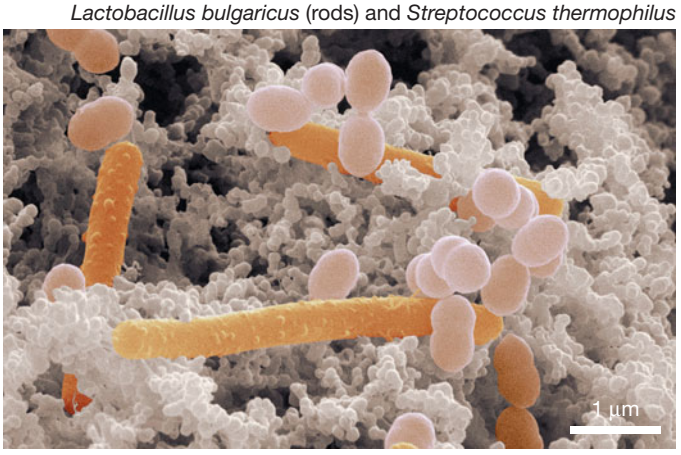

FIGURE 29.15 Firmicutes in Yogurt. (The cells in this scanning electron micrograph have been colorized.)

Bacteria > Cyanobacteria

The cyanobacteria were formerly known as the "blue-green algae"—even though algae are eukaryotes. Only about 80 species of cyanobacteria have been described to date, but they are among the most abundant organisms on Earth. In terms of total mass, cyanobacteria dominate the surface waters in many marine and freshwater environments.

Morphological diversity Cyanobacteria may be found as independent cells, in chains that form filaments (**FIGURE 29.16**), or in the loose aggregations of individual cells called colonies. The shape of *Nostoc* colonies varies from flat sheets to ball-like clusters of cells.

Metabolic diversity All perform oxygenic photosynthesis; many can also fix nitrogen. Because cyanobacteria can synthesize virtually every molecule they need, they can be grown in culture media that contain only CO_2, N_2, H_2O, and a few mineral nutrients. Some species associate with fungi, forming lichens, while others form associations with protists, sponges, or plants. In each case the cyanobacterium provides some form of nutritional benefit to the host. ✔ **You should be able to mark the origin of oxygenic photosynthesis on Figure 29.7.**

Human and ecological impacts If cyanobacteria are present in high numbers, their waste products can make drinking water smell bad. Some species release molecules called microcystins that are toxic to plants and animals. Cyanobacteria were responsible for the origin of the oxygen atmosphere on Earth. Today they still produce much of the oxygen and nitrogen and many of the organic compounds that feed other organisms in freshwater and marine environments.

Nostoc species

FIGURE 29.16 Cyanobacteria Contain Chlorophyll and Are Green.

Bacteria > Actinobacteria

Actinobacteria are sometimes called the "high-GC Gram positives" because **(1)** their cell-wall material appears purple when treated with the Gram stain—meaning that they have a peptidoglycan-rich cell wall and lack an outer membrane—and **(2)** their DNA contains a relatively high percentage of guanine and cytosine. In some species, G and C represent over 75 percent of the bases present. Over 1100 species have been described to date (**FIGURE 29.17**). ✔ **You should be able to mark the origin of this high-GC genome on Figure 29.7.**

Morphological diversity Cell shape varies from rods to filaments. Many of the soil-dwelling species are found as chains of cells that form extensive branching filaments called **mycelia.** Because of their morphology they were initially misclassified as fungi, and the incorrect name Actinomyces persists.

Metabolic diversity Many are heterotrophs that use an array of organic compounds as electron donors and oxygen as an electron acceptor. There are several parasitic species that get most of their nutrition from host organisms.

Human and ecological impacts Two serious human diseases, tuberculosis and leprosy, are caused by parasitic *Mycobacterium* species. Over 500 distinct antibiotics have been isolated from species in the genus *Streptomyces*; 60 of these—including streptomycin, neomycin, tetracycline, and erythromycin—are now actively prescribed to treat diseases in humans or domestic livestock. One actinobacterium species is critical to the manufacture of Swiss cheese. Species in the genus *Streptomyces* and *Arthrobacter* are abundant in soil and are vital as decomposers of dead plant and animal material. Some species live in association with plant roots and fix nitrogen; others can break down toxins such as herbicides, nicotine, and caffeine.

Streptomyces griseus

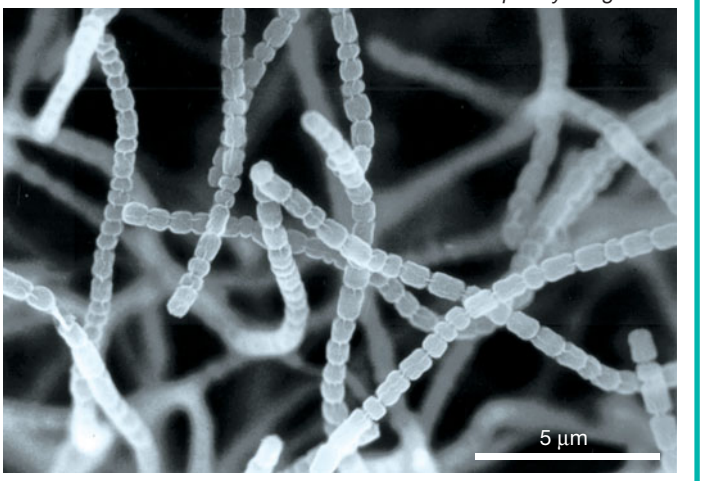

FIGURE 29.17 A *Streptomyces* Species That Produces the Antibiotic Streptomycin.

Bacteria > Spirochaetes (Spirochetes)

Based on numbers of species, the spirochetes are one of the smaller bacterial phyla: Only 13 genera and a total of 62 species have been described to date.

Morphological diversity Spirochetes are distinguished by their unique corkscrew shape and flagella (**FIGURE 29.18**). Instead of extending into the water surrounding the cell, spirochete flagella are contained within a structure called the outer sheath, which surrounds the cell. When these flagella beat, the cell lashes back and forth and swims forward. ✔ **You should be able to mark the origin of the spirochete flagellum on Figure 29.7.**

Metabolic diversity Most spirochetes manufacture ATP via fermentation. The substrate used in fermentation varies among species and may consist of sugars, amino acids, starch, or the pectin found in plant cell walls. A spirochete that lives only in the hindgut of termites can fix nitrogen.

Human and ecological impacts The sexually transmitted disease syphilis is caused by a spirochete. Syphilis is thought to have been brought by European explorers to the Western hemisphere, where it was responsible for killing tens of millions of native people. Lyme disease, also caused by a spirochete, is transmitted to humans by deer ticks. Spirochetes are extremely common in freshwater and marine habitats; many live only under anaerobic conditions.

Treponema pallidum

FIGURE 29.18 Spirochetes Are Corkscrew-Shaped Cells Inside an Outer Sheath.

Bacteria > Chlamydiae

In terms of numbers of species living today, Chlamydiae may be the smallest of all major bacterial lineages. Although the group is highly distinct phylogenetically, only 13 species are known. All are Gram-negative.

Morphological diversity Chlamydiae are spherical. They are tiny, even by bacterial standards.

Metabolic diversity All known species in this phylum live as parasites *inside* host cells and are termed **endosymbionts** ("inside-together-living"). Chlamydiae acquire almost all of their nutrition from their hosts. In **FIGURE 29.19**, the chlamydiae have been colored red; the animal cells that they live in are colored brown. ✔ **You should be able to mark the origin of the endosymbiotic lifestyle in this lineage on Figure 29.7.** (The endosymbiotic lifestyle has also arisen in other bacterial lineages, independently of Chlamydiae.)

Human and ecological impacts *Chlamydia trachomatis* infections are the most common cause of blindness in humans. When the same organism is transmitted from person to person via sexual intercourse, it can cause serious urogenital tract infections. If untreated in women, this disease can lead to ectopic pregnancy, premature births, and infertility. One species causes epidemics of a pneumonia-like disease in birds.

Chlamydia trachomatis

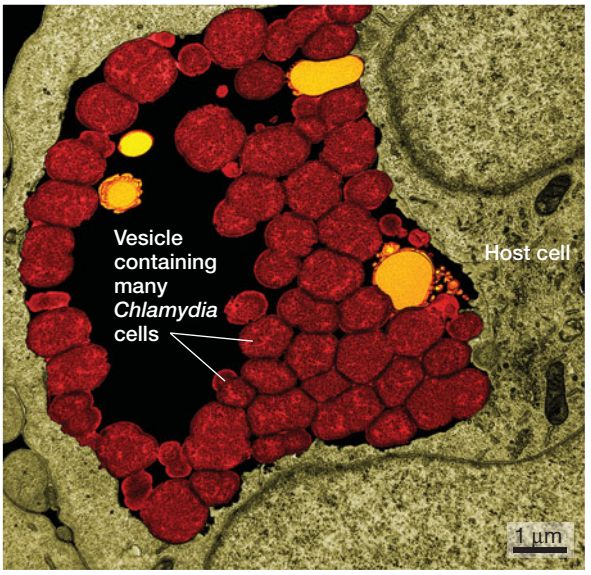

FIGURE 29.19 Chlamydiae Live Only Inside Animal Cells.

Bacteria > Proteobacteria

The approximately 1200 species of proteobacteria form five major subgroups, designated by the Greek letters α (alpha), β (beta), γ (gamma), δ (delta), and ε (epsilon). Because they are so diverse in their morphology and metabolism, the lineage is named after the Greek god Proteus, who could assume many shapes.

Morphological diversity Proteobacterial cells can be rods, spheres, or spirals. Some form stalks (**FIGURE 29.20a**). Some are motile. In one group, cells may move together to form colonies, which then transform into the specialized cell aggregate shown in **FIGURE 29.20b**. This structure is known as a **fruiting body.** At their tips, the fruiting bodies produce cells that are surrounded by a durable coating. These spores sit until conditions improve, and then they resume growth.

Metabolic diversity Proteobacteria make a living in virtually every way known to bacteria—except that none perform oxygenic photosynthesis. Various species may perform cellular respiration by using organic compounds, nitrite, methane, hydrogen gas, sulfur, or ammonia as electron donors and oxygen, sulfate, or sulfur as electron acceptors. Some perform anoxygenic photosynthesis.

Human and ecological impacts *Escherichia coli* may be the best studied of all organisms and is a key species in biotechnology (see Chapter 20, and **BioSkills 13** in Appendix B). Pathogenic proteobacteria cause Legionnaire's disease, cholera, food poisoning, plague, dysentery, gonorrhea, Rocky Mountain spotted fever, typhus, ulcers, and diarrhea. *Wolbachia* infections are common in insects and are often transmitted from mothers to offspring via eggs. Biologists use *Agrobacterium* cells to transfer new genes into crop plants. Certain acid-loving species of proteobacteria are used in the production of vinegars. Species in the genus *Rhizobium* (α-proteobacteria) live in association with plant roots and fix nitrogen. A group in the δ-proteobacteria, the bdellovibrios, are predators—they drill into other proteobacterial cells and digest them. Because some species use nitrogen-containing compounds as electron acceptors, proteobacteria are critical players in the cycling of nitrogen atoms through terrestrial and aquatic ecosystems.

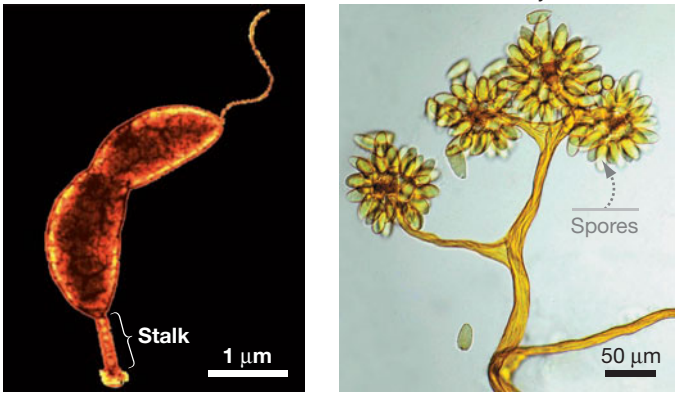

FIGURE 29.20 Some Proteobacteria Grow on Stalks or Form Fruiting Bodies. The stalked bacterium (a) has been colorized.

Archaea > Thaumarchaeota

The Thaumarchaeota were recently recognized as a monophyletic, ancient lineage of archaea. Members of this phylum are extremely abundant in oceans, estuaries, and terrestrial soils. Unlike the extremophiles, species in this lineage are considered mesophilic because they grow best at moderate temperatures.

Morphological diversity Only a few members of this group have been observed, and all consist of rod-shaped cells that are less than 1 micrometer (μm) in length, smaller than typical prokaryotes. One species, *Nitrosopumilus maritimus* (**FIGURE 29.21**), is so abundant it is estimated to constitute possibly 25 percent of the total prokaryotic cell biomass in open oceans.

Metabolic diversity Members of this phylum are called ammonia oxidizers because they use ammonia as a source of electrons and generate nitrite as a by-product. They use the energy from ammonia oxidation to fix CO_2.

Human and ecological impacts Because of their abundance, these organisms are thought to play a major role in Earth's nitrogen and carbon cycles (see Chapter 56). Their presence in deep ocean waters that lack reduced carbon and sunlight may help explain the productivity of these habitats. The species *Cenarchaeum symbiosum* lives as an endosymbiont inside a marine sponge.

Nitrosopumilus maritimus

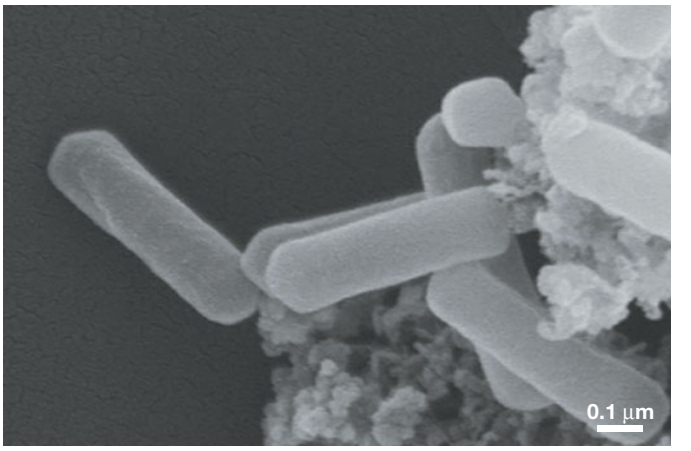

FIGURE 29.21 This Species of Thaumarchaeota Has Rod-Shaped Cells and Is Extremely Abundant in the Open Ocean.

✔**QUANTITATIVE** Use the scale bar in the figure to measure the length of a *N. maritimus* cell. If these cells were placed end to end, how many of them would fit along a meter stick?

Archaea > Crenarchaeota

The Crenarchaeota got their name because they are considered similar to the oldest archaeans; the word root *cren–* refers to a source or fount. Biologists have named only 37 species so far, but they are virtually certain that thousands are yet to be discovered.

Morphological diversity Crenarchaeota cells can be shaped like filaments, rods, discs, or spheres. One species that lives in extremely hot habitats has a tough cell wall consisting solely of glycoprotein.

Metabolic diversity Depending on the species, cellular respiration can involve organic compounds, sulfur, hydrogen gas, or Fe^{2+} ions as electron donors and oxygen, nitrate, sulfate, sulfur, carbon dioxide, or Fe^{3+} ions as electron acceptors. Some species make ATP exclusively through fermentation pathways.

Human and ecological impacts Crenarchaeota have yet to be used in the manufacture of commercial products. In certain extremely hot, high-pressure, cold, or acidic environments, crenarchaeota may be the only life-form present (**FIGURE 29.22**). Acid-loving species thrive in habitats with pH 1–5; some species are found in ocean sediments at depths ranging from 2500 to 4000 m below the surface.

Sulfolobus species

FIGURE 29.22 Some Crenarchaeota Live in Sulfur-Rich Hot Springs. The cells in the micrograph have been colorized to make them more visible.

Archaea > Euryarchaeota

The Euryarchaeota are aptly named, because the word root *eury–* means "broad." Members of this phylum live in every conceivable habitat. Some species are adapted to high-salt habitats with pH 11.5—almost as basic as household ammonia. Other species are adapted to acidic conditions with a pH as low as 0. Species in the genus *Methanopyrus* live near hot springs called black smokers that are 2000 m (over 1 mile) below sea level (**FIGURE 29.23**).

Morphological diversity Euryarchaeota cells can be spherical, filamentous, rod shaped, disc shaped, or spiral. Rod-shaped cells may be short or long or arranged in chains. Spherical cells can be found in ball-like aggregations. Some species have several flagella. Some species lack a cell wall; others have a cell wall composed entirely of glycoproteins.

Metabolic diversity The group includes a variety of methane-producing species. These **methanogens** can use up to 11 different organic compounds as electron acceptors during cellular respiration; all produce CH_4 as a by-product of respiration. In other species of Euryarchaeota, cellular respiration is based on hydrogen gas or Fe^{2+} ions as electron donors and nitrate or sulfate as electron acceptors. Species that live in high-salt environments can use the molecule retinal—which is responsible for light reception in your eyes—to capture light energy and perform photosynthesis.

Human and ecological impacts Species in the genus *Ferroplasma* live in piles of waste rock near abandoned mines. As a by-product of metabolism, they produce acids that drain into streams and pollute them. Methanogens live in the soils of swamps and the guts of mammals (including yours). They are responsible for adding about 2 billion tons of methane to the atmosphere each year. A methanogen in this phylum was also recently implicated in gum disease.

CHAPTER 29 REVIEW

For media, go to MasteringBiology

If you understand . . .

29.1 Why Do Biologists Study Bacteria and Archaea?

- Bacteria and archaea are the most abundant organisms on Earth and are found in every habitat that has been sampled.
- Bacteria and archaea are very small, prokaryotic cells, and most are unicellular.
- Bacteria and archaea can be distinguished by their different kinds of membrane lipids and cell walls as well as by their different transcription machinery.
- Bacteria play many beneficial roles in animal digestion, bioremediation, and the production of antibiotics.
- Bacteria cause some of the most dangerous human diseases, including plague, syphilis, botulism, cholera, and tuberculosis.

✔ **You should be able to explain the difference between a bacterium, an archaeon, and a eukaryote.**

29.2 How Do Biologists Study Bacteria and Archaea?

- Enrichment cultures are used to grow large numbers of bacterial or archaeal cells that thrive under specified conditions.
- Using metagenomic analysis, biologists can study bacteria and archaea that cannot be cultured by extracting DNA directly from an environment and then sequencing and characterizing DNA fragments. Information obtained is used to identify biochemical processes and novel organisms that are then placed on the tree of life.

✔ **You should be able to explain how metagenomic analysis might be used to reveal whether bacteria carry out nitrogen fixation in the gut of an insect.**

29.3 What Themes Occur in the Diversification of Bacteria and Archaea?

- Metabolic diversity and complexity are the hallmarks of the bacteria and archaea, just as morphological diversity and complexity are the hallmarks of the eukaryotes.
- Among bacteria and archaea, a wide array of inorganic or organic compounds with high potential energy may serve as electron donors in cellular respiration, and a wide variety of inorganic or organic molecules with low potential energy may serve as electron acceptors. Dozens of distinct organic compounds are fermented.
- Photosynthesis is widespread in bacteria. In cyanobacteria, water is used as a source of electrons and oxygen gas is generated as a by-product. But in other species, the electron excited by photon capture comes from a source other than water, and no oxygen is produced.
- To acquire building-block molecules containing carbon–carbon bonds, some bacteria and archaea species use the enzymes of the Calvin cycle to reduce CO_2. But several other biochemical pathways found in bacteria and archaea can also reduce simple organic compounds to sugars or carbohydrates.
- Because of their metabolic diversity, bacteria and archaea play a large role in carbon and nitrogen cycling and alter the global atmosphere, oceans, and terrestrial environments.
- Nitrogen-fixing species provide nitrogen in forms that can be used by many other species, including plants and animals.

✔ **You should be able to explain why species that release H_2S as a by-product and that use H_2S as an electron donor often live side by side.**

29.4 Key Lineages of Bacteria and Archaea

- Prokaryotes can be divided into two lineages, the Bacteria and the Archaea, based on a wide variety of morphological, biochemical, and molecular characters.
- Bacteria are divided into 21 major lineages including organisms that play major roles in ecosystems as primary producers, decomposers, and parasites.
- Archaea are divided into four major lineages and were thought to exist only in extreme environments; they are now recognized to be widespread.

✔ TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. How do the molecules that function as electron donors and those that function as electron acceptors differ?
   a. Electron donors are almost always organic molecules; electron acceptors are always inorganic.
   b. Electron donors are almost always inorganic molecules; electron acceptors are always organic.
   c. Electron donors have relatively high potential energy; electron acceptors have relatively low potential energy.
   d. Electron donors have relatively low potential energy; electron acceptors have relatively high potential energy.
2. What do some photosynthetic bacteria use as a source of electrons instead of water?
   a. oxygen (O_2)
   b. hydrogen sulfide (H_2S)
   c. organic compounds (e.g., CH_3COO^-)
   d. nitrate (NO_3^-)
3. What is distinctive about the chlorophylls found in different photosynthetic bacteria?
   a. their membranes
   b. their role in acquiring energy
   c. their role in carbon fixation
   d. their absorption spectra
4. What are organisms called that use inorganic compounds as electron donors in cellular respiration?
   a. phototrophs
   b. heterotrophs
   c. organotrophs
   d. lithotrophs
5. True or False. Certain aerobic bacteria in the presence of oxygen can convert nitrogen gas to ammonia.
6. Unlike plant cell walls that contain cellulose, bacterial cell walls are composed of _____.

TEST YOUR UNDERSTANDING

Answers are available in Appendix A

7. What has metagenomic analysis allowed researchers to do for the first time?
- **a.** sample organisms from an environment and grow them under defined conditions in the lab
- **b.** isolate organisms from an environment and sequence their entire genome
- **c.** study organisms that cannot be cultured (grown in the lab)
- **d.** identify important morphological differences among species

8. Biologists often use the term energy source as a synonym for "electron donor." Why?

9. The text claims that the tremendous ecological diversity of bacteria and archaea is possible because of their impressive metabolic diversity. Do you agree with this statement? Why or why not?

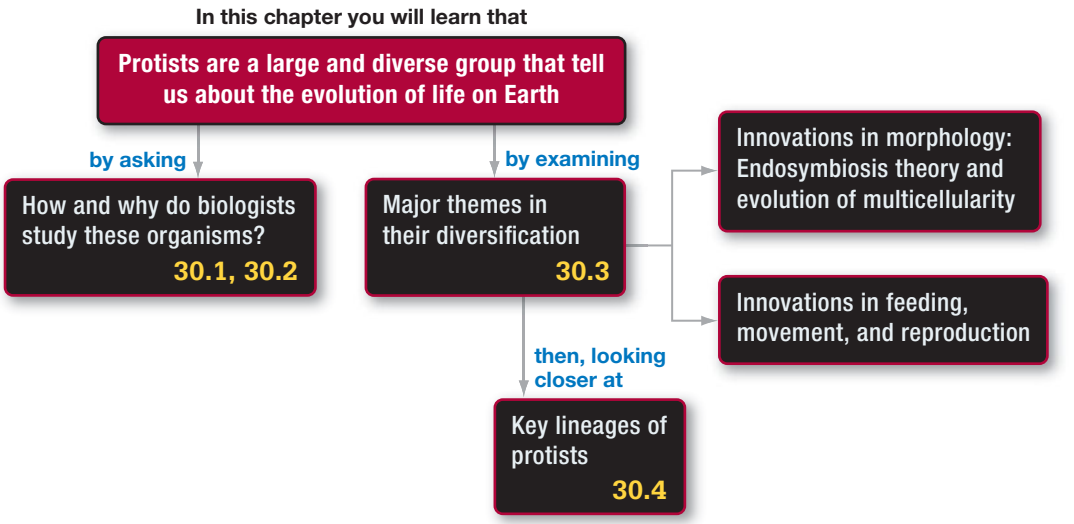
10. Would you predict that disease-causing bacteria, such as those listed in Table 29.2, obtain energy from light, organic molecules, or inorganic molecules? Explain your answer.

11. The text claims that the evolution of an oxygen atmosphere paved the way for increasingly efficient cellular respiration and higher growth rates in organisms. Explain.

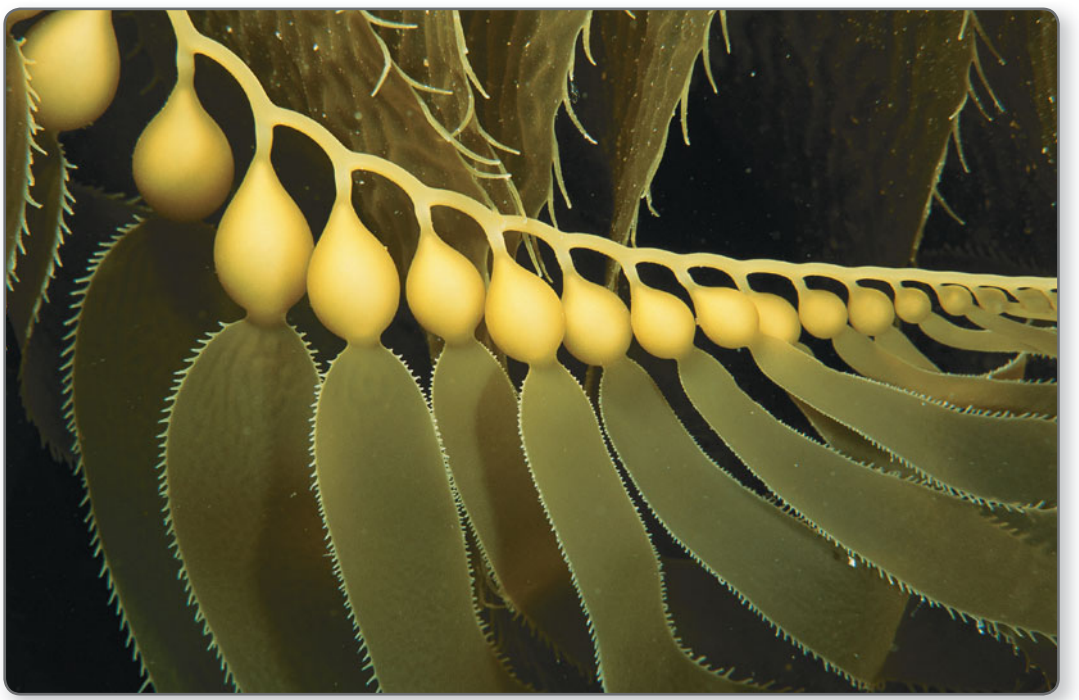
12. From what we know about the evolutionary relationship between the three largest domains, as depicted in Figure 29.1, explain the statement, "Prokaryotes are a paraphyletic group."

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A



13. When using Koch's postulates, which of the following is an essential requirement for the suspected pathogen?
- **a.** It is present in all organisms with the disease.
- **b.** It can be cultured on an agar plate.
- **c.** It is pathogenic on a wide variety of organisms.
- **d.** It can reproduce sexually within the host.



14. The researchers who observed that magnetite was produced by bacterial cultures from the deep subsurface carried out a follow-up experiment. These biologists treated some of the cultures with a drug that poisons the enzymes involved in electron transport chains. In cultures where the drug was present, no more magnetite was produced. Does this result support or undermine their hypothesis that the bacteria in the cultures perform cellular respiration? Explain your reasoning.

15. *Streptococcus mutans* obtains energy by oxidizing sucrose. This bacterium is abundant in the mouths of Western European and North American children and is a prominent cause of cavities. The organism is virtually absent in children from East Africa, where tooth decay is rare. Propose a hypothesis to explain this observation. Outline the design of a study that would test your hypothesis.

16. Suppose that you've been hired by a firm interested in using bacteria to clean up organic solvents found in toxic waste dumps. Your new employer is particularly interested in finding cells that are capable of breaking a molecule called benzene into less toxic compounds. Where would you go to look for bacteria that can metabolize benzene as an energy or carbon source? How would you design an enrichment culture capable of isolating benzene-metabolizing species?

30 Protists

The brown alga (giant kelp) shown here lives attached to rocks in ocean waters. This algae and other species featured in this chapter are particularly abundant in the world's oceans.

This chapter introduces the third domain on the tree of life: the **Eukarya.** Eukaryotes range from single-celled organisms that are the size of bacteria to sequoia trees and blue whales. The largest and most morphologically complex organisms on the tree of life—algae, plants, fungi, and animals—are eukaryotes.

Although eukaryotes are astonishingly diverse, they share fundamental features that distinguish them from bacteria and archaea:

- Compared to bacteria and archaea, most eukaryotic cells are large, have many more organelles, and have a much more extensive system of structural proteins called the cytoskeleton.

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

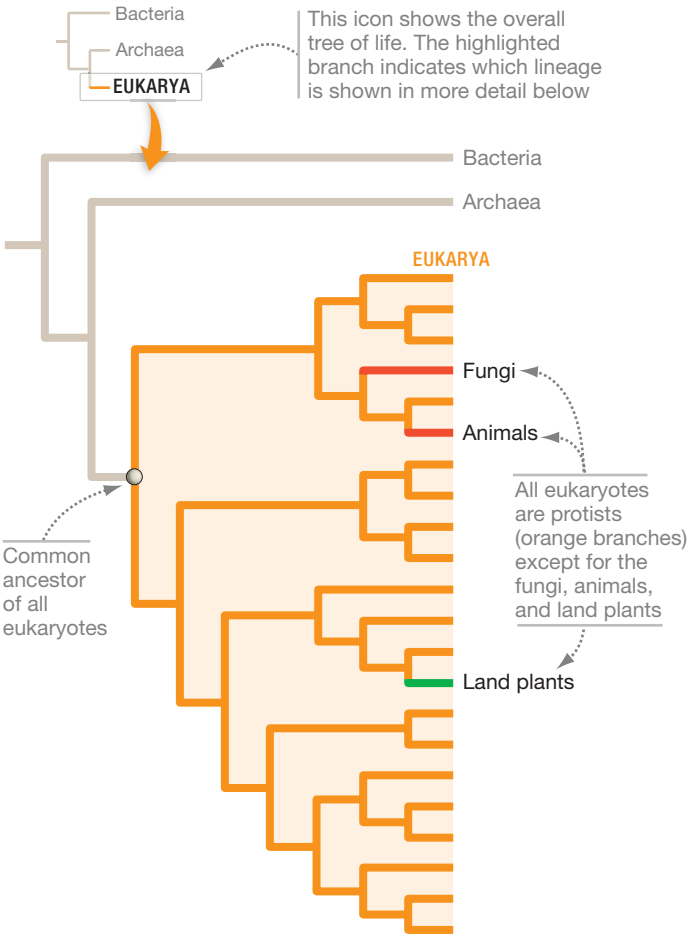
- The nuclear envelope is a **synapomorphy** that defines the Eukarya. Recall that a synapomorphy is a shared, derived trait that distinguishes major monophyletic groups (see Chapter 28).
- Multicellularity is rare in bacteria and unknown in archaea, but has evolved multiple times in eukaryotes.
- Bacteria and archaea reproduce asexually by fission; many eukaryotes reproduce asexually via mitosis and cell division.
- Many eukaryotes undergo meiosis and reproduce sexually.

One of this chapter's fundamental goals is to explore how these morphological innovations—features like organelles and the nuclear envelope—evolved. Another goal is to analyze how morphological innovations allowed eukaryotes to pursue novel ways of performing basic life tasks such as feeding, moving, and reproducing.

In introducing the Eukarya, this chapter focuses on a diverse collection of lineages known as the protists. The term **protist** refers to all eukaryotes that are not land plants, fungi, or animals. Protist lineages are colored orange in **FIGURE 30.1**.

Protists do not make up a monophyletic group. Instead, they refer to a **paraphyletic group**—they represent some, but not all, of the descendants of a single common ancestor. No synapomorphies define the protists. Protists have no trait that is found only in protists and in no other organisms.

By definition, then, the protists are a diverse lot. The common feature among protists is that they tend to live in environments where they are surrounded by water most of the time (**FIGURE 30.2**). Most plants, fungi, and animals are terrestrial, but protists are found in wet soils and aquatic habitats or inside the bodies of other organisms—including, perhaps, you.



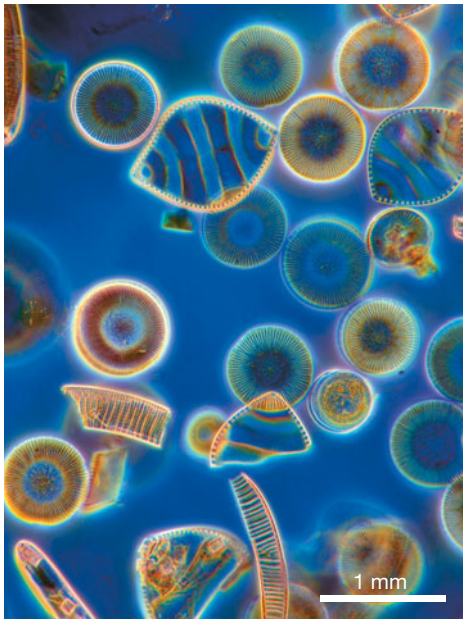


FIGURE 30.1 Protists Are Paraphyletic. The protists include some, but not all, descendants of a single common ancestor.

Open ocean: Surface waters teem with microscopic protists, such as these diatoms.

Shallow coastal waters: Gigantic protists, such as these kelp, form underwater forests.

Intertidal habitats: Protists such as these sea palms are particularly abundant in tidal habitats.

FIGURE 30.2 Protists Are Particularly Abundant in Aquatic Environments.

30.1 Why Do Biologists Study Protists?

Biologists study protists for three reasons, in addition to their intrinsic interest: **(1)** they are important medically, **(2)** they are important ecologically, and **(3)** they are critical to understanding the evolution of plants, fungi, and animals. The rest of the chapter focuses on why protists are interesting in their own right and how they evolved. Let's first consider their impact on human health and the environment.

Impacts on Human Health and Welfare

The most spectacular crop failure in history, the Irish potato famine, was caused by a protist. In 1845 most of the 3 million acres that had been planted to grow potatoes in Ireland became infested with *Phytophthora infestans*—a parasite that belongs to a group of protists called water molds. Potato tubers that were infected with *P. infestans* rotted in the fields or in storage.

As a result of crop failures in Ireland for two consecutive years, an estimated 1 million people out of a population of less than 9 million died of starvation or starvation-related illnesses. Several million others emigrated. Many people of Irish heritage living in North America, New Zealand, and Australia trace their ancestry to relatives who left Ireland to evade the famine. As devastating as the potato famine was, however, it does not begin to approach the misery caused by the protist *Plasmodium*.

Malaria Physicians and public health officials point to three major infectious diseases that are currently afflicting large numbers of people worldwide: tuberculosis, HIV, and malaria. Tuberculosis is caused by a bacterium (see Chapter 25); HIV is caused by a virus (see Chapter 36). Malaria is caused by a protist—specifically, by apicomplexan species in the eukaryotic lineage Alveolata.

Malaria ranks as one of the world's worst infectious diseases. In India alone, over 30 million people each year suffer from debilitating fevers caused by malaria. At least 300 million people worldwide are sickened by it each year, and nearly 1 million die from the disease annually. The toll is equivalent to eight 747s, loaded with passengers, crashing every day. Most of the dead are children of preschool age.

Five species of the protist *Plasmodium* are capable of parasitizing humans. Infections start when *Plasmodium* cells enter a person's bloodstream during a mosquito bite. As **FIGURE 30.3** shows, *Plasmodium* initially infects liver cells; later, some of the *Plasmodium* cells change into a distinctive cell type that infects the host's red blood cells. The *Plasmodium* cells multiply asexually inside the host cells, which are killed as parasite cells exit to infect additional liver cells or red blood cells. Large numbers of *Plasmodium* cells in a human host's blood increase the chance that a mosquito's blood meal will contain some of them.

After blood from an infected human is transferred to a mosquito during a bite, *Plasmodium* cells differentiate to form gametes. Inside the mosquito, gametes fuse to form a diploid zygote, which undergoes meiosis. Sexual reproduction in the mosquito is beneficial to the parasite because it generates genetic diversity to help evade the host's immune system. The haploid cells that result from meiosis can infect a human when the mosquito bites again.

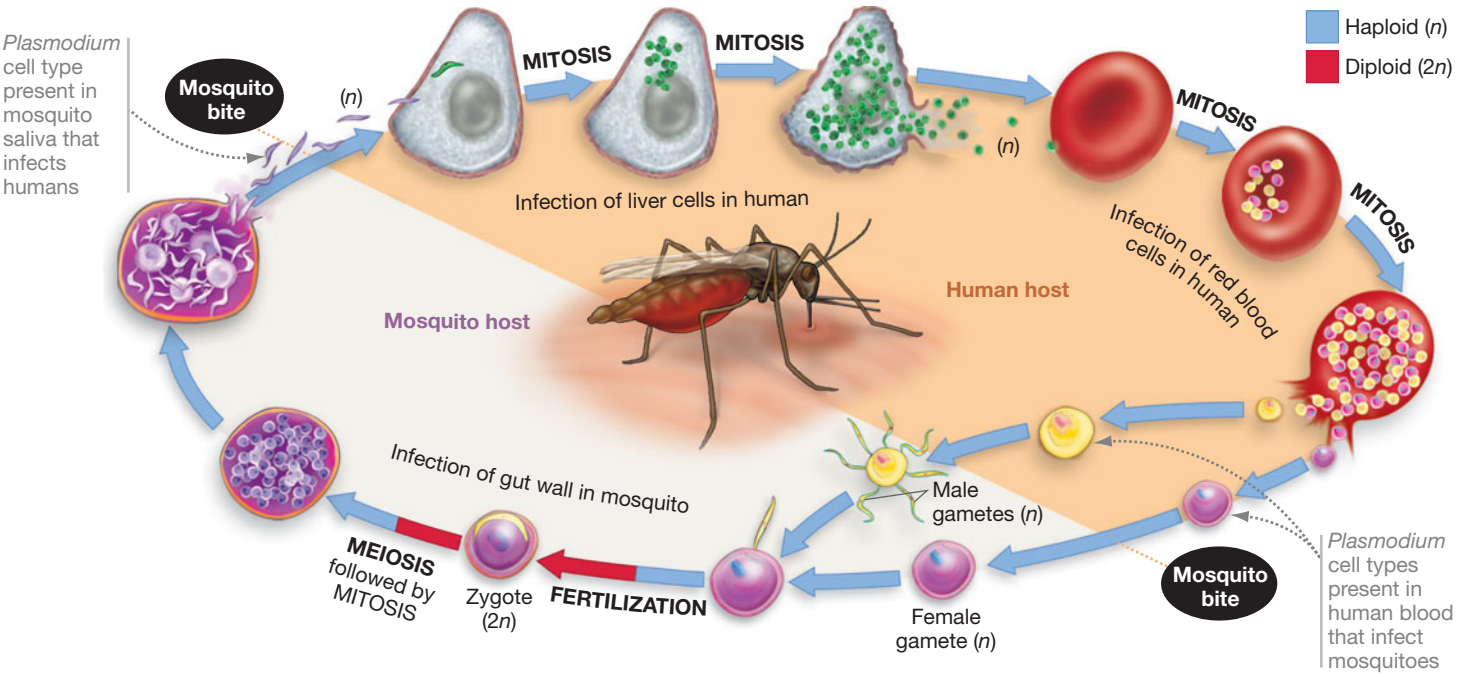

FIGURE 30.3 *Plasmodium* Lives in Mosquitoes and in Humans, Where It Causes Malaria. Over the course of its life cycle, *Plasmodium falciparum* alternates between a mosquito host where sexual reproduction takes place, and a human host where asexual reproduction takes place. In humans, it infects and kills liver cells and red blood cells, contributing to anemia and high fever. In mosquitoes, the protist lives in the gut and salivary glands.

TABLE 30.1 Some Human Health Problems Caused by Protists

Species	Disease
Five species of *Plasmodium,* primarily *P. falciparum* and *P. vivax*	Malaria has the potential to affect 40 percent of the world's total population.
Toxoplasma gondii	Toxoplasmosis may cause eye and brain damage in infants and in AIDS patients.
Many species of dinoflagellates	Toxins released during harmful algal blooms accumulate in clams and mussels and poison people if eaten.
Many species of *Giardia*	Diarrhea due to giardiasis (beaver fever) can last for several weeks.
Trichomonas vaginalis	Trichomoniasis is a reproductive tract infection and one of the most common sexually transmitted diseases. About 2 million young women are infected in the United States each year; some of them become infertile.
Several species of *Leishmania*	Leishmaniasis can cause skin sores or affect internal organs—particularly the spleen and liver.
Trypanosoma gambiense and *T. rhodesiense*	Trypanosomiasis ("sleeping sickness") is a potentially fatal disease transmitted through bites from tsetse flies. Occurs in Africa.
Trypanosoma cruzi	Chagas disease affects 16–18 million people and causes 50,000 deaths annually, primarily in South and Central America.
Entamoeba histolytica	Amoebic dysentery results from severe infections.
Phytophthora infestans	An outbreak of this protist wiped out potato crops in Ireland in 1845–1847, causing famine.

Although *Plasmodium* is arguably the best studied of all protists, researchers have still not been able to devise effective and sustainable measures to control it.

- *Plasmodium* has evolved resistance to some of the drugs used to control its growth in infected people.
- Efforts to develop a vaccine against *Plasmodium* have been fruitless to date, in part because the parasite evolves so quickly. Flu virus and HIV pose similar problems (see Chapter 51).
- Natural selection has favored mosquito strains that are resistant to the insecticides that have been sprayed in their breeding habitats in attempts to control malaria's spread.

Unfortunately, malaria is not the only important human disease caused by protists. **TABLE 30.1** lists some protists that cause human suffering and economic losses.

Harmful Algal Blooms When a unicellular species experiences rapid population growth and reaches high densities in an aquatic environment, it is said to "bloom." Unfortunately, a handful of the many protist species involved in blooms can be harmful.

Harmful algal blooms are usually due to photosynthetic protists called dinoflagellates. Certain dinoflagellates synthesize toxins to protect themselves from predation by small animals called copepods. Because these organisms sometimes have high concentrations of accessory pigments called xanthophylls, their blooms can sometimes discolor seawater (**FIGURE 30.4**).

Algal blooms can be harmful to people because clams and other shellfish filter photosynthetic protists out of the water as food. During a bloom, high levels of toxins can build up in the flesh of these shellfish. Typically, the shellfish themselves are not harmed. But if a person eats contaminated shellfish, several types of poisoning can result.

Paralytic shellfish poisoning, for example, occurs when people eat shellfish that have fed heavily on protists that synthesize poisons called saxitoxins. Saxitoxins block ion channels that have to open for electrical signals to travel through nerve cells

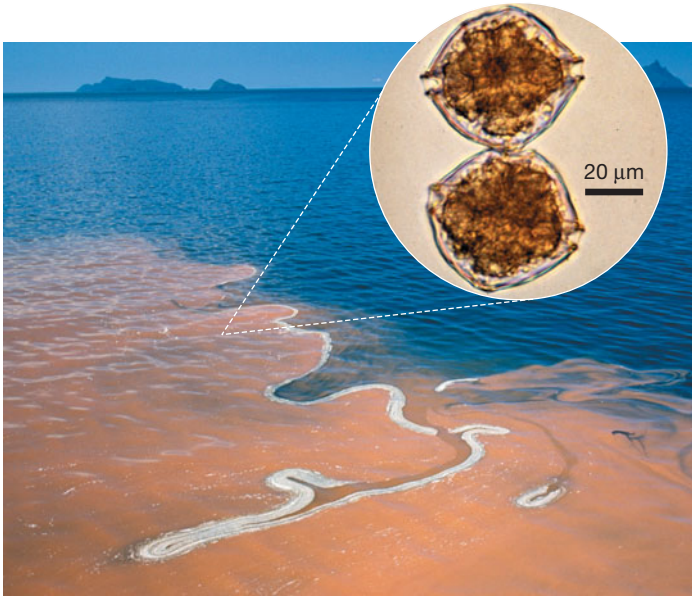

FIGURE 30.4 Harmful Algal Blooms Are Caused by Dinoflagellates.

(see Chapter 46). In humans, high dosages of saxitoxins cause unpleasant symptoms such as prickling sensations in the mouth or even life-threatening symptoms such as muscle weakness and paralysis.

But like the bacteria and archaea, most species of protists are not harmful. Let's have a look at some protists that are essential to healthy ecosystems.

Ecological Importance of Protists

As a whole, the protists represent just 10 percent of the total number of named eukaryote species. Although the number of named species of protists is relatively low, their abundance is extraordinarily high. The number of individual protists found in some habitats is astonishing.

- One milliliter of pond water can contain well over 500 single-celled protists that swim with the aid of flagella.
- Under certain conditions, dinoflagellates can reach concentrations of 60 thousand cells per milliliter of seawater.

Why is this important?

Protists Play a Key Role in Aquatic Food Chains Photosynthetic protists take in carbon dioxide from the atmosphere and reduce, or "fix," it to form sugars or other organic compounds with high potential energy (see Chapter 10). Photosynthesis transforms some of the energy in sunlight into chemical energy that organisms can use to grow and produce offspring.

Species that produce chemical energy in this way are called **primary producers.** Diatoms, in the Stramenopila lineage, are photosynthetic protists that rank among the leading primary producers in the oceans simply because they are so abundant. Primary production in the ocean represents almost half of the total carbon dioxide that is fixed on Earth.

Diatoms and other organisms that drift in the open oceans or lakes are called **plankton.** The sugars and other organic compounds produced by photosynthetic plankton are the basis of food chains in freshwater and marine environments.

A **food chain** describes nutritional relationships among organisms, and thus how chemical energy flows within ecosystems. In this case, photosynthetic protists and other primary producers are eaten by primary consumers, many of which are protists. Primary consumers are eaten by fish, shellfish, and other secondary consumers, which in turn are eaten by tertiary consumers—whales, squid, and large fish (such as tuna).

Many of the species at the base of food chains in aquatic environments are protists.

Could Protists Help Limit Global Climate Change? Carbon dioxide levels in the atmosphere are increasing rapidly because humans are burning fossil fuels and forests (see Chapter 56). Carbon dioxide traps heat that is radiating from Earth, so high CO_2 levels in the atmosphere contribute to the rise in temperatures associated with global climate change—an issue that many observers consider today's most pressing environmental problem.

The carbon atoms in carbon dioxide molecules move to organisms on land or in the oceans and then back to the atmosphere, in what researchers call the **global carbon cycle.** To restrict global climate change, researchers are trying to figure out ways to decrease carbon dioxide concentrations in the atmosphere and increase the amount of carbon stored in terrestrial and marine environments.

To understand how this might be done, consider the marine carbon cycle diagrammed in **FIGURE 30.5**. The cycle starts when CO_2 from the atmosphere dissolves in water and is taken up by primary producers—photosynthetic plankton called phytoplankton—and converted to organic matter. The plankton are eaten by primary consumers, die and are consumed by decomposers or scavengers, or die and sink to the bottom of the ocean. There they may enter one of two long-lived repositories:

1. ***Sedimentary rocks*** Several lineages of protists have shells made of calcium carbonate ($CaCO_3$). When these shells rain down from the ocean surface and settle in layers at the bottom, the deposits that result are compacted by the weight of the water and by sediments accumulating above them. Eventually the deposits turn into rock. The limestone used to build the pyramids of Egypt consists largely of protist shells.
2. ***Petroleum*** Although the process of petroleum (oil) formation is not well understood, it begins with accumulations of dead bacteria, archaea, and protists at the bottom of the ocean.

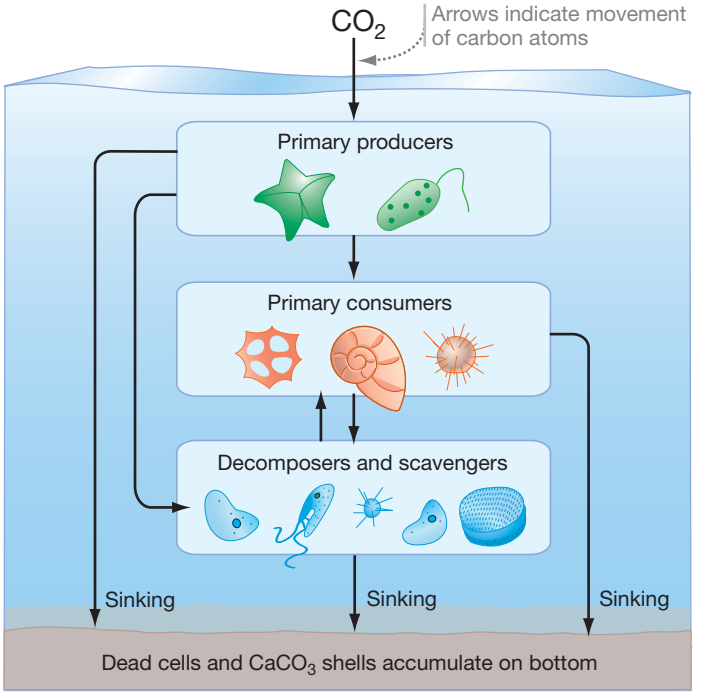

FIGURE 30.5 Protists Play a Key Role in the Marine Carbon Cycle. At the surface, carbon atoms tend to shuttle quickly among organisms. But if carbon atoms sink to the bottom of the ocean in the form of shells or dead cells, they may be locked up for long periods in carbon sinks. (The bottom of the ocean may be miles below the surface.)

Recent experiments have shown that the carbon cycle speeds up when habitats in the middle of the ocean are fertilized with iron. Iron is a critical component of the electron transport chains responsible for photosynthesis and respiration, but it is in particularly short supply in the open ocean. After iron is added to ocean waters, it is not uncommon to see populations of protists and other primary producers increase by a factor of 10.

Some researchers hypothesize that when these blooms occur, the amount of carbon that rains down into carbon sinks in the form of shells and dead cells may increase. If so, then fertilizing the ocean to promote blooms might be an effective way to reduce CO_2 concentrations in the atmosphere.

The effectiveness of iron fertilization is hotly debated, however. Fertilizing the ocean with iron might lead to large accumulations of dead organic matter and the formation of anaerobic dead zones (see Chapter 29). But if further research shows that iron fertilization is safe and effective, it could be added to the list of approaches to limit global climate change.

check your understanding

C Y U

If you understand that . . .

- Malaria is caused by a protist that lives in mosquitoes and in humans in different parts of its life cycle.
- Harmful algal blooms are caused by protists that produce a toxin as a defense against predation.
- Protists are key primary producers in aquatic environments. As a result, they play a key role in the global carbon cycle.

✔ You should be able to . . .

1. Explain why public health workers are promoting the use of insecticide-treated sleeping nets as a way of reducing malaria.
2. Make a flowchart showing the chain of events that would start with massive iron fertilization and end with large deposits of carbon-containing compounds on the ocean floor.

Answers are available in Appendix A.

30.2 How Do Biologists Study Protists?

Although biologists have made great strides in understanding pathogenic protists and the role that protists play in the global carbon cycle, they have found it extremely difficult to gain any sort of solid insight into how the group as a whole diversified over time. The problem is that the eukaryotic lineages split over a billion years ago and diverged so much that it is not easy to find any overall patterns in the evolution of the group.

Recently, researchers have made progress in understanding protist diversity by combining data on the morphology of key groups with phylogenetic analyses of DNA sequences. However, despite the progress, significant questions remain about how the Eukarya diversified. Let's analyze how this work is being done, beginning with classical results on the morphological traits that distinguish major eukaryote groups.

Microscopy: Studying Cell Structure

Using light microscopy (see **BioSkills 11** in Appendix B), biologists were able to identify and name many of the protist species known today. For example, the early microscopist Anton van Leeuwenhoek identified the parasite *Giardia intestinalis* by examining samples of his own feces.

When transmission electron microscopes became available, a major breakthrough in understanding protist diversity occurred: Detailed studies revealed that protists could be grouped according to overall cell structure, according to organelles with distinctive features, or both.

For example, both light and electron microscopy confirmed that the species that caused the Irish potato famine has reproductive cells with an unusual type of **flagellum.** Flagella are organelles that project from the cell and whip back and forth to produce swimming movements (see Chapter 7). In reproductive cells of this species, one of the two flagella present has tiny, hollow, hairlike projections. Biologists noted that kelp and other species of brown algae also have cells with this type of flagellum.

To make sense of these results, researchers interpreted these types of distinctive morphological features as synapomorphies. Species that have a flagellum with hollow, hairlike projections became known as stramenopiles (literally, "straw-hairs"); the hairs typically have branches at the tip (**FIGURE 30.6**).

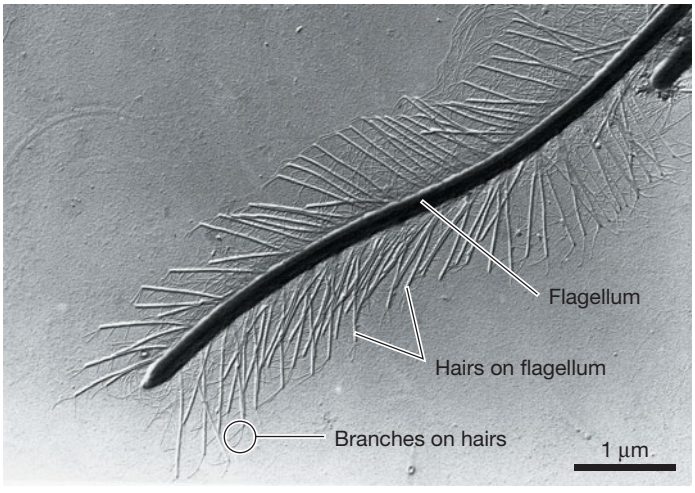

FIGURE 30.6 Species in the Lineage Called Stramenopila Have a Distinctive Flagellum. The unusual, hollow "hairs" that decorate the flagella of stramenopiles often have three branches at the tip.

SUMMARY TABLE 30.2 Major Lineages of Eukaryotes

Lineage	Distinguishing Morphological Features (synapomorphies)
Amoebozoa	Cells lack cell walls. When portions of the cell extend outward to move the cell, they form large lobes.
Opisthokonta	Reproductive cells have a single flagellum at their base. The cristae inside mitochondria are flat, not tube-shaped as in other eukaryotes. (This lineage includes protists as well as the fungi and the animals. Fungi and animals are discussed separately (see Chapters 32 through 35).
Excavata	Most cells have a pronounced "feeding groove" where prey or organic debris is ingested. Most species lack typical mitochondria, although genes derived from mitochondria are found in the nucleus.
Plantae	Cells have chloroplasts with a double membrane.
Rhizaria	Cells lack cell walls, although some produce an elaborate shell-like covering. When portions of the cell extend outward to move the cell, they are slender in shape.
Alveolata	Cells have sac-like structures called alveoli that form a continuous layer just under the plasma membrane. Alveoli are thought to provide support.
Stramenopila	If flagella are present, cells usually have two—one of which is covered with hairlike projections.

In recognizing the Stramenopila lineage, investigators hypothesized that because an ancestor had evolved a distinctive flagellum, all or most of its descendants also had this trait. The qualifier *most* is important, because it is not unusual for certain subgroups within a lineage to lose particular traits over the course of evolution, much as humans are gradually losing fur and tailbones.

Eventually, seven major groups of eukaryotes came to be identified on the basis of diagnostic morphological characteristics. These groups and the synapomorphies that identify them are listed in **TABLE 30.2**. Notice that in almost every case, the synapomorphies that define eukaryotic lineages are changes in structures that protect or support the cell or that influence the organism's ability to move or feed. The plants, fungi, and animals represent subgroups within two of the seven major eukaryotic lineages (see Chapters 31 through 35).

Evaluating Molecular Phylogenies

When researchers began using DNA sequence data to estimate the evolutionary relationships among eukaryotes, the analyses suggested that the seven groups identified on the basis of distinctive morphological characteristics were indeed monophyletic. This was important support for the hypothesis that the distinctive morphological features were shared, derived characters that existed in a common ancestor of each lineage.

The phylogenetic tree in **FIGURE 30.7** is the current best estimate of the eukaryotes' evolutionary history. As you read this tree, note that:

- The Amoebozoa and the Opisthokonta—which include fungi and animals—form a monophyletic group called the Unikonta.
- The other five major eukaryotic lineages form a monophyletic group called the Bikonta.

Understanding where the root or base of the tree of Eukarya lies has been more problematic. Finding it will help researchers understand what the common ancestor looked like and how eukaryotic lineages evolved over time. One hypothesis suggested that the first eukaryotic split was between unikonts and bikonts—meaning, between eukaryotes that have one flagellum and those with two flagella. This hypothesis is tentative and controversial, however, given the data analyzed to date. Researchers continue to work on the issue of placing the root of the Eukarya.

Discovering New Lineages via Direct Sequencing

The effort to refine the phylogeny of the Eukarya is ongoing. But of all the research frontiers in eukaryotic diversity, the most exciting may be the one based on the technique called direct sequencing.

Direct sequencing is based on sampling soil or water, analyzing the DNA sequence of specific genes in the sample, and using the data to place the organisms in the sample on a phylogenetic tree. Direct sequencing and metagenomics have led to the discovery of previously unknown but major lineages of Archaea (see Chapter 29). To the amazement of biologists all over the world, the same thing happened when researchers used direct sequencing to survey eukaryotes.

The first direct sequencing studies that focused on eukaryotes were published in 2001. One study sampled organisms at depths from 250 to 3000 meters (m) below the surface in waters off Antarctica; another focused on cells at depths of 75 m in the Pacific Ocean, near the equator. Both studies detected a wide array of species that were new to science.

Investigators who examined the samples microscopically were astonished to find that many of the newly discovered eukaryotes were tiny—from 0.2 micrometers (μm) to 5 μm in diameter. Subsequent work has confirmed the existence of many,

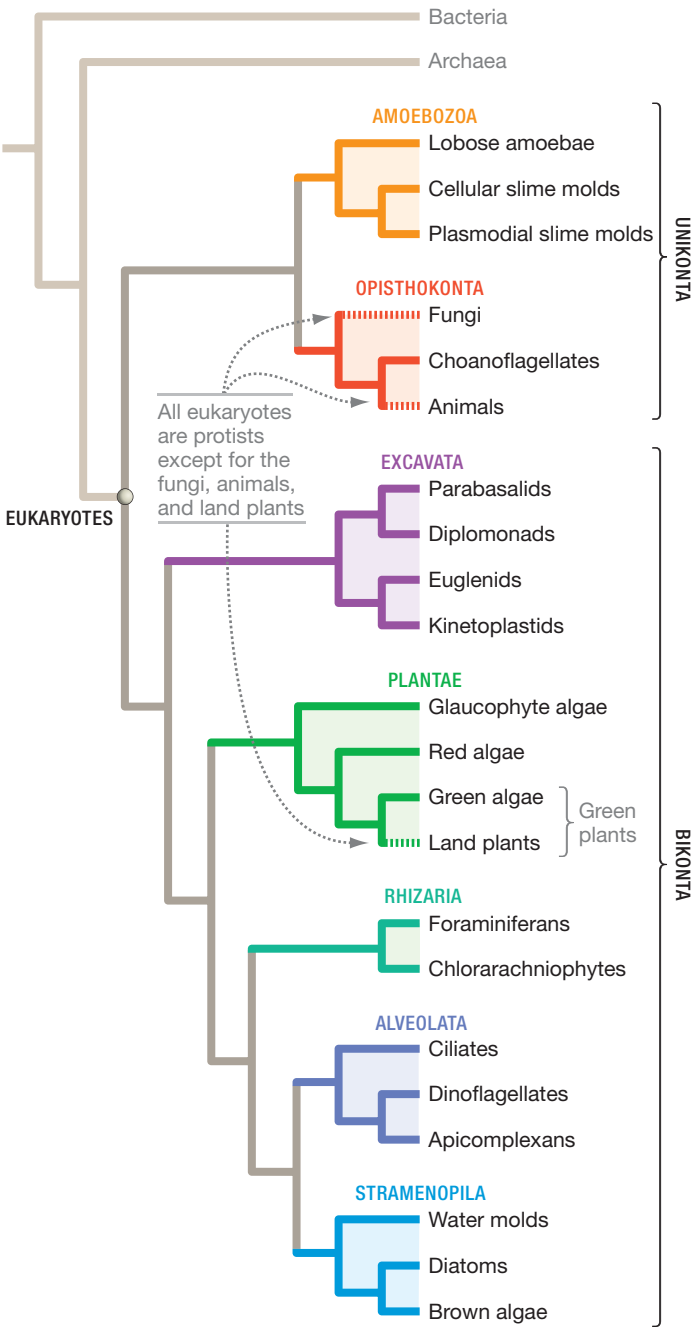

FIGURE 30.7 Phylogenetic Analyses Have Identified Seven Major Lineages of Eukaryotes. This tree shows selected subgroups from the seven major lineages discussed in this chapter. Kinetoplastids are not discussed in detail elsewhere in the chapter, but they include the pathogens *Trypanosoma* and *Leishmania* described in Table 30.1.

diverse species of protists that are less than 0.2 μm in diameter. These cells overlap in size with bacteria, which typically range from 0.5 μm to 2 μm in diameter.

Eukaryotic cells are much more variable in size than previously imagined. A whole new world of tiny protists has only recently been discovered.

check your understanding

If you understand that . . .

- According to the most recent analyses, the domain Eukarya comprises seven major lineages. Members of each lineage have distinctive aspects of cell structure.
- Direct sequencing has allowed investigators to recognize large numbers of previously undescribed eukaryotes, some of which are extremely small.

✓ You should be able to . . .

1. Explain why opisthokonts, alveolates, and stramenopiles got their names. (The root *opistho* refers to the back of a cell; the root *kont* refers to a flagellum.)
2. Explain why direct sequencing studies allow researchers to characterize species that have never been seen before.

Answers are available in Appendix A.

30.3 What Themes Occur in the Diversification of Protists?

The protists range in size from bacteria-sized single cells to giant kelp. They live in habitats from the open oceans to the guts of termites. They are almost bewildering in their morphological and ecological diversity. Because they are a paraphyletic group, they do not share derived characteristics that set them apart from all other lineages on the tree of life.

One general theme that can help tie protists together is their amazing diversity. Once an important new innovation arose in protists, it triggered the evolution of species that live in a wide array of habitats and make a living in diverse ways.

What Morphological Innovations Evolved in Protists?

Virtually all bacteria and all archaea are unicellular. Given the distribution of multicellularity in eukaryotes, it is logical to conclude that the first eukaryote was also a single-celled organism.

Further, all eukaryotes alive today have **(1)** either mitochondria or genes that are normally found in mitochondria, **(2)** a nucleus and endomembrane system, and **(3)** a cytoskeleton. Based on the distribution of cell walls in living eukaryotes, it is likely that the first eukaryotes lacked this feature.

Using these observations, biologists hypothesize that the earliest eukaryotes were probably single-celled organisms with mitochondria, a nucleus and endomembrane system, and a cytoskeleton, but no cell wall.

It is also likely that the first eukaryotic cells swam using a novel type of flagellum. Eukaryotic flagella are completely different structures from bacterial flagella and evolved independently.

The eukaryotic flagellum is made up of microtubules, and dynein is the major motor protein. An undulating motion occurs as dynein molecules walk down microtubules (see Chapter 7). The flagella of bacteria and archaea, in contrast, are composed primarily of a protein called flagellin. Instead of undulating, prokaryotic flagella rotate to produce movement.

✔ **If you understand the synapomorphies that identify the eukaryotes as a monophyletic group, you should be able to map the origin of the nuclear envelope and the eukaryotic flagellum on Figure 30.7.** Once you've done that, let's consider how several of these key new morphological features arose and influenced the subsequent diversification of protists, beginning with one of the traits that define the Eukarya.

Endosymbiosis and the Origin of the Mitochondrion Mitochondria are organelles that generate adenosine triphosphate (ATP) using pyruvate as an electron donor and oxygen as the ultimate electron acceptor (see Chapter 9).

In 1981 evolutionary biologist Lynn Margulis expanded on a radical hypothesis—first proposed in the nineteenth century—to explain the origin of mitochondria. The **endosymbiosis theory** proposes that mitochondria originated when a bacterial cell took up residence inside another cell about 2 billion years ago.

The theory's name was inspired by the Greek word roots *endo, sym,* and *bio* (literally, "inside-together-living"). **Symbiosis** is said to occur when individuals of two different species live in physical contact; **endosymbiosis** occurs when an organism of one species lives inside the cells of an organism of another species.

How and when this momentous event occurred is hotly debated. Some scientists think a primitive amoeba-like eukaryote engulfed a bacterium and simply failed to digest it in its lysosome, allowing it to take up residence. Evidence that was used to support this theory includes the similar feeding habits of today's amoeba, and the existence of some protist species that seem to lack mitochondria.

Recent evidence, however, indicates that all protists originally had mitochondria, and some lost them. A new idea gaining support is that the first eukaryote may have been formed as a result of an endosymbiosis between two prokaryotes—an archaeal host and a bacterium (**FIGURE 30.8**). After this chance union occurred, cells developed nuclei and became much larger. Both of these changes appear to have been triggered by the bacterial invader.

The relationship between the archaeal host and the engulfed bacterial cell was presumed to be stable because a mutual advantage existed between them: The host supplied the bacterium with protection and carbon compounds from its prey, while the bacterium produced much more ATP than the host cell could synthesize on its own.

When Margulis first began promoting the endosymbiosis theory, it met with a storm of criticism—largely because it seemed slightly preposterous. But gradually biologists began to examine it rigorously. For example, endosymbiotic relationships between protists and bacteria exist today. Among the α-proteobacteria alone (see Chapter 29), three major groups are found *only* inside eukaryotic cells. In many cases, the bacterial cells are transmitted to offspring in eggs or sperm and are required for survival.

PROCESS: THE ENDOSYMBIOSIS THEORY

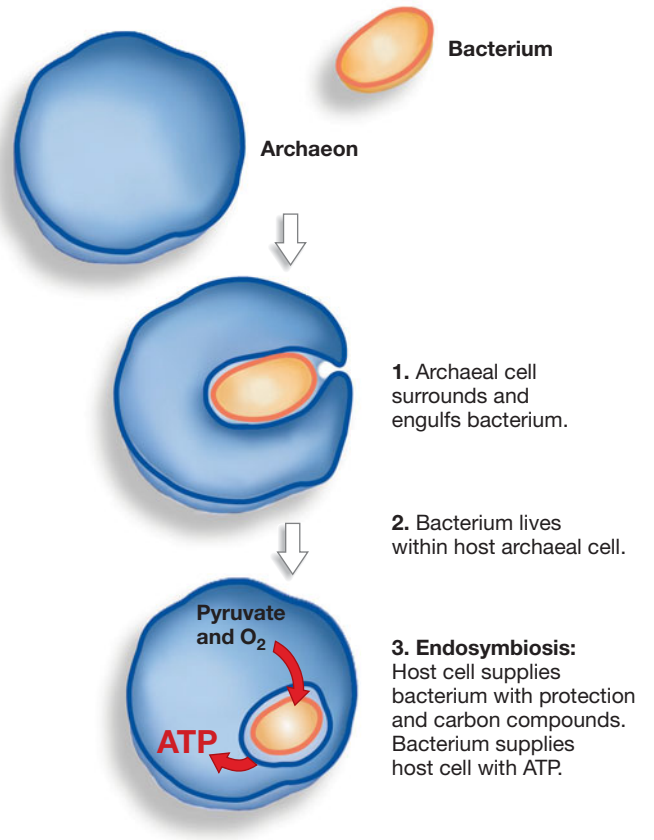

FIGURE 30.8 Proposed Initial Steps in the Evolution of the Mitochondrion.

✔**QUESTION** According to this hypothesis, how many membranes should surround a mitochondrion? Explain your logic.

Several observations about the structure of mitochondria are also consistent with the endosymbiosis theory:

- Mitochondria are about the size of an average α-proteobacterium.
- Mitochondria replicate by fission, as do bacterial cells. The duplication of mitochondria takes place independently of division by the host cell. When eukaryotic cells divide, each daughter cell receives some of the many mitochondria present.
- Mitochondria have their own ribosomes and manufacture some of their own proteins. Mitochondrial ribosomes closely resemble bacterial ribosomes in size and composition and are poisoned by antibiotics such as streptomycin that inhibit bacterial, but not eukaryotic, ribosomes.
- Mitochondria have double membranes, consistent with the engulfing mechanism of origin illustrated in Figure 30.8.
- Mitochondria have their own genomes, which are organized as circular molecules—much like a bacterial chromosome. Mitochondrial genes code for a few of the proteins needed to conduct electron transport and RNAs needed to translate the mitochondrial genome.

Although these data are impressive, they are only consistent with the endosymbiosis theory. Stated another way, they do not exclude other explanations. This is a general principle in science: Evidence is considered strong when it cannot be explained by reasonable alternative hypotheses. In this case, the key was to find data that tested predictions made by Margulis's idea against predictions made by an alternative theory: that mitochondria evolved within eukaryotic cells, separately from bacteria.

A breakthrough occurred when researchers realized that according to the "within-eukaryotes" theory, the genes found in mitochondria are derived from nuclear genes in ancestral eukaryotes. Margulis's theory, in contrast, proposed that the genes found in mitochondria were bacterial in origin.

These predictions were tested by studies on the phylogenetic relationships of mitochondrial genes. Specifically, researchers compared gene sequences isolated from eukaryotic mitochondrial DNA with sequences of similar genes isolated from eukaryotic nuclear DNA and with DNA from several species of bacteria. Exactly as the endosymbiosis theory predicted, mitochondrial gene sequences are much more closely related to the sequences from the α-proteobacteria than to sequences from the nuclear DNA of eukaryotes.

The result diagrammed in **FIGURE 30.9** was considered overwhelming evidence that the mitochondrial genome came from an α-proteobacterium rather than from a eukaryote. The endosymbiosis theory was the only reasonable explanation for the data.

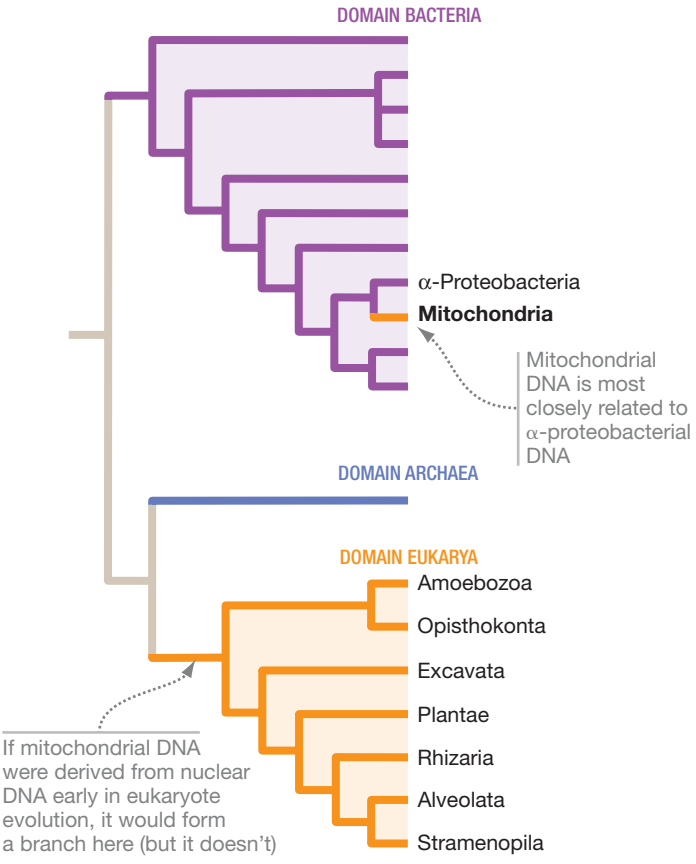

FIGURE 30.9 Phylogenetic Data Support the Endosymbiosis Theory.

The results were a stunning vindication of a theory that had once been intensely controversial. Mitochondria evolved via endosymbiosis between an α-proteobacterium and an archaeal host.

One intriguing feature of mitochondrial genomes is that they typically encode less than 50 genes, whereas the genomes of their bacterial cousins encode about 1500 genes. Most of the genes from the endosymbiotic bacterium moved into the nuclear genome in what was one of the most spectacular **lateral gene transfer** events in the history of life (see Chapter 21). Some unnecessary genes were lost, but many still encode proteins that are synthesized by cytosolic ribosomes and imported into mitochondria.

✔ **If you understand the endosymbiosis theory and the evidence for it, you should be able to describe how the chloroplast—the organelle that is the site of photosynthesis in eukaryotes—could arise via endosymbiosis.**

Now let's turn to another distinguishing feature of eukaryotic cells—the nucleus, with its unique double membrane called the nuclear envelope. The origin of the nuclear envelope is also a subject of debate.

The Nuclear Envelope The leading hypothesis to explain the origin of the nuclear envelope is based on infoldings of the plasma membrane. As the drawings in **FIGURE 30.10** show, a stepwise process could give rise to small infoldings that were elaborated

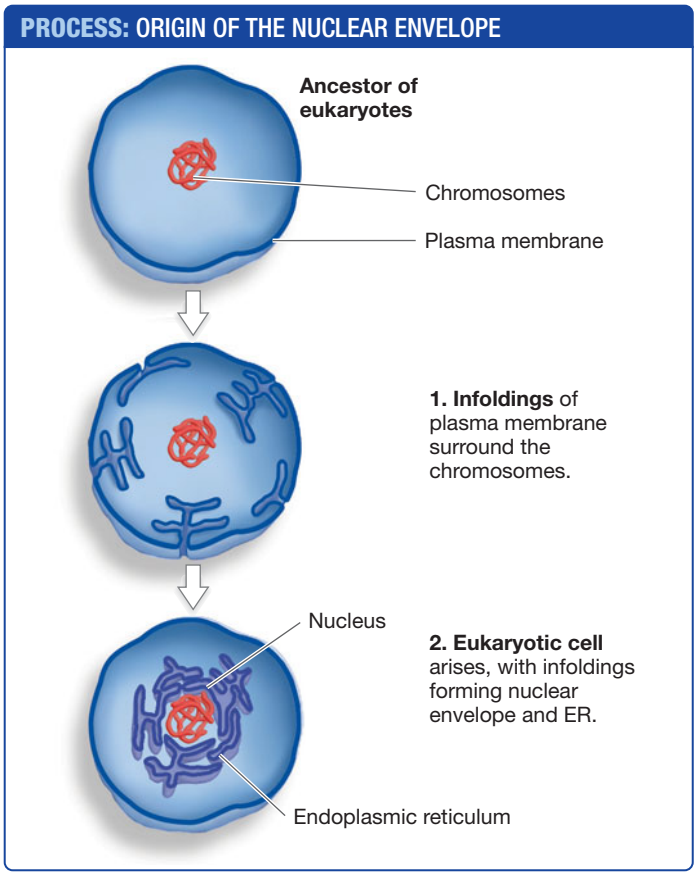

FIGURE 30.10 A Hypothesis for the Origin of the Nuclear Envelope. Infoldings of the plasma membrane, analogous to those shown here, have been observed in bacteria living today.

by mutation and natural selection over time, and the infolding could eventually become detached from the plasma membrane. Note that the infoldings would have given rise to the nuclear envelope and the endoplasmic reticulum (ER) together.

Two lines of evidence support this hypothesis: Infoldings of the plasma membrane occur in some bacteria living today, and the nuclear envelope and ER of today's eukaryotes are continuous (see Chapter 7). ✔ **If you understand the infolding hypothesis, you should be able to explain why these observations support it.**

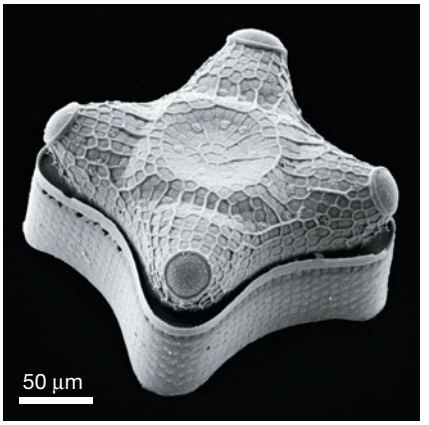
According to current thinking, the evolution of the nuclear envelope was advantageous because it separated transcription and translation. Recall that RNA transcripts are processed inside the nucleus but translated outside the nucleus (see Chapter 17). In bacteria and archaea, transcription and translation occur together.

With a simple nuclear envelope in place, alternative splicing and other forms of RNA processing could occur—giving the early eukaryotes a novel way to control gene expression (see Chapter 19). The take-home message here is that an important morphological innovation gave the early eukaryotes a new way to manage and process genetic information.

Once a nucleus had evolved, it underwent diversification. In some cases, unique types of nuclei are associated with the founding of important lineages of protists.

- Ciliates (Alveolata) have a diploid micronucleus that is involved only in reproduction, and a polyploid macronucleus where transcription occurs.
- Diplomonads (Excavata) have two nuclei that look identical; it is not known how they interact.
- In foraminifera (Rhizaria), red algae (Plantae), and plasmodial slime molds (Amoebozoa), certain cells contain many nuclei.
- Dinoflagellates (Alveolata) have chromosomes that lack histones and attach to the nuclear envelope.

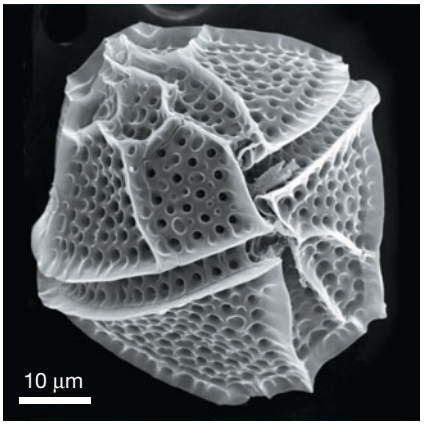
In each case, the distinctive structure of the nucleus is a synapomorphy that allows biologists to recognize these lineages as distinct monophyletic groups.



Structures for Support and Protection Many protists have cell walls outside their plasma membrane; others have hard external structures called a **shell;** others have rigid structures inside the plasma membrane. In many cases, these novel structures represent synapomorphies that identify monophyletic groups among protists. For example:

- Diatoms (Stramenopila) are surrounded by a glass-like, silicon-dioxide cell wall (**FIGURE 30.11a**). The cell wall is made up of two pieces that fit together in a box-and-lid arrangement, like the petri plates you may have seen in lab.
- Dinoflagellates (Alveolata) have a cell wall made up of cellulose plates (**FIGURE 30.11b**).
- Within the foraminiferans (Rhizaria), some subgroups secrete an intricate, chambered calcium carbonate shell (**FIGURE 30.11c**).
- Members of other foraminiferan subgroups, and some amoebae, cover themselves with tiny pebbles.
- The parabasalids (Excavata) have a unique internal support rod, consisting of cross-linked microtubules that run the length of the cell.
- The euglenids (Excavata) have a collection of protein strips located just under the plasma membrane. The strips are supported by microtubules and stiffen the cell.
- All alveolates (Alveolata) have distinctive sac-like structures called alveoli, located just under the plasma membrane, that help stiffen the cell.

In many cases, the diversification of protists has been associated with the evolution of innovative structures for support and protection.



Multicellularity One of the most significant changes in the history of life on Earth occurred when organisms containing more than one cell evolved. The mutations leading to **multicellularity** probably first caused cells to simply stick together after cell division. Selection pressures could then act on these larger, colonial organisms, allowing them to evolve and diversify.

FIGURE 30.11 Hard Outer Coverings in Protists Vary in Composition.

Eventually cells became specialized for different functions. In the simplest multicellular species, certain cells are specialized for producing or obtaining food while other cells are specialized for reproduction. The key point about multicellularity is that not all cells express the same genes.

A few species of bacteria are capable of aggregating and forming structures called fruiting bodies (see Chapter 29). Because cells in the fruiting bodies of these bacteria differentiate into specialized stalk cells and spore-forming cells, they are considered multicellular. But the vast majority of multicellular species are members of the Eukarya.

Multicellularity arose independently in a wide array of eukaryotic lineages, including the green plants, fungi, animals, brown algae, slime molds, and red algae.

To summarize, an array of novel morphological traits played a key role as protists diversified: the mitochondrion, the nucleus and endomembrane system, structures for protection and support, and multicellularity. Evolutionary innovations allowed protists to build and manage the eukaryotic cell in new ways.

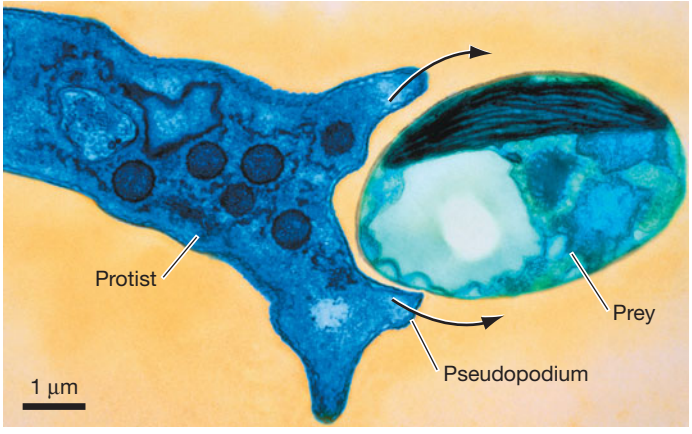
Once a new type of eukaryotic cell or multicellular individual existed, subsequent diversification was often triggered by novel ways of finding food, moving, or reproducing. Let's consider each of these life processes in turn.

How Do Protists Obtain Food?

Bacteria and archaea can use a wide array of molecules as electron donors and electron acceptors during cellular respiration (see Chapter 29). Some get these molecules by absorbing them directly from the environment. Other bacteria don't absorb their nutrition—instead, they make their own food via photosynthesis. Many groups of protists are similar to bacteria in the way they find food: They perform photosynthesis or absorb their food directly from the environment.

But one of the most important stories in the diversification of protists was the evolution of a novel method for finding food. Many protists ingest their food—they eat bacteria, archaea, or even other protists whole. This process is called **phagocytosis** (see Chapter 7). When phagocytosis occurs, an individual takes in packets of food much larger than individual molecules. Thus, protists feed by either **(1)** ingesting packets of food, **(2)** absorbing organic molecules directly from the environment, or **(3)** performing photosynthesis.

Some protists ingest food as well as performing photosynthesis—meaning that they use a combination of feeding strategies. It's also important to recognize that all three lifestyles—ingestive, absorptive, and photosynthetic—can occur within a single lineage.



To drive this last point home, consider the monophyletic group called the alveolates. This lineage has three major subgroups—dinoflagellates, apicomplexans, and ciliates. About half of the dinoflagellates are photosynthetic, but many others are parasitic and absorb nutrients from their hosts. Apicomplexans are parasitic. Ciliates include many species that ingest prey, but some ciliates live in the guts of cattle or the gills of fish. Other ciliate species make a living by holding algae or other types of photosynthetic endosymbionts inside their cells.

The punch line? Within each of the seven major lineages of eukaryotes, different methods for feeding helped trigger diversification.

Ingestive Feeding Ingestive lifestyles are based on eating live or dead organisms or on scavenging loose bits of organic debris. Protists such as the cellular slime mold *Dictyostelium discoideum* are large enough to engulf bacteria and archaea; many protists are large enough to surround and ingest other protists or even microscopic animals.

Feeding by phagocytosis is possible in protists that lack a cell wall. A flexible membrane and dynamic cytoskeleton give these species the ability to surround and "swallow" prey using long, fingerlike projections called **pseudopodia** ("false-feet") (**FIGURE 30.12a**). Phagocytosis was a prerequisite for the endosymbiosis event that led to chloroplasts.

(a) Pseudopodia engulf food.

(b) Ciliary currents sweep food into gullet.

FIGURE 30.12 Ingestive Feeding. Methods of prey capture vary among ingestive protists. **(a)** Some predators engulf prey with pseudopodia; **(b)** other predators sweep them into their gullets with water currents set up by the beating of cilia. Note that the cells in part (a) have been colorized.

Although many ingestive feeders actively hunt down prey and engulf them, others do not. Instead of taking themselves to food, these species attach themselves to a surface. Protists that feed in this way have cilia that surround the mouth and beat in a coordinated way. The motion creates water currents that sweep food particles into the cell (**FIGURE 30.12b**).

Absorptive Feeding Absorptive feeding occurs when nutrients are taken up directly from the environment, across the plasma membrane, usually through transport proteins. Absorptive feeding is common among protists.

Some protists that live by absorptive feeding are **decomposers,** meaning that they feed on dead organic matter, or **detritus.** But many of the protists that absorb their nutrition directly from the environment live inside other organisms. If an absorptive species damages its host, that species is called a **parasite.**

Photosynthesis—Endosymbiosis and the Origin of Chloroplasts You might recall that photosystems I and II evolved in bacteria, and that both photosystems occur in cyanobacteria (see Chapter 10). None of the basic machinery required for photosynthesis evolved in eukaryotes. Instead, they "stole" it—via endosymbiosis.

The endosymbiosis theory contends that the eukaryotic chloroplast originated when a protist engulfed a cyanobacterium. Once inside the protist, the photosynthetic bacterium provided its eukaryotic host with oxygen and glucose in exchange for protection and access to light. If the endosymbiosis theory is correct, today's chloroplasts trace their ancestry to cyanobacteria.

All of the photosynthetic eukaryotes have both chloroplasts and mitochondria. The evidence for an endosymbiotic origin for the chloroplast is persuasive.

- Chloroplasts have the same list of bacteria-like characteristics presented earlier for mitochondria.
- Many examples of endosymbiotic cyanobacteria are living inside the cells of protists or animals today.
- Chloroplasts contain a circular DNA molecule containing genes that are extremely similar to cyanobacterial genes.
- The photosynthetic organelle of one group of protists, the glaucophyte algae, has an outer layer containing the same constituent (peptidoglycan) found in the cell walls of cyanobacteria.

Like mitochondria, the chloroplast genome is very small compared with genomes of living cyanobacteria; most of the original genes were either lost or transferred to the nucleus.

✔If you understand the evidence for the endosymbiotic origin of the chloroplast, you should be able to add a label indicating the location of chloroplast genes on the phylogenetic tree in Figure 30.7.

Photosynthesis—Primary versus Secondary Endosymbiosis Which eukaryote originally obtained a photosynthetic organelle? Because all species in the Plantae have chloroplasts with two membranes, biologists infer that the original, or primary, endosymbiosis occurred in these species' common ancestor. That species eventually gave rise to all subgroups in the Plantae lineage—the glaucophyte algae, red algae, and green plants (green algae and land plants).

But chloroplasts also occur in four of the other major lineages of protists—the Excavata, Rhizaria, Alveolata, and Stramenopila. In these species, the chloroplast is surrounded by more than two membranes—usually four.

To explain this observation, researchers hypothesize that the ancestors of these groups acquired their chloroplasts by ingesting photosynthetic protists that already had chloroplasts. This process, called secondary endosymbiosis, occurs when an organism engulfs a photosynthetic eukaryotic cell and retains its chloroplasts as intracellular symbionts. Secondary endosymbiosis is illustrated in **FIGURE 30.13**.

FIGURE 30.14 shows where primary and secondary endosymbiosis occurred on the phylogenetic tree of eukaryotes. Once

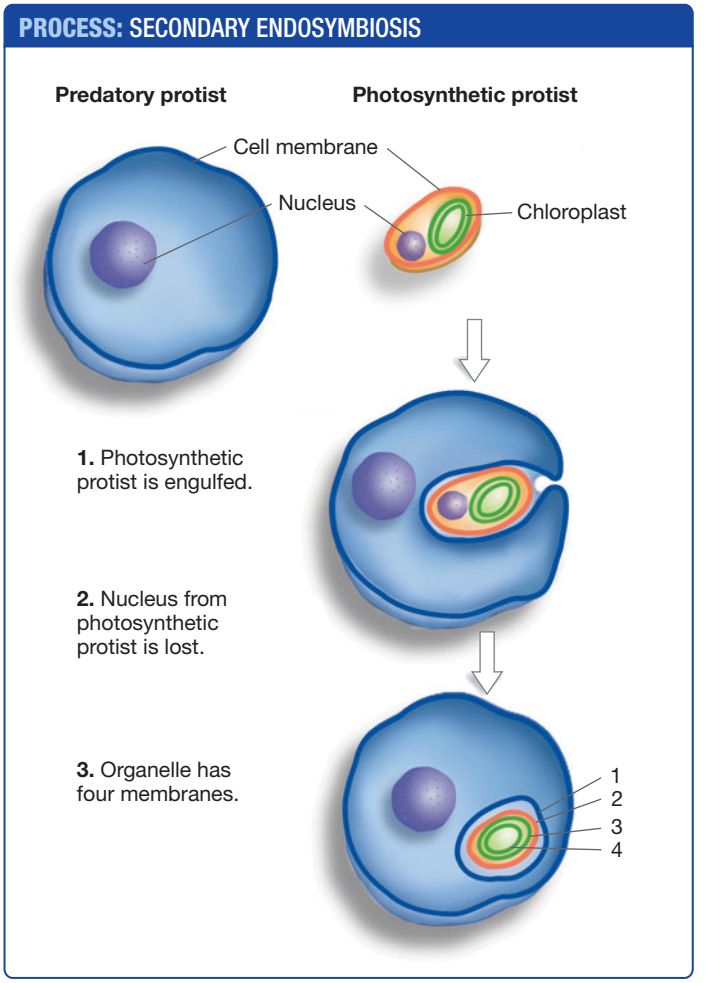


FIGURE 30.13 Secondary Endosymbiosis Leads to Organelles with Four Membranes. The chloroplasts found in some protists have four membranes and are hypothesized to be derived by secondary endosymbiosis. In species where chloroplasts have three membranes, biologists hypothesize that secondary endosymbiosis was followed by the loss of one membrane.

protists obtained the chloroplast, it was "swapped around" to new lineages via secondary endosymbiosis.

✔ **If you understand endosymbiosis, you should be able to assess and explain why the primary and secondary endosymbiosis events introduced in this chapter represent the most massive lateral gene transfers in the history of life, in terms of the number of genes moved at once.** (To review lateral gene transfer, see Chapter 21.)

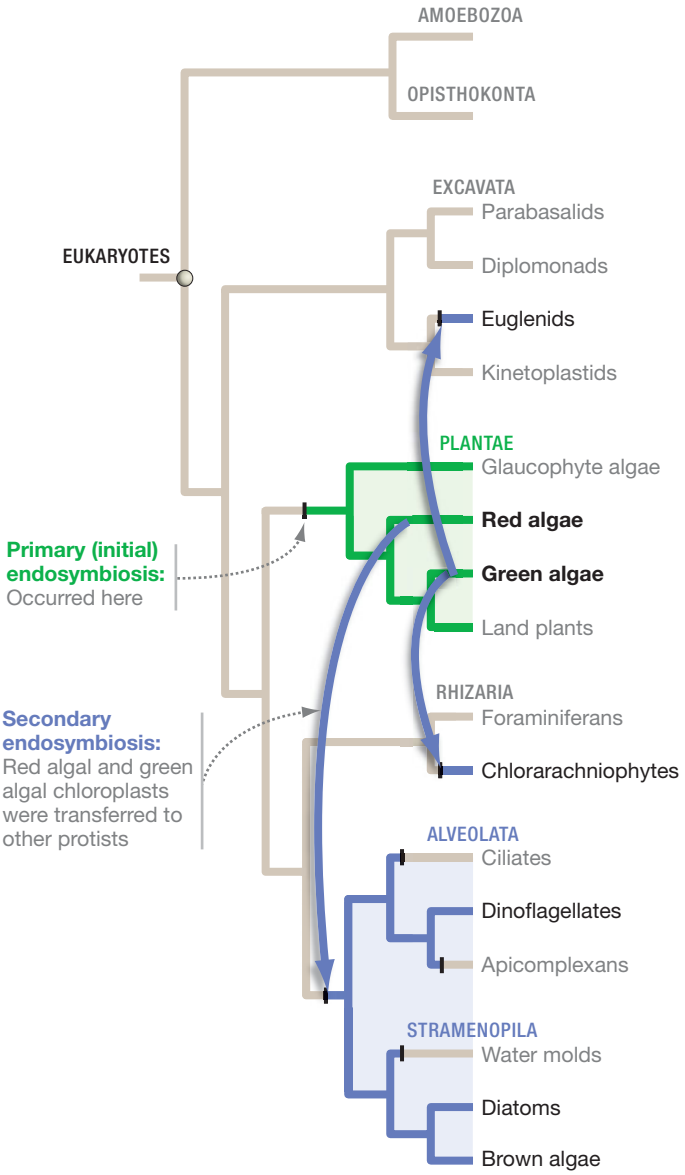

FIGURE 30.14 Photosynthesis Arose in Protists by Primary Endosymbiosis and Then Spread among Lineages via Secondary Endosymbiosis. Biochemical similarities link the chloroplasts found in alveolates and stramenopiles with red algae and the chloroplasts found in euglenids and chlorarachniophytes with green algae. Notice that among the alveolates and stramenopiles, only the dinoflagellates, diatoms, and brown algae have photosynthetic species. In ciliates, apicomplexans, and water molds, the chloroplast has been lost or has changed function.

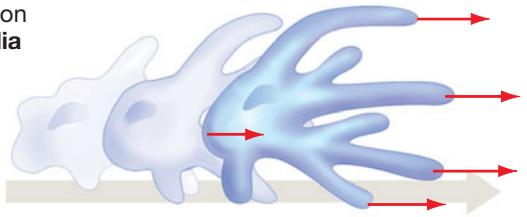

How Do Protists Move?

Many protists actively move to find food. Predators such as the slime mold *Dictyostelium discoideum* crawl over a substrate in search of prey. Most of the unicellular, photosynthetic species are capable of swimming to sunny locations, though others drift passively in water currents. How are these crawling and swimming movements possible?

Amoeboid motion is a sliding movement observed in some protists. In the classic mode illustrated in **FIGURE 30.15**, pseudopodia stream forward over a substrate, and the rest of the cytoplasm, organelles, and plasma membrane follow. The motion requires ATP and involves interactions between proteins called actin and myosin inside the cytoplasm. The mechanism is related to muscle movement in animals (see Chapter 48). But at the level of the whole cell, the precise sequence of events during amoeboid movement is still uncertain. The issue is attracting researchers' attention, because key immune system cells in humans use amoeboid motion as they hunt down and destroy disease-causing agents.

The other major mode of locomotion in protists involves flagella or cilia (**FIGURE 30.16**, see page 566). Recall that flagella and cilia both consist of nine sets of doublet (paired) microtubules arranged around two central, single microtubules (see Chapter 7). Flagella are long and are usually found alone or in pairs; cilia are short and usually occur in large numbers on any one cell.

Amoeboid motion via **pseudopodia**

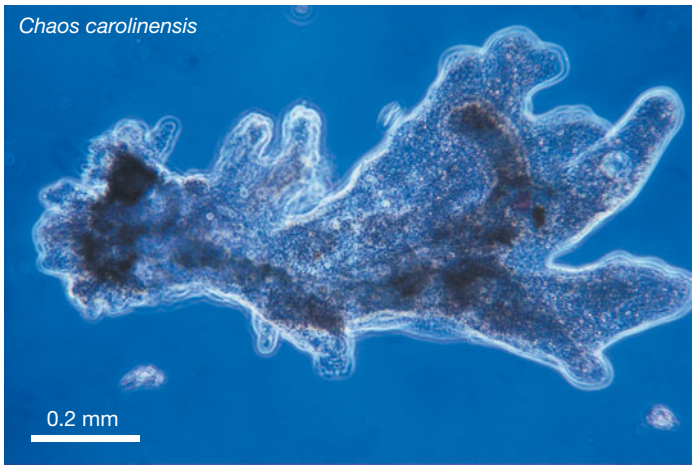

FIGURE 30.15 Amoeboid Motion Is Possible in Species That Lack Cell Walls. In amoeboid motion, long pseudopodia stream out from the cell. The rest of the cytoplasm, organelles, and external membrane follow.

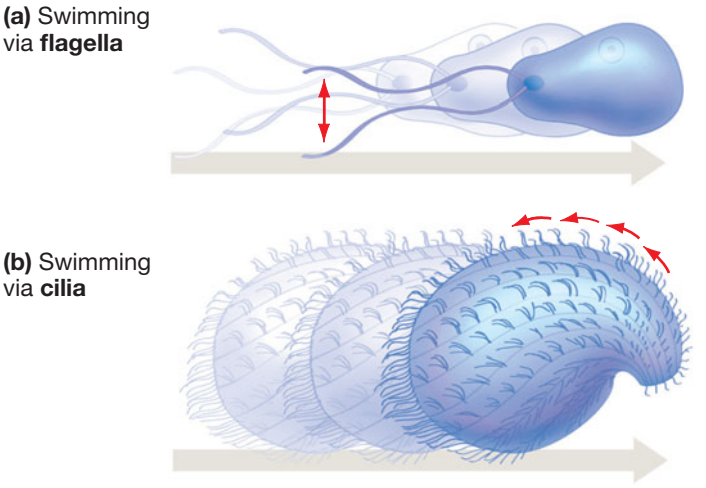

FIGURE 30.16 Many Protists Swim Using Flagella or Cilia. **(a)** Flagella are long and few in number. **(b)** Cilia are short and numerous. In many cases they are used in swimming.

Even closely related protists can use radically different forms of locomotion. For example, within the Alveolata, the ciliates swim by beating their cilia, the dinoflagellates swim by whipping their flagella, and mature apicomplexan cells move by amoeboid motion (though their gametes swim via flagella). It is also common to find protists that do not exhibit active movement, but instead float passively in water currents.

Movement is yet another example of the extensive diversification that occurred within each of the seven major monophyletic groups of eukaryotes.

How Do Protists Reproduce?

Sexual reproduction originated in protists. Sexual reproduction can best be understood in contrast to asexual reproduction (see Chapter 13). The key issues are the type of nuclear division involved and the consequences for genetic diversity in the offspring produced.

- Asexual reproduction is based on mitosis and cell division in eukaryotic organisms and on fission in bacteria and archaea. It results in daughter cells that are genetically identical to the parent.
- Sexual reproduction is based on meiosis and fusion of gametes. It results in daughter cells that are genetically different from their parents and from each other.

Most protists undergo asexual reproduction routinely. But sexual reproduction occurs only intermittently in many protists—often at one particular time of year, or when individuals are stressed by overcrowding or scarce food supplies.

The evolution of sexual reproduction ranks among the most significant evolutionary innovations observed in eukaryotes.

Sexual versus Asexual Reproduction The leading hypothesis to explain why meiosis evolved states that genetically variable offspring may be able to thrive if the environment changes. For example, offspring with genotypes different from those of their parents may be better able to withstand attacks by parasites that successfully attacked their parents (see Chapter 13). This is a key point because many types of parasites, including bacteria and viruses, have short generation times and evolve quickly.

Because the genotypes and phenotypes of parasites are constantly changing, natural selection favors host individuals with new genotypes. The idea is that novel genotypes in offspring generated by meiosis may contain combinations of alleles that allow hosts to withstand attack by new strains of parasites. In short, many biologists view sexual reproduction as an adaptation to fight disease.

✔ **If you understand the changing-environment hypothesis for the evolution of sex, you should be able to evaluate and explain whether it is consistent with the observation that many protists undergo meiosis when food is scarce or the population density is high.**

Life Cycles—Haploid versus Diploid Dominated

A life cycle describes the sequence of events that occur as individuals grow, mature, and reproduce. The evolution of meiosis introduced a new event in the life cycle of protist species; what's more, it created a distinction between haploid and diploid phases in the life of an individual.

Recall that diploid individuals have two of each type of chromosome inside each cell (see Chapter 13). Haploid individuals have just one of each type of chromosome inside each cell. When meiosis occurs in diploid cells, it results in the production of haploid cells.

The life cycle of most bacteria and archaea is extremely simple: A cell divides, feeds, grows, and divides again. Bacteria and archaea are always haploid.

In contrast, virtually every aspect of a life cycle is variable among protists—whether meiosis occurs, whether asexual reproduction occurs, and whether the haploid or the diploid phase of the life cycle is the longer and more prominent phase.

FIGURE 30.17 illustrates some of this variation. Figure 30.17a depicts the haploid-dominated life cycle observed in many unicellular protists. The specific example given here is the dinoflagellate *Gyrodinium uncatenum*.

To analyze a life cycle, start with **fertilization**—the fusion of two gametes to form a diploid zygote. Then trace what happens to the zygote. In this case, the diploid zygote undergoes meiosis. The haploid products of meiosis then grow into mature cells that eventually undergo asexual reproduction or produce gametes by mitosis and cell division.

Now contrast the dinoflagellate life cycle in Figure 30.17a with the diploid-dominated life cycle in Figure 30.17b. The specific organism shown here is the diatom *Thalassiosira punctigera*. Notice that after fertilization, the diploid zygote develops into a sexually mature, diploid adult cell that can reproduce asexually by dividing mitotically. Meiosis occurs in the adult and results in the formation of haploid gametes, which then fuse to form a diploid zygote. The important contrasts with the

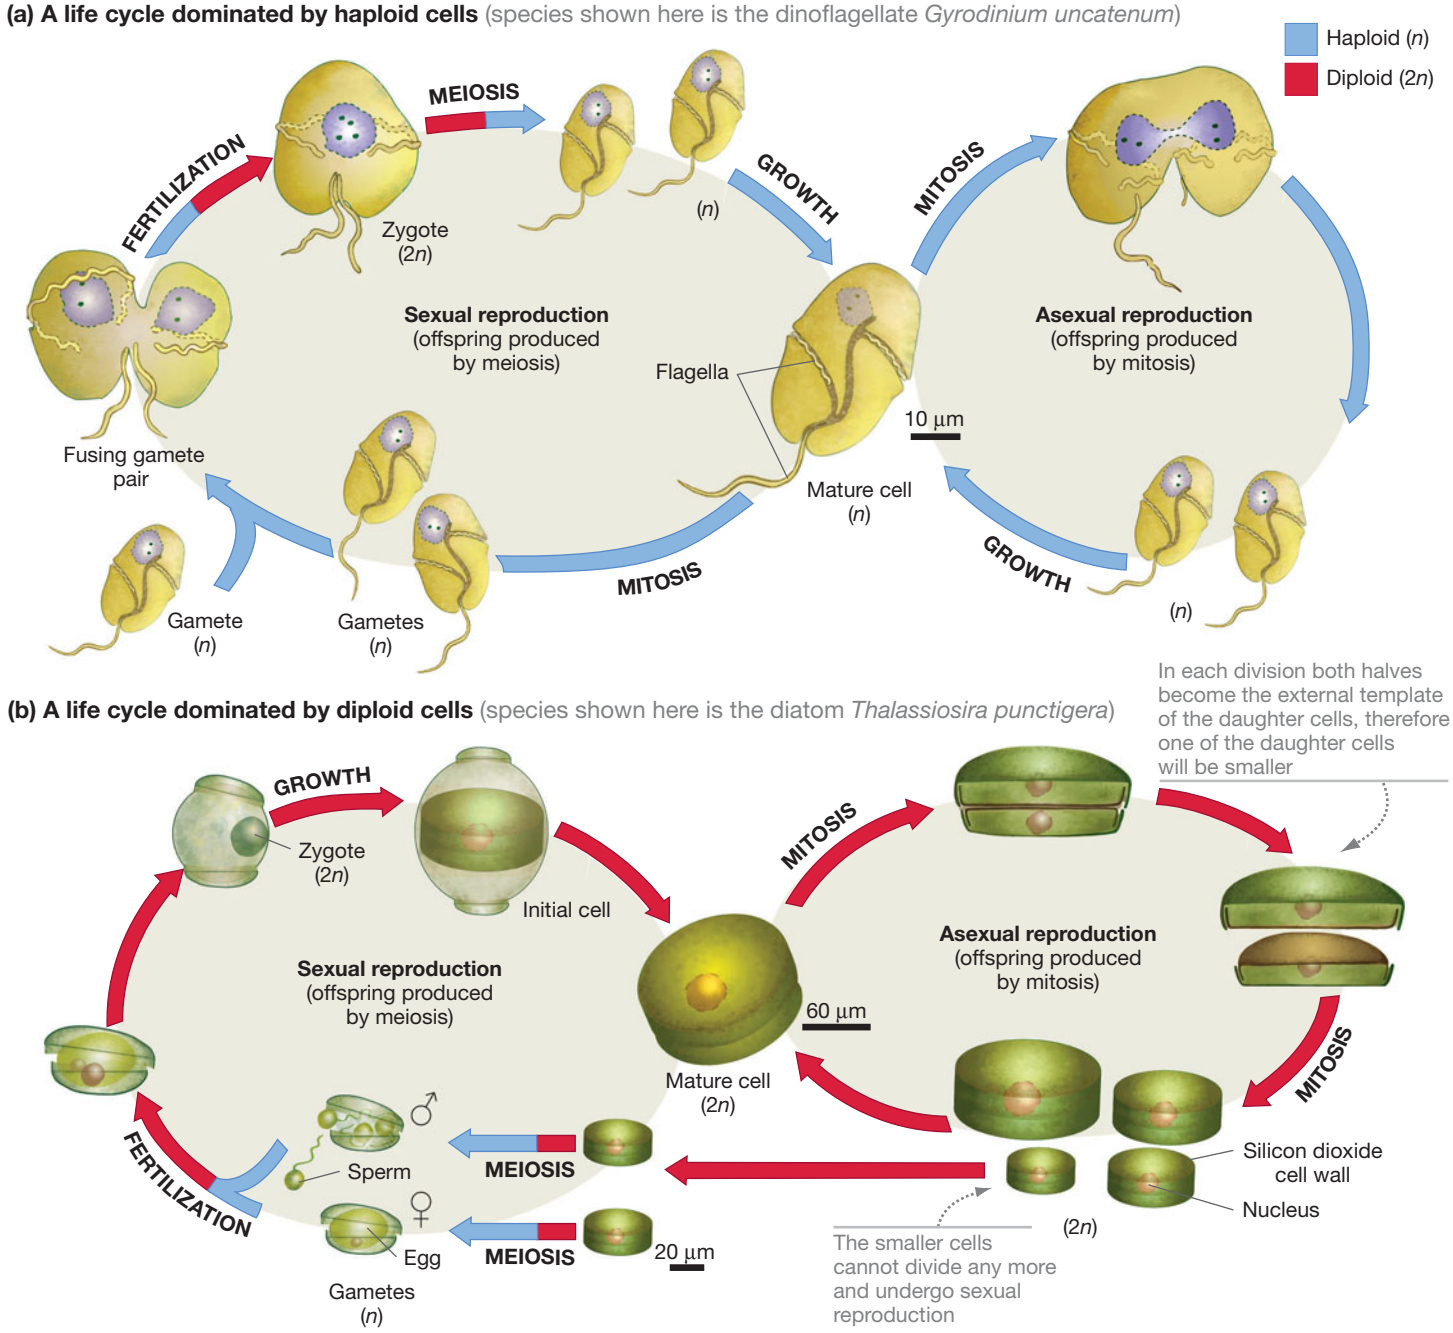

FIGURE 30.17 Life Cycles Vary Widely among Unicellular Protists. Many unicellular protists can reproduce by both sexual reproduction and asexual reproduction. The cell may be **(a)** haploid for most of its life or **(b)** diploid for most of its life.

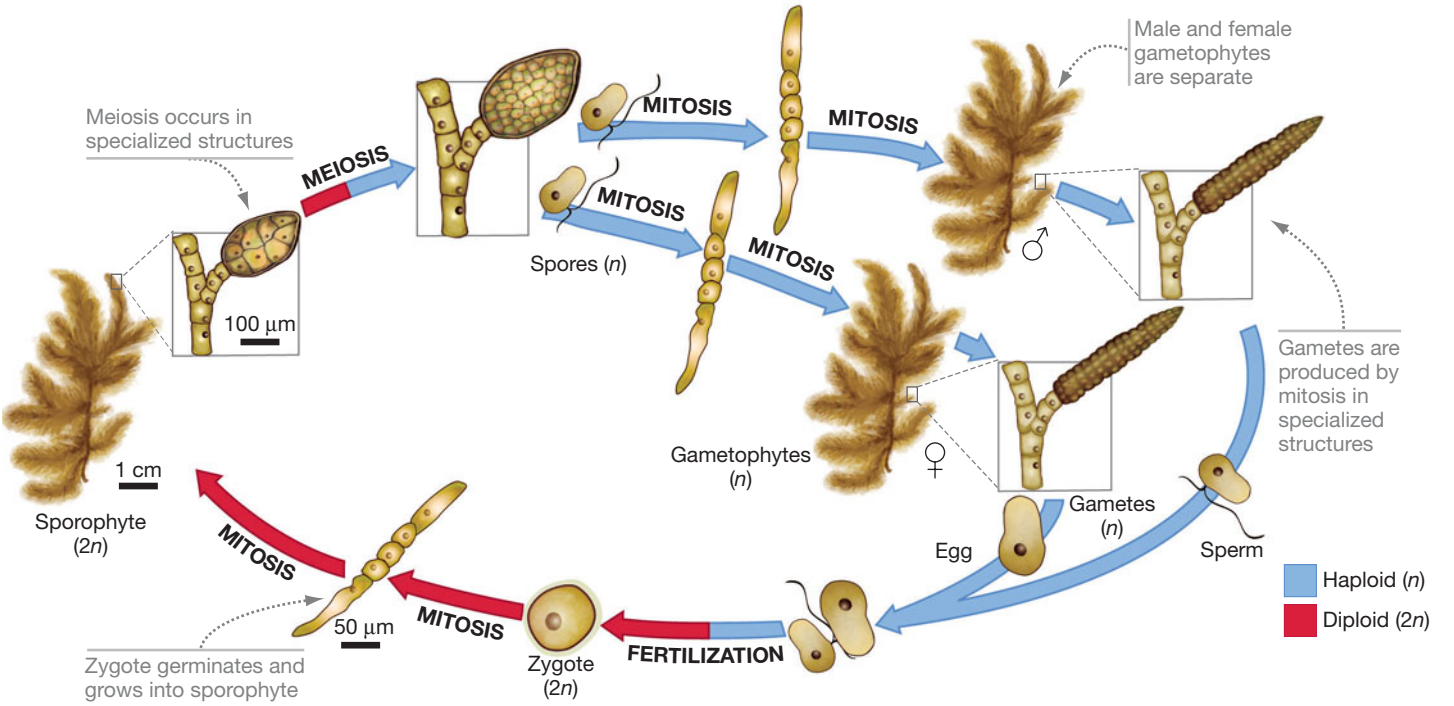
haploid-dominated life cycle are that **(1)** meiosis occurs in the adult cell rather than in the zygote, and **(2)** gametes are the only haploid cells in the life cycle.



Life Cycles—Alternation of Generations In contrast to the relatively simple life cycles of single-celled protists shown in Figure 30.17, many multicellular protists have a multicellular haploid form in one phase of their life cycle alternating with a multicellular diploid form in another phase. This alternation of multicellular haploid and diploid forms is known as **alternation of generations.**

- The multicellular haploid form is called a **gametophyte,** because specialized cells in this individual produce gametes by mitosis and cell division.
- The multicellular diploid form is called a **sporophyte** because it has specialized cells that undergo meiosis to produce haploid cells called spores.
- A **spore** is a single haploid cell that divides mitotically to form a multicellular, haploid gametophyte. A gamete is also a single haploid cell, but its role is to fuse with another gamete to form a zygote.

When alternation of generations occurs, a diploid sporophyte undergoes meiosis and cell division to produce haploid spores. Each spore then divides by mitosis to form a haploid, multicellular gametophyte. The haploid gametes produced mitotically by gametophytes then fuse to form a diploid zygote, which grows into the diploid, multicellular sporophyte.

Gametophytes and sporophytes may be identical in appearance, as in the brown alga called *Ectocarpus siliculosus* (**FIGURE 30.18a**). In many cases, however, the gametophyte and sporophyte look different, as in the brown algae in the genus *Laminaria* (**FIGURE 30.18b**). Among the protists, alternation of generations evolved independently in brown algae, red algae, and other groups.

(a) Alternation of generations in which multicellular haploid and diploid forms look identical (*Ectocarpus siliculosus*)

(b) Alternation of generations in which multicellular haploid and diploid forms look different (*Laminaria* sp.)

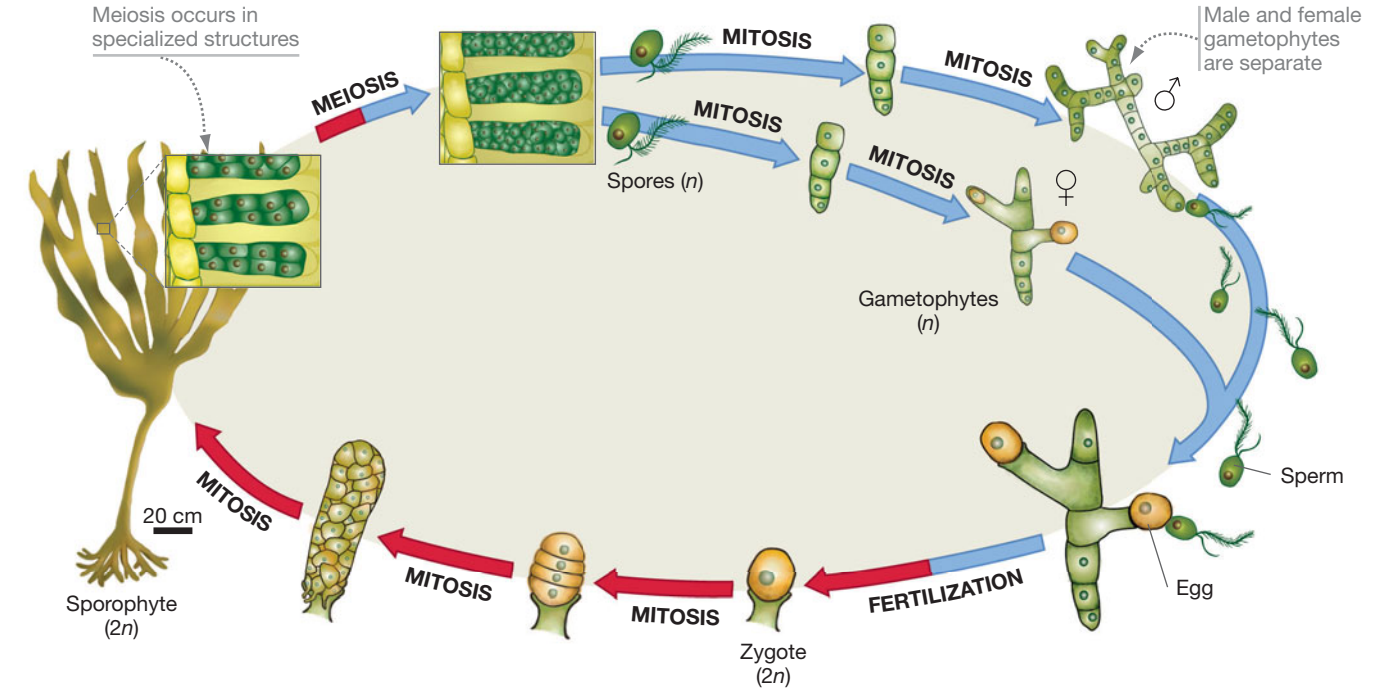


FIGURE 30.18 Alternation of Generations Occurs in Many Multicellular Protists. Compared here, two species of brown algae.

To understand alternation of generations, some students find it helpful to memorize this sentence: Sporophytes produce spores by meiosis; gametophytes produce gametes by mitosis.

✔ If you understand how life cycles vary among multicellular protists, you should be able to (1) define the terms alternation of generations, gametophyte, sporophyte, spore, zygote, and gamete; and (2) diagram a life cycle where alternation of generations occurs, without looking at Figure 30.18.

Why does so much variation occur in the types of life cycles observed among protists? The answer is not known. Variation in life cycles is a major theme in the diversification of protists and is discussed further in the chapter on green algae and land plants (see Chapter 31). Explaining why that variation exists remains a topic for future research.

30.4 Key Lineages of Protists

Each of the seven major Eukarya lineages has at least one distinctive morphological characteristic. But once an ancestor evolved a distinctive cell structure, its descendants diversified into a wide array of lifestyles. For example, parasitic species evolved independently in all seven major lineages. Photosynthetic species exist in most of the seven, and multicellularity evolved independently in at least four. Similar statements could be made about the evolution of life cycles and modes of locomotion.

In effect, each of the seven lineages represents a similar radiation of species into a wide array of lifestyles. Let's take a more detailed look at some representative taxa from six of the seven major lineages, starting with an overview of each one. The seventh major lineage—the opisthokonts—is featured in the chapters on fungi and the animals (see Chapters 32–35). The lineage called green plants is analyzed separately (see Chapter 31).

Amoebozoa

Species in the Amoebozoa lack cell walls and take in food by engulfing it. They move via amoeboid motion and produce large, lobe-like pseudopodia. They are abundant in freshwater habitats and in wet soils; some are parasites of humans and other animals.

Major subgroups in the lineage are lobose amoebae, cellular slime molds, and plasmodial slime molds. The cellular slime mold *Dictyostelium discoideum* is described in detail in **BioSkills 13** in Appendix B. **✔ You should be able to mark the origin of this lineage's amoeboid form on Figure 30.7 and explain whether it evolved independently of the amoeboid form in Rhizaria.**

- Amoebozoa > Plasmodial Slime Molds

Excavata

The unicellular species that form the Excavata are named for the morphological feature that distinguishes them—an "excavated" feeding groove found on one side of the cell. Because some lack recognizable mitochondria, excavates were once thought to trace their ancestry to eukaryotes that existed before the origin of mitochondria. But researchers have found that excavates either have **(1)** genes in their nuclear genomes that are of mitochondrial origin, or **(2)** unusual organelles that appear to be vestigial mitochondria. These observations support the hypothesis that the ancestors of excavates had mitochondria, but that these organelles were lost or reduced over time in this lineage. **✔ You should be able to mark the loss of the mitochondrion on Figure 30.7.**

- Excavata > Parabasalids, Diplomonads, and Euglenids

Plantae

Biologists are beginning to use the name **Plantae** to refer to the monophyletic group that includes glaucophyte algae, red algae, green algae, and land plants.

The glaucophyte algae are unicellular or colonial. They live as plankton or attached to substrates in freshwater environments—particularly in bogs or swamps. Some glaucophyte species have flagella or produce flagellated spores, but sexual reproduction has never been observed in the group. The chloroplasts of glaucophytes have a distinct bright blue-green color.

All subgroups within Plantae are descended from a common ancestor that engulfed a cyanobacterium, beginning the endosymbiosis that led to the evolution of the chloroplast—their distinguishing morphological feature. This initial endosymbiosis probably occurred in an ancestor of today's glaucophyte algae. To support this hypothesis, biologists point to several important similarities between cyanobacterial cells and the chloroplasts that are found in the glaucophytes.

- Both have cell walls that contain peptidoglycan and that can be disrupted by the antibacterial compounds lysozyme and penicillin.
- The glaucophyte chloroplast also has a membrane outside its wall that is similar to the membrane found in Gram-negative bacteria (see Chapter 29).

Consistent with these observations, phylogenetic analyses of DNA sequence data place the glaucophytes as the sister group to all other members of the Plantae. **✔ You should be able to mark the origin of the plant chloroplast on Figure 30.7.**

Green algae and land plants are described later (see Chapter 31); here we consider just the red algae in detail.

- Plantae > Red Algae

Rhizaria

The rhizarians are single-celled amoebae that lack cell walls, though some species produce elaborate shell-like coverings. They move by amoeboid motion and produce long, slender pseudopodia. Over 11 major subgroups in this lineage have been identified and named, including the planktonic organisms called actinopods—which synthesize glassy, silicon-rich skeletons—and the chlorarachniophytes, which obtained a chloroplast via secondary endosymbiosis and are photosynthetic. The best-studied and most abundant group is the foraminiferans. **✔ You should be able to mark the origin of the rhizarian amoeboid form on Figure 30.7.**

- Rhizaria > Foraminiferans

Alveolata

Alveolates are distinguished by small sacs, called alveoli, that are located just under their plasma membranes. Although all members of this lineage are unicellular, the ciliates, the dinoflagellates, and the apicomplexans are remarkably diverse in morphology and lifestyle. ✔ **You should be able to mark the origin of alveoli on Figure 30.7.**

- Alveolata > Ciliates, Dinoflagellates, and Apicomplexans

Stramenopila (Heterokonta)

Stramenopiles are sometimes called heterokonts, which translates as "different hairs." At some stage of their life cycle, all stramenopiles have flagella that are covered with distinctive hollow "hairs." The structure of these flagella is unique to the stramenopiles (Figure 30.6). ✔ **You should be able to mark the origin of the "hairy" flagellum on Figure 30.7.** The lineage includes a large number of unicellular forms, although the brown algae are multicellular and include the world's tallest marine organisms, the kelp.

- Stramenopila > Water Molds, Diatoms, and Brown Algae

Amoebozoa > Plasmodial Slime Molds

The plasmodial slime molds got their name because individuals form a large, weblike structure that consists of a single cell containing thousands of diploid nuclei (**FIGURE 30.19**). Like water molds, the plasmodial slime molds were once considered fungi on the basis of their general morphological similarity (see Chapter 32).

Morphology The huge "supercell" form, with many nuclei in a single cell, occurs in few protists other than plasmodial slime molds. ✔ **You should be able to mark the origin of the supercell on Figure 30.7.**

Feeding and locomotion Plasmodial slime molds feed on microorganisms associated with decaying vegetation and move by amoeboid motion or cytoplasmic streaming.

Reproduction Some evidence suggests that when food becomes scarce, part of the amoeba forms a stalk topped by a ball-like structure in which nuclei undergo meiosis and form spores. The spores are then dispersed to new habitats by the wind or small animals. After spores germinate to form amoebae, two amoebae fuse to form a diploid cell that begins to feed and eventually grows into a supercell.

Human and ecological impacts Like cellular slime molds, plasmodial slime molds influence nutrient cycling by feeding on microorganisms. Some species are important model organisms for the study of cell biology and the origin of multicellularity.

Physarum polycephalum

FIGURE 30.19 Plasmodial Slime Molds Are Important Decomposers in Forests.

The lineage Excavata includes free-living and symbiotic species, and some that are parasites. All are single-celled, and many lack functional mitochondria.

All of the 300 known species of parabasalids live inside animals; some live only in the guts of termites, where they aid in the digestion of cellulose. The relationship between termites and parabasalids is considered mutualistic, because both parties benefit from the symbiosis.

About 100 species of diplomonads have been named. Many live in the guts of animal species without causing harm to their host; other species live in stagnant-water habitats.

There are about 1000 known species of euglenids. Although most live in freshwater, a few are found in marine habitats.

Morphology Parabasalid cells have a distinctive rod of cross-linked microtubules that runs the length of the cell. The rod is attached to the basal bodies where a cluster of flagella arise (**FIGURE 30.20**). Diplomonad cells have two nuclei, which resemble eyes when viewed under the microscope (**FIGURE 30.21**). Each nucleus is associated with four flagella, for a total of eight flagella per cell. Euglenid cells have a unique system of interlocking proteins just inside the plasma membrane that stiffen and support the cell. Some euglenid cells have a light-sensitive "eyespot" and use flagella to swim toward light (**FIGURE 30.22**).

Feeding and locomotion Some euglenids have chloroplasts and perform photosynthesis, and some diplomonads are parasitic, but most other members of the Excavata feed by engulfing bacteria, archaea, and organic matter. Most swim using their flagella. ✔ **You should be able to explain how the observation of ingestive feeding in euglenids relates to the hypothesis that this lineage gained chloroplasts via secondary endosymbiosis.**

Trichomonas vaginalis

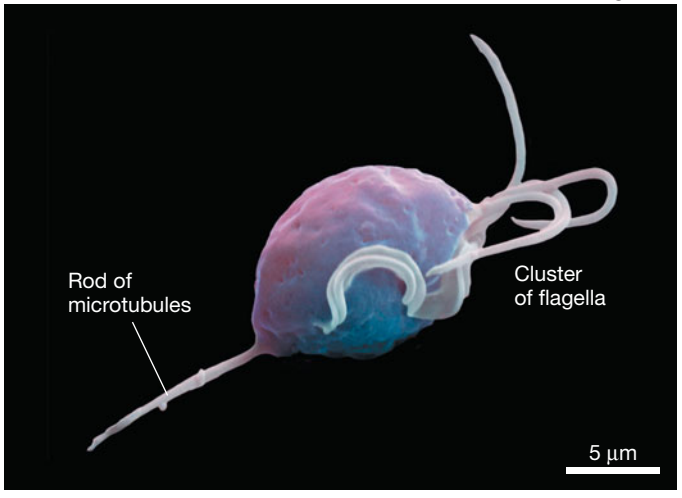

FIGURE 30.20 *Trichomonas* Causes the Sexually Transmitted Disease Trichomoniasis. The cell in this micrograph has been colorized.

Giardia intestinalis

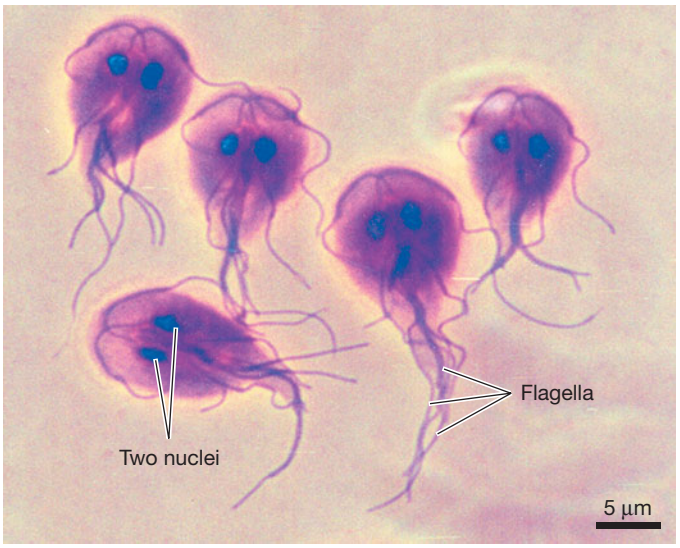

FIGURE 30.21 *Giardia* Causes Intestinal Infections in Humans.

Reproduction Nearly all members of the Excavata are known to reproduce only asexually. Sexual reproduction has been observed in just a few species of parabasalids.

Human and ecological impacts Infections of *Trichomonas*, a parabasalid, can sometimes cause reproductive tract problems in humans. However, members of this genus may also live in the gut or mouth of humans without causing harm. The diplomonad *Giardia intestinalis* is a common intestinal parasite in humans and causes giardiasis, or beaver fever. Euglenids are important components of freshwater plankton and food chains.

Euglena velata

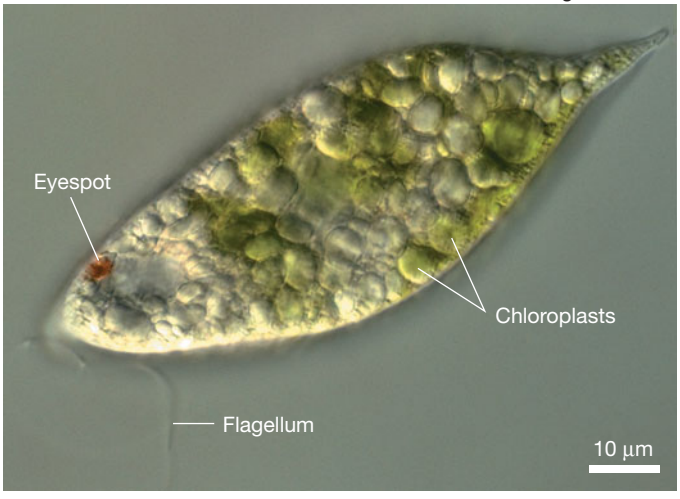

FIGURE 30.22 Euglenids Are Common in Ponds and Lakes.

Plantae > Red Algae

The 6000 species of red algae live primarily in marine habitats. One species lives over 200 m below the surface; another is the only eukaryote capable of living in acidic hot springs. Although their color varies, many species are red because their chloroplasts contain large amounts of the accessory pigment phycoerythrin, which absorbs strongly in the blue and green portions of the visible spectrum. Because blue light penetrates water better than other wavelengths, red algae are able to live at considerable depth in the oceans. ✔ **You should be able to mark the origin of high phycoerythrin concentrations on Figure 30.7.**

Morphology Red algae cells have walls that are composed of cellulose and other polymers. A few species are unicellular, but most are multicellular. Many of the multicellular species are filamentous; others grow as thin, hard crusts on rocks or coral. Some species have erect, leaf-like structures called thalli (**FIGURE 30.23**).

Feeding and locomotion The vast majority of red algae are photosynthetic, though a few parasitic species have been identified. Red algae are the only type of algae that lack flagella.

Reproduction Asexual reproduction occurs through production of spores by mitosis. Alternation of generations is common, but the types of life cycles observed in red algae are extremely variable.

Human and ecological impacts On coral reefs, some red algae become encrusted with calcium carbonate. These species contribute to reef building and help stabilize the entire reef structure. Cultivation of *Porphyra* (or nori) for sushi and other foods is a billion-dollar-per-year industry in East Asia. Microbiological agar is also derived from the cell walls of various species of red algae.

Mesophyllum lichenoides

FIGURE 30.23 Red Algae Adopt an Array of Growth Forms.

Rhizaria > Foraminiferans

Foraminiferans, or forams, got their name from the Latin *foramen*, meaning "hole." Forams produce shells that have holes (see **FIGURE 30.24**) through which pseudopodia emerge. ✔ **You should be able to mark the origin of the foram shell on Figure 30.7.** Fossil shells of foraminifera are abundant in marine sediments—a continuous record of fossilized forams dates back 530 million years. A foram species was recently found living in sediments at a depth of 11,000 m below sea level. They are abundant in marine plankton as well as bottom habitats.

Morphology Foraminiferan cells generally have multiple nuclei. The shells of forams are usually made of organic material stiffened with calcium carbonate ($CaCO_3$), and most species have several chambers. One species known from fossils was 12 cm long, but most species are much smaller. The size and shape of the shell are traits that distinguish foram species from each other.

Feeding and locomotion Like other rhizarians, forams feed by extending their pseudopodia and using them to capture and engulf bacterial and archaeal cells or bits of organic debris, which are digested in food vacuoles. Some species have symbiotic algae that perform photosynthesis and contribute sugars to their host. Forams do not move actively but simply float in the water.

Reproduction Members of the foraminifera reproduce asexually by mitosis. When meiosis occurs, the resulting gametes are released into the open water, where pairs fuse to form new diploid individuals.

Human and ecological impacts The shells of dead forams commonly form extensive sediment deposits when they settle out of the water, producing layers that eventually solidify into chalk, limestone, or marble. Geologists use the presence of certain foram species to date rocks—particularly during petroleum exploration.

Globigerinoides ruber

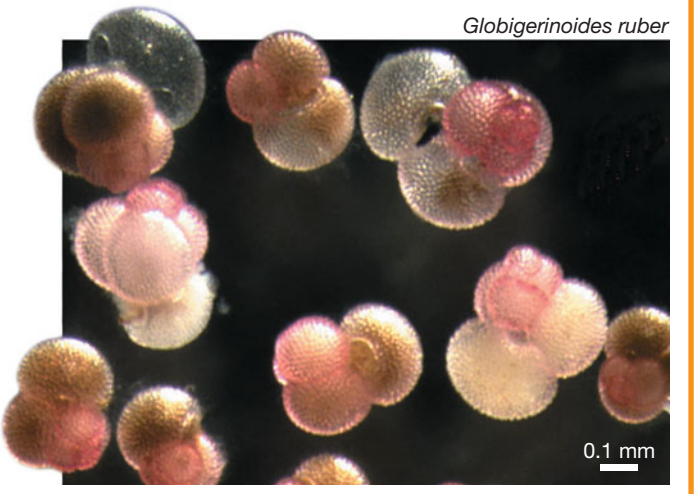

FIGURE 30.24 Forams Are Shelled Amoebae.

Members of the lineage Alveolata comprise three subgroups of single-celled species that are diverse in morphology and nutrition. All alveolates contain flattened, membrane-bound vesicles called alveoli that support the plasma membrane.

Ciliates are named for the cilia that cover them. Some 12,000 species are known from freshwater, marine, and wet soil environments. Most of the 4000 known species of dinoflagellates are marine or freshwater plankton. All of the 5000 known species of apicomplexans are parasitic.

Morphology Ciliate cells have two distinctive nuclei: a polyploid macronucleus that is actively transcribed and a diploid micronucleus that is involved only in gene exchange between individuals (both are stained dark red in **FIGURE 30.25**). ✔ **You should be able to mark the origin of the macronucleus/micronucleus structure on Figure 30.7.**

Each dinoflagellate species has a distinct shape, in some species maintained by cellulose plates. Apicomplexan cells lack cilia or flagella.

Feeding and locomotion Ciliates may be filter feeders, predators, or parasites. They use cilia to swim and have a mouth area where food is ingested. About half of the dinoflagellates are photosynthetic. They are distinguished by the arrangement of their two flagella, which allows them to swim in a spinning motion: One flagellum projects out from the cell while the other runs around the cell. Some dinoflagellate species are capable of **bioluminescence,** meaning they emit light via an enzyme-catalyzed reaction (**FIGURE 30.26**). Being parasitic, all apicomplexans absorb nutrition directly from their host. Some species can move by amoeboid motion.

Reproduction Ciliates undergo an unusual type of gene exchange called conjugation, in which micronuclei are passed between individuals. Both asexual and sexual reproduction occur in dinoflagellates. In some apicomplexan species, the life cycle involves two distinct hosts, and cells must be transmitted from one host to the next.

Human and ecological impacts Ciliates are abundant marine plankton and are also common in the digestive tracts of mammalian grazers, where they feed on plant matter and help the host animal digest it. Photosynthetic dinoflagellates are important primary producers in marine ecosystems. A few species are responsible for harmful algal blooms (see Figure 30.4). Apicomplexan species in the genus *Plasmodium* cause malaria. *Toxoplasma* is an important pathogen in people infected with HIV (**FIGURE 30.27**).

Noctiluca scintillans

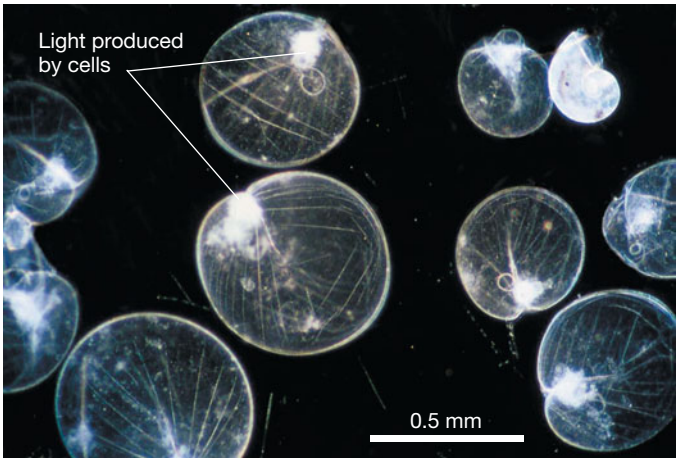

FIGURE 30.26 Some Dinoflagellate Species Are Bioluminescent.

Toxoplasma gondii

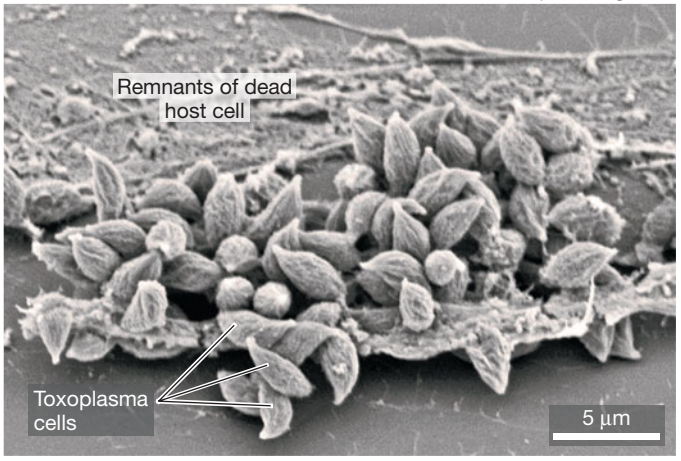

FIGURE 30.27 *Toxoplasma* Causes Infections in AIDS Patients.

The stramenopiles are a large and morphologically diverse group of eukaryotes. They include parasitic, saprophytic, and photosynthetic species, and they range in size from tiny, single-celled members to some of the largest multicellular organisms in the oceans.

Several morphological features are shared among the subgroups of stramenopiles, including flagella that are covered with tiny, hollow projections (see Figure 30.6). Photosynthetic diatoms and brown algae contain chloroplasts that originated from a secondary endosymbiosis involving a red alga (see Figure 30.13).

Morphology Some water molds are unicellular and some form long, branching filaments called **hyphae** (**FIGURE 30.28**). Most diatoms are unicellular (**FIGURE 30.29**), often in a box-and-lid arrangement (see Figure 30.11a). All species of brown algae are multicellular; the body typically consists of leaflike blades, a stalk known as a stipe, and a rootlike holdfast (**FIGURE 30.30**). ✔ **You should be able to mark the origin of brown algal multicellularity on Figure 30.7.**

Phytophthora infestans

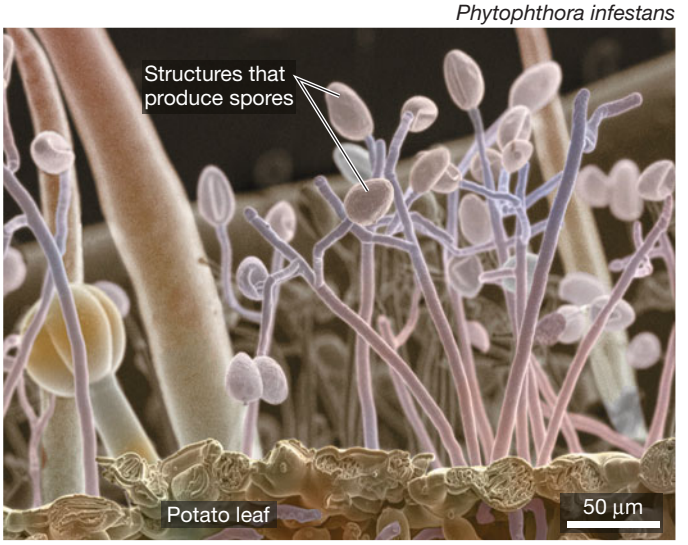

FIGURE 30.28 *Phytophthora Infestans* Infects Potatoes. This is a colorized scanning electron micrograph.

Isthmia nervosa

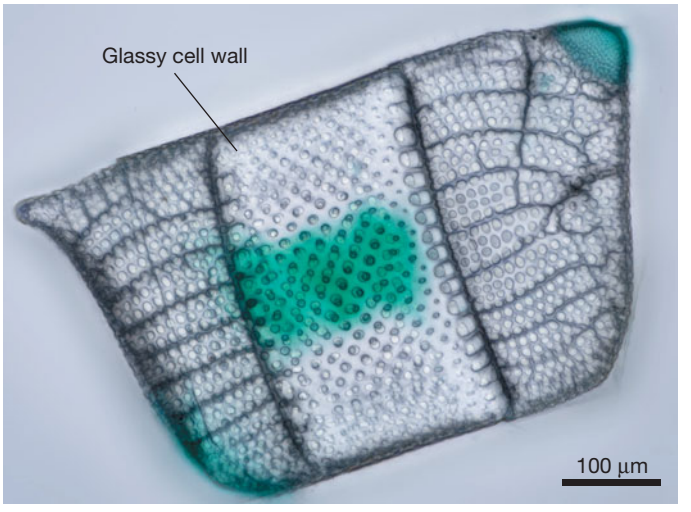

FIGURE 30.29 Diatoms Have Glass-Like Cell Walls.

Feeding and locomotion Most species of water molds feed on decaying organic material; a few are parasitic. Mature individuals are **sessile**—that is, permanently fixed to a substrate. Both diatoms and brown algae are photosynthetic, but diatoms are planktonic whereas brown algae are sessile.

Reproduction Many species of stramenopiles exhibit diploid-dominant life cycles. Several produce spores via asexual or sexual reproduction. Water mold spores form in special structures, like those shown in Figure 30.28. Most species of brown algae exhibit alternation of generations.

Human and ecological impacts Water molds are extremely important decomposers in freshwater ecosystems. Parasitic forms that affect humans indirectly include the organism that caused the Irish potato famine. Other water mold species are responsible for epidemic diseases of trees, including the diebacks currently occurring in oaks.

Diatoms are considered the most important primary producer in fresh and salt water. Their glassy cell walls settle into massive accumulations that are mined and sold as diatomaceous earth, which is used in filtering applications and as an ingredient in polishes, paint, cosmetics, and other products.

In many coastal areas with cool water, brown algae form kelp forests that are important habitats for a wide variety of animals.

Durvillaea potatorum

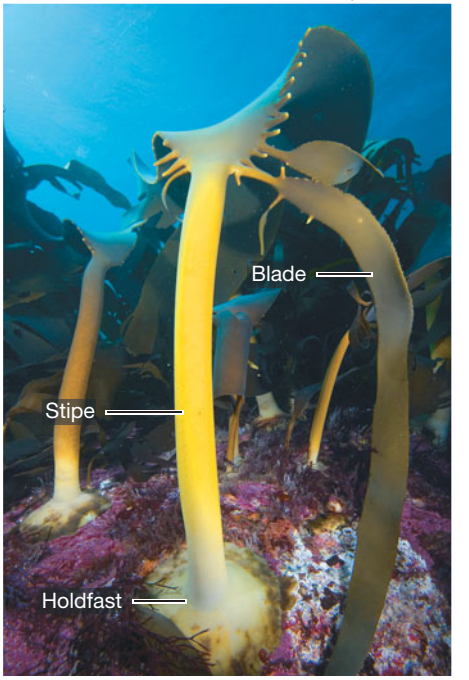

FIGURE 30.30 Many Brown Algae Have a Holdfast, Stalk (Stipe), and Leaflike Blades.

If you understand . . .

30.1 Why Do Biologists Study Protists?

- Protists include all eukaryotes except the land plants, fungi, and animals.
- Protists are often tremendously abundant in marine and freshwater plankton and other habitats. Protists provide food for many organisms in aquatic ecosystems and fix so much carbon that they have a large impact on the global carbon budget.
- Parasitic protists cause several important diseases in humans, including malaria.
- Toxin-producing protists that grow to high densities can result in a harmful algal bloom.

✔ **You should be able to explain what is "primary" about primary production by photosynthetic protists.**

30.2 How Do Biologists Study Protists?

- Microscopic investigation of protists led to the understanding that many are single celled. Unlike bacteria, they contain mitochondria, a nucleus and endomembrane system, and a cytoskeleton.
- Direct sequencing has revealed important new groups of protists.
- Phylogenies based on molecular data confirmed that there are seven major lineages of protists and that the group is paraphyletic.

✔ **You should be able to describe the major differences between eukaryotic cells and prokaryotic cells.**

30.3 What Themes Occur in the Diversification of Protists?

- The first eukaryote probably resulted from an ancient endosymbiosis that occurred when a prokaryotic host cell (likely an archaeal cell) engulfed an α-proteobacterium. This bacterium evolved into today's mitochondria.
- The nuclear envelope probably evolved to spatially separate the processes of transcription and translation.
- Multicellularity evolved in several different protist groups independently.
- Protists vary widely in the way they obtain food. They exhibit predatory, parasitic, or photosynthetic lifestyles, which evolved in many groups independently.
- The evolution of ingestive feeding was important for two reasons: **(1)** It allowed eukaryotes to obtain resources in a new way—by eating bacteria, archaea, and other eukaryotes; and **(2)** it made endosymbiosis and the evolution of mitochondria and chloroplasts possible.
- The chloroplast's size and its circular chromosome, ribosomes, and double membrane are consistent with the hypothesis that this organelle originated as an endosymbiotic cyanobacterium.
- After primary endosymbiosis occurred, chloroplasts were "passed around" to new lineages of protists via secondary endosymbiosis.
- Protists vary widely in the way they reproduce. They undergo cell division based on mitosis and reproduce asexually. Many protists also undergo meiosis and sexual reproduction at some phase in their life cycle.
- Alternation of generations is common in multicellular protist species—meaning the same species has separate haploid and diploid forms. When alternation of generations occurs, haploid gametophytes produce gametes by mitosis; diploid sporophytes produce spores by meiosis.

✔ **You should be able to explain the original source of (1) the two membranes in a plant chloroplast and (2) the four membranes in the chloroplast-derived organelle of *Plasmodium*.**

30.4 Key Lineages of Protists

- Protists are a highly diverse group of eukaryotic species organized into seven lineages.
- Protist lineages are defined by DNA sequence evidence and morphological traits such as the presence of chloroplasts or unique flagella.
- A wide range of traits including parasitism, autotrophy, and multicellularity evolved independently in several different lineages of protists.

TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. Why are protists considered paraphyletic?
   a. They include many extinct forms, including lineages that no longer have any living representatives.
   b. They include some but not all descendants of their most recent common ancestor.
   c. They represent all of the descendants of a single common ancestor.
   d. Not all protists have all of the synapomorphies that define the Eukarya, such as a nucleus.
2. What material is *not* used by protists to manufacture hard outer coverings?
   a. cellulose
   b. lignin
   c. glass-like compounds that contain silicon
   d. mineral-like compounds such as calcium carbonate ($CaCO_3$)
3. What does amoeboid motion result from?
   a. interactions among actin, myosin, and ATP
   b. coordinated beats of cilia
   c. the whiplike action of flagella
   d. action by the mitotic spindle, similar to what happens during mitosis and meiosis
4. According to the endosymbiosis theory, what type of organism is the original ancestor of the chloroplast?
   a. a photosynthetic archaean
   b. a cyanobacterium
   c. an algal-like, primitive photosynthetic eukaryote
   d. a modified mitochondrion
5. True or False: All protists are unicellular.
6. The most important primary producers in marine ecosystems are _____.

TEST YOUR UNDERSTANDING

Answers are available in Appendix A

7. Which of the following is true of the parasite that causes malaria in humans?
   a. It undergoes meiosis immediately following zygote formation.
   b. It is a complex prokaryote.
   c. It makes gametes by meiosis.
   d. It has a diploid-dominant life cycle.
8. Explain the logic behind the claim that the nuclear envelope is a synapomorphy that defines eukaryotes as a monophyletic group.
9. Consider the endosymbiosis theory for the origin of the mitochondrion. What did each partner provide the other, and what did each receive in return?
10. Why was finding a close relationship between mitochondrial DNA and bacterial DNA considered particularly strong evidence in favor of the endosymbiosis theory?
11. The text claims that the evolutionary history of protists can be understood as a series of morphological innovations that established seven distinct lineages, each of which subsequently diversified based on innovative ways of feeding, moving, and reproducing. Explain how the Alveolata support this claim.

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A

12. Multicellularity is defined in part by the presence of distinctive cell types. At the cellular level, what does this criterion imply?
    a. Individual cells must be extremely large.
    b. The organism must be able to reproduce sexually.
    c. Cells must be able to move.
    d. Different cell types express different genes.
13. Consider the following:
    - *Plasmodium* has an unusual organelle called an apicoplast. Recent research has shown that apicoplasts are derived from chloroplasts via secondary endosymbiosis and have a large number of genes related to chloroplast DNA.
    - Glyphosate is one of the most widely used herbicides. It works by poisoning an enzyme located in chloroplasts.
    - Biologists are testing the hypothesis that glyphosate could be used as an antimalarial drug in humans.

    How are these observations connected?
14. Suppose a friend says that we don't need to worry about the rising temperatures associated with global climate change. Her claim is that increased temperatures will make planktonic algae grow faster and that carbon dioxide (CO_2) will be removed from the atmosphere faster. According to her, this carbon will be buried at the bottom of the ocean in calcium carbonate shells. As a result, the amount of carbon dioxide in the atmosphere will decrease and global warming will decline. Comment.
15. Biologists are beginning to draw a distinction between "species trees" and "gene trees." A species tree is a phylogeny that describes the actual evolutionary history of a lineage. A gene tree, in contrast, describes the evolutionary history of one particular gene, such as a gene required for the synthesis of chlorophyll *a*. In some cases, species trees and gene trees don't agree with each other. For example, the species tree for green algae indicates that their closest relatives are protists and plants. But the gene tree based on chlorophyll *a* from green algae suggests that this gene's closest relative is a bacterium, not a protist. What's going on? Why do these types of conflicts exist?

31 Green Algae and Land Plants

In this chapter you will learn that

Adaptations allowed Green Algae and Land Plants to colonize and dominate the land

- asking → Why and how do biologists study these organisms? **31.1, 31.2**
- examining → Major themes in their diversification **31.3**
  - looking more closely at → Key lineages of green algae and land plants **31.4**
  - focusing on → The transition to life on land
    - Controlling water loss
    - Surviving intense sunlight
    - Growing upright in air
    - Reproducing without water
    - Using animals to carry pollen and seeds

Earth has been called the Blue Planet, but it would be just as accurate to call it the Green Planet.

In terms of their total mass and their importance to other organisms, the green plants dominate terrestrial and freshwater habitats. When you walk through a forest or meadow, you are surrounded by green plants. If you look at pond or lake water under a microscope, green plants are everywhere.

The green plants comprise two major types of organisms: the green algae and the land plants. Green algae are important photosynthetic organisms in aquatic habitats—particularly lakes, ponds, and other freshwater settings. Land plants are the key photosynthesizers in terrestrial environments.

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

Although green algae have traditionally been considered protists, it is logical to study them along with land plants for two reasons: **(1)** They are the closest living relatives to land plants and form a monophyletic group with them, and **(2)** the transition from aquatic to terrestrial life occurred when land plants evolved from green algae.

Land plants were the first organisms that could thrive with their tissues completely exposed to the air instead of being partially or completely submerged. Before they evolved, likely the only life on the continents consisted of bacteria, archaea, and single-celled protists that thrive in wet soils. By colonizing the continents, plants transformed the nature of life on Earth. It was, in the words of plant evolutionist Karl Niklas, "One of the greatest adaptive events in the history of life." Land plants made the Earth green.

31.1 Why Do Biologists Study the Green Algae and Land Plants?

Biologists study the green plants because they are fascinating, and because we couldn't live without them. Along with most other animals and fungi, humans are almost completely dependent on land plants for food. People rely on plants for other necessities of life as well—oxygen, fuel, the fibers used to make clothing and other products, building materials, and pharmaceuticals. But we also rely on land plants for important intangible value such as the aesthetic appeal of landscaping and bouquets. To drive this point home, consider that the sale of cut flowers generates over $1 billion each year in the United States alone.

Based on these observations, it is not surprising that agriculture, forestry, and horticulture are among the most important endeavors supported by biological science. Tens of thousands of biologists are employed in research designed to better understand plants, to increase their productivity, and to create new ways of using them for the benefit of people. Research programs also focus on two types of land plants that cause problems for people: weeds that decrease the productivity of crop plants, and newly introduced species that invade and then degrade natural areas.

Plants Provide Ecosystem Services

An **ecosystem** consists of all the organisms in a particular area, along with physical components of the environment such as the atmosphere, precipitation, surface water, sunlight, soil, and nutrients. Green algae and land plants provide **ecosystem services** because they enhance the life-supporting attributes of the atmosphere, surface water, soil, and other physical components of an ecosystem. Green plants alter the environment in ways that benefit many other organisms.

Plants Produce Oxygen Recall that plants perform oxygenic (literally, "oxygen-producing") photosynthesis (see Chapter 10). In this process, electrons that are removed from water molecules are used to reduce carbon dioxide (CO_2). In the process of stripping electrons from water, plants release oxygen molecules (O_2) as a by-product.

Oxygenic photosynthesis evolved in cyanobacteria and was responsible for the origin of an oxygen-rich atmosphere (see Chapter 29). The evolutionary success of plants continued this trend because plants add huge amounts of oxygen to the atmosphere.

Without the green plants, we and other aerobic organisms would be in danger of suffocating for lack of oxygen.

Plants Build and Hold Soil Fallen leaves, roots, and stems that are not eaten when they are alive provide food for worms, fungi, bacteria, archaea, protists, and other decomposers in the soil. These organisms add organic matter to the soil, which changes the soil structure and the ability of soils to hold nutrients and water. These changes are beneficial to other organisms.

The extensive network of fine roots produced by trees, grasses, and other land plants helps hold soil particles in place. And by taking up nutrients in the soil, plants prevent the nutrients from being blown or washed away.

When areas are devegetated by grazing, farming, logging, or suburbanization, large quantities of soil and nutrients are lost to erosion by wind and water (**FIGURE 31.1**).

Plants Hold Water and Moderate Climate Plant tissues take up and retain water. Intact forests, prairies, and wetlands also prevent rain from quickly running off a landscape: Plant leaves soften the physical impact of rainfall on soil, and plant organic matter builds the soil's water-holding capacity.

By providing shade, plants reduce temperatures beneath them and increase relative humidity. They also reduce the impact of winds that dry out landscapes.

When plants are removed from landscapes to make way for farms or suburbs, habitats become much drier and are subject to more extreme temperature swings.

Plants are Primary Producers Land plants are the dominant primary producers in terrestrial ecosystems. Primary producers convert energy in sunlight into chemical energy (see Chapter 30). The

FIGURE 31.1 Devegetation Leads to Erosion.

sugars that land plants produce by photosynthesis support virtually all of the other organisms present in terrestrial habitats.

Plants are eaten by herbivores ("plant-eaters"), which range in size from insects to elephants. These consumers are eaten by carnivores ("meat-eaters"), ranging in size from the tiniest spiders to polar bears. Humans are an example of omnivores ("all-eaters"), organisms that eat both plants and animals. Omnivores feed at several different levels in the food chain. For example, people consume plants, herbivores such as chicken and cattle, and carnivores such as salmon and tuna.

Because of their role in primary production, land plants are the key to the carbon cycle on the continents. Plants take CO_2 from the atmosphere and reduce it to make sugars. Although green algae and land plants also produce a great deal of CO_2 as a result of cellular respiration, they fix much more CO_2 than they release.

The loss of plant-rich prairies and forests due to suburbanization or conversion to agriculture has contributed to increased concentrations of CO_2 in the atmosphere. Higher carbon dioxide levels, in turn, are partly responsible for the rising temperatures associated with global climate change (see Chapter 56).

Plants Provide Humans with Food, Fuel, Fiber, Building Materials, and Medicines

It is difficult to overstate the importance of plant research to the well-being of human societies. Plants provide our food supply as well as a significant percentage of the fuel, fibers, building materials, and medicines that we use.

Food Agricultural research began with the initial domestication of crop plants, which occurred independently at several locations around the world starting about 12,000 years ago (**FIGURE 31.2a**). By actively selecting individuals with the largest and most nutritious seeds, leaves, or other plant parts year after year, our ancestors gradually changed the characteristics of certain wild species. This process is called **artificial selection** (see Chapter 25).

FIGURE 31.2b compares kernel size in modern maize and its wild ancestor—a grass called teosinte that is native to Central America. Artificial selection has been responsible for dramatic increases in the protein content of maize kernels over the past 100 years (see data in Chapter 1). A current focus in agricultural research is the improvement of crop varieties through genetic engineering (see Chapter 20).

Fuel For perhaps 100,000 years, wood burning was the primary source of energy used by all humans. Wood has now been replaced in the industrialized countries by fossil fuels, including coal and petroleum or natural gas. Each of these forms of energy, however, is derived from plants that either grew during our lifetime or when dinosaurs roamed the earth.

Starting in the mid-1800s, people in England, Germany, and the United States began to mine coal deposits that originally formed during the Carboniferous period some 359–299 million years ago. The coal fueled blast furnaces that smelted vast quantities of iron ore into steel and powered the steam engines that sent trains

(a) Plants were domesticated at an array of locations.

(b) Artificial selection changes the traits of domesticated species.

FIGURE 31.2 Crop Plants Are Derived from Wild Species via Artificial Selection. (a) Crop plants have originated on virtually every continent. **(b)** In some cases, artificial selection has changed domesticated species so radically that they bear little resemblance to their wild ancestors.

streaking across Europe and North America. It is no exaggeration to claim that the organic compounds synthesized by plants more than 300 million years ago fueled the industrial revolution.

Coal still supplies about 20 percent of the energy used in Japan and Western Europe and 80 percent of the energy used in China. Current research is focused on finding cleaner and more efficient ways of mining and burning coal.

Fiber and Building Materials Although nylon and polyester derived from petroleum are increasingly important in manufacturing, cotton and other types of plant fibers are still important sources of raw material for clothing, rope, and household articles like towels and bedding.

Woody plants also provide lumber for houses and furniture. Relative to its density, wood is a stiffer and stronger building material than concrete, cast iron, aluminum alloys, or steel.

Woody plants also provide most of the fibers used in papermaking. The cellulose fibers obtained from trees or bamboo and then used in paper manufacturing are stronger under tension (pulling) than nylon, silk, chitin, collagen, tendon, or bone—even though cellulose is 25 percent less dense. One line

TABLE 31.1 Some Drugs Derived from Land Plants

Source	Compound	Use
Belladonna plant	Atropine	Dilating pupils during eye exams
Opium poppy	Codeine, morphine	Pain relief, cough suppressant (codeine)
Foxglove	Digitalin	Heart medication
Ipecac	Ipecac	Treating amoebic dysentery, poison control
Peppermint	Menthol	Cough suppressant, relief of stuffy nose
Papaya	Papain	Reducing inflammation, treating wounds
Quinine tree	Quinine	Malaria prevention
	Quinidine	Heart medication
Aspen, willow trees	Salicin	Pain relief (aspirin)
Wild yams	Steroids	Precursor compounds for manufacture of birth control pills and cortisone (to treat inflammation)
Pacific yew	Taxol	Treating ovarian cancer
Curare vine	Tubocurarine	Muscle relaxant used in surgery
Rosy periwinkle	Vinblastine, vincristine	Treating leukemia (cancer of blood)

of research is focused on bioengineering to reduce lignin content of certain woody species, so fewer pollutants are generated in extracting lignin during the papermaking process.

Pharmaceuticals In both traditional and modern medicine, plants are a key source of drugs. **TABLE 31.1** lists some of the more familiar medicines derived from land plants; overall, an estimated 25 percent of the prescriptions written in the United States each year include at least one molecule derived from plants.

In most cases, plants synthesize these compounds in order to repel insects, deer, or other types of herbivores. For example, experiments have confirmed that morphine, cocaine, nicotine, caffeine, and other toxic compounds found in plants are effective deterrents to herbivores. Researchers continue to isolate and test new plant compounds for medicinal use in humans and domesticated animals.

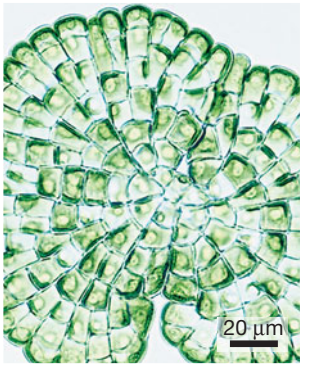
31.2 How Do Biologists Study Green Algae and Land Plants?

Given the importance of plants to the planet in general and humans in particular, it is not surprising that knowing as much as possible about plants, including how they evolved, is a key component of biological science. To understand how green plants originated and diversified, biologists analyze **(1)** morphological traits, **(2)** the fossil record, and **(3)** phylogenetic trees estimated from similarities and differences in DNA sequences from homologous genes and whole genomes.

These approaches are complementary and have produced a remarkably clear picture of how land plants evolved from green algae and then diversified. Let's consider each of these research strategies.

Analyzing Morphological Traits

The green algae include species that are unicellular, colonial, or multicellular and that live in marine, freshwater, or moist terrestrial habitats. The vast majority are aquatic. Although some land plants also live in ponds or lakes or rivers, the vast majority live on land.



Similarities Between Green Algae and Land Plants The green algae have long been hypothesized to be closely related to land plants, because key traits are similar in the two groups.

- Their chloroplasts contain the photosynthetic pigments chlorophyll *a* and *b* and the accessory pigment β-carotene.
- They have similar arrangements of the internal, membrane-bound sacs called thylakoids (see Chapter 10).
- Their cell walls, sperm, and peroxisomes are similar in structure and composition. (Recall that peroxisomes are organelles in which specialized oxidation reactions take place; see Chapter 7.)
- Their chloroplasts synthesize starch as a storage product.

Of all the green algal groups, the two most similar to land plants are the Coleochaetophyceae (coleochaetes) and Charophyceae (stoneworts; **FIGURE 31.3**). Because the species that make up these groups are multicellular and live in ponds and other types of freshwater environments, biologists hypothesize that land plants evolved from multicellular green algae that lived in freshwater habitats.

Major Morphological Differences among Land Plants Based on morphology, the land plants were traditionally clustered into three broad categories:

1. **Nonvascular plants** (also called bryophytes) lack **vascular tissue**—specialized groups of cells that conduct water and

Coleochaetophyceae (coleochaetes)

Charophyceae (stoneworts)

FIGURE 31.3 Most Green Algae Are Aquatic. Examples of species from the green algal lineages closely related to the land plants.

(a) Nonvascular plants

Do not have vascular tissue to conduct water and provide support (for example, mosses)

(b) Seedless vascular plants

Have vascular tissue but do not make seeds (for example, ferns)

(c) Seed plants

Have vascular tissue and make seeds (for example, flowering plants, or angiosperms)

FIGURE 31.4 Morphological Diversity in Land Plants.

nutrients from one part of the plant body to another. Mosses are one group of nonvascular plants (**FIGURE 31.4a**).

2. Seedless vascular plants have vascular tissue but do not make seeds. Instead, they make microscopic spores that are carried by wind to new habitats. Ferns are an example of seedless vascular plants (**FIGURE 31.4b**).
3. Seed plants have vascular tissue. A **seed** consists of an embryo and a store of nutritive tissue, surrounded by a tough protective layer. The flowering plants, or **angiosperms** (literally, "encased seeds"), are a group of seed plants (**FIGURE 31.4c**).

How are nonvascular plants, seedless vascular plants, and seed plants related to each other, and to green algae?

Using the Fossil Record

The first green plants in the fossil record are green algae, found in rocks from 700 to 725 million years old. The first land plant fossils are found in rocks that are about 475 million years old. Because green algae appear long before land plants, the data support the hypothesis that land plants are derived from green algae.

At roughly the same time that green algae appeared and began to diversify, the oceans and atmosphere were starting to become oxygen rich—as never before in Earth's history. Based on this time correlation, it is reasonable to hypothesize that the evolution of green algae contributed to the rise of oxygen levels on Earth. The origin of the oxygen atmosphere occurred not long before the appearance of animals in the fossil record and may have played a role in their origin and early diversification.

The fossil record of the land plants themselves is massive. In an attempt to organize and synthesize the database, **FIGURE 31.5** breaks it into five time intervals—each encompassing a major event in the diversification of land plants.

Origin of Land Plants The oldest interval begins about 475 million years ago (mya), spans some 60 million years, and documents the origin of the group.

Most of the fossils dating from this period are microscopic. They consist of the reproductive cells called spores and sheets of a waxy coating called cuticle. Several observations support the hypothesis that these fossils came from green plants that were growing on land.

1. Cuticle is a watertight barrier that coats the aboveground parts of today's land plants and helps them resist drying.
2. The fossilized spores are surrounded by a sheetlike coating. Under the electron microscope, the material appears almost

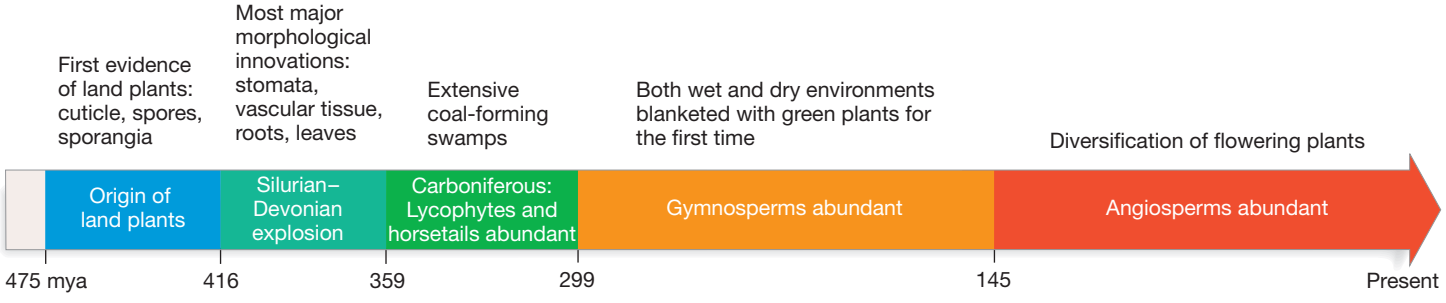


FIGURE 31.5 The Fossil Record of Land Plants Can Be Broken into Five Major Intervals. Note that the first insects are found in the fossil record at about 400 mya, the first terrestrial vertebrate animals at 365 mya, and the first mammals at 190 mya.

identical in structure to a waxy material called **sporopollenin**. Sporopollenin also encases spores and pollen from modern land plants and helps them resist drying.

3. Fossilized spores that are 475 million years old have recently been found in association with spore-producing structures, called **sporangia** (singular: **sporangium**), that are similar to sporangia observed in some nonvascular plants.

Silurian–Devonian Explosion The second major interval in the fossil record of land plants is called the "Silurian–Devonian explosion." In rocks dated 416–359 mya, biologists find fossils from most of the major plant lineages. Virtually all of the adaptations that allow plants to occupy dry, terrestrial habitats are present, including water-conducting tissue and roots.

According to the fossil record, plants colonized the land in conjunction with fungi that grew in a mutually beneficial symbiosis. The fungi grew belowground and helped provide land plants with nutrients from the soil; in return, the plants provided the fungi with sugars and other products of photosynthesis (see Chapters 32 and 39).

The Carboniferous Period The third interval in the fossil history of plants spans the aptly named Carboniferous period. In sediments dated from about 359 to 299 mya, biologists find extensive deposits of coal. Coal is a carbon-rich rock packed with fossil spores, branches, leaves, and tree trunks.

Most of these fossils are derived from seedless vascular plants in the Lycophyta (the lycophytes or club mosses), Equisetophyta (horsetails), and Pteridophyta (ferns). Although the only living lycophytes and horsetails are small, during the Carboniferous these groups were species rich and included a wide array of tree-sized forms.

Because coal formation is thought to start only in the presence of water, the Carboniferous fossils indicate the presence of extensive forested swamps.

Diversification of Gymnosperms The fourth interval in land plant history is characterized by seed plants called **gymnosperms** ("naked-seeds"). Five major groups of gymnosperms are living today: Ginkgophyta (ginkgoes), Cycadophyta (cycads), Cupressophyta (redwoods, junipers, and yews), Pinophyta (pines, spruces, and firs), and Gnetophyta (gnetophytes).

Because gymnosperms grow readily in dry habitats, biologists infer that both wet and dry environments on the continents became blanketed with green plants for the first time during this interval. Gymnosperms are prominent in the fossil record from 299 mya to 145 mya.

Diversification of Angiosperms The fifth interval in the history of land plants is still under way. This is the age of flowering plants—the angiosperms. The first flowering plants in the fossil record appear about 150 mya. The plants that produced the first flowers are the ancestors of today's grasses, orchids, daisies, oaks, maples, and roses.

According to the fossil record, then, the green algae appear first, followed by the nonvascular plants, seedless vascular plants, and seed plants. Organisms that appear late in the fossil record are often less dependent on moist habitats than are groups that appear earlier. For example, the sperm cells of mosses and ferns swim to accomplish fertilization, while gymnosperms and angiosperms produce pollen grains that are transported via wind or insects and that then produce sperm.

These observations support the hypotheses that green plants evolved from green algae and that land plants evolved to colonize dry habitats.

To test the validity of these observations, biologists analyze data sets that are independent of the fossil record. Foremost among these are DNA sequences used to infer phylogenetic trees. Does the phylogeny of land plants confirm or contradict the patterns in the fossil record?

Evaluating Molecular Phylogenies

The phylogenetic tree in **FIGURE 31.6** is a recent version of results emerging from laboratories around the world. The black bars across some branches show when key innovations occurred.

Each of the following bullets states a key observation about this tree, followed by an interpretation—often, a hypothesis that is supported by the observation.

- The green plants are monophyletic.
  Interpretation: A single common ancestor gave rise to all of the green algae and land plants.
- Green algae are paraphyletic.
  Interpretation: The green algae include some but not all of the descendants of a single common ancestor.
- Charophyceae are the closest living relative to land plants.
  Interpretation: Land plants evolved from a multicellular green alga that lived in freshwater habitats.

check your understanding

If you understand that . . .

- Biologists use the fossil record and phylogenetic analyses to study how green plants diversified.
- The data analyzed to date support the hypotheses that green plants are monophyletic and that land plants evolved from multicellular green algae that inhabited freshwater.
- The fossil record and molecular analyses agree that the nonvascular plants evolved first, followed by the seedless vascular plants and the seed plants.

✓ You should be able to . . .

Explain why (1) morphological data, (2) the fossil record, and (3) molecular phylogenies all support the hypothesis that land plants evolved from green algae.

Answers are available in Appendix A.

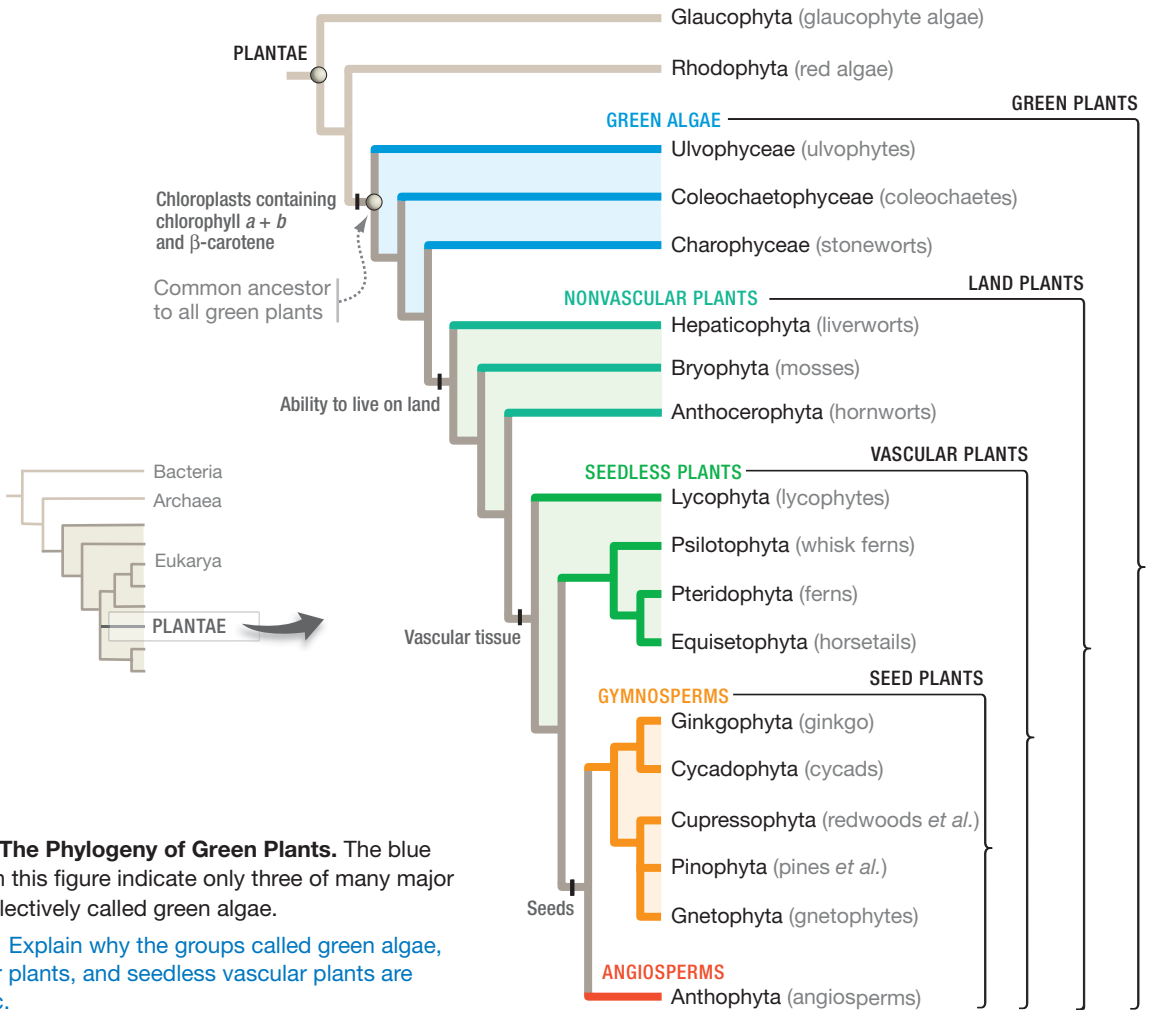

FIGURE 31.6 The Phylogeny of Green Plants. The blue branches on this figure indicate only three of many major lineages collectively called green algae.

✔ **QUESTION** Explain why the groups called green algae, nonvascular plants, and seedless vascular plants are paraphyletic.

- Land plants are monophyletic.
  Interpretation: There was only one successful transition from freshwater environments to land.
- The nonvascular plants are the earliest-branching groups among land plants.
  Interpretation: The nonvascular plants are the most ancient living group of land plants.
- The nonvascular plants are paraphyletic.
  Interpretation: The nonvascular plants include some but not all descendants of a single common ancestor.
- The seedless vascular plants are paraphyletic, but the vascular plants as a whole are monophyletic.
  Interpretation: Vascular tissue evolved once.
- The seed plants—the gymnosperms plus angiosperms—are monophyletic.
  Interpretation: The seed evolved once.
- The gymnosperms are a monophyletic group, as are the angiosperms.

Interpretation: Among seed plants, there was a major divergence in how seeds develop—either "naked" (in gymnosperms) or protected inside a capsule (in angiosperms).

Although the tree in Figure 31.6 will undoubtedly change and improve as additional data accumulate, biologists are confident about its most fundamental message: The fossil record and the phylogenetic tree based on DNA sequence data agree on the order in which groups appeared. Land plant evolution began with nonvascular plants, proceeded to seedless vascular plants, and continued with the evolution of seed plants.

31.3 What Themes Occur in the Diversification of Land Plants?

Land plants have evolved from algae that grew on the muddy shores of ponds 475 million years ago to organisms that enrich the soil, produce much of the oxygen you breathe and most of the food you eat, and serve as symbols of health, love, and beauty. How did this happen?

Answering this question begins with recognizing the most striking trend in the phylogeny and fossil record of green plants: The most ancient groups in the lineage are dependent on wet habitats, while the more recently evolved groups can live and reproduce in dry—or even desert—conditions. The story of land plants is the story of adaptations that allowed photosynthetic organisms to move from aquatic to terrestrial environments.

Let's first consider adaptations that allowed plants to grow in dry conditions without drying out and dying, and then analyze the evolution of traits that allowed plants to reproduce efficiently on land. This section closes with a brief look at the radiation of flowering plants, which are the most important plants in many of today's terrestrial environments.

The Transition to Land, I: How Did Plants Adapt to Dry Conditions with Intense Sunlight?

For aquatic green algae, terrestrial environments are deadly. Compared with a habitat in which the entire organism is bathed in water, in terrestrial environments only a portion, if any, of the plant's tissues are in direct contact with water. Tissues that are exposed to air tend to dry out and die.

Once green plants made the transition to survive out of water, though, growth on land offered a bonanza of resources.

- ***Light*** The water in ponds, lakes, and oceans absorbs and reflects light. As a result, the amount of light available to drive photosynthesis is drastically reduced even a meter or two below the water's surface.
- ***Carbon dioxide*** CO_2—the most important molecule required by photosynthetic organisms—is more abundant in the atmosphere and diffuses more readily there than it does in water.

Natural selection favored early land plants with adaptations that solved the drying problem. These adaptations arose in three steps: **(1)** preventing water loss, which kept cells from drying out and dying; **(2)** providing protection from harmful ultraviolet (UV) radiation; and **(3)** moving water from tissues with direct access to water to tissues without direct access. Let's examine each step in turn.

Preventing Water Loss: Cuticle and Stomata Section 31.2 points out that sheets of the waxy substance called cuticle are present early in the fossil record of land plants, along with encased spores. This observation is significant because the presence of cuticle in fossils is a diagnostic indicator of land plants.

Cuticle is a watertight sealant that covers the aboveground parts of plants and gives them the ability to survive in dry environments (**FIGURE 31.7a**). If biologists had to point to one innovation that made the transition to land possible, it would be the random mutations that led to the production of cuticle.

Covering surfaces with wax creates a problem, however, regarding the exchange of gases across those surfaces. Plants need to take in carbon dioxide (CO_2) from the atmosphere in order to perform photosynthesis. But cuticle is almost as impervious to CO_2 as it is to water.

Most plants solve this problem with a structure called a **stoma** ("mouth"; plural: **stomata**). A stoma consists of an opening surrounded by specialized **guard cells** (**FIGURE 31.7b**). The opening, called a **pore,** opens or closes as the guard cells change shape. When guard cells lose water, they become flaccid or "limp" and the stomata close. Pores are normally closed at night to limit water loss from the plant when CO_2 uptake is not needed. But when

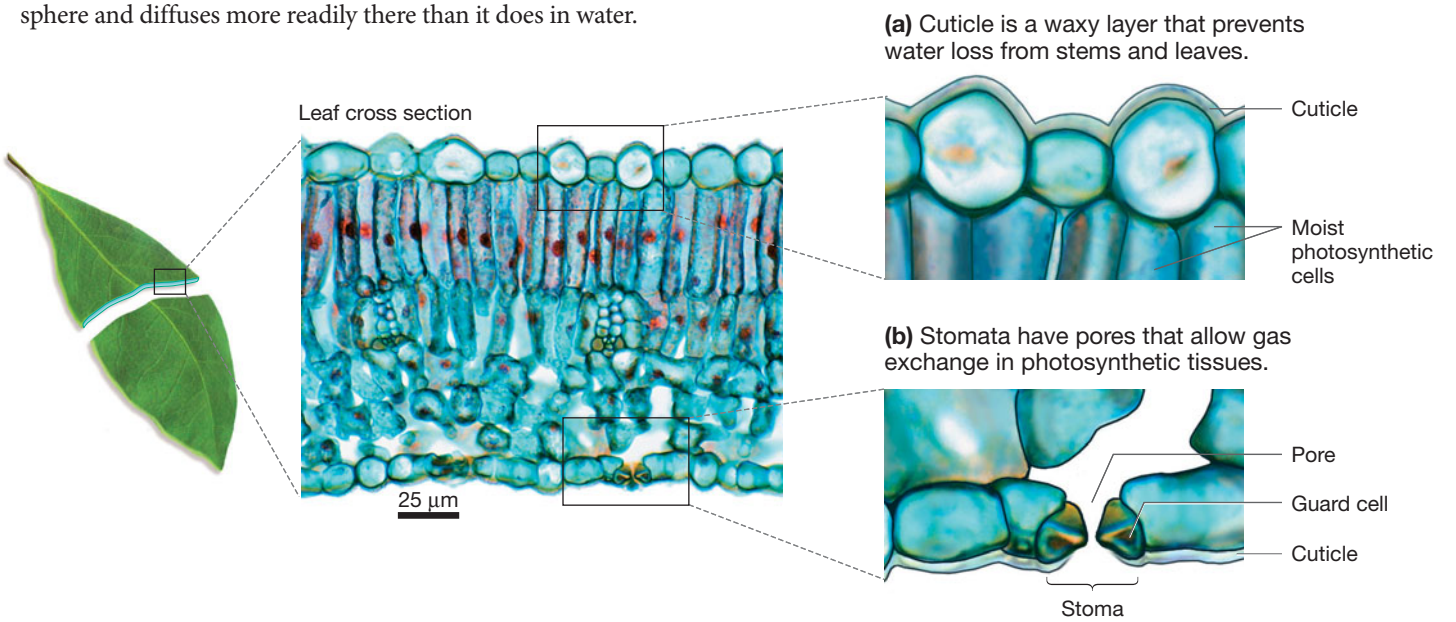

FIGURE 31.7 Cuticle and Stomata Are the Most Fundamental Plant Adaptations to Life on Land. In these micrographs, leaf cells have been stained blue to make their structure more visible. **(a)** The interior of plant leaves and stems is extremely moist; cuticle (stained red) prevents water from evaporating away. **(b)** Stomata, which are opened and closed by guard cells, create pores to allow CO_2 to diffuse into the interior of leaves and stems where cells are actively photosynthesizing. Stomata are often on the underside of leaves.

guard cells absorb water and then become turgid or "taut," they open the pore. Open stomata allow CO_2 to diffuse into the interior of leaves and stems where cells are actively photosynthesizing. (The mechanism behind guard-cell movement is explored in Chapter 40.)

Stomata are present in all land plants except the liverworts, which have pores but no guard cells. These data suggest that the earliest land plants evolved pores that allowed gas exchange to occur at breaks in the cuticle-covered surface. Later, the evolution of guard cells gave land plants the ability to regulate gas exchange—and control water loss—by opening and closing their pores.

Providing Protection From UV Irradiation Life out of water gave land plants a distinct advantage. Because they were exposed to higher light intensities, the plants could carry out photosynthesis faster. However, out of water they were also exposed to the UV rays of the sun. UV light is known to damage DNA by causing thymine dimers (see Chapter 15). Water absorbs UV light, so algae did not face this problem to the same extent.

Researchers think that many species of algae probably colonized the wet soil near their home ponds, but only some were able to survive the harsh sunlight. The plants that survived were those that by chance made compounds that absorb UV light. Most plants today accumulate UV-absorbing compounds, called flavonoids, to protect their DNA from damage. These flavonoids are plant pigments that function as a sunscreen for leaves and stems. Humans use similar compounds to manufacture sunscreen.

The first plants had a cuticle to keep from drying out, and UV-absorbing compounds to act as sunscreen, so they could grow on the water-saturated soils of lake or pond edges. The next challenge? Defying gravity.

The Importance of Upright Growth Multicellular green algae can grow erect because they float. They float because the density of their cells is similar to water's density. But outside of water, the body of a multicellular green alga collapses. The water that fills its cells is 1000 times denser than air. Although the cell walls of green algae are strengthened by the presence of cellulose, their bodies lack the structural support to withstand the force of gravity and to keep an individual erect in air.

Based on these observations, biologists hypothesize that the first land plants were small or had a low, sprawling growth habit. Besides lacking rigidity, the early land plants would have had to obtain water through pores or through cells that lacked cuticle—meaning they would have had to grow in a way that kept many or most of their tissues in direct contact with moist soil. If this hypothesis is correct, then competition for space and light would have become intense soon after the first plants began growing on land.

In a terrestrial environment, individuals that can grow erect have much better access to sunlight than individuals that are incapable of growing erect. But two problems have to be overcome for a plant to grow erect: **(1)** transporting water from tissues that are in contact with wet soil to tissues that are in contact with dry air, against the force of gravity; and **(2)** becoming rigid enough to avoid falling over in response to gravity and wind. As it turns out, vascular tissue solved both problems.

The Origin of Vascular Tissue Paul Kenrick and Peter Crane explored the origin of water-conducting cells and erect growth in plants by examining the extraordinary fossils found in a rock formation in Scotland called the Rhynie Chert. These rocks formed about 400 million years ago and contain some of the first large plant specimens in the fossil record—as opposed to the microscopic spores and cuticle found in older rocks.

The Rhynie Chert contains numerous plants that fossilized in an upright position. This indicates that many or most of the Rhynie plants grew erect. How did they stay vertical?

By examining fossils with the electron microscope, Kenrick and Crane established that species from the Rhynie Chert contained elongated cells that were organized into tissues along the length of the plant. Based on these data, the biologists hypothesized that the elongated cells were part of water-conducting tissue and that water could move from the base of the plants upward to erect portions through these specialized water-conducting cells.

- Some of the fossilized water-conducting cells had simple, cellulose-containing cell walls like the water-conducting cells found in today's mosses (**FIGURE 31.8a**, see page 586).
- Some of the water-conducting cells present in the early fossils had cell walls with thickened rings containing a molecule called lignin (**FIGURE 31.8b**).

Lignin is a complex polymer built from six-carbon rings. It is extraordinarily strong for its weight and is particularly effective in resisting compressing forces such as gravity.

These observations inspired the following hypothesis: The evolution of lignified cell walls gave stem tissues the strength to remain erect in the face of wind and gravity. Today, the presence of lignin in the cell walls of water-conducting cells is considered the defining feature of vascular tissue. The evolution of vascular tissue allowed early plants to support erect stems and transport water from roots to aboveground tissues. (See Chapter 38 for additional details on the structure and function of plant vascular tissue.)

Elaboration of Vascular Tissue: Tracheids and Vessels Once simple water-conducting tissues evolved, evolution by natural selection favored more complex tissues that were more efficient in providing support and transport.

In fossils that are about 380 million years old, biologists find the advanced water-conducting cells called tracheids. **Tracheids** are long, thin, tapering cells that have

- a thickened, lignin-containing **secondary cell wall** in addition to a cellulose-based **primary cell wall;** and

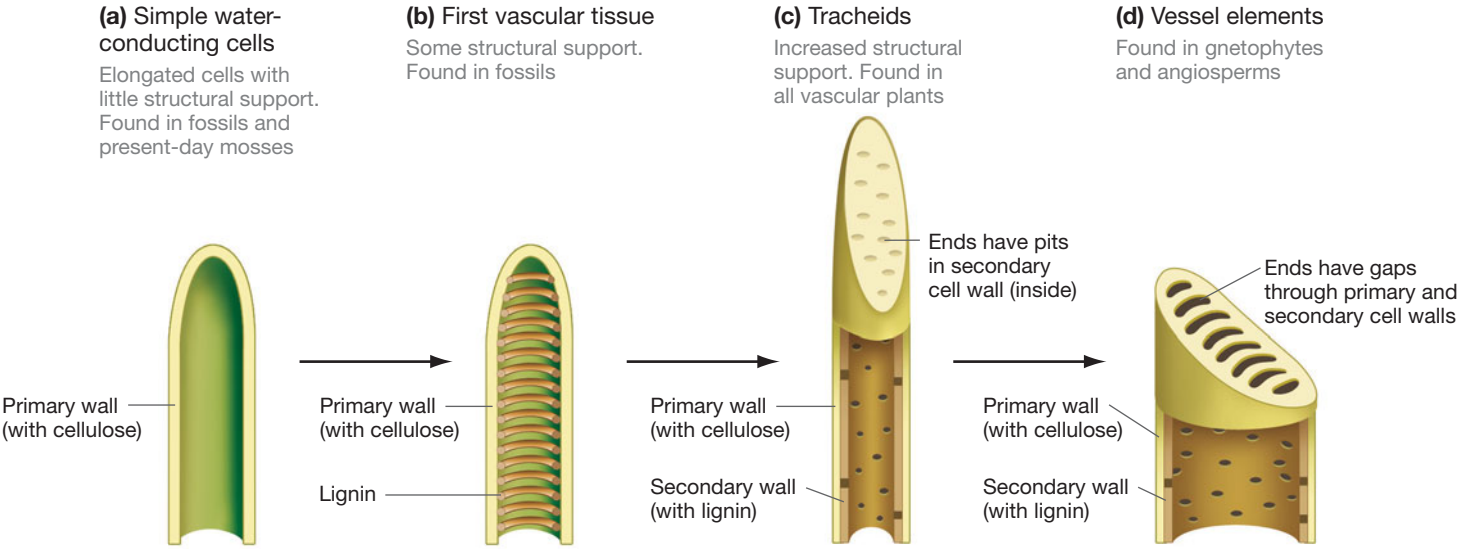

FIGURE 31.8 Evolutionary Sequence Observed in Water-Conducting Cells. According to the fossil record and the phylogeny of green plants, water-conducting cells became stronger over time due to the evolution of lignin and secondary cell walls. Efficient water transport was maintained through pits where the secondary cell wall is missing, or gaps where both the secondary and primary cell wall are absent.

✔ **QUESTION** Biologists claim that vessels are more efficient than tracheids at transporting water, in part because vessels are shorter and wider than tracheids. Why does this claim make sense?

- pits in the sides and ends of the cell where the secondary cell wall is absent, where water can flow efficiently from one tracheid to the next (**FIGURE 31.8c**).

The secondary cell wall gave tracheids the ability to provide better structural support, but water could still move easily through the cells because of the pits. Today, all vascular plants contain tracheids.

In fossils dated to 250–270 million years ago, biologists have documented the most advanced type of water-conducting cells observed in plants. **Vessel elements** are shorter and wider than tracheids, and their upper and lower ends have gaps where both the primary and secondary cell wall are missing. The width of vessels and the presence of open gaps reduce resistance and make water movement more efficient (**FIGURE 31.8d**). In vascular tissue, vessel elements are lined up end to end to form a continuous pipelike structure.

In the stems and branches of some vascular plant species, tracheids or a combination of tracheids and vessels form the extremely strong support material called **wood.** (The anatomy of wood is explained in detail in Chapter 37.) The ability of plants to make lignified vascular tissues allowed them to grow tall and transport water from soil all the way to the top—a remarkable engineering feat.

Mapping Evolutionary Changes on the Phylogenetic Tree

Cuticle, stomata, and vascular tissue were key adaptations that allowed early plants to colonize and thrive on land. **FIGURE 31.9** summarizes how land plants adapted to dry conditions by mapping on the phylogenetic tree where major innovations occurred as the group diversified.

As you study the tree in Figure 31.9, note that fundamentally important adaptations to dry conditions—such as cuticle, pores, stomata, vascular tissue, and tracheids—evolved just once. But convergent evolution also occurred (see Chapter 28). When convergence occurs, similar traits evolve independently in two distinct lineages. Vessels evolved independently in gnetophytes and angiosperms.

The evolution of cuticle, stomata, and vascular tissue made it possible for plants to avoid drying out and to grow upright, while moving water from the base of the plant to its apex. Plants gained adaptations that allowed them not only to survive on land, but also to flourish. Now the question is, how did they reproduce?

The Transition to Land, II: How Do Plants Reproduce in Dry Conditions?

Life cycles of sexually reproducing eukaryotes, including plants, serve several different functions:

- increase genetic variability as a result of meiosis and fertilization;
- increase the number of individuals; and
- disperse individuals to new habitats.

Each of these functions is necessary if a species is to survive. To understand the role of each stage of a life cycle and how life cycles evolve, researchers ask a series of key questions. Is a species mobile or sessile? Does it live in water or on land?

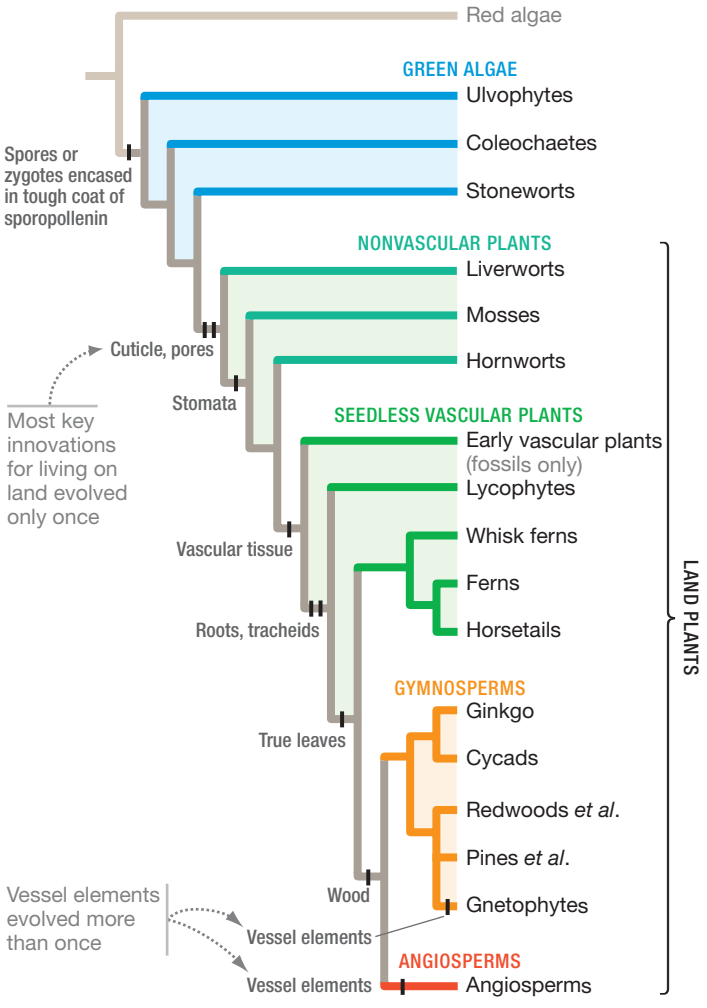

FIGURE 31.9 A Series of Evolutionary Innovations Allowed Plants to Adapt to Life on Land.

✔ **QUESTION** Explain the logic that biologists use to map the location of the innovations on phylogenetic trees.

In some organisms, all three functions are accomplished at one stage of the life cycle. For example, after meiosis coral polyps release many gametes into the water, where they fuse and disperse. Even though adult corals are sessile animals, they use water currents to move their genetically variable gametes and larvae. Terrestrial animals are mobile, so adults can easily disperse and join other adults for mating.

How do green plants reproduce? Keep in mind two important points—the impact of the transition from water to land on the dispersal stage of the life cycle, and the fact that land plants are sessile. Each of these factors has profoundly affected how life cycles of land plants evolved.

Section 31.2 introduces one of the key adaptations for reproducing on land: spores that resist drying because they are encased in a tough coat of sporopollenin. Sporopollenin-like compounds are found in the walls of some green algal zygotes, and thick-walled, sporopollenin-rich spores appear early in the fossil record of land plants. Based on these observations, biologists infer that sporopollenin-encased spores were one of the innovations that made the initial colonization of land possible.

Two other innovations that occurred early in land plant evolution were instrumental for efficient reproduction in a dry environment: **(1)** Gametes were produced in complex, multicellular structures; and **(2)** the embryo was retained on the parent (mother) plant and was nourished by it.

Producing Gametes in Protected Structures The fossilized gametophytes of early land plants contain specialized reproductive organs called **gametangia** (singular: **gametangium**). Although members of the green algae group Charophyceae (stoneworts) also develop gametangia, the gametangia found in land plants are larger and more complex.

The evolution of an elaborate gametangium was important because it protected gametes from drying and from mechanical damage. Gametangia are present in all land plants living today except angiosperms, where structures inside the flower perform the same functions.

In both the Charophyceae and the land plants, individuals produce distinctive male and female gametangia (**FIGURE 31.10**, see page 588).

- The sperm-producing gametangium is called an **antheridium** (plural: **antheridia**).
- The egg-producing gametangium is called an **archegonium** (plural: **archegonia**).

In terms of their function, antheridia and archegonia are analogous to the testes and ovaries of animals.

Retaining Offspring: Land Plant Embryos Are Nourished by Their Parent The second innovation that occurred early in land plant evolution involved the eggs that formed inside archegonia. Instead of shedding their eggs into the water or soil, land plants retain them.

Eggs are also retained in the green algal lineages that are most closely related to land plants: In Charophyceae and other closely related groups, sperm swim to the egg, fertilization occurs, and the resulting zygote stays attached to the parent. Either before or after fertilization, the egg or zygote receives nutrients from the mother plant. But the parent plant dies each autumn as the temperature drops. The zygote remains on the dead parental tissue, settles to the bottom of the lake or pond, and overwinters. In spring, meiosis occurs, and the resulting spores develop into haploid adult plants.

In land plants, the zygote is also retained on the parent plant after fertilization. But in contrast to the zygotes of most green algae, the zygotes of all land plants begin to develop on the living parent plant, forming a multicellular embryo that remains attached to the parent and can be nourished by it. This is important because land plant embryos do not have to manufacture

FIGURE 31.10 In All Land Plant Groups but Angiosperms, Gametes Are Produced in Gametangia. Gametangia such as in this moss (*Polytrichium*) are complex, multicellular structures that protect developing gametes from drying and mechanical damage.

their own food early in life. Instead, they receive most or all of their nutrients from the parent plant.

The retention of the embryo was such a key event in land plant evolution that the formal name of the group is **Embryophyta**—literally, the "embryo-plants." The retention of the fertilized egg in **embryophytes** is analogous to pregnancy in mammals, where offspring are retained by the mother and nourished through the initial stages of growth. Thick-walled spores, elaborate gametangia, and the embryophyte condition weren't the only key innovations associated with reproducing on land, though. In addition, all land plants undergo the phenomenon known as **alternation of generations** (see Chapter 30).

Alternation of Generations When alternation of generations occurs, individuals represent a multicellular haploid phase or a multicellular diploid phase. The multicellular haploid stage is called the **gametophyte;** the multicellular diploid stage is called the **sporophyte**. The two phases of the life cycle are connected by distinct types of reproductive cells—gametes and spores.

Although alternation of generations is observed in a wide array of eukaryotic lineages and in some groups of green algae, it does not occur in the algal groups most closely related to land plants. In the coleochaetes and stoneworts, the multicellular form is haploid. Only the zygote is diploid. As **FIGURE 31.11** shows, the zygote undergoes meiosis to form haploid spores. After dispersing with the aid of flagella, the spores begin dividing by mitosis and eventually grow into adult, haploid individuals. You might recall that this haploid-dominant life cycle is common in protists (see Chapter 30).

These data suggest that alternation of generations originated in land plants independently of its evolution in other groups of eukaryotes, and that it originated early in their history—soon after they evolved from green algae. Why was this strategy successful?

Multicellular sporophytes can make many spores and easily disperse them through wind currents. Male gametes produced by multicellular gametophytes swim through moist soil or water droplets on the surface of the gametophyte. As you'll see below, when male gametes no longer needed to swim, there was no need for a free-living gametophyte stage in the life cycle.

Alternation of generations always involves the same basic sequence of events, illustrated in **FIGURE 31.12**. To review how this type of life cycle works, put your finger on the sporophyte in the figure and trace the cycle clockwise to find the following five key events in a land plant:

1. The sporophyte produces spores by meiosis. Spores are haploid.
2. Spores germinate and divide by mitosis to develop into multicellular, haploid gametophytes.

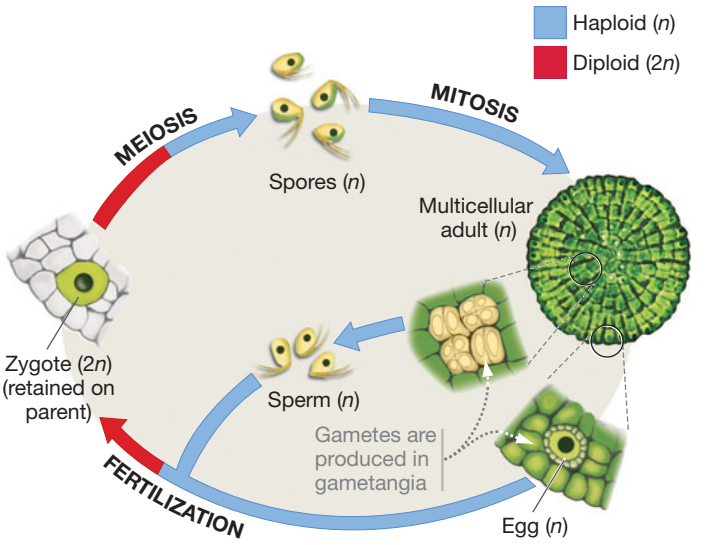

FIGURE 31.11 In Green Algae That Are Closely Related to Land Plants, Only the Zygote Is Diploid. The coleochaetes and stoneworts do not have alternation of generations. The multicellular stage is haploid.

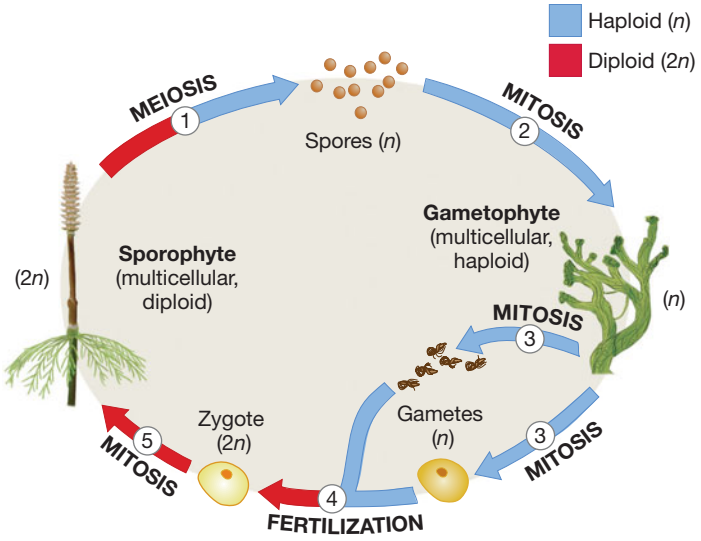

FIGURE 31.12 All Land Plants Undergo Alternation of Generations. Alternation of generations always involves the same sequence of five events.

3. Gametophytes produce gametes by mitosis. Both the gametophyte and the gametes are haploid, but gametophytes are multicellular while gametes are unicellular.
4. Two gametes unite during fertilization to form a diploid zygote.
5. The zygote divides by mitosis and develops into a multicellular, diploid sporophyte.

Once you've traced the cycle successfully, take a moment to compare and contrast zygotes and spores.

- Zygotes and spores are both single cells that divide by mitosis to form a multicellular individual. Zygotes develop into sporophytes; spores develop into gametophytes.
- Zygotes are diploid and spores are haploid.
- Zygotes result from the fusion of two haploid cells, such as a sperm and an egg, but spores are not formed by the fusion of gametes.
- Spores are produced by meiosis inside structures called sporangia; gametes are produced by mitosis inside gametangia.

Alternation of generations can be a difficult topic to master, for two reasons: **(1)** It is unfamiliar because it does not occur in humans or other animals, and **(2)** gamete formation results from mitosis—not meiosis, as it does in animals (see Chapter 13).

✔If you understand the basic principles of alternation of generations, you should be able to describe this type of life cycle and explain one hypothesis for why this life cycle might have evolved in land plants.

The Gametophyte-Dominant to Sporophyte-Dominant Trend in Life Cycles The five steps illustrated in Figure 31.12 occur in all species with alternation of generations. But in land plants, the relationship between the gametophyte and sporophyte is highly variable.

In nonvascular plants such as mosses, the sporophyte is small and short lived and is largely dependent on the gametophyte for nutrition (**FIGURE 31.13**). When you see leafy-looking mosses growing on a tree trunk or on rocks, you are looking at gametophytes. Because the gametophyte is long lived and produces most of the food required by the individual, it is considered the dominant part of the life cycle.

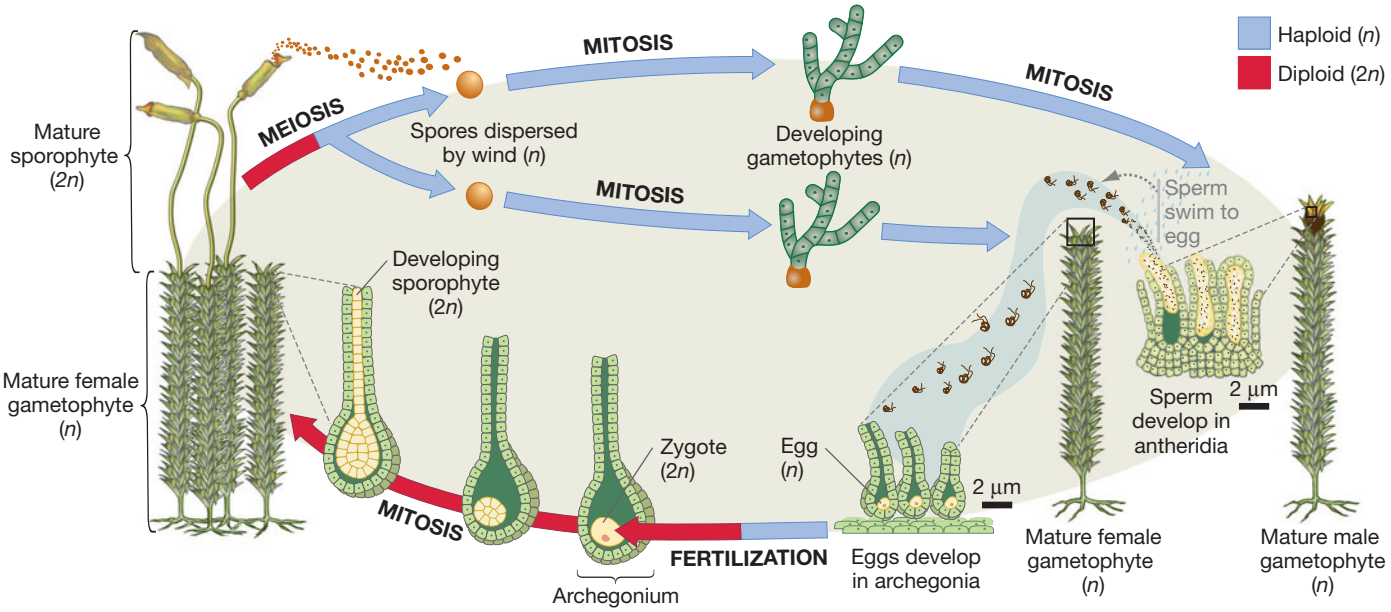

FIGURE 31.13 Gametophyte-Dominated Life Cycles Evolved Early. Like today's mosses, the earliest land plants in the fossil record have gametophytes that are much larger and longer lived than the sporophyte. The sporophyte depends on the gametophyte for nutrition.

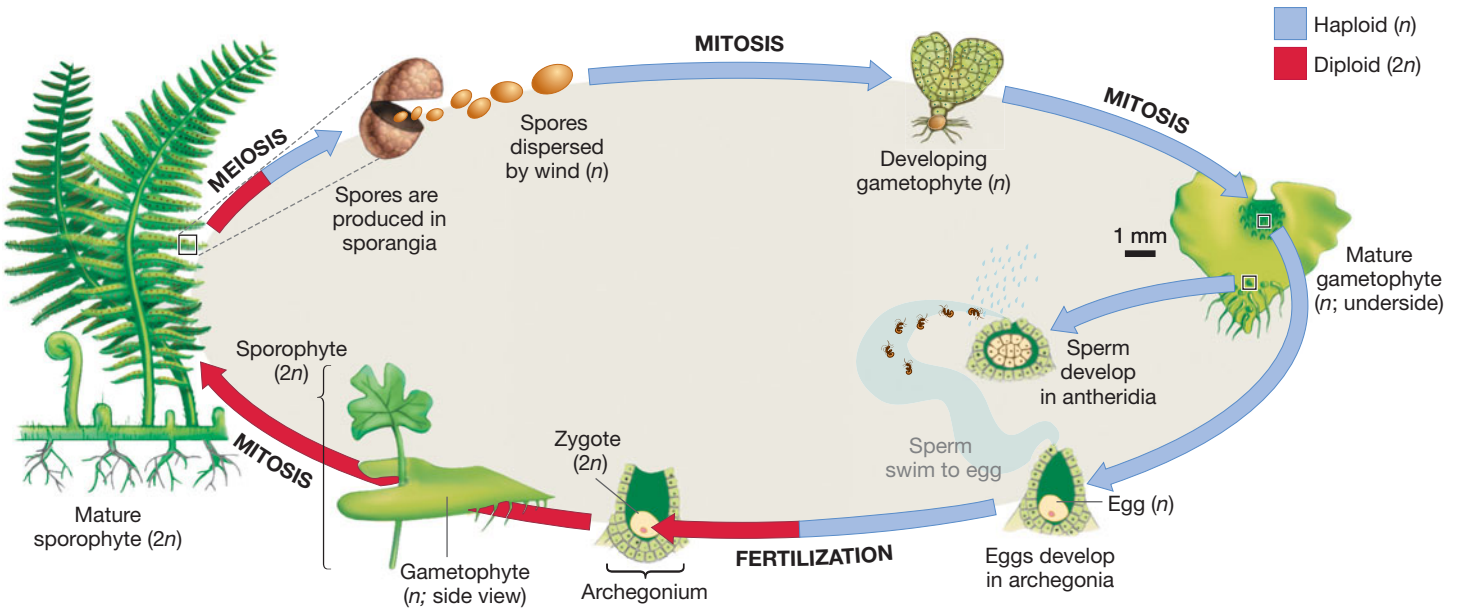

FIGURE 31.14 Sporophyte-Dominated Life Cycles Evolved Later. In lineages that evolved later, such as ferns, the sporophyte is much larger and longer lived than the gametophyte. However, when young, the sporophyte also depends on the gametophyte for nutrition.

✔ **QUESTION** How can you tell that alternation of generations occurs in mosses (Figure 31.13) and ferns (Figure 31.14)?

In contrast, in ferns and other vascular plants the sporophyte is much larger and longer lived than the gametophyte (**FIGURE 31.14**). The ferns you see growing in gardens or forests are sporophytes. You'd have to hunt on your hands and knees to find their free-living gametophytes, which are typically just a few millimeters in diameter. As you'll learn later in the chapter, the gametophytes of gymnosperms and angiosperms are even smaller—they are microscopic—and are retained within the sporophyte. Ferns and other vascular plants are said to have a sporophyte-dominant life cycle.

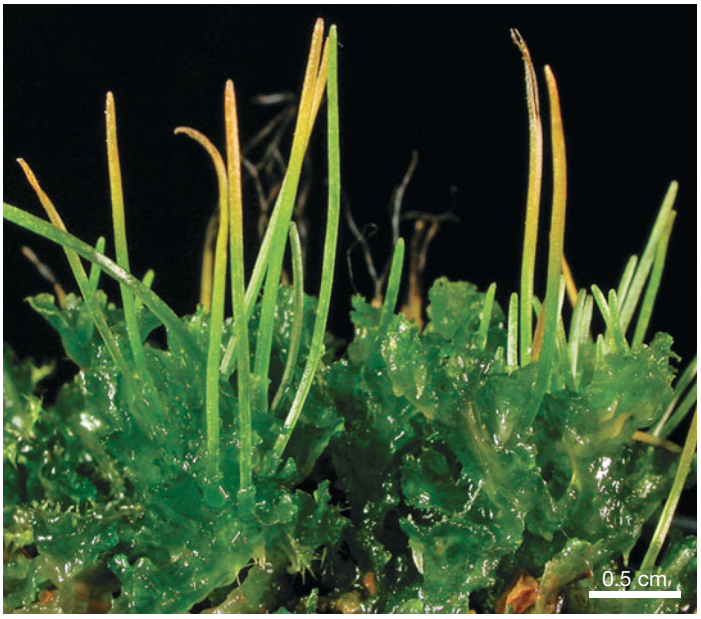
✔**If you understand the difference between gametophyte-dominant and sporophyte-dominant life cycles, you should be able to examine the photos of hornworts (a nonvascular plant) and horsetails (a seedless vascular plant) in FIGURE 31.15 and identify which is the gametophyte and which is the sporophyte.**

The transition from gametophyte-dominated life cycles to sporophyte-dominated life cycles is one of the most striking of all trends in land plant evolution. To explain why it occurred, biologists hypothesize that sporophyte-dominated life cycles were advantageous because diploid cells can respond to varying environmental conditions more efficiently than haploid cells can—particularly if the individual is heterozygous at many genes. This idea has yet to be tested rigorously, however.

Heterospory In addition to sporophyte-dominated life cycles, another important innovation found in seed plants is called **heterospory**—the production of two distinct types of spores by different structures.

All of the nonvascular plants and most of the seedless vascular plants are homosporous. **Homospory** is the production of a single type of spore. (Among the seedless vascular plants, some lycophytes and a few ferns are heterosporous.) Homosporous species produce spores that develop into bisexual gametophytes that produce both eggs and sperm (**FIGURE 31.16a**). If these gametophytes are isolated in nature, they can self-fertilize and produce offspring. If two bisexual gametophytes are close enough for the exchange of sperm, outcrossing is favored because it increases genetic variation (see Chapter 13). The mechanisms that prevent self-fertilization in this case are poorly understood.

The two types of spore-producing structures in heterosporous species are often found on the same individual (**FIGURE 31.16b**).



1. **Microsporangia** are spore-producing structures that produce microspores. **Microspores** develop into male gametophytes, which produce the small gametes called sperm.
2. **Megasporangia** are spore-producing structures that produce megaspores. **Megaspores** develop into female gametophytes, which produce the large gametes called eggs.

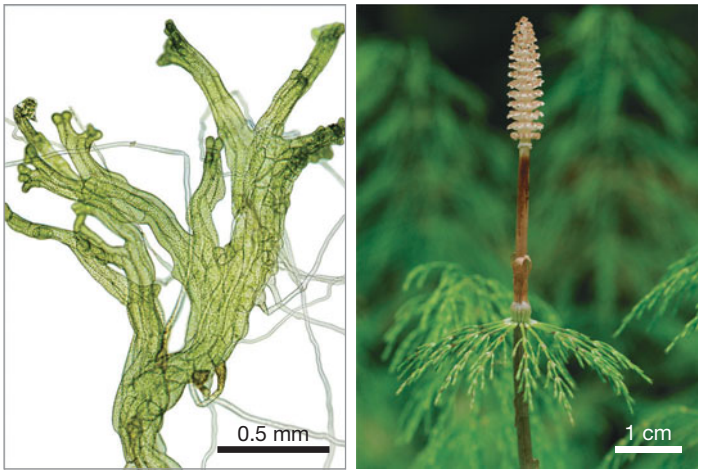
Thus, the gametophytes of seed plants are either male or female, but never both.

The evolution of heterospory was a key event in land plant evolution because it made possible one of the most important adaptations for life in dry environments—pollen.

Pollen The nonvascular plants and the seedless vascular plants have sperm that swim to the egg to perform fertilization. For a sperm cell to swim, there has to be a continuous sheet of water

(a) Hornwort gametophytes and sporophytes

(b) Horsetail gametophyte and sporophyte



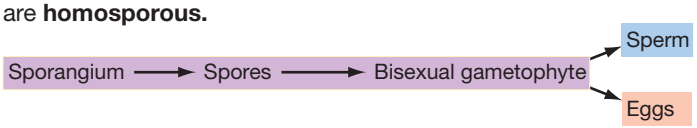


FIGURE 31.15 The Reduction of the Gametophyte Is One of the Strongest Trends in Land Plant Evolution. (a) A hornwort with spike-like sporophytes emerging from the gametophyte. **(b)** A horsetail species, both as a tiny, microscopic gametophyte and as a large, macroscopic sporophyte.

between the male and female gametophytes, or a raindrop has to splash sperm onto a female gametophyte.

In species that live in dry environments, these conditions are rare. The land plants made their final break with their aquatic origins and were able to reproduce efficiently in dry habitats when a structure evolved that could move their gametes without the aid of water.

In heterosporous seed plants, the microspore germinates to form a tiny male gametophyte that is surrounded by a tough coat of sporopollenin, resulting in a **pollen grain.**

(a) Nonvascular plants and most seedless vascular plants are **homosporous.**

(b) Seed plants are **heterosporous.**

FIGURE 31.16 Unlike Homosporous Plants, Heterosporous Plants Produce Male and Female Spores That Are Morphologically Distinct.

Pollen grains can be exposed to the air for long periods of time without dying from dehydration. They are also tiny enough to be carried to female gametophytes by wind or animals. Upon landing near the egg, the male gametophyte releases the sperm cells that accomplish fertilization.

When pollen evolved, then, heterosporous plants lost their dependence on water to accomplish fertilization. Instead of swimming to the egg as a naked sperm cell, their tiny gametophytes took to the skies.

Seeds The evolution of large gametangia protected the eggs and sperm of land plants from drying. Embryo retention allowed offspring to be nourished directly by their parent, and pollen enabled fertilization to occur in the absence of water.

Retaining embryos has a downside, however: In ferns and horsetails, sporophytes have to live in the same place as their parent gametophyte. Seed plants overcome this limitation. Their embryos are portable and can disperse to new locations. The dispersal stage of the life cycle thus shifted from the haploid spore to the young diploid sporophyte.

A seed is a structure that, like a bird's egg, includes an embryo and a food supply surrounded by a tough coat that allows for effective dispersal of embryos (**FIGURE 31.17**). Spores are an effective dispersal stage in nonvascular plants and seedless vascular plants, but they lack the stored nutrients found in seeds.

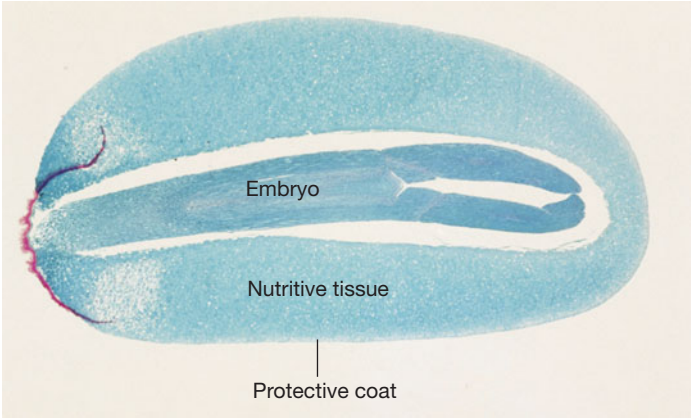

FIGURE 31.17 Seeds Contain an Embryo and a Food Supply and Can Be Dispersed. (This *Pinus* (pine) specimen has been stained.)

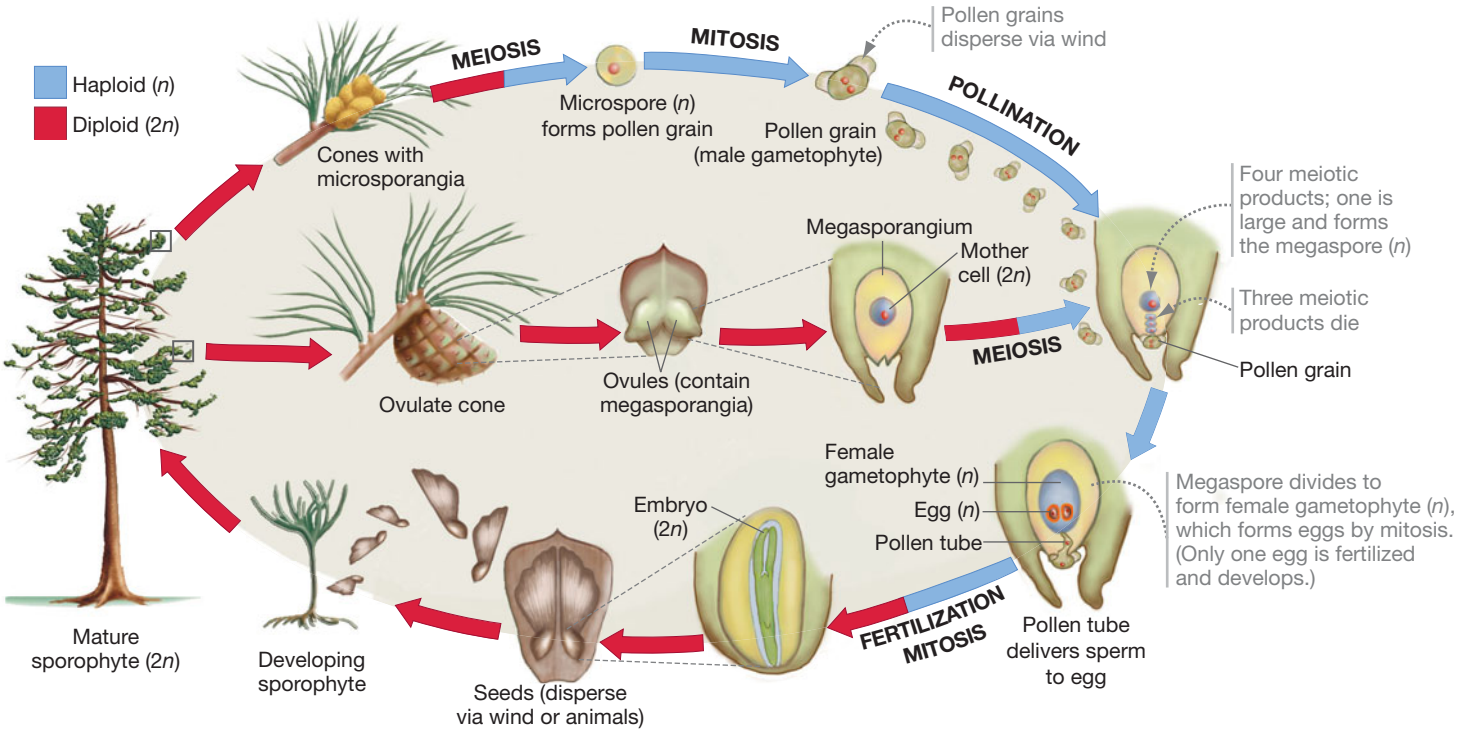

FIGURE 31.18 Heterospory in Gymnosperms: Microspores Produce Pollen Grains; Megaspores Produce Female Gametophytes.

✔ **QUESTION** Compare the life cycle of the pine tree in Figure 31.18 with that of the fern pictured in Figure 31.14. Is the gymnosperm gametophyte larger than, smaller than, or about the same size as a fern gametophyte? Compared with ferns, is the gymnosperm gametophyte more or less dependent on the sporophyte for nutrition?

The evolution of heterospory, pollen, and seeds triggered a dramatic radiation of seed plants starting about 299 million years ago. To make sure that you understand these key processes and structures, study the life cycle of the pine tree pictured in **FIGURE 31.18**.

1. Starting with the sporophyte on the left, note that this and many other gymnosperm species have separate structures, called cones, where microsporangia and megasporangia develop. In this case, the two types of spores associated with heterospory develop in separate cones.
2. The microsporangia contain a cell that divides by meiosis to form microspores, which then divide by mitosis to form pollen grains—tiny male gametophytes.
3. Megasporangia are found inside protective structures called ovules. Megasporangia contain a mother cell that divides by meiosis to form a megaspore.
4. The megaspore undergoes mitosis to form the female gametophyte, which contains egg cells.
5. The female gametophyte stays attached to the sporophyte as pollen grains arrive and produce sperm that fertilize the eggs.
6. Seeds mature as the embryo develops. Inside the seed, cells derived from the female gametophyte become packed with nutrients provided by the sporophyte.

When the seed disperses and germinates, the cycle of life begins anew.

Flowers Flowering plants, or angiosperms, are the most diverse land plants living today. About 250,000 species have been described, and more are discovered each year. Their success in terms of geographical distribution, number of individuals, and number of species revolves around a reproductive organ—the **flower.**

Most flowers contain two key reproductive structures: the stamens and carpels illustrated on the left-hand side of **FIGURE 31.19**. Stamens and carpels are responsible for heterospory.

- A **stamen** includes a structure called an anther, where microsporangia develop. Meiosis occurs inside the microsporangia, forming microspores. Microspores then divide by mitosis to form pollen grains.
- A **carpel** contains a protective structure called an **ovary,** where the ovules are found.

The presence of enclosed ovules inspired the name angiosperm ("encased-seed") as opposed to gymnosperm ("naked-seed").

As in gymnosperms, ovules contain the megasporangia. A cell inside the megasporangium divides by meiosis to form the megaspore, which then divides by mitosis to form the female

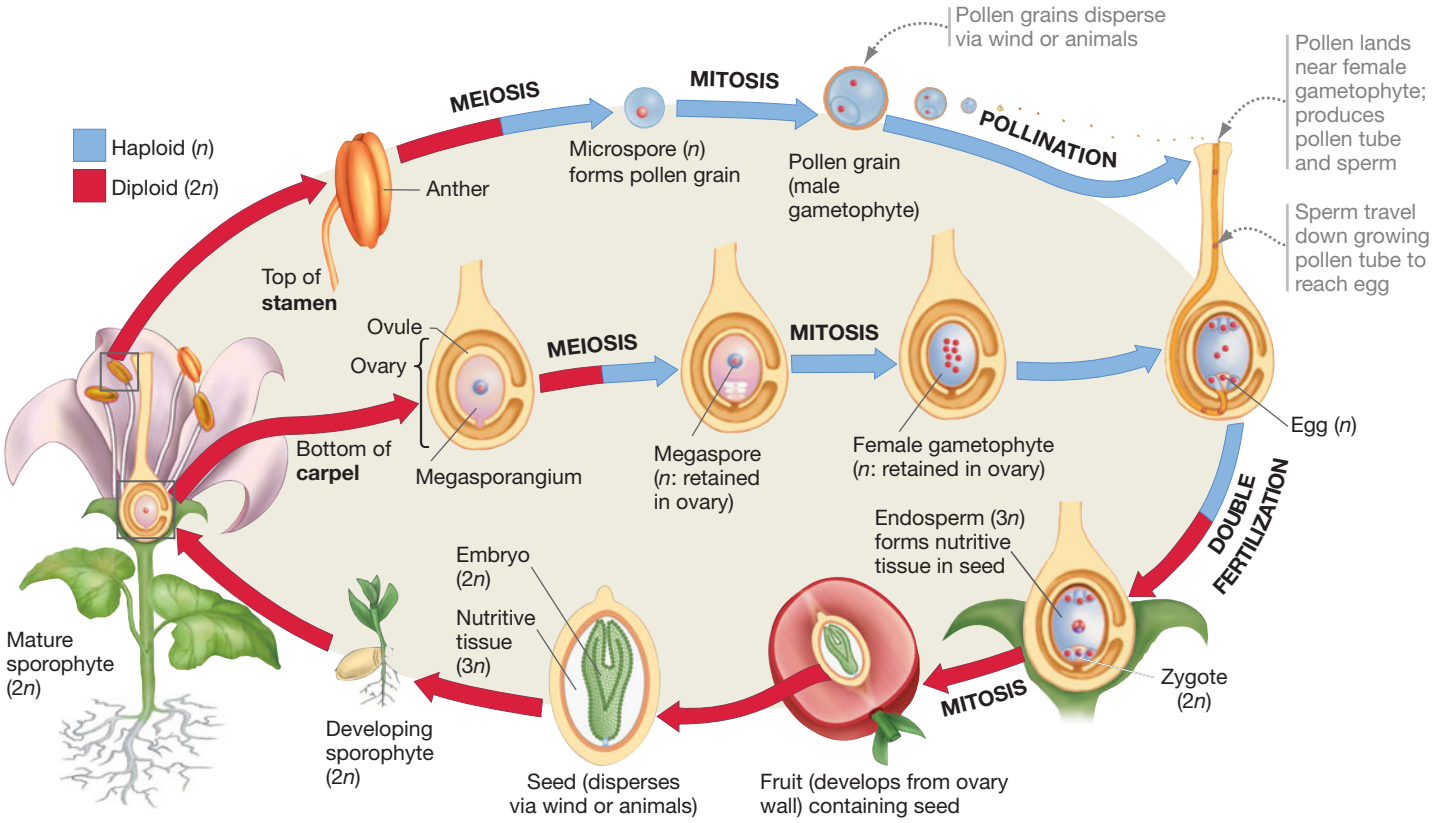

FIGURE 31.19 Heterospory in Angiosperms: Flowers Contain Microspores and Megaspores.

✔ **QUESTION** Gymnosperm pollen grains typically contain from 4 to 40 cells; mature angiosperm pollen grains contain three cells. Gymnosperm female gametophytes typically contain hundreds of cells; angiosperm female gametophytes typically contain seven. Do these observations conflict with the trend of reduced gametophytes during land plant evolution, or are they consistent with it? Explain your logic.

gametophyte. After a pollen grain lands on a carpel and produces sperm, fertilization takes place, as shown on the right-hand side of Figure 31.19.

Angiosperm fertilization is unique, however, because it involves *two* sperm cells. One sperm fuses with the egg to form the diploid ($2n$) zygote, while a second sperm fuses with two nuclei in the female gametophyte to form a triploid ($3n$) nutritive tissue called **endosperm.** The involvement of two sperm nuclei is called **double fertilization.**

The evolution of the flower, then, is an elaboration of heterospory. The key innovation was the evolution of the ovary, which helps protect female gametophytes from insects and other predators.

Double fertilization is another striking innovation associated with the flower, but its adaptive significance is still not well understood. Explaining the significance of double fertilization is a major challenge for biologists interested in understanding how land plants diversified.

Pollination by Insects and Other Animals The story of the flower doesn't end with the ovary. Once stamens and carpels evolved, they became enclosed by modified leaves called **sepals** and **petals.** The four structures then diversified to produce a fantastic array of sizes, shapes, and colors—from red roses to blue violets. Specialized cells inside flowers also began producing a wide range of scents.

To explain these observations, biologists hypothesize that flowers are adaptations to increase the probability that an animal will perform **pollination**—the transfer of pollen from one individual's stamen to another individual's carpel. Instead of leaving pollination to an undirected agent such as wind, the hypothesis is that natural selection favored structures that reward an animal—usually an insect—for carrying pollen directly from one flower to another.

Under the directed-pollination hypothesis, natural selection has favored flower colors and shapes and scents that are successful in attracting particular types of pollinators. A pollinator is an animal that disperses pollen. Pollinators are attracted to flowers because flowers provide the animals with food in the form of protein-rich pollen or a sugar-rich fluid known as **nectar.** In this way, the relationship between flowering plants and their pollinators is mutually beneficial. The pollinator gets food; the plant gets sex (fertilization).

What evidence supports the hypothesis that flowers vary in size, structure, scent, and color in order to attract specific pollinators?

The first type of evidence on this question is correlational in nature. In general, the characteristics of a flower correlate closely with the characteristics of its pollinator. A few examples of these so-called **pollination syndromes** will help drive this point home:

- *Scent* The carrion flower in **FIGURE 31.20a** produces molecules that smell like rotting flesh. The scent attracts carrion flies, which normally lay their eggs in animal carcasses. In effect, the plant tricks the flies. While looking for a place to lay their eggs on a flower, the flies become dusted with pollen. If the flies are already carrying pollen from a visit to a different carrion flower, they are likely to deposit pollen grains near the plant's female gametophyte. In this way, the carrion flies pollinate the plant.
- *Flower shape* Flowers that are pollinated by hummingbirds typically have petals that form a long, tubelike structure corresponding to the size and shape of a hummingbird's beak (**FIGURE 31.20b**). Nectar-producing cells are located at the base of the tube. When hummingbirds visit the flower, they insert their beaks and harvest the nectar. In the process, they transfer pollen grains attached to their throats or faces.
- *Flower color* Hummingbird-pollinated flowers tend to have red petals (**FIGURE 31.20b**), while bee-pollinated flowers tend to be purple or yellow (**FIGURE 31.20c**). Hummingbirds are attracted to red; bees have excellent vision in the purple and ultraviolet end of the spectrum.

The directed-pollination hypothesis also has strong experimental support. Consider, for example, recent work on South American petunias. Field observations led researchers to conclude that a white-flowered species (*Petunia axillaris*) was primarily pollinated at night by hawk moths, while a purple-flowered species (*P. integrifolia*) was pollinated during the day by bumblebees. (Note that white is highly visible at night, and purple is the color most easily seen by bees.)

Was flower color the key to flower choice by these insects? This is difficult to determine because of the many other differences in flower characteristics between two plant species, such as flower shape, odor, and nectar composition. In this experiment, researchers identified a gene named *AN2* responsible for the pigmentation in the purple petunia and introduced it into the genome of the white petunia, producing new plants that now had purple flowers. The researchers then documented that other than color, the wild-type and genetically altered flowers were identical.

In a controlled, greenhouse experiment, hawk moths and bumblebees were allowed to choose between the two *P. axillaris* plants, and as predicted by the directed-pollination hypothesis, flower color was key to pollinator preference (**FIGURE 31.21**). These data strongly support the hypothesis that flower color is an adaptation that increases the frequency of pollination by particular insects.

Based on results like this, biologists contend that the spectacular diversity of angiosperms resulted, at least in part, from natural selection exerted by the equally spectacular diversity of insect, mammal, and bird pollinators. Mutations that change flower color can change gene flow and start speciation (see Chapter 27).

Fruits The evolution of the ovary was an important event in land plant diversification, but not only because it protected the female gametophytes of angiosperms. It also made the evolution of fruit possible.

A **fruit** is a structure that is derived from the ovary and encloses one or more seeds (**FIGURE 31.22a**). Tissues derived from the ovary are often nutritious and brightly colored (**FIGURE 31.22b**). Animals eat these types of fruits, digest the nutritious tissue

(a) Carrion flowers: Smell like rotting flesh and attract carrion flies

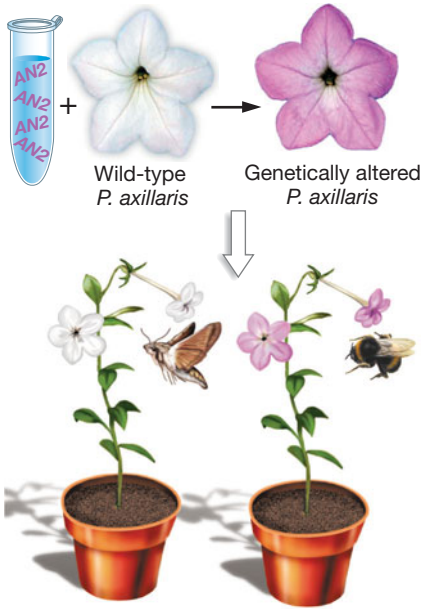
FIGURE 31.20 Flowers with Different Fragrances, Shapes, and Colors Attract Different Pollinators.



RESEARCH

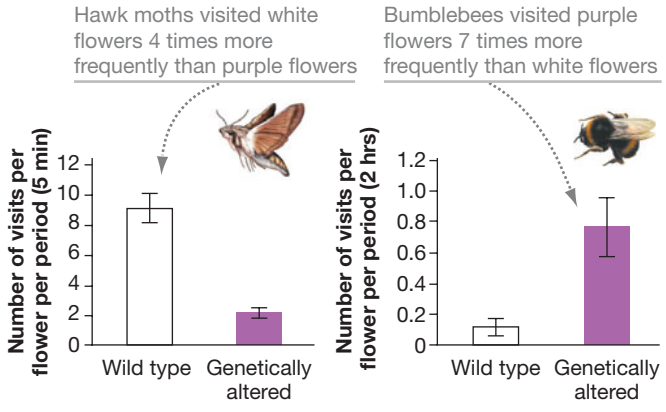
QUESTION: Does flower color influence pollinator preference?

HYPOTHESIS: Hawk moths prefer white petunias while bumblebees prefer purple, even when the flowers are otherwise identical.

NULL HYPOTHESIS: Neither insect has a clear preference for white- or purple-flowered petunias.

EXPERIMENTAL SETUP:

1. Isolate *AN2* gene for purple flower color from a related species (*P. integrifolia*) and insert it into *P. axillaris*.



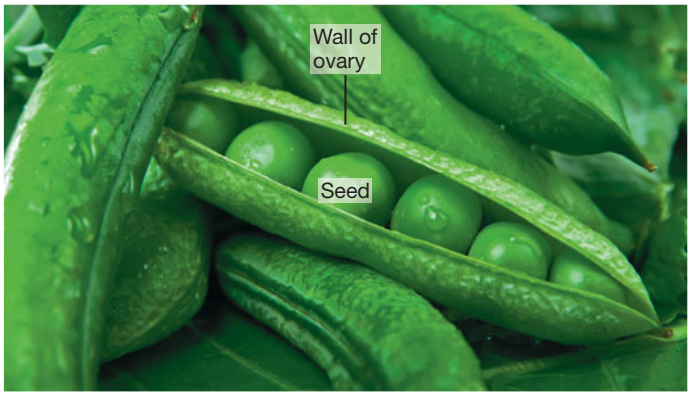
2. Grow wild-type (white) and genetically altered (purple) *P. axillaris* in controlled greenhouse conditions.

3. Count number of visits by hawk moths and bumblebees to white and purple flowers.

PREDICTION: Hawk moths will visit white-flowered *P. axillaris* more frequently, while bumblebees will visit purple-flowered *P. axillaris* more frequently.

PREDICTION OF NULL HYPOTHESIS: Both insects will visit white and purple flowers equally.

RESULTS:



CONCLUSION: Petunia flower preference among bumblebees and hawk moths is significantly influenced by flower color.

FIGURE 31.21 The Adaptive Significance of Flower Color.

✔ **QUESTION** Why did the researchers measure pollination in a greenhouse? Why did they plot flower visits on different scales?

(a) Fruits are derived from ovaries and contain seeds.

(b) Many fruits are dispersed by animals.

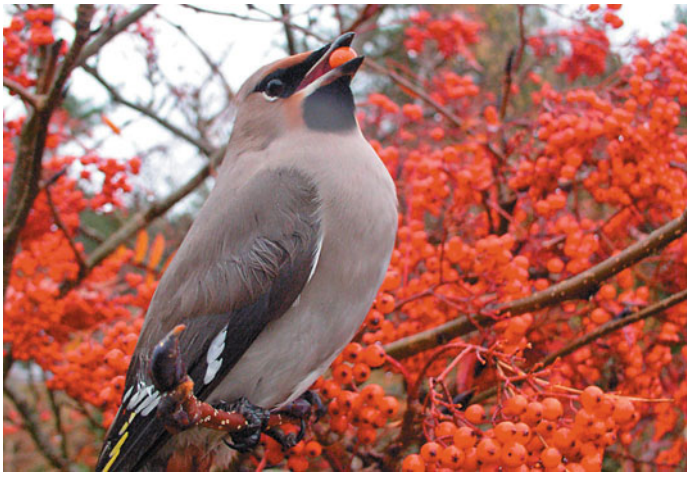

FIGURE 31.22 Fruits Are Derived from Ovaries Found in Angiosperms. (a) A pea pod is one of the simplest types of fruit. **(b)** The ovary wall often becomes thick, fleshy, and nutritious enough to attract animals that disperse the seeds inside.

around the seeds, and disperse seeds in their feces. In other cases, the tissues derived from the ovary help fruits disperse via wind or water. The evolution of flowers made efficient pollination possible; the evolution of fruits made efficient seed dispersal possible.

The list of adaptations that allow land plants to reproduce in dry environments is impressive; **FIGURE 31.23** (see page 596) summarizes them. Once land plants had vascular tissue and could grow efficiently in dry habitats, the story of their diversification revolved around traits that allowed sperm cells to reach eggs efficiently and helped seeds disperse to new locations.

The Angiosperm Radiation

For the past 125 million years, land plant diversification has really been about angiosperms. The Anthophyta or angiosperms represent one of the great adaptive radiations in the history of

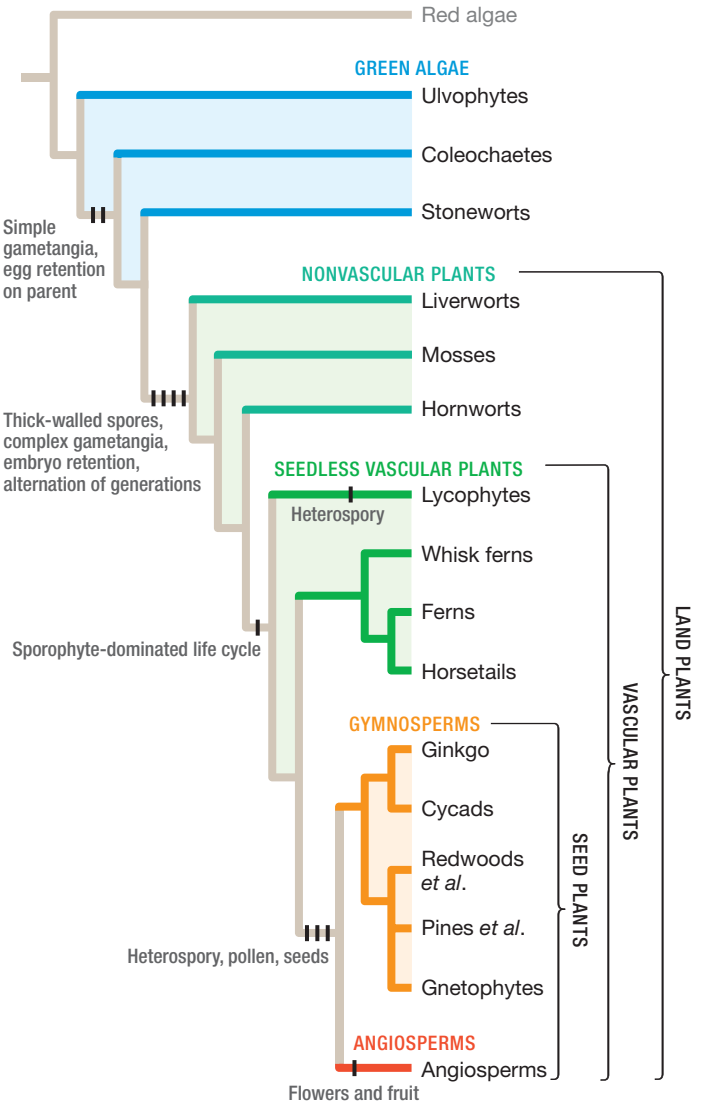

FIGURE 31.23 Evolutionary Innovations Allowed Plants to Reproduce Efficiently on Land.

✔ **EXERCISE** Redwoods, pines, gnetophytes, and angiosperms are the only land plants that do not have flagellated sperm that swim to the egg (at least a short distance). Mark the loss of flagellated sperm on Figure 31.6.

life. An **adaptive radiation** occurs when a single lineage produces a large number of descendant species that are adapted to a wide variety of habitats (see Chapter 28).

The diversification of angiosperms is associated with three key adaptations: **(1)** water-conducting vessels, **(2)** flowers, and **(3)** fruits. In combination, these traits allow angiosperms to transport water, pollen, and seeds efficiently. Based on these observations, it is not surprising that most land plants living today are angiosperms.

On the basis of morphological traits, the 250,000 species of angiosperms identified to date have traditionally been classified into two major groups: the monocotyledons, or **monocots,** and the dicotyledons, or **dicots.** Some familiar monocots include the grasses (such as corn and wheat), orchids, palms, and lilies; familiar dicots include beans, roses, buttercups, daisies, oaks, and maples.

The names of the two groups were inspired by differences in a structure called the cotyledon. A **cotyledon** ("seed-leaf") stores nutrients and supplies them to the developing embryonic plant. As **FIGURE 31.24** shows, monocots have a single cotyledon (hence the "mono") while dicots have two cotyledons (hence the "di"). The figure also highlights other major morphological differences observed in monocots and dicots, including the arrangement of vascular tissue and leaf veins and the characteristics of flowers.

It would be misleading, however, to think that all species of flowering plants fall into one of these two groups—either monocots or dicots. Recent work has shown that dicots do not form a monophyletic group consisting of a common ancestor and all of its descendants.

To drive this point home, consider the phylogeny illustrated in **FIGURE 31.25**. These relationships were estimated by comparing the sequences of several genes that are shared by all angiosperms. Notice that species with dicot-like characters are found in multiple lineages of the angiosperm phylogenetic tree. Based on this analysis, biologists have concluded that although monocots are monophyletic, dicots are not. Dicots are paraphyletic.

Biologists have adjusted the names assigned to angiosperm lineages to reflect this new knowledge of phylogeny. The most important of these changes was identifying the **eudicots** ("true dicots") as a monophyletic lineage that includes most of the plants once considered dicots. One flowering plant that is neither a monocot nor a eudicot is the magnolia tree. Plant systematists continue to work toward understanding relationships throughout the angiosperm phylogenetic tree; there will undoubtedly be more name changes as knowledge grows.

check your understanding

C Y U

If you understand that . . .

- Land plants were able to make the transition to growing in terrestrial environments, where sunlight and carbon dioxide are abundant, based on a series of evolutionary innovations.
- Adaptations for growing on land included cuticle, stomata, UV-absorbing compounds, and vascular tissue.
- Adaptations for effective reproduction on land included gametangia, the retention of embryos on the parent, pollen, seeds, flowers, and fruits.

✔ **You should be able to . . .**

1. Explain why the evolution of cuticle, UV-absorbing compounds, and vascular tissue was important in survival or reproduction.
2. On Figure 31.6, map where the origin of pollen, flowers, and fruits occurred.

Answers are available in Appendix A.

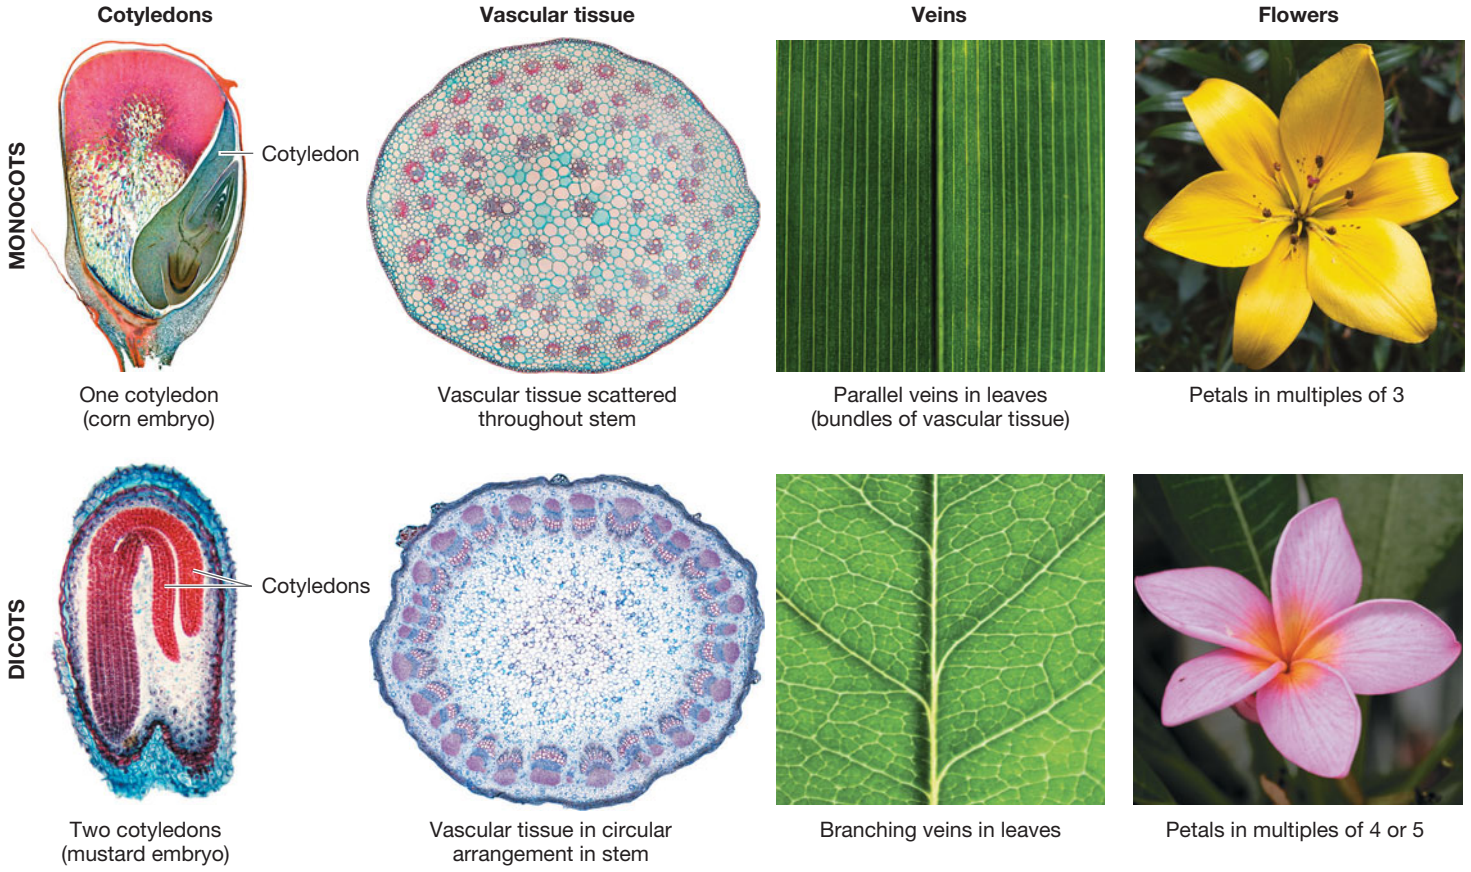

FIGURE 31.24 Four Morphological Differences between Monocots and Dicots. (The stem cross sections, showing vascular tissue and cotyledons, have been stained.)

