magnetic field prevents birds from navigating properly. When scientists fitted homing pigeons with little caps that reversed the polarity of the magnetic field, the pigeons flew in the direction opposite to the one they were trained to fly in.

What enables birds to sense magnetic fields? It is likely a combination of factors. One hypothesis is that deposits of iron inside sensory neurons in the beak play a role in stimulating a response to changes in the magnetic field. In support of this hypothesis, cutting these neurons prevents birds from responding to artificial changes in the magnetic field in the lab. To complicate matters, however, magnetoreception in birds is apparently also dependent on vision. Covering the right eye—but not the left eye—of migrating birds interferes with their ability to navigate using magnetic cues.

This complication highlights a key feature of sensory perception: Animals do not use individual senses in isolation, but rather combine sensations of many types when locating prey, evading predation, or communicating with other animals. Whether it is a homing pigeon using magnetoreception and photoreception to find its way home, or a rattlesnake using a visual and thermal image to strike at a mouse, all animals depend on sensory systems that work together to provide the animal with the information it requires to survive.

C Y U

If you understand that . . .

- Thermoreceptors, nociceptors, electroreceptors, and magnetoreceptors convey information about temperature, painful stimuli, electric fields, and magnetic fields, respectively.
- Animals combine input from multiple senses to locate prey, escape from predators, and communicate with other animals.

✔ You should be able to . . .

1. Identify one or more habitat types in which electrogenic fishes may have a survival advantage.
2. Propose a mechanism by which a female sea turtle migrates to lay eggs on the beach she was born on decades earlier.

Answers are available in Appendix A.

CHAPTER 47 REVIEW

For media, go to MasteringBiology MB

If you understand . . .

47.1 How Do Sensory Organs Convey Information to the Brain?

- If the membrane potential of a sensory cell is altered substantially enough in response to a stimulus, the pattern of action potentials that it sends to the brain changes. In this way, sensory stimuli as different as sound and light are transduced to electrical signals.
- The brain is able to distinguish different types of stimuli because axons from different types of sensory neurons project to different regions of the brain.

✔ **You should be able to suggest a hypothesis to explain why people who have had limbs amputated experience "phantom pain"—the perception that their missing tissue hurts.**

47.2 Mechanoreception: Sensing Pressure Changes

- Pressure receptors detect direct physical stimulation, including stimulation from sound.
- Hair cells, the major sensory detectors in the vertebrate ear, undergo a change in membrane potential in response to bending of their stereocilia.
- Sound waves of a certain frequency cause a certain part of the cochlea's basilar membrane to vibrate. Hair cells at this location stimulate action potentials in sensory neurons in response to the vibration.
- Hair cells in the lateral line systems of fishes and aquatic amphibians are stimulated by pressure changes in the water.

✔ You should be able to identify the key feature common to gravity sensing, hearing, and the lateral line system.

47.3 Photoreception: Sensing Light

- In the vertebrate eye, photoreceptors are located in rods and cones. Although these two cell types differ in structure and function, both contain molecules that consist of retinal paired with opsin (called rhodopsin in rod cells).
- The rhodopsin found in rods is stimulated by even the faintest light.
- Color vision is possible because cones contain opsins that respond to specific wavelengths of light absorbed by retinal.
- Humans distinguish colors based on the pattern of stimulation of three types of opsins found in cones. People who lack one of the functional cone opsins are color blind, meaning they cannot distinguish as many colors as people with all three opsins can.

✔ You should be able to explain how different animal species are able to see different colors.

47.4 Chemoreception: Sensing Chemicals

- Chemoreceptors detect the presence of certain foodborne or airborne molecules.
- Taste buds contain taste cells with membrane proteins that respond to toxins, salt, acid, and other types of molecules in food. Sodium ions and protons enter taste cells via channels and depolarize the membrane directly, producing the sensations of saltiness and acidity. Sugars and some toxic compounds bind to membrane receptors and trigger action potentials that are interpreted by the brain as sweet and bitter flavors, respectively.
- Smell, or olfaction, is used to scan molecules from the outside environment. Airborne chemicals are detected by hundreds of different odor-receptor proteins located in the membranes of receptor cells in the nose.

✔ You should be able to explain why people with nasal congestion complain that food tastes bland, and why the brain can perceive so many different flavors based on inputs from just four or five basic types of taste receptors.

47.5 Other Sensory Systems

- Thermoreceptors respond to changes in temperature.
- Nociceptors respond to painful stimuli, including extreme temperatures, certain chemicals, excessive pressure, and tissue damage.
- Electroreceptors contain modified hair cells that respond to electric fields.
- Magnetoreceptors respond to magnetic fields and are often used in navigation and orientation.

✔ You should be able to explain why the chemical capsaicin, found in chili peppers, feels hot on the tongue.

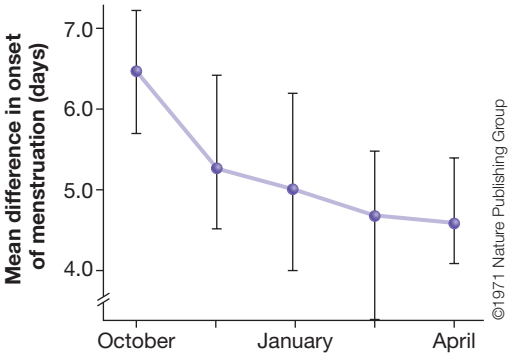
TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. What is echolocation?
   a. use of echoes from high-frequency vocalizations to detect objects
   b. use of extremely low-frequency vocalizations to communicate over long distances
   c. vision based on input from many independent lenses, functioning like pixels on a computer screen
   d. variation in the structure of opsin proteins, which allows animals to see different colors
2. In the human ear, how do different hair cells respond to different frequencies of sound?
   a. Waves of pressure move through the fluid in the cochlea.
   b. Hair cells are "sandwiched" between membranes.
   c. Receptors in the stereocilia of each hair cell are different; each receptor protein responds to a certain range of frequencies.
   d. Because the basilar membrane varies in stiffness, it vibrates in certain places in response to certain frequencies.
3. Which of the following comparisons of rods and cones is *false*?
   a. Most human eyes have one type of rod and three types of cones.
   b. Rods are more sensitive to dim light than cones are.
   c. Nocturnal animals have fewer rods than diurnal animals.
   d. Both rods and cones use retinal and opsins to detect light.
4. Which of the following statements about taste is *true*?
   a. Sweetness is a measure of the concentration of hydrogen ions in food.
   b. Sodium ions from foods can directly depolarize certain taste cells.
   c. All bitter-tasting compounds have a similar chemical structure.
   d. Membrane receptors are involved in detecting acids.
5. True or false: A rattlesnake's facial pits detect the presence of prey using photoreception.
6. What type of sensory system do migrating birds use to detect direction?



TEST YOUR UNDERSTANDING

Answers are available in Appendix A

7. Considering that sounds and odors both trigger changes in the patterns of action potentials from sensory cells, how does the brain perceive which sense is which when the action potentials reach the brain?
- **a.** The action potentials stimulated by sounds are different in size and shape from those stimulated by an odor.
- **b.** The axons from different sensory neurons go to different areas of the brain.
- **c.** Mechanoreception is not consciously perceived by the brain, whereas chemoreception is.
- **d.** Chemoreception is not consciously perceived by the brain, whereas mechanoreception is.

8. Give three examples of how the sensory abilities of an animal correlate with its habitat or method of finding food and mates.

9. **QUANTITATIVE** Scientists collected data on the date of onset of the menstrual cycles of a group of women who moved into a college dormitory together in the fall. The *y*-axis of the graph shows the average difference (in days) between the onset of a woman's cycle and the average onset date of the rest of the women. Describe how these data provide evidence for the existence of a human pheromone.

DATA: McClintock, M. K. 1971. *Nature* 229: 244–245, Figure 1.

10. Explain how the bending of stereocilia in a hair cell and binding by a bitter-tasting molecule can both result in an ion channel opening.

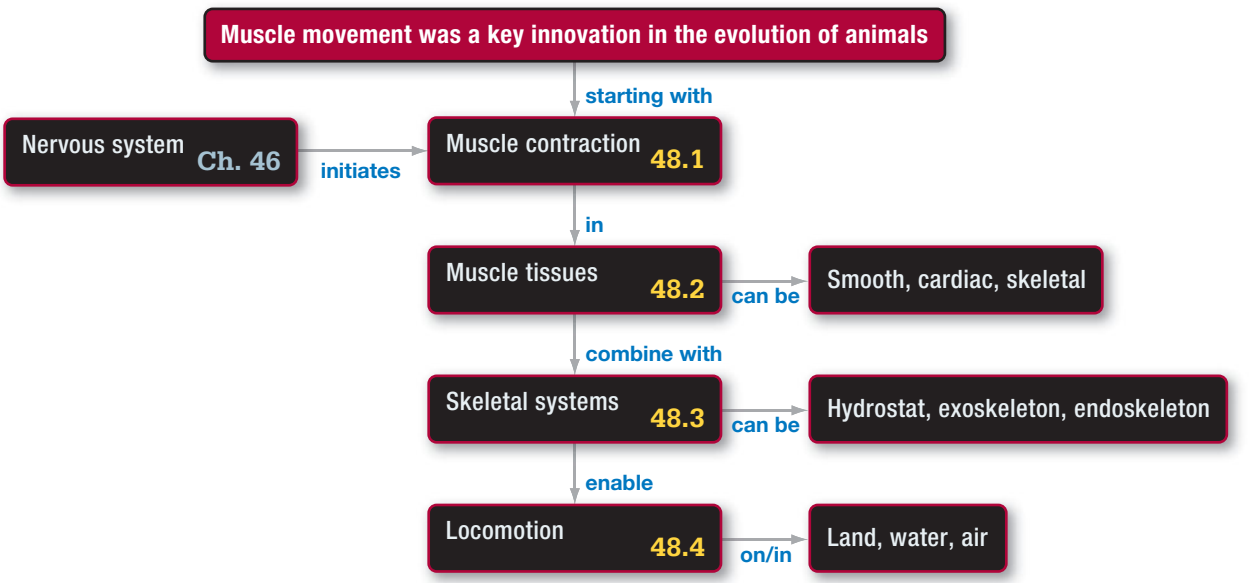
11. Scientists generally think that a "good hypothesis" is one that is reasonable and testable and inspires further research into the phenomenon. Using these criteria, was Dalton's hypothesis about color vision a good hypothesis? Was it correct? Explain your answer.

12. Design experiments to test the hypothesis that electric eels are both electrogenic and electroreceptive.

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A

13. Which of the following animals is *least* likely to have a well-developed vomeronasal organ?
- **a.** fish
- **b.** salamander
- **c.** rodent
- **d.** snake



14. Compare and contrast the lateral line system of fishes with electroreception in sharks.

15. A company is marketing perfumes that it claims are attractive to the opposite sex because they contain "pure reaction-grade human pheromones." Explain why this is unlikely to be truth in advertising.

16. Houseflies have about 800 ommatidia in each of their compound eyes. Dragonflies, in contrast, have up to 10,000 ommatidia per eye. Houseflies feed by lapping up watery material from piles of excrement or rotting carcasses, which they locate by scent. Dragonflies are aerial predators and hunt by sight. How would you test the hypothesis that the large numbers of ommatidia in dragonflies make them more efficient hunters?

48 Animal Movement

In this chapter you will learn that

Basilisk lizards are able to run on water—literally. This impressive escape strategy demonstrates the extent to which muscle-generated movements have diversified among animals. For most animals, complex muscle movements make the difference between life and death.

BIG PICTURE

This chapter is part of the Big Picture. See how on pages 840–841.

You may have discovered while studying biology that plants and animals are more similar to each other than they initially appear. For example, plants and animals both require water and nutrients in specific quantities, have highly specialized tissues and complex reproductive structures, and launch defenses against parasites and predators. You can see a comparison of these and other traits in the Big Picture of Plant and Animal Form and Function on pages 840–841.

However, animals possess a quality that clearly distinguishes them from plants and other organisms: movement by virtue of muscle contractions. Muscle-generated movements were a key innovation in animal evolution. Rapid movements, along with sophisticated sensory structures

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

(Chapter 47) and complex information processing systems (Chapter 46), were vital to animal diversification (Chapter 33), and these attributes made animals efficient eating machines in diverse ecosystems.

Muscles generate movement by exerting force and causing shape changes. Movement falls into two general categories:

1. ***Movement of the entire organism relative to its environment.*** **Locomotion,** movement of an animal under its own power, enables animals to seek food, water, mates, and shelter as well as avoid predators. Modes of locomotion include undulating, jetting, swimming, walking, running, jumping, gliding, and flying (introduced in Chapter 33).
2. ***Movement of one part of the animal relative to other parts (not involved in locomotion).*** This type of movement also has important functions—for example, to ventilate gills for gas exchange and to grasp prey. Even sessile organisms like sea anemones and barnacles use complex, muscle-generated movements to survive and reproduce.

How do animals accomplish their spectacular movements? This chapter starts by probing into the mechanism of muscle contraction that serves as the "engine" for most animal movements and then considers how muscle and skeletal systems work together to produce locomotion. The latter discussion introduces a research field called **biomechanics,** in which the principles of physics and engineering are applied to questions about the mechanical structure and function of organisms. Let's jump in.

48.1 How Do Muscles Contract?

The mechanism responsible for the contraction of muscle has fascinated and perplexed scientists for many centuries. Before the advent of microscopes and modern research techniques, scientists could only speculate about what makes muscles contract and relax.

Early Muscle Experiments

In the second century C.E., the Roman physician and philosopher Galen proposed that spirits flowed from nerves into muscles, inflating them and increasing their diameter. This "inflation" hypothesis persisted into the seventeenth century, when the French philosopher René Descartes suggested that nerves carry fluid from the pineal gland—which is in the brain and was considered to be the seat of the soul—to the muscles, making them shorten and swell.

Later that century, Dutch anatomist Jan Swammerdam tested Descartes' inflation hypothesis with a simple yet elegant experiment. He placed a piece of frog muscle into an airtight syringe with the nerve protruding through a small hole in the side and a small drop of water in the tip. He then stimulated the nerve, causing the muscle to contract. If the muscle's volume changed during contraction, the drop of water in the tip of the syringe would move. But it did not. The volume of the muscle remained constant.

Swammerdam's experiment demonstrated an important point: The contraction mechanism is inherent to the muscle itself—muscle is not like a balloon, and the nerve is not like a water hose filling a balloon. This insight was confirmed by Italian scientist Luigi Galvani in the 1790s, when he severed the nerve to a frog's leg muscle and then connected the two sides of the cut with a metal conductor. Contraction occurred. He concluded that the nerve and muscle possess "animal electricity" that can induce contraction.

If the shape of muscle does not change by inflation, what is the mechanism of muscle contraction?

The Sliding-Filament Model

Early microscopists established that the muscle tissue in vertebrate limbs and hearts is composed of slender fibers. A **muscle fiber** is a long, thin muscle cell. Within each of the muscle cells are many threadlike, contractile filaments called **myofibrils.** The myofibrils inside muscle fibers often look striped or striated due to the alternating light–dark units called **sarcomeres,** which repeat along the length of a myofibril (**FIGURE 48.1**).

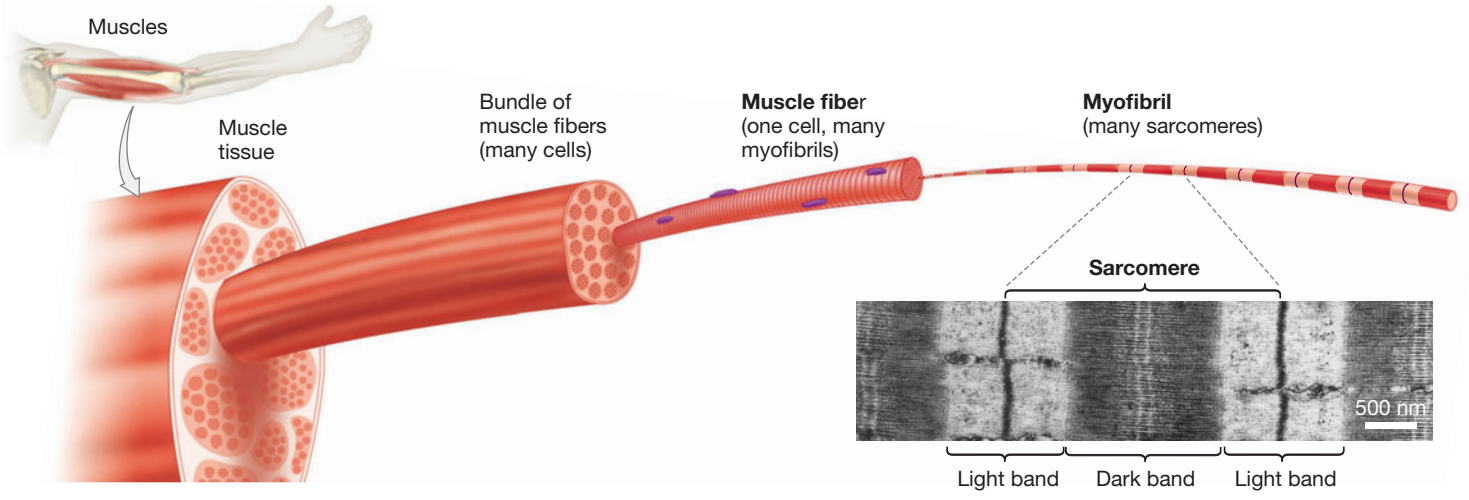


FIGURE 48.1 Muscle Cells Contain Many Myofibrils, Which Contain Many Sarcomeres. Skeletal muscle cells (fibers) have a striped appearance due to repeating sarcomeres, which are units of alternating light–dark bands.

The microscopists observed that sarcomeres shorten as myofibrils contract. Sarcomeres then lengthen when the cell relaxes and an external force stretches the muscle. Based on these observations, it became clear that the question of how muscles contract simplifies to the question of how sarcomeres shorten.

Biologists knew that the answer must involve the two types of protein that had been found in sarcomeres: **actin** and **myosin**. But they did not know the shapes of these molecules or how they were arranged within the sarcomere. Did both types of molecules span the entire length of the sarcomere? Or were the filaments restricted to certain bands within the sarcomere?

In 1952, biologist Hugh Huxley produced electron micrographs of sarcomeres in cross section. He observed that there were two types of filaments, **thin filaments** and **thick filaments**, and that these filaments overlapped in the dark bands but not in the light bands. Huxley and his collaborator Jean Hanson also observed that sarcomeres stripped of their myosin had no dark bands. They concluded that the thick filaments must be composed of myosin, and the thin filaments must be composed of actin.

How did myosin and actin interact to shorten the sarcomere? In 1954, Huxley and Hanson hit on the key insight when they observed how the light and dark bands in sarcomeres changed when the muscles were relaxed versus contracted. Overall, the width of the dark bands did not change during a contraction, but the light bands became narrower.

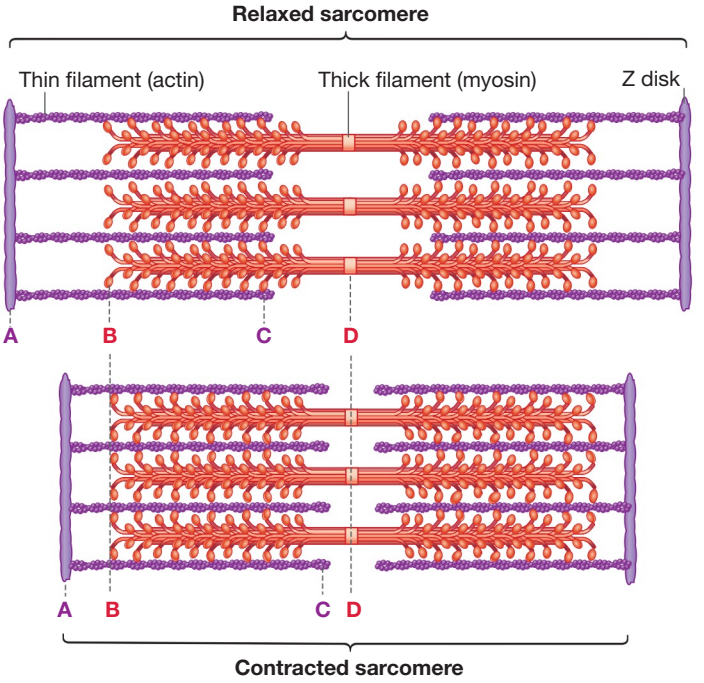

FIGURE 48.2 The Sliding-Filament Model Explains Important Aspects of Sarcomere Contraction. When a sarcomere contracts, the lengths of the thin filaments (distance from A to C) and thick filaments (distance from B to D) do not change. Rather, the filaments slide past one another.

✔**QUESTION** According to the model shown here, why is the dark band in a sarcomere (see Figure 48.1) dark and the light band light?

To explain these observations, Huxley and Hanson proposed the **sliding-filament model** illustrated in **FIGURE 48.2**. The hypothesis was that the filaments slide past one another during a contraction. That is, the sarcomere can shorten with no change in lengths of the thin and thick filaments themselves:

- The distance from point A to point C does not change, and the distance from point B to point D does not change.
- Points A and B move closer to each other during contraction, as do points C and D.

Another pair of researchers, Andrew F. Huxley (no relation to Hugh) and Rolf Niedergerke, published the same result at the same time. Follow-up research has shown that the Huxley–Hanson model is correct in almost every detail.

Structurally, thin filaments are composed of two coiled chains of actin, a common component of the cytoskeleton of eukaryotic cells (see Chapter 7). One end of each thin filament is anchored to a structure called the **Z disc,** which forms the end wall of the sarcomere. The other end of a thin filament is free to interact with thick filaments. Thick filaments are composed of multiple strands of myosin. They span the center of the sarcomere and are free at both ends to interact with thin filaments.

To appreciate how the sliding-filament model works, consider the following analogy: Two large trucks are parked 50 m apart, facing each other. Each has a long rope attached to the front bumper. Six burly weightlifters stand in a line in front of each truck, grab onto the rope, and pull, hand over hand, so that the two trucks roll toward one another. ✔ **If you understand the model, you should be able to explain which elements in the analogy represent the Z discs, which are the thin filaments, and which elements are the thick filaments.**

How Do Actin and Myosin Interact?

How does this sliding action occur at the molecular level? Early work on the three-dimensional structure of myosin revealed that each myosin molecule is made up of a pair of subunits with "tails" coiled around one another and "heads" bent to the side. Each myosin head can bind to actin, and the head region can catalyze the hydrolysis of ATP into adenosine diphosphate (ADP) and a phosphate ion. These results suggested that myosin—not actin—was the site of active movement.

In addition, electron microscopy revealed that myosin and actin are locked together shortly after an animal dies, and its muscles enter the stiff state known as rigor mortis. Because ATP is unavailable in dead tissue, the data suggested that ATP is involved in getting myosin to release from actin once the two molecules have bound to each other.

Later, Ivan Rayment and colleagues solved the detailed three-dimensional structure of the myosin head (**FIGURE 48.3**). Using X-ray crystallographic techniques (see **BioSkills 11** in Appendix B), Rayment's group determined the location of the actin-binding site and examined how myosin's structure

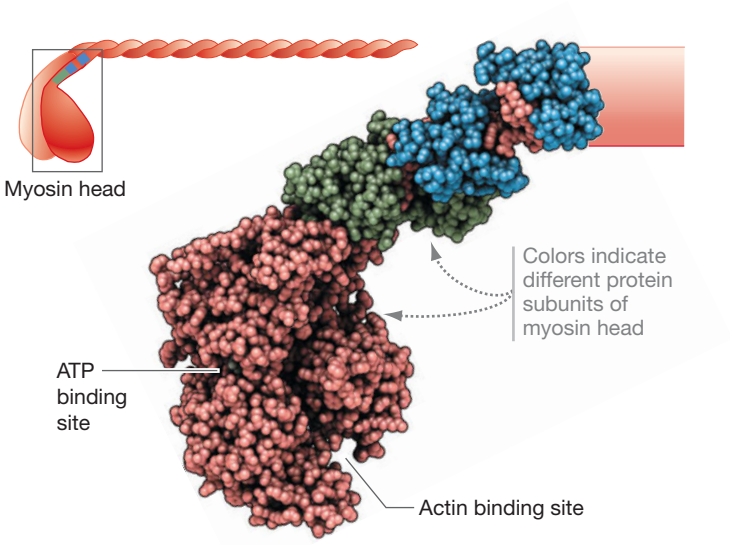

FIGURE 48.3 Myosin's "Head" Binds ATP and Actin. Each myosin molecule consists of two subunits with their tails coiled together and their two heads exposed. The heads contain binding sites for ATP and actin; when one of these subunits binds, its myosin head changes shape.

changed when ATP or ADP bound to it. As predicted, the protein's conformation changed significantly when bound to ATP versus ADP.

Based on these data, Rayment and co-workers proposed a four-step model for actin–myosin interaction (**FIGURE 48.4**):

Step 1 ATP binds to the myosin head, causing a conformational change that releases the head from the actin in the thin filament.

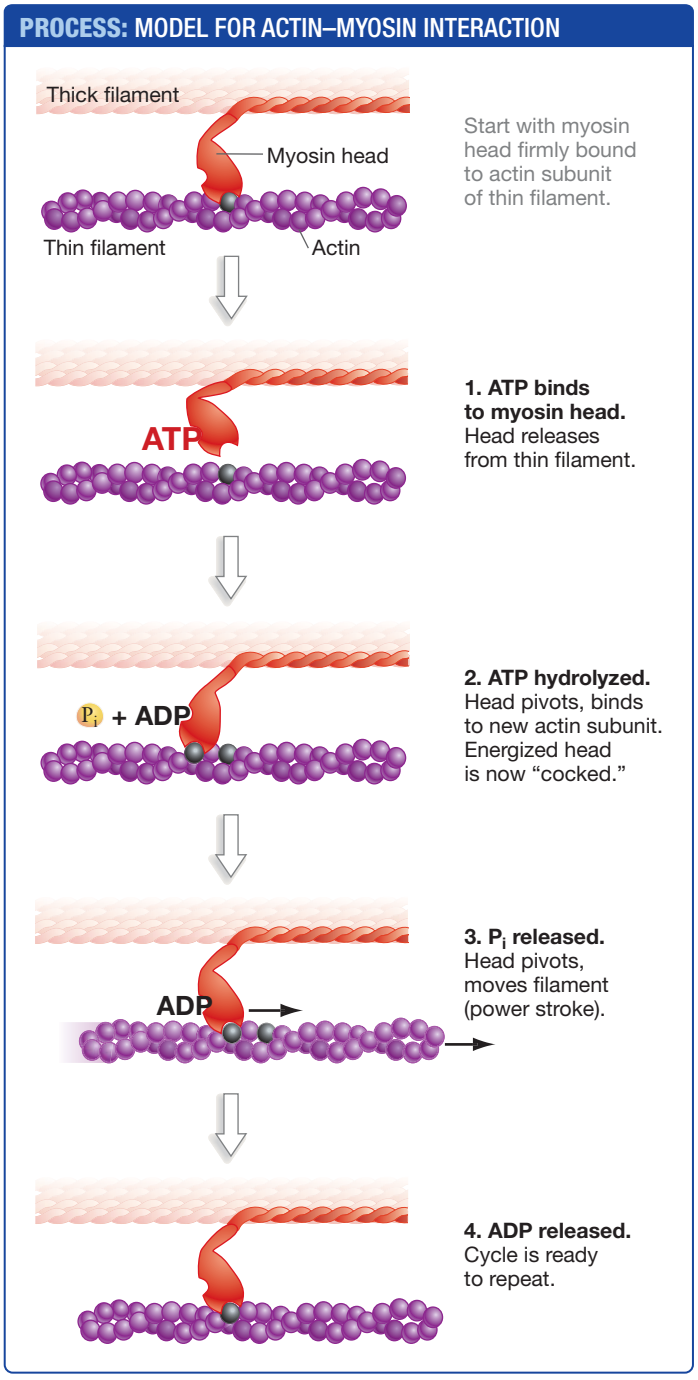
Step 2 When ATP is hydrolyzed to ADP and inorganic phosphate, the neck of the myosin straightens and the head pivots. The myosin head then binds to a new actin subunit farther down the thin filament. In this position, the myosin head is "cocked" in its high-energy state, ready for the power stroke.

Step 3 When inorganic phosphate is released, the neck bends back to its original position. This bending, called the power stroke, moves the entire thin filament relative to the thick filament.

Step 4 After ADP is released, the myosin head is ready to bind to another molecule of ATP.

As ATP binding, hydrolysis, and release continue, the two ends of the sarcomere are pulled closer together. (The transition from step 4 to step 1 cannot occur after death. Rigor mortis sets in as ATP supplies run out.)

The same basic ratcheting mechanism between actin and myosin is responsible for the amoeboid movement observed in amoebae and slime molds (see Chapter 30) as well as the streaming of cytoplasm observed in algae and land plants. Actin and myosin have played a critical role in the diversification of eukaryotes because they make movement possible in the absence of cilia and flagella.



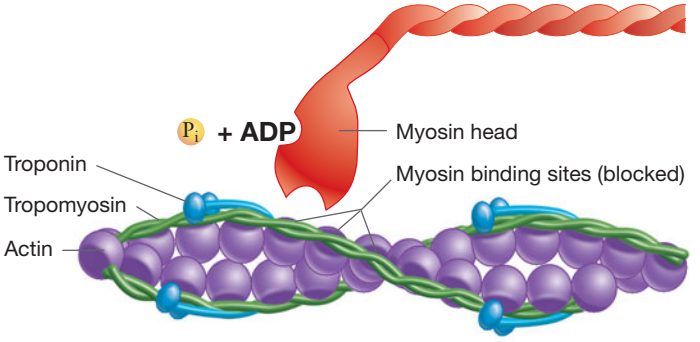


FIGURE 48.4 Myosin and Actin Interact during Muscle Contraction. Summary of the current model of how myosin and actin interact as a sarcomere contracts. The four steps repeat rapidly. (Only one head of the myosin molecule is shown, for simplicity.)

Considering that ATP is almost always available in living muscles, how do muscles ever stop contracting and relax? Besides actin, thin filaments contain two key proteins called **tropomyosin** and **troponin.** Tropomyosin and troponin work together to block the myosin binding sites on actin. The myosin–actin interaction cannot then occur, and thick and thin

(a) Muscle relaxed: Tropomyosin and troponin work together to block the myosin binding sites on actin.

(b) Contraction begins: When a calcium ion binds to troponin, the troponin–tropomyosin complex moves, exposing myosin binding sites.

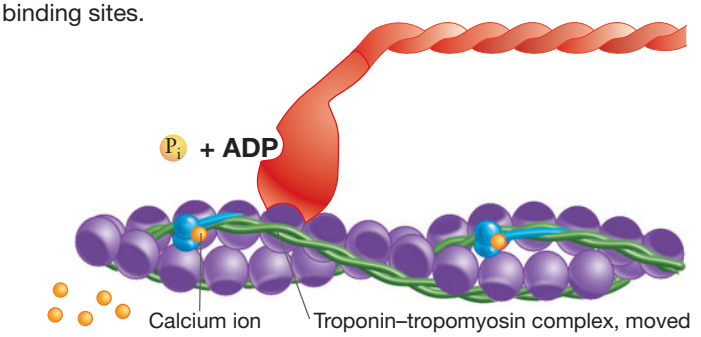

FIGURE 48.5 Troponin and Tropomyosin Regulate Muscle Activity. Note that the myosin head is in its energized state when a muscle is relaxed.

filaments cannot slide past each other. As a result, the muscle relaxes (**FIGURE 48.5a**).

But when calcium ions bind to troponin, the troponin–tropomyosin complex moves in a way that exposes the myosin binding sites on actin. As **FIGURE 48.5b** shows, myosin then binds and contraction can begin.

How are calcium ions released so that contraction can begin? The process begins with the arrival of an action potential—an electrical signal from a motor neuron.

How Do Neurons Initiate Contraction?

You are probably sitting as you read. If so, contract your calf muscles to point your toes. Your nervous system just played a critical role in controlling the timing of your muscle contractions. First, your central nervous system—your brain—received input from an array of sensory cells in your peripheral nervous system, such as the ones in the retina of your eyes as you read this paragraph. Then your brain integrated this information and triggered action potentials in the motor neurons of the peripheral nervous system of your legs. (See Chapter 46 to review the structure and function of the nervous system.)

FIGURE 48.6 summarizes what happens when an action potential from a motor neuron arrives at a muscle cell:

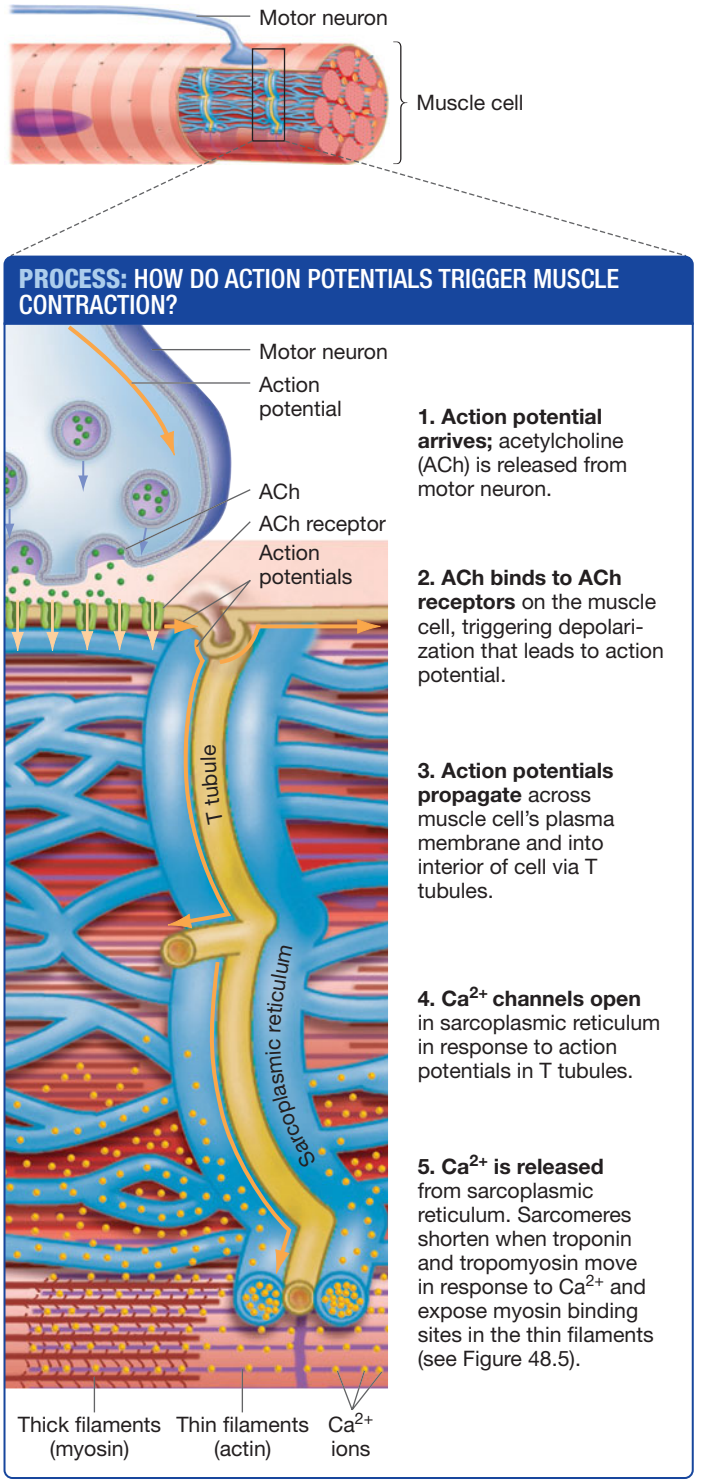

FIGURE 48.6 Action Potentials Trigger Ca^{2+} Release. Action potentials at the neuromuscular junction trigger the release of Ca^{2+}, which binds to troponin–tropomyosin and allows myosin to form a cross-bridge with actin.

1. Action potentials trigger the release of the neurotransmitter **acetylcholine** from the motor neuron into the synaptic cleft between the motor neuron and the muscle cell. (See Figure 46.12 on page 939 for a review of the synaptic cleft.)

2. Acetylcholine diffuses across the synaptic cleft and binds to acetylcholine receptors on the plasma membrane of the muscle cell. By recording voltage changes in muscle cells, biologists showed that a membrane depolarization occurs in response to the binding of acetylcholine. If enough acetylcholine is applied to a muscle cell, depolarization triggers action potentials in the fiber itself.
3. The action potentials propagate along the length of the muscle fiber and spread into the interior of the fiber via invaginations of the muscle cell membrane called **T tubules.** (The T stands for transverse, meaning extending across.)
4. T tubules intersect with extensive sheets of smooth endoplasmic reticulum called the **sarcoplasmic reticulum.** When an action potential passes down a T tubule and reaches one of these intersections, a protein in the T-tubule membrane changes conformation and opens calcium channels in the sarcoplasmic reticulum.
5. Calcium causes the myosin binding sites on the actin filaments to be exposed, enabling the contraction to begin.

By this series of events, the interaction of the nervous system and muscle tissue at the neuromuscular junction precisely regulates muscle contractions—and thus complex movement.

check your understanding

CYU

If you understand that . . .

- Muscles shorten when thick filaments of myosin slide past thin filaments of actin in a series of binding events mediated by the hydrolysis of ATP.
- Muscle cells shorten in response to action potentials, which trigger the release of calcium ions that enable actin and myosin to interact.

✔ You should be able to . . .

1. Describe the sliding-filament model.
2. Predict the effect on muscle function of drugs that have the following actions: increase acetylcholine release at the neuromuscular junction, prevent conformational changes in troponin, and block uptake of calcium ions into the sarcoplasmic reticulum.

Answers are available in Appendix A.

48.2 Muscle Tissues

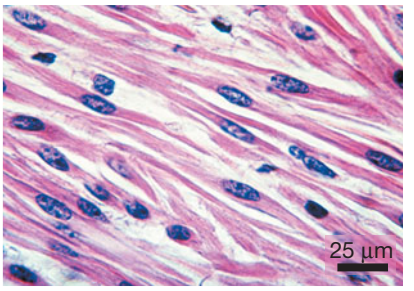
How do muscle cells and muscle tissues vary? After years of careful anatomical study, biologists concluded that animals have three classes of muscle tissue: **(1)** smooth muscle, **(2)** cardiac muscle, and **(3)** skeletal muscle. You, and all other vertebrates, have all three.

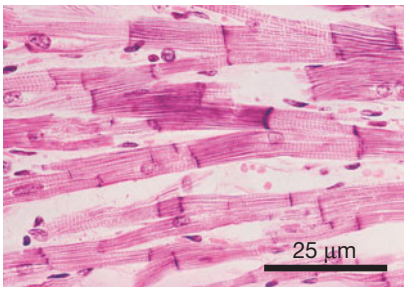
Smooth, cardiac, and skeletal muscle share several properties. They all contract as described by the sliding-filament model, and they all contract in response to electrical stimulation. However, the three classes of muscle also differ in important ways, summarized in **TABLE 48.1** (see page 978):

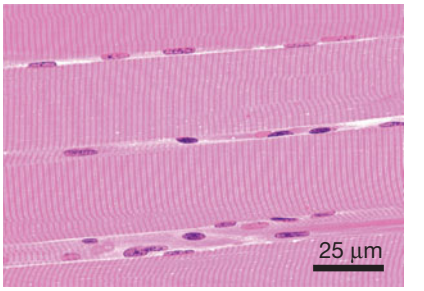
- *Voluntary versus involuntary* **Voluntary muscles** can contract in response to conscious thought (and also by unconscious reflexes) and are stimulated by neurons in the somatic division of the peripheral nervous system. **Involuntary muscles** contract only in response to unconscious electrical activity and are stimulated and inhibited by neurons in the autonomic division of the peripheral nervous system. (See Chapter 46 for a review of the somatic and autonomic divisions of the nervous system.)
- *Multinucleate versus uninucleate* Muscle cells may have one or many nuclei depending on the size of the cells.
- *Striated versus unstriated* In some muscle cells, the actin and myosin filaments are aligned in rows forming sarcomeres, giving the cells and tissues a banded appearance; for this reason, it is often called **striated muscle.** Other muscle cells are unstriated.

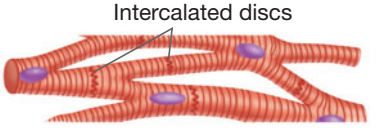
Let's apply these characteristics to each class of muscle tissue in more detail.

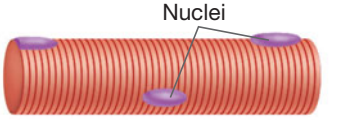
Smooth Muscle











Smooth muscle cells are unbranched, tapered at each end, and often organized into thin sheets. They lack the sarcomeres that are found in skeletal and cardiac muscle; hence, they are unstriated and appear smooth. Smooth muscle cells are relatively small and have a single nucleus.

Smooth muscle is essential to the function of the lungs, blood vessels, digestive system, urinary bladder, and reproductive system. Bronchioles in the lungs have a layer of smooth muscle that controls the size of airways; similarly, smooth muscles in the blood vessels can contract or relax to alter blood-flow patterns and blood pressure (Chapter 45). Layers of smooth muscle in the gastrointestinal tract help mix and move food (Chapter 44), and uterine smooth muscle is responsible for expelling the fetus during birth (see Chapter 50).

Smooth muscle is innervated by autonomic motor neurons, and it is thus involuntary. Acetylcholine from parasympathetic ("rest-and-digest") neurons aids digestion by stimulating contraction of smooth muscle in the stomach and intestine (Chapter 46).

In contrast, sympathetic ("fight-or-flight") neurons release the neurotransmitter **norepinephrine;** and the adrenal glands adjacent to the kidneys release the hormone **epinephrine,** also called **adrenaline** (see Chapter 49). Norepinephrine and epinephrine have the opposite effect to that of acetylcholine: they inhibit contraction of muscle in the stomach and intestine. Different smooth muscles are stimulated or inhibited by autonomic motor neurons depending on the type of neurotransmitter and neuron receptors they have.

SUMMARY TABLE 48.1 Classes of Muscle in Vertebrates

	Smooth Muscle	Cardiac Muscle	Skeletal Muscle
			
Location	Intestines, arteries, other	Heart	Attached to the skeleton
Function	Move food, help regulate blood pressure, etc.	Pump blood	Move skeleton
Cell characteristics			
	Single nucleus	1 or 2 nuclei	Multinucleate
	Unstriated	Striated	Striated
	Unbranched	Branched; intercalated discs form direct cytoplasmic connection end to end	Unbranched
	No sarcomeres	Contains sarcomeres	Contains sarcomeres
	Activity is "involuntary," meaning that signal from motor neuron is not required	Activity is "involuntary," meaning that signal from motor neuron is not required	Activity is "voluntary," meaning that signal from somatic motor neuron is required

Cardiac Muscle

Cardiac muscle makes up the walls of the heart and is responsible for pumping blood throughout the body. Unlike smooth muscle, cardiac muscle cells contain sarcomeres and are striated. Further, cardiac muscle cells have a unique branched structure, and they are directly connected end-to-end via specialized regions called intercalated discs. These discs are critical to the flow of electrical signals from cell to cell and thus to the coordination of the heartbeat (Chapter 45).

Like smooth muscle, cardiac muscle is involuntary—it contracts following spontaneous depolarizations. During rest, parasympathetic neurons release acetylcholine onto the heart. This neurotransmitter slows down the rate of depolarization of cardiac cells. The result is a slower heart rate.

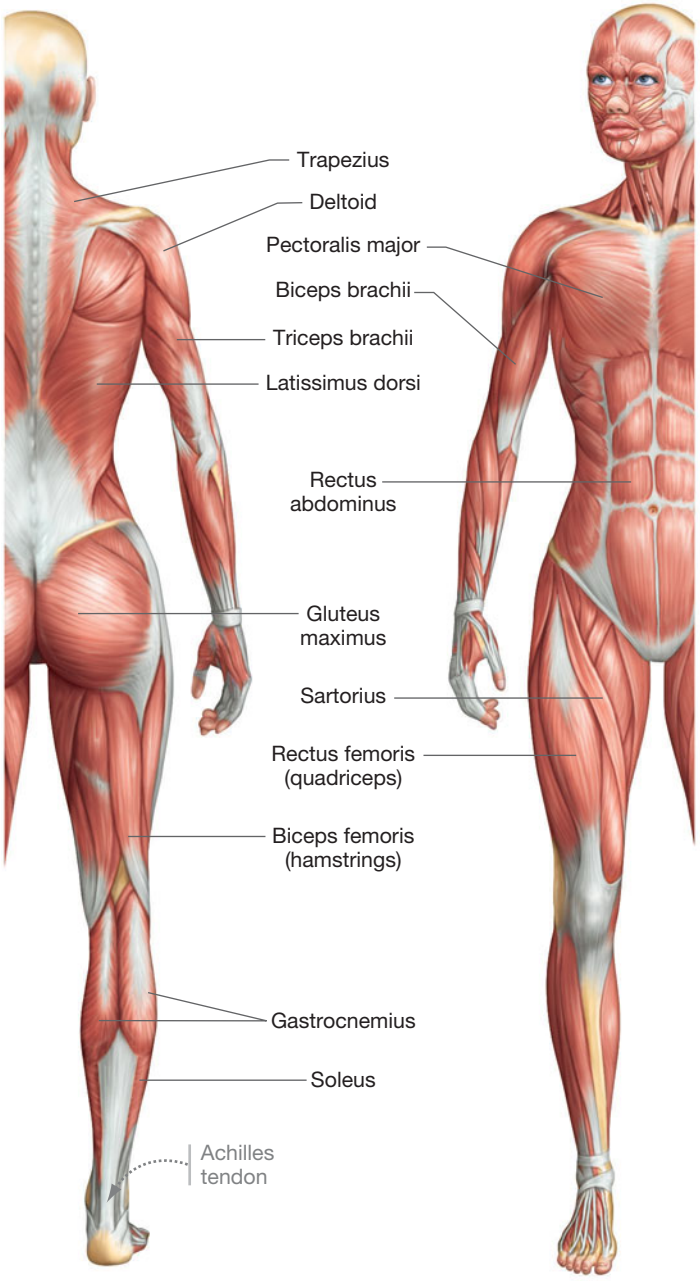
During exercise, or when an animal is frightened, stressed, or otherwise stimulated, sympathetic neurons release norepinephrine onto the heart, and the adrenal gland releases epinephrine. Norepinephrine and epinephrine have an opposite effect to that of acetylcholine: they increase heart rate and strengthen the force of cardiac muscle contraction. The result is that more blood is pumped from the heart—an essential component of the fight-or-flight response of the sympathetic nervous system (Chapter 46).

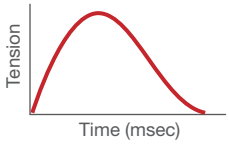
Skeletal Muscle

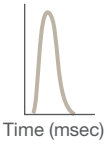
Skeletal muscle consists of exceptionally long, unbranched muscle fibers. For example, a muscle fiber of a cat may be 0.4 mm wide and 40 mm long—enormous compared to most cells. These large cells result from the fusion of many smaller embryonic cells during development, accounting for the multiple nuclei spread out along the cell. Each muscle fiber is packed with myofibrils, each of which may contain thousands of sarcomeres, giving skeletal muscle its striated appearance.

Skeletal muscle is so named because it usually attaches to the skeleton. When skeletal muscle contracts, it exerts a pulling force on the skeleton, causing it to move—powering the sprint of cheetahs, the flight of hummingbirds, and the pinch of crab claws. In addition, skeletal muscle encircles the openings of the digestive and urinary tracts and controls swallowing, defecation, and urination.

A significant fraction of the body of many animals is composed of skeletal muscle. For example, 63 percent of the body weight of trout is skeletal muscle, and mammals—including humans—of all sizes are 40 to 45 percent muscle. Clearly, skeletal muscle plays an important role in animal biology. Some of the major skeletal muscles in the human body are shown in **FIGURE 48.7**.







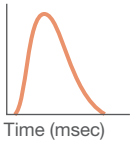


FIGURE 48.7 Major Skeletal Muscles Make Up a Large Portion of the Human Body.

Skeletal muscle is distinguished from cardiac and smooth muscle in being voluntary. Skeletal muscle must be stimulated by somatic motor neurons to contract (Chapter 46). If these motor neurons are damaged, as can occur with a spinal cord injury, skeletal muscle cannot contract and becomes paralyzed.

Although all muscles contract as described by the sliding-filament model, not all skeletal-muscle fibers have the same contractile properties. The force output of skeletal muscles depends on **(1)** the relative proportion of different fiber types, **(2)** the organization of fibers within the muscle, and **(3)** how the muscle is used. Let's take a closer look at these sources of variation in muscle performance.

SUMMARY TABLE 48.2 Skeletal-Fiber Types

Slow fiber	Fast fiber	Intermediate fiber
Red	White	Pink or red
High myoglobin concentration	Low myoglobin concentration	High myoglobin concentration
Derive most ATP via aerobic respiration (slow oxidative)	Derive most ATP via glycolysis (fast glycolytic)	Derive ATP from glycolysis and aerobic respiration (slow glycolytic)
Many mitochondria	Few mitochondria	Many mitochondria
Slow twitch 	Fast twitch 	Intermediate twitch 
Fatigues slowly	Fatigues quickly	Intermediate fatigue

Skeletal-Fiber Types Skeletal muscle fibers can be divided into general types based on their structural and functional characteristics, summarized in **TABLE 48.2**:

- **Slow muscle fibers** (slow oxidative fibers) appear red because they contain a high concentration of myoglobin, an iron-bearing pigment that carries oxygen (similar to but distinct from hemoglobin in the blood). Slow fibers contract slowly because the myosin hydrolyzes ATP at a slow rate. They also fatigue slowly because they have many mitochondria and can generate steady quantities of ATP using oxidative phosphorylation—that is, aerobic respiration (Chapter 9)—thanks to the plentiful supply of oxygen delivered by myoglobin.
- **Fast muscle fibers** (fast glycolytic fibers) appear white because they have a low myoglobin concentration. They contract rapidly because the myosin hydrolyzes ATP at a rapid rate, but they also fatigue rapidly because their primary source of ATP is glycolysis rather than aerobic respiration.
- **Intermediate muscle fibers** (fast oxidative fibers) appear pink or red. Their contractile properties vary but are intermediate between slow and fast fibers because they derive ATP from both glycolysis and aerobic respiration.

The different fiber types are present in all skeletal muscles, but their relative abundances differ from muscle to muscle. Slow

fibers are abundant in muscles specialized for endurance—such as the leg muscles of birds that excel at swimming or walking (the "dark meat" of chicken legs). In humans, the soleus muscle in the back of the calf is an example of a muscle with a high proportion of slow fibers—it helps to keep you upright when you stand.

Fast fibers contract and relax up to three times faster than slow fibers, making them well suited for bursts of activity. The "white meat" of chicken breasts, specialized only for quick bursts of flight to escape predators, are made primarily of fast fibers. The muscles that control your eye movements are another example.

✔If you understand muscle fiber types, you should be able to predict whether the breast meat of pigeons (which are capable of prolonged flights) is composed of dark meat or white meat and explain why there is a color difference between these muscle types.

Can humans change their fiber types through training? Experiments have shown that endurance training can increase the density of blood vessels, mitochondria, and myoglobin in muscle fibers, enabling athletes to improve their muscle performance. However, training does not change slow fibers to fast fibers, nor the reverse. The ratio of muscle-fiber types in muscles is heritable—that is, genetically determined.

Skeletal-Fiber Organization The force of a muscle is proportional to the cross-sectional area of the muscle—the number of sarcomeres lined up side by side exerting a pull in synchrony. By contrast, the length change of the muscle is determined by the length of the muscle fibers—how many sarcomeres are lined up in a row in each fiber. Thus, the arrangement of muscle fibers within a muscle influences the contractile properties of the muscle.

For a given muscle volume, some muscles are organized to maximize length change, because the fibers are parallel to each other in long bands (**FIGURE 48.8**, left)—the longer the chain of sarcomeres in series in the myofibril, the greater the length change. The sartorius muscle in the human thigh has parallel fibers.

Other muscles are organized to maximize force, because the fibers are in a diagonal, or pennate, pattern (penna means feather; **FIGURE 48.8**, right)—the greater the number of sarcomeres pulling in parallel, the greater the force produced. The gastrocnemius muscle in the human calf is a pennate muscle.

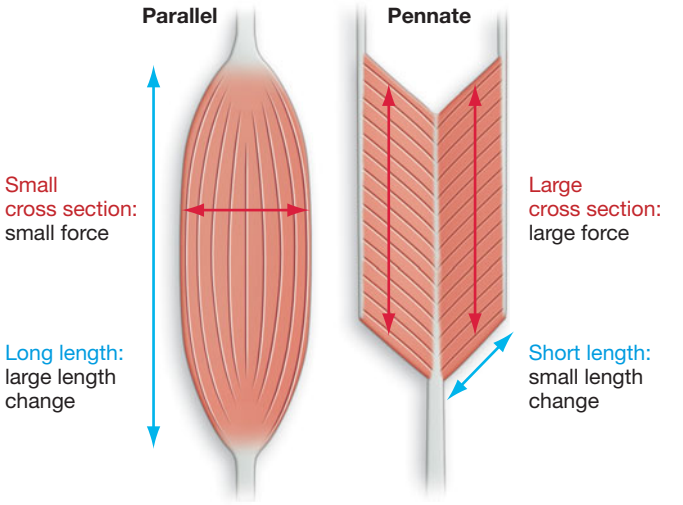

FIGURE 48.8 Muscle-Fiber Patterns Affect Contractile Properties. Most muscles have fibers arranged in either a parallel or pennate pattern. The orientation of muscle fibers affects the contractile properties of the muscle.

Context of Muscle Contraction The relative abundances of fiber types and organization of muscle fibers are not sufficient to account for the diversity of muscle contraction properties of skeletal muscles. Muscle tension also varies according to how extended the muscle is when it contracts and how rapidly it is allowed to shorten—if at all. Muscles like the quadriceps in your thigh can even exert a force while they are lengthening, such as when you ease your weight down a step.

These circumstances depend on the interaction between the muscle and the skeleton. Let's take a closer look at how the muscle and skeletal systems interact to produce movement.

48.3 Skeletal Systems

All a muscle can do is pull. How can complex movements be accomplished using an engine that can only pull? Also, muscles are limited in how much they can shorten. How, then, can they cause dramatic shape changes in animal bodies?

Muscle forces and shape changes are transmitted to other parts of the body and to the environment via the skeleton. Skeletal systems perform four main functions:

1. ***Protection*** from physical and biological assaults.
2. ***Maintenance of body posture*** despite the downward pull of gravity and the vagaries of wind and waves.
3. ***Re-extension of shortened muscles*** If no mechanism of re-extension existed, muscles would shorten only once.
4. ***Transfer of muscle forces*** to other parts of the body and to the environment, enabling a much greater range of force production and shape change than can be accomplished by muscle alone.

The relative importance of these roles varies among animals according to their lifestyles and environments. For example, natural selection has favored turtles with robust shells in some environments—a skeletal adaptation for protection. In other environments, natural selection has favored highly reduced shells—an adaptation for rapid locomotion. There are trade-offs between protection and mobility (see Chapter 25).

Despite the stunning diversity in animal bodies, virtually all animals can be considered to have one (or more) of three types of skeletal systems:

1. Hydrostatic skeletons use the hydrostatic pressure of enclosed body fluids or soft tissues to support the body.
2. Endoskeletons have rigid structures inside the body.
3. Exoskeletons have rigid structures on the outside of the body.

Let's consider how each skeletal system transmits muscle forces and shape changes.

Hydrostatic Skeletons

Despite their squishy appearance, soft-bodied animals do have skeletons—hydrostatic skeletons. First let's look at how they are built, and then consider how they function.

Structure **Hydrostatic skeletons** ("still-water skeletons"), or hydrostats, are constructed of an extensible body wall in tension surrounding a fluid or deformable tissue under compression. When fluid is under compression, its pressure increases. The pressurized internal fluid, rather than a rigid structure, enables soft-bodied animals to maintain posture, re-extend muscles, and transfer muscle forces to the environment.

Hydrostatic skeletons occur in diverse animals, from sea anemones and jellyfish to mollusks and many types of worms (Chapter 34). Hydrostats also support *parts* of animals, such as the tongues and penises of humans and the tube feet of echinoderms (see Chapter 35).

The structures of hydrostatic skeletons are diverse as well. The body wall of hydrostats may include different numbers and orientations of muscle layers and fiber-reinforced cuticles or connective tissues. The interior may include seawater, coelomic fluid, blood, or soft organs such as intestines. Hydrostatic skeletons composed mostly of muscle, such as tongues and tentacles, are called muscular hydrostats (Chapter 34).

Function How do animals with hydrostatic skeletons move? Consider an earthworm. Its body wall consists of a cuticle reinforced with collagen fibers as well as two layers of muscle—longitudinal muscles, oriented along the length of the animal, and circumferential muscles, oriented in bands around each segment. When the circumferential muscles contract, they make the segments narrower and squeeze the internal coelomic fluid and tissue, thus increasing internal pressure. The pressure pushes outward in all directions, extending the relaxed longitudinal muscles, lengthening the segment (**FIGURE 48.9**).

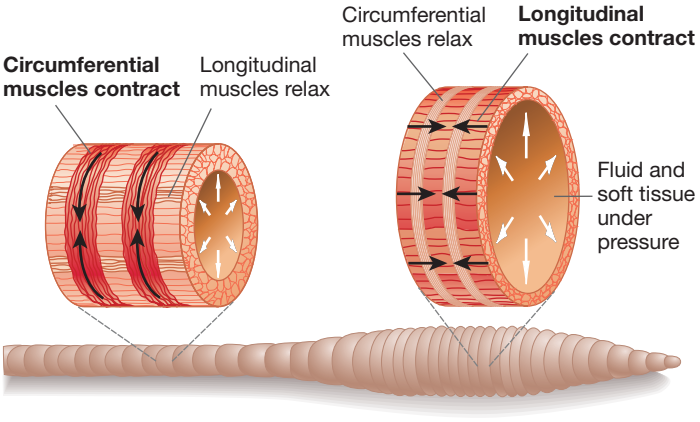

FIGURE 48.9 Antagonistic Muscle Groups Cause Shape Changes in Hydrostatic Skeletons. The pressure of the internal fluid or tissue transmits forces between muscle groups and between muscles and the environment.

When the longitudinal muscles contract and the circumferential muscles relax, the reverse occurs—the segments become wider and shorter, pushing sideways against the soil. Alternating contractions of longitudinal and circumferential muscles pass down the earthworm in waves, called **peristalsis.** In this way, earthworms move forward (or backward) within their underground burrows.

Longitudinal and circumferential muscles in earthworms make up an **antagonistic muscle group,** a group of two or more muscles that re-extend one another via the skeleton.

✔ **If you understand how a hydrostatic skeleton works, you should be able to explain how earthworms can push laterally against the walls of their burrows despite having muscles that can only pull.**

Endoskeletons

Even though parts of you, like your tongue, are supported by a hydrostatic skeleton, your endoskeleton is what keeps you standing up and on the move.

Structure **Endoskeletons** ("inside skeletons") are rigid structures that occur within the body. Even the most ancient of animal lineages, the sponges, secrete spicules—stiff spikes of silica or calcium carbonate ($CaCO_3$)—that provide structural support for the body. In echinoderms, the endoskeleton consists of calcium carbonate plates just beneath the skin—fused into a rigid case in sea urchins, but suspended in a flexible matrix that enables bending of the arms in sea stars.

The vertebrate endoskeleton differs from those of most sponges and echinoderms—and from hydrostatic skeletons—in that it is composed of rigid levers (the bones) separated by joints. Vertebrates change the shapes of their bodies largely by changing the *joint angles* between bones in the limbs and between the limbs and the body, rather than changing the shapes of body segments themselves.

Vertebrate skeletons are composed of four main elements:

1. **Bones** are made up of cells in a hard extracellular matrix of calcium phosphate ($CaPO_4$) with small amounts of calcium carbonate and protein fibers. The adult human body contains 206 bones (**FIGURE 48.10a**, see page 982). The meeting places where adjacent bones interact are called **articulations,** or **joints.** Bones articulate in ways that limit the range of motion, for example enabling a swivel in the shoulder joint but a hinge in the elbow joint (**FIGURE 48.10b**).
2. **Cartilage** is made up of cells scattered in a gelatinous matrix of polysaccharides and protein fibers. Cartilage can be quite rigid, such as in the clam-crushing jaws of some stingrays, or more rubbery, such as in the pads that cushion the joints in your knees and back.
3. **Tendons** are bands of fibrous connective tissue, primarily collagen, that connect skeletal muscles to bones. The ropelike structure of tendons transmits muscle forces to precise locations on the bones, sometimes quite a distance away from the muscle itself.

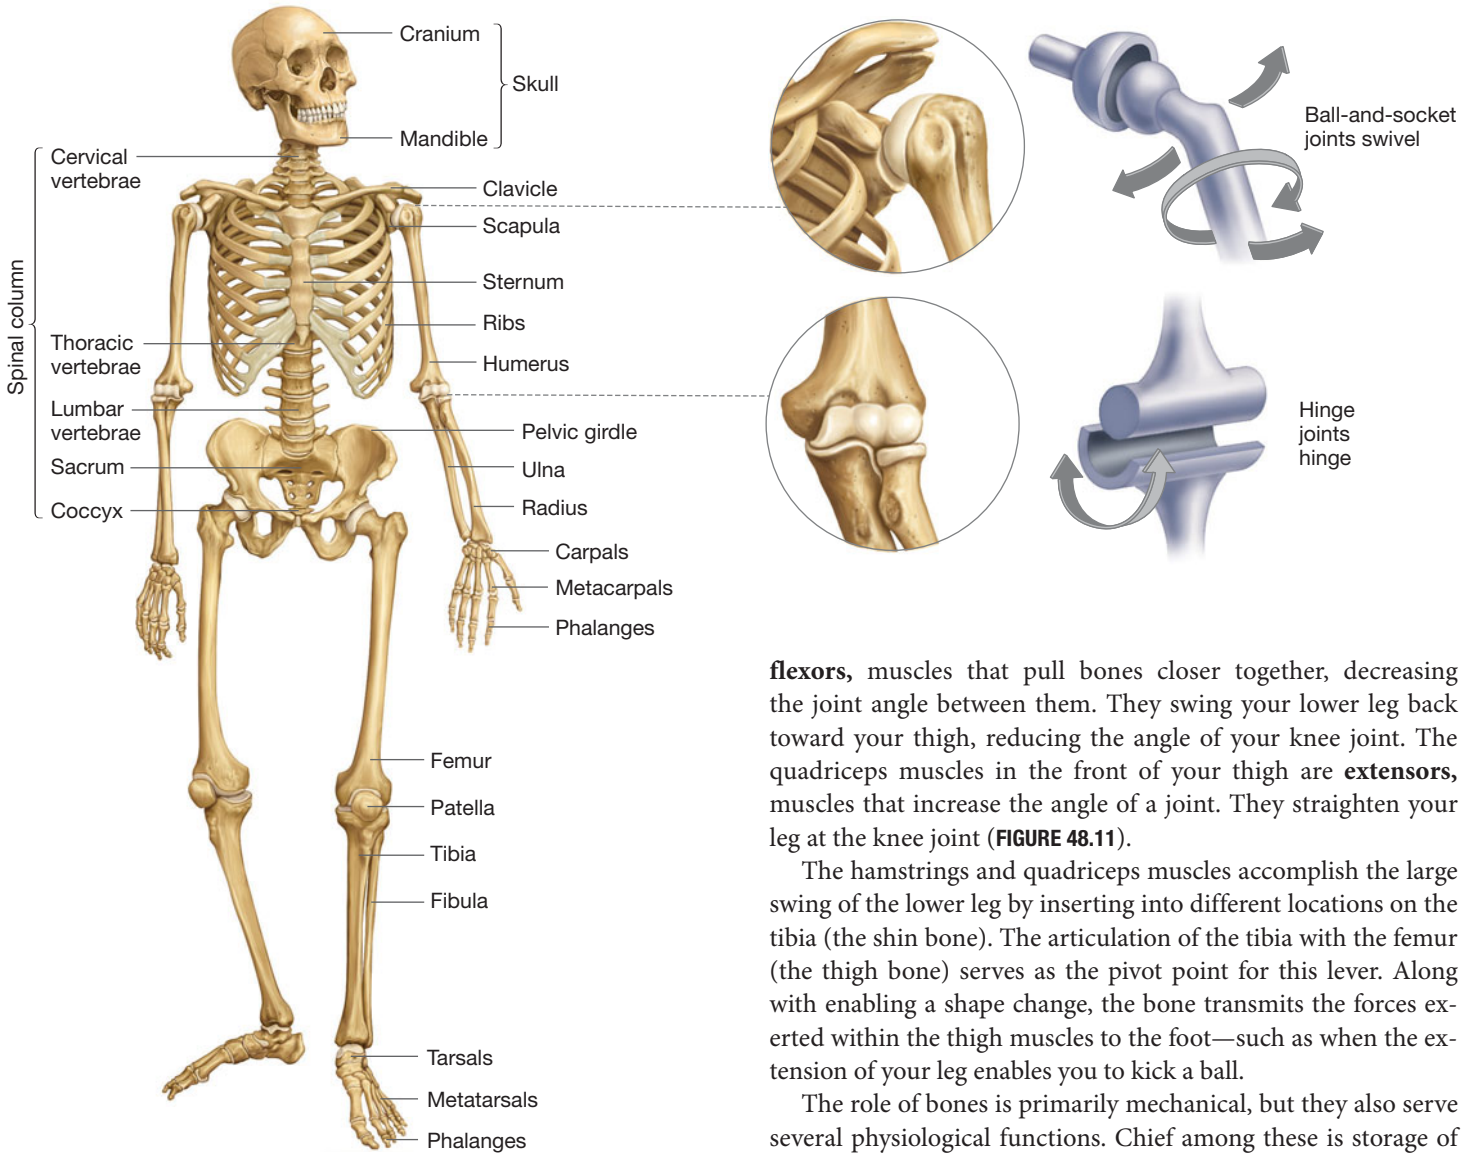

FIGURE 48.10 Bones of the Human Endoskeleton. Since bones are rigid and cannot change shape themselves, they articulate at joints that make specific types of movement possible, such as the swiveling and hinging shown here.

4. **Ligaments** are bands of fibrous connective tissue, primarily collagen, that bind bones to other bones. Ligaments stabilize the joints.

Function Bones and cartilages are structures that do a good job of resisting compression (pushing) and bending, whereas tendons and ligaments do a good job of resisting tension (pulling). These structures combine with muscle in ways that enable the efficient transmission of muscle forces and shape changes.

Vertebrate skeletons move by means of changes in joint angles controlled by antagonistic muscle groups. For example, consider how your thigh muscles flex and extend your knee joint. The hamstring muscles in the back of your thigh are **flexors,** muscles that pull bones closer together, decreasing the joint angle between them. They swing your lower leg back toward your thigh, reducing the angle of your knee joint. The quadriceps muscles in the front of your thigh are **extensors,** muscles that increase the angle of a joint. They straighten your leg at the knee joint (**FIGURE 48.11**).

The hamstrings and quadriceps muscles accomplish the large swing of the lower leg by inserting into different locations on the tibia (the shin bone). The articulation of the tibia with the femur (the thigh bone) serves as the pivot point for this lever. Along with enabling a shape change, the bone transmits the forces exerted within the thigh muscles to the foot—such as when the extension of your leg enables you to kick a ball.

The role of bones is primarily mechanical, but they also serve several physiological functions. Chief among these is storage of calcium and other minerals. When blood calcium falls to low levels, the bones release calcium to maintain blood–calcium homeostasis. The interior of long bones, called bone marrow, is also

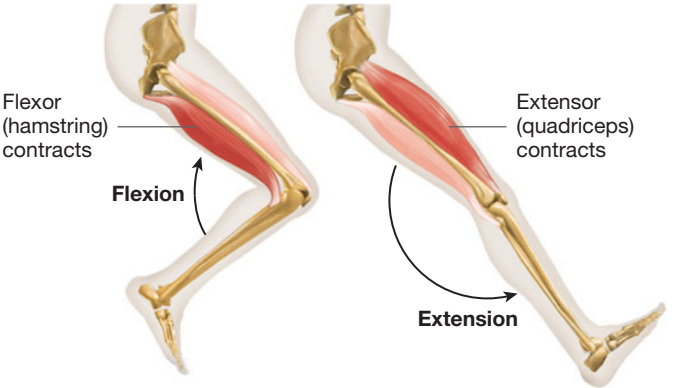

FIGURE 48.11 Endoskeletons Move by Contraction and Relaxation of Flexor and Extensor Muscles.

the source of red blood cells needed to carry oxygen in the blood (Chapter 45) and white blood cells needed for the immune system (Chapter 51).

Exoskeletons

The mechanical function of rigid cuticle in exoskeletons is similar in many ways to that of endoskeletons. Exoskeletons occur primarily in arthropod animals, including insects, crustaceans, and arachnids (spiders, ticks, scorpions).

Structure An **exoskeleton** ("outside skeleton") is an exterior skeleton that encloses and protects an animal's body. The origin of the exoskeleton was a key innovation that preceded the spectacular diversification of arthropods. Arthropods, especially insects, are the most diverse and abundant animals on Earth (Chapter 34).

The material composition of exoskeletons varies. Insect exoskeletons consist of a cuticle formed from a composite of proteins and the polysaccharide chitin (Chapter 43). Chitinous ingrowths of the skeleton form **apodemes,** where muscles attach. Crustaceans such as crabs and lobsters have a cuticle that is mineralized with calcium carbonate, making their shells relatively thick and hard—and heavy. Most crustaceans are marine, so their buoyancy in water helps support their weight.

Function Like vertebrates, arthropods have paired flexor–extensor muscles that operate their jointed skeletons, causing movements that are based on changes in joint angles rather than changes in the dimensions of the segments themselves (**FIGURE 48.12**). Unlike vertebrates, however the muscles of arthropods must be packed *within* the skeletal tubes.

One solution to the problem of the interior placement of muscles is that many arthropod muscles have the pennate, or feather-like arrangement of muscle fibers illustrated in Figure 48.8. This arrangement boosts force output by effectively increasing the muscle cross-sectional area but not the muscle width during a contraction.

The disadvantage of pennate muscles is that their length change is small, so they have limited range of motion. Arthropods compensate for this constraint in part by the placement of their apodemes, which can transduce a small shortening of a muscle into a large change in joint angle.

The rigid levers of vertebrate skeletons can grow continuously as the rest of the body grows. But since the rigid exoskeletons of arthropods encase the growing soft tissue like a suit of armor, they must be shed—molted—periodically and replaced with a bigger one. Arthropods are vulnerable to predation during molts because their skeleton is soft and dysfunctional at that time (Chapter 34).

Hydrostatic skeletons, endoskeletons, and exoskeletons all transmit muscle forces and shape changes to other parts of the body and to the environment. While hydrostatic skeletons are the most widespread in terms of the number of animal phyla that contain species with skeletons of this type (virtually all—even arthropods, echinoderms, and vertebrates), the lever-based, segmented, jointed skeletons of arthropods and vertebrates win the prize for overall functional diversity (Chapters 34 and 35).

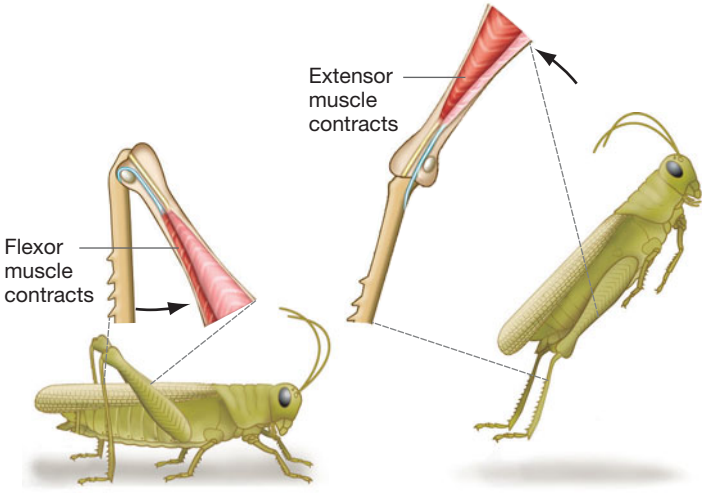

FIGURE 48.12 Exoskeletons Move by Contraction and Relaxation of Flexor and Extensor Muscles.

check your understanding

If you understand that . . .

- Hydrostatic skeletons, endoskeletons, and exoskeletons transmit muscle forces and shape changes to other parts of the animal and to the environment.
- Antagonistic muscles re-extend one another via the skeleton.
- In contrast to hydrostatic skeletons, shape changes in endoskeletons and exoskeletons involve changes in angles between rigid segments rather than in the segments themselves.

✔ You should be able to . . .

1. Compare and contrast the structure and function of hydrostatic skeletons, endoskeletons, and exoskeletons.
2. Predict what would happen if neurons simultaneously stimulated the biceps and triceps muscles to contract.

Answers are available in Appendix A.

48.4 Locomotion

The most spectacular capability conferred on animals by the combination of muscle contractions and skeletal systems is efficient locomotion. Animals locomote to seek food, water, mates, and shelter, and to avoid predators. In the process, some animals

migrate thousands of miles per year, and others perform astonishing feats of acrobatics. Locomotion has been shaped by natural selection and has been central to complex ecological relationships since the radiation of animals during the Cambrian Explosion more than 500 million years ago (Chapter 33).

Many of the diverse modes of locomotion are already familiar to you. Here are some examples.

- ***On land*** Crawling, walking, running, climbing, hopping, jumping, burrowing
- ***In water*** Undulating, jetting, swimming, rowing
- ***In air*** Flying, gliding

What variables do biologists analyze to unlock the secrets of animal locomotion?

How Do Biologists Study Locomotion?

Experimental studies on locomotion have increased exponentially in recent years, partly due to the conceptual breakthrough offered by the field of biomechanics—applying the principles of engineering to quantify the mechanics of organisms. Biomechanics studies the physical act of locomotion at different levels, including

- material properties
- structures
- motions
- forces
- energetics
- ecology and evolution

Let's examine each of these levels, starting with materials.

How Are the Material Properties of Tissues Important to Locomotion? Because the active contractile properties of skeletal muscle are central to understanding the generation of forces in locomotion, a great deal of research has been devoted to analyzing the contractile properties of muscle, introduced in Section 48.1. However, the passive material properties of the skeletal elements are also essential to understanding the transmission of forces.

Consider how you move. A pioneer of biomechanics, R. McNeill Alexander, observed that the movement and energy exchange of the center of mass of a person walking is mechanically similar to that of an upside-down pendulum, whereas running is mechanically similar to a bouncing ball. Based on this insight, Alexander hypothesized that the large tendons of the lower legs of terrestrial animals—for example, the Achilles tendon at the back of your ankle (see Figure 48.7)—work as springs when animals run.

To test this hypothesis, Alexander measured the elastic properties of tendon by clamping a piece of tendon in an engineering device that measures the pulling force of the tissue as it is stretched to different lengths and released. The tendon returned 93 percent of the energy invested, losing only 7 percent to heat. This high rate of elastic-energy storage explains how tendons add a spring to the steps of runners, reducing the amount of muscle-generated power that must be generated from step to step.

The importance of the material properties of muscles and skeletal tissues is most obvious when they fail, whether in subtle or catastrophic ways. You may have firsthand experience with the debilitating consequences of broken bones or strained tendons.

How Is Musculoskeletal Structure Adapted for Locomotion? Many biologists begin their study of locomotion by examining the size and shape of the skeletal elements. Careful measurements of skeleton geometries can reveal a great deal about the posture of the organism, range of motion of joints, and skeletal function in general. For example, a team of biologists recently used structural analysis to test the hypothesis that an early tetrapod amphibian, called *Ichthyostega,* could walk on all four limbs like today's salamanders (see **FIGURE 48.13**).

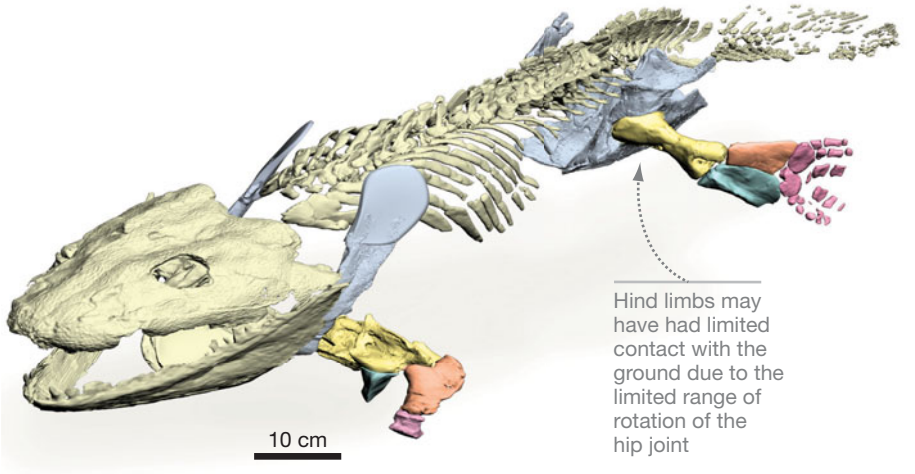

FIGURE 48.13 The Relationship between Structure and Function Can Be Studied Using Computer Models. This computer image of an early tetrapod, *Ichthyostega,* was built using high-resolution scans of fossil bones. The 3D model measures the range of rotation of the major limb joints based on skeleton geometry, determining the overall range of motion of the limbs. The model found that the range of rotation of the shoulder and hip joints was more limited than previously thought, rejecting the hypothesis that these animals could walk on all fours.

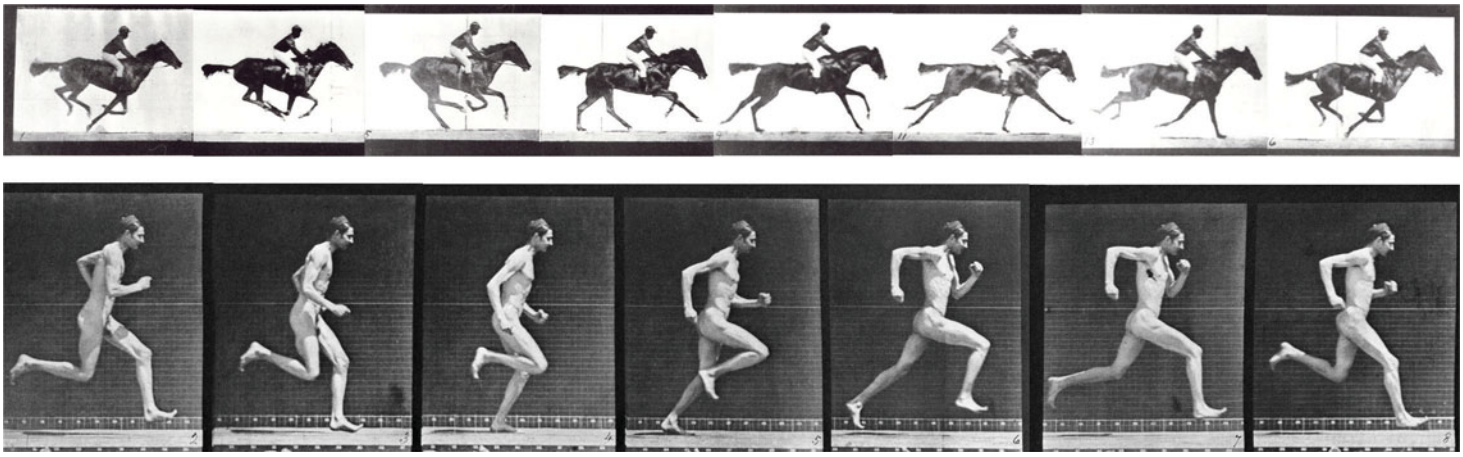

FIGURE 48.14 The Motions of Locomotion Can Be Captured on Film. Eadweard Muybridge shot many photo series of animals during locomotion to enable precise analysis of limb and body motions over time.

Similar mechanical principles can be applied to relate the shapes of wings to flying ability, and the shapes of aquatic animals to their ability to swim through water. Sometimes, however, you just have to watch the action itself to understand how an animal uses its body to locomote.

What Does Locomotion Look Like in Living Animals? All the motions of different parts of the skeleton, such as the angular rotation of limbs and the pattern of footfall on the ground, together produce locomotion.

Photographer Eadweard Muybridge is famous for his pioneering photo sequences of locomotion. His work with animals reportedly began when he was commissioned by a racehorse owner to settle a wager on whether horses are ever completely airborne during a gallop. His results are shown in the top sequence of **FIGURE 48.14**. High-speed video and digital images of many other animals have since been recorded, providing insights into many forms of locomotion, such as

- The gait of human sprinters (Figure 48.14, bottom)
- The complex wing-beat patterns of hovering bees and hummingbirds
- The upright, bipedal (two-footed) gait of basilisk lizards running across the surface of water (see chapter opening image)
- The footfall pattern that prevents centipedes from tripping on their own legs
- The aerial undulating of snakes that glide down from treetops
- The limb-like use of fins in lungfish "walking"
- Peristalsis in the muscular feet of crawling snails

For most animals, the pattern of movement during locomotion varies with speed. For example, horses walk at slow speeds, trot at intermediate speeds, and gallop at fast speeds—each gait has a distinct pattern of leg motions.

Computers facilitate the analysis of the many images captured in motion studies. The results are themselves insightful, but they also serve as an important stepping-stone to understanding the forces involved in locomotion.

What Forces Are Involved in Locomotion? If an animal wants to move forward, it must push something backward, as predicted by Newton's third law of motion. Otherwise, the animal could move but not get anywhere, like a person with smooth shoes on slick ice. The types of forces that are important to locomotion vary according to whether the animal is locomoting on land, in water, in air, or some combination of the three.

On land, gravitational forces and inertial forces dominate. The gravitational force experienced by an animal is its weight, which is the product of its mass and the acceleration due to gravity (9.8 m/sec^2 on Earth). Weight is important on land because most terrestrial animals must hold themselves up to move forward. Inertial forces are proportional to mass and velocity, and they represent resistance of bodies and limbs to acceleration and deceleration. Note in the horse and human photo sequences in Figure 48.14 that the arms and legs must swing back and forth dramatically—an energy-intensive process of acceleration and deceleration.

In water, gravitational forces are less important than on land, due to the counteracting buoyant forces supporting the animal's weight in water. However, aquatic animals must overcome drag, the force that resists forward motion through fluids. Convergent evolution of torpedo-shaped bodies has occurred in diverse aquatic animals, from tuna to dolphins and ichthyosaurs, due to the strong selection for bodies that minimize drag during rapid locomotion (Chapter 28). Aquatic animals that move more slowly face less drag and thus are morphologically more diverse.

Water and air are both fluids, but air is a thousand times less dense than water. Buoyant forces are therefore negligible in air, making gravitational forces very important to fliers—most animals that locomote by flying or gliding have adaptations that make them lightweight. They must produce a force called lift to counteract gravity, and they must also minimize drag. As a result, fast fliers tend to have very streamlined shapes.

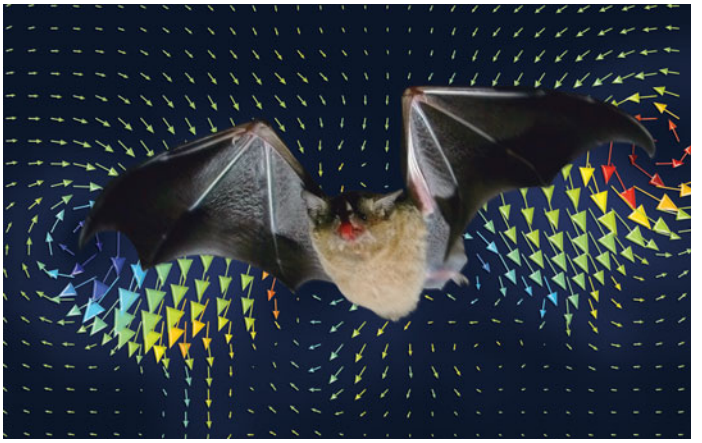

FIGURE 48.15 Visualization of Airflow Is Used to Analyze the Forces Involved in the Hovering of a Bat. The lift and drag forces acting on flying and swimming animals can be measured by observing fluid flow around the animal. The arrows represent the velocity of tiny water droplets illuminated by a laser in front of a high-speed camera.

How are forces measured? Scientists can measure ground force—the force with which a terrestrial animal strikes the substratum during a step—by coaxing an animal to walk, run, or hop upon an instrument called a force plate. Quantifying forces in fluids is more nuanced. It often requires indirect measurement by visualizing the airflow or waterflow around the animal, such as the flow of air around the wings of a hovering bat shown in **FIGURE 48.15**.

What Is the Cost of Locomotion? Animals must spend energy to find food and mates and escape from predators. However, the more energy an animal spends on locomotion, the less it can spend on producing offspring. There is strong selection pressure to minimize the cost of locomotion. How do biologists measure this cost?

To get a sense of variables that determine the cost of locomotion, consider the classic studies by Alexander on the gait transition from walking to running in humans. Alexander discovered that walking is an efficient mode of transport because you exchange potential energy at the top of your stride with kinetic energy midstride. However, the resulting pendulum-like motion of your center of mass is not efficient at higher speeds, when it becomes more cost effective to run using your spring-like tendons and other skeletal tissues to store energy between strides.

Alexander hypothesized that animals locomote using the most energy-efficient gait at each speed. To test this hypothesis in horses, physiologists Dan Hoyt and Richard Taylor trained horses to walk, trot, and gallop at a range of unnatural speeds—for example, trotting at a speed where the horse would normally have preferred to gallop. Hoyt and Taylor fitted each horse with an oxygen mask and ran it on a treadmill, so that they could measure oxygen consumption and speed simultaneously. The rate of oxygen consumption is a measure of energy use. (Oxygen consumption is proportional to ATP production during aerobic respiration; see Chapter 9.) The researchers then plotted energy use as a function of speed for each gait.

Hoyt and Taylor also filmed the horses moving freely around their paddock and measured the speeds at which the horses used different gaits when given free choice. The researchers then compared the lab data to the gait preference in the paddock.

The graph in **FIGURE 48.16** shows Hoyt and Taylor's results. The three curves at the top represent the energy used per distance traveled at the three gaits—the dips in the curves indicate the speeds at which the gaits were most efficient. The bars at the bottom of the graph show which gaits and speeds the horses chose when they were able to locomote freely in the paddock. The data support the hypothesis that the horses use the most energy-efficient gaits at different speeds and avoid intermediate speeds where the cost of locomotion is higher.

Similar studies have been conducted for diverse animals running, swimming, and flying, with similar results. Natural selection favors animals that locomote efficiently because they have more energy available for other vital activities.

Evolution and Ecology: What Is the Context? Some biologists study animal locomotion with a strictly mechanistic focus, investigating proximate causes via "how" questions. Alexander's study of the elastic energy storage of the Achilles tendon falls in this category. However, biologists also examine the ultimate causation of locomotion by asking "why" questions, which require an analysis of evolutionary history and ecological context.

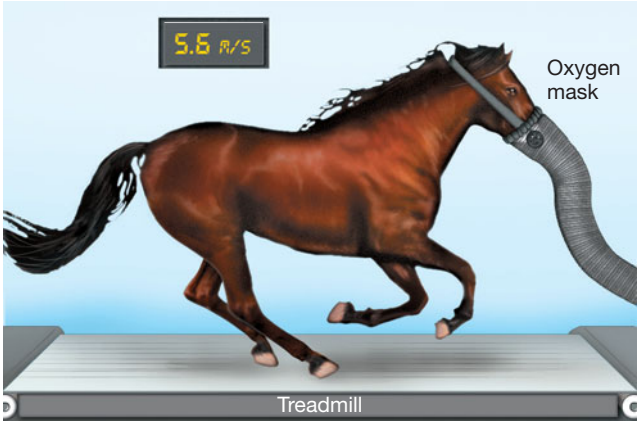
For example, why do dolphins and ichthyosaurs have such similar torpedo-like shapes? Both taxa are fast-swimming predators in their marine environments, yet phylogenetic analysis shows that they are not closely related (see Figure 28.3). Rather, the torpedo-like shape evolved independently in both lineages because it substantially reduces drag during rapid locomotion in water, improving the efficiency of locomotion and thus increasing fitness (the number of viable, fertile offspring produced).

But locomotion cannot be "perfected" over evolutionary time. Natural environments are spatially complex and change over time, so the context for locomotion is not static. Further, there are numerous constraints and fitness trade-offs to different aspects of locomotion. Some trade-offs occur within locomotory systems (such as the trade-off between stability and maneuverability) while others occur between locomotion and other aspects of behavior (such as using appendages both for locomotion and feeding). Overall, a thorough study of locomotion requires an integrative approach with evolutionary and ecological context.

Size Matters

Animals that use muscles to power locomotion span a vast range of sizes—an astonishing 10 orders of magnitude (10,000,000,000), from tiny ants to giant whales. Many of these animals also grow over a large size range during their development. As is true for many other aspects of animal structure and function, size matters.

RESEARCH



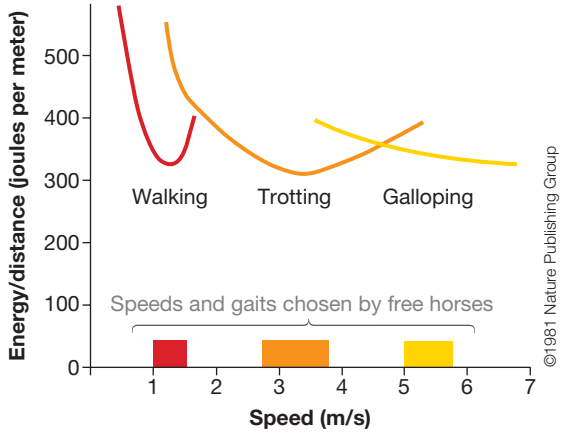
QUESTION: Do horses minimize the cost of locomotion?

HYPOTHESIS: Horses choose gaits that minimize energy use at different speeds.

NULL HYPOTHESIS: Horses do not choose gaits based on cost of locomotion.

EXPERIMENTAL SETUP:

1. Measure oxygen consumption of horses trained to walk, trot, and gallop at a range of speeds on a treadmill. Calculate energy used per distance travelled at different speeds.



2. Videotape the same horses locomoting freely in the paddock, and measure the gaits and speeds they choose to use naturally.

PREDICTION: For each gait, there is a range of speeds where energy use is minimized. Horses will favor these gaits and speeds.

PREDICTION OF NULL HYPOTHESIS: There will be no correlation between chosen gaits and energy consumption.

RESULTS:

CONCLUSION: Horses choose gaits that minimize energy use at different speeds and avoid speeds with high energy consumption.

FIGURE 48.16 Horses Minimize the Cost of Locomotion by Choosing Appropriate Gaits.

SOURCE: Hoyt, D. F., and C. R. Taylor. 1981. Gait and the energetics of locomotion in horses. *Nature* 292: 239–240.

✔**QUANTITATIVE** Use the graph to estimate the relative energy expense of galloping rather than trotting at 3.5 meters/second (m/s).

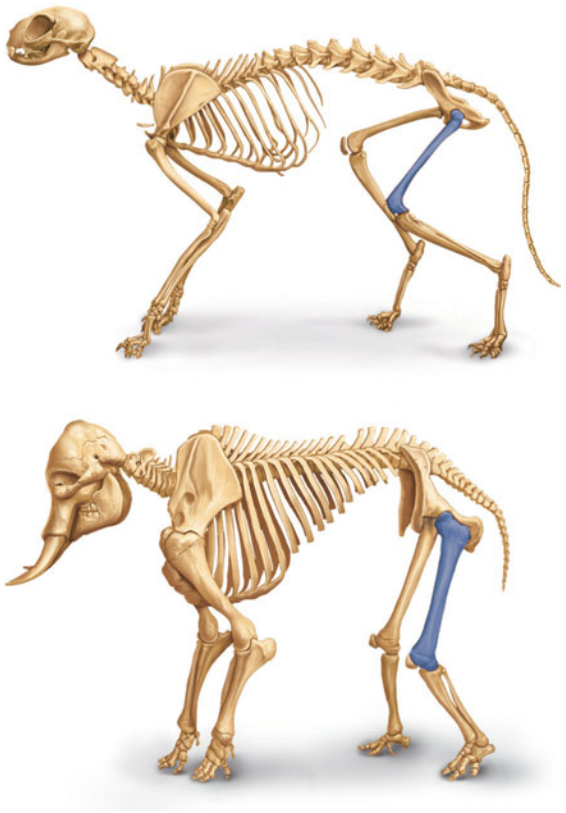


FIGURE 48.17 Size Influences Skeleton Geometry. When scaled to the same size, you can see that the elephant has thicker bones and a more upright stance than a cat does, due to the disproportionate burden of gravity on larger animals. The femurs are highlighted for comparison.

Two organisms may be geometrically similar—that is, they may have exactly the same proportions—but if they are different sizes, they are more different than they seem. To start, the ratio of surface area to volume decreases as the organism gets larger, because surface area is proportional to length squared, while volume is proportional to length cubed (see Chapter 42). This concept has far-reaching implications for physiology. It also has important mechanical implications.

The weight of an animal is proportional to its volume, and the ability of leg bones to support the weight is proportional to their cross-sectional area. Thus, large terrestrial organisms have disproportionately hefty skeletal elements to avoid breaking their legs—something that Galileo observed 400 years ago when he compared skeletons of small and large organisms (**FIGURE 48.17**).

So, in the late 1980s, it was surprising when Andrew Biewener discovered that animals of different sizes maintain similar stresses in their skeletal tissues. How do they do that?

Biewener observed that posture and behavior are important variables. Small animals locomote in a more crouched posture and make great leaps, while large animals like elephants are more straight-legged, so that their skeletons, rather than their muscles, can support their body weight. Larger animals also locomote more gently. If a house cat were enlarged to be the size of an elephant, it would break its own bones when attempting a pounce.

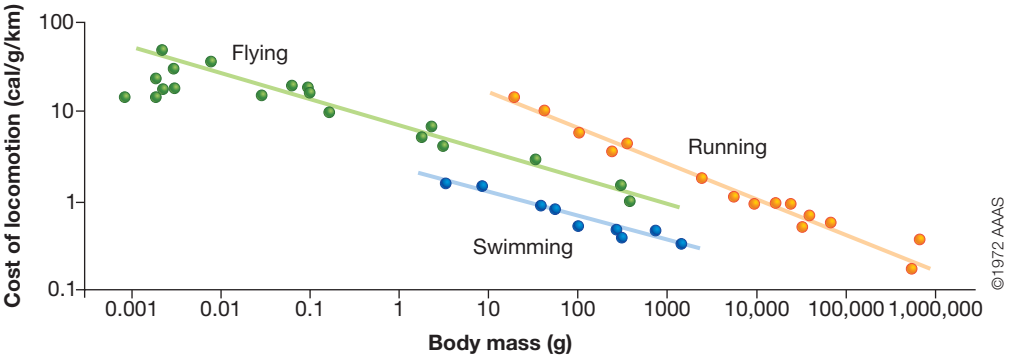

FIGURE 48.18 Cost of Locomotion for Swimming, Running, and Flying Animals Decreases with Mass.

DATA: Schmidt-Nielsen, K. 1972. Locomotion: Energy cost of swimming, flying, and running. *Science* 177: 222–228.

✔**QUANTITATIVE** About how much more costly is it to run than to swim for animals with a body mass of 100 g?

Size is also of paramount importance in determining how organisms locomote through fluids. Fluids have an inherent viscosity, or stickiness, that is of minor concern to animals that are very large and/or fast (thus have high inertia), like dolphins, which can glide through water with little effort. But viscosity is of enormous concern to animals that are very small and/or slow (thus have low inertia), like plankton. If you were the size of a grain of rice and went for a swim in a lake, the water would feel like corn syrup.

Size also affects the cost of locomotion. Physiologist Knut Schmidt-Nielsen, in the early 1970s, was the first to make an energy comparison between different modes of locomotion. To account for widely different body sizes and distances traveled, he normalized all the data to the energy cost in calories per gram of body per kilometer traveled and then plotted the data on a log–log plot (see **BioSkills 6** in Appendix B).

Schmidt-Nielson's data showed that larger organisms use less energy per gram of body tissue per distance traveled than smaller organisms—all the lines slope down to the right (**FIGURE 48.18**). The data also show that for any given body size, running is a more expensive mode of transport than flying, and swimming is the least expensive.

Many other aspects of locomotion can also be plotted as a function of body size. The results reveal general principles that can be used to make predictions for diverse animals, even those that are extinct.

The take-home message? The laws of physics establish very definite constraints on the realm of possible sizes, shapes, and modes of locomotion in animals. Understanding these principles helps illuminate themes and variations among the diversity of animals.

CHAPTER 48 REVIEW

For media, go to MasteringBiology

If you understand that . . .

48.1 How Do Muscles Contract?

- The muscles of vertebrate limbs are composed of muscle cells, called muscle fibers, that contain threadlike contractile elements called myofibrils, each divided into contractile units called sarcomeres.
- Sarcomeres appear striated, or banded, due to the aligned arrangement of thick filaments (myosin) and thin filaments (actin).
- Sarcomeres shorten when thick filaments of myosin slide past thin filaments of actin in a series of binding events mediated by the hydrolysis of ATP.
- Calcium ions play an essential role in muscle contraction by making the actin in thin filaments available for binding by myosin.
- Acetylcholine released from somatic motor neurons is the neurotransmitter that stimulates contraction of skeletal muscle.

✔**You should be able to predict the primary symptom of botulism, which occurs when a toxin prevents release of acetylcholine from the neuromuscular junction. Explain your answer.**

48.2 Muscle Tissues

- Smooth muscle lines bronchioles, blood vessels, the gastrointestinal tract, and certain reproductive organs. Smooth muscle cells are small and unstriated and have a single nucleus. Contractions are involuntary.
- Cardiac muscle occurs in the heart and forces blood through the circulatory system. Cardiac muscle cells are striated, branched, and connected to one another by intercalated discs. Contractions are involuntary.
- Most skeletal muscles are attached to the skeleton and are responsible for voluntary movement of the body. Skeletal muscle cells are long, striated, and multinucleate.
- Skeletal muscle fibers are specialized to contract slowly or quickly and to have a high or low endurance. These properties depend on the concentration of myoglobin present and the use of aerobic respiration and/or glycolysis for the production of ATP.

- Skeletal muscle fibers are organized in a parallel arrangement, which maximizes shortening, or a pennate pattern, which maximizes force production.

✔**You should be able to describe the major structural and functional differences among the three classes of muscle tissue.**

48.3 Skeletal Systems

- Hydrostatic skeletons are composed of a body wall in tension surrounding a fluid or soft tissue under compression.
- Endoskeletons are internal skeletons, surrounded by soft tissue. In vertebrates, the jointed endoskeleton is composed of bones, cartilages, tendons, and ligaments.
- Exoskeletons are external skeletons, enclosing soft tissue. In arthropods, the muscles occur within the rigid, jointed cuticle composed of chitin, proteins, and sometimes minerals. Exoskeletons must be shed to enable growth.
- Movement is based on antagonistic muscle groups that act on a skeleton. In vertebrates and arthropods, these muscles are called flexors and extensors. They change the joint angle between rigid skeletal segments—especially in limbs.

✔**You should be able to compare and contrast the types of shape changes that are caused by muscle contractions in the different types of skeletons.**

48.4 Locomotion

- Locomotion is movement relative to the environment and requires the transmission of muscle forces to the land, water, or air surrounding the animal.
- Locomotion can be studied at different levels: material properties, structures, motions, forces, and energetics, and within the larger context of evolution and ecology.
- Locomotion on land is usually dominated by gravitational and inertial forces. Swimmers must overcome drag. Fliers must overcome drag and must generate enough lift to overcome gravitational forces.
- Body size is important to the mechanics of locomotion.

✔**You should be able to give general examples of how physical constraints affect the locomotion of animals on land, in water, and in air.**

TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. Which of the following classes of muscle is/are voluntary?
   a. skeletal muscle
   b. cardiac muscle
   c. smooth muscle
   d. all of the above
2. Which of the following is a neurotransmitter that stimulates contraction of skeletal muscle?
   a. norepinephrine
   b. adrenaline
   c. acetylcholine
   d. calcium
3. In muscle cells, myosin molecules continue moving along actin molecules as long as
   a. ATP is present and troponin is not bound to Ca^{2+}.
   b. ADP is present and tropomyosin is released from intracellular stores.
   c. ADP is present and intracellular acetylcholine is high.
   d. ATP is present and intracellular Ca^{2+} is high.
4. True or false: The postural muscles of your legs are composed mostly of slow muscle fibers.
5. Which of the following is critical to the function of most exoskeletons, endoskeletons, and hydrostatic skeletons?
   a. Muscles interact with the skeleton in antagonistic groups.
   b. Muscles attach to each of these types of skeleton via tendons.
   c. Muscles extend joints by pushing skeletal elements.
   d. Segments of the body or limbs are extended when paired muscles relax in unison.
6. True or false: A large animal will experience twice the gravitational forces of a small animal half its size if their geometries are the same.

TEST YOUR UNDERSTANDING

Answers are available in Appendix A

7. How did data on sarcomere structure inspire the sliding-filament model of muscle contraction? Explain why the observation that muscle cells contain many mitochondria and extensive smooth endoplasmic reticulum turned out to be logical once the molecular mechanism of muscular contraction was understood.

8. If a sprinter began an endurance running program, which of the following would occur?
a. Some slow fibers would become fast fibers.
b. Some fast fibers would become slow fibers.
c. Some fibers would develop a higher mitochondrial density.
d. Some fibers would develop a lower mitochondrial density.

9. Acetylcholine has very different effects on cardiac muscle and skeletal muscle. Explain.

10. Rigor mortis is the stiffening of a body after death that occurs when myosin binds to actin but cannot unbind. Why does myosin bind, and what prevents it from unbinding?

11. R. McNeill Alexander discovered that the arch of the human foot operates like a spring during running. Predict how a runner's oxygen consumption would change if a runner wore shoes that prevented the arches from changing shape. Explain your reasoning.

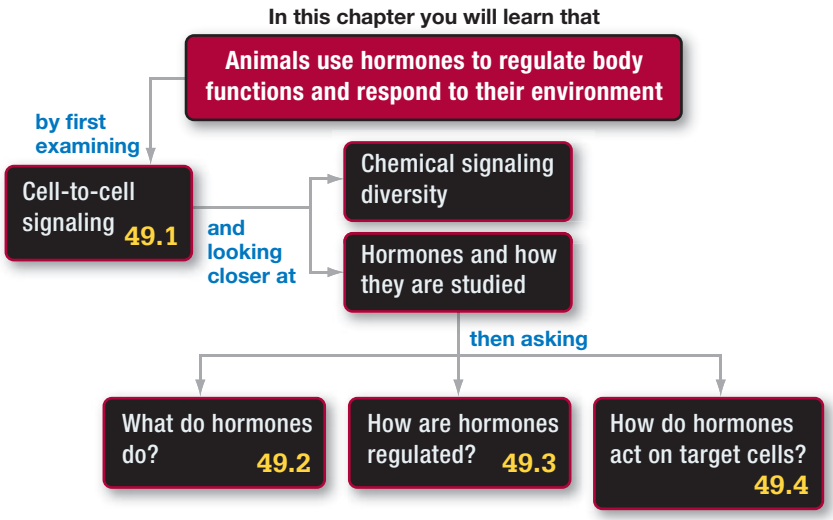
12. Explain how the physical constraints of locomotion on land, in water, and in air influence convergent evolution.

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A

13. Predict the effect of ingestion of the toxin atropine on heart rate. Atropine is a naturally occurring compound in many poisonous nightshade plants. It blocks acetylcholine receptors in the heart. Explain your logic.

14. The force exerted by the shortening of a sarcomere depends on the length of the sarcomere when the stimulus is received. Based on your understanding of the sliding-filament model, predict how force would differ if the sarcomere were in a greatly stretched state at the beginning of the contraction versus in an average resting position. Explain your reasoning.



15. **QUANTITATIVE** The speed at which you switch from a walk to a run can be predicted using what is called the Froude number, based on the relative importance of gravitational and inertial forces of your pendulum-like walking gait.

$$\text{Froude number} = \frac{(\text{speed of locomotion})^2}{\text{gravitational acceleration} \times \text{leg length}}$$

Most mammals change from a walk to a run at a Froude number of 0.5. If gravitational acceleration is 9.8 m/s^2, and your leg length is 0.9 m, at what speed are you likely to switch from a walk to a run?
a. 2.0 m
b. 1.9 m/s
c. 2.1 m/s
d. 2.0 m/s^2

16. If you have seen the film *Jurassic Park*, you can imagine the nightmarish sight of *Tyrannosaurus rex* in high-speed pursuit of you as you flee in a jeep. Evaluate whether the data collected on the biomechanics of locomotion in living species are sufficient to determine how fast a large dinosaur like *T. rex* could run.

49 Chemical Signals in Animals

The spectacular transformation that occurs during insect metamorphosis is triggered by chemical signals called hormones.

In response to sights, sounds, and other sensory stimuli, an animal's nervous system sends rapid messages, in the form of action potentials, to precise locations in the body. In many cases, these messages result in immediate, temporary responses such as muscle contractions and movement.

In response to changes in external or internal conditions, cells in the central nervous system (CNS) or the endocrine system release certain molecules. These molecules produce longer-term responses in a broad range of tissues and organs.

The **endocrine system** is a collection of organs and cells that secrete chemical signals into the bloodstream. A chemical signal that circulates through body fluids and affects distant target cells is called a **hormone.**

BIG PICTURE

This chapter is part of the Big Picture. See how on pages 840–841.

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

As you read this, a large suite of hormones is coursing through your circulatory system. These molecules are regulating the maturation of sperm or eggs by your reproductive system, changing the composition of the urine forming in your kidneys, and controlling the release of digestive enzymes in your gastrointestinal tract. Earlier in your life, changes in hormone concentrations led to the dramatic physical changes associated with puberty.

The goal of this chapter is to explore how hormones and other types of internal chemical signals work in animals. Together, animal nervous systems and endocrine systems process information about the internal and external environment—a function that is one of the five key attributes of life (see Chapter 1).

Let's begin with an overview of chemical signaling systems and then plunge into analyzing how hormones regulate the activity of target cells.

49.1 Cell-to-Cell Signaling: An Overview

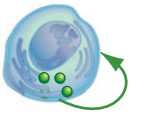
Animal chemical signals are present in extremely low concentrations but can have enormous effects on their target cells. Unlike action potentials, which are electrical impulses that have a short-term effect on a single cell or on a small population of adjacent cells, the messages that chemical signals carry can have a relatively long-lasting effect.

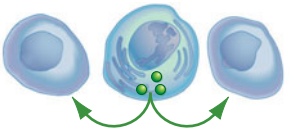
In combination, electrical and chemical signals allow animals to coordinate the activities of cells throughout the body. They are the mechanism responsible for maintaining trillions of cells as an integrated unit called an individual.

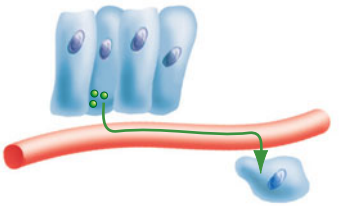
Major Categories of Chemical Signals

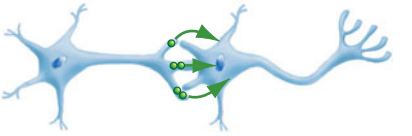
The chemical signals found in animals have diverse structures and functions. **TABLE 49.1** summarizes how biologists go about organizing the diversity of chemical signals, based on where the molecules originate and where they act.

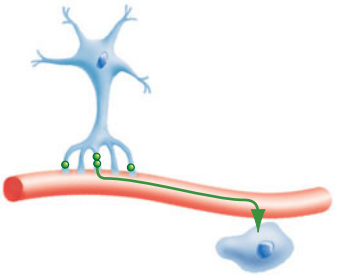
Notice that the names for most of the categories use the Greek word root *crin*, meaning separated. Its use captures something essential about how chemical signals act: They are released from cells and thus are separated from them.











It's important to note that these five classes of chemical messenger do not coincide with five structurally distinct classes of molecules. For example, the endocrine signals found in a particular organism routinely belong to several families of chemical compounds, ranging from amino acid derivatives to lipids. And a particular family of molecules—say, peptides or the lipids called steroids—may function as endocrine, autocrine, and paracrine signals in the same individual.

Autocrine Signals Act on the Same Cell That Secretes Them

Translated literally, autocrine means same-separated. The name is appropriate because **autocrine** signals affect the same cell that releases them.

Perhaps the best-studied autocrine signals are **cytokines** ("cell-movers"). Most cytokines amplify the response of a cell to a stimulus. An example is interleukin 2, which in the course of fighting an infection is synthesized and released by a type of white blood cell called a T cell. Interleukin 2 activates T cells to help eliminate the infection. It also causes the cells to divide repeatedly, producing more activated T cells for host defense.

SUMMARY TABLE 49.1 Five Categories of Chemical Signals in Animals

Type of Chemical Signal	Source and Target
Autocrine signals act on the same cell that secretes them.	
Paracrine signals diffuse locally and act on nearby cells.	
Endocrine signals are hormones carried between cells by blood or other body fluids.	
Neural signals diffuse a short distance between neurons.	
Neuroendocrine signals (neurohormones) are hormones released from neurons.	

Paracrine Signals Act on Neighboring Cells

Translated literally, **paracrine** means beside-separated. Paracrine signals diffuse locally and act on target cells near the source cell. Cytokines, for example, may act as paracrine signals as well as autocrine signals, because they can trigger responses by other nearby cells of the immune system (see Chapter 51).

It is common, in fact, to observe that a single chemical messenger can be assigned to more than one category of signal, based on its mode of action. Like some cytokines, the cell–cell signals named **insulin, glucagon,** and **somatostatin** cross categories. These molecules are produced by three distinct populations of cells within a region of the **pancreas** called the islets of Langerhans. The molecules act on nearby pancreatic cells as paracrine signals and ensure a smooth, steady response to

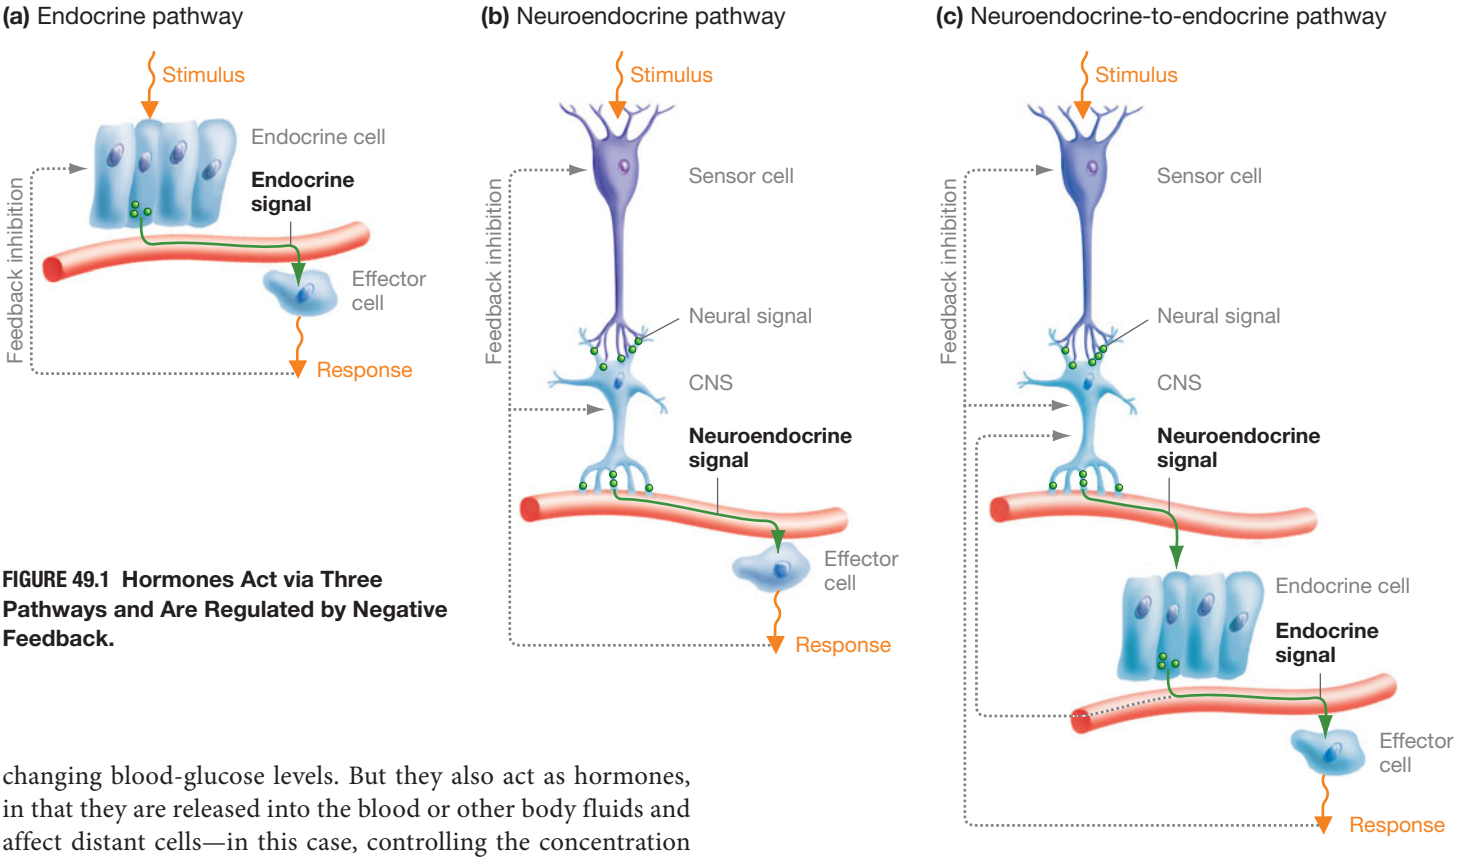


FIGURE 49.1 Hormones Act via Three Pathways and Are Regulated by Negative Feedback.

changing blood-glucose levels. But they also act as hormones, in that they are released into the blood or other body fluids and affect distant cells—in this case, controlling the concentration of glucose in the blood.

Endocrine Signals Are Hormones **Endocrine** ("inside-separated") signals are carried to distant cells by blood or other body fluids. The cells that produce endocrine signals may be organized into discrete organs called **glands** or may be interspersed among the cells of other organs—as are the islets of Langerhans in the pancreas.

Because hormones are well studied and particularly important to understanding how animals work, they serve as the focus of this chapter. Many or most of the principles discussed are relevant to the other categories of animal cell–cell signals as well, however.

Neural Signals Are Neurotransmitters You might recall that when an action potential arrives at a synapse, it triggers the release of neurotransmitters that bind to receptors on the postsynaptic cell and induce a change in membrane potential—altering the tendency for the postsynaptic cell to fire action potentials (see Chapter 46).

Neural signaling can be very fast, because action potentials propagate rapidly and neurotransmitters have to diffuse only a short distance—across the tiny gap between two neurons, called the synaptic cleft. Neural signals also tend to be short-lived, because the signaling molecules are broken down or taken back up by the presynaptic cell.

Neuroendocrine Signals Act at a Distance Even though they are released from neurons, **neuroendocrine** ("nerve-inside-separated") signals are considered hormones and are therefore often called **neurohormones.** They share a key attribute with endocrine signals: They act on distant cells. Unlike neural signals, they do not act at the adjacent synapse.

Antidiuretic hormone (ADH; also called vasopressin) is a particularly well studied neuroendocrine signal. ADH is produced by neurons that originate in the hypothalamus of the brain. But instead of acting as a neural signal, ADH acts on cells in the collecting duct of the kidney to help regulate water excretion (see Chapter 43).

Hormone Signaling Pathways

In plants, sensory cells perceive changes in the environment and broadcast a hormonal signal that triggers an appropriate response from effector cells (see Chapter 40). Some animal hormones are also sent directly from endocrine cells to effector cells, in response to a stimulus (**FIGURE 49.1a**). But frequently, hormonal signaling in animals involves additional steps.

In many cases, information about external or internal conditions is gathered by sensory receptors and then integrated by neurons in the central nervous system (CNS) before the production of a hormonal signal. Neurons in the CNS respond by releasing neuroendocrine signals that act on effector cells directly (**FIGURE 49.1b**) or stimulate cells in the endocrine system, which respond by producing a hormone (**FIGURE 49.1c**).

All three types of signaling pathway—direct from an endocrine cell, direct from the CNS, or CNS-to-endocrine-system—are regulated by **negative feedback,** or **feedback inhibition.** In

feedback inhibition, the product of a process inhibits its production. Negative feedback is key to homeostasis (see Chapter 42).

In the endocrine pathway, the hormone produced by the effector cells feeds back on endocrine cells, lowering production of the hormone and down-regulating the response (Figure 49.1a). An effector's response also feeds back to cells that initiate the neuroendocrine and neuroendocrine-to-endocrine pathways. A change in input from these cells then lowers production of the signal and reduces the response (see Figures 49.1b and 49.1c). Neuroendocrine-to-endocrine signaling pathways have an additional layer of regulation, because the endocrine signal usually inhibits production of the neuroendocrine signal (Figure 49.1c).

The take-home message? The nervous system and endocrine system are tightly integrated. Endocrine signals are released in response to electrical signals; in turn, endocrine signals modulate the electrical signals transmitted by the nervous system.

Feedback inhibition in the endocrine system is analogous to temperature control by a heat-sensitive thermostat. If the temperature is too high, the thermostat sends a signal that turns the furnace off; if the temperature is too low, the thermostat sends a signal that turns the furnace on. The result is a constant air temperature. In animal cell–cell signaling, feedback inhibition reduces production or secretion of the hormone, or both.

✔ **If you understand this concept, you should be able to explain which parts of the thermostat analogy correspond to the sensory input, CNS, cell-to-cell signal, and effector in a hormone signaling pathway. You should also be able to predict what happens to hormone concentrations when feedback inhibition fails in a hormone signaling pathway.**

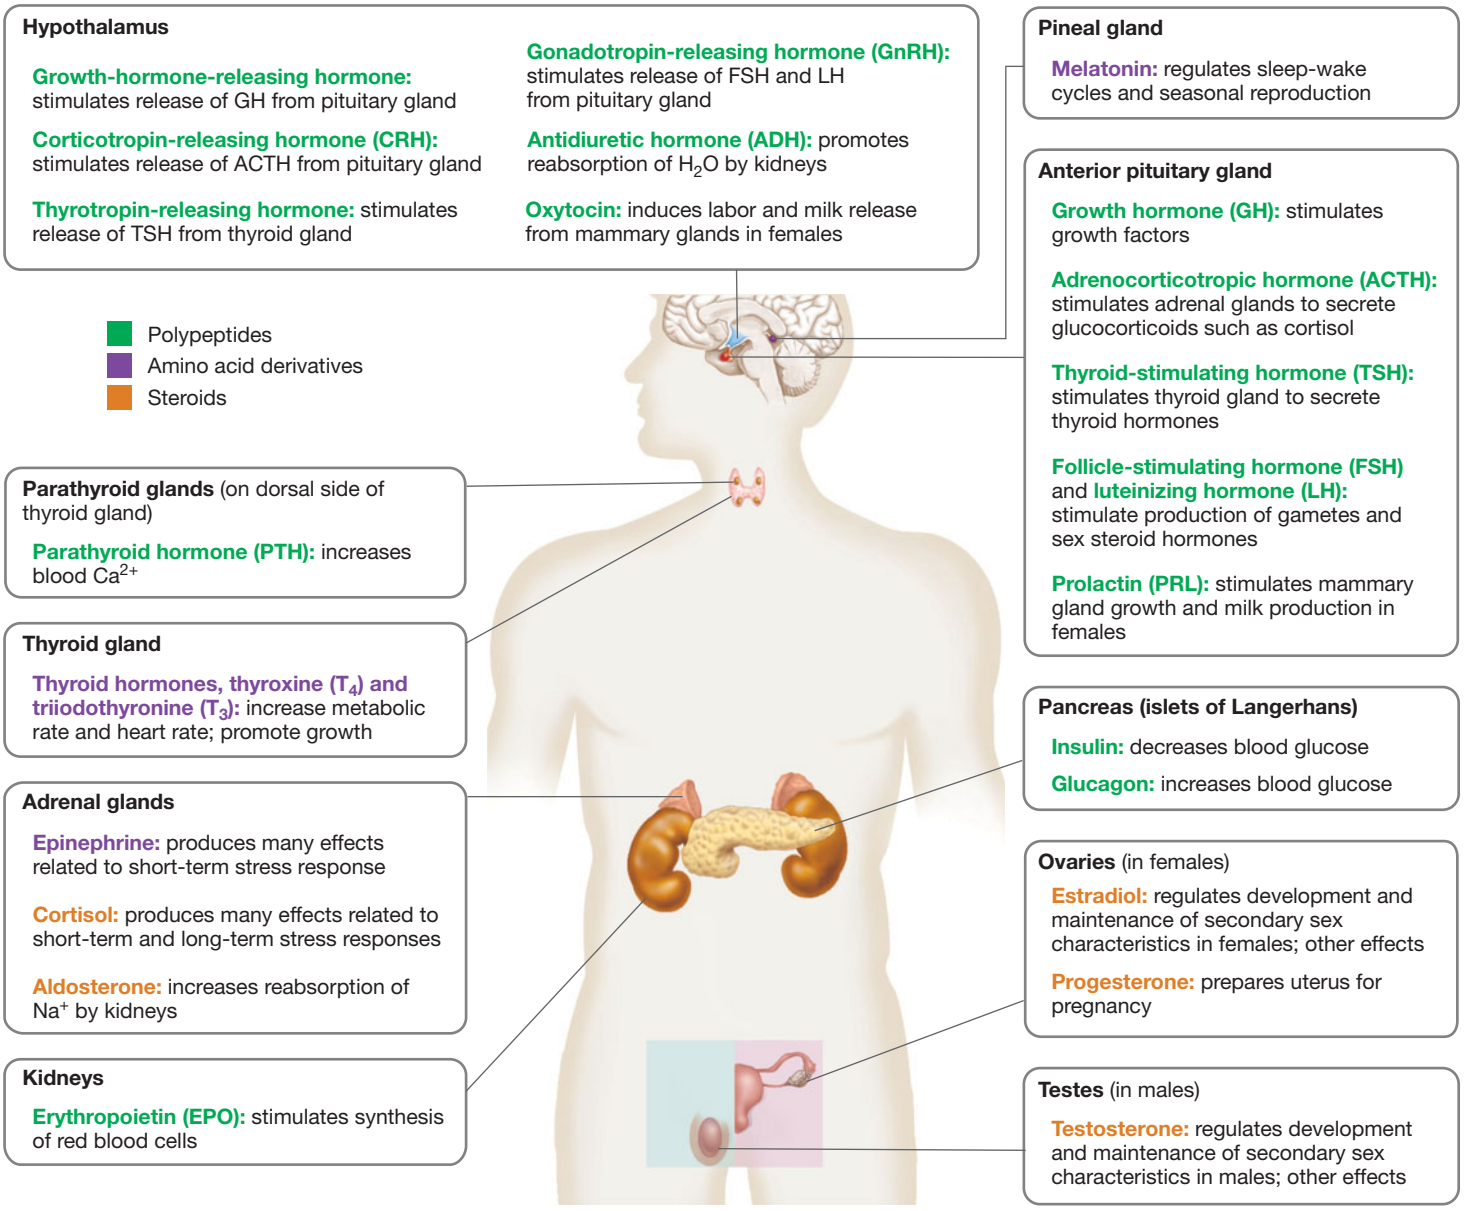

FIGURE 49.2 Humans Possess a Diverse Array of Endocrine Glands and Hormones. This list is only partial. The heart, gastrointestinal tract, adipose (fat) tissue, and many other organs and cells also produce hormones.

What Makes Up the Endocrine System?

The endocrine system is the collection of cells, tissues, and organs responsible for hormone production and secretion. Organs that secrete a hormone into the bloodstream are called **endocrine glands.**

The tissues and organs that make up the endocrine system vary widely among animals. For example, neurons that manufacture and secrete hormones are particularly important in insects, where they regulate molting, metamorphosis, and other processes. Salmon have an unusual gland that secretes a hormone responsible for regulating calcium ion concentration.

Even within one species, the diversity of endocrine system components can be impressive. For example, **FIGURE 49.2** shows major human glands with endocrine functions. As mentioned earlier, hormone-secreting cells are not always organized into discrete glands. In many cases, they are located in other kinds of organs. (The islets of Langerhans were mentioned earlier as an example.)

It's important to note that not all glands in the body are part of the endocrine system. **Exocrine glands,** in contrast to endocrine glands, deliver their secretions through outlets called ducts into a space other than the circulatory system. Most of the digestive glands are either exocrine glands—an example is the salivary glands—or mixed endocrine and exocrine glands, such as the pancreas (see Chapter 44). The exocrine cells of the pancreas secrete digestive enzymes through ducts into the intestine. The endocrine portion of the pancreas consists of cells that secrete insulin and glucagon directly into the bloodstream.

At first glance, the diversity of hormones, glands, and their effects can seem overwhelming, especially considering that Figure 49.2 represents just a partial catalog for a single species. But the picture can be simplified somewhat by recognizing that most animal hormones belong to one of just three major structural families: polypeptides, amino acid derivatives, or steroids.

Chemical Characteristics of Hormones

FIGURE 49.3 illustrates the three major classes of chemicals that can act as hormones in animals:

1. Polypeptides, which are chains of amino acids linked by peptide bonds (see Chapter 4)
2. Amino acid derivatives
3. Steroids, which are a family of lipids distinguished by a four-ring structure (see Chapter 6)

Secretin, a hormone produced in the small intestine to stimulate the exocrine portion of the pancreas, is a polypeptide; the hormone epinephrine is synthesized in the medulla of the **adrenal glands** from the amino acid tyrosine; and the hormone cortisol is synthesized in the cortex of the adrenal glands from the steroid cholesterol.

Hormone Concentrations Are Low, but Their Effects Are Large

Hormones vary widely in structure but share a common characteristic: They have profound effects on individuals, even though they are present at vanishingly small concentrations. As an example, consider research that led to the discovery of **growth hormone (GH).**

Several researchers noted that rats and other laboratory animals stopped growing when their pituitary glands were removed. Based on this observation, it was widely suspected that

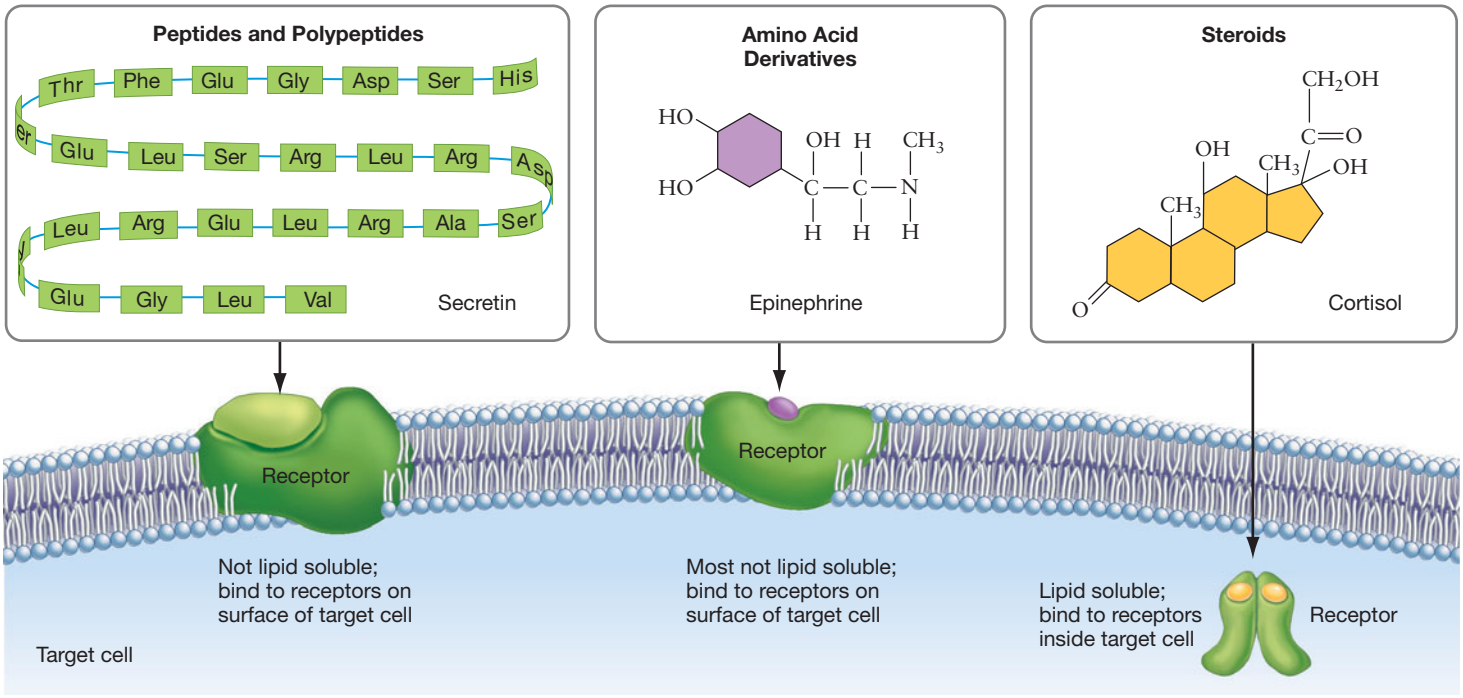

FIGURE 49.3 Most Animal Hormones Belong to One of Three Chemical Families.

the pituitary produces a chemical signal that promotes cell division and other aspects of growth.

To test this hypothesis, a research group purified a polypeptide from cow pituitary glands, injected the polypeptide into lab rats, and documented rapidly accelerated growth. When the researchers injected 0.01 mg of the molecule each day for nine days into rats that lacked pituitary glands, the width of the growth plates in the rats' leg bones increased by 50 percent. The individuals also gained an average of 10 g compared with rats that lacked a pituitary and did not receive the hormone treatment. Stated another way, an additional 0.09 mg of hormone led to a weight gain of 10,000 mg.

Further, 1 kg of cow pituitary tissue yielded a mere 0.04 g of growth hormone. By mass, the hormone makes up just 4 one-thousandths of 1 percent of the cow pituitary.

Only Some Hormones Can Cross Cell Membranes Given that small amounts of polypeptide, amino-acid-derived, and steroid hormones have large effects on the activity of cells, organs, and systems, how do the three types of hormones differ? The major difference is that steroids are lipid soluble, but polypeptides and most amino acid derivatives are not (see Figure 49.3).

Important exceptions to this rule are the **thyroid hormones, triiodothyronine** (also known as T_3) and **thyroxine** (also known as T_4), that are produced by the **thyroid gland.** The thyroid hormones are derived from the amino acid tyrosine but are lipid soluble.

Differences in solubility are important because steroids and thyroid hormones cross plasma membranes much more readily than do other types of hormones. To affect a target cell, all polypeptides and most amino acid derivatives bind to a receptor on the cell surface. Lipid-soluble hormones, in contrast, can diffuse through the plasma membrane and bind to receptors inside the cell.

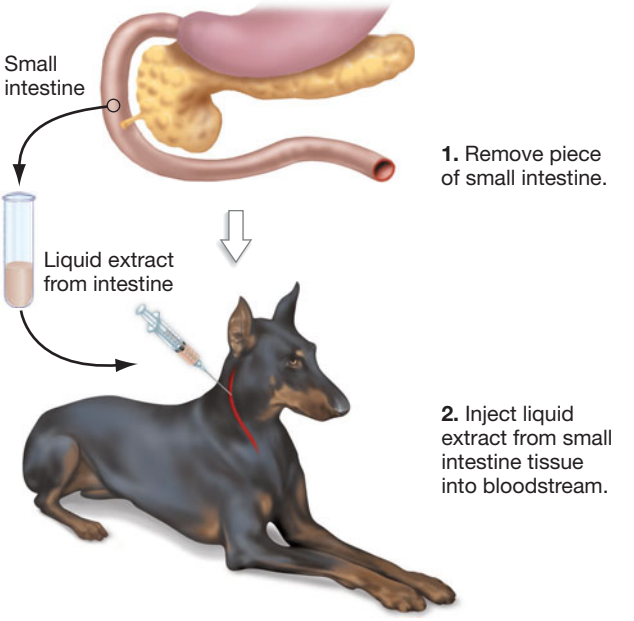
Before exploring the consequences of this difference in more detail, let's consider how researchers discovered the array of hormones introduced here.

How Do Researchers Identify a Hormone?

Research on animal hormones began in earnest in the early 1900s, when researchers found that adding dilute hydrochloric acid (HCl) to the small intestine, to mimic the arrival of acidic material from the stomach, stimulated the pancreas to secrete compounds that neutralized the acid (see Chapter 44).

How could stimulating the small intestine lead to a response by the pancreas? The working hypothesis was that a chemical traveled from the small intestine to the pancreas by way of the bloodstream, to signal the arrival of acid.

To test this idea, researchers did the experiment summarized in **FIGURE 49.4**. An extract from the small intestine was injected into blood vessels in a dog's neck. A short time later, the pancreas secreted an alkaline solution. This result was strong evidence that the extract from the small intestine contained a cell–cell signaling molecule. The hormone was later purified and named **secretin.**

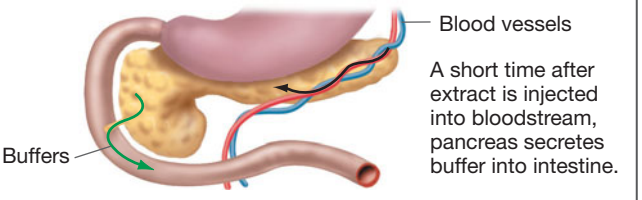


RESEARCH

QUESTION: How could stimulating the small intestine with acid cause the pancreas to secrete buffers that neutralize the acid?

HYPOTHESIS: A chemical messenger from the small intestine reaches the pancreas via the bloodstream.

NULL HYPOTHESIS: There is no blood-borne chemical messenger from the small intestine that acts on the pancreas.



EXPERIMENTAL SETUP:

PREDICTION: Liquid extract in bloodstream will signal pancreas to secrete buffer.

PREDICTION OF NULL HYPOTHESIS: Liquid extract in bloodstream will not signal pancreas to secrete buffer.

RESULTS:

CONCLUSION: A hormone from the small intestine (secretin) signals cells in the pancreas via the bloodstream.

FIGURE 49.4 Researchers Studied Digestive Processes to Find Experimental Evidence of a Hormone. Follow-up work succeeded in isolating the molecule secretin.

SOURCE: Bayliss, W. M., and E. H. Starling. 1902. The mechanism of pancreatic secretion. *Journal of Physiology* 28: 325–353.

✔**QUESTION** What would be an appropriate control in this experiment?

In essence, using liquid extracts from suspected endocrine glands is a way to deliver a suspected hormone and evaluate the effect. The opposite strategy has also been productive: observing the consequences of removing specific organs or tissues. For

example, removing the adrenal glands of an animal rapidly leads to death due to low blood sodium, low blood sugar, and low blood pressure. But injecting adrenal extracts into the blood of animals lacking adrenal glands corrects these abnormalities. Results like these provided strong evidence that hormones secreted by the adrenal glands help regulate blood-sugar concentrations and blood pressure.

A Breakthrough in Measuring Hormone Levels

Documenting an association between a particular gland or hormone and an effect in the body is just a first step. To understand hormone action, researchers have to figure out how these signals help animals stay alive and produce offspring.

The key to this goal is the ability to quantify the levels of hormones circulating in the bloodstream. Given that hormones are present in such small amounts, this ability eluded researchers for decades.

The breakthrough came in the 1950s when Rosalind Yalow developed the **radioimmunoassay,** a feat for which she later received the Nobel Prize in Medicine. In a radioimmunoassay, the quantity of hormone in a blood sample can be estimated by adding radioactively labeled hormones that compete with the unknown amount of hormone to bind to an antibody (see **BioSkills 9** in Appendix B). This technique revolutionized the field of endocrinology and the treatment of endocrine diseases, allowing the precise concentrations of hormones to be measured from blood samples drawn from animals or patients. Currently, radioimmunoassays are used every day in endocrine research and in medical laboratories. Much of what researchers know about hormone function was learned in studies employing the radioimmunoassay.

check your understanding

C Y U

If you understand that . . .

- Cell-to-cell signaling occurs through a variety of pathways, and distant signaling is accomplished via the nervous system or endocrine system.
- Three main chemical families of hormones affect cells in different ways.

✓ You should be able to . . .

1. Discuss why it is often difficult to differentiate between the functions of the nervous and endocrine systems.
2. Predict the location of thyroid hormone receptors.

Answers are available in Appendix A.

49.2 What Do Hormones Do?

At the beginning of this chapter, you read that hormones are chemical messengers. If so, what do hormones "say"?

A first step in answering this question is to recognize that a single hormone can exert a variety of effects. For example, the thyroid hormones, T_3 and T_4, stimulate metabolism in humans and thus oxygen consumption throughout the body. But they also promote growth, increase heart rate, and stimulate the synthesis of many important macromolecules.

A second step in grasping what hormones do is to recognize that several different hormones may affect the same aspect of physiology. Insulin, glucagon, epinephrine, and cortisol all influence glucose levels in the blood.

Some hormones have extremely diverse effects; in other hormones, the functions appear to overlap. These observations begin to make sense when hormone action is viewed in the context of the whole organism. Hormones coordinate the activities of cells in three arenas: (1) development, growth, and reproduction; (2) response to environmental challenges; and (3) maintenance of homeostasis.

Let's analyze each of these functions in turn.

How Do Hormones Direct Developmental Processes?

In animals, as in plants, hormones play a key role in regulating growth and development. Growth hormones and sex hormones play crucial roles in promoting cell division, increasing overall body size, and promoting sexual differentiation as an individual matures; certain hormones direct the development of particular cells and tissues at critical junctures in an individual's life.

Let's explore two of the most dramatic examples of hormonal control—metamorphosis in amphibians and in insects—and then survey other developmental processes that are affected by hormone action.

T_3's Role in Amphibian Metamorphosis Frogs, toads, and salamanders are called amphibians ("double-lives") because in most species, juveniles live in water while adults live on land. The process of changing from an immature, aquatic larva to a sexually mature, terrestrial frog, toad, or salamander is an example of **metamorphosis** ("change-form") (**FIGURE 49.5**; see page 998).

Two sets of complementary experiments, published in 1912 and 1916, established that frog metamorphosis depends on thyroid hormones. Researchers could induce frog tadpoles to undergo metamorphosis by feeding them ground-up thyroid glands from horses; they could prevent metamorphosis by surgically removing the tadpoles' thyroid glands.

Follow-up work showed that the thyroid hormone triiodothyronine, or T_3, is responsible for many of the changes observed in metamorphosis. In response to a signal from the brain, the pituitary gland secretes thyroid-stimulating hormone, which stimulates the thyroid gland to produce thyroxine (T_4). The T_4 is then converted to T_3 at the target tissues.

In juvenile amphibians, cells respond to increased levels of T_3 by growing and forming new structures, such as legs. Other structures—such as a tadpole's tail—disintegrate or are absorbed. Still other tissues change structure and function. For example,

T_3

T_3

Juvenile frog (tadpole)	
Locomotion	Swim via movements of muscular tail
Respiration	Gas exchange occurs in gills, across skin, and in lungs
Nutrition	Most are herbivorous; have a long gut specialized for digesting algae and plants
Excretion	Most nitrogenous wastes excreted as ammonia

Adult frog	
Locomotion	Tailless; walk, jump, or swim using limbs
Respiration	Gas exchange occurs across skin, and in lungs
Nutrition	Most are carnivorous; have a large mouth or large tongue for catching prey; short gut specialized for digesting proteins
Excretion	Most nitrogenous wastes excreted as urea

FIGURE 49.5 Amphibian Metamorphosis Is a Continuous Process. When metamorphosis begins in a frog, toad, or salamander, the individual stays active and feeding. The continuous and gradual transition from juvenile to adult is mediated by T_3.

changes in existing cells are responsible for the switch from a tadpole's long intestine, specialized for digesting plant material, to an adult's short intestine, specialized for digesting insects and other prey. In the liver, cells respond to T_3 by manufacturing the enzymes required to excrete urea—the nitrogenous waste product released by adults—instead of the ammonia produced by tadpoles.

✔ **If you understand the basic principles of hormone action, you should be able to suggest a hypothesis explaining why different frog cells can respond to T_3 in such different ways.**

Hormone Interactions Regulate Insect Metamorphosis Some insects show a remarkable type of juvenile-to-adult transition, called holometabolous metamorphosis (see Chapter 33). In species that undergo this process, juveniles are called larvae. As in amphibians, insect larvae look completely different from adults, live in different habitats, and eat different food.

As larvae grow, they undergo a series of molts in which they shed their old exoskeleton, expand their bodies, and produce a new exoskeleton. After a specific number of these juvenile molts, however, they secrete a tough case called a pupal case. Inside the pupal case, specific populations of larval cells give rise to a completely new adult body. The rest of the larval body disintegrates (**FIGURE 49.6**).

In insects, metamorphosis depends on interactions between two hormones. If **juvenile hormone (JH)** is present at a high concentration in the larva, surges of the hormone **ecdysone** induce the growth of a juvenile insect via molting. But if JH levels are low, ecdysone triggers a complete remodeling of the body—metamorphosis—and the transition to adulthood and sexual maturity.

Sexual Development and Activity in Vertebrates In mammals and other vertebrates, long-distance cell-to-cell signals play key roles as embryos develop. Hormones also direct anatomical and physiological changes that occur later in life. Some of the most important of these changes involve the reproductive organs.

Low **JH** + **ecdysone**

FIGURE 49.6 Insect Metamorphosis Occurs during a Resting Stage. When metamorphosis begins in a holometabolous insect, the individual enters a resting stage called the pupa.

Events early in development dictate whether the sex organs, or **gonads,** of a vertebrate embryo become male (**testes**) or female (**ovaries**). This process is called primary sex determination. In mammals, primary sex determination depends on genes on sex chromosomes.

Once testes or ovaries develop, they begin producing different hormones. In human males, the early testes produce two hormones:

1. A steroid hormone called **testosterone** induces early development of the male reproductive tract.
2. A polypeptide hormone called **Müllerian inhibitory substance** inhibits development of the female reproductive tract.

In females, the ovaries produce the steroid hormone **estradiol,** which is in the family of molecules called **estrogens.** Estradiol is required for further development of the female reproductive tract.

Sex hormones also play a key role in the juvenile-to-adult transition. When humans reach early adolescence, for example, surges of sex hormones lead to the physical and emotional changes associated with **puberty.** These developmental changes create the adult phenotype and the ability to produce offspring.

In boys, surges of sex hormones lead to changes that include enlargement of the penis and testes and growth of facial and body hair. In girls, an increased concentration of estradiol leads to the enlargement of breasts, the onset of menstruation, and other changes. In both sexes, a growth surge begins at puberty. This growth is stimulated by growth hormone (GH) produced in the pituitary gland (see Figure 49.2). GH regulates growth factors, which are signals that control the cell cycle (see Chapter 12). Growth originates in the epiphyseal plate, a small piece of cartilage separating the shaft from the end at both extremities of long bones.

Puberty is associated with a growth spurt because the effect of GH on the human skeleton is enhanced by the action of sex hormones, which surge during adolescence. Although GH and sex hormones continue to be produced long after puberty, growth in humans stops when the epiphyseal plates are replaced with bone, and no further growth is possible.

The sex hormones continue to play a key role in adults. In humans, sex hormones are instrumental in regulating sperm production and the menstrual cycle (see Chapter 50). The result of this steady release of sex hormones is that humans can mate year-round. In many animals, reproductive behavior is instead confined to specific times of the year. In these species, environmental cues such as increasing day length, warmth, or the onset of seasonal rains trigger the release of sex hormones (see Chapter 53).

How Photoperiod Affects Sex Hormone Release The increase in day length—or increasing **photoperiod**—during spring is particularly important in stimulating the release of sex hormones in seasonally reproducing mammals, lizards, and birds. The lengthening spring photoperiod is sensed by photoreceptors, which are sensory receptors that respond to light (see Chapter 47). These photoreceptors send signals to the hypothalamus, a brain region that initiates a series of signals directing production of sex hormones.

The location of the photoreceptors depends on the animal. In mammals, photoreceptors in the retinas of the eyes sense light and send signals to the **pineal gland** via a pathway leading through the brain and spinal cord. The pineal gland secretes the hormone **melatonin,** which relays photoperiodic information to the hypothalamus. It also regulates sleep–wake cycles.

Maximal melatonin secretion occurs in the dark, so stimulation of the pineal gland by photoreceptors *reduces* melatonin secretion. Animals therefore experience a daily rhythm in melatonin levels, which are highest at night. As photoperiod increases in spring, there are fewer hours of dark, resulting in lower *overall* levels of melatonin (**FIGURE 49.7**). This decline in melatonin "informs" the hypothalamus to stimulate the testes and ovaries to make sex hormones.

Many diurnal lizard species do not rely solely on retinal photoreceptors. These lizards have a small hole in the top of their skull, covered only by a thin layer of skin; this hole is often called the pineal eye or parietal eye (**FIGURE 49.8**, see page 1000). The pineal gland lies just below this opening and responds to direct light. Interestingly, in birds, neither retinal nor pineal photoreceptors are responsible for relaying photoperiodic information to the hypothalamus. It appears that their photoreceptors are located diffusely throughout the brain.

The common thread among mammals, lizards, birds, and other vertebrates is that information about photoperiod is transduced from a signal detected by photoreceptors into a hormonal signal originating at the hypothalamus. The role of the hypothalamus is discussed in more detail in Section 49.3.

Some Chemicals Can Disrupt Hormone Signaling In 1962, Rachel Carson stunned the world with her book *Silent Spring*, in which she described how commercially produced synthetic chemicals—even at low concentrations—can adversely affect humans and

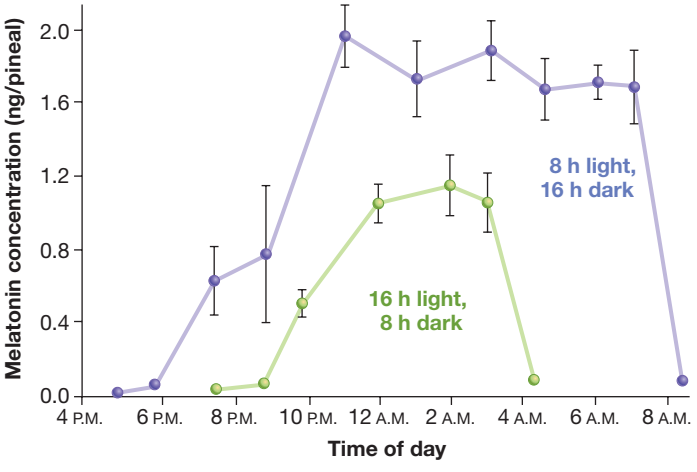


FIGURE 49.7 Melatonin Levels Are Affected by Time of Day and Photoperiod in Seasonal Breeders. Melatonin levels are highest at night, and they are higher overall when photoperiod is short (8 h light, 16 h dark) than when it is long (16 h light, 8 h dark).

wildlife. Since then, evidence has continued to accumulate that many pesticides, industrial chemicals, and other pollutants interfere with normal endocrine function in many animal species.

In the early 1990s, scientists coined the term **endocrine disruptor** to describe chemicals that interfere with normal hormonal signaling. This interference can happen in a number of ways, including binding of the chemical to hormone receptors and altering the metabolism of hormones, thereby affecting physiological processes and behavior.

Many endocrine disruptors are **xenoestrogens**—foreign chemicals that bind to estrogen receptors and induce estrogen-like effects. For example, exposure to the widely used herbicide atrazine causes feminization and even sex change of male frogs, induces reproductive-tissue abnormalities and reduced spawning in fishes, and is associated with low sperm counts and increased risk of birth defects in humans.

Another well-known xenoestrogen is bisphenol A (BPA), an industrial chemical used in many plastic or metal products, including containers for food and water. Laboratory animals exposed to BPA show abnormal development of reproductive and brain tissues, along with increased risk of some types of cancers.

As research continues into the possible health effects of xenoestrogens and other endocrine disruptors, many states and countries are limiting or banning their use. For example, atrazine is currently banned in the European Union, and BPA is banned in some countries for use in products such as baby bottles.

How Do Hormones Coordinate Responses to Stressors?

When an animal is thrust into a dangerous or unpredictable situation, hormones play a part in both the short-term and long-term responses. Let's explore each of these response categories in turn.

Short-Term Responses to Stress The short-term reaction, called the **fight-or-flight response,** is triggered by the sympathetic nervous system (see Chapter 46). If you were being chased by a grizzly bear, action potentials from your sympathetic nerves would stimulate your adrenal medulla and lead to the release of the hormone **epinephrine,** also known as **adrenaline.** (The Greek word roots *epi* and *nephron* mean "top-kidney"; the Latin word roots *ad* and *renal* also mean "top-kidney.")

To determine how epinephrine affects the body, researchers injected human volunteers with a saline solution—as a control—or epinephrine. Each point graphed in the "Results" section of **FIGURE 49.9** represents data from one of the volunteers; the data in the table are average values from the seven study participants.

The data indicate dramatic increases in an array of physiological processes: concentrations of free fatty acids and glucose in the blood, pulse rate, blood pressure, and oxygen consumption by the brain. In addition, the volunteers reported strong subjective feelings of anxiety and excitement.

Other experiments showed that epinephrine redirects blood away from the skin and digestive system and toward the heart, brain, and muscles. Epinephrine relaxes smooth muscle in blood vessels leading to these tissues—increasing blood delivery.

Taken together, the responses to epinephrine lead to a state of heightened alertness and increased energy use that prepares the body for rapid, intense action such as fighting or fleeing. Epinephrine coordinates the activities of cells in many organs and systems throughout the body to prepare an individual to cope with a life-threatening situation.

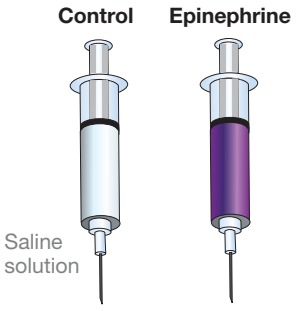
Long-Term Responses to Stress If you have ever experienced the fight-or-flight response, you may recall that the state is short lived. Once an epinephrine "rush" wears off, most people feel exhausted and want to rest and eat.

What happens if the stress continues and turns into a long-term condition? In the course of a lifetime, it is not unusual for a person to experience periods of starvation or fasting, prolonged emotional distress, or chronic illness. How do hormones help humans and other animals cope with extended stress?

Early studies of long-term stress in human subjects suggested a role for the hormone **cortisol,** which is produced in the adrenal cortex. Increased levels of cortisol were found in airplane pilots and crew members during long flights, athletes who were training for intense contests, parents of children undergoing treatment for cancer, and college students who were preparing for final exams. Why?