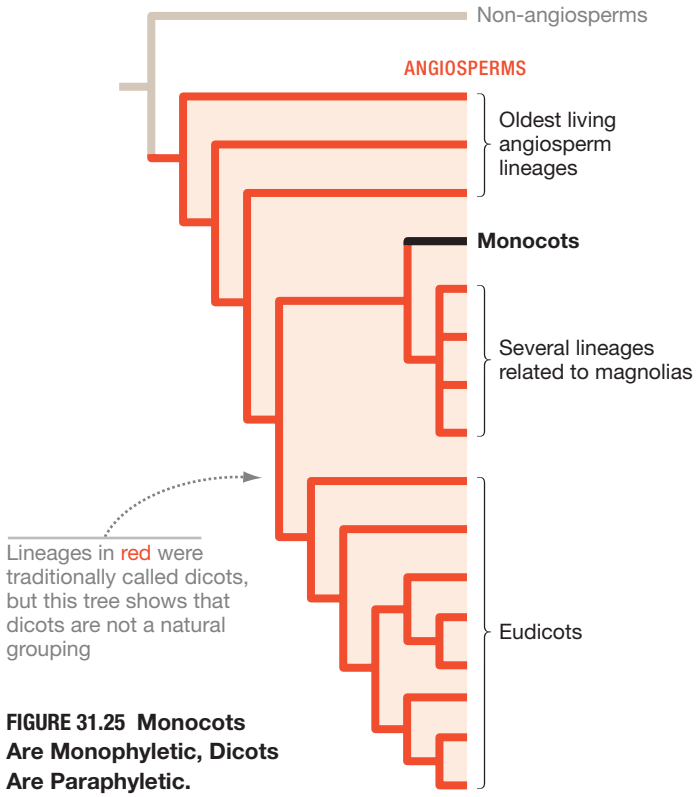

FIGURE 31.25 Monocots Are Monophyletic, Dicots Are Paraphyletic.

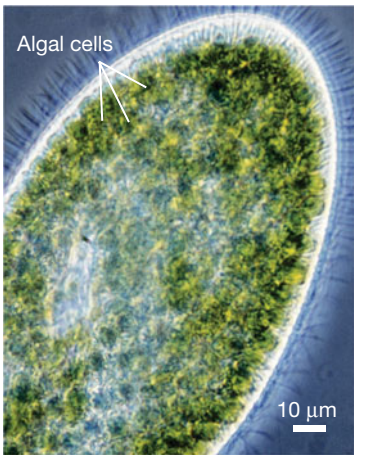
31.4 Key Lineages of Green Algae and Land Plants

The evolution of cuticle, pores, stomata, UV-absorbing compounds, and water-conducting tissues allowed green plants to grow on land, where resources for photosynthesis are abundant. Once the green plants were on land, the evolution of gametangia, retained embryos, pollen, seeds, and flowers enabled them to reproduce efficiently even in dry environments. The adaptations reviewed in Section 31.3 allowed the land plants to make the most important water-to-land transition in the history of life.

To explore green plant diversity in more detail, let's take a closer look at some major groups of green algae and land plants. The first part of this section considers broad groupings of lineages; the "index cards" that follow focus on particular monophyletic groups.



Green Algae

The **green algae** are a paraphyletic group that totals about 7000 species. Their bright green chloroplasts are similar to those found in land plants. Specifically, green algal chloroplasts have a double membrane and contain chlorophylls *a* and *b*. And like land plants, green algae synthesize starch in the chloroplast as a

(a) Green algae with red carotenoid pigments are responsible for pink snow.

(b) Many unicellular protists harbor green algae.

(c) Most lichens are an association between fungi and microscopic green algae.

FIGURE 31.26 Some Green Algae Live in Unusual Environments.

storage product of photosynthesis. They also have a cell wall that is composed primarily of cellulose.

Green algae are important primary producers in nearshore ocean environments and in all types of freshwater habitats. They are also found in several types of more exotic environments, including snowfields at high elevations, pack ice, and ice floes. These habitats are often splashed with bright colors due to large concentrations of unicellular green algae (**FIGURE 31.26a**). Although these cells live at near-freezing temperatures, they make all their own food via photosynthesis.

In addition, green algae live in close association with an array of other organisms.

- Unicellular green algae are common endosymbionts in planktonic protists that live in lakes and ponds (**FIGURE 31.26b**). The association is considered mutually beneficial: The algae supply the protists with food; the protists provide protection to the algae.
- **Lichens** are stable associations between green algae and fungi, or between cyanobacteria and fungi, and are often found in terrestrial environments that lack soil, such as tree bark or bare rock (**FIGURE 31.26c**). The algae or cyanobacteria in a lichen are protected from drying by the fungus; in return, they provide sugars produced by photosynthesis.

Of the 17,000 species of lichens described to date, about 85 percent involve green algae. The green algae that are involved are unicellular or grow in long filaments. (Lichens are explored in more detail in Chapter 32.)

Green algae are a large and fascinating group of organisms. In this final section of the chapter, let's take a closer look at just three of the many lineages.

- Green Algae > Ulvophyceae (Ulvophytes)
- Green Algae > Coleochaetophyceae (Coleochaetes)
- Green Algae > Charophyceae (Stoneworts)

Nonvascular Plants

The initial lineages to branch off the phylogeny of living land plants are sometimes known as nonvascular plants.

All of the nonvascular plant species present today have a low, sprawling growth habit. In fact, it is unusual to find species that are more than 5 to 10 centimeters tall.

Individuals are anchored to soil, rocks, or tree bark by structures called **rhizoids.** Although simple water-conducting cells and tissues are found in some mosses, nonvascular plants lack vascular tissue with lignin-reinforced cell walls.

All nonvascular plants have flagellated sperm that swim to eggs through raindrops or small puddles on the plant surface. Spores are dispersed by wind.

- Nonvascular Plants > Hepaticophyta (Liverworts)
- Nonvascular Plants > Bryophyta (Mosses)
- Nonvascular Plants > Anthocerophyta (Hornworts)

Seedless Vascular Plants

The seedless vascular plants are a paraphyletic group between the nonvascular plants and the seed plants. All species of seedless vascular plants have conducting tissues with cells that are reinforced with lignin. Tree-sized lycophytes and horsetails are abundant in the fossil record, and tree ferns are still common inhabitants of certain habitats, such as in New Zealand and on mountain slopes in the tropics.

The sporophyte is the larger and longer-lived phase of the life cycle in all of the seedless vascular plants. The gametophyte is physically independent of the sporophyte, however. Eggs are retained on the gametophyte, and sperm swim to the egg with the aid of flagella. Thus, seedless vascular plants depend on the presence of water for reproduction—they need enough water to form a continuous layer that "connects" gametophytes and allows sperm to swim to eggs. Sporophytes develop on the

gametophyte and are nourished by the gametophyte when they are small.

- Seedless Vascular Plants > Lycophyta (Lycophytes, or Club Mosses)
- Seedless Vascular Plants > Psilotophyta (Whisk Ferns)
- Seedless Vascular Plants > Pteridophyta (Ferns)
- Seedless Vascular Plants > Equisetophyta (or Sphenotophyta) (Horsetails)

Seed Plants

The seed plants are a monophyletic group consisting of the gymnosperms—ginkgo, cycads, redwoods, pines, and gnetophytes—and the angiosperms. The group is defined by two key synapomorphies, traits common to a lineage and found in no other lineages: the production of seeds and the production of pollen grains.

1. Seeds are a specialized structure for dispersing embryonic sporophytes to new locations. Seeds are the mature form of a fertilized ovule, the female reproductive structure that encloses the female gametophyte and egg cell.
2. Pollen grains are tiny, sperm-producing gametophytes that are easily dispersed through air as opposed to water.

Seed plants are found in virtually every type of habitat, and they adopt every growth habit known in land plants. Their forms range from mosslike mats to shrubs and vines to 100-meter-tall trees. Seed plants can be **annual** (have a single growing season) or **perennial** (live for many years), with life spans ranging from a few weeks to almost five thousand years. (See Chapters 37 through 41 to further explore the structure and function of seed plants.)

- Seed Plants > Gymnosperms > Ginkgophyta (Ginkgoes)
- Seed Plants > Gymnosperms > Cycadophyta (Cycads)
- Seed Plants > Gymnosperms > Cupressophyta (Redwoods, Junipers, Yews)
- Seed Plants > Gymnosperms > Pinophyta (Pines, Spruces, Firs)
- Seed Plants > Gymnosperms > Gnetophyta (Gnetophytes)
- Seed Plants > Anthophyta (Angiosperms)

Green Algae > Ulvophyceae (Ulvophytes)

The Ulvophyceae are a monophyletic group composed of several diverse and important subgroups, with a total of about 4000 species. Members of this lineage range from unicellular to multicellular.

Many of the large green algae in habitats along ocean coastlines are members of the Ulvophyceae. *Ulva*, the sea lettuce (**FIGURE 31.27**), is a representative marine species. But freshwater lakes and streams also contain large numbers of unicellular or small multicellular species that are free-floating plankton.

Reproduction Most ulvophytes reproduce both asexually and sexually. Asexual reproduction often involves production of spores that swim with the aid of flagella. Sexual reproduction usually results in production of a resting stage—a cell that is dormant in winter. In many species the gametes are not called eggs and sperm, because they are the same size and shape. In most species gametes are shed into the water, so fertilization takes place away from the parent plants.

Life cycle Many unicellular forms are diploid only as zygotes. Alternation of generations occurs in multicellular species. When alternation of generations occurs, gametophytes and sporophytes may look identical or different.

Human and ecological impacts Ulvophyceae are important primary producers in freshwater environments and in coastal areas of the oceans.

Ulva lactuca

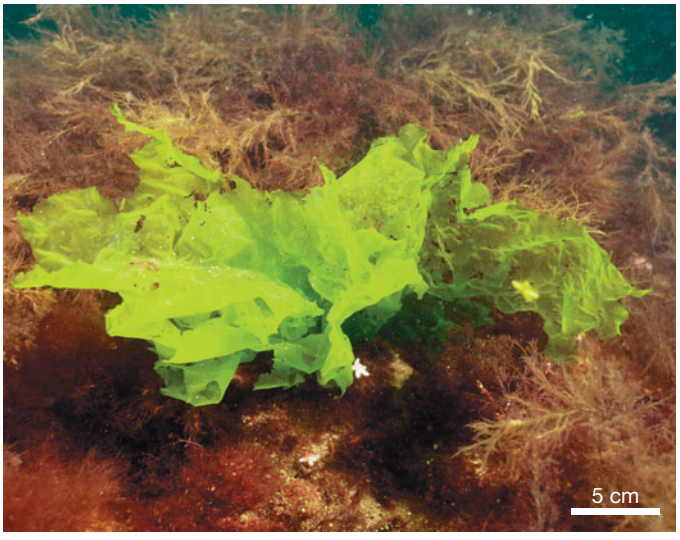


FIGURE 31.27 Green Algae Are Important Primary Producers in Aquatic Environments.

Green Algae > Coleochaetophyceae (Coleochaetes)

This group includes 19 species. Most coleochaetes are barely visible to the unaided eye and grow as flat sheets of cells (**FIGURE 31.28**). They are considered multicellular because they have specialized photosynthetic and reproductive cells and because they contain **plasmodesmata** that connect adjacent cells in plants (see Chapter 11).

The coleochaetes are strictly freshwater algae. They grow attached to aquatic plants such as water lilies and cattails or over submerged rocks in lakes and ponds. When they grow near beaches, they are often exposed to air when water levels drop in late summer.

Reproduction Asexual reproduction is common in coleochaetes and involves production of flagellated spores. During sexual reproduction, eggs are retained on the parent and are nourished after fertilization with the aid of transfer cells—a situation similar to that observed in land plants. In some species certain individuals are male and produce only sperm, while other individuals are female and produce only eggs.

Life cycle Alternation of generations does not occur. Multicellular individuals are haploid; the only diploid stage in the life cycle is the zygote.

Human and ecological impacts Because they are closely related to land plants, coleochaetes are studied intensively by researchers interested in how land plants made the water-to-land transition.

Coleochaete orbicularis

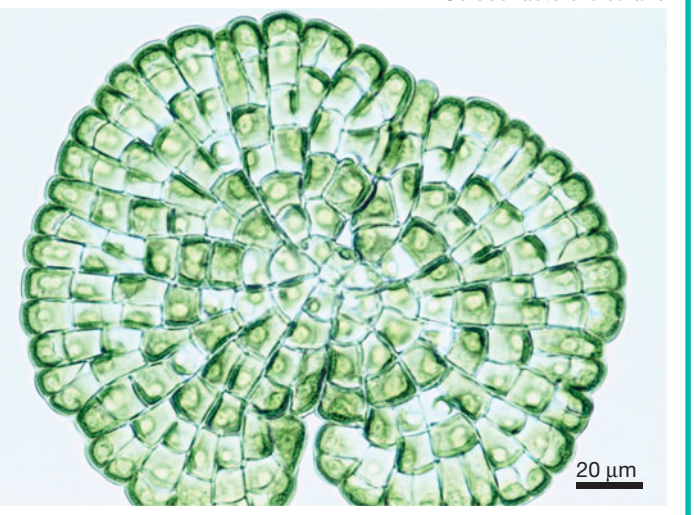

FIGURE 31.28 Coleochaetes Are Thin Sheets of Cells.

Green Algae > Charophyceae (Stoneworts)

This group includes several hundred species. They are collectively known as stoneworts, because they commonly accumulate crusts of calcium carbonate ($CaCO_3$) over their surfaces. Like the coleochaetes, they have plasmodesmata and are multicellular. ✔ **You should be able to mark the origin of plasmodesmata on Figure 31.6.** (They do not occur in ulvophytes.) Some species of stonewort can be a meter or more in length.

The stoneworts are freshwater algae. Certain species are specialized for growing in relatively deep waters, though most live in shallow water near lake beaches or pond edges.

Reproduction Sexual reproduction is common and involves production of prominent, multicellular gametangia similar to those observed in early land plants. In stoneworts, as in coleochaetes, the eggs are retained on the parent plant, which supplies eggs with nutrients before fertilization. ✔ **You should be able to mark the origin of egg retention on Figure 31.6.** (Egg retention does not occur in ulvophytes.)

Life cycle Alternation of generations does not occur. Multicellular individuals are haploid; the only diploid stage in the life cycle is the zygote.

Human and ecological impacts Some species form extensive beds in lake bottoms or ponds and provide food for ducks and geese as well as food and shelter for fish (**FIGURE 31.29**). They are a good indicator that water is not polluted.

Chara species

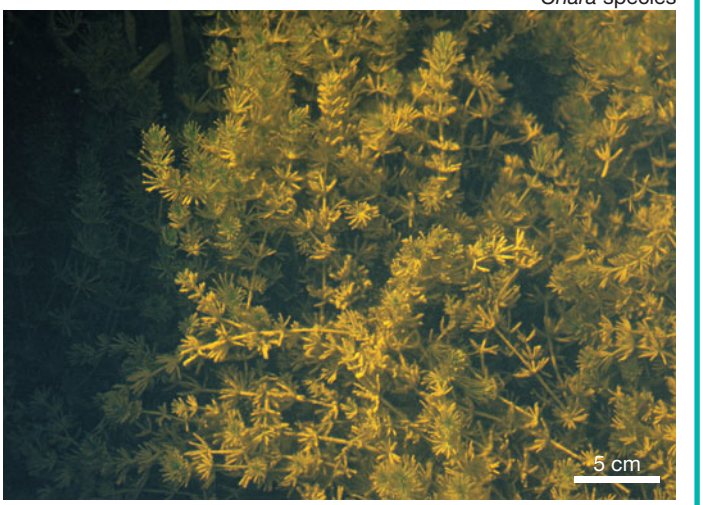

FIGURE 31.29 Stoneworts Can Form Beds on Lake Bottoms.

Nonvascular Plants > Hepaticophyta (Liverworts)

Liverworts got their name because some species native to Europe have liver-shaped leaves. According to the medieval *Doctrine of Signatures*, God indicated how certain plants should be used by giving them a distinctive appearance. Thus, liverwort teas were hypothesized to be beneficial for liver ailments. (They are not.) About 6500 species are known. They are commonly found growing on damp forest floors or riverbanks, often in dense mats (**FIGURE 31.30**), or on the trunks or branches of tropical trees.

Adaptations to land Liverworts are covered with cuticle. Some species have pores that allow gas exchange; in species that lack pores, the cuticle is thin.

Reproduction Asexual reproduction occurs when fragments of a plant are broken off and begin growing independently. Some species also produce small structures called **gemmae** asexually, during the gametophyte phase. Mature gemmae are knocked off the parent plant by rain and grow into independent gametophytes. During sexual reproduction, sperm and eggs are produced in gametangia.

Life cycle The gametophyte is the largest and longest-lived phase in the life cycle. Sporophytes are small, grow directly from the gametophyte, and depend on the gametophyte for nutrition. Spores are shed from the sporophyte and are carried away by wind or rain.

Human and ecological impacts When liverworts grow on bare rock or tree bark, their dead and decaying body parts contribute to the initial stages of soil formation. The liverwort *Marchantia polymorpha*, shown in Figure 31.30, is an important model organism in plant biology.

Marchantia polymorpha

FIGURE 31.30 Liverworts Thrive in Moist Habitats.

Nonvascular Plants > Bryophyta (Mosses)

Over 12,000 species of mosses have been named and described to date, and more are being discovered every year—particularly in the tropics.

Although mosses are common in moist forests, they can also be found in more extreme environments, such as deserts and windy, treeless habitats in the Arctic, Antarctic, or on mountaintops. In these severe conditions, mosses are able to thrive because their bodies can become extremely dry without dying. When the weather makes photosynthesis difficult, individuals dry out and become dormant, or inactive. Then when rains arrive or temperatures warm, the plants rehydrate and begin photosynthesis and reproduction.

Adaptations to land One subgroup of mosses contains simple conducting tissues consisting of cells that are specialized for the transport of water or food. But because these cells do not have walls that are reinforced by lignin, they are not considered true vascular tissue. ✔ **You should be able to mark the origin of the simple water-conducting cells and tissues in this moss subgroup on Figure 31.6.** Because they lack true vascular tissue, most mosses are not able to grow much taller than a few centimeters.

Reproduction Asexual reproduction often occurs by fragmentation, meaning that pieces of gametophytes that are broken off by wind or a passing animal can begin growing independently. In many species, sexual reproduction cannot involve self-fertilization because the sexes are separate—meaning that an individual plant produces only eggs, in archegonia, or only sperm, in antheridia. A typical sporophyte produces up to 50 million tiny spores. Spores are usually distributed by wind.

Life cycle The moss life cycle is similar to that of liverworts and hornworts: The sporophyte is retained on the much larger and longer-lived gametophyte and gets most of its nutrition from the gametophyte.

Human and ecological impacts Species in the genus *Sphagnum* are often the most abundant plant in wet habitats of northern environments (**FIGURE 31.31a**, page 602). Because *Sphagnum*-rich environments account for 1 percent of Earth's total land area, equivalent to half the area of the United States, *Sphagnum* species are among the most abundant plants in the world. *Sphagnum*-rich

(Continued on next page)

Nonvascular Plants > Bryophyta (Mosses) *continued*

(a) *Sphagnum* moss is abundant in northern wet habitats.

(b) Semi-decayed *Sphagnum* moss forms peat.

FIGURE 31.31 *Sphagnum* Mosses Are among the Most Abundant Plants in the World.

habitats are waterlogged, nitrogen poor, and often anaerobic, however, so the decomposition of dead mosses and other plants is slow. As a result, large deposits of semi-decayed organic matter, known as **peat,** accumulate. Researchers estimate that the world's peatlands store about 400 billion metric tons of carbon. If peatlands begin to burn or decay rapidly due to rising temperatures associated with global climate change, the CO_2 released will exacerbate the warming trend (see Chapter 56).

Peat is harvested as a traditional heating and cooking fuel in some countries (**FIGURE 31.31b**). It is also widely used as a soil additive in gardening, because *Sphagnum* can absorb up to 20 times its dry weight in water. This high water-holding capacity is due to the presence of large numbers of dead cells in the leaves of these mosses, which readily fill with water via pores in their walls.

Nonvascular Plants > Anthocerophyta (Hornworts)

Hornworts got their name because their sporophytes have a horn-like appearance (**FIGURE 31.32**) and because "wort" is the Anglo-Saxon word for plant. About 100 species have been described to date. Hornworts can be found worldwide but are more common in tropical regions in damp soil or on the bark of trees.

Anthoceros sp.

FIGURE 31.32 Hornworts Have Horn-Shaped Sporophytes.

Adaptations to land In most species of hornworts, sporophytes have stomata that function much like those of vascular plants. Sporophytes have cell layers that change shape when exposed to low humidity, facilitating the release of spores.

Reproduction Depending on the species, gametophytes may contain only egg-producing archegonia or only sperm-producing antheridia, or both. Stated another way, individuals of some species are either female or male, while in other species each individual has both types of reproductive organs.

Life cycle The gametophyte is the longest-lived phase in the life cycle. Although sporophytes grow directly from the gametophyte, they are green because their cells contain chloroplasts. Sporophytes manufacture some of their own food but also get nutrition from the gametophyte. Spores disperse from the parent plant via wind or rain.

Human and ecological impacts Some species harbor symbiotic cyanobacteria that fix nitrogen.

Seedless Vascular Plants > Lycophyta (Lycophytes, or Club Mosses)

Although the fossil record documents lycophytes that were 2 m wide and 40 m tall, the 1000 species of lycophytes living today are all small in stature (**FIGURE 31.33**). Most lycophytes live on the forest floor or on the branches or trunks of tropical trees. Because of their appearance, they are often called ground pines or club mosses—even though they are neither pines nor mosses.

Adaptations to land Lycophytes are the most ancient land plant lineage with **roots**—a belowground system of tissues that anchors the plant and is responsible for absorbing water and mineral nutrients. Roots differ from the rhizoids observed in nonvascular plants, because roots contain vascular tissue and thus are capable of conducting water and nutrients to the upper reaches of the plant. Unusual leaves called microphylls, which extend from the stems, are a synapomorphy found in lycophytes. ✔ **You should be able to mark the origin of microphylls on Figure 31.6.**

Reproduction Asexual reproduction can occur by fragmentation or gemmae. During sexual reproduction, spores of some species give rise to bisexual gametophytes—meaning that each gametophyte produces both eggs and sperm. Self-fertilization is extremely rare, however. In the genera *Selaginella* and *Isoetes*, in contrast, heterospory occurs and gametophytes are either male or female.

Life cycle The gametophytes of some species live entirely underground and get their nutrition from symbiotic fungi. In certain species, gametophytes live 6 to 15 years and give rise to a large number of sporophytes over time.

Human and ecological impacts Tree-sized lycophytes were abundant in the coal-forming forests of the Carboniferous period. In coal-fired power plants today, electricity is being generated by burning fossilized lycophyte and fern tissues. Spores of some members are highly flammable. Before the invention of electric flashbulbs, these spores were used as flash powder in early photography.

Lycopodium species

FIGURE 31.33 Lycophytes Living Today Are Small in Stature.

Seedless Vascular Plants > Psilotophyta (Whisk Ferns)

Only two genera of whisk ferns are living today, and there are perhaps six distinct species. Whisk ferns are restricted to tropical regions and have no fossil record. They are extremely simple morphologically; their aboveground parts consist of branching stems that have tiny, scale-like outgrowths instead of leaves (**FIGURE 31.34**).

Because they lack roots and leaves, the whisk ferns were considered an evolutionary "throwback"—a group that retained traits found in the earliest vascular plants. However, molecular phylogenies support an alternative hypothesis: The morphological simplicity of whisk ferns is a derived trait—meaning that complex structures have been lost in this lineage.

Adaptations to land Whisk ferns lack roots. Some species gain most of their nutrition from fungi that grow in association with the whisk ferns' underground stems, called **rhizomes.** Other species grow in rock crevasses or as **epiphytes** ("upon-plants"), meaning that they grow on the branches of other plants—in this case, on the branches of tree ferns. ✔ **After reviewing where leaves and roots originated during land plant evolution (see Figure 31.9), you should be able to mark the loss of leaves and roots in whisk ferns on Figure 31.6.**

Psilotum nudum

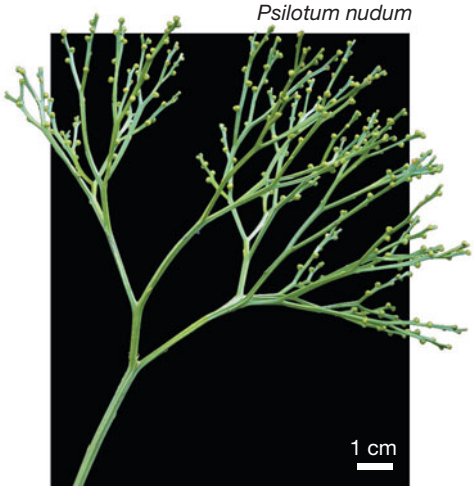

FIGURE 31.34 Psilotophytes Are Extremely Simple Morphologically.

Reproduction Asexual reproduction occurs via the extension of rhizomes and the production of new aboveground stems. When spores mature, they are dispersed by wind and germinate into gametophytes that contain both archegonia and antheridia.

Life cycle Sporophytes may be up to 30 cm tall, but gametophytes are less than 2 mm long and live under the soil surface. Gametophytes absorb nutrients directly from the soil or from symbiotic fungi. Fertilization takes place inside the archegonium, and the sporophyte develops directly on the gametophyte.

Human and ecological impacts Some whisk fern species are popular landscaping plants, particularly in Japan. The same species can be a serious pest in greenhouses.

With 12,000 species, ferns are by far the most species-rich group of seedless vascular plants. They are particularly abundant in the tropics. About a third of the tropical species are epiphytes, usually growing on the trunks or branches of trees. Species that can grow epiphytically live high above the forest floor, where competition for light is reduced, without making wood and growing tall themselves. The growth habits of ferns are highly variable among species, however, and ferns range in size from rosettes the size of your smallest fingernail to 20-meter-tall trees.

Adaptations to land Ferns are the only seedless vascular plants that have large, well-developed leaves—commonly called **fronds.** Young fronds are coiled and because of their shape are called "fiddleheads"; they uncoil as they develop (**FIGURE 31.35a**). Leaves give the plant a large surface area, allowing it to capture sunlight for photosynthesis efficiently.

Reproduction In a few species, gametophytes reproduce asexually via production of gemmae. Typically, species that can reproduce via gemmae never produce gametes or sporophytes. In most species, however, sexual reproduction is the norm. Ferns are homosporous, but gametophytes develop as males or are bisexual, depending on light intensity, proximity to other gametophytes, and other environmental conditions. In bisexual gametophytes, maturation of male and female gametes is staggered to minimize self-fertilization.

Life cycle Although fern gametophytes contain chloroplasts and are photosynthetic, the sporophyte is typically the larger and longer-lived phase of the life cycle. In mature sporophytes, sporangia are usually found in clusters called **sori** on the undersides of leaves (**FIGURE 31.35b**). The structure of the sporangia is a distinctive feature of ferns. When mature, the side wall of a sporangium ruptures and a thickened row of cells along the other side of the sporangium shrinks, pulling the open sporangium back. When the humidity is low the sporangium springs back, catapulting the spores into the dry air currents. ✔ **You should be able to mark the evolution of the distinctive fern sporangium on Figure 31.6.**

Human and ecological impacts In many parts of the world, people gather the fiddleheads of ferns in spring as food. Ferns are also widely used as ornamental plants in landscaping.

(a) Fern fronds develop as coiled "fiddleheads."

Sadleria cyatheoides

(b) Fern sporangia are often in clusters (sori) on the underside of fronds.

Polypodium vulgare

FIGURE 31.35 Fern Fronds Uncoil as They Develop and Form Clusters of Sporangia (Sori) When They Mature.

Although horsetails are prominent in the fossil record of land plants, just 15 species are known today. All 15 are in the genus *Equisetum*. Translated literally, *Equisetum* means "horse-bristle." Both the scientific name and the common name, horsetail, come from the brushy appearance of the stems and branches in some species (**FIGURE 31.36a**). Horsetails may be locally abundant in wet habitats such as stream banks or marsh edges.

Adaptations to land Horsetails have an adaptation that allows them to flourish in waterlogged, oxygen-poor soils: Their stems are hollow, so oxygen readily diffuses down the stem to reach roots that cannot obtain oxygen from the surrounding soil. Horsetails are also distinguished by having whorled leaves and branches. Horsetail spores have appendages, called elaters, that change position with changes in humidity and cause spores to fall over wet habitats where gametophytes are more likely to survive (**FIGURE 31.36b**). ✔ **You should be able to mark the origin of the distinctive spore elaters on Figure 31.6.**

Reproduction Asexual reproduction is common in sporophytes and occurs via fragmentation or the extension of rhizomes. From these rhizomes, two types of erect, specialized stems may grow—stems that contain tiny leaves and chloroplast-rich branches and that are specialized for photosynthesis, or stems that bear clusters of sporangia and produce huge numbers of spores by meiosis.

Life cycle Gametophytes perform photosynthesis but are small and short lived. They normally produce both antheridia and archegonia, but in most cases the sperm-producing structure matures first. This pattern is thought to be an adaptation that minimizes self-fertilization and maximizes cross-fertilization.

Human and ecological impacts Horsetail stems are rich in silica granules. The glass-like deposits not only strengthen the stem but also made these plants useful for scouring pots and pans before the invention of other scrubbing tools—hence these plants are often called "scouring rushes."

(a) Fertile shoots bear conelike clusters of sporangia.

Equisetum arvense

(b) As spores inside sporangia dry out, their elaters unfurl, tossing out the spores.

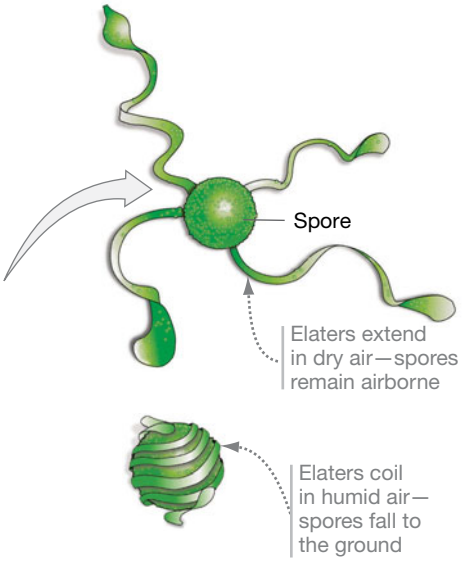

FIGURE 31.36 Horsetails Have a Distinctive Brushy Appearance and Unusual Spores.

Seed Plants > Gymnosperms > Ginkgophyta (Ginkgoes)

Although ginkgoes have an extensive fossil record, just one species is alive today. Leaves from the ginkgo, or maidenhair, tree are virtually identical in size and shape to those observed in fossil ginkgoes that are 150 million years old (**FIGURE 31.37**).

(a) Fossil ginkgo

Ginkgo huttoni

(b) Living ginkgo

Ginkgo biloba

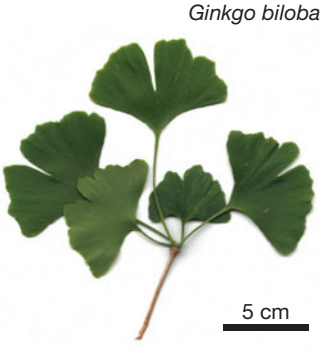

FIGURE 31.37 The Ginkgo Tree Is a "Living Fossil."

Adaptations to land Unlike most gymnosperms, the ginkgo is **deciduous**—meaning that it loses its leaves each autumn. This adaptation allows plants to be dormant during the winter, when photosynthesis and growth are difficult.

Reproduction and life cycle Sexes are separate—individuals are either male or female. Pollen is transported by wind. Sperm have flagella, however. Once pollen grains land near the female gametophyte and mature, the sperm cells leave the pollen grain and swim to the egg cells.

Human and ecological impacts Although today's ginkgo trees are native to southeast China, they are planted widely as an ornamental. They are especially popular in urban areas because they are tolerant of air pollution. Male trees are usually planted because the seeds produced by female trees contain butyric acid, making them smell like rancid butter. However, in some countries, the inside of the seed is eaten as a delicacy.

Seed Plants > Gymnosperms > Cycadophyta (Cycads)

The cycads are so similar in overall appearance to palm trees, which are angiosperms, that cycads are sometimes called "sago palms." Although cycads were extremely abundant when dinosaurs were present on Earth 150–65 million years ago, only about 140 species are living today. Most are found in the tropics (**FIGURE 31.38**).

Adaptations to land Cycads do not make wood but are supported by stiff stems. They are unique among gymnosperms in having compound leaves—meaning that each leaf is divided into many smaller leaflets. ✔ **You should be able to mark the origin of the distinctive cycad leaf on Figure 31.6.**

Reproduction and life cycle In cycads each sporophyte individual bears either microsporangia or megasporangia, but not both. Like other seed plants, cycads are heterosporous. Pollen is carried by insects (usually beetles or weevils) or, in some species, wind. Cycad seeds are large and often brightly colored. The colors attract birds and mammals, both of which eat and disperse the seeds.

Human and ecological impacts Cycads harbor large numbers of symbiotic cyanobacteria in specialized, aboveground root structures. The cyanobacteria are photosynthetic and fix nitrogen. The nitrogen acts as an important nutrient for nearby plants as well as for the cycads themselves. Cycads are popular landscaping plants in some parts of the world.

Encephalartos transvenosus

FIGURE 31.38 Cycads Resemble Palms but Are Not Closely Related to Them.

Seed Plants > Gymnosperms > Cupressophyta (Redwoods, Junipers, Yews)

The species in this lineage vary in growth form from sprawling juniper shrubs to the world's largest plants. Redwood trees growing along the Pacific Coast of North America can reach heights of over 115 m (375 ft) and have trunk diameters of over 9.5 m (30 ft). These species were recently confirmed as a monophyletic group, independent of the Pinophyta, which also reproduce via cone-bearing structures.

Adaptations to land All of the species in this lineage are trees or large shrubs. Most have narrow leaves, which in many cases are arranged in overlapping scales (**FIGURE 31.39**). Narrow leaves have a small amount of surface area, which is not optimal for capturing sunlight and performing photosynthesis. But because the small surface area reduces water loss from leaves, many species in this lineage thrive in dry habitats or in cold environments where water is often frozen.

FIGURE 31.39 Some Species in the Cupressophyta Have Scale-like Leaves.

Reproduction and life cycle The species in this group are wind pollinated. As in all seed plants, the female gametophyte is retained on the parent. Thus, fertilization and seed development take place in the female cone. As in gymnosperms, seeds do not form inside an encapsulated structure. Depending on the species, the seeds are dispersed by wind or by seed-eating birds or mammals.

Human and ecological impacts Redwoods, red cedar, white cedar, and yellow cedar have wood that is highly resistant to decay and thus prized for making furniture, decks, and house siding, or for other applications where wood is exposed to the weather. Yew wood is often preferred for making traditional archery bows, and the berry-like cones of juniper are used to flavor gin. The anticancer drug taxol was originally found in Pacific yew trees.

Seed Plants > Gymnosperms > Pinophyta (Pines, Spruces, Firs)

The gymnosperms include two major lineages of cone-bearing species: the pines and allies discussed here, and the group already described that includes redwoods, junipers, and yews. Species in both lineages have a reproductive structure called the cone, which produces microsporangia or megasporangia (**FIGURE 31.40**).

Pinophyta include the familiar pines, spruces, firs, Douglas fir, tamaracks, and true cedars. These are among the largest and most abundant trees on the planet, as well as some of the most long lived. One of the bristlecone pines native to southwestern North America is at least 4750 years old.

Adaptations to land Pinophyta have needle-like leaves whose small surface area allows them to thrive in habitats where water is scarce. Pines are common on sandy soils that have poor water-holding capacity, and spruces and firs are common in cold environments where water is often frozen. All of the living species make wood as a support structure.

Reproduction and life cycle Sexes are separate, and pollen is transferred to female cones by the wind. Female cones take two years to mature and are usually found high in trees. Male cones are usually found lower in the tree—possibly to reduce self-pollination from falling pollen.

Human and ecological impacts In terms of biomass, pines, spruces, firs, and other species in this group dominate forests that grow at high latitudes and high elevations as well as at sandy sites in warmer regions. Their seeds are key food sources for a variety of birds, squirrels, and mice, and their wood is the basis of the building products and paper industries in many parts of the world. The paper in this book was made from species in this group.

(a) Cones that produce microsporangia and pollen
Picea abies

(b) Cones that produce megasporangia and eggs
Picea abies

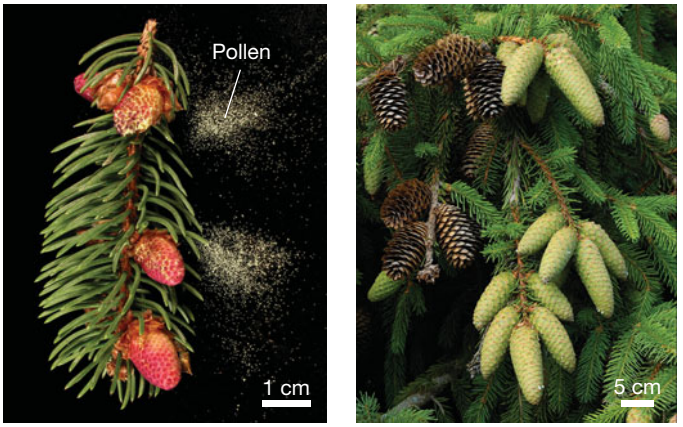

FIGURE 31.40 Pollen-Bearing Cones Produce Microsporangia; Ovulate Cones Produce Megasporangia.

Seed Plants > Gymnosperms > Gnetophyta (Gnetophytes)

The gnetophytes comprise about 70 species in three genera: *Gnetum* comprises vines and trees from the tropics; *Ephedra* is made up of desert-dwelling shrubs, including what may be the most familiar gnetophyte—the shrub called Mormon tea, which is common in the deserts of southwestern North America; *Welwitschia* contains a single species that probably qualifies as the world's most bizarre plant (**FIGURE 31.41**), *W. mirabilis*, which is native to the deserts of southwest Africa. Although it has large belowground structures, the aboveground part consists of just two strap-like leaves, which grow continuously from the base and die at the tips. The leaves also split lengthwise as they grow and age.

Adaptations to land Gnetophytes have vessel elements in addition to tracheids. All of the living species make wood as a support structure.

Reproduction and life cycle The microsporangia and megasporangia are arranged in clusters at the end of stalks, similar to the way flowers are clustered in some angiosperms. Pollen is transferred by the wind or by insects. Double fertilization occurs in two of the three genera. As in other gymnosperms, seeds do not form inside an encapsulated structure.

Human and ecological impacts The drug ephedrine was originally isolated from species of *Ephedra* that are native to northern China and Mongolia. Ephedrine is used in the treatment of hay fever, colds, and asthma.

Welwitschia mirabilis

FIGURE 31.41 *Welwitschia* Is an Unusual Plant.

Seed Plants > Anthophyta (Angiosperms)

The flowering plants, or angiosperms, are far and away the most species-rich lineage of land plants. Over 250,000 species have already been described. They range in size from *Lemna gibba*—a floating, aquatic species that is less than half a millimeter wide—to massive oak trees. Angiosperms thrive in desert to freshwater to rain forest environments and are found in virtually every habitat except the deep oceans. They are the most common and abundant plants in most terrestrial environments.

The defining adaptation of angiosperms is the flower. Flowers are reproductive structures that hold either pollen-producing microsporangia or the megasporangia that produce megaspores and eggs, or both. Nectar-producing cells are often present at the base of the flower, and the color of petals helps attract insects, birds, or bats that carry pollen from one flower to another (**FIGURE 31.42a**). Some angiosperms are pollinated by wind, however. Wind-pollinated flowers lack both colorful petals and nectar-producing cells (**FIGURE 31.42b**).

Adaptations to land In addition to flowers, angiosperms evolved water-conducting vessels, the conducting cells that make water transport particularly efficient. Most angiosperms contain both tracheids and vessels.

Reproduction and life cycle Unlike gymnosperms, angiosperms have a carpel, a structure within the flower that contains an ovary. The ovary encloses one or more ovules, each of which encloses a female gametophyte. In most cases, male gametophytes are carried to female gametophytes by animal pollinators that are inadvertently dusted with pollen as they visit flowers to find food. Depending on the angiosperm species, self-fertilization may be common or absent. When the egg produced by the female gametophyte is fertilized, the ovule develops into a seed. When the ovary matures, it forms a fruit that contains the seed or seeds.

Human and ecological impacts It is almost impossible to overstate the importance of angiosperms to humans and other organisms. In most terrestrial habitats today, angiosperms supply the food that supports virtually every other species. For example, many insects eat flowering plants. Historically, the diversification of angiosperms correlated closely with the diversification of insects, which are by far the most species-rich lineage on the tree of life. It is not unusual for a single tropical tree to support dozens or even hundreds of insect species. Angiosperm seeds and fruits have also supplied the staple foods of virtually every human culture that has ever existed.

CHAPTER 31 REVIEW

For media, go to MasteringBiology

If you understand . . .

31.1 Why Do Biologists Study the Green Algae and Land Plants?

- Plants are important primary producers and a source of oxygen, and they hold soil and water in place.
- Plants improve the quality of the environment for other organisms.
- Humans depend on plants for food, fiber, pharmaceuticals, building materials, and fuel.

✔ **You should be able to predict how the ongoing and massive loss of plant species and plant communities will affect soils around the world.**

31.2 How Do Biologists Study Green Algae and Land Plants?

- Scientists analyze morphological traits, examine the fossil record, and evaluate molecular phylogenies to study and compare green algae and land plants.
- Morphological differences suggest that land plants evolved from multicellular, freshwater green algae from the Charophyceae.
- The fossil record reveals that the first, simple land plants evolved about 475 million years ago and then diversified into plants with vascular systems, seeds, and flowers.

✔ **You should be able to describe the synapomorphies that define all green algae and land plants.**

31.3 What Themes Occur in the Diversification of Land Plants?

- The evolution of cuticle allowed plant tissues to be exposed to air without dying.
- UV-absorbing compounds allowed the first land plants to tolerate the harsh UV rays from the sun.
- The evolution of stomata, breaks in the cuticle consisting of pores controlled by guard cells, allowed plants to maximize gas exchange and minimize water loss.
- Vascular tissue conducts water and has secondary cell walls reinforced with lignin that provides structural support allowing plants to grow upright. This adaptation reduces competition for light.
- Tracheids are water-conducting cells found in all vascular plants; in addition, angiosperms and gnetophytes have water-conducting cells called vessels.
- All land plants are embryophytes, meaning that eggs and embryos are retained on the parent plant. Consequently, the developing embryo can be nourished by its mother.
- All land plants have alternation of generations. Over the course of land plant evolution, the gametophyte phase became reduced in terms of size and life span, and the sporophyte phase became more prominent. Heterospory also became more common.

- The evolution of pollen was an important breakthrough in the history of life, because sperm no longer needed to swim to the egg—tiny male gametophytes could be transported through the air via wind or animals.
- Seed plant embryos are dispersed from the parent plant to a new location, encased in a protective housing, and supplied with a store of nutrients.

✔ **You should be able to discuss (compare and contrast) the advantages and disadvantages of having spores or seeds serve as the dispersal stage in a plant life cycle.**

31.4 Key Lineages of Green Algae and Land Plants

- Green algae include single-celled and multicellular freshwater species that share numerous characteristics with land plants. Single-celled species are symbionts with protists, fungi, and animals.
- Nonvascular plants include mosses and liverworts that are small and have a gametophyte-dominant life cycle.
- Seedless vascular plants include lycopods and ferns that have small, free-living gametophytes and large, longer-lived sporophytes. Dispersal is carried out using spores.
- Seed plants include gymnosperms and angiosperms that dominate the world's floras. Animals are often used to disperse seeds and, in angiosperms, to transport pollen between flowers.

✔ TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. Which of the following groups is definitely monophyletic?
   a. nonvascular plants
   b. green algae
   c. green plants
   d. seedless vascular plants
2. The appearance of cuticle and stomata correlated with what event in the evolution of land plants?
   a. the first erect growth forms
   b. the first woody tissues
   c. growth on land
   d. the evolution of the first water-conducting tissues
3. What is a pollen grain?
   a. male gametophyte
   b. female gametophyte
   c. male sporophyte
   d. sperm
4. What do seeds contain?
   a. male gametophyte and nutritive tissue
   b. female gametophyte and nutritive tissue
   c. embryo and nutritive tissue
   d. mature sporophyte and nutritive tissue
5. Land plants may have reproductive structures that **(a)** protect gametes as they develop, **(b)** allow sperm to be transported in the absence of water, **(c)** provide stored nutrients and a protective coat so that offspring can be dispersed by wind away from the parent plant, and **(d)** provide nutritious tissue around seeds that facilitates dispersal by animals. Name each of these four structures, and state which land plant group or groups have each structure.
6. What does it mean to say that a life cycle is gametophyte dominant versus sporophyte dominant?

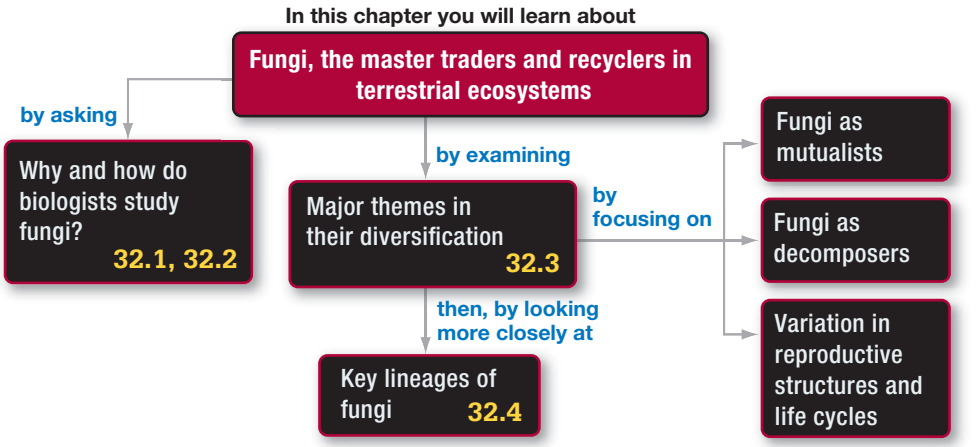
✔ TEST YOUR UNDERSTANDING

Answers are available in Appendix A

7. In the life cycle of an angiosperm, the egg
   a. forms from meiosis of cells inside the seed.
   b. must be fertilized by a sperm that swims to it with its flagella.
   c. is one of the cells formed by mitosis in the ovule.
   d. is part of a mobile female gametophyte.
8. Soils, water, and the atmosphere are major components of the abiotic (nonliving) environment. Describe how green plants affect the abiotic environment in ways that are advantageous to humans.
9. The evolution of cuticle presented land plants with a challenge that threatened their ability to live on land. Describe this challenge, and explain why stomata represent a solution. Compare and contrast stomata with the pores found in liverworts.
10. Why was the evolution of lignin-reinforced cell walls significant?
11. Explain the difference between homosporous and heterosporous plants. Where are the microsporangium and megasporangium found in a tulip? What happens to the spores that are produced by these structures?
12. Describe the advantage that flowering plants gain by using animals to transfer pollen from one individual to another.

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A



13. Which of the following statements is *not* true?
- **a.** Green algae in the lineage called Charophyceae are the closest living relatives of land plants.
- **b.** The nonvascular plants form a monophyletic group.
- **c.** The horsetails and the ferns form a distinct lineage. They have vascular tissue but reproduce via spores, not seeds.
- **d.** According to the fossil record and phylogenetic analyses, angiosperms evolved before the gymnosperms. Angiosperms are the only land plants with vessels.

14. Angiosperms such as grasses, oaks, and maples are wind pollinated. The ancestors of these subgroups were probably pollinated by insects, however. As an adaptive advantage, why might a species "revert" to wind pollination? (Hint: Think about the costs and benefits of being pollinated by insects versus wind.) Why is it logical to observe that wind-pollinated species usually grow in dense stands containing many individuals of the same species? Why is it logical to observe that in wind-pollinated deciduous trees, flowers form very early in spring—before leaves form?

15. Vessel elements transport water much more efficiently than tracheids, but they are much more susceptible than tracheids to being blocked by air bubbles. Suggest a hypothesis to explain why the vascular tissue of angiosperms consists of a combination of vessel elements and tracheids.

16. You have been hired as a field assistant for a researcher interested in the evolution of flower characteristics in orchids. Design an experiment to determine whether color, size, shape, scent, or amount of nectar is the most important factor in attracting pollinators to a particular species. Assume that you can change any flower's color with a dye and that you can remove petals or nectar stores, add particular scents, add nectar by injection, or switch parts among species by cutting and gluing.

32 Fungi

Chicken-of-the-woods (*Laetiporus sulphureus*) is a common edible mushroom that tastes somewhat like chicken. Most of its body consists of microscopic filaments that grow into dead trees, decomposing the wood.

Fungi are eukaryotes that grow as single cells or as large, branching networks of multicellular filaments. Familiar fungi include the mushrooms you've encountered in the woods or a grocery store, the molds and mildews in your home, the organism that causes athlete's foot, and the yeasts used in baking and brewing.

Along with the land plants and the animals, the **fungi** are one of three major lineages of large, multicellular eukaryotes that occupy terrestrial environments. When it comes to making a living, the species in these three groups use radically different strategies. Land plants make their own food through photosynthesis. Animals and fungi both feed on plants, protists, fungi, or each other by releasing digestive enzymes and absorbing small molecules, but while many animals carry out digestion in a dedicated digestive tract, fungi release their digestive enzymes to the external environment.

Fungi that absorb nutrients from dead organisms are the world's most important decomposers. Although a few types of organisms are capable of digesting the cellulose in plant cell walls, certain fungi and a handful of bacterial species are the only organisms capable of digesting both the lignin and

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

cellulose that make up wood. Without fungi, Earth's surface would be piled so high with dead tree trunks and branches that there would be almost no room for animals to move or plants to grow.

Other fungi specialize in absorbing nutrients from living organisms. When fungi absorb these nutrients without providing any benefit in return, they lower the fitness of their host organism and act as parasites. If you've ever had athlete's foot or a vaginal yeast infection, you've hosted a parasitic fungus.

Most of the fungi that live in association with other organisms benefit their hosts, however. In these cases, fungi are not parasites but **mutualists.**

- The roots of most land plants are colonized by an array of mutualistic fungi that provide water and key nutrients such as nitrogen and phosphorus in exchange for sugars that are synthesized by the host plant. The soil around you is alive with an enormous network of fungi that are fertilizing the plants you see aboveground.
- Fungi living inside the shoots of certain plants help ward off herbivores by making toxic compounds.
- Many insects harbor single-celled fungi in their guts that aid their digestion.
- Some insects grow gardens of fungi that they feed with pieces of leaves. The insects then feed off the fungi, which they maintain and continue to cultivate.

In short, fungi are the master traders and recyclers in terrestrial ecosystems. Some fungi release nutrients from dead plants and animals; others obtain nutrients that they then transfer to living plants and animals. Because they recycle key elements such as carbon, nitrogen, and phosphorus and because they transfer key nutrients to plants and animals, fungi have a profound influence on ecosystem productivity and biodiversity. In terms of nutrient cycling, fungi make the world go around.

32.1 Why Do Biologists Study Fungi?

Given their importance to life on land and their intricate relationships to other organisms, it's no surprise that fungi are fascinating to biologists. But there are important practical reasons as well for humans to study fungi. They nourish the plants that nourish us. They affect global climate change, because they are critical to the carbon cycle on land. Unfortunately, many fungi can cause debilitating diseases in humans and crop plants. Let's take a closer look at some of the ways that fungi affect human health and welfare.

Fungi Have Important Economic and Ecological Impacts

In humans, parasitic fungi cause athlete's foot, vaginitis, diaper rash, ringworm, pneumonia, and thrush, among other miseries. But even though these maladies can be serious, in reality no more than approximately 200 species of fungi—out of the hundreds of thousands of existing species—regularly cause illness in humans. Compared with the frequency of diseases caused by bacteria, viruses, and protists, the incidence of fungal infections in humans is low.

It would be easy to argue, in fact, that fungi have done more to promote human health than degrade it. The first antibiotic that was widely used, penicillin, was isolated from a fungus, and soil-dwelling fungi continue to be the source of many of the most important antibiotics prescribed against bacterial infections.

The major destructive impact that fungi have on people is through the food supply. Fungi known as rusts, smuts, mildews, wilts, and blights cause annual crop losses computed in the billions of dollars. These fungi are particularly troublesome in wheat, corn, barley, and other grain crops (**FIGURE 32.1a**). Saprophytic fungi are also responsible for enormous losses due to spoilage—particularly for fruit and vegetable growers (**FIGURE 32.1b**).

In nature, epidemics caused by fungi have killed 4 billion chestnut trees and tens of millions of American elm trees in North America. The fungal species responsible for these epidemics were accidentally imported on species of chestnut and elm native to other regions of the world. When the fungi arrived in North America and began growing in chestnuts and elms native to North America, the results were catastrophic. The local chestnut and elm populations had virtually no genetic resistance to the pathogens and quickly succumbed. Living chestnut root systems continue to sprout shoots, but these trees rarely live long enough to reproduce.

The chestnut and elm epidemics radically altered the composition of upland and floodplain forests in the eastern United States. Before these fungal epidemics occurred, chestnuts and elms dominated these habitats.

(a) Parasitic fungi infect corn and other crop plants.

(b) Saprophytic fungi rot fruits and vegetables.

FIGURE 32.1 Fungi Cause Problems with Crop Production and Storage. (a) A wide variety of grain crops are parasitized by fungi. Corn smut is a serious disease in sweet corn, although in Mexico the smut fungus is eaten as a delicacy. **(b)** Fungi decompose fruits and vegetables as well as leaves and tree trunks.

Fungi also have important positive impacts on the human food supply:

- Mushrooms are consumed in many cultures; in the industrialized nations they are used in sauces, salads, and pizza.
- The yeast *Saccharomyces cerevisiae* was domesticated thousands of years ago; today it and other fungi are essential to the manufacture of bread, soy sauce, cheese, beer, wine, whiskey, and other products. In most cases, domesticated fungi are used in conditions where the cells grow via fermentation, creating ethanol and by-products like the CO_2 that causes bread to rise and beer and champagne to fizz.
- Chocolate is made from the seeds of *Theobroma cacao*, but it is edible only after the seeds are fermented by several species of fungi.
- Enzymes derived from fungi are used to improve the characteristics of foods ranging from fruit juice and candy to meat.

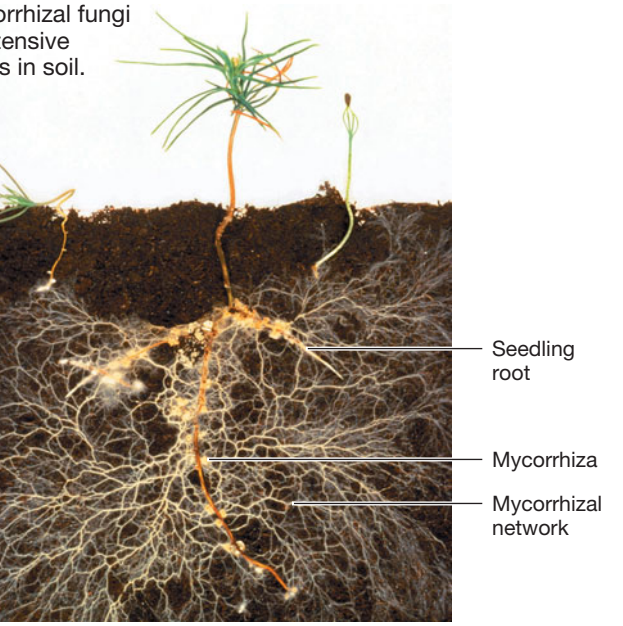
Fungi Provide Nutrients for Land Plants

Fungi that live in close association with plant roots are said to be **mycorrhizal** (literally, "fungal-root"; see **FIGURE 32.2a**). When biologists first discovered how extensive these fungi–plant associations are, they asked an obvious question: Does plant growth suffer if mycorrhizal fungi are absent?

FIGURE 32.2b shows a result typical of many experiments. In this case, seedlings were grown in the presence and absence of the mycorrhizal fungi normally found on their roots. The photographs document that this species grows three to four times faster in the presence of its normal fungal associates than it does without them.

For farmers, foresters, and ranchers, the presence of normal mycorrhizal fungi can mean the difference between profit and loss. Fungi are critical to the productivity of forests, croplands, and rangelands.

Fungi Accelerate the Carbon Cycle on Land



Fungi that make their living by digesting dead plant material are called **saprophytes.** To understand why saprophytic fungi play a key role in today's terrestrial environments, recall that cells in the vascular tissues of land plants have secondary cell walls containing both lignin and cellulose (see Chapter 31). Wood forms when stems grow in girth by adding layers of lignin-rich vascular tissue.

When trees die, certain fungi are the organisms that break down wood into sugars and other small organic compounds (**FIGURE 32.3**). Fungi use these molecules as food, as do many microorganisms. In addition, when fungi die or are eaten, the molecules are passed along to a wide array of other organisms.

Fungi play an important role in cycling carbon atoms through terrestrial ecosystems. Note that there are two basic components of the **carbon cycle** on land:

1. The fixation of carbon by land plants—meaning that carbon in atmospheric CO_2 is reduced to form sugar, which is then used to synthesize cellulose, lignin, and other complex organic compounds in the bodies of plants.

(a) Mycorrhizal fungi form extensive networks in soil.

(b) Mycorrhizal fungi increase plant growth.

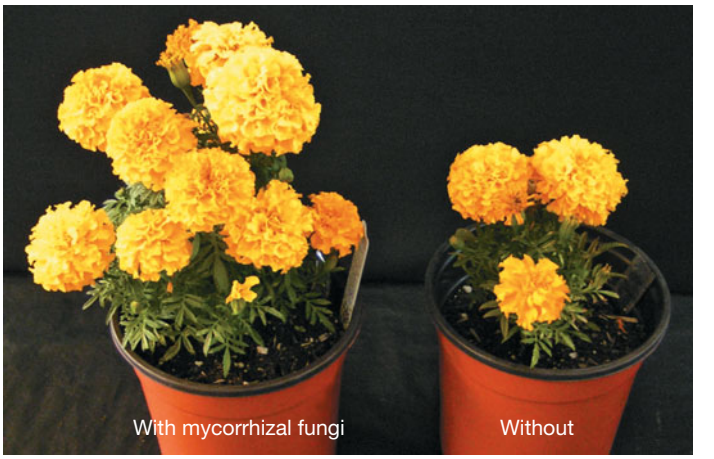


FIGURE 32.2 Plants Grow Better in the Presence of Mycorrhizal Fungi. (a) Root system of a larch tree seedling; the mycelia from a mycorrhizal fungus are visible. **(b)** Typical experimental results when plants are grown with and without their normal mycorrhizal fungi. (Fungi are not visible in the photo.)

2. The release of CO_2 from nearly all organisms as the result of cellular respiration—meaning the oxidation of glucose and production of the ATP that sustains life.

The fundamental point is that, for many carbon atoms, saprophytic fungi connect the two parts of the carbon cycle.

If fungi had not evolved the ability to digest lignin and cellulose soon after land plants evolved the ability to make these compounds, carbon atoms would have been sequestered in wood for millennia instead of being rapidly recycled into glucose molecules and CO_2. Terrestrial environments would be radically different than they are today, and probably much less productive. On land, fungi make the carbon cycle turn much more rapidly than it would without fungi.

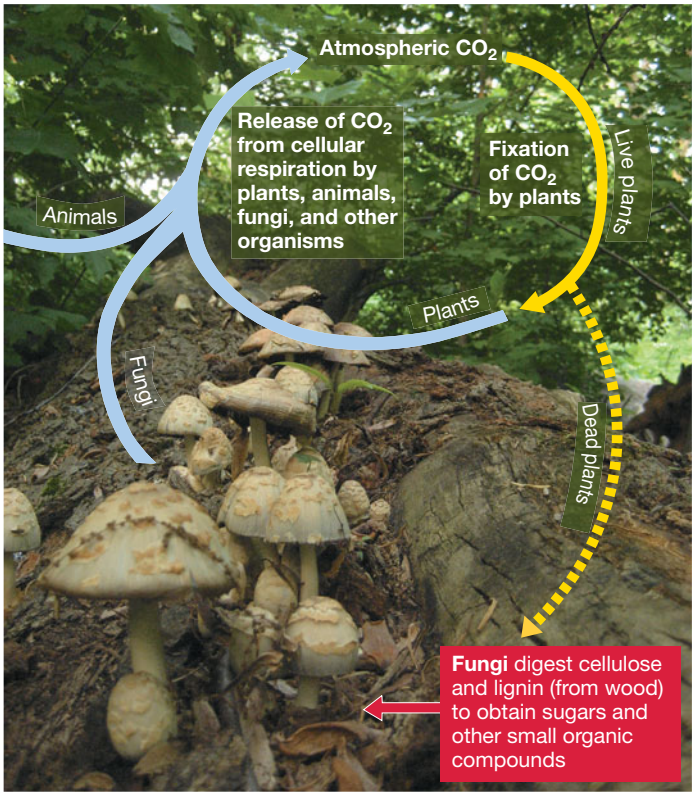

FIGURE 32.3 Fungi Speed Up the Carbon Cycle as They Break Down Dead Trees in Terrestrial Ecosystems.

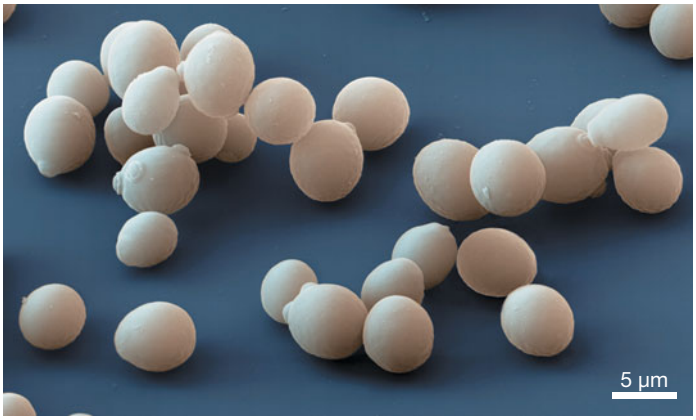
To summarize, biologists study fungi because they affect a wide range of species in nature, including humans. What tools are helping researchers understand the diversity of fungi?



32.2 How Do Biologists Study Fungi?

About 110,000 species of fungi have been described and named to date, and several hundreds more are discovered each year. But the fungi are so poorly studied that the known species are widely regarded as a tiny fraction of the actual total.

To predict the actual number of fungal species alive today, David Hawksworth looked at the ratio of vascular plant species to fungal species in the British Isles—the area where the two groups are the most thoroughly studied. According to Hawksworth's analysis, these islands have an average of six species of fungus for every species of vascular plant. If this ratio holds worldwide, then the estimated total of 275,000 vascular plant species implies that there are perhaps 1.5 million species of fungi.

Although this estimate sounds large, recent data on fungal diversity suggest that it may be an underestimate. Consider what researchers found when they analyzed fungi growing on Barro Colorado Island, Panama: Living on the healthy leaves of just two tropical tree species were a total of 418 distinct morphospecies of fungi. (Recall from Chapter 27 that morphospecies are distinguished from each other by some aspect of morphology.) Because over 310 species of trees and shrubs grow on Barro Colorado, the data suggest that tens of thousands of fungi may be native to this island alone. If further work on fungal diversity in the tropics supports these conclusions, there may turn out to be many millions of fungal species.

(a) Single-celled fungi are called yeasts.

(b) Multicellular fungi have weblike bodies called mycelia.

FIGURE 32.4 Fungi Have Just Two Growth Forms. Fungi grow **(a)** as single-celled yeasts and/or **(b)** as multicellular mycelia made up of long, thin, highly branched filaments. Both of these scanning electron micrographs are colorized.

This viewpoint of fungal diversity was reinforced by an analysis of the fungi living in the guts of beetles. In this study, researchers isolated fungi from 27 species of beetles and characterized them by observing various morphological and physiological traits. In addition, the direct sequencing approach was used to analyze the gene that codes for the RNA molecule in the small subunit of fungal ribosomes (see Chapter 30). The data showed that over 650 fungal species were living in the beetle guts, 200 of which had never been described. Biologists are only beginning to realize the extent of species diversity in fungi.

Let's consider how biologists are working to make sense of all this diversity, beginning with an overview of fungal morphology.

Analyzing Morphological Traits

Compared with animals and land plants, fungi have simple bodies. Only two growth forms occur among them: **(1)** single-celled forms called **yeasts** (**FIGURE 32.4a**), and **(2)** multicellular, filamentous

structures called **mycelia** (singular: **mycelium; FIGURE 32.4b**). Many species of fungus grow either as yeasts or as a mycelium, but some regularly adopt both growth forms.

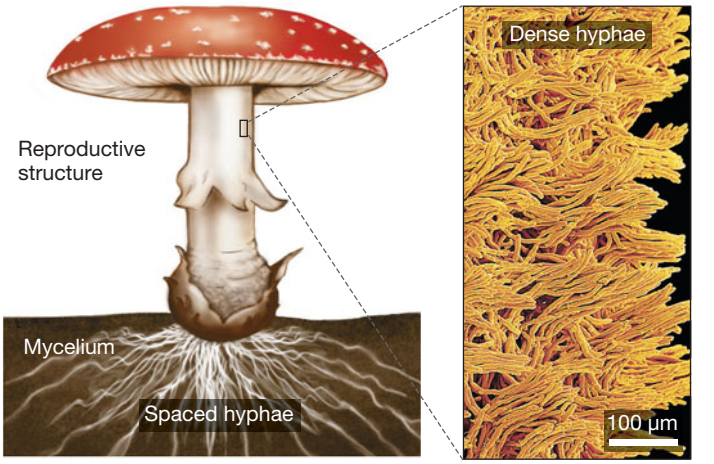
The fossil record for land plants and animals has been extremely useful in understanding their early evolution (see Chapters 25 and 31). In contrast, fossils of fungi are very rare, so biologists rely on morphological and molecular data to explore their past. Because most fungi form mycelia and because this body type is so fundamental to the absorptive mode of life, most studies of fungal morphology have focused on them.

The Nature of the Fungal Mycelium If food sources are plentiful, mycelia can be long lived and grow to be extremely large. Researchers discovered a mycelium of the fungus *Armillaria* growing across 2100 acres (8.8 km^2) in Oregon. This is an area substantially larger than most college campuses. The biologists estimated the individual's weight at hundreds of tons and its age at thousands of years, making it one of the largest and oldest organisms known.

Although most mycelia are much smaller and shorter lived than the individual in Oregon, all mycelia are dynamic. Mycelia constantly grow in the direction of food sources and die back in areas where food is running out. The body shape of a fungus can change almost continuously throughout its life.

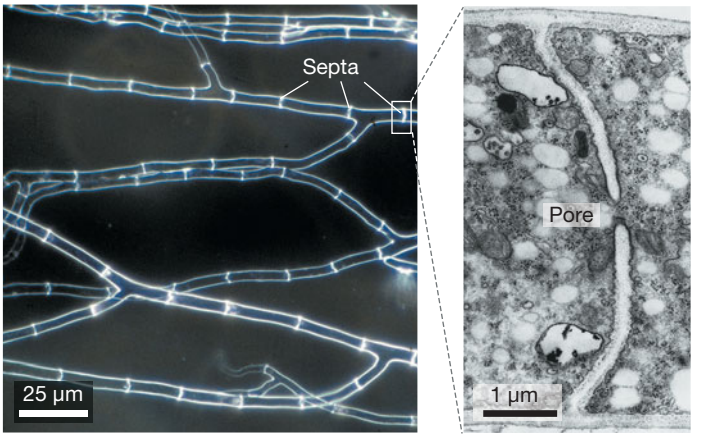
The Nature of Hyphae The filaments within a mycelium are called **hyphae** (singular: **hypha).** As **FIGURE 32.5a** shows, hyphae are long, narrow filaments that branch frequently.

In most terrestrial fungi, each filament is divided into cells by cross-walls called **septa** (singular: **septum; FIGURE 32.5b**). Septa do not close off the cells along hyphae completely. Instead, gaps called pores enable a wide variety of materials, even nuclei and other organelles, to flow from one compartment to the next.



Some fungal lineages have hyphae that are **coenocytic** ("common-celled"; pronounced *see-no-SIT-ick*)—meaning that they are not divided into separate cells and thus lack septa (**FIGURE 32.5c**). Coenocytic fungi have hundreds or thousands of nuclei scattered throughout the mycelium. In effect, they are a single, gigantic, multinucleate cell.

Fungi lack complex, long-distance transport systems like those found in plants and animals. One advantage of most fungi having pores in septa is that nutrients can move rapidly from regions of uptake to regions of mycelial growth. Because nutrients and some organelles can flow through the entire mycelium—at least to a degree—the fungal mycelium is intermediate between a multicellular land plant or animal and an enormous single-celled organism.



Mycelia Have a Large Surface Area It's important to appreciate just how thin hyphae are. Plant root tips are typically about 1 mm in diameter, but fungal hyphae are typically less than 10 µm in diameter, or 1/100th the size of a root tip. Fungal mycelia can penetrate tiny fissures in soil and absorb nutrients that are inaccessible to plant roots.

Perhaps the most important aspect of mycelia and hyphae, however, is their shape. Because mycelia are composed of complex, branching networks of extremely thin hyphae, fungi have the highest surface-area-to-volume ratios observed in multicellular organisms and are therefore the best at absorption.

(a) Both the reproductive structure and mycelium are composed of hyphae.

(b) Most hyphae are broken into compartments by septa.

(c) Coenocytic hyphae consist of multinucleate cells.

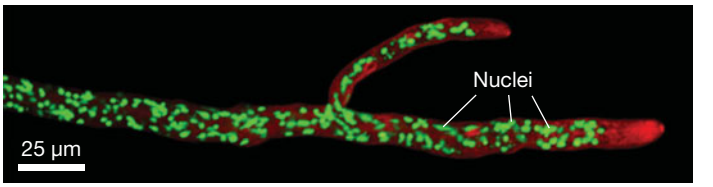


FIGURE 32.5 Multicellular Fungi Have Unusual Bodies. (a) The feeding structure of a fungus is a mycelium, which is made up of hyphae. In some species, hyphae come together to form multicellular structures such as mushrooms, brackets, or morels that emerge from the ground. **(b)** Hyphae of some terrestrial fungi are divided into cell-like compartments by partitions called septa that contain pores. As a result, the cytoplasm of different compartments is continuous. **(c)** Hyphae of some coenocytic fungi are composed of giant, multinucleate cells.

To drive this point home, consider that the hyphae found in any fist-sized ball of rich soil typically have a surface area equivalent to half a page of this book. Because of their large surface area, fungi are extremely efficient at absorbing nutrients.

The extraordinarily high surface area in a mycelium has a downside, however. The amount of water that evaporates from an organism is a function of its surface area—meaning that these organisms are prone to drying out. As a result, fungi are most abundant in moist habitats.

When conditions dry, the fungal mycelium may die back partially or completely. Reproductive cells called **spores** that are produced by sexual or asexual reproduction are resistant to drying, however. As a result, spores can endure dry periods and then germinate to form a new mycelium when conditions improve. Mycelial growth is dynamic, changing with moisture availability or food supply.

Reproductive Structures Mycelia are an adaptation that supports external digestion and the absorptive lifestyle of fungi. Fungi also produce reproductive organs, which are thick, fleshy structures.

Mushrooms, puffballs, and other dense, multicellular structures that arise from mycelia do not absorb food. Instead, they function in reproduction. Typically they are the only part of a fungus that is exposed to the atmosphere, where drying is a problem. The mass of hyphal filaments on the inside of mushrooms is protected from drying by the densely packed hyphae forming the surface.

In many fungi, including some entire lineages, sexual reproduction has never been observed. In those lineages that do reproduce sexually, important morphological differences among lineages are seen. Most fungal species that undergo sexual reproduction produce one of four types of distinctive reproductive structures.

1. ***Swimming gametes and spores*** In certain species that live primarily in water or wet soils, the gametes produced during sexual reproduction have flagella, as do the spores produced during asexual reproduction (**FIGURE 32.6a**). These are the only motile cells known in fungi. Species with swimming gametes are traditionally known as chytrids (pronounced *KYE-trids*).
2. ***Zygosporangia*** In some species, haploid hyphae from two individuals meet and become joined, like oxen with a yoke, as shown in **FIGURE 32.6b**. Cells from yoked hyphae fuse to form a distinctive spore-producing structure called a **zygosporangium** (plural: **zygosporangia;** the Greek root *zygo* means to be yoked [see **BioSkills 2** in Appendix B]). Species with a zygosporangium are traditionally known as zygomycetes.
3. ***Basidia*** Mushrooms, brackets, and puffballs form specialized club-like cells called **basidia** (singular: **basidium;** "little-club") at the ends of hyphae, each producing four spores (**FIGURE 32.6c**). Species with basidia are traditionally called basidiomycetes or "club fungi."
4. ***Asci*** Cups, morels, and some other types of fungi form reproductive structures, specialized sac-like cells called **asci** (singular: **ascus**) at the ends of hyphae, on the surfaces of the fungi, each producing eight spores (**FIGURE 32.6d**). Species with asci are traditionally known as ascomycetes or "sac fungi."

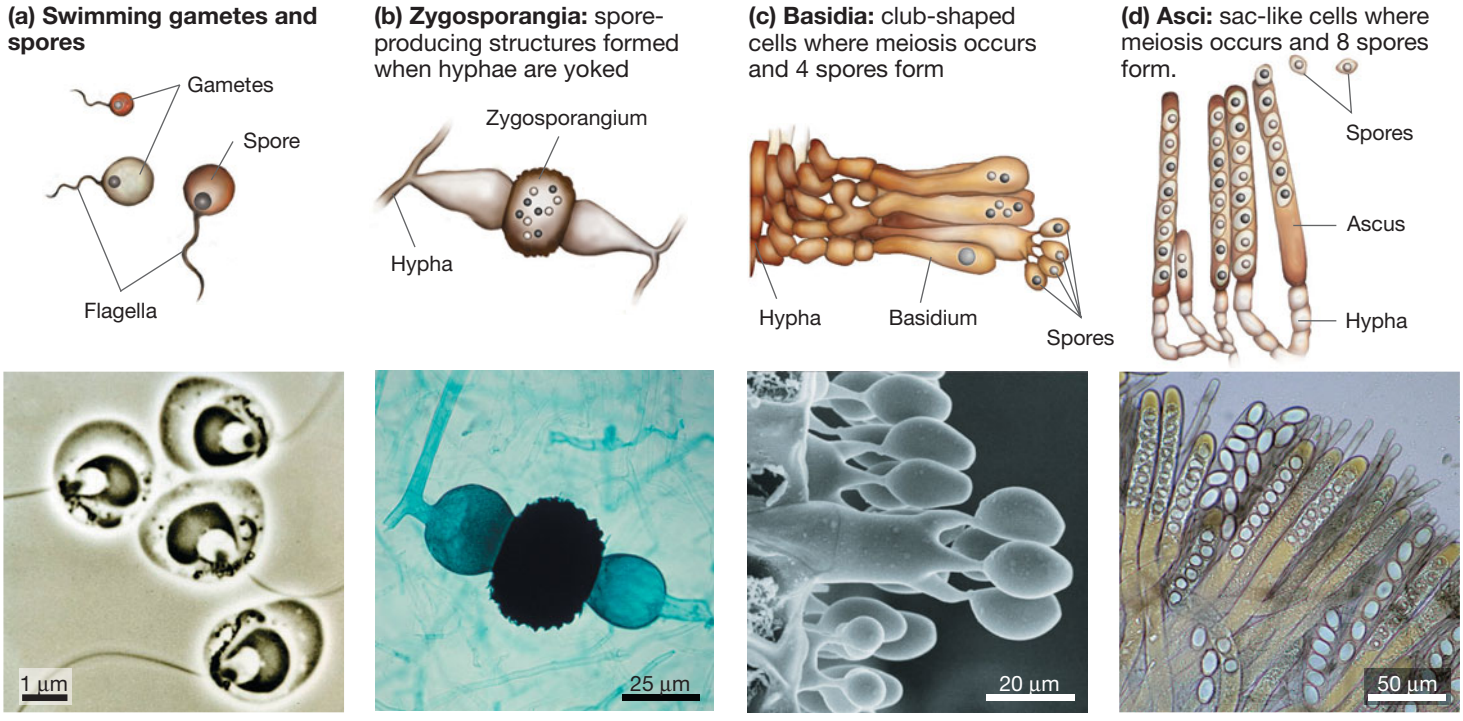

FIGURE 32.6 Four Types of Reproductive Structures Are Observed in Fungi. The dots in the illustrations represent nuclei.

In sum, morphological studies allowed biologists to describe and interpret the mycelial growth habit as an adaptation that makes external digestion and nutrient absorption extremely efficient. Careful analyses of morphological features also allowed researchers to identify four major types of sexual reproductive structures.

Now the question is, within the Fungi, do species that produce swimming gametes and spores, zygosporangia, basidia, and asci each form monophyletic groups—meaning that these distinctive reproductive structures evolved just once? Also, which eukaryotes are most closely related to the fungi?

Evaluating Molecular Phylogenies

Researchers have sequenced and analyzed an array of genes and genomes to establish where fungi fit on the tree of life. In fact, the first complete genome sequence of a eukaryotic species was that of a fungus, the model organism baker's yeast, *Saccharomyces cerevisiae*. The phylogenetic position of fungi as a whole is now well established; the position of lineages within fungi is still the subject of intense research.

Fungi Are Closely Related to Animals **FIGURE 32.7** shows that fungi are much more closely related to animals than they are to land plants.

The close evolutionary relationship between fungi and animals explains why fungal infections in humans are much more difficult to treat than bacterial infections. Fungi and humans shared a common ancestor relatively recently. As a result, their enzymes and cell components are similar in structure and function. Drugs that disrupt fungal enzymes and cells are also likely to damage humans.

In addition to DNA sequence data, three key morphological traits link animals and fungi:

1. Most animals and fungi synthesize the tough structural material called chitin (see Chapter 5). Chitin is a prominent component of the cell walls of fungi.
2. The flagella that develop in chytrid spores and gametes are similar to those observed in animals: As in animals, the flagella in chytrids are single, are located at the back of reproductive cells, and move in a whiplike manner.
3. Both animals and fungi store food by synthesizing the polysaccharide glycogen. (Green plants, in contrast, synthesize starch as their storage product.)

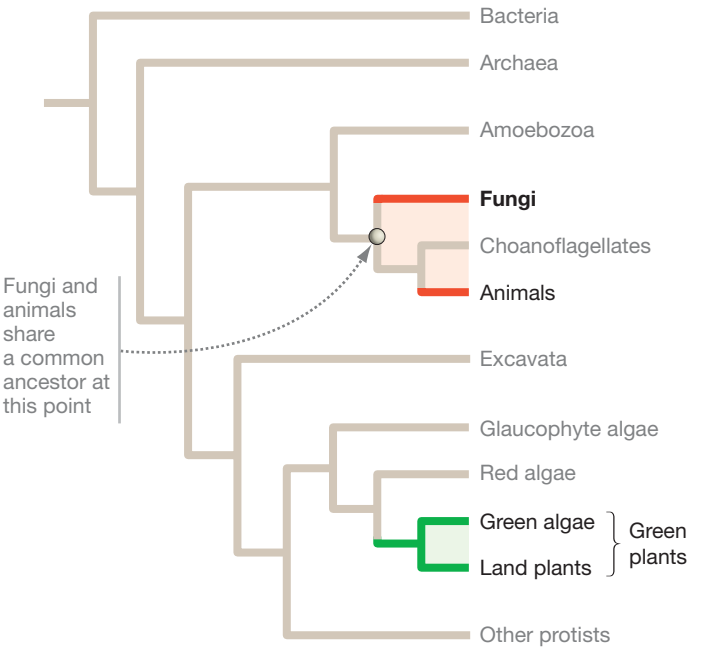

FIGURE 32.7 Fungi Are More Closely Related to Animals than to Land Plants. Phylogenetic tree showing the evolutionary relationships among the green plants, animals, fungi, and some groups of protists. (Choanoflagellates are solitary or colonial protists found in freshwater; see Chapter 33).

What Are the Relationships Among the Major Fungal Groups? To understand the relationships among species with swimming gametes and spores, zygosporangia, basidia, and asci, biologists have sequenced a series of genes from an array of fungal species and used the data to estimate the phylogeny of the group. The results, shown in **FIGURE 32.8**, support several important conclusions:

- The single-celled, parasitic eukaryotes called microsporidians are actually fungi.
  Interpretation: They are not a distantly related sister group to fungi, as initially thought. This point is important. Researchers are now testing the hypothesis that **fungicides**—molecules that are lethal to fungi—can cure microsporidian infections in bee colonies, silkworm colonies, and AIDS patients.
- The chytrids and zygomycetes are poorly resolved. The actual order of branching events among lineages with these reproductive structures is still not known (in Figure 32.8, they are collapsed into a **polytomy;** see Chapter 28 and **BioSkills 7** in Appendix B).
  Interpretation: Swimming gametes and the zygosporangium evolved more than once. Or, both structures were present in a common ancestor but then were lost in certain lineages.
- An important group called the Glomeromycota is monophyletic.
  Interpretation: The adaptations that allow these species to live in association with plant roots as mycorrhizae (AMF, discussed in Section 32.3) evolved once.
- The basidiomycetes are monophyletic—they form a lineage called Basidiomycota, or club fungi.
  Interpretation: The basidium evolved once.
- The ascomycetes are monophyletic—they form a lineage called Ascomycota, or sac fungi.
  Interpretation: The ascus evolved once.
- Together, the Basidiomycota and Ascomycota form a monophyletic group.
  Interpretation: Because basidiomycetes and ascomycetes both form septate hyphae and large "fruiting" structures, this growth habit evolved once.

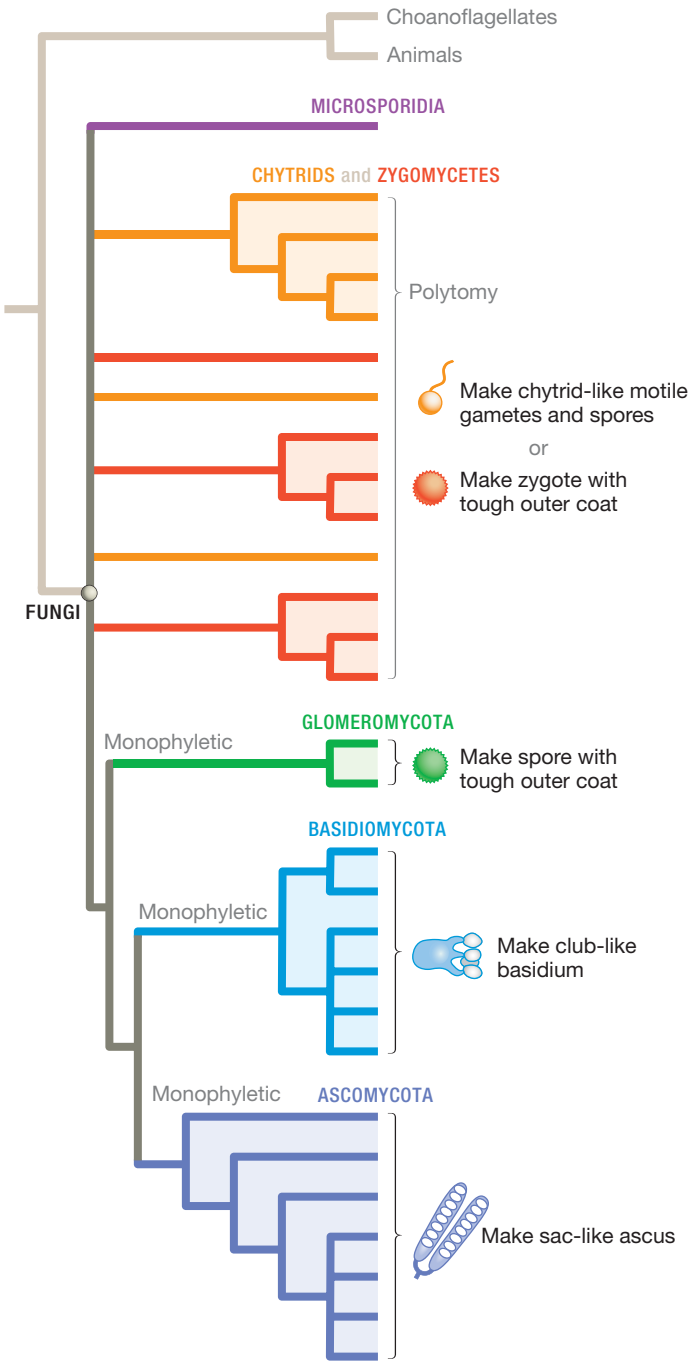

FIGURE 32.8 Phylogeny of the Fungi. A phylogenetic tree based on analyses of DNA sequence data. The icons represent the types of sexual reproductive structures observed in each major lineage.

- The sister group to fungi comprises animals plus protists called choanoflagellates.
  Interpretation: Because choanoflagellates and the most ancient groups of animals are aquatic, and because chytrids are aquatic, it is reasonable to hypothesize that the earliest fungi were aquatic and that the switch to terrestrial life occurred early in the evolution of the Fungi.

Although recently advances have been made in understanding the evolutionary history of fungi, the phylogenetic tree in Figure 32.8 is still a work in progress. For example, it is not yet clear where microsporidians are placed relative to several lineages of chytrids and zygomycetes. (Microsporidians lack both swimming gametes and yoked hyphae.) Future work should clarify exactly how fungi diversified.

C Y U

If you understand that . . .

- The bodies of fungi are either single-celled yeasts or multicellular mycelia.
- During sexual reproduction, different groups of fungi produce distinct reproductive structures.

✔ You should be able to . . .

1. Explain why mycelia are interpreted as an adaptation to an absorptive lifestyle.
2. Identify the four types of sexual reproductive structures observed in fungi.

Answers are available in Appendix A.

32.3 What Themes Occur in the Diversification of Fungi?

Why are there so many different species of fungi? This question is particularly puzzling given that fungi share a common attribute: They all make their living by absorbing food directly from their surroundings. In contrast to the diversity of food-getting strategies observed in bacteria, archaea, and protists, all fungi make their living in the same basic way. In this respect, fungi are like plants—virtually all of which make their own food via photosynthesis.

The diversification of land plants was driven not by novel ways of obtaining food, but by adaptations that allowed plants to grow and reproduce in a diverse array of terrestrial habitats (see Chapter 31). Recall that associations with animal pollinators were especially important in the diversification of flowering plants. What drove the diversification of fungi? The answer is the evolution of novel methods for absorbing nutrients from a diverse array of food sources.

This section introduces a few of the ways that fungi go about absorbing nutrients from different food sources, as well as how they produce offspring. Let's explore the diversity of ways that fungi do what they do.

Fungi Participate in Several Types of Symbioses

The first plants in the fossil record are closely associated with fungal fossils; the ability to absorb nutrients from fungi may have been crucial in the early evolution of land plants (see Chapter 31). Close associations between land plants and fungi continue today. Researchers estimate that 90 percent of land plants live in physical contact with fungi. Stated another way, fungi and land plants often have a **symbiotic** ("together-living") relationship.

Although some species of fungi live in association with an array of different land plant species, some documented fungi–plant associations are specific. It is not uncommon for one fungal species to live in only a particular type of tissue, in one plant species.

Scientists categorize these symbiotic relationships as **mutualistic** if they benefit both species, **parasitic** if one species benefits at the expense of the other, or **commensal** if one species benefits while the other is unaffected. However, it is sometimes difficult to know if a species really benefits from the relationship.

Not long after associations between fungi and the roots of land plants were discovered, researchers found that two types of plant–mycorrhizal interactions are particularly common, involving **ectomycorrhizal fungi (EMF)** and **arbuscular mycorrhizal fungi (AMF).** The two major types of mycorrhizae have distinctive morphologies, geographic distributions, and functions.

- EMF are usually species from the Basidiomycota, though some ascomycetes participate.
- AMF include species from the Glomeromycota.

Mycorrhizae aren't the only type of symbiotic fungi found in plants, however. Researchers have also become interested in fungi that live in close association with the aboveground tissues of land plants—their leaves and stems. Fungi that live in the aboveground parts of plants are called **endophytic** ("inside-plants").

Recent research has shown that endophytic fungi are much more common and diverse than previously suspected. Further, data indicate that at least some species of endophytes are mutualistic.

Ectomycorrhizal Fungi (EMF) EMF like the one shown in **FIGURE 32.9a** are found on many of the tree species in the temperate regions of the world, where warm summers alternate with cold winters (see Chapter 52). In this type of association, hyphae form a dense network that covers a plant's root tips. As Figure 32.9a shows, individual hyphae penetrate between cells in the outer layer of the root, but hyphae do not enter the root cells.

The Greek root *ecto*, which refers to "outer," describes this association accurately: The fungi form an outer sheath on root tips that is often 0.1 mm thick. Hyphae also extend out from the sheath-like portion of the mycelium into the soil.

How do these trees and fungi interact, once they start living together? In the habitats where EMF are abundant, nitrogen atoms tend to remain tied up in dead tissues, in amino

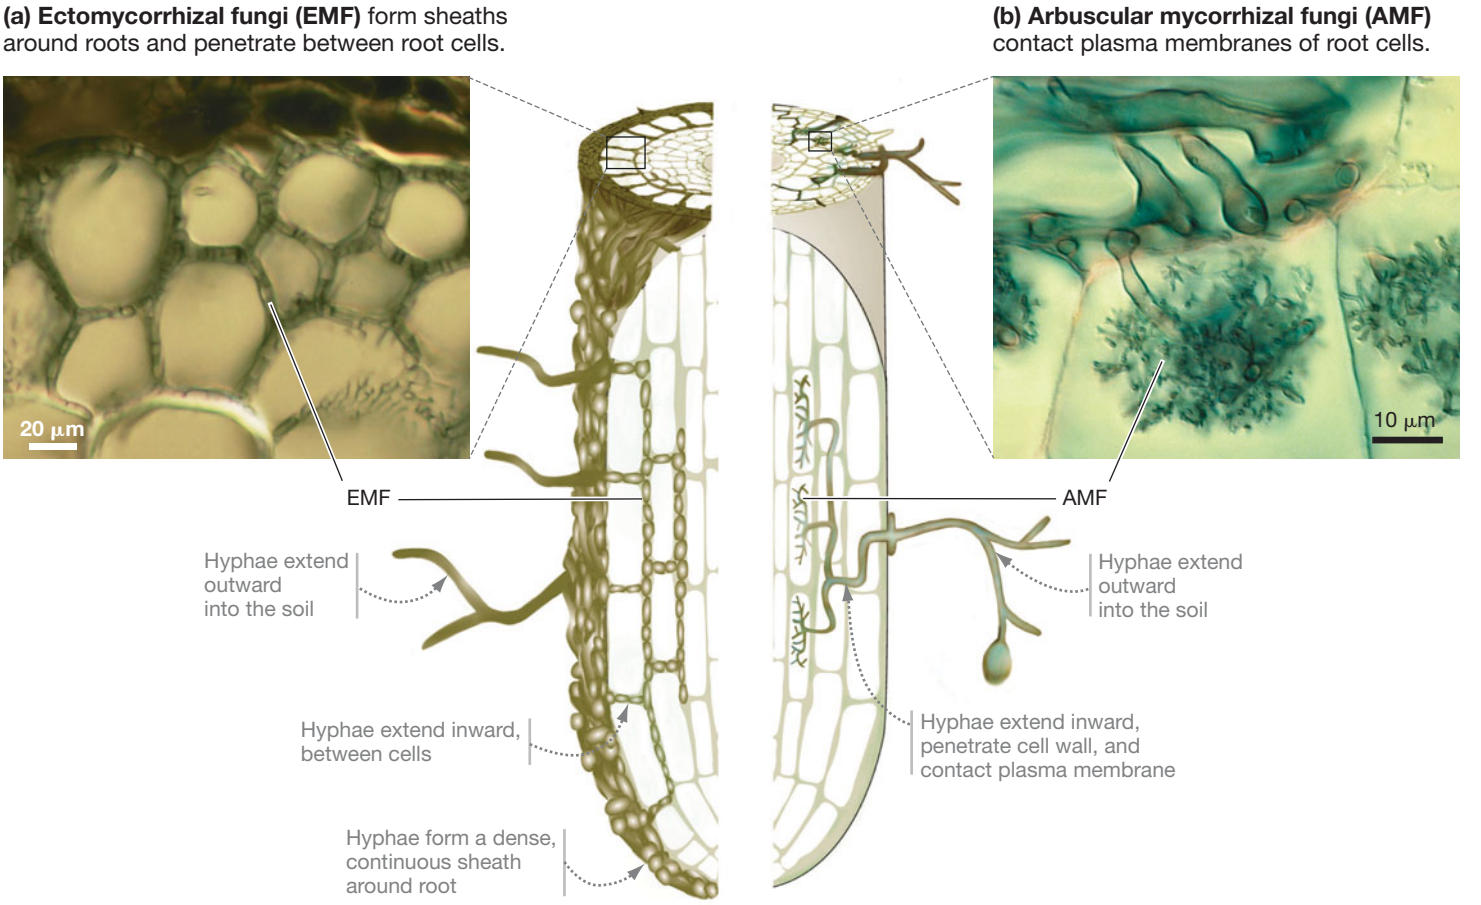

FIGURE 32.9 Mutualistic Fungi Interact with the Roots of Plants in Two Distinct Ways. (a) Ectomycorrhizal fungi (EMF) form a dense network around the roots of plants. Their hyphae penetrate the intercellular spaces of the root but do not enter the root cells. **(b)** The hyphae of arbuscular mycorrhizal fungi (AMF) penetrate the walls of root cells, where they branch into bushy structures or balloon-like vesicles that are in close contact with the root cell's plasma membrane.

acids and nucleic acids, instead of being available in the soil. The hyphae of EMF penetrate decaying material and release enzymes called peptidases that cleave the peptide bonds between amino acids in dead tissues. The amino acids released by this reaction are absorbed by the hyphae and transported to spaces between the root cells of trees, where they can be absorbed by the plant.

EMF are also able to acquire phosphate ions that are bound to soil particles and transfer the ions to host plants. In return, the fungi receive sugars and other complex carbon compounds from the tree.

Researchers have found that when birch tree seedlings are grown with and without their normal EMF in pots filled with forest soil, only the seedlings with EMF are able to acquire significant quantities of nitrogen and phosphorus. Inspired by such data, one biologist has referred to ectomycorrhiza as the "dominant nutrient-gathering organs in most temperate forest ecosystems."

The hyphae of EMF are like an army of miners that discover, excavate, and deliver precious nuggets of nitrogen to trees. The productivity of the world's most important commercial forests depends on EMF.

Arbuscular Mycorrhizal Fungi (AMF) In contrast to the hyphae of EMF, the hyphae of arbuscular mycorrhizal fungi (AMF) grow *into* the cells of root tissue. The name *arbuscular* ("little-tree") was inspired by the bushy, highly branched hyphae, shown in **FIGURE 32.9b**, that form between the cell walls and the plasma membrane of root cells. AMF are also called **endomycorrhizal fungi,** because they penetrate the interior of root cell walls.

The key point is that the hyphae of AMF penetrate the cell wall and make direct contact with the plasma membrane of root cells. The highly branched hyphae inside the plant cell wall are thought to be an adaptation that increases the surface area available for exchange of molecules between the fungus and its host. However, AMF do not form a tight sheath around roots, as do EMF. Instead, they form a pipeline extending from inside plant roots into the soil well beyond the root.

AMF are found in a whopping 80 percent of all land plant species. They are particularly common in grasslands and in tropical forests. They are also widespread in temperate climates.

What do AMF do? Plant tissues decompose quickly in the grasslands and tropical forests where AMF flourish because the growing season is long and warm. As a result, nitrogen is often readily available to plants. Phosphorus is usually in short supply, though, because it tends to leach out of soils that experience high rainfall.

To explore the nature of fungi–plant symbioses in detail, researchers have used isotopes as tracers for specific elements (**FIGURE 32.10**, see page 622). For example, to test the hypothesis that fungi obtain food in the form of carbon-containing compounds from their plant associates, biologists have introduced radioactively labeled carbon dioxide into the air surrounding plants that do or do not contain symbiotic fungi. The labeled CO_2 molecules are incorporated into the sugars produced during photosynthesis, and the location of the radioactive atoms can then be followed over time by means of a device that detects radioactivity. If plants feed their fungal symbionts, then labeled carbon compounds should be transferred from the plant to the fungi.

To test the hypothesis that plants are receiving nutrients from their symbiotic fungi in return for sugars, researchers have added radioactive phosphorus atoms or the heavy isotope of nitrogen (^{15}N) to potted plants that do or do not contain symbiotic fungi. If fungi facilitate the transfer of nutrients from soil to plants, then plants grown in the presence of their symbiotic fungi should receive much more of the radioactive phosphorus or heavy nitrogen than do plants grown in the absence of fungi.

Experiments with isotopes used as tracers have shown that sugars and other carbon-containing compounds produced by plants via photosynthesis are transferred to their fungal symbionts. In some cases, as much as 20 percent of the sugars produced by a plant end up in their symbiotic fungi. In exchange, the symbiotic fungi facilitate the transfer of phosphorus or nitrogen—or both—from soil to the plant.

Because phosphorus and nitrogen are in extremely short supply in most environments, the nutrients supplied by symbiotic fungi are critical to the success of the plant. In this way, studies with isotopes have supported the hypothesis that most relationships between fungi and land plants are mutually beneficial.

AMF are also extremely important in soil formation. The cell walls of their hyphae contain large quantities of a glycoprotein called **glomalin.** When the cells die, the glomalin enriches the organic matter in soil and helps bind organic compounds to sand or clay particles. Some recent estimates suggest that over 25 percent of all of the organic matter in soil consists of glomalin.

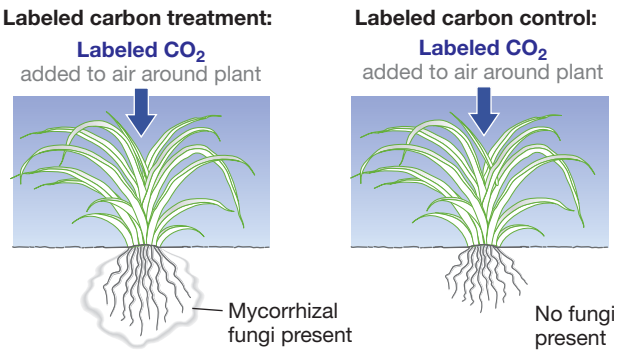
Are Endophytes Mutualists? Although endophytic fungi were unknown before the 1940s, they are turning out to be both extremely common and highly diverse.

- Biologists in Brazil are examining tree leaves for the presence of fungi; each time they do, they are discovering several new species of endophytes.
- Recall from Section 32.2 that a study in Panama found hundreds of fungal species living in the leaves of just two tree species. These species are endophytes.

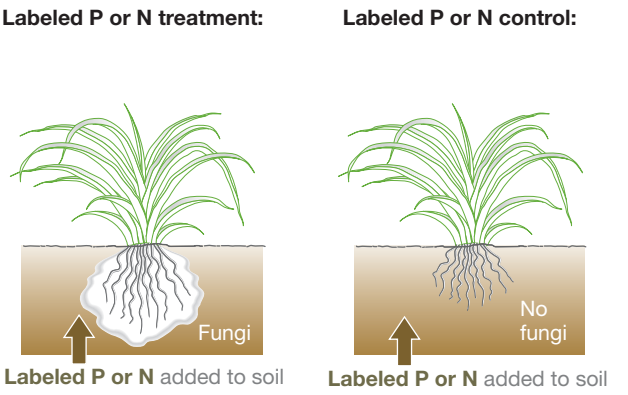
Recent research has shown that some endophytes increase the drought tolerance of their host plants. Endophytes found in some grasses also produce compounds that benefit plants. The compounds deter or even kill herbivores. In exchange for these benefits, endophytes absorb sugars from the plant.

Based on these results, biologists have concluded that the relationship between endophytes and grasses is mutualistic. Similar types of anti-herbivore compounds have recently been documented in an endophyte that lives in morning glories.

In other types of plants, however, researchers have not been able to document benefits for the plant host. The current consensus is that at least some endophytic fungi may be commensals—meaning the fungi and the plants simply coexist with no observable effect, either deleterious or beneficial, on the host plant.



RESEARCH

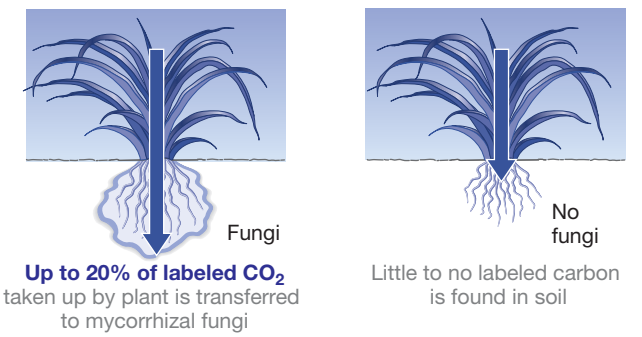


QUESTION: Are mycorrhizal fungi mutualistic?

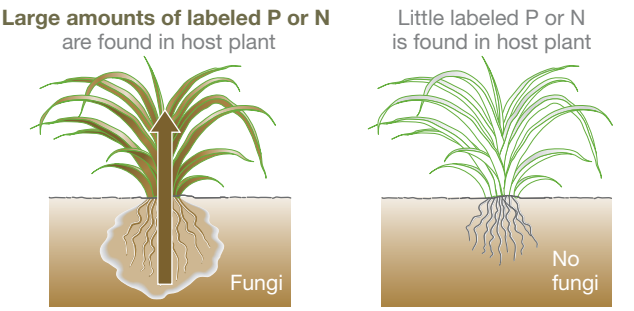
HYPOTHESIS: Host plants provide mycorrhizal fungi with sugars and other photosynthetic products. Mycorrhizal fungi provide host plants with phosphorus and/or nitrogen from the soil.

NULL HYPOTHESIS: No exchange of food or nutrients occurs between plants and mycorrhizal fungi. The relationship is not mutualistic.

EXPERIMENTAL SETUP:



PREDICTION FOR LABELED CARBON: A large percentage of the labeled carbon taken up by the plant will be transferred to mycorrhizal fungi. In the control, little labeled carbon will be present in the soil surrounding the roots.



PREDICTION OF NULL HYPOTHESIS, LABELED CARBON: There will be no difference in the localization of carbon in the two treatments.

PREDICTION FOR LABELED P OR N: A large percentage of the labeled P or N taken up by the fungi will be transferred to the plant. In the control, little or no labeled P or N will be taken up by the plant.

PREDICTION OF NULL HYPOTHESIS, LABELED P OR N: There will be no difference between amounts of labeled P or N found in plant in presence or absence of fungi.

RESULTS:

CONCLUSION: The relationship between plants and mycorrhizal fungi is mutualistic. Plants provide mycorrhizal fungi with carbohydrates. Mycorrhizal fungi supply host plants with nutrients.

FIGURE 32.10 Experimental Evidence that Mycorrhizal Fungi and Plants Are Mutualistic. Sugars flow from plants to mycorrhizal fungi; key nutrients flow from mycorrhizal fungi to plants.

SOURCES: Bücking, H., and W. Heyser. 2001. Microautoradiographic localization of phosphate and carbohydrates in mycorrhizal roots of *Populus tremula* × *Populus alba* and the implications for transfer processes in ectomycorrhizal associations. *Tree Physiology* 21: 101–107.

✓ **QUESTION** What do these "labeled nutrient" experiments tell you that you didn't already know from experiments like Figure 32.2, where plants are grown with and without mycorrhizae?

FIGURE 32.11 Leaf-cutter Ants Engage in a Symbiosis with Fungi in Underground Nests. The ants provide the fungus with leaf pieces on which to grow and then the ants feed on the fungus. Of the two partners, only the fungus can digest cellulose.

These results support the general realization that most plants are covered with fungi—from the ends of their branches to the tips of their roots. Throughout their lives, many or even most plants are involved in several distinct types of mutualistic relationships with fungi.

Mutualisms with Other Species Do fungi take up residence with species other than land plants? As you'll recall, the answer is yes.

- **Lichens** are a mutualistic partnership usually between a species of ascomycete and either a cyanobacterium or an alga. The nature of this relationship is explored in Section 32.4.
- Many plant-eating insects harbor diverse arrays of yeast species in their guts, where they may aid digestion or detoxification of plant compounds.
- Some ant species actively farm fungi inside their colonies by inoculating leaf pieces with symbiotic fungi. They fertilize and "weed" their fungal gardens and then harvest parts of the fungi for food (**FIGURE 32.11**).

The many unique properties of fungi have made them useful partners in a wide array of symbiotic relationships.

What Adaptations Make Fungi Such Effective Decomposers?

The saprophytic fungi are master recyclers. Although bacteria and archaea are also important decomposers in terrestrial environments, some fungi and a few bacterial species are the only organisms that can digest wood completely. Given enough time, fungi can turn even the hardest, most massive trees into soft soils.

How do fungi do it? You've already been introduced to two key adaptations:

- The large surface area of a mycelium makes nutrient absorption exceptionally efficient.
- Saprophytic fungi can grow toward the dead tissues that supply their food.

What other adaptations help fungi decompose plant tissues?

Extracellular Digestion Large molecules such as starch, lignin, cellulose, proteins, and RNA cannot diffuse across plasma membranes. Only sugars, amino acids, and other small molecules can enter the cytoplasm of cells through membrane carrier proteins or transporters (see Chapter 6). As a result, fungi, like most animals, have to digest their food before they can absorb it.

Fungi perform **extracellular digestion**—digestion that takes place outside the organism. The simple compounds that result from enzymatic action are then absorbed by the hyphae. Most animals also perform extracellular digestion, but it takes place in a digestive tract (see Chapter 44).

As an example of how this process occurs in fungi, consider the enzymes responsible for digesting lignin and cellulose—the two most abundant organic molecules on Earth.

- Lignin is an extremely strong, complex polymer built from monomers that contain six-carbon rings. Recall that most lignin is found in the secondary cell walls of plant vascular tissues, where it furnishes structural support (see Chapter 31).
- Cellulose is a polymer of glucose and is found in the primary and secondary cell walls of all plant cells.

Some basidiomycetes can degrade lignin and digest cellulose completely—to CO_2 and H_2O. Let's take a closer look at how they do it.

Lignin Degradation Biologists have been keenly interested in understanding how basidiomycetes digest lignin. Paper manufacturers are also interested in this process because they need safe, efficient ways to degrade lignin in order to make soft, absorbent paper products.

To find out how lignin-digesting fungi do it, biologists began analyzing the proteins that these species secrete into extracellular space. After purifying these molecules, the investigators tested each protein for the ability to degrade lignin. Using this approach, investigators from two labs independently discovered an enzyme called lignin peroxidase.

Lignin peroxidase catalyzes the removal of a single electron from an atom in the ring structures of lignin. This oxidation step creates a free radical—an atom with an unpaired electron (see Chapter 2). This is an extremely unstable electron configuration, and it leads to a series of uncontrolled and unpredictable reactions that split the polymer into smaller units.

Biologists have referred to this mechanism of lignin degradation as enzymatic combustion. The phrase is apt: The uncontrolled oxidation reactions triggered by lignin peroxidase are analogous to the uncontrolled oxidation reactions that occur when gasoline burns in a car engine.

The unpredictable nature of the reaction is remarkable, because virtually all of the other reactions catalyzed by enzymes are extremely predictable. The lack of predictability here makes

sense, however. Unlike proteins, nucleic acids, and most other polymers with a regular and predictable structure, lignin is extremely heterogeneous. Over 10 types of covalent linkages are routinely found between the monomers that make up lignin. But once lignin peroxidase has created a free radical in the ring structure, any of these linkages can be broken.

However, fungi cannot grow with lignin as their sole source of food. The 6-carbon rings in lignin are extremely difficult to metabolize, and as a result they accumulate in soil. If wood-rotting fungi don't use lignin as food, why do they produce enzymes to digest it? The answer is simple. In wood, lignin forms a dense matrix around long strands of cellulose. Degrading the lignin matrix gives hyphae access to huge supplies of energy-rich cellulose. Saprophytic fungi are like miners. But instead of seeking out rare, gem-like nitrogen or phosphorus atoms as do EMF and AMF, the saprophytes use lignin peroxidase to blast away enormous lignin molecules, exposing rich veins of cellulose that can fuel growth and reproduction.

Cellulose Digestion Once lignin peroxidase has softened wood by stripping away its lignin matrix, the long strands of cellulose that remain can be attacked by enzymes called cellulases.

Like lignin peroxidase, cellulases are secreted into the extracellular environment by fungi. But unlike the uncontrolled chain reaction catalyzed by lignin peroxidase, degradation of cellulose by cellulases is extremely predictable.

Biologists have purified seven different cellulases from the fungus *Trichoderma reesei*. Two of these enzymes catalyze a critical early step in digestion—they cleave long strands of cellulose into a disaccharide called cellobiose. The other cellulases are equally specific and also catalyze hydrolysis reactions. In combination, the suite of seven enzymes in *T. reesei* transforms long strands of cellulose into a simple monomer—glucose—that the fungus can absorb and use as a source of food.

Variation in Reproduction

Recall from Section 32.2 that fungi may produce swimming gametes and spores, yoked hyphae in which nuclei from different individuals fuse to form a zygosporangium inside a protective structure, or specialized spore-producing cells called basidia and asci. As fungi diversified, in addition to adapting to a variety of food sources, they evolved an array of ways to reproduce.

Spores as Key Reproductive Cells The spore is the most fundamental reproductive cell in fungi. Spores are the dispersal stage in the fungal life cycle and are produced during both asexual and sexual reproduction. (Recall from Chapter 13 that asexual reproduction is based on mitosis, while sexual reproduction is based on meiosis.) Fungi produce spores in such prodigious quantities that it is not unusual for them to outnumber pollen grains in air samples.

If a spore falls on a food source and is able to germinate, a mycelium begins to form. As the fungus expands, hyphae grow in the direction in which food is most abundant. But if food begins to run out, mycelia respond by making spores, which are dispersed by wind or animals.

Why would mycelia reproduce when food is low? The leading hypothesis to answer this question is that spore production allows starving mycelia to disperse offspring to new habitats where more food might be available. Thus, spore production is favored by natural selection when individuals are under nutritional stress.

Multiple Mating Types In some fungal lineages, hyphae come in many different mating types. Instead of having morphologically distinct males and females that produce sperm and eggs, hyphae of different mating types appear identical.

Hyphae of the same mating type will not combine during sexual reproduction. When zygomycete hyphae grow close to each other, for example, they will not fuse unless the individuals have different alleles of one or more genes involved in mating. If chemical messengers released by two hyphae indicate that they are of different mating types, then fusion and zygosporangium formation follows.

In this way, mating types function as sexes. Instead of having just two sexes, a single fungal species may have tens of thousands of sexes. The basidiomycete *Schizophyllum commune*, for example, is estimated to have 28,000 mating types.

Why so many? The leading hypothesis to explain the existence of mating types is that it helps generate genetic diversity in offspring by increasing the probability of outcrossing. Genetic diversity, in turn, is known to be advantageous in fighting off infections and responding to changes in the environment (see Chapter 13).

How Does Fertilization Occur? Compared with green plants, protists, and animals, fertilization in fungi has important unique features:

- Only some chytrids produce gametes, which are not considered eggs and sperm. Both male and female gametes are motile, and female gametes are only slightly larger than male gametes.
- In all other lineages of fungi, fertilization occurs in two distinct steps: **(1)** fusion of hyphae and **(2)** fusion of nuclei from the fused hyphae. These two steps can be separated by long time spans and even long distances.

In many fungi, the process of sexual reproduction begins when hyphae from two different mating types fuse to form a hybrid cell. When the cytoplasm of two individuals fuses in this way, **plasmogamy** (pronounced *plaz-MAH-ga-mee*) is said to occur (**FIGURE 32.12**). Often, plasmogamy does not immediately lead to nuclear fusion. Rather, the genetically distinct, haploid nuclei persist in the same cell or mycelium. When two or more genetically distinct nuclei exist within a single mycelium, it is **heterokaryotic** ("different kernel"). Most hyphae in heterokaryotic mycelia are **dikaryotic** ("two kernel")—they are divided by septa, and each cell contains two nuclei, one from each mating type.

The distinct nuclei in dikaryotic and heterokaryotic mycelia function independently, even though gene expression must be coordinated for growth and development to occur. For

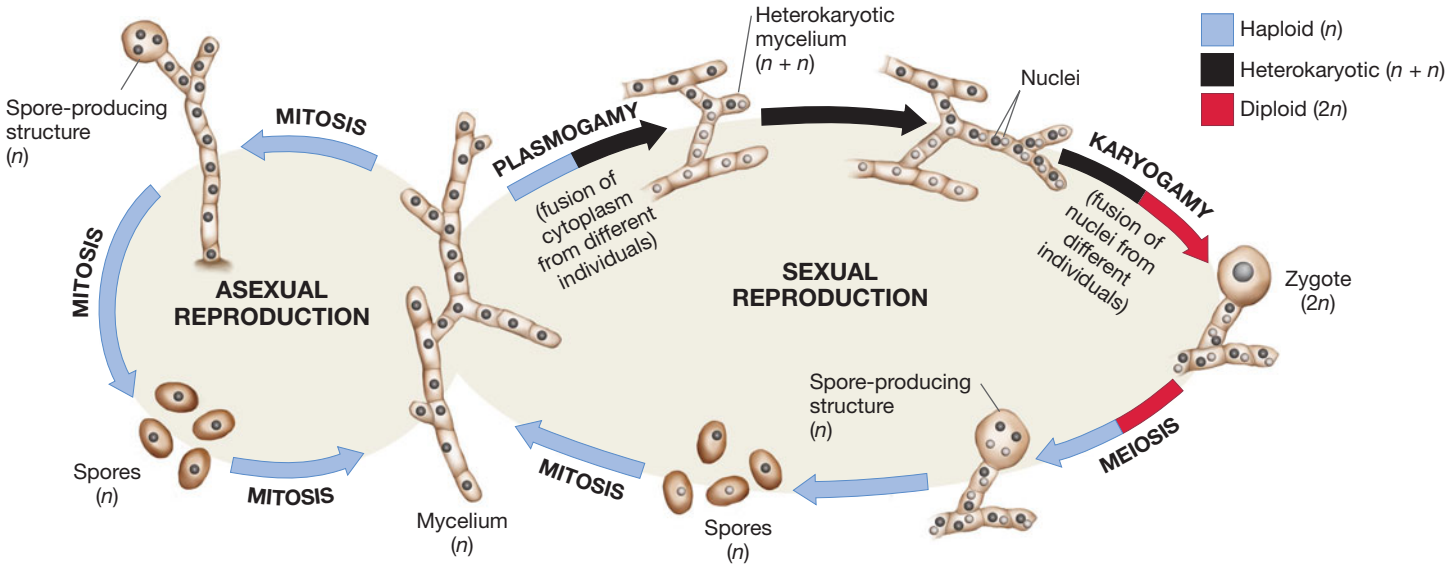


FIGURE 32.12 Fungi Have Unusual Life Cycles. A generalized fungal life cycle, showing both asexual and sexual reproduction.

✔ **QUESTION** Fungi spend most of their lives feeding. Which is the longest-lived component of this life cycle?

example, in septate fungi the two types of nuclei divide as the hyphae expand, so each compartment that is divided by a septum contains one of each of the two types of nuclei. Biologists are currently investigating how the activities of the two nuclei are coordinated.

In a dikaryotic or heterokaryotic mycelium, one or more pairs of unlike nuclei may eventually fuse to form a diploid zygote. The fusion of nuclei is called **karyogamy** (pronounced *ka-ree-AH-ga-mee*). The nuclei that are produced by karyogamy then divide by meiosis to form haploid spores.

✔ **If you understand the relationship between plasmogamy and karyogamy, you should be able to compare and contrast these events with the life cycles of other eukaryotes. For example, which human cells undergo plasmogamy and karyogamy? Are any human cells heterokaryotic?**

Asexual Reproduction As the left side of Figure 32.12 indicates, fungal species can reproduce asexually as well as sexually. In fact, large numbers of ascomycetes have never been observed to reproduce sexually.

During asexual reproduction, spore-forming structures are produced by a haploid mycelium, and spores are generated by mitosis. As a result, offspring are clones—meaning that they are genetically identical to their parent.

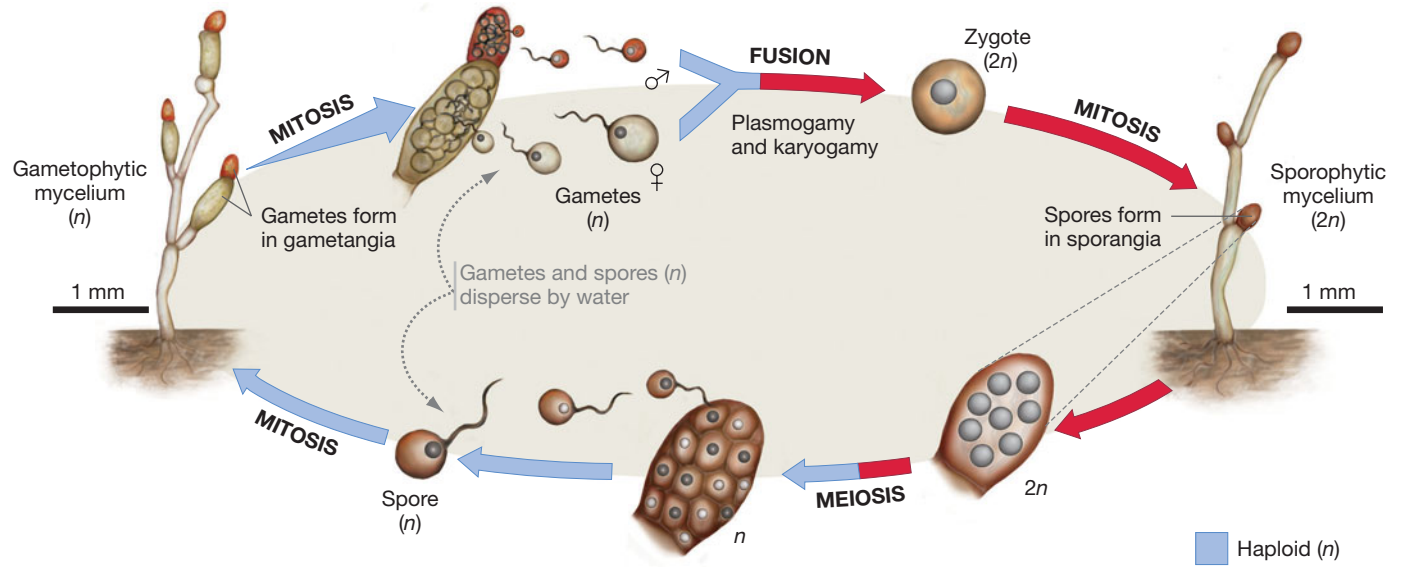
Producing microscopic spores that are carried by wind was an adaptation to life on land that allowed terrestrial fungi to disperse widely and to colonize new habitats.

Four Major Types of Life Cycles

Among the sexually reproducing species of fungi, the presence of a heterokaryotic stage and the morphology of the spore-producing structure vary. Morphologies of reproductive structure were introduced in Section 32.2. Let's now take a closer look at the sexual reproduction portion of each of the four major types of life cycles that have been observed in fungi.

Chytrid Life Cycle The chytrids are the only type of fungi with species that exhibit alternation of generations. **FIGURE 32.13a** (see page 626) shows how alternation of generations occurs in the well-studied genus *Allomyces*. Here are the key stages in its life cycle:

1. Haploid adults form gametangia, in which male and female swimming gametes are produced by mitosis.
2. Gametes from the same individual or different individuals fuse to form a diploid zygote.
3. The zygote grows into a diploid sporophyte.



The life cycle continues when meiosis occurs in the sporophytic mycelium, inside a structure called a sporangium. The haploid spores produced by meiosis disperse by swimming.

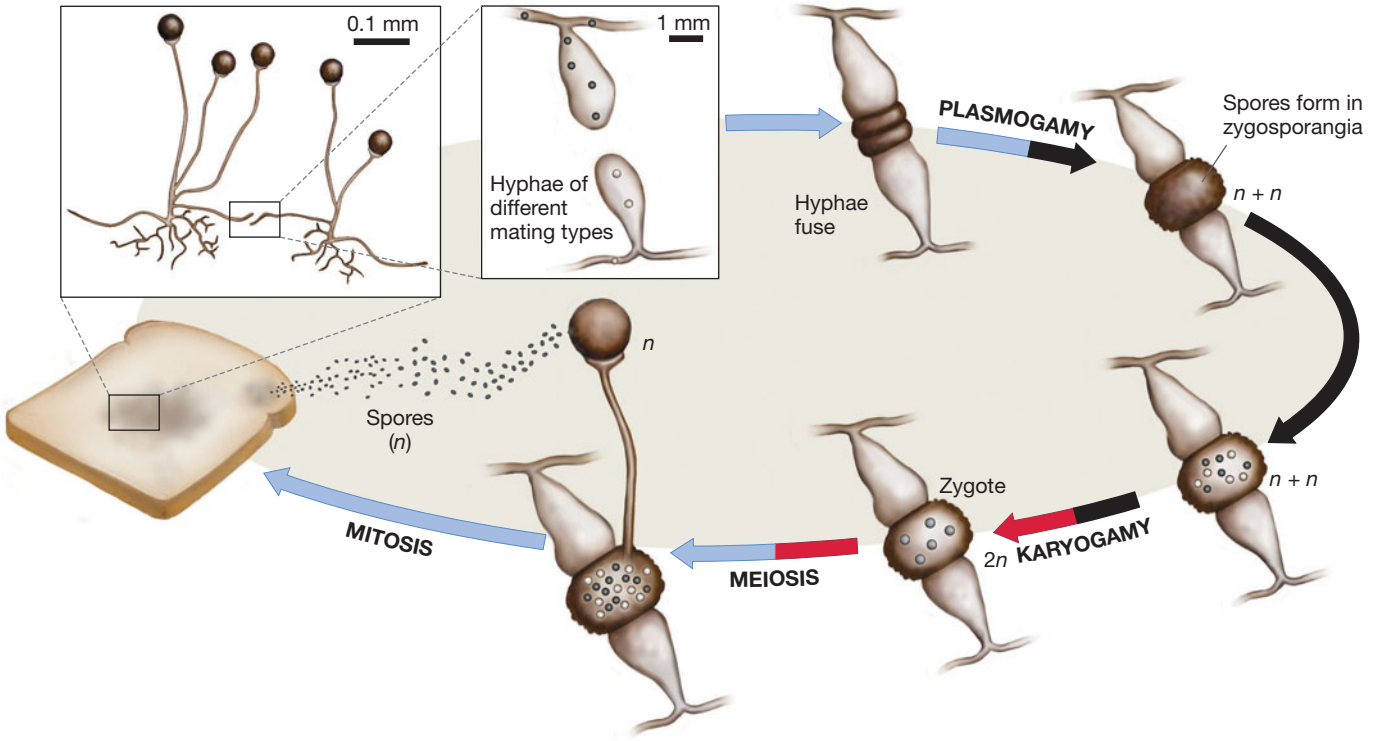
Zygomycete Life Cycle In zygomycetes, sexual reproduction starts when hyphae from different mating types fuse, as shown in **FIGURE 32.13b**. Plasmogamy forms a spore-forming structure called a zygosporangium that develops a tough, resistant coat. Inside the zygosporangium, nuclei from the mating partners fuse—meaning that karyogamy occurs.

The zygosporangium can persist if conditions become too cold or dry to support growth. When temperature and moisture conditions are again favorable, however, meiosis occurs and the zygosporangium germinates and forms a sporangium. The meiotic products within the sporangium produce haploid spores.

When spores are released and germinate, they grow into new mycelia. These mycelia can reproduce asexually by making sporangia whose haploid spores are produced by mitosis and dispersed by wind.

(a) Chytrids include the only fungi in which alternation of generations occurs. (Species: *Allomyces macrogynus*)

(b) Zygomycetes form yoked hyphae that produce a spore-forming structure. (Species: *Rhizopus stolonifer*)



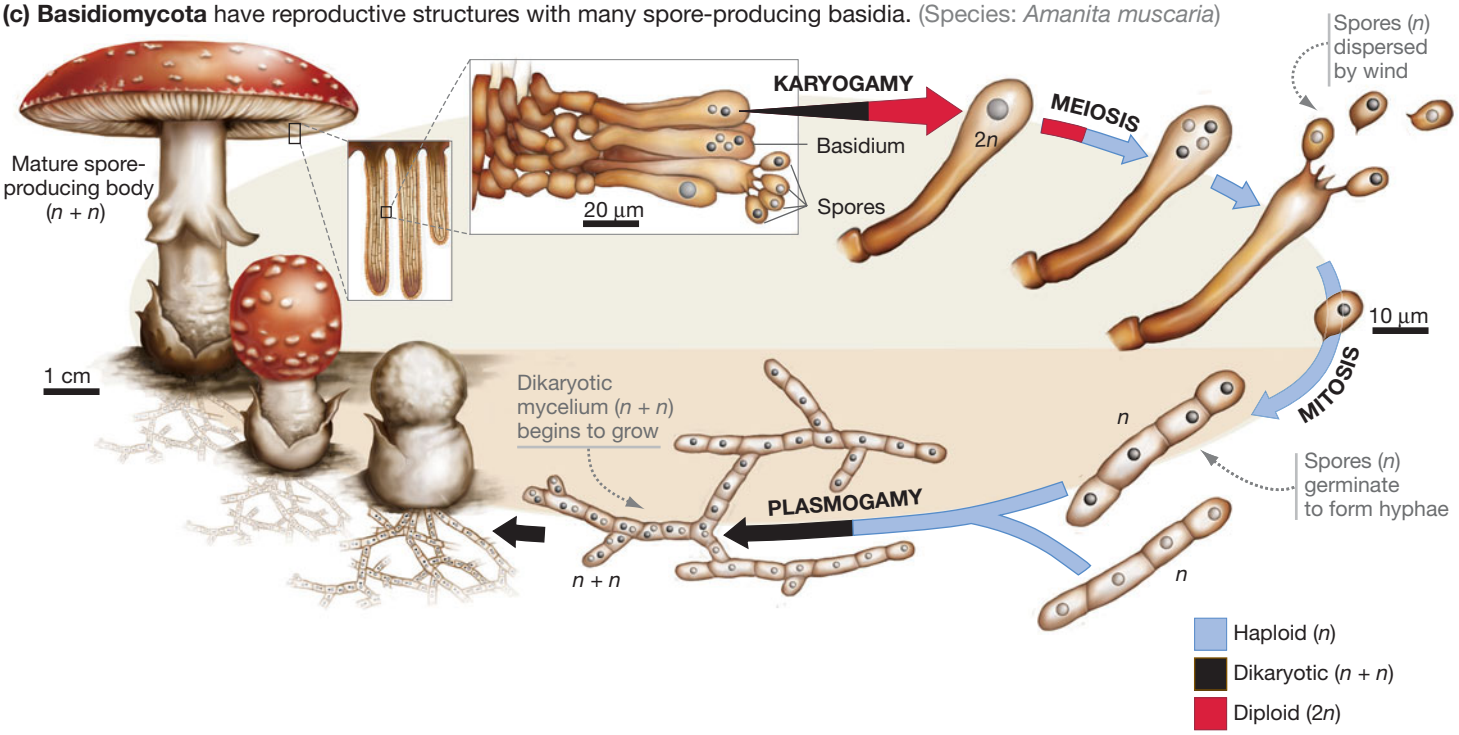


FIGURE 32.13 Variation in Sexual Reproduction in Fungi. The sexual part of the life cycle in four major groups of fungi: **(a)** chytrids, **(b)** zygomycetes, **(c)** Basidiomycota, and **(d)** Ascomycota.

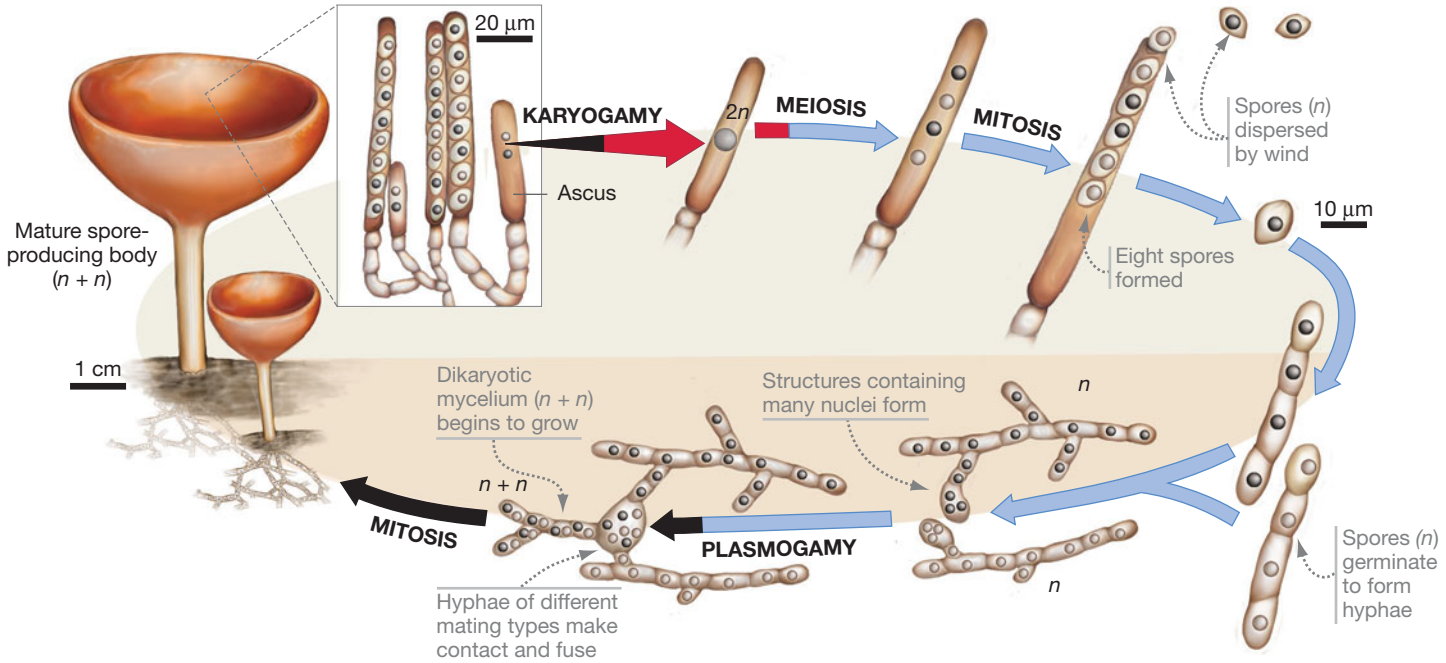
✔ **QUESTION** Asexual reproduction, as shown in Figure 32.12, is extremely common in zygomycetes and ascomycetes. What is the difference between mycelia produced via asexual versus sexual reproduction?



Basidiomycota Life Cycle Mushrooms, bracket fungi, and puffballs are sexual reproductive structures produced by members of the Basidiomycota (**FIGURE 32.13c**). Even though their size, shape, and color vary enormously from species to species, all basidiomycete reproductive structures originate from the dikaryotic hyphae of mated individuals.

Inside a mushroom or bracket fungus or puffball, the club-like, spore-producing cells called basidia form at the ends of dikaryotic hyphae. Karyogamy occurs within the basidia. The diploid nucleus that results undergoes meiosis, yielding four haploid spores. The spores are dispersed by wind and then germinate to form a new hyphae.

(c) Basidiomycota have reproductive structures with many spore-producing basidia. (Species: *Amanita muscaria*)

(d) Ascomycota have reproductive structures with many spore-producing asci. (Species: *Cookeina speciosa*)

Spores are eventually ejected from the end of the basidia and are dispersed by the wind. It is not unusual for a single puffball or mushroom to produce a billion spores.

Ascomycota Life Cycle The mature sexual reproductive structure in Ascomycota is produced by a dikaryotic hypha.

As **FIGURE 32.13d** illustrates, the process usually begins when hyphae or specialized structures from different mating types fuse, forming a heterokaryotic cell containing many independent nuclei. A short dikaryotic hypha with cells containing two nuclei, one from each parent, emerges and eventually grows into a complex reproductive structure whose hyphae have the sac-like, spore-producing structures called asci at their tips.

After karyogamy occurs inside each ascus, meiosis takes place and eight haploid spores are produced. When the ascus matures, the spores inside are forcibly ejected.

C Y U

If you understand that . . .

- Most fungi live in close association with land plants as mycorrhizae, endophytes, or saprophytes.
- When plants are alive, mycorrhizal fungi associate with their roots, and many fungal species grow as endophytes.
- When plants die, saprophytic fungi degrade their tissues and release nutrients.
- Instead of being based on the fusion of gametes, sexual reproduction in most fungi begins with plasmogamy, or the fusion of hyphae, followed by karyogamy, or nuclear fusion, and meiosis.

✔ You should be able to . . .

1. Describe evidence that mutualism occurs in EMF.
2. Compare and contrast what happens inside a zygosporangium, basidium, and ascus.

Answers are available in Appendix A.

32.4 Key Lineages of Fungi

Based on the current hypothesized phylogeny for the Fungi, it is clear that neither chytrids nor zygomycetes form monophyletic groups and should not be named as single lineages (see Figure 32.8). Researchers continue to collect and analyze additional data—mostly DNA sequences—to identify monophyletic groups and explain the early evolution of fungi.

In addition, the Ascomycota lineage is exceptionally diverse, and the phylogenetic relationships among major subgroups are still being worked out. As a result, the discussion of "key lineages" that follows distinguishes two lifestyles observed in Ascomycota, and not monophyletic groups within the phylum. Research on the phylogenetic relationships within fungi continues.

- Fungi > Microsporidia
- Fungi > Chytrids
- Fungi > Zygomycetes
- Fungi > Glomeromycota
- Fungi > Basidiomycota (Club Fungi)
- Fungi > Ascomycota > Lichen-Formers
- Fungi > Ascomycota > Non-Lichen-Formers

Fungi > Microsporidia

All of the estimated 1500 species of microsporidians are single-celled and parasitic on animal cells. They are distinguished by a unique structure called the polar tube (**FIGURE 32.14**), which allows them to enter the cells they parasitize. The tube shoots out from the microsporidian, penetrates the membrane of the host cell, and acts as a conduit for the contents of the microsporidian cell to enter the host cell. Once inside, the microsporidian replicates and produces a generation of daughter cells, which go on to infect other host cells.

Microsporidians have a dramatically reduced genome. One species has the smallest genome known among eukaryotes—the total number of base pairs present is over 1000 times smaller than the human genome. Unlike other fungi, microsporidians lack functioning mitochondria. As in other fungi, the polysaccharide chitin is a prominent component of their cell wall **✔You should be able to mark the origin of the polar tube and the loss of mitochondria on Figure 32.8.**

Absorptive lifestyle Most microsporidians parasitize insects or fish. Because they enter the interior of host cells, they are called intracellular parasites. Their small genome size and lack of functional mitochondria are both adaptations to this lifestyle.

Life cycle Variation in life cycles is extensive. Some species appear to reproduce only asexually. Others produce several different types of sexual or asexual spores, and some must successfully infect several different host species to complete their life cycle.

Human and ecological impacts Species from eight different genera can infect humans. In most cases, however, microsporidians cause serious infections only in AIDS patients and other individuals whose immune systems are not functioning well. Some microsporidians are serious pests in honeybee and silkworm colonies, while others cause severe infections in grasshoppers and are marketed as a biological control agent to reduce crop damage caused by grasshoppers.

Nosema tractabile

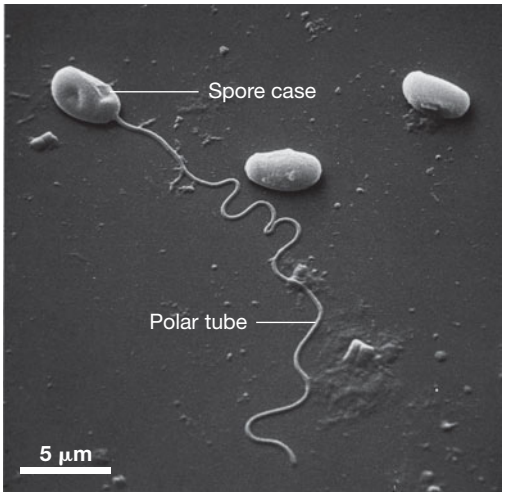

FIGURE 32.14 Microsporidia Infect Other Cells via a Polar Tube.

Fungi > Chytrids

Chytrids are largely aquatic and are common in freshwater environments. Some species live in wet soils, and a few have been found in desert soils that are wet only during a rainy season. Species found in dry soils have tough spores that endure harsh conditions. Spores from chytrids have been shown to germinate after a resting period of as long as 31 years. Members of this group are the only fungi that produce motile cells. In each case, the motile gametes use flagella to swim.

Absorptive lifestyle Many species of chytrids have enzymes that allow them to digest cellulose. As a result, these species are important decomposers of plant material in wet soils, ponds, and lakes (**FIGURE 32.15**). However, many of the freshwater species are parasitic, and parasitic chytrids sometimes cause disease epidemics in algae or aquatic insects (including mosquitoes). Other species parasitize mosses, ferns, or flowering plants. Mutualistic chytrids are among the most important of the many organisms living in the guts of deer, cows, elk, and other mammalian herbivores, because the chytrids help these animals digest their food. Chytrids secrete cellulases that degrade the cell walls of grasses and other plants ingested by the animal, releasing sugars that are used by both the chytrids and their hosts.

Life cycle During asexual reproduction, most chytrid species produce spores that swim to new habitats via a flagellum. A few species reproduce sexually as well as asexually and exhibit alternation of generations. (Recall from Section 32.3 that these chytrids are the only fungal species to do so.) In species that reproduce sexually, plasmogamy and karyogamy may occur in a variety of ways: through fusion of hyphae, gamete-forming structures, or gametes.

Human and ecological impacts In addition to the species that serve as decomposers and mutualists, many chytrids are parasites. Biologists are investigating the possibility of using a chytrid that parasitizes mosquito larvae as a biological control agent; potato tubers are sometimes invaded and spoiled by a parasitic chytrid that causes black wart disease. The parasitic chytrid *Batrachochytrium dendrobatidis* is largely responsible for catastrophic declines occurring recently in amphibian populations all over the world.

Allomyces macrogynus

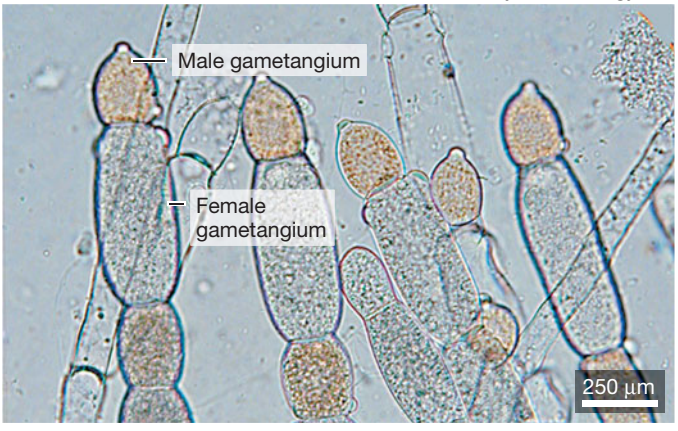

FIGURE 32.15 A Chytrid That is a Common Inhabitant of Soils and Ponds Worldwide.

Fungi > Zygomycetes

The zygomycetes ("yoked-fungi") are primarily soil-dwellers. Their hyphae yoke together and fuse during sexual reproduction and then form a durable, thick-walled zygosporangium.

Absorptive lifestyle Many members of zygomycete lineages are saprophytes and live in plant debris. Some parasitize other fungi, however, or are important parasites of insects and spiders.

Life cycle Asexual reproduction is extremely common. Ball-like sporangia are produced at the tips of hyphae that form stalks, and mitosis results in the production of spores that are dispersed by wind. During sexual reproduction, fusion of hyphae occurs only between individuals of different mating types.

Human and ecological impacts The common bread mold *Rhizopus stolonifer* is a frequent household pest—probably the zygomycete that is most familiar to you. Saprophytic and parasitic members of these lineages are responsible for rotting strawberries and other fruits and vegetables and causing large losses in these food industries. The black bread mold pictured in **FIGURE 32.16** is a familiar example of a saprophytic zygomycete. Some species of *Mucor* are used in the production of steroids for medical use. Species of *Rhizopus* and *Mucor* are used in the commercial production of organic acids, pigments, alcohols, and fermented foods.

Rhizopus nigricans

FIGURE 32.16 Black Bread Molds Are Zygomycetes.

Fungi > Glomeromycota

Recent phylogenetic analyses have shown that the arbuscular mycorrhizal fungi (AMF) form a distinct lineage, indicating that Glomeromycota is a major monophyletic group. ✔**You should be able to mark the origin of the AMF association on Figure 32.8.**

Absorptive lifestyle Recall from Section 32.3 that AMF absorb phosphorus-containing ions or molecules in the soil and transfer them, along with other nutrients and water, into the roots of most of the plants living in grasslands and tropical forests (**FIGURE 32.17**). In exchange, the host plant provides the symbiotic fungi with sugars and other organic compounds.

Life cycle Most species form large spores underground. Glomeromycetes are difficult to grow in the laboratory, so their life cycle is not well known. No one has yet discovered a sexual phase in these species.

Human and ecological impacts Because grasslands and tropical forests occupy large areas of terrestrial habitats on Earth, the AMF are enormously important to both human and natural economies.

FIGURE 32.17 AMF Penetrate the Walls of Plant Root Cells.

Fungi > Basidiomycota (Club Fungi)

Although most basidiomycetes form mycelia and produce multicellular reproductive structures, some species have the unicellular growth form. The group is named for basidia, the club-like cells where meiosis and spore formation occur. ✔**You should be able to mark the origin of the basidium on Figure 32.8.** About 31,000 species of basidiomycetes have already been described, and more are discovered each year.

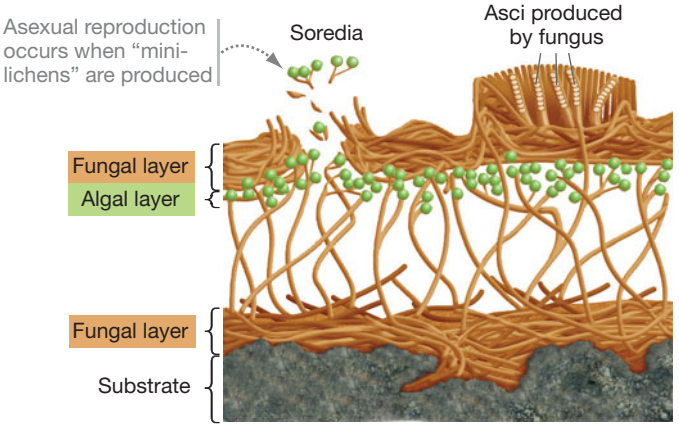
Absorptive lifestyle Basidiomycetes are important saprophytes. Along with a few soil-dwelling bacteria, some members of this lineage are the only organisms capable of synthesizing lignin peroxidase and are therefore important in wood decomposition. Some basidiomycetes are ectomycorrhizal fungi (EMF) that associate with trees in temperate forests. One subgroup consists entirely of parasitic forms called rusts, including species that cause serious infections in many crop plants. The plant parasites called smut fungi specialize in infecting grasses; a few infect other fungi. Thus, as in other lineages of fungi, the entire array of lifestyles—saprophytic, mutualistic, and parasitic—is found within Basidiomycota.

Life cycle Asexual reproduction through production of spores is common in the Basidiomycota, although not as prevalent as in other groups of fungi. Asexual reproduction also occurs through growth and fragmentation of mycelia in the soil or in rotting wood, resulting in genetically identical individuals that are physically independent. During sexual reproduction, all basidiomycetes—even unicellular ones—produce basidia. In the largest subgroup in this lineage, basidia form in large, aboveground reproductive structures called mushrooms, brackets, earthstars, or puffballs (**FIGURE 32.18**). Members of the Basidiomycota and Ascomycota are the only fungi that have heterokaryotic (dikaryotic) mycelia. ✔**You should be able to mark the origin of the dikaryotic mycelia on Figure 32.8.**

Astraeus hygrometricus

FIGURE 32.18 Puffballs Can Produce Billions of Spores.

Human and ecological impacts EMF are enormously important in forestry. The temperate forests where these fungi are particularly abundant provide most of the hardwoods and softwoods used in building construction, furniture-making, and papermaking. Throughout the world, mushrooms are cultivated or collected from the wild as a source of food. The white button, crimini, and portabella mushrooms you may have seen in grocery stores are all varieties of the same species, *Agaricus bisporus*. Some of the toxins found in poisonous mushrooms are used in biological research; others are hallucinogens.



About half of the ascomycetes grow in mutualistic association with cyanobacteria and/or single-celled green algae, forming the structures called lichens. Over 15,000 different lichens have been described to date; in most, the fungus involved is an ascomycete (although a few basidiomycetes participate as well). To name a lichen, biologists use the species name assigned to the fungus that participates in the association. Most lichen-formers are found in a single monophyletic group within the Ascomycota. ✔**Based on this observation, you should be able to mark the primary origin of the lichen-forming habit on Figure 32.8.**

Absorptive lifestyle The fungus in lichens appears to protect the photosynthetic bacterial or algal cells. The fungal hyphae form a dense protective layer that shields the photosynthetic species and reduces water loss. In return, the cyanobacterium or alga provides carbohydrates that the fungus uses as a source of carbon and energy. However, the hyphae of some lichen-forming fungi have been observed to invade algal cells and kill them. This observation suggests a partially parasitic relationship in at least some lichens. The nature of lichen-forming associations is the subject of ongoing research.

Life cycle As **FIGURE 32.19a** shows, many lichens reproduce asexually via the production of small "mini-lichen" structures called soredia that contain both symbionts. Soredia disperse to a new location via wind or water and then develop into a new, mature individual via the growth of the algal or bacterial and fungal symbionts. In addition, the fungal partner may form asci. Spores that are shed from asci germinate to form a small mycelium. If the growing hyphae encounter the appropriate algal or bacterial cells, a new lichen can form.

Human and ecological impacts In abundance and diversity, lichens dominate the Arctic and Antarctic tundras and are extremely common in boreal forests (see Chapter 52). They are the major food of caribou in the winter as well as the most prevalent colonizers of bare rock surfaces throughout the world (**FIGURE 32.19b**). Rock-dwelling lichens are significant because they produce acids that break down the rock surface as they grow—launching the first step in soil formation. Lichens are particularly sensitive to air pollution and are often used as bioindicators of air quality.

(a) Cross section of a lichen, showing three layers

(b) Top view of lichen on a rock

FIGURE 32.19 Lichens Are Associations between a Fungus and a Cyanobacterium or Green Alga. (a) In a lichen, cyanobacteria or green algae live within a dense network of fungal hyphae. **(b)** Lichens often colonize surfaces, such as tree bark or bare rock, where other organisms are rare.

The ascomycetes that do not form lichens are found in virtually every terrestrial habitat as well as some freshwater and marine environments. Although most ascomycetes form mycelia, many are single-celled yeasts. The ascus is a distinguishing characteristic of the Ascomycota. ✔**You should be able to mark the origin of the ascus on Figure 32.8.**

Absorptive lifestyle Many ascomycetes form mutualistic ectomycorrhizal fungi (EMF) associations with tree roots. Ascomycetes are also the most common endophytic fungi on aboveground tissues. Large numbers are saprophytic and are abundant in forest floors and in grassland soils. Parasitic forms are common as well. As in other fungal lineages, the entire array of absorptive lifestyles found in fungi has evolved independently within the Ascomycota.

In addition, about 65 species in one Ascomycota lineage are predatory—primarily on amoebae and other unicellular protists. Some are large enough to capture the microscopic animals called roundworms, however. The predatory ascomycetes trap their prey by means of sticky substances on their cell walls, or they catch prey in snares consisting of looped hyphae (**FIGURE 32.20**). Once a prey individual is captured, hyphae invade its body, digest it, and absorb the nutrients that are released. A predatory ascomycete has been found in fossilized material that is 100 million years old. ✔**You should be able to mark the origin of predation on Figure 32.8.**

Life cycle The aboveground, asci-bearing reproductive structures of these fungi may be a cup or saucer shape (**FIGURE 32.21**). Spores are also routinely produced asexually, at the ends of specialized hyphae.

Human and ecological impacts Some saprophytic ascomycetes can grow on jet fuel or paint and are used to help clean up contaminated sites. *Penicillium* is an important source of antibiotics, and *Aspergillus* produces citric acid used to flavor soft drinks and candy. Truffles are so highly prized that they can fetch $2000 per pound, and the multibillion-dollar brewing, baking, and wine-making industries would collapse without the yeast *Saccharomyces cerevisiae*. A few parasitic ascomycetes cause infections in humans and other animals. In land plants, parasites from this group cause diseases including Dutch elm disease and chestnut blight.

If you understand . . .

32.1 Why Do Biologists Study Fungi?

- Many fungi species live in close association with land plants. The roots of most plants are infected by mutualistic fungi that provide the plant with nitrogen, phosphorus, and water in exchange for sugars and other products of plant photosynthesis.
- Parasitic fungi are responsible for devastating blights in crops and other plants.
- Once plants die, saprophytic fungi degrade the lignin and cellulose in wood and use nutrients from decaying plant material.
- Because they free up carbon atoms that would otherwise be locked up in wood, fungi speed up the carbon cycle in terrestrial ecosystems.
- Fungi are used widely in the food processing, cheese-making, baking, and brewing industries.

✔ **You should be able to predict the results of using fungicides to experimentally exclude fungi from 10-m × 10-m plots in a forest or grassland near your campus.**

32.2 How Do Biologists Study Fungi?

- Morphological analyses of fungi have revealed adaptations that make fungi exceptionally effective at absorbing nutrients from the environment.
- Researchers have determined that fungi exhibit two growth forms—single-celled "yeasts" or mycelia composed of long, filamentous hyphae. Mycelia provide fungi with extremely high surface-area-to-volume ratios. Some fungal bodies are extremely large.
- Septa divide hyphae into cells, but pores in the septa facilitate transport of nutrients and organelles through the hyphae.
- Scientists have determined from morphological studies that fungi possess four known, distinctive types of reproductive structures: **(1)** chytrids produce motile gametes; **(2)** zygomycetes make tough zygosporangia; **(3)** members of the Basidiomycota have club-like, spore-forming structures; and **(4)** members of the Ascomycota have sac-like, spore-forming structures.
- Recent analyses of DNA sequence data have revealed that fungi are more closely related to animals than they are to plants, and that the Basidiomycota, Ascomycota, and Glomeromycota each form monophyletic groups. Researchers are still trying to understand how the various groups of chytrids and zygomycetes are related to each other and to the other fungal lineages.

✔ **You should be able to explain why fungal infections are more difficult to treat than bacterial infections.**

32.3 What Themes Occur in the Diversification of Fungi?

- All fungi make their living by absorbing nutrients from living or dead organisms.
- Many fungi live in leaves and stems; in some grasses and other species, these endophytic fungi secrete toxins that discourage herbivores.
- Extracellular digestion, in which enzymes are secreted into food sources, enables fungi to break down extremely large molecules before absorbing them.
- Lignin decomposes through a series of uncontrolled oxidation reactions triggered by the enzyme lignin peroxidase.
- Cellulose digestion occurs in a carefully regulated series of steps, each catalyzed by a specific cellulase.
- Many species of fungi have never been observed to reproduce sexually. Most species can produce haploid spores either sexually or asexually, however.
- Sexual reproduction usually starts when hyphae from genetically different mating types fuse—an event called plasmogamy. If the fusion of nuclei, or karyogamy, does not occur immediately, a heterokaryotic mycelium forms, which in some species is dikaryotic. Heterokaryotic cells may eventually produce spore-forming structures where karyogamy and meiosis take place.

✔ **You should be able to explain why most fungi don't need to have gametes to accomplish sexual reproduction.**

32.4 Key Lineages of Fungi

- Microsporidia are parasitic, single-celled fungi with reduced genomes and an unusual polar tube used to infect host cells.
- Chytrids are usually aquatic with motile, flagellated spores. Some are terrestrial decomposers and some are parasites.
- Zygomycetes are largely saprophytic on dead plant tissue. During sexual reproduction, they form zygosporangia after hyphae from different mating types are yoked.
- The Glomeromycota is a monophyletic group of soil fungi that form arbuscular mycorrhizae with most land plants.
- The Basidiomycota is a monophyletic group of terrestrial fungi that form four airborne spores on each club-shaped basidium within mushrooms, brackets, and puffballs. Some can degrade wood. Others form ectomycorrhizae with certain trees.
- Ascomycota is a monophyletic group of terrestrial fungi that form eight airborne spores in each ascus. Some form lichens in association with green algae or cyanobacteria.

✔ **You should be able to describe some of the characteristics of each major lineage of fungi.**

TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. The mycelial growth habit leads to a body with a high surface-area-to-volume ratio. Why is this important?
   a. Mycelia have a large surface area for absorption.
   b. The hyphae that make up mycelia are long, thin tubes.
   c. Most hyphae are broken up into compartments by walls called septa, although some exist as single, gigantic cells.
   d. Hyphae can infiltrate living or dead tissues.
2. What is plasmogamy?
   a. production of gametes, after fusion of hyphae from different individuals
   b. exchange of nutrients between symbiotic fungi and hosts
   c. fertilization—the fusion of cytoplasm and nuclei from different individuals
   d. fusion of the cytoplasm from different mating types, without nuclear fusion
3. The hyphae of arbuscular mycorrhizal fungi (AMF) form bushy structures after making contact with the plasma membrane of a root cell. Why?
   a. They anchor the fungus inside the root, so the association is more permanent.
   b. They increase the surface area available for the transfer of nutrients.
   c. They produce toxins that protect the plant cells against herbivores.
   d. They break down cellulose and lignin in the plant cell wall.
4. What does it mean to say that a hypha is dikaryotic?
   a. Two nuclei fuse during sexual reproduction to form a zygote.
   b. Two independent nuclei, derived from different individuals, are present in each cell.
   c. The nucleus is diploid or polyploid—not haploid.
   d. It is extremely highly branched, which increases its surface area and thus absorptive capacity.
5. Explain how pores in septa of certain fungi allow mycelia to become larger.
6. Symbiotic partnerships in which one partner benefits and the other is unaffected are called _____.

TEST YOUR UNDERSTANDING

Answers are available in Appendix A

7. The Greek root *ecto* means "outer." Why are ectomycorrhizal fungi, or EMF, aptly named?
   a. Their hyphae form tree-like branching structures inside plant cell walls.
   b. They are mutualistic.
   c. Their hyphae form dense mats that envelop roots but do not penetrate the cell walls.
   d. They transfer nitrogen from outside their plant hosts to the interior.
8. Explain why fungi that degrade dead plant materials are important to the global carbon cycle. Do you accept the text's statement that, without these fungi, "Terrestrial environments would be radically different than they are today and probably much less productive"? Why or why not?
9. Lignin and cellulose provide rigidity to the cell walls of plants. But in most fungi, chitin performs this role. Why is it logical that most fungi don't have lignin or cellulose in their cell walls?
10. Biologists claim that EMF and AMF species are better than plants at acquiring nutrients because they have more surface area and because they are more effective at acquiring phosphorus (P) and/or nitrogen (N). Compare and contrast the surface area of mutualistic fungi and plant roots. Explain why fungi are particularly efficient at acquiring P and N, compared to plants.
11. Using information from Chapters 3 through 6, list two key macromolecules found in plants that contain phosphorus. Because phosphorus is often limiting to plant growth, explain how certain fungi are necessary for rapid plant growth.
12. Compare and contrast the way that fungi degrade lignin with the way that they digest cellulose.

TEST YOUR PROBLEM-SOLVING SKILLS

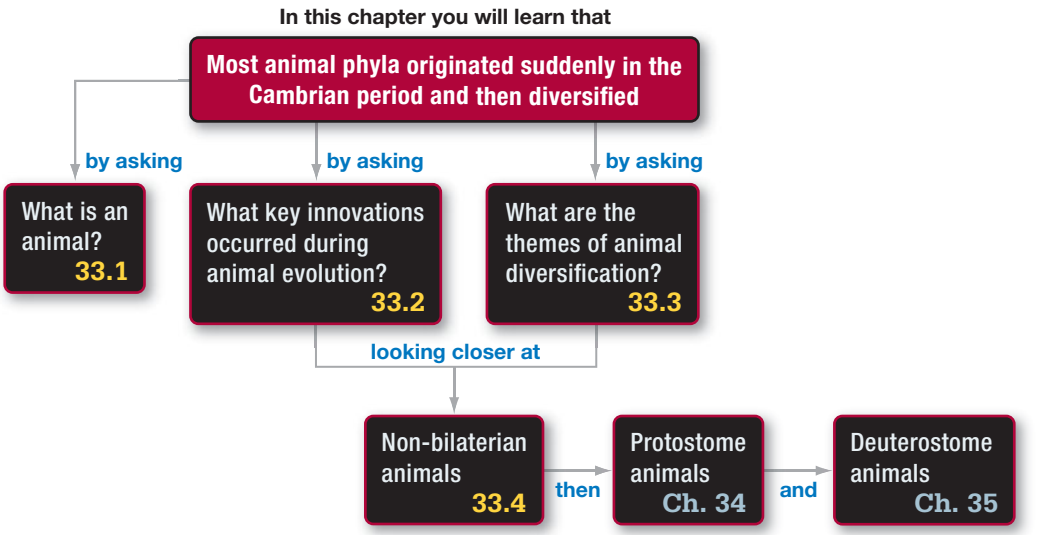
Answers are available in Appendix A

13. Lawns are sometimes fertilized with nitrate that can be washed into neighboring woodlots by rain. If the trees in that woodlot are associated with EMF, what effect might the excess nitrate have on the fungi and/or trees?

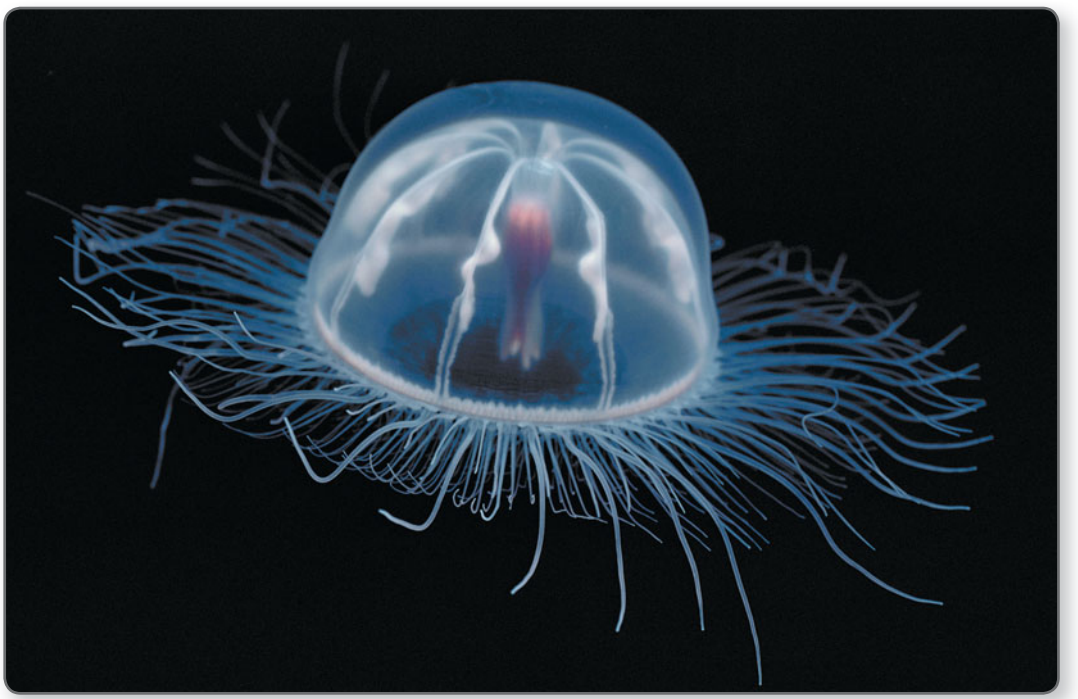
a. Fungal growth may be stimulated, causing the trees to transport more sugars to the fungi.

b. The fungi may secrete more peptidases to break down the nitrate.

c. The trees may take up the nitrate directly into their roots and rely less on the fungi.



d. The excess nitrate may stimulate the fungi to transport more sugar to the trees.



14. The box on chytrids in Section 32.4 mentions that they may be responsible for massive die-offs currently occurring in amphibians. Review Koch's postulates; then design a study showing how you would use Koch's postulates to test the hypothesis that chytrid infections are responsible for the frog deaths (see Chapter 29).

15. Experiments indicate that cellulase genes are transcribed and translated together. If cells are selected to be extremely efficient at digesting cellulose, is this result logical? Would you predict that the gene that codes for lignin peroxidase is transcribed along with the cellulase genes? How would you test your prediction?

16. Many mushrooms are extremely colorful. Fungi do not see, so it is unlikely that colorful mushrooms are communicating with one another. One hypothesis is that the colors serve as a warning to animals that eat mushrooms, much like the bright yellow and black stripes on wasps. Design an experiment capable of testing this hypothesis.

33 An Introduction to Animals

Jellyfish such as this hydromedusa are among the most ancient of all animals—they appear in the fossil record over 560 million years ago.

You're an animal, and you have plenty of company—animals are an extraordinarily diverse and species-rich lineage on the tree of life.

The radiation of animals began around 550 million years ago during an event called the **Cambrian explosion** (see Chapter 28). After a slow start, diverse animals suddenly appeared in the fossil record with shells, exoskeletons, internal skeletons, legs, heads, tails, eyes, antennae, jaw-like mandibles, segmented bodies, muscles, and brains. The Cambrian explosion was arguably the most spectacular period of evolutionary change in the history of life.

Today, estimates suggest that there are between 8 million and 50 million animal species alive on our planet, some strikingly similar to their Cambrian ancestors, others quite different. These species range in size and complexity from tiny sponges, which attach to a substrate and contain just a few

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

cell types, to blue whales, which migrate thousands of kilometers each year in search of food and contain trillions of cells, dozens of distinct tissues, an elaborate skeleton, and highly sophisticated sensory and nervous systems.

Only about 1.4 million animal species have been described and given scientific names to date. As scientists race to discover and describe more animal species, the impact of humans on the planet—ranging from habitat loss to pollution, overharvesting, spread of invasive species, and climate change—is causing the modern rate of animal extinction to accelerate. Some species may go extinct before they are ever described (see Chapter 57).

To analyze the almost overwhelming number and diversity of species in the animal lineage, this chapter presents a broad overview of how these species diversified, along with more detailed information on the characteristics of the lineages that appear first in the fossil record. (See Chapters 34 and 35 to focus on the most species-rich groups.) Let's start by considering what characteristics define animals.

33.1 What Is an Animal?

The ancestors to animals were single-celled protists (Chapter 30). **FIGURE 33.1** reviews how animals fit in the tree of life. Animals occur in a clade, or lineage, called Opisthokonta, along with fungi and the single-celled protists called choanoflagellates. Although scientists cannot be sure exactly what the protist ancestor to all animals looked like, it was likely very similar to today's choanoflagellates.

What characteristics define the animal lineage? Although you may be able to recognize most animals as animals when you see them, some animals look more like plants, fungi, or even protists.

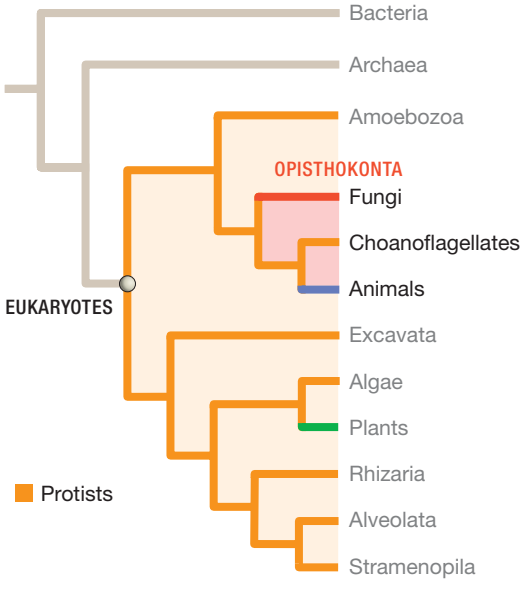


FIGURE 33.1 Choanoflagellates are the Closest Living Relatives to Animals.

Animals are eukaryotes that share key traits:

- *All animals are multicellular*, with cells that lack cell walls but have an extensive **extracellular matrix** (ECM; see Chapter 11). The ECM includes proteins specialized for cell–cell adhesion and communication.
- *All animals are heterotrophs*, meaning that they obtain the carbon compounds they need from other organisms. Most ingest ("eat") their food, rather than absorbing it across their exterior body surfaces.
- *All animals move* under their own power at some point in their life cycle.
- *All animals other than sponges have* **(1)** *neurons* (nerve cells) that transmit electrical signals to other cells; and **(2)** *muscle cells* that can change the shape of the body by contracting.

Multicellular fungi and animals are similar in that they are both multicellular heterotrophs that digest (break down) and absorb nutrients. However, animals are the only multicellular heterotrophs on the tree of life that usually ingest their food first, before they digest it. As a result, digestion in animals typically occurs within the space, or lumen, of the digestive tract rather than in the open exterior, as occurs with fungi.

In most animals, neurons connect to each other, forming a nervous system, and some neurons connect to muscle cells—which may contract in response to electrical signals from neurons. Muscles and neurons are adaptations that allow a large, multicellular body to move efficiently.

What is produced by the combination of multicellularity, heterotrophy, and efficient movement? Eating machines—animals are the largest predators, herbivores, and detritivores on Earth. They are key consumers in virtually every ecosystem, from the deep oceans and tropical forests to alpine ice fields.

Biologists currently recognize 30–35 **phyla,** or major lineages, of animals—the exact number is constantly being debated and revised as additional information comes to light. **TABLE 33.1** (see page 638) lists 29 phyla that are included in most published analyses. How can we make sense of all this diversity? Let's first take a closer look at the key events that occurred during the origin of major animal lineages. Then let's examine the key themes of diversification that occurred *within* lineages.

33.2 What Key Innovations Occurred during the Evolution of Animals?

Biologists who study the evolution of animals consider three types of data:

1. *Fossils* are important because they provide the only direct evidence of what ancient animals looked like, when they existed, and where they lived. However, the fossil record does not represent all animals equally. Fossils are more likely to occur for animals that were abundant, had hard parts, lived in areas where sedimentation was occurring, and/or lived recently (Chapter 28).

TABLE 33.1 An Overview of Major Animal Phyla

Group and Phylum	Common Name or Example Taxa	Number of Described Species
Non-bilaterian Groups		
Porifera	Sponges	8500
Placozoa	Placozoans	1
Ctenophora	Comb jellies	190
Cnidaria	Jellyfish, corals, anemones, hydroids, sea fans	11,500
Acoela	Acoelomate worms	350
Protostomes (lacks typical protostome development)		
Chaetognatha	Arrow worms	120
Protostomes: Lophotrochozoa		
Rotifera	Rotifers	2100
Platyhelminthes	Flatworms	20,000
Nemertea	Ribbon worms	1200
Gastrotricha	Gastrotrichs	400
Acanthocephala	Acanthocephalans	1150
Entoprocta	Entoprocts, kamptozoans	170
Gnathostomulida	Gnathostomulids	100
Annelida	Segmented worms	16,800
Mollusca	Mollusks (clams, snails, octopuses)	85,000
Phoronida	Horseshoe worms	10
Bryozoa	Bryozoa, ectoprocts, moss animals	5700
Brachiopoda	Brachiopods (lamp shells)	550
Protostomes: Ecdysozoa		
Nematoda	Roundworms	25,000
Kinorhyncha	Kinorhynchs	130
Nematomorpha	Hair worms	330
Priapula	Priapulans	16
Onychophora	Velvet worms	165
Tardigrada	Water bears	1045
Arthropoda	Arthropods (spiders, insects, crustaceans)	1,160,000
Deuterostomes		
Echinodermata	Echinoderms (sea stars, sea urchins, sea cucumbers)	7000
Xenoturbellida	Xenoturbillidans	2
Hemichordata	Acorn worms	108
Chordata	Chordates: tunicates, lancelets, sharks, bony fish, amphibians, reptiles (including birds), mammals	65,000

2. *Comparative morphology* provides information about which embryonic, larval, or adult morphological characteristics are common among groups of animals and which are unique to individual lineages (synapomorphies). These data can be used to define the fundamental architecture, or **body plan,** of each animal lineage. In a phylogenetic context, these data can be used to infer which characteristics arose first during the evolution of animals, and which animal groups are more closely related.
3. *Comparative genomics* provides information about the relative similarity of genes or whole genomes of diverse organisms (see Chapter 21). This relatively new source of data is providing dramatic insights into phylogenetic relationships and evolutionary history.

Sometimes these various sources of data on animal evolution suggest the same sequence of evolutionary events. Sometimes they don't. Consider one of the most influential papers on the phylogeny of animals, published in 1997. Using sequences from a gene that codes for RNA in the small subunit of the ribosome, Anna Marie Aguinaldo and colleagues estimated the phylogeny of species from 14 animal phyla. The results were revolutionary, suggesting a different pattern of relationships among animal lineages than had been accepted for years based on morphological data.

The phylogenetic tree in **FIGURE 33.2** is an updated version of the 1997 result, based on further studies of many gene and protein sequences. Some important morphological innovations are mapped onto the tree. Let's explore them by starting at the root of the tree and working toward the branch tips. (See **BioSkills 7** in Appendix B to review how to interpret phylogenetic trees.)

Origin of Multicellularity

Put your finger on the root of the animal tree in Figure 33.2, where the single-celled choanoflagellates outgroup meets the most basal animal branches. What happened at that node?

The first important insight is that animals are a monophyletic group, meaning that all animals share a common ancestor. Data from fossils, comparative morphology, and comparative genomics agree on a single origin of animals.

The second point to note is that sponges (phylum Porifera) include the two most basal, or ancient, lineages of animals. That is, multicellularity appears to have originated in a sponge-like animal. This hypothesis is well supported by diverse evidence. Let's take a closer look.

Fossil Evidence Sponges are the earliest animals to appear in the fossil record, more than 600 million years ago. The early presence of multicellular sponges and absence of fossils of other multicellular organisms are consistent with the basal position of sponges on the phylogeny.

Morphological Evidence Sponges share several key characteristics with the choanoflagellate outgroup:

- Both choanoflagellates and sponges are **sessile,** meaning that adults live permanently attached to a substrate.

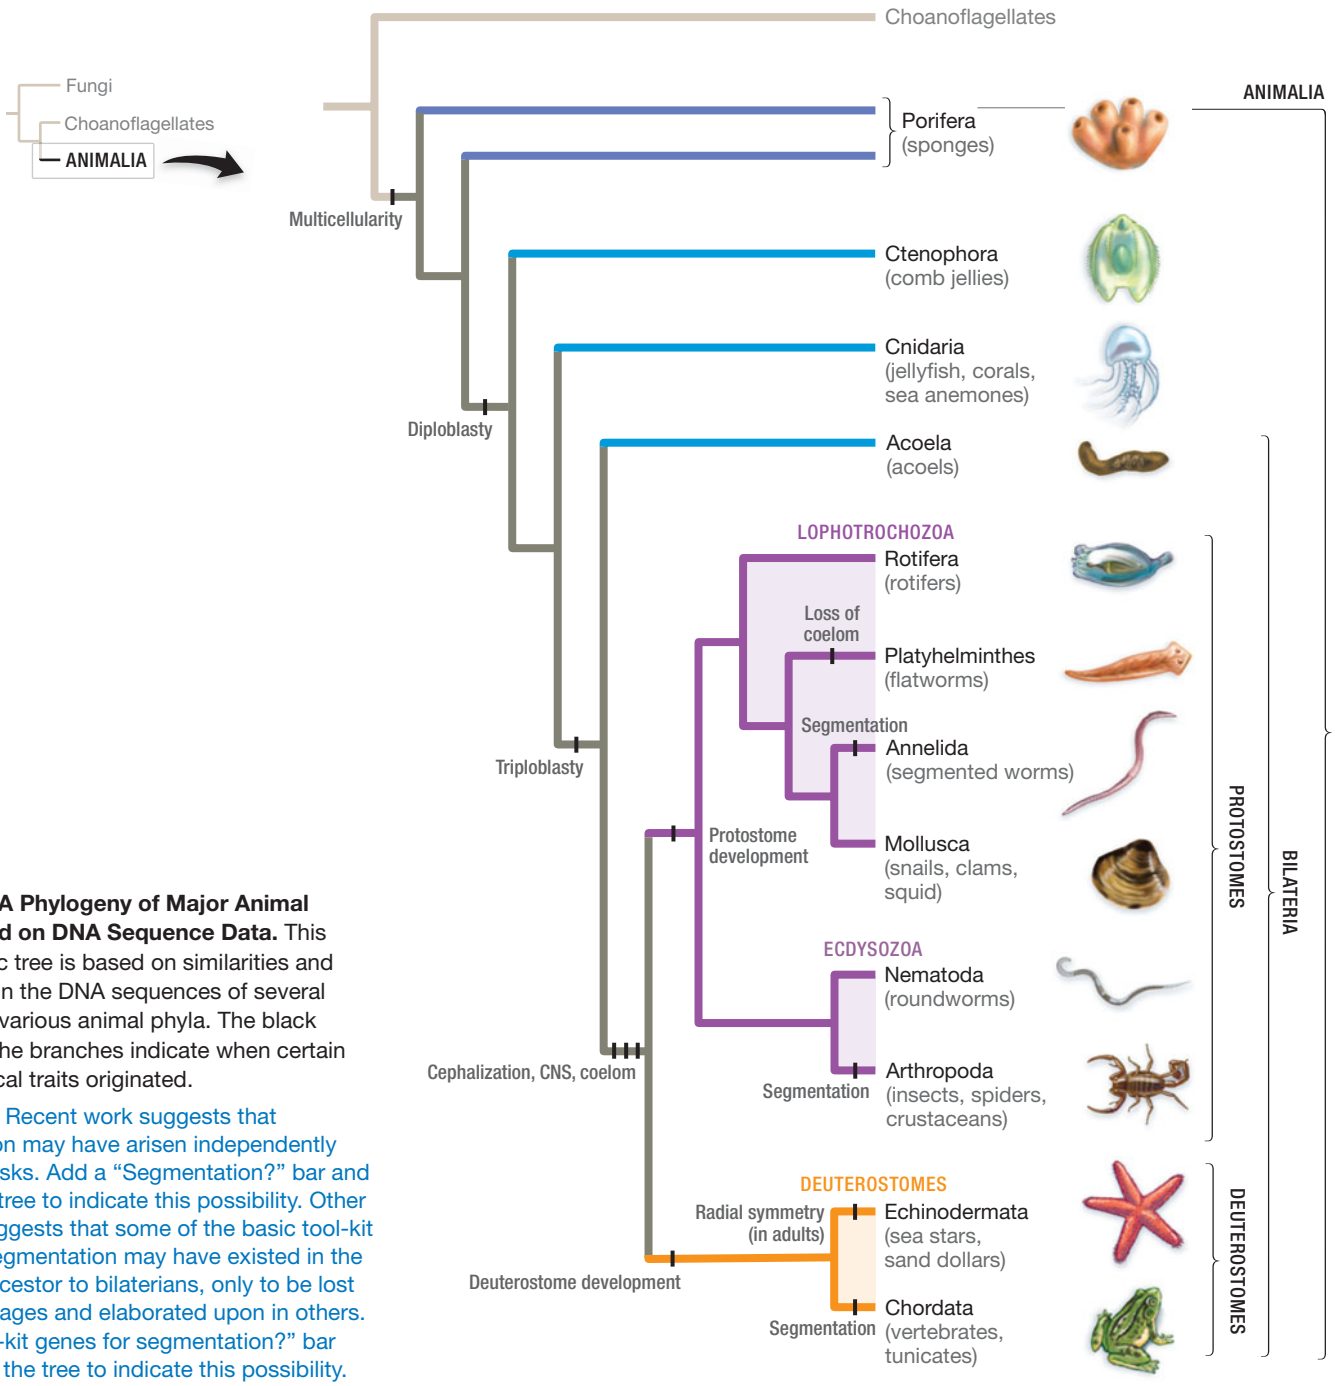

FIGURE 33.2 A Phylogeny of Major Animal Phyla Based on DNA Sequence Data. This phylogenetic tree is based on similarities and differences in the DNA sequences of several genes from various animal phyla. The black bars along the branches indicate when certain morphological traits originated.

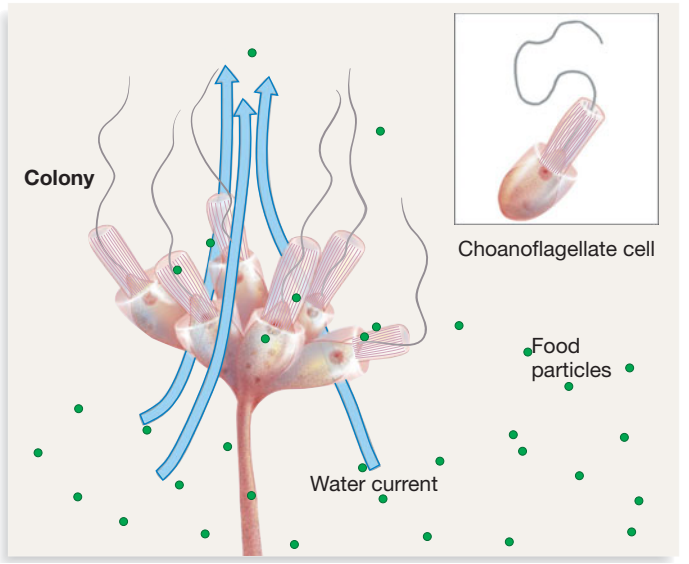

✔ **EXERCISE** Recent work suggests that segmentation may have arisen independently within mollusks. Add a "Segmentation?" bar and label to the tree to indicate this possibility. Other research suggests that some of the basic tool-kit genes for segmentation may have existed in the common ancestor to bilaterians, only to be lost in some lineages and elaborated upon in others. Add a "Tool-kit genes for segmentation?" bar and label to the tree to indicate this possibility.

- Both feed in a similar way, using cells with nearly identical morphology. As **FIGURE 33.3** (see page 640) shows, the beating of flagella creates water currents that bring organic debris toward the feeding cells of choanoflagellates and sponges. Sponge feeding cells are called **choanocytes.** Within these choanocytes, food particles are trapped and ingested.

As you can see in the figure, choanoflagellates sometimes form **colonies**—groups of individuals that are attached to each other. Some biologists once considered sponges to be colonies of single-celled protists due to the ability of sponge cells to re-aggregate after being dissociated. But sponges contain many specialized cell types that are dependent on each other, some of which occur in organized layers surrounded by extracellular matrix (ECM). Recent research has shown that some sponges have true **epithelium**—a layer of tightly joined cells that covers the interior and/or exterior surface of the animal. Epithelium is essential to animal form and function (Chapter 42).

Sponges are diverse in size, shape, and composition, distinguished in part by the type of **spicules** they produce—stiff spikes of silica or calcium carbonate ($CaCO_3$) that, along with collagen fibers, provide structural support to the ECM. Despite this morphological diversity, many biologists have described sponges as a

(a) Choanoflagellates are sessile protists; some are colonial.

(b) Sponges are multicellular, sessile animals.

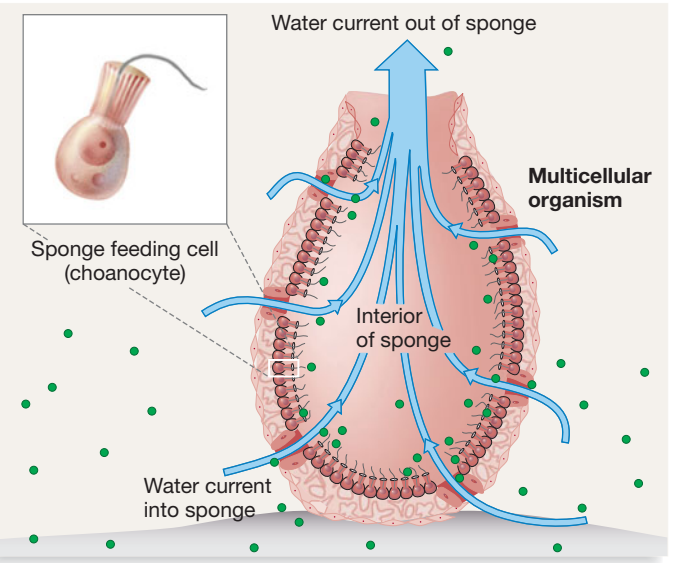

FIGURE 33.3 Choanoflagellates and Sponge Feeding Cells Are Almost Identical in Structure and Function. **(a)** Choanoflagellates are suspension feeders. **(b)** A cross section of a simple sponge as it suspension feeds. The beating of flagella produces a water current that brings food into the body of the sponge, where it can be ingested by feeding cells.

monophyletic group based on their unique body plan—systems of tubes and pores that create channels for water currents. Other biologists reject the monophyly of sponges. The recent availability of gene sequence data for diverse sponges has helped to advance the debate, but there is still no consensus.

Molecular Evidence Comparative genomic studies support the hypothesis that sponges are the most basal group of animals, but some reject the hypothesis that the phylum Porifera is monophyletic. According to these studies, sponges are paraphyletic—containing some, but not all, descendants of a common ancestor (see Table 28.2). This concept is indicated on Figure 33.2 by two blue lines, instead of one, representing the sponges.

The paraphyly of sponges is important to the study of animal origins because it provides extra support for the hypothesis that the common ancestor of all animals was sponge-like. If sponges were a monophyletic group, it would be more plausible that their distinguishing characteristics could have evolved later rather than in the common ancestor to all animals (the same way that the most recent common ancestor of humans and chimpanzees was not necessarily chimp-like).

What were the other qualities of the animal ancestor? Comparative genomic studies suggest something surprising. Despite the relative morphological simplicity of sponges, they possess a remarkably complex developmental **tool kit** of genes (Chapter 22). This tool kit contains the genes necessary for all the basic molecular processes required by animals:

- Specialization of cell types
- Regulation of cell cycling and growth
- Adhesion among cells, and between cells and extracellular matrix
- Recognition of self and nonself, thus innate immunity
- Developmental signaling and gene regulation
- Programmed cell death

Thus, a series of important genetic innovations appears to have occurred at the very root of the animal tree along with multicellularity. Subsequent duplication and diversification of these genes contributed to the diversification of animal lineages. ✔**If you understand this, you should be able to explain why cancer, which typically involves the mutation of genes in the basic animal genetic tool kit, is thought to be as ancient as multicellularity itself.**

Origin of Embryonic Tissue Layers

Sponges possess the basic genetic tool kit for cell–cell adhesion and cell–ECM adhesion, and some sponges even have rudimentary epithelium. However, sponges do not have complex **tissues,** groups of similar cells that are organized into tightly integrated structural and functional units. Animals other than sponges are typically divided into two major groups based on the number of embryonic tissue layers they have. Animals whose embryos have two types of tissue are called **diploblasts** (literally, "two-buds"); animals whose embryos have three types of tissue are called **triploblasts** ("three-buds").

The embryonic tissues are organized in layers, called **germ layers** (Chapter 23). In diploblasts these germ layers are called **ectoderm** and **endoderm** (**FIGURE 33.4**). The Greek roots *ecto* and

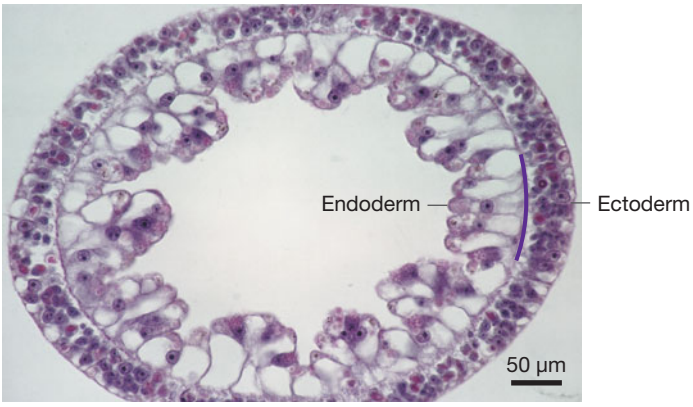

FIGURE 33.4 Diploblastic Animals Have Bodies Built from Ectoderm and Endoderm. This is a cross section through the tube-shaped portion of a hydra's body (phylum Cnidaria). The cells have been stained to make them more visible.

endo refer to outer and inner, respectively; the root *derm* means "skin." (See **BioSkills 2** in Appendix B to review common Latin and Greek roots.) In most cases the outer and inner "skins" of diploblast embryos are connected by a gelatinous material that may contain some cells. In triploblasts, however, there is a germ layer called **mesoderm** between the ectoderm and endoderm. (The Greek root *meso* refers to "middle.")

The embryonic tissues found in animals develop into distinct adult tissues, organs, and organ systems. In triploblasts:

- *Ectoderm* gives rise to skin and the nervous system.
- *Endoderm* gives rise to the lining of the digestive tract.
- *Mesoderm* gives rise to the circulatory system, muscle, and internal structures such as bone and most organs.

In general, then, ectoderm produces the covering of the animal and endoderm generates the digestive tract. Mesoderm gives rise to the tissues in between. The same pattern holds in diploblasts, except that **(1)** muscle is simpler in organization and is derived from ectoderm, and **(2)** reproductive tissues are derived from endoderm.

Look again at the animal phylogeny in Figure 33.2. Traditionally, two groups of animals have been recognized as diploblasts: the Ctenophora (pronounced *ten-AH-for-ah*), or comb jellies, and the Cnidaria (pronounced *ni-DARE-ee-uh*), which include the jellyfish, corals, sea pens, hydra, and anemones. Recent data suggest that some cnidarians have true mesoderm and are triploblasts, complicating the question of exactly when the triploblast body plan evolved. However, the take-home message for the animal phylogeny is still the same—the relatively simple diploblast body plan of ctenophores and cnidarians appears to have originated from ancestral animals later than the sponge lineages but before the other major groups of animals, which are all triploblasts.

The evolution of mesoderm was important because it gave rise to the first complex muscle tissue used in movement. Sponges lack muscle and are generally sessile, or nonmoving, as adults. Ctenophores have muscle cells that can change the body's shape, but both larvae and adults swim using cilia. Adult cnidarians have muscle cells that can extend and retract the body, such as in sea anemones, and can enable swimming by jet propulsion in jellyfish; but these movements are relatively simple compared to the complex movements performed by many triploblasts.

Origin of Bilateral Symmetry, Cephalization, and the Nervous System

Body symmetry is a key morphological aspect of an animal's body plan. A body is said to be symmetrical if it can be divided by a plane such that the resulting pieces are nearly identical.

Ctenophores, many cnidarians, and some sponges have **radial symmetry** ("spoke symmetry")—meaning that they have at least two planes of symmetry. For example, almost any plane sectioned through the center of the hydra in **FIGURE 33.5a** produces two identical halves. Radial symmetry evolved independently in the phylum Echinodermata (pronounced *ee-KINE-oh-derma-ta*)—a group including species such as sea stars, sea urchins, feather stars, and brittle stars.

Organisms with **bilateral symmetry** ("two-sided symmetry") in contrast, have one plane of symmetry and tend to have a long, narrow body. The annelid worm in **FIGURE 33.5b**, for example, has only one plane of symmetry—running lengthwise down its middle.

Based on the topology of branches on the animal phylogeny in Figure 33.2, radial symmetry appears to have arisen earlier in the evolution of animals than bilateral symmetry. Bilateral symmetry occurs in all triploblastic lineages. Where on the tree did bilateral symmetry originate? The answer is more complex than it would seem at first glance. Let's explore why.

(a) Radial symmetry **(b)** Bilateral symmetry

FIGURE 33.5 Body Symmetry. These colorized SEMs of **(a)** hydra (looking down on oral surface; phylum Cnidaria) and **(b)** a polychaete worm (phylum Annelida) illustrate the difference between radial and bilateral symmetry.

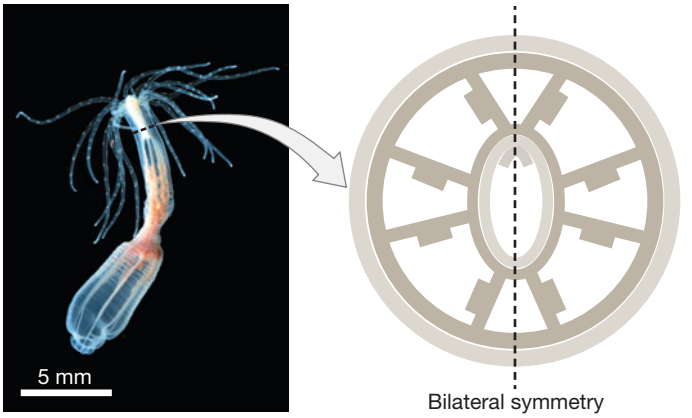

FIGURE 33.6 Morphological Evidence for Bilateral Symmetry in a Sea Anemone. Some corals and sea anemones have long been known to have bilateral symmetry despite the outward appearance of radial symmetry. *Nematostella* is a small sea anemone that burrows in soft marine sediments.

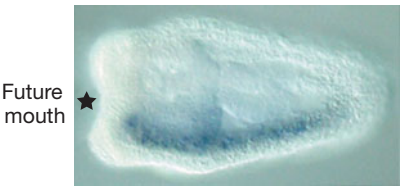
Homology or Convergent Evolution? Nearly all cnidarians appear radially symmetric at first glance, but a closer inspection of their internal morphology reveals bilateral symmetry in some species, especially in sea anemones (**FIGURE 33.6**). Recall that homology is defined as similarity in traits due to inheritance from a common ancestor (Chapter 25). Is the bilateral symmetry in sea anemones homologous to bilateral symmetry in triploblastic animals, or is it an example of convergent evolution?

Developmental biologists John Finnerty, Mark Martindale, and colleagues used developmental regulatory genes as a tool to address this evolutionary question. In triploblastic, bilaterally symmetric animals, called **bilaterians** for short, bilateral symmetry is achieved by the combination of anterior–posterior ("head–tail") axis formation and dorsal–ventral ("back–belly") axis formation. *Hox* genes are important in the development of the anterior–posterior axis (see Chapter 22), and *decapentaplegic* (*dpp*) genes are important in the development of the dorsal–ventral axis.

Finnerty and Martindale predicted that if bilateral symmetry in the sea anemone *Nematostella vectensis* (an increasingly important model organism in biology) is homologous to bilateral symmetry in bilaterians, the pattern of *Hox* and *dpp* gene expression in the sea anemone would be similar to that found in bilaterians. If convergent evolution had occurred, either *Hox* and *dpp* genes would not be expressed in *Nematostella* or their expression patterns would be unrelated to those in bilaterians.

FIGURE 33.7 shows Finnerty and Martindale's results. During *Nematostella* development, *Hox* genes are expressed along the anterior–posterior axis and *dpp* is expressed asymmetrically about the dorsal–ventral axis, a pattern of gene expression that is parallel to that observed in bilaterians. This evidence supports the hypothesis that bilateral symmetry in this sea anemone is homologous to bilateral symmetry in triploblastic animals—meaning that parts of the genetic tool kit that determine bilateral symmetry arose before the evolutionary split of the cnidarian and bilaterian lineages.

RESEARCH



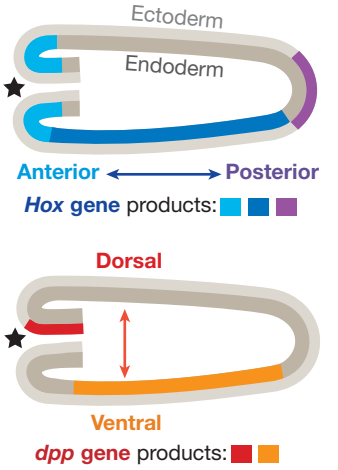
QUESTION: Is bilateral symmetry in sea anemones homologous to bilateral symmetry in bilaterians?

HYPOTHESIS: Bilateral symmetry is homologous in sea anemones and bilaterians.

NULL HYPOTHESIS: Bilateral symmetry arose independently in sea anemones and bilaterians.

EXPERIMENTAL SETUP:

1. Stain gene products (proteins) of *Hox* gene in developing *Nematostella* embryos and larvae to reveal location of expression.



2. Repeat for other *Hox* and *dpp* gene products.

PREDICTION: The pattern of expression of *Hox* and *dpp* genes in *Nematostella* will be similar to that found in bilaterians.

PREDICTION OF NULL HYPOTHESIS: The pattern of expression of *Hox* and *dpp* genes in *Nematostella* will be unrelated to that found in bilaterians.

RESULTS: Schematic summary of gene expression patterns (longitudinal section):

CONCLUSION: Bilateral symmetry is homologous in *Nematostella* and bilaterians.

FIGURE 33.7 Genetic Evidence that Bilateral Symmetry Originated in a Common Ancestor of Cnidaria and Bilateria.

SOURCE: Finnerty, J. R., K. Pang, P. Burton, et al. 2004. Origins of bilateral symmetry: *Hox* and *dpp* expression in a sea anemone. *Science* 304: 1335–1337.

✔ **QUESTION** What results would have supported the null hypothesis?

However, *Hox* and *dpp* gene expression in *Nematostella* is not identical to that in bilaterians—and the bilateral symmetry in *Nematostella* is not as extensive as in bilaterians. The take-home message is that the entire genetic tool kit for bilateral symmetry

did not evolve all at once in the early Cambrian before the diversification of bilaterians. Some components of the tool kit evolved earlier—in the ancestor to cnidarians and bilaterians—and others evolved later, after the split of these two lineages.

Origin of the Nervous System Over 99 percent of modern animals are bilaterally symmetric. Is this body plan a "key innovation" that led to the diversification of the bilaterians during the Cambrian explosion? One hypothesis is that the evolution of the nervous system and the evolution of the head are tightly linked to bilateral symmetry and that together, these characteristics contributed to the radiation of bilaterians.

How are symmetry and nervous systems related? The function of neurons and nervous systems is to transmit and process information in the form of electrical signals (see Chapter 46).

- Sponges generally lack both nerve cells and symmetry.
- Ctenophores and cnidarians have nerve cells that are organized into a diffuse arrangement called a **nerve net** (**FIGURE 33.8a**). These generally radially symmetric animals either float in water or live attached to a substrate. Radially symmetric organisms are more likely to encounter prey and other aspects of the environment in any direction. As a result, a diffuse nerve net can receive and send signals efficiently.
- All other animals have a **central nervous system,** or CNS. In a CNS, some neurons are clustered into one or more large tracts or cords that project throughout the body; others are clustered into masses called **ganglia** (**FIGURE 33.8b**). Most of the bilaterally symmetric animals living today move through their environment. Bilaterally symmetric organisms tend to encounter prey and other aspects of the environment at the leading end. As a result, it is advantageous to the animal to have many neurons concentrated at that end, with nerve tracts that carry information down the length of the body.

It is intuitive that the evolution of the CNS would coincide with **cephalization:** the evolution of a head, or anterior region, where structures for feeding, sensing the environment, and processing information are concentrated. The large mass of neurons that is located in the head, and that is responsible for processing information to and from the body, is called the cerebral ganglion or **brain.**

To explain the pervasiveness of bilateral symmetry, biologists point out that locating and capturing food is particularly efficient when movement is directed by a distinctive head region and powered by the rest of the body. In combination with the origin of mesoderm, a bilaterally symmetric body plan enabled rapid, directed movement and hunting. Lineages with a triploblastic, bilaterally symmetric, cephalized body had the potential to diversify into an array of formidable eating and moving machines.

Notice in Figure 33.2 that the acoels (phylum Acoela), tiny worms that tend to live among sand grains, are bilaterally symmetric and triploblastic but have a nerve net rather than a CNS—and no head region. Although the position of the aceol branch on the tree is hotly debated, its current position supports the hypothesis that the CNS and cephalization were key to the subsequent radiation of bilaterians.

Acoel worms are named for their lack of a coelom. What is a coelom? What role did it play in the diversification of bilaterians?

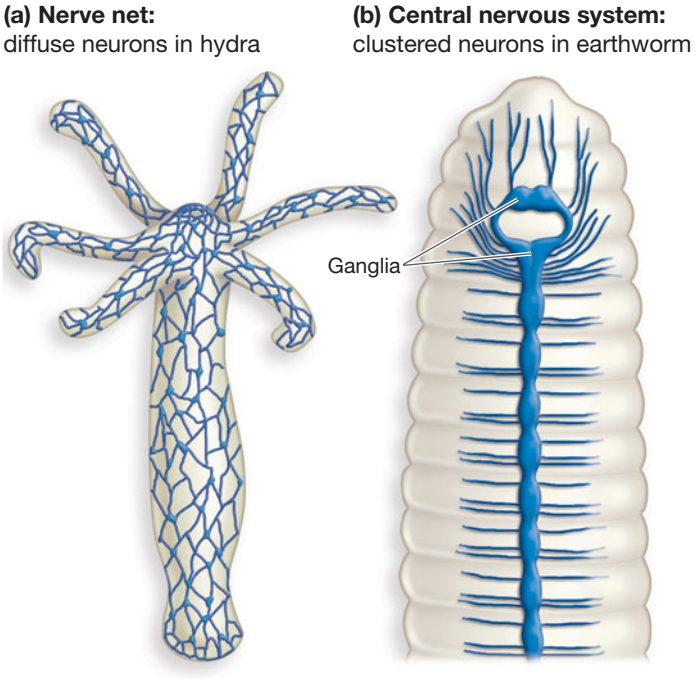


FIGURE 33.8 Associations between Body Symmetry and the Nervous System. (a) Radially symmetric animals, like this hydra, have a nerve net. **(b)** Bilaterally symmetric animals, like this earthworm, have a central nervous system.

Origin of the Coelom

What would you expect an animal body to look like that is triploblastic (formed from ectoderm, mesoderm, and endoderm), bilaterally symmetric, elongated, and cephalized? The basic bilaterian body shape is a *tube within a tube.* The inner tube is the individual's gut with a mouth at one end and an anus at the other, and the outer tube forms the nervous system and skin (**FIGURE 33.9**). The mesoderm in between forms muscles and organs.

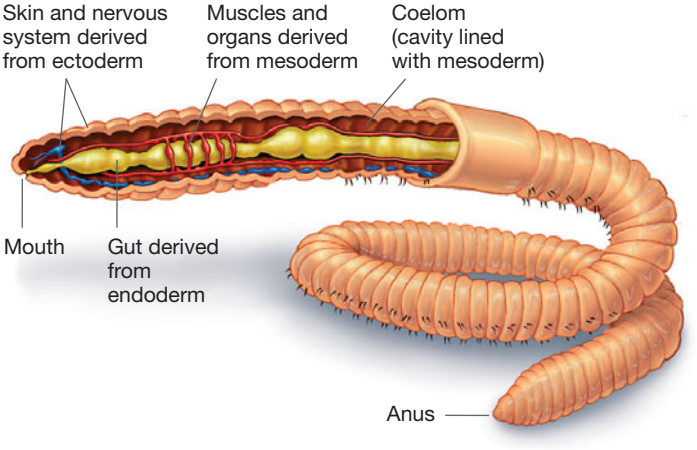

FIGURE 33.9 The Tube-within-a-Tube Body Plan Is Common in Animals.

The "tube-within-a-tube" body plan can pose a potential biomechanical and physiological challenge if the inner tube is attached to the outer tube via the mesoderm. One bypass to this physical constraint is a fluid-filled cavity between the inner and outer tubes, called a **coelom** (pronounced *SEE-lum*), as shown in the earthworm in Figure 33.9. The coelom provides a space for the circulation of oxygen and nutrients. It also enables the internal organs to move independently of each other.

Phylogenetic evidence suggests that the coelom arose in the common ancestor of protostomes and deuterostomes (Figure 33.2). The bilaterians that possess a coelom that is completely lined in mesoderm are known as true **coelomates** (**FIGURE 33.10a**). The bilaterians that subsequently lost their coelom, such as the flatworms, are called **acoelomates** ("no-cavity-form"; see **FIGURE 33.10b**). The bilaterians that retained a coelom but lost the mesodermal lining in parts of their coelom, such as nematodes (roundworms), are known as **pseudocoelomates** ("false-cavity-form"; **FIGURE 33.10c**).

The coelom was a critically important innovation during animal evolution, in part because an enclosed, fluid-filled chamber can act as an efficient **hydrostatic skeleton.** Soft-bodied animals with hydrostatic skeletons can move effectively even if they do not have fins or limbs.

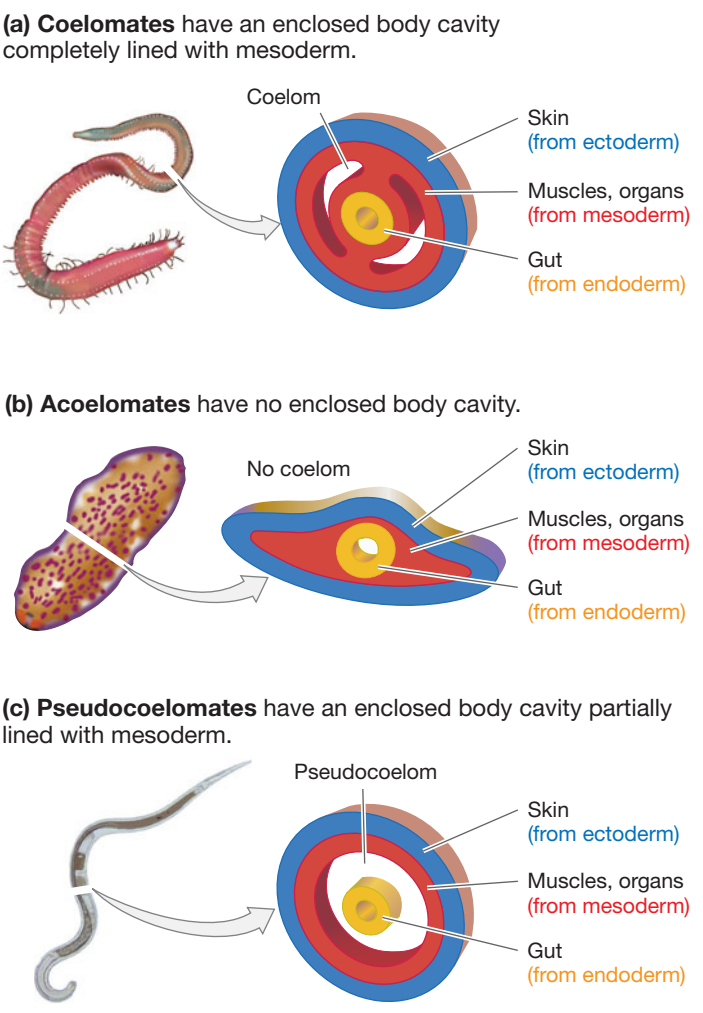

FIGURE 33.10 Animals May or May Not Have a Body Cavity.

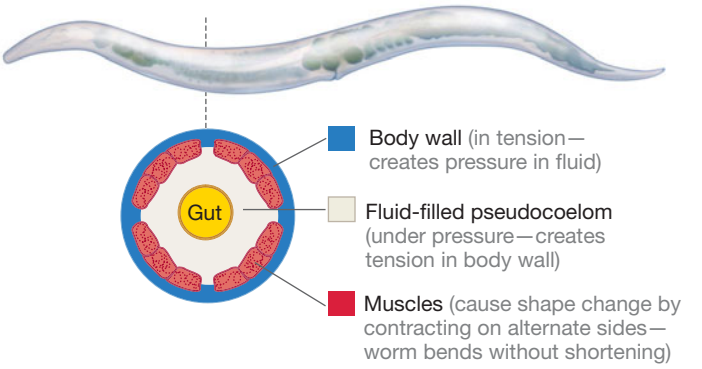

FIGURE 33.11 Hydrostatic Skeletons Allow Limbless Animals to Move.

For example, movement in nematodes is possible because the fluid inside the pseudocoelom stretches the body wall—much like water stretches the wall of a water balloon—putting the wall under tension (**FIGURE 33.11**). In turn, this tension exerts pressure on the fluid inside the coelom. When certain muscles in the body wall contract against the pressurized fluid, the force is transmitted through the fluid, changing the body's shape.

Coordinated contractions and relaxations of different muscles in the body wall enable various shape changes and forms of locomotion (see Chapter 48). The evolution of the coelom improved the ability of bilaterians to move in search of food.

Origin of Protostomes and Deuterostomes

Turn back to Figure 33.2 and put your finger on the node at the origin of the Bilateria, the monophyletic lineage of bilaterians. Now move your finger one node to the right, past the divergence of the Acoels. The common ancestor that existed at this node during the Cambrian was a bilaterally symmetric triploblast with a CNS, cephalization, and a coelom. This ancestor gave rise to a remarkable radiation of diverse animal lineages, only some of which are included in the tree.

What major groups occur within the Bilaterian coelomates? Despite the staggering diversity of adult animals, common themes during embryonic development have enabled biologists to recognize two major subgroups:

1. **protostomes,** in which the mouth develops before the anus, and blocks of mesoderm hollow out to form the coelom; and
2. **deuterostomes,** in which the anus develops before the mouth, and pockets of mesoderm pinch off to form the coelom.

Translated literally, protostome means "first-mouth" and deuterostome means "second-mouth."

To understand the contrasts in how protostome and deuterostome embryos develop, recall that the three embryonic germ layers form during a process called gastrulation (Chapter 23), which begins when cells move from the outside into the center of the embryo. These cell movements create a pore that opens to the outside (**FIGURE 33.12a**). In protostomes, this pore becomes the mouth. The other end of the gut, the anus, forms later. In

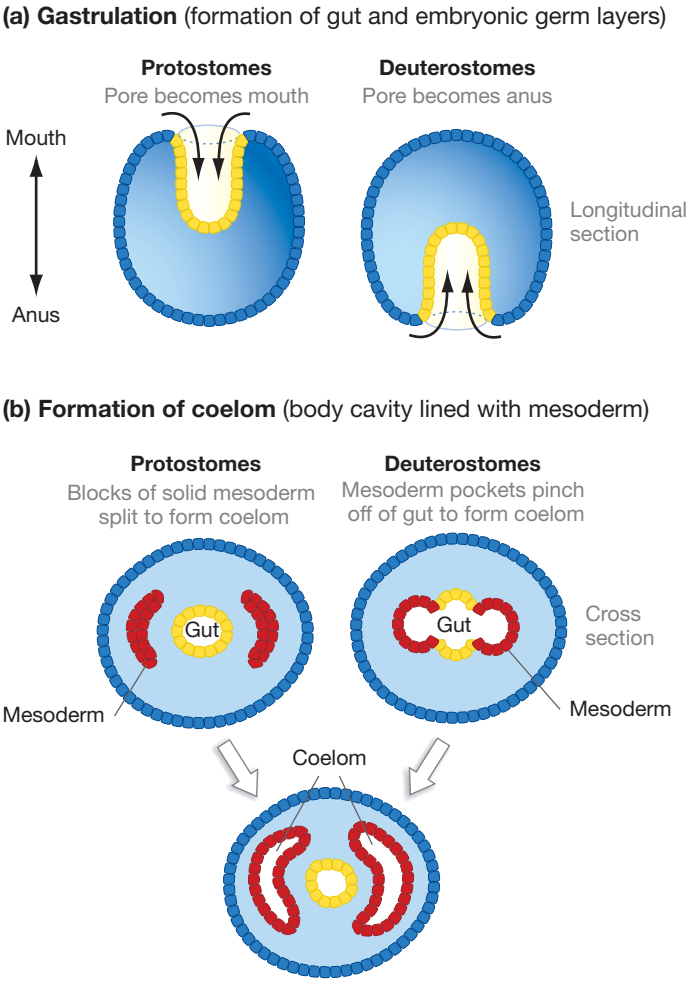

FIGURE 33.12 In Protostomes and Deuterostomes, Events in Early Development Differ. The differences between protostomes and deuterostomes show that there is more than one way to build a bilaterally symmetric, coelomate body plan.

deuterostomes, however, this initial pore becomes the anus; the mouth forms later.

The other developmental difference between the groups arises as gastrulation proceeds and the coelom begins to form. Protostome embryos have two blocks of mesoderm beside the gut. As the left side of **FIGURE 33.12b** indicates, their coelom begins to form when cavities open within each of the two blocks of mesoderm. In contrast, deuterostome embryos have layers of mesodermal cells located on either side of the gut. As the right side of Figure 33.12b shows, their coelom begins to form when these layers bulge out and pinch off to create fluid-filled pockets lined with mesoderm.

In essence, the protostome and deuterostome patterns of development represent two distinct ways of achieving the same end—the construction of a bilaterally symmetric body that contains a cavity lined with mesoderm. The functional or adaptive significance of the differences—if any—is not known.

Two major groups occur within the protostomes: **(1)** the Lophotrochozoa (pronounced *low-foe-tro-ko-ZOH-ah*) includes the mollusks, annelids, flatworms, and rotifers; and **(2)** the Ecdysozoa (pronounced *eck-die-so-ZOH-ah*) includes the arthropods and the nematodes. **Lophotrochozoans** grow continuously when conditions are good. **Ecdysozoans** grow by shedding their external skeletons or outer coverings and expanding their bodies.

Species in the phylum Platyhelminthes (flatworms) are protostomes but lack a coelom—meaning that the coelom was lost during flatworm evolution. The coelom has also been reduced in an array of lineages including arthropods—which have limbs and thus rely less on hydrostatic skeletons for movement.

The vast majority of animal species are protostomes (see Chapter 34). However, the largest animals and most voracious predators tend to be deuterostomes (see Chapter 35).

Origin of Segmentation

Segmentation is defined by the presence of repeated body structures. A segmented backbone is one of the defining characteristics of **vertebrates,** a monophyletic lineage within the Chordata that includes fish, reptiles (including birds), amphibians, and mammals. Of the animals that are not vertebrates, called **invertebrates** (a paraphyletic group), segmentation occurs in annelids (earthworms and other segmented worms) and arthropods (insects, spiders, and crustaceans)—both very prolific and diverse lineages. Recent evidence suggests that segmentation also occurs to some extent in mollusks (snails, clams, squid).

Before molecular data were available, biologists grouped segmented animals like annelids and arthropods together in the same clade. Then Aguinaldo's landmark 1997 revision of animal relationships overturned this view, suggesting that segmentation arose independently in these groups (see Figure 33.2).

Is segmentation in different phyla an example of convergent evolution? Applying the same logic that Finnerty and Martindale used in their study of bilateral symmetry in sea anemones, several researchers are investigating whether the genes that regulate segmentation in different phyla are homologous. For example, one recent study found that one of the same gene regulatory pathways that regulate segmentation in arthropods, called the hedgehog pathway, is also important in regulating the segmentation in annelid worms.

The conclusion so far is that some of the tool-kit genes for segmentation may have arisen early in animal evolution, meaning that they are homologous in different phyla. However, these genes would subsequently have been lost in some lineages and co-opted in different ways and elaborated upon in others, contributing to the diversity of bilaterian body plans we see today. Research continues to test this hypothesis.

Why have organisms with segmented bodies been so successful in terms of diversity? One leading hypothesis is that segmentation enables specialization. Small changes in the expression of certain tool-kit genes along the length of a body can result in novel numbers, shapes, and sizes of body segments and appendages. *Hox* genes are a good example (see Chapters 22 and 34). Natural selection can then favor variations that have adaptive specializations for life in certain aquatic or terrestrial environments—leading to diversification.

In summing up this tour of the animal phylogeny, it's important to note that although biologists are increasingly confident that most or all of these inferences about animal relationships are correct, the phylogeny of animals is still a work in progress. As more taxa are sampled, larger numbers of characters are analyzed, and methods of phylogenetic analysis are refined, the resolution of the tree of life will continue to improve. Stay tuned.

check your understanding

If you understand that . . .

- The origin of body plans in the major lineages of animals was marked by changes in four fundamental features: the number of embryonic tissues present; the evolution of nervous systems and a bilaterally symmetric, cephalized body; the evolution of a body cavity; and protostome versus deuterostome patterns of development.

✔ You should be able to . . .

1. Describe whether your body has a tube-within-a-tube design. Justify your answer.
2. Explain why cephalization was important.

Answers are available in Appendix A.

33.3 What Themes Occur in the Diversification of Animals?

One of the great unresolved mysteries in the study of animal diversity is this: Why did almost all of the phylum-level body plans evolve all at once during the Cambrian, rather than more gradually over time? Animals diversified tremendously *within* phyla after the Cambrian, but no major new lineages arose during the last 500 million years.

One mechanistic hypothesis is that gene regulatory networks are responsible for limiting the origin of new body plans. These networks determine patterns of animal development and thus lay down the body plan. The scientists studying these networks have observed that once the networks are established, they are very resistant to change—that is, changes tend to be fatal. However, a multitude of "switches" and "plug-ins" can be added to networks, providing a mechanism for diversification within lineages after the body plans are established.

As research continues on the origin of body plans, biologists' understanding of the subsequent diversification within lineages is also steadily improving. Several variables have been hypothesized to play a role in animal diversification (Chapter 28):

- ***Higher oxygen levels*** An increase in oxygen levels may have made the evolution of big, mobile animals possible due to the efficiency of aerobic respiration.
- ***The evolution of predation*** The earliest animals were sessile and ate organic material. When predators evolved, they exerted selection pressure on other animals for shells, skeletons, rapid movement, and other adaptations for escaping capture.
- ***New niches beget more new niches*** As animals diversified, they themselves created new niches that could support yet more ecological diversification.
- ***New genes, new bodies*** As the animal genetic tool kit evolved—such as the duplication and diversification of *Hox* genes—the potential for morphological diversity increased.

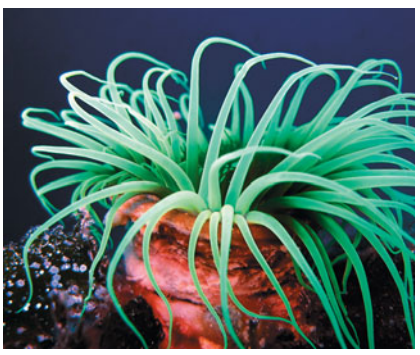
It is likely that a combination of all of these variables was important to the diversification of animals. The result? Animals with the same body plan diversified in their strategies for finding food, ingesting food, and reproducing in different ecological niches. Conversely, animals with different body plans have independently evolved similar strategies for feeding and reproducing when they occupy similar ecological niches. What are the major themes of diversification?

Sensory Organs

The evolution of a cephalized body was a major breakthrough in the evolution of animals. Along with a mouth and brain, a concentration of sensory organs in the head region—where the animal initially encounters the environment—is a key aspect of cephalization.

Certain senses are almost universal in animals (see Chapter 47). The common senses include sight, hearing, taste/smell, and touch (see examples in **TABLE 33.2**). At least some ability to sense temperature is also common. But as animals diversified, a wide array of specialized sensory abilities also evolved. For example:

- ***Magnetic field*** Many birds, sea turtles, sea slugs, and other animals can detect Earth's magnetic field and use it as an aid in navigation.
- ***Electric field*** Some aquatic predators, such as sharks, are so sensitive to electric fields that they can detect electrical activity in the muscles of passing prey.
- ***Barometric pressure*** Some birds can sense changes in air pressure, which may aid them in avoiding storms.



Variation in sensory abilities is important: It allows different species of animals to collect information about a wide array of environments, including the presence of food, predators, and mates.

Feeding

To organize the diversity of ways that animals find food, biologists distinguish *what* individuals eat from *how* they eat. Animals within a lineage often pursue different food sources and feeding strategies when they occupy different niches. For example, sea cucumbers and sea stars both have the same echinoderm body plan, but they have different food sources and feeding strategies—the sea cucumber mops up detritus from the seafloor, and the sea star pries open clams and mussels and devours them.

Conversely, animals from *different* lineages often pursue the *same* food sources and feeding strategies when they occupy similar niches. For example, burrowing sea cucumbers and some burrowing polychaete worms (phylum Annelida and

SUMMARY TABLE 33.2 Diversification of Sensory Organs

Sense	Example
Sight *Stimulus:* light	 Flies use their compound eyes to find food and mates, and to escape predators
Hearing *Stimulus:* sound	 Bats use their sense of hearing to find prey and to avoid obstacles in the dark
Taste/smell *Stimulus:* molecules	 Some male moths have elaborate antennae to detect pheromones in the air
Touch *Stimulus:* contact, pressure	 Sea anemones detect and capture prey using their sense of touch

Other senses	Examples
Stimulus: temperature (thermal energy)	Pit vipers
Stimulus: magnetic field	Sea turtles
Stimulus: electric field	Sharks
Stimulus: barometric pressure	Birds
Stimulus: gravity	Squid

Echinodermata, respectively) have different body plans but use a similar strategy of consuming detritus on the seafloor.

What Animals Eat: Diversification of Ecological Roles Animals can be classified as **(1) detritivores** that feed on dead organic matter, **(2) herbivores** that feed on plants or algae, or **(3) carnivores** that feed on animals (see **TABLE 33.3**). **Omnivores** eat both plants and animals. These ecological roles have important implications for whole ecosystems because animal feeding moves both energy and nutrients through food webs (Chapter 56).

Another way to categorize the diverse ecological impacts of animal consumption is to consider the impacts on the organisms that animals consume. **Predators** kill and consume all or most of their prey. Predators are usually larger than their prey and kill them quickly using an array of mouthparts and hunting strategies.

SUMMARY TABLE 33.3 Diversification of Ecological Roles

Ecological Role	Example
Detritivores Feed on dead organic matter	 Millipedes feed on decaying leaves
Herbivores Feed on plants or algae	 Pandas eat vast amounts of bamboo
Carnivores Feed on animals	 Owls sit and wait for prey
Omnivores Feed on both plants and animals	*Example:* Humans

Herbivores usually consume plant tissue without killing the whole organism. However, seed predators are an exception because seeds contain an entire—although embryonic—plant.

Like herbivores, **parasites** often harvest nutrients from certain parts of their hosts, but parasites are usually much smaller than their victims. **Endoparasites** live inside their hosts and usually have simple, wormlike bodies. Tapeworms, of the phylum Platyhelminthes (flatworms), are endoparasites with no digestive system. Instead of a mouth, they have hooks or other structures on their head that attach to their host's intestinal wall. Instead of digesting food themselves, they absorb nutrients directly from their surroundings. **Ectoparasites** live on the outside of their hosts. Ectoparasites usually have limbs or mouthparts that allow them to grasp the host, and mouthparts that allow them to pierce their host's skin and suck the nutrient-rich fluids inside. Aphids and ticks are ectoparasites.

Whether animals consume their victims completely or partially, these consumers can drastically affect the fitness of the consumed organisms. Thus, animals are an important agent of natural selection—influencing the evolution of the species they eat (see Chapter 55).

How Animals Feed: Four General Strategies Animal mouthparts vary, and the structure of an animal's mouthparts correlates closely with its method of feeding. Keep this in mind as you review the four general tactics that animals use to obtain food, summarized in **TABLE 33.4**.

Suspension feeders, also known as **filter feeders,** employ a wide array of structures to trap suspended particles—usually detritus or plankton, small organisms that drift in the currents. Sponges, like the individual illustrated in Figure 33.3, are suspension feeders. So are clams and mussels, which pump water through their bodies and trap suspended food on their feathery gills—structures that also function in gas exchange. Baleen whales suspension feed by gulping water, squeezing it out between the horny baleen plates that line their mouths, and trapping shrimp-like organisms called krill inside. Barnacles capture particles with their feathery, jointed legs.

Because particles float in water much more readily than in air, suspension feeding is particularly common in aquatic environments. Many suspension feeders are sessile.

Many **deposit feeders** digest organic matter in the sediments; their food consists of sand- or mud-dwelling bacteria, archaea, protists, and fungi, along with detritus that settles on the surface of the sediments. Earthworms, for example, are annelids that swallow soil as well as leaves and other detritus on the surface of the soil.

The seafloor is also rich in organic matter, which rains down from the surface and collects in food-rich deposits. These deposits are exploited by a wide array of segmented worms (annelids) as well as sea cucumbers.

Unlike suspension feeders, which are diverse in size and shape and use various trapping or filtering systems, deposit feeders tend to be similar in appearance. They usually have simple mouthparts, and their body shape is wormlike. Like suspension feeders, however, deposit feeders occur in a wide variety of lineages.

SUMMARY TABLE 33.4 Diversification of Feeding Strategies

Strategy	Example
Suspension feeders (filter feeders) Capture food by filtering out or concentrating particles floating in water or drifting through the air	 Barnacles use specialized legs to capture plankton
Deposit feeders Ingest organic material that has been deposited within a substrate or on its surface	 Sea cucumbers use feeding tentacles to mop up detritus from the seafloor
Fluid feeders Suck or mop up liquids like nectar, plant sap, blood, or fruit juice	 Butterflies and moths drink nectar through their extensible, hollow proboscis
Mass feeders Take chunks of food into their mouths	 Lions bite chunks of meat off of prey carcasses

Fluid feeders range from butterflies and moths that feed on nectar with a straw-like proboscis to vampire bats that feed on blood. Fluid feeders are found in a wide array of lineages and often have mouthparts that allow them to pierce seeds, stems, skin, or other structures in order to withdraw the fluids inside.

Mass feeders ingest chunks of food. The structure of their mouthparts correlates with the type of food pieces that they harvest and ingest. Lions, for example, have razor-like teeth for tearing tough flesh into pieces small enough to be swallowed. Snails use a rasp-like structure called a radula to scrape bits of plant tissue or animal flesh into their mouths.

Movement

Animal locomotion provides an array of important functions: finding food, finding mates, escaping from predators, and dispersing to new habitats. Animals move in highly variable ways; they burrow, slither, swim, fly, crawl, walk, or run—mostly powered by muscle (Chapter 48).

Limbs are a prominent feature of species in many phyla. They develop as outpockets of the body wall and tend to be perpendicular to the anterior–posterior and dorsal–ventral body axes. Limbs can take a variety of forms, from the lobe-like limbs of onychophorans (velvet worms) to the jointed limbs of arthropods and vertebrates to the more flexible tube feet of echinoderms and tentacles of mollusks (**TABLE 33.5**).

Traditionally, biologists have hypothesized that the major types of jointed and unjointed animal limbs were not homologous—that is, not descended from a common ancestor. Because the structure of animal appendages is so diverse, it was logical to maintain that at least some appendages evolved independently of each other. As a result, biologists predicted that completely different genes are responsible for each major type of appendage.

Recent results have challenged this view, however. The experiments in question involve a gene called *Distal-less,* or *Dll*, that was originally discovered in fruit flies. (*Distal* means "away from the body.") The *Dll* protein product seems to deliver a simple message as a fruit fly embryo develops: "Grow appendage out this way."

Biologists in Sean Carroll's lab set out to test the hypothesis that *Dll* might be involved in the initial phase of limb or appendage formation in other animals. The team used a fluorescent marker that sticks to the *Dll* gene product to locate tissues where the gene is expressed. When they introduced the fluorescent marker into embryos from annelids, arthropods, echinoderms, and other phyla, they found that it bound to *Dll* in all of them. More important, the highest concentrations of *Dll* gene products were found in cells that form appendages—even in phyla with wormlike bodies that have extremely simple appendages (**FIGURE 33.13**; see page 650). Other experiments have shown that *Dll* is also involved in limb formation in vertebrates.

Based on these findings, biologists are concluding that all animal appendages have some degree of genetic homology and that they are all derived from appendages that were present in a common ancestor. The idea is that simple appendages evolved early in the history of the Bilateria and that, subsequently, evolution by natural selection produced the diversity of limbs observed today.

SUMMARY TABLE 33.5 Diversification of Limbs

Type of Limb	Example
Lobe-like limbs	 Onychophorans (velvet worms) use lobe-like limbs to crawl
Jointed limbs	 The jointed limbs of arthropods (such as this crab) and vertebrates are used for many modes of feeding and locomotion
Parapodia	 Polychaete worms use bristled parapodia to crawl and swim
Tube feet	 Echinoderms like this sea star use tube feet to crawl
Tentacles	 Octopuses use muscular tentacles to crawl and grab prey

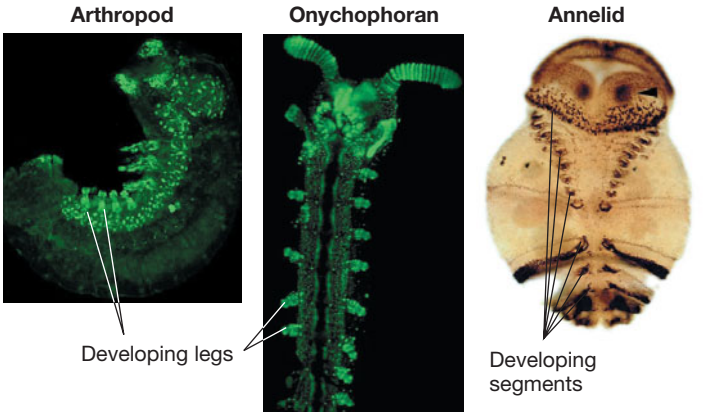


FIGURE 33.13 Genetic Evidence that All Animal Appendages Are Homologous. In diverse organisms, *Dll* gene products (stained green and dark brown) are localized in areas of the embryos where appendages are forming. These data suggest that the appendages are related by common ancestry.

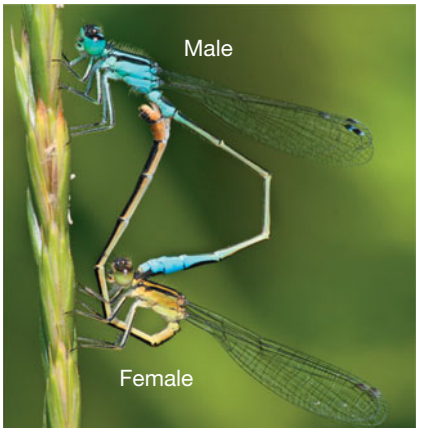
Reproduction

An animal may be efficient at moving and eating, but if it does not reproduce, the alleles responsible for its effective locomotion and feeding will not increase in frequency in the population. Evolution by natural selection occurs when individuals with certain alleles produce more surviving offspring than other individuals do (Chapter 25). Organisms live to reproduce.

Given the array of habitats and lifestyles of animals, it's not surprising that they vary tremendously in how they reproduce (**TABLE 33.6**). A few examples here will help illustrate the diversity of animal reproduction (see Chapter 50 for details).



Asexual or Sexual Reproduction? In the phylum Rotifera, an entire lineage called the bdelloids (pronounced *DELL-oyds*) reproduces only asexually, through mitosis, by producing diploid eggs that can mature into adults without being fertilized (a process called parthenogenesis). Even certain fish, lizard, and snail species have never been observed to undergo sexual reproduction.

However, sexual reproduction via meiosis and fusion of gametes is much more common than asexual reproduction in animals; and some animals, like coral polyps, can reproduce either way depending on environmental circumstances. Asexual reproduction tends to be more efficient than sexual reproduction, but sexual reproduction leads to greater genetic diversity, which can be favored by natural selection in variable or unfavorable environments (Chapter 13).

Where Does Fertilization Occur? When sexual reproduction does occur, fertilization may be internal, usually within the body of the female, or external, in the environment.

When internal fertilization takes place, a male typically inserts a sperm-transfer organ into the body of a female. In some animal species, males produce sperm in packets, which females then pick up and insert into their own bodies. But in seahorses, females insert eggs into the male's body, where they are fertilized. (The male is pregnant for a time and then gives birth to live young.)

SUMMARY TABLE 33.6 Diversification of Reproduction

Reproductive Strategy	Example
Asexual reproduction	
Polyps within a coral colony are genetically identical clones. They are produced by fission (splitting) or budding	
Sexual reproduction	
External fertilization	
Sea cucumbers reproduce sexually by releasing eggs and sperm into the open water, where fertilization occurs	
Internal fertilization	
When damselflies copulate, the male holds the female behind her head with claspers and the female retrieves sperm from the male's sperm-transfer organ with the tip of her abdomen	

Modes of embryonic development following internal fertilization	Examples
Viviparous species nourish embryos internally and give birth to live young	Most mammals
Oviparous species deposit fertilized eggs; embryos are nourished by yolk	Most insects, birds
Ovoviviparous species retain eggs internally and then give birth to live young	Guppies, garter snakes

External fertilization is extremely common in aquatic species. Females lay eggs onto a substrate or release them into open water. Males shed sperm, which swim, on or near the eggs or into open water.

Where do Embryos Develop? Following internal fertilization, eggs and embryos may be retained in the female's body during development, or fertilized eggs may be laid outside of the body to develop independently of the mother:

- **Viviparous** ("live-bearing") species such as humans and most other mammals nourish embryos inside the body and give birth to live young.
- **Oviparous** ("egg-bearing") species such as chickens and crickets deposit fertilized eggs. The embryos within are nourished by yolk.
- **Ovoviviparous** ("egg-live-bearing") species such as guppies and garter snakes retain eggs inside their body during early development, but the growing embryos are nourished by yolk inside the egg and not by nutrients transferred directly from the mother, as in viviparous species. Ovoviviparous females then give birth to well-developed young.

Most mammals and a few species of sea stars, velvet worms, fish (including sharks), amphibians, and lizards are viviparous; some snails, insects, reptiles, and fishes are ovoviviparous. But the vast majority of animals are oviparous.

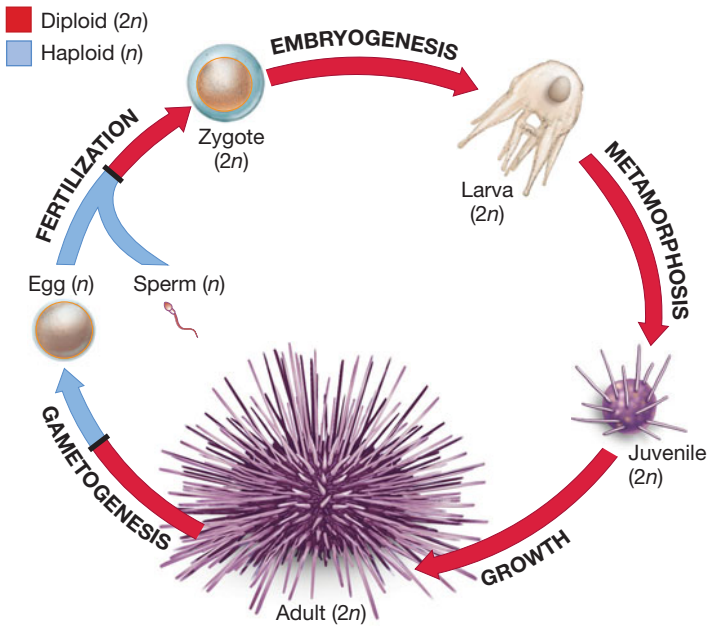


FIGURE 33.14 Many Animal Life Cycles Include Metamorphosis. Most sea urchins have a planktonic, feeding larva that is very different from the sessile adult. Drawings are not to scale.

✔ **EXERCISE** A few sea urchins produce especially large, yolk-rich eggs that develop directly into juveniles and adults, bypassing the feeding larval stage. Circle the part of the life cycle that would be different in this case, and pose a hypothesis to explain why or under what conditions this difference might be adaptive.

Life Cycles

Reproduction is just one component of the diverse life cycles of animals. The vast majority of sexually reproducing animals have diploid-dominant life cycles because the haploid stages—the gametes—are relatively short lived and single celled. But even this general pattern has interesting exceptions, such as haploid males in honeybee colonies. How else do animal life cycles vary?

Perhaps the most spectacular innovation in animal life cycles involves the phenomenon known as **metamorphosis** ("change-form")—a drastic change from one developmental stage to another. The young of some animals, such as zebras, look similar to adults when they are born. Their development is said to be *direct*. However, other animals, such as sea urchins, undergo a dramatic transformation—a metamorphosis—during their life cycle and are said to undergo *indirect* development (**FIGURE 33.14**).

During indirect development, embryogenesis produces **larvae** (singular: **larva**) that look radically different from adults, live in different habitats, and eat different foods. In the case of the sea urchin in Figure 33.14, the larva is bilaterally symmetric and planktonic, and it suspension feeds on single-celled algae; but the adult is radially symmetric and sessile, and it scrapes macroalgae off of rocks.

Through the process of metamorphosis, larvae transform into **juveniles;** they look like adults and live in the same habitats and eat the same foods as adults, but they are still sexually immature. It is only after a period of growth and maturation that juveniles become **adults,** the reproductive stage in the life cycle.

Metamorphosis is extremely common in marine animals as well as in insects (insect metamorphosis is described in Chapter 34) and many amphibians. Why would natural selection favor such an indirect path to adulthood? One hypothesis emphasizes dispersal. In marine species that have limited or no movement as adults—such as sponges, corals, sea anemones, clams, and sea urchins—larvae function as a dispersal stage. They are a little like the seeds of many land plants—a life stage that allows individuals to move to new habitats.

Another hypothesis for the occurrence of metamorphosis emphasizes feeding efficiency. Because larvae and adults feed on different foods in different ways, they do not compete with each other and can specialize to take advantage of available food sources. For example, the caterpillar larvae of butterflies can feast on nutritious leaves to acquire the energy needed for growth, while adult butterflies feast on flower nectar to acquire energy needed for finding mates and reproducing.

The diversification of life cycles occurred not only among species in diverse lineages but also within species—such as in organisms that can opt between asexual and sexual reproduction or direct and indirect development, depending on environmental circumstances. The diversification of life cycles, as well as that of sensory structures, ecological roles, feeding strategies, limbs, and reproductive strategies, represent the consequences of evolutionary processes played out in ecological contexts over millions of years.

Let's now examine how the general themes of diversification apply to individual phyla, starting with the most ancient lineages first and then moving on to the extremely diverse protostomes (Chapter 34) and deuterostomes (Chapter 35).

CYU

If you understand that . . .

- Most of the animal body plans originated during the Cambrian and subsequently diversified.
- Themes of diversification include evolution of different sensory organs, ecological roles, feeding strategies, type of limbs, type of reproduction, and life cycles.

✓ You should be able to . . .

1. Explain how the mouthparts of deposit feeders and mass feeders are expected to differ.
2. Suggest why external fertilization is particularly common in aquatic environments, and internal fertilization is particularly common in terrestrial environments.

Answers are available in Appendix A.

33.4 Key Lineages of Animals: Non-Bilaterian Groups

The fossil record indicates that the phyla Porifera (sponges), Ctenophora (comb jellies), and Cnidaria (jellyfish and others) are the most ancient of all major animal lineages. The phylogeny of animals presented in this chapter is consistent with the fossil record—the first sponges, ctenophores, and cnidarians appear at the base of the tree (Figure 33.2). As you consider each group in more detail, try to pick out which characteristics are unique to the group, and which are common to organisms living in similar environments.

- Porifera (Sponges)
- Ctenophora (Comb Jellies)
- Cnidaria (Jellyfish, Corals, Anemones, Hydroids)

Porifera (Sponges)

About 8500 species of sponges have been described to date. Although a few freshwater species are known, most are marine. All sponges are **benthic,** meaning that they live at the bottom of aquatic environments. Sponges are particularly common in rocky, shallow-water habitats of the world's oceans. One sponge species native to the Caribbean can grow to heights of 2 meters (m).

Sponges have commercial and medical value to humans. The dried bodies of certain sponge species are able to hold large amounts of water and thus are prized for use in bathing and washing. In addition, researchers are increasingly interested in the array of toxins that sponges produce to defend themselves against predators and bacterial parasites—possibly for use in cancer chemotherapy.

Feeding Most sponges are suspension feeders. Their cells beat in a coordinated way to produce a water current that flows through small pores in the outer body wall, into chambers inside the body, and out through a single larger opening (**FIGURE 33.15**). As water passes by feeding cells, organic debris and bacteria, archaea, and small protists are filtered out of the current and then digested. Some deep-sea sponges are predators, however—they capture small crustaceans on hooks that project from the body.

Movement Most adult sponges are sessile, though a few species are reported to move at rates of up to 4 millimeters (mm) per day. Most species produce larvae that swim with the aid of cilia, so they are capable of dispersal. Recent research has confirmed that at least one species can contract its body to expel waste products.

Reproduction Asexual reproduction occurs in a variety of ways, depending on the species. Some sponge cells are totipotent, meaning that when a fragment breaks off, small groups of adult cells have the capacity to develop into complete new adult organisms. Although individuals of most species produce both eggs and sperm, self-fertilization is rare because individuals release their male and female gametes at different times.

Ectyoplasia ferox

FIGURE 33.15 Sponges Are Sessile Suspension Feeders.

Ctenophora (Comb Jellies)

Ctenophores are transparent, ciliated, gelatinous diploblasts that live in marine habitats (**FIGURE 33.16**). Although a few species live on the ocean floor, most are planktonic. Only about 190 species have been described to date, but some are abundant enough to represent a significant fraction of the total planktonic biomass. Accidental introductions of the ctenophore *Mnemiopsis leidyi*, which preys on fish larvae, have devastated fish production in the Black Sea and Caspian Sea. If you have gone swimming in an ocean or bay, you may have bumped up against ctenophores without realizing it since they can be abundant yet nearly invisible in the water. (Don't worry, they are harmless.) Some comb jellies can also be seen at night when they emit pulses of faint phosphorescent light.

Feeding Ctenophores are predators, but lack the stinging cells that are characteristic of Cnidarians. Feeding occurs in several ways, depending on the species. Some comb jellies have long tentacles covered with cells that release an adhesive when they contact prey. These tentacles are periodically wiped across the ctenophore's mouth so that captured prey can be ingested. In other species, prey can stick to mucus on the body and be swept toward the mouth by cilia. Still other species ingest large prey whole.

Movement Adults move via the beating of cilia, which occur in comblike plates. The plates form rows that run the length of the body. Ctenophores are the largest adult animals known to use cilia for locomotion. ✔**You should be able to indicate the origin of adult swimming via rows of coordinated cilia on Figure 33.2.**

Reproduction Most species have both male and female organs and routinely self-fertilize, though fertilization is external. Larvae are free swimming.

Mnemiopsis leidyi

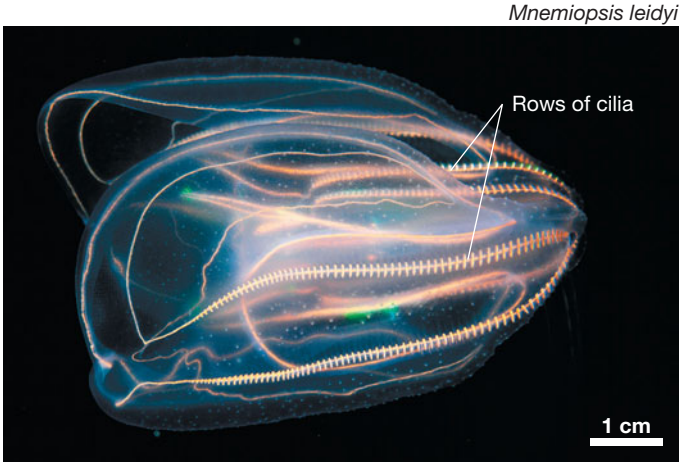

FIGURE 33.16 Ctenophores Are Planktonic Predators.

Cnidaria (Jellyfish, Corals, Anemones, Hydroids)

Although a few species of Cnidaria inhabit freshwater, the vast majority of the 11,500 species are marine. They are found in all of the world's oceans, occupying habitats from the surface to the substrate, and are important predators. The phylum comprises four main lineages, as shown in **FIGURE 33.17**.

Many cnidarians are radially symmetric diploblasts consisting of ectoderm and endoderm layers that sandwich gelatinous material known as **mesoglea,** which contains a few scattered ectodermal cells. Recent research indicates that at least some jellyfish are triploblastic and have bilaterally symmetric larvae or are bilaterally symmetric as adults. Cnidarians have a gastrovascular cavity instead of a flow-through gut—meaning there is only one opening to the environment for both ingestion and elimination of wastes (see Chapter 44).

Jellyfish have a life cycle that includes both a sessile **polyp** form that reproduces asexually and a free-floating **medusa** that reproduces sexually, as shown in the case of a hydrozoan in **FIGURE 33.18** (see page 654). Anemones and coral, however, exist only as polyps—never as medusae. Reef-building corals secrete outer skeletons of calcium carbonate that create the physical structure of a coral reef—one of the world's most productive habitats (see Chapter 56).

Feeding A key synapomorphy of the cnidarians is a specialized cell called a **cnidocyte,** which is used in prey capture. When cnidocytes sense a fish or other type of prey, the cells forcibly eject a barbed, spear-like structure, which may contain toxins. The barbs hold the prey, and the toxins subdue it until it can be brought

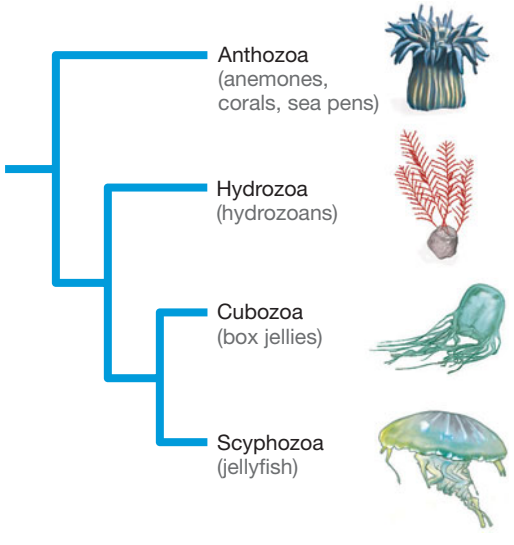

FIGURE 33.17 There are Four Main Lineages within the Cnidaria.

(Continued on next page)

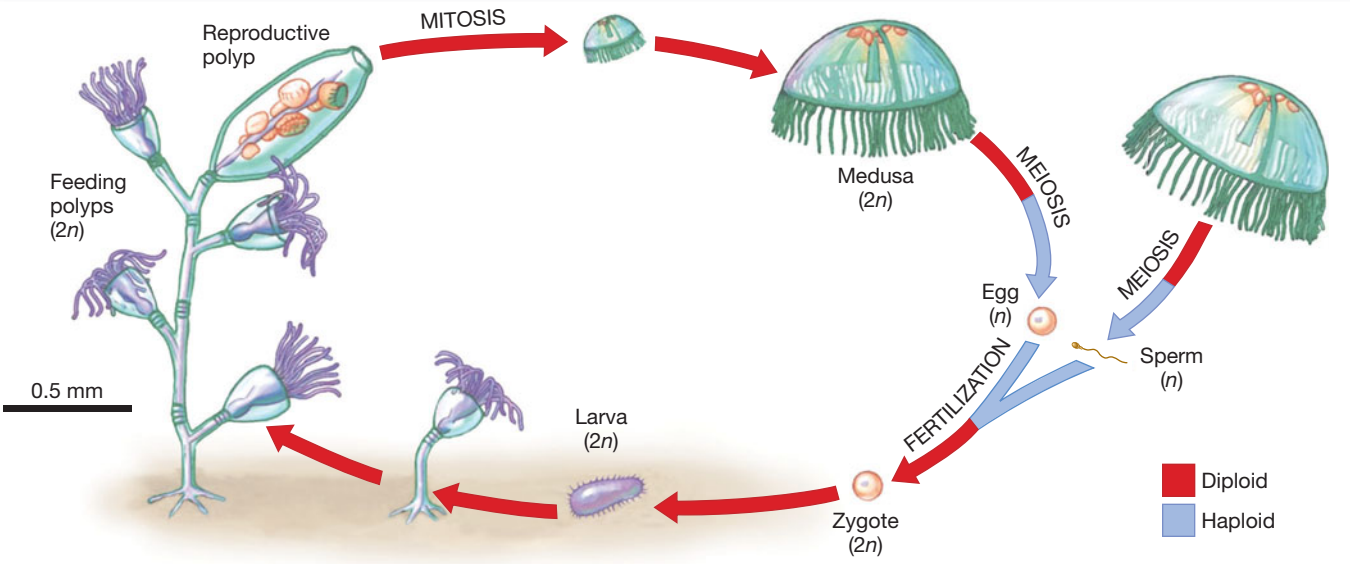

FIGURE 33.18 Cnidarian Life Cycles May Include a Polyp and Medusa Form. This is an example of a hydrozoan called *Obelia*. Colonies are often found attached to seaweed, shells, or rocks and contain hundreds of polyps.

to the mouth and ingested. Cnidocytes are commonly located near the mouths of cnidarians or on elongated structures called tentacles. In a very small number of species, cnidarian toxins can be deadly to humans as well as to prey organisms; in Australia, twice as many people die each year from stings by box jellyfish as from shark attacks (**FIGURE 33.19**). ✔**You should be able to indicate the origin of cnidocytes on Figure 33.2.**

Besides capturing prey actively, most species of coral, some jellyfish, and many anemones host photosynthetic dinoflagellates. The relationship is mutually beneficial, because the protists supply the cnidarian host with food in exchange for protection.

Movement Both polyps and medusae are capable of movement. In polyps, the gut cavity acts as a hydrostatic skeleton that works with the aid of muscle-like cells to contract or extend the body. Many polyps can also creep along a substrate, using muscle-like cells at their bases. Medusae can contract the muscle-like cells in the rims of their bell-shaped body rhythmically, enabling paddling motions as well as jet propulsion—the forcible flow of water in the opposite direction of movement. Cnidarian larvae swim by means of cilia.

Reproduction Polyps may produce new individuals asexually by **(1)** budding, in which a new organism grows out from the body wall of an existing individual; **(2)** fission, in which an existing adult splits lengthwise to form two individuals; or **(3)** fragmentation, in which parts of an adult regenerate missing pieces to form a complete individual. During sexual reproduction, gametes are usually released from the mouth of a polyp or medusa, and fertilization takes place in the open water. Eggs hatch into larvae that become part of the plankton before settling and developing into polyps.

Chironex fleckeri

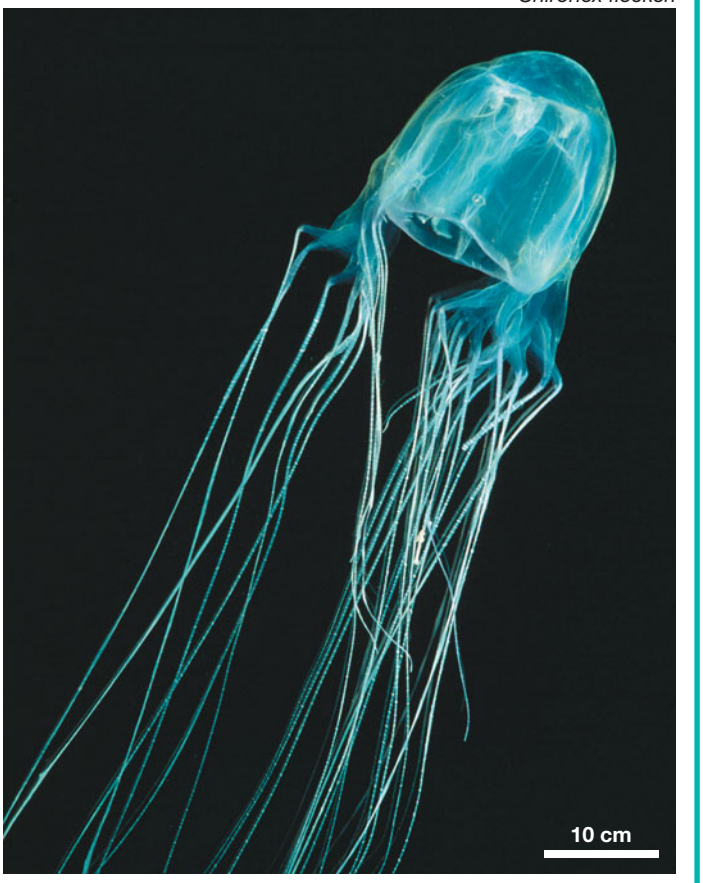

FIGURE 33.19 Some Jellyfish Have Long Tentacles, Packed with Cnidocytes That Sting Prey.

If you understand . . .

33.1 What Is an Animal?

- Animals are multicellular, heterotrophic eukaryotes that lack cell walls and ingest their prey.
- All animals move under their own power at some point in their life cycle. All animals other than sponges have specialized nerve and muscle cells that enable complex movements.
- Animals are eating machines, the largest consumers on Earth.
- Animals comprise 30–35 phyla and may number 8 million or more species.

✔ **You should be able to predict how the total amount of plant material in a forest would change if all animals were excluded for one year.**

33.2 What Key Events Occurred during the Evolution of Animals?

- Animals are a monophyletic group that originated from a protist ancestor that was probably similar to choanoflagellates.
- The basic genetic tool kit for multicellular animals originated at the very root of the animal lineage.
- Sponges lack highly organized, complex tissues other than rudimentary epithelium.
- Most ctenophores and cnidarians have radial symmetry, two embryonic germ layers, and neurons organized into a nerve net. However, some of the regulatory genes responsible for bilateral symmetry arose before the split of cnidarians and bilaterians.
- Most animal species are bilaterians. They have bilateral symmetry, three embryonic tissues, and a coelom—features that gave rise to a tube-within-a-tube body plan.
- Most bilaterians also have a centralized nervous system and cephalized bodies—meaning that a distinctive head region contains the mouth, brain, and sensory organs.
- The bilaterian tube-within-a-tube design is built in one of two fundamental ways—via the protostome or deuterostome patterns of embryonic development.
- Segmentation is a key innovation in annelids, arthropods, and vertebrates.

✔ **You should be able to draw a bilaterian that lacks limbs, and label the gut, outer body wall, muscle layers, head region, mouth, anus, brain, and major nerve tracts.**

33.3 What Themes Occur in the Diversification of Animals?

- Sensory abilities and sensory structures vary among species and correlate with their habitats and feeding methods.
- Animals fill three different ecological roles depending on their source of food: they are detritivores, herbivores, or carnivores—or omnivores, a combination.
- Animals capture food in four ways: Suspension or filter feeders filter organic material or small organisms from water; deposit feeders swallow sediments; fluid feeders lap or suck up liquids; mass feeders harvest chunks of tissue.
- Although the types of appendages used in animal locomotion range from simple lobe-like limbs to complex jointed legs, the genes that indicate where appendages develop may be homologous.
- Asexual reproduction occurs in many species, but sexual reproduction is predominant. Fertilization may be external or internal, and embryos may complete development inside or outside the mother.
- Development may be direct or indirect. During indirect development, a dramatic morphological transformation takes place from one life stage to another, called metamorphosis.

✔ **You should be able to select a phylum and give examples of how the themes of diversification apply within that phylum.**

33.4 Key Lineages of Animals: Non-Bilaterian Groups

- Sponges are diverse, benthic suspension feeders.
- Ctenophores are planktonic predators, the largest animals to use cilia for locomotion.
- Cnidarians are diverse and abundant in habitats around the world. The cnidocyte, or stinging cell, is a synapomorphy for this group.

✔ **You should be able to recognize sponges, ctenophores, or cnidarians based on their morphology.**

TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. What synapomorphy (shared, derived trait) distinguishes animals as a monophyletic group, distinct from choanoflagellates?
   a. multicellularity
   b. coloniality
   c. heterotrophy
   d. no cell walls
2. True or false? All coelomates are triploblasts.
3. In _____, the mouth develops before the anus; but in _____, the anus develops before the mouth.
4. Why do some researchers maintain that the limbs of all animals are homologous?
   a. Homologous genes, such as *Dll*, are involved in their development.
   b. Their structure—particularly the number and arrangement of elements inside the limb—is the same.
   c. They all function in the same way—in locomotion.
   d. Animal appendages are too complex to have evolved more than once.
5. In a tube-within-a-tube body plan, what is the interior tube?
   a. ectoderm
   b. mesoderm
   c. the coelom
   d. endoderm
6. Which of the following characteristics does not apply to cnidarians?
   a. usually diploblastic
   b. possess a gastrovascular cavity with one opening
   c. undergo metamorphosis
   d. have a central nervous system

TEST YOUR UNDERSTANDING

Answers are available in Appendix A

7. Explain the difference between a diploblast and a triploblast. How was the evolution of mesoderm associated with the evolution of a coelom?
8. Why is it ecologically significant that animals are heterotrophic *and* multicellular?
9. **QUANTITATIVE** To estimate the relative abundance of the major phyla, calculate how many named species of arthropods, mollusks, and nematode worms exist per named species of chordate (see Table 33.1). Do you think these calculations are likely to be underestimates, or overestimates? Why?
10. Explain how an animal mother nourishes an embryo in oviparous species versus viviparous species.
11. Specific genes are known to play an important role in the segmentation of arthropods. What approach could you use to test the hypothesis that segmentation in vertebrates (phylum Chordata) is homologous to segmentation in arthropods (phylum Arthropoda)?
12. Which of the following is an example of homology (similarity due to common ancestry)?
    a. suspension feeding in sponges and clams
    b. ectoparasite lifestyle in aphids and ticks
    c. cnidocytes (stinging cells) in jellyfish and sea anemones
    d. metamorphosis in sea urchins and insects

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A

13. Suppose that a gene originally identified in nematodes (roundworms) is found to be homologous with a gene that can cause developmental abnormalities in humans. Would it be possible to study this same gene in fruit flies? Explain.
14. Some sea anemones can produce large colonies by reproducing asexually, but they can also produce planktonic larvae by reproducing sexually. Predict the circumstances under which each mode of reproduction would be favored.
15. Radial symmetry evolved in echinoderms (sea stars and sea urchins) from bilaterally symmetric ancestors. Predict whether the echinoderm nervous system is centralized or diffuse. Explain your logic.
16. You have a unique opportunity to explore a pristine coral reef in the South Pacific. You come across a small organism that you do not recognize and that is not in your field guide. Which of the following suites of characteristics would be most helpful in identifying the organism's phylum?
    a. sessile, green, 2 cm tall, abundant
    b. radial symmetry, suspension feeder
    c. nonsegmented, sessile, changes shape
    d. radial symmetry, sessile, two tissue layers

34 Protostome Animals

In this chapter you will learn that

Protostomes are the most diverse and abundant animals on Earth

starting with

What is a protostome? 34.1

then asking

What is a lophotrochozoan? 34.2

and examining

Key lineages (especially mollusks)

then asking

What is an ecdysozoan? 34.3

and examining

Key lineages (especially arthropods)

In numbers of individuals and species richness, protostomes are the most abundant and diverse of all animals—and the insects are by far the most abundant and diverse of the protostomes. The insects shown here come from all over the world.

Protostome animals are spectacularly diverse and abundant. To put this in perspective, consider that of the more than 30 animal phyla known to exist, at least 22 are protostomes. Table 33.1 summarized the major protostome phyla. You will likely recognize many of the more familiar ones:

- *Arthropoda*, including the insects, crustaceans (shrimp, lobsters, crabs), chelicerates (spiders and mites), and myriapods (millipedes, centipedes)
- *Mollusca*, including the snails, clams, octopuses, and squid
- *Annelida*, including the segmented worms such as the earthworms, polychaete worms, and leeches

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

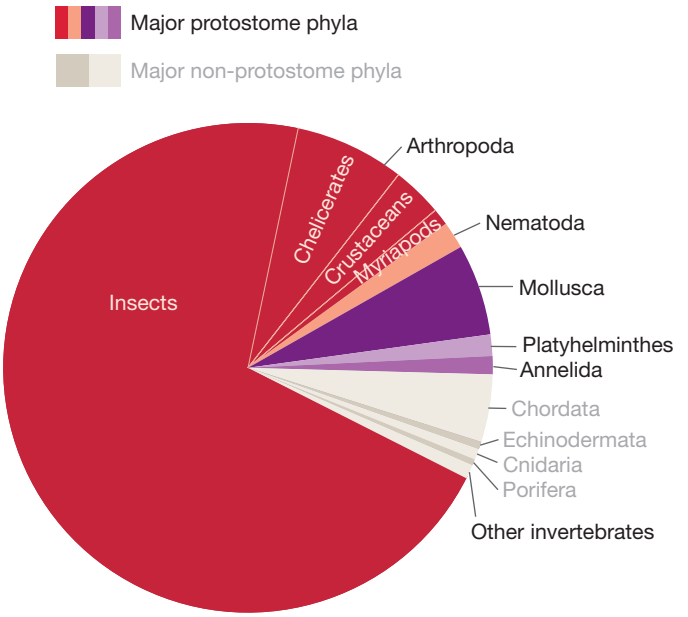

FIGURE 34.1 The Relative Diversity of Animal Lineages. Most animals are protostomes. About 70 percent of all known species of animals on Earth are insects, most of them beetles. (Humans and other vertebrates are deuterostomes, in the phylum Chordata.)

DATA: Chapman, A. D. 2009. *Numbers of Living Species in Australia and the World,* 2nd ed. Canberra: Australian Biological Resources Study.

Some protostome phyla have only a few named species, such as the phylum Priapula, which contains 16 named species. On the other end of the spectrum, over 85,000 mollusks have been named thus far, and about 1.2 million arthropod species, of which about a million are insects. Scientists estimate that the actual number of arthropod species may be over 10 million.

The pie chart in **FIGURE 34.1** shows the relative numbers of named species in various animal phyla. Notice that the wedges representing non-protostome phyla, labeled Chordata, Cnidaria, Echinodermata, and Porifera, are small. Almost all animal species are protostomes.

Certain protostomes are not only diverse (in numbers of species), but also extremely abundant (in numbers of individuals). A typical acre of pasture in England is home to almost 18 *million* individual beetles and up to 9 *billion* roundworms. The world population of ants is estimated to be 1 million billion (1,000,000,000,000,000) individuals.

Given the diversity and abundance of protostomes, you should not be surprised that they fill very important ecological roles. As a group, protostomes live in virtually every aquatic and terrestrial habitat in the world and can be detritivores, herbivores, or carnivores. If one of biology's most fundamental goals is to understand the diversity of life on Earth, then protostomes—particularly the mollusks and arthropods—demand our attention.

The ecological importance of protostomes extends to the health and welfare of humans in profound and diverse ways. For example:

- Protostomes, especially shellfish (clams, oysters, scallops, crabs, shrimp, lobsters), are a major direct source of food for humans, which makes them economically important.
- Humans also rely on protostomes indirectly for their ecosystem services. For example, many farmers rely on protostomes like earthworms to prepare the soil, and on bees and other insects to pollinate their crops.
- Some insects have a massive negative impact on food production by damaging crops, while other insects protect crops from pests.
- Some protostomes produce valuable materials such as silk and pearls.
- Many protostomes play an important role in causing or transmitting human diseases, and are common parasites.
- The protostomes include two of the most important model organisms in all of biological science: the fruit fly *Drosophila melanogaster* and the roundworm *Caenorhabditis elegans* (see **BioSkills 13** in Appendix B).

Let's take a closer look at what defines the protostomes and then explore the diversity within the major phyla.

34.1 What Is a Protostome?

There are two major groups of bilaterally symmetric, triploblastic animals: the protostomes and deuterostomes (Chapter 33). The **protostomes** are distinguished from the deuterostomes by two developmental characteristics:

1. During gastrulation, the initial pore that forms in the embryo becomes the mouth—protostome translates to "first-mouth." (In deuterostomes the pore develops into the anus, and the mouth develops later.)
2. If a **coelom** (a body cavity) forms later in development, it forms from cavities that arise within blocks of mesodermal cells (rather than as mesoderm pockets pinching off the gut, as in deuterostomes).

Phylogenetic studies have long supported the hypothesis that protostomes are a monophyletic group, meaning the protostome developmental sequence arose just once. But biologists have found it difficult to sort out the relationships among protostome lineages. During the 500 million years of evolution that followed the diversification of protostomes during the Cambrian explosion, some morphological characteristics evolved independently in different lineages, resulting in convergent evolution. Other characteristics thought to be synapomorphies—shared, derived traits within a lineage—were lost in some groups. As a result, morphological data have led to many alternative hypotheses about phylogenetic relationships.

Recent analyses of DNA sequence data have rejected many previous hypotheses of relationships based on morphological data. As the phylogenetic tree in **FIGURE 34.2** shows, the recent data support two major subgroups within the protostomes. The Lophotrochozoa (pronounced *low-foe-tro-ko-ZOH-ah*) include mollusks and annelid worms. The Ecdysozoa (pronounced *eck-die-so-ZOH-ah*) include the arthropods.

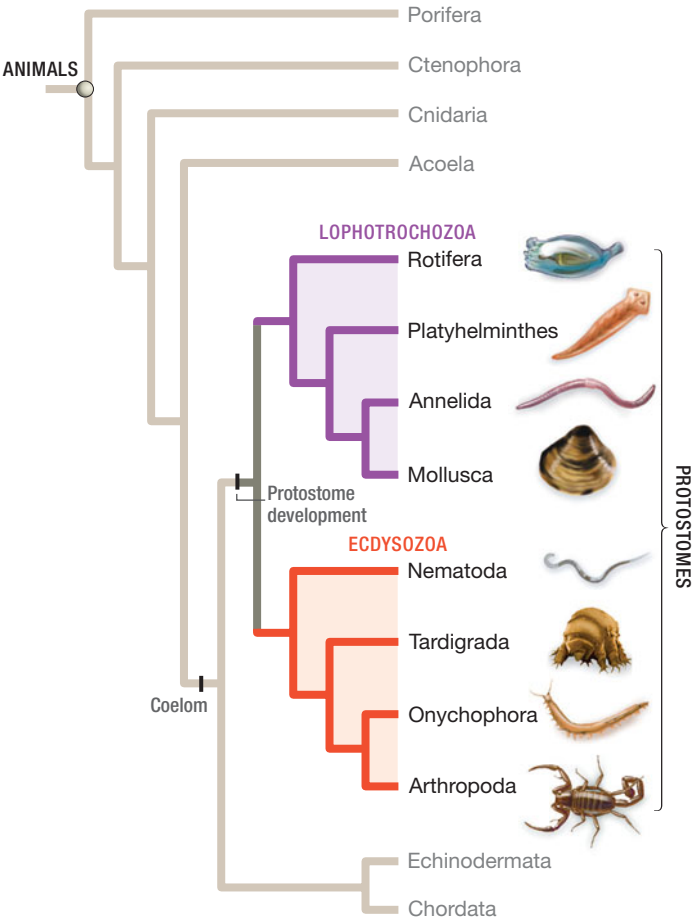

FIGURE 34.2 Protostomes Are a Monophyletic Group Comprising Two Major Lineages. There are 22 phyla of protostomes, but the eight major phyla shown account for about 99.5 percent of the known species.

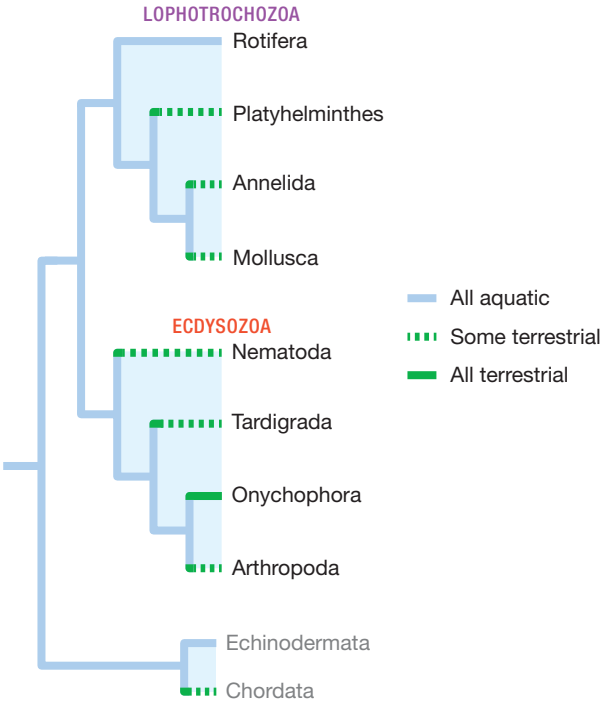

FIGURE 34.3 The Water-to-Land Transition Occurred Several Times in the Protostomes. The transition occurred only once in the deuterostomes, in phylum Chordata.

✔ **QUESTION** According to this tree, terrestrial living arose seven different times independently in protostomes. Why would you not instead conclude that terrestrial living was ancestral and the aquatic lifestyle arose seven times independently?

Before considering each of these groups in more detail, let's examine the key themes in the evolutionary diversification of the protostomes. Recall that all animal lineages evolved diverse ways of sensing the environment, feeding, moving, reproducing, and developing (see Chapter 33). In addition, diversification in protostomes was triggered by the transition from aquatic to terrestrial habitats, and the modular design of many protostome body plans.

The Water-to-Land Transition

Fossils from the Burgess Shale in Canada, Chengjiang in China, and other sites show that protostome lineages originated in marine environments—that is, in the ocean. Today, protostomes are the most abundant animals in the world's oceans as well as in virtually every freshwater and terrestrial habitat. Like land plants and fungi, protostomes made the transition from aquatic to terrestrial environments.

To help put this achievement in perspective, note that green plants made the move from freshwater to land just once (Chapter 31). It is not yet clear whether fungi moved from aquatic habitats to land once or several times (Chapter 32). Only one lineage among deuterostomes moved onto land (Chapter 35). But protostomes made a water-to-land transition multiple times as they diversified (**FIGURE 34.3**).

Water-to-land transitions are important because they open up entirely new habitats and new types of resources to exploit. Based on this reasoning, biologists propose that the ability to live in terrestrial environments was a key event in the diversification of several protostome phyla.

Several adaptations were required for protostomes to thrive on land, such as the ability to:

1. exchange gases,
2. avoid drying out, and
3. hold up their bodies under their own weight.

Recall that an **adaptation** is a trait that increases the fitness (reproductive success) of individuals in a particular environment.

Land animals exchange gases with the atmosphere readily as long as they have a large, moist surface area that is exposed to the air (Chapter 45). The bigger challenge is to prevent the gas-exchange surface and other parts of the body from drying out. How do terrestrial protostomes solve this problem?

- Roundworms, earthworms, and other terrestrial protostomes live in humid soils or other moist environments and exchange gases across their body surface. They have a high surface-area-to-volume ratio, which increases the efficiency of gas exchange.

- Some terrestrial arthropods and mollusks have gills or other respiratory structures located *inside* the body, minimizing water loss, such as tracheae in insects (Chapter 43).
- Insects evolved a waxy layer to minimize water loss from the body surface, with openings to respiratory passages that can be closed if the environment dries.
- Insect eggs have a thick membrane that keeps moisture in, and the eggs of slugs and snails have a thin calcium carbonate shell that helps retain water. Desiccation-resistant eggs evolved repeatedly in populations that made the transition to life on land.

Unlike land plants and fungi, many land animals can also move to moister habitats if the area they are in gets too dry.

What are some of the mechanical constraints of living on land? Think for a moment of the weightless feeling you experience in a swimming pool. The upward buoyant force provided by the water counteracts the downward pull on your body mass that is exerted by gravity. Without this buoyant force, animals on land require greater structural support to hold their bodies up and to move. Further, as an animal doubles in length (assuming no change in shape), its weight increases by a factor of 8—so larger organisms feel the effect of gravity more than smaller organisms (Chapter 48). This mechanical constraint has limited the size of many protostomes, including insects, on land.

Modular Body Plans

Morphological and physiological diversification has a genetic basis. Until recent decades, biologists assumed that very different genetic instructions were required to create very different organisms. This reasoning seems logical but turns out to be false. Consider that:

- Multicellular animals have a common tool kit of genes that establish the animal body plan during development. *Hox* genes have been featured in several chapters because they are an important part of this tool kit (see Chapters 22 and 33).
- The genetic tool kit can direct the development of dramatically different types and numbers of structures when the genes are expressed at different times and places during development.

The upshot is that the diversification of animal body plans can occur not just by the generation of new genes over time, but also—and especially—by the changing of the expression pattern of existing genes, in particular regulatory genes. Sean Carroll and colleagues demonstrated this principle clearly when they showed that the *Distal-less* gene is essential to the formation of different types of limbs in diverse lineages, ranging from annelids and arthropods to chordates (see Chapter 33).

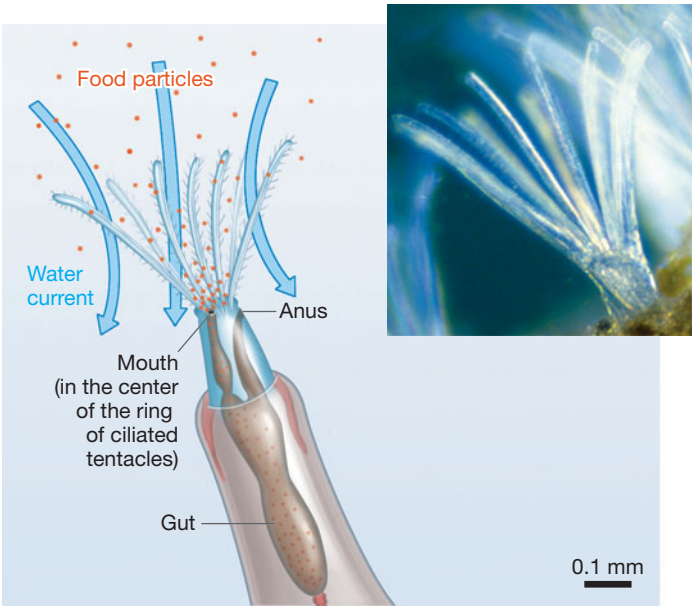
When comparing diverse organisms within a lineage, genetically based *modularity* in body plans is evident, meaning that a small set of elements can be reused and rearranged to produce a large variety of outcomes. For example, the change in expression patterns of regulatory genes can account for both the dramatic increase in the number of vertebrae (back bones) in snakes as well as the loss of limbs in this group (Chapter 22). Thus, a change in expression of preexisting genes generated a dramatically different body plan from that of a shorter, limbed ancestor. Keep the concept of modularity in mind as you read on about the diversity of protostomes.

34.2 What Is a Lophotrochozoan?

The 13 phyla of protostome subgroup Lophotrochozoa include the mollusks, annelids, and flatworms (phylum Platyhelminthes; pronounced *plah-tee-hell-MIN-theez*). Lophotrochozoans are named for two of the three unique morphological traits that define the lineage:

1. a feeding structure called a *lophophore*, which is found in three phyla;
2. a type of larva called a *trochophore*, which is common to many of the phyla; and
3. a spiral pattern of cleavage in embryos.

As **FIGURE 34.4a** shows, a **lophophore** (literally, "tuft-bearer") is a specialized structure that rings the mouth and functions in suspension feeding. Lophophores are found in bryozoans (moss animals), brachiopods (lamp shells), and phoronids (horseshoe worms), together called the lophophorates.



Trochophores are a type of larvae common to marine mollusks, marine annelids, and several other phyla in the Lophotrochozoa. As **FIGURE 34.4b** shows, a **trochophore** (literally, "wheel-bearer") larva has a ring of cilia around its middle. These cilia allow swimming and, in some species, sweep food particles into the mouth.

Trochophore larvae, like other larvae, occur in animals that undergo indirect development—where larvae often look radically different from adults, live in different habitats, and eat different foods (Chapter 33). The process of metamorphosis from larvae to adults in marine species is hypothesized to be an adaptation that allows larvae of sessile or slow-moving adults to disperse to new habitats by floating or swimming in the plankton.

Larvae are not unique to lophotrochozoans—even the earliest known animals, the sponges, had larvae. However, recent analyses suggest that the trochophore larva originated early in the evolution of lophotrochozoans and then evolved into different larval types later in some groups.

Recent phylogenetic analyses of lophotrochozoans have inspired the hypothesis that the spiral pattern of cleavage in embryos is a synapomorphy for this monophyletic group. When cells divide at oblique angles to each other during early embryogenesis, a spiraling pattern of cells results in the blastula (**FIGURE 34.5**). This is in contrast to other patterns of cleavage, such as radial cleavage, where cells divide at right angles to each other. Although spiral cleavage has been highly conserved in some lophotrochozoan phyla, it has been modified or lost in others. ✔ **You should be able to indicate the origin of spiral cleavage on Figure 34.2.**

(a) Lophophores function in suspension feeding in adults.

(b) Trochophore larvae swim and may feed.

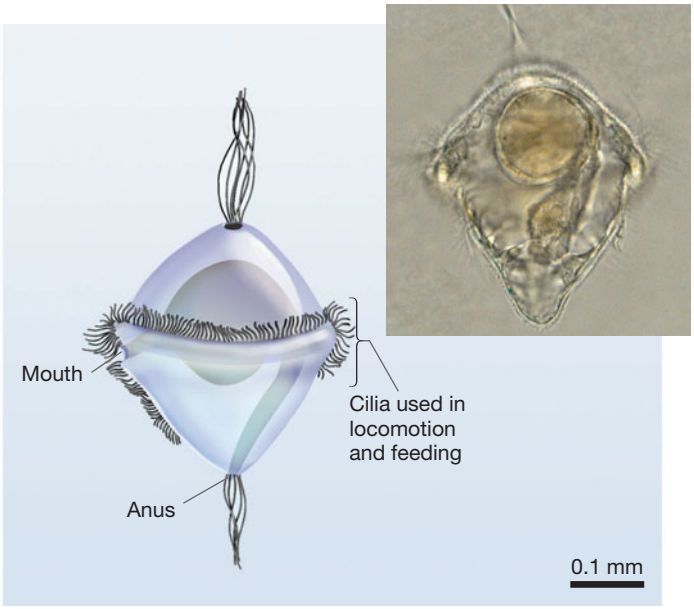


FIGURE 34.4 Lophotrochozoans Have Distinctive Traits. (a) Three phyla of lophotrochozoans, including the bryozoan shown here, have the feeding structure called a lophophore. **(b)** Many phyla of lophotrochozoans have the type of larva called a trochophore.

The implications of spiral cleavage to adult diversity are becoming evident as modern molecular techniques are applied to studies of comparative embryology. For example, spiral cleavage is clockwise in some snails but counterclockwise in others, resulting in adults with right-handed and left-handed whorls, respectively. It turns out that the cleavage pattern determines the downstream expression of *Nodal* and *Pitx*—tool-kit genes that establish the asymmetry of snails. *Nodal* and *Pitx* are also important in the left-right asymmetries of vertebrates, illustrating how homologous tool-kit genes can have similar but different effects in different lineages.

(a) Spiral cleavage is unique to lophotrochozoans.

(b) Radial cleavage, for comparison

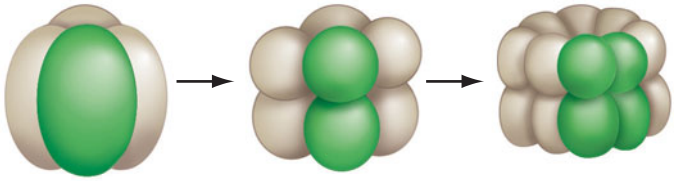

FIGURE 34.5 Spiral Cleavage is a Synapomorphy for the Lophotrochozoans. This pattern of early cell divisions, here contrasted with radial cleavage, has been modified or lost in some lineages. (Some of the cells are stained to help compare the patterns.)

In sum, if you were to observe a lophophore, a trochophore larva, or spiral cleavage in an unfamiliar animal, you could be confident that the animal belongs to the Lophotrochozoa. However, all lophotrochozoans do not possess all three of these characteristics.

Let's briefly consider the diversity of wormlike lophotrochozoans and then look at the most diverse and abundant phylum, the mollusks.

Wormlike Lophotrochozoans

Most protostome phyla include species that have long, thin, tube-like bodies that lack limbs. That is, they are **worms** with a basic tube-within-a-tube design (Chapter 33). The outside tube is the skin, which is derived from ectoderm; the inside tube is the gut, which is derived from endoderm. Muscles and organs derived from mesoderm are located between the two tubes.

Since the coelom evolved in the common ancestor of protostomes and deuterostomes (see Figure 34.2), many lophotrochozoans have a well-developed coelom—not only allowing space for fluids to circulate among organs but also serving as part of a hydrostatic skeleton for movement. The hydrostatic skeleton enables worms to crawl, burrow, and even swim. Specific movements depend on factors such as the organization of muscles within the body, whether the worms are segmented or unsegmented, and the presence or absence of bristles or other structures on the body surface.

As with spiral cleavage and the trochophore larva, however, the coelom was reduced or lost in several lineages. For example, the flatworms—which are mostly small and thin or parasitic—lack a coelom entirely.

FIGURE 34.6 Many Wormlike Lophotrochozoans Have Specialized Mouthparts. These three examples are polychaete worms, phylum Annelida.

✔ **EXERCISE** It is common to find diverse worms in the same habitat. Suggest a hypothesis to explain why this is possible.

Wormlike lophotrochozoans include suspension, deposit, liquid, and mass feeders (see Chapter 33). Exploiting a diversity of foods is possible in part because worms have such a wide variety of mouthparts for capturing and processing food.

The lophophore feeding structure that is used by lophophorates, such as phoronid worms, is an example of one type of specialized mouthpart (see Figure 34.4a). Let's consider several other examples from the phylum Annelida, the segmented worms.

Segmented worms are a diverse group, especially the marine polychaetes (**FIGURE 34.6**). For example, they may live in tubes and extend their feathery tentacles into the water to suspension feed, burrow in the sediments and reach out with their spaghetti-like tentacles to deposit feed, or spear prey with sharp fangs on the tip of a tubular, extensible feeding appendage called a **proboscis.**

While the diversity of wormlike lophotrochozoans is impressive, you can see from the pie wedges in Figure 34.1 that they do not quite compare to the mollusks in terms of diversity.

What Is a Mollusk?

Mollusks exhibit the lophotrochozoan mode of growth and development. But unlike the lophotrochozoans as a whole, the mollusks can be identified by distinctive characteristics. Mollusks have a specialized body plan based on three major components (**FIGURE 34.7**):

1. the **foot,** a large muscle located at the base of the animal and usually used in movement;
2. the **visceral mass,** the region containing most of the main internal organs and the external gill; and
3. the **mantle,** an outgrowth of the body wall that covers the visceral mass, forming an enclosure called the mantle cavity. In many species, the mantle secretes a hard calcium carbonate shell.

✔ **You should be able to indicate the origin of the molluscan body plan on Figure 34.2.**

Once the molluscan body plan evolved, subsequent diversification was largely driven by adaptations that allowed the mollusks to move, feed, or reproduce in novel ways. The result was a dramatic radiation of mollusks into several lineages, including **bivalves** (clams and mussels), **gastropods** (slugs and snails), **chitons** (mollusks with dorsal shells made of plates), and **cephalopods** (squid and octopuses).

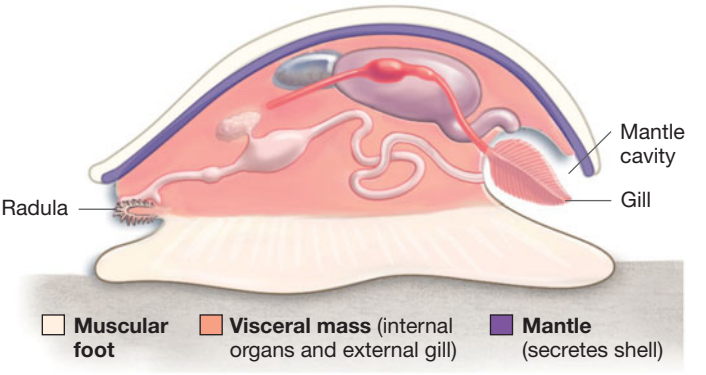

FIGURE 34.7 Mollusks Have a Specialized Body Plan. This diagram of a generalized mollusk shows that the mollusk body plan is based on a foot, a visceral mass, and a mantle. Gills are located inside a cavity created by the mantle.

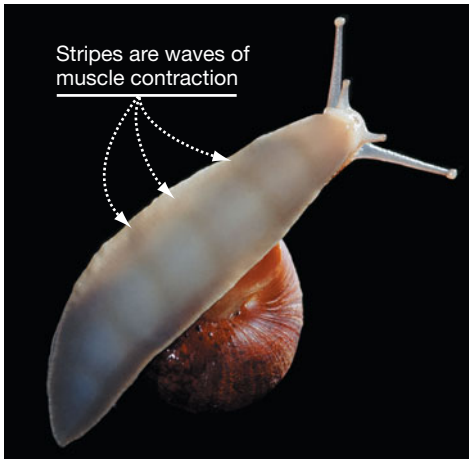

FIGURE 34.8 How Snails Walk on One Foot. Waves of muscle contractions, moving forward or backward along the length of the foot, allow mollusks like this snail to creep along a substrate.

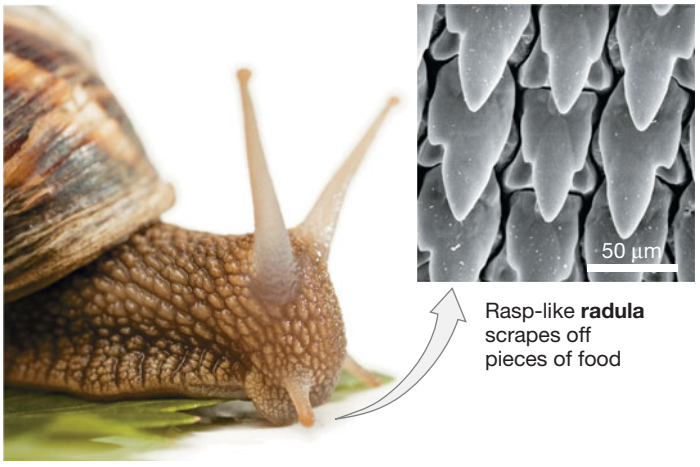

FIGURE 34.9 The Radula Is Unique to Mollusks. The size and shape of the radular teeth is highly correlated with the type of food eaten by the species.

The Foot Is a Muscular Hydrostat Snails and chitons have a large, muscular foot at the base of the body that—like your tongue—works as a type of hydrostatic skeleton called a muscular hydrostat. How can an animal move with just one foot? Waves of muscle contractions sweep backward or forward along the length of the foot, allowing individuals to crawl along a surface (**FIGURE 34.8**). Biologists in the field of biomechanics have measured the mechanical properties of snail mucus. They observed that it has the remarkable ability to increase traction for the parts of the foot that are not moving, while lubricating motion for the parts that are advancing.

In bivalves such as clams, the foot is modified as a digging appendage. The foot of cephalopods like squid and octopus is modified to form tentacles for crawling and grasping.

The Visceral Mass Separates Internal Organs from the Hydrostatic Skeleton The visceral mass is the space in all mollusks where organs and surrounding fluids are located. This might not seem like much of an innovation, but compare this body plan to that of worms, where the hydrostatic skeleton and internal organs are inseparable. The separation of the foot and visceral mass in mollusks may have enabled diversification of both.

The coelom itself is highly reduced in most mollusks, functioning mostly in reproduction and excretion of wastes. The organs occupy a different type of body cavity called a **hemocoel** ("blood-hollow"; pronounced *HEE-mah-seal*), where body fluids bathe the organs directly in an open circulatory system (see Chapter 45). A hemocoel is different from a coelom because it is not lined in mesoderm.

At the anterior end of the visceral mass, the mouth has a unique molluscan feeding structure called a **radula**, which functions like a rasp or file. The mollusk moves the radula back and forth over the food source, causing the many sharp plates to scrape material so that it can be ingested (**FIGURE 34.9**). Since it is highly unlikely that such a unique structure would evolve more than once, the radula probably evolved early in molluscan evolution. It was later lost in the bivalves, which acquire food by suspension feeding.

The Mantle Secretes a Shell In many species the mantle secretes a shell made of calcium carbonate. Some mollusk species have a shell consisting of one, two, or eight parts, or valves; others have no shell at all. The ability to secrete a protective shell may have been an important adaptation during the Cambrian and beyond as the number of predators increased. Note, however, that shells made of calcium carbonate are heavy. Thus, there is a trade-off between protection and mobility. As you might predict, mollusks with thick shells are constrained to aquatic habitats where buoyant forces help support the load. The largest and most agile of all aquatic mollusks, cephalopods such as squid and octopus, have highly reduced shells or none at all. Terrestrial mollusks have thin shells or none at all.

The mantle was also modified in many ways to serve diverse functions other than secreting shells. For example, cephalopods have a mantle lined with muscle. When the cavity surrounded by the mantle fills with water and the mantle muscles contract, a stream of water is forced out of a tube called a **siphon.** The force of the water propels the squid in a form of locomotion called jet propulsion (**FIGURE 34.10**, see page 664). The mantle of bivalves such as clams is modified to form two siphons to control incurrent and excurrent water flow over their gills.

Modular Mollusks How did the novel body plan and lifestyle of mollusks such as squid evolve? Mark Martindale and his colleagues tried to address this question by looking at the role of *Hox* genes in the organization of the squid body plan. They found that:

- Squid have nine *Hox* genes that are homologous to those found in other bilaterians (recall that *Hox* genes are important in establishing the anterior–posterior axis of animals).
- Although *Hox* genes are usually organized in a collinear fashion (see Chapter 22), they were co-opted in a new pattern in

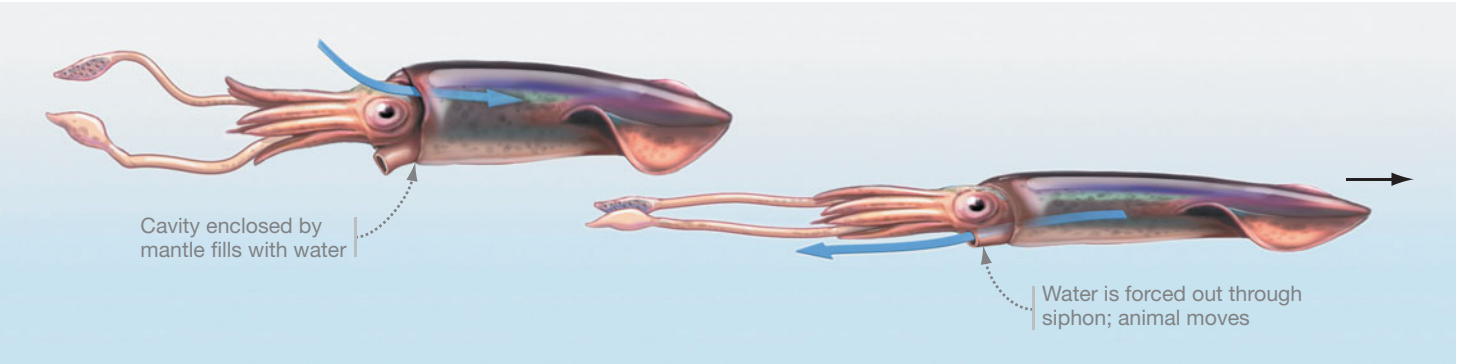

FIGURE 34.10 Jet Propulsion in Mollusks. In jet propulsion, muscular contractions of the mantle force the water out through a movable siphon.

✔ **EXERCISE** Circle the part of the squid that is homologous to the snail foot.

squid, suggesting a mechanism by which a change in the regulation of tool-kit genes could result in novel body structures, such as the modification of the molluscan foot into a crown of muscular tentacles.

The take-home message is that mollusks have a modular design. That is, while all mollusks have a foot, visceral mass, and mantle, the sizes, shapes, and functions of these structures have diversified in ways that enable drastically different methods of feeding, moving, and reproducing.

Let's take a closer look at some of the diversity within the main lophotrochozoan phyla.

check your understanding

C Y U

If you understand that . . .

- Flatworms, annelids, and mollusks are all diverse phyla within the Lophotrochozoa, and all three phyla made the water-to-land transition.
- The mollusk body plan includes a muscular foot, a visceral mass, and a mantle.

✔ **You should be able to . . .**

1. Predict three ways you would expect a snail that lives on land to differ from a snail that lives in the ocean.
2. Design an experiment to test whether the tentacles of an octopus are homologous to the foot of a snail.

Answers are available in Appendix A.

Key Lineages: Lophotrochozoans

The phyla within Lophotrochozoa are united by shared mechanisms of early development and growth, but they are highly diverse in terms of their resulting morphology. You might not even recognize some of them as having a bilaterally symmetrical body plan.

Let's take a closer look at five key lophotrochozoan phyla: **(1)** Bryozoa, **(2)** Rotifera, **(3)** Platyhelminthes, **(4)** Annelida, and **(5)** Mollusca. Because the Mollusca is so species rich and diverse, the detailed descriptions in this section consider the four most familiar lineages of mollusks separately:

- Lophotrochozoans > Bryozoa (Bryozoans)
- Lophotrochozoans > Rotifera (Rotifers)
- Lophotrochozoans > Platyhelminthes (Flatworms)
- Lophotrochozoans > Annelida (Segmented Worms)
- Lophotrochozoans > Mollusca > Bivalvia (Clams, Mussels, Scallops, Oysters)
- Lophotrochozoans > Mollusca > Gastropoda (Snails, Slugs, Nudibranchs)
- Lophotrochozoans > Mollusca > Polyplacophora (Chitons)
- Lophotrochozoans > Mollusca > Cephalopoda (Nautilus, Cuttlefish, Squid, Octopuses)

Lophotrochozoans > Bryozoa (Bryozoans)

Bryozoans, sometimes also called ectoprocts or moss animals, are tiny lophophorate animals that live in colonies that look more like a sponge or coral than a bilaterian (**FIGURE 34.11**). The oldest bryozoan fossils date back to the late Cambrian, giving this group the distinction of being the most recent animal phylum to appear in the fossil record. Today, bryozoans live mostly in marine environments, especially in the tropics, but also in some freshwater environments. So far, 5700 species have been described. The colonies range in size, from millimeters to meters, and in shape, from fans to encrusting sheets.

Feeding Bryozoan individuals, or zooids, suspension feed on plankton using a lophophore (see Figure 34.4).

Movement Most bryozoans are sessile. Only the (non-trochophore) larvae are capable of dispersing to new habitats.

Reproduction Bryozoans can increase the size of their colony by asexual reproduction, by budding. They can also reproduce sexually—zooids are hermaphrodites, some having both male and female reproductive organs at the same time, other serving first as males then as females.

Triphyllozoan species

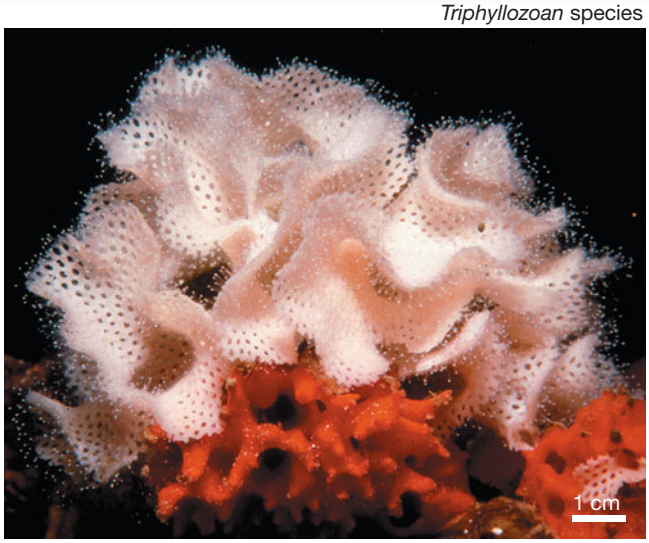

FIGURE 34.11 A Bryozoan Colony. You can see what an individual animal looks like in Figure 34.4.

Lophotrochozoans > Rotifera (Rotifers)

The 2100 **rotifer** species that have been identified thus far live in damp soils as well as marine and freshwater environments. They are important components of the plankton in freshwater and in brackish (slightly salty) waters. Rotifers have a coelom, and most are less than 1 millimeter (mm) long. Although rotifers do not have a lophophore or a trochophore larval stage, their mode of growth and DNA sequences identify them as a member of the lophotrochozoan lineage.

Feeding Rotifers have a cluster of cilia called a **corona** at their anterior end (**FIGURE 34.12**). In many species, the beating of the cilia in the corona makes suspension feeding possible by creating a current that sweeps microscopic food particles into the mouth. The corona is a synapomorphy of this group. ✔ **You should be able to indicate the origin of the corona on Figure 34.2.**

Movement Although a few species of rotifers are sessile, most swim via the beating of cilia in the corona.

Reproduction Most reproduction is sexual, but females of some rotifer species can reproduce asexually by a process called **parthenogenesis**—the female produces unfertilized eggs by mitosis; the eggs then hatch into new, asexually produced individuals. In a group of rotifers called the bdelloids, only females have been found and all reproduction appears to be by parthenogenesis. Whether reproduction is sexual or asexual, rotifer development is direct, meaning that fertilized eggs hatch and grow into adults without going through metamorphosis.

Philodina roseola

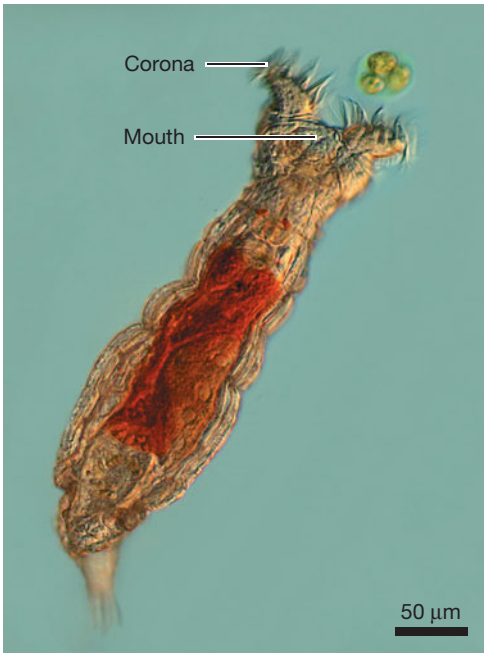

FIGURE 34.12 Rotifers Are Tiny, Aquatic Suspension Feeders.

The flatworms are a large and diverse phylum. More than 20,000 species have been described in four major lineages:

- *Turbellaria* are free-living flatworms. Although a few turbellarian species are terrestrial, most live on the substrates of freshwater or marine environments. Some marine flatworms are brightly colored and several centimeters long (**FIGURE 34.13a**). However, the freshwater planarians common to biology labs, such as *Dugesia*, are drab and only a few millimeters long.
- *Cestoda* are endoparasitic tapeworms that parasitize fish, mammals, or other vertebrates (**FIGURE 34.13b**).
- *Trematoda* are endoparasitic or ectoparasitic flukes that parasitize vertebrates, arthropods, annelids, and mollusks (**FIGURE 34.13c**). In humans, a fluke is responsible for schistosomiasis—a serious public health issue in many tropical and subtropical nations.
- *Monogenea* are ectoparasites that parasitize fish.

Flatworms are named for the broad, flattened shape of their bodies. (The Greek roots *platy* and *helminth* mean "flat-worm.") Species in the Platyhelminthes are unsegmented and lack a coelom. They also lack structures that are specialized for gas exchange. Further, they do not have blood vessels for circulating oxygen and nutrients to their cells. Based on these observations, biologists interpret the flattened bodies of these animals as an adaptation that gives flatworms an extremely high surface-area-to-volume ratio. This flat body plan allows nutrients and gases to diffuse efficiently to all of the cells inside the animal. The downside is that the body surface has to be moist for gas exchange to take place. Flatworms are restricted to aquatic and moist terrestrial environments.

✔ **You should be able to indicate the origin of the flattened, acoelomate body plan on Figure 34.2.**

Feeding The Platyhelminthes lack a lophophore and have a digestive tract that is "blind"—meaning it has only one opening for ingestion of food and elimination of wastes.

- Most turbellarians are hunters that prey on protists or small animals; others scavenge dead animals.
- Tapeworms are strictly parasitic and feed on nutrients provided by hosts. They do not have a mouth or a digestive tract, and they obtain nutrients by diffusion across their body wall.
- Flukes are parasites and feed by gulping host tissues and fluids through a mouth.

Movement In general, flatworms do not move much. Some turbellarians can swim by undulating their bodies, and most can creep along substrates with the aid of cilia on their ventral surface. Adult cestodes have hooked attachment structures at their anterior end that permanently attach them to the interior of their host.

Reproduction Turbellarians can reproduce asexually by splitting themselves in half. If they are fragmented as a result of a predator attack, the body parts can regenerate into new individuals. Most turbellarians contain both male and female organs and reproduce sexually by aligning with another individual and engaging in mutual and simultaneous fertilization.

In flukes and tapeworms, individuals reproduce sexually and either cross-fertilize or self-fertilize. The reproductive systems and life cycles of flukes and tapeworms are extremely complex, however. In many cases the life cycle involves two or even three distinct host species; sexual reproduction occurs in the **definitive host,** and asexual reproduction occurs in one or more **intermediate hosts.** For example, humans are the definitive host of the blood fluke *Schistosoma mansoni*, and snails are the intermediate host.

(b) Cestodes are endoparasitic.

Taenia species

(c) Trematodes are endoparasitic.

Dicrocoelium dendriticum

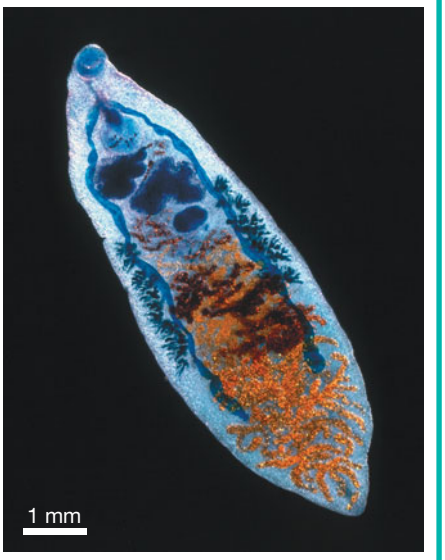

FIGURE 34.13 Flatworms Have Simple, Flattened Bodies.

Most **annelids** have a segmented body and a coelom. ✔**You should be able to indicate the origin of annelid segmentation on Figure 34.2.** The 16,800 described species were traditionally divided into groups called Polychaeta (*pol-ee-KEE-ta*) and Clitellata. Recent analyses have supported Clitellata as a monophyletic group, composed of Hirudinea (leeches), and Oligochaeta (*oh-LIG-oh-keet-a;* earthworms and other oligochaetes). However, the Polychaeta are paraphyletic—that is, including some but not all members of a clade (**FIGURE 34.14**). Further, unsegmented worms called Sipunculida and Echiura, which were traditionally thought to be independent phyla, are actually groups within Annelida—they lost their segmentation.

The common ancestor of the annelids had a key synapomorphy in addition to segmentation: numerous, bristle-like extensions called **chaetae** that extend from appendages called **parapodia.** As the name suggests, polychaetes ("many-bristles"; **FIGURE 34.15a**) have more chaetae than oligochaetes ("few-bristles"; **FIGURE 34.15b**). However, highly mobile polychaetes have larger parapodia and more chaetae than more sedentary polychaetes, which have reduced parapodia and chaetae adapted for burrowing in sediments or living in tubes.

Feeding The polychaete lineages have a wide variety of methods for feeding, including suspension feeding, deposit feeding, and mass feeding (Figure 34.6). Virtually all oligochaetes, in contrast, make their living by deposit feeding in soils. The tunnels that they make are critically important in aerating soil, and their feces contribute large amounts of organic matter. About half of the leeches are ectoparasites that attach themselves to fish or other hosts and suck blood and other body fluids (**FIGURE 34.15c**). The nonparasitic leech species are predators or scavengers.

Movement Polychaetes and oligochaetes crawl or burrow with the aid of their hydrostatic skeletons; the parapodia of polychaetes also act as paddles or tiny feet that aid in movement. Many polychaetes and leeches are good swimmers.

Reproduction Asexual reproduction occurs in some polychaetes and oligochaetes by transverse fission or fragmentation—meaning that body parts can regenerate a complete individual. Sexual reproduction in polychaetes may begin with internal or external fertilization, depending on the species. Most of the polychaete lineages have separate sexes and usually release their eggs directly into the water. Some species produce eggs that hatch into trochophore larvae, then go on to develop into other larval forms. In oligochaetes and leeches, individuals produce both sperm and eggs and engage in mutual, internal cross-fertilization. Eggs are enclosed in a mucus-rich, cocoon-like structure; after fertilization, offspring develop directly into miniature versions of their parents.

FIGURE 34.15 Annelids Are Segmented Worms.

Lophotrochozoans > Mollusca > Bivalvia (Clams, Mussels, Scallops, Oysters)

The bivalves are so named because they have a shell with two separate parts, or valves, made of calcium carbonate. The protective shell is hinged, and closes with the aid of muscles attached to the two valves (**FIGURE 34.16**). Because most bivalves live on or under the ocean floor and because they are covered by a hard shell, their bodies are often buried in sediment after death. Bivalves thus fossilize readily and have the most extensive fossil record of any animal, plant, or fungal group.

The smallest bivalves are freshwater clams that are less than 2 mm long; the largest bivalves are giant marine clams that may weigh more than 200 kilograms (kg). All bivalves can sense gravity, touch, and certain chemicals; scallops even have eyes.

Feeding Most bivalves are suspension feeders that take in any type of small animal or protist, or detritus. Suspension feeding is based on a flow of water across gas-exchange structures called **gills** located within the mantle cavity. A single oyster can filter the organic matter from as much as 60 gallons of seawater each day. Bivalves are the only major group of mollusks that lack the feeding structure called a radula.

Movement Clams burrow into sediments with the aid of their muscular foot but are otherwise sedentary. Scallops are able to swim along the surface of soft substrates by clapping their shells together and forcing water out, a form of jet propulsion. Mussels and oysters are sessile, attached to rocks or other solid surfaces.

Chlamys pallium

FIGURE 34.16 Bivalves Have Shells with Two Parts.

Reproduction Most bivalves reproduce sexually. Eggs and sperm are shed into the water, and fertilized eggs develop into trochophore larvae. Trochophores then metamorphose into a distinct type of larva called a **veliger,** which continues to feed and swim before settling to the substrate and metamorphosing into an adult form that secretes a shell.

Lophotrochozoans > Mollusca > Gastropoda (Snails, Slugs, Nudibranchs)

The gastropods ("belly-feet") are named for the large, muscular foot on their ventral side. Marine and terrestrial snails have shells (**FIGURE 34.17**), into which they can retract when they are attacked or when their tissues begin to dry out. Land slugs and nudibranchs (pronounced *NEW-da-branks*; also called sea slugs) lost their shells independently; these gastropods often contain toxins or foul-tasting chemicals to protect them from being eaten. About 70,000 species of gastropods are known, ranging in size from microscopic to almost a meter long. They are the only group of mollusks that made the water-to-land transition.

Feeding The gastropod radula is diverse, varying in size and shape among species (see Figure 34.9). Although most gastropods are herbivores or detritivores, specialized types of teeth allow some gastropods to act as predators. Species called drills, for example, use their radula to bore a hole in the shells of other mollusks.

Movement Waves of contractions along the length of the foot allow gastropods to move by creeping (see Figure 34.8). Sea butterflies are gastropods with a reduced or absent shell but a large, winglike foot that flaps and powers swimming movements.

Reproduction Most reproduction is sexual, but females of some gastropod species can reproduce asexually by producing eggs parthenogenetically. Sexual reproduction in some gastropods begins with internal fertilization. Most marine gastropods produce a veliger larva that may disperse up to several hundred kilometers from the parent. But in some marine species and all terrestrial forms, larvae are not free living. Instead, offspring remain in an egg case while passing through several larval stages and then hatch as miniature versions of the adults.

Maxacteon flammea

FIGURE 34.17 Gastropods Have a One-Part Shell or Lack Shells.

Lophotrochozoans > Mollusca > Polyplacophora (Chitons)

The name *Polyplacophora* ("many-plate-bearing") is apt because chitons (pronounced *KITE-uns*) have eight calcium carbonate plates, or valves, along their dorsal surface (**FIGURE 34.18**). The plates form a protective shell. The approximately 1000 species of chitons are exclusively marine, and are found worldwide; the largest reaches 33 centimeters (cm). They are usually found on rocky surfaces in the intertidal zone, where rocks are periodically exposed to air at low tides.

Feeding Chitons have a radula that they use to scrape algae and other organic matter off rocks.

Movement Chitons move by creeping on their broad, muscular foot—as gastropods do.

Reproduction In most chiton species, the sexes are separate and fertilization is external. In some species, however, sperm that are shed into the water enter the female's mantle cavity and fertilize eggs there. Depending on the species, eggs may be enclosed in a membrane and released, or they may be retained until hatching and early development are complete. Most species have trochophore larvae.

Tonicella lineata

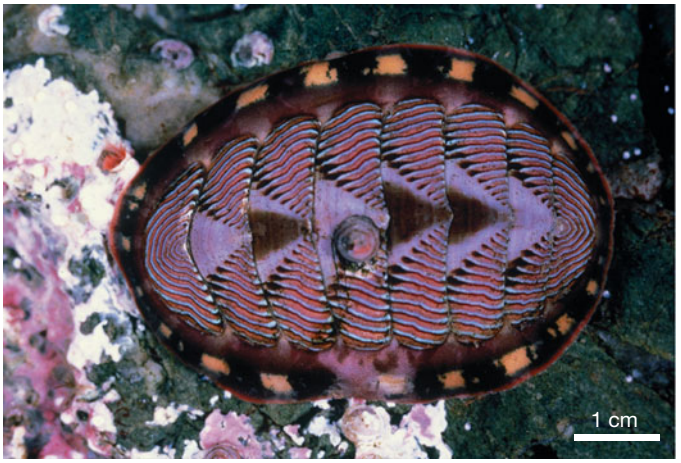

FIGURE 34.18 Chitons Have Eight Shell Plates.

Lophotrochozoans > Mollusca > Cephalopoda (Nautilus, Cuttlefish, Squid, Octopuses)

The cephalopods ("head-feet") have a well-developed "head" that actually consists of the visceral mass, and a foot that is modified to form **tentacles:** long, thin, muscular extensions that aid in movement and prey capture (**FIGURE 34.19**). Except for the nautilus with its chambered shell, the cephalopod species living today have either highly reduced shells or none at all. Most have large brains and image-forming eyes with sophisticated lenses. They also include the largest of all invertebrates living today, the giant squid, which can be more than 10 m long, including the tentacles. The skin of cephalopods contains sophisticated chromatophore ("color-bearing") cells that enable the rapid color changes used for camouflage and communication.

Feeding Cephalopods are highly intelligent predators that hunt by sight and use their tentacles to capture prey—usually fish or crustaceans. They have a radula as well as a structure called a **beak,** which can exert powerful biting forces. Some cuttlefish and octopuses also inject poisons into their prey to subdue them.

Movement Cephalopods can swim by moving their fins to "fly" through the water, or by jet propulsion using the mantle cavity and siphon (see Figure 34.10). Squid are built for speed and hunt small fish by chasing them down. Octopuses, in contrast, crawl along the substrate using their tentacles. They chase down crabs or other crustaceans, or they pry mussels or clams from the substrate and then use their beaks to crush the exoskeletons of their prey. Most cephalopods are able to escape their own predators by releasing a jet of "ink" that disorients their predators while they slip away.

Reproduction Cephalopods have separate sexes, and some species have elaborate courtship rituals that involve color changes and interaction of tentacles. When a male is accepted by a female, he deposits sperm that are encased in a structure called a **spermatophore.** The spermatophore is transferred to the female, and fertilization is internal. Females lay eggs. When they hatch, juveniles develop directly into adults—that is, there is no larval stage.

Octopus bimaculatus

FIGURE 34.19 Cephalopods Have Highly Modified Bodies.

34.3 What Is an Ecdysozoan?

Lophotrochozoans grow continuously and incrementally (**FIGURE 34.20a**)—the ancestral manner of growth for animals. In contrast, the Ecdysozoa are defined by a clear synapomorphy: All ecdysozoans grow intermittently by **molting**—that is, by shedding an exoskeleton or external covering.

The Greek root *ecdysis*, which means "to slip out or escape," is appropriate because during a molt, an individual sheds its outer layer, or **cuticle**—called an **exoskeleton** if it is hard—and slips out of it (**FIGURE 34.20b**). Once the old covering is gone, the body is pumped up with fluid to cause it to expand, and a larger cuticle or exoskeleton forms. As ecdysozoans grow and mature, they undergo a succession of molts, sometimes undergoing dramatic morphological transformations along the way.

A stiff body covering is advantageous because it provides an effective structure for muscle attachment and affords protection. However, the trade-off is that during molting, the soft bodies of ecdysozoans are exposed and vulnerable to predators. When a crab or other crustacean has shed an old exoskeleton, its new exoskeleton takes several hours to harden. During this interval, molting individuals hide and do not feed or move about. Experiments have shown that it is much easier for predators to attack and subdue individuals that are not protected by an exoskeleton during the intermolt period.

A hormone called ecdysone is important in regulating the molting cycle (Chapter 49). Is ecdysone a key innovation for the ecdysozoans? No—studies show that this steroid hormone serves a variety of functions in many other animals. Thus, it appears that ecdysone was co-opted in the ecdysozoans to serve a novel function.

The most prominent of the seven ecdysozoan phyla are the roundworms (Nematoda) and arthropods (Arthropoda). Here, let's consider the implications of having an exoskeleton for the most diverse phylum of animals on Earth, the arthropods.

(a) Lophotrochozoans grow incrementally.

(b) Ecdysozoans grow by molting.

FIGURE 34.20 Lophotrochozoans and Ecdysozoans Differ in Their Mechanism of Growth. (a) Lophotrochozoans do not molt. The growth bands on this clam show periods of slow and rapid incremental growth. **(b)** Ecdysozoans such as this cicada must crawl out of their old exoskeletons and grow new, larger ones.

What Is an Arthropod?

In terms of duration in the fossil record, species diversity, and abundance of individuals, arthropods are the most important phylum within the Ecdysozoa. Arthropods appear in the fossil record over 520 million years ago and have long been the most abundant animals observed in both marine and terrestrial environments. Well over a million living species have been described, and biologists estimate that millions or perhaps even tens of millions of arthropod species have yet to be discovered. In terms of species diversity, arthropods are easily the most successful lineage of eukaryotes.

The Arthropod Body Plan In addition to their bilateral symmetry and other protostome characteristics, **arthropods** (literally "joint-foot") are defined by three key features:

1. a *segmented body*, which is organized into prominent regions, or **tagmata,** such as the head, thorax, and abdomen in the grasshopper (**FIGURE 34.21**);
2. an *exoskeleton* made primarily of the polysaccharide chitin (see Chapter 5), strengthened by calcium carbonate ($CaCO_3$) in crustaceans; and
3. *jointed appendages,* which enable the rigid bodies to move.

Instead of being based on muscle contraction within a hydrostatic skeleton, most arthropod locomotion is based on muscles

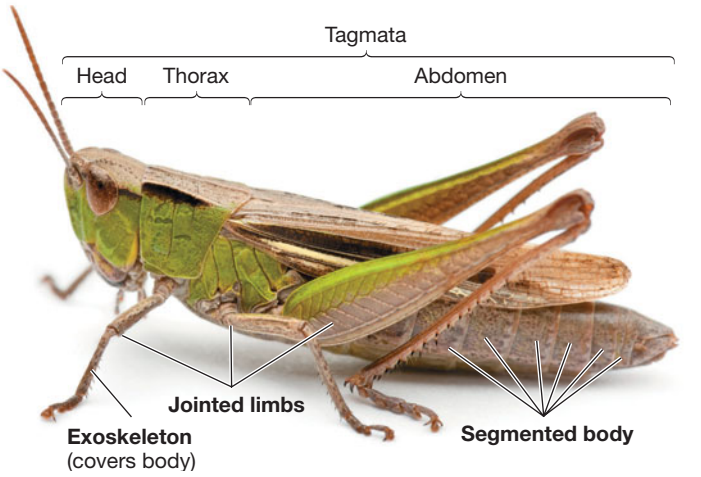

FIGURE 34.21 Arthropods Have a Specialized Body Plan. Arthropods have segmented bodies and jointed limbs, which enable these animals to move despite their hard outer covering, the exoskeleton. Different arthropods have a different number of tagmata, or body regions; insects have three.

that apply force against rigid levers—the exoskeleton—to move legs or wings at the joints. This skeletal architecture enables very rapid and precise movements (Chapter 48).

Arthropods have a highly reduced coelom but, like mollusks, possess an extensive body cavity called a hemocoel. The hemocoel enables movements via a hydrostatic skeleton in caterpillars and other types of arthropod larvae.

The jointed appendages of arthropods are organized in pairs along the segmented body. They have an array of functions: exchanging gases, sensing the environment, feeding, and locomotion via swimming, walking, running, jumping, or flying (Chapter 33). Arthropod appendages provide the ability to sense stimuli and make sophisticated movements in response. ✔ **You should be able to indicate the origin of jointed appendages on Figure 34.2.**

Why Has the Arthropod Body Plan Been So Successful? You have already learned that mollusk bodies are modular in evolutionary terms. The modularity of arthropod segments, however, takes the prize for evolutionary potential.

Studies on the role of tool-kit genes—such as the *Hox* genes—during development of different arthropods have contributed enormously to our understanding of the process of arthropod diversification. These studies show that small changes in the timing and location of expression of certain tool-kit genes along the length of an arthropod can result in novel shapes and sizes of body segments and appendages.

To understand the evolutionary potential of modularity, consider a hypothetical ancestral arthropod with many uniform body segments, each with a pair of uniform appendages. The redundancy of this body plan can provide a fertile starting place for diversification because some of the segments can continue to function the old way, say for crawling, while other segments can become co-opted for new functions. For example, the appendages at the head end could become specialized as antennae or claws without compromising the ability of the animal to crawl.

Thus, genetic opportunity in the form of variation in the expression of tool-kit genes can combine with ecological opportunity by the process of natural selection to result in the diversification of arthropod body segments and appendages. **FIGURE 34.22** shows an example of how diverse, functionally specialized appendages can result in an animal with a "serialized" body plan, a reflection of its modular structure. The crayfish limbs are said to have serial homology.

Origin of the Wing The process of co-opting old parts for new functions is key to the origin of one of the most remarkable adaptations in the history of life—the insect wing. There are more species of animals on the planet today with insect wings than without. According to data in the fossil record, insects were also the first animals on Earth that had wings and could fly. How did wings evolve?

Some biologists have proposed that wings arose as outgrowths from the thorax, independent from the legs. Others have argued that wings arose from gill-like projections on the branched legs of a wingless ancestor, essentially co-opting the gill-like structures

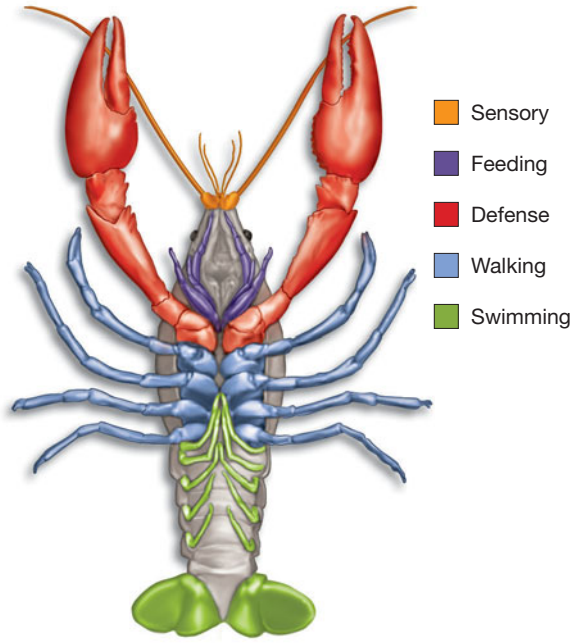

FIGURE 34.22 Arthropods Have a Modular Body Plan. This ventral view of a crayfish illustrates how arthropod segments and appendages can be specialized for different functions.

(**FIGURE 34.23**). Insects have unbranched appendages, but arthropods such as crustaceans have branched appendages.

Michalis Averof and Stephen Cohen attempted to settle the wing debate using developmental genetics. They probed the developing limbs of brine shrimp (a member of an ancient lineage of crustaceans) for the presence of tool-kit genes *nubbin* and *apterous*. These genes are known to be important in wing development in insects. The results were striking. *Nubbin* and *apterous* are expressed in the gill-like lobe of the crustacean limb, but nowhere else. These results provide strong support for the origin of insect wings from the gill-like branches of ancestral crustacean limbs.

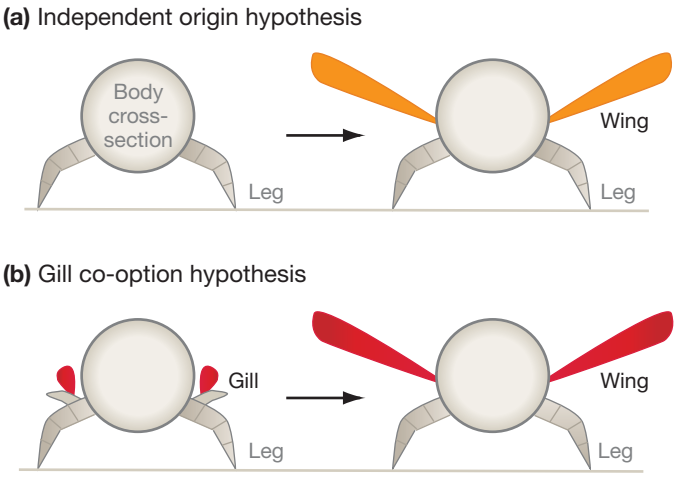

FIGURE 34.23 Alternative Hypotheses for the Origin of Wings in Insects.

Co-opting one structure to form another may sometimes require thousands or millions of years of evolution within a lineage. It is all the more remarkable, then, that dramatic shape changes can also occur during the lifetime of a single individual. Natural selection operates at all developmental stages in a life cycle.

Arthropod Metamorphosis

Many arthropods undergo a morphological transformation from a larva to a very different adult form. Others do not. Let's use insects as a case study to consider the adaptive implications of metamorphosis in arthropods.

Two Types of Insect Metamorphosis In insects, the presence or absence of a larval stage defines two distinct types of metamorphosis.

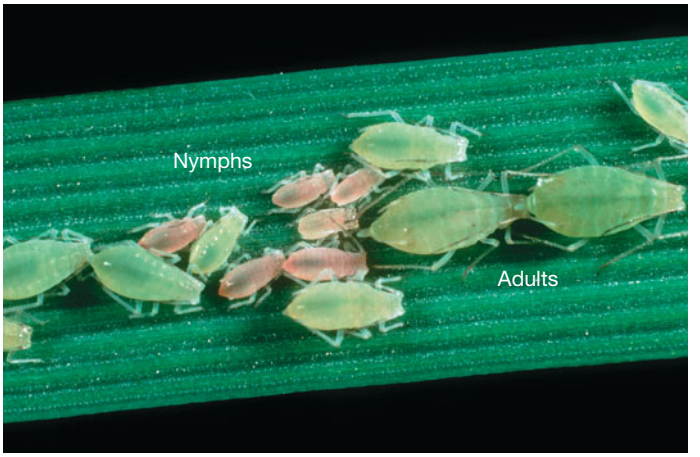
In **hemimetabolous** ("half-change") **metamorphosis**—also called **incomplete metamorphosis**—juveniles called nymphs look like miniature versions of the adult. The aphid nymphs in **FIGURE 34.24a**, for example, shed their external skeletons several times and grow—gradually changing from wingless, sexually immature nymphs to sexually mature adults, some of which can fly. But throughout their life, aphids live in the same habitats and feed on the same food source in the same way: They suck sap.

In **holometabolous** ("whole change") **metamorphosis**—also called **complete metamorphosis**—there is a distinct larval stage. As an example, consider the life cycle of the mosquito, illustrated in **FIGURE 34.24b**:

1. Newly hatched mosquitoes live in quiet bodies of freshwater, where they suspension feed on bacteria, algae, and detritus.
2. When a larva has grown sufficiently, the individual stops feeding and moving and secretes a protective case. The individual is now known as a **pupa** (plural: pupae). During pupation, the pupa's body is completely remodeled into a new, adult form.
3. The adult mosquito flies and feeds—females take blood meals from mammals and males drink nectar from flowers.

What Is the Adaptive Significance of Metamorphosis? In insects, holometabolous metamorphosis is 10 times more common than hemimetabolous metamorphosis. How can this be explained?

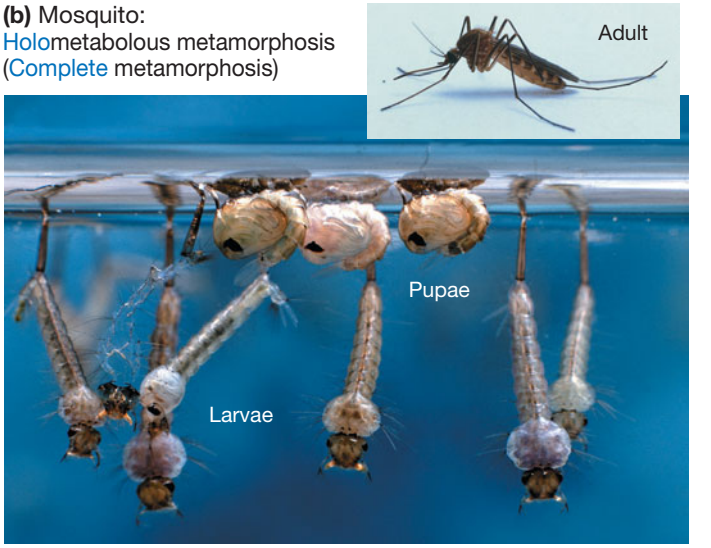
Since most adult insects are mobile, using a larval stage for dispersal does not seem to be a sufficient explanation. The leading hypothesis is based on efficiency in feeding. Because juveniles and adults from holometabolous species feed on different materials in different ways and sometimes even in different habitats, they do not compete with each other.



An alternative hypothesis is based on the advantages of functional specialization. In many moths and butterflies, larvae are specialized for feeding, whereas adults are specialized for mating and feed rarely, if ever. Larvae are largely sessile, whereas adults are highly mobile. If specialization leads to higher efficiency in feeding and reproduction and thus higher fitness, then holometabolous metamorphosis would be advantageous. These hypotheses are not mutually exclusive, however—meaning that both could be correct, depending on the species being considered.

Let's explore the diversity of feeding, moving, and reproducing habits of ecdysozoans in more depth by examining the key lineages separately.

Key Lineages: Ecdysozoans



Seven phyla are currently recognized in the Ecdysozoa (see Table 33.1). Second in diversity to Arthropoda, the phylum Nematoda, or roundworms, is especially noteworthy due to its large number of described species and the mind-boggling abundance of individuals. Of the smaller phyla, Onychophora (*on-ee-KOFF-er-uh*) and Tardigrada are of special interest due to their close relationship to arthropods. They are similar to arthropods

(a) Aphid:
Hemimetabolous metamorphosis
(Incomplete metamorphosis)

Nymphs look like miniature versions of adults and eat the same foods.

(b) Mosquito:
Holometabolous metamorphosis
(Complete metamorphosis)

Larvae look substantially different from adults and eat different foods.

FIGURE 34.24 Insect Metamorphosis Can Be Incomplete or Complete.

(a) Onychophorans are called velvet worms.

Peripatus species

(b) Tardigrades are called water bears.

Echiniscus species

FIGURE 34.25 Onychophorans and Tardigrades Have Lobe-Shaped Limbs with Claws. The scanning electron micrograph in part (b) has been colorized.

in having a segmented body and limbs. Unlike arthropods, they do not have an exoskeleton and their limbs are not jointed.

The onychophorans, or velvet worms, are small, caterpillar-like organisms that live in moist leaf litter and prey on small invertebrates. Onychophorans have lobe-shaped appendages and segmented bodies with a hemocoel (**FIGURE 34.25a**).

The tardigrades, or water bears, are microscopic animals that live in diverse marine, freshwater, and terrestrial environments, such as in the film of water that covers plants in moist habitats. Tardigrades have a reduced coelom but a prominent hemocoel, and they walk on their clawed, lobe-shaped legs (**FIGURE 34.25b**). Most feed by sucking fluids from plants or animals; others are detritivores, feeding on dead organic matter.

Although the phylogeny of arthropods is still being worked out, most data agree that the phylum as a whole is monophyletic. However, the relationships of lineages within the phylum are currently undergoing a major revision. Insects and myriapods have long been considered sister groups within the arthropods, due in part to their unbranched appendages. However, recent molecular phylogenetic studies—as well as comparisons of new morphological data, developmental data, and evidence in the fossil record—provide strong support for the placement of the insect clade *within* the crustacean lineage, making the crustaceans paraphyletic. It appears that crustaceans successfully invaded land as insects.

In the following exploration of ecdysozoan diversity, insects are described in a separate box, following tradition. However, the revised relationship between insects and crustaceans is then illustrated in the Crustacea box:

- Ecdysozoans > Nematoda (Roundworms)
- Ecdysozoans > Arthropoda > Myriapoda (Millipedes, Centipedes)
- Ecdysozoans > Arthropoda > Insecta (Insects)
- Ecdysozoans > Arthropoda > Crustacea (Shrimp, Lobsters, Crabs, Barnacles, Isopods, Copepods)
- Ecdysozoans > Arthropoda > Chelicerata (Sea Spiders, Horseshoe Crabs, Daddy Longlegs, Mites, Ticks, Scorpions, Spiders)

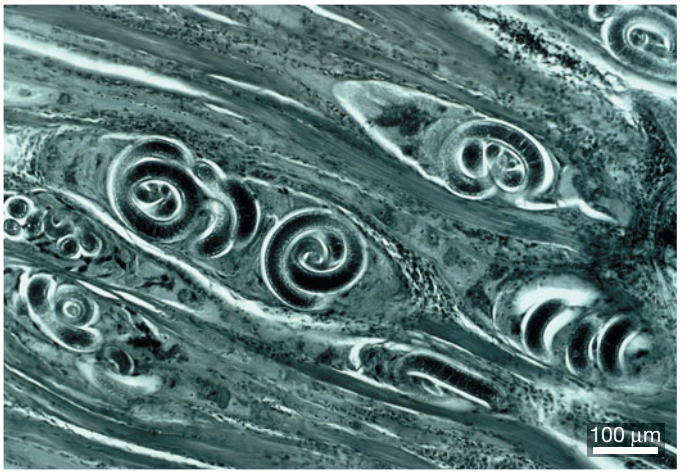
Species in the phylum Nematoda are commonly called **roundworms** or **nematodes.** Roundworms are unsegmented worms with a pseudocoelom, a tube-within-a-tube body plan, no appendages, and a thick, elastic cuticle that must be molted during growth. Although some nematodes can grow to lengths of several meters, most species are tiny—much less than 1 mm long. They lack specialized systems for exchanging gases and for circulating nutrients. Instead, gas exchange occurs across the body wall, and once ingested, nutrients move by simple diffusion from the gut to other parts of the body.

The nematode *Caenorhabditis elegans* is one of the most thoroughly studied model organisms in biology (see **BioSkills 13** in Appendix B). Species that parasitize humans have also been studied intensively. Pinworms, for example, infect about 40 million people in the United States alone, and *Onchocerca volvulus* causes an eye disease that infects around 20 million people in Africa and Latin America. Advanced infections by the roundworm *Wuchereria bancrofti* result in the blockage of lymphatic vessels, causing fluid accumulation and massive swelling—the condition known as elephantiasis. The potentially fatal disease trichinosis is caused by species in the genus *Trichinella.* The parasites are passed from infected animals to humans by ingesting raw or undercooked meat. An array of symptoms results, including discomfort caused by *Trichinella* larvae encasing themselves in cysts within muscle or other types of tissue (**FIGURE 34.26a**).

A recent phylogenetic analysis of the nematodes has produced an interesting insight: Convergent morphological evolution appears to be extensive. Animal parasitism and plant parasitism both arose several times in different lineages of nematodes. Thus, some nematodes that look very similar and fill a very similar ecological role may be distantly related.

Parasites represent a relatively small fraction of the nematode species that have been described to date, however. The free-living nematodes are important ecologically because they are found in virtually every habitat known (**FIGURE 34.26b**).

While around 25,000 species of roundworms have been named, the actual total may be over a million. Nematodes are also fabulously abundant. Biologists have found 90,000 roundworms in a single rotting apple and have estimated that rich farm soils contain up to 9 billion roundworms per acre. Although they are not the most species-rich animal group, they are among the most abundant. The simple nematode body plan has been extraordinarily successful.



Feeding Roundworms feed on a wide variety of materials, including bacteria, fungi, plant roots, small protists or animals, or detritus. In most cases, the structure of their mouthparts is specialized in a way that increases the efficiency of feeding on a particular type of organism or material.

Movement Roundworms move with the aid of their hydrostatic skeleton. They have no muscles that can change the diameter of the body—their body musculature consists solely of longitudinal muscles that bend the stiff body laterally. ✔ **You should be able to indicate the loss of circumferential muscles on Figure 34.2.** Most roundworms live in soil or inside a host, so when contractions of their longitudinal muscles cause them to undulate, the movements are resisted by a stiff substrate. As a result, the worm pushes off the substrate, and the body advances.

Reproduction Sexes are separate in most nematode species (but not in *C. elegans*, which is mostly hermaphroditic). Sexual reproduction begins with internal fertilization and culminates in egg laying and the direct development of offspring. Individuals go through a series of four molts over the course of their lifetime.

(a) Parasitic larvae encysted in muscle tissue

Trichinella spiralis

(b) Most nematodes are free living.

Caenorhabditis elegans

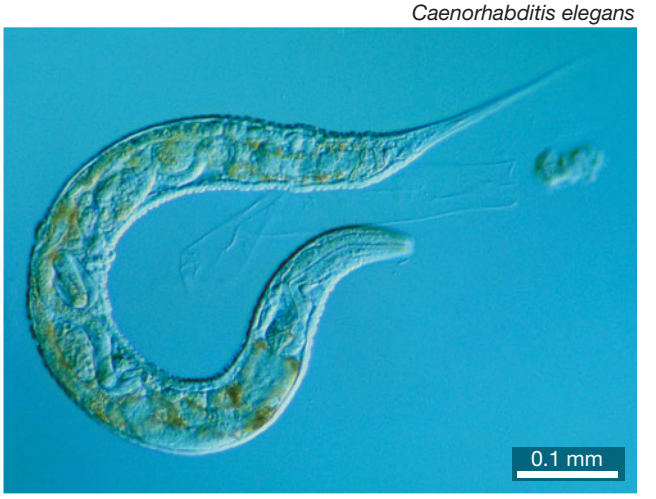


FIGURE 34.26 Some Nematodes Are Parasites, but Most Are Free Living.

Ecdysozoans > Arthropoda > Myriapoda (Millipedes, Centipedes)

The **myriapods** have relatively simple bodies, with a head region and a long trunk featuring a series of segments, each bearing one or two pairs of legs (**FIGURE 34.27**). If eyes are present, they consist of a few to many simple structures clustered on the sides of the head. The 16,000 species that have been described to date inhabit terrestrial environments all over the world.

Feeding Millipedes and centipedes have mouthparts that can bite and chew. These organisms live in rotting logs and other types of dead plant material that litters the ground in forests and grasslands. Millipedes are detritivores. Centipedes, in contrast, use a pair of poison-containing fangs just behind the mouth to hunt an array of insects. Large centipedes, with lengths up to 30 cm, can inject enough poison to debilitate a human.

Movement Myriapods walk or run on their many legs; a few species burrow. Some millipedes have over 190 trunk sections, each with two pairs of legs, for a total of over 750 legs. Centipedes usually have fewer than 30 segments, with one pair of legs per segment.

Reproduction Myriapod sexes are separate, and fertilization is internal. Males deposit sperm in packets that are picked up by the female or transferred to her by the male. After females lay eggs in the environment, the eggs hatch into juveniles that develop into adults via a series of molts.

Scolopendra species

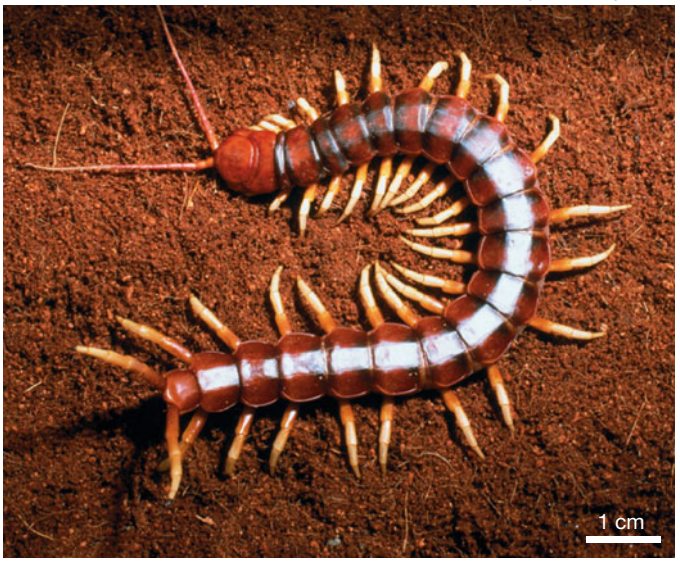

FIGURE 34.27 Myriapods Have One or Two Pairs of Legs on Each Body Segment.

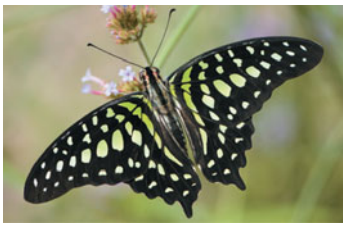
Ecdysozoans > Arthropoda > Insecta (Insects)

About one million species of insects have been named thus far, but it is certain that many more exist. In terms of species diversity and numbers of individuals, insects dominate terrestrial environments. In addition, the larvae of some species are common in freshwater streams, ponds, and lakes. **TABLE 34.1** (see page 676) describes seven of the most prominent orders of insects. The fruit fly *Drosophila melanogaster,* in the order Diptera, is one of the most thoroughly studied model organisms in biology (see **BioSkills 13** in Appendix B).



Insects are distinguished by having three tagmata—the head, **thorax,** and **abdomen** (see Figure 34.21). Three pairs of walking legs are mounted on the lateral surface of the thorax. Most species have one or two pairs of wings, mounted on the dorsal (back) side of the thorax. Typically the head contains four mouthpart structures, a pair of slender **antennae** that are used to touch and smell, and a pair of compound eyes. A **compound eye** contains many lenses, each associated with a light-sensing, columnar structure (see Chapter 47). (Human and cephalopod eyes are **simple eyes,** meaning they have just one lens.)

Feeding Most insect species have four mouthpart structures (labrum, paired mandibles, paired maxillae, and labium), which have diversified in structure and function in response to natural selection. As a result, insects are able to feed in every conceivable manner and on almost every type of food source available on land. In species with complete (holometabolous) metamorphosis, larvae have wormlike bodies; most tunnel their way through food sources, though some feed by biting leaves. Adults, however, are predators or parasites on plant or animal tissues. Thus, diversification in food sources occurs even within species. Because so many insects make their living by feeding on plant tissues or fluids, the diversification of insects was closely correlated with the diversification of land plants.

Movement Insects use their legs to walk, run, jump, or swim, or they use their wings to fly. When insects walk or run, the sequence of movements usually results in three of their six legs maintaining contact with the ground at all times.

Reproduction Insect sexes are separate, and sexual reproduction is the norm. Mating usually takes place through direct copulation; the male inserts a sperm-transfer organ into the female. Most females lay eggs, but in a few species eggs are retained until hatching. Many species are also capable of reproducing asexually through parthenogenesis, the production of unfertilized eggs via mitosis. Complete metamorphosis is far more common than incomplete metamorphosis.

TABLE 34.1 Prominent Orders of Insects

	Order	Description
	**Coleoptera** ("sheath-winged") Beetles 360,000 known species	**Key traits:** Hardened forewings, called elytra, protect the membranous hindwings that power flight and act as stabilizers. **Feeding:** Adults are important predators and scavengers. Larvae are called grubs and often have chewing mouthparts. **Life Cycle:** All have complete metamorphosis. **Notes:** The most species-rich lineage on the tree of life—about 25 percent of all described species are beetles.
	**Lepidoptera** ("scale-winged") Butterflies, moths 180,000 known species	**Key traits:** Wings are covered with tiny, often colorful scales. The forewings and hindwings often hook together and move as a unit. **Feeding:** Larvae usually have chewing mouthparts and either bore through food material or bite leaves; adults often feed on nectar. **Life Cycle:** All have complete metamorphosis. **Notes:** Some species migrate long distances.
	**Diptera** ("two-winged") Flies (including mosquitoes, gnats, midges) 150,000 known species	**Key traits:** Reduced hindwings, called halteres, act as stabilizers during flight. **Feeding:** Adults are usually liquid feeders; many larvae are maggots, which may be parasitic or feed on rotting material. **Life Cycle:** All have complete metamorphosis. **Notes:** The first flies in fossil record appear 240 million years ago.
	**Hymenoptera** ("membrane-winged") Ants, bees, wasps 115,000 known species	**Key traits:** Membranous forewings and hindwings lock together. **Feeding:** Most ants feed on plant material; most bees feed on nectar; wasps are predatory and often have parasitic larvae. **Life Cycle:** All have complete metamorphosis. Males are haploid (they hatch from unfertilized eggs) and females are diploid (they hatch from fertilized eggs). Larvae are cared for by adults. **Notes:** Most species live in colonies, and many are eusocial.
	**Hemiptera** ("half-winged") Bugs (including leaf hoppers, aphids, cicadas, scale insects) 85,000 known species	**Key traits:** Some have a thickened forewing with a membranous tip. Mouthparts are modified for piercing and sucking. **Feeding:** Most suck plant juices, but some are predatory. **Life Cycle:** All have incomplete metamorphosis. **Notes:** Called "half-winged" because the forewings of some bugs are hardened near the bases but membranous near the tips.
	**Orthoptera** ("straight-winged") Grasshoppers, crickets 25,000 known species	**Key traits:** Large, muscular hind legs enable jumping. **Feeding:** Most have chewing mouthparts and are leaf eaters. **Life Cycle:** All have incomplete metamorphosis. **Notes:** In many species, males give distinctive songs to attract mates. They produce sound by rubbing their wings against their legs or against each other, a process called stridulation.
	**Odonata** ("toothed") Dragonflies, damselflies 6,500 known species	**Key traits:** Four membranous wings and long, slender abdomens. **Feeding:** Larvae and adults are predatory, often on flies. The "odon" refers to strong, toothlike structures on their mandibles. **Life Cycle:** All have complete metamorphosis: Nymphs are aquatic, adults are terrestrial. **Notes:** They hunt by sight and have reduced antennae (used for touch and smell) but enormous eyes with up to 28,000 lenses.

The 47,000 species of **crustaceans** that have been identified to date live primarily in marine and freshwater environments; they are the most diverse arthropods of the sea. A few species of crab and some isopods (known as sowbugs and pillbugs) are terrestrial, however, and recent phylogenetic evidence suggests that the insects represent a highly successful branch of terrestrial crustaceans (**FIGURE 34.28**). (For the purpose of describing diversity here, insects are covered separately on the previous page.)

Crustaceans—especially the planktonic copepods—are common in surface waters around the world, where they are important consumers. Crustaceans are also important grazers and predators in shallow-water benthic environments.

The segmented body of most crustaceans is divided into two distinct regions, or tagmata: (1) the cephalothorax, which combines the head and thorax, and (2) the abdomen. Many crustaceans have a **carapace**—a platelike section of their exoskeleton that covers and protects the cephalothorax (**FIGURE 34.29**). They are the only type of arthropod with two pairs of antennae, and have sophisticated, compound eyes—usually mounted on stalks. Crustacean appendages are usually branched (insect appendages are unbranched). Other than trilobites—a major arthropod lineage that did not survive the end-Permian mass extinction, 250 million years ago (Chapter 28)—crustaceans were the first arthropods to appear in the fossil record. The tiny ostracods (seed shrimp) have a particularly rich fossil record dating back to the Cambrian.

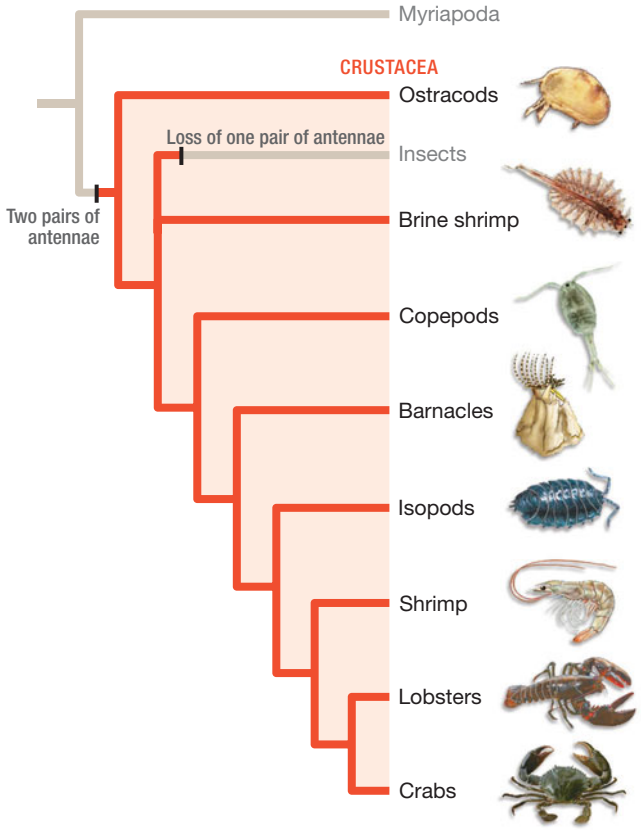


FIGURE 34.28 Phylogeny of the Major Groups of Crustaceans. This phylogeny illustrates the current hypothesis that insects are a terrestrial clade within the crustaceans, overturning traditional classification (which is nonetheless still in widespread use due to its long history).

Feeding Most crustaceans have 4–6 pairs of mouthparts that are derived from jointed appendages, and as a group they use every type of feeding strategy known. Barnacles and many shrimp are suspension feeders that use feathery structures located on head or body appendages to capture prey. Crabs and lobsters are active hunters, herbivores, and scavengers. Typically they have a pair of mouthparts called **mandibles** that bite or chew. Individuals capture and hold their food source with claws or other feeding appendages and then use their mandibles to shred the food into small bits that can be ingested.

Movement Crustaceans typically have many pairs of limbs with diverse forms and functions, including claws, paddle-shaped forms used in swimming, feathery structures used in capturing food that is suspended in water, and slender legs that make sophisticated walking or running movements possible (see Figure 34.22). Barnacles are one of the few types of sessile crustaceans. Adult barnacles cement their heads to a hard substrate, secrete a protective shell of calcium carbonate, and use their feathery legs to capture food particles and transfer them to the mouth.

Reproduction Most individual crustaceans are either male or female, and sexual reproduction is the norm. Fertilization is usually internal, and eggs are typically retained by the female until they hatch. Most crustaceans pass through several distinct larval stages; many species include a larval stage called a **nauplius,** which is usually planktonic. A nauplius has a single eye and appendages that develop into the two pairs of antennae, the mouthparts, and walking/swimming legs of the adult.

Cherax quadricarinatus

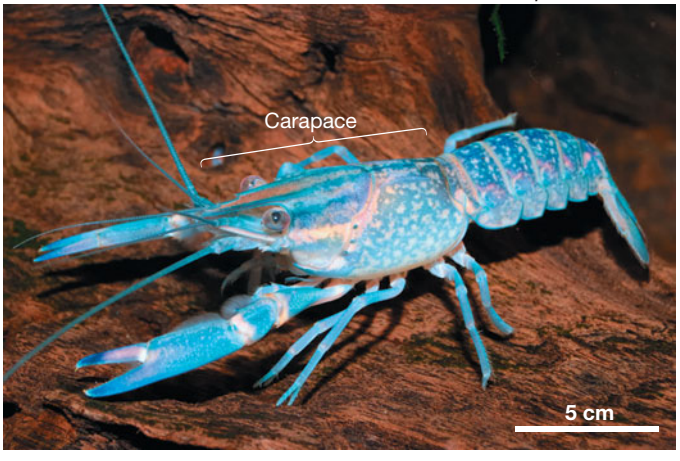

FIGURE 34.29 Crustaceans Have Two Tagmata: A Cephalothorax and an Abdomen. The carapace protects the cephalothorax (literally "head-chest").

The most prominent lineage within the Chelicerata is the Arachnida, including spiders, scorpions, ticks, mites and daddy longlegs (**FIGURE 34.30**). Most of the 100,000 species of chelicerates are terrestrial, but the horseshoe crabs and sea spiders are marine.

The chelicerate body consists of 2 tagmata, the cephalothorax (prosoma) and abdomen (opisthosoma), and 6 pairs of appendages (**FIGURE 34.31**). The cephalothorax lacks antennae for sensing touch or odor but usually contains eyes. The group is named for a pair of appendages called **chelicerae,** found near the mouth. Depending on the species, the chelicerae are used in feeding, defense, copulation, movement, or sensory reception. In addition to 4 pairs of legs and 1 pair of chelicerae, chelicerates also have a pair of pedipalps, which can be used for diverse functions.

Feeding Spiders, scorpions, and daddy longlegs capture insects or other prey. Although some of these species are active hunters that rove around in search of prey, most spiders are sit-and-wait predators that either pounce on prey that wander near, or that create sticky webs to capture prey. In this case, the spider senses the vibrations of the struggling prey on the web, pounces on it, and administers a toxic bite. Regardless of the mode of capture, spiders generally consume their meals in soup form—they secrete digestive enzymes into the prey to enable digestion to begin externally, then drink up the nutritious liquid. Often all that remains of the prey is an empty exoskeleton.

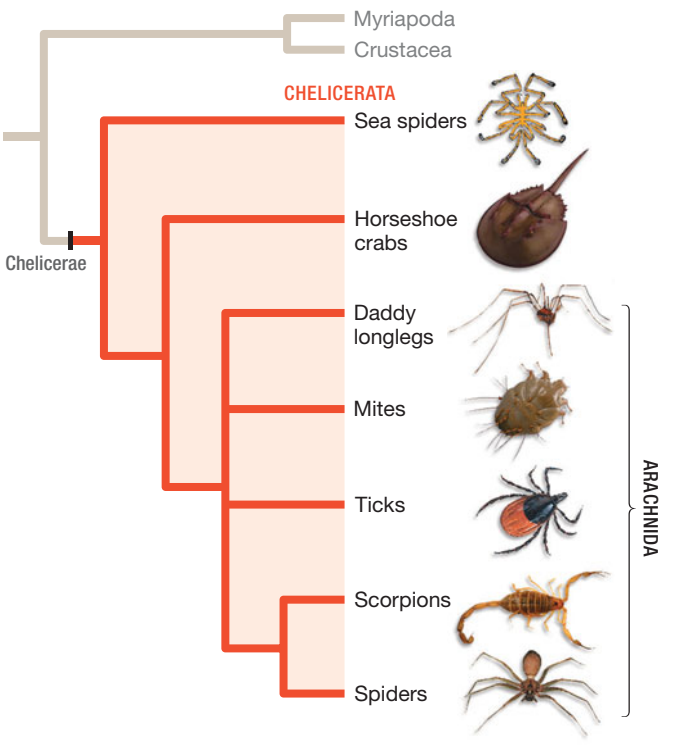

FIGURE 34.30 Phylogeny of the Major Groups of Chelicerates.

Mites and ticks are ectoparasitic and use their piercing mouthparts to feed on host animals or, in the case of dust mites, on their hosts' dead skin. Horseshoe crabs eat a variety of animals as well as algae and detritus. Most scorpions feed on insects; the largest scorpion species occasionally eat snakes and lizards. Although the venom of scorpion stings is an effective defense against predators, it is primarily used to kill or paralyze prey.

Movement Like other arthropods, chelicerates move with the aid of muscles attached to an exoskeleton. They walk or crawl on their four pairs of jointed walking legs; some species are also capable of jumping. Horseshoe crabs and some other marine forms can swim slowly. Newly hatched spiders spin long, silken threads that serve as balloons and that can carry them on the wind more than 400 kilometers from the point of hatching.

Reproduction Sexual reproduction is the rule in chelicerates, and fertilization is internal in most groups. Courtship displays are extensive in many chelicerates and may include both visual displays and the release of chemical odorants. In spiders, males may present a dead insect as a gift that the female eats as the pair mates; in some species, the male himself is eaten as sperm is being transferred—the longer the meal lasts, the more successful the sperm transfer. Males use pedipalps to transfer sperm to females. These organs fit into the female reproductive tract in a "lock-and-key" fashion. Differences in the size and shape of male genitalia are often the only way to identify closely related species of spider.

Development in chelicerates is direct, meaning that larval forms and metamorphosis do not occur. In scorpions, females retain fertilized eggs. After the eggs hatch, the young climb on the mother's back. They remain there until they are old enough to hunt for themselves.

Holconia immanis

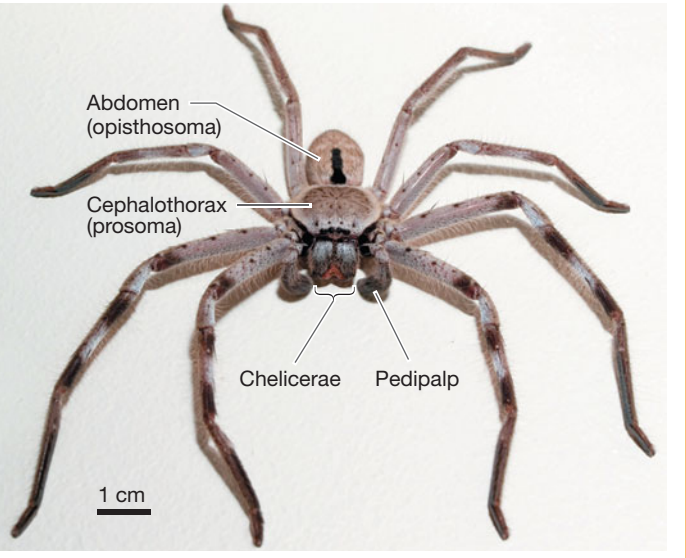

FIGURE 34.31 Chelicerates Have Chelicerae and Two Tagmata.

If you understand . . .

34.1 What Is a Protostome?

- Molecular evidence supports the hypothesis that protostomes are a monophyletic group divided into two major subgroups: the Lophotrochozoa and the Ecdysozoa.
- All protostomes are bilaterally symmetric and triploblastic, but the coelom has been reduced or lost in several phyla.
- Protostomes diversified in their methods of sensing their environments, feeding, moving, reproducing, and developing.
- The transition to living on land occurred several times independently during the evolution of protostomes, opening new habitats and driving diversification. The transition was facilitated by watertight shells and exoskeletons, the evolution of specialized structures to minimize water loss and manage gas exchange, and the ability to move to moist locations.
- Many protostome body plans are highly modular due to the underlying expression patterns of developmental tool-kit genes.

✔ **You should be able to explain how both ecological opportunity and genetic opportunity were important in the diversification of protostomes.**

34.2 What Is a Lophotrochozoan?

- Lophotrochozoans grow incrementally. Some phyla have characteristic feeding structures called lophophores, and many have a distinctive type of larvae called trochophores. Spiral cleavage is a synapomorphy for the group but was modified or lost in some phyla.
- Mollusks, annelids, and flatworms are the most diverse phyla within the Lophotrochozoa. All three phyla made the water-to-land transition.
- The mollusk body plan includes a muscular foot, a visceral mass, and a mantle. These components diversified in many ways, enabling mollusks to occupy most aquatic, and some terrestrial, habitats.

✔ **You should be able to explain why the absence of a trait known to be found in a clade, such as a trochophore larva, spiral cleavage, or a coelom, does not necessarily exclude a species from that clade.**

34.3 What Is an Ecdysozoan?

- Species in the Ecdysozoa grow by molting—meaning that they shed their old external covering and grow a new, larger one.
- Arthropods and nematodes are the most diverse phyla within the Ecdysozoa. A majority of animals on Earth are arthropods.
- The arthropod body plan is segmented and protected by an exoskeleton made primarily of chitin. Appendages are jointed. The diversification of arthropod body plans is based on variation in the number and functional specialization of segments.
- Complete (holometabolous) metamorphosis enables larvae and adults to specialize, creating opportunities for diversification.
- Crustaceans are the most diverse group of arthropods in the sea, and insects are the most diverse group on land. (Recent data suggest that insects are a terrestrial subgroup of Crustacea.)

✔ **You should be able to compare modularity in arthropod body plans with modularity in vertebrates.**

TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. **True or false?** The transition from water to land reduced protostome diversity.
2. What is a lophophore?
   a. a specialized filter-feeding structure
   b. the single opening in species with a blind gut
   c. a distinctive type of larva with a band of cilia
   d. a synapomorphy that defines lophotrochozoans
3. What is the function of the arthropod exoskeleton?
   a. Because hard parts fossilize more readily than do soft tissues, the presence of an exoskeleton has given arthropods a good fossil record.
   b. It has no well-established function. (Trilobites had an exoskeleton, and they went extinct.)
   c. It provides protection and functions in locomotion.
   d. It makes growth by molting possible.

4. Why is it logical that Platyhelminthes have flattened bodies?
   a. They have simple bodies and evolved early in the diversification of protostomes.
   b. They lack a coelom, so their body cannot form a rounded tube-within-a-tube design.
   c. A flat body provides a large surface area for gas exchange, which compensates for their lack of gas-exchange organs.
   d. They are sit-and-wait predators that hide from passing prey by flattening themselves against the substrate.

5. One trait that is shared by the Lophotrochozoa and Ecdysozoa is_____.

6. Which protostome phylum is distinguished by having body segments organized into tagmata?
   a. Mollusca
   b. Arthropoda
   c. Annelida
   d. Nematoda

TEST YOUR UNDERSTANDING

Answers are available in Appendix A

7. **QUANTITATIVE** Put the following phyla in order from least diverse (in terms of number of named species) to most diverse: Annelida, Mollusca, Arthropoda, Rotifera.
   a. Annelida, Rotifera, Mollusca, Arthropoda
   b. Mollusca, Rotifera, Annelida, Arthropoda
   c. Rotifera, Annelida, Arthropoda, Mollusca
   d. Rotifera, Annelida, Mollusca, Arthropoda

8. Predict why annelids and arthropods were thought to be closely related, before the phylogenetic analyses in the late 1990s.

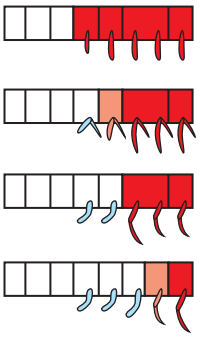
9. Pose a hypothesis to explain why a larval stage is adaptive in clams. How could you test your hypothesis?

10. Use your understanding of protostome evolution to predict two adaptations for terrestrial living that occurred in land plants.

11. Pose a hypothesis to explain why the evolution of the wing was such an important event in the evolution of insects.

12. Propose a scenario wherein hemimetabolous metamorphosis would be adaptive.

TEST YOUR PROBLEM-SOLVING SKILLS



Answers are available in Appendix A

13. Recall that the phylum Platyhelminthes includes three major groups: the free-living turbellarians, the parasitic cestodes, and the parasitic trematodes. Because the parasitic forms are so simple morphologically, researchers suggest that they are derived from more complex, free-living forms. Draw a phylogeny of Platyhelminthes that would support the hypotheses that ancestral flatworms were morphologically complex, free-living organisms and that parasitism is a derived condition.

14. Brachiopoda is a phylum within the Lophotrochozoa. Even though they are not closely related to mollusks, brachiopods look and act like bivalve mollusks (clams or mussels). Specifically, brachiopods suspension feed, live inside calcium carbonate shells with two valves that hinge together in some species, and attach to rocks or other hard surfaces on the ocean floor. How is it possible for brachiopods and bivalves to be so similar if they did not share a recent common ancestor?

15. The Mollusca includes a group of about 370 wormlike species called the Aplacophora. Although aplacophorans do not have a shell, their cuticle secretes calcium carbonate scales or spines. They lack a well-developed foot, and some species have a simple radula. They are mostly carnivores and detritivores in the deep sea. The reduced forms of several molluscan synapomorphies suggest that they are ancestral to other mollusks—that is, the earliest group to branch off in the molluscan phylogeny. Evaluate this hypothesis. How could you test it?

16. Examine the figure below summarizing the expression of *Ubx-AbdA Hox* genes (colored red) in different body segments during early development in four crustaceans. The blue appendages represent a novel type of feeding appendage called a maxilliped. Which statement best summarizes the data?

   a. Maxillipeds were lost in segments where *Ubx-AbdA* genes were expressed.
   b. Maxillipeds arose in segments where *Ubx-AbdA* genes were no longer expressed.
   c. Maxillipeds arose in segments where *Ubx-AbdA* genes were expressed.
   d. The presence of maxillipeds does not correlate with the pattern of *Ubx-AbdA* gene expression.

35 Deuterostome Animals

In this chapter you will learn that

Deuterostomes include the largest and most complex animals on Earth

- by asking: What is an echinoderm? 35.1
- by asking: What is a chordate? 35.2
  - then asking: What is a vertebrate? 35.3
    - then examining: The primates and hominins 35.4

In most habitats the "top predators"—animals that prey on other animals and aren't preyed upon themselves—are deuterostomes.

The **deuterostomes** include the largest-bodied and some of the most morphologically complex of all animals. They range from the sea stars that cling to dock pilings to the fish that dart in and out of coral reefs to the wildebeests that migrate across the Serengeti Plains of East Africa.

The deuterostomes were initially grouped together because they all undergo early embryonic development in a similar way. When a humpback whale, sea urchin, or human is just beginning to grow, the gut starts developing from posterior to anterior—the anus forms first and the mouth second. A coelom, if present, develops from outpocketings of mesoderm (see Chapter 33).

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

More recently, phylogenies based on molecular evidence have confirmed the monophyly of the deuterostomes. Today, most biologists recognize four deuterostome phyla: the Echinodermata, Hemichordata, Xenoturbellida, and Chordata (**FIGURE 35.1**):

- The echinoderms include the sea stars and sea urchins.
- The hemichordates, or "acorn worms," burrow in marine sands or muds and make their living by deposit feeding or suspension feeding.
- A lone genus with two wormlike species, called *Xenoturbella,* was recognized as a distinct phylum in 2006. The phylogenetic placement of these small, ciliated animals has been debated by scientists for years.
- The chordates include the **vertebrates,** or animals with backbones. The vertebrates, in turn, comprise the hagfish, lampreys, sharks and rays, bony fishes, amphibians, mammals, and reptiles (including birds).

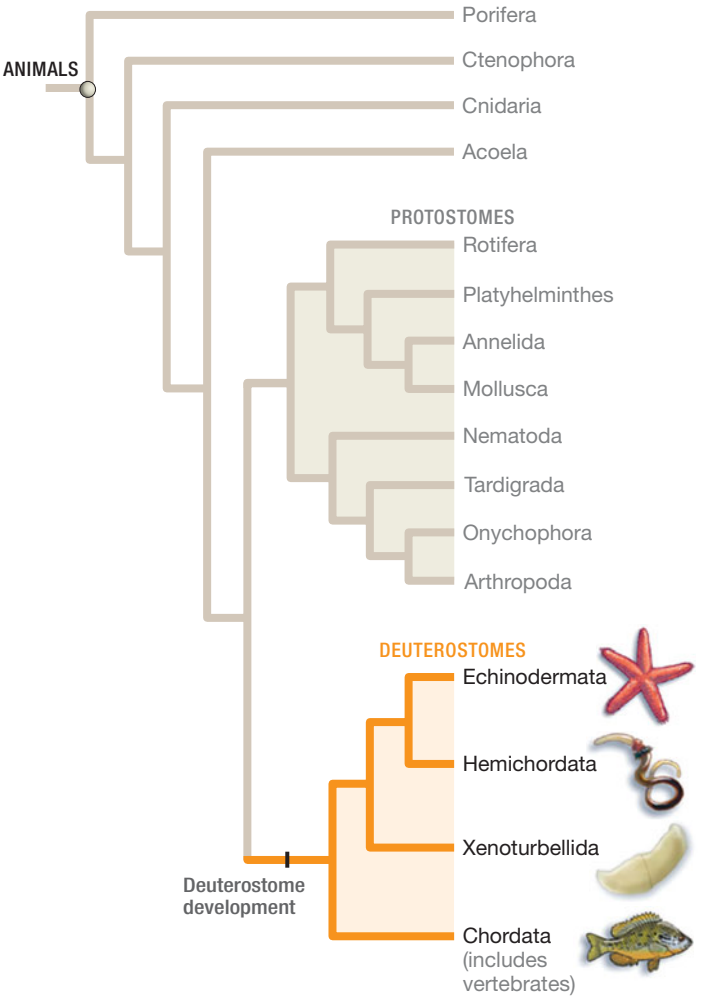


FIGURE 35.1 There Are Four Phyla of Deuterostomes. Vertebrates are in the phylum Chordata.

✔ **QUESTION** Are invertebrates monophyletic or paraphyletic? (Hint: See Table 28.2 if you need help.)

Animals that are not vertebrates are collectively known as **invertebrates.** Over 95 percent of the known animal species are invertebrates—but the vertebrates dominate the deuterostomes.

Although deuterostomes share important features of embryonic development, their adult body plans and their feeding methods, modes of locomotion, and reproductive strategies are highly diverse. This chapter explores deuterostome diversity by introducing the echinoderms and chordates and then taking a more in-depth look at the vertebrates and our own closest ancestors: the hominins.

35.1 What Is an Echinoderm?

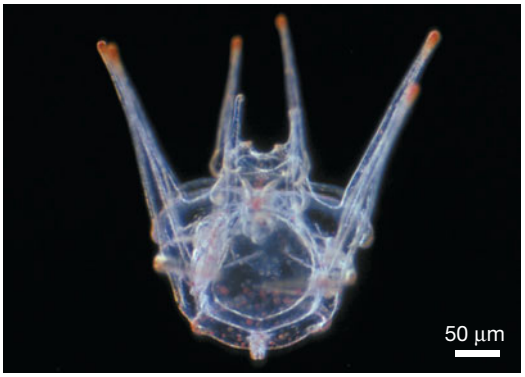
The echinoderms (literally, "spiny-skins") were named for the spines or spikes observed in many species. Echinodermata is a large and diverse phylum but is exclusively marine.

In numbers of species and range of habitats occupied, echinoderms are the second-most successful lineage of deuterostomes—next to the vertebrates. To date, biologists have cataloged about 7000 species of echinoderms.

Echinoderms are also abundant. In some deepwater environments, species in this phylum represent 95 percent of the total mass of organisms.

How are these animals put together?

The Echinoderm Body Plan



All deuterostomes are considered bilaterians, because they evolved from an ancestor that was bilaterally symmetric (see Chapter 33). Echinoderm larvae are also bilaterally symmetric (**FIGURE 35.2a**). But a remarkable event occurred early in the evolution of **echinoderms:** the origin of five-sided radial symmetry, called pentaradial symmetry, in adults (**FIGURE 35.2b**).

Radially symmetric animals do not have heads (Chapter 33). As a result, they tend to interact with the environment in all directions at once instead of facing the environment in one direction. Adult echinoderms that are capable of movement tend to move equally well in all directions.

A second noteworthy feature of the echinoderm body is its **endoskeleton:** a hard structure, located just inside a thin layer of epidermal tissue, which provides protection and support (shown without skin in Figure 35.2b). As an individual is developing, cells secrete plates of calcium carbonate inside the skin. Depending on the species, the plates may remain independent and result in a flexible structure or fuse into a rigid case. If the plates do not fuse, they are connected by an unusual tissue that can be reversibly stiff or flexible—depending on conditions.

Another remarkable event in echinoderm evolution was the origin of a unique morphological feature: a series of branching, fluid-filled tubes and chambers called the **water vascular system.** In some groups, one of the tubes is open to the exterior where it meets the body wall, so seawater can flow into and out

(a) Echinoderm larvae are bilaterally symmetric.

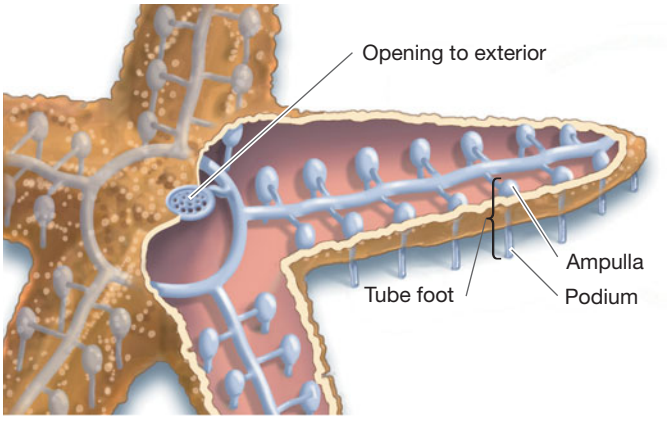
(b) Adult echinoderms are radially symmetric.

FIGURE 35.2 Body Symmetry Differs in Adult and Larval Echinoderms. (a) Bilaterally symmetric sea urchin larva. **(b)** Radially symmetric adult endoskeleton.

of the system. Inside, fluids move via the beating of cilia that line the interior of the tubes and chambers.

FIGURE 35.3a highlights a particularly important part of the water vascular system called tube feet. **Tube feet** are elongated, fluid-filled appendages, each consisting of a balloon-like *ampulla* on the inside of the body and a tube-like *podium* (literally, "foot"; plural *podia*) projecting on the outside (**FIGURE 35.3b**). The water vascular system forms a specialized hydrostatic skeleton that operates the tube feet. As tube feet extend and contract in a coordinated way along the base of an echinoderm, they alternately grab and release the substrate or food source, enabling movement and feeding. Tube feet can also aid in respiration by increasing the surface area of soft tissue exposed to the aquatic environment.

Radial symmetry in adults, an endoskeleton of calcium carbonate, and the water vascular system are all synapomorphies—traits that identify echinoderms as a monophyletic group. (Turn to Chapter 28 and **BioSkills 7** in Appendix B to review how to read phylogenetic trees.)



How Do Echinoderms Feed?

Depending on the lineage and species in question, echinoderms make their living by mass feeding on algae or other animals, suspension feeding, or deposit feeding. In most cases, an echinoderm's tube feet play a key role in obtaining food.

Many sea stars, for example, prey on bivalves. Clams and mussels respond to sea star attacks by contracting muscles that close the two halves of their shell tight. But by clamping onto each half of the shell with their tube feet, making their endoskeleton rigid, and pulling, sea stars are often able to pry the shell apart a few millimeters (**FIGURE 35.4a**, see page 684). Once a gap exists, the sea star extrudes its stomach from its body and forces the stomach through the opening in the bivalve's shell. Upon contacting the visceral mass of the bivalve, the stomach of the sea star secretes digestive enzymes. It then begins to absorb the small molecules released by enzyme action. Eventually, only the shell of the prey remains.

Tube feet are also used in suspension feeding (**FIGURE 35.4b**). In most cases, tube feet are extended out into the water. When food particles contact them, the tube feet flick the food down to cilia, which sweep the particles toward the animal's mouth.

(a) Echinoderms have a water vascular system.

(b) Tube feet project from the underside of the body.

FIGURE 35.3 Echinoderms Have a Water Vascular System. (a) The water vascular system is a series of tubes and chambers that radiates throughout the body, forming a sophisticated hydrostatic skeleton. **(b)** Tube feet aid in movement because they extend from the body and can grab and release the substrate.

(a) Tube feet enable sea stars to get a grip on their prey.

(b) Tube feet enable feather stars to suspension feed.

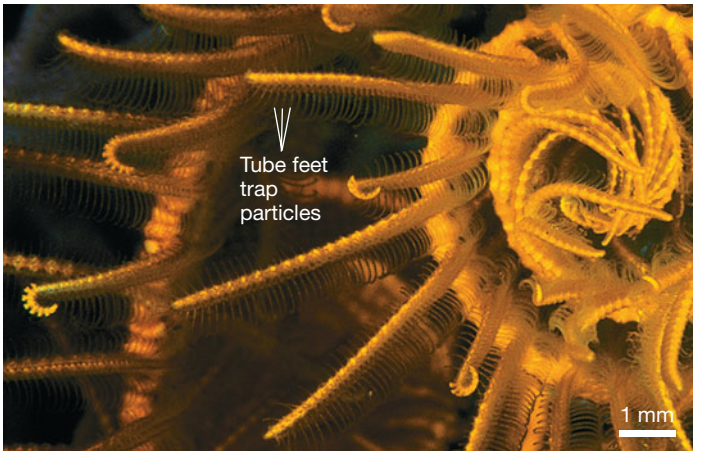


FIGURE 35.4 Echinoderms Use Their Tube Feet in Feeding.

In deposit feeders, tube feet secrete mucus that is used to sop up food material on the substrate. The tube feet then roll the food-laden mucus into a ball and move it to the mouth.

Key Lineages: The Echinoderms

The echinoderms living today make up five major lineages: **(1)** feather stars and sea lilies, **(2)** sea stars, **(3)** brittle stars and basket stars, **(4)** sea urchins and sand dollars, and **(5)** sea cucumbers (**FIGURE 35.5**). ✔ **You should be able to indicate the origin of pentaradial symmetry in adults, the water vascular system, and the echinoderm endoskeleton on Figure 35.5.**

- Most feather stars and sea lilies are sessile suspension feeders.
- Brittle stars and basket stars have five or more long arms that radiate out from a small central disk. They use these arms to suspension feed, deposit feed, or capture small prey animals.
- Sea cucumbers are sausage-shaped animals that suspension feed or deposit feed with the aid of modified tube feet called tentacles that are arranged in a whorl around their mouths.

Sea stars and the sea urchins and sand dollars are described in detail in the two boxes that follow.

- Echinodermata > Asteroidea (Sea Stars)
- Echinodermata > Echinoidea (Sea Urchins and Sand Dollars)

check your understanding

If you understand that . . .

- Echinoderms have a distinctive body plan: pentaradial symmetry in adults, an endoskeleton, and a water vascular system.
- Most echinoderms use their tube feet to move, but they feed in a wide variety of ways—including using their tube feet for mass feeding, suspension feeding, or deposit feeding.

✔ **You should be able to . . .**

Explain how you would determine whether an unidentified animal you encounter along the seashore is an echinoderm.

Answers are available in Appendix A.

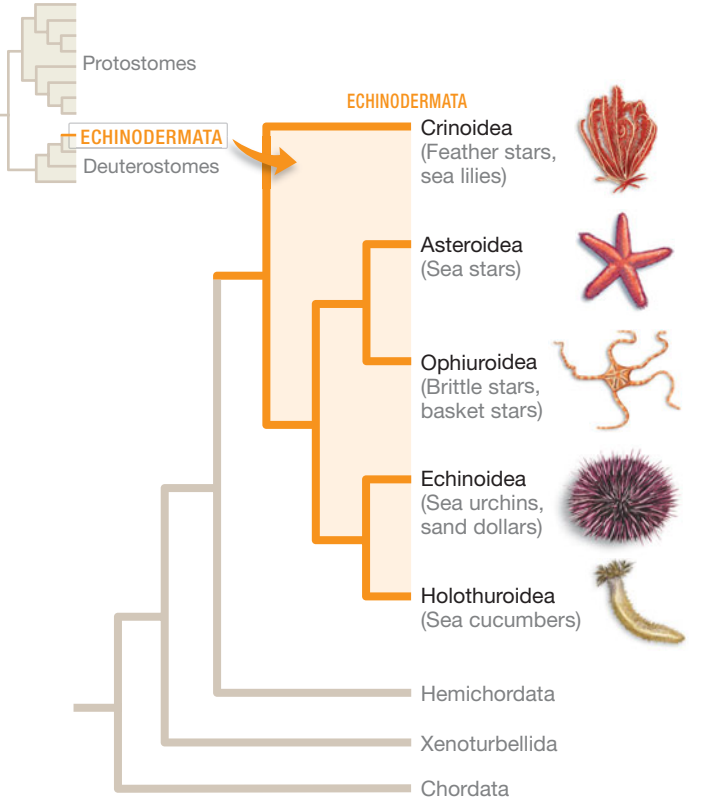

FIGURE 35.5 There Are Five Major Lineages of Echinoderms.

Echinodermata > Asteroidea (Sea Stars)

The 1900 known species of sea stars have bodies with five or more long arms—in some species, up to 40—radiating from a central region that contains the mouth, stomach, and anus (**FIGURE 35.6**). The sea star's arms are not set off from the central region by clear, joint-like articulations, in contrast to their sister group, the brittle stars. ✔ **You should be able to indicate the origin of arms, and the origin of arms that are continuous with the central region, as in sea stars, on Figure 35.5.** When fully grown, sea stars can range in size from less than 1 cm in diameter to 1 m across. They live on hard or soft substrates along the coasts of all the world's oceans. Although the spines that are characteristic of some echinoderms are reduced to knobs on the surface of most sea stars, the crown-of-thorns star and a few other species have prominent, upright, movable spines.

Feeding Sea stars are predators or scavengers. Some species pull bivalves apart with their tube feet and feed by everting their stomach into the prey's visceral mass. In some cases, sea star predation on bivalves opens up habitat for other organisms in the community—increasing biodiversity (see Chapter 55). Sponges, barnacles, and snails are also common prey. The crown-of-thorns sea star specializes in feeding on corals and is native to the Indian Ocean and western Pacific Ocean. Its population has skyrocketed recently—possibly because people are harvesting the sea star's major predator, a large snail called the triton, for its shell. Large crown-of-thorns star populations have led to the destruction of large areas of coral reef.

Movement Sea stars crawl with the aid of their tube feet.

Reproduction Sexual reproduction predominates in sea stars, and sexes are separate. At least one sea star arm in each individual is filled with reproductive organs that produce massive amounts of gametes—millions of eggs per female in some species. Some species care for their offspring by holding fertilized eggs on their body until the eggs hatch. Larvae are long-lived and may spend weeks or months in the plankton, possibly dispersing thousands of kilometers. Most sea stars are capable of regenerating arms that are lost in predator attacks or storms. Some species can reproduce asexually by dividing the body in two; each of the two individuals then regenerates the missing half.

Crossaster papposus

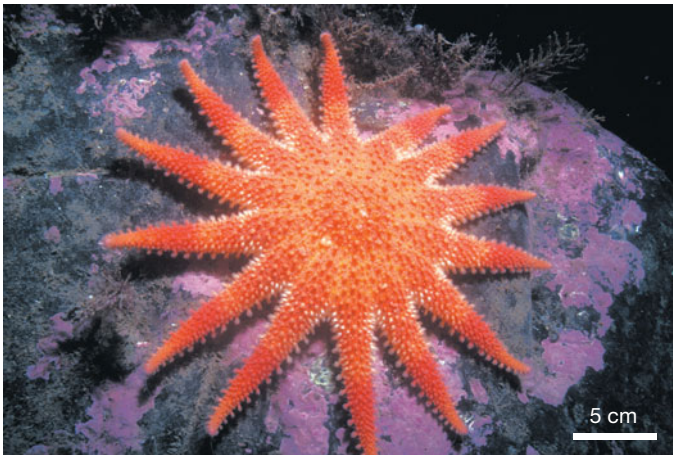

FIGURE 35.6 Sea Stars May Have Many Arms.

Echinodermata > Echinoidea (Sea Urchins and Sand Dollars)

About 1000 species of echinoids are living today; most are sea urchins or sand dollars. Sea urchins have globe-shaped bodies and long spines and crawl along substrates. Sand dollars are flattened and disk-shaped, have short spines, and burrow in soft sediments. ✔ **You should be able to indicate the origin of globular or disk-shaped bodies on Figure 35.5.**

Feeding Most types of sea urchins are herbivores. In some areas of the world, urchins are extremely important grazers on kelp and other types of algae. In cases when humans have removed predators such as sea otters, and urchin populations have grown in response, the urchins' grazing can destroy kelp forests. The urchins chew away a structure called a holdfast, which anchors kelp to the substrate; the kelp then float away and die. Most echinoids have a unique, jaw-like feeding structure in their mouths, called an Aristotle's lantern, that is made up of five calcium carbonate teeth attached to muscles (**FIGURE 35.7a**, see page 686). In many species, this apparatus can extend and retract as the animal feeds, allowing it to reach more food material. Sand dollars, in contrast, are suspension feeders. The beating of cilia on their spines creates tiny water currents that bring organic material toward the body. The food particles are then trapped in mucus and transported in long strings to the mouth. In this way, sand dollars harvest nutritious detritus found in sand or in other soft substrates (**FIGURE 35.7b**).

Movement Using their spines, sea urchins crawl and sand dollars burrow. Some species also use their tube feet to aid movement, or just to hold on to the substrate to prevent being washed away by waves and currents.

Reproduction Sexual reproduction predominates in sea urchins and sand dollars (see Figure 33.14). Fertilization is external, and sexes are separate. As in sea stars, larvae are long-lived and may disperse long distances. The larvae of some species undergo asexual reproduction by dividing in two or budding off new individuals, before they undergo metamorphosis.

35.2 What Is a Chordate?

You are a chordate, yet chordates are so diverse that you would probably find it difficult to identify familiar features in some of your fellow chordates—such as the sea squirts, whose small, sessile, globular bodies hardly resemble animals at all. Which characteristics are shared within this phylum?

All **chordates** are defined by the presence of four morphological features at some stage in their life cycles:

1. openings into the throat called **pharyngeal gill slits;**
2. a **dorsal hollow nerve cord,** which runs the length of the body, composed of projections from neurons;
3. a stiff and supportive but flexible rod called a **notochord,** which runs the length of the body; and
4. a muscular, post-anal tail—meaning a tail that contains muscle and extends past the anus.

Electrical signals carried by the dorsal hollow nerve cord coordinate muscle movement, and the notochord stiffens the muscular tail. Together, these traits create a "torpedo"—a long, streamlined animal that can swim rapidly. Fossil evidence suggests that chordates diversified early during the Cambrian radiation of animals, about 550 million years ago.

Three Chordate "Subphyla"

The phylum Chordata is made up of three major lineages: the **(1)** cephalochordates, **(2)** urochordates, and **(3)** vertebrates. Let's examine the four chordate morphological features in each group.

The Cephalochordates **Cephalochordates** are also called lancelets or amphioxus; they are small, mobile, torpedo-shaped animals with a "fish-like" appearance, and they make their living by suspension feeding (**FIGURE 35.8a**). Adult cephalochordates live in ocean-bottom habitats, where they burrow in sand and suspension feed with the aid of their pharyngeal gill slits.

The dorsal hollow nerve cord in cephalochordates runs parallel to a notochord. Because the notochord stiffens the cephalochordates' bodies, muscle contractions on either side result in fishlike movement when the animals swim during dispersal or mating.

The Urochordates **Urochordates** are also called tunicates or sea squirts. As **FIGURE 35.8b** shows, pharyngeal gill slits are present in both larvae and adults; these structures function in both feeding and gas exchange.

The dorsal hollow nerve cord, notochord, and tail are present in larvae and in the sexually mature forms of species that move as adults. As in cephalochordates, these features combine to enable swimming movements. As larvae swim or float in the upper water layers of the ocean, they drift to new habitats where food might be more abundant. As a result, larvae function as a dispersal stage in the life cycle.

The Vertebrates Vertebrates (**FIGURE 35.8c**) include the hagfish, lampreys, sharks and rays, several lineages of bony fishes, amphibians, mammals, and reptiles (including birds). In vertebrates, the dorsal hollow nerve cord is the familiar spinal cord—a bundle of nerve cells that runs from the brain to the posterior of the body. Electrical signals from the spinal cord control movements and the function of organs (see Chapter 46).

Structures called pharyngeal pouches are homologous to pharyngeal gill slits and are present in all vertebrate embryos.

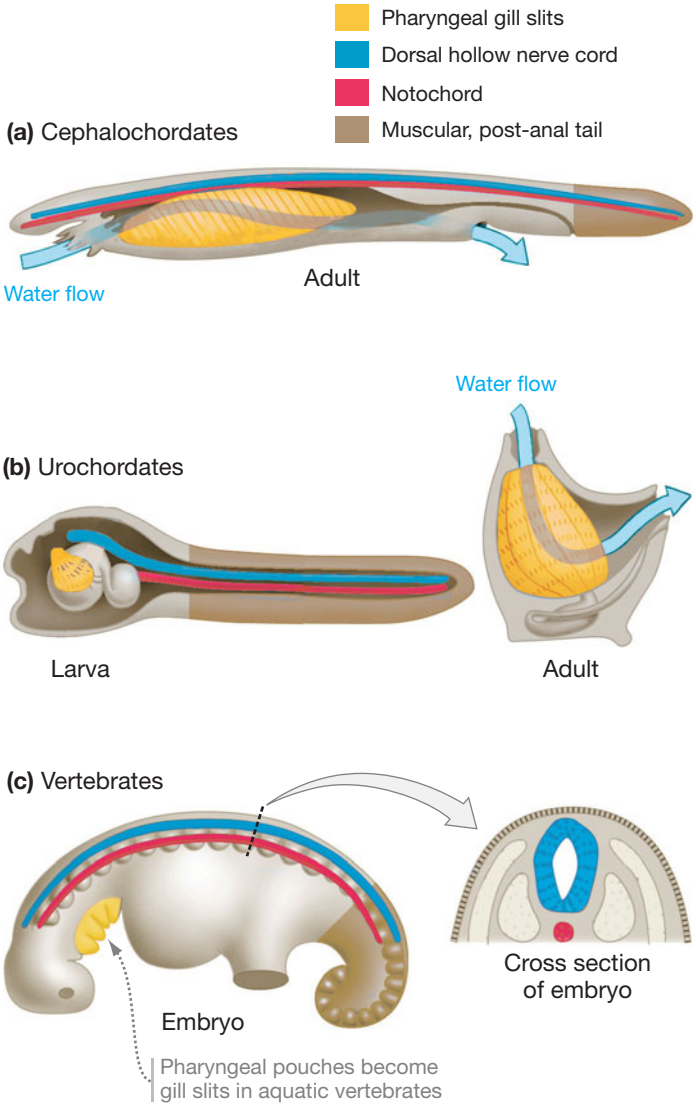

FIGURE 35.8 Four Features Distinguish the Three Lineages of Chordates.

In aquatic species, the creases between pouches open into gill slits and develop into part of the main gas-exchange organ—the **gills.** In terrestrial species, however, gill slits do not develop after the pharyngeal pouches form. In these species, the pharyngeal pouches are a vestigial trait (see Chapter 25).

A notochord develops in all vertebrate embryos. It no longer functions in body support and movement, however, for these roles are filled by the vertebral column. Instead, the notochord helps organize the body plan early in development. The notochord secretes proteins that help induce the formation of somites—segmented blocks of tissue that form along the length of the body (Chapter 23). Although the notochord itself disappears, cells in the somites later differentiate into the vertebrae, ribs, and skeletal muscles of the back, body wall, and limbs. In this way, the notochord is instrumental in the development of the trait that gave vertebrates their name.

Key Lineages: The Invertebrate Chordates

There are about 24 species of lancelets, 3000 species of tunicates, and over 62,000 vertebrates. Because they are so species rich and diverse, vertebrate chordates rate their own section in this chapter (Section 35.3). Here let's focus on the tunicates and lancelets. These lineages are sometimes referred to as the invertebrate chordates—meaning, members of the Chordata that lack vertebrae. They are of great interest to evolutionary biologists, who study the morphology, development, and genetics of these animals to better understand the evolutionary history of our own subphylum, the vertebrates.

- Chordata > Cephalochordata (Lancelets)
- Chordata > Urochordata (Tunicates)

Chordata > Cephalochordata (Lancelets)

About two dozen species of cephalochordates have been described to date, all of them found in marine sands. Lancelets—also called amphioxus—have several characteristics that are intermediate between invertebrates and vertebrates. Chief among these is a notochord that is retained in adults, where it functions as an endoskeleton.

Feeding Adult cephalochordates feed by burrowing in sediment until only their heads are sticking out into the water (**FIGURE 35.9**). They take water in through their mouths and trap food particles with the aid of mucus on their pharyngeal gill slits.

Movement Adults have large blocks of muscle arranged in a series along the length of the notochord. Lancelets are efficient swimmers because the flexible, rod-like notochord stiffens the body, making it wriggle when the blocks of muscle contract.

Reproduction Asexual reproduction is unknown, and individuals are either male or female. Gametes are released into the environment, and fertilization is external.

Branchiostoma lanceolatum

FIGURE 35.9 Lancelets Look Like Fish but Are Not Vertebrates.

Chordata > Urochordata (Tunicates)

The urochordates are also called tunicates; they comprise two major sub-lineages: the sea squirts (or ascidians) and salps. All of the species described to date live in the ocean. Sea squirts live on the ocean floor (**FIGURE 35.10a**); salps live in open water (**FIGURE 35.10b**). The synapomorphies that define the urochordates include an external coat of polysaccharide, called a tunic, that covers and supports the body; a U-shaped gut; and two body openings, called siphons.

Feeding Adult urochordates use their pharyngeal gill slits to suspension feed. A mucus sheet on the inside of the pharynx traps particles present in the water that enters one siphon, passes through the slits, and leaves through the other siphon.

Movement Larvae swim with the aid of the notochord, which functions as a simple endoskeleton. Larvae are a dispersal stage and do not feed. Adult sea squirts are sessile while salps drift in currents.

Reproduction In most species, individuals produce both sperm and eggs. In some species, both sperm and eggs are shed into the water and fertilization is external; in other species, sperm are released into the water but eggs are retained, so that fertilization and early development are internal. Asexual reproduction by budding is also common in some groups, forming large sessile colonies in some sea squirts, and long chains in salps.

35.3 What Is a Vertebrate?

The vertebrates are a monophyletic group distinguished by two synapomorphies:

- a column of cartilaginous or bony structures called **vertebrae,** which form along the dorsal side of the body; and
- a **cranium,** a bony, cartilaginous, or fibrous case that encloses the brain. (A skull consists of the cranium in jawless vertebrates, and the cranium and mandible—or jaw—in jawed vertebrates.)

The vertebral column is important because it protects the spinal cord. The cranium is important because it protects the brain along with sensory organs such as eyes. Together, the vertebrae and cranium protect the central nervous system (CNS) and key sensory structures (see Chapter 33).

The vertebrate brain develops as an outgrowth of the most anterior end of the dorsal hollow nerve cord, and it is important to the vertebrate lifestyle. Vertebrates are active predators and herbivores that must sense stimuli in their environments and make rapid, directed movements in response. More complex brains enable more complex interactions with the environment.

In early vertebrates, the brain was divided into three regions with important sensory functions:

1. The **forebrain** housed the sense of smell;
2. the **midbrain** was associated with vision; and
3. the **hindbrain** was responsible for balance and, in some species, hearing.

All vertebrates living today have retained these three regions, but the structures and functions of the regions have evolved over time. For example, in the jawed vertebrates, or **gnathostomes** (pronounced *NATH-oh-stomes*), the hindbrain consists of enlarged regions called the **cerebellum** and **medulla oblongata.** Part of the forebrain also became elaborated into a large structure called the **cerebrum,** especially in birds and mammals. (The structure and functions of the vertebrate brain are analyzed in detail in Chapter 46.) The evolution of a large, three-part brain, protected by a hard cranium, was a key innovation in vertebrate evolution.

An Overview of Vertebrate Evolution

Vertebrates have been the focus of intense research for well over 300 years, in part because they are large and conspicuous and in part because they include humans. All this effort has paid off in an increasingly thorough understanding of how the vertebrates diversified. Let's consider what the data from the fossil record have to say about key events in vertebrate evolution and then examine the current best estimate of the phylogenetic relationships among vertebrates.

The Vertebrate Fossil Record Vertebrate fossils are present in the Chengjiang formation of China, dated to the Cambrian explosion. The detailed vertebrate fossils show that the earliest members of this lineage lived in the ocean about 540 million years ago; they had streamlined, fishlike bodies and a cranium made of cartilage (see an artist's interpretation of an early vertebrate species called *Haikouichthys* in Figure 28.12). **Cartilage** is a strong but flexible tissue—found in your ear and the tip of your nose—that consists of scattered cells in a gel-like matrix of polysaccharides and protein fibers (Chapter 42).

A cartilaginous endoskeleton is a basic vertebrate feature; only in the bony fishes and their descendants, the **tetrapods** (literally, "four-footed"), does the skeleton become composed of bone in the adult. **Bone** is a tissue consisting of cells and blood vessels encased in a matrix made primarily of calcium phosphate, along with a small amount of protein fibers. In species with bony skeletons, growing bones are cartilaginous first and become bony only later in their development.

Following the appearance of vertebrates, the fossil record documents a series of key innovations that occurred as this lineage diversified (**FIGURE 35.11**):

- *Bony exoskeleton* Fossil vertebrates from the early part of the Ordovician period, about 480 million years ago, are the first fossils to have bone. When bone first evolved, it did not occur in the endoskeleton ("inside-skeleton"). Instead, bone was deposited in scalelike plates that formed an **exoskeleton** ("outside-skeleton") (compare with arthropod exoskeletons in Chapter 34). Most of your skull is made up of this type of dermal ("skin") bone—making your skull similar to the "head shields" in Ordovician fishes. Based on the fossils' overall morphology, biologists infer that these animals swam with the aid of a notochord and that they breathed and fed by gulping water and filtering it through their pharyngeal gill slits. Presumably, the bony plates helped provide protection from predators.
- *Jaws* The first fishes with jaws show up early in the Silurian, about 440 million years ago. The evolution of jaws was significant because it improved the ability of fish to use suction feeding to capture prey, and also to bite, meaning that vertebrates were no longer limited to suspension feeding or deposit feeding. Instead, they could make a living as herbivores or predators. Soon after, jawbones with teeth appear in the fossil record. With jaws and teeth, vertebrates became armed and dangerous. The fossil record shows that a spectacular radiation of jawed fishes followed, filling marine and freshwater habitats.

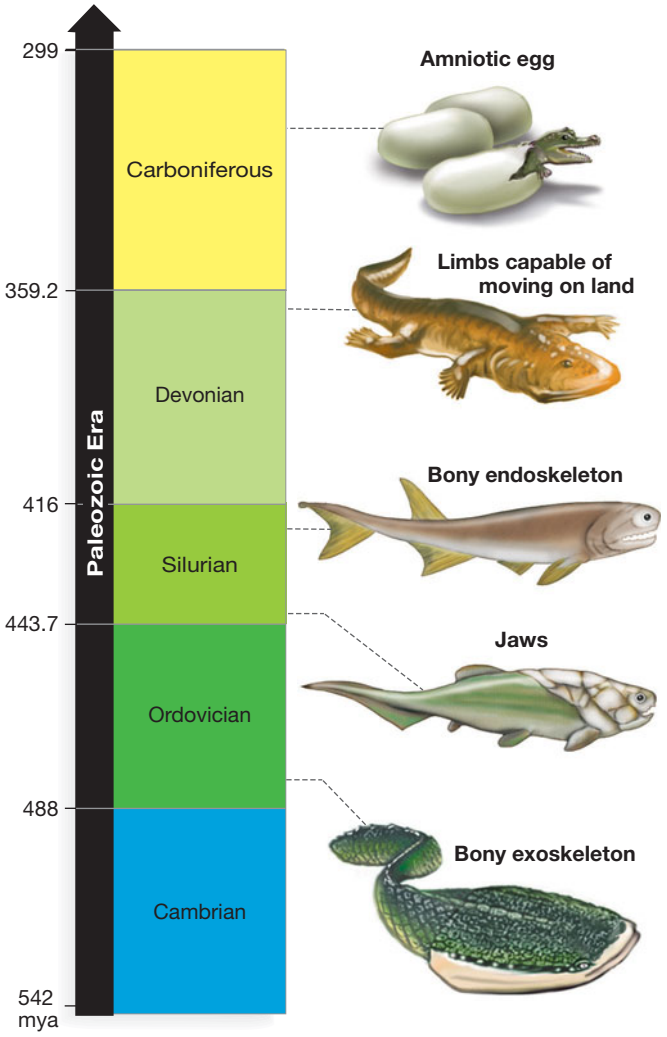

FIGURE 35.11 Timeline of the Early Vertebrate Fossil Record.

- *Bony endoskeleton* In some lineages of fishes from late in the Silurian period, the cartilaginous endoskeleton began to be stiffened by the deposition of bone. Unlike the dermal bone that had evolved earlier, the bony endoskeleton functioned to support movement—rapid swimming.
- *Limbs capable of moving on land* The next great event in the evolution of vertebrates was the transition to living on land. The first animals that had limbs and were capable of moving on land are dated to about 365 million years ago, late in the Devonian. These were the first of the tetrapods—animals with four limbs.
- *Amniotic egg* About 20 million years after the appearance of tetrapods in the fossil record, the first amniotes are present. The Amniota is a lineage of vertebrates that includes all tetrapods other than amphibians. The **amniotes** are named for a signature synapomorphy and adaptation: the amniotic egg. An **amniotic egg** is an egg that has membranes

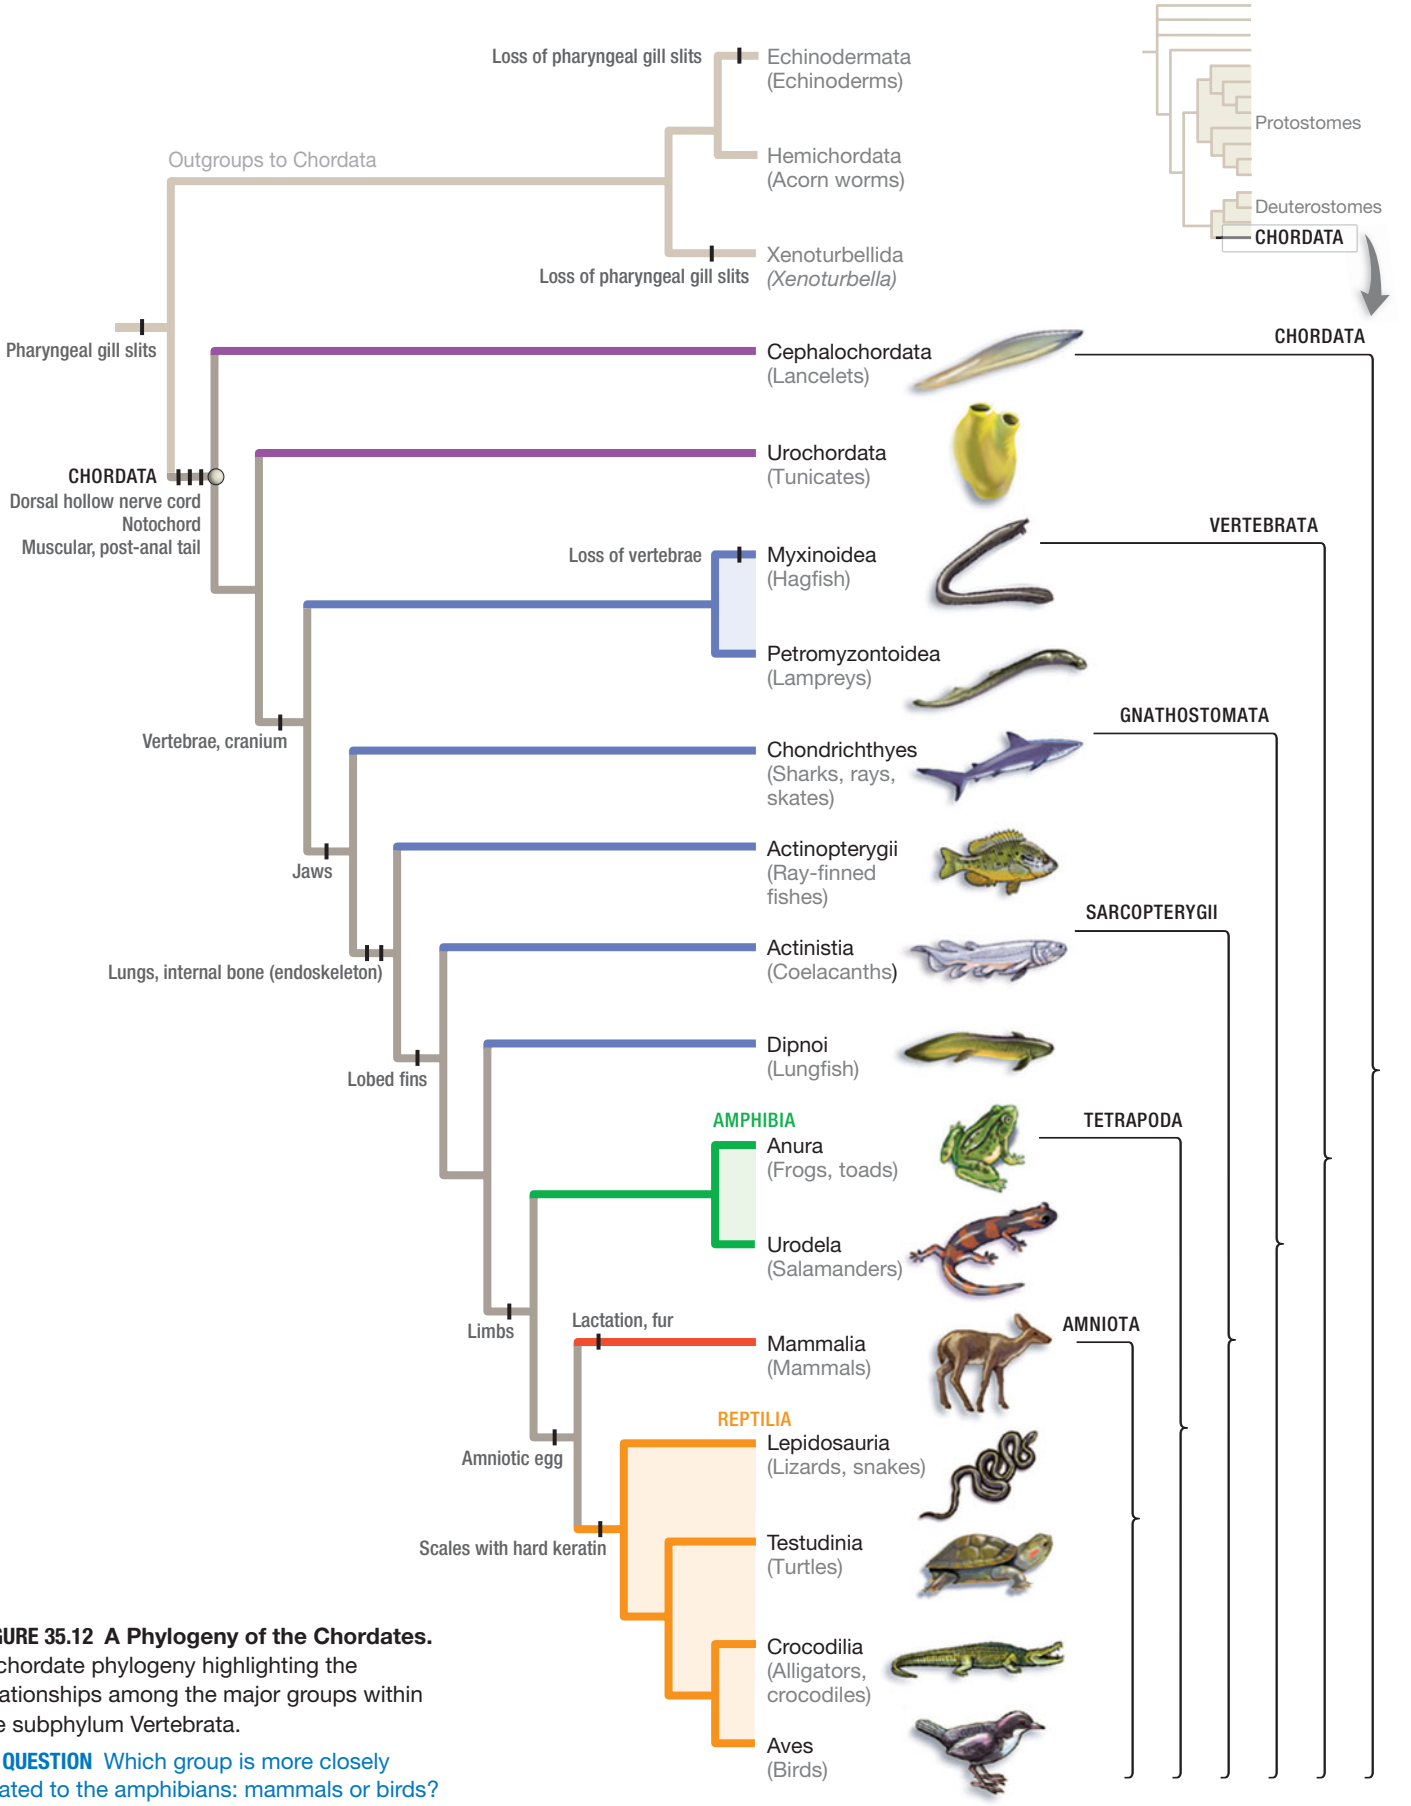

FIGURE 35.12 A Phylogeny of the Chordates.
A chordate phylogeny highlighting the relationships among the major groups within the subphylum Vertebrata.

✔ **QUESTION** Which group is more closely related to the amphibians: mammals or birds?

surrounding a food supply, a water supply, and a waste repository. These membranes provided support and extra surface area for gas exchange, allowing amniotes to produce larger, better-developed young.

To summarize, the fossil record indicates that vertebrates evolved through a series of major steps, beginning about 540 million years ago with vertebrates whose endoskeleton consisted of a notochord. The earliest vertebrates gave rise to fishes with bony exoskeletons. These fishes gave rise to the jawed vertebrates, including the cartilaginous fishes (sharks and rays) and several lineages of fishes with bony endoskeletons. After the tetrapods emerged and amphibians resembling salamanders began to live on land, the evolution of the amniotic egg paved the way for the diversification of amniotes—specifically, reptiles and the animals that gave rise to mammals. Do phylogenetic trees estimated from analyses of DNA sequence data agree or conflict with these conclusions?

Evaluating Molecular Phylogenies **FIGURE 35.12** provides a phylogenetic tree that summarizes the relationships among living chordates, especially vertebrates, based on DNA and other molecular sequence data. The labeled bars on the tree indicate where major morphological innovations occurred as lineages diversified. Although the phylogeny of deuterostomes continues to be a topic of intense research, researchers are increasingly confident that the relationships described in Figure 35.12 are accurate. There are a few important take-home messages from the tree:

- ***Outgroup to vertebrates*** According to the most recent molecular data, the urochordates are the closest living relatives of the vertebrates.
- ***Living outgroup to gnathostomes*** The phylogenetic relationships among hagfish, lampreys, and the gnathostomes have been hotly debated. Two hundred years ago, hagfish and lampreys were grouped together as the class Cyclostomata ("round-mouthed"), based on their unique mouthparts. Then, starting in the 1970s, morphologists began to take a closer look and placed hagfish and lampreys in two independent lineages with lampreys as the sister group to gnathostomes. But molecular phylogenies have not supported this view, instead leaning toward the Cyclostomata grouping. So which is correct? Analysis of a new source of data—evolutionarily conserved microRNAs (Chapter 19)—has decided in favor of the Cyclostomata hypothesis. This result is important because it emphasizes that the ancestor to gnathostomes was probably not lamprey-like. Rather, some vertebrate characteristics appear to have been *lost* in the hagfish/lamprey lineages, especially in hagfish.
- ***Fossil outgroup to gnathostomes*** The diverse lineages of extinct armored fishes are not included in the tree of living vertebrates. If pictured, they would occur as outgroups to the gnathostomes—more closely related to jawed vertebrates than are hagfish and lampreys.
- ***"Fish"*** No monophyletic group includes all of the living fishlike lineages. Instead, "fishy" organisms are a series of independent monophyletic groups (the living ones are indicated by blue branches in Figure 35.12). Taken together, they form what biologists call a **grade**—a sequence of lineages that are paraphyletic (that include some, but not all, of the descendants of a common ancestor). ✔ **If you understand the difference between a paraphyletic and monophyletic group, you should be able to draw what Figure 35.12 would look like if there actually were a monophyletic group called "The Fishes."** (See Table 28.2 if you need help.)
- ***Mammals*** Mammals and reptiles are sister groups and thus are more closely related to each other than either is to the amphibians.
- ***Birds*** Birds occur within the monophyletic group called reptiles. That is, birds *are* reptiles.

To understand what happened during the diversification of vertebrates, let's explore some of the major morphological innovations involved in feeding, movement, and reproduction in more detail. (For an overview of these themes, see Chapter 33.)

Key Innovations in Vertebrates

Among vertebrates, the most species-rich and ecologically diverse lineages are the ray-finned fishes and the tetrapods. Ray-finned fishes occupy habitats ranging from deepwater environments, which are perpetually dark, to shallow ponds that dry up each year. Tetrapods include the large herbivores and predators in terrestrial environments all over the world. About the same number of species of ray-finned fishes and tetrapods are living today (**FIGURE 35.13**).

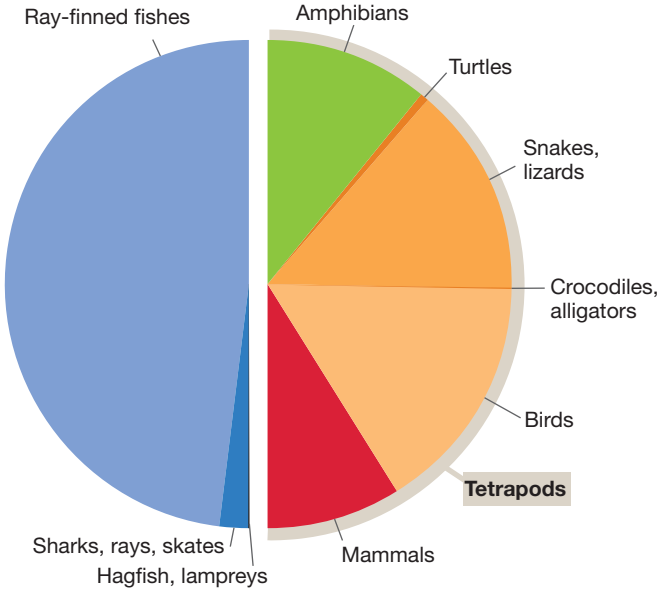

FIGURE 35.13 Relative Species Abundance among Vertebrates. Of the 63,000 species of described vertebrates, about half are ray-finned fishes and about half are tetrapods.

DATA: American Museum of Natural History; birdlife.org; fishbase.org; IUCN red list 2010; Reptile-database.org.

The Vertebrate Jaw The most ancient vertebrates in the fossil record had relatively simple mouthparts that lacked jaws. Until jaws evolved, vertebrates were not able to harvest food by biting.

The leading hypothesis for the origin of the jaw proposes that natural selection acted on developmental regulatory genes that determine the morphology of **gill arches,** which are curved regions of tissue between the gills. The jawless vertebrates have bars of cartilage that stiffen these gill arches. The gill-arch hypothesis proposes that mutation and natural selection increased the size of the most anterior arch and modified its orientation slightly, producing the first working jaw (**FIGURE 35.14**). Four lines of evidence support this hypothesis:

1. Both gill arches and jaws consist of flattened bars of bony or cartilaginous tissue that hinge and bend forward.
2. During development, the same population of cells gives rise to the muscles that move jaws and the muscles that move gill arches.
3. Unlike most other parts of the vertebrate skeleton, both jaws and gill arches are derived from specialized cells in the embryo called neural crest cells.
4. The expression patterns of key developmental regulatory genes, including *Hox* and *Dlx*, are similar in jaws and gill arches.

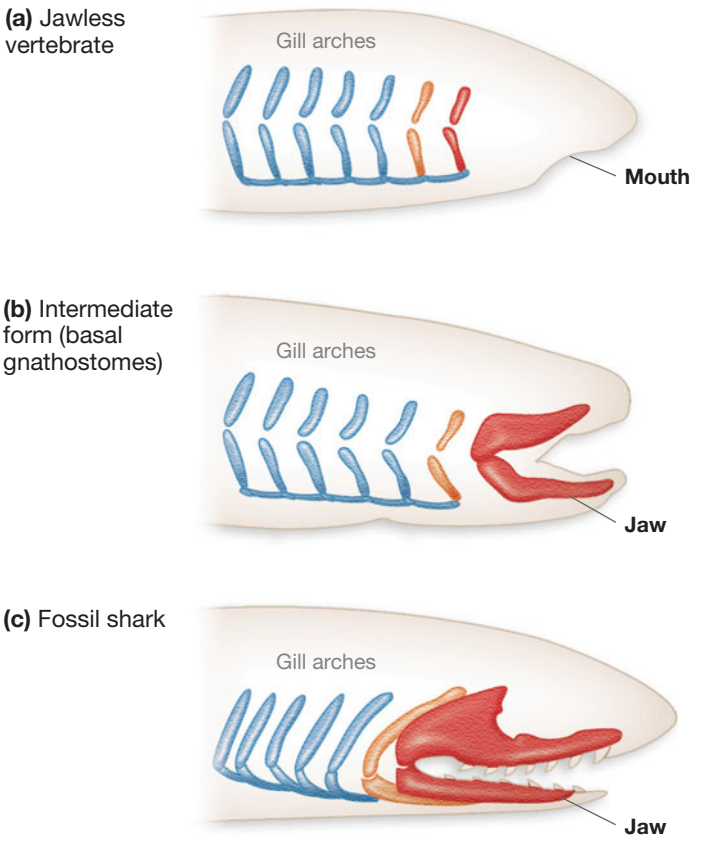

FIGURE 35.14 The Gill-Arch Hypothesis for the Evolution of the Jaw. (a) Gill arches support the gills in jawless vertebrates. **(b)** This intermediate form has yet to be found in the fossil record. **(c)** Fossil sharks that appeared later had more elaborate jaws.

Once jaws originated, changes in size and shape enabled a rapid diversification of feeding strategies from suction feeding to biting. Other modifications to the jaw also occurred:

- In most ray-finned fishes, the jaw is protrusible—meaning it can be extended to nip or bite at food.
- Several species-rich lineages of ray-finned fishes have a second specialized jaw called a **pharyngeal** ("throat") **jaw,** consisting of modified gill arches. It is located in the back of the throat and makes food processing particularly efficient. (For more on the structure and function of pharyngeal jaws, see Chapter 44.)

To summarize, the radiation of ray-finned fishes was triggered largely by the evolution and diversification of the jaw, by modifications that made it possible to protrude the jaw, and by the origin of the pharyngeal jaw. The story of tetrapods is different, however. Although jaw structure varies somewhat among tetrapod groups, the adaptation that triggered their initial diversification involved the ability to move and get to food, not to bite it and process it.

The Tetrapod Limb To understand how tetrapods made the water-to-land transition, consider the morphology and behavior of their closest living relatives, the lungfish (**FIGURE 35.15**). Most living species of lungfishes inhabit shallow, oxygen-poor water. To supplement the oxygen taken in by their gills, they have lungs and breathe air. (Note that although lungs originated before the divergence of ray-finned fishes and the Sarcopterygii, they serve primarily as a swim bladder to maintain buoyancy in ray-finned fishes.) Some lungfishes also have fleshy fins supported by bones and are capable of walking short distances along watery mudflats or the bottoms of ponds. In addition, some species can survive extended droughts by burrowing in mud.

Lungfish have a series of adaptations that allow them to survive on land for short periods. Could a lungfish-like organism have evolved into the first land-dwelling vertebrate with limbs?

Fossils provide strong links between the limbs of the ancestors of today's lungfish and the earliest land-dwelling vertebrates. **FIGURE 35.16** shows a phylogeny of the species involved. Note that during the Devonian, the fossil record documents a series of species that indicate a gradual transition from a lobe-like fin to a limb that could support walking on land. The fossil record

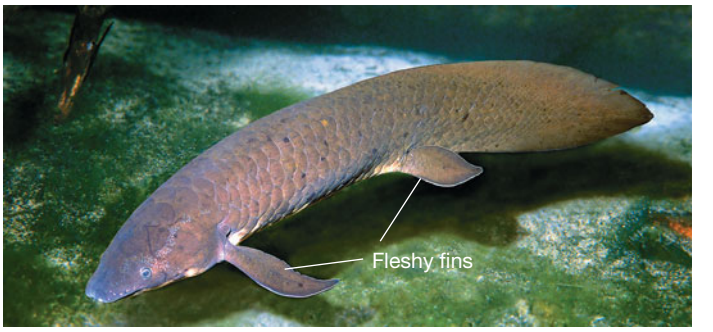

FIGURE 35.15 Lungfish Have Limb-like Fins. Some lungfishes can walk or crawl short distances on their fleshy fins.

is actually more complete than shown here—the figure is just a sample of the tetrapod and tetrapod-like species known from this interval.

The color coding in Figure 35.16 emphasizes that each fin or limb has a single bony element that is proximal (closest to the body; in blue) and then two bones that are distal (farther from the body) and arranged side by side (these are shown in red), followed by a series of distal elements (in orange). Because the structures are similar, and because no other animal groups have limb bones in this arrangement, the evidence for homology is strong.

The hypothesis that tetrapod limbs evolved from fish fins has also been supported by molecular genetic evidence. Recent work has shown that several regulatory proteins involved in the development of cartilaginous fish fins and ray-finned fish fins and the upper parts of mammal limbs are homologous. For example, the proteins produced by several different *Hox* genes are found at the same times during development and in the same locations in fins and limbs.

These data suggest that these appendages are patterned by the same genes. As a result, the data support the hypothesis that tetrapod limbs evolved from fins. Once the tetrapod limb evolved, natural selection elaborated it into diverse structures that are used for running, gliding, crawling, burrowing, swimming, and flying.

Once tetrapods made the water-to-land transition, they had to survive a number of new terrestrial challenges other than locomotion, such as keeping their eggs from drying out.

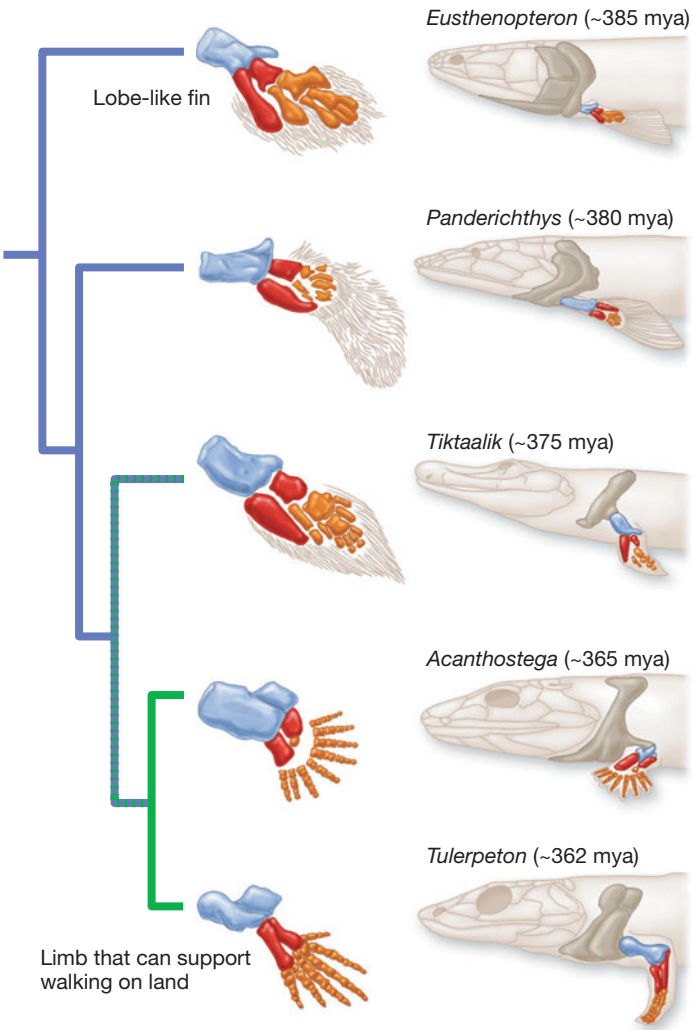

FIGURE 35.16 Evidence for a Fin-to-Limb Transition. The fossil record documents a series of species that indicate a gradual transition from a lobe-like fin to a limb that could support walking on land.

✔ **QUESTION** This phylogeny was estimated from traits other than the morphology of the limb. Why is this important in addressing how limbs evolved?

The Amniotic Egg Amphibians (frogs and toads, salamanders, and limbless species called caecilians) keep their eggs from drying out by laying their jelly-coated eggs in water. In contrast, reptiles (including birds) and the egg-laying mammals produce an amniotic egg, which has a protective covering that reduces the rate of drying significantly. Species that produce amniotic eggs lay them outside of water.

Amphibian eggs are surrounded by a single membrane, whereas amniotic eggs have four. As **FIGURE 35.17** shows, the outermost membrane of an amniotic egg encloses a supply of water in a protein-rich solution called **albumen.** Albumen cushions the developing embryo and provides nutrients. The three inner membranes surround the embryo itself, the yolk provided by the mother, and the waste from the embryo. The additional membranes are thought to be advantageous because they:

1. provide mechanical support—an important consideration outside of a buoyant aquatic environment; and
2. increase the surface area available for exchange of gases and other materials. Efficient diffusion of molecules is important because it allows females to lay larger eggs that hatch into larger, more independent young.

In addition, amniotic eggs are surrounded by a shell. This layer is leathery in lizards and snakes. It is stiffened by some calcium carbonate deposits in turtles and crocodiles, and by extensive

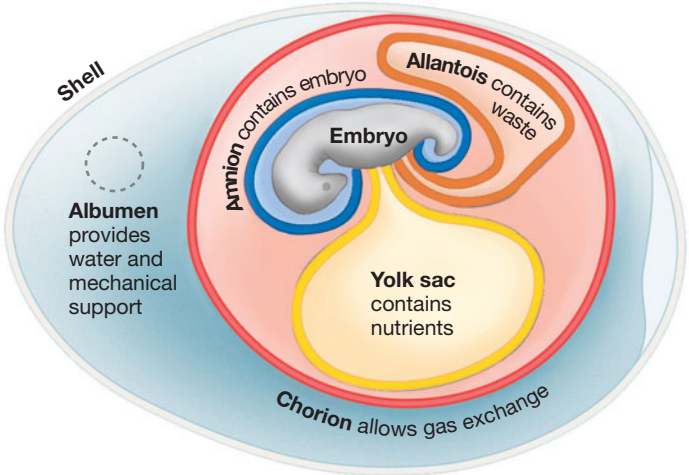

FIGURE 35.17 An Amniotic Egg. Amniotic eggs have four membrane-bound sacs.

calcium carbonate deposits in birds. Lizards, snakes, turtles, and crocodiles often bury their eggs in moist soils, but bird eggs are more watertight and are laid in nests that are exposed to air.

During the evolution of mammals, however, a second major innovation in reproduction occurred—one that eliminated the need for any type of egg laying.

The Placenta Egg-laying animals are said to be **oviparous,** while species that give birth are termed **viviparous** (Chapter 33). In many viviparous animals, females produce an egg that contains a nutrient-rich yolk. Instead of laying the egg, however, the mother retains it inside her body. In these **ovoviviparous** species, the developing offspring depends on the resources in the egg yolk.

In caecilians, some lizards, and most mammals, however, the eggs that females produce have little yolk. After fertilization occurs and the egg is retained, a combination of maternal and embryonic tissues produces a placenta within the uterus or oviduct. The embryo's contributions are the allantois and chorion—membranes that are involved in gas exchange in an amniotic egg. In the placenta, tissues derived from the allantois and chorion are also involved in the diffusion of gases, nutrients, and wastes.

The **placenta** is an organ that is rich in blood vessels and that facilitates a flow of oxygen and nutrients from the mother to the developing offspring, as well as the removal of nitrogenous wastes and carbon dioxide from the offspring (**FIGURE 35.18**). After a development period called **gestation,** the embryo emerges from the mother's body.

Why did viviparity and the placenta evolve? The leading hypotheses are that retaining the embryo inside the body has several advantages:

1. Offspring develop at a more constant, favorable temperature.
2. Offspring are protected.
3. Offspring are portable—mothers are not tied to a nest.

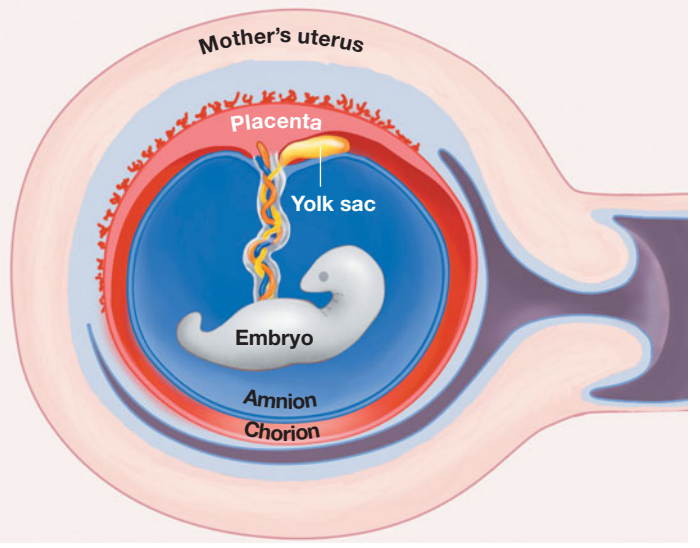

FIGURE 35.18 A Placenta Nourishes a Fetus Internally.

✔ **QUESTION** Compare the relative size of the yolk sac here with that in the amniotic egg (Figure 35.17).

In effect, a placenta and viviparity are mechanisms for increasing the level of **parental care:** behavior by a parent that improves the ability of its offspring to survive. What other types of parental care evolved in vertebrates?

Parental Care In species that provide extensive parental care—even if only in the form of exceptionally large amounts of yolk in eggs—mothers participate in a fitness trade-off (see Chapter 25). They can produce fewer offspring, but the offspring that they do produce have a higher probability of survival.

In animals, mechanisms of parental care include incubating eggs to keep them warm during early development, keeping young warm and dry, supplying young with food, and protecting them from danger. In some insect and frog species, mothers carry eggs or newly hatched young on their bodies. In fishes, parents commonly guard eggs during development and fan them with oxygen-rich water.

Mammals and birds provide particularly extensive parental care. In both groups, the mother (and often the father, in birds) continues to feed and care for individuals after birth or hatching—sometimes for many years. Female mammals also **lactate**—meaning that they produce milk and use it to feed their offspring after birth (**FIGURE 35.19**).

Among large animals, the evolution of extensive parental care is hypothesized to be a major reason for the evolutionary success of mammals and birds. In both lineages, mothers produce relatively small numbers of large, high-quality offspring.

Wings and Flight Following the transition from water to land, the origin of the amniotic egg, and the elaboration of parental care, amniotes made another big transition—into the air. Wings and flight evolved independently in three lineages of tetrapod amniotes: the extinct flying reptiles called pterosaurs (pronounced *TARE-oh-sors*), the bats, and the birds.

FIGURE 35.19 Parental Care Is Extensive in Mammals. Female mammals, such as this timber wolf, produce highly nutritious milk to nourish their young.

How did flight evolve? The best data sets on this question involve feathered flight in birds. Since the early 2000s, paleontologists have discovered a spectacular series of feathered dinosaur fossils. The newly discovered species and exceptionally well-preserved feather specimens address key questions about the evolution of birds, feathers, and flight:

- ***Did birds evolve from dinosaurs?*** On the basis of skeletal characteristics, all of these recently discovered fossil species clearly show that birds are part of the monophyletic group called dinosaurs. That is—birds *are* dinosaurs.
- ***How did feathers evolve?*** The early fossils support a model of feathers evolving in a series of steps, beginning with simple projections from the skin (popularly called "dinofuzz") and culminating in the complex, branched structures familiar today. Although diverse, feathers observed in many nonavian dinosaurs were not strong enough to support gliding or flight. They may have been used for insulation and/or mating displays—recent analysis of pigments in fossil feathers have shown striking color patterns in some dinosaurs (**FIGURE 35.20**).
- ***Did birds begin flying from the ground up or from the trees down?*** More specifically, did flight evolve with running species that began to jump and glide or make short flights, with the aid of feathers to provide lift? Or did flight evolve from tree-dwelling species that used feathers to glide from tree to tree, much as flying squirrels do today? This question is still unresolved. The observation that many early feathered dinosaurs had "flight" feathers on their legs adds an intriguing piece to the puzzle (see Figure 35.20).

Once dinosaurs evolved feathers and took to the air, the fossil record shows that a series of adaptations made powered, flapping flight increasingly efficient (**FIGURE 35.21**).

- Most dinosaurs have a flat sternum ("breastbone"), but the bird sternum has a projection called the keel, which provides a large surface area to which flight muscles attach.

FIGURE 35.20 Feathers Evolved in Dinosaurs. This artist's depiction of what *Anchiornis huxleyi,* a feathered dinosaur, might have looked like in life incorporates recent data on fossil feather colors. The colors may have been important in mating displays. Unlike modern birds, many feathered dinosaurs had large feathers on their legs.

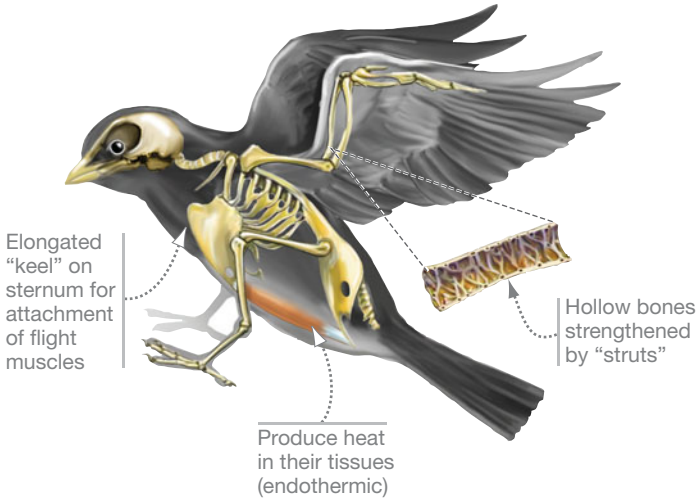

FIGURE 35.21 In Addition to Feathers, Birds Have Several Features That Enable Flight.

- Birds are extraordinarily light for their size, primarily because they have a drastically reduced number of bones and because their larger bones are thin walled and hollow—though strengthened by bony "struts."
- Birds are capable of sustained activity year-round because they are **endotherms** ("inside-heated")—they maintain a high body temperature by producing heat in their tissues.

From dinosaurs that jumped or glided from tree to tree, birds have evolved into extraordinary flying machines.

To summarize, the evolution of the jaw gave tetrapods the potential to capture and process a wide array of foods. With limbs, they could move efficiently on land in search of food. The amniotic egg and placenta further enabled vertebrates to diversify into terrestrial niches, and parental care increased the survivorship of their offspring. Finally, some tetrapods were able to defy the pull of gravity, expanding their realm into the air.

If you understand that . . .

- Vertebrates have a distinctive body plan: bilateral symmetry with vertebrae that protect a spinal cord and a cranium that protects the brain.
- An array of key innovations occurred during the evolution of vertebrates: jaws, the tetrapod limb, the amniotic egg, the placenta, extensive parental care, and flight.

✔ You should be able to . . .

1. Explain the adaptive significance of each key innovation.
2. Compare adaptations in protostomes (Chapter 34) and deuterostomes for living on land.

Answers are available in Appendix A.

Key Lineages: The Vertebrate Chordates

The fossil record provides an increasingly clear picture of early vertebrate evolution; intensive and continuing research has explored the origins of key vertebrate innovations such as the jaw, the tetrapod limb, and the amniotic egg. Now that you've been introduced to key vertebrate features, let's take a closer look at the key lineages.

"Fish" As discussed earlier, fish are a paraphyletic group consisting of diverse lineages, many of which are extinct. Four of the boxes that follow feature the six major lineages of fishes that are living today:

- Myxinoidea (Hagfish) and Petromyzontoidea (Lampreys)
- Chondrichthyes (Sharks, Rays, Skates)
- Actinopterygii (Ray-Finned Fishes)
- Actinistia (Coelacanths) and Dipnoi (Lungfish)

Amphibia Unlike fish, the **amphibians** form a monophyletic group, the Amphibia. Most amphibians lay their eggs in water and undergo metamorphosis from an aquatic larva to a terrestrial or semiterrestrial adult. The three lineages of amphibians are discussed together in one box:

- Amphibia (Frogs and Toads, Salamanders, Caecilians)

Mammalia **Mammals** are a monophyletic group, today comprising three major lineages:

- Mammalia > Monotremata (Platypuses, Echidnas)
- Mammalia > Marsupiala (Marsupials)
- Mammalia > Eutheria (Placental Mammals)

The relationships among these groups are shown in **FIGURE 35.22**. Monotremes lay eggs; marsupials have a poorly developed placenta but well-developed pouch for rearing offspring; eutherians have a well-developed placenta and extended pregnancy.

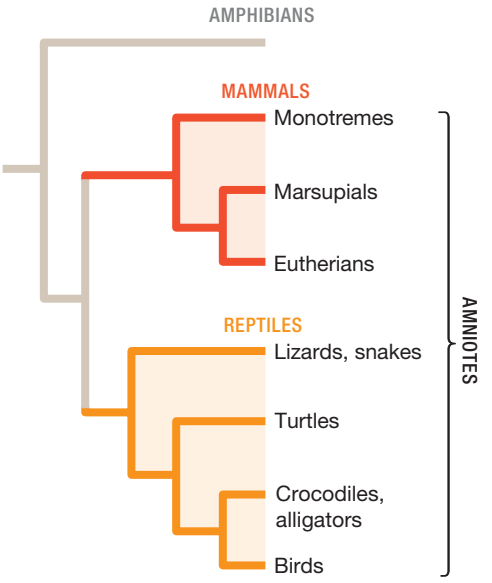

FIGURE 35.22 Mammals and Reptiles Are Monophyletic Groups.

Mammals are endotherms that maintain high body temperatures by oxidizing large amounts of food and generating large amounts of heat. Instead of insulating themselves with feathers, though, mammals retain heat because the body surface is covered with layers of hair or fur. Endothermy evolved independently in mammals and birds. In both groups, endothermy is thought to be an adaptation that enables individuals to maintain high levels of activity—particularly at night or during cold weather.

In addition to being endothermic and having fur, mammals have **mammary glands**—unique structures that make lactation possible. The evolution of mammary glands gave mammals the ability to provide their young with particularly extensive parental care. Mammals are also the only vertebrates with cheek muscles and lips—traits that make suckling milk possible—and the only vertebrates that have a lower jaw formed from a single bone. ✔ **You should be able to mark the origin of mammary glands and fur on Figure 35.22.**

Mammals evolved when dinosaurs and other reptiles were the dominant large herbivores and predators in terrestrial and aquatic environments. The earliest mammals in the fossil record appear about 195 million years ago; most were small animals that were probably active only at night. Many of the 5500 species of mammals living today have good nocturnal vision and a strong sense of smell, as their ancestors presumably did.

The adaptive radiation that gave rise to today's diversity of mammalian orders did not take place until after the dinosaurs went extinct. Long after the dinosaurs were gone, the mammals diversified into lineages that included large herbivores and large predators—ecological roles that had once been filled by dinosaurs and the ocean-dwelling, extinct reptiles called ichthyosaurs and plesiosaurs.

Reptilia The **reptiles** are a monophyletic group and represent the second major living lineage of amniotes besides mammals (Figure 35.22). One major diagnostic feature distinguishing the reptilian and mammalian lineages is the number and placement of openings in the side of the skull. These skull openings are important: Jaw muscles required for biting and chewing pass through them and attach to bones on the upper part of the skull.

Reptiles have several adaptations for life on land. Their skin is made watertight by a layer of scales made of the protein keratin. Reptiles breathe air through well-developed lungs and lay shelled, amniotic eggs. In snakes and lizards, the egg has a leathery shell; in other reptiles, the shell includes some calcium carbonate.

In many reptiles, the sex of an individual is determined by the environment it experiences during early development. In certain species, for example, high temperatures produce mostly males while low temperatures produce mostly females.

The reptiles include the dinosaurs, ichthyosaurs, plesiosaurs, pterosaurs (flying reptiles), and other extinct lineages that flourished from about 250 million years ago until the mass extinction

at the end of the Cretaceous period, 65 million years ago. Today the Reptilia are represented by four major lineages:

- Reptilia > Lepidosauria (Lizards, Snakes)
- Reptilia > Testudinia (Turtles)
- Reptilia > Crocodilia (Crocodiles, Alligators)
- Reptilia > Aves (Birds)

Except for birds, almost all of the reptiles living today are **ectotherms** ("outside-heated")—meaning that individuals do not use internally generated heat to regulate their body temperature. It would be a mistake, however, to conclude that reptiles other than birds do not regulate their body temperature closely. Reptiles bask in sunlight, seek shade, and perform other behaviors to keep their body temperature at an appropriate level.

Chordata > Vertebrata > Myxinoidea (Hagfish) and Petromyzontoidea (Lampreys)

Hagfish and lampreys are the only living jawless vertebrates, comprising about 120 species. Their relationship to jawed vertebrates has been hotly debated; however, the most recent microRNA evidence suggests that the two groups are more closely related to each other than either is to the jawed vertebrates. These data indicated that hagfish and lampreys, collectively the cyclostomes ("round mouths"), may have *lost* many vertebrate characters over time.

Hagfish and lampreys have long, slender bodies and are aquatic (**FIGURE 35.23**). Hagfish are strictly marine; lampreys include both marine and freshwater forms. Most species are less than a meter long when fully grown. Adult hagfish lack any sort of vertebral column, but adult lampreys have small pieces of cartilage along the length of their dorsal hollow nerve cord. Both hagfish and lampreys have brains protected by a cranium, as do all vertebrates.

Feeding Hagfish are scavengers and predators. They deposit feed on the carcasses of dead fish and whales, and some are thought to burrow through ooze at the bottom of the ocean, feeding on polychaete worms and other buried prey. Lampreys, in contrast, are ectoparasites. They attach to fish or other hosts by suction and then use spines in their mouth and tongue to rasp a hole in the side of their victim. Once the wound is open, they suck blood and other body fluids.

Movement Hagfish and lampreys have a well-developed notochord and swim by making undulating movements. Hagfish are particularly flexible, sometimes forming "knots" with their bodies to rid themselves of the copious slime they create as a defense mechanism when disturbed. Lampreys can move themselves upstream, against the flow of water, by attaching their suckers to rocks and looping the rest of their body forward, like an inchworm. Both groups have tail fins, and lamprey have a dorsal (back) fin; but neither group has the paired lateral (side) appendages found in other vertebrates.

Reproduction Virtually nothing is known about hagfish mating or embryonic development. Some lampreys live in freshwater; others are **anadromous**—meaning they spend their adult life in the ocean but swim up streams to breed. Fertilization is external, and adults die after breeding once. Lamprey eggs hatch into larvae that look and act like lancelets (cephalochordates). The larvae burrow into sediments and suspension feed for several years before metamorphosing into free-swimming adults.

(b) Lamprey

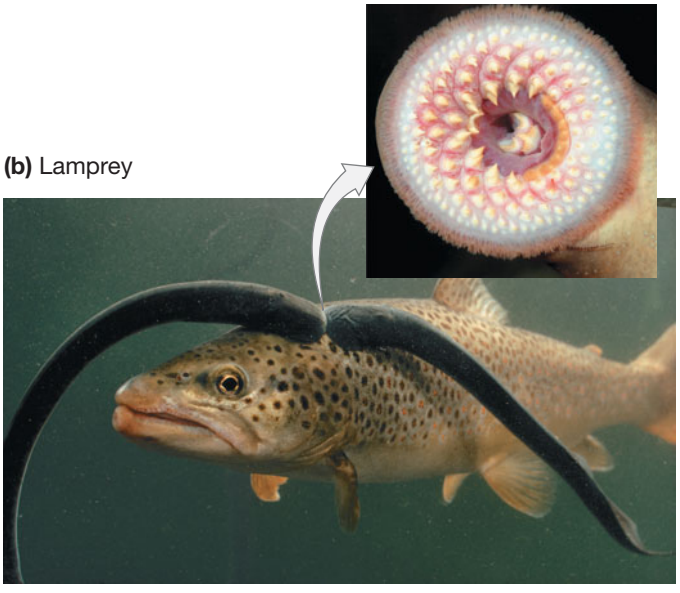

FIGURE 35.23 Hagfish and Lampreys Are Jawless Vertebrates.

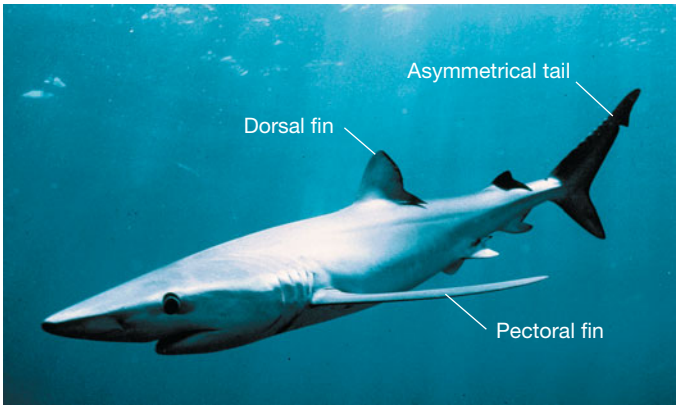
Chordata > Vertebrata > Chondrichthyes (Sharks, Rays, Skates)

This lineage is distinguished by a specialized type of reinforced cartilaginous skeleton (*chondrus* is the Greek word for cartilage). Along with jawed vertebrates, or gnathostomes, sharks, rays, and skates also have jaws. They, like the other fish-like gnathostomes, also have paired lateral fins. Paired fins were an important evolutionary innovation because they stabilize the body during rapid swimming—keeping it from pitching up or down, yawing to one side or the other, or rolling. ✔ **You should be able to indicate the origin of paired fins and the chondrichthyan form of cartilage on Figure 35.12.**

Most of the 1200 species of sharks, rays, and skates are marine, though a few species live in freshwater. Sharks have streamlined, torpedo-shaped bodies and an asymmetrical tail—the dorsal portion is longer than the ventral portion (**FIGURE 35.24a**). In contrast, the dorsal–ventral plane of the body in rays and skates is strongly flattened (**FIGURE 35.24b**).



Feeding A few species of sharks and rays suspension feed on plankton, but most species in this lineage are predators. Skates and rays hunt along the ocean floor for snails, clams, and other benthic animals; electric rays capture their prey by stunning them with electric discharges of up to 200 volts. Most sharks, in contrast, are active hunters that chase down prey in open water and bite them. The larger species of sharks feed on large fish or marine mammals. In many marine ecosystems, sharks are referred to as the "top predator" because they are at the top of the food chain—nothing eats them. Yet the largest of all sharks, the whale shark, is a suspension feeder. Whale sharks filter plankton out of water as it passes over their gills.

Movement Rays and skates swim by flapping their greatly enlarged pectoral fins. Sharks swim by undulating their bodies from side to side and beating their large tails.

Reproduction Sharks use internal fertilization, and fertilized eggs may be shed into the water or retained until the young are hatched and well developed. In some viviparous species, embryos are attached to the mother by specialized tissues in a placenta, where the exchange of gases, nutrients, and wastes takes place. (A placenta evolved in certain shark lineages independently of its evolution elsewhere on the tree of life.) Skates are oviparous, but rays are viviparous.

(a) Sharks are torpedo shaped.

Prionace glauca

(b) Skates and rays are flat.

Dasyatis americana

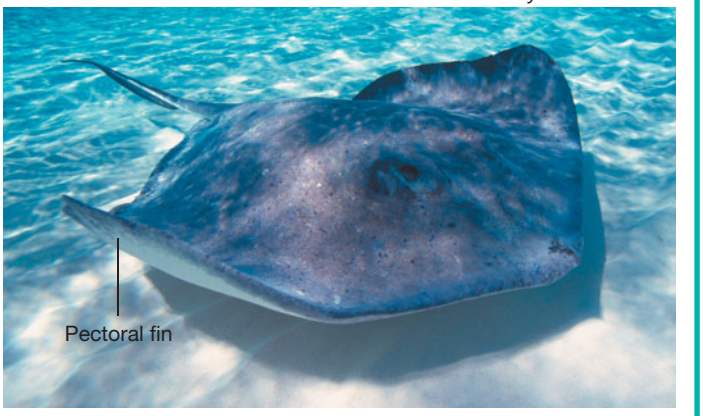


FIGURE 35.24 Sharks and Rays Have Cartilaginous Skeletons.

Chordata > Vertebrata > Actinopterygii (Ray-Finned Fishes)

Actinopterygii (pronounced *ack-tin-op-teh-RIJ-ee-i*) means "ray-finned." These **ray-finned fishes** have fins that are supported by long, bony rods arranged in a ray pattern, in addition to a skeleton made of bone (**FIGURE 35.25**). Their bodies are covered with interlocking scales that provide a stiff but flexible covering, and many have a gas-filled **swim bladder** that evolved from the lungs found in the earliest lineages of fish. The evolution of the swim bladder was an important innovation because it allowed ray-finned fishes to avoid sinking. Most tissues are heavier than water, so the bodies of aquatic organisms tend to sink. Sharks and rays, for example, have to swim to avoid sinking. But in ray-finned fishes, gas is added to the bladder when a fish swims down; gas is removed when the fish swims up. In this way, ray-finned fishes maintain neutral buoyancy in water of various depths and thus various pressures. ✔ **You should be able to indicate the origin of rayed fins and the swim bladder on Figure 35.12.**

The actinopterygians are the most successful vertebrate lineage based on number of species, duration in the fossil record, and extent of habitats occupied. About 30,500 species of ray-finned fishes are known, including the smallest known vertebrate—a species whose adult females average less than 8 mm in length.

(Continued on next page)

Chordata > Vertebrata > Actinopterygii (Ray-Finned Fishes) *continued*

Holocentrus rufus

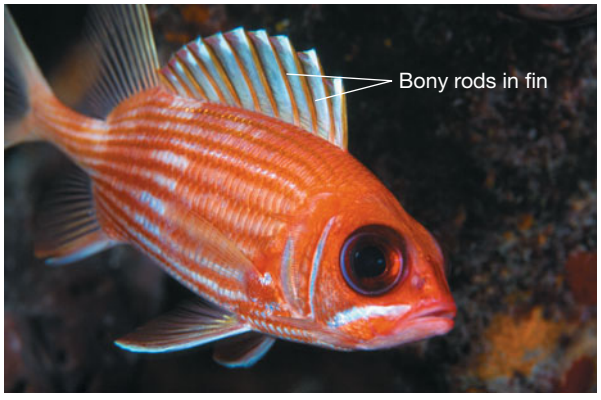

FIGURE 35.25 In Ray-Finned Fishes, Fins Are Supported by Long, Bony Rods.

The most important major lineage of ray-finned fishes is the Teleostei. About 96 percent of all living fish species, including familiar groups like the tuna, trout, cod, and goldfish, are teleosts. The teleosts underwent an adaptive radiation about the same time that mammals did.

Feeding Teleosts can suck food toward their mouths, grasp it with their protrusible jaws, and then process it with teeth on their jaws and with pharyngeal jaws in their throat. The size and shape of the mouth, the jaw teeth, and the pharyngeal jaw teeth all correlate with the type of food consumed. For example, most predatory teleosts have long, spear-shaped jaws armed with spiky teeth, as well as bladelike teeth on their pharyngeal jaws. Besides being major predators, ray-finned fishes are the most important large herbivores in both marine and freshwater environments.

Movement Like other fish, ray-finned fishes swim by alternately contracting muscles on the left and right sides of their bodies from head to tail, resulting in rapid, side-to-side undulations. Their bodies are streamlined to reduce drag in water. Teleosts have a flexible, symmetrical tail, which reduces the need to use their pectoral (side) fins as steering and stabilizing devices during rapid swimming.

Reproduction Most ray-finned fish species rely on external fertilization and are oviparous; some species have internal fertilization with external development; still others have internal fertilization and are viviparous. Although it is common for fish eggs to be released in the water and left to develop on their own, parental care occurs in some species. Parents may carry fertilized eggs on their fins, in their mouth, or in specialized pouches to guard them until the eggs hatch. In other cases the eggs are laid into a nest that is actively guarded and cared for. In freshwater teleosts, offspring develop directly; but marine species have larvae that undergo metamorphosis into a very different juvenile form, which then grows into an adult.

Chordata > Vertebrata > Actinistia (Coelacanths) and Dipnoi (Lungfish)

Although coelacanths (pronounced *SEEL-uh-kanths*) and lungfish represent independent lineages, they are sometimes grouped together and called **lobe-finned fishes.** Lobe-finned fishes are common and diverse in the fossil record in the Devonian period, about 400 million years ago, but only eight species are living today. They are important, however, because they represent a crucial evolutionary link between the fishes and the tetrapods. Early fishes in the fossil record have fins supported by stiff structures that extend from a base of bone. In ray-finned fishes, the bony elements are reduced. But in lobefins the bony elements extend down the fin, and they branch—similar to the bony elements in the limbs of tetrapods (**FIGURE 35.26**). ✔ **You should be able to indicate the origin of extensive fin bones on Figure 35.12.**

Coelacanths are marine and occupy habitats 150–700 m below the surface. In contrast, lungfish live in shallow, freshwater ponds and rivers (see Figure 35.15). As their name implies, lungfish have lungs and breathe air when oxygen levels in their habitats drop. Some species burrow in mud and enter a quiescent, sleeplike state when their habitat dries up during each year's dry season.

Feeding Coelacanths prey on fish. Lungfish are omnivorous ("all-eating"), meaning that they eat algae and plant material as well as animals.

Movement Coelacanths and lungfish swim by undulating their bodies; some lungfish can also use their fins to walk along pond bottoms.

Reproduction Sexual reproduction is the rule; fertilization is internal in coelacanths and external in lungfish. Coelacanths are ovoviviparous; lungfish lay eggs. Lungfish eggs hatch into larvae that resemble juvenile salamanders.

Latimeria menadoensis

FIGURE 35.26 Coelacanths Are Lobe-Finned Fishes.

Chordata > Vertebrata > Amphibia (Frogs and Toads, Salamanders, Caecilians)

Amphibians are found throughout the world and occupy ponds, lakes, or moist terrestrial environments. Translated literally, their name means "both-sides-living." The name is appropriate because adults of most amphibians feed on land but lay their eggs in water (**FIGURE 35.27**). In many amphibians, gas exchange occurs exclusively or in part across their moist, mucus-covered skin. ✔ **You should be able to indicate the origin of "skin-breathing" on Figure 35.12.** The 6800 named species of amphibians living today form three distinct clades: **(1)** frogs and toads, **(2)** salamanders, and **(3)** caecilians (pronounced *suh-SILL-ee-uns*). Caecilians lack limbs, and so resemble worms or snakes. They burrow underground in wet tropical regions.

Feeding Adult amphibians are carnivores. Most frogs and toads are sit-and-wait predators that use their long, extensible tongues to capture passing prey. Salamanders also have an extensible tongue, which some species use in feeding. Terrestrial caecilians prey on earthworms and other soil-dwelling animals; aquatic forms eat vertebrates and small fish.

Movement Most amphibians have four well-developed limbs. In water, frogs and toads move by kicking their hind legs to swim; on land, they kick their hind legs out to jump or hop. Salamanders walk on land; in water they undulate their bodies to swim. Caecilians lack limbs; terrestrial forms burrow in moist soils.

Reproduction Reproduction is sexual, breeding occurs in water, and larvae undergo a dramatic metamorphosis into land-dwelling adults. For example, the fishlike tadpoles of frogs and toads develop limbs, and their gills are replaced with lungs. Frogs have external fertilization, but salamanders and caecilians have internal fertilization. Frogs and most salamanders are oviparous, but many caecilians are viviparous.

Rana temporaria

FIGURE 35.27 Amphibians Are the Most Ancient Tetrapods.

Chordata > Vertebrata > Mammalia > Monotremata (Platypuses, Echidnas)

The **monotremes** are the most basal lineage of mammals living today and are found in nature only in Australia. Monotremes lay eggs and have metabolic rates that are lower than those of other mammals. Five species exist: one species of platypus (**FIGURE 35.28a**) and four species of echidnas (**FIGURE 35.28b**).

Feeding Monotremes have a leathery beak or bill. The platypus feeds on insect larvae, mollusks, and other small animals in streams. Echidnas feed on ants, termites, and earthworms.

Movement Platypuses swim with the aid of their webbed feet and walk when on land. Echidnas walk on their four legs.

Reproduction Platypuses lay their eggs in a burrow, while echidnas keep their eggs in a pouch on their belly. Young monotremes hatch quickly, and the mother must continue keeping them warm and dry for another four months. Like other mammals, monotremes produce milk and nurse their young. They lack well-defined nipples, however, and instead secrete milk from glands in the skin.

(a) Platypus

Ornithorhynchus anatinus

(b) Echidna

Tachyglossus aculeatus

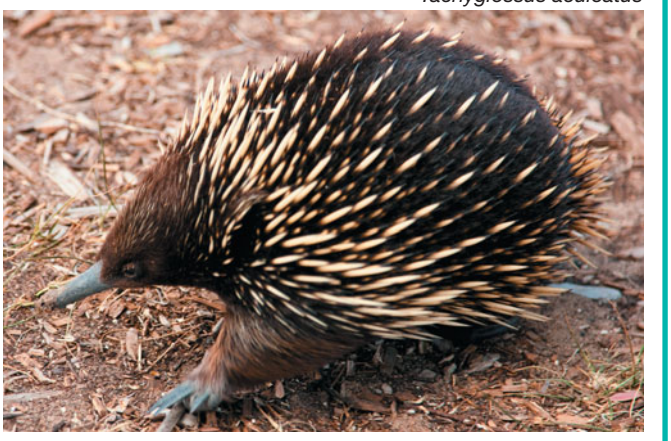

FIGURE 35.28 Platypuses and Echidnas Lay Eggs.

Chordata > Vertebrata > Mammalia > Marsupiala (Marsupials)

The 350 known species of **marsupials** live in the Australian region and the Americas and include the familiar opossums (**FIGURE 35.29**), kangaroos, wallabies, and koala.

Feeding Marsupials are herbivores, omnivores, or carnivores. In many cases, convergent evolution has resulted in marsupials that are similar to placental species in morphology and way of life. For example, a recently extinct marsupial called the Tasmanian wolf was a long-legged hunter similar to the wolves of North America and northern Eurasia. A species of marsupial native to Australia specializes in eating ants and looks and acts much like the South American anteater, which is not a marsupial.

Movement Marsupials move by crawling, gliding, walking, running, or hopping.

Reproduction Although females have a placenta that nourishes embryos during development, the young are born after a short embryonic period and are poorly developed. They crawl from the opening of the female's reproductive tract to her nipples, located within a pouch, where they suck milk. They stay attached to their mother until they grow large enough to move independently. ✔ **You should be able to indicate the origin of the placenta and viviparity—traits that are also found in eutherian mammals—on Figure 35.22.**

Didelphis virginiana

FIGURE 35.29 Marsupials Give Birth after a Short Embryonic Period. Opossums are the only marsupials living in North America.

Chordata > Vertebrata > Mammalia > Eutheria (Placental Mammals)

The 5100 described species of **placental mammals,** or **eutherians,** are distributed worldwide. They are far and away the most species-rich and morphologically diverse group of mammals.

Biologists group placental mammals into 29 lineages called orders. The six most species-rich orders are the rodents (rats, mice, squirrels; 2255 species), bats (1150 species), insectivores (hedgehogs, moles, shrews; 450 species), artiodactyls (pigs, hippos, whales, deer, sheep, cattle, horses; 329 species), carnivores (dogs, bears, cats, weasels, seals; 285 species), and primates (lemurs, monkeys, apes, humans; 414 species).

Feeding The size and structure of the teeth correlate closely with the diet of placental mammals. Herbivores have large, flat teeth for crushing leaves and other coarse plant material; predators have sharp teeth that are efficient at biting and tearing flesh. The structure of the digestive tract also correlates with the placental mammals' diet. In some plant eaters, for example, the stomach hosts unicellular organisms that digest cellulose and other complex polysaccharides.

Movement In placental mammals, the structure of the limb correlates closely with the type of movement performed. Eutherians fly, glide, run, walk, swim, burrow, or swing from trees. Hindlimbs are reduced or lost in aquatic groups such as whales and dolphins, which swim by undulating their bodies.

Reproduction Eutherians have internal fertilization and are viviparous. An extensive placenta develops from a combination of maternal and fetal tissues; and at birth, young are much better developed than in marsupials—some are able to walk or run minutes after emerging from the mother. ✔ **You should be able to indicate the origin of delayed birth (extended development before birth) on Figure 35.22.** All eutherians feed their offspring milk until the young have grown large enough to process solid food. A prolonged period of parental care, extending beyond the nursing stage, is common as offspring learn how to escape predators and find food on their own. Some eutherians are highly social (**FIGURE 35.30**).

Suricata suricatta

FIGURE 35.30 Eutherians Are Familiar and Diverse.

Chordata > Vertebrata > Reptilia > Lepidosauria (Lizards, Snakes)

Most lizards and snakes are small reptiles with elongated bodies and scaly skin. As these animals grow, they can shed the keratinized surface layer of their skin—all in one piece in snakes, and in flakes in lizards. ✔ **You should be able to indicate the origin of scaly skin on Figure 35.22.** Most lizards have well-developed jointed legs, but snakes are limbless (**FIGURE 35.31**). The hypothesis that snakes evolved from limbed ancestors is supported by the presence of vestigial hip and leg bones in boas and pythons. About 8900 species of lizards and snakes are alive now.

Feeding Small lizards prey on insects. Although most of the larger lizard species are herbivores, the spectacular 3-meter-long monitor lizard from the island of Komodo is a predator that can eat deer. Snakes are carnivores; some subdue their prey by injecting poison through modified teeth called fangs. Snakes prey primarily on small mammals, amphibians, and invertebrates, which they swallow whole—usually headfirst.

Movement Lizards crawl, climb, or run on their four limbs. Some lizards, such as the water dragons, use their powerful tails for swimming. Snakes and lizards that are limbless burrow through soil, crawl over the ground, or climb trees by undulating their bodies. One genus of snakes in Asia has several adaptations that enable them to glide down from treetops.

Morelia viridis

FIGURE 35.31 Snakes Are Limbless Predators.

Reproduction Although most lizards and snakes lay eggs, many are ovoviviparous; viviparity has also evolved numerous times in lizards. Most species reproduce sexually, but asexual reproduction, via the production of eggs by mitosis (parthenogenesis), is known to occur in six groups of lizards (including the Komodo dragon) and one snake lineage.

Chordata > Vertebrata > Reptilia > Testudinia (Turtles)

The 320 known species of turtles inhabit freshwater, marine, and terrestrial environments throughout the world. The testudines are distinguished by a shell composed of bony plates that fuse to the vertebrae and ribs (**FIGURE 35.32**). The shell functions in protection from predators—when threatened, most turtles can withdraw their head and legs into it. ✔ **You should be able to indicate the origin of the turtle shell on Figure 35.22.** The turtles' skulls are highly modified versions of the skulls of other reptiles. Turtles lack teeth, but their jawbone and lower skull form a bony beak. They range in size from the 2-m-long, 900-kg leatherback sea turtle to the 8-cm-long, 140-g speckled padloper tortoise. Tortoises are known for their longevity—some individuals are known to have lived well over 150 years.

Feeding Turtles are either carnivorous—feeding on whatever animals they can capture and swallow—or herbivorous. They may also scavenge dead material. Most marine turtles are carnivorous. Leatherback turtles, for example, feed primarily on jellyfish, and they are only mildly affected by the jellyfish's stinging cnidocytes (see Chapter 33). In contrast, species in the lineage of terrestrial turtles called the tortoises are plant eaters.

Testudo hermanni

FIGURE 35.32 Turtles Have a Shell Consisting of Bony Plates.

Movement Turtles swim, walk, or burrow. Some fully aquatic species have feet that are modified to function as flippers.

Reproduction All turtles are oviparous. Other than digging a nest prior to depositing eggs, parental care is lacking. Some aquatic species navigate long distances to their natal beaches with pinpoint accuracy, to lay eggs.

Chordata > Vertebrata > Reptilia > Crocodilia (Crocodiles, Alligators)

About 24 living species of crocodiles and alligators are known. Most are tropical and live in freshwater or marine environments. They have eyes located on the top of their heads, nostrils located at the top of their long snouts, and other adaptations that allow them to sit semi-submerged in water for long periods of time, breathing air and visually monitoring activity around them (**FIGURE 35.33**).

Feeding Crocodilians are predators. Like other toothed vertebrates, except mammals, their jaws are filled with conical teeth that are continually replaced as they fall out during feeding. Their usual method of killing small prey is by biting through the body wall. Large prey are usually subdued by drowning. Crocodilians eat amphibians, turtles, fish, birds, and mammals; one of the common hunting strategies of crocodiles is to leap out of the water to snatch unwary prey that have come to drink.

Movement Crocodiles and alligators walk on land. In water they swim with the aid of their large, muscular tails.

Reproduction Although crocodilians are oviparous, parental care is extensive. Eggs are laid in earth-covered nests or mounds of vegetation that are guarded by the parents. When young inside the eggs begin to vocalize, parents dig them out and often carry the newly hatched young inside their mouths to nearby water.

Alligator mississippiensis

FIGURE 35.33 Alligators Are Adapted for Aquatic Life.

Crocodilian young can hunt when newly hatched but stay near their mother for up to three years. ✔ **You should be able to indicate the origin of extensive parental care in crocodilians—which also occurs in birds (and other dinosaurs)—on Figure 35.22.**

Chordata > Vertebrata > Reptilia > Aves (Birds)

The fossil record provides conclusive evidence that birds descended from a lineage of dinosaurs that had **feathers.** Feathers provide insulation, are used for display, and furnish the lift, power, and steering required for flight (**FIGURE 35.34**). Birds have many other adaptations that make flight possible, including large breast muscles used to flap the wings. Bird bodies are lightweight because they have a reduced number of bones and organs and because their hollow bones are filled with air sacs linked to the lungs. Instead of teeth, birds have a horny beak. They are endotherms, meaning that they have a high metabolic rate and use the heat produced, along with the insulation provided by feathers, to maintain a constant body temperature. The 10,000 bird species alive today occupy virtually every habitat, including the open ocean. ✔ **You should be able to indicate the origin of feathers, endothermy, and flight on Figure 35.22.**

Feeding Plant-eating birds usually feed on nectar or seeds. Some birds are omnivores, although many are predators that capture insects, small mammals, fish, other birds, lizards, mollusks, or crustaceans. The shape of a bird's beak correlates with its diet.

Movement Almost all bird species can fly, although flightlessness has evolved repeatedly in certain groups. The size and shape of birds' wings correlate closely with the type of flying they do. Birds that glide or hover have long, thin wings; species that specialize in explosive takeoffs and short flights have short, stocky wings. Many seabirds are efficient swimmers, using their webbed feet to paddle or flapping their wings to "fly" underwater. Some ground-dwelling birds such as ostrich can run long distances at high speed.

Reproduction Birds are oviparous but provide extensive parental care. In most species, one or both parents build a nest and incubate the eggs. After the eggs hatch, parents feed offspring until they are large enough to fly and find food on their own.

Eudocimus albus

FIGURE 35.34 Birds Are Descendants of Feathered Dinosaurs.

35.4 The Primates and Hominins

Although humans occupy a tiny twig within the mammal branch on the tree of life, there has been a tremendous amount of research on human origins. This section introduces the lineage of mammals called the Primates, the fossil record of human ancestors, and data on the relationships among human populations living today.

The Primates

The lineage known as Primates consists of two main groups: prosimians and anthropoids.

- The **prosimians** ("before-monkeys") typically consist of the lemurs, found in Madagascar, and the lorises, pottos, and tarsiers of Africa and south Asia. However, recent phylogenetic analyses indicate that tarsiers are more closely related to the anthropoids than to the other prosimians, making the prosimians a paraphyletic group (**FIGURE 35.35a**). Most prosimians living today are relatively small in size, reside in trees, and are active at night.

(a) Prosimians

Lemur catta

(b) Anthropoids

Gorilla gorilla

FIGURE 35.35 There Are Two Main Lineages of Primates.

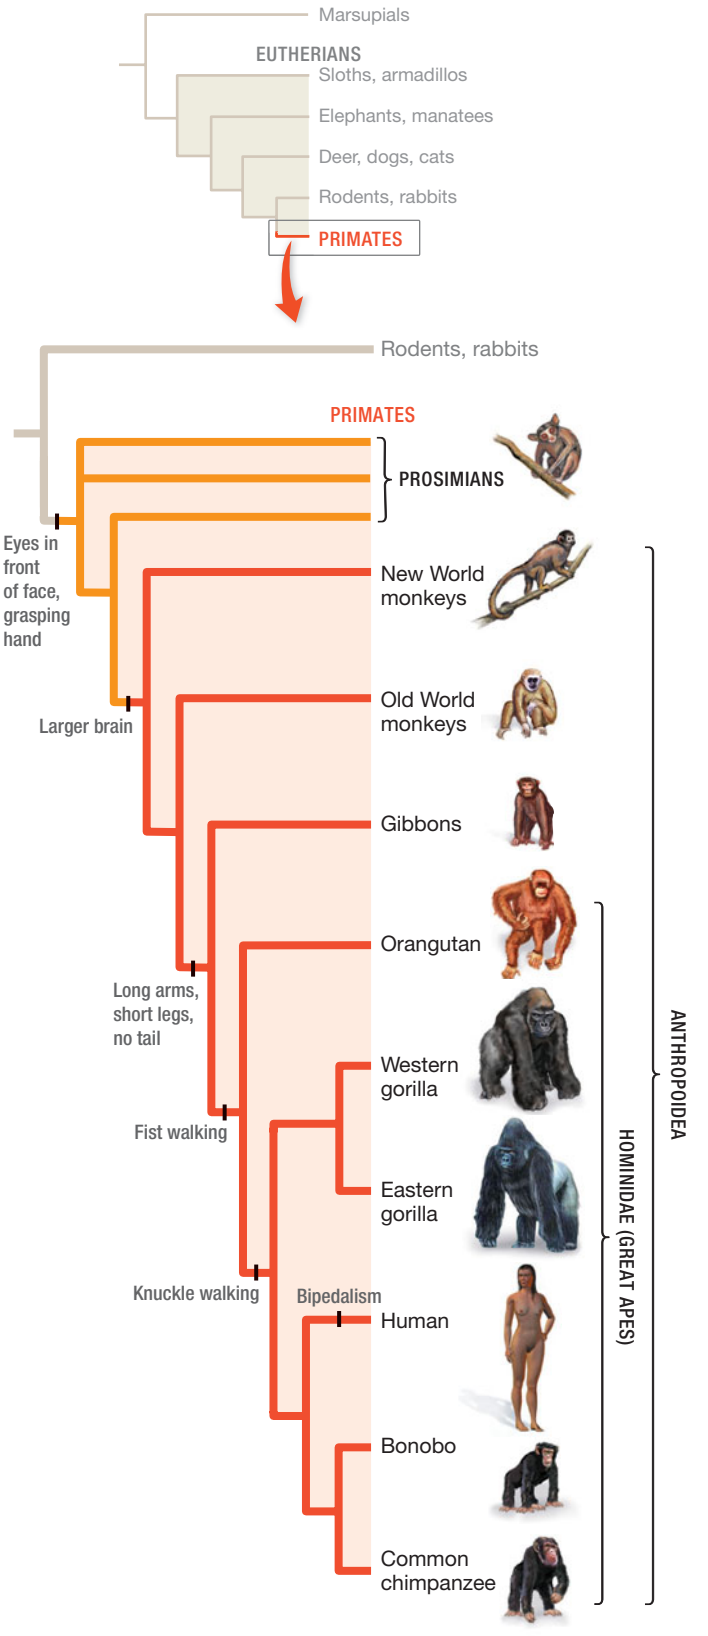

FIGURE 35.36 A Phylogeny of the Primates. Phylogenetic tree estimated from extensive DNA sequence data. According to the fossil record, humans and chimps shared a common ancestor 6 to 7 million years ago.

- The Anthropoidea or **anthropoids** ("human-like") include the New World monkeys found in Central and South America, the Old World monkeys that live in Africa and tropical regions of Asia, the gibbons of the Asian tropics, and the Hominidae, or **great apes**—orangutans, gorillas, chimpanzees, and humans (**FIGURE 35.35b**).

The phylogenetic tree in **FIGURE 35.36** shows the evolutionary relationships among these groups.

What Makes a Primate a Primate? **Primates** tend to have hands and feet that are efficient at grasping, flattened nails instead of claws on the fingers and toes, brains that are large relative to overall body size, color vision, complex social behavior, and extensive parental care of offspring.

Along with other mammal groups that live in trees or make their living by hunting, primates have eyes located on the front of the face. Eyes that look forward provide better depth perception than do eyes on the sides of the face. The hypothesis here is that good depth perception is important in species that run or swing through trees and/or attack prey.

What Makes a Great Ape a Great Ape? The great apes are also called **hominids.** Compared with most types of primate, the hominids are relatively large bodied and have long arms, short legs, and no tail.

Although all of the great ape species except for the orangutans live primarily on the ground, they have distinct ways of walking.

- When orangutans come to the ground, they occasionally walk with their knuckles pressed to the ground. More commonly though, they fist walk—that is, they walk with the backs of their hands pressed to the ground.
- Gorillas and chimps only knuckle walk. They also occasionally rise up on two legs—usually in the context of displaying aggression.
- Humans are the only living great ape that is fully **bipedal** ("two-footed")—meaning they walk upright on two legs. Fossil footprints in Tanzania provide direct evidence that bipedalism occurred at least 3.6 million years ago.

Bipedalism is the synapomorphy that defines the hominins. The **hominins** are a monophyletic group comprising *Homo sapiens* and more than twenty extinct, bipedal relatives.

Fossil Humans

From extensive comparisons of DNA sequence data, it is clear that humans are most closely related to the common chimpanzees and bonobos, and that our next nearest living relatives are the gorillas. According to the fossil record, the common ancestor of chimps and humans lived in Africa 6 to 7 million years ago.

The fossil record of hominins, though not nearly as complete as investigators would like, is rapidly improving. More than 20 species have been named to date, and new fossils that inform the debate over the ancestry of humans are discovered every year.

Although naming the hominin species and interpreting their characteristics remain intensely controversial, most researchers agree that the hominins can be organized into four major groups that appeared after the recently characterized *Ardipithecus ramidus*—the oldest hominin known to date. **TABLE 35.1** summarizes key data for

TABLE 35.1 Characteristics of Selected Hominins

Genus	Species	Location of Fossils	Estimated Average Braincase Volume (cm^3)	Estimated Average Body Size (kg)	Associated with Stone Tools?
Ardipithecus	*A. ramidus*	Africa	325	40	no
Australopithecus	*A. afarensis*	Africa	460	38	no
	A. africanus	Africa	465	34	no
Paranthropus	*P. boisei*	Africa	480	41	no?
Early *Homo*	*H. habilis*	Africa	610	33	**yes**
	H. ergaster	Africa	760	64	**yes**
	H. erectus	Africa, Asia	1000	58	**yes**
Recent *Homo*	*H. heidelbergensis*	Africa, Europe	1200	71	**yes**
	H. neanderthalensis	Middle East, Europe, Asia	1430	72	**yes**
	H. floresiensis	Flores (Indonesia)	380	28	**yes**
	H. sapiens	Middle East, Europe, Asia	1480	64	**yes**

Robson, S. L., and B. Wood. 2008. Hominin life history: Reconstruction and evolution. *Journal of Anatomy* 212: 394–425.

✔ **QUANTITATIVE** How much smaller is the average body size of *H. floresiensis* compared to the average *H. sapiens*? Express your answer as a percentage. How much smaller is the braincase volume of *H. floresiensis* compared to *H. sapiens?* What do these numbers suggest?

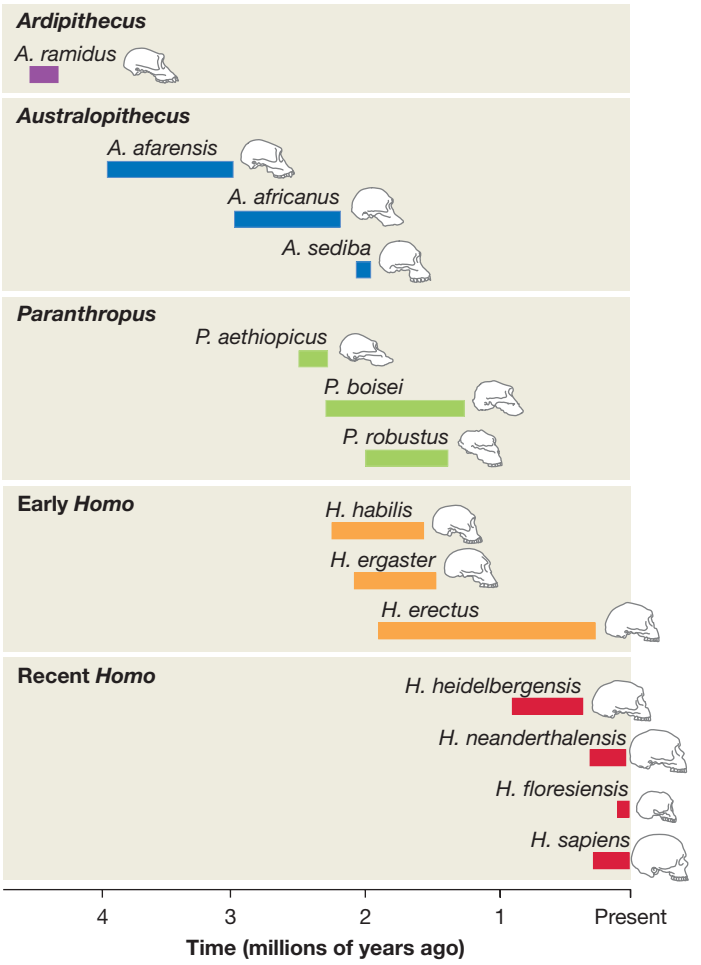

FIGURE 35.37 A Timeline of Hominin Evolution. The colored bars indicate the first appearance and last appearance in the fossil record of each species. (Not all named species are shown.)

DATA: Lieberman, D.E. 2009. *Nature* 459: 41–42.

✔ **QUANTITATIVE** Of the species of hominin shown, how many existed 1.8 million years ago (mya) and 100,000 years ago?

selected species within the four groups. **FIGURE 35.37** provides the time range of each of these species in the fossil record.

Gracile Australopithecines The small hominins called gracile australopithecines are referred to as *gracile*, or "slender," because they had a slight build. Adult males were about 1.5 meters tall, and their estimated weight was about 36 kg.

The gracile australopithecines are placed in the genus *Australopithecus* ("southern ape"). The name was inspired by the earliest specimens, which came from South Africa. The most recent *Australopithecus* to be named, *A. sediba* in 2010, is also from South Africa.

Several lines of evidence support the hypothesis that the gracile australopithecines were bipedal. The shape of the australopithecine knee and hip are consistent with bipedal locomotion, and the hole in the back of their skulls where the spinal cord connects to the brain is oriented downward (**FIGURE 35.38a**), just as it is in our species, *Homo sapiens*. In chimps, gorillas, and other vertebrates that walk on four feet, this hole is oriented backward.

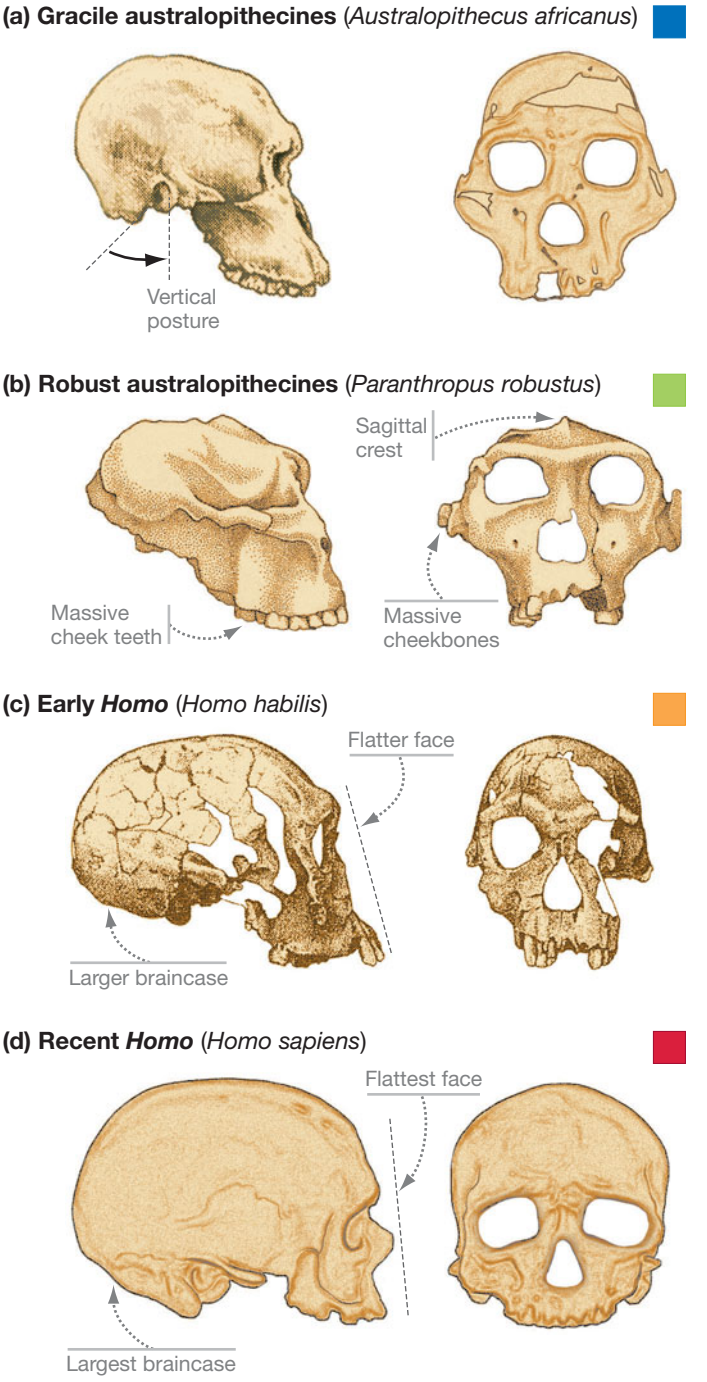

FIGURE 35.38 African Hominins Comprise Four Major Groups. The color key links these fossils with Figure 35.37 and Table 35.1.

✔ **QUESTION** The skulls are arranged as they appear in the fossil record, from most ancient (a) to most recent (d). How did the forehead and brow ridge of hominins change through time?

Robust Australopithecines The robust australopithecines are grouped in the genus *Paranthropus* ("beside-human"). The name *Paranthropus* was inspired by the hypothesis that the three known species are a monophyletic group that was a side branch during human evolution—an independent lineage that went extinct.

Like the gracile australopithecines, these robust australopithecines were bipedal. They were much stockier than the gracile

forms, however—about the same height but an estimated 8–10 kilograms (20 pounds) heavier on average. In addition, their skulls were much broader and more robust.

All three *Paranthropus* species had massive cheek teeth and jaws, very large cheekbones, and a sagittal crest—a flange of bone at the top of the skull (**FIGURE 35.38b**). Because muscles that work the jaw attach to the sagittal crest and cheekbones, researchers conclude that these organisms had tremendous biting power—inspiring the nickname "nutcracker man" for one species. Recent analysis of tooth enamel revealed that the biting power of *Paranthropus* was probably used to crush large quantities of tough grasses.

Early *Homo* Species in the genus *Homo* are called **humans.** As **FIGURE 35.38c** shows, species in this genus have flatter and narrower faces, smaller jaws and teeth, and larger braincases than the earlier hominins do. (The **braincase** is the portion of the skull that encloses the brain.)

The appearance of early members of the genus *Homo* in the fossil record coincides closely with the appearance of tools made of worked stone—most of which are interpreted as handheld choppers or knives. Although the fossil record does not exclude the possibility that *Paranthropus* made tools, many researchers favor the hypothesis that extensive toolmaking was a diagnostic trait of early *Homo*.

Recent *Homo* The recent species of *Homo* date from 1.2 million years ago to the present. As **FIGURE 35.38d** shows, these species have even flatter faces, smaller teeth, and larger braincases than the early *Homo* species do. The 30,000-year-old fossil in the figure, for example, is from a population of *Homo sapiens* (our species) called the **Cro-Magnons.**

The Cro-Magnons were accomplished painters and sculptors who buried their dead in carefully prepared graves. There is also evidence that another species, the **Neanderthal** people (*Homo neanderthalensis*) made art and buried their dead in a ceremonial fashion.

Perhaps the most striking recent *Homo*, though, is *H. floresiensis*. This new species was discovered in 2003 on the island of Flores in Indonesia—also home to a species of dwarfed elephants. *H. floresiensis* consisted of individuals that had braincases smaller than those of gracile australopithecines and that were about a meter tall, inspiring the nickname Hobbit. While some researchers propose that the fossils represent a population of *H. sapiens* stunted by disease, most support full species status. Fossil finds suggest that *H. floresiensis* inhabited Flores from about 100,000 to as recently as 12,000 years ago.

What Can Be Deduced from the Hominin Fossil Record? Although researchers do not have a solid understanding of the phylogenetic relationships among the hominin species, several points are clear from the available fossil data.

1. The shared, derived character that defines the hominins is bipedalism.
2. Several species from the lineage were present simultaneously during most of hominin evolution.
3. Compared with the gracile and robust australopithecines and the other great apes, species in the genus *Homo* have extremely large brains relative to their overall body size.

Why did humans evolve such gigantic brains? The leading hypothesis on this question is that early *Homo* began using symbolic spoken language and tools. The logic here is that increased language use and toolmaking triggered natural selection for the capacity to reason and communicate, which required a larger brain.

To summarize, *Homo sapiens* is the sole survivor of an adaptive radiation of hominins that began in Africa 6–7 million years ago. Why all but one species went extinct is still a mystery, though climate change and competition for food and space may have played a part.

The Out-of-Africa Hypothesis

If hominins originated in Africa and then spread around the world, where did *H. sapiens* originate?

The leading hypothesis for the evolution of *H. sapiens* is called the **out-of-Africa hypothesis.** It contends that *H. sapiens* evolved its distinctive traits in Africa and then dispersed throughout the world. Further, it claims that *H. sapiens* evolved independently of the earlier European and Asian species of *Homo*—meaning there was no interbreeding between *H. sapiens* and Neanderthals, *H. erectus*, or *H. floresiensis*. Do the data support this hypothesis?

Fossil Evidence The first *H. sapiens* fossils appear in East African rocks that date to about 195,000 years ago. For some 130,000 years thereafter, the fossil record indicates that our species occupied Africa while *H. neanderthalensis* resided in Europe and the Middle East. Some evidence suggests that *H. erectus* may still have been present in Asia at that time.

In rocks dated between 60,000 and 30,000 years ago, however, *H. sapiens* fossils are found throughout Europe, Asia, Africa, and Australia. *H. erectus* had disappeared by this time, and *H. neanderthalensis* went extinct after coexisting with *H. sapiens* in Europe for thousands of years.

Taken together, the fossil evidence provides strong support for the African origin of *H. sapiens* and subsequent migration, but it cannot resolve the question of whether *H. sapiens* ever interbred with Neanderthals during their coexistence.

Molecular Evidence Some researchers have taken a molecular approach to understanding the history of our species, providing several major insights.

For example, Luigi Cavali-Sforza and others have created phylogenetic trees based on genetic comparisons of diverse human populations living today. These data agree with the pattern in the fossil record. As **FIGURE 35.39** (see page 708) shows, the first lineages to branch off led to descendant populations that live in Africa today. Later branches gave rise to lineages in central Asia, Europe, East Asia, Polynesia, and the Americas. Based on this observation, it is logical to infer that the ancestral population of modern humans lived in Africa.

Did *H. sapiens* leave Africa in one wave? Sequence data from modern Aboriginal Australians support the hypothesis that

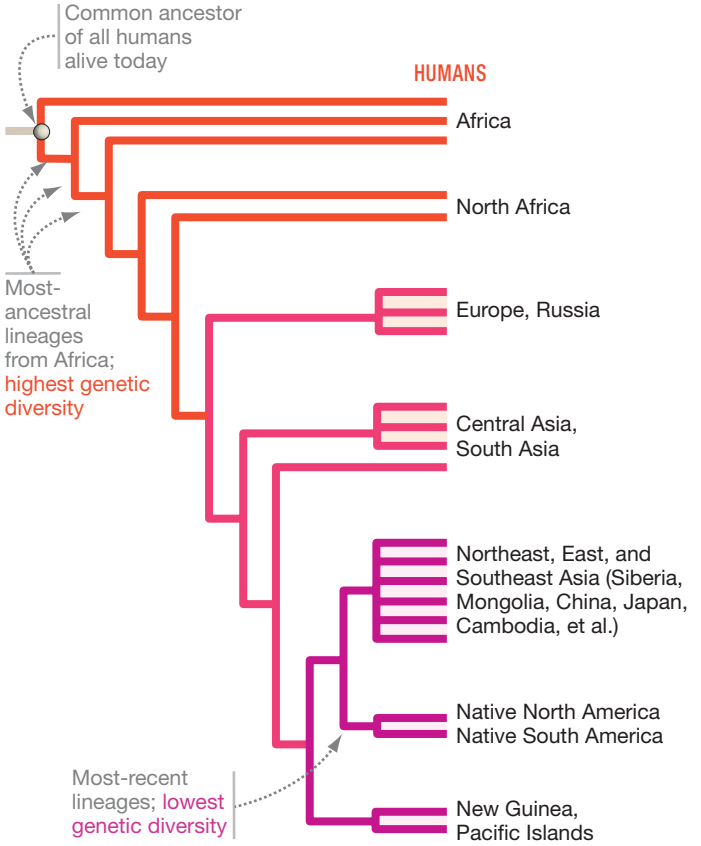

FIGURE 35.39 Phylogeny of Human Populations Living Today. The phylogeny was estimated from DNA sequence data. As predicted by the out-of-Africa hypothesis, the lineages with the highest genetic diversity and deepest history occur in Africa.

the human migration out of Africa occurred in more than one wave—the first wave moved east and south to Australia, and the second wave moved to Europe and the rest of mainland Asia. While the exact migration routes of *H. sapiens* are hotly debated, **FIGURE 35.40** provides a general summary.

What about the question of interbreeding? There are now two lines of evidence that *H. sapiens* interbred with other species as they migrated out of Africa. First, Svante Pääbo and his colleagues compared gene sequences of extinct Neanderthals and diverse modern humans. They made the remarkable observation that 1 to 4 percent of the genome of indigenous Europeans and Asians—but not Africans—is derived from Neanderthals. These data suggest that *H. sapiens* and Neanderthals interbred in the Middle East after *H. sapiens* left Africa, but before migrating through Europe and Asia.

Second, sequence data from modern Asians and Aboriginal Australians suggest that modern humans interbred with a recently discovered descendant population of *H. erectus*, called the Denisovans, in Asia during their first migration out of Africa. As a result, Aboriginal Australians and their island neighbors—descendants of the first migration—inherited about 5 percent of their nuclear DNA from Denisovans.

In summary, the Neanderthal and Denisovan data reject the strict interpretation of the out-of-Africa hypothesis since a small amount of gene flow occurred between *H. sapiens* and Neanderthals as well as between *H. sapiens* and the Denisovans. However, other fossil and molecular evidence supports the general concept of the out-of-Africa hypothesis. That is, the overall data support an out-of-Africa hypothesis with "leakage."

The study of human evolution is an exciting and dynamic field. And humans continue to evolve.

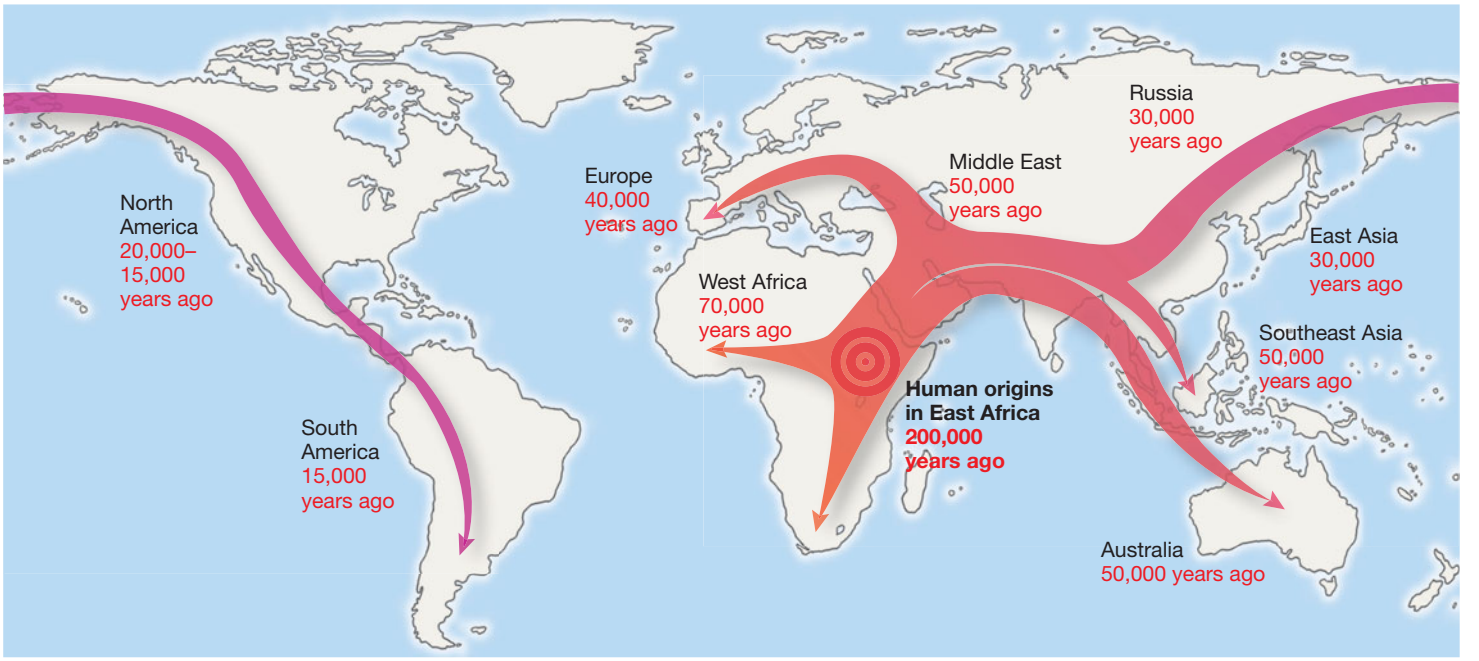

FIGURE 35.40 *Homo sapiens* Originated in Africa and Spread throughout the World. The migration out of Africa probably occurred in two waves—first east and south to Australia, and later to Europe and the rest of Asia and the Americas.

If you understand . . .

35.1 What Is an Echinoderm?

- Echinoderms are among the most important predators and herbivores in marine environments. They include the sea stars, sea urchins, sea cucumbers, and feather stars.
- Echinoderm larvae are bilaterally symmetric but most undergo a metamorphosis into radially symmetric adults.
- Echinoderms have a calcium carbonate endoskeleton.
- The echinoderm water vascular system is composed of fluid-filled tubes and chambers called tube feet. Tube feet may be used for movement, feeding, or respiration.

✔ **You should be able to predict what happens when (1) sea stars that prey on mussels and clams are excluded from experimental plots, and (2) sea urchins that graze on kelp are excluded from experimental plots.**

35.2 What Is a Chordate?

- Chordates are distinguished by the presence of pharyngeal gill slits, a dorsal hollow nerve cord, a notochord, and a muscular tail that extends past the anus.
- Chordates include cephalochordates, urochordates, and vertebrates.

✔ **You should be able to make a simple cartoon of a generic chordate showing its defining features.**

35.3 What Is a Vertebrate?

- Vertebrates are distinguished by the presence of a cranium and vertebrae. In some groups of vertebrates, the body plan features an extensive endoskeleton composed of bone.
- The origin of jaws in ray-finned fishes enabled these fishes and their descendants to bite food and process it with teeth.
- The origin of limbs in tetrapods enabled walking and running on land, and flying. Tetrapods include the amphibians, mammals, and reptiles (which include birds).
- The evolution of the amniotic egg allowed tetrapods to lay large eggs on land.
- Parental care was an important adaptation in some groups of ray-finned fishes and tetrapods—particularly mammals.
- Vertebrates are the most important large-bodied predators and herbivores in both marine and terrestrial environments.

✔ **You should be able to explain why the tetrapod limb could have evolved in an animal that was aquatic.**

35.4 The Primates and Hominins

- Humans are a tiny twig on the tree of life. Chimpanzees and humans diverged from a common ancestor that lived in Africa 6–7 million years ago.
- The fossil record of the past 4.5 million years contains many distinct species of hominins. *Homo sapiens* is the sole surviving representative of an adaptive radiation.
- For most of human evolution, several species were present in Africa or Europe at the same time. Some lineages went extinct without leaving descendant populations.
- The phylogeny of living humans, based on comparisons of DNA sequences, agrees with evidence in the fossil record that *H. sapiens* originated in Africa and later spread throughout Asia, Europe, and the Americas.