What Does Cortisol Do? In humans, cortisol's primary role is to ensure the continuing availability of glucose for use by the brain during long-term stress. Cortisol manages three main processes that maintain glucose production:

1. Cortisol induces the synthesis of liver enzymes that make glucose from amino acids and other chemical precursors.
2. Cortisol makes adipose tissue—fat tissue—and resting muscles resistant to insulin. Insulin normally stimulates **adipocytes**



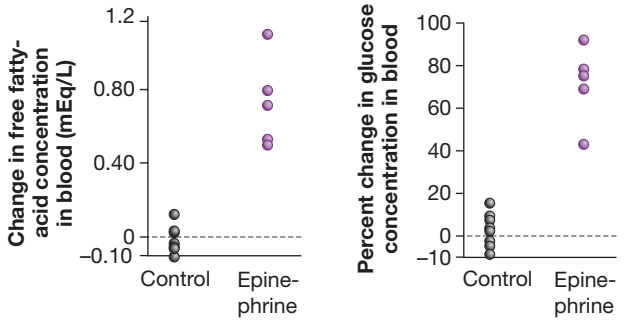
RESEARCH

QUESTION: How does epinephrine affect the body?

HYPOTHESIS: Epinephrine causes changes involved in the fight-or-flight response.

NULL HYPOTHESIS: Epinephrine is not involved in the fight-or-flight response.

EXPERIMENTAL SETUP:



1. Inject human volunteers with saline solution or epinephrine.

2. Document changes in fatty-acid and glucose concentrations in blood, pulse rate, blood pressure, and oxygen consumption in brain.

PREDICTION: Epinephrine increases fatty-acid and glucose concentrations in blood, pulse rate, blood pressure, and brain oxygen consumption relative to controls.

PREDICTION OF NULL HYPOTHESIS: No differences in physiological state of individuals based on molecule injected.

RESULTS:

	Control	Epinephrine
Pulse rate (beats/min)	78.3	89.6
Blood pressure (average, mm Hg)	90.9	108.7
O_2 consumption in brain (cc O_2/100 g/min)	3.41	4.16

CONCLUSION: Epinephrine causes an array of changes associated with the fight-or-flight response.

FIGURE 49.9 Epinephrine Prepares the Body for Action.

✔**QUESTION** Why did researchers bother to inject volunteers in the control group with saline? Why inject them with anything?

and resting muscle cells to remove glucose from the bloodstream. But when cortisol makes these cells resistant to insulin, glucose is reserved for use by the brain and exercising muscles.

3. Cortisol promotes the release of fatty acids—the body's major fuel molecules—from adipose tissue, for use by the heart and muscles.

Because of its importance in regulating blood glucose, cortisol is referred to as a **glucocorticoid.**

The long-term stress response comes at a high price, however, as any victim of a serious injury or illness knows. Glucocorticoids make amino acids available for glucose synthesis by promoting the degradation of contractile proteins in muscle. The resulting loss of muscle mass may cause severe weakness. Also, glucocorticoids impair wound healing and suppress immune and inflammatory responses. These processes are costly in terms of energy use, but reducing them makes the body more susceptible to infection.

The overall concept here is that the long-term stress response is a compromise—a fitness trade-off (see Chapter 42). The fuel requirements of the brain are met at the expense of other tissues and organs.

✔ **If you understand the effects of chronically elevated cortisol in stressed individuals, you should be able to predict its effect on their ability to heal wounds and fight pathogens.**

How Are Hormones Involved in Homeostasis?

Recall that homeostasis is the maintenance of relatively constant physical and chemical conditions inside the body. Homeostatic systems depend on three components (see Figure 42.14):

1. A sensory receptor that monitors conditions relative to a normal value, or set point
2. An integrator that processes information from the sensor
3. Effector cells that return conditions to the set point

In homeostatic systems, messages often travel from integrators to effectors in the form of hormones.

Leptin and Energy Reserves Healthy animals keep energy in reserve for use during periods of decreased food availability. This energy reserve typically takes the form of the lipid triglyceride (see Chapter 6). Triglyceride is an effective energy-storage molecule because large amounts of ATP can be generated when its three fatty-acid subunits are oxidized.

Although some triglyceride is present in muscle cells, most is stored in adipocytes. These cells make up the fat bodies found in insects and other species and the adipose tissue of mammals. Even a lean 70-kg human male stores enough energy in adipose tissue to survive for over 30 days without eating.

Is there a homeostatic system that regulates triglyceride stores? An answer started to emerge in the 1970s, when biologists began studying mutations in mouse genes called *obese* and *diabetic*. Homozygous *obese* (*ob/ob*) and *diabetic* (*db/db*) mice eat large quantities of food and move much less than heterozygous

FIGURE 49.10 In Mice, Mutations in the *obese* and *diabetic* Genes Can Cause Obesity. These mice are siblings from the same litter. At the *ob* gene, the lean mouse is heterozygous and the obese mouse is homozygous.

or wild-type siblings do. The homozygotes also become extremely obese (**FIGURE 49.10**).

To test the hypothesis that the *obese* and *diabetic* gene products are involved in cell–cell signaling, researchers turned to an experimental technique called **parabiosis,** which works as follows:

1. Two closely related animals are surgically united by suturing the pelvis, shoulders, and abdominal walls together.
2. The newly created twin animal is allowed to recover from the procedure.
3. Within a short time, capillaries form between the two parabiotic partners. As a result, the two individuals develop a shared circulatory system.
4. The united circulatory system permits the passage of certain hormones and other long-lived molecules between the two partners. The system does not allow passage of molecules that are rapidly metabolized, such as glucose and fatty acids.
5. No new nerves grow between the two animals. As a result, they can influence one another through endocrine signals but not through electrical signals.

When researchers performed parabiosis between *db/db, ob/ob*, and lean mice, the results were striking (**FIGURE 49.11**):

- When a *db/db* animal was joined to either a lean animal or an *ob/ob* animal, the *db/db* mouse continued to eat and grow normally; but its partner stopped eating, lost weight, and eventually died of apparent starvation.
- When *ob/ob* animals were joined to lean animals, the *ob/ob* mice ate less food and gained weight less rapidly than did *ob/ob* mice joined to other *ob/ob* mice.

In addition, when two *db/db* animals were joined, both partners ate and grew as expected—both became obese. There was no difference between the two in survival.

To interpret these results, biologists hypothesized that mice produce a satiation, or "stop-eating," hormone—a negative feedback signal in homeostasis with respect to fat stores. The explanation was that *db/db* mice lack the receptor required for the hormone to affect target cells.

As *db/db* mice got fatter and fatter, they would produce more and more hormone—to no avail. This model explained why the signal from *db/db* mice greatly reduced food intake in their parabiotic partners but had no effect on the *db/db* mouse.

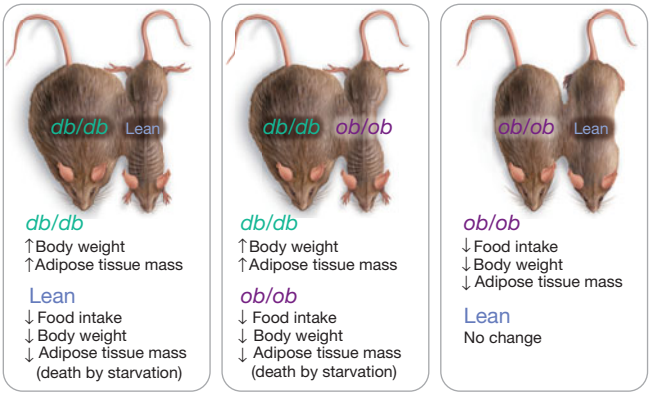
RESEARCH

QUESTION: Are the *diabetic* (*db*) and *obese* (*ob*) gene products involved in endocrine function?

HYPOTHESIS: The gene products are involved in hormonal signaling that affects appetite.

NULL HYPOTHESIS: The gene products are not involved in hormonal signaling.

EXPERIMENTAL SETUP:



Perform parabiotic surgery on closely related mice with different genotypes, so blood-borne products will pass between the mice in each pair.

PREDICTION: *db/db* mice parabiosed to either *ob/ob* or lean mice will gain weight while their partners lose weight; *ob/ob* mice parabiosed to a lean mouse will lose weight.

PREDICTION OF NULL HYPOTHESIS: No changes in phenotypes of parabiotic mice will occur.

RESULTS:

CONCLUSION: Gene products of *db* and *ob* are involved in hormonal signaling that affects appetite.

FIGURE 49.11 Parabiosis of Genetically Obese and Lean Mice Provides Evidence of a "Satiation Hormone."

✔**QUESTION** Suppose a mouse were doubly homozygous *(ob/ob db/db)*. Would its phenotype be the same as or different from singly homozygous individuals? Explain your reasoning.

©2010 Nature Publishing Group

The satiation hormone itself was postulated to be encoded by the *obese* gene. As a result, *ob/ob* mice do not produce the hormone. They respond to the signal if it is available from a normal partner, however.

A key idea here is that the two genotypes produce the same phenotype because they disable different parts of the same hormone-signaling system. For a system to function, the hormone must be present and the target tissues must have receptors for that specific hormone.

This model was confirmed in 1994, when the *obese* gene product, called **leptin,** was shown to be a polypeptide hormone. Leptin is secreted into the blood by adipocytes and interacts with a specific receptor located in many tissues, including areas of the brain known to control feeding behavior.

In mice, leptin injections correct the obesity of *ob/ob* (leptin-deficient) mice but not of *db/db* (leptin-receptor-deficient) individuals. Unfortunately, leptin injections are not helpful for the vast majority of obese humans.

Follow-up work has shown that leptin levels in the blood vary in proportion to total adipose tissue mass. When adipose mass falls below a set point, the leptin level in the blood also falls. The brain senses the decrease in leptin level and generates both an increase in appetite and a decrease in energy expenditure. These responses promote eating and restore energy balance.

When sufficient food intake has occurred to restore triglyceride stores, leptin levels rise. The result is diminished appetite, increased energy expenditure, and the stabilization of adipose tissue mass. This is a striking example of homeostasis achieved by feedback inhibition.

ADH, Aldosterone, and Water and Electrolyte Balance Recall that when an individual is dehydrated, **antidiuretic hormone (ADH)** is released from the pituitary gland (see Chapter 43). ADH increases the permeability of the kidney's collecting ducts to water, causing water to be reabsorbed from urine and saved.

ADH is instrumental in achieving homeostasis with respect to water balance. For example, the ethanol in alcoholic beverages inhibits the release of ADH from the pituitary. People who imbibe large quantities of these beverages produce large quantities of dilute urine. The resulting water loss can lead to dehydration and nausea—symptoms associated with an alcoholic hangover.

When sodium concentration in body fluids is low, **aldosterone** is released from the adrenal cortex (see Chapter 43). Because aldosterone increases reabsorption of sodium ions in the distal tubules of the kidney, it plays a key role in homeostasis with respect to electrolyte concentrations and overall volume of body fluids. Adrenal hormones with this effect are called **mineralocorticoids.**

ADH saves water; aldosterone saves sodium. Together, they are key players in maintaining water and electrolyte balance.

EPO and Oxygen Availability **Erythropoietin (EPO)** is a crucial element in the homeostatic system for blood oxygen levels. When blood oxygen levels fall, the kidneys and other tissues release EPO, which stimulates the production of red blood cells. The more red blood cells, the higher the oxygen-carrying capacity of blood is. If you moved to a place at high elevation and experienced chronic oxygen deficit, your body would respond by releasing EPO and increasing red blood cell concentration. This explains why many athletes train at high altitudes.

Unfortunately, some endurance athletes have turned to EPO injections as a way to increase the oxygen-carrying capacity of their blood and give themselves a competitive edge. The practice is dangerous, as well as illegal. EPO abuse is thought to be responsible for the collapse and death of several cyclists during races in the mid-1990s.

The increased viscosity of blood in EPO abusers is accentuated during exercise, when blood plasma volume drops due to dehydration. The combination of high blood viscosity and low blood volume can impair blood flow through capillaries, increasing the risk of tissue damage and blood clotting. If clots form in blood vessels that lead to the heart or brain, heart attack or stroke may occur.

1. Compare and contrast the roles of the hormones involved in metamorphosis of amphibians and insects.
2. Explain how the various changes induced by elevated cortisol result in a response to long-term stress.

Answers are available in Appendix A.

49.3 How Is the Production of Hormones Regulated?

Most hormones are released in response to an environmental cue or a message from an integrator in a homeostatic system. Often, the nervous system is closely involved. For example, environmental cues that signal the onset of the breeding season or the presence of a predator are received by sensory receptors and interpreted by the brain. Similarly, integration in most homeostatic systems is done by neurons in the central nervous system (CNS)—the brain and spinal cord (see Chapter 46).

Based on these observations, the short answer to the question posed in the title of this section is simple: In many cases, hormone production is directly or indirectly controlled by the nervous system.

The Hypothalamus and Pituitary Gland

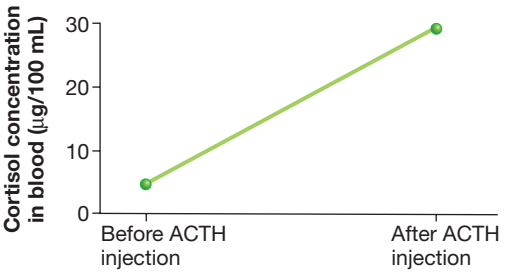
The **pituitary gland,** located at the base of the brain, is directly connected to the brain region called the **hypothalamus.** This physical link between the hypothalamus and pituitary is the basis of the connection between the CNS and the endocrine system.

The pituitary has two distinct segments: the **anterior pituitary** and the **posterior pituitary.** In 1930, a biologist documented the consequences of removing the entire pituitary in laboratory rats: The animals stopped growing, could not maintain a normal body temperature, and suffered atrophy (shrinkage) of their genitals, thyroid glands, and adrenal cortexes. Not surprisingly, their life span shortened dramatically.

These experiments suggested that, in addition to secreting growth hormone, the pituitary secretes hormones that regulate the production of a wide variety of other hormones. As a case study, let's look at the pituitary hormone that acts on the adrenal glands.

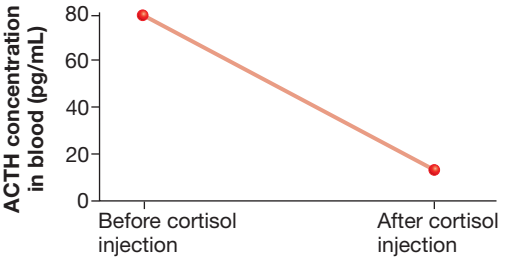
Controlling the Release of Glucocorticoids Early work on rats suggested that a molecule from the pituitary gland affects the adrenal gland. This molecule soon came to be called **adrenocorticotropic hormone,** or **ACTH** (*adreno* refers to the adrenal glands; *cortico* refers to the outer portion, or cortex, of the gland; and *tropic* means affecting the activity of).

ACTH was purified and characterized in 1943. When human volunteers were injected with ACTH, cortisol levels in their blood rose (**FIGURE 49.12a**). This result provided evidence that ACTH is a regulatory hormone. The adrenal cortex secretes glucocorticoids in response to ACTH released from the pituitary.



What regulates ACTH? Biologists from two laboratories independently showed that ACTH is released in response to a molecule produced by the hypothalamus. After years of effort, a different team of researchers succeeded in purifying a peptide—just 41 amino acids long—called **corticotropin-releasing hormone (CRH).** When the hypothalamus releases CRH, it stimulates cells in the anterior pituitary to secrete ACTH into the bloodstream.

Feedback Inhibition by Glucocorticoids What *stops* glucocorticoid secretion? The key is to recognize that glucocorticoids themselves suppress ACTH production by the pituitary gland. Glucocorticoids accomplish feedback inhibition—they suppress their own production.



When human volunteers were injected with cortisol, ACTH levels in their bloodstream dropped dramatically (**FIGURE 49.12b**). Cortisol also inhibits release of CRH from the hypothalamus. Thus, if glucocorticoid levels become too high, ACTH levels fall. But if glucocorticoid levels become too low, ACTH levels rise and drive a compensatory increase in glucocorticoid production. **FIGURE 49.12c** summarizes the relationships among CRH, ACTH, and the glucocorticoid cortisol.

What happens when feedback inhibition fails? Certain pituitary tumors diminish the ability of cortisol to suppress ACTH production, leading to persistently high blood ACTH and cortisol levels. The result is **Cushing's disease,** an unrelenting stress response that depletes the body's protein reserves. It is fatal if not treated.

DATA: Upton, G. V., A. Corbin, C. C. Mabry, et al. 1973. *Acta Endocrinologica* 73: 437–443.

✔**EXERCISE** How would you use the data in part (a) to devise a test for adrenal failure in humans?

Patterns in Glucocorticoid Release Under ordinary circumstances, the production of CRH by the hypothalamus displays a daily rhythm and reaches its highest level in the early

morning hours. This pattern drives a corresponding daily rhythm in ACTH production and blood cortisol level.

Ordinarily, the morning peak in blood cortisol levels coincides with arousal and initiation of the day's activities—and the effect is saving glucose for use by the brain. As an aside, the unpleasant symptoms of jet lag are due in part to the daily cortisol rhythm being out of synchrony with local time for several days after you arrive in a new time zone.

When the brain processes stimuli that produce pain or anxiety, it initiates a long-term stress response and a sustained increase in CRH production. Increased CRH production causes blood ACTH and cortisol levels to remain much higher throughout the day than they are in the unstressed state.

The Hypothalamic–Pituitary Axis—An Overview The CRH-ACTH-glucocorticoid relationship is just one of many hormone systems based on interactions among the hypothalamus, pituitary, and target glands or cells. The **hypothalamic–pituitary axis** actually forms two anatomically distinct systems (**FIGURE 49.13**). The anterior pituitary develops from cells in an embryo's mouth and throat lining; the posterior pituitary is an extension of the brain.

Two distinct populations of neurons in the hypothalamus influence the posterior versus anterior sections of the pituitary gland. Both types of hypothalamic neurons synthesize and release neurohormones and are called **neurosecretory cells.** The neurosecretory cells release hormones under the control of brain regions responsible for integrating information about the external or internal environment. For example, information about an upcoming exam or athletic contest might trigger action potentials that lead to the release of CRH.

The Posterior Pituitary Even though both parts of the gland contain neurosecretory cells, the anterior pituitary and posterior pituitary function in different ways. As Figure 49.13a indicates, the posterior portion of the pituitary is an extension of the hypothalamus itself.

Neurosecretory cells that project from the hypothalamus produce the hormones ADH and oxytocin, which are then stored

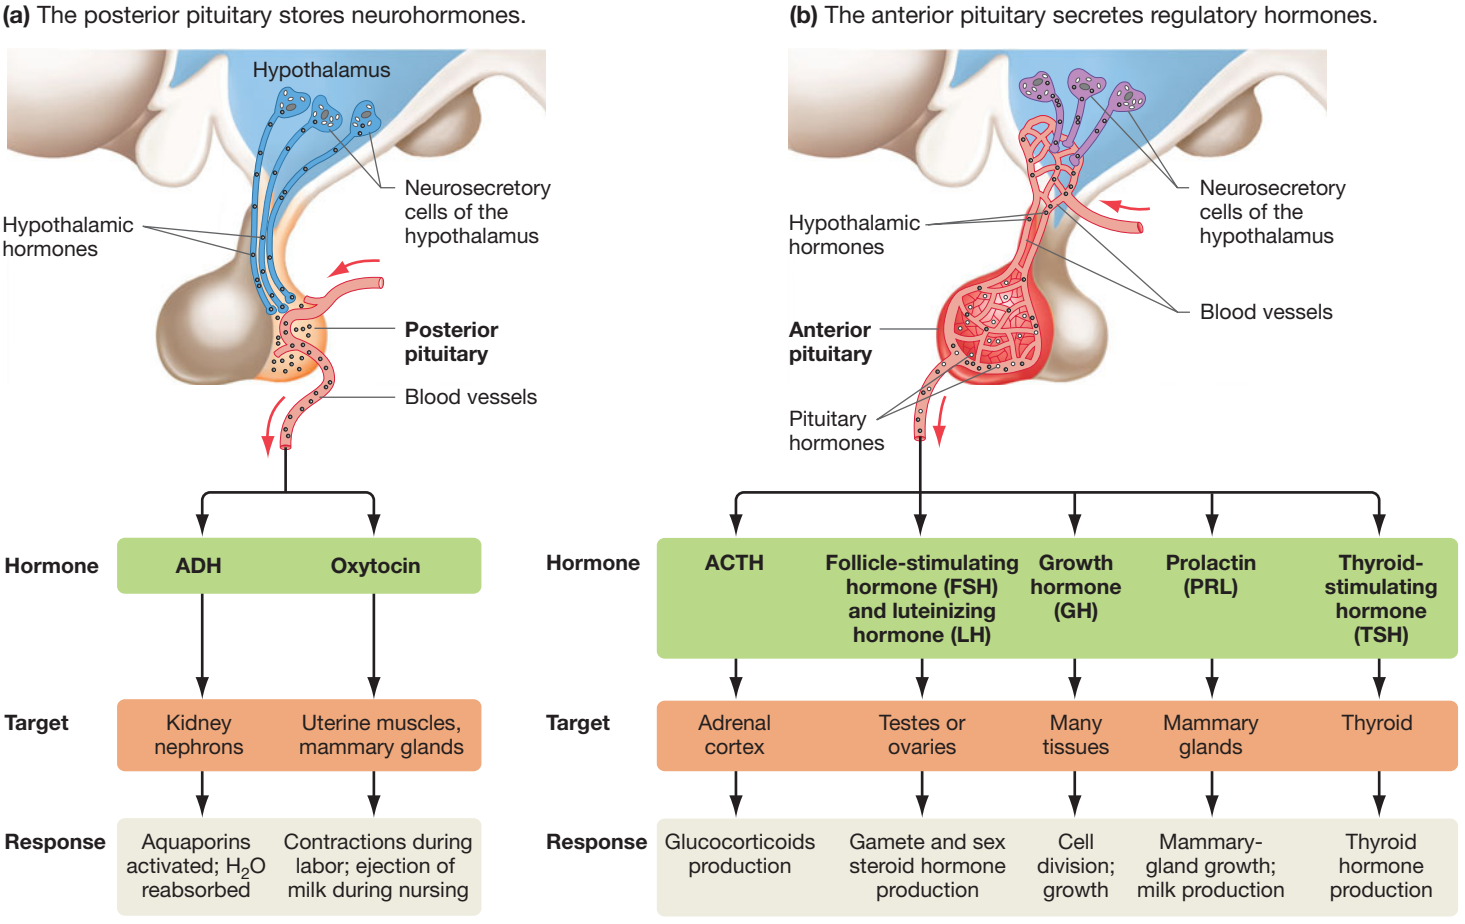

FIGURE 49.13 The Hypothalamus and Pituitary Interact Closely. (a) Developmentally and anatomically, the posterior pituitary is an extension of the hypothalamus. Neurosecretory cells in the hypothalamus extend directly into the posterior pituitary and secrete ADH (vasopressin) and oxytocin. **(b)** The hypothalamus and the anterior pituitary communicate indirectly, via blood vessels. Hormones produced by other populations of neurosecretory cells in the hypothalamus travel in the blood to the anterior pituitary, where they control the release of pituitary hormones.

in the posterior pituitary. From there, ADH and oxytocin are released into the bloodstream. This is an example of the neuroendocrine pathway of hormone action. Recall that ADH aids in the reabsorption of water by the kidneys. **Oxytocin** helps induce labor and milk release in female mammals.

The Anterior Pituitary Unlike the situation in the posterior pituitary, the hypothalamus and anterior pituitary are connected indirectly. Neurosecretory cells from the hypothalamus secrete stimulatory or inhibitory hormones into tiny blood vessels to the anterior pituitary. In response, the anterior pituitary alters its secretion of hormones that enter the general bloodstream and act on target tissues or glands. This is an example of the neuroendocrine-to-endocrine pathway of hormone action.

Many of the hormones produced by the anterior pituitary stimulate the production of other hormones. The anterior pituitary hormones include ACTH; **follicle-stimulating hormone (FSH)** and **luteinizing hormone (LH),** which are involved in stimulating the gonads to produce sex hormones and gametes; GH; **prolactin,** which stimulates mammary gland growth and milk production in mammals; and **thyroid-stimulating hormone (TSH),** which triggers the production of thyroid hormones.

Control of Epinephrine by Sympathetic Nerves

When biologists analyze how the nervous system and endocrine system interact to control the release of epinephrine, the distinction between the two systems begins to blur. Section 49.2 introduced how epinephrine acts as an endocrine signal. During the fight-or-flight response, sympathetic nerves trigger the release of epinephrine from the adrenal medulla into the bloodstream. But in addition, some sympathetic nerves release the related molecule **norepinephrine** directly onto target cells.

In effect, the endocrine system broadcasts a messenger by secreting it into the bloodstream whereas the nervous system delivers a chemical messenger directly to particular cells. Epinephrine and norepinephrine, which differ from one another only by the presence of an additional methyl group on epinephrine, are members of the family of molecules called **catecholamines.**

Catecholamines function as neurotransmitters as well as hormones. Similarities between hormones and neurotransmitters do not end there, however. In some cases, their mode of action is similar.

Some neurotransmitters initiate changes in gene expression in neurons (see Chapter 46). You might recall that in the sea slug *Aplysia*, repeated application of serotonin led to gene activation and changes in the behavior of the synapse. By altering synapses in this way, neurotransmitters play a central role in learning and memory.

Similarly, many hormones exert their effects by activating particular genes in target cells. Understanding how gene activation occurs in response to neurotransmitters and hormones is the subject of intense research at laboratories around the world. It is also the subject of Section 49.4.

check your understanding

If you understand that . . .

- Hormone concentrations are tightly regulated—in some cases by negative feedback, in other cases by stimulatory or inhibitory signals from the hypothalamus.

✔ You should be able to . . .

1. Explain how feedback inhibition occurs in production of ACTH.
2. Discuss the relationship between processing centers in the brain, neurosecretory cells in the hypothalamus, and hormone-secreting cells in the anterior pituitary.

Answers are available in Appendix A.

49.4 How Do Hormones Act on Target Cells?

The key to understanding how hormones act on target cells is to recognize that only some hormones are lipid soluble and cross plasma membranes readily (see Figure 49.3). More specifically, steroid hormones are small lipids that enter cells without difficulty. But the peptide and polypeptide hormones—as well as most amino acid derivatives, with the exception of thyroid hormones—do not cross plasma membranes easily because of their large size and electrical charge.

Differences in the lipid solubility of hormones are important because they relate to the location of hormone receptors in a target cell. Steroid and thyroid hormones bind to intracellular receptors, while most amino acid derivatives and all polypeptides bind to receptors on the surface of the plasma membrane.

To compare these two distinct paths of hormone action, let's consider how estradiol and epinephrine affect target cells. As a steroid and a nonsteroid, they serve as model systems for target cell responses to hormonal signals.

Steroid Hormones Bind to Intracellular Receptors

Estrogens are steroids that direct the development of female secondary sex characteristics in many animal species. In humans and other mammals, the most important estrogen is the molecule estradiol (formally, 17 β-estradiol).

Because of its importance in reproduction by humans and domesticated animals, estradiol's mode of action has been the topic of intense investigation for over 50 years. How do target cells receive the signal carried by estradiol?

Identifying the Estradiol Receptor In 1966, biologists succeeded in isolating the estradiol receptor in laboratory rats. **FIGURE 49.14** indicates the experimental approach. In essence, the research team introduced labeled hormone molecules into females and

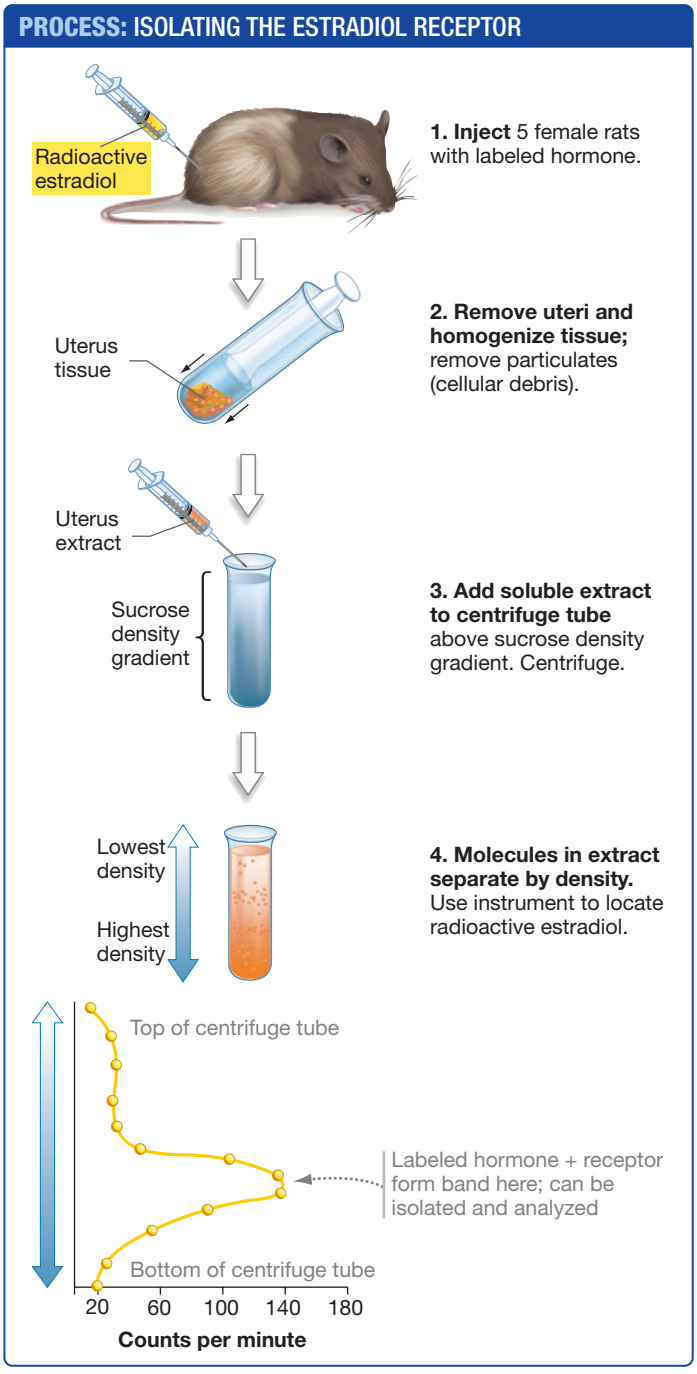

FIGURE 49.14 Labeled Hormones Can Be Used to Find Hormone Receptors. If radioactive estradiol binds to its receptor in the uterus, the hormone–receptor complex should form a distinct band of radioactivity when molecules from uterine cells are separated by centrifugation.

DATA: Toft, D., and J. Gorski. 1966. *Proceedings of the National Academy of Sciences, USA* 55: 1574–1581.

then used density-gradient centrifugation—a technique introduced in **BioSkills 10** in Appendix B—to separate molecules in target cells by size.

When centrifugation was complete, the biologists found that the labeled estradiol was concentrated in a narrow band comprised of the labeled hormone bound to its receptor. After purifying the receptor molecule, they found that proteinase enzymes could destroy it. Based on this result, they inferred that the estradiol receptor was a protein.

Follow-up experiments established that the estradiol receptor is primarily located in the nucleus but is not associated with the nuclear envelope. Further, the receptor is found only in estradiol target tissues, including the uterus, hypothalamus, and mammary glands. The latter finding was particularly exciting, because it clarified how hormones act in a tissue-specific way.

This is a crucial point: Hormones are broadcast throughout the body via the bloodstream, but they act only on cells that express the appropriate receptor. Target cells respond to a particular hormone because they contain a receptor for that hormone.

Later, biologists found that the gene for the estradiol receptor is similar to the genes that encode receptors for the glucocorticoids, testosterone, and other steroid hormones. This result suggested that all steroid receptors are descended from an ancestral receptor molecule, and that the binding of any steroid hormone to its receptor affects the target cell via a similar mechanism.

What happens once the hormone–receptor complex is present inside the nucleus of a target cell?

Documenting Changes in Gene Expression During the 1970s and 1980s, work in several laboratories suggested that estradiol and other steroid hormones affect gene transcription after they bind to their receptors. For example, researchers injected laboratory animals with estradiol or other steroid hormones and documented changes in the mRNAs and proteins produced in target cells. These data showed that steroid hormones can cause dramatic changes in the amount or timing of mRNA production by a large number of genes.

How? The estradiol receptor, like other members of the steroid-hormone receptor family, has two copies of a distinctive DNA-binding region called a zinc finger. DNA-binding domains are sections of a protein that make physical contact with DNA. The presence of zinc fingers in the estradiol receptor suggested that once estradiol had bound to it, the hormone–receptor complex might affect gene expression by binding directly to DNA.

Follow-up work confirmed that steroid hormone–receptor complexes bind to specific sites in DNA called **hormone-response elements.** Hormone-response elements are located just "upstream" (in the 5′ direction) from the start of target genes. Gene expression changes when a regulatory molecule such as a steroid hormone–receptor complex binds to the hormone-response element for that gene.

FIGURE 49.15 (see page 1008) summarizes the current model of how steroid hormones affect target cells. Because each hormone–receptor complex leads to the production of many copies of the gene product, the signal from the hormone is amplified. In this way, a small number of hormone molecules produces a large change in the activity of target cells and tissues.

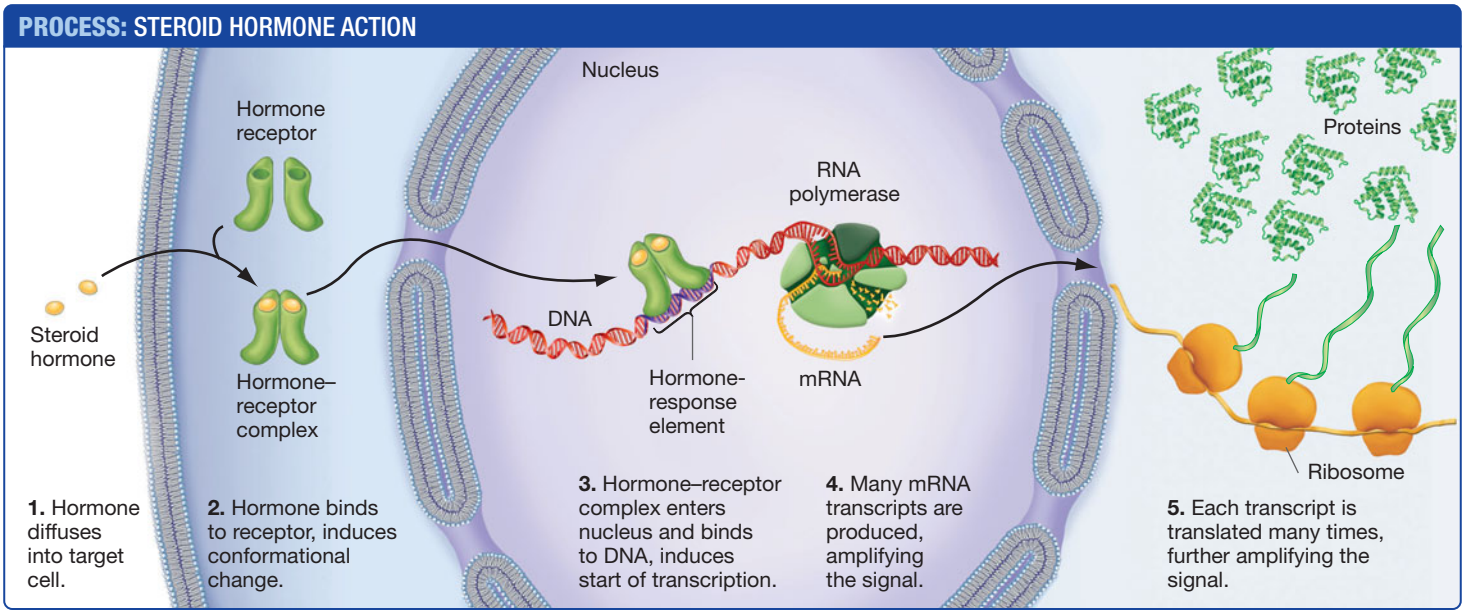

FIGURE 49.15 Steroid Hormones Bind to Receptors Inside Target Cells and Affect Gene Expression.

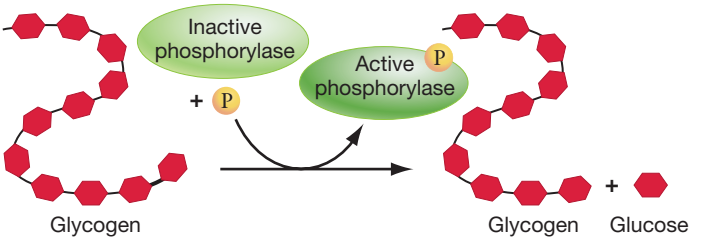
Hormones That Bind to Cell-Surface Receptors

Most polypeptide hormones and amino-acid-derived hormones are not lipid soluble. For these molecules to affect a cell, they must bind to receptors on the cell surface. Because the messenger never enters the target cell, its message must be transduced—changed into a form that is active inside the cell. This phenomenon is known as **signal transduction** (Chapter 11).

To explore how signal transduction occurs, let's first examine hormone receptors that reside in the plasma membrane and then explore the molecules that process the message inside the cell. In both cases, epinephrine will be used as a model system.

Identifying the Epinephrine Receptor In 1948 a biologist published an exhaustive set of studies on how epinephrine affects dogs, cats, rats, and rabbits. The responses fell into two distinct categories, depending on the tissue being considered. To explain this observation, the researcher suggested that epinephrine binds two distinct types of receptor. He called these hypothetical proteins the alpha receptor and the beta receptor.



Follow-up work with molecules that block epinephrine receptors documented that there are actually two types of alpha receptors and two types of beta receptors. Thus, there are four distinct epinephrine receptors. Each is found in a distinct tissue type, and each induces a different response from the cell.

The discovery of four epinephrine receptors reinforces the concept of tissue specificity observed in experiments on the estradiol receptor. Hormones are transmitted throughout the body, not unlike a cell phone signal that is broadcast through the atmosphere. But their message is received only by cells with the appropriate receptor—just as a cell phone signal is received only by equipment with the appropriate antenna. Since there are four distinct epinephrine receptors, the same hormone can trigger different effects in different cells. What happens once epinephrine binds to one of these receptors?

What Acts as the Second Messenger? Signal transduction occurs when a chemical message binds to a cell-surface receptor and triggers a response inside the cell.

How does a signal from epinephrine increase glucose levels in the blood? To answer this question, biologists focused on the enzyme **phosphorylase,** which catalyzes a reaction that cleaves glucose molecules off glycogen (**FIGURE 49.16a**). Phosphorylase exists in active and inactive forms; the enzyme switches between

(a) Phosphorylase catalyzes the production of glucose from glycogen.

(b) Phosphorylase is activated in response to epinephrine.

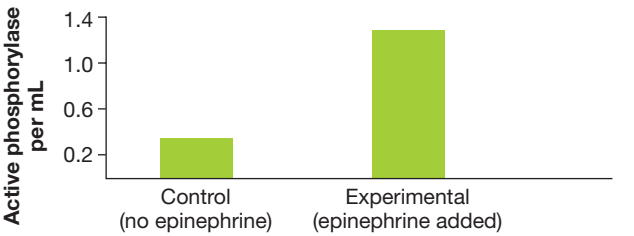


FIGURE 49.16 Epinephrine Activates the Enzyme That Catalyzes the Formation of Glucose from Glycogen. (a) Phosphorylase is activated when an enzyme adds a phosphate group to it. **(b)** When epinephrine is added to cell-free extracts from liver tissue, the amount of activated phosphorylase increases dramatically.

DATA: Rall, T. W., E. W. Sutherland, and J. Berthet. 1957. *Journal of Biological Chemistry* 224: 463–475.

these states when it is phosphorylated or dephosphorylated by another enzyme.

Phosphorylase is present in liver cells—the primary source of blood glucose during the fight-or-flight response. As predicted, when researchers added epinephrine to extracts from homogenized (ground up) liver cells, much larger amounts of phosphorylase were activated relative to cell extracts that did not receive epinephrine (**FIGURE 49.16b**).

This observation suggested there was something in the homogenized cells that activated phosphorylase when epinephrine was present. By purifying components from the liver cell extracts and testing them one by one, researchers eventually found the ingredient that activated phosphorylase: a molecule called cyclic adenosine monophosphate, or **cyclic AMP (cAMP).**

The role of cAMP in epinephrine signaling was confirmed when researchers studied epinephrine's effects on the rat heart. During the fight-or-flight response, heart rate and the contractile force of the heart rise dramatically—increasing cardiac output. Cardiac output is a measure of how much blood the heart pumps per unit time.

The graphs in **FIGURE 49.17** show how cardiac muscle cells respond to epinephrine. In each graph, the *x*-axis plots time, in seconds, after epinephrine is applied.

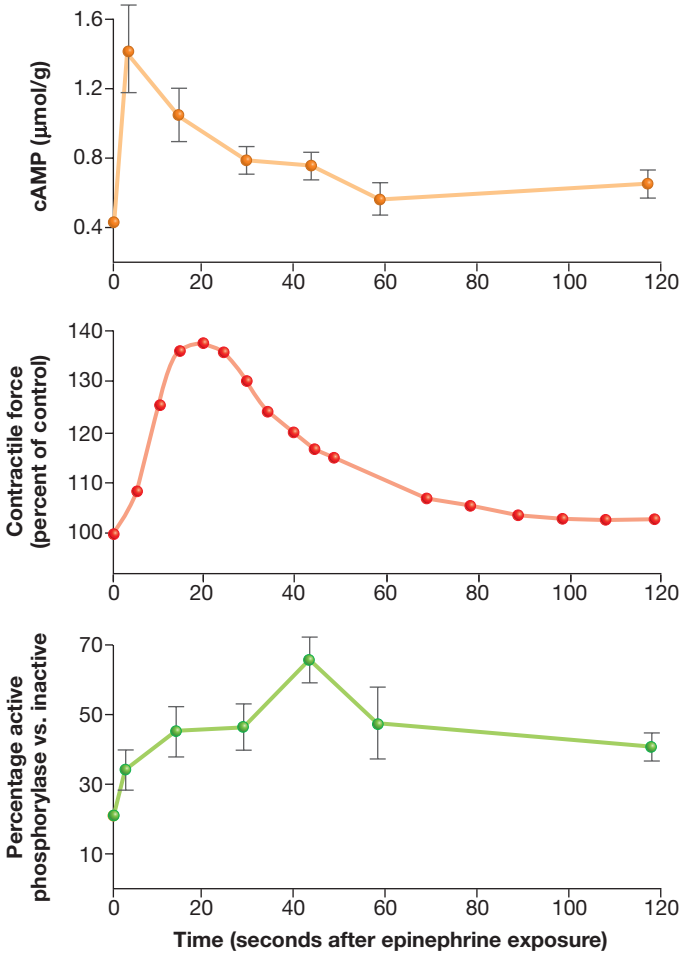

FIGURE 49.17 The Chemistry and Activity of Heart Muscle Cells Change in Response to Epinephrine.

DATA: Robison, G. A., R. W. Butcher, I. Oye, et al. 1965. *Molecular Pharmacology* 1: 168–177.

- ***Top*** Almost immediately, there is a striking increase in cAMP levels inside the cells.
- ***Middle*** A few seconds later, the contractile force of the cells increases, peaking about 18 seconds after the hormone's arrival.
- ***Bottom*** Phosphorylase activity also rises, but peaks later—about 40 seconds after the signal.

To capture the importance of cAMP in triggering these effects, biologists refer to it as a second messenger. Recall that a **second messenger** is a nonprotein signaling molecule that increases in concentration inside a cell in response to a received signal—a molecule that binds at the surface (see Chapter 11).

A Phosphorylation Cascade How does cAMP transfer the hormonal signal on the cell surface to phosphorylase inside the cell? Follow-up work revealed the mechanism for epinephrine action on liver cells (**FIGURE 49.18**).

When epinephrine binds to its receptor, it activates a G protein (see Chapter 11), which then activates the enzyme adenylyl cyclase. Adenylyl cyclase catalyzes a reaction that converts ATP to cAMP. Next, cAMP initiates a chain of events called a **signal transduction cascade,** by binding to an enzyme called

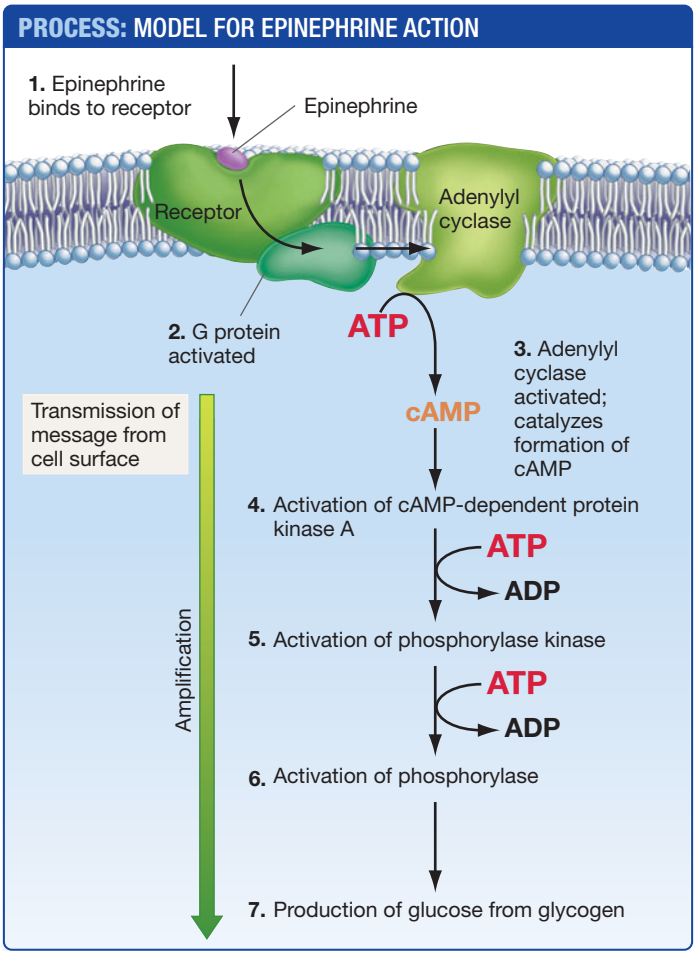

FIGURE 49.18 Epinephrine Triggers a Signal Transduction Cascade. Epinephrine's signal is amplified at each of steps 3–6.

cAMP-dependent protein kinase A. This enzyme responds by phosphorylating the enzyme phosphorylase kinase, which then phosphorylates phosphorylase.

In studying this model, it is crucial to recognize two points:

1. cAMP transmits the signal from the cell surface to the signaling cascade.
2. Together, cAMP production and the subsequent phosphorylation events amplify the original signal from epinephrine.

To appreciate the second point, consider that, in response to stimulation by the hormone–receptor complex, adenylyl cyclase is thought to catalyze the formation of at least 100 molecules of cAMP. In turn, each of these cAMP molecules activates many molecules of cAMP-dependent protein kinase A. Subsequently, each protein kinase molecule activates many molecules of phosphorylase kinase, and so on.

In this way, the binding of just a single molecule of epinephrine may trigger the release of millions or even billions of glucose molecules. Amplification through a signal transduction cascade explains why tiny amounts of hormones can have such huge effects on an individual.

The model in Figure 49.18 was inspired by experiments on the epinephrine receptor called the beta-1 receptor. But other researchers showed that when epinephrine binds to an alpha-1 receptor, a completely different signal transduction event occurs. In this and many other receptor systems, calcium ions (Ca^{2+}) serve as the second messenger in conjunction with another molecule called IP_3. Diacylglycerol (DAG) and 3′, 5′-cyclic GMP (cGMP) are also common second messengers in hormone response systems.

Why Do Different Target Cells Respond in Different Ways?

Researchers are increasingly impressed with the diversity and complexity of signal transduction cascades. For example, target cells that have the same receptor protein may have different second messengers or different enzyme systems that are available for activation. As a result, the same hormone and receptor can give rise to different responses in different target cells.

This finding helps explain one of the most fundamental observations about hormones: The same chemical messenger can trigger different responses in cells from different organs or in cells at different developmental stages. The reason is that the cells contain different receptors, second messengers, amplification steps, protein kinases, enzymes, or transcriptionally active genes.

To summarize this section, steroid and thyroid hormones tend to exert their effects through changes in gene expression. In contrast, polypeptide and most amino-acid-derived hormones activate a specific protein or set of proteins, usually by phosphorylation. Steroid and thyroid hormones activate transcription factors that lead to the production of new proteins; nonsteroid hormones trigger signal transduction cascades that activate existing proteins.

check your understanding

C Y U

If you understand that . . .

- Hormones act on target cells by binding to receptors.
- The response to a hormone is tissue specific, because only certain cells contain receptors for particular hormones.
- In response to binding by lipid-soluble hormones, hormone–receptor complexes bind to DNA and induce changes in gene expression.
- In response to binding by lipid-insoluble hormones, activated cell-surface receptors induce the production of second messengers and the activation of signal transduction cascades that result in the phosphorylation of existing proteins.

✓ You should be able to . . .

1. Predict what would happen to the estradiol response if an individual had mutations that changed the DNA sequence of its hormone-response element.
2. Suppose a steroid hormone binds to a cell-surface receptor. Explain how its mode of action would compare to a polypeptide hormone.

Answers are available in Appendix A.

CHAPTER 49 REVIEW

For media, go to MasteringBiology

If you understand . . .

49.1 Cell-to-Cell Signaling: An Overview

- Hormones are chemical messengers that are released from neurons or cells of the endocrine system, circulate in the blood or other body fluids, and trigger a response in target cells containing an appropriate receptor.
- Hormones have a variety of chemical structures. Most animal hormones are polypeptides, amino acid derivatives, or steroids.

✓ **You should be able to explain the relationship between electrical signals from the nervous system and chemical signals from the nervous system and endocrine system, as they work in combination to coordinate the body's response to environmental change.**

49.2 What Do Hormones Do?

- Together with the nervous system, hormones coordinate the activities of diverse cells and tissues. A single hormone may affect a wide array of cells and tissues and induce a variety of responses.
- Estradiol is an example of a hormone that regulates development and sexual maturation. Estradiol stimulates the formation of female sex characteristics in human embryos and the maturation of these tissues in adolescence.
- Melatonin is a hormone that regulates reproductive physiology in response to seasonal changes in day length.
- Epinephrine and cortisol are examples of hormones that help individuals cope with environmental changes. These hormones activate the short-term and long-term responses to stressors, triggering the fight-or-flight response or inducing changes that conserve glucose for use by the brain.
- Hormones are involved in a wide array of homeostatic interactions. For example, hormones are involved in directing cells that modify the concentrations of water, sodium ions, and other components of the blood and interstitial fluid. Homeostasis with respect to triglyceride stores is also under endocrine control.

✔ **You should be able to explain why hormones—instead of electrical signals from the nervous system—are primarily responsible for regulating responses to environmental change, embryonic and sexual development, and homeostasis.**

49.3 How Is the Production of Hormones Regulated?

- In many cases, the release of a hormone is regulated by chemical messengers from the anterior pituitary.
- Hormone-secreting cells in the anterior pituitary are regulated by hormones released by the hypothalamus region of the brain.
- The long-term stress response is a well-studied example of hormone regulation. The brain responds to long-term stress by triggering the release of the hypothalamic hormone CRH. CRH activates the release of ACTH by the pituitary gland, which stimulates the production of cortisol by cells in the adrenal cortex. Because cortisol inhibits the production of ACTH and CRH, the chain of events is regulated by feedback inhibition.

✔ **You should be able to predict the consequences if negative feedback fails to occur after the release of CRH.**

49.4 How Do Hormones Act on Target Cells?

- Animal hormones have two basic modes of action. Steroid and thyroid hormones are lipid soluble, cross plasma membranes readily, and often bind to receptors inside cells. Most polypeptide and amino-acid-derived hormones are not lipid soluble; they bind to receptors located in the membranes of target cells. In both cases, the response to a hormone is tissue specific because only certain cells express certain receptors.
- Most steroid and thyroid hormones act by inducing a change in gene expression.
- Polypeptide and most amino-acid-derived hormones trigger signal transduction cascades that activate one or more target proteins by phosphorylation.
- Although they are produced in tiny concentrations, hormones have large effects because they trigger gene expression or because their message is amplified through a signal transduction cascade.

✔ **You should be able to predict whether a cell can respond to more than one hormone at a time, and explain why or why not.**

TEST YOUR KNOWLEDGE

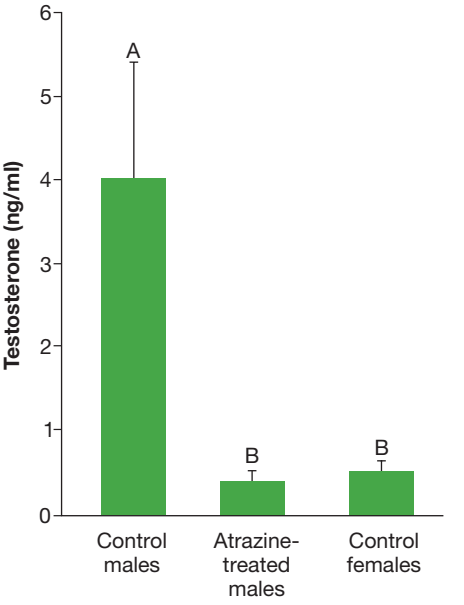
Answers are available in Appendix A

1. Both epinephrine and cortisol are involved in the body's response to stress. How do the two molecules differ?
   a. Cortisol is an amino acid derivative; epinephrine is a steroid.
   b. Cortisol binds to receptors on the plasma membranes of target cells; epinephrine binds to receptors in the interior of target cells.
   c. Epinephrine mediates the short-term response; cortisol mediates the short- and long-term responses.
   d. Cortisol controls the release of epinephrine from the adrenal glands.

2. How do steroid hormones differ from polypeptide hormones and most amino-acid-derived hormones?
   a. Steroids are lipid soluble and cross plasma membranes readily.
   b. Polypeptide and amino-acid-derived hormones are longer lived in the bloodstream and thus exert greater signal amplification.
   c. Polypeptide hormones are the most structurally complex and induce permanent changes in target cells.
   d. Only polypeptide and steroid hormones bind to receptors in the plasma membrane.

3. Which of the following developmental processes is *not* controlled by hormones?
   a. the initial development of male and female gonads, soon after fertilization
   b. overall growth
   c. molting in insects and other invertebrate animals
   d. metamorphosis in insects and other invertebrate animals
4. What is a hormone-response element?
   a. a receptor for a steroid hormone
   b. a receptor for a polypeptide hormone
   c. a segment of DNA where a hormone–receptor complex binds
   d. an enzyme that is activated in response to hormone binding and produces a second messenger
5. Where are the photoreceptors that sense day length located in mammals? In lizards? In birds?
6. True or False: In hormone systems, feedback inhibition occurs when the presence of a hormone inhibits release of the hormone.

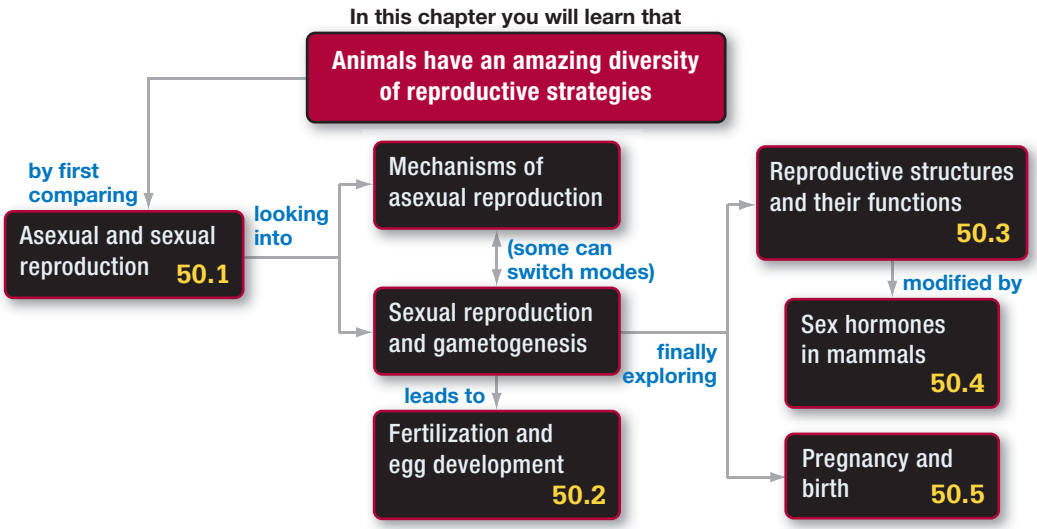
TEST YOUR UNDERSTANDING



Answers are available in Appendix A

7. Hormones are present in tiny concentrations, yet have large effects on target cells and on the individual as a whole. This is possible because a single hormone molecule
   a. can bind to many receptors at once.
   b. can activate many intracellular enzymes.
   c. can initiate transcription of DNA by binding to cell-surface receptors.
   d. can bind irreversibly to its receptor.
8. Why is the observation that one hormone may bind to more than one type of receptor important?
9. Compare and contrast the structure and function of the anterior and posterior pituitary glands.
10. Compare and contrast the modes of action of steroid and nonsteroid hormones.
11. Design a study to test the hypothesis that the symptoms of jet lag are caused by disruption of normal daily cortisol rhythms.
12. You see an advertisement on television for a leptin supplement that claims to result in dramatic weight loss. Explain why this supplement is unlikely to be effective.

TEST YOUR PROBLEM-SOLVING SKILLS



Answers are available in Appendix A

13. You are a physician supervising a patient's recovery from the surgical removal of the posterior pituitary. Which of the following symptoms would you expect to have to treat?
   a. amenorrhea (cessation of the menstrual cycle)
   b. cessation of growth
   c. dehydration
   d. high blood-glucose levels
14. Suppose that during a detailed anatomical study of a marine invertebrate, you found a small, previously undescribed structure. How would you test the hypothesis that the structure is a gland that releases one or more hormones?
15. Suppose that a researcher announces the discovery of a hormone that affects the metabolism of fats in lab rats. Preliminary data indicate that the hormone is a polypeptide, about 50 amino acids long. The researcher suggests that the hormone activates transcription of a gene for a protein that stimulates fat breakdown. Explain why this researcher's hypothesis is reasonable or unreasonable.
16. **QUANTITATIVE** Scientists set out to test the hypothesis that atrazine is an endocrine disruptor that feminizes male amphibians. They treated male amphibians with atrazine, then later compared their circulating testosterone concentrations with those of control males and females. The results are shown here. Bars with different letters are significantly different from one another. Was the hypothesis supported? Why or why not?

50 Animal Reproduction

The swollen, red rump of this female Hamadryas baboon indicates that she is about to produce an egg. She will probably mate with several males before the egg is fertilized. This chapter discusses how hormones regulate the female reproductive cycle and the consequences of multiple mating.

All the cells, tissues, organs, and systems introduced in Unit 8 exist for one reason: They allow animals to survive long enough and gather enough resources to reproduce. Stated another way, producing offspring is the reason that adaptations exist. Reproduction is the underlying purpose of virtually everything that an animal does. Replication is a fundamental attribute of life (see Chapter 1).

But if evolution by natural selection explains *why* animals reproduce, the goal of this chapter is to explore *how* reproduction occurs. Section 50.1 introduces research on animals that cycle between asexual and sexual modes of reproduction and explains how both modes occur at the cellular level. Section 50.2 surveys the diverse ways in which animals accomplish fertilization once gametes have formed. The final three sections focus on mammalian reproduction, using humans as the primary model organism.

BIG PICTURE

This chapter is part of the Big Picture. See how on pages 840–841.

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

The chapter includes topics of urgent practical interest, such as human birth control methods and the recent and dramatic declines in the death rate of human mothers during childbirth. Understanding and manipulating animal reproductive systems is an important issue for physicians, veterinarians, farmers, zookeepers, conservation biologists, and many others in biology-related professions.

50.1 Asexual and Sexual Reproduction

Several earlier chapters have explored how asexual and sexual reproduction differ. When reproduction is asexual, it occurs without fusion of gametes. **Asexual reproduction** is usually based on mitosis and results in offspring that are genetically identical to their parent. **Sexual reproduction,** in contrast, is based on meiosis and fusion of gametes. Due to genetic recombination during meiosis and the fusion of haploid gametes—usually from different parents—during fertilization, sexual reproduction results in offspring that are genetically different from each other and from their parents.

Let's first consider how animals engage in asexual reproduction to make genetically identical copies of themselves, then review the mechanisms responsible for sexual reproduction.

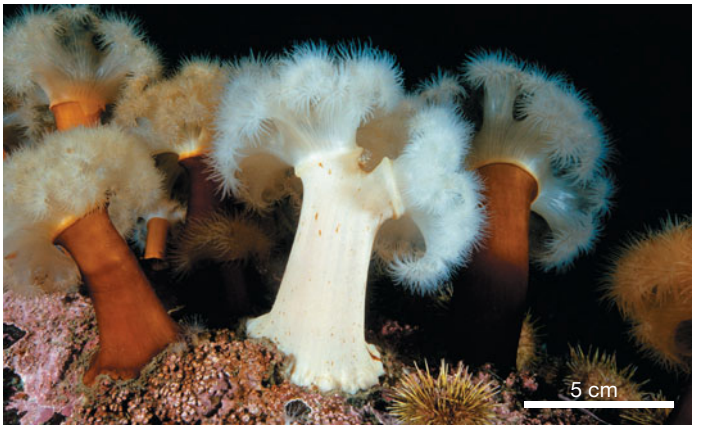
How Does Asexual Reproduction Occur?

In thousands of animal species, individuals can **clone** themselves—that is, produce large numbers of identical copies of themselves asexually.

There are three main mechanisms of asexual reproduction:

1. **Budding** An offspring begins to form within or on a parent (**FIGURE 50.1a**). The process is complete when the offspring—a miniature version of the parent—breaks free and begins to grow on its own.
2. **Fission** An individual simply splits into two or more descendants (**FIGURE 50.1b**).
3. **Parthenogenesis** (literally, "virgin-origin") Females produce offspring without fertilization by a male. Usually, parthenogenetic eggs are produced by mitosis, or by meiosis that occurs after chromosome number has doubled, but without crossing over and recombination. In both of these cases, offspring are genetically identical to the mother. Parthenogenesis occurs in a wide diversity of lineages, including certain invertebrates, fishes, lizards, snakes, and birds (**FIGURE 50.1c**).

Many animal species regularly switch between reproducing asexually and reproducing sexually. Why?



Switching Reproductive Modes: A Case History

Daphnia are crustaceans that live in freshwater habitats throughout the world. In a typical year, *Daphnia* produce only diploid, female offspring throughout the spring and summer, via parthenogenesis. The eggs produced by parthenogenesis develop in a structure called a brood pouch (**FIGURE 50.2**) and are released when the female molts her exoskeleton.

(a) Budding in hydra

(b) Fission in anemones

(c) Parthenogenesis in lizards

FIGURE 50.1 Mechanisms of Asexual Reproduction in Animals Are Diverse.

In late summer or early fall, however, many *Daphnia* females begin producing unfertilized, asexually produced eggs, some of which develop into males. Once the males have matured, sexual reproduction ensues: Haploid **sperm,** the male gametes, produced by meiosis in the males, fertilize haploid **eggs,** the female gametes, that females produce via meiosis.

Fertilization is the fusion of sperm and egg. In *Daphnia*, fertilized eggs are released into a durable case that falls to the bottom

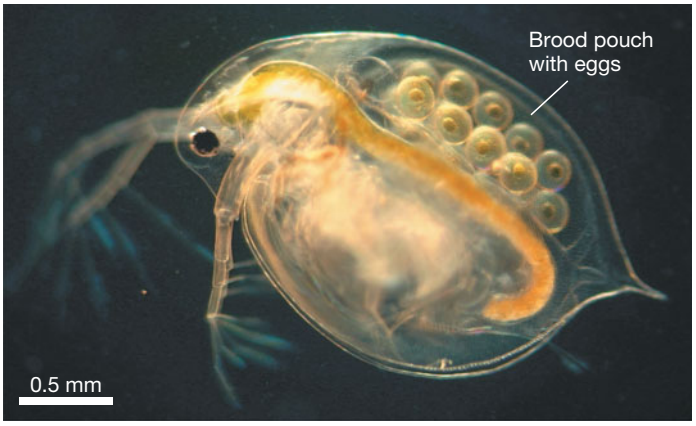


FIGURE 50.2 Female *Daphnia* Can Produce Eggs by Parthenogenesis.

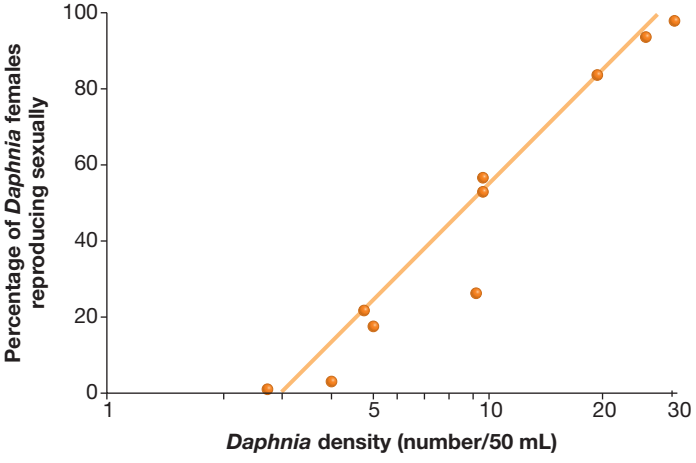
of the pond or lake for the winter. In spring, the sexually produced offspring hatch and the females begin reproducing asexually.

Biologists try to explain observations like this at two levels (see Chapter 53):

1. **Proximate causation** addresses *how* a trait is produced. When researchers identify the genetic, developmental, hormonal, or neural mechanisms responsible for a phenotype, they are working at the proximate level.
2. **Ultimate causation** addresses *why* a trait occurs, in terms of its effect on fitness. Researchers who work at the ultimate level try to understand the evolutionary history of traits.

Let's consider work on proximate aspects of the asexual–sexual switch in *Daphnia* and then consider ultimate causation.



What Environmental Cues Trigger the Switch? For decades, most researchers contended that day length triggered the asexual–sexual switch. The idea was that the shortening days of late summer or fall affected sensors in the brain (see Chapter 49), and these receptors produced electrical or hormonal signals that induced the production of males and haploid eggs.

In 1965, however, biologists showed that high population densities are also a factor. Researchers who brought *Daphnia pulex* populations into the lab and kept day length constant found a strong, positive correlation between population density and the percentage of females reproducing sexually. When you read the graph in **FIGURE 50.3a**, note that the *x*-axis is logarithmic (see **BioSkills 6** in Appendix B). The highest proportion of sexually reproducing offspring is found at high density.

Another group of investigators built on this result by pinpointing the specific aspects of crowding that affected the animals. These biologists brought a closely related species—*D. magna*—into the laboratory and altered day length, the amount of food available to individuals, and the quality of the water the *Daphnia* occupied. To vary water quality, the investigators used either clean water or "crowded" water taken from tanks where *D. magna* were being maintained at high density.

As **FIGURE 50.3b** shows, individuals in the study population switched to sexual reproduction only if they were exposed to poor-quality, "crowded" water, low food availability, *and* short day lengths. In short, *D. magna* needs three different cues from the environment to switch to sexual reproduction. Two of these cues were associated with high population density; the third is associated with the onset of winter.

(a) Sexual reproduction is more common in crowded populations of *Daphnia pulex* than in sparse populations.

(b) In *Daphnia magna*, which environmental cues trigger the switch to sexual reproduction?

Water quality	Food concentration	Day length	Sexual broods (%)
Clean	Low	Short	0
Crowded	Low	Short	44
Clean	Low	Long	0
Crowded	Low	Long	0
Clean	High	Short	0
Crowded	High	Short	0
Clean	High	Long	0
Crowded	High	Long	0

FIGURE 50.3 In *Daphnia*, Environmental Cues Signal the Switch from Asexual to Sexual Reproduction.
(a) There is a strong, positive correlation between the percentage of females that reproduce sexually and the density of the population (plotted on a log scale here). **(b)** Environmental conditions were varied experimentally for *Daphnia*. "Crowded" water was taken from tanks containing dense populations.

DATA: Kleiven, O. T., P. Larsson, and A. Hoboek. 1992. *Oikos* 65: 197–206.

✔**QUESTION** How would you go about determining which molecule or molecules in "crowded" water serve as a signal that triggers sexual reproduction?

Why Do *Daphnia* Switch between Asexual and Sexual Reproduction? *Daphnia* appear to start sexual reproduction when conditions worsen. Why?

The leading hypothesis in answer to this question points out that sexually produced offspring are genetically diverse. When the environment changes, genetically diverse offspring are likely to include individuals that will survive better and reproduce more than will offspring that are identical to their parents. Parasites evolve rapidly, changing the environment for their hosts. According to the hypothesis, snails with greater genetic variability are likely to adapt better to those changes.

Genetically variable offspring have higher fitness in environments with rapidly evolving parasites, deteriorating physical conditions, or other types of rapid environmental change. Genetic variability increases the likelihood that at least some of the offspring will be able to survive and reproduce in such an environment. ✔ **If you understand this concept, you should be able to predict the conditions under which asexual reproduction would be found as the only method of producing offspring.**

To date, however, the variable-environment hypothesis has yet to be tested rigorously in *Daphnia*. Research on the adaptive significance of sex in this species and other organisms continues.

Mechanisms of Sexual Reproduction: Gametogenesis

The mitotic cell divisions, meiotic cell divisions, and developmental events that produce male and female gametes, or sperm and eggs, are collectively called **gametogenesis** (see Chapter 23). **Spermatogenesis** is the formation of sperm; **oogenesis** is the formation of eggs (**FIGURE 50.4**).

In the vast majority of animals, gametogenesis occurs in a sex organ, or **gonad.** Male gonads are called **testes;** female gonads are called **ovaries.** Early in development, reproductive cells known as germ cells enter the testes and ovaries and give rise to diploid cells that will undergo gametogenesis.

Spermatogenesis in Mammals Figure 50.4a summarizes the events that take place during spermatogenesis. Note that in the male gonad, diploid cells called **spermatogonia** (singular: **spermatogonium**) divide by mitosis. Some of the resulting cells continue to function as spermatogonia; others change to form specialized cells that are committed to developing into sperm.

The specialized cells produced by spermatogonia are called **primary spermatocytes.** They undergo meiosis I and produce two **secondary spermatocytes,** which then undergo meiosis II. The result is four haploid cells called **spermatids.**

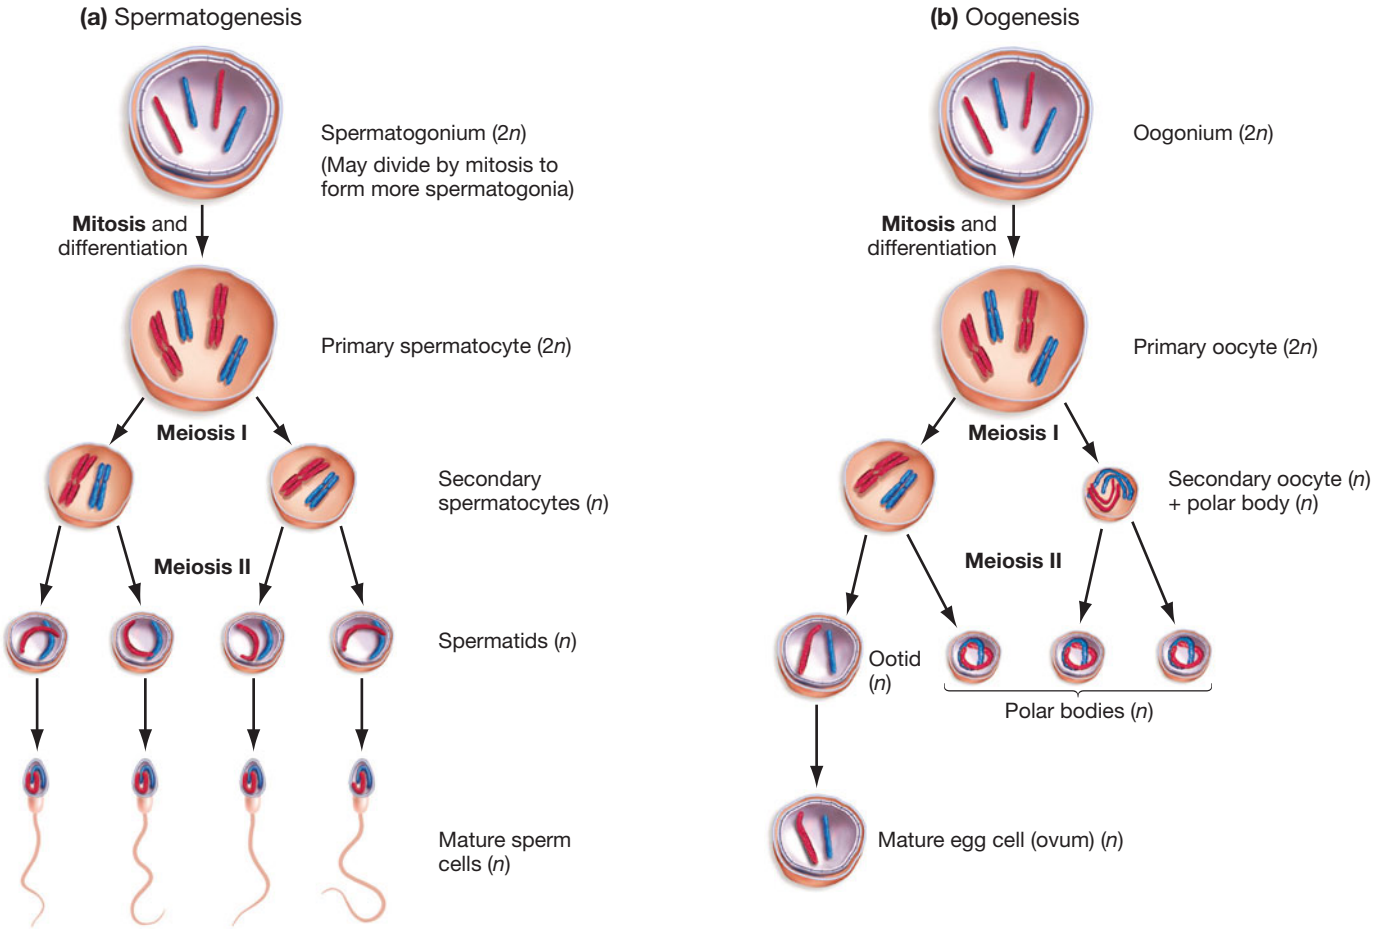


FIGURE 50.4 Gametogenesis in Sexually Reproducing Animals Produces Sperm or Eggs via Meiosis.

Each haploid spermatid matures into a sperm—a cell that is specialized for carrying a haploid genome from the male through the female reproductive tract and fertilizing an egg. The production of spermatogonia, primary spermatocytes, and sperm occurs continuously throughout a male's adult life.

Structure and Function of Sperm As a mammalian sperm cell matures, it acquires the four main compartments shown in **FIGURE 50.5**: the head, neck, midpiece, and tail.

- The head region contains the nucleus and an enzyme-filled structure called the **acrosome.** The enzymes stored in the acrosome allow the sperm to penetrate the barriers surrounding the egg.
- The neck encloses a centriole that will combine with a centriole contributed by the egg to form a centrosome (see Chapter 7). The centrosome is required for spindle formation during mitosis (see Chapter 12).
- The midpiece is packed with mitochondria (see Chapter 9), which produce the ATP required to power movement.
- The tail region consists of a **flagellum**—a long structure, composed of microtubules and surrounded by plasma membrane, that whips back and forth to make swimming possible (see Chapter 7).

Sperm are race cars—stripped down, streamlined, souped-up cells that are specialized for racing other sperm to the egg. Eggs, in comparison, are like semitrailers—bulky, far less mobile storage containers that are packed with valuable merchandise and securely locked.

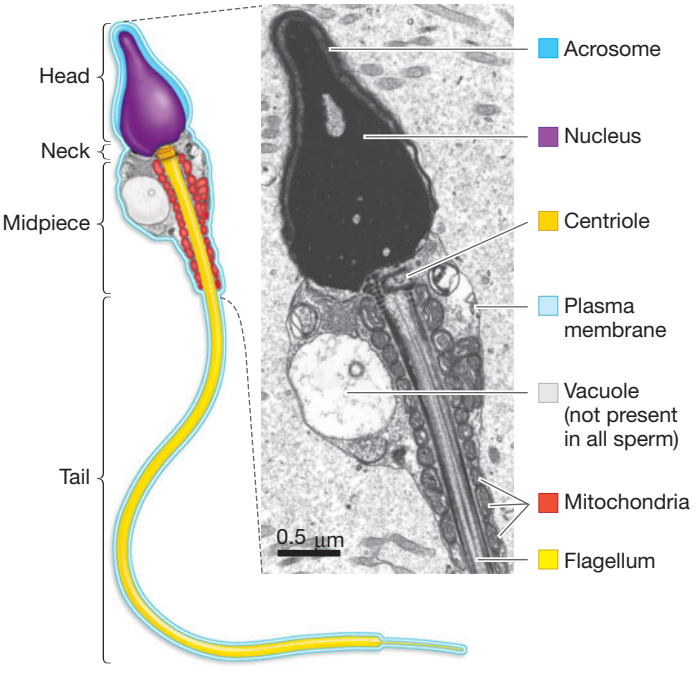

FIGURE 50.5 Mammalian Sperm Are Specialized for Motility and Fusing with an Egg Cell. The morphology of human sperm is typical of many mammal species.

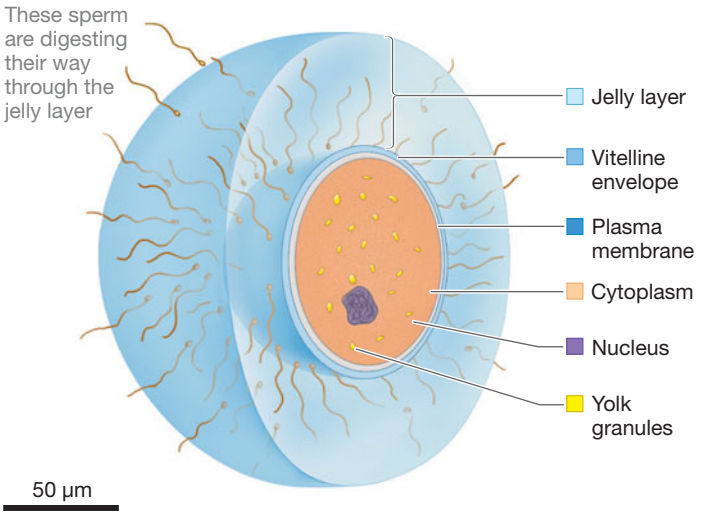
Oogenesis in Mammals The top of Figure 50.4b highlights an important similarity between spermatogenesis and oogenesis: In the female gonad, diploid cells called **oogonia** (singular: **oogonium**) divide by mitosis. Some of the resulting cells continue to function as oogonia; others change to form specialized cells that are committed to producing an egg. In this respect, oogonia and spermatogonia are similar.

However, subsequent steps in gametogenesis are markedly different in females. The specialized cells produced by an oogonium are called **primary oocytes.** When these cells undergo meiosis, only one of the haploid products, known as a **secondary oocyte,** can eventually mature into an egg. The secondary oocyte is arrested in the final stages of meiosis II until it is fertilized by a sperm; it then completes meiosis to become an ootid, which matures into an **ovum,** or a mature egg cell.

The other cells produced by meiosis in females have a tiny amount of cytoplasm and do not mature into eggs. Because the distribution of cytoplasm is so unequal during each meiotic division in females, the smaller cells are called **polar bodies.** (Recall that polar refers to inequality or opposites.) Polar bodies degenerate shortly after their formation.

In addition, the production of primary oocytes stops early in development in many mammals; in humans, it stops before a female fetus is born. The primary oocytes enter prophase of meiosis I during fetal development but then stop developing for months, years, or decades.



Structure and Function of Eggs Animal gametes are easy to tell apart: Sperm are small and motile; eggs are large and nonmotile. Eggs are large mainly because they contain the nutrients required for the embryo's early development. The quantity of nutrients present in the egg varies widely among species, however.

- In mammals, embryos start to obtain nutrition through a maternal organ called the **placenta** within a week or two after fertilization. Thus, the egg only has to supply nutrients for early development and is relatively small.
- In species where females lay eggs into the environment, the stores in the egg are the *only* source of nutrients until organs have formed and a larva or juvenile hatches and begins to feed. In these species, the nutrients required for early development are provided by **yolk**—a fat- and protein-rich cytoplasm that is loaded into egg cells as they mature. Yolk may be present as one large mass or as many small granules.

Just outside the plasma membrane of eggs, a fibrous, mat-like sheet of glycoproteins called the **vitelline envelope** forms and surrounds the egg. In many aquatic animals, such as the sea urchin, a large gelatinous matrix known as a jelly layer surrounds the vitelline envelope to further enclose and protect the egg (see **FIGURE 50.6a**, on page 1018).

In the eggs of humans and other mammals, the vitelline envelope structure is unusually thick and is called the **zona pellucida**. This structure is surrounded by a layer of cells, called the corona radiata, that a sperm must penetrate before it can fertilize the oocyte (**FIGURE 50.6b**).

(a) Sea urchin eggs are surrounded by a jelly coat.

(b) Human oocytes are surrounded by a protective layer called the corona radiata.

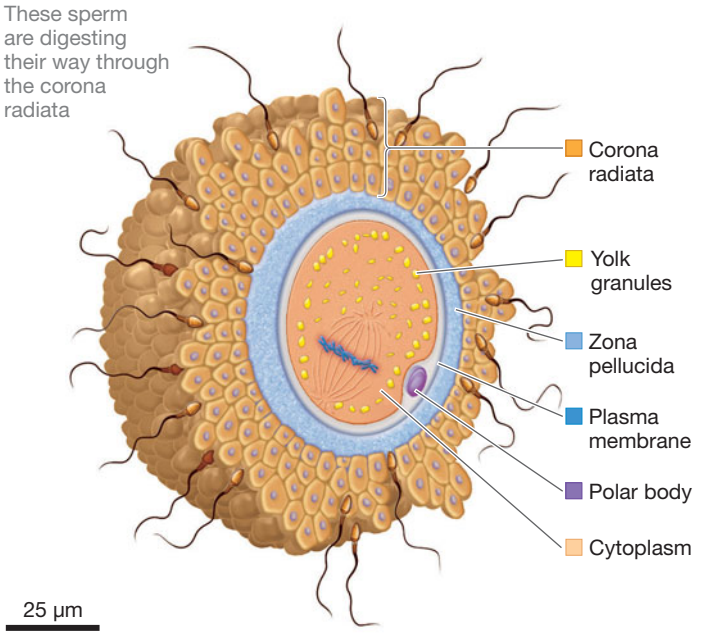


FIGURE 50.6 Eggs Are Surrounded by Protective Structures.

50.2 Fertilization and Egg Development

Fertilization is the joining of a sperm and an egg to form a diploid **zygote.** Recall that during this process, a sperm makes contact with an egg and penetrates the egg's membrane. The molecular mechanisms of sperm–egg binding have been well characterized using the sea urchin as a model organism (see Chapter 23).

The following discussion focuses on the range of fertilization mechanisms observed among animals and the question of what happens to fertilized eggs. In many species, individuals release their gametes into their environment synchronously (at the same time), and external fertilization occurs. In other animals, sperm is deposited into the reproductive tracts of females, and internal fertilization occurs.

External Fertilization

Most animals that rely on external fertilization live in aquatic environments. The correlation between external fertilization and aquatic environments is logical, because gametes and embryos must be protected from drying. If external fertilization occurred in a terrestrial environment, either the gametes or the resulting zygote would likely die of desiccation.

Another observation is that species with external fertilization tend to produce exceptionally large numbers of gametes. For example, a female sea star *Asterias amurensis* typically releases 100,000,000 eggs into the surrounding seawater during spawning. Males release many times that number of sperm. The leading hypothesis to explain this pattern is that the probability of a sperm and egg meeting in an ocean or lake is small unless large numbers of gametes are present. In addition, production of a large number of embryos is beneficial because so many of them fall prey to predators.

Given that sperm and eggs from different individuals must be released into the environment synchronously for external fertilization to work, how is gamete release coordinated? The answer has two parts.

1. Gametogenesis usually occurs in response to environmental cues, such as lengthening days and warmer water temperatures, that indicate a favorable season for breeding.
2. Gametes are released in response to specific cues from individuals of the same species.

In fishes and other aquatic animals with well-developed eyes, external fertilization by spawning is often the culmination of an elaborate courtship ritual between a male and female. In contrast, courtship behavior appears to be much less important—or even absent—in species such as clams, sea urchins, and sea cucumbers. How do animals that cannot see their mates time the release of their gametes?

Recent research indicates that the chemical messengers called **pheromones** (see Chapter 47) might be involved in synchronizing gamete release. For example, biologists maintained two groups of sea cucumbers under natural conditions of light and temperature for 15 months. In one treatment, individuals were isolated in separate tanks; in another, they were kept in tanks containing other sea cucumbers. The researchers found that all the individuals that shared their tanks released gametes during the normal spawning period. In contrast, only about 10 percent of the individuals maintained in isolation released gametes.

Although these data suggest that pheromones might be involved in coordinating external fertilization in sea cucumbers, they are not definitive. Only recently have biologists begun to identify the actual pheromones involved in mating of marine invertebrates. Accumulation of data on pheromones in multiple

species will help solidify the case that spawning is coordinated by pheromones.

Internal Fertilization

Internal fertilization occurs in the vast majority of terrestrial animals as well as in a significant number of aquatic animals. Internal fertilization occurs in one of two ways:

1. After copulation, in which males deposit sperm directly into the female reproductive tract with the aid of a copulatory organ, usually called a **penis.**
2. After males package their sperm into a structure called a **spermatophore,** which is then picked up and placed into the female's reproductive tract by the male or female.

In some salamander species, for example, the male places the spermatophore on the ground within its territory. Later the female picks it up with her **cloaca,** a chamber that both the reproductive and excretory systems flow into and that opens to the environment. In this case, the result is internal fertilization without any direct physical contact between the sexes.

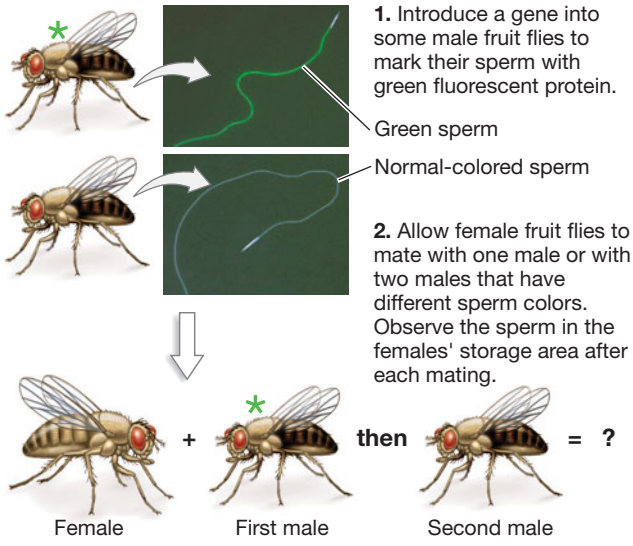
What Is Sperm Competition? In terms of understanding animal behavior, perhaps the most important insight about internal fertilization originated with Geoff Parker. In 1970 Parker published experiments, on dung flies, that confirmed the existence of **sperm competition**—competition between sperm from different males to fertilize the eggs of the same female.

Parker's experiments consisted of a series of matings of one female with two males. In each experiment, the two males were selected in such a way that Parker could distinguish between their offspring. The proportion of offspring fathered by each male was not 50:50. Instead, whichever male was last to copulate fathered an average of 85 percent of the offspring produced.

In addition to suggesting that sperm were competing to fertilize eggs, these data indicated that, in this experiment, the second male won. Follow-up research has confirmed that **second-male advantage** is widespread, although not universal, in insects and some other animal groups. How does it occur?

Sperm Competition and Second-Male Advantage To explore why second-male advantage occurs, biologists turned to the fruit fly *Drosophila melanogaster*. A research group introduced a gene into male fruit flies that produced sperm with green fluorescent tails (**FIGURE 50.7**). When a mating by a green-spermed male was followed with a second mating—by a male having normal-colored sperm—many fewer green-tailed sperm were found in the female's sperm-storage area compared with the number observed when no second mating took place.

To interpret this finding, the biologists suggested that the sperm of the second male physically dislodged the first male's gametes from the female sperm-storage area and inserted themselves in their place. The researchers also showed that the fluid that accompanies sperm during fertilization is able to displace stored sperm from competing males. More recent research has shown that in addition to these factors, females are able to eject

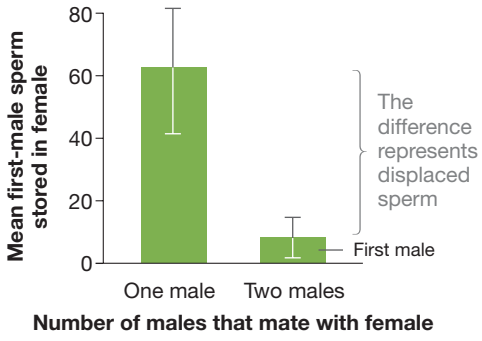


RESEARCH

QUESTION: How does the "second-male advantage" occur in sperm competition?

HYPOTHESIS: In sperm-storage areas, sperm from the second male displaces sperm from the first male.

NULL HYPOTHESIS: The mechanism does not involve sperm displacement from sperm-storage areas.



EXPERIMENTAL SETUP:

PREDICTION: When females mate twice, little sperm from the first male remains in storage.

PREDICTION OF NULL HYPOTHESIS: When females mate twice, most or all of the sperm deposited by the first male is still present.

RESULTS:

CONCLUSION: If a female mates a second time, most sperm from the first male she mated with disappears.

FIGURE 50.7 Experimental Evidence Supports Second-Male Advantage in *Drosophila*. The graph shows the average number of green sperm stored in females when males with green sperm were the only male to mate or the first of two males to mate.

Price, C. S. C., K. A. Dyer, and J. A. Coyne. 1999. Sperm competition between *Drosophila* males involves both displacement and incapacitation. *Nature* 400: 449–452.

✔**QUESTION** Based on these data, is the claim that sperm from the second male physically displaces sperm from the first male valid?

sperm from their reproductive tracts. Together these mechanisms resulted in the second male's sperm fertilizing most of the eggs laid.

Why Is Testes Size Variable among Species? Research on sperm competition has recently contributed another major finding. In species where females routinely mate with multiple males before laying eggs or giving birth, males have extraordinarily large testes for their size and produce proportionately larger numbers of sperm.

The leading hypothesis to explain this observation is that fertilization is similar to a lottery in which each sperm represents a ticket. The more tickets a male enters in the competition, the higher his chance of "winning" fertilizations and passing his alleles on to the next generation. Males with exceptionally large testes produce exceptionally large numbers of sperm, and they are more likely to win the lottery.

The lottery model has been challenged, however, by evidence that females often store sperm and exert control over which sperm are successful in fertilization. In other words, females do not always accept the results of sperm competition passively.

Females of some species actively choose which male performs the last copulation before fertilization takes place. In other species, females physically eject sperm from undesirable males. This phenomenon has been dubbed cryptic female choice. The name is appropriate because the selection of sperm by females is hidden from males.

Unusual Mating Strategies

Studies on animal sexual reproduction have documented some of the most remarkable behaviors and structures observed in nature. The list that follows is just a sampling, offered simply to illustrate the diversity of mating arrangements in animals.

- ***Femmes fatales*** When Australian redback spiders mate, the male does a somersault after inserting his penis-like organ. The somersault places his dorsal surface in front of the female's mouthparts. In many cases the female responds by eating the male. (Biologists refer to females who cannibalize males as femmes fatales—a phrase used to describe murderous human females in movies.) Cannibalized males copulate longer and fertilize more eggs than non-cannibalized males, probably because sperm transfer continues until the meal is over.
- ***Giant sperm*** In the fruit fly *Drosophila bifurca*, males average 1.5 mm in total body length. Their sperm, however, are each 6 cm long. The coiled, bulky sperm fill the female's sperm-storage area and make it impossible for another male's sperm to enter.
- ***Infidelity*** When researchers assess paternity in bird species that appear to be monogamous, they find that up to 60 percent of nests contain at least one offspring fathered by a male that is not mated to the resident female. In most cases, females actively solicit copulations from males holding nearby territories.

FIGURE 50.8 Snails Stab with Love Darts. Stabbing a mate with a mucus-covered love dart increases reproductive success.

- ***Love darts*** Many snails and slugs are **hermaphroditic,** meaning an individual has both male and female gonads. During mating, two individuals simultaneously receive and deposit sperm to fertilize each other's eggs. In some species, individuals fire mucus-covered "love darts" from their genitalia into the mating partner (**FIGURE 50.8**). A substance in the mucus increases the chance that sperm will successfully fertilize eggs.
- ***Hypodermic insemination*** Some bedbugs have hypodermic penises, meaning that they function like a hypodermic needle. Males force the organ through the female's abdominal wall and deposit sperm directly into her body cavity.

Why Do Some Females Lay Eggs While Others Give Birth?

For females, many aspects of fertilization and egg laying vary among species: for example, a female's size or age at first breeding; the number and size of eggs she produces; the number of times she reproduces over the course of a lifetime. Here let's consider a different aspect of variation in animal reproduction: whether eggs are laid outside the body or retained inside the body.

In **oviparous** ("egg-bearing") animals, the embryo completes most of its development inside an egg that is laid into the environment. In some oviparous species, such as sea stars, sea urchins, and most insects, no further care is provided by the parents; the eggs and embryos are left to fend for themselves. Birds, however, incubate their eggs and feed the young after hatching; fish may guard their eggs from predators and fan the clutches to oxygenate them.

In **viviparous** ("live-bearing") species, embryonic development takes place entirely within the mother's body. The embryo attaches to the reproductive tract of the mother and receives nutrition directly from her—via diffusion from her circulatory system. In **ovoviviparous** species, offspring develop inside the mother's body but are nourished by nutrient-rich yolk stored in the egg.

Why does oviparity exist in some groups and viviparity or ovoviviparity in others? Biologists tackled this question by

studying the lizard genus *Sceloporus*. Some *Sceloporus* populations are oviparous; others are ovoviviparous.

To understand how oviparity and ovoviviparity evolved, the biologists analyzed a phylogenetic tree—based on molecular and morphological data—of many *Sceloporus* species (**FIGURE 50.9**). Two conclusions should make sense to you (see **BioSkills 7** in Appendix B for help with interpreting phylogenetic trees):

1. Because the basal branches of the tree represent oviparous species, egg laying probably represents the original or ancestral condition.
2. As the red branches on the tree show, ovoviviparity evolved independently in two groups.

Using a similar research strategy, biologists have found that ovoviviparous populations of sea stars have evolved from oviparous populations on several occasions.

Why did natural selection favor these changes between egg laying and live birth? Ovoviviparity or viviparity should evolve when it leads to higher numbers of surviving young.

Researchers have long hypothesized that natural selection favoring live birth should be especially strong in cold habitats. Low temperatures slow the development of embryos. Thus, in cold habitats, it might be advantageous for females to retain eggs inside their bodies so that they can thermoregulate to maintain the offspring at a more favorable temperature for development. This hypothesis is supported by the fact that ovoviviparous *Sceloporus* species live in the highlands of the southwestern United States and central Mexico, where temperatures can be cool.

Sceloporus lizards have been a productive group in which to study this question because the trait has evolved multiple times in extremely closely related species—making it easier to find correlations between live birth and other characteristics, such as living in cold habitats. The issue is much more difficult to study in mammals, where viviparity evolved just once. Monotremes (duck-billed platypus and echidna) are oviparous, while marsupials and placental mammals are viviparous (see Chapter 35). It is still not clear why, and how, viviparity evolved in mammals before the marsupial–placental split. Is the cold-habitats hypothesis relevant? To date, nobody knows.

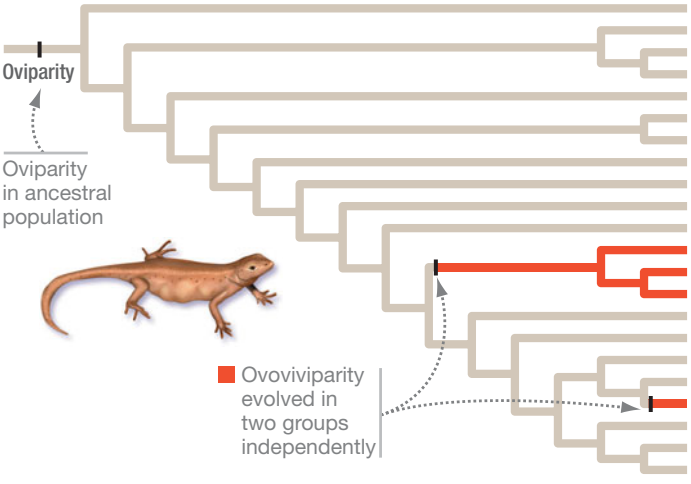


FIGURE 50.9 Ovoviviparity Has Evolved More than Once in *Sceloporus* Lizards. Each twig on this phylogenetic tree represents a *Sceloporus* species or population from central Mexico.

check your understanding

If you understand that . . .

- Some of the most basic aspects of reproduction differ among animal populations or species: whether reproduction is sexual or asexual, whether fertilization is external or internal, and whether fertilized eggs develop in the environment or in the mother's body.
- When females mate with more than one male, sperm from different males compete to fertilize eggs. Females may also select sperm from different males.

✓ You should be able to . . .

1. Describe the advantages and disadvantages of oviparity and viviparity.
2. Suppose that female fruit flies can release a molecule called spermkillerene into their sperm-storage areas. Design an experiment to test the hypothesis that it can destroy sperm.

Answers are available in Appendix A.

50.3 Reproductive Structures and Their Functions

The first two sections of this chapter considered **(1)** the broad contrast between asexual and sexual reproduction and **(2)** general patterns in fertilization and egg care. Now let's explore the mechanics of sexual reproduction in more detail. The first task is to understand the anatomy of the male and female reproductive systems—focusing primarily on mammals.

The Male Reproductive System

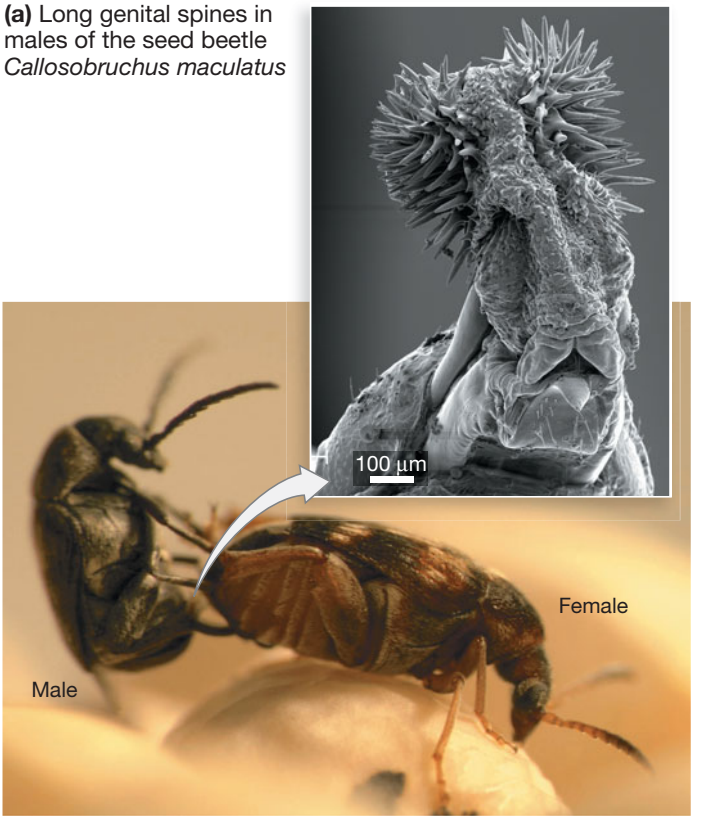
In humans, the external anatomy of the male reproductive system consists of the scrotum and the penis. The saclike **scrotum** holds the testes; the penis functions as the organ of copulation necessary for internal fertilization.

Biologists who have compared these structures among animal species have been struck by their variability and complexity. For example, a scrotum occurs only in certain mammal species. Whales, elephants, hedgehogs, moles, and many other mammal groups, along with all other vertebrates, lack the structure entirely and instead have testes that are located well within the abdominal cavity. Among species that do have a scrotum, the structure's size and shape vary from tiny to prominent. In many primate species, the scrotum is brightly colored and appears to function in courtship or other sexual display behaviors.

How Does External Anatomy Affect Sperm Competition? Diversity in scrotal morphology pales in comparison with variation in the structure of the penis or other types of male **genitalia,** meaning external copulatory organs. In many groups of insects and spiders, for example, closely related species are morphologically identical except for their distinctive genitalia. Why are these organs so diverse?

The leading hypothesis on this question is that certain genitalia shapes give males an advantage in sperm competition. To test this idea, biologists measured the size of the spines found on the tips of male genitalia in a species of seed beetle (**FIGURE 50.10a**) and then documented which males were most successful at fertilizing eggs when females mated with two males.

The *x*-axis in **FIGURE 50.10b** plots variation in the length of genital spines; the *y*-axis plots the proportion of eggs fertilized by the second male to copulate with a female, during experimental matings. The data points on the graph indicate genital spine length in each second-to-mate male tested. Note that second-to-mate males with the longest genital spines fathered a higher percentage of offspring than did others. The mechanism appears to be the ability of long spines to stick in the female's reproductive tract and prolong copulation time, even if the female is ready for copulation to end.



The upshot? Size matters, in seed beetles. Natural selection that occurs during sperm competition may explain why genitalia are so diverse among insect and spider species.

Internal Anatomy of Human Male Reproductive Organs Although it consists of many structures, the reproductive system in human males has just three basic functional components. **FIGURE 50.11** shows the relevant structures in side view and front view.

1. ***Spermatogenesis and sperm storage*** Sperm are produced in the testes and stored nearby in the **epididymis.**
2. ***Production of accessory fluids*** Complex solutions form in the **seminal vesicles, prostate gland,** and **bulbourethral gland.** These accessory fluids are added to sperm before **ejaculation,** or expulsion from the body. **TABLE 50.1** lists some components of these accessory fluids, which combine with sperm to form **semen.**
3. ***Transport and delivery*** A **vas deferens** is a muscular tube that transports sperm from the epididymis to the short **ejaculatory duct,** where it is mixed with accessory fluids to form semen. The semen then enters the **urethra,** a longer tube that passes through the penis and services both the reproductive and urinary systems in males. The semen is expelled during ejaculation.

The composition of the accessory fluids varies widely among animals. In many insects, spiders, and vertebrates, molecules in the accessory fluids congeal after they arrive in the female reproductive tract and plug it. Experiments have shown that these copulatory plugs can serve as an effective deterrent to future matings. In some species, though, females or second males actively remove them.

(a) Long genital spines in males of the seed beetle *Callosobruchus maculatus*

(b) During sperm competition, males with longer genital spines father more offspring.

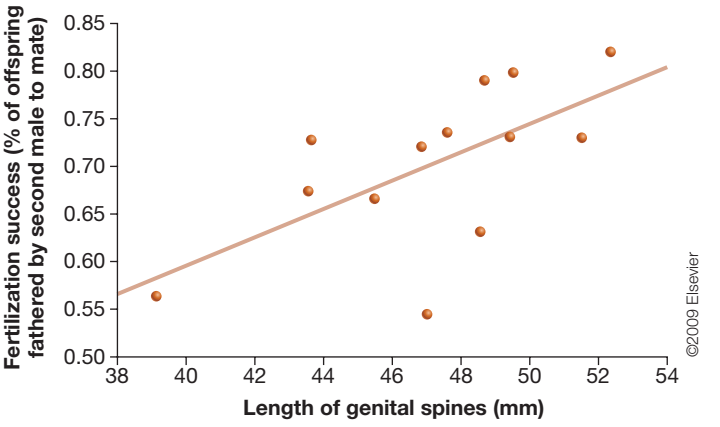


FIGURE 50.10 In Some Insects and Spiders, Variation of Male Genitalia among Individuals May Affect Reproductive Success. **(a)** An elaborate male reproductive structure in a seed beetle, used to transfer sperm to the female. The spiky structures at the top of the inset photo are called genital spines. **(b)** Data from experiments on reproductive success during sperm competition.
DATA: Hotzy, C., and G. Arnqvist. 2009. *Current Biology* 19: 404–407.

Another diverse aspect of male internal anatomy is a bone inside the penis called the **baculum.** Some mammal species, including humans, lack this feature. But in rodents, the shape of the baculum is so variable that it can be used to distinguish among species. And in seals, baculum size correlates with mating system—the mating practices observed in a species. For example,

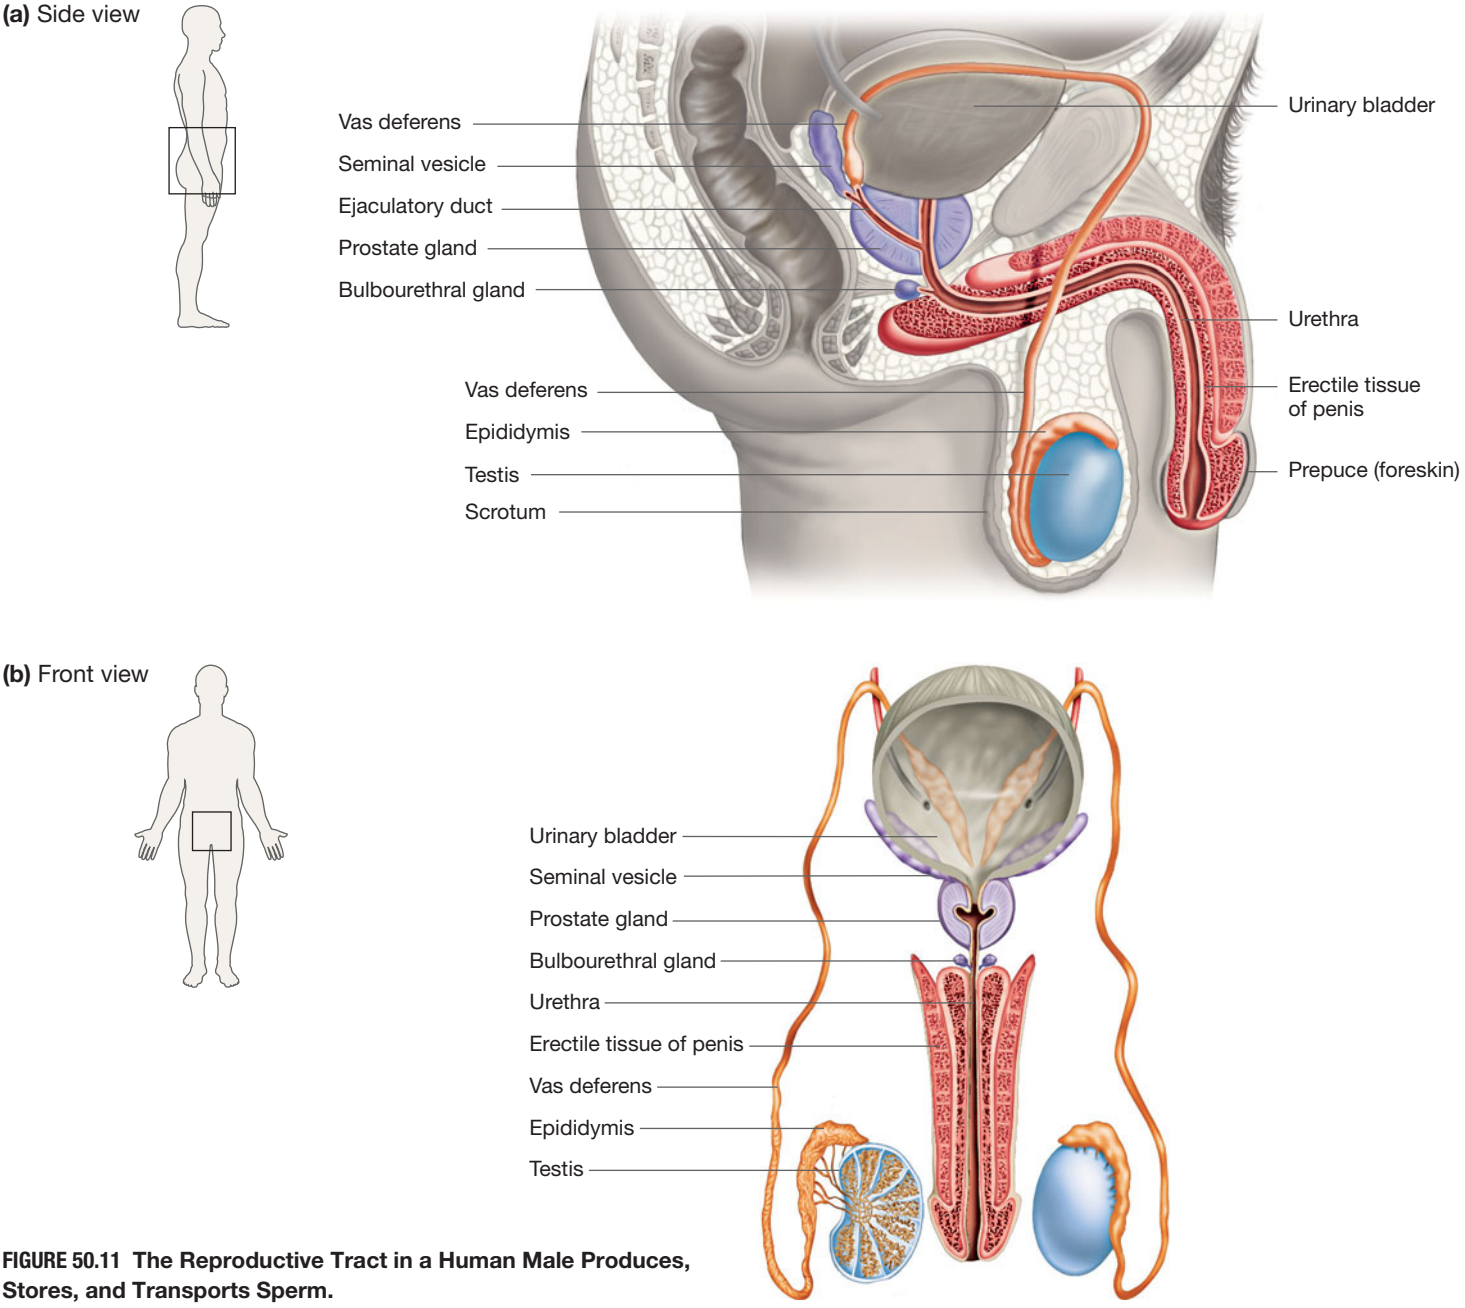

FIGURE 50.11 The Reproductive Tract in a Human Male Produces, Stores, and Transports Sperm.

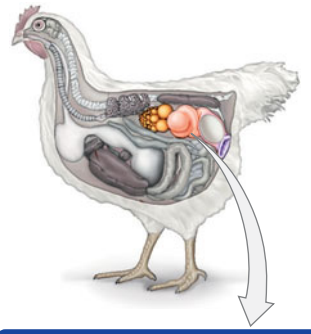
SUMMARY TABLE 50.1 Accessory Fluids in Human Semen

Source	Content	Function
Seminal vesicles	Fructose (a sugar)	Source of chemical energy for sperm movement
	Prostaglandins	Stimulate smooth-muscle contractions in uterus
Prostate gland	Antibiotic compound	Prevent urinary tract infections in males
	Citric acid	Nutrient used by sperm
Bulbourethral gland	Alkaline mucus	Lubricate tip of penis; neutralize acids in urethra

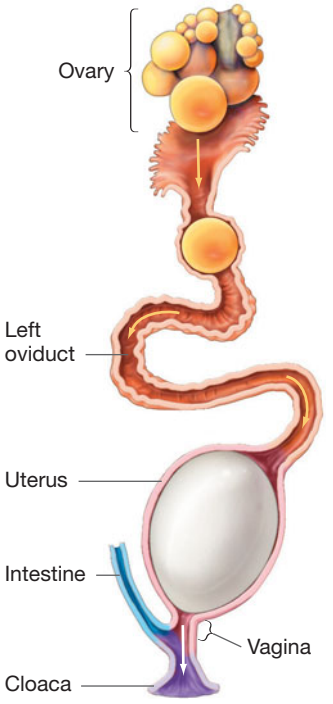
in seal species in which females routinely mate with several males before becoming pregnant, males have not only large testes for their size but also a large baculum. The testes and baculum are much smaller in species in which females mate with a single male. In all species where it appears, the baculum helps stiffen the penis during copulation.

The Female Reproductive System



In animals, the most important part of the female reproductive system is the ovary—where meiosis occurs and mature egg cells, or ova, are produced. In the vast majority of species, the mature egg cell is a membrane-bound structure consisting of a haploid nucleus, a full complement of other organelles, and a large supply of nutrients in the form of yolk.

In the gelatinous eggs of invertebrates, fishes, and amphibians, the extensive outer layers and plasma membranes play a key role in binding sperm from the same species and initiating fertilization. Other animals produce membrane-rich amniotic eggs, which evolved as an innovation that allowed tetrapods to lay large eggs that do not desiccate on land (see Chapter 35).



To probe variation in egg structure and female reproductive systems further, let's consider two highly specialized examples, the reproductive systems of female birds and mammals. Birds lay an amniotic egg protected by a hard shell; most mammals are viviparous.

The Reproductive Tract of Female Birds

FIGURE 50.12 diagrams the bird reproductive system. Starting with the ovary, the labels on the drawing indicate the sequence of events that takes place as the egg moves down the reproductive tract. The result is a hard-shelled egg—like the familiar chicken eggs you buy in the store—that can be laid into the environment and incubated. All birds are oviparous.

PROCESS: MATURATION OF A BIRD EGG

1. Meiosis and maturation of follicles. Follicles are ova (egg cells) attached to yolk (yellow spheres).

2. Entry of the follicle into oviduct. Fertilization takes place if the hen has mated with a cock (hens can store sperm for up to 30 days).

3. Addition of egg white.

4. Addition of outer membranes.

5. Formation of eggshell.

6. Egg is laid. Egg passes through the vagina and is "laid" out of the cloaca.

FIGURE 50.12 All Birds Are Oviparous.

From the time the egg is released from the ovary until the zygote undergoes mitosis and the embryo begins to develop, a bird egg is a single cell. The ostrich egg, which can be over 15 cm (6 inches) in diameter, contains one of the largest single cells known in animals. The structure stores enough nutrients and water to sustain development until hatching.

Note that although male birds have two testes, females of most bird species have just one functional ovary. The presence of a single working ovary is thought to be an adaptation that reduces weight and makes flight more efficient.

External and Internal Anatomy of Human Females

FIGURE 50.13 shows side and front views of the human female reproductive system. The external anatomy features the **labia minora** (singular: **labium minus**) and the **labia majora** (singular: **labium majus**), the opening of the urethra, and the opening of the vagina.

- The labia are folds of skin that cover the urethral and vaginal openings.
- The **clitoris** is an organ that develops from the same population of embryonic cells that gives rise to the penis in males. It becomes erect during sexual stimulation and is covered with a protective sheath called the *prepuce*, homologous with the prepuce (foreskin) that covers the end of the penis.
- The urethral opening, where urine is expelled, is separate from the reproductive structures.
- The **vagina,** or birth canal, is the chamber where semen is deposited during sexual intercourse and where the baby is delivered during childbirth.

The internal anatomy of the female reproductive system in humans and other mammals is dominated by structures serving the system's two functions:

1. ***Production and transport of eggs*** Eggs are produced in the paired ovaries. During **ovulation,** a secondary oocyte is expelled from the ovary and enters the **oviduct,** also known as the **fallopian tube,** where fertilization may take place. Fertilized eggs are then transported through the oviduct to the muscular sac called the **uterus.**
2. ***Development of offspring*** The uterus is where embryonic development takes place. During childbirth, the developed embryo (now called a fetus) passes through an opening in the **cervix**—the bottom part of the uterus—and into the vagina.

Passage of the fetus through the cervix and vagina is the norm in mammals. However, the spotted hyena has evolved a fascinating alternative. In female hyenas, the birth canal is enclosed within an inch-wide, 7-inch-long clitoris that resembles a male's penis (**FIGURE 50.14**). Mating and birthing occur through the clitoris, which often tears during delivery of the Chihuahua-sized cubs.

Although the adaptive significance of the hyena clitoris is unknown, scientists have determined that it results from very high levels of male-typical sex hormones in females. These hormones also cause females to be larger and more muscular than males and socially dominant over them.

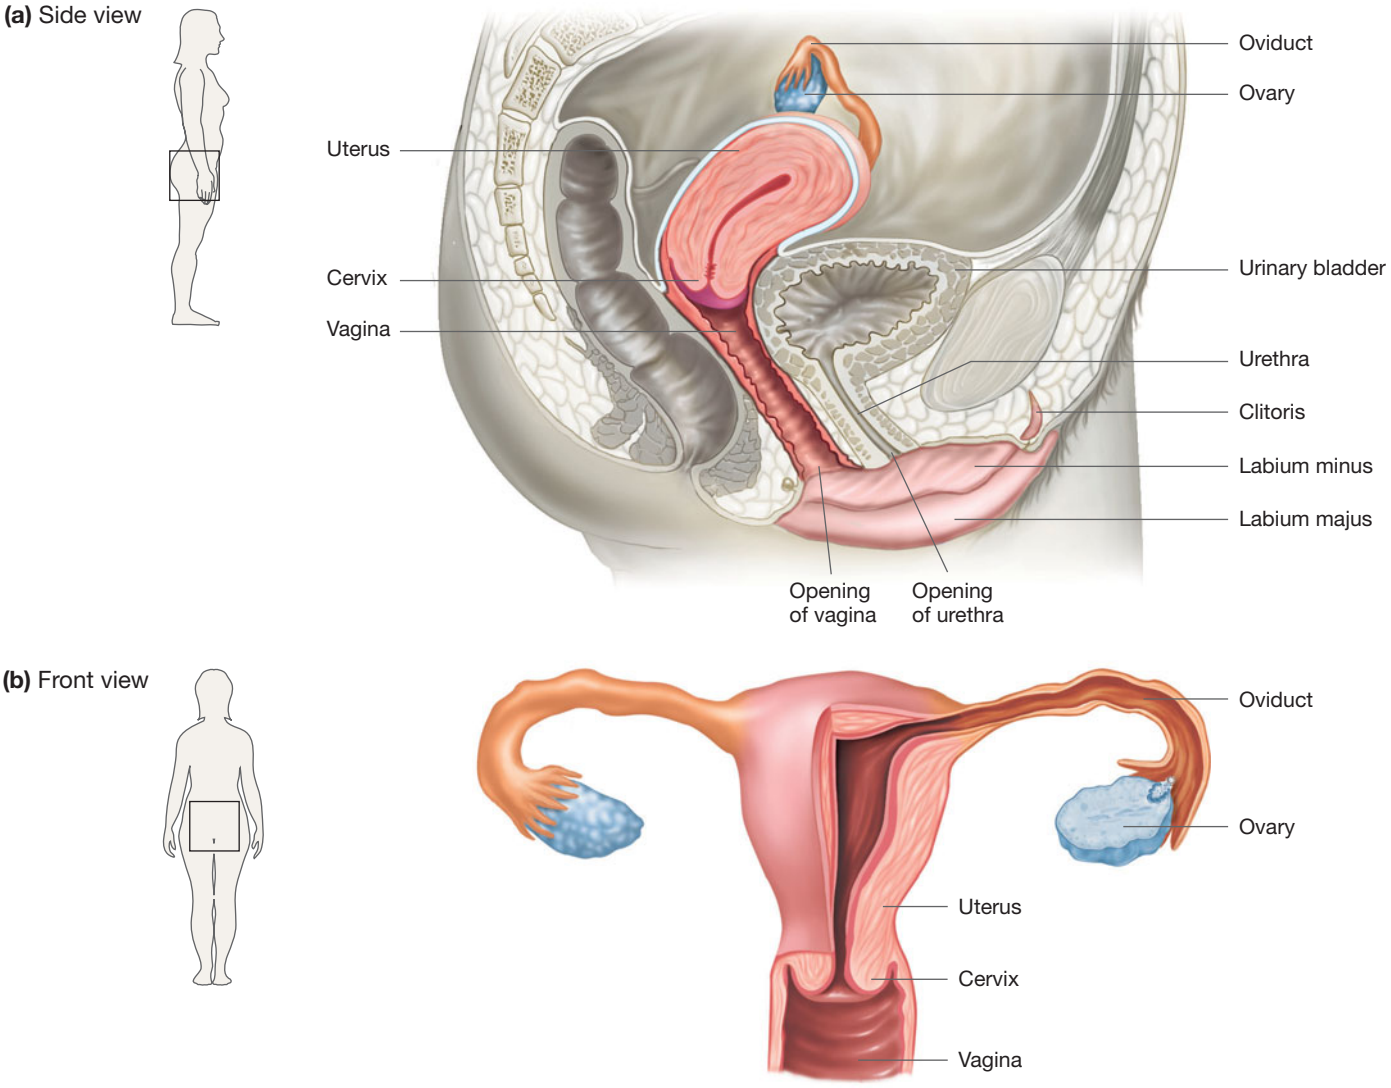


FIGURE 50.13 The Reproductive Tract in a Human Female Produces Eggs and Nurtures the Embryo and Fetus.

✔**QUESTION** Generate a hypothesis to explain why male and female gonads are paired in mammals. How would you test your hypothesis?

FIGURE 50.14 Female Spotted Hyenas Have Enlarged Clitori. High levels of testosterone are responsible for the male-like anatomy of female hyenas. They copulate and give birth through the long, narrow clitoris.

Let's take a further look at how sex hormones control reproduction, focusing on a mammal—specifically, humans—as an illustrative example. But it is important to note that the same or very similar hormones control reproduction in all vertebrates, from fishes to birds.

50.4 The Role of Sex Hormones in Mammalian Reproduction

Recall that the sex hormones **testosterone** and **estradiol** are steroids; the latter belongs to a class of hormones known as estrogens (see Chapter 49). Testosterone and estradiol bind to receptors within the cytoplasm or nucleus of target cells. The resulting hormone–receptor complexes bind to DNA and trigger changes in gene expression.

Testosterone and estradiol are classified as gonadal hormones because they are produced in the gonads. Most testosterone is synthesized in specialized cells inside the testes; most estradiol and other estrogens are synthesized in the ovaries. More specifically, the female sex hormones are produced by cells that surround each developing egg. These surrounding cells form a structure called a **follicle** around the egg.

The sex hormones play a key role in three events:

1. Development of the reproductive tract in embryos
2. Maturation of the reproductive tract during the transition from childhood to adulthood
3. Regulation of spermatogenesis and oogenesis in adults

To explore the action of sex hormones, let's take a closer look at their role in the transition from human juvenile to adult.

Which Hormones Control Puberty?

Puberty is the process that leads to sexual maturity in humans. In amphibians, the juvenile-to-adult transition is triggered by the hormone T_3 (triiodothyronine); in insects, the transition occurs in response to ecdysone (see Chapter 49). But in humans, the transition is directed by increased levels of gonadal hormones—testosterone in boys and estradiol in girls.

A group of physicians recently offered dramatic evidence for testosterone's role: a 2-year-old boy whose symptoms included an enlarged penis, the development of pubic hair, and facial acne. Through careful interviewing, the doctors discovered that the child's father was a bodybuilder who was smearing a testosterone cream on his own arms in an attempt to build muscle mass. The child was apparently absorbing enough testosterone from being carried by his father to trigger puberty-like symptoms. All his symptoms except for penile enlargement subsided once his father discontinued the testosterone cream.

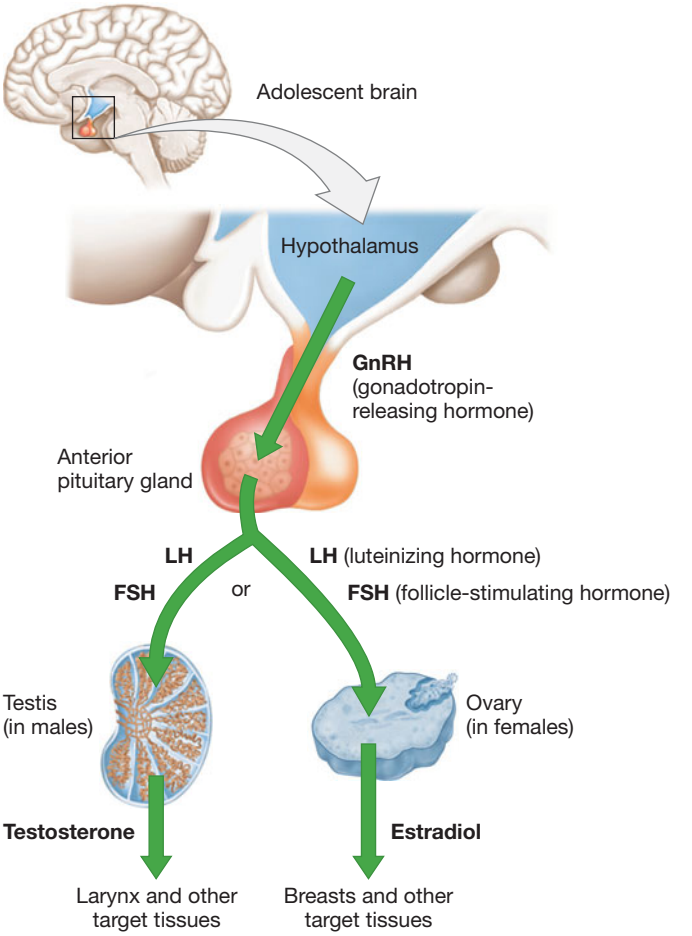

FIGURE 50.15 In Humans, Puberty Is Triggered by Hormones from the Hypothalamus and Pituitary.

✔**QUESTION** How does control of testosterone and estradiol production compare with control of cortisol release by the adrenal gland? (See Figure 49.12c.)

What Regulates the Gonadal Hormones? Researchers suggested that sex hormone production is regulated by the hypothalamic–pituitary axis (see Chapter 49). Recall that chemical signals from the hypothalamus lead to the release of regulatory hormones from the pituitary gland, which then cause the release of hormones from other glands.

Two advances made it possible to test this hypothesis rigorously:

1. Researchers isolated a hormone called **gonadotropin-releasing hormone (GnRH)** from the hypothalamus.
2. Investigators noted that boys and girls who were entering puberty experienced pulses in the concentration of two pituitary hormones, **luteinizing hormone (LH)** and **follicle-stimulating hormone (FSH).**

These observations inspired the hypothesis that GnRH directs LH and FSH pulses, which then trigger increases in testosterone and estradiol (**FIGURE 50.15**).

To test this idea, researchers administered pulses of GnRH to boys and girls who had deficits in their hypothalamus and were experiencing delays in the onset of puberty. As predicted, the GnRH treatment induced surges in LH and FSH, followed by puberty onset.

What Regulates the Hypothalamic and Pituitary Hormones? The model in Figure 50.15 raises a question: What triggers GnRH increases at the appropriate age? Although this question remains unanswered, there is some evidence that nutritional state is involved. For example:

- The current average age for the onset of menstruation in females in the United States is slightly over 12 years. This is much earlier than the average age of 17 years during the eighteenth and nineteenth centuries, when the general nutritional state of the population was poorer.
- Among girls living today, individuals with large fat stores tend to enter puberty earlier than do girls who are thin.
- The hormone leptin is produced by fat cells (see Chapter 49), and leptin levels are higher in people with more fat. In mice, leptin accelerates the onset of puberty, suggesting that leptin may be involved in triggering the GnRH surge.

Research continues on how age, nutritional condition, and perhaps other factors interact to promote the release of GnRH.

If you recall the discussion of how the adrenal hormone cortisol is controlled, however, you might suspect that the model of sex-hormone regulation in Figure 50.15 is simplified (see Chapter 49). Many hormones participate in negative feedback—also called feedback inhibition—meaning that the presence of the hormone inhibits the factor that triggers its release.

Do sex hormones participate in negative feedback? The short answer to this question is yes. To appreciate the details, let's investigate hormonal control of the human menstrual cycle.

Which Hormones Control the Menstrual Cycle in Mammals?

FIGURE 50.16 illustrates the sequence of events in the human ovary during the **menstrual cycle,** a monthly reproductive cycle. Although the cycle's length varies among women, 28 days is about average.

In conjunction with changes in the ovary illustrated in the figure, the lining of the uterus undergoes a dramatic thickening and regression. Ultimately, if fertilization and implantation do not occur, part of the uterine lining sloughs off and is expelled through the vagina.

Day 0 in the menstrual cycle is marked by the beginning of **menstruation**—the expulsion of the uterine lining. The remainder of the cycle has two distinct phases:

1. ***Follicular phase*** A follicle matures during the **follicular phase,** which lasts an average of 14 days. Primary oocytes complete meiosis I during this phase. Ovulation occurs when the follicle is mature and releases its secondary oocyte into the oviduct.
2. ***Luteal phase*** The **luteal phase** begins with ovulation and averages 14 days in length. Its name was inspired by the formation and subsequent degeneration of a structure called the **corpus luteum** ("yellowish body") from the ruptured follicle.

The regular occurrence of ovulation throughout the year makes human females extremely unusual among mammals. Although some mammals ovulate multiple times during the year, most ovulate only during a single prescribed breeding season—often in response to environmental cues such as changing photoperiod; less often in response to cues from males.

In addition, only humans and other great apes menstruate. In the vast majority of mammals, the lining of the uterus is reabsorbed if pregnancy does not occur. These females are described as having an **estrous cycle** and are sexually receptive only during estrus—also known as being "in heat."

Whether an estrous or menstrual cycle occurs, the basic sequence of events, with a follicular phase preceding ovulation and a luteal phase following ovulation, is shared among mammals. Hormonal control of the estrous and menstrual cycles is also similar.

How Do Pituitary and Ovarian Hormones Change during a Menstrual Cycle?

By monitoring hormone concentrations in the blood or urine of a large number of women over the course of the menstrual cycle, researchers were able to document dramatic changes in the concentrations of estradiol and several other hormones. During each cycle,

- LH and FSH are produced in the anterior pituitary gland in response to GnRH;
- the steroid hormone **progesterone** is produced along with estrogens, including estradiol, in the ovaries.

Several observations jump out of the data in **FIGURE 50.17** (see page 1028):

1. LH levels are fairly constant except for a spike that begins just before ovulation, suggesting that LH might be the trigger for this event.

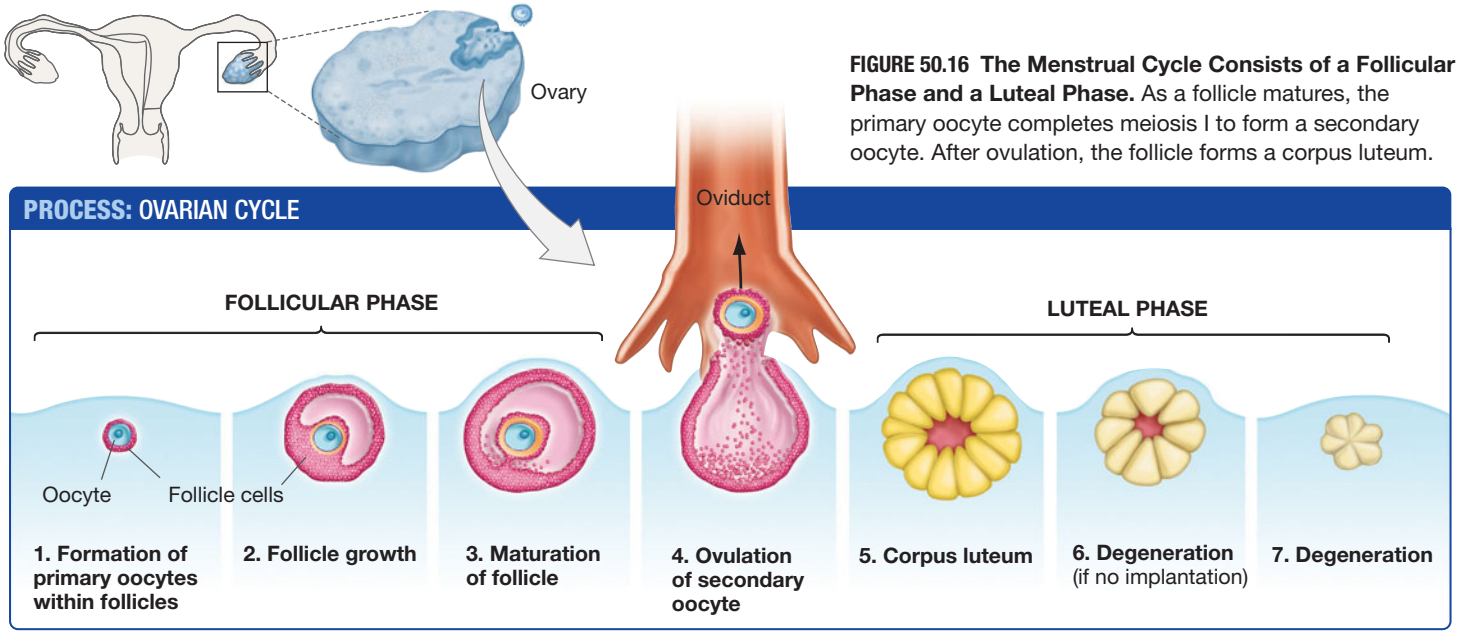

FIGURE 50.16 The Menstrual Cycle Consists of a Follicular Phase and a Luteal Phase. As a follicle matures, the primary oocyte completes meiosis I to form a secondary oocyte. After ovulation, the follicle forms a corpus luteum.

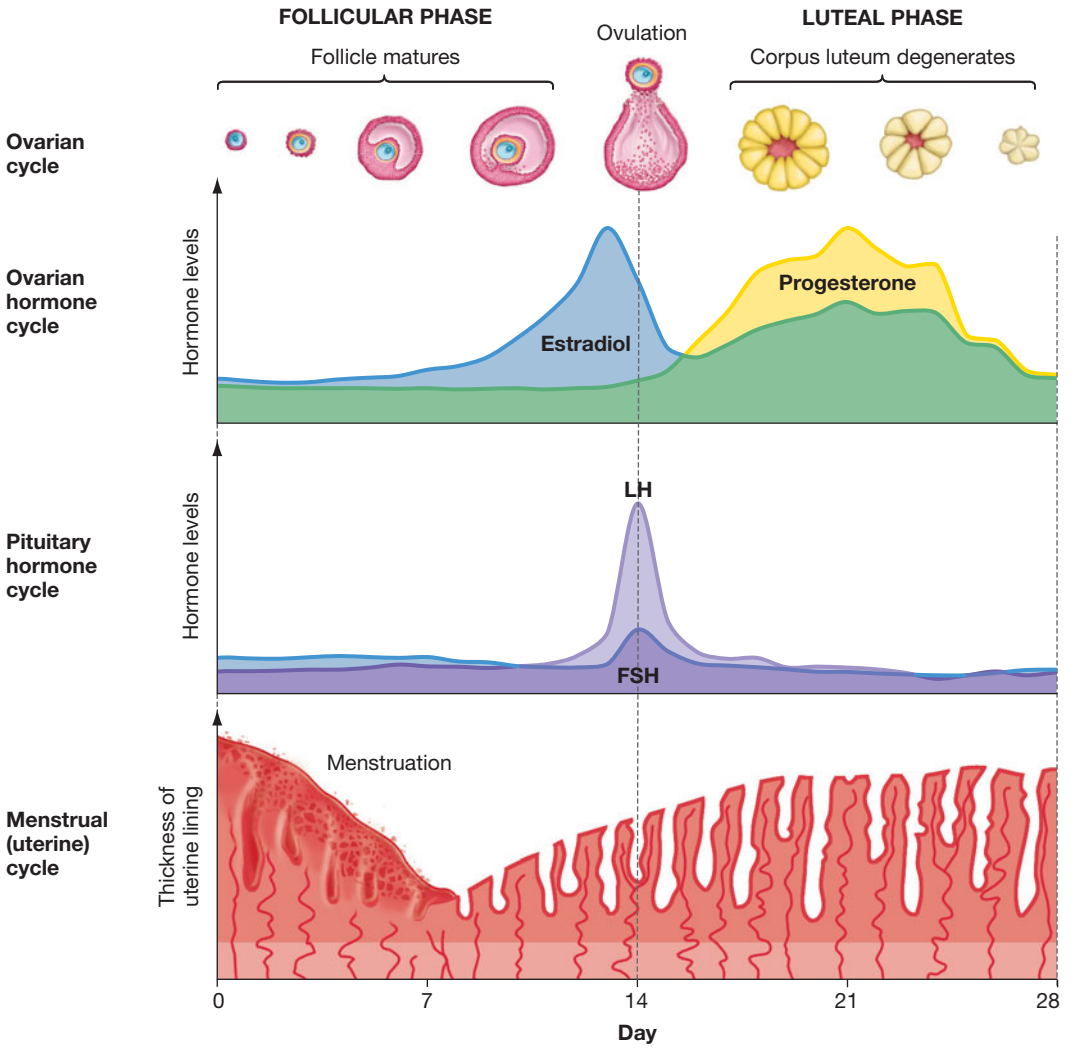

FIGURE 50.17 Hormones Regulate Events in the Human Menstrual Cycle.

2. FSH concentrations are relatively high during the follicular phase and low during the luteal phase, though they also make a small spike before ovulation.
3. Estradiol concentrations change in a complex way, highlighted by a peak late in the follicular phase.
4. Progesterone is present at very low levels during the follicular phase but at high levels during the luteal phase. This observation suggests that progesterone might support the maturation of the thickened uterine lining.

In general, estradiol surges during the follicular phase, while progesterone surges during the luteal phase. Similar patterns are observed in other mammals, ranging from marsupials to mice.

Now the question is: How are these changes regulated? You might hypothesize (based on reading Chapter 49) that the pituitary hormones released in response to GnRH trigger the release of gonadal hormones, and that feedback occurs. If so, you'd be correct.

How Do Pituitary and Ovarian Hormones Interact? Experiments helped establish that changes in the concentration of estradiol and progesterone affect the release of the pituitary hormones LH and FSH. Researchers worked with three volunteers whose ovaries had been removed because of cancerous growths or other problems. The women were receiving low, maintenance-level doses of estradiol, which appeared to exert negative feedback on LH and FSH.

But when the investigators injected the women with larger doses of estradiol or with progesterone, dramatic changes took place. For example, a large increase in estradiol stimulated a dramatic spike in LH levels. This result suggested that positive feedback was occurring. High levels of estradiol increase the release of LH, even though low doses of estradiol suppress it. This is a key observation: When feedback occurs, estradiol's effect on the pituitary hormones is dosage dependent. In contrast, progesterone injections appeared to inhibit both FSH and LH. Progesterone exerts only negative feedback on the pituitary hormones.

To summarize the interplay between LH, FSH, estradiol, and progesterone, let's start at day 0 and follow key events as the cycle progresses (**FIGURE 50.18**).

Day 0–7

- As the uterus is shedding much of its lining, a follicle is beginning to develop in one ovary under the influence of FSH.

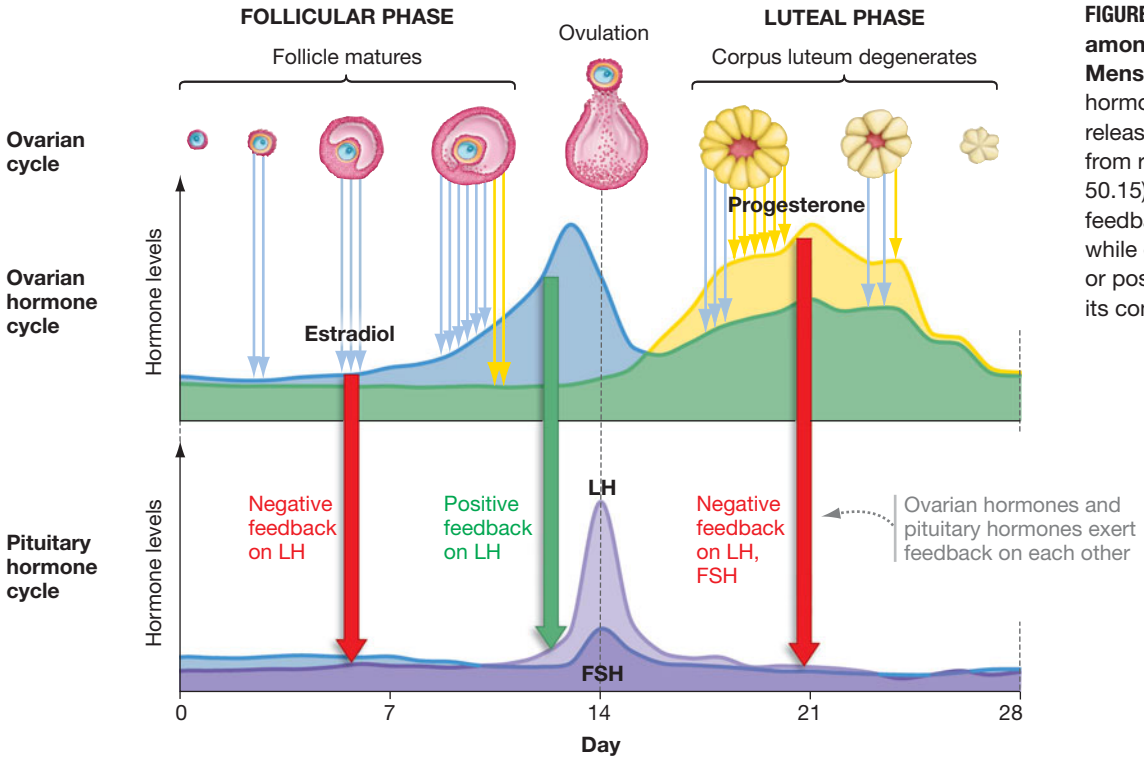

FIGURE 50.18 Complex Interactions among Hormones Regulate the Menstrual Cycle. The pituitary hormones FSH and LH control the release of estradiol and progesterone from reproductive tissues (see Figure 50.15). Progesterone exerts negative feedback on the pituitary hormones, while estradiol exerts either negative or positive feedback, depending on its concentration.

- The follicle produces estradiol and a small amount of progesterone.
- While its levels are still relatively low, estradiol suppresses LH secretion through negative feedback inhibition.

Day 8–14

- As the follicle grows, its production of estradiol gradually increases. The increase in estradiol stimulates mitosis and an increase in cell number in the uterine lining.
- The enlarged follicle produces large quantities of estradiol, which begin to exert positive feedback on LH secretion.
- Positive feedback results in a spike in LH levels, just after estradiol concentrations peak.
- The LH surge triggers ovulation and ends the follicular phase.

✔ If you understand that estradiol's effect on LH changes from negative regulation to positive regulation, you should be able to predict the effect of (1) injecting a female volunteer with high estradiol concentrations early in a cycle, and (2) using a drug to keep estradiol production low throughout the cycle.

Day 15–21

- As the corpus luteum develops from the remains of the ruptured follicle, it secretes large amounts of progesterone and small quantities of estradiol, in response to LH.
- The rise in progesterone lowers production of LH and FSH and activates the thickened uterine lining, creating a spongy tissue with a well-developed blood supply. In this way, progesterone fosters an environment that supports embryonic development if fertilization occurs.

Day 22–28

- If fertilization does not occur, the corpus luteum degenerates.
- Progesterone levels fall as the corpus luteum shrinks.
- When progesterone declines, the thickened lining of the uterus degenerates. This causes the menstrual bleeding that marks the first day of the next cycle.
- GnRH, LH, and FSH are released from the inhibitory control that progesterone exerts.
- LH and FSH levels rise, and a new menstrual cycle begins.

The interplay between ovarian and pituitary hormones is similar in other mammal species that have been studied to date.

Manipulating Hormone Levels to Prevent Pregnancy Data on hormonal control of the menstrual cycle opened new avenues in birth control research. Specifically, researchers have found that manipulating levels of progesterone and estradiol can prevent ovulation and serve as a safe and effective method of **contraception,** or preventing unwanted pregnancies.

Hormone-based contraceptive methods deliver synthetic versions of progesterone or of progesterone and estradiol. These hormones suppress the release of GnRH, FSH, and LH through negative feedback inhibition. Because an LH spike does not occur during the follicular phase of the cycle, the follicle does not mature and ovulation does not occur.

In the United States, birth control pills are the most widely used contraceptive method. Hormone-containing pills are taken for three weeks and then stopped for one week to allow menstruation to occur. Other popular hormonal contraceptives include injections and hormone-secreting patches and implants.

SUMMARY TABLE 50.2 Comparing Methods of Birth Control

Type	Name	Mode of Action	Percent Effectiveness*
Hormone-based methods	The Pill, the Patch, the Ring, the Shot, the Implant	Provides continuous or cyclical delivery of progesterone, or progesterone plus estradiol.	92 to 99.9†
Barrier methods	Condom	Covers penis and prevents sperm from entering uterus.	85
	Female condom	Covers labia, vagina, and cervix and prevents sperm from entering uterus.	79
	Diaphragm	Covers cervix and prevents sperm from entering uterus.	84
	Sponge	Covers cervix and prevents sperm from entering uterus; also contains a molecule that immobilizes sperm.	84
	Spermicide	Foam or jelly covers cervix and prevents sperm from entering uterus; contains a molecule that immobilizes sperm.	71
Behavioral methods	Rhythm method	Couple refrains from vaginal intercourse around time of ovulation.	80
	Withdrawal	Man withdraws penis before ejaculation.	73
Fertilization prevention	Intrauterine device (IUD)	Small T-shaped structure inserted into uterus; induces uterus to produce substances hostile to sperm and eggs.	99
	Emergency contraception	Delivers progesterone or progesterone and estradiol after unprotected vaginal intercourse.	92
Pregnancy termination	Mifepristone	Blocks progesterone receptors so menstruation occurs even after fertilization and implantation.	92

*"Percent Effectiveness" indicates the average percentage of women who do not become pregnant during one year of typical use.

†Depends on delivery system used.

But as **TABLE 50.2** indicates, hormone-based methods are just one of several approaches to preventing pregnancy. Other methods work by preventing sperm from contacting the oocyte or by interfering with implantation of the embryo.

The "Percent Effectiveness" column on the far right of the table indicates the average percentage of women who do not become pregnant during one year of typical use of that method. Percent effectiveness usually increases dramatically if couples are able to use a method "perfectly"—meaning, exactly as specified for optimal effectiveness, during every episode of sexual intercourse.

When sperm and egg do unite successfully, the menstrual cycle is interrupted. The corpus luteum does not degenerate, and progesterone and estradiol levels stay high. Menstruation does not occur. Instead, the mother is now pregnant.

check your understanding

C Y U

If you understand that . . .

- During the follicular phase of the menstrual cycle, FSH and LH stimulate the follicle to develop and secrete estradiol, which prepares the uterine lining for implantation of an embryo.
- During the luteal phase, progesterone protects the uterine lining. If fertilization does not occur, progesterone drops and the lining is shed.

✔ You should be able to . . .

1. Describe the function of FSH, and explain how FSH levels increase at the end of one cycle and the start of the next cycle.
2. Predict the consequences of a drug that inhibits the release of FSH.

Answers are available in Appendix A.

50.5 Pregnancy and Birth in Mammals

Viviparity allows the mother to provide a warm, protected environment for offspring during early development. Oviparous species that guard or incubate their eggs also provide warm, safe surroundings for their young.

Any investment that parents make in an offspring comes at a cost, however: The more a mother invests in each offspring, the lower the number of offspring she can produce.

Pregnancy and **lactation**—providing milk that nourishes offspring after birth—represent some of the most extreme forms of parental care known in animals. And in some mammal species, parental care continues long after lactation ends. Humans, for

example, are largely or completely dependent on their parents for protection and nutrition until puberty or young adulthood.

Let's examine how mammals make this investment, starting with marsupials and then turning to the eutherian mammals.

Gestation and Early Development in Marsupials

You might recall that mammals comprise three major monophyletic groups: monotremes, eutherians, and marsupials (see Chapter 35). Although all mammals are endothermic, have fur, and lactate, the three lineages are distinguished by their mode of reproduction:

- Monotremes lay eggs and incubate them until hatching.
- In eutherians, mothers carry offspring internally for relatively long periods of development and nourish them via a placenta.
- In marsupials, the corpus luteum is not maintained as it is in eutherians, and no placenta forms.

In marsupials, young are ejected from the mother's body at the end of the estrous cycle. As a result, they are far less developed than eutherian mammal offspring, which undergo a lengthier **gestation**—the developmental period that takes place inside the mother.

The jaws, gut, lungs, and forelimbs of a newly born marsupial are relatively well developed at birth. As a result, the offspring is able to climb from its mother's vagina to a nipple, which is usually enclosed in a pouch created by a flap of skin (**FIGURE 50.19a**). The offspring clamps onto the nipple and continues to develop, fed by the mother's milk (**FIGURES 50.19b** and **50.19c**).

Even after growing large enough to leave the pouch and begin moving and feeding on its own, offspring will return to the pouch for protection. Marsupial mothers invest a great deal in their offspring, even though a relatively short period of development takes place inside their bodies.

Major Events during Human Pregnancy

Marsupials and eutherians differ sharply in terms of how long the developing embryo is retained inside the mother's body. Let's consider humans as a model organism in eutherian reproduction.

When a secondary oocyte is released from the human ovary, the cell is viable for less than 24 hours. Human sperm, in contrast, remain capable of fertilizing an egg for up to five days. Therefore, sexual intercourse in humans has to occur less than five days before ovulation or immediately after ovulation for pregnancy to result.

Although an ejaculation may contain hundreds of millions of sperm, most die as they travel through the uterus. Only 100 to 300 actually succeed in reaching the oviduct, where fertilization takes place.

You might recall that when sperm and oocyte meet, enzymes released from the head of the sperm create a path through the material surrounding the oocyte membrane. Once the membranes of the oocyte and sperm have fused, the oocyte nucleus completes meiosis II. The two nuclei then unite to form a diploid zygote.

Implantation Smooth-muscle contractions in the oviduct gradually move the zygote toward the uterus. As it travels, the cell begins to divide by mitosis. By the time it reaches the lining of the uterus, the embryo consists of a hollow ball of cells. It then undergoes **implantation**—meaning that it becomes embedded in the thickened, vascularized wall of the uterus. It will stay in the uterus for approximately 270 days (9 months).

Once the embryo is implanted in the uterine lining, its cells begin synthesizing and secreting the hormone human chorionic gonadotropin; this hormone is later produced in larger quantities by the placenta. **Human chorionic gonadotropin (hCG)** is a chemical messenger that prevents the corpus luteum from degenerating. When hCG is present, the ovary continues secreting progesterone, and the menstrual cycle is arrested. Since hCG is excreted in the mother's urine, it is the chemical used to detect pregnancy in pregnancy tests.

The First Trimester Human gestation is divided into 3-month stages called trimesters. Not long after implantation is complete, mass movements of cells result in the formation of the three major embryonic tissues, called ectoderm, endoderm, and mesoderm (see Chapter 23). By 8 weeks into gestation, these tissues have differentiated into the various organs and systems of

(a) Brushtail possum shortly after birth **(b)** 1.5 months after birth **(c)** 3.5 months after birth

FIGURE 50.19 Marsupials Trade a Long Gestation Period for a Long Lactation Period. Relative to eutherians, marsupial offspring—like this brushtail possum—spend a short time developing in the uterus and a relatively long time being fed milk after birth and being protected in the mother's pouch.

the body. Also by this time, the heart has begun pumping blood through a circulatory system. The embryo at this stage is called a **fetus** (**FIGURE 50.20a**).

Early in development, the embryonic ectoderm contributes to several important membranes. One of these membranes, the **amnion,** completely surrounds the embryo. The amnion eventually fills with amniotic fluid, which provides the embryo with a protective cushion.

The other key event in the first trimester is the formation of the placenta. This organ, which starts to form on the uterine wall a few weeks after implantation, is composed of tissues from both mother and embryo (see Chapter 35). Because the placenta contains a dense supply of blood vessels from the mother, it provides nutrition for the growing fetus. Arteries transport blood from the circulatory system of the fetus, through the **umbilical cord,** to an extensive capillary bed in the placenta. This capillary bed provides a large surface area for the exchange of gases, nutrients, and wastes between maternal and fetal blood, even though the maternal and fetal blood do not commingle.

The placenta secretes a variety of hormones, including large amounts of progesterone and estrogens. Because these hormones suppress the release of GnRH, LH, and FSH through negative feedback, they prevent the maturation and ovulation of additional follicles. By the end of the first trimester, the placenta is producing more than enough progesterone to replace the amount that had been produced by the corpus luteum, which has degenerated by this time. In essence, the placenta takes over from the corpus luteum in secreting the hormones required to maintain the pregnancy.

✔ **If you understand how hormones influence pregnancy, you should be able to explain (1) why women who produce low levels of progesterone from the corpus luteum are prone to miscarriage, and (2) why a pregnancy test administered to a woman in her third trimester would register negative.**

The Second and Third Trimesters After the fetal organs and placenta form during the first trimester, the rest of development consists mainly of growth (**FIGURES 50.20b** and **50.20c**). During the last weeks of pregnancy, the brain and lungs undergo particularly dramatic growth and development. If a baby is born prematurely, intervention may be required to keep the baby alive until the lungs can complete their development.

The machinery and level of hospital care required by premature infants emphasize just how superbly adapted mothers are for nourishing a growing fetus in the uterus. It costs hundreds of thousands of dollars for health care providers to do what mothers do naturally in the last trimester. Let's take a closer look at this critical aspect of pregnancy.

How Does the Mother Nourish the Fetus?

In oviparous and ovoviviparous species, mothers produce relatively large eggs that contain all of the nutrients and fluids that the embryo needs for development until hatching. But in some viviparous species, eggs are relatively small and contain almost no nutrients.

In species such as humans, the developing embryo depends on the mother's body for oxygen, chemical energy in the form of sugars, amino acids and other raw materials for growth, and waste removal. What physiological changes occur in human mothers to accommodate these demands?

Oxygen Exchange between Mother and Fetus During pregnancy, a mother's respiratory and circulatory systems change in ways that increase the efficiency of nutrient transfer and gas exchange with the fetus. For example:

- A woman's total blood volume expands by as much as 50 percent during pregnancy.
- To accommodate the increase in blood volume, maternal blood vessels dilate (widen) and blood pressure drops.
- The mother's heart enlarges and beats faster, increasing her total cardiac output by almost 50 percent.
- The mother's breathing rate and breathing volume increase to accommodate the fetus's demand for oxygen and its production of carbon dioxide.

In addition, important adaptations heighten the efficiency of gas exchange between the mother and the embryo, in the placenta. In many species, such as sheep, maternal and fetal blood

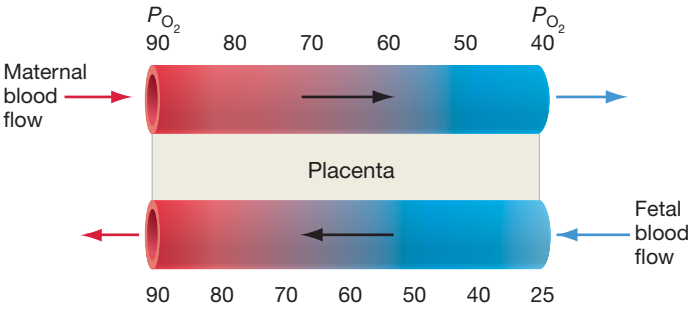
(a) 1st trimester

(b) 2nd trimester

(c) 3rd trimester

FIGURE 50.20 Development of the Human Fetus Can Be Divided into Three Trimesters.

in the placenta flow in a countercurrent fashion (**FIGURE 50.21a**). Countercurrent flows maintain a concentration gradient that increases the efficiency of diffusion or other types of exchange (see Chapter 42).



Countercurrent flow does not occur in the human placenta. Instead, oxygen exchange between mother and fetus is efficient because of another mechanism. Maternal arteries in humans empty into a space at the junction of the maternal and fetal portions of the placenta. This space is packed with small projections called villi, which contain the fetal blood vessels. Thus, a large surface area from the fetus is bathed with highly oxygenated maternal blood. The fetal villi are analogous to the alveoli of the lungs (see Chapter 45), which provide a large surface area for gas exchange.

FIGURE 50.21b illustrates another adaptation that increases the rate of oxygen delivery to a human fetus. Notice that the axes on this graph give the partial pressure of oxygen in blood versus the percentage of hemoglobin that holds oxygen at that pressure. Recall that this type of graph is an **oxygen–hemoglobin equilibrium curve** (see Chapter 45).

The key message of this graph is that the data for fetal hemoglobin are shifted to the left of the data for adult hemoglobin. This means that the fetus's blood always has a higher affinity for oxygen than does the mother's blood. Even if the partial pressure of oxygen is the same in the mother and fetus, oxygen will move from the mother's blood to the fetus's blood because it is held more tightly by the fetal hemoglobin.

Biologists interpret this pattern as an adaptation. The high oxygen affinity of fetal hemoglobin ensures that the fetus is always able to acquire oxygen from the mother.

(a) Countercurrent blood flow in the sheep placenta

(b) Oxygen–hemoglobin saturation curves in the human fetus and mother

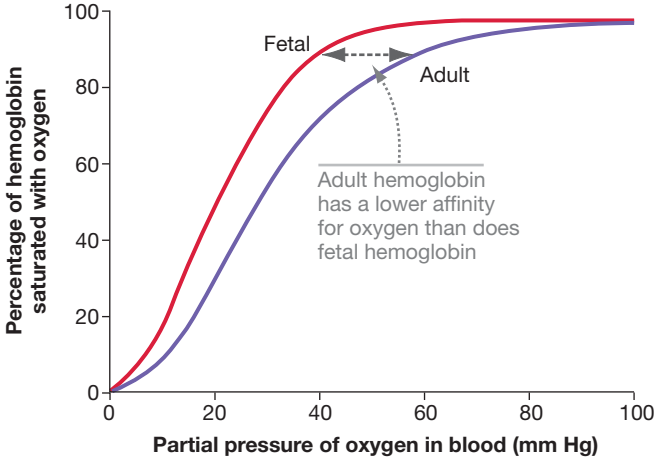


FIGURE 50.21 Mammals Have Adaptations That Increase Delivery of Oxygen to the Fetus.

DATA: Swayze, V. W., II, Johnson, V. P., Hanson, J. W., et al. 1997. *Pediatrics* 99: 232–240.

Toxic Chemicals Can Be Transferred from Mother to Fetus

Mothers and embryos exchange more than nutrients and wastes—they can also exchange dangerous molecules. As an example, consider the thalidomide tragedy. During the 1950s, hundreds of children were affected by their mothers' consumption of the tranquilizer thalidomide, which was prescribed to treat morning sickness. The molecule diffused into the fetal bloodstream and caused birth defects—often a dramatic shortening of the arms.

Although thalidomide is now banned for use by pregnant women, alcohol use continues to affect newborns. Compared to children of mothers who do not drink alcohol, children of mothers who imbibe ethanol are at high risk for hyperactivity, severe learning disabilities, and depression. Collectively, these symptoms are termed **fetal alcohol syndrome (FAS).**

To investigate why FAS occurs, researchers used a technique called magnetic resonance imaging (MRI) to compare the total brain volumes of patients suffering from fetal alcohol syndrome with those of healthy controls. They found that the brains of children with FAS were over 20 percent smaller than those of healthy children (**FIGURE 50.22**). In adolescents and adults with FAS, brain volume was 28 percent smaller than in healthy people of the same age, suggesting that prenatal exposure to alcohol stunts brain development throughout life.

The MRIs also revealed numerous structural abnormalities in the brain. These abnormalities, along with the reduced brain volume, are thought to be responsible for dramatic reductions in IQ and other measures of intelligence and learning ability. On the basis of results like these, public health officials strongly advise pregnant women against drinking *any* alcohol.

Birth

Although the mechanisms responsible for initially triggering the birthing process are not completely understood, the posterior pituitary hormone **oxytocin** is important in stimulating smooth-muscle cells in the uterine wall to begin contractions. The contractions that expel the fetus from the uterus constitute **labor.**

When the birthing process starts, the uterus contracts at relatively low frequency. Then, as **FIGURE 50.23** shows,

1. The cervical canal at the base of the uterus begins to open, or dilate. Once the cervix is fully dilated, uterine contractions become more forceful, longer, and more frequent.
2. The fetus is expelled through the cervix and into the vagina.
3. After the baby is delivered, the placenta remains attached to the uterine wall. At this point, caregivers clamp and cut the umbilical cord that connects the child and the placenta. When the mother delivers the placenta and accompanying membranes, birth is complete.

PROCESS: BIRTHING SEQUENCE

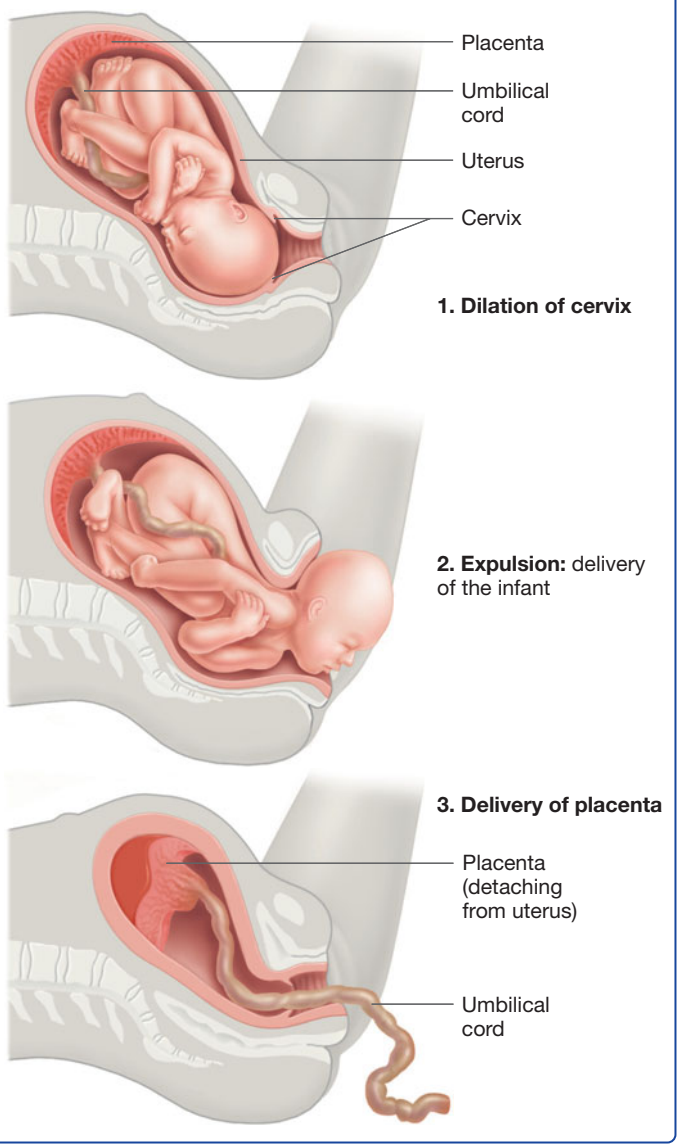

FIGURE 50.23 Human Birth Occurs in Three Stages.

✔**QUESTION** Human babies are normally born headfirst and face down, as shown. Predict the consequences of a baby positioned face up or feet first in the birth canal.

Although this description sounds straightforward, in reality a large number of complications are possible. For example, **FIGURE 50.24** shows the number of Swedish mothers who died, per 100,000 live births, in five-year intervals between 1760 and 1980. In 1760, approximately 1.4 mothers died for every 100 infants successfully delivered. In most cases, the cause of death was blood loss or infection following delivery. Note that the steepest drops in mortality rate occurred with the introduction of hand-washing in the late 1870s.

As a result of sterile techniques, antibiotics, and blood transfusion technology, Sweden's mortality rate has now declined to less than 0.007 percent. Improved nutrition, sanitation, and medical care have also reduced infant mortality rates in many countries.

The huge decline in the rate of death associated with childbirth qualifies as one of the great triumphs of modern medicine. Unfortunately, because many developing nations lack sterile facilities and antibiotics, the mortality of mothers and infants remains high in those countries.

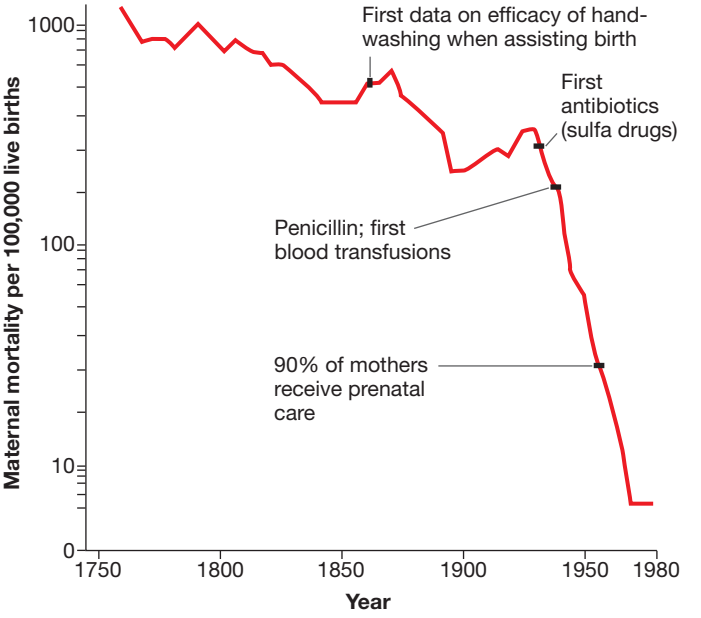

FIGURE 50.24 Maternal Mortality in Childbirth Has Decreased Dramatically. These data are from Sweden; the scale on the vertical axis is logarithmic. *Note:* Data showing that hand-washing dramatically reduced maternal mortality during childbirth were published in 1861, but doctors resisted the idea until well after Pasteur had published the germ theory of disease in 1878.

DATA: Högberg, U., and I. Joelsson. 1985. *Acta Obstetricia et Gynecologica Scandinavica* 64: 583–592.

✔**QUANTITATIVE** If a woman living in Sweden in 1760 had 10 children over the course of her lifetime, what was her overall chance of dying in childbirth?

If you understand . . .

50.1 Asexual and Sexual Reproduction

- Asexual reproduction produces offspring with genetic material from the mother only.
- Sexually produced offspring are genetically unique because of recombination during meiosis and the fusion of haploid gametes from different parents during fertilization.
- Asexual reproduction is favored in constant environments, whereas sexual reproduction is favored in changing environments, or when food availability is low and availability of mates is high.

✔ You should be able to explain why sexually produced offspring would have higher fitness than asexually produced offspring in a population of animals that is highly parasitized.

50.2 Fertilization and Egg Development

- In human males, spermatogenesis is continuous throughout adult life, but in human females, all primary oocytes are formed early in development. Meiosis of oocytes is arrested for long periods of time, and cell division after meiosis is so unequal in females that just one egg—not four—is produced from each primary oocyte.
- Fertilization is external in many aquatic animals but internal in almost all terrestrial species.
- When sperm competition occurs, males have large testes relative to their body size, and the last male to mate usually fathers a disproportionately large number of offspring.
- Once eggs are fertilized, females, depending on their species, may lay the eggs or may retain them and give birth to live offspring. In some groups at least, viviparity may be an adaptation that increases the survival of young in cold habitats.

✔ You should be able to explain why fish that care for their young are expected to produce fewer eggs per year than fish that do not care for their young, and also whether sperm competition is common in fish.

50.3 Reproductive Structures and Their Functions

- In humans, the male reproductive system includes structures specialized for producing and storing sperm, synthesizing other components of semen, or transporting and delivering semen.
- The female reproductive system includes structures specialized for producing eggs, receiving sperm, and nourishing offspring during early development.

✔ You should be able to suggest ways to surgically sterilize human males and females for birth control.

50.4 The Role of Sex Hormones in Mammalian Reproduction

- In mammals, GnRH from the hypothalamus triggers the release of FSH and LH from the pituitary gland. The pituitary hormones regulate the production of the gonadal hormones, testosterone and estradiol, in the testes and ovaries, respectively.
- During the human menstrual cycle, estradiol and progesterone exert feedback (estradiol, positive and negative feedback; progesterone, negative only) on the production of FSH and LH. Interactions between the pituitary and ovarian hormones are responsible for regulating cyclical changes in the ovaries and uterus.

✔ You should be able to predict whether FSH and LH concentrations would increase or decrease following ovariectomy (surgical removal of ovaries).

50.5 Pregnancy and Birth in Mammals

- If fertilization occurs, the developing embryo and placenta secrete the hormone hCG, which arrests the menstrual cycle and allows pregnancy to continue.
- During the first trimester, the embryo becomes implanted in the thickened uterine wall, organs develop, and the nutritive organ called the placenta forms.
- To make rapid growth possible during the second and third trimesters, the mother's heart rate and blood volume increase. Nutrients and gases are exchanged efficiently in the placenta.

✔ You should be able to explain why the placenta is highly vascularized (consists mainly of blood vessels).

TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. What term describes the mode of asexual reproduction in which offspring develop from unfertilized eggs?
   a. parthenogenesis; **b.** budding; **c.** regeneration; **d.** fission
2. In sperm competition, what is "second-male advantage"?
   a. the observation that when females mate with two males, each male fertilizes the same number of eggs
   b. the observation that when females mate with two males, the second male fertilizes most of the eggs
   c. the observation that females routinely mate with at least two males before laying eggs or becoming pregnant
   d. the observation that accessory fluids prevent matings by second males—for example, by forming copulatory plugs
3. How are the human penis and clitoris similar?
   a. They develop from the same population of embryonic cells.
   b. Both develop during the earliest stages of puberty.
   c. Both contain the urethra.
   d. Both produce accessory fluids required during sexual intercourse.
4. Which of the following hormones would you expect to be more elevated in female hyenas compared to females of other species of mammals?
   a. follicle-stimulating hormone
   b. testosterone
   c. progesterone
   d. oxytocin
5. What two pituitary hormones are involved in regulating the human menstrual cycle?
6. True or false: The corpus luteum is retained upon implantation due to the presence of the hormone human chorionic gonadotropin (hCG).

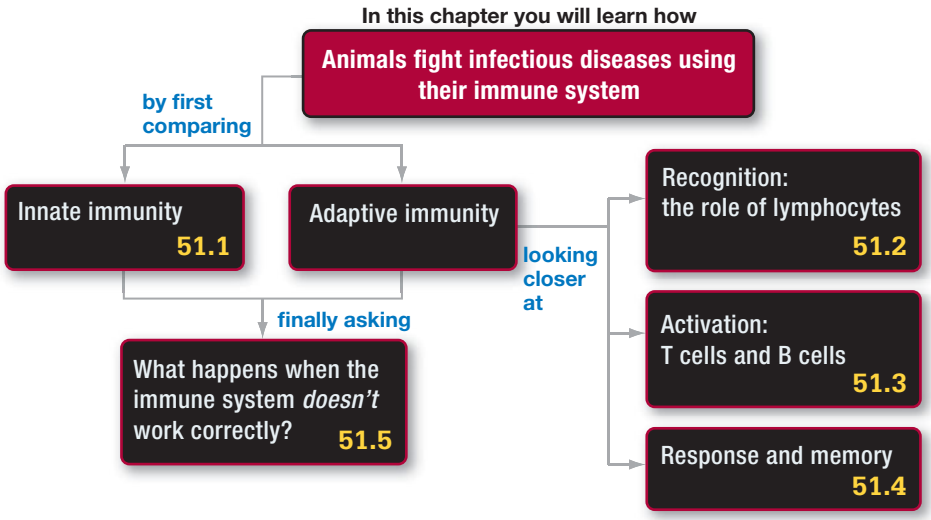
TEST YOUR UNDERSTANDING

Answers are available in Appendix A

7. What is the fundamental difference between sexual and asexual reproduction, in terms of the characteristics of offspring?
8. Summarize the experimental evidence that *Daphnia* require three cues to trigger sexual reproduction. Discuss what these cues indicate about the environment. Generate a hypothesis for why sexual reproduction is adaptive for these animals.
9. Contrast spermatogenesis with oogenesis in humans. How do these processes differ with respect to numbers of cells produced, gamete size, and timing of the second meiotic division?
10. Give examples of negative feedback and positive feedback in hormonal control of the human menstrual cycle. Why can high estradiol levels be considered a "readiness" signal from a follicle?
11. In hormone production, how do the follicle and corpus luteum compare?
    a. Both produce primarily estradiol.
    b. Both produce primarily progesterone.
    c. The follicle produces more estradiol than progesterone; the corpus luteum produces more progesterone than estradiol.
    d. The follicle produces mostly progesterone; the corpus luteum produces estradiol and progesterone.
12. Suppose that females of a certain insect species routinely mate with two males and choose their mates based on courtship displays or other traits. Predict whether females would be choosier about the first male or the second male that they mate with, or equally choosy about both males. Explain the logic behind your prediction.

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A



13. Researchers have recently developed methods for cloning mammals. In effect, biologists can now induce asexual reproduction in species that do not normally reproduce asexually. Suppose this practice becomes so widespread in the future that most of the sheep in the world become genetically identical. Discuss some possible consequences of this development.
14. Suppose that you've been given a chance to study several populations of lizards—some of them viviparous, some of them oviparous. Which populations would you expect to produce especially large eggs, relative to their overall body size?
15. When marsupial eggs are developing, a shell membrane appears for a short time and then disintegrates. State a hypothesis to explain this observation.
16. **QUANTITATIVE** Consider the data in the table below, showing the average body mass index (BMI, where higher values represent heavier girls for a given height; see Chapter 44) of pre-pubertal and post-pubertal girls. Which conclusion can you make from the data?

	BMI	
Age	Pre-pubertal	Post-pubertal
11	−0.22	0.75
12	−0.28	0.52
13	−0.56	0.34

DATA: Anderson, S. E., G. E. Dallal, and A. Must. 2003. *Pediatrics* 111: 844–850.

   a. At a given age, there are more girls with low BMI than with high BMI.
   b. At a given age, girls with high BMI are more likely to hit puberty than girls with low BMI.
   c. 11-, 12-, and 13-year-olds are equally likely to hit puberty.
   d. There is no relationship between BMI and age at puberty.

51 The Immune System in Animals

Colorized scanning electron micrograph of human immune system cells attacking *Wuchereria bancrofti*—a parasitic nematode that clogs lymph vessels and causes the dramatic swelling called elephantiasis. This chapter explores how immune system cells are able to recognize parasitic worms, bacteria, and viruses as foreign and eliminate them.

Infectious disease threatens the survival of every living organism. For example, animals alone may be infected by thousands of different disease-causing bacteria, viruses, parasitic worms, fungi, and protists—collectively referred to as **pathogens.** Given the ability of these pathogens to cause illness and death, it is remarkable that so many animals stay healthy for most of their lives.

If an animal contracts a bacterial or viral illness, however, it may eventually recover, even without medical intervention. Frequently, after recovering from an infection, the animal will be immune to (literally, "exempt" from) the disease—that is, it will not contract the same disease in the future. **Immunity** is a resistance to or protection against a disease-causing pathogen.

Thus, the **immune system** is responsible for defending animals against pathogens. The successful function of the immune system involves three key processes. It must **(1)** prevent the entry of

BIG PICTURE

This chapter is part of the Big Picture. See how on pages 840–841.

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

SUMMARY TABLE 51.1 Comparison of Innate and Adaptive Immune Systems

Innate Immune System	Adaptive Immune System
Occurs in all animals	Occurs only in vertebrates
Has both cell-mediated and secreted components	Has both cell-mediated and secreted components
Rapid response	Slow response
Broadly specific response against types of pathogens	Specific response against pathogen strains
Response does not vary when infections recur (no memory)	Response is more rapid and efficient when infections recur (memory)

potential pathogens; **(2)** detect the presence of a pathogen by distinguishing it from the animal's own body; and **(3)** eliminate the pathogen.

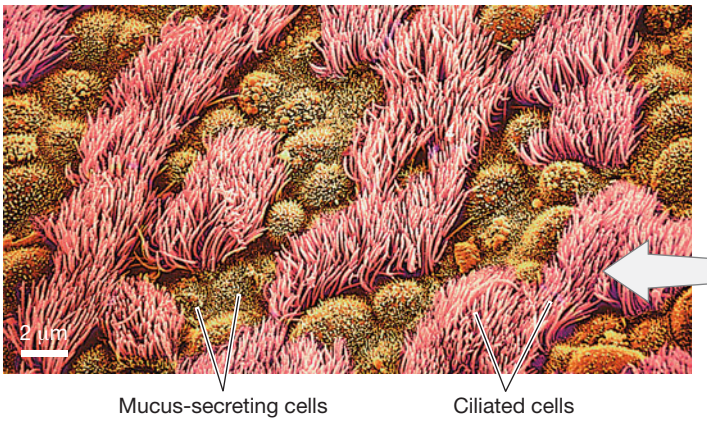
When biologists began analyzing the immune system, they found that certain immune system cells are ready to respond to foreign invaders at all times, while others must be activated first. Cells that are always ready confer **innate immunity.** Cells that must first be selectively activated to tailor their response against a specific pathogen confer **adaptive immunity.**

In combination, the innate and adaptive immune responses form a powerful system for protecting individuals against a formidable and ever-changing array of pathogens. **TABLE 51.1** illustrates the different roles of the innate and adaptive immune systems. This chapter explores the different roles of these two systems and how their cells and secreted cellular products collaborate to battle infections. It then considers the problems that arise when the immune system does not function properly.

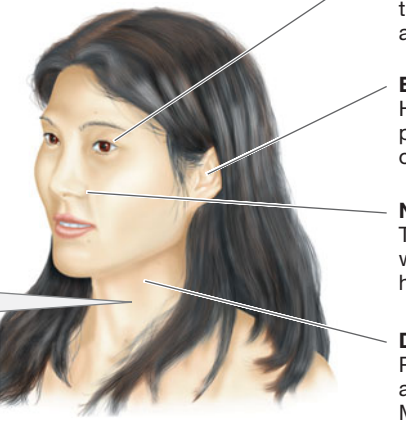
51.1 Innate Immunity

Innate immunity is so named because it is inherent in all animals and is ready to go from the moment of birth. In contrast, adaptive immunity occurs in only 1 percent of animals—the vertebrates—and is not fully developed until 6 months after birth. Clearly, the innate immune system on its own has succeeded in protecting a spectacular abundance and diversity of animals, both invertebrates and vertebrates. It is the first line of defense and includes exterior anatomical structures that protect animals from invading pathogens as well as interior detection and response systems.

To launch an investigation into innate immunity, let's first focus on how the body prevents entry by foreign invaders. Then let's consider what happens if some do get in.



Barriers to Entry



The most effective way for animals to avoid getting an infection is to prevent pathogens from entering their bodies in the first place. In humans and many other animals, the most important deterrent to infection is the exterior surface. For example,

- The armored bodies of insects are difficult for pathogens to enter because they are covered with the tough layer called cuticle, along with a layer of wax (see Chapter 43).
- Soft-bodied organisms like slugs, snails, and earthworms are covered with a protective layer of **mucus** (the adjective is mucous), a slimy mix of glycoproteins and water that traps pathogens and sloughs off.
- Human skin has an outer layer of dead cells that are reinforced with tough fibers of the protein keratin.

Besides providing a tough physical barrier, these outer surfaces also ensure a restrictive chemical environment. The oil secreted by skin cells is converted to fatty acids by bacteria that live

Airways (lining of trachea)
Most pathogens are trapped in mucus before they can reach the lungs. Beating cilia sweep pathogens up and out of the airway.

Eyes
Blinking wipes tears across the eye. Tears contain the antibacterial enzyme lysozyme.

Ears
Hairs and earwax trap pathogens in the passageway of the external ear.

Nose
The nasal passages are lined with mucous secretions and hairs that trap pathogens.

Digestive tract
Pathogens are trapped in saliva and mucus, then swallowed. Most are destroyed by the low pH of the stomach.

FIGURE 51.1 The Body Protects Openings. The scanning electron micrograph of mucus-secreting and ciliated cells has been colorized.

harmlessly on the surface. The fatty acids lower the pH of the surface to about 5, creating a dry, acidic environment that prevents the growth of most pathogens.

Unless this protective exterior surface is broken by an injury, the most vulnerable places in animal bodies are the gaps in the surface where the digestive tract, reproductive tract, gas-exchange surfaces, and sensory organs make contact with the environment.

How Are Openings in the Body Protected? As **FIGURE 51.1** shows, gaps in the outer surface of animal bodies are protected by a complex array of chemical substances that discourage pathogen entry.

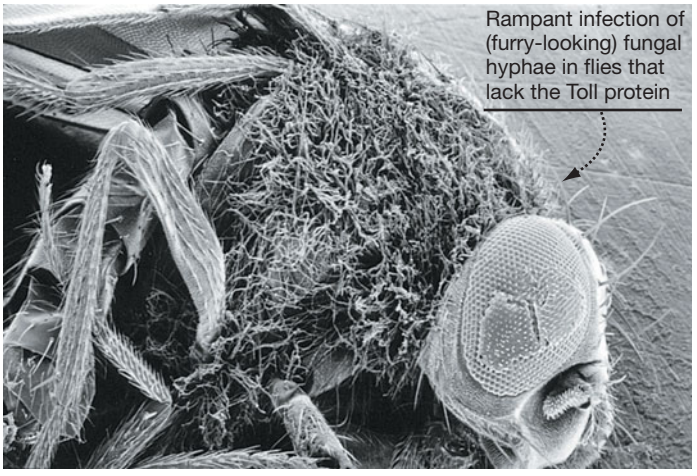
The mucus that protects the surface of soft-bodied invertebrates is equally important in protecting the surface openings in vertebrates. For example, many of the pathogens that you breathe in or ingest while eating or drinking stick to the mucus that lines your airways and digestive tract. Pathogens that are stuck in mucus cannot come in contact with the plasma membranes of epithelial tissues. In mammals, many of these pathogens are either coughed out or swallowed and killed in the acidic environment of the stomach. In the respiratory tract, they are swept out of harm's way by the beating of cilia (see Figure 51.1).

Gaps in the body that are not covered with mucous layers — the eyes, for example—are often protected by other types of secretions. Your ears are protected by waxy secretions, and your eyes by tears that contain the enzyme **lysozyme.** Lysozyme acts as an **antibiotic** by digesting bacterial cell walls.

How Do Pathogens Gain Entry? When preventive measures fail, as they sometimes do, pathogens gain entry to tissues beneath the skin. Flu viruses, for example, have an enzyme on their surface that disrupts the mucous lining of the respiratory tract. When the outer surface of the virus makes contact with a host cell beneath the mucous layer, the virus is able to enter the cell and begin an infection.

Falls, wounds, and other types of physical trauma provide another important mode of entry. When the skin is broken, bacteria and other pathogens gain direct access to the tissues inside.

To viruses, bacteria, and fungi, your body is a tropical paradise, brimming with resources. Given that a single bacterium could give rise to a population of 100 trillion in a day, something must be done, and fast, when the outer defenses of the body are penetrated. What happens then?



The Innate Immune Response

If foreign invaders penetrate the body's protective barrier, particular cells initiate the **innate immune response**—the body's first response to pathogens. As a group, these cells are called white blood cells to distinguish them from red blood cells. More formally, they are known as **leukocytes** ("white-cells").

The leukocytes involved in innate immunity provide an immediate, *generic* response that is directed against the general type of pathogen encountered. The response is considered generic since it is directed against broad groups of pathogens instead of specific organisms. For example, the innate response is able to distinguish between fungi and bacteria but cannot identify a specific strain within either group.

How Are Pathogens Recognized by the Innate Immune System? The answer to this question emerged from a breakthrough in the late 1990s, when results from unrelated studies came together. Earlier, German researchers had identified a protein that was important in the early development of fruit flies. When flies were mutated to no longer express this protein, their larvae developed abnormally. The strange appearance of the larvae inspired the researchers to name it the Toll protein (in German, "toll" means amazing).

Jules Hoffmann and his colleagues found that Toll protein also served an important immune function: Adult fruit flies lacking Toll could not defend themselves from fungal infection (see **FIGURE 51.2**). Just a year later, two separate labs identified Toll-like

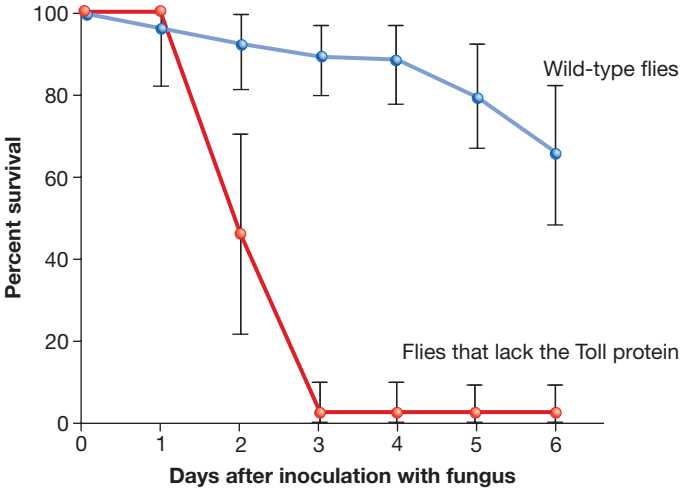


FIGURE 51.2 Toll Protein Is Critical to Immune Response. Researchers learned this by comparing the survival rate of wild-type flies and mutants unable to express Toll protein after exposure to a fungal pathogen. The error bars represent the confidence interval for each point with $p \leq 0.05$. This means that there is 95 percent confidence that if the experiment were repeated, the value for each time point would fall within the bracketed range.

DATA: Lemaitre, B., et al. 1996. *Cell* 86: 973–983.

proteins in humans, demonstrating their universality. This was an exciting discovery, but the function of these Toll-like proteins was still not understood.

The riddle of Toll-like proteins was solved by Bruce Beutler and his colleagues, who studied how mutant mice reacted to antigens. An **antigen** is any foreign molecule that can initiate an immune system response. Earlier researchers observed that a molecule called lipopolysaccharide (LPS), harvested from the surface of Gram-negative bacteria (see Chapter 29), reliably caused a powerful immune response in animals. However, Beutler had a mutant mouse that did not respond to this antigen—and the mouse had defective Toll-like proteins.

Beutler had discovered that the Toll-like protein functions as a receptor that receives the signal that a pathogen is present, in this case a Gram-negative bacterium. This breakthrough was key to understanding how the innate immune system could become engaged.

Toll-like receptors (TLRs) are a subset of a larger group of proteins called **pattern-recognition receptors,** which serve as sentinels to signal the presence of molecules associated with pathogens. The TLRs have been observed in fungi and plants, suggesting that they arose in a common ancestor of eukaryotes. Eleven TLRs have been identified in humans, each one responding to a different kind of antigen. For example,

- TLR2 binds to zymosan, a common molecule in fungi.
- TLR4 binds to lipopolysaccharide (LPS) from Gram-negative bacteria (the one in Beutler's study).
- TLR5 binds to flagellin from the flagella of motile bacteria.
- TLR7 binds to single-stranded viral RNA.

What all these antigens have in common is that they are ubiquitous within the broad group in which they have been identified (e.g., *all* of the countless Gram-negative bacteria produce LPS), yet they do not occur in the host animal. Thus, these antigens serve as reliable signals of attack for the innate immune system. A mere 11 TLRs in humans is enough to detect virtually any type of invasion.

Pattern-Recognition Receptors Transduce Signals

When pattern-recognition receptors, such as TLRs, on the surface of a leukocyte receive the signal that an invader is present, they trigger a signal cascade within the cell that will have different consequences depending on which TLRs were activated (see Chapter 11 for an introduction to signal transduction). This step is vital to determining and orchestrating the innate immune responses to follow. For example,

- When the Toll protein in healthy flies detects a fungal infection, a signal cascade activates the expression and secretion of antimicrobial peptides, which function as antibiotics to destroy the fungal pathogens.
- When TLR4 in humans is activated by LPS, a signal cascade leads to the expression and secretion of **cytokines** ("cell movers"). Cytokines are a class of diverse molecules that signal other parts of the immune system in various ways, such as attracting other immune cells to the site of infection or stimulating other immune cells into action.
- When TLR7 in humans detects the single-stranded RNA of a virus, the cell may produce and secrete a specific type of cytokine called interferon, which stimulates neighboring cells to improve their resistance to the imminent viral infection.

✔ **QUANTITATIVE** **If you understand the role of pattern-recognition receptors, you should be able to return to Figure 51.2 and predict how the same two groups of flies would respond to a Gram-negative bacterial pathogen. Draw a line on the graph to represent flies lacking the Toll protein after treatment, and explain your reasoning. Assume the survival rate of wild-type flies would be similar to what is shown in the figure.**

Once the general signal of an invasion is received by TLRs, the first response is sent out and a cascade of further actions occurs that result in a fully engaged immune response. For example, consider what would happen if you were to trip on the sidewalk while running across campus and scrape your elbow. If this wound resulted in an infection, you would observe redness, swelling, pain, and heat in the infected area. What is responsible for all of these changes?

The Inflammatory Response in Humans

The physical signs of an infected injury are a direct consequence of the innate immune response being called into action to contain and eliminate the infection. **FIGURE 51.3** summarizes the major steps in this **inflammatory** ("in-flames") **response,** a multistep, innate immune response observed in an array of animals.

Step 1 A break in the skin allows bacteria to enter the body. If capillaries and other small blood vessels are broken, the wound bleeds.

Step 2 Immediately after the injury, blood components called **platelets** release proteins that form clots and lessen bleeding. Other clotting proteins in the blood form cross-linked structures that help wall off the wound and reduce blood loss.

Step 3 Wounded tissues and leukocytes called **macrophages** secrete **chemokines** ("chemical-movers"), which are signaling molecules that recruit other cells to the site of infection. The localized production of chemokines is important because it forms a gradient that marks a path to the wound site.

Step 4 **Mast cells** release chemical messengers such as **histamine** that constrict blood vessels at the site of the wound—reducing blood flow and thus blood loss. Mast cells also release other signaling molecules that induce blood vessels slightly farther from the wound to dilate and become more permeable.

Step 5 The combination of dilated blood vessels and a chemokine gradient is like a 911 call that provides specific directions to the scene of a fire. Leukocytes called neutrophils move out of dilated blood vessels and migrate to the site of the infection. **Neutrophils** are major players in the innate response. They destroy invading cells by phagocytosis ("cell eating")—meaning that they engulf them. Once inside neutrophils, the invading cells are killed with a complex array of antimicrobial

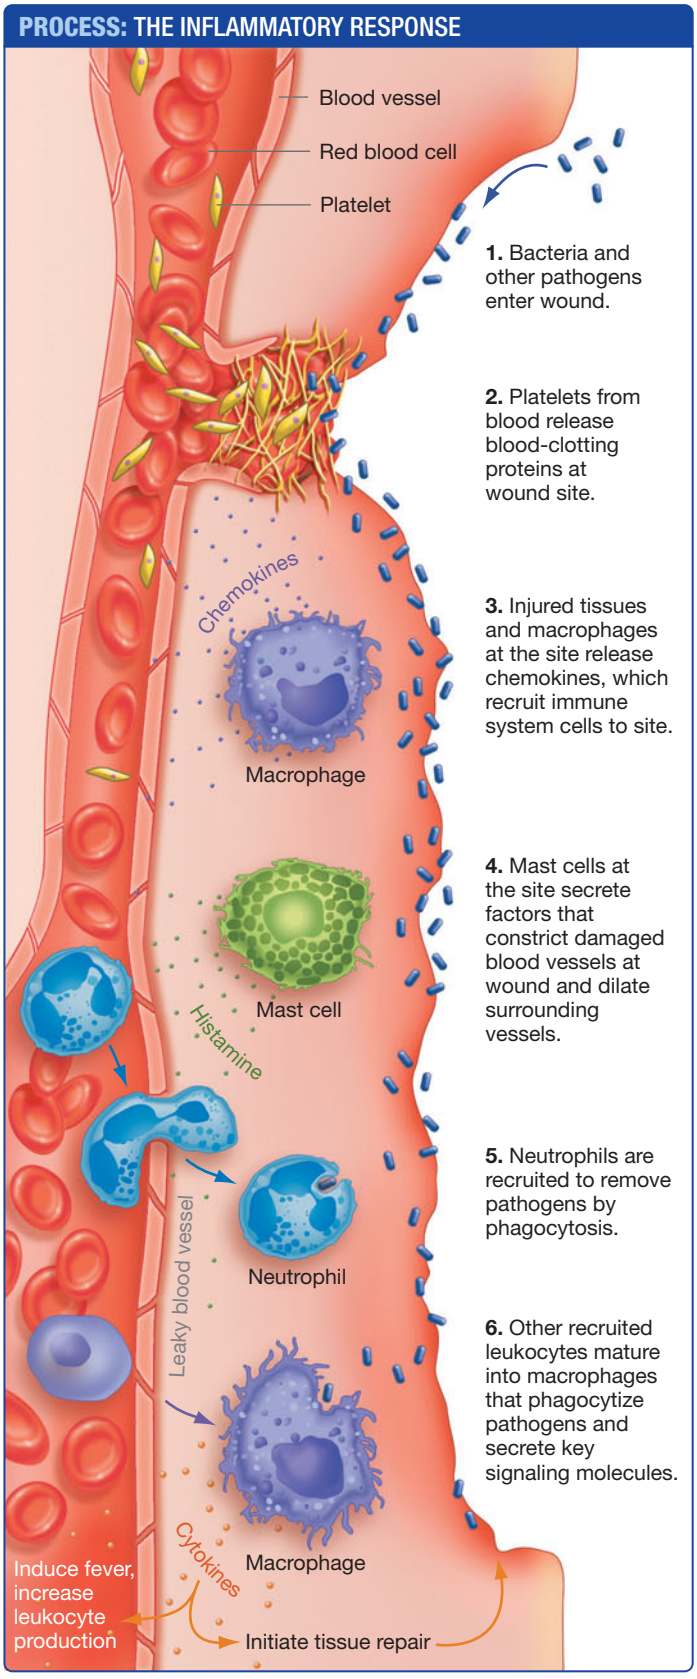

FIGURE 51.3 The Inflammatory Response of Innate Immunity Has Many Elements.

✔**QUESTION** How do these events lead to the classical signs of an infection, which include rubor (reddening), calor (heat), and tumor (swelling), among others?

compounds—including lysozyme, which degrades bacterial cell walls. Cells that perform this activity are collectively referred to as phagocytes.

Step 6 Cells that will mature into macrophages arrive. Besides secreting chemokines, these macrophages produce additional cytokines that have an array of effects. Some of these cytokines stimulate bone marrow to make and release additional leukocytes, induce fever—an elevated body temperature that aids in healing—and activate cells involved in tissue repair and wound healing. Like neutrophils, macrophages are also phagocytes that help clear invaders from the area.

This overview actually simplifies the situation—many other cell types and cell–cell signals are involved in responding to pathogens at a site of infection.

The inflammatory response continues until all foreign material is eliminated and the wound is repaired. **TABLE 51.2** on page 1042 summarizes key cells and molecules involved in the response.

But what happens when the innate immune system of a vertebrate fails to contain and eliminate invading pathogens?

check your understanding

C Y U

If you understand that . . .

- The innate immune response occurs when macrophages and mast cells that reside in tissues, and neutrophils that circulate in the blood, react in a generic way to signals from invading pathogens.

✔ **You should be able to . . .**

Describe how the following steps that first-aid workers use when initially treating a wound mimic events in the innate immune response:

1. Applying direct pressure to close blood vessels
2. Cleaning the wound to remove dirt and debris
3. Applying bandages containing compounds that halt blood flow from the wound

Answers are available in Appendix A.

51.2 Adaptive Immunity: Recognition

In addition to the innate immune response, vertebrates have evolved the ability to recognize specific antigens, and can differentiate between different species and even different strains of pathogens. The leukocytes involved can customize their response to the particular invader, so this arm of the immune system is often referred to as the **adaptive immune response.**

Given the array of pathogens that exist, an animal is almost certain to be exposed to an enormous variety of antigens in the course of its lifetime. Is there a limit to how many different antigens its adaptive immune system responds to?

SUMMARY TABLE 51.2 The Innate Immune System

(a) Key Cells

Name	Primary Function
Mast cells	Release signals that constrict blood flow from wound and increase blood flow to wound area
Neutrophils	Kill invading cells via phagocytosis
Macrophages	Release cytokines that recruit other cells to wound site and stimulate a variety of activities; kill invading cells via phagocytosis

(b) Key Signaling Molecules

Name	Produced By	Received By	Message/Function
Histamine	Mast cells	Blood vessels	High concentration constricts blood vessels at wound site, among other activities
Chemokines*	Injured tissues and macrophages in tissues	Neutrophils and macrophages	Mark path to wound; promote dilation and increased permeability of blood vessels
Cytokines other than chemokines	Macrophages	Leukocytes	Mark path to wound
		Bone marrow	Increase production of macrophages and neutrophils
		CNS	Induce fever by raising set point for control of body temperature
		Local tissues	Stimulate cells involved in wound repair

*Note that chemokines are a subset of cytokines.

Research conducted in the early 1920s answered this question. Researchers synthesized organic compounds that do not exist in nature, injected the novel molecules into rabbits, and observed whether they activated the animals' adaptive immune system. To the amazement of the scientists, the rabbits were able to recognize and respond to every novel antigen tested. More specifically, each of the animals produced proteins in their blood called antibodies that specifically bound to the particular antigen that was injected. **Antibodies** are secreted proteins that bind to a specific part of a specific antigen.

The take-home message is that the adaptive immune system can specifically respond to an almost limitless array of antigens. This observation, and subsequent research on antibody production, led to the identification of four key characteristics of the adaptive immune response:

1. ***Specificity*** Antibodies and other components of the adaptive immune system bind only to specific sites on specific antigens.
2. ***Diversity*** The adaptive immune response recognizes an almost limitless array of antigens.
3. ***Memory*** The adaptive immune response can be reactivated quickly if it recognizes antigens from a previous infection.
4. ***Self–nonself recognition*** Molecules that are produced by the individual do not act as antigens, meaning that the adaptive immune system can distinguish between self and nonself. Nonself molecules are antigens; self molecules are not.

The next question is, What are the cells and organs that are responsible for this adaptive immune response?

An Introduction to Lymphocytes

The leukocytes that carry out the major features of the adaptive immune response are called **lymphocytes.** In contrast to the diversity of leukocytes involved in the innate immune response, lymphocytes are primarily divided into two distinct cell types that differ in their role in the adaptive immune response and their site of maturation.

The Discovery of B Cells and T Cells In 1956 a group of researchers provided an important insight into the adaptive immune system, by accident. The biologists were investigating the immune system's response to the bacterium *Salmonella typhimurium*, a common cause of food poisoning in humans. To do this work, they needed to produce and isolate antibodies to a particular antigen from *S. typhimurium*—an antigen that is toxic. Their plan was to inject a large number of chickens with the antigen and collect the antibodies that the treated animals produced in response.

In addition to injecting many normal chickens, though, the biologists happened to include some chickens that had undergone

experimental removal of an organ called the bursa. Six of the nine chickens that lacked a bursa and that were injected with the antigen died. The other three birds without a bursa survived, but failed to produce antibodies to the antigen. In contrast, all of the chickens with the bursa intact survived and produced large quantities of antibodies. To make sense of these results, the researchers proposed that the bursa is critical for antibody production and that antibodies are important in neutralizing the toxic antigens.

Not long after this observation was published, three groups of scientists independently conducted a related experiment. To explore the function of the thymus in mammals, these groups removed the organ from newborn mice. Mice lacking a thymus developed pronounced defects in their immune systems. For example, when pieces of skin from other mice were grafted onto the experimental individuals, their immune systems did not recognize the tissue as foreign. In contrast, individuals with an intact thymus quickly mounted an immune response that killed the foreign skin cells.

The results of these and follow-up experiments showed that lymphocytes from the bursa and thymus have different functions. The two types of lymphocytes became known as bursa-dependent and thymus-dependent lymphocytes, or B cells and T cells, respectively.

- **B cells** produce antibodies. Later work showed that in humans and other species where the bursa organ does not exist, B cells mature in bone marrow.
- **T cells** are involved in graft rejection along with an array of other immune functions, including recognizing and killing host cells that are infected with a virus. T cells mature in the thymus.

The requirement for maturation in a particular organ distinguishes the lymphocytes from other leukocytes that were introduced in Section 51.1. What is the origin of these lymphocytes, and where do they go after they mature?

Where Are Lymphocytes Found? The colored structures in **FIGURE 51.4** mark the major sites in the human body that play a key role in the life of a lymphocyte.

- ***Lymphocyte origin*** All lymphocytes are produced in **bone marrow**—a tissue that fills the internal cavities in bones.
- ***Lymphocyte maturation*** B cells mature in the bone marrow in humans and many other animals. T cells mature in the **thymus**—an organ located in the upper part of the chest of vertebrates (just behind the breastbone in humans).
- ***Lymphocyte activation*** Lymphocytes recognize antigens and become activated in the spleen and lymph nodes. The **spleen** is an organ located near the stomach in the abdominal cavity and is also involved in destroying old blood cells. **Lymph nodes** are small, oval organs that are located all around the body. Lymph nodes filter the lymph passing through them. Recall that **lymph** is a mixture of fluid and lymphocytes (see Chapter 45).

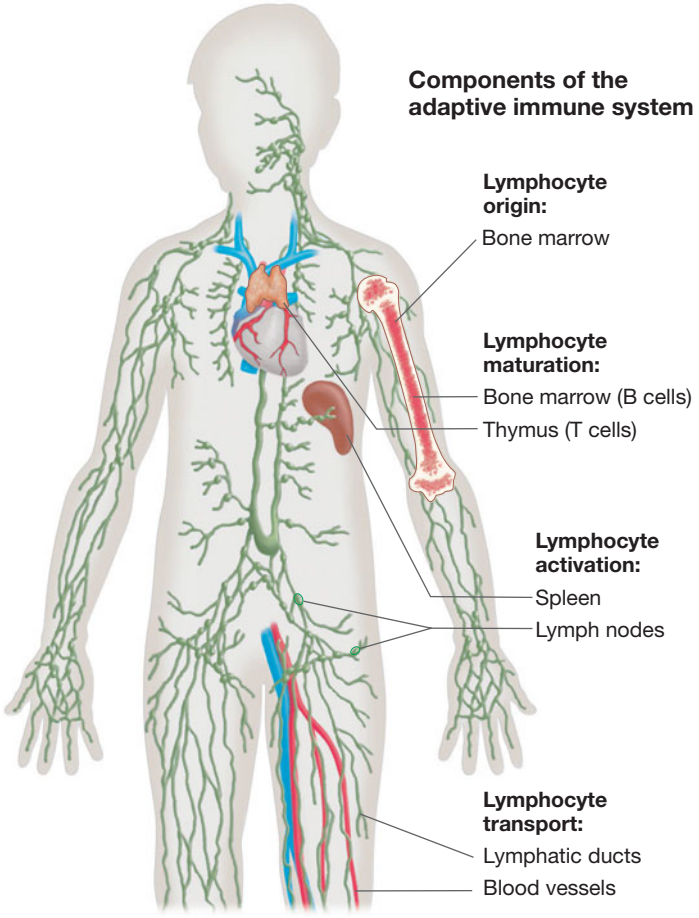

FIGURE 51.4 Lymphocytes Are Formed, Activated, and Transported in the Immune System.

The liquid portion of lymph originates in fluid that is forced out of capillaries by blood pressure.

- ***Lymphocyte transport*** Lymphocytes circulate through the blood and the secondary organs of the immune system—lymph nodes, spleen, and lymphatic ducts. Lymphatic ducts are thin-walled, branching tubules that transport lymph throughout the body and, along with lymph nodes, make up the **lymphatic system.**

Besides being found in bone marrow, the thymus, spleen, lymph nodes, lymphatic ducts, and blood vessels, large numbers of lymphocytes, along with other leukocytes, are associated with skin cells and with epithelial tissues that secrete mucus—primarily in the digestive tract and respiratory tract. Collectively, the immune system cells found in the gut and respiratory organs are called **mucosal-associated lymphoid tissue (MALT).** Leukocytes in the skin and MALT are important because they guard points of entry against pathogens.

Now let's turn to one of the most fundamental questions in immunology: How are B cells and T cells able to recognize so many different antigens? Let's begin with a look at the B-cell and T-cell receptors—the molecules that start the adaptive immune response.

Lymphocytes Recognize a Diverse Array of Antigens

By the 1960s, biologists understood that B cells can produce antibodies to a seemingly limitless number of antigens and that each antibody is specific to a particular antigen. They hypothesized that each B cell formed in the bone marrow has thousands of copies of a receptor on its surface that recognizes only one antigen. What's more, each B cell expresses a unique receptor relative to the other B cells. What would such a receptor look like?

The Discovery of B-Cell Receptors To test the hypothesis that B cells have antigen-specific receptors on their surfaces, researchers injected experimental animals with radioactively labeled antigens. This strategy was similar to the experiments with labeled estradiol that allowed biologists to isolate that hormone's receptor (see Chapter 49).

As predicted, the labeled antigens bound to a protein on the surface of only those B cells that produced antibody to the antigen. Chemical analysis of this **B-cell receptor (BCR)** protein showed that it has the same overall structure as the antibodies produced by the B cells and secreted into the blood.

The BCR protein consists of two distinct polypeptides (**FIGURE 51.5a**). The smaller polypeptide is called the **light chain.** The larger polypeptide is roughly twice the size of the light chain and is called the **heavy chain.** Each BCR has two copies of the light chain and two copies of the heavy chain that are all held together by disulfide bonds. The heavy chain includes a transmembrane domain that anchors the protein in the plasma membrane of the B cell.

The antibodies produced by a B cell are identical in structure to its BCR, except that they lack the transmembrane domains. Instead of being inserted into the plasma membrane, antibodies are secreted from the cell and circulate throughout the body.

Both the BCR and the antibodies produced by B cells belong to a family of proteins called the **immunoglobulins (Ig).** Immunoglobulins are crucial to the adaptive immune response.

TABLE 51.3 shows the five classes of immunoglobulin proteins that act as antibodies. The five types are symbolized IgG, IgD, IgE, IgA, and IgM. Each class is distinguished by unique amino acid sequences in the heavy-chain region, and each has a distinct

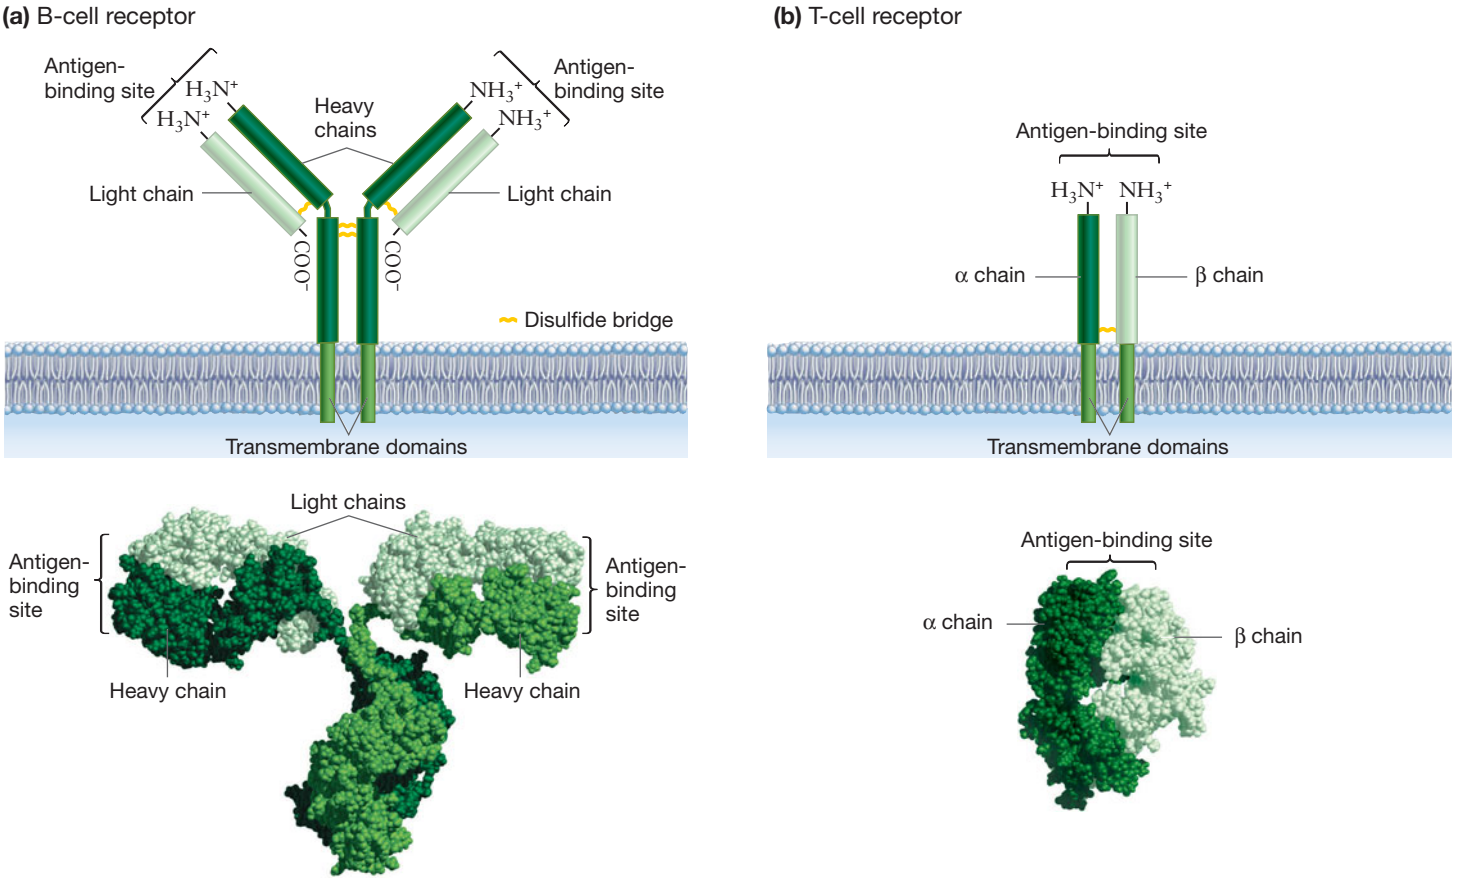

FIGURE 51.5 B-Cell Receptors and T-Cell Receptors Have Transmembrane Domains and Antigen-Binding Sites. (a) Schematic and space-filling models of the B-cell receptor, which is shaped like a Y. **(b)** The shape of the T-cell receptor resembles one "arm" of the Y-shaped B-cell receptor. The space-filling models for each receptor do not show the transmembrane domains that anchor them in the plasma membrane.

TABLE 51.3 Five Classes of Immunoglobulins

Name	Structure (Secreted Form)	Function
IgG	Monomer 	The most abundant type of secreted antibody. Circulates in blood and interstitial fluid. Protects against bacteria, viruses, and toxins.
IgD	Monomer 	Present on membranes of immature B cells; rarely secreted. Serves as BCR.
IgE	Monomer 	Secreted in minute amounts. Involved in response to parasitic worms. Also responsible for hypersensitive reaction that produces allergies.
IgA	Dimer 	Most common antibody in breast milk, tears, saliva, and the mucus lining the respiratory and digestive tracts. Prevents bacteria and viruses from attaching to mucous membranes; helps immunize breastfed newborns.
IgM	Pentamer 	First type of secreted antibody to appear during an infection. Binds many antigens at once; effective at clumping viruses and bacteria so that they can be killed. Monomeric form also serves as BCR.

function in the immune response. Besides acting as antibodies, IgD and monomeric forms of IgM also serve as BCRs.

The Discovery of T-Cell Receptors It took much longer for researchers to isolate and characterize the **T-cell receptor (TCR).** The technique used to identify BCRs was not useful for the receptors on T cells, suggesting that they cannot bind antigens on their own. It turns out that the T cells require other cells to **(1)** process the antigens and **(2)** present them to the TCRs. This means that for a TCR to recognize an antigen, the foreign molecule must first undergo a complex process called **antigen presentation.**

This is a fundamentally important distinction. B cells bind to antigens directly; T cells bind only to antigens that are displayed by other cells.

Other data showed that the TCR is composed of two protein chains: an alpha (α) chain and a beta (β) chain (**FIGURE 51.5b**). The overall shape of the TCR is similar to one of the two "arms" of an antibody or BCR molecule.

Antibodies and Receptors Bind to Epitopes Antibodies, BCRs, and TCRs do not bind to the entire antigen. Instead, they bind to a selected region of the antigen called an **epitope.**

To understand the relationship between an antigen and an epitope, consider that every bacterium, virus, fungus, and protist is made up of a large number of different molecules. Many of these molecules are antigens, because they would be recognized

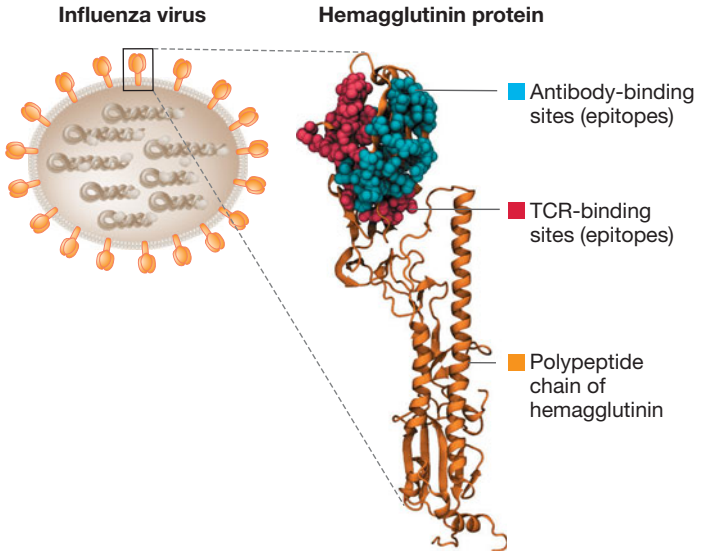

FIGURE 51.6 Most Antigens Have Multiple Epitopes for B-Cell Receptors and T-Cell Receptors. The envelope of the influenza virus includes the protein hemagglutinin. This version of hemagglutinin has several distinct epitopes for BCRs and TCRs. One example of each type is highlighted as a space-filling model.

as being foreign to your cells. In turn, each antigen may have many different epitopes, where binding by antibodies and lymphocyte receptors actually takes place.

FIGURE 51.6 illustrates a protein called hemagglutinin, which is found on the surface of the influenza virus. This antigen has several distinct epitopes, two of which are identified in the figure. Often, the epitopes for BCRs are different from those recognized by TCRs because of how epitopes are presented to the different receptors: BCRs bind to epitopes in the context of the intact antigen, while TCRs bind to epitopes that have been processed and presented by other cells. Each epitope is recognized by a particular antibody, BCR, or TCR. It is not unusual for an antigen to have between 10 and 100 different epitopes.

How do the immunoglobulins recognize specific epitopes? The answer to this question emerged through detailed studies of the heavy and light chains.

What Is the Molecular Basis of Antibody Specificity and Diversity?

In the 1950s, biologists developed an important model system for studying immunoglobulin structure. The model cells were B-cell tumors, or myelomas, that could be grown in laboratory culture.

Each type of myeloma arises from a single cell that produces a single type of antibody. When researchers compared the immunoglobulins produced by different myelomas, they found that the sequence of amino acids in the light chains consisted of two regions: one that is virtually identical among the myelomas, and another that is unique. These light-chain segments have come to be known as the **constant (*C*) regions** and **variable (*V*) regions,** respectively. Heavy chains also have a *C* region and a *V* region.

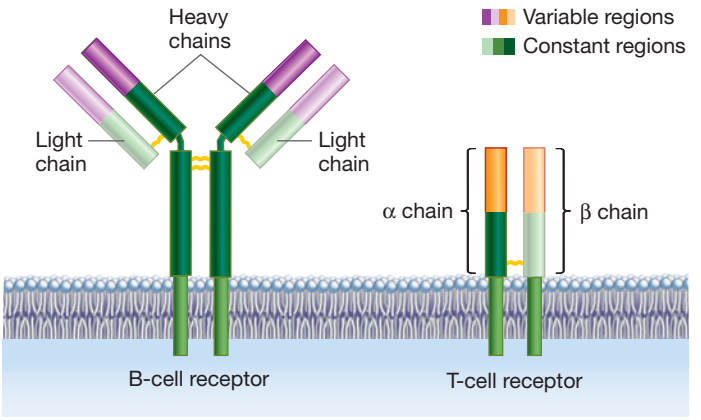

FIGURE 51.7 The Variable Regions of B-Cell Receptors and T-Cell Receptors Face Away from the Plasma Membrane.

FIGURE 51.7 makes two important points:

1. The *V* regions of heavy and light chains in a BCR are adjacent to one another and face away from the plasma membrane.
2. The *V* and *C* regions of a TCR are arranged in a similar manner as the BCR.

The presence of unique amino acid sequences in the *V* regions of every antibody, BCR, and TCR explains why each of these proteins binds to a unique epitope. Your body can respond to an almost limitless number of antigens because the number of different BCRs, antibodies, and TCRs is virtually limitless. How does all this variation come to be?

The Discovery of Gene Recombination In 1965, W. J. Dryer and J. Claude Bennett proposed a fantastic-sounding explanation for how immunoglobulin genes code for so many different variable regions and thus so many different proteins. They hypothesized that as a lymphocyte is maturing, a segment from a variable-region gene is cut and combined with a segment from the constant-region gene. Further, they proposed that this cutting and pasting is done in a different way in each lymphocyte. The result is that each lymphocyte has a novel "*V* + *C* gene" for the light-chain protein.

At the time, this type of genetic recombination in cells had not been observed, and most researchers considered the hypothesis wildly implausible.

Eleven long years passed before the first experimental evidence was obtained to support their hypothesis. In 1976, researchers showed that the amount of DNA in the *V* + *C* region of mature lymphocytes is shorter than it is in immature lymphocytes. This is exactly what the gene-recombination hypothesis predicts.

The flurry of studies inspired by this result showed that the genes for light chains have dozens of different *V* segments, several different joining (*J*) segments, and a single constant (*C*) segment. The heavy-chain gene includes diversity (*D*) segments along with a set of *V* and *J* segments similar to those in the light-chain gene. The genes that encode the α and β chains of the TCR have a similar arrangement of distinct segments, each with multiple versions.

As a lymphocyte matures, the various gene regions are mixed and matched to produce unique receptors. **FIGURE 51.8** illustrates the steps involved in the production of the BCR light chain. A similar process occurs in the DNA encoding the heavy chain gene. Consider how these recombination events lead to BCR diversity:

1. In the light chain, one of the 40 *V* segments recombines with one of the 5 *J* segments. This step can produce $40 \times 5 = 200$ different light chains.
2. In the heavy chain, any one of the 51 *V* segments, 27 *D* segments, and 6 *J* segments can recombine.
3. The light-chain and heavy-chain rearrangements occur independently, but the final BCR includes the polypeptides from each gene to form the antigen-specific variable region.

✔ **QUANTITATIVE** **If you understand how unique genes for the light and heavy chains of the BCR are made, you should be able to calculate the number of different antigen-specific BCRs that could made by this process in (1) a human and (2) a single human B cell.**

In addition, gene segments do not always join precisely during DNA recombination. Some variation occurs where the *V* and *D* segments join and where the *D* and *J* segments join. As a result, an estimated 10^{10} to 10^{14} different BCRs can form in a single individual. TCR production is just as diverse.

Gene recombination is the molecular mechanism responsible for the specificity and diversity of the adaptive immune system. This process allows each lymphocyte to produce a unique BCR, antibody, or TCR—enabling it to recognize a unique epitope. The charges and geometry at each surface make the way the receptor and epitope fit together extremely specific.

How Does the Immune System Distinguish Self from Nonself?

If the adaptive immune system has the remarkable ability to generate specific, targeted responses against virtually any substance, what keeps it from reacting against itself? If a receptor responded to a **self molecule**—that is, a molecule belonging to the host—the receptor would trigger an immune response. Because this type of response is extremely rare compared to responses against foreign antigens, biologists hypothesized that there must be some mechanism for eliminating self-reactive B cells and T cells.

To test this hypothesis, researchers injected B cells and T cells possessing anti-self receptors into mice and found that the injected lymphocytes were eliminated. Follow-up work showed that if B cells and T cells maturing in the bone marrow and thymus have anti-self receptors, the cells are likely to be destroyed or permanently inactivated before they leave these organs. The conclusion? Some form of "self-education" occurs during the maturation phase of lymphocyte development.

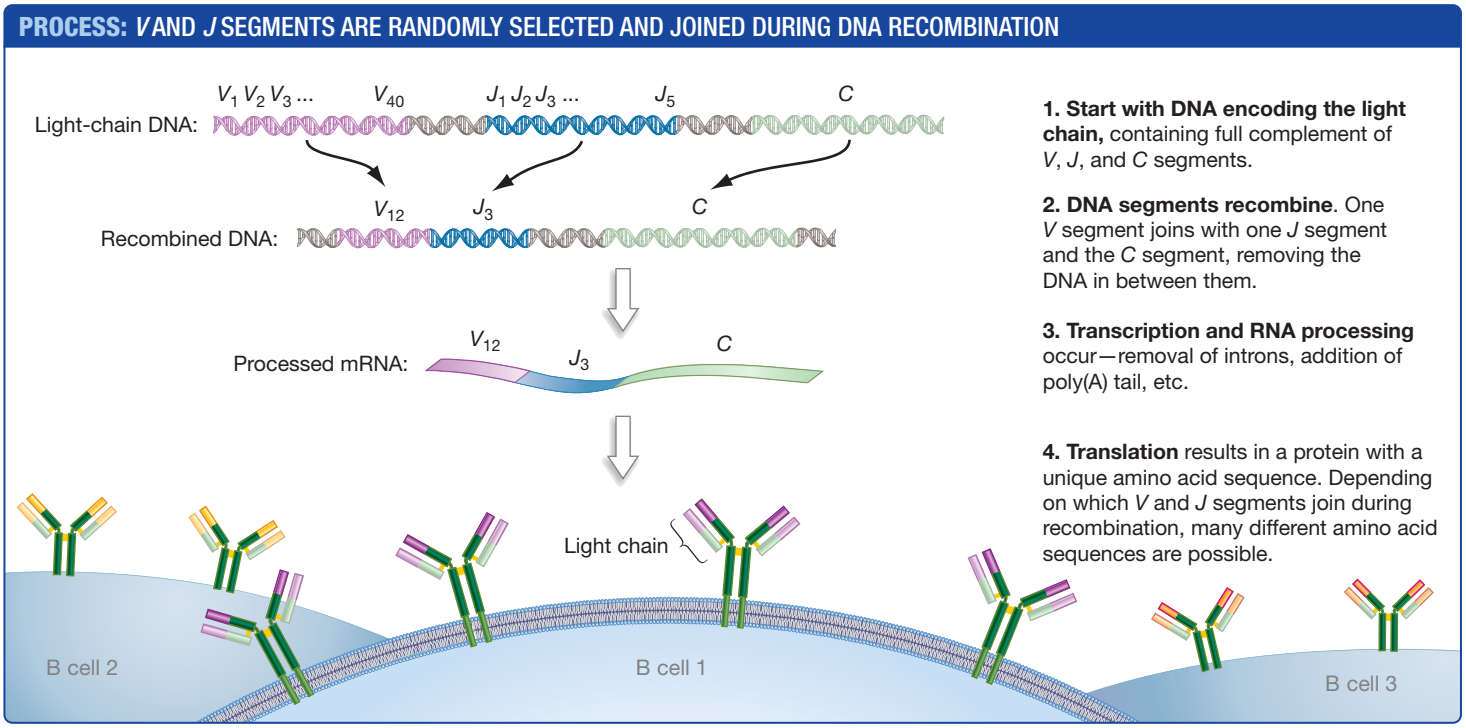

FIGURE 51.8 As B Cells Mature, Immunoglobulin-Gene Segments Recombine to Form a Single Gene. In the mature B cell 1, the final light-chain gene consists of the V_{12}, J_3, and C segments spliced together; the final heavy-chain gene might consist of the V_{48}, D_{22}, J_1, and C segments spliced together (not shown).

Researchers have also identified another type of T cell that acts as a regulatory cell. Regulatory T cells suppress certain parts of the immune system to limit the intensity of normal responses, and may help inhibit any self-reactive cells that slip through the self-education system. Defective or insufficient regulatory T cells may be partly responsible for the development of immune disorder diseases (see Section 51.5).

Even after the self-reactive lymphocytes are inactivated or removed, the structural diversity still present in the receptors of mature B and T cells is sufficient for recognizing virtually any foreign antigen. But this diversity alone is not enough to mount an effective immune response. The enormous repertoire of possible BCRs and TCRs means that only a few cells will express any particular epitope-specific receptor. To engage the invading pathogen successfully, these few lymphocytes must reproduce. How does this selective expansion take place?

check your understanding

C Y U

If you understand that . . .

- The adaptive immune response is performed by lymphocytes that circulate in the lymph, blood, and organs of the immune system.
- Lymphocytes can respond to a wide array of antigens because gene segments recombine to produce receptors that bind to unique epitopes on antigens.
- Lymphocytes that express self-reactive receptors are eliminated or inactivated to prevent immune responses against the body's own cells.

✓ You should be able to . . .

1. Cite two key events that must occur during lymphocyte maturation to ensure a safe and effective adaptive immune response.
2. Explain the benefit of assembling the variable region from discrete segments rather than having multiple intact variable regions.

Answers are available in Appendix A.

51.3 Adaptive Immunity: Activation

Lymphocytes are normally in a resting, or inactive, state. Over the course of a day, an inactive lymphocyte may hang out in the skin or MALT, enter the lymphatic vessels, migrate through a lymph node, cross over into the blood, pass through the spleen, return to the blood, and so on.

If an inactive lymphocyte does not encounter the epitope that it is programmed to respond to, the cell eventually dies. As it turns out, this is the fate of most of the lymphocytes that originate from the bone marrow. During an infection, however, some of these inactive lymphocytes will go on to mount a massive attack that is targeted against the specific invader.

The Clonal Selection Theory

The diversity of the adaptive response is useful only if it can be directed against an infection. In the 1950s, Frank Bernet and colleagues developed the **clonal selection theory** to explain how only the most useful lymphocytes are activated during an infection. Their theory made several key claims about how the adaptive immune system works:

- ***Antigens are recognized by receptors on B cells and T cells.*** Each lymphocyte formed in the bone marrow or thymus expresses a unique receptor on its surface that binds to a unique epitope in an antigen.
- ***Lymphocytes require receptor-epitope binding to become activated.*** When the receptor on a lymphocyte binds to an epitope, a switch is thrown in the lymphocyte that may ultimately push the cell from a quiescent to an activated state.
- ***Activated lymphocytes are cloned.*** An activated lymphocyte divides and makes many identical copies of itself. In this way, specific cells are selected and cloned in response to an infection.
- ***Activated lymphocytes endure.*** Some of the cloned cells descended from an activated lymphocyte persist long after the pathogen is eliminated. As a result, the cloned cells are able to respond quickly and effectively if the infection recurs.

FIGURE 51.9 summarizes the assertions made by the clonal selection theory, using a B cell model. ✔ **If you understand the clonal selection theory, you should be able to explain what "clonal" and "selection" refer to.**

The activation of the relevant B cells and T cells, however, is a carefully controlled, stepwise process. The mechanism is reminiscent of the precautions that nations with powerful missiles take to avoid accidental deployment. For the most dangerous weapons, the signal to launch is checked and cross-checked, using a series of codes and signals. In the immune system, the checking and cross-checking occur through protein–protein interactions on the surfaces of cells, and the release and receipt of cytokines and other signaling molecules.

Let's first take a look at how T cells are activated and then examine how they play a role in the full activation of B cells.

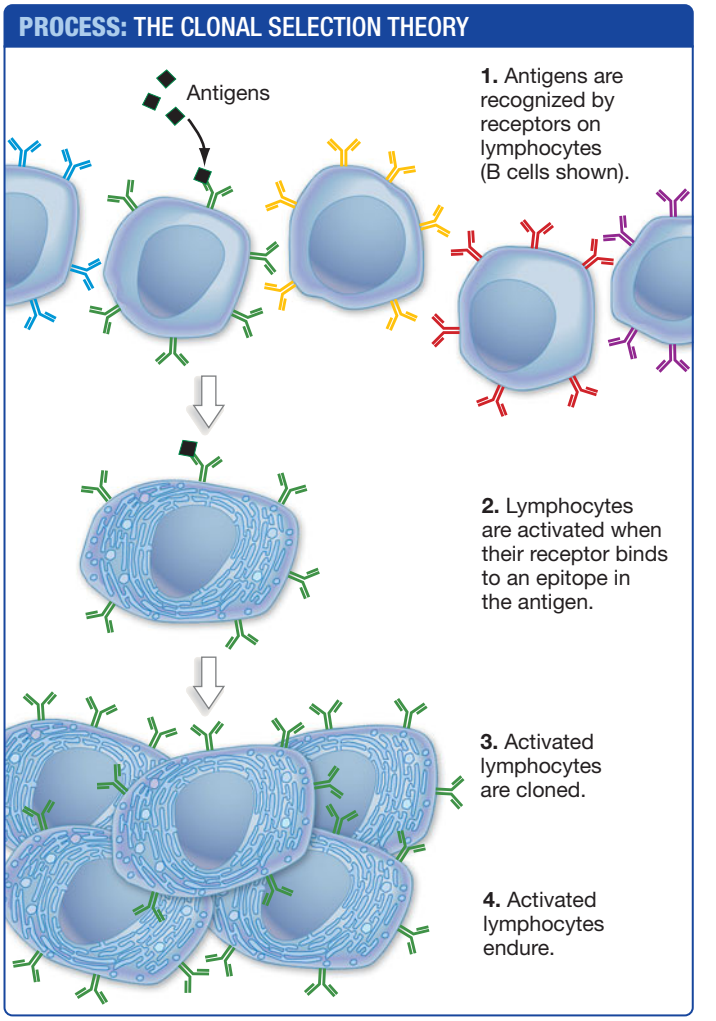

FIGURE 51.9 The Clonal Selection Theory. The clonal selection theory maintains that certain lymphocytes are "selected" by binding to an antigen and that the selected cells then multiply.

T-Cell Activation

As the innate immune response is battling the invaders at the site of infection, leukocytes known as **dendritic** ("tree-like") **cells** are gobbling up antigens and debris via phagocytosis. These dendritic cells are like messengers that collect antigens from the battle scene and then report to the lymph nodes, where they present them to lymphocytes. Antigen presentation is a key event that links the innate and adaptive arms of the immune system; without this transfer of information, the adaptive immune response would not be activated to respond to the infection.

To understand how the activation system works, let's explore how the antigens taken up by dendritic cells are processed and presented to T lymphocytes. T cells are classified as $CD4^+$ or $CD8^+$, based on the presence of key proteins called **CD4** or **CD8** on their plasma membranes. $CD4^+$ T cells and $CD8^+$ T cells have distinct functions in the adaptive immune response.

Antigen Presentation via MHC Proteins Recall that the receptors on T cells can bind only to epitopes that have been processed and presented on the surface of other cells. The surface proteins responsible for presenting these epitopes are called **major histocompatibility (MHC) proteins.** MHC proteins have a groove that binds to small peptide fragments that are typically 8 to 20 amino acids in length (see **FIGURE 51.10**).

MHC proteins come in two types, called **class I** and **class II MHC proteins.** Dendritic cells present peptides in both classes of MHC proteins, but the origins of the peptides differ between the two: class I MHC proteins bind antigens inside the endoplasmic reticulum (ER); class II MHC proteins bind antigens inside endosomes. The proteins that are processed and loaded onto the class I MHC are derived from the cell's cytosol, while those loaded onto the class II MHC are obtained from the external environment.

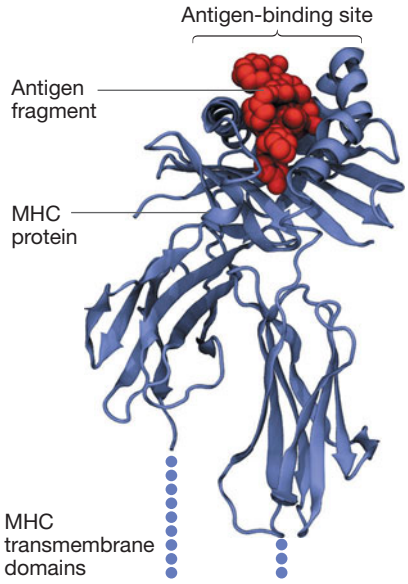

FIGURE 51.10 MHC Structure Promotes Peptide Binding. A peptide processed from the hemagglutinin antigen fits onto the epitope-binding groove in this class II MHC protein like a hot dog in a bun. The class I MHC has a similar epitope-binding groove.

FIGURE 51.11 shows how dendritic cells process antigens and load the peptides onto the class II MHC molecules (a similar process takes place for class I molecules in the ER).

Step 1 Dendritic cells ingest antigens at a site of infection.

Step 2 The antigen is moved from the phagosome to an endosome, where an enzyme complex breaks the protein into small peptide fragments (see Chapter 7).

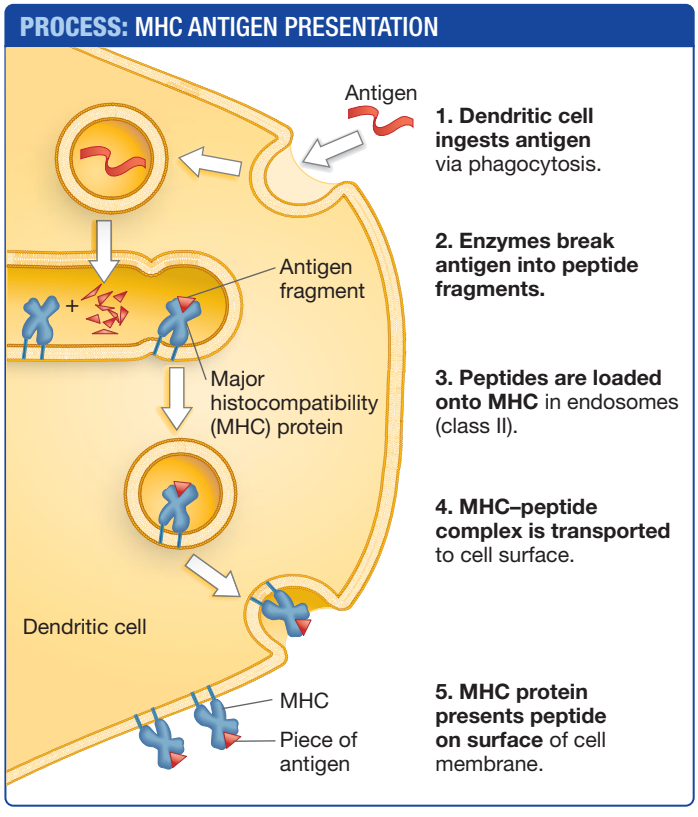

FIGURE 51.11 Dendritic Cells Present Antigens. Dendritic cells take in antigens, break them into pieces, and present the fragments in the groove of an MHC protein.

Step 3 Some of the peptides are bound to the groove of the class II MHC molecules, which were made in the rough ER and transported to the endosome.

Step 4 The MHC–peptide complexes are exported from the endosomes into vesicles for transport to the cell surface.

Step 5 The vesicles fuse with the plasma membrane, displaying the MHC–peptide complexes on the cell surface.

It's important to note that humans have several genes encoding class I and class II MHC proteins. As a result, you can produce several distinct proteins of each class that vary in the type of peptide that is presented. In addition, the MHC genes are among the most polymorphic of any genes known—meaning that many different alleles exist in the population (see Chapter 14). Because so many distinct alleles exist, a wide array of peptides can be bound and presented—allowing these cells to activate a response to many different pathogens.

How Are T Cells Activated by Antigen-Presenting Cells?

FIGURE 51.12 illustrates what happens when T cells recognize the MHC–peptide complexes on a dendritic cell. $CD4^+$ T cells interact with class II MHC–bound epitopes on dendritic cells; $CD8^+$ T cells interact with class I MHC–bound epitopes.

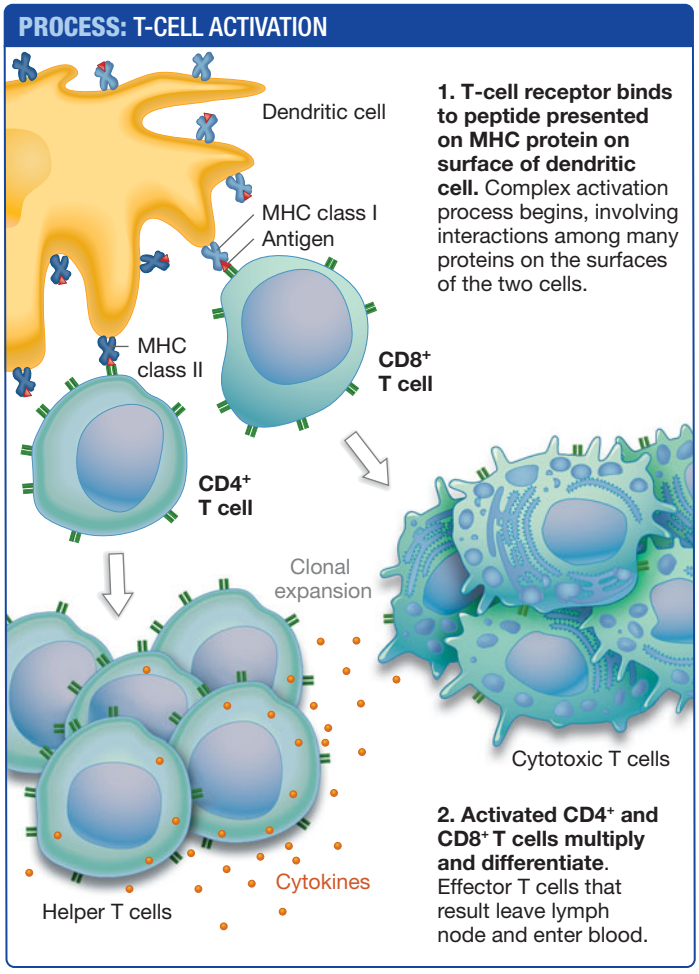

FIGURE 51.12 T Cells Are Activated by Interacting with MHC–Peptide Complexes.

To the T cell, the antigen-presenting cell carries the message "I've found antigen—response required." If the TCR binds, the activation process starts in response to interactions with proteins on the dendritic cell. In most cases, full activation of $CD8^+$ T cells also requires interactions with cytokines produced by activated $CD4^+$ T cells.

An activated T cell divides to produce a series of genetically identical daughter cells. This event, called clonal expansion, is a crucial step in the adaptive immune response. It leads to a large population of lymphocytes capable of responding specifically to the antigen that has entered the body. During this clonal expansion, many morphological changes also occur that prepare the cells for their specific functional roles in the immune response.

Cytotoxic T Cells and Helper T Cells When activated $CD8^+$ T cells undergo clonal expansion, the daughter cells develop into **cytotoxic** ("cell-poison") **T cells,** also known as cytotoxic T lymphocytes (CTLs) or killer T cells. The adjectives cytotoxic and killer are appropriate: $CD8^+$ T cells kill cells that are infected with an intracellular pathogen.

In contrast, the daughter cells of activated $CD4^+$ lymphocytes differentiate into **helper T cells.** The adjective helper is also appropriate: Helper T cells assist with the activation of other cells in the immune response. There are two types of helper T cells, designated T_H1 and T_H2, and they have distinct functions: T_H1 cells help activate cytotoxic T cells; T_H2 cells help activate B cells. During the activation phase, the dendritic cell will often direct which type of helper T cell the $CD4^+$ lymphocyte becomes. The outcome usually depends on which types of TLRs were activated in the dendritic cell at the site of infection.

✔ **If you understand the role of antigen presentation by MHC proteins, you should be able to create a table that summarizes the roles of the class I and class II MHC proteins with regard to the origin of the peptides, type of T cells that bind to them, and the activity that is stimulated in these T cells via the interaction.**

Helper T cells and cytotoxic T cells are capable of participating in the adaptive immune response and are thus referred to as **effector** T cells. Following clonal expansion and maturation, effector T cells leave the lymph node through a lymphatic duct, enter the blood, and migrate to the site of infection. One role of the T_H2 cells is to identify and activate particular B cells that produce antibodies directed against the invading pathogens. How does this work?

B-Cell Activation and Antibody Secretion

Like the T cells, when B cells are activated, they replicate and undergo significant morphological changes. As **FIGURE 51.13a** shows, inactive B cells have a large nucleus, little cytoplasm, few mitochondria, and a ruffled membrane. Upon full activation, B cells produce a massive amount of rough ER and a large number of mitochondria (**FIGURE 51.13b**).

Recall that many of the proteins synthesized in a cell's rough ER are inserted into the plasma membrane or secreted from the cell (see Chapter 7). The increased rough ER in this activated B cell is required for manufacturing and secreting antibodies.

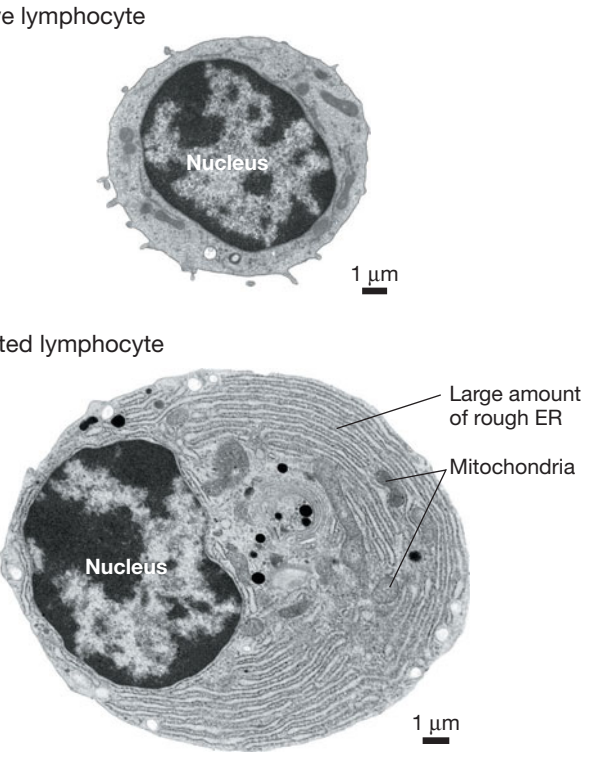

FIGURE 51.13 Lymphocytes Exist in Two States: Inactive and Activated. (a) This inactive B cell has a small amount of cytoplasm and few organelles. **(b)** This activated B cell, called a plasma cell, has extensive rough endoplasmic reticulum (ER) and many mitochondria—suggesting that a great deal of protein synthesis is taking place.

The activation process that leads to these changes involves several steps (**FIGURE 51.14**):

Step 1 The BCRs on B cells interact directly with antigens that are floating free in lymph or blood. The BCR–antigen interaction results in the first part of B-cell activation. The bound antigen is internalized and digested into fragments, which are then loaded onto class II MHC proteins. As a result, a B cell that encounters its antigen displays the antigen's epitopes on its own surface, and the peptides are cradled in the groove of a class II MHC protein.

Step 2 When an *activated* $CD4^+$ T_H2 cell with a complementary receptor arrives, it binds to the MHC–peptide complex on the B cell. The interaction between a B cell and a helper T cell supplies activation signals that stimulate the helper T cell.

Step 3 The helper T cell responds by releasing cytokines that provide a second signal to the B cell that fully activates it.

Step 4 The now fully activated B cell replicates, and some of the daughters differentiate into effector B lymphocytes called **plasma cells.** Plasma cells produce and secrete large quantities of antibodies. Recall that antibodies are identical to B-cell receptors, except that they lack a transmembrane domain and are secreted instead of being found in the plasma membrane.

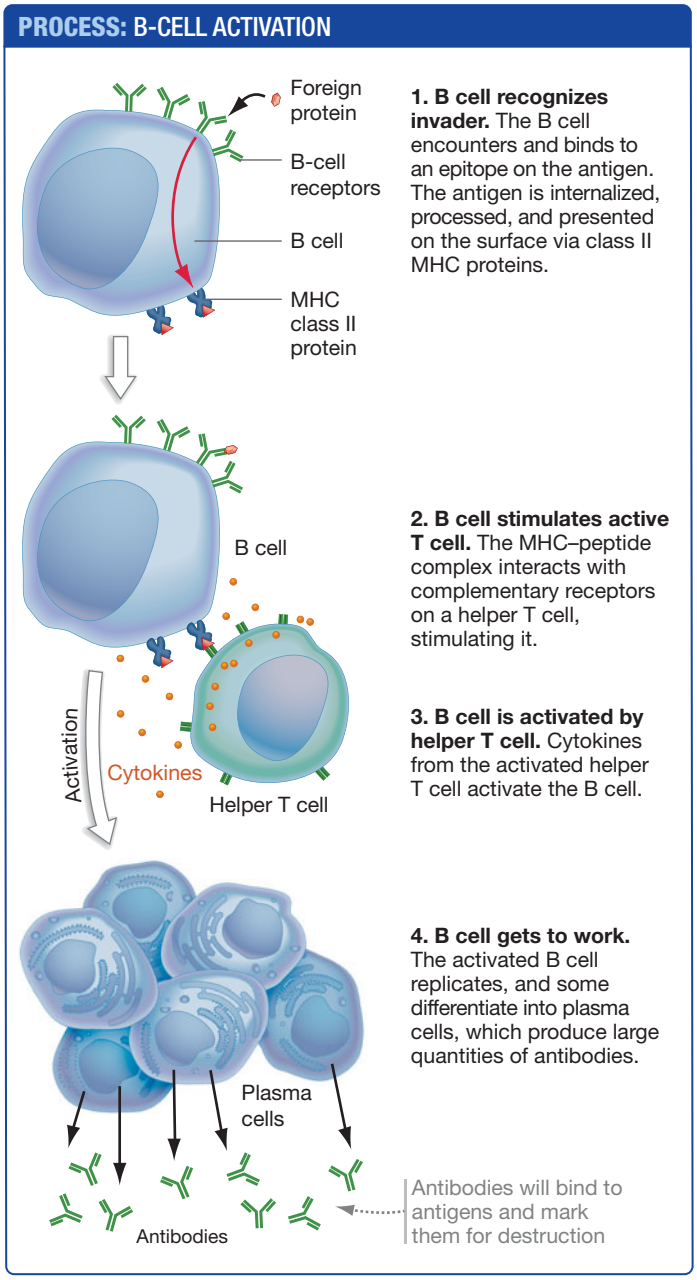

FIGURE 51.14 B Cells Are Activated by Binding to Antigens and Interacting with Helper T Cells.

When B cells are first activated to replicate by binding to the free antigen, they migrate to a specialized area in the lymph node called the germinal center. There, the DNA sequences that code for the variable region of the immunoglobulin gene undergo rapid mutations that modify the variable region of the receptors. B cells with receptors that bind best to the free antigen live and produce daughter cells; those that bind to the antigen less effectively die.

This process of **somatic hypermutation** fine-tunes the immune response. The BCRs that result from somatic hypermutation bind to the antigen more tightly than those formed during maturation in the bone marrow.

Once the effector B cells and T cells have been activated, the adaptive immune response is in full swing. Cytotoxic and helper T cells move into the site of infection, and antibodies specific to the invading pathogen begin to circulate in the blood and lymph. The adaptive immune system has recognized the invaders and initiated its response.

Now let's look at what happens once the secreted antibodies and activated cells are recruited to the site of infection. For pathogens, the results are usually devastating.

check your understanding

If you understand that . . .

- T cells are activated when their receptor binds to an MHC–peptide complex displayed on an antigen-presenting cell.
- B cells are stimulated when their receptor binds to an antigen; then they are fully activated via interactions with a T_H cell activated by the same antigen.
- Activated lymphocytes undergo dramatic changes in morphology and divide rapidly.

✓ You should be able to . . .

Generate a hypothesis to explain the observation that humans who are heterozygous for the genes encoding MHC proteins tend to be healthier than individuals who are homozygous for these genes.

Answers are available in Appendix A.

51.4 Adaptive Immunity: Response and Memory

In combination with the leukocytes involved in the innate immune system, the cells of the adaptive immune system are almost always successful in eliminating threats from bacteria, parasites, fungi, and viruses.

The array of mechanisms used by the adaptive immune system to dispose of foreign invaders are broadly grouped into two responses:

1. The **cell-mediated response** is promoted by T_H1 cells and involves cytotoxic T lymphocytes (activated $CD8^+$ cells) among others. This response primarily takes place via cell–cell contact.
2. The **humoral response** is promoted by T_H2 cells and involves the production of antibodies and other proteins secreted into the blood and lymph. (The Latin root *humor* means fluid.)

To understand how the adaptive immune system actually eliminates pathogens, let's examine how these two responses deal with invaders that remain extracellular versus those that reside within cells.

How Are Extracellular Pathogens Eliminated?

During the innate immune response to an infection, macrophages and dendritic cells at the site phagocytize some of the invaders. In addition to killing the foreign cells, these leukocytes process and present antigens via the MHC class II proteins. Macrophages display the processed epitopes on their surfaces at the site of infection, while dendritic cells move to the lymph nodes to present epitopes of the antigens. If the epitopes are recognized by helper T cells, the now activated T cells move into the site of infection.

If an activated T_H1 cell binds to the class II MHC proteins presented by these antigen-laden macrophages, two things happen. First, the phagocytic activity of the macrophages is enhanced. Second, the T_H1 cells secrete cytokines that recruit additional phagocytic cells to the site—increasing the inflammatory response.

In addition, antibodies from plasma cells begin attaching to extracellular bacteria, fungi, viruses, and other foreign material. These bound antibodies interfere with the infection in four ways (**FIGURE 51.15**):

1. ***Opsonization ("preparation for eating")*** Antibodies from plasma cells begin coating pathogens at the infection site. Pathogens that are tagged with antibodies are readily destroyed by phagocytes.
2. ***Neutralization*** Coated pathogens are blocked from interacting with—and thus infecting—host cells. Their participation in the infection is neutralized.
3. ***Agglutination ("gluing together")*** In many cases, antibodies cause the clumping of antigens, including cells and viruses, via a process called **agglutination.** Each antibody has at least two binding sites (pentameric IgM antibodies have 10), so a single antibody can bind epitopes on foreign cells and cross-link them. Clumped cells and viruses are not able to infect the cells of the body and are easy targets for phagocytes.
4. ***Co-stimulation of complement proteins*** Antibodies that are bound to pathogens also stimulate a lethal group of proteins called the **complement system.** Complement proteins circulate in the bloodstream and assemble at antigen–antibody complexes. When complement proteins activate, they punch deadly holes in the plasma membranes of pathogens.

Within a few days, this combination of killing mechanisms—armies of phagocytic cells and complement proteins that home in on antibody-tagged material—usually eliminates all of the extracellular pathogens. But what about those pathogens that reside within the cells of the body?

How Are Intracellular Pathogens Eliminated?

Virtually all nucleated cells in the body express class I MHC proteins on their cell surface. Recall that these MHC proteins display peptides that were processed from cytosolic proteins. This means that if a cell were infected, peptides from the foreign proteins expressed inside the cell would be loaded into some of the MHC proteins and presented to circulating T cells.

Cells that display the antigens of intracellular pathogens are effectively waving a flag that says, "I'm infected. If you destroy me, you'll destroy the infection." As activated $CD8^+$ cells migrate into the area, those that recognize the class I MHC–peptide complex are stimulated to respond to the signal.

After cytotoxic T cells have recognized their target, they form a tight attachment with the cell to direct the secretion of molecules from the T cell to the target cell's surface without disturbing adjacent cells. Some of these secreted products assemble into pores in the target cell's plasma membrane that allow other molecules from the T cell to pass through. As shown in **FIGURE 51.16**,

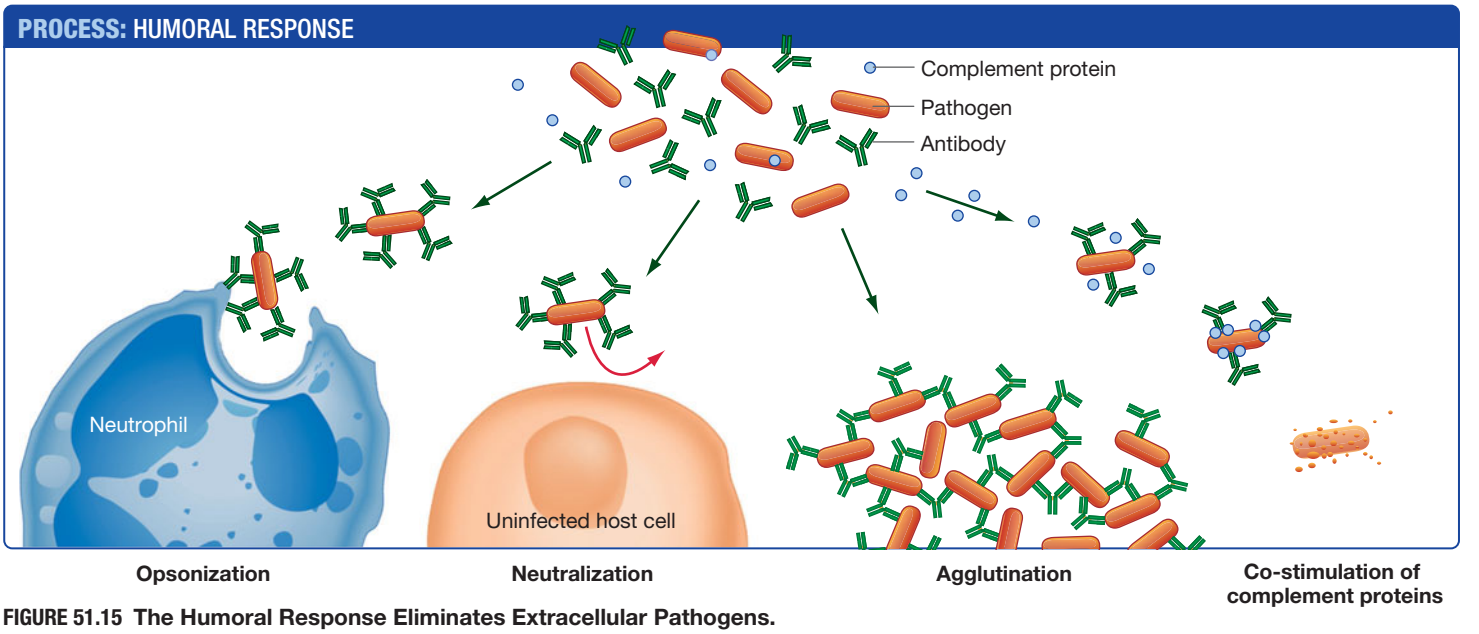

FIGURE 51.15 The Humoral Response Eliminates Extracellular Pathogens.

these molecules pass directly into the cytoplasm of the target cell and activate a signaling cascade that causes the cell to self-destruct via **apoptosis** (see Chapter 22). The result of apoptosis is the death and fragmentation of a cell into smaller vesicles, called apoptotic bodies, which are ingested by phagocytes like macrophages.

Once the cytotoxic T cell has delivered this signal, often referred to as the "kiss of death," the T cell releases the dying cell and seeks out another infected cell to kill. Over time, all of the infected cells are eliminated.

If the pathogen is able to replicate only inside host cells, as is the case with viruses, this cell-mediated response limits the spread of the infection by preventing the production of new generations of pathogens.

Why Does the Immune System Reject Foreign Tissues and Organs?

The innate and adaptive immune responses have devastating effects on invading pathogens. Unfortunately, they are equally deadly in response to tissues or organs that are introduced into a patient to heal a wound or cure a disease.

Consider the problems that can arise with blood transfusions. You might recall that certain individuals have red blood cells with membrane glycoproteins called A and B (see Chapter 14). These molecules act as antigens if they are introduced into a person whose own blood cells lack those glycoproteins.

For example, if you have type A blood, it means that your blood cells have the A glycoprotein. If your blood is transfused into a person who lacks the A glycoprotein—meaning someone who has type B or type O blood—the recipient's immune system will recognize the A glycoprotein as an antigen and mount a devastating response against it. For a blood transfusion to be successful, the recipient may have to receive blood that lacks the A and B glycoproteins entirely (type O) or that contains the same "antigens" found in his or her own blood.

Similar problems arise in organ transplants, except that the molecules directing the rejection of these tissues are the class I MHC proteins. The adaptive system mounts a response against the foreign MHC proteins, and the innate response is activated based on the *absence* of "self MHC" signals. If transplanted cells do not display the same class I MHC proteins as the host, components of the innate immune system kill them.

To prevent strong immune reactions against transplanted organs or tissues, physicians seek donors who have MHC proteins that are extremely similar to those of the recipient, as is often seen in siblings. Even with close relatives, however, molecular differences will exist between the donor and recipient. Thus, physicians must also treat the recipient with drugs that suppress the immune response.

Thanks to steady improvements in drug development and in systems for matching MHC types between donors and recipients, the success rate for organ transplants has improved dramatically in recent years.

As the blood transfusion and organ transplant examples show, the immune system rejects foreign cells because they either contain nonself molecules or lack molecules that serve as indicators of self. To your immune system, a mismatched blood transfusion or an organ transplant is indistinguishable from a massive influx of bacteria, viruses, or other foreign invaders.

Responding to Future Infections: Immunological Memory

In addition to producing the cells that implement the humoral and cell-mediated responses, activated B cells and T cells produce specialized daughter cells called memory cells. **Memory cells** do not participate in the initial adaptive response, or **primary immune response.** Instead, they provide a surveillance

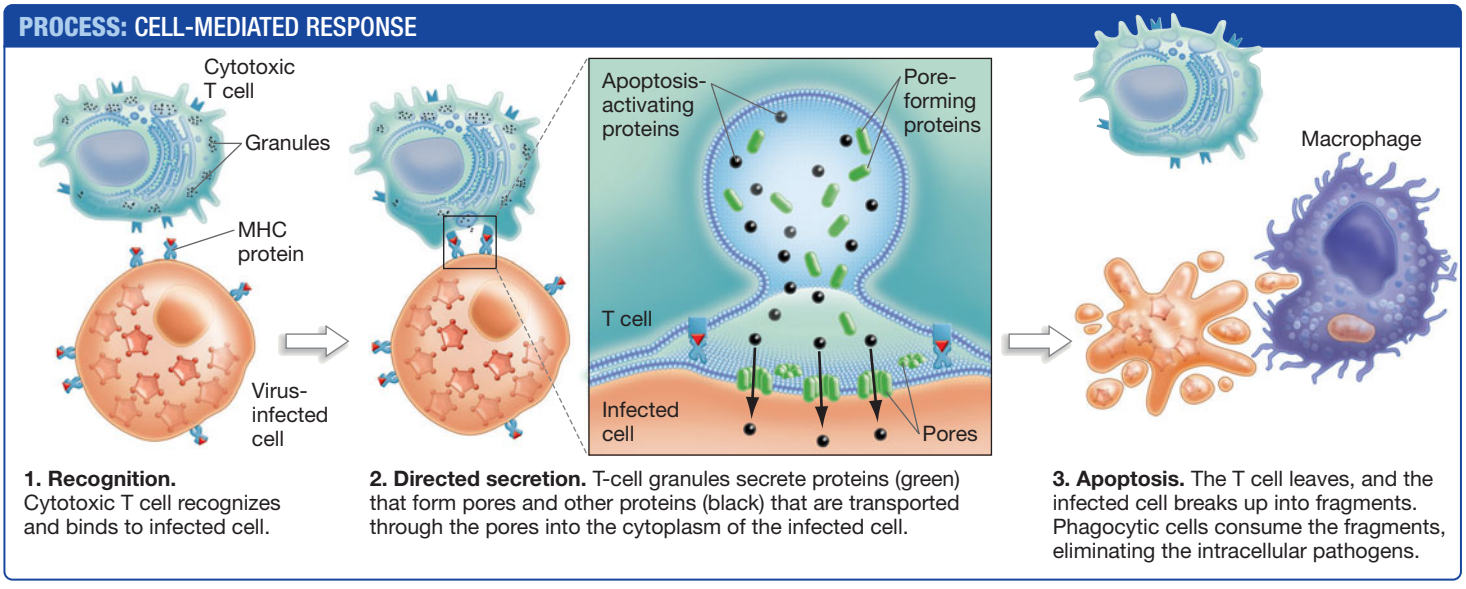

FIGURE 51.16 The Cell-Mediated Response Eliminates Intracellular Pathogens.

service after the original infection has been cleared. Memory cells remain in the spleen and lymph nodes for years or decades, ready to provide a rapid response should an infection with the same antigen recur.

The production of memory cells is a hallmark of the vertebrate immune response. It occurs only to a limited degree, if at all, in invertebrates. How do memory cells protect an individual from future infections?

The Secondary Response Is Strong and Fast If the same antigen enters the body a second time, memory cells recognize certain epitopes of the antigen and trigger a second adaptive response, or **secondary immune response.** **FIGURE 51.17** compares the rate of antibody production during the first and second exposures to a virus. The launching of a secondary immune response by means of memory cells is known as **immunological memory.**

The secondary immune response is faster and more efficient than the primary response. It is faster because the presence of an expanded pool of memory T and B cells increases the likelihood that lymphocytes with the correct antigen-specific receptors will find the antigen and activate quickly. It is more efficient because some of the memory B cells pass through another round of somatic hypermutation, the same process that occurred at the start of the primary immune response (see Section 51.3). Memory B cells with receptors that bind best to the antigen's epitope live and produce daughter cells.

To review immunological memory, starting with how B cells and T cells are activated, expanded, and differentiated into the various effector cells, study **TABLE 51.4**.

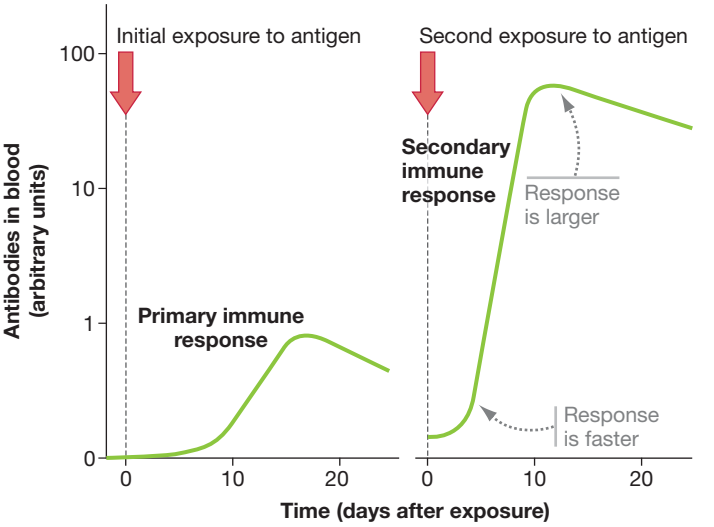

FIGURE 51.17 The Secondary Immune Response Is Faster and Stronger than the Primary Response. The graphs represent results that are commonly observed when biologists inject the same antigen into a mouse at two different times and measure the concentration of antibody in the blood (plotted on logarithmic scale). The change in antibody concentration over time indicates the speed and strength of the response to the antigen.

✔**EXERCISE** Imagine you injected a new antigen at the same time you began the second exposure to the original antigen. Draw a line on the graph to show what you predict would be the response to this new antigen in terms of antibody concentration.

Vaccination Leads to Immunological Memory The production and effectiveness of memory cells explain phenomena that have been observed throughout recorded history. For example, when plague struck Athens in 430 B.C., the historian Thucydides noted that only people who had recovered from the illness could nurse the sick, because they did not become ill a second time. In the middle ages, Chinese and Turkish practitioners protected people from smallpox by intentionally exposing them to the dried crusts of smallpox pustules taken from infected individuals. These are examples of **immunization**—the conferring of immunity to a particular disease.

In the late 1700s Edward Jenner refined this immunization technique. In Jenner's day, milkmaids were considered pretty because their faces were not pockmarked with scars from smallpox infections. Jenner knew that cows suffered from a smallpox-like

SUMMARY TABLE 51.4 Activation and Function of Adaptive Immune System Cells

Type of Lymphocyte	Method of Activation	Cells That Result from Activation and Clonal Expansion	Function of Resulting Cells
B cell	Receptor binds to free antigen, then class II MHC–peptide complex interacts with TCR of T_H2 cell	Plasma cells	Secrete antibodies
		Memory B cells	Participate in secondary response (secrete antibodies)
$CD4^+$ T cell	Receptor binds to class II MHC–peptide complex on dendritic cell or other antigen-presenting cell	T_H1 helper T cells	Activate cytotoxic T cells; regulate inflammatory response
		T_H2 helper T cells	Activate B cells
		Memory T cells	Participate in secondary response
$CD8^+$ T cell	Receptor binds to class I MHC–peptide complex on dendritic cell or other antigen-presenting cell; T cell is then stimulated by cytokines of T_H1 cells	Cytotoxic T cells	Kill infected host cells that present complementary class I MHC–peptide complex
		Memory T cells	Participate in secondary response

disease called cowpox. He reasoned that milkmaids became immune to smallpox because they had been exposed to cowpox while milking cows.

To test this hypothesis, Jenner inoculated a boy with fluid from a cowpox pustule. Later he inoculated the same child with fluid from a smallpox pustule. That is, he first inoculated the boy with cowpox pathogens and then with smallpox pathogens.

As predicted, the boy did not contract smallpox. Jenner's technique was named **vaccination.** (The Latin root *vacca* means cow.) Vaccination is the introduction of a **vaccine,** a preparation containing antigens from a weakened or altered pathogen, to prime the body's immune system so it fights later infections effectively.

The data in Figure 51.17 explain why vaccination is an effective defense against certain pathogens—it speeds up the body's response to an infection. The antigens used in a vaccine are usually components of a pathogen's exterior, because antibodies can readily attach to them.

Consider the three general types of vaccines against viruses:

1. *Subunit vaccines* consist of isolated viral proteins: familiar examples include vaccines against hepatitis B and influenza.
2. *Inactivated viruses* have been damaged by chemical treatments—often exposure to formaldehyde—or exposure to ultraviolet light. They do not cause infections, but are antigenic. If you have been vaccinated for hepatitis A or polio, you may have received an inactivated virus.
3. *Attenuated viruses* are also called "live" virus vaccines because they consist of complete virus particles. Researchers make these viruses harmless by culturing them on cells from species other than the normal host. In adapting to growth on the atypical cells, the viruses usually lose the ability to grow rapidly in their normal host cells. The smallpox and measles vaccines consist of attenuated viruses.

After vaccination, the body mounts a primary immune response that produces memory cells. If a second infection occurs later, these memory cells respond quickly and eliminate the threat before illness appears. Vaccinations function like fire drills or earthquake preparedness exercises—they prepare the immune system for a specific threat.

Unfortunately, viruses such as the human immunodeficiency virus (HIV) mutate so rapidly that traditional vaccines have been ineffective for immunization. Memory cells generated from HIV vaccination are unlikely to recognize the changed epitopes in the rapidly evolving strains. Currently, the only "cure" for HIV infection is prevention.

check your understanding

CYU

If you understand that . . .

- Extracellular pathogens are eliminated by the humoral response, which includes antibodies, complement proteins, and other secreted products that opsonize, neutralize, agglutinate, or directly lyse the invaders.
- Intracellular pathogens are eliminated by activated cytotoxic T cells that recognize epitopes displayed on infected cells and kill them before the pathogens inside can replicate.
- Immunological memory provides a rapid, efficient secondary response against future infections with the same pathogen.

✓ You should be able to . . .

Compare and contrast inactivated and attenuated vaccines, and predict which would result in a more effective cell-mediated immune response.

Answers are available in Appendix A.

51.5 What Happens When the Immune System *Doesn't* Work Correctly?

The vertebrate immune system is a marvel of adaptation. A healthy immune system is able to defeat the vast majority of infections without medical intervention and with little impact on the body. The immune system is a formidable threat to pathogens, but if its response is dysfunctional, it can also be a liability to the health and even survival of the animal.

To appreciate this point, let's first examine what happens when the immune system activates inappropriate responses and then look at the consequences when it fails to respond.

Allergies

For some people, walking through a field of ragweed or petting a cat is a prescription for developing a runny nose, itchy eyes, and labored breathing. For other people, being stung by a bee or eating a peanut is a life-threatening experience. These are examples of allergies—immune responses that are overreacting to foreign substances.

An **allergy,** or allergic reaction, is an abnormal response to an antigen. For reasons that are still not clear, certain people produce the IgE class of antibodies in response to specific molecules found in cat dander, nuts, plant pollen, or other products. Molecules that trigger this response are called **allergens** instead of antigens.

Allergic reactions are considered inappropriate responses because the normal role of IgE antibodies is to defend against infections by parasitic worms. Recent research has also shown that in areas where infections with intestinal worms are common, allergies are almost unknown. These data suggest that allergies don't occur if IgEs are expressed normally—that is, in response to worm infections.

The presence of IgE antibodies in an allergic response is important because it triggers a series of events known as the **hypersensitive reaction.** When a susceptible person is first exposed to an allergen, the IgE antibodies that are produced bind to receptors on mast cells and certain other leukocytes. This binding

occurs at the constant region of the IgE heavy chains—the "tail" of the antibody. Once this binding event occurs, the cells (and the person) are said to be sensitized.

If the person is later exposed to the same allergen, the variable regions of these IgE antibodies bind to the allergen molecules and send a signal to the sensitized cells to rapidly secrete large quantities of histamine, cytokines, and other compounds. In response to these molecules, blood vessels dilate and become more permeable, smooth-muscle cells contract, and other cells secrete mucus. Common manifestations of these hypersensitive reactions are hay fever, hives, and asthma.

In more severe responses, blood vessels can dilate to the point where blood pressure plummets, oxygen delivery to the brain is reduced dramatically, and the person loses consciousness. In addition, severe smooth-muscle contractions in the digestive system and respiratory system can induce vomiting, diarrhea, and complete constriction of the airway passages. This combination of events, known as anaphylactic shock, is lethal unless the person receives immediate medical attention.

What can be done about allergies? The number one approach is to avoid the allergen. If exposure does occur, drugs called antihistamines can sometimes reduce symptoms by blocking histamine receptors. In some cases, corticosteroids applied to the skin can reduce swelling. Longer-term solutions are still in the experimental stage, however. Developing effective treatments for allergies is an important research frontier in biomedicine.

Although allergic reactions are considered abnormal, they are still directed against substances that are foreign to the body. What happens when the immune system turns against the body's own tissues?

Autoimmune Diseases

An immune response directed against molecules or cells that normally exist in the host is known as **autoimmunity.** Autoimmune reactions often result in disease due to the destruction of the body's own cells and structures.

- Multiple sclerosis (MS) results from the production of cytotoxic T cells that attack the myelin sheath of nerve fibers (see Chapter 46). Because damage to myelin reduces the efficiency of nerve signaling, coordination problems result.
- Rheumatoid arthritis develops when self-reactive antibodies alter the lining of joints, causing painful inflammation.
- Type 1 diabetes mellitus occurs when cytotoxic T cells attack and kill insulin-secreting cells in the pancreas, resulting in a lack of insulin and inability to regulate blood glucose levels (see Chapter 44).

The cause and treatment of immune-mediated diseases are active areas of research. The mechanisms behind these diseases are still poorly understood, but an interesting connection is emerging. Beginning in the late 1960s, several studies have shown that the risk of developing allergies and autoimmune diseases increases in individuals who live in homes with a high level of sanitation.

Results from these studies have led to the development of the **hygiene hypothesis,** which claims that autoimmune and allergic responses arise in individuals who, because of hygienic practices, have experienced less exposure to pathogens and parasites. Recall that allergies are virtually absent in areas where intestinal worms are common. This effect is also seen for autoimmune diseases, which do not involve the IgE-based hypersensitivity reaction.

This correlation between hygiene and immune disorders points to the close ties that have been forged during the coevolution of the immune system and the invaders it defends us against. Low infant mortality and other benefits of sanitary lifestyles appear to come at the cost of inappropriate immune responses.

But, what happens when the immune system fails to respond at all?

Immunodeficiency Diseases

Children who are born with a genetic disorder called severe combined immunodeficiency (SCID) lack a normal immune system and are unable to fight off infections. The results are devastating. Without a functional immune system, the number of potential infectious agents grows to include "opportunistic" pathogens that would normally be incapable of causing disease.

You may recall that one form of SCID, designated SCID-X1, is caused by mutations in a gene on the X chromosome (see Chapter 20). The gene codes for a receptor protein necessary for the development of T cells. In another type of SCID, called Omenn syndrome, there is a genetic defect in one of the enzymes responsible for DNA recombination in maturing lymphocytes. As a result, cells are unable to generate normal T-cell and B-cell receptors.

In both cases, the adaptive immune response is badly impaired. Afflicted individuals suffer debilitating illness from infections that other children fight off easily. If not given a bone-marrow transplant or kept in a completely sterile environment, children with SCID typically will die before they are 2 years old.

Similarly, people who are infected with the **human immunodeficiency virus (HIV)** suffer from a progressive failure of the immune system. HIV infects and kills $CD4^+$ T cells and macrophages (see Chapter 36). Recall that these cells are required for both the humoral and cell-mediated immune responses. As the infection continues, populations of $CD4^+$ T cells gradually decline to a point where the immune system can no longer mount an effective response to infection.

Eventually, HIV-infected people develop **acquired immune deficiency syndrome (AIDS).** They succumb to illnesses that physicians almost never see in people with healthy immune systems.

Over the past three decades, the incidence of HIV infections has skyrocketed throughout the world, devastating the immune systems of millions of people. This, coupled with the marked increase in allergies and autoimmune diseases in the developed world, illustrates the importance of continued research into the many nuances of the immune system.

If you understand . . .

51.1 Innate Immunity

- Animals protect themselves from infection by establishing barriers that prevent the entry of pathogens.
- The innate immune system provides a rapid, generic response against broad classes of pathogens based on the recognition of pathogen-associated molecules by pattern-recognition receptors.
- During the innate immune system's inflammatory response, leukocytes respond to an infection by phagocytizing foreign material and cells and releasing cytokines that stimulate neighboring cells to respond to the infection and recruit more leukocytes into the area.

✔ **You should be able to explain the role of Toll-like receptors in the innate immune response.**

51.2 Adaptive Immunity: Recognition

- The vertebrate immune system possesses T cells and B cells that recognize specific epitopes on antigens via unique receptors found on the T- and B-cell surfaces.
- The receptor proteins expressed on the surfaces of T cells and B cells are generated through DNA recombination—a rearrangement of gene segments.
- Because every receptor that results from DNA recombination is slightly different, the immune system is able to recognize and respond to an almost limitless array of antigens.

✔ **You should be able to predict how the BCR locus in the genomic DNA of immature B cells is different from that in mature B cells.**

51.3 Adaptive Immunity: Activation

- The clonal selection theory explains how the most appropriate cells for controlling an infection are selected and expanded to mount an effective immune response.
- T cells are activated when their receptors recognize epitopes displayed in MHC proteins on antigen-presenting cells. Full activation and differentiation of T cells often requires secondary signals from cytokines.
- B cells are activated when their receptors bind to free antigens. B cells differentiate into plasma cells and memory cells only when fully activated by helper T cells.

✔ **You should be able to explain how antigen-presenting cells of the innate immune response are required for the differentiation of B cells into plasma cells.**

51.4 Adaptive Immunity: Response and Memory

- Extracellular pathogens are eliminated via phagocytosis and soluble components secreted by the humoral response, which include antibodies. Antibodies contribute to the response by opsonizing, neutralizing, or agglutinating pathogens, or by co-stimulating the lytic activity of the complement proteins.
- Intracellular pathogens are eliminated via the cell-mediated response, in which infected host cells are induced to self-destruct by cytotoxic T cells.
- The immune system rejects blood and tissue transplants based on the presence of nonself molecules, often in the form of carbohydrates or MHC proteins, or on a lack of self recognition.
- The production of memory lymphocytes, via a primary infection or vaccination, allows the immune system to respond rapidly and effectively to future infections by the same pathogen.

✔ **You should be able to explain how viruses are eliminated by both humoral and cell-mediated immune responses.**

51.5 What Happens When the Immune System *Doesn't* Work Correctly?

- Allergies are abnormal, hypersensitive responses that are generated against allergens, which are antigens that are not associated with infection.
- Autoimmune diseases occur when self-reactive lymphocytes elicit an immune response against the body's own tissues.
- Immunodeficiency diseases arise from genetic mutations or viral infections that disrupt the function of key components in the immune system.

✔ **You should be able to predict the consequences of producing IgE against a self molecule.**

TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. What is the primary difference between the innate and adaptive responses?
   - **a.** The innate response does not distinguish between pathogens, while the adaptive response does.
   - **b.** Only the innate response is triggered by antigens.
   - **c.** The adaptive response generates immunological memory and is more specific than the innate response.
   - **d.** The innate response does not kill cells; the adaptive response does.
2. The overall role of the inflammatory response is to
   - **a.** contain and eliminate foreign cells and material at the site of infection.
   - **b.** increase heat at the site of infection to activate enzymes used in the immune response.
   - **c.** produce antibodies that bind to invading cells and eliminate them.
   - **d.** increase blood flow at the site of the wound to flush out invading pathogen.
3. What is the difference between an epitope and an antigen?
   - **a.** An epitope is any foreign substance; an antigen is a foreign protein.
   - **b.** An epitope is the part of an antigen where an antibody or lymphocyte receptor binds.
   - **c.** An antigen is the part of an epitope where an antibody or lymphocyte receptor binds.
   - **d.** Antigens are recognized by B cells and antibodies; epitopes are recognized by T cells.
4. How do B-cell receptors and antibodies differ?
5. What is one of the differences between $CD4^+$ and $CD8^+$ T cells?
   - **a.** $CD4^+$ cells are immature and $CD8^+$ cells are mature.
   - **b.** $CD4^+$ cells are activated and $CD8^+$ cells are not.
   - **c.** $CD4^+$ cells interact with class II MHC proteins, and $CD8^+$ cells interact with class I MHC proteins.
   - **d.** $CD4^+$ cells activate cell-mediated responses, and $CD8^+$ cells activate humoral responses.
6. What is the hygiene hypothesis?

TEST YOUR UNDERSTANDING

7. Explain how B cells are fully activated to differentiate into plasma cells.
8. Compare and contrast how B-cell receptors and T-cell receptors recognize antigens.
9. What do vaccines need to contain in order to be effective? Why don't we have vaccines for HIV?
10. Why is clonal selection necessary for the adaptive immune response but not the innate immune response?
    - **a.** The adaptive response uses receptors to recognize pathogens, and the innate response does not.
    - **b.** There is more diversity in the receptors in the adaptive response compared to the innate response.
    - **c.** Cells in the innate response do not require activation, and those in the adaptive response do.
    - **d.** This process is used for targeting pathogens, and the innate response is used only to stop blood flow from the wound.
11. Compare and contrast the interaction between pathogens and the pattern-recognition receptors on leukocytes versus that between antigens and BCRs or TCRs.
12. Explain how DNA recombination leads to the production of almost limitless numbers of different B-cell receptors, T-cell receptors, and antibodies.

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A

13. Which of the following outcomes would be expected if there were a mutation that inhibited somatic hypermutation?
    - **a.** The diversity of pattern-recognition receptors would be significantly lowered.
    - **b.** B and T lymphocytes would not be able to produce receptors that recognize antigens.
    - **c.** The adaptive immune system would not be able to respond to pathogens.
    - **d.** The secondary immune response to a repeat infection would produce the same antibodies as those made in the primary immune response.
14. Predict how self-reactive B cells are identified and eliminated during maturation.
15. It seems astonishing that the immune system can produce antibodies to compounds that were recently synthesized for the first time in the lab. Given that viruses and other pathogens evolve rapidly, why would natural selection favor individuals having genes that made extensive antibody diversity possible?
16. During World War II, physicians discovered that if they removed undamaged skin from a patient and grafted it onto the site of a burn on the same patient, the tissue healed well. But if the grafted tissue came from a different individual, the skin graft was rejected. What is responsible for this difference?

52 An Introduction to Ecology

This heavily oiled bird is being rescued from the Gulf of Mexico following the Deepwater Horizon oil spill in 2010. Increasingly, ecology is the study of how humans are altering the environment in ways that make life difficult for other organisms.

Ecology is the study of how organisms interact with each other and their environment. Except for the episode 65 million years ago, when a mountain-sized asteroid struck Earth, environments are changing more rapidly right now than they have at any time in the past 3.6 billion years. Humans are causing widespread habitat loss and degradation, pollution, introduction of exotic organisms, and climate change—transforming the Earth in unprecedented ways. Efforts to maintain diversity of life, functioning ecological processes, and human health and welfare depend on our ability to cope with these environmental changes. Ecology has become one of the most important and dynamic fields in biological science.

Ecology is also among the most synthetic and integrative fields in biological science. In this unit, you'll be applying what you've learned about biochemistry, genetics, development, physiology,

BIG PICTURE

This chapter is part of the Big Picture. See how on pages 1196–1197.

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

evolution, and the diversity of life. Ecologists work in subdisciplines ranging from ecological developmental biology to physiological ecology and conservation genetics.

Of these subdisciplines, the intersection of ecology and evolution has been appreciated the longest. The diversity of life (Unit 6) is the result of the evolutionary processes (Unit 5) as they played out in a changing ecological context over 3.6 billion years. Evolution and ecology are intertwined and codependent. It was no coincidence that the German biologist Ernst Haeckel first defined "oekologie" less than a decade after Charles Darwin published *On the Origin of Species by Means of Natural Selection* in 1859 (see Chapter 25).

Ecology's primary goal is to understand the distribution and abundance of organisms. How do interactions with other organisms and the physical environment dictate why certain species live where they do, and how many individuals live there? Some biologists ask why orangutans are restricted to forests in Borneo and Northern Sumatra and why their numbers are declining so rapidly. Other biologists create mathematical models to predict how quickly the human immunodeficiency virus will increase in India, or how long it will take for the current human population of 7 billion to double.

Distribution and abundance are core questions in today's world. Land-use changes and climate change are having dramatic effects on species' distributions, and expanding human populations are causing the abundance of many species to decline, sometimes to zero. Let's delve in.

52.1 Levels of Ecological Study

To understand why organisms live where they do and in what numbers, biologists consider ecology at several levels of analysis. This is a common strategy in biological science. Cell biologists study how cells work, at different levels of organization—from individual molecules to cellular structures, cells, and multicellular organisms. Physiologists analyze processes at the level of ions and molecules as well as whole cells, tissues and organs, and complete systems. You can review the levels of organization in The Big Picture of Doing Biology (pages 16–17).

In ecology, researchers work at five main levels: **(1)** organisms, **(2)** populations, **(3)** communities, **(4)** ecosystems, and **(5)** the biosphere. The levels aren't rigid or exclusive; researchers routinely draw on multiple levels—including lower levels—to explore a particular question. Let's consider how these levels apply to sockeye salmon, summarized in **TABLE 52.1**.

Organismal Ecology

At the organismal level, researchers explore the morphological, physiological, and behavioral adaptations that allow individuals to live in a particular area (see Chapter 53). For example, after spending four or five years feeding and growing in the ocean, sockeye salmon travel hundreds or thousands of kilometers to return to the stream where they hatched. Females create nests in

SUMMARY TABLE 52.1 Five Main Levels of Ecological Study

Level	Sockeye Salmon Example
Organismal ecology How do individuals interact with each other and their physical environment?	 Salmon migrate from saltwater to freshwater environments to breed
Population ecology How and why does population size change over space and time?	 Each female salmon produces thousands of eggs. On average, only a few offspring will survive to return to the same stream to breed
Community ecology How do species interact, and what are the consequences?	 Salmon are prey as well as predators
Ecosystem ecology How do energy and nutrients cycle through the local environment?	 Salmon die and then decompose, releasing nutrients that are used by other organisms
Global ecology How is the biosphere affected by global changes in nutrient cycling and climate?	 Worldwide populations of salmon are affected by climate change

the gravel stream bottom and lay eggs. Nearby males compete for the chance to fertilize eggs as they are laid. When breeding is finished, all the adults die.

Biologists want to know how these individuals interact with their physical surroundings and with other organisms in and around the stream. How do individuals cope with the transition from living in salt water to living in freshwater? Which females get the best nesting sites and lay the most eggs, and which males are most successful in fertilizing eggs?

Population Ecology

A **population** is a group of individuals of the same species that lives in the same area at the same time. When biologists study population ecology, they focus on how the number and distribution of individuals in a population change over time (see Chapter 54).

For example, researchers use mathematical models to predict the future of salmon populations. Many of these populations have declined due to overharvesting and the loss of habitat quality caused by pollution and dam construction. If the factors that affect population size can be described accurately enough, mathematical models can assess the impact of proposed dams, changes in weather patterns, altered harvest levels, or specific types of protection efforts.

Community Ecology

A biological **community** consists of populations of different species that interact with each other within a particular area. Community ecologists ask questions about the nature of the interactions between species and the consequences of those interactions (see Chapter 55). Research might concentrate on predation, parasitism, and competition or explore how communities respond to fires, floods, and other disturbances.

As an example, consider the interactions among salmon and other species in the marine and stream communities where they live. When they are at sea, salmon eat smaller fish and are themselves hunted and eaten by orcas, sea lions, humans, and other mammals; when they return to freshwater to breed, they are preyed on by bears and bald eagles. In both marine and freshwater habitats, salmon are subject to parasitism and disease. They are also heavily affected by disturbances—particularly changes in their food supply and the quality of their breeding streams.

Ecosystem Ecology

Ecosystem ecology is an extension of organismal, population, and community ecology. An **ecosystem** consists of all the organisms in a particular region along with nonliving components. These physical and chemical, or **abiotic** (literally, "not-living"), components include air, water, and the nonliving parts of soil. At the ecosystem level, biologists study how nutrients and energy move among organisms and through the surrounding atmosphere and soil or water (see Chapter 56).

Salmon are interesting to study at the ecosystem level because they link marine and freshwater ecosystems. They harvest nutrients in the ocean and then, when they migrate, die, and decompose, they transport those molecules to streams and streamside forests. In this way, salmon transport chemical energy and nutrients from one habitat to another.

Global Ecology

Biologists define the **biosphere** as a thin zone surrounding the Earth where all life exists—the sum of all terrestrial and aquatic ecosystems. It extends to about 5 km below the land surface and 10 km down in the deepest trenches of the sea to over 10 km up into the atmosphere. This may sound like a thick layer, but it represents only 0.002 percent of the diameter of the Earth—and most of life occupies a much thinner layer, comparable to the layer of varnish on a typical classroom globe.

The young field of global ecology is growing rapidly as ecologists scramble to quantify the effects of human impacts on the biosphere. Humans are modifying landscapes and releasing massive amounts of energy and nutrients to the biosphere, causing changes that transcend individual ecosystems.

Since the biosphere is practically a closed system, the actions of people in one part of the world may alter distant ecosystems, creating difficult education and public policy challenges. For example, salmon are sensitive to changes in water temperature. Who is accountable for the impacts of climate change on salmon?

Conservation Biology Applies All Levels of Ecological Study

The five levels of ecological study are synthesized and applied in conservation biology. **Conservation biology** is the effort to study, preserve, and restore threatened genetic diversity in populations, species diversity in communities, and ecosystem function (see Chapter 57).

Conservation biologists are like physicians. But instead of prescribing treatments for sick people, they prescribe remedies for threatened environments to preserve biodiversity, clean air, pure water, and productive soils.

Each chapter in this unit focuses on a different level of ecological study, ending with the study of biodiversity and conservation. Turn to the Big Picture of Ecology (pages 1196–1197) to visualize how the different levels of ecology interact. In this introductory chapter, let's take a global look at factors that determine the distribution and abundance of organisms. In particular, what abiotic factors set the stage for life on Earth?

52.2 What Determines the Distribution and Abundance of Organisms?

When you look around at the plants and animals in your neighborhood, you can tell right away that you are not located deep in the Amazon rain forest—no scarlet macaws, jaguars, anacondas, blue morpho butterflies, or giant kapok trees out there. Different organisms live in different places. Why?

Understanding why organisms are found where they are is one of ecology's most basic tasks. The study of how organisms are distributed geographically is called **biogeography.** Let's consider how both abiotic and biotic factors determine the distribution and abundance of organisms.

Abiotic Factors

The most fundamental observation about the **range,** or geographic distribution, of organisms is simple: No one species can survive the full array of environmental conditions present on Earth.

Temperature is particularly important in determining ranges because temperature has a big impact on the physiology of organisms, and organisms are limited in their ability to regulate their own temperatures (see Chapter 42). *Thermus aquaticus* can thrive in hot springs with temperatures above 70°C because its enzymes do not denature at near-boiling temperatures. But the same cells would die instantly if they were transplanted to the frigid waters near polar ice—even though vast numbers of other microbes are present. The cold-water species have enzymes that work efficiently at near-freezing temperatures.

No organism thrives in both hot springs and cold ocean water. The reason is fitness trade-offs (introduced in Chapter 25). No enzyme can function well in both extremely high temperatures and extremely low temperatures. Because of fitness trade-offs, organisms tend to be adapted to a limited set of physical conditions, or abiotic factors—for example, to a particular temperature and moisture regime on land, or a particular salinity, water depth, and movement regime in water. Every organism has a specific range of tolerance of abiotic conditions.

Adaptation to a limited set of abiotic conditions is just the start of the story explaining why a particular species lives where it does. For example, the temperature and moisture regimes of southern California, in North America, are almost identical to those found in the Mediterranean region of Europe and northern Africa. But the species present at the sites are almost completely different. Why?

Biotic Factors

The ability of a species to persist in a given area is often limited by **biotic** ("living") factors—meaning interactions with other organisms (see Chapters 54 and 55). As an example, consider the distributions of hermit warblers and Townsend's warblers along the Pacific Coast of North America (introduced in Chapter 27).

- Both hermit warblers and Townsend's warblers live in evergreen forests.
- Experiments have shown that male Townsend's warblers directly attack male hermit warblers and evict them from breeding territories.
- The geographic range of Townsend's warblers has been expanding steadily at the expense of hermit warblers.

These observations support the hypothesis that a biotic factor—competition with another species—is limiting the range of hermit warblers. Competition is not the only biotic factor to affect species range, however.

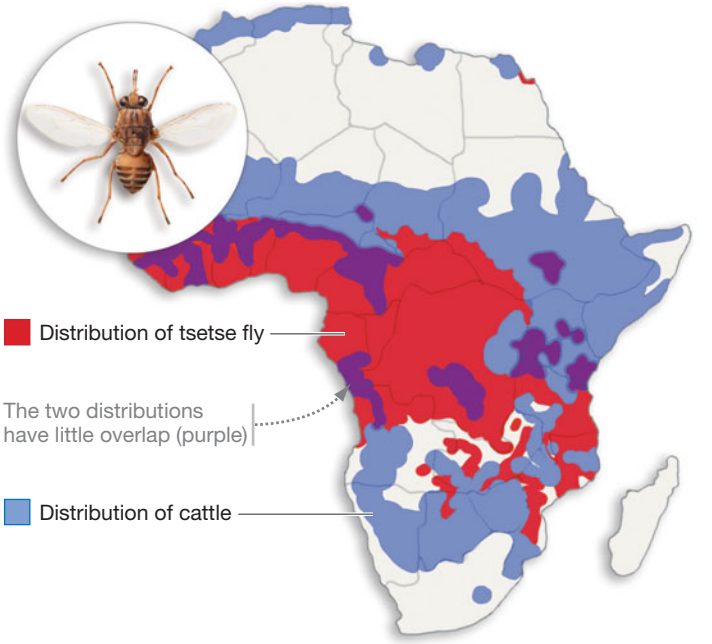

FIGURE 52.1 In Africa, Tsetse Flies Limit the Distribution of Cattle. Tsetse flies carry a disease that is fatal to cattle.

DATA: Food and Agriculture Organization of the United Nations

✔**QUESTION** What do you think would happen to the range of cattle in Africa if the tsetse fly were eradicated?

- Yucca moths lay their eggs only in the flowers of yucca plants. As a result, this species does not exist outside the range of yucca plants.
- In Africa, the range of domestic cattle is limited by the distribution of tsetse flies (**FIGURE 52.1**). Tsetse flies transmit a parasite that causes the disease trypanosomiasis, which is fatal in cattle (and can be fatal in humans unless treated).
- Most of the songbirds native to Hawaii are limited to alpine habitats—above the range of the mosquitoes that transmit avian malaria.

These examples hint at a key insight: The distribution of organisms is determined not only by conditions present today but also by events in the past. Let's take a closer look at the importance of history.

History Matters: Past Abiotic and Biotic Factors Influence Present Patterns

The abiotic and biotic factors that influence the distribution of organisms are dynamic—they are constantly changing, in part because the Earth itself is changing. The landforms and oceans that may appear static now have been in constant flux for the entire history of life—mountains rise and fall, islands and lakes form and disappear, and whole continents crash together and break apart (see Chapter 28). Associated fluctuations in climate cause glaciers and ice caps to form and melt and sea levels to rise and fall.

These events have an important impact on **dispersal,** the movement of individuals from their place of origin to the location where they live and breed as adults. For example, the formation 3 million years ago of the land bridge from North America to South America, today known as the Isthmus of Panama (see Figure 27.5), created opportunities for dispersal from each continent to the other, introducing new biotic interactions on both continents. Meanwhile, this same geological event separated the Pacific Ocean from the Caribbean Sea, creating barriers to dispersal for marine species.

Alfred Russel Wallace was among the first to document this phenomenon. In addition to codiscovering evolution by natural selection (see Chapter 25), Wallace founded the study of biogeography.

The Wallace Line: Barriers to Dispersal While working in the Malay Archipelago, Wallace realized that the plants and animals native to the more northern and western islands were radically different from the species found on the more southern and eastern islands. Sumatra, to the northwest, has tigers, rhinos, and other species with close relatives in southern Asia. New Guinea, to the southeast, has tree kangaroos and other species with close relatives on Australia. But both islands are tropical wet forests.

This biogeographical demarcation, now known as the **Wallace line,** separates species with Asian and Australian affinities (**FIGURE 52.2**). It exists because a deep trench in the ocean maintained a water barrier to dispersal, even when ocean levels dropped during the most recent glaciations. As a result, landforms on either side of the line remained isolated at a time when most of the other islands became connected.

The Influence of Humans The events Wallace studied occurred before the dispersal of modern humans around the globe from Africa, beginning at least 70,000 years ago (see Chapter 35). Humans have influenced the distribution of species for thousands of years by hunting, clearing forests, and physically moving organisms around. Humans have transported thousands of plants, birds, insects, and other species across physical barriers to new locations—sometimes purposefully and sometimes by accident.

If an **exotic species**—one that is not native—is introduced into a new area, spreads rapidly, and competes successfully with native species, it is said to be an **invasive species.** In North America alone, dozens of invasive species have had devastating effects on native plants and animals. Examples include kudzu (**FIGURE 52.3**, see page 1064), purple loosestrife, reed canary grass, garlic mustard, Russian thistle (also known as tumbleweed), European starlings, African honeybees, red imported fire ants, Argentine ants, and zebra mussels. Similar lists could be compiled for other regions of the world.

The microorganisms that humans introduce to new areas can also dramatically affect species distributions by causing disease. A microscopic fungus introduced to North America in the 1920s swept across the continent, wiping out most Dutch elm trees in its path in a matter of decades.

Humans continue to influence the distribution of species by affecting both biotic and abiotic factors.

FIGURE 52.2 The "Wallace Line" Divides Organisms with Asian versus Australian Affinities.

Biotic and Abiotic Factors Interact

In many cases, biotic and abiotic factors interact to determine the distribution and abundance of organisms. How can this interaction be measured?

Consider the case of the Argentine ant, *Linepithema humile*, native to South America and rapidly expanding around the world. These small ants form unusually large supercolonies because they mix freely with other Argentine ants while fighting aggressively against native ants. This invasion creates a huge pest-control problem in homes, businesses, and farms, and it also has grave ecological implications. For example, horned lizards are in decline in southern California due to the disappearance of the native ants that they are specialized to eat.

FIGURE 52.3 Introduced Species Can Cause Problems. Kudzu, imported from Asia, has taken over parts of the southeastern U.S.

Argentine ants are dispersed by humans to different continents in food shipments like coffee. But these ants don't thrive everywhere they land—they are most successful in Mediterranean-like ecosystems that have adequate moisture, winters that are not too cold, and summers that are not too hot.

Sean Menke, David Holway, and colleagues took a closer look at factors affecting dispersal of Argentine ants in southern California. They observed that soil moisture was very important in determining the species' range. They also observed that the invasive ants tend to wipe out native ants. But does competition with native ants *interact* with abiotic factors in some way, or do abiotic factors trump biotic factors in this invasive species' success?

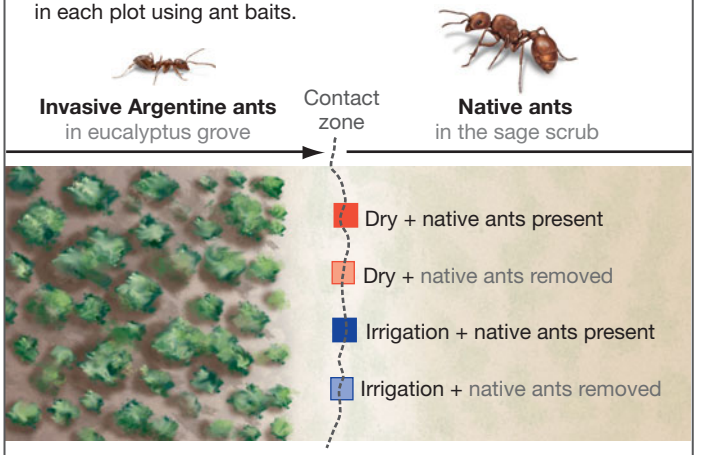
To find out, the researchers set up 28 study plots along a contact zone between Argentine ants and native ants at the local edge of the Argentine ant's range—an edge that had been stable for over 10 years. What was keeping the invasive ants from extending their range?

The study plots were randomly assigned to four groups varying in soil moisture and competition, as shown in the "Experimental Setup" section of **FIGURE 52.4**. By counting the number of Argentine ants found in ant baits in each plot at the start of the experiment and again after 12 weeks, the researchers could measure the relative importance of soil moisture and competition to the dispersal of the invasive ants.

As the graph in the "Results" section of Figure 52.4 shows, the Argentine ants did not spread into dry study plots (red bars), even when native ants were not present. They did, however, spread into irrigated plots (blue bars), even when native ants were present—but the native ants slowed them down.

The take-home message is that the interaction of biotic and abiotic factors slowed the spread of invasive ants more than the abiotic factors alone. Argentine ants are at a competitive advantage in moist soils, but at a disadvantage compared to native ants in dry soils. This information can help scientists to predict the dispersal pattern of Argentine ants and design strategies to limit the spread of these invaders.

RESEARCH



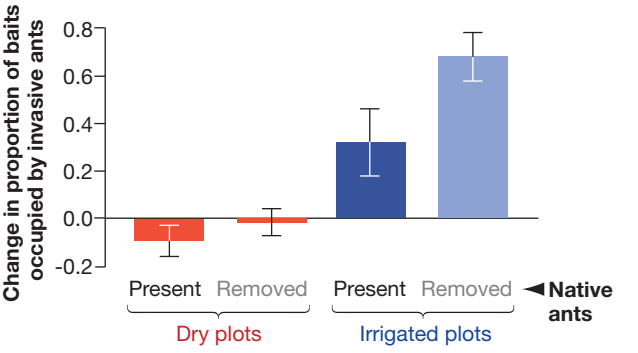
QUESTION: Do abiotic and biotic factors interact to determine the distribution of a species?

HYPOTHESIS: Abiotic and biotic factors interact to determine the distribution of invasive Argentine ants.

NULL HYPOTHESIS: Abiotic conditions alone determine the distribution of invasive Argentine ants.

EXPERIMENTAL SETUP:

1. Set up 28 plots (10 × 10 m) in the contact zone between Argentine ants and native ants. Measure invasive ant activity in each plot using ant baits.



2. Vary soil moisture and presence of native ants as shown above.

3. After 12 weeks, remeasure invasive ant activity in each plot.

PREDICTION: Invasive ants will displace native ants only in irrigated plots—more so in plots where native ants were removed.

PREDICTION OF NULL HYPOTHESIS: Invasive ants will displace native ants only in irrigated plots—with no difference in plots with native ants present and native ants removed.

RESULTS:

CONCLUSION: Abiotic factors (soil moisture) and biotic factors (competition with native ants) interact in determining the distribution of Argentine ants.

FIGURE 52.4 Experimental Test of the Relative Importance of Biotic and Abiotic Factors in Limiting the Dispersal of a Species. SOURCE: Menke, S. B., et al. 2007. Biotic and abiotic controls of Argentine ant invasion success at local and landscape scales. *Ecology* 88(12): 3164–3173.

✔**QUANTITATIVE** The bars in the graphs represent the means of several plots. How many replicate plots were used for each treatment? Why were replicates important for this experiment?

The range of every species on Earth is limited by a combination of abiotic and biotic factors that occurred in the past, and that occur in the present. The range of a particular species depends on the capacity to survive climatic conditions, the ability to find food and avoid being eaten, and the ability to disperse.

If a modest amount of irrigation can have a large effect on the dispersal of an ant species, you can imagine how abiotic factors like precipitation can have far-reaching consequences on ecology on a global scale. Let's take a closer look at climate as a major abiotic determinant of the distribution of life on the planet.

52.3 Climate Patterns

Species are adapted to the abiotic conditions present where they live. An array of abiotic factors affect organisms, including the chemistry of water in aquatic habitats, the nature of soils in terrestrial habitats, and **climate**—the prevailing, *long-term* weather conditions found in an area. **Weather** consists of the specific *short-term* atmospheric conditions of temperature, precipitation, sunlight, and wind.