✔ **You should be able to describe evidence supporting the hypothesis that *Homo sapiens* originated in Africa.**

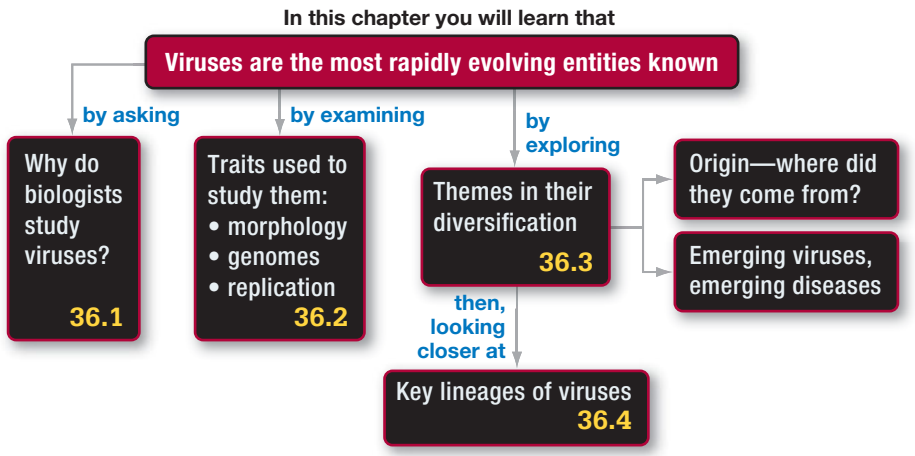
TEST YOUR KNOWLEDGE

Answers are available in Appendix A

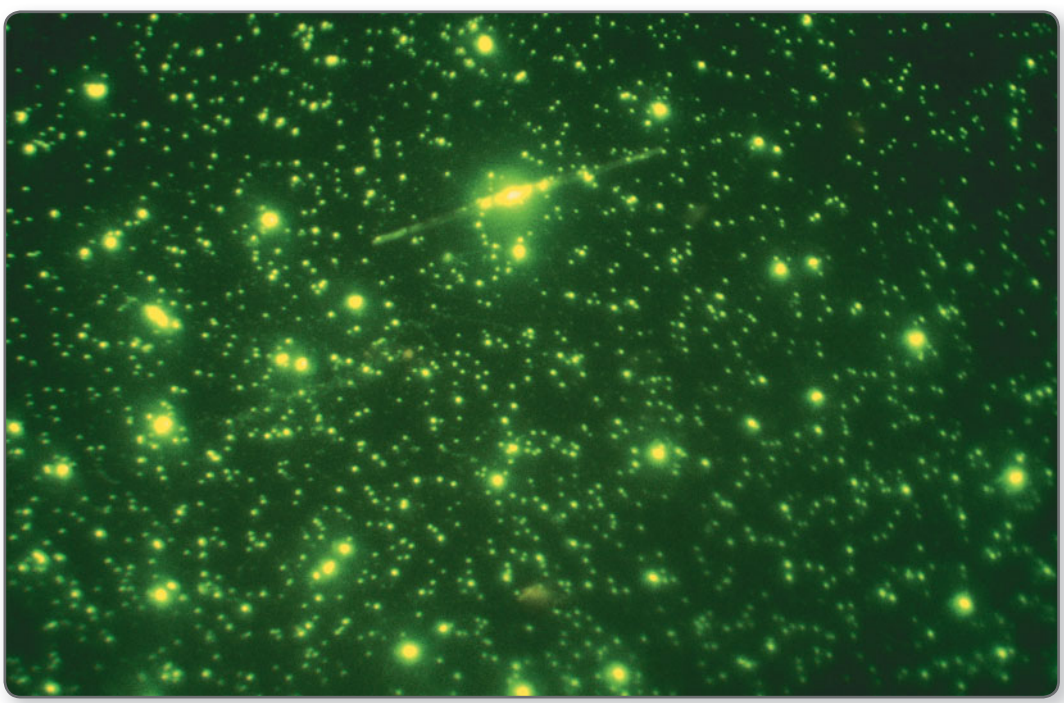
1. True or false? Both echinoderms and vertebrates have endoskeletons.
2. What trait(s) define(s) the vertebrates?
   a. vertebrae and a cranium
   b. jaws and a spinal cord
   c. endoskeleton constructed of bone
   d. endoskeleton constructed of reinforced cartilage
3. Why are the pharyngeal jaws of many ray-finned fishes important?
   a. They allow the main jaw to be protrusible (extendable).
   b. They make it possible for individuals to suck food toward their mouths.
   c. They give rise to teeth that are found on the main jawbones.
   d. They help process food.
4. The two major lineages that make up the living Amniota are reptiles and _____.
5. In chordates, what is the relationship between the dorsal hollow nerve cord and the spinal cord?
   a. The dorsal hollow nerve cord is found only in embryos; the spinal cord is found in adults.
   b. The dorsal hollow nerve cord stiffens the body and functions in movement; the spinal cord relays electrical signals.
   c. The dorsal hollow nerve cord is found in early fossils of chordates; living species have a spinal cord.
   d. The spinal cord is a type of dorsal hollow nerve cord.
6. Most species of hominins are known only from Africa. Which species have been found in other parts of the world as well?
   a. early *Homo*—*H. habilis* and *H. ergaster*
   b. *H. erectus*, *H. neanderthalensis*, and *H. floresiensis*
   c. gracile australopithecines
   d. robust australopithecines

TEST YOUR UNDERSTANDING

Answers are available in Appendix A



7. Mammals and birds are both endothermic. Which statement is true?
   a. They both inherited this trait from a common ancestor.
   b. Birds are more closely related to mammals than to reptiles.
   c. Endothermy arose independently in these two lineages.
   d. All reptiles are ectothermic.
8. Explain why each of the four key synapomorphies that distinguish chordates is important in feeding or movement. Why is it possible to say that a certain animal is an "invertebrate chordate"?
9. The cells that make up jaws and gill arches are derived from the same population of embryonic cells. Why does this observation support the hypothesis that jaws evolved from gill arches in fish?
10. Explain how the evolution of the placenta and lactation in mammals improved the probability that mammalian offspring would survive, compared to offspring of species without parental care.
11. The text claims that *Homo sapiens* is the sole survivor of an adaptive radiation that took place over the past 6–7 million years. Do you agree with this statement? Why or why not?
12. Describe a phylogeny of modern humans that would reject the out-of-Africa hypothesis.



TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A

13. There is some evidence that pharyngeal gill slits occur in certain species of echinoderms that appear early in the fossil record. If confirmed, what do these data suggest?
    a. Echinoderms are chordates.
    b. Pharyngeal gill slits were present in the earliest echinoderms and lost later.
    c. Some lineages of echinoderms are more closely related to chordates than others.
    d. Pharyngeal gill slits should not be used as a trait in phylogenetic analysis.
14. Animals in the species *Xenoturbella* have extremely simple, wormlike bodies. For example, they have a blind gut (only one opening) and no brain. Propose a hypothesis to explain how this simple body plan evolved in this lineage.
15. In arthropods such as crustaceans and insects, changes in the expression patterns of tool-kit genes enabled a dramatic diversification of their segmented appendages and bodies. Design an experiment to test whether this concept applies to vertebrates.
16. **QUANTITATIVE** Genetic diversity in living human populations is highest in Africa and decreases as a function of distance from Africa. Draw a graph to show this result. Add a label where you would expect to find a data point for the Yanomamö tribe of South America. Why is it important to use indigenous people for this study?

36 Viruses

Photomicrograph created by treating seawater with a fluorescing compound that binds to nucleic acids. The smallest, most abundant dots are viruses. The larger, numerous spots are bacteria and archaea. The largest splotches are protists.

If you have ever been laid low by a high fever, cough, scratchy throat, body ache, and debilitating lack of energy, you may have wondered what hit you. What hit you was probably a **virus:** an obligate, intracellular parasite.

Why obligate? Viral replication is *completely* dependent on host cells. Why intracellular? Viruses must enter a host cell for replication to occur. Why parasite? Viruses reproduce at the expense of their host cells.

Viruses can also be defined by what they are not:

- They are not cells and are not made up of cells, so they are not considered organisms.
- They cannot manufacture their own ATP or amino acids or nucleotides, and they cannot produce proteins on their own.

Viruses enter a **host cell,** take over its biosynthetic machinery, and use that machinery to manufacture a new generation of viruses. Outside of host cells, viruses simply exist.

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

SUMMARY TABLE 36.1 Viruses versus Organisms

Characteristics	Viruses	Organisms
Hereditary material	DNA or RNA; can be single stranded or double stranded	DNA; always double stranded
Plasma membrane present?	No	Yes
Can carry out transcription independently?	No—even if a viral polymerase is present, transcription of viral genomes requires use of nucleotides provided by host cell	Yes
Can carry out translation independently?	No	Yes
Metabolic capabilities	Virtually none	Extensive—synthesis of ATP, reduced carbon compounds, vitamins, lipids, nucleic acids, etc.

When you have the flu, influenza viruses enter the cells that line your respiratory tract and use the machinery inside to make copies of themselves. Every time you cough or sneeze, you eject millions or billions of their offspring into the environment. If one of those infectious particles is lucky enough to be breathed in by another person, it may enter his or her respiratory tract cells and start a new infection.

Viruses are not organisms. Most biologists would argue that viruses are not alive, because they are dependent on their host cell to satisfy the five attributes of life (see Chapter 1). Yet viruses have a genome, they are superbly adapted to exploit the metabolic capabilities of their host cells, and they evolve. **TABLE 36.1** summarizes some characteristics of viruses and how they differ from organisms.

The diversity and abundance of viruses almost defy description. Each type of virus infects a specific unicellular species or cell type in a multicellular species, and nearly all organisms examined thus far are parasitized by at least one kind of virus. The surface waters of the world's oceans teem with bacteria and archaea, yet viruses outnumber them in this habitat by a factor of 10 to 1. If you leaned over a boat and filled a wine bottle with seawater, it would contain about 10 billion virus particles—close to one and a half times the world's population of humans.

36.1 Why Do Biologists Study Viruses?

Any study of life's diversity would be incomplete unless it included a look at the acellular parasites that contribute to that diversity. Viruses have directly participated in organismal diversity by introducing foreign genes into cellular genomes. They can pick up cellular genes and shuttle them from one organism to another. In this way, viruses can promote **lateral gene transfer** (see Chapter 21).

In addition, viruses also contribute their own genetic material to organisms. Researchers estimate that 5–8 percent of the human genome consists of remnants of viral genomes from past infections. Some of these viral genes have even evolved to be part of what makes us human. For example, a protein that is encoded by an abandoned viral gene is necessary for proper development and function of the human placenta.

Viruses are also important from a practical standpoint. To health-care workers, agronomists, and foresters, these parasites are a persistent—and sometimes catastrophic—source of misery and economic loss. Much of the research on viruses is motivated by the desire to minimize the damage they can cause. In the human body, virtually every system, tissue, and cell can be infected by at least one kind of virus, and each of these viruses often infects more than one site (**FIGURE 36.1**).

Recent Viral Epidemics in Humans

Physicians and researchers use the term **epidemic** (literally, "upon-people") to describe a disease that rapidly affects a large number of individuals over a widening area.

Viruses have caused the most devastating epidemics in recent human history. During the eighteenth and nineteenth centuries, it was not unusual for Native American tribes to lose 90 percent of their members over the course of a few years to measles, smallpox, and other viral diseases spread by contact with European settlers. To appreciate the impact of these epidemics, think of 10 close friends and relatives—then remove nine.

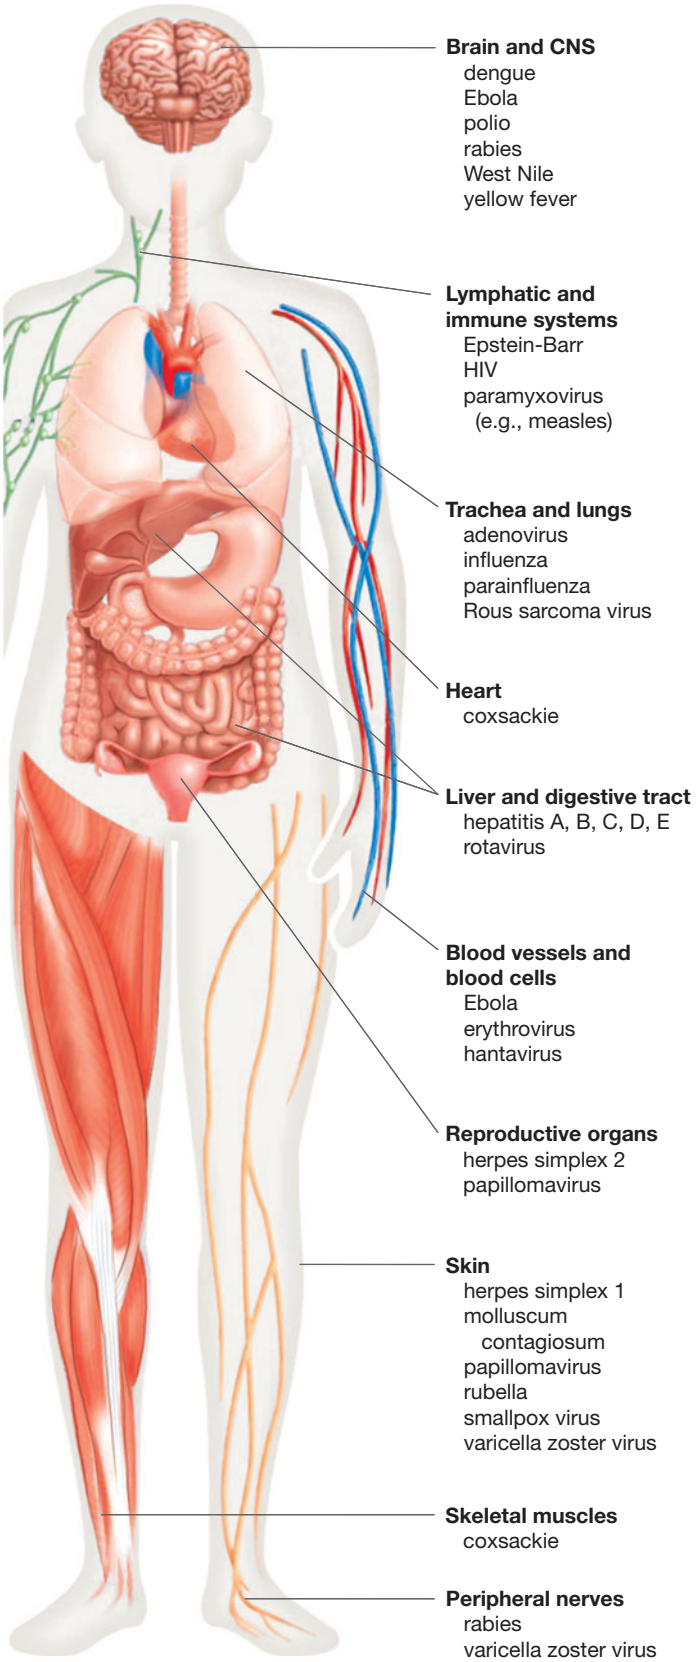
An epidemic that is worldwide in scope is called a **pandemic.** The influenza outbreak of 1918–1919, called Spanish flu, qualifies as the most devastating pandemic recorded to date. The strain of influenza virus that emerged in 1918 infected people worldwide and was particularly **virulent**—meaning it tended to cause severe disease. The viral outbreak occurred just as World War I was drawing to a close and killed far more people in eight months than did the five-year conflict itself.

FIGURE 36.2 illustrates the impact of this pandemic in relation to the life expectancy in the United States during the twentieth century. Worldwide, the Spanish flu is thought to have killed up to 50 million people. An estimated 20 million died in the first 8 months of the pandemic.

Current Viral Pandemics in Humans: AIDS

In terms of the total number of people affected, the measles and smallpox epidemics and the 1918 influenza pandemic are almost certain to be surpassed by the incidence of **acquired immune deficiency syndrome (AIDS).** AIDS is an affliction caused by the **human immunodeficiency virus (HIV).**

HIV is now the one of the most intensively studied of all viruses. Since the early 1980s, governments and private corporations from around the world have spent hundreds of millions of dollars on



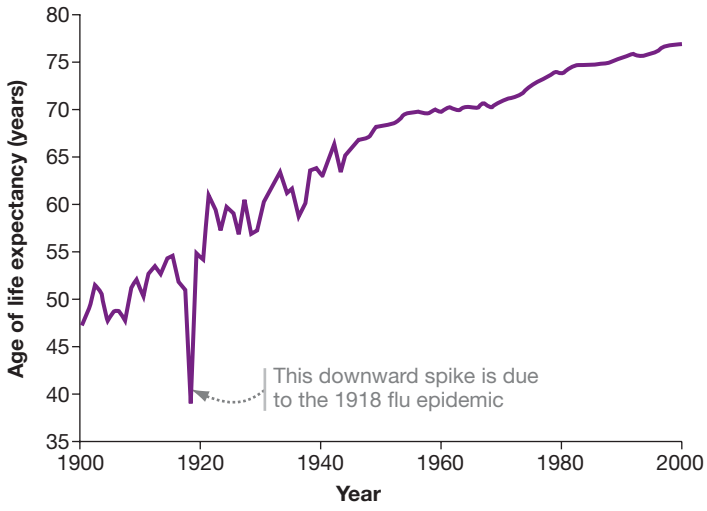


FIGURE 36.1 Human Organs and Systems That Are Parasitized by Viruses. Viruses shown in this figure may infect more than one tissue, but for simplicity, usually only one tissue is shown.

HIV research. Given this virus's current and projected impact on human populations around the globe, the investment is justified.

How Does HIV Cause Disease? Like other viruses, HIV parasitizes specific types of cells—most notably, the helper T cells of the **immune system,** which is the body's defense system against disease. Helper T cells are crucial to the immune system's response to invading pathogens (see Chapter 51).

If an HIV particle succeeds in infecting a helper T cell and reproduces inside, the cell will die as hundreds of new progeny particles are released and infect more cells. Although the body continually replaces helper T cells, the number produced does not keep pace with the number being destroyed by HIV. As

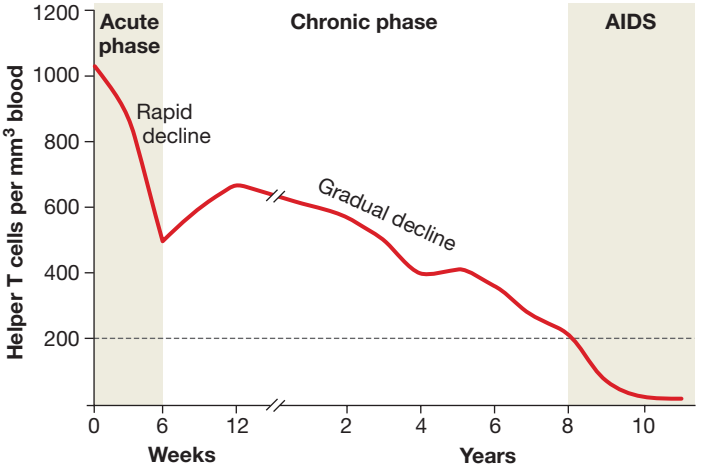

FIGURE 36.3 T-Cell Counts Decline during an HIV Infection. Graph of changes in the number of helper T cells that are present in the bloodstream over time, based on data from a typical patient infected with HIV. The acute phase may be associated with symptoms such as fever. Few or no disease symptoms occur in the chronic phase. AIDS typically occurs when T-cell counts dip below 200 per mm^3 of blood.

DATA: Pantaleo, G., and Fauci, A. S. 1996. *Annual Review of Microbiology* 50: 825-854.

a result, the total number of helper T cells in the bloodstream gradually declines as an HIV infection proceeds (**FIGURE 36.3**).

As the T-cell count drops, the immune system's responses to invading pathogens become less and less effective. Eventually, too few helper T cells are left to fight off pathogens efficiently, allowing bacteria, fungi, protists, or other viruses to multiply unchecked. In almost all cases, one or more of these "opportunistic" infections proves fatal. HIV kills people indirectly—by making them susceptible to diseases that normally do not arise in those with functioning immune systems.

What Is the Scope of the AIDS Pandemic? Researchers with the United Nations AIDS program estimate that AIDS has already killed almost 30 million people worldwide. HIV infection rates have been highest in east and central Africa, where one of the greatest public health crises in history is now occurring. In Botswana, for example, blood-testing programs have confirmed that over 20 percent of the population is HIV positive. Although there may be a lag of as much as 8 to 12 years between the initial infection and the onset of illness, virtually all people who become infected with the virus will die of AIDS.

Currently, the UN estimates the total number of HIV-infected people worldwide at about 34 million. An additional 2.7 million people are infected each year. Most infectious diseases afflict the very young and the very old, but because HIV is primarily a sexually transmitted disease, young adults are most likely to contract the virus and die.

People who become infected with HIV in their late teens or twenties die of AIDS in their twenties or thirties. Tens of millions of people are being lost in the prime of their lives. Physicians, politicians, educators, and aid workers all use the same word to describe the epidemic's impact: staggering.

36.2 How Do Biologists Study Viruses?

Many researchers who study viruses focus on two goals: **(1)** developing vaccines that help hosts fight off disease if they become infected and **(2)** developing antiviral drugs that prevent a virus from replicating efficiently inside the host. Both types of research begin with attempts to isolate the virus in question to learn more about its structure and mode of replication.

Isolating viruses takes researchers into the realm of nanobiology, in which structures are measured in billionths of a meter. (One nanometer, abbreviated nm, is 10^{-9} meter.) Viruses range from about 20 to 300 nm in diameter. They are dwarfed by eukaryotic cells and even by most bacterial cells (**FIGURE 36.4**). Millions of viruses can fit on the period at the end of this sentence.

If virus-infected cells can be grown in culture or harvested from a host individual, researchers can usually isolate the virus by passing solutions of infected cultures or patient samples (e.g., blood, saliva, feces) through a filter. The filters used to study viruses have pores that are large enough for viruses to pass through but are too small to admit cells. If exposing susceptible host cells to the filtrate results in infection, the hypothesis that a virus caused the disease is supported.

In this way, researchers can isolate a virus and confirm that it is the causative agent of infection. These steps are inspired by Koch's postulates, which established the criteria for linking a specific infectious agent with a specific disease (see Chapter 29).

Once biologists have isolated a virus, how do they study and characterize it? The answer is threefold—by analyzing **(1)** the structure of the extracellular infectious particle, referred to as the **virion; (2)** the nature of the genetic material that is transmitted

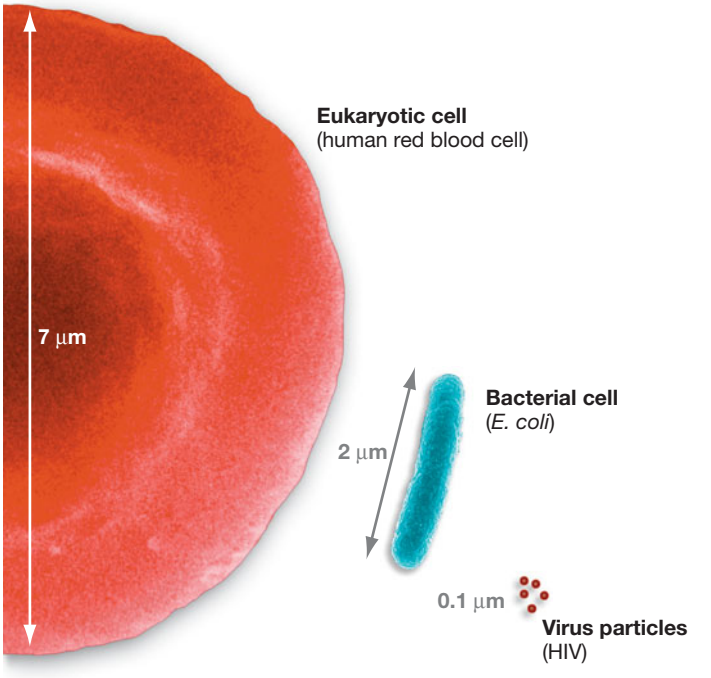

FIGURE 36.4 Viruses Are Tiny.

by virions from one host to another; and **(3)** variations in how viruses replicate. Let's begin with morphological traits.

Analyzing Morphological Traits

To see the virion of a particular virus, researchers usually rely on transmission electron microscopy (see **BioSkills 11** in Appendix B). Only the very largest viruses, such as the smallpox virus, are visible with a light microscope. Electron microscopy has revealed that viruses come in a wide variety of shapes, and many viruses can be identified by shape alone.

In terms of overall structure, most viruses fall into two general categories: **(1)** those that are enclosed by just a shell of protein called a **capsid** and **(2)** those enclosed by both a capsid and a membrane-like **envelope.**

Most viruses produce virions with capsid shapes that are either helical or icosahedral (an icosahedron is a polyhedron with 20 triangular faces) (**FIGURE 36.5a** and **b**). Some viruses, like bacteriophage T4 and the smallpox virus, however, have more complex capsid shapes (**FIGURE 36.5c** and **d**). A virion's capsid serves two functions: it protects the genome while outside the host and is also able to release the genome when infecting a new cell.

Nonenveloped viruses, often called "naked" viruses, use only the capsid shell to protect their genetic material. The naked icosahedral virion illustrated in Figure 36.5b is an adenovirus. You undoubtedly have adenoviruses on your tonsils or in other parts of your upper respiratory passages right now.

Enveloped viruses also have genetic material inside a capsid, or bound to capsid proteins, but the capsid is further enclosed in one or more membranes like the smallpox virus shown in Figure 36.5d. The envelope consists of viral proteins embedded in a phospholipid bilayer derived from a membrane found in a host cell—specifically, the host cell in which the virion was manufactured. Later sections of this chapter will detail how viruses obtain their envelope from an infected host cell.

Analyzing the Genetic Material

In addition to morphology, viruses can be categorized based on the nature of their genome. This is not true for cells. DNA is the hereditary material in all cells, and information flows from DNA to mRNA to proteins (Chapter 16). Although all cells follow this pattern, which is called the central dogma of molecular biology, many viruses break it.

This conclusion traces back to work done in the 1950s, when Heinz Fraenkel-Conrat and colleagues were able to separate the protein and nucleic acid components of a plant virus known as the tobacco mosaic virus, or TMV. Surprisingly, the nucleic acid

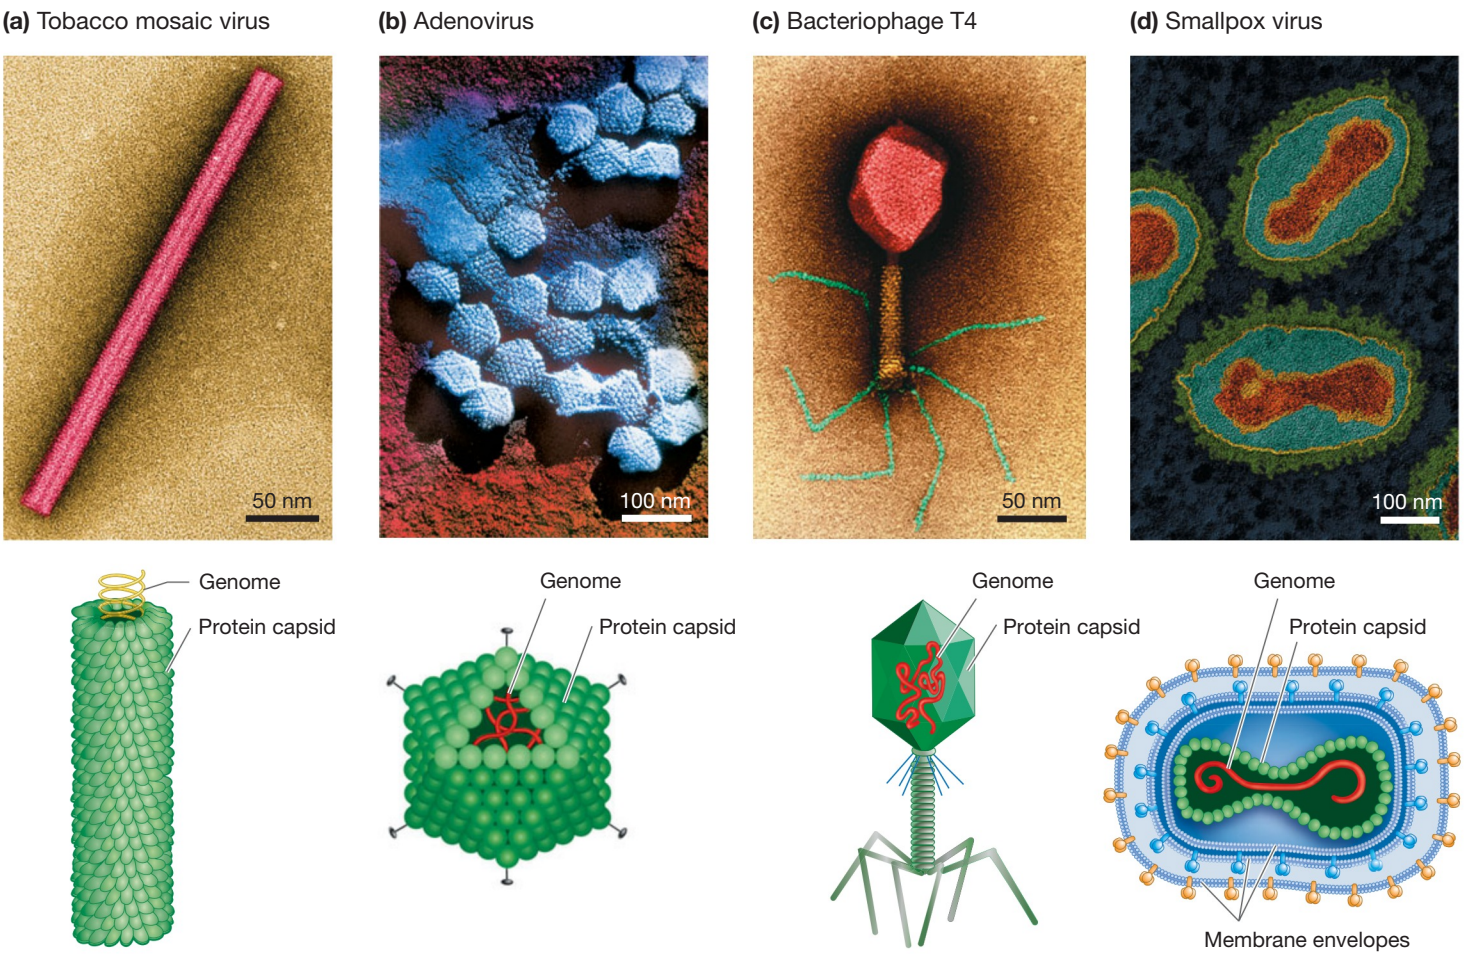

FIGURE 36.5 Viruses Vary in Size and Shape, and May Be "Naked" or Enveloped.

portion of this virus consisted of RNA, and the RNA of TMV, by itself, could infect plant tissues and cause disease. This was a confusing result because it showed that the RNA—not DNA—functions as TMV's genetic material.

Subsequent research revealed an amazing diversity of viral genome types. In some groups of viruses, such as the agents that cause measles and flu, the genome consists of RNA. In others, such as the viruses that cause herpes and smallpox, the genome is DNA. Viral genomes may be linear or circular and may consist of a single molecule or be broken up into several different segments.

Further, the RNA and DNA genomes of viruses can be either single stranded or double stranded. The single-stranded RNA genomes can also be classified as "positive sense" or "negative sense" or "ambisense."

- In a **positive-sense** RNA virus, the genome contains the same sequences as the mRNA required to produce viral proteins.
- In a **negative-sense** RNA virus, the base sequences in the genome are complementary to those in viral mRNAs.
- In an **ambisense** RNA virus, the genome has at least one strand that contains two regions: one is positive sense and the other negative sense.

The nature of viruses has been understood only since the 1940s, but they have been the focus of intense research ever since. Although likely millions of types of virus exist, they all appear to infect their host cells in one of two general ways: via **replicative growth,** which produces the next generation of virions and often kills the host cell, or in a dormant manner that suspends production of virions and allows the virus to coexist with the host for a period of time. Let's look first at the more immediately deadly mode.

Analyzing the Phases of Replicative Growth

Six phases are common to replicative growth in virtually all viruses: **(1)** attachment to a host cell and entry into the cytosol; **(2)** transcription of the viral genome and production of viral proteins; **(3)** replication of the viral genome; **(4)** assembly of a new generation of virions; **(5)** exit from the infected cell; and **(6)** transmission to a new host.

FIGURE 36.6 shows the replicative growth of a bacteriophage. A **bacteriophage** (literally, "bacteria-eater") is a virus that infects bacterial cells. This cycle is referred to as the **lytic cycle,** since it ends with lysis (destruction) of the cell. One thing should stand out as you examine this process: in a single replicative cycle, one virus particle can produce many progeny.

FIGURE 36.7 shows how a bacteriophage's tremendous capacity for replication results in nonlinear growth that proceeds in a stepwise manner. This growth curve is very different from what is observed in the host cells, where each cell produces only two progeny in each generation.

Each type of virus has a particular way of entering a host cell and completing the subsequent phases of the cycle. Let's take a closer look at each phase.

How Do Viruses Enter a Cell? The replicative cycle of a virus begins when a free virion enters a target cell. This is no simple task. All cells are protected by a plasma membrane, and many also have a cell wall. How do viruses breach these defenses, insert themselves into the cytosol inside, and begin an infection?

Most plant viruses are inserted directly into the host-cell cytosol via abrasions or the mouthparts of sucking or biting insects. In contrast, viruses that infect bacterial or animal cells must first attach to a specific molecule on the cell wall or plasma membrane.

After a bacteriophage attaches to its host, it uses an enzyme called lysozyme to degrade part of the cell wall and expose the plasma membrane. The genome of the bacteriophage is then transferred to the cytosol in a process referred to as uncoating, which varies depending on the structure of the virus. The T4 bacteriophage shown in Figure 36.6, for example, uncoats its

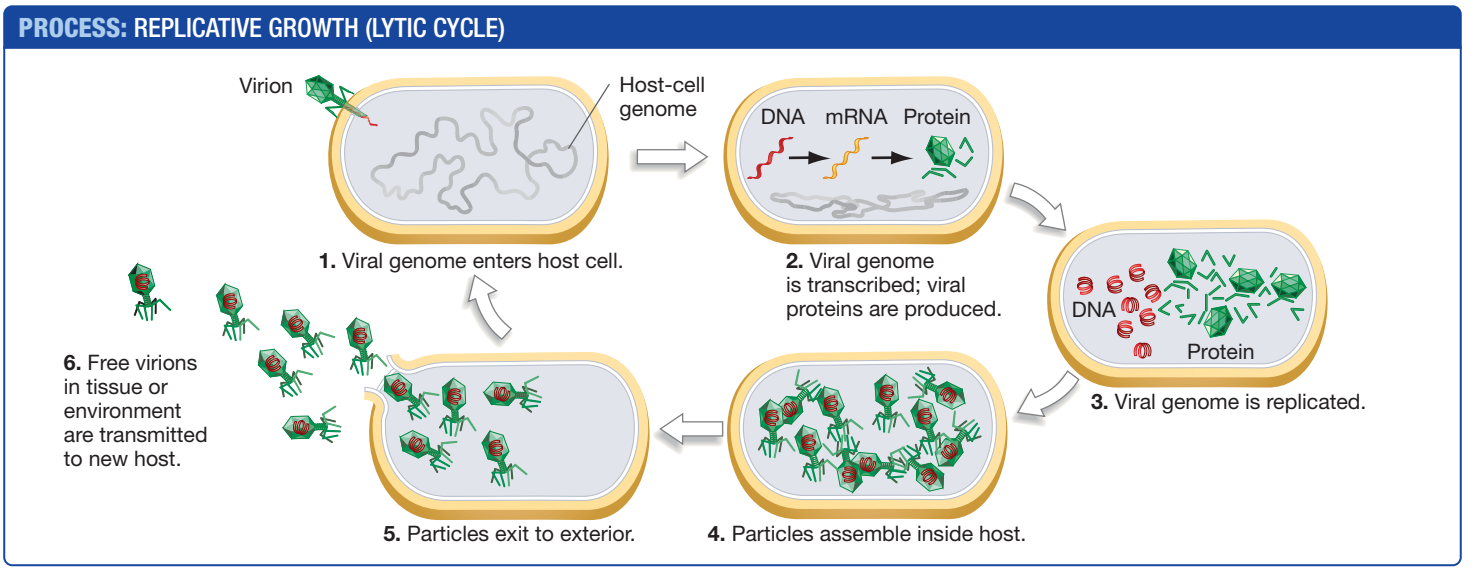

FIGURE 36.6 The Viral Replicative Cycle. Many viruses follow the same general cycle as this bacteriophage model.

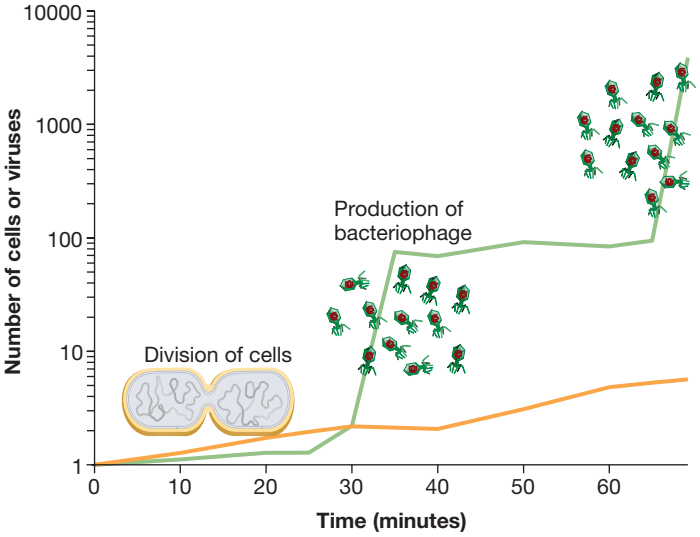

FIGURE 36.7 Growth Patterns Differ between Viruses and Their Host. Cells reproduce in an exponential manner, as indicated by a linear pattern when plotted on a logarithmic scale. The production of virions is not exponential; instead, reproduction of bacteriophage like T4 exhibits a stepwise pattern.

✔**QUANTITATIVE** Based on the information and trends in this graph, predict the number of extracellular virions that would be produced after 90 minutes if all of those released by 40 minutes were allowed to infect new host cells. Compare this to the number of cells you would predict to be present after 90 minutes.

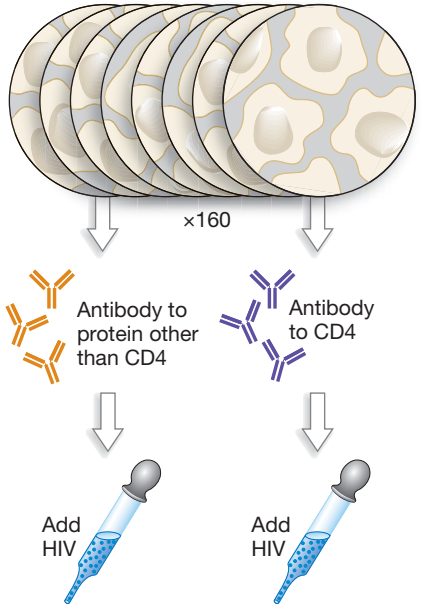
genome by injecting it through a hollow needle that is stabbed into the bacterial membrane.

Viruses that attack animal cells must first attach to one or more specific molecules in the host cell's plasma membrane. These molecules, often referred to as virus receptors, are typically either membrane proteins or the carbohydrates attached to glycoproteins or glycolipids.

To appreciate how investigators identify virus receptors, consider research on HIV. In 1981—right at the start of the AIDS epidemic—biomedical researchers realized that people with AIDS had few or no T cells possessing a particular membrane protein called **CD4.** These cells, symbolized as $CD4^+$, are called helper T cells because of their key supportive role in the immune response (see Chapter 51).

Two research groups hypothesized that CD4 serves as the receptor for HIV attachment. To test this hypothesis, the researchers systematically blocked different membrane proteins on helper T cells and determined which membrane proteins are involved in HIV attachment. They used **antibodies** to specifically bind to host membrane proteins, including several that bound to CD4 (see **BioSkills 9** in Appendix B to review the activity of antibodies).

The key assumption in their experiments was that antibodies directed against the virus receptor would prevent HIV from entering and infecting the cell. After completing their work, both research teams reached exactly the same result: Antibodies to CD4 inhibited HIV from infecting host cells (**FIGURE 36.8**).



RESEARCH

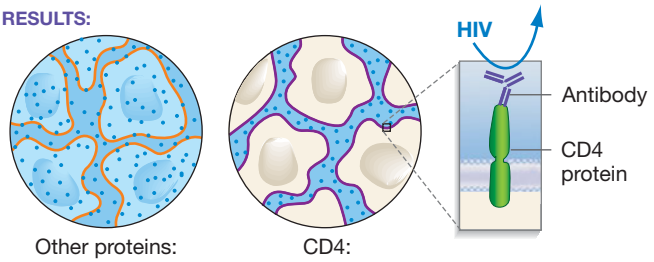
QUESTION: Does CD4 protein function as the receptor HIV uses to enter host cells?

HYPOTHESIS: CD4 is the membrane protein HIV uses to enter cells.

NULL HYPOTHESIS: CD4 is not the membrane protein HIV uses to enter cells.

EXPERIMENTAL SETUP:

1. Take 160 identical samples of helper T cells from a large population of T cells growing in culture.



2. Add a different antibody to each sample of cells—each antibody will "block" a specific membrane protein.

3. Add a constant number of HIV virions to all samples. Incubate cultures under conditions optimal for virus entry.

PREDICTION: HIV will not infect cells with antibody to CD4 but will infect other cells.

PREDICTION OF NULL HYPOTHESIS: HIV will infect cells with antibody to CD4.

RESULTS:

CONCLUSION: HIV uses CD4 as the receptor to enter helper T cells. Thus, only cells with free, unbound CD4 on their surface can be infected by HIV.

FIGURE 36.8 Experiments Confirmed that CD4 Is the Receptor Used by HIV to Enter Host Cells. In this experiment, the antibodies added to each culture bound to a specific protein found on the surface of helper T cells. Antibody binding blocked the membrane protein, so the protein could not be used by HIV to gain entry to the cells.

✔ **QUESTION** Does this experiment show that CD4 is the only membrane protein required for HIV entry? Explain why or why not.

Although CD4 is necessary for HIV attachment, uncoating the viral genome will not occur unless the virion also binds to a second membrane protein, called a **co-receptor.** In most individuals, membrane proteins called CXCR4 and CCR5 function as co-receptors. Once the virion binds to both CD4 and a co-receptor, the lipid bilayers of the virion's envelope and the plasma membrane of the T cell fuse (**FIGURE 36.9a**). When fusion occurs, HIV has breached the cell boundary. The viral capsid then enters the cytosol and disassembles to release the genomic RNAs, and infection proceeds.

Another common uncoating process is shown in **FIGURE 36.9b**, where the virion is first internalized via endocytosis (see Chapter 7). After a virion, in this case influenza, attaches to a component on the cell surface, it is pulled into the cell in the form of a vesicle called an endosome. When the endosome acidifies—a normal part of endocytosis—the structure of the viral attachment proteins change in a way that promotes fusion of the viral envelope and the endosomal membrane.

Endocytosis is also commonly used by naked viruses to enter animal cells. As with enveloped viruses, acidification of the

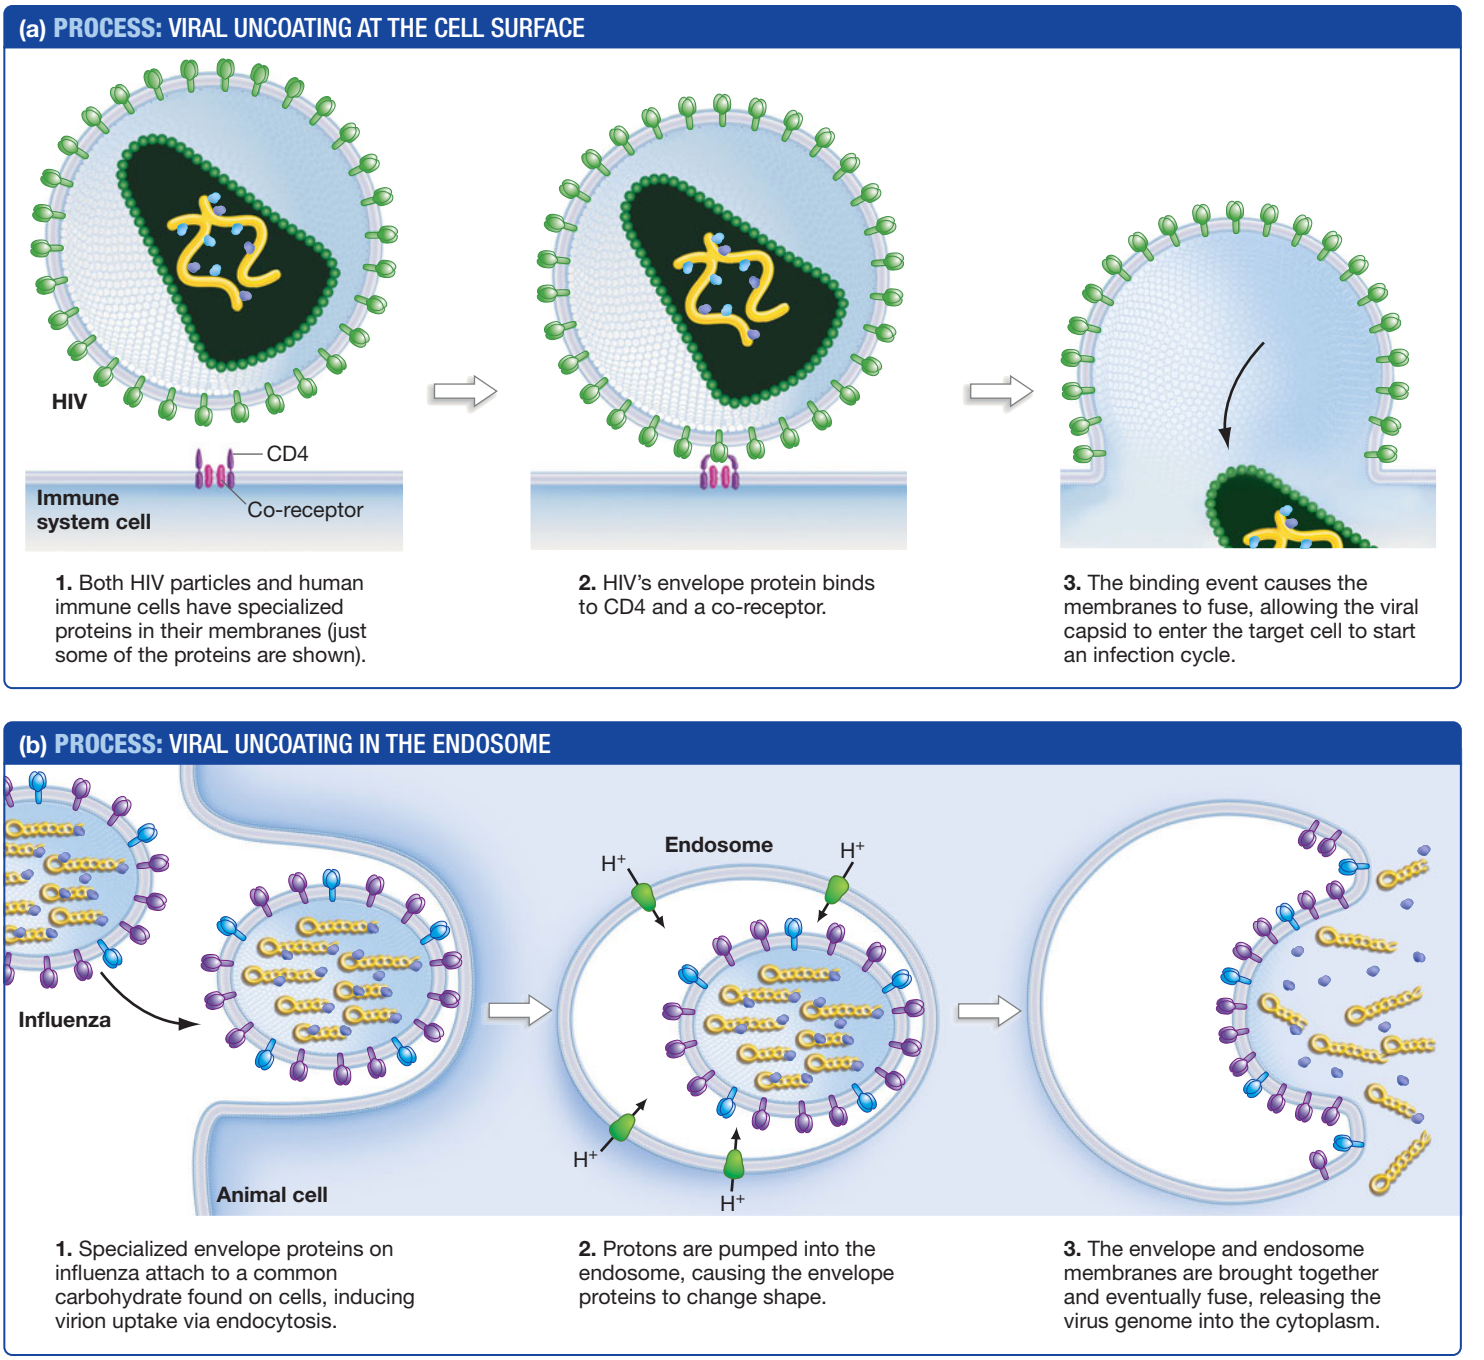

FIGURE 36.9 Enveloped Viruses Bind to Host Membranes and Uncoat via Fusion.

endosome serves as a signal for uncoating the genetic material. In this case, low pH alters the structure of the capsid proteins, which disrupts the endosomal membrane so the viral genetic material may enter the cytosol.

The discovery of virus receptors and requirements for uncoating has inspired a search for compounds that block these early events of the replicative cycle. As a result, drugs have been designed to block attachment and uncoating of HIV by targeting the HIV envelope protein and host CCR5 co-receptor. Drugs that interfere with either viral infection or replication of viruses are called **antivirals.**

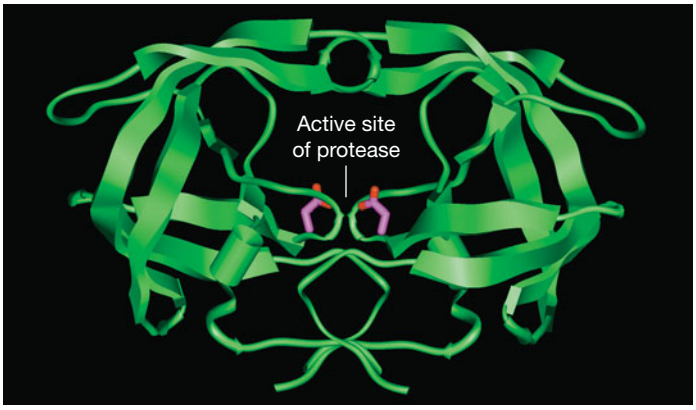
How Do Viruses Produce Proteins? Production of viral proteins begins soon after the virus uncoats its genome. Depending on the virus, transcription of the viral genome may be accomplished by either host or viral RNA polymerases. In all viruses, however, translation of viral transcripts is entirely dependent on the host. Viruses lack the ribosomes, amino acids, ATP, and most of the other biosynthetic machinery required for translating their own mRNAs into proteins.

Viral proteins are produced and processed in one of two ways, depending on whether the proteins end up in the envelope of a virion or in a capsid.

Viral mRNAs that code for envelope proteins are translated as if they were mRNAs for the cell's own membrane proteins. They are translated by ribosomes attached to the rough endoplasmic reticulum (rough ER), where carbohydrates are added to the protein (see Chapter 7). Depending on the virus, the proteins then may be transported to the Golgi apparatus for further processing. In some viruses, such as HIV, the finished glycoproteins are transported to the plasma membrane, where they are assembled into new virions.

A different route is taken by mRNAs that code for proteins that make up the capsid of a virion. These mRNAs are translated by free ribosomes in the cytosol, just as if they were cellular mRNAs for cytosolic proteins.

In some viruses, long polypeptide sequences called polyproteins are cut into individual proteins by viral enzymes called **proteases.** These enzymes cleave viral polyproteins at specific locations—a critical step in the production of finished viral proteins. In HIV, for example, a polyprotein must be cleaved before it can assemble into new viral capsids.



The discovery that HIV produces a protease triggered research for drugs that would inhibit the enzyme. This effort got a huge boost when researchers identified the three-dimensional structure of HIV's protease, using X-ray crystallographic techniques (see **BioSkills 11** in Appendix B). The enzyme has an opening in its interior where the active site is located (**FIGURE 36.10a**). Viral polyproteins fit into the opening and are cleaved at the active site.

Based on these data, researchers immediately began searching for molecules that could fit into the opening and prevent protease from functioning by blocking the active site (**FIGURE 36.10b**). Several HIV protease inhibitors are currently being used to interfere with viral replication.

How Do Viruses Copy Their Genomes? In addition to transcription and translation, viruses must also copy their genetic material to make a new generation of virions. Viruses depend on the host cell for nucleotide monomers. In addition, some DNA viruses also depend on the host-cell DNA polymerase machinery to replicate their genomes.

In viruses that have an RNA genome, however, the virus must supply its own enzyme to make copies of its genome. Viral enzymes called **RNA replicases** function as *RNA-dependent* RNA polymerases. In other words, RNA replicases synthesize RNA *from an RNA template*, using ribonucleotides provided by the host cell. For example, the RNA replicases of positive-sense single-stranded RNA viruses first convert the genome into double-stranded RNA and then produce multiple positive-sense copies from the negative-sense complementary strand.

(a) HIV's protease enzyme

(b) Could a drug block the active site?

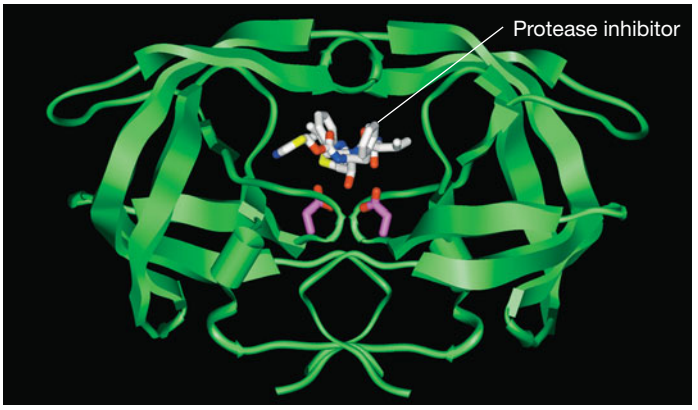


FIGURE 36.10 The Three-Dimensional Structure of HIV's Protease. (a) Ribbon diagram depicting the three-dimensional shape of HIV's protease enzyme. **(b)** Once protease's structure was solved, researchers began synthesizing compounds that were predicted to fit into the active site and prevent the enzyme from working.

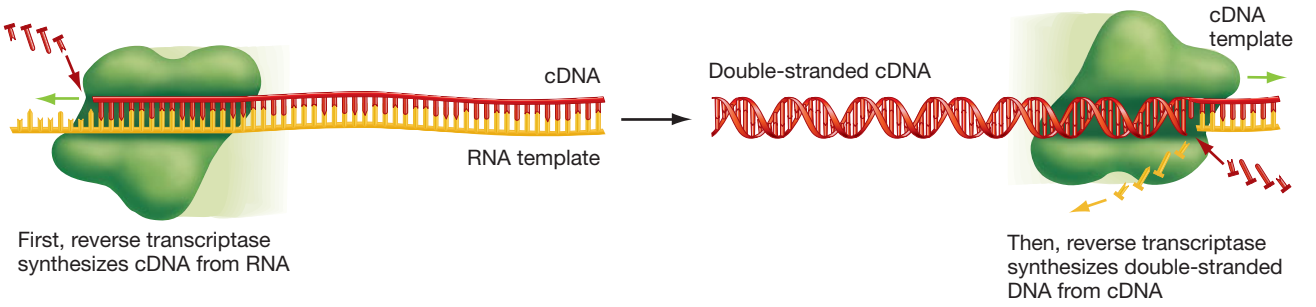

FIGURE 36.11 Reverse Transcriptase Catalyzes Synthesis of a Double-Stranded DNA from an RNA Template. The DNA produced by reverse transcriptase is called a cDNA because its base sequence is complementary to the RNA template.

But not all RNA viruses replicate using RNA replicases. In certain RNA viruses, the genome is first transcribed from RNA to DNA by a viral enzyme called **reverse transcriptase.** This enzyme is an unusual DNA polymerase—one that can make DNA from either an RNA or a DNA template. It first makes **complementary DNA,** or **cDNA,** from a single-stranded RNA template (see Chapter 20). Reverse transcriptase then removes the RNA strand and catalyzes the synthesis of a second, complementary DNA strand, resulting in a double-stranded DNA (**FIGURE 36.11**). The DNA copy is then inserted into the host genome and used as a template for host cellular machinery—including an RNA polymerase—to produce viral mRNAs and genomic RNAs.

Viruses that reverse-transcribe their genome in this way are called **retroviruses** ("backward viruses"). The name is apt because the initial flow of genetic information in this type of virus is RNA → DNA—the opposite of the central dogma (see Chapter 16). HIV is an example of a reverse-transcribing RNA virus.

The first antiviral drugs that were developed to combat HIV act by inhibiting reverse transcriptase. Logically enough, drugs of this type are called reverse transcriptase inhibitors.

How Are New Virions Assembled? Once viral proteins have been produced and the viral genome has been replicated, assembly of a new generation of virions can take place.

During assembly, viral genomes are packaged into capsids. Some viruses also include copies of non-capsid proteins, often enzymes like polymerases, inside the capsid. In many cases, the details of the assembly process are not well understood. Some viruses assemble the capsid first and then use motor proteins to pull the viral genome inside, while others assemble the capsid around the genomic material.

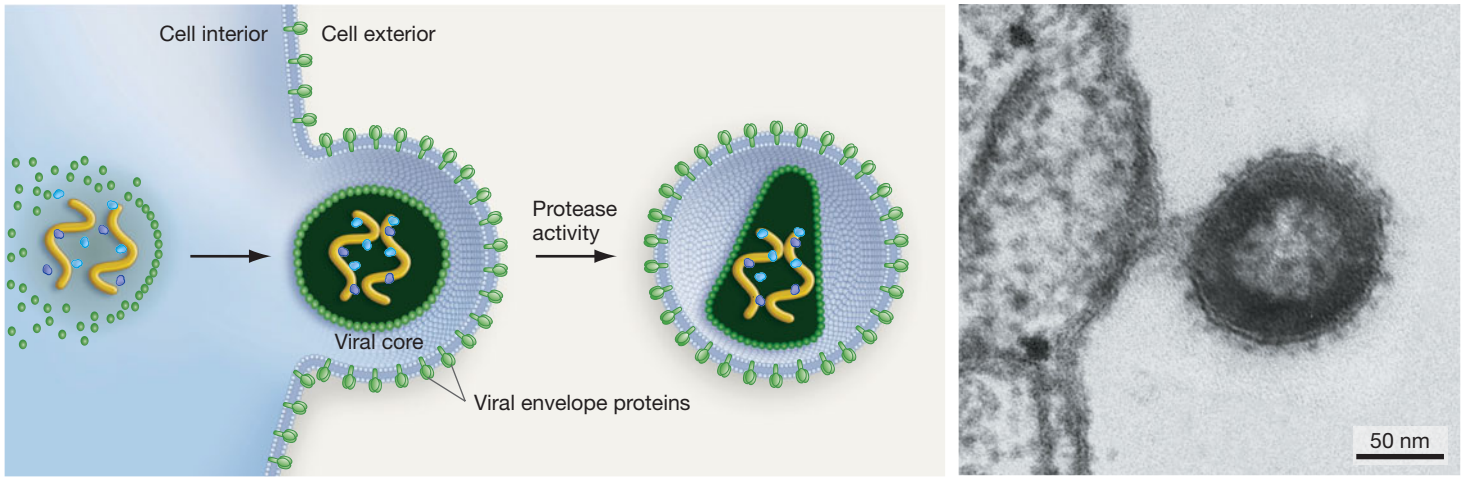
Enveloped viruses use the host endomembrane system (see Chapter 7) to transport their envelope proteins to the appropriate membrane for assembly. For example, virions of HIV and influenza assemble at the host cell's surface and acquire their envelope from its plasma membrane. Other enveloped viruses may assemble at the surface of internal membranes, such as the rough ER or Golgi apparatus.

In most cases, self-assembly occurs—though some viruses produce proteins that provide scaffolding where new virions are put together. To date, researchers have yet to develop drugs that inhibit the assembly process during a viral infection.

How Do Progeny Virions Exit an Infected Cell? Most viruses leave a host cell in one of two ways: by budding from cellular membranes or by bursting out of the cell. In general, enveloped viruses bud; nonenveloped viruses burst.

Viruses that bud from one of the host cell's membranes take some of that membrane with them. As a result, their envelope includes host-cell phospholipids along with envelope proteins encoded by the viral genome. In **FIGURE 36.12a**, HIV is shown budding from the plasma membrane. After the budding step, the HIV capsid is further processed by its protease, giving the virion its characteristic cone-like appearance.

Viruses that bud through internal membranes, such as those of the rough ER or Golgi apparatus, are secreted from the cell by being escorted through the endomembrane system (see Chapter 7). Regardless of the membrane used for producing enveloped viruses, exit from the host cell does not require the death of the host.



In contrast, most nonenveloped viruses release their virions from the cell by lysing it—commonly referred to as the burst. For example, bacteriophages produce lytic enzymes that break down the cell wall of the host. Because the cell exerts pressure on the wall, the cell will explode when the wall is damaged—dispersing a new generation of virions into the environment. **FIGURE 36.12b** shows T4 bacteriophages bursting from an infected *E. coli* cell.

How Are Virions Transmitted to New Hosts? Once the replicative cycle is complete, dozens to several hundred newly assembled virions are in the extracellular space. What happens next?

If the host cell is part of a multicellular organism, the new generation of virions may be transported through the body—often via the bloodstream or lymphatic system. In vertebrates, antibodies produced by the immune system may bind to the virions and mark them for destruction. But if a virion contacts an appropriate host cell before it encounters antibodies, then a new replicative cycle will be started.

The long-term success of the virus, however, is dependent on its ability to be transmitted through the environment from one organism to another. For example, when people cough, sneeze,

(a) Budding of enveloped viruses

(b) Bursting of nonenveloped viruses

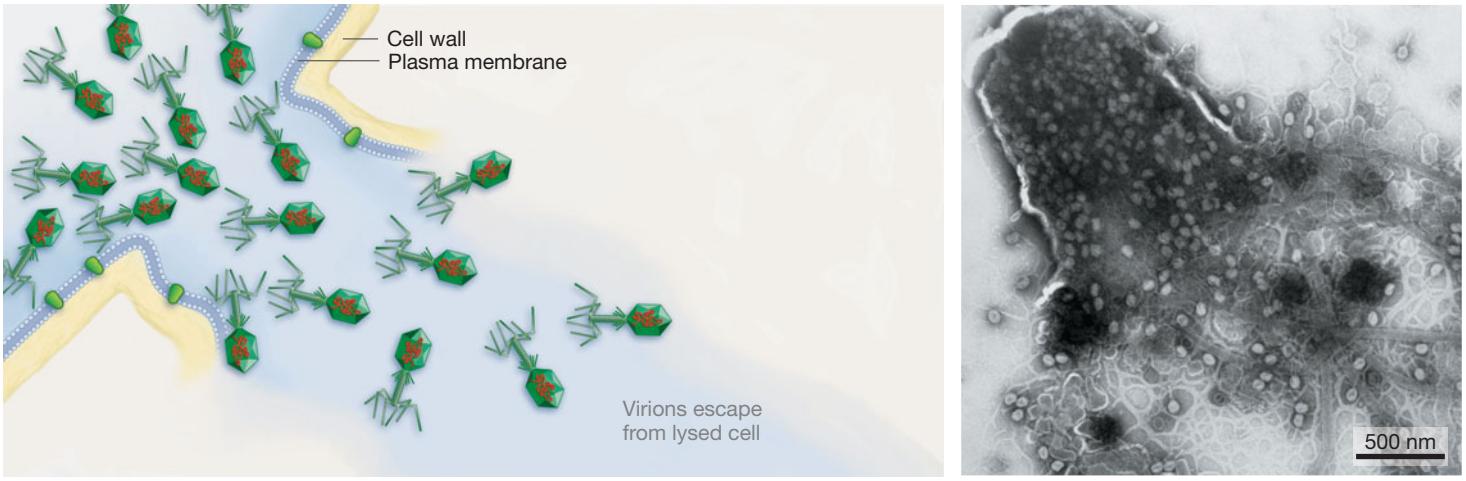


FIGURE 36.12 Viruses Leave Infected Cells by Budding or Bursting. (a) In enveloped viruses such as HIV, virions are formed as they bud from membranes of the host cell. **(b)** Naked viruses normally exit the host cell by bursting the cell, as in T4 bacteriophage. Bursting kills the host cell; budding does not require cell death to occur.

✔**QUESTION** Propose a hypothesis to explain why cells often die after extensive budding of enveloped viruses.

wipe a runny nose, or defecate, they help rid their body of viruses and bacteria. But they also expel the pathogens into the environment, sometimes directly onto a new host.

From the virus's point of view, a new host represents an unexploited habitat brimming with resources in the form of target cells. The situation is analogous to that of a multicellular animal dispersing to a new habitat and colonizing it. The alleles carried by these successful colonists increase in frequency in the total population. In this way, natural selection favors alleles that allow viruses to do two things: **(1)** replicate within a host and **(2)** be transmitted to new hosts.

✔ **If you understand how different types of viruses produce a new generation of virions, you should be able to compare and contrast the replicative cycles of bacteriophage T4 and HIV.**

Analyzing How Viruses Coexist with Host Cells

All viruses undergo replicative growth, but some can arrest the replicative cycle and enter a dormant state. Note that only certain types of viruses are capable of switching between replicative growth and dormant coexistence with the host cell. In bacteriophages, this alternate type of infection is called **lysogeny** (**FIGURE 36.13**, page 722).

The onset of lysogeny is triggered by molecular cues in the host that push the virus out of the replicative cycle. Instead of actively transcribing and replicating the viral DNA, it becomes incorporated into the host's chromosome and the expression of most of the viral genes is shut down.

Although no virions are produced during lysogeny, the host's DNA polymerase replicates the viral DNA each time the cell divides. Copies of the viral genome are passed on to daughter cells

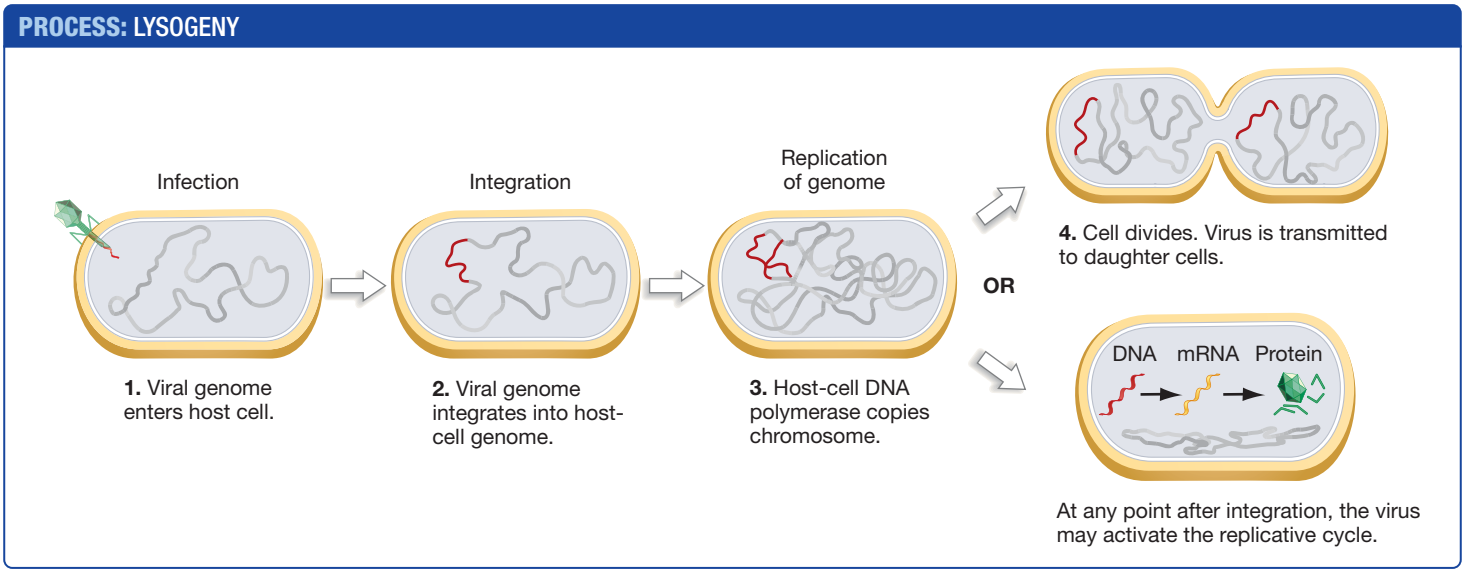

FIGURE 36.13 Some Bacteriophages Can Switch between the Lytic Cycle and Lysogeny. Molecular cues from the host can direct certain bacteriophages toward either lysogeny or the lytic cycle.

just as if it were one of the host's own genes. Some of these introduced genes have been known to significantly alter bacterial hosts. For example, many of the pathogenic strains of *E. coli* that have recently emerged in humans are more virulent due to expression of phage toxins that were introduced via lysogeny.

An integrated bacteriophage genome may be "awakened" by different cues from the host cell, often associated with host stress. Activation leads to excision of the viral DNA from the host genome and reentry into the replicative growth cycle.

In viruses that infect animal cells, the dormant state is called **latency.** As with bacteriophages, only certain animal viruses are capable of arresting their replicative growth cycle. Depending on the virus involved, the genome may or may not be integrated into the host genome.

HIV has a well-characterized latency period that occurs at the start of many new infections. After reverse transcriptase makes a double-stranded DNA version of the viral genome, the viral DNA is inserted into the host-cell genomic DNA. But integration alone is not enough to trigger expression of the viral genes. The helper T cell host must first be activated by the immune response to drive expression of the HIV genome. Until this occurs, HIV remains hidden and silent.

Current antivirals are ineffective against an HIV infection when HIV genes aren't being expressed. For this reason, reducing the likelihood of **transmission**—the spread of pathogens from one individual to another—is presently the most effective way to combat a viral disease like AIDS.

HIV is transmitted from person to person via body fluids such as blood, semen, or vaginal secretions. Faced with decades of disappointing results in drug and vaccine development, public health officials are aggressively promoting preventive medicine, through

- aggressive treatment of venereal diseases—because the lesions caused by chlamydia, genital warts, and gonorrhea encourage the transmission of HIV-contaminated blood during sexual intercourse;
- condom use; and
- sexual abstinence or monogamy.

The effectiveness of preventive medicine underscores one of this chapter's fundamental messages: Viruses are a fact of life.

If you understand that . . .

- Viruses replicate using the energy, substrates, and protein synthesis machinery of their host cells to produce a new generation of virions.
- After infecting a cell, the manner in which viruses proceed through the steps of the replicative cycle will vary depending on the type of virus.

✓ You should be able to . . .

Evaluate the claim that the viral replicative cycle more closely resembles the mass production of automobiles than the reproduction of cells.

Answers are available in Appendix A.

36.3 What Themes Occur in the Diversification of Viruses?

The tree of life will never be free of viruses. Mutation and natural selection guarantee that viral genomes will continually adapt to the defenses offered by their hosts, whether those defenses are devised by an immune system or by biomedical researchers.

Two other points are critical to recognize about viral diversity: **(1)** Biologists do not have a solid understanding of how new viruses originate, but **(2)** it is certain that viruses will continue to diversify. Because most viral polymerases have high error rates and because viruses lack error repair enzymes, mutation rates are extremely high. Many viruses change constantly—giving them the potential to evolve rapidly.

Where Did Viruses Come From?

No one knows how viruses originated. To address this question, biologists are currently considering three hypotheses to explain where viruses came from.

Origin in Plasmids and Transposable Elements? Like viruses, plasmids and transposable elements are acellular, mobile genetic elements that replicate with the aid of a host cell (see Chapters 20 and 21). Certain viruses are actually indistinguishable from plasmids except for one feature: They encode proteins that form a capsid and allow the genes to exist outside of a cell.

Some biologists hypothesize that simple viruses represent "escaped gene sets." This hypothesis proposes that mobile genetic elements are descended from clusters of genes that physically escaped from prokaryotic or eukaryotic chromosomes long ago.

According to this hypothesis, the escaped gene sets took on a mobile, parasitic existence because they happened to encode the information needed to replicate themselves at the expense of the genomes that once held them. In the case of viruses, the hypothesis is that the escaped genes included the instructions for making a protein capsid and possibly envelope proteins. According to the escaped-genes hypothesis, it is possible that each of the distinct types of viruses represent distinct "escape events."

To support the escaped-genes hypothesis, researchers would need to discover a virus that had so recently derived from intact prokaryotic or eukaryotic genes that the viral genomes still strongly resembled the DNA sequence of those genes.

Origin in Symbiotic Bacteria? Some researchers contend that DNA viruses with large genomes trace their ancestry back to free-living bacteria that once took up residence inside eukaryotic cells. The idea is that these organisms degenerated into viruses by gradually losing the genes required to synthesize ribosomes, ATP, nucleotides, amino acids, and other compounds.

Although this idea sounds speculative, it cannot be dismissed lightly. For example, there is evidence that the mitochondria and chloroplasts of eukaryotic cells originated as intracellular symbionts from ancestors that were independent, free-living cells (see Chapter 30). Investigators contend that, instead of evolving into intracellular symbionts that aid their host cell, DNA viruses became parasites capable of replication and transmission from one host to another.

To support the degeneration hypothesis, researchers have pointed to mimivirus, the largest known virus that infects certain protists. In addition to its large size, the genome of this virus was found to contain some of the genes involved in protein synthesis—genes that are common to cells, but had not previously been observed in viruses. It is still not clear, though, whether these genes are remnants from an ancestral cell or were acquired from a host cell that was infected relatively recently. The discovery of a cell that possesses a genome similar to that of the mimivirus would support the degeneration hypothesis for the origin of this virus.

Origin at the Origin of Life? Recently, some researchers have started to discuss a third alternative to explain the origin of viruses: that they trace their ancestry back to the first, RNA-based forms of life on Earth. If this hypothesis is correct, then the RNA genomes of some viruses are descended from genes found in early inhabitants of the RNA world (see Chapter 4). Some researchers have even suggested that retrovirus-like parasites may have been responsible for transforming the genetic material of cells from RNA to DNA.

To support this hypothesis, advocates point to the ubiquity of viruses—which suggests that they have been evolving along with organisms since life began. The RNA world-origin hypothesis also addresses a problem that weakens the other two hypotheses: Several proteins that are commonly expressed in many viruses are not expressed in any cell examined thus far. If viruses originated at the time of the origin of the cell, then the genes coding for these proteins may have come from an RNA-world pool of genes instead of a cell.

Currently, there is no one widely accepted view of where viruses came from. Because viruses are so diverse, all three hypotheses may be valid.

Emerging Viruses, Emerging Diseases

Although it is not known how the various types of viruses originated, it is certain that viruses will continue to diversify. With alarming regularity, the front pages of newspapers carry accounts of deadly viruses that are infecting humans for the first time.

HIV is an example of a virus responsible for an **emerging disease:** a new illness that suddenly affects significant numbers of individuals in a host population. Another, and perhaps the most infamous of such outbreaks occurred in 1995, when the Ebola virus infected 200 individuals in the Democratic Republic of Congo and had a fatality rate of 80 percent. In both cases, the causative agents were considered emerging viruses because they had switched from their traditional host species to a new host—humans.

Some Emerging Viruses Arise from Genome Reassortment Each year the World Health Organization worries about a new influenza pandemic, one that might resemble the devastating outbreak of 1918. The small changes that arise from the influenza virus's error-prone RNA replicase are primarily responsible for the need for yearly vaccine updates. But influenza can also acquire alleles that are entirely new to the strain. (A virus **strain** consists of populations that have similar characteristics and is the lowest, or most specific, level of taxonomy for viruses.) How do new strains of influenza originate?

Influenza has a single-stranded RNA genome that consists of eight segments, most of which encode only one protein. If two viruses infect the same cell, the replicated genomic segments

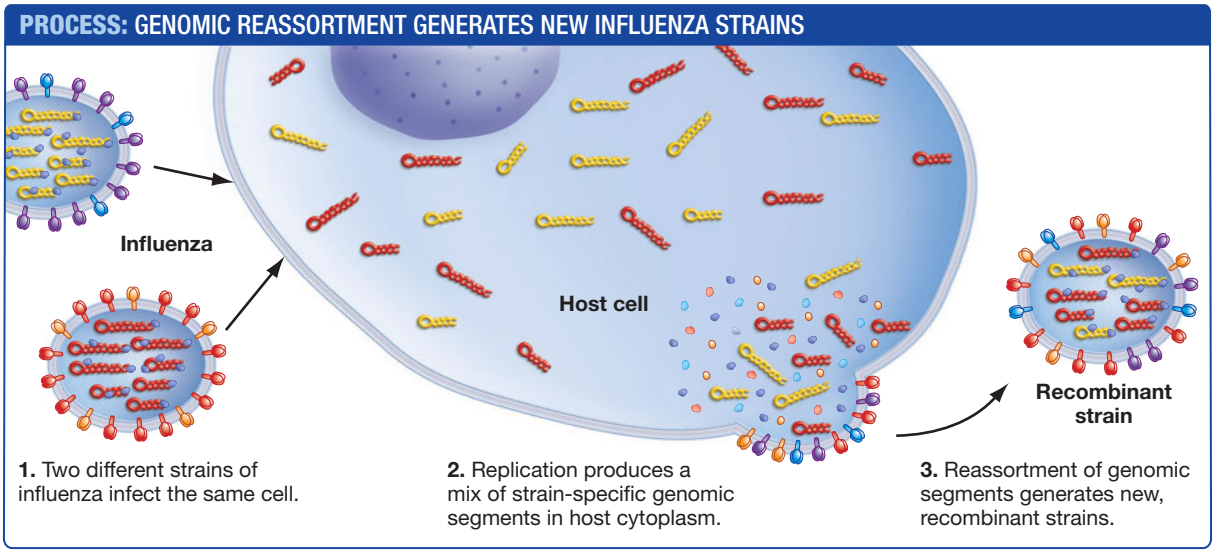

FIGURE 36.14 Influenza Can Generate New Strains via Genomic Reassortment.

are randomly shuffled in the cytosol. Thus when the progeny are assembled, many have segments from each parent virus (**FIGURE 36.14**).

The ability to randomly mix genomic segments becomes particularly significant when two different strains infect the same cell. In addition to humans, different strains of influenza can infect other animals, such as birds and pigs. While the avian strains do not efficiently infect humans, they can infect pigs—and so can human viral strains. The last point is key—pigs can serve as mixing vessels to produce new recombinant strains. Pandemic strains are thought to emerge from this type of reassortment.

Using Phylogenetic Trees to Understand Emerging Viruses How do researchers know that an emerging virus has "jumped" to a new host? The answer is to analyze the evolutionary history of the virus in question and then estimate a phylogenetic tree that includes its close relatives.

HIV, for example, belongs to a group of viruses called the lentiviruses, which infect a wide range of mammals including house cats, horses, goats, and primates. (*Lenti* is a Latin root that means "slow"; here it refers to the long period observed between the start of an infection by these viruses and the onset of the diseases they cause.) Consider the conclusions that can be drawn from the phylogenetic tree of HIV, shown in **FIGURE 36.15**.

- ***There are immunodeficiency viruses.*** Many of HIV's closest relatives parasitize cells that are part of the immune system. Several of them cause diseases with symptoms reminiscent of AIDS. These viruses infect monkeys and chimpanzees and are called simian immunodeficiency viruses (SIVs).
- ***There are two HIVs.*** There are two distinct types of human immunodeficiency viruses, called HIV-1 and HIV-2. Although both can cause AIDS, HIV-1 is far more virulent and is the better studied of the two.

HIV-1's closest known relatives are immunodeficiency viruses isolated from chimpanzees that live in central Africa. In contrast, HIV-2's closest relatives are immunodeficiency viruses that parasitize monkeys called sooty mangabeys.

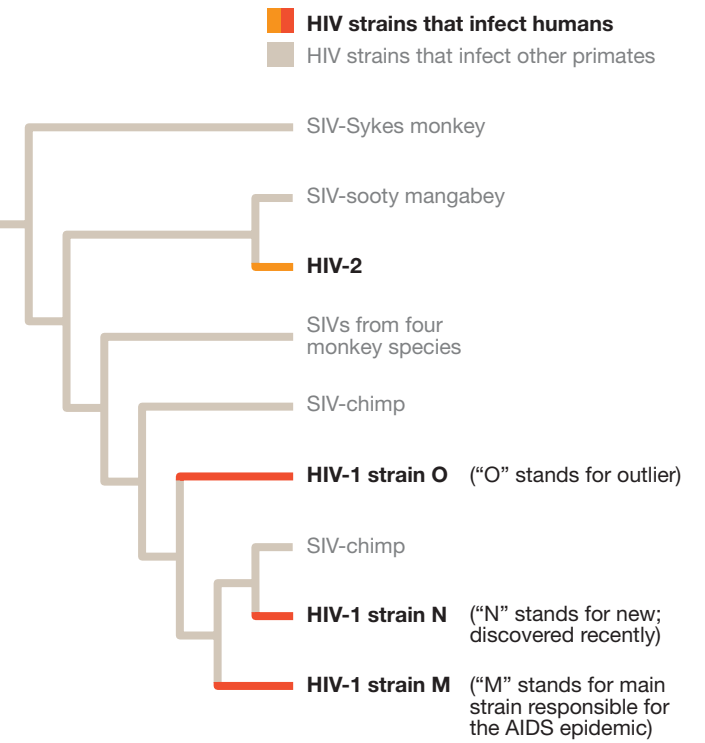

FIGURE 36.15 Phylogeny of HIV Strains and Types. Phylogenetic tree showing the evolutionary relationships among some of the immunodeficiency viruses that infect primates—including chimpanzees, humans, and several species of monkeys.

✔**EXERCISE** On the appropriate branches, indicate where an SIV jumped to humans (draw and label bars across the appropriate branches).

In central Africa, where HIV-1 infection rates first reached epidemic proportions, contact between chimpanzees and humans is extensive. Chimps are hunted for food and kept as pets. Similarly, sooty mangabeys are hunted and kept as pets in western Africa, where HIV-2 infection rates are highest.

- ***Multiple "jumps" have occurred.*** Several strains of HIV-1 exist. The most important are called O for outlier (meaning, the most distant group relative to other strains), N for new, and M for main. Each of these strains likely represents an independent origin of HIV-1 from a chimp SIV strain.

The last point is particularly important. The existence of distinct strains suggests that HIV-1 has jumped from chimps to humans several times. It may do so again in the future.

Responding to a Virus Outbreak Physicians become alarmed when they see a large number of patients with identical, and unusual, disease symptoms in the same geographic area over a short period of time. The physicians report these cases to public health officials, who take on two urgent tasks: **(1)** identifying the agent that is causing the new illness and **(2)** determining how the disease is being transmitted.

Several strategies can be used to identify the pathogen responsible for an emerging disease. In 1993, an outbreak of an unknown pulmonary syndrome rocked the U.S. Southwest, killing half of the individuals who came down with the disease. Officials recognized strong similarities between symptoms in these cases and symptoms caused by a hantavirus native to northeast Asia, called Hantaan virus. The Hantaan virus rarely causes disease in North America, but it is known to infect rodents.

To determine whether a Hantaan-like virus was responsible for the U.S. outbreak, researchers began capturing mice in the homes and workplaces of afflicted people. About a third of the captured rodents tested positive for the presence of a Hantaan-like virus. Genome sequencing studies confirmed that the virus was a previously undescribed type of hantavirus, and it was aptly named the *sin nombre* virus (Spanish for "no-name virus"). Further, the sequences found in the mice matched those found in infected patients. Based on these results, officials were confident that this rodent-borne hantavirus was causing the wave of human infections.

The next step in the research program, identifying how the agent is being transmitted, is equally critical and takes old-fashioned detective work. By interviewing patients about their activities, researchers called epidemiologists decide how each patient could have acquired the virus. Was there a particular environment or source of food or water shared by those who were infected? Was the illness showing up in health-care workers who were in contact with infected individuals, implying that it was being transmitted from human to human?

If the virus identified as the cause of an illness can be transmitted efficiently from person to person, then the outbreak has the potential to become an epidemic. To date, the sin nombre virus has not been transmitted efficiently from person to person in the United States—only inefficiently from mice to people.

check your understanding

CYU

If you understand that . . .

- The origin of viruses is unknown, but three hypotheses have been developed to address it.
- Emerging viruses arise either from genomic reassortment between different strains of virus or via switching host species.

✔ You should be able to . . .

1. Compare and contrast the three hypotheses for the origin of viruses.
2. Predict what type of a mutation in an avian flu virus would make it more dangerous to humans, and explain how this change might occur.

Answers are available in Appendix A.

36.4 Key Lineages of Viruses

Because scientists are almost certain that viruses originated more than once throughout the history of life, there is no such thing as the phylogeny of all viruses. Stated another way, unlike the organisms discussed in previous chapters, viruses have no single phylogenetic tree that represents their evolutionary history. Instead, researchers most often focus on comparing base sequences in the genetic material of small, closely related groups of viruses to reconstruct the phylogenies of particular lineages, exemplified by the tree in Figure 36.15.

To organize the genomic diversity of viruses, researchers group them into seven general categories based on the nature of their genetic material and how they replicate. David Baltimore first proposed this approach in 1971; thus, it is called the Baltimore classification. **FIGURE 36.16** (page 726) summarizes the seven classes.

Notice that each of the Baltimore classes has its own unique strategy for transcription and replication of the genetic material. (See Section 36.2 to review how viruses copy their genomes.) All these strategies, however, share the need to produce mRNA, which is then translated by the host cell to make viral proteins.

Within the Baltimore classification system, researchers further distinguish viruses according to **(1)** virion morphology, **(2)** nature of the host species, and **(3)** the type of disease resulting from infection. Using these criteria, biologists identify a total of about 70 virus families.

Although the phylogenetic relationships among viruses is not as clear as what is observed in organisms, those within families are grouped into distinct genera for convenience. Within genera, biologists identify and name types of virus, such as HIV, the measles virus, and smallpox. Within each of these viral types, populations with distinct characteristics may be identified and named as strains.

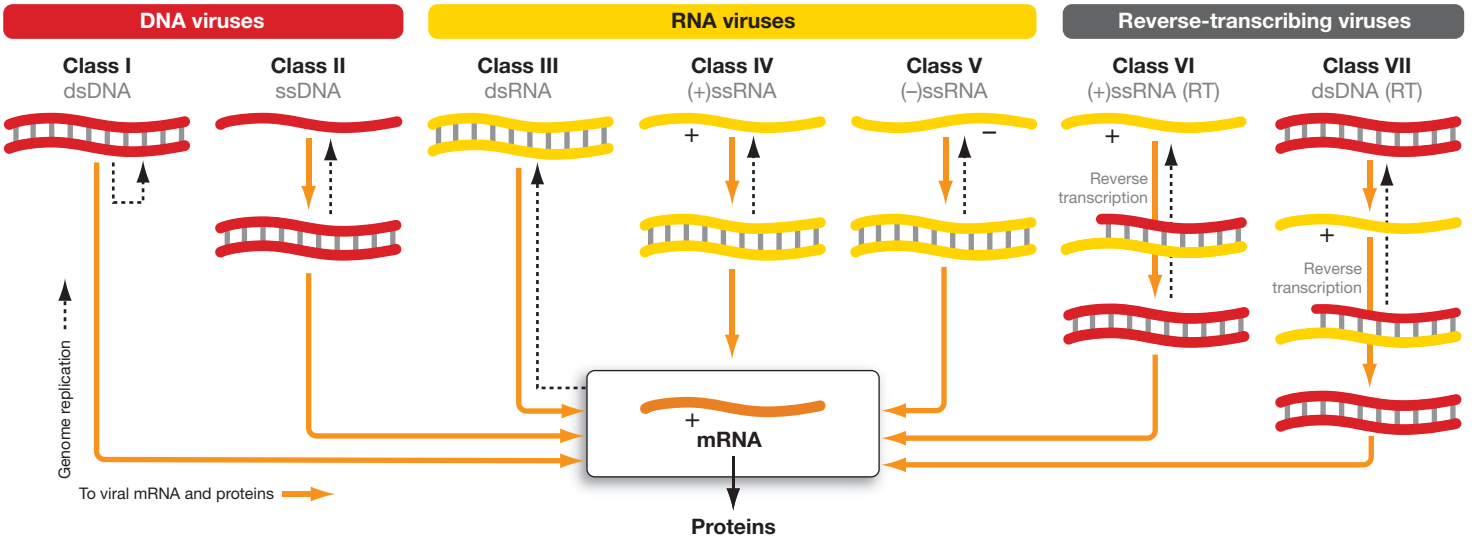

FIGURE 36.16 The Seven Different Strategies for Expression of Viral Genetic Material Converge on the Translation of mRNA. Notice that, although classes I and IV have the same types of genomes as classes VII and VI, they differ in the ways their genomes are replicated.

To get a sense of viral diversity, let's survey some of the most prevalent groups that can be distinguished based on the nature of their genetic material and mode of replication.

- Double-Stranded DNA (dsDNA) Viruses
- Double-Stranded RNA (dsRNA) Viruses
- Positive-Sense Single-Stranded RNA ([+]ssRNA) Viruses
- Negative-Sense Single-Stranded RNA ([−]ssRNA) Viruses
- RNA Reverse-Transcribing Viruses (Retroviruses)

Double-Stranded DNA (dsDNA) Viruses

The double-stranded DNA viruses are a large group, composed of some 21 families and 65 genera. Smallpox is perhaps the most familiar of these viruses (**FIGURE 36.17**). Although smallpox had been responsible for millions of deaths throughout human history, it was eradicated by worldwide vaccination programs. In 1977, smallpox was declared to be extinct in the wild; the only remaining samples of the virus are stored securely in research labs.

Genetic material As their name implies, the genes of these viruses consist of a single molecule of double-stranded DNA. The molecule may be linear or circular.

Host species These viruses parasitize hosts throughout the tree of life, with the notable exception of land plants. They include bacteriophage families called the T-series (T1–T7) and λ, which infect *E. coli*. Other common animal viruses with double-stranded DNA genomes include the human papilloma virus (HPV), herpesviruses, and adenoviruses.

Replicative cycle In most double-stranded DNA viruses that infect eukaryotes, viral genes have to enter the nucleus to be replicated. Often these viruses will replicate their genomes only during S phase, when the host cell's chromosomes are being replicated. Viruses like HPV are able to induce the cells to enter S phase despite the absence of the normal growth signals. This ability may, in fact, be responsible for the link between HPV infections and cervical cancer in women.

FIGURE 36.17 In Humans, Smallpox Can Cause Disease with Easily Recognizable Symptoms.

Double-Stranded RNA (dsRNA) Viruses

There are 7 families of double-stranded RNA viruses and a total of 22 genera. Most of the viruses in this group are nonenveloped.

Genetic material In some families, virions have a genome consisting of 10–12 double-stranded RNA molecules; in other families, the genome is composed of just 1–3 RNA molecules.

Host species A wide variety of organisms, including fungi, land plants, insects, vertebrates, and bacteria, are hosts for viruses with double-stranded RNA genomes. Particularly prominent are viruses that cause disease in rice, corn, sugarcane, and other crops. The bluetongue virus, a double-stranded RNA virus that is transmitted through midges and other biting insects, causes an often fatal disease that has significantly affected the livestock industry (**FIGURE 36.18**). In humans, reovirus and rotavirus infections are the leading cause of infant diarrhea and are responsible for over 110 million cases and a devastating 440,000 infant deaths each year.

Replicative cycle Once inside the cytosol of a host cell, the double-stranded genome of these viruses serves as a template for the synthesis of mRNAs, which are then translated into viral proteins. Some of the proteins form the capsids for a new generation of virions. The genome is copied by a viral enzyme that converts the mRNA transcripts into double-stranded RNA within the newly formed capsids.

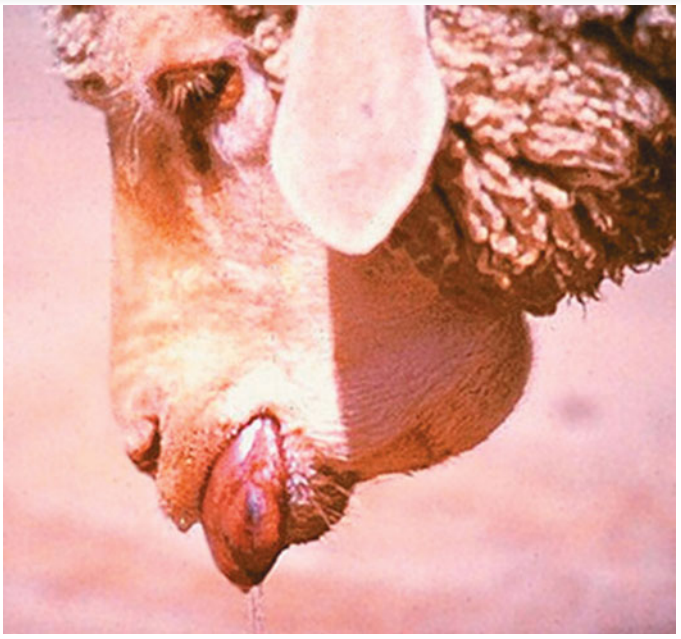

FIGURE 36.18 dsRNA Viruses Parasitize a Wide Array of Organisms, Such as Livestock Infected by the Bluetongue Virus.

Positive-Sense Single-Stranded RNA ([+]ssRNA) Viruses

This is the largest group of viruses known. It has 21 families and 81 genera that include both enveloped and nonenveloped morphologies.

Genetic material The sequence of bases in a positive-sense single-stranded RNA virus is the same as that of a viral mRNA. Stated another way, the genome does not need to be transcribed in order for proteins to be produced. Depending on the species, the genome consists of 1–3 double-stranded RNA molecules.

Host species Most of the commercially important plant viruses belong to this group. Because they kill groups of cells in the host plant and turn patches of leaf or stem white, they are often named mottle viruses, spotted viruses, chlorotic (meaning, lacking chlorophyll) viruses, or mosaic viruses. **FIGURE 36.19** shows a healthy cowpea leaf and a cowpea leaf that has been attacked by a positive-sense single-stranded RNA virus. This group of viruses is also known to infect bacteria, fungi, and animals. Viruses within this group that infect humans include the rhinovirus (common cold), polio, SARS CoV, West Nile virus, and hepatitis A, C, and E.

Replicative cycle When the genome of these viruses enters a host cell, the positive-sense single-stranded RNA is immediately translated into a protein, often a polyprotein that is cleaved to generate functionally distinct proteins. These proteins include proteases that process the polypeptides and polymerases that copy the genome and produce mRNA for translation.

FIGURE 36.19 (+)ssRNA Viruses, Such as the Cowpea Mosaic Virus, Cause Important Plant Diseases.

Negative-Sense Single-Stranded RNA ([−]ssRNA) Viruses

This group has 7 families and 30 genera. Most members of this group are enveloped, but some negative-sense single-stranded RNA viruses lack an envelope.

Genetic material The sequence of bases in a negative-sense single-stranded RNA virus is opposite in polarity to the sequence in a viral mRNA. Stated another way, the virus genome is complementary to the viral mRNA. Depending on the family, the genome may consist of one single-stranded RNA molecule or up to eight separate RNA molecules.

Host species A wide variety of plants and animals are parasitized by viruses that have negative-sense single-stranded RNA genomes. If you have ever suffered from the flu, the mumps, or the measles, then you are painfully familiar with these viruses (**FIGURE 36.20**). The Ebola, sin nombre, and rabies viruses also belong to this group.

Replicative cycle When the genome of a negative-sense single-stranded RNA virus enters a host cell, a viral RNA-dependent RNA polymerase must accompany it to make new viral RNAs. Some of these transcripts serve as mRNA to be translated into viral proteins, while others function as templates for replicating the viral genome.

FIGURE 36.20 (−)ssRNA Viruses, Such as the Measles Virus, Cause Some Common Childhood Diseases.

RNA Reverse-Transcribing Viruses (Retroviruses)

The genomes of the RNA reverse-transcribing viruses are composed of positive-sense single-stranded RNA. This group has only one family, called the retroviruses, with 7 genera.

Genetic material Virions have two copies of a positive-sense single-stranded genome.

Host species Species in this group are known to parasitize only vertebrates—specifically birds, fish, or mammals. The Rous sarcoma virus (chickens), the mouse mammary tumor virus, and the murine (mouse) leukemia virus are well-studied retroviruses that have been shown to contribute to the development of cancer. Of the retroviruses, HIV is the most familiar and, in terms of the human population, by far the deadliest virus in this group (**FIGURE 36.21**).

Replicative cycle Although retroviruses have positive-sense single-stranded RNA, their genome is not translated immediately after it enters the host-cell cytosol. Instead, viral reverse transcriptase, which enters the cell along with the genome, catalyzes the synthesis of a double-stranded DNA version of the viral genome. This DNA is transported into the nucleus and integrated into the host genome by a viral protein called integrase. The virus may remain dormant for a period until induced by host-cell signals, such as the activation of HIV via the immune response. Activation starts up the replicative cycle. Genes are transcribed to mRNA to begin the production of a new generation of virions.

FIGURE 36.21 Some Retroviruses, Such as HIV, Severely Impair the Physiology of the Host.

If you understand . . .

36.1 Why Do Biologists Study Viruses?

- Viruses cause illness and death in organisms from all three domains of life.
- Viruses are specialists—different types of viruses infect particular species and types of cells.

✔ **You should be able to explain how HIV causes AIDS and why it takes close to eight years before the clinical signs appear.**

36.2 How Do Biologists Study Viruses?

- Most viruses have a capsid made of protein that is either icosahedral or helical in shape. Some viruses are covered by a host-derived membrane called an envelope.
- Viral genomes exhibit considerable diversity. The genetic material may consist of one or more molecules of DNA or RNA that is either double stranded or single stranded.
- Viral entry often depends on specific interactions between viral proteins and molecules on the host-cell surface, called virus receptors. Attachment is followed by uncoating, which is when the viral genome is released into the cytosol.
- The protein-production and genome-replication phases of the replicative cycle depend on biosynthetic machinery, chemical energy, and substrates provided by the host cell.
- Enveloped viruses exit a cell by budding; naked viruses often exit a cell by lysis—killing the host cell in the process.
- Some viruses may enter a dormant phase, when they do not produce virions, but instead coexist with the host cell and transmit genetic material to daughter cells when the host divides.

✔ **You should be able to explain how three of the six phases of a viral replicative cycle can be stopped by antivirals, using HIV as an example.**

36.3 What Themes Occur in the Diversification of Viruses?

- Three hypotheses have been developed to explain the origin of viruses: (1) They are escaped gene sets from cells; (2) they are the products of degenerate cellular parasites; (3) they coevolved with cells from the RNA world.
- Viruses continue to evolve. Factors influencing rates of viral evolution are errors during genome replication and genomic reassortment.
- Many viruses currently infecting humans are examples of emerging diseases—that is, diseases caused by viruses transmitted from other host species.

✔ **You should be able to apply what you know of Darwin's four postulates on natural selection (see Chapter 25) to explain how it is possible for viruses to evolve even though they are not alive.**

36.4 Key Lineages of Viruses

- In addition to morphology and the nature of the genetic material, viruses also vary in how the genome is replicated and transcribed to produce mRNA.

✔ **You should be able to compare and contrast the transcription and replication of the RNA genomes of class IV and class VI viruses.**

TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. What do host cells provide for viruses?
   a. nucleotides and amino acids
   b. ribosomes
   c. ATP
   d. all of the above
2. How do viruses that infect animals enter an animal's cells?
   a. The viruses pass through a wound.
   b. The viruses bind to a membrane component.
   c. The viruses puncture the cell wall.
   d. The viruses lyse the cell.
3. What does reverse transcriptase do?
4. When do most enveloped virions acquire their envelope?
   a. during entry into the host cell
   b. during budding from the host cell
   c. as they burst from the host cell
   d. as they integrate into the host cell's chromosome
5. In the viral replicative cycle, what reaction do viral proteases catalyze?
   a. polymerization of amino acids into peptides
   b. folding of long peptide chains into functional proteins
   c. cutting of polyprotein chains into functional proteins
   d. assembly of virions
6. What features distinguish the seven major categories of viruses?

TEST YOUR UNDERSTANDING

Answers are available in Appendix A

7. The outer surface of a virion consists of either a membrane-like envelope or a protein capsid. How does the outer surface correlate with a virus's mode of exiting a host cell, and why?
8. Compare and contrast the bacteriophage lytic cycle versus lysogeny by addressing (1) replication of the viral genome, (2) production of virions, and (3) effect on the host cell.
9. Propose a reason why the development of antiviral drugs is more difficult than developing the antibiotics used to treat bacterial infections.
10. How does the diversity of viral genome types support the hypothesis that viruses originated several times independently?
11. What types of data convinced researchers that HIV originated when a simian immunodeficiency virus "jumped" to humans?
12. Of the viruses highlighted in Section 36.4, predict which of the following would be able to make viral proteins by injecting nothing more than its genome into a suitable host cell.
    a. cowpea mosaic ([+]ssRNA) virus
    b. bluetongue (dsRNA) virus
    c. measles ([−]ssRNA) virus
    d. human immunodeficiency (RNA reverse-transcribing) virus

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A

13. Suppose you could isolate a virus that parasitizes the pathogen *Staphylococcus aureus*—a bacterium that causes acne, boils, and a variety of other afflictions in humans. How could you test whether this virus might serve as a safe and effective treatment for a staph infection?
14. If you were in charge of the government's budget devoted to stemming the AIDS epidemic, would you devote most of the resources to drug development or preventive medicine? Defend your answer.
15. Latency is a key adaptation in some animal viruses and likely evolved to prolong the infection by avoiding a strong and effective immune response. Which of the following types of viruses would you expect to require periods of latency?
    a. viruses that have large genomes and require a long time for replication
    b. viruses that require a long time for transmission to new host organisms
    c. viruses that require a long time for assembling into complex structures
    d. viruses that infect cells of the immune system
16. Consider these two contrasting definitions of life: **(1)** An entity is alive if it is capable of replicating itself via the directed chemical transformation of its environment; **(2)** An entity is alive if it is an integrated system for the storage, maintenance, replication, and use of genetic information. According to these definitions, are viruses alive? Explain.

37 Plant Form and Function

In this chapter you will learn how

Plant structure lays the foundation for plant function

by examining

- **Themes and variations in plant form** 37.1
  - looking closer at: Roots, Shoots, Leaves
  - and: **Plant tissue systems (dermal, ground, vascular) and their cells** 37.3
- which develop from: **Primary growth (extends the plant body)** 37.2
  - and: **Secondary growth (widens shoots and roots)** 37.4

All plants are able to harvest diffuse resources and concentrate them in cells and tissues, but their forms and strategies are diverse. These baobab trees in Madagascar may live to be hundreds of years old despite drought conditions, in part by storing water in their enormous trunks.

Photosynthetic plants carry out the most remarkable biochemistry of any terrestrial organisms. Using the energy in sunlight and the simplest of starting materials—carbon dioxide, water, and ions containing nitrogen, phosphorus, potassium, and other key atoms—plants synthesize thousands of different carbohydrates, proteins, nucleic acids, and lipids. They use these compounds to build bodies that may live for thousands of years.

This feat is even more impressive when you consider that the simple starting materials that plants need to grow are tiny and diffuse—carbon dioxide molecules, water molecules, nitrate ions, and other resources are usually found at low concentrations over a large area. To gather the raw materials required for their sophisticated biosynthetic machinery, a plant's roots and shoots grow outward, extending the individual into the soil and atmosphere.

BIG PICTURE

This chapter is part of the Big Picture. See how on pages 840–841.

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

In essence, a plant's body harvests diffuse resources and concentrates them in cells and tissues. The structure of its body is dynamic, because most plants exhibit **indeterminate growth**; that is, they grow throughout their lives. A 4750-year-old bristlecone pine has roots and shoots that are still growing. In response to favorable conditions, a plant sends shoots and roots in the most promising directions, seeking light and the simple compounds it requires.

The contrast between the plant and animal way of life is striking. Most animals move around, eat concentrated sources of food, and avoid stressful conditions. But plants stay in one place, extend their roots and shoots to harvest diffuse resources, make their own food, and cope with stress where they stand.

This chapter focuses on three fundamental questions:

1. How is the plant body organized?
2. Why are plants so diverse in size and shape?
3. How do plants grow throughout their lives?

Instead of surveying the entire catalog of land plants, though, the focus here is on the flowering plants, or angiosperms. Recall that angiosperms are the most recent major group of plants to appear in the fossil record (see Chapter 31). With about 250,000 species described, they are by far the most abundant, species rich, and geographically widespread plant group today. It is also difficult to overstate their economic and medical importance to humans. Most of the food we eat and many of the medicines we use are derived from angiosperms.

If you look outside or down the produce aisle of a grocery store, you will see a wide diversity of plants and plant products. By the time you finish this chapter, you'll understand how these plant bodies are put together and how they grow. Exploring questions about the anatomy of flowering plants is vital to understanding the world at large as well as the other chapters in this unit. (You can review the importance of plant form and function in the Big Picture of plant and animal physiology on pages 840–841.)

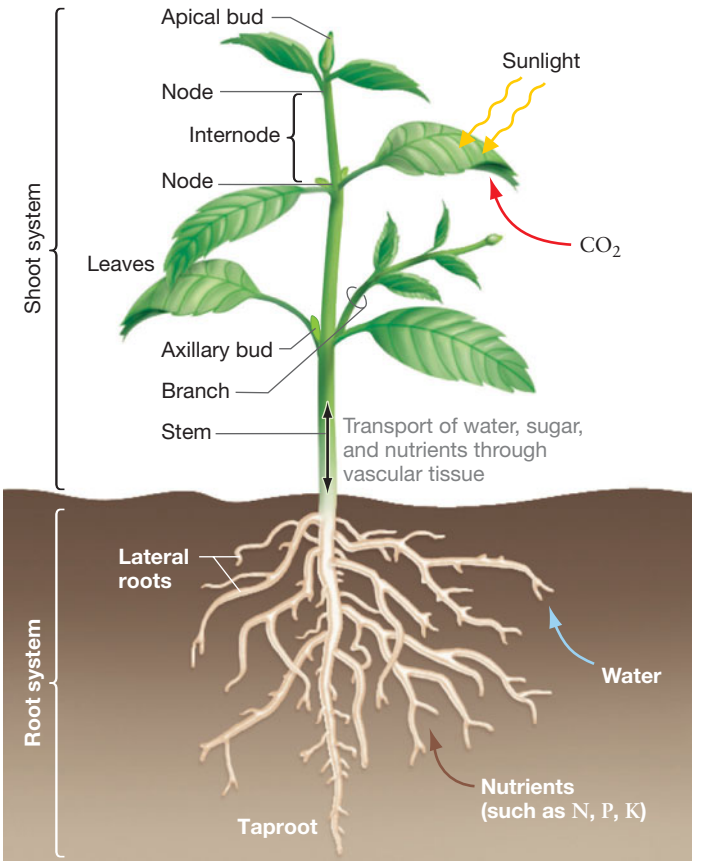

FIGURE 37.1 Typical Root and Shoot Systems Acquire and Transport Resources. Shoot systems are specialized for harvesting light and CO_2. Root systems absorb water and key nutrients such as nitrogen (N), phosphorus (P), and potassium (K).

✔**QUESTION** Suppose that this plant's growth was limited by access to light and nutrients, and that the plant had a new deposit of nutrient-rich soil to the left and much more sunlight suddenly available to the right. Explain what you would expect this individual to look like in one month.

37.1 Plant Form: Themes with Many Variations

Plants—along with algae, cyanobacteria, and a variety of protists—obtain energy and carbon to grow and reproduce (see Chapter 10). Plants use light energy to synthesize carbohydrates using carbon dioxide from the air and water from the soil.

For photosynthesis to occur efficiently, plants need large amounts of light and carbon dioxide, along with water as an electron source. Plants also need large amounts of water to fill their cells and maintain them at normal volume and pressure.

To synthesize nucleic acids, enzymes, phospholipids, and the other molecules needed to build and maintain cells, plants must obtain nitrogen (N), phosphorus (P), potassium (K), magnesium (Mg), and a host of other nutrients. Most of these key elements exist in nature as ions that dissolve in water found in soil.

FIGURE 37.1 labels the major structures in the two basic systems that plants use to acquire the resources they need for photosynthesis. A belowground portion called the **root system** anchors the plant and takes in water and nutrients from the soil; an aboveground portion called the **shoot system** harvests light and carbon dioxide from the atmosphere to produce sugars. Both systems grow throughout the life of the individual, allowing the plant to increase in size, acquire resources, and reproduce.

In most plants, vascular tissue connects the root and shoot systems. Through vascular tissue, water and nutrients are transported from roots to shoots; sugars can be transported in both directions. As you learn about how the plant form has evolved to serve necessary functions, compare and contrast what you learn with how animals have adapted to new environmental challenges. In many ways the two groups are remarkably similar.

The Importance of Surface Area/Volume Relationships

Before exploring the nature of root and shoot systems in more detail, it's important to recognize a key structural relationship that is critical to their function.

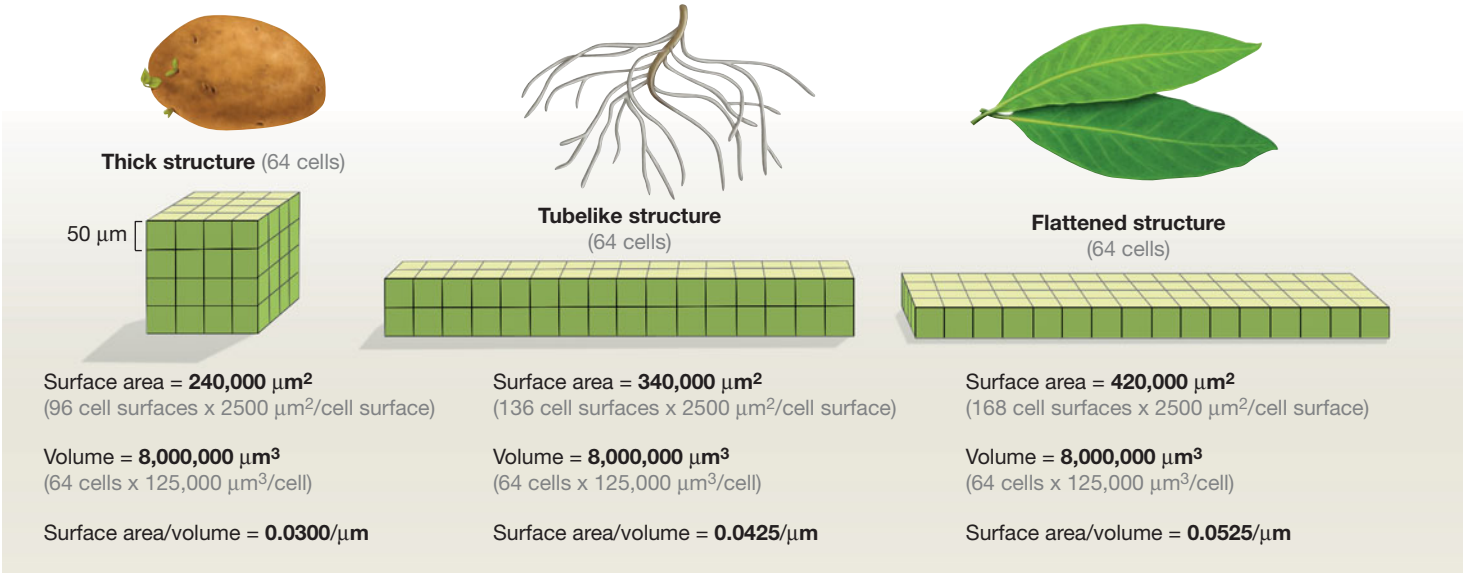

FIGURE 37.2 The Morphology of Roots and Leaves Gives Them a High Surface-Area-to-Volume Ratio. In this example, the "thick structure" represents a tree trunk or potato-like storage organ; the "tubelike structure" represents a root; the "flattened structure" represents a leaf. Note that each schematic structure has the same number of cells and the same total volume—but a very different surface area.

Root and shoot systems both function in absorption—of water and key ions, or of light, respectively. Absorption takes place across a surface. But the cells that use the absorbed molecules and light occupy a volume. Thus, a plant body is more efficient as an absorption-and-synthesis machine when it has a large surface area relative to its volume.

FIGURE 37.2 illustrates this point. In this example, the cells in a plant are represented by cubes; the side of each cell is 50 μm long. Thus, each face of a cell has a surface area of $50 \times 50 = 2500\ \mu m^2$; each cell has a volume of $50 \times 50 \times 50 = 125{,}000\ \mu m^3$. Follow the calculations in the figure and note that:

- If 64 cells are arranged in a cube, the surface area/volume relationship is 0.0300/μm.
- If 64 cells are arranged in a long tube, the surface area/volume relationship is 0.0425/μm.
- If 64 cells are arranged in a flat sheet, the surface area/volume relationship is 0.0525/μm.

This simple exercise has an important punch line: Tubes and sheets have much more surface area relative to their volume than cubes. It's no surprise, then, that the absorptive regions of a root system are tubelike, and the absorptive regions of a shoot system are the flattened structures called leaves. Storage tissues such as tubers and seeds have a low surface-area-to-volume ratio because they are not involved in absorption.

The Root System

Many root systems have a vertical **taproot,** as well as numerous **lateral roots** that run more or less horizontally. The root system anchors the plant in soil, absorbs water and ions from the soil, conducts water and selected ions to the shoot, obtains energy in the form of sugar from the shoot, and stores material produced in the shoot for later use.

Root systems can be impressive in extent. For example, in 1937 botanist Howard Dittmer grew a winter rye plant in a container full of soil for four months. He then unearthed the plant and meticulously measured its roots. The root system of this single individual contained more than 14 billion identifiable structures with a combined length of over 11,000 km—over one-fourth of Earth's circumference! The total surface area of the root system was almost 640 m^2, or about the size of 1.5 basketball courts. A root system like this is clearly adapted to absorbing diffuse resources located underground.

Other studies have shown that **(1)** the roots of trees routinely extend beyond the width of their aboveground canopy, and **(2)** it is not unusual for a plant's root system to represent over 80 percent of its total mass. Many plants devote a great deal of energy and resources to the growth of their root systems.

Although most root systems contain the same general structures, the root systems are diverse. This diversity can be analyzed on three levels:

1. morphological diversity among species;
2. phenotypic plasticity, or changes in the structure of an individual's root system in response to the environment; and
3. modified roots that are specialized for unusual functions.

Let's consider each level in turn.

Morphological Diversity in Root Systems

As an example of the range of morphological diversity observed in the root systems of angiosperms, consider prairie plants.

Prairies are grassland ecosystems found in areas of the world such as central North America, the Serengeti Plain of East Africa,

the Pampas region of Argentina, and the steppes of central Asia (see Chapter 52). Rain is abundant enough in these areas to support a lush growth of **herbaceous plants**—seed plants that lack woody tissue. Rain is scarce enough to exclude trees and most shrubs, however. The growth of woody species is also discouraged by fires that regularly sweep through these ecosystems.

Although the aboveground portions of prairie plants burn during fires and die back during the winter or dry season, their root systems are **perennial,** meaning that they live for many years. The root system sends up a new shoot system each spring and also after a fire.

To examine the root systems of prairie plants, researchers excavate around a particular plant to expose the roots. **FIGURE 37.3** shows that the root systems of prairie plants can be very different, even if they live next to each other. For example, the dense, fibrous root systems of junegrass and switchgrass do not have a taproot, whereas the taproot of a compass plant can reach depths of over 4.5 m.

Diversity in root system structure has important consequences for competition between species. The tips of the smallest roots are where most water and nutrient absorption take place, but in prairies, the small root tips of different species are often found at different depths in the soil.

To explain the diversity of root systems observed among species that grow in the same habitat, biologists suggest that natural selection has favored structures that minimize competition for water and nutrients.

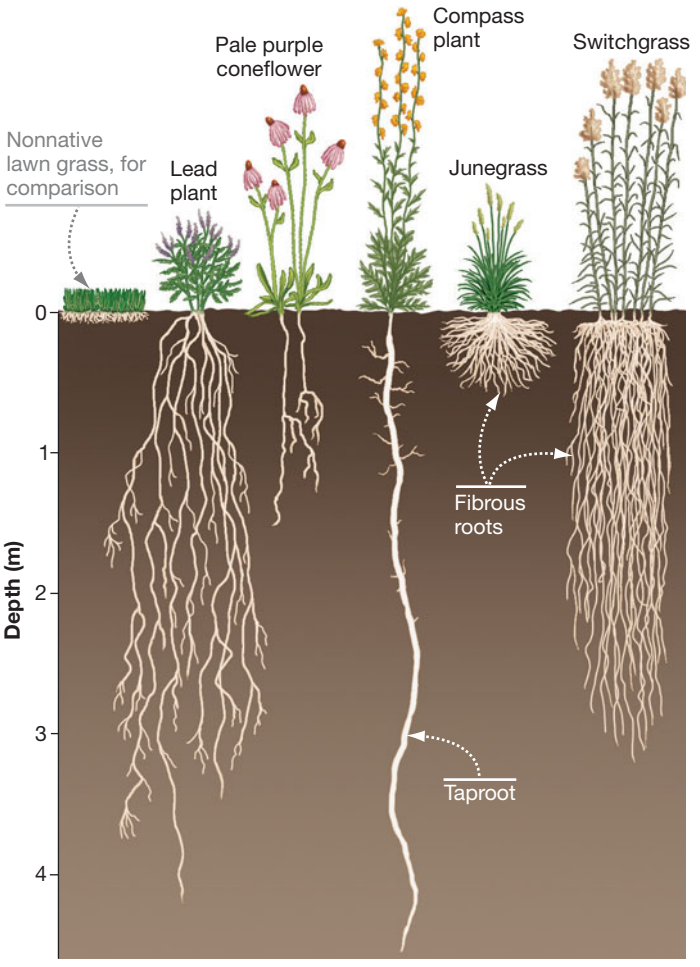

FIGURE 37.3 Plants Have Diverse Root Systems. The roots of prairie plants that live side by side can be very different.

✔**QUESTION** Why are lawns not drought tolerant?

Phenotypic Plasticity in Root Systems Morphological diversity in roots occurs within species as well as among species. Some of the within-species variation is due to genetic diversity among individuals, but some is due to how roots respond to the environment.

Roots show a great deal of **phenotypic plasticity**—meaning that their form is changeable, depending on environmental conditions. For example, spruce trees growing in waterlogged soils tend to have root systems less than a meter deep. Their roots are shallow because the wet soil lacks oxygen, and root cells, like animal cells, suffocate in the anoxic conditions. The same tree growing in drier soil would develop a root system several meters deep.

The key point is that even genetically identical individuals will have very different root systems if they grow in different environments.

Phenotypic plasticity is particularly important in plants because they grow throughout their lives, and sometimes their environment changes. Root systems that grow into nutrient-rich septic fields or sewer pipes that leak human waste are a prime example. Roots actively grow into areas of soil where resources are abundant; roots stop growing or die back in areas where resources are used up or lacking.

Modified Roots The taproots and fibrous roots illustrated earlier do not begin to exhaust the types of roots found among plants (**TABLE 37.1**). For example, some roots are **adventitious**—meaning they develop from an unusual source, the shoot system instead of the root system.

- In ivy, anchor roots—adventitious roots that grow from nodes in the shoot system—help anchor individuals to brick walls or other structures.
- The prop roots of corn are adventitious roots that help brace individuals in windy weather.

Even roots that are part of the root system can have specialized functions—meaning that they do things other than absorbing water and nutrients and anchoring the shoot system.

The pneumatophores of mangroves in the genus *Avicennia* are specialized lateral roots that function in gas exchange. These mangroves grow in submerged habitats where fine silt is deposited, cutting off the oxygen supply to their roots. Their root cells do not suffocate, however, because oxygen from the atmosphere can diffuse into the root system through the pneumatophores. These roots grow upward—not downward—in response to gravity.

The thick taproot of some biennial plants, such as carrots, stores starch during the first of the plants' two growing seasons. Carrot roots, the ones we eat, are normally harvested at this point. If carrots were not harvested, the plants would resume

SUMMARY TABLE 37.1 Form and Function of Modified Roots

Modified Root	Example

✔**QUESTION** Why do root cells need oxygen?

growth after the winter and use that stored energy during a second summer to "go to seed," producing a large flowering shoot. Starch in the taproot makes the energy-intensive reproductive process possible.

The Shoot System

As Figure 37.1 indicates, the shoot system has an array of important anatomical features.

- The shoot system consists of one or more **stems,** which are vertical aboveground structures.
- A stem consists of **nodes,** where leaves are attached, and **internodes,** or segments between nodes.
- A **leaf** is an appendage that projects from a stem laterally. Leaves usually function as photosynthetic organs.
- The nodes where leaves attach to the stem are also the site of **axillary** (or **lateral**) **buds,** which form just above the site of leaf attachment.
- If conditions are appropriate, an axillary bud may grow into a **branch**—a lateral extension of the shoot system.
- The tip of each stem and branch contains an **apical bud,** where growth occurs that extends the length of the stem or branch.
- If conditions are appropriate, apical or axillary buds may develop into flowers or other reproductive structures.

In essence, the shoot system is a repeating series of nodes, internodes, leaves, and apical and axillary buds. As plants grow, the number of nodes, internodes, and leaves increases. After an initial period of growth, however, an internode does not increase much in length over time.

As with root systems, diversity in shoots can be analyzed on three levels: morphological diversity among species, phenotypic plasticity within individuals, and modified shoots with specialized functions.

Morphological Diversity in Shoot Systems The shoot systems of plants, essentially the visible part of the plant, range in size from species like the tiny (<5 mm diameter) duckweed that you may have seen growing on the surface of stagnant ponds to redwood trees that reach heights of over 100 m (300 ft) and giant sequoias with trunks that weigh 2.6 million kg (over 5.7 million lb)—about the same as 10 diesel locomotives.

The shape of the shoot system also varies a great deal among species. For example, the manner in which new branches are added as the shoot system grows affects the shape of the individual and its ability to compete for light. As **FIGURE 37.4** shows, a plant growing with wide branching angles and short internodes has a very different shape from that of a plant with narrow branching angles and long internodes.

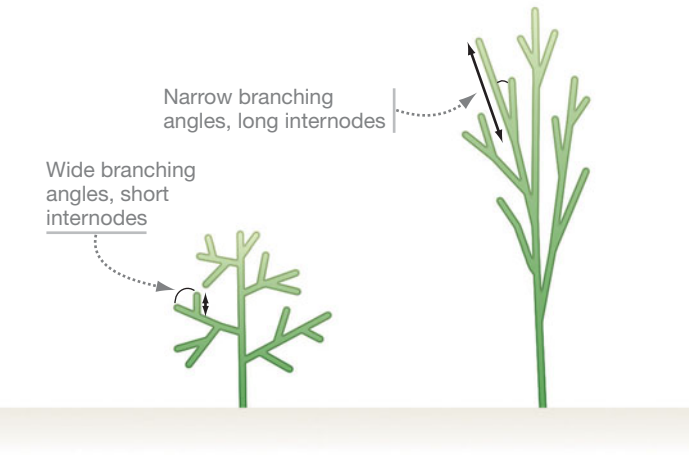

FIGURE 37.4 Plant Form Can Vary as a Function of Branch Angle and Internode Length.

Variation in the size and shape of the shoot system is important: It allows plants of different species to harvest light at different locations and thus minimize competition. It also allows plants to thrive in a wide array of habitats.

As an example of how the shape of a shoot system varies among species in different environments, consider the silversword plants native to Hawaii. You might recall that all of the silverswords are believed to be descended from the same ancestor—a species of tarweed that arrived in Hawaii from the west coast of North America about 5 million years ago (see Chapter 28).

Silverswords represent an adaptive radiation: a lineage that rapidly split into many species occupying a wide array of habitats. Their shoot systems are particularly diverse in size, shape, and growth habit (see Figure 28.9). Some silverswords grow low to the ground in dense mats; some form bunched rosettes of leaves; some are vines; others are woody shrubs or even small- to medium-sized trees.

Biologists interpret this diversity of shoot systems as a suite of adaptations for harvesting light and carbon dioxide in different environments.

- In lush habitats, where competition for light is intense, woody individuals that grow tall are favored by natural selection.
- In dry, windblown habitats, individuals with short stems or rosettes thrive because they require less water than taller individuals, and they don't blow over.

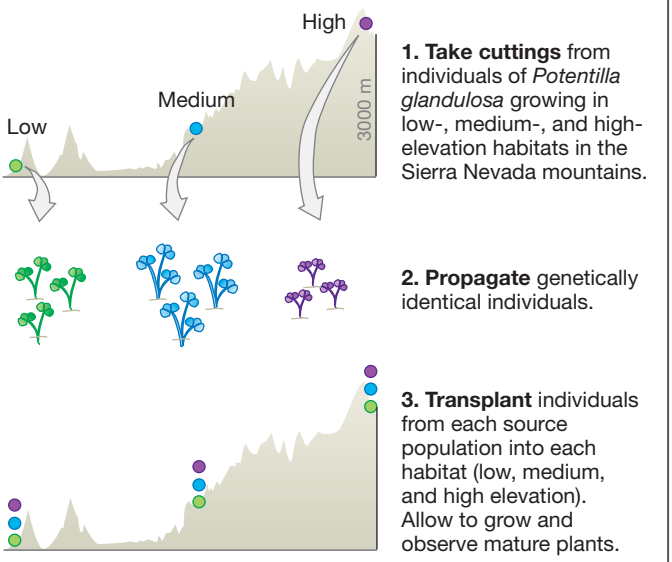
The adaptive radiation of silverswords has been based in part on diversification in their shoot systems.

Phenotypic Plasticity in Shoot Systems The size and shape of an individual's shoot system can vary dramatically based on variation in growing conditions: temperature, exposure to wind, and availability of water, nutrients, and light.

This conclusion was driven home in an experiment conducted by Jens Clausen and colleagues in the late 1930s. These biologists transplanted several species of herbaceous plants between sites along an elevational gradient: from sea level to alpine habitats. In each case, the transplanted individuals were propagated from cuttings—meaning that they were genetically identical to individuals growing at the other locations. As the "Results" section in **FIGURE 37.5** shows, the overall size and shape of the shoot system varied markedly among locations.

Because a plant's shoot system continues to grow over the course of its lifetime, it can respond to changes in environmental conditions just like the root system can. Experiments on phototropism, for example, established that shoot systems can bend toward light if an individual is shaded on one side (see Chapter 40). Plants also undergo differential growth, producing more branches and leaves in regions of the body that are exposed to the highest light levels. A plant's shoot system grows in directions that maximize its chances of capturing light.

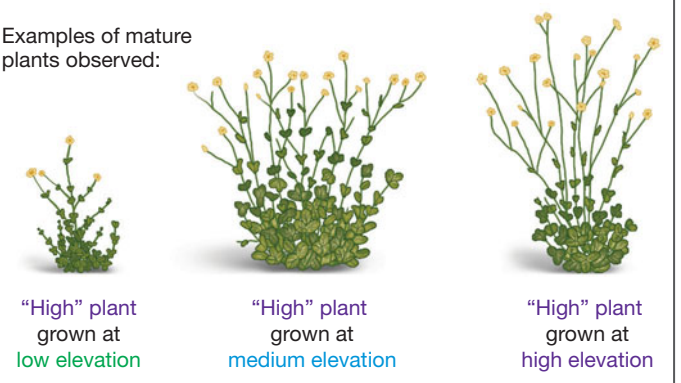
Modified Stems As in root systems, the stems of many plants have modified structures to serve various functions (**TABLE 37.2**).



- Many desert cacti have highly modified stems. Instead of functioning primarily to support leaves, cactus stems often

RESEARCH

QUESTION: How much does a plant's growth form depend on its environment?



HYPOTHESIS: (No explicit hypothesis—the goal of this experiment was to explore the interaction between genetic makeup versus environmental influence on size and shape.)

EXPERIMENTAL SETUP:

PREDICTION: (No explicit predictions.)

RESULTS:

CONCLUSION: Environmental conditions have a profound influence on body size and shape (genetically identical plants look different at each site). BUT, genetic makeup also has a large influence on plant morphology. (Though not pictured here, plants from each source population look different, even when grown in the same habitat.)

FIGURE 37.5 Experimental Evidence for Phenotypic Plasticity in Shoot Systems.

SOURCE: Clausen, J., D. D. Keck, and W. M. Hiesey. 1945. Experimental studies on the nature of species. II. Plant evolution through amphiploidy and autoploidy, with examples from the Madiinae. Publication No. 564. Washington, DC: Carnegie Institute of Washington.

✔ **QUESTION** Why was it important for the researchers to propagate the individuals from cuttings?

SUMMARY TABLE 37.2 Form and Function of Modified Stems

Modified Stem	Example
Water-storage structures Cactus stems (shown in cross section) store water	
Stolons Strawberry stolons produce new individuals at nodes aboveground	
Rhizomes Rhizomes produce new individuals at nodes belowground, and store carbohydrates	
Tubers Tubers such as potatoes store carbohydrates such as starch	
Thorns Thorns provide protection from herbivores	

enlarge into water-storage organs. Water accounts for up to 98 percent of the weight of a cactus stem. These cactus stems also contain the plant's photosynthetic tissue.

- **Stolons** are modified stems that grow horizontally along the soil surface, producing adventitious roots and leaves at each node. Because new plants form at these nodes, stolons function in asexual reproduction (see Chapter 13).
- Like stolons, **rhizomes** are stems that grow horizontally instead of vertically. They produce new plants at nodes and thus participate in asexual reproduction. But while stolons grow aboveground, rhizomes spread belowground. One quaking aspen plant in Utah was found to have 47,000 stems rising from a network of rhizomes, making it one of the largest organisms known. What we see as individual aspen trees are actually stems that are connected underground.
- **Tubers** are underground, swollen rhizomes that function as carbohydrate-storage organs. The eyes of a potato—a typical tuber—are nodes in the stem where new branches may arise.
- **Thorns** are modified stems that help protect the plant from attacks by large **herbivores,** or plant eaters, such as deer, giraffe, or cattle.

The Leaf

In most plant species, the vast majority of photosynthesis occurs in the part of the shoot system we call leaves. The total area of leaf produced by a single plant can be enormous—a single tree can have hundreds of thousands of leaves with a total surface area equivalent to that of a football field. All of this area is available for absorbing photons and supporting photosynthesis.

A simple leaf (**FIGURE 37.6a** on page 738) is composed of just two major structures: an expanded portion called the **blade** and a stalk called the **petiole.** But leaves exhibit many variations on the central theme of a flattened structure specialized for performing photosynthesis.

Morphological Diversity in Leaves Glance outside or stroll through a garden, and you'll find many types of simple leaves with an easily recognizable blade and petiole. (Grass leaves will stump you, though, because they lack petioles entirely.) You will also find compound leaves that have blades divided into a series of leaflets (**FIGURE 37.6b**). You may even encounter doubly compound leaves, which have leaflets that are again divided (**FIGURE 37.6c**).

Not all leaf blades are thin with a large surface area, however. For example, plants that thrive in deserts and in cold, dry habitats tend to have needle-shaped leaves (**FIGURE 37.6d**). The leading hypothesis to explain this pattern is based on two observations: **(1)** Water is often in short supply in these environments because it is scarce in deserts, or frozen and thus unavailable in cold habitats; and **(2)** leaves with large surface areas lose large amounts of water through an evaporative process called **transpiration** (discussed in Chapter 38).

Thus, needlelike leaves are interpreted as adaptations that minimize transpiration in water-scarce habitats. Small, narrow

(a) Simple leaves have a petiole and a single blade.

(b) Compound leaves have blades divided into leaflets.

(c) Doubly compound leaves are large yet rarely damaged by wind or rain.

(d) Needlelike leaves are characteristic of species adapted to very cold or hot climates.

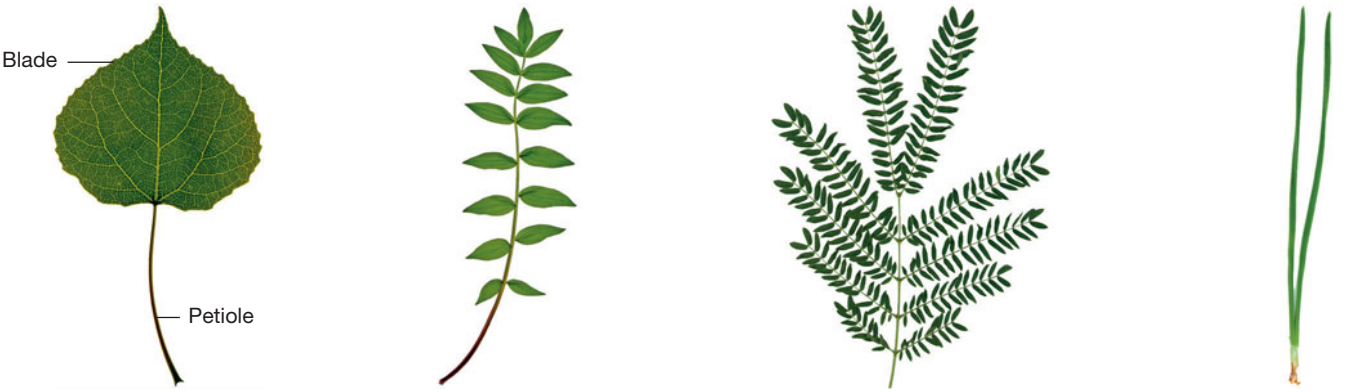


FIGURE 37.6 Leaves Vary in Size and Shape. The structures in parts **(a)** through **(c)** represent single leaves; part **(d)** shows two leaves.

✔**QUESTION** For capturing photons, what is the advantage of having a leaf with a large surface area? In terms of wind damage and water loss, what is the disadvantage of having a leaf with a large surface area?

leaves are also much less susceptible to wind damage than are large, broad leaves.

The arrangement of leaves on a stem can vary as much as leaf shape. For example, leaves can be:

- arranged to alternate on either side of the stem (**FIGURE 37.7a**);
- paired opposite each other on the stem (**FIGURE 37.7b**);
- arranged in a whorl (**FIGURE 37.7c**);
- found in a compact basal arrangement where internodes are extremely short—leading to the rosette growth form (**FIGURE 37.7d**).

Leaf shape and the arrangement of leaves on a stem are usually determined genetically, so these characters are often used for plant identification.

Phenotypic Plasticity in Leaves Even though leaves do not grow continuously, they exhibit phenotypic plasticity just like root systems and stems do.

Leaves from the same individual that grow in sun versus shade serve as a prominent example of phenotypic plasticity in leaf morphology. As the oak tree leaves in **FIGURE 37.8** show:

- *Sun leaves* are thicker and have a relatively small surface area, which reduces water loss in areas of the body where light is abundant.
- *Shade leaves* are relatively thin and broad, providing a high surface area that maximizes absorption of rare photons.

Water loss is less of a problem for shade leaves because temperatures are cooler in shade than in bright sun.

(a) Alternate leaves

(b) Opposite leaves

(c) Whorled leaves

(d) Rosette

FIGURE 37.7 The Arrangement of Leaves on Stems Varies.

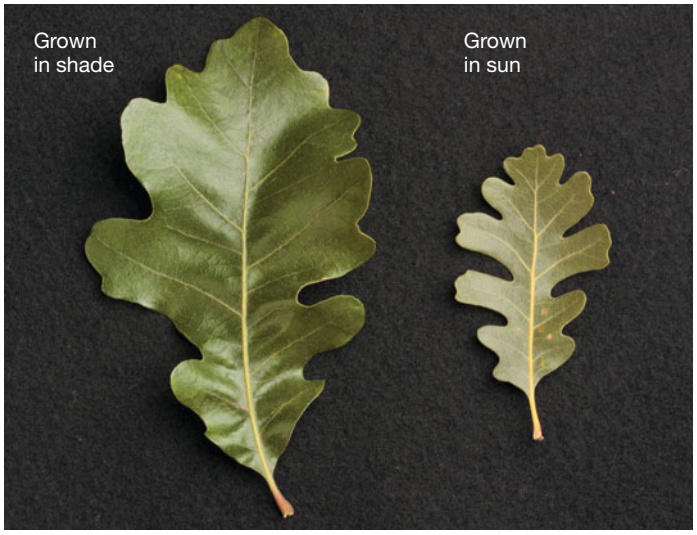

FIGURE 37.8 Phenotypic Plasticity in Leaves. These leaves came from the same tree.

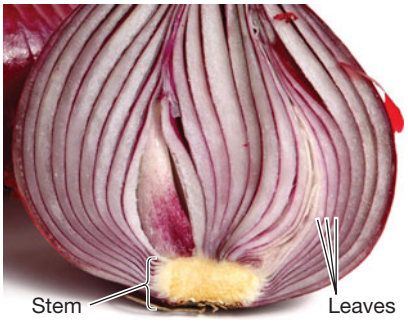
Modified Leaves Not all leaves function primarily in photosynthesis; some perform other roles (**TABLE 37.3**).

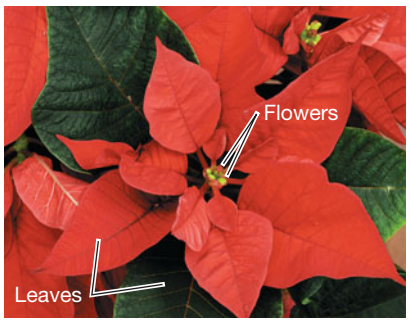
- Onion bulbs consist of thickened leaf bases that store nutrients, separated by highly condensed internodes.
- The thick leaves of plants called succulents, such as aloe vera, store water.
- The tendrils that enable garden peas and other vines to climb are modified leaflets or leaves.
- The bright red leaves of poinsettias attract pollinators to the tiny yellow flowers that they surround.

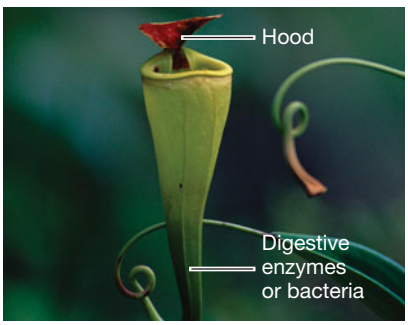
check your understanding

C Y U

If you understand that . . .







- The plant body is organized into a root system and a shoot system.
- Roots and shoots explore the environment via continuous growth and efficiently absorb diffuse resources like water, ions, carbon dioxide, and sunlight.
- Roots and stems may also function to anchor the plant, store water, produce offspring asexually, provide protection, or store carbohydrates.
- Leaves vary among species and within individuals, and they may be modified to store food or water, capture insects, make climbing possible, attract pollinators, or protect the stem.

✓ You should be able to . . .

1. Diagram a generalized version of the angiosperm body, labeling each major part.
2. Provide two examples each of root systems, stems, and leaves that differ in structure and/or function from the generalized body shown in Figure 37.1.

Answers are available in Appendix A.

SUMMARY TABLE 37.3 Form and Function of Modified Leaves

Modified Leaves	Example
Bulbs	 Onion leaves store food
Succulent leaves	 Aloe vera leaves store water
Tendrils	 Pea tendrils aid in climbing
Floral mimics	 Red poinsettia leaves attract pollinators
Traps	 Pitcher plant leaves trap entering insects, which are discouraged from flying out by the "hood," then are digested

- The tubelike leaves of the pitcher plant trap insects. When insects enter, they feed on the plant's nectar and appear to become dizzy. Eventually they fall into the bottom of the tube and drown in water that has accumulated. The insects are then digested by bacteria or enzymes secreted by the plant, and the released nutrients are taken up by epidermal cells.
- Cactus **spines** are modified leaves that protect the stem (see top image in Table 37.2).

The variability of plant roots, stems, and leaves is impressive. Diversity, plasticity, and dynamism are recurring themes in the study of plant anatomy.

37.2 Primary Growth Extends the Plant Body

Plants grow continuously because they have many **meristems**—populations of undifferentiated cells that retain the ability to undergo mitosis and produce new cells. When meristematic cells divide, some of the daughter cells remain in the meristem, allowing the meristem to persist. Other cells, though, undergo differentiation. You might recall that differentiation is a developmental process that produces a specialized cell—one that expresses only certain genes and has a distinctive structure and function (see Chapter 22).

Apical meristems are located at the tip of each root and shoot. As cells in apical meristems divide, enlarge, and differentiate, root and shoot tips extend the plant body outward, allowing it to explore new space.

This process is **primary growth,** which is common to all plants. The major consequence of primary growth is to increase the length of the root and shoot systems. Cells that are derived from apical meristems form the primary plant body.

To understand how primary growth occurs, let's look at the overall organization of the primary plant body and then delve into a detailed look at its tissues and cells.

How Do Apical Meristems Produce the Primary Plant Body?

Whether located in the root or the shoot, apical meristems give rise to three distinct populations of **primary meristem** cells: protoderm, ground meristem, and procambium. These cells are partially differentiated but retain the character of meristematic cells because they keep dividing.

The three types of primary meristematic cells are important because they give rise to three major tissue systems that extend throughout the plant body. A **tissue** is a group of cells that functions as a unit.

FIGURE 37.9 indicates where the apical meristems and the primary meristems—protoderm, ground meristem, and procambium—are found in shoots and roots.

- **Protoderm** gives rise to the **dermal** (literally, "skin") **tissue system.** The dermal tissue system, or **epidermis,** is a single layer of cells that covers the plant body and protects it.
- **Ground meristem** gives rise to the **ground tissue system,** which makes up the bulk of the plant body and is responsible for photosynthesis and storage.
- **Procambium** gives rise to the **vascular tissue system,** which provides support and transports water, nutrients, and photosynthetic products between the root system and shoot system.

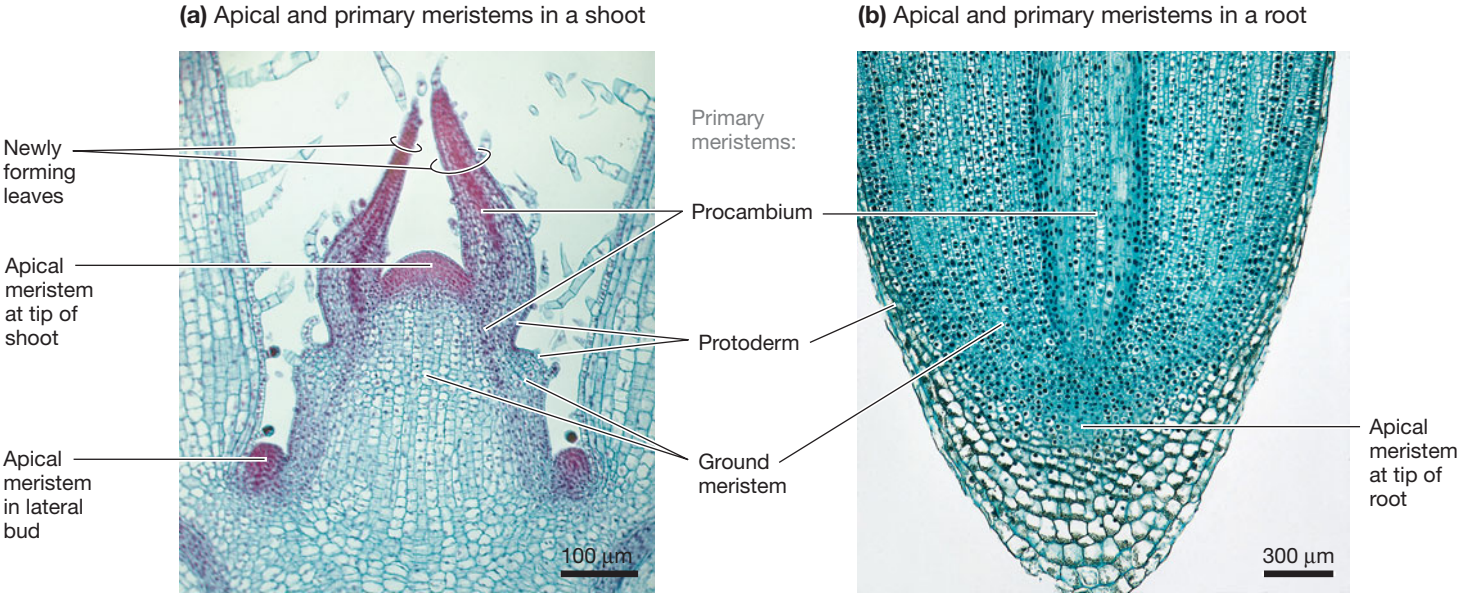


FIGURE 37.9 The Structure of Apical and Primary Meristems in the Shoot and Root. Apical meristems consist of small, similar-looking cells that divide when conditions are favorable. Three types of primary meristem cells—protoderm, ground meristem, and procambium—are derived from the apical meristem and consist of partially differentiated cells that can still divide.

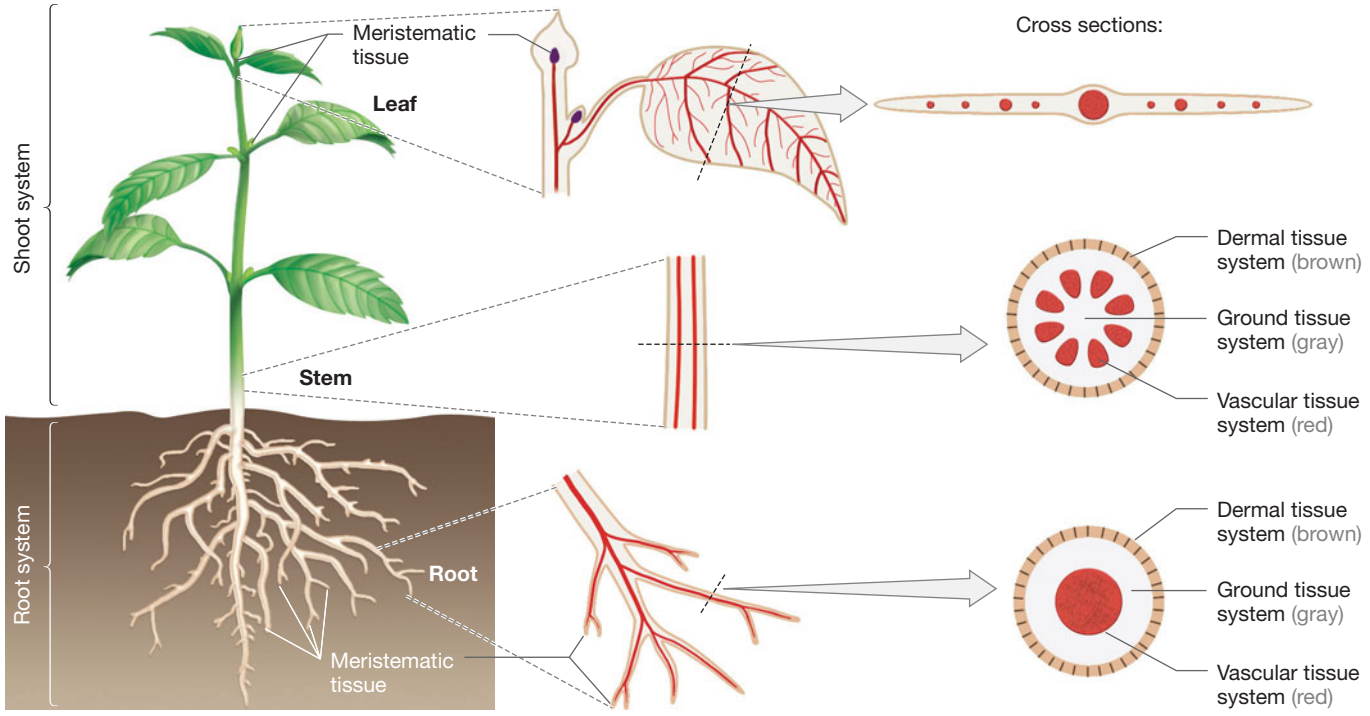

FIGURE 37.10 The Primary Plant Body Comprises the Dermal, Ground, and Vascular Tissue Systems. The dermal, ground, and vascular tissue systems arise from the protoderm, ground meristem, and procambium, respectively, as illustrated in Figure 37.9.

Vascular tissue runs through ground tissue, so the cells that make up ground tissue are usually close to cells that conduct the water and nutrients they need. **FIGURE 37.10** shows how the dermal, ground, and vascular tissues are distributed in the plant body. In contrast to these tissues, apical meristematic cells are localized at the tips of shoots and roots.

The key point to remember is that the dermal, ground, and vascular tissue systems are originally derived from cells in primary meristems, which originated from apical meristems. Thus, they represent the primary plant body.

How Is the Primary Root System Organized?

Roots have several features that allow them to grow into new regions of the soil, so they can furnish cells throughout the plant body with water and key nutrients.

As **FIGURE 37.11** shows, a group of cells called the **root cap** protects the root apical meristem. Cells produced by the meristem constantly replenish the cap, which regularly loses cells.

In addition to protecting the root tip, root cap cells are important in sensing gravity and determining the direction of growth. They also synthesize and secrete a slimy, polysaccharide-rich substance that helps lubricate the root tip, reducing friction and protecting the meristem as it is pushed through the soil.

Three distinct populations of cells exist behind the root cap:

1. The **zone of cellular division** contains the apical meristem, where cells are actively dividing, along with the protoderm, ground meristem, and procambium, where additional cell division occurs.

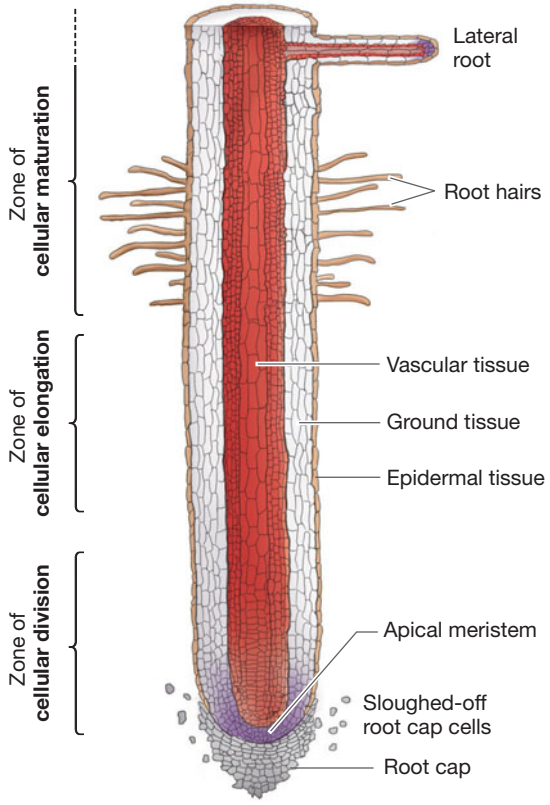

FIGURE 37.11 Roots Extend into the Soil via Growth of Apical Meristems and Cell Elongation. This is a longitudinal (lengthwise) section. The zone of cellular maturation is actually much larger than can be shown here. Most absorption of water and nutrients occurs at root hairs.

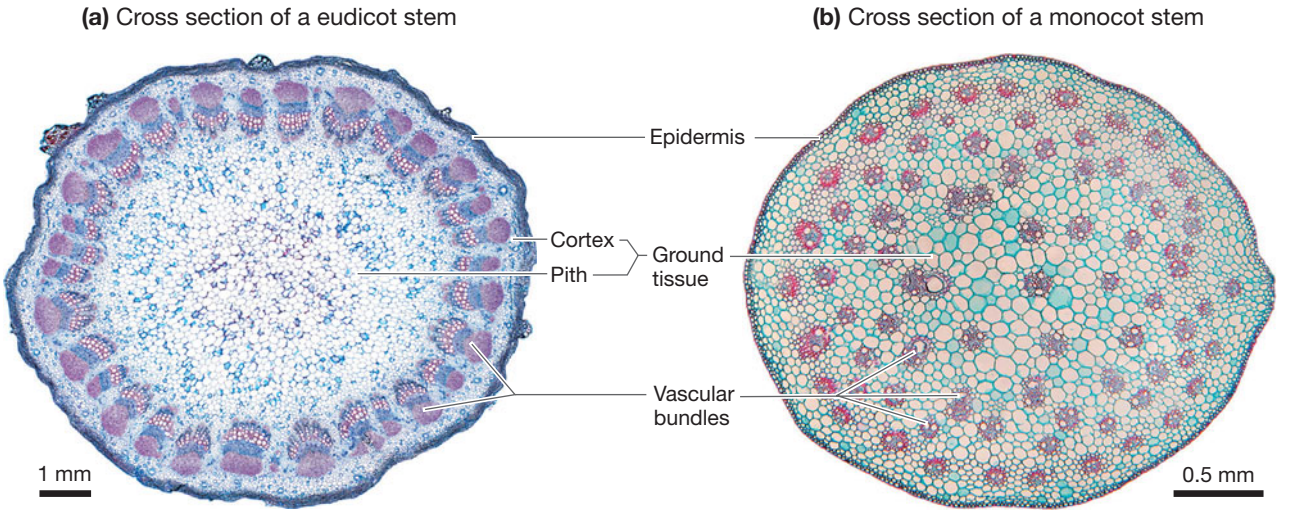

FIGURE 37.12 Stems Contain a Variety of Cell and Tissue Types. Vascular bundles are **(a)** arranged in a ring near the perimeter of eudicot stems but **(b)** scattered throughout the ground tissue in monocots.

2. The **zone of cellular elongation** is made up of cells that are recently derived from the primary meristematic tissues and that increase in length.
3. The **zone of cellular maturation** is where older cells complete their differentiation into dermal, vascular, and ground tissues.

The zone of cellular elongation is the region most responsible for the growth of roots through the soil. The cells in this region increase in length by taking up water. Their expansion provides the force that pushes the root cap and apical meristem through the soil. When environmental conditions are good, roots can extend by as much as 4 centimeters per day.

The zone of cellular maturation is the most important root segment in terms of water and nutrient absorption. In this region, epidermal cells produce outgrowths called **root hairs,** which greatly increase the surface area of the dermal tissue.

Root hairs furnish the actual sites of water and nutrient absorption. The rest of the root system provides structural support for the root hairs, conducts water and ions to the shoot, stores the products of photosynthesis, and anchors the plant in the soil. Uptake of water and nutrients by root hairs is vital to plants (portions of Chapters 38 and 39 focus on how these processes occur).

The zone of cellular maturation is also where lateral roots begin to grow. In contrast to lateral branches in the shoot, which arise from meristems in axillary, or lateral buds (see Figure 37.1), lateral roots arise from cells within a ring of cells surrounding the vascular tissue and then erupt through the surrounding ground tissue.

How Is the Primary Shoot System Organized?

If you visit a garden regularly, you can imagine how the growing root tips push through the soil and expand to form complex networks underground. But even a casual observer can watch the growth of shoot systems over time, as the tips of stems extend and branch and as new leaves form and expand.

Just behind each shoot apical meristem, the primary meristematic cells give rise to dermal, ground, and vascular tissues. **FIGURE 37.12a** shows how these tissues are arranged in the stem of a sunflower plant when it matures. Note that the vascular tissues are grouped into **vascular bundles,** which form strands running the length of the stem.

In sunflowers and other eudicots, the vascular bundles are arranged in a ring near the stem's perimeter (see Chapter 31). The ground tissue that the vascular tissue runs through is divided into two major regions: **pith,** the ground tissue that is inside the vascular bundles, and **cortex,** the ground tissue that is outside the vascular bundles.

The arrangement of the vascular bundles and ground tissue is dramatically different in the stems of monocots such as grasses, lilies, and orchids, however. As **FIGURE 37.12b** shows, vascular bundles in monocot stems are normally scattered throughout the ground tissue. (Review other comparisons of monocots and eudicots in Chapter 31.)

Now let's drill down a bit deeper, and look at the composition of the dermal, ground, and vascular tissue systems. Each of these tissue systems is made up of an array of distinct cell and tissue types. What do they look like, and what are their functions?

37.3 Cells and Tissues of the Primary Plant Body

Recall that all eukaryotic cells, including those of plants and animals, share most of their key characteristics: chromosomes enclosed in a nuclear envelope, a plasma membrane studded with proteins that regulate the passage of materials in and out, mitochondria that produce ATP by oxidizing sugars, and an array of other organelles that synthesize or degrade key molecules (see Chapter 7).

In addition, plant cells have several features that are absent in animal cells (**FIGURE 37.13a**):

1. All plant cells are surrounded by a stiff, cellulose-rich **cell wall** that supports the cell and defines its shape.

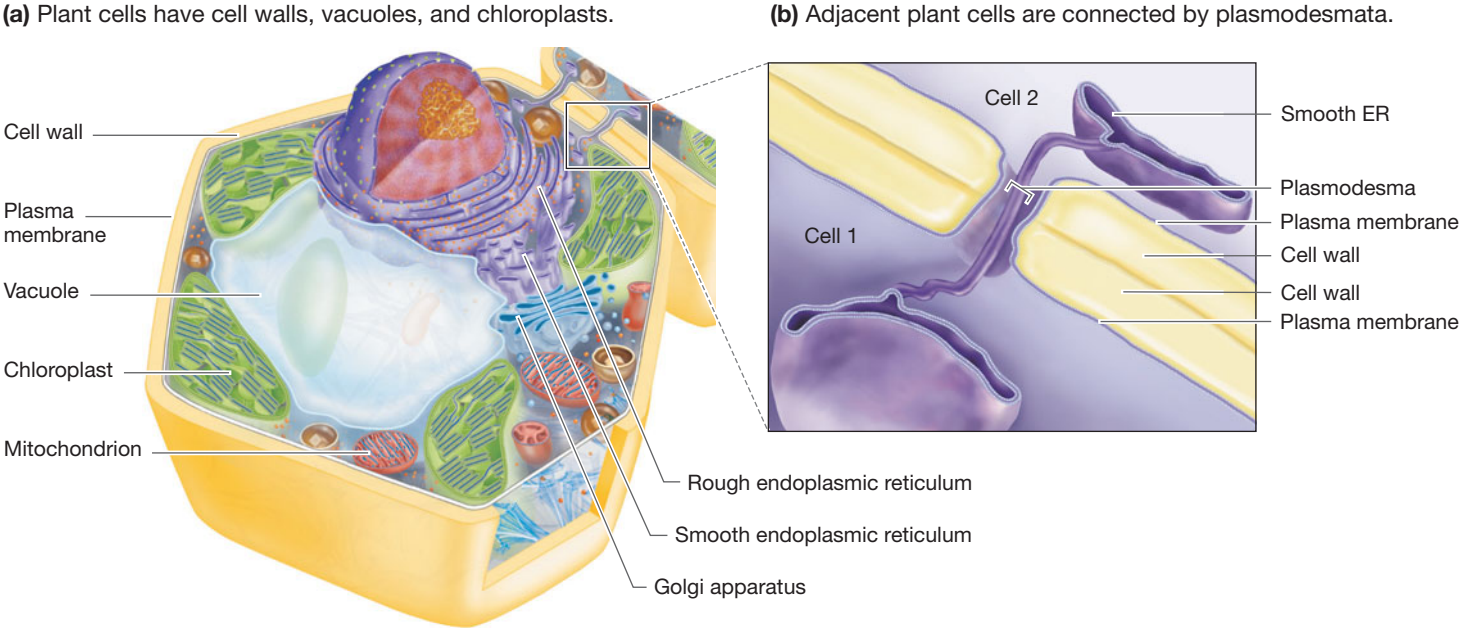

FIGURE 37.13 A Generalized Plant Cell. Plant vacuoles are similar to animal lysosomes; however, the cell wall, chloroplasts, and plasmodesmata are unique to plants. Unlike the extracellular matrix of animals, the plant cell wall is rigid.

2. The cytoplasm of adjacent plant cells is often connected via **plasmodesmata** (singular: **plasmodesma**) (see Chapter 11). Plasmodesmata consist of cytoplasm and segments of smooth endoplasmic reticulum (smooth ER) that run through tiny, membrane-lined gaps in the cell wall (**FIGURE 37.13b**).
3. Plant cells often contain several types of organelles that are not found in animals—specifically chloroplasts and a large, membrane-bound organelle called a vacuole, which fills most of the cell's volume.

Chloroplasts are the site of photosynthesis (see Chapter 10). Non-photosynthetic cells found in roots, seeds, flower petals, and other locations may have organelles that are related to chloroplasts but are specialized for storing pigments, starch, oils, or proteins.

Vacuoles, which contain an aqueous solution called **cell sap,** store wastes and in some cases also digest wastes, as do animal lysosomes. In addition, plant vacuoles store water and nutrients. They may also hold pigments that provide color, or poisons that deter herbivores.

Another important distinction between plant cells and animal cells is that plant cells do not change position once they form. Some animal cells migrate within the body either early in the development of an individual or as mature (differentiated) cells.

Let's examine the cells and tissues of the three primary plant tissue systems in turn.

The Dermal Tissue System

Dermal tissue is the interface between the organism and the external environment. Its primary function in shoots is to protect the plant body—from water loss, disease-causing agents, and herbivores. In roots the dermal tissue includes root hairs, and it functions primarily in water and nutrient absorption.

Most tissues are made up of several different cell types, each with a distinct structure and function. Let's consider the cell types found in dermal tissue.

Epidermal Cells Protect the Surface Most of the cells in the dermal tissue system are epidermal cells, which in shoots are flattened and usually lack chloroplasts.

Epidermal cells in the shoot system fulfill their protective role in part by secreting the **cuticle**—a waxy layer that forms a continuous sheet on the surface (see Chapter 31). Waxes are lipids and are therefore highly hydrophobic. As a result, the presence of cuticle on stems and leaves drastically reduces the amount of water that these structures lose by evaporation.

From a human perspective, the water-repellent properties of cuticle make it a valuable ingredient in polishes and lipsticks. The carnauba wax used in car and floor polishes, for example, is secreted by epidermal cells in the leaves of carnauba palms native to Brazil.

Besides minimizing water loss, cuticle forms a barrier to protect the plant from viruses, bacteria, and the spores or growing hyphae of parasitic fungi. In this way, the plant epidermis forms the first line of defense against disease-causing agents, or **pathogens.**

Waxes found in the cuticle can also be detrimental to the plant, however, by reducing gas exchange. This can be a serious problem because photosynthesis depends on the free flow of carbon dioxide to photosynthetic cells. The problem is solved by specialized structures in dermal tissue, called stomata.

Stomata Regulate Gas Exchange and Water Loss Most land plants have structures called **stomata** (singular: **stoma**) that allow carbon dioxide to enter photosynthetically active tissues.

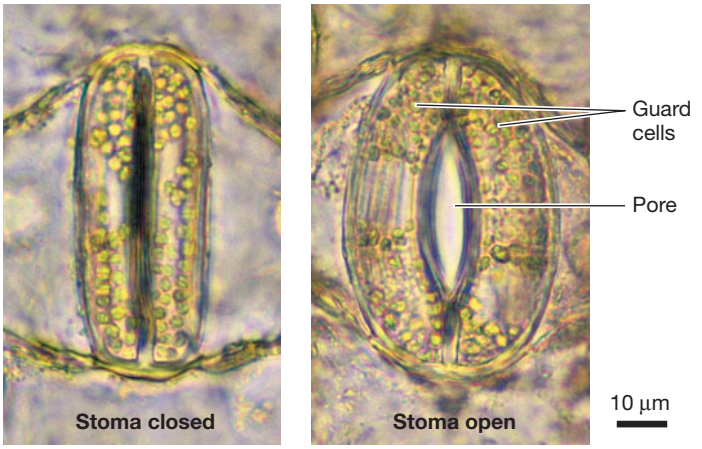

FIGURE 37.14 A Stoma's Guard Cells Regulate the Opening of a Pore.

FIGURE 37.15 Epidermal Cells Produce Trichomes That Provide Protection. Some trichomes on this leaf are hairlike extensions of a single cell, while others are multicellular structures. (The structures that are colored orange here hold toxins.)

A stoma consists of two specialized **guard cells,** which change shape to open or close an opening in the epidermis known as a **pore** (**FIGURE 37.14**).

When stomata are open, CO_2, O_2, water vapor, and other gases can move between the atmosphere and the interior of the plant by diffusion. Stomata open when CO_2 is needed inside the leaf. When stomata are open, water vapor diffuses from the moist interior of the leaf to the atmosphere. Stomata close when CO_2 is not needed. This prevents large amounts of water from being lost by transpiration. In a later chapter, we explore the molecular mechanisms responsible for stomatal opening and closing (see Chapter 40).

Trichomes Perform an Array of Functions In addition to minimizing water loss and regulating gas exchange in shoots, cells in dermal tissue may protect the individual from the damaging effects of intense sunlight and attacks by herbivores.

Trichomes are hairlike appendages made up of specialized epidermal cells. They are found in shoot systems and come in a wide variety of shapes, sizes, and abundances.

Depending on the species, trichomes may **(1)** keep the leaf surface cool by reflecting sunlight; **(2)** reduce water loss by forming a dense mat that limits transpiration; **(3)** provide barbs, or store toxic compounds that thwart herbivores (**FIGURE 37.15**); or **(4)** trap and digest insects.

The Ground Tissue System

Most photosynthesis, as well as most carbohydrate storage, takes place in ground tissue. Cells in ground tissue are also responsible for most of the synthesis and storage of specialized products such as colorful pigments, the chemical signals called hormones, and toxins required for defense.

If the primary function of the dermal tissue system is protection, the ground tissue is all about producing and storing valuable molecules.

Ground tissue is made up of three distinct tissue types: parenchyma (pronounced *pa-REN-ki-ma*), collenchyma (*ko-LEN-ki-ma*), and sclerenchyma (*skle-REN-ki-ma*).

Parenchyma Are "Workhorse" Cells **Parenchyma cells** have relatively thin cell walls and are the most abundant and versatile plant cells. Groups of parenchyma cells form parenchyma tissue.

The parenchyma tissue in leaves consists of parenchyma cells filled with chloroplasts, and it is the primary site of photosynthesis (**FIGURE 37.16a**). But in other organs, parenchyma cells store starch granules (**FIGURE 37.16b**). When you eat a potato or an apple, you are ingesting primarily parenchyma cells in ground tissue.

Many parenchyma cells are **totipotent**, meaning they retain the capacity to divide and develop into a complete, mature plant. The totipotency of parenchyma cells is important in healing wounds and in reproducing asexually via stolons or rhizomes. In each case, parenchyma cells may begin to divide, grow, and differentiate to form new roots and shoots.

The totipotency of parenchyma cells also allows gardeners to clone plants by making cuttings. For example, if you cut a piece of stem from a coleus plant and place it in water, parenchyma cells will divide to produce a mass of undifferentiated cells called a **callus.** Roots then develop from the callus (**FIGURE 37.17**), and the new individual can be planted in soil.

Bananas, seedless grapes, and several other commercially important plants cannot undergo sexual reproduction to produce seeds. Instead, they are propagated entirely by cuttings.

Collenchyma Cells Function Primarily in Shoot Support **Collenchyma cells** have cell walls that are thicker in some areas than others, and their overall shape is longer and thinner than that of parenchyma cells. Groups of collenchyma cells form collenchyma tissue that supports the plant body.

Even when collenchyma cells are mature, their cell walls retain the ability to stretch and elongate. As a result, collenchyma cells can continue to lengthen as they provide structural support to the growing regions of shoots.

Collenchyma tissue is often found just under the epidermis of stems, especially outside vascular bundles. The ability of collenchyma cells to stretch allows stems to flex in the wind without tearing or breaking. The "strings" you may have peeled from a

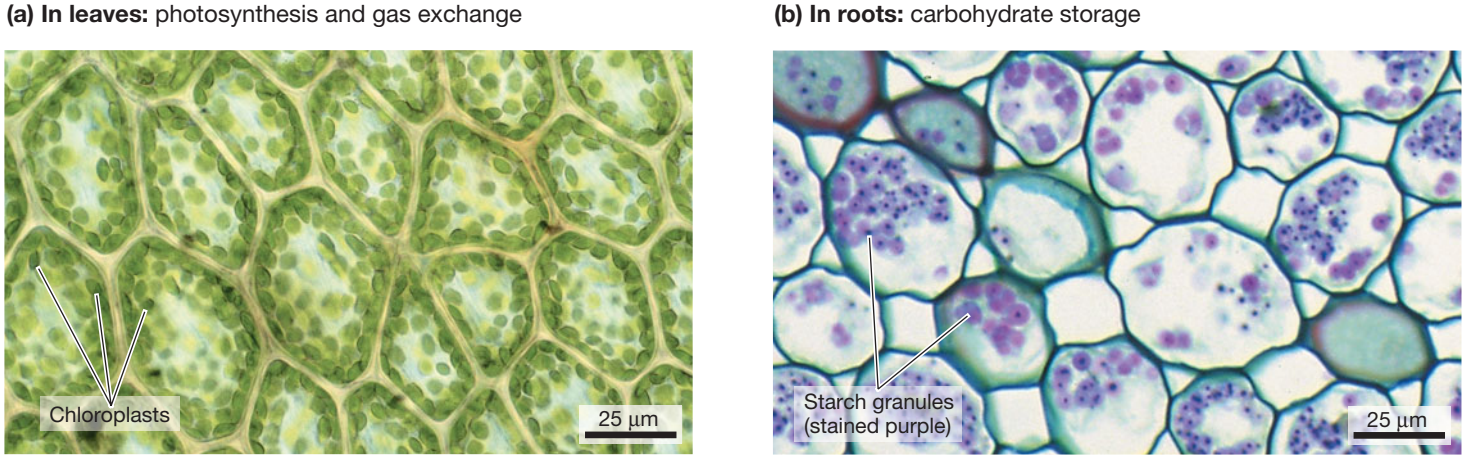

FIGURE 37.16 Parenchyma Cells Perform a Wide Array of Tasks.

✔**EXERCISE** Give an example of a gene that is likely to be expressed in these leaf cells, but not in the root cells.

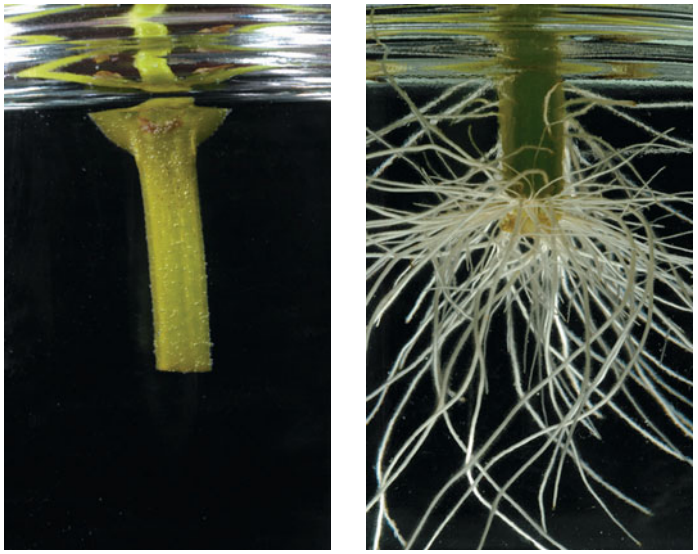

FIGURE 37.17 Parenchyma Cells in Cut Stems Can Form Adventitious Roots. Parenchyma cells in a cut coleus stem (left) divide to form a mass of undifferentiated cells called a callus, which then sprouts roots (right).

stalk of celery or rhubarb—which is actually the petiole of a celery or rhubarb leaf—include many strands of collenchyma cells (**FIGURE 37.18**).

Sclerenchyma: Two Types of Specialized Support Cells The cells that are classified as **sclerenchyma** produce a thick **secondary cell wall** in addition to the relatively thin **primary cell wall** found in all cells. Unlike a primary cell wall, the secondary cell wall contains the tough, rigid compound **lignin** in addition to **cellulose** (see Chapter 31).

Collenchyma cells can support actively growing parts of the plant because they have an expandable primary cell wall. In contrast, the nonexpandable secondary cell wall of sclerenchyma cells specializes them for supporting stems and other structures after growth has ceased. Another key difference between collenchyma and sclerenchyma is that sclerenchyma cells are usually dead at maturity—meaning they contain no cytoplasm.

Ground tissue typically contains two types of sclerenchyma cells: fibers and sclereids.

- **Fibers** are extremely elongated. The fiber cells from ramie plants, a species of Asian nettle, can be over half a meter long.

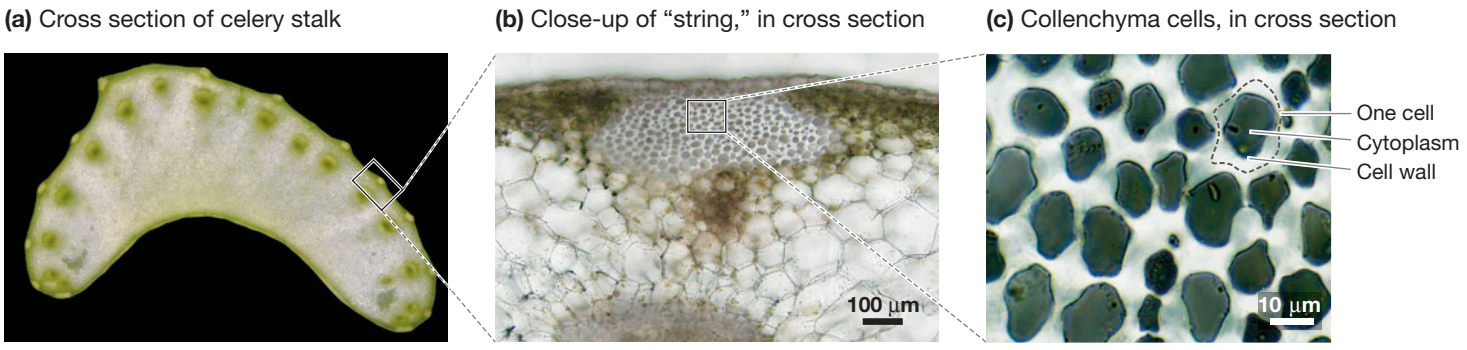

FIGURE 37.18 Collenchyma Cells Support Growing Tissues. A celery stalk is actually a petiole; the strands you can peel from it are columns of collenchyma cells.

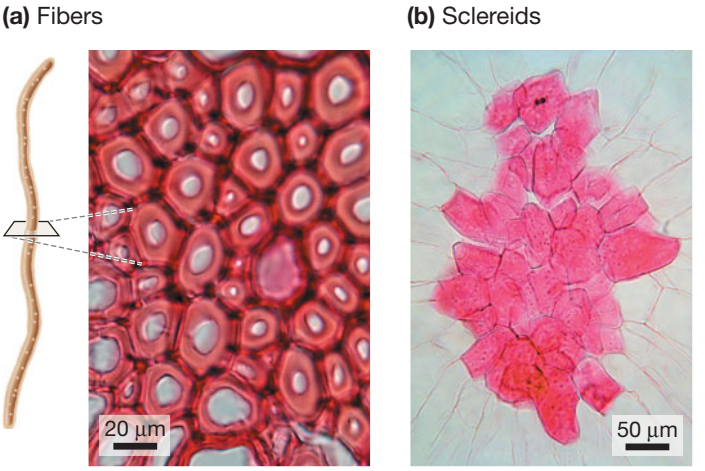

FIGURE 37.19 Sclerenchyma Cells Support Mature Tissues. **(a)** Fibers and **(b)** sclereids (stained pink) have thickened secondary cell walls. These cells provide support or protection for tissues that are no longer growing.

Fiber cells are important in the manufacture of paper, hemp or jute ropes, or linen and other fabrics (**FIGURE 37.19a**).

- **Sclereids** are relatively short, have variable shapes, and often function in protection. The tough coats of seeds and the thick shells of nuts are composed of sclereids; these cells are also responsible for the gritty texture of pears (**FIGURE 37.19b**).

The Vascular Tissue System

The vascular tissue system functions in support and in long-distance transport of water and dissolved nutrients. It also moves the products of photosynthesis that are made and stored in ground tissue.

Plant tissues that consist of a single cell type are called simple tissues; tissues that contain several types of cells are termed complex tissues. The vascular tissue system is made up of two complex tissues, xylem and phloem.

- **Xylem** (pronounced *ZYE-lem*) conducts water and dissolved ions in one direction: from the root system to the shoot system.
- **Phloem** (*FLO-em*) conducts sugar, amino acids, chemical signals, and other substances in two directions: from roots to shoots and from shoots to roots.

Xylem Structure Two important cell types in xylem tissue are tracheids and vessel elements.

- In all vascular plants, xylem contains water-conducting cells called **tracheids** (*TRAY-kee-ids*).
- In angiosperms and species in the group Gnetophyta, xylem also contains conducting cells called **vessel elements** (see Chapter 31).

Tracheids and vessel elements have thick, lignin-containing secondary cell walls that are often deposited in ringlike or spiral patterns. Both tracheids and vessel elements are dead at maturity. As a result, they have no membranes and are filled with the fluids that they conduct instead of with cytoplasm.

Tracheids are long, slender cells with tapered ends (**FIGURE 37.20a**). The sides and ends of tracheids have **pits,** which are gaps in the secondary cell wall where only the primary cell wall is present. Because the cell is dead, pits have no plasma membrane spanning the opening. When water is moving up a plant through tracheids, it moves from cell to cell both vertically and laterally through pits, because that is where resistance to flow is lowest.

Vessel elements, in contrast, are shorter and wider than tracheids (**FIGURE 37.20b**). In addition to having pits, vessel elements have **perforations**—openings that lack both primary and secondary cell walls. In some species, the ends of vessel elements

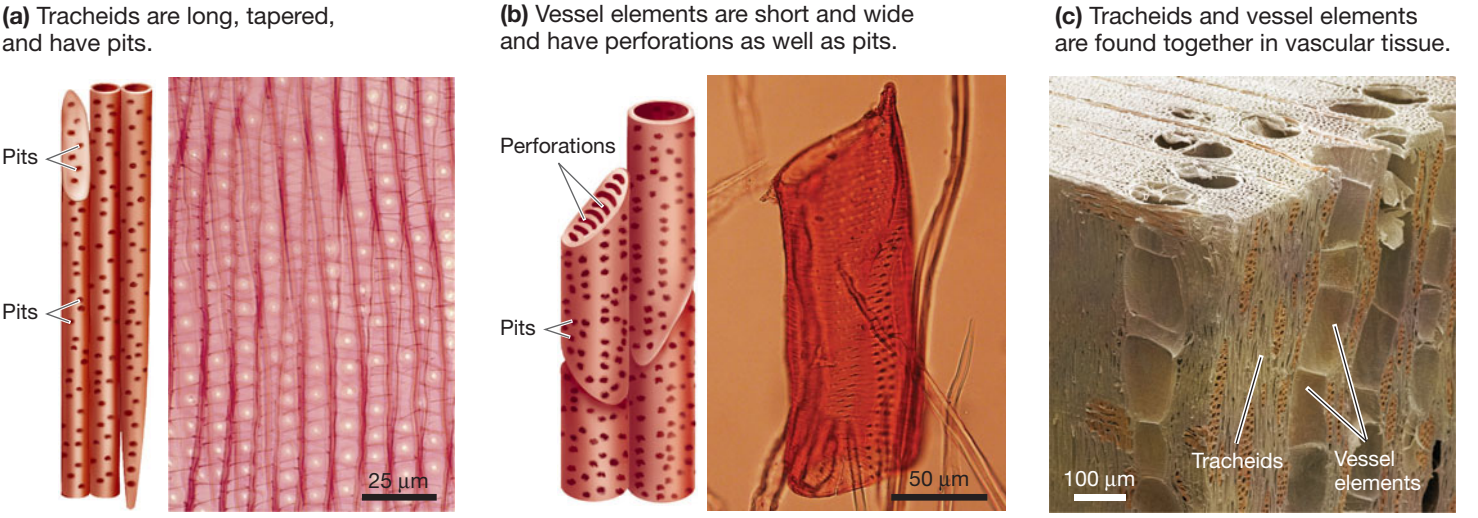

FIGURE 37.20 Xylem May Contain Two Types of Water-Conducting Cells. **(a)** Tracheids are long and thin compared to **(b)** vessel elements, which are much shorter and wider. **(c)** Both types of water-conducting cells are found in the vascular tissue of angiosperms. The image in (a) is a light micrograph of stained tissue; the images in (b) and (c) are colorized scanning electron micrographs.

lack any cell wall at all, and stacked cells form open pipes called vessels. Vessel elements conduct water more efficiently than do tracheids, because their width and perforations offer less resistance to flow.

In angiosperms, tracheids and vessel elements are found adjacent to each other (**FIGURE 37.20c**). Xylem also contains sclerenchyma cells (fibers) and some parenchyma cells that transport materials laterally in the stem—not vertically.

Phloem Structure In most vascular plants, phloem is made up primarily of two specialized types of parenchyma cells: sieve-tube elements and companion cells. Both are alive at maturity, lack lignified secondary cell walls, and arise from division of a common precursor cell.

- **Sieve-tube elements** are long, thin cells that have perforated ends called **sieve plates** (**FIGURE 37.21**). They are responsible for transporting sugars and other nutrients.
- **Companion cells** are not conducting cells, but instead provide materials to maintain the cytoplasm and plasma membrane of sieve-tube elements.

Interestingly, sieve-tube elements lack nuclei and most other organelles, but they are directly connected to adjacent companion cells by means of numerous plasmodesmata (see Figure 37.13b). Companion cells contain most of the organelles normally found in a plant cell and support the function of sieve cells.

Companion cells are also involved in loading and unloading carbohydrates and other nutrients into and out of sieve-tube elements (see Chapter 38 for more detail). Phloem also contains sclerenchyma tissue (fibers and sclereids), which provides mechanical support.

TABLE 37.4 (page 748) summarizes the major tissues and cell types found in the dermal, ground, and vascular tissue systems. Once you've mastered the structure and function of the primary plant body, you're ready to consider the next level of complexity: secondary growth.

check your understanding

C Y U

If you understand that . . .

- Primary growth results from cell division in apical meristems. Its function is to extend the shoot system into the air and the root system into the soil.
- Apical meristems produce three types of primary meristematic cells: protoderm, ground meristem, and procambium. The dermal, ground, and vascular tissue systems that arise from these meristematic cells extend throughout the individual and make up the primary plant body.
- The dermal system protects the individual and controls the exchange of gases and nutrients with the environment; the ground system produces and stores the carbohydrates that make life possible; the vascular system moves those molecules from place to place and holds the plant up. Each of these systems consists of an array of distinctive cell and tissue types.

✓ You should be able to . . .

1. Explain the relationship between an apical meristem and the three primary meristematic tissues.
2. Describe the structure and function of epidermal cells, parenchyma cells, tracheids, and sieve-tube elements.

Answers are available in Appendix A.

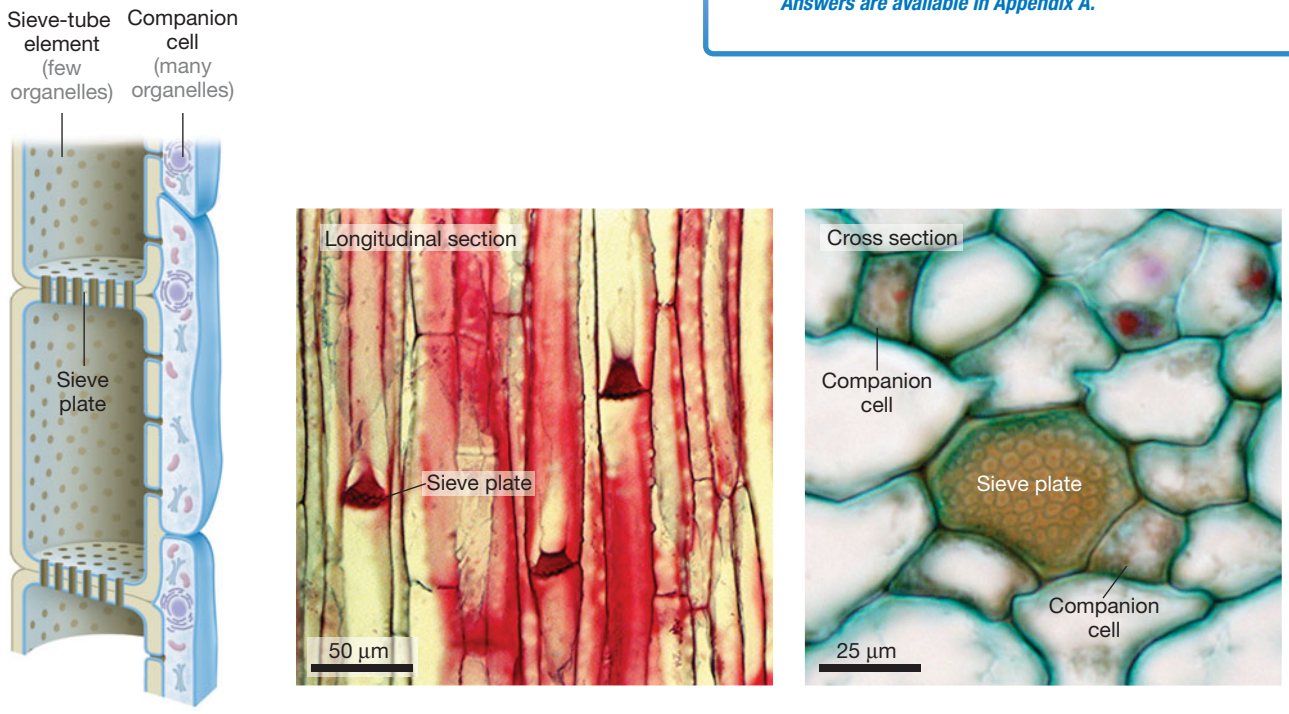

FIGURE 37.21 Phloem Consists of Sieve-Tube Elements and Companion Cells. Sieve-tube elements conduct sucrose throughout the body; companion cells support sieve-tube elements.

SUMMARY TABLE 37.4 Components of the Primary Plant Body

Tissues Present	Description of Tissue	Function
Dermal Tissue System (arises from protoderm)		
Epidermal	Complex tissue consisting of epidermal cells, guard cells, trichome cells, and root hair cells	Shoots: Protection, gas exchange Roots: Protection, water and nutrient absorption
Ground Tissue System (arises from ground meristem)		
Parenchyma	Simple tissue consisting of parenchyma cells	Synthesis and storage of sugars and other compounds
Collenchyma	Simple tissue consisting of collenchyma cells	Support (flexible cell walls)
Sclerenchyma	Simple tissues consisting of sclerenchyma cells: sclereids or fibers	Support and protection (rigid cell walls; dead at maturity)
Vascular Tissue System (arises from procambium)		
Xylem	Complex tissue consisting of tracheids, vessels, and parenchyma cells and sclerenchyma cells (fibers)	Transport of water and ions; structural support (tracheids, vessels and fibers are dead at maturity)
Phloem	Complex tissue consisting of parenchyma cells (sieve-tube elements, companion cells) and sclerenchyma cells (fibers)	Transport of sugars, amino acids, hormones, etc.; support (fibers are dead at maturity)

37.4 Secondary Growth Widens Shoots and Roots

Primary growth increases the length of roots and shoots; its major function is to extend the reach of the root and shoot system and thus increase a plant's ability to absorb photons and acquire carbon dioxide, water, and ions.

In some plants, **secondary growth** increases the width of the plant body. Its major function is to increase the amount of conducting tissue available and provide the structural support required for extensive primary growth. Recall that the evolution of conducting tissues allowed the vascular plants to grow taller to compete for light (see Chapter 31). Without the support provided by secondary growth, however, roots would not be massive enough to anchor large shoot systems, and long stems would fall over or break. Only with secondary growth could vascular plants become the giants seen today.

What Is a Cambium?

Secondary growth produces **wood** and occurs in species that have a cambium in addition to apical meristems. A **cambium** (plural: cambia) is a special type of meristem (also called a lateral meristem) that differs from an apical meristem in two ways:

1. A cambium forms a cylinder that runs the length of a root or stem and is made up of a single layer of meristematic cells. In contrast, apical meristems are localized at root tips and shoot tips and are dome shaped.
2. In a cambium, cells divide in a way that increases the width of roots and shoots (**FIGURE 37.22a**). Cells in an apical meristem divide in a way that extends the root and shoot tips.

As **FIGURE 37.22b** shows, there are two distinct types of cambium in plants that undergo secondary growth.

- A cylinder of meristematic cells called the **vascular cambium** is located between the secondary xylem and secondary phloem, inside the stem and root.
- Another cylinder of meristematic cells called the **cork cambium** is located near the perimeter of the stem and root.

One other observation is critical to understanding how cambia work: The cork cambium produces new cells primarily to the outside. Vascular cambium, in contrast, generates new layers of cells both to the inside and outside. The new cells formed to the inside push all of the other cells toward the outside, causing an increase in girth.

TABLE 37.5 summarizes the major mature tissue types and cell types that arise from each type of meristem. Now let's consider how these meristems work.

What Does Vascular Cambium Produce?

Vascular cambium in roots and stems produces both phloem and xylem (see Figure 37.22b). New cells that are produced to the outside of the vascular cambium differentiate into secondary phloem; new cells produced to the inside differentiate into secondary xylem. (In contrast, the procambium at each apical meristem produces *primary* phloem and *primary* xylem.)

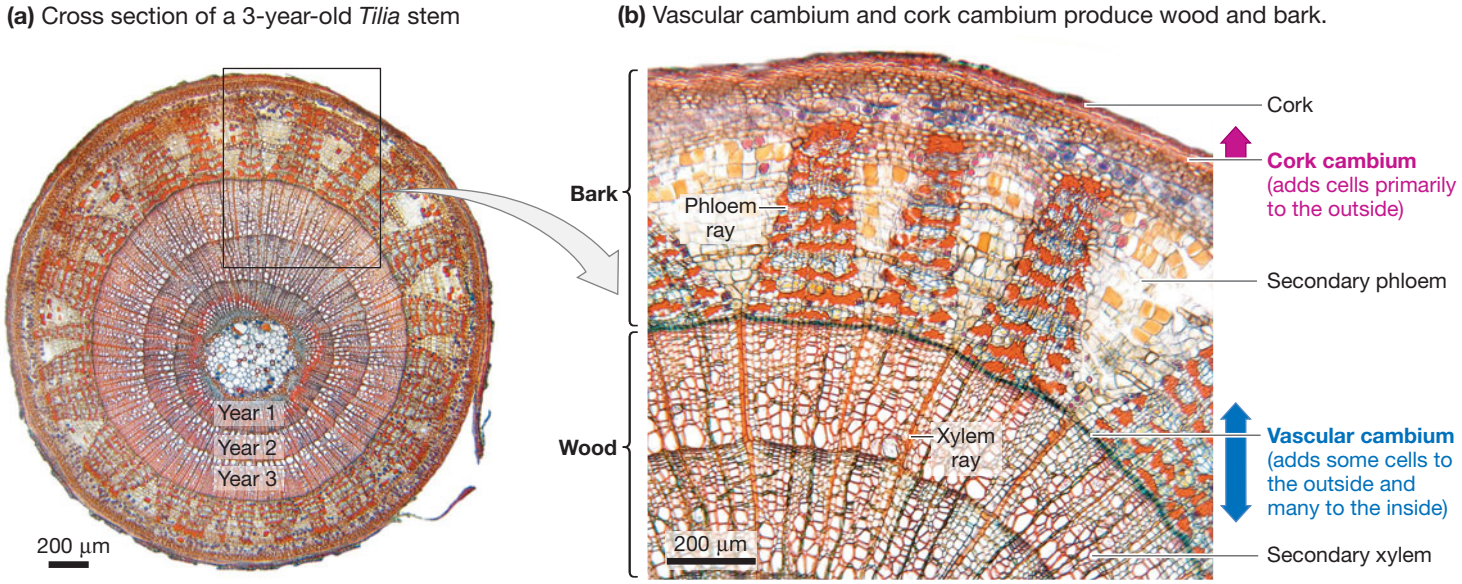

FIGURE 37.22 Vascular Cambium Is Responsible for Secondary Growth. Tree trunks contain two types of cylindrical cambia: cork cambium and vascular cambium. Bark consists primarily of the cork cells produced by the cork cambium and secondary phloem. Wood consists of secondary xylem and parenchyma cells produced by vascular cambium.

Secondary phloem and secondary xylem cells are not always produced simultaneously. In most cases, the vascular cambium produces many more secondary xylem cells than secondary phloem cells.

Primary phloem and xylem are produced by all vascular plants, but secondary phloem and xylem are found only in some lycophytes, all gymnosperms, and certain angiosperms.

Structurally, primary and secondary phloem and primary and secondary xylem are complex tissues, made up of more than one cell type. Functionally, primary and secondary phloem are similar, as are primary and secondary xylem.

- Primary and secondary phloem function in sugar transport.
- Primary and secondary xylem function in water transport and structural support.

Secondary xylem makes up the structural material called wood, while secondary phloem makes up the inner part of a tree's bark, which we describe later.

Besides producing conducting cells such as sieve-tube elements, tracheids, and vessel elements, the vascular cambium also produces sclerenchyma cells (fibers) for additional strength, along with some parenchyma cells. The parenchyma cells are formed in rows that radiate laterally across the xylem and phloem. These rows of cells are called **rays** (see Figure 37.22b), and they form a living conduit through which water and nutrients are transported laterally across the stem.

It's important to realize, though, that the results of cell division in vascular cambium are highly asymmetrical. As the

SUMMARY TABLE 37.5 Components of Secondary Growth

Meristematic Tissue	Mature Tissue	Direction of Growth	Mature Cell Composition	Mature Tissue Function
Cork Cambium	**Cork**	Produced to the outside	Cork cells	Protection
Vascular Cambium	**Secondary phloem**	Produced to the outside	Parenchyma cells (sieve-tube elements, companion cells) and sclerenchyma cells (fibers)	Transport of sugars, amino acids, hormones, etc.
	Secondary xylem*	Produced to the inside	Tracheids, vessels, parenchyma cells (arranged in rays) and sclerenchyma cells (fibers)	Transport of water and ions; structural support

*Secondary xylem is also called wood.

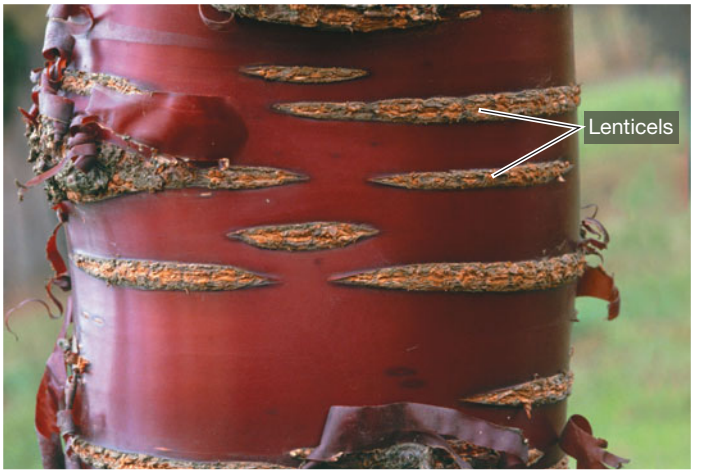

FIGURE 37.23 Lenticels in the Bark of Paperbark Cherry (*Prunus serrula*). Lenticels are natural breaks in cork tissue through which oxygen can enter a stem.

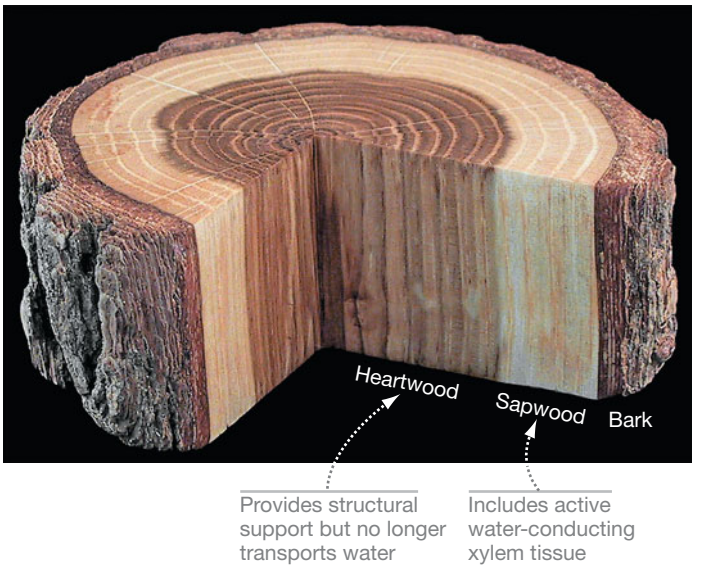
vascular cambium grows, all of the secondary xylem is retained and accumulates, but the primary xylem in the center of the stem eventually clogs and may rot away. In addition, the outermost secondary phloem becomes fragmented and compressed as the stem increases in diameter. As a result, mature woody roots and stems are dominated by secondary xylem, or wood.

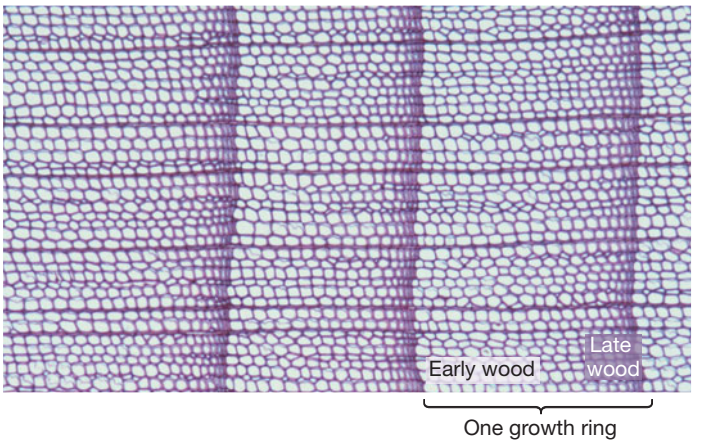
✔ **If you understand this concept, you should be able to explain why a nail hammered into a tree at eye level doesn't move up as the tree grows.**

What Does Cork Cambium Produce?



The cork cambium's primary role is to produce **cork cells** to the outside (Figure 37.22b). Together with the secondary phloem, the cork cambium and cork cells make up the tissue called **bark.**

Bark provides a particularly tough barrier in species whose cork cells secrete a strong secondary cell wall containing lignin. Bark also helps prevent water loss because cork cells produce a layer of wax and other molecules inside their cell walls, making them impermeable to water and gases. Gas exchange can still occur between the atmosphere and living tissues inside the stem, though—through small, spongy openings in the bark called **lenticels** (**FIGURE 37.23**).



Cork cells die when they mature. As a stem continues to widen, the cork layer often cracks and flakes, and the outer layers might even slough off the tree.

Bark is important because it protects the woody stem from damage and pathogens as it increases in girth. As a woody stem or root matures, the epidermal tissue produced by the apical meristem during primary growth is replaced by the bark, which takes over the role of preventing water loss and protecting the stem and root from pathogens and herbivores. In some species, exceptionally thick bark can even protect the shoot system from fire damage. Redwood trees, for example, are adapted to fire-prone habitats and can have bark that is 20 cm (12 in.) thick.

(a) Heartwood and sapwood have different functions.

(b) Growth rings result from seasonal variation in cell size.

(c) Patterns in growth rings can tell a tree's history.

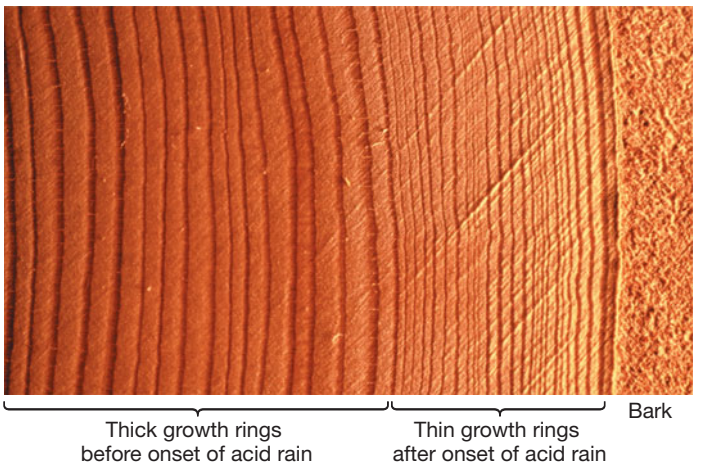


FIGURE 37.24 Anatomy of a Tree Trunk. (a) Unstained section of wood. **(b)** Section of wood, stained to show individual cells. **(c)** Unstained section through a fir tree from Germany's Black Forest.

✔**EXERCISE** In part (c), pick a thick growth ring and label the early wood and late wood.

The Structure of a Tree Trunk

Trees are perennial plants that live for many years. As a tree matures and grows in width, the innermost xylem layers stop transporting water—only the xylem from the most recent years actually transports fluid.

Heartwood and Sapwood Xylem that no longer transports begins accumulating protective compounds secreted by other tissues. These compounds form resins, gums, and other complex mixtures. The deposition of these molecules causes the oldest portions of secondary xylem to become darker than the younger portions.

The darker-colored, inner xylem region is called **heart-wood,** while the lighter-colored, outer xylem is called **sapwood** (**FIGURE 37.24a**). If you look closely at wood furniture or flooring, you may see a color difference between sapwood and heartwood in some boards.

Annual Growth Rings Another important phenomenon occurs in environments where the vascular cambium stops growing for a portion of each year. This period of **dormancy** occurs during the winter in cold climates and during the dry season in tropical habitats.

When the vascular cambium resumes growth in the spring or at the start of the rainy season, it produces large, relatively thin-walled cells, called early wood. As the growing season nears its end, conditions tend to dry out or become cooler; the secondary xylem cells that are produced at this time tend to be smaller, thicker walled, and darker and are called late wood. Thus, when growth is seasonal, regions of large, thin-walled cells alternate with layers of small, thick-walled cells, resulting in annual growth rings in the secondary xylem (**FIGURE 37.24b**).

Analyzing patterns in tree growth rings is an important field of study in biology. Because trees grow faster when moisture and nutrients are plentiful, wide tree rings are reliable indicators of wet years. In contrast, narrow rings signal drought years—or in the case of the fir tree shown in **FIGURE 37.24c**, years when abundant acid rain, due to air pollution, reduced growth.

By studying the growth rings in fossil trees and extremely old living trees, biologists can often assemble a continuous record that dates back thousands of years. In doing so, they gain a better understanding of climate changes that occurred in the past. With continued research, researchers also hope to predict how forests might respond to the rising temperatures associated with the global climate change that is currently under way.

check your understanding

C Y U

If you understand that . . .

- Secondary growth occurs in species with a vascular cambium and cork cambium and results in a broadening of the shoot and root systems.
- Vascular cambium gives rise to secondary xylem and secondary phloem tissues. Cork cambium gives rise to the protective tissue called bark.

✔ You should be able to . . .

1. Describe what the rings in a cross section of a tree trunk would look like if the individual is heavily shaded on one side but exposed to sunlight on the other side.
2. Draw from memory a three-year-old woody stem in cross section, labeling secondary xylem and phloem, vascular and cork cambium, and cork. Add arrows showing the direction of growth in each meristem.

Answers are available in Appendix A.

CHAPTER 37 REVIEW

If you understand . . .

37.1 Plant Form: Themes with Many Variations

- The root and shoot systems of plants are specialized for harvesting the light, water, and nutrients required for performing photosynthesis. Structures involved in absorption have a high surface-area-to-volume ratio.
- Roots extract water and nutrients such as nitrogen, phosphorus, and potassium from the soil.
- The shoot system consists of all aboveground portions of the plant, including stems and leaves.
- Leaves carry out photosynthesis by capturing light and carbon dioxide from the atmosphere and usually consist of a flattened blade that extends from a petiole.
- The overall morphology of root and shoot systems varies widely among plant species, allowing individuals to reduce competition for resources.
- Roots and shoots may be modified to perform a variety of other functions, however, including nutrient storage, water storage, protection, and asexual reproduction.
- Because roots and shoots grow throughout life, a plant is able to respond appropriately to changes in environmental conditions.

✔ You should be able to explain why phenotypic plasticity in roots and shoots is expected to be more important (1) in environments where conditions are variable versus stable, and (2) in long-lived versus short-lived species.

37.2 Primary Growth Extends the Plant Body

- Each apical meristem gives rise to three primary meristematic tissues: protoderm, ground meristem, and procambium.
- The primary meristematic tissues give rise to the dermal, ground, and vascular tissue systems, which extend throughout the plant body.
- Behind the root apical meristem, or the zone of cellular division, cells become longer in the zone of cellular elongation and acquire specialized functions in the zone of cellular maturation.

✔ **You should be able to explain why most of the water and nutrient absorption by roots takes place in the zone of cellular maturation.**

37.3 Cells and Tissues of the Primary Plant Body

- The dermal tissue system is usually one cell layer thick and plays a role in protection and water absorption by roots. In shoots the epidermis synthesizes the cuticle, which aids in water conservation.
- Stomata are formed by pairs of epidermal guard cells that open and close to control CO_2 uptake and water loss by leaves.
- The ground tissue system performs photosynthesis and stores carbohydrates and other compounds.
- The vascular tissue system transports materials throughout the plant. Within the vascular system, xylem tissue transports water and dissolved ions up the plant; phloem tissue transports sugars up and down.
- Ground tissue contains (**1**) parenchyma cells, which function in material synthesis, transport and storage; (**2**) collenchyma cells, which provide structural support for growing regions; and (**3**) sclerenchyma cells, fibers and sclereid cells, that strengthen regions of the body that have stopped growing.

✔ **You should be able to predict the results of an experiment where a drug was used to (1) poison an apical meristem in the shoot and an apical meristem in the root, and (2) selectively poison protoderm cells in a shoot apical meristem.**

37.4 Secondary Growth Widens Shoots and Roots

- In some plant species, shoots and roots are widened by cylindrical meristems called vascular cambium that produce secondary xylem and secondary phloem, and cork cambium that produces cork.
- Cork cells produce waxes that protect stems from water loss.
- Wood consists of secondary xylem, while bark consists of all tissue outside of the vascular cambium.

✔ **You should be able to predict the results of an experiment where a drug was used to (1) slow the growth of the vascular cambium but not the cork cambium, and (2) slow the growth of both the vascular and cork cambia on one side of a tree trunk.**

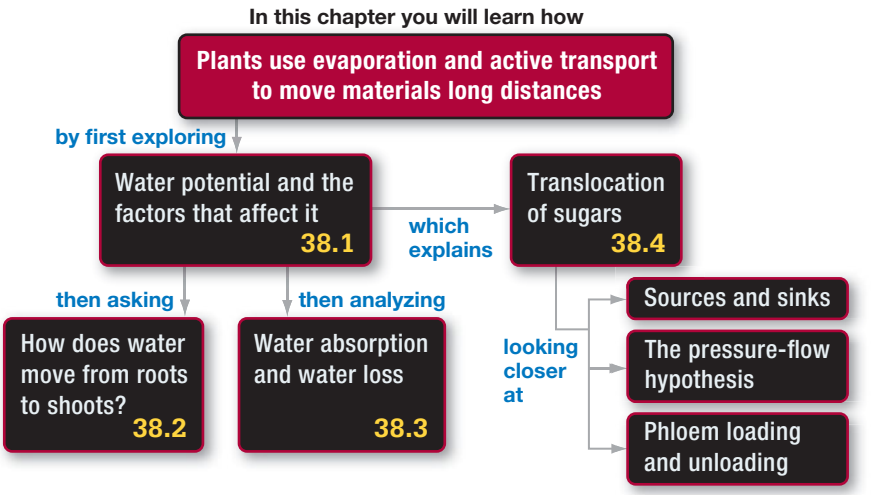
✔ TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. Which of the following functions is not performed by parenchyma cells?
   a. synthesizing key molecules
   b. providing mechanical support
   c. performing photosynthesis
   d. storing nutrients
2. What is a sieve-tube element?
   a. the sugar-conducting cell found in phloem
   b. the widened, perforation-containing, water-conducting cell found only in angiosperms
   c. the nutrient- and water-absorbing cell found in root hairs
   d. the nucleated and organelle-rich support cell found in phloem
3. Which statement best characterizes primary growth?
   a. It does not occur in roots, only in shoots.
   b. It leads to the development of cork.
   c. It produces the dermal, ground, and vascular tissues.
   d. It produces rings of xylem and phloem tissue as well as rings of cork tissue.
4. Which statement best characterizes secondary growth?
   a. It results from divisions of the vascular and cork cambium cells.
   b. It increases the length of the plant stem.
   c. It results from divisions in the apical meristem cells.
   d. It often produces phloem cells to the inside and xylem cells to the outside of the vascular cambium.
5. To illustrate the concept that a plant structure can be modified for many different functions, give an example of a leaf and a stem that protect individuals against large herbivores.
6. Compare and contrast the structure and function of collenchyma and sclerenchyma cells.

TEST YOUR UNDERSTANDING

Answers are available in Appendix A



7. How do tracheids differ from vessel elements, in addition to their overall shape?
   a. Tracheids are stacked end to end to form continuous, open columns.
   b. In tracheids, water flows from cell to cell primarily through gaps in the secondary cell wall called pits.
   c. Tracheids are dead at maturity.
   d. Tracheids have secondary cell walls reinforced with lignin.
8. Describe the general function of the shoot system and the general function of the root system. Which tissues are continuous throughout these two systems? Suggest a hypothesis to explain why the shoot and root systems of different species are so variable in size and shape.
9. Explain why continuous growth enhances the phenomenon known as phenotypic plasticity.
10. What does cuticle do? What do stomata do? Predict how the thickness of cuticle and the number of stomata differ in plants from wet habitats versus dry habitats.
11. Compare and contrast the roles of parenchyma cells in the ground tissue system versus the vascular tissue system.
12. Describe how the vascular cambium produces secondary xylem and secondary phloem.

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A

13. Which one of the following tissues is most likely to be the source of nutrition for insects that kill trees?
   a. primary xylem
   b. secondary xylem
   c. vascular cambium
   d. cork
14. Identify the structure you are consuming when you eat each of the following vegetables: asparagus, Brussels sprouts, celery, spinach, carrot, potato.
15. Why do mahogany trees, and other trees that grow in tropical rain forests, lack growth rings?
16. Trees can be killed by girdling—meaning the removal of bark and vascular cambium in a ring all the way around the tree. Explain why.

38 Water and Sugar Transport in Plants

This chapter explores how plants move water from their roots to their leaves and how they transport sugars to all of their tissues—sometimes over great distances.

On a hot summer day, a large deciduous tree can lose enough water to fill three 55-gallon drums. To understand why, recall that the surfaces of leaves are dotted with stomata (see Chapter 37), which in most plants open during the day so gas exchange can occur between the atmosphere and the cells inside the leaf. This exchange is crucial. For photosynthesis to take place, leaf cells must acquire carbon dioxide (CO_2).

There's a catch, however. While stomata are open, the moist interior of the leaf is exposed to the dry atmosphere. As a result, large quantities of water evaporate from the leaf. If the lost water is not replaced with water absorbed by roots, plant cells will dry out and die.

Evaporation from leaves is a challenge for plants, but it is also beneficial. Because water enters a plant through its roots and exits through its leaves, there is a regular flow of water from roots to shoots. Minerals that are absorbed by roots are carried to the leaves by this flow. Without this

BIG PICTURE

This chapter is part of the Big Picture. See how on pages 840–841.

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

movement of water, shoots would be unable to receive the minerals they need to grow.

In addition, under hot conditions, evaporation cools the plant, just like sweating cools your body. Heavy rates of evaporation can lower leaf temperatures by as much as 10−15°C.

But the source of water can be a long distance from where it is needed. In the case of certain redwood trees, the leaves that lose water may be 100 meters (m) from the root hairs that absorb water. How do plants transport water against the force of gravity—in some cases, the length of a football field? And how do plants move the sugar they produce from active photosynthetic sites to sites where sugar is stored or needed for growth? These questions are the heart and soul of this chapter. Answering them is a fundamental part of understanding how plants work. (You can review plant form and function in the Big Picture of Plant and Animal Form and Function, on pages 840–841.)

38.1 Water Potential and Water Movement

Loss of water via evaporation from the aerial parts of a plant is called **transpiration.** Transpiration occurs whenever two conditions are met: **(1)** Stomata are open, and **(2)** the air surrounding leaves is drier than the air inside leaves.

The first condition is usually met during the day, when photosynthesis takes place. The second condition occurs whenever atmospheric humidity is less than 100 percent.

One of the most astonishing observations in biology is that water moves from roots to leaves passively—that is, with no expenditure of ATP. Plants do not need a heart muscle to pump water from roots to shoots. Even in 100-m-tall redwood trees, water flows passively from the root system to the shoot system. This movement occurs because of differences in the potential energy of water.

What Is Water Potential?

Recall that potential energy is stored energy (see Chapter 2). Changes in potential energy are associated with changes in position, such as the position of a molecule or an electron.

Biologists use the term **water potential** to indicate the potential energy that water has in a particular environment compared with the potential energy of pure water at room temperature and atmospheric pressure. Under these conditions, pure water has a water potential of 0.

Water potential is symbolized by the Greek letter ψ (psi, pronounced sigh). Differences in water potential determine the direction that water moves. Water always flows from areas of higher water potential to areas of lower water potential. Several factors can contribute to differences in water potential.

What Factors Affect Water Potential?

To understand how water moves from cell to cell in a plant, first consider the cell in the beaker on the left in **FIGURE 38.1a**. Notice that it is suspended in a **solution**—a homogenous, liquid mixture containing several substances. In this case, the solution consists of water and dissolved substances, or **solutes.**

In the beaker on the left, the solute concentrations in the cell and in the surrounding solution are the same. Such a solution is said to be **isotonic** to the cell (see Chapter 6). When two solutions are isotonic, there is no net movement of water between them.

The Role of Solute Potential What happens when the cell is transferred to the beaker on the right in Figure 38.1a? This beaker contains pure water, which has no solutes. As a result, the solution surrounding the cell is strongly **hypotonic** relative to the cell.

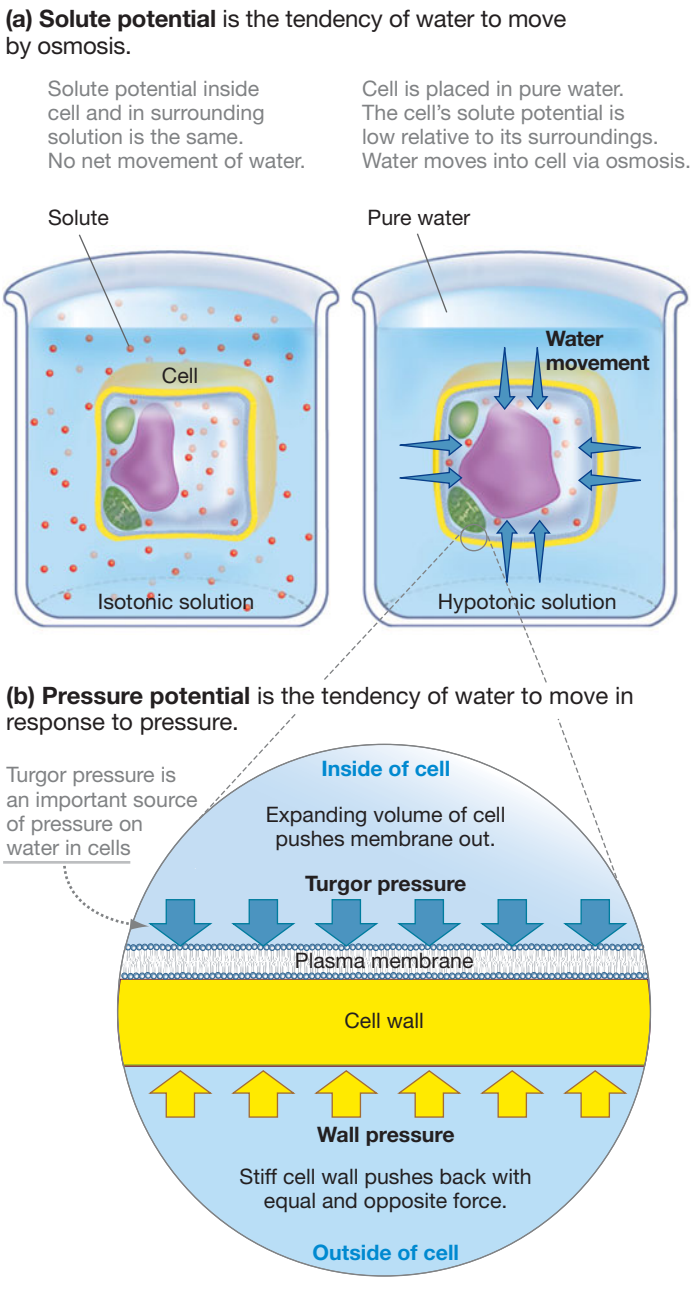


FIGURE 38.1 Water Potential Has Two Major Components: Solute Potential and Pressure Potential.

The concentration of the solution is important because when solutions are separated by a selectively permeable membrane, such as the plasma membrane of a cell, water passes through the membrane from regions of low solute concentration to regions of high solute concentration. This movement of water across membranes, in response to differences in solute concentration, is called **osmosis** (see Chapter 6).

The tendency for water to move in response to differences in solute concentrations is called the **solute potential (ψ_S).** The presence of solutes can only decrease a solution's solute potential below that of pure water.

The solute potential of a solution is defined by its total solute concentration relative to pure water. If water contains a high concentration of solutes, then it has a low solute potential compared with pure water. Water moves down its potential gradient toward the region of higher solute concentration.

The Role of Pressure Potential When an animal cell is placed in a hypotonic solution and water enters the cell via osmosis, the volume of the cell increases until the cell bursts. This does not happen to plant cells, however.

If a plant cell swells in response to incoming water, its plasma membrane pushes against the relatively rigid cell wall. The cell wall resists expansion of the cell volume by pushing back, much as the walls of a basketball push back when the ball is inflated.

The force exerted by the wall is called **wall pressure** (**FIGURE 38.1b**). As water moves into the cell, the pressure inside the cell, known as **turgor pressure,** increases until wall pressure is induced. Cells that are firm and that experience wall pressure are said to be **turgid.**

Turgor pressure is important because it counteracts the movement of water due to osmosis. In the example on the right in Figure 38.1a, the solute potential favors water moving into the cell. However, the rigid cell wall limits the amount of water that can enter the cell.

Pressure potential (ψ_P) refers to any kind of physical pressure on water. Inside a cell, the pressure potential consists of turgor pressure. While the solute potential of a solution can be only 0 (pure water) or negative, pressure potential can be either positive or negative. When pressure is negative, it is called tension.

When osmosis and pressure affect a cell at the same time, how do biologists determine the direction of water movement?

Calculating Water Potential

As a form of potential energy, water potential (ψ) can be thought of as water's stored energy or its tendency to move to a new position. Thus, a water potential summarizes the stored energy that will tend to make water move—in response to the combined effects of a pressure potential and a solute potential.

When selectively permeable membranes are present, water tends to move by osmosis from areas of high solute potential to areas of low solute potential. When no membranes are present to stop it, water moves from areas of high pressure potential to areas of low pressure potential.

If we ignore the effects of gravity, water potential is defined by the following equation:

$$\psi = \psi_P + \psi_S$$

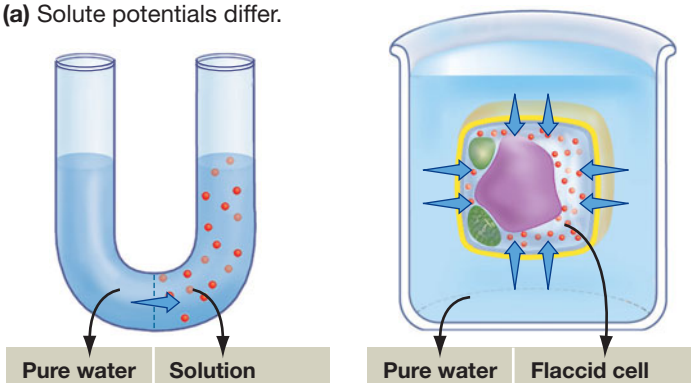
In words, the potential energy of water in a particular location is the sum of the pressure potential and the solute potential that it experiences.

Assigning Units of Pressure and Signs Water potential is measured in units called **megapascals (MPa,** 10^6 Pa). A **pascal (Pa)** is a unit of measurement commonly applied to pressures—force per unit area. A car tire is inflated to about 0.2 MPa, and the water pressure in home plumbing is usually 0.2 to 0.3 MPa.

Solute potentials (ψ_S) are always negative because they are measured relative to the solute potential of pure water. Because pure water contains no dissolved substances, it has a solute potential of 0 megapascal (MPa). And because there are always some solutes inside a cell, the water inside always has a solute potential lower than that of pure water. Therefore pure water will always tend to move *into* the cell. Increasing the concentration of solutes in a cell lowers its solute potential even more—making it more negative.

In contrast to the solute potential in cells, the pressure potential (ψ_P) from turgor pressure is positive inside *living* cells. But as you will see later, the pressure potential in dead cells can sometimes be negative. Let's first consider how solute and pressure potentials combine to drive water movement into and out of living cells.

Water Movement in the Absence of Pressure In the U-shaped tube on the left side of **FIGURE 38.2a**, two solutions are separated by a selectively permeable membrane. The system is open to the atmosphere and thus is not under additional pressure, meaning $\psi_P = 0$ MPa.



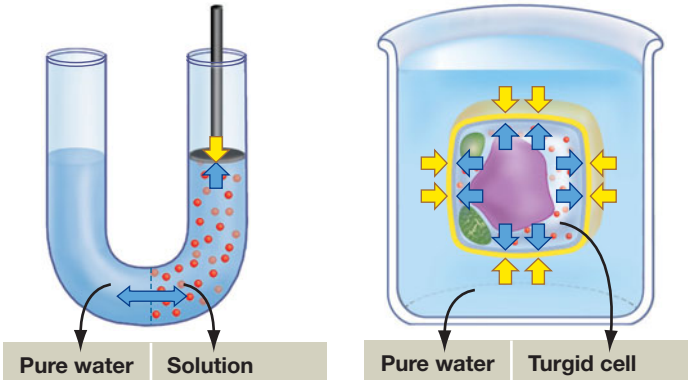
Note that the left side of the tube contains pure water, which has a ψ_S of 0 MPa. The ψ_S for the solution on the right side of the membrane is −1.0 MPa. Because water potential is higher on the left side of the tube than on the right side, water moves from left to right.

The right side of Figure 38.2a models the same situation with a cell that is initially **flaccid**—meaning it has no turgor pressure and thus a pressure potential of 0. Note that the cell has been placed in a solution of pure water. Because the cell has low solute potential (−1.0 MPa) and the pure water has a higher water potential than the cell, water enters the cell via osmosis.

✔ **QUANTITATIVE** **If you understand the concept of solute potential, you should be able to explain (1) how you would change the solute potential of the pure water on the left of Figure 38.2a to make it lower than the solute potential in the solution to the right, and (2) what the consequences for water movement in the tube would be.**

Water Movement in the Presence of a Solute Potential and Pressure Potential On the left side of **FIGURE 38.2b**, the concentrations in the U-shaped tube are the same as in Figure 38.2a, but the solution on the right side of the tube experiences pressure exerted by a plunger. If the force on the plunger produces a

(a) Solute potentials differ.



Pure water	Solution
$\psi = 0$ MPa	$\psi_P =$ 0 MPa $\psi_S = -1.0$ MPa $\psi = -1.0$ MPa

Water moves left to right—from area with higher water potential to area with lower water potential

Pure water	Flaccid cell
$\psi = 0$ MPa	$\psi_P =$ 0 MPa $\psi_S = -1.0$ MPa $\psi = -1.0$ MPa

Water moves into cell—from area with higher water potential to area with lower water potential

(b) Solute and pressure potentials differ.

Pure water	Solution
$\psi = 0$ MPa	$\psi_P = +1.0$ MPa $\psi_S = -1.0$ MPa $\psi = 0.0$ MPa

Water potentials are equal—no net movement

Pure water	Turgid cell
$\psi = 0$ MPa	$\psi_P = +1.0$ MPa $\psi_S = -1.0$ MPa $\psi = 0.0$ MPa

Water potentials are equal—no net movement

FIGURE 38.2 Solute Potential and Pressure Potential Interact.

✔**QUANTITATIVE** In the left side of part (a), does the solute potential on the right side of the tube increase, decrease, or stay the same when water flows from left to right by osmosis?

pressure potential of 1.0 MPa on the right side, and if the ψ_S for the solution on the right side of the membrane is still −1.0 MPa, then the water potential of the right side is −1.0 MPa + 1.0 MPa = 0.

In this case, the water potential on both sides of the membrane is equal and there will be no net movement of water. If the force on the plunger is greater than 1.0 MPa, the solution on the right side would have a *higher* water potential and water would flow from right to left.

The right side of Figure 38.2b models this situation in a living cell. In this case, the incoming water creates turgor pressure. When the positive turgor pressure (+1.0 MPa) plus the cell's negative solute potential (−1.0 MPa) equals 0 MPa—the water potential of pure water—the system reaches equilibrium. At equilibrium, there is no additional net movement of water. In this way, turgor pressure acts like the plunger in Figure 38.2b.

✔**QUANTITATIVE** **If you understand the concept of pressure potential, you should be able to explain how you would use the plunger in Figure 38.2b to create a negative pressure instead of a positive pressure.**

Water Potentials in Soils, Plants, and the Atmosphere

The water contained within leaf, stem, or root tissues has a pressure potential and a solute potential, just like the water inside a cell does. Likewise, both the soil surrounding the root system and the air around the shoot system have a water potential.

Water Potential in Soils In moist soil, the water that fills crevices between soil particles usually contains relatively few solutes and normally is under little pressure. As a result, its water potential tends to be high relative to the water potential found in a plant's roots, which is higher in solutes.

There are important exceptions to this rule, however.

- ***Salty soils*** The soils near ocean coastlines have water potentials as low as −4MPa or less due to high solute concentrations. This is much lower than the water potential typically found inside plant roots.
- ***Dry soils*** When soils dry, water no longer flows freely in the spaces between soil particles. All of the remaining water adheres tightly to soil particles, creating a tension that lowers the water potential of soil water.

When the water potential in soil drops, water is less likely to move from soil into plants. If soil water potential is low enough, water may even move from plants to the soil. This situation would be deadly to plants.

This is an enormously important issue for world agriculture. When soils are irrigated to boost crop yields, much of the water evaporates. The solutes in the irrigation water are left behind and tend to collect in the first few inches below the surface. Over time, then, irrigated soils tend to become salty. In some parts of the world, formerly productive soils have become so salty that they are now abandoned as cropland.

How Do Plants That Are Adapted to Salty or Dry Habitats Cope?

Salt-adapted species often respond to low water potentials in soil by accumulating solutes in their root cells, which lowers their solute potential. These plants have enzymes that increase the concentration of certain organic molecules in the cytoplasm. As a result, they can keep the water potential of their tissues even lower than the water potential of salty soils.

Species that are adapted to dry sites cope by tolerating low solute potentials. For example, let's look at the changes in solute

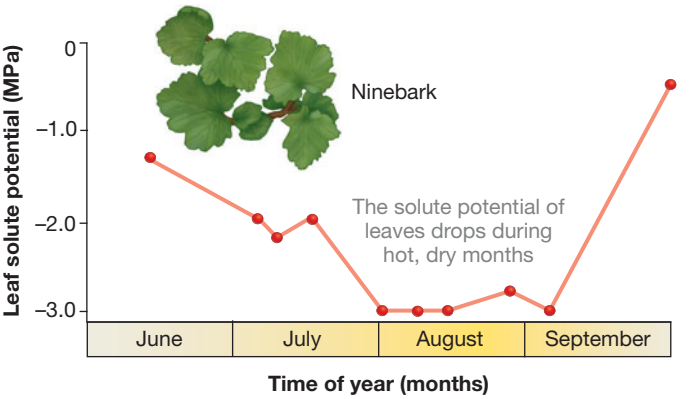


FIGURE 38.3 Plants with Low Solute Potentials Can Grow in Dry Soils. As soils dry, their water potential declines. But if a plant's solute potential also drops, it can maintain a water-potential gradient that continues to bring water into the plant.

DATA: Cline, R. G., and W. S. Campbell. 1976. *Ecology* 57: 367–373.

FIGURE 38.4 Wilting Occurs When Water Loss Leads to Loss of Turgor Pressure. Wilting is a life-threatening condition in plants, analogous to severe dehydration in humans.

potential that were recorded in tissue from a shrub species called ninebark. In **FIGURE 38.3** each data point represents the solute potential recorded on a particular day; the lines between the data points are drawn simply to make the trend clear.

Ninebarks thrive on dry sites in the Rocky Mountains of western North America. Notice that the solute potential of tissue is relatively high in June, at the start of the growing season. In the Rockies, June tends to be rainy and cool. July and August are progressively hotter and drier, however. As the graph indicates, the solute potential in tissue drops dramatically during this period.

This is a key observation. As the summer progresses and water potential in soil drops, ninebark shrubs are able to keep acquiring water and grow because the solute potentials of their tissues can drop to stay below the soil water potential.

Plants that are adapted to wetter sites cannot tolerate such low solute potentials in their tissues. When conditions get hot and dry, they have to close their stomata and stop photosynthesis—meaning that their growth will stop or slow down dramatically compared to dry-adapted plants.

If plants keep their stomata open and leaf cells lose water faster than the water is replaced, the positive turgor pressure normally inside living cells drops to 0. If the cells do not regain turgor quickly, they are at risk of dehydration and death as cells shrivel like grapes drying into raisins. When an entire tissue loses turgor pressure, it will **wilt** (**FIGURE 38.4**).

Turgor pressure is required for growth to occur; without it, cells cannot expand once cell division is complete. In addition, turgor pressure provides structural support—which is why turgid plants do not wilt. Unless corrected, extensive wilting may lead to the death of the tissue and, eventually, the plant.

Water Potential in Air In the atmosphere, water exists as a vapor with a solute potential of 0 MPa. The pressure exerted by water vapor in the atmosphere depends on temperature and humidity. The lower the pressure potential, the faster the rate of evaporation from liquid water to the atmosphere.

- When air is dry, there are few water molecules present and the pressure they exert is low, increasing the rate of evaporation.
- When air is warm, water molecules move farther apart and also exert lower pressure.

Warm, dry air has an extremely low water potential, often approaching −100 MPa. When the weather is cool and rainy or foggy, however, the water potential of the atmosphere may be equal to the water potential inside a leaf. But normally, the water potential of the atmosphere is much lower than the water potential inside a leaf, so water evaporates quickly.

check your understanding

C Y U

If you understand that . . .

- Water moves along a water-potential gradient, from areas of high water potential to areas of low water potential.
- In areas separated by a selectively permeable membrane, part of water's potential energy is made up of its solute potential—its tendency to move via osmosis.
- Water also has a pressure potential. In living plant cells, for example, the cell wall can exert pressure on water and affect its pressure potential.
- Soils, plant tissues, and the atmosphere all have a water potential made up of a solute potential and a pressure potential.

✔ You should be able to . . .

1. Explain why the water potential of a cell in equilibrium with pure water can be zero even though it contains solutes.
2. Compare and contrast the solute potential of an irrigated agricultural field before and after a long, hot day of evaporation.

Answers are available in Appendix A.

FIGURE 38.5 A Water-Potential Gradient Exists between Soil, Plants, and Atmosphere. Water moves from regions of high water potential to regions of low water potential.

In most cases, water potential is highest in soil, lower in roots, lower yet in leaves, and lowest in the atmosphere. This situation sets up a **water-potential gradient** that causes water to move up through the plant. To move *up* a plant, water moves *down* the water-potential gradient that exists between the soil, its tissues, and the atmosphere. When it does so, it replaces the water lost through transpiration (**FIGURE 38.5**).

38.2 How Does Water Move from Roots to Shoots?

Suppose that you are caring for the wilted plant in Figure 38.4. If you add water to the soil, the water potential of the soil increases and water will move into the plant along a water-potential gradient.

Water moves into root cells by osmosis, but how does it move up to the shoots, against gravity? Biologists have tested three major hypotheses for how the water could be transported to shoots:

1. Root pressure—a pressure potential that develops in roots—could drive water up against the force of gravity.
2. Capillary action could draw water up the cells of xylem.
3. Cohesion-tension, a force generated in leaves by transpiration, could pull water up from roots.

Note that all three hypotheses could be correct—they are not mutually exclusive.

Let's begin by considering how water and solutes move from the soil across the root and into the **vascular tissue,** which contains xylem and phloem. Then we can analyze each of the three hypotheses for how water and solutes finish the trip up the xylem to the shoot system.

Movement of Water and Solutes into the Root

To understand how water enters a root, consider the cross section through a young buttercup root shown in **FIGURE 38.6** (see also Chapter 37). Starting at the outside of the root and working inward, notice that several distinct tissues are present:

- The **epidermis** (literally, "outside skin") is a single layer of cells. In addition to protecting the root, some epidermal cells produce **root hairs,** which greatly increase the total surface area of the root.
- The **cortex** consists of ground tissue—usually parenchyma cells—and stores carbohydrates.

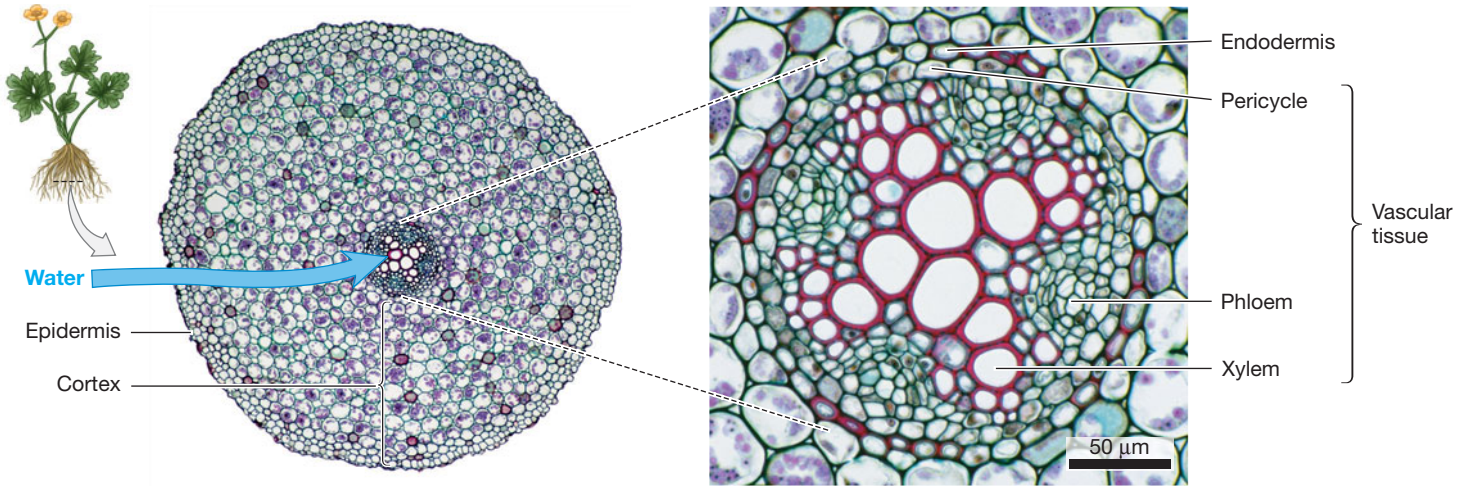

FIGURE 38.6 In Roots, Water Has to Travel through Several Tissue Layers to Reach Vascular Tissue. This cross section through a buttercup root shows the anatomy that is typical of roots in eudicots.

- The **endodermis** ("inside skin") is a cylindrical layer of cells that forms a boundary between the cortex and the vascular tissue. The function of the endodermis is to control ion uptake and prevent ion leakage from the vascular tissue.
- The **pericycle** ("around-circle") is a layer of cells that forms the outer boundary of the vascular tissue. The pericycle can become meristematic and produce lateral roots.
- Conducting cells of the vascular tissue function in transport between roots and shoots, and are located in the center of roots in buttercups and other eudicots. Notice that, in these plants, phloem is situated between each of four arms formed by xylem, which is arranged in a cross-shaped pattern.

Three Routes through Root Cortex to Xylem When water enters a root along a water-potential gradient, it does so through root hairs. As water is absorbed, it moves through the root cortex toward the xylem through three distinct routes (**FIGURE 38.7**).

1. The *transmembrane route* is based on flow through aquaporin proteins—water channels located in the plasma membranes of root cells (see Chapter 6). Some water may also diffuse directly across plasma membranes.
2. The *apoplastic route* is outside the plasma membranes. The **apoplast** consists of cell walls, which are porous, and the spaces that exist between cells. The name apoplastic is apt because movement takes place outside the plasma membrane and cell interior. Water moving along the apoplastic route *must* eventually pass into the cytoplasm of endodermal cells before entering xylem.
3. The *symplastic route* is inside the plasma membranes. The **symplast** consists of the cytosol and the continuous connections through cells that exist via plasmodesmata (see Chapter 11).

In essence, water can flow through tissues by crossing membranes via aquaporins, or by passing around cells via the apoplast, or by passing through the symplast via plasmodesmata.

The Role of the Casparian Strip The situation changes when water reaches the endodermis. Endodermal cells are tightly packed and secrete a narrow band of wax called the **Casparian strip.** This layer is composed primarily of a compound called **suberin,** which forms a water-repellent cylinder at the endodermis.

The Casparian strip blocks the apoplastic route by preventing water from moving through the walls of endodermal cells and

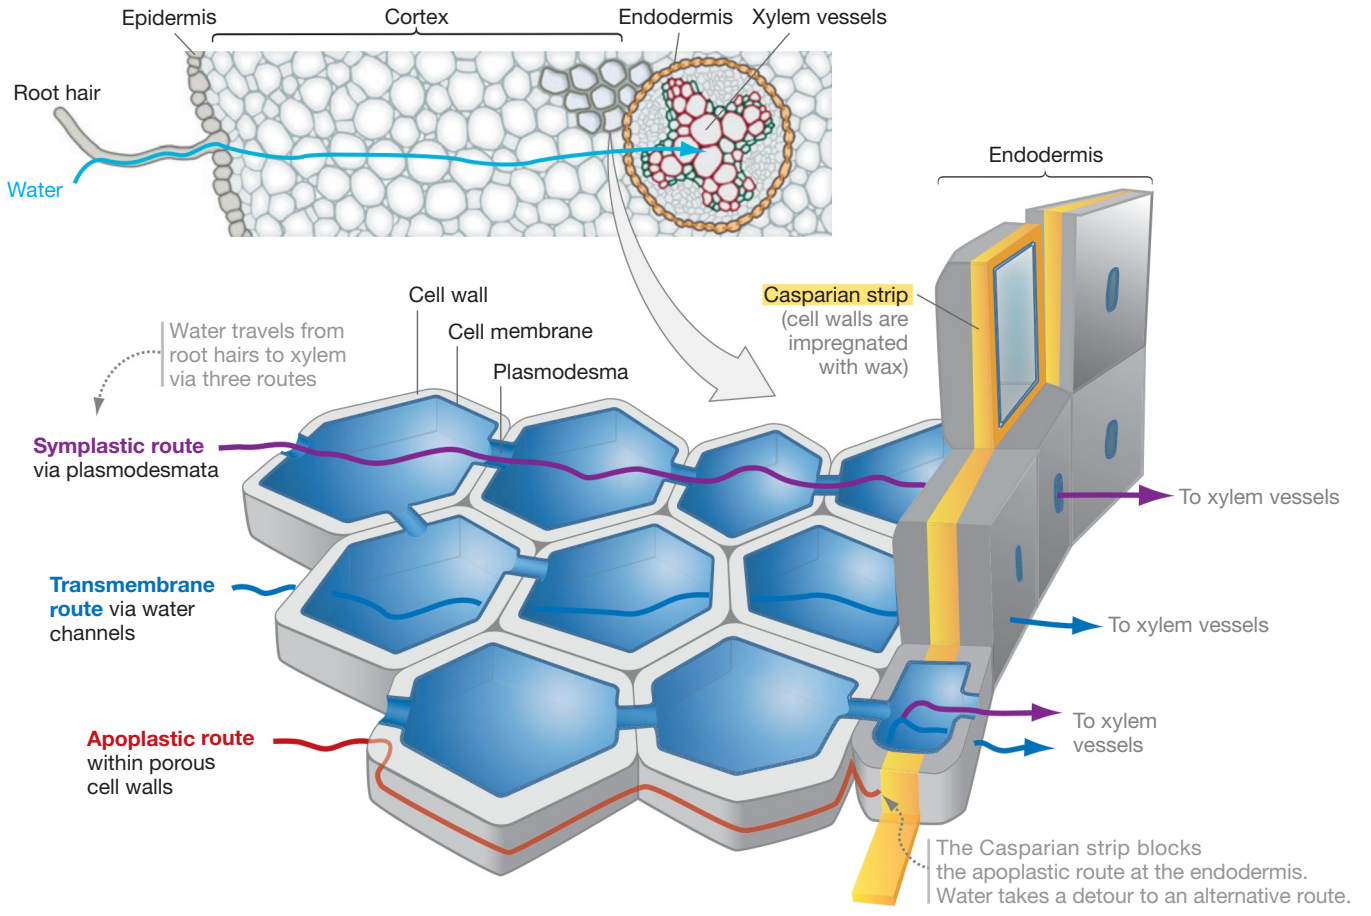

FIGURE 38.7 How Water Travels from Root Hair to Xylem.

✔**EXERCISE** Add dots representing aquaporins in the transmembrane route.

proceeding to the vascular tissue (Figure 38.7). The Casparian strip does not affect water and ions that move through the symplastic route.

The Casparian strip is important because it means that for water and solutes to reach vascular tissue, they have to move into the cytoplasm of an endodermal cell. Endodermal cells, in turn, act as filters.

By forcing water and ions to cross at least two membranes on their way from the soil to the xylem, one entering the symplast outside the Casparian strip and one leaving the symplast inside the Casparian strip, plants can use specific channel and carrier proteins (see Chapter 6) to control what moves to the shoots. Endodermal cells allow ions such as potassium (K^+) that are needed by the plant to pass through to the vascular tissue. In contrast, these cells can prevent the passage of ions such as sodium (Na^+) or heavy metals that are not needed or may be harmful.

✔ **If you understand this concept, you should be able to predict what would happen if a plant had a mutation that prevented synthesis of suberin and formation of the Casparian strip.**

Water Movement via Root Pressure

Have you ever walked barefoot through grass early in the morning and gotten your feet wet? Where does that water come from? Let's explore this phenomenon.

Movement of ions and water into the root xylem is responsible for the process known as **root pressure.** Recall that root pressure is one of three hypothesized mechanisms for moving water up xylem, from root to shoot.

The Casparian strip in endodermal cells is essential for root pressure to develop. Without an apoplastic barrier between the xylem and the environment, ions and water would simply leak out of roots.

Stomata normally close during the night, when photosynthesis is not occurring and CO_2 is not needed. Their closure minimizes water loss and slows the movement of water through plants. But roots often continue to accumulate ions that their epidermal cells acquire from the soil as nutrients, and these nutrients are actively pumped into the xylem. The influx of ions lowers the water potential of xylem below the water potential in the surrounding cells.

As water flows into xylem from other root cells in response to the solute gradient, a positive pressure is generated at night that forces fluid up the xylem. More water moves up xylem and into leaves than is being transpired from the leaves.

In low-growing plants, enough water can move to force water droplets out of the leaves, a phenomenon known as **guttation.** Some of the water that gets your feet wet early in the morning spent part of the night moving through plants (**FIGURE 38.8**).

At one time, positive root pressure formed the basis of a leading hypothesis to explain how water moves from roots to leaves in trees. However, research showed that over long distances, such as the height of a tree, the force of root pressure is not enough to overcome the force of gravity on the water inside xylem.

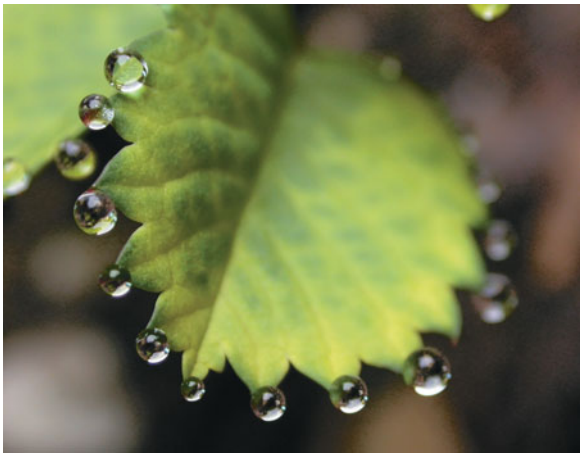

FIGURE 38.8 Root Pressure Causes Guttation. When ions accumulate in the xylem of roots at night, enough water enters the xylem via osmosis to force water up and out of low-growing leaves.

In addition, researchers demonstrated that cut stems, which have no contact with the root system, are still able to transport water to leaves. Biologists concluded that there must be some other mechanism involved in the long-distance transport of water. What is it?

Water Movement via Capillary Action

Researchers have also evaluated a hypothesis based on the phenomenon of **capillarity** (also called capillary action), or movement of water up a narrow tube. When a thin glass tube is placed upright in a pan of water, water creeps up the tube (**FIGURE 38.9**). The movement occurs in response to three forces: **(1)** adhesion, **(2)** cohesion, and **(3)** surface tension. Let's consider each force in turn.

Adhesion is a molecular attraction among unlike molecules. In this case, water interacts with a solid substrate—such as the glass walls of a capillary tube or the cell walls of tracheids or vessel elements—through hydrogen bonding. As water molecules

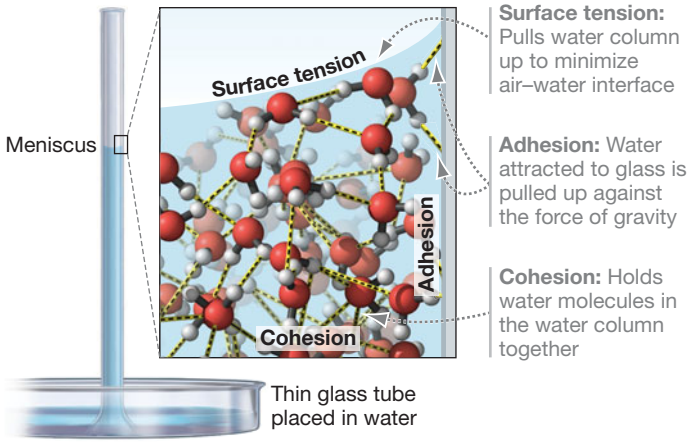

FIGURE 38.9 Water Can Rise in Xylem via Capillarity. Capillary action occurs through a combination of three forces, all of which are generated by hydrogen bonding and together are acting against gravity.

bond to each other and adhere to the side of the tube, they are pulled upward.

Cohesion is a molecular attraction among like molecules, such as the hydrogen bonding that occurs among molecules in water. Because water molecules cohere, the upward pull by adhesion is transmitted to the rest of the water column. The water column rises against the pull of gravity.

The effects of adhesion, cohesion, and gravity are responsible for the formation of a concave surface boundary called a **meniscus** (plural: **menisci**). A meniscus forms at most air–water interfaces—including those found in narrow tubes. Menisci form because adhesion and cohesion pull water molecules up along the sides of the tube, while gravity pulls the water surface down in the middle.

Surface tension is a force that exists among water molecules at an air–water interface. In the body of a water column, all the water molecules present are surrounded by other water molecules and form hydrogen bonds in all directions. Water molecules at the surface, however, can form hydrogen bonds only with the water molecules beside and below them. As a result, surface molecules share stronger attractive forces. This enhanced attraction results in tension that minimizes the total surface area. When a meniscus forms, surface tension exerts a pull against gravity.

Capillary action results when adhesion creates an upward pull at the water–container interface, surface tension creates an upward pull all across the surface, and cohesion transmits both forces to the water below. All three forces counteract the effect of gravity, and the result is capillarity.