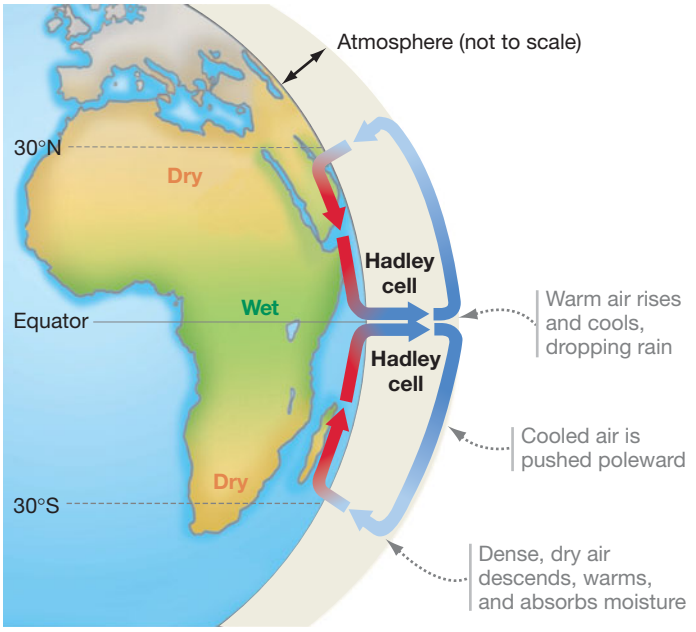
Although your local meteorologist might not always make a good prediction on the night's snowfall, climate occurs in relatively predictable global patterns.

Why Are the Tropics Wet?

One of the most striking climate patterns on Earth involves precipitation. When average annual rainfall is mapped for regions around the globe, it is clear that areas along the equator receive the most moisture. In contrast, locations about 30 degrees latitude north and south of the equator are among the driest on the planet. Why do these patterns occur?

Simple questions often have fascinating answers. It turns out that a major cycle in global air circulation, called a **Hadley cell,** is responsible for making the Amazon River basin wet and the Sahara Desert dry. Hadley cells are named after George Hadley, who in 1735 conceived of the idea of enormous air circulation patterns.

To understand how Hadley cells work, put your finger on the equator in **FIGURE 52.5a** and follow the arrows.



- Air that is heated by the strong sunlight along the equator expands, lowering its pressure and causing it to rise. Note that this warm air holds a great deal of moisture, because warm water molecules tend to stay in vapor form instead of condensing into droplets.
- As air rises above the equator, it radiates heat to space. It also expands into the larger volume of the upper atmosphere, which lowers its density and temperature.
- As rising air cools, its ability to hold water declines. When water vapor cools, water condenses.

The result? High levels of precipitation occur along the equator.

The story is just beginning, however.

- As more air is heated along the equator, the cooler, "older" air above Earth's surface is pushed poleward.
- When the air mass has cooled enough, its density increases and it begins to sink.

(a) Circulation cells exist at the equator ...

(b) ... and at higher latitudes.

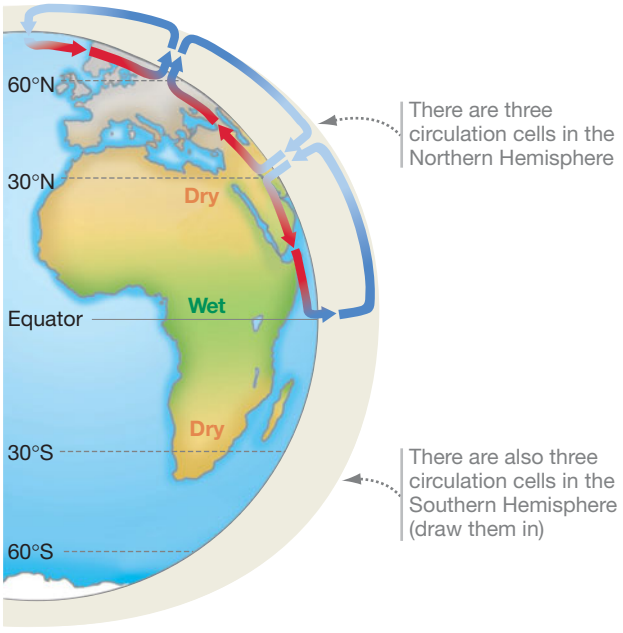


FIGURE 52.5 Global Air Circulation Patterns Affect Rainfall. Hadley cells explain why the tropics are much wetter than regions near 30° latitude north and south. Regions with rising air, such as those at the equator, tend to be wetter than regions with descending air.

- As it sinks, it absorbs more and more solar radiation reflected from Earth's surface and begins to warm while being pushed to the surface by higher-density air above it.
- As the air warms, it also gains water-holding capacity. Thus the air approaching the Earth "holds on" to its water, and little rain occurs where it returns to the surface.

The result? A band of deserts in the vicinity of 30° latitude north and south. These areas are bathed in warm, dry air.

Similar air circulation cells occur between 30° latitude and 60° latitude, and between 60° latitude and the poles, north and south (**FIGURE 52.5b**). ✔ **If you understand how Hadley cells work, you should be able to add diagrams to Figure 52.5b showing the three cells that occur in the Southern Hemisphere.**

Why Are the Tropics Warm and the Poles Cold?

In general, areas of the world are warm if they receive a large amount of sunlight per unit area; they are cold if they receive a small amount of sunlight per unit area. Over the course of a year, regions at or near the equator receive much more sunlight per unit area—and thus much more energy in the form of heat—than regions that are closer to the poles.

- At the equator, the Sun is often directly overhead. As a result, sunlight strikes the surface at or close to an angle of 90 degrees. At these angles, Earth receives a maximum amount of solar radiation per unit area (**FIGURE 52.6**).
- Because Earth's surface slopes away from the equator, the Sun strikes the surface at lower and lower angles moving toward the poles. When sunlight arrives at a low angle, much less energy is received per unit area.

The pattern of decreasing average temperature with increasing latitude is a result of Earth's spherical shape.

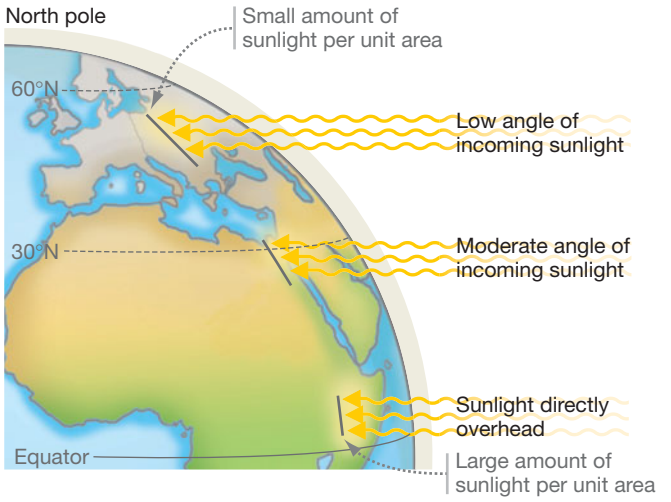

FIGURE 52.6 Solar Radiation per Unit Area Declines with Increasing Latitude. Over the course of a year, the Sun is frequently almost directly overhead at the equator. As a result, equatorial regions receive a large amount of solar radiation per unit area compared to high-latitude regions.

What Causes Seasonality in Weather?

The striking global patterns in temperature and moisture that you've just reviewed are complicated by the phenomenon of seasons. Seasons are defined as regular, annual fluctuations in temperature, precipitation, or both.

As **FIGURE 52.7** shows, seasonality occurs because Earth is tilted on its axis by 23.5 degrees. As a result of this incline, the Northern Hemisphere is tilted toward the Sun in June. In this position, it faces the Sun most directly. In June, the Northern Hemisphere presents its least-acute angle to the Sun and receives the largest amount of solar radiation per unit area.

The Southern Hemisphere, in contrast, is tilted away from the Sun in June. As a result, it presents a steep angle for incoming sunlight and receives its smallest quantity of solar radiation per unit area.

The upshot? In June it is summer in the Northern Hemisphere and winter in the Southern Hemisphere. Conversely, in December it is summer in the Southern Hemisphere and winter in the Northern Hemisphere. In March and September, the equator faces the Sun most directly. During these months, the tropics receive the most solar radiation. If Earth did not tilt on its axis, there would be no seasons.

What Regional Effects Do Mountains and Oceans Have on Climate?

The broad patterns of climate that are dictated by global heating patterns, Hadley cells, and seasonality are modified by regional effects. The most important of these are due to the presence of mountain ranges and proximity to an ocean.

FIGURE 52.8 shows how mountain ranges affect regional climate, using the Cascade Mountain range along the Pacific Coast of North America as an example.

- In this area of the world, the prevailing winds are from the west. These winds bring moisture-laden air from the Pacific Ocean onto the continent.
- As the air masses begin to rise over the mountains, the air cools and releases large volumes of water as rain.
- Once cooled air has passed the crest of a mountain range, the air is relatively dry because much of its moisture content has already been released. Areas that receive this dry air are said to be in a **rain shadow.**

The area along the Pacific Coast from northern California to southeast Alaska hosts some of the only high-latitude rain forests in the world. One area along the Pacific Coast of Washington State gets an average of 340 cm (134 in.) of precipitation each year. Mountain ranges also occur along the Pacific Coast of Southern California and Mexico, but these areas are arid because they are dominated by dry air that is part of the Hadley circulation.

Logically enough, one of the few high-latitude deserts in the world exists to the east of the Cascade Mountains. It is created by a rain shadow and averages less than 25 cm (10 in.) of moisture

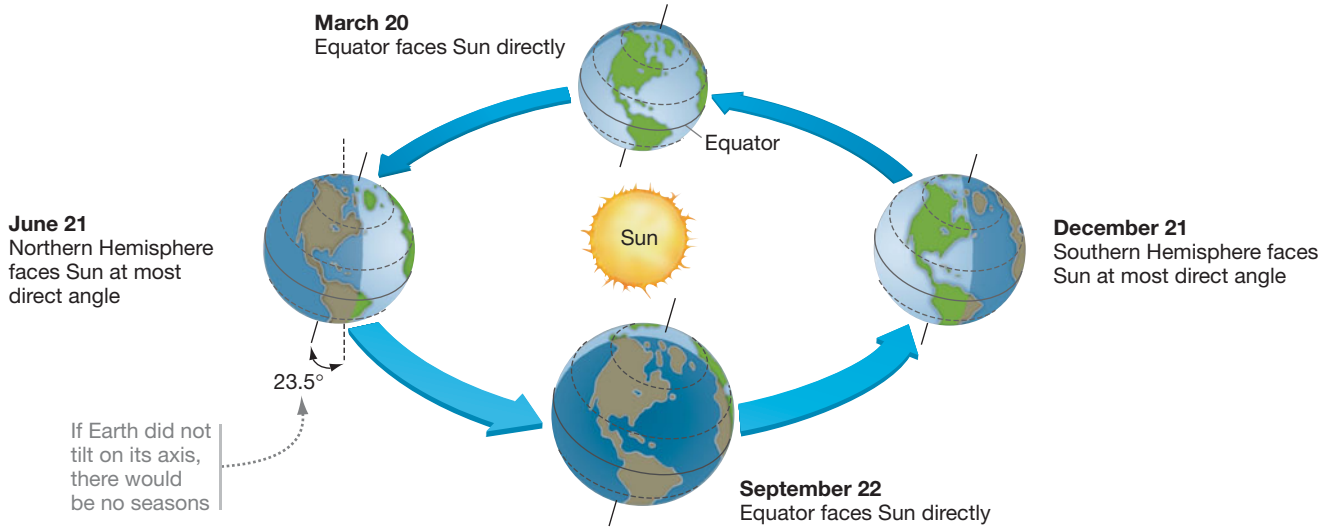

FIGURE 52.7 Earth's Orbit and Tilt Create Seasons at High Latitudes. Seasons occur due to annual variation in the amount of solar radiation that different parts of the Earth receive.

annually. Similar rain shadows create the Great Basin desert of western North America, the Atacama Desert of South America, and the dry conditions of Asia's Tibetan Plateau.

While the presence of mountain ranges tends to produce extremes in precipitation, the presence of an ocean has a moderating influence on temperature. Water has an extremely high **specific heat,** meaning that it has a large capacity for storing heat energy (Chapter 2). Because water molecules form hydrogen bonds with each other, it takes a great deal of heat energy to boil water or melt ice—in fact, to change the temperature of water at all. The hydrogen bonds have to be broken before the water molecules themselves can begin to absorb heat and move faster, which we measure as increased temperature.

Because water has a high specific heat, it can absorb a great deal of heat from the atmosphere in summer, when the water temperature is cooler than the air temperature. As a result, the ocean moderates summer temperatures on nearby landmasses. This is why the air temperature is cooler near the ocean on a hot summer's day than it is a few miles inland. Similarly, the ocean releases heat to the atmosphere in winter, when the water temperature is warmer than the air temperature. This is why on a calm winter's day the air temperature can be warmer near the ocean than it is a few miles inland. Because of the large capacity of water for storing heat energy, islands and coastal areas have much more moderate climates than do inland areas.

How do all these climate patterns combine to determine the distribution of organisms on Earth?

check your understanding

C Y U

If you understand that . . .

- Global climate patterns are dictated by differential heating of Earth's surface, Hadley cells, and seasonality.
- These general patterns are modified at a regional scale by the presence of mountains and oceans.

✔ You should be able to . . .

1. Predict whether the North Pole is rainy.
2. Predict where on the globe the highest risk of skin cancer would occur and explain why.

Answers are available in Appendix A.

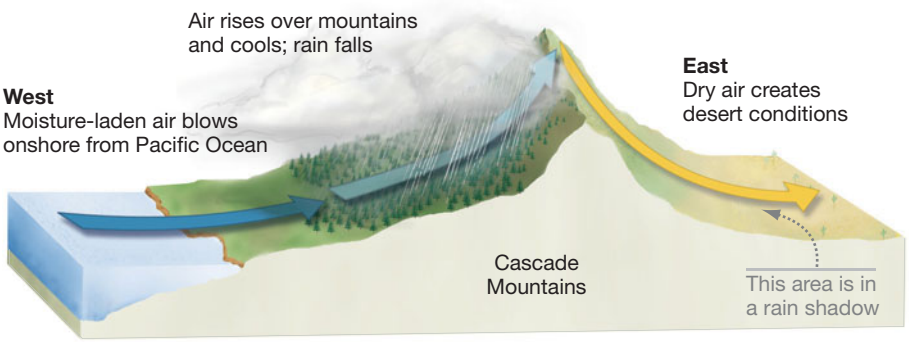

FIGURE 52.8 Mountain Ranges Create Rain Shadows. When moisture-laden air rises over a mountain range, the air cools enough to condense water vapor. As a result, moisture falls to the ground as precipitation. On the other side of the mountain, little water is left to provide precipitation.

52.4 Types of Terrestrial Biomes

If you could walk from the equator in South America to the North Pole, you would notice startling changes in the organisms around you. Lush tropical forests with broad-leaved evergreen trees would give way to seasonally dry forests and then to deserts. The deserts would yield to the vast grasslands of central North America, which terminate at the boreal forests of the subarctic. If you pressed on, you would reach the end of the trees and the beginning of the most northerly community—the arctic tundra.

If you walked from sea level to the top of the Cascade Mountains of British Columbia, you would experience similar types of changes. Wet forests along the coast would give way to drier forests at higher elevations. Near the peaks, trees would thin and eventually yield to alpine tundras filled with hardy, low-growing plants. Broad-leaved evergreen forests, deserts, grasslands, and tundras are **biomes:** regions characterized by distinct abiotic characteristics and dominant types of vegetation.

Natural Biomes

The global distribution of the most common types of naturally occurring terrestrial biomes is shown in **FIGURE 52.9**—ignoring, for the moment, the effects of humans on the landscape. Notice that different ecosystems may belong to the same biome. For example, the Sonoran Desert in North America and the Sahara Desert in Africa are both part of the same biome—subtropical desert—but each is a unique ecosystem with its own community of indigenous organisms.

Each of the terrestrial biomes found around the world is associated with a distinctive set of abiotic conditions determined largely by climate:

- *Temperature* is critical because the enzymes that make life possible work at optimal efficiency only in a narrow range of temperatures (see Chapter 8). Temperature also affects the availability of moisture: Water freezes at low temperatures and evaporates rapidly at high temperatures.
- *Moisture* is significant because it is required for life, and because terrestrial organisms constantly lose water to the environment through evaporation or transpiration. To stay alive, they must reduce water loss and replace lost water.
- *Sunlight* is essential because it is required for photosynthesis.
- *Wind* is important because it exacerbates the effects of temperature and moisture. Wind increases heat loss due to evaporation and convection, and it increases water loss due to evaporation and transpiration. Wind also has a direct physical impact on organisms such as birds, flying insects, and plants—it pushes them around.

Of the four components of climate, variation in temperature and moisture are far and away the most important in determining plant distribution and abundance. More specifically, the nature of the terrestrial biome that develops in a particular region

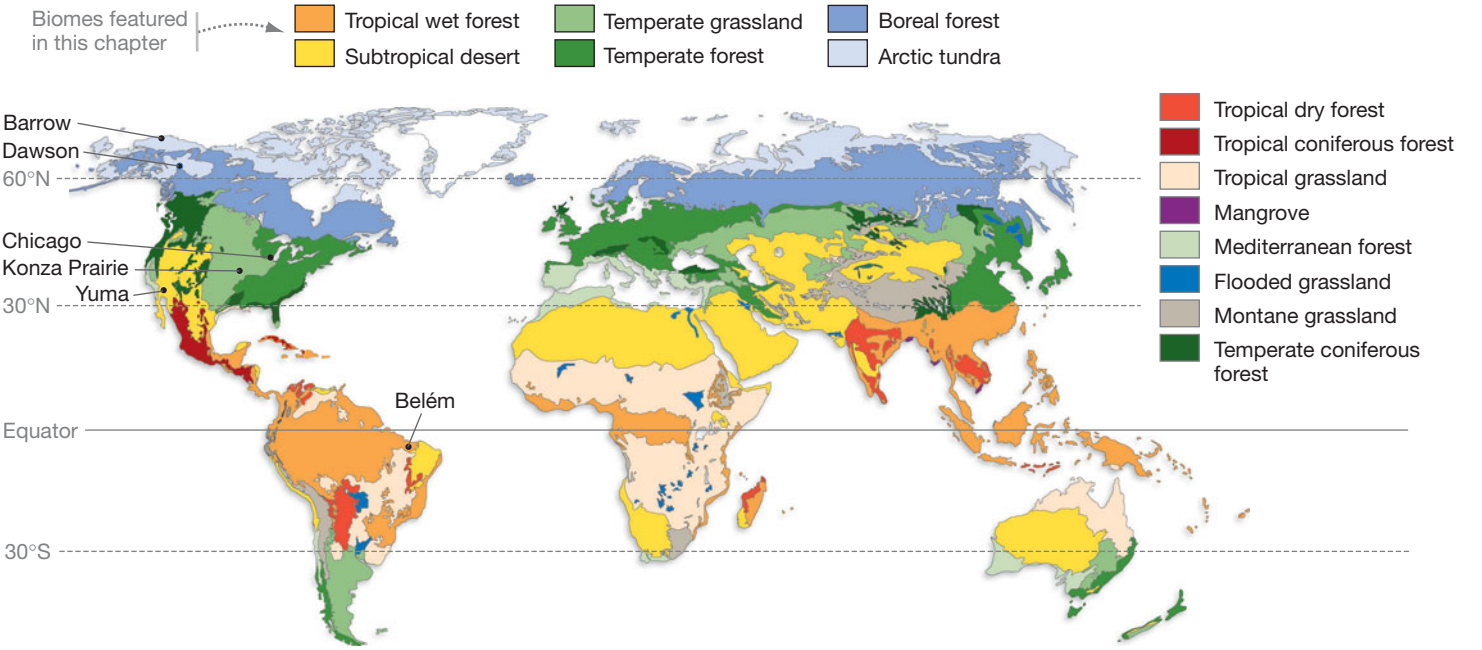

FIGURE 52.9 Distinct Terrestrial Biomes Are Found throughout the World. The six major biomes listed above the map are featured in this chapter, citing data from the labeled locations on the left.

DATA: Olson, D. M., E. Dinerstein, E. D. Wikramanayake, et al. 2001. *BioScience* 51: 933–938.

is governed by **(1)** average annual temperature and precipitation, and **(2)** annual variation in temperature and precipitation. Each biome contains species that are adapted to a particular temperature and moisture regime.

Biologists are particularly concerned with how temperature and moisture influence **net primary productivity (NPP).** NPP is defined as the total amount of carbon that is fixed per year minus the amount that is oxidized during cellular respiration. Fixed carbon that is consumed in cellular respiration provides energy for the organism but is not used for growth—that is, production of **biomass** (see Chapter 56).

NPP is crucial because it represents the organic matter that is available as food for other organisms. In terrestrial environments, NPP is often estimated by measuring **aboveground biomass**—the total mass of living plants, excluding roots.

Photosynthesis, plant growth, and NPP are maximized on land when temperatures are warm and conditions are wet. Conversely, photosynthesis cannot occur efficiently at low temperatures or under drought stress. Photosynthetic rates are maximized in warm temperatures, when enzymes work efficiently, and in humid weather, when stomata can remain open and CO_2 is readily available.

To help you understand how temperature and precipitation influence biomes, let's take a detailed look at the six terrestrial biomes that represent Earth's most extensive natural vegetation types (see boxes on pages 1070–1072). In each case, you'll be analyzing temperature and precipitation data from a specific location ranging from the wet tropics to the arctic (labeled in Figure 52.9). Data plotted in red indicate the daily average temperature in each biome, graphed throughout the year; data plotted in purple indicate the average monthly precipitation.

- Terrestrial Biomes > Tropical Wet Forest
- Terrestrial Biomes > Subtropical Deserts
- Terrestrial Biomes > Temperate Grasslands
- Terrestrial Biomes > Temperate Forests
- Terrestrial Biomes > Boreal Forests
- Terrestrial Biomes > Arctic Tundra

Anthropogenic Biomes

The map in Figure 52.9 shows the distribution of terrestrial biomes as they would occur naturally. This map is important because it represents the product of 3.6 billion years of interplay between geology, climate, evolution, and ecology.

Now for the rest of the story. The exponential increase in the human population (Chapter 54) is driving land-use changes and other impacts that are so significant that some researchers have called for a new epoch of history, the Anthropocene (see Chapter 28). Consider these data:

- More than 75 percent of Earth's ice-free land shows evidence of direct alteration by humans—for example, farming, logging, and urban development (*not* including the effects of pollution, invasive species, or climate change).
- The remaining regions, or wildlands, account for just 11 percent of terrestrial net primary productivity.

What does the distribution of biomes look like with human impact factored in? Biogeographer Erle Ellis and colleagues have pioneered efforts to map anthropogenic biomes, or "anthromes" worldwide, and with eye-opening results. **FIGURE 52.10** zooms in on one part of the world, eastern North America, to show a close-up of the distribution of anthropogenic biomes. The remaining wildlands (pale gray-green on the map) are so sparse that they are difficult to locate.

As you can see, humans are directly affecting the distribution of terrestrial ecosystems by physically changing the landscape, one forest and suburb at a time. Humans are also changing the global distribution of ecosystems in a more indirect way—by changing the global climate.

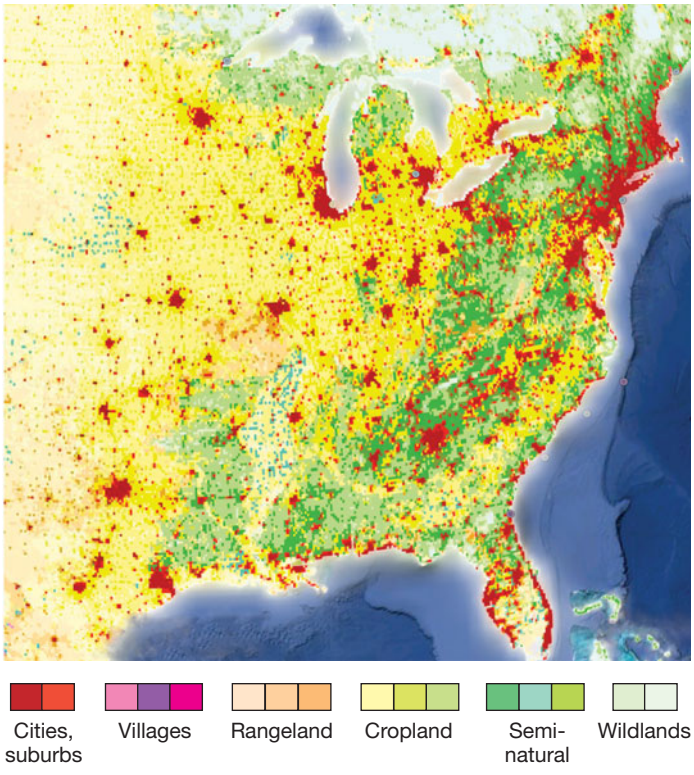

FIGURE 52.10 Anthropogenic Biomes in Eastern North America. Several color subcategories have been consolidated in the key for simplicity. For example, cropland can be irrigated or rain-fed, residential, sparsely populated, or remote.

DATA: Ellis, E. C., K. Klein Goldewijk, S. Siebert, et al. 2010. *Global Ecology and Biogeography* 19: 589–606.

✔**QUESTION** Where do the remaining wildlands occur?

Terrestrial Biomes > Tropical Wet Forest

Tropical wet forests—also called tropical rain forests—are found in equatorial regions around the world. Plants in this biome have broad leaves and are evergreen. Favorable year-round growing conditions produce riotous growth, leading to extremely high productivity, aboveground biomass, and species diversity. It is not unusual to find over 200 tree species in a single study plot. The diversity of plant sizes and growth forms in wet forest communities produces extraordinary structural diversity, presenting a wide array of habitat types for animals. ✔You should be able to explain why vines and epiphytes increase the productivity of tropical wet forests.

Temperature Compared to other biomes, tropical wet forests show almost no seasonal variation in temperature (**FIGURE 52.11**). This is important because temperatures are high enough to support growth throughout the year.

Precipitation Even the driest month of the year (November in Belém, Brazil) receives over 5 cm (2 in.) of rainfall—considerably more than the *annual* rainfall of many deserts.

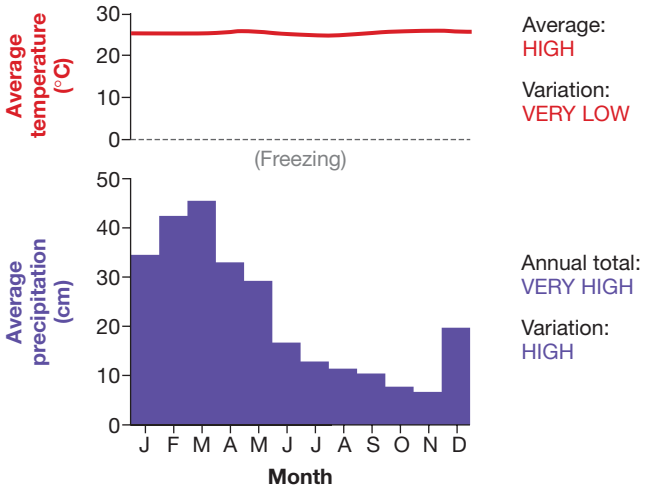

FIGURE 52.11 Climate Data from Belém, Brazil.

Terrestrial Biomes > Subtropical Deserts

Subtropical deserts are found throughout the world at 30 degrees latitude north and south—a pattern that is explained in Section 52.3. Desert species adapt to the extreme temperatures and aridity by growing at a low rate year-round, or breaking dormancy and growing rapidly in response to any rainfall. Cacti can grow year-round because they have no leaves, or small leaves modified as spines; a thick, waxy coating; and the CAM pathway for photosynthesis (see Chapter 10). The average productivity of desert communities is extremely low. ✔You should be able to explain why most desert plant species have a small surface area.

Temperature Mean monthly temperatures in subtropical deserts vary more than in tropical wet climates (**FIGURE 52.12**). Temperatures fall below freezing in some subtropical deserts.

Precipitation The most striking feature of the subtropical desert climate is low precipitation; average annual precipitation in Yuma, Arizona, is just 7.5 cm (3 in.).

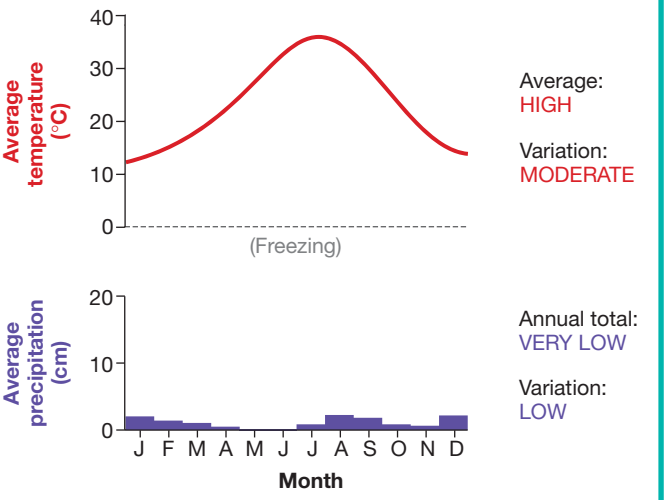

FIGURE 52.12 Climate Data from the Sonoran Desert.

Terrestrial Biomes > Temperate Grasslands

Temperate grasslands are commonly called prairies in North America and steppes in central Eurasia. Grasses are the dominant life-form in temperate grasslands for one of two reasons: **(1)** Conditions are too dry to enable tree growth, or **(2)** encroaching trees are burned out by prairie fires. In contrast to deserts, plant life is extremely dense—virtually every square centimeter is filled, not only on the surface, but also underground where root systems are extensive. Although the productivity of temperate grasslands is generally lower than that of forest communities, grassland soils are often highly fertile. ✔You should be able to explain why grasslands of North America and Eurasia are the breadbaskets of those continents.

Temperature In the **temperate** zone, plant growth is possible only in spring, summer, and fall months when moisture and warmth are adequate (**FIGURE 52.13**).

Precipitation Conditions are still slightly too hot and dry to support forests; average annual precipitation in Konza Prairie (Kansas) is 83.4 cm (32.5 in.).

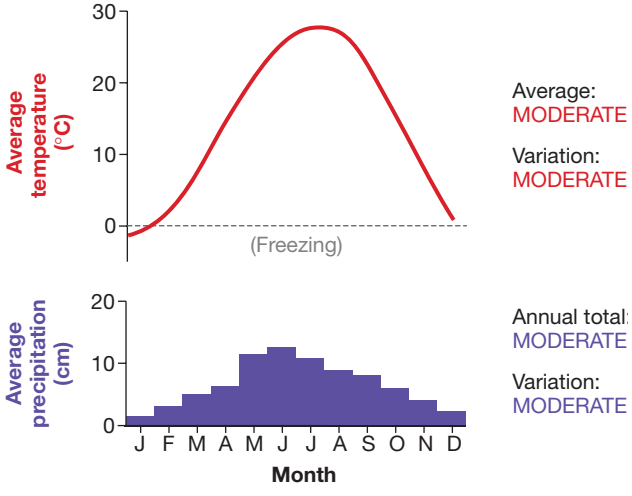

FIGURE 52.13 Climate Data from Konza Prairie, Kansas.

Terrestrial Biomes > Temperate Forests

Temperate forests in North America and Europe are dominated by deciduous species, which are leafless in winter and grow new leaves each spring and summer. Needle-leaved evergreens are also common. Most temperate forests have productivity levels that are lower than those of tropical forests yet higher than those of deserts or grasslands. The level of diversity is also moderate. Temperate forests have moderate productivity simply because temperatures do not support photosynthesis year-round. ✔You should be able to predict the vegetation found in regions with climate characteristics intermediate between those of grasslands and temperate forests.

Temperature Temperate forests experience moderate fluctuations in mean monthly temperatures, sometimes falling below freezing, as in the Chicago area (**FIGURE 52.14**).

Precipitation Precipitation in temperate forests is moderate, and relatively constant throughout the year compared to grassland climates; average annual precipitation in the Chicago area is 85 cm (34 in.), exceeding 5 cm (2 in.) during most months.

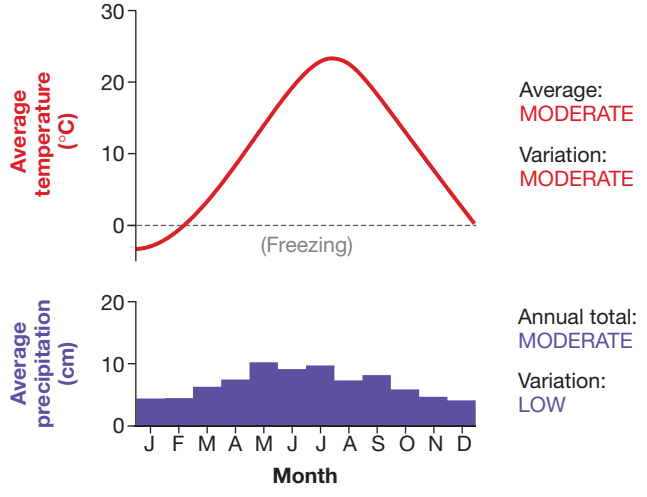

FIGURE 52.14 Climate Data from Chicago Temperate Forest.

Terrestrial Biomes > Boreal Forests

Boreal forests, or **taiga,** stretch across most of Canada, Alaska, Russia, and northern Europe and are dominated by highly cold-tolerant conifers, including pines, spruce, fir, and larch trees. Productivity is low, but aboveground biomass is high because slow-growing tree species may be long lived and gradually accumulate large standing biomass. Boreal forests also have exceptionally low species diversity—there are just seven or fewer tree species in Alaska. They also lack most elements of structure seen in tropical or even temperate forests—they often have just a tree layer and a ground layer. ✔You should be able to predict how the global distribution of boreal forests will change in response to global warming.

Temperature Boreal forests have very cold winters and cool, short summers—an annual fluctuation of over 40°C in the Yukon Territory (**FIGURE 52.15**), and up to 70°C in some areas.

Precipitation Annual precipitation is low, but temperatures are so cold that evaporation is minimal; as a result, moisture is usually abundant enough to support tree growth.

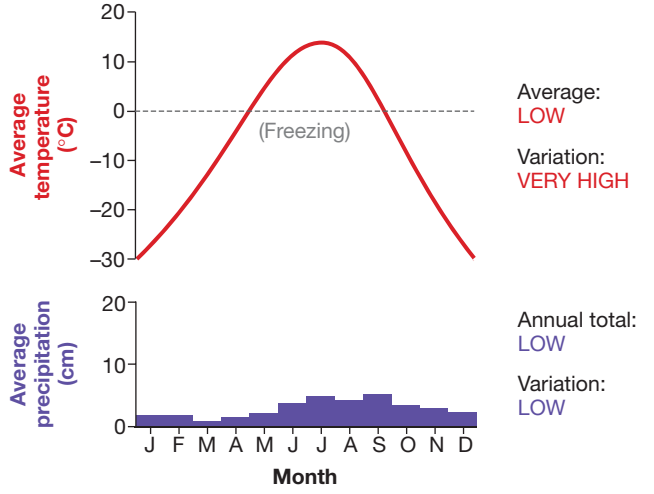

FIGURE 52.15 Climate Data from Yukon Territory.

Terrestrial Biomes > Arctic Tundra

Arctic tundra occurs throughout the arctic regions of the Northern Hemisphere. Tundra has low species diversity, low productivity, and low aboveground biomass—and it is treeless. Most tundra soils are in the perennially frozen state known as **permafrost,** which limits both the release and uptake of nutrients. Unlike desert biomes, however, the ground surface in tundra communities is completely covered with plants or lichens. Animal diversity also tends to be low, although insect abundance—particularly of biting flies—can be staggeringly high. ✔You should be able to explain why the types of vegetation in arctic tundra are similar to the types found in alpine tundra, which occurs at high elevation.

Temperature The growing season is very short, 10–12 weeks at most in Barrow, Alaska; for the remainder of the year, temperatures are below freezing (**FIGURE 52.16**).

Precipitation Precipitation on the arctic tundra is extremely low, but many arctic soils are saturated year-round due to extremely low evaporation rates.

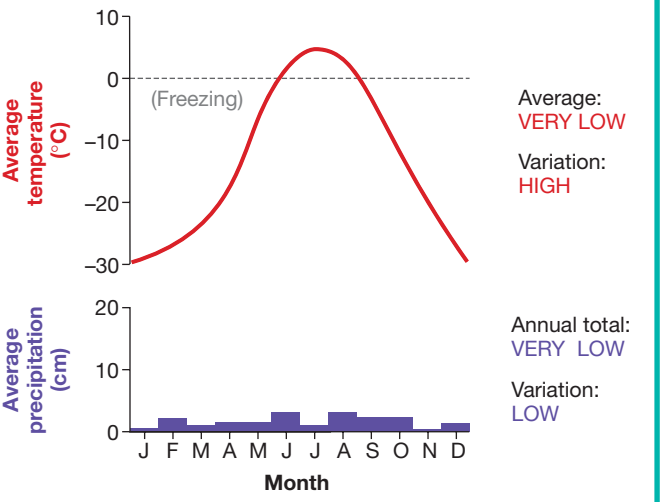

FIGURE 52.16 Climate Data from Barrow, Alaska.

How Will Global Climate Change Affect Terrestrial Biomes?

It is now well established that human-caused emissions of greenhouse gases like CO_2 are causing climate change (see Chapter 56). Climate has changed frequently and radically throughout the history of life, but recent increases in average temperatures around the globe, combined with a projected increase of up to 5.8°C over the next 100 years, represent one of the most rapid periods of climate change since life began.

How will global climate change affect the overall distribution of life on Earth? Biologists use four tools to make predictions:

1. *Simulation studies* are based on computer models of weather patterns in local regions. By increasing average temperatures in these models, researchers can predict how wind and rainfall patterns, storm frequency and intensity, and other aspects of weather and climate will change. In effect, simulation studies predict how temperature and precipitation profiles, like those in this chapter's "Terrestrial Biome" boxes, will change—and how the distribution of organisms might change as a result.
2. *Observational studies* are based on long-term monitoring at fixed sites around the globe. Researchers are documenting changes in key physical variables—temperature and precipitation—as well as changes in the distribution and abundance of organisms, such as the timing of insect emergence and bird migrations. By extrapolation, they can predict how change may continue at these sites.
3. *Historical studies* examine the relationship between CO_2 levels, climate change, and the distribution and abundance of organisms during events that occurred millions of years ago. For example, researchers have been able to measure the pattern of change in the biodiversity of the Amazonian rain forest as a function of past climate fluctuations. These patterns provide valuable data for models designed to predict future changes.
4. *Experiments* are designed to simulate changed climate conditions and to record responses by the organisms present.

Even though the scientific community did not become alert to the reality of global climate change until the 1980s, a large number of multiyear experiments have already been done. Because arctic regions are projected to experience particularly dramatic changes in temperature and precipitation, many of these experiments have been conducted in the tundra biome.

FIGURE 52.17 shows one example of how these experiments are set up. Transparent, open-topped chambers are placed at random locations around a study site, and the characteristics of the vegetation inside the chambers are recorded annually. The same measurements are made in randomly assigned study plots that lack chambers.

Across experiments, the average annual temperature inside the open-topped chambers increases by 1–3°C. This increase is consistent with conservative projections for how temperatures will change over the next century.

FIGURE 52.17 Experimental Increases in Temperature Change Species Composition in Arctic Tundra. The transparent, open-topped chambers shown here are an effective way to increase average annual temperature. Inside the chambers, species composition changes relative to otherwise similar sites nearby.

✔**QUESTION** Why does a clear chamber like this increase average temperature inside?

In an analysis of data from 11 such study sites scattered throughout the arctic, several strong patterns emerged:

- Overall, species diversity decreases.
- Compared with control plots, grasses and shrubs increase inside the chambers, and mosses and lichens decrease.

These experimental results support simulation and observational studies predicting that arctic tundra environments are giving way to boreal forest. Biomes are changing right before our eyes.

Note that not all areas are expected to transition smoothly and incrementally from one biome to another based on changes in temperature and/or rainfall. There is growing evidence that small perturbations in climate in some areas will cause abrupt changes to biomes. For example, scientists predict that decreased rainfall over the Amazon will cause a rapid transition from forest to grassland due to positive feedback loops in the system. Decreases in forest cover will decrease the rate of rain-cloud formation, which will further decrease the rainfall. Decreased rainfall will increase the prevalence of fires, which will further decrease forest cover. The predicted result is a rapid change—a tipping point—from a forested stable state to a grassland stable state, with dramatic effects on biodiversity.

Other simulation and observational studies have converged on a remarkable conclusion: Increases in average global temperature are increasing variability in temperature and precipitation. Stated another way, global climate change is making climates more extreme. Average temperature and average annual precipitation in many regions may not be changing substantially, even though variation is. For example, thus far the frequency of monsoon rains, cyclones, hurricanes, and other types of storm events is not changing. However, the amount of precipitation and the wind speeds associated with these events are increasing. The severity of droughts is also on the rise.

Both human land-use patterns and climate change cause dramatic alterations in the composition and distribution of terrestrial biomes. These factors also affect aquatic biomes. Let's take a closer look.

check your understanding

C Y U

If you understand that . . .

- In terrestrial environments, distinctive biomes develop based on two aspects of temperature and moisture: average value and variability over the year.
- Human land-use practices are changing terrestrial biomes.
- Global climate change is affecting terrestrial biomes.

✔ You should be able to . . .

1. Predict whether tropical dry forests, which have high year-round temperatures but a distinct dry season, are more or less productive than tropical wet forests.
2. Predict how the biome where you live will change over the course of your lifetime.

Answers are available in Appendix A.

52.5 Types of Aquatic Biomes

About 70 percent of the surface of the Earth is covered in water. What types of biomes occur there? And what are the characteristics that distinguish aquatic biomes?

Let's think back to the sockeye salmon in the beginning of the chapter. Most salmon begin their lives in streams, travel to the ocean to feed and grow, then return to their natal streams to mate and die. Thus salmon migrate between a freshwater aquatic biome (a stream) and a marine aquatic biome (the ocean). The major abiotic factors that distinguish streams from oceans include salinity, water depth, water flow, and nutrient availability. Let's consider each factor in turn.

Salinity

Water is an excellent solvent—one reason why it is so essential to life (see Chapter 2). The water in clouds is nearly pure, but as rainwater percolates through soils and flows across rocks, it picks up solutes. The freshwater of ponds, lakes, and rivers has very low solute concentrations. However, as this freshwater steadily flows into the ocean, it continually adds solutes. Over millions of years, this process has resulted in a relatively high concentration of solutes in seawater.

The proportion of solutes dissolved in water determines its **salinity,** generally measured as the number of grams of solute per kilogram of water—a unitless number described as parts per thousand. The salinity of freshwater varies from about 0.06 to 0.3 parts per thousand, whereas the salinity of the open ocean is fairly constant at 35 parts per thousand.

What makes the ocean "salty"? Solutes with a positive charge—like sodium, potassium, magnesium, and calcium—combine with solutes with a negative charge—like chlorine, bromine, and fluorine—to form salts. The concentration of different salts in the ocean is determined by their solubility in water. For example, calcium carbonate has a low solubility in water, so it precipitates as limestone at the bottom of the ocean. But sodium chloride (familiar to you as table salt) has such a high solubility in water that it makes up about 86 percent of sea salt.

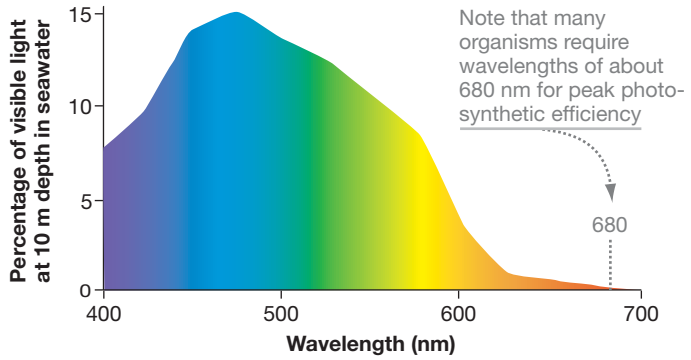
Salinity has dramatic effects on osmosis and water balance in organisms (see Chapters 38 and 43); species have physiological adaptations that allow them to cope with a specific range in salinity. Thus salinity is a major determinant of the distribution of organisms in aquatic biomes.

Water Depth

Water absorbs and scatters light, so the amount and types of wavelengths available to organisms change dramatically as water depth increases. Light availability has a major influence on productivity.

At the water surface, all wavelengths of light are equally available. But as **FIGURE 52.18a** shows, ocean water dramatically removes light in the red region of the visible spectrum, resulting in the familiar blue hue of underwater scenes (**FIGURE 52.18b**). This is important because wavelengths in the red region are unavailable for photosynthesis underwater, despite the high absorption peaks for red wavelengths in key photosynthetic pigments like chlorophyll (see Chapter 10).

The quantity of light available to organisms also diminishes rapidly with increasing depth. In pure seawater, the total amount of light available at a depth of 10 m is less than 40 percent of what it is at the surface; virtually no light reaches depths greater than 40 m (131 ft).



Further, seawater is rarely pure and may contain high concentrations of algae, sediments, and other light-reducing components. The **turbidity,** or cloudiness, of water is an important determinant of light penetration. Turbidity is sometimes caused by natural processes such as erosion of river sediments by floodwaters and the erosion of coastal sediments by wave action. Turbidity is also caused by many human activities, such as runoff from agricultural fields and algae blooms caused by nutrient pollution (see Chapter 56).

Water Flow

Water movement is a critical factor in aquatic ecosystems because it presents a physical challenge. It can literally sweep organisms away.

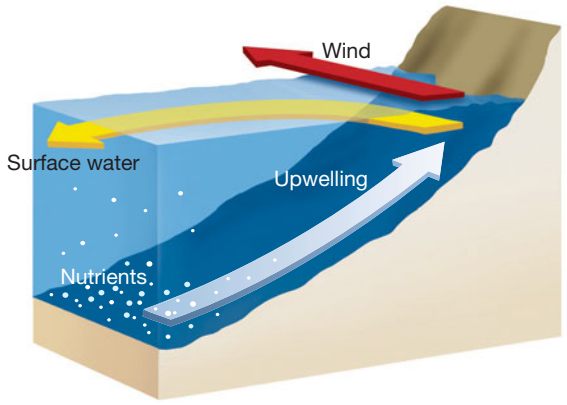
Organisms that live in fast-flowing streams have to cope with the physical force of the water, which constantly threatens to move them downstream. Stream-dwelling organisms like

(a) Red wavelengths are not available underwater.

(b) Blue wavelengths dominate underwater.

FIGURE 52.18 Light Is Limited Underwater.

DATA: Saffo, M. B. 1987. *BioScience* 37: 654–664.



mayfly larvae have streamlined shapes and behavioral adaptations that help them to maintain their position in the stream. Marine organisms that live in intertidal regions are also exposed to water flow—sometimes to violent wave action during storms—and to tidal currents. A growing field of biomechanics (see Chapter 48) studies the mechanical implications of water flow to the physiology, evolution, and ecology of aquatic organisms.

Water flow can also influence non-mechanical aspects of the abiotic environment, including the availability of oxygen, light, and nutrients. For example, the fast-moving water near the source of streams tends to be high in O_2, clear, and low in nutrients. The slower-flowing water downstream tends to be lower in O_2, more turbid, and more nutrient rich.

Nutrient Availability

In many aquatic ecosystems, nutrients such as nitrogen and phosphorus are in short supply. If water is moving, such as in a small salmon stream, nutrients tend to be washed away. If water is still, nutrients tend to fall to the bottom and collect in the form

PROCESS: OCEAN UPWELLING

1. Winds blow: Along the coast of Peru, the prevailing winds blow north, moving water at the surface.

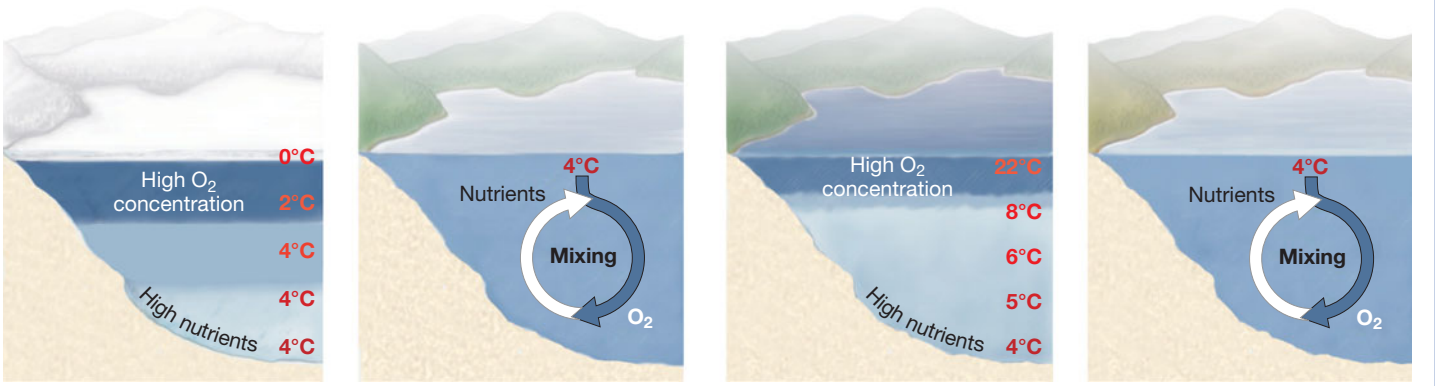
2. Surface water moves: As the Earth rotates, the moving surface water is forced offshore.

3. Upwelling: As surface water leaves, it is replaced by nutrient-laden water welling up from the bottom.

FIGURE 52.19 Ocean Upwellings Bring Nutrients to the Surface.

of debris. Nutrient levels are important: The scarcity of nutrients limits growth rates in the photosynthetic organisms that provide food for other species.

Let's consider two important events that affect nutrient availability in lakes and oceans. In both cases, they are mechanisms that bring nutrients from the bottom up to the water surface, where they can nourish the growth of photosynthetic species.



Ocean Upwelling In the oceans, nutrients in the sunlit surface waters are constantly lost in the form of dead organisms that rain down into the depths. In certain coastal regions of the world's oceans, however, nutrients are brought up to the surface by currents that cause upwellings.

FIGURE 52.19 shows how this happens off the coast of Peru. Here the prevailing winds blow along the coastline, pushing surface water to the north. Because the Earth rotates constantly, this wind-driven water current is slowly moved offshore. As the surface water moves away from the coast, it is steadily replaced by water moving up from the ocean bottom.

The upwelling water is nutrient rich. In effect, it recycles nutrients that earlier had fallen to the ocean floor. The nutrients support luxuriant growths of photosynthetic cells, which feed an array of small grazing animals, which in turn feed small fish called anchoveta. When currents are favorable and upwelling is steady, the anchoveta fishery is the most productive in the world.

Lake Turnover Because they were scoured by glaciers as recently as 10,000 years ago, the higher latitudes of the world host many lakes. Each year, these bodies of water undergo remarkable changes known as the spring and fall **turnovers.**

PROCESS: LAKE TURNOVER

1. Winter stratification: Dense 4°C water at the bottom becomes nutrient rich while colder water near surface becomes oxygenated.

2. Spring turnover: Surface water warms to 4°C and sinks, carrying O_2 down and driving nutrients up.

3. Summer stratification: Dense 4°C water at the bottom becomes nutrient rich while warmer water near surface becomes oxygenated.

4. Fall turnover: Surface water cools to 4°C and sinks, carrying O_2 down and driving nutrients up.

FIGURE 52.20 In Temperate Regions, Lakes Turn Over Each Spring and Fall.

The spring and fall lake turnovers occur in response to changes in air temperature. To see how this happens, examine the temperature profiles in **FIGURE 52.20**.

Note that in winter, water at the surface of a northern lake is locked up in ice at a temperature of 0°C. The water just under the ice is slightly warmer and is relatively oxygen rich because it was exposed to the atmosphere as winter set in. Because water is densest at 4°C, the water at the bottom of the lake is at 4–5°C. The bottom water is also oxygen poor because organisms that decompose falling organic material use up available oxygen in the process.

A gradient in temperature such as this is called a **thermocline** ("heat-slope"). Thermal stratification is said to occur.

The ice begins to melt, however, when spring arrives. The temperature of the water on the surface rises until it reaches 4°C. The water at the surface of the lake is now heavier than the water below it. As a result, the water on the surface sinks. The water at the bottom of the lake is displaced and comes to the surface, completing the spring turnover.

During the spring turnover, water at the bottom of the lake carries sediments and nutrients from the bottom up to the surface. This flush of nutrients triggers a rapid increase in the growth of photosynthetic algae and bacteria; biologists call it the spring bloom. The lake then stratifies again in the summer.

When temperatures cool in the fall, the water at the surface reaches a temperature of 4°C and sinks, displacing water at the bottom and creating the fall turnover. The fall turnover is important because it brings oxygen-rich water from the surface down to the bottom, and because it again brings nutrients from the bottom up to the sunlit surface waters.

Without the spring and fall turnovers, most freshwater nutrients would remain on the bottom of lakes. These aquatic ecosystems would be much less productive as a result.

The boxes that follow summarize the types of aquatic biomes that are classified based on whether they are freshwater or marine as well as on their water depth, water flow, and nutrient availability.

- Aquatic Biomes > Freshwater > Lakes and Ponds
- Aquatic Biomes > Freshwater > Wetlands
- Aquatic Biomes > Freshwater > Streams
- Aquatic Biomes > Freshwater/Marine > Estuaries
- Aquatic Biomes > Marine > Oceans

How Are Aquatic Biomes Affected by Humans?

Just as on land, humans are affecting aquatic biomes worldwide by causing both direct and indirect effects. For example:

Direct Effects Humans cause physical changes to aquatic ecosystems by filling or draining wetlands, damming streams, and removing water from ponds and rivers for agricultural irrigation. Humans also cause biological changes by transporting organisms—such as the invasive zebra mussel, which has become a scourge in the Great Lakes of North America and other regions of the world—and overexploiting marine resources, especially top predators such as tuna and sharks, causing cascading effects on food webs (see Chapters 56 and 57).

Indirect Effects Global climate change influences aquatic ecosystems by the same mechanisms discussed for terrestrial ecosystems. In addition, increased atmospheric CO_2 is causing waterways to become more acidic, limiting the ability of organisms like corals to build skeletons, and having other far-reaching effects (see Chapter 56).

The importance of climate and other abiotic factors to the distribution and abundance of organisms was the main focus of this chapter. Next, let's take a closer look at the biotic factors. How do interactions among organisms of the same species and interactions among different species affect the overall distribution and abundance of organisms?

Aquatic Biomes > Freshwater > Lakes and Ponds

Lakes and ponds are distinguished from each other by size. Ponds are small; lakes are large enough that the water can be mixed by wind and wave action. Most natural lakes and ponds occur in high latitudes—they formed in depressions created by the scouring action of glaciers thousands of years ago.

Water depth Biologists describe the structure of lakes and ponds by naming zones, some of which overlap (**FIGURE 52.21**).

- The **littoral** ("seashore") **zone** consists of the shallow waters along the shore, where flowering plants are rooted.
- The **limnetic ("lake") zone** is offshore and comprises water that receives enough light to support photosynthesis.
- The **benthic ("depths") zone** occurs at the substrate.
- Regions of the littoral, limnetic, and benthic zones that receive sunlight are part of the **photic zone.**
- Portions of a lake or pond that do not receive sunlight make up the **aphotic zone.**

Water flow and nutrient availability Water movement is driven by wind and temperature. The littoral and limnetic zones are typically much warmer and better oxygenated than the benthic zone, but the benthic zone is relatively nutrient rich because dead and decomposing bodies sink and accumulate there. The movement of nutrients from the benthic to littoral zones is often dependent on seasonal turnovers.

Organisms Cyanobacteria, algae, and other microscopic organisms, collectively called **plankton,** live in the photic zone, as do the fish and small crustaceans—organisms related to shrimp and crabs—that eat them. In shallow parts of the photic zone, rooted plants are common. Animals (invertebrates and fish) that consume dead organic matter, or **detritus,** are particularly abundant in the benthic zone. ✔You should be able to predict which zone of lakes and ponds produces the most grams of organic material per square meter per year, and to explain your logic.

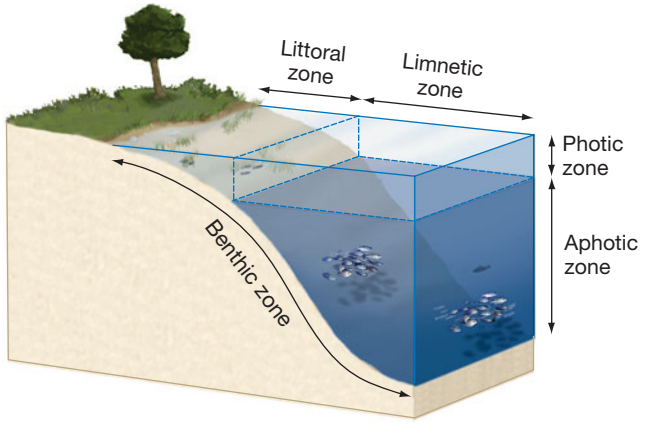


FIGURE 52.21 Lakes Have Distinctive Zones.

Aquatic Biomes > Freshwater > Wetlands

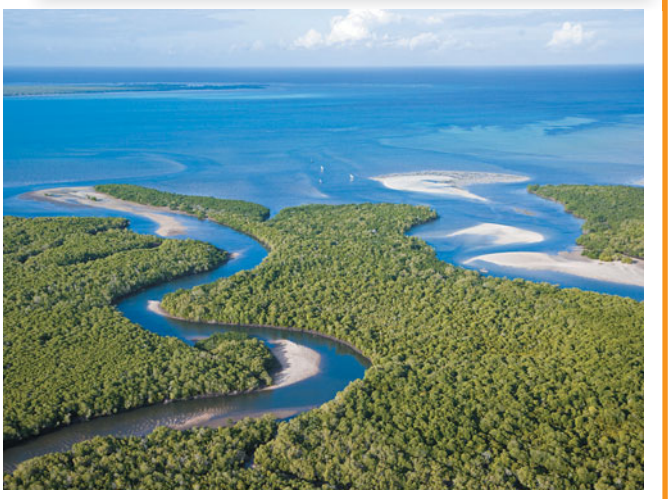
Wetlands are shallow-water habitats where the soil is saturated with water for at least part of the year. They are usually distinguished from terrestrial habitats by the presence of "indicator plants" that grow only in saturated soils.

Water depth Wetlands are distinct from lakes and ponds for two reasons: They have only shallow water, and they have **emergent vegetation**—meaning plants that grow above the surface of the water. All or most of the water in wetlands receives sunlight; emergent plants capture sunlight before it strikes the water.

Water flow and nutrient availability Freshwater marshes and swamps are wetland types characterized by a slow but steady flow of water. **Bogs,** in contrast, develop in depressions where water flow is low or nonexistent. If water is stagnant, oxygen is used up during the decomposition of dead organic matter faster than it enters via diffusion from the atmosphere. As a result, bog water is oxygen poor or even anoxic, resulting in slow decomposition rates. Organic acids and other acids build up, lowering the pH of the water. At low pH, nitrogen becomes unavailable to plants. As a result, bogs are nutrient poor. Marshes and swamps, in contrast, are relatively nutrient rich. In terms of total area, bogs are nearly as common as marshes and swamps but occur mostly at northern latitudes.

Organisms The combination of acidity, lack of available nitrogen, and anoxic conditions makes bogs extremely unproductive habitats. Marshes and swamps, in contrast, offer ample supplies of oxygenated water and sunlight, along with nutrients available from rapid decomposition. As a result, they are extraordinarily productive. **Marshes** lack trees and typically feature grasses, reeds, or other nonwoody vegetation; **swamps** are dominated by trees and shrubs. Because their physical environments are so different, there is little overlap in the types of species found in bogs, marshes, and swamps. ✔You should be able to explain why carnivorous plants, which capture and digest insects, are relatively common in bogs but rare in marshes and swamps.

Aquatic Biomes > Freshwater > Streams



Streams are bodies of water that move constantly in one direction. Creeks are small streams; rivers are large streams.

Water depth Most streams are shallow enough that sunlight reaches the bottom. Availability of sunlight is usually not a limiting factor for organisms, except when turbidity is high.

Water flow and nutrient availability The structure of a typical stream varies along its length. Where it originates at a mountain glacier, lake, or spring, a stream tends to be cold, narrow, and fast. As it descends toward a lake, ocean, or larger river, a stream accepts water from tributaries and becomes larger, warmer, and slower. Oxygen levels tend to be high in fast-moving streams because water droplets are exposed to the atmosphere when moving water splashes over rocks or other obstacles. In contrast, slow-moving streams that lack rapids tend to become relatively oxygen poor. Also, cold water holds more oxygen than warm water does (see Chapter 45). Slow-moving streams tend to be more nutrient rich than fast-moving streams, because decaying matter does not flush away as quickly.

Organisms It is rare to find photosynthetic organisms in small, fast-moving streams; nutrient levels tend to be low, and most of the organic matter present consists of leaves and other materials that fall into the water from outside the stream. Fish, insect larvae, mollusks, and other animals have adaptations that allow them to maintain their positions in the fast-moving portions of streams. As streams widen and slow down, conditions become more favorable for the growth of algae and plants, and the amount of organic matter and nutrients increases. As a result, the same stream often contains completely different types of organisms near its source and near its end, or mouth. ✔You should be able to explain why, in terms of their ability to perform cellular respiration, fish species found in cold, fast-moving streams tend to be much more active than fish species found in warm, slow-moving streams.

Aquatic Biomes > Freshwater/Marine > Estuaries

Estuaries form where rivers meet the ocean—meaning that freshwater mixes with salt water. In essence, an estuary includes saline marshes (from slightly to highly saline) as well as the body of water that moves in and out of these environments. Salinity varies with **(1)** changes in river flows—it declines when the river floods and increases when the river ebbs—and **(2)** with proximity to the ocean. Salinity has dramatic effects on osmosis and water balance (see Chapters 38 and 43); species that live in estuaries have physiological adaptations that allow them to cope with variations in salinity.

Water depth Most estuaries are shallow enough that sunlight reaches the substrate. Water depth may fluctuate dramatically, however, in response to tides, storms, and floods.

Water flow and nutrient availability Water flow in estuaries fluctuates daily and seasonally due to tides, storms, and floods. The fluctuation is important because it alters salinity, which in turn affects which types of organisms are present. Estuaries are nutrient rich because nutrient-laden sediments are deposited when flowing river water slows as it enters the ocean.

Organisms Because the water is shallow and sunlit, and because nutrients are constantly replenished by incoming river water, estuaries are among the most productive environments on Earth. They serve as a nursery for young fish, which feed on abundant vegetation, benthic invertebrates, and plankton while hiding from predators. Estuaries also tend to have high species diversity—some species may occur throughout the estuary while others occupy specialized zones according to salinity and other abiotic factors. Estuaries are also important feeding grounds for both residential and seasonal bird populations. ✔You should be able to explain why estuaries and freshwater marshes contain few of the same species, even though they are both shallow-water habitats filled with rooted plants.

Oceans form a continuous body of salt water and are remarkably uniform in chemical composition. Regions within an ocean vary markedly in their physical characteristics, however, and have profound effects on the organisms found there.

Water depth Biologists describe the structure of oceans by naming zones (**FIGURE 52.22**).

- The **intertidal** ("between tides") **zone** consists of a rocky, sandy, or muddy beach that is exposed to the air at low tide but submerged at high tide.
- The **neritic zone** extends from the intertidal zone to depths of about 200 m. Its outermost edge is defined by the end of the **continental shelf**—the gently sloping, submerged portion of a continental plate.
- The **oceanic zone** is the "open ocean"—the deepwater region beyond the continental shelf.
- The bottom of the ocean is the **benthic zone.**
- The intertidal and sunlit regions of the neritic, oceanic, and benthic zones make up a **photic zone.**
- Areas that do not receive sunlight are in an **aphotic zone.**

The ocean is indeed very deep (average depth = 3.7 km), but its depth is small compared to its breadth, like a piece of paper.

Water flow and nutrient availability Water movement in the ocean is dominated by different processes at different depths. In the intertidal zone, tides and wave action are the major influences. In the neritic zone, currents that bring nutrient-rich water from the benthic zone of the deep ocean toward shore have a heavy impact. Throughout the ocean, large-scale currents circulate water in the oceanic zone in response to prevailing winds and the Earth's rotation. In general, nutrient availability is dictated by water movement. The neritic and intertidal zones are relatively nutrient rich because they receive nutrients from rivers and upwelling. The oceanic zone, in contrast, constantly loses nutrients due to a steady rain of dead organisms drifting to the benthic zone.

Organisms Each zone in the ocean is populated by distinct species that are adapted to the physical conditions present. Organisms that live in the intertidal zone must be able to withstand physical pounding from waves and desiccation and high temperatures at low tide. Productivity is high, however, due to the availability of sunlight and nutrients contributed by estuaries as well as by currents that sweep in nutrient-laden sediments from offshore areas.

Productivity is also high on the outer edge of the neritic zone, due to nutrients contributed by upwelling at the edge of the continental plate. Almost all of the world's major marine fisheries exploit organisms that live in the neritic zone. In the tropics, shallow portions of the neritic zone may host **coral reefs**—large assemblages of colonial marine corals (related to sea anemones; see Chapter 33) that provide habitat for many other organisms. Mutualistic algae living within the corals are the autotrophs in coral reef ecosystems. Because the water is warm and sunlight penetrates to the ocean floor in these habitats, coral reefs are among the most productive environments in the world (see Chapter 56).

If coral reefs are the rain forests of the ocean, then the oceanic zone is the desert. Sunlight is abundant in the photic zone of the open ocean, but nutrients are extremely scarce. When the photosynthetic organisms and the animals that feed on them die, their bodies drift downward out of the photic zone and are lost. In the open ocean, the benthic zone can be several kilometers below the surface, and there is no mechanism for bringing nutrients back up from the bottom. The aphotic zone of the open ocean is also extremely unproductive because light is absent and photosynthesis is impossible. Most organisms present in the aphotic zone survive on the rain of dead bodies from the photic zone. ✔You should be able to predict whether animals that live in the aphotic zone have functioning eyes.

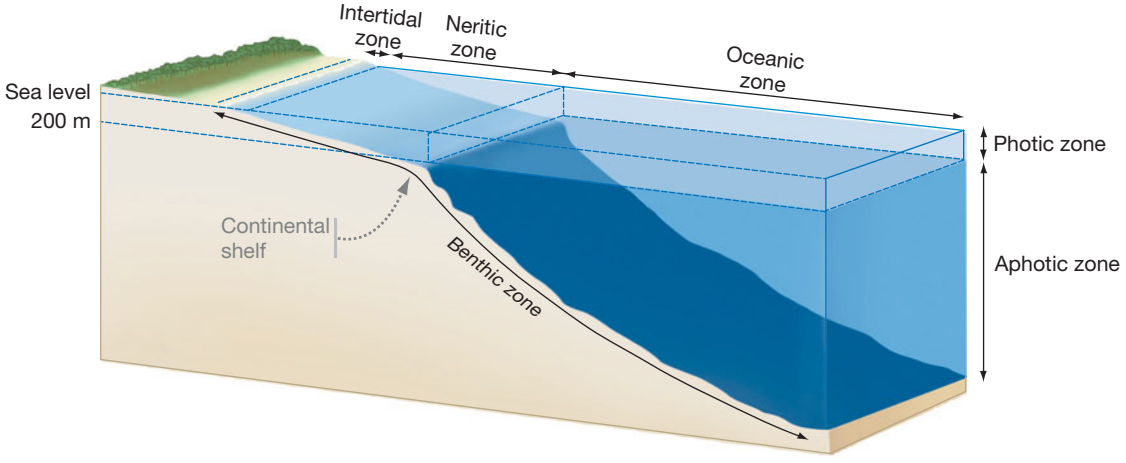


FIGURE 52.22 Oceans Have Distinctive Zones.

If you understand . . .

52.1 Levels of Ecological Study

- Biologists study ecology at five main levels: **(1)** organisms, **(2)** populations, **(3)** communities, **(4)** ecosystems, and **(5)** the biosphere.
- The goal of organismal ecology is to understand how individuals interact with other organisms and their physical surroundings.
- Population ecology focuses on how and why populations grow or decline in time and space.
- Community ecology is the study of how different species interact.
- Ecosystem ecology analyzes interactions between organisms and their abiotic environment—particularly the flow of energy and nutrients.
- Global ecology studies processes that transcend ecosystems, such as the effects of climate change.
- To preserve endangered species and communities, conservation biologists apply analytical methods and results from all levels.

✔ **You should be able to explain why these five levels are hierarchical.**

52.2 What Determines the Distribution and Abundance of Organisms?

- For each species, a unique combination of abiotic and biotic factors determines where individuals live and the size of populations.
- Understanding historical events, such as the movement of entire continents, is important to interpreting current patterns of species distributions.
- Abiotic and biotic factors often interact to produce a different effect on species distributions than either type of factor would have on its own.

✔ **You should be able to predict what would happen to the range of Argentine ants in southern California if dry scrubland is converted to irrigated agricultural fields.**

52.3 Climate Patterns

- Climate varies around the globe because sunlight is distributed asymmetrically—equatorial regions receive on average more solar radiation than do regions toward the poles.
- Hadley cells create bands of wet and dry habitats, and the tilt of Earth's axis causes seasonality in the amount of sunlight that nonequatorial regions receive.
- The presence of mountains can create local areas of wet or dry habitats, and proximity to an ocean moderates temperatures in nearby terrestrial habitats.

✔ **You should be able to explain how climate would be expected to vary around the Earth if the planet were cylindrical and spun on an axis that was at a right angle to the Sun.**

52.4 Types of Terrestrial Biomes

- Terrestrial biomes are defined by climatic regimes and distinct types of terrestrial vegetation.
- The major terrestrial biomes include tropical wet forest, subtropical desert, temperate grassland, temperate forest, boreal forest, and arctic tundra.
- Because photosynthesis is most efficient when temperatures are warm and water supplies are ample, the productivity and degree of seasonality in biomes varies with temperature and moisture.
- Humans are changing the terrestrial landscape, creating new anthropogenic biomes—such as cities, suburbs, farms, and ranchlands—in place of natural biomes.
- Global climate change is causing temperature profiles and precipitation patterns to change in ecosystems around the planet.

✔ **You should be able to predict how global climate change may affect terrestrial biomes due to increased transpiration from plants.**

52.5 Types of Aquatic Biomes

- Salinity, water depth, water flow, and nutrient availability are key factors determining types of aquatic biomes.
- Aquatic biomes include lakes and ponds, wetlands, streams, estuaries, and oceans.
- Humans are affecting aquatic biomes by physically altering them (such as by damming a river), by changing their chemistry (such as by polluting and causing ocean acidification), and by changing species compositions (such as by introducing invasive species).

✔ **You should be able to explain why the open ocean is similar to the desert, and why it is not.**

TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. Name the five main levels of study in ecology.
2. Why are certain exotic species considered "invasive"?
   a. They are found in areas where they are not native.
   b. They were introduced by humans—often accidentally.
   c. They spread aggressively and displace native species.
   d. They benefit from being in a new environment.
3. Where do rain shadows exist?
   a. the part of a mountain that receives prevailing winds and heavy rain
   b. the region beyond a mountain range that receives dry air masses
   c. the region along the equator where precipitation is abundant
   d. the region near 30° N and 30° S latitude that receives hot, dry air masses
4. What is the predominant type of vegetation in a tropical wet forest?
   a. shrubs and bunchgrasses
   b. herbs, grasses, and vines
   c. broad-leaved deciduous trees
   d. broad-leaved evergreen trees
5. What is one expected consequence of global climate change?
   a. Average rainfall will increase.
   b. Average rainfall will decrease.
   c. Variability in rainfall will increase.
   d. We cannot make predictions about future rainfall.
6. Typically, where are oxygen levels highest and nutrient levels lowest in a stream?
   a. near its source
   b. near its mouth, or end
   c. where it flows through a swamp or marsh
   d. where it forms an estuary

TEST YOUR UNDERSTANDING

Answers are available in Appendix A

7. Write questions about the ecology of humans that are relevant to each of the five levels of ecological study.
8. Explain how biotic and abiotic factors determine the distribution of invasive Argentine ants.
9. Why does the Australian Outback receive so little rainfall?
   a. The Australian Outback is in a rain shadow.
   b. A Hadley cell drops warm, dry air in this region.
   c. A Hadley cell pulls warm, moist air up from this region.
   d. The climate in Australia is moderated by the surrounding ocean.
10. Contrast the productivities of the intertidal, neritic, and oceanic zones of marine environments. Explain why large differences in productivity exist.
11. Compare and contrast the terrestrial biomes found at increasing elevation on a mountain with the biomes found at increasing latitude in Figure 52.9.
12. Compare the distribution of the natural terrestrial biomes of eastern North America with the distribution of anthropogenic biomes.

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A

13. Mars has an even more pronounced tilt than Earth does. Does Mars experience seasons? Why or why not?
   a. Yes, the tilt will cause seasons because the Northern and Southern Hemispheres will be tilted toward the Sun, then away, at different times of the year.
   b. Yes, because the tilt will cause the orbit of Mars to be closer to the Sun during part of the year.
   c. No, because the tilt of Mars does not affect the distance of its orbit from the Sun.
   d. No, because the tilt of Mars does not affect the average amount of solar radiation received.
14. Very similar reptile fossils have been discovered on the east coast of South America and the west coast of Africa. Pose a hypothesis to explain this distribution.
15. Scientists are concerned about the future of species that are adapted to high elevations. Do you think their concern is justified?
16. Scientists predict that global climate change will cause a greater increase in average temperature at higher latitudes than in the tropics. This seems like good news since most of the world's biodiversity occurs in the tropics. However, recent data suggest that a smaller temperature change in the tropics will cause a *larger* physiological response there than the larger temperature change will in organisms in temperate areas. Based on what you have learned in this chapter, pose a hypothesis to explain this result.

53 Behavioral Ecology

In this chapter you will learn that

Behavioral ecology integrates genetics, development, anatomy, physiology, evolution, and ecology

starting with

An introduction: Proximate and ultimate causation and cost–benefit analysis 53.1

then applying these to

- What should I eat? 53.2
- Who should I mate with? 53.3
- Where should I live? 53.4
- How should I communicate? 53.5
- When should I cooperate? 53.6

This male satin bowerbird is decorating his display area with objects of his preferred color: blue. A female will inspect the bower. She may mate with the male if she finds him, and the display, attractive enough.

To biologists, **behavior** is action—specifically, the response to a stimulus. Pond-dwelling bacteria swim toward drops of blood that fall into the water. Time-lapse movies of growing sunflowers document the steady movement of their flowering heads throughout the day, as they turn to face the shifting Sun. Filaments of the fungus *Arthrobotrys* form loops and then release a molecule that attracts roundworms. When a roundworm touches a loop, the fungal filaments swell—ensnaring the worm. The fungus then grows into the worm's body and digests it.

Among animals, action may be frequent and even spectacular. Peregrine falcons reach speeds of up to 320 km/hr (200 mph) when they dive in pursuit of ducks or other flying prey. Hognose snakes

BIG PICTURE

This chapter is part of the Big Picture. See how on pages 1196–1197.

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

go belly-up and feign death—mouths agape—when harassed by predators. Deep inside a hive, honeybees communicate about food sources by "dancing."

Ecology is the study of how organisms interact with their physical and biological environments; **behavioral ecology** is the study of how organisms respond to particular stimuli from their environments. What does an *Anolis* lizard do when it gets too hot? How does that same individual respond when a member of the same species approaches it? Or when a house cat approaches? You can see how behavior fits into the Big Picture of Ecology on pages 1196–1197.

Although all organisms respond in some way to signals from their environment, most behavioral research is performed on animals, especially vertebrates, arthropods, or mollusks. With their sophisticated nervous systems and skeletal–muscular systems, these animals can sense, process, and respond rapidly to a wide array of environmental stimuli.

53.1 An Introduction to Behavioral Ecology

Behavior is a particularly integrative field in biological science. While the primary focus of behavioral ecology is at the level of the organism (see Chapter 52 and The Big Picture of Doing Biology on pages 16–17), this field integrates levels from molecules up to ecosystems, depending on the question being asked. To understand why animals and other organisms do what they do, researchers have to ask questions about genetics, development, anatomy, physiology, evolution, and ecology.

To make sense of this diversity, it's helpful to recognize that behavioral ecologists ask questions and test hypotheses at two fundamental levels—proximate and ultimate. Let's first explore these levels and then consider different types of behaviors.

Proximate and Ultimate Causation

The eminent evolutionary biologist Ernst Mayr wrote an influential paper on "cause and effect in biology" in 1961. He made a clear distinction between two types of biological causation:

1. **Proximate** (or mechanistic) **causation** explains *how* actions occur in terms of the genetic, neurological, hormonal, and skeletal–muscular mechanisms involved. For example, does a neural or hormonal signal trigger an animal's courtship display? Does the display vary according to diet, photoperiod, temperature, or other factors?
2. **Ultimate** (or evolutionary) **causation** explains *why* actions occur—based on their evolutionary consequences and history. (Behavior is just like any other phenotype in that it can evolve by natural selection.) Is a particular behavior currently adaptive, meaning that it increases an individual's fitness—its ability to produce viable, fertile offspring? If so, how does the behavior help individuals to produce offspring in a particular environment?

It's important to recognize that efforts to explain behavior at the proximate and ultimate levels are complementary. To understand what an organism is doing, biologists want to know how the behavior happens and why.

To illustrate the proximate and ultimate levels of causation, consider the Argentine ant (*Linepithema humile*) (introduced in Chapter 52). These ants originated in Argentina but have been shipped inadvertently with fruits and other cargoes around the world. Argentine ants are the subject of intense research due to their extreme success as an invasive species.

Argentine Ant Behavior In their native South America, Argentine ants live in colonies and defend their feeding areas, or **territories,** by fighting with neighboring Argentine ants. However, in places where they have been introduced, such as southern California, Argentine ants from adjacent colonies are "friendly" to each other—workers and queens move freely from nest to nest, forming huge "supercolonies." But when the Argentine ants from supercolonies meet native ants, they are especially aggressive (**FIGURE 53.1**). What's going on?

Proximate Causes Ants identify each other by smelling waxy hydrocarbon "tags" on each other's exoskeletons. Biochemical research has shown that introduced Argentine ants accept most other members of their species as nest mates because they smell the same as nest mates. That is, they display the same scent tags.

Follow-up research suggests that the introduced ants smell similar because the genes that determine their scent tags are similar; unlike the Argentine ant populations in South America, there is little genetic variation for this trait among colonies in California. Thus the proximate cause for unusually friendly behavior among Argentine ants is the genetically determined scent signal that says "nest mate: don't fight." By contrast, the very unfamiliar scents from native ants signal "foreigner: attack!"

Ultimate Causes Why is genetic diversity in the supercolonies low? Argentine ants appear to have low genetic variation due to a genetic bottleneck that occurred when the first few ants were introduced to California (see Chapter 26 for a review of genetic bottlenecks).

FIGURE 53.1 Tiny Invasive Argentine Ants Attack a Native Ant.

This chance event happened to be adaptive. Since Argentine ants in supercolonies are not fighting to maintain their feeding territories, they have more time and energy available to produce offspring, thus increasing their fitness. The resulting high density of the supercolonies contributes to their invasiveness. A single, tiny Argentine ant is rarely successful in combat against a single, larger native ant. But when Argentine ants recruit help and fight in mobs, they are a powerful force.

Note, however, that low genetic diversity has its dangers (see Chapter 13). If the supercolony becomes exposed to a virulent pathogen or other environmental change, the entire colony may collapse—a possibility that humans are trying to exploit.

This example illustrates how behavioral ecologists work at the interface of many fields and at both proximate and ultimate levels to address *how* and *why* questions about organisms in their environments. Before considering some of the most prominent questions in behavioral ecology, let's take a closer look at types of behavior.

Types of Behavior: An Overview

Behavior encompasses a diverse array of responses to stimuli. To establish a framework to organize this diversity, let's explore both axes of the graph shown in **FIGURE 53.2**.

Behaviors Vary in Their Flexibility The horizontal axis of Figure 53.2 maps how flexible a behavior is in terms of its expression within and between individuals of the same species. This axis forms a continuum ranging from fixed, stereotyped behaviors to highly flexible, conditional behaviors.

Consider what happens to a kangaroo rat that is feeding at night and hears the sound of a rattlesnake's rattle. It jumps back—away from the direction of the stimulus. The jump-back behavior is performed the same way every time. Highly inflexible, stereotyped behavior patterns like a kangaroo rat's jump-back behavior are called **fixed action patterns,** or **FAPs.** In humans, yawns and sneezes are familiar FAPs.

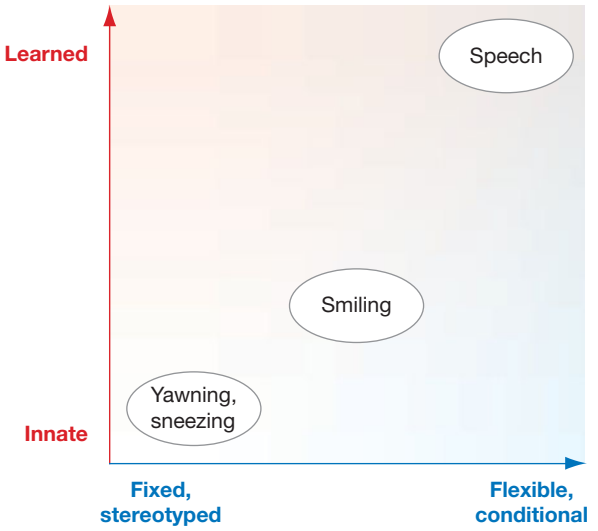

FIGURE 53.2 Behavioral Traits Vary in Flexibility and Dependence on Learning. These two axes represent one way to organize the diversity of behavioral traits. Three human behaviors are mapped as examples.

At the other end of this axis, behaviors show a great deal of flexibility in response to environmental conditions. For example, human speech is highly flexible and dependent upon factors ranging from inherited sound-making ability to upbringing, education, emotional state, circumstance, and so on. Most behaviors lie between these two extremes of inflexibility and flexibility.

Behaviors Vary in the Extent to Which They Are Learned The vertical axis of Figure 53.2 plots how much learning is involved in the nature of the behavioral response.

Behaviors that require no learning are said to be innate. **Innate behavior** is inherited—meaning that it is passed genetically from parents to offspring. FAPs are examples of innate behaviors because they are "hardwired"—the jump-back behavior of kangaroo rats and your ability to sneeze are not learned.

When the pioneering behavioral researchers Konrad Lorenz, Niko Tinbergen, and Karl von Frisch first began to explore animal behavior experimentally, they focused on these types of inflexible, innate actions—such as the way goose chicks imprint on their mother and follow her around. This research strategy is common in biological science. If you are addressing a new question—whether it's how DNA is transcribed or how ions cross plasma membranes—it's helpful to start by studying the simplest possible system. Once simple systems are understood, investigators can delve into more complex situations and questions. Lorenz, Tinbergen, and von Frisch won a joint Nobel Prize in 1973 for their behavioral work.

At the other end of the continuum from innate behavior is **learning,** an enduring change in behavior that results from a specific experience in an individual's life. Behaviorist B. F. Skinner is famous for his experiments with rats and mice showing that their behaviors are subject to conditioning. For example, a rat can be trained to pull a lever if food is released as a reward.

The examples plotted in Figure 53.2 indicate that there is a general tendency for innate behaviors to be more fixed and for learned behaviors to be more flexible. For example, in humans, yawning is a relatively fixed, innate behavior while speech is flexible and highly dependent upon learning.

Flexible, Learned Behaviors Often Involve Choice Most animals have a range of actions that they can perform in response to a situation. Animals take in information from the environment and, based on that information, make decisions about what to do. Animals make choices.

To link condition-dependent behavior to fitness—and thus the ultimate level of explanation—biologists use a framework called **cost–benefit analysis.** Animals appear to weigh the costs and benefits of responding to a particular situation in various ways. Costs and benefits are measured in terms of their impact on fitness—the ability to produce viable, fertile offspring.

Note the phrase "appear to weigh" in the previous paragraph. The decisions made by nonhuman organisms are not—as far as is

known—conscious. An Argentine ant does not identify another ant by smell and then consider the pros and cons of reacting as friend or foe. Instead, evolution has shaped the ant's genome to direct a nervous and endocrine system that is capable of **(1)** taking in information and **(2)** directing behavior that is likely to pass that genome on to the next generation.

Five Questions in Behavioral Ecology

The following five sections of this chapter introduce some of the most prominent questions in behavioral ecology. In each case, the question is posed as a decision that an animal has to make. The ensuing discussion is divided into research on how the question has been answered at the proximate level and at the ultimate level.

The goals of this chapter are to explore some key topics in behavioral ecology and illustrate the spirit and synthetic nature of the field. Let's begin with an introduction to research on a resource that every animal has to find in its environment: food.

53.2 What Should I Eat?

When animals seek food, they are **foraging.** In some cases, the food source that a species exploits is extremely limited. Giant pandas, for example, subsist almost entirely on the shoots and leaves of bamboo. But individuals must still make decisions about which bamboo plants to harvest and which parts of a particular plant to eat and which to ignore.

In most cases, animals have a relatively wide range of foods that they exploit over the course of their lifetime. To understand why individuals eat the way they do, let's consider **(1)** research on genetic variation in foraging behavior and **(2)** the concept of optimal foraging.

Proximate Causes: Foraging Alleles in *Drosophila melanogaster*

When Marla Sokolowski was working as an undergraduate research assistant, she noticed that some of the fruit fly larvae she was studying tended to move after feeding at a particular location, while others tended to stay put. She reared these "rovers" and "sitters" to adulthood, bred them, and found that the offspring of rovers also tended to be rovers, while offspring of sitters tended to be sitters (**FIGURE 53.3**). Thus, this aspect of behavior is inherited. In fruit flies, variation in larval foraging behavior is at least partly due to genetic variation among individuals.

Using information from the *Drosophila melanogaster* genome sequence (see Chapter 21 and BioSkills 13 in Appendix B) and genetic mapping techniques (Chapter 20), Sokolowski found and cloned a gene associated with the rover–sitter difference. She named it *foraging* (*for*).

Follow-up work showed that the protein product of the *for* gene involved in a signal transduction cascade (see Chapters 11 and 49)—meaning it is involved in the response to a cell–cell

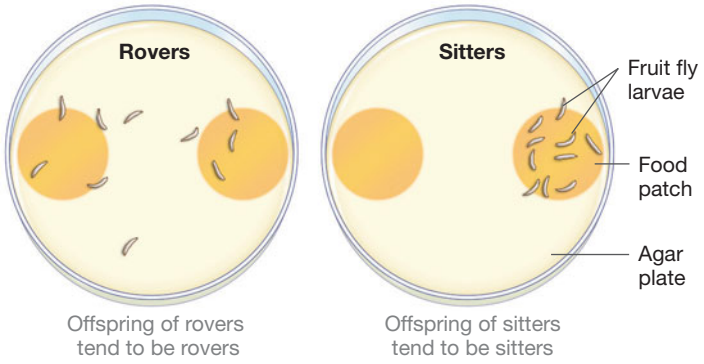

FIGURE 53.3 Foraging Behavior in Fruit Fly Larvae Is Heritable.

signal. Rovers and sitters tend to behave differently when they are foraging because they have different alleles of the *for* gene.

Genes that are homologous to *for* have now been found in honeybees and the roundworm *Caenorhabditis elegans*. Currently, researchers are focused on finding out which signaling pathway uses the *for* gene product and how different alleles change feeding behavior. Presumably, the signaling pathway is associated with feeding or nervous system development. When this aspect of fly feeding is thoroughly understood at the proximate level, biologists will know why variants of the same protein make larvae more likely to move or stay in place after feeding.

Ultimate Causes: Optimal Foraging

By altering population density experimentally and documenting the reproductive success of rovers and sitters, Sokolowski has shown that the rover allele in fruit fly larvae is favored when population density is high and food is in short supply. In contrast, the sitter allele reaches high frequency in low-density populations, where food is abundant. Rovers do better at high density because they are more likely to find unused patches of food; sitters do better at low density because they don't waste energy moving around.

These results are exciting because they link a proximate mechanism with an ultimate outcome. In this case, the presence of certain alleles is responsible for a difference in fitness in specific types of habitats.

In *Drosophila* larvae, foraging is a relatively inflexible and innate behavior—individuals don't "decide" to be rovers or sitters. It is the variability of food supplies that maintains both alleles in the population. But in *Drosophila* adults and in most animal species, foraging behavior is much more flexible and dependent upon learning.

Introduction to Optimal Foraging When biologists set out to study why animals forage in a particular way, they usually start by assuming that individuals make decisions that maximize the amount of usable energy they take in, given the costs of finding and ingesting their food and the risk of being eaten while they're at it. This hypothesis—that animals maximize their feeding efficiency—is called **optimal foraging.**

The specific costs and benefits of foraging depend on the feeding strategy and the environmental conditions of the organism. Different animals have different types of choices and thus different variables subject to optimization. For example:

- Antarctic fur seals forage by diving for small shrimp-like krill. They optimize their foraging by adjusting the duration and location of each dive depending on the depth and density of patches of krill.
- Shorebirds called oystercatchers feed on a variety of prey, including clams, which they have to open to eat. They optimize their foraging by selecting clams of intermediate size. The small clams provide less energy than the large clams, but opening the large clams can take more time and effort, and it can damage the birds' bills.

How do biologists test the optimal foraging hypothesis?

A Test of Optimal Foraging in Desert Gerbils Consider one example from the long-term study of optimal foraging in gerbils. Behavioral ecologists Zvika Abramsky, Michael Rosenzweig, and Aziz Subach posed an interesting question: Do gerbils "weigh" the costs and benefits of foraging? More specifically, if the presence of predators *decreases* the amount of time gerbils spend foraging, and the presence of extra food *increases* foraging time, how much extra food will offset the risk of predation?

To answer this question, Abramsky and his team set up an experiment using two replicate 2-hectare plots in the natural habitat of the gerbil *Gerbillus allenbyi* in the Negev Desert of Israel (**FIGURE 53.4**). Each of these plots had two subplots: a control half and a treatment half, with portals in the fencing to allow gerbils to switch sides. Abramsky started by removing all the gerbils from the plots, setting up seed stations to control the amount of supplementary food that would be available, and setting up sampling stations to measure gerbil track density (number of tracks per given area) during each trial. Earlier research had shown that gerbil track density served as a reliable indicator of the time gerbils spent foraging.

Abramsky and his team then introduced 34 gerbils into each subplot and conducted the following three treatments, replicating their experiments on three different nights:

1. No extra predation risk or seeds in treatment subplots.
2. Increased predation risk—captive barn owls were trained to fly over the treatment subplots three times per hour during the two-hour trials.
3. Increased predation risk plus increased seed availability—varying quantities of supplementary seeds were offered to the treatment subplots during different trials.

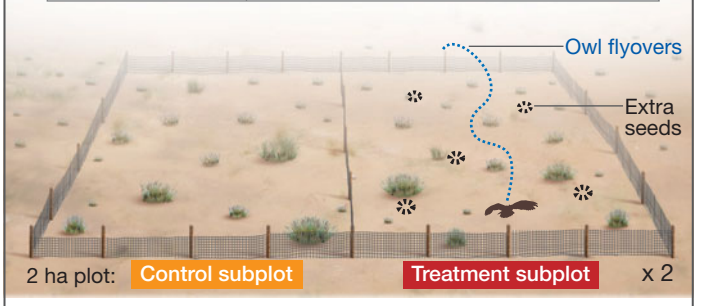
What did they find out? The graph at the bottom of Figure 53.4 shows that foraging activity in control and treatment subplots was the same in the absence of owls and extra seed. But when owls were flown over treatment subplots, foraging activity declined dramatically—and some gerbils fled through portals into the control subplots, increasing foraging activity there.

RESEARCH

QUESTION: Do gerbils "weigh" the costs and benefits of foraging?

HYPOTHESIS: Gerbils reconcile the risk of predation and the benefits of extra food availability.

NULL HYPOTHESIS: Foraging activity is independent of predation and food availability.

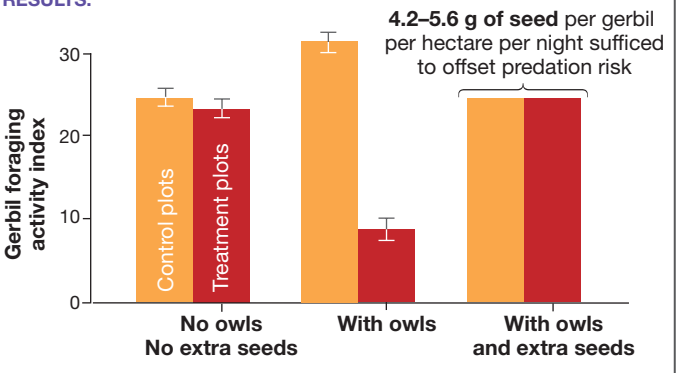


EXPERIMENTAL SETUP:

1. Start with 34 gerbils in each 1-hectare desert subplot in the Negev Desert of Israel.

2. Use the density of gerbil tracks in sampling stations as an index of foraging activity in control versus treatment subplots where:

Treatment 1	Treatment 2	Treatment 3
No owl fly-overs No extra seeds	Owl flyovers No extra seeds	Owl flyovers Extra seeds of varying quantities



3. Replicate experiment on three different nights.

PREDICTION: A certain amount of added seeds will compensate for the decrease in foraging activity due to predation risk.

PREDICTION OF NULL HYPOTHESIS: Gerbil foraging activity will be independent of the presence of owls, extra seeds, or both.

RESULTS:

CONCLUSION: Gerbils weigh the relative risk of predation and benefits of extra seeds when they forage.

FIGURE 53.4 Optimal Foraging in Desert Gerbils

SOURCE: Abramsky, Z., M. L. Rosenzweig, and A. Subach. 2002. The costs of apprehensive foraging. *Ecology* 85: 1330–1340.

✔**QUESTION** Why did the researchers measure foraging activity in the treatment plot before adding owls or seeds?

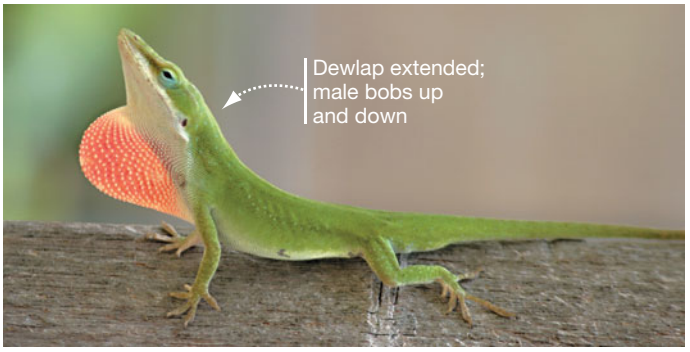
The researchers also observed a direct relationship between the gerbils' foraging activity and the amount of supplementary seed offered, even with owl flyovers. It turns out that 5 grams of supplementary seeds per individual per hectare per night was sufficient to compensate for the extra risk of predation—that is, to eliminate the difference in foraging between control and treatment subplots. This study was insightful because it enabled predation risk to be measured in energetic terms.

The logic behind optimal foraging is that animals that maximize their feeding efficiency will have more time and energy available for reproduction—thus higher fitness. Animals that forage optimally are expected to be favored by natural selection—thus pass on their heritable behavior patterns to the next generation.

check your understanding

C Y U

If you understand that . . .



- Feeding behavior can be explored at both proximate and ultimate levels.
- Optimal foraging minimizes fitness costs and maximizes fitness benefits.

✔ You should be able to . . .

Predict how the results of the gerbil foraging experiment would change if the owls were permitted to *hunt* in the treatment subplots rather than just flying over, and pose a proximate explanation for the change.

Answers are available in Appendix A.

(a) Display behavior of a male *Anolis* lizard

(b) Changes in sexual organs through the year

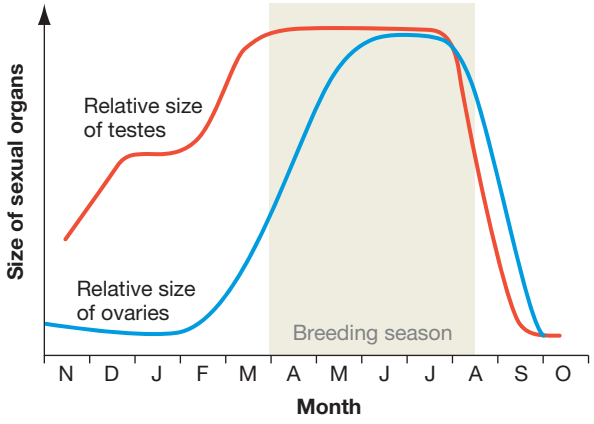


FIGURE 53.5 Sexual Behavior in *Anolis* Lizards Is Seasonal.
DATA: Crews, D. 1975. *Science* 189: 1059–1065.

53.3 Who Should I Mate With?

Biologists sometimes claim that almost all animal behavior revolves around food or sex. Section 53.2 focused on food; here the subject is sex. Let's start by considering the proximate mechanisms responsible for triggering sexual activity in lizards and then go on to explore the ultimate question of why animals choose their mates.

Proximate Causes: How Is Sexual Activity Triggered in *Anolis* Lizards?

Anolis carolinensis lives in the woodlands of the southeastern United States. After spending the winter under a log or rock, males emerge in January and establish feeding and breeding territories (**FIGURE 53.5a**). Females become active a month later, and the breeding season begins in April. By May, females are laying an egg every 10–14 days. By the time the breeding season is complete three months later, the eggs produced by a female will total twice her body mass.

FIGURE 53.5b graphs how sexual condition changes throughout the year, by plotting the size of the testes in males and ovaries of females—relative to an individual's overall body size. Individuals come into breeding condition in spring, although males experience growth of gonads long before females do. In both sexes, the gonads shrink in size during the fall and winter.

Testosterone and Estradiol What causes the onset of sexual behavior? The proximate answer is sex hormones—testosterone in males and estradiol in females. Testosterone is produced in the testes of males, and estradiol in the ovaries of females (see Chapter 50). The evidence for the effects of sex hormones is direct. Testosterone injections induce courtship activity in castrated males with no prior courtship activity; estradiol injections induce sexual activity in females whose ovaries have been removed.

But a full proximate explanation must also consider environmental and social cues. What environmental cues trigger the production of sex hormones in early spring? How do male and female *Anolis* lizards synchronize their sexual readiness?

Testing the Effects of Light and Social Stimulation To answer these questions, behavioral ecologist David Crews brought a large group of sexually inactive adult lizards into the laboratory during the winter and divided them into five treatment groups. The physical environment was exactly the same in all treatments.

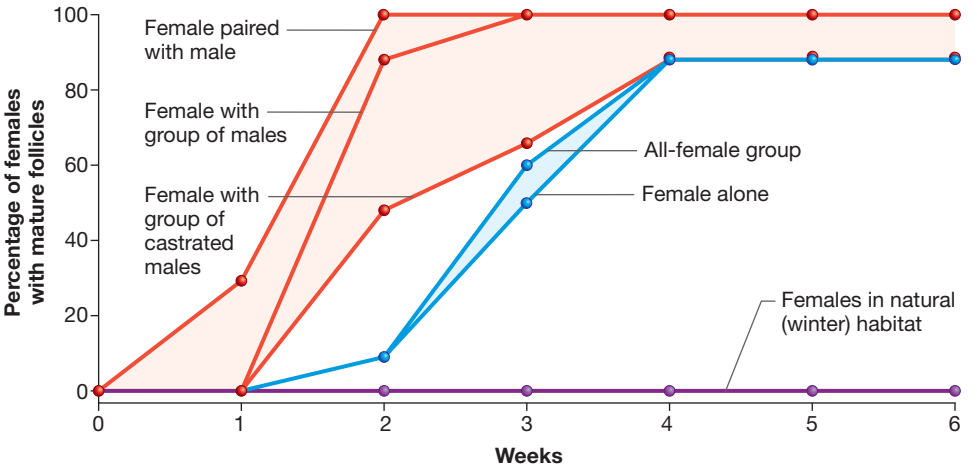

FIGURE 53.6 Exposure to Springlike Conditions and Breeding Males Stimulates Female Lizards to Produce Eggs. The percentage of female lizards with mature follicles, plotted over time. Five treatment groups were exposed to springlike light and temperature in the lab; data are also plotted for females left in a natural (winter) habitat. Each data point represents the average value for a group of 6–10 females.

DATA: Crews, D. 1975. *Science* 189: 1059–1065.

✔**QUESTION** Some critics contend that the females that remained outside do not represent a legitimate control in this experiment. What conditions would represent a better control?

Each lizard received identical food, high "daytime" temperatures, and slightly lower "nighttime" temperatures. Crews also continued to monitor the condition of lizards that remained in natural habitats nearby.

To test the hypothesis that changes in day length signal the arrival of spring and trigger initial changes in sex hormones, Crews exposed the five treatment groups in the laboratory to artificial lighting that simulated the long days and short nights of spring.

To test the hypothesis that social interactions among individuals are re sponsible for synchronizing sexual behavior, he varied the social setting among the five treatment groups:

1. a single isolated female;
2. a group of females;
3. a single female with a single male;
4. a single female with a group of castrated (nonbreeding) males; and
5. a single female with a group of uncastrated (breeding) males.

Each week, Crews examined the ovaries of females in each treatment. He also monitored the ovaries of females in nearby natural habitats under winter conditions.

As **FIGURE 53.6** shows, the differences in the animals' reproductive systems were dramatic. The data points on this graph represent the average percentage of females with mature ovarian follicles, in each treatment; the points are connected by lines to help you keep track of the different treatments and see the overall patterns. Note two key points:

1. Females that were exposed to springlike conditions began producing eggs; females in the field that were not exposed to springlike conditions did not.
2. Females that were exposed to breeding males began producing eggs much earlier than did the females placed in the other treatment groups.

These results support the hypothesis that two types of stimulation are necessary to produce the hormonal changes that lead to sexual behavior. Females need to experience springlike light and temperatures *and* exposure to breeding males.

Visual Cues from Males Trigger Female Readiness

What is it about breeding males that triggers earlier estradiol release and egg production in females?

When males court females, they bob up and down in push-up fashion and extend a brightly colored patch of skin called a dewlap (see Figure 53.5a). To test the hypothesis that this visual stimulation triggers changes in estradiol production, Crews repeated the previous experiment but added a twist: He placed some females with males that had intact dewlaps, and other females with males whose dewlaps had been surgically removed.

The result? Females that were living with dewlap-less males were slow to produce eggs. They were just as slow, in fact, as the females in the first experiment that had been grouped with castrated males. These latter females had not been courted at all.

These data suggest that the dewlap is a key visual signal. The experiments succeeded in identifying the environmental cues—long day length and bobbing dewlaps—that trigger hormone production and the onset of sexual behavior.

Ultimate Causes: Sexual Selection

Why are environmental cues and bobbing dewlaps important to mating lizards? One reason is that lizards that succeed in synchronizing their sexual readiness will likely bear more offspring and have higher fitness than those that do not. *Anolis* lizards are most successful if they reproduce early in the spring when food supplies are increasing but snakes and other predators are not yet hunting to feed their own young. Failing to synchronize their sex or having sex too late would be disastrous for the *Anolis* lizards.

Also, bobbing dewlaps serve as an important signal in mate choice. A specific pattern of selection called **sexual selection** favors individuals possessing traits that increase their ability to obtain mates (introduced in Chapter 26). According to theory and experimental data:

- Females are usually the gender that is pickiest about mate choice because females spend a disproportionate amount of energy on their gametes compared to males.
- Females choose males that contribute good alleles and/or resources to their offspring.

Research on bird species such as zebra finches (see Chapter 26) has shown that individuals with particularly long tails, bright colors, and energetic courtship displays are usually the healthiest and best fed in the population. Because it takes large amounts of energy and resources to produce traits like these, they serve as an honest signal of male quality.

Are bright dewlaps honest signals of male quality? So far, the brightness of lizard dewlaps does not appear correlated with the nutritional health of the lizards. However, lizards with enlarged dewlaps tend to have high bite forces, which are important in fighting with other males to defend their feeding and breeding territories. Males are known to defend their territories fiercely, sometimes with costly consequences. The bobbing dewlap territorial displays serve as honest signals of physical vigor that can help to avert actual confrontation.

There are two types of sexual selection. When females choose males, intersexual ("between-sexes") selection is said to occur. When males compete with one another for mates, intrasexual ("within-sexes") selection is taking place (see Chapter 26). The data on *Anolis* lizards so far suggest that even though female sexual readiness is triggered by male displays, male competition for territories is the main factor determining mate choice.

Data on mate choice in *Anolis* lizards reinforce a central theme of this chapter: Animals usually make decisions in a way that maximizes their fitness.

If you understand that . . .

- The proximate causes of sexual readiness include hormonal, environmental, and social cues.
- At the ultimate level, animals use physical and behavioral cues to choose mates that will increase their fitness.

✓ You should be able to . . .

1. Propose one proximate cause of human sexual readiness that is similar to that in *Anolis* lizards.
2. Propose one ultimate cause of human mate choice that is similar to that in *Anolis* lizards.

Answers are available in Appendix A.

53.4 Where Should I Live?

Most animals select the food they eat and the individuals they mate with. In most cases, they also select the habitat where they live. Biologists have explored an array of questions related to habitat selection:

- Should juveniles disperse from the area where they were raised, or should they stay?
- How large an area should be defended against competitors in species that maintain a territory for breeding or feeding, as in *Anolis* lizards?
- Do individuals have higher fitness when they occupy crowded, high-quality habitats or uncrowded, poor-quality habitats?

Let's take a closer look at one of these "lifestyle" decisions: the proximate and ultimate mechanisms responsible for migration. In ecology, **migration** is defined as the long-distance movement of a population associated with a change of seasons. At the proximate level, how do animals know where to go between one seasonal "home" and another? At the ultimate level, what are the fitness benefits of having more than one home range that could overcome the costs of long-distance migrations?

Proximate Causes: How Do Animals Navigate?

To organize research into how animals find their way during migratory movements, biologists distinguish three categories of navigation:

1. **Piloting** is the use of familiar landmarks.
2. **Compass orientation** is movement that is oriented in a specific direction.
3. **True navigation (map orientation)** is the ability to locate a specific place on Earth's surface.

Imagine that you asked someone to blindfold you, drive you to a remote area 100 miles from home, and drop you off by the side of the road without your cell phone. After removing your blindfold, how would you find your way home? Which type of navigation would you use?

Piloting If you were lucky, you might recognize some landmarks and remember from a previous experience how to return home. The offspring of some migratory birds and mammals navigate in a similar way. They memorize the route when following their parents one or more times—south in the fall and north in the spring—and later are able to pilot the route on their own.

Compass Orientation If you were dropped off on the side of the road and did not recognize any specific landmarks, which way would you start walking? If you had a compass and knew which direction to head, that would be a big help. Once you got closer to home and found a familiar landmark, you could pilot the rest of the way home.

How do animals perform compass orientation? To date, most research on compass orientation has been done on migratory birds, such as European robins. To determine where north is, these animals appear to use the Sun, the stars, and Earth's magnetic field.

The Sun is difficult to use as a compass reference because its position changes during the day. It rises in the east, is due south at noon (in the Northern Hemisphere), and sets in the west. To use the Sun as a compass reference, then, an animal must have an internal clock that defines morning, noon, and evening. Fortunately, most animals have such a clock. The **circadian clock**

that exists in organisms maintains a 24-hour rhythm of chemical activity. The clock is set by the light–dark transitions of day and night. It tells individuals enough about the time of day that they can use the Sun's position to find magnetic north.

The situation is actually simpler on clear nights because migratory birds in the Northern Hemisphere can use the North Star to find magnetic north and select a direction for migration. But what if the weather is cloudy?

Under these conditions, migratory birds appear to orient using Earth's magnetic field. There are two main hypotheses for how animals detect magnetism. One hypothesis contends that animals can detect magnetism by their visual system, through a chemical reaction that involves electron transfer among molecules. An alternative hypothesis maintains that individuals have small particles of magnetic iron—the mineral called magnetite—in their bodies, such as in the upper beaks of birds. Changes in the positions of magnetic particles, in response to Earth's magnetic field, could then be detected and provide reliable information for compass orientation. So far, the data suggest that birds may be capable of both mechanisms.

Although research on mechanisms of compass orientation continues, one important point is clear: Birds and other organisms have multiple mechanisms of finding a compass direction. At least some species can use a Sun compass, a star compass, and a magnetic compass. Which system an individual uses depends on the weather and other circumstances.

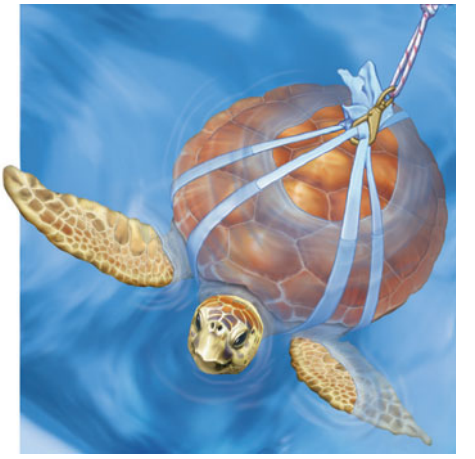
True Navigation (Map Orientation) If you were dropped off on the side of the road with a compass *and a map* of your location, finding your way home would be easy.

Do animals have the equivalent of map orientation? Neurobiologist and ecologist Kenneth Lohmann and his colleagues tested this question in green sea turtles. Sea turtles have the remarkable ability to travel around vast areas of the ocean and then return to a specific coastal nesting or feeding site with pinpoint accuracy. How do they do it?

The Earth's magnetic field varies around its surface in predictable gradients of both intensity and angle, or inclination. Lohmann's hypothesis was that the turtles use this magnetic field as a source of precise positional information, much like we use latitude and longitude coordinates to locate ourselves on a map.

To test this hypothesis, Lohmann captured green sea turtles at their coastal feeding grounds in Melbourne Beach, Florida, fitted them with soft harnesses attached to a tracking device, and then let them swim one at a time in a circular pool (**FIGURE 53.7**). A coil system around the pool was used to change the magnetic field to replicate the magnetic signature of locations to the north and south of Melbourne Beach.

The data at the bottom of Figure 53.7 show how the turtles responded. Each dot represents the average swimming direction for one turtle. The arrow represents the average for the whole group of turtles. When the magnetic field in the pool simulated a location 337 km north of Melbourne Beach, the turtles swam south, the direction of "home." When the magnetic field in the pool simulated a location 337 km south of Melbourne Beach, the



RESEARCH

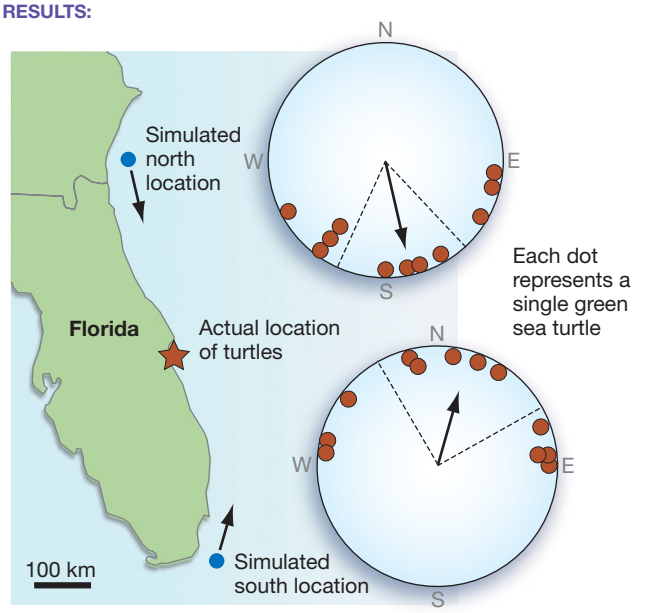
QUESTION: How do sea turtles find their way?

HYPOTHESIS: Green sea turtles use magnetic map orientation to navigate.

NULL HYPOTHESIS: Green sea turtles use compass orientation and piloting to navigate.

EXPERIMENTAL SETUP:

1. Capture green sea turtles in Melbourne Beach, Florida.



2. Place turtles in soft cloth harnesses attached to electronic tracking device in a swimming arena.

3. Monitor direction of swimming in different magnetic fields simulating locations to the north and south of Melbourne Beach.

PREDICTION: Sea turtles will swim south in a simulated north location, and swim north in a simulated south location.

PREDICTION OF NULL HYPOTHESIS: Sea turtles will swim in random directions with respect to the two simulated locations.

RESULTS:

CONCLUSION: Green sea turtles use magnetic map orientation to navigate.

✔**QUESTION** Sketch what the data for the two sites would have to look like to reject Lohmann's hypothesis.

turtles swam north. Note that the direction of magnetic north did not change in either case, so compass orientation alone could not account for the ability of the turtles to navigate. Rather, the turtles were able to locate themselves on the map—they possess map orientation.

Ultimate Causes: Why Do Animals Migrate?

Why do some animals have more than one home range? Migratory movements can be spectacular in their extent and in the navigation challenges they pose:

- Arctic terns nest during summer in tundra in the far north. One population flies south along the coast of Africa to wintering grounds off Antarctica and then flies back north along the eastern coast of South America (**FIGURE 53.8**). Chicks follow their parents south but make the return trip on their own. The journey totals over 32,000 km (20,000 miles).
- Many of the monarch butterflies native to North America spend the winter in the mountains of central Mexico or southwest California. Tagged individuals are known to have flown over 3000 km (1870 miles) to get to a wintering area. In spring, monarchs begin the return trip north. They do not live to complete the trip, however. Instead, mating takes place along the way, and females lay eggs en route. Although adults die on the journey, offspring continue to head north. After several generational cycles of reproduction and death in the original habitats in northern North America, individuals again migrate south to overwinter. Instead of a single generation making the entire migratory cycle, then, the round trip takes several generations.
- Salmon that hatch in rivers along the Pacific Coast of North America and northern Asia migrate to the ocean when they are a few months to several years old, depending on the species. After spending several years feeding and growing in the North Pacific Ocean, they return to the stream where they hatched. There they mate and die (see Chapter 52).

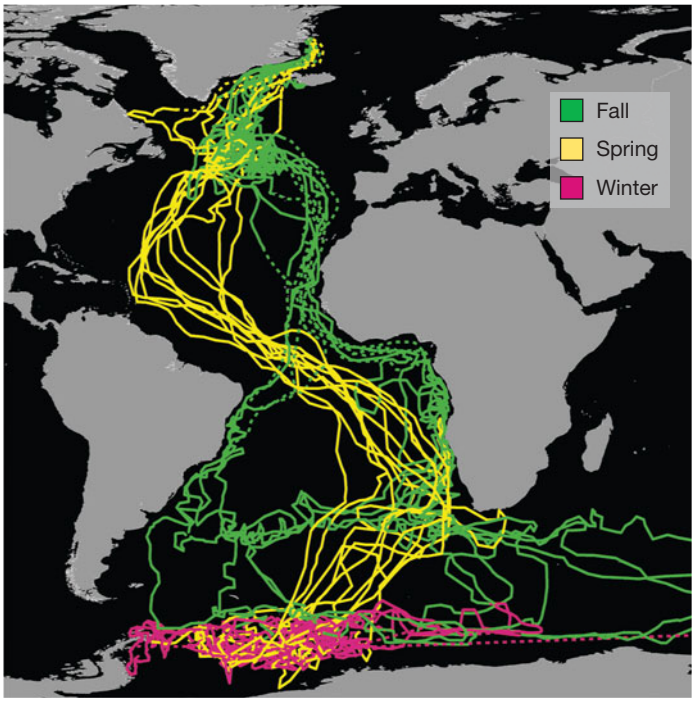

FIGURE 53.8 Arctic Terns Have Spectacular Migrations. The map shows the pathway of 11 arctic terns for a year based on data collected using tiny geolocators.

In most cases, at the ultimate level it is relatively straightforward to generate hypotheses explaining why migration exists.

- Arctic terns feed on fish that are available in different parts of the world at different seasons. Thus, individuals that do not migrate might starve; individuals that do migrate should achieve higher reproductive success.
- Monarch butterflies may achieve higher reproductive success by migrating to wintering areas and new breeding areas than by trying to overwinter in northern North America.
- Salmon eggs and young are safer and thrive better in freshwater habitats than they do in the ocean. But adult salmon can find much more food in saltwater habitats than in freshwater and thus grow to bigger size, which confers a benefit in competition for nest sites and mates.

Testing these hypotheses rigorously is more difficult because researchers must compare the fitness of individuals that do and do not migrate. Recently, however, researchers have documented the evolution of sockeye salmon populations that do not migrate to the ocean—in watersheds where migratory sockeye were introduced by humans. The nonmigratory populations are much smaller bodied than the migratory populations—presumably because less food is available in the freshwater habitats.

The fitness of migrant and nonmigrant sockeye salmon appears to be similar in this case, due to fitness trade-offs (see Chapter 25). The larger-bodied migratory salmon are more successful in competing for nesting sites and mates. However, the migratory salmon also experience higher costs in terms of time, energy, and predation risk.

At the ultimate level, researchers are also struggling to understand how a nonmigratory population can evolve into a migratory one that travels to a completely different part of the world. It's likely that habitat changes occurring in response to global climate change (see Chapter 56) will furnish an example. Changes in the range and arrival times of migratory species have already been documented; it may be only a matter of time before a nonmigratory population begins to migrate, to cope with habitat shifts caused by global climate change.

53.5 How Should I Communicate?

The song of a bird, the bobbing dewlap of a male lizard, and the sentences in this text all have the same overall goal: communication. In biology, **communication** is defined as any process

in which a signal from one individual modifies the behavior of a recipient individual. A **signal** is any information-containing behavior or characteristic. Communication is a crucial component of animal behavior. It creates a stimulus that elicits a response.

By definition, communication is a social process. For communication to occur, it is not enough that a signal is sent; the signal must be received and acted on. How does this process play out in honeybees?

Proximate Causes: How Do Honeybees Communicate?

Honeybees are highly social animals that live in hives. Inside the hive, a queen lays eggs that are cared for by workers. Besides caring for young and building and maintaining the hive, workers obtain food for themselves and other members of the colony by gathering nectar and pollen from flowering plants.

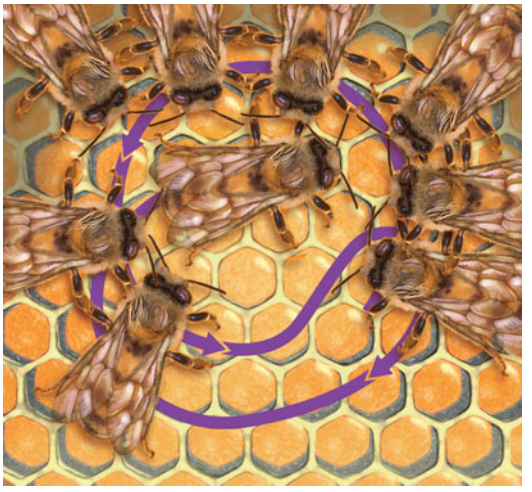
Biologists noticed that bees appear to recruit to food sources, meaning that if a new source is discovered by one or a few individuals, many more bees begin showing up over time. This observation inspired the hypothesis that food-finders have some way of communicating the location of food to others. How do bees "talk" to each other?

The Dance Hypothesis In the 1930s Karl von Frisch began studying bee communication by observing bees that built hives inside the glass-walled chambers he had constructed. He found that if he placed a feeder containing sugar water near one of these observation hives, a few of the workers began moving in a circular pattern on the vertical, interior walls of the hive.

Von Frisch called these movements the "round dance" (**FIGURE 53.9a**). Other workers appeared to follow the progress of the dance, first by touching the displaying bee as it danced and then by flying away from the hive in search of the food source.

To investigate the function of these movements further, von Frisch placed feeders containing sugar water at progressively greater distances from the hive. Using this technique, he was able to get bees to visit feeders at a distance of several kilometers from the hive. By catching bees at the feeders and dabbing them with paint, he could individually mark successful food-finders. Follow-up observations at the hive confirmed that marked foragers **(1)** danced when they returned to the hive, and **(2)** returned to the food source with unmarked bees.

To explain these data, von Frisch proposed that the round dance contained information about the location of food. Because bee hives are completely dark, he hypothesized that workers got information from the dance by touching the dancer and following the dancer's movements.



Communicating Directions and Distances When von Frisch began placing feeders at longer distances from the hive, he found that successful food-finders used a new type of display. He named these movements the "waggle dance," because they combined circular movements like those of the round dance with short, straight runs (**FIGURE 53.9b**). During these runs, the dancer vigorously moved her abdomen from side to side.

These observations supported the hypothesis that both the round dance and waggle dance communicate information about food sources. Recent work has shown that the round and waggle dances are actually the same type of behavior—round dances just have a short waggle phase.

Three key observations allowed von Frisch to push our understanding of bee language further:

1. The orientation of the waggle part of the dance varied.
2. The direction of the waggle run correlated with the direction of the food source from the hive.
3. The length of the straight, "waggling" run was proportional to the distance the foragers had to fly to reach the feeder.

(a) The round dance

(b) The waggle dance

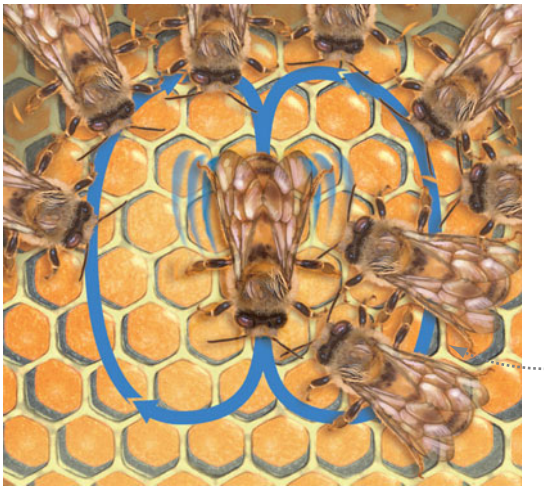


FIGURE 53.9 Honeybees Perform Two Types of Dances. (a) During the round dance, successful food-finders move in a circle. **(b)** During the waggle dance, successful foragers move in a circle but then make straight runs through the circle. During the straight part of the dance, the dancer waggles her abdomen.

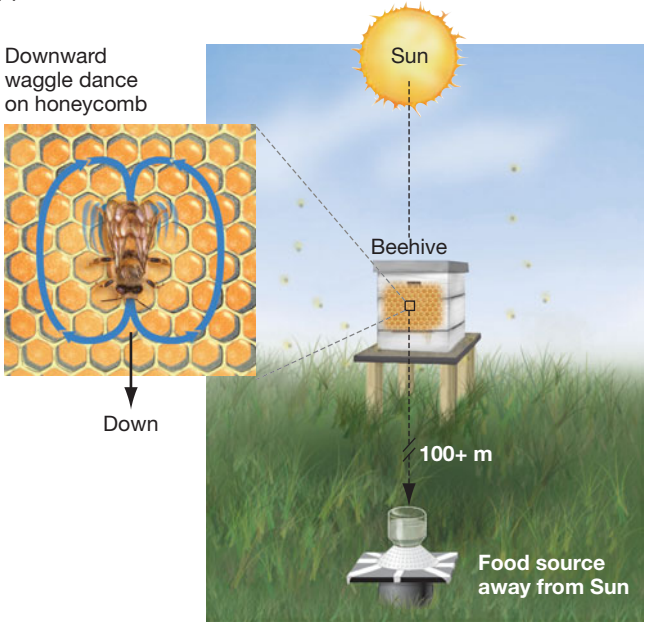
By varying the location of the food source and observing the orientation of the waggle dance given by marked workers, von Frisch was able to confirm that dancing bees were communicating the position of the food relative to the current position of the Sun. For example:

- If food is directly away from the Sun's current position, marked bees do the waggle portion of their dance directly downward (**FIGURE 53.10a**).
- If the food is 90 degrees to the right of the Sun, marked bees waggle 90 degrees to the right of vertical (**FIGURE 53.10b**).

These results are nothing short of astonishing. Honeybees do not have large brains, yet they are capable of symbolic language. What's more, they are able to interpret the angle of the waggle dance performed on a vertical surface and to respond by flying horizontally along the corresponding angle.

Further work has confirmed that the dance language of bees includes several modes of communication: tactile information in the movements themselves, sounds made during the dance, and scents that indicate the nature of the food source.

Ultimate Causes: Why Do Honeybees Communicate the Way They Do?



At the ultimate level, it's straightforward to come up with a hypothesis for why honeybees use a complex method of communication to share information about food sources. If more workers find a rich food source quickly, then the total amount of resources harvested as well as the number of offspring produced by the hive should increase. Thus the frequency of bee colonies with successful communication should increase over time.

In general, why do animals use the modes of communication that they do? One of the most general observations about communication is that the type of signal used by an organism correlates with its habitat. Bees, ants, and termites that live in hives or underground rely on olfactory and tactile communication. Similarly, bats, wolves, and other animals that are active at night communicate via sound or scent. In contrast, animals that are active during the day and that live in open or treeless habitats tend to rely on visual communication.

Sound travels much farther than light in aquatic habitats. Based on this observation, it is logical to observe that humpback whales rely on songs for long-distance communication. In some cases, humpback whale songs can travel hundreds of kilometers. Groups of whales use acoustic communication to keep together during migrations, and individual males sing to attract mates and warn rivals.

Each mode of communication has advantages and disadvantages. Songs and calls can carry information over long distances, but are short lived. Thus they have to be repeated to be effective, and frequent repetition requires a large expenditure of time and energy. In addition, acoustic communication attracts predators. It is no surprise that when a hawk or falcon approaches a marsh inhabited by courting red-winged blackbirds, things get very quiet. Communication systems have been honed by natural selection to maximize their benefits and minimize their costs.

(a) Straight runs down the wall of the hive indicate that food is opposite the direction of the Sun.

(b) Straight runs to the right indicate that food is 90° to the right of the Sun.

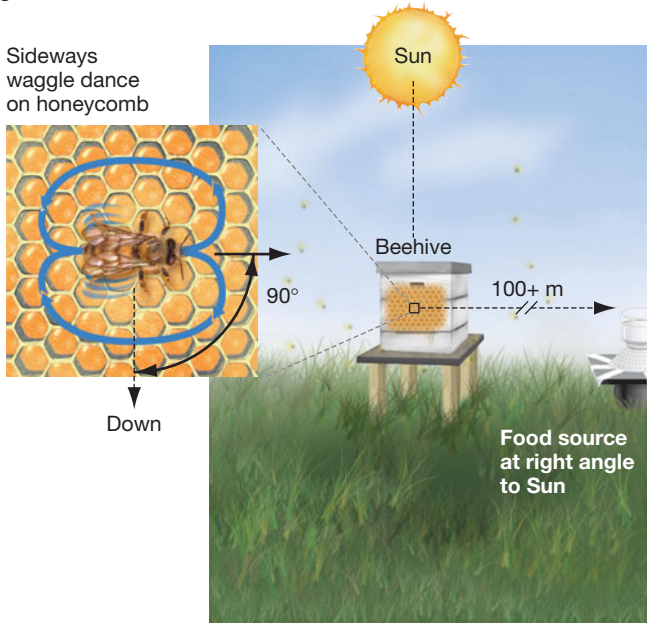


FIGURE 53.10 The Direction of the Waggle Dance Indicates the Location of Food Relative to the Sun.
Waggle dances are done only when the food is at least 100 m from the hive.

✔**EXERCISE** The length of the straight run in the waggle dance indicates the relative distance of the food. Diagram a waggle dance that indicates food in the direction of the Sun and twice as far away as the food sources indicated by the dances drawn here.

When Is Communication Honest or Deceitful?

At the ultimate level, one of the questions that biologists ask about communication concerns the quality of the information. Is the signal reliable?

As far as is known, honeybees are always honest. Stated another way, honeybee dances consistently "tell the truth" about the location of food sources. This observation is logical, because the honeybees that occupy a hive are closely related and cooperate extensively in the rearing of offspring. As a result, it is advantageous for an individual to convey information accurately. If a food-finder provided inaccurate or misleading information to its hivemates, fewer offspring would be reared and the food-finder's fitness would be reduced.

In many cases, however, natural selection has favored the evolution of deceitful communication. Recent research on deceitful communication has highlighted just how complex interactions between signalers and receivers can be. A few examples will help drive this point home.

Deceiving Individuals of Another Species **FIGURE 53.11** illustrates two of the hundreds of examples of deceitful communication that have been documented among members of different species. Many of the best-studied instances involve prey deceiving predators or predators deceiving prey:

- Hognose snakes are famous for their theatrical ability to play dead (Figure 53.11a). When perturbed by a predator, hognose snakes turn belly up, produce a foul odor, hang their tongues out of their gaping mouths, and may even produce a couple of droplets of blood from their mouths. When turned back onto their bellies, they quickly flip onto their backs again and sustain the charade until the coast is clear.
- Male and female fireflies flash a species-specific signal to each other during courtship. Predatory *Photuris* fireflies can mimic the pattern of flashes given by females of several other species. A *Photuris* female attracts a male of different species with the appropriate set of flashes and then attacks and eats him (Figure 53.11b).

In each of these examples, individuals increase their fitness by providing inaccurate or misleading information to members of a different species. It's important to realize, though, that the signaler is not consciously "lying." Instead, natural selection has simply favored certain behavioral traits that effectively communicate deceitful information.

Deceiving Individuals of the Same Species In some cases, natural selection has favored the evolution of traits or actions that deceive members of an organism's own species. Perhaps the best-studied type of deceit in nonhuman animals involves the mating system of bluegill sunfish. Male bluegills set up nesting territories in the shallow water along lake edges, fertilize the eggs laid in their nests, care for the developing embryos by fanning them with oxygen-rich water, and protect newly hatched offspring from large predators.

(a) Hognose snakes play dead to avoid being eaten.

(b) Female *Photuris* fireflies flash the courtship signal of another species and then eat males that respond.

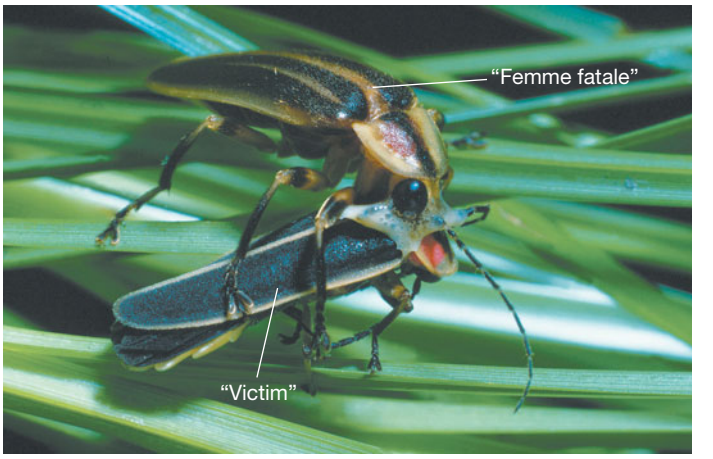

FIGURE 53.11 Deceitful Communication Is Common in Nature.

Some males cheat on this system, however, by mimicking females. To understand how this happens, examine the female, normal male, and female-mimic male in **FIGURE 53.12**. Mimics look like females but have well-developed testes and produce large volumes of sperm. Mimics also act like females during courtship movements with territory-owning males. They even adopt the usual egg-laying posture. When normal females approach the nest and begin courtship, the mimics join in.

The territory-owning male appears to tolerate the mimic, courting the two females at the same time. But when the actual female begins to lay eggs, the mimic responds by releasing sperm—and thus fertilizing some of the eggs—and then darting away. In this way, the mimic fathers offspring but does not help care for them. In addition, mimics do not have to expend time and energy in growing large and making and defending a nest.

Why aren't all males mimics? It turns out that as the number of mimics increases, the reproductive success of mimics declines. This is a common observation in studies of deceitful

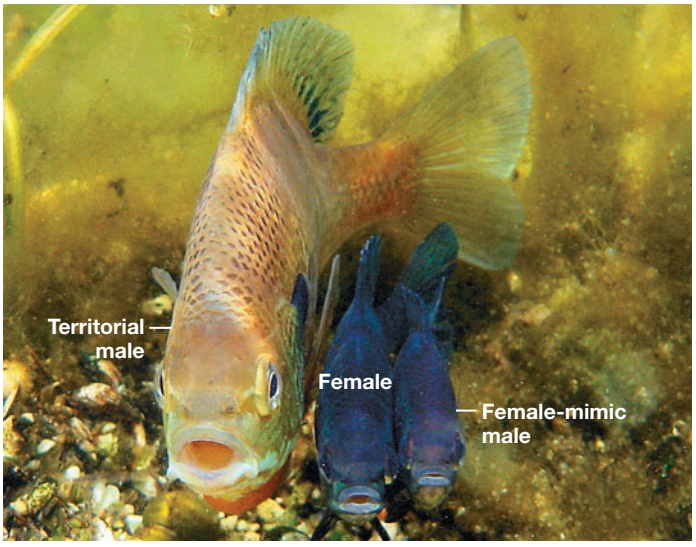

FIGURE 53.12 In Bluegill Sunfish, Some Males Look and Act Like Females.

communication—cheating works best within a population when it is relatively rare. The logic behind this hypothesis runs as follows: If deceit becomes extremely common, then natural selection will strongly favor individuals that can detect and avoid or punish liars. But if liars are rare, then natural selection will favor individuals that are occasionally fooled but are more commonly rewarded by responding to signals in a normal way. This is an example of frequency-dependent selection (see Chapter 26).

Further, as the number of mimic males increases in sunfish, competition with other mimics for mating opportunities increases and aggression by territory-owning males on mimic males also increases, lowering the reproductive success of the mimics.

check your understanding

If you understand that . . .

- Communication is an exchange of information between individuals.
- In most instances, the mode of communication that animals use maximizes the probability that the information will be transferred efficiently.
- Communication can be honest or deceitful, depending on the nature of the information received.

✔ You should be able to . . .

1. Explain the costs and benefits of auditory, olfactory, and visual communication.
2. Predict why natural selection favors individuals that can detect deceitful communication and either avoid "liars" or punish them.

Answers are available in Appendix A.

53.6 When Should I Cooperate?

The types of behavior reviewed thus far all have a key common element: They help individuals respond to environmental stimuli in a way that increases their fitness. There is a type of behavior that appears to contradict this pattern, however: altruism.

Altruism is behavior that has a fitness cost to the individual exhibiting the behavior and a fitness benefit to the recipient of the behavior. It is the formal term for self-sacrificing behavior. Altruism decreases an individual's ability to produce offspring but helps others produce more offspring.

In terms of ultimate causation, altruistic behavior appears to be paradoxical. If certain alleles make an individual more likely to be altruistic, those alleles should be selected against (Chapter 25). Meanwhile, individuals with selfish alleles should be more likely to survive and produce more offspring. Over time, selfish alleles should increase in frequency while self-sacrificing alleles should decrease in frequency. Does altruism actually occur? Let's consider four explanations for apparent altruistic behavior.

Kin Selection

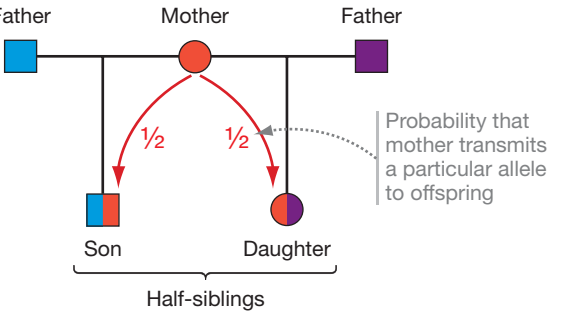
There is no question that self-sacrificing behavior occurs in nature. For example, black-tailed prairie dogs perform a behavior called alarm calling (**FIGURE 53.13**). These burrowing mammals live in large communities, called towns, throughout the Great Plains region of North America. When a badger, coyote, hawk, or other predator approaches a town, some prairie dogs give alarm calls that alert other prairie dogs to run to mounds and scan for the threat.

Giving these calls is risky. In several species of ground squirrels and prairie dogs, researchers have shown that alarm-callers draw attention to themselves by calling and are in much greater danger of being attacked than non-callers are.

FIGURE 53.13 Black-Tailed Prairie Dogs Are Highly Social. Prairie dogs live with their immediate and extended family within large groups called towns. The individual with the upright posture has spotted an intruder and may give an alarm call.

QUANTITATIVE METHODS 53.1 Calculating the Coefficient of Relatedness

The coefficient of relatedness, *r*, varies between 0.0 and 1.0. If two individuals have no identical alleles that were inherited from the same ancestor, then their *r* value is 0.0. Because every allele in pairs of identical twins is identical, their coefficient of relatedness is 1.0.



What about other relationships? **FIGURE 53.14a** shows how *r* is calculated between half-siblings. (To review what the boxes, circles, and lines in a pedigree mean, see Figure 14.22.) Half-siblings share one parent. Thus, *r* represents the probability that half-siblings share alleles as a result of inheriting alleles from their common parent. It is critical to realize that in each parent-to-offspring link of descent, the probability of any particular allele being transmitted is 1/2. This is so because meiosis distributes alleles from the parent's diploid genome to their haploid gametes randomly. Thus half the gametes produced by a parent get one of the alleles present at each gene, and half the gametes produced get the other allele. Half-siblings are connected by two such parent-to-offspring links. The overall probability of two half-siblings sharing the same allele by descent is $1/2 \times 1/2 = 1/4$. (To review rules for combining probabilities, see **BioSkills 5** in Appendix B.)

To think about this calculation in another way, focus on the red arrows in Figure 53.14a. The left arrow represents the probability that the mother transmits a particular allele to her son. The right arrow represents the probability that the mother transmits the same allele to her daughter. Both probabilities are 1/2. Thus the probability that the mother transmitted the same allele to both her son and daughter is $1/2 \times 1/2 = 1/4$.

FIGURE 53.14b shows how *r* is calculated between full siblings. The challenge here is to calculate the probability of two individuals sharing the same allele as a result of inheriting it through their mother or through their father. The probability that full siblings share alleles as a result of inheriting them from one parent is 1/4. Thus the probability that full siblings share alleles inherited from either their mother or their father is 1/4 + 1/4 = 1/2.

(a) What is the probability that half-siblings inherit the same allele from their common parent?

***r* between half-siblings:**
½ × ½ = ¼

(b) What is the probability that full siblings inherit the same allele from their father or their mother?

Probability that they inherit same allele from **father**:
½ × ½ = ¼

Probability that they inherit same allele from **mother**:
½ × ½ = ¼

***r* between full siblings:**
¼ + ¼ = ½

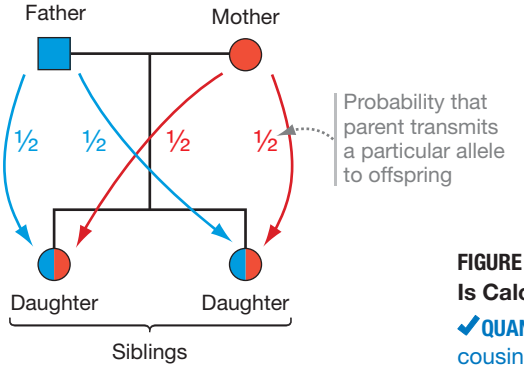


FIGURE 53.14 The Coefficient of Relatedness (*r*) Is Calculated from Information in Pedigrees.

✔**QUANTITATIVE** What is the *r* between first cousins?

Hamilton's Rule

How can natural selection favor the evolution of self-sacrificing behavior? William D. Hamilton answered this question by creating a mathematical model to assess how an allele that contributes to altruistic behavior could increase in frequency in a population.

To model the fate of altruistic alleles, Hamilton represented the fitness cost of the altruistic act to the actor as *C* and the fitness benefit to the recipient as *B*. Both *C* and *B* are measured in units of offspring produced. His model showed that the allele could spread if

$$Br > C$$

where *r* is the **coefficient of relatedness.** The coefficient of relatedness is a measure of how closely the actor and beneficiary are related. Specifically, *r* measures the fraction of alleles in the actor and beneficiary that are identical by descent—that is, inherited from the same ancestor (**Quantitative Methods 53.1**).

The formulation $Br > C$ is called **Hamilton's rule.** It states that altruistic behavior is most likely when three conditions are met:

1. The fitness benefits are high for the recipient.
2. The altruist and recipient are close relatives.
3. The fitness costs to the altruist are low.

When Hamilton's rule holds, alleles associated with altruistic behavior will be favored by natural selection—because close relatives are very likely to have copies of the altruistic alleles. These alleles will increase in frequency in the population.

Inclusive Fitness

Hamilton's rule is important because it shows that individuals can pass on their alleles to the next generation not only by having their own offspring but also by helping close relatives produce more offspring. To capture this point, biologists refer to direct fitness and indirect fitness.

- Direct fitness is derived from an individual's own offspring. Parents can increase their direct fitness by spending resources to ensure the welfare of their offspring. This behavior is called parental care (Chapter 35).
- Indirect fitness is derived from helping relatives produce more offspring than they could produce on their own.

The combination of direct and indirect fitness components is called **inclusive fitness.**

Biologists use the term **kin selection** to refer to natural selection that acts through benefits to relatives at the expense of the individual. While kin selection decreases the direct fitness of an individual, it increases the indirect fitness, resulting in an overall increase in an individual's inclusive fitness. ✔ **If you understand kin selection, you should be able to explain why it is likely to be common in humans.**

Testing Hamilton's Rule Does Hamilton's rule work? Do animals really favor relatives when they act altruistically? To test the kin-selection hypothesis, behavioral ecologist John Hoogland studied which of the inhabitants of a black-tailed prairie dog town were most likely to give alarm calls.

Within a large prairie dog town, individuals live in small groups called coteries that share the same underground burrow. Members of each coterie defend a territory inside the town.

By tagging offspring that were born over several generations, Hoogland identified the genetic relationships among individuals in the town. He determined whether each individual had:

- no close genetic relatives in its coterie;
- no offspring in the coterie but at least one sibling, cousin, uncle, aunt, niece, or nephew; or
- at least one offspring or grandoffspring in the coterie.

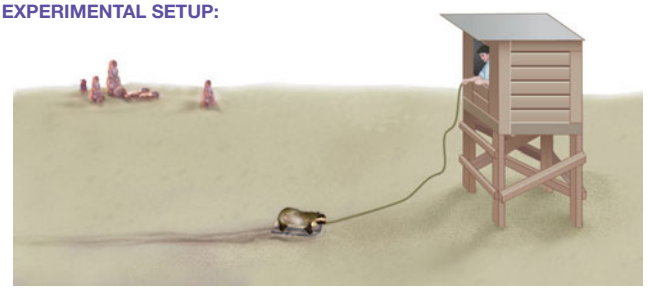
The kin-selection hypothesis predicts that individuals who do not have close genetic relatives nearby will rarely give an alarm call. To evaluate this prediction, Hoogland recorded the identity of callers during 698 experiments. In these studies, a stuffed badger was dragged through the colony on a sled.

Were prairie dogs with close relatives nearby more likely to call, or did kinship have nothing to do with the probability of alarm calling? The bar charts in **FIGURE 53.15** show the average proportion of times that individuals in each of the three categories called during an experiment. The data indicate that black-tailed prairie dogs are much more likely to call if they live in a coterie that includes close relatives.

This same pattern—of preferentially dispensing help to kin—has been observed in many other species of social mammals and birds. Most cases of self-sacrificing behavior that have been analyzed to date are consistent with Hamilton's rule and are hypothesized to be the result of kin selection.

Manipulation

Note that altruism refers to a type of behavior with specific fitness consequences to an organism, not to the generosity of an organism. Sometimes altruistic behavior is involuntary.



RESEARCH

QUESTION: Do black-tailed prairie dogs prefer to help relatives when they give an alarm call?

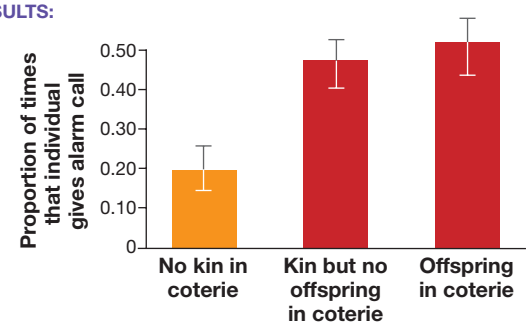
HYPOTHESIS: Individuals give an alarm call only when close relatives are near.

NULL HYPOTHESIS: The presence of relatives has no influence on the probability of alarm calling.

EXPERIMENTAL SETUP:

1. Determine relationships among individuals in prairie dog coterie.

2. Drag stuffed badger across territory of coterie.



3. From observation tower, record which members of coterie give an alarm call.

4. Repeat experiment 698 times. Each prairie dog coterie is tested 6–9 times over a 3-year period.

PREDICTION OF KIN-SELECTION HYPOTHESIS: Individuals in coteries that contain a close genetic relative are more likely to give an alarm call than are individuals in coteries that do not contain a close genetic relative.

PREDICTION OF NULL HYPOTHESIS: The presence of relatives in coteries will not influence the probability of alarm calling.

RESULTS:

CONCLUSION: Alarm calling usually benefits relatives.

FIGURE 53.15 Experimental Evidence That Black-Tailed Prairie Dogs Are More Likely to Give Alarm Calls if Relatives Are Nearby.

SOURCE: Hoogland, J. L. 1983. Nepotism and alarm calling in the black-tailed prairie dog *(Cynomys ludovicianus)*. *Animal Behavior* 31: 472–479.

✔**QUESTION** What would be an appropriate control in this experiment, and what hypothesis would it test?

For example, one of the most famous applications of Hamilton's rule is in explaining the complex social structure of organisms such as the bees discussed earlier, as well as ants and wasps. In these societies, workers sacrifice most or all of their direct reproduction to help rear the queen's offspring, a phenomenon called **eusociality.**

Why would workers be so altruistic? In insect societies that have a single, diploid queen who mates once with a *haploid* male, all the workers are highly related, with a coefficient of relatedness of 0.75—much higher than the 0.5 of their daughters. These numbers suggest that it would be more adaptive for workers to raise sisters than to raise their own offspring, supporting Hamilton's rule.

However, the queens in some insect societies mate with diploid males, or with multiple males, reducing the coefficient of relatedness of workers. Inclusive fitness is still important, but it is not sufficient to explain why less than 1 in 1000 workers would lay eggs. What else is going on?

One factor is that workers are sometimes manipulated into altruistic behavior. The queen and/or other workers police the nest and kill any eggs laid by workers. The more effective the policing, the less likely the workers are to continue expending energy to lay eggs. In other cases, the queen suppresses reproduction in the workers via pheromones or other chemical signals. Manipulation, or "enforced altruism," makes sense at the ultimate level because efficient colonies will be favored by natural selection, while rampant "cheating" can cause colonies to collapse.

Reciprocal Altruism

During long-term studies of highly social animals such as horses, elephants, dolphins, lions, chimpanzees, and vampire bats, biologists have observed nonrelatives helping each other. Chimps and other primates, for example, may spend considerable time grooming unrelated members of their social group—cleaning their fur and removing ticks and other parasites from their skin. In vampire bats, individuals that have been successful in finding food are known to regurgitate blood meals to non-kin that have not been successful and that are in danger of starving.

How can self-sacrificing behavior like this evolve if kin selection is not acting? The leading hypothesis to explain altruism among nonrelatives is called **reciprocal altruism:** an exchange of fitness benefits that are separated in time. Reciprocal altruists help individuals who have either helped them in the past or are likely to help them in the future.

Data that have been collected so far support the reciprocal altruism hypothesis in some instances.

- Among vervet monkeys, individuals are most likely to groom unrelated individuals that have groomed or helped them in the past.
- Vampire bats are most likely to donate blood meals to non-kin that have previously shared food with them.

Reciprocal altruism is also widely invoked as an explanation for the helpful and cooperative behavior commonly observed among unrelated humans.

Cooperation and Mutualism

Some behaviors may appear altruistic, but actually may be selfish because they increase, rather than decrease, the fitness of the animal exhibiting the behavior. That is, the benefits of assisting others can exceed the costs.

- African wild dogs cannot hunt large prey alone, but they can succeed by hunting as a pack. The fitness of all the dogs increases when they work together. This is an example of cooperation among members of the same species.
- Female horses that spend more time in grooming relationships with other female horses tend to suffer less harassment from males—and to have more foals.

When cooperation occurs among individuals of different species, mutualism is said to occur. The relationship between cleaner shrimp and their host fish is mutualistic because both the shrimp and the fish benefit when the shrimp clears off—and eats—parasites from the fish's gills and jaws (see Chapter 55).

To summarize, organisms are altruistic when doing so either increases their direct fitness or their inclusive fitness, or when they are coerced. As with feeding, mating, finding a place to live, and communicating, helping others has costs and benefits that must be weighed by the organism. This "decision making" occurs at the proximate level through genetic and physiological mechanisms, and at the ultimate level through evolutionary processes.

CHAPTER 53 REVIEW

If you understand . . .

53.1 An Introduction to Behavioral Ecology

- Proximate causation: Experiments and observations focus on understanding how specific gene products, neuron activity, and hormonal signals cause behavior.
- Ultimate causation: Researchers seek to understand the adaptive significance of behavior, or why it enables individuals to survive and reproduce, thus increasing their fitness.
- Behaviors vary in the extent to which they are inflexible or flexible, and in the extent to which they are innate or learned.
- Animals appear to weigh the costs and benefits of responding to a particular situation in various ways. Costs and benefits are measured in terms of their impact on fitness.

✔ **You should be able to explain the proximate and ultimate causes for increased sex drive in human teens.**

53.2 What Should I Eat?

- Proximate causation: Fruit fly larvae will be sitters or rovers depending on which alleles they carry for a certain gene.
- Ultimate causation: The sitter and rover alleles are maintained in fruit fly populations because the fitness consequences of the alleles depend on fluctuating environmental circumstances.
- Optimal foraging theory predicts that animals will make foraging decisions that maximize energy gain and minimize energy loss, time spent, and predation risk, among other factors. For example, gerbils balance the benefits of foraging for food with the costs of exposure to owls.

✔ **You should be able to suggest what variables you would have to consider in testing the principle of optimal foraging in a web-building spider.**

53.3 Who Should I Mate With?

- Proximate causation: The onset of sexual behavior in *Anolis* lizards depends on surges of the sex hormones testosterone and estradiol that are triggered by springlike temperatures *and* courtship displays from males.
- Ultimate causation: Sexual selection favors individuals with traits that increase their ability to obtain mates. Females tend to choose mates that provide good alleles and valuable resources. Males compete for the opportunity to mate with females.
- Sexual selection in *Anolis* lizards is determined more by male–male competition than by female choice.

✔ **You should be able to generate a hypothesis for why nest decorations are a reliable signal of male quality in bowerbirds (see chapter-opening photo).**

53.4 Where Should I Live?

- Many animals migrate between different habitats rather than staying in one place due to the seasonable availability of food and the location of good nesting and mating places.
- Proximate causation: Animals can find their way by following familiar landmarks (piloting); by getting compass information from the Sun, the stars, and Earth's magnetic field; and/or by using the magnetic field for true navigation (map orientation).
- Ultimate causation: The benefits of migrating to food sources and mating and nesting areas must outweigh the energetic costs and danger of the migration.

✔ **You should be able to provide an evolutionary hypothesis for the observation that some bird species do not migrate if people supply food for them in feeders.**

53.5 How Should I Communicate?

- Honeybees have a symbolic language—their dancing movements communicate accurate information about the direction and distance of food sources.
- Proximate causation: Animals communicate with touch, sounds, scents, and/or sight depending on the environment.
- Ultimate causation: The ability to communicate effectively increases the fitness of animals.
- Communication can be honest or deceitful. Deceitful communication can be adaptive when it is rare.

✔ **You should be able to predict the consequences for deceitful communication in bluegill sunfish if most large, territory-owning males were fished out of a lake.**

53.6 When Should I Cooperate?

- Proximate causation: Altruistic behavior can be voluntary or coerced.
- Ultimate causation: Altruistic behavior appears paradoxical because it lowers the direct fitness of an individual.
- When altruistic behavior is directed toward close relatives, alleles that lead to self-sacrificing may increase in frequency due to kin selection (increasing the inclusive fitness of the altruist).
- Some animals that live in close-knit social groups engage in reciprocal altruism—meaning they exchange help over time.
- Other animals cooperate because everyone benefits, such as in cooperative foraging. Cooperation among species is called mutualism.

✔ **You should be able to describe the characteristics of a species for which helpful behavior is expected to be common.**

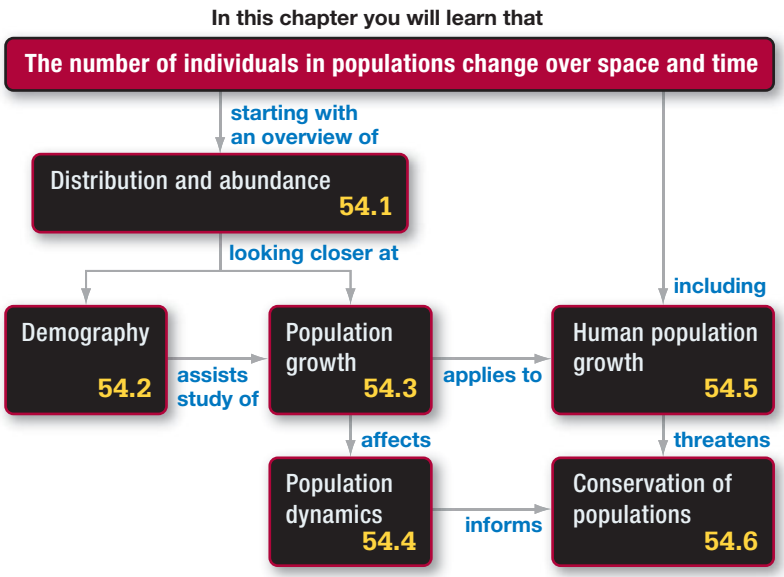
TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. What do proximate explanations of behavior focus on?
   a. how displays and other types of behavior have changed through time, or evolved
   b. the functional aspect of a behavior, or its "adaptive significance"
   c. genetic, neurological, and hormonal mechanisms of behavior
   d. appropriate experimental methods when studying behavior
2. What do ultimate explanations of behavior focus on?
3. What unit(s) do biologists use when analyzing the costs and benefits of behavior?
   a. proximate versus ultimate
   b. body size (e.g., large versus small)
   c. time
   d. fitness—the ability to survive and produce offspring
4. Which of the following statements about the waggle dance of the honeybee is not correct?
   a. The length of a waggling run is proportional to the distance from the hive to a food source.
   b. Sounds and scents produced by the dancer provide information about the nature of the food source.
   c. The speed of waggling is proportional to the distance from the hive to a food source.
   d. The orientation of the waggling run provides information about the direction of the food from the hive, relative to the Sun's position.
5. Why are biologists convinced that the sex hormone testosterone is required for normal sexual activity in male *Anolis* lizards?
   a. Male *Anolis* lizards with larger testes court females more vigorously than do males with smaller testes.
   b. Testosterone is not found in female *Anolis* lizards.
   c. Male *Anolis* lizards whose gonads had been removed did not develop dewlaps.
   d. Male *Anolis* lizards whose gonads had been removed did not court females.
6. Why does altruism seem paradoxical?
   a. Sometimes altruistic behavior is actually selfish.
   b. Altruism does not actually help others.
   c. Alleles that cause an organism to behave altruistically should be selected against since these alleles should lower the organism's fitness.
   d. Animals behave altruistically to help the species, but sometimes their behavior harms the species.

TEST YOUR UNDERSTANDING

Answers are available in Appendix A



7. Explain the ultimate causes of honeybee dancing.
8. Is it true that all organisms forage optimally? Why or why not?
9. Why do behaviors like *Anolis* lizard bobbing displays serve as honest signals of male quality?
10. What environmental stimuli cause changes in hormone levels that lead to egg laying in *Anolis* lizards? What biologically relevant information do these stimuli provide?
11. Evaluate this statement: For green sea turtles to return from the open ocean to the beach where they were hatched, they must have both a "map" and a "compass."
12. **QUANTITATIVE** Hamilton's rule states that an altruistic allele could spread in a population if $Br > C$, where B represents the fitness benefit to the recipient, r is the coefficient of relatedness between altruist and recipient, and C represents the fitness cost to the altruist. If $r = 0.5$ between the altruist and the recipient, what would the ratio of costs to benefits have to be for the altruistic allele to spread?
    a. $C/B > 0.5$
    b. $C/B > 0$
    c. $C/B < 0.5$
    b. $C/B < 0$

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A

13. To date, the rover and sitter alleles have been shown to affect foraging behavior only in fruit fly larvae. Design an experiment to test the hypothesis that adults with the rover allele tend to fly farther in search of food sources than adults with the sitter allele.
14. You are invited on a summer internship to study the behavioral ecology of howler monkeys in Costa Rica. Your task will be to follow a troop of howler monkeys during the day and identify what types of fruits and leaves the troop consumes. Which of these general principles will help guide your work? Select all that apply.
    a. condition-dependent behavior
    b. optimal foraging
    c. Hamilton's rule
    d. cost–benefit analysis
15. **QUANTITATIVE** A biologist once remarked that he'd be willing to lay down his life to save two brothers or eight cousins. Explain what he meant.
16. Based on the theory of reciprocal altruism, predict the conditions under which people are expected to donate blood.

54 Population Ecology

This vivid school of crescent-tail bigeyes off the coast of Papua New Guinea demonstrates how individuals associate together in populations. The distribution and abundance of individuals in populations changes over space and time.

If you asked a biologist to name two of today's most pressing global issues, she might say global climate change and extinction of species. If you were asked to name two of the most pressing issues facing your region, you might say traffic and the price of housing. All four problems have a common cause: recent and dramatic increases in the size of the human population.

In 1940, for example, Mexico City had a population of about 1.6 million. The city grew to 5.4 million in 1960, 13.9 million in 1980, and over 21 million in 2010. How much bigger will it get over the next 50 years? And how large will the entire human population be by the time your kids are in college?

BIG PICTURE

This chapter is part of the Big Picture. See how on pages 1196–1197.

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

A **population** is a group of individuals of the same species that live in the same area at the same time; **population ecology** is the study of how and why the number of individuals in a population changes over time and space. (You can see how population ecology fits into the Big Picture of Ecology on pages 1196–1197).

With the explosion of human populations across the globe, the massive destruction of natural habitats, changes in climate, and the resulting threats to species throughout the tree of life, population ecology has become a vital field in biological science. The mathematical and analytical tools introduced in this chapter help biologists predict changes in population size and design management strategies to save threatened species.

Let's start by considering some of the basic tools that biologists use to study populations and then follow up with examples of how biologists study changes in the population size of humans and other species over time. The chapter concludes by asking how all of these elements fit together in efforts to limit human population growth and conserve biodiversity.

54.1 Distribution and Abundance

If you were interested in studying the population biology of the blue-ringed octopus, Florida strangler fig, or any other species, you might want to start by asking, "Where do they live, and how many are there?" Distribution and abundance are two fundamental concepts in ecology.

Most species identification guides show the **range,** or geographic distribution, of different species. Two types of factors determine range:

- *Abiotic factors*, such as temperature, rainfall, the presence of geographical structures like mountains and oceans, and large-scale ongoing and historical processes such as continental drift (see Chapter 52);
- *Biotic factors*, such as the past and current presence of other species that provide habitat, food, or competition (discussed in detail in Chapter 55).

Ranges are dynamic—in constant flux as abiotic and biotic factors change over time.

The range of a species can also be considered at different scales. For example, the map in **FIGURE 54.1** shows the vast global range of the common lizard, *Lacerta vivipara* (sometimes called *Zootoca vivipara*), from Ireland in western Europe to Japan in eastern Asia. This map indicates that *L. vivipara* can live in a variety of habitats and is cold adapted—it lives farther north than other reptiles, and only at high altitudes at the southern extent of its range.

Lizards are not distributed uniformly within this range, however. The **population density**—the number of individuals per unit area—of *L. vivipara* varies throughout its range. If you zoom in on one region, such as the British Isles, you can observe that *L. vivipara* is remarkably widespread, yet absent from some areas. Zooming in further still, the distribution of *L. vivipara* is

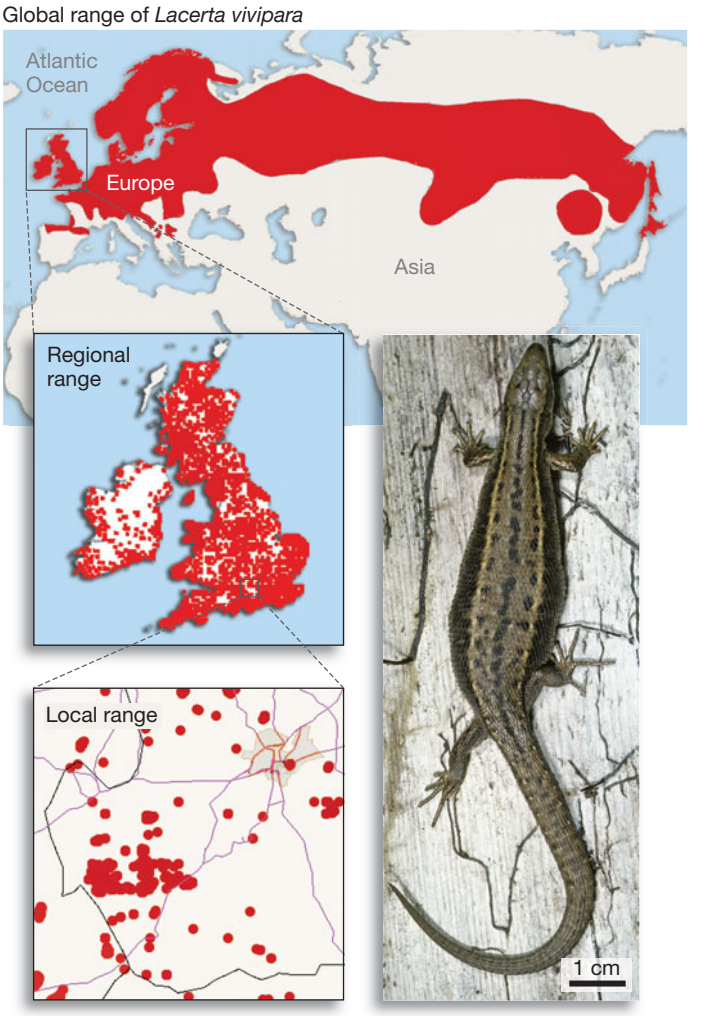


FIGURE 54.1 Geographic Range of *Lacerta vivipara*.

clumped according to the distribution of suitable habitats, such as meadows and open woodland.

In general, individual organisms can be arranged in different patterns within populations. The arrangement may be

- *random*, if the position of each individual is independent of the others, as may occur when seeds are dispersed by the wind;
- *clumped*, if the quality of the habitat is patchy or the organisms associate in social groups (such as schools of fish); or
- *uniform*, if negative interactions occur among individuals, such as competition for space, water, or other resources.

Within a certain patch of habitat, the distribution of *L. vivipara* individuals may be relatively uniform due to their maintenance of feeding and mating territories (see Chapter 53). However, as with most species, the distribution of lizards is clumped overall due to varying density of individuals in habitat patches of different quality. The particular dispersion pattern of a population has both proximate causes, in terms of physiological and behavioral mechanisms, and ultimate causes, in terms

QUANTITATIVE METHODS 54.1 Mark–Recapture Studies

To begin a mark–recapture study, researchers catch individuals and mark them with leg bands, ear tags, or some other method of identification. After the marked individuals are released, they are allowed to mix with the unmarked animals in the population for a period of time. Then a second trapping effort is conducted, and the percentage of marked individuals that were captured is recorded.

To estimate the total population from these data, researchers make a key assumption: The percentage of marked and recaptured individuals is equal to the percentage of marked individuals in the entire population. This assumption should be valid if individuals are not moving in and out of the study area, and if no bias exists regarding which individuals are caught in each sample attempt. It is important that individuals do not learn to avoid or seek out traps after being caught once and that they do not change their behavior or die as a result of being marked or trapped.

The relationship between marked and unmarked individuals can be expressed algebraically:

Number of marked animals in the second sample (the recapture) / Number of marked animals in the first sample

$$\frac{m_2}{n_2} = \frac{m_1}{N}$$

Total number of animals (marked and unmarked) in the second sample / Total population size

(Eq. 54.1)

Having measured m_2, n_2, and m_1, the researcher can estimate N.

✔**QUANTITATIVE** **If you understand how to estimate population size in a mark–recapture study, you should be able to do so in this example: Suppose researchers marked 255 animals and later were able to trap a total of 162 individuals in the population, of which 78 were marked. What is the estimate for total population size? Solve for *N* (give the nearest integer) and check your answer.**[1] (Answer is given below.)

[1] $N = 530$.

of evolutionary adaptations (see Chapter 53 for an overview of proximate and ultimate causation).

If a species range is small, it may consist of a single population of interbreeding individuals. If a range is large, it may consist of many populations—sometimes contiguous, and sometimes isolated in space. If individuals from a species occupy many small patches of habitat, so that they form many independent populations, they are said to represent a **metapopulation**—a population of populations connected by migration. Because humans are reducing large, contiguous areas of forest and grasslands to isolated patches or reserves, more and more species are being forced into a metapopulation structure.

How can the population size, density, or distribution pattern of individuals be determined? It depends on the species. For sedentary (largely immobile) organisms such as trees and barnacles, researchers sample habitats by counting the individuals that occur along lines of known position and length—called *transects*—or inside rectangular plots—called *quadrats*—set up at random locations in the habitat. These counts can be extrapolated to the entire habitat area to estimate the total population size. In addition, they can be compared to later censuses to document trends over time.

In contrast, counting organisms that are mobile and that do not congregate into herds or flocks or schools is much more challenging. For example, the number of lizards inside sample quadrats or along transects changes constantly as individuals move. Further, it can be difficult to track whether a particular individual has already been counted. But if individuals can be captured and then tagged in some way, the total population size of a mobile species can be estimated by using a research approach called mark–recapture (**Quantitative Methods 54.1**).

Note that individuals within populations vary, and populations are not static in time and space. To get a better understanding of how researchers quantify population size and structure, let's first examine a field of study in ecology called demography.

54.2 Demography

The number of individuals present in a population depends on four processes: birth, death, immigration, and emigration.

- Populations grow as a result of births—here, meaning any form of reproduction—and **immigration,** which occurs when individuals enter a population by moving from another population.
- Populations decline due to deaths and **emigration,** which occurs when individuals leave a population to join another population.

Analyzing birth rates, death rates, immigration rates, and emigration rates is fundamental to **demography**: the study of factors that determine the size and structure of populations through time.

To predict the future of a population, biologists have to know something about its makeup. They need to know the population's **age structure**—how many individuals of each age are alive. They also need to know how likely individuals of different ages are to survive to the following year, how many offspring are produced by females of different ages, and how many individuals of different ages immigrate and emigrate each **generation**—the average time between a mother's first offspring and her daughter's first offspring.

If a population consists primarily of young individuals with a high survival rate and reproductive rate, the population size

should increase over time. But if a population comprises chiefly old individuals with low reproductive rates and low survival rates, then it is almost certain to decline over time. Life tables are useful tools for analyzing this type of information.

Life Tables

A **life table** summarizes the probability that an individual will survive and reproduce in any given time interval over the course of its lifetime. Life tables were invented almost 2000 years ago; ancient Romans used them to predict food needs. In modern times, life insurance companies use life tables to predict the likelihood of a person dying at a given age. Biologists use life tables to study the demographics of endangered species.

***Lacerta vivipara*: A Case Study** To understand how researchers use life tables, consider again the lizard *L. vivipara*. As their name suggests—vivipara means "live birth"—most populations are ovoviviparous and give birth to live young (see Chapter 33).

European biologists Henk Strijbosch and Raymond Creemers set out to construct a life table of a low-elevation population of *L. vivipara* in the Netherlands, with the goal of comparing the results to data that other researchers had collected from *L. vivipara* populations in the mountains of Austria and France and in lowland habitats in Britain and Belgium. They wanted to know whether populations that live in different environments vary in basic demographic features.

To begin the study, Strijbosch, Creemers, or their students visited their study site daily during the seven months that these lizards are active during the year. Each day, the research team captured and marked as many individuals as possible.

Because this program of daily monitoring continued for seven years, the biologists were able to document the number of young produced by each female in each year of her life. If a marked individual was not recaptured in a subsequent year, they assumed that it had died sometime during the previous year. The data allowed researchers to calculate the number of individuals that survived each year in each particular age group as well as how many offspring each female produced. What did the numbers reveal?

TABLE 54.1 shows the data Strijbosch and Creemers collected for females. In most cases, biologists focus on females when calculating life-table data, because the number of males present rarely affects population growth. There are almost always enough males present to fertilize all of the females in breeding condition, so growth rates depend entirely on females. Let's walk through Table 54.1 step by step.

Age Class and Number Alive The first column in Table 54.1 lists the age classes of *L. vivipara*. An **age class** is a group of individuals of a specific age—for example, all female lizards between 4 and 5 years old. These data show that *L. vivipara* females have a maximum life span of about seven years.

But not all females live to be this old. The second column in the table shows how many female lizards survived to reach each age class. Suppose 1000 female *L. vivipara* are born in a particular year. These individuals represent a **cohort**—a group of the same age that can be followed through time. How many individuals would survive to age 1, age 2, and so on? On average, 424 would still be alive one year later, and 308 would still be alive two years later.

Survivorship The third column in Table 54.1 converts the data in the second column to proportions. **Survivorship**—a key component of a life table—is defined as the proportion of offspring produced that survive, on average, to a particular age. For example, the survivorship from birth to age 1 was 0.424 in the Netherlands population. Survivorship from birth to age 2 was 0.308.

Life tables do not usually include data bars—the bars in this table, such as the orange bars for survivorship, are intended to help you visualize the patterns in the numbers in the different columns. Since survivorship varies by several orders of magnitude, in this case from 1.000 to 0.002, biologists typically plot the logarithm of the number of survivors versus age. Using a

TABLE 54.1 Life Table for *Lacerta vivipara* Females in the Netherlands

Age Class (x)	Number of Survivors (N_x)	Survivorship (l_x)	×	Age-Specific Fecundity (m_x)	=	Average Births/Year/Original Female ($l_x m_x$)
0	1000	1.000		0.00		0.00
1	424	0.424		0.04		0.02
2	308	0.308		1.47		0.45
3	158	0.158		2.07		0.33
4	57	0.057		2.44		0.14
5	10	0.010		3.25		0.04
6	7	0.007		3.25		0.03
7	2	0.002		3.25		+ 0.01
						$R_0 = 1.00$ = Net reproductive rate

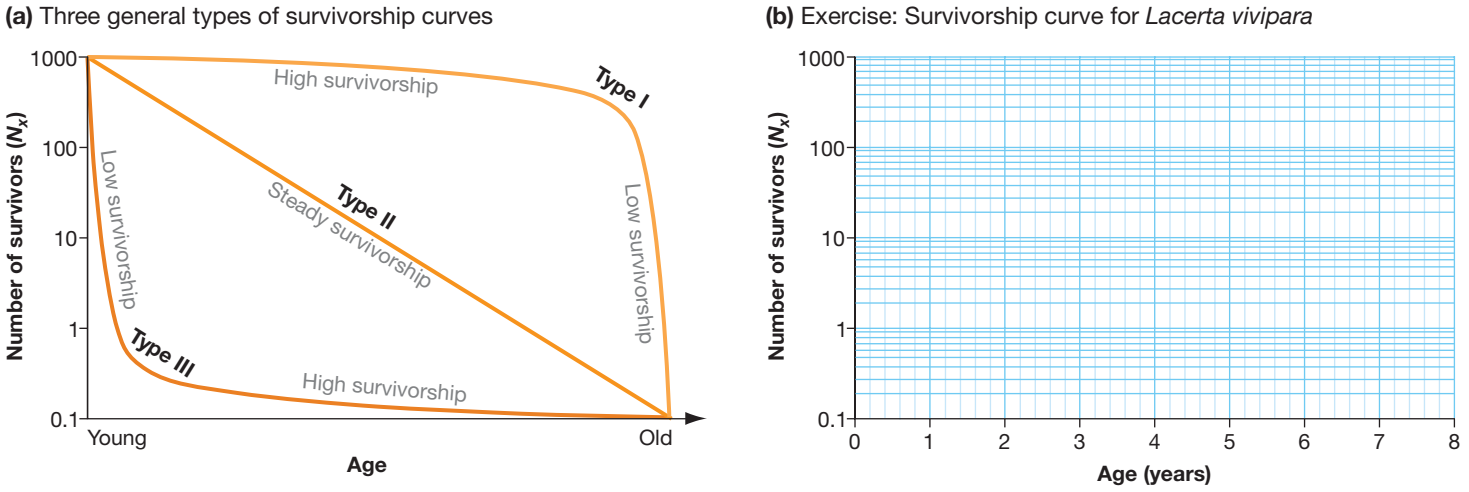

FIGURE 54.2 Survivorship Curves Identify When Mortality Rates Are Low, Steady, or High.

✔**QUANTITATIVE** Fill in the graph in part (b) with data on survivorship of *Lacerta vivipara* given in Table 54.1. Compare the shape of the curve to the generalized graphs in part (a).

logarithmic scale on the *y*-axis is a matter of convenience—it makes patterns easier to see (see **BioSkills 6** in Appendix B). The resulting graph is called a **survivorship curve.** Studies on a wide variety of species indicate that three general types of survivorship curves exist (**FIGURE 54.2a**).

1. Humans have what biologists call a type I survivorship curve. In this pattern, survivorship throughout life is high—most individuals approach the species' maximum life span.
2. Type II survivorship curves occur in species where individuals have about the same probability of dying in each year of life. Blackbirds and other songbirds have this type of curve.
3. Many plants have Type III curves—a pattern defined by extremely high death rates for seeds and seedlings but high survival rates later in life.

FIGURE 54.2b provides a graph for you to plot survivorship of *L. vivipara*, using the data reported in Table 54.1. Note the logarithmic scale on the *y*-axis of the graph. What type of survivorship curve does *L. vivipara* have?

Fecundity The fourth column in Table 54.1 shows the data for **fecundity,** the number of female offspring produced by each female in the population. Because the researchers documented the reproductive output of the same *L. vivipara* lizard females year after year, they were able to calculate a quantity called **age-specific fecundity**: the average number of female offspring produced by a female in each age class. The blue data bars in Table 54.1 illustrate the pattern of fecundity in lizards of different ages: older female lizards have a higher age-specific fecundity than younger females.

Reproductive Rate If survivorship is higher in young lizards and fecundity is higher in older lizards, what is the outcome? The purple bars in the fifth column of Table 54.1 show the product of survivorship multiplied by fecundity—most of the offspring in the population are produced by females of intermediate age.

The sum of the purple bars is a measure of **net reproductive rate,** which indicates whether the population is increasing or decreasing (as long as immigration and emigration are insignificant). Since this sum is equal to 1, this population of *L. vivipara* is stable. **Quantitative Methods 54.2** (see page 1106) walks through the calculations in the life table in more detail.

How do the data on the Netherlands populations of *L. vivipara* compare with populations in different types of habitats?

The Role of Life History

The life-table data in Table 54.1 are interesting because they contrast with results from other populations of *L. vivipara*. Consider data on fecundity:

- In the Netherlands, almost no 1-year-old female *L. vivipara* reproduce.
- In Brittany, France, 50 percent of 1-year-old female lizards reproduce.
- In the mountains of Austria, females don't begin breeding until they are 4 years old.

The contrasts are equally stark when looking at survivorship. In the Austrian population, most females live much longer than do individuals in either lowland population—in the Netherlands or France.

In Brittany, fecundity is high but survivorship is low; in Austria, fecundity is low but survivorship is high. The population in the Netherlands is intermediate. In this species, key aspects of the life table vary dramatically among populations.

What Are Fitness Trade-Offs? Why isn't it possible for *L. vivipara* females to have both high fecundity and high survival? The answer is **fitness trade-offs** (see Chapters 25 and 42).

Fitness trade-offs occur because every individual has a restricted amount of time and energy at its disposal—meaning that its resources are limited. If a female lizard devotes a great deal of

QUANTITATIVE METHODS 54.2 Using Life Tables to Calculate Population Growth Rates

If immigration and emigration are not occurring, the data in a life table can be used to calculate a population's growth rate. This approach is logical, because survivorship and fecundity are ways to express death rates and birth rates—the other two factors influencing population size. To see how a population's growth rate can be estimated from life-table data, let's look at each component in a life table more carefully. Recall that life tables usually focus exclusively on females.

Survivorship is symbolized as l_x, where x represents the age class being considered. Survivorship for age class x is calculated by dividing the number of females in that age class (N_x) by the number of females that existed as offspring (N_0):

Survivorship: $l_x = \frac{N_x}{N_0}$ — N_x: Number of females in age class x; N_0: Number of original females

(Eq. 54.2)

Age-specific fecundity is symbolized m_x, where x again represents the age class being considered. Age-specific fecundity is calculated as the total number of female offspring produced by females of a particular age, divided by the total number of females of that age class present. It represents the average number of female offspring produced by a female of age x.

Documenting age-specific survivorship and fecundity allows researchers to calculate the average number of female offspring produced by females during each age of life, as $l_x m_x$. For example, if 30 percent of the females in a population live to be 2 years old, and if 2-year-old females have an average of 2 offspring, then the average number of births at age 2, per female born into the population, is $l_x m_x = 0.30 \times 2 = 0.6$.

Summing $l_x m_x$ values over the entire life span of a female gives the net reproductive rate, R_0, of a population:

Net reproductive rate: $R_0 = \sum_{i=0}^{x} l_x m_x$ — Sum of all ages; Survivorship at age x; Fecundity at age x

(Eq. 54.3)

Here the Greek letter sigma (Σ) stands for "sum." The expression on the right-hand side of the equals sign is read, "sum the $l_x m_x$ values from each year of life, starting from birth or hatching ($i = 0$), through age x."

The net reproductive rate represents the growth rate of a population per generation. The logic behind the equation for R_0 is that the growth rate of a population per generation equals the average number of female offspring that each female produces over the course of her lifetime. A female's average lifetime reproduction, in turn, is a function of survivorship and fecundity at each age class. In Table 54.1, R_0 is the sum of the survivorship multiplied by the fecundity values in the right column.

If R_0 is greater than 1, then the population is increasing in size. If R_0 is less than 1, then the population is declining. ✔**QUANTITATIVE**

If you understand these concepts, you should be able to use the data in Table 54.1 to determine how many female offspring an average *L. vivipara* female produces over the course of her lifetime,[1] and describe whether the population is growing, stable, or declining.[2]

[1] 1.00; [2] The population is stable.

energy to producing a large number of offspring, she is not able to devote that same energy to her immune system, growth, nutrient stores, or other traits that increase survival. That is, a female can maximize fecundity, maximize survival, or strike a balance between the two.

An organism's **life history** describes how an individual allocates resources to growth, reproduction, and activities or structures that are related to survival. Traits such as survivorship, age-specific fecundity, age at first reproduction, and growth rate are all aspects of an organism's life history. Understanding variation in life history is all about understanding fitness trade-offs.

In almost all cases, biologists find that life history is shaped by natural selection in a way that maximizes an individual's fitness in its environment. In *L. vivipara* populations, biologists contend that females who live a long time but mature late and have few offspring each year have high fitness in cold, high-elevation habitats, such as Austria. In these habitats, females have to reduce their reproductive output and put more energy into traits that increase survival in a harsh environment. In contrast, females who have short lives but mature early and have large numbers of offspring each year do better in warm, low-elevation habitats, such as Brittany.

✔ **If you understand the role that fitness trade-offs play in determining life-history patterns, you should be able to (1) predict how survivorship and fecundity should compare in *L. vivipara* in the warmest versus coldest parts of their range, and (2) comment on why females in these populations lay many eggs instead of giving birth to a relatively small number of live young.**

Life-History Patterns across Species The life-history data you've reviewed thus far all involve comparisons of populations within a species. But the same patterns exist when many different species are compared.

In general, individuals from species with high fecundity tend to grow quickly, reach sexual maturity at a young age, and produce many small eggs or seeds. The mustard plant *Arabidopsis thaliana*, for example, germinates and grows to sexual maturity in just 4 to 6 weeks. In this species, individuals usually live only a few months but may produce as many as 10,000 tiny seeds. They live fast and die young.

In contrast, individuals from species with high survivorship tend to grow slowly and invest resources in traits that reduce damage from enemies and increase their own ability to compete for water, sunlight, or food. A coconut palm, for example, may take a decade to mature but live 60–70 years and produce offspring each

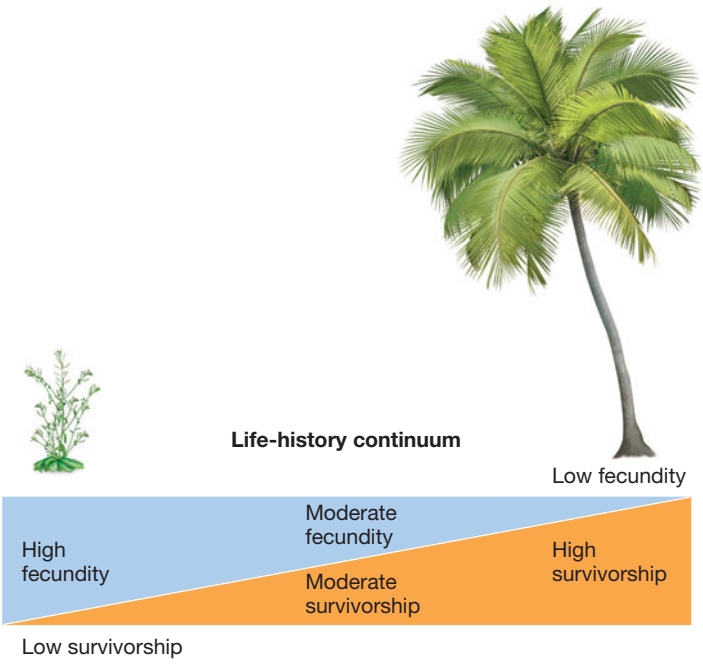

FIGURE 54.3 Life-History Traits Form a Continuum. Every organism can be placed somewhere on this life-history continuum. The placement of a species is most meaningful when it is considered relative to closely related species.

year. Coconut palms invest resources in making stout stems that allow them to grow tall, a relatively extensive root system, large fruits (coconuts), molecules that make herbivores sick, and enzymes that reduce infections from disease-causing fungi. These traits increase survivorship but decrease fecundity.

An *Arabidopsis thaliana* plant and a coconut palm represent two ends of a broad continuum of life-history characteristics (**FIGURE 54.3**). How does a species' location on this continuum affect its population growth rate?

54.3 Population Growth

Life tables provide a snapshot of a population, linking life-history patterns to population growth. Let's take a closer look at changes in population size over time. For conservation biologists, analyzing and predicting changes in population size is fundamental to managing threatened species.

Recall that four processes affect a population's size: Births and immigration add individuals to the population; deaths and emigration remove them. It follows that a population's overall growth rate is a function of birth rates, death rates, immigration rates, and emigration rates.

Quantifying the Growth Rate

A population's growth rate is the change in the number of individuals in the population (ΔN) per unit time (Δt). Here the Greek symbol Δ (delta) means change.

If no immigration or emigration is occurring, then a population's growth rate is equal to the number of individuals (N) in the population times the difference between the birth rate per individual (b) and death rate per individual (d). The difference between the birth rate and death rate per individual is called the per capita rate of increase and is symbolized r. (Per capita means "for each individual.")

If the per capita birth rate is greater than the per capita death rate, then r is positive and the population is growing. But if the per capita death rate begins to exceed the per capita birth rate, then r becomes negative and the population declines. Within populations, r varies through time. Its value can be positive, negative, or 0.

When conditions are optimal for a particular species—meaning birth rates per individual are as high as possible and death rates per individual are as low as possible—then r reaches a maximal value called the **intrinsic rate of increase**, r_{max}. When this occurs, a population's growth rate is expressed as

$$\frac{\Delta N}{\Delta t} = r_{max}N$$

In species such as *Arabidopsis* and fruit flies, which breed at a young age and produce many offspring each year, r_{max} is high. In contrast, r_{max} is low in species such as giant pandas and coconut palms, which take years to mature and produce few offspring each year. Stated another way, r_{max} is a function of a species' life-history traits.

Each species has a characteristic r_{max} that does not change. But at any specific time, a population has an instantaneous growth rate, or per capita rate of increase, symbolized by r. Whereas r_{max} tells you what the maximum growth rate is, r tells you what it is at a particular time. So r is always less than or equal to r_{max}.

The instantaneous growth rate of a population at a particular time is actually likely to be much lower than r_{max}. A population's r is also likely to be different from r values of other populations of the same species (such as in upland and lowland populations of *L. vivipara*), and to change over time (such as in wet years versus dry years). The instantaneous growth rate is dynamic. However, let's consider the simplest case first, where r is constant.

Exponential Growth

The graph in **FIGURE 54.4** (see page 1108) plots changes in population size, for various values of r, under the condition known as exponential growth. **Exponential population growth** occurs when r does not change over time.

The key point about exponential growth is that the growth rate does not depend on the number of individuals in the population. Biologists say that this type of population growth is **density independent.**

It's important to emphasize that exponential growth adds an increasing number of individuals as the total number of individuals, N, gets larger. As an extreme example, an r of 0.02 per year in a population of 1 billion adds over 20 million individuals per year. The same growth rate in a population of 100 adds just

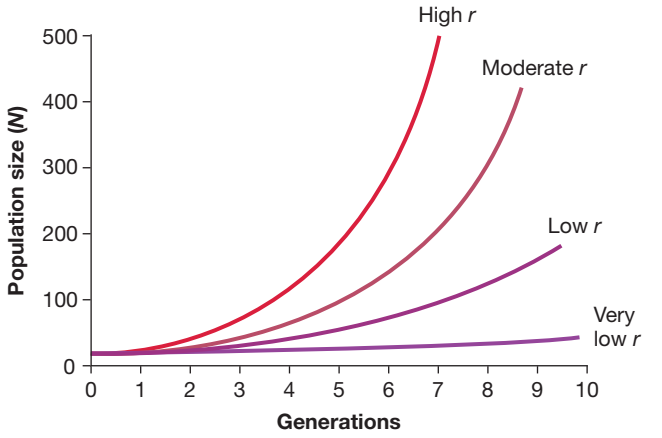

FIGURE 54.4 Exponential Growth Is Independent of Population Size. When the per capita growth rate *r* does not change over time, exponential growth occurs. Population size may increase slowly or rapidly, depending on the size of *r*.

over 2 individuals per year. Even if *r* is constant, the number of individuals added to a population is a function of *N*. The *rate* of increase is the same, but the number of individuals added is not.

In nature, exponential growth is common in two circumstances: **(1)** a few individuals found a new population in a new habitat, or **(2)** a population has been devastated by a storm or some other type of catastrophe and then begins to recover, starting with a few surviving individuals. But it is not possible for exponential growth to continue indefinitely.

If *Arabidopsis* populations grew exponentially for a long period of time, they would eventually fill all available habitat. When population density gets very high, the population's per capita birth rate will decrease and the per capita death rate will increase, causing *r* to decline. Stated another way, growth is often **density dependent.**

Logistic Growth

To analyze what happens when growth is density dependent, biologists use a parameter called carrying capacity. **Carrying capacity, *K*,** is defined as the maximum number of individuals in a population that can be supported in a particular habitat over a sustained period of time.

The carrying capacity of a habitat depends on many factors: food, space, water, soil quality, and resting or nesting sites. Carrying capacity can change from year to year, depending on conditions.

A Logistic Growth Equation If a population of size *N* is below the carrying capacity *K*, then the population should continue to grow. More specifically, a population's growth rate is proportional to $(K-N)/K$:

$$\frac{\Delta N}{\Delta t} = r_{max} N \left[\frac{K-N}{K}\right]$$

This expression is called a logistic growth equation.

In the expression $(K - N)/K$, the numerator defines the number of additional individuals that can be accommodated in a habitat with carrying capacity *K*; dividing $K - N$ by *K* turns this number of individuals into a proportion. Thus $(K - N)/K$ describes the proportion of "unused resources and space" in the habitat. It can be thought of as the environment's resistance to growth.

- When *N* is small, then $(K-N)/K$ is close to 1 and the growth rate should be high. For example: $(1000 - 10)/1000 = 0.99$.
- As *N* gets larger, $(K-N)/K$ gets smaller. For example: $(1000 - 900)/1000 = 0.10$.
- When *N* is at carrying capacity (meaning that $K = N$), then $(K-N)/K$ is equal to 0 and growth stops.

Thus, as a population approaches a habitat's carrying capacity, its growth rate should slow.

The logistic growth equation describes **logistic population growth,** or changes in growth rate that occur as a function of population size. Whereas exponential growth is density independent, logistic growth is density dependent. **Quantitative Methods 54.3** (see pages 1110–1111) explores population growth models in more detail and explains how they relate to the net reproductive rate calculated in the life table.

Graphing Logistic Growth **FIGURE 54.5a** illustrates density-dependent growth in a hypothetical population. The graph plots changes in population size over time, and has three sections.

1. Initially, growth is exponential—meaning that *r* is constant.
2. With time, *N* increases to the point where competition for resources or other density-dependent factors begins to occur. As a result, the growth rate begins to decline.
3. When the population is at the habitat's carrying capacity, the growth rate is 0—the graph of population size versus time is flat.

This is exactly what happened in an experiment on laboratory populations of ciliates, *Paramecium aurelia* and *P. caudatum* (see Chapter 30). Russian biologist Georgii Gause placed 20 individuals from one of the *Paramecium* species into 5 mL of a solution. He created many replicates of these 5-mL environments for each species separately. He kept conditions as constant as possible by adding the same number of bacterial cells every day for food, washing the solution every second day to remove wastes, and maintaining the pH at 8.0.

In the graphs in **FIGURE 54.5b**, each data point represents population size for one of the species—the average of the replicates in the experiment. Note that both species exhibited logistic growth in this environment. The carrying capacity differed in the two species, however. The maximum density of *P. aurelia* averaged 448 individuals per mL, but that for *P. caudatum* averaged just 128 individuals per mL. (When the two species are grown together, one species gets eliminated; see Chapter 55.)

In both of the *Paramecium* species in this experiment, exponential growth could be sustained for only about five days. What factors cause growth rates to change?

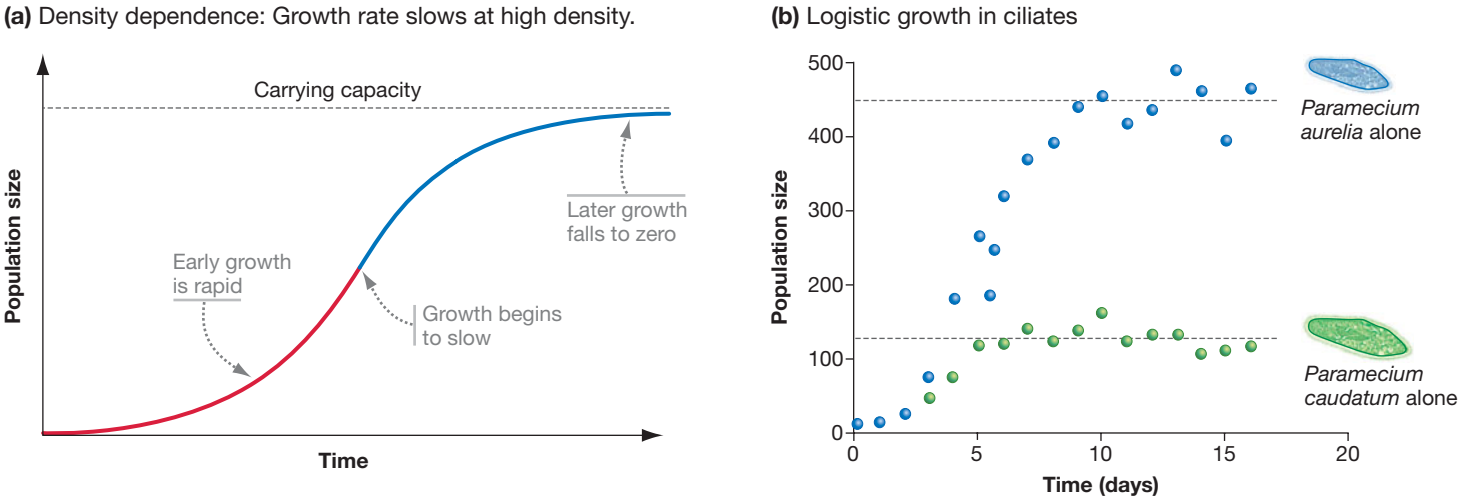

FIGURE 54.5 Logistic Growth Is Dependent on Population Size. (a) A curve illustrating the pattern predicted by the logistic growth equation. This pattern often occurs when a small number of individuals colonize an unoccupied habitat. Initially, *r* is high because competition for resources is low to nonexistent. Carrying capacity depends on the quality of the habitat and can vary over time. **(b)** Data from laboratory experiments with two species of *Paramecium*.

DATA: Gause, G. F. 1934. *The Struggle for Existence*. New York: Hafner Press.

What Limits Growth Rates and Population Sizes?

Population sizes change as a result of two general types of factors:

1. *Density-independent factors* alter birth rates and death rates irrespective of the number of individuals in the population, and they usually involve changes in the abiotic environment—variation in weather patterns, or catastrophic events such as cold snaps, hurricanes, volcanic eruptions, or drought.
2. *Density-dependent factors* change in intensity as a function of population size, and they are usually biotic. When trees crowd each other, they have less water, nutrients, and sunlight at their disposal and make fewer seeds.

A Closer Look at Density Dependence To get a better understanding of how biologists study the density-dependent factors that affect population size, consider the data in **FIGURE 54.6**.

The graph in Figure 54.6a presents results of an experimental study of a coral-reef fish called the bridled goby. Each data point represents the average of eight artificial reefs constructed by ecologists Graham Forrester and Mark Steele from pieces of real coral reefs. The initial density, plotted along the *x*-axis, represents the number of bridled gobies released per area at the start of the experiment. The proportion surviving, plotted on the vertical axis, represents the individuals that were still living at that reef 30 days later. The researchers compared the survivorship of

DATA: Forrester, G. E. and M. A. Steele 2000. *Ecology* 81: 2416–2427; Arcese, P., and J. N. M. Smith. 1988. *Journal of Animal Ecology* 57: 119–136.

✔**QUESTION** When song sparrow populations are at high density and extra food is provided to females experimentally, average clutch size is much higher than expected from the data in part (b). Based on these data, state a hypothesis to explain why average clutch size declines at high density.

QUANTITATIVE METHODS 54.3 Developing and Applying Population Growth Equations

To explore how biologists model changes in population size in more detail, let's consider data on whooping cranes, which are large, wetland-breeding birds native to North America (**FIGURE 54.7**). Whooping cranes may live more than 20 years in the wild, but it is common for females to be six or seven years old before they breed for the first time. Female cranes lay just one or two eggs per year and usually rear just one chick. Based on these life-history characteristics, you should understand why the growth rate of the whooping crane populations is extremely low.

Conservation biologists monitor this species closely because hunting and habitat destruction reduced the total number of individuals in the world to about 20 in the mid-1940s. Since then, intensive conservation efforts have resulted in a current total population of about 571. That number includes a group of 279 individuals that breed in Wood Buffalo National Park in the Northwest Territories of Canada.

FIGURE 54.7 Whooping Cranes Have Been the Focus of Intensive Conservation Efforts.

In addition to the Wood Buffalo population, two new populations of cranes have been established by releasing offspring raised in captivity. One of these groups lives near the Atlantic coast of Florida year-round; the other group migrates from breeding areas in northern Wisconsin to wintering areas along Florida's Gulf Coast.

According to the biologists who are managing whooping crane recovery, the species will no longer be endangered when the two newly established populations have at least 25 breeding pairs, and when neither population needs to be supplemented with captive-bred young in order to be self-sustaining. How long will this take?

Discrete Growth

Whooping cranes breed once per year, so the simplest way to express a crane population's growth rate is to compare the number of individuals at the start of one breeding season to the number at the start of the following year's breeding season.

To create a general expression for how populations grow over a discrete time interval, biologists use N to symbolize population size. N_0 is the population size at time zero (the starting point), and N_1 is the population size one breeding interval later. In equation form, the growth rate is given as

Finite rate of increase: $\lambda = \frac{N_1}{N_0}$ (Population size one breeding interval later / Population size at time zero)

(Eq. 54.4)

The parameter λ (lambda) is called the **finite rate of increase.** (In mathematics, a *finite rate* refers to an observed rate over a given period of time. A *parameter* is a variable or constant term that affects the shape of a function.) The current population size at Wood Buffalo is 279. Suppose that biologists count 300 cranes on the breeding grounds next year. The population growth rate could be calculated as $290/279 = 1.039 = \lambda$. Stated another way, the population will have grown at the rate of 3.9 percent per year. Rearranging the expression in Equation 54.4 gives

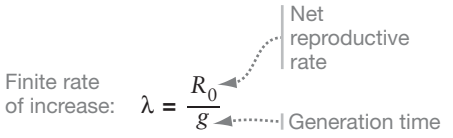
$$N_1 = N_0\lambda \qquad \textbf{(Eq. 54.5)}$$

Stated more generally, the size of the population at the end of year t will be given by:

Population size at end of year t: $N_t = N_0\lambda^t$ (Population size at time zero; Finite rate of increase to the power of t)

(Eq. 54.6)

This equation summarizes how populations grow when breeding takes place seasonally. The size of the population at time t is equal to the starting size, times the finite rate of increase multiplied by itself t times.



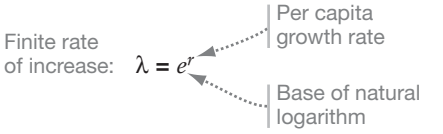
In a sense, λ works like the interest rate at a bank. For species that breed once per year, the "interest" on the population is compounded annually. A savings account with a 5 percent annual interest rate increases by a factor of 1.05 per year.

If a population is growing, then its λ is greater than one. The population is stable when λ is 1.0 and declining when λ is less than 1.0.

If a population's age structure is stable, meaning that the proportion of females in each age class is not changing over time, then its finite rate of increase also has a simple relationship to its net reproductive rate (discussed in Quantitative Methods 54.2):

gobies with natural predators present (orange data points), and also with predators excluded from the study areas by cages (red data points). The higher the original density of gobies on the reef, the least likely these fish were to survive. More specifically, a majority of the gobies in the low-density trials survived the study period. In contrast, only about 20 percent of the gobies in the high-density trials survived. This graph shows a strong density-dependent relationship in *survivorship* both with and without predators.

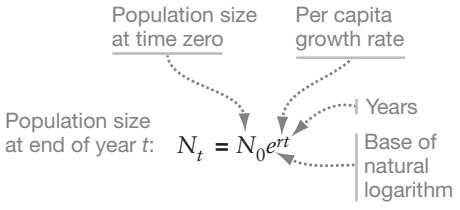
The graph in Figure 54.6b is from Peter Arcese and James Smith's long-term study of song sparrows on Mandarte Island, British Columbia. Each data point represents a different year.



(Eq. 54.7)

In essence, dividing the net reproductive rate by generation time transforms it into a discrete rate.

Continuous Growth

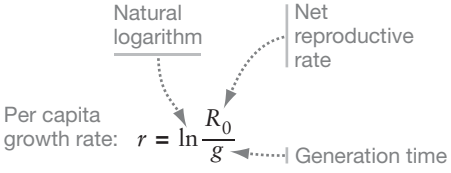


The parameters λ and r (the finite rate of increase and the per capita growth rate, respectively) have a simple mathematical relationship. The best way to understand their relationship is to recall that λ expresses a population's growth rate over a discrete interval of time. In contrast, r gives the population's per capita growth rate at any particular instant. This is why r is also called the instantaneous rate of increase. The relationship between the two parameters is given by

(Eq. 54.8)

where e is about 2.72. (For help with using logarithms, see **BioSkills 6** in Appendix B. Also, note that the relationship between any finite rate and any instantaneous rate is given by finite rate $= e^{\text{instantaneous rate}}$.)

Substituting Equation 54.8 into Equation 54.6 gives



(Eq. 54.9)

This expression summarizes how populations grow when they breed continuously, like humans and bacteria do, instead of at defined intervals. For species that breed continuously, the "interest" on the population is compounded continuously. When the growth rates λ and r are equivalent, however, the differences between discrete and continuous growth are negligible.

Because r represents the growth rate at any given time, and because r and λ are so closely related, biologists routinely calculate r for species that breed seasonally. In the whooping crane example, $\lambda = 1.039$ per year $= e^r$. To solve for r, take the natural logarithm of both sides. (**BioSkills 6** in Appendix B explains how to calculate a natural logarithm using your calculator.) In this case, $r = 0.038$ per year.

The instantaneous rate of increase, r, is also directly related to the net reproductive rate, R_0:

(Eq. 54.10)

Thus, r can be calculated from life-table data. It is a more useful measure of growth rate than R_0, because r is independent of generation time.

To summarize, biologists have developed several ways of calculating and expressing a population's growth rate:

Finite rate of increase (λ): easiest to understand, but applies only to populations that breed seasonally.

Net reproductive rate (R_0): can be calculated directly from life-table data, but is dependent on generation time.

Instantaneous rate of increase (r): more difficult conceptually, but is the most useful expression for growth rate because it is independent of generation time and is relevant for species that breed either seasonally or continuously.

Applying the Models

To get a better feel for r and for Equation 54.9, consider the following series of questions about whooping cranes. The key to answering these questions is to realize that Equation 54.9 has just four parameters. Given three of these parameters, you can calculate the fourth. **✔QUANTITATIVE If you understand this concept, you should be able to solve these three problems:**

1. If 20 individuals were alive in 1941 and 571 existed in 2011, what is r? Here $N_t = 571$, $N_0 = 20$, and $t = 70$ years. Substitute these values into Equation 54.9 and solve for r. Then check your answer at the end of this box.[1]
2. The most recent report issued by the biologists working on the Wood Buffalo crane recovery program estimates that that the flock should be able to sustain an r of 0.048 for the foreseeable future. If the flock currently contains 279 individuals, how long will it take that population to double? Here $N_0 = 279$ and $N_t = 2 \times 253 = 558$. In this case, you solve Equation 54.9 for t. Then check your answer.[2]
3. In 2002, a pair of birds in the flock that lives in Florida year-round successfully raised offspring (nine years after the first cranes were introduced there). In 2003, another pair of cranes in this population bred successfully. If the number of breeding pairs had continued to double each year, how long would it have taken to reach the goal of 25 breeding pairs? (Note that $\lambda = 2.0$ if a population is doubling each year.) Solve for r first (Equation 54.8); then, given that $N_0 = 2$ and $N_t = 25$, solve for t and check your answer.[3]

[1] $r = 0.048$; [2] $t = 14$ years; [3] $t = 3.64$ years.

The density of females, plotted along the horizontal axis, is the number of females that bred on the island; the clutch size, plotted on the vertical axis, is the average number of eggs laid by each female. Females at low density had about 0.5 eggs more per clutch, on average, than females at high density. This graph indicates a strong density-dependent relationship in *fecundity*.

Density-dependent changes in survivorship and fecundity cause logistic population growth. In this way, density-dependent factors define a particular habitat's carrying capacity. If gobies get crowded, they die or emigrate. If song sparrows are crowded, the average number of eggs and offspring that they produce declines.

Carrying Capacity Is Not Fixed It's important to recognize that K varies among species and populations. K varies because for any particular species, some habitats are better than other habitats due to differences in food availability, space, and other density-dependent factors. Stated another way, K varies in space. It also varies with time, because conditions are better in some years than in others.

What's more, the same habitat may have a very different carrying capacity for different species—as the experiment with growing paramecia in 5-mL vials showed. The same area will tend to support many more individuals of a small-bodied species than of a large-bodied species, for example, simply because large individuals demand more space and resources.

These simple observations help explain the variation in total population size that exists among species and among populations of the same species.

check your understanding

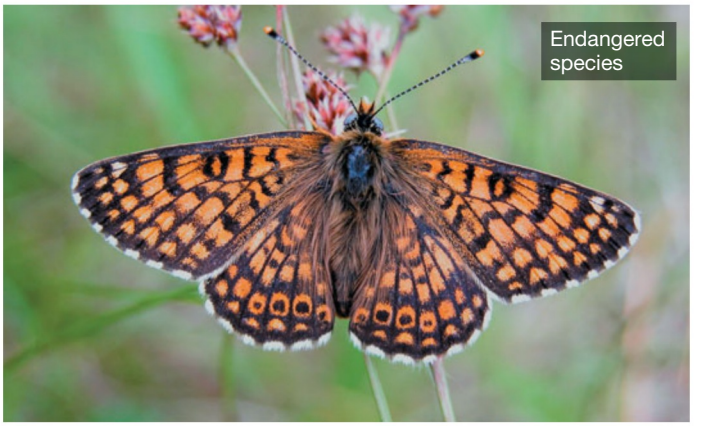
If you understand that . . .

- Populations grow exponentially unless slowed by density dependence.
- Density-dependent factors that influence population growth rates include competition for resources such as food and sunlight.

✔You should be able to . . .

Propose a density-dependent factor that limits growth in *Lacerta vivipara* and design an experiment to test this hypothesis.

Answers are available in Appendix A.



54.4 Population Dynamics

The tools introduced in the previous two sections provide a foundation for exploring how biologists study **population dynamics**—changes in populations through time and space. Let's pull together what you have learned about the spatial distribution of populations, demography, and population growth rates—and bring immigration and emigration into the discussion—by considering one of the most important patterns observed: the "blinking on and off" of fragmented metapopulations.

How Do Metapopulations Change through Time?

Glanville fritillaries are an endangered species of butterfly native to the Åland islands off the coast of Finland (**FIGURE 54.8a**). They are a well-studied example of a metapopulation because they occupy isolated patches of habitat within their geographic range. Recent research on Glanville fritillaries by Ilkka Hanski and colleagues illustrates the consequences of dynamic metapopulation structure for endangered species.

(a) Glanville fritillaries live in patches of meadow in Finland.

(b) A metapopulation is made up of small, isolated populations.

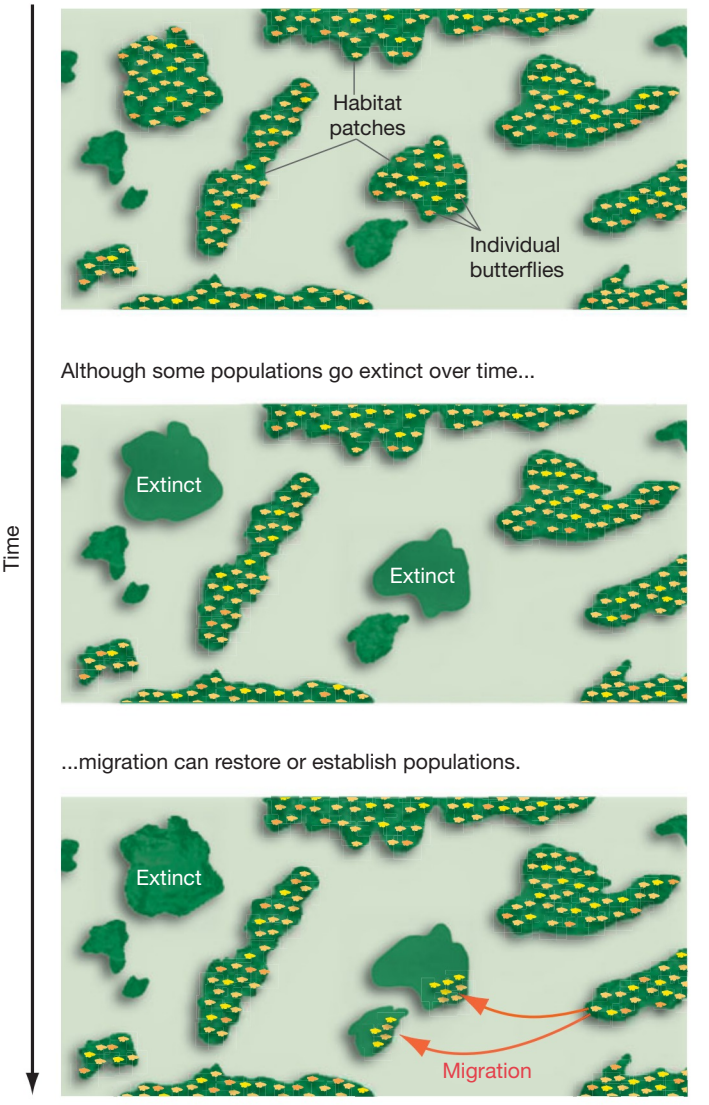


FIGURE 54.8 Metapopulation Dynamics Depend on Extinction and Recolonization. The overall size of a metapopulation stays relatively stable even if populations go extinct. These populations may be restored by migration, or unoccupied habitats might be colonized.

Metapopulations Should Be Dynamic Research on Glanville fritillaries began with a survey of meadow habitats on the islands. Because fritillary caterpillars feed on just two types of host plant, *Plantago lanceolata* and *Veronica spicata*, the team was able to pinpoint potential butterfly habitats.

Hanski's group estimated the fritillary population size within each patch of habitat by counting the number of larval webs in the patch. Of the 1502 meadows that contained the host plants, 536 had Glanville fritillaries. The patches ranged from 6 m^2 to 3 ha in area. Most had only a single breeding pair of adults and one larval group, but the largest population contained hundreds of pairs of breeding adults and 3450 larvae.

FIGURE 54.8b illustrates how a metapopulation like this is expected to change over the years.

- Given enough time, each population within the larger metapopulation is expected to go extinct. The cause could be a catastrophe, such as a storm; it could also be a disease outbreak or a sudden influx of predators.
- Migration from nearby populations can reestablish populations in empty habitat fragments.

In this way, the balance between extinction and recolonization exists within a metapopulation. Even though populations blink on and off over time, the overall metapopulation is maintained at a stable number of individuals.

An Experimental Test Does this metapopulation model correctly describe the population dynamics of fritillaries? To answer this question, Hanski's group conducted a mark–recapture study. They caught and marked many individuals, released them, and revisited fritillary habitats later to recapture as many individuals as possible (see Quantitative Methods 54.1).

Of the 1731 butterflies that the biologists marked and released, 741 were recaptured over the course of the summer study period. Of the recaptured individuals, 9 percent were found in a previously unoccupied patch. This migration rate is high enough to suggest that patches where a population has gone extinct will eventually be recolonized.

Hanski and co-workers repeated the survey two years after their initial census. Just as the metapopulation model predicted, some populations had gone extinct and others had been created. On average, butterflies were lost from 200 patches each year; 114 unoccupied patches were colonized and newly occupied each year. The overall population size was relatively stable even though constituent populations came and went.

To summarize, the history and future of a metapopulation is driven by the birth and death of populations, just as the dynamics of a single population are driven by the birth and death of individuals. Further, migration is an important source of individuals to recolonize patches of vacated habitats. As the final section in this chapter shows, these dynamics have important implications for conserving biodiversity.

Why Do Some Populations Cycle?

Density-dependent factors can be based on *intraspecific* ("within-species") interactions, such as competition among members of a cohort for food, or *interspecific* ("between-species") interactions, such as predation, parasitism, or competition among species for food (discussed in detail in Chapter 55). Analyzing population cycles has been a particularly productive way to understand how intraspecific and interspecific interactions interact. **FIGURE 54.9** shows a classic case of population cycling that involves two species: snowshoe hare and lynx in northern Canada.

The *x*-axis on this graph plots a 50-year interval; the *y*-axes show changes in hare population density (on the left, with a logarithmic scale) and changes in lynx density (on the right). Data for hares are plotted in tan; data for lynx are plotted in blue. Note three key points:

1. The scales on the *y*-axes are different—there are many more hares than lynx. (The *y*-axis for hares is logarithmic to compress the values so they can be compared more easily to changes in the lynx population.)
2. The hare and lynx populations cycle every 10 years on average.
3. Changes in lynx density lag behind changes in hare density by about two years.

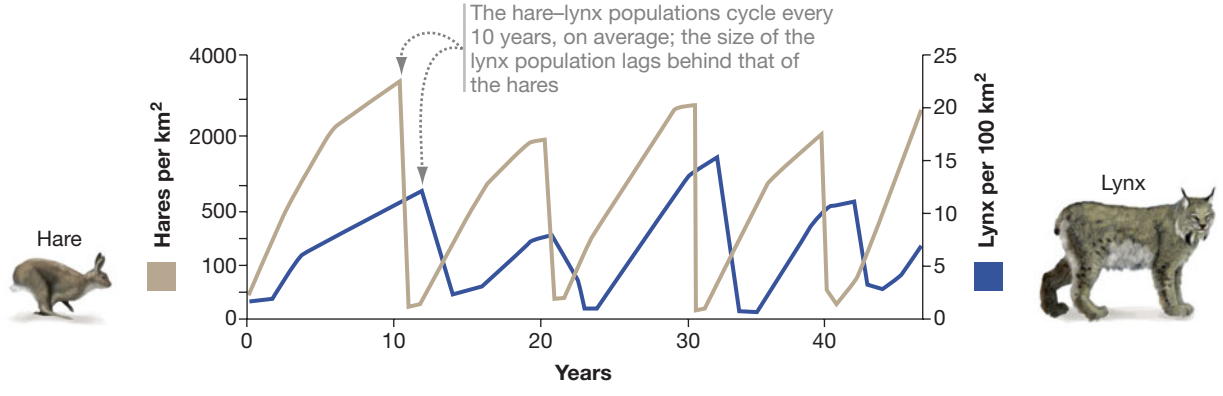

FIGURE 54.9 The Hare and Lynx Population Cycles Are Synchronous, but Lagged.

DATA: MacLulich, D. A. 1937. *University of Toronto Studies Biological Series* 43.

Snowshoe hares are herbivores—they subsist on leaves and stems that grow close to the ground. Lynx are predators, and they subsist mainly on snowshoe hares.

Is It Food or Predation? To explain the hare–lynx cycle, biologists posed two hypotheses based on density-dependent factors:

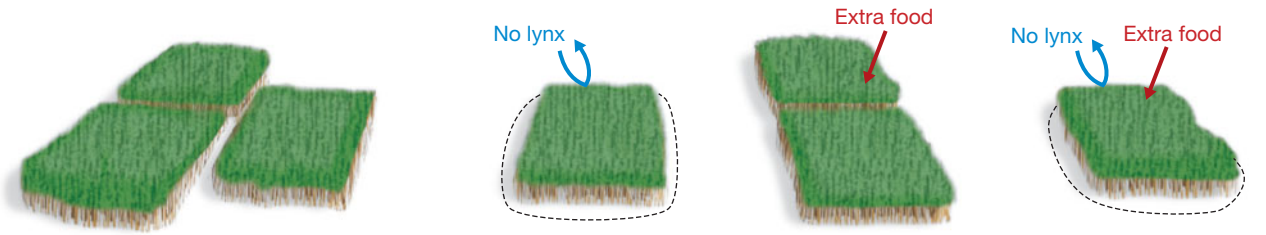
1. Hares use up all their food when their populations reach high density and starve; in response, lynx also starve.
2. Lynx populations reach high density in response to increases in hare density. At high density, lynx eat so many hares that the prey population crashes.

Stated another way, hares control lynx population size, or lynx control hare population size. The cycle could be controlled by intraspecific competition for food or interspecific interactions.

A Field Experiment To test these hypotheses, Charles Krebs and colleagues set up a series of 1-km^2 study plots in boreal forest habitats that were as identical as possible (**FIGURE 54.10**).

- Three plots were left as unmanipulated controls.
- One plot was ringed with an electrified fence made up of a mesh that excluded lynx but allowed hares to pass freely.
- Two plots received additional food for hares year-round (fertilizer was used to increase plant growth).

RESEARCH



QUESTION: What factors control the hare–lynx population cycle?

HYPOTHESIS: Predation, food availability, or a combination of those two factors controls the hare–lynx cycle.

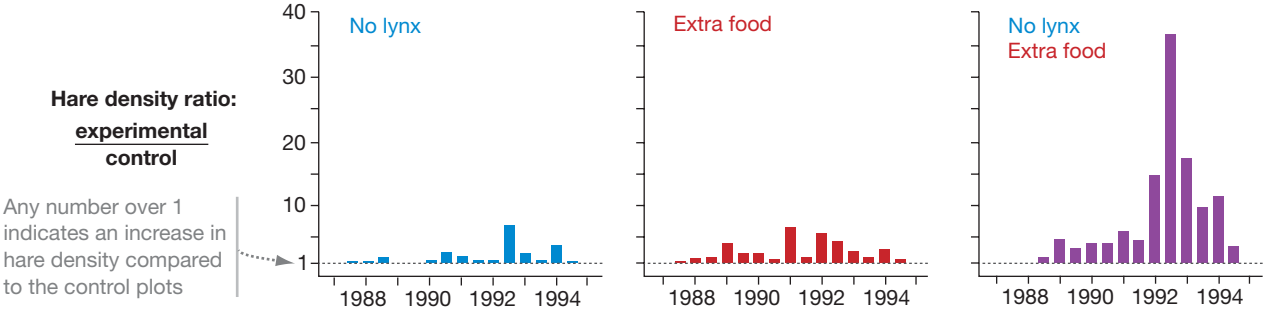
NULL HYPOTHESIS: The hare–lynx cycle isn't driven by predation, food availability, or a combination of those two factors.

EXPERIMENTAL SETUP:

Document hare population in seven study plots (similar boreal forest habitats, each 1 km^2) from 1987 to 1994 (most of a population cycle).

3 plots: Unmanipulated controls

1 plot: Electrified fence excludes lynx but allows free access by hares.



2 plots: Supply extra food for hares.

1 plot: Electrified fence excludes lynx but allows free access by hares; supply extra food for hares.

PREDICTION: Hare populations in at least one type of manipulated plot will be higher than the average population in control plots.

PREDICTION OF NULL HYPOTHESIS: Hare populations in all of the plots will be the same.

RESULTS:

CONCLUSION: Hare populations are limited by both predation and food availability. When predation and food limitation occur together, they have a greater effect than either factor does independently.

FIGURE 54.10 Experimental Evidence that Predation and Food Availability Drive the Hare–Lynx Cycle.

SOURCE: Krebs, C. J., S. Boutin, R. Boonstra, et al. 1995. Impact of food and predation on the snowshoe hare cycle. *Science* 269: 1112–1115.

✔**QUESTION** Why do you think the extra food did not cause a more dramatic increase in hare density at the *beginning* of the population cycle?

- One plot had a predator-exclusion fence and was also supplemented with food for hares year-round.

The biologists then used the mark–recapture method and radio collars to monitor the size of the hare and lynx populations over an 8-year period.

The graphs in Figure 54.10 plot average hare density in the lynx-exclusion, food-addition, and combination plots relative to controls. A value of 1 on the *y*-axis means that hare density in the experimental and control plots were the same. Each bar represents the average population density over a six-month interval.

The graphs should convince you that plots with predators excluded showed higher hare populations than did control plots. This result supports the hypothesis that predation by lynx reduces hare populations. Plots with supplemental food also had higher populations than controls. But the plot with supplemental food *and* predators excluded had a hare population that became as much as 35 times denser than the population in the control plots.

Note that the effects of the treatments were not even over the course of the study—most of the effects occurred during the decline phase of the cycle, which occurred from 1992 to 1994. As control plots were crashing, the experimental plots retained some or many hares.

These data support the hypothesis that hare populations are limited by availability of food as well as by predation and that food availability and predation intensity interact—meaning the combined effect of food and predation is much larger than their impact in isolation. The leading hypothesis to explain this combined effect is that when hares are at high density, individuals are weakened by nutritional stress and are more susceptible to predation.

Research on population cycles has increased our understanding of density dependence factors in population dynamics. Now let's consider factors that determine dynamics in the human population.

54.5 Human Population Growth

As the life-table data presented in Section 54.1 showed, age dramatically affects the probability that an individual will reproduce and survive to the following year. A population's age structure, in turn, dramatically influences the population's growth over time.

Age Structure in Human Populations

To study age structure in our species, researchers use stacks of horizontal bars to plot the number of males and the number of females in each age cohort—often in five-year intervals between birth (0) and 100. The resulting graph is called a population pyramid or age pyramid.

Age Pyramids In countries where industrial and technological development took place generations ago, like Sweden, survivorship has been high and fecundity low for several decades. An age pyramid like that in **FIGURE 54.11a** results. The most striking pattern in these data is that most of the age classes contain similar numbers of people. The evenness occurs because about the same number of infants are being born each year, and because most of them survive to old age.

In contrast, the age distribution is bottom heavy in less-developed nations like Honduras (**FIGURE 54.11b**). These populations are dominated by the very young, because they are undergoing rapid growth—the number of children being born recently is higher than the number of people existing in older age classes.

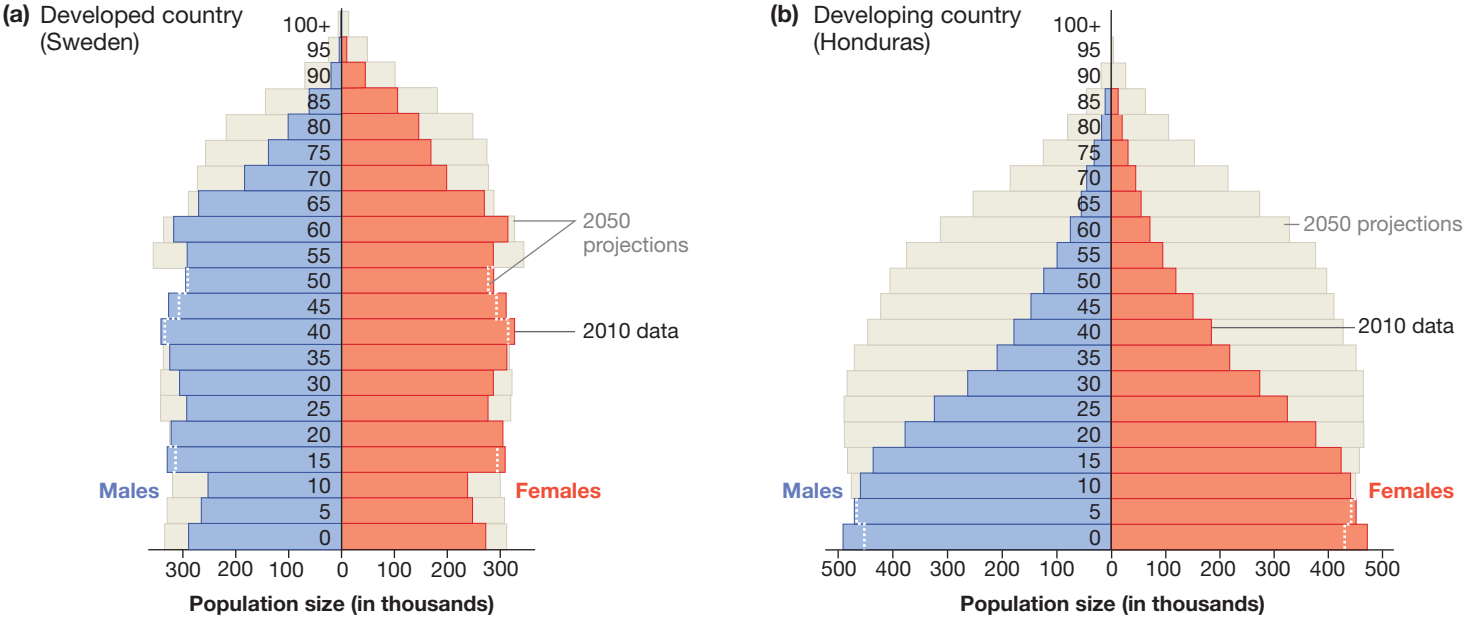

FIGURE 54.11 The Age Structure of Human Populations Varies Dramatically.

DATA: United Nations, *World Population Prospects: The 2010 Revision*.

Analyzing an age pyramid can give biologists important information about a population's history. But studying age distributions can also help researchers predict a population's future.

Look again at Figure 54.11a, and note that the white lines and lighter bars show what the age structure of Sweden is projected to be in 2050. Modest changes in the age distribution will occur because survivorship has increased while fecundity remains the same. But the population is not expected to grow quickly, because only modest numbers of individuals reach reproductive age. The projections highlight a major public policy concern in the industrialized countries: how to care for an increasingly aged population.

Now consider Figure 54.11b again. Thanks to dramatic improvements in health care, most young Hondurans survive to reproductive age. The projected age distribution in 2050 does not continue to flare out, however, because fecundity is declining. The projections illustrate a major public policy concern in less-developed countries: providing education and jobs for an enormous group of young people who will be reaching adulthood during the lifetimes of preceding generations.

Population "Momentum" The data in Figure 54.11b make another important point: Because of recent and rapid population growth in developing countries, overall population size will increase dramatically in these nations over the course of your lifetime. Honduras will have many more people in 2050 than it does now.

A large part of this increase will be due to increased survivorship. But the number of offspring being born each year is also expected to stay high, even though fecundity is predicted to *decline*. This result seems paradoxical, but it is based on a key observation: These populations now contain so many young women that the overall number of births will stay high, even though the average number of children *per female* is much lower than it was a generation ago.

To capture this point, biologists say that these populations have momentum or inertia. Combined with high survivorship, age structures like these make continued increases in the total human population almost inevitable.

Analyzing Change in the Growth Rate of Human Populations

Fossil and molecular evidence indicates that *Homo sapiens* originated in Africa about 200,000 years ago, then migrated into Asia, Europe, Australia, and eventually North and South America (see Chapter 35). The geographic range of our species now consists of most of the land surface of the planet. How did our population size change over that time?

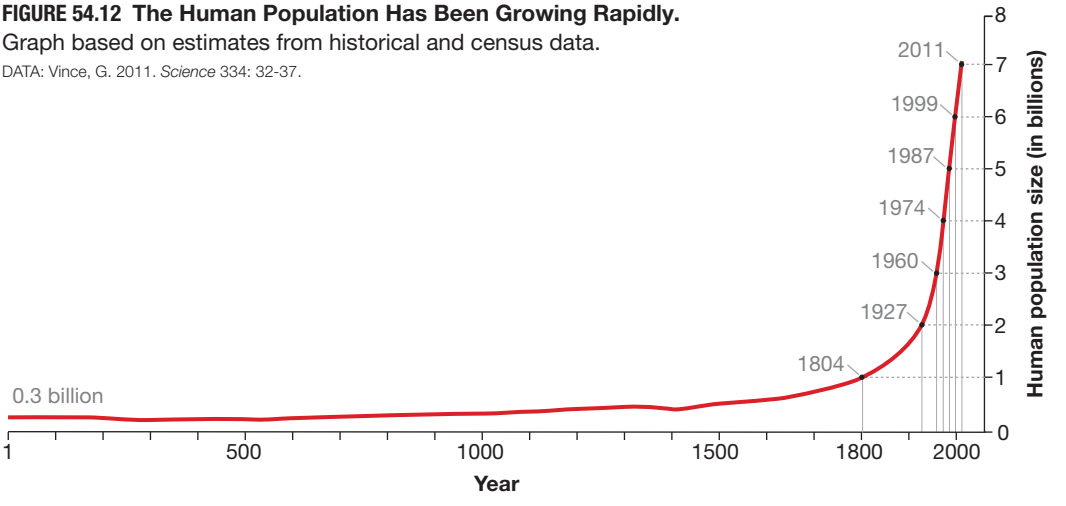

FIGURE 54.12 plots changes in the human population over the past 2000 years. Although the curve's shape looks superficially similar to exponential growth, the growth rate for humans has—until recently—actually *increased* over time, leading to a steeply rising curve.

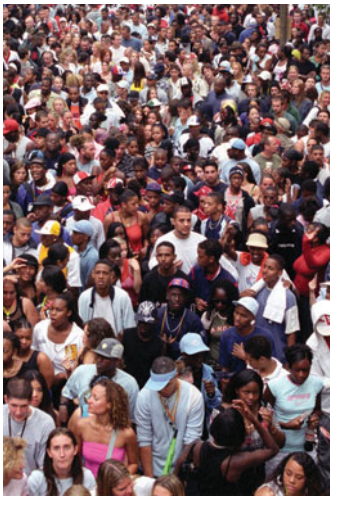

It is almost impossible to overemphasize just how dramatically the human population has grown recently. It took all of human history to reach a population size of 1 billion in 1804, and only 123 years to reach 2 billion. Most recently, it took only 12 years to add 1 billion people to the population to reach 7 billion.

Consider that until your grandparents' generation, no individual had lived long enough to see the human population double. But many members of the generation born in the early 1920s have lived to see the population *triple*. And to drive home the impact of continued population doubling, consider this: If you were given a penny on January 1, then $0.02 on January 2, $0.04 on January 3, and so on, you would be handed $10,737,418.00 on January 31.

The astonishing growth rate of the human population has raised a sense of alarm that we will overshoot the carrying capacity of our planet—and this concern is not new. For example, Thomas Robert Malthus's book, *An Essay on the Principle of Population*, was widely influential in the early 1800s. Malthus warned that the population cannot continue to increase unchecked—competition for resources will eventually slow population growth, whether by famine, war, or voluntary reduction of family size. Malthus was an important source of inspiration for Charles Darwin in his formulation of the theory of evolution by natural selection (Chapter 25).

FIGURE 54.12 The Human Population Has Been Growing Rapidly.
Graph based on estimates from historical and census data.
DATA: Vince, G. 2011. *Science* 334: 32-37.

How Large Is the Current Human Population? As this book goes to press, the world population is estimated at over 7 billion. About 77 million additional people—more than double the population of California—are being added each year.

The consequences of recent and current increases in human population are profound (see Chapter 57). Aside from being the primary cause of habitat loss and species extinctions, overpopulation is linked by researchers to declines in living standards, mass movements of people, political instability, and acute shortages of water, fuel, and other basic resources in many parts of the world.

The one encouraging trend in the data is that the growth rate of the human population has already peaked and begun to decline. The highest growth rates occurred between 1965 and 1970, when populations increased at an average of 2.04 percent per year. Between 1990 and 1995, the overall growth rate in human populations averaged 1.46 percent per year; the current growth rate is 1.2 percent annually.

In humans, r may be undergoing the first long-term decline in history. The question is: Will the human population stabilize or decline in time to prevent global—and potentially irreversible—damage?

Will Human Population Size Peak in Your Lifetime? The United Nations Population Division makes regular projections for how human population size will change between now and 2050. For most readers of this book, these projections describe what the world will look like as you reach your early 60s.

The UN projections are based on three scenarios, which hinge on different values for **fertility** rates—the average number of surviving children that each woman has during her lifetime. Currently, the worldwide average fertility rate is 2.5 children per woman. This represents an enormous reduction in fertility from the 1950s, which averaged 5.0 children per woman. **FIGURE 54.13** shows how total population size is expected to change by 2050 if average fertility continues at 2.5 (high), or declines to 2.0 (medium), or 1.6 (low) children per woman.

The middle number in the projections is statistically the most likely scenario. Its value is close to the replacement rate of the population, 2.1. The **replacement rate** is the average fertility required for each woman to produce exactly enough offspring to replace herself and her offspring's father. (It is slightly above 2.0 to account for the mortality of some women before they bear children). When this fertility rate is sustained for a generation, $r = 0$, and there is **zero population growth.**

A glance at Figure 54.13 should convince you that the three scenarios are starkly different. If average fertility around the world stays at its current level, world population will be closing in on 11 billion about the time you might consider retiring—a 50 percent increase over today's population with no signs of peaking. The low-fertility projection, in contrast, predicts that the total human population in 2050 will be just over 8 billion and will have peaked.

The Role of Fertility Rates The UN's population projections make an important point: The future of the human population hinges on fertility rates—on how many children each woman living today decides to have. Those decisions, in turn, depend on a wide array of factors, including how free women are to choose their family size and how much access women have to education.

Why education? When women are allowed to become educated, they tend to delay having children and have a smaller overall family size. Access to education and reliable birth control methods (see Chapter 50), in addition to overall economic development and access to quality health care, will play a large role in determining how world population changes over your lifetime.

To summarize, the human population may be approaching the end of a period of rapid growth that lasted well over 500 years. Changes in fertility rates will be a major factor in determining how quickly population growth rates decline and how large the population eventually becomes.

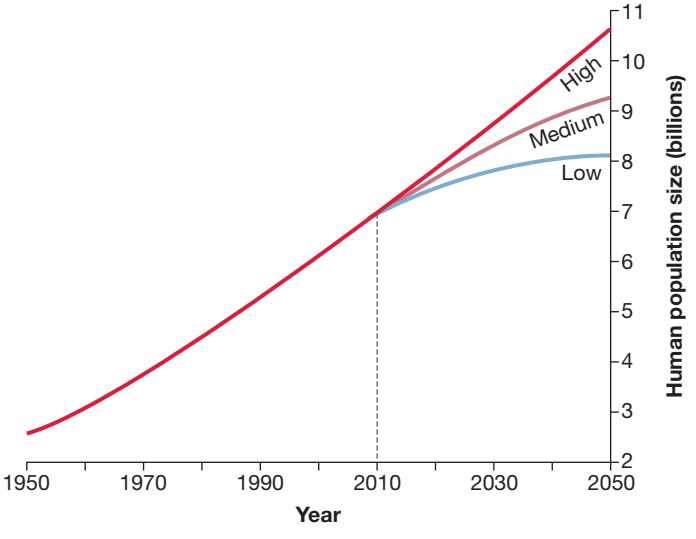

FIGURE 54.13 Projections for Human Population Growth to 2050. The "High," "Medium," and "Low" labels refer to fertility rates.

DATA: United Nations, *World Population Prospects: The 2010 Revision*.

check your understanding

If you understand that . . .

- A population's age structure reflects changes in survivorship and fertility rates over time.
- Age structure affects population dynamics because it dictates how many females of reproductive age are in the population.

✔You should be able to . . .

1. Explain why the age structure of human populations differs between developed and developing nations.
2. Explain why changes in fertility rates have such a dramatic impact on projections for the total human population in 2050.

Answers are available in Appendix A.

The human population boom is central to ecology because the growing human population dramatically affects other organisms via habitat destruction, pollution, overharvesting of fish and other resources, and climate change. As the human population rises, the impact on other species increases.

54.6 How Can Population Ecology Help Conserve Biodiversity?

When designing programs to save species threatened with extinction, conservation biologists draw heavily on concepts and techniques from population ecology. As habitat destruction and global climate change push species into decline, the study of population growth rates and population dynamics has taken on an increasingly applied tone.

To illustrate one of the ways that biologists apply the theory and results introduced in this chapter, let's analyze how an understanding of life-table data and geographic structure can help direct conservation action.

Using Life-Table Data

Suppose that you were in charge of reintroducing a population of lizards to a nature reserve, and that earlier research had documented survivorship and fecundity data (**FIGURE 54.14a**).

Your initial plan is to take 1000 newly hatched female lizards from a captive breeding center and release them into the natural habitat, along with enough males for breeding to occur. Is this population likely to become established and grow on its own, or will you need to keep introducing offspring that have been raised in captivity?

Making Population Projections To answer this question, you need to use the life-table data in Figure 54.14a and calculate two values:

1. How many adults survive to each age class each year?

(a) Life table data from previous study

Age (x)	Survivorship (l_x)	Fecundity (m_x)
0 (birth)	----	0.0
1	0.33	3.0
2	0.20	4.0
3	0.04	5.0

1st-year cohort
2nd-year cohort
3rd-year cohort
4th-year cohort

(b) Predictions: Fate of first-generation females

Year	0 (newborns)	1-year-olds	2-year-olds	3-year-olds	Total population size (N)
1st	1000 (just introduced)				1000
2nd	990 (= 330 × 3.0)	330 (= 1000 × 0.33)			1320 (= 990 + 330)
3rd	800 (= 200 × 4.0)		200 (= 1000 × 0.20)		?
4th	200 (= 40 × 5.0)			40 (= 1000 × 0.04)	?

(c) Predictions: Fate of first- and second-generation females

Year	0 (newborns)	1-year-olds	2-year-olds	3-year-olds	Total population size (N)
1st	1000				1000
2nd	990	330			1320
3rd	800 + 981 (981 = 327 × 3.0)	327 (= 990 × 0.33)	200		?
4th	200 + 792 (792 = 198 × 4.0)		198 (= 990 × 0.20)	40	?

(d) Predictions: Fate of first-, second-, and third-generation females

4th	200 + 792 + ?	?	198	40	?

FIGURE 54.14 Life-Table Data Can Be Used to Project the Future of a Population.

✔**QUANTITATIVE** Fill in the blanks indicated by the gray question marks. Note that in the bottom row, you must calculate the number of 1-year-olds in the 3rd-year cohort (indicated by blue) and the number of newborns produced by those 1-year-olds (part of the 4th-year cohort, in green).

2. How many offspring are produced by each adult age class—each year over the course of several years?

FIGURE 54.14b starts these calculations for you. The predicted fate of the original 1000 females is indicated in red. Note that in the start of the second year, just 330 of these year-old individuals are expected to survive; only 200 will survive to be 2-year-olds; only 40 will survive to be 3-year-olds.

How many offspring will this first cohort produce? Remember that just 330 of the original 1000 females are expected to remain after one year. As the purple number in Figure 54.14b indicates, these survivors have an average of 3.0 female offspring apiece. Thus, they contribute 990 new female offspring to the population. In the second year, the 200 females that are left from the original cohort have an average of 4.0 female offspring each and contribute 800 juveniles. In their third year, the 40 surviving females average 5.0 offspring and contribute 200 juveniles.

FIGURE 54.14c extends the calculations by predicting what will happen as the offspring of the original females, indicated in purple, begin to breed. ✔**QUANTITATIVE** **By continuing the analysis until the third year, you should be able to predict whether the population of lizards will stay the same, decline, or increase over time.** In this way, life-table data can be used to predict the future of populations.

Altering Values for Survivorship and Fecundity Part of the value of a population projection based on life-table data—like the one begun in Figure 54.14—is that it allows biologists to alter values for survivorship and fecundity at particular ages and assess the consequences. For example, suppose that a predatory snake began preying on juvenile lizards. The survivorship of juveniles would decline, decreasing the number of individuals that survive to reproduce each year—with potentially dire consequences for the population size over time.

Analyses like this allow biologists to determine which aspects of survivorship and fecundity are especially sensitive for particular species. The studies done to date support some general conclusions:

- Whooping cranes, sea turtles, spotted owls, and many other endangered species have high juvenile mortality, low adult mortality, and low fecundity. In these species, the fate of a population is extremely sensitive to increases in adult mortality. Based on this insight, conservation biologists have recently begun an intensive campaign to reduce the loss of adult female sea turtles in fishing nets (**FIGURE 54.15**). Previously, most conservation action had focused on protecting eggs and nesting sites.
- Climate change has enormous implications for the life-history traits of populations. For example, the sex of many reptiles is determined by the temperature of the eggs in the nest. Researchers have observed a change in sex ratio of some reptile species due to the warmer climate, and this finding has significant implications for the growth rates of these populations. Direct measurements of life-history traits of populations in the field are essential to mathematical models used to predict ongoing effects of global climate change.

In some or even most cases, the population projections made from life-table data may be too simplistic to be useful. For example, conservationists may need to expand the basic demographic models to account for occasional disturbances such as fires or storms or disease outbreaks. What about species whose overall population dynamics are dictated by a metapopulation structure?

Preserving Metapopulations

Habitat destruction caused by suburbanization and other human activities leaves small populations isolated in pockets of intact habitat (**FIGURE 54.16**; see Chapter 57). Work on Glanville fritillaries and other species has shown that a small, isolated population—even one within a nature preserve—is unlikely to survive over the long term. What can be done about this?

FIGURE 54.15 The mortality of adult sea turtles in fishing nets has a dramatic impact on sea turtle populations. Data from population ecology helps to prioritize conservation action.

FIGURE 54.16 Human activities are turning once intact populations into metapopulations by dividing habitats into fragments.

In Glanville fritillaries, data collected by Hanski's group have identified four attributes of populations that are most likely to persist:

1. They have larger population sizes.
2. They occupy larger geographical ranges.
3. They are closer to neighboring populations (and hence more likely to be colonized).
4. They have higher genetic diversity.

Results like these have important messages for conservation biologists:

- Areas that are being protected for threatened species should be substantial enough in area to maintain large populations that are unlikely to go extinct in the near future. Large populations are more likely than small populations to endure disasters such as storms, and they are much less susceptible to the damaging effects of inbreeding.
- When it is not possible to preserve large tracts of land, an alternative is to establish systems of smaller tracts that are connected by corridors of habitat, so that migration between patches is possible. Constructing "wildlife corridors" is particularly important when patches of appropriate habitat are separated by highways, subdivisions, rivers, or other obstacles to dispersal.
- If the species that is threatened exists as a metapopulation, it is crucial to preserve at least some patches of unoccupied habitat to provide future homes for immigrants. If a population is lost from a preserve, the habitat should continue to be protected so it can be colonized in the future. This can be difficult to do—nonscientists are often skeptical about preserving scarce land that does not (yet) contain the species of interest.

These results are made more complex by climate change. Data on existing populations show that changes in temperature and precipitation are already changing the ranges of species. For some species with large ranges, such as the lizard *Lacerta vivipara* (see Figure 54.1), local extinctions may occur in some populations, such as in the mountains of Spain, while the range expands northward elsewhere. Other species with smaller ranges or the inability to relocate rapidly are likely to go extinct. Population ecology helps quantify past trends in the distribution and abundance of organisms as well as predict future trends, enabling conservation biologists to prioritize their efforts.

CHAPTER 54 REVIEW

For media, go to MasteringBiology

If you understand . . .

54.1 Distribution and Abundance

- The geographic ranges of species vary in size and patchiness and are determined by a combination of abiotic and biotic factors.
- Individuals in a population have a random, clumped, or uniform distribution depending on the availability of resources, dispersal ability, social behavior, and other factors.
- There are many methods for measuring population size, population density, and distribution patterns—the best method to use depends on the behavior of the species.

✔ **You should be able to devise a method for using the pellets (feces) of snowshoe hares to estimate population density.**

54.2 Demography

- Life tables summarize how likely it is that individuals of each age class in a population will survive and reproduce.
- Three general types of survivorship curves have been observed: **(I)** high survivorship throughout life, **(II)** a constant probability of dying at each year of life, and **(III)** high mortality in juveniles followed by high survivorship in adults.
- There is a trade-off between survival and reproduction due to the limited availability of resources.
- In analyzing life history, there is a continuum between populations or species with high survivorship and low fecundity and populations or species with low survivorship and high fecundity.

✔ **You should be able to predict how the data in the life tables constructed in ancient Rome would differ from a life table for present-day Rome.**

54.3 Population Growth

- The growth rate of a population can be calculated from life-table data or from the direct observation of changes in population size over time.
- Exponential growth occurs when the per capita growth rate, *r*, does not change over time.
- During logistic growth, growing populations approach the carrying capacity, *K*, of their environment and *r* declines to 0.
- Density dependence in population growth is due to competition for resources, disease, predation, or other factors that increase in intensity when population size is high. At high density, survivorship and fecundity decrease.

✔ **QUANTITATIVE You should be able to draw a logistic growth curve, describe how *r* changes along the length of the curve, and suggest factors responsible for each change in *r*.**

54.4 Population Dynamics

- In some metapopulations, populations may blink on and off over time even though the overall metapopulation size is stable. Migration can reestablish populations in empty habitat fragments.
- Predator–prey interactions and food availability are density-dependent factors that drive the population cycle of the snowshoe hare and other species.

✔ **Mosquitoes lay their eggs in water and have an aquatic larval stage. You should be able to predict a pattern of mosquito density over time as a function of rain.**

54.5 Human Population Growth

- Age structure has a profound impact on population dynamics. A population with few juveniles and many adults past reproductive age, like the human populations of developed nations, may be declining or stable in size. In contrast, a population with a large proportion of juveniles is likely to increase rapidly in size.
- The total human population has been increasing rapidly and is currently over 7 billion.
- Based on various scenarios for average female fertility, the total human population in 2050 is expected to be between 8 and 11 billion. The future of the human population hinges on fertility rates.

✔ **You should be able to explain why the human population is projected to continue rapid growth, even though fertility rates are declining.**

54.6 How Can Population Ecology Help Conserve Biodiversity?

- Data from population ecology studies help biologists design effective management strategies for endangered species and help prevent other species from becoming endangered.

✔ **You should be able to explain why a small, isolated population is virtually doomed to extinction, but why population size may be stable in a species consisting of a large number of small, isolated populations.**

Answers are available in Appendix A

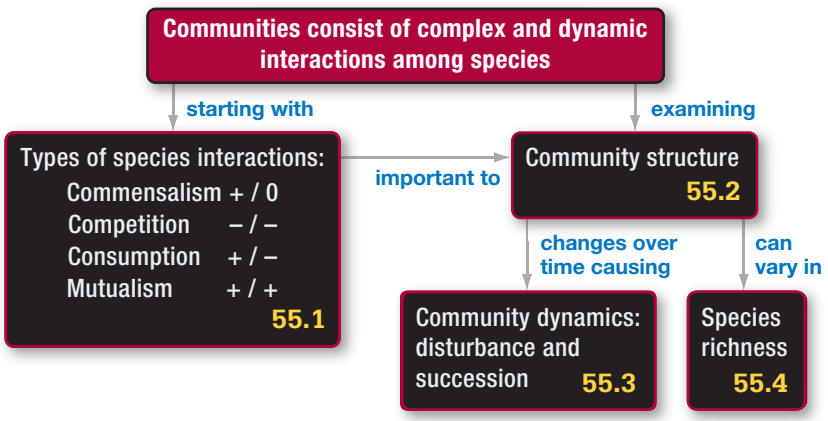
1. What is the defining feature of exponential growth?
   a. The population is growing very quickly.
   b. The growth rate is constant.
   c. The growth rate increases rapidly over time.
   d. The growth rate is very high.
2. List four factors that define population growth.
3. In what populations does exponential growth tend to occur?
   a. populations that colonize new habitats
   b. populations that experience intense competition
   c. populations that experience high rates of predation
   d. populations that have surpassed their carrying capacity
4. True or False? Climate change can influence the population growth of species.
5. If most individuals in a population are young, why is the population likely to grow rapidly in the future?
   a. Death rates will be low.
   b. The population has a skewed age distribution.
   c. Immigration and emigration can be ignored.
   d. Many individuals will begin to reproduce soon.
6. Why have population biologists become particularly interested in the dynamics of metapopulations?
   a. because humans exist as a metapopulation
   b. because whooping cranes exist as a metapopulation
   c. because many populations are becoming restricted to small islands of habitat
   d. because metapopulations explain why populations occupying large, contiguous areas are vulnerable to extinction

✔ TEST YOUR UNDERSTANDING

Answers are available in Appendix A

7. Describe the life-history traits of elephants.
   a. high survivorship, high fecundity
   b. low survivorship, high fecundity
   c. high survivorship, low fecundity
   d. low survivorship, low fecundity
8. Make a table to show what types of traits you would expect to see on the left, middle, and right of the life history continuum (see Figure 54.3). Consider growth habit (herbaceous, shrub, or tree) as well as relative disease- and predator-fighting ability, seed size, seed number, and body size.

9. Offer a hypothesis to explain why humans have undergone near-exponential growth for over 500 years. Why can't exponential growth continue indefinitely? Describe two examples of density-dependent factors that may influence human population growth.
10. Explain why biologists want to maintain (a) "habitat corridors" that connect populations in a metapopulation, and (b) unoccupied habitat that is appropriate for the species in question.
11. Predict which geographic subpopulations of *Lacerta vivipara* may be most vulnerable to the effects of climate change.
12. What is the difference between r (the per capita rate of increase) and r_{max} (the maximum or intrinsic growth rate)?



TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A

13. When wild plant and animal populations are logged, fished, or hunted, only the oldest or largest individuals tend to be taken. Many of the commercially important species are long lived and are slow to begin reproducing. If harvesting is not regulated carefully and exploitation is intense, what impact does harvesting have on a population's age structure? How might harvesting affect the population's life table and growth rate?
14. Design a system of nature preserves for an endangered species of beetle whose larvae feed on only one species of sunflower. The sunflowers tend to be found in small patches that are scattered throughout dry grassland habitats.
15. Make a rough sketch of the age distribution in developing versus developed countries, and explain why the shapes of the diagrams are different. How is AIDS, which is a sexually transmitted disease, affecting the age distribution in countries hard hit by the epidemic?
16. In most species the sex ratio is at or near 1.00, meaning that the number of males and females is approximately equal. In China, however, there is a strong preference for male children. According to the 2000 census there, the sex ratio of newborns is almost 1.17, meaning that close to 117 boys are born for every 100 girls. Based on these data, researchers project that China will soon have about 50 million more men than women of marriageable age. Evaluate whether this skewed sex ratio will affect the population growth rate in China.
    a. No, growth rate is not affected by males.
    b. Yes, growth rate will increase.
    c. Yes, growth rate will decrease.
    d. No, the sex ratio affects only fecundity.

55 Community Ecology

In this chapter you will learn that

This chapter explores how species that live in coral reefs and other communities interact with each other, and how communities change over time.

Populations are dynamic. They grow and decline over time and through space (Chapter 54). However, populations do not exist in isolation—individuals within populations also interact with individuals of other species, forming complex assemblages called communities.

A biological **community** consists of all of the species that interact in a certain area. Ecologists want to know how communities work, and how to manage them in a way that will preserve biodiversity, ecosystem function, and an environment that people want to live in. You can see how community ecology fits into the Big Picture of Ecology on pages 1196–1197.

The goal of this chapter is to explore how species interact with each other and to analyze the structure and dynamics of biological communities—how they develop and change over time. Let's delve in.

BIG PICTURE

This chapter is part of the Big Picture. See how on pages 1196–1197.

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

55.1 Species Interactions

The species in a community interact constantly. Organisms eat each other, exchange nutrients, compete for resources, and provide habitats for each other. In many cases, a population's fate is tightly linked to the other species that share its habitat.

To study species interactions, biologists begin by analyzing the effects of one species on the fitness of another. Recall that the **fitness** of an individual is defined by its ability to survive and produce viable, fertile offspring (Chapter 25).

Does the relationship between two species provide a fitness benefit to members of one species (a "+" interaction) but hurt members of the other species (a "−" interaction)? Or does the association have no effect on the fitness of a participant (a "0" interaction)? There are four general types of interactions:

1. **Commensalism** occurs when one species benefits but the other species is unaffected (+/0).
2. **Competition** occurs when individuals use the same resources—resulting in lower fitness for both (−/−).
3. **Consumption** (including herbivory, predation, and parasitism) occurs when one organism eats or absorbs nutrients from another. The interaction increases the consumer's fitness but decreases the victim's fitness (+/−).
4. **Mutualism** occurs when two species interact in a way that confers fitness benefits to both (+/+).

Let's consider each type of species interaction in more detail. As you analyze each one, watch for three key themes:

1. ***Species interactions can affect the distribution and abundance of a particular species.*** Species interactions can affect geographic ranges, such as the effect of disease-carrying tsetse flies on the distribution of cattle in Africa (Chapter 52). Species interactions can also have impacts on population size, such as the effects of lynx on hare populations in northern Canada (Chapter 54).
2. ***Species act as agents of natural selection when they interact.*** Deer are fast and agile in response to natural selection exerted by their major predators, wolves and cougars. The speed and agility of deer, in turn, promote natural selection that favors wolves and cougars that are fast and that have superior eyesight, senses of smell, and hunting strategies. To capture this point, biologists say that **coevolution** is occurring—a pattern of evolution where two species influence each other's adaptations over time.

   As species interact over time, it is common to observe a **coevolutionary arms race**—a repeating cycle of reciprocal adaptation. In human civilizations, an arms race occurs when one nation develops a new weapon, which prompts a rival nation to develop a defensive weapon, which pushes the original nation to manufacture an even more powerful weapon, and so on. In biology, coevolutionary arms races occur between predators and prey, parasites and hosts, and other types of interacting species.
3. ***The outcome of interactions among species is dynamic and conditional.*** Just as two people may alternately help or compete with each other depending on circumstances, the interactions between different organisms may change over time and space.

Commensalism

Of the four general types of interactions, commensalism (+/0) is the least studied. Commensalism can be challenging to demonstrate, because an absence of fitness benefits or costs ("0") can be difficult to quantify. Commensalism is also very conditional.

An example is the relationship between antbirds and the army ants that they follow in the tropics. As the ants march along the forest floor, they hunt insects and small vertebrates. The antbirds follow and pick off prey species that fly or jump up out of the way of the ants (**FIGURE 55.1**). The antbirds benefit, but the ants are not affected.

However, if antbird attacks start to force other insects into the path of the ants, then both ants and birds benefit, and the

(a) Ants stir up insects while hunting ...

(b) ... antbirds tag along and benefit.

FIGURE 55.1 Commensals Gain a Fitness Advantage but Don't Affect the Species They Depend On. Birds that associate with army ants are commensals. They have no measurable fitness effect on the ants, but gain from the association by capturing insects that try to fly or climb out of the way of the ants.

relationship becomes mutualistic. But if the antbirds begin to steal prey that would otherwise be taken by ants, then the relationship becomes competitive. The outcome of the interaction may depend on the number and types of prey, birds, and ants present and may change over time.

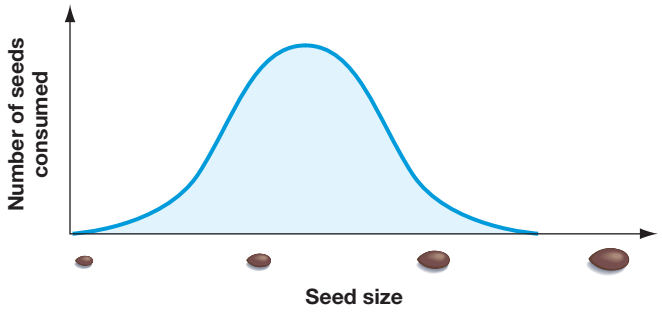
Competition

Competition (−/−) lowers the fitness of the individuals involved for a simple reason: When competitors use resources, those resources are not available to help other individuals survive better and produce more offspring.

Competition that occurs between members of the same species is called **intraspecific** (literally, "within species") **competition.** Intraspecific competition for space, sunlight, food, and other resources intensifies as a population's density increases. As a result, intraspecific competition is a major cause of density-dependent growth (see Chapter 54). **Interspecific** ("between species") **competition** occurs when individuals from different species use the same limiting resources.

Using the Niche Concept to Analyze Interspecific Competition

Early work on interspecific competition focused on the concept of the niche. A **niche** can be thought of as the range of resources that the species is able to use, or the range of conditions it can tolerate. For example, *Anolis* lizards that occupy the crowns of trees on the island of Jamaica occupy a different niche than *Anolis* lizards that live on the ground (Chapter 28).



G. Evelyn Hutchinson proposed that a species' niche could be envisioned by plotting its habitat requirements along a series of axes. **FIGURE 55.2a**, for example, represents one niche axis for a hypothetical species. In this case, the habitat requirement plotted is the size of seeds eaten by members of this population, determined by variables such as mouth or tooth size. Other niche axes could represent other types of foods used or the temperatures, humidity, and other environmental conditions tolerated by the species. In these types of graphs, the *y*-axis represents the number or proportion of resources used, averaged over the population.

Interspecific competition occurs when the niches of two species overlap. The two species plotted in **FIGURE 55.2b**, for example, compete for seeds of intermediate size—assuming that seeds are a limited resource. Individuals that use this "joint" resource are at a disadvantage relative to individuals that use other resources, because they are likely to acquire fewer seeds and have lower fitness as a result. However, if both species experience a similar decrease in fitness due to the overlap of their niches, then **symmetric competition** is said to occur and both species may persist in the area of overlap, even if in reduced numbers.

What Happens when One Species Is a Better Competitor? When **asymmetric competition** occurs, one species suffers a greater fitness decline than the other species does. The outcome of this interaction depends on the amount of overlap in their niches.

What outcomes are possible? To explore this type of competitive interaction, G. F. Gause conducted a series of experiments with two species of the unicellular pond-dweller *Paramecium*.

(a) One species eats seeds of a certain size range.

(b) Partial niche overlap: competition for seeds of intermediate size

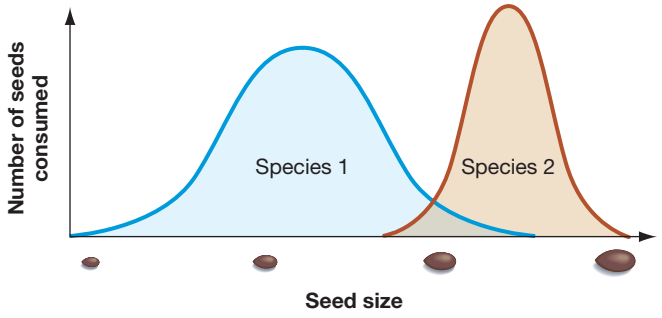


FIGURE 55.2 Niche Overlap Leads to Competition. (a) A graph describing one aspect of a species' fundamental niche, meaning the range of resources that it can use or range of conditions it can tolerate. **(b)** Competition occurs when the niches of different species overlap.

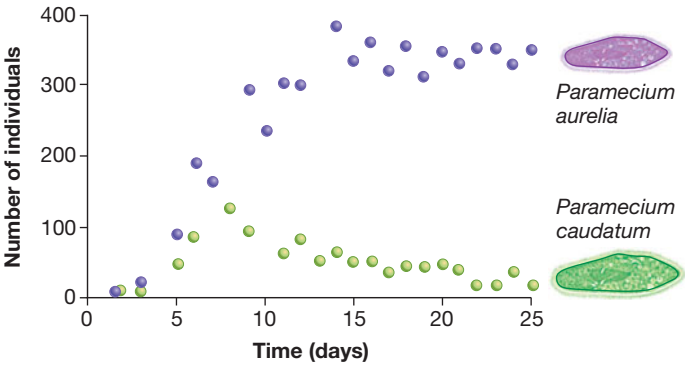

- When *P. caudatum* and *P. aurelia* grew in separate laboratory cultures, both species exhibited logistic growth—the number of individuals increased rapidly at first, then leveled off as the population reached its carrying capacity (see Chapter 54).
- When the two species grew in the same culture together, only the *P. aurelia* population exhibited a logistic growth pattern. *P. caudatum*, in contrast, was driven to extinction (**FIGURE 55.3a**, see page 1126).

The stronger competitor drove out the weaker competitor because the two laboratory populations had completely overlapping niches (**FIGURE 55.3b**). Based on these data, Gause proposed that two species that occupy the same niche cannot coexist, a hypothesis called the **competitive exclusion principle.** Some biologists invoke this principle to explain the disappearance of Neanderthals (*Homo neanderthalensis*) after thousands of years of coexistence with our species, *Homo sapiens* (see Chapter 35).

But what happens if the niches of the two species do not overlap completely? The species that is the weaker competitor should be able to retreat to, or persist in, the area of non-overlap. In cases like this, an important distinction arises.

- A **fundamental niche** is the total theoretical range of environmental conditions that a species can tolerate.

(a) Observation: asymmetric competition

(b) Explanation: competitive exclusion due to complete niche overlap

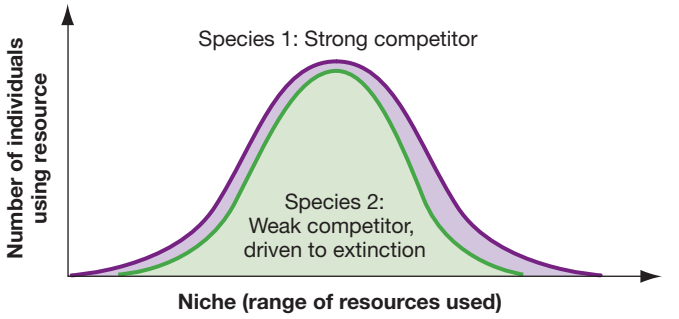

FIGURE 55.3 Competitive Exclusion in *Paramecium*.

DATA: Gause, G. F. 1934. *The Struggle for Existence*. New York: Hafner Press.

- A **realized niche** is the portion of the fundamental niche that a species actually occupies, given limiting factors such as competition with other species (**FIGURE 55.4**).

Let's take a look at an important field experiment that demonstrated the difference between a fundamental and realized niche.

Experimental Studies of Competition in Nature Joseph Connell began a classic study of competition in the late 1950s, after observing an interesting pattern in an intertidal rocky shore in Scotland. He noticed that there were two species of barnacles with distinctive distributions. The adults of one species, *Chthamalus stellatus*, occurred in an upper intertidal zone. The adults of the other species, *Semibalanus balanoides*, were restricted to a lower intertidal zone. The upper intertidal zone is a more severe environment for barnacles, because it is exposed to the air and intense heat for longer periods at low tide each day.

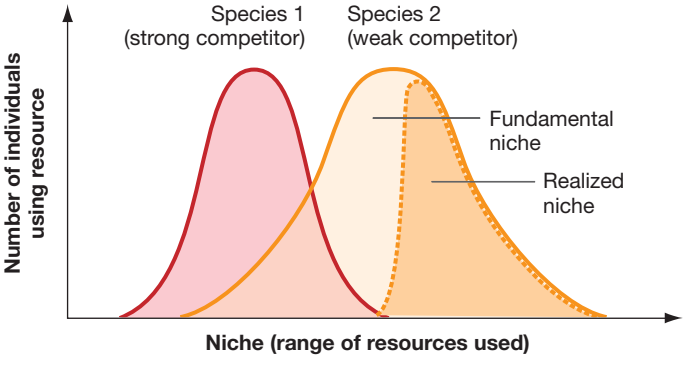

FIGURE 55.4 Fundamental Niches Are Broader than Realized Niches.

Although adult barnacles live attached to rocks, their planktonic larvae are mobile. The young of both species were found together in the lower intertidal zone. Why aren't *Chthamalus* adults found there as well?

To answer this question, Connell considered two hypotheses:

1. Adult *Chthamalus* are outcompeted in the lower intertidal zone by *Semibalanus*.
2. Adult *Chthamalus* are absent from the lower intertidal zone because they do not thrive in the physical conditions there.

Connell tested these hypotheses by performing the experiment shown in **FIGURE 55.5**. He began by removing a number of rocks that had been colonized by *Chthamalus* from the upper intertidal zone and transplanting them into the lower intertidal zone. He screwed the rocks into place and allowed *Semibalanus* larvae to colonize them. Once the spring colonization period was over, Connell divided each rock into two sides. In one half, he removed all *Semibalanus* that were in contact with or next to a *Chthamalus*.

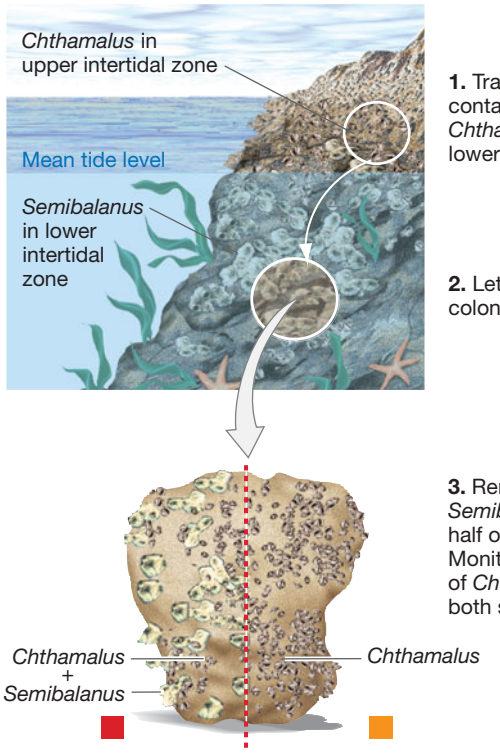
This experimental design allowed Connell to document *Chthamalus* survival in the absence of competition with *Semibalanus*, and compare it with survival during competition. This is a common experimental strategy in competition studies: One of the competitors is removed, and the response by the remaining species is observed.

Connell's results supported the competition hypothesis. On the rocks with both species present, *Semibalanus* killed many of the *Chthamalus* by growing against them and lifting them off the substrate. As the orange bar in the "Results" section of Figure 55.5 shows, *Chthamalus* survival was much higher when all of the *Semibalanus* were removed.

The fundamental niches of these two species partially overlap. Under the conditions tested in this experiment, *Semibalanus* is a superior competitor for space, but *Chthamalus* is able to thrive in a smaller realized niche where *Semibalanus* cannot survive. ✔ **If you understand this result, you should be able to sketch and label a graph of the fundamental and realized niches of the two barnacle species as a function of depth in the intertidal zone.**

Fitness Trade-Offs in Competition Why haven't *Semibalanus* and other successful competitors taken over the world? Biologists answer this question by invoking the concept of **fitness trade-offs**—inevitable compromises in adaptation (see Chapter 25).

The key insight is that the ability to compete for a particular resource—like space on rocks or edible seeds of a certain size—is only one aspect of an organism's niche. If individuals are extremely good at competing for a particular resource, then they are probably not as good at enduring drought conditions, warding off disease, or preventing predation.

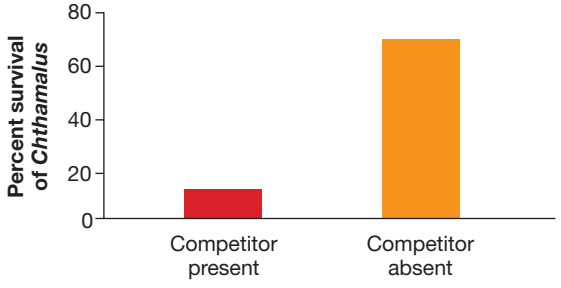


RESEARCH

QUESTION: Why is the distribution of adult *Chthamalus* restricted to the upper intertidal zone?

HYPOTHESIS: Adult *Chthamalus* are outcompeted in the lower intertidal zone.

NULL HYPOTHESIS: Adult *Chthamalus* do not thrive in the physical conditions of the lower intertidal zone.



EXPERIMENTAL SETUP:

PREDICTION: *Chthamalus* will survive better in the absence of *Semibalanus*.

PREDICTION OF NULL HYPOTHESIS: *Chthamalus* survival will be low and the same in the presence or absence of *Semibalanus*.

RESULTS:

CONCLUSION: *Chthamalus* do not occur in the lower intertidal zone because they are outcompeted by *Semibalanus*.

FIGURE 55.5 Experimental Evidence of Competition.

SOURCE: Connell, J. H. 1961. The influence of interspecific competition and other factors on the distribution of the barnacle *Chthamalus stellatus*. *Ecology* 42: 710–723.

✔**QUESTION** Why was it important to carry out both treatments on the same rock? Why not use separate rocks?

In the case of *Semibalanus* and *Chthamalus* growing in the intertidal zone, the fitness trade-off is rapid growth and success in competing for space versus the ability to endure the harsh physical conditions of the upper intertidal zone. *Semibalanus* are fast-growing and large; *Chthamalus* grow slowly but can survive long exposures to the air and to intense sun and heat. Neither species can do both things well.

Also, competitive ability is not an inherent quality of species—it depends on environmental conditions. For example, Argentine ants have unremarkable competitive abilities in their native South America, due to the checks and balances provided by thousands of years of species interactions. But when these ants were introduced to California and the Mediterranean in food shipments, they began to attack aggressively and outcompete native species (Chapter 52). The remarkable competitive success of invasive species poses a threat to communities around the world—and conservation biologists are very concerned about it (see Chapter 57).

Mechanisms of Coexistence: Niche Differentiation It's important to realize that because competition is a −/− interaction, there is strong natural selection on both species to avoid it. **FIGURE 55.6** shows the predicted outcome of competition over many generations: An evolutionary change in traits reduces the amount of niche overlap, and thus the amount of competition.

An *evolutionary* change in resource use, caused by competition over generations, is called **niche differentiation** or resource partitioning. The evolutionary change that occurs in species' traits, and that enables species to exploit different resources, is called **character displacement.** Character displacement makes niche differentiation possible.

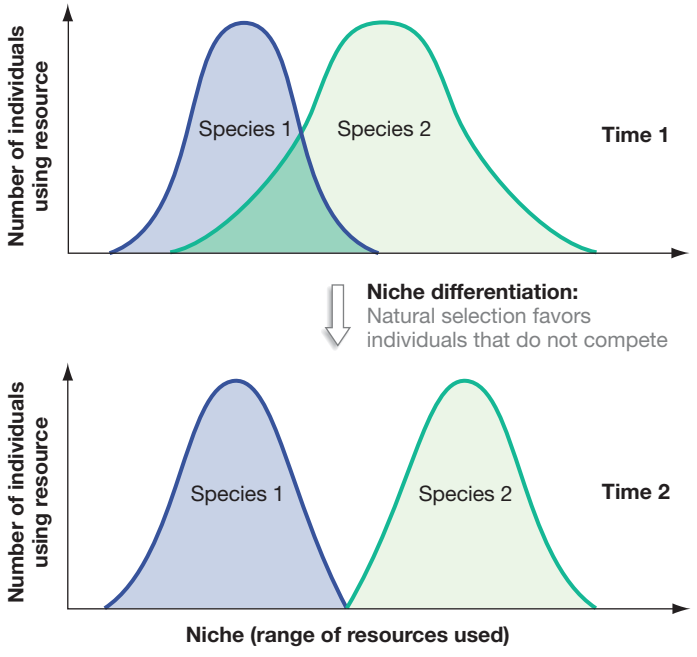


FIGURE 55.6 Competition Can Lead to Niche Differentiation. Over evolutionary time, natural selection favors individuals that do not compete.

One spectacular example of character displacement involves the Galápagos finches, famous for their diversity in beak shapes (Chapter 25). Specializations in beak shape are adaptations for harvesting particular food types, such as small or large seeds.

Beak shape varies not only among species of Galápagos finches but also within species. For example, **FIGURE 55.7** shows the frequency of beak depths (in this case, measured from the top half of the beak only) in a population of medium ground finch, *Geospiza fortis*, on the island of Daphne Major in the 1940s. You can see on the *x*-axis that beak depth, an important measure of beak shape, ranged from 3.5 to 5.6 mm. However, on the island of Santa Cruz at around the same time, *G. fortis* lived alongside the small ground finch, *G. fuliginosa*, and had a broader and higher range of beak depths, from 4.0 to 7.5 mm. From these data you could hypothesize either that competition causes character displacement in *G. fortis*, or that the difference between populations is due to other factors such as predation or food availability.

No data were available from the 1940s to test these hypotheses, but Peter and Rosemary Grant observed character displacement in *G. fortis* on Daphne Major more recently. In addition to recording six beak size measurements for hundreds of medium ground finches over three decades starting in 1970, they also made careful observations of feeding behavior, the amount of rainfall each year, the availability of different types of seeds, and the presence of other species.

The Grants observed that the large ground finch, *G. magnirostris*, established a breeding population on Daphne Major in 1982, living alongside or "sympatric" with *G. fortis*. True to its name (*magnirostris* translates to "large beak"), this finch has a large beak capable of opening large, hard, drought-tolerant seeds. What effect did competition with *G. magnirostris* have on *G. fortis*?

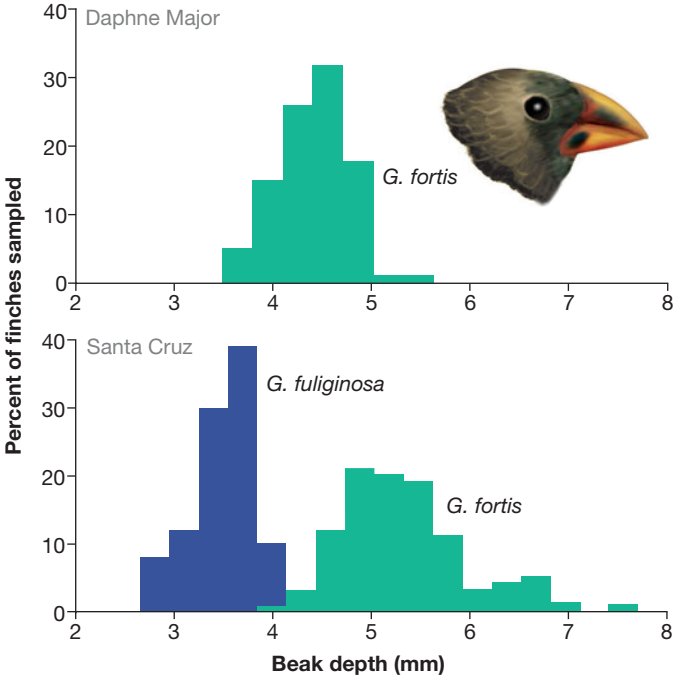

FIGURE 55.7 Niche Differentiation in Galápagos Finches Average beak depths in *Geospiza fortis* were higher on the island with a competitor present.

DATA: Grant, P. 1999. *Ecology and Evolution of Darwin's Finches*. Princeton, NJ: Princeton University Press.

At first the Grants observed a slow but steady decline in average beak size in *G. fortis* after the arrival of *G. magnirostris*. Then in 2004, during a severe drought when competition with *G. magnirostris* was at its most intense, most finches died of starvation. The Grants observed that

- Only *G. fortis* that could eat extremely small seeds efficiently could survive.
- The larger-beaked *G. fortis* had been chased off from the feeding sites with the large seeds by *G. magnirostris*.
- Overall, the average beak size of *G. fortis* declined sharply.

The Grants had observed evolution in action—directional selection on *G. fortis* beak size causing character displacement (reduced average beak size) and niche differentiation (adaptation for different seed sizes). That is, natural selection had favored *G. fortis* individuals that did not compete with *G. magnirostris*.

✔ If you understand niche differentiation, you should be able to sketch and label a graph predicting the fundamental niches of the barnacles *Semibalanus* and *Chthamalus* many years after Connell's experiment, if niche differentiation were to occur.

Consumption

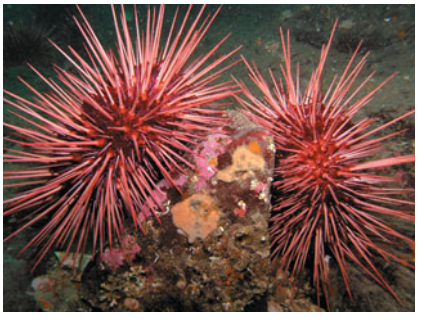
Consumption is a +/− interaction that occurs when one organism eats another. There are three major types of consumption:

1. **Herbivory** takes place when **herbivores** ("plant-eaters") consume plant tissues. Caterpillars chew leaves; marine iguanas feed on algae.
2. **Parasitism** occurs when a **parasite** consumes relatively small amounts of tissue or nutrients from another individual, called the **host.** Parasitism often occurs over a long period. It is not necessarily fatal, and parasites are usually small relative to their host. An array of worms, ticks, mites, and unicellular protists parasitizes humans. In some cases, though, the term parasitism is used more broadly, to denote use of other resources. For example, birds that lay their eggs in other species' nests and induce the other species to raise the young are called social parasites.
3. **Predation** occurs when a predator kills and consumes all or most of another individual. The consumed individual is called the prey. Woodpeckers eat bark beetles; ladybird beetles devour aphids; orcas eat seals. Although many researchers use predation to refer specifically to **carnivores** ("meat-eaters"), predation can also refer to the consumption of plants, especially seeds (which contain entire plant embryos).

To illustrate how biologists analyze the impact of consumption, let's consider a series of questions about herbivores, parasites, predators, and their victims.

Constitutive Defenses From the standpoint of fitness, consumption is costly for prey and beneficial for consumers. Prey individuals do not passively give up their lives to increase the fitness of their predators, however. Natural selection strongly favors traits that allow individuals to avoid being eaten. Prey species may hide, flee, poison or threaten to poison their predators, school together to confuse their predators, or deploy armor or weapons in defense (**TABLE 55.1**). Traits like these are called **standing or constitutive defenses,** because they are present even in the absence of predators.

The diversity and specificity of constitutive defenses is nothing short of mind-boggling. Consider the discovery made by naturalist Henry Walter Bates as he collected butterflies in the Amazonian rain forest in the mid-1800s. Bates found an astonishing diversity of butterflies in his study area—many more species than in all of Europe—and there was a surprising pattern among the diversity. He noticed pairs of species from different taxonomic groups that were not closely related, yet had very similar wing patterns and occupied the same parts of the forest. One example of this pattern of one species resembling another, called **mimicry,** is shown in **FIGURE 55.8**.



Based on what you have learned about niche differentiation, you might have expected that the traits of species occupying similar niches would become more *different* over time, not more alike. What could explain this seeming paradox in butterflies?

Bates had an insight when he observed that some of the butterflies exuded foul substances when he handled them and that these butterflies were passed over by would-be predators. Concluding that the foul substance thwarted predators, he hypothesized that natural selection favored mimic species that

FIGURE 55.8 Why Do these Butterflies Look So Similar? Henry Walter Bates observed that these two Amazonian butterflies are distantly related, but look more like each other than either does to its closer relatives.

SUMMARY TABLE 55.1 Constitutive Defenses

Type of Defense	Example
Cryptic coloration	 Cryptic coloration helps prey such as this leaf grasshopper escape detection
Escape behavior	 Prey may have adaptations to detect predators and run, fly, jump, or swim away
Toxins and other defense chemicals	 Prey may lace their tissues with toxic compounds. Many advertise their toxicity with warning coloration
Schooling/flocking	 Predators can become confused by groups of prey
Defense armor and weapons	 Prey may have protective shells, sharp spines, or other defense structures

resembled the unpalatable species, a form of mimicry now known as **Batesian mimicry.** Follow-up experimental studies supported this hypothesis—and recent genetic studies have discovered some of the molecular mechanisms responsible for the shared color patterns.

Bates also noticed that some pairs of similar but distantly related butterflies are *both* unpalatable. What was the fitness advantage of this pattern? Several hypotheses were proposed, but German naturalist Fritz Müller hit on the key idea—that the existence of similar-looking unpalatable prey in the same habitat increases the likelihood that predators will learn to avoid them. Thus, co-mimicry boosts the fitness of both species. This type of mimicry, now known as **Müllerian mimicry,** was subsequently supported by field experiments.

Butterflies are not the only organisms to engage in mimicry. Bates and Müller both observed diverse examples, some of them quite shocking, such as a caterpillar with a close resemblance to a venomous snake. **FIGURE 55.9** provides a comparison of Batesian and Müllerian mimics in the case of stinging and nonstinging insects with the familiar yellow and black warning coloration.

One of the take-home messages from studies of mimicry is that the +/− consumption interaction between two species can cause unexpected consequences to other species in the community. That is, natural selection in the form of predator–prey interactions can result in mutualism, commensalism, and other types of interactions among prey species.

Inducible Defenses Although constitutive defenses can be extremely effective, they can also be expensive due to the energy and resources that must be devoted to producing and maintaining them. Based on this observation, it should not be surprising to learn that many prey species have **inducible defenses**: physical, chemical, or behavioral defensive traits that are induced in the prey in response to the presence of a predator.

Induced defenses decline in prey species if predators leave the habitat. Inducible defenses are efficient energetically, but they are slow—it takes time to produce them.

To see how inducible defenses work, consider research on the blue mussels that live in an estuary along the coast of Maine. Biologists had documented that predation on mussels by crabs was high in an area of the estuary with relatively slow tidal currents (a "low-flow" area) but low in an area of the estuary with relatively rapid tidal currents (a "high-flow" area). Mark Bertness and colleagues hypothesized that if blue mussels possess inducible defenses, then heavily defended prey individuals should occur in the low-flow area, where predation pressure is higher, but not in the high-flow area, where water movement reduces the number of crabs present. This is exactly the trend they observed: Blue mussels had thicker shells in the part of the estuary with many crabs.

The correlation between crab density and mussel shell thickness is not enough to demonstrate that predation pressure induced shell thickening. One alternate hypothesis is that crabs eliminated mussels with thin shells from the low-flow areas. The observed differences could also be due to variation in light, temperature, or other abiotic factors that might affect mussel traits but have nothing to do with predation.

To test the inducible-defense hypothesis more rigorously, Bertness and his team carried out the experiment diagrammed in **FIGURE 55.10**. The tank on the right allowed the researchers to measure shell growth in mussels that were "downstream" from crabs, such that they were exposed to the scent of crabs. As predicted by the inducible-defense hypothesis, the mussels exposed to a crab in this way developed significantly thicker shells than did mussels that were not exposed to the scent of a crab. These results suggest that, even without direct contact, mussels can sense the presence of crabs and increase their investment in defenses.

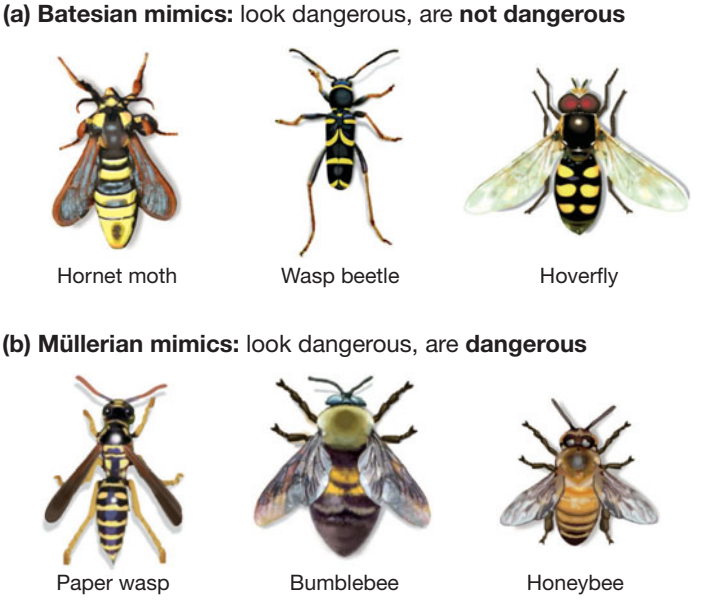


FIGURE 55.9 Prey Species Display Two Basic Forms of Mimicry.

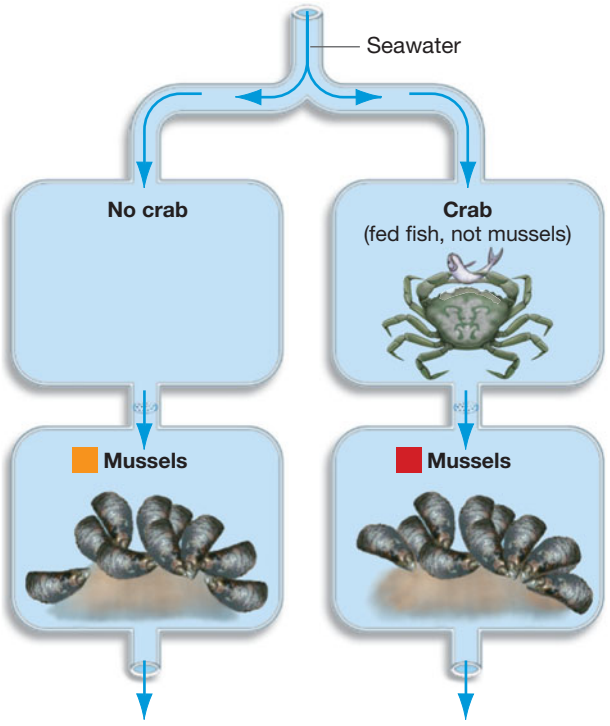
Are Animal Predators Efficient Enough to Reduce Prey Populations?

Prey are typically smaller than predators, have larger litter or clutch sizes, and tend to begin reproducing at a younger age. As a result, they have a much larger intrinsic growth rate. This quantity, symbolized r_{max}, is the maximum growth rate that a population can achieve under ideal conditions (Chapter 54).

If prey reproduce rapidly and are also well defended, can predators kill enough of them to reduce the prey population significantly?

Data from predator-removal programs—in which human hunters actively kill wolves, cougars, coyotes, or other predators—suggest that the answer is yes. For example, when a wolf control program in Alaska during the 1970s decreased predator abundance, the population of moose, on which wolves prey, tripled. This observation suggests that wolves had reduced this moose population far below the carrying capacity—the number that could be supported by the available space and food (see Chapter 54).

Other types of experiments are consistent with this result. For example, the regular population cycles of snowshoe hares appear

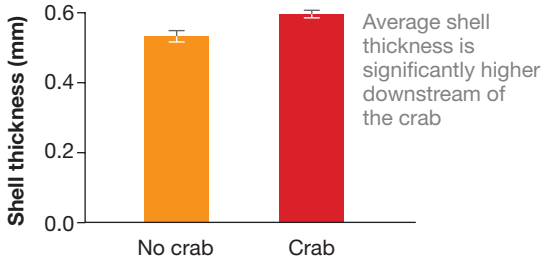


RESEARCH

QUESTION: Are mussel defenses induced by the presence of crabs?

HYPOTHESIS: Mussels increase investment in defense in the presence of crabs.

NULL HYPOTHESIS: Mussels do not increase investment in defense in the presence of crabs.



EXPERIMENTAL SETUP:

PREDICTION: Mussels downstream of the crab tank will have thicker shells than mussels downstream of the empty tank.

PREDICTION OF NULL HYPOTHESIS: Mussels in the two tanks will have shells of equal thickness.

RESULTS:

CONCLUSION: Mussels increase investment in defense when they detect crabs. Shell thickness is an inducible defense.

FIGURE 55.10 Experimental Evidence for Inducible Defenses.

SOURCE: Leonard, G. H., M. D. Bertness, and P. O. Yund. 1999. Crab predation, waterborne clues, and inducible defenses in the blue mussel, *Mytilus edulis*. *Ecology* 80: 1–14.

✔**QUESTION** Why did the researchers feed the crabs fish instead of mussels?

to be driven, at least in part, by density-dependent increases in predation by lynx (Chapter 54). Taken together, the data indicate that in many instances, predators are efficient enough to reduce prey populations below carrying capacity.

Why Don't Herbivores Eat Everything—Why Is the World Green?

If predators affect the size of populations in prey that can run or fly or swim away, then consumers should have a devastating impact on plants and on mussels, anemones, sponges, and other sessile (nonmoving) animals.

In some cases, this prediction turns out to be correct. For example, consider the results of a recent **meta-analysis**—a study of studies, meaning an analysis of a large number of data sets on a particular question. Biologists who compiled the results of more than 100 studies on herbivory found that the median percentage of mass removed from aquatic algae by herbivores was 79 percent. Herbivores eat the vast majority of algal food available in aquatic biomes. The figure dropped to just 30 percent for aquatic plants, however, and only 18 percent for terrestrial plants.

Why don't herbivores eat more of the food available on land? Stated another way, why is the world green? Biologists routinely consider two hypotheses:

1. ***Top-down control hypothesis: Herbivore populations are limited by predation and disease.*** The "top-down" name is inspired by the food-chain concept (introduced in Chapter 30 and explored in detail in Chapter 56). In a food chain, herbivores are "on top of" plants.

   The logic of top-down control is simple: Predators and parasites remove herbivores that eat plants. As a result, a great deal of plant material remains uneaten.

   In a recent test of this idea, researchers monitored herbivory on islands created by a 1986 dam project in Venezuela. On some small islands in the new lake, predators disappeared. On the predator-free islands, there are now many more herbivores than on similar sites nearby where predators are present. As predicted by the top-down control hypothesis, a much higher percentage of the total plant material is being eaten on the predator-free islands. For example, predator-free islands had just 25 percent of the small trees found on islands that contained predators.

2. ***Bottom-up limitation hypothesis: Plant tissues offer poor nutrition and are well defended.*** The "bottom-up" name reflects the position of plants as the base or bottom of a food chain. The idea here is that herbivore numbers are limited because plant tissues offer poor nutrition, or that plant tissues aren't eaten because they are toxic.

   The poor-nutrition aspect of this hypothesis was inspired by the observation that plant tissues have less than 10 percent of the nitrogen found in animal tissues, by weight. If the growth and reproduction of herbivores are limited by the availability of nitrogen, then their populations will be low and the impact of herbivory on plants relatively slight. Herbivores could eat more plant material to gain nitrogen, but at

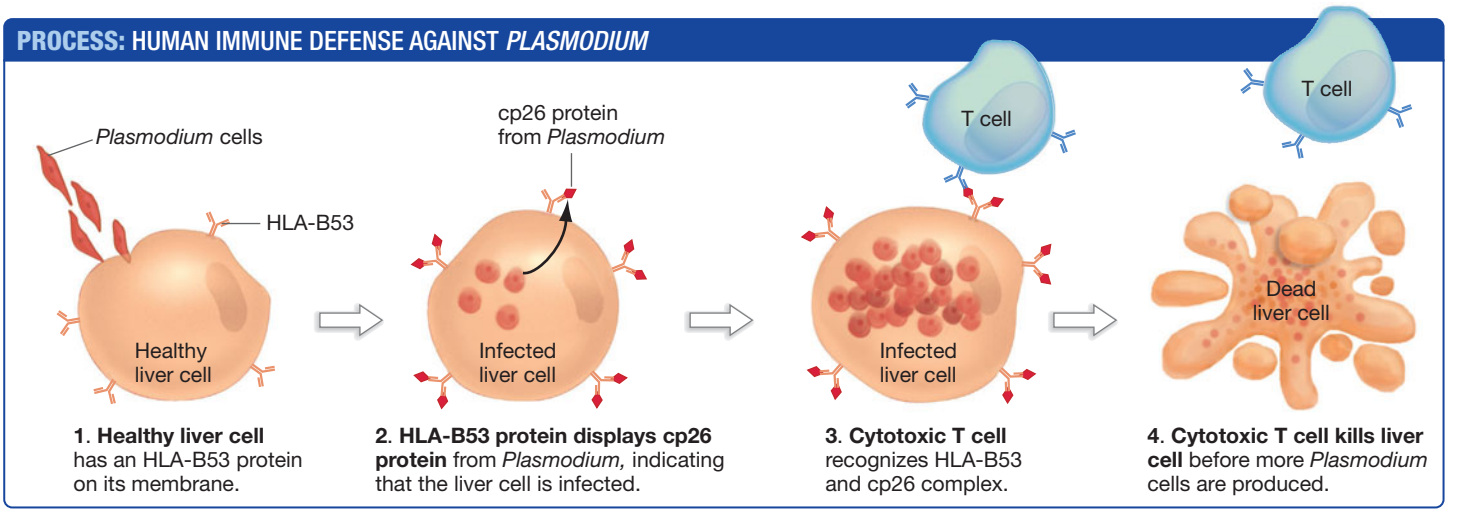


FIGURE 55.11 Interactions between the Human Immune System and *Plasmodium*. If HLA-B53 binds to a particular *Plasmodium* protein, then infected cells are recognized and destroyed.

a cost—they would be exposed to predation and expend energy processing the food. Indeed, when nitrogen concentration in plants is increased experimentally by fertilization, it is not unusual to see significant increases in herbivore growth rates.

What's more, most plant tissues are defended by weapons such as thorns, prickles, or hairs, or by potent poisons such as nicotine, caffeine, and cocaine. The punchline? Both top-down control and bottom-up limitations—such as nitrogen limitation and effective defense—are important factors in limiting the impact of herbivory. The mix of factors that keeps the world green varies from species to species and habitat to habitat.

Adaptation and Arms Races Over the long term, how do species that interact via consumption affect each other's evolution? When predators and prey or herbivores and plants interact over time, coevolutionary arms races result. Traits that increase feeding efficiency evolve in predators and herbivores. In response, traits that make prey unpalatable or elusive evolve. In counter-response, selection favors consumers with traits that overcome the prey adaptation. And so on. Coevolution is a major driver of evolutionary change.

To see a coevolutionary arms race in action, consider interactions between humans and the most serious of all human parasites—species in the genus *Plasmodium*. *Plasmodium* species are unicellular protists that cause malaria (Chapter 30). Malaria kills at least 1 million people a year, most of them young children. Recent data suggest that humans and *Plasmodium* are locked in a coevolutionary arms race.

In West Africa, for example, there is a strong association between an allele called *HLA-B53* and protection against malaria. Malaria infections start when *Plasmodium* cells enter a person's bloodstream during a mosquito bite. The *Plasmodium* individuals then infect liver cells, where they begin to multiply.

In liver cells that are infected by *Plasmodium*, HLA-B53 proteins on the surface of the liver cell display a parasite protein called cp26 (**FIGURE 55.11**). The display is a signal that immune system cells can read. It means "I'm an infected cell. Kill me before they kill all of us." Immune system cells destroy the liver cell before the parasite cells inside can multiply.

In this way, people who have at least one copy of the *HLA-B53* allele are better able to beat back malarial infections. People who have the *HLA-B53* allele appear to be winning the arms race against malaria.

Follow-up research has shown that the arms race is far from won, however. *Plasmodium* populations in West Africa now have a variety of alleles for the protein recognized by HLA-B53. Some of these variants bind to HLA-B53 and trigger an immune response in the host, but others escape detection (**TABLE 55.2**). To make sense of these observations, researchers suggest that natural selection has favored the evolution of *Plasmodium* strains with weapons that counter HLA-B53.

Can Parasites Manipulate Their Hosts? To thrive, parasites do not just have to invade tissues and grow while evading defensive responses by their host. They also have to be transmitted to new

TABLE 55.2 Some *Plasmodium* Strains Are Particularly Effective at Infecting Humans

Plasmodium Strain	Infection Rate	Interpretation

hosts. To a parasite, an uninfected host represents uncolonized habitat, teeming with resources. What have biologists learned about how parasites are transmitted to new hosts?

To answer this question, consider species of tree-dwelling ants (**FIGURE 55.12a**) that are parasitized by nematodes (roundworms). When nematodes have matured inside a host individual, they lay eggs in the ant's abdomen. The exoskeleton in the area becomes translucent, and the yellow eggs inside make the structure look reddish instead of the normal black color (**FIGURE 55.12b**). Infected ants also hold the abdomen up in a "flagging" posture, making them look like the berries that grow on the trees occupied by the ants (**FIGURE 55.12c**). Experiments have shown that fruit-eating birds are much more likely to pluck the abdomen from infected ants than uninfected ants.

Why is this interesting? To complete their life cycle, the nematodes have to grow inside birds, before being shed in bird feces that are subsequently eaten by ants.

To interpret their observations, biologists suggest that these nematodes not only change the appearance of the ants, but they also manipulate their behavior. The changes make the parasite much more likely to be transmitted to a new host.

Biologists have now cataloged a large number of case studies like this, from an array of parasites and hosts. Parasite manipulation of hosts is another example of extensive coevolution.

(a) Uninfected ant

(b) Infected ant

(c) Infected ants resemble berries that are eaten by birds.

FIGURE 55.12 A Parasite That Manipulates Host Behavior. When the tropical ant *Cephalotes atratus* becomes infected with parasitic nematodes, its appearance and behavior change.

✔**EXERCISE** Design an experiment to test the hypothesis that infected ants are more likely than uninfected ants to be eaten by birds.

Using Consumers as Biocontrol Agents Research on the dynamics of predator–prey interactions and other aspects of consumption has paid off in practical benefits: In some cases, biologists have been able to control pests by introducing predators or parasites.

The invasive plant purple loosestrife, for example, had succeeded in taking over large expanses of wetlands in North America. Through careful experimentation, however, biologists were able to find two insect species that feed exclusively on purple loosestrife. By introducing the herbivores into wetlands, researchers have been able to reduce purple loosestrife infestations dramatically.

In agriculture and forestry, the use of predators, herbivores, and parasites as biocontrol agents is a key part of **integrated pest management**: strategies to maximize crop and forest productivity while using a minimum of insecticides or other types of potentially harmful compounds. Integrated pest management is a promising and growing area of research. However, ecologists warn that introducing species to communities to limit one species can have unexpected consequences to others, so it is of utmost importance to proceed with extreme caution.

Mutualism

Mutualisms are +/+ interactions that involve a wide variety of organisms and rewards.

- Bees visit flowers to harvest nectar and pollen. The bees benefit by using nectar and pollen as a food source; flowering plants benefit because in the process of visiting flowers, foraging bees carry pollen from one plant to another and accomplish pollination. Adaptations found in flowering plants increase the efficiency of pollination (Chapters 31 and 41).
- One of the most important of all mutualisms occurs between mycorrhizal fungi and plant roots. For example, experimental evidence indicates that mycorrhizal fungi receive sugars and other carbon-containing compounds in exchange for nitrogen or phosphorus acquired by the plant partner (Chapter 32). The plant feeds the fungus; the fungus fertilizes the plant.
- Mutualism occurs between nitrogen-fixing bacteria and the plant species that house them in their tissues (Chapters 29 and 37). The host plants provide sugars and protection to the bacteria; the bacteria supply ammonia or nitrate in return.
- **FIGURE 55.13a** (see page 1134) shows ants in the genus *Crematogaster*, which live in acacia trees native to Africa. The ants live in bulbs at the base of acacia thorns and feed on small structures that grow from leaf tips. The ants protect the tree by attacking and biting herbivores, and by cutting vegetation from the ground below the host tree.
- **FIGURE 55.13b** illustrates cleaner shrimp in action. These shrimp pick external parasites from the jaws and gills of fish. In this mutualism, one species receives dinner while the other obtains medical attention.

The Role of Natural Selection in Mutualism As the examples you've just reviewed show, the rewards from mutualistic interactions range from transporting gametes to acquiring food, housing,

(a) Mutualism between ants and acacia trees

(b) Mutualism between cleaner shrimp and fish

FIGURE 55.13 Mutualisms Take Many Forms. (a) In certain species of acacia tree, ants in the genus *Crematogaster* live in large bulbs at the base of tree spines and attack herbivores that threaten the tree. The ants eat nutrient-rich tissue produced at the tips of leaves. **(b)** Cleaner shrimp remove and eat parasites that take up residence on the gills of fish.

✔**EXERCISE** Name a possible cost of these mutualistic associations to the acacia tree, the ants, the cleaner shrimp, and the host fish.

medical help, and protection. It is important to note, however, that even though mutualisms benefit both species, the interaction does not involve individuals from different species being altruistic or "nice" to each other.

Expanding on a point that Charles Darwin introduced in 1862, Judith Bronstein described mutualisms as "a kind of reciprocal parasitism; that is, each partner is out to do the best it can by obtaining what it needs from its mutualist at the lowest possible cost to itself." Her point is that the benefits received in a mutualism are a by-product of each individual pursuing its own self-interest by maximizing its fitness—its ability to survive and produce viable offspring.

In this light, it is not surprising that some species "cheat" on mutualistic systems. For example, deceit pollination occurs when certain species of plants produce a showy flower but no nectar reward. Pollinators receive no reward for making a visit and carrying out pollination. Evolutionary studies show that deceit pollinators evolved from ancestral species that did provide a reward. Over time, a +/+ interaction evolved into a +/− interaction.

Mutualisms Are Dynamic A recent experimental study of mutualism provides another good example of the dynamic nature of these interactions. This study focused on ants and treehoppers. Treehoppers are small, herbivorous insects that feed by sucking sugar out of the phloem of plants. Treehoppers excrete the sugary solution called honeydew from their posteriors. The ants, in turn, harvest the honeydew for food.

It is clear that ants benefit from this association. But do the treehoppers? J. Hall Cushman and Thomas Whitham hypothesized that the ants might protect the treehoppers from their major predator, jumping spiders. These spiders feed heavily on juvenile treehoppers.

To test the hypothesis that ants protect treehoppers, Cushman and Whitham studied ant–treehopper interactions over a three-year period. As **FIGURE 55.14** shows, the researchers marked out a 1000-m^2 study plot. Each year they removed the ants from one group of the treehopper host plants inside the plot but left the others alone to serve as a control. Then they compared the growth and survival of treehoppers on plants with and without ants.

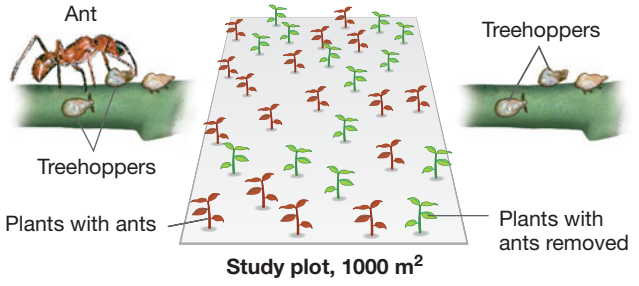
Recall that this is a common research strategy for studying species interactions. To assess the fitness costs or benefits of the interaction, researchers remove one of the participants experimentally and document the effect on the other participant's survival and reproduction, compared with the survival and reproduction of control individuals that experience a normal interaction.

In both the first and third years of the study, the number of treehopper young on host plants increased in the treatment with ants but showed a significant decline in the treatment with no ants. This result supports the hypothesis that treehoppers benefit from the interaction with ants, because the ants protect the treehoppers from predation by jumping spiders.

In the second year of the study, however, Cushman and Whitham found a very different pattern. There was no difference in offspring survival, adult survival, or overall population size between treehopper populations with ants and those without ants.

Why? The researchers were able to answer this question because they also measured the abundance of spiders that prey on treehoppers in each of the three years. Their census data showed that in the second year of the study, spider populations were very low.

Based on these results, Cushman and Whitham concluded that the benefits of the ant–treehopper interaction depend entirely on predator abundance. Treehoppers benefit from their interaction with ants in years when predators are abundant, but are unaffected in years when predators are scarce. If producing honeydew is costly to treehoppers, then the +/+ mutualism changes to a +/− interaction when spiders are rare.

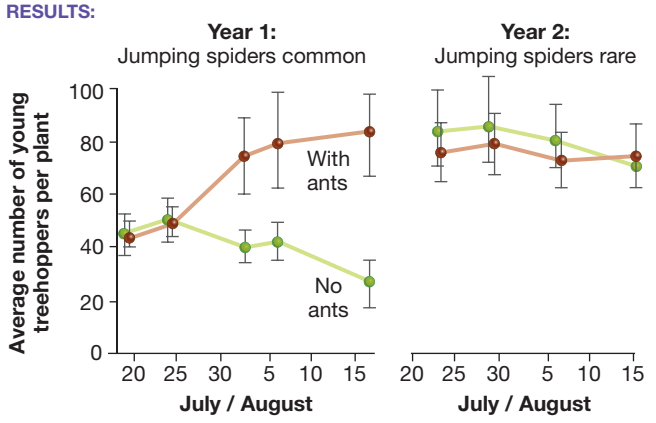


RESEARCH

QUESTION: Is the relationship between ants and treehoppers mutualistic?

HYPOTHESIS: Ants harvest food from treehoppers. In return, they protect treehoppers from jumping spiders.