Like root pressure, capillarity can transport water only a limited distance. Capillary action moves water along the surfaces of mosses and other low-growing, non-vascular plants; but it can raise the water in the xylem of a vertical stem only about 1 m.

Thus, root pressure and capillary action cannot explain how water moves from soil to the top of a redwood tree—an organism that can grow 5 to 6 stories higher than the Statue of Liberty. How then does it actually happen?

The Cohesion-Tension Theory

The leading hypothesis to explain long-distance water movement in vascular plants is the **cohesion-tension theory,** which states that water is pulled to the tops of trees along a water-potential gradient, via forces generated by transpiration at leaf surfaces.

To understand how the cohesion-tension force works, start with step 1 in **FIGURE 38.10**. Notice that spaces inside the leaf are filled with moist air as a result of evaporation from the surfaces of surrounding cells. When a stoma opens, this humid air is exposed to the atmosphere, which in most cases is much drier. This creates a steep water-potential gradient between the leaf interior and its surroundings. The steeper the gradient, the faster water vapor diffuses out through the stomata.

Step 2 shows that as water is lost from the leaf to the atmosphere, the humidity of the gas-filled space inside the leaf drops. In response, more water evaporates from the walls of the parenchyma cells. At the microscopic level, cell walls are not perfectly smooth, so menisci form at the air–water interface. As more water evaporates, the menisci become steeper and the total area of the air–water interface increases.

In 1894 Henry Dixon and John Joly hypothesized that the formation of steep menisci produces a force capable of pulling water up from the roots, dozens or hundreds of meters into the air. Is this really possible?

The Role of Surface Tension in Water Transport The key concept in the cohesion-tension theory is that the negative force or pull (tension) generated at the air–water interface is transmitted through the water outside of leaf cells (step 3 in Figure 38.10), to the water in xylem (step 4), to the water in the vascular tissue of roots (step 5), and finally to the water in the soil (step 6).

The transmission of pulling force from the leaf surface to the root is possible because **(1)** there are continuous columns of water throughout the plant, and **(2)** all of the water molecules present hydrogen bonds to one another (cohesion).

Note that the plant does not expend energy to create the pulling force. The force is generated by energy from the Sun, which drives evaporation from the leaf surface. Water transport is solar powered.

In effect, the cohesion-tension theory of water movement states that, because of the hydrogen bonding between water molecules, water is pulled up through xylem in continuous columns.

Creating a Water Potential Gradient You can also think about the cohesion-tension theory in terms of water potentials. Note that because tracheids and vessels are dead at maturity, the water in xylem does not cross plasma membranes. As a result, water does not move between cells by osmosis. In xylem, water movement is driven entirely by differences in pressure potential. The water in a column of xylem cells moves by **bulk flow**—a mass movement of molecules along a pressure gradient.

The pulling force generated at menisci in leaf cell walls lowers the pressure potential of water in leaves. Even though the tension created at each meniscus is relatively small, there are so many menisci in the leaves of an entire plant that the tension created by summing many small pulling forces is remarkable. It creates a water-potential gradient between leaves and roots that is steep enough to overcome the force of gravity and pull water up long distances.

To appreciate just how great the forces involved are, think of the vessel elements or tracheids in xylem as groups of drinking straws. When you use a straw, the vacuum that you create causes liquid to rise. Sucking on a drinking straw creates a pressure difference of about −0.1 MPa, which can draw water up a maximum of about 10 m. In contrast, the negative pressure exerted by the menisci in leaves can be as low as −2.0 MPa. The tension in xylem tissue may be 10 times the amount of pressure on a fully inflated car tire. (But note that the pressure on a car tire is positive, not negative.) The force is enough to draw water up 100 m.

The Importance of Secondary Cell Walls If you suck on a drinking straw hard enough, the pressure gradient between the

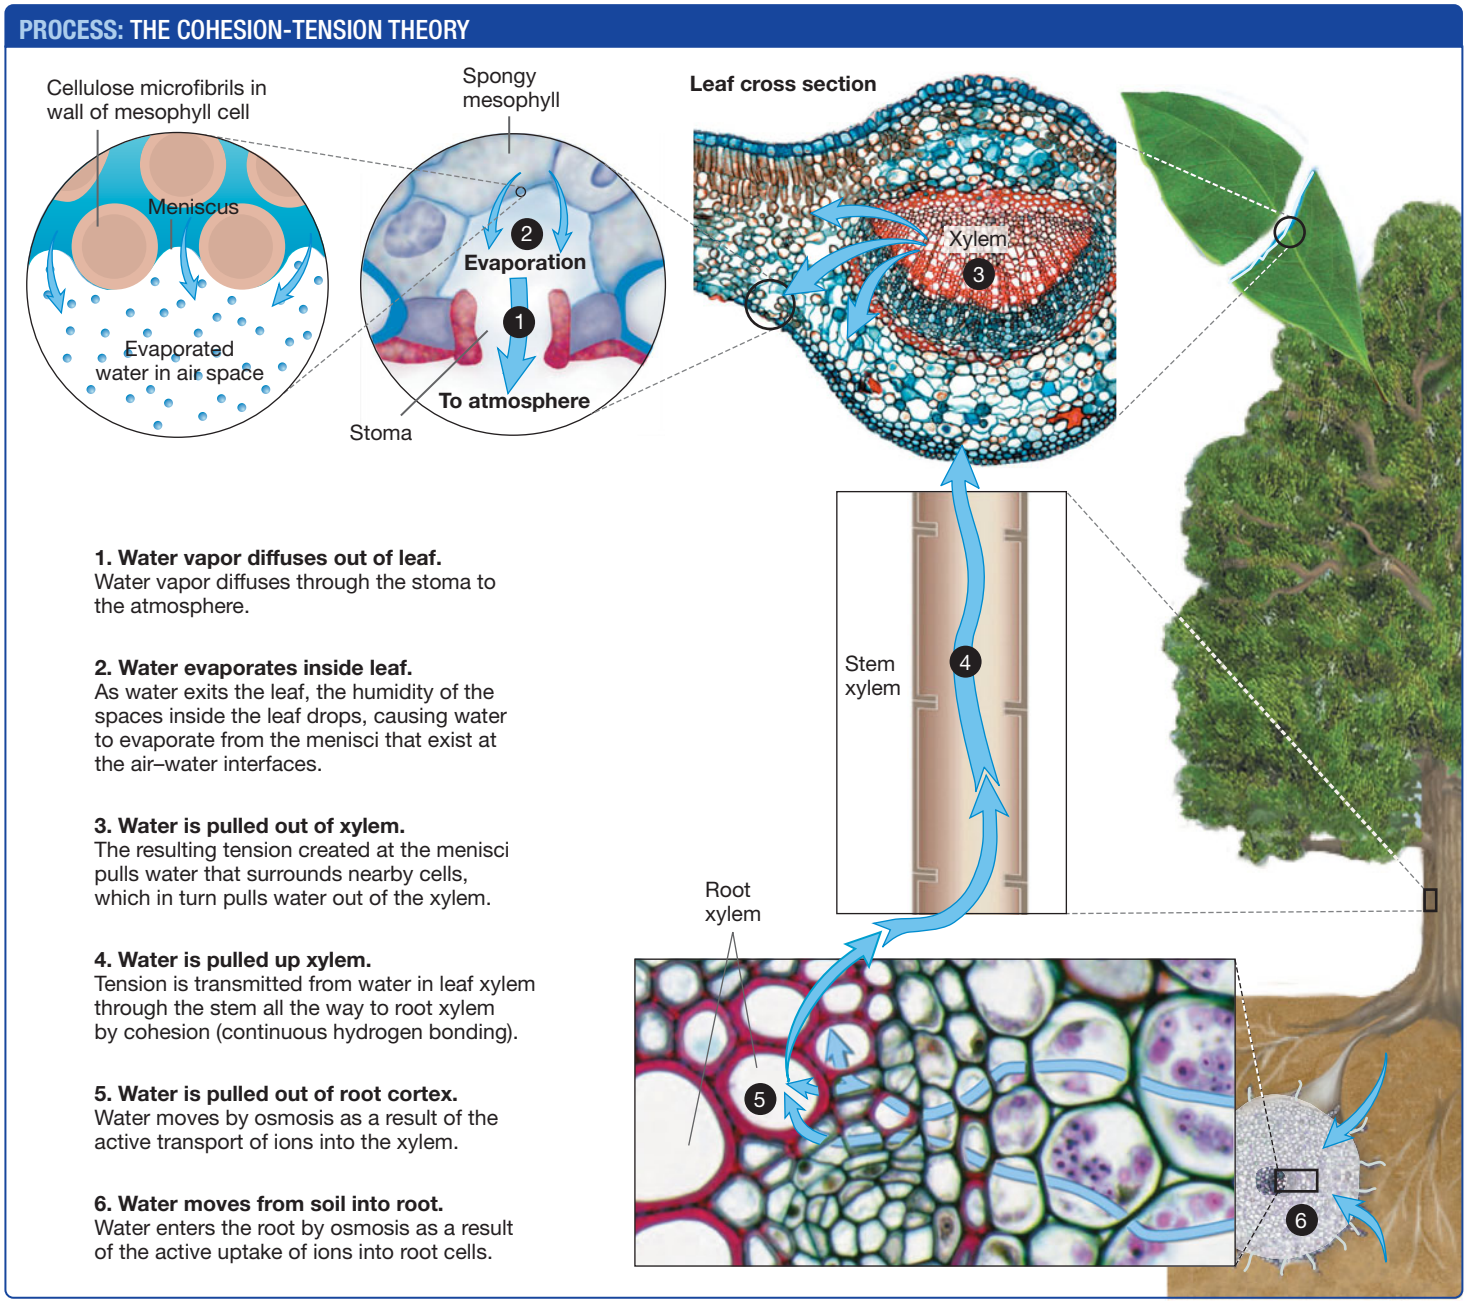

FIGURE 38.10 Transpiration Creates Tension That Is Transmitted from Leaves to Roots.

inside of the straw and the atmosphere can overcome the stiffness of the straw and cause it to collapse. How can vascular tissue withstand negative pressures as low as −2.0 MPa without collapsing?

The answer is found in a key adaptation: the secondary thickenings characteristic of the cell walls in tracheids and vessel elements. The cells in vascular tissue have walls that are reinforced with tough lignin molecules (see also Chapter 31).

The evolution of lignified secondary cell walls was an important event in the evolution of land plants because it allowed vascular tissue to withstand extremely negative pressures. The result? Tall trees.

What Evidence Do Biologists Have for the Cohesion-Tension Theory? If the cohesion-tension theory is correct, the water present in xylem should experience a strong pulling force. A simple experiment supports this prediction.

If you find a leaf that is actively transpiring and cut its petiole, the watery fluid in the xylem, or xylem sap, withdraws from the edge toward the inside of the leaf (**FIGURE 38.11**, see page 764). According to the cohesion-tension theory, this observation is due to a transpirational pull at the air–water interface in parenchyma cells of leaves.

Although the observation that xylem sap is under tension was important, the cohesion-tension theory remained controversial.

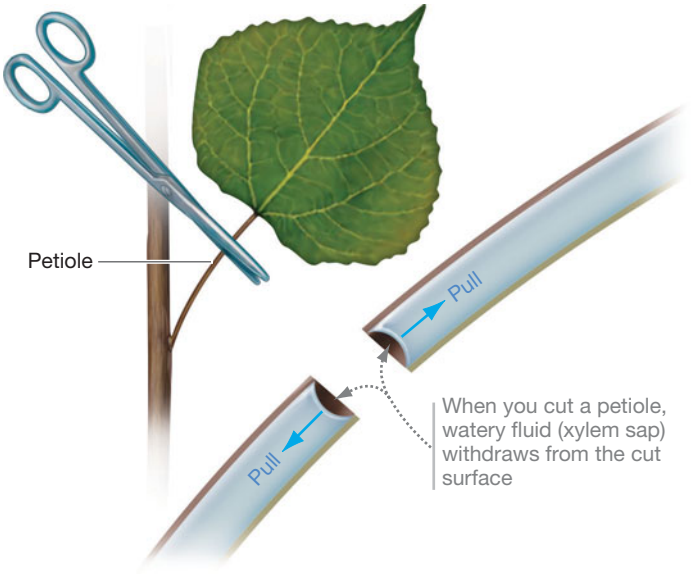

FIGURE 38.11 Xylem Sap in Cut Stems "Snaps Back."

For example, several studies failed to document rapid changes in xylem pressure when temperature and humidity—and thus the severity of the water-potential gradient—were changed experimentally. Advocates of the theory blamed the negative results on instruments that could not document small, rapid changes in pressure potential. Who was right?

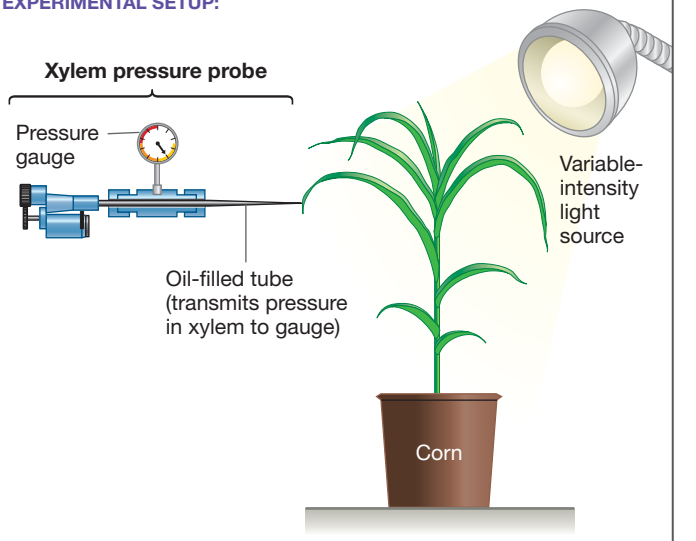
Chunfang Wei, Melvin Tyree, and Ernst Steudle answered the question in the late 1990s with an instrument called a xylem pressure probe (**FIGURE 38.12**). A xylem pressure probe includes an oil-filled glass tube that can be inserted directly into the xylem of a leaf. The oil transmits changes in pressure within the xylem to a gauge, allowing researchers to record changes in xylem pressure instantly and directly.

To test the cohesion-tension theory, the researchers altered xylem pressure by raising light levels to alter transpiration rates in the leaves of corn plants. Their results?

- The graph in Figure 38.12 plots how xylem pressure changed as the researchers changed light levels over a 7-minute period. Note that as light intensity increased, the xylem pressure probe documented increased tension, or pull—negative pressure.
- In addition, higher light levels reduced the weight of the entire plant—suggesting that higher transpiration rates caused water loss.

Both observations are consistent with predictions that follow from the cohesion-tension theory.

These experiments convinced most biologists that increased transpiration leads to increased tension on xylem sap. Rising tension, in turn, lowers the water potential of leaves and exerts a pull on water in the roots, where the water potential is high. On the basis of these and other results, most biologists now accept the cohesion-tension theory.

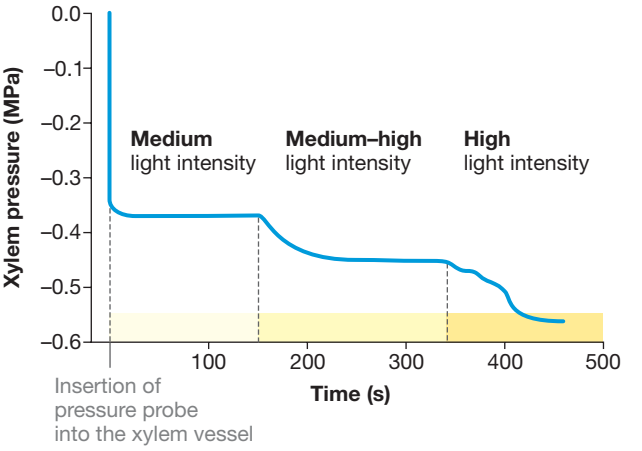


RESEARCH

QUESTION: Do direct measurements of pressure in xylem tissue support the cohesion-tension theory?

HYPOTHESIS: Increasing transpiration by raising light intensity will lower xylem pressure in leaves.

NULL HYPOTHESIS: Increasing light intensity will not affect xylem pressure in leaves.



EXPERIMENTAL SETUP:

PREDICTION: Xylem pressure will decrease as transpiration increases with higher light levels.

PREDICTION OF NULL HYPOTHESIS: Xylem pressure will not be affected by light intensity.

RESULTS:

CONCLUSION: Xylem pressure decreases when light intensity increases. The data support the cohesion-tension theory.

check your understanding

C Y U

If you understand that . . .

- Water can move a short distance in xylem via root pressure or capillarity.
- Long-distance transport of water depends on movement along a steep water-potential gradient. This gradient is created primarily by the negative pressure potential of water in leaves, due to surface tension that develops in response to transpiration.

✔ You should be able to . . .

1. Explain how transpiration at the surface of a meniscus near a stoma creates a pull on the water in leaves and xylem.
2. Predict what happens to the meniscus when each of the following occurs: A nearby stoma closes, a rain shower starts, and weather changes as dry air blows in.

Answers are available in Appendix A.

38.3 Water Absorption and Water Loss

One of the most important features of the cohesion-tension theory is that it does not require plants to expend energy to lift the water that the roots take in by osmosis. To absorb water, roots must expend energy to accumulate the ions that maintain a solute potential that is lower than the soil. Once the water with dissolved nutrients is in the root xylem, the Sun furnishes the energy required to pull the solution from roots to shoots—not ATP supplied by the plant.

1. Energy from the Sun heats water molecules at the air–water interface inside leaves enough to break the hydrogen bonds between them and cause transpiration.
2. Rapid transpiration creates deep menisci in the walls of leaf cells, causing tension that lowers the water potential of leaves.
3. Hydrogen bonding between water molecules transmits this tension down to water molecules in the roots.

Xylem acts as a passive conduit—a set of narrow pipes that allows water to move from a region of high water potential (the roots) to a region of low water potential (the leaves). Water flows from roots to shoots as long as the water-potential gradient—from root to leaf to atmosphere—is intact.

When soils begin to dry, however, it becomes difficult for plants to replace water being lost via transpiration. If water is not replaced fast enough, the solute potentials of leaves drop and leaves and branches begin to wilt. In response, stomata may close down partially or completely to reduce transpiration rates and conserve water. However, closing stomata affects the ability of plants to carry on photosynthesis, because CO_2 acquisition slows or stops.

The balance between conserving water and maximizing photosynthesis is termed the photosynthesis-transpiration compromise. This compromise is particularly delicate for species that grow on dry sites. How do they cope?

Limiting Water Loss

Plants that thrive in dry sites have several adaptations that help them slow transpiration and limit water loss. Consider the oleander plant, which is native to the dry shrub-grassland habitats of southern Eurasia. The micrograph in **FIGURE 38.13** shows a cross section through an oleander leaf, which has the following special features:

- A particularly thick cuticle covers the upper surface of oleander leaves. This waxy layer minimizes water loss from cells that are directly exposed to sunlight. In general, species that are adapted to dry soils have much thicker cuticles than do species adapted to wet soils.
- The stomata of oleanders are located on the undersides of their leaves, inside deep pits in the epidermis. Hairlike extensions of epidermal cells called **trichomes** (see Section 37.3) shield these pits from the atmosphere. The leading hypothesis to explain these traits is that they slow the loss of water vapor from stomata to the dry air surrounding the leaf by creating a layer of still air surrounding the stomata.

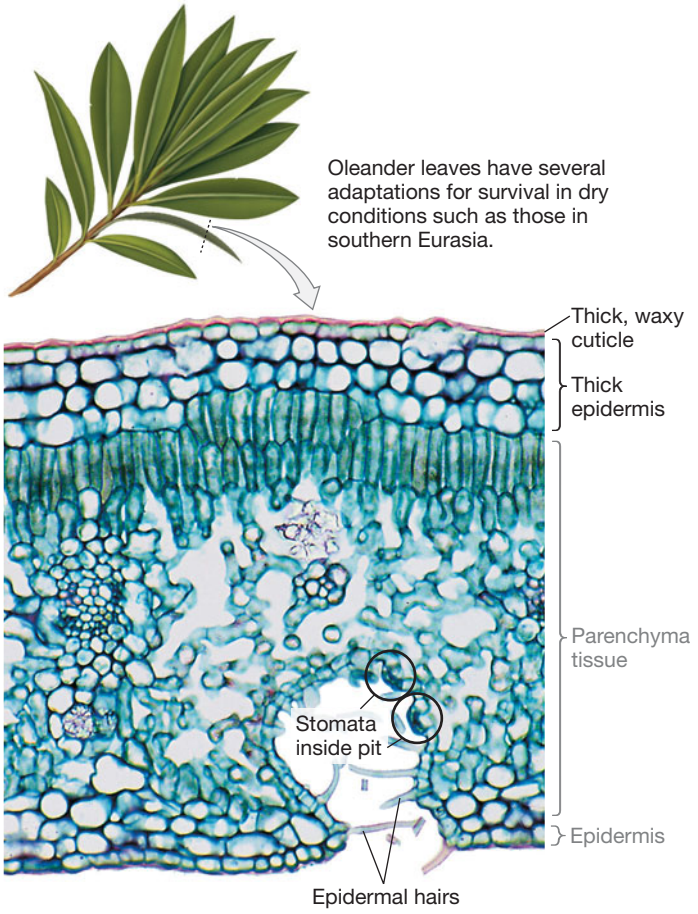

FIGURE 38.13 Species That Are Adapted to Dry Habitats Have Modified Leaf Structures.

Other species have other adaptations for limiting water loss. For example, recall that many species adapted to water-limited habitats—either cold environments where water is often frozen or deserts where rainfall is rare—have needlelike leaves (see Chapter 37). Long, thin leaf shapes minimize the surface area exposed to sunlight and thus minimize transpiration. Plants adapted to wetter habitats, in contrast, tend to have broad leaves with a large surface area.

Obtaining Carbon Dioxide under Water Stress

Many of the species that thrive in deserts and other hot, dry habitats can continue photosynthesizing even when soil moisture content is low. Recall that two novel biochemical pathways, **crassulacean acid metabolism (CAM)** and **C_4 photosynthesis,** allow plants to increase CO_2 concentrations in their leaves and conserve water (see Chapter 10).

CAM plants open their stomata at night and store the CO_2 that diffuses into their tissues by adding the carbon dioxide molecules to organic acids. When sunlight is available during the day and photosynthesis begins, the CO_2 molecules are released from the organic acids and converted to sugar by **rubisco**—the enzyme, found in all green plants, that initiates the Calvin cycle. In this way, CAM plants can photosynthesize and grow even with their stomata closed during the day.

C_4 plants minimize the extent to which their stomata open because they use CO_2 so efficiently. Mesophyll cells in C_4 plants take up CO_2 and add it to organic acids. The CO_2 is then transferred to specialized cells called **bundle-sheath cells** (see Chapter 10), where the Calvin cycle operates. In effect, the C_4 cycle is a mechanism for concentrating carbon dioxide in cells deep inside the leaf, so stomata do not have to be wide open continuously.

Like the cuticle and stomata-containing pits of oleanders, CAM and C_4 plants have adaptations that help them conserve water by limiting transpiration.

38.4 Translocation of Sugars

Translocation is the movement of sugars by bulk flow throughout a plant—specifically, from sources to sinks. In vascular plants, a **source** is a tissue where sugar enters the phloem; a **sink** is a tissue where sugar exits the phloem.

Where do sources and sinks occur in a plant? The answer often depends on the time of year.

- ***During the growing season*** Mature leaves and stems that are actively photosynthesizing produce sugar in excess of their own needs. These tissues act as sources. Sugar moves from leaves and stems to a variety of sinks, where sugar use is high and production is low. Apical meristems, lateral meristems, developing leaves, flowers, developing seeds and fruits, and storage cells in roots all act as sinks (**FIGURE 38.14**).
- ***Early in the growing season*** When a plant resumes growth after the winter or the dry season, sugars move from storage areas to growing areas. Storage cells in roots and seeds act as sources; developing leaves act as sinks.

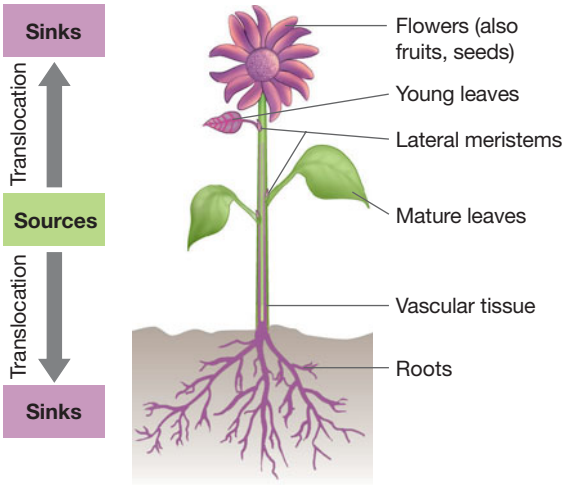

FIGURE 38.14 Sugars Move from Sources to Sinks.

Tracing Connections between Sources and Sinks

To explore the relationship between sources and sinks in more detail, consider research on sugar-beet plants that were exposed to carbon dioxide molecules containing the radioactive isotope ^{14}C. The goal was to track where carbon atoms moved after they were incorporated into sugars via photosynthesis.

The location of ^{14}C atoms inside a plant can be documented in two ways: **(1)** by measuring the amount of radioactive CO_2 emanating from different tissues, or **(2)** by laying plant parts on X-ray film and allowing the radioactivity to expose and blacken the film.

Many researchers have enclosed individual leaves of intact plants in a bag and introduced a known amount of radioactive CO_2 for a short period of time. One typical experiment documented that mature leaves retained just over 9 percent of the labeled carbon. In contrast, growing leaves retained 67 percent. These data are consistent with the prediction that fully expanded leaves act as sources of sugar, while actively growing leaves and roots act as sinks.

In similar experiments, researchers have exposed all the leaves on a growing plant to labeled carbon. One such experiment found that over 16 percent of the total carbon was translocated to root tissue within 3 hours. This result is consistent with the prediction that, during the growing season, roots also act as sinks.

Similar experiments support two generalizations.

1. Sugars can be translocated rapidly—typically 50–100 centimeters per hour (cm/hr).
2. There is a strong correspondence between the physical locations of sources and sinks.

The second point is particularly interesting. For example, mature leaves that act as sources send sugar to tissues on the same side of the plant (**FIGURE 38.15a**). In addition, experiments with tall herbaceous plants show that leaves on the upper part of the stem

send sugar to apical meristems, but leaves on the lower part of the plant send sugar to the roots (**FIGURE 38.15b**).

Why would leaves send sugar to tissues on a certain side or part of the body? The answer hinges on understanding the structure of phloem.

The Anatomy of Phloem

Two specialized parenchyma cell types make up phloem: **sieve-tube elements** and **companion cells** (see Chapter 37). Unlike the tracheids and vessel elements that make up most of the xylem, sieve-tube elements and companion cells are alive at maturity.

Recall that, in most plants, sieve-tube elements lack nuclei and most other organelles. They are connected to one another, end to end, by perforated **sieve plates** (**FIGURE 38.16**). The pores create a direct connection between the cytoplasms of adjacent cells.

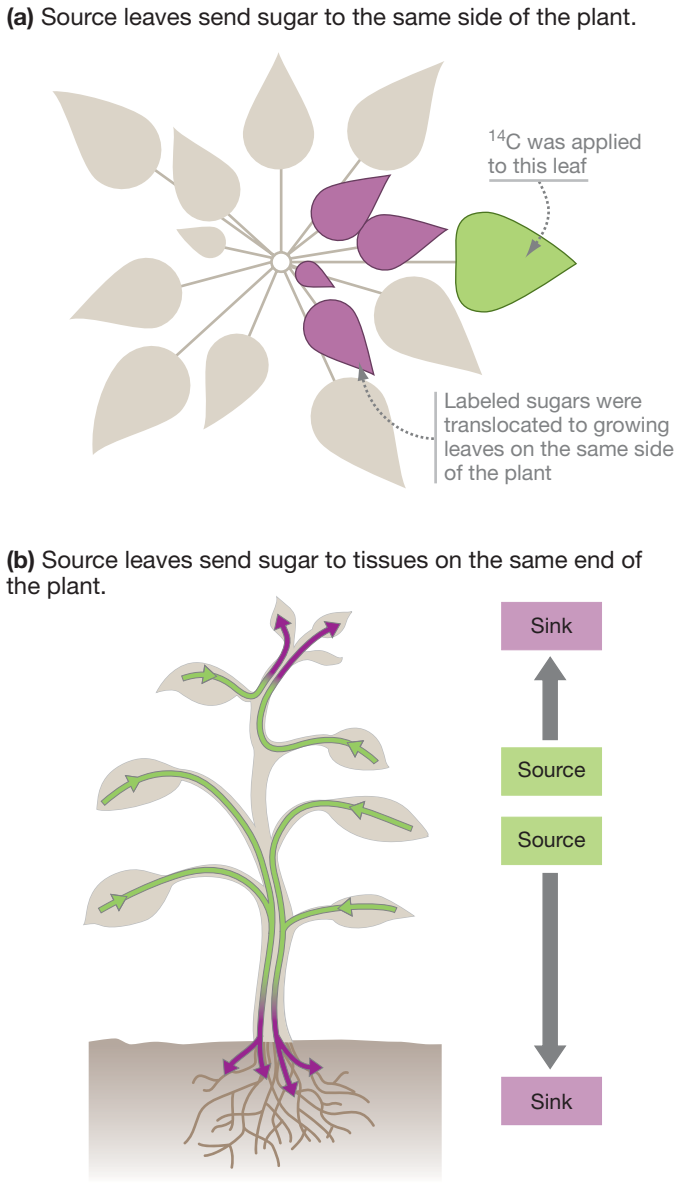

FIGURE 38.15 Sources Supply Sinks on the Same Side and Same End of the Body.

Companion cells, in contrast, have nuclei and a rich assortment of ribosomes, mitochondria, and other organelles. Companion cells function as "support staff" for sieve-tube elements.

You might also recall that the phloem in primary and secondary vascular tissue is continuous throughout the plant—meaning that there is a direct anatomical connection between the phloem from the tips of shoots to the tips of roots (see Chapter 37). The sieve-tube elements in phloem represent a continuous system for transporting sugar throughout the plant body.

Each vascular bundle runs the length of stems and roots, and certain bundles extend into specific branches, leaves, and lateral roots. Phloem sap does not move from one vascular bundle to another—instead, each bundle is independent.

Based on these results, the physical relationships observed between sources and sinks in herbaceous plants are logical. For example, the phloem in the leaves on one side of a plant connects directly with the phloem of branches, stems, and roots on the same side of the individual, through a specific set of vascular bundles.

The phloem sap that flows through vascular tissue is often dominated by the disaccharide **sucrose**—table sugar. Phloem sap can contain small amounts of minerals, amino acids, mRNAs, hormones, and other compounds as well. How does this solution move? What mechanism is responsible for translocating sugars from sources to sinks?

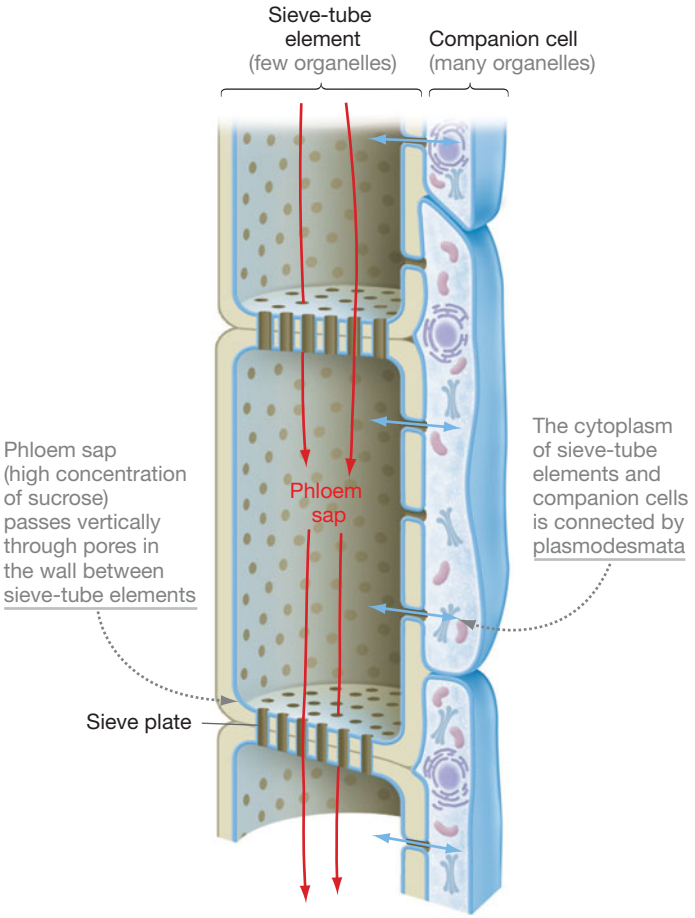

FIGURE 38.16 Sieve-Tube Elements Are Connected by Pores.

The Pressure-Flow Hypothesis

In 1926 Ernst Münch proposed the **pressure-flow hypothesis,** which states that events at source tissues and sink tissues create a pressure potential gradient in phloem (**FIGURE 38.17**). The water in phloem sap moves down this pressure gradient, and sugar molecules are carried along by bulk flow.

Like the cohesion-tension theory for water transport in xylem, the pressure-flow hypothesis is based on movement along a water-potential gradient created by changes in pressure potential. Unlike the cohesion-tension model, however, transpiration does not provide the driving force to move phloem sap. Instead, differences between turgor pressure in the phloem near source tissues and turgor pressure in the phloem near sink tissues generate the necessary force. Creating these differences in turgor pressure usually requires an expenditure of ATP.

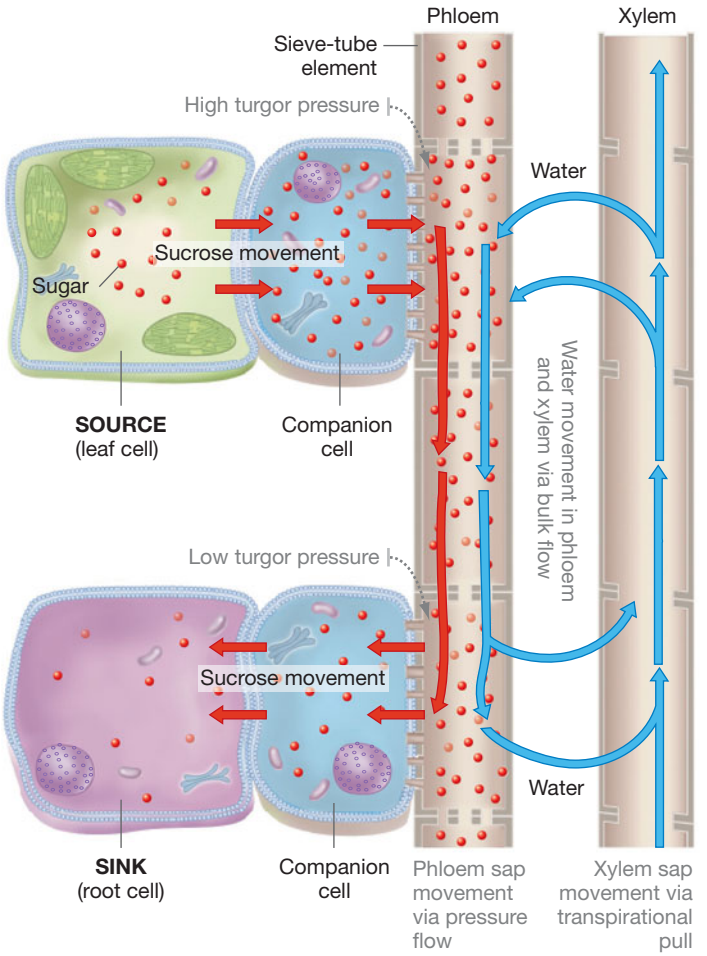

FIGURE 38.17 The Pressure-Flow Hypothesis: High Turgor Pressure Near Sources Causes Phloem Sap to Flow to Sinks. The pressure-flow hypothesis predicts that water cycles between xylem and phloem, and that water movement in phloem, is a response to a gradient in pressure potential.

✔**EXERCISE** This diagram shows how water moves between xylem and phloem in the middle of the growing season, when leaves are sources and roots are sinks. Add new arrows, in new colors, to indicate the direction of water and phloem sap flow in spring, when roots act as sources and leaves act as sinks.

Creating High Pressure Near Sources and Low Pressure Near Sinks To understand how Münch's model works, start with the source cell at the upper left in Figure 38.17. The small red arrows reflect Münch's proposal that sucrose moves from source cells into companion cells and from there into sieve-tube elements.

Because of this phloem loading, the phloem sap in the source tissue has a high concentration of sucrose. Compared to the water in the adjacent xylem cells in a vascular bundle, the phloem sap has a very low solute potential.

As the blue arrows in the upper part of the diagram show, water moves along a water-potential gradient—flowing passively from xylem across the selectively permeable plasma membrane of sieve-tube elements. In response, turgor pressure begins to build in the sieve-tube elements in the source region.

What is happening at the sink? Münch proposed that cells in the sink (bottom left in Figure 38.17) remove sucrose from the phloem sap by passive or active transport. As a result of this phloem unloading—a loss of solutes—the water potential in sieve-tube elements increases until it is higher than the water potential in adjacent xylem cells. As the blue arrows at the bottom of the figure show, water flows across the selectively permeable membranes of sieve-tube elements into xylem along a water-potential gradient. In response, turgor pressure in the sieve-tube elements in the sink drops.

The net result of these events is high turgor pressure in phloem at a source tissue and low turgor pressure in phloem at the sink, created by the loading and unloading of sugars, respectively. This difference in pressure potential drives phloem sap from source to sink via bulk flow. There is a one-way flow of sucrose and a continuous loop of water movement. Water returns to the source tissue via the xylem.

Testing the Pressure Flow Model The pressure-flow hypothesis is logical, given the anatomy of vascular tissue and the principles that govern water movement. But has any experimental work supported the theory? Some of the best tests have relied on aphids—small insects that make their living ingesting phloem sap.

Aphids insert a syringe-like mouthpart, called a stylet, into sieve-tube elements. The pressure on the fluid in these cells forces it through the stylet and into the aphid's digestive tract. Excess water and sucrose that the aphid does not need is excreted out its anus as droplets of "honeydew" (**FIGURE 38.18**).

If the aphids are then severed from their stylets, sap continues to flow out through the stylets. This phenomenon allows researchers to collect phloem sap efficiently for analysis. It also confirms that the aphids do not actively suck the fluid. As predicted by the pressure-flow model, phloem is indeed under pressure.

This observation supports one of the fundamental predictions of the pressure-flow hypothesis. Now the question is, How does sucrose enter and leave phloem in a way that sets up the water-potential gradient?

FIGURE 38.18 Aphids Feed on Phloem Sap. The tip of this aphid's mouthpart (the stylet) is in a sieve-tube element within the plant stem. The droplet emerging from the aphid's anus is honeydew, which consists of sugary phloem sap.

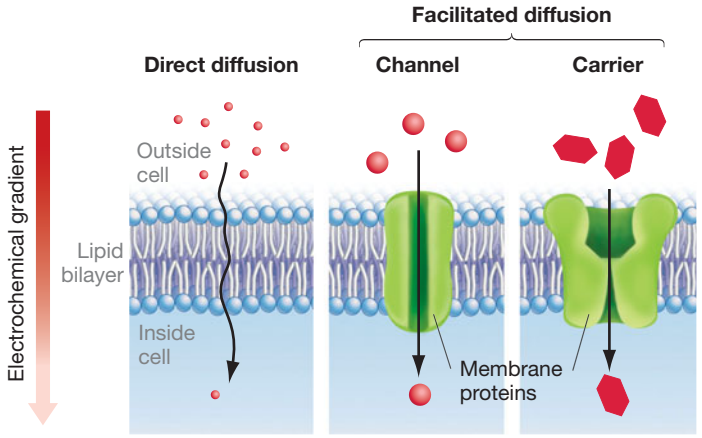

FIGURE 38.19 Passive Transport Is Based on Diffusion. In passive transport, ions or molecules diffuse across membranes—meaning they follow their electrochemical gradient. The movement can occur directly through the phospholipid bilayer or be facilitated by a channel or carrier protein.

Phloem Loading

In contrast to the cohesion-tension model of water movement in xylem, pressure flow often requires that plants expend energy to set up a water-potential gradient in phloem. To establish a high-pressure potential in sieve-tube elements near source cells, large amounts of sugar have to be transported into the phloem sap—enough to raise the solute concentration of sieve-tube elements. This requirement is illustrated in Figure 38.17, top left.

In some cases, loading is active—it requires an expenditure of ATP and some sort of membrane transport system. But when sucrose concentrations in source cells are extremely high, movement of sucrose into sieve-tube elements can also occur via passive diffusion through plasmodesmata.

Phloem unloading at sinks can also be active or passive, depending on the tissue. When sugar is unloaded against its concentration gradient, an expenditure of ATP and a second membrane transport mechanism is required. How do phloem loading and unloading occur? What specific membrane proteins are involved?

To answer these questions, let's start by reviewing how transport proteins make it possible for sugars and other large or charged substances to cross a phospholipid bilayer.

How Are Sucrose and Other Solutes Transported across Membranes?

Passive transport (**FIGURE 38.19**) occurs when ions or molecules move across a plasma membrane by diffusion—that is, along their electrochemical gradient. The adjective passive is appropriate because no expenditure of energy is required for the movement to occur.

Recall that small, uncharged molecules diffuse across phospholipid bilayers rapidly (Figure 38.19, left). But ions and many large molecules diffuse across phospholipid bilayers slowly if at all, even when their movement is favored by a strong electrochemical gradient. To diffuse rapidly, they must avoid direct contact with the phospholipid bilayer by passing through a membrane protein.

Two types of membrane protein—channels and carriers—facilitate the passive diffusion of specific ions or molecules (see Chapter 6).

- **Channel proteins** form pores that selectively admit certain ions (Figure 38.19, middle).
- **Carrier proteins** work like enzymes, undergoing a conformational change that transports a bound molecule across the lipid bilayer (Figure 38.19, right).

Channels and carriers are responsible for **facilitated diffusion.**

Active transport (**FIGURE 38.20**) occurs when ions or molecules move across a plasma membrane against their electrochemical gradient. The adjective active is appropriate because cells must expend energy in the form of ATP to move solutes in an energetically unfavorable direction.

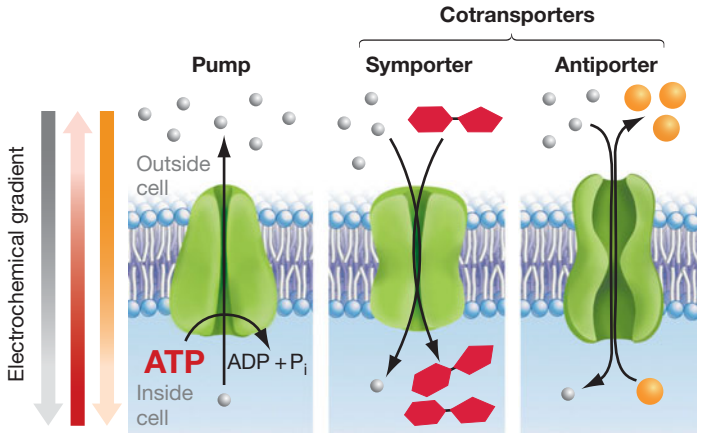

FIGURE 38.20 Active Transport Moves Ions or Molecules against an Electrochemical Gradient. All forms of active transport require an expenditure of ATP. Pumps use ATP directly; cotransport proteins use ATP indirectly. Cotransport depends on a previous expenditure of ATP by a pump.

Active transport always involves membrane proteins. **Pumps** are proteins that change shape when they bind ATP or a phosphate group from ATP. As they move, pumps transport ions or molecules against an electrochemical gradient.

Pumps establish an electrochemical gradient that favors the movement of an ion or molecule across the plasma membrane. For example, the pump on the left side of Figure 38.20 has established an electrochemical gradient for bringing the ions or molecules symbolized by the light gray balls into the cell.

In many cases, the electrochemical gradients established by pumps are used to transport other molecules or ions by two types of membrane proteins called **cotransporters.**

- **Symporters** transport solutes *against* a concentration gradient, using the energy released when a different solute moves in the same direction *along* its electrochemical gradient. The red molecules in the middle of Figure 38.20 are moving through a symporter.
- **Antiporters** work in a similar way, except that the solute being transported against its concentration gradient moves in the direction *opposite* that of the solute moving down its concentration gradient. The orange ions in Figure 38.20, right, are moving through an antiporter.

When solutes move through cotransport proteins, **secondary active transport** occurs.

Active transport, secondary active transport, and passive transport are all involved in moving sugars around plants. Let's look first at events at source tissues, where the active transport of sucrose into sieve-tube elements results in a high-pressure potential. The chapter concludes with a look at how the same molecules are unloaded to maintain low-pressure potentials at sinks.

How Are Sugars Concentrated in Sieve-Tube Elements at Sources?

Because sucrose may be more highly concentrated in companion cells than in photosynthetic cells where it is produced, researchers hypothesized that sucrose transport from source cells into companion cells may be active. Another key observation—that strong pH differences exist between the interior and exterior of phloem cells—suggested that sucrose might enter companion cells with protons, by secondary active transport.

FIGURE 38.21 explains the logic behind this hypothesis. Note this key claim: A membrane protein in companion cells hydrolyzes ATP and uses the energy that is released to transport protons (H^+) across the membrane to the exterior of the cell. Proteins like these are called **proton pumps,** or more formally, **H^+-ATPases.**

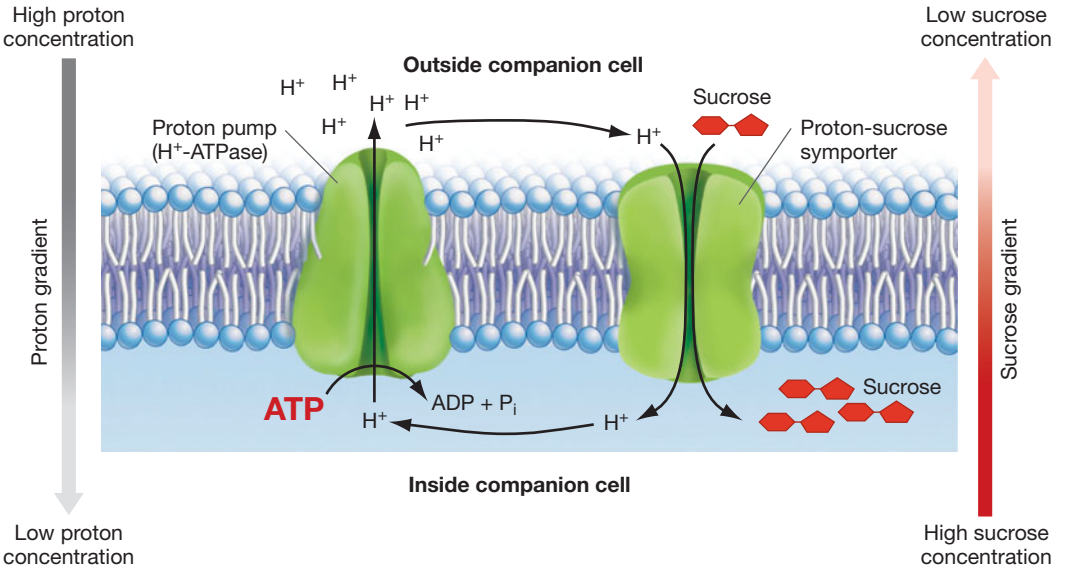
Proton pumps establish a large difference in charge and in hydrogen ion concentration on the two sides of the membrane. The resulting electrochemical gradient favors the entry of protons into the cell.

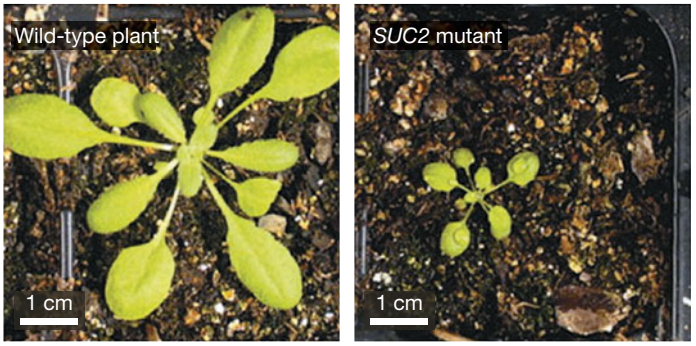
The right side of the figure shows the second key claim: A symporter acts as a conduit for protons and sucrose to enter the cell together. With this symporter, protons move along their electrochemical gradient; sucrose moves against its concentration gradient.

If phloem loading depends on the activity of a proton–sucrose symporter, a mutation in the gene encoding this protein should result in a plant that cannot export sucrose from leaves to various sink tissues. What would this mutant plant look like?

Michael Sussman's lab used the model plant *Arabidopsis thaliana* (see **BioSkills 13** in Appendix B) to isolate a mutant lacking a gene called *SUC2*. This gene was known to be expressed in vascular tissue and to encode a proton–sucrose symporter.

Mutant plants grew much more slowly than wild-type plants, indicating that something was indeed wrong with the mutant (**FIGURE 38.22a**). When the researchers looked at leaves under a microscope, they found that chloroplasts from mutant plants accumulated huge amounts of starch, an indication that they could not efficiently export sugar to the rest of the plant (**FIGURE 38.22b**). To test this hypothesis, the researchers then applied radioactive sucrose to a single source leaf on mutant and wild-type plants and measured where it went 5 hours later.





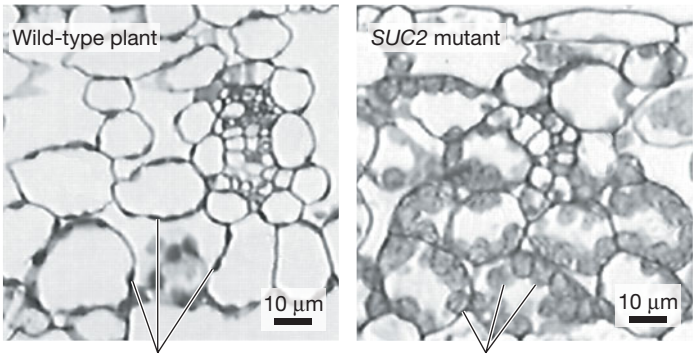


FIGURE 38.21 A Model for Cotransport of Protons and Sucrose. According to the model of cotransport, a proton pump hydrolyzes ATP to move hydrogen ions to the exterior of the cell. The resulting high concentration of H^+ outside the cell establishes an electrochemical gradient that allows the transport of sucrose into the cell against its concentration gradient.

(a) 21-day-old wild-type versus mutant plants

(b) Starch accumulation in wild type versus mutant

(c) Sucrose movement in wild type versus mutant

FIGURE 38.22 The Role of a Proton–Sucrose Symporter in Long-Distance Transport in Plants.

DATA: Gottwald, J. R., P. J. Krysan, J. C. Young, et al. 2000. *Proceedings of the National Academy of Sciences* 97: 13979–13984.

✔**QUESTION** Why did the researchers measure radioactivity after only 5 hours, and not wait a longer period such as 24 hours?

As **FIGURE 38.22c** shows, mutant leaves that were supplied with radioactive sucrose retained much more of the sucrose than wild-type leaves. Also, sink tissues in the mutant plants received much less radioactive sucrose than wild-type sink tissues. Without the proton–sucrose symporter in companion cells, mutant plants were impaired in their ability to load sucrose into phloem cells for long-distance transport and the excess sugar accumulated in leaves as starch.

There is now considerable genetic and biochemical evidence to support the following model for phloem loading:

1. Proton pumps in the membranes of companion cells create a strong electrochemical gradient that favors a flow of protons into companion cells.
2. A symporter in the membranes of companion cells uses the proton gradient to bring sucrose into companion cells from the surrounding cell walls and intercellular spaces around source cells.
3. Once inside companion cells, sucrose travels into sieve-tube elements via plasmodesmata.

Although work on the mechanism of phloem loading in *Arabidopsis* and other species continues, most researchers are convinced that proton pumps and proton–sucrose symporters play a key role. Now, once sucrose has been loaded into sieve-tube elements near sources and follows a water-potential gradient to sinks, how is it unloaded?

Phloem Unloading

The membrane proteins that are involved in transporting sucrose molecules out of the phloem, and the mechanism of movement, vary among different types of sinks within the same plant. Mechanisms for phloem unloading also vary among different species of plants.

To appreciate this diversity, consider how sucrose is unloaded in the phloem of sugar beets—a crop grown for the storage tissues in its root, which is a major source of the granulated and powdered sucrose sold in grocery stores.

check your understanding

C Y U

If you understand that . . .

- Phloem sap moves from areas of high water potential to areas of low water potential.
- In phloem, high turgor pressure is observed in the sieve-tube elements near source cells. This pressure is created by pumps that actively load sucrose into companion cells against a concentration gradient. Water follows by osmosis, creating high turgor pressure inside sieve tubes.
- At sinks, turgor pressure is much lower than it is at sources because storage cells or growing tissues remove sucrose from phloem sap. The removal of solutes in phloem causes water to leave phloem and enter xylem.

✔ You should be able to . . .

1. Explain why flow of phloem sap in a stem often changes direction between early spring and midsummer.
2. Explain the adaptive value of sieve cells having no nuclei and few other organelles.

Answers are available in Appendix A.

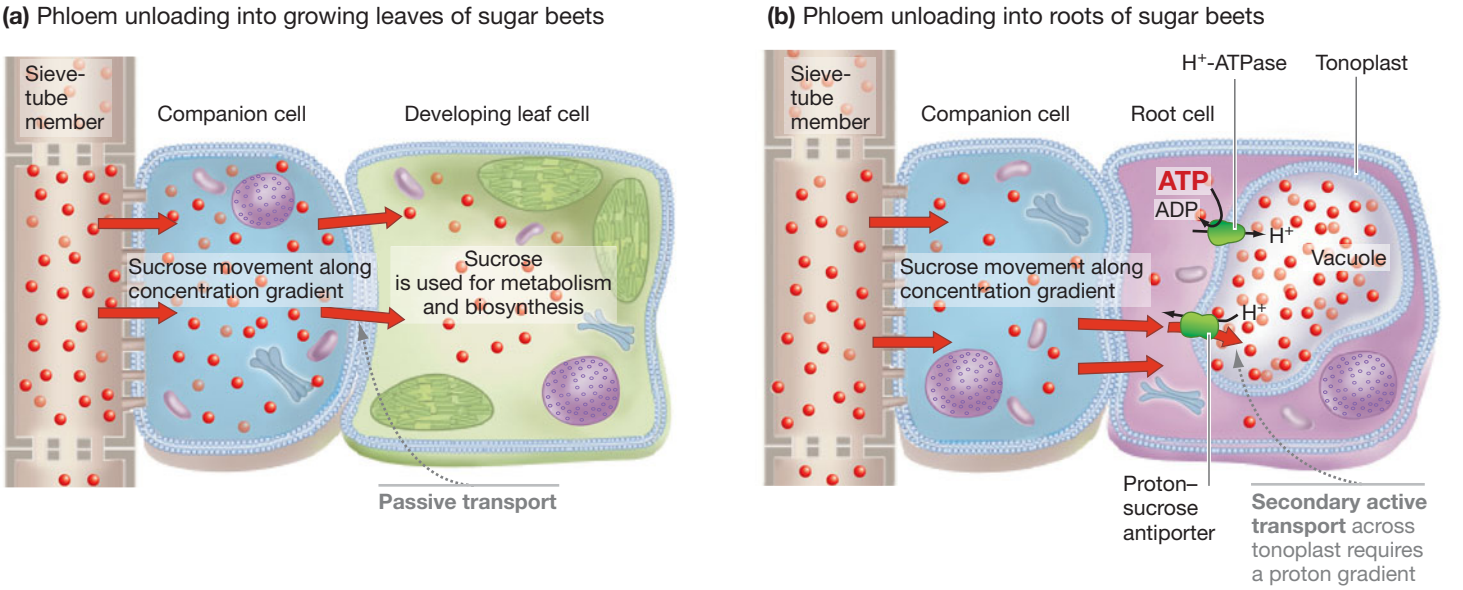

FIGURE 38.23 Phloem Unloading Occurs when Sucrose Is Moved Out of Phloem Tissue in Sinks. The mechanism of phloem unloading can vary from sink to sink, such as in **(a)** young leaves and **(b)** roots of the same plant.

In sugar beets, sucrose is unloaded along a concentration gradient into an important sink: young, growing leaves. The passive transport occurs because sucrose is rapidly used up inside the cells to provide energy for ATP synthesis and carbon for the synthesis of cellulose, proteins, nucleic acids, and phospholipids needed by the growing cells (**FIGURE 38.23a**).

In the roots of the same plant, however, an entirely different mechanism is responsible for unloading sucrose. Root cells in this species have a large vacuole that stores sucrose. The membrane surrounding this organelle is called the **tonoplast.** It contains two proteins that work together to accumulate sucrose in the vacuole, much like the phloem loading process described earlier. A different proton pump hydrolyzes ATP and uses the energy released to transport protons into the vacuole, against its concentration gradient (**FIGURE 38.23b**). A proton–sucrose cotransporter then uses the proton gradient to move sucrose up its concentration gradient. An important distinction in this case is that the cotransporter is an antiporter, while in source tissues it is a symporter.

The active transport of sucrose into the vacuole allows sucrose to move passively from phloem into the storage cells, keeping the water potential of the phloem sap near the sink low—as required by the Münch pressure-flow model.

To summarize, more than seven decades of research provide convincing evidence that the pressure-flow hypothesis is fundamentally correct.

The cohesion-tension theory for water movement and the pressure-flow model for phloem sap movement represent major advances in our understanding of how plants work.

CHAPTER 38 REVIEW

For media, go to MasteringBiology

If you understand . . .

38.1 Water Potential and Water Movement

- Plants lose water as an inevitable consequence of exchanging gases with the atmosphere. The flow of water from soil to air via plant tissues transports minerals to the shoot and follows a water-potential gradient.
- Water potential (ψ) is a measure of the tendency of water to move down its potential energy gradient and is expressed as megapascals (MPa).
- In plants, water potential has two components: **(1)** a solute potential, formed by the concentration of solutes in a cell or tissue; and **(2)** a pressure potential, provided by the cell wall and other factors. The water potential of a cell, tissue, or plant is the sum of its solute potential and pressure potential.
- When selectively permeable membranes are present, water moves by osmosis from areas of high solute potential to areas of low solute potential.

- When no membranes are present, water moves by bulk flow from areas of high pressure to areas of low pressure, independently of differences in solute potential.

✔ **You should be able to explain why water in the xylem of a root moves up through the shoot in response only to a pressure gradient—not a solute gradient.**

38.2 How Does Water Move from Roots to Shoots?

- According to the cohesion-tension theory, water is pulled in one continuous column from the soil to roots to shoots, against the force of gravity, by the surface tension caused by transpiration from leaves.
- Surface tension occurs at menisci that form as water evaporates from the walls of leaf cells, and it is transmitted downward via hydrogen bonding between water molecules. In this way, the energy in sunlight is responsible for the movement of water from roots to shoots.

✔ **You should be able to suggest a hypothesis for why the pressure potential of water in a leaf, and thus the rate of water movement up a stem, change when the Sun goes behind a cloud.**

38.3 Water Absorption and Water Loss

- Plants that occupy dry habitats have traits that limit the amount of water they lose to transpiration. These include narrow, needle-like leaves or stomata that are located in pits on the undersides of their leaves.
- CAM and C_4 photosynthetic cycles are adaptations in some plants that limit water loss in dry habitats.

✔ **You should be able to explain how CAM plants avoid losing very much water despite living in deserts.**

38.4 Translocation of Sugars

- Translocation is the movement of sucrose and other products through the plant.
- According to the Münch pressure-flow model, sugars move from sources to sinks via bulk flow along a pressure gradient that develops in phloem.
- A pressure gradient is generated by the active transport of sugars into sieve-tube elements in source tissues, coupled with the transport of sucrose out of sieve-tube elements at sink tissues. Water moves osmotically from xylem into sieve-tube elements near sources and cycles back to xylem near sinks.

✔ **You should be able to explain why the pressure-flow model would not work if xylem and phloem were not bundled together.**

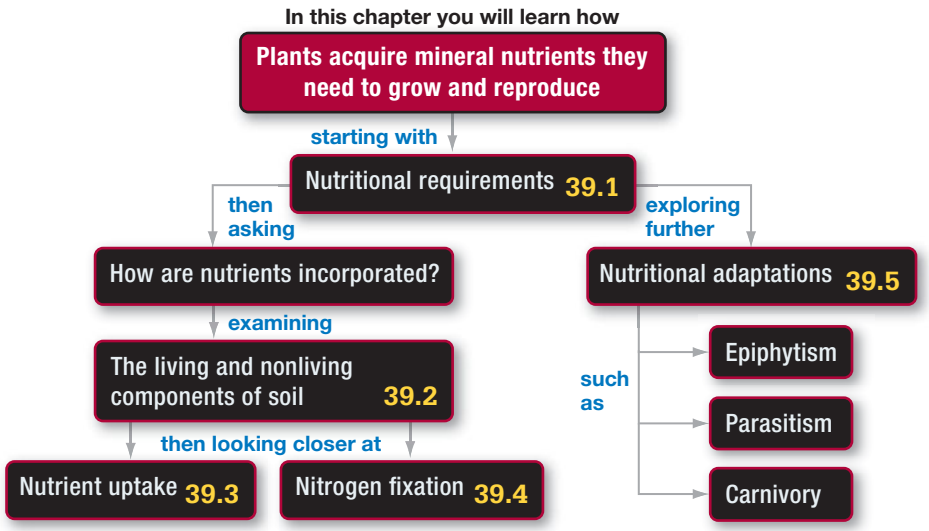
TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. Under what conditions does the rate of transpiration increase?
   a. when the temperature of a leaf decreases
   b. when stomata close at night
   c. during rainstorms, when atmospheric pressure is low
   d. when the weather changes and air becomes drier
2. The cells of a certain plant species can accumulate solutes to create very low solute potentials. Which of the following statements is correct?
   a. The plant's transpiration rates will tend to be extremely low.
   b. The plant can compete for water effectively and live in dry soils.
   c. The plant will grow most effectively in soils that are saturated with water year round.
   d. The plant's leaves will wilt easily.
3. What forces are responsible for capillarity?
   a. adhesion of water molecules to the sides of xylem cells, cohesion of water molecules to each other, and surface tension
   b. surface tension created by transpiration and cohesion of water molecules in a continuous flow from leaf to root
   c. high solute potentials created by the entry of ions during the night, when transpiration rates are low, followed by an influx of water
   d. gravity and wall pressure (from the sides of xylem cells)
4. What is a proton pump?
   a. a membrane protein that transports sucrose against a concentration gradient
   b. a membrane protein that transports protons against an electrochemical gradient
   c. a membrane protein that transports protons *along* an electrochemical gradient and sucrose *against* a concentration gradient
   d. any membrane protein that acts as a channel—meaning it does not consume ATP
5. The Casparian strip is located in what type of root cells?
6. Proteins in sieve-tube elements must be encoded by nuclei in what cells?

TEST YOUR UNDERSTANDING

Answers are available in Appendix A



7. Why is the transport of phloem sap considered an active process?
   a. The manufacture of sucrose via photosynthesis is driven by the energy in sunlight.
   b. Transpiration is driven by the energy in sunlight.
   c. ATP is used to transport sucrose into companion cells near sources, against a concentration gradient.
   d. In spring, phloem sap moves against the force of gravity.
8. Draw a plant cell in pure water. Add dots to indicate solutes inside the cell. Now add dots to indicate an increase in solute potential inside the cell. Add an arrow showing the direction of water movement in response. Add arrows showing the direction of wall pressure and turgor pressure in response to water movement. Repeat the same exercise; but this time, add solutes to the solution outside the cell at a concentration that is greater than the inside of the cell.
9. Compare and contrast the forces involved in transporting water in xylem via root pressure, capillarity, and transpiration. Which of these mechanisms is/are passive?
10. Why are "cohesion-tension" and "pressure-flow" sensible names for the hypotheses analyzed in this chapter?
11. How does the movement of solutes through cotransport proteins result in phloem loading?
12. A seed is a sink when it is forming inside the parent plant. When is it a source?

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A

13. A mutant plant lacking the ability to pump protons out of leaf companion cells will be unable to do which of the following?
   a. transpire from leaves
   b. load sucrose into sieve cells
   c. carry out photosynthesis
   d. transport water through the xylem
14. Suppose that plants over 1 meter tall had to expend energy to transport water from their roots to their leaves. What would be the consequences in terms of growth rates and overall height?
15. When young trees are transplanted to a new site, it takes several weeks or months for their root systems to grow and establish a high capacity to take up water. If a heat wave occurs during this period, the trees are likely to die—but not of starvation or loss of turgor. What kills them?
16. A recent paper indicates that the aquaporins in plasma membranes of cells throughout a plant close in response to drought stress. How does the closing of these channels help plant cells maintain turgor?

39 Plant Nutrition

In most plants, roots obtain the water and key nutrients required for individuals to survive and thrive.

The most urgent tasks facing any organism are to acquire **(1)** carbon-containing molecules that will be used as cellular building blocks and **(2)** the chemical energy required to make ATP. Plants acquire both of these by producing sugar through the process of photosynthesis.

Yet plants cannot live on sugar alone. Besides making the carbohydrates they need, plants synthesize all of their own nucleic acids, amino acids, enzymes, chlorophylls, enzyme cofactors, and other molecules necessary to grow and reproduce. Plants do some of the world's most impressive synthetic organic chemistry.

A plant's ability to perform sophisticated reactions depends on its capacity to harvest as raw materials a wide variety of elements in the form of simple ions and molecules. In addition to carbon dioxide and water, plants have to obtain nitrogen, phosphorus, potassium, sulfur, magnesium, and other elements. Most of these nutrients exist in soil, the majority as ions that are dissolved in soil

BIG PICTURE

This chapter is part of the Big Picture. See how on pages 840–841.

water at low—sometimes extremely low—concentrations. Once these ions are inside roots, the one-way flow of water up the xylem carries the nutrients throughout the plant body.

The plant body is an efficient machine for harvesting these diffuse resources and concentrating them in cells and tissues. You have been introduced to how the organization and growth of the plant root and shoot systems make resource acquisition possible (see Chapter 37) and how water and nutrients are transported throughout the plant body (see Chapter 38). This chapter concentrates on how plants take up elements from the soil so that these nutrients can be transported to the cells that need them.

Questions about nutrition are fundamental to understanding how plants work, increasing agricultural productivity and maintaining the productivity of forests that supply lumber and fuel—as well as mitigate temperature increases associated with global climate change (see Chapter 56) by transforming atmospheric CO_2 into wood. Let's begin by analyzing the basic nutritional needs of plants—the equivalent of the minimum daily requirements in humans.

39.1 Nutritional Requirements of Plants

What do plants need to live? In the early 1600s, Jean-Baptiste van Helmont performed a classic experiment designed to answer this question. Van Helmont wanted to know where the mass of a growing plant comes from, and he used a willow tree as a study organism.

As **FIGURE 39.1** shows, he began by placing 90 kilograms (kg) of soil in a pot with a 2-kg willow sapling. He allowed the plant to grow for five years, adding only water. At the end of the experiment, he weighed the willow and the soil. The willow had gained about 74 kg while the soil had lost only 60 grams (g).

Where had the additional 74 kg of tree come from? Because he was not aware that gases have mass, van Helmont hypothesized that the new plant material came from water. He also ignored the loss of 60 g in the soil, chalking it up to measurement error.

As it turned out, van Helmont's measurements were not the problem—his conclusions were. Most of the added mass of the tree came from carbon dioxide in the atmosphere. The 60 g removed from the soil contained vital elements—the nutrients that are the focus of this chapter. What are they?

About half the elements in the periodic table—more than 60—can be found in the tissues of one or more plant species. The question that biologists, farmers, and foresters ask is, Which of these elements are essential for growth and reproduction in most species, and in what quantities?

Which Nutrients Are Essential?

Biologists define an **essential nutrient** as an element or compound that is required for normal growth and reproduction—meaning that the plant cannot complete its life cycle without this nutrient. Essential nutrients cannot be synthesized by the organism.

Researchers test whether a nutrient is essential by denying a specific element to plants and documenting what happens to the plants over time. For most vascular plants, 17 elements are essential. Just three of these—carbon, hydrogen, and oxygen—typically make up about 96 percent of the dry weight of a plant. The remaining 14 elements are sometimes called mineral nutrients, because they originate in soil.

Although different classification schemes for the essential elements have been proposed, the most common is based on

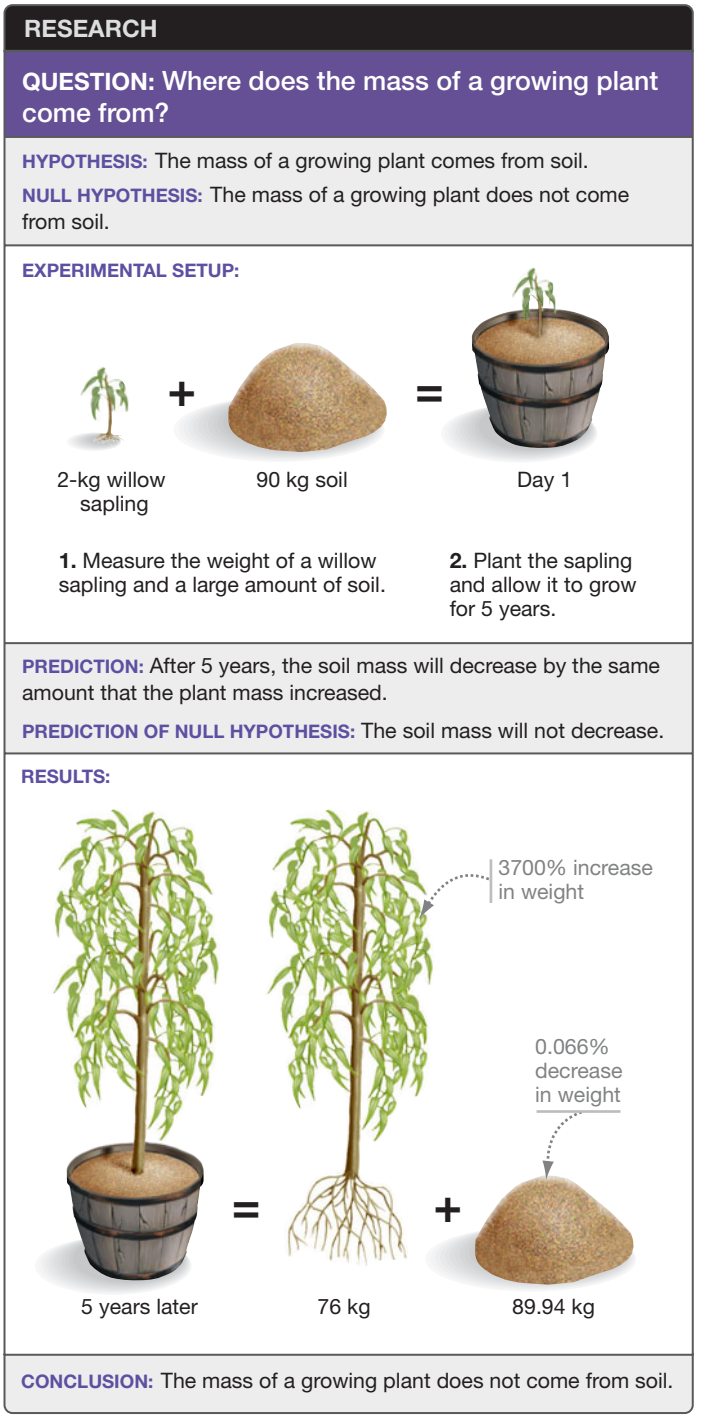

FIGURE 39.1 An Early Experiment on the Role of Soil in Plant Nutrition.

✔**QUESTION** Many nonbiologists think that most of a plant's mass comes from soil or water. Describe an experiment that would convince someone that most of a plant's mass comes from CO_2.

distinguishing nutrients that are obtained from water or air versus soil and then dividing soil nutrients into macronutrients and micronutrients based on their abundance in plants (**TABLE 39.1**, see page 778).

Macronutrients Certain elements in the soil are required by plants in relatively large quantities; these are called **macronutrients.** Some of these are major components of nucleic acids, proteins, and phospholipids, all of which are plentiful in plants.

Among the macronutrients, nitrogen (N), phosphorus (P), and potassium (K) are particularly important because they often act as **limiting nutrients,** meaning their availability limits plant growth. If N, P, and/or K are added in appropriate quantities to soil as fertilizer, plant growth usually increases. This observation explains why the leading ingredients in virtually every commercial fertilizer are N, P, and K.

Micronutrients In contrast to macronutrients, **micronutrients** are required in small quantities. When plant tissues are dried and analyzed, micronutrients are typically present in only trace amounts. Instead of acting as components of macromolecules, micronutrients usually function as cofactors for specific enzymes—substances that are required for normal enzyme function (see Chapter 3).

It's important not to underestimate the importance of micronutrients, even though only tiny amounts are needed. For example, a typical plant contains just one molybdenum atom for every 60 million hydrogen atoms in its body, not including water. Yet plants die without molybdenum, because it functions as a cofactor for several enzymes involved in nitrogen processing. What happens to plants when other essential nutrients are missing?

What Happens When Key Nutrients Are in Short Supply?

In some cases, biologists can examine a plant that is growing poorly and diagnose a nutrient deficiency (**FIGURE 39.2**). For example, if older leaves are in poor condition, the problem is probably due to lack of N, P, K, or magnesium. These elements are mobile—meaning they are readily transported from older leaves to younger leaves when they are in short supply—so older leaves deteriorate first when these elements are scarce. Immobile nutrients like iron or calcium, in contrast, stay tied up in older leaves. When they are in short supply, younger leaves are the first to show deficiency symptoms. Deficiencies in the various nutrients produce symptoms specific to each nutrient (see Table 39.1).

In large part, the ability to diagnose nutrient deficiencies is based on studies involving hydroponic growth systems. **Hydroponic growth** takes place in liquid cultures, without soil, so researchers can precisely control the availability of each nutrient.

Consider an experiment on copper deficiency in tomatoes (**FIGURE 39.3**). Researchers grew seedlings in two types of treatments. One treatment consisted of flasks containing water and

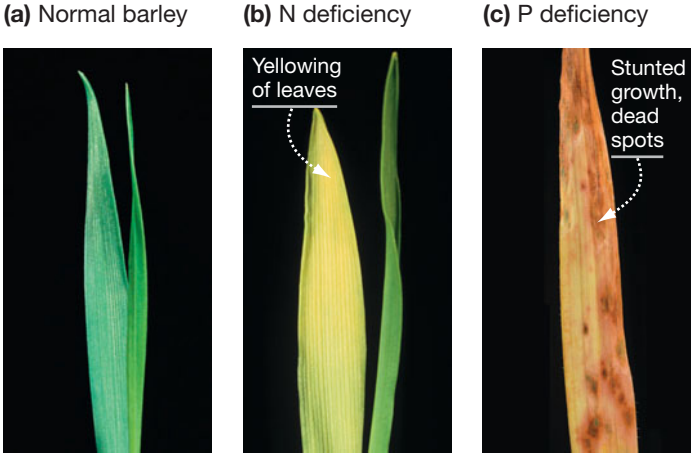

FIGURE 39.2 Nutrient Deficiencies Can Have Distinctive Symptoms.

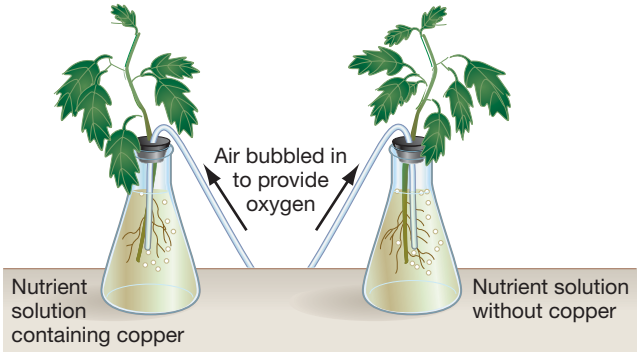

RESEARCH

QUESTION: How does copper deficiency affect plants?

HYPOTHESIS: Plants denied copper will grow poorly.

NULL HYPOTHESIS: Plants denied copper will grow normally.

EXPERIMENTAL SETUP:

PREDICTION: The copper-deficient plant will grow less than the normal plant.

PREDICTION OF NULL HYPOTHESIS: Both plants will grow the same.

RESULTS:

CONCLUSION: Copper deficiency leads to poor growth. All tissues appear to be affected adversely.

FIGURE 39.3 Hydroponics Is Used to Study Nutrient Deficiencies.

✔**QUESTION** What problem would arise if this experiment had been done in soil with and without added copper?

all the essential nutrients in the relative concentrations that are optimal for tomato growth. The second treatment was identical, except that the nutrient solution lacked copper.

As Figure 39.3 shows, copper-deprived individuals have stunted shoots, unnaturally light-colored foliage, and curled leaves. Given copper's role as a cofactor or component of several enzymes involved in redox reactions required for ATP production, it is understandable that all tissues in the plant were severely affected. And because copper is a micronutrient, it is reasonable to expect that a relatively small amount would cure the deficiency. In line with this prediction, the researchers found that the symptoms were prevented if the plants were cultured in a solution containing just 0.002 milligrams per liter (mg/L) of copper. Analogous studies have been done on the other essential nutrients.

For farmers, foresters, and plant ecologists, understanding which nutrients are essential, and why, is basic to understanding why certain plants thrive and others fail. Now, where do these nutrients come from? The answer—soil—is simple. But soil itself is astonishingly complex.

39.2 Soil: A Dynamic Mixture of Living and Nonliving Components

The process of soil building begins with solid rock. As **FIGURE 39.4** shows, **weathering**—the forces applied by rain, running water, temperature changes, and wind—continually breaks tiny pieces off large rocks. The weathering process is accelerated if small cracks develop in the rock. If plant roots grow into the crack, they expand as they grow, widen the crack, and break off small flakes or pebbles. A similar effect occurs in high latitudes or at high elevations when water enters the cracks, freezes in winter, expands, and breaks off pieces.

Depending on their size and composition, the particles resulting from these processes are called gravel, sand, silt, or clay. These rock fragments are the first ingredient in soil. As organisms occupy the substrate, they add dead cells and tissues and feces. This decaying organic matter is called **humus** (pronounced *HEW-muss*).

With time, soil eventually becomes a complex and dynamic mixture of inorganic particles, organic particles, and living organisms. In a single gram of soil there are normally dozens of small animals and plant roots; hundreds of thousands of protists, fungi, and microscopic animals; and hundreds of millions of bacteria and archaea (**FIGURE 39.5**).

Both the parent rock that contributes inorganic soil components and the organisms and organic matter that occupy soils vary from one site to another. **Texture**—the proportions of gravel, sand, silt, and clay—and other soil qualities vary as well. Soil texture is important for several reasons:

- Texture of a soil affects the ability of roots to penetrate and obtain water and nutrients, as well as to anchor and support the plant body. For example, soil that is dominated by clay-sized particles tends to compact and resist root penetration.
- Texture affects a soil's ability to hold water and make it available to plants. Water tends to adhere to clay and silt particles but runs through sand and gravel.
- A soil's texture and water content dictate the availability of oxygen. Like other eukaryotes, plants have to take in oxygen to use as an electron acceptor during cellular respiration. The oxygen used by plant root cells is found in air pockets among soil particles. This explains why overwatering a plant is just as detrimental as underwatering it: Overwatering drowns a plant's roots.

The best soils for plants, called loams, contain roughly equal amounts of sand, silt, and clay, along with a high proportion of humus.

Loams that have good texture and large amounts of organic matter can take thousands of years to develop through the weathering of rocks and the continual addition of humus. Unfortunately, it can take just a few years of abuse by humans for loams to blow or wash away.

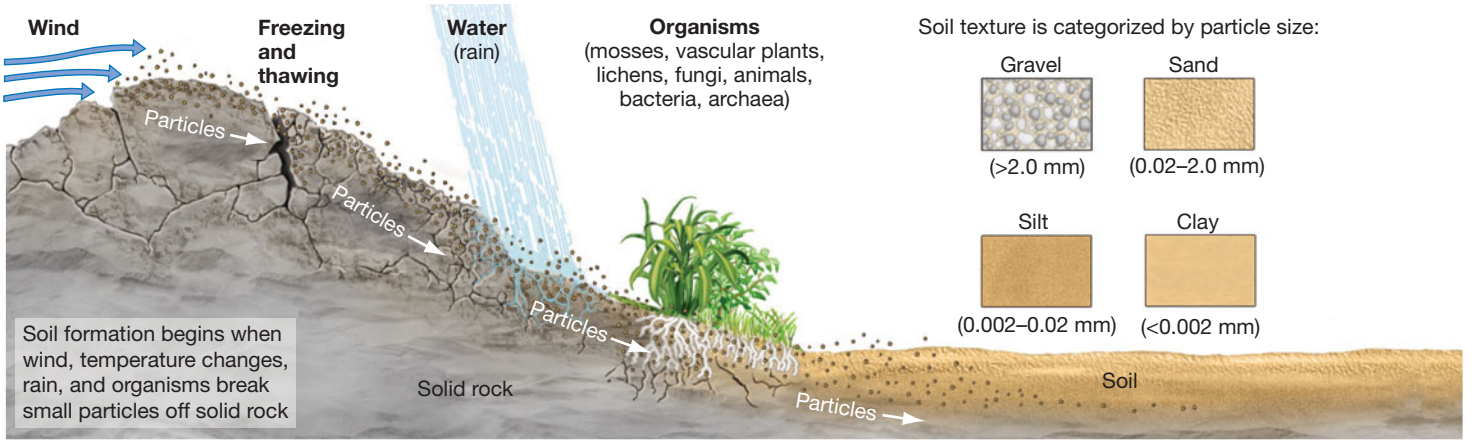

FIGURE 39.4 Soil Formation Begins with Weathering of Rock.

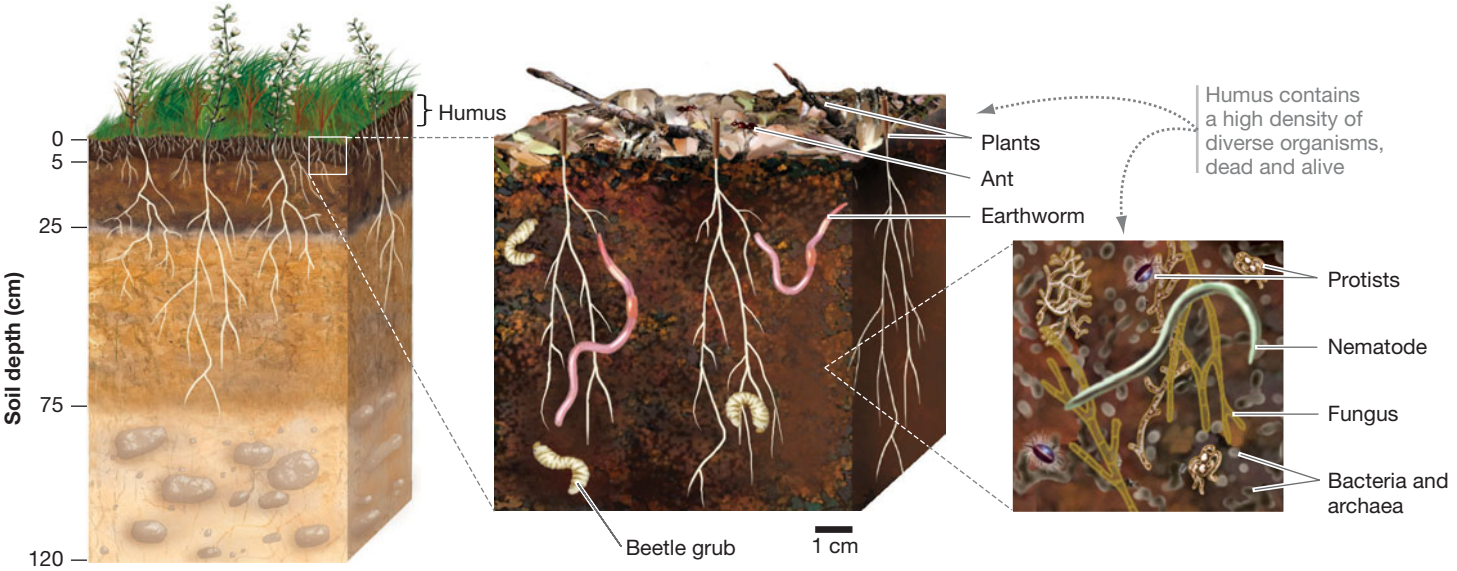

FIGURE 39.5 Mature Soils Are a Complex Mixture of Organic and Inorganic Components. In addition to mineral particles, soil contains humus—organic material derived from dead organisms—and a wide array of living organisms.

The Importance of Soil Conservation

Soil erosion occurs when soil is carried away from a site by wind or water. Soil erosion occurs naturally, such as when rivers cut away at their banks and carry material downstream. In most natural environments, though, the rate of soil formation exceeds the rate of soil erosion, so soils build up over time. Unfortunately, the situation can change dramatically when humans exploit an area.

When plant cover is removed for forestry, farming, or suburbanization, stems and leaves can't lessen the force of wind and rain, and plant roots no longer hold soil particles in place. The results can be devastating. At some locations in the United States, 8–10 centimeters (cm) of topsoil were blown away during the Dust Bowl of the 1930s, when drought and poor farming practices left thousands of hectares of soil unprotected (**FIGURE 39.6a**).

U.S. soil erosion rates have declined dramatically since then. Still, researchers estimate that almost 30 percent of all croplands in the United States are eroding too fast to maintain their long-term productivity. Deforestation is also exposing forest soils, contributing to disasters such as the mudslides and flooding that occurred in the Dominican Republic and Haiti in 2004, killing close to 5000 people. **FIGURE 39.6b** provides an aerial view of devastating mudslides that occurred in 2007 in the U.S. state of Washington, after recent deforestation. Worldwide, an estimated 36 billion tons of soil are lost to erosion every year.

(b) Mudslides caused by deforestation

FIGURE 39.6 Soil Erosion Can Have Devastating Consequences.

TABLE 39.1 Essential Nutrients

Element	Form Available to Plants	Functions	Average % Dry Weight*	Deficiency Symptoms
Obtained from Water or Air: H_2O or CO_2				
Oxygen	O_2, H_2O	Electron acceptor in cellular respiration; major component of organic compounds	45	Usually affects roots: cells suffocate, leading to root rot and wilting
Carbon	CO_2	Substrate for photosynthesis; major component of organic compounds	45	Slow growth (starvation)
Hydrogen	H_2O	Major component of organic compounds; functions in electrical balance and establishment of electrochemical gradients	6	Slow growth due to cell death (desiccation)
Obtained from Soil: Macronutrients				
Nitrogen	NO_3^- (nitrate) NH_4^+ (ammonium ion)	Component of proteins, nucleic acids, ATP, chlorophyll, hormones, and coenzymes	1.5	Failure to thrive; chlorosis (yellowing of older leaves)
Potassium	K^+	Necessary for osmotic adjustment in cells; required for synthesis of organic molecules; cofactor for some enzymes	1.0	Chlorosis at margins of leaves or in mottled pattern; weak stems; short internodes
Calcium	Ca^{2+}	Regulatory functions; role in cell wall structure; stabilizes membranes; involved in signal transduction; enzyme cofactor	0.5	Necrosis (small spots of dead cells) in meristems; deformation of young leaves; stunted, highly branched root system
Magnesium	Mg^{2+}	Chlorophyll component; activates many enzymes	0.2	Chlorosis between leaf veins; premature leaf drop
Phosphorus	$H_2PO_4^-$ (dihydrogen phosphate ion) HPO_4^{2-} (hydrogen phosphate ion)	Component of ATP, nucleic acids, phospholipids, and several coenzymes	0.2	Stunted growth in young plants; dark green leaves with necrosis
Sulfur	SO_4^{2-} (sulfate ion)	Component of proteins containing methionine and cysteine; electron transport proteins and coenzymes	0.1	Stunted growth; chlorosis
Obtained from Soil: Micronutrients				
Chlorine	Cl^- (chloride ion)	Needed for water-splitting step of photosynthesis; functions in water balance and electrical balance	0.01	Wilting at leaf tips; general chlorosis and necrosis of leaves or development of bronze color
Iron	Fe^{3-} (ferric ion) Fe^{2-} (ferrous ion)	Necessary for chlorophyll synthesis; component of cytochromes and ferredoxin; enzyme cofactor	0.01	Chlorosis between veins of young leaves
Manganese	Mn^{2+}	Involved in photosynthetic O_2 evolution; enzyme activator; important in electron transfer	0.005	Chlorosis between leaf veins and small necrotic spots
Zinc	Zn^{2+}	Involved in synthesis of the plant hormone auxin, maintenance of ribosome structure, enzyme activation	0.002	Small internodes; stunted and distorted ("puckered") leaves
Boron	$H_2BO_3^-$ (borate ion)	Strengthens cell walls; required for pollen tube growth and normal membrane function	0.002	Black necrosis in young leaves and buds
Copper	Cu^+ (cuprous ion) Cu^{2+} (cupric ion)	Cofactor of some enzymes; present in lignin of xylem	0.0006	Light-green leaves with necrotic spots; twisted and malformed leaves
Nickel	Ni^{2+}	Cofactor for enzyme functioning in nitrogen metabolism	[no data]	Necrosis at leaf tips
Molybdenum	MoO_4^{2-} (molybdate ion)	Cofactor in nitrogen reduction; essential for nitrogen fixation	0.00001	Chlorosis between veins; necrosis of older leaves

*These percentages were obtained by drying vascular plants and documenting what proportion of the waterless mass consists of various elements.

If soil is managed carefully, however, it can be a renewable resource. Techniques that maintain long-term soil quality and productivity are the basis of **sustainable agriculture** and sustainable forestry. Farmers can reduce soil loss dramatically by

- planting rows of trees as windbreaks;
- using techniques that minimize the amount of plowing and tilling needed to control weeds; and
- planting crops in strips that follow the contour of hillsides.

Farmers can also maintain soil quality by adding organic material in the form of manures and, soon after a harvest, planting cover crops that are plowed in and allowed to decompose.

What Factors Affect Nutrient Availability?

The elements required for plant growth are found in the soil not as atoms, but as **ions.** The second column of Table 39.1 lists the ion forms of some essential nutrients available to plants. Notice that some of these nutrients are available as elemental ions, such as K^+ or Cl^-, while others exist as molecular ions, such as HPO_4^{2-} or NO_3^-.

Anions and Cations Behave Differently The ions present in soil tend to behave in one of two ways, depending on their charge (**FIGURE 39.7**). Anions—ions with negative charges—usually dissolve in soil water, because they interact with water molecules via hydrogen bonding. Phosphate ions, an exception to this rule, tend to form insoluble complexes with iron, aluminum, calcium, or other positively charged cations.

Because they exist as solutes, negatively charged anions are readily available to plants for absorption. They are also easily washed out of the soil by rain, however. The loss of nutrients via the movement of water through soil is called **leaching.**

Cations—ions with positive charges—dissolve in soil water but are not as immediately available as anions. In solution, cations interact with the negative charges found on two types of soil particles: **(1)** organic matter that is rich in negatively charged organic acids; and **(2)** the surfaces of the tiny, sheetlike particles called clay, which are rich in mineral anions (see Figure 39.7).

Organic soils that contain clay tend to retain nutrients, because few positively charged cations leach away and because these soils hold water (and thus anions) better than sandy soils do. The presence of clay makes cations more difficult for plants to extract and use because the cations are tightly bound to the clay.

The Role of Soil pH In addition to soil texture, other factors can influence the availability of essential elements. Perhaps the most important of these is soil pH.

Recall that the pH scale indicates the relative concentration of hydrogen ions in a solution, and that it ranges from 0 to 14 (see Chapter 2). Soils with low pH have a relatively high concentration of hydrogen ions and are considered acidic. Soils with a high pH contain relatively few hydrogen ions and are termed basic or alkaline.

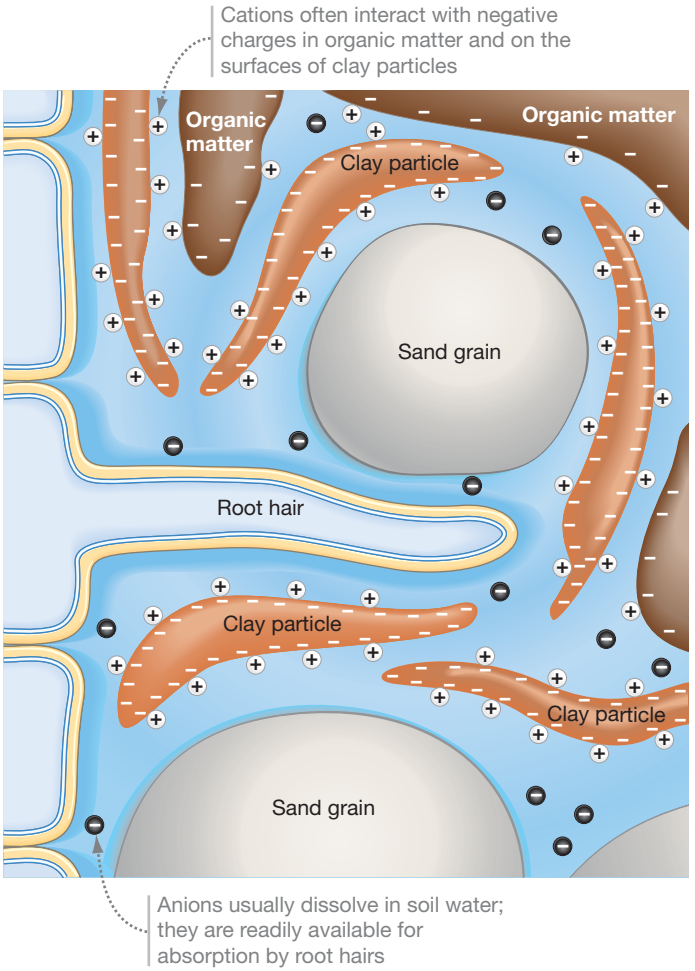

FIGURE 39.7 Cations Tend to Bind to Clay Particles and Organic Matter; Anions Stay in Solution.

Acidic soils are found in regions such as conifer forests, where the decomposition of organic matter produces carbonic acid, phosphoric acid, or nitric acid. Alkaline soils, in contrast, are common in regions where limestone ($CaCO_3$) is abundant. When limestone reacts with water, the calcium ions that are released take the place of protons that cling to soil particles. The protons then react with CO_3^{2-} to form bicarbonate ions (HCO_3^-), lowering the hydrogen ion concentration of the soil and raising its pH.

Most plants thrive in soils with a relatively neutral pH—between 6 and 7. But some plants, such as blueberries, grow best in acidic soils (pH around 3 to 5); others such as lavender, rosemary, and fennel, thrive on alkaline soils (pH above 8).

Cation Exchange Soil pH affects the availability of plant nutrients in a number of ways. For example, the presence of protons in soil water can cause the release of cations that are bound to soil particles. The process responsible is called **cation exchange.** Cation exchange occurs when protons or other soluble cations bind to negative charges on soil particles and

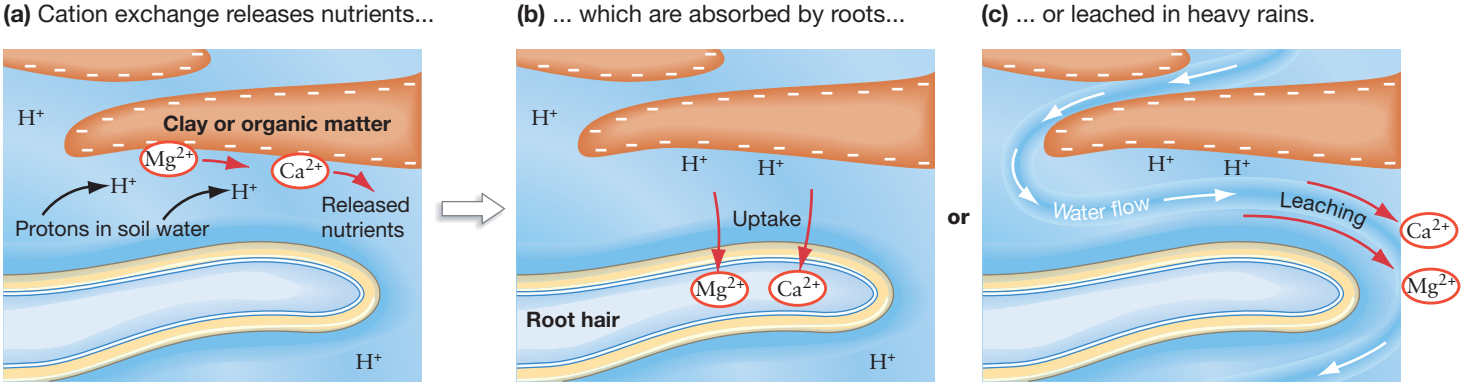

FIGURE 39.8 Cation Exchange Releases Nutrients Bound to Soil Particles. When cation exchange occurs, a proton binds to negative charges on clay or organic matter, releasing bound cations.

cause bound cations, such as magnesium or calcium, to be released from the soil (**FIGURE 39.8a**). Nutrients that are released by cation exchange become available for uptake by nearby plant roots (**FIGURE 39.8b**).

Plants influence cation exchange because root cells release CO_2 as a by-product of cellular respiration (see Chapter 9). The CO_2 reacts with H_2O to form carbonic acid, which releases protons.

If soil is too acidic, however, rain may leach cations away before the roots can take up nutrients (**FIGURE 39.8c**). In many tropical rain forests around the world, deforestation for agriculture has resulted in acidic, nutrient-poor soils that are not productive.

To summarize, anions stay in solution in soil water. They are readily available to plants but may wash away easily. Positive ions, in contrast, tend to bind to soil particles but can be released by cation exchange.

TABLE 39.2 details how the presence of sand, clay, and organic matter affects ion availability and other soil properties, including water availability. Based on these properties, it is not surprising that the most productive soils are loams that are a mixture of sand, clay, and organic matter.

Nutrients are found at extremely low concentrations in soil but at high concentrations in plant cells. How are plants able to bring N, P, K, and other key elements into their bodies against a concentration gradient?

39.3 Nutrient Uptake

In most species of plants, the root system is the site of nutrient uptake. You have been introduced to the general features of root anatomy (see Chapter 37) and the role of roots in water uptake (see Chapter 38). Now we need to explore the detailed anatomy of roots and analyze events that occur in the plasma membranes of their epidermal and cortex cells.

Most nutrient uptake occurs just above the growing root tip, in the region called the **zone of maturation.** Recall that epidermal cells in this part of the root have extensions called **root hairs** (**FIGURE 39.9**). Root hairs dramatically increase the surface area available for nutrient and water absorption. For example, the root system of a single annual rye plant can have a total surface area the size of a basketball court. Most of this area—60 percent—is found in an estimated 10^{10} root hairs.

Root hairs are so numerous and so efficient at absorbing nutrients from soil that, over time, they create a "zone of nutrient depletion" in soil immediately surrounding them. The creation of this mined-out region is why continued root growth is vital to a plant's health. Because roots continue to grow throughout a plant's life, the zone of maturation is continually entering new and potentially nutrient-rich areas of soil.

If an epidermal cell encounters soil where nutrients are available, what happens? How do ions enter?

TABLE 39.2 Effects of Soil Composition on Soil Properties

Composition	Water Availability	Nutrient Availability	Oxygen Availability	Root Penetration Ability
Sand	Low: water drains through	Low: poor capacity for cation exchange; anions leach out	High: many air-containing spaces	High: does not pack tight
Clay	High: water clings to charged surface	High: large capacity for cation exchange; anions remain in solution	Low: few air-containing spaces	Low: packs tight
Organic matter	High: water clings to charged surface	High: source of nutrients; large capacity for cation exchange; anions remain in solution	High: many air-containing spaces	High: does not pack tight

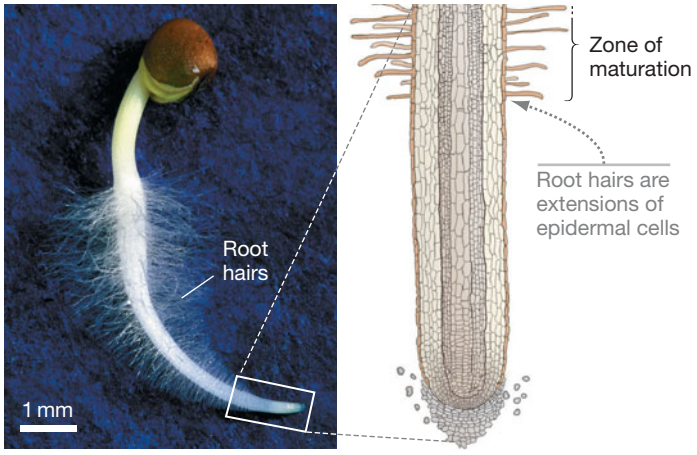

FIGURE 39.9 Root Hairs Increase the Surface Area Available for Nutrient Absorption.

Mechanisms of Nutrient Uptake

Ions, small molecules, and even large molecules can pass through the plant cell wall freely. The plasma membrane, in contrast, is highly selective. Recall that the plasma membrane is a fluid, sheetlike structure consisting of a phospholipid bilayer studded with proteins (see Chapter 6). Because the interior of the phospholipid bilayer is nonpolar and hydrophobic, it resists the passage of ions—even ions that are required by the plant. Some membrane proteins span the bilayer, however, and allow specific ions to cross the membrane.

Because root hairs have such a large surface area, they contain large numbers of membrane proteins that bring nutrients into the cytosol of root cells. These membrane proteins cannot import the ions that the plant needs completely on their own, however. They often function in tandem with another protein, a proton pump.

Establishing a Proton Gradient Plants harvest diffuse nutrients and concentrate them in their tissues. In an epidermal cell, ions such as potassium (K^+), hydrogen phosphate (HPO_4^{2-}), and nitrate (NO_3^-) are many times more concentrated than they are in the soil water outside the cell. For these and other ions to enter the cell, they have to cross the plasma membrane against a strong concentration gradient. How is this possible?

As **FIGURE 39.10a** shows, the answer hinges on **proton pumps,** or H^+-ATPases. These proteins are found in the plasma membranes of root epidermal and cortex cells, and they are similar to the pumps that make it possible for companion cells to load sucrose into phloem against a strong concentration gradient. Recall that when a phosphate group from ATP binds to the pumps, they change conformation in a way that allows them to transport protons to the exterior of the cell (see Chapter 38).

The activity of proton pumps leads to a strong excess of protons on the exterior of the plasma membrane relative to the interior. In the case of root cells, this differential results in a strong pH gradient favoring the movement of protons back into the cell. In addition, the outside of the membrane becomes positively charged relative to the inside. Stated another way, there is a separation of charge—a **voltage**—across the membrane.

Proton pumps are found in all types of plant cells, and all plant cell membranes carry a voltage. Because voltage is a form of potential energy, the charges that are separated by the membrane create a **membrane potential,** or difference in electrical charge across a cell membrane. How is the membrane potential used to transport ions?

Using a Proton Gradient to Import Cations In the membranes of root cells, the electrical gradient established by proton pumps, which favors the entry of positive ions, is strong enough to overcome the pH gradient, which opposes the entry of these cations. In essence, plant cells are batteries that are charged up to attract nutritionally necessary cations.

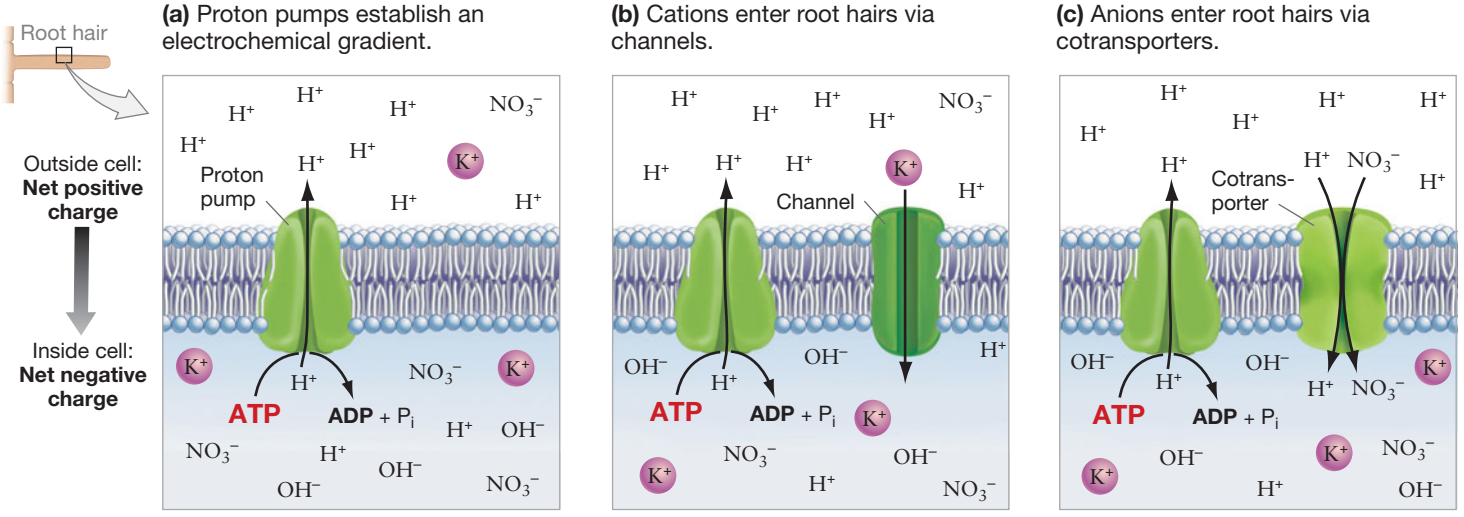

FIGURE 39.10 Ions Enter Roots along Electrochemical Gradients Created by Proton Pumps.

✔**EXERCISE** In part (b), add an arrow labeled "Proton gradient." In part (c), add an arrow labeled "Electrical gradient" and indicate its positive–negative polarity.

To drive this point home, consider potassium cations. Potassium is an essential nutrient in plants because it is required as a cofactor by over 40 enzymes. In addition, it is found at relatively high concentrations inside plant cells and plays a key role in bringing water into cells via osmosis and maintaining normal turgor pressure.

Researchers who added radioactive potassium ions to the solution outside a root cell and followed their movement found that K^+ does indeed accumulate in cells due to an electrochemical gradient (**FIGURE 39.10b**). In follow-up experiments, biologists were able to isolate the membrane protein responsible for the uptake of K^+ and sequence the gene that encodes the protein.

✔ If you understand this concept, you should be able to explain what happens to cation uptake if (1) H^+-ATPases fail, and (2) a molecule blocks a cation channel.

Cations like K^+ enter root hairs through membrane proteins along an electrochemical gradient, but how is it possible for anions to enter? The negatively charged interior of the cell should repel these ions.

Using a Proton Gradient to Import Anions **FIGURE 39.10c** shows how anions such as NO_3^- are able to enter root hairs against their electrochemical gradient. The key is that anions enter through membrane transport proteins called cotransporters (see Chapter 38), which transport two solutes at once. In this case, the cotransporter is a symporter: It brings NO_3^- into the cell along with a proton, and both solutes move in the same direction.

Here's the key observation: So much energy is released when a proton enters the cell along its electrochemical gradient that nitrate, phosphate ions, or other anions can be cotransported against their electrochemical gradients.

To summarize, the electrochemical gradient set up by proton pumps makes it possible for plant roots to absorb key cations and anions via ion channels and symporters, respectively. **✔ If you understand this concept, you should be able to explain what happens to anion uptake if (1) H^+-ATPases fail, and (2) a molecule blocks an anion symporter.**

Once ions have crossed the plasma membrane of an epidermal or cortex cell in the root, they continue to move via the symplast and through the endodermis toward the central vascular tissue. Recall that the endodermis is the site of the Casparian strip, which blocks the movement of ions and water through the apoplast (see Chapter 38). Once inside the endodermal layer, ions are actively transported out of cells, where they accumulate in the xylem sap. The ions are then transported passively by bulk flow to tissues throughout the plant.

Nutrient Transfer via Mycorrhizal Fungi To synthesize proteins and nucleic acids, plants need to extract large quantities of nitrogen and phosphorus from the soil. But soils typically contain such low concentrations of these nutrients that they limit plant growth. For example, in many habitats soil nitrogen is largely unavailable to plants because it is found in proteins that are part of the organic matter. How do plants absorb enough N and P to satisfy their nutritional needs? In most cases, they rely on partnerships with fungi that live in close association with their roots.

You might recall that fungi and plant roots that live in association are called **mycorrhizae** (literally, "fungus-root") (see Chapter 32). Mycorrhizal fungi and plants are **symbiotic** ("living-together"), meaning that they live in physical contact with each other. Biologists estimate that more than 80 percent of all vascular plant species associate with mycorrhizal fungi.

In some habitats, plants receive large quantities of nitrogen from mycorrhizal fungi. The fungal symbionts in these associations are particularly efficient at digesting macromolecules (proteins and nucleic acids) in decaying organic material and absorbing the amino acids (a source of nitrogen) and phosphate ($H_2PO_4^-$) that are released. As supported by experimental evidence described earlier (see Chapter 32), the mycorrhizal fungi then transport the nutrients from soil to plant roots (**FIGURE 39.11**). In exchange for these nutrients, the plant symbionts transfer sugars and other photosynthetic products to the fungi. Because there is a reciprocal exchange of nutrients, the symbiotic relationship is considered **mutualistic,** or mutually beneficial.

Fungi are particularly efficient at acquiring the nutrients required by plants, for two reasons:

1. Networks of filamentous hyphae increase the surface area available for absorbing nutrients by up to 700 percent.
2. Fungi can acquire nutrients from macromolecules in the soil that are unavailable to non-mycorrhizal plants.

Most plant species grow slowly and are overwhelmed by competitors if denied their mycorrhizal associates.

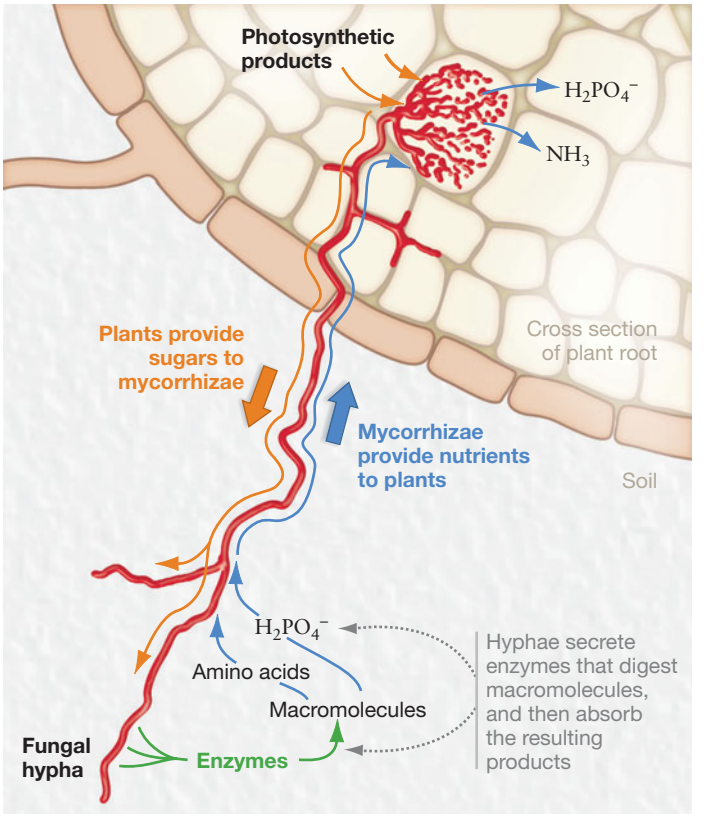

FIGURE 39.11 Most Mycorrhizal Fungi and Plants Are Mutualists. The fungus illustrated here provides nutrients to its host plant in exchange for photosynthetic products.

Mechanisms of Ion Exclusion

Plants have sophisticated systems for absorbing nutrients using membrane transporters and energy from the proton gradients they generate. Not all ion uptake is beneficial, however.

Certain types of natural soils—as well as soils that have been contaminated by waste products from mining or smelting operations—contain enough cadmium, zinc, nickel, lead, or other metals to poison enzymes in most plants. Sodium is also detrimental at high concentrations: Too much Na^+ inside cells can disrupt enzyme function, and too much Na^+ in extracellular spaces can create a solute potential that pulls enough water out of cells to result in a loss of turgor.

Sodium poisoning is a key issue in an array of environments, including **(1)** ocean coastlines, **(2)** habitats near roads that are treated with salt to melt ice and snow, and **(3)** irrigated farmlands. When soils are irrigated, solutes are left behind when water evaporates from the surface—leading to salt buildup over time.

How do plants exclude ions that are detrimental?

Passive Exclusion Ions move across roots following the same routes that water follows: the apoplastic, transmembrane, and symplastic pathways (see Chapter 38). Many ions do not enter the root symplast, simply because epidermal and cortex cells lack the requisite membrane transporters. If cells lack the membrane protein required for a certain ion to enter the cell, the ion won't enter. This is a form of passive exclusion.

Ions that move across the root cortex via the apoplastic pathway may never make it to xylem. To understand why, recall that the Casparian strip forces all solutes that travel through the root apoplast to cross the plasma membrane of endodermal cells before moving into the xylem (see Chapter 38). Ions that cannot enter endodermal cells via membrane transporters are excluded from entering the rest of the plant.

By having membrane transporters only for the ions that it requires, a plant can control which ions enter the symplast. Ions that reach the endodermis via the apoplastic pathway are blocked by the presence of the Casparian strip, so endodermal cells act as a selective filter—preventing unnecessary ions from reaching the xylem. The Casparian strip also qualifies as a mechanism for the passive exclusion of metals, sodium, or other ions (**FIGURE 39.12**).

The number of ion transporters present in a root is also important in determining the toxicity to certain ions. For example, salt-tolerant strains of corn transport much less salt into their roots than salt-intolerant strains—possibly because of genetic variation in the number of sodium channels found in root cells. Among species, rice is notoriously sensitive to salt buildup. Barley, in contrast, is relatively tolerant to high salt concentrations in soil.

Active Exclusion by Metallothioneins Plants also have mechanisms for coping with toxins once they are inside their cells. This is important because even essential nutrients are toxic at high enough concentrations.

Copper channels, for example, admit the small amounts of copper ions required for normal cell function. But plants that grow on soils near copper-mining operations experience large concentration gradients that favor an influx of this nutrient, so a surplus is likely to build up inside the plant body. How do plants deal with copper and other types of excess nutrients before they poison key enzymes?

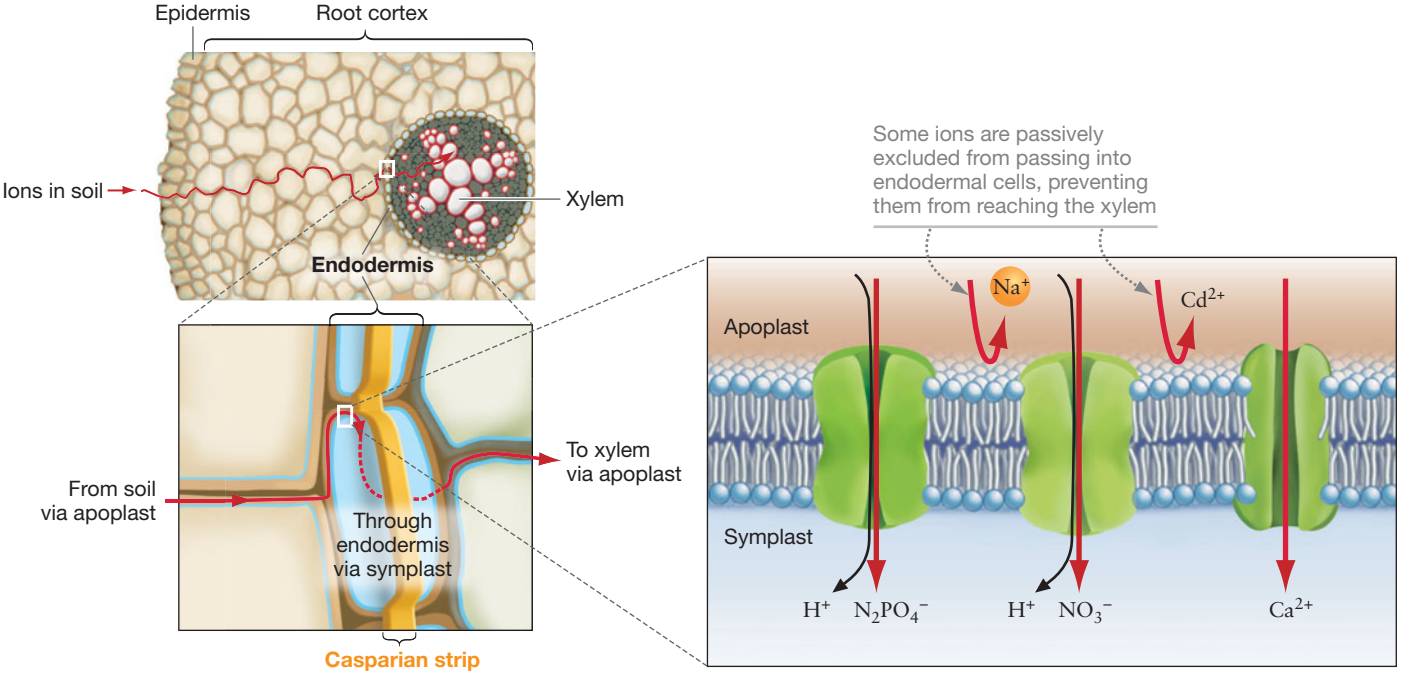

FIGURE 39.12 Passive Exclusion Occurs at the Plasma Membrane. Certain ions are excluded from cells because it is difficult for them to cross the plasma membrane.

One mechanism for coping with toxic concentrations of metals involves small proteins called **metallothioneins.** Metallothioneins bind to metal ions and prevent them from acting as a poison. Producing metallothionein proteins requires an expenditure of energy and represents a form of active exclusion.

Genes for metallothioneins have been found in a wide variety of organisms—bacteria, fungi, and animals as well as plants. Recent research on the mustard-family species *Arabidopsis thaliana* has shown that individuals from populations with a high tolerance for copper produce many more metallothionein proteins than do individuals from populations with a low tolerance for copper. (For more on the importance of *Arabidopsis thaliana* as a model organism, see **BioSkills 13**, Appendix B.)

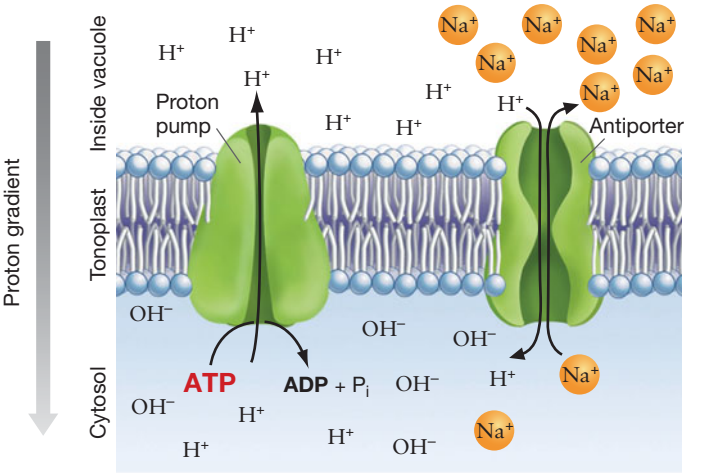
Active Exclusion by Antiporters A second mechanism for actively neutralizing specific toxins involves transport proteins located in the **tonoplast**—the membrane surrounding the large, central vacuole. Proteins in the tonoplast membrane allow plants to actively remove toxic substances from the cytosol and store them in the vacuole.

Perhaps the best-studied example involves proteins that move sodium ions from the cytosol into vacuoles, where they cannot poison enzymes (**FIGURE 39.13a**). H^+-ATPases in the tonoplast move protons into the vacuole, creating an electrochemical

check your understanding

C Y U

If you understand that . . .



- Plants absorb most of the nutrients they need via membrane proteins in root hairs.
- Proteins in the plasma membranes of root-hair, cortex, and endodermal cells pump protons out of the cells, creating an electrochemical gradient that favors the entry of selected ions via ion channels or cotransporters.
- In many species, mycorrhizal fungi are important for bringing ions that contain nitrogen or phosphorus atoms into the root.
- If no membrane proteins in the epidermal, cortex, or endodermal cells of a root admit a certain type of ion, that ion is passively excluded from entering the root.
- Plants can actively exclude toxic ions by pumping them into vacuoles or binding them to metallothionein proteins.

✓ You should be able to . . .

1. Explain how plants generate and use electrical power to import cations and anions.
2. Make a diagram that traces a cadmium ion (Cd^{2+}) from the soil into the plant, showing how it is excluded at different locations by passive and active mechanisms of ion exclusion.

Answers are available in Appendix A.

(a) In the tonoplast, antiporters send H^+ out of, and Na^+ into the vacuole.

(b) Plants with additional H^+/Na^+ antiporters tolerate salt.

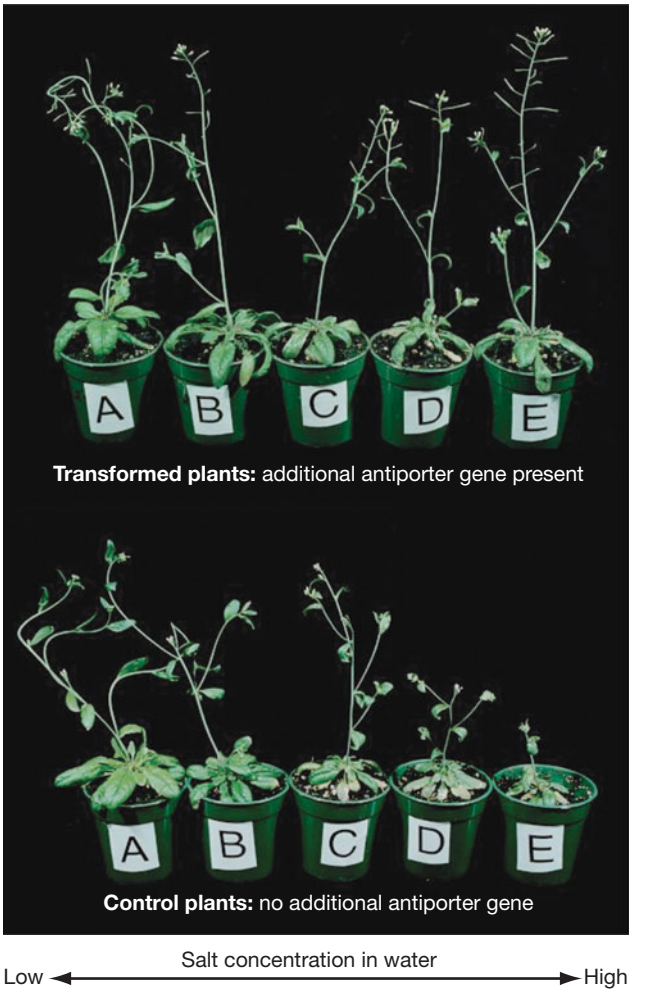


FIGURE 39.13 In Salt-Tolerant Plants, an Antiporter Concentrates Sodium in Vacuoles. (a) In the tonoplast of salt-tolerant species, proton pumps establish a proton gradient. This gradient allows antiporters to concentrate sodium ions inside the vacuole, where they cannot poison enzymes in the cytoplasm. **(b)** *Arabidopsis* plants that were transformed with the gene for the antiporter protein grow well even when watered with salty water.

gradient that favors the movement of H^+ out of the vacuole. A transport protein that functions as an **antiporter** then uses this gradient to conduct protons *out* of the vacuole, move them down their electrochemical gradient, and bring sodium ions *into* the vacuole—against the sodium concentration gradient.

Recall that an antiporter is a cotransporter involved in moving the solutes in opposite directions instead of the same direction—as solutes do through symporters (see Chapter 38).

Knowledge of this H^+/Na^+ antiporter has created a great deal of excitement among biologists, because it offers a way to alter crop plants genetically so that they can grow well in salty soils created by poor irrigation practices. As an example, consider an experiment in which normal *Arabidopsis* plants and individuals transformed with extra copies of the *Arabidopsis* gene for the H^+/Na^+ antiporter were exposed to different levels of NaCl. The genetically transformed plants accumulated more sodium in their vacuoles, and as **FIGURE 39.13b** shows, they were able to grow efficiently even when exposed to high concentrations of salt.

39.4 Nitrogen Fixation

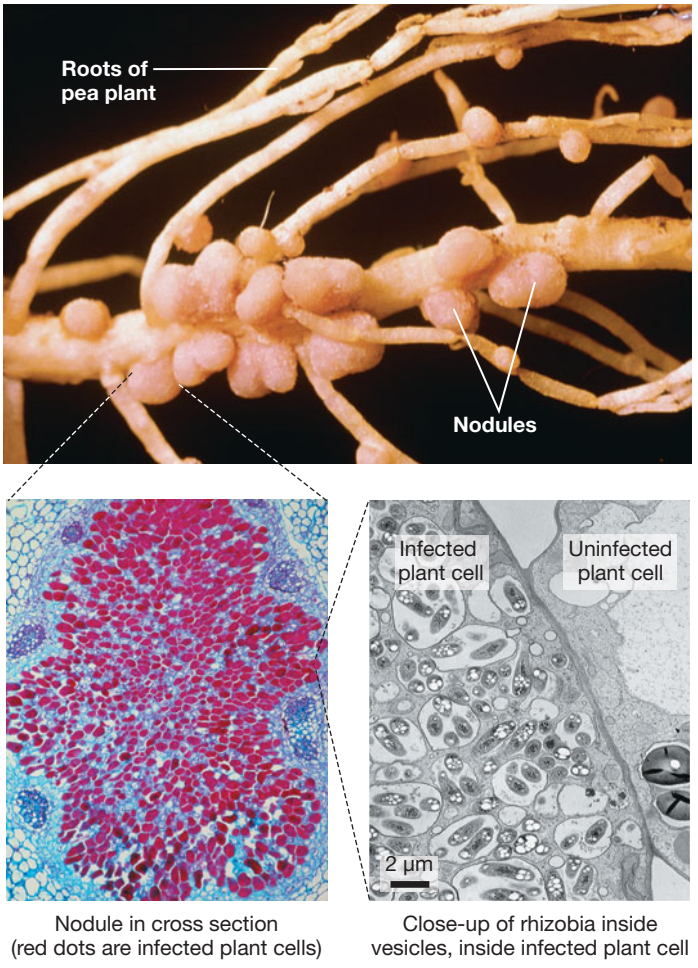
Nitrogen gas (N_2) makes up 80 percent of the atmosphere. Unfortunately, plants and other eukaryotes cannot use nitrogen in this form. Nitrogen gas is unreactive because it takes a great deal of energy to break the triple bond between the two nitrogen atoms.

To synthesize amino acids, nucleic acids, and other nitrogen-containing compounds, plants normally absorb nitrogen in forms such as ammonium (NH_4^+) or nitrate ions. But these ions are in short supply in many soils, meaning that plant growth is often limited by the availability of usable nitrogen. Most crop plants grow much faster when they receive a nitrogen-containing fertilizer.

Nitrogen-based fertilizers have drawbacks, however. Fertilizer production is extremely energy intensive, and in many parts of the world, ammonia and other nitrogen-based fertilizers are too expensive for farmers. In more affluent regions, these fertilizers are used so extensively that they are causing serious pollution problems (see Chapter 29). For these and other reasons, there is intense interest in understanding the molecular basis of a phenomenon called biological nitrogen fixation.

The Role of Symbiotic Bacteria

Among all the organisms on the tree of life, only a few species of bacteria and archaea are able to absorb N_2 from the atmosphere and convert it to ammonia (NH_3), nitrites (NO_2), or nitrates. This process is called **nitrogen fixation.**



Nitrogen fixation requires a series of specialized enzymes and cofactors, including a large multi-enzyme complex called nitrogenase. The process is extremely energy demanding. An expenditure of 8 high-energy electrons and 16 ATP molecules is required for nitrogenase to reduce one molecule of N_2 to two molecules of NH_3. The process can be summarized as follows:

$$N_2 + 8\,e^- + 8\,H^+ + 16\,ATP \longrightarrow 2\,NH_3 + H_2 + 16\,ADP + 16\,P_i$$

In some cases, bacterial cells that are capable of nitrogen fixation take up residence *inside* plant root cells. Although several different bacteria and plant hosts can be involved, the best-studied nitrogen-fixing bacteria are members of the genus *Rhizobium* that associate with plants in the **legume** family, which includes peas, soybeans, clover, and alfalfa. Members of the bacterial genus *Rhizobium* and closely related species are often called **rhizobia.**

Because of their ability to fix nitrogen, legumes are extremely important agricultural crops. A legume crop is often planted after harvesting a grain crop such as corn or wheat, so it can add nitrogen to the soil. This type of crop rotation results in "free" nitrogen fertilizer that benefits the next grain crop. Because legumes are rich in nitrogen, they are an important part of the human diet in many parts of the world.

As **FIGURE 39.14** shows, the infected root cells of legumes form distinctive structures called **nodules,** where nitrogen-fixing rhizobia are found. The nodules are pink because they contain an iron-containing molecule called leghemoglobin (short for legume hemoglobin). **Leghemoglobin** is related to the hemoglobin that carries oxygen in your blood. Like hemoglobin, leghemoglobin binds oxygen.

Nodule in cross section (red dots are infected plant cells)

Close-up of rhizobia inside vesicles, inside infected plant cell

FIGURE 39.14 In Some Plants, Roots Form Nodules Where Nitrogen-Fixing Bacteria Live.

Leghemoglobin is important because nitrogenase—the enzyme complex responsible for nitrogen fixation—is poisoned by the presence of oxygen. Inside root nodules, oxygen molecules bind to leghemoglobin instead of binding to nitrogenase. In this way, leghemoglobin keeps levels of free oxygen low enough for nitrogenase to function while maintaining a source of oxygen for electron transport to occur. Intense cellular respiration and ATP synthesis are necessary to supply nitrogenase with the energy it requires.

If roots allowed bacterial pathogens to enter, the plant would possibly die from the subsequent infection. How do roots distinguish beneficial bacteria from pathogens and allow only the rhizobia to infect the roots?

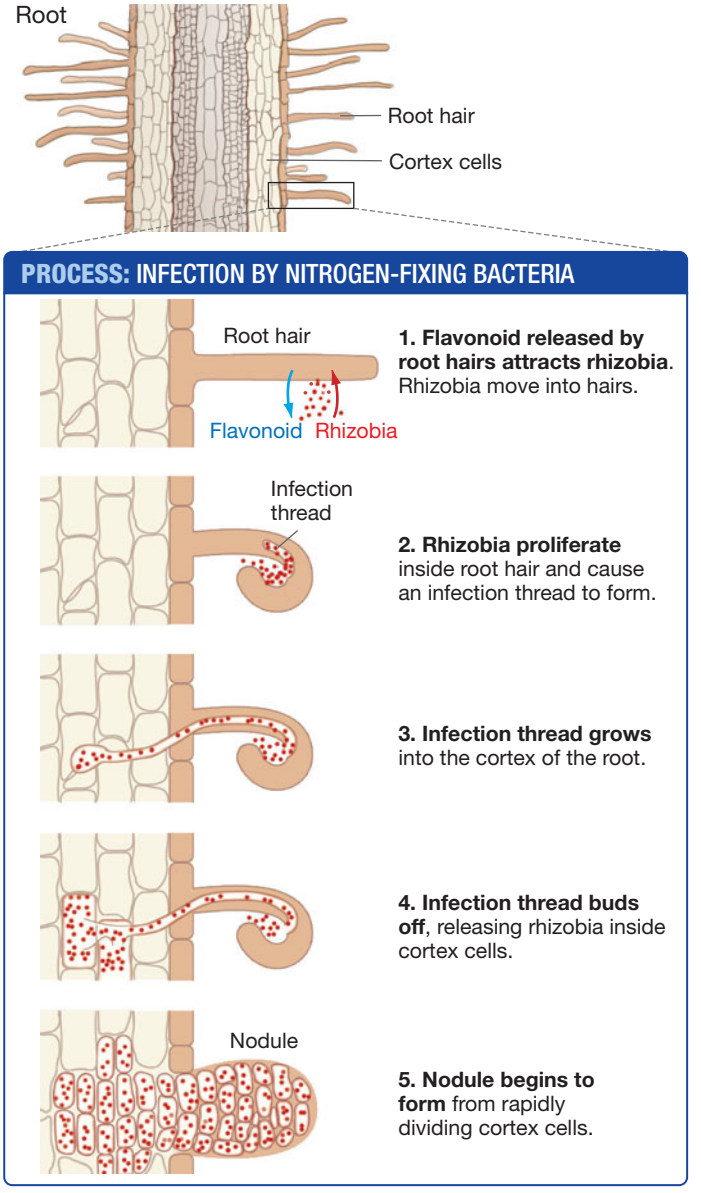


FIGURE 39.15 Infection by Nitrogen-Fixing Bacteria Is a Multistep Process. After rhizobia bind to a root hair, they enter the cytoplasm in a membrane-lined infection thread and travel into the root cortex, where they enter cortex cells.

How Do Nitrogen-Fixing Bacteria Infect Plant Roots?

Like mycorrhizal fungi and their host plants, legumes and rhizobia have a mutualistic relationship. The nitrogen-fixing bacteria provide the plant with ammonia, while the legume provides the bacteria with carbohydrates and protection. The association is costly for the host plant, however. For the bacteria to synthesize the enormous amounts of high-energy electrons and ATP required to manufacture ammonia, plants have to supply them with large quantities of sugar.

Given the cost of the plant–bacterium interaction and its importance to both species, it's not surprising that the infection process is carefully regulated.

When a legume seed germinates, its roots do not contain a population of rhizobia. Instead, the roots make contact with bacterial cells existing in the soil, the rhizobia infect root cells, and the root cells grow into a nodule.

The first event in infection is a recognition step that occurs between a legume-family plant and its symbiotic bacterium. First, young roots release compounds called flavonoids. When rhizobia contact the flavonoids, the bacteria respond by producing sugar-containing molecules called **Nod factors** (for *nod*ule formation). Nod factors, in turn, bind to signaling proteins on the membrane surface of root hairs.

The recognition step is specific to the species involved. Each legume species produces a different flavonoid that acts as a recognition signal, and each rhizobium species responds with one or more unique Nod factors. When researchers have switched recognition signals or Nod factors between species, the recognition step fails.

When Nod factors bind to the root-hair surface, they set off a chain of events that leads to dramatic morphological changes in the host legume, as **FIGURE 39.15** shows.

1. The bacterial cells contact the root-hair surface.
2. Rhizobia begin to multiply and move, through an invagination of the root-hair plasma membrane called an **infection thread.**

check your understanding

C Y U

If you understand that . . .

- Certain species of bacteria infect plant root cells and fix nitrogen, which is then made available to the plant.

✔ You should be able to . . .

Generate hypotheses addressing two additional questions about nitrogen fixation:

1. Why don't all plants have symbiotic bacteria that fix nitrogen?
2. Why is the interaction that establishes the infection by nitrogen-fixing bacteria so complex?

Answers are available in Appendix A.

3. The infection thread extends into the root, invading the cortex.
4. Portions of the infection thread bud off, forming membrane-bound clusters within cortex cells, each filled with rhizobia.
5. The infected cortex cells divide, forming root nodules.

The interaction between rhizobia and legumes is one of the most complex and best studied of all mutualisms.

39.5 Nutritional Adaptations of Plants

Based on the data available so far, over 95 percent of vascular plants take up nutrients from soil. And over 80 percent of all plants supplement their "diet" with nutrients acquired from mycorrhizal fungi, while a small but significant fraction associate with nitrogen-fixing bacteria. Perhaps 99 percent of all living plant species make their own sugar through the process of photosynthesis.

What about the small number of plant species that don't follow these rules? Some appear to live on air, some parasitize other plants, and others catch insects and digest them.

Epiphytic Plants

Species from a diverse array of plant lineages do not absorb nutrients from soil. In fact, these species never even make contact with soil. As **FIGURE 39.16a** shows, they often grow on the trunks or branches of trees. For this reason they are called **epiphytes** ("upon-plants").

In northern forests, it is common for mosses and ferns to grow epiphytically on tree trunks. The so-called Spanish moss that hangs from oak trees in the southeastern United States is another familiar epiphyte—although this species is actually not a moss but a bromeliad, a relative of the pineapple. In the tropics and subtropics, one-third of all ferns grow as epiphytes, and there are thousands of species of epiphytic orchids, bromeliads, and lycophytes.

Epiphytes absorb most of the water and nutrients they need from rainwater, dust, and particles that collect in their tissues or in the crevices of bark. As **FIGURE 39.16b** shows, some epiphytic bromeliads have leaves that grow in rosettes and form "tanks" that collect water and organic debris. In such cases, nutrients are actually absorbed through the leaves themselves.

Parasitic Plants

Parasites are organisms that live in close physical contact with individuals from another species and that lower the fitness of those individuals, usually by obtaining water or nutrients from the host. Biologists estimate that about 3000 species of angiosperms are parasitic—less than 1 percent of the plant species that have been studied and named to date.

Some plant parasites are non-photosynthetic and obtain all of their nutrition by tapping into the vascular tissue of the host individual. But most parasitic plants make their own sugars through photosynthesis and tap the xylem of other species for water and essential nutrients.

For example, the mistletoe (**FIGURE 39.17**, see page 790) is green and photosynthetic but has structures called **haustoria** (singular: **haustorium**) that penetrate a host's xylem and extract water and ions that the mistletoe uses as nutrients. In the forests of western North America, mistletoe infection is a serious cause of economic loss.

Carnivorous Plants

Carnivorous plants trap insects and other animals, kill them, and then digest the prey to absorb its nutrients. Carnivorous species make their own carbohydrates via photosynthesis but use carnivory to supplement the nitrogen available in the environment. Most are found in bogs or other habitats where nitrogen is scarce or unavailable.

(a) Epiphytes grow on trees.

(b) Water-holding "tanks" formed by leaves of an epiphyte

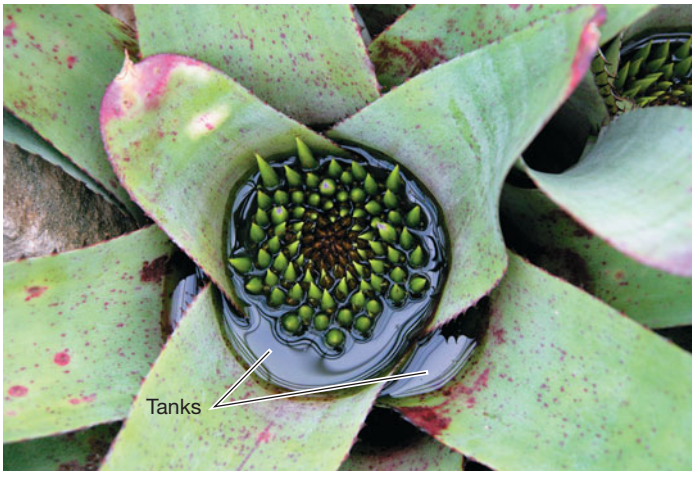

FIGURE 39.16 Epiphytes Are Adapted to Grow in the Absence of Soil. The environments where many epiphytes grow—tree trunks and branches—are dry and nutrient poor.

FIGURE 39.17 Some Plant Parasites Tap into the Vascular Tissue of Their Hosts.

✔**QUESTION** The bromeliads in Figure 39.16 and mistletoe both grow on other plants. How do they differ in their relationship to the trees that support them?

Modified Leaves Form an Array of Trapping Mechanisms Carnivorous plants use modified leaves or roots to trap insects. For example, the leaves of pitcher plants form tubes (see Table 37.3). Prey are enticed to the tube by an attractive odor and then have a difficult time climbing back out. Eventually they fall into the pool of water below, where they drown. Enzymes released by the plant digest the prey, and the plant absorbs the nutrients obtained from the insects' dead bodies.

Sundews have an alternative hunting strategy: They have modified leaves that function like flypaper. The leaf surfaces develop hairs that exude a sticky substance and trap insects (**FIGURE 39.18**). Glands near the sundew's trap release enzymes that digest the prey. The leaf then absorbs the nutrients that are released.

In the Venus flytrap, modified leaves trap insects mechanically. Sensory hairs protrude from the epidermis of each leaf. When an insect lands on the trap and bumps two or three of these hairs, the hair cells produce an electrical signal and the leaf responds by snapping shut (see Chapter 40). If the prey continues to stimulate hairs, the leaf secretes enzymes that digest the prey.

Costs and Benefits of Carnivory Initially, research on carnivorous plants focused on documenting that meat-eating was adaptive. Early experiments in natural environments supported this hypothesis by showing that, compared to individuals of the same species that are not fed fruit flies, carnivorous plants that were fed fruit flies grew faster and flowered more often.

Follow-up work explored the costs as well as the benefits of carnivory. For example, several teams of researchers showed that when carnivorous plants are provided with nitrogen-based fertilizers, they produce fewer of their specialized insect-trapping leaves and a higher proportion of leaves that function primarily in photosynthesis. These results suggest carnivory is a trait that shows phenotypic plasticity (see Chapter 37): Plants increase investment in prey-capture devices when nitrogen is rare, but they decrease investment in prey-capturing structures when nitrogen is readily available.

Currently, some research groups are doing "evo-devo" research (see Chapter 22) on carnivory. They are working to identify the novel alleles that made the evolution of carnivory possible in certain groups. Meat-eating may be relatively rare in plants, but it has inspired interesting new directions for research.

FIGURE 39.18 Sundews Have Modified Leaves with Sticky Surfaces That Catch Insects.

If you understand . . .

39.1 Nutritional Requirements of Plants

- About 96 percent of the dry weight of a typical plant consists of carbon, hydrogen, and oxygen. Plants obtain these elements by absorbing carbon dioxide from the atmosphere and water from the soil.
- The other 4 percent of the plant body consists of a complex suite of elements, acquired from soil, that are required for normal growth and reproduction. These essential elements are usually absorbed in the form of ions.
- Nutrients are usually classified as macronutrients, needed in large supply, and micronutrients, needed in only trace amounts.
- When plants are lacking in an essential nutrient, they usually develop predictable deficiency symptoms.

✔ **You should be able to design a field experiment that would determine whether nitrogen is a limiting nutrient in a habitat near your campus.**

39.2 Soil: A Dynamic Mixture of Living and Nonliving Components

- Soil is a complex and dynamic mixture of inorganic particles such as clay and sand, organic matter, and organisms. Soil provides plants with oxygen, water, and nutrients as well as a physical substrate for anchoring and supporting the plant body.
- Plants absorb nutrients in the form of ions. Anions in soil water are normally available to roots, but cations adhere to soil particles and are made available only after cation exchange.

✔ **You should be able to explain why loam is an ideal soil for most plants.**

39.3 Nutrient Uptake

- Nutrients are present at low concentrations in the soil surrounding roots. Plants import nutrients against a concentration gradient by pumping protons into the extracellular space.
- A large excess of protons outside the root hair creates a strong electrochemical gradient favoring the entry of positively charged ions through membrane transporters.
- The proton gradient in root-hair membranes also allows negatively charged ions to cross the plasma membrane via symporters.
- In addition to acquiring nutrients by establishing a proton gradient, many plants obtain nitrogen or phosphorus through a mutualistic relationship with mycorrhizal fungi in exchange for carbohydrates derived from photosynthesis.
- Passive and active systems also exist for excluding certain ions. This is important because all nutrients are toxic at high concentrations.

✔ **You should be able to predict the consequences of mutations that allow root cells to establish a membrane voltage that is much more negative than normal, without a large increase in energy expenditure.**

39.4 Nitrogen Fixation

- Certain plants, including those in the legume family, are capable of symbiosis with nitrogen-fixing bacteria. The bacteria colonize the interior of root cells after exchanging species-specific signals.
- Nitrogen-fixing bacteria receive protection and sugar from the host plant, in exchange for producing ammonia, a useable form of nitrogen for the plant, from nitrogen gas.

✔ **You should be able to design an experiment, using radioactive carbon and the heavy isotope of nitrogen ($^{15}N_2$), that would test whether the rhizobia–pea plant interaction is mutualistic.**

39.5 Nutritional Adaptations of Plants

- Epiphytes grow on the trunks and branches of other plants and absorb mineral nutrients from rainwater, dust, or decaying matter trapped in the bark of their host plant.
- Some parasitic plants produce their own carbohydrates through photosynthesis but obtain water and nutrients by penetrating the xylem of host plants.
- Carnivorous plants have evolved mechanisms for trapping and digesting insects and other animals. The primary benefit of carnivory is to obtain nitrogen in low-nitrogen environments.

✔ **You should be able to explain why epiphytes in tropical rain forests and desert plants often have similar adaptations to minimize water loss**

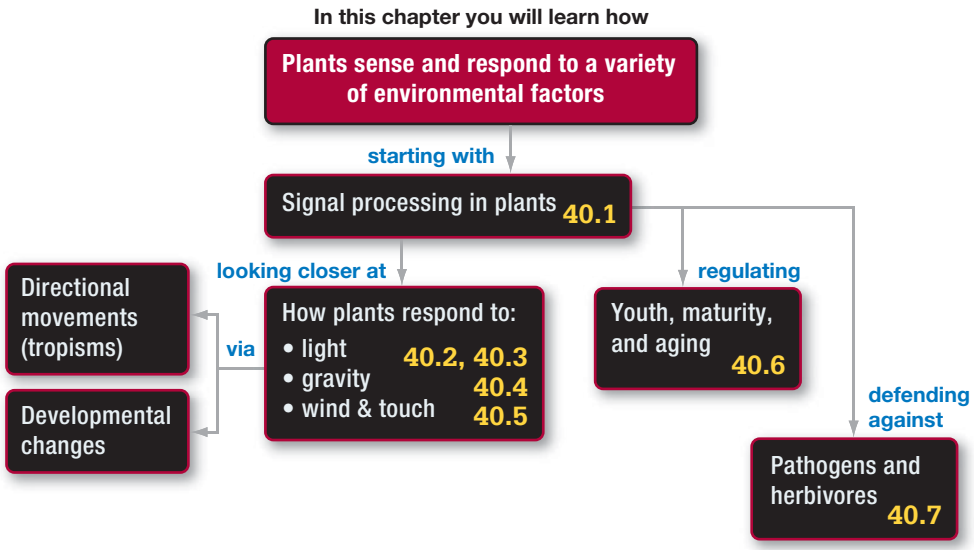
TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. Which of the following characteristics defines an element as essential for a particular species?
   a. It has to be added as fertilizer to achieve maximum seed production.
   b. If it is missing, a plant cannot grow or reproduce normally.
   c. If it is present at high concentration, plant growth increases.
   d. If it is absent, other nutrients may be substituted for it.
2. Why is the presence of clay particles important in soil?
   a. They provide macronutrients—particularly nitrogen, phosphorus, and potassium.
   b. They bind metal ions, which would be toxic if absorbed by plants.
   c. They allow water to percolate through the soil, making oxygen-rich air pockets available.
   d. The negative charges on clay bind to positively charged ions and prevent them from leaching.
3. Where does most nutrient uptake occur in roots?
   a. at the root cap, where root tissue first encounters soil away from the zone of nutrient depletion
   b. at the Casparian strip, where ions must enter the symplast before entering xylem cells
   c. in the symplastic and apoplastic pathways
   d. in root hairs, in the zone of maturation
4. Why are proton pumps in root-hair plasma membranes important?
   a. They pump protons into cells, generating a membrane potential (voltage).
   b. They allow toxins to be concentrated in vacuoles, so the toxins do not poison enzymes in the cytoplasm.
   c. They set up an electrochemical gradient that makes it possible for roots to absorb cations and anions.
   d. They set up the membrane voltage required for action potentials to occur.
5. Some plants obtain nitrogen from symbiotic fungi or bacteria. What were the original sources of N that the fungi and bacteria obtained?
6. Before the formation of a root nodule, which partner secretes a Nod factor, the plant or the bacterium?

TEST YOUR UNDERSTANDING

Answers are available in Appendix A



7. Why is the relationship between most mycorrhizal fungi and their host plants considered mutualistic?
   a. They live in close physical association.
   b. Both species benefit from the association.
   c. The host plant cannot live without the mycorrhizae.
   d. The mycorrhizae cannot live without the host plant.
8. A farmer is concerned that her corn crop is suffering from iron deficiency. Design an experiment that uses hydroponic cultures to identify (1) the symptoms of iron deficiency in corn and (2) the minimum amount of iron required to support normal growth rates.
9. Explain why carnivorous and parasitic plants are most common in nutrient-poor habitats.
10. Would you expect plant productivity to be higher in sandy soils or in soils containing both sand and clay? Why?
11. Why is it important for plants to exclude certain ions? Summarize the difference between active and passive exclusion mechanisms.
12. Why is it logical for biologists to (1) distinguish nutrients that are obtained from the atmosphere or water (C, H, and O) from mineral nutrients obtained from soil, and (2) distinguish macronutrients from micronutrients?

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A

13. **QUANTITATIVE** There is a conflict between van Helmont's data on willow tree growth and the data on essential nutrients listed in Table 39.1. According to the table, nutrients other than C, H, and O should make up about 4 percent of a willow tree's weight. Most or all of these nutrients should come from soil. But van Helmont claimed that the soil in his experiment lost just 60 g, while the tree gained 74,000 g. Calculate the percentage of added weight contributed by soil. State at least one hypothesis to explain the conflict between expected and observed results. How would you test this hypothesis?
14. Acid rain occurs when sulfur oxides and nitrous oxides released by cars or factories react with water vapor, forming sulfuric and nitric acids, respectively. In areas affected by acid rain, cations can quickly leach out of the soil. Explain why.
15. Design an experiment using the drug vanadate, which poisons proton pumps, to test the hypothesis that phosphate ions enter cells via an H^+/HPO_4^{2-} cotransporter.
16. Alder trees have nitrogen-fixing bacteria associated with their roots and have a much higher proportion of nitrogen in their tissues than do spruce trees that grow in the same habitat. Which species should decay faster after death: alder or spruce? Explain your logic.

40 Plant Sensory Systems, Signals, and Responses

Plants have sophisticated information processing systems. These radish seedlings sense the presence of light and are bending toward it.

BIG PICTURE

This chapter is part of the Big Picture. See how on pages 840–841.

Imagine standing in place for several hundred years, like an oak tree. Each spring you produce flowers. All summer you absorb light from the Sun, carbon dioxide from the atmosphere, and water and nutrients from the soil. Water, ions, and sugars flow up and down your vascular tissue. For six months or more your body grows upward, outward, and downward. In fall, thousands of your offspring drop to the ground as acorns. Then as winter approaches, your metabolism slows and you stop growing. Like a hibernating animal, you spend the long, hard months of winter in a state of suspended animation, before resuming growth the following spring.

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

To stay alive, an oak needs to gather information about its environment. It has to sense the season of the year, the time of day, the pull of gravity, the force of wind, and attacks by enemies. It needs to sense when its leaves are being shaded and which leaves are receiving the wavelengths of light that are required to support photosynthesis.

Plants may not have eyes or ears, but they can sense light, gravity, pressure, and wounds. They have the equivalent of a sense of smell, because they can perceive certain airborne molecules. It can even be argued that they have a sense of taste, because their roots sense the presence of nutrients in the soil.

In addition to gathering information about the conditions around them, plants have to respond in an appropriate way. They do not jump or swim or run, but their shoot systems grow toward light or end up shorter and stockier in response to wind. In response to gravity, shoots grow up and roots grow down. In response to touch, the modified leaves of a Venus flytrap shut fast enough to catch flying insects. If a plant is being attacked or if it senses that a neighboring individual is under attack, it may lace its tissues with toxic compounds or mobilize other defenses.

The message of this chapter is simple: Plants have sophisticated systems for collecting information about their environment and responding in ways that maximize their chances of surviving, thriving, and producing offspring. The ability to gather information and respond to it is one of the five fundamental attributes of life (see Chapter 1).

PROCESS: STEPS IN INFORMATION PROCESSING

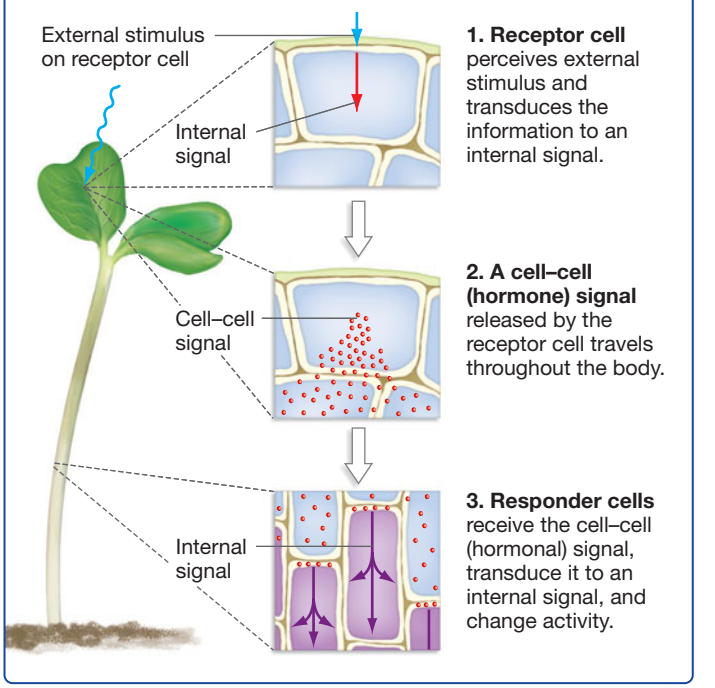


FIGURE 40.1 In Many Cases, Cell–Cell Signals Link a Stimulus and a Response.

40.1 Information Processing in Plants

Every environment is full of information. But, like other organisms, plants monitor only aspects of the environment that matter to them—those that affect their ability to stay alive and produce offspring.

FIGURE 40.1 summarizes the three-step process by which plants gather, process, and respond to the information they monitor:

1. Receptor cells receive an external signal and change it to an intracellular signal.
2. Receptor cells send a signal to cells in other parts of the body that can respond to the information.
3. Responder cells receive this signal, transduce it to an intracellular signal, and change their activity in a way that produces an appropriate response.

Let's briefly consider how each of these steps works, then explore some of the details of how plants sense and respond to light, gravity, and other signals from the environment.

How Do Cells Receive and Transduce an External Signal?

When you text a friend, the signal travels from you to their receiver via airwaves. When the message arrives, the receiving cell phone changes the information in the airwaves into electrical signals and then into words that your friend can understand.

Plants work in much the same way. When light strikes a sensory cell, for example, the information that it carries has to be changed into a form that is meaningful to that cell. Signals from the environment are usually detected by proteins specialized for that function. Receptor proteins change shape in response to an environmental stimulus, such as being struck by a particular wavelength of light, having pressure applied, or binding to a particular type of molecule.

When a receptor changes shape in response to a stimulus, the information changes form—from an external signal to an intracellular signal. This process is called **signal transduction** (**FIGURE 40.2**); the verb transduce means "to convert energy from one form to another." Once information has been transduced to an intracellular form, it travels down what biologists call a signal transduction pathway.

You might recall that there are two basic types of signal transduction pathways in all organisms: phosphorylation cascades and second messengers (see Chapter 11). Both begin with a receptor protein in the plasma membrane.

- **Phosphorylation cascades** are triggered when the change in the receptor protein's shape leads to the transfer of a phosphate group (PO_4^{3-}) from ATP to the receptor or an associated protein. Phosphorylation activates proteins involved in signal transduction cascades, causing them to phosphorylate and activate a different set of proteins, which in turn catalyze the phosphorylation and activation of still other proteins, and so on.

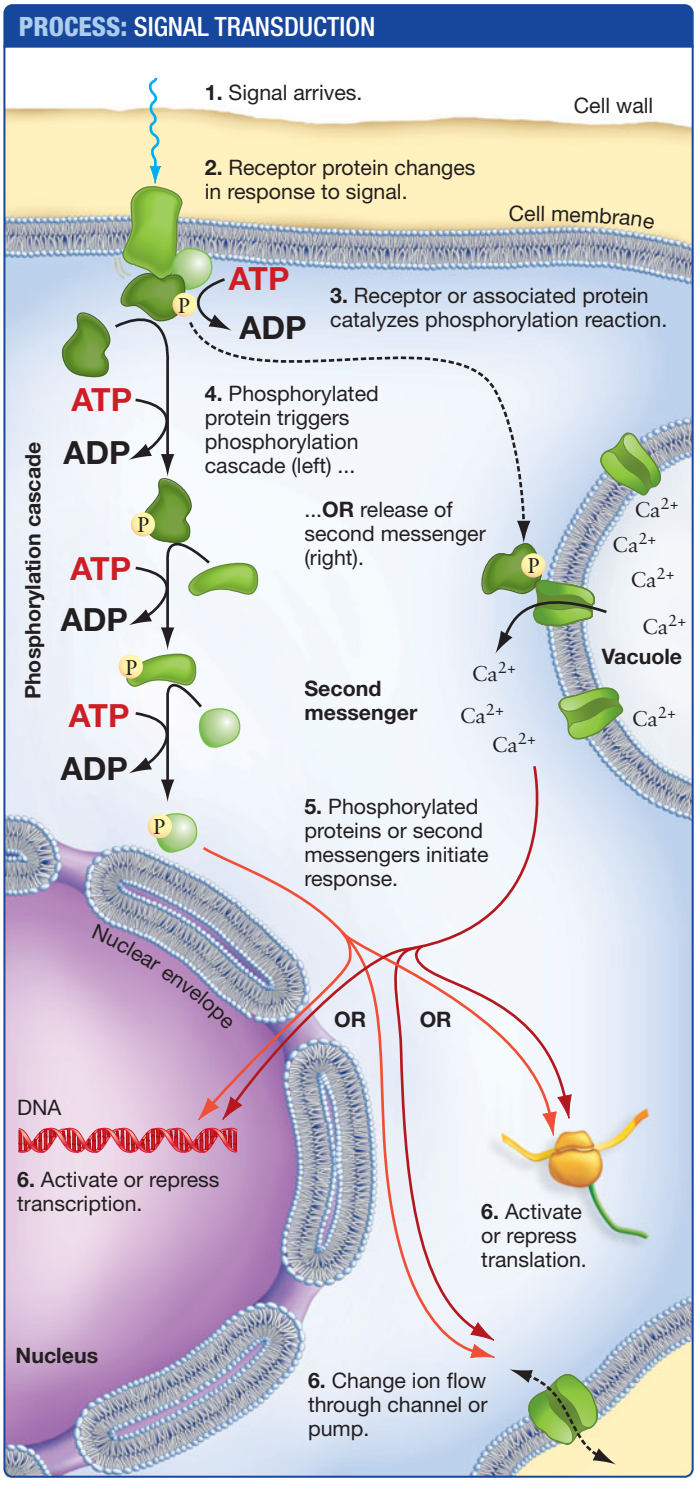

FIGURE 40.2 Signal Transduction Changes an External Signal to an Internal Signal. After an environmental or cell–cell signal is transduced to an intracellular signal, it triggers a change in the cell's activity.

- **Second messengers** are produced when receptor proteins trigger the production of intracellular signals or their release from storage areas. Calcium ions (Ca^{2+}) stored in the vacuole, ER, or cell wall are one of several ions or molecules that function as the second messenger in plants.

In some cases, phosphorylation cascades and second messengers interact.

Signal transduction primes the receptor cell for action. In many cases, though, the cells that receive information from the environment are located in a part of the body that is distant from the cells that need to respond to the information. How does information from activated receptor cells get to responder cells?

In most cases, the answer involves a **hormone**—an organic compound that is produced in small amounts in one part of a plant and transported to target cells, where it causes a physiological response. Signal transduction in a receptor cell often results in the release of a hormone that carries information to responder cells.

How Are Cell–Cell Signals Transmitted?

Because plants perceive such a wide array of stimuli, they have a wide array of hormones coursing through their bodies. These signals may be transmitted from cell to cell by specialized transport proteins in cell membranes, in xylem sap or phloem sap, or by simple diffusion from the originating cell. In most cases the signals act on target tissues throughout the body.

Plant cells routinely receive information from several different hormones at the same time, so it is common for different types of hormones to interact with each other and modulate the cell's response.

How Do Cells Respond to Cell–Cell Signals?

Cells are exposed to a constant stream of hormones. Many of these signals have little to no effect on what is happening inside a given cell. The reason is simple: Hormones can elicit a response only if a cell has an appropriate receptor.

If a receptor exists on or in the cell, an arriving hormone binds to it. When the receptor changes shape in response, the effect is like a knock on the door of your room. The signal—often received at the cell's periphery—is rapidly transduced to a series of phosphorylated proteins or the release of a second messenger inside the cell. The result may be a dramatic change in the cell's activity.

To understand why these binding events can have such significant effects on cell activity, look again at Figure 40.2. Activation of a signal transduction cascade results in the production of many phosphorylated proteins, or the release of many second messengers. These events amplify the original signal many times. In this way, low concentrations of plant hormones can have a large impact on target cells. Hormones are small molecules in low concentrations, but because the information they carry is amplified during signal transduction, they produce big results.

As Figure 40.2 shows, the response to hormone binding can include

- activation of membrane transport proteins (see Chapter 6), which produces a change in the membrane's electrical potential or the cell wall's pH; or
- changes in gene expression—via alterations in transcription activators or repressors (see Chapter 19) or the translation

machinery—that result in new suites of proteins or RNAs in the cell.

The response to the signal is important. When cells respond to a hormone, the change in their activity helps the plant cope with the environmental change sensed by the receptor cell.

check your understanding

CYU

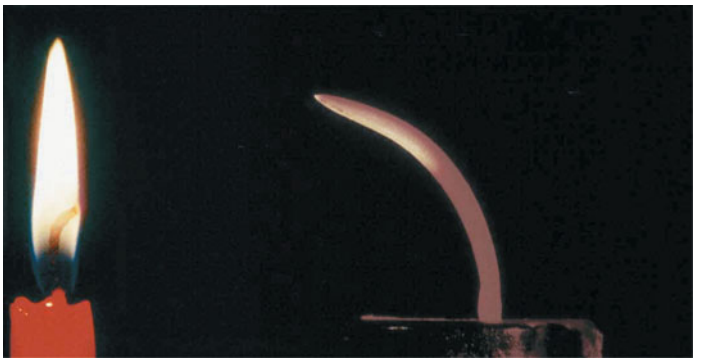
If you understand that . . .

- Plants can respond to changes in their environment because sensory cells receive information from the environment, sensory cells produce hormones or other cell–cell signals, and target cells respond to hormones.
- Information processing in sensory cells and the cells that respond to cell–cell signals involves three steps:
  Step 1 A receptor molecule changes in response to the signal.
  Step 2 A signal transduction pathway transforms the hormonal signal into an intracellular signal.
  Step 3 The intracellular signal triggers a response—changes in the transcription of target genes, activity of specific enzymes or transport proteins, or other changes in cell activity.

✔ You should be able to . . .

1. Explain why only certain cells in the plant body—not all—respond to an environmental signal, and why only certain cells respond to a hormone.
2. Explain how cell–cell signals are amplified inside a target cell.

Answers are available in Appendix A.



40.2 Blue Light: The Phototropic Response

Most of the general principles of plant communication emerged from studies of how plants respond to light. For example, consider the claim that plants are highly selective about the information they process. Light is made up of a wide array of wavelengths (see Chapter 10), but plants sense and respond to only a few.

This conclusion traces back to experiments that Charles Darwin and his son Francis performed in 1881 with coleoptiles of a monocot called reed canary grass. A **coleoptile** is a modified leaf that forms a sheath protecting the emerging shoots of young grasses.

The Darwins germinated seeds in the dark, placed the young, straight coleoptiles next to a light source, and noted that they grew toward the light—a response, due to differential cell elongation, called bending (**FIGURE 40.3a**). You have probably seen the same response in houseplants that are near a window (see the photo at the start of the chapter). Directed movement in response to light is called **phototropism** (literally, "light-turn").

(a) Shoots bend toward full-spectrum light.

(b) Shoots bend specifically toward blue light.

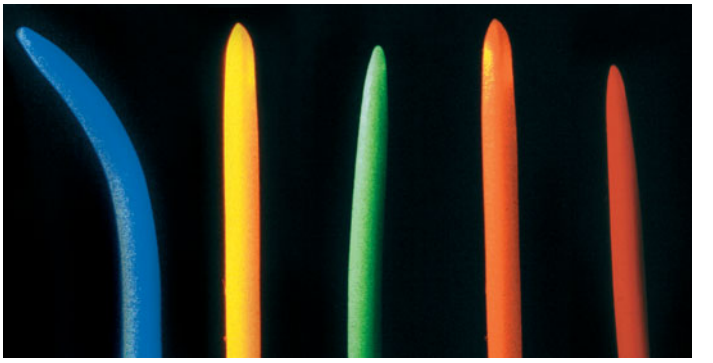


FIGURE 40.3 Experimental Evidence that Plants Sense Specific Wavelengths of Light. Though a candle is shown here, the Darwins used paraffin lamps or other sources of artificial light in their original experiments.

When the Darwins exposed coleoptiles to light filtered through a solution of potassium dichromate, however, the coleoptiles did not bend toward the light. Potassium dichromate solutions filter out wavelengths in the blue part of the visible spectrum. The photo in **FIGURE 40.3b** shows the results of a follow-up experiment with coleoptiles that have been exposed to blue, yellow, green, orange, and red light. Bending occurs only toward light that contains blue wavelengths.

It is important to understand the specificity of this response. Recall that **(1)** chlorophylls *a* and *b* are the primary photosynthetic pigments, and **(2)** these pigments absorb strongly in the blue and red parts of the spectrum (see Chapter 10). Plants exhibit a phototropic response if blue wavelengths are available, but show no response if blue wavelengths are not present. Plants move toward blue light, which is important in photosynthesis.

Let's look at what happens when blue light strikes a receptor cell, and follow the signal to examine the cells that undergo differential growth in response.

Phototropins as Blue-Light Receptors

Although biologists knew that the blue-light receptor must be a **pigment**—a molecule that absorbs certain wavelengths of

light—it took decades to find it. A key breakthrough came in the early 1990s, when researchers found a membrane protein in the tips of emerging shoots that gains a phosphate group in response to blue light. Researchers hypothesized that the membrane protein becomes activated when it is phosphorylated in response to blue light, and that the activated protein then triggers the phototropic response.

Subsequent work succeeded in isolating the gene that codes for the membrane protein. The gene, named *PHOT1*, was found by analyzing mutant *Arabidopsis thaliana* individuals that do *not* show a phototropic response to blue light. Further experiments by Shin-ichiro Inoue and colleagues showed that *PHOT1* codes for a blue-light receptor. An important question remained, however. Is the PHOT1 protein activated by phosphorylation, and does this trigger bending of the plant?

As a first step in answering this question, Inoue and colleagues identified an amino acid in the PHOT1 protein that becomes phosphorylated after plants are exposed to blue light. During this analysis, they constructed a mutated *PHOT1* gene, called *phot1-m*, which coded for an altered protein with an amino acid that cannot be phosphorylated. This altered protein provided the researchers with a way to test whether phosphorylation of the PHOT1 protein was required for a phototropic response. **FIGURE 40.4** shows their experimental setup.

The key to the experiment was to compare bending in response to blue light in wild-type *Arabidopsis* with the response in mutant plants that lacked a PHOT1 protein. When Inoue and colleagues introduced the *phot1-m* gene into a mutant plant, the altered protein failed to rescue phototropism. However, when the normal *PHOT1* gene was introduced into a mutant plant, phototropism was restored.

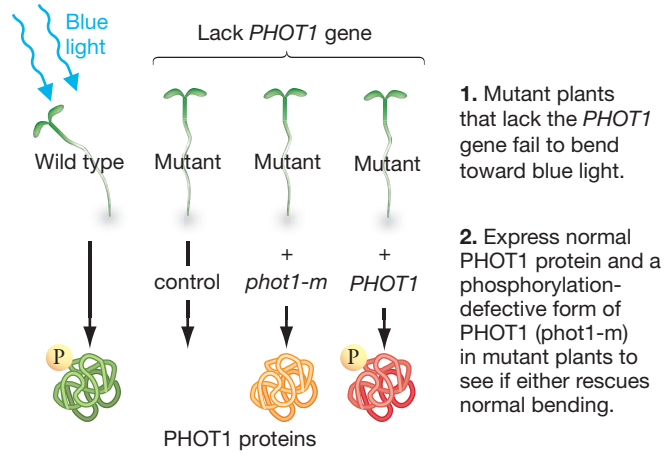
The current consensus is that *PHOT1* encodes a blue-light receptor in plants. A phototropic response is initiated when this receptor protein is phosphorylated.

Recent research indicates that *Arabidopsis* has a second blue-light receptor related to PHOT1, called PHOT2. Collectively, **photoreceptors** that detect blue light and initiate phototropic responses are known as **phototropins.**

Given its importance to photosynthesis, it's not surprising that blue light triggers an array of responses in addition to bending. The phototropins, for example, trigger signal transduction cascades that result in at least two other responses.

1. Chloroplast movements inside leaf cells. These movements put chloroplasts in positions to optimize light absorption. In high light the chloroplasts move to the sides of cells to shade each other while in low light they spread out.
2. Opening of stomata. As a result, carbon dioxide can diffuse into cells as blue light triggers photosynthesis.

In addition to the phototropins, several other kinds of blue-light receptors have been identified in plants that also help control the opening of stomata, as well as stem elongation and flower production. Phototropism, however, ranks as the best studied of all blue-light responses. How is the signal from PHOT proteins transmitted to the cells that respond by bending?

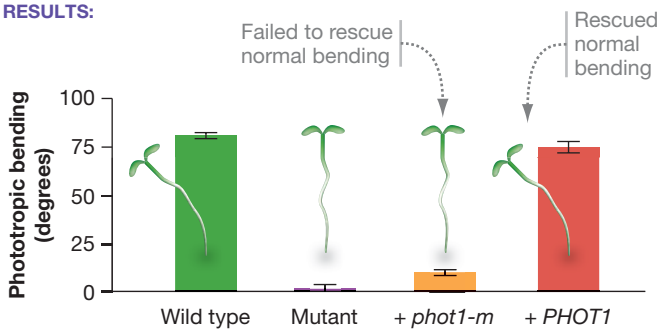


RESEARCH

QUESTION: Is PHOT1 activated by phosphorylation?

HYPOTHESIS: Phototropism in *Arabidopsis* is triggered by phosphorylation of PHOT1 protein.

NULL HYPOTHESIS: Phototropism in *Arabidopsis* is not triggered by phosphorylation of PHOT1 protein.



EXPERIMENTAL SETUP:

PREDICTION: Mutant plants expressing the normal *PHOT1* gene will bend toward blue light, but mutant plants expressing the defective form of *PHOT1* (*phot1-m*) will not bend toward blue light.

PREDICTION OF NULL HYPOTHESIS: Mutant plants expressing either the normal or the defective form of the *PHOT1* gene will both bend toward blue light.

RESULTS:

CONCLUSION: Phosphorylation of PHOT1 triggers phototropic bending in response to blue light.

FIGURE 40.4 The Role of PHOT1 Phosphorylation in Phototropic Bending: An Experimental Test.

SOURCE: Inoue, S., T. Kinoshita, M. Matsumoto, et al. 2008. Blue light-induced autophosphorylation of phototropin is a primary step for signaling. *Proceedings of the National Academy of Sciences* 105: 5626–5631.

✔**QUESTION** Why did the researchers put the mutant and normal PHOT1s into PHOT1-deficient plants and not wild-type plants?

Auxin as the Phototropic Hormone

Long before the phototropins were identified, biologists knew that receptor cells responded to blue light by releasing a hormone. The Darwins established this result when they followed

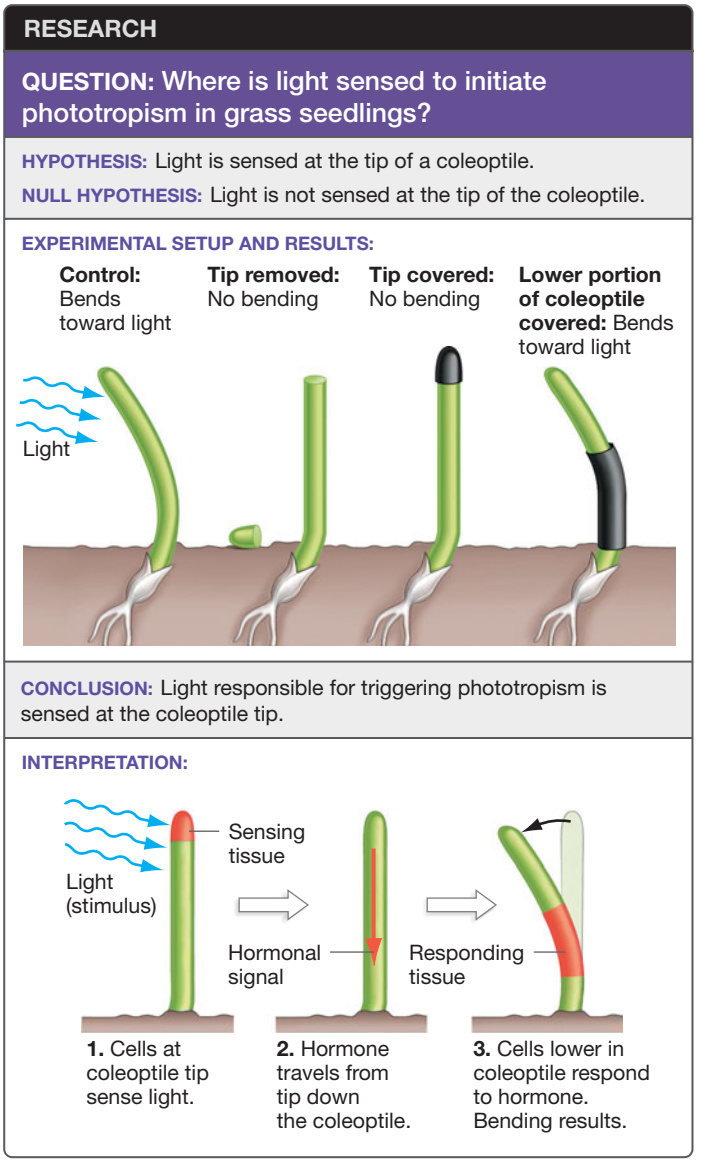


FIGURE 40.5 The Sensory and Response Cells Involved in Phototropism Are Not the Same.

SOURCE: Darwin, C., and F. Darwin. 1897. *The Power of Movement in Plants.* New York: D. Appleton & Co.

✔**QUESTION** A critic could argue that this experiment lacked appropriate controls for the treatments labeled "Tip removed" and "Tip covered." Suggest better controls for these treatments than the unmanipulated individual at the far left.

up on their initial experiments. **FIGURE 40.5** shows their experimental setup and results.

- If they removed the tips of coleoptiles, they found that the decapitated seedlings stopped bending toward the light.
- If they covered the tips of coleoptiles with opaque material, the seedlings did not bend toward light.
- If they put opaque collars below the tips, in the area where bending occurs, the seedlings bent toward light normally.

These data provided evidence that the blue-light sensors were located in the tips of the coleoptiles, and not in the part of the coleoptile that bends.

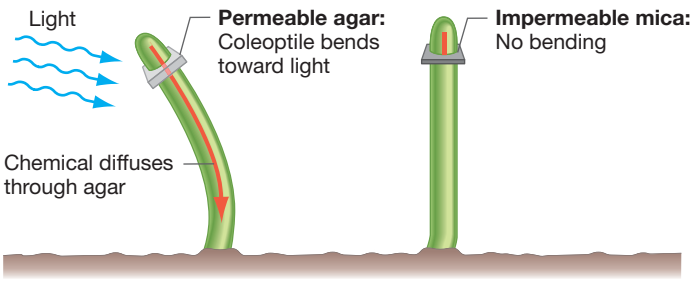
How did the sensory cells in the tip communicate with the cells that actually elongate? The Darwins proposed that phototropism depends on "some matter in the upper part which is acted on by light, and which transmits its effects to the lower part." Their hypothesis was that a substance produced at the tip of the coleoptile acts as a signal and is transported to the area of bending. This was the first explicit hypothesis stating that hormones—signaling molecules that can act at a distance—must exist.

The hormone hypothesis was not tested rigorously until 1913, when Peter Boysen-Jensen

1. cut the tips off young oat coleoptiles;
2. put a tip and a porous block of the gelatinous compound called agar on some of the decapitated coleoptiles; and
3. put a tip and a piece of mica (a nonporous mineral) on the rest of the decapitated coleoptiles.

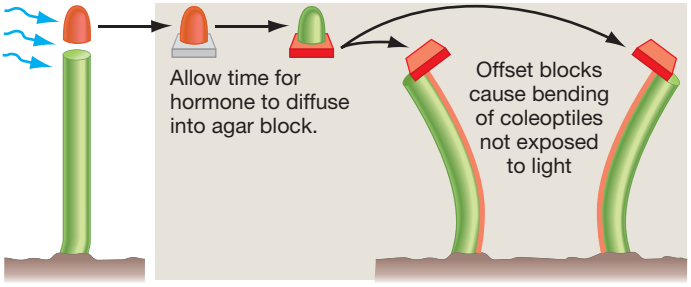
As **FIGURE 40.6a** shows, only the coleoptiles treated with the porous agar block showed normal phototropism. Based on this observation, Boysen-Jensen concluded that the phototropic signal was indeed a chemical and that it could diffuse. He also inferred that the molecule was water soluble, because the agar that he used was a water-based gelatin.

Twelve years later, Frits Went extended these results. He placed the decapitated tips of oat coleoptiles on agar blocks, with the goal of collecting the hypothesized hormone controlling phototropism. Then he did something clever: He placed agar blocks that had been exposed to oat tips off-center on the decapitated coleoptiles of other individuals (**FIGURE 40.6b**). He also did the same with agar blocks that had *not* been exposed to oat tips, as a control (not shown).



Even though the coleoptiles were kept in the dark during the entire experiment, they responded by bending if their agar block had been exposed to oat tips. In this way, Went succeeded in producing the phototropic response without the stimulus of light.

Because it promotes cell elongation in the shoot, Went named the hormone **auxin** (from the Greek *auxein*, "to increase"). Auxin was the first plant hormone ever discovered.



Isolating and Characterizing Auxin After years of effort, researchers in two laboratories independently succeeded in isolating and characterizing auxin. The hormone turned out to be indoleacetic acid, or IAA. It was difficult to identify because it is present in such low concentrations. Depending on the species and tissue involved, IAA concentrations range from 3 to 500 nanograms per gram of tissue. (The prefix *nano–* refers to billionths.)

Like the other plant hormones introduced in this chapter, auxin is a small molecule with a relatively simple structure. It is present in quantities so small that its concentration is difficult to measure. Yet its impact is huge. Auxin can bend stems—producing, in some cases, tree trunks that are permanently bowed.

(a) The phototropic signal is a chemical.

(b) The hormone can cause bending in darkness.

(c) The hormone causes bending by elongating cells.

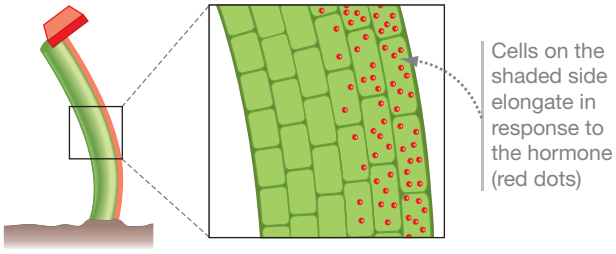


FIGURE 40.6 Experimental Evidence Supports the Hormone Hypothesis for Phototropism. (a) Coleoptiles bend in response to light if substances from the tip are allowed to move downward. **(b)** If bending can take place in darkness, then light is not directly required for the response. Only the hormone is required. **(c)** During the phototropic response, bending occurs because cells on the shaded side of the coleoptile elongate.

The Cholodny–Went Hypothesis Went's experiments were a breakthrough in research on information processing: They confirmed the hormone hypothesis and led to the discovery and characterization of IAA. But Went's experiments also inspired an important hypothesis for *how* the hormone produces the bending response. Working independently, both N. O. Cholodny and Went proposed that phototropism results from an asymmetric distribution of auxin.

The Cholodny–Went hypothesis makes three predictions:

1. Auxin produced in the tips of coleoptiles moves from the lighted side of the tip to the shaded side.
2. Auxin is then transported straight down one side of the coleoptile.
3. The asymmetric distribution of auxin causes cells on the shaded side of the coleoptile to elongate more than cells on the illuminated side (**FIGURE 40.6c**).

Bending results. In essence, bending results from differential elongation.

To test the Cholodny–Went model, Winslow Briggs used thin sheets of mica inserted into coleoptile tips to block the movement of auxin. As predicted by the model, auxin concentrations were the same on the lighted and shaded sides of divided tips. If a path for auxin movement was maintained, more of the auxin accumulated on the shaded side of the tip.

The Cholodny–Went asymmetric distribution model was correct. It explained how auxin leads to asymmetric cell elongation, and thus the bending response called phototropism. Biologists now know that the stems of eudicots and the coleoptiles of monocots respond to phototropic signals in essentially the same way.

The Cell Elongation Response How do cells in the stem respond to auxin? Experiments in corn plants and *Arabidopsis* suggest that auxin-binding proteins are found in stem and leaf cells. Researchers proposed that once auxin binds to these receptors, the signal transduction cascade that follows increases the activity of membrane H^+-ATPases, or proton pumps, in the plasma membrane.

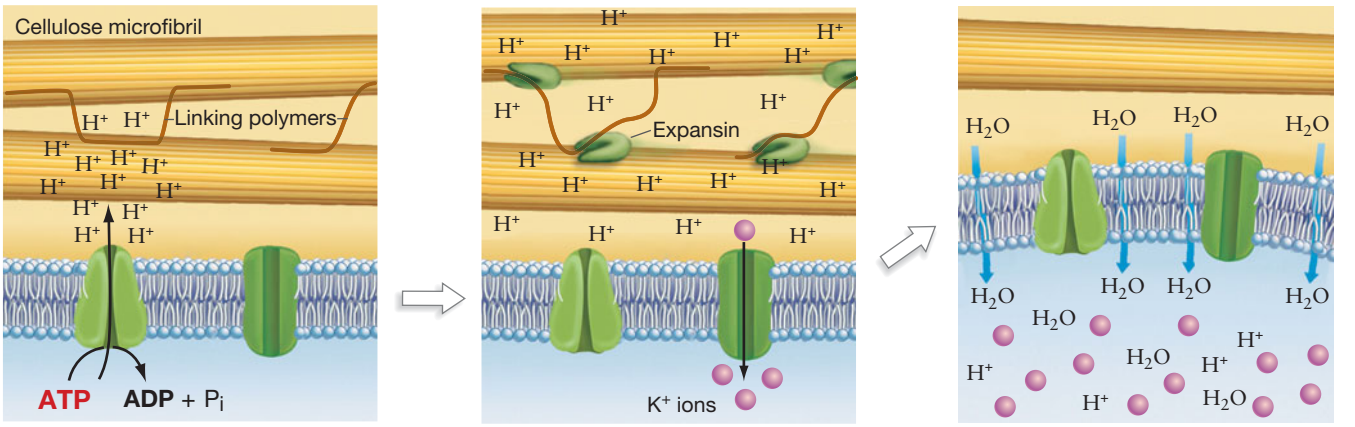
Recall that **proton pumps** use the energy in ATP to drive protons out of the cell against an electrochemical gradient (see Chapter 38). Because the pH of the cell wall decreases when

check your understanding

C Y U

If you understand that . . .

The chain of events involved in phototropism can be summarized as follows:



- When phototropins in coleoptile-tip cells absorb blue light, auxin is redistributed to the shaded side of the tip.
- Auxin is transported down the shoot and binds to receptors in target cells.
- These cells elongate when activated receptors lead to the activation of proton pumps, acidification of the cell wall, and activation of expansin proteins.

✔ You should be able to . . .

1. Assuming that you have a large supply of purified auxin, state how you would manipulate a large bed of roses so their stems bend toward the east.
2. Based on the information in this section, predict the phenotype of a mutant plant in which the auxin-binding protein in stems is always in the active state, even in the absence of auxin.

Answers are available in Appendix A.

PROCESS: ACID-GROWTH HYPOTHESIS FOR CELL ELONGATION

1. Proton pumps acidify cell wall outside the plasma membrane.

2. Wall loosens as activated expansins "unzip" hydrogen bonds connecting cellulose microfibrils to other cell-wall polymers. Electrochemical gradient brings ions into cell.

3. Water follows by osmosis. Increased turgor pressure pushes loosened wall out, elongating the cell.

FIGURE 40.7 The Acid-Growth Hypothesis Requires Expansion of Cell Wall and Intake of Water. When activated proton pumps lower the pH outside the cell membrane in response to auxin; a series of events lead to elongation of the cell.

H^+-ATPases are active, the idea that these pumps are responsible for cell elongation became known as the **acid-growth hypothesis.**

To understand the rationale behind the acid-growth hypothesis, it's important to realize that two things have to happen for a plant cell to get larger:

1. The cell wall has to expand to create a larger volume.
2. Water has to enter the cell and generate turgor pressure on the cell wall to make an increase in volume possible.

As **FIGURE 40.7** shows, both processes are triggered by pumping protons into the cell wall.

When proton pumping lowers the pH of the wall to 4.5, cell-wall proteins called **expansins** are activated. Expansins "unzip" the hydrogen bonds that form between cellulose microfibrils and other polymers in the cell wall, loosening the structure.

As protons are pumped out of the cell, an electrochemical gradient is established. The inside of the membrane becomes much more negative than the outside, favoring the entry of potassium (K^+) or other positively charged ions. As the concentration of solutes increases inside the cell, water follows via osmosis.

This is a key point: Cells don't move water directly. Instead, they create an osmotic gradient that favors water movement. Pumping protons *out* of a cell is a way to bring water *into* the cell. The incoming water increases turgor pressure, which pushes out the loosened cell wall. The cell gets bigger.

The upshot? When cell walls on one side of a stem are acidified in response to a signal from auxin, bending results. Auxin's role in phototropism is an exquisite example of information processing in plants.

Given the importance of light to plants, it shouldn't be surprising that they have photoreceptors that detect other wavelengths of light. We will explore one of these photoreceptors in the next section.

40.3 Red and Far-Red Light: Germination, Stem Elongation, and Flowering

Plants are sensitive to wavelengths in the red and far-red portions of the visible spectrum, as well as to blue light. This sensitivity is interesting because red wavelengths (about 660 to 700 nm) and far-red wavelengths (over 710 nm) signal very different things to a plant.

- Red light drives photosynthesis, just as blue light does.
- Far-red wavelengths are not absorbed strongly by photosynthetic pigments, so they tend to pass through leaves. As a result, far-red wavelengths are prominent in light that is filtered through tree leaves before it reaches the forest floor. Far-red light indicates shade.

The Red/Far-Red "Switch"

The first hint that plants monitor red and far-red light emerged from studies by H. A. Borthwick and colleagues in the early 1950s on how lettuce seeds germinate. By exposing lettuce seeds to various wavelengths of light and plotting their frequency of germination, researchers discovered that germination rates peak when seeds receive red light (about 660 nm).

This observation made sense, because lettuce thrives best when it grows in bright sunlight. But the stimulatory effect of just 1 minute of red light disappeared if seeds were then exposed to 4 minutes of far-red light.

TABLE 40.1 How Do Red Light and Far-Red Light Affect the Germination of Lettuce Seeds?

Biologists exposed moistened lettuce seeds to flashes of light containing one of two wavelengths: red or far-red (FR). After exposure to light, the seeds were held in the dark for several days.

Light Exposure	Germination (%)
None (control)	9
Red	98
Red → FR	54
Red → FR → Red	100
Red → FR → Red → FR	43
Red → FR → Red → FR → Red	99
Red → FR → Red → FR → Red → FR	54
Red → FR → Red → FR → Red → FR → Red	98

SOURCE: H. A. Borthwick, S. B. Hendricks, M. W. Parker, et al. 1952. A reversible photoreaction controlling seed germination. *PNAS* 38: 662–666, Table 1.

✔**QUANTITATIVE** According to the data above, what is the average germination rate of lettuce seeds that were last exposed to red light? To far-red light? How would these values compare with the germination rate of seeds that are buried underground and receive no light at all?

This observation also made sense because far-red light indicates that the seeds are shaded. Wavelengths near 735 nm inhibit germination the most effectively.

Follow-up experiments showed that red and far-red light act like an on-off switch for lettuce seed germination (**TABLE 40.1**). Red light promotes lettuce germination; far red inhibits it.

The key observation, though, is that the last wavelength sensed by the seed determines whether germination occurs at a high rate. How could this happen?

Phytochromes as Red/Far-Red Receptors

To interpret the red/far-red switch in seed germination, biologists hypothesized that the same pigment absorbs both wavelengths. Further, they suggested that the pigment exists in two shapes, or conformations: One shape absorbs red light, and one shape absorbs far-red light.

The idea was that switching behavior, or **photoreversibility,** occurs because light absorption makes the photoreceptor pigment change shape, like a light switch moving up or down in response to touch. Each conformation would be responsible for a different response.

Biologists called the hypothesized pigment **phytochrome** ("plant-color"). Phytochrome was thought to be a specialized light receptor, different from any of the pigments involved in absorbing light during photosynthesis or phototropism.

FIGURE 40.8 illustrates the photoreversibility hypothesis. One conformation of phytochrome, called P_r (phytochrome red), absorbs red light. Another conformation of the same molecule, called P_{fr} (phytochrome far-red), absorbs far-red light. According to the photoreversibility hypothesis, each conformation switches to the other when it absorbs its specific wavelength.

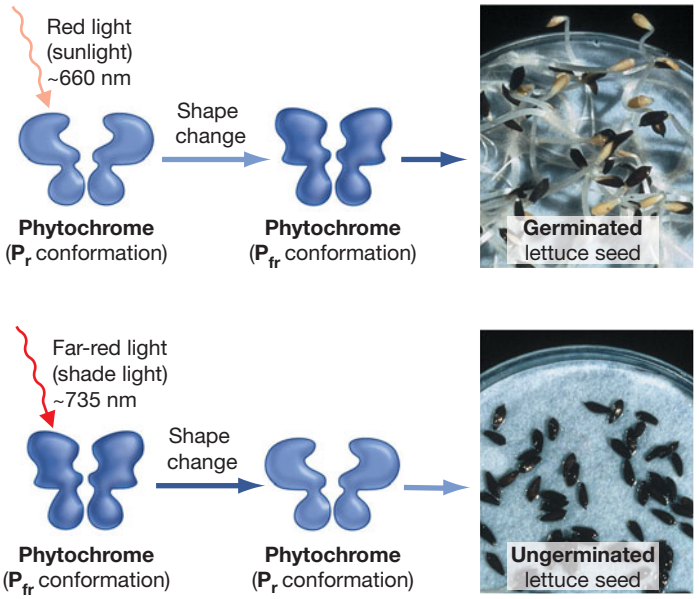


FIGURE 40.8 The Photoreversibility Hypothesis for Phytochrome Behavior. According to the photoreversibility hypothesis, phytochrome switches between the P_r conformation and the P_{fr} conformation when it absorbs red or far-red light, respectively. Only the P_{fr} form promotes germination.

How Were Phytochromes Isolated?

Young corn and bean plants lengthen their stems in response to light deprivation or exposure to excessive far-red light. If you have grown these seeds indoors, you have seen this response to far-red light firsthand. The shoots get long and spindly.

Corn and beans normally grow in open sunlight. If they are grown indoors under incandescent light, which is deficient in red wavelengths as compared with far-red wavelengths, the plants react as though they are being shaded—they attempt to grow high enough to reach full sunlight. This behavior suggests that young corn and bean plants have a receptor protein for far-red light.

To follow up on this observation, researchers purified proteins from corn coleoptiles and succeeded in isolating one that was photoreversible. Specifically, when the protein was placed in solution and exposed to alternating red and far-red light, the color of the solution switched back and forth between blue and blue-green. The color switches supported the hypothesis that the same protein absorbed red as well as far-red light. Phytochrome was found.

Follow-up work showed that a region of the phytochrome molecule changes shape in response to red and far-red light. The shape changes cause phytochrome to take on or lose a phosphate group, just as the shape changes triggered by blue light result in phosphorylation of the phototropins. Conformational changes in proteins are frequently associated with a change in phosphorylation.

The photoreversibility hypothesis explains the red/far-red switch seen in seed germination and stem elongation. But can

it also explain other plant responses? Let's consider another key event in plant growth—flowering—and the signals that trigger it.

Signals That Promote Flowering

Anatomically, a flower is a modified shoot that develops from a compressed stem and highly modified leaves. In essence, flower formation begins when an apical meristem stops making energy-harvesting stems and leaves and begins to produce the modified stems and leaves that make up flowers (see Chapter 24). Instead of making more food through photosynthesis, a sporophyte commits to investing energy in sexual reproduction—by producing gametophytes that will produce gametes.

When does this happen? Early experiments on the environmental signals that promote flowering focused on the number of hours of light and dark during a day. As it turns out, the switch that triggers flowering in response to changes in day length also shows red/far-red photoreversibility. Phytochrome plays a key role in a phenomenon called photoperiodism.

Photoperiodism is any response by an organism that is based on photoperiod—the relative lengths of day and night. In plants, the ability to measure photoperiod is important because it allows individuals to respond to seasonal changes in climate—for example, to flower when pollinators are available and when resources for producing seeds are abundant. Let's take a closer look.

Responding to Changes in Photoperiod Experiments on photoperiodism in plants have shown that, with respect to flowering, plants fall into three main categories:

1. **Long-day plants** bloom in midsummer, when days are longest and nights shortest. Radishes, lettuce, spinach, corn, irises, and other long-day plants flower only when days are longer than a certain length—usually between 10 and 16 hours, depending on the species.
2. **Short-day plants** bloom in spring, late summer, or fall. Asters, chrysanthemums, poinsettias, and other short-day plants flower only if days are shorter than a certain species-specific length.
3. **Day-neutral plants** flower without regard to photoperiod. Day length has no effect on flowering in roses, snapdragons, dandelions, tomatoes, cucumbers, and many **weeds**—plants that are adapted to grow in soils that have been disturbed enough to remove or damage existing vegetation.

How do plants sense changes in day length and initiate the chain of events that leads to flowering? Early experiments suggested that phytochrome is involved.

FIGURE 40.9 summarizes some of the key experiments. Researchers showed that interrupting the night period with a light flash changed the flowering response. In short-day plants, for example, flowering was inhibited if the dark period was interrupted by red light—wavelengths around 660 nm. But a subsequent flash of far-red light—wavelengths around 735 nm—erased the effect. In some way, the phytochrome switch linked changes in day length to flowering.

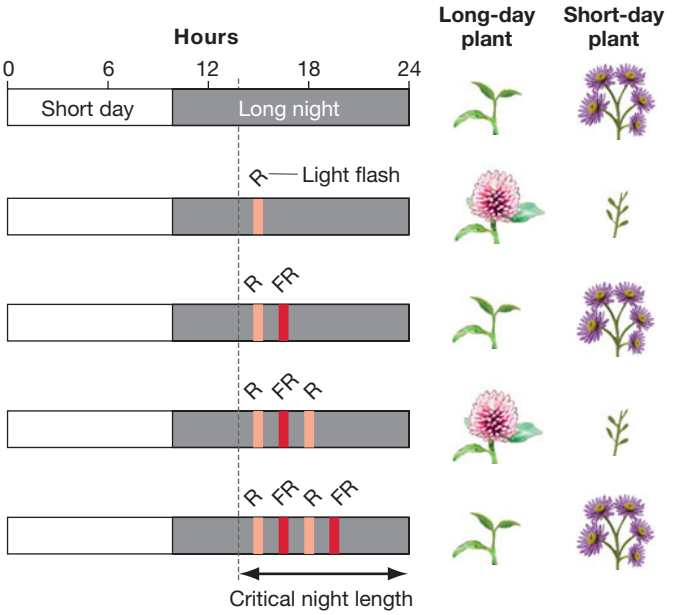

FIGURE 40.9 Flashes of Red Light and Far-Red Light Switch the Photoperiod Response On and Off. If flashes of red light (R) and far-red light (FR) are alternated during the night, the plant's flowering response correlates with the last light it experiences. A flash of red light turns a long night into a short night; a flash of far-red light restores the perception of a long night.

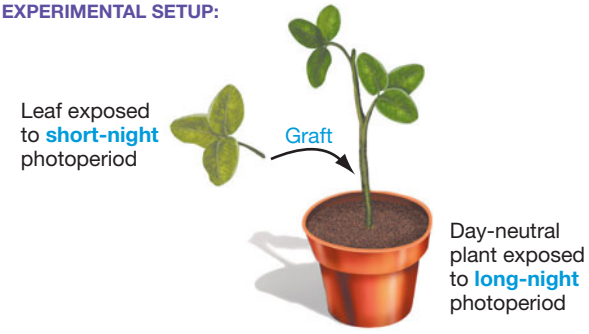
More recent research has shown that phytochrome's effect is closely tied to the molecular mechanisms of timekeeping in plants. Plants have a clock that is reset each morning. Clock protein levels rise during the day and trigger expression of a gene called *CONSTANS* (*CO*). The CO protein is a transcription factor that affects the production of a flowering hormone. When phytochrome is activated by light, it stabilizes CO—so that CO accumulates in cells.

- In long-day plants, high levels of CO stimulate production of the flowering hormone.
- In short-day plants, high levels of CO *inhibit* production of the flowering hormone.

Many questions remain, however, and research is continuing. In the meantime, it is clear that a complex interaction takes place between clock proteins, phytochrome activation, and the production of the signal that initiates flowering. What is that signal?

Discovery of the Flowering Hormone Since the 1930s, biologists have known that exposing even one leaf on a plant to the conditions necessary to induce flowering may result in the whole plant flowering. This result suggests that the signal to flower comes from leaves and travels to the apical meristem.

Grafting experiments, in which an organ from one individual is physically attached to a different individual, support this result. If you provide an experimental plant with the appropriate flower-triggering night length and then cut off a leaf or stem and graft it onto a second, experimental plant that has never been exposed



RESEARCH

QUESTION: Can signals from different plants induce flowering?

HYPOTHESIS: Signals from grafted leaves can induce flowering.

PREDICTION OF NULL HYPOTHESIS: Plant will not flower.

RESULTS:

CONCLUSION: A signal from a grafted leaf can induce flowering.

FIGURE 40.10 Experimental Support for the Hypothesis that a Hormone for Flowering Exists.

SOURCE: Lang, A., M. K. Chailakhyan, and I. A. Frolova. 1977. Promotion and inhibition of flower formation in a day-neutral plant in grafts with a short-day plant and a long-day plant. *Proceedings of the National Academy of Sciences, USA* 74: 2412–2416.

✔**QUESTION** For this experiment to support the claim that a flowering hormone exists, a control treatment needs to be carried out. What is this control treatment? If the hypothesis is correct, what is the predicted outcome of the control treatment?

to the correct photoperiod for flowering, the experimental plant will flower (**FIGURE 40.10**).

Like the experiments on phototropism with agar blocks (Figure 40.6), this result supported the hypothesis that some substance produced in the transplanted leaf must travel up the recipient plant. This substance would then trip a developmental switch in the apical meristem, causing the change from vegetative growth to flowering. Biologists were so convinced that flowering must be induced by a hormone that they named it **florigen,** even though the actual hormone had not been discovered.

Almost 80 years later, researchers finally found the florigen molecule. This work began by focusing on the *FLOWERING LOCUS T (FT)* gene in *Arabidopsis*, which is known to promote flowering when activated. When researchers exposed leaves to short nights, they found that the gene was expressed in the leaf vascular tissue. Subsequently, some research indicates that the protein product of the *FT* gene is transported from leaves to the shoot apical meristem, and that the protein's presence triggers the activation of genes required for converting the stem to a flower.

Details are emerging on how the information present in the P_r/P_{fr} switch is translated into action that affects germination, stem elongation, flowering, timekeeping, and other responses to red and far-red light.

Given their reliance on photosynthesis for both energy and reduced carbon compounds, it isn't surprising that plants are highly tuned to their light environment. They also need to tell which end is up. Next, let's explore how they sense gravity.

check your understanding

C Y U

If you understand that . . .

- Plants respond to red and far-red light via phytochromes, which change shape and activity when they absorb red or far-red light.
- Red light acts as a sunlight or day indicator, while far-red light acts as a shade or night indicator.
- Flowering occurs at specific times of the year and is controlled by night length through phytochrome signals.

✔ You should be able to . . .

1. Explain why it is adaptive for red light to trigger germination in lettuce seeds while far-red light inhibits it.
2. Explain why it is adaptive for changes in night length to affect the tendency to flower in some species.

Answers are available in Appendix A.

40.4 Gravity: The Gravitropic Response

The wavelengths, quantity, and direction of light that a plant receives change with the season, weather, time of day, and shading by other plants. However, gravity is constant and unidirectional. Light means food; gravity provides information about how the plant should orient itself in space.

Shoots usually respond to gravity by growing in an upward direction; roots usually respond by growing downward or laterally. How do plants sense gravity, so that it can be used as a signal to orient the body?

In 1881 Charles and Francis Darwin published one of the first experimental results on **gravitropism** ("gravity-turn")—the ability to move in response to gravity. Recall that the ends of root tips are covered by a protective tissue called the **root cap** (see

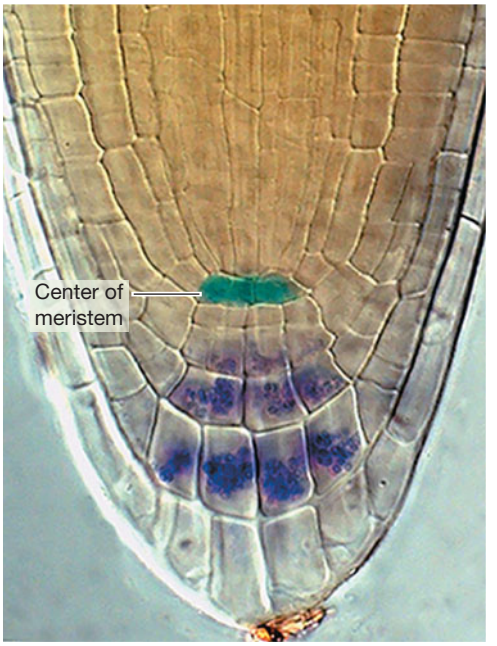

FIGURE 40.11 Gravity Sensing Occurs in the Root Cap. The root cap is a protective structure. Gravity-sensing cells in the center of the cap contain starch granules (stained dark purple).

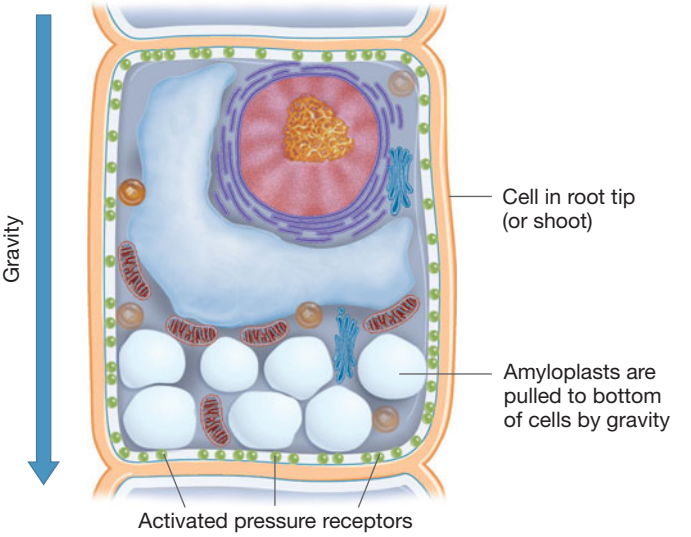

FIGURE 40.12 The Statolith Hypothesis States that Amyloplasts Stimulate Sensory Cells. Amyloplasts are filled with starch. They are dense, so they sink in response to gravity. The statolith hypothesis predicts that pressure receptors in the plasma membrane become activated as a result.

✔**EXERCISE** Assuming that the receptor is a protein, suggest a hypothesis to explain how signal transduction occurs in response to pressure from a statolith.

Chapter 37). The Darwins found that roots stop responding to gravity if the root caps are removed. This observation suggested that gravity sensing occurs somewhere inside the root cap.

Recently biologists demonstrated precisely which cells are involved in gravity sensing in *Arabidopsis* roots. By killing tiny blocks of cells with laser beams, researchers showed that cells located at the center of the root cap are the most important for regulating the gravitropic response. Importantly, these cells always contain starch (**FIGURE 40.11**). Cells in the root cap respond to gravity and initiate gravitropism. Does starch play a role in sensing gravity?

The Statolith Hypothesis

The leading explanation for how plants sense gravity—the **statolith hypothesis**—is based on two interconnected ideas:

1. **Amyloplasts** are organelles that contain starch granules; starch is denser than water. These organelles are pulled to the bottom of root cap cells by the force of gravity (**FIGURE 40.12**).
2. The position of the amyloplasts activates sensory proteins located in the plasma membrane. These sensory proteins initiate the gravitropic response.

The statolith hypothesis was inspired by animals that use dense particles to sense gravity. Lobsters, for example, take up grains of sand that become positioned in specialized gravity-sensing organs in their antennae. The grains of sand are called **statoliths** ("place-stones"). When the animal tilts or flips over, the statoliths move in response to gravity. Inside the organ, the sand grain ends up pushing against a sensory cell. When this cell is activated, it indicates that the animal is no longer upright.

According to the statolith hypothesis, the same thing happens in root cap cells. If the wind tips a plant over, for example, the amyloplasts settle onto the new "lower" cell walls. The weight activates receptors, which signal that the root no longer faces in the correct direction.

Although recent experiments strongly support the statolith hypothesis, the search for the gravity receptor itself continues. In contrast, the second and third steps of information processing in response to gravity—the production of a cell–cell signal and the response of target cells—are much better understood.

Auxin as the Gravitropic Signal

Root cap cells that sense changes in the direction of gravitational pull respond by changing the distribution of auxin in the root tip. **FIGURE 40.13** illustrates this chain of events.

Step 1 Under normal conditions, auxin flows down the middle of the root, then toward the perimeter, and finally away from the root cap.

Step 2 If the root is tipped, sensory receptors trigger changes in the position of auxin transport proteins that redistribute auxin.

Step 3 Auxin is redistributed: The lower portion of the root receives increased concentrations of auxin; the upper portion receives lower concentrations.

Step 4 Because high auxin concentrations inhibit growth in roots, the differences in auxin concentrations trigger differential growth. Cells in the lower portion of the root elongate

more slowly compared with cells in the upper portion. The result is bending.

Note that the way root cells respond to auxin redistribution during the gravitropic response is opposite to the way that cells in the stem respond during phototropism. In stems, high concentrations of auxin lead to *increased* cell elongation and bending. In roots, high concentrations of auxin lead to *decreased* cell division and elongation. Roots bend as cells on the upper side of the zones of cellular division and elongation (see Chapter 37) continue to grow.

If you understand that . . .

- Cells in root caps sense gravity via pressure that amyloplasts exert on receptors.
- Changes in gravity-sensing cells result in a redistribution of auxin and changes in the growth rate of root tips.

✓ You should be able to . . .

1. Explain the similarities and differences that exist between auxin redistribution in shoots and roots and the responses called phototropism and gravitropism.
2. Explain why auxin could be considered a gravitropic hormone.

Answers are available in Appendix A.

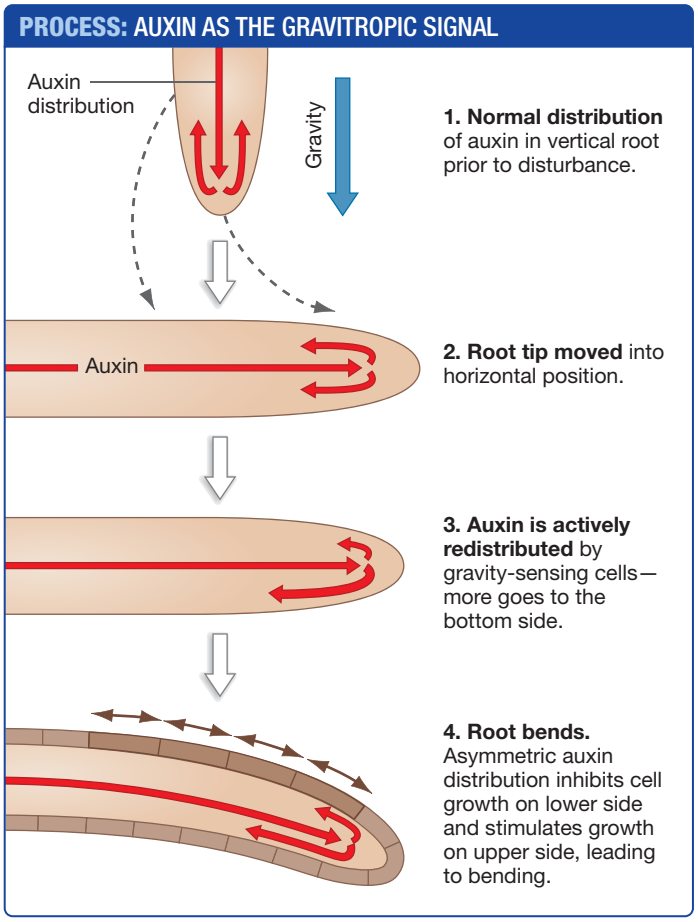

FIGURE 40.13 The Auxin Redistribution Hypothesis for Gravitropism. This sequence of events might begin when a growing root tip hits a rock and is displaced horizontally or when a plant is tipped in a windstorm and partially uprooted.

40.5 How Do Plants Respond to Wind and Touch?

Light and gravity are not the only physical forces that plants sense and respond to. Plants also react to mechanical stresses such as wind and touch.

Let's analyze two of the best-studied responses to pushing or pulling forces: growth responses that lead to exceptionally stout, stiff stems, and movement responses that make a Venus flytrap snap shut.

Changes in Growth Patterns

When plants are buffeted by wind, receptor cells transduce the mechanical force into an internal signal in the form of phosphorylated proteins or second messengers. Although the exact receptor and transduction pathway are not known, studies in *Arabidopsis thaliana* have shown that transcription of a large suite of genes is turned up or down in response to touch or other mechanical stimuli that mimic the effect of wind. Some of the new protein products act to stiffen cell walls, resulting in plants that are shorter and stockier than plants that do not experience repeated vibrations or touching.

FIGURE 40.14 shows what this response looks like in *Arabidopsis*. In this experiment, plants were either touched lightly 2 times per day or left untouched. The flowing stalks of the touched plants were much shorter.

In response to wind, then, plants change their growth patterns in ways that make them more likely to withstand the force, stay upright, and live long enough to produce flowers and fruit.

FIGURE 40.14 Plant Growth Changes in Response to Wind or Touch. The *Arabidopsis* plants on the right were touched several times daily, while plants on the left were untouched.

Movement Responses

In some cases, plants respond to touch by moving. This response, **thigmotropism** ("touch-bending"), can be fast. For example, species that grow by climbing up objects or other plants may have modified leaves or stems that form long, thin structures called tendrils. When a tendril makes contact with an object, it responds by wrapping itself around the item as fast as one or more times per hour (**FIGURE 40.15**). Plants that climb in this way are able to grow taller toward light without needing to invest considerable resources in making wood.

Movement is even faster in "touch-sensitive" plants. A Venus flytrap, for example, closes fast enough to catch insects. Extremely rapid movements like this are possible when a touch-receptor cell transduces the mechanical signal to an electrical signal.

To understand how plants use electrical signaling, recall that proton pumps in the plasma membrane of most plant cells give them a negative charge relative to the exterior environment (see Chapter 38). The separation of charges creates a membrane voltage, or **membrane potential.** If a receptor protein responds to touch by allowing ions to flow across the membrane—which changes the amount of charge on either side—then the membrane potential changes. In this way, the mechanical signal (touch) can be transduced to an electrical signal.

To travel from a sensory cell to a response cell, electrical signals are propagated in a characteristic form called an **action potential.** In animals, action potentials carry signals along the plasma membrane of nerve cells (see Chapter 46). In a Venus flytrap, action potentials generated by sensory hairs inside the trap race across the leaf at a rate of about 10 cm/sec.

How do plant action potentials move across tissues, when those tissues lack nerve cells? Recall that most plant cells are connected by membrane-lined **plasmodesmata** (see Chapter 37). Action potentials move more slowly in plants than in animals, but they can still carry information long distances in a hurry.

When the action potentials in a Venus flytrap reach cells on the outer surface of the trap, the cells change shape and push the trap shut (**FIGURE 40.16**). The response is rapid enough to resemble the way an animal's muscle contracts in response to an action potential.

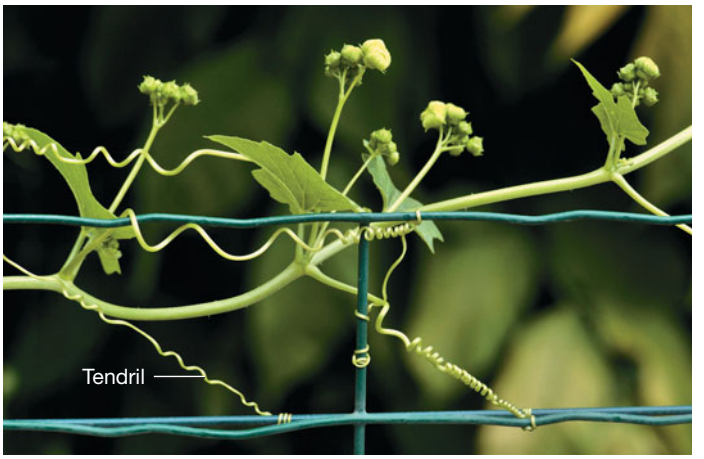

FIGURE 40.15 Thigmotropism Is Movement in Response to Touch. Portions of grape plants called tendrils wind around support structures after contacting them. The attachment provided by the tendrils allows plants to climb.

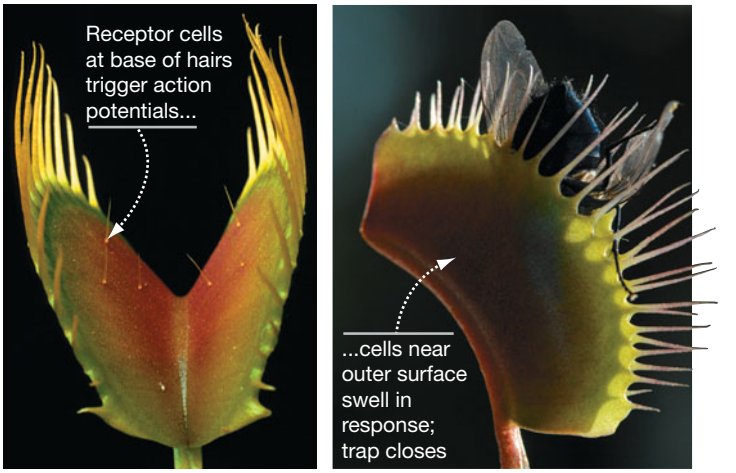

FIGURE 40.16 Venus Flytraps Close in Response to Action Potentials Generated by Sensory Hairs.

Next, let's explore how various signaling molecules control a plant's growth throughout its life cycle.

40.6 Youth, Maturity, and Aging: The Growth Responses

Plants grow throughout their lives, from the time they germinate until the time they die. As the plant body grows, it matures into an efficient machine for absorbing sunlight, water, nutrients, and other diffuse resources. But growth is not constant. It speeds up when water, light, and nutrients are abundant and slows or stops when conditions are poor, or when it is time for leaves to drop or fruits to ripen.

Controlling growth in response to changes in age or environmental conditions is one of the most important aspects of information processing in plants. Hormones play key roles in regulating growth.

To explore how plants grow in response to changing conditions, let's consider six of the best-studied hormones involved in growth responses, which are appropriately referred to as plant growth regulators. We'll start with auxin—the molecule responsible for phototropism and gravitropism.

Auxin and Apical Dominance

When **apical dominance** occurs, growth is restricted to the main stems; the lateral buds in the axils of each leaf remain dormant. But if the apical bud dies or is eaten by an herbivore, the dormancy of the lateral buds is broken and lateral branches begin to grow. **FIGURE 40.17** shows this phenomenon in action.

What caused the change? Because auxin is produced in shoot tips, researchers suspected that it might have a role in apical dominance as well as phototropism. This hypothesis was

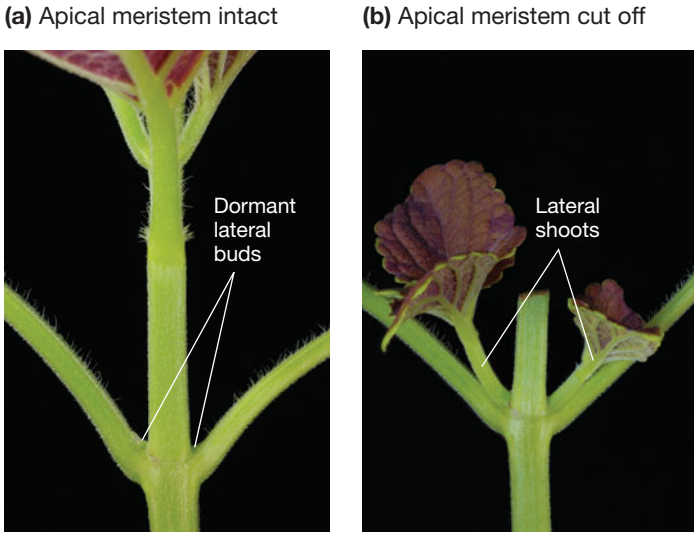

FIGURE 40.17 When Apical Dominance Occurs, Growth of Lateral Buds Is Suppressed. (a) The stem of a coleus plant is shown still intact. **(b)** The same plant, several weeks after the stem was cut. The lateral shoots will orient themselves vertically.

confirmed when it was shown that apical dominance could be sustained by applying auxin to a shoot's cut surface after its tip had been removed.

Auxin's role in apical dominance suggests that tip cells send a constant stream of information down to other organs and tissues. A stop in the signal means that apical growth has been interrupted. In response, lateral branches sprout and begin to take over for the main shoot. Now the question is, How does this signal move?

Polar Transport of Auxin Auxin transport is **polar,** or unidirectional. If radioactively labeled auxin is added to the top end of a stem segment, the hormone emerges from the basal end. But if labeled auxin is added to the basal end of the segment, it is not transported toward the top. Auxin is the only plant hormone known to be transported through individual cells in one direction only.

Studies with labeled auxin have also shown that the hormone is transported all the way down the stem through the root, via parenchyma cells in the ground tissue and vascular tissue. Auxin enters the apical end of cells via a specialized membrane protein, diffuses to the other end of the cell, and then is transported out by carrier proteins located only in the basal portion of the plasma membrane. Labeled auxin moves from cell to cell at about 10 cm/hr—approximately 10 times more slowly than substances traveling in the phloem or xylem.

Because enzymes break down some auxin molecules as they travel down the long axis of the plant, polar transport sets up a strong gradient in auxin concentration. Auxin concentrations are much higher in shoots than they are in roots.

What Is Auxin's Overall Role? Auxin clearly plays a key role in controlling growth via apical dominance, phototropism, and gravitropism. But this chemical messenger has other important effects as well:

- Auxin produced by seeds within the fruit promotes fruit development.
- Falling auxin concentrations are involved in the **abscission,** or shedding of leaves and fruits, associated with the genetically programmed aging process called senescence.
- The presence of auxin in growing roots and shoots is essential not only for the proper differentiation of xylem and phloem cells in vascular tissue but also for the development of vascular cambium (see Chapter 37).
- Auxin stimulates the development of adventitious roots in tissue cultures and cuttings.

Auxin has so many different effects on plants that it has been difficult for biologists to understand its overall role. Recently, several investigators have proposed that auxin's overall function is to signal where cells are in the plant body. The idea is that auxin concentration identifies where a cell is located relative to the root–shoot axis; a high concentration would inform the cell that it was near the tip of the shoot.

If conditions relating to the root–shoot axis change—for instance, a windstorm tips the plant or a deer eats the shoot apex—changes in auxin concentration effectively signal how the individual's tissues should respond. Phototropism, gravitropism, apical dominance, and the production of adventitious roots are all ways of coping with changes along the root–shoot axis of the plant.

Cytokinins and Cell Division

Cytokinins are a group of plant hormones that promote cell division. (*Cyto* is the Greek root for cell; *kinin* refers to kinesis, meaning movement or division.)

The Discovery of Cytokinins When biologists were first attempting to grow plant cells and embryos in culture, they found that coconut milk, which stores nutrients used by growing coconut embryos, promoted cell division. This was the first hint that certain molecules can promote cell division in plants. Later experiments showed that molecules derived from the nitrogenous base adenine also stimulate the growth of cells in culture.

Eventually, naturally occurring adenine derivatives that stimulate growth were discovered in corn and apples, and were named cytokinins. Zeatin, the cytokinin found in the most species, is derived from adenine.

Cytokinins are synthesized in root tips, young fruits, seeds, growing buds, and other developing organs. But most of the zeatin and other cytokinins that are active in plants are synthesized in the apical meristems of roots and transported up into the shoot system via the xylem. Biologists still add cytokinins to plant cells growing in culture, to stimulate cell division (see **BioSkills 12** in Appendix B).

How Do Cytokinins Promote Cell Division? After years of searching, biologists have now isolated and characterized a group of closely related proteins that act as cytokinin receptors. When cytokinins bind to these receptors in the plasma

membranes of target cells, the receptors activate genes that regulate cell division.

Recent research on cytokinins has explored whether they affect molecules that regulate the cell cycle, including the cyclins and the cyclin-dependent kinases (Cdks; see Chapter 12). Recall that activated cyclins and Cdks allow cells to progress through checkpoints in the cell cycle and continue dividing.

To assess whether cytokinins affect cell-cycle genes, researchers grew *Arabidopsis* cells in culture so the nutrients and other molecules available could be carefully controlled. The biologists starved the cells of cytokinins for a day and then added the hormones again to half of the cells. When they assessed the level of mRNA from a cyclin gene called *CycD3*, they documented significant increases in the cells that were treated with cytokinins compared with the level in untreated cells.

This is strong evidence that cytokinins regulate growth by activating genes that keep the cell cycle going. In the absence of cytokinins, cells arrest at the G_2 checkpoint in the cell cycle and stop dividing (**FIGURE 40.18**).

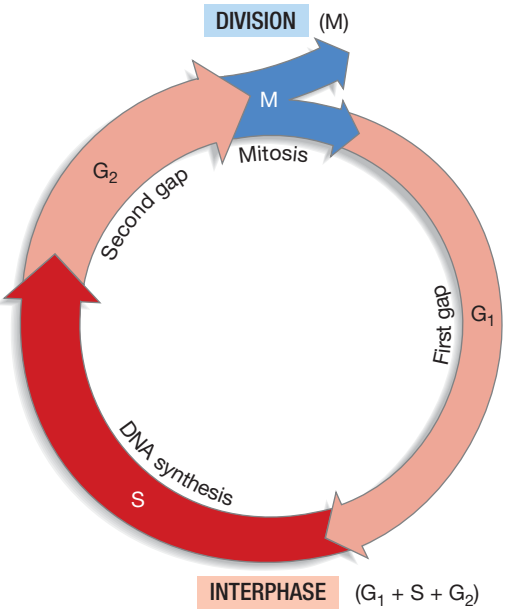

FIGURE 40.18 Cytokinins Affect the Cell Cycle.

Gibberellins and ABA: Growth and Dormancy

In high latitudes and at high elevations, most seeds and mature plants start growing in spring. Conditions for growth are good at that time of year, because temperatures are warming and soil moisture levels are usually at their peak. Seedlings and mature plants continue to grow throughout the summer and early fall if moisture and nutrients are still available.

During drought conditions, however, growth stops. Growth also stops in the embryos inside seeds. Embryos begin to develop as seeds mature, but cease this initial growth and remain dormant throughout the cold winter months. **Dormancy** is a temporary state of reduced metabolic activity.

Which signals initiate growth in response to changing environmental conditions, and which signals stop it? Two hormones provide the answer. **Gibberellins,** a large family of closely related compounds, stimulate growth in plants. **Abscisic acid,** commonly abbreviated **ABA,** inhibits growth. In at least some cases, the two hormones interact like start and stop signals.

The Discovery of Gibberellins Over 100 years ago, Japanese farmers noticed that some of their rice seedlings grew exceptionally quickly but fell over before they could be harvested. Biologists found that the plants with this "foolish seedling disease" were infected with the fungus *Gibberella fujikuroi.*

Researchers confirmed a causal connection between *Gibberella* infection and rapid stem elongation when they treated rice seedlings with an extract from the fungus. As predicted, the treated seedlings produced abnormally long shoots.

The active component in the extract was eventually isolated and named gibberellic acid (GA), which is a gibberellin. Follow-up research showed that rice plants produce their own gibberellin but respond to applications of additional hormone by elongating their stems. In effect, the infected rice seedlings were suffering from a gibberellin overdose. Fungi that manipulate their host plants in this way release their spores higher off the ground, so they are likely to blow farther away from their parent.

Gibberellins are found in a wide array of fungi and plants. Most plant species produce several different gibberellins that are active hormones.

Even though gibberellins have dramatic effects on growth, they are present in vanishingly small concentrations. In growing stems and leaves, active forms of gibberellin may be present in concentrations of about 10 nanograms per gram of tissue.

Defective Gibberellin Genes Cause Dwarfing To find the genes that are responsible for producing gibberellins, biologists analyzed mutant plants with abnormal stem length (**FIGURE 40.19**). Recall that Gregor Mendel analyzed the transmission of two alleles at a single gene that affected stem height in garden peas (see Chapter 14). One allele was associated with tall stems; the other was associated with dwarfed growth. The tall allele was dominant to the dwarf allele.

The gene responsible for the stem-length differences in garden peas is known as *Le* (for *le*ngth). Early work on dwarf mutants showed that they attain normal height if they are treated with the gibberellin called GA_1. This observation suggested that dwarf peas can respond to gibberellins normally—meaning that the problem is not with a hormone receptor.

In follow-up experiments, biologists treated dwarf peas with a radioactively labeled molecule used in the synthesis of GA_1. These plants did not produce radioactively labeled GA_1, even though plants with the normal allele did. Based on these results, researchers became convinced that the *Le* locus encodes an enzyme involved in GA synthesis.

Investigators recently identified the gene at the *Le* locus and confirmed that in dwarf plants, it contains a mutation that renders the enzyme inactive. Over 100 years after Mendel did his

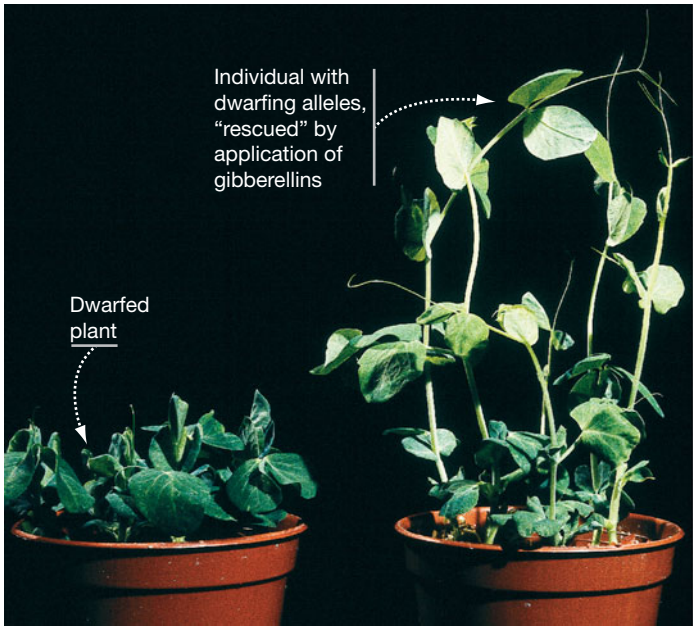

FIGURE 40.19 Dwarfed Individuals May Have Mutations That Affect Gibberellins. Dwarfed plants have much shorter stems than do normal individuals of the same age. By analyzing dwarfed individuals, biologists were able to identify genes involved in gibberellin synthesis.

✔**QUESTION** If dwarfed individuals receive the same amount of sun and thus perform as much photosynthesis as taller individuals, they often produce more flowers and seeds. Why?

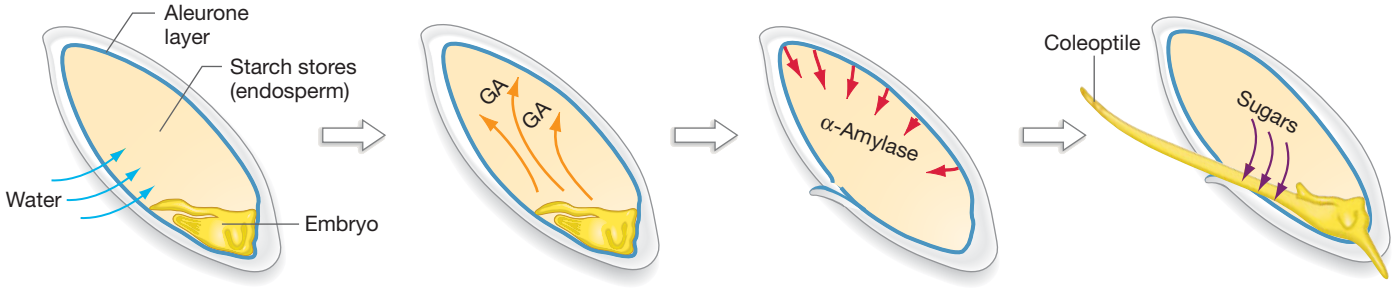
experiments, biologists finally understood the molecular basis of the dwarfing phenotype he studied.

In stems, gibberellins appear to promote both cell elongation and rates of cell division. But it is well established that auxin also promotes cell elongation, and that cytokinins also promote cell division. Research continues on how GAs, cytokinins, and auxin interact on the molecular level to control plant growth and development.

Gibberellins and ABA Interact during Seed Dormancy and Germination Many plants produce seeds that have to undergo a period of drying or a period of cold, wet conditions before they are able to germinate. A requirement for drying ensures that mature seeds will not sprout on the parent plant; an obligatory cold period prevents seeds from germinating just before the onset of winter, when young seedlings would be more likely to perish. Some seeds also have to receive a dose of red light, which indicates that they are in a sunny location.

In essence, then, seeds have an "off" setting that discourages germination and an "on" setting that initiates growth. The appropriate state for the on/off switch is determined by environmental cues such as temperature, moisture, and light.

By applying hormones to seeds, researchers learned that in many plants, ABA is the signal that inhibits seed germination and gibberellins are the signal that triggers germination. To understand how these messengers interact, researchers have studied a specific event: the production of an enzyme called α-amylase in germinating oat or barley seeds.



α-Amylase acts as a digestive enzyme that breaks the bonds between the sugar subunits of starch. (Your saliva contains an amylase that acts on the starch in food. In humans and other mammals, this enzyme initiates carbohydrate digestion in the mouth.)

FIGURE 40.20 shows that, during the germination of a barley seedling, α-amylase is released from a tissue called the aleurone layer. The enzyme diffuses into the starch-filled storage tissue in the seed called endosperm, which is dead when seeds germinate. Digestion of starch releases sugars that can be used by the growing embryo. Adding GA to the aleurone layer increases the production and release of α-amylase; adding ABA to that layer decreases α-amylase levels.

Research on the molecular interaction between GA and ABA carries several important messages:

- A cell's response to a hormone often occurs because specific genes are turned on or off.
- Hormones don't act on genes directly. Instead, a receptor on the surface of a cell or in the cytosol receives the message and

PROCESS: GIBBERELLINS (GAs) ACTIVATE PRODUCTION OF α-AMYLASE

1. The seed absorbs water, and germination begins.

2. Gibberellins diffuse from the embryo to the aleurone layer.

3. Cells in the aleurone layer respond by releasing digestive enzymes, such as α-amylase.

4. The enzymes digest starch, releasing sugars and other molecules to the growing plant.

FIGURE 40.20 The Molecular Mechanism of Gibberellin Action in Seed Germination.

responds by initiating a signal transduction cascade, which activates specific gene regulatory proteins—the activators and repressors of transcription (see Chapter 19).

- Different hormones interact at the molecular level because they induce different gene regulatory proteins, which increase or decrease expression of key genes.

The logic runs as follows: Different hormones trigger the production of different regulatory transcription factors. Hormone concentration affects the amount of each transcription factor produced. Changes in transcription factors are responsible for changes in gene expression.

GA's role in seed germination has important commercial applications. For example, in the production of beer, brewers routinely use gibberellins in the malting process—the conversion of starches stored in barley seeds to sugars. The sugars that are released in response to GA treatment support fermentation by yeast and provide flavor and alcohol in the finished beer.

ABA Closes Guard Cells in Stomata One of the major challenges faced by land plants is replacing water that is lost to the atmosphere when **stomata** are open (see Chapter 38). Because stomata open in response to blue light, they allow gas exchange to occur while the plant is receiving the wavelengths of light used in photosynthesis.

However, if plant roots are unable to obtain enough water to replace what is lost from the leaves, stomata close. Closing stomata is an adaptive response when roots cannot find adequate water, because continued transpiration would lead to wilting and potential tissue damage.

Early work on the mechanism of stomatal closing suggested that ABA is involved. For example, applying ABA to the exterior of stomata causes them to close within seconds.

To explore the hypothesis that a hormone regulates stomatal closing, researchers performed the experiments summarized in **FIGURE 40.21**. The fundamental idea was to grow plants whose roots had been divided. Only one side of the experimental plants was watered, while both sides of the control plants were watered. During this treatment, investigators documented that the water potential of the leaves remained the same in both control and experimental plants. Yet the stomata of experimental plants began to close. This result suggested that roots from the dry side of the pot were signaling drought stress, even though the leaves were not actually experiencing a water shortage.

Follow-up experiments have supported two important predictions: ABA concentrations in roots on the dry side of the pot are extraordinarily high relative to the watered side, and ABA concentrations in the leaves of experimental plants are much higher than in the leaves of control plants.

These results suggest that ABA from roots is transported to leaves and that it serves as an early warning of drought stress. In doing so, ABA overrides the signal from the blue-light photoreceptors introduced earlier in this chapter and causes stomata to close to conserve water.

RESEARCH

QUESTION: Can roots communicate with shoots?

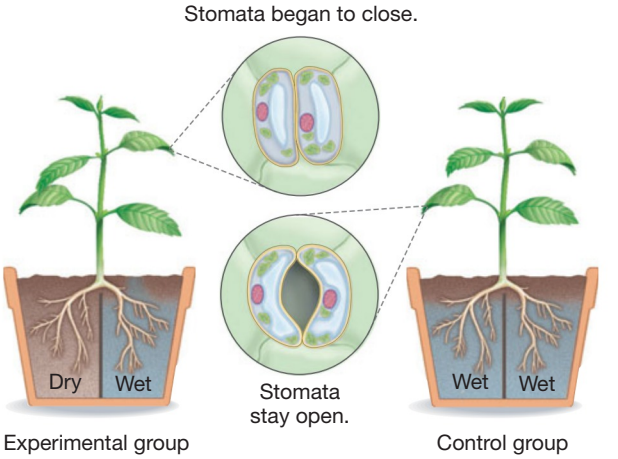
HYPOTHESIS: Roots that are dry can signal shoots to close stomata.

NULL HYPOTHESIS: Roots cannot communicate with the shoot.

EXPERIMENTAL SETUP:

1. Divide roots of many plants into two sides.

2. In experimental group, water one side.



3. In control group, water both sides.

4. In both groups, measure water potential of leaves and observe stomata.

PREDICTION: Stomata in experimental plants will close; stomata in control plants will stay open.

PREDICTION OF NULL HYPOTHESIS: Stomata in both experimental and control plants will stay open.

RESULTS: No difference between experimental and control plants in water potential of leaves.

CONCLUSION: Roots can communicate with shoots. Dry roots signal the shoot and cause stomata to close, even though leaves are receiving sufficient water (from roots on the wet side of the plant).

FIGURE 40.21 Experimental Evidence that Roots Produce an "It's Too Dry" Signal.

SOURCE: Blackman, P. G., and W. J. Davies. 1985. Root to shoot communication in maize plants of the effects of soil drying. *Journal of Experimental Botany* 36: 39–48.

✔**QUESTION** Why was it important to show that the water potential of leaves was the same in the two treatments?

The Molecular Mechanism of Guard-Cell Closure To understand how stomata open and close, recall that a stoma consists of two **guard cells** (see Chapter 37). When the vacuoles of guard cells are filled with water, the cells are turgid. The shape of turgid guard cells results in an open pore between the two cells, which allows gas exchange between the atmosphere and the interior of the leaf. But when vacuoles lose water and guard cells become flaccid and lack turgor, cell shape changes in a way that closes the pore and stops both gas exchange and loss of water via transpiration.

Based on these observations, pursuing the question of how stomata open and close is the same as asking how guard cells become turgid or flaccid—meaning, how water flows into or out of vacuoles. Activation of PHOT by blue light leads to water entry and stomatal opening; activation of ABA receptors leads to water exit and stomatal closing.

Remember that cells do not transport water directly. Instead, they change ion concentrations, creating osmotic gradients that result in water movement.

Considering this process, it shouldn't be surprising to learn that guard-cell opening and closing is based on changes in the activity of H^+-ATPases and ion transporters in the plasma membrane.

When photoreceptors are stimulated by blue light, large numbers of protons are pumped out of each guard cell. As **FIGURE 40.22a** shows, increased H^+-ATPase activity creates a strong electrochemical gradient that brings potassium and chloride ions into

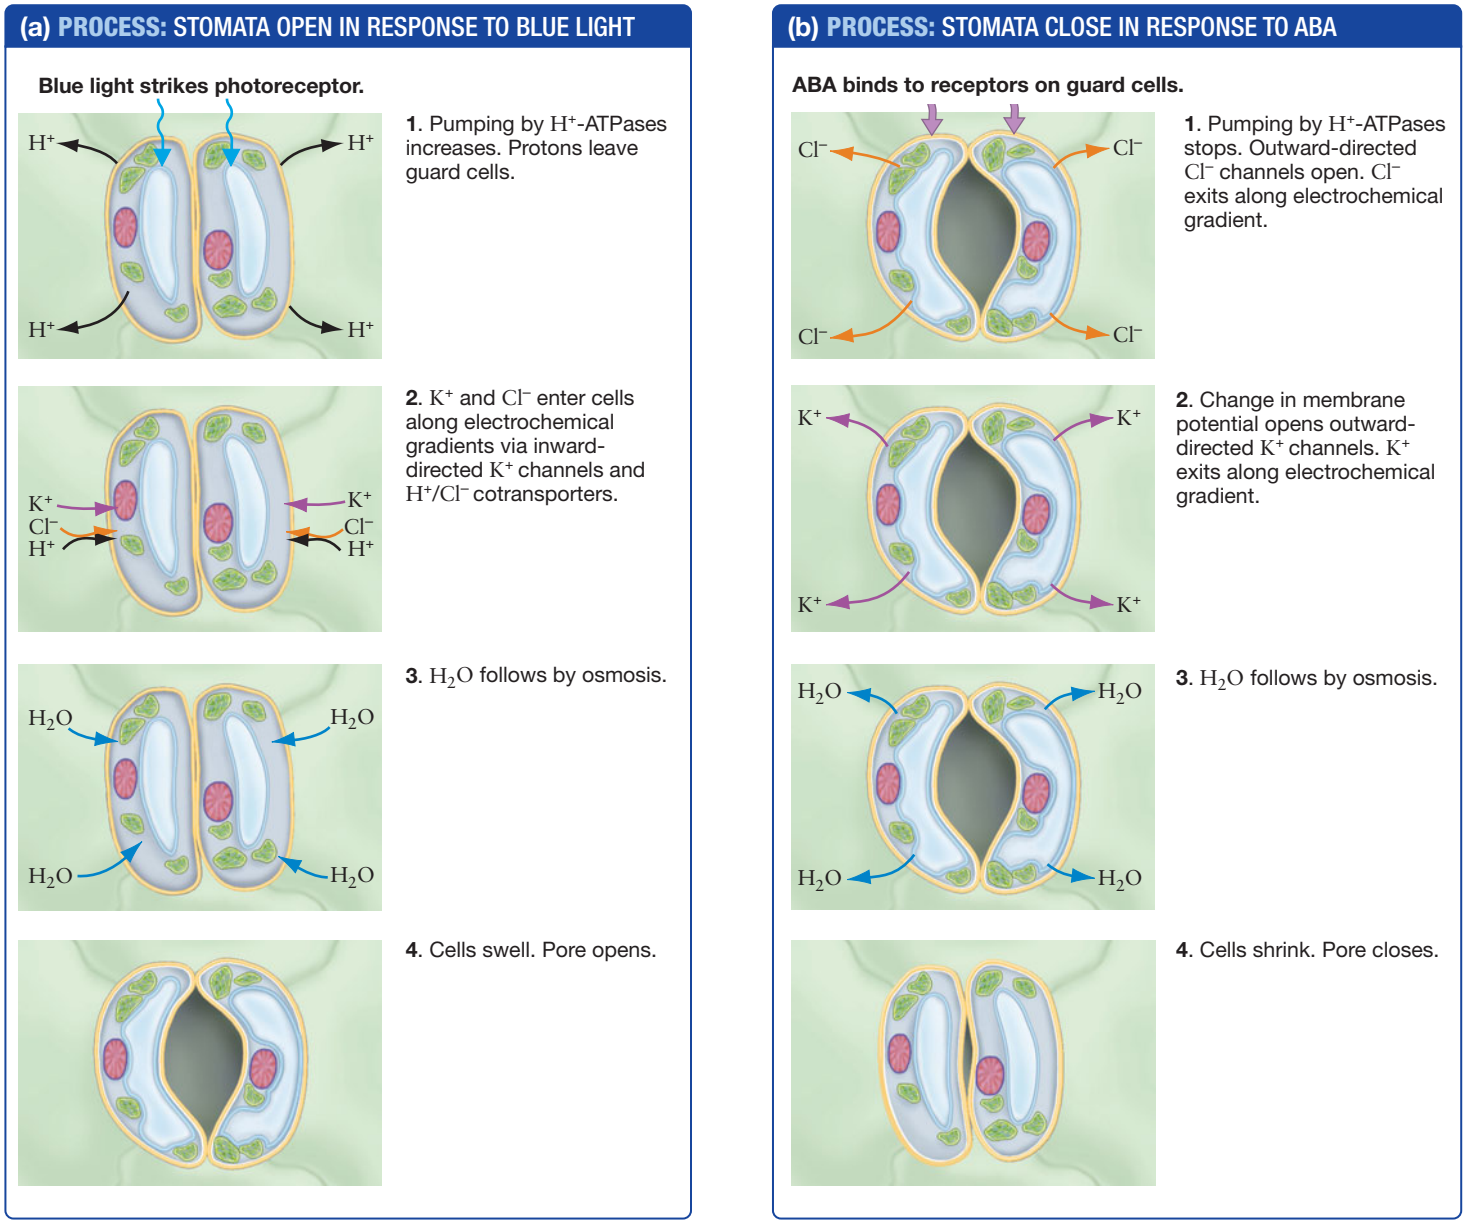


FIGURE 40.22 Changes in Ion Flows Are Responsible for Opening and Closing Stomata. (a) Activated blue-light receptors trigger ion flows into guard cells. The cells swell when water follows by osmosis. **(b)** Activated ABA receptors trigger ion flows out of guard cells. The cells shrink when water follows by osmosis.

the interior of the guard cells. Water follows the incoming ions via osmosis. The upshot? The cells swell and pores open.

But as **FIGURE 40.22b** shows, guard cells respond to ABA in a very different way. When ABA reaches the guard cells, two things happen:

1. H^+-ATPases are inhibited.
2. Channels that allow chloride and other anions to leave along their electrochemical gradients are opened.

When the anions leave guard cells, the change in membrane potential causes outward-directed potassium channels to open. Large amounts of K^+ leave the cells, and water follows by osmosis. The result is a loss of turgor and closing of the pore.

Whether it acts on guard cells or seeds, ABA fulfills a general role in plants as a dormancy or "no-growth" signal. In many cases, its action depends on input from other hormones and photoreceptors. To survive and reproduce successfully, plants have to integrate information from a variety of sources.

Brassinosteroids and Body Size

When you went through puberty, you experienced a growth spurt triggered by surges in steroid hormones called testosterone and estradiol. In plants, growth spurts are triggered by surges in similar steroid hormones called **brassinosteroids.**

The name brassinosteroid was inspired by two observations:

1. The hormones were initially discovered in 1979 in *Brassica napus*—a crop plant that is the source of the canola oil you may use in cooking.
2. They are **steroids**—part of a family of lipid-soluble compounds (see Chapter 6).

Brassinosteroids promote growth and are a key regulator of overall body size in plants. In the model organism *Arabidopsis thaliana*, for example, mutant individuals that cannot synthesize brassinosteroids are extremely dwarfed (see **BioSkills 13**, see Appendix B).

Recent research has highlighted a fascinating difference between the brassinosteroids and the steroid hormones found in animals. Steroid hormones in animals act by entering cells, binding to receptors in the cytosol, and forming a hormone-receptor complex that enters the nucleus (see Chapter 49). This complex then binds to DNA and directly changes gene expression. Because steroids are lipid soluble, researchers were not surprised to find that testosterone and estradiol—animal hormones—cross the plasma membrane before binding to a receptor.

Brassinosteroids, in contrast, are more hydrophilic than animal hormones and never enter the cell. Instead, they bind to receptors on the plasma membrane and activate signal transduction events—probably phosphorylation cascades—that lead to changes in gene expression.

The genes for the synthesis of brassinosteroids appear to be homologous with the genes required for steroid hormone synthesis in animals, meaning that they are derived from a similar gene in the common ancestor of plants and animals. So how do brassinosteroids interact with auxin, cytokinins, and gibberellins to regulate growth and body size? These are questions for future research.

Ethylene and Senescence

Senescence is a regulated process of aging and eventual death of an entire organism or organs such as fruits and leaves. Like most aspects of plant growth and development, senescence is regulated by complex interactions between several hormones in response to changes in temperature, light, and other factors.