NULL HYPOTHESIS: Ants harvest food from treehoppers but are not beneficial to treehopper survival.



EXPERIMENTAL SETUP:

PREDICTION: Treehopper reproduction will be higher when ants are present than when ants are absent.

PREDICTION OF NULL HYPOTHESIS: There will be no difference in the number of young treehoppers on the plants.

RESULTS:

CONCLUSION: Treehoppers benefit from the interaction with ants only when jumping spiders are common.

FIGURE 55.14 Experimental Evidence of Mutualism. The data points on the graphs represent average values from many study plots.

Cushman, J. H., and T. G. Whitham. 1989. Conditional mutualism in a membracid–ant association: temporal, age-specific, and density-dependent effects. *Ecology* 70: 1040–1047.

✔**QUESTION** The researchers assigned the treatments to different plants at random, and they did many replicates of each treatment. Why was this method important?

Mutualism is like parasitism, competition, and other types of species interactions in an important respect: The outcome of the interaction depends on current conditions. Because the costs and benefits of species interactions are fluid, an interaction between the same two species may range from parasitism to mutualism to competition. **TABLE 55.3** (see page 1136) summarizes the fitness effects, short-term impacts on population size, and long-term evolutionary aspects of species interactions.

check your understanding

C Y U

If you understand that . . .

- Natural selection favors the evolution of traits that decrease competition, resulting in changes in species' niches over time.
- Consumers may reduce the population size of the species they feed on, and they often exert strong natural selection for effective defense mechanisms.
- Mutualisms benefit the species involved and can lead to highly coevolved associations, such as mycorrhizal fungi and symbiotic nitrogen-fixing bacteria.
- Coevolution is a major driver of evolutionary change.

✔ **You should be able to . . .**

1. Explain why niche differentiation (resource partitioning) does not involve a conscious choice by the individuals involved.
2. Explain what a coevolutionary arms race is, and give an example.

Answers are available in Appendix A.

55.2 Community Structure

Up to this point, the focus has been on interactions that occur between two species. But in a community, each species interacts with dozens or hundreds or even thousands of other species within a defined area. The resulting complexity of interactions is mind-boggling. How can biologists begin to characterize communities? In general, a community structure has four key attributes:

1. the total number of species;
2. the relative abundance of those species;
3. the sum of interactions among all species; and
4. the physical attributes of the community, which may include abiotic factors such as geographic size or altitude gradient, and biotic factors such as the physical structure provided by the primary vegetation type, as in a forest or grassland (see Chapter 52).

The processes that shape a particular community can be quite complex. To get a better sense of these processes, let's consider some of the ways that a community's structure can be either predictable or unpredictable.

How Predictable Are Communities?

The first question that biologists asked about woodlands and deserts and shorelines concerned structure: Do biological communities have a tightly prescribed organization and composition, or are they merely loose assemblages of species?

SUMMARY TABLE 55.3 Species Interactions

Type of Interaction	Fitness Effects	Short-Term Impact: Distribution and Abundance	Long-Term Impact: Coevolution
Commensalism	+/0	Population size and range of commensal may depend on population size and distribution of host.	Strong selection on commensal to increase fitness benefits in relationship; no selection on host
Competition	−/−	Reduces population size of both species; if competition is asymmetric, the weaker competitor may become locally extinct, or it may retreat to a part of its niche that does not overlap with the stronger competitor.	Niche differentiation via selection to reduce competition
Consumption	+/−	Impact on prey population depends on predator density, prey density, and effectiveness of defenses.	Strong selection on prey for effective defense; strong selection on consumer for traits that overcome defenses
Mutualism	+/+	Population size and range of both species are dependent on each other.	Strong selection on both species to maximize fitness benefits and minimize fitness costs of relationship

The Clements–Gleason Dichotomy Beginning with a paper published in 1936, Frederick Clements hypothesized that biological communities are stable and orderly entities with a highly predictable composition. His reasoning was that species interactions are so extensive—and coevolution so important—that communities have become highly integrated and interdependent units in nature. Stated another way, the species within a community cannot live without each other.

In developing this hypothesis, Clements likened the development of a plant community to the development of an individual organism. He argued that communities develop over time by passing through a series of predictable stages dictated by extensive interactions among species. Eventually, this developmental progression culminates in a final stage, known as a **climax community.** The climax community is stable—it does not change over time.

According to Clements, the nature of a climax community is determined by the area's climate. He predicted that if a fire or other disturbance destroys the climax community, it will reconstitute itself by repeating its predictable developmental stages.

Henry Gleason, in contrast, contended that the community found in a particular area is neither stable nor predictable. He claimed that plant and animal communities are ephemeral associations of species that just happen to share similar climatic requirements.

According to Gleason, it is largely a matter of chance whether a similar community develops in the same area after a disturbance occurs. Gleason downplayed the role of biotic factors, such as species interactions, in structuring communities. Instead, chance historical events—for example, which seeds and juvenile animals happened to arrive after a disturbance—were key elements in determining which species are found at a particular location.

Which viewpoint is more accurate? Let's consider experimental and observational data.

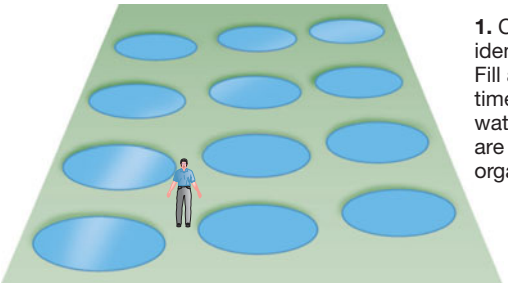
An Experimental Test To explore the predictability of community structure experimentally, ecologists David Jenkins and Arthur Buikema constructed 12 identical ponds (**FIGURE 55.15**). They filled the ponds at the same time with water that contained enough chlorine to kill any preexisting organisms. The Clements and Gleason hypotheses make clear and contrasting predictions:

- If community structure is predictable, then each pond should develop the same community of species once the chlorine has vaporized and made the water habitable.
- If community structure is unpredictable, then each pond should develop a different community.

To test these predictions, the researchers sampled water from the ponds repeatedly for one year. They measured temperature, chemical makeup, and other physical characteristics of the water and recorded the diversity and abundance of each planktonic species by examining the samples under the microscope. Species that make up **plankton** drift in the water and swim little, if at all.

Their results? The rows of colored bars on the graph in Figure 55.15 indicate whether a particular species was found in each of the 12 ponds. Note that the researchers found a total of 61 planktonic species in all of the ponds. However, individual ponds had only 31 to 39 species apiece. This observation is important. Each pond contained just half to two-thirds of the total number of species that lived in the experimental area and that were available for colonization. Several species occurred in most or all 12 of the ponds, but each pond had a unique species assemblage. Why?

To explain their results, Jenkins and Buikema contended that some species are particularly good at dispersing and are likely to colonize all or most of the available habitats. Other species disperse more slowly and tend to reach only one or a few of the



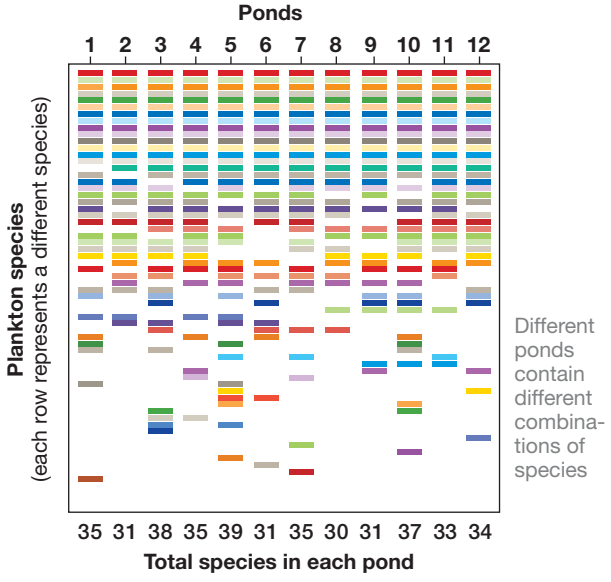
RESEARCH

QUESTION: Are communities predictable or unpredictable?

COMMUNITIES-ARE-PREDICTABLE HYPOTHESIS: The group of species present at a particular site is highly predictable.

COMMUNITIES-ARE-UNPREDICTABLE HYPOTHESIS: The group of species present at a particular site is highly unpredictable.

EXPERIMENTAL SETUP:



1. Construct 12 identical ponds. Fill at the same time and sterilize water so that there are no preexisting organisms.

2. Examine water samples from each pond. Identify each plankton species present in each sample.

COMMUNITIES-ARE-PREDICTABLE PREDICTION: Identical plankton communities will develop in all 12 ponds.

COMMUNITIES-ARE-UNPREDICTABLE PREDICTION: Different plankton communities will develop in different ponds.

RESULTS (AFTER 1 YEAR):

CONCLUSION: Although about half of the species present appear in all or most ponds, each pond has a unique composition. Both hypotheses are partially correct.

FIGURE 55.15 Experimental Evidence that Identical Communities Do Not Develop in Identical Habitats.

SOURCE: Jenkins, D. G., and A. L. Buikema. 1998. Do similar communities develop in similar sites? A test with zooplankton structure and function. *Ecological Monographs* 68: 421–443.

✔**QUESTION** At least 20 species are found in most or all of the ponds. Does this observation suggest that community composition is predictable or unpredictable?

available habitats. Further, the investigators proposed that the arrival of certain competitors or predators early in the colonization process greatly affects which species are able to invade successfully later. As a result, the specific details of community assembly and composition are somewhat contingent and difficult to predict. At least to some degree, communities are a product of chance and history.

Mapping Current and Past Species' Distributions If communities are predictable assemblages, then the ranges of species that make up a particular community should be congruent—meaning that the same group of species should almost always be found living together.

When biologists began documenting the ranges of tree species along elevational gradients, however, they found that species came and went independently of each other. As you go up a mountain, for example, you might find white oak trees growing with hickories and chestnuts. As you continue to gain elevation, chestnuts might disappear, but white oaks and hickories remain. Farther upslope, hickories might drop out of the species mix as white pines and red pines start to appear.

Data on the historical composition of plant communities supported these observations. Studies of fossil pollen documented that the distribution of plant species and communities at specific locations throughout North America has changed radically since the end of the last ice age about 11,000 years ago.

An important pattern emerged from these data: Species do not come and go in the fossil record in tightly integrated units. Instead, the ranges of individual species tend to change independently of one another.

The overall message of research on community structure is that Clements's position was too extreme and that Gleason's view may be closer to being correct. Although both biotic interactions and climate are important in determining which species exist at a certain site, chance and history also play a large role.

How Do Keystone Species Structure Communities?

Even though communities are not predictable assemblages dictated by obligatory species interactions, biotic interactions are still critically important. And not all species are equal. The presence of a particular plant, for example, can have a huge effect on community structure, such as the presence of redwood trees in a redwood forest. Removal of these structural species by harvesting, disease, competition with an invasive species, climate change, or other factors can cause dramatic changes to community structure.

The presence of certain consumers can also have an enormous impact on the species present. In some cases, the structure of an entire community can change dramatically if a single species of predator or herbivore is removed from a community or added to it.

As an example of this research, consider an experiment that Robert Paine conducted in intertidal habitats of the Pacific Northwest of North America. In this environment, the sea star

(a) Predator: *Pisaster ochraceous*

(b) Prey: *Mytilus californianus*

(c) Effect of keystone predator on species richness

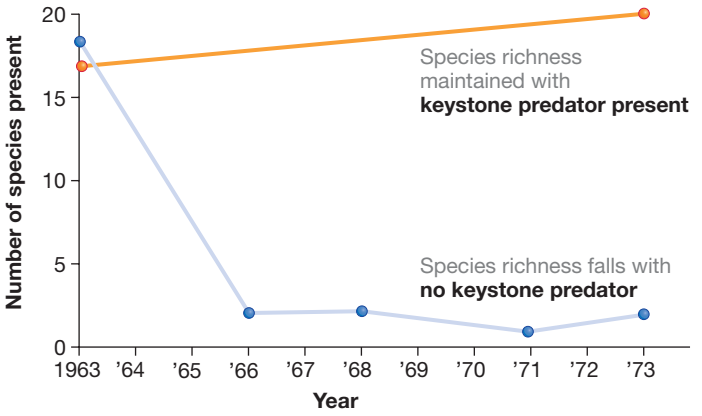


FIGURE 55.16 Keystone Predation Alters Community Structure in a Rocky Intertidal Habitat. Each data point in part (c) represents the average number of species present in several study plots.

DATA: Paine, R. T. 1966. *American Naturalist* 100: 65–75.

Pisaster ochraceous is an important predator (**FIGURE 55.16a**). Its preferred food is the California mussel *Mytilus californianus*.

When Paine removed *P. ochraceous* from experimental areas, what had been diverse communities of algae and invertebrates became overgrown with solid stands of mussels (**FIGURE 55.16b**). *M. californianus* is a dominant competitor, but its populations had been held in check by sea star predation.

The graph in **FIGURE 55.16c** shows the number of species present in experimental plots where *P. ochraceous* was present or excluded. When the predator was absent, the species richness of the habitat changed radically.

To capture the effect that a predator such as *P. ochraceous* can have on a community, Paine coined the term keystone species. A **keystone species** has a much greater impact on the distribution and abundance of the surrounding species than its abundance and total biomass would suggest.

An important take-home message of Paine's study is that sea stars are not just affecting their prey. They are also indirectly affecting many other species that interact with their prey. When considering the effects of a keystone species or any other species on the community, it is helpful for biologists to think in terms of the **food web,** the network of exchanges of energy and nutrients among producers, consumers, and decomposers in an ecosystem (see Chapter 56). Food webs focus only on feeding interactions, not all types of species interactions, but are central to the structure of communities.

55.3 Community Dynamics

Once biologists had a basic understanding of how species interact and how communities are structured, they turned to questions about how communities change through time. Like cells, individuals, and species, communities can be described in one word: dynamic.

Disturbance and Change in Ecological Communities

Community composition and structure may change radically in response to changes in abiotic and biotic conditions. Biologists have become particularly interested in how communities respond to disturbance. A **disturbance** is any strong, short-lived disruption to a community that changes the distribution of living and/or nonliving resources.

Forest fires, windstorms, floods, the fall of a large canopy tree, disease epidemics, and short-term explosions in herbivore numbers all qualify as disturbances. These events are important because they alter light levels, nutrients, unoccupied space, or some other aspect of resource availability.

Biologists have come to realize that the impact of disturbance is a function of three factors: **(1)** the type of disturbance, **(2)** its frequency, and **(3)** its severity—for example, the speed and duration of a flood, or the intensity of heat during a fire. Biologists have also come to realize that most communities experience a characteristic type of disturbance. In most cases, disturbances occur with a predictable frequency and severity.

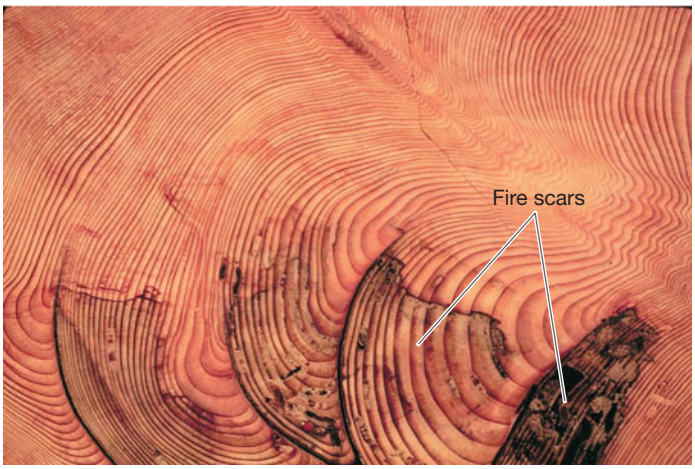
To capture this point, biologists refer to a community's **disturbance regime.** For example, fires kill all or most of the existing trees in a boreal forest every 100 to 300 years, on average.

FIGURE 55.17 Giant Sequoia after a Fire.

In contrast, many small-scale tree falls, usually caused by windstorms, occur in temperate and tropical forests every few years.

To appreciate why biologists are so interested in understanding disturbance regimes, consider a recent study on the fire history of giant sequoia groves in California (**FIGURE 55.17**). Giant sequoias grow in small, isolated groves on the western side of the Sierra Nevada range. Individuals live more than a thousand years, and many have been scarred repeatedly by fires.

Thomas Swetnam, a specialist on tree-ring research, obtained samples of cross sections through the bases of 90 giant sequoias in five different groves. As **FIGURE 55.18a** shows, the cross sections contained many growth rings that had been scarred by fire. To determine the date of each disturbance, he counted tree rings back from the present.



The graph in **FIGURE 55.18b** plots the average number of fires that occurred each century in the groves, from the year 0 C.E. to 1900. Swetnam found that in most of the groves, 20–40 fires had occurred each century. The data indicated that each tree had been burned an average of 64 times.

This study established that fires had been extremely frequent in these forests for most of recorded history. Because not enough time would pass for large amounts of fuel to accumulate between fires, they were probably of low severity. However, recent human intervention has reduced the frequency of forest fires—with unintended and unfortunate consequences. When fires do occur, the buildup of fuel causes massive conflagrations that are often devastating to the forest community.

Partly because of this work, the biologists responsible for managing sequoia groves now set controlled fires or let low-intensity natural fires burn instead of suppressing them immediately. To maintain communities in good condition, biologists have to ensure that the normal disturbance regime occurs. Otherwise, community composition changes dramatically.

Similarly, studies of disturbance regimes along the Colorado River in southwestern North America inspired land managers to begin releasing a huge pulse of water from the reservoirs behind dams, at intervals. The floods that have resulted were designed

(a) Fire scars in the growth rings

(b) Reconstructing history from fire scars

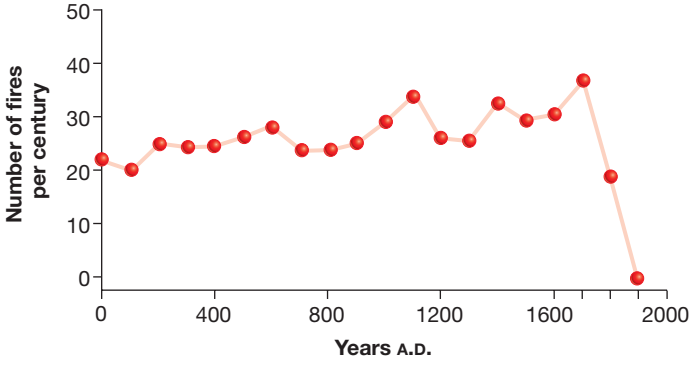


FIGURE 55.18 History of Disturbance in a Fire-Prone Community. Because trees form one ring (light band/dark band) every year, researchers can count the rings to determine how often fires have occurred during the last 2000 years in giant sequoia groves.

DATA: Swetnam, T. W. 1993. *Science* 262: 885–889.

to mimic the natural disturbance regime. According to follow-up studies, the artificial floods appear to have benefited the plant and animal communities downstream by depositing nutrients and creating additional sandbar habitat.

Succession: The Development of Communities after Disturbance

Severe disturbances remove all or most of the organisms from an area. The recovery that follows is called **succession.** The name was inspired by the observation that species with certain types of life history strategies tend to succeed others over time.

- **Primary succession** occurs when a disturbance removes the soil and its organisms as well as organisms that live above the surface. Glaciers, floods, volcanic eruptions, and landslides often initiate primary succession.
- **Secondary succession** occurs when a disturbance removes some or all of the organisms from an area but leaves the soil

intact. Fire and logging are examples of disturbances that initiate secondary succession.

How does recovery proceed after a severe disturbance? Imagine a landscape before primary succession begins, such as the area surrounding the Kilauea volcano in Hawaii. There are no animals, no plants, *and no soil*. The process of soil building begins with solid rock, which weathers over time to produce gravel, sand, silt, and clay (Chapter 39). As organisms occupy the substrate, they add dead cells and tissues and feces. With time, soil eventually becomes a complex and dynamic mixture of inorganic particles, organic particles, and living organisms that enable plants to take root and add structure to the landscape.

During secondary succession, soil is already present. **FIGURE 55.19** shows a typical sequence of plant communities that develops as succession proceeds. Early successional communities are dominated by species that are short lived, small in stature, and disperse their seeds over long distances. Late successional or climax communities are dominated by species that tend to be long lived, large, and good competitors for resources such as light and nutrients.

The particular sequence of species that appears over time is called a successional pathway. What determines the pattern and rate of species replacement during succession at a certain time and place? To answer this question, biologists focus on three factors:

1. the particular traits of the species involved;
2. how the species interact; and
3. historical and environmental circumstances, such as the size of the area involved and weather conditions.

Let's consider each factor in turn.

The Role of Species Traits Species traits, such as dispersal capability and the ability to withstand extreme dryness, are particularly important early in succession. As common sense would predict, recently disturbed sites tend to be colonized by plants and animals with good dispersal ability. When these organisms arrive, however, they often have to endure harsh environmental conditions.

Pioneering species tend to have "weedy" life histories. A **weed** is a plant that is adapted for growth in disturbed soils. Because soil is often disturbed when biomass is removed, weeds tend to thrive at the start of secondary succession.

Early successional species devote most of their energy to reproduction and little to competitive ability. They are at the "high fecundity, low survivorship" end of the life-history continuum (Chapter 54).

More specifically, pioneering species have small seeds, rapid growth, and a short life span, and they begin reproducing at an early age. As a result, they have a high reproductive rate (high r_{max}—see Chapter 54). But in addition, they can tolerate severe abiotic conditions such as high light levels, poor nutrient availability, and desiccation.

The Role of Species Interactions Once colonization is under way, the course of succession tends to depend less on how species

PROCESS: SECONDARY SUCCESSION

1. Pioneering species
Weedy species become established in disturbed soils.

2. Early successional community
Weedy species are replaced by longer-lived herbaceous species.

3. Mid-successional community
Shrubs and short-lived trees begin to invade.

4. Climax community
Long-lived tree species mature.

FIGURE 55.19 Secondary Succession in Midlatitude Temperate Forests. Succession leads to the development of a temperate forest from a disturbed state (in this case, an abandoned agricultural field).

cope with aspects of the abiotic environment and more on how they interact with other species. This change occurs because plants that grow early in succession change abiotic conditions in a way that makes the conditions less severe.

For example, because plants provide shade, they reduce temperatures and increase humidity. Their dead bodies also add organic material and nutrients to the soil. During succession, existing species can have one of three effects on subsequent species:

1. **Facilitation** takes place when the presence of an early-arriving species makes conditions more favorable for the arrival of certain later species, such as by providing shade or nutrients.
2. **Tolerance** means that existing species do not affect the probability that subsequent species will become established.
3. **Inhibition** occurs when the presence of one species inhibits the establishment or regrowth of another. For example, a plant species that requires high light levels to germinate may be inhibited late in succession by the presence of mature trees that prevent sunlight from reaching the forest floor. Alternately, an established species may produce a chemical that inhibits the growth of other species.

The Role of Chance and History In addition to species traits and species interactions, the pattern and rate of succession depend on their historical and environmental context. For example, the communities that developed after forest fires disturbed Yellowstone National Park in 1988 depended on the size of the burned patch and how hot the fire had been at that location.

Succession is also affected by the particular weather or climate conditions that occur during the process. Variation in weather and climate causes different successional pathways to occur in the same place at different times.

Analyzing species traits, species interactions, and the historical–environmental context provides a useful structure for understanding why particular successional pathways occur. To see this theoretical framework in action, let's examine data on the course of succession that has occurred in Glacier Bay, Alaska.

A Case Study: Glacier Bay, Alaska An extraordinarily rapid and extensive glacial recession is taking place at Glacier Bay (**FIGURE 55.20**). In just 200 years, glaciers that once filled the bay have retreated approximately 100 km, exposing tracts of barren glacial sediments to colonization. Because of this event, Glacier Bay has become an important site for studying succession.

Figure 55.20 shows the plant communities found in the area.

- Locations that have been ice free for 20 years or less do not have a continuous plant cover. Instead, they host scattered individuals of willow and a small shrub called *Dryas*.
- Areas that have been deglaciated for about 100 years are inhabited by dense thickets of a shrub called Sitka alder and scattered Sitka spruce trees.
- The oldest sites, ranging from 150 to 200 years of soil exposure, are dense forests of Sitka spruce and western hemlock.

FIGURE 55.20 Successional Stages in Glacier Bay.

These observations inspired a hypothesis for the pattern of succession in Glacier Bay: With time, the youngest communities of *Dryas* and willow succeed to alder thickets, which subsequently become dense spruce–hemlock forests. The key claim is that the entire bay is following a single successional pathway.

Research has challenged this hypothesis, however. Biologists who reconstructed the history of each community by studying tree rings found that at least two distinct successional pathways have occurred:

1. In the lower part of the bay, soon after the ice retreated, Sitka spruce began growing and quickly formed dense forests. Western hemlock arrived after spruce and is now common.
2. At middle-aged sites in the upper part of the bay, alder thickets were dominant for several decades, and spruce is just beginning to become common. These forests will probably never be as dense as the ones in the lower bay, however, and there is no sign that western hemlock has begun to establish itself.

In contrast, the youngest sites in the uppermost part of the bay may be following a third pathway. Alder thickets became dominant fairly early, but spruce trees are scarce. Instead, cottonwood trees are abundant.

These data raise an important question: How do species traits, species interactions, and dispersal patterns interact to generate the observed successional pathways?

- ***Species traits*** Western hemlock is abundant at older sites but largely absent from young ones. This pattern is logical for this species, because its seeds germinate and grow only in soils containing a substantial amount of organic matter. In addition, young hemlock trees can tolerate deep shade but not bright sunlight. Because of these traits, Western hemlock does not tolerate early successional conditions, but thrives later in succession.
- ***Species interactions*** Sitka alder facilitates the growth of Sitka spruce. The facilitating effect occurs because symbiotic bacteria that live inside nodules on the roots of alder convert atmospheric nitrogen (N_2) to nitrogen-containing molecules that alder use to build proteins and nucleic acids. When alder leaves fall and decay or roots die, the nitrogen becomes available to spruce. Although spruce trees are capable of invading and growing without the presence of alder, they grow faster when alder stands have added nitrogen to the soil. Note that spruce gains from the association. Alder is either unaffected, or negatively affected if it becomes shaded by spruce.

  Competition is another important species interaction. For example, shading by alder trees reduces the growth of spruce trees until spruce trees are tall enough to protrude above the alder thicket. Once the spruce trees breach the alder canopy, however, alder trees die out, unable to compete with spruce trees for light.
- ***Historical and environmental context*** According to geological evidence, glacial ice was more than 1100 m thick in the upper part of Glacier Bay during the mid-1700s. Because forests grow to an elevation of only 700 m or 800 m in this part of Alaska, the glacier eliminated all of the existing forests. But in the lower part of the bay, the ice was substantially thinner. As a result, some forests remained on the mountain slopes beyond the ice, even at the height of glaciation.

  The difference is crucial. In the lower part of the bay, nearby forests provided a ready source of Sitka spruce and western hemlock seed. But in the upper part of the bay, no forests remained to contribute seed. As a result, two dramatically different successional pathways were set in motion.

To summarize, successional pathways are determined by the adaptations that certain species have to their abiotic environment, interactions among species, and the history of the site. Species traits and species interactions tend to make succession predictable; history and chance events contribute a degree of unpredictability to succession.

check your understanding

C Y U

If you understand that . . .

- Disturbance is a normal part of communities.
- The impact of a disturbance depends on its type, frequency, and severity.
- After a disturbance occurs, a succession of species and communities replace those that were lost.
- The exact sequence of species observed is a function of their traits, their interactions, and the history of the site.

✔ You should be able to . . .

1. Explain how early successional species alter the environment in ways that make growing conditions more difficult for themselves.
2. Explain how the presence or absence of a species like alder, where nitrogen fixation occurs, might alter the course of succession.

Answers are available in Appendix A.

55.4 Global Patterns in Species Richness

The diversity of species present is a key feature of biological communities, and it can be quantified in two ways.

1. **Species richness** is a simple count of how many species are present in a given community.
2. **Species diversity** is a weighted measure that incorporates the species' relative abundance.

Although these terms sound similar, they can be very different in communities where a few species dominate. In such a case, species richness might be high but species diversity low (see

QUANTITATIVE METHODS 55.1 Measuring Species Diversity

Consider the composition of the three hypothetical communities shown in **FIGURE 55.21**. These data can be used to compare two measures of diversity, *species richness* and *species diversity*. Species richness is simply the number of species found in a community. In this case, communities 1 and 2 have equal species richness, and community 3 is lower in richness by one species. It is important to note, however, that communities 2 and 3 have similar relative abundances of each species, or what biologists call high *evenness*. Community 1, in contrast, is highly uneven. Fifty-five percent of the individuals in community 1 belong to species A, and other species are relatively rare. An uneven community has lower effective diversity than its species richness would indicate.

To take evenness into account, other diversity indices have been developed. A simple example is the Shannon index of species diversity, given by the following equation:

$$H' = -\sum_{i=1}^{n} p_i \ln p_i$$

In this equation, p_i is the proportion of individuals in the community that belong to species i. The index is summed over all the species in the study (n).

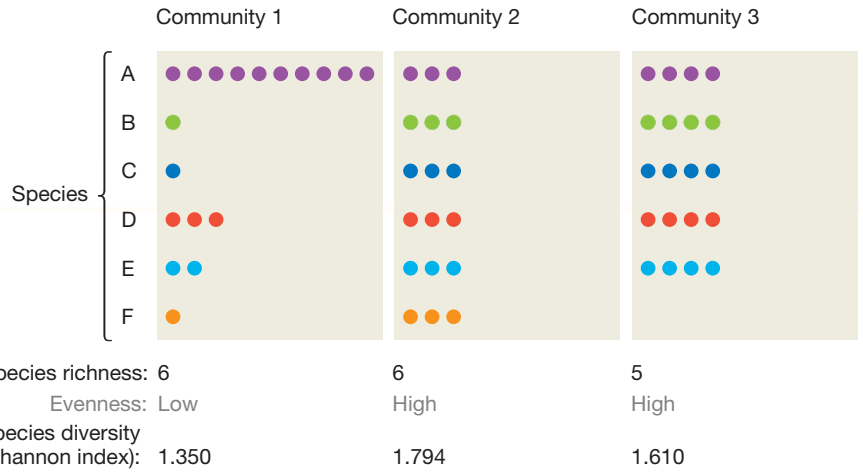

FIGURE 55.21 Species Diversity Can Be Quantified.

The Shannon index of species diversity for the hypothetical communities shown in Figure 55.21 was calculated by **(1)** computing the proportion of individuals in each community that belong to each species, **(2)** taking the natural logarithm of each of these proportions (see **BioSkills 6** in Appendix B for a review of logarithms), **(3)** multiplying each natural logarithm times the proportion for each species, and **(4)** summing the total across the six species in the community and multiplying by −1. ✔ **QUANTITATIVE If you understand the equation, you should be able to do these calculations and get the same result given in Figure 55.21.** Notice that while communities 1 and 2 have the same species richness, community 2 has higher diversity because of its greater evenness. Community 3 has lower species richness than community 1 but higher diversity.

Quantitative Methods 55.1. At scales above that of relatively small study plots, however, it is rare to have data on relative abundance. As a result, species richness is the most popular measure, and biologists sometimes use the terms species richness and species diversity interchangeably.

To introduce research on richness and diversity, let's focus on a simple question: Why are some communities more species rich than others?

Predicting Species Richness: The Theory of Island Biogeography

When researchers first began counting how many species are present in various areas, a strong pattern emerged: Larger patches of habitat contain more species than do smaller patches of habitat. The observation is logical because large areas should contain more types of niches and thus support higher numbers of species.

Early work on species richness highlighted another pattern, however—one that was harder to explain. Islands in the ocean have smaller numbers of species than do areas of the same size on continents. Why?

As it turned out, answering this question has had far-reaching implications in ecology and conservation biology. This situation often happens in biological science: Research on a seemingly esoteric question—often done out of the sheer joy of discovery—turns out to have important implications for completely unrelated issues, or even applications to practical problems that had previously been intractable.

The Role of Immigration and Extinction Robert MacArthur and Edward O. Wilson tackled the question of why islands in the ocean have smaller numbers of species than do areas of the same size on continents. They assumed that speciation occurs so slowly that the number of species on an island is a product of just two processes: immigration and extinction, which should vary with the number of species already present.

- Immigration rates should decline as the number of species on the island increases, because individuals that arrive are more likely to be members of a species that is already there. In addition, competition should prevent new species from becoming established when many species are already present on an island—meaning that immigration should seldom result in establishment of a new population.

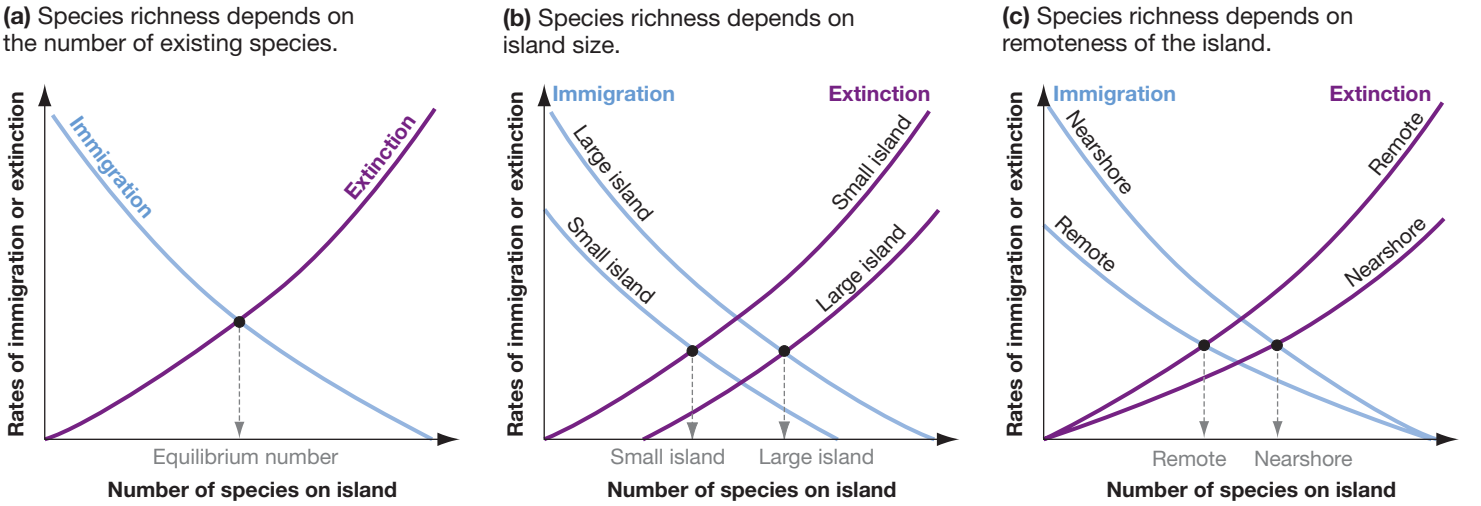

FIGURE 55.22 Theoretical Models Predicting Species Richness as a Function of Island Characteristics. The models illustrate how two key factors affecting species richness—immigration and extinction—depend on the number of existing species, island size, and island remoteness.

✔**QUESTION** Suppose that the mainland habitats closest to an island were wiped out by suburbanization. How would this affect the curves in part (c)?

- Extinction rates should increase as species richness increases, because niche overlap and competition for resources will be more intense.

The curves in **FIGURE 55.22a** illustrate these two predictions. Note that when the two processes interact, the result is an equilibrium—a balance between the arrival of new species and the extinction of existing ones. If species richness changes due to a hurricane or fire or some other disturbance, then continued immigration and extinction should restore the equilibrium value.

The Role of Island Size and Isolation MacArthur and Wilson also realized that immigration and extinction rates should vary as a function of island size and how far the island is from a continent or other source of immigrants.

- Immigration rates should be higher on large islands that are close to mainlands, because immigrants are more likely to find large islands that are close to shore than small ones that are far from shore.
- Extinction rates should be highest on small islands that are far from shore, because fewer resources are available to support large populations, and because fewer individuals arrive to keep the population going.

Their theory makes two predictions: Species richness should be higher on **(1)** larger islands than smaller islands (**FIGURE 55.22b**), and **(2)** nearshore islands versus remote islands (**FIGURE 55.22c**).

Applying the Theory The MacArthur–Wilson model, called the theory of island biogeography, is important for several reasons:

- It is relevant to a wide variety of island-like habitats such as alpine meadows, lakes and ponds, and caves. It is also relevant to national parks and other reserves that are surrounded by human development, forming islands of habitat.
- It is relevant to species that have a metapopulation structure (Chapter 54). Immigration and extinction rates in subpopulations should follow the dynamics predicted by the theory.
- It made specific predictions that could be tested. For example, researchers have measured species richness on tiny islands, removed all of the species present, and then measured whether the same number of species recolonized the island and reached an equilibrium number. Predictions about immigration and extinction rates have also been measured by observing the same islands over time.
- It can help inform decisions about the design of natural preserves. In general, the most species-rich reserves should be ones that are **(1)** relatively large, and **(2)** located close to other relatively large habitat areas (Chapters 54 and 57).

Global Patterns in Species Richness

Biologists have long understood that large habitat areas tend to be species rich, and the theory of island biogeography has been successful in framing thinking about how species richness should vary among island-like habitats. But researchers have had a much more difficult time explaining what may be the most striking pattern in species richness.

The Latitudinal Gradient Biologists who began cataloging the flora and fauna of the tropics in the mid-1800s quickly

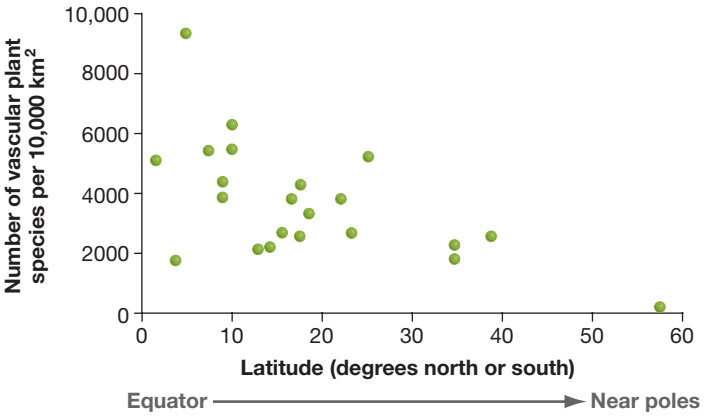

FIGURE 55.23 Species Richness of Vascular Plants Has a Strong Latitudinal Gradient.

DATA: Reid, W. V., and K. R. Miller. 1989. *Keeping Options Alive: The Scientific Basis for Conserving Biodiversity*. Washington, DC: World Resources Institute.

recognized that these habitats contain many more species than do temperate or subarctic environments. Data compiled in the intervening years have confirmed the existence of a strong latitudinal gradient in species diversity—for communities as a whole as well as for many taxonomic groups.

In birds, mammals, fish, reptiles, many aquatic and terrestrial invertebrates, and trees, species diversity declines as latitude increases. **FIGURE 55.23** graphs data on the number of vascular plant species present from the equator toward the poles. This pattern is widespread, although not universal—a number of marine groups, as well as shorebirds, show a *positive* relationship between latitude and diversity. Why does a latitudinal gradient often occur?

To explain why species diversity might decline with increasing latitude, biologists have to consider two fundamental principles:

1. The causal mechanism must be abiotic, because latitude is a physical phenomenon produced by Earth's shape (see Chapter 52). It must be a physical factor that varies predictably with latitude and that could produce changes in species diversity.
2. The species diversity of a particular area is the sum of four processes: speciation, extinction, immigration (colonization), and emigration (dispersal). Thus, the latitudinal gradient must be caused by an abiotic factor that affects the rate of speciation, extinction, immigration, or emigration in a way that would lead to more species in the tropics and fewer near the poles.

Over 30 hypotheses have been proposed to explain the latitudinal gradient. Let's consider three of the most prominent ideas.

The High-Productivity Hypothesis High productivity in the tropics could promote high diversity by increasing speciation rates and decreasing extinction rates. (Recall from Chapter 52 that productivity is the total amount of photosynthesis per unit area per year.) The logic here is that increased biomass production supports more herbivores and thus more predators, parasites, and scavengers. If higher population sizes lead to more intense competition, then speciation rates should increase as niche differentiation occurs within populations of herbivores, predators, parasites, and scavengers.

The evidence for the high-productivity hypothesis is still inconclusive.

- The hypothesis is supported by global patterns in productivity (see Chapter 56). For example, productivity is extremely high in biomes such as tropical rain forests and coral reefs, which have high species diversity.
- It is not supported by experimental addition of fertilizer to aquatic or terrestrial communities. In most of these studies, productivity increases but species diversity decreases. However, critics contend that the temporal and spatial scale of these experiments is too small to be relevant to global patterns.
- It is not supported in some highly productive habitats, such as estuaries (see Chapter 52), where species diversity can be low.

The Energy Hypothesis The energy hypothesis is an extension of the high-productivity hypothesis. Recognizing that some highly productive habitats are species poor, investigators proposed that the key factor can't be productivity alone.

The energy hypothesis claims that high temperatures increase species diversity by increasing both productivity and the likelihood that organisms can tolerate the physical conditions in a region. The idea is that high energy inputs—rather than high nutrient inputs—are the key to high speciation rates and low extinction rates.

Although the energy hypothesis is relatively new, some data support it. For example, biologists who analyzed data on gastropods and other marine invertebrates have documented a strong correlation between the temperature of marine waters and species diversity.

The Area and Age Hypothesis Temperate and arctic latitudes were repeatedly scoured by ice sheets over the last 2 million years, but tropical regions were not. In addition, the land area of the tropics has historically been larger than the land area at high latitudes. Thus, tropical regions have had more time and more space for speciation to occur than other regions have.

Recent data suggest, however, that tropical forests were dramatically reduced in size by widespread drying trends during the ice ages. Existing tropical forests may be much younger than originally thought. If so, then the contrast in the age of northern and southern habitats may not be enough to explain the dramatic difference in species diversity.

What can you conclude from all this? The current consensus is that each of the factors discussed here may influence the species diversity of communities. It is tempting to look for single causes to explain important patterns such as the latitudinal gradient. But in this case, it is probably more realistic to say there are multiple causes.

If you understand . . .

55.1 Species Interactions

- Two interacting species may each experience a net fitness cost (−) or benefit (+) from the interaction. These costs and benefits depend on the conditions that prevail at a particular time and place and may change through time.
- Commensalism (+/0) occurs when one species benefits but the other is unaffected.
- Competition (−/−) occurs when the niches of two species overlap—meaning they use the same resources. Competition may result in the complete exclusion of one species (the weaker competitor). It may also result in niche differentiation, in which competing species evolve traits that allow them to exploit different resources.
- Consumption (+/−) occurs when consumers eat part or all of other individuals, which resist through constitutive defenses or inducible defenses.
- Predators are efficient enough to reduce the size of many prey populations.
- Levels of herbivory are relatively low in terrestrial ecosystems, because predation and disease limit herbivore populations, plants provide little nitrogen, and many plants have defenses.
- Parasites are consumers that generally spend all or part of their life cycle in or on their host (or hosts). They usually have traits that allow them to escape host defenses and even manipulate host behavior to increase their likelihood of transmission to a new host. In turn, hosts have evolved counter-adaptations that help fight off parasites.
- Mutualism (+/+) provides individuals with food, shelter, transport of gametes, defense against predators, or other services. For each species involved, the costs and benefits of mutualism may vary over time and from place to place.
- Interactions among species have two main outcomes: (1) They affect the distribution and abundance of the interacting species, and (2) they are agents of natural selection and thus affect the evolution of the interacting species, by a process called coevolution.

✔ **You should be able to give an example of how a mutualistic relationship can evolve into a parasitic one.**

55.2 Community Structure

- The attributes of community structure include the number of species present, their relative abundance, the sum of their interactions, and the physical attributes of the community as determined by a combination of abiotic and biotic factors.
- Historical and experimental evidence supports the view that communities are dynamic rather than static, and that their composition is neither entirely predictable nor stable over time.
- The assemblage of species found in a community is primarily a function of climate and chance historical events.
- In some cases, the structure of an entire community can change dramatically if a single species is removed from it or added to it.

✔ **You should be able to predict the effects of an invasive species on community structure.**

55.3 Community Dynamics

- Each community has a characteristic disturbance regime—meaning a type, severity, and frequency of disturbance that it experiences.
- Three types of factors influence the pattern of succession that occurs after a disturbance: **(1)** A species' physiological traits influence when it can successfully join a community; **(2)** interactions among species influence if and when a species can become established; and **(3)** the historical and environmental context of the site affects which species are present.

✔ **You should be able to explain why climate makes the three successional pathways documented in Glacier Bay similar, and why chance historical events make them different.**

55.4 Global Patterns in Species Richness

- Species richness is higher in large islands near continents than in small, isolated islands, due to differences in immigration and extinction.
- The theory of island biogeography is relevant to a wide variety of isolated habitats.
- Species richness is higher in the tropics and lower toward the poles, but the mechanism responsible for this pattern is still hotly debated.

✔ **You should be able to propose how the theory of island biogeography could be applied by conservation biologists to species richness in a national park.**

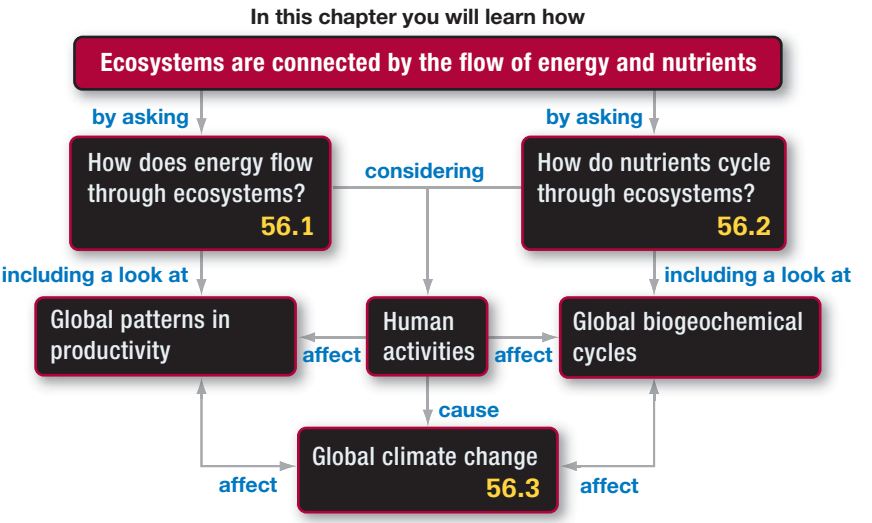
TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. True or false? Species act as agents of natural selection when they interact.
2. What is niche differentiation?
   a. the evolution of traits that reduce niche overlap and competition
   b. interactions that allow species to occupy their fundamental niche
   c. the degree to which the niches of two species overlap
   d. the claim that species with the same niche cannot coexist
3. The relationship between ants and treehoppers in the presence of spiders is an example of
   a. commensalism.
   b. competition.
   c. consumption.
   d. mutualism.
4. What is one advantage of inducible defenses?
   a. They are always present; thus, an individual is always able to defend itself.
   b. They make it impossible for a consumer to launch surprise attacks.
   c. They result from a coevolutionary arms race.
   d. They make efficient use of resources, because they are produced only when needed.
5. Pioneer species tend to have high _____ and lower survivorship.
6. Which of these factors is *not* generally correlated with species diversity?
   a. latitude
   b. productivity
   c. longitude
   d. island size

TEST YOUR UNDERSTANDING

Answers are available in Appendix A



7. The text claims that species interactions are conditional and dynamic. Do you agree with this statement? Why or why not? Cite specific examples to support your answer.
8. Why does the phrase "coevolutionary arms race" appropriately characterize the long-term effects of species interactions?
   a. Both plants and animals have evolved weapons for defense that are so effective that many plants are not eaten, and predators cannot reduce prey populations to extinction.
   b. Adaptations that give one species a fitness advantage in an interaction are likely to be countered by adaptations in the other species that eliminate this advantage.
   c. In all species interactions except for mutualism, at least one species loses (suffers decreased fitness).
   d. Even mutualistic interactions can become parasitic if conditions change. As a result, interacting species are always "at war."
9. Biologists have tested the hypotheses that communities are highly predictable versus highly unpredictable. State the predictions that these hypotheses make with respect to (a) changes in the distribution of the species in a particular community over time, and (b) the communities that should develop at sites where abiotic conditions are identical. Which hypothesis appears to be more accurate?
10. What is a disturbance? Consider the role of fire in a forest. Compare and contrast the consequences of high-frequency versus low-frequency fire, and high versus low severity of fire.
11. Summarize the life-history attributes of early successional species. Why are these attributes considered adaptations?
12. Explain why high productivity should lead to increased species richness in habitats such as tropical rain forests and coral reefs.

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A

13. Some insects harvest nectar by chewing through the wall of the structure that holds the nectar. As a result, they obtain a nectar reward, but pollination does not occur. Suppose that you observed a certain bee species obtaining nectar in this way from a particular orchid species. Over time, how might you expect the characteristics of the orchid population to change in response to this bee behavior?
14. You are a walking, talking community that includes trillions of bacterial and archaeal cells. Your gut, in particular, contains a complex microbial community. In some circumstances, the use of probiotics, which stimulate the rapid growth of bacteria that are mutalistic or commensal with humans, can eliminate the need to use antibiotics, which can wipe out helpful bacteria along with harmful bacteria. The use of probiotics is an example of which process?
   a. succession
   b. competitive exclusion
   c. parasitism
   d. niche differentiation
15. Suppose that a two-acre lawn on your college's campus is allowed to undergo succession. Describe how species traits, species interactions, and the site's history might affect the community that develops.
16. Design an experiment to test the hypothesis that increasing species richness increases a community's productivity.

56 Ecosystems and Global Ecology

The reservoir at the Harbeespoort Dam in South Africa is notorious for its spectacular algae blooms caused by nutrient pollution. This chapter explores how humans are altering ecosystems all over the planet.

The data in this chapter carry a simple, but important, message: Some of the most urgent problems facing humans are rooted in ecosystems and global ecology. Acid rain, nitrate pollution, declining freshwater supplies, soil erosion, and global climate change are just a few of the large-scale issues that ecologists are documenting.

The chapter has a simple theme, as well: In nature, everything is connected. This is because the components of an **ecosystem**—the species present in a region, along with abiotic components such as the soil, climate, water, and atmosphere—are linked by the flow of energy and the cycling of **nutrients** needed to sustain life, such as carbon and nitrogen. Further, ecosystems are themselves linked by the global exchange of energy and nutrients throughout the **biosphere,** the thin zone of life surrounding the Earth.

BIG PICTURE

This chapter is part of the Big Picture. See how on pages 1196–1197.

✔ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.

Humans are removing species, changing landscapes, and adding massive amounts of energy and nutrients to ecosystems all over the planet. The biological, chemical, and geological consequences have been so dramatic that scientists have proposed naming a new epoch in the geological timescale—the Anthropocene ("new human epoch") (Chapter 28).

Let's begin our analysis of large-scale ecology by considering the basics of how energy flows through the components of an ecosystem. Then, let's examine the cycling of nutrients. Finally, you will see how the flow of energy and the cycling of nutrients are central to understanding global climate change. You can see how ecosystems fit into the Big Picture of Ecology on pages 1196–1197.

56.1 How Does Energy Flow through Ecosystems?

One of the defining characteristics of life is the use of energy (Chapter 1). Energy enters ecosystems via the primary producers. A **primary producer** is an **autotroph** (literally, "self-feeder")—an organism that can synthesize its own food from inorganic sources. In most ecosystems, primary producers use solar energy to manufacture food via photosynthesis (see Chapter 10). But in deep-sea hydrothermal vents and iron-rich rocks deep below Earth's surface, primary producers use the chemical energy contained in inorganic compounds such as methane (CH_4) or hydrogen sulfide (H_2S) to make food (see Chapter 29).

Primary producers do not *create* energy. Rather, they are *transforming* the energy in sunlight or inorganic compounds into the chemical energy stored in sugars. Recall that the first law of thermodynamics states that energy cannot be created or destroyed, but only transferred and transformed (Chapter 8).

The total amount of chemical energy produced in a given area and time period is called **gross primary productivity (GPP).** The primary producers use this chemical energy in two ways:

1. ***Cellular Respiration*** It takes energy just to stay alive. Primary producers have to use chemical energy to fuel cellular respiration (or in anaerobic microbes, fermentation) to produce the energy currency, ATP (Chapter 9). ATP, in turn, is used to fuel a diverse array of metabolic processes.
2. ***Growth and Reproduction*** Chemical energy that isn't used for cellular respiration can be applied to growth and reproduction. Energy that is invested by primary producers in building new tissue or offspring is called **net primary productivity (NPP).**

Because cellular respiration, growth, and reproduction are not perfectly efficient (second law of thermodynamics), some energy is lost during these processes as molecular waste and heat without being used. Linking these concepts together:

$$\mathbf{NPP = GPP - R}$$

(where R = energy used in cellular respiration, or lost)

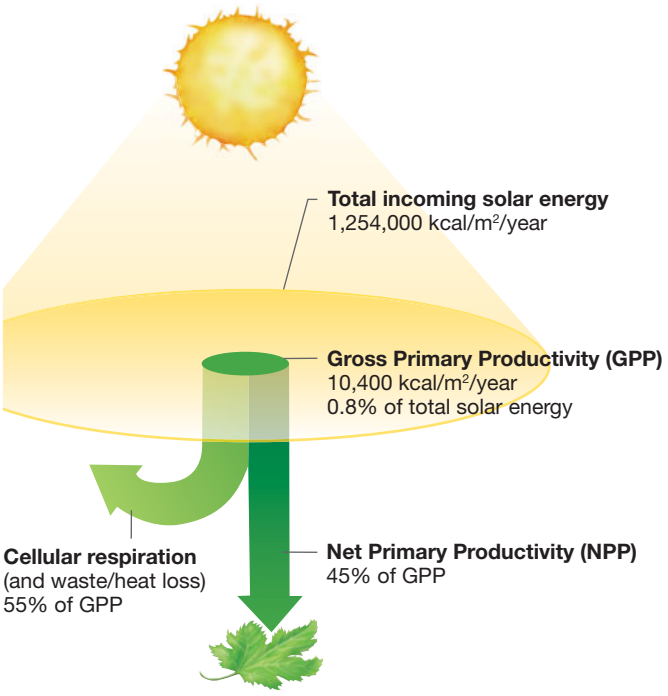


FIGURE 56.1 Measuring the Energy That Enters Ecosystems. These data are from the Hubbard Brook Experimental Forest.

NPP represents the total amount of chemical potential energy that is stored in organic material, or **biomass.** NPP is critically important because it is the amount of energy available via primary producers to the other organisms of an ecosystem.

How Efficient Are Autotrophs at Capturing Solar Energy?

How much of the energy that enters an ecosystem is captured as NPP? To answer this question, let's look at data from the world's most intensively studied ecosystem. Since the early 1960s, ecologists Gene Likens, Herbert Bormann, and colleagues have been studying how energy and nutrients flow through a temperate forest ecosystem in the northeastern United States: the Hubbard Brook Experimental Forest in New Hampshire.

During one year, from June 1, 1969, to May 31, 1970, 1,254,000 kcal of solar radiation per square meter (m^2) entered this ecosystem in the form of sunlight. If this amount of energy were available in the form of electricity, it would easily power two 150-watt lightbulbs per square meter of land, burning continuously for one year.

By documenting rates of photosynthesis in a large sample of forest plants, Likens and Bormann calculated that the plants used 10,400 kcal/m^2 of this energy in photosynthesis—a mere 0.8 percent of the incoming sunlight (**FIGURE 56.1**). Why so inefficient? For comparison, the best solar panels produced today have an efficiency of about 20 percent in normal outdoor conditions.

The answer includes several components.

- Even when conditions are ideal, the pigments that drive photosynthesis can absorb only a fraction of the light wavelengths available and thus a fraction of the total energy received.

- Plants in temperate biomes have drastically reduced photosynthetic rates in winter.
- If conditions get dry during the summer, stomata close to conserve water. Photosynthesis stalls due to a lack of CO_2.
- The efficiency of enzymes is very temperature dependent.

How much of the gross primary production goes to the production of new biomass? By measuring plant growth, Likens and Bormann estimated that only about 45 percent of GPP went to NPP. The other 55 percent either was used for cellular respiration or lost.

Other biologists have done similar studies in other ecosystems. The general pattern is that only a tiny fraction of incoming sunlight is converted to chemical energy, and only a fraction of this gross primary productivity is used to build biomass. What happens to the new biomass once it is formed?

What Happens to the Biomass of Autotrophs?

Graduate student Raymond Lindeman made a key insight about the fate of autotroph biomass in the 1940s, based on his research at Cedar Creek Bog in Minnesota. Lindeman proposed the *energy flow model* for ecosystems, whereby energy could flow from autotrophs through other organisms in the form of biomass.

- **Consumers** eat living organisms. **Primary consumers** eat primary producers; **secondary consumers** eat primary consumers; **tertiary consumers** eat secondary consumers, and so on. You are a primary consumer when you eat a salad, a secondary consumer when you eat beef, and a tertiary consumer when you eat tuna.
- **Decomposers,** or **detritivores,** obtain energy by feeding on the remains of other organisms or waste products. Dead animals and dead plant tissues ("plant litter") are collectively known as **detritus.** Many fungi and bacteria are decomposers, but humans rarely act as decomposers.

Energy flows when one organism eats another. However, a key take-home message is that energy constantly dissipates as it flows through ecosystems and is ultimately "lost" as heat, whereas nutrients continue to cycle (**FIGURE 56.2**). Consider that all the *energy* stored in your tissues right now ultimately will be released into the atmosphere, but all the carbon, nitrogen, and other *nutrients* present in your tissues will persist in other organisms and the abiotic environment for millennia.

Fifteen years after Lindeman's model was published, Howard Odum carried the concept of energy flow to the next level by quantifying energy flow in an aquatic ecosystem. Odum categorized organisms according to their roles. Organisms that obtained energy from the same type of source were said to occupy the same **trophic** ("feeding") **level.**

Trophic Structure: Food Chains and Food Webs Biologists often begin with a simple model and add complexity. A **food chain** focuses on one possible pathway of energy flow among trophic levels in an ecosystem. **FIGURE 56.3** shows two examples of food chains: a **grazing food chain** and a **decomposer food chain.**

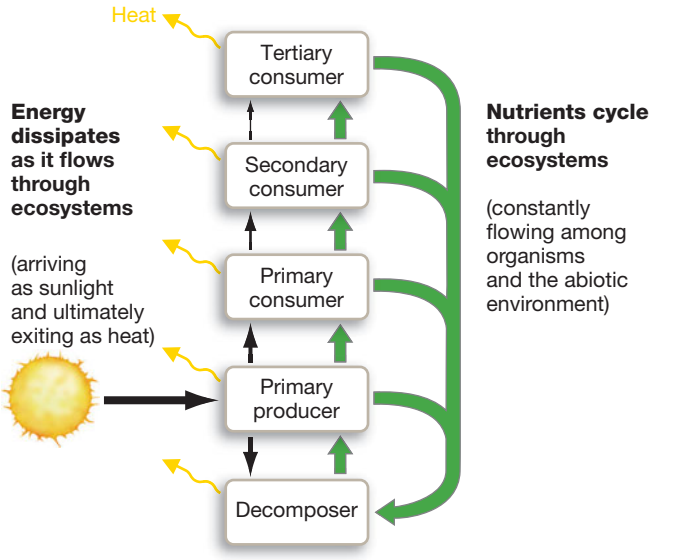

FIGURE 56.2 Energy Eventually Dissipates, but Nutrients Cycle.

At the second trophic level, the decomposer food chain has a **primary decomposer,** which feeds on plant detritus, rather than a primary consumer. Note several key points:

- At higher trophic levels, the grazing and decomposer food chains often merge. For example, the robin in the figure functions as

Trophic level	Feeding strategy	Grazing food chain	Decomposer food chain
5	Quaternary consumer		Cooper's hawk
4	Tertiary consumer	Cooper's hawk	Robin
3	Secondary consumer	Robin	Earthworm
2	Primary decomposer or consumer	Cricket	Bacteria, archaea

FIGURE 56.3 Trophic Levels Identify Steps in Energy Transfer.

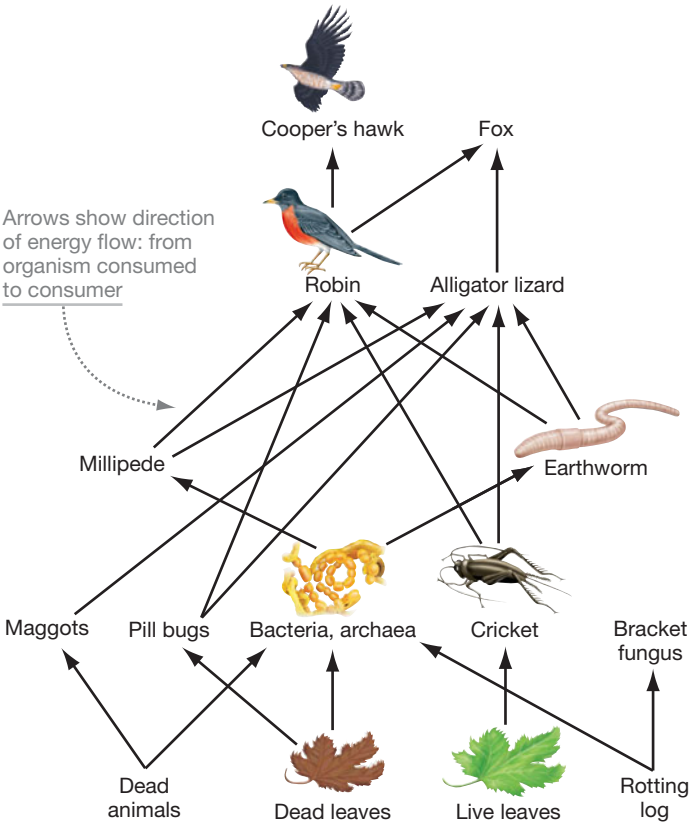

FIGURE 56.4 Food Webs Describe Trophic Relationships in an Ecosystem. Food webs offer a more comprehensive analysis of feeding relationships than food chains do (compare to Figure 56.3). This food web shows only a fraction of the total feeding relationships and species of a temperate deciduous forest.

a secondary consumer in the grazing food chain and a tertiary consumer in the decomposer food chain.

- It is common for consumers—such as humans and robins—to feed at multiple trophic levels.

Because most consumers feed on a wide array of organisms and at multiple trophic levels, food chains are embedded in more complex **food webs.** The food web shown in **FIGURE 56.4** is a more detailed description of the trophic relationships among the organisms in Figure 56.3. A complete food web would include *all* the organisms interacting in this ecosystem, along with estimates of the amount of energy transferred at each link. Food webs are a way to summarize energy flows and to document the complex trophic interactions that occur in ecosystems.

Energy Flow to Grazers versus Decomposers Figures 56.3 and 56.4 show that the primary producers—maple leaves in this case—are a source of energy whether alive or dead. How much biomass gets eaten alive versus dead?

The answer to this question varies among habitats. In forest ecosystems, the percentage of NPP consumed alive can be as low as 5–7 percent, because indigestible wood isn't transferred to other organisms until it decays. But in marine habitats, where algae account for most of the primary production, the percentage

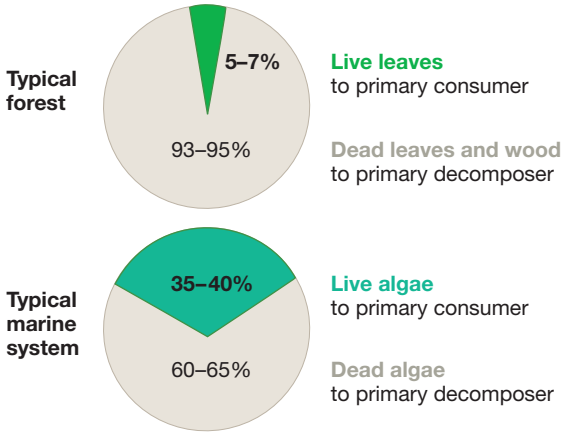

FIGURE 56.5 How Much Biomass Gets Eaten Dead versus Alive?

of NPP that gets consumed alive is much higher—often 35–40 percent (**FIGURE 56.5**). This is an important point, for two reasons:

1. If you want to understand energy flow in a forest, you have to understand decomposers. Decomposition is less of a factor in marine ecosystems, where primary consumers are key.
2. The decomposer food chain is "leaky." At Hubbard Brook, large amounts of energy leave the forest ecosystem in the form of detritus that washes into streams. In these streams, photosynthesis by aquatic algae and plants introduced only about 10 kcal/m^2/yr versus 6039 kcal/m^2/yr that washed in from the surrounding forest. In marine ecosystems, energy exits in the form of dead bodies that rain down to the ocean floor.

The "dead versus alive" percentage can vary from season to season or even week to week according to ambient temperatures, light levels, nutrient levels, and species interactions.

Energy Transfer between Trophic Levels

All ecosystems share a characteristic pattern: The total biomass produced each year declines from lower trophic levels up to the higher levels. To understand why, let's go back to the Hubbard Brook Experimental Forest.

Chipmunks are small rodents that are seed predators at Hubbard Brook. On average, these primary consumers harvest 31 kcal/m^2 of energy each year. Of that total, how much is used to create biomass? Careful measurements revealed that, on average:

- 17.7 percent is unused—meaning that it is not digested and absorbed. Instead, it is excreted.
- 80.7 percent is used for cellular respiration.
- 1.6 percent goes into the production of new chipmunk tissue by growth and reproduction.

The same pattern would be seen in a secondary consumer—a Cooper's hawk, for example, that eats chipmunks and other primary consumers. Consider the energy that a hawk expends to catch prey. This energy cannot be used to make hawk biomass.

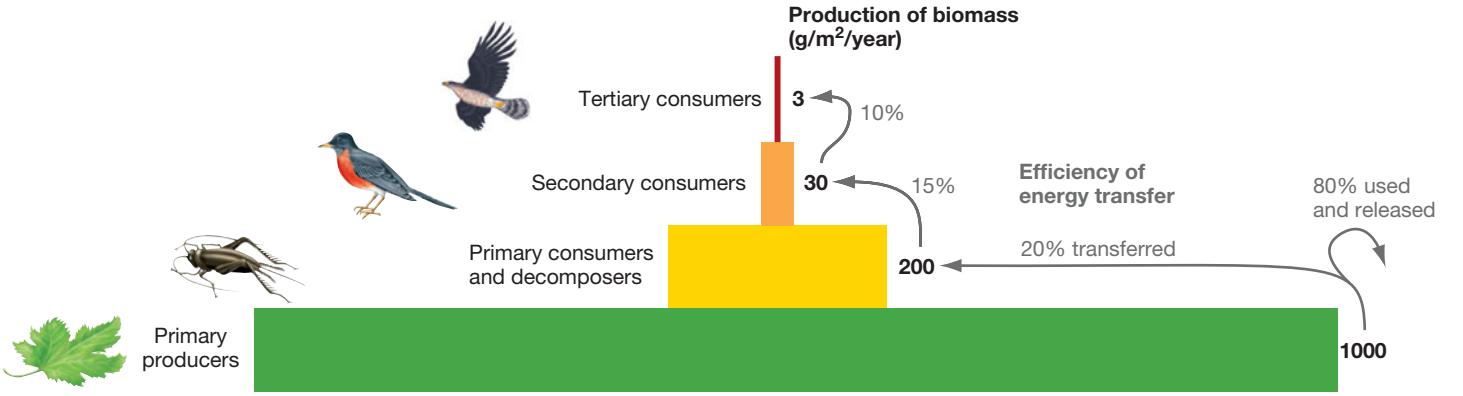

FIGURE 56.6 Productivity Declines at Higher Trophic Levels. This pattern is called the pyramid of productivity.

The general point is simple: Because most of the total energy consumed is used for cellular respiration rather than growth and reproduction, the amount of biomass produced at the second trophic level must be less than the amount at the first trophic level; productivity at the third trophic level must be less than that at the second.

The Pyramid of Productivity The data in **FIGURE 56.6** depict the biomass produced at trophic levels 1–4 in a temperate deciduous forest. A separate horizontal bar represents each trophic level. Note that the graph reports two numbers:

1. Productivity is a rate, measured here in units of grams of biomass produced by growth and reproduction per square meter of area each year ($g/m^2/year$).
2. Efficiency is a ratio and thus dimensionless—the units cancel out. (It is reported here as a percentage.) Efficiency is the fraction of biomass transferred from one trophic level to the next.

Biomass production at each trophic level varies widely among ecosystems. But as a rough rule of thumb, the efficiency of biomass transfer from one trophic level to the next is only about 10 percent. ✔ **QUANTITATIVE If you understand this concept, you should be able to explain why it takes about 10 times more energy to grow a kilogram of beef than a kilogram of wheat.**

Efficiency Varies It's important to recognize that the "10 percent rule" in ecological efficiency masks a great deal of interesting variation. For example:

- Large mammals are more efficient at producing biomass than small mammals, because large animals have a smaller surface-area-to-volume ratio and lose less heat (see Chapter 42).
- Biomass production is much more efficient in ectotherms than in endotherms. Ectotherms rely principally on heat gained from the environment and do not oxidize sugars to keep warm (see Chapter 42). As a result, they devote much less energy to cellular respiration than endotherms do. Chipmunks devote just 1.5 percent of their energy intake to growth; lizards and other ectotherms may devote 20–40 percent.

✔ **If you understand this concept, you should be able to explain why it may be more efficient to eat lobster than chicken, even though the two animals feed at the same trophic level.**

Biomagnification

The pyramid of productivity helps explain how some pollutants become concentrated in food webs. Some types of molecules do not break down quickly in the environment and are neither digested by organisms nor excreted efficiently. These include heavy metals like mercury, emitted mostly from coal-fired power plants, and organic compounds called POPs—persistent organic pollutants—which are used for herbicides, pesticides, and other industrial applications. Mercury and POPs undergo **biomagnification**—meaning that they increase in concentration at higher levels in a food chain. Why?

Biomagnification begins when persistent atoms or molecules are taken up from air or water by primary producers. A very large quantity of pollutants can be taken up by primary producers—even if the concentration of the pollutant in the environment is low—because of the very large biomass of primary producers at the bottom of the productivity pyramid (Figure 56.6).

Remember that organisms at each trophic level eat about 10 g of tissue to make 1 g of their own tissue. When the primary consumers consume the biomass of the primary producers, they take up all the pollutants but concentrate them in their smaller biomass—because little or none of the pollutant is metabolized or excreted. As a result, the pollutant becomes more concentrated as it moves up each trophic level (**FIGURE 56.7**). The greater the number of trophic levels, the higher the consequences to the top consumers. In many cases, concentrations get high enough in secondary and tertiary consumers to poison them.

One POP, called DDT (dichlorodiphenyltrichloroethane), was made famous by ecologist Rachel Carson in her 1962 book, *Silent Spring*. Carson was alarmed that many birds were dying in areas that were sprayed with DDT to control mosquitoes—the pesticide caused birds to lay thin-shelled eggs that became crushed in the nest. Carson's resulting campaign for responsible chemical use spurred the beginning of the environmental

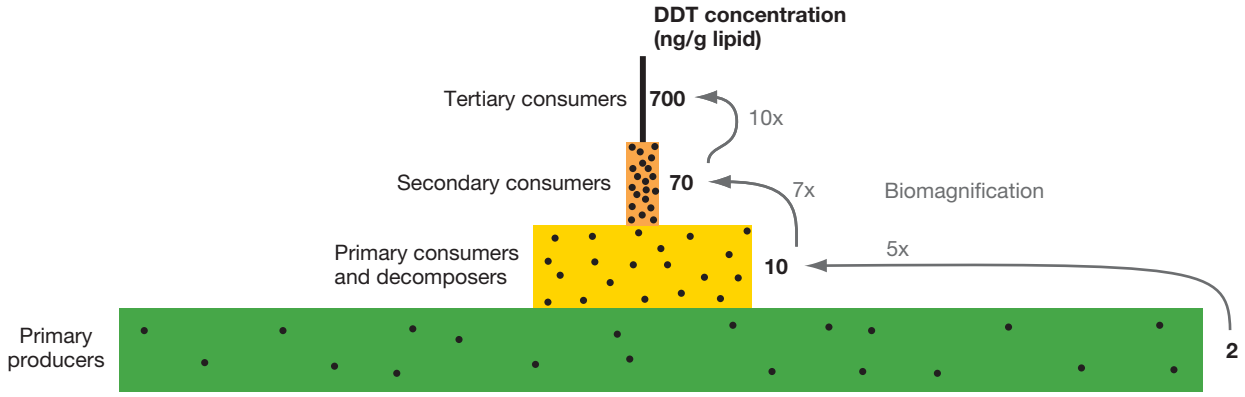

FIGURE 56.7 Biomagnification Can Lead to High Concentrations of Toxic Substances at Higher Trophic Levels.
DDT is a pesticide once commonly used to control mosquitoes and other insects.

movement. DDT was banned in the United States in 1972. Populations of top predators like ospreys and bald eagles are back on the rise.

Humans are top predators too, and are vulnerable to biomagnification. ✔ **If you understand biomagnification, you should be able to explain how you could get mercury poisoning from eating tuna every day, but not from eating the same quantity of sardines every day.**

Top-Down Control and Trophic Cascades

Top predators are not abundant compared to other organisms in the food web (as indicated by the tiny biomass at the peak of the productivity pyramid in Figure 56.6), and usually don't get eaten by other consumers. Are top predators important?

One way to answer this question is to remove top predators from an ecosystem and see what happens. Robert Paine used this approach in his study of the keystone species, *Pisaster ochraceous* (Chapter 55). When Paine removed this sea star from a rocky intertidal habitat on the Pacific Coast, mussels took over—and dramatically changed which other species were present in the community. When a consumer limits a prey population in this way, biologists say that **top-down control** is occurring.

It is rarely practical to remove a top predator from an ecosystem, but sometimes events present an opportunity for a natural experiment. That's exactly what happened in the Greater Yellowstone ecosystem of western North America, where wolves were hunted out in the early 1900s but reintroduced in 1995.

What effect did the absence of wolves have on the Greater Yellowstone ecosystem? During the 1990s, ecologists William Ripple and Robert Beschta had been trying to determine why aspen trees had been declining for most of the last century. Then they made an important connection—the number of aspen trees started to decline at the same time that the wolves had disappeared. Ripple and Beschta hypothesized that there was an indirect link between aspen trees and wolves.

How could they test their hypothesis? One way was to see if the number of aspen trees would begin to increase as the reintroduced wolf population increased. Although the Yellowstone wolf population has grown to only about 150 individuals since reintroduction, their presence has already led to an increase in aspen—and to many other changes in the food web (**FIGURE 56.8**, see page 1154).

- In Yellowstone, wolves primarily feed on elk. As elk numbers declined and individuals changed their feeding habits due to fear of being in the open, populations of favorite elk foods like aspen, cottonwood, and willow have increased.
- The changes in willow and other plant species triggered an increase in beavers, which compete with elk for these plants.
- Beavers dam streams, forming ponds that provide habitat for frogs, turtles, and an array of other species, whose numbers have increased.
- Wolves do not tolerate coyotes. As coyotes declined, mouse populations increased. The increase in mouse populations led to larger populations of hawks that prey on mice.

When changes in top-down control cause conspicuous effects two or three links away in a food web, biologists say that a **trophic cascade** has occurred. Trophic cascades have been observed in many ecosystems. Atlantic cod and other large predators, for example, have virtually disappeared from large parts of the Atlantic Ocean due to overfishing. Shrimp and crab—species that cod used to eat—have increased in response; the primary producers that shrimp and crab eat have decreased.

The message from these studies is clear: The removal of top predators from ecosystems can have widespread, and sometimes unexpected, effects on the abundance of many species in a community. The underlying cause is energy flow—one of the factors that links components in an ecosystem.

Global Patterns in Productivity

Top predators are not the only players that can profoundly affect the abundance of species in a community. The productivity of primary producers is also very important, and it can have a "bottom-up" effect. Let's consider two big-picture questions about NPP: Where is most of it produced, and what limits its production to those areas?

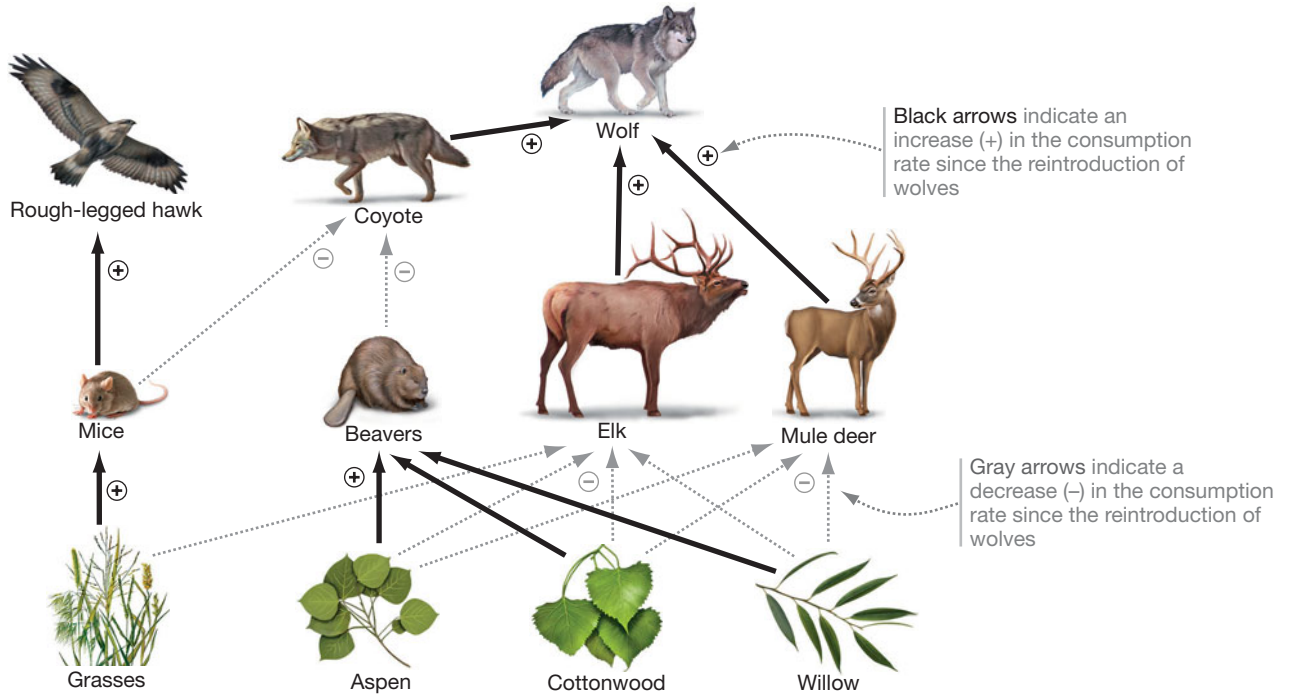

FIGURE 56.8 The Reintroduction of Wolves to Yellowstone Caused a Trophic Cascade. This food web shows only a few of the hundreds of species affected by the reintroduction of wolves.

Keep in mind that productivity is limited by any factor that limits the rate of photosynthesis. The top candidates are temperature and the availabilities of water, sunlight, and nutrients (see Chapter 10 and Unit 7). Let's consider how different limiting factors prevail in different environments.

Is Productivity Higher on the Land or in the Sea? **FIGURE 56.9** summarizes data on NPP from around the globe. Note that the highest NPP is indicated in red, yellow, and green, and that these colors occur only on land. In general, NPP on land is much higher than it is in the oceans. Why?

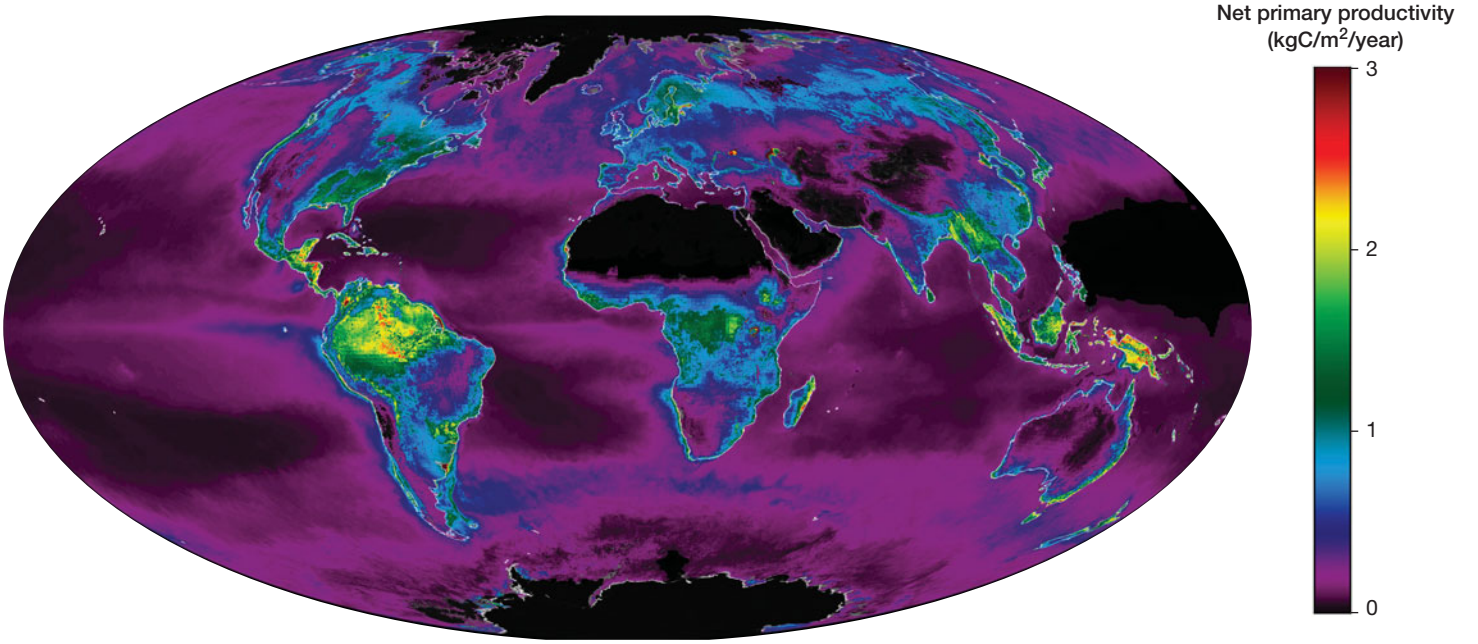

FIGURE 56.9 Net Primary Productivity Varies among Geographic Regions. The terrestrial ecosystems with the highest primary productivity are found in the tropics; tundra and deserts have the lowest. The highest productivity in the oceans occurs in nutrient-rich coastal areas.

DATA: http://earthobservatory.nasa.gov.

The leading hypothesis to explain this pattern is simply that much more light is available to drive photosynthesis on land than in marine environments. Water quickly absorbs many of the light wavelengths that are used in photosynthesis (see Chapter 52). This simple observation also underlines the importance of the evolution of land plants (see Chapter 31). Before green plants invaded the land, NPP in terrestrial environments may have been as low as it is in today's oceans.

Which Terrestrial Ecosystems Are Most Productive? The terrestrial ecosystems with highest productivity are located in the wet tropics. Except in the world's major deserts (such as the large black area representing the Sahara Desert in northern Africa), NPP on land declines from the equator toward the poles. Why? The availability of sunlight and average temperature decreases with latitude. The low productivity in deserts is an exception attributed to the low annual rainfall caused by air circulation patterns (see Chapter 52).

You might recall that the equator-to-poles gradient in NPP is thought to be important in explaining the equator-to-poles gradient in species richness that occurs in most types of plants and animals (see Chapter 55). Areas of high productivity tend to be "hotspots" for high species richness (see Chapter 57).

The global productivity of terrestrial ecosystems is limited by a combination of temperature and availability of water and sunlight. At a local level, however, NPP on land is also limited by nutrient availability. When biologists fertilize a terrestrial ecosystem with nitrogen or phosphorus, NPP almost always increases. Recent research has also shown that NPP in temperate and boreal forests is increasing due to nitrogen that is blowing in from agricultural fields hundreds or thousands of miles away, where it was originally applied as a fertilizer.

Which Marine Ecosystems Are Most Productive? Productivity patterns in marine ecosystems contrast strongly with those of terrestrial environments. Marine productivity is highest along coastlines, and it can be as high near the poles as in the tropics. Why? The shallow water along coasts receives more nutrients:

- Rivers carry nutrients from terrestrial ecosystems and deposit them on the coasts.
- Nearshore ocean currents bring nutrients from the cold, deep water of the oceanic zone up to the surface, a process called upwelling (Chapter 52).

The coastal areas colored deep blue in Figure 56.9 include most of the world's most important fisheries.

In contrast, the oceanic zones, colored black in Figure 56.9, have extremely low NPP. They lack both river inputs and upwelling. In addition, nutrients in organisms near the surface of the open ocean—where sunlight is abundant—constantly fall to dark, deeper waters in the form of dead cells, where they are no longer available to organisms near the surface. Typically, a square meter (m^2) of open ocean produces a maximum of 35 g (1.2 oz) of organic matter each year. In terms of productivity per m^2, the open ocean is a desert.

Which Biomes Are Most Productive? **FIGURE 56.10** presents NPP data a different way—organized by biome instead of by geography

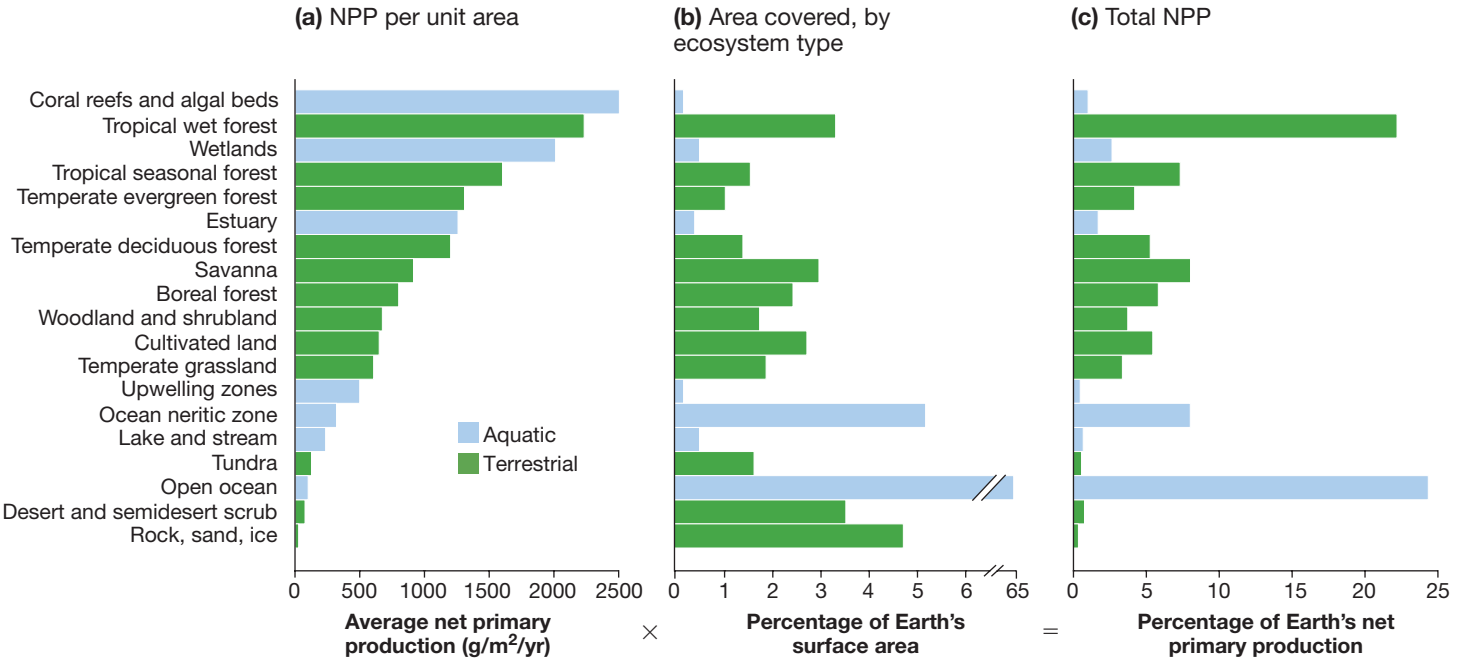

FIGURE 56.10 Net Primary Productivity Varies among Biomes.

DATA: Leith, H., and R. H. Whittaker (eds.). 1975. *Primary Productivity in the Biosphere*. Ecological Studies and Synthesis Vol. 14. New York: Springer-Verlag.

✔**QUANTITATIVE** Estimate the average NPP per unit area for the open ocean and the total area covered by the open ocean. How do these numbers explain the results in column (c)?

(see Chapter 52). Figure 56.10a provides data on average NPP per square meter per year for each biome; Figure 56.10b documents the total area that is covered by each type of ecosystem; and Figure 56.10c presents the percentage of the world's total productivity—the result of multiplying the data in part (a) by the data in part (b). In each case, data from different types of biomes are plotted as horizontal bars. Note these observations:

- Tropical wet forests and tropical seasonal forests (which have a dry season) cover less than 5 percent of Earth's surface but together account for over 30 percent of total NPP.
- Among aquatic ecosystems, the most productive habitats are algal beds and coral reefs, wetlands, and estuaries.
- Although NPP per square meter is extremely low in the open ocean, this biome is so extensive that its total NPP is high.

One of the reasons biologists are so concerned about the destruction of tropical rain forests and coral reefs is that these are the world's most productive habitats.

The "Human Appropriation" Of the total NPP available on our planet, how much are humans using? A research group led by Helmut Haberl answered this question recently in terms of *potential* NPP—meaning, NPP that would exist without human activity. Using data from a wide array of sources, Haberl's team estimated that humans are currently preventing or appropriating 24 percent of potential NPP. Of this percentage,

- 53 percent is directly harvested and used (timber, food, etc.);
- 40 percent is prevented through land-use changes (such as parking lots and other forms of development); and
- 7 percent is destroyed due to human-induced fires.

This analysis is astonishing. One species—our own—is appropriating almost a quarter of the planet's biomass. Given increases in human population projected to occur over your lifetime (see Chapter 54), the demand for NPP is likely to reach the physical limit of what can be appropriated.

Humans are affecting the flow of energy through ecosystems as well as the cycling of nutrients within and among ecosystems. Let's take a closer look at nutrient cycling.

check your understanding

C Y U

If you understand that . . .

- In an ecosystem, energy flows from sunlight to primary producers, and from there to consumers and decomposers.
- Productivity diminishes at each subsequent trophic level in the ecosystem.
- In most ecosystems, NPP is limited by conditions that limit the rate of photosynthesis: temperature and/or the availability of sunlight, water, and nutrients.

✔You should be able to . . .

1. Explain why net productivity diminishes with increasing trophic levels.
2. Predict the effect of global warming on NPP.

Answers are available in Appendix A.

56.2 How Do Nutrients Cycle through Ecosystems?

Energy is transferred when one organism eats another. But tissues also contain carbon (C), nitrogen (N), phosphorus (P), sulfur (S), calcium (Ca), and other elements that act as nutrients and are essential for normal metabolism, growth, and reproduction. The transfer of both energy and nutrients links the biotic and abiotic components of ecosystems.

Atoms are constantly reused as they move through trophic levels, but they also spend time suspended in air, dissolved in water, or held in soil. The path an element takes as it moves from abiotic systems through producers, consumers, and decomposers and back again is referred to as its **biogeochemical** ("life-Earth-chemical") **cycle.** Because humans are disturbing biogeochemical cycles on a massive scale, research on the topic is exploding.

Nutrient Cycling within Ecosystems

To understand the basic features of a biogeochemical cycle, study the generalized terrestrial nutrient cycle in **FIGURE 56.11**. Start with the "Uptake" arrow on the bottom left, which indicates that nutrients such as nitrogen and phosphorus are taken up from the soil by plants and assimilated into plant tissue; carbon enters primary producers as carbon dioxide from the atmosphere. Note that if the plant tissue is eaten, the nutrients pass to the consumer food web; if the plant tissue dies, the nutrients enter the region labeled "Detritus," which contains wastes and dead organisms.

What happens as detritus decomposes? Nutrients that reside in plant litter, animal excretions, and dead animal bodies are used by bacteria, archaea, roundworms, fungi, and other primary decomposers. These microscopic decomposers and the carbon-containing compounds that they release combine to form what biologists call **soil organic matter**, a complex mixture of partially and completely decomposed detritus. When the detritus becomes completely decayed, it is called **humus** because it is rich in a family of carbon-containing molecules called humic acids. (Chapter 39 described other components of the soil.)

Eventually, decomposition converts the nutrients in soil organic matter to an inorganic form. For example, cellular respiration by soil-dwelling bacteria and archaea converts the nitrogen present in amino acids to ammonium (NH_4^+) or nitrate (NO_3^-) ions, and the carbon to carbon dioxide. Once decomposition is accomplished, the nutrients are available for uptake by plants, completing the cycle of nutrient flow through ecosystems.

What Factors Control the Rate of Nutrient Cycling? Of the many links in a nutrient cycle, the decomposition of detritus most

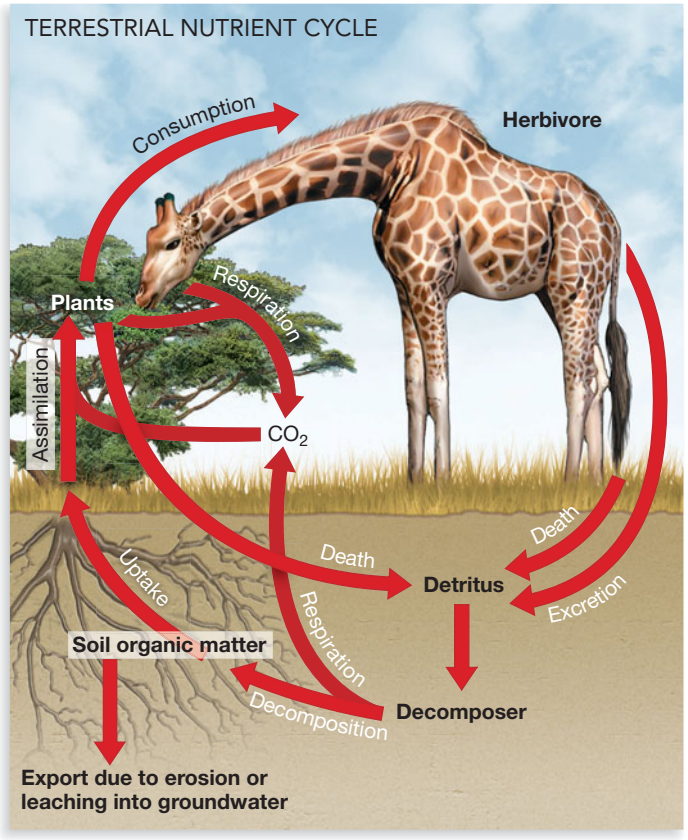

FIGURE 56.11 Generalized Terrestrial Nutrient Cycle. Nutrients cycle from organism to organism in an ecosystem via assimilation, consumption, and decomposition. Nutrients are exported from ecosystems when water or organisms leave the area.

often limits the overall rate at which nutrients move through an ecosystem. Until decomposition occurs, nutrients stay tied up in intact tissues. The decomposition rate, in turn, is influenced by three types of factors:

1. abiotic conditions such as oxygen availability, temperature, and precipitation;
2. the quality of the detritus as a nutrient source for the fungi, bacteria, and archaea that accomplish decomposition; and
3. the abundance and diversity of detritivores present.

To appreciate the importance of abiotic conditions on the decomposition rate, consider the difference in detritus accumulation between boreal forests and tropical wet forests—two moist biomes that differ in temperature. Boreal forests are cool, so the rate of decomposition is slow. Tropical wet forests are warm all year long, so the rate of decomposition is high. **FIGURE 56.12** illustrates typical soils from boreal forests and tropical wet forests. Notice that the uppermost part of the soil in a boreal forest consists of a thick layer of partially decomposed detritus and organic matter. In a tropical forest, this layer is virtually absent.

The contrast occurs because the cold conditions in boreal forests limit the metabolic rates of decomposers. As a result, decomposition fails to keep up with the input of detritus, and organic

(a) Boreal forest: Accumulation of detritus and organic matter

(b) Tropical wet forest: Almost no organic accumulation

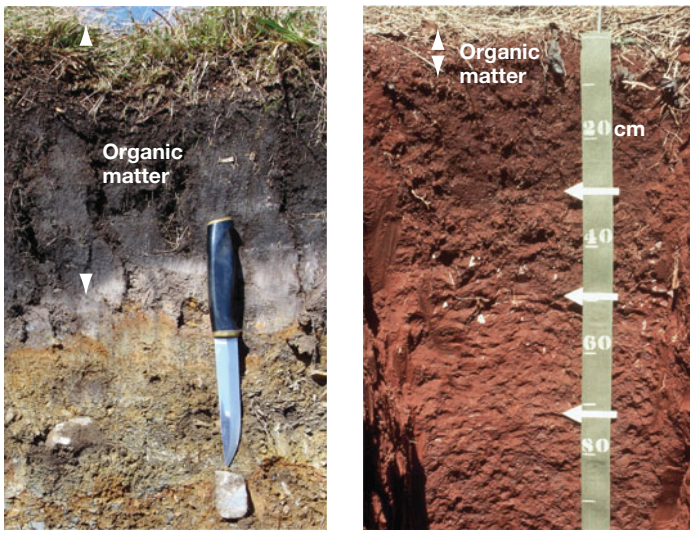

FIGURE 56.12 Temperature and Moisture Affect Decomposition Rates.

matter accumulates. In the tropics, conditions are so favorable for fungi, bacteria, and archaea that decomposition keeps pace with inputs. Nutrients cycle slowly through boreal forests but rapidly through wet tropical forests. As a result, most of the biomass in a tropical forest is living. ✔ **If you understand this concept, you should be able to explain why farms created by clearing tropical rain forests tend to perform poorly.**

The quality of detritus also exerts a powerful influence on the growth of decomposers, and thus the decomposition rate. Decomposition is inhibited if detritus is **(1)** low in nitrogen, or **(2)** high in lignin. When nitrogen is scarce, such as in acidic bogs, cells have a difficult time making additional proteins and nucleic acids. Lignin—an important constituent of wood—is extremely difficult to digest (see Chapter 32). The presence of lignin is a major reason why wood takes much longer to decompose than leaves do. Only basidiomycete fungi and a few bacteria have the enzymes required to completely degrade lignin.

The presence of oxygen is also critically important. If soils or water become depleted of oxygen, such as in some wetlands, decomposition slows dramatically. Fungi can perform cellular respiration only by using oxygen as the final electron acceptor (see Chapter 9). And even though many bacteria and archaea can thrive in the absence of oxygen and continue decomposition, the growth rates of anaerobic species are a tiny fraction of rates in aerobic bacteria and archaea (to understand why, see Chapter 29).

Sources of Local Nutrient Export and Import Although nutrients are constantly cycled within individual ecosystems, they can also be lost from one ecosystem and exported to another.

- If an herbivore eats a plant and moves out of the ecosystem before excreting the nutrients or dying, the nutrients are exported.

- Nutrients leave ecosystems when flowing water or wind removes particles or inorganic ions and deposits them somewhere else.

Several of the major impacts that humans have on ecosystems—such as farming, logging, burning, and soil erosion—accelerate nutrient export. Farming and logging remove biomass in the form of plants; burning releases nutrients to the atmosphere; soil erosion moves nutrients that are bound to soil particles or dissolved in water. Further, these processes are often interrelated, as when logging leads to soil erosion and runoff.

For an ecosystem to function normally, nutrients that are exported must be replaced by imports. There are three major mechanisms to replace nutrients:

1. Ions that act as nutrients are released as rocks weather (see Chapter 39).
2. Nutrients can blow in on soil particles or arrive dissolved in streams.
3. Nitrogen—a particularly important nutrient in maintaining NPP—is added when nitrogen-fixing bacteria (introduced in Chapter 39) convert molecular nitrogen (N_2) in the atmosphere to usable nitrogen in ammonium or nitrate ions.

In ecosystems that humans manage, nutrients usually have to be actively replaced to maintain productivity. People accomplish this by adding fertilizers or planting nitrogen-fixing crops.

An Experimental Study The ideas presented thus far are logical and provide a strong conceptual foundation for thinking about nutrient cycles. But to explore nutrient movement in more depth, researchers have turned to experiments.

One of the first large-scale experiments on nutrient cycling took place at the Hubbard Brook Experimental Forest, introduced earlier in the chapter. A group of researchers led by Likens and Bormann began by choosing two similar **watersheds**—areas drained by a single stream—for study. Before starting the experiment, they documented that 90 percent of the nutrients in the watersheds was in soil organic matter; 9.5 percent was in plant biomass. The nutrients in the soil were either dissolved in water or attached to small particles of sand or clay (see Chapter 39).

To begin the experimental treatment, the researchers cut all vegetation, including the trees, in one of the two watersheds (**FIGURE 56.13**). In each of the following three years, the clear-cut watershed was treated with an herbicide to prevent vegetation from regrowing. As a result, the experimental watershed was devegetated. Researchers left the other watershed untreated to serve as a control.

The graph in Figure 56.13 documents the amount of total dissolved substances that washed out of the streams in each watershed over the course of the four years of devegetation. Losses from the devegetated site were typically over 10 times as high as they were from the control site.

Why? Plant roots were no longer able to hold soil particles in place, so some of the soil itself washed away. Further, plant roots

RESEARCH

QUESTION: How does the presence of vegetation affect the rate of nutrient export in a temperate-forest ecosystem?

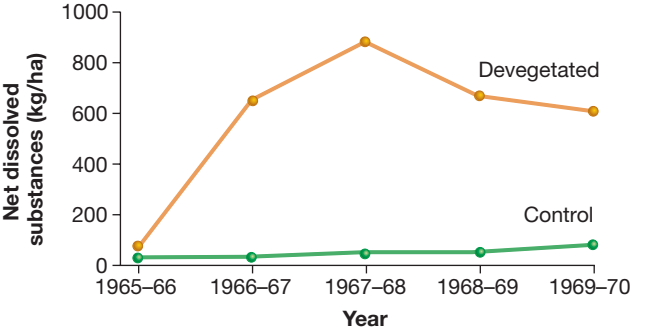
HYPOTHESIS: Presence of vegetation lowers the rate of nutrient export because it increases soil stability and recycling of nutrients.

NULL HYPOTHESIS: Presence of vegetation has no effect on the rate of nutrient export.

EXPERIMENTAL SETUP:

1. Choose two similar watersheds. Document nutrient levels in soil organic matter, plants, and streams.

2. Devegetate one watershed, and leave the other intact.



3. Monitor the amount of dissolved substances in streams.

PREDICTION: Amount of dissolved substances in stream in devegetated watershed will be much higher than amount of dissolved substances in stream in control watershed.

PREDICTION OF NULL HYPOTHESIS: No difference will be observed in amount of dissolved substances in the two streams.

RESULTS:

CONCLUSION: Presence of vegetation limits nutrient export. Removing vegetation leads to large increases in nutrient export.

FIGURE 56.13 Experimental Evidence that Deforestation Increases the Rate of Nutrient Export from Ecosystems.

SOURCE: Likens, G. E., F. H. Bormann, N. M. Johnson, et al. 1970. Effects of forest cutting and herbicide treatment on nutrient budgets in the Hubbard Brook watershed-ecosystem. *Ecological Monographs* 40: 23–47.

✔**QUESTION** Propose a hypothesis to explain why the level of nutrient export from the experimental site appears to peak and then decline.

no longer took up and recycled nutrients that were dissolved in the remaining soil water. Instead, massive quantities of nitrate and other nutrients washed out of the soil and were exported from the ecosystem in runoff water.

Long-term devegetation of this type has occurred in formerly forested areas of the Middle East, North Africa, and elsewhere, due to intensive farming and grazing. Nutrients that used to occur within those soils—and the soils themselves—were exported. Today, the productivity of these regions is a tiny fraction of what it once was. Once soil is lost, it is difficult to regain—soil takes a very long time to form (Chapter 39).

Global Biogeochemical Cycles

When nutrients leave one ecosystem, they enter another. In this way, the movement of ions and molecules among ecosystems links local biogeochemical cycles into one massive global system. As an introduction to how these global biogeochemical cycles work, let's consider the global water, nitrogen, and carbon cycles. These cycles have recently been heavily modified by human activities—with serious ecological consequences.

To understand how biogeochemical cycling works on a global scale, researchers focus on three fundamental questions:

1. What are the nature and size of the reservoirs—areas or "compartments" where elements are stored for a period of time? In the case of carbon, the biomass of living organisms is an important reservoir, as are sediments and soils. Another significant carbon reservoir is buried in the form of coal and oil.
2. How fast does the element move between reservoirs, and what processes are responsible for moving elements from one reservoir to another? The global photosynthetic rate, for example, measures the rate of carbon flow from carbon dioxide (CO_2) in the atmosphere to living biomass. When fossil fuels burn, carbon that was buried in coal or petroleum moves into the atmosphere as CO_2.
3. How does one biogeochemical cycle interact with another biogeochemical cycle? For example, researchers are trying to understand how changes in the nitrogen cycle affect the carbon cycle.

The Global Water Cycle A simplified version of the **global water cycle** appears in **FIGURE 56.14**. The diagram shows the estimated amount of water that moves between major reservoirs over the course of a year, powered by energy from the sun.

To analyze this cycle, begin at the left with evaporation of water out of the ocean, and the subsequent precipitation of water back into the ocean. For the marine component of the cycle, evaporation exceeds precipitation—meaning that, over the oceans, there is a net gain of water to the atmosphere.

When this water vapor moves over the continents, it is joined by a small amount of water that evaporates from lakes and streams and a large volume of water that is transpired (lost) by plants (see Chapter 38). The total volume of water in the atmosphere over land is balanced by the amount of rain and other forms of precipitation that falls on the continents.

The cycle is completed by the water that moves from the land back to the oceans via streams and **groundwater**—water that is found underground. Overall, there is no net gain or loss of water.

Note that 97.5 percent of the Earth's water is salt water (in the ocean). Most of the remaining 2.5 percent of freshwater is locked up in the ice caps and glaciers, leaving about 0.5 percent available for drinking in lakes and rivers, and in groundwater. Most

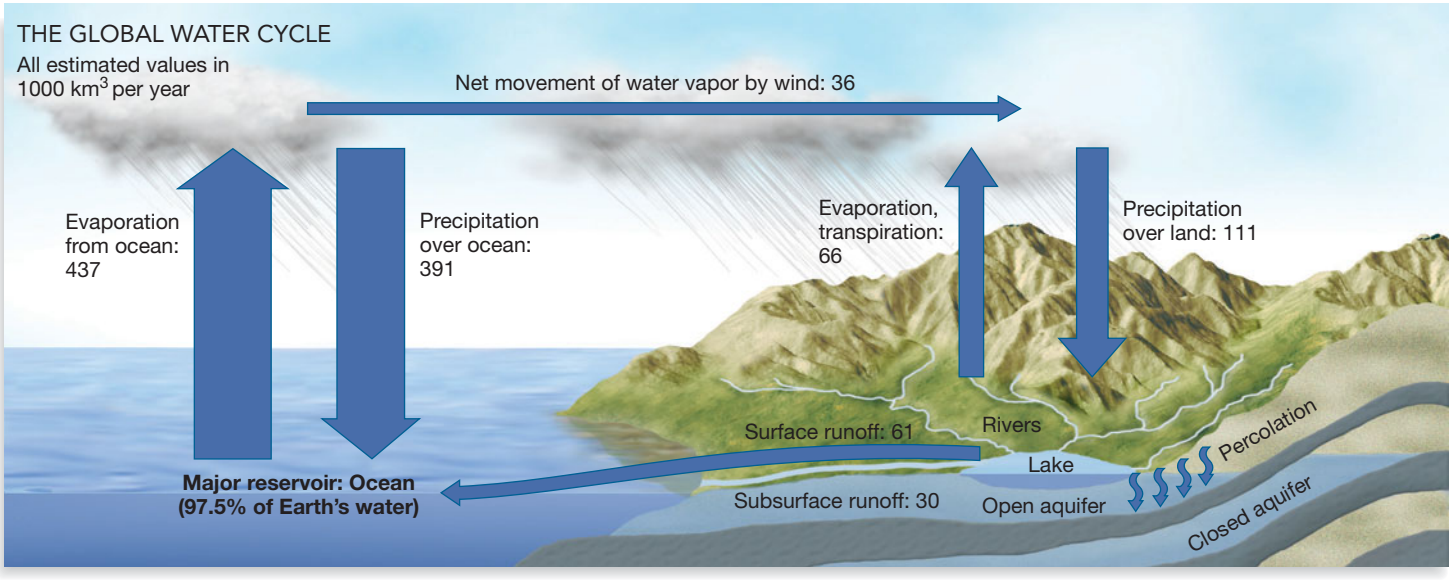


FIGURE 56.14 The Global Water Cycle.

DATA: Oki, T., and S. Kanae. 2006. *Science* 313: 1068–1072.

✔**QUESTION** Predict how the amount of water evaporated from the ocean is changing in response to global warming. Discuss one possible consequence of this change.

groundwater is stored in **aquifers**—layers of porous rock, sand, or gravel that are saturated with water. Aquifers are said to be closed (contained) when nonporous rock layers overlie them, and open (uncontained) when they can be replenished by water percolating down from the surface (Figure 56.14). Closed aquifers may take thousands of years to recharge.

What effects are humans having on the water cycle? Perhaps the simplest and most direct impacts concern rates of groundwater depletion.

- Asphalt and concrete surfaces reduce the amount of water that percolates from the surface to deep soil and rock layers.
- When grasslands and forests are converted to agricultural fields, root systems that hold water are lost. More water runs off into streams and less percolates into groundwater.
- Irrigated agriculture, along with industrial and household use, is removing massive amounts of water from groundwater storage and bringing it to the surface. The Ogallala–High Plains Aquifer is the largest underground reservoir of freshwater in the United States, underlying 430,000 square kilometers (176,700 square miles) of the Midwest from South Dakota to Texas, and supplying 30 percent of the irrigation water for the country. Billions of gallons are withdrawn each day. The water in this aquifer is estimated to be 10,000 years old, and it is being depleted much faster than it is being recharged (**FIGURE 56.15**), raising concerns about the future supply. Most of the aquifer is closed; only the areas shown in blue have recharged.

The **water table**—the level where soil is saturated with stored water—is dropping on every continent. For example, between 1986 and 2006, the water table north of Beijing, China, experienced a drop of 61 m (200 ft). Throughout India, water tables are falling at a rate of between 1 m and 3 m per year. Similar rates are being documented in Yemen, parts of Mexico, and states in the southern Great Plains region of the United States.

Humans are mining freshwater from aquifers in many parts of the world—meaning that populations have already grown beyond carrying capacity for water. About 40 percent of the world's population has insufficient water resources. Water scarcity tends to lead to strife within and among populations.

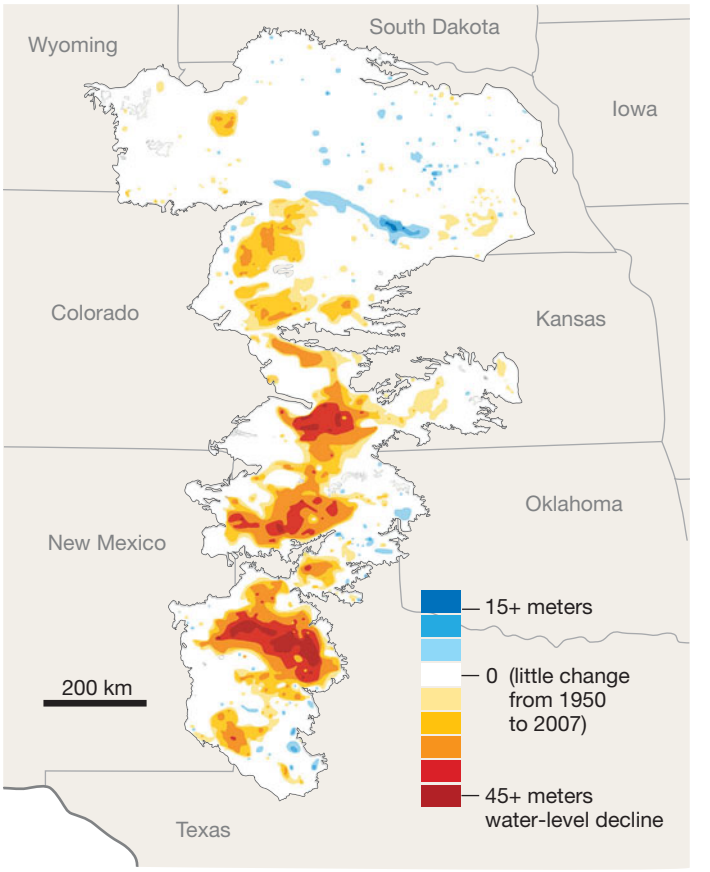

FIGURE 56.15 Declining Water Levels in the Ogallala–High Plains Aquifer from 1950 to 2007.
DATA: U.S. Geological Survey.

The Global Nitrogen Cycle **FIGURE 56.16** illustrates the **global nitrogen cycle.** To follow the cycle, start at the top in the atmosphere. This represents the main reservoir for nitrogen in the form of nitrogen gas (N_2)—a biologically inert molecule that comprises about 78 percent of the air you breathe. Nitrogen is usable by organisms only when it is reduced, or "fixed," meaning that it is converted from unusable atmospheric N_2 to usable ammonium (NH_4^+) or nitrate ions (NO_3^-; see Chapter 39).

The fixation of nitrogen is usually a slow process, so nitrogen often limits primary productivity in terrestrial and aquatic ecosystems. Reduced nitrogen builds up slowly in soils and water over time and then cycles relatively rapidly among soil, microorganisms, fungi, plants, and animals within both terrestrial and aquatic ecosystems. Ultimately, bacteria digest nitrogen-containing molecules and return N_2 to the atmosphere, completing the cycle.

Nitrogen fixation occurs naturally due to lightning-driven reactions in the atmosphere and from enzyme-catalyzed reactions in bacteria that live in the soil and oceans. However, the nitrogen cycle has been profoundly altered by human activities. The amount of nitrogen fixation from human sources almost equals the amount of nitrogen fixation from natural sources. As the labels on the right side of the graph in **FIGURE 56.17** indicate, there are three major sources of this human-fixed nitrogen:

1. industrially produced fertilizers;
2. the cultivation of crops, such as soybeans and peas that harbor nitrogen-fixing bacteria; and
3. the burning of fossil fuels, which releases nitric oxide.

Adding nitrogen to terrestrial ecosystems usually increases productivity. But overfertilization with nitrogen has important consequences.

- Nitrogen-laced runoff from agricultural fields causes algae blooms in aquatic ecosystems, such as the lake shown in **FIGURE 56.18**. When the algae die and are decomposed by microbes, oxygen is depleted from the water, causing the formation of oxygen-free "dead zones" (see Chapter 29).
- When nitrogen is added to experimental plots in grasslands in midwestern North America, a few competitively dominant

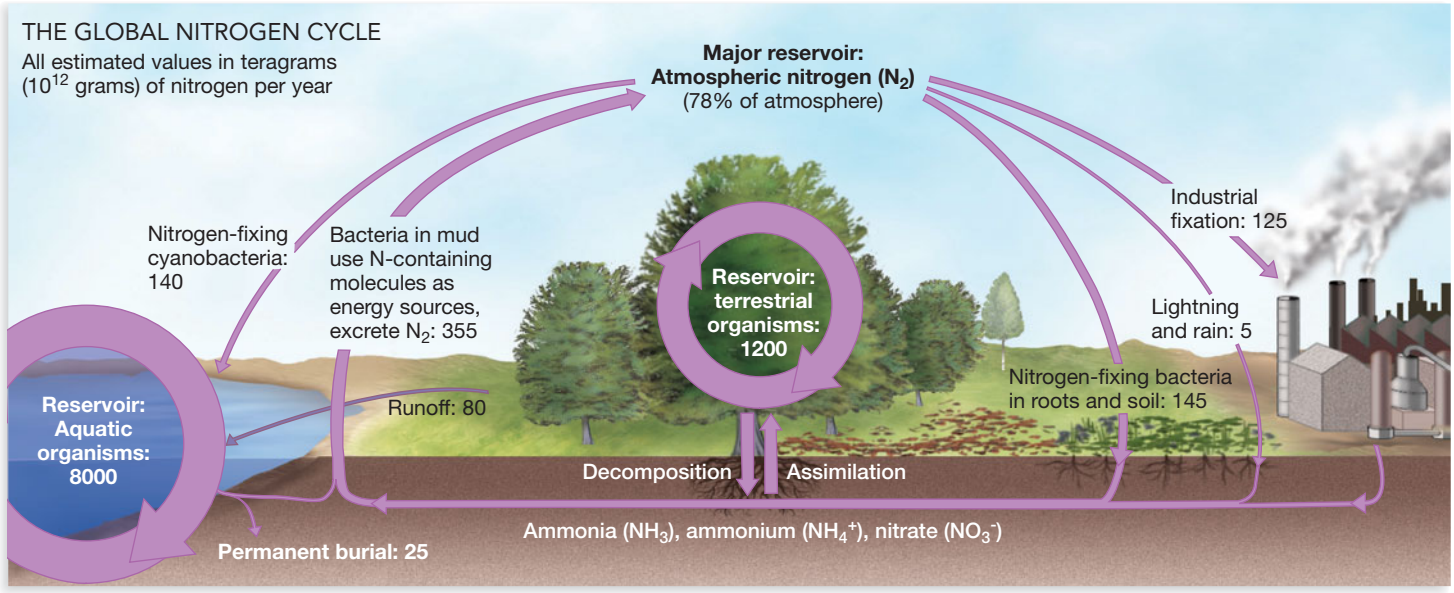

FIGURE 56.16 The Global Nitrogen Cycle. Nitrogen enters ecosystems as ammonia or nitrate via fixation from atmospheric nitrogen. It is exported in runoff and as nitrogen gas given off by bacteria that use nitrogen-containing compounds as an electron acceptor.

DATA: Gruber, N., and J. N. Galloway. 2008. *Nature* 451: 293–296.

species grow rapidly and displace other species that do not respond to nitrogen inputs as strongly. Productivity increases, but species diversity decreases (Chapter 57).

The Global Carbon Cycle The **global carbon cycle** documents the movement of carbon among terrestrial ecosystems, the oceans, and the atmosphere (**FIGURE 56.19**, see page 1162). Of these three reservoirs, the ocean is by far the largest. The atmospheric reservoir is also important despite its relatively small size, because carbon moves into and out of it rapidly—through organisms.

In both terrestrial and aquatic ecosystems, photosynthesis is responsible for taking carbon out of the atmosphere and incorporating it into tissue. Cellular respiration, in contrast, releases carbon that has been incorporated into living organisms to the atmosphere, in the form of carbon dioxide.

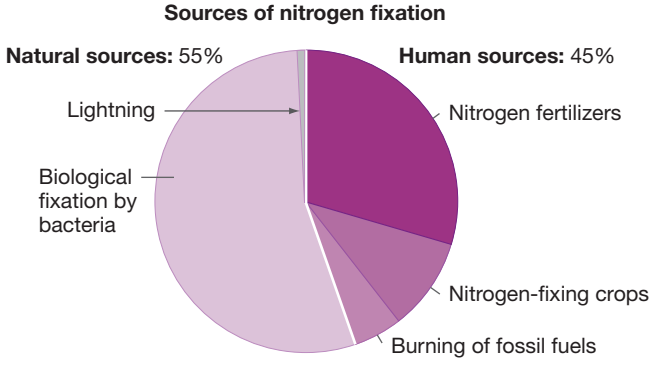

FIGURE 56.17 Humans Are Adding Nitrogen to Ecosystems.

DATA: Canfield, D. E., A. N. Glazer, and P. G. Falkowski. 2010. *Science* 330: 192–196.

How have humans changed the carbon cycle? For thousands of years, humans have altered the global carbon cycle by deforesting land for agriculture and settlements—releasing the carbon stored in trees to the atmosphere.

But the human influence on the carbon cycle increased sharply during the industrial revolution. Burning fossil fuels moves massive amounts of carbon from an inactive geological reservoir, in the form of petroleum or coal (the remains of ancient organisms), to an active reservoir—the atmosphere. When you burn gasoline, you are releasing carbon atoms that have been locked up in petroleum reservoirs for hundreds of millions of years.

FIGURE 56.18 Nutrient Runoff Causes Harmful Algae Blooms. Blooms, in turn, can lead to oxygen-starved dead zones.

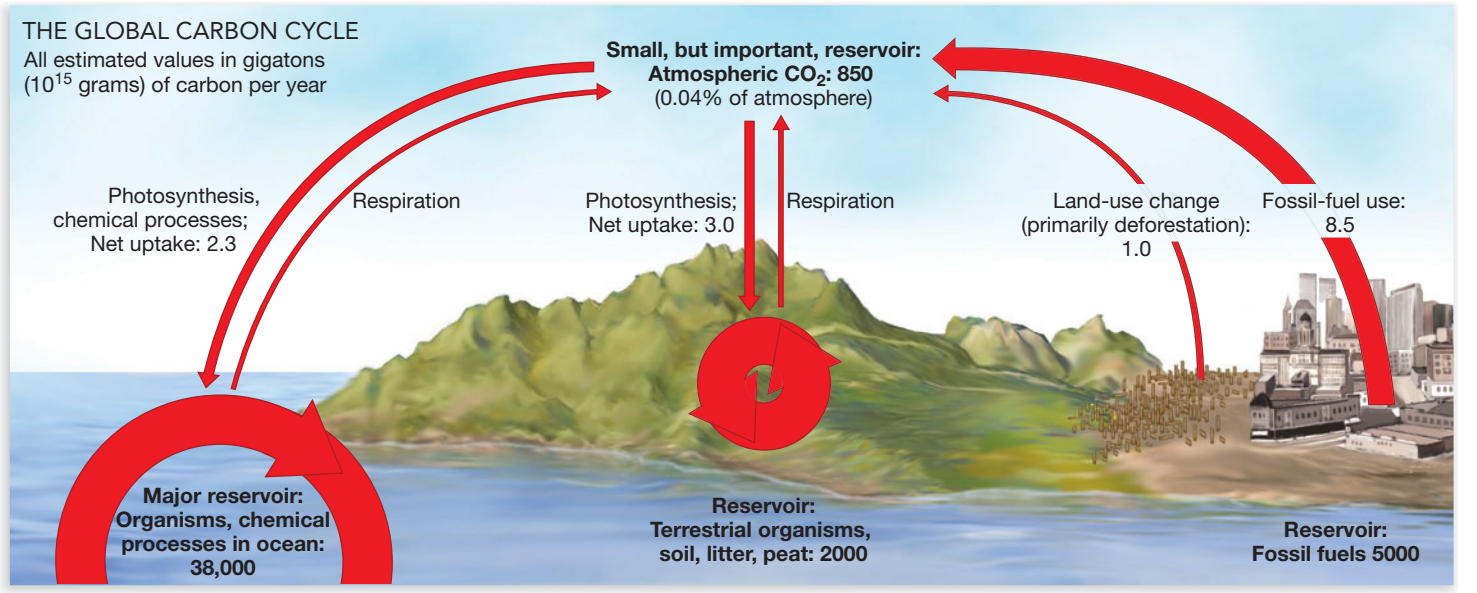

FIGURE 56.19 The Global Carbon Cycle. The arrows indicate how carbon moves into and out of ecosystems. Photosynthesis and cellular respiration move carbon in and out of the atmosphere in the form of CO_2. The burning of fossil fuels moves carbon from an inactive geological reservoir, in the form of petroleum or coal, to an active reservoir, the atmosphere.

DATA: Hönisch, B., A. Ridgwell, D. N. Schmidt, et al. 2012. *Science* 335: 1058–1063.

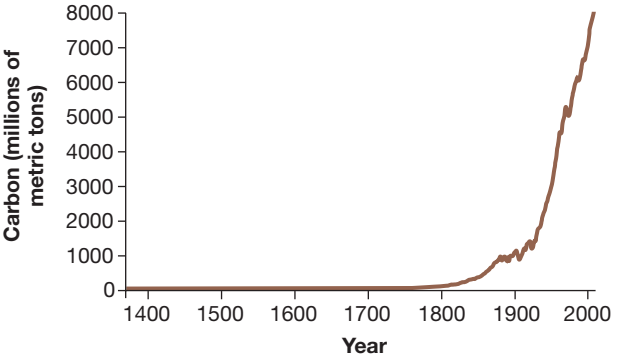
FIGURE 56.20a highlights the dramatic increase in carbon released from fossil-fuel burning over the past century; **FIGURE 56.20b** shows corresponding changes in CO_2 concentrations. Note that CO_2 levels in the atmosphere have now risen to 392 parts per million (ppm), far above the 280 ppm that was typical before 1860. Analysis of CO_2 levels in air bubbles trapped in Antarctic ice reveals that CO_2 fluctuated within a range of about 170 to 300 ppm for the extent of the record—800,000 years. This means that current CO_2 levels are 30 percent higher than the highest level measured over the last 800,000 years.

Why is the increase in atmospheric CO_2 so important? Because it changes the climate.

check your understanding

C Y U

If you understand that . . .



- Biogeochemical cycles trace the movement of water and elements within and among ecosystems.
- Biologists analyze three aspects of these cycles: (1) the nature and size of reservoirs where elements are stored or captured, (2) the processes responsible for moving elements among reservoirs, and (3) interactions among cycles.

✔You should be able to . . .

Compare how human activities are altering the global water, nitrogen, and carbon cycles.

Answers are available in Appendix A.

(a) Increases in fossil-fuel use

(b) Global changes in atmospheric CO_2 over time

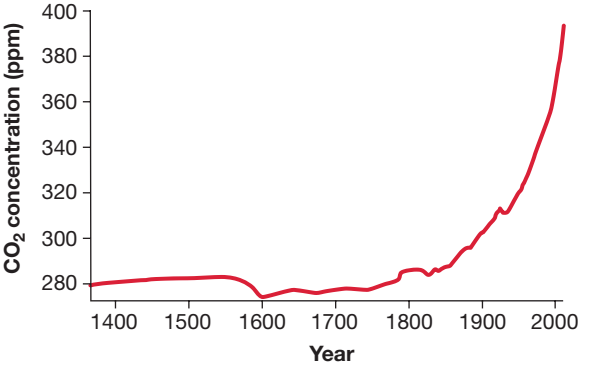


FIGURE 56.20 Humans Are Causing Increases in Atmospheric Carbon Dioxide. (a) Rates of carbon flow from fossil-fuel burning have increased as human populations have increased. **(b)** For centuries, average CO_2 concentrations in the atmosphere were about 280 parts per million (ppm).

56.3 Global Climate Change

If you are in your late teens or early twenties as you read this text, you are part of a generation that will experience the most dramatic episode of environmental change in human history. The epic event has three main interacting drivers: changes in land use (Chapters 52 and 57), the massive loss of species (see Chapter 57), and global climate change, also called global warming.

Global warming and global climate change refer to the same phenomenon, but with different emphases:

- **Global warming** refers to the increase in the *average* temperature of the planet. The average temperature is very important in determining physical, chemical, and biological processes.
- **Global climate change** refers to the sum of all the changes in local temperature and precipitation patterns that result from global warming—including the frequency and intensity of storms, droughts, and other events. The effects of global warming vary depending on geography, local weather patterns, ocean currents, and other factors. But averaged over the entire planet and over time, the Earth is already much warmer than it was just a few decades ago and is projected to get even warmer.

Why is this warming such a problem? Let's explore the underlying cause of global climate change and then consider the consequences.

What Is the Cause of Global Climate Change?

Climate change is normal. Throughout Earth's history, the average temperature of the atmosphere and local weather patterns have fluctuated. Scientists today are not alarmed because there is change; they are alarmed because the *rate* of change is unprecedented, and because it is caused by human activities. What is going on?

The Greenhouse Effect By the 1950s, scientists were aware that humans were releasing tremendous amounts of CO_2 into the atmosphere. The common reassuring argument at the time was that the vast ocean would be able to absorb this excess CO_2.

However, Roger Revelle, a pioneer in oceanography, and his colleague Hans Suess reported in 1957 that the complex chemistry of the ocean limits how much CO_2 it can absorb. Their data supported a stunning hypothesis posed by the eminent chemist and physicist Svante Arrhenius half a century earlier: The atmospheric CO_2 would rise, which would lead to global warming. Why? Carbon dioxide is a **greenhouse gas:** It traps heat that has been radiated from Earth and keeps it from being lost to space, similar to the way the glass of a greenhouse traps heat (**FIGURE 56.21**).

How could the global warming hypothesis be tested? At the time of Revelle and Suess's research, there were no reliable records of baseline atmospheric CO_2 levels—local CO_2 measurements varied widely due to fluctuating emissions from cities and other variables. So Revelle hired a young geochemist, Charles David Keeling, to gather precise measurements of CO_2 concentrations in remote, pristine locations, one of which was the Mauna Loa Observatory in Hawaii. By 1961, Keeling was able to confirm that global CO_2 was rising. Despite many obstacles, he persevered in collecting invaluable records for more than 40 years.

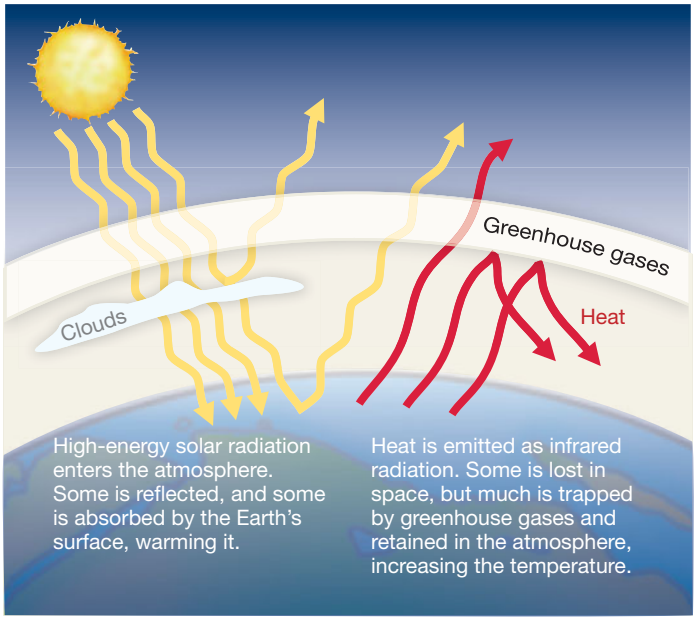

FIGURE 56.21 The Greenhouse Effect. Greenhouse gases in the atmosphere have an effect that is similar to glass in a greenhouse—high-energy radiation in the form of light can easily pass through the gases, but low-energy infrared radiation gets trapped by them.

FIGURE 56.22 (see page 1164) shows CO_2 data from Mauna Loa over the last three decades, along with temperature and solar energy data.

- There is no indication that the rate of increase of CO_2 is slowing, despite an array of regulations and incentives to reduce CO_2 emissions.
- The temperature fluctuates, but there is a clear increase in average temperature.
- Even though the amount of solar energy cycles regularly, there is no net increase over time. Thus, fluctuations in solar energy are not sufficient to account for the marked increase in temperature, as one alternative hypothesis had predicted.

Carbon dioxide is only one of several important greenhouse gases in the atmosphere, including methane (CH_4) and nitrous oxide (N_2O). All these gases collectively increase the atmosphere's heat-trapping potential—causing global warming.

Why Is the Climate Changing So Rapidly? The rate of increase of atmospheric CO_2 and temperature are alarming. Why so fast? There are two main reasons. First, the human population has exploded in size. The planet now has over 7 billion people, a 700 percent increase over a mere two centuries—a blink of an eye in Earth's history (see Chapter 54). But an equally important part of the answer involves resource use. The average per capita (per

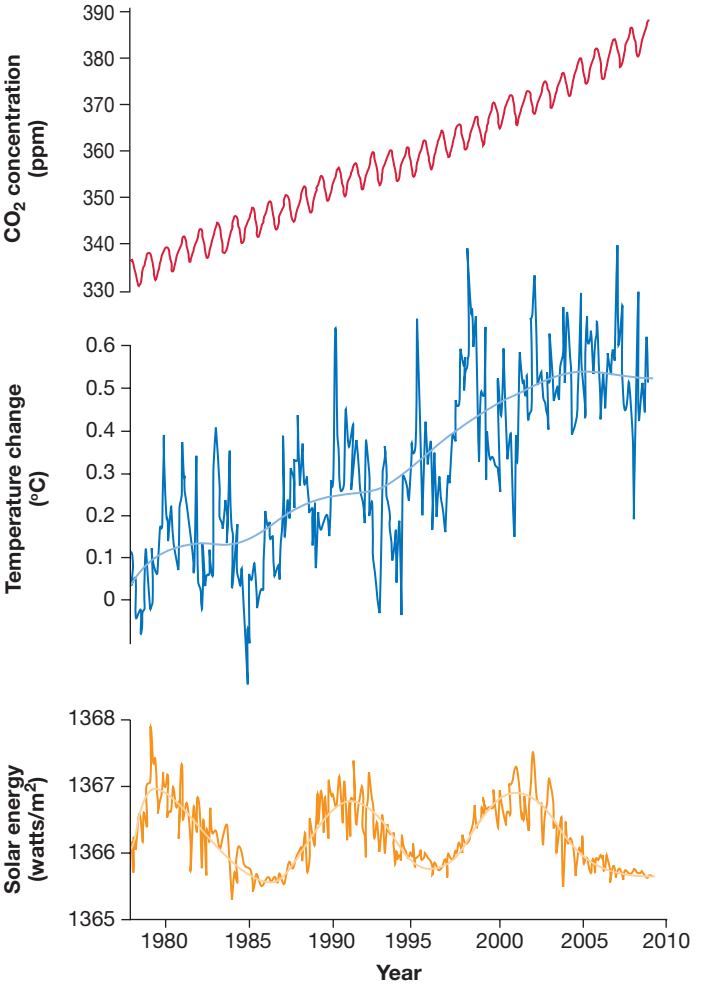

FIGURE 56.22 Recent Changes in Atmospheric CO_2, Temperature, and Solar Radiation.

✔**QUESTION** Notice the annual cycles in CO_2. Why are atmospheric CO_2 concentrations low in the Northern Hemisphere in summer and high in winter?

person) use of fossil fuels is skyrocketing—especially in industrialized countries.

The data in **FIGURE 56.23** illustrate the consequences of population size and resource use. By multiplying the total population size of a country (left graph) by the quantity of CO_2 emissions per person in that country (center graph), the total emissions per country can be calculated (right graph). For example, even though the average person in China causes only a quarter of the CO_2 emissions that an average person from the United States does, the total emissions from China surpass all others due to its enormous population size.

Conversely, although the United States represents less than 5 percent of the world population, Americans produce an astonishing one-fifth of the global CO_2 emissions due to their heavy use of fossil fuels. Looking at the data in another way, the population of the United States was twice that of Nigeria in 2008, but the average American produced 22 times as much CO_2 as the average Nigerian that year.

The bottom line is that the recent exponential increase of the human population, plus the steep increase in per capita fossil fuel use—as well as land-use changes such as deforestation—have caused a steep increase in the emission of CO_2 and other greenhouse gasses. These changes, in turn, have caused the recent and dramatic increase in the average temperatures and climate variability around the globe. The rapid rate of climate change is ultimately rooted in human behavior.

How Much Will the Climate Change?

In 1988 an international group composed of hundreds of scientists, called the Intergovernmental Panel on Climate Change (IPCC), was formed to evaluate the consequences of well-documented increases in CO_2 and other heat-trapping gases to climate. The group has since produced a series of reports summarizing the state of scientific knowledge on the issue. How has climate already changed, and what changes can we expect in the future?

Temperature The latest IPCC report concludes that the average global temperature increased 0.74°C (1.3°F) during the 20th century, which was double the increase of the 19th century. More recently, four independent records of temperature summarized by NASA concur that the last decade has been the warmest in recorded history.

Predicting the future state of a system as complex and variable as Earth's climate is extremely difficult. Global climate models are the primary tool that scientists use to make these projections. A global climate model is based on a large series of equations that describe how the concentrations of various gases in the atmosphere, solar radiation, transpiration rates, and other parameters interact to affect climate.

The models currently being used suggest that average global temperature will undergo additional increases of 1.1–6.4°C (2.0–11.5°F) by the year 2100. The low number is based on models that assume no further increase in greenhouse gas emissions over present levels; the high number is based on models that assume continued intensive use of fossil fuels and increases in greenhouse gas emissions. To get a sense of what these numbers mean, consider the data in **FIGURE 56.24**. Under a higher-emissions scenario, parts of the southern United States that currently experience about 60 days per year of temperatures above 90°F are expected to experience 150 or more of such days by the end of the century.

Predicting how temperature will change in the future is particularly difficult because ecosystems respond to warming in ways that increase or decrease the concentrations of CO_2 and other greenhouse gases and that affect other drivers of global climate, such as the size of the polar ice caps. In essence, warming has a domino effect on other factors that may either further accelerate or reduce warming.

Documenting Positive and Negative Feedback Positive feedback in climate change occurs when changes due to global warming

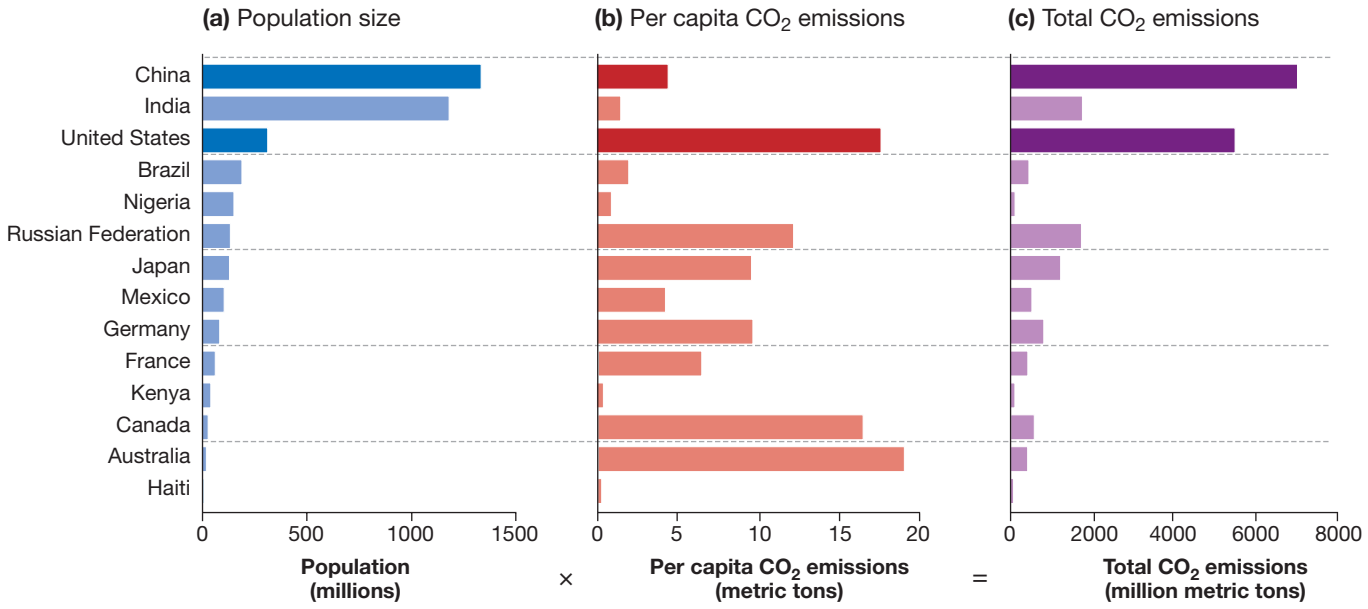

FIGURE 56.23 Total Emissions Depend on Population Size and Resource Use.

result in the further acceleration of warming. Many types of positive feedback have been documented. For example:

- Warmer and drier climate conditions have increased the frequency of forest fires in the Rocky Mountains of North America as well as in the boreal forests of Canada. Forest fires release CO_2, which leads to even more warming.
- Traditionally, tundra sequesters carbon in the form of soil organic matter, because decomposition rates are extremely low. During a series of warm summers, however, researchers found that decomposition rates in tundra increased sufficiently to release carbon from stored soil organic matter and to produce a net flow of carbon to the atmosphere.
- Other studies of soil microbes observed that elevated CO_2 levels triggered release of CH_4 and N_2O, greenhouse gases that are less abundant than CO_2 but have a more potent effect on warming.
- Melting of the polar ice caps exposes more open water to the sun. The darker open water absorbs more solar radiation than ice, increasing the rate of warming there.

Negative feedback in climate change occurs when changes due to global warming result in increased uptake and sequestration of CO_2 and other greenhouse gases—meaning that global warming should be reduced. For example, recent experiments have shown that the growth rates of many plant species, including some agricultural crops (but not others), increase in direct response to increasing atmospheric CO_2, thus acting to reduce atmospheric CO_2.

Will ecosystem responses increase or decrease global warming? While the specific predictions of different models vary, the overall trend is the same—it's going to keep getting hotter.

Climate Factors Other than Temperature Increasing temperatures affect other aspects of climate, and elevated levels of greenhouse gases themselves affect climate, with various negative and positive feedback interactions.

- Temperatures affect the water cycle, changing where, when, and how much water falls as precipitation. Average precipitation has increased about 5 percent in the United States during the past 50 years. Models predict that northern areas may become wetter in the future, but the Southwest is likely to become drier.
- Temperature and precipitation are becoming more variable, and the severity of extreme weather events such as monsoon rains, tornados, and hurricanes is increasing, in part because warmer air can hold more moisture (Chapter 52).
- Warmer temperatures have caused the sea level to rise due to expansion of the oceans and the melting of glaciers and polar ice caps.
- The melting of the ice caps affects other aspects of climate such as ocean currents and cloud cover.

Climate is an abiotic component of ecosystems. How does climate change affect organisms?

Consequences to Organisms

Even though global temperatures have risen only slightly in comparison with projections for the next 50–100 years, biologists have already documented dramatic impacts on organisms. The main types of consequences of global climate change to organisms are summarized in **TABLE 56.1**.

Phenology Shifts The timing of seasonal events, or **phenology,** is changing in many biomes. Spring arrives in the United States 10 days to two weeks earlier than it did just 20 years ago. As a result, many biological activities associated with spring occur earlier. Recent studies have confirmed that migratory bird species are arriving on their breeding grounds in the northeastern United States an average of 13 days earlier than in previous decades, and fruit trees are ripening as much as 18 days earlier.

Note, however, that different species in an ecosystem do not necessarily synchronize changes in their timing. Mismatches can result, disrupting trophic interactions and other types of species interactions (Chapter 55). For example:

- Insectivorous birds like great tits (*Parus major*) rely on the abundance of caterpillars to feed their hatchlings. However, a 20-year study has shown that the peak caterpillar biomass now occurs earlier due to the warmer spring, but the reproductive timing of great tits has not changed. Thus, there is a mismatch that has resulted in fewer and lower-weight great tit fledglings.
- Other researchers observed interactions in a community of plankton in the North Sea for 40 years. Plankton at different trophic levels responded to climate change differently over this period, causing mismatches in trophic relationships and thus a restructuring of the food web.
- Mismatches in interactions due to phenology are not always trophic. The mutualistic interaction between flowers and pollinators is disrupted when the timing of flowering and the emergence of insect pollinators becomes asynchronous.

Geographic Range Shifts The geographic ranges of many organisms are shifting as their "climate envelopes" of suitable habitat move toward the poles, toward higher altitudes, or toward areas of adequate precipitation.

- Until recently, the range of mountain pine beetles was limited in North America by freezing temperatures. Milder temperatures have triggered massive infestations of beetles in areas where they had not been abundant before (Table 56.1). Researchers fear that an ongoing expansion of these voracious beetles northward and eastward in Canada will threaten the boreal forest ecosystem.
- Copepods are small crustaceans that serve as key primary consumers in marine plankton. Copepods have been studied intensively because they are important commercially: They are eaten by fish that are in turn eaten by other fish that are eaten by humans. A 40-year study in the North Atlantic showed that a southern species of copepod has moved north, while the range of cold-water species has declined.
- When you buy a package of seeds or a potted plant, the planting instructions often indicate which hardiness zones are appropriate for its growth. The U.S. Department of Agriculture released an updated map of hardiness zones in 2012 based on recent temperature and precipitation data. The zones have shifted northward—signifying a range shift of many species.

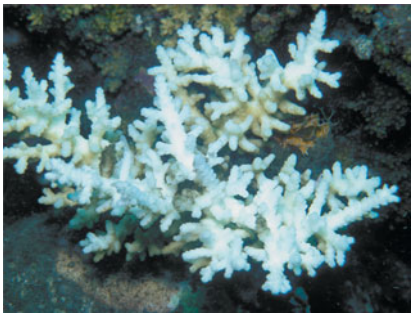
As with changes in phenology, shifts in the geographic distribution of species can lead to mismatches between species and resources. Mismatches can act as an agent of natural selection and cause evolution, or they can result in the extinction of species.

Evolutionary Adaptation In some populations, changing climate and species interactions are already causing allele frequencies to change—meaning that some species are evolving in response to global climate change. There are clearly both evolutionary winners and losers, depending on the ecological context and adaptive capacity of the organisms.

For example, ecologists Paul Brakefield and Peter de Jong recently concluded that increasing temperatures in the Netherlands have caused evolution in the two-spot ladybird beetle, *Adalia bipunctata*. There are two heritable color patterns of these beetles: black with red spots and red with black spots (Table 56.1). The frequency of the black morph has declined from 60 percent to 20 in one area in just 30 years. It turns out that the black morphs have lower fitness under warmer conditions because they absorb more solar energy and overheat.

How predictable are evolutionary adaptations to climate change? Luc de Meester and colleagues conducted artificial selection experiments with the water flea, *Daphnia magna*, at different temperatures to try to measure its adaptive capacity. They observed that isolated clones of *Daphnia* evolved in different ways than *Daphnia* living in the presence of competitors, predators, and parasites. Thus, predictive models must consider the complexity of species interactions when making predictions about adaptive capacity—a formidable task.

If changes occur too quickly relative to the life span of the organism, local extinction is likely to occur, rather than adaptation.



Extinctions Biologists are concerned that rapid changes in climate, coupled with other stressors such as land-use changes, will continue to cause high extinction rates (discussed in detail in Chapter 57).

- Behavioral ecologist Barry Sinervo and his team of colleagues found that 12 percent of local lizard populations have gone extinct in Mexico since 1975 because the temperature is changing too rapidly for the lizard populations to adapt. The team used physiological models to discover the mechanism—since lizards were unable to regulate their body temperatures in the heat, they stayed out of the sun during the day, limiting their ability to search for food and thus lowering their fitness.
- As the climate warms, alpine tundra habitats are disappearing. Some plants and animals that have restricted geographic ranges and grow on mountaintops are "running out of habitat" and going extinct.
- Researchers are concerned that habitats may change so rapidly that long-lived trees with limited dispersal will not be able to keep up—their ranges will not be able to change fast enough.
- Polar bears live on sea ice in the Arctic. As sea ice melts, the polar bears are losing their habitat (Table 56.1). If present trends continue, polar bears may be extinct in the wild by 2100.
- Amphibians are in rapid decline globally due to numerous threats—40 percent of amphibian species face imminent extinction. Local changes to temperature and precipitation not only shrink or eliminate the already narrow ranges of many amphibians but also create conditions that favor the chytrid fungus that is causing widespread amphibian mortality.
- Coral reefs are extremely productive in part because corals house symbiotic algae that perform photosynthesis. Warmer water temperatures cause some reef-building corals to expel their photosynthetic algae. When this "coral bleaching" continues due to sustained exposure to warm water, corals begin to die of starvation.

Effects of Ocean Acidification Although the ocean's capacity to absorb CO_2 is not limitless, it is still vast—about one-third of global CO_2 emissions per year is absorbed by the oceans. This absorption has complex consequences for organisms.

When atmospheric CO_2 dissolves, it reacts with water to form bicarbonate (H_2CO_3), which then drops a proton to form

SUMMARY TABLE 56.1 Effects of Climate Change on Organisms

Type of Effect	Example
Phenology Shifts The change in the timing of seasonal events such as migration, flowering, hatching, and feeding can result in mismatches between species; such as flower and pollinator.	
Geographic Range Shifts The geographic redistribution of species to more favorable climate envelopes can change ecological interactions. Mountain pine beetles are spreading north and east, devastating pine forests.	
Evolutionary Adaptation Change in allele frequencies can increase fitness in new conditions. The red morph of the ladybird beetle is more adaptive than heat-absorbing black morph in warmer environments.	
Extinction Species that are not able to survive and/or reproduce under new physical or biological conditions go extinct. Polar bears rely on sea ice, which is melting.	
Acidification The ocean becomes more acidic as it absorbs CO_2, causing a wide range of consequences, such as the slowing of skeletal growth in corals, and coral bleaching.	

carbonic acid (HCO_3^-). Increased CO_2 levels in the atmosphere are increasing the rate of this reaction, and the protons that are released are lowering the pH of the oceans. ✔ **If you understand this concept, you should be able to predict what happens to the pH of a glass of water when you blow bubbles into it with a straw.** The acidity of seawater has climbed by 30 percent over the past 150 years—it's now more acidic than it has been for 20 million years. How does acidity affect organisms?

Research is showing that increasing acidity has devastating effects on diverse processes, ranging from the ability of larval fish to smell predators to the ability of sperm to swim. But by far the greatest amount of research has gone into understanding the effects of acidity on skeleton growth. Increased acidity reduces the availability of calcium carbonate ions to organisms that build calcium carbonate skeletons—such as corals, mollusks, and echinoderms. The more acidic the water, the slower the skeletons form. In some conditions, skeletons can dissolve altogether.

Coral reefs are the subject of a tremendous amount of research because they are among the most productive and species-rich ecosystems in the world. Reefs are large, undersea structures built by colonies of corals that secrete calcium carbonate skeletons. A reduction in skeleton growth due to acidity, changes in temperature, or a combination of the two (in addition to bleaching caused by these factors) threatens the ability of corals to create habitat and food for other organisms.

Consequences to Ecosystems

The combination of local changes in climate and corresponding effects on organisms result in changes to whole ecosystems. Understanding the complex impacts of climate change on ecosystems—and predicting future changes—are among the most challenging and important tasks of ecologists today.

As the first two sections of this chapter emphasized, NPP is the basis of both energy flow and nutrient cycling in ecosystems. Thus, ecologists are monitoring effects of climate change on NPP closely.

How Is NPP Changing on Land? A study from 1982 to 1999 showed an overall increase in global terrestrial productivity. However, the most recent data set, from 2000 to 2009—the warmest decade on record—revealed a different trend. The green areas of **FIGURE 56.25** indicate increased productivity, while the blue areas indicate decreased productivity. Overall, the global terrestrial NPP declined.

This result does not seem intuitive at first, because an increase in atmospheric CO_2 would be expected to increase rates of photosynthesis. The researchers of this study, Maosheng Zhao and Steven Running, point out that large-scale droughts in the Southern Hemisphere have decreased NPP in some of the world's most productive forests, counteracting the overall increase in NPP in the Northern Hemisphere.

Other studies have supported this conclusion. For example, a drying trend in the Amazon rain forest, combined with clear-cutting and burning, threatens to turn one of the world's largest carbon sinks into a carbon source. These data illustrate the complex interaction of effects of CO_2, temperature, and precipitation on productivity.

How Is NPP Changing in the Oceans? As on land, there is considerable variation in local productivity in the oceans. For example, productivity has dropped dramatically in large areas of the pelagic zone, but it has increased in a number of other regions. Overall, scientists agree that there is a general correlation between surface water temperatures and decreased productivity—NPP is decreasing in the oceans. What's going on?

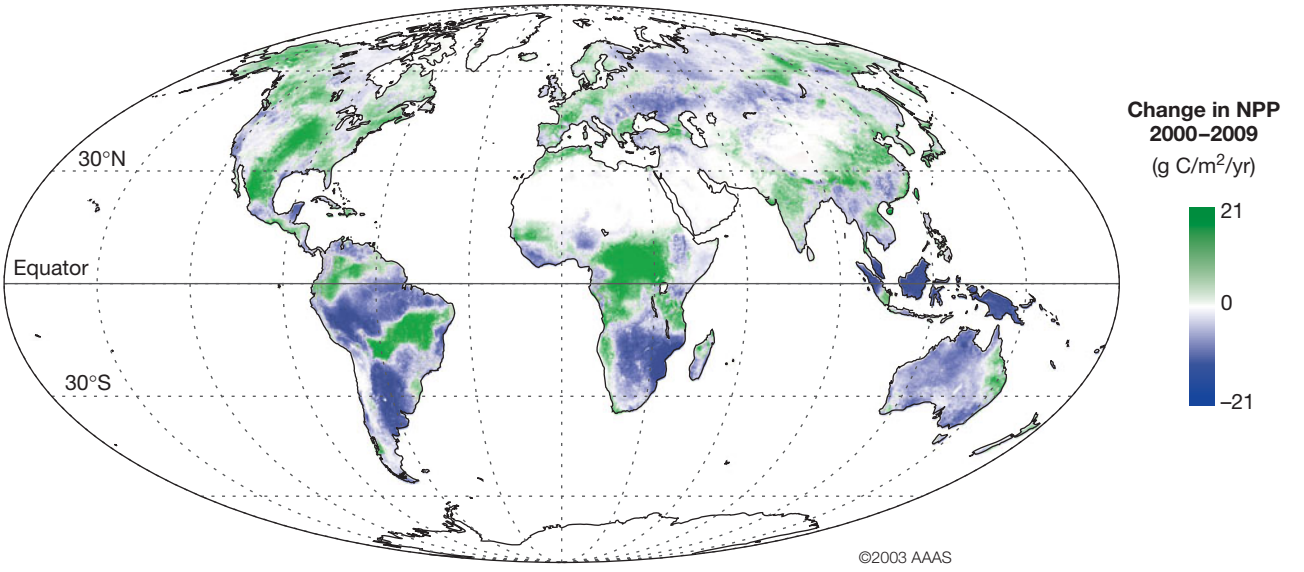


FIGURE 56.25 Recent Changes in Terrestrial NPP. The data shown represent the average annual change in terrestrial NPP from 2000 to 2009.

DATA: Zhao, M., and S. W. Running. 2010. *Science* 329: 940–943.

One of the leading explanations for the drop in marine productivity hinges on changes in water density. To understand the logic behind this hypothesis, recall that lakes can become stratified—that is, have layers of different densities (see Chapter 52). Stratification occurs because water reaches its highest density at 4°C and becomes much less dense at higher temperatures.

Seawater also becomes stratified. This layering is important because the 4°C water in the benthic zone is nutrient rich due to the rain of decomposing organic material from the surface. When warmer surface water becomes lighter, water currents are much less likely to be strong enough to overcome the density difference and bring nutrient-rich, 4°C water all the way up to the surface, where nutrients can spur the growth of photosynthetic bacteria and algae (**FIGURE 56.26**). In this way, the warming global climate is causing surface waters to become more nutrient poor.

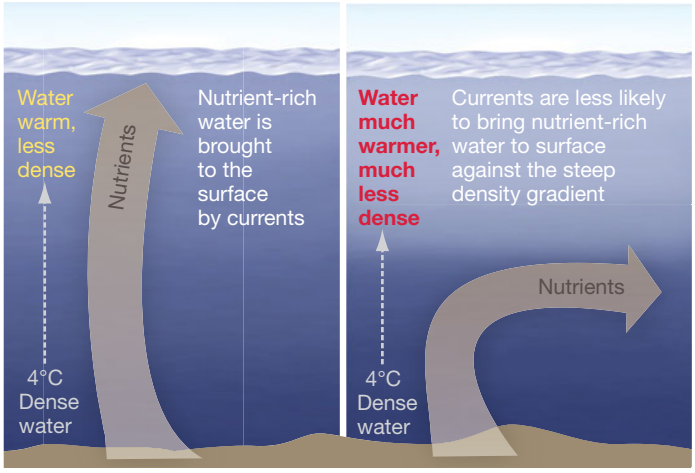

FIGURE 56.26 Temperature Stratification in the Ocean May Affect Productivity.

Local and Global Consequences What are the consequences of these unprecedented global changes in NPP? There are two main take-home messages:

1. Changes in NPP cause feedback on the rate and pattern of climate change. If terrestrial and marine NPP continue to decline, the rate of absorption of CO_2 will decline, exacerbating climate change with far-reaching effects to humans and other organisms.
2. Changes in NPP combine with other factors, such as changes in precipitation patterns and ocean acidification, to alter food web dynamics—and thus ecosystem function. Maintaining ecosystem function is critical to the preservation of biodiversity and the ecosystem services that humans rely upon for survival (see Chapter 57).

This chapter began with the theme that everything in nature is connected. As you've seen, humans are very much a part of these connections. Understanding how humans fit into the big picture is key to taking actions to improve ecosystem health and slow global climate change.

CHAPTER 56 REVIEW

For media, go to MasteringBiology

If you understand . . .

56.1 How Does Energy Flow through Ecosystems?

- Net primary productivity (NPP) is the foundation of ecosystems because it represents the energy, in the form of biomass, available for consumption by other organisms. Humans are reducing and appropriating a large percentage of NPP.
- The feeding relationships among species in a particular ecosystem are described by a food web. Energy is constantly dissipated as it flows from producers to consumers and decomposers in a food web.
- Organisms that acquire energy from the same type of source are said to occupy the same trophic level. Because energy transfer from one trophic level to the next is inefficient, ecosystems have a pyramid of productivity: Biomass production is highest at the lowest trophic level and lower at each higher trophic level.
- Persistent toxins can be magnified in concentration as they are passed up trophic levels in a food web.
- Changes in the species composition of a food web can cause trophic cascades.
- Among terrestrial ecosystems, NPP is highest in tropical wet forests and tropical dry forests. The productivity of terrestrial ecosystems is limited by warmth and moisture.
- Among aquatic ecosystems, productivity is highest in coral reefs, wetlands, and estuaries. Nutrient availability is the key constraint in aquatic ecosystems.
- Although productivity is extremely low in the oceanic zone, the area covered by this ecosystem is so extensive that it accounts for the highest percentage of Earth's overall productivity.

✔ **You should be able to explain why it is more energy efficient to eat a pound of tofu (bean curd) than a pound of hamburger.**

56.2 How Do Nutrients Cycle through Ecosystems?

- Unlike energy that enters an ecosystem and is ultimately dissipated as heat, nutrients such as carbon, nitrogen, phosphorus, and sulfur move indefinitely through ecosystems in biogeochemical cycles.

- To analyze nutrient cycles, biologists focus on the nature of the reservoirs where elements reside and the processes that move elements between reservoirs.
- The rate of nutrient cycling is strongly affected by the rate of decomposition of detritus.
- Nutrients "leak" from one ecosystem to another when biomass is exported. Experiments have shown that vegetation serves an important role in preventing nutrient export by reducing runoff.
- Humans are harvesting freshwater from reservoirs faster than it can be replenished by natural processes.
- Human activities have doubled the amount of usable nitrogen that enters ecosystems each year, leading to increased productivity and to pollution as well as to loss of biodiversity.
- The burning of fossil fuels by humans releases massive amounts of carbon from an inactive geological reservoir to the atmosphere. Current CO_2 levels are 30 percent higher than the highest level measured over the last 800,000 years.

✔ **You should be able to describe conditions under which decomposition rates in terrestrial and marine environments could be extremely low—creating a carbon sink due to a buildup of organic matter.**

56.3 Global Climate Change

- Average global temperatures are increasing rapidly because land-use changes and burning of fossil fuels have increased the flow of carbon in the form of CO_2 into the atmosphere. CO_2 is one of the greenhouse gases that trap heat in the atmosphere.
- Both positive and negative feedback are occurring in response to global warming.
- Average temperature is increasing, but local temperatures and precipitation vary. The variability of temperature and rainfall is also increasing. Storm events are becoming more severe.
- Biologists have documented an array of consequences of climate change to organisms, including changes to phenology, geographic ranges, adaptations, extinctions, and acidification.
- Recent data show that the warming associated with climate change is causing a decrease in average NPP both on land and in the oceans, influencing both climate and ecosystem function.

✔ **You should be able to propose two mechanisms that humans could adopt to reduce global warming, and explain the logic behind each.**

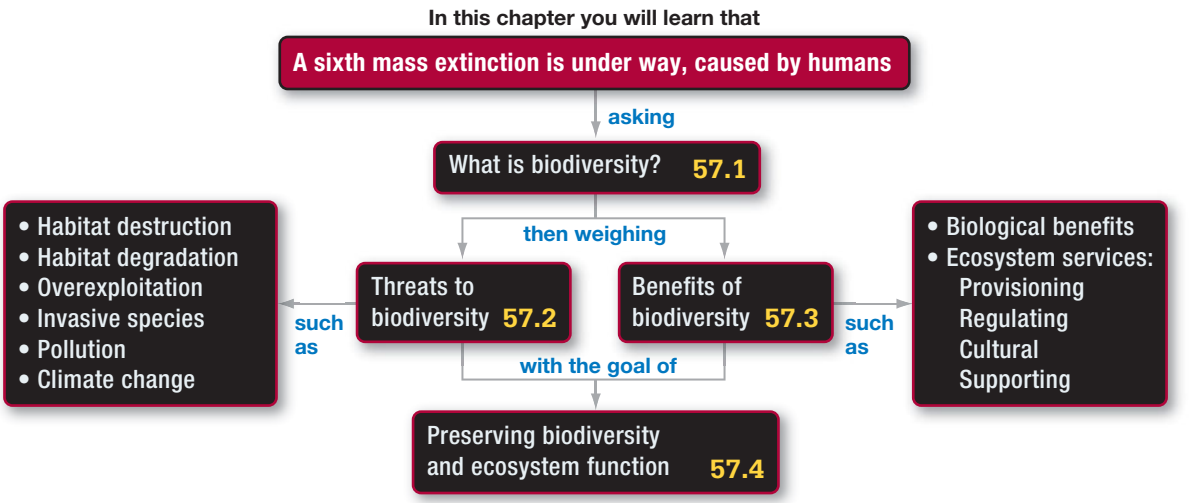
1. True or false? An ecosystem comprises a community and its abiotic environment.
2. Which of the following ecosystems would you expect to have the highest primary production?
   a. subtropical desert
   b. temperate grassland
   c. boreal forest
   d. tropical dry forest
3. Most of the net primary productivity that is consumed is used for what purpose?
   a. respiration by primary consumers
   b. respiration by secondary consumers
   c. growth by primary consumers
   d. growth by secondary consumers
4. What is biomagnification?
   a. biological imaging that provides images or data at fine spatial scales
   b. conversion of an energy input (e.g., sunlight) to chemical energy in the form of sugars, by primary producers
   c. accumulation of certain molecules at high concentration at upper trophic levels
   d. increases in nutrients that lead to pollution
5. Which of the following is normally the longest-lived reservoir for carbon?
   a. atmospheric CO_2
   b. marine plankton (primary producers *and* consumers)
   c. petroleum
   d. wood
6. Devegetation has what effect on ecosystem dynamics?
   a. It increases belowground biomass.
   b. It increases nutrient export.
   c. It increases rates of groundwater recharge (penetration of precipitation to the water table).
   d. It increases the pool of soil organic matter.

TEST YOUR UNDERSTANDING

Answers are available in Appendix A



7. **QUANTITATIVE** If the GPP of a grassland is 5000 kcal/m^2/year and 55 percent is used up by cellular respiration, what is the NPP?
   a. 2250 kcal/m^2/year
   b. 2750 kcal/m^2/year
   c. 5000 kcal/m^2/year
   d. Not enough information is provided.
8. Predict why the large-scale removal of sharks from the oceans has caused some coral reefs to become overgrown with algae, even though sharks don't eat algae.
9. Explain why decomposition rates in a field in Nebraska would differ from the decomposition rates in a field in the Amazon. How do decomposers regulate nutrient availability in an ecosystem?
10. If you were to select a study organism to measure the effects of climate change on trophic interactions in food webs, would corals be a good choice? Explain your reasoning.
11. Use forests as an example to contrast positive and negative feedbacks on global warming.
12. Why are the open oceans nutrient poor? Why are coastal areas and intertidal habitats relatively nutrient rich?

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A

13. Suppose you had a small set of experimental ponds at your disposal and an array of pond-dwelling algae, plants, and animals. How could you use a radioactive isotope of nitrogen to study the effects of fertilizer runoff in these experimental ecosystems?
14. Suppose that record snows blanket your campus this winter. Your friend says this is proof that global warming isn't really occurring. What is the flaw in your friend's logic?
   a. The average temperature of the Earth is not actually increasing.
   b. Global warming refers to temperatures, but snow is a type of precipitation.
   c. While the average global temperature is increasing, local temperatures and precipitation will vary.
   d. He is confusing global warming and global climate change.
15. Suppose that herbivores were removed from an area within a temperate deciduous forest ecosystem (e.g., by fencing to exclude herbivorous mammals and by spraying insecticides to kill herbivorous insects). Predict what would happen to the rate of nitrogen cycling. Explain the logic behind your prediction.
16. During the Carboniferous period, rates of decomposition slowed even though plant growth was extensive (probably due to the formation of vast, oxygen-poor swamp habitats). As a result, large amounts of biomass accumulated in terrestrial environments (much of this biomass is now coal). The fossil record indicates that atmospheric oxygen increased, atmospheric carbon dioxide decreased, and global temperatures dropped. Explain why.

57 Biodiversity and Conservation Biology

The island of Borneo contains some of the most spectacular rain forest in the world, yet it is being cleared at an alarming rate to make way for oil palm plantations. This action threatens both biodiversity and ecosystem function.

When conservation biologist Willie Smits gazed out upon an area near Samboja on the Southeast Asian island of Borneo in 2002, he saw a devastated wasteland:

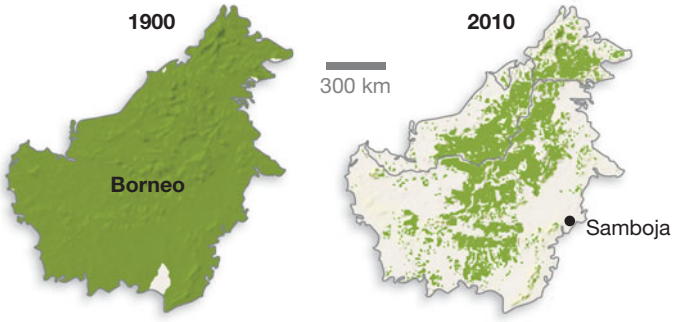
- almost total extinction of plant and animal life;
- depleted soil fertility and failing crops;
- unusually severe climate: droughts, floods, fires; and
- a destitute human population: 50 percent unemployed, high crime rate, poor nutrition, low life expectancy.

Things were not always this way. Borneo is famous for having some of the most luxuriant rain forests on the planet—15,000 species of plants, 222 species of mammals, and hundreds of birds,

BIG PICTURE

This chapter is part of the Big Picture. See how on pages 1196–1197.

✓ When you see this checkmark, stop and test yourself. Answers are available in Appendix A.



amphibians, and fish. Six thousand of these species occur nowhere else on Earth. What happened in Samboja?

Starting in the 1950s, loggers started cutting down the valuable hardwood trees. Following the eventual clear-cut, the remnants were burned to make room for oil palm plantations to supply the world's demand for cooking oil, products such as lipstick, and biodiesel. This transition to agriculture has been pervasive in Borneo. In just 20 years, Borneo has lost as much forest as would fit in Florida (**FIGURE 57.1a**).

The orangutans have been one major casualty of this land transformation, which is how Smits became interested in Samboja (**FIGURE 57.1b**). For these apes, already threatened by poaching for the pet trade, the massive loss of habitat was the last straw. Smits realized that if he wanted to save the orangutans, he would have to save the rain forest.

The scenario at Samboja is not unique. As the human population soars (Chapter 54) and the available resources plummet, more and more wild areas on Earth are being tamed, often with species losses and unintended consequences for ecosystems and humans. The goal of this chapter is to size up the problem and then explore positive steps that can enable a happier outcome. Let's begin by defining a concept that is key to the discussion—biodiversity.

(a) Rapid deforestation of Borneo

(b) Orangutans are one casualty of deforestation

FIGURE 57.1 The Deforestation of Borneo (a) Borneo is a large island in Southeast Asia, once completely forested. **(b)** The clearing of lowland rain forest for oil palm plantations has had a devastating effect on species like the orangutan. Conservationist Willie Smits was inspired by the plight of these animals to work toward a solution.

57.1 What Is Biodiversity?

In essence, **biodiversity** means biological diversity. But this concept is more complex than it might seem at first. Perhaps the simplest way to think about biodiversity is in terms of the tree of life—the phylogenetic tree of all organisms (introduced in Chapter 1 and explored in detail in Chapters 29 through 36). If biologists are eventually able to estimate the complete tree of life (using the techniques reviewed in Chapter 28), the branches would represent all of the lineages of organisms living today; the tips would represent all of the species.

When biodiversity increases, branches and tips are added, and the tree of life gets fuller and bushier. When extinctions occur, tips and perhaps branches are removed; the tree of life becomes thinner and sparser (see Chapter 28 and The Big Picture of Evolution on pages 526–527).

Coordinated, multinational efforts are under way to estimate the tree of life—particularly major lineages such as the land plants and vertebrates—and to understand how the tree has changed over time. But even though the tree of life is a compelling way to document biodiversity, it does not tell the entire story.

Biodiversity Can Be Measured and Analyzed at Several Levels

To get a complete understanding of the diversity of life, biologists recognize and analyze biodiversity at the genetic, species, and ecosystem levels. Let's consider each level in turn.

Genetic Diversity **Genetic diversity** is the total genetic information contained within all individuals of a population, species, or group of species. It is measured as the number and relative frequency of all genes (and their alleles) present in a group.

At the genetic level, biodiversity is everywhere around you, from the variety of apples at the grocery store to the variation in singing ability of sparrows in your backyard. Distinct populations of the same species often contain unique alleles that are maintained by genetic drift or have been favored by natural selection as adaptations to local conditions (see Chapter 26).

Recently, efforts to catalog genetic diversity have been advanced by two technical breakthroughs (see Chapter 21):

1. the ability to sequence the entire genome of multiple members of the same species, and
2. the research protocol called environmental sequencing.

In environmental sequencing, researchers take a sample from the soil or water present in a habitat and sequence all or most of the genes present. It's a way to document genetic diversity even if the species present are unknown.

Genetic diversity is important because it represents the adaptive capacity of a population or higher taxonomic group—the

ability of that group to persist over time despite changes in the environment.

Species Diversity The diversity of species present is a key feature of biological communities. It is usually quantified in two ways:

1. **Species richness** is a simple count of how many species are present in a given community.
2. **Species diversity** is a weighted measure that incorporates the species' relative abundance.

The key difference is in evenness. In communities that are dominated by a few species, species richness might be high but species diversity low (see Chapter 55). Be aware that since relative abundance data are often not available, biologists sometimes use the terms interchangeably.

Ecologists traditionally measure species diversity by spending hours at their field sites employing transects, traps, quadrats, mark-and-recapture techniques, and other methods to quantify the species present (see Chapter 54). This important work can be painstaking, especially in biodiverse areas such as the mountains of Papua New Guinea where, for example, a lamp can be used to attract hundreds of moth species in a single night.

One new technique for identifying such species is called **bar coding**: the use of a well-characterized gene sequence to identify distinct species, using the phylogenetic species concept (see Chapter 27). The idea is that variation in one gene—such as the gene for cytochrome *c* oxidase subunit 1 in the mitochondria of animals—allows biologists to recognize different species in the same way that variations in bar codes enable grocery store scanners to recognize different products. To date, tens of thousands of species have been bar-coded.

It is important to remember, however, that counting species is not like counting beans in a bowl—all species are not equal. Each species has an evolutionary and ecological context.

In terms of evolution, some species occur in lineages that are extremely species rich—they have what biologists call taxonomic diversity. Prominent examples include the beetles, with 360,000 species, and the orchids, with 35,000 species. Other species occur in lineages that are extremely species poor, such as that of the red panda of Asia, which is represented by a single species (**FIGURE 57.2**). When preservation of taxonomic diversity is important, then the preservation of species from species-poor lineages is a priority. If species like the red panda are wiped out, an entire lineage is lost forever.

In terms of ecology, some species have particularly influential roles in a community: they may be key primary producers, important ecosystem engineers creating habitat for other species, keystone predators, or nitrogen fixers (see Chapter 55). When functional diversity is a priority, preservation of species with unique ecological roles is important.

Ecosystem Diversity Communities vary in the number of species that occur within each trophic level (horizontal diversity) and the number of trophic levels (vertical diversity). **Ecosystem diversity** is a measure of these complex factors plus interactions

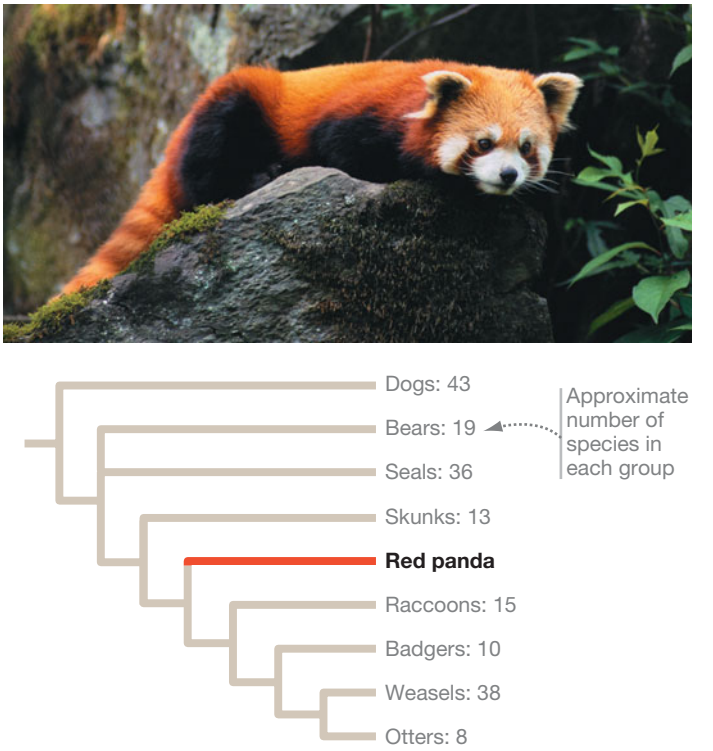

FIGURE 57.2 Phylogenetically Distinct Species May Be High-Priority Targets for Conservation. The red panda has few close relatives and represents a distinct branch on the tree of life. It is a high priority for the preservation of taxonomic diversity.

with the nonliving environment. It is the most difficult level of biodiversity to define and measure because the complexity of ecosystems is so vast.

Intertwined with the concept of ecosystem diversity is **ecosystem function,** which refers to the sum of biological and chemical processes that are characteristic of a given ecosystem—such as primary production, nitrogen cycling, decomposition, and carbon storage. These functions emerge from the sum of the feeding, growing, moving, respiring, excreting, and decomposing processes of the interacting member organisms within their abiotic context. As the field of conservation biology develops, the importance of preserving ecosystem function is gaining more attention.

Note that the three levels of biodiversity are not independent of each other. For example, consider what might happen if the sole species of nitrogen-fixing bacteria disappeared from a grassland community: The genes that code for the nitrogen-fixing enzymes would be lost, followed by loss of the species that depend on that nitrogen as well as loss of important nutrient cycling functions of the ecosystem.

Change through Time Biodiversity can be recognized and quantified on several distinct levels, but it is also dynamic.

- Mutations that create new alleles increase genetic diversity; natural selection, genetic drift, and gene flow may eliminate certain alleles or change their frequency, leading to an increase or decrease in overall genetic diversity (Chapter 26).

- Speciation increases species diversity; extinction decreases it (Chapter 28).
- Changes in climate or other physical conditions can result in the formation of new ecosystems or ecosystem functions, as can the evolution of new species—such as reef-building corals and salt-tolerant marsh grasses. Disturbances such as volcanic eruptions, human activities, and glaciation can destroy ecosystems or ecosystem functions.

Biodiversity is not static. It has been changing since life on Earth began.

How Many Species Are Living Today?

One of the simplest questions about biodiversity is also one of the most difficult to answer: How many species are there on Earth? The answer is not known, but educated guesses range from 10 to 100 million. Given the massive effort that it would take to document every form of life on Earth, the answer will probably never be known.

Biologists are well aware, though, that the approximately 1.5 million species cataloged to date represent a tiny fraction of the number actually present. The issue is even more acute in poorly studied lineages like bacteria and archaea, where researchers routinely discover dozens of new species in each environmental sequencing or direct sequencing study (see Chapters 21 and 29). For example, a recent direct sequencing study estimated that over 500 species of bacteria live in the human mouth, but only about half had been described and named already. Even among well-studied groups like birds and mammals, new species are discovered every year—including new species of primates.

Given that only a fraction of the organisms alive have been discovered to date, how can biologists go about estimating the total number of species on Earth? One approach is based on intensive surveys of species-rich taxonomic groups in defined sites; a second strategy is based on attempts to identify all of the species present in a particular region.

Taxon-Specific Surveys In a taxon-specific survey, biologists conduct an intensive search for a specific taxon in a well-defined area. For example, in their classic study carried out in 1980, Terry Erwin and Janice Scott fogged several trees with insecticide in a Panamanian jungle and recovered 1000 species of beetles. Many of the species were new to science.

More recently, Philippe Bouchet and colleagues conducted a massive survey of marine mollusks in coral-reef habitats along the west coast of New Caledonia, a tropical island in the southwest Pacific Ocean. The team spent more than a year collecting mollusks at 42 sites over a total area of almost 300 km^2. The survey represented the most thorough sampling effort ever made to determine the species diversity of mollusks, and produced more than 127,000 individuals representing 2738 species. These numbers far exceed the mollusk diversity recorded for any comparable-sized area.

In reporting their findings, Bouchet and his team emphasized that 20 percent of the species found were represented by a single specimen. This observation suggests that many species are exceedingly rare and thus likely to be missed by less intensive sampling efforts. And when the investigators compared their data with a survey in progress at a second site, different in reef structure but only 200 km away from the original site, they found that only 36 percent of species were shared between the two sites. Taken together, the results support the hypothesis that the 85,000 known mollusk species may represent just a third to a half of the actual total.

All-Taxa Surveys As the name suggests, in an all-taxa survey, biologists attempt to find and catalog all of the species present in an area. The most spectacular example of an all-taxa survey so far is the Census of Marine Life, a massive international effort to record the global diversity of life in the oceans. About 2700 scientists from more than 80 countries launched 540 expeditions over a 10-year period ending in 2010 to survey the number and distribution of marine species around the globe—ranging from deep-sea vents to coral reefs to intertidal mud flats.

The participants collected over 30 million records, including 6000 potentially new species. Even a small sediment core only 7 centimeters in diameter and 10 centimeters deep yielded a surprisingly diverse assemblage of deep-sea animals (**FIGURE 57.3**). Many animal phyla are represented in this sample, most of them miniaturized—a possible adaptation to low nutrient availability in the deep sea. The total number of marine species is currently estimated by the census to be 250,000.

FIGURE 57.3 Estimating Species Richness via All-Taxa Surveys. A sample of the diverse, tiny animals sifted from a small core of deep-sea sediments.

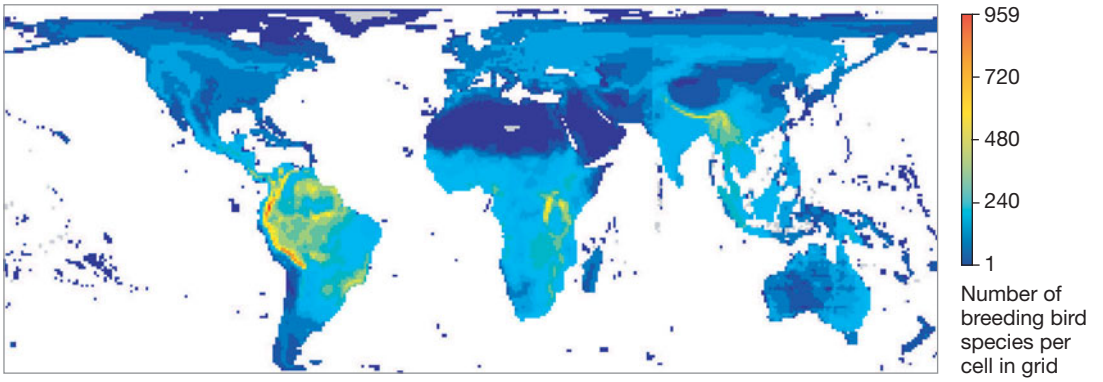
Where Is Biodiversity Highest?

Both taxon-specific surveys and all-taxa surveys provide data on the total number of species as well as on their geographic distributions. What patterns of biodiversity emerge?

Mapping Species Richness and Endemism Patterns of biodiversity are usually measured by dividing geographic areas into a grid of cells and mapping the biodiversity within each cell.

The map in **FIGURE 57.4a**, for example, was constructed by dividing the world's landmasses into a grid of cells 1° latitude by 1° longitude. Using published data, a team of researchers then plotted how many species of birds breed in each cell in the grid, a measure of species richness. The narrow red-and-orange area on the map shows that the number of breeding bird species per area is particularly high in the Andes Mountains of western South America.

Another approach to measuring the distribution of biodiversity is to identify which regions of the world have a high proportion of **endemic species**—meaning, species that are found in a particular area and nowhere else. **FIGURE 57.4b** maps the location of endemic species of breeding birds, based on the same cells and data as the species richness map in Figure 57.4a. Once again, the area of highest species per area occurs in the Andes Mountains. However, the two maps are not identical, so evaluating both species richness and endemism can be more insightful than evaluating either alone.



As you might expect, the areas of highest biodiversity are different for different taxonomic groups. However, some trends do appear.

- The most prominent geographic pattern in the distribution of biodiversity corresponds to latitude: In most, but not all, taxonomic groups, species richness is highest in the tropics and declines toward the poles (see Chapter 55).
- Biodiversity is also higher on land than in the sea. Even though land covers only about 30 percent of Earth's surface, about nine out of 10 species (microbes aside) are terrestrial.
- Areas with greater geographical variation tend to have higher biodiversity than areas that are flat or featureless.

Overall, tropical rain forests are particularly species rich. Even though they represent just 7 percent of Earth's land area, they are thought to contain at least 50 percent of all species present.

Understanding *why* tropical forests are so species rich and *why* the other biodiversity patterns occur is an active research area. The mechanisms that determine patterns of biodiversity are complex because they combine local abiotic factors (solar energy, temperature, precipitation, topography, nutrient availability; Chapters 52 and 56), biotic factors (species interactions; Chapter 55), and historical context (evolutionary history, biogeography; Chapter 52). To complicate matters further, the mechanisms that determine biodiversity differ at the local scale and the regional scale.

(a) Biodiversity distribution in terms of **species richness of birds**

(b) Biodiversity distribution in terms of **endemic species of birds**

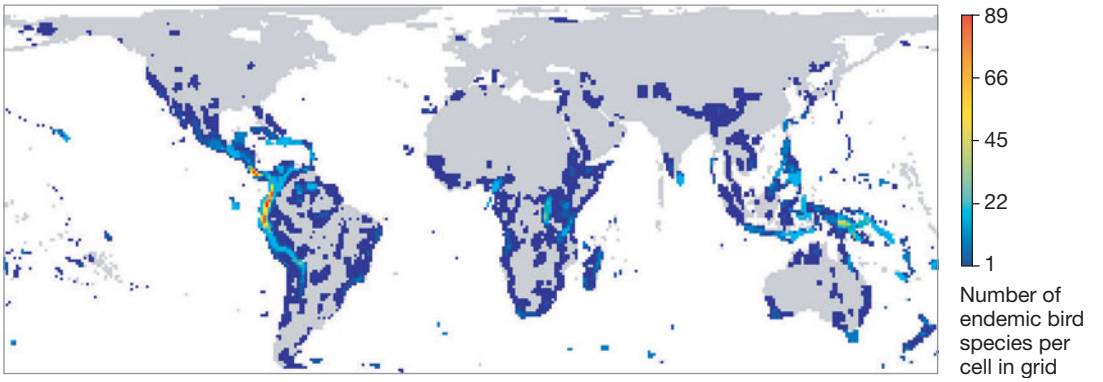


FIGURE 57.4 Biodiversity Distribution Maps Show Regions with Extraordinarily High Species Richness and Endemism. Both maps are based on a grid of cells that is 1° longitude by 1° latitude.

Mapping Biodiversity Hotspots In 1988, conservation biologist Norman Myers pioneered the term **biodiversity hotspot** to characterize regions that are in most urgent need of conservation action—areas where efforts to preserve habitat would have the highest return on investment.

Since 1988, Myers and many collaborators, including organizations such as Conservation International, have identified 34 hotspots that meet two criteria:

1. They contain at least 1500 endemic vascular plant species (more than 0.5 percent of the world's total).
2. They have lost at least 70 percent of their traditional or primary vegetation.

Although these areas represent just 2.3 percent of Earth's land area, they contain over 50 percent of all known plant species and 42 percent of all known terrestrial vertebrate species as endemics.

One criticism of the second criterion of biodiversity hotspots is that it considers cumulative past loss, not current rate of loss. Most notably, hotspots do not include the rain forests found in the Amazon, the Congo River basin, and New Guinea—because those environments have not yet lost 70 percent of their primary vegetation. Effectively preserving these areas along with the hotspots would provide protection for over 65 percent of all land plants in just 5 percent of Earth's land surface.

Further, hotspots focus on species diversity rather than ecosystem diversity—but the importance of ecosystem diversity is becoming more apparent every year. In 2002, scientists in collaboration with the World Wildlife Fund created a map of 238 ecoregions—subsets of biomes (see biome maps in Chapter 52). The ecoregion map, shown in **FIGURE 57.5**, highlights particularly rich areas of biodiversity; it also includes areas with unique communities or abiotic conditions (such as in tundra or desert biomes) or a unique evolutionary history (such as the Galápagos Islands; Chapter 25)—all of which should be priorities for proactive conservation.

Whether global maps of biodiversity hotspots are based on species richness, endemism, level of threat, and/or unique ecological or evolutionary characteristics, they are all useful in their own ways for creating priorities for managing threats to biodiversity.

check your understanding

C Y U

If you understand that . . .

- Biologists document biodiversity at the genetic, species, and ecosystem levels.
- On average, biodiversity tends to be higher in the tropics than near the poles, higher on land than in the sea, and higher in areas with geographic diversity. Tropical rain forests are particularly species rich.
- Biodiversity can be mapped according to species richness, endemism, level of threat, and ecological or evolutionary characteristics.

✓ You should be able to . . .

Design a study that would quantify species diversity on your campus.

Answers are available in Appendix A.

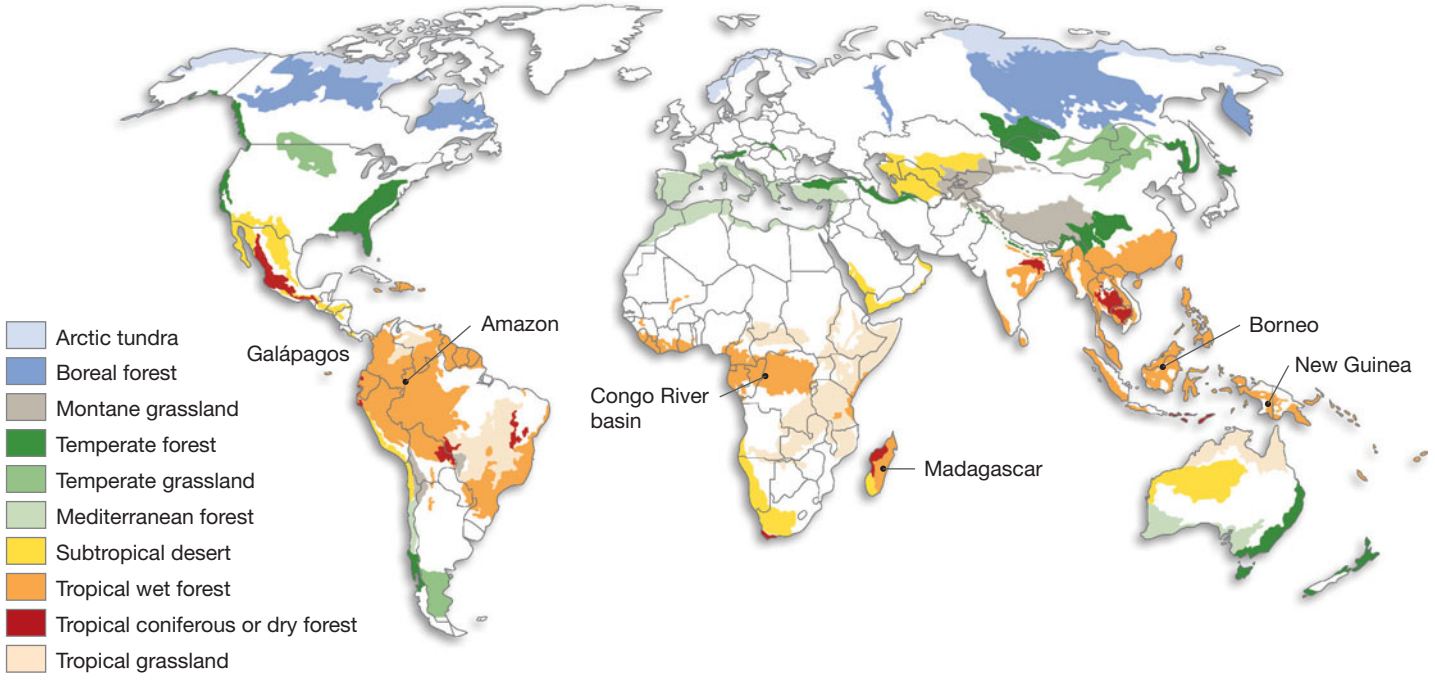

FIGURE 57.5 Ecoregions Designated as High Priority for Conservation. Areas that have the same color belong to the same biome (see Chapter 52).

57.2 Threats to Biodiversity

No species lasts forever. Extinction, like death, is a fact of life. If extinction is natural, why are biologists so concerned about habitat and species conservation? The answer is rate.

Today, species are vanishing faster than at virtually any other time in Earth's history. Modern rates of extinction are 100 to 1000 times greater than the average, or "background," rate recorded in the fossil record over the past 550 million years (see Chapter 28). According to data on the rates of extinction in birds and other well-studied groups, 60 percent of all species are likely to be wiped out within 500 years, a blink of an eye on the evolutionary time scale.

Either directly or indirectly, current extinctions are being caused by the demands of a rapidly growing human population—currently at over 7 billion and increasing by about 80 million people per year (Chapter 54). The island that is planet Earth is far more crowded than it used to be.

How do biologists track extinctions that are under way? Beginning in 1994, an organization called the International Union for the Conservation of Nature (IUCN) began compiling the Red List to quantify the risk of extinction of different species. For example, the data in **FIGURE 57.6** show that an astonishing 13 percent of birds, 25 percent of mammals, and 41 percent of amphibians are threatened—that is, they are either Critically Endangered, Endangered, or Vulnerable. An **endangered species** is a species whose numbers have decreased so drastically that it is almost certain to go extinct unless effective conservation programs are put in place.

Based on the data in hand, the vast majority of biologists agree that the sixth mass extinction in the history of multicellular life is occurring. Between the time you are reading this and the time your great-grandchildren are grown, human impacts on the planet promise to equal or exceed those of the gigantic asteroid that smashed into Earth 65 million years ago (see Chapter 28).

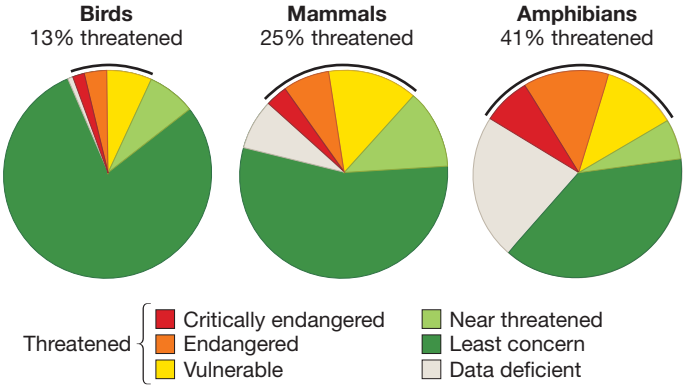

FIGURE 57.6 IUCN Designations of Threatened Species. The total number of threatened species in each group was estimated assuming that the species in the gray (data-deficient) category have the same rate of being threatened as the others. Extinct species are not included.

DATA: IUCN 2012. The IUCN Red List of Threatened Species. Version 2012.2.

Multiple Interacting Threats

What factors are causing so many species to be endangered? Consider a recent study conducted by ecologists Oscar Venter, James Grant, and colleagues. They examined 488 species of endangered plants and animals native to Canada, and they quantified the frequency of different threats based on the categories compiled by the IUCN. The bar graphs in **FIGURE 57.7** show the results. The data reveal several patterns:

- Habitat loss is the single most important factor in the decline of these species. It is a significant issue for over 90 percent of endangered species in terrestrial environments.
- Virtually all of the endangered species are affected by more than one factor. This is important information, because it means that conservation biologists may have to solve more than one problem for any given species to recover.
- Overexploitation is the dominant problem for marine species, while pollution plays a large role for freshwater species.
- Factors beyond human control can be important. These include predation or competition with native species, natural disturbances such as fires or droughts, or the fact that some species have narrow niches and historically are rare. Stated another way, background extinctions will continue to occur.

Similar studies have been conducted for other parts of the world. Do the same conclusions hold up globally? The degree of importance of the different threats varies somewhat according to region, but the take-home message is consistent with the Canadian data. Let's take a closer look at the major threats to species.

Habitat Destruction Humans cause **habitat destruction** (habitat loss) by logging and burning forests, damming rivers, dredging or filling estuaries and wetlands, plowing prairies, grazing livestock, excavating minerals, and building housing

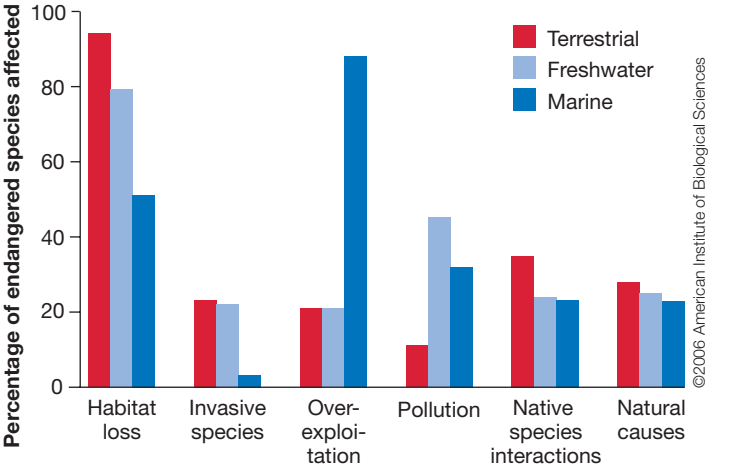

FIGURE 57.7 Endangerment Is Caused by Multiple Factors. These data are from Canada.

✔**QUANTITATIVE** Why do the data for terrestrial, freshwater, and marine species each add up to more than 100 percent?

DATA: Ventner, O. et al. 2006. *BioScience* 56: 903-910.

developments, golf courses, shopping centers, office complexes, airports, and roads. Today, less than a quarter of Earth's land is in its wild state (see map in Figure 52.10), and most of the wild land is near the poles, where biodiversity is lowest.

On a global scale, one of the most important types of habitat destruction is deforestation—especially the conversion of primary forests to agricultural fields and human settlements. Primary forests—which have never been cut—tend to have high biodiversity due to their complex ecological interactions and deep evolutionary history. Research comparing primary forest and reforested areas shows that primary forest is irreplaceable for sustaining biodiversity.

To appreciate the extent of deforestation in some areas, consider satellite images of wet tropical rain forest in the Brazilian state of Mato Grosso that were made in 1985 and in 2000 (**FIGURE 57.8**). Analyses of satellite photos such as these have shown that as many as 3 million hectares were deforested in the Amazon each year during the 1990s. (A hectare, abbreviated ha, is 100 meters by 100 meters—approximately the size of two football fields.)

More recent analyses suggest that the global rate of deforestation has now slowed compared to an average net loss of 16 million ha/year in the 1990s. The latest report from the United Nations Food and Agriculture Organization, released in 2010, states that the world's forests experienced a net loss of about 13 million ha/year between 2000 and 2010.

But conservationists greeted this report with caution. Net losses dropped because of extensive forest regrowth in China, North America, and Europe, even though over 40 million ha of primary forest have been lost in South America, Southeast Asia, and Africa since 2000. If this rate of tropical deforestation continues, over 28 percent of the wet tropical forest that exists today will be gone in your lifetime, including almost half of the Brazilian Amazon.

Forest losses in the tropics are particularly worrisome because these forests contain many biodiversity hotspots, and they moderate the effects of climate change by storing carbon. Further, when forests are cut, soil and nutrients are often lost from the ecosystem due to erosion, inhibiting future recovery (Chapter 56). Meanwhile, the human population continues to increase rapidly in these areas, putting increased pressure on the forests. Addressing the interaction of these scientific and social variables represents one of the most formidable challenges of our time.

Habitat Degradation Aside from destroying natural areas outright, human activities can also cause **habitat degradation**, a reduction in the quality of a habitat. Humans can degrade habitats in many ways, even by using artificial light at night and creating traffic noise. One of the most pervasive patterns of habitat degradation is **habitat fragmentation,** the parsing of contiguous areas of natural habitats into small, isolated fragments. For some species, a narrow road or pipe intruding into their habitat is a sufficient barrier to limit dispersal.

Habitat fragmentation concerns biologists for several reasons. First, like habitat destruction, fragmentation can reduce habitats to a size that is too small to support some species. This situation is especially true for top predators (see Chapters 55 and 56) such as wolves, mountain lions, and grizzly bears, which need vast natural spaces in which to feed, find mates, and reproduce successfully.

When top predators in food webs are lost, trophic cascades may occur, affecting species throughout the food web in complex ways (see Chapter 56). Trophic cascades often have unexpected impacts on many aspects of ecosystem function, ranging from susceptibility to fire, disease, and invasive species to changes in primary productivity and nutrient cycling.

The second concern about habitat fragmentation is that it can force many species into a metapopulation structure (see Chapter 54). The small, isolated populations that make up a metapopulation are much more likely than large populations to be wiped out, for two reasons:

1. Catastrophic events such as storms, disease outbreaks, or fires exterminate small populations more readily than large populations. Biologists refer to episodes like this as stochastic—meaning, chance—events.

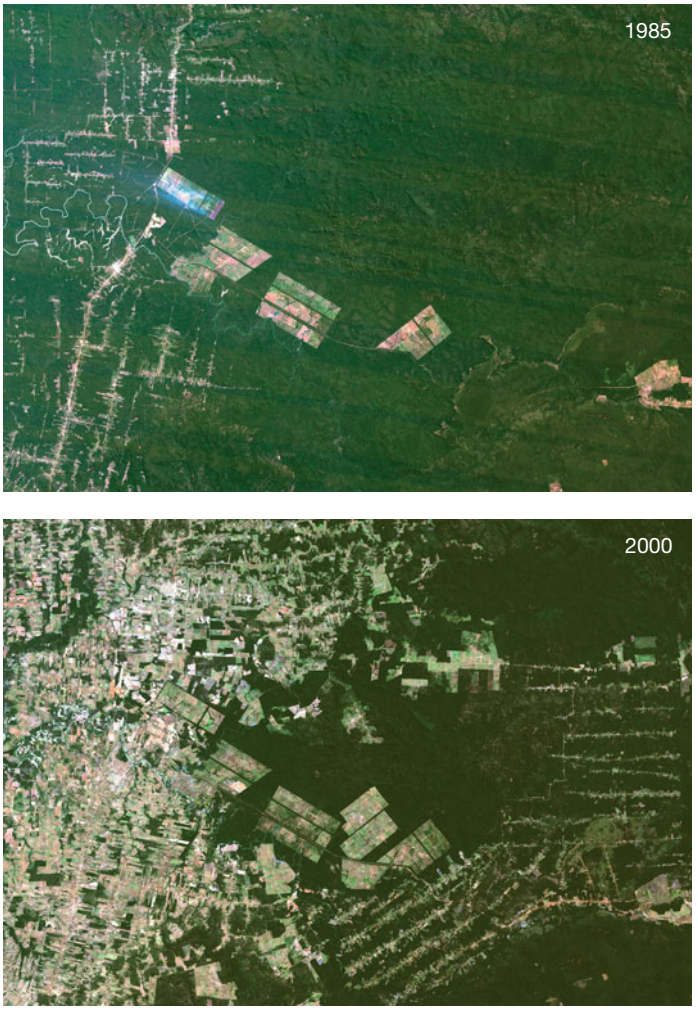

FIGURE 57.8 Rates of Deforestation in Tropical Wet Forests Are High. In the satellite image from Mato Grosso, Brazil, at top, the dark green areas are intact forest. In the lower image of the same location 15 years later, the light areas have been burned or logged and converted to agricultural fields and pastures.

2. Small populations suffer from inbreeding depression and random loss of alleles due to genetic drift.

Why do genetic problems occur? Small populations become inbred simply because so few potential mates are available. Over time, virtually all individuals become related. In most populations, inbreeding leads to lowered fitness due to deleterious recessive alleles being homozygous more frequently—a phenomenon known as inbreeding depression (see Chapter 26).

In addition, genetic drift is much more pronounced in small populations than large populations (see Chapter 26). Because drift leads to the random loss or fixation of alleles, it reduces genetic variation in populations. This result is a concern, because if the environment changes due to the evolution of a new disease or global climate change, the population may lack alleles that confer high fitness in the new environment.

Third, fragmentation creates large amounts of degraded "edge" habitat. The edges of intact habitat are subject to invasion by weedy species and are exposed to more intense sunlight and wind, creating difficult conditions for plants.

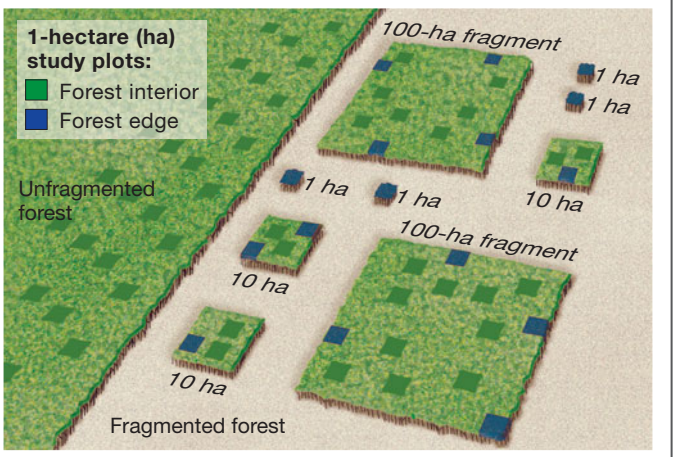
The degradation of habitat caused by fragmentation is being documented in a long-term experiment in a tropical wet forest. In an area near Manaus, Brazil, that was slated for clear-cutting, ecologists William Laurance, Thomas Lovejoy, and their colleagues set up 66 square, 1-ha experimental plots that remained uncut. Thirty-nine of these study plots were located in fragments designed to contain 1, 10, or 100 ha of intact forest. Twenty-seven of the plots were set up nearby, in continuous wet forest. As the "Experimental setup" section of **FIGURE 57.9** shows, the distribution of the study plots allowed the research team to monitor changes inside forest fragments of different sizes and to compare these changes with conditions in unfragmented forest. Note that many of the study plots were located on forest edges.

When the research group surveyed the plots at least 10 years after the initial cut, they recorded two predominant effects:

1. A startling drop in aboveground **biomass,** or the total amount of fixed carbon, took place in the study plots located near the edges of logged fragments. As the graph in the "Results" section of Figure 57.9 shows, most of the loss occurred within 2–4 years of the fragmentation event.
2. On average, biomass did not decrease in the interior (control) plots. Further, the rate of biomass loss increased as the distance from the plots to the nearest forest edge decreased.

In tropical wet forests, most of the biomass is concentrated in large trees. Due to exposure to high winds and dry conditions, the edges of the experimental plots contained many downed and dying trees. Follow-up work showed that in edge habitats and in the fragmented patches, large-seeded, slow-growing trees typical of undisturbed forests are being replaced by early successional, "weedy" species (see Chapter 55). A large number of bird and understory plant species have disappeared as well.

The take-home message of this experiment and other research is clear: When habitats are fragmented, the quality *and* quantity of habitats decline drastically. In addition to losing over 8 million ha of primary forest in South America, Southeast Asia, and Africa each year to clear-cutting, we are losing large amounts of high-quality habitat throughout the world to fragmentation.

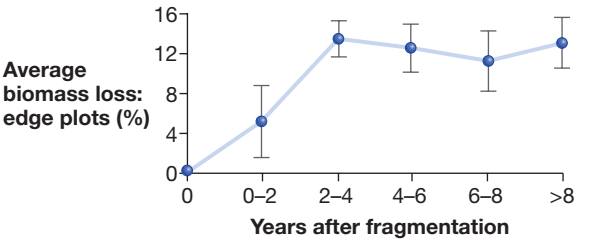


RESEARCH

QUESTION: How does fragmentation affect the quality of tropical wet forest habitats?

HYPOTHESIS: Fragmentation reduces the quality of wet forest habitats.

NULL HYPOTHESIS: Fragmentation has no effect on the quality of wet forest habitats.



EXPERIMENTAL SETUP:

PREDICTION: Biomass will decline in forest fragments compared with those of the forest interior, particularly along edges of fragments.

PREDICTION OF NULL HYPOTHESIS: Biomass will be the same inside forest fragments and along edges as in the forest interior.

RESULTS:

CONCLUSION: Biomass declines sharply along edges of forest fragments.

FIGURE 57.9 Experimental Evidence for Edge Effects in Fragmented Forests. Researchers tracked 66 study plots among four 1-hectare (ha) fragments, three 10-ha fragments, and two 100-ha fragments.

SOURCE: Laurance, W. F., S. G. Laurance, L. V. Ferreira, et al. 1997. Biomass collapse in Amazonian forest fragments. *Science* 278: 1117–1118.

✔**QUESTION** The locations of the fragments and study plots were assigned at random. Why was this step important?

Overexploitation **Overexploitation** refers to any unsustainable removal of wildlife from the natural environment for use

by humans. Overexploitation is the dominant threat for marine species.

- Two-thirds of harvestable marine species are now considered fully exploited or depleted, and a recent study of the global fishing industry concluded that 90 percent of individuals in large-bodied fish species from bottom or open-water habitats have already been removed from the world's oceans (see **TABLE 57.1**). The affected species include tuna, swordfish, marlin, cod, halibut, and flounder—and many species of sharks, which are harvested for their fins. Unless stricter fishing limits are established quickly, these popular species will go extinct. Further, removal of these top predators has an immense impact on species at lower trophic levels, causing a cascade of effects on food webs (Chapter 56).
- Overhunting has also emerged recently as a major threat to many mammal populations. Aside from the traditional hunt for game species, the recent growth of the "bushmeat" trade has devastated populations of primates and other mammals in Africa and elsewhere. Adding to the problem, many animals are hunted not for their meat, but for their ivory, skins, horns, or other body parts valued in folk medicines or decorations.
- The capture of exotic animals for the pet trade continues at a rapid rate despite many laws to prevent it. Exotic pets range widely from primates like tamarins and macaques to parrots, iguanas, frogs, corals, and tropical fish.

Overexploitation is a grave concern for marine and terrestrial species worldwide due to the increasing demand and decreasing supply. Ten thousand years ago, only 0.1 percent of Earth's mammalian biomass consisted of humans and their domesticated animals. Today, this number has risen to 90 percent.

Invasive Species A nonnative species that is introduced into a new area is called an **exotic species.** Exotic species do not necessarily pose problems, and can even be beneficial in some circumstances—such as the arrival of coyotes in the eastern United States (from the west) to fill the niche vacated by wolves and other top predators, which were hunted out.

But some exotic species pose a direct threat to native species by eating them, competing with them, causing disease, or other types of interactions. They can also pose indirect threats by changing the local biotic or abiotic resources. You might recall that if an exotic species is introduced to a new area, grows to large population size, and disrupts species native to the area, it is called an **invasive species** (see Chapter 52).

Global trade and global travel have vastly increased the rate of exchange of plants, animals, fungi, and microorganisms—both purposeful and accidental—sometimes with dire consequences. For example, after brown tree snakes were introduced to the Pacific island of Guam 60 years ago (see Table 57.1), the snake population increased exponentially, causing the extinction of 12 native bird species, decreasing populations of small mammals and lizards, and indirectly affecting plant communities. Islands are particularly vulnerable to the effects of invasive species.

SUMMARY TABLE 57.1 Major Threats to Biodiversity

Threat	Example
Habitat destruction and degradation	 The conversion of primary forest to agricultural fields is a particularly devastating cause of habitat destruction.
Overexploitation	 Overexploitation is the dominant threat for marine species, especially for large predators in top trophic levels, like these endangered bluefin tuna.
Invasive species	 Invasive species, like this brown tree snake in Guam, are introduced to a new area, multiply rapidly, and threaten native species.
Pollution	 Chemical pollutants have reached every corner of the globe, but are particularly threatening to aquatic species.
Climate change	 Climate change poses different types of threats to different species. For example, some corals become bleached (lose their symbiotic photosynthetic algae) when water temperature warms.

Pollution Humans change both the biotic environment and the abiotic environment by releasing chemicals into ecosystems. Many types of major pollutants pose both direct and indirect threats to species:

- Industrial pollutants include sulfur (causing acid rain), arsenic, mercury, and lead as well as greenhouse gases such as CO_2 and nitric oxide (NO_2).
- Pharmaceutical pollutants (drugs) like oral contraceptives and ibuprofen are excreted in human urine and pass through wastewater-processing facilities into streams and rivers, where they are still biologically active.
- Pesticides and herbicides are a type of persistent organic pollutant (POP) that have a direct effect where they are used, but also affect species far away—sometimes in extremely remote locations—by dispersing in waterways and undergoing biomagnification in food webs (Chapter 56).
- Nutrients like nitrogen and phosphorus run off of farms and fields, causing eutrophication (Chapter 56).
- Garbage fills landfills, waterways, and ocean gyres, posing both physical and chemical threats.

Many pollutants are persistent. They last in organisms and the environment for a long time and may continue to cause harm long after their initial release—and at great distances from their initial release. Freshwater organisms are particularly vulnerable to chemical pollutants.

Climate Change The acceleration of global climate change due to the burning of fossil fuels, deforestation, and other processes has already had an impact on species, including extinctions (see Chapter 56). Biologists have begun to record how several factors related to climate change influence biodiversity:

- As the global temperature increases, polar and alpine habitats are disappearing, endangering species native to arctic and high-elevation tundra.
- Coastal habitats are threatened by sea-level rise caused by the melting of polar ice caps and glaciers. The most recent analyses project that sea levels will rise an additional 0.8 to 2.0 m by the year 2100, inundating many coastal habitats, including areas with biodiversity hotspots.
- Biomes are becoming redistributed due to changes in both temperature and rainfall, causing mismatches between species distributions and abiotic conditions.
- The species compositions of communities are changing because trees and other slowly dispersing species are unable to keep up with rapid changes in climate.
- Coral reefs are suffering from "bleaching" induced in some species by high temperatures; this change is causing a cascade of effects in those ecosystems.
- Ocean acidification—due to the rise of atmospheric carbon dioxide concentrations and the consequent increase in carbonic acid formation in the oceans—is interfering with many aspects of organismal physiology, including the ability of corals, crustaceans, and other animals to make calcium carbonate skeletons (see Table 56.1).

Although climate change is a natural phenomenon, the climate is currently changing at an extreme rate.

How Will These Threats Affect Future Extinction Rates?

What impact will the different threats have on biodiversity in the future? The formulation of biodiversity projections is a rapidly growing area of research, due to major advances in computer modeling, increased availability of paleontological and current data to input into the models, and increased demand for projections as the world is faced with important decisions about conservation.

The formulation of biodiversity scenarios is a highly integrative field of ecology because it must use information from multiple levels, including

- the effects of evolutionary processes on genetic variation, adaptation, and extinction in populations (Chapter 26);
- the impact of abiotic factors such as temperature and precipitation on the distribution and abundance of organisms (Chapter 52);
- the behavior of organisms in response to changing conditions (Chapter 53);
- the basic demographic characteristics of populations, such as fecundity and survivorship (Chapter 54);
- the consequences of species interactions at the level of communities (Chapter 55) and ecosystems (Chapter 56); and
- the effect of biodiversity threats at all these levels.

You can see how all these levels fit together in the Big Picture of Ecology on pages 1196–1197. Different models integrate different subsets of this list. Let's consider three examples of models ranging from single populations up to global species distributions.

Estimating the Probability that an Individual Species Will Go Extinct A population viability analysis, or PVA, is a model that estimates the likelihood that a population will avoid extinction for a given time period. In most cases, a PVA attempts to combine data on

- age-specific survivorship and fecundity (Chapter 54),
- geographic structure (Chapter 52), and
- rate and severity of habitat disturbance (Chapter 55).

Typically, a population is considered viable if the analysis predicts that it has a 95 percent probability of surviving for at least 100 years. This type of analysis is particularly useful for creating management plans for species like the northern spotted owl and island foxes, which are listed as endangered in the IUCN Red List, the U.S. Endangered Species Act, or other metrics.

Estimating the Effect of Habitat Area on Species Richness One strategy for predicting the future of Earth's biodiversity focuses on

QUANTITATIVE METHODS 57.1 Species–Area Plots

The goal of species–area plots is to quantify the relationship between species richness and habitat area. **FIGURE 57.10** gives an example of a species–area curve—a graph that plots habitat area on the *x*-axis and the number of species present on the *y*-axis. In this case, the habitat areas are islands in the Bismarck Archipelago near New Guinea, in the South Pacific, and the species documented are birds. Each data point represents the number of species found on a different island. Note that the relationship between habitat area and the number of species present is linear when both axes are logarithmic. (For help interpreting logarithms, see **BioSkills 6** in Appendix B.)

The "log–linear" relationship turns out to be typical for other habitats and taxonomic groups as well. When biologists have plotted species–area relationships for plants, butterflies, mammals, or birds from islands or continental habitats around the globe, the relationship is consistently described by a function of the form $S = cA^z$, where:

- S is the number of species.
- A represents the habitat area.
- The c term is a constant that scales the data. Its value is high in species-rich areas, such as coral reefs or tropical wet forests, and low in species-poor areas, such as arctic tundra.
- The exponent z represents the slope of the line on a log–log plot. Thus, z describes how rapidly species numbers change with area. Typically, z is about 0.25.

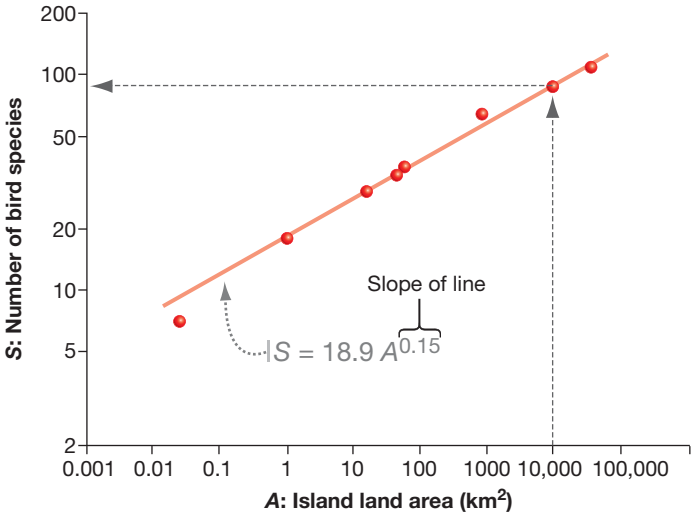


FIGURE 57.10 Species–Area Plots Quantify the Relationship between Species Richness and Habitat Area. The dashed arrows on this graph show the number of bird species that are expected to live on an island with an area of 10,000 km^2.

DATA: Diamond, J. M. 1975. *Biological Conservation* 7: 129–146.

For example, the solid line drawn through the points in Figure 57.10 is described by the function $S = (18.9)\, A^{0.15}$. This equation can be used to predict the species richness of other areas of a given size, such as an island that has not yet been sampled. If an unsampled island is known to have an area of 8 km^2, the species richness would be predicted as $S = 18.9 \times 8^{0.15} = 26$.

✔ **QUANTITATIVE** If you understand species–area curves, you should be able to predict the species richness of birds of an island in the Bismarck Archipelago that is 5000 km^2.

Answer: 68

the consequences of the most urgent problem: habitat loss. Given reasonable projections of how much habitat will be lost over a given time period, biologists can estimate rates of extinction based on **species–area relationships.** The concept here is to use species–area curves (see **Quantitative Methods 57.1**) to extrapolate backward to determine the species richness of a given habitat if its area were to decline due to habitat destruction or climate change.

To understand how biologists use the species–area curve in Quantitative Methods 57.1 to project extinction rates, ask yourself the following question: If sea-level rise and deforestation wiped out 90 percent of the habitats in part of the Bismarck Archipelago—for example, if A were reduced from 10,000 km^2 to 1000 km^2—what percentage of species would disappear? According to the graph, the number of bird species present would drop from about 75 to about 53. Thus, the answer is that roughly 30 percent of species would vanish. The slope of the line in species–area curves is species dependent.

The caveat with this method is that using the curve to extrapolate backward can cause overestimation of extinction rates due to assumptions inherent to the model. Thus, the technique must be used with caution and cross-referenced with other projection methods.

Estimating the Effect of Global Climate Change on Species Distributions How will climate change affect the global distribution of species? Can reliable predictions be made? Bioclimate envelope models, also called niche-based models, use the relationship between current species distributions and abiotic variables such as temperature and precipitation to project the future distributions of species under climate change.

For example, behavioral ecologist Barry Sinervo and an international team of colleagues took a two-step approach. First, they collected extensive data from one part of the globe, measuring extinction rates of 48 species of lizards at 200 sites in Mexico since 1975. The results were shocking: Twelve percent of local populations had already gone extinct because the temperature is changing too rapidly for the lizard populations to adapt (Chapter 56).

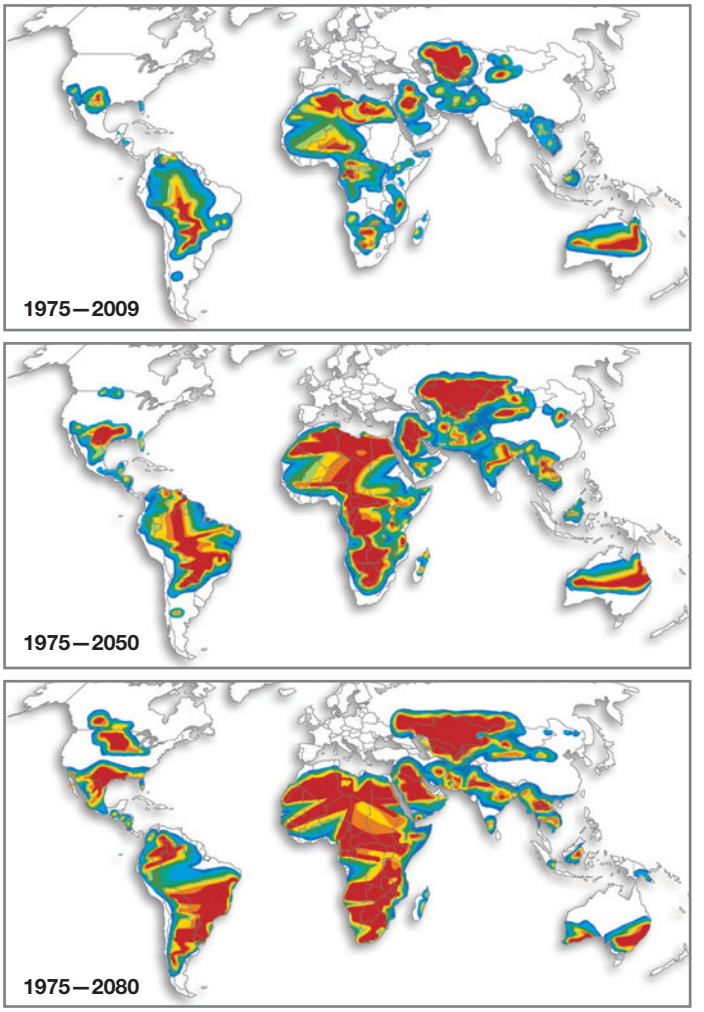

FIGURE 57.11 Predictions of Global Extinction Rates of Lizards. The projections are based on current extinction rates in Mexico and projections of global climate change, and were validated using observed extinction rates in regions of four other continents.

DATA: Sinervo, B., F. Mendez-De-La-Cruz, D. B. Miles, et al. 2010. *Science* 328: 894–899.

Sinervo and his team then used their data to predict worldwide responses to global warming given projected climate changes and the relationship between lizard extinctions and climate (**FIGURE 57.11**). They estimated that 4 percent of local lizard populations have already gone extinct worldwide and that lizard species extinctions could reach 20 percent by 2080. These alarming projections were validated with local data, suggesting that climate change is not a problem of the future—it is already a matter of life and death for lizard populations today.

Take-Home Messages about Making Biodiversity Predictions It is important to note that at all levels of study, a great deal of variation exists in projected future biodiversity. And this variation has different sources:

- Projections must make assumptions about future levels of threats to biodiversity, such as the extent of global warming, but these levels are unknown and depend on how rapidly humans are able to reduce emissions of greenhouse gases and improve land-use practices.
- Variation in some projections is due to knowledge gaps in basic biology. More data collection is greatly needed in these cases for accurate projections.
- Some of the variation is due to differences in how the models are constructed. Scientists address this issue by using multiple models to cross-check projections, and by validating their models with empirical data from the real world.

One of the greatest challenges of making projections is the ability to measure how different factors interact. For example, the precipitous worldwide decline in amphibians is due to a combination of factors ranging from habitat loss, pollution, and climate change to infection by a chytrid fungus. These factors affect each other in complex feedback loops, requiring a systems biology approach that quantifies the network of interactions.

check your understanding

C Y U

If you understand that . . .

- Species face multiple, interacting threats including habitat destruction and degradation, overexploitation, invasive species, pollution, and climate change.
- Projected extinction rates can be estimated from multiple methods by using a combination of empirical data and mathematical models.

✓ You should be able to . . .

1. Explain why fragmentation reduces habitat quality and leads to genetic problems.
2. Describe how you would determine whether each of the threats in Table 57.1 was affecting the orangutans of Borneo.

Answers are available in Appendix A.

57.3 Why Is Biodiversity Important?

One of the questions biologists have to address about biodiversity is one that you may have heard from friends or relatives: Who cares? People are concerned about their grades or job or health or car or love life. Why should they worry about something as abstract as biodiversity?

The answer has two parts, one biological and the other economic and cultural. Let's consider each part in turn.

Biological Benefits of Biodiversity

Do biological communities and ecosystems function better when species diversity is high? The effort to answer this question began in the mid-1980s and has blossomed.

Biodiversity Increases Productivity **FIGURE 57.12** summarizes a classic experiment on how species richness affects one of the most basic aspects of an ecosystem function: the production of biomass. Net primary productivity (NPP) is important because it is the source of chemical energy used by species throughout a food web (see Chapter 56).

As the "Experimental Setup" portion of the figure shows, David Tilman and colleagues divided 32 grassland plant species into five functional categories. The functional groups differ by the timing of their growing season and by whether they allocate most of their resources to manufacturing woody stems or seeds. The researchers planted 13-m by 13-m plots with a mixture of

RESEARCH

QUESTION: Do high species richness and high functional diversity of species increase aspects of ecosystem function such as net primary productivity (NPP)?

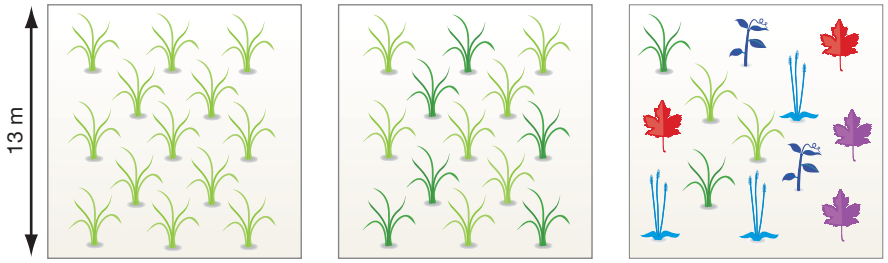
HYPOTHESIS: NPP increases with increasing species richness and with increasing functional diversity of species.

NULL HYPOTHESIS:

EXPERIMENTAL SETUP:

Plant a total of 289 experimental plots, each with up to 32 species and up to 5 functional groups:

Cool-season grasses: Grow in spring



Warm-season grasses: Grow in summer

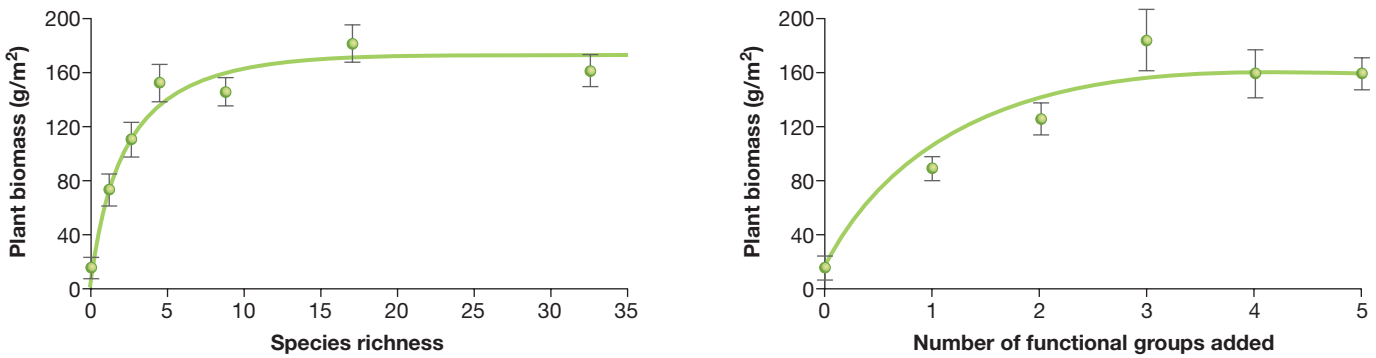
Legumes: Fix nitrogen

Woody plants: Trees, shrubs

Forbs: Lots of seeds

Examples of experimental plots:

1 species
1 functional group



2 species
1 functional group

6 species
4 functional groups

PREDICTION:

PREDICTION OF NULL HYPOTHESIS:

RESULTS:

CONCLUSION: In this plant community, NPP increases with increasing species richness and increasing functional diversity of plants, at least up to a point.

FIGURE 57.12 Evidence that the Productivity of Ecosystems Depends on the Number and Types of Species Present.

SOURCE: Tilman, D., J. Knops, D. Wedin, et al. 1997. The influence of functional diversity and composition on ecosystem processes. *Science* 277: 1300–1302.

✔**EXERCISE** Write in the null hypothesis and both sets of predictions.

between 0 and 32 randomly chosen species, representing from 0 to 5 functional categories, and measured the amount of aboveground biomass produced in each plot (see **FIGURE 57.13**).

The results, graphed in the "Results" section of Figure 57.12, indicate that both the number and type of species present had important effects on biomass production. Experimental plots with more species and with a wider diversity of functional groups were more productive.

Note that total biomass leveled off as species richness and functional diversity increased, however. This observation suggests that increasing species diversity improves ecosystem function only up to a point. This pattern suggests that at least some species in ecosystems are redundant in terms of their ability to contribute to productivity—a characteristic that is important to resilience.

Follow-up experiments in an array of ecosystems supported the conclusion that species richness has a positive impact on NPP, and they showed that several causal mechanisms may be at work.

- ***Resource use efficiency*** Diverse assemblages of plant species make more efficient use of the sunlight, water, and nutrients available and thus lead to greater overall productivity. For example, some prairie plants extract water near the soil surface, while others use water available a meter or more below the surface, a result of niche differentiation (Chapter 55). When species diversity is high, more overall water is used and more photosynthesis can occur.
- ***Facilitation*** Certain species or functional groups facilitate the growth of other species by providing them with nutrients, partial shade, or other benefits. In prairies, the presence of plants in the onion family may discourage herbivores, or the decaying roots, stems, and leaves from nitrogen-fixing species may fertilize other species.

FIGURE 57.13 Tilman's classic biodiversity study is among many conducted at the Cedar Creek Natural History Area in Minnesota.

- ***Sampling effects*** In many habitats, it is common to observe that one or two species are extremely productive. If the number of species in a study plot is low, it is likely that the "big producer" will be missing and NPP will be low. But if the number of species in a study plot is high, then likely the big producer is present and NPP will be high. Simply due to sampling, then, high-species plots will tend to outproduce low-species plots.

The three mechanisms listed are not mutually exclusive—several can operate at the same time. Further, long-term and large-scale experiments have shown that the reason for the pattern can change over time, that the slope of the curve can continue to rise over time, and that the strength of the diversity–productivity relationship depends on the evolutionary history of the species involved.

Does Biodiversity Lead to Stability? When biologists refer to the stability of a community, they mean its ability to

1. recover to former levels of productivity or species richness after a disturbance;
2. maintain productivity and other aspects of ecosystem function as conditions change over time.

Resistance is a measure of how much a community is affected by a disturbance. **Resilience** is a measure of how quickly a community recovers following a disturbance.

To test the hypothesis that diversity increases resistance and resilience, Tilman's team that did the work highlighted in Figure 57.12 followed up on a natural experiment. A **natural experiment** occurs when comparison groups are created by an unplanned, unmanipulated change in conditions.

In 1987–1988, a severe drought hit their study site. When the drought ended, the team asked whether species richness affected the response to the disturbance. As predicted, drought resistance appeared to be higher in more diverse communities than in less diverse ones.

In addition, the group analyzed the change in biomass in each plot four years after the drought versus the biomass before the drought. The data indicated that most plots containing five or fewer species showed a significant lowering of biomass after the disturbance, whereas all of the plots that contained more than five species regained the same biomass that they had before the disturbance. This is strong evidence that species-rich areas are more resilient following a disturbance.

More recent experiments on California grasslands suggest that species-rich ecosystems also may be less prone to invasion by exotic species. The hypothesis here is that species-rich communities use resources more efficiently—leaving less room for invasives. Taken together, these results from North American grasslands—and similar results from ecosystems around the world—lead biologists to be increasingly confident that species richness has a strongly positive effect on how ecosystems function.

Communities that are more diverse appear to be more productive, more resistant to disturbance and invasion, and more resilient

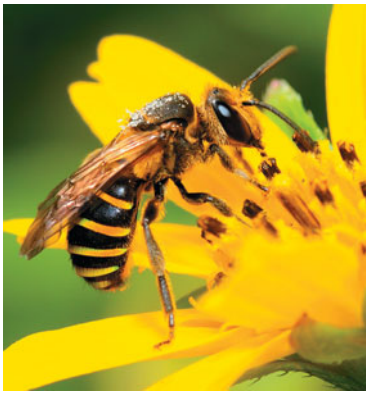
than communities that are less diverse. Increased species richness increases the services provided by ecosystems. By implication, biologists can infer that if ecosystems are simplified by extinctions, then productivity and other attributes might decrease.

Ecosystem Services: Economic and Social Benefits of Biodiversity and Ecosystems

The biological benefits of biodiversity—increased productivity, resistance, and resilience—benefit humans too. But this is just the beginning. The prosperity, health, and happiness of humans are completely dependent upon, and intertwined with, the preservation of biodiversity and functioning ecosystems.

Some species provide obvious direct benefits—bluefin tuna are prized as a food source, and tigers are a cultural icon. Other species offer direct benefits that are more difficult to observe—such as the control of crop-eating insects by bats, a service recently valued at $4 billion/year.

Further, many species indirectly benefit humans simply by serving ecological roles in functioning ecosystems, which in turn provide invaluable services such as soil formation and climate moderation. Considered collectively, all the direct and indirect benefits that humans derive from organisms and the ecosystems they compose are called **ecosystem services.**



In 1997 a team of ecologists and economists led by Robert Costanza estimated the value of ecosystem services at $33 trillion—almost twice the gross national product of all nations combined. Let's take a closer look at some of the material and nonmaterial services that nature provides, summarized in **TABLE 57.2**.

Provisioning Services Wild species have provided the raw material to fuel the development of human societies ever since the first large-scale, highly organized cultures began to develop about 10,000 years ago. People felled vast tracts of forest for building materials and fuel; selectively bred wild plants to yield food and fibers; domesticated animals to provide food, labor, and material goods; harvested the oceans for protein; and processed plants, animals, and fungi as sources of medicines. Today as much as ever, humans rely on other organisms for most of their food and material needs.

The value of provisioning services is relatively easy to quantify because food, fuels, wood, and other materials are traded in the marketplace. For example, mushrooms have an annual food value over $1 billion, the fishing industry has a value of $80–100 billion, and raw materials provided by tropical forests are valued at $300 billion.

Bioprospecting—the exploration of bacteria, archaea, protists, plants, fungi, and animals as novel sources of drugs or ingredients in consumer products—has benefited from the recent explosion of genetic and phylogenetic information. Biologists can now search genomes from a wide array of species to find alleles with desired functions. Recent advances are impressive: researchers have developed a potent painkiller from the paralyzing sting of tropical cone snails and a blood anticoagulant from the saliva of vampire bats.

SUMMARY TABLE 57.2 Ecosystem Services

Type of Service	Example
Provisioning services provide raw materials • Food • Fuel • Fiber and other materials • Medicines • Genetic resources	
Regulating services are part of Earth's life-support system • Climate moderation • Soil formation • Erosion control • O_2 and CO_2 regulation • Water capture • Water purification • Air cleaning • Flood control • Storm mitigation • Waste decomposition • Bioremediation	
Cultural services enrich quality of life • Aesthetics • Recreation • Education • Spiritual value • Human mental and physical health	
Supporting services enable all the other ecosystem services • Primary productivity • Nutrient cycling • Pollination • Biological control	

Regulating Services Services provided by functioning ecosystems—such as water purification, flood control, and waste decomposition—are part of Earth's life-support system. Yet, these regulating services are often taken for granted until human actions disrupt their function.

This was the case in New York City in the 1990s. New York City is known for its excellent drinking water, piped in from the watersheds of the Catskill Mountains. But the water quality declined as those watersheds became developed—and something had to be done. A cost–benefit analysis revealed that it was far cheaper to restore the ecosystem function of the watersheds ($1 billion) than to filter the water artificially ($6–8 billion up front plus $300 million annually). The "free" water purification services that had been provided by the forested Catskill ecosystem suddenly became quite valuable.

Cultural Services People integrate nature in their lives in diverse cultural ways, ranging from artistic celebrations to recreation, education, and spiritual contemplation. Eminent biologist and author Edward O. Wilson coined the term biophilia to refer to the innate, unconscious bond between humans and other organisms as a result of our coevolutionary history. Wilson's hypothesis is that this bond inspires our deep need for, and appreciation of, nature.

An increasing number of studies are showing that humans who are removed from natural environments—such as people who spend most of their time in cities—often suffer both physical and psychological setbacks. Conversely, people who spend more time outdoors in nature, especially as children, tend to have: reduced stress; reduced rates of obesity, diabetes, depression, and attention deficit and hyperactivity disorder; improved problem-solving skills; enhanced creativity and curiosity; improved sleep patterns; and improved vision, among other traits.

On average, people who spend more time surrounded by nature tend to be healthier and happier. (How much time do you spend outdoors?) Government agencies and businesses are taking note because human health and happiness also have economic value.

Supporting Services Some ecosystem services support all the other categories of services. Primary productivity is a key example because the amount of biomass generated affects the provisioning, regulating, and cultural services that ecosystems can provide.

In a similar way, pollination and pest control are critical to multiple ecosystem services. The value of pollination became clear in a region in China where the excessive use of pesticides led to a particularly sharp decline of bees. Human workers must now pollinate apple, pear, and peach orchards by hand, at great expense (**FIGURE 57.14**). In the United States alone, insect-pollinated crops like almonds, apples, and chocolate produce $40 billion worth of products annually.

The air you breathe, the water you drink, and the soils that grow the food you eat are services that ecosystems provide. The quality of your life is tied to the quality of those ecosystems.

FIGURE 57.14 Hand Pollination of Fruit Trees. Following a decline of bees due to pesticide use, workers in Maoxian County, China, hand pollinate entire orchards.

An Ethical Dimension?

The data reviewed in this section suggest that there are sound economic and biological reasons to preserve species and ecosystem function. People live better, and ecosystems work better, when biodiversity is high.

But in addition, an array of biologists, philosophers, and religious leaders argue that humans have an ethical obligation to preserve species and ecosystems. There are at least three arguments for this position:

1. Organisms have intrinsic worth. Humans diminish the world by extinguishing species and destroying ecosystems.

check your understanding

C Y U

If you understand that . . .

- Experimental plots with higher species richness tend to have higher productivity and show increased stability in response to disturbance or changed abiotic conditions.
- Biodiversity and functioning ecosystems provide many provisioning, regulating, cultural, and supporting services to humans.

✓ You should be able to . . .

Design an experiment to test the hypothesis that the rain forest of Borneo is more effective at building soil, retaining soil nutrients, and minimizing soil erosion than the oil palm plantations are.

Answers are available in Appendix A.

2. Industrialized nations are responsible for most of the environmental harm, yet poor countries are disproportionately affected by the consequences of these actions. It is unethical for rich countries to inflict hardship on poor countries.
3. It is unethical for the current generation to deprive future generations of ecosystem services.

Thus, extinction and disruption of ecosystem function are moral issues as well as biological and economic problems. One of the most important reasons to preserve biodiversity and ecosystem function may simply be that it is the right thing to do.

57.4 Preserving Biodiversity and Ecosystem Function

Extinction is irreversible—and biodiversity loss is not slowing down. But there is reason for hope.

Solving any global problem requires a common goal to be defined. In the case of preserving biodiversity and ecosystem function, the objective is to sustain diverse communities in natural landscapes while supporting the extraction of resources required to maintain the health and well-being of the human population. Given the extreme rate of deterioration of present conditions on Earth, conservation biologists often feel like doctors in a busy emergency room: Triage is necessary to maximize positive outcomes. This effort generates sober acceptance of some inevitable losses but vigorous fighting for important gains.

A number of international organizations and agreements are striving to reduce the threats to biodiversity. Central among them is the Convention on Biological Diversity (CBD), which convened in 1992 to establish conservation targets for 2010—many of which were not met. The CBD convened again in 2010 to establish new goals for 2020. These goals serve as an important organizational framework for the international effort. What's working? And what can you do to help?

Addressing the Ultimate Causes of Loss

To begin, most biologists recognize that it will be impossible to preserve high species diversity and high-functioning ecosystems if two things happen:

1. the human population grows to 10 billion or more—from its current 7 billion—over the next half-century, as projected by the "high-fertility" scenario (see Chapter 54); and
2. the rate of consumption of fossil fuels and other resources does not decline, especially in industrialized nations and growing developing nations (see Chapter 56), because consumption threatens biodiversity not only directly but also indirectly via climate change.

While it is complex and controversial to pinpoint a human carrying capacity for the planet (Chapter 54), it is clear that humans are nearing, or have surpassed, some of the recoverable limits of available resources. The way forward involves both reducing population growth and improving **sustainability**—the managed use of resources at a rate only as fast as the rate at which they are replaced.

You may be familiar with efforts to develop renewable sources of energy, promote agricultural and forestry practices that maintain productivity without the addition of synthetic fertilizers or groundwater, limit fishing catches so that populations do not crash irrecoverably, and recycle metals and other raw materials. In essence, the challenge is to create ways for humans to live off the resources that are being produced continuously on Earth rather than using species to extinction and exhausting resources like petroleum, groundwater, and topsoils that have been stored for centuries or millennia.

It may take decades for human population size and resource use to stabilize and for sustainable development practices to become widespread. In the meantime, thousands of species and untold ecosystem services may be lost. What specific approaches do conservationists use to protect natural resources?

Let's consider several examples, while asking: "What level of biodiversity is this targeting?" and "What threats to biodiversity does this approach address?"

Conservation of Genetic Diversity, Populations, and Species

Despite the discouraging persistence of biodiversity loss, conservation efforts have managed a number of successes in preserving genetic diversity, populations, and species in many locations around the globe. What are these successes?

Management Plans for Invasive Species The costs of eradicating some invasive species are so enormous that they outweigh the benefits. However, global awareness of the problem has slowly led to measures that limit the exchange of species, such as requirements that ships exchange ballast water out at sea (an inhospitable environment for coastal species) rather than in port, that cargoes are inspected at border crossings, and that nurseries stop selling invasive plants. Prevention is more effective than treatment, so education is the key.

Seed Banks Agricultural scientists are preserving diverse strains of crop plants in **seed banks**—long-term storage facilities. In addition, they are using wild relatives of domesticated species in breeding programs aimed at improving crop traits. The goal of both efforts is to avoid the loss of valuable genetic diversity.

Ex Situ Conservation and Reintroduction Some species—including Pere David's deer, Przewalski's horse, and the Arabian oryx—are extinct in the wild and exist only in captivity. These animals are examples of **ex situ conservation**—the preservation of species in zoos, aquaria, wildlife ranches, botanical gardens, or other artificial settings.

Translated literally, ex situ means out of place. The name was inspired by a contrast with in situ ("in place") conservation—the establishment of protected areas where populations can be

maintained in their natural habitat. Ex situ conservation is not ideal, but it is preferred over extinction.

In some cases, captive breeding of ex situ individuals and reintroduction into the wild have succeeded in creating wild populations of endangered species. Recall, for example, the successful effort to establish new flocks of whooping cranes by using eggs and young produced in zoos and other breeding centers (see Chapter 54). The peregrine falcon, California condor, and several other species have been rescued from the brink of extinction by captive breeding and reintroduction to the wild.

Genetic Restoration When habitat fragmentation results in small, isolated populations that are vulnerable to the loss of genetic diversity from chance events, genetic restoration can sometimes be accomplished by artificial gene flow.

Consider the case of a remnant population of the endangered Florida panther in the swampland of southern Florida. By the early 1990s, only about 25 adults remained, and they exhibited several recessive disorders and low genetic diversity—both signs of inbreeding. Using a population viability analysis (PVA; see Section 57.2), conservationists gave the population a 95 percent likelihood of extinction in two decades.

In an effort to prevent this outcome, the U.S. Department of the Interior moved eight panthers (locally called "pumas") from Texas to Florida to introduce new alleles into the Florida population. Geneticist Stephen O'Brien and colleagues followed the genetic consequences, some of which are shown in **FIGURE 57.15** (see inbreeding depression data in Chapter 26). The success of the genetic restoration was evident. The number of panthers quadrupled in 10 years, and the offspring of hybridized animals were larger, stronger, and had reduced incidents of defects.

Note, however, that as time went on, the rate of increase in population size leveled off. Also, the panther habitat continues to deteriorate. Ongoing conservation efforts are needed to successfully protect this panther population from extinction.

Wildlife Corridors One longer-term solution to enabling gene flow among isolated populations is the establishment of **wildlife corridors,** strips of undeveloped habitat that connect preserved areas. In some cases, wildlife corridors are as simple as a walkway under a major highway, so that animals such as salamanders can move from one side to the other without being killed. In other cases, a corridor can consist of 1000 km of makeshift paths across private and public lands, such as the corridors used by isolated populations of tigers in southern India.

By facilitating the movement of individuals, the goals of corridors are to

- allow areas to be recolonized if a species or a population was lost;
- encourage gene flow that introduces new alleles—counteracting the deleterious effects of genetic drift and inbreeding.

Do wildlife corridors actually work? To answer this question experimentally, ecologist Ellen Damschen and colleagues established a series of restored natural areas in the middle of a large, species-poor pine plantation in South Carolina. This project was the equivalent of restoring patches of grassland habitat in the middle of an enormous cornfield. Some of the restoration sites were connected by corridors, while others were isolated. By monitoring the composition of species inside each habitat patch over time, the group was able to show that when compared to unconnected patches, connected patches are steadily gaining more species over time (**FIGURE 57.16**). This is strong evidence that wildlife corridors can increase overall species richness in a metapopulation.

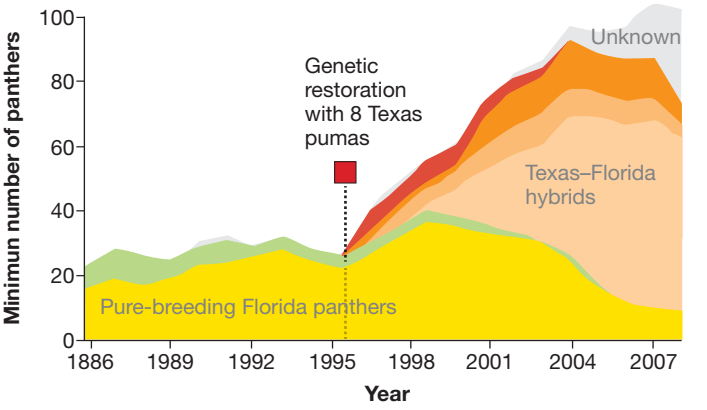


FIGURE 57.15 Experimental Evidence that Gene Flow Can Alleviate Genetic Problems in Small Populations. After eight Texas pumas were introduced to Florida in 1995, the Florida population of panthers quadrupled in size.

DATA: Johnson, W. E., D. P. Onorato, M. E. Roelke, et al. 2010. *Science* 329: 1641–1645.

Designing Effective Protected Areas By far the most effective strategy for preserving biodiversity is to protect entire areas of land and sea from exploitation in the first place.

The bad news is that more than two-thirds of the terrestrial biodiversity hotspots lack protection entirely, or have incomplete protection, and less than 0.5 percent of the oceans are protected. Incomplete protection occurs when areas are designated as protected but have insufficient enforcement—such as from poachers.

The good news is that the total amount of protected area is increasing at a steady rate globally. By strategically protecting prime habitat areas, countries worldwide can realize many benefits. For

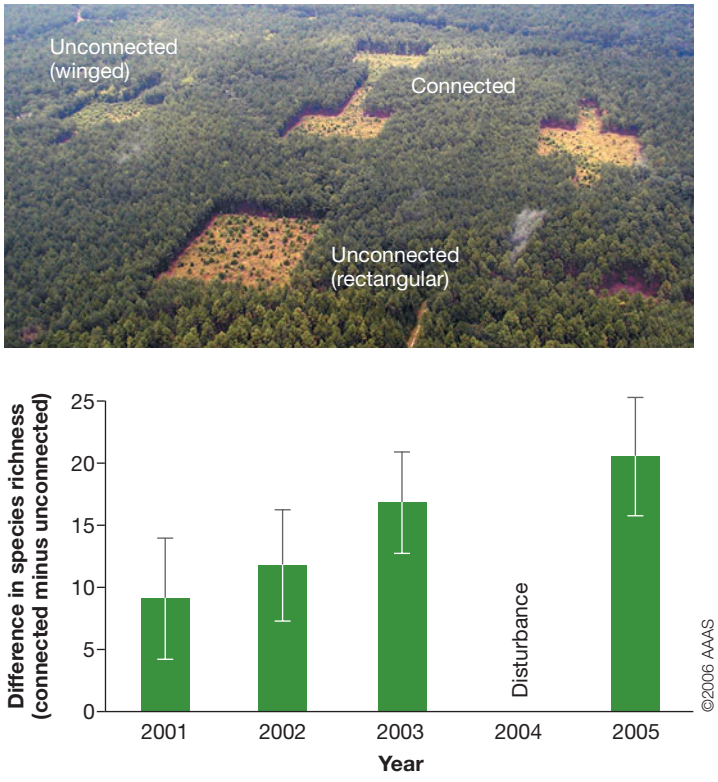

FIGURE 57.16 Experimental Evidence that Wildlife Corridors Work. This graph plots the difference in species richness between connected and unconnected plots. Species richness could not be assessed in 2004 because the study plots were burned as part of a program to restore natural habitats.

✔**QUANTITATIVE** Draw and label bars showing what this graph would look like if corridors had no effect on species richness.

example, preservation of rain forest in Borneo solves many problems: reducing incidence of droughts, floods, and fires, protecting diverse species, and storing carbon.

Researchers are using a geographic approach called the Gap Analysis Program (GAP) to assess the effectiveness of the current system of protected areas. A GAP tries to identify gaps between geographic areas that are particularly rich in biodiversity and areas that are actually managed for the preservation of biodiversity. Mismatches help to identify areas that are high priorities for conservation efforts.

Conservation of Ecosystem Function

As the biological and economic value of the associated services becomes more apparent, many countries are paying more attention to the conservation and restoration of ecosystem function than ever before. Can degraded ecosystems be restored?

Ecosystem Restoration In many areas of the world, ecosystems are already heavily degraded or lost. The state of Illinois, for example, was estimated to contain 22 million acres of prairie when European settlers arrived; today only about 2000 acres of this biome remain (0.009 percent). When natural areas are badly degraded or gone, biologists turn to restoration.

Thousands of large-scale and small-scale ecosystem restoration and reforestation projects are now occurring around the globe. Recall the dire scenario in Borneo described at the beginning of this chapter. Willie Smits had been working in Borneo for two decades in a desperate attempt to slow the rate of deforestation and save orangutans from the brink of extinction. Frustrated by his lack of progress, he decided to try a new approach—the restoration of 2000 ha of clear-cut rain forest in Samboja.

While Smits would be the first to agree that primary forest is of greater ecological value than restored forest, his progress in just a few years since 2002 is remarkable:

- Over 1600 tree species in a multilayered canopy
- 137 species of birds (up from 5); 9 species of primates
- rainfall up 25 percent; temperature down 3–5°C
- 3000 people earning income

The cornerstone of Smits's Samboja Lestari ("Everlasting Forest") project is integrating the ecological restoration of the forest along with the economic restoration of the local Dayak tribe—a win–win scenario (**FIGURE 57.17**). Although the size of Samboja Lestari is relatively small and the clear-cutting of rain forest continues in Borneo at a rapid pace, Smits's success is reason for hope. How successful are ecosystem restoration projects in general?

Ecologists Holly Jones and Oswald Schmitz analyzed 240 of such restoration projects to determine the resilience of ecosystems after human disturbances. **FIGURE 57.18** (on page 1192) shows some of their surprising results. Recovery of biomass following disturbances was much slower in forests than in other ecosystems, but unexpectedly fast overall—decades rather than centuries. Similarly, biomass recovery was much slower in agricultural and deforested areas, but more rapid overall than anticipated.

FIGURE 57.17 Ecosystem Restoration Effort in Samboja Lestari, Borneo. Rain forest restoration in Borneo is critical to the survival of orangutans. Indonesian workers prepare rescued orangutans for release into forest sanctuaries like Samboja.

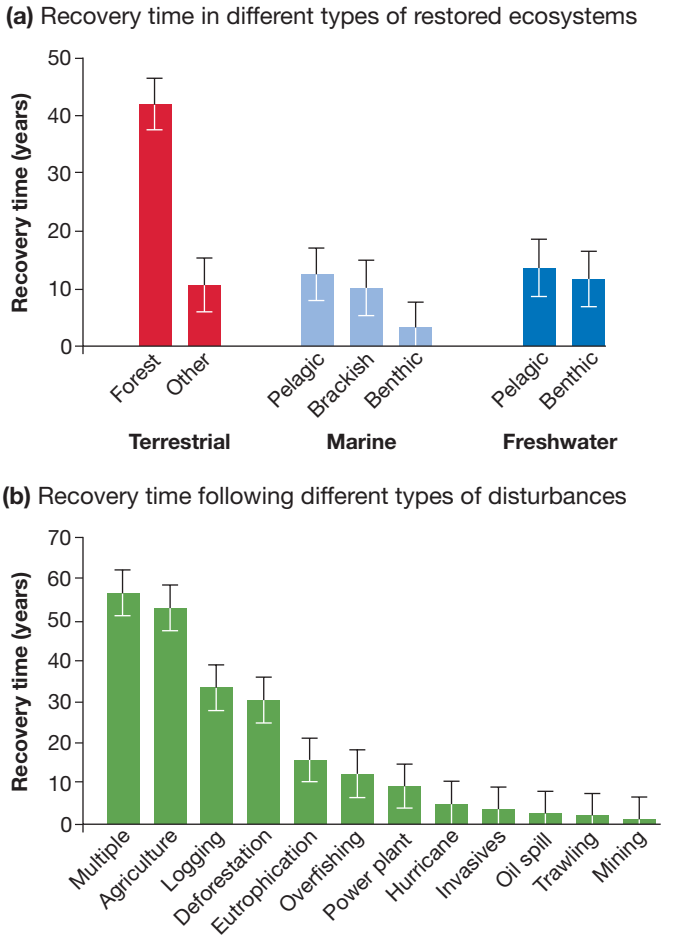

FIGURE 57.18 Average Recovery Times of Ecosystem Biomass. **(a)** Recovery of biomass following disturbances was much slower in forests than in other ecosystems, but surprisingly fast overall. **(b)** Recovery was much slower in agricultural and deforested areas, but relatively rapid in other areas.

DATA: Jones, H. P., and O. J. Schmitz. 2009. *PLoS ONE* 4: e5653.

Biomass recovery is not equivalent to biodiversity or ecosystem function, but many of the restoration projects show positive outcomes in terms of species richness and other variables. It is not too late to restore many degraded habitats.

In general, restoration success is positively correlated with the size of the area restored, its connectedness, remoteness, and the intactness of surrounding areas. However, another take-home message from the restoration studies is that an accumulation of many small changes can also have a big effect. If you and all your neighbors planted several native trees, shrubs, or other plants in your yards or neighborhoods, you could have a very positive effect on biodiversity and ecosystem function right where you live.

Quantifying Ecosystem Services Many ecologists are convinced that the traditional approaches to conservation are doomed to fail on their own—nature reserves are too small and isolated to succeed in preserving sufficient biodiversity and ecosystem function. Many of these scientists advocate for an ecosystem services approach to conservation—a quantification of ecosystem services to make explicit in the marketplace that long-term human prosperity depends on the preservation of these services.

The idea is that the cost of replacing ecosystem services is at least 10 to 100 times higher than the cost of maintaining them—if they are replaceable at all (in which case they are infinitely valuable). Therefore, it is an economic imperative to protect these services before they are lost.

The problem is that quantifying ecosystem services is not an easy task, and incorporating these services into the marketplace requires a complicated collaboration among scientists, governments, nongovernmental organizations (NGOs), businesses, educators, communities, and local leadership. Further, policy mechanisms can be challenging to implement.

Successful experiments are under way, however. For example, the Costa Rican government has made policy changes that allow landowners to be compensated for the ecosystem services provided by their properties, such as carbon storage, biodiversity conservation, and scenic beauty. The payments are funded largely from transportation taxes. The logic here is that the Costa Rican economy will profit more in the long term from **ecotourism**—recreational visits to their wild places (**FIGURE 57.19**)—if their wild places are preserved from logging by private owners in the short term. But the private owners must be compensated.

Numerous other similar programs are in development. A global program called REDD (Reducing Emissions from Deforestation

FIGURE 57.19 Ecotourism in Costa Rica. Ecotourists flock to witness the spectacular biodiversity of the Monteverde Cloud Forest Reserve in Costa Rica.

and forest Degradation) is designed to reduce emissions from deforestation by paying landowners *not* to clear-cut—thereby slowing climate change. Other than curbing the production of greenhouse gases in the first place, the preservation of forests is currently the single most effective method of slowing climate change—which is otherwise expected to have enormous economic impacts.

In general, although social and political changes are difficult to implement, outcomes that boost biodiversity and ecosystem function are a boon to humans.

Take-Home Message

Your generation is facing the most serious global environmental crisis in the history of our species. The decisions you make, ranging from how many children you have to how much you drive a car, will have far-reaching consequences. Change happens one person at a time. It can be done.

As someone with a background in biology, you have the intellectual tools to make an important, positive impact. In addition to studying life, biologists have an obligation to help save it.

CHAPTER 57 REVIEW

For media, go to MasteringBiology

If you understand . . .

57.1 What Is Biodiversity?

- Biodiversity is quantified at the level of genetic diversity, species diversity, and ecosystem diversity.
- Only about 1.5 million species have been named out of an estimated 10 to 100 million species on Earth.
- On average, biodiversity tends to be higher in the tropics than near the poles, higher on land than in the sea, and higher in areas with geographic diversity.
- Tropical rain forests are particularly species rich, containing at least 50 percent of all species.
- Biodiversity hotspots can be mapped based on species richness, areas of endemism, degree of threat, and/or unique ecological or evolutionary characteristics.

✔ **You should be able to explain how you could measure biodiversity in the restored rain forest of Borneo at the genetic, species, and ecosystem levels.**

57.2 Threats to Biodiversity

- The sixth mass extinction in the history of life is occurring due to human impacts. Species are vanishing faster than at virtually any other time in Earth's history.
- Habitat destruction and degradation are currently the leading causes of extinction. Conversion of primary forest to agricultural fields and housing developments is particularly devastating.
- Although overexploitation also occurs on land, it is the dominant threat for marine species.
- Invasive species are a long-standing problem on islands, but now they also threaten communities on continents.
- Many types of pollutants are found virtually everywhere on Earth, but they are particularly threatening to aquatic species.
- Climate change is a significant threat to biodiversity due to both direct and indirect impacts.
- To estimate how many species will go extinct in the near future, biologists make calculations based on combinations of variables including current extinction rates, habitat sizes, predicted shifts in climate envelopes, demographics, and species interactions.

✔ **You should be able to explain why small, geographically isolated populations of orangutans in isolated islands of forest are at high risk of extinction.**

57.3 Why Is Biodiversity Important?

- At the ecosystem level, experiments have shown that high species richness increases aspects of ecosystem function such as productivity, resistance to disturbance, and ability to recover from disturbance.
- Humans gain direct economic benefits from fishing, forestry, agriculture, and other activities that depend on materials provided by ecosystems.
- Humans also benefit from the ability of functioning ecosystems to build and hold soil, moderate local climates, retain and cycle nutrients, retain surface water and recharge groundwater, prevent flooding, and produce oxygen.
- Human happiness and health depend on healthy ecosystems.

✔ **You should be able to explain why the high species richness of rain forests leads to high productivity, in terms of the efficiency of resource use, when compared to oil palm plantations.**

57.4 Preserving Biodiversity and Ecosystem Function

- The major threats to biodiversity—habitat destruction and climate change—will not lessen until the human population stabilizes and resource use becomes sustainable.
- Solutions to the biodiversity crisis include preserving genetic diversity, protecting key habitats, restoring ecosystems, and integrating conservation with public policy so that protecting ecosystem services is a greater part of both global and local decision-making processes.
- Ecosystem restoration efforts are having a positive impact on biodiversity around the world. Conservation efforts make a difference.

✔ **You should be able to evaluate whether the 12 percent of land area protected thus far will be enough to avert a mass extinction.**

TEST YOUR KNOWLEDGE

Answers are available in Appendix A

1. What does a species–area plot show?
   - **a.** the overall distribution, or area, occupied by a species
   - **b.** the relationship between the body size of a species and the amount of territory or home range it requires
   - **c.** the number of species found, on average, in tropical versus northern areas
   - **d.** the number of species found, on average, in a habitat of a given size
2. What does species richness refer to?
   - **a.** the number of species in an area
   - **b.** the quality of species in an area
   - **c.** the functional importance of a species
   - **d.** the abundance of individuals within a species
3. What is resilience?
   - **a.** resistance to change during a disturbance
   - **b.** the ability to recover from a disturbance
   - **c.** production of aboveground biomass
   - **d.** total biomass production (above- and belowground)
4. What is a biodiversity "hotspot"?
   - **a.** an area where an all-taxon survey is under way
   - **b.** an area where an environmental sequencing study has been completed
   - **c.** a habitat with high NPP
   - **d.** an area with high species richness and high threat
5. Why do small populations become inbred?
   - **a.** They are often part of a metapopulation structure.
   - **b.** Genetic drift becomes a prominent evolutionary force.
   - **c.** Over time, all individuals become increasingly related.
   - **d.** Natural selection does not operate efficiently in small populations.
6. What is the primary cause of endangerment in marine environments?

TEST YOUR UNDERSTANDING

Answers are available in Appendix A

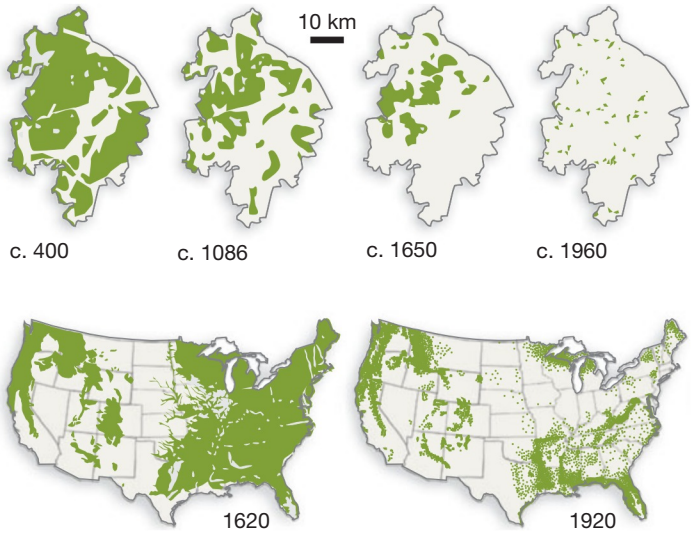
7. If you were asked to evaluate building materials, what would be most "sustainable" about the use of bamboo as a building material?
   - **a.** Bamboo is an invasive species due to its rapid growth rate.
   - **b.** Bamboo is harvested at the same rate at which it grows.
   - **c.** Bamboo is durable so it does not need to be replaced often.
   - **d.** Bamboo plantations create habitat for other species.
8. Biologists claim that the all-taxa survey now under way at the Great Smoky Mountains National Park in the United States will improve their ability to estimate the total number of species living today. Discuss the benefits and limitations that this data set will provide in understanding the extent of global biodiversity.
9. Some biologists prefer to focus efforts on preserving endangered species while others prefer to focus on preserving ecosystems. What is your opinion?
10. What evidence supports the hypothesis that species richness increases ecosystem functions, such as productivity, resistance to disturbance, and resilience?
11. Explain why the construction of wildlife corridors can help maintain biodiversity in a fragmented landscape.
12. What are ecosystem services? Does anyone own them or pay for them—that is, can you make money from them? How does quantifying ecosystem services affect efforts to protect ecosystems?

TEST YOUR PROBLEM-SOLVING SKILLS

Answers are available in Appendix A

13. The population size of mountain pine beetles in the American Northwest has long been held in check by freezing temperatures during the winters. As winters warm, populations of pine beetles are increasing, killing whitebark pine forest. Grizzly bears rely on the nuts of whitebark pine trees. Do you think climate change is affecting the fitness of the grizzly bear population?

a. No, because climate change is not occurring yet.



b. No, because climate change is affecting the beetles, not the bears.

c. Yes, because climate change is decreasing the food supply of the bears, which means they will be less strong.

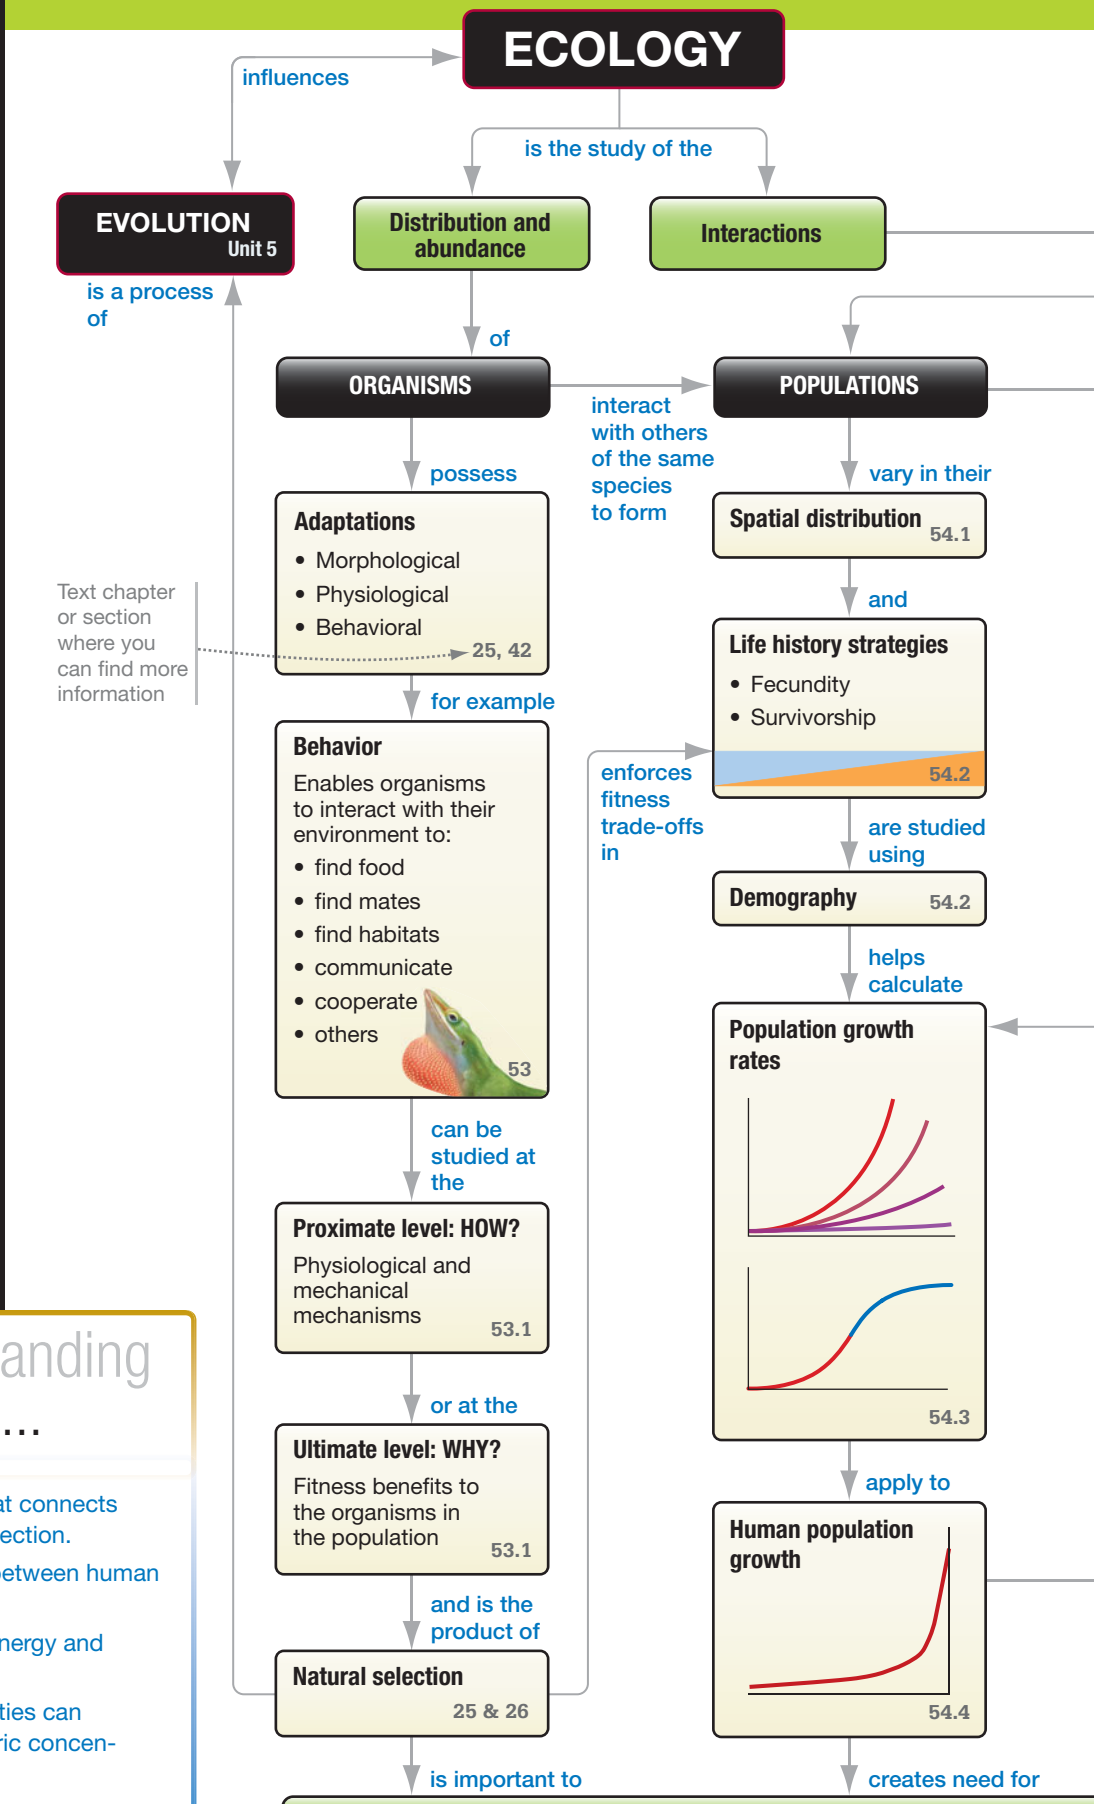
d. Yes, because climate change is decreasing the food supply of the bears, which is likely to reduce their ability to survive or reproduce.

14. You are helping to design a series of reserves in a tropical country. List the steps you would recommend for gathering data and creating a plan that would protect a large amount of biodiversity in a small amount of land.

15. The maps to the right chronicle the loss of old-growth forest (more than 200 years old) that occurred in Warwickshire, England, and in the United States. In your opinion, under what conditions is it ethical for conservationists who live in these countries to lobby government officials in Brazil, Indonesia, and other tropical countries to slow the rate of loss of old-growth forest?

16. Make a list of characteristics that would render a species particularly vulnerable to extinction by humans. Make a list of characteristics that would render a species particularly resistant to pressure from humans. Try to think of an example of each type of species.

The Big Picture



BIG PICTURE

Ecology's primary goal is to understand the distribution and abundance of organisms. To reach this goal, ecologists study how organisms interact with each other and their abiotic environments.

Human activities are causing radical changes in population sizes, climate, soils, water, and atmosphere. As a result, virtually every box and arrow in this concept map is being affected.

In addition to documenting changes, biologists are educating the public and policy makers about the value of biodiversity and healthy ecosystems, and researching the most effective ways to preserve species and keep ecosystems functioning normally.

Note that most boxes in the concept map indicate chapters and sections where you can go for review. Also, be sure to do the blue exercises in the Check Your Understanding box below.

CHAPTER 1

IN-TEXT QUESTIONS AND EXERCISES

p. 4 Fig. 1.2 analyze If Pasteur had done any of the things listed, he would have had more than one variable in his experiment. This would allow critics to claim that he got different results because of the differences in broth types, heating, or flask types—not the difference in exposure to preexisting cells. The results would not be definitive.
p. 6 apply The average kernel protein content would decline, from 11 percent to a much lower value over time.
p. 6 CYU apply The data points would all be about 11 percent, indicating no change in average kernel protein content over time.
p. 7 Fig. 1.4 apply Molds and other fungi are more closely related to green algae because they differ from plants at two positions (5 and 8 from left) but differ from green algae at only one position (8).
p. 8 Fig. 1.6 apply The eukaryotic cell is roughly 10 times the size of the prokaryotic cell.
p. 9 CYU evaluate From the sequence data provided, species A and B differ only in one ribonucleotide of the rRNA sequence (position 10 from left). Species C differs from species A and B in four ribonucleotides (positions 1, 2, 9, and 10). A correctly drawn phylogenetic tree would indicate that species A and B appear to be closely related, and species C is more distantly related. See **FIGURE A1.1**.
p. 13 (1) analyze You could conclude that the ants weren't navigating normally, because they had been caught and released and transferred to a new channel. **(2)** analyze You could conclude that the ants can't navigate normally on their manipulated legs.
p. 13 CYU The key here is to test predation rates during the hottest part of the day (when desert ants actually feed) versus other parts of the day. The experiment would best be done in the field, where natural predators are present. One approach would be to capture a large number of ants, divide the group in two, and measure predation rates (number of ants killed per hour) when they are placed in normal habitat during the hottest part of the day versus an hour before (or after). **(1)** analyze The control group here is the normal condition—ants out during the hottest part of the day. If you didn't include a control, a critic could argue that predation did or did not occur because of your experimental setup or manipulation, not because of differences in temperature. **(2)** analyze You would need to make sure that there is no difference in body size, walking speed, how they were captured and maintained, or other traits that might make the ants in the two groups more or less susceptible to predators. They should also be put out in the same habitat, so the presence of predators is the same in the two treatments.
p. 13 Fig. 1.10 analyze The interpretation of the experiment would not likely change, but your confidence in the conclusions drawn would be reduced if you used just one ant.

IF YOU UNDERSTAND . . .

1.1. understand Dead cells cannot regulate the passage of materials between exterior and interior spaces, replicate, use energy, or process information. **1.2** understand Observations on thousands of diverse species supported the claim that all organisms consist of cells. The hypothesis that all cells come from preexisting cells was supported when Pasteur showed that new cells do not arise and grow in a boiled liquid unless they are introduced from the air. **1.3** understand If seeds with higher protein content leave the most offspring, then individuals with low protein in their seeds will become rare over time. **1.4** understand A newly discovered species can be classified as a member of the Bacteria if the sequence of its rRNA contains some features found only in Bacteria. The same logic applies to classifying a new species in the Archaea or Eukarya. **1.5** understand (1) A hypothesis is an explanation of how the world works; a prediction is an outcome you should observe if the hypothesis is correct. (2) Experiments are convincing because they measure predictions from two opposing hypotheses. Both predicted actions cannot occur, so one hypothesis will be supported while the other will not.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. remember d **2.** understand d **3.** remember populations **4.** understand b **5.** understand An individual's ability to survive and reproduce **6.** understand c

✔ Test Your Understanding

7. evaluate That the entity they discovered replicates, processes information, acquires and uses energy, is cellular, and that its populations evolve. **8.** understand a **9.** understand Over time, traits that increased the fitness of individuals in this habitat became increasingly frequent in the population. **10.** understand Individuals with certain traits are selected, in the sense that they produce the most offspring. **11.** analyze Yes. If evolution is defined as "change in the characteristics of a population over time," then those organisms that are most closely related should have experienced less change over time. On a phylogenetic tree, species with substantially similar rRNA sequences would be diagrammed with a closer common ancestor—one that had the sequences they inherited—than the ancestors shared between species with dissimilar rRNA sequences. **12.** understand A null hypothesis specifies what a researcher should observe when the hypothesis being tested isn't correct.

✔ Test Your Problem-Solving Skills

13. analyze A scientific theory is not a guess—it is an idea whose validity can be tested with data. Both the cell theory and the theory of evolution have been validated by large bodies of observational and experimental data. **14.** apply If all eukaryotes living today have a nucleus, then it is logical to conclude that the nucleus arose in a common ancestor of all eukaryotes, indicated by the arrow you should have added to the figure. See **FIGURE A1.2**. If it had arisen in a common ancestor of Bacteria or Archaea, then species in those groups would have had to lose the trait—an unlikely event. **15.** evaluate The data set was so large and diverse that it was no longer reasonable to argue that noncellular lifeforms would be discovered. **16.** apply b

BIG PICTURE Doing Biology

p. 16 CYU (1) understand Biologists design and carry out a study, either observational or experimental, to test their ideas. As part of this process, they state their ideas as a hypothesis and null hypothesis and make predictions. They analyze and interpret the data they have gathered, and determine whether the data support their ideas. If not, they revisit their ideas and come up with an alternative hypothesis and design another study to test these new predictions. **(2)** understand There are many possible examples. Consider, for example, the experiment on navigation in foraging desert ants (Chapter 1). In addition to testing how the ants use information on stride length and number to calculate how far they are from the nest (multicellular organism and population levels), researchers also could test how the "pedometer" works at the level of cells and molecules. **(3)** analyze A hypothesis is a testable statement to explain a specific phenomenon or a set of observations. The word theory refers to proposed explanations for very broad patterns in nature that are supported by a wide body of evidence. A theory serves as a framework for the development of new hypotheses. **(4)** analyze The next step is to relate your findings to existing theories and the current scientific literature, and then to communicate your findings to colleagues through informal conversations, presentations at scientific meetings, and eventually publication in peer-reviewed journals.

CHAPTER 2

IN-TEXT QUESTIONS AND EXERCISES

p. 20 Fig. 2.3 apply There are 15 electrons in phosphorus, so there must be 15 protons, which is the atomic number. Since the mass number is 31, then the number of neutrons is 16.
p. 23 understand *Water:* arrows pointing from hydrogens to oxygen atom; *ammonia:* arrows pointing from hydrogens to nitrogen atom; *methane:* double arrows between carbons and hydrogens; *carbon dioxide:* arrows pointing from carbon to oxygens; *molecular nitrogen:* double arrows between nitrogens.
p. 23 Fig. 2.7 understand Oxygen and nitrogen have high electronegativities. They hold shared electrons more tightly than C, H, and many other atoms, resulting in polar bonds.
p. 24 CYU evaluate See **FIGURE A2.1**.

FIGURE A1.1

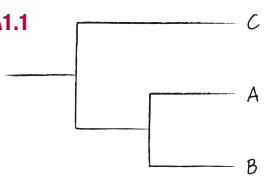

FIGURE A1.2

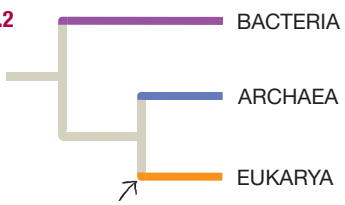

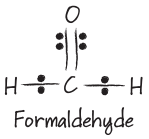

FIGURE A2.1

p. 25 (1) evaluate $^{\delta+}H–O^{\delta-}–H^{\delta+}$ **(2)** apply If water were linear, the partial negative charge on oxygen would have partial positive charges on either side. Compared to the actual, bent molecule, the partial negative charge would be much less exposed and less able to participate in hydrogen bonding.
p. 26 Fig. 2.14 understand Oils are nonpolar. They have long chains of carbon atoms bonded to hydrogen atoms, which share electrons evenly because their electronegativities are similar. When an oil and water are mixed, the polar water molecules interact with each other via hydrogen bonding rather than with the nonpolar oil molecules, which interact with themselves instead.
p. 28 Table 2.2 understand "Cause" (Row 1): electrostatic attractions between partial charges on water and opposite charges on ions; hydrogen bonds; water and other polar molecules. "Biological Consequences" (Row 2): ice to float; freezing solid. "Cause" (Row 4): lots of heat energy; break hydrogen bonds and change water to a gas.
p. 29 apply The proton concentration would be 3.2×10^{-9} M.
p. 29 Fig. 2.17 apply The concentration of protons would decrease because milk is more basic (pH 6.5) than black coffee (pH 5).
p. 30 apply The bicarbonate concentration would increase. The protons (H^+) released from carbonic acid would react with the hydroxide ions (OH^-) dissociated from NaOH to form H_2O, leaving fewer protons free to react with bicarbonate to reform carbonic acid.
p. 32 CYU (1) apply The reaction would be spontaneous based on the change in potential energy; the reactants have higher chemical energy than the products. The entropy, however, is not increased based on the number of molecules, although heat given off from the reaction still results in increased entropy. **(2)** understand The electrons are shifted farther from the nuclei of the carbon and hydrogen atoms and closer to the nuclei of the more electronegative oxygen atoms.
p. 32 Fig. 2.19 remember See **FIGURE A2.2**.
p. 33 Fig. 2.21 analyze The water-filled flask is the ocean; the gas-filled flask is the atmosphere; the condensed water droplets are rain; the electrical sparks are lightning.
p. 37 Table 2.3 understand All the functional groups in Table 2.3, except the sulfhydryl group (–SH), are highly polar. The sulfhydryl group is only very slightly polar.

IF YOU UNDERSTAND . . .

2.1. understand The bonds in methane and ammonia are all covalent, but differ in polarity: Methane has nonpolar covalent bonds while ammonia has polar covalent bonds. Sodium chloride does not have covalent bonds; instead, ionic bonds hold the ionized sodium and chloride together. **2.2** understand Assuming neutral pH, amino and hydroxyl groups would interact with the partial negative charge on water's oxygen, because they both carry a positive charge (partial for the hydrogen in the hydroxyl). The carboxyl group would interact with the partial positive charges on water's hydrogens, since it would carry a negative charge after losing the proton from its hydroxyl. **2.3** understand Like solar radiation, the energy in electricity generates free radicals that would promote the reaction. **2.4** understand "Top-down" approach: The reaction responsible for synthesizing acetic acid is observed in cells and can serve as an intermediate for the formation of a more complex molecule (acetyl CoA) that is used by cells throughout the tree of life. "Bottom-up" approach: This reaction can also occur under conditions that mimic the early Earth environment in deep-sea vents. **2.5** apply The hydroxyls would increase the solubility of octane by introducing polar covalent bonds, which would make the molecule more hydrophilic. The high electronegativity of oxygen would decrease the potential energy of the modified molecule.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. understand b **2.** remember a **3.** remember c **4.** remember d
5. remember Potential energy and entropy. **6.** remember The prebiotic soup model and the surface metabolism model.

✔ Test Your Understanding

7. apply c. Acetic acid has more highly electronegative oxygen atoms than the other molecules. When bonded to carbon or hydrogen, each oxygen will result in a polar covalent bond. **8.** apply Relative electronegativities would be F > O > H > Na. One bond would form with sodium, and it would be ionic. **9.** understand When oxygen is covalently bonded to hydrogen, the difference in electronegativities between the atoms causes the electrons to spend more time near the oxygen. In contrast, the atoms in H_2 and O_2 have the same electronegativities, so they equally share electrons in their covalent bonds. **10.** apply See **FIGURE A2.3**. **11.** apply The dissociation reaction of carbonic acid lowers the pH of the solution by releasing extra H^+ into the solution. If additional CO_2 is added, the sequence of reactions would be driven to the right, which would make the ocean more acidic. **12.** understand The carbon framework determines the overall shape of an organic molecule. The functional groups attached to the carbons determine the molecule's chemical behavior, because these groups are likely to interact with other molecules.

✔ Test Your Problem-Solving Skills

13. analyze b. **14.** analyze No, they don't conflict. Shells that are farther from the protons (positive charges) in the nucleus house electrons that have greater potential energy than shells closer to the nucleus. **15.** analyze One possible concept map relating the structure of water to its properties is shown below (see **FIGURE A2.4**). **16.** create In hot weather, water absorbs large amounts of heat due to its high specific heat and high heat of vaporization. In cold weather, water releases the large amount of heat that it has absorbed.

FIGURE A2.2

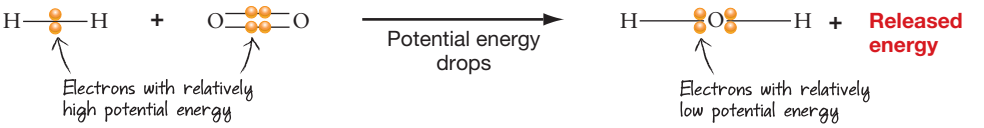

FIGURE A2.3

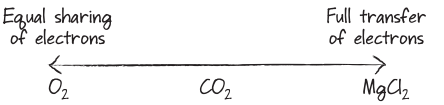

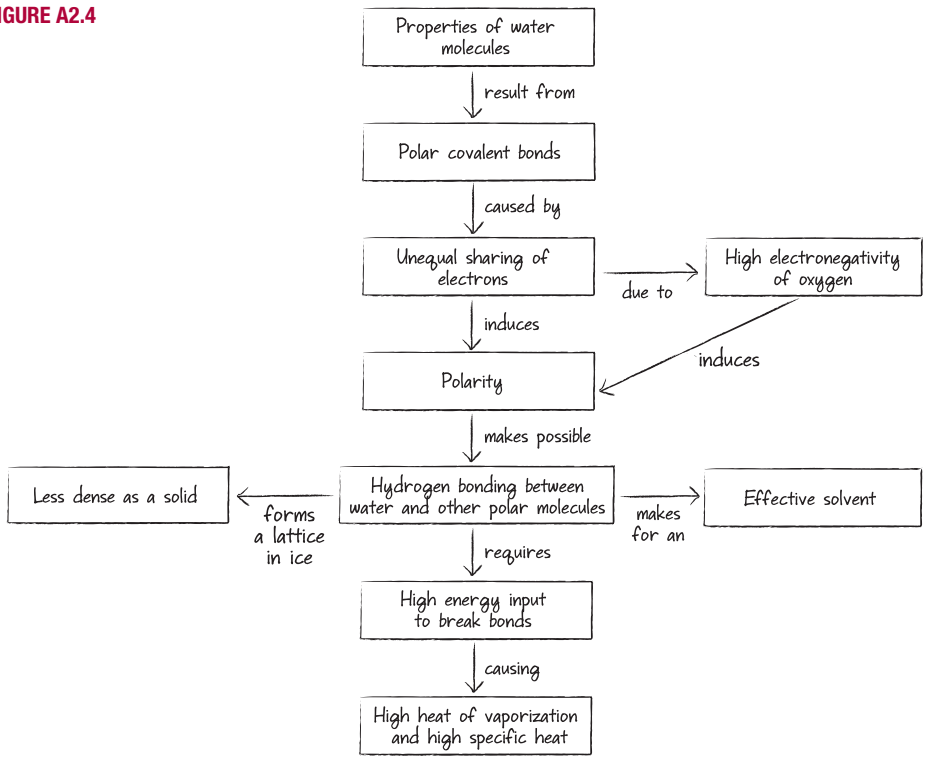

FIGURE A2.4

CHAPTER 3

IN-TEXT QUESTIONS AND EXERCISES

p. 43 Fig. 3.2 understand The green R-groups contain mostly C and H, which have roughly equal electronegativities. Electrons are evenly shared in C–H bonds and C–S bonds, so the groups are nonpolar. Cysteine has a sulfur that is slightly more electronegative than hydrogen, so it will be less nonpolar than the other green groups. All of the pink R-groups have a highly electronegative oxygen atom with a partial negative charge, making them polar.
p. 44 apply From most hydrophilic to most hydrophobic: (1) aspartate, (2) asparagine, (3) tyrosine, (4) valine. The most hydrophilic amino acids will have side chains with full charges (ionized), like aspartate, followed by those with the largest number of highly electronegative atoms, like oxygen or nitrogen. Highly electronegative atoms produce polar covalent bonds with carbon or hydrogen. The most hydrophobic will not have oxygen or nitrogen in their side chains, but instead will have the largest number of C–H bonds, which are nonpolar covalent.
p. 47 CYU understand See **FIGURE A3.1**.
p. 52 CYU (1) understand Secondary, tertiary, and quaternary structure all depend on bonds and other interactions between amino acids that are linked in a chain in a specific order (primary structure). **(2)** apply There would be 20^5 different peptides, or 3.2×10^6 different primary sequences.
p. 55 CYU apply Amino acid changes would be expected to be in the active site or in regions that affect the folded structure of this site. Either of these changes could result in a different active site that either binds a new substrate or catalyzes a different reaction.

IF YOU UNDERSTAND . . .

3.1. understand Look at the R-group of the amino acid. If there is a positive charge, then it is basic. If there is a negative charge, then it is acidic. If there is not a charge, but there is an oxygen atom, then it is polar uncharged. If there is no charge or oxygen, then it is nonpolar.
3.2 apply Nonpolar amino acid residues would be found in the interior of a globular protein, grouped with other nonpolar residues due to hydrophobic interactions.
3.3 analyze Both calmodulin and infectious prions require some form of induction to achieve their active conformations. Calcium ions are required for calmodulin to fold into its functional structure while prions are induced to change their shape by other, improperly folded prion proteins. **3.4** analyze *Catalysis:* Proteins are made of amino acids, which have many reactive functional groups, and can fold into different shapes that allow the formation of active sites. *Defense:* Similar to catalysis, the chemical properties and capacity for different shapes allows proteins to be made that can attach to virtually any type of invading virus or cell. *Signaling:* The flexibility in protein structure allows protein activities to be quickly turned on or off based on binding to signal molecules or ions.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. remember d **2.** remember The atoms and functional groups found in the side chains. **3.** remember b **4.** remember b
5. understand The order and type of amino acids (i.e., the primary structure) contains the information that directs folding. **6.** understand a

✔ Test Your Understanding

7. understand Because the nonpolar amino acid residues are not able to interact with the water solvent, they are crowded together in the interior of a protein and surrounded by a network of hydrogen-bonded water molecules. This crowding leads to the development of van der Waals interactions that help glue the nonpolar side chains together. **8.** understand No, polymerization is a nonspontaneous reaction because the product molecules have lower entropy than the free form of the reactants and there would be nothing to prevent hydrolysis from reversing the reaction. **9.** understand Many possible correct answers, including (1) the presence of an active site in an enzyme that is precisely shaped to fit a substrate or substrates in the correct orientation for a reaction to occur; (2) the doughnut shape of porin that allows certain substances to pass through it; (3) the cable shape of collagen to provide structural support for cells and tissues.
10. create Proteins are highly variable in overall shape and chemical properties due to variation in the composition of R-groups and the array of secondary through quaternary structures that are possible. This variation allows them to fulfill many different roles in the cell. Diversity in the shape and reactivity of active sites also makes them effective catalysts. **11.** understand c **12.** create In many proteins, especially those involved in cell signaling, their structure is affected by binding to other molecules or ions. Since the shape of the protein is directly involved in its function, the protein's activity is regulated by controlling how it is folded. If proteins were inflexible, this type of control could not occur.

✔ Test Your Problem-Solving Skills

13. analyze The side chain of proline is a cyclic structure that is covalently bonded to the nitrogen in the core amino group. This restricts the movement of the side chain relative to the core nitrogen, which further restricts the backbone when the nitrogen participates in a peptide bond with a neighboring amino acid. **14.** create See **FIGURE A3.2** **15.** apply b. Phosphates have a negative charge, so they are most likely to form ionic bonds with the positively-charged side chains of basic amino acid residues. **16.** apply The inherited forms likely have some alteration in the primary structure such that the infectious form is spontaneously generated at a higher rate than normal. The amino acid sequence in these prions would likely differ from those transmitted between animals.

CHAPTER 4

IN-TEXT QUESTIONS AND EXERCISES

p. 59 understand See **FIGURE A4.1**.

FIGURE A3.1

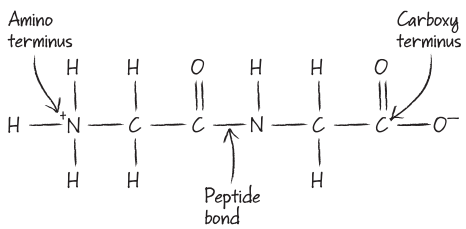

FIGURE A3.2

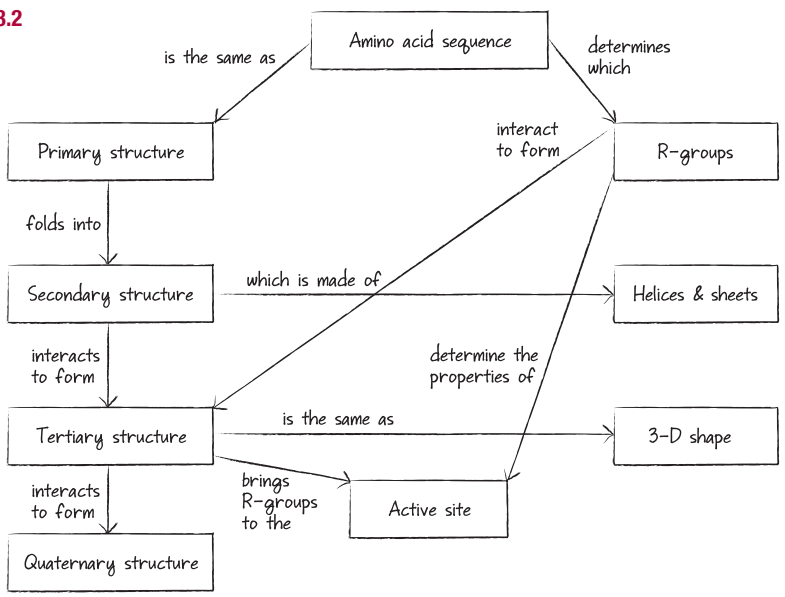

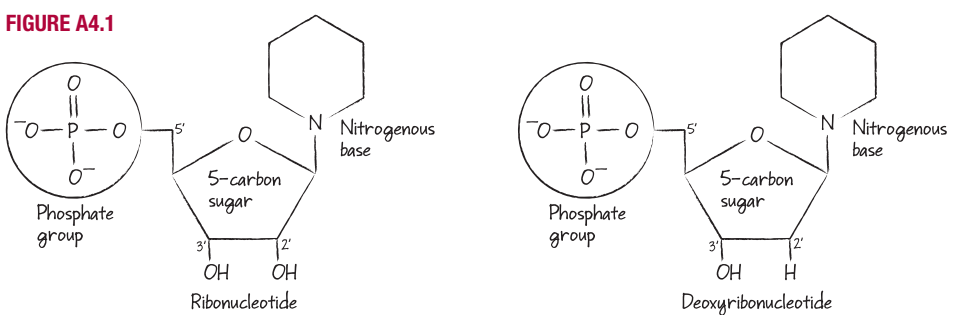

FIGURE A4.1

p. 60 Fig. 4.3 understand 5′-UAGC-′3
p. 61 CYU understand See **FIGURE A4.2**.
p. 63 understand If the two strands were parallel, the G-C pairing would align N−H groups together and C=O groups together, which would not allow hydrogen bonds to form.
p. 64 Fig. 4.8 analyze It is not spontaneous—energy must be added (as heat) for the reaction to occur.
p. 65 CYU remember See **FIGURE A4.3**.

IF YOU UNDERSTAND . . .

4.1. understand Cells activate nucleotides by linking additional phosphates to an existing 5′ phosphate. Activation increases the chemical energy in the nucleotides enough to offset the decrease in entropy that will result from the polymerization reaction. **4.2** understand C-G pairs involve three hydrogen bonds, so they are more stable than A-T pairs with just two hydrogen bonds. **4.3** analyze A single-stranded RNA molecule has unpaired bases that can pair with other bases on the same RNA strand, thereby folding the molecule into stem-and-loop configurations. These secondary structures can further fold on themselves, giving the molecule a tertiary structure. Because DNA molecules are double stranded, with no unpaired bases, further internal folding is not possible. **4.4** understand Examples would include (1) the production of nucleotides, and (2) polymerization of RNA. It is thought that nucleotides were scarce during chemical evolution, so their catalyzed synthesis by a ribozyme would have been advantageous. Catalysis by an RNA replicase would have dramatically increased the reproductive rate of RNA molecules.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. remember c **2.** remember c **3.** remember a **4.** remember d **5.** remember One end has a free phosphate group on the 5′ carbon; the other end has a free hydroxyl group bonded to the 3′ carbon. **6.** understand DNA is a more stable molecule than RNA because it lacks a hydroxyl group on the 2′ carbon and is therefore more resistant to cleavage, and because the two sugar-phosphate backbones are held together by many hydrogen bonds between nitrogenous bases.

✔ Test Your Understanding

7. apply In DNA, the secondary structure requires that every guanine pairs with a cytosine and every thymine pairs with an adenine, resulting in consistent ratios between the nucleotides. Chargaff's rules do not apply to RNA, since it is single-stranded and the pairing is not consistent throughout the molecules. **8.** apply a; if 30 percent is adenine, then 30 percent would be thymine, since they are base-paired together. This means that 40 percent consists of G-C base pairs, which would be equally divided between the two bases. **9.** apply The DNA sequence of the new strand would be 5′-ATCGATATC-3′. The RNA sequence would be the same, except each T would be replaced by a U. **10.** understand DNA has limited catalytic ability because it (1) lacks functional groups that can participate in catalysis and (2) has a regular structure that is not conducive to forming shapes required for catalysis. RNA molecules can catalyze some reactions because they (1) have exposed hydroxyl functional groups and (2) can fold into shapes that that can function in catalysis. **11.** apply No. Catalytic activity in ribozymes depends on the tertiary structure generated from single-stranded molecules. Double-stranded nucleic acids do not form tertiary structures. **12.** understand An RNA replicase would undergo replication and be able to evolve. It would process information in the sense of copying itself, and it would use energy to drive polymerization reactions. It would not be bound by a membrane and considered a cell, however, and it would not be able to acquire energy. It would best be considered as an intermediate step between nonlife and true life (as outlined in Chapter 1).

✔ Test Your Problem-Solving Skills

13. create See **FIGURE A4.4** **14.** apply Yes—if the complementary bases lined up over the entire length of the two strands, they would twist into a double helix analogous to a DNA molecule. The same types of hydrogen bonds and hydrophobic interactions would occur as observed in the "stem" portion of hairpins in single-stranded RNA. **15.** apply In a triple helix, the bases are unlikely to align properly for hydrogen bonding to occur, so hydrophobic interactions would probably be more important. **16.** apply b; the high temperature would make it more likely that the secondary and tertiary structures would be denatured in the ribozymes. To overcome this effect, you would expect the hairpins to possess more G-C pairs, since they consist of three hydrogen bonds compared to the two found in A-T pairs.

CHAPTER 5

IN-TEXT QUESTIONS AND EXERCISES

p. 73 Fig. 5.2 understand See the structure of mannose in **FIGURE A5.1**.
p. 75 CYU apply See **FIGURE A5.2**.
p. 78 CYU remember They could differ in (1) location of linkages (e.g., 1,4 or 1,6); (2) types of linkages (e.g., α or β); (3) the sequence of the monomers (e.g., two galactose and then two glucose, versus alternating galactose and glucose); and/or (4) whether the four monomers are linked in a line or whether they branch.
p. 79 Fig. 5.6 apply The percentage of inhibition would not change for the intact glycoprotein bar. The purified

FIGURE A4.2

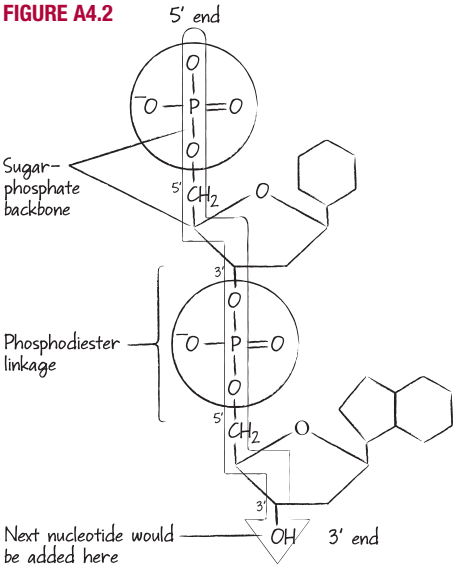

FIGURE A4.3

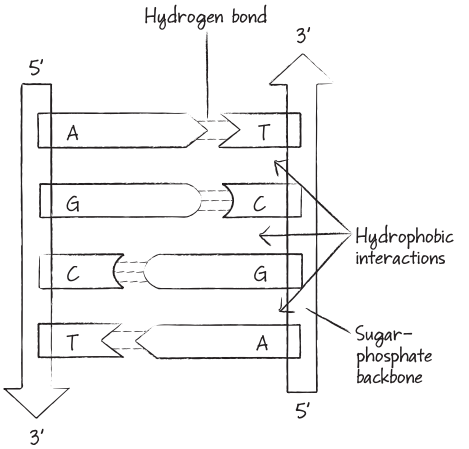

FIGURE A4.4

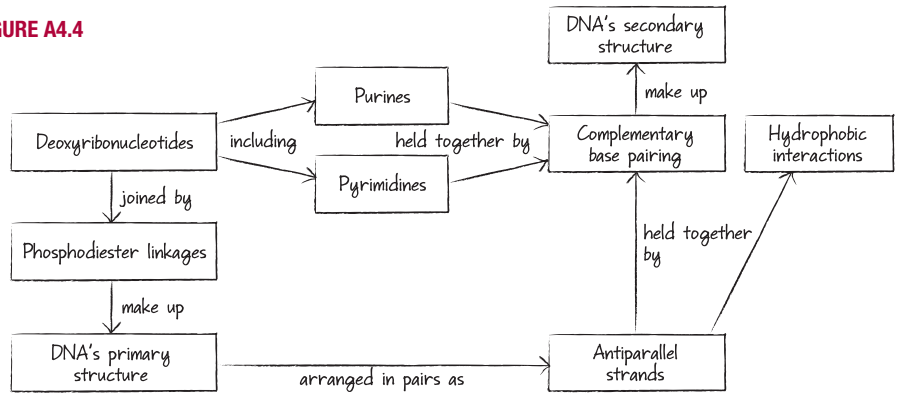

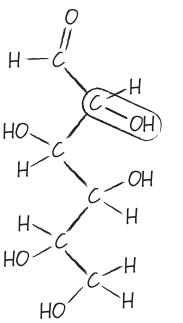

FIGURE A5.1

carbohydrate bar would be at zero inhibition, and the glycoprotein with digested carbohydrate bar would be similar to the intact glycoprotein bar.
p. 80 Fig. 5.7 understand All of the C–C and C–H bonds should be circled.
p. 81 CYU (1) understand *Aspect 1:* The β-1,4-glycosidic linkages in these molecules result in insoluble fibers that are difficult to degrade. *Aspect 2:* When individual molecules of these carbohydrates align, bonds form between them and produce fibers or sheets that resist pulling and pushing forces. **(2)** apply Most are probably being broken down into glucose, some of which in turn is being broken down in reactions that lead to the synthesis of ATP. Some will be resistant to digestion, such as the insoluble cellulose that makes up dietary fiber. This will help retain water and support the digestion and passage of fecal material.

IF YOU UNDERSTAND . . .