The hormone most strongly associated with senescence is **ethylene.** Like other plant hormones, ethylene is simple in structure and active at small concentrations. Unlike other plant hormones, however, ethylene is a gas at normal temperatures.

Ethylene is synthesized from the amino acid methionine and is involved in the following senescence events:

1. fruit ripening, which eventually leads to the aging and rotting of fruit;
2. flowers fading; and
3. leaf abscission—meaning their detachment and fall.

In addition, ethylene influences plant growth, and it is a stress hormone induced by drought and other conditions. Ethylene regulates a surprisingly large range of physiological responses.

The Discovery of Ethylene

Ethylene was initially discovered in ancient China, when fruit growers noticed that burning incense in closed rooms made pears ripen faster. Westerners made a similar observation in the late 1800s, when gas street lamps came into wide use in cities and the plants growing near leaky gas lines dropped their leaves prematurely.

Researchers showed that ethylene in lamp gas was the molecule responsible for the leaf loss; ethylene is likewise present in incense smoke. In the 1930s ethylene was also found in the gases that are released by ripe apples.

Subsequently, biologists documented sharp spikes in ethylene production during fruit ripening in tomatoes, bananas, and certain other species in addition to apples. Follow-up research on these species showed that ethylene induces **(1)** the production of some of the enzymes required for the ripening process, and **(2)** an increase in cellular respiration, which furnishes ATP.

Ethylene and Fruit Ripening

During ripening, stored starch is converted to sugar, enhancing sweetness; protective toxins are removed or destroyed; cell walls are degraded, softening the fruit; chlorophyll is broken down; and pigments and aromas that signal ripeness are produced. Biologists interpret fruit ripening as an adaptation that enhances its attractiveness to birds, mammals, and other animals that disperse seeds to new locations.

Today, fruit sellers manipulate ethylene levels to control fruit ripening. For example, they treat green bananas with ethylene after the bananas have been shipped, to stimulate ripening (**FIGURE 40.23**). Conversely, apples are stored in warehouses with high concentrations of CO_2 and low concentrations of O_2, which inhibits ethylene production in the fruit. Apples stored under these conditions can be sold long after their original harvest date, when untreated fruits have rotted.

FIGURE 40.23 Ethylene Speeds Ripening and Other Aspects of Senescence. These bananas are identical, except that the bunch on the right was exposed to the plant hormone ethylene.

Ethylene and Leaf Abscission Ethylene's effects on leaf senescence and leaf abscission involve complex interactions with auxin and cytokinins. In addition to being synthesized in apical meristems, auxin is produced in healthy leaves. It is then transported from the leaf to the stem through the petiole. In response to age or to changes in ambient temperature or day length, leaves sometimes produce less auxin (**FIGURE 40.24**). As a result, cells in a region of the leaf petiole called the **abscission zone** become more sensitive to ethylene in the tissue.

Increased ethylene sensitivity activates enzymes that weaken the walls of cells in the abscission zone. At the same time, chlorophyll in the leaf is broken down, and nutrients are withdrawn and stored in parenchyma cells in the stem. Eventually the cell walls at the base of the petiole degrade enough that the leaf falls.

Applications of cytokinins, in contrast, reverse these effects and dramatically extend the life span of leaves. As a result, ethylene and cytokinins are thought to have opposite effects on at least some of the processes involved in senescence.

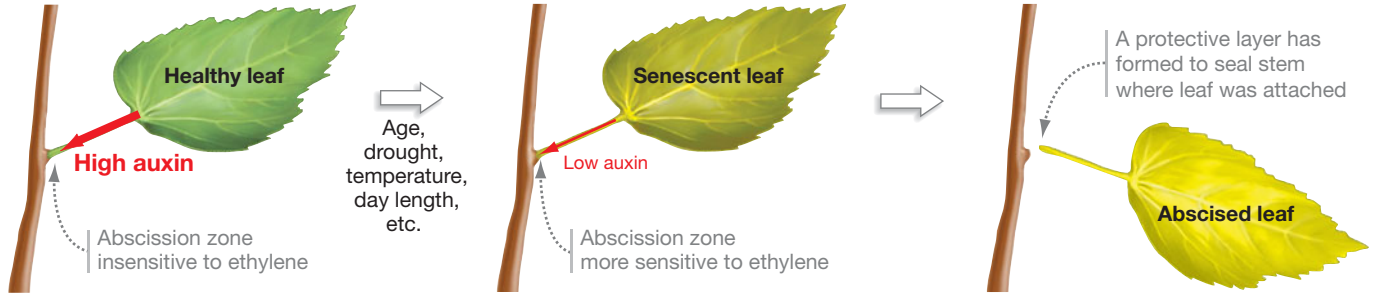
An Overview of Plant Growth Regulators

Understanding how different signals interact is an exciting frontier in research on plant hormones that are growth regulators. Knowledge of the environmental signals that change hormone levels and the genes that they regulate is rapidly improving. In contrast, a great deal remains to be learned about how the information is carried by signal transduction pathways, how those pathways interact, and how plant cells respond.

check your understanding

C Y U

If you understand that . . .



- Auxin's primary role is to signal the position of cells along the long axis of the plant body. This is possible because auxin is produced in developing leaves and undergoes polar transport to the roots, forming a concentration gradient.
- GAs are general signals to initiate or continue growth.
- ABA is a general signal to stop growth or remain dormant.
- Ethylene is a signal that controls senescence.
- Brassinosteroids promote large body size.
- GAs and ABA interact at the molecular level to control seed germination and dormancy.
- Signals from blue light and ABA interact to control the opening and closing of stomata.

✓ You should be able to . . .

1. Predict the effects of watering a large number of daisy plants, each in a pot in a greenhouse, with water that contains either ABA or GAs.
2. Write a hypothesis to explain the adage "one rotten apple spoils the whole bushel."

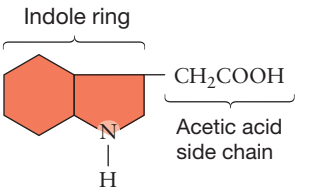
Answers are available in Appendix A.

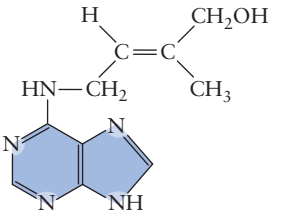
PROCESS: LEAF SENESCENCE AND ABSCISSION

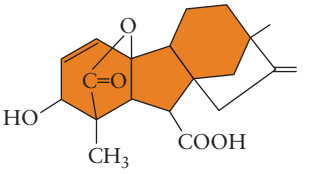
1. High auxin: Leaf functions normally.

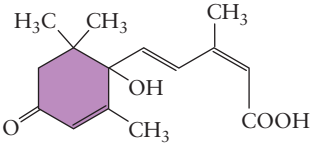
2. Low auxin: Leaf senescence begins.

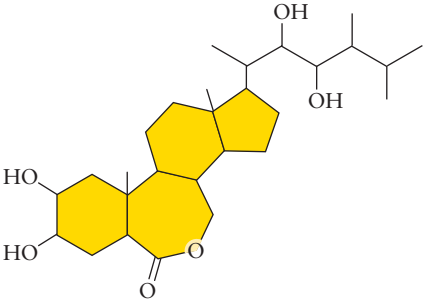
3. Leaf detaches at the abscission zone.











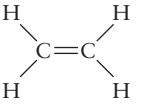


FIGURE 40.24 Leaves Drop in Response to Signals from Auxin and Ethylene. Older leaves produce much less auxin than young leaves do, leading to an increase in ethylene sensitivity and leaf abscission.

TABLE 40.2 provides notes on the structure and function of hormones discussed in this section. As you study this table, two key observations should emerge:

1. It is common for a single hormone to affect many different target tissues. This means that there can be an array of responses to the same cell–cell signal. To interpret this pattern, biologists point out that hormones may carry a common message to a variety of tissues and organs. Auxin can define the root–shoot axis of the body; gibberellins trigger stem growth; cytokinins promote cell division; ABA slows or prevents growth; ethylene signals senescence; and brassinosteroids increase overall mass.
2. In most cases, several different hormones can affect the same response. Stated another way, hormones do not work independently—they interact with each other. To make sense of this pattern, biologists point out that individual hormones tend to be produced in response to an environmental cue at a certain location, such as water availability at root tips. Many environmental cues may be changing at the same time, however. For plants to respond appropriately, they need to integrate information from various environmental cues perceived at various locations in the body.

Cross-talk is the interaction between the signal transduction cascades triggered by different hormones (see Chapter 11). The

SUMMARY TABLE 40.2 Plant Growth Regulators

Hormone	Notes	Chemical Structure
Auxin	• Involved in cell elongation and apical dominance • Promotes differentiation of xylem and phloem • Helps to define long axis of body (phototropism and gravitropism responses) • First plant hormone isolated and characterized • Produced in shoot apical meristems and young leaves	
Cytokinins	• Promote cell division in the presence of auxin • Promote chloroplast development and break lateral bud dormancy • Delay senescence (aging) • Produced in root apical meristems, many other tissues	
Gibberellins (GAs)	• Promote stem growth via both cell elongation and division • Promote seed germination • Produced in apical meristems, immature seeds, and anthers (pollen-producing organs)	
Abscisic Acid (ABA)	• Inhibits bud growth and seed germination • Induces closure of stomata in response to water stress • Acts as a stress hormone analogous to cortisol in humans • Produced in almost all cells	
Brassinosteroids	• Promote cell elongation in stems and leaves • Structurally related to steroid hormones in animals • Act on receptors at cell surface • Produced in almost all tissues	
Ethylene	• Exists in gas form • Involved in fruit ripening • Induces senescence of fruits, flowers and leaves • Produced in all organs when plants are under stress	

key insight to remember is that signaling systems form communication networks. Cross-talk is the molecular mechanism responsible for integrating information from many sensory cells and signals.

The complex interactions among hormones involved in the growth response have a purpose: allowing individuals to survive and thrive long enough to reproduce. The same can be said for the hormones involved in protecting plants from danger.

40.7 Pathogens and Herbivores: The Defense Responses

Plants cannot run away from danger. Instead, they have to stand and fight.

Like humans and other animals, plants are constantly threatened by an array of disease-causing viruses, bacteria, and parasitic fungi. In addition, plant roots are susceptible to attacks by nematodes—the soil-dwelling roundworms (see Chapter 34).

Disease-causing agents are termed **pathogens.** If plants were not able to sense attacks by pathogens and respond to them quickly and effectively, the landscape would be littered with dead and dying vegetation.

The waxy cuticle that covers epidermal cells is an effective barrier to most viruses, bacteria, fungi, and other disease-causing agents, and the structures called thorns, spines, and trichomes help protect leaves and stems from damage by herbivores (see Chapter 37).

In addition, many plants lace their tissues with **secondary metabolites**—molecules that are closely related to compounds in key synthetic pathways but are not found in all plants. Some secondary metabolites function in plant defense by poisoning herbivores.

- The flavorful oils in peppermint, lemon, basil, and sage have insect-repellent properties.
- The pitch that oozes from pines and firs contains a molecule called pinene, which is toxic to bark beetles.
- The pyrethroids produced by *Chrysanthemum* plants are a common ingredient in commercial insecticides.
- Molecules called tannins are found in a wide array of plant species; when they are ingested by animals, tannins bind to digestive enzymes and make the herbivores sick.
- Compounds like opium, caffeine, cocaine, nicotine, and tetrahydrocannabinol (THC) disrupt the nervous systems of plant-eating insects and vertebrates.

Although these defenses are effective, they are also expensive to produce in terms of the ATP and materials invested. It is not surprising that plants often produce defenses or increase their existing defenses only in direct response to attacks by pathogens or herbivores.

Responses to attacks in both plants and animals are called **inducible defenses,** because they are induced by the presence of a threat. Let's first consider how plants sense and respond to viruses and other pathogens and then explore what they do when attacked by insects and other herbivores.

How Do Plants Sense and Respond to Pathogens?

Like animals, plants have remarkably swift and diverse defense mechanisms to resist attacks by viruses, bacteria, and fungi. Plants use a wide variety of sensory proteins to detect invading pathogens and use signaling pathways to carry out their defense. Successful pathogens, in turn, have evolved elaborate mechanisms to evade these defenses.

An Evolutionary Arms Race Most plant pathogens are very specific, infecting only one or a few host species. This is in part due to the long history of coevolution of the pathogen and its host (see Chapter 55).

If a pathogen evolves a mechanism to exploit its host more effectively, the host may evolve new abilities to detect the pathogen and defend itself from attack. In response, the pathogen may then evolve an alternate strategy to evade detection by the host.

The complex interactions that have resulted from this back-and-forth "arms race" have proved challenging for biologists to understand. The human food supply is estimated to be reduced 50 percent worldwide because of plant disease. In the mid-1800s, Ireland experienced a potato famine in which millions of people faced starvation because of a potato pathogen. Pathogens can also be devastating to native species. The once-dominant American chestnut tree was nearly wiped out by a fungal pathogen in the early 1900s.

To cause disease, plant pathogens must first get past the surface of a host plant and begin growing in the apoplast, outside the plasma membranes of cells. Most pathogens enter through stomata or wounds. Once inside the plant, some pathogens kill host cells and feed on the cell debris. More commonly, a pathogen feeds on nutrients from a host cell while it is still alive. How do the plant cells respond to an attack in progress?

The Hypersensitive Response Plant cells contain a variety of receptor proteins that can bind to molecules derived from pathogen cells. When contact is made, these 'surveillance' proteins signal to the plant cell that a pathogen is present, which triggers a cascade of signals that lead to

1. stomatal closure, preventing more pathogen cells from entering the plant;
2. production of toxin molecules targeted to the pathogen;
3. reinforcement of the neighboring plant cell walls to limit movement of the pathogen; and
4. rapid suicide of cells in the infected region.

These events take place within hours of the start of an infection and are termed the **hypersensitive response (HR).** The HR results in small brown spots in leaves—those cells dead by

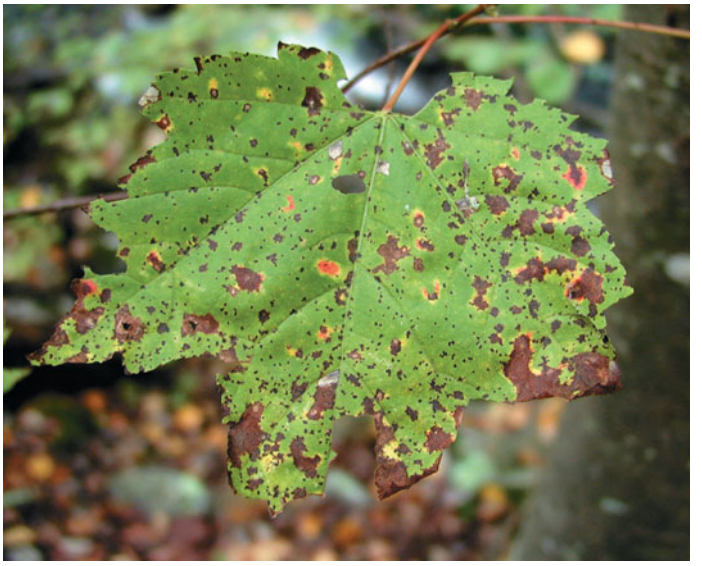

FIGURE 40.25 The Hypersensitive Response Protects Plants from Pathogens. This red maple leaf is riddled with evidence of past infections.

suicide—that accumulate over the growing season (**FIGURE 40.25**). By the end of the growing season, it is rare to find leaves lacking these brown spots. Plants that can detect an infection quickly and induce an HR remain healthy and show no further signs of disease. The HR is similar to the cell-mediated immune response in mammals, which leads to the death of infected cells (see Chapter 51).

✔ If you understand this concept, you should be able to explain the adaptive value of the hypersensitive response despite the death of plant cells.

In the 1990s biologists discovered that a mutant of *Pseudomonas*, a bacterial pathogen, could infect plant cells if it was artificially introduced inside leaves, but the pathogen was unable to cause disease if applied to the outside of leaves. This mutant could not produce a small molecule called coronatine, but the role coronatine played in infection was not clear.

Plants normally respond to *Pseudomonas* by closing their stomata within an hour of detecting the pathogen, effectively slamming the door on future invasions. The normal bacteria, however, are able to interfere with this defense by causing the stomata to re-open several hours later, allowing more bacteria to enter the leaf. In 2006, Maeli Melotto and coworkers discovered that coronatine is the molecule that causes the stomata to re-open. Without the ability to make coronatine, the mutant bacteria couldn't re-open the stomata and were at a clear disadvantage.

Plant defenses are based on good communication not only from cell to cell, as in the HR, but also throughout the plant and even to neighboring plants.

An Alarm Hormone Extends the HR

Once the HR is under way in a localized area of infection, a hormone produced at the infection site travels throughout the body and triggers a slower

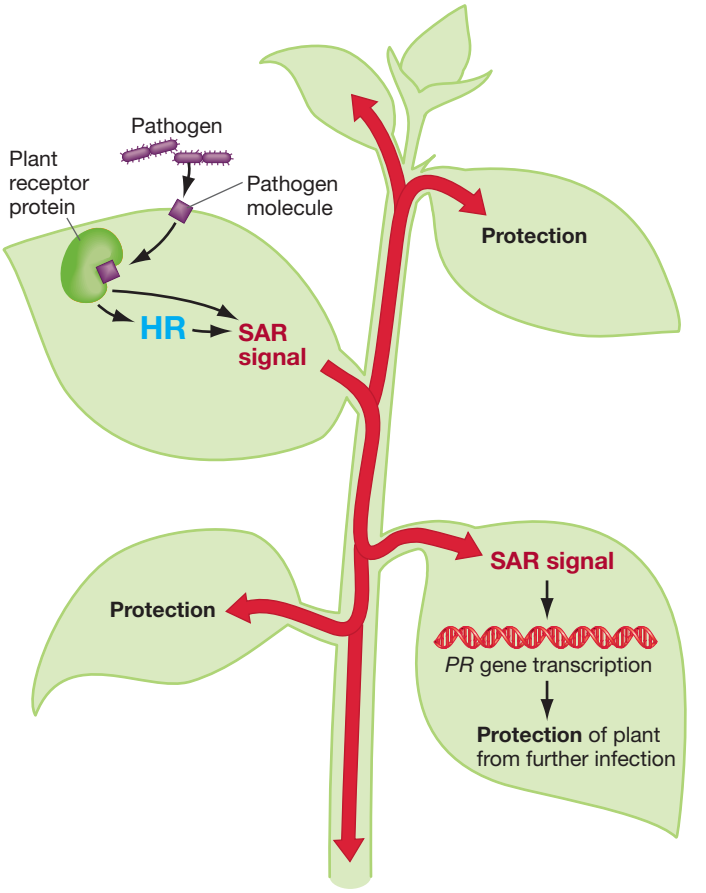

FIGURE 40.26 The Hypersensitive Response Produces a Signal That Induces Systemic Acquired Resistance (SAR). This diagram summarizes the current consensus on how the HR and SAR interact.

and more widespread set of events called **systemic acquired resistance (SAR).** Over the course of several days, SAR primes cells throughout the root or shoot system for resistance to assault by a pathogen—even cells that have not been directly exposed to the disease-causing agent.

FIGURE 40.26 illustrates how the HR and SAR are thought to work together. In addition to triggering the HR, detection of a pathogen leads to the release of a hormone that initiates SAR. This signal acts globally as well as locally—that is, at the point of infection—and results in the expression of a large suite of genes called the pathogenesis-related (*PR*) genes.

When biologists set out to locate the hormone responsible for SAR, they found that levels of **methyl salicylate (MeSA)**—a molecule derived from salicylic acid—increase dramatically after tissues are infected with a pathogen. Follow-up work revealed these findings:

- Phloem sap leaving infected sites has elevated levels of MeSA.
- Treatments that reduce MeSA reduce or abolish SAR.
- Adding MeSA to the lower leaves of tobacco plants leads to SAR in the upper, untreated leaves.

Biologists are working to understand these complex interactions in order to genetically engineer crop plants that can resist diseases. Despite these interventions, however, pathogens continue to evolve, in a never-ending arms race.

How Do Plants Sense and Respond to Herbivore Attack?

Over a million species of insects have been discovered and named so far. Most of them make their living by eating leaves, stems, phloem sap, seeds, roots, or pollen. Plants have effective induced defenses in response to pathogens like viruses, bacteria, and fungi. But can they ramp up defenses in response to insect attack?

The Role of Proteinase Inhibitors When researchers started studying why some plant tissues are more palatable and digestible than others, biochemists discovered that many seeds and some storage organs, such as potato tubers, contain proteins called **proteinase inhibitors.**

Proteinase inhibitors block the enzymes—found in the mouths and stomachs of animals—that are responsible for digesting proteins. When an insect or a mammalian herbivore ingests a large dose of a proteinase inhibitor, the herbivore gets sick. As a result, herbivores learn to detect proteinase inhibitors by taste and avoid plant tissues containing high concentrations of these molecules.

Although many plant tissues contain proteinase inhibitors in low concentrations, biologists wanted to test the hypothesis that these proteins might also be part of an induced defense by the plant. To evaluate this idea, researchers allowed herbivorous beetles to attack one leaf on each of several potato plants.

- In liquid extracted from the other leaves on the attacked plants, proteinase inhibitor concentrations averaged 336 μg per mL of leaf juice.
- In control plants, where no insect damage had occurred, proteinase inhibitor levels averaged just 103 μg per mL.

This result supported the hypothesis that a hormone produced by wounded cells travels to undamaged tissues and induces the production of proteinase inhibitors.

The Discovery of Systemin Biologists isolated the wound-response hormone by purifying the compounds found in tomato leaves and testing them for the ability to induce the synthesis of proteinase inhibitors. The hormone that is active in tomato plants and closely related species turned out to be **systemin,** a polypeptide just 18 amino acids long. Systemin was the first peptide hormone ever described in plants.

Researchers who labeled copies of systemin with a radioactive carbon atom, injected the hormone into plants, and then monitored its location confirmed that systemin moves from damaged tissues to undamaged tissues.

Currently, work on the production of systemin and proteinase inhibitors focuses on determining each step in the signal transduction pathway that alerts undamaged cells to danger (**FIGURE 40.27**). The data have yielded the following results:

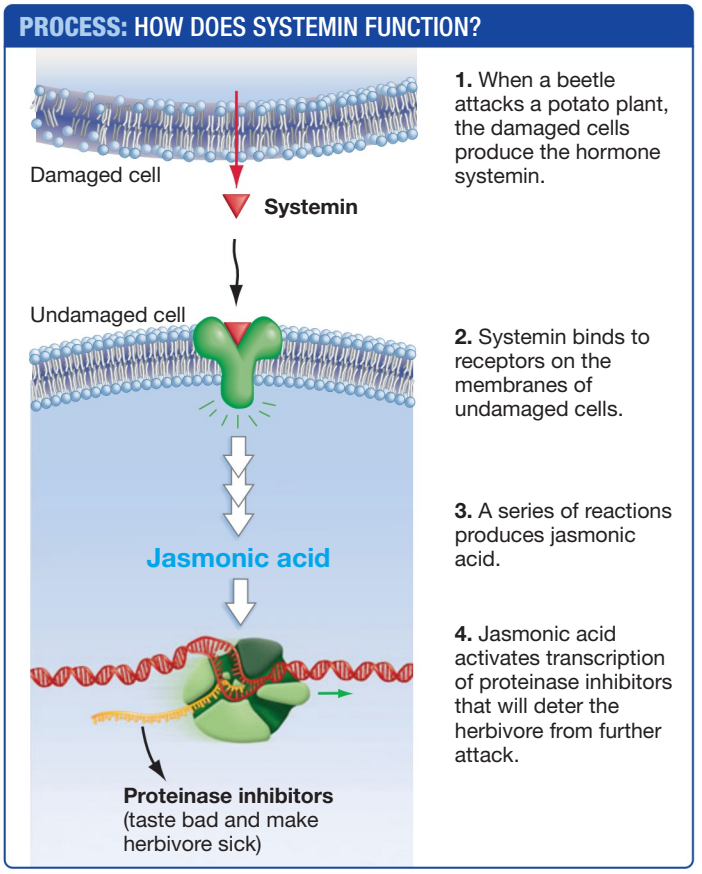

FIGURE 40.27 Signals from Insect-Damaged Cells Prepare Other Cells for Attack. Systemin, a hormone produced by herbivore-damaged cells, initiates a protective response in undamaged cells.

1. Systemin is released from damaged cells.
2. Systemin travels through the body via phloem and binds to membrane receptors on target cells.
3. The activated receptor triggers a series of chemical reactions that eventually synthesize a molecule called jasmonic acid.
4. Jasmonic acid activates the production of at least 15 new gene products, including proteinase inhibitors.

In this way, plants build potent concentrations of insecticides in tissues that are in imminent danger of attack.

"Talking Trees": Responses from Nearby Plants When an insect starts munching on a leaf, volatile compounds evaporate from the leaf's surface and travel through the air. In the 1980s, researchers began to suspect that plants growing near other plants under herbivore attack "eavesdrop" on these volatiles. In response, they increase their own defenses—even though they've yet to be attacked.

The "talking trees" hypothesis has received extensive support, primarily through experiments based on exposing plants to volatiles in the absence of any insects. Even if the volatiles come from

an entirely different species, research has shown that plants can sense the presence of these chemicals and respond by increasing the production of proteinase inhibitors and other defense compounds.

In some cases, plants that are under attack even call for help from other organisms.

Pheromones Released from Plant Wounds Recruit Help from Wasps Caterpillars and other herbivorous insects have enemies of their own—often wasps that lay their eggs in the insects' bodies. When wasp eggs hatch inside a caterpillar, the wasp larvae begin eating the host from the inside out. An organism that is free living as an adult but parasitic as a larva, such as these wasps, is called a **parasitoid** (**FIGURE 40.28**).

Biologists observed that parasitoids are particularly common when insect outbreaks occur in croplands. They wondered whether wounded plants release compounds that actively recruit parasitoids. More specifically, they hypothesized that plants produce **pheromones**—chemical messengers that are synthesized by an individual and released into the environment, and that elicit a response from a different individual. Hormones act on cells inside an individual; pheromones act on another individual.

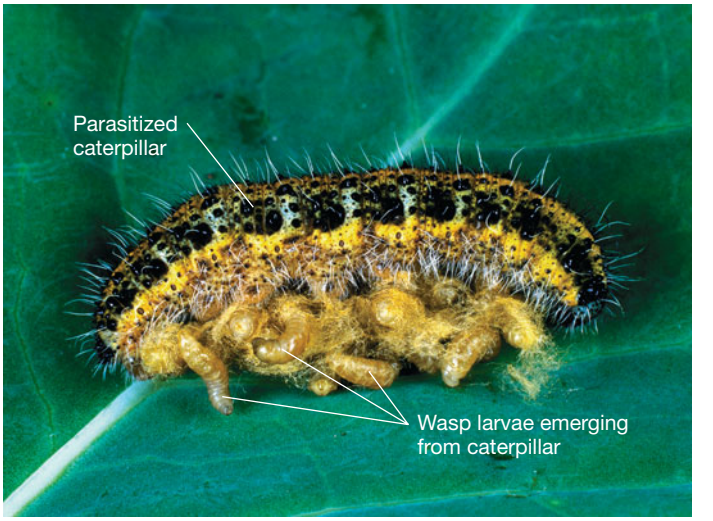

FIGURE 40.28 Parasitoids Kill Herbivores. When this plant was first attacked by this caterpillar, it produced pheromones that attracted a female wasp. The wasp laid her eggs in the caterpillar. As the wasp larvae grew and developed into pupae, they devoured the caterpillar.

SUMMARY TABLE 40.3 Selected Sensory Systems in Plants

Stimulus	Receptor	Signal Transduction	Response	Adaptive Significance
Blue light	PHOT1 and other phototropins in stem and leaves	PHOT1 autophosphorylates; remainder of signal transduction systems unknown	Phototropism occurs; also involved in stomatal opening	Stems grow toward light with wavelengths needed for photosynthesis
Red light	Phytochrome in seeds and elsewhere	Phytochrome changes to P_{fr} form and activates responses	Seed germinates	Sunlight triggers germination
Far-red light	Phytochrome in stem and elsewhere	P_r moves into nuclei and induces genetic responses	Stems lengthen	Species that require full sunlight attempt to escape shade from leaves
Gravity	Proteins located in plasma membrane	Details unknown	Cells on opposite side of root or shoot elongate; tissue curves	Roots grow down; shoots grow up
Touch or wind	Stretch receptors; location unknown	Details unknown, but result is transcription activation in target genes	Stems grow shorter and thicker; in some cases vining (twining) growth	Individual is more resistant to damage; plants grow toward light
Touch	Receptor hair cell in Venus flytrap	Electrical changes in receptor cell's plasma membrane trigger action potentials	Target cells change shape; trap shuts	Plant can capture prey
Pathogens	Receptor protein products	Details unknown	Hypersensitive response (HR); death of infected cells	Pathogens starve, so infection is slowed or stopped
Herbivores	Unknown; activated in response to molecule from herbivore	Details unknown	Insecticide production; signals to parasitoids	Herbivores are sickened or killed

To explore this idea, researchers analyzed compounds that were released from corn seedlings during attacks by caterpillars. The insect-damaged leaves produced 11 molecules that were not produced by undamaged leaves. These compounds were not released by leaves that had been cut with scissors or crushed with a tool; only insect damage triggered their production.

To follow up on this result, the investigators put female wasps in an arena that contained leaves damaged by insects and leaves that had suffered only mechanical damage. In more than two-thirds of the tests that were performed, the wasps preferred to fly toward the insect-damaged leaves.

These results support the hypothesis that plants produce wasp attractants in response to attack by caterpillars. Biologists are increasingly convinced that plants can produce pheromones that recruit help in the form of egg-laden wasps.

From the research that has been done on plant sensory systems, it is abundantly clear that plants don't just sit there. These organisms may be stationary, but they constantly monitor and respond to a wide array of information about their environment (**TABLE 40.3**). Gaining a better understanding of phototropism, gravitropism, response to disease, and other aspects of plant behavior forms an exciting frontier in biology.

check your understanding

C Y U

If you understand that . . .

- The presence of receptor protein products allows plants to recognize attacks by parasites such as viruses, bacteria, and fungi.
- When a receptor protein binds to a molecule derived from a pathogen, a signal transduction sequence results in the hypersensitive response (HR).
- When plants are attacked by insect herbivores, damaged tissues release signals that trigger the production of toxins in undamaged leaves and that recruit enemies of the insects.

✔ You should be able to . . .

1. Explain the fitness advantage of having a wide array of receptor proteins in a single individual.
2. Explain why plants do not maintain high proteinase inhibitor concentrations in their tissues at all times.

Answers are available in Appendix A.

CHAPTER 40 REVIEW

For media, go to MasteringBiology MB

If you understand . . .

40.1 Information Processing in Plants

- In most cases, information processing in plants starts when a receptor protein changes shape in response to a stimulus.
- When signal transduction occurs, an external signal is changed into an intracellular signal.
- In receptor cells, signal transduction culminates in the production of hormones that are transported throughout the plant body.
- If a hormone binds to a receptor on a target cell, signal transduction occurs and culminates in changes in gene expression, altered translation rates, or changes in the activity of specific membrane pumps, channels, or ion carriers.

✔ **You should be able to explain the analogy between how a plant sensory cell works and the following events: A person sees a barn on fire and calls the rural fire department; the dispatcher rings a siren; in response, members of the volunteer fire department race to the station to get the pumper truck.**

40.2 Blue Light: The Phototropic Response

- Phototropins are blue-light receptors that become phosphorylated and then initiate signal transduction pathways.
- In the phototropic response, cells near the tips of coleoptiles sense changes in blue light and respond by altering the distribution of the hormone auxin. Cells on one side of the coleoptile elongate in response to auxin much more than do cells on the other side of the coleoptile. In this way, plants bend toward sunlight.

✔ **You should be able to predict whether the phototropic response differs in plants that require high-light conditions versus plants that thrive best in low-light conditions.**

40.3 Red and Far-Red Light: Germination, Stem Elongation, and Flowering

- Phytochrome is a red/far-red switch that allows plants to detect shade from other plants and regulates a wide variety of plant growth responses including germination, stem elongation, and flowering.
- The phytochrome protein changes shape when it absorbs red light. The same protein changes to an alternate shape when it absorbs far-red light.

✔ **You should be able to state a hypothesis to explain why animals do not have phytochromes (a red/far-red light switch).**

40.4 Gravity: The Gravitropic Response

- Cells in the center of root caps contain amyloplasts with starch granules that function as statoliths and cause roots to grow down in response to gravity.
- Redistribution of auxin in response to gravity results in downward growth of roots and upward growth of shoots.

✔ **You should be able to explain why starch granules make good gravity-sensing bodies.**

40.5 How Do Plants Respond to Wind and Touch?

- Some plants respond to touch, including wind, by growing more slowly and becoming stocky.
- Thigmotropism is a direction response to touch, such as tendril coiling and closing of Venus flytraps.

✔ **You should be able to describe the adaptive significance of the response to wind.**

40.6 Youth, Maturity, and Aging: The Growth Responses

- Several key hormones regulate plant growth.
- Auxin establishes and maintains the long axis of the plant body, playing a key role in phototropism and gravitropism and maintaining apical dominance. All of these responses rely on the polar transport of auxin, which establishes a gradient in auxin from the plant's shoot tips to its root tips.
- Cytokinins promote cell division by regulating the cell cycle, and they delay senescence.
- Gibberellins (GAs) signal that conditions for growth are good and promote the initiation or continuation of growth and development.
- Abscisic acid (ABA) signals that environmental conditions are bad by suppressing growth, enforcing dormancy, and closing stomata.
- Regulation of dormancy and growth by ABA and by GAs are examples of how hormones interact—allowing plants to integrate information from several different stimuli and respond appropriately.
- Brassinosteroids are steroid hormones that regulate growth.
- Ethylene is a gaseous hormone that triggers senescence and fruit ripening, and it plays a role in leaf abscission.

✔ **You should be able to suggest a hypothesis explaining why some hormones are not transported in a single direction.**

40.7 Pathogens and Herbivores: The Defense Responses

- Plants have receptor proteins that detect pathogen infection and trigger the hypersensitive response, which limits the spread of disease.
- Herbivores trigger plant responses that lead to the synthesis of molecules that make plants less palatable.
- Localized infection or herbivory stimulates long-distance signaling and defense responses throughout the plant.
- Volatile signals triggered by herbivory attract parasitoids that attack the herbivores.

✔ **You should be able to explain why cell suicide is beneficial to a plant.**

TEST YOUR KNOWLEDGE

Answers are available in Appendix A

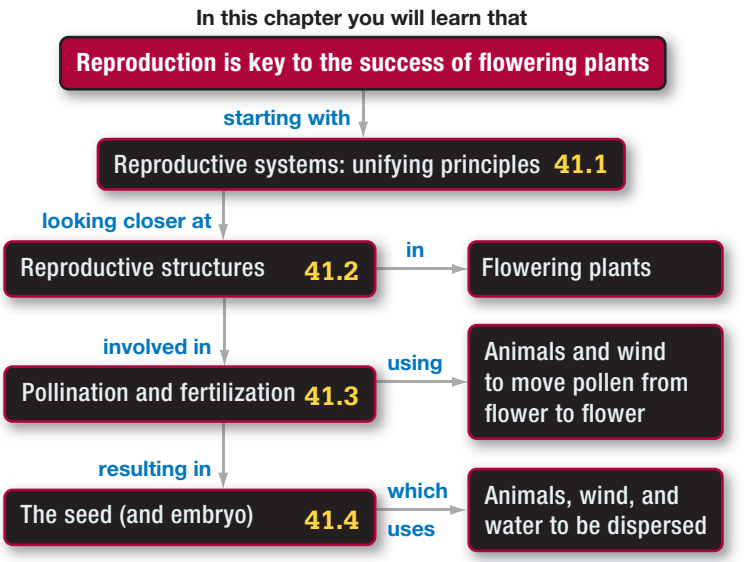
1. Which of the following statements about phytochrome is *not* correct?
   a. It is photoreversible.
   b. Its function was understood long before the protein itself was isolated.
   c. The P_{fr} form activates the responses to red light.
   d. It is involved in guard-cell opening.

2. If a plant is touched repeatedly over the course of many days or if it experiences long-term exposure to wind, what happens?
   a. Growth of the root system is accelerated, making the plant more stable.
   b. Large-scale changes in gene expression occur, resulting in shoots that are short and stout.
   c. Electrical signals cause leaves to fold up, avoiding damage.
   d. Continued mechanical stimulation indicates that the individual is threatened with destruction, so it initiates flowering in an attempt to reproduce before it dies.

3. Which of the following statements about hormones is correct?
   a. They tend to be large molecules.
   b. They exert their effects only on the same cells that produce them.
   c. They can exert strong effects only when they are present in high concentrations.
   d. They trigger a response by binding to receptors in target cells.
4. What evidence suggests that ABA from roots can signal guard cells to close?
   a. If roots are given sufficient water, guard cells close anyway.
   b. If roots are dry, guard cells begin to close—even though leaves are not experiencing water stress.
   c. Applying ABA on guard cells directly causes them to close.
   d. If roots are dry, ABA concentrations in leaf cells drop dramatically.
5. What is the rapid death of plant cells in response to a pathogen attack called?
6. Unlike animal steroid hormone receptors, where are brassinosteroid receptors located?

TEST YOUR UNDERSTANDING

Answers are available in Appendix A



7. Why was it logical to predict that amyloplasts function as statoliths?
   a. They are dense and settle to the bottom of gravity-sensing cells.
   b. They are present only in gravity-sensing cells.
   c. They make a direct physical connection with membrane proteins that have been shown to be the gravity-receptor molecule.
   d. Their density changes in response to gravity.
8. Phytochromes can be considered "shade detectors," while phototropins such as PHOT1 can be considered "sunlight detectors." Explain why these characterizations are valid.
9. What does transduce mean? Compare and contrast two types of transduction processes described for a sensory or a defense process.
10. A plant's response to a given hormone depends on the cells or tissues that receive the signal, the plant's developmental stage or age, the concentration of the hormone, and the concentration of other plant hormones that are present. Provide examples that support each of these claims.
11. Discuss the general role that ethylene serves in plants, and predict how produce dealers deal with benefits or costs of the effects of ethylene.
12. Suppose that a mutant plant is unable to make methyl salicylate. Explain why it is not likely to survive in the wild.

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A

13. To explore how hormones function, researchers have begun to transform plants with particular genes. In one experiment, a gene involved in cytokinin synthesis was introduced into tobacco plants. Which one of the following results would be expected?
   a. Individuals produced more lateral branches.
   b. Stems grew extremely tall and slender.
   c. Roots were incapable of responding to gravity.
   d. Stomata were closed most of the time.
14. In general, small seeds that have few food reserves must be exposed to red light before they will germinate. (Lettuce is an example.) In contrast, large seeds that have substantial food reserves typically do not depend on red light as a stimulus to trigger germination. State a hypothesis to explain these observations.
15. In many species native to tropical wet forests, seeds do not undergo a period of dormancy. Instead, they germinate immediately. Make a prediction about the role of ABA in these seeds. How would you test your prediction?
16. Researchers have shown that transforming plants with genes encoding resistance proteins makes these plants resistant to more pathogens. How might the pathogens evolve when exposed to these genetically altered plants?

41 Plant Reproduction

This chapter focuses on the structure and function of plant reproductive structures like those of this flower.

t would be difficult to overemphasize the importance of the reproductive organs and processes that are analyzed in this chapter—for plants, for biologists, and for you.

- For plants, every structure in the body and every physiological process—from water transport to photosynthesis—exist for one reason: to maximize the chances that the individual will produce offspring. Reproduction is the unconscious goal of everything that an organism does (see Chapter 1).
- For biologists, plant reproduction is not only fundamental to understanding how plants work but also the basis for major industries. Agriculture, horticulture, forestry, biotechnology, and ecological restoration draw extensively on what biologists know about plant reproduction.

BIG PICTURE

This chapter is part of the Big Picture. See how on pages 840–841.

✓ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

- For you, plant reproduction for the most part means food. Human diets are based on consuming plant reproductive structures—primarily the seeds and fruits derived from flowers. A **flower** is a reproductive structure that produces gametes, attracts gametes from other individuals, nourishes embryos, and develops seeds and fruits. **Seeds** consist of an embryo and nutrient stores surrounded by a protective coat. **Fruits** develop from the flower's seed-producing organ and contain seeds.

This chapter's analysis of plant reproduction focuses on angiosperms, for three reasons: (**1**) Angiosperms represent over 85 percent of the land plants described to date; (**2**) virtually every important domesticated plant is an angiosperm; and (**3**) aspects of reproduction in other land plant lineages were described previously (see Chapter 31). By the end of this chapter, you'll appreciate the practical aspects of flowers as well as their beauty.

41.1 An Introduction to Plant Reproduction

Plant reproductive structures and processes vary among species. Consider just one aspect of reproductive organs—size. Flowers vary from microscopic to the size of a small child; seeds and fruits range from dustlike particles to coconuts.

Fortunately for students of plant biology, several basic principles unify this diversity of reproductive systems. Let's begin by defining sex.

Sexual Reproduction

Most plants reproduce sexually. **Sexual reproduction** is based on meiosis and fertilization, and it results in offspring that are genetically unlike each other and unlike their parents (see Chapter 13). In plants, meiosis and fertilization occur in alternate phases of a life cycle.

To review briefly, **meiosis** is a type of nuclear division that results in four daughter cells, each of which has half the number of chromosomes present in the parent cell. **Fertilization** is the fusion of haploid cells termed **gametes.** The result of fertilization is the production of a single, diploid cell called the **zygote,** which will develop into a multicellular individual. Male gametes, or **sperm,** are small cells that contribute genetic information in the form of DNA but few or no nutrients to the offspring. Female gametes, or **eggs,** also contain DNA. But the female parent contributes nutrient stores as well. The important point is that although both sperm and egg contribute DNA, the male and female parents contribute vastly different amounts of other resources to the offspring.

Meiosis and fertilization result in offspring that are genetically unlike the parents. Sexual reproduction produces genetically diverse offspring that can potentially be more successful than their parents at warding off attacks from viruses, bacteria, and other pathogens (see Chapter 13).

The advantages of sexual reproduction are common to all eukaryotes that undergo meiosis. When and where meiosis occurs, however, is highly variable. Let's take a closer look.

The Land Plant Life Cycle

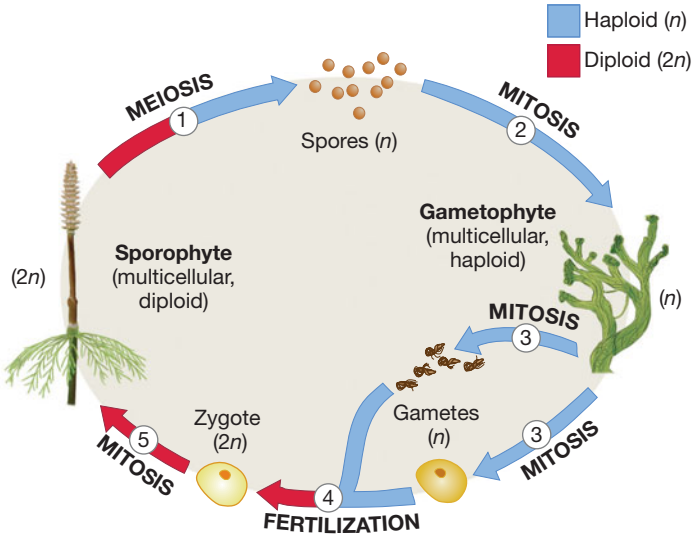
In most animals, meiosis leads directly to the formation of gametes. In plants, the situation is much different.

Land plants are characterized by a life cycle with two distinct multicellular forms—one diploid and one haploid. An individual in the diploid phase of the life cycle is called a **sporophyte,** while an individual in the haploid phase of the life cycle is called a **gametophyte.**

This type of life cycle, called **alternation of generations,** has evolved independently in various protists and land plant groups (see Chapters 30 and 31).

What Is Alternation of Generations? Key features of alternation of generations are reviewed in **FIGURE 41.1**. When alternation of generations occurs, meiosis does not lead directly to the formation of gametes, as it does in humans and other animals. Instead, it leads to the production of haploid cells called spores. A **spore** is a cell that grows directly into an adult individual. Several structures and processes are common to all land plant life cycles:

1. Meiosis occurs in sporophytes and results in the production of haploid spores. Unlike zygotes, spores are not produced by the fusion of two cells. Unlike gametes, spores produce an adult without fusing with another cell. Meiosis and spore production occur inside structures called **sporangia.**
2. Spores undergo mitosis and divide to form multicellular, haploid gametophytes.
3. Gametophytes produce gametes using mitosis.
4. Fertilization occurs when two gametes fuse to form a diploid zygote.



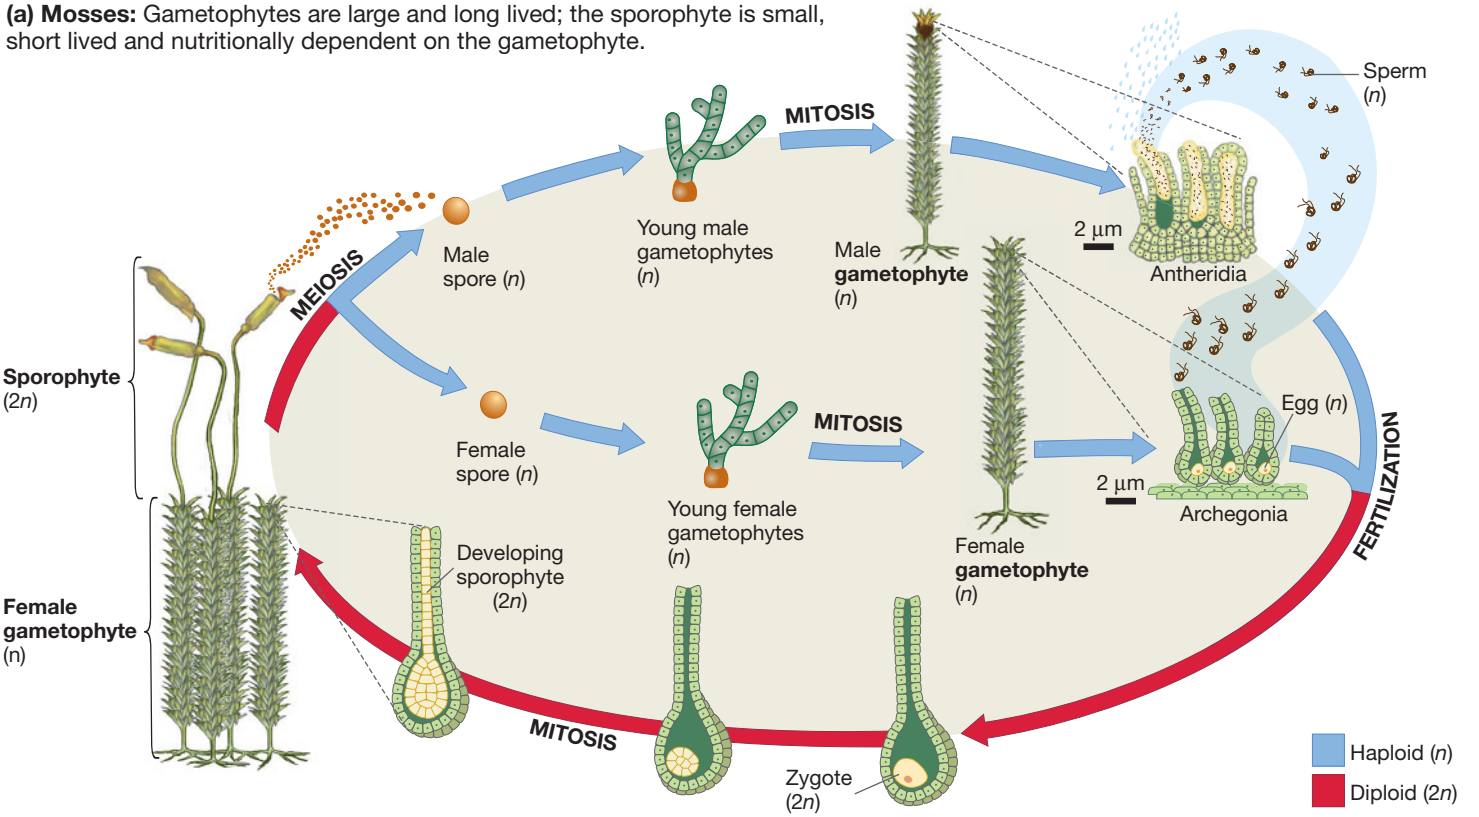


FIGURE 41.1 All Plants Undergo Alternation of Generations.

(a) Mosses: Gametophytes are large and long lived; the sporophyte is small, short lived and nutritionally dependent on the gametophyte.

(b) Angiosperms: Sporophyte is large and long lived; gametophytes are small (microscopic), short lived, and nutritionally dependent on the sporophyte.

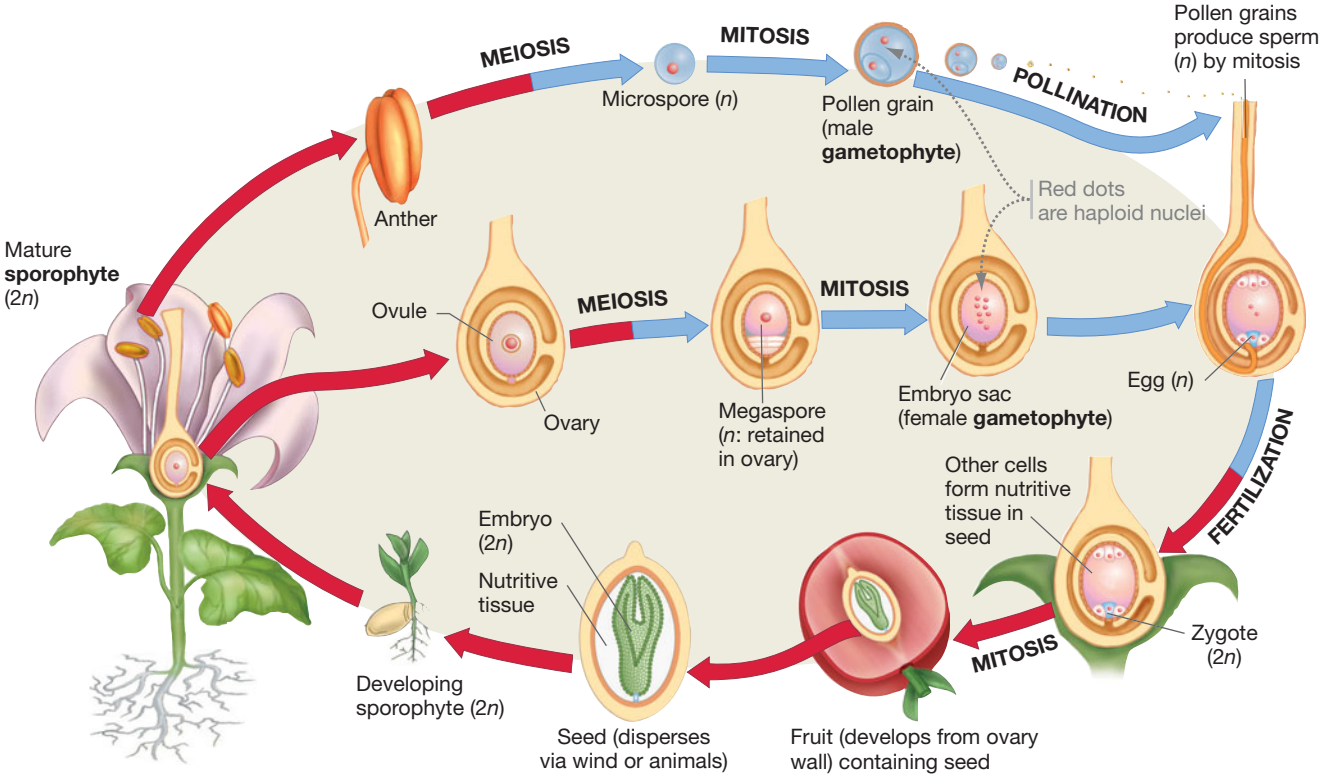

FIGURE 41.2 There Is Wide Variation in Plant Life Cycles. (a) Mosses, **(b)** Angiosperms.

5. The zygote undergoes mitosis and grows to form the multicellular sporophyte.

A good way to keep these terms straight is to remember that sporophyte means spore-plant, while gametophyte means gamete-plant. Sporophytes produce spores by meiosis. Gametophytes produce gametes by mitosis.

Variation in Plant Life Cycles Land plant species vary a great deal in how large and long lived the gametophyte and sporophyte are relative to each other (see Chapter 31). The examples in **FIGURE 41.2** represent the extremes of the variation in life cycles observed within land plants.

- Figure 41.2a diagrams the life cycle of a moss. Notice that the largest stage in the moss life cycle is the gametophyte. The sporophyte is dependent on the gametophyte for nutrition.
- Figure 41.2b diagrams the life cycle of an angiosperm. Notice that the male and female gametophytes are microscopic, physically separate, and completely dependent on the sporophyte for nutrition.

✔ If you understand the angiosperm life cycle, you should be able to (1) identify the male spore and female spore in Figure 41.2b, and (2) provide evidence to support the statement that in angiosperms, female gametophytes never leave their parent plant.

The non-vascular plants (sometimes called bryophytes), which include mosses, are the sister group to all other land plants, and they are found early in the fossil record. Angiosperms, in contrast, are the most recent lineage of land plants to appear in the fossil record and the most derived branch on the evolutionary tree. Based on these observations, biologists have concluded that over the course of land plant evolution, gametophytes became reduced while sporophytes became more conspicuous.

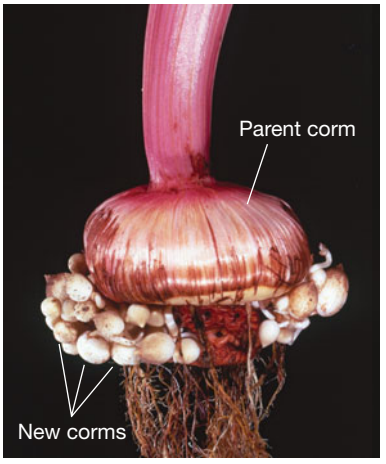
Why this trend occurred is still unknown. The adaptive significance of the gametophyte and sporophyte phases remains a challenge for biologists interested in plant reproduction.

Asexual Reproduction

Asexual reproduction does not involve fertilization and results in the production of **clones**—genetically identical copies of the parent plant.

Some plants extend their life indefinitely by asexual reproduction. The oldest of all known plants is a ring of creosote bushes in the Mojave Desert of California. The bushes comprise a clone that originated from a parent plant estimated to have germinated 12,000 years ago.

Although all asexual reproduction is based on mitosis, a wide array of mechanisms exists.



- **FIGURE 41.3a** shows grass shoots and roots emerging from nodes on underground horizontal stems called **rhizomes.** If the individuals emerging from the nodes become separated from the parent plant, they represent asexually produced offspring.
- The gladiolus plant in **FIGURE 41.3b** has propagated itself via modified stems called **corms,** which grow under the surface of the soil.
- The kalanchoe in **FIGURE 41.3c** produces "plantlets" (small plants) from meristematic tissue located along the margins of its leaves. When the plantlets mature, they drop off the parent plant and grow into independent individuals.
- In dandelion and certain other species, mature seeds can form without fertilization occurring. This phenomenon, known as **apomixis,** results in seeds that are genetically identical to the parent.

The key characteristic of asexual reproduction is efficiency. If an herbivore or a disease wipes out the plants surrounding a grass plant, the grass can quickly send out horizontal stems. Its asexually produced offspring are likely to fill the unoccupied space before seeds from competitors can establish themselves and grow. The parent plant can also nourish these progeny as they become established.

(c) Plantlets

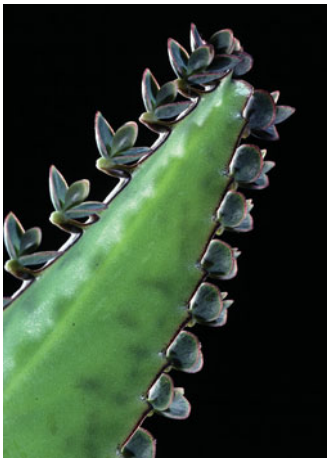

FIGURE 41.3 The Mechanisms of Asexual Reproduction Are Diverse. These are just three of many mechanisms of asexual reproduction in plants.

Although asexual reproduction is extremely common in plants, it does have a downside. The most important is that a fungus or other disease-causing agent that infects an individual plant will probably succeed in infecting the plant's cloned offspring as well, even if they are no longer physically connected.

This hypothesis is based on the observation that plants fight disease with a wide variety of molecules (see Chapter 40). Because sexually produced offspring are genetically unlike their parents, these offspring have unique combinations of disease-fighting molecules and may be able to resist infections that devastate their parents.

This is an important point in agriculture and horticulture because asexually propagated apples, bananas, and other crops are more susceptible to epidemics than are sexually propagated species. How does sexual reproduction occur?

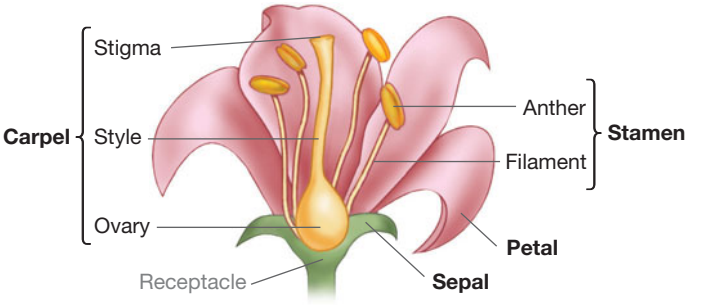
41.2 Reproductive Structures

Each major group of plants, from mosses to angiosperms, has a characteristic variation on the theme of alternation of generations, as well as characteristic male and female reproductive structures (see Chapter 31). Here, though, the focus is on the flower.

The General Structure of the Flower

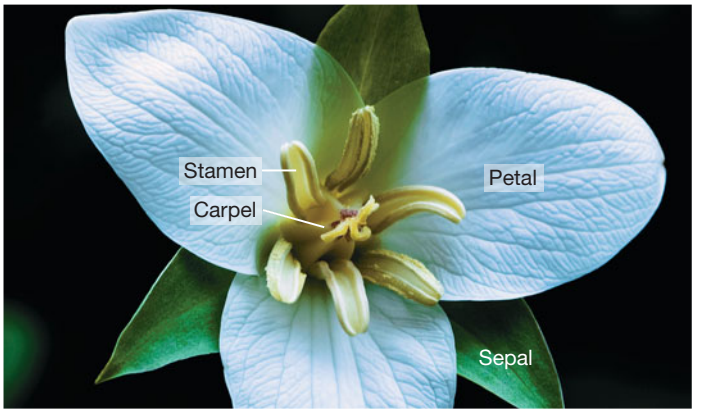
Structurally, all flowers are variations on a theme. They are made up of four basic organs that are essentially modified leaves: **(1)** sepals, **(2)** petals, **(3)** stamens, and **(4)** one or more carpels. These organs are attached to a compressed portion of stem called the receptacle (**FIGURE 41.4a**).

Not all four organs are present in all flowers, however; and as **FIGURE 41.4b** shows, the coloration, size, and shape of these four components are fabulously diverse. Let's consider each of the four parts, in turn.

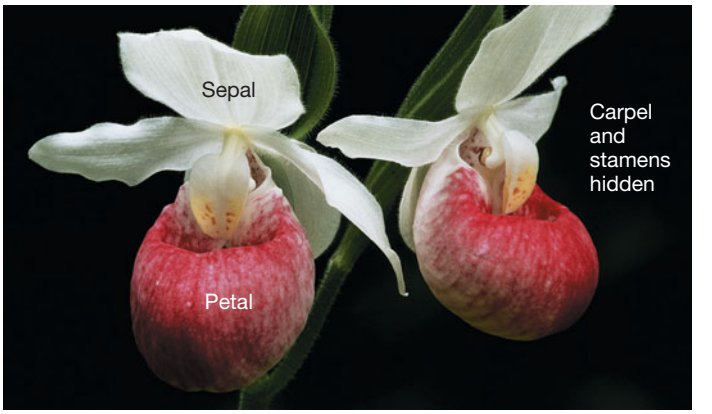


Sepals Form an Outer, Protective Whorl **Sepals** are leaflike structures that make up the outermost parts of a flower. Sepals are usually green and photosynthetic, and they are relatively thick compared with other parts of the flower.

Because they are attached to the receptacle in a circle or whorled arrangement, sepals enclose the flower bud as it develops and grows—protecting young buds from damage by insects or disease-causing agents. The entire group of sepals in the flower is called the **calyx.**



Petals Furnish a Visual Advertisement Like sepals, **petals** are arranged around the receptacle in a whorl. Often brightly colored and scented, petals function to advertise the flower to bees, flies, hummingbirds, and other pollinators.



In some cases, the color of the petals correlates with the visual abilities of particular animals. Bees, for example, respond strongly to wavelengths in the blue and purple regions of the light spectrum, as well as yellow (they don't see red well). Flowers

(a) Basic parts of a flower

(b) Examples of flower diversity

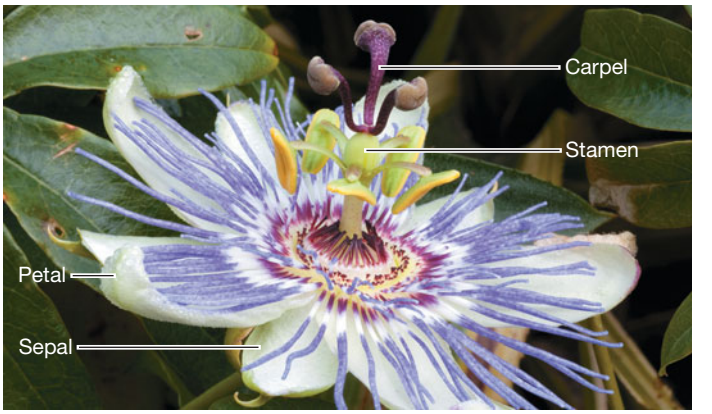


FIGURE 41.4 The Basic Structures in Flowers Are Highly Variable. **(a)** Flowers comprise sepals, petals, stamens, and carpels. **(b)** The four parts vary among species.

(a) What you and a bee see **(b)** What a bee sees in addition

FIGURE 41.5 Insects See in the Ultraviolet Range. (a) The inflorescence (flower cluster) of a black-eyed Susan, seen by the unaided human eye. **(b)** The same structure, photographed with a camera that records ultraviolet wavelengths that are visible to bees but invisible to humans.

that attract bees, in turn, often have yellow, blue, or purple petals with ultraviolet patches.

The ultraviolet regions of petals in "bee flowers" frequently highlight the center of the flower (**FIGURE 41.5**), where the stamens and carpels are located. Why? In these flowers, the base of the petals contains a gland called a **nectary.** The nectary produces the sugar-rich fluid **nectar,** which is harvested by many of the animals that visit flowers, along with pollen. In the process of collecting pollen or nectar, the visiting animal usually deposits pollen from a different plant on the female parts—accomplishing pollination.

The entire group of petals in a flower is called the **corolla.** In some species, the petals within the corolla vary in size, shape, and function:

- Flattened petals may provide a landing pad for flying insects.
- Elongated, tubelike petals frequently have a nectary at their base that can be reached only by animals with a long beak or tongue-like proboscis.
- Some petals protect the reproductive organs located inside the corolla.
- Specialized cells in some petals synthesize and release molecules that provide a scent attractive to certain species of pollinating animals.

In contrast, wind-pollinated angiosperms such as oaks, birches, pecans, and grasses have flowers that have small petals or no petals at all, and they lack nectaries. These species do not invest in structures that aren't required for pollination.

Stamens Produce Pollen **Stamens** are reproductive structures that produce male gametophytes—also known as pollen grains. The male gametophytes, in turn, produce sperm.

Each stamen consists of two components:

1. a slender stalk termed the **filament,** and
2. the pollen-producing organs called **anthers** (see Figure 41.4a).

The anther is the business end of the stamen—where meiosis and pollen formation take place. The filament holds the stamen in a place where wind, insects, hummingbirds, bats, or other agents can make contact with the pollen grains produced in the anther.

Carpels Produce Ovules The fourth reproductive structure is the **carpel,** which produces female gametophytes. A carpel consists of three regions:

1. The **stigma** is a sticky tip that receives pollen.
2. The **style** is a slender stalk.
3. The **ovary** is an enlarged structure at the base of the carpel (see Figure 41.4a).

Inside the ovary, female gametophytes are produced in structures called **ovules.** An ovary may contain more than one ovule. When the female gametophytes that are produced inside ovules mature, they produce eggs.

The "Sex" of Flowers Varies In most angiosperm species, stamens and carpels are produced on the same individual. Flowers that contain both stamens and carpels are referred to as **perfect.**

Flowers can also be **imperfect,** however, meaning they contain either stamens *or* carpels, but not both. Imperfect flowers that contain only stamens can be considered "male" flowers. Similarly, imperfect flowers that contain only carpels can be considered "female" flowers.[1]

In some cases, separate stamen- or carpel-producing flowers occur on the same individual. Species like these, including the corn plants illustrated in **FIGURE 41.6a** (see page 828), are **monoecious** (literally, "one-house"). In corn, the tassel is a collection of stamen-producing "male" flowers, and the ear contains a group of carpel-producing "female" flowers.

Species that are monoecious or that have perfect flowers are like hermaphroditic species of animals, which contain both male and female reproductive organs and produce sperm and eggs (see Chapter 50).

In contrast, some species with imperfect flowers are **dioecious** ("two-houses")—meaning that each individual plant produces either stamen-bearing flowers only, and could be considered "male," or carpel-bearing flowers only and could be considered "female." *Cannabis sativa* is a dioecious species (**FIGURE 41.6b**). Dioecious plants are like animal species with individuals that have either male or female reproductive organs—not both.

How Are Female Gametophytes Produced?

What purposes do the three parts of the carpel serve? The function of the stigma and style will become clear in Section 41.3; for now, let's concentrate on what happens inside the ovary.

[1]Technically, flowers are not referred to as male and female. Instead, they are staminate or carpellate. Staminate flowers produce stamens, which produce pollen grains, which produce male gametes (sperm). Carpellate flowers produce carpels, which contain ovaries. Female gametophytes develop inside ovaries and produce female gametes (eggs). For convenience, though, the text will sometimes refer to male and female flowers and reproductive structures.

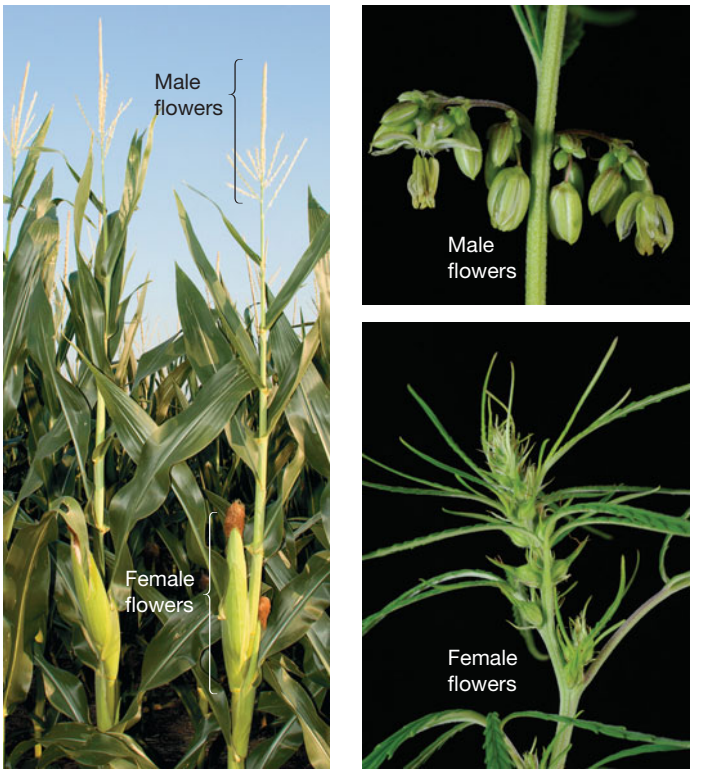

FIGURE 41.6 "Male" and "Female" Flowers Can Occur on the Same Individual or on Different Individuals. (a) The tassels of corn contain male flowers; ears contain female flowers. **(b)** In *Cannabis sativa*, male and female flowers are found on different individuals.

FIGURE 41.7 illustrates a longitudinal section showing the inside of a typical angiosperm ovary. Notice that it contains one or more ovules. Each ovule contains a structure called the megasporangium, which contains a diploid cell called the megasporocyte. (The use of "mega" is appropriate, because these structures are much larger than their counterparts in the stamen.) The megasporangium is comparable to spore-producing organs found in other plants, such as the sporangia found on the back of fern leaves.

When you study Figure 41.7, note four important points:

1. The megasporocyte divides by meiosis.
2. Four haploid nuclei called **megaspores** result from meiosis, but three degenerate. No one is sure how or why this happens.
3. The surviving megaspore divides by mitosis to produce a structure with haploid nuclei. This is the female gametophyte—usually known as the **embryo sac.**
4. The haploid nuclei segregate to different positions in the embryo sac, and cell walls form around some of them.

In the carpel, then, a diploid megasporocyte divides by meiosis to form a megaspore, which then divides by mitosis to form the female gametophyte. Female gametophytes are encased in an ovary, are retained in the flower, and produce an egg.

In many angiosperms, the embryo sac contains eight haploid nuclei and seven cells. Typically, two **polar nuclei** stay together within one central cell—the largest cell in the ovule. The number of polar nuclei varies among species, however.

The egg cell is located at one end of the female gametophyte, near an opening in the ovule called the **micropyle** ("little-gate"). The micropyle is where a sperm nucleus will enter the ovule before fertilization.

How Are Male Gametophytes Produced?

FIGURE 41.8 provides a detailed look at the stamen and the steps that occur in the production of male gametophytes. Recall that a stamen consists of two major parts: an anther and a filament.

PROCESS: FORMATION OF FEMALE GAMETOPHYTE

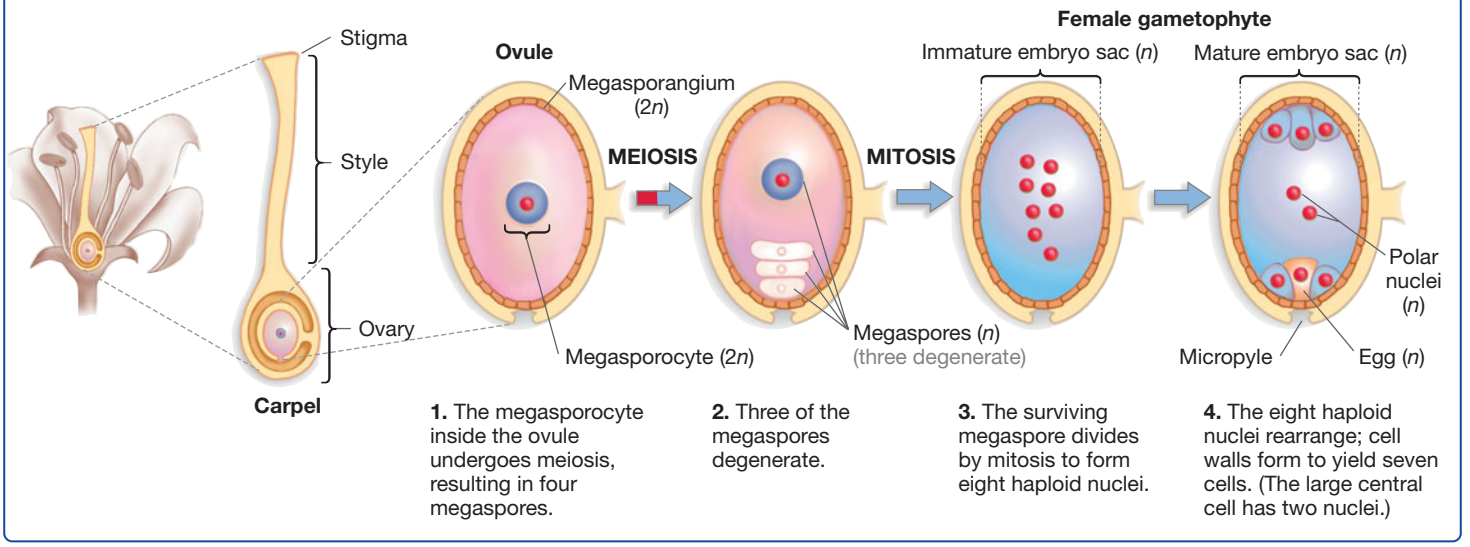

FIGURE 41.7 In Angiosperms, Megaspores Produce Female Gametophytes.

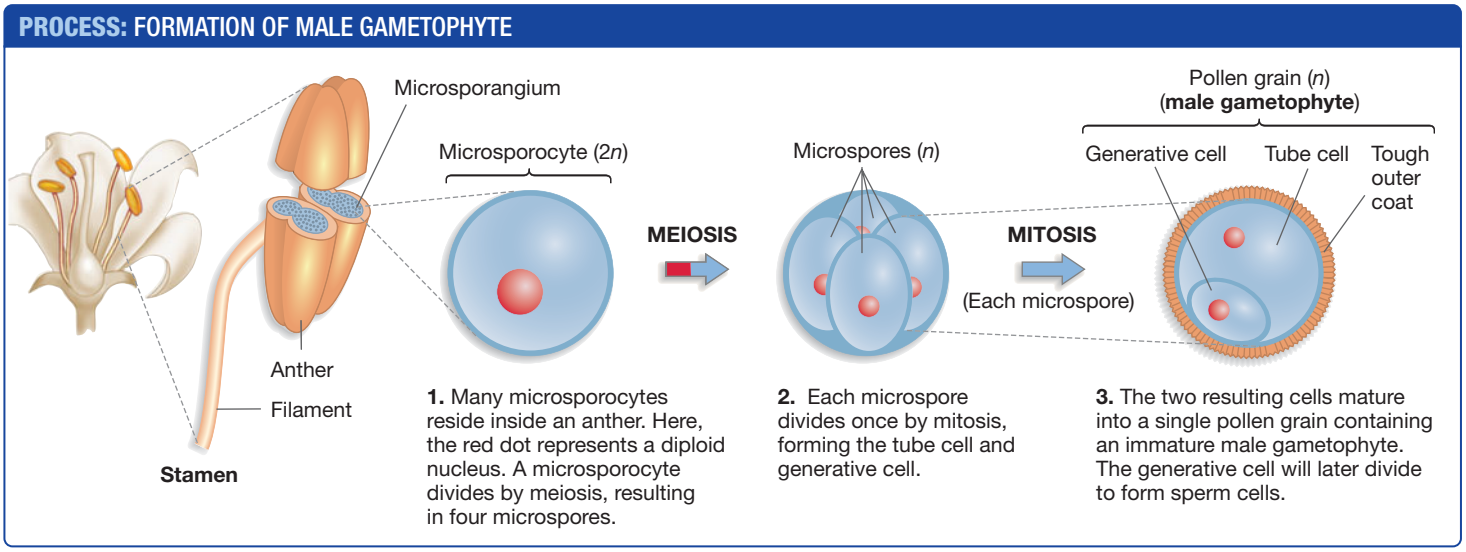

FIGURE 41.8 In Angiosperms, Microspores Produce Male Gametophytes.

✔**QUESTION** Define a gametophyte. Why do pollen grains conform to the definition of a gametophyte?

Inside the anther, structures known as microsporangia contain diploid cells called microsporocytes.

When you study Figure 41.8, note three important points:

1. Microsporocytes undergo meiosis.
2. Each haploid cell that results is a **microspore.** Normally, all of the microspores survive. Microspores divide by mitosis.
3. The two nuclei that result from mitotic division in a microspore form a haploid, immature male gametophyte, also known as the **pollen grain.**

In the anther, then, a diploid microsporocyte divides by meiosis to form microspores, which then divide by mitosis to form male gametophytes. Male gametophytes are dispersed from the flower and eventually produce sperm.

At the immature stage—before it has produced sperm—the male gametophyte consists of two cells: a small generative cell enclosed within a larger tube cell. The male gametophyte is considered mature when the haploid generative cell undergoes mitosis and produces two sperm cells.

In some species, this maturation step occurs while pollen is still in the anther. In other species, maturation and sperm production don't occur until after the pollen grain lands on a stigma and begins to grow. The reasons for this difference are not understood.

The wall of a pollen grain develops a tough outer coat that includes the watertight compound called **sporopollenin** (introduced in Chapter 31). This coat protects the male gametophyte when the pollen is released from the parent plant into the environment. Depending on the species, pollen grains may be dispersed by an animal, the wind, or water currents.

And now we're finally ready to explore the moment of truth: How does a pollen grain get to the mature carpel of the same species, where an egg cell is waiting?

check your understanding

C Y U

If you understand that . . .

- In angiosperm sporophytes, flowers produce megaspores and microspores that develop into female and male gametophytes, respectively.
- The female reproductive structures called carpels contain ovaries. Ovaries enclose structures called ovules. Female gametophytes are produced inside ovules.
- Formation of a female gametophyte begins when a diploid megasporocyte inside an ovule undergoes meiosis. The product of meiosis is a haploid megaspore. The megaspore divides by mitosis to form the female gametophyte—including the egg and polar nuclei.
- Male gametophytes are produced inside reproductive structures called anthers.
- Formation of the male gametophyte begins when a diploid microsporocyte undergoes meiosis to form haploid microspores. Microspores divide by mitosis to form the male gametophyte—including a tube cell and a generative cell that will divide by mitosis to form two sperm cells.

✔ You should be able to . . .

1. Compare and contrast a megasporocyte and a microsporocyte.
2. Compare and contrast a female gametophyte and a male gametophyte.

Answers are available in Appendix A.

41.3 Pollination and Fertilization

Pollination is the transfer of pollen grains from an anther to a stigma; fertilization occurs when a sperm and an egg actually unite to form a diploid zygote. The two events are separated in space and time.

Pollination is not restricted to angiosperms. Gymnosperms (introduced in Chapter 31) also package their male gametophytes into pollen grains. This section will focus on pollination and fertilization in flowering plants. Managing pollination and fertilization in angiosperms is a critical challenge for fruit growers and plant breeders.

In addition, angiosperms' pollination and fertilization systems are thought to be key to their evolutionary success. What aspects of pollination and fertilization allowed flowering plants to become so successful in terms of their numbers of species?

Pollination

Pollen can fall on the stigma of the same individual or the stigma of a different individual. **Self-fertilization,** or selfing, occurs when a sperm and an egg from the same individual combine to produce an offspring. In most cases, though, plants **outcross**—meaning that sperm and eggs from different individuals combine to form an offspring. Outcrossing is the result of **cross-pollination**—when pollen is carried from the anther of one individual to the stigma of a different individual.

Selfing versus Outcrossing: Costs and Benefits Selfing and outcrossing each have advantages and disadvantages. The primary advantage of selfing is that successful pollination is virtually assured—it doesn't depend on agents other than the plant itself.

Biologists have documented the benefit of pollination assurance by hand-pollinating plants that normally outcross. In most cases, the hand-pollinated individuals produce far more seed than do individuals that are pollinated naturally.

Other things being equal, self-fertilization should result in the production of many more seeds than outcrossing. Other things are not equal, however. Selfing has a distinct disadvantage: Even though it still involves meiosis, selfed offspring are usually much less diverse genetically than outcrossed offspring are (see Chapter 13). In some cases, selfed offspring may also suffer from inbreeding depression (see Chapter 26).

Although outcrossing is riskier in terms of the chances that pollination will occur, it results in genetically diverse offspring that may be much more successful at warding off attacks from viruses, bacteria, and other pathogens (see Chapter 13).

Outcrossing is much more common than selfing. In many cases, plants have elaborate mechanisms to prevent selfing:

- *Temporal avoidance* In some species that have perfect flowers, male and female gametophytes mature at different times. Thus, selfing cannot occur.
- *Spatial avoidance* Selfing isn't possible in dioecious species and may be rare in monoecious species, unless pollinators transfer pollen between different-"sexed" flowers on the same individual. And in some species with perfect flowers, the anthers and stigma are so far apart that self-pollination is extremely unlikely—if pollen falls inside the flower, there is almost no chance that it will land on the stigma.
- *Molecular matching* In species that normally outcross, it is common to find that the interaction of proteins on the surfaces of the pollen and stigma determines whether pollination will be successful. Pollination is blocked if proteins on the pollen-grain surface match proteins on the stigma—indicating that the pollen and stigma are from the same individual.

Pollination Syndromes Cross-pollination can be accomplished in various ways: Pollen can be carried from flower to flower by physical agents such as wind or water, or by organisms such as insects, birds, or bats.

Animals visit flowers to eat pollen grains, harvest nectar, or both. As an animal feeds from a flower, pollen grains adhere to its body incidentally. When the same individual visits another flower of the same species to feed, some of these grains are deposited on a stigma of the second flower.

In most cases, animal pollination is an example of **mutualism:** a mutually beneficial relationship between two species. Pollinators usually benefit by receiving food; flowering plants gain by having their male gametophytes transferred to a different individual so that outcrossing takes place.

Pollination syndromes are suites of flower characters that are associated with certain types of pollinators. For example, many bird-pollinated flowers tend to be red and unscented, and they open during the day when birds are active. In contrast, moths and bats are usually active at night. If they feed on nectar or pollen, the flowers they visit tend to be white—and thus more visible in low light, have a strong scent, and open at night.

Structures associated with pollination syndromes are thought to be adaptations: traits that increase the fitness of individuals in a particular environment. In this case, flowers and pollinators have adaptations that increase pollination frequency and feeding efficiency, respectively. To capture this point, biologists say that **coevolution** has occurred (see Chapter 55).

One of the most famous examples of coevolution in pollination involves a species called Darwin's orchid (**FIGURE 41.9**), which is native to Madagascar. When first discovered by Western scientists, the orchid attracted a great deal of attention because it has a "spur" that can be as much as 28 cm (11 in) long, and there is a nectary at its base. Charles Darwin hypothesized that it must be pollinated by a moth with a tongue-like proboscis as long as the spur. The idea seemed preposterous at the time, but 40 years later, a hawkmoth species with a proboscis that averages 24 cm in length was discovered pollinating the orchid in the wild.

Why Did Pollination Evolve? In mosses, ferns, and other groups that do not form pollen, sperm have flagella and swim to the egg through droplets of water, or are transferred on water droplets that cling to the legs of tiny soil insects, such as springtails and mites. In conifers and most other gymnosperms, wind transmits

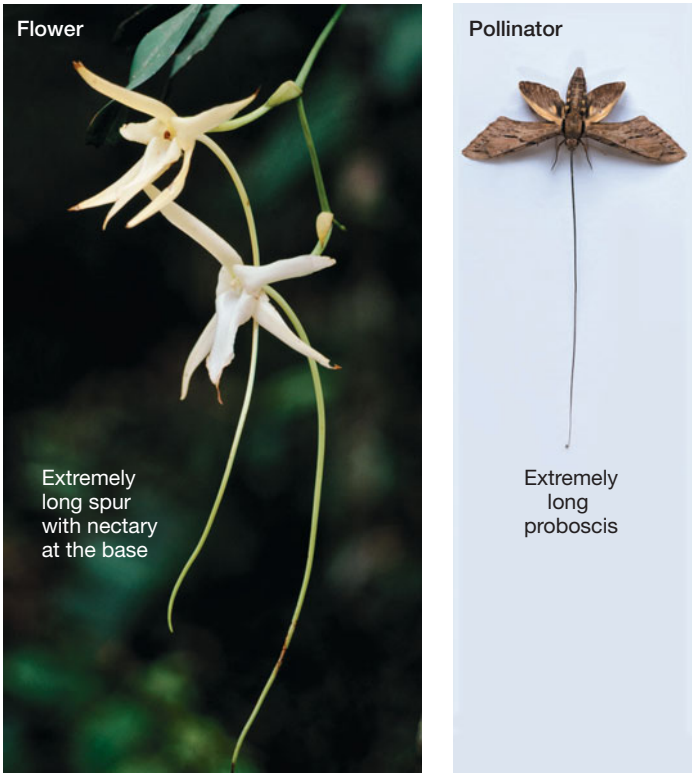

FIGURE 41.9 Pollinators Can Sometimes Be Inferred from Flower Structure and Color. Charles Darwin hypothesized that this white orchid flower with an extremely long spur must be pollinated by a moth with a tongue-like proboscis that was long enough to reach the nectar at the end. He was right.

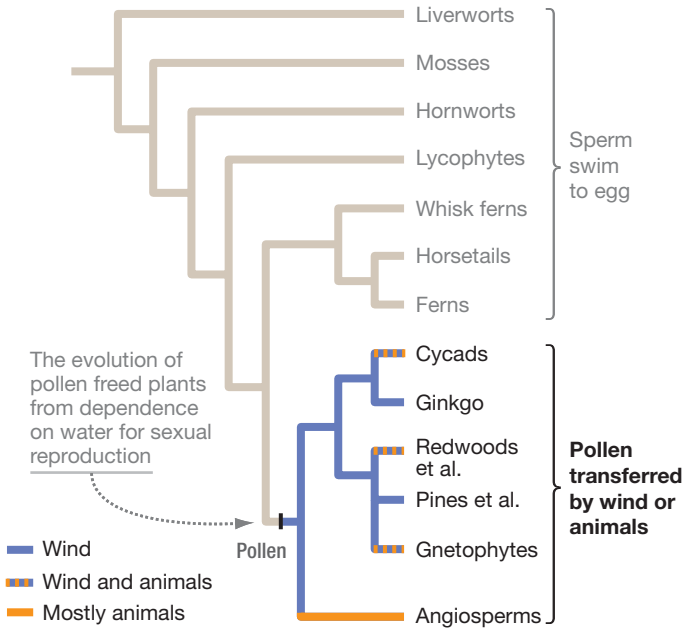

FIGURE 41.10 Pollen Is a Relatively Recent Innovation in Land Plant Evolution. Evolutionary relationships among the major groups of plants. In the lineages colored gray, sperm have flagella and swim to the egg. In the lineages colored blue or orange, sperm are produced by pollen grains.

pollen from male to female. In some of the other groups that produce pollen, such as the cycads, gnetophytes, and angiosperms, many species are pollinated by animals—particularly by insects.

When these observations are mapped onto the phylogenetic tree shown in **FIGURE 41.10**, two important patterns emerge.

1. Pollination evolved late in land plant evolution. Mosses and other groups that do not form pollen appear first in the fossil record of land plants. Conifers and other groups that are strictly or primarily wind pollinated evolved later but before angiosperms.
2. Seed plants do not need water for sexual reproduction to occur. As a result, the evolution of pollen allowed these species to be much less dependent on wet habitats. Along with the evolution of the seed—highlighted in Section 41.4—pollen paved the way for the colonization of drier environments.

In addition, it's critical to realize that pollination became a much more precise process when plants began to recruit animals to act as pollinators. Wind-borne pollen grains have a low probability of landing successfully on a flower stigma. Animal-borne pollen, in contrast, is much more likely to be successfully transferred to flowers of the same species.

Wind-pollinated species invest in making large numbers of pollen grains; animal-pollinated species make fewer pollen grains but invest in structures that attract and reward animals.

In effect, plants "pay" nectar- and pollen-eating animals to work for them. Wind is free, but animals are more precise. Animal pollination is an important adaptation because it makes sexual reproduction much more efficient.

Does Pollination by Animals Encourage Speciation? In addition to affecting the fitness of individual plants, does pollination by animals make the formation of entirely new species more likely?

To answer this question, consider the following situation. A biologist has documented that two populations of a mountain-dwelling species called the alpine skypilot have flowers with different characteristics.

- Alpine skypilots that grow in forested habitats at or below timberline have small flowers with short stalks and an aroma described as "skunky."
- Individuals that grow in the tundra habitats above timberline have large flowers with long stalks and a sweet smell.

These differences are interesting, because different insects pollinate the two populations. Small flies are abundant at slightly lower elevations, are attracted to skunky odors, and pollinate the timberline individuals; large bumblebees are abundant at higher elevations, are attracted to sweet odors, and pollinate the tundra flowers.

Experiments have shown that bumblebees prefer to pollinate big flowers—probably because larger flowers can support their larger mass. Because flies and bumblebees prefer to visit different types of flowers, gene flow between the two skypilot populations is low and they are evolving distinct characteristics. The two populations may be on their way to becoming different species.

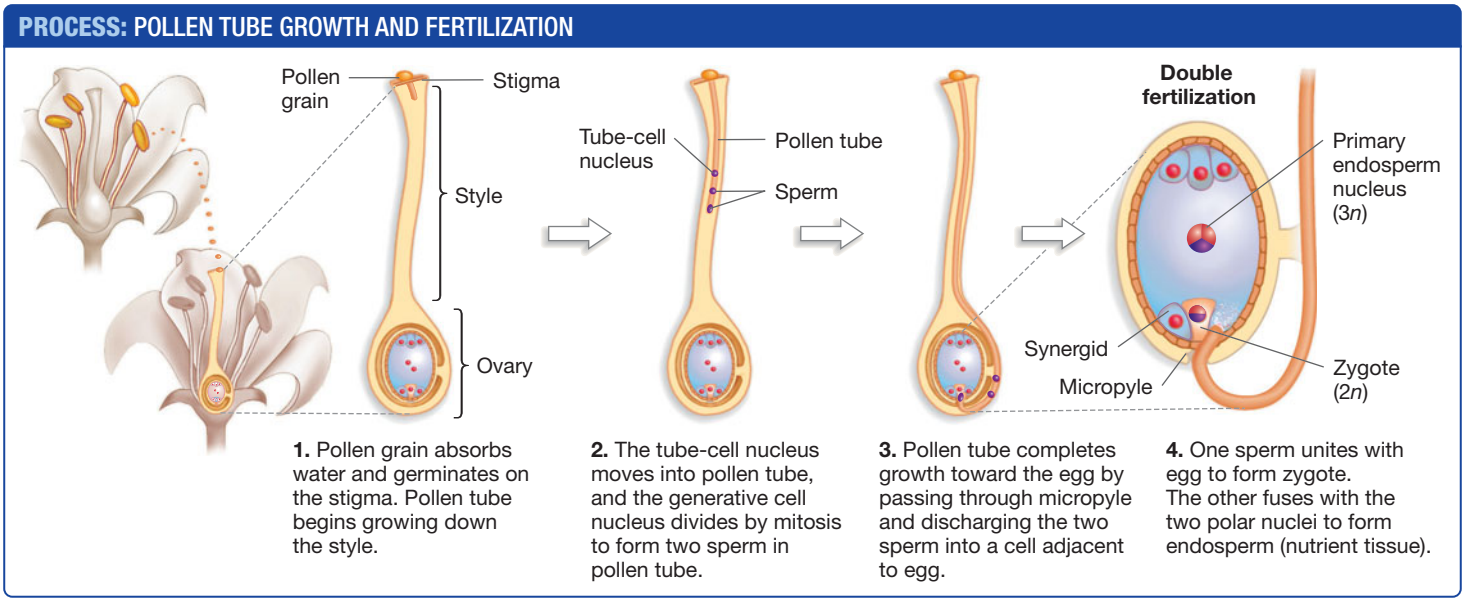

FIGURE 41.11 Double Fertilization Produces a Zygote and an Endosperm Nucleus. When the pollen tube reaches the female gametophyte, one sperm nucleus fertilizes the egg while the second fuses with the polar nuclei.

The message here is that evolutionary changes in the size or food-finding habits of a pollinator affect the angiosperm populations they pollinate. In return, changes in flower size and shape affect the insects pollinating that population. If a small population of Darwin's orchids evolved longer spurs, for example, the hawkmoth pollinators that lived in that area would be under intense selection that favored the evolution of a longer proboscis.

Because mutation continuously introduces variations in traits, insect and angiosperm populations frequently change, diverge, and form new species. Changes in pollination can trigger the evolution of new species. It is no surprise that insects and angiosperms are exceptionally species-rich groups.

It is clear that pollination was a crucial innovation during plant evolution. Now let's get down to mechanics. What happens once a pollen grain is deposited on a stigma?

Fertilization

FIGURE 41.11 walks you through the steps in fertilization.

Step 1 After landing on the stigma of a mature flower from the same species, a pollen grain absorbs water and germinates. **Germination** is a resumption of growth and development.

Step 2 When the male gametophyte germinates, a long tubular cell called a **pollen tube** grows through the stigma and down the length of the style. The direction of growth is affected by chemical attractants, called LUREs, which are small proteins released by synergids. Synergids are haploid cells in the female gametophyte that lie close to the egg. In the species illustrated in the figure, the tube-cell nucleus and the generative cell travel down the length of the tube, and the generative cell divides to form two sperm.

Step 3 When the pollen tube reaches the micropyle of the ovule, it grows through it and enters the interior of the female gametophyte.

Step 4 Fertilization—the fusion of sperm and egg to form a diploid zygote—occurs. In most plant groups, fertilization is straightforward—sperm and egg simply combine, and a diploid nucleus is formed. In angiosperms, however, an unusual event called **double fertilization** takes place. One sperm nucleus unites with the egg nucleus to form the zygote. The other sperm nucleus moves through the female gametophyte and fuses with the polar nuclei in the central cell. In most cases, two polar nuclei are present and a large triploid ($3n$) cell forms.

check your understanding

C Y U

If you understand that . . .

- Wind, water, or animals carry pollen grains from one plant to another.
- When a pollen grain lands on a stigma, the grain germinates. A pollen tube forms and grows until it reaches the ovule.
- Sperm cells produced by the male gametophyte fertilize the egg and combine with the polar nuclei, forming a diploid zygote and in most cases a triploid endosperm, respectively.

✓ You should be able to . . .

1. Explain why insects increase their fitness by visiting flowers and why flowers increase their fitness by rewarding insects.
2. Describe the function of the cells produced by double fertilization.

Answers are available in Appendix A.

✔ **If you understand double fertilization, you should be able to identify in a female gametophyte, immediately after fertilization occurs, which cells are haploid, diploid, and triploid.**

The triploid nucleus resulting from this second fertilization undergoes mitosis and cytokinesis to form the **endosperm** ("inside-seed") tissue. In most species, endosperm is triploid and functions to store nutrients. Endosperm cells are loaded with starch or oils (lipids) plus proteins and other nutrients that the embryo will need after it germinates. But before germination can occur, seeds must develop and be dispersed.

41.4 The Seed

Fertilization triggers the development of a young, diploid sporophyte. In angiosperms, the first stage in the sporophyte's life is the maturation of the seed.

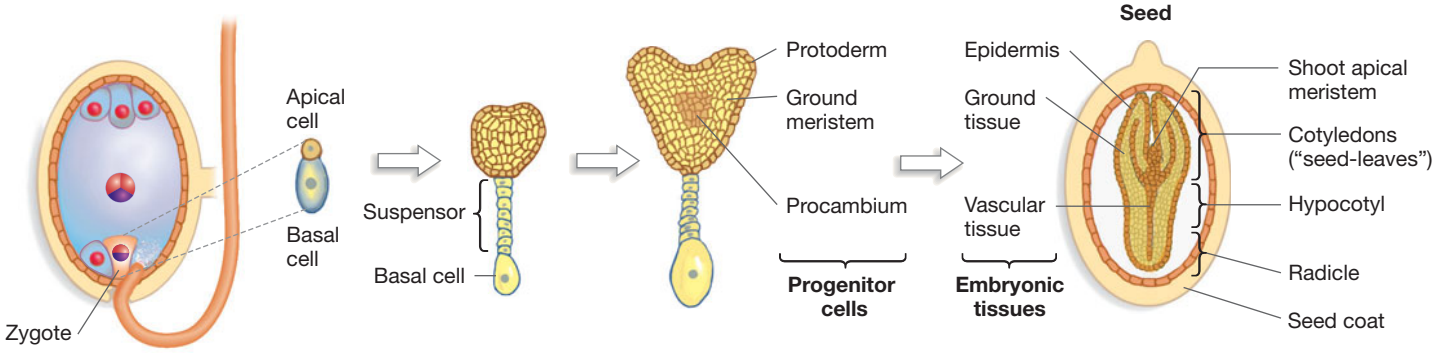
As a seed matures, the embryo and endosperm develop inside the ovule and become surrounded by a covering called a **seed coat.** At the same time, the ovary around the ovule develops into a fruit, which encloses and protects the seed (or seeds, if a single ovary contains multiple ovules). In addition to providing protection, fruits often aid in dispersing seeds away from the parent plant. The mature seed consists of an embryo, a food supply—originating with endosperm—and a seed coat. In most cases, mature seeds leave the parent plant encased in a fruit.

Along with pollen, the evolution of the seed was a crucial innovation as land plants diversified. Because seeds contain stored nutrients, they allow offspring to be much more successful in colonizing habitats that are crowded with competitors than are offspring produced from spores, which are single cells. As a young plant emerges from the seed, it can subsist on stored nutrients until it is well enough established to absorb water from the soil and feed itself via photosynthesis.

Let's analyze how seeds work, beginning with a closer look at how the embryo develops.

Embryogenesis

Recall that **embryogenesis** is the process by which a single-celled zygote becomes a multicellular embryo (see Chapter 24). As **FIGURE 41.12** shows, embryogenesis in angiosperms can be analyzed as a four-step process.



Step 1 The zygote divides to form the two daughter cells.

Step 2 The lower daughter cell, or basal cell, divides to form a cell that forms part of the root tip and a cell that produces a row of cells. This row of cells, called the suspensor, provides a route for nutrient transfer from the parent plant to the developing embryo. The upper daughter cell, or apical cell, is the parent of almost all the cells in the embryo. It divides to form a mass of cells.

Step 3 Cells within the mass differentiate into groups conforming to one of the three adult tissue types (see Chapter 37). The exterior layer of embryonic cells, the **protoderm,** is the progenitor of the adult dermal tissue, or epidermis. The **ground meristem**—the cells just within the protoderm—gives rise to the ground tissue found in adults. And the **procambium** is a group of cells in the core of the embryo that becomes the vascular tissue.

Step 4 As the embryo continues to develop, the long axis of the plant begins to emerge and several important structures take shape: **(1) cotyledons** ("seed-leaves"), which absorb nutrients from the endosperm and supply them to the rest of the embryo, **(2)** the **hypocotyl** ("under-cotyledon"), which is the embryonic stem, and **(3)** the **radicle,** or embryonic root. Some embryos also have an **epicotyl** ("above-cotyledon"), which is a portion of the embryonic stem that extends above the cotyledons.

PROCESS: EMBRYO DEVELOPMENT AND SEED MATURATION

1. Zygote divides into two daughter cells.

2. The two daughter cells divide into a cell mass and a basal cell plus suspensor.

3. The cell mass differentiates into progenitors of the three adult tissues.

4. The three tissue types mature into the precursors of the root and shoot systems. The long axis of the mature embryo becomes apparent.

FIGURE 41.12 Embryonic Tissues and Structures Develop Inside Seeds. The embryo inside a seed has cotyledons and the beginnings of root and shoot systems. The embryonic epidermis and the ground and vascular tissues are organized in distinct layers.

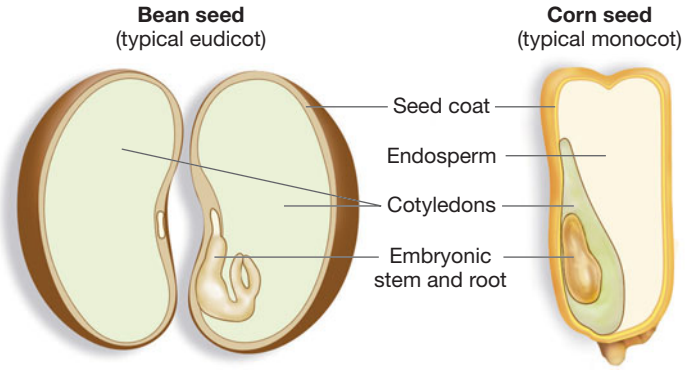


FIGURE 41.13 Seeds Contain an Embryo and a Food Supply Surrounded by a Tough Coat. In beans (left), the nutrients in the endosperm have been absorbed by the cotyledons and stored. In corn (right), the endosperm is intact.

✔ If you understand the basic steps in embryonic development, you should be able to compare and contrast a cotyledon with a radicle in terms of their tissue composition and the progenitor cells they originated from.

Recall that one prominent lineage of angiosperms—the monocots—have just one cotyledon, whereas eudicots have two (see Chapter 31). In most eudicots, the cotyledons take up the nutrients that were initially stored in the endosperm and store them again. In these species, there is no endosperm left by the time the seed matures—instead, the cotyledons function as the nutrient storage organ in mature seeds. **FIGURE 41.13** compares the seed structure in beans and corn—a representative eudicot and monocot, respectively.

By the time a seed matures, then, the three major embryonic tissue types have developed. The precursors of the root and shoot systems, along with the seed leaves, have formed. Once these events are accomplished, the seed tissues dry and the embryo becomes quiescent—meaning it stops growing and waits.

The Role of Drying in Seed Maturation

The seeds of many species dry out, or desiccate, as they mature. Water makes up 90 percent of normal plant cells, but dried seeds contain just 5–20 percent water.

Loss of water is an adaptation that prevents seeds from germinating until after they are dispersed. The dry condition of seeds ensures that they will not germinate until water is available. This is adaptive in temperate species because water is crucial to the survival of germinated seedlings. Dry seeds are also less susceptible than wet seeds to damage from freezing.

How do the cellular structures in the embryo and endosperm survive the drying process? When researchers reduce the amount of water surrounding isolated membranes or isolated proteins to the levels observed in extremely dry seeds, the membranes disintegrate and the proteins denature. Clearly, something is happening at the molecular level in seeds to keep these cell components intact.

Researchers established that one of these "somethings" involves sugars. As water leaves the seed during drying, sugars become concentrated and maintain the integrity of plasma membranes and proteins. If drying is extreme, the sugars form an extremely viscous liquid that contains little if any water. Substances such as this are considered vitrified, or glass-like (glass is a liquid solution with the viscosity of a solid). Biologists propose that this glassy state helps maintain the integrity of plasma membranes and proteins in seeds that experience extremely dry conditions. When seeds imbibe water, the glassy sugars dissolve and germination proceeds.

Drying is only one part of the seed maturation process, however. Equally important is the development of tissues surrounding the seed itself. In many cases, these tissues are required for the seed to be dispersed from the parent plant.

Fruit Development and Seed Dispersal

Fertilization in angiosperms initiates the development of the fruit as well as the seed and embryo.

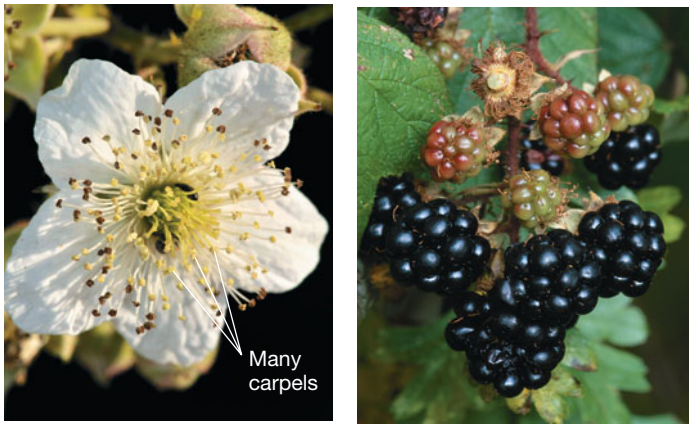
Fruit Structure Fruits come in three basic types (**FIGURE 41.14**).

- **Simple fruits** like the cherry develop from a single flower that contains a single carpel or several carpels that are fused together. This is the most common type of fruit.
- **Aggregate fruits** like the blackberry also develop from a single flower, but one that contains many separate carpels.
- **Multiple fruits** like the pineapple develop from many flowers and thus many carpels.

As a fruit matures, the walls of the ovary thicken to form the **pericarp,** the part of the fruit that surrounds and protects the seed or seeds (**FIGURE 41.15**). Fruits can be dry when they are mature, as in nuts, or fleshy, as in cherries and tomatoes. Note that fruits are formed from tissues derived from the mother—not the embryo.

Fruit Function Fruits have two functions: They protect seeds from physical damage and seed predators, and they frequently aid in seed dispersal. Dispersal is important to the fitness of the young sporophyte. This is especially true in long-lived species, in which the offspring would compete with the parent plant for light, water, and nutrients if there were no dispersal.

Fruits sometimes split open and release seeds to be dispersed directly. In many cases, however, seeds are dispersed to new locations while they are still enclosed in the fruit.



Dry fruits may simply fall to the ground or be dispersed by wind, propulsion, or animals. Some dry fruits have hooks or barbs that adhere to passing animals, while nuts are dispersed by seed predators. Fruits that are dispersed by wind often have external structures to catch the breeze and extend the distance they travel; the fruits of dandelions and maple trees are familiar examples. Fruits that float, such as coconuts, can disperse seeds in water.

Some plants actually disperse dry fruits via propulsion. The sandbox tree, for example, produces a seed pod that shrinks as it dries. Eventually the pod splits apart violently, spraying seeds in all directions with so much force that the plant is sometimes

(a) Simple fruit (e.g., cherry):
Develops from a single flower with one carpel or fused carpels

(b) Aggregate fruit (e.g., blackberry):
Develops from a single flower with many separate carpels

(c) Multiple fruit (e.g., pineapple):
Develops from many flowers with many carpels

FIGURE 41.14 Three Major Types of Fruits. The structure of a fruit depends on the number of carpels found in each flower and whether or not the carpels are fused.

✔**QUESTION** When fruits ripen, their color changes in a way that makes them more conspicuous to fruit eaters. State a hypothesis to explain why this color change might increase the fitness of an individual.

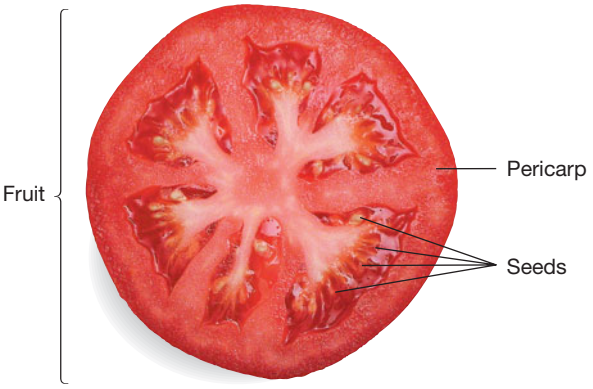


FIGURE 41.15 As Fruits Mature, the Ovary Wall Develops into a Pericarp That Surrounds the Seed or Seeds. A fruit consists of a pericarp and the enclosed seeds.

called the dynamite tree. The bursting seed pod sounds like a pistol shot, and seeds can be scattered as much as 40 m away from the parent plant. Similarly, the dwarf mistletoe fruit fills with sugars as it matures. Enough water follows via osmosis to make the fruit explode and shoot seeds as far as 5 m.

Animals are the most common dispersal agent for fleshy fruits. Just as plants have evolved to use animals for pollination, they have also evolved to use specific types of animals for seed dispersal. In cases like this, seed dispersal is an example of mutualism. The plant provides a fruit rich in sugars and other nutrients; in return, the animal carries the fruit to a new location and excretes the seeds along with a supply of fertilizer.

Mammals and birds are the most common seed dispersers. Mammals are often active at night and use their well-developed sense of smell to locate fruits. As you might imagine, fruits of mammal-dispersed seeds are usually dull colored and fragrant. In contrast, birds are usually active in the day and see well. Fruits of bird-dispersed seeds are usually brightly colored.

Some animals are seed predators that compete with dispersers. For example, birds usually swallow fruit whole and disperse seeds over long distances. Fruit-eating mice, on the other hand, chew their food, often killing the seeds inside. How can plants discourage seed predators such as mice from eating their fruits? The answer is one that might be familiar to you. Some plants such as chili peppers lace their fruits with a spicy-hot repellent called capsaicin. But does it work?

An experiment by ecologists Joshua Tewksbury and Gary Nabhan in 2001 tested the hypothesis that capsaicin promoted dispersal by the curve-billed thrasher and deterred predation by cactus mice (**FIGURE 41.16**, see page 836). Each animal was offered three kinds of fruit: hackberries, fruits from a strain of chilies that can't synthesize capsaicin (non-pungent chilies), and pungent chilies that have lots of capsaicin. All three fruits looked similar and had equivalent nutritional value. For each animal tested, the researchers recorded the percentage of each fruit eaten during a specific time interval. They then calculated the average amount of fruit that was eaten by five test individuals from each species.

Curve-billed thrashers ate all three fruits equally, but the mice ate fewer non-pungent chilies and avoided the capsaicin-laced fruits entirely. In a follow-up experiment, the researchers fed non-pungent chilies to each kind of animal. When the seeds had passed through the animal's digestive tract and were excreted, the researchers collected and planted the seeds. About 60 percent of the seeds that passed through the birds germinated, but none of those eaten by the mice germinated. Capsaicin appears to be an effective deterrent to seed predation.

Seed Dormancy

Once they have dispersed from the parent plant, seeds may not germinate for a period of time. This condition is known as **dormancy.**

Dormancy is usually a feature of seeds from species that inhabit seasonal environments, where for extended periods of time conditions may be too cold or dry for seedlings to thrive. Based on this observation, dormancy is interpreted as an adaptation that allows seeds to remain viable until conditions improve.

Consistent with this hypothesis, dormancy is rare or nonexistent in seeds produced by plants that inhabit tropical wet forests or other areas where conditions are suitable for germination year-round.

What molecular mechanisms are responsible for dormancy?

How Do Hormones Regulate Dormancy? The answer to this question is not well understood, but the hormone abscisic acid (ABA) plays important roles in seed development and dormancy (see Chapter 40). Mutants of some plants that cannot either make or respond to ABA exhibit a property called vivipary, in which the seeds germinate on the parent plant as soon as they are mature. In many species ABA triggers the accumulation of storage compounds, desiccation tolerance, and the prevention of germination.

After a seed has been dispersed from the parent plant, it may remain dormant in the soil for years or even centuries before it will germinate. The current record for longevity is a lotus seed that germinated after being submerged in an ancient lakebed in China for 1450 years.

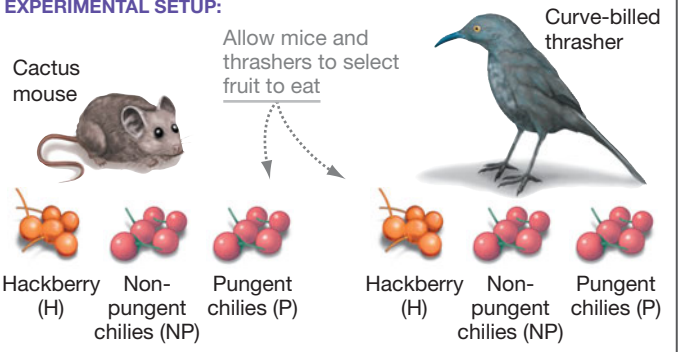
What finally causes dormant seeds to germinate? Thanks to the wide range of habitats in which plants are adapted, germination depends on a wide variety of internal and external factors.

How Dormancy Is Broken? The coats of some seeds are thick enough to prevent water and oxygen from physically reaching the embryo. For germination to occur, these seed coats must be disrupted, or **scarified.**

Crop seeds that require scarification are placed in large, revolving drums with pieces of sandpaper that abrade and scarify the seeds. When planted, these scarified seeds germinate quickly and uniformly. In nature, impermeable seed coats protect nutritious seeds from being killed by soil bacteria and fungi, and they often prevent seeds from germinating for many years.

To germinate, most seeds must experience particular environmental conditions. Species native to high latitudes or high elevations often produce seeds that must undergo cool, wet conditions before they will germinate. Without this level of control, germination before the ensuing winter would likely result in death of the seedling. Recent studies indicate that germination is regulated by two hormones, gibberellin and ABA, and that the levels of these hormones in seeds are affected by temperature (see Chapter 40). After experiencing a winter, gibberellin levels increase and germination begins.

Because small seeds have few nutrient reserves in their cotyledons or endosperm, many small-seeded species need to germinate near the soil surface, where individuals are exposed to light and can feed themselves via photosynthesis. Lettuce seeds and

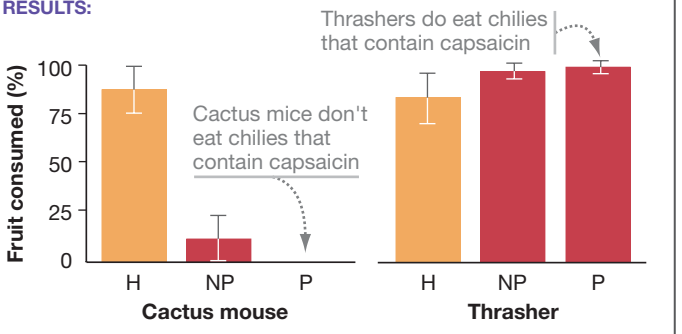


RESEARCH

QUESTION: Does the presence of capsaicin in chilies deter some predators but not others?

HYPOTHESIS: Capsaicin deters cactus mice (seed predators) but not birds (seed dispersers).

NULL HYPOTHESIS: Cactus mice and birds respond to capsaicin in the same way.



EXPERIMENTAL SETUP:

PREDICTION: Both will eat hackberry, but only thrashers will eat pungent chilies.

PREDICTION OF NULL HYPOTHESIS: No difference between thrashers and mice in fruit consumed.

RESULTS:

CONCLUSION: The presence of capsaicin deters cactus mice but not thrashers.

FIGURE 41.16 Experimental Support for the Hypothesis that Capsaicin Deters Seed Predators but Not Seed Dispersers.

SOURCE: Tewksbury, J. J., and G. P. Nabhan. 2001. Directed deterrence by capsaicin in chilies. *Nature* 412: 403–404.

✔**QUESTION** Why were hackberries used in this experiment?

other small seeds must be exposed to red light before they will break dormancy and germinate (see Chapter 40). Red light is an important environmental cue, because wavelengths in the red portion of the light spectrum are absorbed by chlorophyll. Red light and blue light indicate that sunlight is abundant and that the seedling will not be shaded by other plants.

Finally, many of the seeds produced by species native to habitats where wildfires are frequent, such as the California chaparral and South African fynbos, have an unusual chemical requirement to break dormancy: They must be exposed to fire or smoke before they will germinate. In fact, the commercial food product "liquid smoke" induces germination in these seeds as well as actual smoke does. In fire-prone habitats, it is advantageous for seeds to germinate after fire has cleared away existing vegetation.

The message here is that dormancy can be broken in response to a wide variety of environmental cues. In general, the cue that triggers germination is a reliable signal that conditions for seedling growth are favorable for a particular species in a particular environment.

Seed Germination

Even if specific environmental signals are required to break dormancy, seeds do not germinate without water. Water uptake is the first event in germination. Once the seed coat allows water penetration, water enters by moving along a steep water-potential gradient, because the seed is so dry.

Water uptake in a typical angiosperm seed has three distinct phases:

Phase 1 Germination begins with a rapid influx of water. Oxygen consumption and protein synthesis in the seed increase dramatically, but no new messenger RNAs are transcribed. Based on these observations, biologists have concluded that some of the key early events in germination are driven by mRNAs that are stored in the seed before maturation.

Phase 2 The second phase is an extended period during which water uptake stops. New mRNAs are transcribed and translated into protein products. Mitochondria also begin to multiply. In effect, seeds take up enough water in phase 1 to hydrate their existing proteins and membranes and then begin to manufacture the proteins and mitochondria needed to support growth.

Phase 3 Water uptake resumes as growth begins. This renewed phase of water uptake enables cells to develop enough turgor pressure to enlarge. Eventually, the seedling bursts from the seed coat.

FIGURE 41.17 shows what happens as eudicot and monocot embryos emerge from the seed. The radicle emerges first, and it subsequently develops into the mature root system. This is important because the seedling must have a source of water in order to grow. Initially, leaves are less important because of the nutrients stored in the seed.

In eudicots, the shoot system with its cotyledons usually emerges shortly after the radicle appears. In monocots such as corn, the emerging shoot is protected by the coleoptile. Note that in eudicots, the emerging stem has a hook shape. Like the coleoptile of monocots, this trait is thought to protect the apical meristem from damage as the shoot works its way upward through rough soil particles.

The next major event in the seedling's life occurs when either the cotyledons or the earliest leaves produced by the growing seedling commence photosynthesis. The seedling is said to be established when the young plant no longer relies on food reserves in its endosperm or cotyledons; instead, it receives all of its nourishment from its own photosynthetic products. With this, a new generation is under way.

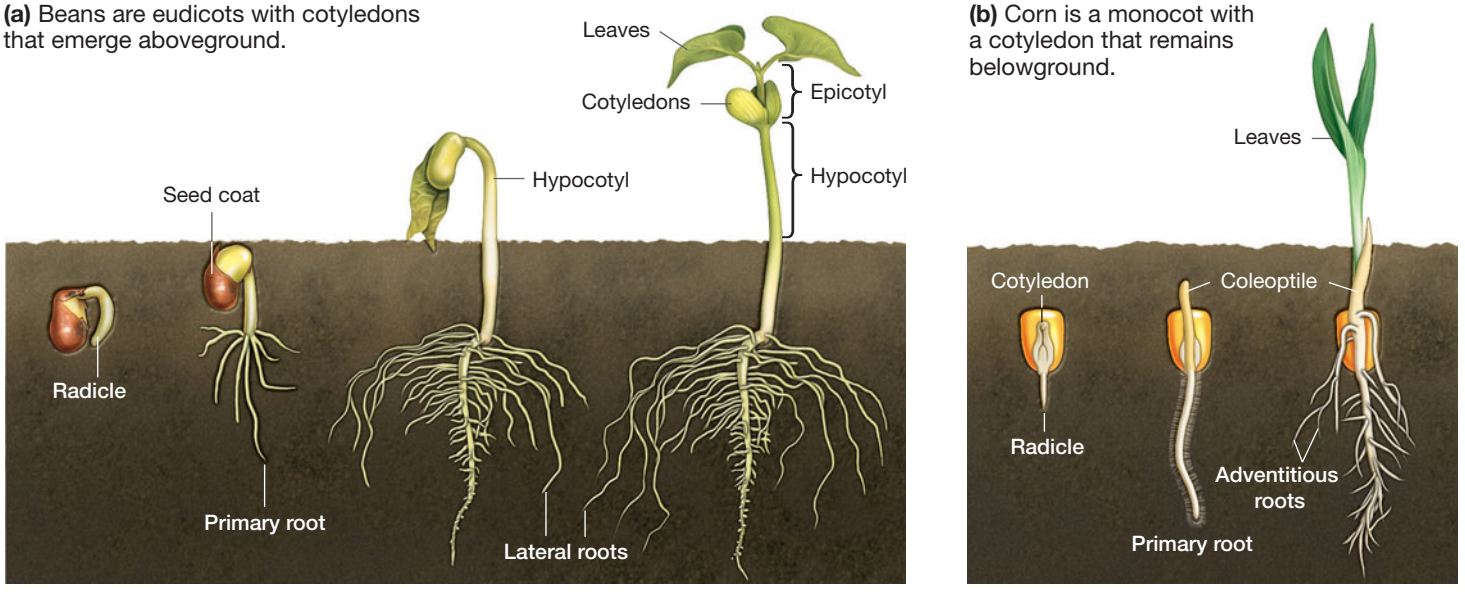


FIGURE 41.17 The Germination Sequence Varies among Species.

✔**QUESTION** In which of these species are cotyledons photosynthetic?

If you understand . . .

41.1 An Introduction to Plant Reproduction

- Plants undergo alternation of generations, in which a diploid sporophyte phase alternates with a haploid gametophyte phase. Sporophytes produce spores by meiosis. Gametophytes produce gametes by mitosis.
- The relative size and life span of the gametophyte and sporophyte phases vary a great deal among plant groups.
- In the most basal groups of land plants, gametophytes are larger and longer-lived than sporophytes, and sporophytes depend on gametophytes for nutrition.
- In angiosperms, or flowering plants, sporophytes are the large and long-lived phase where photosynthesis takes place; gametophytes consist of just a few cells.

✔ **You should be able to state the ploidy of a sporophyte, gametophyte, spore, gamete, and zygote.**

41.2 Reproductive Structures

- In angiosperms, male and female gametophytes are microscopic and are produced inside flowers. Flowers are made up of sepals, petals, stamens, and one or more carpels.
- The lower part of the carpel, the ovary, contains one to many ovules. Within the ovule, a megasporocyte undergoes meiosis, producing a megaspore that develops into the female gametophyte.
- In the anthers of stamens, microsporocytes undergo meiosis. The resulting microspores develop into male gametophytes, which are enclosed in pollen grains.

✔ **You should be able to describe what would happen if all meiotic products in megasporangia went on to form female gametophytes.**

41.3 Pollination and Fertilization

- Pollination occurs when pollen grains are transported to the stigma of the carpel. In most cases, the structure of a flower correlates with the morphology and behavior of its pollinator.
- If allowed to germinate on the stigma, a pollen grain sends a long pollen tube down the style. Two sperm travel down the pollen tube and enter the female gametophyte.
- In double fertilization, one sperm fuses with the egg to form a zygote, while the other fuses with polar nuclei within the female gametophyte. The fusion of sperm and polar nuclei produces endosperm—nutritive tissue that in most species is triploid.

✔ **You should be able to explain why the endosperm of a seed is called a triploid tissue and how it compares with the zygote.**

41.4 The Seed

- Seeds contain an embryo and a food supply surrounded by a coat.
- The development of an angiosperm embryo includes the formation of dermal tissue (epidermis), ground tissue, and vascular tissue layers and the development of the radicle, hypocotyl, and cotyledons.
- As an embryo develops, endosperm cells divide to form a nutrient-rich tissue. In addition, cells along the outside of the ovules form a protective seed coat, and the ovary develops into a fruit.
- In many cases, the mature fruit contains structures that help disperse the mature seed via wind, water, propulsion, or animals.
- Many seeds do not germinate immediately but instead experience a period of dormancy.
- A wide variety of conditions, ranging from scarification to exposure to red light, may break seed dormancy. In many cases, the event that triggers germination ensures that the seed germinates when environmental conditions are favorable.
- Germination begins when the seed takes up water and mRNAs already present in the seed are translated. It ends when the radicle breaks the seed coat and begins to penetrate the soil.

✔ **You should be able to explain why it is adaptive for many seeds from plants native to high latitudes to require a cold period before germination.**

TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. What is the major evolutionary trend in land plant life cycles?
   a. Instead of being approximately the same size and shape, gametophytes and sporophytes began to look different.
   b. Sporophytes became larger and long lived while gametophytes became drastically reduced.
   c. In lineages that evolved more recently, such as angiosperms, spores are no longer produced.
   d. Sporophytes began to rely on gametophytes for all of their nutritional needs.
2. What happens when double fertilization occurs?
   a. Two zygotes are formed, but only one survives.
   b. Two sperm fertilize the egg, forming a triploid zygote.
   c. One sperm fertilizes the egg, while another sperm fuses with the polar nuclei.
   d. One sperm fertilizes the egg, while two other sperm fuse with a polar nucleus.
3. What is a fruit?
   a. an expanded ovary that includes a seed or seeds
   b. a structure consisting of an embryo and a food supply surrounded by a tough coat
   c. a female gametophyte
   d. a male gametophyte
4. Why is the interaction between angiosperms and pollinators considered mutualistic?
   a. New species can form if mutant flowers attract new types of pollinators.
   b. Flowers may have an array of traits, including corolla shape, color, scent, and the presence of nectar, to attract a specific type of pollinator.
   c. Wind pollination is much "cheaper," but animal pollination is much more precise.
   d. Angiosperms get their pollen dispersed, while pollinators get food.
5. In the angiosperm life cycle, which cells undergo meiosis? Which cells are spores? Which structures are gametophytes?
6. What events take place during pollination and fertilization?

TEST YOUR UNDERSTANDING

Answers are available in Appendix A

7. Why is the emergence of the radicle an important first step in germination?
   a. Its hook helps protect the shoot that emerges later.
   b. It carries out photosynthesis to supply the embryo with food.
   c. It is important for establishing a supply of water to the growing embryo.
   d. It is necessary to break the seed coat.
8. In terms of maximizing reproductive success, what is the advantage of asexual reproduction? What is the disadvantage?
9. How do the structure and function of sepals and petals differ? How would you expect these structures to differ in species that are pollinated by wind versus bumblebees?
10. What are the advantages and disadvantages of self-fertilization versus those of outcrossing?
11. Consider a carpel, an ovary, and an ovule. Which is responsible for producing the female gametophyte, and which produces the pericarp of a fruit? Are these structures part of the sporophyte, the gametophyte, or a combination of the two?
12. What is the relationship between the endosperm of corn and the cotyledons of beans?

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A

13. What happens when outcrossing occurs?
   a. Inbred offspring are produced.
   b. The same flower can be visited by many different types of pollinators—not a single specialist species.
   c. Gametes from different individuals fuse to form a zygote.
   d. Gametes from the same individual fuse.
14. **QUANTITATIVE** Because wind is less efficient than animals at moving pollen from plant to plant, wind-pollinated plants generate far more pollen than animal-pollinated plants. How much of that pollen is wasted? Consider a typical field-corn plant that makes one ear. Ears contain about 600 kernels, each of which is fertilized by an individual pollen grain. Male flowers clustered in the tassel at the top of the plant release about 10 million pollen grains per plant. Using these numbers, what percentage of corn pollen is wasted?
15. Some flowering plants "cheat" their pollinators because they offer no food reward. Likewise, certain pollinators cheat plants by removing nectar from flowers without picking up pollen. (In some cases, they do so by chewing through the petals that hold the store of nectar.) Speculate on the types of mutations that might modify insect behavior and/or plant structure in a way that limits cheating and enforces mutualism.
16. Consider the following fruits: an acorn, a cherry, a burr, and a dandelion seed. Based on the structure of each of these fruits, predict how the seed is dispersed. Design a study that would estimate the average distance that each type of seed is dispersed from the parent plant.

BIG PICTURE

The Big Picture

Plants and animals are diverse lineages of multicellular eukaryotes. They are different in important ways. Each lineage evolved independently from a different single-celled protist—plants with the ability to make their own food by photosynthesis, and animals reliant on obtaining energy from other organisms. Further, plants are sessile, while most animals are capable of complex movements and locomotion.

Yet despite these differences, plants and animals face many of the same challenges to survive and reproduce in water and on land. Use this concept map to explore some of their similarities and differences in form and function.

Note that each box in the concept map indicates the chapters where you can go for more information. Also, be sure to do the blue exercises in the Check Your Understanding box below.

• Move water by bulk flow in xylem tissue, driven by transpiration  • Move sugars in phloem tissue along pressure gradient from sources to sinks 38	• Detect light, gravity, heat, touch, wind, pathogens, herbivores, chemical signals • Hormones (plant growth regulators) carry information and induce responses 40	• Incapable of locomotion, but gametes and seeds can disperse • Some can move slowly via differential growth or rapidly via cell shape changes 40, 41	• Most can reproduce sexually, some asexually • Undergo alternation of generations (haploid and diploid stages are both multicellular) • Angiosperms have internal fertilization (within ovary of flower) 41	• Have both physical and chemical defenses against pathogens and herbivores • Infection launches a hypersensitive response  40
• Most move air or water through tracheae, lungs, or gills • Circulatory systems may be open or closed • In most, pumping heart moves blood through the body 45	• Detect light, gravity, heat, touch, sound, pathogens, predators, chemical signals • Nervous system enables rapid response • Endocrine system enables slower, longer-term responses via hormones 46, 47, 49	• Most are capable of movement using muscles  • Muscles work in combination with skeletal systems: hydrostatic skeletons, exoskeletons, and endoskeletons 48	• Most can reproduce sexually, some asexually • Multicellular stage is usually diploid; gametes are haploid • Fertilization may be external or internal  50	• Have both physical and chemical defenses against pathogens and predators • Infection launches: (1) nonspecific, innate immune response, and sometimes also (2) specific, adaptive immune response 51

42 Animal Form and Function

Oryx are adapted to desert life. They have an exceptional ability to withstand heat and can acquire most of their water from the food they eat.

The Sahara and Arabian deserts are extreme environments. In some parts of the Sahara, several years can pass between rainfalls. In a single day, temperatures in these deserts can fluctuate between −0.5°C and 37.5°C; midday temperatures in summer can exceed 50°C. Yet few places in the Sahara or Arabian deserts are devoid of life. Even large animals, such as the oryx, thrive in both regions.

How do animals native to these areas cope? Small animals avoid the midday heat by retreating to a cool burrow deep underground or the shade of a small shrub. Large mammals have a harder time hiding from sunlight but possess traits that allow them to keep cool and conserve water.

The Arabian oryx, for example, seldom drinks. It gets 86 percent of the water it needs from the vegetation it eats and the other 14 percent from water synthesized as a by-product of cellular

BIG PICTURE

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

respiration—what biologists call **metabolic water.** To conserve what water they have, Arabian oryx produce extremely concentrated urine and exceptionally dry fecal pellets.

In addition, oryx do not sweat to cool off. Instead, their body temperature rises from a normal 37°C to just over 40°C as temperatures increase during the day. The excess body heat is released during the cool desert nights, when their body temperature returns to normal.

In contrast to oryx, humans may die of dehydration when denied water for just three days. And for a human, having a body temperature of 40°C is a life-threatening situation—equivalent to running a fever of 104°F. How do oryx do it? What aspects of their anatomy and physiology allow them to thrive in such an extreme environment?

Anatomy is the study of an organism's physical structure. **Physiology** is the study of how the physical structures in an organism function. The anatomy and physiology of an oryx are clearly different from those of a human—or those of a shark, frog, bird, fruit fly, or crab, for that matter. This chapter is an introduction to the study of anatomy and physiology in animals. You can review the importance of animal form and function in the Big Picture on pages 840–841.

42.1 Form, Function, and Adaptation

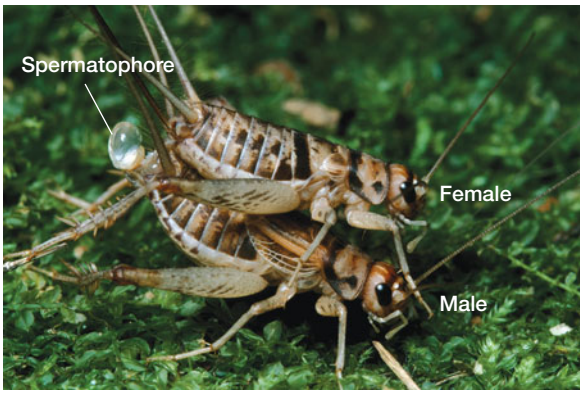
Biologists who study animal anatomy and physiology are studying **adaptations**—heritable traits that allow individuals to survive and reproduce in a certain environment better than individuals that lack those traits (see Chapter 25).

Recall that adaptation results from evolution by natural selection. Natural selection, in turn, occurs whenever individuals with certain alleles leave more offspring that survive to reproductive age than do individuals with different alleles. Because of this difference in reproductive success, the frequency of the selected alleles increases from one generation to the next.

Oryx with alleles that allow them to extract more water from their feces survive better and produce more offspring than do oryx with alleles that allow water to be lost in feces. The ability to produce extremely dry fecal pellets is an adaptation that helps oryx thrive in water-short environments.

The Role of Fitness Trade-Offs

Adaptations increase fitness—the ability to produce viable offspring. But no adaptation is "perfect." Instead, adaptations are limited by which alleles are present in a population and by the nature of the traits that already exist—because all adaptations derive from preexisting traits.



The human spine, for example, is a highly modified form of the vertebral column in ancestors that walked on all fours (see Chapter 35). The modifications in the human spine can be considered adaptations to support our upright posture, but they are far from perfect—most adults experience back pain at some point during their lives. The evolution of the human spine has been constrained by the nature of the ancestral trait and by a lack of alleles that would improve its structure and function.

The most important constraint on adaptation, though, may be **trade-offs**—inescapable compromises between traits. For example, it takes a lot of energy to produce offspring through the process of reproduction and also to mount an immune response during an infection. Animals sometimes do not have enough energy to satisfy both needs. In these cases, a trade-off emerges: The animal may devote more energy to reproduction at the expense of strong immune function, or vice versa, or both traits might be negatively affected.

How do biologists study trade-offs in animal physiology? Let's consider experimental work on trade-offs in crickets. During mating, a male cricket deposits a **spermatophore** on the female's genital opening (**FIGURE 42.1a**). This spermatophore consists of a packet of sperm surrounded by a large, gelatinous mass. After mating, the female begins to eat the gelatinous mass (**FIGURE 42.1b**). The sperm packet remains behind and the sperm slowly begin to enter her reproductive tract.

The longer it takes for the female to eat the mass, the more sperm are transferred to her, increasing the number of eggs fertilized by the male. It might seem advantageous for the male to make as large a spermatophore as possible. However, there is a

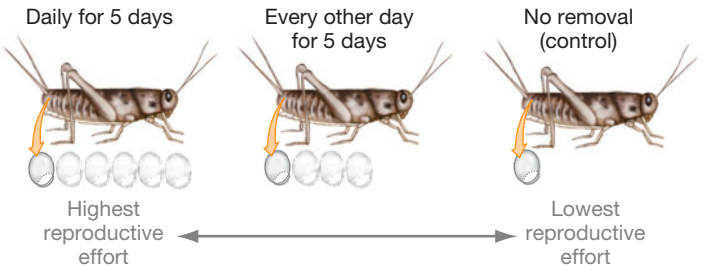
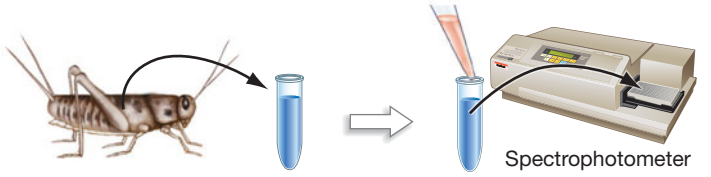
RESEARCH



QUESTION: Is there a trade-off between reproductive and immune function in male crickets?

HYPOTHESIS: Male crickets need to make an energy trade-off between reproductive function and immune function.

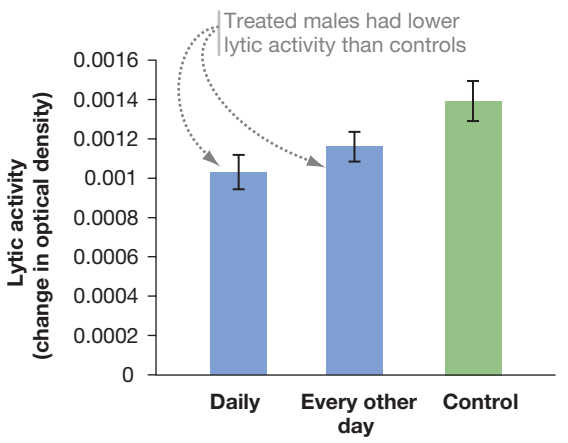
NULL HYPOTHESIS: No energy trade-off between reproductive function and immune function is required.



EXPERIMENTAL SETUP:

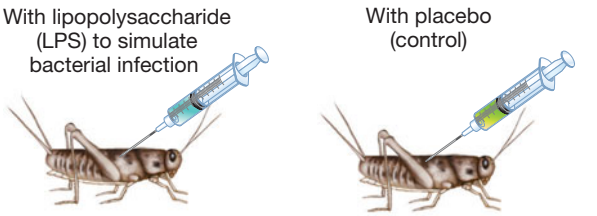
1. Remove spermatophores from male crickets:

2. Draw hemolymph samples from the three sets of crickets.



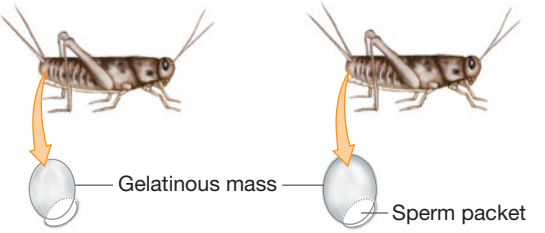
3. Add bacteria to samples; measure lysis of bacteria.

PREDICTION: Hemolymph from males forced to produce more spermatophores will exhibit lower lytic activity than controls.



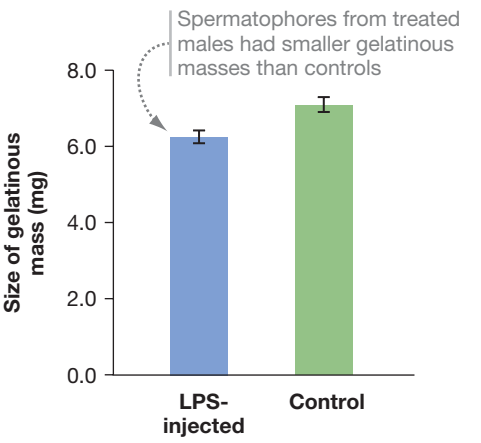
PREDICTION OF NULL HYPOTHESIS: There will be no difference in lytic activity between treated males and control males.

RESULTS:



EXPERIMENTAL SETUP:

1. Inject male crickets:



2. Remove spermatophores and measure size of gelatinous mass.

PREDICTION: Spermatophores from LPS-injected males will have smaller gelatinous masses than those from control males.

PREDICTION OF NULL HYPOTHESIS: There will be no difference in gelatinous mass size between treated and control males.

RESULTS:

CONCLUSION: Male crickets must make an energy trade-off to support increased reproductive effort.

FIGURE 42.2 Trade-offs Between Reproduction and Immune Function in Male Crickets. This study showed that males with experimentally increased investment in reproduction had a lower ability to kill bacteria than control males, and that males with experimentally stimulated immune function had lower reproductive function than control males.

SOURCE: Kerr, A. M., S. N. Gershman, and S. K. Sakaluk. 2010. Experimentally induced spermatophore production and immune responses reveal a trade-off in crickets. *Behavioral Ecology* 21: 647–654.

✔**QUESTION** If the null hypothesis were supported by the results, what would each graph look like?

cost involved. Spermatophores weigh up to 6 percent of a male cricket's body mass, and it takes males more than three hours to make a new one. During the time males spend making new spermatophores, they lose other mating opportunities.

Losing out on new mates while making spermatophores may not be the only cost a male cricket accrues. When an insect is infected with a pathogen such as a bacterium, it mounts an immune response. Activation of the insect defense system is energetically expensive. Is there a trade-off in male crickets between producing spermatophores and mounting an immune response?

To answer this question, biologists carried out an experiment using a powerful method—a reciprocal design. They altered the energetic investment crickets made into each of the systems in question—reproduction and immune function—and observed the effect on the other system (**FIGURE 42.2**).

First, the biologists removed spermatophores from male crickets, causing them to make new ones, daily or every other day. The biologists then took a sample of the crickets' hemolymph, or blood, and added bacteria to find out whether the hemolymph was able to destroy the pathogen. As bacteria are lysed, or ruptured, the opaque hemolymph becomes clear. Lytic activity was measured using a spectrophotometer to calculate the change in the opacity, or optical density, of the hemolymph over time.

Compared to control crickets, which did not have their spermatophores removed, the experimental crickets had lower lytic activity (fewer bacteria destroyed). Even more striking, the crickets that had to make new spermatophores daily had lower lytic activity than those that had to make new spermatophores only every other day. This suggested that increased investment into making spermatophores was traded off against investment into immune function.

Next, the biologists injected crickets with a component of the cell walls of bacteria called lipopolysaccharide (LPS), which caused the crickets to mount an immune response. What was the effect on spermatophore size? The result was dramatic. Male crickets injected with LPS produced smaller spermatophores than control crickets. When the researchers looked more closely, they realized the size of the sperm packet remained largely unchanged, but the size of the gelatinous mass decreased in injected crickets. This suggests that mounting an immune response may reduce male crickets' reproductive success. How? By causing males to make smaller gelatinous masses, which decreases the time females spend eating them, reducing sperm transfer.

Taken together, these two sets of experiments provide very strong evidence that there is a trade-off between reproductive and immune function in crickets.

Trade-offs, such as the compromise between energetic investment and the competing demands of reproductive and immune function, are common in nature. Desert animals that sweat to cool off are threatened with dehydration. An eagle's beak is superbly adapted for tearing meat but not for weaving nesting materials together. In studying animal anatomy and physiology, biologists study compromise and constraint as well as adaptation.

Adaptation and Acclimatization

In biology, adaptation refers to a genetic change in a population in response to natural selection exerted by the environment. Short-term, reversible responses to environmental fluctuations are referred to as **acclimatization.** Acclimatization is a phenotypic change in an individual in response to short-term changes in the natural environment. Acclimation is similar to acclimatization, but acclimation refers to changes that occur in organisms in a laboratory setting.

If you moved to Tibet, your body would acclimatize to high elevation by making more of the oxygen-carrying pigment hemoglobin and more hemoglobin-carrying red blood cells. But populations that have lived in Tibet for many generations are adapted to this environment through genetic changes. Among native Tibetans, for example, an allele that increases the ability of hemoglobin to hold oxygen has increased to high frequency. In populations of Tibetans that do not live at high elevations, this allele is rare or nonexistent.

The ability to acclimatize is itself an adaptation. Light-skinned humans, for example, vary in the ability to tan in response to sunlight. Some individuals tan easily—they have alleles that allow them to acclimatize efficiently to environments with intense sunlight—while others do not. In this and many other cases, the ability to acclimatize is a genetically variable trait that can respond to natural selection.

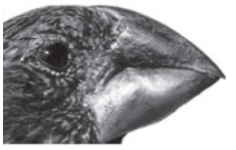
42.2 Tissues, Organs, and Systems: How Does Structure Correlate with Function?

If a structure found in an animal is adaptive—meaning that it helps the individual survive and produce viable offspring—it is common to observe that the structure's size, shape, or composition correlates closely with its function.

For example, recall that biologists have documented extensive changes in beak size and shape in medium ground finches from the Galápagos Islands (see Chapter 25). Such changes are due to natural selection. Individuals with deep beaks are better able to crack the large fruits that predominate during drought years, while individuals with small beaks are better able to harvest the small seeds that predominate during wet years.

As **FIGURE 42.3** (see page 846) shows, a strong correlation between diet and beak structure is also found *among* species of Galápagos finch. Species with large, cone-shaped beaks eat large seeds; species with small, cone-shaped beaks eat small seeds. Species with long, tweezer-like beaks pick insects off tree trunks or other surfaces.

The mechanism responsible for these structure–function correlations is straightforward: If a mutant allele alters the size or shape of a structure in a way that makes it function more efficiently, individuals who have that allele will produce more offspring than will other individuals. As a result, the allele will increase in frequency in the population over time.

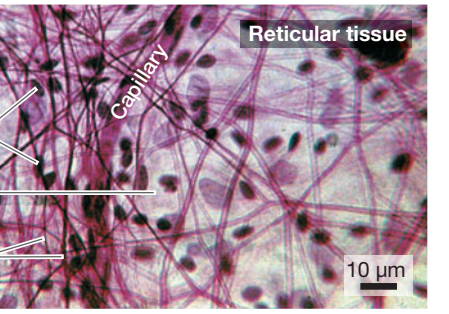


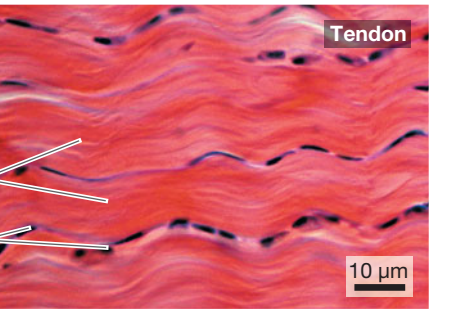
Species of Galápagos finch		Food source
Geospiza fuliginosa		Small seeds
Geospiza fortis		Medium seeds
Geospiza magnirostris		Large seeds
Certhidea olivacea		Insects, nectar

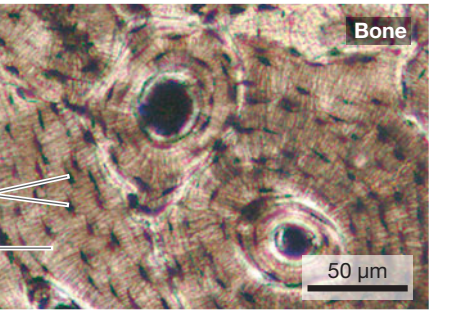
FIGURE 42.3 In Animal Anatomy and Physiology, Form Often Correlates with Function.

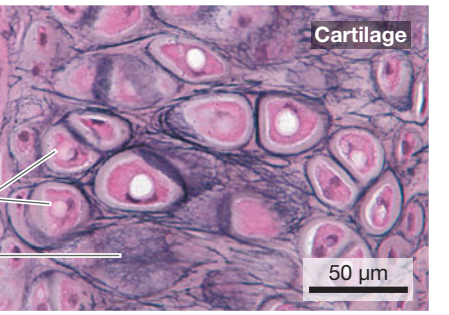
Structure–Function Relationships at the Molecular and Cellular Levels

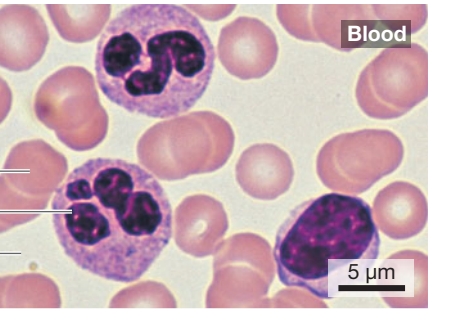
Correlations between form and function start at the molecular level. For example, earlier chapters emphasized that the shape of proteins correlates with their role as enzymes, structural components of the cell, or transporters. The membrane proteins called channels form pores that allow specific ions or molecules to pass in or out of cells (see Chapter 6). The ends and interior of a channel are hydrophilic, which allows the protein to interact with the surrounding solution or the interior of the cell, while the perimeter is hydrophobic—allowing the protein to interact with the lipid bilayer. The protein's structure fits its function.











Similar correlations between structure and function occur at the level of the cell. In fact, it is possible to predict a cell's specialized function by examining its internal structure. Cells that manufacture and secrete hormones or digestive enzymes are packed with rough endoplasmic reticulum (ER) and Golgi apparatuses; cells that store energy are dominated by large fat droplets; cells that ingest and destroy invading bacteria have many lysosomes.

The overall shape of a cell can also correlate with its function. For example, cells that are responsible for transporting materials into or out of the body often have extremely large areas of plasma membrane. As a result, they have room to accommodate the thousands of membrane channels, transporters, and pumps required for extensive transport.

Tissues Are Groups of Cells That Function as a Unit

Animals are **multicellular,** meaning that their bodies contain distinct types of cells that are specialized for different functions. Frequently, animal cells that are similar in structure and function are physically attached to each other and form a tissue. A **tissue** is a group of cells that function as a unit.

SUMMARY TABLE 42.1 Connective Tissues

Type	Example
Loose *soft* extracellular matrix; provides padding	
Dense *fibrous* extracellular matrix; provides connections	
Supporting *firm* extracellular matrix; functions in structural support and protection	
	
Fluid *liquid* extracellular matrix; functions in transport	

The embryonic tissues called ectoderm, mesoderm, and endoderm are found in most animals (see Chapter 23 and Chapter 33). As an individual develops, the embryonic tissues give rise to four adult tissue types: (**1**) connective tissue, (**2**) nervous tissue, (**3**) muscle tissue, and (**4**) epithelial tissue. In each case, the structure of the tissue correlates closely with its function. Let's consider each type in turn.

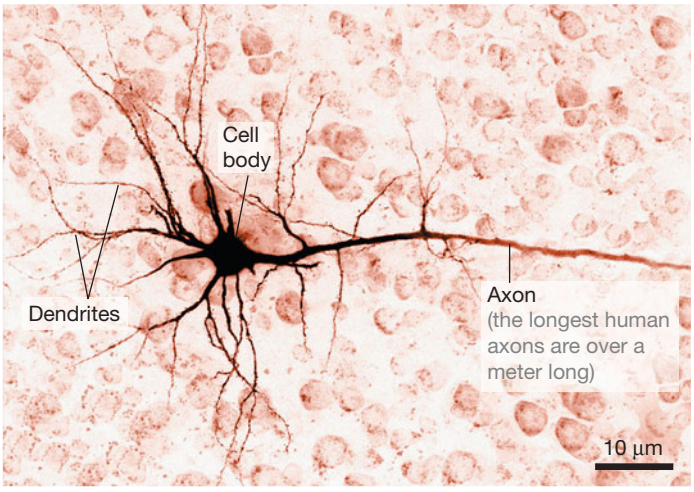
Connective Tissue **Connective tissue** consists of cells that are loosely arranged in a liquid, jellylike, or solid matrix. The matrix comprises extracellular fibers and other materials, and it is secreted by the connective tissue cells themselves (**TABLE 42.1**). Each type of connective tissue secretes a distinct type of extracellular matrix. The nature of the matrix determines the nature of the connective tissue.

- **Loose connective tissue** contains an array of fibrous proteins in a soft matrix; it serves as a packing material between organs or padding under the skin. Reticular connective tissue—in lymphoid organs such as the spleen and bone marrow—and adipose tissue, or fat tissue, are loose connective tissues made up of cells suspended in a matrix of fibers and fluid.
- **Dense connective tissue** is found in the tendons and ligaments that connect muscles, bones, and organs. As Table 42.1 shows, the matrix in tendons and ligaments is dominated by tough collagen fibers (introduced in Chapter 11).
- **Supporting connective tissue** has a firm extracellular matrix. **Bone** and **cartilage** are connective tissues that provide structural support for the vertebrate body as well as protective enclosures for the brain and other components of the nervous system.
- **Fluid connective tissue** consists of cells surrounded by a liquid extracellular matrix. **Blood,** which transports materials throughout the vertebrate body, contains a variety of cell types and has a specialized extracellular matrix called plasma (see Chapter 45).

Nervous Tissue **Nervous tissue** consists of nerve cells, which are also called **neurons,** and several types of supporting cells. Neurons transmit electrical signals, which are produced by changes in the permeability of the cell's plasma membrane to ions (see Chapter 46). Supporting cells have many functions, including regulating ion concentrations in the space surrounding neurons, supplying neurons with nutrients, or serving as scaffolding or support for neurons.

Although they vary widely in shape, all neurons have projections that contact other cells. As **FIGURE 42.4** shows, most neurons have two distinct types of projections from the cell body, where the nucleus is located: **(1)** highly branched, relatively short processes called **dendrites,** and **(2)** a relatively long structure called an **axon.** Dendrites contact other cells and transmit electrical signals from them to the cell body; the axon carries electrical signals from the cell body to other cells.

Muscle Tissue **Muscle tissue** was a key innovation in the evolution of animals—like nervous tissue, it appears in no other



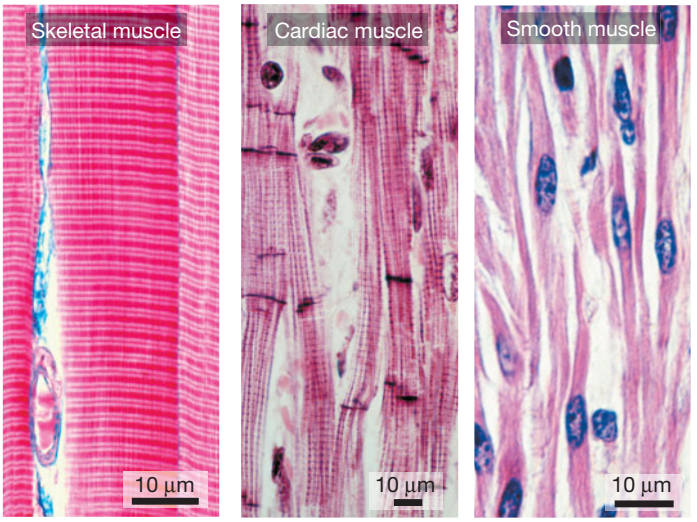


FIGURE 42.4 Neurons Transmit Electrical Signals. In a neuron, information is transmitted from dendrites to the cell body to the axon.

✔**QUESTION** Based on the structure of a neuron, does it provide signals to specific cells and tissues, or does it broadcast signals widely throughout the body?

lineage on the tree of life (see Chapter 33). Some of the functions of muscle include movement of the body, pumping of the heart, and mixing of food in the gastrointestinal tract. There are three types of muscle tissue (**FIGURE 42.5**); you, along with other vertebrates, have all three.

1. **Skeletal muscle** attaches to the bones of the skeleton and exerts a force on them when it contracts. Skeletal muscle is responsible for most body movements. In addition, it encircles the openings of the digestive and urinary tracts and controls swallowing, defecation, and urination.

Long cells, voluntary movement | **Branched cells,** involuntary movement | **Tapered cells,** involuntary movement

FIGURE 42.5 Muscle Tissues Comprise Cells That Contract. The three types of muscle tissue have distinctive structures and functions.

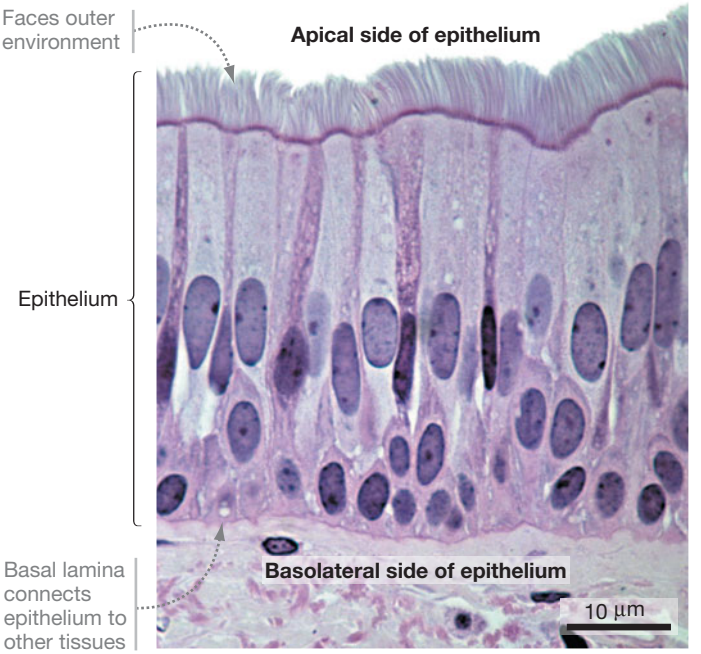

FIGURE 42.6 Epithelial Cells Provide Protection and Regulate which Materials Pass across Body Surfaces.

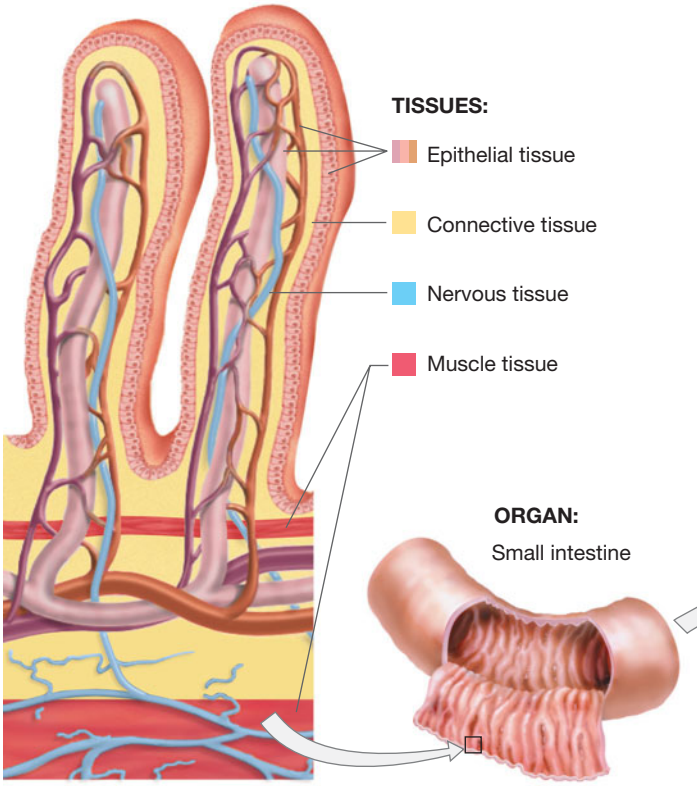
2. **Cardiac muscle** makes up the walls of the heart and is responsible for pumping blood throughout the body.
3. **Smooth muscle** cells, which are tapered at each end, form a muscle tissue that lines the walls of the digestive tract and the blood vessels.



Muscle tissue and movement are explored in detail in Chapter 48.

Epithelial Tissues **Epithelial tissues** are also called **epithelia** (singular: **epithelium**). Epithelium covers the outside of the body, lines the surfaces of organs, and forms glands. An **organ** is a structure that serves a specialized function and consists of several tissues; a **gland** is an organ that secretes specific molecules or solutions such as hormones or digestive enzymes.

Epithelia form the interface between the interior of an organ or body and the exterior. In addition to providing protection, epithelial tissues are gatekeepers. Water, nutrients, and other substances are transported, often selectively, across epithelia.

Because the primary function of epithelium is to act as a barrier and protective layer, it's not surprising to observe that epithelial cells typically form layers of closely packed cells (**FIGURE 42.6**).

(a) Tissues are organized into organs.

(b) Organs are organized into organ systems.

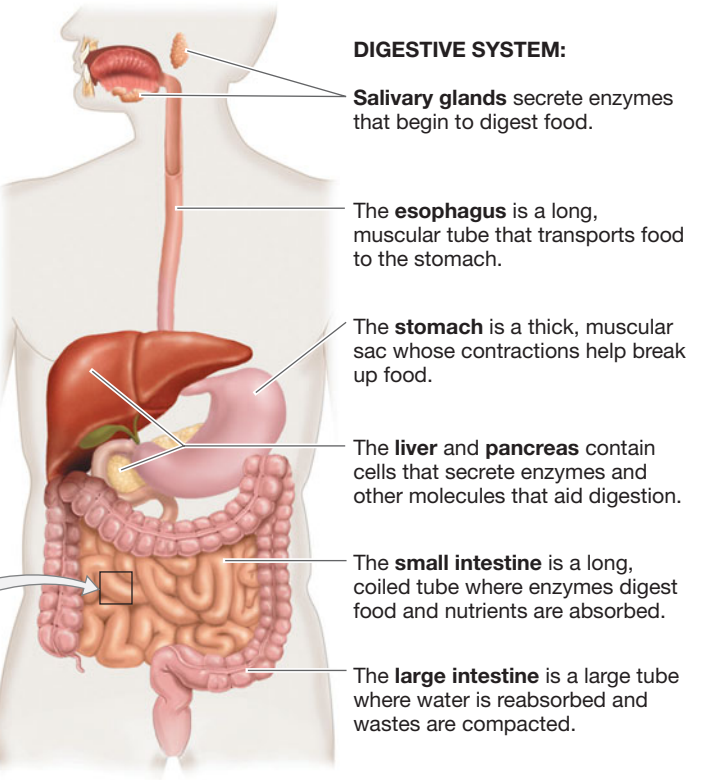


FIGURE 42.7 Organs Are Composed of Tissues; Organ Systems Are Made Up of Organs. (a) The human small intestine is an organ composed of all four major tissue types. **(b)** The human digestive system is essentially one long tube divided into chambers where food is processed and nutrients are absorbed. The salivary glands, liver, and pancreas are organs that secrete specific enzymes or compounds into the tube.

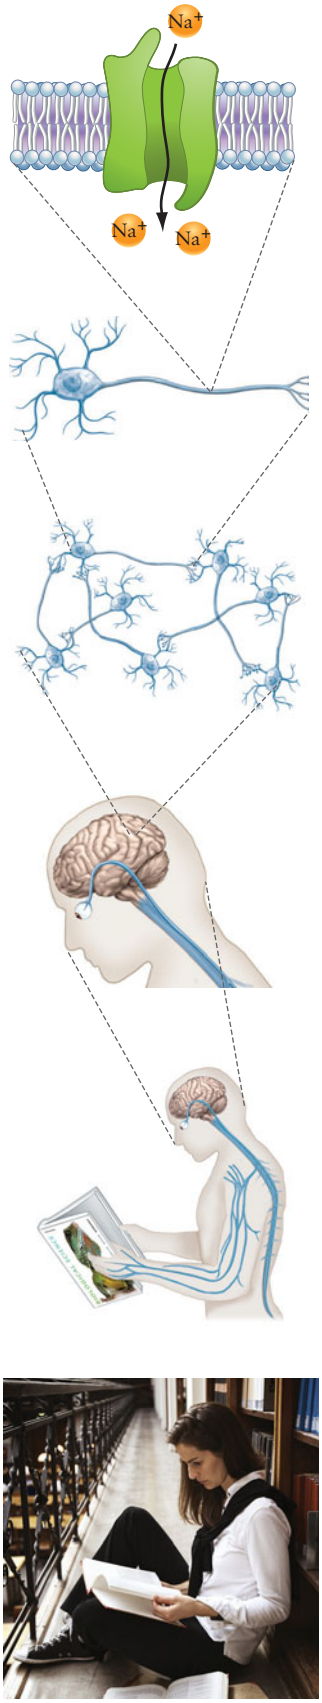
In many cases, adjacent epithelial cells are joined by structures that hold them tightly together, such as tight junctions and desmosomes (introduced in Chapter 11).

Epithelial tissue has polarity, or sidedness. An epithelium has an **apical** side, which faces away from other tissues and toward the environment, and a **basolateral** side, which faces the interior of the animal and connects to connective tissues. This connection is made by a layer of fibers called the **basal lamina.**

The apical and basolateral sides of an epithelium have distinct structures and functions. Epithelial cells, for example, line the surface of your trachea, or windpipe. The apical side of these cells secretes mucus and is covered with cilia that help sweep away dust, bacteria, and viruses. The basolateral side lacks these features but is cemented to the basal lamina.

Epithelial cells have short life spans. The cells that line your esophagus—the tube connecting your mouth and stomach—live for 2 to 3 days, while the cells that line your large intestine live for a maximum of 6 days. Muscle cells and neurons, in contrast, normally live as long as the individual animal does. Epithelial cells are short lived because they are exposed to harsh environments, where they are likely to be killed or scraped away.

The tissue as a whole does not wear away, however, because it includes cells that actively undergo mitosis and cytokinesis—producing new epithelial cells to replace those lost on the side that faces the environment.



Organs and Organ Systems

Cells with similar functions are organized into tissues, and tissues are organized into specialized structures called organs. Recall that an organ is a structure that serves a specialized function and consists of several types of tissues. The small intestine, for example, consists of muscle, nervous, connective, and epithelial tissues (**FIGURE 42.7a**).

An **organ system** consists of groups of tissues and organs that work together to perform one or more functions. Using the digestive system as an example, **FIGURE 42.7b** illustrates how the structure of organs correlates with their function and how the components of an organ system work together in an integrated fashion.

Because an animal's body contains molecules, cells, tissues, organs, and organ systems, biologists who study animal anatomy and physiology must work at various levels of organization to understand how that body operates.

FIGURE 42.8 illustrates these levels of organization, using the human nervous system as an example. Because the structure and function of each component in the body are integrated with those of other components, and because each level of organization is integrated with other levels of organization, the organism as a whole is greater than the sum of its parts. In other words, an organism is more than just a collection of individual systems, and each system is more than just a collection of individual cells or tissues or even organs.

Atomic and molecular levels:
Membrane protein in neurons regulates flow of ions.

Cellular level:
Electrical signal travels down length of neuron.

Tissue level:
Electrical signals travel from cell to cell in nervous tissue.

Organ level:
Nervous tissue and connective tissue in brain aid in sight, smell, memory, and thought.

Organ system level:
Brain and nerves send signals throughout the body to control breathing, digestion, movement, and other functions.

Organism level:
Nervous system coordinates the functions of other systems to support life.

FIGURE 42.8 Biologists Study Anatomy and Physiology at Many Levels. The levels of organization within an organism are not independent of each other. Instead, they are tightly integrated.

In effect, each subsequent chapter in this unit focuses on a different organ system found in animals, beginning with the excretory system and ending with the immune system. Each of these systems can be interpreted as a suite of adaptations and trade-offs. Each system accomplishes a specific task required for survival and reproduction, and each works in conjunction with other systems.

Before delving into the various systems, however, it's essential to examine general phenomena that affect all systems in animals. Let's start by looking at how body size affects animal physiology.

- Events at each level of organization in an individual interact to form an integrated whole that responds to the environment in appropriate ways.

✔ You should be able to . . .

Describe and compare the structure and function of the four major types of animal tissues.

Answers are available in Appendix A.

42.3 How Does Body Size Affect Animal Physiology?

Animals are living machines, made up of molecules, cells, tissues, organs, and organ systems that have changed over time in response to natural selection.

The laws of physics affect the anatomy and physiology of a living machine. The force of gravity, for example, limits how large an animal can be and still move efficiently. Or consider the forces exerted by the medium in which animals live. Because water is much denser than air, it is harder for animals to move through water. As a result, fish and aquatic mammals have much more streamlined bodies than terrestrial animals do.

Physical laws clearly affect body size. Just as clearly, body size has pervasive effects on how animals function. Large animals need more food than small animals do. Large animals also produce more waste, take longer to mature, reproduce more slowly, and tend to live longer. Conversely, small animals are more susceptible to damage from cold and dehydration than large animals are, because they lose heat and water faster. Juveniles and adults of the same species face different challenges simply because their body sizes are different.

Why is body size such an important factor in how animals work? How do biologists study the consequences of size? Let's consider each question in turn.

Surface Area/Volume Relationships: Theory

From microscopic roundworms to gigantic blue whales, animals span an incredible range of body masses—a total of 12 orders of magnitude. Many of the challenges posed by increasing size are based on this fundamental relationship between surface area and volume.

You learned previously that the relationship between the surface area and volume of the roots and shoots of plants affects water and light absorption by the plant (see Chapter 37). Similarly, surface area is important in animals because oxygen and nutrients such as glucose must diffuse into the animal's body, and waste products such as urea and carbon dioxide must diffuse out. The rate at which these and other molecules and ions diffuse depends in part on the amount of surface area available for diffusion. In contrast, the rate at which nutrients are used and heat and waste products are produced depends on the volume of the animal.

The contrast between processes that depend on surface area and those that depend on volume is important for a simple reason. As an animal gets larger, its volume increases much faster than its surface area does.

Reviewing a little basic geometry will convince you why this is so. As **FIGURE 42.9a** shows:

- The surface area of a cube increases as a function of its linear dimension *squared*. Because a cube has six sides, the surface area of a cube of length l is $6l^2$ (six times the area of any one side).
- The volume of the same structure increases as a function of its linear dimension *cubed*. Hence, the volume (or mass) of a cube of length l is l^3.

Area has two dimensions; volume has three. In general:

$$\text{Surface area} \propto (\text{length})^2$$
$$\text{Volume (or mass)} \propto (\text{length})^3$$
$$\text{Surface area} \propto (\text{volume})^{2/3}$$

(The symbol $\propto$ means "is proportional to.")

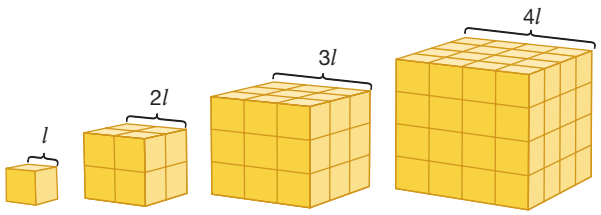

FIGURE 42.9b graphs the consequences of these relationships. The x-axis plots the length of a side in a cube; the y-axis plots the cube's volume (orange line) or surface area (yellow line). As a cube gets bigger, its surface area increases much more slowly than does its volume (or mass).

The same general relationship holds for cells, tissues, organs, and organ systems. Larger cells, for example, have lower surface area/volume ratios than smaller cells. Quantities that are based on volume, such as body mass, increase disproportionately fast with increases in linear dimensions.

✔ If you understand the relationship between surface area and volume, you should be able to predict which of the following has the higher surface area/volume ratio: a newborn or an adult human.

How does the relationship between surface area and volume affect animal form and function?

(a) What are the surface area and volume of each cube?

	l	$2l$	$3l$	$4l$
Surface area	$6l^2$	$6(2l)^2 = \mathbf{24}l^2$	$6(3l)^2 = \mathbf{54}l^2$	$6(4l)^2 = \mathbf{96}l^2$
Volume	l^3	$(2l)^3 = \mathbf{8}l^3$	$(3l)^3 = \mathbf{27}l^3$	$(4l)^3 = \mathbf{64}l^3$
Ratio (surface area/volume)	**6:1**l	**3:1**l	**2:1**l	**1.5:1**l

(b) Surface area and volume of a cube versus length of a side

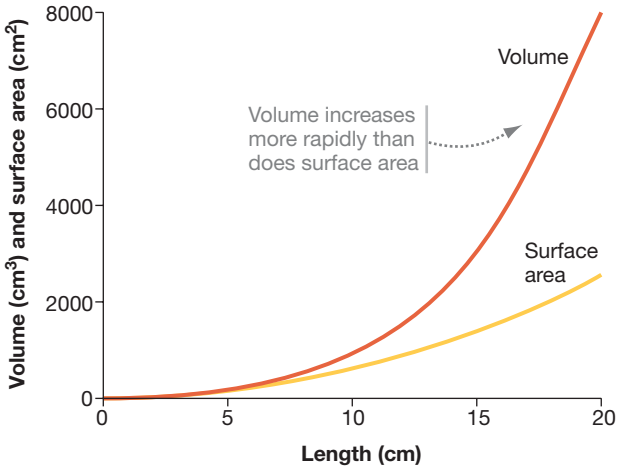

FIGURE 42.9 Surface Area and Volume Change as a Function of Overall Size. (a) The surface area of an object increases as the square of the length (l). The volume increases as the cube of the length. **(b)** Volume increases much more rapidly than does surface area as linear dimensions increase.

Surface Area/Volume Relationships: Data

As an example of how surface area/volume relationships affect an animal's physiology, consider the metabolic rate of mammals. **Metabolic rate** is the overall rate of energy consumption by an individual. Because consumption and production of energy in mammals depend largely on aerobic respiration, metabolic rate is often measured in terms of oxygen consumption, and it is typically reported in units of milliliters of O_2 consumed per hour.

Because it is so much larger, an elephant consumes a great deal more oxygen per hour than a mouse does. But what is going on at the levels of cells and tissues in these animals?

Comparing Mice and Elephants To compare metabolic rates in different species, biologists divide metabolic rate by overall mass and report a mass-specific metabolic rate in units of milliliters of oxygen per gram per hour (mL O_2/g/hr). This mass-specific metabolic rate gives the rate of oxygen consumption per gram of tissue.

Because an individual's metabolic rate varies dramatically with its activity, the accepted convention is to report the **basal metabolic rate (BMR)**—the rate at which an animal consumes oxygen while at rest, with an empty stomach, under normal temperature and moisture conditions.

FIGURE 42.10 plots per-gram or "mass-specific" BMR as a function of average body mass. Notice that the x-axis on the graph is logarithmic, to make it easier to compare very small species with very large ones. For help with logarithms, see **BioSkills 6** in Appendix B.

The graph's take-home message? On a per-gram basis, small animals have higher BMRs than do large animals. An elephant has more mass than a mouse, but a gram of elephant tissue consumes much less energy than a gram of mouse tissue does.

The leading hypothesis to explain this pattern is based on surface area/volume ratios. Many aspects of metabolism—including oxygen consumption, food digestion, delivery of nutrients to tissues, and removal of wastes and excess heat—depend on exchange across surfaces. As an organism's size increases, its mass-specific metabolic rate must decrease. Otherwise the surface area available for exchange of materials would fail to keep up with the metabolic demands generated by the organism's enzymes.

Changes during Development A king salmon weighs a few milligrams or less at hatching but grows into an adult weighing 50 kg or more—a millionfold increase in body mass. To explore the consequences of this change, biologists have studied how gas

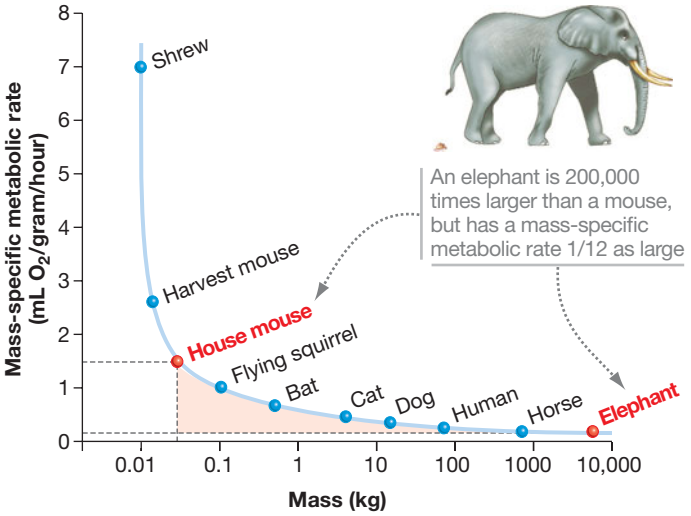

FIGURE 42.10 Small Animals Have Higher Relative Metabolic Rates than Large Animals Do. Overall body mass, plotted on a logarithmic scale, versus metabolic rate per gram of tissue.

✔**QUESTION** Which mammal has to eat more to support each gram of its tissue: a puppy or an adult dog?

exchange—uptake of oxygen and removal of carbon dioxide—occurs in newly hatched Atlantic salmon.

Like most fish species, young salmon have rudimentary gills but also exchange gases across their skin. In aquatic animals, **gills** are organs that allow the exchange of gases and dissolved substances between the animals' blood and the surrounding water.

To document the amount of gas exchange that occurs in the gills versus the skin, researchers inserted the heads of individual larval and juvenile salmon through a pinhole in a soft rubber membrane and then recorded the rate of oxygen uptake on either side of the membrane. As the "Experimental Setup" section of **FIGURE 42.11** indicates, the gills were responsible for oxygen uptake on one side of the membrane; skin was responsible for oxygen uptake on the other side of the membrane.

The graph in the figure's "Results" section plots the percentage of total oxygen uptake that took place across the skin (green line) versus gills (purple line), as a function of body mass. Each data point represents the recordings from an individual fish.

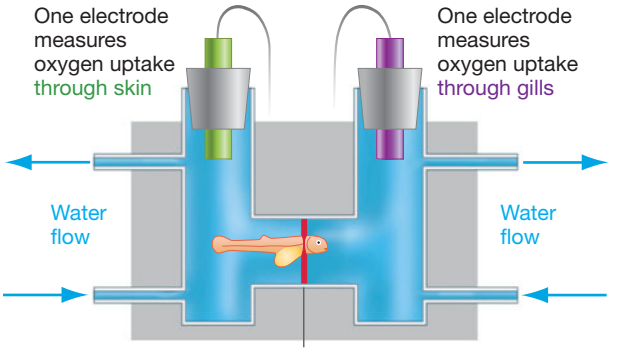
Note that newly hatched larvae take up most of the oxygen they need by diffusion across the body surface. As an individual grows, however, its skin surface area decreases in relation to its volume. To avoid suffocation, individuals switch from skin-breathing to gill-breathing at a body mass of about 0.1 grams. What makes gills so effective in oxygen uptake?

Adaptations That Increase Surface Area

If the function of a cell or tissue depends on diffusion, it usually has a shape that increases its surface area relative to its volume. Flattening, folding, and branching are effective ways for structures to have a high surface area/volume ratio:

- *Flattening* Fish have **gill lamellae** (**FIGURE 42.12a**)—thin sheets of epithelial cells that provide the gill with an extremely high surface area relative to its volume. Because the surface available is so large, gases are able to diffuse across the gills rapidly enough to keep up with the growth in the volume of a developing fish.
- *Folding* In portions of the digestive tract where nutrients are transported into the body, the surface of the structure is folded. Extending from these folds are narrow projections called **villi** (**FIGURE 42.12b**). Together, the folds and villi make an extensive surface area available. Folded surfaces are common in diffusion-dependent organs.
- *Branching* The highly branched network shown in **FIGURE 42.12c** is a system of small, thin-walled blood vessels called **capillaries.** Capillaries have a high surface area available for gases, nutrients, and waste products to diffuse into and out of blood; branching increases the surface available in each square centimeter of tissue. In general, highly branched structures increase the surface area available for diffusion.

The amount of surface area created by flattening, folding, and branching can be impressive. The highly branched capillaries in a human have a total surface area of up to 1000 m^2; extensive folding gives a total surface area of about 140 m^2 in your lungs and

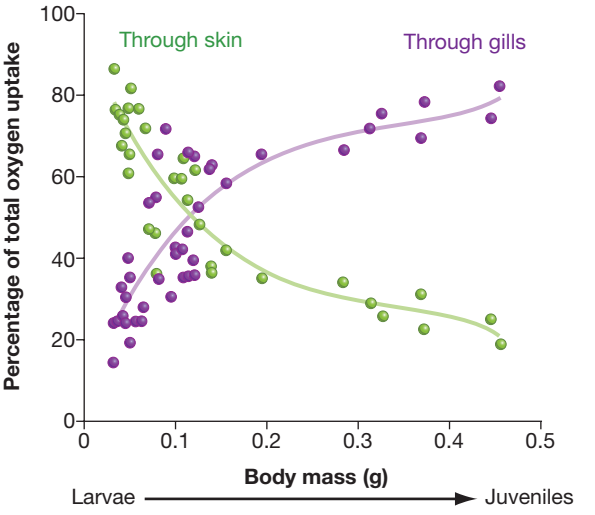


RESEARCH

QUESTION: Newly hatched salmon can breathe through their skin and through their gills. Which predominates?

HYPOTHESIS: The relative amount of gas exchange across gills and skin changes as a salmon grows.

NULL HYPOTHESIS: The relative amount of gas exchange across gills and skin does not change as a salmon grows.



EXPERIMENTAL SETUP:

PREDICTION: Juveniles will exchange a higher percentage of gas across gills and a lower percentage of gas across skin than larvae.

PREDICTION OF NULL HYPOTHESIS: Juveniles and larvae will exchange the same percentage of gas across gills and skin.

RESULTS:

CONCLUSION: Breathing changes from skin to gills as larvae grow. Interpretation: Gills provide larger surface area relative to increasing volume of body.

CUE

If you understand that . . .

- An animal's overall size is important in part because body mass is affected by an array of physical forces.
- The amount of heat and waste that an animal produces and the amount of food and oxygen that it requires are proportional to its mass or volume.
- The amount of surface area available relative to that mass or volume is critical, because heat exchange and other important processes take place across surfaces.

✓ You should be able to . . .

1. Explain why large animals have a relatively low surface area/volume ratio.
2. Explain why a squirrel needs to eat more energy per unit body mass than a bear.

Answers are available in Appendix A.

42.4 Homeostasis

Adaptation and surface area/volume ratios are important themes in the analysis of animal form and function. So is homeostasis.

Homeostasis (literally, "alike-standing") is defined as stability in the chemical and physical conditions within an animal's cells, tissues, and organs. Although conditions may vary as an animal's environment changes, internal chemical and physical states are usually kept within a tolerable range.

Homeostasis: General Principles

Many of the structures and processes observed in animals can be interpreted as mechanisms for maintaining homeostasis with respect to some quantity, such as pH, temperature, or calcium ion concentration. Let's review some important general ideas about homeostasis and then analyze how homeostasis can be maintained in the face of environmental fluctuations.

Two Approaches to Achieving Homeostasis Constancy of physiological state can be achieved by two processes: **(1)** conformation or **(2)** regulation.

1. ***Conformation*** The body temperature of Antarctic rock cod closely matches that of the surrounding seawater, which is typically −1.9°C (seawater is still liquid at this temperature because of the high concentration of solutes). The rock cod does not actively regulate its body temperature to match that of seawater. Instead, its body temperature remains constant because it conforms to the temperature of its constant surroundings. If rock cod were placed into a different environment, for example warmer water, they would not maintain a constant body temperature of −1.9°C. Because these animals are adapted to such constant environmental conditions, their physiological systems cannot function properly outside of these conditions.
2. ***Regulation*** Regulatory homeostasis is based on mechanisms that adjust the internal state to keep it within limits that can be tolerated, no matter what the external conditions. For example, a dog maintains a body temperature of about 38°C whether it's cold or hot outside. If the dog's body temperature rises, it might pant to cool off and maintain homeostasis. If body temperature falls, the dog might shiver to bring its temperature back up to the target value. There

are, however, limits to regulatory homeostasis. If the external temperature gets too cold or hot, animals cannot maintain homeostasis and will die.

The Role of Epithelium Because epithelium is the interface between the internal and external environments, it plays a key role in achieving homeostasis. Epithelium is responsible for forming an internal environment that can be dramatically different from the external environment such that physical and chemical conditions inside an animal can be maintained at relatively constant levels.

As subsequent chapters will show, many epithelial cells are studded with membrane proteins that regulate the transport of ions, water, nutrients, and wastes. No molecule can enter or leave the body without crossing an epithelium. Homeostasis is possible because epithelia control this exchange.

Why Is Homeostasis Important? Much of the answer to this question is based on enzyme function. Recall that enzymes are proteins that catalyze chemical reactions within cells (see Chapter 4). Temperature, pH, and other physical and chemical conditions have a dramatic effect on the structure and function of enzymes. Most enzymes function best under a fairly narrow range of conditions.

Other processes depend on homeostasis, too. Temperature changes affect membrane permeability and how quickly solutes diffuse. To take an extreme case, the expansion of water as it freezes can rip cells apart if tissues are allowed to drop much below 0°C. Conversely, extremely high temperatures can denature proteins—meaning that they lose their tertiary structure and cease to function.

When homeostasis occurs, conditions inside the body allow molecules, cells, tissues, organs, and organ systems to function at an optimal level. However, occasional departures from homeostasis can represent important adaptations. For example, a fever is a response to an infection by a pathogen. This increase in body temperature can help fight off the pathogen.

The Role of Regulation and Feedback

To achieve homeostasis, most animals have regulatory systems that monitor internal conditions such as temperature, blood pressure, blood pH, and blood glucose. If one of these variables changes, a homeostatic system acts quickly to modify it. Like the thermostat in a home heating system, each of these systems has a **set point**—a normal or target range of values for the controlled variable.

Animals have a set point for blood pH, blood oxygen and nutrient concentrations, and other parameters. In most mammals, the set point for body temperature is somewhere between 35°C and 39°C. How does an individual maintain its tissues at the set point despite changes in activity and the environment?

A homeostatic system consists of three general components: a sensor, an integrator, and an effector. **FIGURE 42.13** shows how these components interact:

1. A **sensor** is a structure that senses some aspect of the external or internal environment.

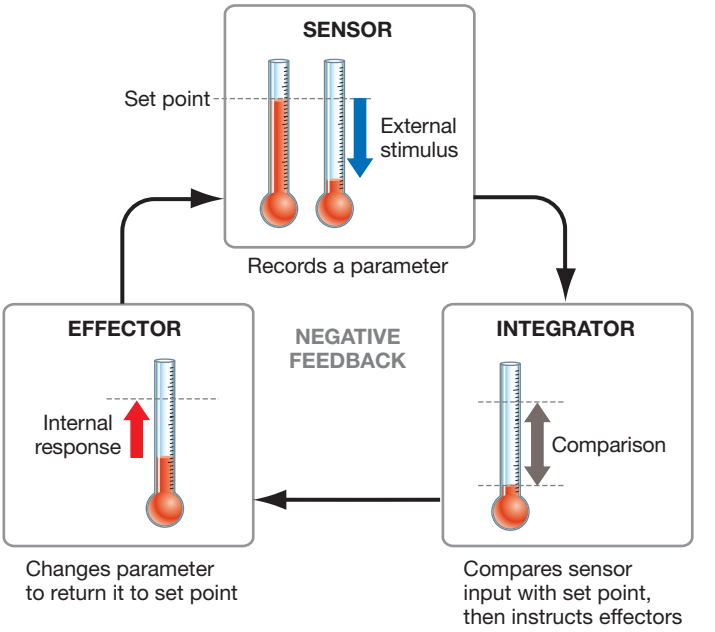

FIGURE 42.13 Animals Achieve Homeostasis through Negative Feedback. Many animals use homeostatic systems similar to this one to maintain a preferred range of hydration, blood pH, blood pressure, calcium ion concentration, body temperature, and so on.

2. An **integrator** evaluates the incoming sensory information and "decides" whether a response is necessary to achieve homeostasis. (The word decides is in quotation marks because the decision is not a conscious one.)
3. An **effector** is any structure that helps restore the desired internal condition.

Without these three elements, homeostatic control systems can't maintain a desired set point; homeostasis is impossible.

Homeostatic systems are based on negative feedback. When **negative feedback** occurs, effectors reduce or oppose the change in internal conditions. For example, a rise in blood pH triggers effectors that act to reduce that rise. Blood pH returns to the set point in response to this negative feedback.

Homeostatic systems are a key aspect of one of the five attributes of life (see Chapter 1): acquiring information from the environment and responding to it. Subsequent chapters in this unit explore how animals use sensor–integrator–effector systems to achieve homeostasis with respect to the solute concentrations of their cells and tissues, their oxygen supply, and nutrient availability. In this chapter, let's focus on how different animals achieve homeostasis with respect to body temperature.

42.5 How Do Animals Regulate Body Temperature?

All animals exchange heat with their environment. Heat flows "downhill," from regions of higher temperature to regions of lower temperature. If an individual is warmer than its

surroundings, it will lose heat; if it is cooler than its environment, it will gain heat.

How does heat exchange occur?

Mechanisms of Heat Exchange

As **FIGURE 42.14** shows, animals exchange heat with the environment in four ways: conduction, convection, radiation, and evaporation.

1. **Conduction** is the direct transfer of heat between two physical bodies that are in contact with each other. For instance, when a turtle sits on a warm rock, heat is transferred from the rock to its body. The rate at which conduction occurs depends on the surface area of transfer, the steepness of the temperature difference between the two bodies, and how well each body conducts heat.
2. **Convection** is a special case of conduction. During conduction, heat is transferred between two solids; but during convection, heat is exchanged between a solid and a moving liquid or gas. For example, the heat loss that occurs when wind blows on your skin is due to convection. As the speed of the air or water flow increases, so does the rate of heat transfer.
3. **Radiation** is the transfer of heat between two bodies that are not in direct physical contact. All objects, including animals, radiate energy as a function of their temperature. The Sun radiates heat; so does your body, but to a much lesser degree.
4. **Evaporation** is the phase change that occurs when liquid water becomes a gas. Conduction, convection, and radiation can cause heat gain or loss, but evaporation leads only to heat loss. The turtle in the photograph is losing heat as water evaporates off its shell and skin. Because of the extensive hydrogen bonding in liquid water, a large amount of energy is needed to heat water and produce evaporation (see Chapter 2). If you get overheated on a summer day, splashing water on your skin and sweating will allow you to use evaporative heat loss to cool your body. Conversely, getting wet on a cold day can be deadly. The water on your skin absorbs so much heat from your body that your temperature may drop dangerously.

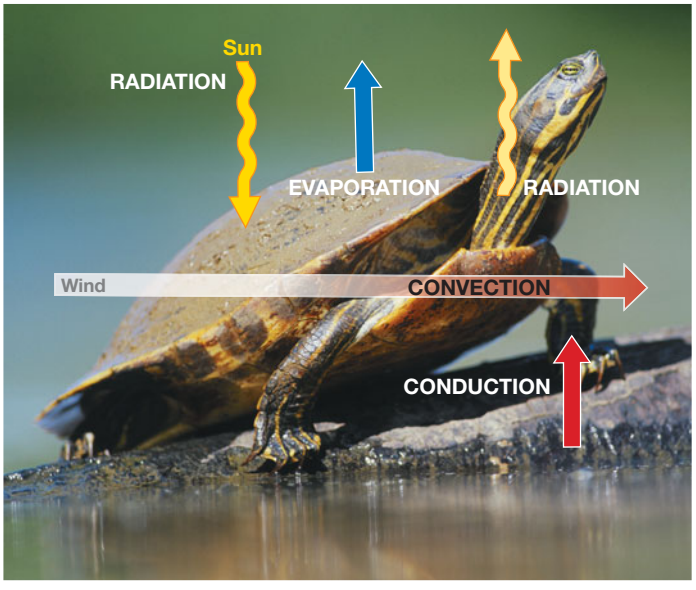

FIGURE 42.14 Four Methods of Heat Exchange. The arrows indicate the direction of heat exchange.

Heat exchange is critical in animal physiology because individuals that get too hot or too cold may die. Overheating can cause enzymes and other proteins to denature and cease functioning. It may also lead to excessive water loss and dehydration. A sharp drop in body temperature, in contrast, can slow enzyme function and energy production. In humans, both heat stroke and hypothermia ("under-heating") are life-threatening conditions.

Although most organisms conform to the environmental temperature, some animals can regulate body temperature to keep it in an optimal range. Let's take a closer look.

Variation in Thermoregulation

The ability of animals to **thermoregulate,** or control body temperature, varies widely. Two ways to organize this variation are by examining **(1)** how animals obtain heat, and **(2)** whether body temperature is held constant.

An **endotherm** ("inner-heat") produces adequate heat to warm its own tissues, while an **ectotherm** ("outer-heat") relies principally on heat gained from the environment. Endotherms and ectotherms represent two extremes along a continuum of heat sources. Many animals fall somewhere in between.

There are also two extremes on a continuum describing whether animals hold their body temperature constant: **Homeotherms** ("alike-heat") keep their body temperature constant, while **heterotherms** ("different-heat") allow their body temperature to rise or fall depending on environmental conditions.

Humans, along with most birds and most other mammals, are strictly endothermic homeotherms. These species produce their own heat and maintain a constant body temperature. In contrast, most freshwater and terrestrial invertebrates, fishes, amphibians, and reptiles are ectothermic heterotherms whose body temperatures change throughout the day and seasonally. But many animal species lie somewhere between these extremes:

- Some desert-adapted mammals, such as the oryx featured in the introduction to this chapter, allow their body temperature to rise during the hotter part of the day—meaning they are somewhat heterothermic.
- Small mammals that inhabit cold climates lose heat rapidly because their surface area is large relative to their volume. To survive when temperatures are cold, species such as dormice reduce their metabolic rate and allow their body temperature to drop, a form of heterothermy. This condition is called **torpor.** In animals in which torpor persists for weeks or months, it is called **hibernation.**
- Naked mole rats are mammals, but lack insulation because they have no fur. They live in underground tunnels and allow their body temperature to rise and fall with burrow

(a) A hornet preys on a honeybee.

(b) A swarm of bees surrounds a hornet ...

(c) ... forming a hot defensive ball.

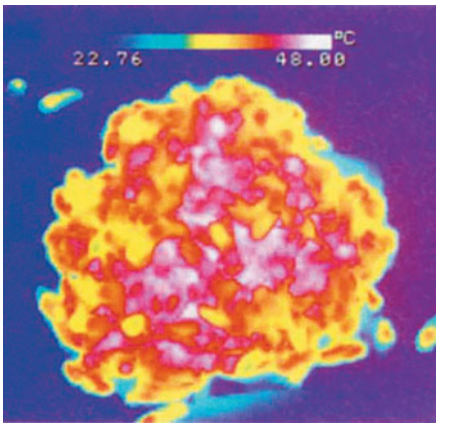

FIGURE 42.15 Honeybees Use Heat to Kill Predators.

temperatures. They are heterothermic and intermediate between ectotherms and endotherms.

- Japanese honeybees exhibit heterothermy when defending their hives from predatory hornets. The honeybees swarm an invading hornet and contract their flight muscles repeatedly to collectively produce heat endothermically (**FIGURE 42.15**). The temperature within the swarm rises to 47°C (117°F), killing the hornet but not the honeybees, which can tolerate temperatures up to 50°C (122°F).

Even in a homeothermic endotherm such as a mammal or bird, body temperature can vary widely in different body regions. When a Canada goose is standing on ice, its feet may be at a temperature of just 9°C, even though its body core is at 35°C. Similar variations exist in tuna and mackerel. These fish are ectotherms but generate heat to warm certain sections of their bodies, such as their eyes or swimming muscles.

Endothermy and Ectothermy: A Closer Look

Endotherms can warm themselves because their basal metabolic rates are extremely high—the heat given off by the high rate of chemical reactions is enough to warm the body. Mammals and birds retain this heat because they have elaborate insulating structures such as feathers or fur.

Ectotherms can also generate heat as a by-product of metabolism. The amount of heat they generate is small compared with the amount generated by endotherms, however, because ectotherms have relatively low metabolic rates. The most important sources of heat gain in ectotherms are radiation and conduction: Ectotherms bask in sunlight or lie on warm rocks or soil.

Endothermy and ectothermy are best understood as contrasting adaptive strategies. Because endotherms maintain a high body temperature at all times, they can be active in winter and at night. Their high metabolic rates also allow them to sustain high levels of aerobic activities, such as running or flying.

These abilities come at a cost, however: To fuel their high metabolic rates, endotherms have to obtain large quantities of energy-rich food. The energy used to produce heat is then unavailable for other energy-demanding processes, such as reproduction and growth.

In contrast, ectotherms are able to thrive with much lower intakes of food. And because they are not oxidizing food to provide heat, they can use a greater proportion of their total energy intake to support reproduction.

What's the downside of ectothermy? Chemical reaction rates are temperature dependent, so muscle activity and digestion slow dramatically as the body temperature of an ectotherm drops. As a result, ectotherms are more vulnerable to predation in cold weather and in general are less successful than endotherms at inhabiting cold environments or remaining active in cool nighttime temperatures.

In short, each suite of adaptations has advantages and disadvantages. Like all adaptations, endothermy and ectothermy involve trade-offs.

Temperature Homeostasis in Endotherms

Thermoregulation is an important aspect of homeostasis in many animals. **FIGURE 42.16** illustrates how the sensor–integrator–effector components of mammals function in thermoregulation.

Temperature receptors located throughout the body constantly monitor information about body temperature. For example, temperature receptors in the skin sense cooling or heating, and they respond by altering the pattern of electrical signals that they send to adjacent neurons. Receptors in the brain region called the **hypothalamus** respond in a similar fashion to changes in blood temperature.

The electrical signals that originate with temperature receptors are transmitted to an integrator, also located in the hypothalamus. Current evidence indicates that separate centers in the hypothalamus of the brain sense and integrate increases and decreases in body temperature.

If a mammal is cold, cells in the hypothalamus send signals to effectors that return body temperature to the set point. Signals from the hypothalamus might induce shivering to generate

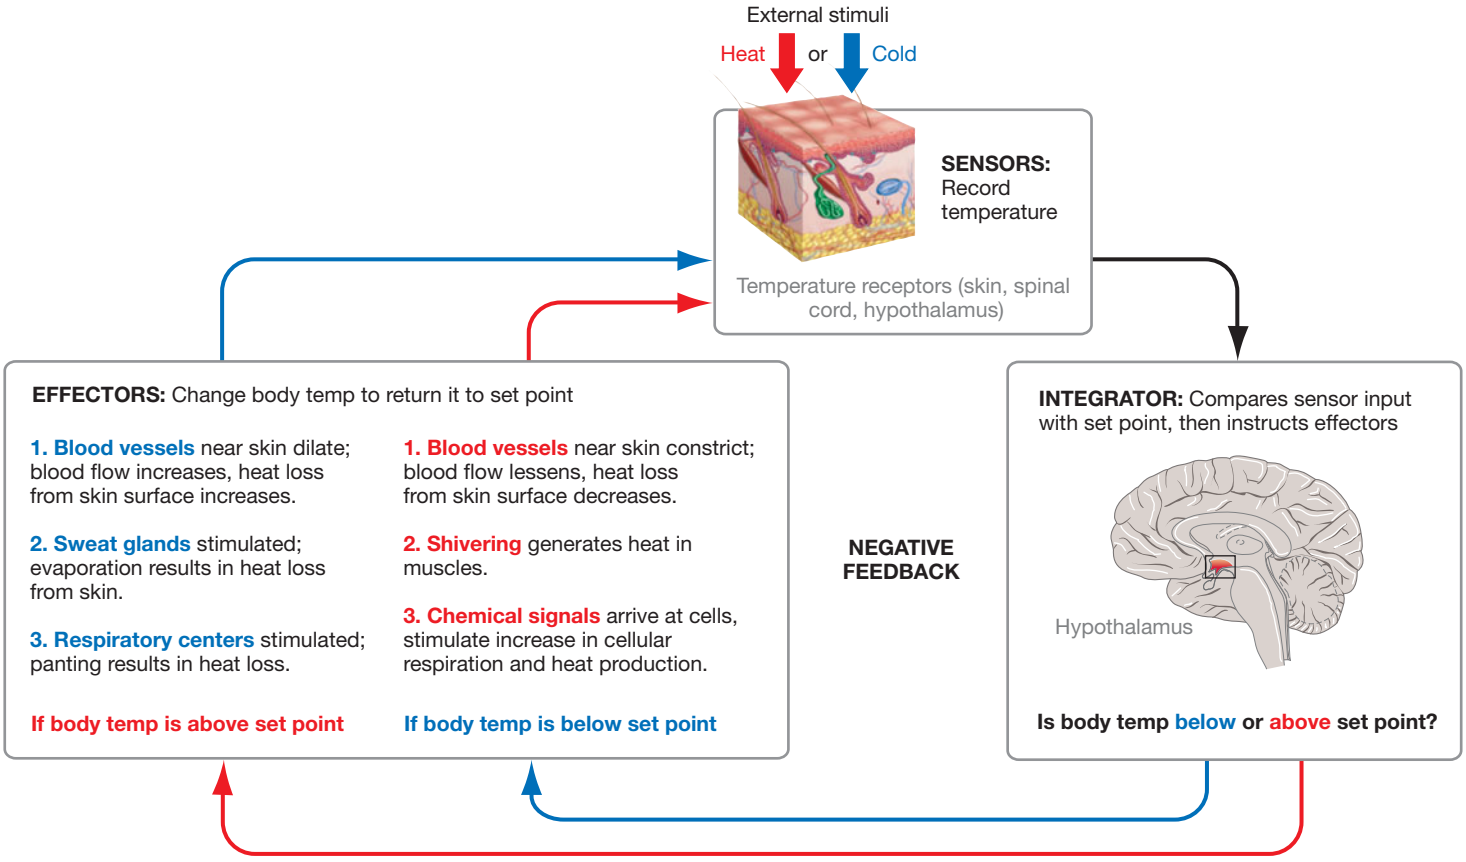

FIGURE 42.16 Mammals Regulate Temperature through Negative Feedback. In mammals, a set point for temperature is maintained by a complex negative feedback system that includes integrators in the anterior and posterior hypothalamus and sensors located throughout the body. The set point varies among species, from 30°C in monotremes to over 39°C in rabbits.

warmth, and fluffing of fur or feathers to improve insulation and retain heat. Signals from the same or nearby cells can also result in the release of blood-borne chemical signals that increase the rate at which cellular respiration takes place throughout the body—generating more body heat.

But if the same individual is too hot, an integrator in the hypothalamus sends signals that initiate sweating or panting—responses that cool the body. Other signals can induce behavioral changes that slow heat production, such as seeking shade or a cool burrow and then resting. Within cells, temperature spikes that are dramatic enough to denature proteins may activate **heat-shock proteins** (introduced in Chapter 3). Heat-shock proteins speed the refolding of proteins—a key step in the recovery process.

In response to either cooling or heating, behavioral and physiological responses move the body temperature back toward the set point via negative feedback. Figure 42.16 makes several points about the effectors that maintain homeostasis:

- It is common to observe redundancy in feedback systems—there are usually several ways to change a parameter.
- Feedback systems usually work in "antagonistic pairs": One set of responses increases a parameter while a corresponding set of responses decreases it.
- Input from sensors and integrators is constant, so feedback systems are constantly making fine adjustments relative to the set point.

Countercurrent Heat Exchangers

Homeothermic endotherms such as birds and mammals have sophisticated systems for thermoregulation. One of their most impressive adaptations allows them to minimize heat loss from limbs. Heat loss is a particularly important problem for mammals that live in aquatic environments. If you've ever gone swimming in cold water, you can appreciate the problem faced by seals, otters, and whales. Water is such an effective conductor of heat that aquatic organisms lose metabolic heat rapidly. To conserve heat, otters have dense, water-repellent fur that maintains a layer of trapped air next to the skin. Seals and whales are insulated by thick layers of fatty blubber. In addition, some marine mammals have specially arranged blood vessels that minimize heat loss.

An Example: Gray Whale Tongues Gray whales have a feature that minimizes heat loss from their tongue, which is exposed to cold water during feeding. The tongue contains bundles of arteries and veins. Each bundle contains an artery that carries warm, oxygenated blood from the body core. The artery is encircled by

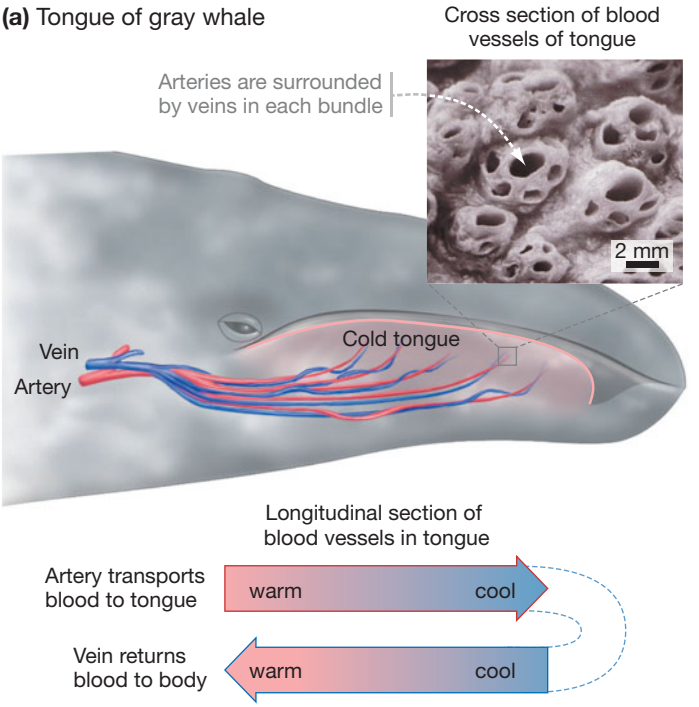

FIGURE 42.17 Countercurrent Exchangers Conserve Heat. **(a)** Bundles of arteries and veins in whale tongues form heat exchangers that minimize heat loss from the tongue to the cold ocean water during feeding. **(b)** Countercurrent arrangements are much more efficient than "concurrent" arrangements. The data given here are hypothetical.

smaller veins, which transport cool blood from the tongue surface back toward the body core (**FIGURE 42.17a**).

The key is that the two types of blood vessel are arranged in an antiparallel fashion. Vessels with warm blood traveling out to the tongue are in close contact with vessels containing cool blood traveling back to the body.

This type of arrangement, with fluids flowing through adjacent pipes in opposite directions, is called a **countercurrent exchanger.** The "exchanger" part of the name is apt because in a case like the whale's tongue, heat is exchanged between the warm blood in the artery and the cool blood in the veins.

To see how the countercurrent exchange system works, study the longitudinal section in **FIGURE 42.17b**. Note that the fluid that enters the countercurrent heat exchanger is initially warm but steadily transfers heat to the adjacent, cooler fluid flowing in the opposite direction. There is a warmer-to-cooler gradient between the two currents at every point along the length of the countercurrent exchanger.

If the two solutions ran in the same direction, as in the right side of Figure 42.17b, the gradient between the two solutions would disappear quickly as the source current cooled and the recipient current heated. Countercurrent exchangers, including heat exchangers, are efficient because they maintain a gradient between the two fluids along their entire length.

A Multiplier Effect A second key point about countercurrent heat exchangers concerns the temperature differential between the solutions. Although the differential is small at any point along the pipes, there is a large temperature differential from one end of each pipe to the other.

In effect, small differences in heat along the length of the exchanger sum up to create a large overall temperature gradient from beginning to end. The longer the system, the greater the overall differential will be. To highlight this property, the systems are sometimes called countercurrent multipliers.

Similar heat-conserving arrangements of arteries and veins are found in the flippers of whales and dolphins, and in the legs of many mammals and birds that live in cold terrestrial environments.

Countercurrent exchangers are just one of many sophisticated adaptations you'll encounter in this unit—structures and systems that allow animals to thrive in a wide array of environments.

check your understanding

C Y U

If you understand that . . .

- Two major aspects of temperature regulation vary among animal species: the amount of heat generated by the animal's own tissues and the degree to which body temperature varies over time.
- Negative feedback allows endothermic homeotherms to maintain homeostasis with respect to body temperature.
- Countercurrent heat exchangers are efficient adaptations for minimizing heat loss from extremities.

✔ You should be able to . . .

1. Discuss the advantages and disadvantages of endothermy and ectothermy.
2. Predict how the temperature of a whale's tongue would change if it employed concurrent rather than countercurrent flow of blood in its arteries and veins. Explain.

Answers are available in Appendix A.

CHAPTER 42 REVIEW

For media, go to MasteringBiology

If you understand . . .

42.1 Form, Function, and Adaptation

- Animal structures and their functions represent adaptations, which are heritable traits that improve survival and reproduction in a certain environment.
- Adaptations involve trade-offs, or inescapable compromises between traits.
- Acclimatization is a reversible response to the environment that improves physiological function in that environment.

✔ **You should be able to provide examples of an adaptation and acclimatization of a mammal to a cold environment.**

42.2 Tissues, Organs, and Systems: How Does Structure Correlate with Function?

- Cells with a common function are grouped together into four general types of tissue: connective tissue, nervous tissue, muscle tissue, and epithelial tissue.
- Epithelium forms the interface between the animal's external and internal environments.
- Organs are structures that are composed of two or more tissues that together perform specific tasks.
- Organ systems comprise organs that work together in an integrated fashion to perform one or more functions.

✔ **You should be able to predict the effect of a drug that loosens the tight junctions between epithelial cells.**

42.3 How Does Body Size Affect Animal Physiology?

- Large animals have smaller surface area/volume ratios than small animals. As animals grow, the volume increases more rapidly than the surface area.
- Large animals have low mass-specific metabolic rates, because they have a relatively small surface area for exchanging the oxygen and nutrients required to support metabolism, the wastes produced by metabolism, and heat.
- The relatively high surface area of small animals means that they lose heat extremely rapidly.

✔ **You should be able to explain why it would be impossible for a gorilla the size of King Kong to have fur. (In answering this question, explain how the surface area/volume ratio of a normal-sized gorilla would compare to Kong's; then relate this to the role of surface area and volume in heat generation and transfer and the function of fur.)**

42.4 Homeostasis

- Homeostasis refers to relatively constant physical and chemical conditions inside the body.
- Homeostasis can be achieved by conformation to a constant environment or by regulation in a fluctuating environment.
- Animals have a set point, or target value, for blood pH, tissue oxygen concentration, nutrient concentrations, temperature, and other parameters.
- When a condition in the body is not at its set point, negative feedback occurs. Responses to negative feedback return conditions to the set point and result in homeostasis.

✔ **You should be able to explain how, due to acclimatization as well as adaptation, the homeostatic system for maintaining body temperature in a species of mammal might change as global temperatures rise.**

42.5 How Do Animals Regulate Body Temperature?

- Animals vary from endothermic to ectothermic and from homeothermic to heterothermic.
- Most mammals have a set point for body temperature. If an individual overheats, it will pant or sweat and seek a cool environment; if an individual is cold, it will shiver, bask in sunlight, or fluff its fur.
- Countercurrent heat exchangers work by placing warm and cool fluids next to each other and running in opposite directions.

✔ **The dinosaur *Apatosaurus* is one of the largest terrestrial animals that has ever lived—over 20 m in length and weighing over 20 metric tons. Do you believe that *Apatosaurus* was homeothermic or heterothermic? Explain.**

TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. True or False: The increase in red blood cell count in tourists visiting Tibet is an example of acclimatization.
2. _____ tissues form the interface between the inside of an animal's body and the environment.
3. As an animal gets larger, which of the following occurs?
   a. Its surface area grows more rapidly than its volume.
   b. Its volume grows more rapidly than its surface area.
   c. Its volume and surface area increase in perfect proportion to each other.
   d. Its volume increases, but its total surface area decreases.
4. Which of the following best describes the set point in a homeostatic system?
   a. the cells that collect and transmit information about the state of the system
   b. the cells that receive information about the state of the system and that direct changes to the system
   c. the various components that produce appropriate changes in the system
   d. the target or "normal" value of the parameter in question
5. What does it mean to say that an animal is a heterothermic endotherm?
   a. Its body temperature varies, but most of its heat is produced by its own tissues.
   b. Its body temperature varies because it gains most of its heat from sources outside its body.
   c. Its body temperature does not vary, because most of its heat is produced by its own tissues.
   d. Its body temperature does not vary, even though it gains most of its heat from sources outside its body.
6. Which of the following is an advantage that ectotherms have over endotherms of the same size?
   a. They require much less food.
   b. They are less vulnerable to predation events during cold weather.
   c. They can remain active in cold weather or at nighttime—when temperatures cool.
   d. They have higher metabolic rates and grow much more quickly.

TEST YOUR UNDERSTANDING

Answers are available in Appendix A

7. Why is epithelium a particularly important tissue in achieving homeostasis with respect to temperature?
8. The metabolic rate of a frog in summer (at 35°C) is about eight times higher than in winter (at 5°C). Compare and contrast the individual's ability to move, exchange gases, and digest food at the two temperatures. During which season will the frog require more food energy, and why?
9. Consider the following:
   - absorptive sections of digestive tract
   - capillaries
   - beaks of Galápagos finches
   - fish gills

   In each case, how does the structure relate to the function?
10. Why is the surface area/volume ratio different in a small sphere versus a large sphere? If materials diffuse into and out of each sphere, in which of the two will diffusion occur more efficiently relative to the volume? Explain your answer.
11. **QUANTITATIVE** Consider three cubes with lengths of 1 cm, 5 cm, and 10 cm. Calculate the surface area and the volume of each cube, and plot them on a graph with length on the *x*-axis and surface area and volume on the *y*-axis. Explain how the graph shows the relationship between size and surface area/volume ratio.
12. Which of the following is an example of negative feedback? Explain why each is or is not negative feedback.
   a. Uterine contractions during childbirth stimulate release of a hormone that stimulates more uterine contractions.
   b. A viral infection stimulates the hypothalamus to increase the set point for body temperature.
   c. High blood sugar concentrations stimulate the release of the hormone insulin, which stimulates the sugars to move from the blood into cells.
   d. The body temperature of the Arabian oryx rises during the hottest parts of the day.

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A

13. When food is scarce, bigger *Geospiza fortis* (medium ground finches) win contests over seeds. Biologists have documented that there is strong natural selection in favor of large body size under these conditions, and that the finch population evolves in response. If so, why aren't *G. fortis* a lot bigger than they are?
14. What data would you need to collect in order to document that adaptation is occurring in a particular population of lizards, as the warming associated with global climate change intensifies?
15. An engineer has to design a system for dissipating heat from a new type of car engine that runs particularly hot. Recall that heat is gained and lost as a function of surface area. Suggest ideas to consider that are inspired by biological structures with exceptionally high surface area/volume ratios.
16. Suppose a friend of yours is trying to decide whether to buy a pet turtle or a pet mouse. In making the decision, all he cares about is how much it will cost to feed the animal. Your friend says he can't decide because the two animals weigh the same and their food costs the same per pound. As a biologist, what's your advice?
   a. Buy the turtle, because it is an ectotherm and will therefore consume less food than the mouse.
   b. Buy the turtle, because it is an endotherm and will therefore consume less food than the mouse.
   c. Buy the mouse, because it is an ectotherm and will therefore consume less food than the turtle.
   d. Buy the mouse, because it is an endotherm and will therefore consume less food than the turtle.

43 Water and Electrolyte Balance in Animals

Terrestrial animals lose water every time they breathe, defecate, and urinate. For many animals, drinking is an important way to gain water and achieve homeostasis. This chapter explores how terrestrial and aquatic animals maintain water balance.

The chemical reactions that make life possible occur in an aqueous solution. If the balance of water and dissolved substances in the solution is disturbed, those chemical reactions—and life itself—may stop. Humans can stay alive for weeks without eating but can survive just three days without drinking water. If hurricanes introduce enough freshwater to the ocean shore to disrupt normal salt concentrations, marine animals die. Maintaining water balance is a matter of life or death.

An animal achieves water balance when its intake of water equals its loss of water. Water balance is an important element in homeostasis—the ability to keep cells and tissues in constant and favorable conditions.

BIG PICTURE

This chapter is part of the Big Picture. See how on pages 840–841.

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

Water balance is intimately associated with sustaining a balanced concentration of electrolytes throughout the body. An **electrolyte** is a compound that dissociates into ions when dissolved in water. Electrolytes got their name because they conduct electrical current.

In many animals, the most abundant electrolytes are sodium (Na^+), chloride (Cl^-), potassium (K^+), and calcium (Ca^{2+}). Cells require precise concentrations of these ions to function normally. In humans, electrolyte imbalances can lead to muscle spasms, confusion, irregular heart rhythms, fatigue, paralysis, or even death.

Water and electrolyte balance is also associated with excretion. Animals produce urine to excrete wastes. Urine contains water, so excretion of urine inevitably leads to water loss. The amount of water lost in the urine of an animal depends both on its hydration state and on the type of wastes it produces.

This chapter is focused on a single question: How do animals maintain water and electrolyte balance in marine, freshwater, and terrestrial environments? Answering it will introduce you to some of the most complex and important homeostatic systems known. You can review the importance of maintaining water and electrolyte balance in the Big Picture of Plant and Animal Form and Function, on pages 840–841.

43.1 Osmoregulation and Excretion

In organisms, electrolytes and water move by two processes—diffusion and osmosis (introduced in Chapter 6).

- **Diffusion** is the net movement of substances from regions of higher concentration to regions of lower concentration.
- **Osmosis** is a special case of diffusion. It is the net movement of water from regions of higher water concentration to regions of lower water concentration, across a selectively permeable membrane.

A membrane that exhibits **selective permeability,** such as a phospholipid bilayer, is a membrane that some solutes can cross more easily than other solutes can. When either diffusion or osmosis occurs, net movement of ions and molecules occurs along their **concentration gradient.**

FIGURE 43.1a illustrates how dissolved substances, or **solutes,** move down their concentration gradients via diffusion across a selectively permeable membrane. When the solutes are randomly distributed throughout the solutions on both sides of the membrane, equilibrium is established. Molecules continue to move back and forth across the membrane at equilibrium, but at equal rates.

As **FIGURE 43.1b** shows, water can also move down its concentration gradient (see Chapter 6). The concentration of dissolved substances in a solution, measured in osmoles[1] per liter, is the solution's **osmolarity**. Because solutes interact with water molecules, an increase in solute concentration reduces the amount of water available for osmosis, effectively lowering water concentration. If dissolved substances are separated by a selectively permeable membrane and the solutes cannot cross that membrane, water moves from areas of lower osmolarity—that is, where solute concentrations are lower and water concentration is higher—to areas of higher osmolarity—where solute concentrations are higher and water concentration is lower.

Now let's examine how osmosis and diffusion affect water and ion balance living in different environments.

What Is Osmotic Stress?

Osmotic stress occurs when the concentration of dissolved substances in a cell or tissue is abnormal. It means that water and solute concentrations are different from their set point.

Many organisms respond to osmotic stress by osmoregulating, just as they respond to heat or cold stress by thermoregulating (see Chapter 42). **Osmoregulation** is the process by which living organisms control the concentration of water and electrolytes in their bodies.

Not all animals encounter osmotic stress. For many marine invertebrates such as sponges, jellyfish, and flatworms, achieving homeostasis with respect to water and electrolyte balance is straightforward. Seawater is a fairly constant ionic and osmotic environment, and it nearly matches the normal electrolyte concentrations found within these animals. These species are **osmoconformers.**

Seawater is **isosmotic** with respect to tissue in these species. Stated another way, solute concentrations inside and outside these animals are equal. Because the tissues of osmoconforming marine invertebrates are isosmotic to seawater, diffusion and osmosis don't alter water and electrolyte balance and induce osmotic stress.

Osmotic Stress in Seawater, in Freshwater, and on Land

In contrast to most marine invertebrates, marine bony fishes are **osmoregulators.** These fishes actively regulate osmolarity inside their bodies to achieve homeostasis.

By osmoregulating, marine bony fishes keep the osmolarity of their tissues lower than seawater. The difference in osmolarity is most important in the gills, which are organs involved in gas exchange. For gas exchange to occur with the environment, the epithelial cells on the surfaces of the gills must be in direct contact with seawater. But because there is a large difference in the concentration of solutes between the inside of each cell and the seawater outside, water tends to flow by osmosis out of the gill epithelium (**FIGURE 43.2**).

Seawater is **hyperosmotic** in comparison to the tissues of marine fishes—the solution inside the body contains fewer solutes than does the solution outside. If the water that marine fishes lose across their gills is not replaced, the cells will shrivel and die. These species face a trade-off between gas exchange and water and electrolyte balance.

Marine fishes replace the lost water by drinking large quantities of seawater. Drinking brings in excess electrolytes, however.

[1]The unit osmole is similar to a mole except that it takes into account molecules that dissociate in solution. For example, because NaCl dissociates into Na^+ and Cl^- in solution, adding 1 mole of NaCl is equivalent to adding 2 osmoles.

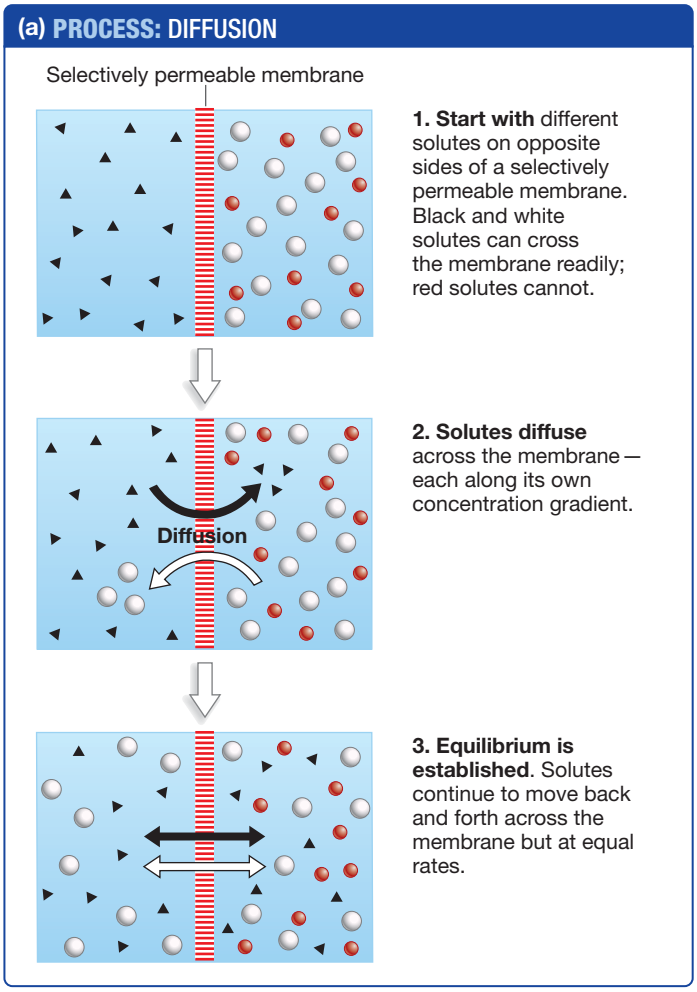

FIGURE 43.1 Solutes Move Down a Concentration Gradient via Diffusion; Water Moves Down a Concentration Gradient via Osmosis. (a) Diffusion occurs any time a solute is at higher concentration in one location than another. **(b)** Osmosis is a special case of diffusion involving the movement of water across a selectively permeable membrane.

✔**QUESTION** Why doesn't the presence of red molecules on the right side of part (a) affect the movement of the black and white molecules?

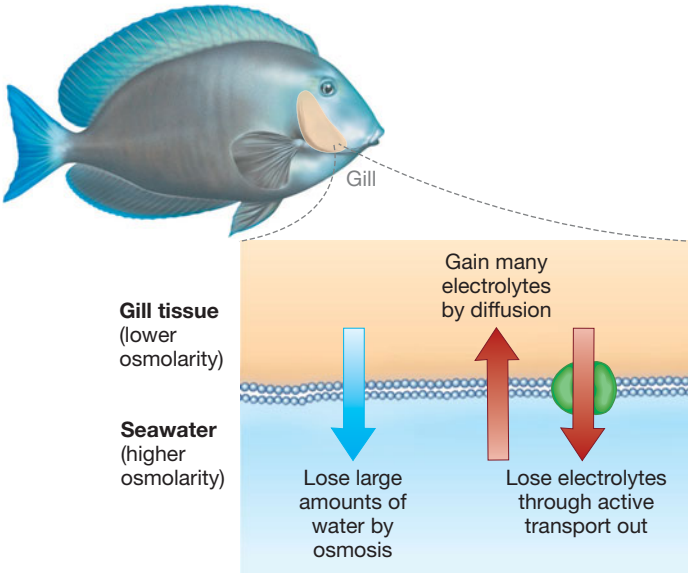

FIGURE 43.2 Marine Fishes Lose Water by Osmosis and Gain Electrolytes by Diffusion.

Electrolyte balance is thrown even further out of whack because ions and other solutes diffuse into the gill epithelium, following a concentration gradient from seawater to tissues.

To rid themselves of these excess electrolytes, marine fishes have to actively pump ions out of their bodies and back into seawater, using membrane proteins found in the gill epithelium.

Freshwater fishes osmoregulate in an environment dramatically different from the ocean. Marine fishes are under osmotic stress because they lose water and gain solutes; freshwater fishes are under osmotic stress because they gain water and lose solutes.

Why? In the gills of freshwater fishes, epithelial cells contain more solutes than the solution outside. The freshwater is **hyposmotic** relative to the fishes' tissues. As a result, the fishes gain water via osmosis across the gill epithelium (**FIGURE 43.3**, see page 864), which puts the body under osmotic stress. Just as in marine fishes, there is a trade-off between gas exchange and osmoregulation.

If a freshwater fish does not get rid of incoming water, its cells will burst and the individual will die. To achieve homeostasis and survive, freshwater fishes excrete large amounts of water in their urine and do not drink.

In addition to gaining water, freshwater fishes undergo osmotic stress because ions and other solutes tend to diffuse out of the gill epithelium into the environment, along a concentration

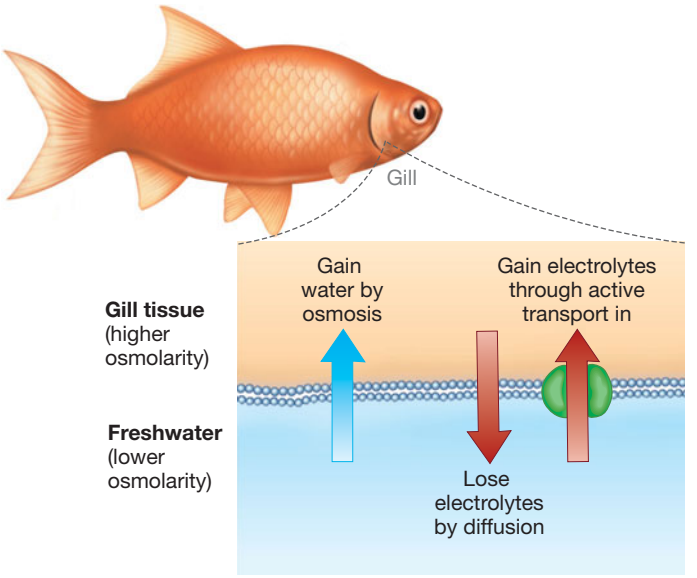

FIGURE 43.3 Freshwater Fishes Gain Water by Osmosis and Lose Electrolytes by Diffusion.

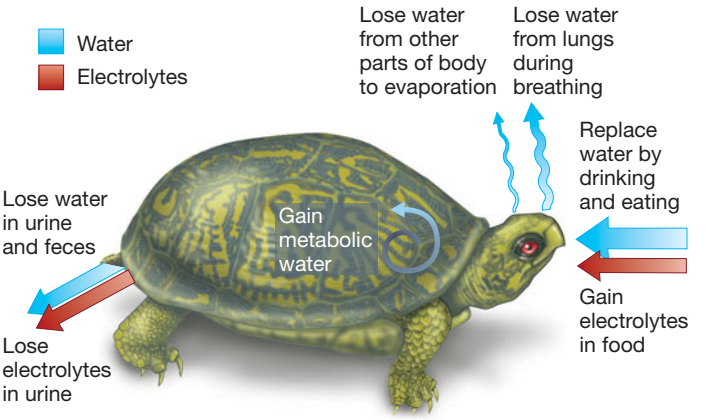

FIGURE 43.4 Maintaining Water and Electrolyte Balance in Terrestrial Environments Is Particularly Challenging. In terrestrial environments, animals lose water by evaporation from the body surface and as water vapor during breathing. Electrolytes are lost primarily in the urine and feces.

gradient. Freshwater animals must replace electrolytes that are lost by obtaining them in food or by actively transporting them from the surrounding water—usually across the gills.

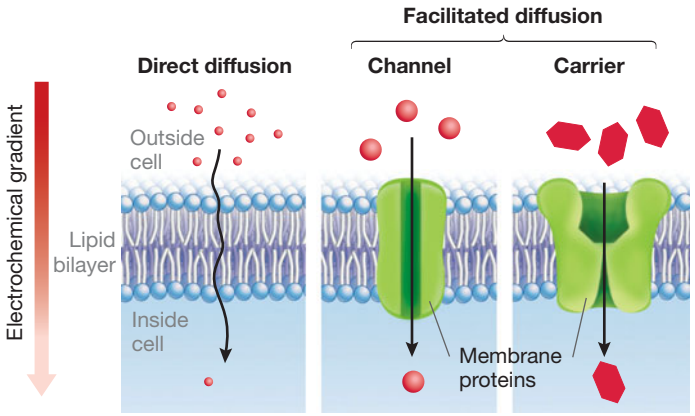
What about land animals? In terms of water balance, terrestrial environments are similar to the ocean. Land animals constantly lose water to the environment, just like many marine animals do. In this case, however, the process involved is not osmosis but evaporation (see Chapter 42).

The epithelial cells that line a turtle's lung and a fruit fly's gas exchange structures have a moist surface, in order to protect the integrity of their plasma membranes and to facilitate diffusion of gases across respiratory epithelia. Because the atmosphere is almost always drier than the wet gas exchange surface, terrestrial animals lose water by evaporation. Once again, there is a trade-off between breathing and balance of water and electrolytes.

Water balance is further complicated because animals lose water in the form of urine, and some terrestrial species lose additional water when they sweat or pant to lower their body temperature (**FIGURE 43.4**). The lost water has to be replaced by drinking, ingesting water in food, or gaining metabolic water—the H_2O produced during cellular respiration (see Chapter 9). The relative importance of each of these methods of replacing water depends on the animal. For example, desert animals like the Arabian oryx (see Chapter 42) do not have access to drinking water throughout much of the year, so they rely more on ingested and metabolic water.

How Do Electrolytes and Water Move across Cell Membranes?

What molecular mechanisms allow animals to cope with the diverse challenges they face in maintaining water and electrolyte balance? You might recall from earlier chapters that solutes move across membranes by passive or active transport. **Passive transport** is driven by diffusion along an electrochemical gradient and does not require an expenditure of energy in the form of ATP. **Active transport,** in contrast, occurs when a source of energy like ATP powers the movement of a solute to establish an electrochemical gradient.



Because ions and large molecules such as glucose do not cross phospholipid bilayers readily, most passive transport and all active transport take place via membrane proteins (see Chapter 6).

- In many cases, passive transport occurs through **channels**—proteins that form a pore, or opening, that selectively admits specific ions or molecules (**FIGURE 43.5a**).
- Passive transport also occurs via **carrier proteins,** which are transmembrane proteins that bind a specific ion or molecule and transport it across the membrane by undergoing a conformational change.
- When solutes move from an area of high to low concentration via channels or carrier proteins, **facilitated diffusion** is said to occur.

Active transport is based on membrane proteins called pumps, which change conformation when they bind ATP or are phosphorylated (**FIGURE 43.5b**). This energy-demanding change in shape allows them to transport ions or molecules against their concentration gradient. The **sodium–potassium pump,** or Na^+/K^+-ATPase (introduced in Chapter 6), is a very important type of pump in animals. Movement of sodium and potassium ions by Na^+/K^+-ATPase is an example of **primary active transport,** where a source of energy like ATP is used to move ions against their gradients.

Once a pump has established an electrochemical gradient, **secondary active transport** can occur. Specifically, a **cotransporter** can use the energy stored in an electrochemical gradient across a cell membrane to transport a different solute *against* its

(a) Passive transport is based on diffusion down a gradient.

(b) Active transport requires an energy source to move molecules against a gradient.

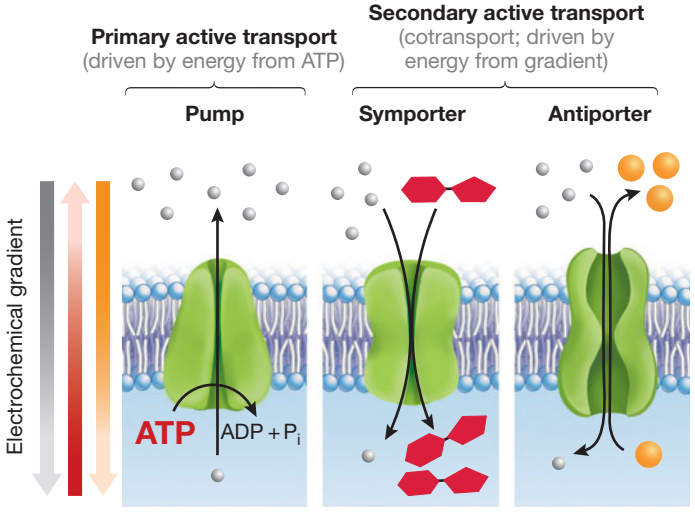


FIGURE 43.5 Mechanisms of Passive and Active Transport.
(a) In passive transport, solutes diffuse along their electrochemical gradient either directly or through a membrane protein.
(b) In primary active transport, a pump uses ATP to move solutes against their electrochemical gradients. In secondary active transport (cotransport), energy stored in an electrochemical gradient for one molecule is used to move another molecule against its gradient.

electrochemical gradient. A cotransporter that moves solutes in the same direction is called a **symporter;** a cotransporter that moves solutes in opposite directions is called an **antiporter.**

How does water move? To date, there are no known mechanisms for actively transporting water across plasma membranes. Instead, cells use pumps to transport ions and set up an osmotic gradient; water then follows by osmosis—often through the specialized membrane channels called **aquaporins** (see Chapter 6). In essence, cells move water by moving solutes.

The body excretes excess solutes, along with waste products, using a urinary system. Because solutes and wastes often must be dissolved in water to be excreted, water balance is fundamentally related to excretion.

Types of Nitrogenous Wastes: Impact on Water Balance

Animal cells contain amino acids and nucleic acids that are used to synthesize proteins, RNA, and DNA. Excess amino acids and nucleic acids can be broken down in catabolic reactions that result in the production of **ammonia** (NH_3). Ammonia is toxic to cells, because at high concentrations it raises the pH of intracellular and extracellular fluids enough to poison enzymes.

Because ammonia must be dissolved in water, excretion of ammonia inevitably leads to water loss. However, the amount of water lost during excretion depends on the method of ammonia excretion.

Forms of Nitrogenous Waste Vary among Species How do animals get rid of ammonia safely and efficiently? Different species solve the problem in different ways (see **TABLE 43.1**, page 866).

- In freshwater fishes, ammonia is diluted to low concentration and excreted in watery urine.
- In freshwater and marine fishes, ammonia diffuses across the gills into the surrounding water along a concentration gradient.
- In mammals (including humans) and adult amphibians, enzyme-catalyzed reactions convert ammonia to a much less toxic compound called **urea,** which is excreted in urine.
- In terrestrial arthropods, birds, and other reptiles, reactions convert ammonia to **uric acid,** the white, paste-like substance that you have probably seen in bird feces.

Uric acid is a particularly interesting form of nitrogenous waste. Compared with urea and ammonia, uric acid is extremely insoluble in water—which explains why it is so difficult to wash bird droppings off a car. As a result, birds, snakes, lizards, and terrestrial arthropods can get rid of excess nitrogen while losing little water.

Why Do Nitrogenous Wastes Vary among Species? The type of nitrogenous waste produced by an animal correlates with its lineage—its evolutionary history. For example, mammals excrete urea while reptiles (including birds) and insects excrete uric acid (Table 43.1).

Evolutionary history is not the entire story, however. Waste production is also related to the habitat that a species occupies, and thus the amount of osmotic stress it endures.

- Terrestrial birds conserve water by excreting about 90 percent of their nitrogenous waste as uric acid and only 3–4 percent as ammonia, but aquatic birds such as ducks excrete just 50 percent of their excess nitrogen as uric acid and 30 percent as ammonia.
- Tadpoles are aquatic and excrete ammonia, but many adult frogs and toads are terrestrial and excrete urea.
- Production of urea and uric acid is particularly common in animals—such as reptiles—that live in dry habitats.

SUMMARY TABLE 43.1 Attributes of Nitrogenous Wastes Produced by Various Animals

Attribute	Ammonia	Urea	Uric Acid
Solubility in water (moles/liter)	high	medium	very low
Water loss (amount required for excretion of waste)	high	medium	very low
Energy cost (amount of ATP required)	low	high	high
Toxicity	high	medium	low
Groups where it is the primary waste	bony fishes, aquatic invertebrates	mammals, amphibians, cartilaginous fishes	birds and other reptiles, most terrestrial insects and spiders (arthropods)
Method of synthesis	product of breakdown of amino acids and nucleic acids	synthesized in liver, starting with amino groups from amino acids	synthesis starts with amino acids and nucleic acids
Method of excretion	in urine, and diffuses across gills	in urine (mammals); diffuses across gills (sharks)	with feces

To make sense of these observations, biologists point out that there is a fitness trade-off between the energetic cost of excreting each type of waste and the benefit of conserving water. Ammonia excretion requires a large water loss but little energy expenditure, because the molecule isn't processed by enzymes. Uric acid excretion, in contrast, requires almost no loss of water but a sophisticated series of enzyme-catalyzed, energy-demanding reactions. Different trade-offs are favored in different environments.

Now that you have a basic understanding of the osmoregulatory and excretory challenges facing animals, let's take a closer look at how marine, freshwater, and terrestrial animals maintain water and electrolyte homeostasis.

43.2 Water and Electrolyte Balance in Marine Fishes

Marine fishes experience severe osmotic stress because they live in water with a very high osmolarity. Since their divergence over 400 million years ago, marine bony and cartilaginous fishes have evolved distinct strategies for dealing with osmotic stress.

Osmoconformation versus Osmoregulation in Marine Fishes

Marine bony fishes are osmoregulators. Recall that they maintain a lower blood osmolarity than seawater by drinking to replace water lost via osmosis, and by actively transporting electrolytes out of the body. This process comes with a significant energetic cost.

Cartilaginous fishes, such as sharks, have a different strategy. They are **osmoconformers**—their blood osmolarity nearly matches that of the sea water. However, the composition of their blood is quite different from seawater. Sharks have low concentrations of ions in their blood, but they maintain relatively high blood concentrations of urea. This increases their blood osmolarity so that it is isosmotic with seawater. The result? Sharks lose less water by osmosis.

If sharks avoid water loss to the surrounding seawater by osmoconforming, then why don't all marine fishes osmoconform? The answer lies in a biological trade-off (see Chapter 42). Sharks must expend energy to make proteins that protect their cells from the toxic effects of high concentrations of urea. Osmoregulation and osmoconformation are two strategies for living in the ocean, and each has its own costs and benefits.

Even though they are osmoconformers, sharks still maintain relatively low concentrations of salt (NaCl) in their blood. Sharks need to excrete salt because sodium and chloride ions diffuse into their gill cells from seawater, down the concentration gradients for the ions. Research on the molecular mechanism of salt excretion in sharks revealed two key points:

1. The mechanism is general. The salt-excreting system discovered in sharks is found in a wide array of species, including *Homo sapiens*. It is functioning in your kidneys, right now.
2. The mechanism represents a critically important concept in physiology. Plant and animal cells use active transport to set up a strong electrochemical gradient for one ion—typically Na^+ in animals and H^+ in plants. The sodium or proton gradient is then used to transport a wide array of other substances, without further expenditure of energy.

This is fundamental stuff. Let's dig in.

How Do Sharks Excrete Salt?

Research on salt excretion in sharks focused on an organ called the **rectal gland,** which secretes a concentrated salt solution. To determine how this gland works, researchers studied it in

vitro—meaning outside the shark's body, in a controlled laboratory environment. The basic approach was to dissect rectal glands, immerse them in a solution with a defined composition and osmolarity, and analyze the fluid that the rectal gland produced in response.

Early experiments showed that normal salt excretion occurred only if the solution in the rectal gland contained ATP. This result supported the hypothesis that salt excretion involves active transport. Ions can be concentrated only if they are actively transported against a concentration gradient. The question was, How does concentration occur?

The Role of Na^+/K^+-ATPase An energy-demanding mechanism for salt excretion implies that a protein in the plasma membrane of epithelial cells is actively pumping Na^+, Cl^-, or both. The best-characterized candidate was the Na^+/K^+-ATPase.

To test the hypothesis that the sodium–potassium pump is involved in salt excretion by sharks, biologists used a plant defense compound called **ouabain** (pronounced *WAA-bane*). This molecule is toxic to animals because it binds to Na^+/K^+-ATPase and prevents it from functioning.

Just as predicted, rectal glands that are treated with ouabain stop producing a concentrated salt solution. This was strong evidence that Na^+/K^+-ATPase is essential for salt excretion.

A Molecular Model for Salt Excretion Subsequent work has shown that salt excretion in sharks is a multistep process, summarized in **FIGURE 43.6**.

1. Na^+/K^+-ATPase pumps sodium ions out of epithelial cells across the basolateral surface, into the extracellular fluid. The pump creates an electrochemical gradient favoring the diffusion of Na^+ into the cell. This "master gradient" allows the cell to transport other ions without an additional expenditure of energy.
2. Na^+, Cl^-, and K^+ all enter the cell by secondary active transport through a cotransporter, powered by the Na^+ master gradient. Note that this master gradient causes Na^+ to diffuse into the cell *along* its electrochemical gradient, allowing Cl^- and K^+ to move into the cell *against* their electrochemical gradients. Movement of Cl^- and K^+ is possible only because these ions move through a cotransporter with Na^+.
3. As Cl^- builds up inside the cell, Cl^- diffuses down its concentration gradient into the lumen of the gland through a chloride channel located in the apical membrane.
4. Following their electrochemical gradient, Na^+ ions diffuse into the lumen of the gland through spaces between the cells.

In many animals, epithelial cells that transport sodium and chloride ions contain the same combination of membrane proteins found in the shark rectal gland. These species include

- marine birds and reptiles that drink seawater and excrete NaCl via salt glands in their nostrils;
- marine fishes that excrete salt from their gills (see Figure 43.2);
- mammals that transport salt in their kidneys.

Research on the shark rectal gland also produced an unforeseen benefit for biomedical research. Several years after the shark chloride channel was characterized, investigators identified a human protein called cystic fibrosis transmembrane regulator

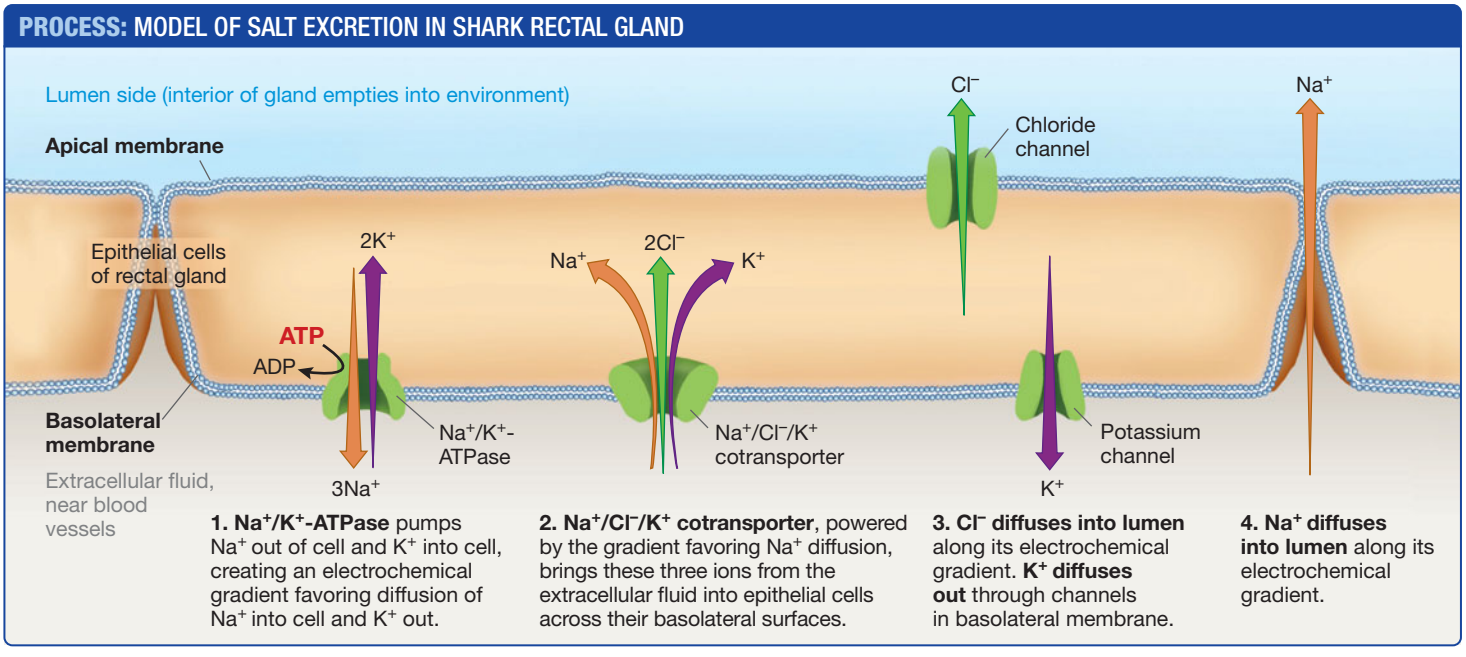

FIGURE 43.6 The Shark Rectal Gland Rids the Body of Excess Salt.

✔**QUESTION** Which of these membrane proteins are involved in (1) primary active transport, (2) secondary active transport, or (3) passive transport?

(CFTR). Cystic fibrosis is the most common genetic disease in populations of northern European extraction (see Chapter 6). Although the disease was known to be associated with defects in the CFTR protein, no one knew what the molecule did.

When investigators realized that the amino acid sequence of CFTR is 80 percent identical to that of the shark chloride channel, it was their first hint that CFTR is involved in Cl^- transport. Subsequent studies supported the hypothesis that cystic fibrosis results from a defect in a chloride channel. With this result, studies on water and electrolyte balance in sharks shed light on an important human disease.

43.3 Water and Electrolyte Balance in Freshwater Fishes

Research on the shark rectal gland and the gills of marine bony fishes has uncovered the molecular mechanisms of salt balance in marine fishes. How do freshwater fishes achieve homeostasis with respect to electrolytes?

How Do Freshwater Fishes Osmoregulate?

Recall from Figure 43.3 that freshwater fishes have to cope with an osmotic stress that is opposite the challenge facing marine fishes. Freshwater fishes lose electrolytes across their gill epithelium by diffusion across a concentration gradient. To maintain homeostasis, they have to actively transport ions back into the body across the gill epithelium. How do they do this?

Salmon and Sea Bass as Model Systems To understand how freshwater fishes gain electrolytes, researchers have focused on sea bass and several species of salmon. Over the course of a lifetime, individuals of these species move between seawater and freshwater. Thus, they move between environments that present dramatically different osmotic stressors.

In marine fishes, specialized cells in the gill epithelium called chloride cells move salt using the combination of membrane proteins illustrated in Figure 43.6. When sea bass and salmon are in seawater, these cells are abundant and active. What happens to these cells when individuals move into freshwater? Do the changes that occur provide any insight into how these species acclimatize to the new environment and avoid dying of osmotic stress?

A Freshwater Chloride Cell? Although research is continuing at a brisk pace, recent results support the hypothesis that there is a freshwater version of the classical chloride cell: one that moves ions in the opposite direction of the seawater version. Instead of excreting salt, these cells import it.

Three lines of evidence have accumulated to date:

1. ***Osmoregulatory cells may be in different locations.*** Young salmon taken from freshwater versus seawater have chloride cells in different locations on the gills. Adult salmon from freshwater versus seawater show the same pattern, and similar changes have been observed in other fish species that switch between freshwater and seawater habitats. The pattern suggests that when the nature of osmotic stress changes, the nature of the gill epithelium changes. Specifically, active pumping of ions takes place in a different population of cells in seawater versus freshwater.
2. ***Different forms of Na^+/K^+-ATPase may be activated.*** The salmon genome contains genes for several different forms of the Na^+/K^+-ATPase. There is now strong evidence that different forms are activated when individuals are in seawater versus freshwater.
3. ***The orientation of key transport proteins "flips."*** In sea bass, researchers have been able to stain epithelial cells to determine the location of the cotransporter illustrated in Figure 43.6—the one that brings Na^+, Cl^-, and K^+ into the cell. When individuals are in seawater, the protein is located in the basolateral side of chloride cells. But when individuals are in freshwater, the protein is located in the apical side (**FIGURE 43.7**).

Taken together, the data suggest that freshwater fishes have a freshwater version of the chloride cell, with different forms of Na^+/K^+-ATPase and transporters that result in the import rather than export of ions. Identifying the mechanisms of electrolyte uptake in freshwater fishes is an important challenge for researchers who want to know how aquatic organisms cope with osmotic stress.

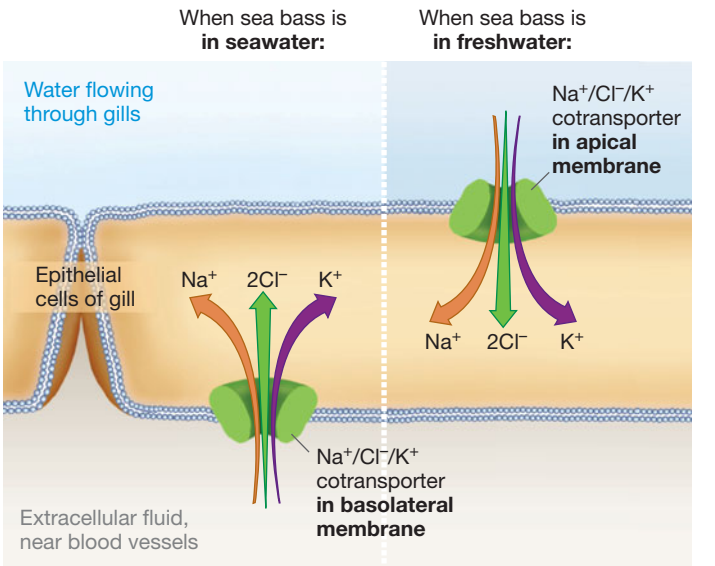

FIGURE 43.7 In the Epithelial Cells of Bass Gills, the Location of a Key Ion Cotransporter Can "Flip." Changes in the position of the $Na^+/Cl^-/K^+$ cotransporter help sea bass deal with osmotic stress in both seawater and freshwater environments. (Other membrane channels and pumps are present but not shown here.)

check your understanding

If you understand that . . .

- Marine fishes lose water by osmosis. To replace it, they have to drink seawater.
- Marine fishes have to rid themselves of salt. They gain salt when they drink seawater or when sodium and chloride ions diffuse into their cells along a concentration gradient.
- Freshwater fishes gain water by osmosis. They have to rid themselves of excess water by urinating.
- Freshwater fishes lose electrolytes to the surrounding water by diffusion. They gain electrolytes in their food and by active transport from the surrounding water.

✔ You should be able to . . .

Predict what happens to the osmolarity of a freshwater fish's tissues when epithelial cells in its gills are treated with ouabain—a molecule that poisons Na^+/K^+-ATPase.

Answers are available in Appendix A.

43.4 Water and Electrolyte Balance in Terrestrial Insects

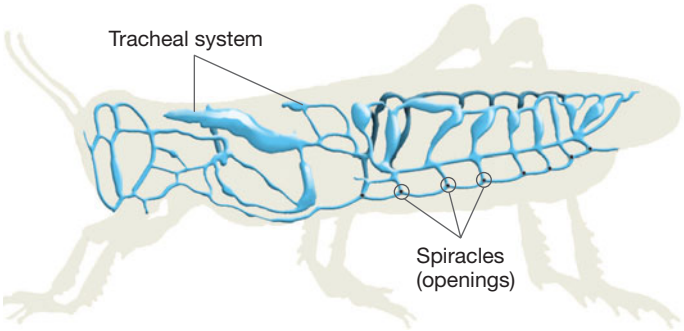
By studying extreme situations or unusual organisms, biologists can often gain insight into how organisms cope with more moderate environments. In studies on the molecular mechanisms of water and electrolyte balance in terrestrial insects, the most valuable model organisms have been the desert locust and a common household pest called the flour beetle. (You may have seen the larvae of flour beetles, called mealworms, in bags of flour that were not shut tightly enough to keep adults from entering and breeding.)

Desert locusts and flour beetles live in environments where osmotic stress is severe. These insects rarely, if ever, drink—simply because little or no water is available in the habitats they occupy.

How do they maintain water and electrolyte balance? The answer has two parts: They minimize water loss from their body surface, and they carefully regulate the amount of water and electrolytes that they excrete in their urine and feces. Let's look at each issue in turn.

How Do Insects Minimize Water Loss from the Body Surface?

Terrestrial animals breathe by exposing an extremely thin layer of epithelium to the atmosphere (see Chapter 45). Oxygen diffuses into this epithelium, and carbon dioxide diffuses out. But water constantly leaks across the thin respiratory surface and is lost to the atmosphere via evaporation.



Evaporation from the body surface itself is another threat—a particular challenge to insects, because they are small. Small organisms have a high surface area/volume ratio (see Chapter 42). Insects have a relatively large surface area from which to lose water but a small volume in which to retain it.

How do desert locusts, flour beetles, and other insects minimize water loss during gas exchange? In these species, gas exchange occurs across the membranes of epithelial cells that line the **tracheae,** an extensive system of tubes. The insect tracheal system connects with the atmosphere at openings called **spiracles** (**FIGURE 43.8a**). Muscles just inside each spiracle open or close the pore, much as guard cells open or close the pores in plant leaves and stems.

When investigators manipulated insects called *Rhodnius* so that their spiracles stayed open and placed the animals in a dry environment, the insects died within three days. These data support the hypothesis that the ability to close spiracles is an important adaptation for minimizing water loss during respiration. If an insect is under osmotic stress, it may be able to close its spiracles and wait until conditions improve before resuming activity.

FIGURE 43.8b shows how insects minimize evaporation from the surface of their bodies. This diagram is a cross-sectional view of the exoskeleton of an insect, which consists of a tough,

(a) Spiracles can be closed to minimize water loss from tracheae.

(b) Except at spiracles, the insect body is covered with wax.

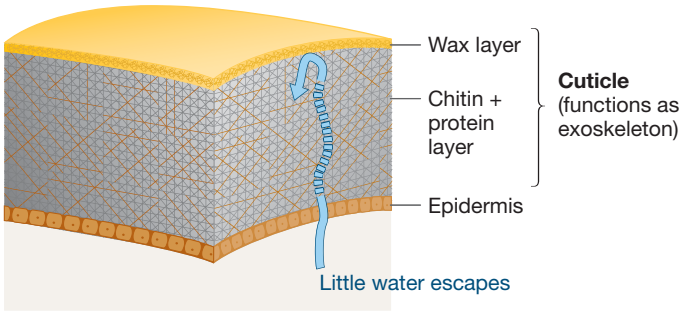


FIGURE 43.8 In Desert Locusts, Adaptations Limit Water Loss during Respiration and from the Body Surface.

✔**QUESTION** In desert grasshoppers, spiracles are located in a row along the underside of the abdomen. Why would this location help minimize water loss?

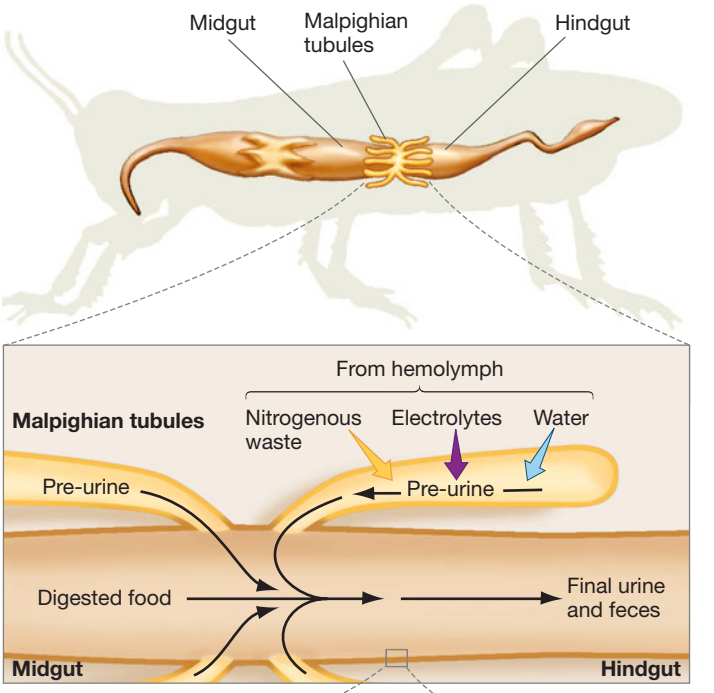
nitrogen-containing polysaccharide called chitin and layers of protein, with a layer of wax on the outside. This combination of chitin, protein, and wax is known as the **cuticle.**

Recall that waxes, a type of lipid, are highly hydrophobic and thus highly impermeable to water (see Chapter 6). Researchers who removed the wax from insect exoskeletons have confirmed that the rate of water loss from the body surface increases sharply. Based on this observation, the wax layer is interpreted as an adaptation that minimizes evaporative water loss.

For insects, minimizing water loss is only half the battle in avoiding osmotic stress. To maintain homeostasis, insects must also carefully regulate the composition of a blood-like fluid called **hemolymph.** Hemolymph is pumped by the heart and transports electrolytes, nutrients, and waste products.

To maintain water and electrolyte balance, insects rely on excretory organs called **Malpighian tubules,** and on their hindgut—the posterior portion of their digestive tract (**FIGURE 43.9a**).

Filtrate Forms in the Malpighian Tubules As Figure 43.9a shows, Malpighian tubules have a large surface area, are in direct contact with the hemolymph, and empty into the hindgut. The Malpighian tubules are responsible for forming a **filtrate** from the hemolymph. This "pre-urine" then passes into the hindgut, where it is processed and modified before excretion.



To explore how the Malpighian tubules work, biologists collected filtrate from the lumen of Malpighian tubules in mealworms and compared its composition with that of hemolymph from the same individuals. The two solutions were roughly isosmotic, but not identical.

How do they differ? Compared to hemolymph, the solution inside the tubules has a lower concentration of Na^+ and a higher concentration of K^+. This observation suggests that the epithelial cells in the Malpighian tubules are relatively impermeable to sodium ions but contain a pump that actively transports potassium ions into the tubules.

To test this hypothesis, researchers dissected the tubules, rinsed them, and bathed their interior and exterior in a solution containing a known concentration of potassium ions. When they measured the concentration of electrolytes on either side of the membrane over time, they found that K^+ accumulated in the tubule lumen, against its concentration gradient.

This result supported the hypothesis that cells in the membranes of Malpighian tubules contain pumps that actively transport potassium ions into the lumen of the organ. Subsequent work has shown that a high concentration of potassium ions brings water into the tubules by osmosis. Other electrolytes and nitrogenous wastes then diffuse into the filtrate along their concentration gradients.

(a) Malpighian tubules produce an isosmotic pre-urine.

(b) Under osmotic stress, the hindgut reabsorbs electrolytes and water to form a hyperosmotic urine.

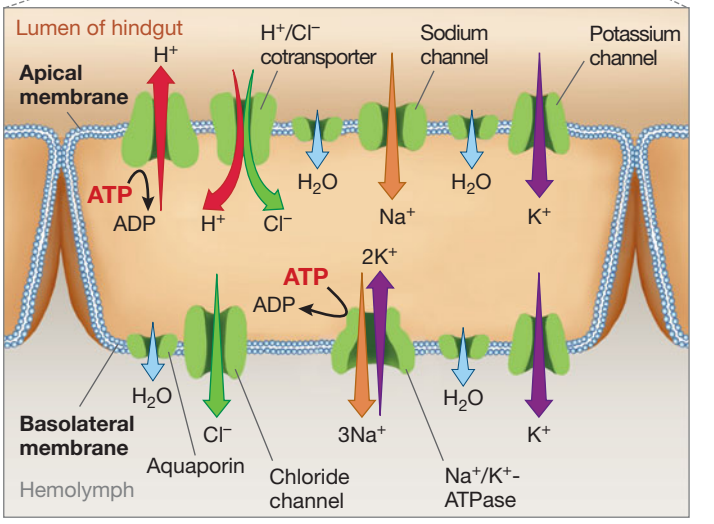


FIGURE 43.9 In Insects, Urine Forms in the Malpighian Tubules and Hindgut. (a) The isosmotic filtrate that forms in the Malpighian tubules empties into the hindgut. **(b)** In the hindgut, the primary driving forces for reabsorption of electrolytes and water are H^+ pumps in the apical membrane and Na^+/K^+-ATPases in the basolateral membrane.

The Hindgut: Selective Reabsorption of Electrolytes and Water The filtrate that accumulates inside the Malpighian tubules flows into the hindgut, where it joins material emerging from the digestive tract. If an insect is osmotically stressed due to a shortage of electrolytes and water, electrolytes and water from the filtrate are reabsorbed in the hindgut and returned to the hemolymph, while the uric acid remains in the hindgut. Reabsorption results in formation of hyperosmotic final urine, conservation of water, and efficient elimination of nitrogenous wastes.

In desert locusts, flour beetles, and other species in extremely dry environments, 80 to 95 percent of the water in the filtrate is reabsorbed and kept inside the body. The ability to recover this

water allows these insects to live in dry habitats such as deserts and flour bins. How does reabsorption happen?

The mechanism involves a series of specific membrane pumps and channels, not unlike the system found in the chloride cells of fishes. To study it, researchers positioned the hindgut epithelium from a desert locust as a sheet dividing two solutions. They manipulated electrolyte concentrations on either side of the hindgut wall and measured changes in the solutions over time.

For example, when investigators removed K^+ and Na^+ from the solution on the lumen side of the organ, water reabsorption stopped. These data established that the hindgut's ability to recover water from urine depends on ion movement: The epithelial cells in the hindgut transport ions out of the filtrate and into the hemolymph. Water follows by osmosis, forming concentrated urine.

How do the ions move? By poisoning the experimental membranes with ouabain, biologists confirmed that Na^+/K^+-ATPase is involved in moving ions out of the lumen and into the hemolymph. Ouabain-treated membranes continued to transport Cl^-, however. Years of experiments on the locust hindgut resulted in the model in **FIGURE 43.9b**:

- H^+ is pumped into the hindgut lumen, creating an electrical gradient that favors movement of K^+ into the cells through potassium channels. Water follows via osmosis.
- H^+ diffuses along its gradient from the lumen into the cell through a H^+/Cl^- cotransporter, bringing Cl^- into the cell against its gradient.
- In the basolateral membrane, Na^+/K^+-ATPase sets up electrochemical and osmotic gradients that favor diffusion of Na^+ from the hindgut lumen into the epithelial cell, and diffusion of Cl^- and K^+ from the epithelial cell into the hemolymph. Water moves into the hemolymph by osmosis.

Regulating Water and Electrolyte Balance: An Overview Several general principles that have emerged from studies of insect excretion turn out to be relevant to vertebrate systems as well:

- Water moves only by osmosis—it is not pumped directly. Water moves between cells or body compartments via osmotic gradients that are set up by the active transport of ions.
- The formation of the filtrate is not particularly selective. Most of the molecules present in the hemolymph are also present in the Malpighian tubules.
- In contrast to filtrate formation, reabsorption is highly selective. The protein pumps and channels involved in reabsorption are highly specific for certain ions and molecules. Waste products do not pass through the hindgut membrane. Instead, they remain in the hindgut and are eliminated along with the feces. Only valuable ions and molecules are reabsorbed.
- In contrast to filtrate formation, reabsorption is tightly regulated. The membrane pumps and channels involved in reabsorption are activated and deactivated in response to osmotic stress. If an insect is dehydrated, virtually all of the water in the filtrate is reabsorbed. But if it has plenty to drink, reabsorption does not occur and the urine is watery and hyposmotic to the individual's hemolymph. The system is dynamic and allows precise control over water and electrolyte balance.

Given the success of insects in terms of the numbers of species and individuals and the array of habitats they occupy, it is clear that their systems for maintaining water and electrolyte balance are remarkably effective.

check your understanding

CYU

If you understand that . . .

- Terrestrial insects are prone to dehydration, primarily via evaporation from their respiratory surfaces.
- Terrestrial insects have a cuticle, respiratory system, and excretory system that are adapted to conserve water.
- In terrestrial insects, urine production begins with formation of a filtrate that is isosmotic with hemolymph, followed by selective and tightly regulated reabsorption of ions, nutrients, and water.

✔ You should be able to . . .

Explain how the following traits are involved in water retention:

1. Excretion of ammonia in the form of uric acid.
2. Selective reabsorption of electrolytes in the hindgut.

Answers are available in Appendix A.

43.5 Water and Electrolyte Balance in Terrestrial Vertebrates

With respect to water loss, terrestrial vertebrates face the same hazards that terrestrial insects do. Crocodiles, turtles, lizards, frogs, birds, and mammals lose water from their body surfaces, from the surface of their lungs every time they breathe, and in their urine. Electrolytes are also lost in urine and, in some species, in sweat. To replace the water they lose, most terrestrial vertebrates drink. They also ingest electrolytes in food.

In land-dwelling vertebrates, osmoregulation occurs primarily through events that take place in the key organ of the urinary system, the **kidney.** The kidney is responsible for water and electrolyte balance, as well as the excretion of nitrogenous wastes. In terms of function, it is analogous to the Malpighian tubules and hindgut of insects. Let's take a closer look at the kidney in mammals.

The Structure of the Mammalian Kidney

Mammalian kidneys occur in pairs and tend to be bean shaped. A large blood vessel called the renal artery brings blood that contains nitrogenous wastes into the organ; the renal vein is a large blood vessel that carries "clean" blood away.

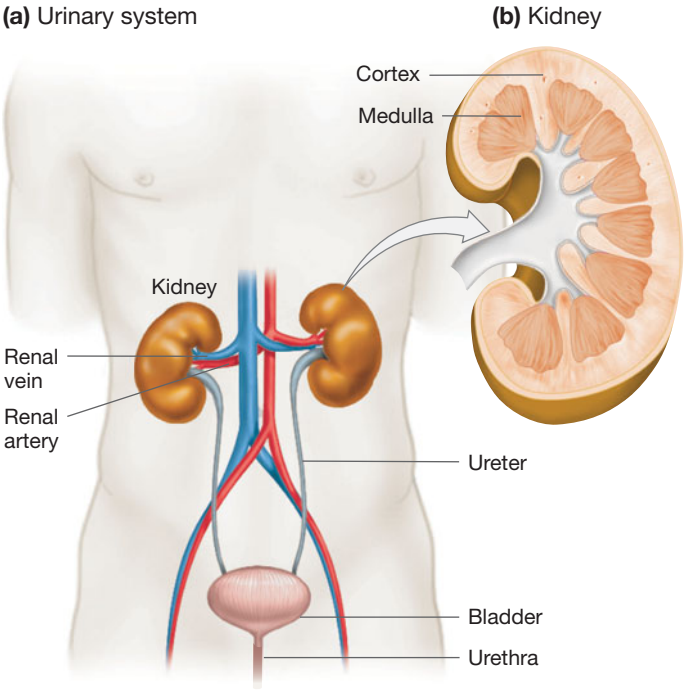

FIGURE 43.10 Anatomy of the Human Urinary System and Kidney. **(a)** In mammals, kidneys are paired and are located near the spinal column. **(b)** The kidney has an outer region called the cortex and an inner area called the medulla.

The urine that forms in the kidney is transported via a long tube called the **ureter** to a storage organ, the **bladder.** From the bladder, urine is transported to the body surface through the **urethra** and then excreted. In most vertebrates, the kidneys are located near the dorsal (back) side of the body. **FIGURE 43.10a** summarizes the parts of the urinary system.

Most of the kidney's mass is made up of small structures called nephrons. The **nephron** is the basic functional unit of the kidney. The work involved in maintaining water and electrolyte balance occurs in the nephron.

Most of the approximately 1 million nephrons in a human kidney are located in the outer region of the organ, or **cortex** (**FIGURE 43.10b**). But some nephrons extend from the cortex into the kidney's inner region, or **medulla.**

The Function of the Mammalian Kidney: An Overview

The nephron shares important functional characteristics with the insect excretory system:

- Water cannot be transported actively—it moves only by osmosis.
- To move water, cells in the kidney set up strong osmotic gradients.
- By regulating these gradients and specific channel proteins, kidney cells exert precise control over loss or retention of water and electrolytes.

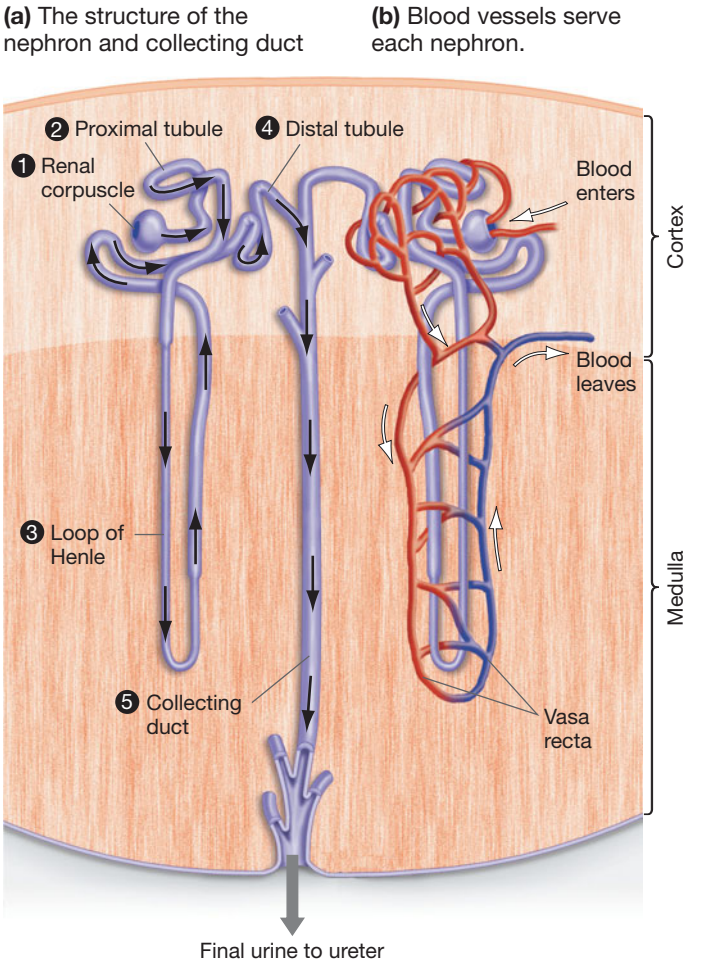

FIGURE 43.11 A Nephron Has Four Major Parts, Empties into a Collecting Duct, and Is Served by Blood Vessels. Urine formation begins in the renal corpuscle and ends in the collecting duct.

FIGURE 43.11a provides a detailed view of the nephron. Note that it has four major regions and is closely associated with a tube called the collecting duct. **FIGURE 43.11b** illustrates a second key point about the anatomy of the nephron: It is served by blood vessels that wrap around each of its four regions.

The four major nephron regions and the collecting duct each have a distinct function:

1. The *renal corpuscle* filters blood, forming a filtrate or "pre-urine" consisting of ions, nutrients, wastes, and water.
2. The *proximal tubule* has epithelial cells that reabsorb nutrients, valuable ions, and water from the filtrate into the bloodstream.
3. The *loop of Henle* establishes a strong osmotic gradient in the interstitial fluid surrounding the loop, with osmolarity increasing as the loop descends.
4. The *distal tubule* reabsorbs ions and water in a regulated manner—one that helps maintain water and electrolyte balance according to the body's needs.
5. The *collecting duct* may reabsorb more water to maintain homeostasis. In addition, urea leaves the base of the collecting

duct and contributes to the osmotic gradient in the interstitial fluid set up by the loop of Henle.

The blood vessels associated with the nephron play a key role as well: They bring "dirty" blood into the nephron and then take away the molecules and ions that are reabsorbed from the initial filtrate.

Now let's delve into the details. The sections that follow trace the flow of material through each component of the nephron and out of the collecting duct.

Filtration: The Renal Corpuscle

In terrestrial vertebrates, urine formation begins in the **renal corpuscle** (literally, "kidney-little-body"). Notice in Figure 43.11a that the nephron consists of a tube that is closed at one end and open at the other. The closed end is the beginning of the nephron; the open end is the terminus of the collecting duct.

As **FIGURE 43.12a** shows, the closed end of the nephron forms a capsule that encloses a cluster of tiny blood vessels, or capillaries. These vessels bring blood to the nephron from the renal artery. Collectively, the cluster of capillaries is called the **glomerulus** ("ball of yarn"). The region of the nephron that surrounds the glomerulus is named **Bowman's capsule.** Together, the glomerulus and Bowman's capsule make up the renal corpuscle.

FIGURE 43.12b illustrates a key feature of the glomerular capillaries: They have large pores, or openings. In addition, they are surrounded by unusual cells whose membranes fold into a series of slits and ridges.

The structure of the renal corpuscle allows it to function as a **filtration** device. Water and small solutes from the blood pass through the pores and slits into the Bowman's capsule. Filtration is based on size: Proteins, cells, and other large components of blood do not fit through the pores and do not enter the nephron. They remain in the blood instead.

Stated another way, urine formation starts with a size-selective filtration step—with blood pressure supplying the force required to perform filtration. In vertebrates, blood is under higher pressure than the surrounding tissues because it is pumped by the heart through a closed system of vessels. This pressure is enough to force water and small solutes through the pores in the glomerulus, so the renal corpuscle strains large volumes of fluid without expending energy in the form of ATP.

✔ **If you understand this concept, you should be able to describe the contents of blood on one side of the filter (glomerulus) and the contents of the filtrate on the other side.**

It is critical to note two additional facts about the filtration step in urine formation:

1. The renal corpuscles of a human kidney are capable of producing about 180 liters of filtrate per day. This is an impressive volume—think of 180 one-liter bottles of soft drink arranged on a supermarket shelf.
2. About 99 percent of the filtrate is reabsorbed—only a tiny fraction of the original volume is actually excreted as urine.

Filtering large volumes from the blood allows wastes to be removed effectively; pairing this process with selective reabsorption allows waste excretion to occur with a minimum of water and nutrient loss.

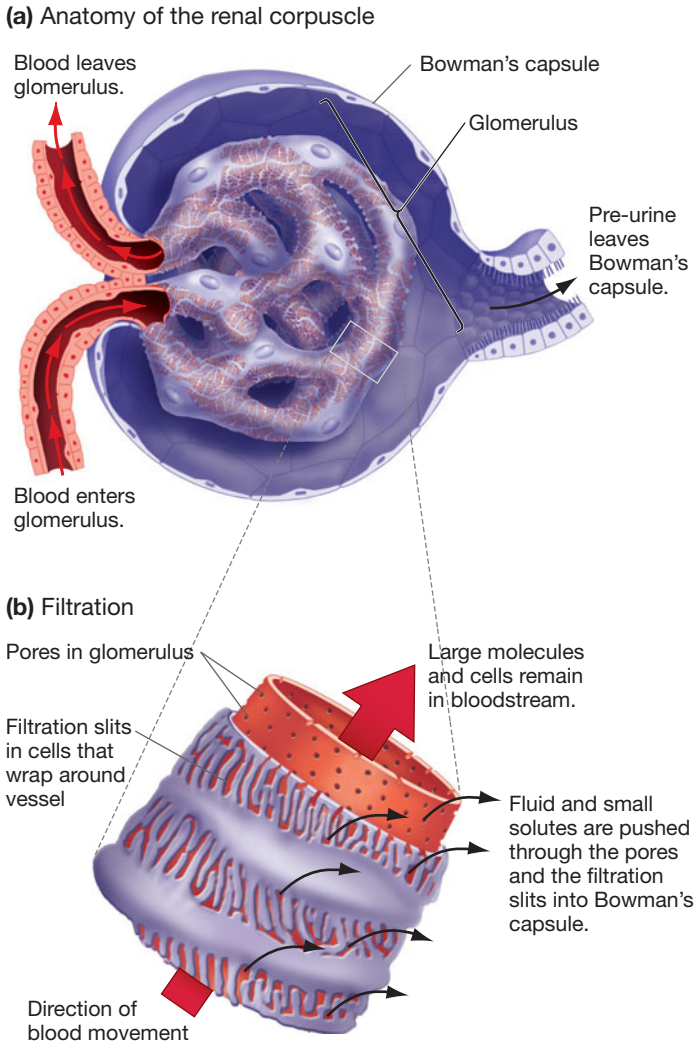

FIGURE 43.12 Urine Formation Begins When Blood Is Filtered in the Renal Corpuscle. (a) The renal corpuscle consists of Bowman's capsule and the glomerulus. **(b)** The capillaries in the glomerulus have pores and are surrounded by cells that have filtration slits. Blood pressure forces water and small molecules out of the capillaries, through the slits, and into Bowman's capsule.

Reabsorption: The Proximal Tubule

Where does filtrate reabsorption begin? Filtrate leaves Bowman's capsule and enters a convoluted structure called the **proximal tubule.** The filtrate inside this tubule contains water and small solutes such as urea, glucose, amino acids, vitamins, and electrolytes. Some of these molecules are waste products; others are valuable nutrients.

Active Transport Occurs in Epithelial Cells The epithelial cells of the proximal tubule have a prominent series of small projections, called **microvilli** ("little shaggy hairs"), facing the lumen. The microvilli greatly expand the surface area of this epithelium.

(a) Microvilli expand surface area of lumen of proximal tubule.

(b) Model of selective reabsorption in proximal tubules

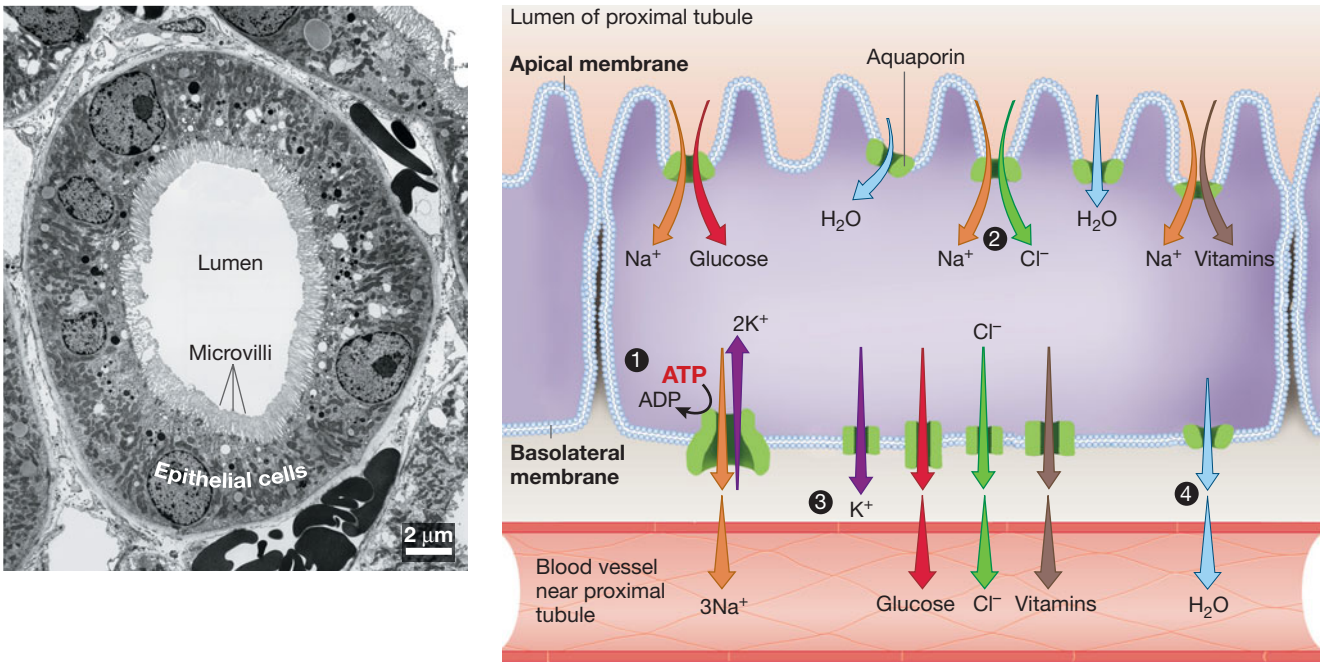

FIGURE 43.13 Water, Electrolytes, and Nutrients Are Reabsorbed in the Proximal Tubule.

A large surface area provides space for membrane proteins that act as pumps, channels, and cotransporters (**FIGURE 43.13a**).

Epithelial cells in the proximal tubule are also packed with mitochondria, which suggests that ATP-demanding active transport is occurring. Based on these observations, biologists hypothesized that the proximal tubule functions in the active transport of selected molecules out of the filtrate.

By injecting solutions of known composition into isolated rabbit and rat proximal tubules in the presence or absence of ATP, researchers confirmed that selected electrolytes and nutrients are actively reabsorbed from the filtrate that enters the tubules.

When solutes move from the proximal tubule into epithelial cells, and then into the bloodstream, water follows along the osmotic gradient. In this way, valuable solutes and water are reabsorbed and returned to the bloodstream.

Ion and Water Movement Is Driven by a "Master Gradient"

FIGURE 43.13b summarizes the current model of the molecular mechanisms involved in selective reabsorption in the proximal tubule:

1. Na^+/K^+-ATPase in the basolateral membranes removes Na^+ from the interior of the cell. The active transport of sodium ions out of the cell creates a gradient favoring the entry of Na^+ from the lumen.
2. In the apical membrane adjacent to the lumen, Na^+-dependent cotransporters use this gradient to remove valuable ions and nutrients selectively from the filtrate. The movement of Na^+ into the cell, *along* its concentration gradient, provides the means for moving other solutes *against* a concentration gradient.
3. The solutes that move into the cell diffuse across the basolateral membrane into the interstitial fluid and then nearby blood vessels.
4. Water follows the movement of ions from the proximal tubule into the cell and then out of the cell and into blood vessels. Recall that water moves by osmosis across the membranes of these epithelial cells through membrane proteins called aquaporins.

Almost all of the nutrients, along with about two-thirds of the NaCl and water that is originally filtered by the renal corpuscle, are reabsorbed in the proximal tubule. The osmolarity of the tubular fluid is unchanged despite this huge change in volume, however, because water reabsorption is proportional to solute reabsorption.

In effect, then, the cells that line the proximal tubule act as a recycling center. The filtration step in the renal corpuscle is based on size; the reabsorption step in the proximal tubule selectively retrieves small substances that are valuable. The pumps and cotransporters in the proximal tubule reabsorb nutrients, electrolytes, and water but leave wastes. As the filtrate flows into the loop of Henle, it has a relatively high concentration of waste molecules and a relatively low concentration of nutrients.

Creating an Osmotic Gradient: The Loop of Henle

In mammals, the fluid that emerges from the proximal tubule enters the **loop of Henle**—named for Jacob Henle, who described it in the early 1860s. In most nephrons, the loop is short and barely enters the medulla. But in about 20 percent of the nephrons present in a human kidney, the loop is long and plunges from the cortex of the kidney deep into the medulla.

In 1942 Werner Kuhn offered a hypothesis, inspired by countercurrent heat exchangers, to explain what the loop of Henle does. Recall that a countercurrent heat exchanger is a system in which two adjacent fluids flow through pipes in opposite directions (see Chapter 42). Kuhn proposed that the loop of Henle is a countercurrent exchanger and multiplier. It doesn't exchange heat, however. Instead, it sets up an osmotic gradient.

Specifically, Kuhn proposed that the osmolarity of the filtrate in the loop of Henle is low in the cortex and high in the medulla. Further, Kuhn maintained that the osmolarity in the interstitial fluid surrounding the loop mirrors the gradient inside the loop. This is a key point.

Testing Kuhn's Hypothesis A series of papers published during the 1950s and early 1960s supplied important experimental support for the countercurrent exchange model. **FIGURE 43.14** reproduces two particularly important data sets, obtained by comparing the osmolarity of kidney tissue slices. In both graphs, the *x*-axis shows the location in the kidney, from cortex to medulla. The *y*-axis indicates osmolarity, measured either as the percentage of the maximum observed or as solute concentration.

- Figure 43.14a shows data on the osmolarity of fluid inside the loop of Henle. The vertical lines represent the range of values observed at a particular location. As predicted by Kuhn's model, a strong gradient in osmolarity exists from the cortex to the medulla.
- Figure 43.14b shows that the concentrations of Na^+, Cl^-, and urea also increase sharply from the cortex to the medulla in the interstitial fluid outside the loop of Henle.

These results suggested that the solutes responsible for the gradient outside the loop are Na^+, Cl^-, and urea. The change in concentration of urea turned out to be particularly important.

How Is the Osmotic Gradient Established? The loop of Henle has three distinct regions: the descending limb, the thin ascending limb, and the thick ascending limb (**FIGURE 43.15a**, see page 876). The thin and thick ascending limbs differ in the thickness of their walls. Do the three regions also differ in their permeability to water and solutes?

It took over 15 years of experiments performed in laboratories around the world to formulate a definitive answer to that question. Researchers punctured the loop of Henle of rodents with a micropipette, analyzed the composition of the fluid inside, and compared it with the nephron's final product—urine.

In the ascending limb of the loop of Henle, Na^+ and Cl^- constituted at least 60 percent of the solutes; urea constituted about 10 percent. But in the distal tubule, urea was the major solute. These data suggested that Na^+ and Cl^-, but not urea, were being removed somewhere in the ascending limb. How?

Na^+ and Cl^- were also present at high concentrations in the tissue surrounding the thick ascending limb, so researchers hypothesized that sodium might be actively pumped out of this portion of the nephron. The hypothesis was that the active transport of Na^+ out of the filtrate in the thick ascending limb would create an electrical gradient that would also favor the loss of Cl^-.

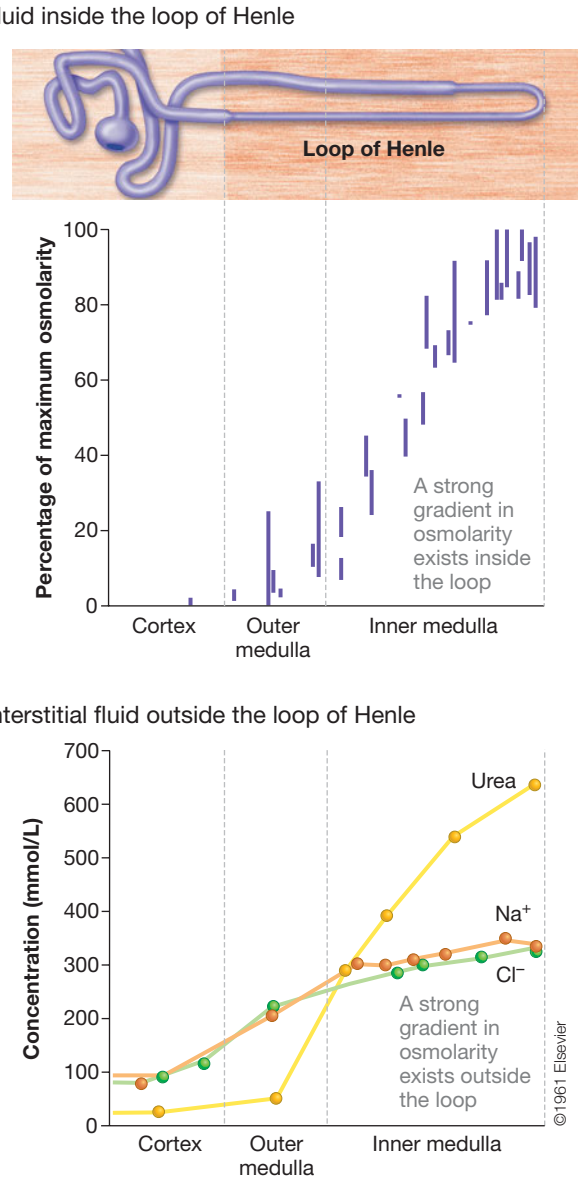

FIGURE 43.14 Data Confirm the Existence of a Strong Osmotic Gradient Both Inside and Outside the Loop of Henle. As the nephron plunges into the inner medulla, the concentration of dissolved solutes increases both inside **(a)** and outside **(b)** the loop of Henle.

DATA: K. J. Ullrich, K. Kramer, and J.W. Boyer. 1961. *Progress in Cardiovascular Diseases* 3: 395–431.

Follow-up experiments using ouabain and other poisons supported the hypothesis that sodium ions are actively transported out of the solution inside the thick ascending limb, and chloride ions follow along an electrochemical gradient. The epithelial cells responsible for salt excretion are configured almost exactly like the epithelium of the shark rectal gland (see Figure 43.6).

What is happening in the descending limb and the thin ascending limb of the loop of Henle? By injecting solutions of known concentration into the nephrons of rabbits, biologists documented that the descending limb is highly permeable to water but almost completely impermeable to solutes. The thin ascending limb of the loop, in contrast, is highly permeable to Na^+

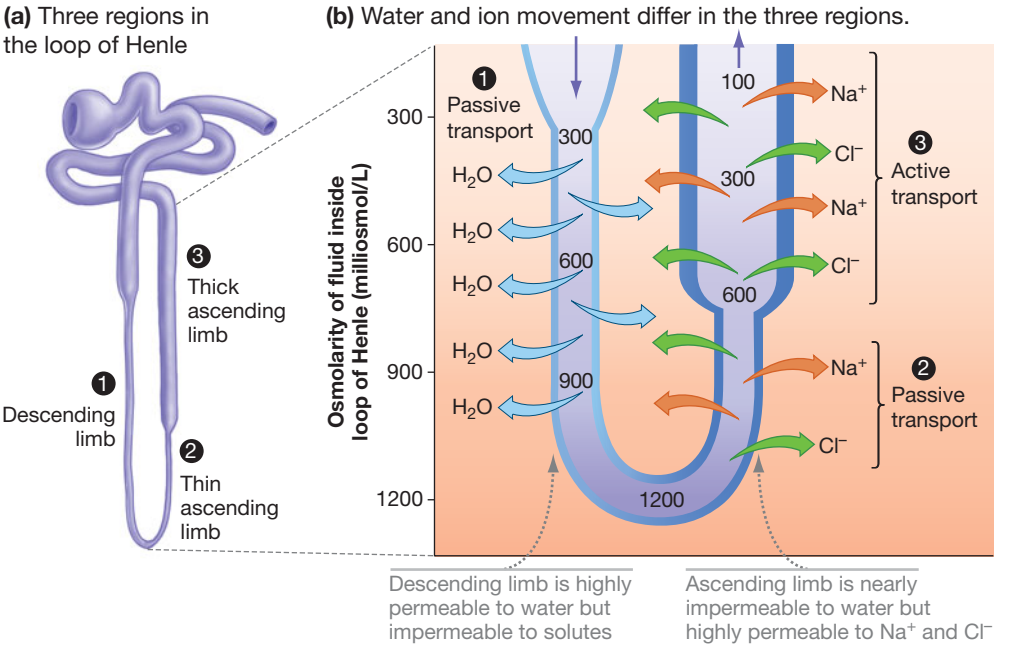

FIGURE 43.15 The Loop of Henle Maintains an Osmotic Gradient because Water Leaves the Descending Limb and Salt Leaves the Ascending Limb. The values inside the loop in part (b) represent the osmolarity of the filtrate.

and Cl^-, moderately permeable to urea, and almost completely impermeable to water.

A Comprehensive View of the Loop of Henle All of the observations just summarized came together in 1972 when two papers, published independently, proposed the same comprehensive model for how the loop of Henle works. To understand this model, follow the events in **FIGURE 43.15b**:

1. As fluid flows down the descending limb, the fluid inside the loop loses water to the interstitial fluid surrounding the nephron. This movement of water is passive—it does not require an expenditure of ATP. The water follows an osmotic gradient created by the ascending limb. At the bottom of the loop—in the inner medulla—the fluids inside and outside the nephron have high osmolarity. The filtrate does not continue to lose water, though, because the membrane in the ascending limb is nearly impermeable to water.
2. The fluid inside the nephron loses Na^+ and Cl^- in the thin ascending limb. The ions move passively, along their concentration gradients.
3. Toward the cortex, the osmolarity of the surrounding interstitial fluid is low. Additional Na^+ and Cl^- ions are actively transported out of the nephron in the thick ascending limb.

The countercurrent flow of fluid, combined with changes in permeability to water and in the types of channels and pumps that are active in the epithelium of the nephron, creates a self-reinforcing system. The presence of an osmotic gradient stimulates water and ion flows that in turn maintain an osmotic gradient.

Here's how it works: Movement of NaCl from the ascending limb into surrounding tissue increases the osmolarity of the fluid outside the descending limb, which results in a flow of water out of the water-permeable walls of the descending limb, via osmosis. This loss of water in the descending limb increases the osmolarity in the fluid entering the ascending limb. The high concentration of salt in the fluid at the base of the ascending limb triggers a passive flow of ions out—reinforcing the osmotic gradient.

✔ **If you understand this concept, you should be able to predict what happens to the osmotic gradient when the drug furosemide inhibits membrane proteins that pump sodium and chloride ions out of the thick ascending limb. Specifically, how does this drug affect (1) water reabsorption in the descending limb, (2) the osmolarity of the filtrate in the bottom of the loop of Henle, and (3) reabsorption of salt in the thin ascending limb?**

The Vasa Recta Removes Water and Solutes That Leave the Loop of Henle What happens to the water and salt that move out of the loop from the filtrate into the interstitial fluid? They quickly diffuse into the **vasa recta,** a network of blood vessels that runs along the loop and eventually joins up with small veins in the kidney. As a result, the water and electrolytes that are reabsorbed are returned to the bloodstream instead of being excreted in urine (**FIGURE 43.16**).

The removal of water that leaves the descending limb is particularly important. If it were not drawn off into the bloodstream, it would dilute the concentrated fluid outside the loop of Henle and quickly destroy the osmotic gradient.

The Collecting Duct Leaks Urea Urea is the solute that is most responsible for the steep osmotic gradient in the space surrounding the nephron. Urea is at high concentration in the interstitial fluid in the inner medulla and low concentration in the outer medulla. This gradient exists because the innermost section of the collecting duct is permeable to urea.

Although the system created by the nephron, vasa recta, and collecting duct may seem complex, its outcome is simple: the creation and maintenance of a strong osmotic gradient with the minimum possible expenditure of energy.

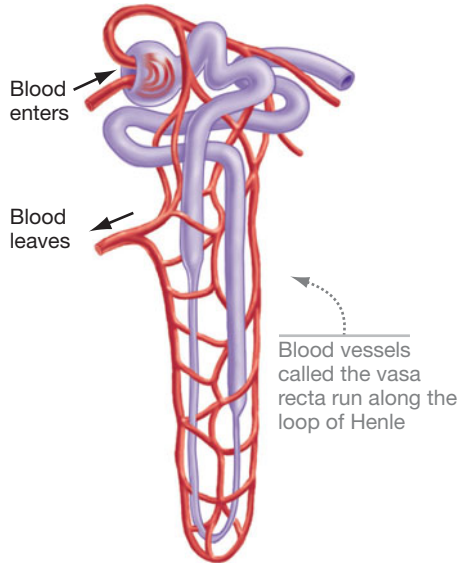

FIGURE 43.16 Blood Supply to the Loop of Henle. Water and solutes reabsorbed from the loop of Henle move into blood vessels (vasa recta).

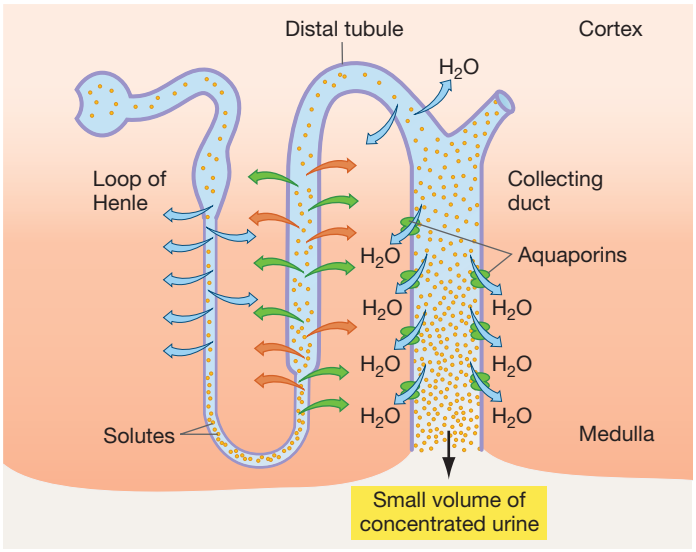
Regulating Water and Electrolyte Balance: The Distal Tubule and Collecting Duct

The first three steps in urine formation—filtration, reabsorption, and establishment of an osmotic gradient—result in a fluid that is slightly hyposmotic to blood. Once the filtrate has passed through the loop of Henle, the major solutes that it contains are urea and other wastes along with a low concentration of ions.

The filtrate that enters the distal tubule is always dilute. In contrast, the urine that leaves the collecting duct is dilute when the individual is well hydrated but concentrated when the individual is dehydrated. How is this possible?

Urine Formation Is under Hormonal Control The answer is based on two observations about the **distal tubule** and **collecting duct:** Their activity is **(1)** highly regulated, and **(2)** altered in response to osmotic stress. The amount of Na^+, Cl^-, and water that is reabsorbed in the distal tubule and in the collecting duct varies with the animal's hydration.

Changes in the distal tubule and collecting duct are controlled by **hormones**—signaling molecules (introduced in Chapter 11 and explored further in Chapter 49). Specifically:



- If Na^+ levels in the blood are low, the adrenal glands release the hormone **aldosterone,** which leads to activation of sodium–potassium pumps and reabsorption of Na^+ in the distal tubule. Water follows by osmosis. Aldosterone saves sodium and water.
- If an individual is dehydrated, the brain releases **antidiuretic hormone (ADH).** (The term diuresis refers to increased urine production, so antidiuresis means inhibition of urine production.) ADH is also referred to as vasopressin or arginine vasopressin. ADH saves water.

How Does ADH Work? Epithelial cells of the collecting duct are joined by tight junctions (see Chapter 11), making them impermeable to water and solutes. ADH has two important effects on the permeability of epithelial cells in the collecting duct:

1. ADH triggers the insertion of aquaporins into the apical membrane. As a result, cells become much more permeable to water and large amounts of water are reabsorbed.
2. ADH increases permeability to urea, which is reabsorbed into the surrounding fluid. This helps create a concentration gradient favoring water reabsorption from the filtrate.

As **FIGURE 43.17a** shows, water leaves the collecting duct passively—following the concentration gradient maintained by

(a) ADH present: Collecting duct is highly permeable to water.

(b) No ADH present: Collecting duct is not permeable to water.

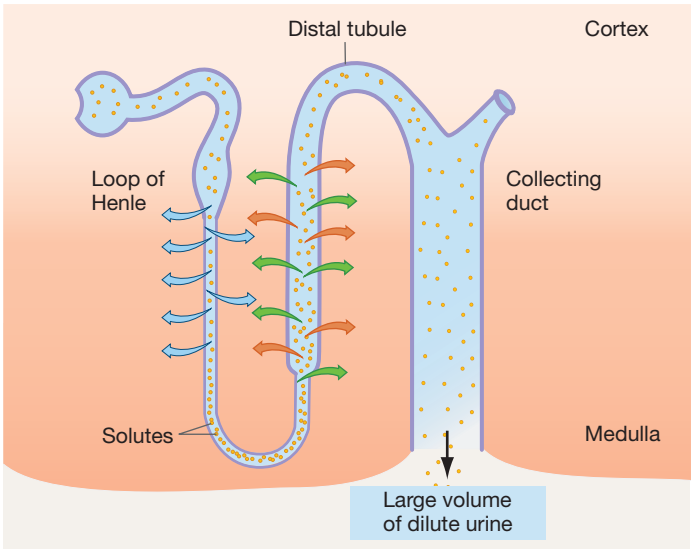


FIGURE 43.17 ADH Regulates Water Reabsorption by the Collecting Duct.

SUMMARY TABLE 43.2 Structure and Function of the Nephron and Collecting Duct

Structure	Function
Renal Corpuscle (Bowman's capsule and glomerulus)	Size-selective filtration: forms filtrate from blood (water and other small substances enter nephron)
Proximal Tubule	Reabsorbs electrolytes (active transport), nutrients, water
Loop of Henle	Maintains osmotic gradient in interstitial fluid from outer to inner medulla
• Descending limb	• Permeable to water (passive transport out of filtrate)
• Thin ascending limb	• Permeable to Na^+, Cl^- (passive transport out of filtrate)
• Thick ascending limb	• Active transport of Na^+, Cl^- out of filtrate
Distal Tubule	With aldosterone: Reabsorbs Na^+. Without aldosterone: Does not reabsorb Na^+.
Collecting Duct	Regulates water retention and loss
• Main portion	• With ADH: Water leaves filtrate; produces small volume of urine that is hyperosmotic to blood Without ADH: Water stays in filtrate; produces large volume of urine that is hyposmotic to blood
• Innermost portion	• Urea leaks out by passive transport to establish and/or maintain high osmolarity of inner medulla

the loop of Henle. When ADH is present, water is conserved and urine is strongly hyperosmotic relative to blood. The collecting duct is the final place in which the composition of the filtrate can be altered. Urine exiting the collecting ducts moves from the kidneys into ureters and then is stored in the bladder until urination.

When ADH is absent, however, few aquaporins are found in the epithelium of the collecting duct, and the structure is relatively impermeable to water (**FIGURE 43.17b**). In this case, a larger quantity of hyposmotic urine is produced.

✔ **If you understand ADH's effect on the collecting duct, you should be able to predict how urine formation is affected by ingestion of ethanol, which inhibits ADH release, versus nicotine, which stimulates ADH release.**

TABLE 43.2 reviews the functions of the four major regions of the nephron and the collecting duct.

Urine Formation in Nonmammalian Vertebrates

The loop of Henle is an important adaptation in mammals and some birds. Water loss is reduced because these animals can produce urine that is hyperosmotic to their blood. In contrast, fishes, amphibians, and non-avian reptiles lack loops of Henle, and their kidneys are therefore unable to produce concentrated urine.

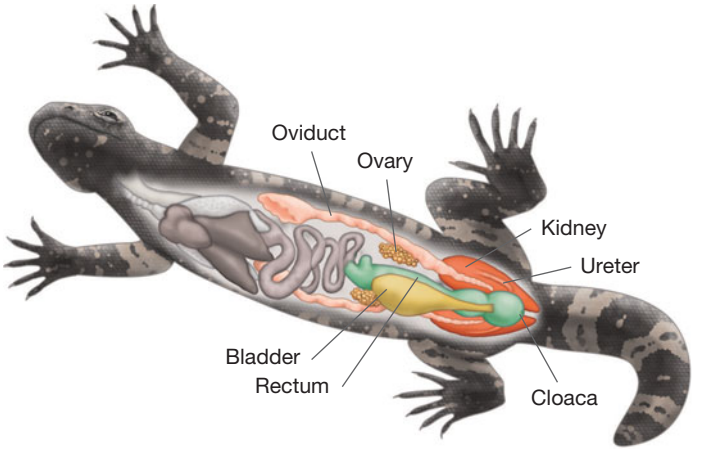

FIGURE 43.18 The Cloaca Is a Cavity into Which the Urinary, Gastrointestinal, and Reproductive Tracts Empty.

Many fishes and amphibians do not need to produce concentrated urine. But conserving water is important in reptiles, especially those inhabiting deserts. Recall that reptiles produce nitrogenous wastes in the form of uric acid, which is excreted with very little water and is therefore hyperosmotic to their body tissues. If reptiles' kidneys produce isosmotic urine, how does it become hyperosmotic?

In most reptiles, the ureters empty isosmotic urine into the **cloaca,** a cavity into which the urinary, gastrointestinal, and reproductive tracts all empty (**FIGURE 43.18**). Reptiles are able to absorb water from urine across the wall of the cloaca into the bloodstream. Eventually, a semisolid uric acid paste is excreted along with the feces.

check your understanding

C Y U

If you understand that . . .

- The mammalian kidney is specialized for the production of hyperosmotic urine.
- The loop of Henle is a countercurrent system that maintains a strong osmotic gradient in the medulla.
- The characteristics of urine change in response to hormonal signals. The signals trigger changes in the nephron and collecting duct that either save or eliminate water and solutes.

✔ **You should be able to . . .**

Predict how the following events would affect urine production: drinking massive amounts of water, eating large amounts of salt, and refraining from drinking water for 48 hours.

Answers are available in Appendix A.

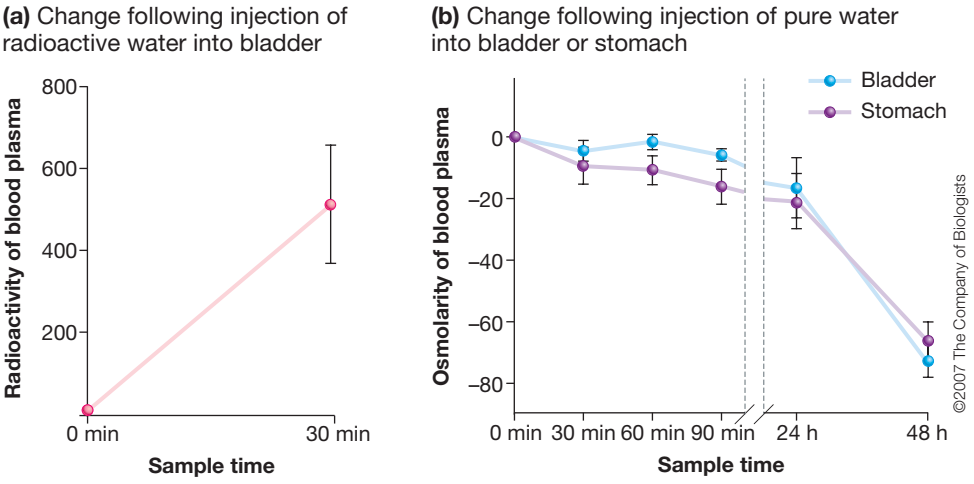

FIGURE 43.19 Gila Monsters Can Reabsorb Water from Their Bladders. **(a)** Radioactively labeled water passes from bladder into bloodstream. **(b)** Pure water reduces blood osmolarity at a similar rate in dehydrated lizards whether added to stomach or to bladder.

DATA: Davis, J. R., and D. F. DeNardo. 2007. *The Journal of Experimental Biology* 210: 1472–1480.

✔**QUESTION** What physiological trade-offs might be imposed by carrying a large amount of water in the bladder?

Some reptiles also have a bladder that collects the isosmotic urine from the ureters and stores it before emptying it into the cloaca. When water is available, these reptiles drink a lot, and their bladders fill up with dilute urine. Researchers hypothesized that the bladder acts as a "canteen" to store water during times when water is unavailable.

To test this hypothesis, the investigators injected the bladders of dehydrated Gila monsters—a large desert lizard—with radioactively labeled water and drew blood samples over time. The radioactivity of the lizards' blood increased within a half hour, which meant that the radioactively labeled water from the bladder was being absorbed into the bloodstream (**FIGURE 43.19a**).

The researchers also examined whether water in the bladder can rehydrate lizards to the same extent as drinking water. Working with two groups of dehydrated Gila monsters, they injected water into the bladders of one group, and—to mimic drinking—they injected water into the stomachs of the second group. They found that the osmolarity of the plasma decreased at the same rate in both groups (**FIGURE 43.19b**).

So, the bladder can indeed act as a "canteen," allowing lizards to carry a water supply that they can access when water is scarce. As water is reabsorbed from the bladder, the urine becomes more and more concentrated, but the osmolarity of the blood remains low.

Whether considering the mammalian nephron or the Gila monster bladder, the vertebrate urinary system is remarkably effective in regulating water and electrolyte balance and achieving homeostasis.

CHAPTER 43 REVIEW

For media, go to MasteringBiology

If you understand . . .

43.1 Osmoregulation and Excretion

- Solutes move across membranes via passive transport, facilitated diffusion, or active transport. Water moves across membranes by osmosis.
- In most animals, epithelial cells that selectively transport water and electrolytes are responsible for homeostasis.
- The mechanisms involved in regulating water and electrolyte balance vary widely among animal groups because different habitats present different types of osmotic stress.
- The type of nitrogenous waste excreted by an animal is affected by its phylogeny and its habitat type. Most fishes excrete ammonia; mammals and most adult amphibians excrete urea; and insects, reptiles, and birds excrete uric acid.

✔**You should be able to explain how an electrochemical gradient for sodium ions makes it possible for other ions and water to move across a membrane passively.**

43.2 Water and Electrolyte Balance in Marine Fishes

- Seawater is strongly hyperosmotic in relation to the tissues of marine bony fishes, so the fishes tend to lose water by osmosis and gain electrolytes by diffusion.
- Marine bony fishes are osmoregulators, whereas cartilaginous fishes such as sharks are osmoconformers.
- Epithelial cells in the shark rectal gland and in the gills of marine bony fishes excrete excess salt using sodium–potassium pumps and sodium–potassium–chloride cotransporters located in the basolateral membrane.
- Salt-excreting cells similar to those found in the shark rectal gland occur in the gills of marine fishes, the salt glands of marine birds and other reptiles, and the kidneys of mammals.

✔**You should be able to compare and contrast the mechanisms by which cartilaginous and bony fishes achieve water and electrolyte balance in the ocean.**

43.3 Water and Electrolyte Balance in Freshwater Fishes

- Freshwater is strongly hyposmotic in relation to the tissues of freshwater fishes, so the fishes tend to gain water by osmosis and lose electrolytes by diffusion.
- Epithelial cells in the gills of freshwater fishes import ions using sodium–potassium pumps (Na^+/K^+-ATPases) located in the basolateral membrane and sodium–potassium–chloride cotransporters located in the apical membrane.

✔ **You should be able to describe the evidence for the hypothesis that new chloride cells form when salmon migrate from the ocean to freshwater.**

43.4 Water and Electrolyte Balance in Terrestrial Insects

- A waxy coating on the insect exoskeleton limits evaporative water loss. The openings to insect respiratory organs close when osmotic stress is severe.
- The Malpighian tubules of insects form a filtrate that is isosmotic with the hemolymph. If pumps in the epithelium of the hindgut are activated, then electrolytes and water are reabsorbed from the filtrate and returned to the hemolymph.
- Insects can form hyperosmotic urine that minimizes water loss during the excretion of nitrogenous wastes.

✔ **You should be able to predict what type of nitrogenous waste is excreted by aquatic insects.**

43.5 Water and Electrolyte Balance in Terrestrial Vertebrates

- Nephrons in the vertebrate kidney form a filtrate in the renal corpuscle and then reabsorb valuable nutrients, electrolytes, and water in the proximal tubule.
- A solution containing urea and electrolytes flows through the loop of Henle of mammalian kidneys, where changes in the permeability of epithelial cells to water and salt—along with active transport of salt—create a steep osmotic gradient.
- If antidiuretic hormone (ADH) increases the water permeability of the collecting duct, water is reabsorbed along the osmotic gradient and hyperosmotic urine is produced.
- The nephrons of fishes, amphibians, and reptiles do not have loops of Henle and therefore cannot produce urine that is hyperosmotic to the body fluids. Some of these vertebrates are able to reabsorb water from the cloaca or bladder to produce hyperosmotic urine.

✔ **You should be able to explain why desert-dwelling kangaroo rats, which are under extreme osmotic stress due to lack of drinking water, have extremely long loops of Henle relative to their body size.**

TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. True or False: Sodium–potassium ATPase pumps move three sodium molecules out of a cell in exchange for two potassium ions, establishing an electrochemical gradient.
2. Which one of the following statements is true of fishes that live in freshwater?
   a. The environment is isosmotic with respect to their tissues. As a result, they do not require a specialized organ to maintain water and electrolyte balance.
   b. They lose water to their environment primarily through the gills. They replace this water by drinking.
   c. Water enters epithelial cells in their gills via osmosis. Electrolytes leave the same cells via diffusion.
   d. They have specialized cells that actively pump Na^+ and Cl^- from blood into epithelial cells, so the ions can be excreted.
3. Which of the following organisms would lose the most water by osmosis across its gills?
   a. marine bony fish
   b. shark
   c. freshwater bony fish
   d. freshwater invertebrate
4. Which of the following gives the correct sequence of the regions of the nephron with respect to fluid flow?
   a. distal tubule → ascending limb of loop of Henle → descending limb of loop of Henle → proximal tubule → collecting duct
   b. ascending limb of loop of Henle → descending limb of loop of Henle → proximal tubule → distal tubule → collecting duct
   c. proximal tubule → ascending limb of loop of Henle → descending limb of loop of Henle → distal tubule → collecting duct
   d. proximal tubule → descending limb of loop of Henle → ascending limb of loop of Henle → distal tubule → collecting duct

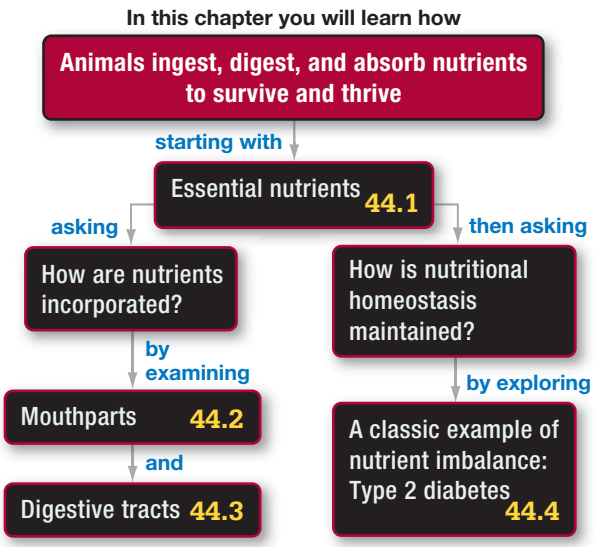
5. What effect does antidiuretic hormone (ADH) have on the nephron?
   a. It increases water permeability of the descending limb of the loop of Henle.
   b. It decreases water permeability of the descending limb of the loop of Henle.
   c. It increases water permeability of the collecting duct.
   d. It decreases water permeability of the collecting duct.
6. Fill in the blank: In Gila monsters, the organ in which water from urine is reabsorbed into the bloodstream is the _____.

TEST YOUR UNDERSTANDING

Answers are available in Appendix A

7. Which of the following organisms would you expect to have the highest concentrations of proteins that protect cells from the toxic effects of ammonia?
   a. shark
   b. freshwater bony fish
   c. terrestrial reptile
   d. mammal
8. Compare and contrast the types of nitrogenous wastes observed in animals. Identify which compound can be excreted with a minimum of water, which is most toxic, and which waste product is found in fishes, in mammals, and in insects. Which type of nitrogenous waste would you expect to find produced by embryos inside eggs laid on land?
9. The chloride cells of fish gills are sometimes called mitochondria-rich cells due to their high density of mitochondria. How does high mitochondrial density relate to the functional role of chloride cells? Would you expect other epithelial cells involved in ion transport to contain large numbers of mitochondria? Explain.
10. This chapter introduced a number of features that help terrestrial animals reduce water loss, including the layer of wax found on insect exoskeletons, the ability of insects to close spiracles, the excretion of nitrogenous wastes as insoluble uric acid, and long loops of Henle in the mammalian kidney. Predict how each of these traits differs in animals that live in very humid versus very dry habitats. How would you test your predictions?
11. Explain why mammals would not be able to produce concentrated urine if they lacked loops of Henle.
12. Scientists have noted that marine invertebrates tend to be osmoconformers, while freshwater invertebrates tend to be osmoregulators. Suggest an explanation for this phenomenon.

TEST YOUR PROBLEM-SOLVING SKILLS



Answers are available in Appendix A

13. Biologists recently have been able to produce mice that lack functioning genes for aquaporins. How does their urine compare to that of individuals with normal aquaporins?
   a. lower volume and lower osmolarity
   b. lower volume and higher osmolarity
   c. higher volume and lower osmolarity
   d. higher volume and higher osmolarity
14. Suppose a grazing mammal ingested the leaves of a plant containing the toxin ouabain. What effect would this toxin have on the mammal's urine volume? Explain.
15. You have isolated a segment of a rat nephron and introduced a solution of known composition. When you compare the fluid collected at the end of the segment with the test solution introduced at the beginning, you find that the volume has decreased by 30 percent and the Na^+ concentration has decreased by 30 percent, but the urea concentration has increased by 50 percent. What processes in this segment might account for these changes?
16. **QUANTITATIVE** To test the hypothesis that mussels are osmoconformers, researchers exposed mussels to water of varying osmolarities and then drew hemolymph samples from the mussels. Is the researchers' hypothesis supported by the data, shown below? Explain.

Water Osmolarity	Hemolymph Osmolarity
250	261
500	503
750	746
1000	992

44 Animal Nutrition

In this chapter you will learn how

A crocodile has just caught a fish. Animals obtain nutrients by ingesting food.

Animals get the two basic requirements for life—**(1)** chemical energy for synthesizing ATP and **(2)** carbon-containing compounds for building complex macromolecules—by ingesting other organisms. In short, they are heterotrophs: They eat to live.

The types of food that are available to different animals vary widely, and food is often in dangerously short supply. From these observations, you might expect animals to have evolved many different means for obtaining food and to be under intense natural selection for making efficient use of the food they have. How do animals get their food, and how do they process it? Which substances in food are used as nutrients, and how do humans and other animals maintain appropriate levels of key nutrients in their bodies?

BIG PICTURE

This chapter is part of the Big Picture. See how on pages 840–841.

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

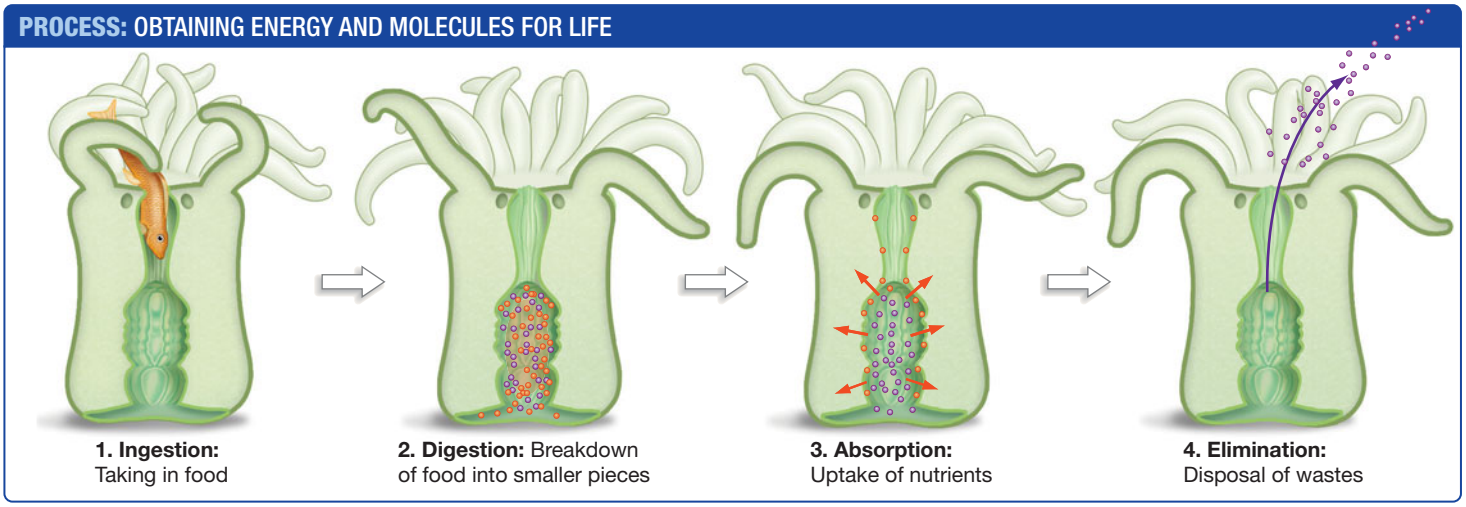


FIGURE 44.1 Animal Nutrition Is a Four-Step Process.

If you're like most people, you've probably given a fair amount of thought to the food you eat but little thought to what happens to that food once it's inside you. As a meal moves through a digestive system, its physical characteristics change dramatically. Large packets of food that enter the mouth are reduced to monomers that can be absorbed into the bloodstream.

Research on feeding and digestion is fundamental to understanding these basic aspects of animal biology, but research on animal nutrition has important practical applications as well. For example, this chapter addresses questions about why several nutrition-related diseases, including diabetes mellitus and obesity, are on the rise in many human populations.

Just as plant nutrition is fundamental to the productivity of agricultural and natural ecosystems, nutrition is a basic component of animal health and welfare. For you or any other animal to stay alive, food must be ingested, digested, and absorbed, and then the wastes must be eliminated (**FIGURE 44.1**). Let's begin with a look at what animals must eat to live.

44.1 Nutritional Requirements

Humans and other animals get the chemical energy and carbon-containing building blocks they need from carbohydrates, proteins, and fats. All these substances are carbon compounds with high potential energy. Previous chapters analyzed the structures of carbohydrates and fats (see Chapter 5 and Chapter 6), and detailed how these compounds are used to synthesize ATP and key macromolecules (see Chapter 9).

A carbohydrate, protein, or fat is an example of a **nutrient**: a substance that an organism needs to remain alive. **Food** is any material that contains nutrients.

The amount of energy provided by foods is measured in kilocalories (on food labels, kilocalories are referred to as Calories). Because fats and other lipids contain more C—H bonds than do carbohydrates such as starch and sugars, fats provide over twice the energy per gram. Specifically, carbohydrates and proteins provide about 4 kcal/g, and fats provide about 9 kcal/g.

Understanding which nutrients an individual needs, and in what amounts, are basic issues in research on human and animal nutrition. Let's consider what humans need to maintain good health.

In 1943 the Food and Nutrition Board of the U.S. National Academy of Sciences[1] published the first Recommended Dietary Allowances (RDAs). The goal of the RDAs was to specify the amount of each essential nutrient that an individual must ingest to meet the needs of most healthy people. **Essential nutrients** are nutrients that cannot be synthesized and must be obtained from the diet.

In addition to obtaining chemical energy and the "building blocks" for chemical synthesis from carbohydrates and other compounds in food, humans require several other essential nutrients:

- Of the 20 amino acids required to manufacture most proteins, humans can synthesize 12 from simpler building blocks (see Chapter 3). The others are called **essential amino acids** because they must be obtained from food.
- **Vitamins** are organic, or carbon-containing, compounds that are vital for health but are required in only minute amounts. They have a variety of roles; several function as coenzymes in critical reactions (see Chapter 3). **TABLE 44.1** (see page 884) lists a few of the vitamins for which RDAs have been established, notes their functions, and indicates the problems that develop if they are missing in the diet.

[1]The National Academy of Sciences is a group of scientists and engineers that advises the U.S. Congress on scientific and technical matters. Its Food and Nutrition Board is made up of biologists who specialize in animal nutrition.

TABLE 44.1 Some Important Vitamins Required by Humans

	Source	Function	Symptoms if Deficient
Vitamin B_1 (thiamine)	legumes, whole grains, potatoes, peanuts	formation of coenzyme in citric acid cycle	beriberi (fatigue, nerve disorders, anemia)
Vitamin B_{12}	red meat, eggs, dairy products; also synthesized by bacteria in intestine	coenzyme in synthesis of proteins and nucleic acids and in formation of red blood cells	anemia (fatigue and weakness due to low hemoglobin content in blood)
Niacin	meat, whole grains	component of coenzymes NAD^+ and $NADP^+$	pellagra (digestive problems, skin lesions, nerve disorders)
Folate	green vegetables, oranges, nuts, legumes, whole grains; also synthesized by bacteria in intestine	coenzyme in nucleic acid and amino acid metabolism	anemia
Vitamin C (ascorbic acid)	citrus fruits, tomatoes, broccoli, cabbage, green peppers	used in collagen synthesis, prevents oxidation of cell components, improves absorption of iron	scurvy (degeneration of teeth and gums)
Vitamin D	fortified milk, egg yolk; also synthesized in skin exposed to sunlight	aids absorption of calcium and phosphorus in small intestine	rickets (bone deformities) in children; bone softening in adults

- **Minerals** are inorganic substances used as components of enzyme cofactors or structural materials (see **TABLE 44.2**). Some, such as calcium and phosphorus, are needed in relatively large quantities. Others, such as iron and magnesium, are required in small or trace amounts.
- **Electrolytes** are mineral ions that influence osmotic balance and are required for normal membrane function. Sodium (Na^+), potassium (K^+), and chloride (Cl^-) are the major ions in the human body.

To obtain nutrients, animals must ingest them, usually via a mouth. The structure of animal mouthparts is therefore often highly specialized to capture specific types of food.

44.2 Capturing Food: The Structure and Function of Mouthparts

Instead of making their own food, as plants do, animals obtain the energy and nutrients they need by feeding on other organisms. Biologists assign animal feeding techniques to one of four strategies (see Chapter 33):

1. **Suspension feeders,** such as sponges and tubeworms, filter small organisms or bits of organic debris from water by means of cilia, mucus-lined "nets," or other structures.
2. **Deposit feeders,** including earthworms and sea cucumbers, swallow sediments and other types of deposited material rich in organic matter.
3. **Fluid feeders** suck or lap up fluids—like blood or nectar.
4. **Mass feeders** are the majority of animals. They seize and manipulate chunks of food by using mouthparts such as jaws and teeth, beaks, or special toxin-injecting organs.

Mouthparts as Adaptations

The types of food that animals harvest range from soupy solutions in decaying carcasses to nuts inside of hard shells. Solutions have to be lapped up; nuts have to be cracked. Given the diversity of food sources that animals exploit, it is not surprising that a wide variety of mouthpart structures have evolved to facilitate capturing and processing food.

Natural selection has closely matched the structure of animal mouthparts to their function in obtaining food. For example,

- Mammals chew their food and swallow distinct packets or boluses. The extinct mammal in **FIGURE 44.2a** illustrates one example of the many tooth shapes that evolved from the relatively simple and uniform teeth in the common ancestor of all mammals. Diversification of tooth shape has allowed mammals to exploit a wide range of foods.
- Complex skull, jawbones, and associated musculature have evolved in snakes. The highly flexible structure that results allows snakes to ingest large prey whole (**FIGURE 44.2b**).

The reason that there is such a close correlation between the structure and function of mouthparts is simple: Natural selection is particularly strong when it comes to food capture, because obtaining nutrients is so fundamental to fitness—the ability to produce offspring.

Let's pursue the correlation between mouthparts and food sources further, by analyzing the structure and function of jaws and teeth in what may be the most diverse lineage within any vertebrate family: the cichlid fishes of Africa.

A Case Study: The Cichlid Jaw

The cichlids that inhabit the Rift Lakes of East Africa are a spectacular example of **adaptive radiation**—the diversification of a

(a) The large canines of saber-toothed cats stabbed and sliced prey.

(b) A highly mobile cranium and jaws allows snakes to swallow large prey whole.

FIGURE 44.2 Mouthpart Structure Correlates with Function.

single ancestral lineage into many species, each of which lives in a different habitat or employs a distinct feeding method (see Chapter 28). Lake Victoria, for example, is home to 300 cichlids that live nowhere else.

In general, each Lake Victoria cichlid species feeds on a different specific item, but as a group they exploit almost every food source in the lake: planktonic organisms, crust-forming algae, leaflike algae, eggs, fish scales, fish fins, whole fish, plants, insects, and snails.

How can a group of closely related species exploit so many different food sources? Many fish species have pharyngeal (throat) jaws located well behind the normal oral (mouth) jaws. Non-cichlids use their pharyngeal jaws to move food down their throats, but cichlids can also use theirs to bite. This is possible

TABLE 44.2 Major Minerals and Electrolytes Required by Humans

	Source in Diet	Function	Symptoms if Deficient
Calcium (Ca)	dairy products, green vegetables, legumes	bone and tooth formation, nerve signaling, muscle response	loss of bone mass, slow growth
Chloride (Cl^-)	table salt or sea salt, vegetables, seafood	fluid balance in cells, protein digestion in stomach (HCl), acid–base balance	weakness, loss of muscle function
Fluorine (F)	fluoridated water, seafood	maintenance of tooth structure	higher frequency of tooth decay
Iodine (I)	iodized salt, algae, seafood	component of the thyroid hormones thyroxine and T_3	goiter (enlarged thyroid gland)
Iron (Fe)	meat, eggs, whole grains, green leafy vegetables, legumes	enzyme cofactor; synthesis of hemoglobin and electron carriers	anemia, weakness
Magnesium (Mg)	whole grains, green leafy vegetables	enzyme cofactor	nerve disorders
Phosphorus (P)	dairy products, meat, grains	bone and tooth formation; synthesis of nucleotides and ATP	weakness, loss of bone
Potassium (K^+)	dairy products; meat; nuts; fruits; potatoes, legumes, and other vegetables	nerve signaling, muscle response, acid–base balance	weakness, muscle cramps, loss of muscle function
Sodium (Na^+)	table salt or sea salt, seafood	nerve signaling, muscle response, blood pressure regulation	weakness, muscle cramps, loss of muscle function, nausea, confusion
Sulfur (S)	any source of protein	amino acid synthesis	swollen tissues, degeneration of liver, mental retardation

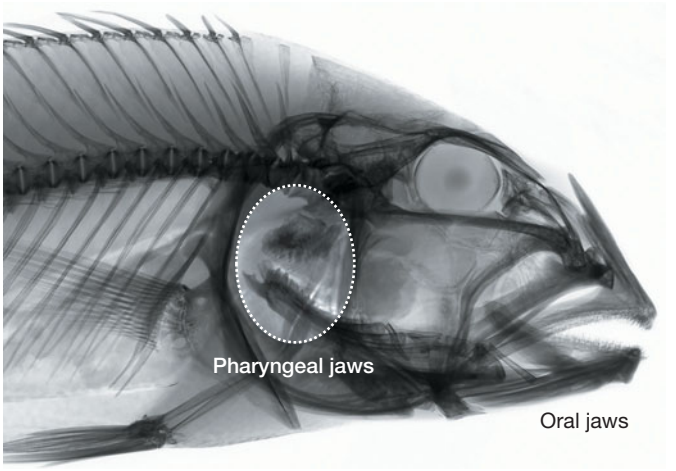

FIGURE 44.3 Rift Lake Cichlids Have Two Sets of Biting Jaws. Oral jaws capture food; pharyngeal jaws process it.

because the upper pharyngeal jaw attaches to the skull in cichlids, and because the muscles of their lower pharyngeal jaw allow it to move against the upper jaw (**FIGURE 44.3**).

In addition to acting as a second set of biting jaws that make food processing more efficient, cichlid pharyngeal jaws provide a more specialized set of toothlike structures. These protuberances vary in size and shape among cichlids, correlating with their function, such as crushing snail shells, tearing fish scales, or compacting algae (**FIGURE 44.4**).

These observations are part of a large body of evidence supporting a general pattern in animal evolution: In response to natural selection, mouthparts have diversified to exploit a diversity of food sources. The structures of jaws, teeth, and other mouthparts correlate with their functions in harvesting and processing food.

44.3 How Are Nutrients Digested and Absorbed?

Animals ingest just about every type of food conceivable. **Ingestion** is the process of bringing food into the **digestive tract**—also known as the alimentary (literally, "nourishment") canal or gastrointestinal (GI) tract. The digestive tract is a chamber or tube where **digestion,** the breakdown of food, takes place. Interestingly, food in the digestive tract is technically *outside* the body. Various glands secrete enzymes into the digestive tract that digest food into particles small enough for efficient **absorption**—the uptake of specific ions and molecules across the membrane of the digestive tract.

Digestion is a key process in animals because they, unlike plants, unicellular organisms, and certain parasites, do not acquire nutrients as individual molecules. Instead, they take in packets of food that must be broken down into small pieces. Nutrients must be extracted from the small pieces, and waste materials must be eliminated. How and where does this processing occur?

An Introduction to the Digestive Tract

Digestive tracts come in two general designs:

1. **Incomplete digestive tracts** have a single opening that doubles as the location where food is ingested and wastes are eliminated. The mouth opens into a chamber, called a gastrovascular cavity, where digestion takes place (**FIGURE 44.5**).
2. **Complete digestive tracts** have two openings—they start at the mouth and end at the anus. The interior of this tube communicates directly with the external environment via these openings (**FIGURE 44.6**).

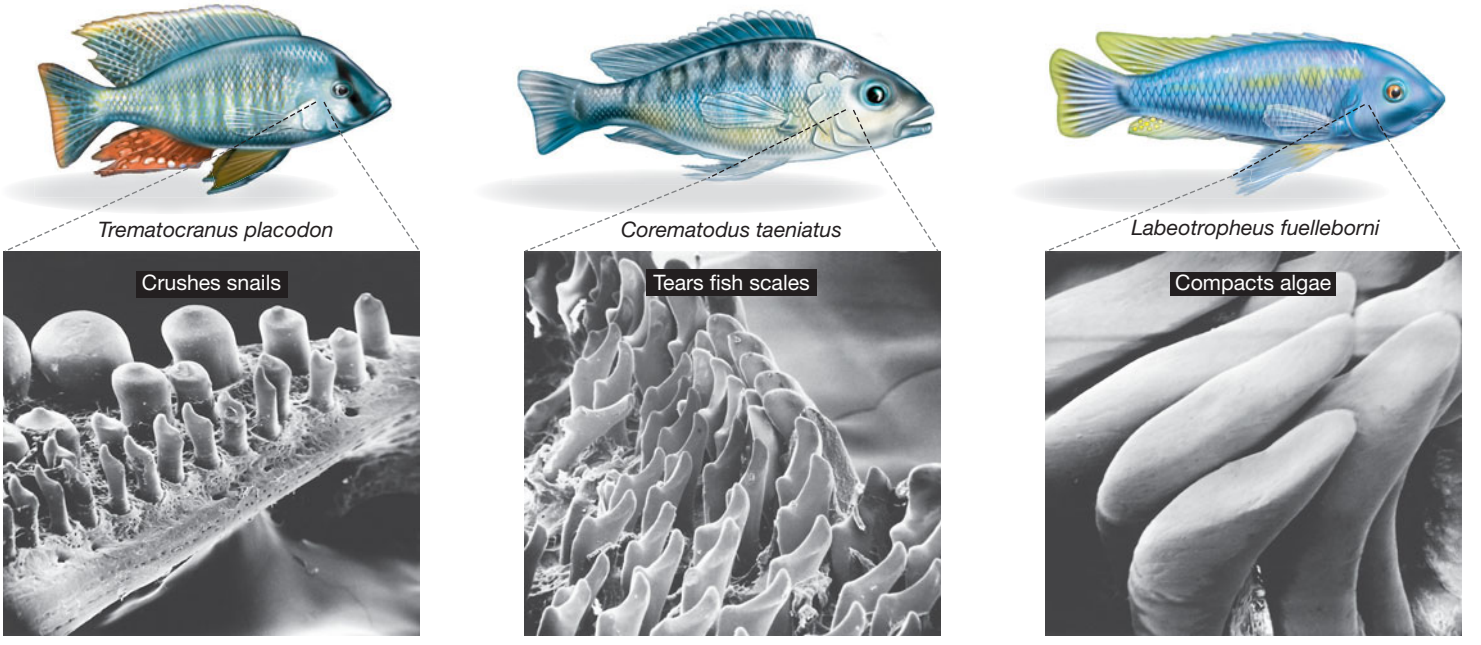

FIGURE 44.4 In Cichlids, the Structure of the Pharyngeal Jaw Correlates with the Type of Food Ingested.

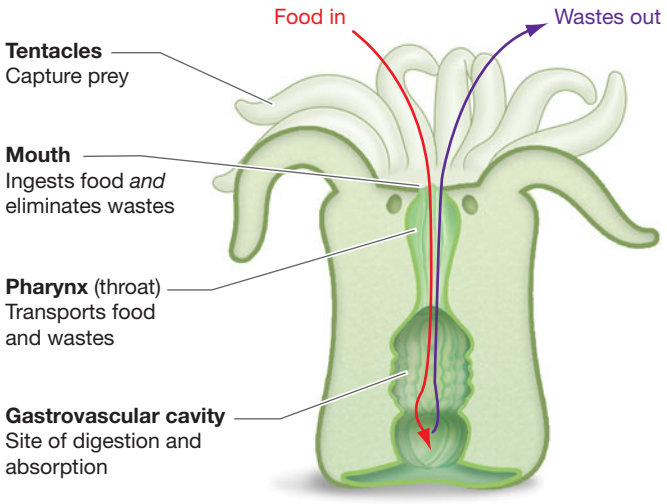

FIGURE 44.5 Anemones Have an Incomplete Digestive Tract. Anemones use stinging cells located on their tentacles to capture small fishes, crustaceans, and other prey. Prey are taken into the mouth and digested in the gastrovascular cavity; then wastes are excreted through the mouth.

A tubelike digestive tract has three advantages:

1. It allows animals to feed on large pieces of food, expanding the range of food sources that can be ingested.
2. Different chemical and physical processes can be confined to different compartments within the canal, so that they occur independently of each other and in a prescribed sequence. The stomach, for example, provides an acidic environment for digestion. Ingested material proceeds from there to the small intestine, where enzymes are specialized to function in a slightly alkaline environment.
3. Because there is a one-way flow of food and wastes, material can be ingested and digested without interruption, instead of alternating with waste removal as occurs in an incomplete digestive tract.

The digestive tract is only one part of the digestive system, however. Several vital organs and glands are connected to the digestive tract. These accessory structures contribute digestive enzymes and other products to specific portions of the tract. They include the salivary glands, liver, gallbladder, and pancreas (see Figure 44.6).

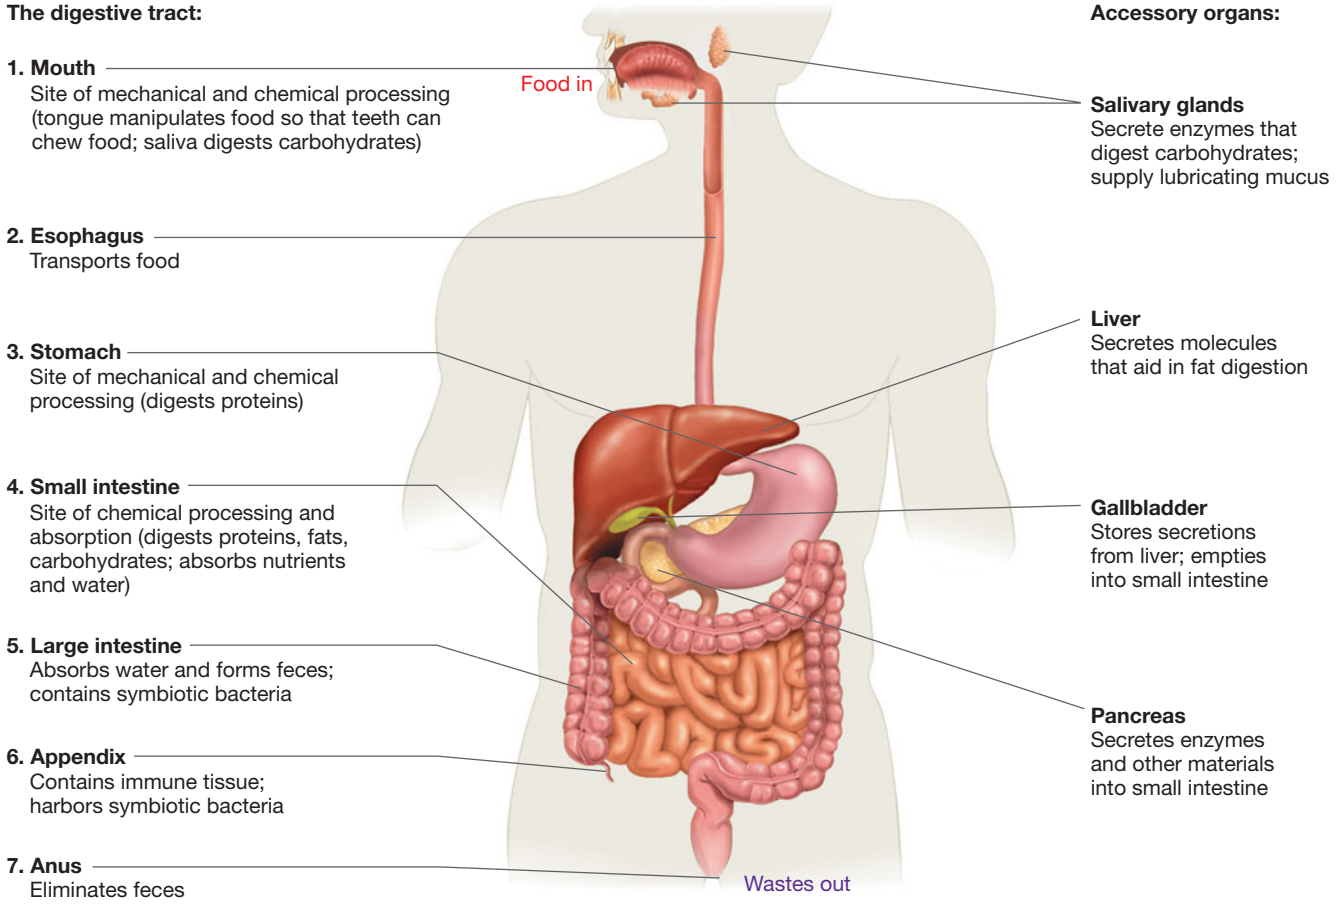

FIGURE 44.6 Humans Have a Complete Digestive Tract. In humans, the digestive tract is a tube that runs from the mouth to the anus. The salivary glands, liver, gallbladder, and pancreas are not part of the tract itself. Instead, they secrete material into the tract at specific points.

An Overview of Digestive Processes

Before analyzing the function of each component of the digestive system in detail, let's consider the general changes that happen to food on its way through the digestive tract. In this brief overview and in the detailed discussion that follows, humans will serve as a model species—simply because so much is known about human digestion.

In mammals, digestion begins with the tearing and crushing activity of teeth. Chewing reduces the size of food particles and softens them. Humans augment the mechanical breakdown of food by their use of knives and cooking. In fact, the invention of cutting tools and cooking, which make food easier to chew, is the leading hypothesis to explain why average tooth size has declined steadily over the past several million years of human evolution.

Distinct chemical changes occur as food moves through each compartment in the digestive tract (**FIGURE 44.7**):

- In the mouth, enzymes in the saliva begin the chemical breakdown of carbohydrates.
- Chemical digestion of protein begins in the acidic environment of the stomach.
- Chemical processing of the three major types of macromolecules—carbohydrates, proteins, and lipids—is completed in the small intestine. The small molecules that result from the digestion of these macromolecules are absorbed in the small intestine, along with water, vitamins, and ions.
- In the large intestine, or colon, more water is absorbed. The material remaining in the large intestine is **feces,** which are eventually excreted.

Because digestion is so important to understanding how animal bodies work, let's analyze each step in more detail. As the following sections track food on its journey from the mouth to the anus in humans—a particularly well-studied animal—watch for notes highlighting the diversity of structures found in the digestive tracts of nonhuman animals.

The Mouth and Esophagus

If you hold a cracker in your mouth long enough, it will start to taste sweet. The sensation occurs because an enzyme in your saliva hydrolyzes some of the starch molecules in the cracker to

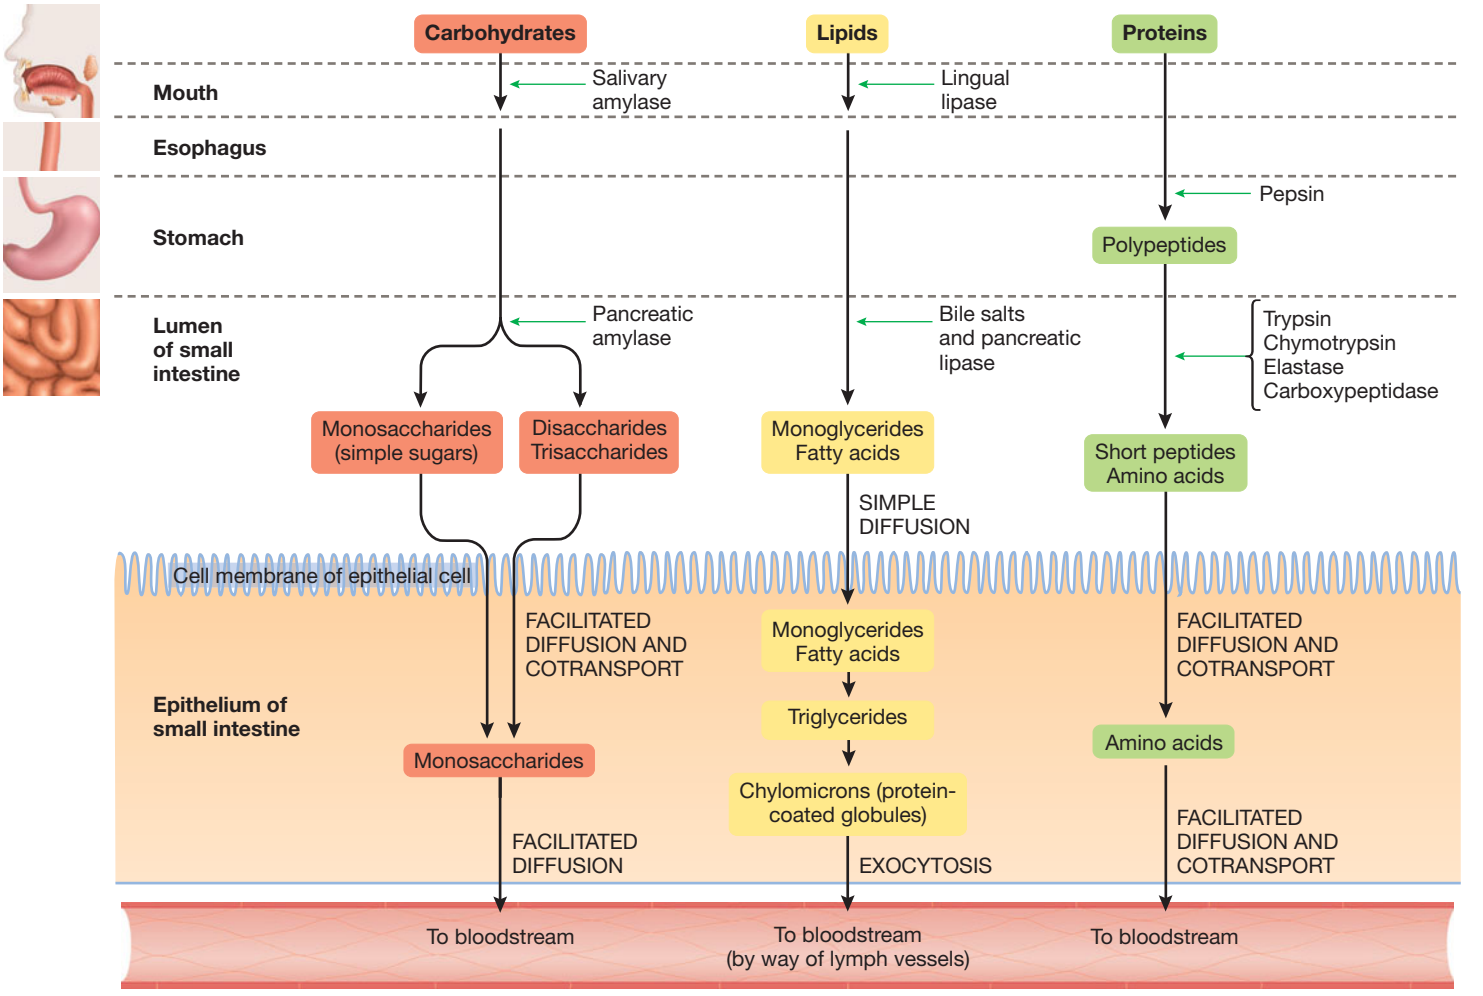

FIGURE 44.7 Carbohydrates, Lipids, and Proteins Are Processed in a Series of Steps. Three key types of macromolecules enter the digestive system (top of diagram). As they proceed through the digestive tract, they are broken apart by various enzymes. Simple sugars, fatty acids, and amino acids then enter epithelial cells in the small intestine and are transported to the bloodstream.

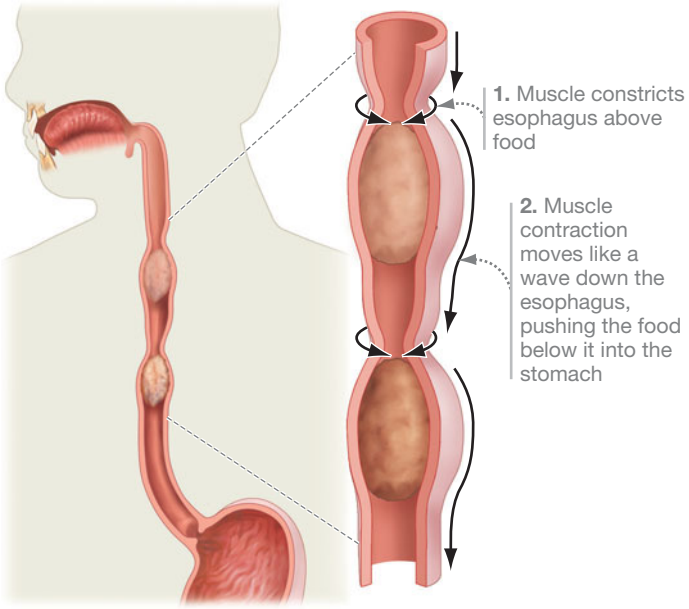

FIGURE 44.8 In the Esophagus, Peristalsis Transports Food to the Stomach. Peristalsis is a wave of muscle contraction that constricts the esophagus behind food and expands it in front of food. The wave of contraction begins at the oral end of the esophagus and propels the food toward the stomach.

maltose. Maltose is a disaccharide that is split in the small intestine to form two glucose monomers.

Starch breakdown was actually the first enzyme-catalyzed reaction ever discovered. In the early 1800s several researchers found that a component of certain plant extracts digested starch; in 1831 the same activity was discovered in human saliva.

Digestion Starts in the Mouth **Salivary amylase,** the enzyme responsible for starch digestion in the mouth is one of the best-studied enzymes. Amylase cleaves bonds to release maltose from starch and glycogen, initiating the digestion of starch.

Cells in the tongue synthesize and secrete another important salivary enzyme, **lingual lipase** (lingual refers to the tongue), which begins the digestion of lipids by breaking triglycerides into diglycerides and fatty acids.

Salivary glands in the mouth not only produce amylase but also release water and glycoproteins called mucins. When mucins contact water, they form the slimy substance called **mucus.** The combination of water and mucus makes food soft and slippery enough to be swallowed.

Peristalsis Moves Material Down the Esophagus Once food is swallowed, it enters a muscular tube called the **esophagus,** which connects the mouth and stomach. A wave of muscular contractions called **peristalsis** propels food down the esophagus. About 6 seconds after being swallowed, food reaches the bottom of the esophagus. Because peristalsis actively moves material along the esophagus, you can swallow even when your mouth is lower than your stomach, such as when you bend over to drink from a stream.

In response to nerve signals, the muscles in the esophagus contract and relax in a coordinated fashion (**FIGURE 44.8**). The resulting wave of muscle contractions propagates down the tube, propelling the food mass ahead of it. These nerve signals are not the result of conscious choice but are a reflex—an automatic reaction to a stimulus—that is stimulated by the act of swallowing.

A Modified Esophagus: The Bird Crop In an array of bird species, the esophagus has a prominent, widened segment called the **crop** where food can be stored and, in some cases, processed.

The structure and function of the crop varies among the bird species that have one. In many groups, the crop is a simple sac that holds food and regulates its flow into the stomach. In these species, the crop is interpreted as an adaptation that allows individuals to eat a large amount in a short time; they then retreat to a safe location while digestion occurs. In addition, some birds store food in their crops and then regurgitate it into the mouths of their young.

The crop has independently evolved into a digestive organ in two leaf-eating species of bird. Leaves are difficult to digest because they contain a large amount of cellulose (see Chapter 5). In the enlarged crop of species called the hoatzin and kakapo, bacteria that are capable of breaking down cellulose perform digestion. The bacterial cells, along with the fatty acids that result from bacterial metabolism, leak out of the crop into the stomach and are used as food by the bird.

The Stomach

Although little if any digestion occurs in the esophagus of most animals, the situation changes dramatically when food reaches the stomach. The **stomach** is a tough, muscular pouch in the digestive tract, bracketed on both ends by ringlike muscles called **sphincters,** which control the passage of material (**FIGURE 44.9**).

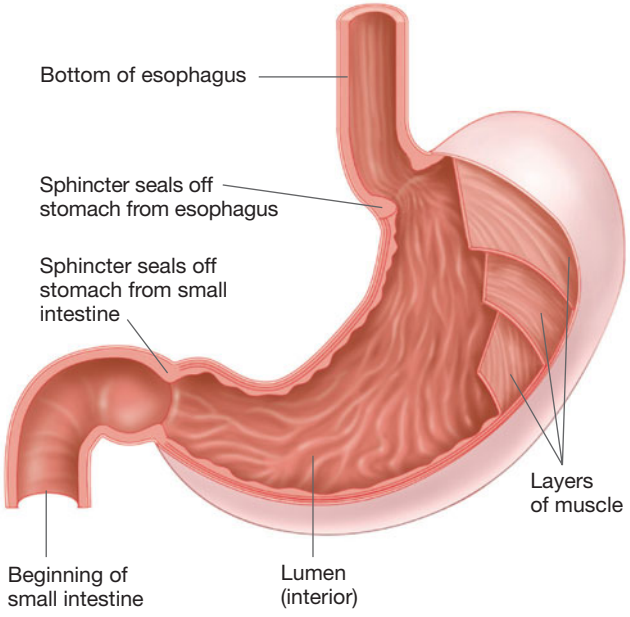

FIGURE 44.9 The Stomach Is a Muscular Pocket of the Digestive Tract. The stomach provides an acidic environment for protein digestion. Its muscular contractions mix food and break it into smaller pieces.

When a meal fills the stomach, muscular contractions churn and mix the stomach contents to a uniform consistency and solute concentration. A certain amount of mechanical breakdown of food also results from this churning. The other main function of the stomach is the partial digestion of proteins.

Compared with the mouth or esophagus (or virtually any other tissue), the lumen of the stomach is highly acidic. Early researchers documented this fact by analyzing vomit or material collected by sponges that were tied to strings, swallowed, and pulled back up; chemists confirmed that the predominant acid in the stomach is hydrochloric acid (HCl).

Not long after this discovery, a physician named William Beaumont established that digestion takes place in the stomach. He reached this conclusion through an extraordinary series of experiments on a young man named Alexis St. Martin.

The Stomach as a Site of Protein Digestion In 1822, when St. Martin was 19 years old, a shotgun accidentally discharged into his abdomen, leaving a series of wounds. Despite repeated attempts, Beaumont was unable to close a hole in St. Martin's stomach. Eventually Beaumont inserted a small tube through the opening; the tube remained in St. Martin's body for the rest of his life. (Today, biologists insert tubes into various parts of the digestive tract of cows or sheep to study how these animals digest different types of feed.)

With the tube in place, Beaumont was able to tie a string onto small pieces of meat or vegetables, insert the food directly into St. Martin's stomach, and draw it out after various intervals. Beaumont also removed liquid from inside the stomach and observed how this gastric (stomach) juice acted on food in vitro. His experiments showed that gastric juice digests food—particularly meat.

Theodor Schwann later purified the enzyme that is responsible for digesting proteins in the stomach and named it **pepsin.** Because it destroys proteins, biologists hypothesized that pepsin must be synthesized and stored in cells while it is in an inactive form—otherwise it would kill the cells that make it.

In 1870 a biologist established through careful microscopy the presence of granules in specialized stomach cells called chief cells. These granules were hypothesized to be a pepsin precursor. Follow-up work confirmed this hypothesis. The precursor compound, which came to be called pepsinogen, is converted to active pepsin by contact with the acidic environment of the stomach.

Secretion of a protein-digesting enzyme in inactive form is important: It prevents destruction of proteins in the cells where the enzyme is synthesized.

Which Cells Produce Stomach Acid? The acidic environment of the human stomach denatures (unfolds) proteins so that pepsin can digest them efficiently. But where does the acid come from?

Researchers who were studying the anatomy of the stomach wall noticed clusters of distinctive **parietal cells** located in pits in the stomach lining (**FIGURE 44.10a**). An investigator also

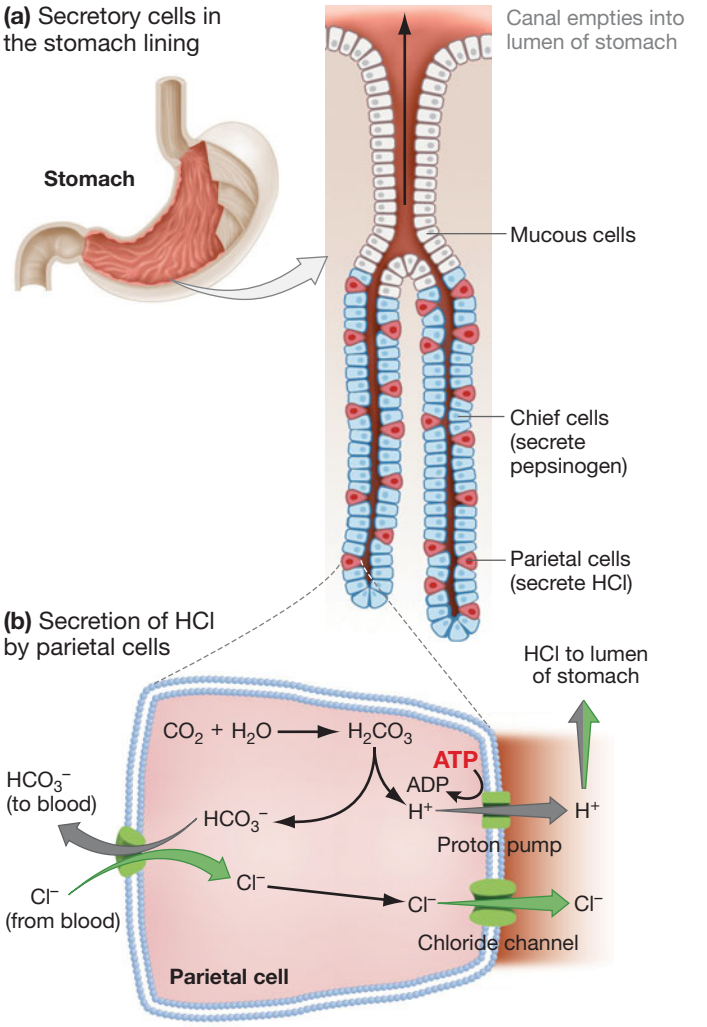

FIGURE 44.10 Cells in the Stomach Lining Secrete Mucus, Pepsinogen, and Hydrochloric Acid.

documented that the shape and activity of these cells appeared to vary as the digestion of a meal proceeded. Based on these observations, he inferred that parietal cells are the source of the HCl in gastric juice, which may have a pH as low as 1.5.

Earlier microscopists had shown that another type of cell, called a **mucous cell,** secretes additional mucus that is found in gastric juice. Mucus lines the gastric epithelium and protects the stomach from damage by HCl. To summarize, these anatomical studies showed that the epithelium of the stomach contains several types of secretory cells, each of which is specialized for a particular function.

How Do Parietal Cells Secrete HCl? The first clue to how parietal cells manufacture HCl emerged in the late 1930s, when a researcher found a high concentration of an enzyme called carbonic anhydrase in parietal cells.

This result was interesting because **carbonic anhydrase** catalyzes the formation of carbonic acid (H_2CO_3) from carbon dioxide and water. In solution, the carbonic acid that is formed

immediately dissociates to form a proton (H^+) and the bicarbonate ion (HCO_3^-):

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$$

A second clue to the formation of HCl came in the 1950s, when transmission electron microscopes allowed researchers to analyze parietal cells at high magnification (see **BioSkills 11** in Appendix B). The micrographs showed that parietal cells are packed with mitochondria. Because mitochondria produce ATP, the structure of parietal cells suggested that they might function in active transport.

Later work confirmed this hypothesis by showing that the protons formed by the dissociation of carbonic acid are actively pumped into the lumen of the stomach. Subsequent studies showed that chloride ions from the blood enter parietal cells in exchange for bicarbonate ions, via a cotransport protein, and then move into the lumen through a chloride channel. **FIGURE 44.10b** diagrams the current model for HCl production.

Ulcers as an Infectious Disease An **ulcer** is an eroded area in an epithelium; it exposes the underlying tissues to damage. Ulcers in the lining of the stomach or in the duodenum—the initial section of the small intestine—can cause intense abdominal pain.

For decades, physicians thought that gastric and duodenal ulcers resulted from the production of excess acid in the stomach. They treated ulcers by prescribing alkaline compounds (bases—see Chapter 2) that neutralized hydrochloric acid in the stomach. In the 1980s, however, scientists discovered that most ulcers are associated with infections from a bacterium called *Helicobacter pylori*. Physicians now routinely prescribe antibiotics to relieve ulcers.

The Ruminant Stomach It is common for animals to have a stomach or stomach-like organ. The structure and function of this organ can vary, however, depending on the nature of the diet. In cattle, sheep, goats, deer, antelope, giraffe, and pronghorn—species that are collectively called **ruminants**—the stomach is specialized for digesting cellulose—not proteins.

Animals do not produce the enzymes required to digest cellulose. Yet cellulose is the main carbohydrate in the leaves, stems, and twigs that ruminants ingest.

Like the hoatzin and kakapo birds described earlier in this chapter, ruminants are able to harvest energy from cellulose thanks to a combination of specialized anatomical structures and symbiotic relationships with bacteria and unicellular protists. The microbes ferment the cellulose to produce food for themselves; meanwhile, other by-products of the fermentation, as well as some of the microbes themselves, are used as food by the ruminant. This is an example of **symbiosis,** in which members of two different species live in close contact with each other.

As **FIGURE 44.11** shows, ruminant mammals have four-chambered stomachs.

1. Food initially enters the largest chamber, the rumen, which serves as a fermentation vat. The rumen is packed with symbiotic bacteria and protists. These organisms have enzymes called **cellulase** capable of breaking apart the chemical bonds in cellulose, yielding glucose. The rumen is an oxygen-free environment, and the symbiotic organisms produce ATP from this glucose via fermentation, releasing fatty acids as a by-product (see Chapter 9). These fatty acids are absorbed by the ruminant and used as an energy source.
2. The chamber adjacent to the rumen, called the reticulum, is similar in function. After plant material has been partially digested in the rumen and the reticulum, the animal regurgitates portions of that material into its mouth, forming a cud. The ruminant chews that regurgitated material further to enhance mechanical breakdown and then re-swallows it.
3. Processed food that moves out of the rumen enters the third chamber, or omasum, where water and some minerals are absorbed.
4. The final chamber is the abomasum, which contains the ruminant's own digestive enzymes and corresponds to a true stomach.

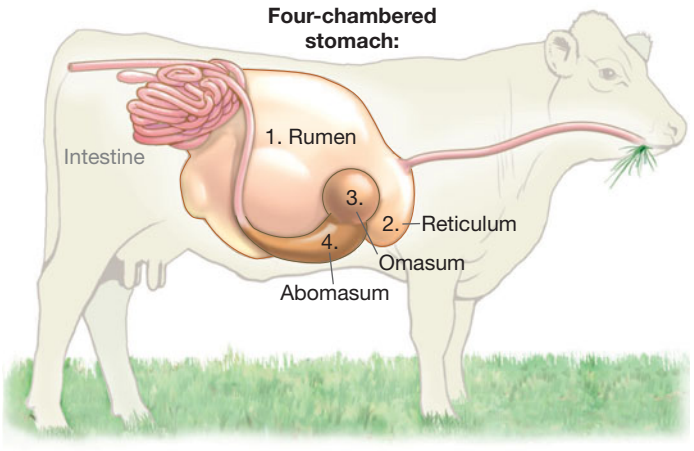

FIGURE 44.11 Ruminant Stomachs Facilitate the Digestion of Cellulose by Symbiotic Organisms. Ruminants obtain many of their nutrients from symbiotic bacteria and protists that live in the rumen and reticulum chambers of the stomach.

Most of a ruminant's food consists of **(1)** fatty acids and other compounds produced as waste products of fermentation reactions in symbiotic organisms, and **(2)** the symbiotic cells themselves.

The Avian Gizzard The avian gizzard is another prominent type of modified stomach. Birds do not have teeth and cannot chew food into small pieces. Instead, most species swallow sand and small stones that lodge in the gizzard. As this muscular sac contracts, food is pulverized by the grit.

The gizzard is particularly large and strong in bird species that eat coarse foods such as seeds and nuts. The gizzard of a wild turkey, for example, can crack large walnuts.

Like the crop, the gizzard is interpreted as an adaptation that allows birds to ingest food quickly—without needing to chew—and digest it later. Biologists invoke the same hypothesis to explain why

ruminants chew cud. The ability to regurgitate material and finish chewing while hiding in a place safe from predators is thought to increase fitness.

The Small Intestine

In humans, the stomach is responsible for mixing the contents of a meal into a homogenous slurry, breaking the food up mechanically, and providing the acid and enzymes required to partially digest proteins. Peristalsis in the stomach wall then moves small amounts of material through the valve created by a sphincter muscle at the base of the stomach and into the small intestine.

The **small intestine** is a long tube that is folded into a compact space within the abdomen. In the small intestine, partially digested food mixes with secretions from the pancreas and the liver and begins a journey of about 6 m (20 ft). When passage through this structure is complete, digestion is finished, and most nutrients—along with large quantities of water—have been absorbed.

Folding and Projections Increase Surface Area The surface area available for nutrient and water absorption in the small intestine is nothing short of remarkable (see Chapter 42). As **FIGURE 44.12** shows, the organ's epithelial tissue is folded and covered with fingerlike projections called **villi** (singular: **villus**). In turn, the cells that line the surface of villi have tiny projections on their apical surfaces called **microvilli** (singular: **microvillus**). Microvilli project into the lumen of the digestive tract.

If the small intestine lacked folds, villi, and microvilli, it would have a surface area of about 3300 cm^2 (3.6 ft^2). Instead, the epithelium covers about 2 million cm^2 (over 2200 ft^2)—an area about the size of a tennis court.

The enormous surface area of the small intestine increases the efficiency of nutrient absorption. And because each villus contains blood vessels and a lymphatic vessel called a **lacteal**, nutrients pass quickly from epithelial cells into the body's transport systems. (The circulatory system and lymphatic system are analyzed in Chapter 45 and Chapter 51, respectively.)

✔ If you understand the importance of surface area in the small intestine, you should be able to explain why surface area is so much higher in this structure than it is in the stomach or esophagus.

To understand how digestion is completed and absorption occurs, let's explore what happens to proteins, lipids, and carbohydrates as they move through this section of the digestive tract—again using humans as a model organism.

Protein Processing by Pancreatic Enzymes The acidic environment of the stomach destroys the secondary and tertiary structures of proteins. In addition, pepsin cleaves the peptide bonds next to certain amino acids, reducing long polypeptides to relatively small chains of amino acids. In the small intestine, protein digestion is completed so that individual amino acids can enter the bloodstream and be transported to cells throughout the body.

How do these final stages of protein digestion occur? By the end of the nineteenth century, it was established that enzymes in the small intestine digest polypeptides to monomers. Later work showed that each of these protein-digesting enzymes, or **proteases,** is specific to certain types or configurations of amino acids in a polypeptide chain. Thus, a suite of proteases is required to completely digest polypeptides to amino acid monomers.

In addition, by 1900 biologists had determined that proteases are synthesized in an inactive form in the **pancreas,** which is connected to the small intestine by the pancreatic duct. Like the production of inactive pepsinogen by chief cells in the stomach,

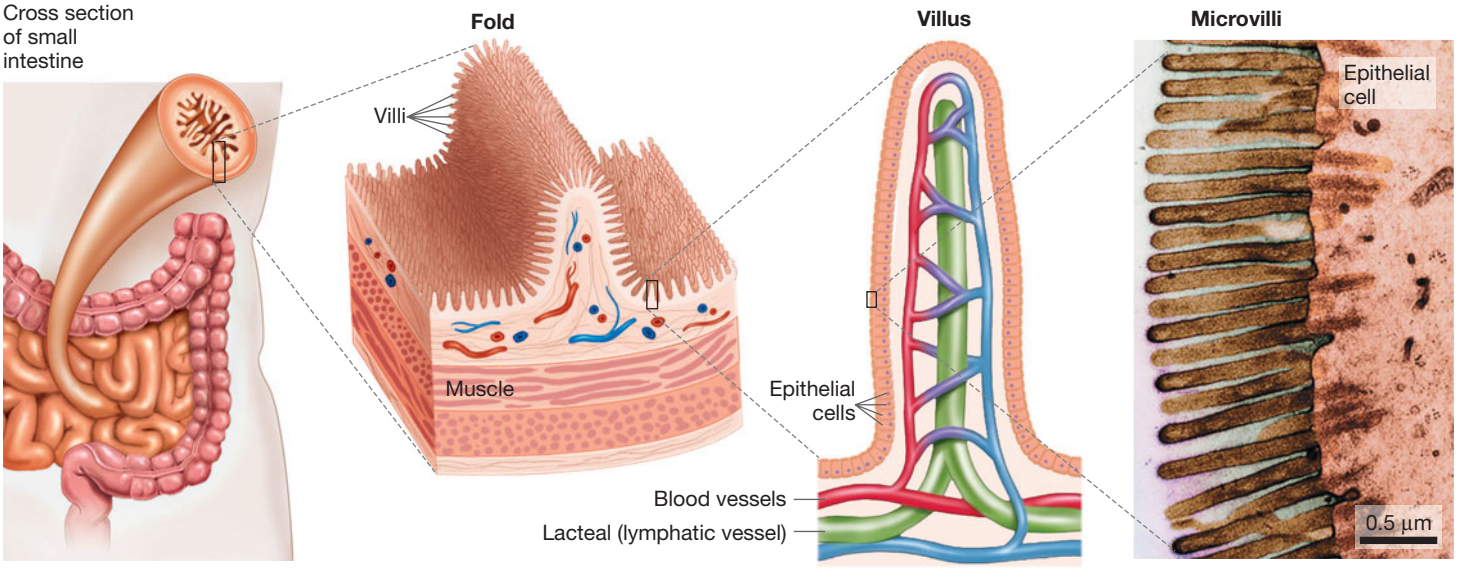

FIGURE 44.12 The Small Intestine Has an Extremely Large Surface Area. The villi that project from folds in the small intestine are covered with microvilli (colorized brown in the micrograph at the far right).

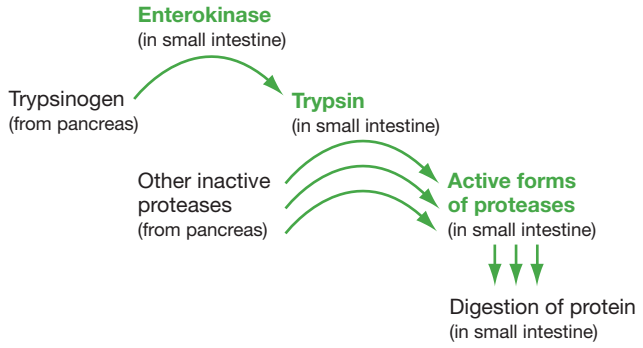

FIGURE 44.13 Enterokinase Triggers an Enzyme-Activation Cascade in the Small Intestine.

the production of digestive enzymes in an inactive conformation prevents pancreatic cells from digesting themselves.

It took decades of work to understand how pancreatic enzymes are activated in the small intestine. In 1900 a researcher showed that contact with juice from the upper part of the small intestine activates pancreatic enzymes. Activation ceased to occur when he heated the intestinal juice, and because he knew that heat denatures enzymes (like all proteins), he hypothesized that the agent responsible for activating the pancreatic enzymes was also an enzyme. He called the unknown enzyme enterokinase.

Decades later, a researcher succeeded in purifying a pancreatic enzyme called trypsinogen and demonstrated that enterokinase activates it in vitro by phosphorylating it, resulting in the active enzyme **trypsin.** Trypsin then triggers the activation of other protein-digesting enzymes, such as chymotrypsin, elastase, and carboxypeptidase (**FIGURE 44.13**). These enzymes are also synthesized by the pancreas and secreted in an inactive form. Once these enzymes are activated in the upper reaches of the small intestine, each begins cleaving specific peptide bonds. Eventually, polypeptides are broken up into amino acid monomers.

What Regulates the Release of Pancreatic Enzymes? Digestive enzymes are needed only when food reaches the small intestine. Based on this simple observation, it was logical to predict that their release would be carefully controlled.

A classic experiment by William Bayliss and Ernest Starling, published in 1902, established how pancreatic enzymes are controlled. Bayliss and Starling began by cutting the nerves that connect to the pancreas and small intestine of a dog. Electrical signaling between the two organs via neurons was now impossible. But when the researchers introduced a weak HCl solution into the upper reaches of the animal's small intestine, to simulate the arrival of material from the stomach, its pancreas secreted enzymes in response.

This observation was startling: The small intestine had successfully signaled the pancreas that food had arrived, even though the nerves connecting the two organs had been cut.

Starling hypothesized that a chemical messenger must be involved, and that the chemical messenger must originate in the small intestine and travel to the pancreas via the blood. He tested this idea by cutting off a small piece of the small intestine, grinding it up, and injecting the resulting solution into a vein in the animal's neck (see Figure 49.4). Minutes later, the pancreas sharply increased secretion.

Bayliss and Starling had discovered the first **hormone**—a chemical messenger that influences physiological processes at very low concentrations. The molecule they detected, which they called **secretin,** is produced by the small intestine in response to the arrival of food from the stomach.

Follow-up work showed that secretin's primary function is to induce a flow of bicarbonate ions (HCO_3^-) from the pancreas to the small intestine. The bicarbonate is important because it neutralizes the acid arriving from the stomach.

Researchers also discovered a second hormone produced in the small intestine. Called cholecystokinin (pronounced *ko-la-sis-toe-KIN-in*), it induces secretion from the liver and gallbladder as well as the pancreas. **Cholecystokinin** (literally, "bile-bag-mover") stimulates the secretion of digestive enzymes from the pancreas and the secretion of molecules from the gallbladder that aid in processing lipids.

Hormones are involved in stomach function as well. For example, after being stimulated by nerves or the arrival of food, certain stomach cells produce the hormone **gastrin.** In response, parietal cells begin secreting HCl.

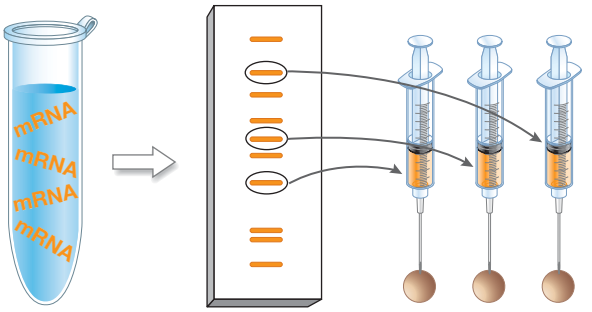
How Are Carbohydrates Digested and Transported? In addition to manufacturing protein-digesting enzymes, the pancreas produces nucleases and an amylase that is similar to the salivary enzyme introduced earlier. **Nucleases** digest the RNA and DNA in food; **pancreatic amylase** continues the digestion of carbohydrates that began in the mouth. Carbohydrate digestion ends with the release of monosaccharides such as glucose.

When digestion of proteins and carbohydrates is complete in the small intestine, the resulting slurry is a mixture of nutrients, water, indigestible plant fibers from food, and bacterial cells that live symbiotically in the gut. What molecular mechanisms make it possible for epithelial cells to transport nutrients, like glucose, from the lumen of the small intestine into the bloodstream?

Two general principles apply to carbohydrate and protein absorption: **(1)** It is highly selective, meaning proteins in the plasma membranes of microvilli are responsible for bringing specific nutrients into the cell; and **(2)** it is active, meaning ATP is expended to bring nutrients into the epithelium across a concentration gradient.

Work over the past several decades has demonstrated both these principles. One of the key results grew out of a series of experiments during the 1980s, which established that glucose absorption depends on the presence of an electrochemical gradient favoring an influx of sodium ions into the epithelium. Based on this finding, biologists hypothesized that the apical membranes of epithelial cells must contain a series of cotransporters—membrane proteins that would bring a nutrient molecule into the cell along with sodium ions. To confirm that such a sodium–glucose cotransporter exists, investigators set out to find the gene that codes for the hypothesized membrane protein.

The researchers began by purifying mRNAs from rabbit intestinal cells (**FIGURE 44.14**), which presumably were transcribing the cotransporter genes. Then the team separated the mRNAs by size via gel electrophoresis (see **BioSkills 9** in Appendix B) and injected one of each type of mRNA into a series of frog eggs—cells that do not normally transport glucose. The frog cells translated the rabbit mRNAs into proteins.



RESEARCH

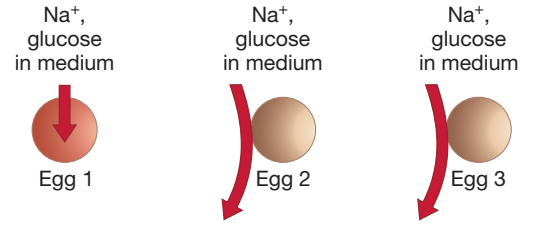
QUESTION: How is glucose transported into epithelial cells of the small intestine?

HYPOTHESIS: Glucose enters epithelial cells along with sodium ions via a Na^+-glucose cotransporter protein.

NULL HYPOTHESIS: Glucose transport does not depend on Na^+ transport.

EXPERIMENTAL SETUP:

1. Purify mRNA from intestinal cells.



2. Separate mRNAs by size via gel electrophoresis.

3. Inject individual mRNAs into frog eggs. Test each egg—can it absorb Na^+ and glucose?

PREDICTION: An egg will be able to absorb Na^+ and glucose, because it received the mRNA that codes for the Na^+-glucose cotransporter.

PREDICTION OF NULL HYPOTHESIS: None of the eggs will be able to absorb Na^+ and glucose.

RESULTS:

CONCLUSION: The egg that absorbs Na^+ and glucose received the mRNA from the Na^+-glucose cotransporter gene.

FIGURE 44.14 The Experimental Protocol for Locating the Na^+-Glucose Cotransporter Gene.

SOURCE: Wright, E. M. 1993. The intestinal Na^+/glucose cotransporter. *Annual Review of Physiology* 55: 575–589.

✔**QUESTION** Why did the researchers inject the RNAs into frog eggs instead of into rabbit epithelial cells?

When tested, one of the experimental eggs was able to import Na^+ and glucose in tandem. The biologists inferred that this egg had received the mRNA for the rabbit Na^+-glucose cotransporter. The researchers made a DNA copy of the mRNA (using techniques introduced in Chapter 20), analyzed it to determine the sequence of the gene, and from that inferred the amino acid sequence of the membrane protein.

The discovery of the Na^+-glucose cotransporter inspired a three-step model for glucose absorption:

1. Na^+/K^+-ATPase (sodium–potassium pump) in the basolateral membrane of the epithelial cells creates an electrochemical gradient that favors the entry of Na^+.
2. Glucose from digested food enters the cell along with sodium via the Na^+-glucose cotransporter in the apical membrane.
3. Glucose diffuses into nearby blood vessels through a glucose carrier in the basolateral membrane.

If this configuration of pumps, cotransporters, and carriers sounds familiar, there is a good reason: The same combination of membrane proteins occurs in the proximal tubule of the kidney, where the proteins are responsible for the reabsorption of sodium and glucose from urine (see Chapter 43).

Follow-up work showed that in the small intestine—just as in the proximal tubule—other cotransporters are responsible for the absorption of other monosaccharides and of amino acids, and specific channels and carriers in the basolateral membrane are responsible for the transport of each substance to the blood.

Digesting Lipids: Bile and Transport The pancreatic secretions include digestive enzymes that act on fats, in addition to enzymes that act on proteins and carbohydrates. Like the lingual lipase added to saliva in the mouth, the enzyme **pancreatic lipase** breaks certain bonds present in complex fats and results in the release of fatty acids and other small lipids.

Recall that fats are insoluble in water (see Chapter 6). As a result, they tend to form large globules as they are churned in the stomach. Before pancreatic lipase can act, the large fat globules that emerge from the stomach must be broken up—a process known as **emulsification.**

In the small intestine, emulsification results from the action of small molecules called bile salts. As **FIGURE 44.15** shows, bile salts function like the detergents that researchers use to break up the lipids in plasma membranes (see Chapter 6).

Bile salts are synthesized in the **liver,** an organ that performs an array of functions related to digestion, and secreted in a complex solution called **bile,** which is stored in the **gallbladder.** When bile enters the small intestine, it raises the pH and emulsifies fats. Once fats are broken into small globules, which increases their surface area, they can be attacked by pancreatic lipase and digested. **TABLE 44.3** summarizes the major digestive enzymes.

The monoglycerides and fatty acids released by lipase activity enter small intestine epithelial cells by simple diffusion and are processed into protein-coated globules called chylomicrons, which move by exocytosis into lacteals—see Figure 44.12—near

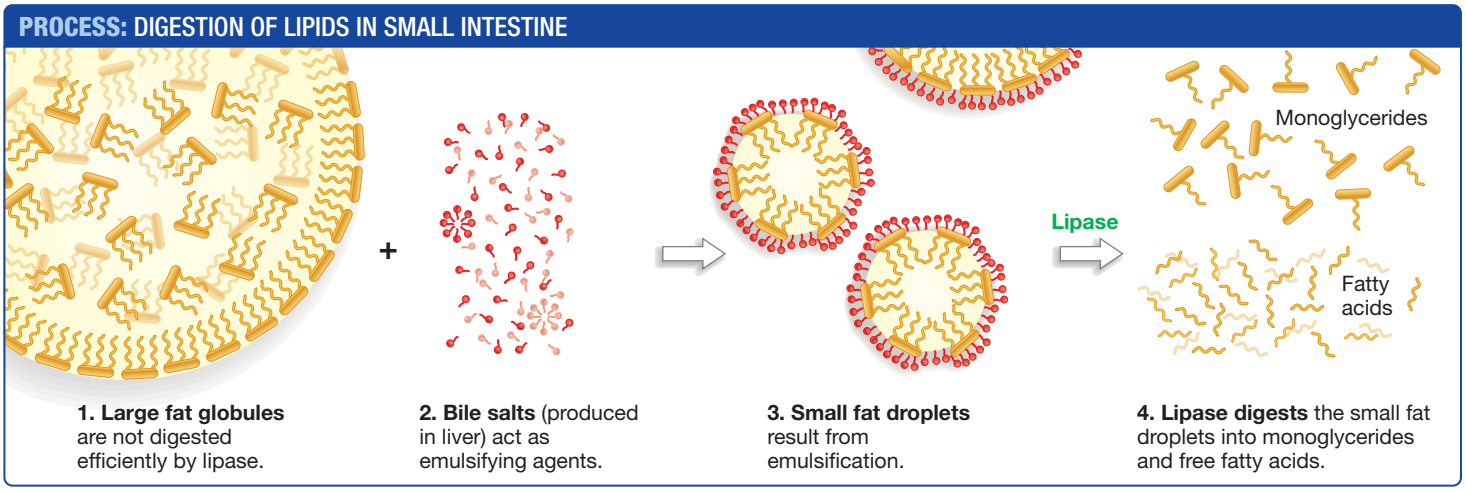


FIGURE 44.15 Emulsifying Agents and Lipases Digest Lipids in the Small Intestine. Once bile salts break up large fat globules, lipase can digest fats efficiently.

SUMMARY TABLE 44.3 Digestive Enzymes in Mammals

Digestion is accomplished by the enzymes listed here, by HCl produced in the stomach in response to the hormone gastrin, and by bile salts from the liver. Bile salts are stored in the gallbladder. They are released in response to the hormone cholecystokinin and emulsify fats in the small intestine.

	Where Synthesized	Regulation	Function
Carboxypeptidase	Pancreas	Released in inactive form in response to cholecystokinin from small intestine; activated by trypsin	In small intestine, breaks peptide bonds in polypeptides—releasing amino acids
Chymotrypsin	Pancreas	Released in inactive form in response to cholecystokinin from small intestine; activated by trypsin	In small intestine, breaks peptide bonds in polypeptides—releasing amino acids
Elastase	Pancreas	Released in inactive form in response to cholecystokinin from small intestine; activated by trypsin	In small intestine, breaks peptide bonds in polypeptides—releasing amino acids
Lingual lipase	Salivary glands	Released in response to taste and smell stimuli	In mouth and stomach, breaks bonds in fats—releasing fatty acids and monoglycerides
Nucleases	Pancreas	Released in response to cholecystokinin from small intestine	In small intestine, break apart nucleic acids—releasing nucleotides
Pancreatic amylase	Pancreas	Released in response to cholecystokinin from small intestine	In small intestine, breaks apart carbohydrates—releasing sugars
Pancreatic lipase	Pancreas	Released in response to cholecystokinin from small intestine	In small intestine, breaks bonds in fats—releasing fatty acids and monoglycerides
Pepsin	Stomach	Released in inactive form (pepsinogen); activated by low pH in stomach lumen	In stomach, breaks peptide bonds between certain amino acids in proteins—releasing polypeptides
Salivary amylase	Salivary glands	Released in response to taste and smell stimuli	In mouth, breaks apart carbohydrates—releasing sugars
Trypsin	Pancreas	Released in inactive form (trypsinogen) in response to cholecystokinin from small intestine; activated by hormone enterokinase from small intestine	In small intestine, breaks specific peptide bonds in polypeptides—releasing amino acids

the epithelial cells. The lacteals merge with larger lymph vessels, which then merge with veins. In this way, fats enter the bloodstream without clogging small blood vessels. Eventually, the products of fat digestion end up in adipose tissue and other tissues.

How Is Water Absorbed? When solutes from digested material are absorbed into the epithelium of the small intestine, water follows passively by osmosis. This is an important mechanism for **(1)** absorbing water that has been ingested, and **(2)** reclaiming liquid that was secreted into the digestive tract in the form of saliva, mucus, and pancreatic fluid.

This mechanism of water absorption inspired an important medical strategy called oral rehydration therapy. If a patient has diarrhea, clinicians frequently prescribe dilute solutions of glucose and electrolytes to be taken orally. When the glucose in the drink is absorbed in the small intestine through sodium-glucose cotransporters, enough water and sodium follow to prevent the life-threatening effects of dehydration. This simple medication saves thousands of lives every year. ✔ **If you understand this concept, you should be able to predict at least two effects of a molecule that selectively blocks the sodium-glucose cotransporter.**

The Large Intestine

By the time digested material reaches the large intestine of a human, a large amount of water (approximately 5 liters per day in total) and virtually all of the available nutrients have been absorbed. The primary function of the **large intestine** is to compact the wastes that remain and to absorb enough water to form feces.

These processes occur in the **colon**—the main section of the large intestine. Feces are held in the **rectum,** which is the final part of the large intestine, until they can be excreted. Although the kidneys are responsible for maintaining water balance, water absorption in the large intestine is important for keeping the body well hydrated.

In addition to compacting wastes and absorbing water, the human colon contains symbiotic microorganisms that digest cellulose. Although fermentation of cellulose is not as important to an omnivorous human as it is to an herbivore like a ruminant, bacteria in the human colon also produce several important nutrients, such as vitamin K.

Aquaporins Play a Key Role in Water Reabsorption Water is absorbed in the large intestine through aquaporins. Recall that **aquaporins** are proteins that act as water channels in plasma membranes, thus increasing the rate of water movement via osmosis (see Chapter 6). The best-studied of these proteins, called AQP1 for aquaporin 1, is common in the nephrons of the kidney. AQP1 is one of the proteins responsible for water reabsorption from urine along the osmotic gradient (described in Chapter 43). To date, four distinct aquaporins have been found in the large intestines of rats, mice, and humans. Researchers are working to unravel exactly how the activity of these aquaporins is regulated.

Variations in Structure and Function The size and function of the large intestine varies dramatically among animals. In insects, the posteriormost portion of the digestive tract, called the hindgut, functions to reabsorb water and ions and excrete uric acid and feces (see Chapter 43). Among vertebrates, the various lineages of fish have no large intestine at all.

In some herbivorous species, the **cecum,** a blind sac at the proximal end of the large intestine, is greatly enlarged and functions in digesting cellulose. These species include rabbits, many rodents, some marsupials, horses, elephants, tapirs, and leaf-eating primates. The cecum contains symbiotic bacteria and protists that ferment cellulose, in much the same way that some birds house cellulose-digesting symbionts in their crop and ruminants house cellulose-digesting symbionts in a modified stomach.

In humans, a narrow pouch called the **appendix** emerges from the cecum. The function of the appendix has long been debated. It has often been described as vestigial—a reduced or incompletely developed trait that is a vestige of evolutionary ancestry (see Chapter 25)—partly because it does not perform any obvious vital function. Indeed, if it becomes inflamed, it can be surgically removed from a patient and cause no ill effects. However, although not vital, the appendix may have important functions: it is imbued with immune cells, and it appears to act as a haven for symbiotic microorganisms that inhabit the colon. For example, serious infections can result in diarrhea that flushes symbiotic bacteria from the colon. The appendix may provide the additional bacteria needed for recolonizing the colon after such an episode.

Rabbits and some other species with a cecum are able to excrete the cecum's contents as pellets, which the animal then reingests and passes through the digestive tract a second time. This particular example of **coprophagy,** or excrement eating, allows the animal to absorb more nutrients from the food.

check your understanding

C Y U

If you understand that . . .

- In humans and many other animals, digestion begins with the mechanical breakdown of food into small pieces that are then acted on by acids, enzymes, emulsifying agents, and other chemical treatments.
- Distinct compartments within a digestive tract have distinct structures and functions.
- Nutrients are absorbed through specific membrane proteins in epithelial cells of the digestive tract.

✔ You should be able to . . .

1. Explain how each compartment in the human digestive tract aids the ingestion and digestion of food, absorption of nutrients, and excretion of wastes.
2. Predict the consequences of treating a person with drugs that inhibit the release of bile salts, that inactivate trypsin, or that block the action of the Na^+-glucose cotransporter in the epithelial cells of the small intestine.

Answers are available in Appendix A.

Another striking structural variation occurs in the rectum of amphibians, reptiles, and birds. Their urine flows from the kidneys into an enlarged portion of the large intestine called the **cloaca** (see Chapter 43). Instead of having two orifices for excretion, these species have one.

44.4 Nutritional Homeostasis—Glucose as a Case Study

When digestion is complete, amino acids, fatty acids, ions, and sugars enter the bloodstream and are delivered to the cells that need them. The body uses or stores these nutrients in order to maintain homeostatic levels in the blood and avoid imbalances. Too much of a nutrient or too little can be problematic or even fatal.

The illness **diabetes mellitus** is a classic example of nutrient imbalance. People with diabetes mellitus experience abnormally high levels of glucose in their blood. Over the course of a lifetime, chronically elevated blood glucose can lead to an array of complications, including blindness, impaired circulation, and heart failure. What causes the imbalance? More important, how is glucose homeostasis normally maintained?

The Discovery of Insulin

In 1879, researchers removed the pancreas from a dog and observed that the dog's blood glucose became very high. This experiment suggested that the pancreas secretes a compound needed for removing glucose from the blood.

When other investigators cut up pancreatic tissues and injected extracts into diabetic dogs, however, they observed no response. Eventually, they decided that digestive enzymes in the pancreas were probably destroying the active agent during the extraction process.

Then, in 1921, Frederick Banting and Charles Best conducted a breakthrough experiment:

1. They began by tying off a dog's pancreatic duct—the tube through which digestive enzymes flow to the small intestine. The logic was that blocking the secretion of digestive enzymes might kill the cells that synthesize them.
2. The investigators waited several weeks for the cells near the duct to die and then removed the pancreas.
3. They froze the pancreatic tissue, ground it up, and injected an extract into a diabetic dog.
4. To their delight, the dog's blood sugar levels stabilized, and the dog became more active and healthy looking.

After Banting and Best repeated the experiment and observed the same result, they grew increasingly confident that they had located the source of the molecule responsible for lowering blood glucose levels. The molecule came to be called insulin.

Insulin's Role in Homeostasis

Insulin is a hormone that is secreted by the pancreas when blood glucose levels are high. It travels through the bloodstream and binds to receptors on cells throughout the body (see Chapter 49 for more detail on the structure and function of hormones and other chemical signals).

In response, cells that have insulin receptors increase their rate of glucose uptake and processing. Specifically, insulin stimulates cells in the liver and skeletal muscle to import glucose from the blood and synthesize glycogen from glucose monomers. As a result, glucose levels in the blood decline.

If blood glucose levels fall, as they do when food is lacking, cells in the pancreas secrete a hormone called **glucagon.** In response to glucagon, cells in the liver catabolize glycogen, and also produce glucose via **gluconeogenesis,** the synthesis of glucose from non-carbohydrate compounds. As a result, glucose levels in the blood rise (**FIGURE 44.16**).

Insulin and glucagon interact to form a negative feedback system capable of achieving homeostasis with respect to glucose concentrations in the blood.

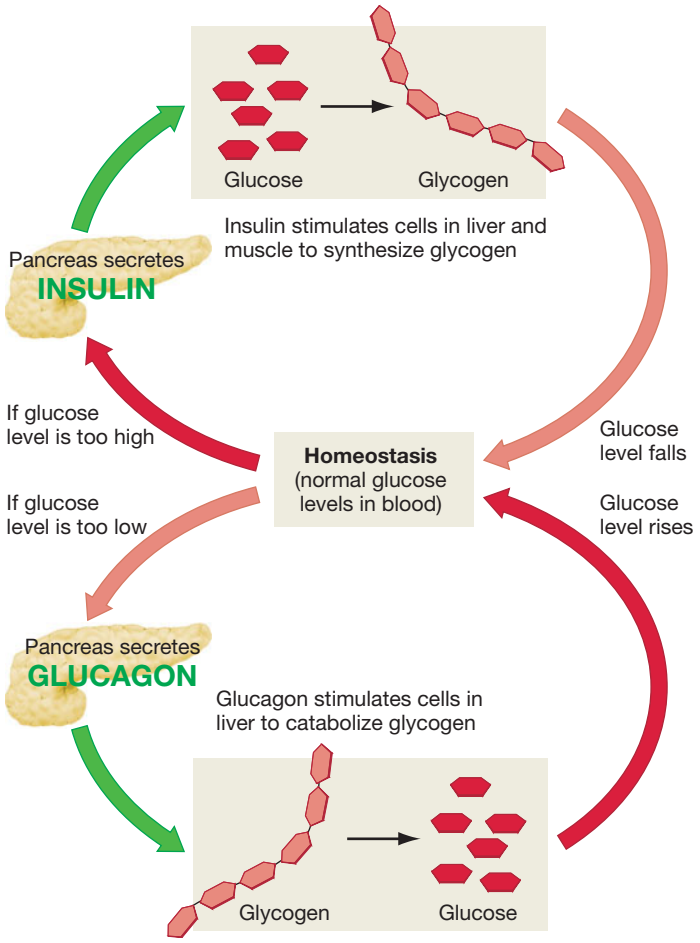

FIGURE 44.16 Insulin and Glucagon Provide Negative Feedback in a Homeostatic System. Both insulin and glucagon are secreted by cells in the pancreas but have opposite effects on blood glucose concentrations.

✔**QUESTION** After reading the descriptions of type 1 and type 2 diabetes mellitus, decide which arrow is disrupted in individuals with type 2 diabetes mellitus and which arrow is disrupted in individuals with type 1 diabetes mellitus.

Diabetes Mellitus Has Two Forms

Diabetes mellitus develops in people who **(1)** do not synthesize sufficient insulin or **(2)** are resistant to insulin, meaning that insulin does not effectively activate its receptor in target cells. The first condition is called type 1 diabetes mellitus; the second condition is type 2 diabetes mellitus. In both cases, effector cells do not receive the signal that would result in a drop in blood glucose levels.

Glucose imbalance has a direct effect on urine formation. Normally, signals from insulin keep blood glucose levels low enough that all of the glucose can be reabsorbed from the filtrate formed in the kidney. But when blood glucose levels are high, so much glucose enters the nephron that it cannot all be reabsorbed. High glucose concentrations in the filtrate increase its osmolarity and decrease the amount of water reabsorbed from it. More water leaves the body, leading to high urine volume in both types of diabetes mellitus.

The word diabetes means "to run through"; water "runs through" people with diabetes. In addition, the word mellitus means "honeyed (sweet)." Before chemical methods of analyzing urine were available, physicians would taste the patient's urine. If the urine was sweet, it was highly likely that the patient was suffering from diabetes mellitus.

Why do these diseases develop? Type 1 diabetes mellitus is an autoimmune disease, meaning that the body's immune system mistakenly targets its own cells for destruction. In the case of type 1 diabetes mellitus, the insulin-producing cells of the pancreas are destroyed. Type 2 diabetes mellitus occurs when the receptors for insulin no longer function correctly or are reduced in number. The primary risk factor for developing type 2 diabetes mellitus is obesity.

Currently, type 1 diabetes mellitus is treated with insulin injections and careful attention to diet; type 2 diabetes mellitus is managed primarily through prescribed diets, exercise, and monitoring blood glucose levels, as well as taking drugs that increase cellular responsiveness to insulin. The challenge is to achieve homeostasis with respect to blood glucose in the absence of the body's normal regulatory mechanisms.

✔ **If you understand the difference between type 1 and type 2 diabetes mellitus, you should be able to explain how, in individuals with each disease and without disease, insulin receptors in the plasma membrane of liver cells interact with insulin and how the liver cells respond to high glucose concentrations in the blood.**

The Type 2 Diabetes Mellitus Epidemic

An epidemic of type 2 diabetes mellitus is currently under way in certain human populations. For example, as of 2011, a total of 11 percent of U.S. adults aged 20 and over were diabetic, and this figure jumps to 27 percent in U.S. adults aged 65 and over. About 90% to 95% of cases are type 2 diabetes mellitus. Minority groups such as African Americans and Hispanics are experiencing much higher rates of new cases of type 2 diabetes mellitus than white non-Hispanic Americans.

Because there is a strong association between the prevalence of diabetes mellitus in parents and in children, researchers have long suspected that some individuals have a genetic predisposition for developing the disease. Researchers have so far identified alleles at 38 different genes that predispose individuals to type 2 diabetes mellitus (using techniques introduced in Chapter 20 and Chapter 21).

However, there is also strong evidence that environmental conditions have an important impact on the incidence of type 2 diabetes mellitus. As an example, consider the Pima Indians of North America.

The Pima consist of two main populations—one in southwest Arizona in the United States and one in a remote area of the Sierra Madre mountains of Mexico. The bars graphed in **FIGURE 44.17a** indicate the average percentage of individuals with type 2 diabetes mellitus, by gender, in Mexican people who are

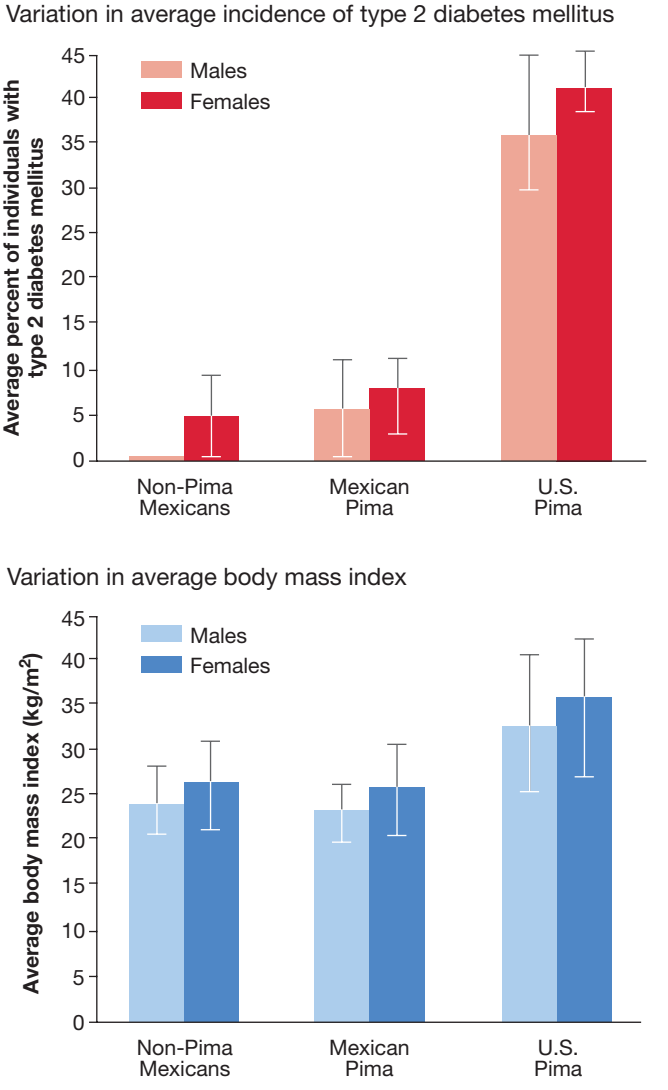

FIGURE 44.17 The Incidence of Type 2 Diabetes Mellitus Is Correlated with Obesity.

DATA: Schultz, L. O., P. H. Bennett, E. Ravussin, et al. 2006. *Diabetes Care* 29: 1866–1871.

✔**QUANTITATIVE** In the graphs above, it is apparent that U.S. Pima have higher rates of type 2 diabetes mellitus and higher body mass indices than the other groups. Does this prove that obesity causes diabetes mellitus? Why or why not?

not members of the Pima and in the two populations of Pima. Although researchers have been unable to find any significant genetic differences between the two groups of Pima, the data indicate there are dramatic differences in the incidence of type 2 diabetes mellitus.

The incidence of type 2 diabetes mellitus is correlated with obesity. As the data graphed in **FIGURE 44.17b** show, Pima from the United States are more likely to be obese than individuals in the other two populations in this study. A person who has a body mass index greater than or equal to 30 is considered obese. The **body mass index** is calculated as weight (in kilograms) divided by height squared (in meters).

The differences in body mass index among the Pima are explained by differences in physical activity and diet. Pima men in Mexico are physically active an average of 33 hours a week, while their counterparts in the United States are active just 12.1 hours per week. Pima women in Mexico average 22 hours of physical activity a week; Pima women in the United States average just 3.1. In addition, Pima in the United States get approximately 40 percent of their calories from fat, compared to 15 percent in the traditional Pima diet.

Although Pima people in the United States have the highest rates of type 2 diabetes mellitus recorded for any people to date, the same trends are occurring in populations all over the world. Nutrition-related diseases have become a major public health concern.

Type 2 diabetes mellitus used to be called adult-onset diabetes because the disease typically appeared in adults. However, that name has been abandoned as more and more young people are diagnosed with the disease. While a multitude of genes can predispose a child or adult to developing diabetes mellitus, the disease is triggered by environmental factors including diet, lack of exercise, and obesity.

In a five-year span in the past decade, obesity rates increased by 10 percent in American children overall and by over 30 percent in children from low-income families and certain racial minority groups. Scientists estimate that one in three children born nowadays will develop diabetes mellitus, and that rates are likely to continue rising. It is clear that diabetes mellitus is a modern-day epidemic.

C Y U

If you understand that . . .

- Insulin and glucagon interact to regulate glucose concentrations in the blood.
- Diabetes mellitus results from a lack of homeostasis in the concentration of the nutrient glucose in the blood.

✓ You should be able to . . .

1. Identify the causes of each type of diabetes mellitus.
2. Prescribe what a person with type 1 diabetes mellitus should do when the blood glucose level is too high and when the blood glucose level is too low.

Answers are available in Appendix A.

CHAPTER 44 REVIEW

For media, go to MasteringBiology

If you understand . . .

44.1 Nutritional Requirements

- The diets of animals include fats, carbohydrates, and proteins that provide energy; vitamins that serve as coenzymes and perform other functions; ions required for water balance and for nerve and muscle function; and elements that are incorporated into molecules synthesized by cells.
- Fats contain the most energy of all nutrients: 9 kcal/g compared to 4 kcal/g for carbohydrates and proteins, making fats an efficient way to store energy in the body.

✓ **QUANTITATIVE** You should be able to calculate and compare the caloric content of skim milk and whole milk. Per serving, skim milk contains 12 g carbohydrates, 8 g protein, and no fat; whole milk contains 12 g carbohydrates, 8 g protein, and 8 g fat.

44.2 Capturing Food: The Structure and Function of Mouthparts

- Most animals are mass feeders that obtain food by seizing and manipulating it with mouthparts such as teeth, jaws, or beaks or with special toxin-injecting organs.
- Natural selection has modified mouthparts in different species to act as efficient tools for obtaining particular types of food.

✓ You should be able to predict the types of mouthparts and the nature of the digestive tract in a mammal that eats only nectar from flowers.

44.3 How Are Nutrients Digested and Absorbed?

- In most animals, the digestive tract begins at the mouth and ends at the anus.
- In many species, chemical digestion of food also begins in the mouth. In mammals, an enzyme in saliva called salivary amylase begins to hydrolyze the bonds linking glucose monomers in starch, glycogen, and other carbohydrates.
- Once food is swallowed, it is propelled down the esophagus by peristalsis.
- Digestion continues in the stomach. In humans, the stomach is a highly acidic environment that denatures proteins and in which the enzyme pepsin begins the cleavage of peptide bonds that link amino acids.
- Food passes from the stomach into the small intestine, where it is mixed with secretions from the pancreas and liver.
- In the small intestine, carbohydrate digestion is continued by pancreatic amylase; fats are emulsified by bile salts and digested by pancreatic lipase; protein digestion is completed by a suite of pancreatic enzymes.
- Cells that line the small intestine absorb the nutrients released by digestion. In many cases, uptake is driven by an electrochemical gradient established by Na^+/K^+-ATPase that favors a flow of Na^+ into the cell.
- As solutes leave the lumen of the small intestine and enter cells, water follows by osmosis.
- Water reabsorption is completed in the large intestine, where feces form.
- The structure of organs in the digestive tract varies widely among species, in ways that support efficient processing of the food a particular species ingests.

✔ **You should be able to compare the optimal pH for amylase and pepsin.**

44.4 Nutritional Homeostasis—Glucose as a Case Study

- Diabetes mellitus is a condition in which concentrations of glucose in the blood are chronically too high.
- Type 1 diabetes mellitus is caused by a defect in the production of insulin—a hormone secreted by the pancreas that promotes the uptake of glucose from the blood.
- Type 2 diabetes mellitus is characterized by a failure of cells to respond to insulin.
- The development of type 2 diabetes is correlated with obesity and is reaching epidemic proportions in some populations.

✔ **You should be able to explain how each type of diabetes mellitus results in high blood glucose.**

Answers are available in Appendix A

1. What does secretin stimulate?
   a. secretion of HCO_3^- from the pancreas
   b. secretion of HCl from the stomach epithelium
   c. secretion of digestive enzymes from the pancreas
   d. uptake of glucose from the bloodstream by cells throughout the body
2. What is an incomplete digestive tract?
   a. a digestive tract that is missing a major compartment—for example, fish lack a large intestine
   b. a ruminant-type tract, where food is regurgitated and re-chewed before digestion is completed
   c. a reduced or vestigial tract like that found in animals that absorb nutrition directly across the body wall
   d. a digestive system with a single opening for ingestion and excretion
3. In mammals, how and where are carbohydrates digested?
   a. by lipases in the small intestine
   b. by pepsin and HCl in the stomach
   c. by aquaporins in the large intestine
   d. by amylases in the mouth and small intestine
4. Cellulose is fermented in which of the following structures in rabbits?
   a. small intestine
   b. cecum
   c. abomasum
   d. rumen
5. A hormone that reduces blood glucose is _____, while a hormone that increases blood glucose is _____.
6. True or False: Type 1 diabetes mellitus is more prevalent in the United States than type 2 diabetes mellitus.

TEST YOUR UNDERSTANDING

Answers are available in Appendix A

7. Explain how the structure of each of the following digestive tract compartments correlates with its function: the bird crop, cow rumen, and elephant large intestine.
8. Why are many digestive enzymes produced in an inactive form and then activated in the lumen of the digestive tract?
9. Explain why oral rehydration therapy with a solution of sodium and glucose is effective.
   a. The sodium and glucose decrease urine output.
   b. The sodium and glucose facilitate water absorption by the small intestine.
   c. The sodium and glucose help kill the intestinal bacteria.
   d. The sodium and glucose make the person thirsty.
10. How does the high type 2 diabetes mellitus rate among Pima Indians in the United States provide evidence for an environmental effect on development of the disease?
11. What do the shapes of human teeth suggest about their function in terms of the types of food humans are adapted to eat?
12. Predict what would happen if a type 1 diabetic took too much insulin.

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A

13. Doctors sometimes prescribe proton pump inhibitors to treat patients with acid reflux. How do these drugs work?
14. An elderly man arrives at the hospital severely dehydrated. The physicians find that there is glucose in his urine and that his blood glucose does not decline much upon administration of an insulin shot. What is he likely to be suffering from?
   a. type 1 diabetes mellitus
   b. type 2 diabetes mellitus
   c. diarrhea
   d. gastric ulcer
15. Scientists who backed the hypothesis that secretion from the pancreas is under nervous control strenuously objected to the conclusions reached in the experiment that led to the discovery of hormonal control. They said the experiment was inconclusive, because of the likelihood that not all the nerves contacting the small intestine had been cut. The biologists who did the experiment replied that even if not all the nerves had been cut, the result was still valid. In your opinion, who is correct? Why?
16. Among vertebrates, the large intestine occurs only in lineages that are primarily terrestrial (amphibians, reptiles, and mammals). Propose a hypothesis to explain this observation.

45 Gas Exchange and Circulation

In this chapter you will learn that

Animals have adaptations for gas exchange across body surfaces and circulation within their bodies

O_2 and CO_2 exchange in air vs. water 45.2

asking

How do different gas exchange organs work? 45.3

exploring

O_2 and CO_2 transport in blood 45.4

asking

How do different circulatory systems work? 45.5

During intense exercise, animal circulatory systems deliver large amounts of oxygen to tissues and remove large amounts of carbon dioxide. This chapter explores how gas exchange occurs in animals that live in aquatic or terrestrial environments.

Animal cells are like factories that run 24 hours a day. Inside the plasma membrane, the chemical reactions that sustain life require a steady input of raw materials. Those reactions also produce a steady stream of wastes. Earlier in this unit, you learned how solid and liquid waste materials are removed from the cells and excreted from the body (see Chapter 43). You also examined how nutrients enter the body (see Chapter 44). Let's now turn our attention to two other major questions:

1. How are two of the most important molecules in the economy of the cell—the oxygen (O_2) required for cellular respiration and the carbon dioxide (CO_2) produced by cellular respiration—exchanged with the environment?

BIG PICTURE

This chapter is part of the Big Picture. See how on pages 840–841.

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

2. How are these gases—along with wastes, nutrients, and other types of molecules—transported throughout the body?

Understanding gas exchange and circulation is fundamental to understanding how animals work. If either process fails, the consequences are dire. Consider the maladies that can develop when gas exchange or circulation is disrupted in humans: anemia, pneumonia, tuberculosis, malaria, heart disease, and stroke are just a few examples.

Let's begin with an overview of animal respiratory and circulatory systems and then plunge into the details of how gases are exchanged and transported.

45.1 The Respiratory and Circulatory Systems

When the mitochondria inside animal cells are producing ATP via cellular respiration, they consume oxygen and produce carbon dioxide. To support continued ATP production, cells have to obtain oxygen and expel excess carbon dioxide continuously (see The Big Picture: Energy, pages 198–199).

How does this gas exchange occur between an animal's environment and its mitochondria? In most cases, gas exchange involves the four steps illustrated in **FIGURE 45.1**:

1. ***Ventilation,*** the movement of air or water through a specialized gas exchange organ, such as lungs or gills.
2. ***Gas exchange,*** the diffusion of O_2 and CO_2 between air or water and the blood at the respiratory surface.
3. ***Circulation,*** the transport of dissolved O_2 and CO_2 throughout the body—along with nutrients, wastes, and other types of molecules—via the circulatory system.
4. ***Cellular respiration,*** the cell's use of O_2 and production of CO_2. In tissues, where cellular respiration has led to low O_2 levels and high CO_2 levels, gas exchange occurs between blood and cells.

Steps 1 and 2 are accomplished by the **respiratory system,** the collection of cells, tissues, and organs responsible for gas exchange between the individual animal and its environment. In essence, a respiratory system consists of structures for conducting air or water to a surface where gas exchange takes place.

In some animals the gas exchange surface is the skin, but in most species it is located in a specialized organ like the lungs of tetrapods, the tracheae of insects, or the gills found in mollusks, arthropods, and fishes. Section 45.3 analyzes the structure and function of gills, tracheae, and lungs in detail.

Step 3 in Figure 45.1 is usually accomplished by a **circulatory system,** which moves O_2, CO_2, and other materials around the body. In many cases, a muscular heart propels a specialized, liquid transport tissue throughout the body via a system of vessels.

Keeping in mind this broad overview of gas exchange and circulatory systems, let's dive into the details by exploring how oxygen and carbon dioxide move between an animal's body and its environment.

45.2 Air and Water as Respiratory Media

Gas exchange between the environment and cells is based on diffusion. Under normal conditions, oxygen concentrations are relatively high in the environment (for example, in air that you inhale or in ocean water) and low in tissues, while carbon dioxide levels are relatively high in tissues and low in the environment. Thus oxygen tends to move from the environment into tissues, and carbon dioxide tends to move from tissues into the environment.

How much oxygen and carbon dioxide are present in the atmosphere versus the ocean? What factors in air and water influence how quickly these gases move by diffusion?

How Do Oxygen and Carbon Dioxide Behave in Air?

The atmosphere is composed primarily of nitrogen (76%) and oxygen (21%) and has trace amounts of argon (0.93%) and CO_2 (0.03%). Nitrogen (N_2) and argon are not important to animals living at sea level and are usually ignored in analyses of gas exchange.

However, the data are actually a little misleading. To understand why, consider that the *percentage* of O_2 in the atmosphere does not vary with elevation. The atmosphere at the top of Mt. Everest is

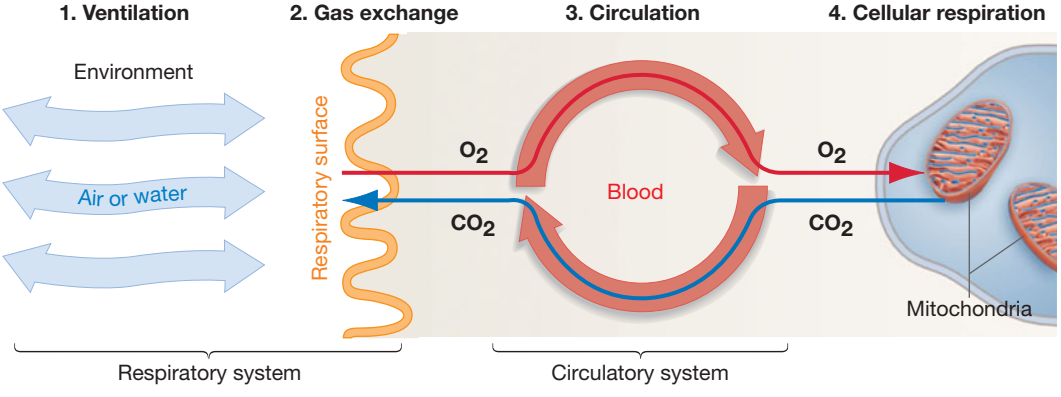

FIGURE 45.1 Gas Exchange Involves Ventilation, Circulation, and Respiration. In animals, oxygen and carbon dioxide are exchanged across the surface of a lung, a gill, the skin, or some other gas exchange organ. In many species these gases are then transported to and from cells—where gas exchange again takes place—in a fluid tissue such as blood.

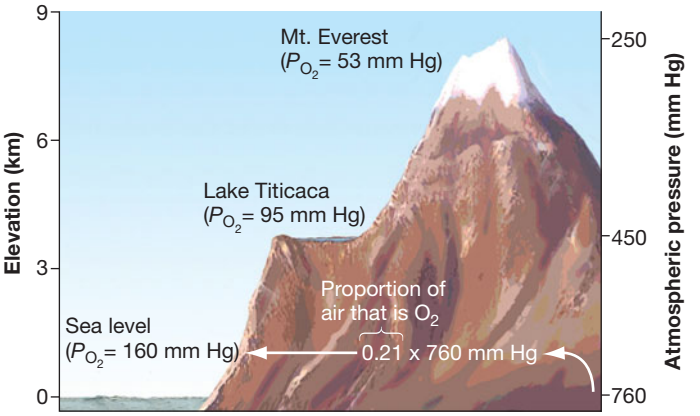

FIGURE 45.2 Oxygen Makes Up 21 Percent of the Atmosphere, but Its Partial Pressure Depends on Altitude. Atmospheric pressure, and thus oxygen partial pressure (P_{O_2}), fall with increasing elevation.

composed of 21 percent oxygen, just as it is at sea level. The key difference is that far fewer molecules of oxygen and other atmospheric gases are present at high elevations than at sea level. Air at the top of Mt. Everest is less dense than air at sea level, so less oxygen is present. To understand how gases move by diffusion, it is important to express their presence in terms of partial pressures instead of percentages. Pressure is a type of force. A **partial pressure** is the pressure of a particular gas in a mixture of gases.

To calculate the partial pressure of a particular gas, multiply the fractional composition (the fraction of air the gas comprises) by the total pressure exerted by the entire mixture (atmospheric pressure). The calculation is valid because the total pressure of a mixture of gases is the sum of the partial pressures of all the individual gases. This relationship is called Dalton's law.

For example, **FIGURE 45.2** shows that the total atmospheric pressure at sea level is 760 mm Hg (millimeters of mercury). If you multiply this value by 0.21, which is the fraction of air that is O_2, you obtain a partial pressure of oxygen, abbreviated P_{O_2}, at sea level of 160 mm Hg. Because the atmospheric pressure is only about 250 mm Hg at the top of Mt. Everest, the P_{O_2} there is only $0.21 \times 250 = 53$ mm Hg.

Oxygen and carbon dioxide diffuse between the environment and cells along their respective partial pressure gradients, just as solutes diffuse along their electrochemical gradients. In both air and water, O_2 and CO_2 move from regions of high partial pressure to regions of low partial pressure. It is hard to breathe at the top of Mt. Everest because the partial pressure of oxygen is low there—meaning that the diffusion gradient between the atmosphere and your lung tissues is small, so fewer molecules of O_2 diffuse into your tissues when you take a breath.

How Do Oxygen and Carbon Dioxide Behave in Water?

To obtain oxygen, water breathers face a much more challenging environment than air breathers do. Aquatic animals live in an environment that contains much less oxygen than the environments inhabited by terrestrial animals. At 15°C, a liter of air can contain up to 209 milliliters (mL) of O_2, while a liter of water may contain a maximum of only 7 mL of O_2. To extract a given amount of oxygen, an aquatic animal has to process 30 times more water than the amount of air a terrestrial animal breathes.

In addition, water is about a thousand times denser than air and flows much less easily. As a result, water breathers have to expend much more energy to ventilate their respiratory surfaces than do air breathers.

What Affects the Amount of Gas in a Solution? Oxygen and carbon dioxide diffuse into water from the atmosphere, but the amount of gas that dissolves in water depends on several factors:

- ***Solubility of the gas in water*** Oxygen has very low solubility in water. Only 0.003 mL of oxygen dissolves in 100 mL of water for each increase of 1 mm Hg in oxygen partial pressure. Because of this low solubility, blood contains a molecule that binds to oxygen and delivers it to tissues. Without this carrier molecule, the rate of blood flow to tissues would have to increase dramatically to meet oxygen demand.
- ***Temperature of the water*** As the temperature of water increases, the amount of gas that dissolves in it decreases. Other things being equal, warm-water habitats have much less oxygen available than cold-water habitats do. For a fish, breathing in warm water is comparable to a land-dwelling animal breathing at high elevation.
- ***Presence of other solutes*** Because seawater has a much higher concentration of solutes than does freshwater, seawater can hold less dissolved gas. At 10°C, up to 8.02 mL of O_2 can be present per liter of freshwater versus only 6.35 mL of O_2 per liter of seawater. As a result, freshwater habitats tend to be more oxygen rich than marine environments.
- ***Partial pressure of the gas in contact with the water*** Gases move from regions of high partial pressure to regions of low partial pressure. So if the partial pressure in a liquid exceeds that in the adjacent gas, the gas will bubble up out of the liquid. This is what happens when the cap is removed from a bottle of carbonated beverage. The partial pressure of carbon dioxide in the newly opened drink is much higher than it is in the atmosphere.

What Affects the Amount of Oxygen Available in an Aquatic Habitat? The partial pressure of oxygen varies in different types of aquatic habitats, just as it varies with altitude on land. In addition to the four factors just listed, other important considerations affect oxygen's availability in water. These include the presence of photosynthetic organisms and decomposers, the amount of mixing that occurs, and the surface area of the body of water. For example,

- Habitats with large numbers of photosynthetic organisms tend to be relatively oxygen rich. In contrast, oxygen content is extremely low in bogs and other stagnant-water habitats because oxygen is quickly depleted by decomposers that use it as an electron acceptor in cellular respiration.

- Unless currents mix water almost continuously, water near the surface has much higher oxygen content than water near the bottom of the same habitat.
- Shallow ponds and streams tend to be much better oxygenated than deep bodies of water because shallower bodies have a higher ratio of surface area to volume.
- Rapids, waterfalls, and other types of whitewater are the most highly oxygenated of all aquatic environments because a large surface area is exposed to the atmosphere as water splashes over rocks and logs and because air bubbles are incorporated into the water.

Now let's consider the structure and function of ventilatory organs. How do the gills of fishes, the tracheae of insects, and the lungs of mammals cope with the differences between air and water?

check your understanding

CYU

If you understand that . . .

- O_2 and CO_2 move from regions of high partial pressure to regions of low partial pressure.
- The partial pressure of oxygen in a body of water depends on the water's temperature, surface area, and amount of mixing, and on the impacts of photosynthetic organisms and decomposers, among other factors.
- Water breathing is much more difficult than air breathing, in part because the partial pressure of oxygen in water is much lower than its partial pressure in air.

✓ You should be able to . . .

1. Explain why oxygen partial pressures are relatively high in mountain streams and relatively low at the ocean bottom.
2. For each of three aquaria, decide whether a large or a small amount of air should be bubbled in. One contains warm-water species, one contains vigorous algal growth, and one contains sedentary animals.

Answers are available in Appendix A.

45.3 Organs of Gas Exchange

Many small animals lack specialized gas exchange organs, such as gills or lungs. Instead, they obtain O_2 and eliminate CO_2 by diffusion across the body surface. This is possible because their size and shape give them an extraordinarily high ratio of surface area to volume (see Chapter 42). In sponges, jellyfish, flatworms, and other species, diffusion across the body surface is rapid enough to fulfill their requirements for taking in O_2 and expelling CO_2.

Most of these animals are restricted to living in wet environments, however. For gas exchange to take place efficiently, the surface where it occurs has to be thin, and thin tissues are prone to water loss. Living in wet or humid environments allows animals to exchange gases across their outer surface while avoiding dehydration.

In contrast, animals that are large or that live in dry habitats need some sort of specialized respiratory organ. Respiratory organs provide a greater surface area for gas exchange—enough to meet the demands of a large body filled with cells. In terrestrial animals, respiratory organs are located inside the body, which helps minimize water loss.

Biologists have long marveled at the efficiency of gills and lungs. To appreciate why, let's examine the physical factors that control diffusion rates and then look at the structure and function of these respiratory organs.

Physical Parameters: The Law of Diffusion

In 1855 Adolf Fick derived an equation regarding diffusion, based on the results of experiments he had performed on the behavior of gases. **Fick's law of diffusion** states that the rate of diffusion of a gas depends on five parameters: the solubility of the gas in the aqueous film lining the gas exchange surface; the temperature; the surface area available for diffusion; the difference in partial pressures of the gas across the gas exchange surface; and the thickness of the barrier to diffusion (**FIGURE 45.3**).

Fick's law identifies traits that allow animals to maximize the rate at which oxygen and carbon dioxide diffuse across surfaces. Specifically, Fick's law states that gases diffuse at the highest rates when three conditions are met:

1. A is large, meaning a large area is available for gas exchange. Based on Fick's law, it is not surprising that the respiratory surface in the human lungs would cover about 140 m^2—about a quarter of a basketball court—if the epithelium were spread flat.
2. D is small, meaning the respiratory surface is extremely thin. In the human lung, this barrier to diffusion is only 0.2 μm thick—about 1/200th of the thickness of this page.
3. $P_2 - P_1$ is large, meaning the partial pressure gradient of the gas across the surface is large. High partial pressure gradients are maintained in part by having an efficient circulatory

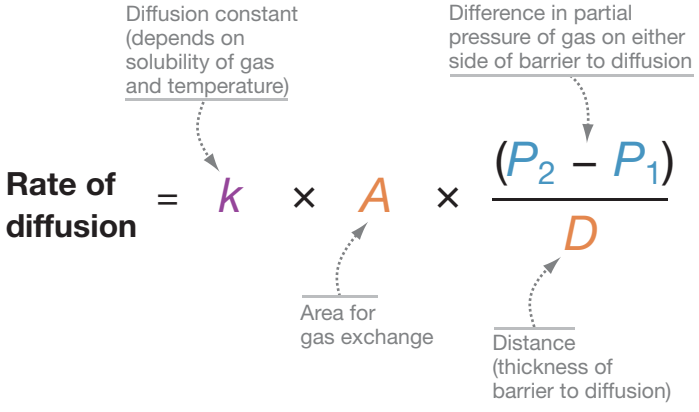

FIGURE 45.3 Fick's Law Describes the Rate of Diffusion.

system in close contact with the gas exchange surface. When blood flows close to the respiratory surface, oxygen is rapidly taken away from the area where inward diffusion is occurring, and carbon dioxide is rapidly brought into the area where outward diffusion is occurring. As a result, $P_2 - P_1$ stays high.

What other aspects of gill and lung structure affect diffusion rate? To answer this question, let's delve into the anatomy of these respiratory organs.

How Do Gills Work?

Gills are outgrowths of the body surface or throat that are used for gas exchange in aquatic animals. Gills are efficient solutions to the problems posed by water breathing, primarily because they present a large surface area for the diffusion of gases across a thin epithelium.

In some species of invertebrates, such as the red tubeworm (**FIGURE 45.4a**), gills project from the body surface and contact the surrounding water directly. In other invertebrate species, such as the crayfish (**FIGURE 45.4b**), gills are located inside the exoskeleton or body wall. If gills are internal, water must be driven over them by cilia, the limbs, or other specialized structures.

In contrast to the diversity of gills found in invertebrates, the gills of bony fishes are all similar in structure. Fish gills are located on both sides of the head and in teleosts (see Chapter 35) consist of four arches, as **FIGURE 45.5** shows.

How Do Fishes Ventilate Their Gills? To move water through their gills so gas exchange can take place, most fishes open and close their mouth and **operculum,** the stiff flap of tissue that covers the gills. The pumping action of the mouth and operculum creates a pressure gradient that moves water over the gills.

In contrast, tuna and other fishes that are particularly fast swimmers force water through their gills by swimming with their mouths open. This process is called ram ventilation.

Regardless of how fish gills are ventilated, water flows in one direction through gills, passing over long, thin structures called **gill filaments** that extend from each gill arch. Each gill filament is composed of hundreds or thousands of **gill lamellae.** Gill lamellae are sheetlike structures, shown in detail at the bottom of Figure 45.5. Note that a bed of small blood vessels called capillaries runs through each lamella.

The Fish Gill Is a Countercurrent System The one-way flow of water through gill lamellae has a profound impact on gill function, for a simple reason: The flow of blood through the capillary bed in each lamella is in the opposite direction to the flow of water. As a result, each lamella functions as a countercurrent exchanger.

Recall that countercurrent exchangers are based on two adjacent fluids flowing in opposite directions (see Chapter 42). **FIGURE 45.6** illustrates why the countercurrent flow is so critical.

Note two key points about the left side of the figure, where water and blood flow in opposite directions:

1. A slight gradient in partial pressure of oxygen (here, 10 percent) exists along the entire length of the lamella.
2. A large difference in oxygen partial pressure exists between the start and end of the system. In this example, the difference is 100% − 15% = 85% in the water and 90% − 5% = 85% in the blood.

The upshot? Most of the oxygen in the incoming water has diffused into the blood.

Now look at the right side of the figure, where water and blood flow in the same direction.

1. A large gradient in partial pressure of oxygen (here, 100 percent) exists at the start of the system. The gradient in oxygen partial pressures declines rapidly and eventually disappears.

(a) External gills are in direct contact with water.

(b) Internal gills must have water brought to them.

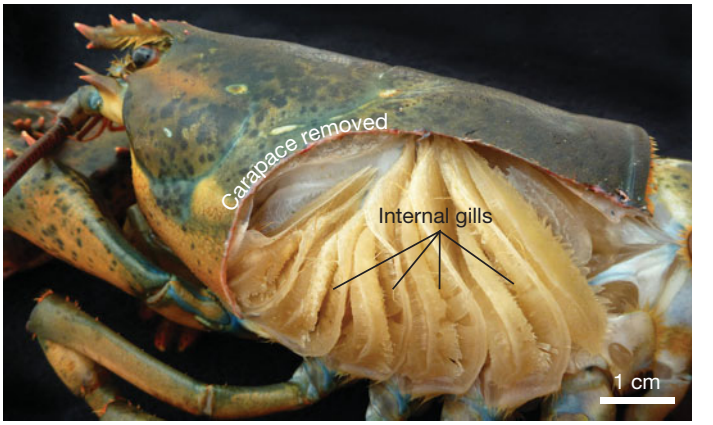

FIGURE 45.4 Gills Can Be External or Internal. (a) Red tubeworms are marine polychaetes with gills that protrude from the body. **(b)** Lobster gills are located inside the main body wall. A portion of the crayfish exoskeleton has been removed to expose the gills.

✔**QUESTION** Predict what the advantages and disadvantages of external versus internal gills might be in terms of fitness.

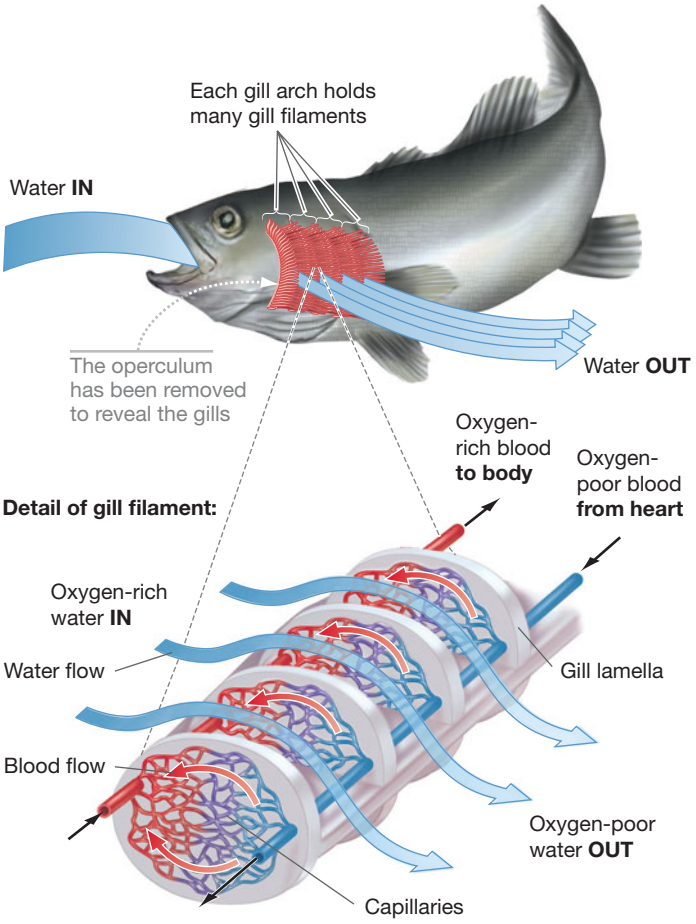

FIGURE 45.5 Fish Gills Are a Countercurrent Exchange System. In fish gills, water and blood flow in opposite directions. In the blood vessels, red represents oxygenated blood, blue represents deoxygenated blood, and purple represents mixed blood.

2. A relatively small difference in oxygen partial pressure exists between the start and end of the system. In this example, the difference is 100% − 50% = 50% in the water and 50% − 0% = 50% in the blood.

With this arrangement, only half of the oxygen in the incoming water has diffused into the blood.

Countercurrent flow makes fish gills extremely efficient at extracting oxygen from water because it ensures that a difference in the partial pressure of oxygen and carbon dioxide in water versus blood is maintained over the entire gas exchange surface.

The effect of countercurrent exchange is to maximize the $P_2 - P_1$ term in Fick's law of diffusion, averaged over the entire gill surface. Based on this observation, biologists cite countercurrent exchange as another example of how gills are optimized for efficient gas exchange.

How Do Insect Tracheae Work?

As noted earlier, air and water are dramatically different ventilatory media, because they have different densities, viscosities, and abilities to hold oxygen and carbon dioxide. In addition, the consequences of exposing the gas exchange surface to air versus water differ.

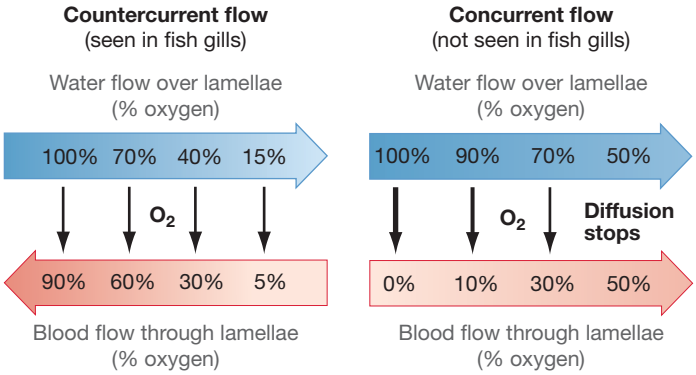

FIGURE 45.6 Countercurrent Exchange Is Much More Efficient than Concurrent Exchange. In the countercurrent system of fish gills, oxygen is transferred along the entire length of the capillaries.

✔**QUESTION** If you understand this concept, you should be able to predict what would happen to oxygen transfer from water to blood if flow were concurrent.

In aquatic habitats, ventilation tends to disrupt water and electrolyte balance, and homeostasis must be maintained by an active osmoregulatory system. Osmosis causes marine animals to lose water across their gas exchange surface and freshwater animals to gain water (see Chapter 43). Diffusion tends to cause marine animals to gain sodium, chloride, and other ions, and freshwater animals to lose them.

In contrast, breathing leads to a loss of water by evaporation in terrestrial environments. How do terrestrial animals minimize water loss while maximizing the efficiency of gas exchange?

To answer this question, consider the tracheal system of insects. Recall that insects have an extensive system of air-filled tubes called **tracheae** located within the body (see Chapter 43). These connect to the exterior through openings called **spiracles,** which can be closed to minimize the loss of water by evaporation. The ends of tracheae are tiny and highly branched. This design allows the tracheal system to transport air close enough to cells for gas exchange to take place directly across their plasma membranes.

Air moves from the atmosphere into the tracheae and then through the tracheae to the tissues in the insect's body. Is simple diffusion efficient enough to ventilate the system, or is some type of breathing mechanism involved?

If insects ventilate their tracheal system with simple diffusion, then according to Fick's law, the distance that the air would have to diffuse down the tracheae would be very important. In other words, the rate of diffusion of air down the tracheae would be limited in part by the length of the tracheae. In effect, only very small insects have tracheae that are short enough to be efficiently ventilated by simple diffusion.

Many insects are far too large to deliver gases to and from their tissues by simple diffusion alone. How do these large insects ventilate their tracheal system?

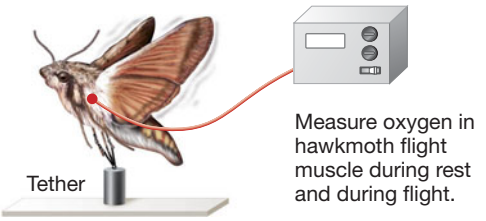
Consider a study on the sweet potato hawkmoth. Yutaka Komai set out to investigate how the amount of O_2 delivered to the wing muscles changes during flight. To document the partial pressure of oxygen in these muscles, he inserted a needlelike electrode into the flight muscles of a hawkmoth. The electrode was attached to an instrument that measured the partial pressure of oxygen, and the hawkmoth was tethered to a stand (**FIGURE 45.7**).

Komai recorded P_{O_2} as the insect rested and then stimulated the moth to fly by exposing it to wind. The "Results" section of Figure 45.7 shows how P_{O_2} changed during one such experiment. (The procedure was repeated on several individuals, and the same pattern was observed.)

To read this graph, put your finger on the left-hand end of the orange line and move it toward the right, to where the insect started flying and the line changes to red. Note that P_{O_2} levels in the flight muscles dropped initially. This is not surprising, because flight is an energetically demanding activity. As flying continued, however, P_{O_2} levels recovered until they were nearly as high as when they were at rest.

To explain this observation, biologists propose that the tracheae are alternately compressed and dilated as the muscles around them contract and relax. The muscle contractions and relaxations produce pressure changes that cause the volume of space inside the tracheal system to change (**FIGURE 45.8**). This is a key point: If the volume occupied by a fixed amount of gas expands, the gas pressure decreases. But if the volume that a fixed amount of gas occupies declines, the gas pressure increases.

The volume of the tracheal system increases when muscles relax, causing pressure inside the system to go down and air from the atmosphere to rush in. What happens when muscles

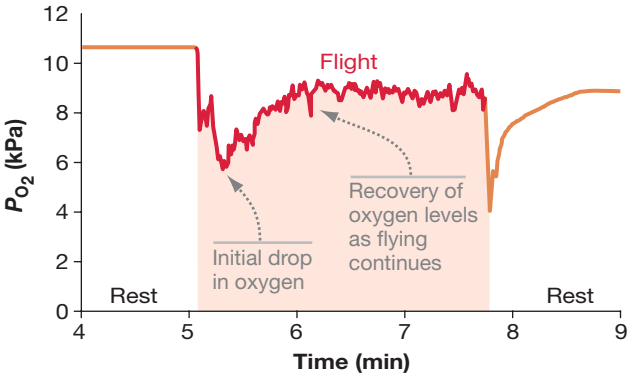


RESEARCH

QUESTION: Does physical activity affect air movement through the tracheal system?

HYPOTHESIS: Air moves through the tracheal system faster during physical activity.

NULL HYPOTHESIS: Physical activity does not affect the rate of air movement.



EXPERIMENTAL SETUP:

PREDICTION: Flying will increase ventilation of tracheal system, causing increase in P_{O_2} in wing muscle.

PREDICTION OF NULL HYPOTHESIS: Flying will not increase ventilation of tracheal system; P_{O_2} in flight muscle will decline steadily during flight.

RESULTS:

CONCLUSION: Muscular contractions may help ventilate the tracheal system in at least some insects.

FIGURE 45.7 Research Suggests the Tracheal System Is Ventilated during Movement. On the graph's *y*-axis, kPa stands for kilopascal, a unit of pressure (or force per unit area).

SOURCE: Komai, Y. 1998. *The Journal of Experimental Biology* 201: 2359–2366.

✔**QUESTION** Why was it important for the researcher to repeat this experiment with several different individuals?

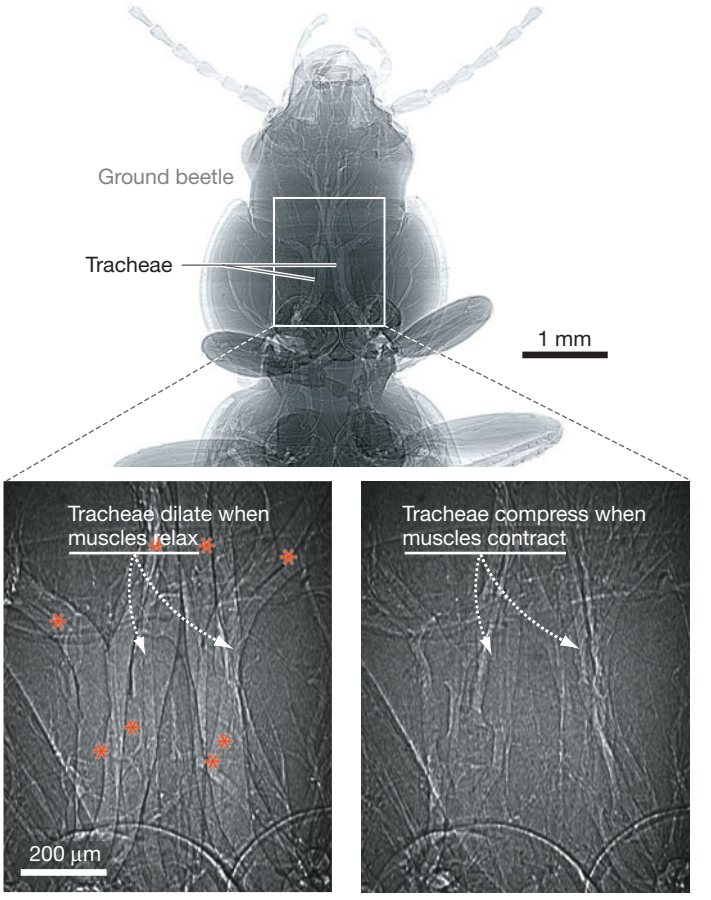


FIGURE 45.8 Tracheae Are Dilated and Compressed during Ventilation. Muscle relaxation and contraction during flight or other activity alternately dilates and compresses tracheae, causing pressure changes that promote air flow in and out of the tracheae. Asterisks in the left image mark tracheal tubes that are compressed in the right image.

contract? The opposite—the volume of the tracheae decreases, pressure inside the system increases, and gas moves out of the tracheae into the atmosphere.

The action of the abdominal and flight muscles therefore stimulates air flow through the insect tracheal system, causing gases to move more quickly than they would by diffusion alone.

In large insects, the movement of gases is further promoted by larger tracheae diameters. These larger diameters increase another variable in Fick's law, the cross-sectional area for gas exchange. As evidence, researchers have shown that the diameter of the tracheae in large beetles is proportionally much larger than that of small beetles. Disproportionally large tracheae allow effective ventilation even in the largest living beetles, which can reach impressive lengths of over 15 cm (6 inches) and weigh over 50 g (3 ounces), the size of a submarine sandwich!

Why don't beetles get even larger than this? Researchers hypothesize that if they did, the size of their tracheae would be so large that there would not be enough space in their limbs for much else. The beetles would lack sufficient muscles and other tissues to support their huge bodies.

In the Paleozoic era about 300 million years ago (mya), however, giant insects flourished. While the largest dragonflies today are about 15 cm in wingspan, during the Paleozoic they grew to be as large as 70 cm (2.3 feet)! How can this be explained?

One major hypothesis posits that giant insects evolved during the Paleozoic era because the atmospheric oxygen concentration was much higher than it is today (**FIGURE 45.9**). Recall that according to Fick's law, the rate of diffusion of a gas from one point to another is affected by the difference in partial pressures of the gas at the two points. During the latter part of the Paleozoic, the value of $P_2 - P_1$ was increased in the equation shown in Figure 45.3. This may have increased the rate of movement of gases through the tracheal system, permitting efficient ventilation in extremely large insects.

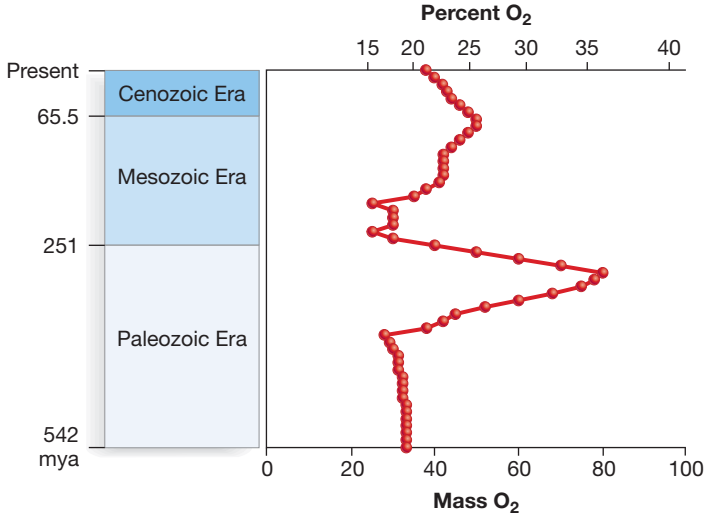

FIGURE 45.9 Atmospheric Oxygen Levels Peaked during the Paleozoic Era.

DATA: Berner, R. A. 1999. *Proceedings of the National Academy of Sciences* 96: 10955–10957.

About 50 to 100 million years later, at the start of the Mesozoic era, atmospheric oxygen concentrations declined precipitously. Giant insects went extinct, likely in part because they could no longer supply their tissues with enough oxygen.

How Do Vertebrate Lungs Work?

In most terrestrial vertebrates, air enters the body through both the nose and mouth. A tube known as the **trachea** (not to be confused with the tracheae of insects) carries the inhaled air to narrower tubes called **bronchi** (singular: **bronchus**). The bronchi branch off into yet narrower tubes, the **bronchioles.** The organs of ventilation, the lungs, enclose the bronchioles and part of the bronchi (**FIGURE 45.10a**, see page 910).

Lungs are internal organs that are used for gas exchange. In addition to being found in terrestrial vertebrates—amphibians, reptiles (including birds), and mammals—they occur in many fishes and certain invertebrates.

Lung Structure and Ventilation Vary among Species The amount of lung surface area available for gas exchange varies a great deal among species. In frogs and other amphibians, the lung is a simple sac lined with blood vessels. The lungs of mammals, in contrast, are finely divided into tiny sacs called **alveoli** (singular: **alveolus; FIGURE 45.10b**).

Each human lung contains approximately 150 million alveoli, which give mammalian lungs about 40 times more surface area for gas exchange than an equivalent volume of frog lung tissue. As **FIGURE 45.10c** shows, an alveolus provides an interface between air and blood that consists of a thin aqueous film, a layer of epithelial cells, some extracellular matrix (ECM) material, and the wall of a capillary.

In addition to total surface area, the other major feature of lungs that varies among species is mode of ventilation. In the lungs of snails and spiders, air movement takes place by diffusion only. Vertebrates, in contrast, actively ventilate their lungs by pumping air via muscular contractions.

One mechanism for pumping air is **positive pressure ventilation,** used by frogs and related animals. A frog lowers the floor of its throat, increasing the volume there and thus drawing in air from the atmosphere through the nasal passages and into the oral cavity. The animal then closes the nasal passages and contracts its throat muscles. These actions increase the pressure on air in the oral cavity and force it into the lungs.

In effect, frogs push air into their lungs. In contrast, humans and other mammals pull air into their lungs. How does this **negative pressure ventilation** work?

Ventilation of the Human Lung The pressure inside the human chest cavity is about 5 mm Hg less than atmospheric pressure. This negative pressure surrounding the lung is just enough to keep the lung expanded. If a wound penetrates the chest wall and the pressure differential between the chest cavity and the atmosphere disappears, the lung on the side of the injury will collapse like a deflated balloon.

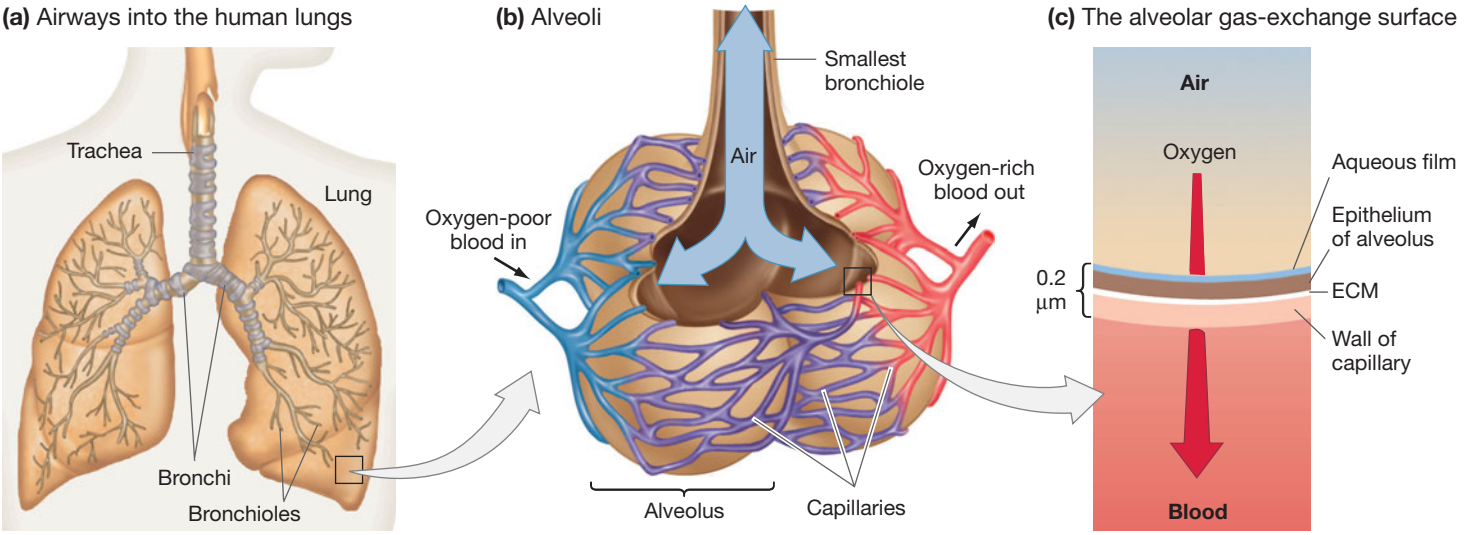

FIGURE 45.10 Lungs Offer a Thin Membrane with a Large Surface Area for Gas Exchange between Air and Blood. (a) The human respiratory tract branches repeatedly from the largest airway, the trachea, to the smallest, called bronchioles. The system of airways ends in clusters of tiny sacs called alveoli. **(b)** Alveoli are covered with capillary networks and are **(c)** the site of gas exchange.

Humans ventilate their lungs by changing the pressure within their chest cavity between about −5 mm Hg and −8 mm Hg relative to the atmosphere. As **FIGURE 45.11a** shows, inhalation is based on increasing the volume of the chest cavity and thus lowering the pressure. The change is caused by a downward motion of the thin muscular sheet called the **diaphragm** and an outward motion of the ribs. As the pressure surrounding the lungs drops, air flows into the airways along a pressure gradient.

Exhalation, in contrast, is a passive process—the volume of the chest cavity decreases as the diaphragm and rib muscles relax. Because the lung is elastic, it returns automatically to its original, collapsed shape if it is not stretched or compressed. During exercise, though, exhalation is an energy-demanding, active process.

The changes in pressure that occur during negative pressure ventilation are analogous to changing the pressure within a jar, as shown in **FIGURE 45.11b**.

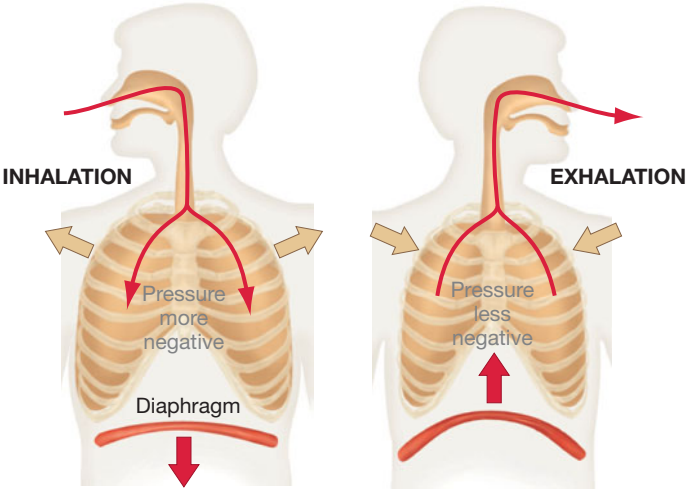
About 450 mL of air moves into and out of the lungs in an average breath. Only about two-thirds of this volume actually participates in gas exchange, however, because 150 mL of the air occupies **dead space**— air passages that are not lined by a respiratory surface. The trachea and bronchi shown in Figure 45.10a, for example, represent dead space.

Breathing is much more efficient during exercise, when the chest cavity undergoes larger changes in volume. When a person is breathing hard, over 2500 mL of air can move with each inhalation–exhalation cycle, but the 150 mL of dead space stays the same.

Ventilation of the Bird Lung Flight is one of the most energy-demanding activities performed by animals. Even so, some birds fly tens of thousands of kilometers during annual migrations.

Even more impressive, geese regularly fly over the top of Mt. Everest. At this elevation, the partial pressure of oxygen is so low that most humans would immediately black out if they were flown there and dropped off. How are birds able to extract enough oxygen from the atmosphere to support long flights and to fly at high elevations?

FIGURE 45.12 provides a diagram of ventilation in birds.



1. During inhalation, air flows through the trachea and enters two large air sacs posterior to the lungs.
2. During exhalation, air leaves the posterior air sacs and enters tiny, branching airways, called parabronchi, in the posterior portion of the lungs.
3. During the next inhalation, air moves into parabronchi in the anterior part of the lungs and on to a system of air sacs anterior to the lungs.
4. During the next exhalation, air moves out of the anterior sacs, through the trachea, and out to the atmosphere. Meanwhile, air from the second inhalation is now flowing through the lungs.

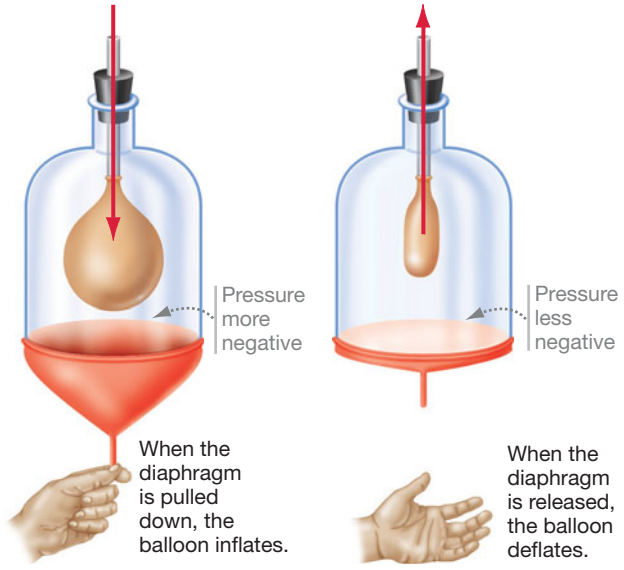
The key conclusion from these observations? Airflow through the avian lung is unidirectional.

Why is the avian respiratory system so efficient?

- Dead space is restricted to the short stretch of trachea between the mouth and the opening of the anterior air sacs. As a result, birds use inhaled air much more efficiently than mammals do.
- Gas exchange occurs during both inhalation and exhalation. In contrast, no gas exchange occurs during the exhalation half of the respiratory cycle in mammals. Bird ventilation resembles the continuous ventilation of fish gills in this respect.
- Blood circulates through the bird lung in capillaries that cross the parabronchi perpendicularly. This crosscurrent pattern is less efficient than the countercurrent circulation of fish gills but far more efficient than the weblike arrangement of capillaries that surrounds mammalian alveoli.

(a) Lungs expand and contract in response to changes in pressure inside the chest cavity.

(b) Ventilatory forces can be modeled by a balloon in a jar.



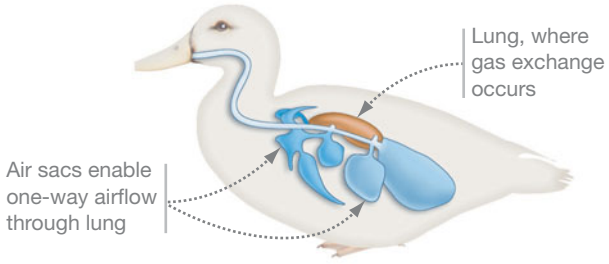


FIGURE 45.11 Changes in the Volume of the Chest Cavity Drive Negative Pressure Ventilation. (a) Inhalation: When the diaphragm and rib muscles contract, the volume of the lung cavity increases, lowering pressure. In response, air flows into the lungs. Exhalation: When the diaphragm and rib muscles relax, the volume of the lung cavity decreases, causing internal pressure to increase. In response, lung volume decreases—due to elasticity of the lungs—and air flows out. **(b)** A model of negative pressure ventilation.

Homeostatic Control of Ventilation

An animal is in trouble if its mechanisms of homeostasis fail to maintain blood oxygenation or to eliminate carbon dioxide. Adequate adenosine triphosphate (ATP) production depends on maintaining the partial pressures of oxygen and carbon dioxide within a narrow range, both during rest and vigorous exercise. How is ventilation controlled to achieve this critical homeostasis?

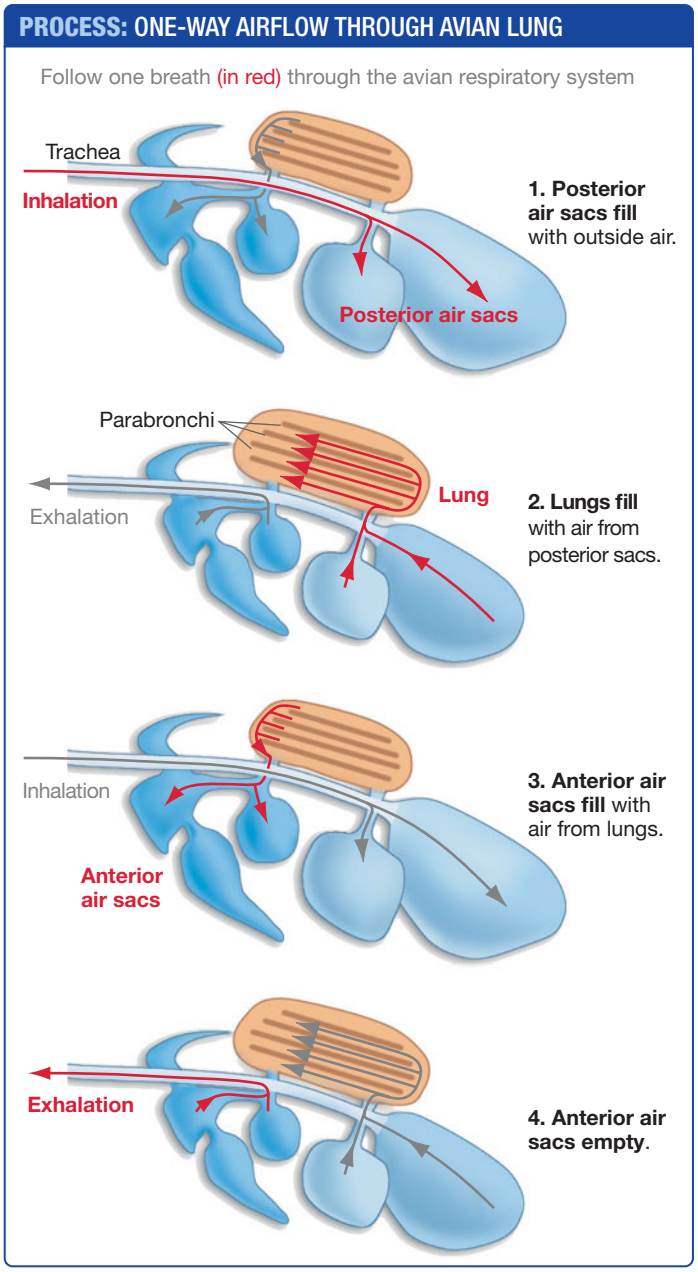

FIGURE 45.12 Air Flows in One Direction through the Bird Lung, Maximizing Gas Exchange.

When mammals are resting, the rate of breathing is established by the medullary respiratory center, an area at the base of the brain, just above the spinal cord. This center stimulates the rib and diaphragm muscles to contract about 12 to 14 times per minute in humans.

But during exercise, things change. Active muscle tissue takes up more oxygen from the blood. As a result, the partial pressure of oxygen (P_{O_2}) in blood drops. Those same muscles release larger quantities of carbon dioxide to the blood, raising its partial pressure (P_{CO_2}) in blood. When carbon dioxide reaches the brain, it rapidly diffuses from the blood into the cerebrospinal fluid that bathes the brain. In both blood and cerebrospinal fluid, CO_2 reacts with water to form carbonic acid (H_2CO_3), which then dissociates to release a hydrogen ion (H^+) and a bicarbonate ion (HCO_3^-):

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$$

The result is a slight drop in the pH of blood and cerebrospinal fluid. The change in blood pH is sensed by specialized neurons located near the large arteries that travel from the heart into the neck and to the base of the brain.

Signals from these neurons or from pH detectors in the medullary respiratory center cause the breathing rate to increase. The resulting rise in ventilation rate increases the rate of oxygen delivery to the tissues and the rate at which carbon dioxide is eliminated from the body, restoring P_{O_2} and P_{CO_2} to their resting levels. This control system is so effective that it can maintain stable blood levels of oxygen and carbon dioxide even during intense exercise.

Now let's look more closely at how blood transports oxygen and carbon dioxide between the gas exchange surface and an animal's tissues.

check your understanding

C Y U

If you understand that . . .

- The rate of diffusion of gases across a respiratory surface depends on the area of the surface, the thickness of the surface, and the difference in partial pressures of the gases across the surface.
- Most large-bodied animals exchange gases via gills, tracheae, or lungs.

✔ You should be able to . . .

1. Identify two features that are common to gills, tracheae, and lungs, as well as one trait that is unique to each.
2. When you hold your breath, what happens to the P_{O_2}, P_{CO_2}, and pH of your blood?

Answers are available in Appendix A.

45.4 How Are Oxygen and Carbon Dioxide Transported in Blood?

Blood is a connective tissue that consists of cells in a watery extracellular matrix. Besides carrying oxygen and carbon dioxide between cells and the lungs, blood transports nutrients from the digestive tract to other tissues in the body, moves waste products to the kidney and liver for processing, conveys hormones from glands to target tissues, delivers immune system cells to sites of infection, and distributes heat throughout the body.

Given the wide variety of functions that blood serves, it is not surprising that it is a complex tissue. In an average human, 50–65 percent of the blood volume is composed of an extracellular matrix called **plasma.** The remainder of the volume comprises cells and cell fragments that are collectively called formed elements.

The formed elements in blood include platelets, several types of white blood cells, and red blood cells.

- **Platelets** are cell fragments that act to minimize blood loss from ruptured blood vessels. They do so by releasing material that helps form the blockages known as clots.
- **White blood cells** are part of the immune system. They fight infections (as Chapter 51 will explain in detail).
- **Red blood cells** transport oxygen from the lungs to tissues throughout the body. They also play a role in transporting carbon dioxide from tissues to the lungs. In humans, red blood cells make up 99.9 percent of the formed elements.

The human body synthesizes new red blood cells at the rate of 2.5 million per second to replace old red blood cells, which die at the same rate. These red blood cells last for about 120 days. Red blood cells, white blood cells, and platelets develop from stem cells located in the tissue inside bone (bone marrow).

Vertebrates other than mammals transport oxygen in red blood cells that retain their nuclei. But in mammals, red blood cells lose their nuclei as they mature, along with their mitochondria and most other organelles. Mammalian red blood cells are essentially bags filled with approximately 280 million copies of the oxygen-carrying molecule **hemoglobin.**

Structure and Function of Hemoglobin

Even though oxygen is not highly soluble in water, it is often found in high concentrations in blood. Blood has a high oxygen-carrying capacity because O_2 readily binds to the hemoglobin molecules in red blood cells.

The evolution of hemoglobin was a key event in the diversification of animals. By increasing the oxygen-carrying capacity of blood, hemoglobin made it possible for cellular respiration rates to increase. High rates of ATP production, in turn, support high rates of growth, movement, digestion, and other activities.

Hemoglobin is a tetramer, meaning that it consists of four polypeptide chains (**FIGURE 45.13**). Each of the four polypeptide chains binds to a nonprotein group called **heme** (represented by black circles in the figure). Each heme molecule, in turn, contains an iron ion (Fe^{2+}) that can bind to an oxygen molecule. As a result, each hemoglobin molecule can bind up to four oxygen molecules. In blood, 98.5 percent of the oxygen is bound to hemoglobin; only 1.5 percent is dissolved in plasma.

What Is Cooperative Binding? Blood leaving the human lungs has a P_{O_2} of about 100 mm Hg, while at rest the muscles and other tissues have a P_{O_2} of about 40 mm Hg. This partial pressure difference creates a diffusion gradient that unloads O_2 from hemoglobin to the tissues.

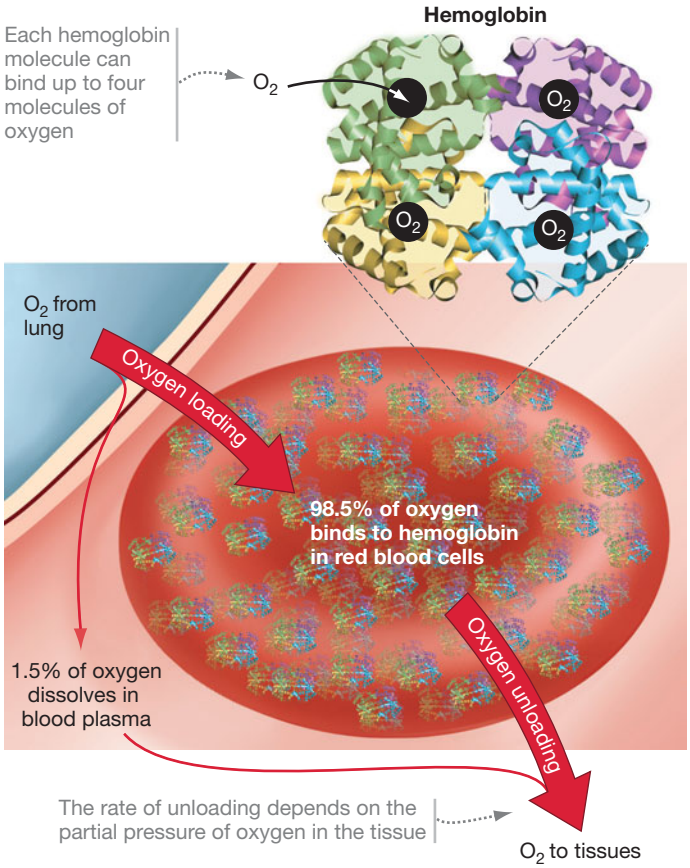

FIGURE 45.13 Hemoglobin Transports Oxygen to Tissues.

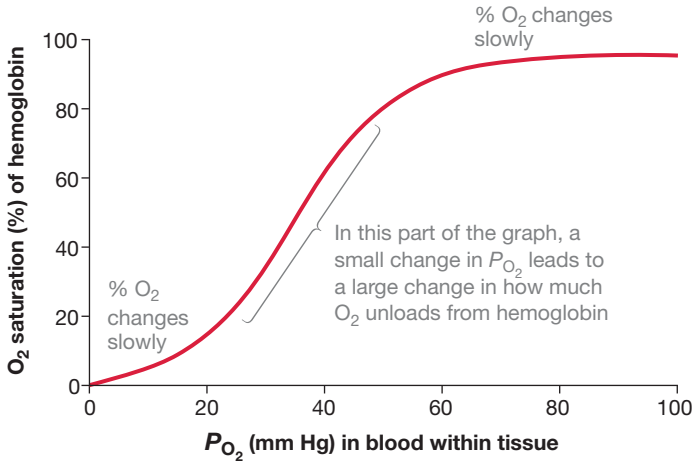

FIGURE 45.14 The Oxygen–Hemoglobin Equilibrium Curve Is Sigmoidal. A sigmoidal curve has three distinct regions.

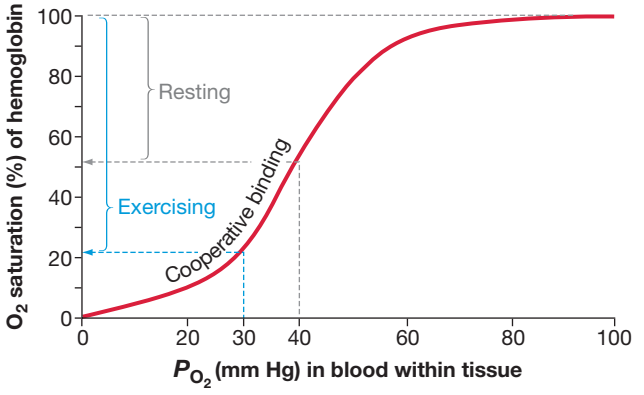
Researchers who studied the dynamics of O_2 unloading in tissues found the pattern shown in **FIGURE 45.14**. This graph plots the percentage of O_2 saturation of hemoglobin in red blood cells versus the P_{O_2} in the blood within tissues. If saturation of hemoglobin is 100 percent, it means that every possible binding site in hemoglobin contains an oxygen molecule.

The graph in Figure 45.14 is called an **oxygen–hemoglobin equilibrium curve,** or an oxygen dissociation curve or hemoglobin saturation curve. Note that the *x*-axis plots the partial pressure of oxygen in tissues. In effect, this represents "demand." Oxygen-depleted tissues, where demand for oxygen is high, are on the left-hand part of the horizontal axis; oxygen-rich tissues are toward the right. The *y*-axis, in contrast, plots the percentage of hemoglobin molecules in blood that are saturated with oxygen—a measure of "supply," or how many oxygen molecules on average are bound to hemoglobin. Each 25 percent change in saturation corresponds to an average of one additional oxygen molecule bound per hemoglobin molecule or one oxygen molecule delivered to tissues.

The most remarkable feature of the oxygen–hemoglobin equilibrium curve is that it is sigmoidal, or S-shaped. The pattern occurs because the binding of each successive oxygen molecule to a subunit of the hemoglobin molecule causes a conformational change in the protein that makes the remaining subunits much more likely to bind oxygen.

This phenomenon is called **cooperative binding.** Conversely, the loss of a bound oxygen molecule changes hemoglobin's conformation in a way that makes the loss of additional oxygen molecules more likely.

Why Is Cooperative Binding Important? To understand why cooperative binding is important, use **FIGURE 45.15a** (see page 914) to figure out what happens to hemoglobin saturation when oxygen demand in tissues changes.



Let's begin with some basic observations. When blood arrives at tissues from the lungs, hemoglobin saturation is close to 100 percent. At rest, tissue P_{O_2} is typically about 40 mm Hg. But during exercise, cells are using so much oxygen in cellular respiration that tissue P_{O_2} drops to about 30 mm Hg. Now,

- Put your finger on the *x*-axis at 40 mm Hg, trace the dashed line up until it hits the equilibrium curve, and check where this point is on the *y*-axis. The answer is about 52 percent. This means that when tissues are at rest, hemoglobin unloads about half of its oxygen (about 48 percent) to the tissues.
- Now put your finger on the *x*-axis at 30 mm Hg, trace the dashed line up, and check hemoglobin saturation at this point on the curve. The answer is about 22 percent. This means that when tissues are exercising, hemoglobin unloads about 78 percent of its oxygen to tissues.

Here's the punch line: In response to a relatively small change in tissue P_{O_2}, there is a relatively large change in the percentage of saturation of hemoglobin. The large change occurs because the equilibrium curve is extremely steep in the range of P_{O_2} values commonly observed in tissues. The curve is steep because of cooperative binding. Cooperative binding is important because it makes hemoglobin exquisitely sensitive to changes in the of P_{O_2} tissues.

✔ **If you understand this concept, you should be able to explain the consequences of an oxygen–hemoglobin equilibrium curve with a middle section that is even steeper than the one shown in Figure 45.15a.**

(a) With cooperative binding, large amounts of O_2 are delivered to resting and exercising tissues.

(b) Without cooperative binding, smaller amounts of O_2 would be delivered to resting and exercising tissues.

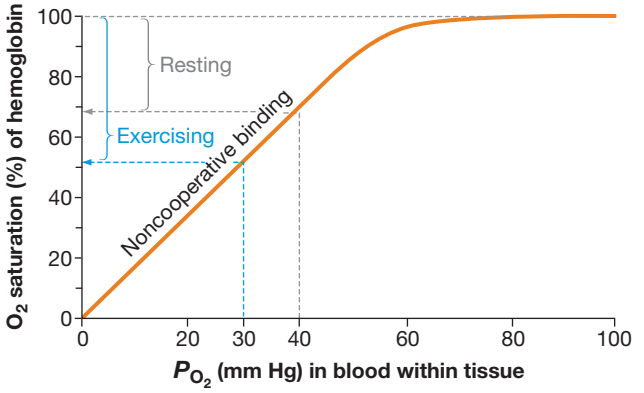


FIGURE 45.15 Cooperative Binding of O_2 by Hemoglobin Results in Greater O_2 Delivery than Noncooperative Binding. The hemoglobin is almost 100 percent saturated with oxygen until it arrives at tissues.

If cooperative binding did not occur, all four subunits of hemoglobin would load or unload oxygen independently of each other. They would lose or gain oxygen in direct proportion to the partial pressure of oxygen in the blood, until the molecule was either completely saturated or unsaturated with oxygen. There would be a linear relationship between hemoglobin saturation and tissue P_{O_2}—not a sigmoidal one.

FIGURE 45.15b shows noncooperative binding. As the dashed lines on this graph indicate, a relatively small change in oxygen delivery would occur when tissue P_{O_2} changes from its resting level of about 40 mm Hg to 30 mm Hg. Specifically, hemoglobin would unload about 100% − 68% = 32% of its oxygen when tissues are at rest, and about 100% − 52% = 48% of its oxygen during exercise. This difference—about 16 percent—is much less than the 30 percent change observed with cooperative binding.

How Do Temperature and pH Affect Oxygen Unloading from Hemoglobin?

Cooperative binding is only part of the story behind oxygen delivery. Hemoglobin—like other proteins—is sensitive to changes in pH and temperature.

As noted above, the temperature and partial pressure of CO_2 rise in active muscle tissue during exercise. The CO_2 produced by exercising muscle reacts with the water in blood to form carbonic acid, which dissociates and releases a hydrogen ion. As a result, the pH of the blood in exercising muscle drops.

Decreases in pH alter hemoglobin's conformation. These shape changes make hemoglobin more likely to unload O_2 at any given value of tissue P_{O_2}. As **FIGURE 45.16** shows, this phenomenon, known as the **Bohr shift,** causes the oxygen–hemoglobin equilibrium curve to shift to the right when pH declines.

The Bohr shift is important because it makes hemoglobin more likely to release oxygen during exercise or other conditions in which P_{CO_2} is high, pH is low, and tissues are under oxygen stress. Increasing temperature has the same result: It shifts the curve to the right, representing a greater unloading of oxygen to tissues at any given P_{O_2}.

Oxygen Delivery by Hemoglobin Is Extremely Efficient

To appreciate cooperative binding and the Bohr shift in action, consider an experiment on how the oxygen transport system in rainbow trout responds to sustained exercise.

To begin, biologists had fish swim continuously against a current in a water tunnel. As the researchers increased the speed of the current and thus the swimming speed of the fish, they periodically sampled the O_2 content of arterial and venous blood. Arterial blood is freshly oxygenated and moving away from the gills; venous blood is returning to the gills from the rest of the body.

Not surprisingly, the biologists found that arterial O_2 levels remained fairly constant as swimming speed increased—meaning the gills continued to work efficiently enough to saturate hemoglobin with oxygen.

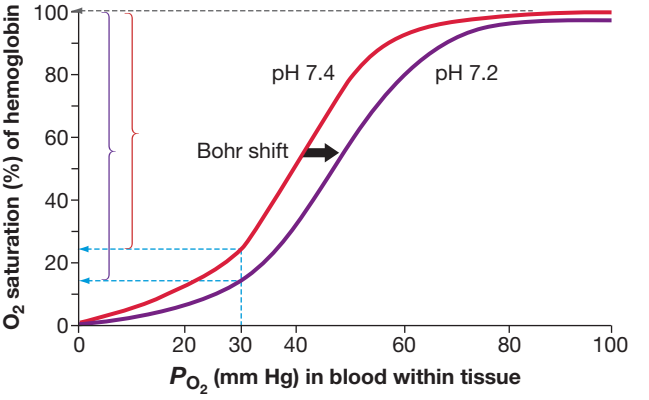

FIGURE 45.16 The Bohr Shift Makes Hemoglobin More Likely to Release Oxygen to Tissues with Low pH. As pH drops, oxygen becomes less likely to stay bound to hemoglobin at all values of tissue P_{O_2}. Exercising tissues have lower pH than resting tissues and thus receive more oxygen from hemoglobin.

✔**QUANTITATIVE** Estimate how much more oxygen is unloaded from hemoglobin at pH 7.2 than at pH 7.4 when the tissue has a P_{O_2} of 30 mm Hg.

In contrast, the O_2 content of venous blood, which had undergone gas exchange with the tissues, dropped steadily as swimming speed increased. When the fish had reached their maximum sustainable speed, virtually all the oxygen that had been available in the blood had been extracted.

The data show that in hard-working tissues, the combination of increased temperature, lower pH, and lower P_{O_2} caused hemoglobin to become almost completely deoxygenated. Oxygen-delivery systems based on hemoglobin are extremely efficient.

Comparing Hemoglobins Hemoglobin molecules from different individuals or species may vary in ways that affect fitness—the ability to survive and produce viable offspring. As an example, consider the oxygen–hemoglobin equilibrium curves in **FIGURE 45.17**. The curve in dark red is from a pregnant woman; the curve in light red is from a fetus she is carrying.

The hemoglobin found in fetuses is encoded by different genes than adult hemoglobin and has a distinctive structure and function. Specifically, the oxygen–hemoglobin equilibrium curve for fetal hemoglobin is shifted to the left with respect to the curve for adult hemoglobin.

Recall that the rightward shift of the curve means that hemoglobin is more likely to release oxygen. The leftward shift in Figure 45.17 means that fetal hemoglobin is less likely to give up oxygen—it binds oxygen more tightly. Stated another way, fetal hemoglobin has a higher affinity for oxygen than adult hemoglobin does at every P_{O_2}.

This shift is crucial. In the placenta, hemoglobin from the mother's blood gets close to hemoglobin from the fetus's blood. Because fetal hemoglobin has such a high affinity for oxygen, there is a transfer of oxygen from the mother's blood to the fetus's blood. The difference in hemoglobin structure and function ensures an adequate supply of oxygen as the fetus develops.

CO_2 Transport and the Buffering of Blood pH

The carbon dioxide that is produced by cellular respiration in the tissues enters the blood, where it reacts with water to form carbonic acid, which dissociates into bicarbonate and hydrogen ions. Recall that the resulting drop in blood pH stimulates an increase in breathing rate. Rapid exhalation of CO_2 then counteracts the drop in blood pH.

Homeostasis with respect to blood pH is reinforced by an elegant series of events that take place inside red blood cells. Biologists were able to work out what was happening when they discovered large amounts of the enzyme **carbonic anhydrase** in red blood cells.

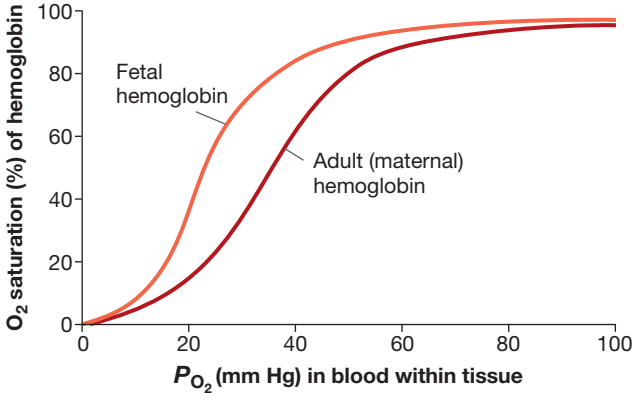

FIGURE 45.17 Fetal Hemoglobin Binds Oxygen More Tightly than Maternal Hemoglobin.

The Role of Carbonic Anhydrase and Hemoglobin Recall that carbonic anhydrase catalyzes the formation of carbonic acid from carbon dioxide in water (see Chapter 44). Consequently, CO_2 that diffuses into red blood cells is quickly converted to bicarbonate ions and protons. The same reaction occurs in the plasma surrounding red blood cells, although much more slowly in the absence of the enzyme.

Why is the carbonic anhydrase activity in red blood cells so important? The answer has two parts.

1. The protons produced by the enzyme-catalyzed reaction induce the Bohr shift, which makes hemoglobin more likely to release oxygen.
2. The partial pressure of CO_2 in blood drops when carbon dioxide is converted to soluble bicarbonate ions, maintaining a strong partial pressure gradient favoring the entry of CO_2 into red blood cells.

Thus, carbonic anhydrase activity makes CO_2 uptake from tissues more efficient (**FIGURE 45.18**).

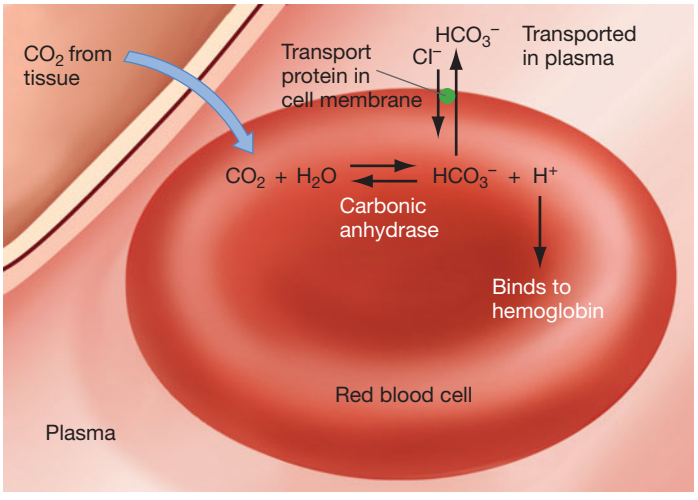

FIGURE 45.18 Carbonic Anhydrase Is Key to CO_2 Transport in Blood. When CO_2 diffuses into red blood cells, carbonic anhydrase quickly converts it to carbonic acid, which dissociates into a bicarbonate ion (HCO_3^-) and a proton (H^+). This reaction maintains the partial pressure gradient favoring the entry of CO_2 into red blood cells. The protons produced by the reaction bind to deoxygenated hemoglobin. Most CO_2 in blood is transported to the lungs in the form of HCO_3^-.

✔**QUESTION** This diagram shows the sequence of events in tissues. After reading the rest of Section 45.4, explain what happens when the red blood cell in the diagram reaches the lungs.

Once bicarbonate ions form in the red blood cell, they are transported into the blood plasma. The outcome is that most CO_2 is transported in blood (specifically in plasma) in the form of HCO_3^-—the bicarbonate ion. In contrast, the protons produced by the reaction stay inside red blood cells.

What ultimately happens to these protons? When hemoglobin is carrying few oxygen molecules, it has a high affinity for protons. As a result, it takes up much of the H^+ that is produced by the dissociation of carbonic acid. The hemoglobin acts as a **buffer**—a compound that minimizes changes in pH.

What Happens When Blood Returns to the Lungs? When deoxygenated blood reaches the alveoli, its environment changes dramatically. In the lungs, a partial pressure gradient favors the diffusion of CO_2 from plasma and red blood cells to the atmosphere within the alveoli. As CO_2 diffuses from the blood into the alveoli, P_{CO_2} in blood declines.

The drop in blood P_{CO_2} reverses the chemical reactions that occurred in tissues:

1. Hydrogen ions (protons) leave their binding sites on hemoglobin.
2. Protons react with bicarbonate to form CO_2.
3. CO_2 diffuses into the alveoli and is exhaled from the lungs.

In the meantime, hemoglobin has picked up O_2. Hemoglobin's affinity for oxygen is high in the alveoli because blood pH rises as P_{CO_2} declines.

When blood leaves the lungs, it has unloaded its carbon dioxide, and its hemoglobin is saturated with oxygen. The cycle begins anew.

check your understanding

C Y U

If you understand that . . .

- In blood, oxygen is bound to hemoglobin and transported inside red blood cells. Carbon dioxide is converted to bicarbonate ions and transported in plasma.
- Hemoglobin has several properties that make it an effective transport protein, including cooperative binding of oxygen, the Bohr shift response to low pH, and the ability to bind the protons that are generated when carbon dioxide is converted to bicarbonate ions.

✔ **You should be able to . . .**

Predict how the oxygen–hemoglobin equilibrium curves measured in Tibetan people, whose ancestors have lived at high elevations for thousands of years, compare to curves from people whose ancestors have lived at sea level for many generations.

Answers are available in Appendix A.

45.5 Circulation

According to Fick's law, differences in the partial pressure of gases are only part of the story when it comes to understanding diffusion rates. Surface area—*A* in the equation featured in Figure 45.3—also plays a key role.

Animals without circulatory systems have various ways of maximizing the surface area available for diffusion of gases and other key solutes:

- Animals that are only a few millimeters in size, like rotifers and tardigrades, have a small enough volume that diffusion over their body surface is adequate to keep them alive.
- The flattened bodies of flatworms and tapeworms give these animals a high surface-area-to-volume ratio (see Chapter 42). In these species, too, molecules are exchanged with the environment directly across the outer body surface.
- Diffusion across the body wall also occurs in roundworms, where gas exchange is facilitated by muscular contractions in the body wall. Diffusion is enhanced as roundworms circulate fluids by sloshing them back and forth.
- Jellyfish and corals have a large, highly folded gastrovascular cavity that offers a large surface area for exchange of molecules with the environment.

In larger animals, however, the problem of providing a large enough surface area for diffusion is solved by a circulatory system. A circulatory system carries transport tissues called blood or hemolymph into close contact with every cell in the body. In this case, "close contact" is a distance of about 0.1 mm between the smallest blood vessels and cells within tissues. Diffusion is efficient at this scale.

To explore how circulatory systems work, let's start by distinguishing the two most basic types—open and closed. Open circulatory systems occur in most invertebrates, while all vertebrates have closed systems.

What Is an Open Circulatory System?

In an **open circulatory system,** a fluid connective tissue called hemolymph is actively pumped throughout the body in vessels. The hemolymph is not confined exclusively to the vessels, however. Instead, hemolymph comes into direct contact with tissues. As a result, the molecules being exchanged between hemolymph and tissues do not have to diffuse across the wall of a vessel. Hemolymph transports wastes and nutrients and may also contain oxygen-carrying pigments, some cells, and clotting agents.

FIGURE 45.19 illustrates the open circulatory system in a clam. Note that a muscular organ called the **heart** pumps hemolymph into vessels that empty into an open, fluid-filled space. Hemolymph is returned to vessels and then the heart when the heart relaxes and its internal pressure drops below that in the body cavity. General body movements also move hemolymph to and from the heart.

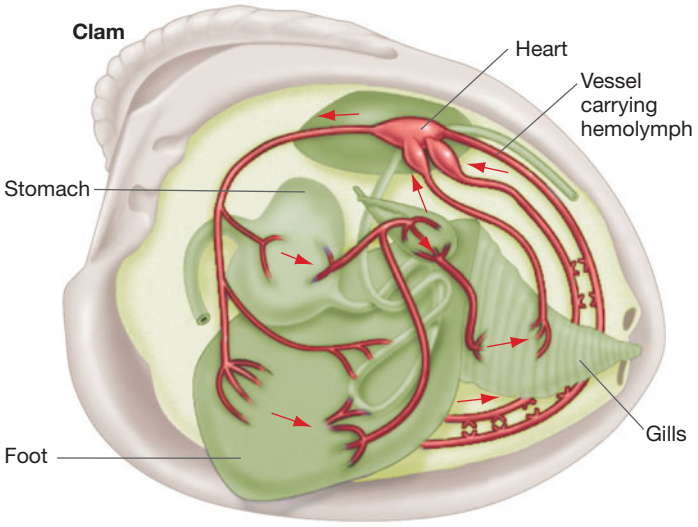

FIGURE 45.19 Clams Have Open Circulatory Systems. This drawing shows a clam with the top of the shell removed. Red arrows show the direction of hemolymph flow.

Because it moves throughout the volume of the body, hemolymph is under relatively low pressure in open circulatory systems. As a result, hemolymph flow rates may also be low. These features make open circulatory systems most suitable for relatively sedentary organisms, which do not have high oxygen demands.

Insects, with their rapid movements and more active lifestyles, are an exception to this rule. In the open circulatory systems of insects, the limitations imposed by low hemolymph pressure are overcome by their tracheal respiratory system, which delivers oxygen directly to the tissues.

Another characteristic of open circulatory systems, because they lack discrete, continuous vessels, is that the flow of hemolymph cannot be directed toward tissues that have a high oxygen demand and CO_2 buildup. An open circulatory system moves hemolymph throughout an animal's body in much the same way that a ceiling fan moves air throughout a room in a house.

Crustaceans are an important exception to this rule, however. Even though their circulatory system is classified as open, these species have a network of small vessels that can preferentially send hemolymph to tissues with the highest oxygen demands.

What Is a Closed Circulatory System?

In a **closed circulatory system,** blood flows in a continuous circuit through the body, under pressure generated by a heart. Because the blood is confined to vessels, a closed system can generate enough pressure to maintain a high flow rate.

In a closed circulatory system, blood flow can also be directed in a precise way in response to the tissues' needs. For example, blood can be shunted to leg muscles during exercise, to the intestines after a meal, or to regions of the brain engaged in particular mental tasks.

Which Lineages Have Closed Circulatory Systems? Closed circulatory systems are found in vertebrates and a few other lineages where individuals tend to be active. Earthworms and other annelids, for example, have a closed circulatory system and exchange gases with the environment across their thin, moist skin, which has a dense supply of capillaries. As a result, annelids are able to obtain and circulate enough oxygen to support intense muscular activity. Most live as active burrowers and hunters.

A similar situation occurs in squid, octopuses, and other cephalopods that hunt down prey. The closed circulatory system of these mollusks generates high rates of blood flow, which oxygenates their muscles well enough to support rapid movements and a predatory lifestyle.

Closed circulatory systems contain various types of blood vessels, each having a distinct structure and function. Let's review the major types of blood vessels and then consider how the vessels of a closed circulatory system interact with the lymphatic system.

Types of Blood Vessels An enormous amount of tubing is required to distribute blood within "diffusion distance" of every cell in the body. If all the blood vessels in a human body were laid end to end, they would stretch about 100,000 km (over 60,000 miles).

Blood vessels are classified as follows:

- **Arteries** are tough, thick-walled vessels that take blood away from the heart. Small arteries are called **arterioles.**
- **Capillaries** are vessels whose walls are just one cell thick, allowing exchange of gases and other molecules between blood and tissues. Networks of capillaries are called **capillary beds.**
- **Veins** are thin-walled vessels that return blood to the heart. Small veins are called **venules.**

The structure of arteries, capillaries, and veins correlates closely with their functions in a closed circulatory system. For example, the heart ejects blood into a large artery, usually called the **aorta.** All arteries have both muscle fibers and elastic fibers in their walls, but elastic fibers dominate the walls of the aorta. As a result, the aorta can expand when blood enters it under high pressure from the heart.

When a contraction of the heart ends, the diameter of the aorta returns to its resting state. This elastic response propels blood away from the heart and augments the force generated by the heart contraction. Similar types of secondary pumping action occur to some extent in other arteries as well. This feature helps maintain forward blood flow in the period between heart contractions.

The walls of arteries and arterioles have a thick layer composed of smooth muscle fibers. When the muscle fibers relax, the vessel diameter increases, resistance to flow is reduced, and blood flow increases in the tissues served by the vessel. But when these muscle fibers contract, the vessel diameter decreases, increasing resistance to flow and slowing the flow of blood in the vessel. In this way, blood flow to tissues can be carefully regulated by signals from the nervous system.

Capillaries are the smallest blood vessels. Their walls are only one cell layer thick, and they are just wide enough to let red blood cells through one at a time (**FIGURE 45.20a**). The extreme thinness of capillaries and the dense network they form throughout the body make them suitable sites for the exchange of gases, nutrients, and wastes between blood and the other tissues.

In some organs, such as the liver, the walls of capillaries contain many small openings that further diminish the barrier to diffusion between blood and the tissues. Despite their thinness, it is rare for capillaries to rupture, because blood pressure drops dramatically as blood passes through arterioles on its way to capillary beds.

After blood from arteries and arterioles passes through capillaries, veins carry it back to the heart. Because blood is under relatively low pressure by the time it exits the tissues, veins have thinner walls and larger interior diameters than arteries do (**FIGURE 45.20b**).

Blood flow in veins is speeded by muscle activity in the extremities, which compresses large veins. Larger veins also contain one-way **valves,** which are thin flaps of tissue that prevent any backflow of blood.

All veins contain some muscle fibers, which contract in response to signals from the nervous system, decreasing the diameter and overall volume of the vessels. Blood pressure in a closed circulatory system is regulated, in part, by actively adjusting the volume of blood contained within the veins.

What Is Interstitial Fluid? The relatively high operating pressure of closed circulatory systems, combined with the thinness of capillaries, produces a small but steady leakage of fluid from these blood vessels into the surrounding space. The area between cells is called interstitial space; the fluid that fills it is **interstitial fluid.** Blood cells are retained within capillaries, so interstitial fluid resembles plasma in its electrolyte composition.

Why does interstitial fluid build up? In 1896 Ernest Starling proposed that two forces were at work (**FIGURE 45.21**):

1. There is an outward-directed hydrostatic force in capillaries, created by the pressure on blood generated by the heart. This force is analogous to the pressure that drives water through the wall of a leaky garden hose.
2. There is also an inward-directed osmotic force across the capillary walls, created by the higher concentration of solutes in the blood plasma than in the interstitial space.

Starling reasoned that at the end of the capillary nearest to an arteriole, the hydrostatic force (the blood pressure) would exceed the osmotic force. If so, then in that location fluid would move out of the capillary into the interstitial space. But because blood pressure drops as fluid passes through a long, thin tube, Starling proposed that at the venous end of the capillary, the inward-directed osmotic force would exceed the outward-directed hydrostatic force. Thus, the fluid that was lost at the arteriolar end of the capillary would be largely reclaimed at the venous end.

Note the adverb "largely," however—not all interstitial fluid is reabsorbed by capillaries. In Figure 45.21, not all of the fluid entering the interstitial space at the arteriolar end of the capillary

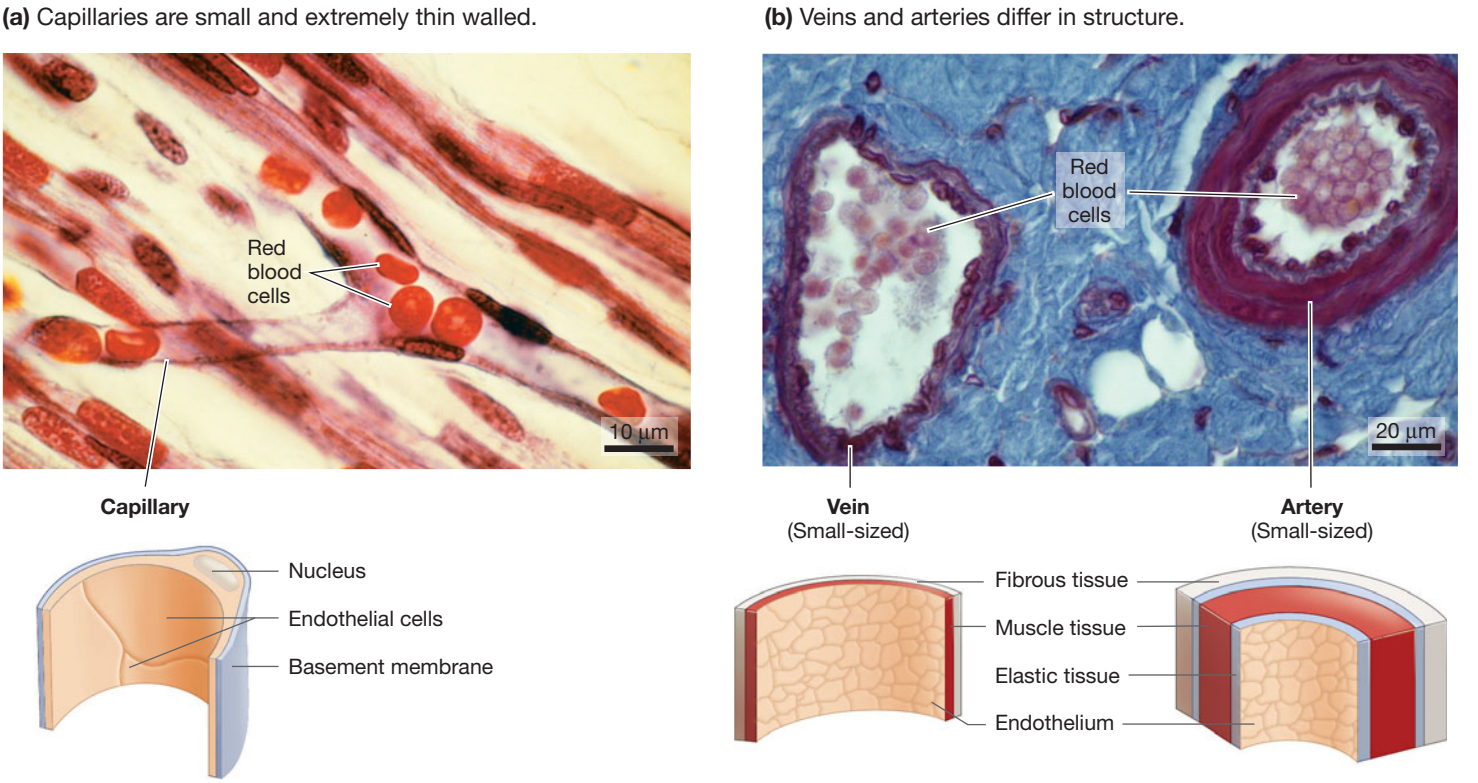

FIGURE 45.20 The Structures of Capillaries, Veins, and Arteries Reflect Their Different Functions.
Notice the differences in relative wall thickness and overall size.

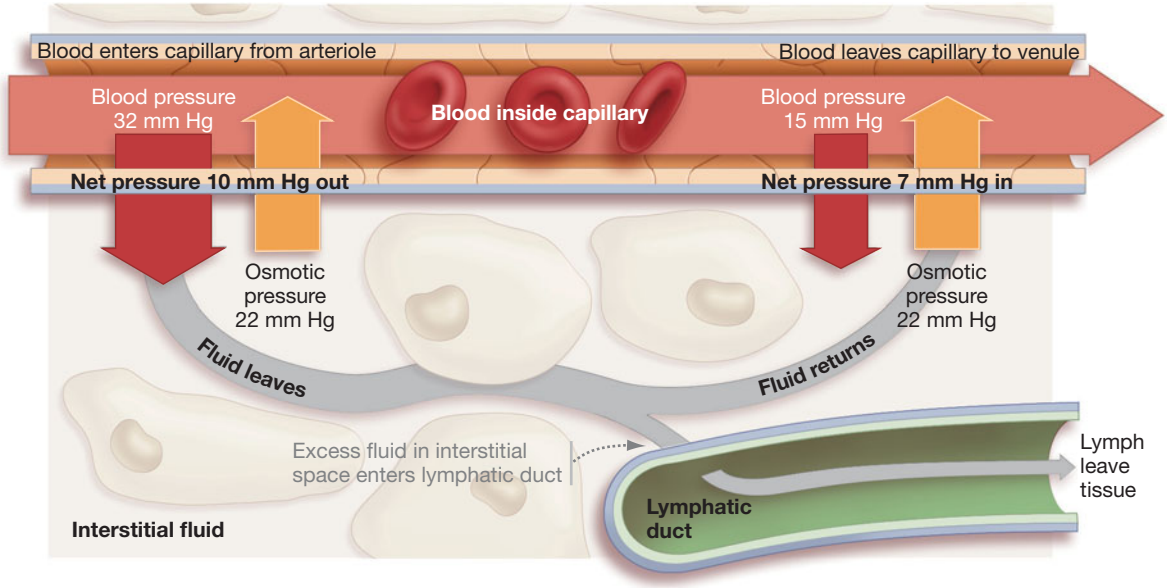

FIGURE 45.21 Pressure Differences in Capillaries Create Interstitial Fluid and Lymph. The balance of blood pressure and osmotic forces favors fluid loss from the beginning (inflow end) of capillaries and fluid recovery at the other (outflow) end. Fluid that is not recovered by the capillaries is transported out of the tissue as lymph, which eventually rejoins the blood circulation.

bed has reentered the bloodstream at the venous end—there is a net buildup of interstitial fluid. What happens to this fluid?

The Role of the Lymphatic System Starling proposed that because interstitial fluid is continually added to the interstitial space, there must be a mechanism for draining the excess fluid. In fact, the fluid is collected in the **lymphatic system:** a collection of thin-walled, branching tubules called lymphatic vessels that permeate all tissues. Interstitial fluid that enters the lymphatic ducts is called **lymph.** Lymphatic vessels join with one another, like the tributaries of a river, to form larger vessels. The largest lymphatic vessels return excess interstitial fluid, in the form of lymph, to the major veins entering the heart.

The importance of the lymphatic system becomes evident when lymphatic vessels are damaged or blocked. For example, a disease called elephantiasis results when the lymphatic vessels in the extremities are blocked by parasitic worms that are transmitted from person to person via mosquito bites. The affected limbs swell dramatically because the lymph cannot be drained, and the skin thickens, cracks, and becomes very painful.

How Does the Heart Work?

In animals with closed circulatory systems, the heart contains at least two chambers: There is at least one thin-walled **atrium** (plural: **atria**), which receives blood, and at least one thick-walled **ventricle,** which generates the force required to propel blood out of the heart and through the circulatory system. Atria are separated from ventricles by atrioventricular valves.

The phylogenetic tree in **FIGURE 45.22** (see page 920) shows the evolutionary relationships among some major vertebrate groups and a simplified sketch of the heart and circulatory system for each lineage. Two points are particularly important to note:

1. The number of atria and ventricles in the heart increased as vertebrates diversified. Fish hearts have one atrium and one ventricle; amphibians, turtles, lizards, and snakes have two atria and one ventricle; crocodilians, birds, and mammals have two atria and two ventricles. It is common to refer to these as two-, three-, and four-chambered hearts, respectively.
2. In fishes, the circulatory system forms a single circuit—one loop services the gills and the body. In other lineages, there are separate circuits to the lungs and to the body.

Why Did Multichambered Hearts and Multiple Circulations Evolve? To understand these evolutionary patterns, let's first consider the relatively simple heart and circulatory system found in fishes. A single atrium and ventricle and single circuit are adequate in fishes. Even though blood pressure drops as blood passes through the gills—due to the mechanical resistance to flow that occurs in the gills' capillary beds—blood pressure stays high enough to move blood throughout the body. This is largely because fishes live in the neutrally buoyant environment of water, where gravity does not have a large impact on blood flow.

In contrast, gravity has a much larger effect on circulation in land-dwelling vertebrates. Gravity has a particularly antagonistic effect on the flow of blood to elevated portions of the body. To overcome gravity in terrestrial environments, blood must be pumped at high pressure. However, the capillaries and alveoli of the lungs are too thin to withstand high pressures.

The successful solution in terrestrial vertebrates was the evolution of two separate pumping circuits:

1. The **pulmonary circulation** is a lower-pressure circuit to and from the lung.
2. The **systemic circulation** is a higher-pressure circuit to and from the rest of the body.

The pulmonary and systemic circulations are completely separated in the four-chambered hearts of crocodilians, birds, and mammals. On the other hand, the pulmonary and systemic

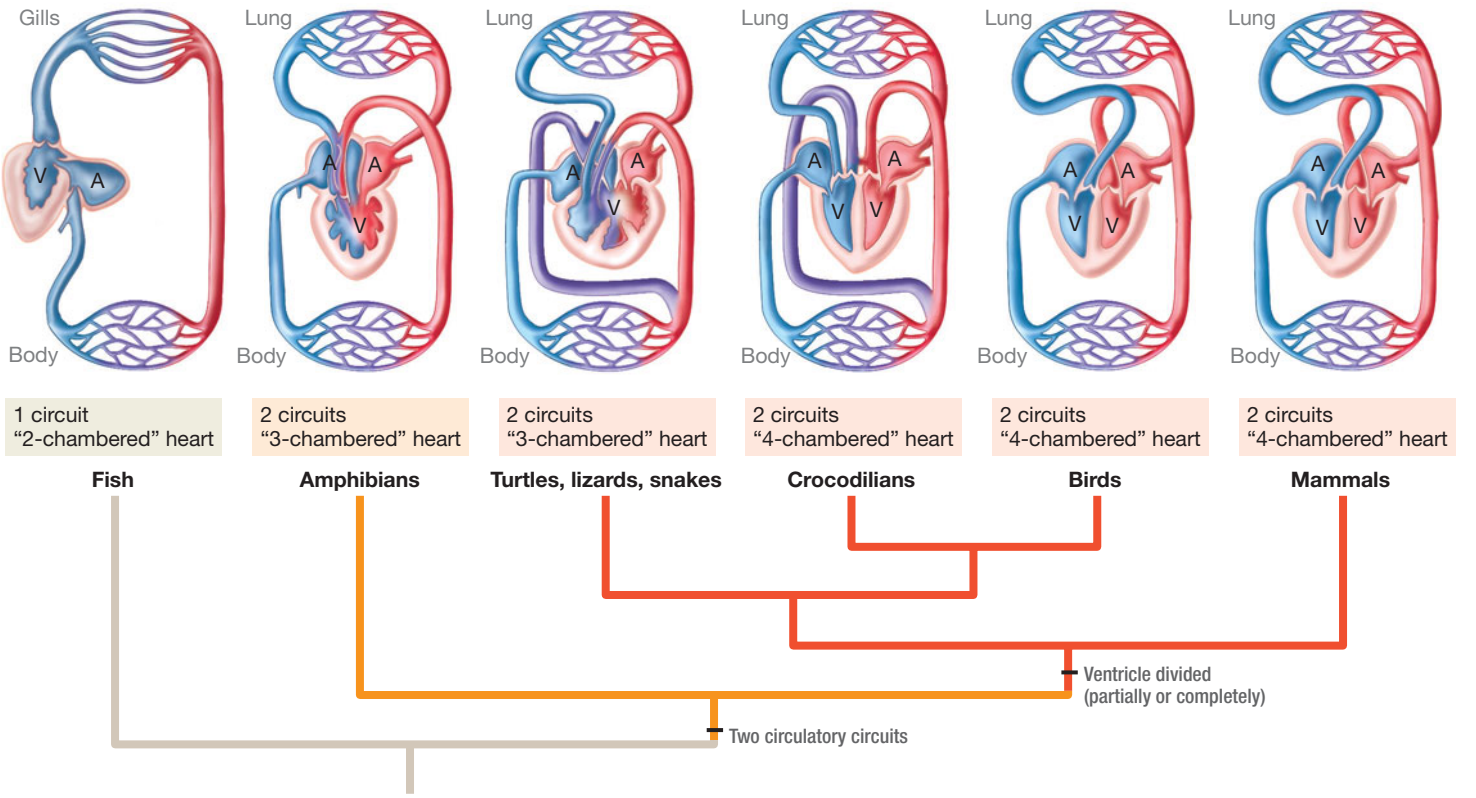

FIGURE 45.22 As Vertebrate Circulatory Systems Evolved, the Number of Atria and Ventricles Increased.
"A" denotes the atria—chambers that receive blood coming into the heart from the body and the gills or lungs.
"V" denotes the ventricles—chambers that pump blood out to the gills or lungs and the body.

circulations are only partially separated in the hearts of amphibians, turtles, lizards, and snakes. In these lineages, blood from the right and left atria may mix in the common ventricle before being expelled from the heart to the lungs or to the body. Turtles, lizards, and snakes, however, have partially divided ventricles that can limit the amount of mixing that occurs there (Figure 45.22).

In addition, turtles, lizards, and snakes have a bypass vessel running from the right side of the ventricle directly into the

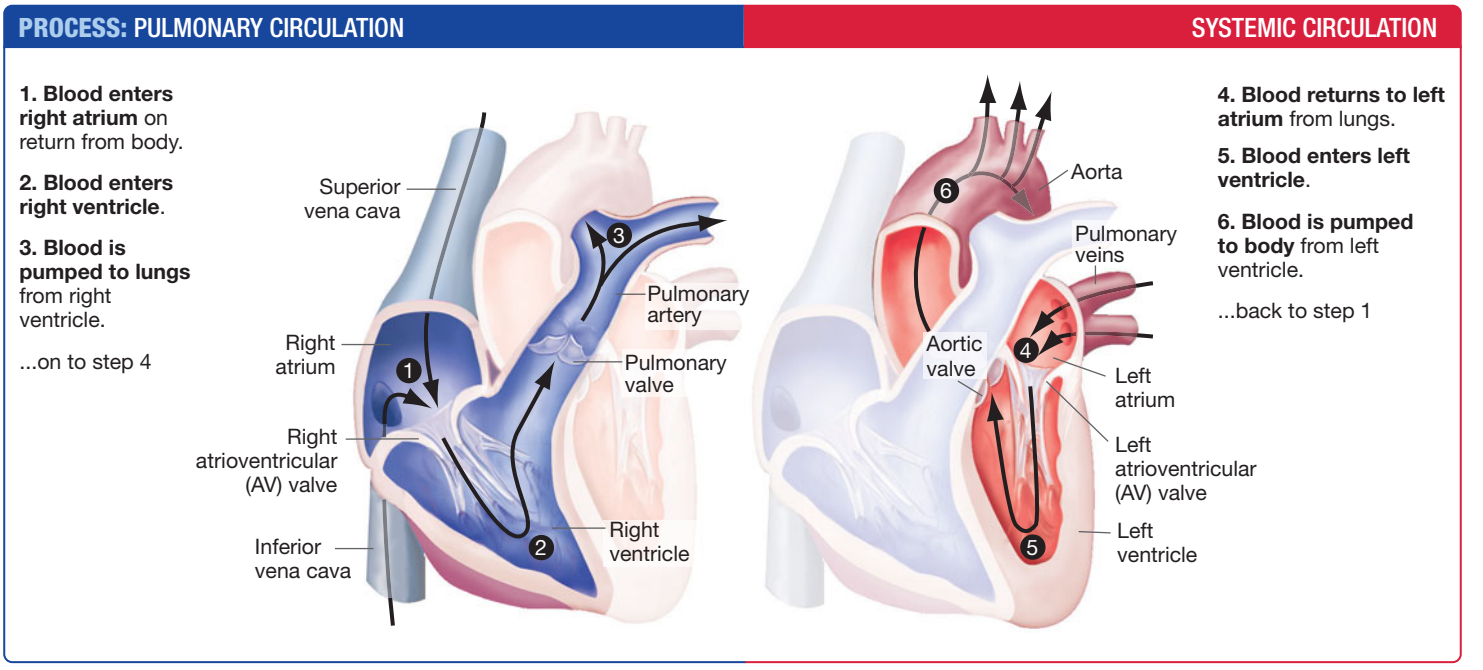

FIGURE 45.23 The Human Heart Maintains Separation of Oxygenated and Deoxygenated Blood. Blood flows through the chambers in the sequence shown.

systemic circulation. This bypass vessel is also observed in the unusual four-chambered hearts of crocodilians. The bypass vessels have an important function: They shunt blood from the pulmonary to the systemic circulation when the animal is underwater and not breathing. The result is a great reduction in blood flow to the lungs at those times.

Unlike reptiles, the hearts of birds and mammals have completely divided ventricles and lack a bypass vessel. This configuration completely separates the pulmonary and systemic circuits.

The Human Heart Your heart is located in the chest cavity, between your lungs, and is roughly the size of your fist. As **FIGURE 45.23** shows, the human circulatory system returns blood from the body to the right atrium of the heart. This blood is low in oxygen, and it arrives via two large veins called the inferior (lower) and superior (upper) **venae cavae** (singular: **vena cava**).

When the muscles that line the right atrium contract, they send deoxygenated blood to the right ventricle. The right ventricle, in turn, contracts and sends blood out to the lungs, via the **pulmonary artery.** In this way, the right ventricle powers the movement of blood through the pulmonary circulation.

Blood flows from atrium to ventricle to artery in only one direction, because one-way valves separate the heart's chambers from each other and from the adjacent arteries. As Figure 45.23 indicates, the valves are flaps, oriented to ensure a one-way flow of blood with little or no backflow. If heart valves are damaged or defective, the resulting backflow can be heard through a stethoscope. The backflow reduces the organ's efficiency and is called a **heart murmur.**

After blood circulates through the capillary beds in the lung's alveoli and becomes oxygenated, it returns to the heart through the **pulmonary veins.** The oxygenated blood enters the left atrium.

When the left atrium contracts, it pushes blood into the left ventricle. The walls of the left ventricle are so thick with muscle cells that their contraction sends oxygenated blood at high pressure through the aorta and into the arteries and capillaries that make up the systemic circulation.

FIGURE 45.24 summarizes the flow pattern through the human circulatory system and the blood gas concentrations at various points in the pulmonary and systemic circulations. Notice that blood vessels are called arteries or veins according to the direction of blood flow relative to the heart, not because of the oxygen content of the blood in them. Thus, the pulmonary artery is called an artery because it takes blood away from the heart, even though this blood is low in oxygen.

In healthy individuals, gas exchange in the lungs and tissues is rapid relative to the rate at which blood flows through capillaries. This situation is beneficial: It ensures that the maximum amount of oxygen is taken up and the maximum amount of carbon dioxide is released.

Similarly, the slow passage of blood through capillaries means that a maximum amount of oxygen is released from blood to tissues and a maximum amount of carbon dioxide is taken up. As a result, partial pressures for oxygen and carbon dioxide in the tissues and the systemic veins are equal.

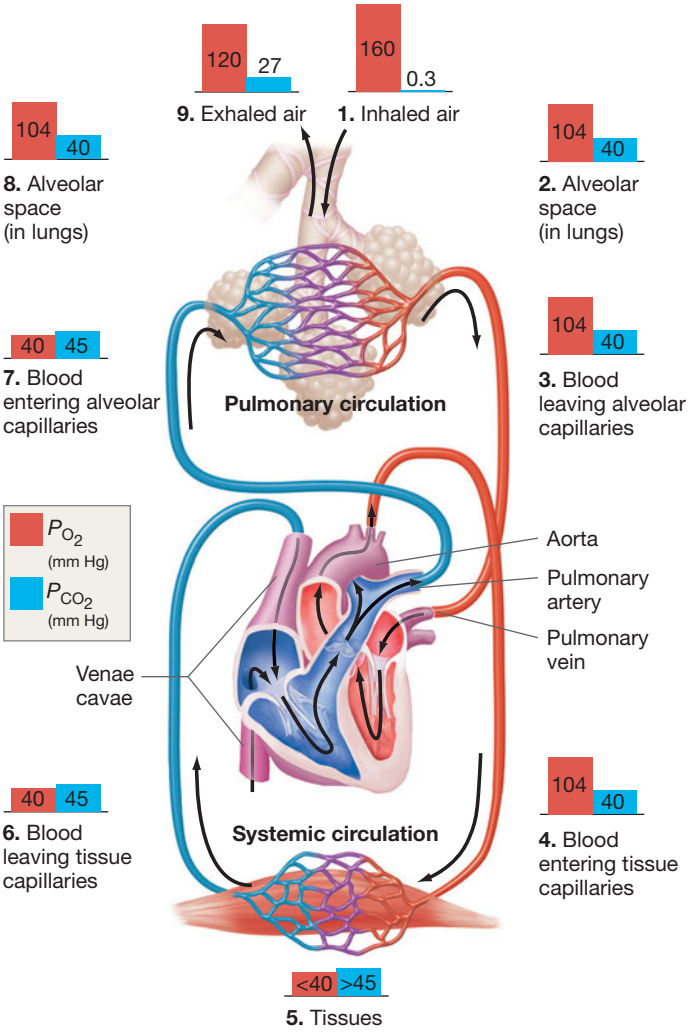

FIGURE 45.24 Partial Pressures of Gases Vary throughout the Human Circulatory System.

✔**QUESTION** Why are the partial pressures of oxygen and carbon dioxide in exhaled air intermediate in magnitude between the partial pressures in inhaled and alveolar air?

Electrical Activation of the Heart Like other muscle cells, cardiac muscle cells contract in response to electrical signals. In invertebrates, the electrical impulses that trigger contraction come directly from the nervous system. But in vertebrates, a group of cells in the heart itself is responsible for generating the initial signal.

The cells that initiate contraction in the vertebrate heart are known as **pacemaker cells.** They are located in a region of the right atrium called the **sinoatrial (SA) node.**

The SA node and the muscle cells of the heart receive input from the nervous system and from chemical messengers carried in the blood. These inputs are important for regulating both the heart rate and the strength of ventricular contraction. In this way, the amount of blood moving through the circulatory system varies in response to electrical signals and hormones. During

the "fight or flight" response (introduced in Chapter 49), for example, a chemical signal called epinephrine causes both heart rate and contraction strength to increase—sending more blood through the body in preparation for rapid movement.

As carefully regulated as the heart rate and contraction strength may be, a vertebrate heart will continue to beat even if all nerves supplying it are severed. Why? An electrical impulse that stimulates contraction is generated in the SA node and rapidly conducted throughout the right and left atria. The signal spreads quickly from cell to cell because of a striking property of cardiac muscle cells: They form physical and electrical connections with each other.

All cardiac muscle cells branch to contact several other cardiac muscle cells, join end to end with these neighboring cells (see Figure 42.5), and connect to them by specialized structures called **intercalated discs.** Because these discs contain many gap junctions (cell-to-cell connections described in Chapter 11), electrical signals pass directly from one cardiac muscle cell to the next.

The electrical activation of the heart is reflected in the orange line on the bottom of **FIGURE 45.25**. This line is an **electrocardiogram,** or **EKG**—a recording of the electrical events that occur over the course of a cardiac cycle. An EKG recording is generated by amplifying the overall electrical signal conducted from the heart to the chest wall through the tissues of the body. By inspecting an EKG, physicians can diagnose disturbances of heart rhythm and detect damage to the heart muscle.

The drawings above the graph in Figure 45.25 show where the key electrical events are happening.

1. The SA node generates an electrical signal.
2. The signal from the SA node is quickly propagated to atrial muscle cells. As a result, the atria contract simultaneously and eject blood into the ventricles.
3. As the atria begin to contract, the signal is conducted to an area of the heart called the **atrioventricular (AV) node.** The AV node delays the signal slightly before passing it to the ventricles. The delay allows the ventricles to fill completely with blood from the atria before they contract.
4. After the delay, the electrical impulse is rapidly transmitted through specialized fibers in the muscular wall that separates the ventricles. The impulse spreads through both ventricles, causing them to contract as the atria relax. The ventricles empty efficiently because the signal and the resulting muscular contraction move from the bottom up to the top of each ventricle—toward the arteries that allow blood to exit.
5. The final electrical event occurs as the ventricles relax and their cells recover—restoring their electrical state before contraction.

✔ If you understand these concepts, you should be able to predict how the amount of blood ejected from the ventricles would change if there were no delay at the AV node.

PROCESS: ELECTRICAL ACTIVATION OF THE HEART

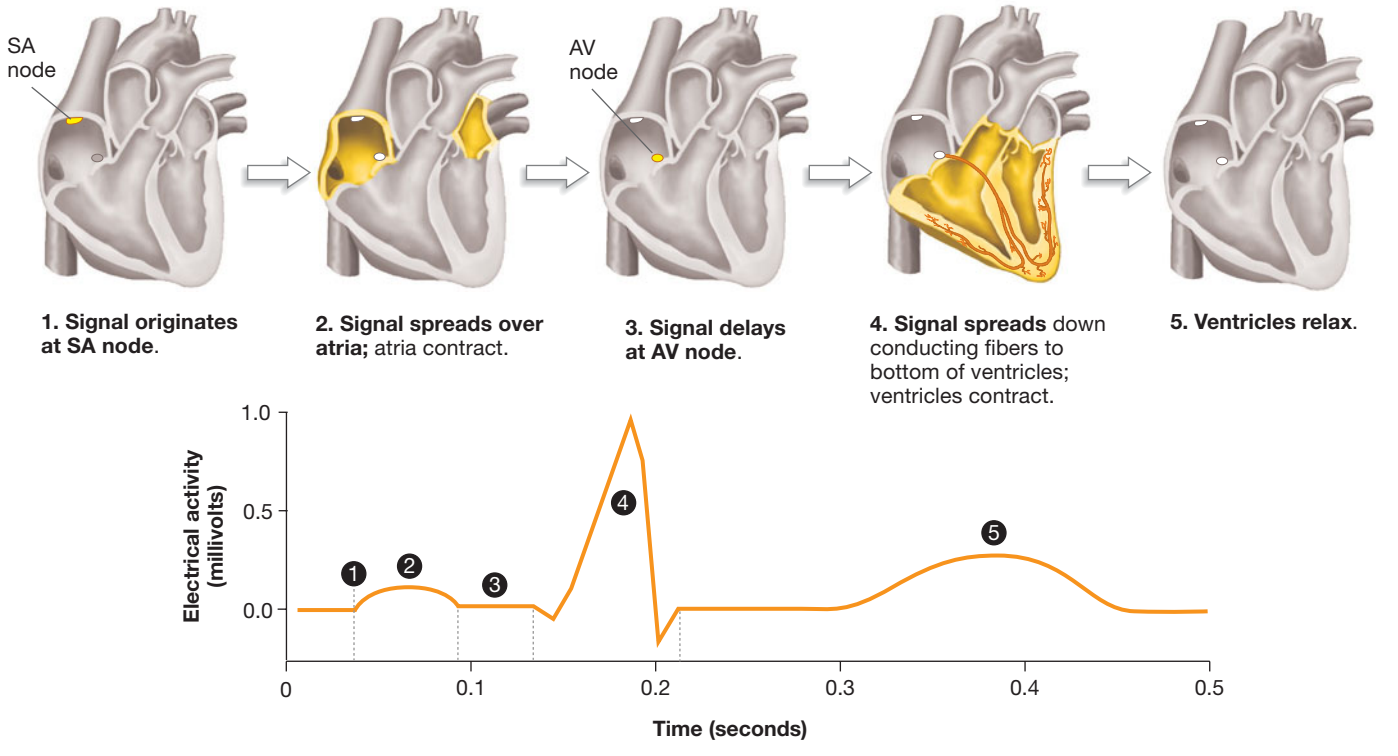

FIGURE 45.25 Sequential Electrical Activation Leads to Coordinated Contraction of the Heart. The rate and strength of contractions control the pressure in the chambers and arteries.

The Cardiac Cycle The electrical signals originating from the SA node ensure that the atria contract simultaneously, and the delay at the AV node ensures that the atria are relaxed by the time the ventricles contract. The contraction phases of the atria and the ventricles, called **systole,** are therefore closely coordinated with their relaxation phases, or **diastole.**

This sequence of contraction and relaxation is called the **cardiac cycle.** It consists of one diastole and one systole for both atria and ventricles.

Ventricular contraction (ventricular systole) leads to a rapid increase in pressure within both ventricles, as recorded in the dark purple line in **FIGURE 45.26**. Blood is ejected into the pulmonary artery and the aorta when ventricular pressure exceeds the pressure within each respective artery. Blood pressure measured in the systemic arterial circulation at the peak of ventricular ejection into the aorta is called the **systolic blood pressure.** Blood pressure measured just before ventricular ejection is called the **diastolic blood pressure.**

Clinicians report blood pressure measurements in fractional notation, where systolic pressure is the numerator and diastolic pressure is the denominator. People with blood pressures consistently higher than 140/90 mm Hg have high blood pressure, or **hypertension.**

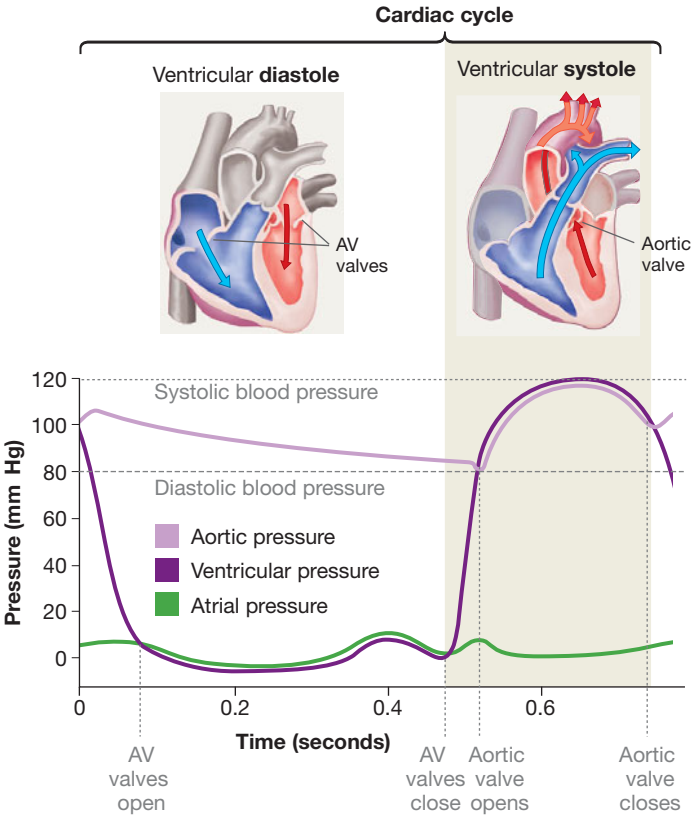

FIGURE 45.26 Blood Pressure Changes during the Cardiac Cycle. These data show the pressures created by the left ventricle and left atrium in the course of a cardiac cycle. In this example, the blood pressure measured in the upper arm would be 120/80 mm Hg. Right ventricle and pulmonary artery pressures would produce a similar pattern except that the blood pressure in the pulmonary artery would be much lower—closer to 25/8 mm Hg.

Hypertension is a serious concern to physicians because it can lead to a variety of defects in the heart and circulatory system. Abnormally high blood pressure puts mechanical stress on arteries. If the walls of an artery fail, the individual may experience heart attack, stroke, kidney failure, and burst or damaged vessels.

Patterns in Blood Pressure and Blood Flow

As blood moves through capillaries, blood pressure drops dramatically—as the top graph in **FIGURE 45.27** indicates. The bottom graph on this figure shows why. Trace the line labeled "Total area" on this graph to see that as arteries branch, rebranch, and eventually form networks of capillaries, the total cross-sectional area of blood vessels in the circulatory system increases—even though the size of individual blood vessels decreases as blood moves away from the heart. Note two key points:

1. Blood pressure in the capillaries drops dramatically (on the top graph) because the amount of mechanical resistance to flow is a function of total cross-sectional area of the vessels—meaning that friction losses are high in capillary beds. The pulsing nature of the pressure observed in the larger arteries diminishes as a result of this pressure drop.
2. As the line labeled "Velocity" in the bottom graph indicates, the velocity of blood flow also decreases significantly in capillary beds relative to arteries and veins, because the same

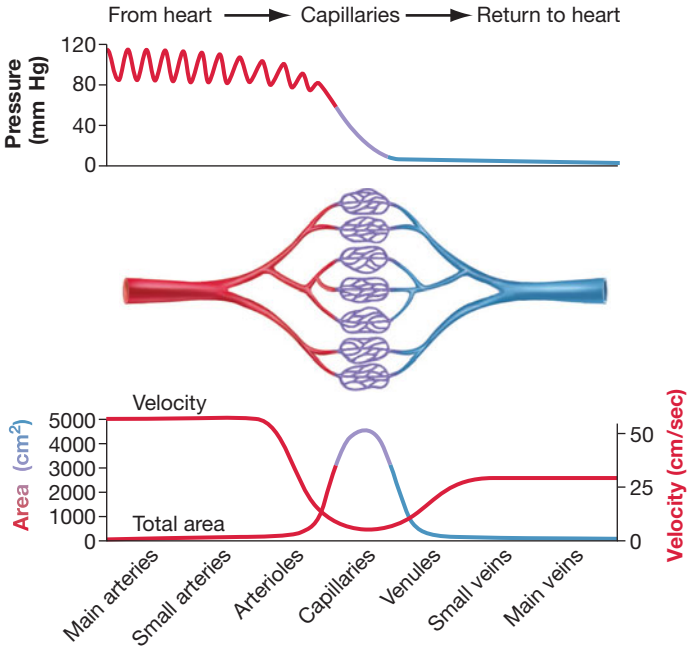

FIGURE 45.27 Blood Pressure Drops Dramatically in the Circulatory System. The top graph shows how blood pressure changes as blood leaves the heart and travels through arteries, capillaries, and veins, as in the branching pattern of the middle diagram. In arteries near the heart, each heartbeat causes fluctuations in blood pressure. These pressure pulses disappear in the capillaries, so blood flows there at a steady speed. The bottom graph plots the total area of blood vessels shown in the diagram, as well as the velocity of blood flow through the vessels.

amount of fluid is passing through a much larger area. Recall that the slow rate of blood flow through capillaries is important: It provides sufficient time for gases, nutrients, and wastes to diffuse between tissues and blood.

Why Is Regulation of Blood Pressure and Blood Flow Important?

The general patterns of blood pressure and blood flow diagrammed in Figure 45.27 don't tell the entire story, however. Blood movement is carefully regulated at an array of points throughout the circulatory system.

Recall that the walls of arterioles are comprised partially of smooth muscle. Contraction or relaxation of this muscle can constrict or allow blood flow to specific regions of the body. This means that the nervous system, along with certain chemical messengers in the circulation, can accurately control blood flow to various tissues by contracting or relaxing the muscle. For example, arterioles in the skin may dilate during exercise, diverting blood flow to the skin to eliminate excess heat. This accounts for the flushed facial appearance induced by vigorous exercise. Regulating blood flow is important for maintaining homeostasis with respect to body temperature.

As another example of how blood pressure and blood flow are regulated, consider what happens if you sit long enough for blood to pool in your lower extremities, under the influence of gravity. If you stand up rapidly, your blood pressure can drop enough to reduce blood flow to the brain and cause dizziness or even a blackout. More serious drops in blood pressure, due to severe dehydration or blood loss, can be fatal. Fortunately, decreases in blood pressure elicit a powerful homeostatic response.

Homeostatic Control of Blood Pressure Recall that all homeostatic responses involve **(1)** sensors that detect the change in condition, **(2)** an integrator that processes information about the change, and **(3)** effectors that diminish the impact of the change (see Chapter 42).

Specialized pressure-sensing receptors called **baroreceptors** detect changes in blood pressure. Baroreceptors are found in the walls of the heart and the major arteries, both as they leave the heart and as they enter the neck. This distribution is logical, because the head tends to be the most elevated part of terrestrial animals, and preserving blood flow to the brain is the highest priority.

When baroreceptors transmit nerve signals to the brain (the integrator) indicating a serious fall in blood pressure, a rapid, three-component effector response ensues:

1. Cardiac output—the volume of blood leaving the left ventricle—increases. This is due to an increase in heart rate and an increase in stroke volume, which is the amount of blood ejected from the ventricles during each cardiac cycle. (Cardiac output = heart rate × stroke volume.)
2. Arterioles serving the capillaries of certain tissues constrict to divert blood to more critical organs. (This occurs in tissues like the skin and intestines, which can endure short-term restrictions in their blood supply without damage.)
3. Veins constrict, decreasing their overall volume. Because more than half of the blood in the circulatory system is contained within the veins, constriction of these vessels shifts blood volume toward the heart and arteries to maintain blood pressure and flow to vital organs.

This coordinated response is mediated both by a portion of the nervous system called the sympathetic nervous system (Chapter 46) and by hormones (Chapter 49) produced by the adrenal glands. Sympathetic nerves and the hormones involved in blood pressure regulation deliver their messages directly to **(1)** the SA node to increase heart rate, **(2)** the ventricles of the heart to increase stroke volume, and **(3)** the muscular walls of the arteries and veins to modify their total volume.

Cardiovascular Disease A healthy circulatory system is obviously critical to your well-being. Indeed, **cardiovascular disease,** which is a group of ailments collectively affecting the heart and blood vessels, is the number one cause of death in humans worldwide.

Many factors contribute to cardiovascular disease, including age, tobacco use, poor diet, obesity, inactivity, and genetics. As people age, their blood vessels harden and lose elasticity—a condition called **arteriosclerosis.** Nicotine in tobacco causes constriction of blood vessels, further reducing the diameter of blood vessels and increasing blood pressure.

High-fat diets and lack of physical activity can compound the problem by leading to the deposition of fatty plaques on the walls of blood vessels, which effectively reduces their diameter. The loss of elasticity and the decline in the diameter of the vessels combine to cause increased blood pressure, which can weaken the walls of arteries.

check your understanding

C Y U

If you understand that . . .

- Animal circulatory systems may be open or closed, but both types of systems circulate blood or hemolymph via pressure generated by one or more hearts.
- In closed systems, regulated changes in the diameter of blood vessels can direct blood to specific regions, and overall blood pressure is carefully regulated through changes in cardiac output.

✓ You should be able to . . .

1. Explain how the mammalian lymphatic system and circulatory system interact.
2. Make a labeled diagram showing how blood circulates through the mammalian heart.

Answers are available in Appendix A.

If the arteries that deliver blood to the heart muscle become completely blocked, a **myocardial infarction,** or heart attack, can occur. In a myocardial infarction, a portion of heart tissue dies within minutes when it is deprived of oxygen. Depending on the location and extent of damage, myocardial infarction can lead to rapid death.

Over 17 million people worldwide died from cardiovascular disease in 2004, and this number is projected to reach 23 million by the year 2030. With the incidence of obesity and diabetes reaching epidemic proportions, these numbers may become even higher. Effectively combating cardiovascular disease will require improved diet, reduced tobacco use, greater amounts of physical activity, and better access to healthcare across the globe.

CHAPTER 45 REVIEW

For media, go to MasteringBiology

If you understand . . .

45.1 The Respiratory and Circulatory Systems

- Animal gas exchange involves ventilation, exchange of gases between the environment and the blood, and exchange of gases between blood and tissues.
- Animal circulation involves transportation of gases, nutrients, wastes, and other substances throughout the body.

✔ **You should be able to identify the process that uses oxygen inside animal cells.**

45.2 Air and Water as Respiratory Media

- As media for exchanging oxygen and carbon dioxide, air and water are dramatically different.
- Compared with water, air contains much more oxygen and is much less dense and viscous. As a result, terrestrial animals have to process a much smaller volume of air to extract the same amount of O_2, and the amount of work required to do so is less than in aquatic animals.
- Both terrestrial and aquatic animals pay a price for exchanging gases: Land-dwellers lose water to evaporation; freshwater animals lose ions and gain excess water; marine animals gain sodium and chloride and lose water.

✔ **You should be able to explain why no water breathers have the extremely high rates of metabolism required for endothermy.**

45.3 Organs of Gas Exchange

- The structure of gills, tracheae, lungs, and other gas exchange organs minimizes the cost of ventilation while maximizing the rate at which O_2 and CO_2 diffuse.
- Consistent with predictions made by Fick's law of diffusion, respiratory epithelia tend to be extremely thin and to be folded to increase surface area.
- In fish gills, countercurrent exchange ensures that the differences in O_2 and CO_2 partial pressures between water and blood are high over the entire length of the ventilatory surface.
- Insect tracheae carry air directly to and from tissues.
- In bird lungs, structural adaptations lead to a high ratio of useful ventilatory space to dead space.
- Breathing rate is regulated to keep the carbon dioxide content of the blood stable during both rest and exercise.

✔ **You should be able to explain why no large animals have gas exchange occurring only across the skin.**

45.4 How Are Oxygen and Carbon Dioxide Transported in Blood?

- The tendency of hemoglobin to give up oxygen varies as a function of the P_{O_2} in surrounding tissue in a sigmoidal fashion. As a result, a relatively small change in tissue P_{O_2} causes a large change in the amount of oxygen released from hemoglobin.
- Oxygen binds less tightly to hemoglobin when pH is low. Because CO_2 tends to react with water to form carbonic acid, the existence of high CO_2 partial pressures in exercising muscle tissues lowers their pH and makes oxygen less likely to stay bound to hemoglobin and more likely to be unloaded into tissues.
- The CO_2 that diffuses into red blood cells from tissues is rapidly converted to carbonic acid by the enzyme carbonic anhydrase. The protons that are released as carbonic acid dissociates bind to deoxygenated hemoglobin. In this way, hemoglobin acts as a buffer that takes protons out of solution and prevents large fluctuations in blood pH.

✔ **You should be able to explain why exposure to large doses of carbon monoxide (CO) can lead to suffocation. (The CO found in furnace and engine exhaust and in cigarette smoke binds to the heme groups in hemoglobin 210 times more tightly than does oxygen.)**

45.5 Circulation

- In many animals, blood or hemolymph moves through the body via a circulatory system consisting of a pump (heart) and vessels.
- In open circulatory systems, overall pressure is low and tissues are bathed directly in hemolymph.

- In closed circulatory systems, blood is contained in vessels that form a continuous circuit. Containment of blood allows higher pressures and flow rates, as well as the ability to direct blood flow accurately to tissues that need it the most.
- In organisms with a closed circulatory system, a lymphatic system returns excess fluid that leaks from the capillaries back to the circulation.
- In amphibians and some reptiles, blood from the pulmonary and systemic circuits may be mixed in the single ventricle.
- In mammals and birds, a four-chambered heart pumps blood into two circuits, which separately serve the lungs and the rest of the body. Crocodilians have a similar heart with a bypass vessel that can shunt blood from the pulmonary to the systemic circuit.
- The cardiac cycle is controlled by electrical signals that originate in the heart itself.
- Heart rate, cardiac output, and contraction of both arterioles and veins are regulated by chemical signals and by electrical signals from the brain.
- Cardiovascular disease is the leading cause of death in humans.

✔ **You should be able to predict the characteristics of the circulatory systems of terrestrial animals with high activity rates.**

✔ TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. O_2 will diffuse from blood to tissue faster in response to which of the following conditions?
   a. an increase in the P_{O_2} of the tissue
   b. a decrease in the P_{O_2} of the tissue
   c. an increase in the thickness of the capillary wall
   d. a decrease in the surface area of the capillary
2. Which of the following does blood *not* do?
   a. transport O_2 and CO_2
   b. distribute body heat
   c. produce new red blood cells and other formed elements
   d. buffer against pH changes
3. In insects, what is the adaptive significance of spiracles?
   a. They dilate and constrict during flight or other types of movement, functioning as a "breathing" mechanism.
   b. They open into the body cavity, allowing direct contact between hemolymph and tissues.
   c. They are thin and highly branched, offering a large surface area for gas exchange.
   d. They close off tracheae to minimize water loss.
4. Which of the following is *not* an advantage of breathing air over breathing water?
   a. Air is less dense than water, so it takes less energy to move during ventilation.
   b. Oxygen diffuses faster through air than it does through water.
   c. The oxygen content of air is greater than that of an equal volume of water.
   d. Air breathing leads to high evaporation rates from the respiratory surface.
5. Which of the following promotes oxygen release from hemoglobin?
   a. a decrease in temperature
   b. a decrease in CO_2 levels
   c. a decrease in pH
   d. a decrease in carbonic anhydrase
6. Describe the ways in which an open circulatory system is less efficient than a closed circulatory system.

✔ TEST YOUR UNDERSTANDING

Answers are available in Appendix A

7. Describe the changes in oxygen delivery that occur as a person proceeds from a resting state to intense exercise.
8. Explain how most carbon dioxide is transported in the blood. In humans, why don't intense exercise and rapid production of CO_2 lead to a rapid reduction in blood pH?
9. Why is ventilation in birds considered much more efficient than the respiratory system of humans and other mammals?
10. Explain how each parameter in Fick's law of diffusion is reflected in the structure of the mammalian lung.

11. Carp are fishes that thrive in stagnant-water habitats with low oxygen partial pressures. Compared with the hemoglobin of many other fish species, carp hemoglobin has an extremely high affinity for O_2. Is this trait adaptive? Explain your answer.

12. Frog lungs have lower surface area for gas exchange than mammalian lungs. Which of the following observations explains this?

a. Frog tissue needs more oxygen than mammalian tissue.
b. Frogs breathe more quickly than mammals.
c. Frogs also obtain oxygen via diffusion across the skin.
d. Frog lung tissue has a greater density of capillary beds than mammalian lung tissue.

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A

13. Predict how the icefish native to the Antarctic are able to transport oxygen and carbon dioxide in their blood even though they lack hemoglobin.

14. Compare and contrast the respiratory and circulatory systems of an insect and a human.

15. Why did separate systemic and pulmonary circulations evolve in species that have the high-pressure circulatory system required for rapid movement of blood?

16. Under certain conditions, cells produce a metabolic byproduct called 2,3-diphosphoglycerate (DPG). Which of the following would support the hypothesis that DPG helps increase oxygen unloading from tissues?

a. DPG shifts the oxygen–hemoglobin equilibrium curve to the left.
b. DPG decreases percentage saturation of hemoglobin with oxygen at a P_{O_2} of 30 mm Hg.
c. DPG increases the pH of the tissues.
d. DPG is produced in greater quantity at low altitude than at high altitude.

46 Animal Nervous Systems

In this chapter you will learn how

Animals use electrical signaling along neurons for internal communication

beginning with

- Principles of electrical signaling **46.1**
  - then asking
- How does the action potential work? **46.2**
  - finally looking at
- Synapses—the interface between neurons **46.3**

then exploring

- The vertebrate nervous system **46.4**
  - including
- The brain, learning, and memory

Diffusion spectrum imaging reveals the activity and trajectory of neurons in the brain. Such advances in brain imaging are allowing neurobiologists to study how neurons in the brain communicate with one another.

Most students and professional biologists are attracted to the study of neurobiology because they want to understand the human brain as well as higher-order processes like consciousness, intelligence, emotion, learning, and memory. But early in the history of neurobiology, researchers realized that the human brain—with its billions of cells—was much too complex to study productively.

Instead biologists did the same thing they did in the early days of studying cells, genetics, and evolution: They started simply. Early research in neurobiology focused on the function of individual nerve cells, or **neurons,** the cells mainly responsible for the working of the brain and the rest of the nervous system. Neurons conduct information in the form of electrical signals from point to point

BIG PICTURE

This chapter is part of the Big Picture. See how on pages 840–841.

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

in the body at speeds of up to 200 m/sec (450 mph). Thus electrical signaling is a crucial aspect of information processing—one of the five attributes of life (introduced in Chapter 1).

Initial research on the electrical properties of single neurons laid a broad foundation for more recent studies of how the human brain works. This chapter proceeds in the same way. Let's begin by focusing on the neurons themselves and how they use electrical signaling to communicate within the body and with each other. By the end of the chapter, you'll be considering how the brain is organized and how phenomena like memory work.

46.1 Principles of Electrical Signaling

The evolution of neurons was a key event in the diversification of animals, along with the evolution of muscles (see Chapter 33). All animals except sponges have neurons and muscle cells. Neurons transmit electrical signals; muscles can respond to signals from neurons by contracting.

Neurons and muscle cells made rapid movement possible. These innovations in cell structure and function enabled animals to evolve into today's flatworms, squid, beetles, sharks, and birds.

Recall that neurons are organized into two basic types of nervous systems:

1. The diffuse arrangement of cells called a **nerve net,** found in cnidarians (jellyfish, hydra, anemones) and ctenophores (comb jellies).
2. A **central nervous system (CNS)** that includes large numbers of neurons aggregated into clusters called ganglia.

In most cases, animals with a CNS have a large cerebral ganglion, or brain, located in their anterior end. You also might recall that this phenomenon—the evolution of a bilaterally symmetric body with structures for information gathering and processing located at the head end—is known as cephalization (see Chapter 33).

Cephalization made animals into efficient eating and moving machines: They face the environment in one direction, and sensory appendages take in information and send it to a nearby brain for processing. After integrating information from an array of sensory cells, the brain sends electrical signals to muscles and other tissues that respond to the sensory stimuli.

Types of Neurons in the Nervous System

The sensory cells that are responsible for gathering information respond to light, sound, touch, or other stimuli. Sensory cells in the animal's skin, eyes, ears, mouth, and nose transmit information about the environment. Sensory cells inside the body monitor conditions that are important in homeostasis, such as blood pH and temperature. In this way, sensory cells monitor conditions both outside and inside the body. Many sensory cells are **sensory neurons** (**FIGURE 46.1**), which carry information to the brain and spinal cord.

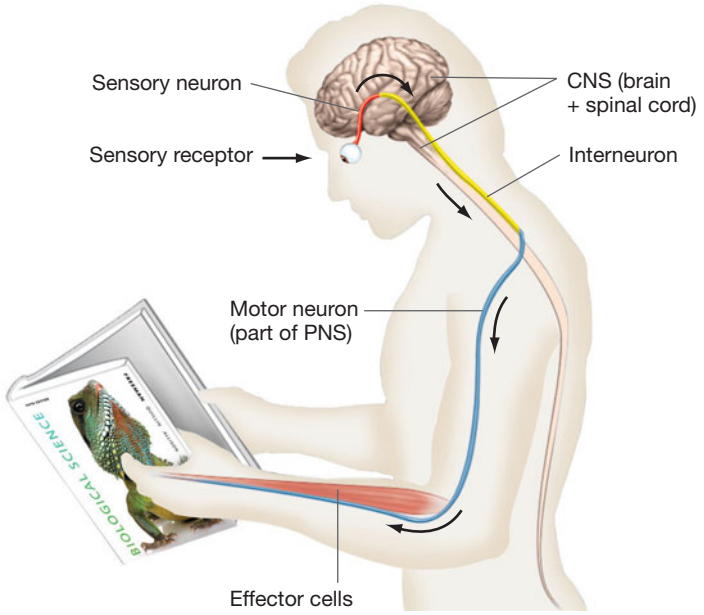

FIGURE 46.1 The Brain Integrates Sensory Information and Sends Signals to Effector Cells. In most cases, sensory neurons send information to the brain, where it is integrated with information from other sources. Once integration is complete, a response is sent to effector cells through motor neurons.

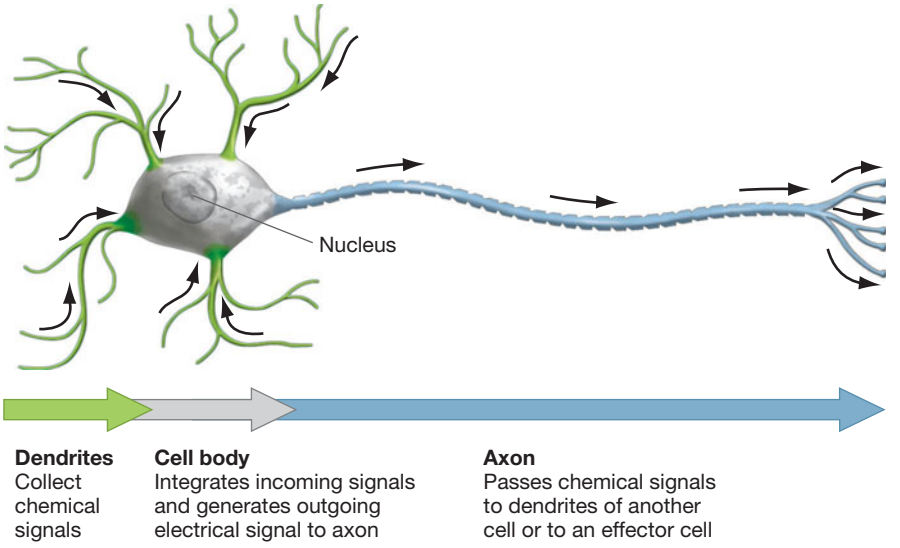
Together, the brain and spinal cord form the CNS of vertebrates. One function of the CNS is to integrate information from many sensory neurons. Cells in the CNS called **interneurons** (literally, "between-neurons"), which pass signals from one neuron to another, perform this integration.

Interneurons also make connections between sensory neurons and **motor neurons,** which are nerve cells that send signals to effector cells in glands or muscles. Motor neurons and sensory neurons are bundled together into long, tough strands of nervous tissue called **nerves.** Recall that effectors are structures that bring about a physiological change in an organism (see Chapter 42).



All neurons and other components of the nervous system that are outside the CNS are considered part of the **peripheral nervous system,** or **PNS.** Section 46.4 describes the structure and function of the PNS in more detail.

Typically, sensory information from receptors in the PNS is sent to the CNS, where it is processed. Then a response is transmitted back to appropriate parts of the body via motor neurons. When you stub your toe, pain receptors in your toe relay sensory information to the brain, which then modifies your movements to avoid further injury. You might hop a bit, for example, and then limp to avoid further pressure on that toe.

The Anatomy of a Neuron

Neurons are difficult to study because they are small, transparent, and morphologically complex. So when Camillo Golgi discovered that some neurons become visible when samples of preserved tissue are treated with a solution containing silver nitrate, his finding was a major advance. The year was 1898.

(a) Information flows from dendrites to the axon.

(b) Neurons form networks for information flow.

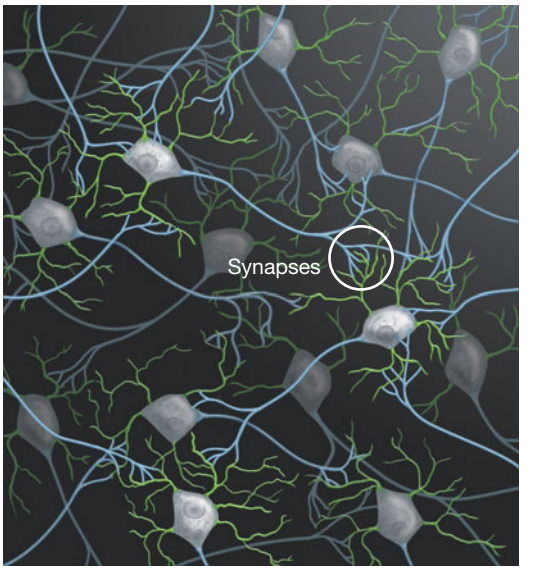


FIGURE 46.2 How Does Information Flow in a Neuron? (a) The structure of a generalized neuron. **(b)** Most neurons receive inputs from many different neurons and send projections to several different neurons.

Through the early decades of the twentieth century, the work of Golgi and Santiago Ramón y Cajal revealed several important points about the anatomy of neurons. Most neurons have the same three parts, shown in **FIGURE 46.2a**:

1. A cell body, which contains the nucleus
2. A highly branched group of relatively short projections called dendrites
3. One or more relatively long projections called axons

Dendrites are rarely more than 2 mm long, but axons can be over a meter in length. The number of dendrites and their arrangement vary greatly from cell to cell. Further, many neurons in the brain have only dendrites and lack axons.

A **dendrite** receives a signal from the axons of adjacent cells; a neuron's **axon** sends a signal to the dendrites and cell bodies of other neurons (**FIGURE 46.2b**). In short, dendrites receive signals; axons pass them on. The **cell body,** or **soma,** also receives signals from axons of other cells. Incoming signals are integrated in the dendrites and cell body, and an outgoing signal is sent to the axon.

Ramón y Cajal maintained that the plasma membrane of each neuron is separated from those of adjacent neurons. This hypothesis was confirmed in the 1950s, when images from electron microscopes showed that most neurons are separated from one another at their junctions by tiny spaces called synapses.

Given that neurons transmit electrical signals, how do they produce them?

An Introduction to Membrane Potentials

Ions carry an electric charge. In virtually all cells, the cytoplasm and extracellular fluids adjacent to the plasma membrane contain unequal distributions of ions. As a result, cells are inherently electrical in nature.

A difference of electrical charge between any two points creates an **electrical potential,** or a **voltage.** If the positive and negative charges of the ions on each side of a plasma membrane do not balance each other, the membrane will have an electrical potential.

When an electrical potential exists across a plasma membrane, the separation of charges is called a **membrane potential.** If there is a large separation of charges across the membrane, the membrane potential is large.

It is important to remember that membrane potentials refer only to a separation of charge immediately adjacent to the plasma membrane, on either side of the membrane. Even if there is a large membrane potential, there may be no charge separation slightly farther away from the membrane.

Units and Signs Membrane potentials are measured in units called millivolts. The **volt** is the standard unit of electrical potential, and a **millivolt (mV)** is 1/1000 of a volt. As a comparison, an AA battery that you buy in the store has an electrical potential of 1500 mV between its + and − terminals. In neurons, membrane potentials are typically about 65 to 80 mV.

By convention, membrane potentials are always expressed in terms of inside relative to outside (the outside value is defined as 0). Because there are usually more negatively charged ions and fewer positively charged ions on the inside surface of a membrane relative to its outside surface, membrane potentials are usually negative in sign.

Electrical Potential, Electric Currents, and Electrical Gradients Membrane potentials are a form of potential energy. Recall that potential energy is energy based on the position of matter.

To convince yourself that ions have potential energy when a membrane potential exists, consider what would happen if

the membrane were removed. Ions would spontaneously move from the region of like charge to the region of unlike charge—causing a flow of charge. This flow of charge, called an **electric current,** would occur because like charges repel and unlike charges attract.

However, charge is not the only form of potential energy. Ions also have different concentrations across membranes. Therefore, a membrane potential also includes energy stored as the concentration gradients of charged ions on the two sides of the membrane. Recall that the combination of an electrical gradient and a concentration gradient is an **electrochemical gradient** (see Chapter 6).

What do all these facts have to do with neuron function? Neurons use the electrochemical gradient of ions across their membranes to power the signals that allow neurons to communicate with one another and with other tissues.

How Is the Resting Potential Maintained?

When a neuron is not communicating with other cells or tissues, the difference in charge across its membrane is called the **resting potential.** To understand why the resting potential exists, consider the distribution of the various ions and other charged molecules on the two sides of the neuron's plasma membrane, shown in **FIGURE 46.3**:

- The interior side of the membrane has relatively low concentrations of sodium (Na^+) and chloride (Cl^-) ions, a relatively high concentration of potassium ions (K^+), and some organic anions—amino acids and other organic molecules that have dropped a proton and thus carry a negative charge.
- In the extracellular fluid, sodium and chloride ions predominate.

If each type of ion diffused across the membrane in accordance with its concentration gradient, organic anions and K^+ would leave the cell, while Na^+ and Cl^- would enter.

Ions cannot cross phospholipid bilayers readily, however. They cross plasma membranes efficiently in only three ways (see Chapter 6):

1. Flowing along their electrochemical gradient through an **ion channel**—a protein that forms a pore in the membrane and allows a specific ion to diffuse along its gradient
2. Carried, via a membrane cotransporter protein, with another ion that diffuses along its electrochemical gradient
3. Pumped against an electrochemical gradient by a membrane protein that hydrolyzes adenosine triphosphate (ATP)

How does the distribution of ions illustrated in Figure 46.3 come to be? The answer hinges on two types of membrane proteins: an ion channel that allows potassium ions to diffuse along their gradient, and a pump that actively transports sodium and potassium ions against their gradients. Let's consider each in turn.

The K^+ Leak Channel At rest, the plasma membrane of neurons is relatively impermeable to most cations. However, neurons have a relatively high number of potassium channels, called K^+ **leak channels,** that allow K^+ to leak out of the cell. K^+ ions slowly

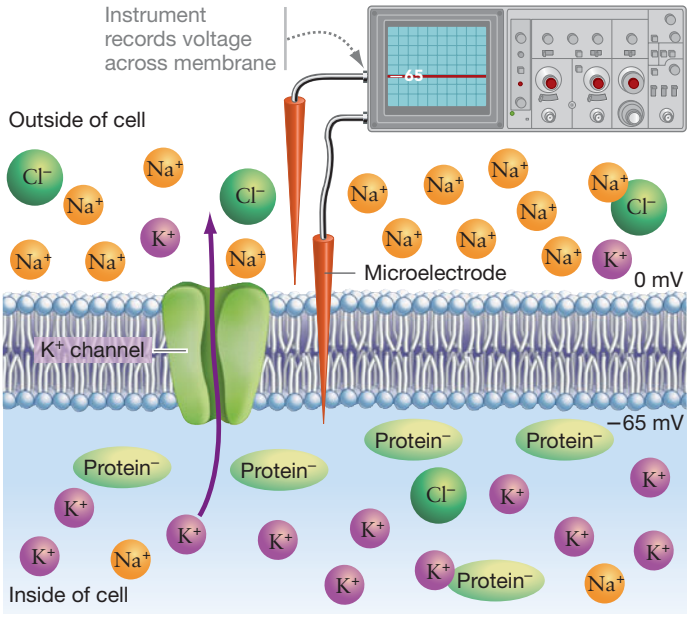

FIGURE 46.3 Neurons Have a Resting Potential. In resting neurons, the membrane is selectively permeable to K^+. As K^+ leaves the cell along its concentration gradient, the inside of the membrane becomes negatively charged relative to the outside. To measure a neuron's membrane potential, researchers insert a microelectrode into the cell and compare that reading with the reading outside the cell.

✔**QUESTION** Will K^+ continue to leave the cell indefinitely? Explain why or why not.

exit the neuron through the leak channels along their electrochemical gradient.

As K^+ moves from the interior of the cell to the exterior through leak channels, the inside of the cell becomes more and more negatively charged relative to the outside. This buildup of negative charge inside the cell begins to attract K^+ and counteract the concentration gradient that had favored the movement of K^+ out.

As a result of the counteracting influences, the membrane reaches a voltage at which equilibrium exists between the concentration gradient that favors movement of K^+ out and the electrical gradient that favors movement of K^+ in. At this voltage, there is no longer a net movement of K^+. This voltage is called the **equilibrium potential** for K^+. **Quantitative Methods 46.1** (see page 932) shows how equilibrium potentials for individual ions are calculated.

Although Cl^- and Na^+ cross the plasma membrane much less readily than does K^+, some movement of these ions also occurs through a small number of leak channels that are selective for each of them. As a result, each type of ion has an equilibrium potential. The membrane as a whole has a membrane potential that combines the effects of the individual ions.

The Role of the Na^+/K^+-ATPase What is responsible for the higher concentration of Na^+ on the outside and K^+ on the inside in the first place? It is the sodium–potassium pump, Na^+/K^+-ATPase, which actively pumps Na^+ out of the cell and K^+ into

QUANTITATIVE METHODS 46.1 Using the Nernst Equation to Calculate Equilibrium Potentials

An equilibrium potential exists whenever there is a concentration gradient for an ion across a membrane and the membrane is permeable to that ion. At the equilibrium potential, the rate at which an ion moves across the membrane down its concentration gradient is equal to the rate at which the ion moves, in the opposite direction, down its electrical gradient. It's the voltage at which the concentration and electrical gradients acting on an ion balance out.

The ion concentration gradients that contribute to equilibrium potentials are produced by the action of Na^+/K^+-ATPase. This membrane protein converts chemical energy in the form of ATP to electrical energy in the form of a membrane potential.

To calculate an equilibrium potential, biologists use the Nernst equation—a formula that converts the energy stored in a concentration gradient to the energy stored as an electrical potential. The concentration gradient for an ion is symbolized as $[ion]_o/[ion]_i$, where $[ion]_o$ and $[ion]_i$ are the concentrations of the ion outside and inside the cell, respectively. The equilibrium potential for that ion is symbolized as E_{ion}. The Nernst equation specifies the equilibrium potential for a given ion as

$$E_{ion} = 2.3 \frac{RT}{zF} \log \frac{[ion]_o}{[ion]_i}$$

In this expression, z is the valence of the ion (for instance, +1 for potassium) and the expression RT/F is known as the thermodynamic potential. The three terms in the thermodynamic potential are the gas constant (R), which acts as a constant of proportionality; the absolute temperature (T), measured in Kelvins; and the Faraday constant (F), which specifies the amount of charge carried by 1 mol of an ion with a valence of +1 or −1.

Note that the Nernst equation is based on the base-10 logarithm of the ion concentration ratio, $[ion]_o/[ion]_i$. Thus, the thermodynamic potential specifies the voltage required to balance a tenfold concentration ratio across the membrane. (For more on using logarithms, see **BioSkills 6** in Appendix B.)

The Nernst equation applies to only a single ion. For example, suppose that the potassium concentration inside the axon of a squid neuron has been measured as 400 mM, yet the outside concentration for this ion is only 20 mM (**Table 46.1**). Potassium has a charge of +1, so at 20°C the RT/zF part of the equation yields +25 mV. In this case, the equilibrium potential for potassium becomes

$$E_K = 2.3 \times 25 \text{ mV} \times \log \frac{20 \text{ mM}}{400 \text{ mM}}$$

$$E_K = 58 \text{ mV} \times \log 0.05 = -75 \text{ mV}$$

The minus sign indicates that the interior of the axon is negatively charged with respect to the exterior.

Repeating this process for Na^+ ions and Cl^- ions yields the following results for the squid axon:

$$E_{Na} = 58 \text{ mV} \times \log \frac{440 \text{ mM}}{50 \text{ mM}} = +54.8 \text{ mV}$$

$$E_{Cl} = -58 \text{ mV} \times \log \frac{560 \text{ mM}}{51 \text{ mM}} = -60 \text{ mV}$$

Again, notice that the equilibrium potential given by the Nernst equation is calculated independently for each ion.

✔**QUANTITATIVE** **If you understand this concept, you should be able to calculate the equilibrium potential at 20°C for calcium (Ca^{2+}) in a cell where the intracellular concentration is 0.0001 mM and the extracellular concentration is 1 mM.**

TABLE 46.1 Concentration of Important Ions across a Squid Neuron's Plasma Membrane at Rest

Ions	Cytoplasm Concentration	Extracellular Concentration	Equilibrium Potential
Na^+	50 mM	440 mM	+54.8 mV
K^+	400 mM	20 mM	−75 mV
Cl^-	51 mM	560 mM	−60 mV
Organic anions	385 mM	—	—

the cell. More specifically, the energy gained by the sodium–potassium pump when it receives a phosphate group from one ATP is used to move three Na^+ ions out of the cell and two K^+ ions into the cell (**FIGURE 46.4**).

Active transport via Na^+/K^+-ATPase ensures that eventually the concentration of K^+ is much higher on the inside of the plasma membrane than outside, while the concentration of Na^+ is lower inside than outside. In addition to setting up concentration gradients of K^+ and Na^+, the pump establishes an electrical gradient: The outward movement of three positive charges and inward movement of two positive charges each time the ATPase pumps makes the interior of the membrane less positive (more negative) than the outside.

To summarize, the neuron has a negative resting membrane potential because the Na^+/K^+-ATPase pumps three cations out for only two cations in, and because K^+ exits the neuron through leak channels along its electrochemical gradient. The resting potential represents energy stored as concentration and electrical gradients in various ions. ✔ **If you understand this concept, you should be able to predict what would happen to the membrane potential if Na^+ or K^+ were allowed to diffuse freely across the membrane.**

Using Microelectrodes to Measure Membrane Potentials

During the 1930s and 1940s, A. L. Hodgkin and Andrew Huxley focused on what has become a classic model system in the study of electrical signaling: the axons of squid.

Squid live in the ocean and are preyed on by fishes and whales. When a squid is threatened, electrical signals travel down the axons to muscle cells. When these muscles contract,

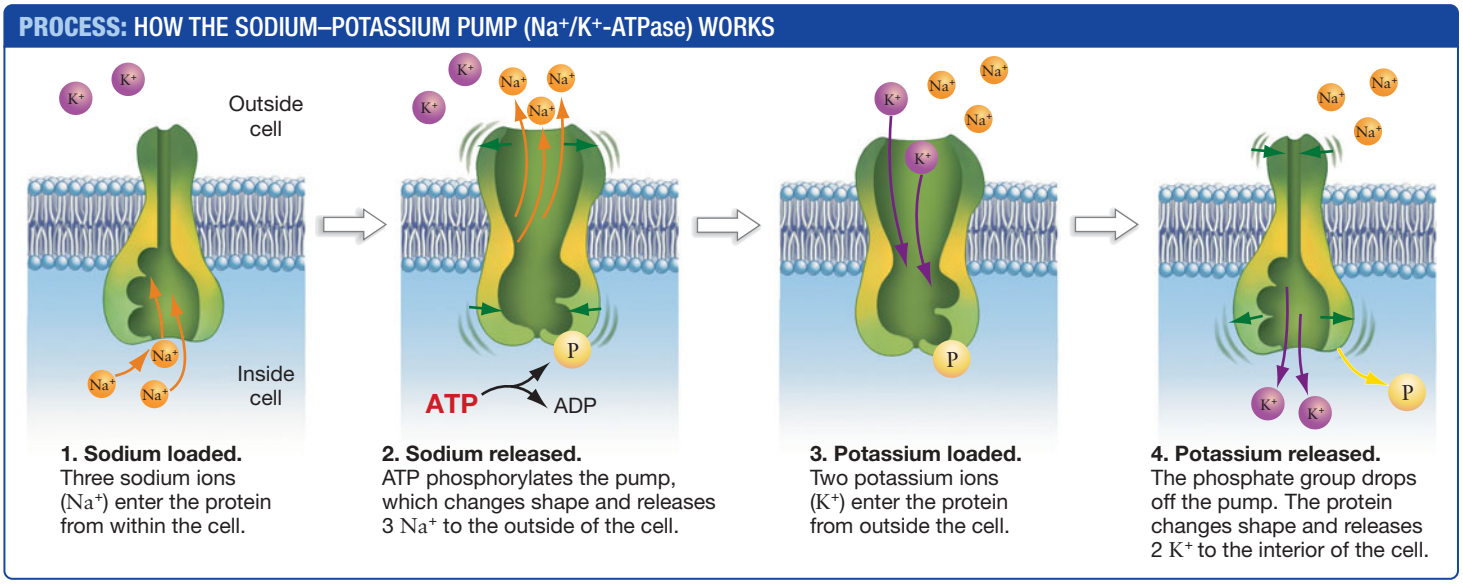

FIGURE 46.4 In Neuron Membranes, Na^+/K^+-ATPase Imports Potassium Ions and Exports Sodium Ions. By following radioactive Na^+ and K^+, biologists found that the pump transports 3 Na^+ out of the cell for every 2 K^+ brought in. Notice that this pump operates via a conformational change.

water is expelled from a cavity in the squid's body. As a result, the squid lurches away from danger by jet propulsion (see Chapter 34). The extremely rapid electrical signal produced in the squid is an adaptation that helps avoid predation.

Hodgkin and Huxley decided to study the squid's axon simply because it is so large. Many of the axons found in humans are a mere 2 μm in diameter, but the squid axon is about 500 μm in diameter—large enough that the researchers could record membrane potentials by inserting a wire down its length.

By measuring the voltage difference between the wire inside the cell and an electrode outside the cell, Hodgkin and Huxley could record the voltage across the plasma membrane and observe how it changed in response to stimuli. Later researchers developed glass microelectrodes that were tiny enough to be inserted into smaller neurons to record membrane voltage.

With their relatively simple early equipment, Hodgkin and Huxley were able to record the axon's resting potential. They documented that it can be disrupted by an event called the action potential when the axon is stimulated.

What Is an Action Potential?

An **action potential** is a rapid, temporary change in a membrane potential. It may qualify as the most important type of electrical signal in cells. When stimulated, neurons mount action potentials that allow them to communicate with other neurons, muscles, or glands.

Although Hodgkin and Huxley initially studied action potentials in the squid giant axon, subsequent work has shown that the action potential has the same general characteristics in all species and in all types of neurons.

A Three-Phase Signal

FIGURE 46.5 shows the form of the action potential that Hodgkin and Huxley recorded from the squid's giant axon—the signal that allows the squid to jet away from predators. The action potential has three distinct phases:

1. **Depolarization** of the membrane. In its resting state, a membrane is said to be polarized because the charges on the two sides are different. Depolarization means that the membrane becomes less polarized than before. During the depolarization phase, the membrane potential becomes less polarized as it moves from highly negative toward zero and then is briefly positive.
2. A rapid **repolarization,** which changes the membrane potential back to negative.
3. A **hyperpolarization** phase, when the membrane is slightly more negative than the resting potential.

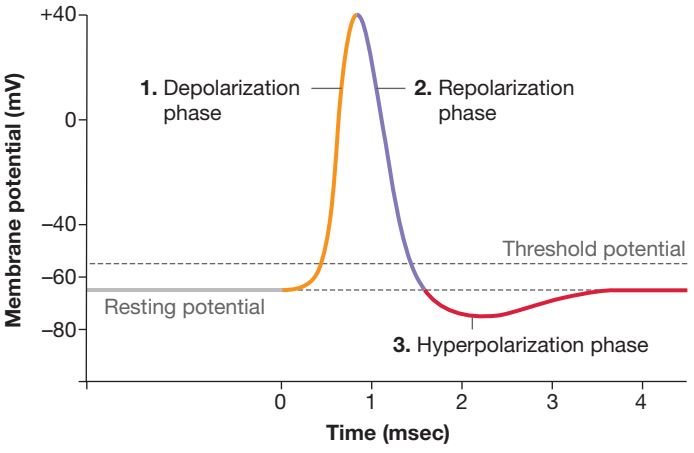

FIGURE 46.5 Action Potentials Have the Same General Shape. An action potential is a stereotyped change in membrane potential—meaning that it occurs the same way every time.

Together, all three phases of an action potential occur within a few milliseconds.

For an action potential to begin in a squid giant axon, the membrane potential must shift from its resting potential of −65 mV to about −55 mV. If the membrane depolarizes less than that, an action potential does not occur. But if this **threshold potential** is reached, certain channels in the axon membrane open and ions rush into the axon, following their electrochemical gradients. The inside of the membrane becomes less negative and then positive with respect to the outside.

When the membrane potential reaches about +40 mV, an abrupt change occurs and the repolarization phase begins. The change is triggered by the closing of certain ion channels and the opening of other ion channels in the membrane.

To summarize, an action potential occurs because specific ion channels in the plasma membrane open or close in response to changes in voltage. An action potential always has the same three-phase form, even though the size of the resting potential, threshold potential, and peak depolarization may vary among species or even among types of neurons in one species.

An "All-Or-None" Signal That Propagates Hodgkin and Huxley made other important observations about the action potential. Besides being fast and having three distinct phases, it is an all-or-none event.

- There is no such thing as a partial action potential.
- All action potentials for a given neuron are identical in magnitude and duration.
- Action potentials are always propagated down the entire length of the axon.

For example, when an action potential was recorded at a particular point on a squid axon, an action potential that was identical in shape and size would be observed farther down the same axon soon afterward. Neurons are said to have **excitable membranes** because they are capable of generating action potentials that propagate rapidly along the length of the axons.

Taken together, these observations suggested a mechanism for electrical signaling. In the nervous system, information is coded in the form of action potentials that propagate along axons. The frequency of action potentials—not their size—is the meaningful signal. In the squid's giant axon, increased frequency of action potentials signals muscles to contract. As a result, the animal escapes from danger.

check your understanding

CYU

If you understand that . . .

- The plasma membranes of neurons maintain a negative resting potential because Na^+/K^+-ATPase pumps 3 Na^+ ions out of the cell and 2 K^+ ions into the cell and because the membrane is selectively permeable to K^+ ions, which leak out.
- Action potentials are three-phase, all-or-none signals that propagate down the length of a neuron.

✓ You should be able to . . .

1. Predict what would happen to the resting potential of a squid axon if potassium leak channels were blocked.
2. Explain why only the frequency of action potentials—not their size—contains information.

Answers are available in Appendix A.

46.2 Dissecting the Action Potential

Of Na^+, Cl^-, and K^+, which ion or ions are most important in the currents that form the action potential? Are different ions responsible for the depolarization and repolarization phases of the event?

Hodgkin made a crucial start in answering this question when he realized that +40 mV was close to the equilibrium potential for Na^+ in the squid giant axon (see **Quantitative Methods 46.1**). If sodium channels opened early in the action potential, then Na^+ should flow into the neuron until the membrane potential was about +40 mV. How could this hypothesis be tested?

Distinct Ion Currents Are Responsible for Depolarization and Repolarization

To understand the currents responsible for the action potential, Hodgkin and Huxley recorded electrical activity in squid axons that were bathed in solutions containing different concentrations of ions.

- Removing Na^+ from the solution surrounding the axon abolished the production of action potentials.
- When axons were bathed in solutions with various concentrations of Na^+, the peak membrane potential paralleled the concentration of Na^+. If Na^+ concentration outside the cell was high, the peak was high. If Na^+ concentration outside the cell was low, the peak was low.

These experiments furnished strong support for the hypothesis that the action potential begins when Na^+ flows into the neuron. In other words, sodium ions are responsible for the depolarization phase.

What happens during the repolarization phase? Using radioactive K^+, Hodgkin and Huxley showed that there was a strong flow of potassium ions out of the cell during the repolarization phase.

The action potential consists of a strong inward flow of sodium ions followed by a strong outward flow of potassium ions. **✓ If you understand this concept, you should be able to add labels that read, "Sodium channels open—Na^+ enters" and "Potassium channels open—K^+ leaves" to Figure 46.5.**

How Do Voltage-Gated Channels Work?

The action potential depends on **voltage-gated channels**—membrane proteins that open and close in response to changes

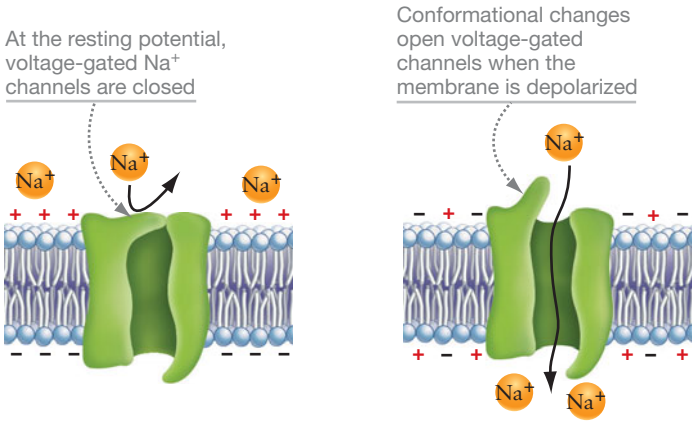

FIGURE 46.6 The Shape of a Voltage-Gated Channel Depends on the Membrane Potential. Changes in the conformation of voltage-gated channels are responsible for changes in a neuron's permeability to ions.

in membrane voltage. The shape of a voltage-gated channel, and thus its ability to admit ions, changes in response to the charges present at the inside of the membrane. **FIGURE 46.6** shows a simple model of how voltage-gated sodium channels change as a function of membrane potential.

Hodgkin and Huxley confirmed that voltage-gated channels exist using a technique called voltage clamping. **Voltage clamping** allows researchers to hold the voltage of a region of an axon at any desired level and record the electrical currents that occur at that voltage. When the researchers held the squid axon at various voltages, different currents resulted. These experiments supported the hypothesis that the behavior of the ion channels depends on voltage.

Patch Clamping and Studies of Single Channels Studying individual ion channels became possible in the 1980s when Erwin Neher and Bert Sakmann perfected a technique known as **patch clamping.** As **FIGURE 46.7** shows, the researchers touched a membrane with a fine-tipped microelectrode and applied suction to capture a single ion channel within the electrode's tip.

Using this technique, the researchers were able to document for the first time the currents that flowed through individual

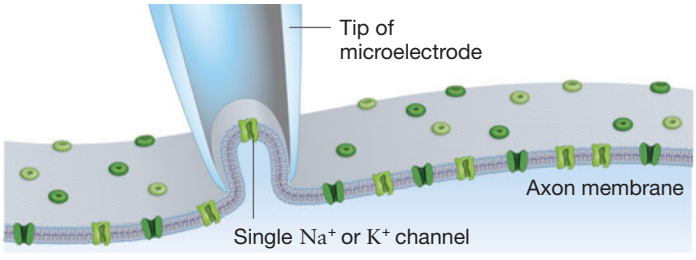

FIGURE 46.7 Patch Clamping Provided Insights into the Action Potential. Patch clamping makes use of extremely fine-tipped microelectrodes. The goal is to isolate one channel and record from it.

channels, and they showed that different ion channels behave differently:

- Voltage-gated channels are either open or closed. There is no gradation in channel behavior. This conclusion is based on the shape of the recorded current: Current flow starts and stops instantly, and the size of the current is always the same.
- Sodium channels open quickly after depolarization. They stay open for about a millisecond, close, and remain inactive for 1 to 2 msec. That explains why the cell can repolarize: Once the sodium channels close, there is a lag before they can open again.
- Potassium channels open with a delay after depolarization. They continue to flip open and closed until the membrane repolarizes. Once the membrane returns to the resting potential, these channels remain closed.

Positive Feedback Occurs during Depolarization More detailed experiments on Na^+ channels also explained why the action potential is an all-or-none event. The key observation was that Na^+ channels become more likely to open as a membrane depolarizes. As a result, an initial depolarization leads to the opening of more Na^+ channels, which depolarizes the membrane further, which leads to the opening of additional Na^+ channels.

The opening of Na^+ channels exemplifies **positive feedback**—meaning that the occurrence of an event makes the same event more likely to recur. When a fuse is lit, for example, the heat generated by the oxidation reaction accelerates the reaction itself, which generates still more heat and leads to additional oxidation reactions and keeps the fuse burning. Positive feedback is rare in organisms: It cannot be employed as a feedback mechanism under many circumstances because it often leads to uncontrolled events. The opening of Na^+ channels during an action potential is one of the few examples known.

✔ **If you understand how voltage-gated sodium and potassium channels work, you should be able to (1) explain how positive feedback occurs in the opening of Na^+ channels, and (2) predict what would happen if Na^+ and K^+ channels were open at the same time.**

Using Neurotoxins to Identify Channels and Dissect Currents In addition to using voltage clamping and patch clamping, researchers have used neurotoxins to explore the dynamics of voltage-gated channels. **Neurotoxins** are poisons that affect neuron function—often resulting in convulsions, paralysis, or unconsciousness. They come from sources as diverse as venomous snakes and foxglove plants.

For example, when biologists treated giant axons from lobsters with tetrodotoxin from puffer fish, they found that the resting potential in treated neurons was normal, but action potentials were abolished. More specifically, the flow of K^+ out of the cell was normal but the influx of Na^+ was wiped out. Researchers concluded that tetrodotoxin blocks the voltage-gated Na^+ channel, probably by binding to a specific site on the channel protein.

How Is the Action Potential Propagated?

To explain how action potentials propagate down an axon, Hodgkin and Huxley suggested the model illustrated in **FIGURE 46.8a**.

Step 1 The influx of Na^+ at the start of an action potential repels intracellular cations, causing them to spread away from the sodium channels.

Step 2 As positive charges are pushed farther from the initial sodium channels, they depolarize adjacent portions of the membrane.

Step 3 Nearby voltage-gated Na^+ channels open when the membrane reaches threshold, resulting in an action potential.

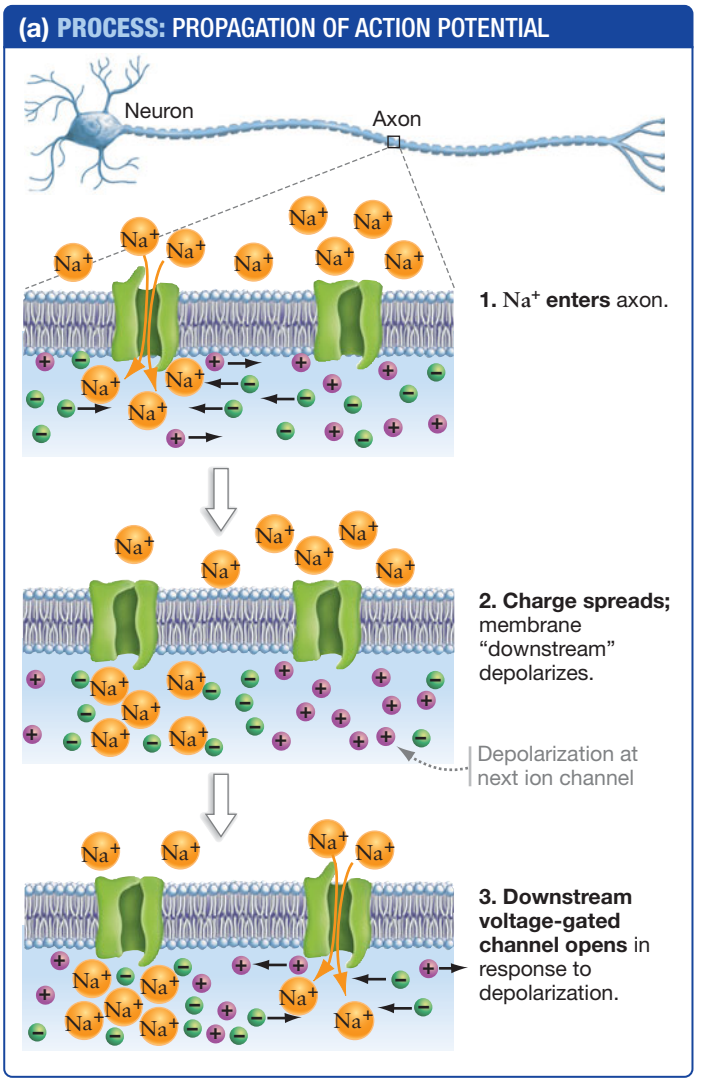
In this way, action potentials are continuously regenerated at adjacent areas of the plasma membrane (**FIGURE 46.8b**). The response is all or none because action potentials are always regenerated along the entire length of the axon.

Why don't action potentials propagate back up the axon in the direction of the cell body? To answer this question, recall that once Na^+ sodium channels have opened and closed, they are less likely to open again for a short period. This is known as the **refractory** state. Action potentials are propagated in one direction only, because "upstream" sodium channels, in the direction of the cell body, are in the refractory state.

The hyperpolarization phase, in which the membrane is more negative than the resting potential, also keeps the charge that spreads upstream from triggering an action potential in that direction, because a much stronger stimulus would be necessary to raise the membrane potential to threshold potential.

Axon Diameter Affects Speed Understanding how the action potential propagates helped researchers explain why the squid's axons are so large. When sodium ions enter the axon interior at the start of an action potential, they repulse intracellular cations, causing them to flow along the inside of the membrane. Cations moving down axons with larger diameters meet less resistance to flow than those moving down narrow axons. As a result, the charge spreads down the membrane more quickly.

The upshot is that the squid's giant axon and other large-diameter neurons transmit action potentials much faster than small axons can. The squid axon's large size is an adaptation that makes particularly rapid signaling possible.



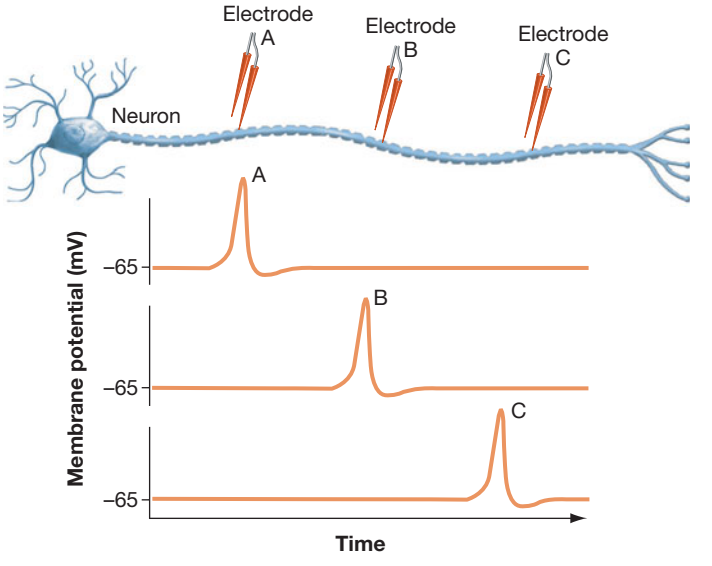


FIGURE 46.8 Action Potentials Propagate because Charge Spreads Down the Membrane. (a) An action potential starts with an inflow of Na^+. The influx of positive charge attracts negative charges inside the cell and repels positive charges. As a result, cations spread away from the channel where the Na^+ enters and depolarize nearby regions of the neuron. Voltage-gated Na^+ channels open in response. **(b)** The action potential is propagated down the axon as a wave of depolarization, but there is no loss of signal because action potentials at one area of the membrane always stimulate action potentials at adjacent areas of the membrane.

Myelination Affects Speed Relatively few vertebrates have giant axons. Instead, vertebrates—and some invertebrates—have specialized accessory cells whose membranes wrap around the axons of certain neurons and increase the efficiency of action potential propagation.

In the central nervous system, the specialized accessory cells are called **oligodendrocytes.** In the peripheral nervous system, described in Section 46.4, the cells are **Schwann cells** (**FIGURE 46.9a**). Oligodendrocytes and Schwann cells are two of several types of nervous system cells that support neurons. Collectively, these accessory cells are called **glia.**

When oligodendrocytes or Schwann cells wrap around an axon, they form a **myelin sheath,** which acts as a type of electrical insulation. As action potentials spread down an axon, the myelin sheath prevents charge in the form of ions from leaking back out across the plasma membrane of the neuron.

Consequently, the cations moving down the membrane are able to spread until they hit an unmyelinated section of the axon, called a **node of Ranvier** (**FIGURE 46.9b**). The node has a dense concentration of voltage-gated Na^+ and K^+ channels, so new action potentials can occur at the node.

Electrical signals "jump" from node to node down a myelinated axon much faster than they can move down an unmyelinated axon of the same diameter. In an unmyelinated axon, sodium and potassium channels are found in all locations, and action potentials occur continuously down its length. Myelination is interpreted as an adaptation that makes rapid transmission of electrical signals possible in axons that have a small diameter.

To appreciate the importance of myelination, consider what happens when it is disrupted. If myelin degenerates, the transmission of electrical signals slows considerably. The autoimmune disease **multiple sclerosis (MS)** develops when the immune system mistakenly targets the oligodendrocytes that make up the myelin sheath in the CNS. As damage to myelin increases and electrical signaling is impaired, coordination among neurons is

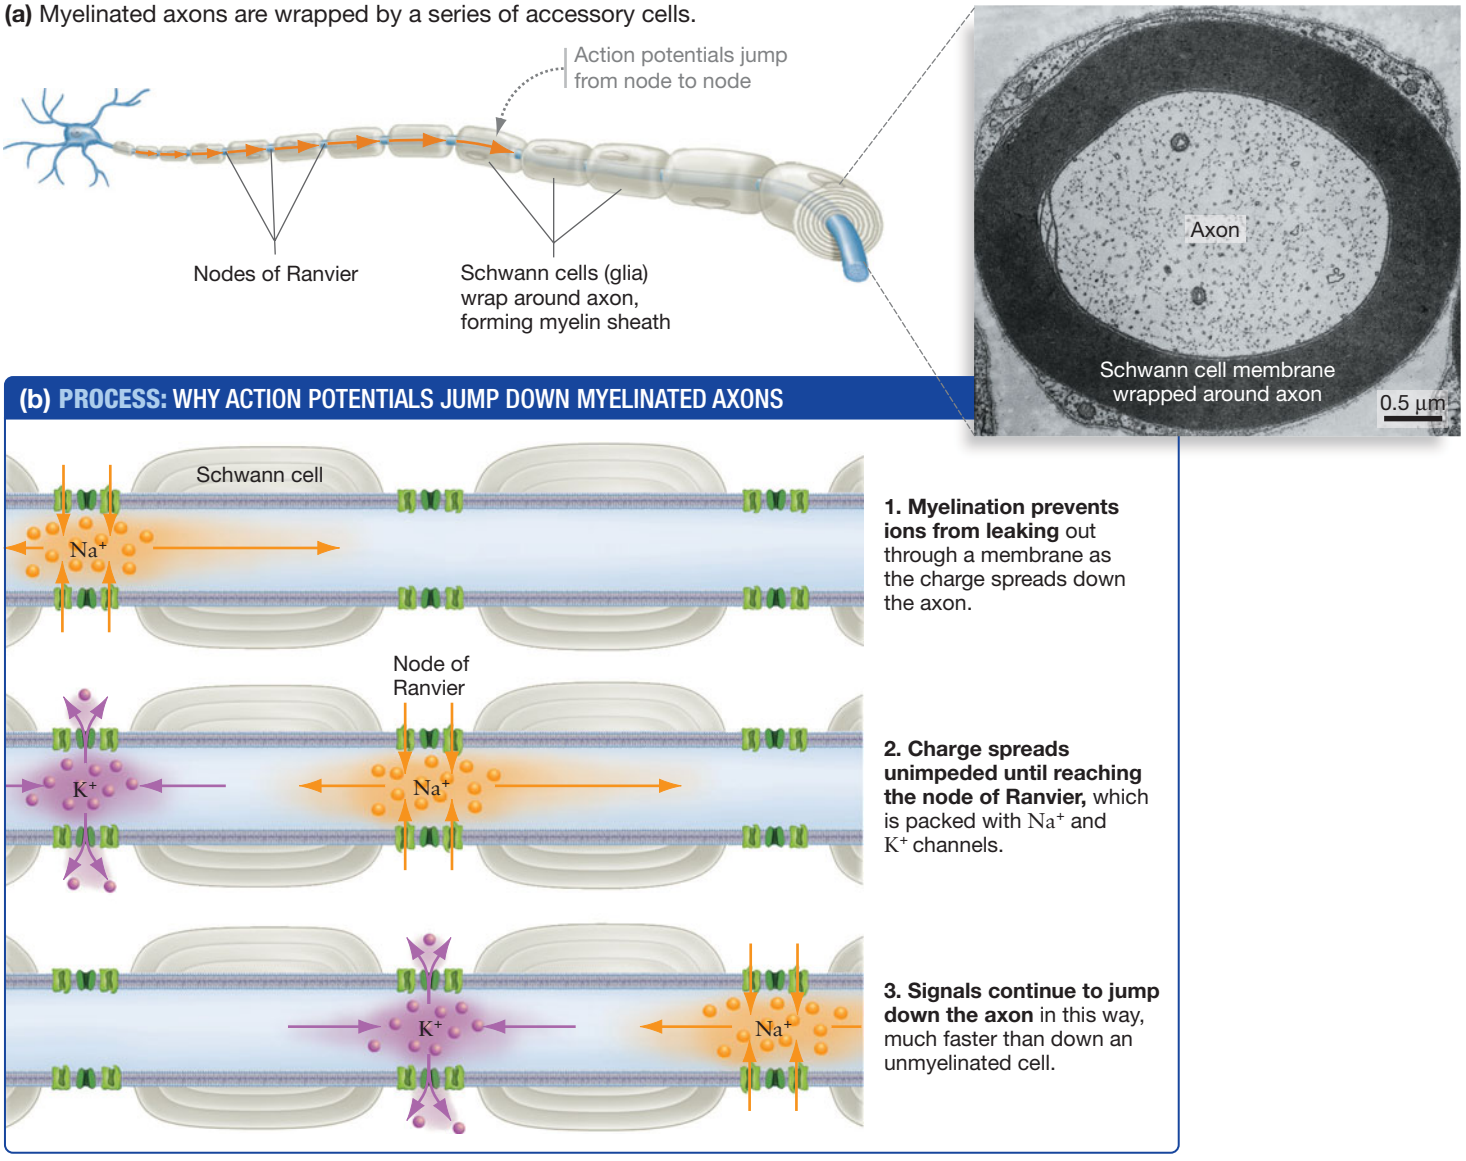

FIGURE 46.9 Action Potentials Propagate Quickly in Myelinated Axons.

affected and muscles weaken. The symptoms of MS are highly variable; in severe cases, the disease progresses and can be crippling.

What happens once an action potential has traveled the length of the axon? In most neurons, the membrane at the end of the axon is adjacent to the membrane of another neuron's dendrite but separated from its surface by a tiny gap. Let's investigate what happens when an action potential arrives at this interface between cells.

check your understanding

CYU

If you understand that . . .

- During an action potential, membrane voltage undergoes rapid changes due to an inflow of sodium ions followed by an outflow of potassium ions.
- Action potentials propagate down an axon because inrushing sodium ions repel intracellular cations that move down the membrane and depolarize adjacent portions of the membrane.

✔ You should be able to . . .

1. Explain why the action potential is an all-or-none phenomenon.
2. Predict what would happen if batrachotoxin, the poison produced by some species of poison dart frogs, were applied to the membrane. (Batrachotoxin binds to voltage-gated sodium channels and maintains them in an open state.)

Answers are available in Appendix A.

46.3 The Synapse

The cytoplasm of most neurons is not directly connected to the cytoplasm of other neurons, yet neurons are able to communicate with one another. Based on this observation, there must be some indirect mechanism that transmits signals from cell to cell, across their plasma membranes.

In the 1920s, Otto Loewi showed that this indirect mechanism involves **neurotransmitters.** Neurotransmitters are chemical messengers that transmit information from one neuron to another neuron, or from a neuron to a target cell in a muscle or gland.

Loewi knew that signals from the vagus nerve slow the heart. To test the hypothesis that the signal from nerve to heart muscle is delivered by a chemical, he performed the experiment diagrammed in **FIGURE 46.10**.

First, Loewi isolated the vagus nerve and heart of a frog. As predicted, the heart rate slowed when he stimulated the vagus nerve electrically. Next, he took the solution that bathed the first heart, applied it to another heart—this time one that was not

accompanied by a vagus nerve—and showed that the second heart rate slowed as well.

This result provided strong evidence for the chemical transmission of electrical signals. The vagus nerve had released a neurotransmitter into the bath.

Synapse Structure and Neurotransmitter Release

When transmission electron microscopy became available in the 1950s, biologists finally understood the physical nature of the interface, or **synapse,** between neurons. As **FIGURE 46.11** shows, **(1)** the membranes of axons and dendrites are separated by a tiny space, the **synaptic cleft,** and **(2)** the ends of axons contain numerous sac-like structures, called **synaptic vesicles.** Synaptic vesicles were hypothesized to be storage sites for neurotransmitters.

Anatomical observations such as these, combined with chemical studies of the synapse, led to the model of synaptic transmission illustrated in **FIGURE 46.12**. Notice that the "sending" cell is the **presynaptic neuron** and the "receiving" cell is the **postsynaptic neuron.**

Step 1 An action potential arrives at the end of the axon.

Step 2 The depolarization created by the action potential opens voltage-gated calcium channels located near the synapse, in the presynaptic membrane. The electrochemical gradient for Ca^{2+} results in the inflow of calcium ions through the open channels.

Step 3 In response to the increased calcium concentration inside the axon, synaptic vesicles fuse with the membrane and release neurotransmitters into the gap between the cells, the synaptic cleft. The delivery of neurotransmitters into the cleft is an example of exocytosis (see Chapter 7).

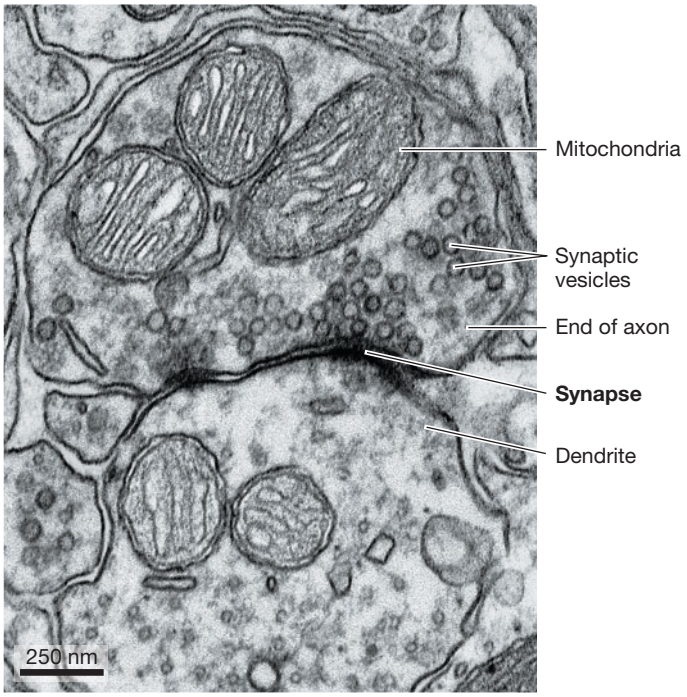

FIGURE 46.11 Synaptic Vesicles Cluster Near Synapses. A cross section of the site where an axon meets a dendrite.

Step 4 Neurotransmitters bind to receptors on the postsynaptic cell, leading to changes in the membrane potential of the postsynaptic cell. The combined effect on membrane potential of many neurotransmitters binding may trigger an action potential in the postsynaptic cell.

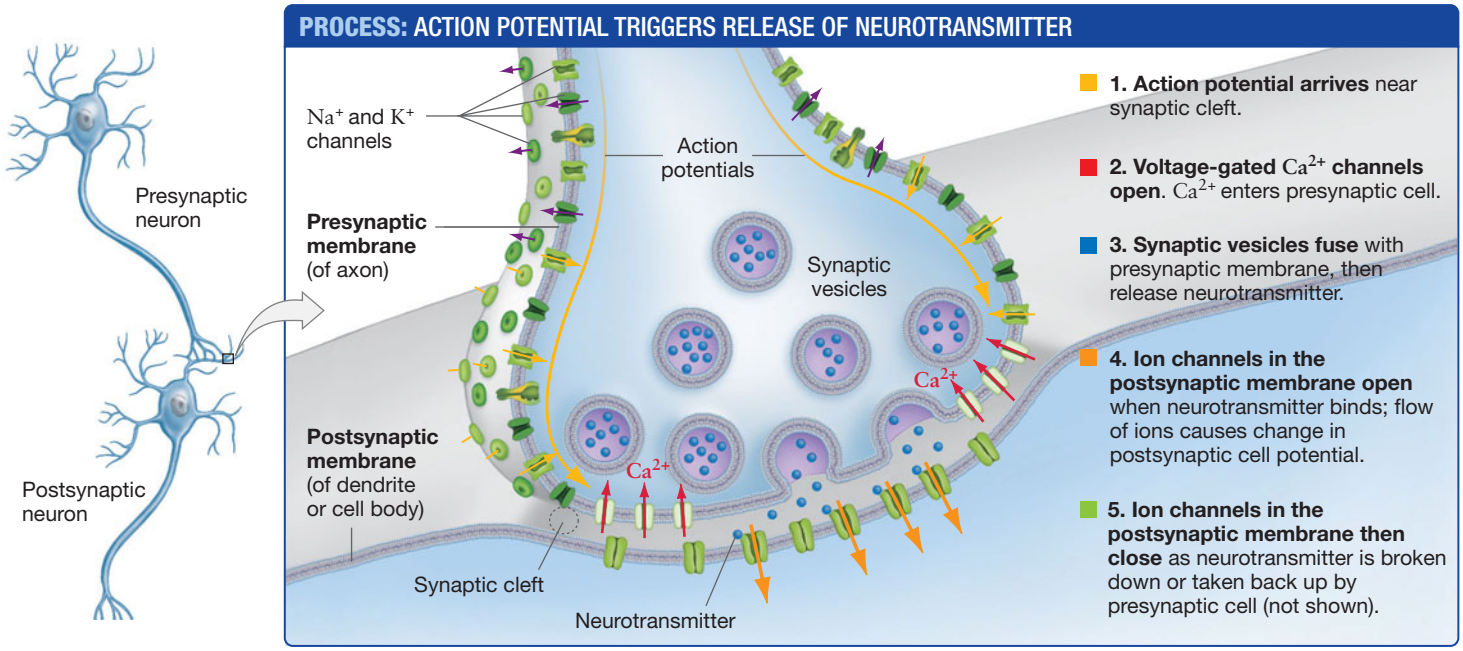

FIGURE 46.12 Neurons Meet and Transfer Information at Synapses. The sequence of events that occurs when an action potential arrives at a synapse.

Step 5 The response ends as the neurotransmitter is broken down and taken back up by the presynaptic cell.

Is the model correct? Let's begin by analyzing the role of neurotransmitters.

What Do Neurotransmitters Do?

Researchers can look for neurotransmitters by stimulating a neuron, collecting the molecules that are released, and analyzing them chemically. To find the receptor for a particular neurotransmitter, researchers can attach a radioactive atom or other type of label to the neurotransmitter and add it to neurons. Once the labeled transmitter has bound to its receptor, the receptor protein can be isolated and analyzed.

Using techniques such as these, biologists have discovered and characterized a wide array of neurotransmitters and receptors. Some of them are listed in **TABLE 46.2**.

By patch-clamping receptors, biologists confirmed that many neurotransmitters function as ligands. A **ligand** is a molecule that binds to a specific site on a receptor molecule. Many neurotransmitters are ligands that bind to receptors called **ligand-gated channels.** These are channel proteins that open in response to binding by a specific ligand—just as voltage-gated channels open in response to a change in voltage.

When a neurotransmitter binds to a ligand-gated ion channel in the postsynaptic membrane, the channel opens and admits a flow of ions along an electrochemical gradient. In this way, the neurotransmitter's chemical signal is transduced to an electrical signal—a change in the membrane potential of the postsynaptic cell. ✔ **If you understand this concept, you should be able to envision a membrane with a resting potential of −65 mV and explain what happens to the membrane potential when a ligand-gated ion channel opens and allows chloride ions to leave the cell. How does this affect the likelihood that the postsynaptic cell will mount an action potential?**

Not all neurotransmitters bind to ion channels, however. Some bind to receptors that activate enzymes whose action leads to the production of a second messenger in the postsynaptic cell. Recall that **second messengers** are chemical signals produced inside a cell in response to a chemical signal that arrives at the cell surface (see Chapter 11).

The second messengers induced by neurotransmitters may trigger changes in enzyme activity, gene transcription, or membrane potential. (Chapter 49 explores the cellular role of second messengers in detail.)

Postsynaptic Potentials

What happens when a neurotransmitter binds to a ligand-gated ion channel in the postsynaptic cell?

Ligand-gated sodium channels on the membranes of dendrites are in particularly high concentration near synapses. When neurotransmitters bind, these channels open to let sodium into the cell, causing depolarization (**FIGURE 46.13a**). In most cases, depolarization makes an action potential in the postsynaptic cell more likely because the membrane potential approaches threshold. Changes in the postsynaptic cell that bring the membrane potential closer to threshold are called **excitatory postsynaptic potentials (EPSPs).**

If the receptor activity at the synapse leads to an outflow of potassium ions or an inflow of chloride ions or other anions in the postsynaptic cell, the postsynaptic membrane hyperpolarizes—making action potentials less likely to occur in the postsynaptic cell (**FIGURE 46.13b**). Changes in the postsynaptic cell that make the membrane potential more negative are called **inhibitory postsynaptic potentials (IPSPs).**

If an EPSP and an IPSP occur at the same time in the same place, they cancel each other out (**FIGURE 46.13c**). Synapses also can be modulatory—meaning that their activity modifies a neuron's response to other EPSPs or IPSPs.

Postsynaptic Potentials Are Graded

It is critical to realize that, unlike action potentials, EPSPs and IPSPs are not all-or-none events. Instead, they are graded in size.

The size of an EPSP or IPSP depends on the amount of neurotransmitter that is released at the synapse at a given time. A higher concentration of neurotransmitter in the synaptic cleft leads to a larger EPSP or IPSP. Both types of signal are short lived because neurotransmitters do not bind irreversibly to channels

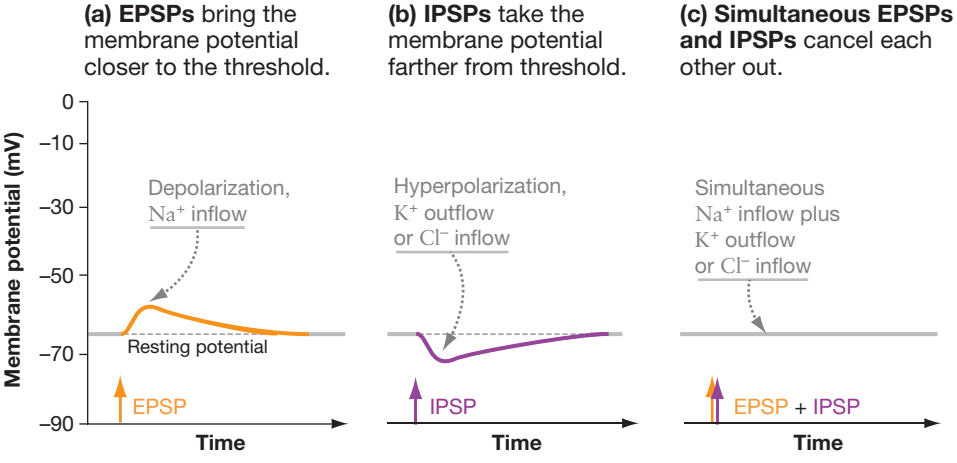

FIGURE 46.13 Events at the Synapse May Lead to Depolarization or Hyperpolarization of the Postsynaptic Membrane. These recordings show what happens to the membrane potential of a postsynaptic neuron with the arrival of signals that cause **(a)** depolarization, **(b)** hyperpolarization, or **(c)** no change. The last result occurs because simultaneous depolarizing and hyperpolarizing signals cancel each other out.

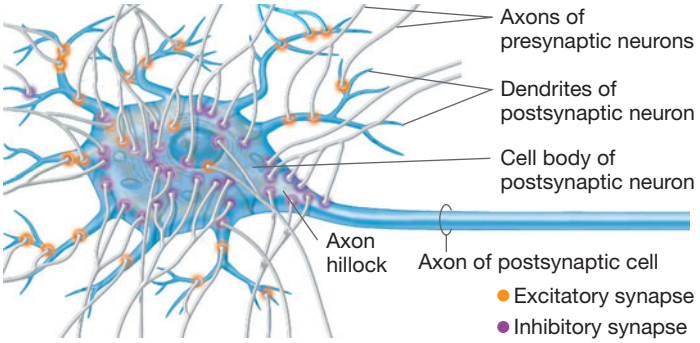
TABLE 46.2 Categories of Neurotransmitters

Neurotransmitter	Site of Action	Action*	Drugs That Interfere†
Acetylcholine	Neuromuscular junction, some CNS pathways	Excitatory (inhibitory in some parasympathetic neurons)	• Botulism toxin blocks release • Black widow spider venom increases, then eliminates, release • Alpha-bungarotoxin (in some snake venoms) binds to and blocks receptor
Monoamines			
Norepinephrine	Sympathetic neurons, some CNS pathways	Excitatory or inhibitory	• Ritalin (used for attention deficit hyperactivity disorder) increases release • Some antidepressants prevent reuptake
Dopamine	Many CNS pathways	Excitatory or modulatory	• Cocaine prevents reuptake • Amphetamine prevents reuptake
Serotonin	Many CNS pathways	Inhibitory or modulatory	• MDMA (ecstasy) causes increased release
Amino Acids			
Glutamate	Many CNS pathways	Excitatory	• PCP (angel dust) blocks receptor
Gamma-aminobutyric acid (GABA)	Some CNS pathways	Inhibitory	• Ethanol mimics response to GABA
Peptides			
Endorphins, enkephalins, substance P	Sensory pathways (pain)	Excitatory, modulatory, or inhibitory	

*Excitatory neurotransmitters make action potentials more likely in postsynaptic cells; inhibitory neurotransmitters make action potentials less likely; modulatory neurotransmitters modify the response at other synapses.



† Drugs that prevent reuptake of neurotransmitters increase their activity.

in the postsynaptic cell. Instead, they are quickly inactivated by enzymes or taken up by the presynaptic cell and recycled.

If either the amount or life span of neurotransmitters is artificially altered, the normal functioning of neurons is altered. The drugs cocaine and amphetamine, for example, exert their effects by inhibiting the uptake and recycling of particular neurotransmitters (see Table 46.2).

Summation and Threshold How do EPSPs and IPSPs affect the postsynaptic cell? As **FIGURE 46.14a** shows, the dendrites and the cell body of a neuron typically make hundreds or thousands of synapses with other cells. At any instant, the EPSPs and IPSPs that occur at each of these synapses lead to short-lived changes in membrane potential in the dendrites and cell body of the postsynaptic cell.

(a) Most neurons receive information from many other neurons.

(b) Postsynaptic potentials sum.

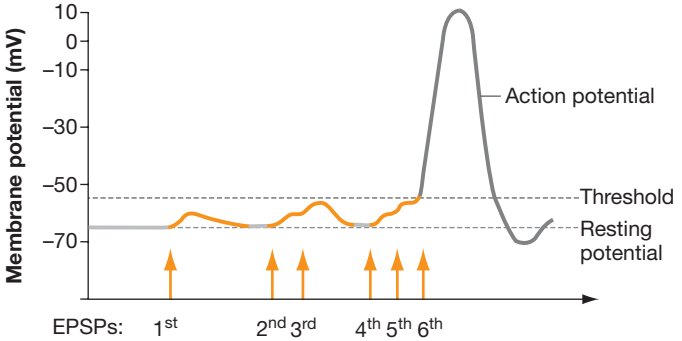


FIGURE 46.14 Neurons Integrate Information from Many Synapses. (a) The dendrites and cell body of a neuron typically receive signals from hundreds or thousands of other neurons. **(b)** When action potentials arrive close together in time, the postsynaptic potentials sum. Here the first EPSP is insufficient to generate an action potential; two EPSPs arriving close together undergo summation but do not reach threshold; the summing of three EPSPs arriving close together does exceed the threshold. This example is simplified—in reality, hundreds or thousands of IPSPs and EPSPs sum to determine action potential frequency.

If an IPSP and EPSP occur close together in space or time, the changes in membrane potential tend to cancel each other out. But if several EPSPs occur close together in space or time, they sum and make the neuron more likely to reach threshold and fire an action potential (**FIGURE 46.14b**). The additive nature of postsynaptic potentials is termed **summation.**

The sodium channels that trigger action potentials in the postsynaptic cell are located near the start of the axon at a site called the **axon hillock** (see Figure 46.14a). As IPSPs and EPSPs are received and interact throughout the dendrites and cell body, charge spreads to the axon hillock. If the membrane at the axon hillock depolarizes past the threshold potential, enough voltage-gated sodium channels open to trigger positive feedback and an action potential. Once an action potential starts at the axon hillock, it propagates down the axon to the next synapse.

Summation is critically important. Because neurons receive input from many synapses, and because IPSPs and EPSPs sum, information in the form of electrical signals is modified at the synapse before being passed along. An action potential in a presynaptic neuron does not always lead to an action potential in a postsynaptic neuron—the response by the postsynaptic cell depends on the information it receives from a wide array of neurons.

Predict the effect on an EPSP of an increase in the concentration of a synaptic enzyme that breaks down an excitatory neurotransmitter.

Answers are available in Appendix A.

46.4 The Vertebrate Nervous System

The first three sections of this chapter examined electrical signaling at the level of molecules, membranes, and individual cells. This section discusses electrical signaling at the levels of tissues, organs, and systems.

To begin, let's consider the overall anatomy of the vertebrate nervous system, and how researchers explore the function of the most complex organ known: the human brain. The chapter concludes by returning to the molecular level (and to studies of invertebrates) to introduce recent work on learning and memory.

What Does the Peripheral Nervous System Do?

Recall from Section 46.1 that the central nervous system (CNS) is made up of the brain and spinal cord and is concerned primarily with integrating information. The peripheral nervous system (PNS) is made up of neurons outside the CNS.

What functions do the cells of the PNS control? Anatomical and functional studies indicate that the PNS consists of two divisions with distinct functions:

1. The **afferent division** transmits sensory information to the CNS.
2. The **efferent division** carries commands from the CNS to the body.

Neurons in the afferent division monitor conditions inside and outside the body. Once information from afferent neurons has been processed in the CNS, neurons in the efferent division carry signals that allow the body to respond to changed conditions in an appropriate way.

As **FIGURE 46.15** shows, the afferent and efferent divisions are part of a hierarchy of PNS functions. The efferent division is further divided into a **somatic nervous system,** which controls voluntary movements, and an **autonomic nervous system,** which controls internal processes such as digestion and heart rate.

- The somatic nervous system carries out voluntary responses, which are under conscious control. Skeletal muscles serve as the effectors.
- The autonomic nervous system carries out involuntary responses, which are not under conscious control. Smooth muscle, cardiac muscle, and glands serve as the effectors.

Many organs and glands are served by two functionally distinct types of autonomic nerves, summarized in **FIGURE 46.16**: One type inhibits activity, whereas the other promotes it.

1. Nerves in the **parasympathetic nervous system** promote "rest and digest" functions that conserve or restore energy.

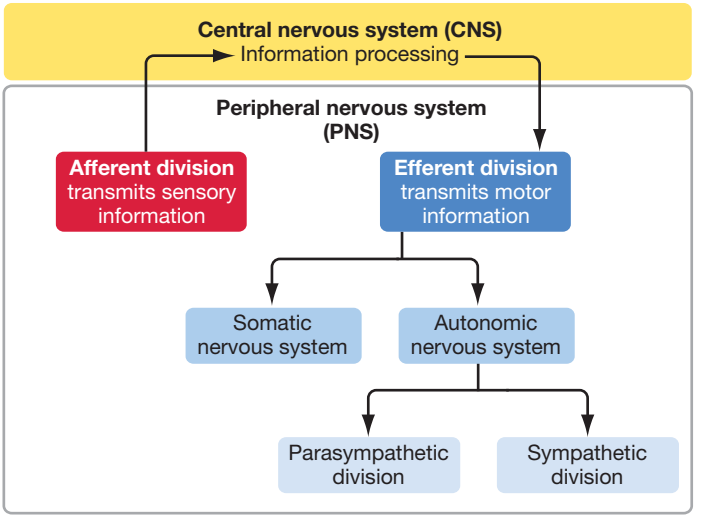

FIGURE 46.15 The Nervous System Has Several Functional Divisions.

For example, the parasympathetic nerves that synapse on the heart slow it down, while those that serve the digestive tract stimulate its activity.

2. Nerves in the **sympathetic nervous system** typically prepare organs for stressful "fight or flight" situations. Sympathetic nerves speed up the heart rate, stimulate the release of glucose from the liver, and inhibit action by digestive organs.

Functional Anatomy of the CNS

Parasympathetic nerves originate at the base of the brain or the base of the spinal cord. Most sympathetic nerves also originate in the spinal cord, but they emerge along the middle of its length. Similarly, most sensory neurons project axons to the spinal cord, and most somatic motor neurons project from the spinal cord.

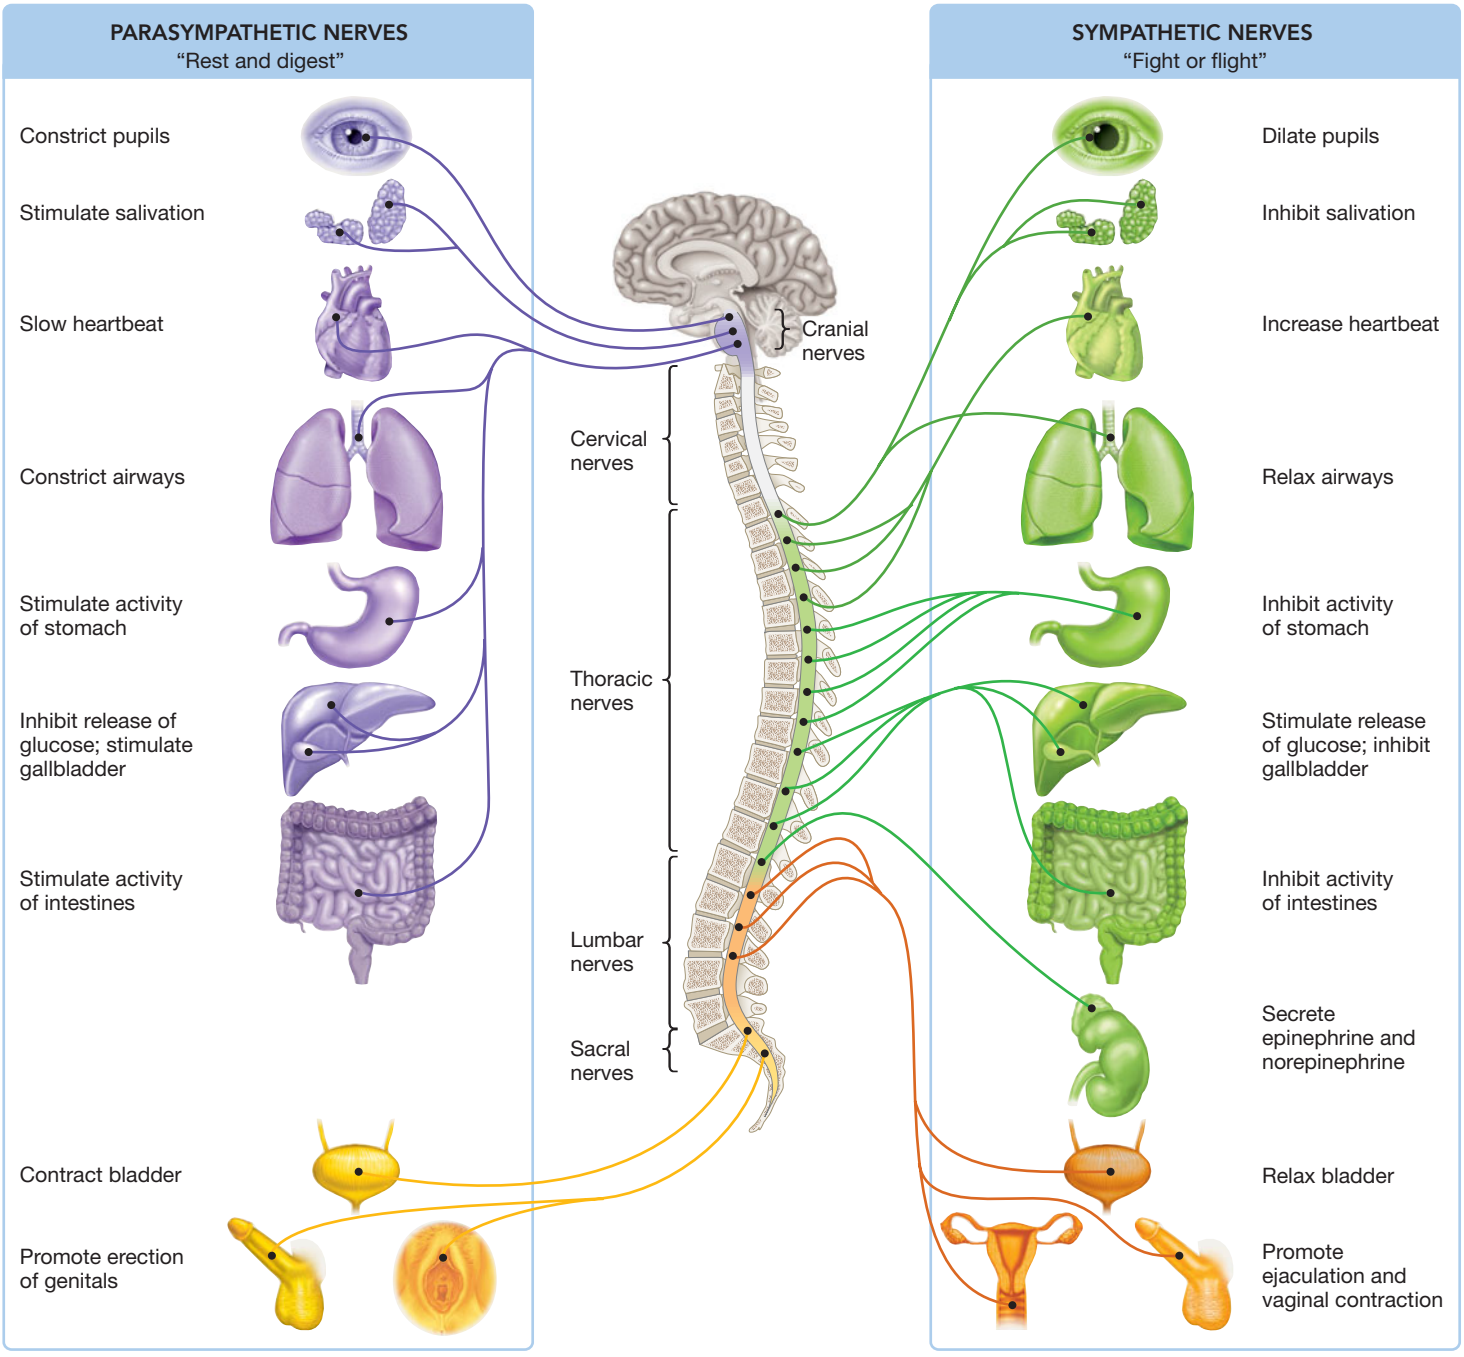

FIGURE 46.16 The Autonomic Nervous System Controls Internal Processes.

✔**QUESTION** Explain how the responses listed here for pupils, heartbeat, and liver support the rest-and-digest versus fight-or-flight functions.

In effect, then, the spinal cord serves as an information conduit. It collects and transmits information throughout the body. Virtually all the information that travels to or from the spinal cord is sent to the brain for processing. An exception is a spinal **reflex,** in which sensory neurons stimulate interneurons in the spinal cord that then directly stimulate motor neurons. This process allows you to withdraw your hand rapidly from a hot burner before your brain becomes aware of the pain.

What happens once sensory signals arrive at the brain? How are thousands of signals integrated to allow an animal to respond to stimuli? Let's begin our exploration of the brain by delving into its anatomy.

General Anatomy of the Human Brain Nineteenth-century anatomists established that the human brain is made up of the four structures labeled in **FIGURE 46.17**: the cerebrum, cerebellum, diencephalon, and brain stem. Each has a distinct function.

- The **cerebrum** makes up the bulk of the human brain. It is divided into left and right hemispheres and is the seat of conscious thought and memory.
- The **cerebellum** coordinates complex motor patterns.
- The **diencephalon** relays sensory information to the cerebrum and controls homeostasis.
- The **brain stem** connects the brain to the spinal cord. It is the autonomic center for regulating cardiovascular, digestive, and other involuntary functions.

Each cerebral hemisphere has four major areas, or lobes: the **frontal lobe,** the **parietal lobe,** the **occipital lobe,** and the **temporal lobe** (**FIGURE 46.18**). The two hemispheres are connected by a thick band of axons called the **corpus callosum.**

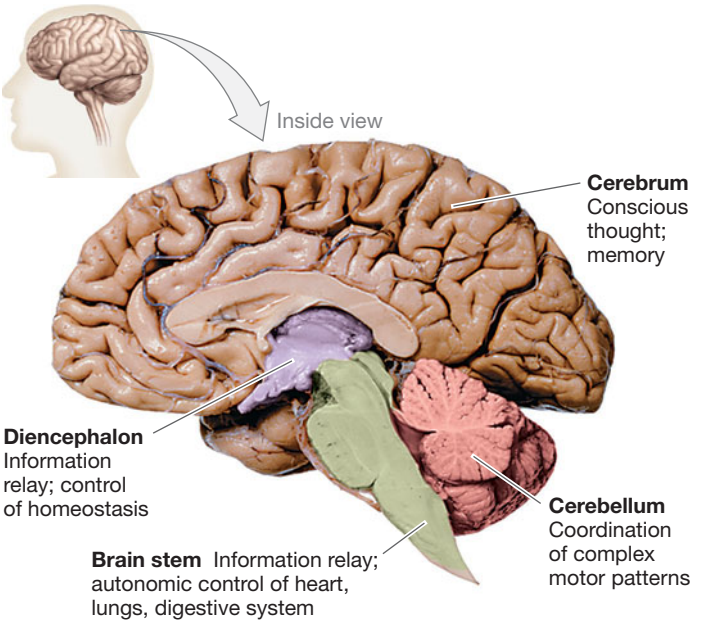

FIGURE 46.17 The Human Brain Contains Four Distinct Structures.

The relative size of the entire brain, and of its component structures, varies greatly among vertebrates (**FIGURE 46.19**). For example, compare the size of the cerebrum in fishes and mammals. In fishes, the cerebrum is quite small and is involved mainly in olfactory sensation. In mammals it is very large and contains regions specialized for memory and reasoning, in addition to the processing of multiple sensory and motor functions. Your own cerebrum is three times bigger than in other species of comparably sized mammals, reflecting its role in the higher brain functions that are so advanced in humans.

What methods do researchers use to explore the function of each area within the cerebrum?

Mapping Functional Areas in the Cerebrum I: Lesion Studies Early work on brain function studied people with specific mental deficits caused by areas of brain damage, or lesions. Paul Broca, for example, studied an individual who could understand language but could not speak. After the person's death in 1861, Broca examined the patient's brain and discovered a damaged area, or lesion, in the left frontal lobe of the cerebrum. Broca hypothesized that this region is responsible for speech. More generally, he formulated the hypothesis that specific regions of the brain are specialized for coordinating particular functions.

Broca's claim that functions are localized to specific brain areas has been verified through extensive efforts to map the cerebrum. In some cases, advances were made by studying the

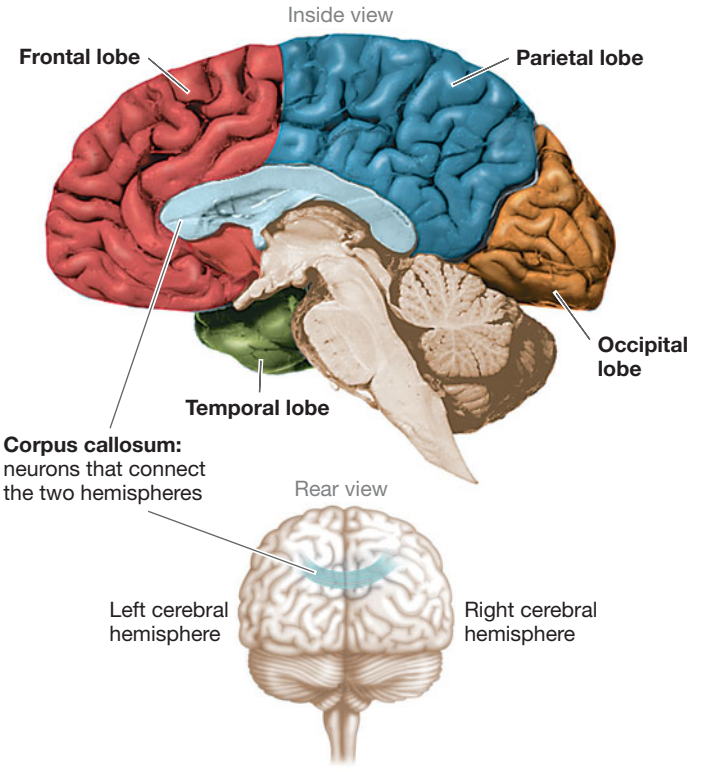

FIGURE 46.18 The Human Cerebrum Has Four Lobes and Two Hemispheres.

✔**EXERCISE** On your own head, point to each of the labeled areas.

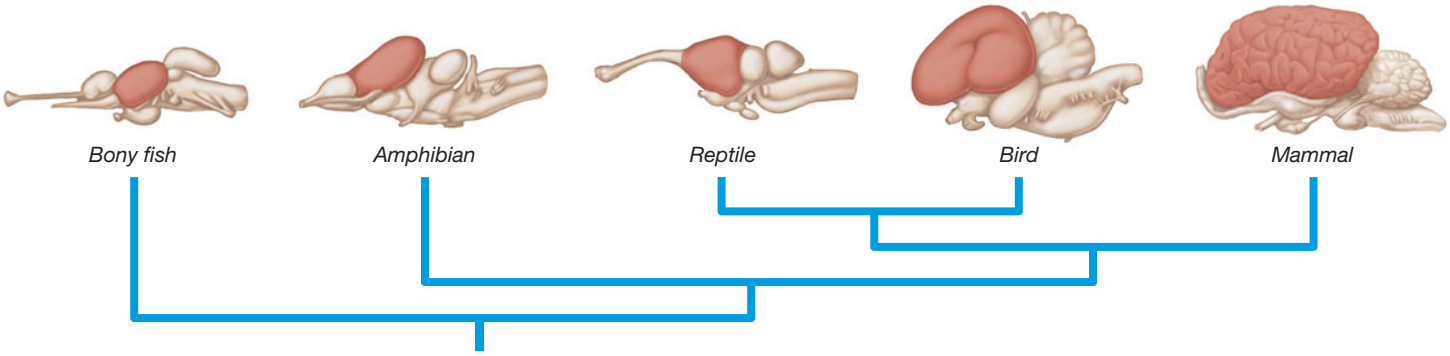

FIGURE 46.19 The Relative Sizes of Brain Regions Differ among Vertebrate Lineages. For example, the cerebrum (in orange) tends to be larger in birds and mammals than in basal vertebrates.

behavior of people known to have had lesions to specific brain regions or to have had specific portions of their brains removed.

In 1848, for example, Phineas Gage was working on a railroad construction site when an iron rod over an inch in diameter was blasted through his skull. The rod entered beneath his left eye, exited through his forehead (**FIGURE 46.20**), and landed some 80 feet away. Miraculously, Gage survived this accident. However, his personality did not fare as well. After the accident, Gage's physician reported him to be "fitful," "irreverent," and "obstinate," a dramatic change from his previous personality. The iron rod had damaged Gage's frontal lobe, providing some of the first clues that this part of the brain plays a role in personality and emotion.

Another fascinating case is that of a 27-year-old man named Henry Gustav Molaison (referred to as "H.M." until his death). In 1953, surgeons treated him for life-threatening seizures by removing a small portion of his temporal lobe and about two thirds of his hippocampus, a structure at the inner edge of the temporal lobe. The man recovered (he died in December 2008, at age 83), had normal intelligence, and vividly remembered his childhood, but he had no short-term memory. Brenda Milner, who studied this individual for over 40 years, had to introduce herself to him every time they met; he could not even recognize a recent picture of himself. Based on case histories like Molaison's and studies of memory in laboratory animals, a consensus has emerged that several aspects of memory are governed by the hippocampus and interior sections of the temporal lobe.

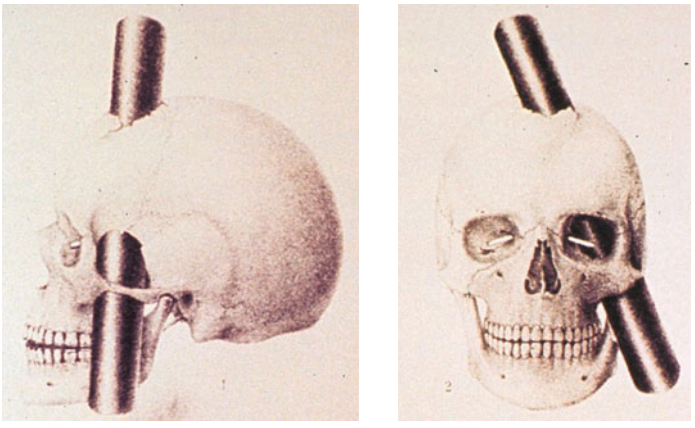

FIGURE 46.20 The Frontal Lobe Injury of Phineas Gage Affected His Personality. In 1848 a railroad worker named Phineas Gage recovered from a brain injury in which an iron rod was blasted through the frontal lobe of his cerebrum. The resulting change in his personality cued scientists that the frontal lobe plays a role in emotion and temperament.

Mapping Functional Areas in the Cerebrum II: Electrical Stimulation of Conscious Patients While working with severe epileptics (people suffering from seizures), Wilder Penfield pioneered a different approach to studying brain function. These individuals were scheduled to have seizure-prone areas of their brains surgically removed. While the patients were awake and under a local anesthetic, Penfield electrically stimulated portions of their cerebrums. His immediate goal was to map essential areas that should be spared from removal if possible.

When Penfield stimulated specific areas, patients reported sensations or experienced movement in particular regions of the body. From these responses, Penfield was able to map the sensory regions of the cerebrum shown in **FIGURE 46.21** (see page 946), as well as the adjacent motor regions. Brain surgeons still use this technique to map critical areas near tumors and seizure-prone areas.

Perhaps the most striking of Penfield's findings was that, on occasion, patients would respond to stimulation of their temporal lobe by having what appeared to be flashbacks. After one region was stimulated, a woman said, "I hear voices. It is late at night around the carnival somewhere—some sort of traveling circus. . . . I just saw lots of big wagons that they used to haul animals in."

Was this a memory, stored in a small set of neurons that Penfield happened to stimulate? The hypothesis that memories are somehow stored in specialized cells is controversial. However, a recent study provided support for it.

Researchers attached tiny electrodes that recorded the electrical activity of individual neurons in the temporal lobes and hippocampi of study subjects. They then showed each subject a set of images of celebrities, places, and objects. In one subject,

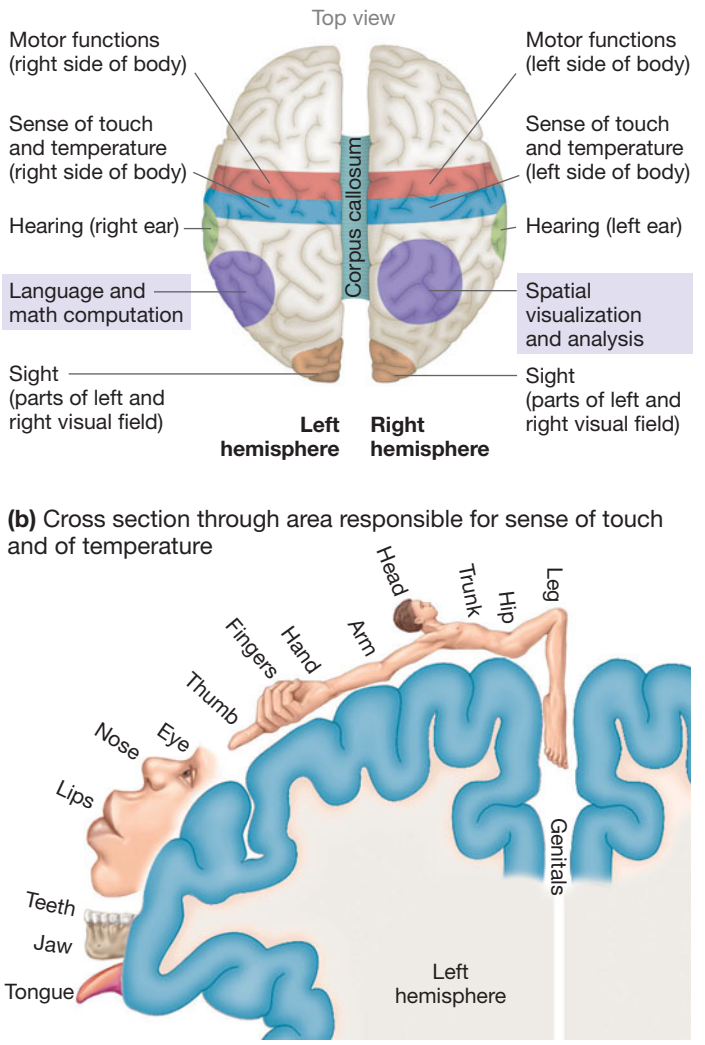

FIGURE 46.21 Specific Brain Areas Have Specific Functions.
(a) Map of the brain, in top view (as if the person is looking at the top of the page), showing the functions of some major regions. The map was compiled from studies of people with damaged brain areas or in whom brain regions had been removed surgically. Note that the corpus callosum is not actually as wide as shown here. **(b)** Researchers mapped the area responsible for the sense of touch and of temperature by stimulating neurons in the brains of patients who were awake. The size of the icons corresponds to the amount of brain area devoted to sensing those parts.

✔**QUESTION** Is there a correlation between the size of the brain area devoted to sensing a particular body part and the size of that body part? Explain.

a specific neuron fired when the subject viewed any of several images of the actress Jennifer Aniston (**FIGURE 46.22**). The neuron did not fire for other images showing spiders, buildings, other actresses, or even Aniston with another person. It appeared that, through experience, at least one of this patient's neurons became singularly devoted to the concept of Jennifer Aniston.

It is important to note that the researchers were testing only a tiny subset of the neurons present in the human brain, so there may be more than one "Jennifer Aniston neuron" in the brain. But the take-home message is that the formation or retrieval of memories associated with specific concepts involves specific neurons. Researchers are still examining exactly how these neurons interact with other parts of the brain during the processes of learning and remembering.

Have other approaches to studying memory been productive?

How Does Memory Work?

Learning is an enduring change in behavior that results from a specific experience in an individual's life. **Memory** is the retention of learned information. Learning and memory are thus closely related and are often studied in tandem. As an introduction to how researchers explore these phenomena, let's first examine work that focuses on neurons and then review research at the molecular level.

Recording from Single Neurons during Memory Tasks How do the action potentials generated by a cell change as learning and memory take place? Researchers have attempted to answer this question by recording from individual neurons in the temporal lobes of humans.

Before operating on patients who were still awake and about to undergo surgery to remove seizure-prone areas of their brains, physicians placed electrodes in specific brain regions. Then they projected words or names of objects on a screen and asked the individuals to read them silently, read them aloud, or remember them and repeat them later. The data showed that individual neurons in the cerebrum's temporal lobe are relatively quiet while patients identify objects but extremely active when the individual remembers the objects and repeats their names aloud.

What do such data mean? Neurons in the temporal lobe are most active during memory tasks. So how could action potentials from particular cells make memory possible?

Documenting Changes in Synapses Research on the molecular basis of memory is based on the idea that learning and memory must involve some type of short-term or long-term change in the neurons responsible for these processes. This change could be structural or chemical in nature. Structural changes might include modifications in the number of synapses that a particular neuron makes, or even the destruction and creation of neurons. Chemical changes might involve alterations in the amount of neurotransmitter released at certain synapses or changes in the number of receptors present in postsynaptic cells.

To explore the molecular basis of learning and memory, Eric Kandel's group has focused on an animal much easier to study than any vertebrate, the sea slug *Aplysia californica* (**FIGURE 46.23a**). Much of their work has explored the reflex diagrammed in **FIGURE 46.23b:** When the siphon, a structure on the animal's back, is touched—for example, by a stream of water—the sea slug responds by withdrawing its gill. The reflex is produced by a sensory neuron that is activated by touch and a motor neuron that projects to a gill muscle. Retracting the gill protects it from predators.

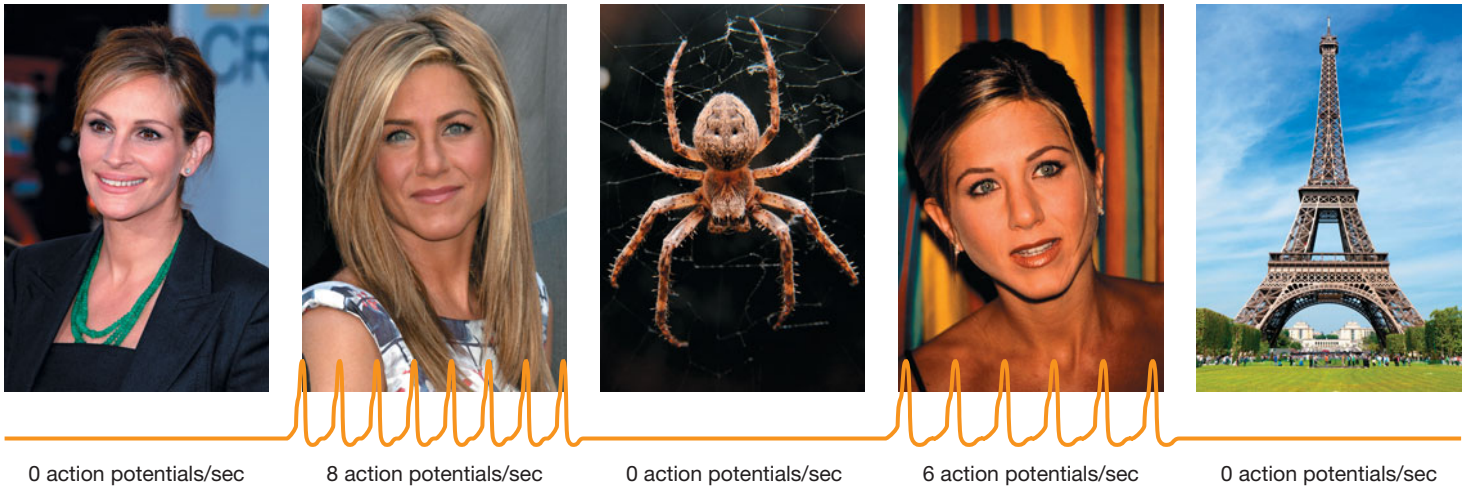

FIGURE 46.22 Single-Neuron Recording Reveals that Some Neurons in the Brain Recognize Specific Concepts. The graphs below each image show how a single neuron fires in response to images of actress Jennifer Aniston but not to other images.

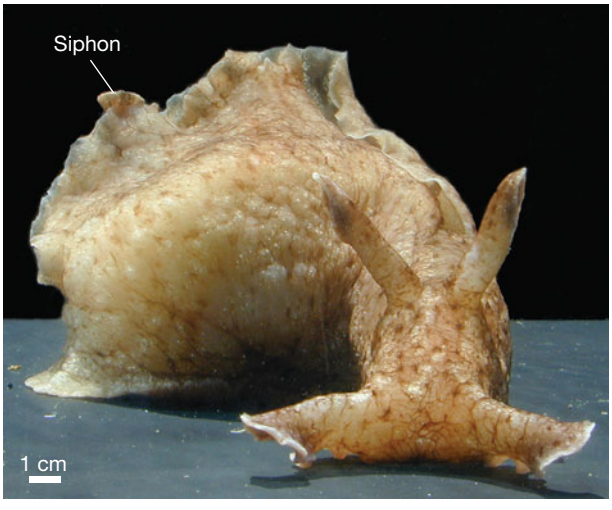

DATA: Quiroga, R. Q., L. Reddy, G. Kreiman, et al. 2005. *Nature* 435: 1102–1107.

Early work established that this simple reflex is modified by learning. For example, *Aplysia* also withdraw their gills when their tails are given an electrical shock. If shocks to the tail are repeatedly combined with a very light touch to the siphon—too light to normally get a response on its own—an *Aplysia* will learn to withdraw its gills in response to a light siphon touch alone.

Follow-up studies on this reflex showed that the neurons involved in learning release the neurotransmitter **serotonin,** which causes an EPSP in the motor neuron to the gill. Repeated application of serotonin mimics what happens at the synapse during learning, when the neurons fire repeatedly. As **FIGURE 46.24a** (see page 948) shows, experimental application of serotonin leads to higher EPSPs, meaning that the motor neuron is more likely to generate action potentials. These results suggest that in *Aplysia*, changes in the nature of the synapse form the molecular basis of learning and memory. This change in responsiveness of the synapse is termed **synaptic plasticity.**

Recently Kandel's team replicated these results with sensory and motor neurons growing in culture. **FIGURE 46.24b** shows two *Aplysia* motor neurons on a culture plate. Each motor neuron synapses with the same sensory neuron. To mimic the learning process, the investigators applied serotonin to one synapse five times over a short period. When they stimulated the sensory neuron a day later, they found a huge increase in EPSPs in the motor neuron postsynaptic to that synapse (**FIGURE 46.24c**). The experimental postsynaptic cells had also established additional synapses. The structure and behavior of the experimental

postsynaptic motor neuron had changed, based on its experience. Neurons that had not received the repeated stimulation with serotonin had normal postsynaptic responses and numbers of synapses.

Documenting Changes in Neurons Synapses change over time, but what about the cells of the central nervous system themselves? When early neurobiologists dissected adult cadaver brains, they found that none of the neurons showed signs of mitosis. From these observations they concluded that **neurogenesis**—the formation of new neurons—does not occur in adults.

In 1983, Steven Goldman and Fernando Nottebohm revisited this long-standing theory. They examined whether new neurons can be formed in the brains of songbirds. Songbirds were chosen because in their brains, specific regions that control singing behavior undergo dramatic seasonal changes in size. The researchers hypothesized that these changes result from an increased rate of neurogenesis during the reproductive season.

To test this hypothesis, the researchers injected canaries (**FIGURE 46.25a**) with radiolabeled thymidine, which becomes incorporated into newly synthesized DNA. The researchers later collected the birds' brains, cut them into very thin slices, mounted the slices onto microscope slides, and brought them into contact with photographic film. In this technique, called autoradiography (see **BioSkills 9** in Appendix B), any new cells with radiolabeled thymidine in their DNA would expose the film, thereby indicating the presence and location of cells that were produced after the bird was injected.

The researchers found that adult songbirds are indeed able to produce large numbers of new neurons. Dozens of studies since Goldman and Nottebohm's experiment have confirmed that new neurons are incorporated into the song-control regions of the brain each spring, causing them to grow dramatically in size (**FIGURE 46.25b**). The new neurons promote learning and memory in the song-control system.

Other scientists around the same time and, indeed, even earlier obtained autoradiographic evidence of neurogenesis in adult mammals. However, the sheer number of new cells was much lower in mammals than in birds, so these reports did

If you understand that . . .

- The CNS and PNS work together to gather information about the external and internal environments, process that information, and signal muscles, glands, and other tissues to make appropriate responses to the information.
- Brain regions have specific functions.
- Changes in synapses and neurogenesis allow animals to learn and create memories.

✓ You should be able to . . .

1. Describe the research strategies that allowed biologists to localize particular functions to specific regions in the brain.
2. Identify the key mechanisms behind learning and memory.

Answers are available in Appendix A.

(a) Male canaries (left) sing to attract females (right).

(b) In songbirds, the size of the brain's song-control region increases in spring.

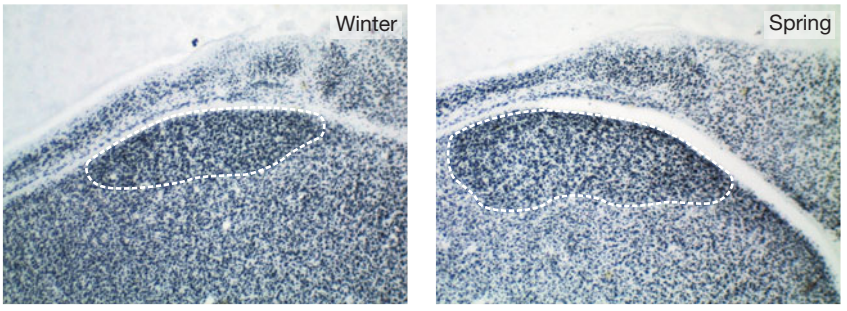

FIGURE 46.25 Neurogenesis Occurs in the Adult Songbird Brain.

not convince all researchers. Skeptics initially suggested that the labeled cells in mammals might actually be glia rather than neurons.

A breakthrough came in the early 1990s with the development of new techniques that specifically label neurons. The markers used in these techniques bind to proteins that are found only in neurons and not in glial cells. Since that time, adult neurogenesis has been definitively shown to occur in all vertebrates, including humans.

Scientists are only beginning to understand the functional role of these new neurons. Is it the same as that of neurons made during development? Can neurogenesis be used to help heal brain injuries? Some studies have even suggested that chronic stress during childhood (the stress of poverty or bullying, for example) can reduce the ability to make new neurons, thereby negatively affecting learning in adults.

Results like these reinforce a growing consensus that learning, memory, and the control of complex behaviors involve not only molecular and structural changes in synapses but also changes in the number of neurons. Further, most researchers now agree that at least some aspects of long-term memory involve changes in gene expression. Chemical messengers called hormones also cause changes in gene expression in target cells (see Chapter 49). But before investigating how hormones work, let's focus on the electrical signals involved in vision, hearing, taste, and movement—the subject of Chapters 47 and 48.

CHAPTER 46 REVIEW

If you understand . . .

46.1 Principles of Electrical Signaling

- All neurons have a cell body and multiple short dendrites that receive signals from other cells. Most neurons also have a single axon that transmits electrical signals to other neurons or to effector cells in glands or muscles.
- Studies of the squid giant axons established that neurons have a resting potential created by the sodium–potassium pump and potassium leak channels. When Na^+/K^+-ATPase hydrolyzes ATP, it transports 3 Na^+ out of the cell and 2 K^+ in.

✔ **You should be able to diagram the plasma membrane of a neuron. Add symbols to show the relative concentrations of Na^+, K^+, and Cl^-. Add labels indicating the role of K^+ leak channels and the Na^+/K^+-ATPase.**

46.2 Dissecting the Action Potential

- Studies of the squid axon established that the action potential is a rapid, all-or-none change in membrane potential.
- An action potential begins with an inflow of Na^+ that depolarizes the membrane. An outflow of K^+ follows and repolarizes the membrane.
- Both Na^+ and K^+ flow through voltage-gated channels.
- As Na^+ flows in, it repulses cations that spread from the site of the action potential, causing the nearby membrane to depolarize enough to trigger an action potential in that adjacent portion of the membrane.
- Propagation takes place most rapidly in large axons or myelinated axons.

✔ **You should be able to explain why every action potential in a given neuron is identical.**

46.3 The Synapse

- When action potentials arrive at a synapse, synaptic vesicles fuse with the axon's membrane and deliver neurotransmitters into the synapse that bind to receptors on the membrane of a postsynaptic cell.
- One class of receptors functions as ligand-gated channels. In response to binding by a neurotransmitter, these channels open and admit ions that depolarize or hyperpolarize the postsynaptic cell's membrane.
- Postsynaptic potentials sum.
- If the membrane at the axon hillock of the postsynaptic neuron depolarizes to a threshold value, an action potential is triggered.

✔ **You should be able to explain how summation in the postsynaptic cell relates to the claim that the cell body integrates information from many different synapses.**

46.4 The Vertebrate Nervous System

- The CNS consists of the brain and spinal cord (in vertebrates); the PNS consists of all nervous system components outside the CNS.
- In vertebrates, the PNS contains somatic and autonomic components. The somatic PNS signals the effector cells producing movement; the autonomic PNS monitors internal conditions and signals the effector cells that change the activity of tissues and organs.
- Early efforts to map functional regions of the brain were based on analyzing deficits in individuals with brain lesions or on stimulating certain regions of the cerebrum.
- Research has established that learning and memory involve modifications in synapses. After learning takes place, certain neurons release more or less neurotransmitter, or make additional synapses, in response to stimulation.
- Recent research shows that vertebrates are capable of adult neurogenesis, which may be an important component of learning and memory.

✔ **You should be able to predict the effects of a brain stem lesion in an animal.**

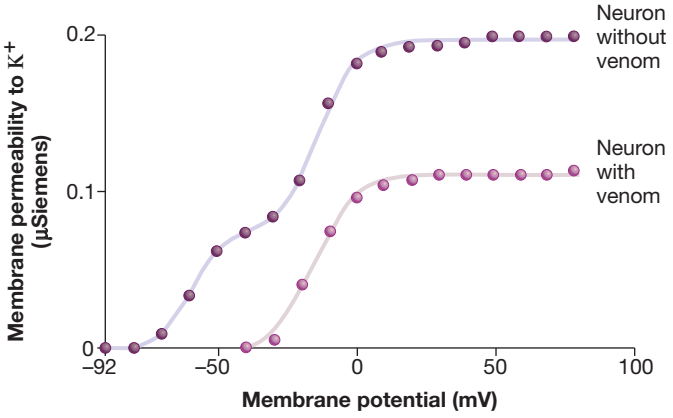
✔ TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. Which ion leaks across a neuron's membrane to help create the resting potential?
   a. Ca^{2+}
   b. K^+
   c. Na^+
   d. Cl^-
2. Why did the squid axon become a model system for studying electrical signaling in animals?
   a. Its action potentials are particularly large and frequent.
   b. It is the tissue from which researchers initially isolated Na^+/K^+-ATPase.
   c. Squids are abundant and easy to obtain.
   d. It was large enough to support intracellular recording by the first microelectrodes.
3. How does myelination affect the propagation of an action potential?
   a. It speeds propagation by increasing the density of voltage-gated channels.
   b. It speeds propagation by increasing electrochemical gradients favoring Na^+ entry.
   c. It speeds propagation because cations do not leak out of the membrane as they spread down the axon.
   d. It slows down propagation because Na^+ channels exist only at unmyelinated nodes (nodes of Ranvier).
4. In a neuron, what creates the electrochemical gradient favoring the outflow of K^+ when the cell is at rest?
   a. Na^+/K^+-ATPase
   b. voltage-gated K^+ channels
   c. voltage-gated Na^+ channels
   d. ligand-gated Na^+/K^+ channels
5. Which of the following brain regions is responsible for formation of new memories?
   a. brain stem
   b. hippocampus
   c. frontal lobe
   d. cerebellum
6. Draw a graph of an action potential and label the axes. Label the parts of the graph, and explain which ion flow or flows are responsible for each part.

TEST YOUR UNDERSTANDING



Answers are available in Appendix A

7. Explain why the Na^+/K^+-ATPase is "electrogenic"—meaning that it creates a voltage across a membrane.
8. Explain the difference between a ligand-gated K^+ channel and a voltage-gated K^+ channel.
9. Describe the role of summation in postsynaptic cells.
10. Compare and contrast the somatic and autonomic components of the PNS.
11. Predict the effect on heart rate of a drug that activates sympathetic nervous system activity.
12. Why is memory thought to involve changes in particular synapses?
    a. In some systems, an increased release of neurotransmitters occurs after learning takes place.
    b. In some systems, the type of neurotransmitter released at the synapse changes after learning takes place.
    c. When researchers stimulated certain neurons electrically, individuals replayed memories.
    d. People who lack short-term memory have specific deficits in synapses within the brain regions responsible for memory.

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A

13. Explain why drugs that prevent neurotransmitters from being taken back up by the presynaptic cell have dramatic effects on the activity of postsynaptic neurons.
14. Discuss the pros and cons of lesion studies and electrical stimulation of conscious patients in determining the functions of particular brain structures.
15. **QUANTITATIVE** The data points on the graph record the movement of potassium ions (in μSiemens, a unit of conductance) observed when neuron membranes were voltage-clamped at the array of voltages indicated on the *x*-axis. The "Neuron with venom" data were generated by adding black mamba venom to the solution bathing the neuron (black mambas are snakes). Which of these conclusions can you draw from the data?

   a. The venom opens all potassium channels.
   b. The venom blocks all potassium channels.
   c. There is more than one type of potassium channel; at least one is affected by the venom while others are not.
   d. Black mamba venom does not affect potassium ion movement.
16. Studies of the brain show that mature neurons do not undergo mitosis to give rise to new neurons, yet adult neurogenesis occurs in all vertebrates. Suggest a hypothesis as to the source of these new neurons.

47 Animal Sensory Systems

In this chapter you will learn how

Animals transform sound, smell, and other stimuli into signals the brain can understand

then looking closer at

- **Mechanoreception 47.2**
- **Photoreception 47.3**
- **Chemoreception 47.4**
- **Sensing temperature and electric and magnetic fields 47.5**

In many species of moth, males have much larger antennae than females do. Receptor cells on the males' feathery antennae detect airborne chemical signals that are produced by sexually mature females. As a result, males can locate females in total darkness.

Many adult moths are active at night, when it is difficult or impossible to see. Instead of *looking* for a mate under these challenging circumstances, sexually mature female moths release a chemical attractant into the air. Male moths can detect even a single molecule of the attractant, due to receptor cells located on their large, feathery antennae. Guided by an airborne gradient of attractant molecules, a male moth flies unerringly toward a female.

As they patrol in search of these airborne molecules, however, male moths are hunted by bats. Like moths, bats are active almost exclusively at night. Instead of hunting by sight, like a falcon or a cheetah, bats hunt with the aid of sonar: They emit a train of high-pitched sounds as they fly and then listen for echoes that indicate the direction and shape of objects in their path. If the object is a moth, the bat flies toward it, catches the moth in its mouth, and eats it.

BIG PICTURE

This chapter is part of the Big Picture. See how on pages 840–841.

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

But some moth species can hear bat calls. When moths detect sounds from an onrushing bat, they tumble out of the sky in chaotic escape flights.

If you were out at night as these dramas unfolded, at best you might be dimly aware that bats and moths were flying about. Humans cannot smell moth attractants or hear the sounds that most bats emit when flying. It took decades of careful experimentation for biologists to understand how moths and bats sense the world around them and respond to the information they receive.

Sensing and interpreting changes in the environment are fundamental to how animals work. Let's begin with a basic question: How are sounds, smells, and other stimuli transformed into a signal that the brain can understand?

47.1 How Do Sensory Organs Convey Information to the Brain?

As a moth flies through the night, its brain receives streams of signals from an array of sensory organs. Antennae provide information about the concentration of female attractant molecules; ears located on various parts of the body send data on the presence of high-pitched sounds; detectors for balance and gravity transmit signals about the body's orientation in space.

Each type of sensory information is detected by a sensory neuron or by a specialized receptor cell that makes a synapse with a sensory neuron. As **FIGURE 47.1** shows, the moth's nervous system integrates the sensory input—the information from sensory neurons—and responds with motor output, via electrical signals, to specific muscle groups (effectors).

The ability to sense a change in the environment depends on three processes:

1. ***Transduction,*** the conversion of an external stimulus to an internal signal in the form of action potentials along sensory neurons
2. ***Amplification*** of the signal
3. ***Transmission*** of the signal to the central nervous system (CNS)

The first step in the sequence, transduction, requires a sensory receptor cell specialized for converting light, sound, touch, or some other signal into an electrical signal. Sensory receptors are located throughout the body and are categorized by type of stimulus:

- **Mechanoreceptors** respond to distortion caused by pressure.
- **Photoreceptors** respond to particular wavelengths of light.
- **Chemoreceptors** perceive specific molecules.
- **Thermoreceptors** detect changes in temperature.
- **Nociceptors** sense harmful stimuli such as tissue injury.
- **Electroreceptors** detect electric fields.
- **Magnetoreceptors** detect magnetic fields.

With such a broad range of possible sensory detectors, it is no wonder that animals can monitor and respond to a wide array of changes in their environments.

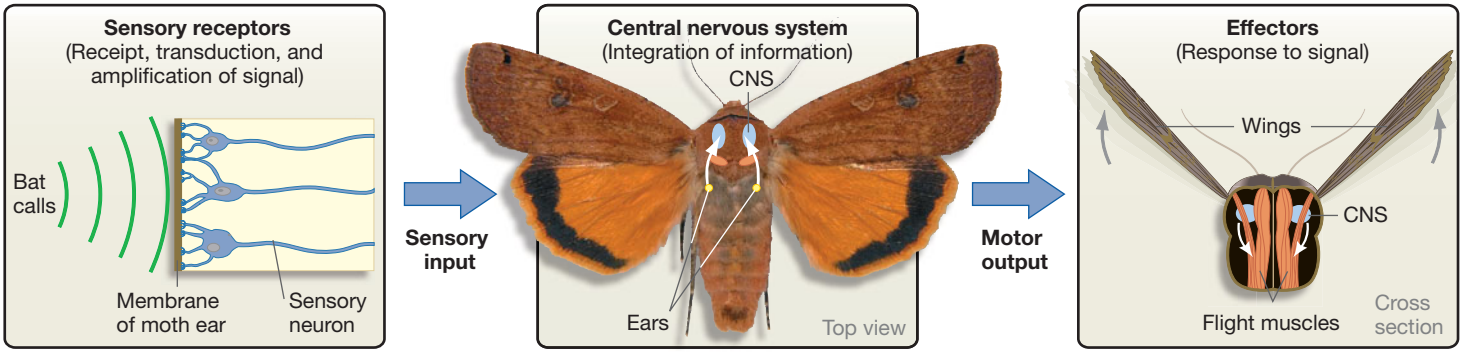
Now, how do sensory cells receive information from the environment and report it to the brain, so an appropriate response can occur?

Sensory Transduction

During the resting state in most sensory cells, the inside of the plasma membrane is more negative than the exterior (see Chapter 46). When ion flows cause the interior to become more positive (less negative), the membrane is **depolarized.** When ions cause the cell interior to become more negative than the resting potential, the membrane is **hyperpolarized.**

Although sensory receptors can detect a remarkable variety of stimuli, they all transduce sensory input—such as light, sounds, touch, and odors—to a change in membrane potential. In this way, different types of information are transduced to a common type of signal—one that can be interpreted by the brain.

If a sensory stimulus induces a large change in a sensory receptor's membrane potential, there is a change in the firing rate of action potentials sent to the brain. The amount of depolarization that occurs in a sound-receptor cell, for example, is proportional to the loudness of the sound. If the depolarization passes



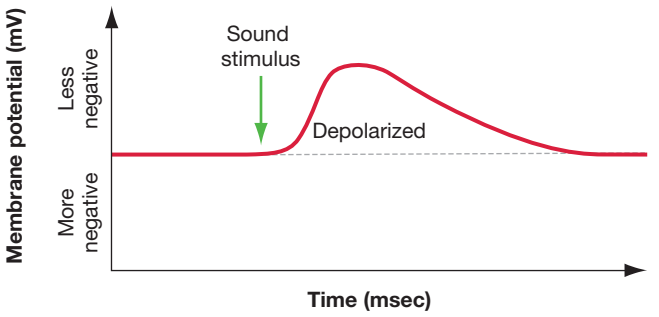


FIGURE 47.1 Sensory Systems, the CNS, and Effectors Are Linked. Sensory neurons relay information about conditions inside and outside an animal to the central nervous system. After integrating information from many sensory neurons, the CNS sends signals to muscles.

(a) Sound-receptor cells depolarize in response to sound.

(b) Sound-receptor cells respond more strongly to louder sounds.

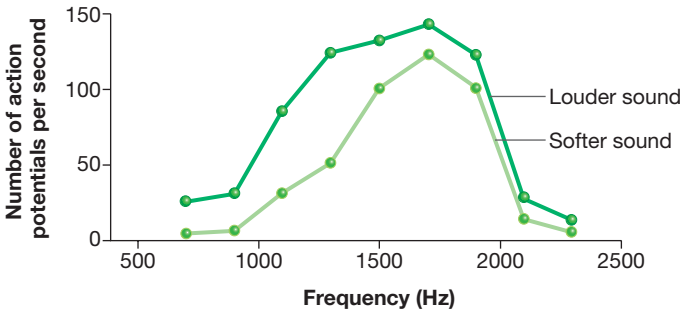

FIGURE 47.2 Sensory Inputs Change the Membrane Potential of Receptor Cells. (a) In response to sensory stimuli, ions flow across the membranes of receptor cells and either depolarize or hyperpolarize the membrane. **(b)** The rate at which action potentials occur in an auditory neuron transmits information about the nature and intensity of the sensory stimulus. (The frequency of a sound, measured in hertz, determines its pitch.)

DATA: Rose, J. E., J. E. Hind, D. J. Anderson, et al. 1971. *Journal of Neurophysiology* 34: 685–699.

threshold, enough voltage-gated sodium channels open to trigger action potentials that are relayed to the brain.

FIGURE 47.2a shows the membrane potential from a sound-receptor cell. If you put your finger on the red line and trace to the right, you'll notice that when the experimenter played a sound, the sound-receptor cell depolarized for a short time in response. Other sensory cells work in a similar way.

Recall that all action potentials from a given neuron are identical in size and shape (see Chapter 46). **FIGURE 47.2b** graphs the action potential "firing rate" recorded from a sound-receptor cell when sounds at various frequencies were played at two distinct intensities. Notice that loud sounds induce a higher rate of action potentials than do soft sounds. In this way receptor cells provide information about the intensity of a stimulus.

But if all types of external stimuli are converted to electrical signals in the form of action potentials, and if all action potentials are alike in size and duration, how does the brain interpret the incoming signals properly?

Transmitting Information to the Brain

There are two keys to understanding how the brain interprets sensory information. First, receptor cells tend to be highly specific. For example, each receptor cell in a human ear responds best to certain pitches of sound. Some receptors are more sensitive to low-pitched sounds, and others respond best to high-pitched sounds. The pattern of action potentials from a cell contains information about the pitch of the sound that is being received, its intensity, and how long the stimulus lasts.

The second key point: Each type of sensory neuron sends its signal to a specific portion of the brain. Axons from sensory neurons in the human ear project to the temporal lobes at the sides of the brain, but axons from sensory receptors in the eye deliver action potentials to the occipital lobe at the back of the brain. Different regions of the brain are specialized for interpreting different types of stimuli.

Now that the basic principles of sensory reception and transduction have been introduced, let's delve into the details of the major sensory systems.

47.2 Mechanoreception: Sensing Pressure Changes

Animals have a variety of mechanisms for **mechanoreception**—the sensation of pressure changes. Crabs, for example, have a fluid-filled organ that helps them sense the pressure created by gravity. The organ, known as a **statocyst,** is lined with pressure-receptor cells and contains a small calcium-rich particle that normally rests on the bottom of the organ. But if the crab is tipped or flipped over, this particle presses against receptors that are *not* on the bottom of the organ. When the brain receives action potentials from these receptors, it responds by activating muscles that restore the animal to its normal posture.

It's also common for animals to have cells that are responsible for detecting direct physical pressure on skin, as well as pressure-receptor cells that monitor how far muscles or blood vessels are stretched. Animals detect sound waves, which produce pressure in air, with hearing, and some aquatic animals detect pressure waves in water via a lateral line system. These pressure-sensing systems are all based on the same mechanism.

Let's briefly examine the general design of a mechanoreceptor cell and its response to pressure, then investigate the specific structures involved in vertebrate hearing and the lateral line system.

How Do Sensory Cells Respond to Sound Waves and Other Forms of Pressure?

The mechanoreceptors responsible for sensing sound, vibrations, and other pressure waves in the environment are relatively simple. In every case, direct physical pressure on a plasma membrane or distortion of membrane structures by bending changes the conformation of ion channels in the membrane and causes the channels to open or close.

The consequent change in ion flow through the channel proteins results either in a depolarization or a hyperpolarization. This changes the pattern of action potentials in a sensory neuron.

The Structure of Hair Cells In vertebrates, ion channels that respond to pressure are often found in hair cells. **Hair cells** are

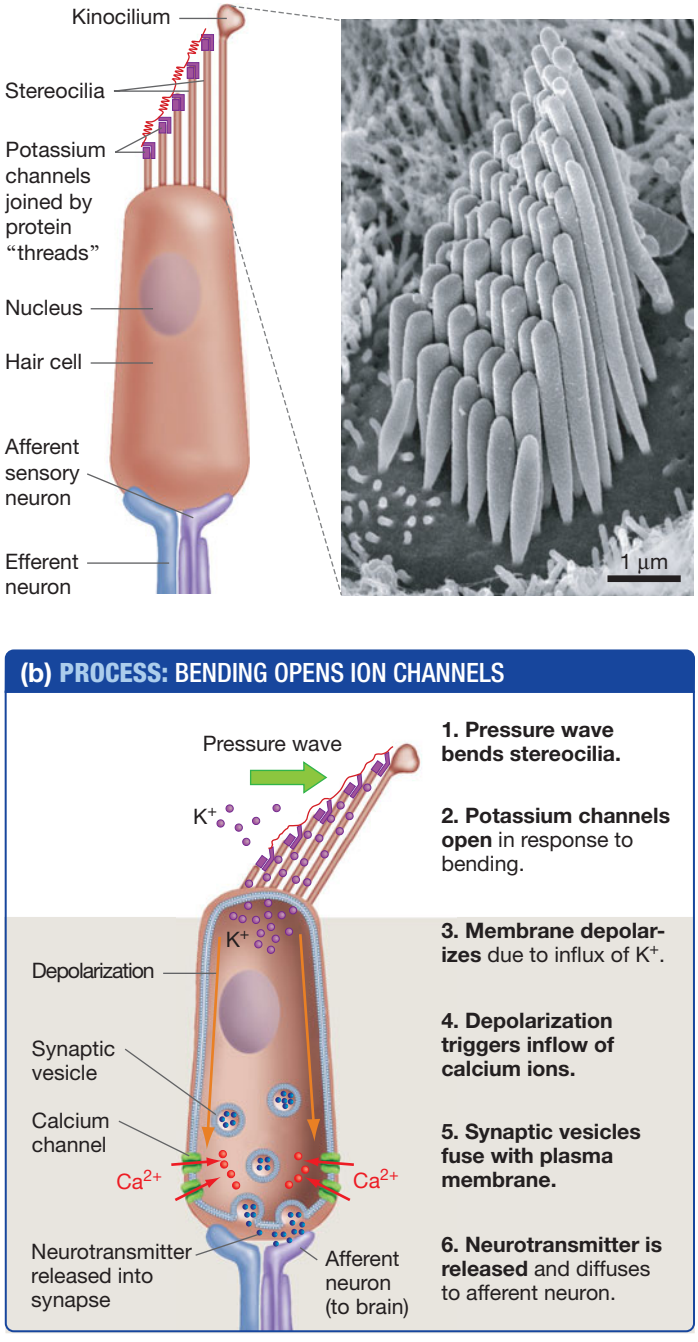

FIGURE 47.3 Hair Cells Transduce Sound Waves to Electrical Signals.

pressure-receptor cells, illustrated in **FIGURE 47.3a**, named for their stiff outgrowths called **stereocilia** (singular: **stereocilium**). The "hairy-looking" stereocilia are microvilli that are reinforced by actin filaments.

Many hair cells also have a single **kinocilium,** a true cilium that contains a 9 + 2 arrangement of microtubules (introduced in Chapter 7). Hair cells are found in the ears of land-dwelling vertebrates and the lateral line system in many species of fishes and some amphibians.

As Figure 47.3a shows, the stereocilia in hair cells are arranged in order of increasing height; if a kinocilium is present, it is the tallest of all the projections. These structures extend into a fluid-filled chamber.

Signal Transduction in Hair Cells If stereocilia are bent in the direction of the kinocilium in response to pressure (**FIGURE 47.3b**), the distortion causes potassium ion (K^+) channels in the stereocilia to open. This is the common theme connecting pressure-sensing cells: Bending opens ion channels.

Recall that the opening of K^+ channels usually causes an outflow of K^+ that hyperpolarizes neurons (see Chapter 46). Hair cell plasma membranes respond differently, however, because they are bathed by extracellular fluid with an extraordinarily high K^+ concentration. As a result, the equilibrium potential for K^+ in hair cells is 0 mV instead of the −85 mV in a typical neuron. The resting potential of the hair cell plasma membrane is −70 mV, so when the channels open, K^+ rushes in and causes a depolarization of approximately 20 mV.

In hair cells, depolarization causes an inflow of calcium ions, which triggers an increase in the amount of neurotransmitter released at the synapse between the hair cell and a sensory neuron. The end result is excitation of the postsynaptic cell, meaning that it becomes more likely to fire an action potential to the brain via an afferent sensory neuron. You might recall that afferent neurons are part of the peripheral nervous system and conduct information to the CNS (see Chapter 46).

If sound pressure waves bend stereocilia the other way, however, the K^+ channels close, and the cell hyperpolarizes by 5 mV. Hyperpolarization of the hair cell decreases the amount of neurotransmitter released at the synapse and inhibits the postsynaptic sensory neuron, making it less likely to trigger action potentials.

How can bending affect ion channels? Electron micrographs show that tiny threads connect the tips of stereocilia to each other. One hypothesis contends that when the stereocilia are bent, the threads somehow pull on the ion channels in the wall of the next tallest stereocilium and open them like tiny trapdoors (see Figure 47.3b, step 2). This hypothesis remains to be confirmed, however. Researchers still do not fully understand how the ion channels involved in pressure reception work.

Hearing: The Mammalian Ear

Hearing is the sensation produced by the wavelike changes in air pressure called sound. A sound consists of waves of pressure in air or in water. The number of pressure waves that occur in 1 second is called the **frequency** of the sound, reported in units called hertz (Hz), or cycles per second. When you hear different sound frequencies, you perceive them as different **pitches.** A high-pitched sound may have a frequency in the range of 8000 Hz, whereas a low-pitched sound frequency might be 1000 Hz.

The ear transduces sound waves into action potentials that send information to the brain. To understand how changes in the membrane potential of hair cells result in hearing, let's focus on the human ear as a case study. The human ear has three sections:

the **outer ear, middle ear,** and **inner ear** (**FIGURE 47.4**). A membrane separates each section from the next.

The path of sound through the ear is traced in Figure 47.4. The outer ear, which projects from the head, collects incoming pressure waves and funnels them into a tube known as the ear canal. At the inner end of the ear canal (see the lower part of Figure 47.4), the waves strike the **tympanic membrane,** or eardrum, which separates the outer ear from the middle ear.

The repeated cycles of air compression cause the tympanic membrane to vibrate back and forth with the same frequency as the sound wave. The vibrations are passed to three tiny bones in the middle ear called the **ear ossicles,** which vibrate against one another in response. The last ossicle, the **stapes** (pronounced *STAY-peez*), vibrates against a membrane called the **oval window,** which separates the middle ear from the inner ear. The oval window oscillates in response and generates waves in the fluid inside a chamber known as the **cochlea** (pronounced *KOK-lee-ah*). These pressure waves are sensed by hair cells in the cochlea.

In effect, the ear translates airborne waves into fluid-borne waves. The system seems extraordinarily complex, though, for such a simple result. Why doesn't the outer ear canal lead directly to the oval window? Why have a middle ear at all?

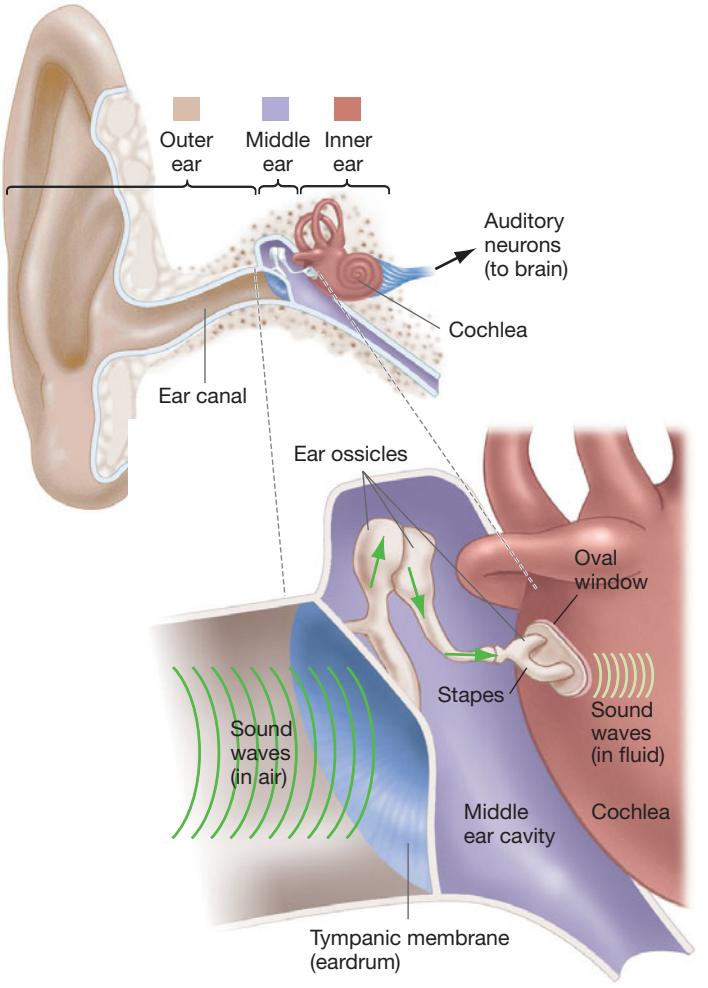

FIGURE 47.4 Mammals Have an Outer Ear, Middle Ear, and Inner Ear. The middle ear starts with the tympanic membrane and ends in the oval window of the cochlea.

The Middle Ear Amplifies Sounds Biologists began to understand the function of the middle ear when they recognized two key aspects of its structure. First, the size difference between the tympanic membrane and the oval window is important. The tympanic membrane is about 15 times larger than the oval window, causing the amount of vibration induced by sound waves to increase by a factor of 15 when it reaches the oval window. This phenomenon is similar to taking the same amount of force used to bang on a very large door and applying it to a very small door.

In addition, the three ossicles act as levers that further amplify vibrations from the tympanic membrane. The overall effect in mammals is to amplify sound by a factor of 22—meaning that soft sounds are amplified enough to stimulate hair cells in the cochlea. Thus, biologists interpret the mammalian middle ear as an adaptation for increasing sensitivity to sound.

To summarize, the mammalian outer ear transmits sound waves from the environment to the middle ear; the middle ear amplifies these waves enough to stimulate the hair cells within the cochlea of the inner ear.

If all hair cells responded equally to all frequencies of sound, you would be able to perceive only one pitch. Everyone's voice—indeed, every noise—would sound the same. How can hair cells distinguish different frequencies?

The Cochlea Detects the Frequency of Sounds As **FIGURE 47.5a** shows, the cochlea is a coiled tube with a set of internal membranes that divide it into three chambers. Hair cells, forming rows in the middle chamber, are embedded in a tissue that sits atop the **basilar membrane** (**FIGURE 47.5b**). In addition, the hair cells' stereocilia touch yet another, smaller surface called the **tectorial membrane.** (The kinocilium is not present in a mature cochlear hair cell.) In effect, hair cells are sandwiched between membranes.

Researchers struggled for decades to understand how these membranes affect hair cell function. It is virtually impossible to study cochleas in living organisms, because the cochleas are tiny, complex, coiled, and buried deep inside the skull. During the 1920s and 1930s, however, Georg von Békésy pioneered work on the structure and function of these organs by performing experiments on cochleas that he had dissected from fresh human cadavers.

Von Békésy was able to vibrate the oval window and record how the cochlea's internal membranes moved in response. He found that when a pressure wave traveled down the fluid in the upper and lower chambers, the basilar membrane vibrated in response. His key finding, though, was that sounds of different frequencies caused the basilar membrane to vibrate maximally at specific points along its length (**FIGURE 47.6**). When the basilar membrane vibrated in a particular location, the stereocilia of the hair cells there were bent one way and then the other by the tectorial membrane.

Von Békésy also noted that the basilar membrane is stiff near the oval window and flexible at the other end. This is why each

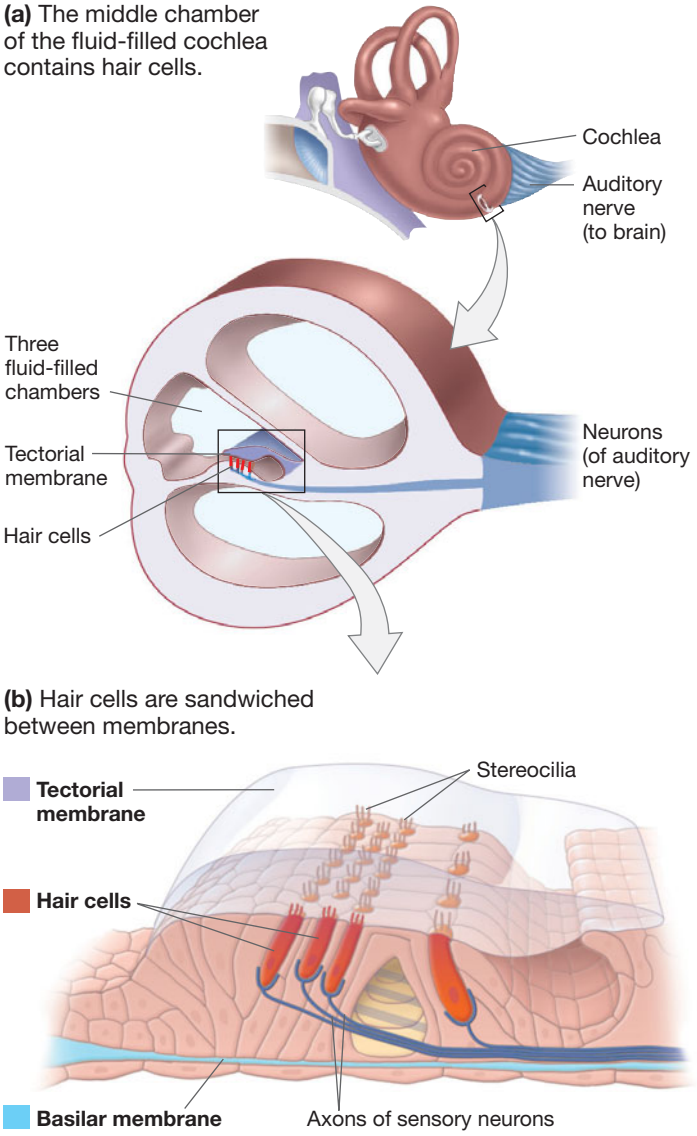

FIGURE 47.5 The Human Cochlea Contains Fluid-Filled Chambers Separated by Membranes.

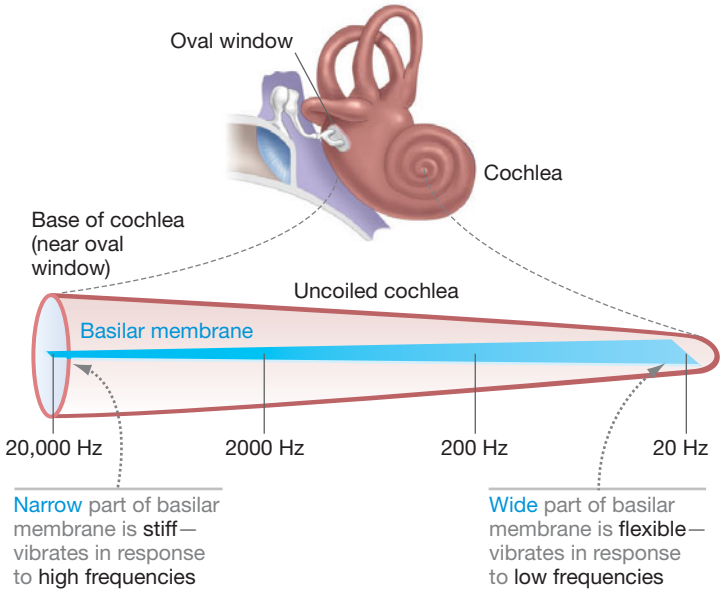

FIGURE 47.6 The Basilar Membrane Varies in Stiffness. Different parts of the basilar membrane respond to different sound frequencies.

segment vibrates in response to a different frequency of sound. Just as a stiff drumhead produces a high-pitched sound and a loose drumhead yields a low-pitched sound, high-frequency sounds cause the stiff part of the basilar membrane to vibrate; low-frequency sounds cause the flexible part to vibrate.

To summarize, certain portions of the basilar membrane vibrate in response to specific frequencies and result in the bending of hair cell stereocilia. In this way, hair cells in a particular place on the membrane respond to sounds of a certain frequency. When the occipital lobe of the cerebrum receives action potentials from neurons associated with specific hair cells, it interprets them as a particular pitch—meaning a specific frequency of sound. The result is the sense called hearing.

Complex sounds contain a wide variety of frequencies and trigger particular combinations of hair cells. Through experience, the brain learns which combinations of frequencies represent music, a fire alarm, or a best friend's voice.

Compared with the hearing of many mammals, human hearing is not particularly acute. Humans can hear sounds between 20 Hz and 20,000 Hz (20,000 Hz is equal to 20 kHz, or kilohertz). But some mammals can sense low-frequency infrasounds that are too low for humans to hear (*infra–* means below or under); others are aware of high-frequency ultrasounds that are above the range of human hearing (*ultra–* means beyond).

Elephants Detect Infrasound When Katherine Payne was observing elephants at a zoo in the mid-1980s, she noticed a subtle throbbing in the air. Payne knew that infrasound can produce such sensations.

To test the hypothesis that the elephants were producing infrasonic vocalizations, Payne returned to the zoo with microphones that could pick up sounds at extremely low frequency. At normal speed, the tape she made was silent. But when she raised the pitch of the sounds by speeding up the tape, she heard a chorus of cow-like noises. The elephants were calling to each other, using low-frequency sounds.

According to follow-up research, elephants have the best infrasonic hearing of any land mammal. Because infrasound can travel exceptionally long distances, biologists hypothesize that infrasonic calls allow wild elephants to coordinate their movements when they are miles apart.

Recent research suggests that in addition to detecting infrasound via their large ears, elephants use their feet to detect a by-product of infrasound: seismic vibrations traveling in the ground.

Bats Detect Ultrasound Ultrasonic hearing in bats was discovered in the late 1930s, when Donald Griffin borrowed the only ultrasonic apparatus then in existence from Robert Galambos,

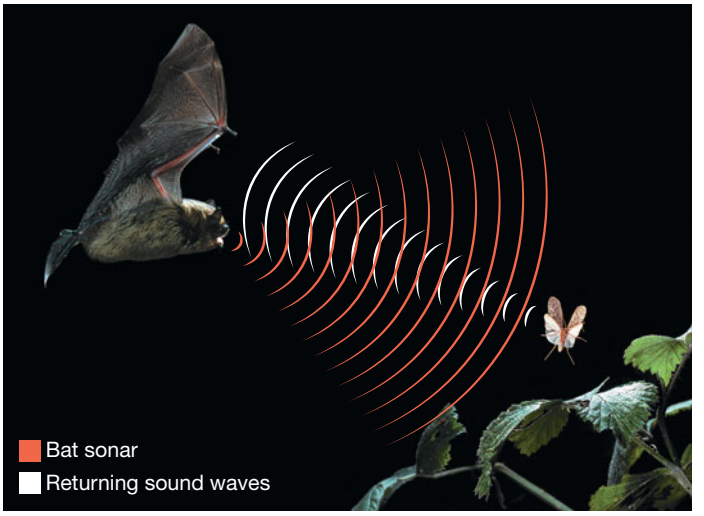

FIGURE 47.7 Bats Emit Ultrasonic Sound Waves That Bounce Off Surfaces. Returning sound waves are sensed by the bat's inner ear.

a fellow graduate student. Griffin used the machine to demonstrate that flying bats constantly emit ultrasounds. In follow-up experiments, he documented that a bat with cotton in its ears, or with its mouth taped shut, crashed into walls when released in a room. Blindfolded bats, in contrast, never crashed.

Griffin and Galambos concluded that bats use sound echoes (sonar) to navigate. This concept, termed **echolocation,** was an outlandish idea at the time. When Galambos described it at a meeting in 1940, another scientist shook him by the shoulders and said, "You can't really mean that!"

Bats generate high-frequency sound waves with the larynx, or voice box. These waves "bounce" off of surfaces (including those of insects), producing echoes that the bat perceives in its inner ear (**FIGURE 47.7**). Recall that different sections of the basilar membrane are specialized for sensing sound waves of different frequencies. In bats, a huge area of the basilar membrane is specialized for sensing the high-frequency sounds of the returning echoes. Similarly, the part of the brain used to process sound is unusually large in bats, highlighting the extremely important role of echolocation in their navigation and hunting.

More recent research has shown that dolphins, shrews, and certain other animals besides bats use sonar. In fact, it is likely that at least some of these species perceive shapes with their ears better than they do with their eyes.

The Lateral Line System in Fishes and Amphibians

Hair cells in the ear allow mammals to sense changes in air pressure that are perceived as sound. But in fishes and aquatic amphibians, hair cells in a different organ allow the perception of pressure changes in water. In most fishes and larval amphibians, groups of hair cells are embedded in gel-like domed structures called cupulae inside canals that run the length of the body (**FIGURE 47.8a**), forming a sensory organ called the **lateral line system.**

Pressure changes in the surrounding water—whether resulting from waves, an animal swimming nearby, or some other force—cause changes in the pressure of water moving through the lateral line system (**FIGURE 47.8b**). These changes cause kinocilia and stereocilia on the hair cells to bend, and the distortion leads to a change in action potentials along sensory neurons to the brain. In this way, most aquatic animals get information about pressure changes at specific points along the head and body.

What use do fishes make of the lateral line system? It seems reasonable that the lateral line system could be helpful for identifying mates, locating prey, or avoiding predators. However, fishes could also use vision, smell, or other senses for these functions. How important is the lateral line system?

To answer this question, Kirsten Pohlmann, Jelle Atema, and Thomas Breithaupt studied how nocturnal catfish locate prey. At night, the catfish cannot use vision to hunt smaller fishes, so they must use stimuli that persist in the wake of their prey after it has moved on. The researchers hypothesized that the nocturnal catfish hunt smaller fishes using the lateral line system.

(a) The lateral line system consists of a series of canals running along the head and body.

(b) Water enters the canals through pores and bends kinocilia on hair cells, activating sensory neurons.

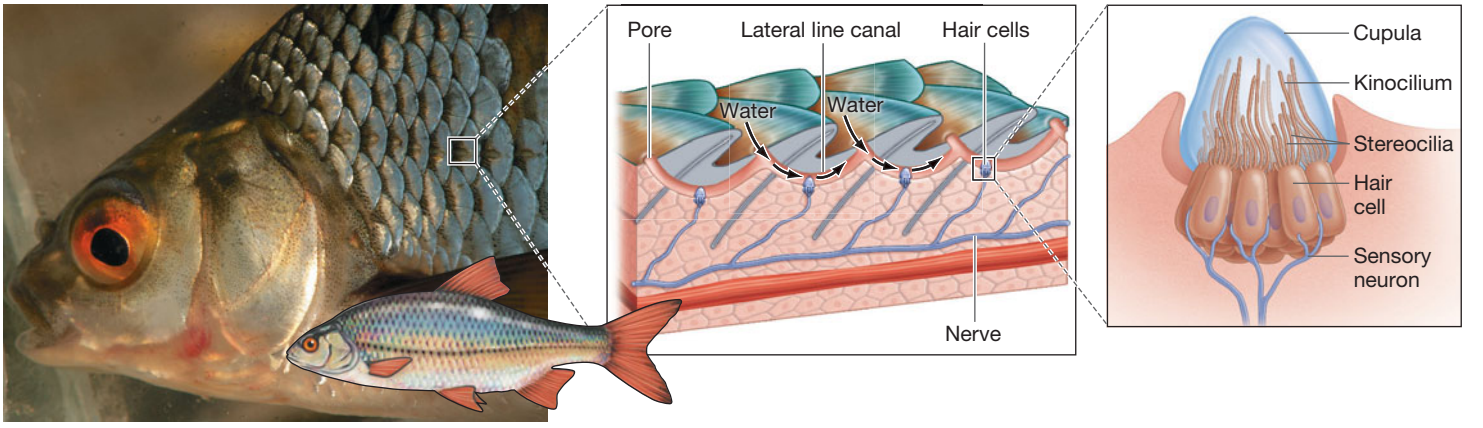

FIGURE 47.8 The Lateral Line System Detects Pressure Waves in Water. (a) Lateral line canals lie just under the fish's epidermis. **(b)** Hair cells within the canals have kinocilia and stereocilia embedded in a gel-like cupula.

To test this hypothesis, the researchers conducted an ablation experiment on the catfish (**FIGURE 47.9**). Ablation is the removal or blocking of a process. In this case, the researchers ablated the lateral line system in one group of catfish, using a chemical that blocks the hair cells from responding to pressure waves. In another group of catfish, they ablated the ability to smell or taste the water by surgically removing the lobes of the brain responsible for these senses.

While the catfish whose smell and taste were ablated took the same amount of time as the non-ablated control group to locate and capture prey, it took the catfish whose lateral line was ablated over twice as long. The researchers concluded that the lateral line system is much more important than other senses in the successful hunting of nocturnal fishes.

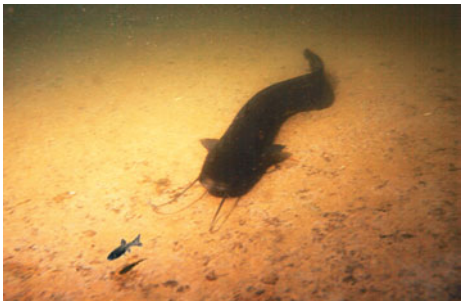
RESEARCH

QUESTION: What cues do predatory fish use to detect prey at night?

HYPOTHESIS: Predatory fish detect prey using the lateral line system.

ALTERNATE HYPOTHESIS: Predatory fish detect prey using smell and taste.

NULL HYPOTHESIS: Predatory fish use neither sense to detect prey.



EXPERIMENTAL SETUP:

1. Three experimental groups of catfish (n=16 for each group):

Lateral line ablated	Smell and taste ablated	Control fish

2. Acclimate catfish to dark tank at night.

3. Add guppies to tank and record capture success rate.

PREDICTION: Fish with their lateral line ablated will have lower capture success than control fish.

PREDICTION OF ALTERNATE HYPOTHESIS: Fish with smell and taste ablated will have lower capture success than control fish.

PREDICTION OF NULL HYPOTHESIS: There will be no capture success difference among groups.

RESULTS:

Percentage of Guppies Captured

Lateral line ablated	Smell and taste ablated	Control fish
17%	60%	65%

CONCLUSION: Nocturnal predatory catfish use the lateral line system to detect prey.

FIGURE 47.9 The Lateral Line System Is Used for Predation.

✔**QUESTION** If you wanted to conduct a study similar to this one on a diurnal species of catfish, what other sense would you need to control for, and how would you do it?

SOURCE: Pohlmann, K., J. Atema, and T. Breithaupt. 2004. The importance of the lateral line in nocturnal predation of piscivorous catfish. *The Journal of Experimental Biology* 207: 2971–2978.

If you understand that . . .

- Mechanoreception is a type of pressure detection that begins when the stereocilia on hair cells bend in response to changes in pressure. The bending movement opens ion channels and results in a change in membrane potential.
- The mammalian ear consists of specialized structures that function in transmitting and amplifying sound and in responding to specific frequencies as well as recognizing changes in intensity.
- The lateral line system in fishes and aquatic amphibians allows them to sense pressure waves in water caused by prey, predators, and potential mates.

✔ **You should be able to . . .**

1. Predict and explain the effect on hearing in each of the following cases: a punctured eardrum, a mutation that results in dramatically shortened stereocilia, and an age-related loss of flexibility in the basilar membrane.
2. Describe the function of the lateral line system in fishes.

Answers are available in Appendix A.

47.3 Photoreception: Sensing Light

Most animals have a way to sense light. The organs involved in **photoreception** range from simple light-sensitive eyespots in flatworms to the sophisticated, image-forming eyes of vertebrates, cephalopod mollusks, and arthropods.

Variation in the structure of light-sensing organs illustrates an important general principle about the sensory abilities of animals: In most cases, a species' sensory abilities correlate with the environment it lives in and its mode of life—how it finds food and mates. Eyes and other sensory structures are adaptations that allow individuals to thrive in a particular environment. Salamander species that live in meadows and forests have sophisticated eyes; those that live in lightless caves have no functional eyes at all.

Keep this point in mind as you delve into the details of how insects and vertebrates see.

The Insect Eye

Insects have a **compound eye,** composed of hundreds or thousands of light-sensing columns called **ommatidia.** As **FIGURE 47.10** shows, each ommatidium has a lens that focuses light onto a small number of receptor cells—usually four. The receptor cells, in turn, send axons to the brain.

Each ommatidium contributes information about one small piece of the visual field, not unlike the contribution of a single pixel on a computer monitor. Thus, the more ommatidia in a compound eye, the better the resolution—meaning the resolving power, or ability to distinguish objects.

In addition, the presence of many light-sensing columns makes species with compound eyes particularly good at detecting movement. Insects that hunt by sight, such as damselflies and dragonflies, have particularly large numbers of ommatidia.

The Vertebrate Eye

Compound eyes are found in insects, crustaceans, and certain other arthropods. Because they appear only in species that are part of the same monophyletic group (see Chapter 28), researchers conclude that this type of eye structure evolved just once—in an ancestor of today's arthropods.

In contrast, the **simple eye**—a structure with a single lens that focuses incoming light onto a layer of many receptor cells—evolved independently in several widely divergent groups, including annelids, cephalopod mollusks (squid and octopuses), and vertebrates. Let's examine the vertebrate version of the simple eye more closely.

The Structure of the Vertebrate Eye **FIGURE 47.11a** shows the major structures in a typical vertebrate eye:

- The outermost layer of the structure is a tough rind of white tissue called the sclera. This is the "white of the eye."
- The front of the sclera forms the **cornea,** a transparent sheet of connective tissue.
- The **iris** is a pigmented, round muscle just inside the cornea. The iris can contract or expand to control the amount of light entering the eye.
- The **pupil** is the hole in the center of the iris.
- Light enters the eye through the cornea and passes through the pupil and a curved, clear **lens.**
- Together, the cornea and lens focus incoming light onto the retina in the back of the eye. The **retina** contains a thin layer of cells with photoreceptors and several layers of neurons.

FIGURE 47.11b provides a closer look at the retina, which is attached to the rest of the eye by a single layer of pigmented epithelial cells. From back to front, the retina comprises three distinct cell layers:

1. The photoreceptors, sensory cells that respond to light, are held in place by the pigmented epithelium.
2. Photoreceptors synapse with an intermediate layer of connecting neurons called **bipolar cells.**
3. Bipolar cells in the intermediate neuron layer connect with one another and with neurons called **ganglion cells,** which form the innermost layer of the retina. The axons of the ganglion cells project to the brain via the **optic nerve.**

Note that vertebrate eyes—including yours—have a blind spot because there are no photoreceptor cells where the optic nerve leaves the retina. If light falls in this area, there are no sensory cells available to respond. No signal is sent to the brain, so the stimulus isn't seen.

What Do Rods and Cones Do? Early anatomists established that the photoreceptors in vertebrate eyes come in two distinct types: small rod-shaped cells and cone-shaped cells, called **rods** and **cones,** respectively (**FIGURE 47.12a**). When technical advances allowed changes in the membrane potentials of these cells to be recorded, it became clear that rods and cones differ in function as well as structure.

(a) Ommatidia are the functional units of insect eyes.

(b) Each ommatidium contains receptor cells that send axons to the CNS.

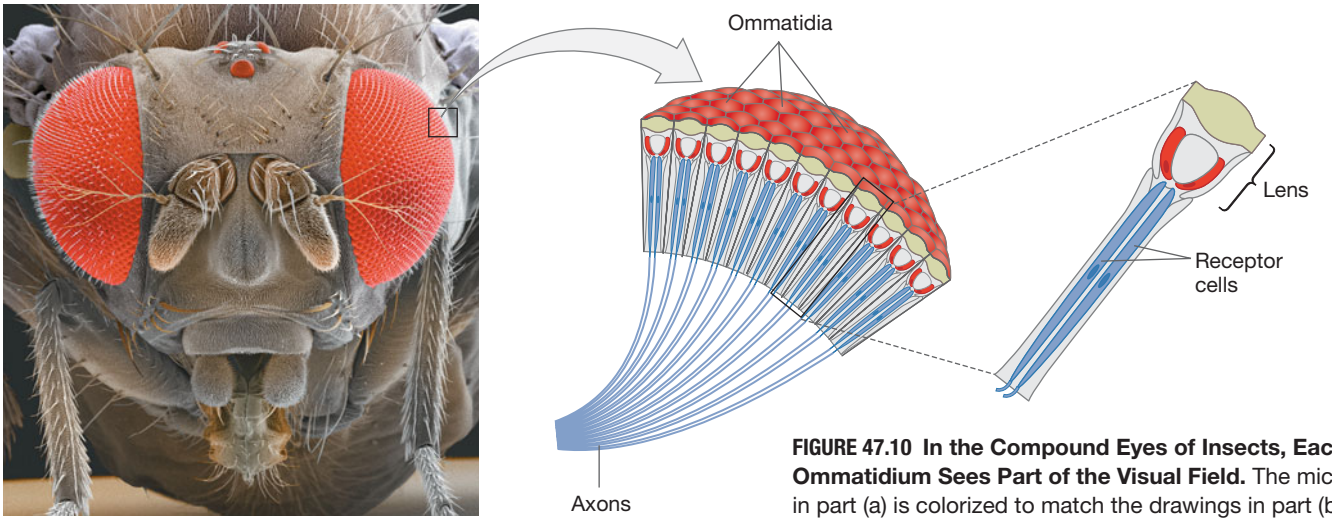

FIGURE 47.10 In the Compound Eyes of Insects, Each Ommatidium Sees Part of the Visual Field. The micrograph in part (a) is colorized to match the drawings in part (b).

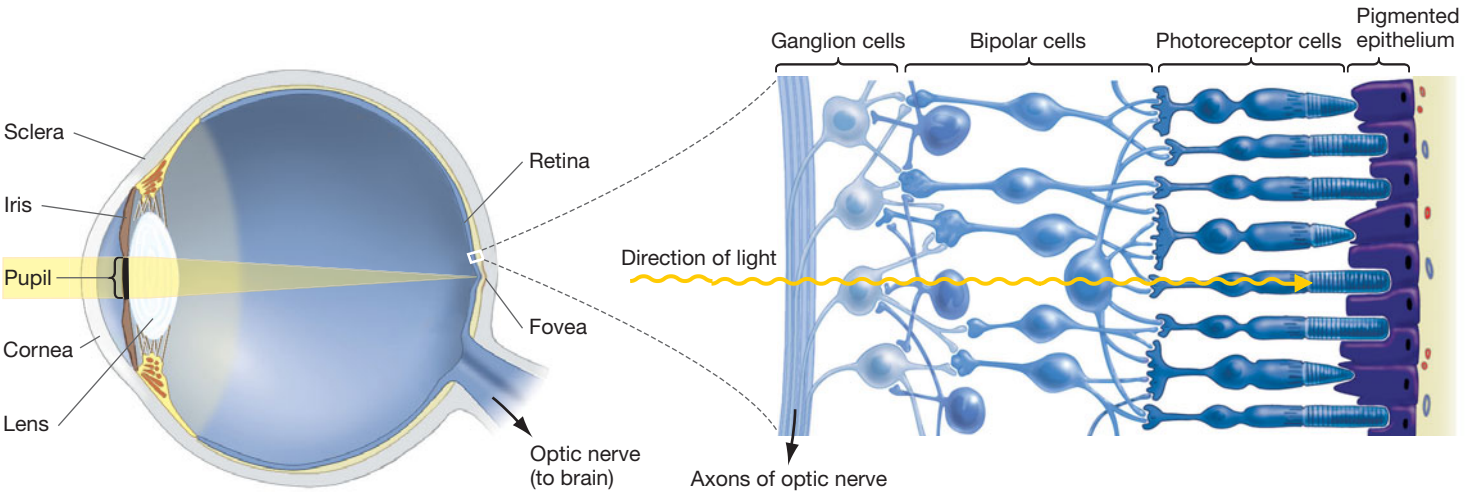

FIGURE 47.11 Simple Eyes Have a Single Lens That Focuses Incoming Light on Receptor Cells. (a) Light passes through the pupil of the eye and is focused onto the retina by the cornea and lens. **(b)** The photoreceptor cells that respond to light are in the "outermost" layer of the retina, furthest from the light source.

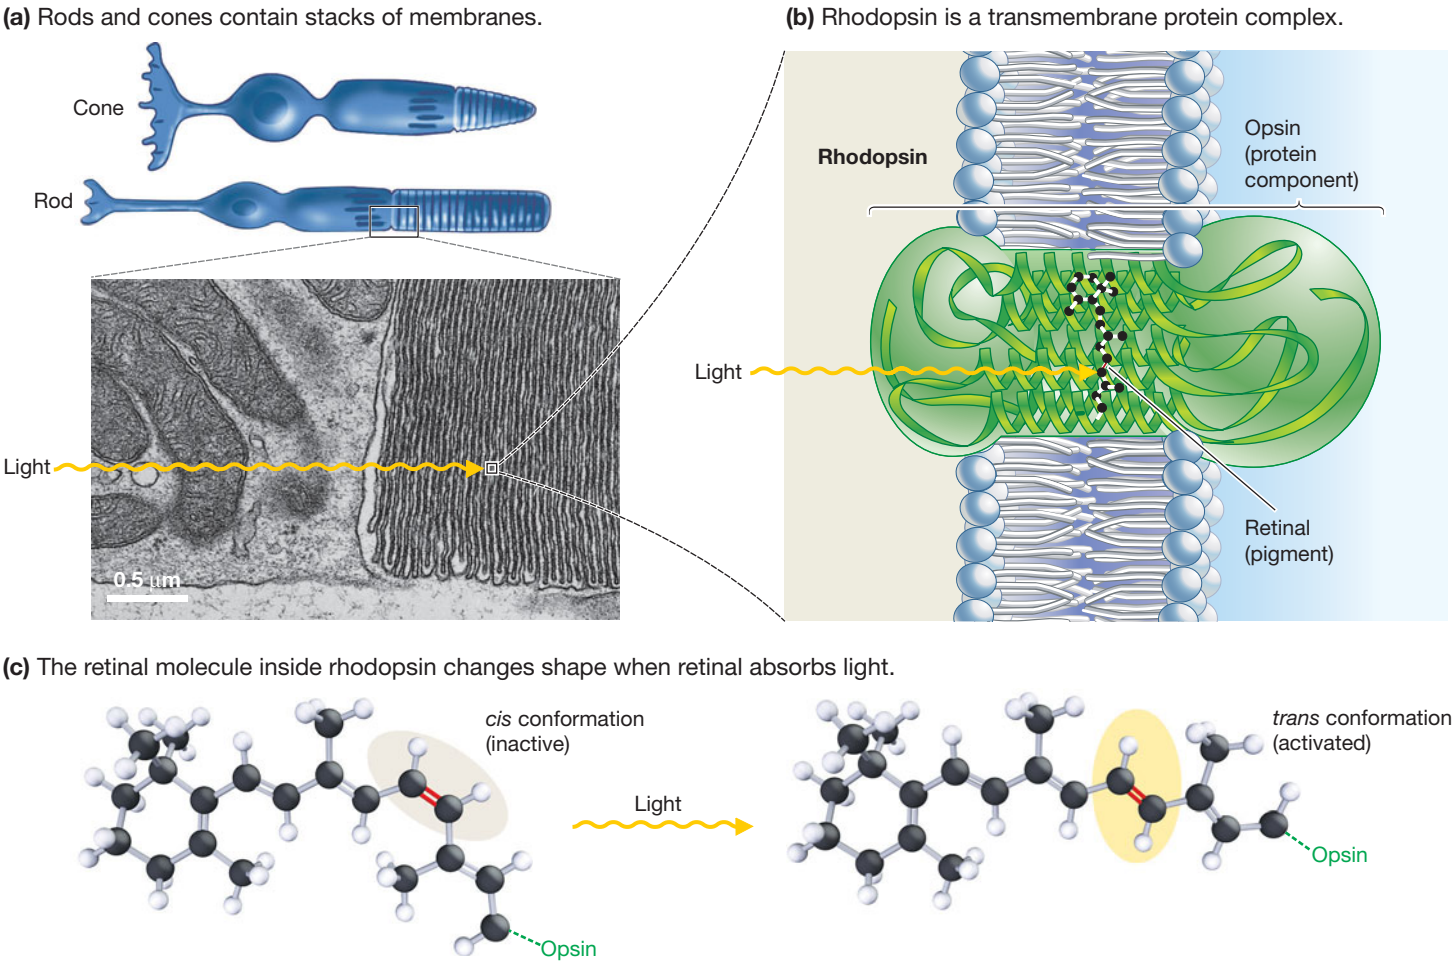

FIGURE 47.12 Rods and Cones Are Packed with Transmembrane Proteins That Contain the Pigment Retinal. **(a)** Rods and cones have membranous disks containing thousands of opsin molecules (called rhodopsin in rods). **(b)** Each opsin holds one retinal molecule. **(c)** Retinal changes conformation when it absorbs light. In response, opsin also changes shape.

✔**QUESTION** Explain why the change from *cis* to *trans* shown in part (c) would affect opsin's function.

Rods are sensitive to dim light but not to color. Cones, in contrast, are much less sensitive to faint light but are stimulated by different wavelengths (i.e., by colors). These discoveries explained why night vision is largely black and white—at night, the rods do most of the work.

Rods dominate most of the retina, but one small spot in the center of the retina has only cones. This is the **fovea** (see Figure 47.11a). When people focus on an object, their eyes move so that the image falls on the fovea of each eye. Based on these observations, biologists concluded that the high density of cones in the fovea maximizes the resolution of the image.

How Do Rods and Cones Detect Light? As Figure 47.12a shows, rods and cones have segments that are packed with membrane-rich disks. The membranes contain large quantities of a transmembrane protein called **opsin.** Each opsin molecule is associated with a molecule of the pigment **retinal.** In rod cells, the two-molecule complex is called **rhodopsin** (**FIGURE 47.12b**).

Experiments with isolated retinal, opsin, and rhodopsin molecules confirmed that retinal changes shape when it absorbs light. Specifically, the number-11 carbon in the retinal molecule changes from the *cis* conformation to the *trans* conformation (**FIGURE 47.12c**). Retinal is a light switch.

The shape change that occurs in retinal triggers a series of events that culminate in a different stream of action potentials being sent to the brain. The sequence of events is unusual, though, because the receipt of a light stimulus does not open ion channels or trigger the release of a neurotransmitter to a sensory neuron.

In vertebrates, the molecular basis of vision is a shape change in retinal that closes ion channels and decreases the amount of neurotransmitter being released to the sensory neuron. In rod cells, electrical activity across the membrane, as well as neurotransmitter release, are maximized in the dark. When retinal has not been activated by light, sodium channels in the rod's plasma membrane are open (**FIGURE 47.13a**), and entry of sodium continually depolarizes the rod cells. Exposure to light transmits information by *inhibiting* both processes.

FIGURE 47.13b shows how shutting down happens:

1. Rhodopsin is activated when light causes retinal to change shape from the *cis* to *trans* conformation.
2. Rhodopsin activation causes a membrane-bound molecule called transducin to activate the enzyme phosphodiesterase (PDE).
3. PDE breaks down a nucleotide called cyclic guanosine monophosphate (cGMP) to guanosine monophosphate (GMP).
4. As cGMP levels decline, cGMP-gated sodium channels in the plasma membrane of the rod cell close.
5. When sodium channels close, Na^+ entry decreases and the membrane hyperpolarizes.

✔ If you understand this sequence of events, you should be able to explain why cGMP acts as both a second messenger and a ligand in this system, and how transducin compares to G proteins (introduced in Chapter 11). You should also be able to explain why shutting Na^+ channels results in hyperpolarization.

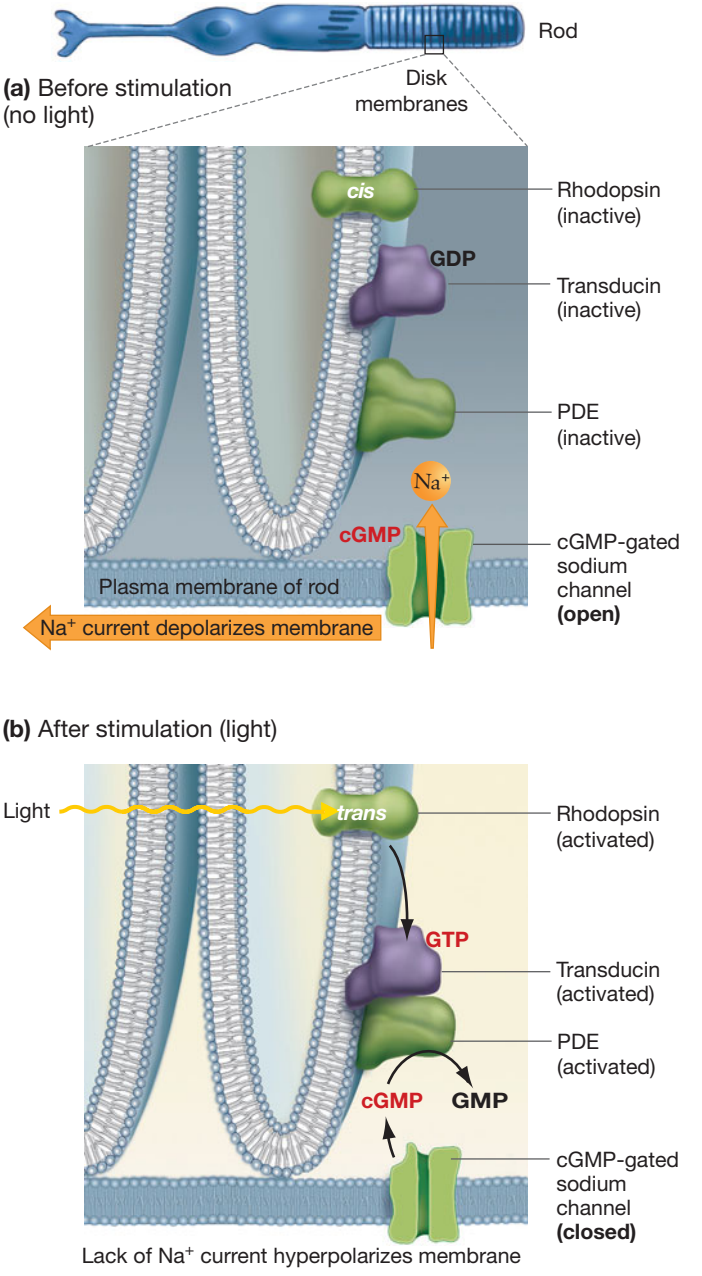

FIGURE 47.13 A Signal-Transduction Pathway Connects Light Absorption to Changes in Membrane Potential. (a) An unstimulated photoreceptor. Notice that sodium ions flow into the cell when light is *not* being received. **(b)** A stimulated photoreceptor. Activation of rhodopsin leads to a reduction in cGMP concentration. With less cGMP available, cGMP-gated sodium channels close, and the membrane hyperpolarizes.

✔**QUESTION** The inflow of sodium ions into a photoreceptor cell is called "the dark current." Why?

In response to the ensuing change in membrane potential, smaller quantities of the neurotransmitter glutamate are discharged at the synapse. The decrease in neurotransmitter indicates to the postsynaptic bipolar cell that the rod has absorbed

FIGURE 47.14 People with Red–Green Color Blindness Cannot Distinguish Red from Green. These images show what a person with red–green color blindness would see, compared to a person with normal color vision.

light. As a result, a new pattern of action potentials is sent to the brain, via neurons called ganglion cells. Axons from ganglion cells are bundled into the optic nerve.

This system is exquisitely sensitive: Biologists have recorded a measurable change in the membrane potentials of rod cells in response to a single photon of light. But how do humans and other animals perceive color?

Color Vision: The Puzzle of Dalton's Eye To answer this question, consider the research program initiated by John Dalton[1] in the late eighteenth century. At the age of 26, Dalton realized that he and his brother saw colors differently than other people did. To them, red sealing wax and green laurel leaves appeared to be the same color, and a rainbow exhibited only two hues. Dalton and his brother could not differentiate the colors red and green. This condition is called red–green color blindness (**FIGURE 47.14**).

In a lecture delivered in 1794, Dalton explained his perceptions by hypothesizing that red wavelengths failed to reach his retinas. Further, he hypothesized that because a normal eyeball is filled with clear fluid, and because blue fluids absorb red light, his defective vision resulted from the presence of bluish fluid rather than clear fluid in his eyes.

[1]Dalton was an accomplished physicist. He was the first proponent of the atomic theory of matter and formulated Dalton's law on the partial pressures of gases (introduced in Chapter 45). Red–green color blindness is sometimes called daltonism in his honor.

To test this hypothesis, Dalton left instructions that his eyes should be removed after his death and examined to see if the fluid inside was blue. When he died 50 years later, an assistant dutifully removed the eyes from Dalton's corpse and examined them. The fluid inside the eye was not blue at all, however, but slightly yellow—the normal color for an older person. Further, when the back was cut off one eye and colored objects were viewed through the lens, the objects looked perfectly normal. Dalton's hypothesis was incorrect.

Color Vision: Multiple Opsins What, then, caused Dalton's color blindness? The key to answering this question was the discovery that the human retina contains three types of color-sensitive photoreceptors: blue, green, and red cones, named for the colors that they best perceive.

To follow up on this result, biologists analyzed opsin molecules from the three cell types and found that each had a distinct amino acid sequence. The three proteins are now called the blue, green, and red opsins (or S, M, and L, for short, medium, and long wavelengths, respectively). Although retinal is the light-absorbing molecule in all photoreceptor cells, the different opsin molecules cause each type to respond to a different range of wavelengths of light.

Based on these results, biologists hypothesized that the brain distinguishes colors by combining signals initiated by the three classes of opsins. **FIGURE 47.15**, for example, graphs how much light is absorbed across a range of wavelengths by the S, M, and

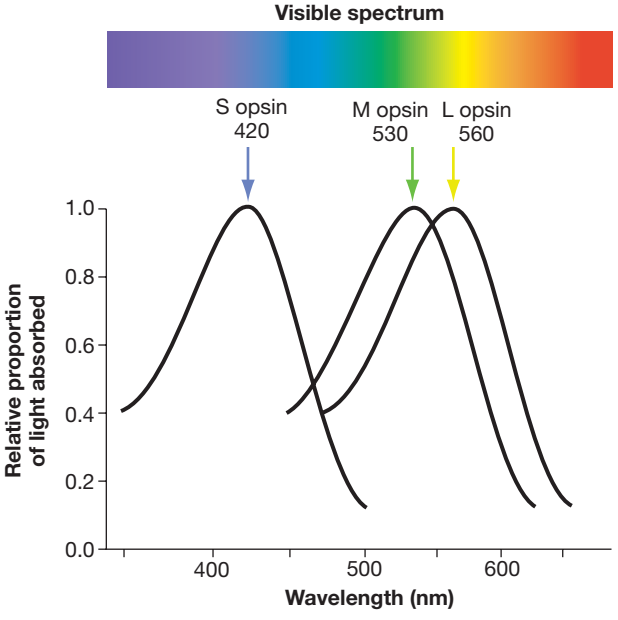

FIGURE 47.15 Color Vision Is Possible because Different Opsins Absorb Different Wavelengths of Light. Each human cone cell contains one of three different types of opsin. Each opsin absorbs a different range of wavelengths.

✔**QUESTION** The retinal molecules in S, M, and L opsins are identical. What is the likely reason that they respond to different wavelengths of light?

L opsins of humans. Notice that a wavelength of 560 nanometers (nm) stimulates L cones strongly, M cones to an intermediate degree, and S cones not at all. In response to the corresponding signals from these cells, the brain perceives the color yellow.

Does this hypothesis explain Dalton's color blindness? According to the data in Figure 47.15, wavelengths from green to red do not stimulate S opsin at all. It is thus unlikely that S opsin is involved in red–green color blindness. Did Dalton fail to distinguish red and green because his M or L cones were defective? Research has shown that red–green color-blind people lack either functional M or L cones, or both. Was the same true of Dalton?

This question was answered in the 1990s, when the genes for the M and L opsins were sequenced. Remarkably, Dalton's eyes had been preserved. Researchers managed to extract DNA from the 150-year-old tissue and analyze his M opsin genes and L opsin genes. They found that Dalton had a normal *L* allele but lacked a functional *M* allele. As a result, he did not have green-sensitive cones. The puzzle of Dalton's color vision was solved.

Red–green color blindness, or the inability to distinguish red and green due to an absence of either M or L cones, is estimated to affect about 5 to 10 percent of men and less than 0.5 percent of women. It is more prevalent in men than in women because it is an X-linked trait (see Chapter 14). In contrast, the inability to distinguish blue from other colors, which would result from absence of the S cone, is an extremely rare, autosomal dominant trait.

Do Other Animals See Color? What about other animals—do they see color the way humans do? The answer is, probably not. Animals that are active at night have relatively few cone cells and many rods, giving them high sensitivity to light but poor color vision. On the other hand, many vertebrate and invertebrate species have four or more types of opsins and probably perceive a world of colors that is much richer than ours.

In general, the types of opsins found in a species correlate with the environment it inhabits and its mode of life. For example,

- A marine fish called the coelacanth (pronounced *SEE-luh-kanth*), which lives in water 200 m deep, has two opsins that respond to the blue region of the spectrum (wavelengths of 478 nm and 485 nm). As a result, coelacanths perceive several distinct hues of blue that we would perceive as a single color. These opsins offered an adaptive advantage to coelacanths because wavelengths in the yellow and red parts of the spectrum do not penetrate well into deep water—only blue light exists in the coelacanth's habitat.
- In humans and other primates that eat fruit, two of the three opsins are sensitive to wavelengths around 550 nm. The presence of these opsins allows individuals to distinguish between the greens, yellows, and reds of unripe and ripe fruits.
- Many animals (for example, some insects and birds) can see ultraviolet light, which has shorter wavelengths than humans can see. This ability can be vital. Certain flowers have ultraviolet patterns that serve as signals for insect pollinators. Also, many birds have strong ultraviolet patterns in their plumage that are invisible to us but are important criteria used by females of some species for selecting mates.

If you understand that . . .

- In vertebrates, light detection begins when retinal changes shape after absorbing light.
- Stimulation of rhodopsin or the photopsins by light causes conformation changes in retinal, which triggers a series of events resulting in the closing of sodium channels in the membrane of a photoreceptor cell. The resulting change in membrane voltage triggers a change in neurotransmitter release from the receptor cell.

✔ You should be able to . . .

1. Explain why retinal can be thought of as a "light switch."
2. Predict the type of vision loss that results from each of the following: detachment of the retina following a car accident, a mutation that knocks out the gene for S opsin, and an age-related clouding of the lens.

Answers are available in Appendix A.

47.4 Chemoreception: Sensing Chemicals

Chemoreception occurs when chemicals bind to chemoreceptors to initiate action potentials in sensory neurons. The sense of taste, called **gustation,** and the sense of smell, called **olfaction,** originate in chemoreceptors. Chemoreceptors detect the presence of particular molecules by undergoing a change in membrane potential when a specific compound is present. In this way, information about the presence of a particular chemical is transduced to an electrical signal in the body.

Until recently, taste and smell were poorly understood in comparison with vision and hearing. It is easy to see why. Eyes and ears respond to relatively simple stimuli—light and sound waves. The tongue and nose, in contrast, respond to thousands of different chemicals. Consequently, taste and smell were difficult to study until techniques became available for identifying how particular molecules bind to certain receptors. But in the past 20 years, research on the chemosenses has exploded.

Taste: Detecting Molecules in the Mouth

The chemoreceptor cells that sense taste are clustered in structures known as **taste buds.** Although humans have taste buds scattered around the mouth and throat, most taste buds are located on the tongue (**FIGURE 47.16**). A taste bud contains about 100 spindle-shaped taste cells, which contain taste receptors and synapse onto sensory neurons.

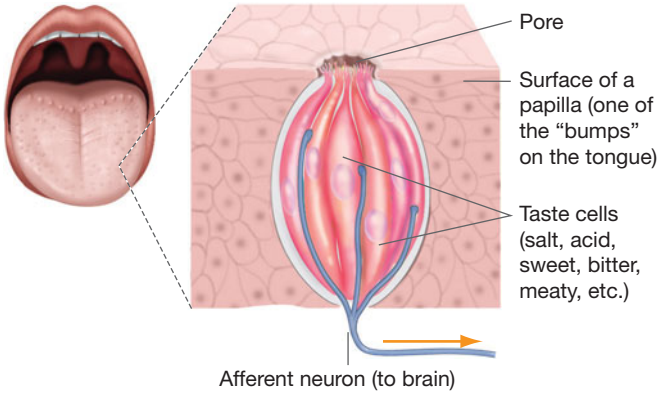

FIGURE 47.16 Taste Buds Contain Many Types of Chemoreceptors.

How do these receptors work on a molecular level, and how do they produce the sensation of taste? Early taste research focused on the hypothesis that four "basic tastes" existed: salty, sour, bitter, and sweet.

Salt and Sour Researchers who analyzed the membrane proteins in taste cells found strong evidence that salt and sour sensations result from the activity of ion channels.

- The sensation of saltiness is due primarily to sodium ions (Na^+) dissolved in food. These ions flow into certain taste cells through open Na^+ channels and depolarize the cells' membranes.
- Sourness is due in part to the presence of protons (H^+), which flow directly into certain taste cells through H^+ channels and depolarize the membrane.

The sour taste of grapefruit and other citrus fruits, for example, results from the release of protons by citric acid. In general, the lower the pH of a food, the more it depolarizes a taste cell's plasma membrane, and the more sour the food tastes.

Compared to salt and sour, the molecular mechanisms responsible for the sensations of bitterness and sweetness have been much more difficult to identify. Researchers have only recently been able to document that certain food molecules actually bind to specific receptors on taste cells to cause bitter and sweet tastes.

Why Do Many Different Foods Taste Bitter? Bitterness has been difficult to understand because molecules with very different structures, such as orange peel or unsweetened cocoa, are all perceived as bitter. How is this possible?

An answer began to emerge after researchers confirmed that some humans genetically lack the ability to taste certain bitter substances. In 1931, Arthur Fox was synthesizing phenylthiocarbamide (PTC) and accidentally blew some of it into the air. A nearby colleague complained of a bitter taste in his mouth, but Fox could not taste anything. Follow-up research confirmed that the ability to taste PTC is inherited and polymorphic. About 25 percent of Americans cannot sense the molecule.

To find the gene responsible for this trait, biologists compared the distribution of genetic markers observed in "tasters" and "nontasters." The mapping effort recently narrowed down this gene's location to several candidate chromosomal segments. (Chapter 20 introduced this type of gene hunt.) In one of the regions, researchers found a family of 40 to 80 genes that encode transmembrane receptor proteins.

Follow-up work has documented that each protein in the family binds to a different type of bitter molecule. A taste cell, however, can have many different receptor proteins from this family. As a result, many different molecules can depolarize the same cell and cause the sensation of bitterness.

Why are so many genes devoted to detecting bitterness? Many of the molecules that bind to these receptors are found in toxic plants; most animals react to bitter foods by spitting them out and avoiding them in the future. In essence, bitterness indicates, "This food is dangerous; don't swallow it."

The proliferation of genes responsible for detecting bitterness hints that the trait is extremely adaptive—meaning that individuals with the capacity to detect a wide array of bitter compounds produce more offspring than do individuals that lack this ability.

What Is the Molecular Basis of Sweetness and Other Tastes? Inspired by progress on bitter receptors, research teams used a similar approach—analyzing mutant mice that could *not* sense sweetness—to understand how the sweet receptor works.

In humans and mice, three closely related membrane receptors are responsible for detecting sweetness as well as glutamate and other amino acids. Glutamate triggers the sensation called **umami,** which is the meaty taste of the molecule monosodium glutamate (MSG). Glutamate is sensed by one particular pair of the three receptors. Sweetness is sensed by a different pair of receptors.

Recent work has solved a long-standing question about sweet sensation—why so many different types of sugars trigger the same sensation. As it turns out, a single receptor has binding sites for multiple types of sweet compounds, meaning that a variety of molecules can stimulate action potentials from the same receptor.

Currently, several teams are studying how the different taste sensations are conveyed to the brain and interpreted. Although taste is beginning to reveal its secrets, the complete story will probably not be known for many years.

Olfaction: Detecting Molecules in the Air

Taste allows animals to assess the quality of their food before swallowing it. Olfaction, in contrast, allows animals to monitor airborne molecules that convey information. Wolves and domestic dogs, for example, can distinguish millions of different airborne molecules at vanishingly small concentrations. The molecules that constitute odor contain information about the movements and activities of prey and other members of their own species.

Odorants Provide Information about the Environment Airborne molecules that convey information about food or the environment are called **odorants**. When they reach the nose, they diffuse

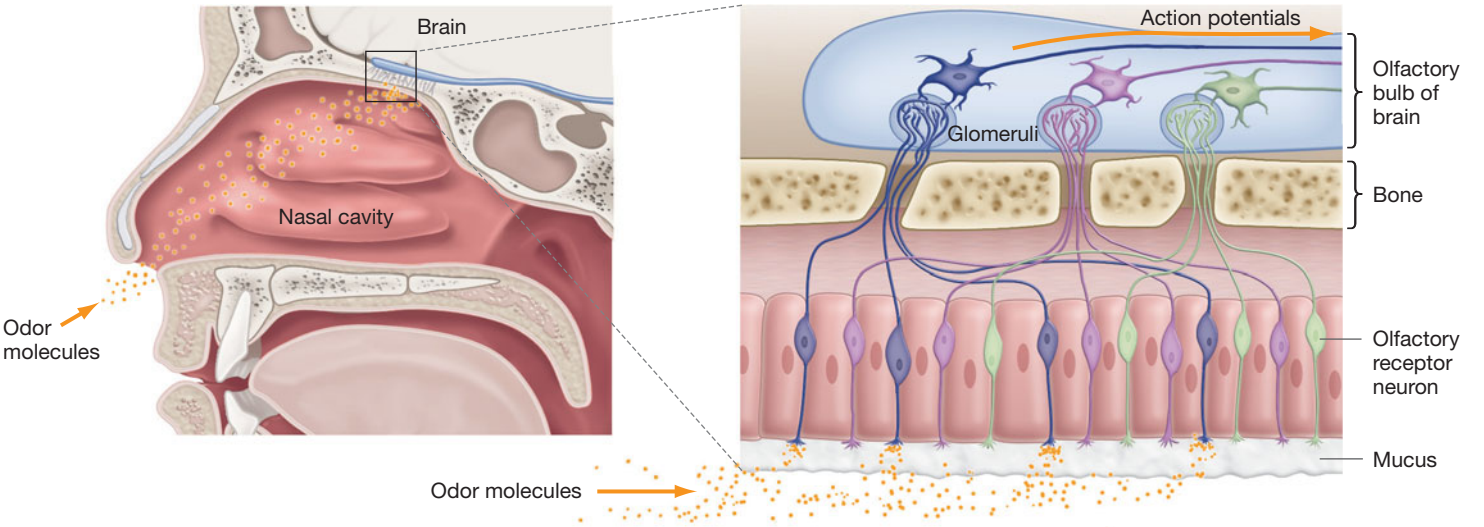

FIGURE 47.17 In Mammals, Chemoreceptor Cells in the Nose Respond to Specific Odorants. Each of the chemosensory neurons in the nose has one type of odor receptor protein on its dendrites. Sensory neurons with the same receptor project to the same glomerulus, or section within the olfactory bulb of the brain.

into a mucus layer in the roof of the nose (**FIGURE 47.17**). There, they activate olfactory neurons by binding to membrane-bound receptor proteins. Axons from these neurons project up to the **olfactory bulb,** the part of the brain where olfactory signals are processed and interpreted.

Understanding the anatomy of the odor-recognition system was a relatively simple task. Understanding how receptor neurons distinguish one molecule from another was much more difficult. Initially, investigators hypothesized that receptors respond to a small set of "basic odors," such as musky, floral, minty, and so on. The idea was that each basic odor would be detected by its own type of receptor, much like the way gustation works.

In 1991, Linda Buck and Richard Axel discovered a gene family in mice that comprises hundreds of distinct coding regions and encodes receptor proteins on the surface of olfactory receptor neurons. Follow-up experiments confirmed that each receptor protein binds to a small set of molecules.

Further work established that most, if not all, vertebrates possess this family of genes. Mammals typically have 800 to 1500 of these genes, meaning mammals could produce at least 800 to 1500 different olfactory receptor proteins. In humans, however, about half of these genes have mutations that probably render them nonfunctional. This observation may explain why the sense of smell is so poor in humans compared with that of most other mammals. But the sense of smell is even worse in whales and dolphins—70% to 80% of their olfactory receptor genes are nonfunctional. These animals rely far more on hearing and vision than on smell to sense their environment.

Buck and Axel's announcement inspired a series of questions. How many different receptors occur in the membrane of each neuron involved in odor reception? How does the brain make sense of the input from so many different receptors?

Recently, scientists determined that each olfactory neuron has only one type of receptor, and neurons with the same type of receptor are linked to distinct regions in the olfactory bulb of the brain. These regions are called **glomeruli** (meaning little balls).

Follow-up work from Axel's lab indicated that each smell recognized by mice is associated with the activation of a different subset of the 2000 glomeruli in the brain. For example, the activation of clumps 130, 256, and 1502 might be perceived as the smell "cinnamon." In essence, then, the sensing of odorants is similar to the visual system's use of three cones to perceive many colors; but odor reception works on a much larger scale.

Interestingly, odorant receptors recently have been identified in locations other than the typical olfactory epithelium—for example, in tissues of the heart and pancreas. Receptors have also been identified in the cell membranes of sperm cells, where they appear to play an important role in guiding the sperm toward the egg. Research on this complex and impressive sense continues at a furious pace.

Pheromones Provide Information about Members of the Same Species Recall from the introduction to this chapter that male silk moths are able to locate female moths from miles away. Males have much larger antennae than females, suggesting that they use these antennae in a sex-specific manner.

These factors led scientists to hypothesize that female moths release a chemical into the environment that binds to chemoreceptors on the males' antennae and acts as an attractant. In 1959, scientists identified this chemical and named it bombykol, after the scientific name of the silk moth (*Bombyx mori*). Bombykol was the first chemically characterized **pheromone,** meaning a chemical that is secreted into the environment and that affects the behavior or physiology of animals of the same species.

Thousands of pheromones have since been identified in invertebrates and vertebrates alike, performing such roles as alerting other members of a beehive to an intruder or signaling a male rodent that a female is ovulating. In insects, pheromones typically

bind to receptors on the antennae. In tetrapod vertebrates, pheromone receptors are often localized in the **vomeronasal organ,** a sensory organ in the nasal region but distinct from the olfactory bulb. The vomeronasal organ and the olfactory bulb send signals to different parts of the brain, although some animals also sense odorants with the vomeronasal organ. For example, a snake may follow a scent trail of prey using its vomeronasal organ.

Do humans release pheromones? This is a hotly debated question. In 1971, Martha McClintock demonstrated that the menstrual cycles of women living in close contact with one another become synchronized as a result of a secretion from the women's armpits, but the responsible chemical has yet to be identified. Other studies have suggested that secretions from men's armpits can alter hormone levels in women, but both the amount of the chemical secreted and the reaction to it vary dramatically among men and women. Until scientists more fully understand the mechanisms by which these human "pheromones" achieve their effects, the jury is out.

If you understand that . . .

- In most cases, chemoreception occurs when a specific molecule in air or food binds to a specific receptor in the nose or mouth and the binding event is transduced to a change in membrane voltage.
- Odorants bind to chemoreceptors to initiate action potentials to the brain, where action potentials from specific receptors are interpreted as particular smells.
- Pheromones bind to chemoreceptors that send action potentials to brain regions that then affect the behavior or physiology of the animal.

✓ You should be able to . . .

1. Discuss why a loss in chemosensory ability occurs when you burn your tongue with extremely hot food.
2. Develop a hypothesis to explain why the vomeronasal organ appears to be vestigial in most primates.

Answers are available in Appendix A.

47.5 Other Sensory Systems

The stimuli and senses discussed so far are the ones you are likely most familiar with. But animals can sense much more than pressure waves, light, and chemicals. All animals can sense temperature and painful stimuli, and some can even perceive electric or magnetic fields. Let's start with temperature and examine each of these other stimuli and senses in turn.

Thermoreception: Sensing Temperature

Recall that many animals thermoregulate to maintain body temperature within an acceptable range (see Chapter 42). Virtually every physiological process, from digestion to metabolic rate, is temperature-dependent, so the ability to sense temperature changes in the environment and respond accordingly is crucial.

Thermoreception Helps Animals Thermoregulate Animals detect heat energy by **thermoreception** and adjust their behaviors or physiological processes, such as shivering and sweating, in response.

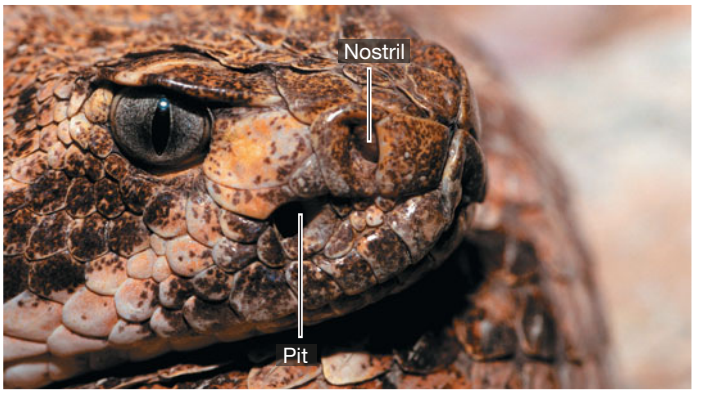
Some thermoreceptors are located in the central nervous system. In mammals, the hypothalamus is the brain region that senses departures from homeostatic body temperature and sends signals to effectors to restore homeostasis (see Figure 42.16).

Thermoreceptors also are commonly found on skin and other outer surfaces of animals, so that changes in the temperature of the environment can be sensed. As an example, several types of thermoreceptors have been identified in mammals. Some receptors depolarize in response to cooling, and others depolarize in response to heating. Picking up a cold object stimulates "cold receptors" in your skin, resulting in an increase in the rate of action potentials in sensory neurons that inform your brain that the object is cold.

Interestingly, extreme temperatures are sensed by a different type of receptor, called a nociceptor, that also senses other painful stimuli such as those produced by certain chemicals, excessive pressure, and tissue damage. If you touch a hot stove burner, the pain you feel arises primarily via stimulation of nociceptors.

Pit Vipers Have Extremely Sensitive Thermoreceptors The pit vipers are a group of snakes named after the two temperature-sensitive pits just beneath their nostrils (**FIGURE 47.18a**, see page 968). Inside each pit is a membrane lined with exquisitely sensitive thermoreceptors—a rattlesnake's thermoreceptors can sense changes in temperature as little as 0.003°C.

Pit vipers use these thermoreceptors to sense the heat energy given off by prey, predators, and even possible burrows in which to hide. The brains of these snakes may combine visual and thermal stimuli into a "thermal image" that might look something like an image from an infrared camera (**FIGURE 47.18b**). Even in complete darkness, rattlesnakes can strike prey with deadly precision.



✓ If you understand this, you should be able to predict whether a rattlesnake could strike effectively at its prey with (1) its eyes covered but pits exposed, (2) its eyes and pits covered with cotton cloth, and (3) its eyes and pits covered with an opaque heat-blocking material.

Electroreception: Sensing Electric Fields

All animals give off weak electrical impulses that arise from the activity of their nerves and muscles. Since water is a good conductor of these electrical impulses, many kinds of fishes use **electroreception,** or sensation of electric fields, to locate prey, detect predators, and navigate.

Sharks Use Electroreception to Hunt and Navigate In sharks, some parts of the lateral line system are specialized to detect electrical fields rather than pressure. Tiny pores scattered across a shark's head contain structures called **ampullae of Lorenzini**

(a) Pit vipers have temperature-sensitive pits.

(b) Warm animals emit infrared radiation.

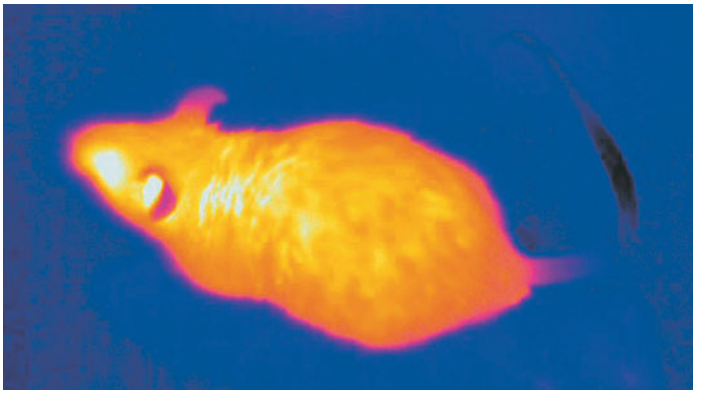


FIGURE 47.18 Pit Vipers Use Thermoreception to Detect Prey. (a) Pits are lined with extremely sensitive thermoreceptors. **(b)** Pit vipers can detect infrared radiation given off by rodents and other prey.

(**FIGURE 47.19**). These ampullae are lined with hair cells that depolarize in response to a change in electrical polarity and send signals to the shark's brain via sensory neurons.

The sensitivity of these ampullae is remarkable—sharks can detect electrical currents as weak as a nanovolt (a billionth of a volt). This ability allows sharks to detect prey that are far away or even buried in the sand at the ocean floor. Combined with their exquisite sense of olfaction—sharks can detect a single drop of blood in a million drops of ocean water—electroreception makes them finely tuned predators.

Although data are scarce, scientists have some evidence to suggest that sharks also use electroreception to navigate. Ocean currents moving through the Earth's magnetic field generate weak electrical currents. Sharks have been observed in the ocean orienting themselves to these fields as well as to artificially created fields in the laboratory.

Electrogenic Fishes Generate Electric Fields **Electrogenic fishes** have specialized organs near their tails that generate electric fields stronger than those of regular nerves or muscles. The currents generated by the electric organ move in an arc through the water (**FIGURE 47.20**). Any item located within that arc will disrupt the currents, allowing the fish's electroreceptors to detect it. In this way, electrogenic fishes use their electric organs to locate prey, sense predators, navigate through murky water, and even communicate with other fishes.

FIGURE 47.19 Ampullae of Lorenzini on Sharks' Heads Detect Electrical Fields to Help Locate Prey and Navigate.

Some electrogenic fishes have the ability to produce extremely strong currents that stun or kill their prey. The electric organs of electric eels take up over 80 percent of their body mass and can generate a 500-volt change in electrical potential and 1 ampere of current in the water around them. This amount of current is enough to kill a person swimming in water with an electric eel.

Magnetoreception: Sensing Magnetic Fields

The Earth produces a magnetic field as it rotates on its axis. Just as a compass uses this magnetic field to determine direction, animals may home in on magnetic fields while navigating. **Magnetoreception** has been described in many groups of organisms, including bacteria, fungi, invertebrates, and all vertebrate classes.

In general, studies of the mechanisms by which animals sense the Earth's magnetic fields are in their infancy. However, scientists are confident that at least several distinct mechanisms have evolved. Recall that sharks can sense magnetic fields indirectly via electric fields produced by ocean currents. Terrestrial organisms, in contrast, have the ability to sense magnetic fields directly.

In 1968, German scientists noticed that European robins being kept in the laboratory with no visual cues to the outside began to sit at one end of their cages at the beginning of the migratory season. This behavior led the scientists to hypothesize that birds use magnetoreception to determine direction as they migrate.

Since then, support for this hypothesis has accumulated. Application of artificial magnetic fields changes the robins' orientation. For example, when placed into circular chambers with artificial magnetic fields, birds always orient themselves in relation to the artificial field. Furthermore, disruption of the

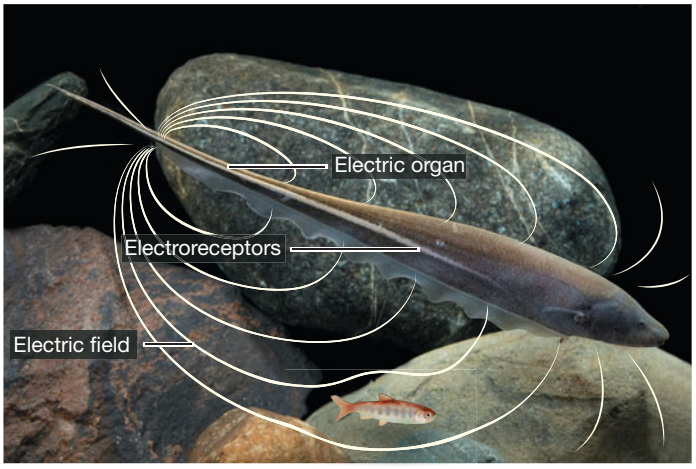

FIGURE 47.20 Electrogenic Fishes Can Create Strong Electric Fields. The fish emits an electric current with its electric organ. When a prey object disrupts the electric field, the fish detects its presence using electroreceptors.