5.1. understand Molecules have to interact in an extremely specific orientation in order for a reaction to occur. Changing the location of a functional group by even one carbon can mean that the molecule will undergo completely different types of reactions. **5.2** analyze Glycosidic linkages can vary more in location and geometry than linkages between amino acids and nucleotides do. This variability increases the structural diversity possible in carbohydrates compared to proteins and nucleic acids. **5.3** understand (1) Polysaccharides used for energy storage are formed entirely from glucose monomers joined by α-glycosidic linkages; structural polysaccharides are made up of glucose or other sugars joined by β-glycosidic linkages. (2) The monomers in energy-storage polysaccharides are linked in a helical arrangement; the monomers in structural polysaccharides are linked in a linear arrangement. (3) Energy-storage polysaccharides may branch; structural polysaccharides do not. (4) Individual chains of energy-storage polysaccharides do not associate with each other; adjacent chains of structural polysaccharides are linked by hydrogen bonds or covalent bonds.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. remember d **2.** remember Monosaccharides can differ from one another in three ways: (1) the location of their carbonyl group; (2) the number of carbon atoms they contain; and (3) the orientations of their hydroxyl groups. **3.** remember a **4.** remember c **5.** remember a **6.** understand The electrons in the C=O bonds of carbon dioxide molecules are held tightly by the highly electronegative oxygen atoms, so they have low potential energy. The electrons in the C–C and C–H bonds of carbohydrates are shared equally, so they have much higher potential energy.

✔ Test Your Understanding

7. understand c. **8.** apply a; lactose is a disaccharide formed from a β-1,4-glycosidic linkage, so if two glucose molecules were linked with this bond, they would resemble units of cellulose and not be digested by human infants or adults. **9.** understand Carbohydrates are ideal for displaying the identity of the cell because they are so diverse structurally. This diversity enables them to serve as very specific identity tags for cells. **10.** understand When you compare the glucose monomers in an α-1,4-glycosidic linkage versus in a β-1,4-glycosidic linkage, the linkages are located on opposite sides of the plane of the glucose rings, and the glucose monomers are linked in the same orientation versus having every other glucose flipped in orientation. β-1,4-glycosidic linkages are much more likely to form linear fibers and sheets, so they resist degradation. **11.** remember Because (1) no mechanism is known for the prebiotic polymerization of sugars; (2) no catalytic carbohydrates have been discovered that can perform polymerization reactions; and (3) sugar residues in a polysaccharide are not capable of complementary base pairing. **12.** understand Starch and glycogen both consist of glucose monomers joined by α-1,4-glycosidic linkages, and both function as storage carbohydrates. Starch is a mixture of unbranched and branched polysaccharides—called amylose and amylopectin, respectively. All glycogen polysaccharides are branched.

✔ Test Your Problem-Solving Skills

13. analyze Carbohydrates are energy-storage molecules, so minimizing their consumption may reduce total energy intake. Lack of available carbohydrate also forces the body to use fats for energy, reducing the amount of fat that is stored. **14.** apply d; lactose is a disaccharide of glucose and galactose, which can be cleaved by enzymes expressed in the human gut to release galactose. **15.** analyze Amylase breaks down the starch in the cracker into glucose monomers, which stimulate the sweet receptors in your tongue. **16.** apply When bacteria contact lysozyme, the peptidoglycan in their cell walls begins to degrade, leading to the death of the bacteria. Lysozyme therefore helps protect humans against bacterial infections.

CHAPTER 6

IN-TEXT QUESTIONS AND EXERCISES

p. 87 understand Fatty acids are amphipathic because their hydrocarbon tails are hydrophobic but their carboxyl functional groups are hydrophilic.
p. 87 Fig. 6.4 apply At the polar hydroxyl group in cholesterol and the polar head group in phospholipids.
p. 88 CYU (1) analyze Fats consist of three fatty acids linked to glycerol; steroids have a distinctive four-ring structure with variable side groups attached; phospholipids have a hydrophilic, phosphate-containing "head" region and a hydrocarbon tail. **(2)** understand In cholesterol, the hydrocarbon steroid rings and isoprenoid chain are hydrophobic; the hydroxyl group is hydrophilic. In phospholipids, the phosphate-containing head group is hydrophilic; the hydrocarbon chains are hydrophobic.
p. 89 apply Amino acids have amino and carboxyl groups that are ionized in water and nucleotides have negatively charged phosphates. Due to their charge and larger size, both would be placed below the small ions at the bottom of the scale (permeability<10^{-12} cm/sec).
p. 90 CYU create See **TABLE A6.1**.
p. 91 Fig. 6.10 apply Increasing the number of phospholipids with polyunsaturated tails would increase permeability of the liposomes. Starting from the left, the first line (no cholesterol) would represent liposomes with 50% polyunsaturated phospholipids, the second line would be 20% polyunsaturated phospholipids, and the third line would contain only saturated phospholipids.
p. 92 apply If there is a difference in temperature, then there would be a difference in thermal motion. The solute concentration on the side with a higher temperature would decrease because the solute particles would be moving faster and hence be more likely to move to the cooler side of the membrane, where they would slow down.
p. 93 Fig. 6.13 apply Higher, because less water would have to move to the right side to achieve equilibrium.

FIGURE A5.2

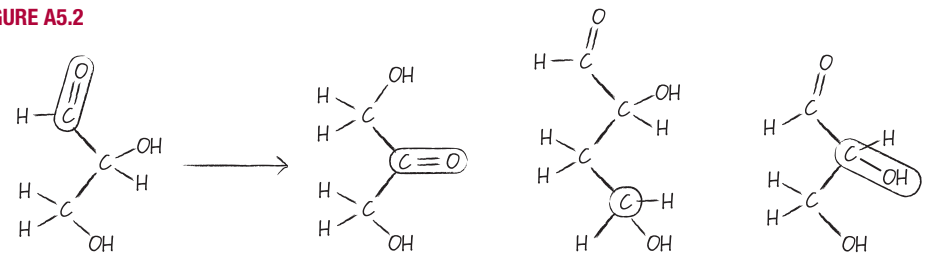

TABLE A6.1

Factor	Effect on permeability	Reason
Temperature	Decreases as temperature decreases.	Lower temperature slows movement of hydrocarbon tails, allowing more interactions (membrane is more dense).
Cholesterol	Decreases as cholesterol content increases.	Cholesterol molecules fill in the spaces between the hydrocarbon tails, making the membrane more tightly packed.
Length of hydrocarbon tails	Decreases as length of hydrocarbon tails increases.	Longer hydrocarbon tails have more interactions (membrane is more dense).
Saturation of hydrocarbon tails	Decreases as degree of saturation increases.	Saturated fatty acids have straight hydrocarbon tails that pack together tightly, leaving few gaps.

p. 94 CYU create See **FIGURE A6.1**.
p. 96 Fig. 6.18 create Repeat the procedure using a lipid bilayer that is free of membrane proteins, such as synthetic liposomes constructed from only phospholipids. If proteins were responsible for the pits and mounds, then this control would not show these structures.
p. 97 apply Your arrow should point out of the cell. There is no concentration gradient for chloride, but the outside has a net positive charge, which favors outward movement of negative ions.
p. 97 Fig. 6.21 analyze No—the 10 replicates where no current was recorded probably represent instances where the CFTR protein was damaged and not functioning properly. (In general, no experimental method works "perfectly.")
p. 101 CYU understand Passive transport does not require an input of energy—it happens as a result of energy already present in existing concentration or electrical gradients. Active transport is active in the sense of requiring an input of energy from, for example, ATP. In cotransport, a second ion or molecule is transported against its concentration gradient along with (i.e., "co") an ion that is transported along its concentration gradient.
p. 101 Fig. 6.26 understand *Diffusion:* description as given; no proteins involved. *Facilitated diffusion:* Passive movement of ions or molecules that cannot cross a phospholipid bilayer readily along a concentration gradient; facilitated by channel or carrier proteins. *Active transport:* Active movement of ions or molecules that will build a gradient; facilitated by pump proteins powered by an energy source such as ATP.

IF YOU UNDERSTAND . . .

6.1. analyze Adding H_2 increases the saturation of the oil by converting C=C bonds into C−C bonds with added hydrogens. Lipids with more C−H bonds tend to be solid at room temperature. **6.2** understand Highly permeable and fluid bilayers possess short, unsaturated hydrocarbon tails while those that are highly impermeable and less fluid contain long, saturated hydrocarbon tails.
6.3 apply (1) The solute will diffuse until both sides are at equal concentrations. (2) Water will diffuse toward the side with the higher solute concentration. **6.4** apply See **FIGURE A6.2**.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. understand c **2.** remember a **3.** understand b **4.** understand d
5. understand For osmosis to occur, a concentration gradient and membrane that allows water to pass, but not the solute, must be present. **6.** analyze Channel proteins form pores in the membrane and carrier proteins undergo conformational changes to shuttle molecules or ions across the membrane.

✔ Test Your Understanding

7. apply b **8.** analyze No, because they have no polar end to interact with water. Instead, these lipids would float on the surface of water, or collect in droplets suspended in water, reducing their interaction with water to a minimum. **9.** understand Hydrophilic, phosphate-containing head groups interact with water; hydrophobic hydrocarbon tails associate with each other. A bilayer is more stable than are independent phospholipids in solution. **10.** apply Ethanol's polar hydroxyl group reduces the speed at which it can cross a membrane, but its small size and lack of charge would allow it to slowly cross membranes—between the rates of water and glucose transport. **11.** understand Only nonpolar, hydrophobic amino acid residues would be found in the portion of the protein that crosses the membrane. In the interior of the bilayer, these residues would be hidden from the water solvent and interact with the nonpolar lipid tails.
12. apply Chloride ions from sodium chloride will move from the left side to the right through the CFTR. Water will initially move from the right side to the left by osmosis, but as chloride ions move to the right, water will follow. Na^+ and K^+ ions will not move across the membrane.

✔ Test Your Problem-Solving Skills

13. apply c **14.** create Flip-flops should be rare, because they require a polar head group to pass through the hydrophobic portion of the lipid bilayer. To test this prediction, you could monitor the number of dyed phospholipids that transfer from one side of the membrane to the other in a given period of time. **15.** apply Organisms that live in very cold environments are likely to have highly unsaturated phospholipids. The kinks in unsaturated hydrocarbon tails keep membranes fluid and permeable, even at low temperature. Organisms that live in very hot environments would likely have phospholipids with saturated tails, to prevent membranes from becoming too fluid and permeable. **16.** analyze Adding a methyl group makes a drug more hydrophobic and thus more likely to pass through a lipid bilayer. Adding a charged group makes it hydrophilic and reduces its ability to pass through the lipid bilayer. These modifications would help target the drug to either the inside or outside of cells, respectively.

BIG PICTURE Chemistry of Life

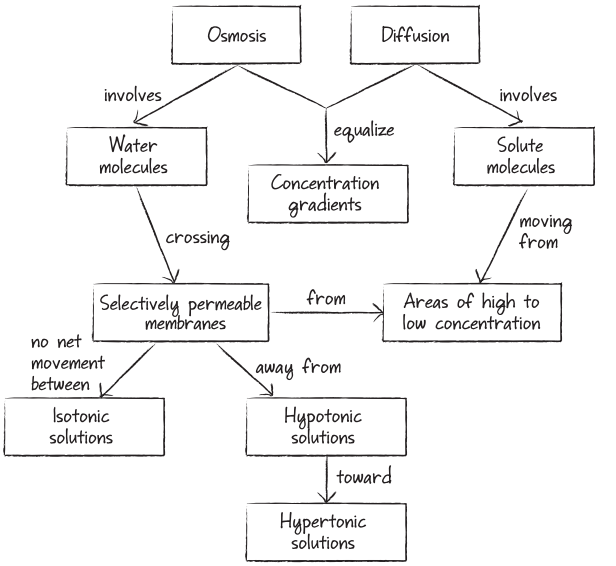
p. 104 CYU (1) understand Oxygen is much more electronegative than hydrogen, so within water, the electrons are unequally shared in the O−H covalent bonds. The resulting partial negative charge around the oxygen and partial positive charges around the hydrogen atoms allow for hydrogen bonds to form among water molecules.
(2) analyze Unlike other macromolecules, nucleic acids can serve as templates for their own replication. RNA is generally single-stranded and can adopt many different three-dimensional structures. The flexibility in structure, combined with the presence of reactive hydroxyl groups, contribute to the formation of active sites that catalyze chemical reactions. One or more of these catalytic RNA molecules may have evolved the ability to self-replicate. DNA is not likely to have catalyzed its own replication, as it is most often double-stranded, with no clear tertiary structure, and it lacks the reactive hydroxyl groups.
(3) remember In the amino acid, the nitrogen in the amino (NH_3^+) group and the carbon in the carboxyl (COO^-) group should be circled. In the nucleotide, the oxygen in the hydroxyl (OH) group and the phosphorus in the phosphate (PO_4^{2-}) group on the nucleotide should be circled. **(4)** understand A line representing a protein should be drawn such that it completely crosses the lipid bilayer at least once. The protein could be involved in a variety of different roles, including transport of substances across the membrane in the form of a channel, carrier, or pump.

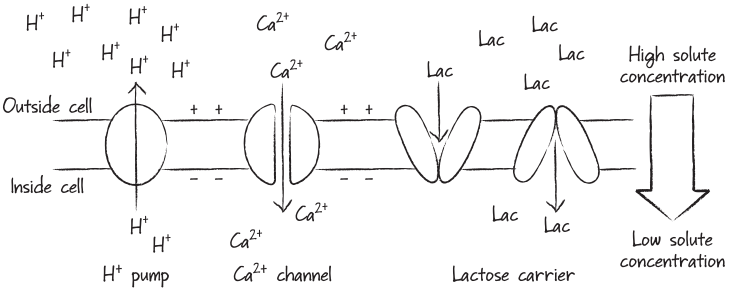
CHAPTER 7

IN-TEXT QUESTIONS AND EXERCISES

p. 110 CYU remember (1) The nucleoid compacts the chromosome to fit inside the cell via supercoiling while still keeping it accessible for replication and transmission of information. (2) Photosynthetic membranes increase food production by providing a large surface area to hold the pigments and enzymes required for photosynthesis. (3) Flagella propel cells through liquid, often toward a food source. (4) The layer of thick, strong material stiffens the cell wall and provides protection from mechanical damage.
p. 114 Fig. 7.12 create Storing the toxins in vacuoles prevents the toxins from damaging the plant's own organelles and cells.

FIGURE A6.1





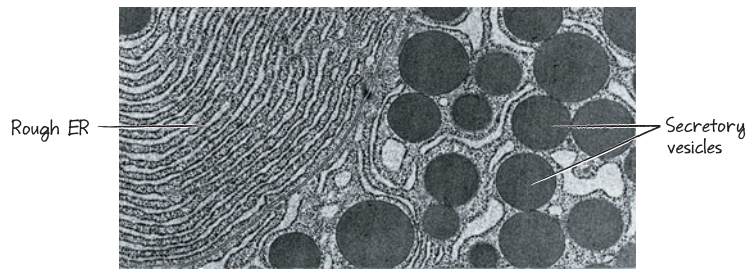


FIGURE A6.2

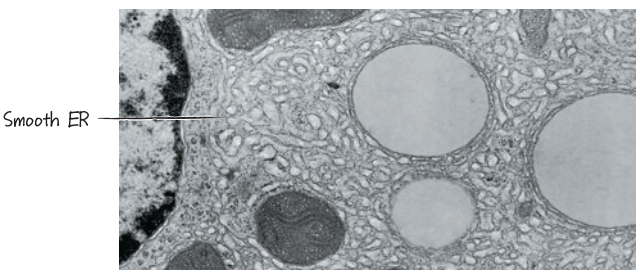
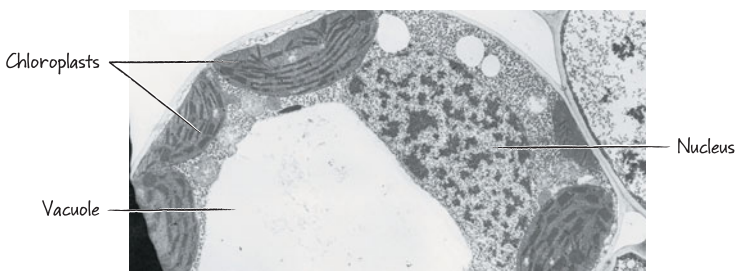
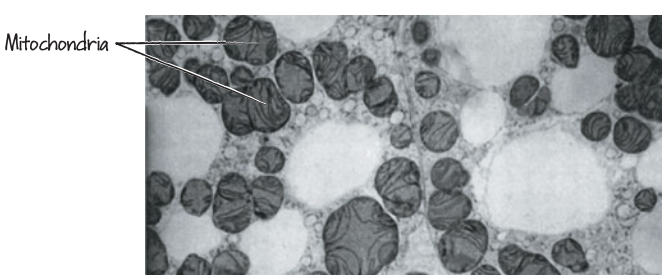


p. 116 CYU (1) understand Both organelles contain specific sets of enzymes. Lysosomal enzymes digest macromolecules in the acidic lumen of this organelle, releasing monomers that can be recycled into new macromolecules. Peroxisomes contain catalase and other enzymes that process fatty acids and toxins via oxidation reactions. **(2)** understand From top to bottom: administrative/information hub, protein factory, large molecule manufacturing and shipping (protein synthesis and folding center, lipid factory, protein finishing and shipping line, waste processing and recycling center), warehouse, fatty-acid processing and detox center, power station, food-manufacturing facility, support beams, perimeter fencing with secured gates, and leave blank.
p. 118 Fig. 7.16 remember See **FIGURE A7.1**.
p. 121 analyze (1) Nucleotides are small enough that they would diffuse through the nuclear pore complex along their gradients—a passive process that would not require energy. (2) Large proteins must be escorted through the nuclear pore complex, which is directional and requires energy, since the protein is concentrated inside the nucleus.
p. 121 Fig. 7.18 apply "Prediction": The labeled tail region fragments or the labeled core region fragments of the nucleoplasmin protein will be found in the cell nucleus. "Prediction of null hypothesis": Either both the fragments (no required signal) or neither of them (whole protein signal) will be found in the nucleus of the cell. "Conclusion": The send-to-nucleus signal is in the tail region of the nucleoplasmin protein.
p. 123 apply During the chase period, proteins appear to have first entered the Golgi after 7 minutes and then started to move into secretory granules after 37 minutes. This means that in this experiment, it took approximately 30 minutes for the fastest-moving proteins to pass through the Golgi.

FIGURE A7.1



(a) Animal pancreatic cell: Exports digestive enzymes.



(b) Animal testis cell: Exports lipid-soluble signals.

(c) Plant leaf cell: Manufactures ATP and sugar.

(d) Brown fat cells: Burn fat to generate heat in lieu of ATP.

p. 126 apply In receptor-mediated endocytosis, the conversion of a late endosome to a lysosome is dependent on receiving acid hydrolases from the Golgi. If this receptor is not present, then the enzymes will not be sent and the late endosome will not mature into a lysosome to digest the endocytosed products.
p. 126 CYU (1) apply Proteins that enter the nucleus are fully synthesized and have an NLS that interacts with another protein to get it into the organelle. The NLS is not removed. Proteins that enter the ER have a signal sequence that interacts with the SRP during translation. The ribosome is moved to the ER and synthesis continues, moving the protein into the ER. The signal is removed once it enters the organelle. **(2)** apply The protein would be in the lysosome. The ER signal would direct the protein into the ER before it is completely synthesized. The M-6-P tag will direct the protein from the Golgi to the late endosome to the lysosome. Thus the complete protein is never free in the cytosol, where the NLS could direct it into the nucleus.
p. 132 CYU analyze Actin filaments are made up of two strands of actin monomers, microtubules are made up of tubulin protein dimers that form a tube, and intermediate filaments are made up of a number of different protein subunits. Actin filaments and microtubules exhibit polarity (or directionality), and new subunits are constantly being added or subtracted at either end (but added faster to the plus end). All three elements provide structural support, but only actin filaments and microtubules serve as tracks for motors involved in movement and cell division.
p. 132 Fig. 7.30 apply The microtubule doublets of the axoneme would slide past each other completely, but the axoneme would not bend.

IF YOU UNDERSTAND . . .

7.1 understand (1) Cells will be unable to synthesize new proteins and will die. (2) In many environments, cells will be unable to resist the osmotic pressure of water entering the cytoplasm and will burst. (3) The cell shape will be different, and cells will not be able to divide.
7.2 understand (1) The cell will be unable to produce a sufficient amount of ATP and will die. (2) Reactive molecules, like hydrogen peroxide, will damage the cell, and it will likely die. (3) Nothing will happen, since plants do not have centrioles. **7.3** analyze The liver cell would be expected to have more peroxisomes and less rough endoplasmic reticulum than the salivary cells would.
7.4 create The addition or removal of phosphates would change the folded structure of the protein, exposing the NLS for nuclear transport. **7.5** create As a group, proteins have complex and highly diverse shapes and chemical properties that allow them to recognize a great number of different zip codes in a very specific manner. **7.6** apply The Golgi is positioned near the microtubule organizing center, which has microtubules running from the minus end out to the plus end (near the plasma membrane). Kinesin would be used to move these vesicles as it walks toward the plus end.

YOU SHOULD BE ABLE TO . . .

✓ Test Your Knowledge

1. understand b **2.** remember They have their own small, circular chromosomes; they produce their own ribosomes; and they divide in a manner that is similar to bacterial fission, independent of cellular division. **3.** remember c **4.** remember b **5.** remember a **6.** understand The phosphate links to the motor protein and causes it to change shape, which results in the protein moving along the filament.

✓ Test Your Understanding

7. analyze All cells are bound by a plasma membrane, are filled with cytoplasm, carry their genetic information (DNA) in chromosomes, and contain ribosomes

(the sites of protein synthesis). Some prokaryotes have organelles not found in plants or animals, such as a magnetite-containing structure. Plant cells have chloroplasts, vacuoles, and a cell wall. Animal cells contain lysosomes and lack a cell wall. **8.** analyze a; the endoplasmic reticulum is responsible for synthesizing the membrane proteins required for the transport of solutes across the plasma membrane. **9.** create The NLS will be used to actively import the protein into the nucleus, leaving very little of the protein in the cytoplasm. Diffusion alone would not drive all the protein into the nucleus. **10.** create Ribosome in cytoplasm (signal is synthesized) → Ribosome at rough ER (protein is completed, folded, and glycosylated) → Transport vesicle → Golgi apparatus (protein is processed; has molecular zip code indicating destination) → Transport vesicle → Plasma membrane → Extracellular space. **11.** create This occurs in microfilaments and microtubules because they have ends that differ structurally and functionally—they have different filament growth rates. Intermediate filaments have identical ends, so there is no difference in the rate of assembly between the two ends. **12.** understand Polarized cytoskeletal filaments (microtubules or microfilaments) are present between the organelles. End-directed motor proteins use ATP to move these transport vesicles between them.

✔ Test Your Problem-Solving Skills

13. understand b; fimbriae are involved in bacterial attachment to surfaces and other cells, which would be important in the ability to grow on teeth. **14.** create The proteins must receive a molecular zip code that binds to a receptor on the surface of peroxisomes. They could diffuse randomly to peroxisomes or be transported in a directed way by motor proteins. **15.** create The tails cleaved from nucleoplasmin could be attached to the gold particles that were excluded from crossing the pore complex owing to their size. If these modified particles entered the nucleus, then the tail is not limited to the nucleoplasmin transport alone. **16.** apply The proteins would likely be found in the cytoplasm (e.g., actin and myosin) or imported into the mitochondria. Since there is a high energy demand, you would predict that there are many active mitochondria.

CHAPTER 8

IN-TEXT QUESTIONS AND ANSWERS

p. 139 apply (1) If ΔS is positive (products have more disorder than reactants), then according to the free energy equation, ΔG is more likely to be negative as temperature (T) increases even if ΔH is positive. The increased temperature represents added heat energy that may be used to drive an endothermic reaction to completion, making the reaction spontaneous. (2) Exothermic reactions may be nonspontaneous if they result in a decrease in entropy—meaning that the products are more ordered than the reactants (ΔS is negative).
p. 139 CYU (1) understand *Gibbs equation:* $\Delta G = \Delta H - T\,\Delta S$. ΔG symbolizes the change in the Gibbs free energy. ΔH represents the difference in enthalpy (heat, pressure, and volume) between the products and the reactants. T represents the temperature (in degrees Kelvin) at which the reaction is taking place. ΔS symbolizes the change in entropy (amount of disorder). **(2)** understand When ΔH is negative—meaning that the reactants have lower enthalpy than the products—and when ΔS is positive, meaning that the products have higher entropy (are more disordered) than the reactants.
p. 140 Fig. 8.4 understand Each point represents the data from a single test, not an average of many experiments, so it is not possible to calculate the standard error of the average.
p. 144 analyze Redox reactions transfer energy between molecules or atoms via electrons. When oxidized molecules are reduced, their potential energy increases. ATP hydrolysis is often coupled with the phosphorylation of another molecule. This phosphorylation increases the potential energy of the molecule.
p. 144 CYU (1) understand Electrons in C–H bonds are not held as tightly as electrons in C–O bonds, so they have higher potential energy. **(2)** understand In part, because its three phosphate groups have four negative charges in close proximity. The electrons repulse each other, raising their potential energy.
p. 144 Fig. 8.9 understand The ΔG in the uncoupled reaction would be positive (>0), and each of the steps in the coupled reaction would have a negative (<0) ΔG.
p. 147 remember (1) binding substrates, (2) transition state, (3) R-groups, (4) structure
p. 146 Fig. 8.12 understand No—a catalyst affects only the activation energy, not the overall change in free energy.
p. 147 Fig. 8.14 analyze See **FIGURE A8.1**.
p. 149 CYU (1) create The rate of the reaction is based primarily on the activity of the enzyme. Once the temperature reaches a level that causes unfolding and inactivation of the enzyme, the rate decreases to the uncatalyzed rate. **(2)** apply The shape change would most likely alter the shape of the active site. If phosphorylation activates catalytic activity, the change to the active site would allow substrates to bind and be brought to their transition state. If phosphorylation inhibits catalytic activity, the shape change to the active site would likely prevent substrates from binding or no longer orient them correctly for the reaction to occur.
p. 150 apply The concentration of A and B would be higher than in the fully functional pathway since they are not depleted to produce C. If D is not being depleted by other reactions, then equilibrium would be established between C and D, resulting in lower concentrations of both.

IF YOU UNDERSTAND . . .

8.1 understand Reactions are spontaneous when the free energy in the products is lower than that of the reactants (ΔG is negative). Enthalpy and entropy are measures used to determine free-energy changes. Enthalpy measures the potential energy of the molecules, and entropy measures the disorder. For exergonic, spontaneous reactions, disorder normally increases and the potential energy stored in the products normally decreases relative to the reactants. **8.2** understand Energetic coupling transfers free energy released from exergonic reactions to drive endergonic reactions. Since endergonic reactions are required for sustaining life, without energetic coupling, life would not exist. **8.3** understand Amino acid R-groups lining the active site interact with the substrates, orienting them in a way that stabilizes the transition state, thereby lowering the activation energy needed for the reaction to proceed. **8.4** analyze Allosteric regulation and phosphorylation cause changes in the conformation of the enzyme that affects its catalytic function. Allosteric regulation involves non-covalent bonding, while phosphorylation is a covalent modification of the enzyme's primary structure. **8.5** apply In the first step of the pathway, the rate would increase as the intermediate, which is the product of the first reaction, is removed. In the last step, the rate would decrease due to the loss of the intermediate, which serves as the substrate for the last reaction.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. remember c **2.** remember a **3.** remember a **4.** remember The enzyme changes shape, but the change is not permanent. The enzyme shape will return to its original conformation after releasing the products. **5.** remember d **6.** remember When the product of a pathway feeds back to interact with an enzyme early in the same pathway to inhibit its function.

✔ Test Your Understanding

7. understand The shape of reactant molecules (the key) fits into the active site of an enzyme (the lock). Fischer's original model assumed that enzymes were rigid; in fact, enzymes are flexible and dynamic. **8.** understand d. Energy, such as the thermal energy in fire, must be provided to overcome the activation energy barrier before the reaction can proceed. **9.** understand The phosphorylation reaction is exergonic because the electrons in ADP and the phosphate added to the substrate experience less electrical repulsion, and thus have less potential energy, than they did in ATP. A phosphorylated reactant (i.e., an activated intermediate) gains enough potential energy to shift the free energy change for the reaction from endergonic to exergonic. **10.** apply For the coupled reaction, step 1 has a ΔG of about −3 kcal/mol and step 2 has a ΔG of about −3 kcal/mol. The uncoupled reaction has a ΔG of about +1.3 kcal/mol. **11.** analyze Both are mechanisms that regulate enzymes; the difference is whether the regulatory molecule binds at the active site (competitive inhibition) or away from the active site (allosteric regulation). **12.** apply Catabolic reactions will often have a negative ΔG based on a decrease in enthalpy and increase in entropy. Anabolic reactions are the opposite—a positive ΔG that is based on an increase in enthalpy and decrease in entropy.

✔ Test Your Problem-Solving Skills

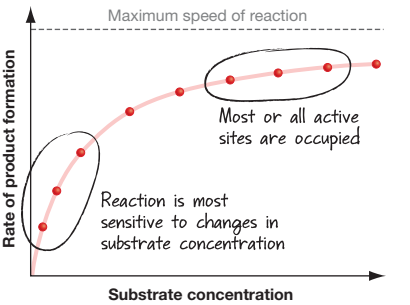
13. create See **FIGURE A8.2**. **14.** apply Without the coenzyme, the free-radical-containing transition state would not be stabilized and the reaction rate would drop dramatically. **15.** analyze The data suggest that the enzyme and substrate form a transition state that requires a change in the shape of the active site, and that each movement corresponds to one reaction. **16.** apply b. The sugar likely functions as an allosteric regulator to activate the enzyme.

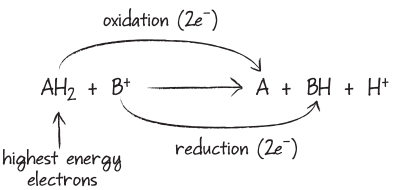
CHAPTER 9

IN-TEXT QUESTIONS AND EXERCISES

p. 156 Fig. 9.2 remember *Glycolysis:* "What goes in" = glucose, NAD^+, ADP, inorganic phosphate; "What comes out" = pyruvate, NADH, ATP. *Pyruvate processing:* "What goes in" = pyruvate, NAD^+; "What comes out" = NADH, CO_2, acetyl CoA. *Citric acid cycle:* "What goes in" = acetyl CoA, NAD^+, FAD, GDP or ADP, inorganic phosphate; "What comes out" = NADH, $FADH_2$, ATP or GTP, CO_2. *Electron transport and oxidative phosphorylation:* "What goes in" = NADH, $FADH_2$, O_2, ADP, inorganic phosphate; "What comes out" = ATP, H_2O, NAD^+, FAD.

FIGURE A8.1





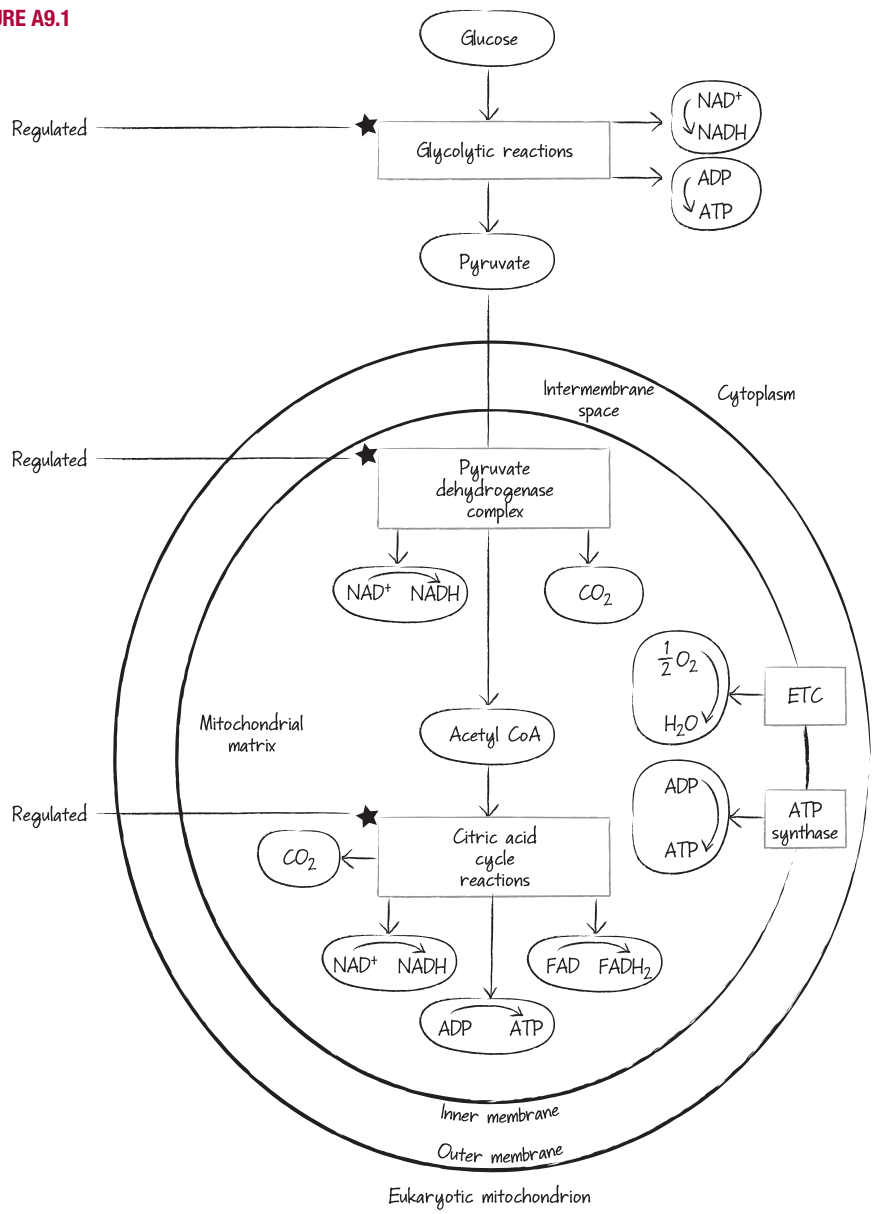


FIGURE A8.2

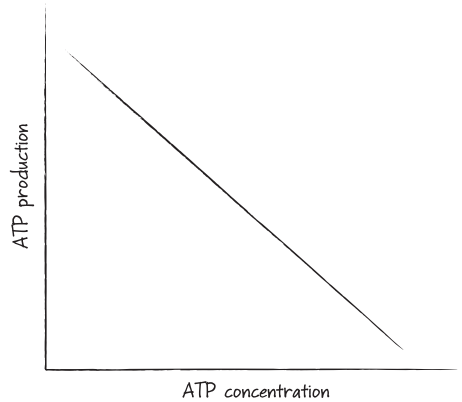
p. 161 apply If the regulatory site had a higher affinity for ATP than the active site, then ATP would always be bound at the regulatory site, and glycolysis would always proceed at a very slow rate.
p. 161 Fig. 9.9 remember "Positive control": AMP, NAD^+, CoA (reaction substrates). "Negative control by feedback inhibition": acetyl CoA, NADH, ATP (reaction products).
p. 165 CYU remember (1) and (2) are combined with the answer to p. 171 CYU (3) Start with 12 triangles on glucose. (These triangles represent the 12 pairs of electrons that will be moved to electron carriers during redox reactions throughout glycolysis and the citric acid cycle.) Move two triangles to the NADH circle generated by glycolysis and the other 10 triangles to the pyruvate circle. Then move these 10 triangles through the pyruvate dehydrogenase square, placing two of them in the NADH circle next to pyruvate dehydrogenase. Add the remaining eight triangles in the acetyl CoA circle. Next move the eight triangles in the acetyl CoA circle through the citric acid cycle, placing six of them in the NADH circle and two in the $FADH_2$ circle generated during the citric acid cycle. (4) These boxes are marked with stars in the diagram.
p. 165 Fig. 9.13 apply NADH would be expected to have the highest amount of chemical energy since its production is correlated with the largest drop in free energy in the graph.
p. 167 Fig. 9.15 understand The proton gradient arrow should start above in the inner membrane space and point down across the membrane into the mitochondrial matrix. *Complex I:* "What goes in" = NADH; "What comes out" = NAD^+, e^-, transported H^+. *Complex II:* "What goes in" = $FADH_2$; "What comes out" = FAD, e^-, H^+. *Complex III:* "What goes in" = e^-, H^+; "What comes out" = e^-, transported H^+. *Complex IV:* "What goes in" = e^-, H^+, O_2; "What comes out" = H_2O, transported H^+.
p. 169 explain "Indirect" is accurate because most of the energy released during glucose oxidation is not used to produce ATP directly. Instead, this energy is stored in reduced electron carriers that are used by the ETC to generate a proton gradient across a membrane. These protons then diffuse down their concentration gradient across the inner membrane through ATP synthase, which drives ATP synthesis.
p. 169 Fig. 9.17 create They could have placed the vesicles in an acidic solution that has a pH below that of the solution in the vesicle. This would set up a proton gradient across the membrane to test for ATP synthesis.
p. 171 CYU understand See **FIGURE A9.1**. To illustrate the chemiosmotic mechanism, take the triangles (electrons) piled on the NADH and $FADH_2$ circles and move them through the ETC. While moving these triangles, also move dimes from the mitochondrial matrix to the intermembrane space. As the triangles exit the ETC, add them to the oxygen to water circle. Once all the dimes have been pumped by the ETC into the intermembrane space, move them through ATP synthase back into the mitochondrial matrix to fuel the formation of ATP.
p. 173 CYU understand Electron acceptors such as oxygen have a much higher electronegativity than pyruvate. Donating an electron to O_2 causes a greater drop in potential energy, making it possible to generate much more ATP per molecule of glucose.

FIGURE A9.1

IF YOU UNDERSTAND . . .

9.1 understand The radioactive carbons in glucose can be fully oxidized by the central pathways to generate CO_2, which would be radiolabeled. Other molecules, like lipids and amino acids, would also be expected to be radiolabeled since they are made using intermediates from the central pathways in other anabolic pathways. **9.2** apply See **FIGURE A9.2**. **9.3** understand Pyruvate dehydrogenase accomplishes three different tasks that would be expected to require multiple enzymes and active sites: CO_2 release, NADH production, and linking of an acetyl group to CoA. **9.4** apply NADH would decrease if a drug poisoned the acetyl CoA and oxaloacetate-to-citrate enzyme, since the citric acid cycle would no longer be able to produce NADH in the steps following this reaction in the pathway. **9.5** apply The ATP synthase allows protons to reenter the mitochondrial matrix after they have been pumped out by the ETC. By blocking ATP synthase, you would expect the pH of the matrix to increase (decreased proton concentration). **9.6** understand Organisms that produce ATP by fermentation would be expected to grow more slowly than those that produce ATP via cellular respiration simply because fermentation produces fewer ATP molecules per glucose molecule than cellular respiration does.

YOU SHOULD BE ABLE TO . . .



✔ Test Your Knowledge

1. understand Glycolysis → Pyruvate processing → citric acid cycle → ETC and chemiosmosis. The first three steps are responsible for glucose oxidation; the final step produces the most ATP. **2.** remember b **3.** understand d **4.** understand Most of the energy is stored in the form of NADH. **5.** remember c **6.** remember a

✔ Test Your Understanding

7. understand Stored carbohydrates can be broken down into glucose that enters the glycolytic pathway. If carbohydrates are absent, products from fat and protein catabolism can be used to fuel cellular respiration or fermentation. If ATP is plentiful, anabolic reactions use

FIGURE A9.2

intermediates of the glycolytic pathway and the citric acid cycle to synthesize carbohydrates, fats, and proteins. **8.** analyze Both processes produce ATP from ADP and P_i, but substrate-level phosphorylation occurs when enzymes remove a "high-energy" phosphate from a substrate and directly transfer it to ADP, while oxidative phosphorylation occurs when electrons move through an ETC and produce a proton-motive force that drives ATP synthase. **9.** understand Aerobic respiration is much more productive because oxygen has extremely high electronegativity compared with other electron acceptors, resulting in a greater release of energy during electron transport and more proton pumping. **10.** apply b **11.** analyze Both phosphofructokinase and isocitrate dehydrogenase are regulated by feedback inhibition, where the product of the reaction or series of reactions inhibits the enzyme activity. They differ in that phosphofructokinase is regulated by allosteric inhibition while isocitrate dehydrogenase is controlled by competitive inhibition. **12.** understand Oxidative phosphorylation is possible via a proton gradient that is established by redox reactions in the ETC. ATP synthase consists of a membrane-associated F_o unit and a F_1 unit joined by a rotor shaft. When protons flow through the F_o unit, it spins the rotor shaft within the fixed F_1 unit. This spinning shaft causes structural changes in the F_1 that drives the synthesis of ATP from ADP and P_i.

Test Your Problem-Solving Skills

13. create When complex IV is blocked, electrons can no longer be transferred to oxygen, the final acceptor, and cellular respiration stops. Fermentation could keep glycolysis going, but it is inefficient and unlikely to fuel a cell's energy needs over the long term. Cells that lack the enzymes required for fermentation would die first. **14.** apply Because mitochondria with few cristae would have fewer electron transport chains and ATP synthase molecules, they would produce much less ATP than mitochondria with numerous cristae. **15.** apply For each glucose molecule, two ATP are produced in glycolysis and two ATP are produced in the citric acid cycle via substrate-level phosphorylation. A total of 10 NADH and 2 $FADH_2$ molecules are produced from glycolysis, pyruvate oxidation, and the citric acid cycle. If each NADH were to yield 3 ATP, and each $FADH_2$ were to yield 2 ATP, then a total of 34 ATP would be produced via oxidative phosphorylation. Adding these totals would result in 38 ATP. A cell will not produce this much ATP, because the proton-motive force is used in other transport steps and because of other issues that may reduce the overall efficiency. **16.** apply b

CHAPTER 10

IN-TEXT QUESTIONS AND EXERCISES

p. 177 understand See **FIGURE A10.1**. This reaction is endergonic because there are more high-energy chemical bonds in the products compared with the reactants, and there is a decrease in entropy.
p. 177 Fig. 10.1 apply See **FIGURE A10.1**.
p. 180 Fig. 10.6 apply See **FIGURE A10.2**.
p. 182 Fig. 10.9 apply The energy state corresponding to a photon of green light would be located between the energy states corresponding to red and blue photons.
p. 183 CYU apply The outer pigments would be more likely to absorb blue photons (short wavelength, high energy), and interior pigments would absorb red photons (long wavelength, low energy). This establishes a pathway to direct photon energy toward the reaction center since resonance energy is transferred from higher to lower energy levels.
p. 184 Fig. 10.11 understand Yes—otherwise, changes in the production of oxygen could be due to differences in the number of chloroplasts, not differences in the rate of photosynthesis.
p. 186 analyze Light → Antenna complex → Reaction center → Pheophytin → ETC → Proton gradient → ATP synthase. Electrons from water are donated to the reaction center to replace those that were transferred to pheophytin.
p. 188 remember (1) Plastocyanin transfers electrons that move through the cytochrome complex in the ETC to the reaction center of photosystem (PS) I. (2) After they are excited by a photon and donated to the initial electron acceptor.
p. 190 CYU analyze In mitochondria, high-energy electrons are donated by NADH or $FADH_2$ (primary donors) and passed through an ETC to generate a proton-motive force. The low-energy electrons at the end of the chain are accepted by O_2 (terminal acceptor) to form water. In chloroplasts, low-energy electrons are donated by H_2O (primary donor), energized by photons or resonance energy, and passed through an ETC to generate a proton-motive force. These electrons are then excited a second time by photons or resonance energy, and the high-energy electrons are accepted by $NADP^+$ (terminal acceptor) to form NADPH.
p. 190 Fig. 10.18 understand The researchers didn't have any basis on which to predict these intermediates. They needed to perform the experiment to identify them.
p. 192 apply Each complete cycle requires 3 ATP and 2 NADPH molecules. To complete 6 runs through the cycle, a total of 18 ATP and 12 NADPH molecules are needed. By following the number of carbons, it is apparent that only three RuBP molecules are required, since they are fully regenerated every 3 cycles: 3 RuBP (15 carbons) fix and reduce 3 CO_2 to generate 6 G3P (18 carbons), yielding 1 G3P (3 carbons); the other 5 are used to regenerate 3 RuBP (15 carbons). The regeneration of RuBP means that only three would be required for continued runs through the Calvin cycle.
p. 194 Fig. 10.24 apply The morning would have the highest concentration of organic acids in the vacuoles of CAM plants, since these acids are made during the night and used up during the day.
p. 195 CYU (1) understand (a) C_4 plants use PEP carboxylase to fix CO_2 into organic acids in mesophyll cells. These organic acids are then transported into bundle-sheath cells, where they release carbon dioxide to rubisco. (b) CAM plants take in CO_2 at night and have enzymes that fix it into organic acids stored in the central vacuoles of photosynthesizing cells. During the day, the organic acids are processed to release CO_2 to rubisco. (c) By diffusion through a plant's stomata when they are open. **(2)** apply The concentration of starch would be highest at the end of the day and lowest at the start of the day. Starch is made and stored in the chloroplasts of leaves during periods of high photosynthetic activity during the day. At night, it is broken down to make sucrose, which is transported throughout the plant to drive cellular respiration. (Cellular respiration also occurs during the day, but the impact is minimized due to the photosynthetic production of sugar.)

IF YOU UNDERSTAND . . .

10.1 understand The Calvin cycle depends on the ATP and NADPH produced by the light-capturing reactions, so it is not independent of light. **10.2** understand Most of the energy captured by pigments in chloroplasts is converted into chemical energy by reducing electron acceptors in ETCs. When pigments are extracted, the antenna complexes, reaction centers, and ETCs have been disassembled, so the energy is given off as fluorescence and heat. **10.3** understand Oxygen is produced by a critical step in photosynthesis: splitting water to provide electrons to PS II. If oxygen production increases, it means that more electrons are moving through the photosystems. **10.4** apply Each CO_2 that is fixed and reduced by the Calvin cycle requires 2 NADPH, which means that 12 NADPH molecules are required for a 6-carbon glucose. Each NADPH is made when two high-energy electrons reduce $NADP^+$. Each of these high-energy electrons originates from H_2O only after being excited by 2 photons (one in PS II and one in PS I). This means that 48 photons are required to produce 24 high-energy electrons to reduce 12 $NADP^+$ molecules for the fixation and reduction of 6 CO_2 to make glucose. Photorespiration would increase the number of photons required, since some of the CO_2 that is fixed would be released.

YOU SHOULD BE ABLE TO . . .

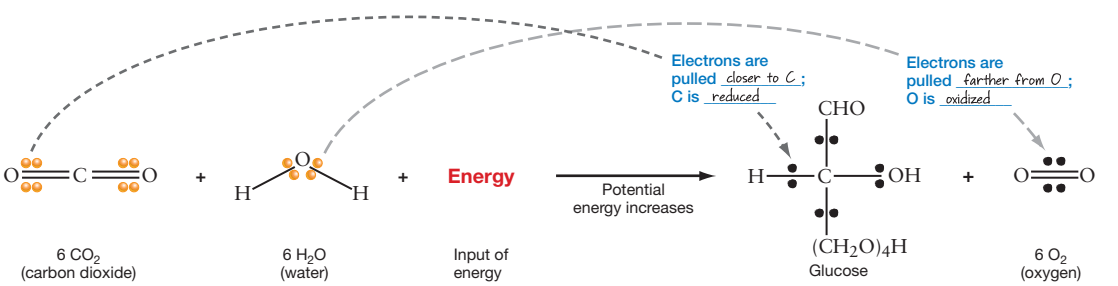
Test Your Knowledge

1. remember d **2.** understand c **3.** remember c **4.** understand b **5.** remember The conversion of light energy to chemical energy occurs when electrons are transferred from excited pigments to an electron carrier in the photosystems. **6.** remember The electron transport chain that accepts electrons from PS II. Plastocyanin is the molecule that transfers electrons from this chain to the PS I reaction center.

Test Your Understanding

7. understand The electrons taken from water in PS II are excited twice by either photons or resonance energy. When excited in PS II, the electrons are transferred to PQ and used to build a proton-motive force that makes ATP. After reaching PS I, they are excited a second time and will either be used to reduce $NADP^+$ to make NADPH (noncyclic) or be transported back to PQ to produce more ATP (cyclic). **8.** analyze c **9.** understand The fixation phase is when CO_2 is fixed to RuBP by rubisco to form 3-phosphoglycerate. The reduction phase uses ATP to phosphorylate the carbons and NADPH to

FIGURE A10.1



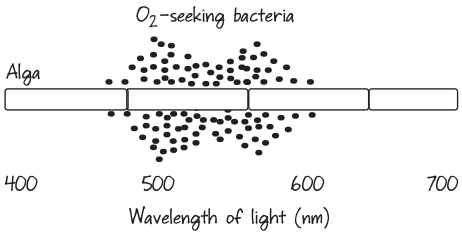


FIGURE A10.2

reduce them with high-energy electrons to form G3P. The regeneration phase uses more ATP to convert some of the G3P to RuBP to continue the cycle. **10.** understand Photorespiration occurs when levels of CO_2 are low and O_2 are high. Less sugar is produced because (1) CO_2 doesn't participate in the initial reaction catalyzed by rubisco and (2) when rubisco catalyzes the reaction with O_2 instead, one of the products is eventually broken down to CO_2 in a process that uses ATP. **11.** understand In both C_4 and CAM plants, atmospheric CO_2 is brought in through stomata and first captured by fixing it to a 3-carbon molecule by PEP carboxylase. The C_4 pathway and CAM differ in the timing of this first fixation step—it occurs during the day in C_4 plants and during the night in CAM plants. They also differ in the location of the Calvin cycle with respect to this first fixation step. In C_4 plants, the two processes occur in different cells, while in CAM plants they occur in the same cell, but at different times (Calvin cycle during the day). **12.** analyze Photosynthesis in chloroplasts produces sugar, which is used as a source of carbon for building organic molecules and energy for cellular respiration. Mitochondria harvest the energy stored in sugar to produce ATP, which is used to drive many cellular activities.

✔ Test Your Problem-Solving Skills

13. apply (1) O_2, ATP, and NADPH would be formed by noncyclic electron flow. (2) No O_2 or NADPH would be formed, but ATP may be made by cyclic electron flow. (3) Initially, O_2 and NADPH would be formed by noncyclic electron flow, but no ATP would be made. Without ATP, the Calvin cycle would halt and, once all the $NADP^+$ is used up, noncyclic electron flow would switch to cyclic electron flow. **14.** evaluate Because rubisco evolved in a high CO_2, low O_2 environment, which would minimize the impact of photorespiration, the hypothesis is credible. But once O_2 levels increased, any change in rubisco that minimized photorespiration would give individuals a huge advantage over organisms with "old" forms of rubisco. There has been plenty of time for such changes to occur, making the "holdover" hypothesis less credible. **15.** analyze b; the wavelength of light could excite PS I, but not PS II, resulting in cyclic electron flow since no electrons could be harvested from water by PS II. **16.** create No—they are unlikely to have the same complement of photosynthetic pigments. Different wavelengths of light are available in various layers of a forest and water depths. It is logical to predict that plants and algae have pigments that absorb the available wavelengths efficiently. One way to test this hypothesis would be to isolate pigments from species in different locations and test the absorbance spectra of each.

BIG PICTURE Energy

p. 198 CYU (1) understand Photosynthesis uses H_2O as a substrate and releases O_2 as a by-product; cellular respiration uses O_2 as a substrate and releases H_2O as a by-product. **(2)** understand Photosynthesis uses CO_2 as a substrate; cellular respiration releases CO_2 as a by-product. **(3)** analyze CO_2 fixation would essentially stop; CO_2 would continue to be released by cellular respiration. CO_2 levels in the atmosphere would increase rapidly, and production of new plant tissue would cease—meaning that most animals would quickly starve to death. **(4)** analyze ATP "is used by" the Calvin cycle; photosystem I "yields" NADPH.

CHAPTER 11

IN-TEXT QUESTIONS AND EXERCISES

p. 204 CYU analyze Plant cell walls and animal ECMs are both fiber composites. In plant cell walls the fiber component consists of cross-linked cellulose fibers, and the ground substance is pectin. In animal ECMs the fiber component consists of collagen fibrils, and the ground substance is proteoglycan.
p. 207 apply Developing muscle cells could not adhere normally, and muscle tissue would not form properly. The embryo would die.
p. 207 Fig. 11.9 apply "Prediction": Cells treated with an antibody that blocks membrane proteins involved in adhesion will not adhere. "Prediction of null hypothesis": All cells will adhere normally.
p. 209 CYU (1) analyze The three structures differ in composition, but their function is similar. The middle lamella in plants is composed of pectins that glue adjacent cells together. Tight junctions are made up of membrane proteins that line up and "stitch" adjacent cells together. Desmosomes are "rivet-like" structures composed of proteins that link the cytoskeletons of adjacent cells. **(2)** understand The plasma membranes of adjacent plant cells are continuous at plasmodesmata and share portions of the smooth endoplasmic reticulum. Gap junctions connect adjacent animal cells by forming protein-lined pores. Both structures result in openings between the cells that allow cytosol, including ions and small molecules, to be shared.
p. 211 Fig. 11.12 create The steroid hormone likely changes the structure of the receptor such that it now exposes a nuclear localization signal, which is required for the protein to be transported into the nucleus.
p. 213 analyze The spy is the signaling molecule that arrives at the cell surface (the castle gate). The guard is the G-protein-coupled receptor in the plasma membrane, and the queen is the G protein. The commander of the guard is the enzyme that is activated by the G protein to produce second messengers (the soldiers).
p. 214 apply **(1)** The red dominos (RTK components) would be the first two dominos in the chain, followed by the black domino (Ras). This black domino would start two or more new branches, each one represented by a single domino of one color (e.g., green) to represent the activation of one type of kinase. Each of these green dominos would then again branch out, knocking down two or more branches consisting of single dominos of a different color (blue). The same branching pattern would result from each blue domino knocking down two or more yellow dominos. **(2)** Each single black domino (Ras) would require 10 green dominos, 100 blue dominos, and 1000 yellow dominos.
p. 215 CYU (1) understand Each cell–cell signaling molecule binds to a specific receptor protein. A cell can respond to a signal only if it has the appropriate receptor. Only certain cell types will have the appropriate receptor for a given signaling molecule. **(2)** understand Signals are amplified if one or more steps in a signal transduction pathway, involving either second messengers or a phosphorylation cascade, result in the activation of multiple downstream molecules.
p. 215 Fig. 11.16 apply **(1)** cell responses A and C **(2)** cell responses A, B, and C **(3)** cell responses B and C.

IF YOU UNDERSTAND . . .

11.1 apply (1) Cells without functional integrin molecules would likely die as a result of not being able to send the appropriate anchorage-dependent survival signals. (2) Cells would be more sensitive to pulling or shearing forces; both cells and tissues would be weaker and more susceptible to damage. **11.2** apply Cells would not be coordinated in their activity, so the heart tissue would not contract in unison and the heart would not beat.
11.3 analyze Adrenalin binds to both heart and liver cells, but the activated receptors trigger different signal transduction pathways and lead to different cell responses.
11.4 analyze The signal transduction pathways are similarly organized in both unicellular and multicellular organisms—consisting of signaling molecules, receptors, and second messengers. There is more variety in the means of transmitting the signal between cells in multicellular organisms compared to unicellular organisms. For example, there are no direct connections such as gap junctions or plasmodesmata in unicellular organisms.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. remember Fiber composites consist of cross-linked fiber components that withstand tension and a ground substance that withstands compression. The cellulose microfibrils in plants and collagen fibrils in animals functionally resemble the steel rods in reinforced concrete. The pectin in plants and proteoglycan in animals functionally resemble the concrete ground substance. **2.** remember b **3.** remember a **4.** understand b **5.** remember d **6.** remember Responses that affect which proteins are produced and those that affect the activity of existing proteins.

✔ Test Your Understanding

7. understand b **8.** understand If each enzyme in the cascade phosphorylates many copies of the enzyme in the next step of the cascade, the initial signal will be amplified many times over. **9.** analyze All three are made up of membrane-spanning proteins that directly interact between adjacent cells. Tight junctions seal adjacent animal cells together; gap junctions allow a flow of material from the cytosol of one to the other. Desmosomes firmly secure adjacent cells to one another but do not affect the movement of substances between cells or into the cells. **10.** understand When dissociated cells from two sponge species were mixed, the cells sorted themselves into distinct aggregates that contained only cells of the same species. By blocking membrane proteins with antibodies and isolating cells that would not adhere, researchers found that specialized groups of proteins, including cadherins, are responsible for selective adhesion. **11.** create Signaling molecule crosses plasma membrane and binds to intracellular receptor (reception) → Receptor changes conformation, and the activated receptor complex moves to target site (processing) → Activated receptor complex binds to a target molecule (e.g., a gene or membrane pump), which changes its activity (response) → Signaling molecule falls off receptor or is destroyed; receptor changes to inactive conformation (deactivation). **12.** understand Information from different signals may conflict or be reinforcing. "Crosstalk" between signaling pathways allows cells to integrate information from many signals at the same time instead of responding to each signal in isolation.

✔ Test Your Problem-Solving Skills

13. apply d **14.** analyze (a) The response would have to be extremely local—the activated receptor complex would have to affect nearby proteins. (b) No amplification could occur, because the number of signaling molecules dictates the amount of the response. (c) The only way to regulate the response would be to block the receptor or make it more responsive to the signaling molecule. **15.** create Chitin forms chains that can cross-link with one another. This fungal cell wall would likely need to be either relaxed or destroyed, and new cell wall synthesis

would be coordinated with the directional growth.
16. create Antibody binding to the two parts of the receptor may be causing them to dimerize. Since dimerization normally results after the signaling molecule binds to the receptor, the antibodies could be activating the receptor by mimicking this interaction. The result would be signal transduction even in the absence of the signaling molecule.

CHAPTER 12

IN-TEXT QUESTIONS AND EXERCISES

p. 223 understand **(1)** Genes are segments of chromosomes that code for RNAs and proteins. **(2)** Chromosomes are made of chromatin. **(3)** Sister chromatids are identical copies of the same chromosome, joined together.
p. 224 Fig. 12.5 apply (1) prophase cells would have 4 chromosomes with 2*x* DNA. (2) Anaphase cells would have 8 chromosomes and 2*x* DNA. (3) Each daughter cell will have 4 chromosomes with *x* DNA.
p. 226 apply See **TABLE A12.1**.
p. 227 Fig. 12.6 apply The chromosome and black bar would move at the same rate toward the spindle pole.
p. 229 CYU (1) apply See **FIGURE A12.1**. **(2)** apply Loss of the motors would result in two problems: (1) It would reduce the ability of chromosomes to attach to microtubules via their kinetochores; (2) cytokinesis would be inhibited since the Golgi-derived vesicles would not be moved to the center of the spindle to build the cell plate.
p. 230 Fig. 12.10 create Inject cytoplasm from an M-phase frog egg into a somatic cell that is in interphase. If the somatic cell starts mitosis, then the meiotic factor is not limited to gametes.
p. 230 Fig. 12.11 analyze In effect, MPF turns itself off after it is activated. If this didn't happen, the cell might undergo mitosis again before the cell has replicated its DNA.

FIGURE A12.1

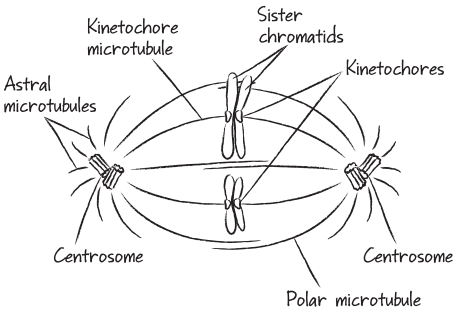

FIGURE A12.2

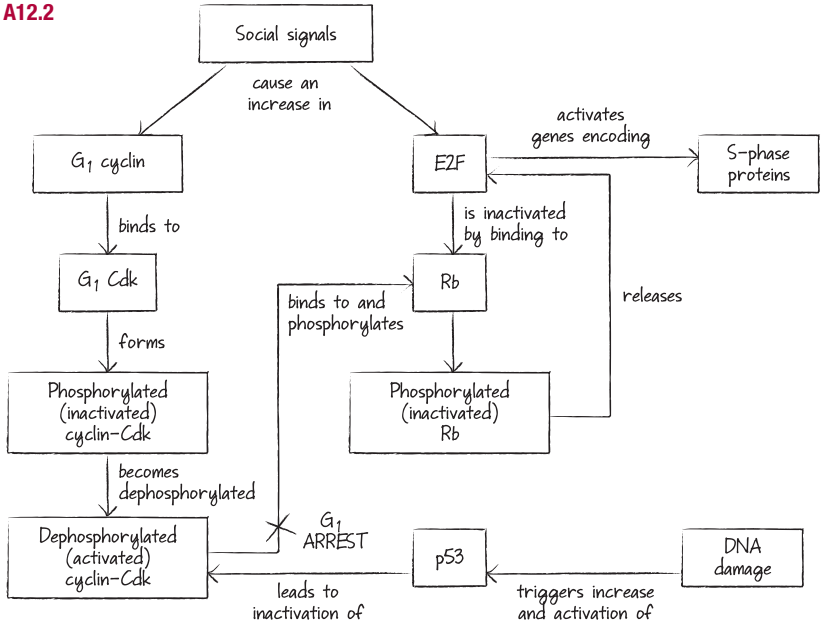

TABLE A12.1

	Prophase	Prometaphase	Metaphase	Anaphase	Telophase
Spindle apparatus	Starts to form	Contacts and moves chromosomes	Anchors poles to membrane and produces tension at kinetochores	Pulls chromatids apart	Defines site of cytokinesis
Nuclear envelope	Present	Disintegrates	Nonexistent	Nonexistent	Re-forms
Chromosomes	Condense	Attach to microtubules	Held at metaphase plate	Sister chromatids separate into daughter chromosomes	Collect at opposite poles

p. 231 understand MPF activates proteins that get mitosis under way. MPF consists of a cyclin and a Cdk, and it is turned on by phosphorylation at the activating site and dephosphorylation at the inhibitory site. Enzymes that degrade cyclin reduce MPF levels.
p. 232 CYU (1) remember $G_1 \rightarrow S \rightarrow G_2 \rightarrow M$. Checkpoints occur at the end of G_1 and G_2 and during M phase. **(2)** understand Cdk levels are fairly constant throughout the cycle, but cyclin increases during interphase and peaks in M phase. This accumulation of cyclin is a prerequisite for MPF activity, which turns on at the end of G_2, initiating M phase, and declines at the end of M phase.

IF YOU UNDERSTAND . . .

12.1 understand The G_1 and G_2 phases give the cell time to replicate organelles and grow before division as well as perform the normal functions required to stay alive. Chromosomes replicate during S phase and are separated from one another during M phase. Cytokinesis also occurs during M phase, when the parent cell divides into two daughter cells. **12.2** apply In cells that do not dissolve the nuclear envelope, the spindle must be constructed inside the nucleus to attach to the chromosomes and separate them. **12.3** apply Cells would prematurely enter M phase, shortening the length of G_2 and resulting in the daughter cells' being smaller than normal. **12.4** analyze The absence of growth factors in normal cells would cause them to arrest in the G_1 phase—eventually all the cells in the culture would be in G_1. The cancerous cells are not likely to be dependent on these growth factors, so the cells would not arrest and would continue through the cell cycle.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. remember b **2.** remember d **3.** remember d **4.** remember c
5. understand Daughter chromosomes were observed to move toward the pole faster than do the marked regions of fluorescently labeled kinetochore microtubules.
6. remember The cycle would arrest in M phase, and cytokinesis would not occur.

✔ Test Your Understanding

7. apply For daughter cells to have identical complements of chromosomes, all the chromosomes must be replicated during the S phase, the spindle apparatus must connect with the kinetochores of each sister chromatid in prometaphase, and the sister chromatids of each replicated chromosome must be partitioned in anaphase and fully separated into daughter cells by cytokinesis. **8.** create One possible concept map is shown in **FIGURE A12.2**. **9.** understand Microinjection experiments suggested that something in the cytoplasm of M-phase cells activated the transition from interphase to M phase. The control for this experiment was to inject cytoplasm from a G_2-arrested oocyte into another G_2-arrested oocyte. **10.** apply Protein kinases phosphorylate proteins. Phosphorylation changes a protein's shape, altering its function (activating or inactivating it). As a result, protein kinases regulate the function of proteins. **11.** understand Cyclin concentrations change during the cell cycle. At high concentration, cyclins bind to a specific cyclin-dependent kinase (or Cdk), forming a dimer. This dimer becomes active MPF by changing its shape through the phosphorylation (activating site) and dephosphorylation (inhibitory site) of Cdk. **12.** analyze b.

✔ Test Your Problem-Solving Skills

13. analyze a; adding up each phase allows you to determine that the cell cycle is 8.5 hours long. After 9 hours, the radiolabeled cells would have passed through a full cycle and be in either S phase or G_2—none would have entered M phase. **14.** apply The embryo passes through multiple rounds of the cell cycle, but cytokinesis does

not occur during M phases. **15.** apply Early detection of cancers leads to a greater likelihood of survival. The widespread implementation of breast and prostate exams allows for the identification and removal of benign tumors before they become malignant. **16.** analyze Cancer requires many defects. Older cells have had more time to accumulate defects. Individuals with a genetic predisposition to cancer start out with some cancer-related defects, but this does not mean that the additional defects required for cancer to occur will develop.

CHAPTER 13

IN-TEXT QUESTIONS AND EXERCISES

p. 239 apply $n = 4$; the organism is diploid with $2n = 8$.
p. 240 remember See **FIGURE A13.1**. Because the two sister chromatids are identical and attached, it is sensible to consider them as parts of a single chromosome.
p. 242 apply There will be four DNA molecules in each gamete because the 8 replicated chromosomes in a diploid cell are reduced to 4 replicated chromosomes per cell at the end of meiosis I. In meiosis II, the sister chromatids of each replicated chromosome are separated. Each cell now contains 4 unreplicated chromosomes, each with a single molecule of DNA.
p. 245 apply Crossing over would not occur and the daughter cells produced by meiosis would be diploid, not haploid. There would be no reduction division.
p. 246 CYU (1) understand Use four long and four short pipe cleaners (or pieces of cooked spaghetti) to represent the chromatids of two replicated homologous chromosomes (four total chromosomes). Mark two long and two short ones with a colored marker pen to distinguish maternal and paternal copies of these chromosomes. Twist identical pipe cleaners (e.g., the two long colored ones) together to simulate replicated chromosomes. Arrange the pipe cleaners to depict the different phases of meiosis I as follows: *Early prophase I:* Align sister chromatids of each homologous pair to form two tetrads. *Late prophase I:* Form one or more crossovers between non-sister chromatids in each tetrad. (This is hard to simulate with pipe cleaners—you'll have to imagine that each chromatid now contains both maternal and paternal segments.) *Metaphase I:* Line up homologous pairs (the two pairs of short pipe cleaners and the two pairs of long pipe cleaners) at the metaphase plate. *Anaphase I:* Separate homologs. Each homolog still consists of sister chromatids joined at the centromere. *Telophase I and cytokinesis:* Move homologs apart to depict formation of two haploid cells, each containing a single replicated copy of two different chromosomes. **(2)** understand During anaphase I, homologs (not sister chromatids, as in mitosis) are separated, making the cell products of meiosis I haploid. **(3)** understand The pairing of homologs in metaphase I and their separation in anaphase I so that one goes to one daughter cell and the other to the other daughter cell means that each daughter cell obtains precisely one copy of each type of chromosome.
p. 248 apply Each gamete would inherit either all maternal or all paternal chromosomes. This would limit genetic variation in the offspring by precluding the many possible gametes containing various combinations of maternal and paternal chromosomes.
p. 248 CYU (1) apply See **FIGURE A13.2**. Maternal chromosomes are white and paternal chromosomes are black. Daughter cells with other possible combinations of chromosomes than shown could result from meiosis of this parent cell. **(2)** understand Crossing over would increase the genetic diversity of these gametes by creating many different combinations of maternal and paternal alleles along each of the chromosomes. **(3)** analyze Asexual reproduction generates no appreciable genetic diversity. Self-fertilization is preceded by meiosis so it generates gametes, through crossing over and independent assortment, that have combinations of alleles not present in the parent. Outcrossing generates the most genetic diversity among offspring because it produces new combinations of alleles from two different individuals.
p. 249 Fig. 13.11 apply See **FIGURE A13.3**.
p. 251 Fig. 13.14 apply Asexually: 64 (16 individuals from generation three produce 4 offspring per individual). Sexually: 16 (8 individuals from generation three form 4 couples; each couple produces 4 offspring).
p. 252 Fig. 13.15 apply The rate of outcrossing is predicted to rise initially, as the pathogen selects for resistant roundworms, and then to fall as the roundworms in the population gain resistance and take advantage of the increased numbers of offspring offered by having more hermaphrodites that can reproduce by self-fertilization.

IF YOU UNDERSTAND . . .

13.1 remember See the right panel of Figure 13.7 and note how the cells transition from diploid to haploid in meiosis I. Also note that each chromosome contains two sister chromatids before and after meiosis I.
13.2 understand (a) See Figure 13.10 and note how the two different ways of aligning two homologous pairs of chromosomes at metaphase I of meiosis can create four different combinations of maternal and paternal chromosomes in daughter cells. (b) See Figure 13.11. Note that for each homologous pair with one crossover, two chromatids are recombinant and two are unaltered. Since each chromatid will produce a chromosome at the end of meiosis II, your drawing should show that two out of four of these chromosomes are recombinant.
13.3 apply (a) Your model should show events similar to those of Figure 13.12. (b) Your model should show two cells with one of each type of chromosome (n), one cell with an extra copy of one chromosome ($n + 1$), and one gamete without any copies of one chromosome ($n - 1$).
13.4 remember Sexual reproduction will likely occur during times when conditions are changing rapidly, because genetically diverse offspring may have an advantage in the new conditions.

YOU SHOULD BE ABLE TO . . .

✓ Test Your Knowledge

1. remember b **2.** remember a **3.** remember b **4.** understand b
5. remember 1/2 **6.** remember mitosis.

✓ Test Your Understanding

7. remember Homologous chromosomes are similar in size, shape, and gene content, and originate from different parents. Sister chromatids are exact copies of a chromosome that are generated when chromosomes are replicated (S phase of the cell cycle). **8.** understand Refer to Figure 13.7 as a guide for this exercise. The four pens represent the chromatids in one replicated homologous pair; the four pencils, the chromatids in a different homologous pair. To simulate meiosis II, make two "haploid cells"—each with a pair of pens and a pair of pencils representing two replicated chromosomes (one of each type in this species). Line them up in the middle of the cell; then separate the two pens and the two pencils in each cell such that one pen and one pencil go to each of four daughter cells. **9.** understand Meiosis I is a reduction division because homologs separate—daughter cells have just one of each type of chromosome instead of two. Meiosis II is not a reduction division because sister chromatids separate— daughter cells have unreplicated chromosomes instead of replicated chromosomes, but still just one of each type. **10.** apply b. **11.** apply Tetraploids produce diploid gametes, which combine with a haploid gamete from a diploid individual to form a triploid offspring. Mitosis proceeds normally in triploid cells because mitosis doesn't require forming pairs of chromosomes. But during meiosis in a triploid, homologous chromosomes can't pair up correctly. The third set of chromosomes does not have a homologous partner to pair with. **12.** understand Asexually produced individuals are genetically identical, so if one is susceptible to a new disease, all are. Sexually produced individuals are genetically unique, so if a new disease strain evolves, at least some plants are likely to be resistant.

FIGURE A13.1

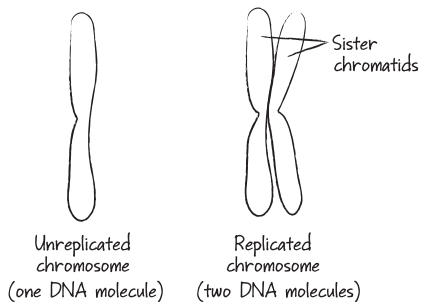

FIGURE A13.3

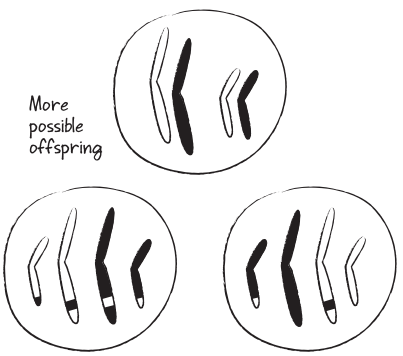

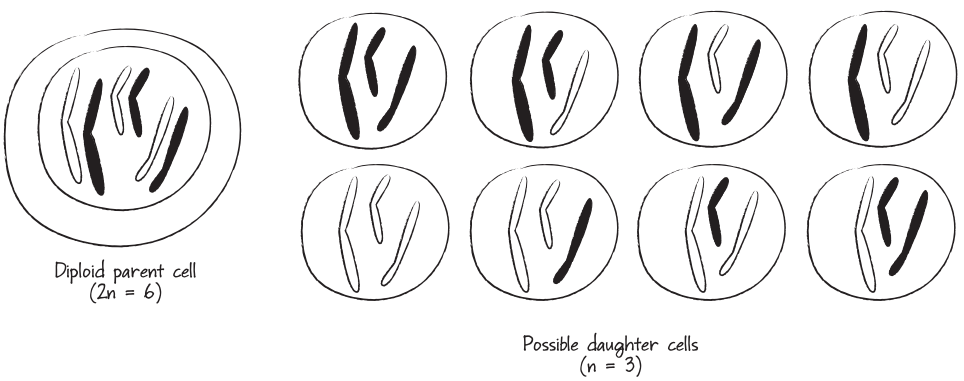

FIGURE A13.2

✔ Test Your Problem-Solving Skills

13. apply The gibbon would have 22 chromosomes in each gamete, and the siamang would have 25. Each somatic cell of the offspring would have 47 chromosomes. The offspring should be sterile because it has some chromosomes that would not form homologous pairs at prophase I of meiosis. **14.** apply c **15.** apply Aneuploidy is the major cause of spontaneous abortion. If spontaneous abortion is rare in older women, it would result in a higher incidence of aneuploid conditions such as Down syndrome in older women, as recorded in the Figure 13.13. **16.** (a) create Such a study might be done in the laboratory, controlling conditions in identical dishes. A population of rotifers infected with fungus could be established in each dish. One dish of rotifers would be kept moist; the other dishes of rotifers would be allowed to dry out. After various periods of time, water would be added to each dish and then the rotifers would be observed to see if fungal infections reappeared. (b) create Wind disperses the rotifer to new and often pathogen-free environments. In this case, the ticket to a sex-free existence is not genetic diversity but the evolution of an alternative means of evading pathogens made possible by fungus-infected rotifers ridding themselves of the pathogen when they dry.

CHAPTER 14

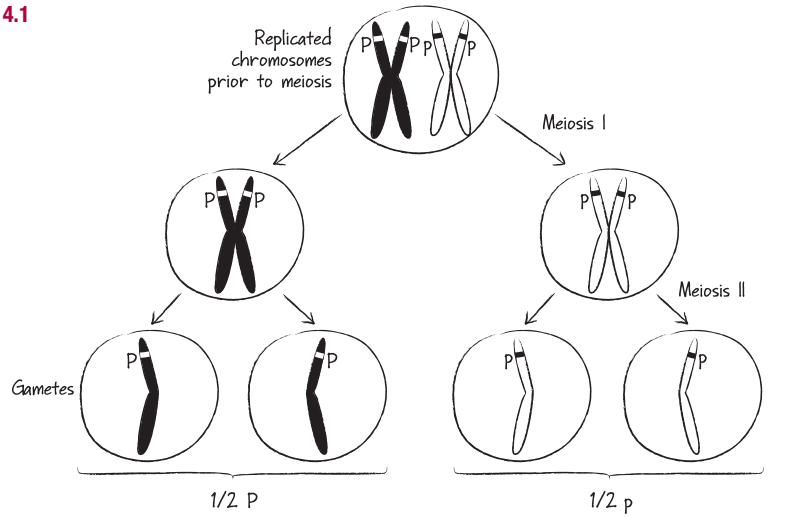
IN-TEXT QUESTIONS AND EXERCISES

p. 260 Fig. 14.3 evaluate An experiment is a failure if you didn't learn anything from it. That is not the case here.
p. 261 Table 14.2 analyze *Row 6:* 3.14 : 1; *Row 7:* 266.
p. 262 apply Filling in the top and side of a Punnett square requires writing out the types and ratios of gametes. For a cross involving one gene (monohybrid cross), this amounts to applying the principle of segregation as one allele is segregated from another. The phenotype ratios are 1 : 1 round : wrinkled; the genotype ratios are 1 : 1 *Rr* : *rr*.
p. 262 Fig. 14.4 understand No—the outcome (the expected offspring genotypes that the Punnett square generates) will be the same.

p. 263 CYU (1) apply See answer to Problem 13 in Test Your Problem-Solving Skills, below. **(2)** apply See answer to Problem 15 in Test Your Problem-Solving Skills.
p. 265 apply *AABb* → *AB* and *Ab*. *PpRr* → *PR, Pr, pR,* and *pr*. *AaPpRr* → *APR, APr, ApR, Apr, aPR, apR, apr,* and *aPr*.
p. 265 CYU (1) apply See answer to Problem 14 in Test Your Problem-Solving Skills. **(2)** apply See answer to Problem 16 in Test Your Problem-Solving Skills.
p. 269 CYU (1) understand See **FIGURE A14.1**. Segregation of alleles occurs when homologs that carry those alleles are separated during anaphase I. One allele ends up in each daughter cell. **(2)** understand See **FIGURE A14.2**. Independent assortment occurs because homologous pairs line up randomly at the metaphase plate during metaphase I. The figure shows two alternative arrangements of homologs in metaphase I. As a result, it is equally possible for a gamete to receive the following four combinations of alleles: *YR, Yr, yR, yr*.
p. 270 Fig. 14.12 apply X*WY*, X*Wy*, X*wY*, X*wy*.

p. 271 Fig. 14.13 analyze Random chance (or perhaps red-eyed, gray-bodied males don't survive well).
p. 273 Fig. 14.16 analyze The gene colored orange is *ruby*; the gene colored blue is *miniature wings*.
p. 275 Fig. 14.19 understand In this case of gene-by-gene interaction, the 9 : 3 : 3 : 1 ratio comes from four different forms of one trait (comb shape), whereas in a standard dihybrid cross, the four different phenotypes come from two different phenotypes for each of two genes.
p. 276 CYU (1) apply The comb phenotype results from interactions between alleles at two different genes, not a single gene. Matings between rose- and pea-comb chickens produce F_2 offspring that may have a new combination of alleles and thus new phenotypes. **(2)** apply Kernel color in wheat is influenced by alleles at many different genes, not a single gene. F_2 offspring have a normal distribution of phenotypes, not a 3 : 1 ratio.
p. 276 Fig. 14.21 understand Because there are many different genotypes that can produce intermediate coloration and fewer that can produce the extremes of coloration.

FIGURE A14.1



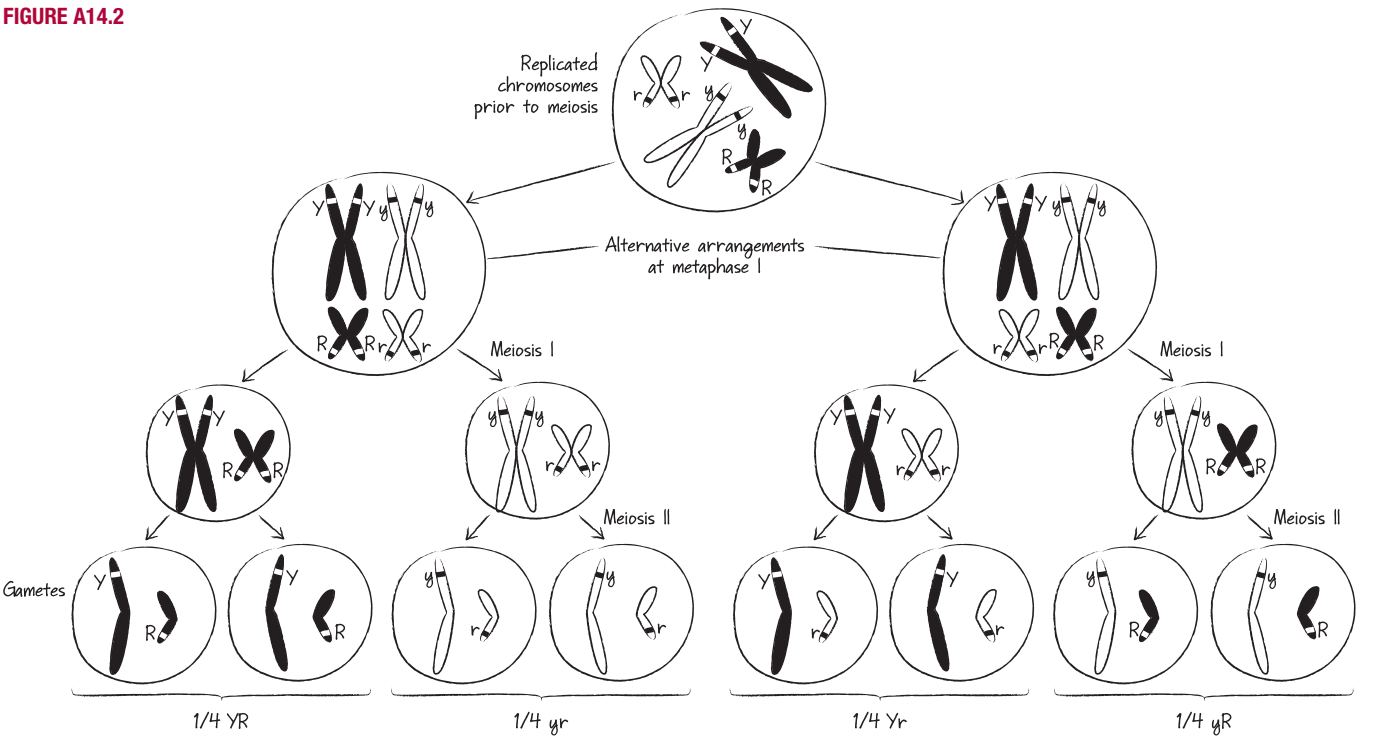


FIGURE A14.2

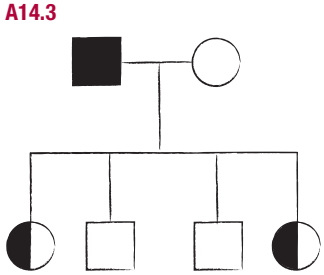
p. 279 Fig. 14.23 apply A heterozygous female and a color-blind male. 1 color-blind male : 1 color-blind female.

IF YOU UNDERSTAND . . .

14.1 understand Because crosses within a pure line never produce individuals with a different phenotype, this indicates that there must be only one allele in pure-line individuals. **14.2** apply *B* and *b*. **14.3** apply *BR*, *Br*, *bR*, and *br*, in equal proportions. The *B* and *b* alleles are located on different but homologous chromosomes, which separate into different daughter cells during meiosis I. The *BbRr* notation indicates that the *B* and *R* genes are on different chromosomes. As a result, the chromosomes line up independently of each other in metaphase of meiosis I. The *B* allele is equally likely to go to a daughter cell with *R* as with *r*; likewise, the *b* allele is equally likely to go to a daughter cell with *R* as with *r*. **14.4** apply There are many ways to show this. If eye color in *Drosophila* is chosen as an example, then a pair of Punnett squares like those in Figure 14.11 illustrate how reciprocal crosses involving an X-linked recessive gene give different results. **14.5** understand Linkage refers to the physical connection of two alleles on the same chromosome. Crossing over breaks this linkage between particular alleles as segments of maternal and paternal homologs are exchanged. **14.6** apply See **FIGURE A14.3** for the pedigree. Note that the birth order of daughters and sons is arbitrary; other birth orders are equally valid. A Punnett square will show that all the sons are predicted to be X^+Y and all the daughters X^+X^c, where X^+ shows the dominant, X-linked allele for normal color vision and X^c shows the X-linked recessive color blindness allele.

YOU SHOULD BE ABLE TO . . .



✔ Test Your Understanding

1. understand d **2.** understand b **3.** understand a **4.** understand d **5.** understand a **6.** understand a **7.** evaluate d **8.** remember b **9.** apply b **10.** understand d

✔ Test Your Problem-Solving Skills

11. apply **Example Solution** Here you're given offspring phenotypes and you're asked to infer parental genotypes. To do this you have to propose hypothetical parental genotypes to test, make a Punnett square to predict the offspring genotypes, and then see if the predicted offspring phenotypes match the data. In this case, coming up with a hypothesis for the parental genotypes is relatively straightforward because the problem states that the trait is due to one gene and two alleles. No information on sex is given, so assume the gene is autosomal (the simplest case). Now look at the second entry in the chart. It shows a 3 : 1 ratio of offspring from a winged individual that self-fertilizes. This result is consistent with the hypothesis that W^+ is dominant and W^- recessive and that this parent's genotype is W^+W^-. Now let's look at the first cross in the chart. If W^+ is dominant, then a wingless parent must be W^-W^-. When you do the Punnett square to predict offspring genotypes from selfing, you find that all the offspring will produce wingless fruits, consistent with the data. In the third cross, all the offspring make winged fruits even though one of the parents produces wingless fruits and thus is W^-W^-. This would happen only if the winged parent is W^+W^+. (If this reasoning isn't immediately clear to you, work the Punnett square.) In the fourth cross, you could get offspring that all make winged fruits if the parents were W^+W^+ and W^+W^+, or if the parents were W^+W^+ and W^+W^-. Either answer is correct. Again, you can write out the Punnett squares to see that this statement is correct.

FIGURE A14.3

12. apply **Example Solution** Here you are given parental and offspring phenotypes and are asked to infer the parental genotypes. As a starting point, assume that the coat colors are due to the simplest genetic system possible: one autosomal gene with two alleles, where one allele is dominant and the other recessive. Because female II produces only black offspring, it's logical to suppose that black is dominant to brown. Let's use *B* for black and *b* for brown. Then the male parent is *bb*. To produce offspring with a 1 : 1 ratio of black : brown coats, female I must be *Bb*. But to produce all black offspring, female II must be *BB*. This model explains the data, so you can accept it as correct.

13. apply 3/4; 1/256 (see BioSkills 5 in Appendix B); 1/2 (the probabilities of transmitting the alleles or having sons does not change over time). **14.** apply Your answer to the first three parts should conform to the F_1 and F_2 crosses diagrammed in Figure 14.5b, except that different alleles and traits are being analyzed. The recombinant gametes would be *Yi* and *yI*. Yes—there would be some individuals with yellow seeds and constricted pods and with green seeds and inflated pods. **15.** apply Cross 1: non-crested (*Cc*) × non-crested (*Cc*) = 22 non-crested (*C_*); 7 crested (*cc*). Cross 2: crested (*cc*) × crested (*cc*) = 20 crested (*cc*). Cross 3: non-crested (*Cc*) × crested (*cc*) = 7 non-crested (*Cc*); 6 crested (*cc*). Non-crested (*C*) is the dominant allele. **16.** apply This is a dihybrid cross that yields progeny phenotypes in a 9 : 3 : 3 : 1 ratio. Let *O* stand for the allele for orange petals and *o* the allele for yellow petals; let *S* stand for the allele for spotted petals and *s* the allele for unspotted petals. Start with the hypothesis that *O* is dominant to *o*, that *S* is dominant to *s*, that the two genes are found on different chromosomes so they assort independently, and that the parent individual's genotype is *OoSs*. If you do a Punnett square for the *OoSs* × *OoSs* mating, you'll find that progeny phenotypes should be in the observed 9 : 3 : 3 : 1 proportions. **17.** analyze Let *D* stand for the normal allele and *d* for the allele responsible for Duchenne-type muscular dystrophy. The woman's family has no history of the disease, so her genotype is almost certainly *DD*. The man is not afflicted, so he must be *DY*. (The trait is X-linked, so he has only one allele; the "*Y*" stands for the Y chromosome.) Their children are not at risk. The man's sister could be a carrier, however—meaning she has the genotype *Dd*. If so, then half of the second couple's male children are likely to be affected. **18.** understand Your stages of meiosis should look like a simplified version of Figure 13.7, except with $2n = 4$ instead of $2n = 6$. The *A* and *a* alleles could be on the red and blue versions of the longest chromosome, and the *B* and *b* alleles could be on the red and blue versions of the smallest chromosomes, similar to the way the hair- and eye-color genes are shown in Figure 13.10. The places you draw them are the locations of the *A* and *B* genes, but each chromosome has only one allele. Each pair of red and blue chromosomes is a homologous pair. Sister chromatids bear the same allele (e.g., both sister chromatids of the long blue chromosomes might bear the *a* allele). Chromatids from the longest and shortest chromosomes are not homologous. To identify the events that result in the principles of segregation and independent assortment, see Figures 14.7 and 14.8 and substitute *A, a,* and *B, b* for *R, r* and *Y, y*. **19.** apply Half their offspring should have the genotype iI^A and the type A blood phenotype. The other half of their offspring should have the genotype iI^B and the type B blood phenotype. Second case: the genotype and phenotype ratios would be 1 : 1 : 1 : 1 I^AI^B (type AB) : I^Ai (type A) : I^Bi (type B) : *ii* (type O). **20.** apply Because the children of Tukan and Valco had no eyes and smooth skin, you can conclude that the allele for eyelessness is dominant to eyes and the allele for smooth skin is dominant to hooked skin. *E* = eyeless, *e* = two eye sets, *S* = smooth skin, *s* = hooked skin. Tukan is *eeSS*; Valco is *EEss*. The children are all *EeSs*. Grandchildren with eyes and smooth skin are *eeS-*. Assuming that the genes are on different chromosomes, one-fourth of the children's gametes are *ee* and three-fourths are *S-*. So 1/4 *ee* × 3/4 *S-* × 32 = 6 children would be expected to have two sets of eyes and smooth skin. **21.** create Although the mothers were treated as children by a reduction of dietary phenylalanine, they would have accumulated phenylalanine and its derivatives once they went off the low-phenylalanine diet as young adults. Children born of such mothers were therefore exposed to high levels of phenylalanine during pregnancy. For this reason, a low-phenylalanine diet is recommended for such mothers throughout the pregnancy. **22.** apply According to Mendel's model, palomino individuals should be heterozygous at the locus for coat color. If you mated palomino individuals, you would expect to see a combination of chestnut, palomino, and cremello offspring. If blending inheritance occurred, however, all the offspring should be palomino. **23.** apply Because this is an X-linked trait, the father who has hemophilia could not have passed the trait on to his son. Thus, the mother in couple 1 must be a carrier and must have passed the recessive allele on to her son, who is XY and affected. To educate a jury about the situation, you should draw what happens to the X and Y during meiosis and then make a drawing showing the chromosomes in couple 1 and couple 2, with a Punnett square showing how these chromosomes are passed to the affected and unaffected children. **24.** apply The curved-wing allele is autosomal recessive; the lozenge-eyed allele is sex-linked (specifically, X-linked) recessive. Let *L* be the allele for long wings and *l* be the allele for curved wings; let X^R be the allele for red eyes and X^r the allele for lozenge eyes. The female parent is LlX^RX^r; the male parent is LlX^RY. **25.** apply Albinism indicates the absence of pigment, so let *b* stand for an allele that gives the absence of blue and *y* for an allele that gives the absence of yellow pigment. If blue and yellow pigment blend to give green, then both green parents are *BbYy*. The green phenotype is found in *BBYY, BBYy, BbYY,* and *BbYy* offspring. The blue phenotype is found in *BByy* or *Bbyy* offspring. The yellow phenotype is observed in *bbYY* or *bbYy* offspring. Albino offspring are *bbyy*. The phenotypes of the offspring should be in the ratio 9 : 3 : 3 : 1 as green : blue : yellow : albino. Two types of crosses yield *BbYy* F_1 offspring: *BByy* × *bbYY* (blue × yellow) and *BBYY* × *bbyy* (green × albino). **26.** apply The chance that their first child will have hemophilia is 1/2. This is because all sons will have the disease and there is a 1/2 chance of having a firstborn son. The chance of having a carrier as their first child is also 1/2. This is because all daughters and none of the sons will be carriers and there is a 1/2 chance of having a firstborn daughter. (Recall that males cannot carry an X-linked recessive trait—with only one X chromosome, males either have the trait or not.) **27.** apply Autosomal dominant.

CHAPTER 15

IN-TEXT QUESTIONS AND EXERCISES

p. 286 Fig. 15.2 analyze The lack of radioactive protein in the pellet (after centrifugation) is strong evidence; they could also make micrographs of infected bacterial cells before and after agitation.
p. 287 Fig. 15.3 apply 5′-TAG-3′.
p. 288 Fig. 15.5 apply The same two bands should appear, but the upper band (DNA containing only ^{14}N) should get bigger and darker and the lower band (hybrid DNA)

should get smaller and lighter in color since each succeeding generation has relatively less heavy DNA.
p. 290 apply See **FIGURE A15.1**. The new strands grow in opposite directions, each in the 5′ → 3′ direction.
p. 292 apply Helicase, topoisomerase, single-strand DNA-binding proteins, primase, and DNA polymerase are all required for leading-strand synthesis. If any one of these proteins is nonfunctional, DNA replication will not occur.
p. 293 apply See **FIGURE A15.2**. If DNA ligase were defective, then the leading strand would be continuous, and the lagging strand would have gaps in it where the Okazaki fragments had not been joined.
p. 294 CYU (1) understand DNA polymerase adds nucleotides only to the free 3′ −OH on a strand. Primase synthesizes a short RNA sequence that provides the free 3′ end necessary for DNA polymerase to start working. **(2)** understand The need to begin DNA synthesis many times on the lagging strand requires many new primers. Since DNA polymerase I is needed to remove primers, it is required predominantly on the primer-rich lagging strand.
p. 296 Fig. 15.13 apply As long as the RNA template could bind to the "overhanging" section of single-stranded DNA, any sequence could produce a longer strand. For example, 5′-CCCAUUCCC-3′ would work just as well.
p. 297 CYU (1) understand This is because telomerase is needed only to replicate one end of a linear DNA and bacterial DNAs lack ends because they are circular. **(2)** understand Since telomerase works by extending one strand of DNA without any external template and because DNA synthesis requires a template, telomerase must contain an internal template to allow it to extend a DNA chain.
p. 299 Fig. 15.16 analyze They are lower in energy and not absorbed effectively by the DNA bases.
p. 300 CYU (1) apply The mutation rate would be predicted to rise because differences in base-pair stability and shape make it possible for DNA polymerase to distinguish correct from incorrect base pairs during DNA replication. **(2)** apply The mutation rate should increase because without a way to distinguish which strand to use as a template for repair, about half of mismatches on average would be repaired using the incorrect strand as a template. **(3)** remember The enzyme that removes the dimer and surrounding DNA is specific to nucleotide excision repair. DNA polymerase and DNA ligase work in both nucleotide excision repair and normal DNA synthesis.
p. 300 Fig. 15.18 apply Exposure to UV radiation can cause formation of thymine dimers. If thymine dimers are not repaired, they represent mutations. If such mutations occur in genes controlling the cell cycle, cells can grow abnormally, resulting in cancers.

IF YOU UNDERSTAND . . .

15.1 apply These results would not allow distinguishing whether DNA or protein was the genetic material.
15.2 understand The bases added during DNA replication are shown in red type.

Original DNA:	CAATTACGGA
	GTTAATGCCT
Replicated DNA:	CAATTACGGA
	GTTAATGCCT
	CAATTACGGA
	GTTAATGCCT

15.3 understand See **FIGURE A15.3**. **15.4** understand Because cancer cells divide nearly without limit, it's important for these cells to have active telomerase so that chromosomes don't shorten to the point where cell division becomes impossible. **15.5** understand If errors in DNA aren't corrected, they represent mutations. When DNA repair systems fail, the mutation rate increases. As the mutation rate increases, the chance that one or more cell-cycle genes will be mutated increases. Mutations in these genes often result in uncontrolled cell division, ultimately leading to cancer.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. remember d **2.** understand a **3.** remember topoisomerase
4. remember b **5.** remember c **6.** remember telomerase

✔ Test Your Understanding

7. remember Labeling DNA or labeling proteins. **8.** understand DNA is constantly damaged, and many pathways have evolved to repair this onslaught of damage. If a DNA repair pathway is inactivated by mutation, damage is inefficiently repaired. Consequently mutation rates increase, and the increased number of mutations increases the probability that cancer-causing mutations will occur. **9.** understand On the lagging strand, DNA polymerase moves away from the replication fork. When helicase unwinds a new section of DNA, primase must build a new primer on the template for the lagging strand (closer to the fork) and another polymerase molecule must begin synthesis at this point. This makes the lagging-strand synthesis discontinuous. On the leading strand, DNA polymerase moves in the same direction as helicase, so synthesis can continue, without interruption, from a single primer (at the origin of replication). **10.** understand Telomerase binds to the overhang at the end of a chromosome. Once bound, it begins catalyzing the addition of deoxyribonucleotides to the overhang in the 5′ → 3′ direction, lengthening the overhang. This allows primase, DNA polymerase, and ligase to catalyze the addition of deoxyribonucleotides to the lagging strand in the 5′ → 3′ direction, restoring the lagging strand to its original length. **11.** apply a (Because the ability to distinguish which strand contains the incorrect base would be lost). **12.** analyze d (The regularity of DNA's structure allows enzymes to recognize any type of damage that distorts this regular structure.)

✔ Test Your Problem-Solving Skills

13. analyze c (If DNA polymerase could synthesize DNA 3′ → 5′ as well as the normal 5′ → 3′, then both newly synthesized DNA strands could be extended to follow the replication fork.) **14.** apply (a) In **FIGURE A15.4**, the gray lines represent DNA strands containing radioactivity. (b) After one round of replication in radioactive solution, one double-stranded DNA would be radioactive in both strands and the other would not be radioactive in either strand. After another round of DNA synthesis, this time in nonradioactive solution, one of the four DNA molecules would be radioactive in both strands and the other three DNA molecules would contain no radioactivity in any strand. **15.** analyze (a) The double mutant of both *uvrA* and *recA* is most sensitive to UV light; the single mutants are in between; and the wild type is

FIGURE A15.1

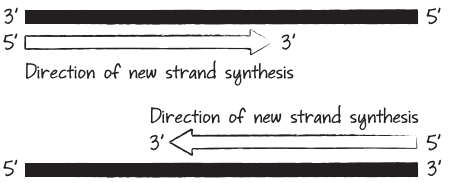


FIGURE A15.2

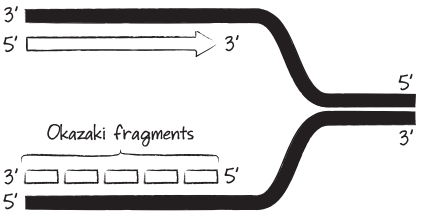

FIGURE A15.3

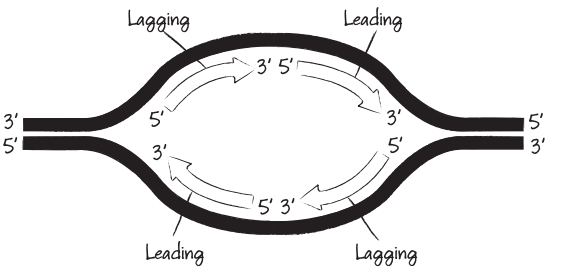

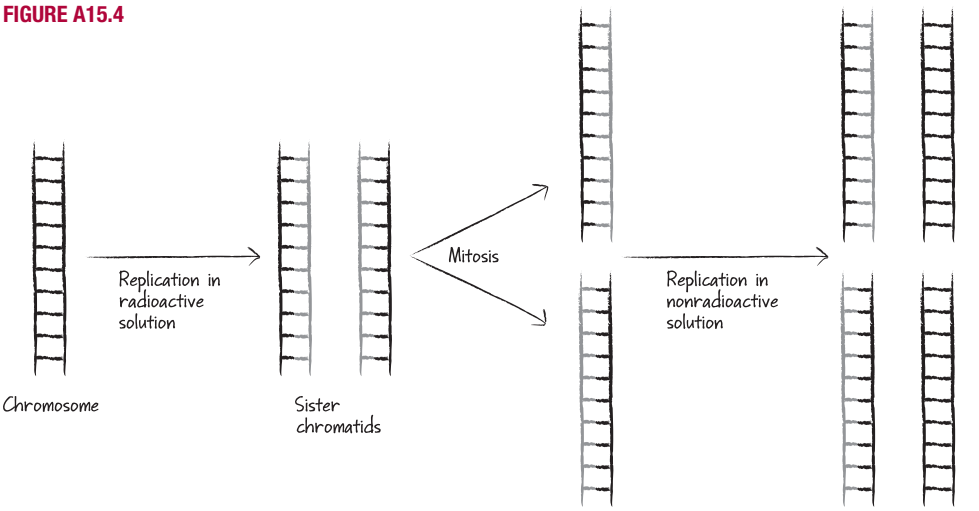

FIGURE A15.4

least sensitive. (b) The *recA* gene contributes more to UV repair through most of the UV dose levels. But at very high UV doses, the *uvrA* gene is somewhat more important than the *recA* gene. **16.** apply About 4600 seconds or 77 minutes. This answer comes from knowing that replication proceeds bidirectionally, so replication from each fork is predicted to replicate half the chromosome. This is 4.6 million base pairs/2 = 2.3 million base pairs. At 500 base pairs per second, this requires 2.3 million base pairs/500 base pairs per second = 4600 seconds. To obtain the time in minutes, divide 4600 seconds by 60 seconds per minute.

CHAPTER 16

IN-TEXT QUESTIONS AND EXERCISES

p. 305 Fig. 16.1 apply No, it could not make citrulline from ornithine without enzyme 2. Yes, it would no longer need enzyme 2 to make citrulline.
p. 306 Fig. 16.2 create Many possibilities: strain of fungi used, exact method for creating mutants and harvesting spores to grow, exact growing conditions (temperature, light, recipe for growth medium—including concentrations of supplements), objective criteria for determining growth or no growth.
p. 309 CYU remember Change in DNA sequence, change in sequence of transcribed mRNA, potential change in amino acid sequence of protein, likely altered protein function (if amino acid sequence was altered), likely change in phenotype.
p. 312 analyze (1) The codons in Figure 16.4 are translated correctly. (2) See **FIGURE A16.1**. (3) There are many possibilities (just pick alternative codons for one or more of the amino acids); one is an mRNA sequence (running 5′ ⟶ 3′): 5′ GCG-AAC-GAU-UUC-CAG 3′. To get the corresponding DNA sequence, write this sequence but substitute Ts for Us: 5′ GCG-AAC-GAT-TTC-CAG 3′. Now write the complementary bases, which will be in the 3′ ⟶ 5′ direction: 3′ CGC-TTG-CTA-AAG-GTC 5′. When this second strand is transcribed by RNA polymerase, it will produce the mRNA given with the proper 5′ ⟶ 3′ orientation.
p. 312 CYU (1) apply Note the 3′ ⟶ 5′ polarity of the DNA sequences in the accompanying table, and in the subsequent answer. This means that the complementary mRNA codon will read 5′ ⟶ 3′. U (rather than T) is the base transcribed from A.

DNA	mRNA Codon	Amino Acid
ATA	UAU	Tyrosine
ATG	UAC	Tyrosine
ATT	UAA	Stop
GCA	UGC	Cysteine

(2) understand The ATA ⟶ ATG mutation would have no effect on the protein. The ATA ⟶ ATT mutation introduces a stop codon, so the resulting polypeptide would be shortened. This would result in synthesis of a mutant protein much shorter than the original protein. The ATA ⟶ GCA mutation might have a profound effect on the protein's conformation because cysteine's structure is different from tyrosine's.
p. 312 Fig. 16.7 apply See **FIGURE A16.1**.
p. 314 Fig. 16.9 analyze Chromosomes 2, 3, 6, 10, 13, 14, 15, 18, 19, 21, 22, and the X chromosome show aneuploidy. Virtually every chromosome has structural rearrangements, and translocations are the most obvious. These are seen when two or more different colors occur on the same chromosome.

IF YOU UNDERSTAND . . .

16.1 understand Ornithine, citrulline or arginine could be added to allow growth. As Figure 16.1 shows, these compounds are made after the steps catalyzed by the enzymes 1, 2, and 3 that are needed to produce arginine. **16.2** understand An inhibitor of RNA synthesis will eventually prevent the synthesis of new proteins because newly synthesized mRNA is needed for translation. **16.3** apply AUG UGG AAA/AAG CAA/CAG **16.4** understand Since redundancy is having more than one codon specify a particular amino acid, redundancy makes it possible for there to be a point mutation without altering the amino acid. This is a silent mutation. A silent mutation is likely to be neutral because there is no change in amino acid sequence.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. remember d **2.** understand a **3.** understand d **4.** remember Because there is no chemical complementarity between nucleotides and amino acids; and because in eukaryotes, DNA is in the nucleus but translation occurs in the cytoplasm. **5.** understand d **6.** remember A codon that signals the end of translation.

✔ Test Your Understanding

7. understand Because the Morse code and genetic code both use simple elements (dots and dashes; 4 different bases) in different orders to encode complex information (words; amino acid sequences).
8.
Substrate 1 $\xrightarrow{A}$ Substrate 2 $\xrightarrow{B}$ Substrate 3 $\xrightarrow{C}$
Substrate 4 $\xrightarrow{D}$ Substrate 5 $\xrightarrow{E}$ Biological Sciazine
apply Substrate 3 would accumulate. Hypothesis: The individuals have a mutation in the gene for enzyme D.
9. understand They supported an important prediction of the hypothesis: Losing a gene (via mutation) resulted in loss of an enzyme. **10.** understand c **11.** understand In a triplet code, addition or deletion of 1–2 bases disrupts the reading frame "downstream" of the mutation site(s), resulting in a dysfunctional protein. But addition or deletion of 3 bases restores the reading frame—the normal sequence is disrupted only between the first and third mutation. The resulting protein is altered but may still be able to function normally. Only a triplet code would show these patterns. **12.** understand A point mutation changes the nucleotide sequence of an existing allele, creating a new one, so it always changes the genotype. But because the genetic code is redundant, and because point mutations can occur in DNA sequences that do not code for amino acids, these point mutations do not change the protein product and therefore do not change the phenotype.

✔ Test Your Problem-Solving Skills

13. apply See **FIGURE A16.2**. **14.** analyze Every copying error would result in a mutation that would change the amino acid sequence of the protein and would likely affect its function. **15.** analyze Before the central dogma was understood, DNA was known to be the hereditary material, but no one knew how particular sequences of bases resulted in the production of RNA and protein products. The central dogma clarified how genotypes produce phenotypes. **16.** analyze c

CHAPTER 17

IN-TEXT QUESTIONS AND EXERCISES

p. 318 Fig. 17.1 remember RNA is synthesized in the 5′ ⟶ 3′ direction; the DNA template is "read" 3′ ⟶ 5′.
p. 321 CYU (1) apply Transcription would be reduced or absent because the missing nucleotides are in the −10 region, one of the two critical parts of the promoter. **(2)** understand NTPs are required because the three phosphate groups raise the monomer's potential energy enough to make the polymerization reaction exergonic.
p. 322 Fig. 17.5 apply There would be no loops—the molecules would match up exactly.
p. 323 CYU (1) understand The subunits contain both RNA (the *ribonucleo-* in the name) and proteins. **(2)** understand The cap and tail protect mRNAs from degradation and facilitate translation.
p. 326 Fig. 17.11 analyze If the amino acids stayed attached to the tRNAs, the gray line in the graph would stay high and the green line low. If the amino acids were transferred to some other cell component, the gray line would decline but the green line would be low.
p. 327 understand (1) The amino acid attaches on the top right of the L-shaped structure. (2) The anticodon is antiparallel in orientation to the mRNA codon, and it contains the complementary bases.
p. 332 CYU understand E is for exit—the site where uncharged tRNAs are ejected; P is for peptidyl (or peptide bond)—the site where peptide bond formation takes place; A is for aminoacyl—the site where aminoacyl tRNAs enter.

IF YOU UNDERSTAND . . .

17.1 apply Transcription would continue past the normal point because the insertion of nucleotides would disrupt the structure of the RNA hairpin that functions as a terminator. **17.2** apply The protein-coding segment of the gene is predicted to be longer in eukaryotes because of the presence of introns. **17.3** understand The tRNAs act as adaptors because they couple the information contained in the nucleotides of mRNA to that contained in the amino acid sequence of proteins. **17.4** apply An incorrect amino acid would appear often in proteins. This is because the altered synthetase would sometimes add the correct amino acid for a particular tRNA and at other

FIGURE A16.1

times add the incorrect amino acid. **17.5** create One possible concept map is shown in **FIGURE A17.1**.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. understand c **2.** remember c **3.** understand To speed the correct folding of newly synthesized proteins **4.** remember d **5.** remember At the 3′ end **6.** apply b

✔ Test Your Understanding

7. understand Basal transcription factors bind to promoter sequences in eukaryotic DNA and facilitate the binding of RNA polymerase. As part of the RNA polymerase holoenzyme, sigma binds to a promoter sequence in bacterial DNA and to allow RNA polymerase to initiate at the start of genes. **8.** analyze The wobble rules allow a single tRNA to pair with more than one type of mRNA codon. This is distinct from redundancy, in which more than one codon can specify a single amino acid. If the wobble rules did not exist, there would need to be one tRNA for each amino-acid-specifying codon in the redundant genetic code. **9.** apply b **10.** apply After a peptide bond forms between the polypeptide and the amino acid held by the tRNA in the A site, the ribosome moves down the mRNA. As it does, an uncharged tRNA leaves the E site. The now-uncharged tRNA that was in the P site enters the E site; the tRNA holding the polypeptide chain moves from the A site to the P site, and a new aminoacyl tRNA enters the A site. **11.** apply The ribosome's active site is made up of RNA, not protein. **12.** understand The separation allows the aminoacyl tRNA to place the amino acid into the ribosome's active site while reaching to the distant codon on the mRNA.

✔ Test Your Problem-Solving Skills

13. create Ribonucleases degrade mRNAs that are no longer needed by the cell. If an mRNA for a hormone that increased heart rate were never degraded, the hormone would be produced continuously and heart rate would stay elevated—a dangerous situation. **14.** apply d **15.** analyze The regions most crucial to the ribosome's function should be the most highly conserved: the active site, the E, P, and A sites, and the site where mRNAs initially bind. **16.** analyze The most likely locations are one of the grooves or channels where RNA, DNA, and ribonucleotides move through the enzyme—plugging one of them would prevent transcription.

CHAPTER 18

IN-TEXT QUESTIONS AND EXERCISES

p. 338 understand See **TABLE A18.1**.
p. 338 Fig. 18.1 analyze Write "Slowest response, most efficient resource use" next to the transcriptional control label. Write "Fastest response, least efficient resource use" next to the post-translational control label.
p. 339 Fig. 18.2 apply Plates from all three treatments must be identical and contain identical growth medium, except for the presence of the sugars labeled in the figure. Also, all plates must be grown under the same physical conditions (temperature, light) for the same time.
p. 340 Fig. 18.3 apply Use a medium with all 20 amino acids when producing a master plate of mutagenized *E. coli* colonies; then use a replica plate that contains all the amino acids except tryptophan. Choose cells from the master plate that did *not* grow on the replica plate.
p. 341 understand *lacZ* codes for the β-galactosidase enzyme, which breaks the disaccharide lactose into glucose and galactose. *lacY* codes for the galactoside permease enzyme, which transports lactose into the bacterial cell. *lacI* codes for a protein that shuts down production of the other *lac* products. When lactose is absent, the *lacI* product prevents transcription. This is logical because there is no reason for the cell to make β-galactosidase and galactoside permease if there is no lactose to metabolize. But when lactose is present, it interacts with *lacI* in some way so that *lacZ* and *lacY* are induced (their transcription can occur). When lactose is present, the enzymes that metabolize it are expressed.
p. 343 apply A mutation that prevents lactose binding to repressor is predicted to prevent transcription of the *lac* operon under any condition. This is because the repressor would never come off the operator. A mutation in the operator that prevents repressor binding is predicted to lead to constitutive expression of the *lac* operon.
p. 343 Fig. 18.8 understand Put the "Repressor protein" on the operator. No transcription will take place. Then put the "RNA polymerase" on the promoter. No transcription will take place. Finally, put "lactose" on the repressor protein and then remove the resulting lactose–repressor complex from the operon. Transcription will begin.
p. 344 CYU (1) understand It is logical that the genes for metabolizing lactose should be expressed only when lactose is available. **(2)** understand See **FIGURE A18.1**.
p. 344 apply This mutation is predicted to lower rates of transcription initiation because AraC's binding to RNA polymerase is essential for AraC to work as an activator.

IF YOU UNDERSTAND . . .

18.1 understand Production of β-galactosidase and galactosidase permease are under transcriptional control—transcription depends on the action of regulatory proteins. The activity of the repressor is under post-translational control. **18.2** apply Treat *E. coli* cells with a mutagen, and create a master plate that is grown at 33°C. Replica-plate this master plate and grow the replica plate at 42°C. Look for colonies that are on the master plate at 33°C but not on the replica plate at 42°C. **18.3** understand The operator is the parking brake; the repressor locks it in place, and the inducer releases it. **18.4** apply *ara* initiator mutations are likely to affect positive and negative control because AraC must bind to the *ara* initiator sequence for both forms of control. **18.5** create Mutations that create operators for the SOS regulon repressor protein would put new genes under control of the repressor and incorporate them into the regulon.

FIGURE A17.1

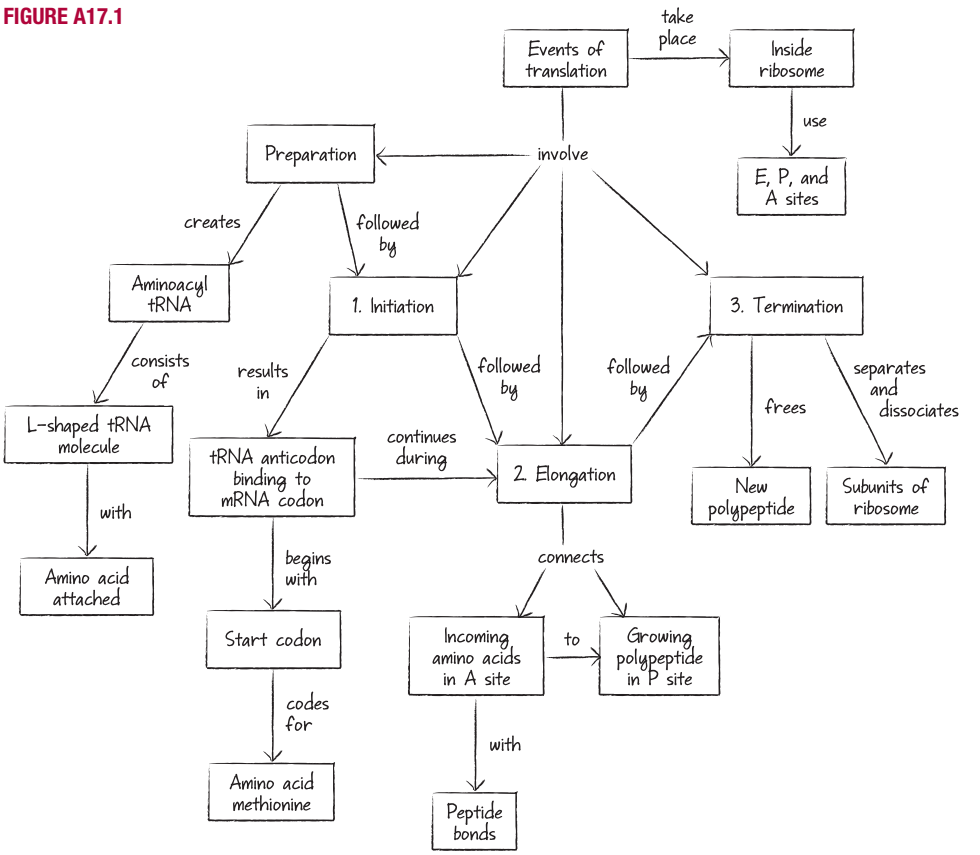

TABLE A18.1

Name	Function
lacZ	Gene for β-galactosidase
lacY	Gene for galactoside permease
Operator	Binding site for repressor
Promoter	Binding site for RNA polymerase
Repressor	Shuts down transcription
Lactose	Binds to repressor and stimulates transcription (removes negative control)
Glucose	At low concentration, increases transcription

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. remember b **2.** understand d **3.** apply b **4.** remember DNA; RNA; **5.** understand When glucose and another sugar are present in the environment, inducer exclusion prevents the use of the other sugar and allows only use of glucose. **6.** remember a

✔ Test Your Understanding

7. understand The glycolytic enzymes are always needed in the cell because they are required to produce ATP, and ATP is always needed. **8.** understand Positive control means that a regulatory protein, when present, causes transcription to increase. Negative control means that a regulatory protein, when present, prevents transcription. **9.** apply b. **10.** apply Regulation of the *lac* operon should be normal. The location of the *lacI* gene isn't important, because the gene produces a protein that diffuses within the cell to the operator. **11.** analyze b (since the activator needs to bind to regulatory sequences to activate gene expression, preventing DNA binding would cripple the regulon and prevent cholera).**12.** analyze The *lac* operon would be strongly induced. Once inside the cell, the IPTG will bind to the repressor, causing it to release from DNA. IPTG cannot be broken down, so its concentration will remain high. Finally, since glucose is absent, there will be no inducer exclusion to inhibit IPTG transport through the galactoside permease transporter.

✔ Test Your Problem-Solving Skills

13. create Set up cultures with individuals that all come from the same colony of toluene-tolerating bacteria. Half the cultures should have toluene as the only source of carbon; half should have glucose or another common source of carbon. The glucose-containing medium serves as a control to ensure that cells can be grown in the lab. Cells will grow in both cultures if they are able to use toluene as a source of carbon; they will grow only in glucose-containing medium if toluene cannot be used as a carbon source. **14.** apply At a rate of 1×10^{-4} mutants per cell, you would on average find one mutant in every 10,000 (1×10^4) cells. Therefore, you should screen a bit more (~ 2–3 times more) than 10,000 cells to be reasonably sure of finding at least one mutant. **15.** apply b **16.** analyze Cells with functioning β-galactosidase will produce blue colonies; cells with *lacZ* mutations or *lacY* mutations will not produce β-galactosidase and will produce white colonies. The *lac* promoter could be mutated so that RNA polymerase cannot bind.

CHAPTER 19

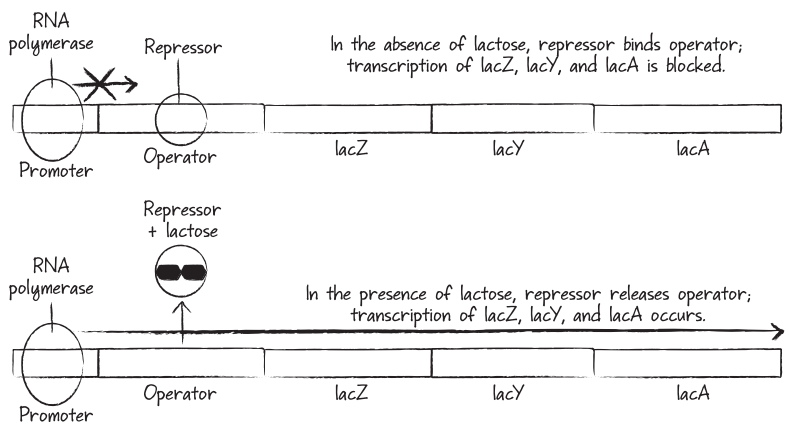
IN-TEXT QUESTIONS AND EXERCISES

p. 352 Fig. 19.4 analyze Acetylation of histones decondenses chromatin and allows transcription to begin, so HATs are elements in positive control. Deacetylation condenses chromatin and inactivates transcription, so HDACs are elements in negative control.
p. 353 CYU (1) apply Many more genes than normal are predicted to be expressed because the inability to methylate DNA would lead to more decondensed chromatin. **(2)** understand Addition of acetyl groups to histones or methyl groups to DNA can cause chromatin to decondense or condense, respectively. Different patterns of acetylation or methylation will determine which genes in muscle cells versus brain cells can be transcribed and which are not available for transcription.
p. 353 Fig. 19.5 create They could do something to change histone modifications to see how this affects gene transcription instead of just making the observation that certain histone modifications and low rates of transcription go together.
p. 355 Fig. 19.6 analyze A typical eukaryotic gene usually contains introns and is regulated by multiple enhancers. Bacterial operons lack introns and enhancers. The promoter-proximal element found in some eukaryotic genes is comparable to the *araC* binding site in the *ara* operon of bacteria. Bacterial operons have a single promoter but code for more than one protein; eukaryotic genes code for a single product.
p. 356 analyze The basal transcription factors found in muscle and nerve cells are similar or identical; the regulatory transcription factors found in each cell type are different.
p. 356 understand DNA forms loops when distant regulatory regions, such as silencers and enhancers, are brought close to the promoter through binding of regulatory transcription factors to mediator.
p. 356 CYU (1) analyze Bacterial regulatory sequences are found close to the promoter; eukaryotic regulatory sequences can be close to the promoter or far from it. Bacterial regulatory proteins interact directly with RNA polymerase to initiate or prevent transcription; eukaryotic regulatory proteins influence transcription by altering chromatin structure or binding to the basal transcription complex through mediator proteins. **(2)** understand Certain regulatory proteins decondense chromatin at muscle- or brain-specific genes and then activate or repress the transcription of cell-type-specific genes. Muscle-specific genes are expressed only if muscle-specific regulatory proteins are produced and activated.
p. 358 understand Alternative splicing does not occur in bacteria because bacterial genes do not contain introns—in bacteria, each gene codes for a single product. Alternative splicing is part of step 3 in Figure 19.1.
p. 359 remember Step 4 and step 5. RNA interference either **(1)** decreases the life span of mRNAs or **(2)** inhibits translation.
p. 360 CYU (1) understand It became clear that a single gene can code for multiple products instead of a single one. **(2)** understand The miRNAs interfere with mRNAs by targeting them for destruction or preventing them from being translated.
p. 362 CYU (1) understand Many different types of mutations can disrupt control of the cell cycle and initiate cancer. These mutations can affect any of the six levels of control over gene regulation outlined in Figure 19.1. **(2)** understand The p53 protein is responsible for shutting down the cell cycle in cells with damaged DNA. If the protein does not function, then cells with damaged DNA—and thus many mutations—continue to divide. If these cells have mutations in genes that regulate the cell cycle, then they may continue to divide in an uncontrolled fashion.

IF YOU UNDERSTAND . . .

19.1 understand Because eukaryotic RNAs are not translated as soon as transcription occurs, it is possible for RNA processing to occur, which creates variation in the mRNAs produced from a primary RNA transcript and in their life spans. **19.2** understand The default state of eukaryotic genes is "off," because the highly condensed state of the chromatin makes DNA unavailable to RNA polymerase. **19.3** understand See **FIGURE A19.1**. **19.4** understand Alternative splicing makes it possible for a single gene to

FIGURE A18.1



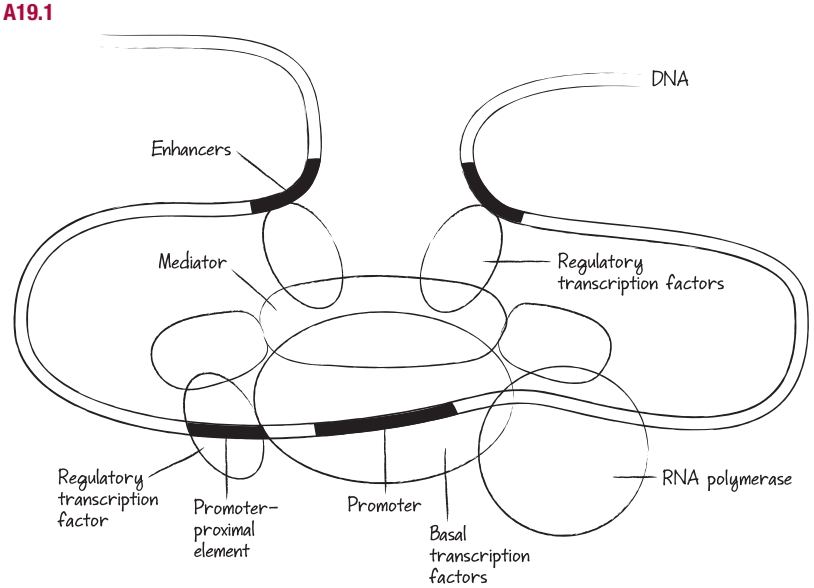


FIGURE A19.1

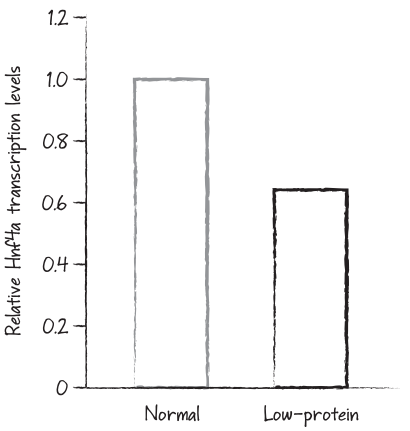
code for multiple products. **19.5** analyze One difference is that, in bacteria, genes that need to be turned on together are often clustered together in operons. Eukaryotes do not use operons. A similarity is in the way eukaryotes turn on many genes together and the strategy of bacterial regulons. Here, genes that are in many different locations share a DNA regulatory sequence and are activated when a regulatory transcription factor binds to the regulatory sequence. **19.6** understand In mutant cells that lack a form of p53 that can bind to enhancers, DNA damage cannot arrest the cell cycle, the cell cannot kill itself, and damaged DNA is replicated. This leads to mutations that can move the cell farther down the road to cancer.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. remember c **2.** remember A tumor suppressor is a gene or protein that holds cell division in check unless conditions are right for the cell to divide. **3.** understand d **4.** remember The set of regulatory transcription factors present in a particular cell, not differences in DNA sequence, are largely responsible for which genes are expressed. **5.** remember b **6.** remember d



✔ Test Your Understanding

7. analyze (a) Enhancers and the *araC* site are similar because both are sites in DNA where regulatory proteins bind. They are different because enhancers generally are located at great distances from the promoter, whereas the *araC* site is located nearer the promoter. (b) Promoter-proximal elements and the *lac* operon operator are both regulatory sites in DNA located close to the promoter. (c) Basal transcription factors and sigma are proteins that must bind to the promoter before RNA polymerase can initiate transcription. They differ because sigma is part of the RNA polymerase holoenzyme, while the basal transcription complex recruits RNA polymerase to the promoter. **8.** understand If changes in the environment cause changes in how spliceosomes function, then the RNAs and proteins produced from a particular gene could change in a way that helps the cell cope with the new environmental conditions. **9.** analyze (a) Enhancers and silencers are both regulatory sequences located at a distance from the promoter. Enhancers bind regulatory transcription factors that activate transcription; silencers bind regulatory proteins that shut down transcription. (b) Promoter-proximal elements and enhancers are both regulatory sequences that bind positive regulatory transcription factors. Promoter-proximal elements are located close to the promoter; enhancers are far from the promoter. (c) Transcription factors bind to regulatory sites in DNA; mediator does not bind to DNA but instead forms a bridge between regulatory transcription factors and basal transcription factors. **10.** apply Inhibition of a histone deacetylase is predicted to leave acetyl groups on histones longer than normal. This is predicted to keep gene transcription going longer than normal, leading to higher levels of particular proteins and a change in the phenotype of the cell. **11.** analyze c; this is because there are many more modifications in the histone code relative to the genetic code. **12.** apply The cell is predicted to arrest in the cell cycle and most likely will commit suicide through activation of apoptosis genes because of the continually active *p53*.

✔ Test Your Problem-Solving Skills

13. apply c; This is because promoters and enhancers are brought into close physical proximity when transcription begins (see Figure 19.8). Since rats of malnourished mothers initiate *Hnf4a* gene transcription infrequently, the promoter and enhancer will be together less often in these animals compared with rats born to well-nourished mothers. **14.** understand See **FIGURE A19.2**. The value for the normal diet should be shown as 1.0 and the value for the low-protein diet should be shown as 0.64 (0.64 comes from the ratio of the cpm of the low-protein diet divided by the cpm of the normal diet, or 7368/11,478). **15.** create You could treat a culture of DNA-damaged cells with a drug that stops transcription and then compare them with untreated DNA-damaged cells. If transcriptional control regulates p53 levels, then the p53 level would be lower in the treated cells versus control cells. If control of p53 levels is post-translational, then in both cultures the p53 level would be the same. *Other approaches:* Add labeled NTPs to damaged cells and see if they are incorporated into mRNAs for p53; or add labeled amino acids to damaged cells and see if they are incorporated into completed p53 proteins; or add labeled phosphate groups and see if they are added to p53 proteins. **16.** create The double-stranded RNA could be cut by the same enzyme that creates double-stranded miRNAs from miRNA precursors. This double-stranded RNA may be incorporated into RISC and converted into a single-stranded RNA. The single-stranded RNA held by RISC would work in RNA interference to trigger the destruction of the complementary viral mRNA.

FIGURE A19.2

BIG PICTURE Genetic Information

p. 366 CYU (1) remember Star = DNA, mRNA, proteins. **(2)** understand RNA "is reverse transcribed by" reverse transcriptase "to form" DNA. **(3)** analyze E = splicing, etc.; E = meiosis and sexual reproduction (along with their links). **(4)** analyze Chromatin "makes up" chromosomes; independent assortment and recombination "contribute to" high genetic diversity.

CHAPTER 20

IN-TEXT QUESTIONS AND EXERCISES

p. 372 understand Isolate the DNA and cut it into small fragments with EcoRI, which leaves sticky ends. Cut copies of a plasmid or other vector with EcoRI. Mix the fragments and plasmids under conditions that promote complementary base pairing by sticky ends of fragments and plasmids. Use DNA ligase to catalyze formation of phosphodiester bonds and seal the sequences.
p. 372 Fig. 20.4 apply No—many times, because many copies of each type of mRNA were present in the pituitary cells, and many pituitary cells were used to prepare the library.
p. 373 apply The probe must be single stranded so that it will bind by complementary base pairing to the target DNA, and it must be labeled so that it can be detected. The probe will base-pair only with fragments that include a sequence complementary to the probe's sequence. A probe with the sequence 5′ AATCG 3′ will bind to the region of the target DNA that has the sequence 5′ CGATT 3′ as shown here:

5′ AATCG 3′
3′ TCCGGTTAGCATTACCATTTT 5′

p. 374 CYU (1) understand When the endonuclease makes a staggered cut in a palindromic sequence and the strands separate, the single-stranded bases that are left will bind ("stick") to the single-stranded bases left where the endonuclease cut the same palindrome at a different location. **(2)** understand The word probe means to examine thoroughly. A DNA probe "examines" a large set of sequences thoroughly and binds to one—the one that has a complementary base sequence.
p. 375 Fig. 20.7 analyze The polymerase will begin at the 3′ end of each primer. On the top strand in part (b), it will move to the left; on the bottom strand, it will move to the right. As always, synthesis is in the 5′-to-3′ direction.
p. 376 CYU (1) understand Denaturation makes DNA single stranded so the primer can bind to the sequence during the annealing step. Once the primer is in place, *Taq* polymerase can synthesize the rest of the strand during the extension step. It is a "chain reaction" because the products of each reaction cycle are used in the next reaction cycle—this is why the number of copies doubles in each cycle. **(2)** apply One of many possible answers is shown in **FIGURE A20.1**.
p. 378 CYU understand If ddNTPs were present at high concentration, they would almost always be incorporated—meaning that only fragments from the first complementary base in the sequence would be produced.
p. 379 understand Using a map with many markers makes it more likely that there will be one marker that is very tightly linked to the gene of interest—meaning that a form of the marker will almost always be associated with the phenotype you are tracking.
p. 382 CYU create Start with a genetic map with as many polymorphic markers as possible. Determine the genotype at these markers for a large number of individuals who have the same type of alcoholism—one that is thought to have a genetic component—as well as a large number of unaffected individuals. Look for particular versions of a marker that is almost always found in affected individuals. Genes that contribute to a predisposition to alcoholism will be near that marker.
p. 383 Fig. 20.11 apply The insertion will probably disrupt the gene and have serious consequences for the cell and potentially the individual.

IF YOU UNDERSTAND . . .

20.1 understand Special features of DNA are needed to allow replication in a cell. It is unlikely that any DNA fragment generated by cutting the DNA of one species with a restriction enzyme would replicate when inserted into a bacterial cell. By placing DNA fragments within plasmids that normally replicate in a bacterial cell, the inserted DNA can be replicated along with the plasmid.
20.2 analyze Advantages of cloning in cells: No knowledge of the sequence is required. Disadvantages of cloning in cells: It is slower and technically more difficult than PCR. PCR advantages: It is fast and easy, and it can amplify a DNA sequence that is rare in the sample. PCR disadvantage: It requires knowledge of sequences on either side of the target gene, so primers can be designed.
20.3 understand The length of each fragment is dictated by where a ddNTP was incorporated into the growing strand, and each ddNTP corresponds to a base on the template strand. Thus the sequence of fragment sizes corresponds to the sequence on the template DNA.
20.4 understand In this case, both affected and unaffected individuals would have the same marker, so there would be no way to associate a particular form of the marker with the gene and phenotype you are interested in.
20.5 understand An advantage of using retrovirus vectors is that any foreign genes they carry are integrated into

human chromosomes, so delivered genes become a permanent feature of the cell's genome. The concern is that they may integrate at sites that alter gene function in ways that harm cell function, or even worse, lead to cancer. **20.6** understand Genes can be inserted into the Ti plasmids carried by *Agrobacterium*, and the recombinant plasmids transferred to plant cells infected by the bacterium.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. understand They cut DNA at specific sites, known as recognition sites, to produce DNA fragments useful for cloning. **2.** remember b **3.** understand ddNTPs lack the −OH (hydroxyl) group on the 3′ carbon of deoxyribose sugar that is required to extend the DNA chain during synthesis. **4.** understand a **5.** remember b **6.** understand d

✔ Test Your Understanding

7. understand When a restriction endonuclease cuts a "foreign gene" sequence and a plasmid, the same sticky ends are created on the excised foreign gene and the cut plasmid. After the sticky ends on the foreign gene and the plasmid anneal, DNA ligase catalyzes closure of the DNA backbone, sealing the foreign gene into the plasmid DNA (see **FIGURE A20.2**). **8.** apply If the DNA at each cycle steadily doubles, it is predicted to yield a 33.6 million-fold increase (a 2^{25}-fold increase). **9.** understand A cDNA library is a collection of complementary DNAs made from all the mRNAs present in a certain group of cells. A cDNA library from a human nerve cell would be different from one made from a human muscle cell, because nerve cells and muscle cells express many different genes that are specific to their cell type. **10.** remember Genetic markers are genes or other loci that have known locations in the genome. When these locations are diagrammed, they represent the physical relationships between landmarks—in other words, they form a map. **11.** understand d; these regulatory sequences promote expression of introduced genes in the endosperm—the rice grain eaten as food. **12.** analyze PCR and cellular DNA synthesis are similar in the sense of producing copies of a template DNA. Both rely on primers and DNA polymerase. The major difference between the two is that PCR copies only a specific target sequence, but the entire genome is copied during cellular DNA synthesis.

✔ Test Your Problem-Solving Skills

13. create You could use a computer program to identify likely promoter sequences in the sequence data and then look for sequences just downstream that have an AUG start codon and codons that could be part of the protein-coding exons of a potential protein about 500 amino acids (500 codons or 1500 bases) long. **14.** analyze False. Since somatic-cell modifications cannot be passed on to future generations, but germ-line modifications may be passed on to offspring, germ-line modification opens a new set of ethical questions. **15.** analyze In both techniques, researchers use an indicator to identify either a gene of interest or a colony of bacteria with a particular trait. The problem is the same—picking one particular thing (a certain gene or a cell with a particular mutation) out of a large collection. **16.** analyze (a) Primer 1b binds to the top right strand and would allow DNA polymerase to synthesize the top strand across the target gene. Primer 1a, however, binds to the upper left strand and would allow DNA polymerase to synthesize the upper strand *away* from the target gene. Primer 2a binds to the bottom left strand and would allow DNA polymerase to synthesize the bottom strand across the target gene. Primer 2b, however, binds to the bottom right strand and would allow DNA polymerase to synthesize away from the target gene. (b) She could use primer 1b with primer 2a.

CHAPTER 21

IN-TEXT QUESTIONS AND EXERCISES

p. 391 understand If no overlap occurred, there would be no way of ordering the fragments correctly. You would be able to put fragments only in random order—not the correct order.
p. 391 Fig. 21.2 understand Shotgun sequencing is based on fragmenting the genome into many small pieces.
p. 393 Fig. 21.3 understand Because the mRNA codons that match up with each strand are oriented in the 5′-to-3′ direction.
p. 395 CYU (1) understand Parasites don't need genes that code for enzymes required to synthesize molecules they acquire from their hosts. **(2)** understand If two closely related species inherited the same gene from a common ancestor, the genes should be similar. But if one species acquired the same gene from a distantly related species via lateral gene transfer, then the genes should be much less similar.
p. 399 Fig. 21.9 understand
Chromosome 1:
ψβ2-ε-Gγ-Aγ-ψβ1-δ-ψβ2-ε-Gγ-Aγ-ψβ1-δ-β
Chromosome 2: β
p. 400 CYU (1) understand Eukaryotic genomes have vastly different numbers of transposable elements and other repeated sequences that don't directly contribute to phenotype. So genome size can vary widely without changing the number of coding genes or the complexity of the organism. **(2)** apply Because most of the genome is transcribed, this number is very close to the percentage of the genome that codes for exons. In humans, the ratio would be roughly 2%.
p. 401 understand Start with a microarray containing exons from a large number of human genes. Isolate mRNAs from brain tissue and liver tissue, and make labeled cDNAs from each. Probe the microarray with cDNA made from each type of tissue, and record where binding occurs. Binding events identify exons that are transcribed in each type of tissue. Compare the results to identify genes that are expressed in brain but not liver, or in liver but not brain.
p. 402 understand Cell replication is an emergent property because it is due to the interaction of proteins working in a network, yet is a property that could not be predicted from the analysis of any one of these proteins.

IF YOU UNDERSTAND . . .

21.1 understand If a search of human gene sequence databases revealed a gene that was similar in base sequence, and if follow-up work confirmed that the mouse and human genes were similar in their pattern of exons and introns and regulatory sequences, then the researchers could claim that they are homologous. **21.2** understand The genome of a parasite is predicted to be smaller and to have fewer genes, particularly for metabolism, than the genome of a nonparasite. **21.3** understand These features include variable numbers of transposable elements; noncoding repeated sequences; and noncoding, nonrepetitive DNA. These add to genome size without adding genes that directly influence phenotype. Additionally, mechanisms such as alternative splicing and the possibility of many noncoding regulatory RNAs can create situations in which few protein-coding genes but many different proteins are expressed in intricately regulated ways—features that would increase morphological complexity without increasing gene number.
21.4 understand Color-coded clusters shown in Figure 21.13 represent networks of interacting proteins that work together to carry out a particular cellular function. But it's clear from the figure that smaller, clusters are also connected into larger networks.

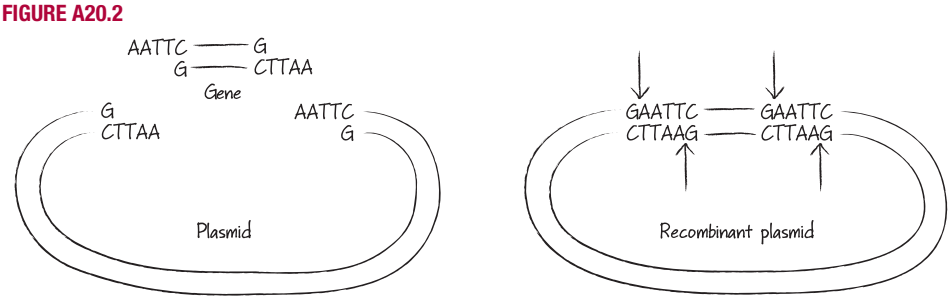
FIGURE A20.1

5′ CATGACTATTACGTATCGGGTACTATGCTATCGATCTAGCTACGCTAGCT 3′
3′ GTACTGATAATGCATAGCCCATGATACGATAGCTAGATCGATGCGATCGA 5′

Primer #1, which will anneal to the 3′ end of the top strand:

5′ AGCTAGCGTAGCTAGATCGAT 3′

Primer #2, which will anneal to the 3′ end of the bottom strand:



5′ CATGACTATTACGTATCGGGT 3′

The primers will bind to the separated strands of the parent DNA sequence as follows:

5′ CATGACTATTACGTATCGGGTACTATGCTATCGATCTAGCTACGCTAGCT 3′
3′ TAGCTAGATCGATGCGATCGA 5′

5′ CATGACTATTACGTATCGGGT 3′
3′ GTACTGATAATGCATAGCCCATGATACGATAGCTAGATCGATGCGATCGA 5′

FIGURE A20.2

Sticky ends on cut plasmid and gene to be inserted are complementary and can base pair

DNA ligase forms four phosphodiester bonds between gene and plasmid DNA at the points indicated by arrows

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. remember c **2.** understand a **3.** remember d **4.** remember b **5.** understand Finding two or more genes of similar sequence in the genome. **6.** remember Having a sequence that is clearly related to a functional gene but with a crippling mutation such as a stop codon or deletion.

✔ Test Your Understanding

7. analyze Computer programs are used to scan sequences in both directions to find ATG start codons, a gene-sized logical sequence with recognizable codons, and then a stop codon. One can also look for characteristic promoter, operator, and other regulatory sites. It is more difficult to identify open reading frames in eukaryotes because their genomes are so much larger and because of the presence of introns and repeated sequences. **8.** evaluate c **9.** apply Water flea gene density is about 31,000 genes/200 Mbp = 155 genes/Mbp. In humans, gene density is about 21,000 genes/3000 Mbp = 7 genes/Mbp. The relative gene density of water flea/human = 155/7 = 22. **10.** analyze Because with many different alleles, the chance that a match is coincidental is low relative to the chance that they match by identity (they come from the same person). **11.** understand A DNA microarray experiment identifies which genes are being expressed in a particular cell at a particular time. If a series of experiments shows that different genes are expressed in cells at different times or under different conditions, it implies that expression was turned on or off in response to changes in age or changes in conditions. **12.** understand Homology is a similarity among different species that is due to their inheritance from a common ancestor. If a newly sequenced gene is found to be homologous with a known gene of a different species, it is assumed that the gene products have similar function.

✔ Test Your Problem-Solving Skills

13. analyze If "gene A" is not necessary for existence, it can be lost by an event like unequal crossing over (on the chromosome with deleted segments) with no ill effects on the organism. In fact, individuals who have lost unnecessary genes are probably at a competitive advantage, because they no longer have to spend time and energy copying and repairing unused genes. **14.** apply If the grave were authentic, it might include two very different parental patterns along with five children whose patterns each represented a mix between the two parents. The other unrelated individuals would have patterns not shared by anyone else in the grave. **15.** apply d; mutation of such a central gene is likely to influence the phenotypes associated with all the genes it interacts with. If these interacting genes are involved in many different functions, the effects of mutation of a central gene are likely to be widespread, or pleiotropic. **16.** apply You would expect that the livers and blood of chimps and humans would function similarly, but that strong differences occur in brain function. The microarray data support this prediction and suggest chimp and human brains are different because certain genes are turned on or off at different times and expressed in different amounts.

CHAPTER 22

IN-TEXT QUESTIONS AND EXERCISES

p. 410 CYU understand Biologists have been able to grow entire plants from a single differentiated cell taken from an adult. They have also succeeded in producing animals by transferring the nucleus of a fully differentiated cell to an egg whose nucleus has been removed.
p. 411 Fig. 22.4 apply Anterior structures are predicted to be shifted farther back in the embryo, since higher-than-normal levels of the anterior-specifying Bicoid protein would be present in posterior regions.
p. 412 Fig. 22.6 apply Since Bicoid is located in the anterior cytoplasm and works to turn on genes that produce anterior structures, a prediction is that this manipulation would create a concentration gradient of Bicoid with its highest point in the middle of the mutant embryo. This would lead to the most anterior-like structures in the center of the embryo and more posterior structures forming on either side.
p. 414 Fig. 22.10 create Genes are usually considered homologous if they have similar DNA sequence and exon–intron structure.
p. 415 CYU (1) understand Bicoid is a transcription factor, and cells that experience a high versus medium versus low concentrations of Bicoid express Bicoid-regulated genes at different levels. **(2)** understand Bicoid proteins control the expression of gap genes, which—in effect—tell cells which third of the embryo they are in along the anterior–posterior axis. Gap genes control the expression of pair-rule genes, which organize the embryo into individual segments. Pair-rule genes control expression of segment polarity genes, which establish an anterior–posterior polarity to each individual segment. Segment polarity genes turn on homeotic genes, which then trigger genes for producing segment-specific structures like wings or legs.

IF YOU UNDERSTAND . . .

22.1 apply The seedling would be misshapen because controlling the plane of cleavage is essential for formation of normal structures in plants. **22.2.** understand Cells in the stem contain a complete set of genes, so if they can be de-differentiated and receive appropriate signals from other cells, they could differentiate into any cell type and cooperate to form any structure of the plant, including roots. **22.3** analyze Because segmentation genes work in a cascade, mutation of a pair-rule gene is expected to influence the expression of genes in the next level, segment polarity genes, but not affect the expression of earlier acting genes, such as gap genes. **22.4** apply This procedure is predicted to lead to the loss of limbs because the regulatory sequence replacement will cause the regions of expression of *Hoxc8* and *Hoxc6* to overlap.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. remember b **2.** remember stem cells **3.** understand a **4.** remember True **5.** remember a **6.** remember a conserved gene that can be expressed at different times and places during development to produce different types of structures in different organisms.

✔ Test Your Understanding

7. understand They occur in both plants and animals, and are responsible for the changes that occur as an embryo develops. **8.** understand If an adult cell used for cloning had some permanent change or loss of genetic information during development, it should not be able to direct the development of a viable adult. But if the adult cell is genetically equivalent to a fertilized egg, then it should be capable of directing the development of a new individual. **9.** understand The researchers exposed adult flies to treatments that induce mutations and then looked for embryos with defects in the anterior–posterior body axis or body segmentation. The embryos had mutations in genes required for body axis formation and segmentation. **10.** understand Development—specifically differentiation—depends on changes in gene expression. Changes in gene expression depend on differences in regulatory transcription factors. **11.** create Differentiation is triggered by the production of transcription factors, which induce other transcription factors, and so on—a sequence that constitutes a regulatory cascade—as development progresses. At each step in the cascade, a new subset of genes is activated—resulting in a step-by-step progression from undifferentiated to fully differentiated cells. **12.** analyze c. This result shows that a mouse tool-kit gene is similar enough (conserved) to a fly gene to be able to take over its function.

✔ Test Your Problem-Solving Skills

13. apply There would be more Bicoid protein farther toward the posterior and less in the anterior—meaning that the anterior segments would be "less anterior" in their characteristics and the posterior segments would be "more anterior." **14.** analyze The result means that the human gene was expressed in worms and that its protein product has performed the same function in worms as in humans. This is strong evidence that the genes are homologous and that their function has been evolutionarily conserved. **15.** apply c. Since the morphogen concentration is halved every 100 μm away from the posterior pole, dropping to 1/16 the highest concentration would require 4 "halvings" of the initial concentration ($1/2 \times 1/2 \times 1/2 \times 1/2 = 1/16$), and this would take place in 4 steps of 100 μm each—or 400 μm from the morphogen source. This is where the leg is predicted to be formed. **16.** create Tool-kit genes—such as *Hox* genes—are responsible for triggering the production of structures like wings or legs in particular segments. One hypothesis to explain the variation is that changes in gene expression of tool-kit genes led to different numbers of segments that express leg-forming *Hox* genes.

CHAPTER 23

IN-TEXT QUESTIONS AND EXERCISES

p. 421 understand If the bindin-like protein were blocked, it would not be able to bind to the egg-cell receptor for sperm. Fertilization would not take place.
p. 422 CYU (1) apply This change is predicted to allow the sperm of species A to bind to—and likely fertilize—the eggs of species B. **(2)** understand The entry of a sperm triggers a wave of calcium ion release around the egg-cell membrane. Thus, calcium ions act as a signal that indicates "A sperm has entered the egg." In response to the increase in calcium ion concentration, cortical granules fuse with the egg-cell membrane and release their contents to the exterior, causing the destruction of the sperm receptor and, in sea urchins, the formation of a fertilization envelope.
p. 424 CYU understand If cytoplasmic determinants could not be localized, they would be distributed to all blastomeres. This would specify the same fate for all blastomeres and their descendants instead of different fates.
p. 426 CYU (1) understand Ectoderm and endoderm, because these are the inside and outside layers. **(2)** apply The future anterior–posterior and dorsal–ventral region of the embryo could first be identified as the blastopore forms and cells begin migrating into the embryo. The blastopore marks the future posterior of the embryo, and the region opposite the blastopore is where the anterior will form. Cells that first migrate into the blastopore come from the dorsal side, so this is the future dorsal region; the ventral region is on the opposite side.
p. 427 Fig. 23.9 understand Because neural tube formation depends on rearrangements of the cytoskeleton, a drug that locked the cytoskeleton in place is predicted to prevent formation of the neural tube.
p. 428 Fig. 23.12 analyze It made gene expression possible in non-muscle cells. A "general purpose" promoter can lead to transcription of an inserted cDNA in any type of cell, including fibroblasts.

IF YOU UNDERSTAND . . .

23.1 understand Bindin and the egg-cell receptor for sperm bind to each other. For this to happen, their tertiary

structures must fit together somewhat like the structures of a lock and key. **23.2** understand If the cytoplasmic determinant is localized to a certain part of the egg cytoplasm, blastomeres will either contain or not contain the determinant, because the egg's cytoplasm becomes divided between blastomeres. **23.3** analyze Both cells would contain cell–cell signals and transcription factors specific to mesodermal cells, but the anterior cell would contain anterior-specific signals and regulatory transcription factors while the posterior cell would contain posterior-specific signals and regulators. **23.4** understand Cell–cell signals from the notochord direct the formation of the neural tube; subsequently, cell–cell signals from the notochord, neural tube, and ectoderm direct the differentiation of somite cells. Cells expand during neural tube formation. Somite cells move to new positions, proliferate, and differentiate.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. remember Bindin is a protein on the sperm-cell head that binds to a receptor on the egg plasma membrane to allow species-specific attachment of sperm and egg. **2.** understand c **3.** understand c **4.** understand d **5.** remember ectoderm; **6.** remember a

✔ Test Your Understanding

7. evaluate As mammals, mice form a placenta that allows the embryo to obtain nutrients from the mother. There's no need for lots of nutrient reserves to support development. Frogs develop outside the mother's body, and the embryo is on its own. There is a need for nutrient reserves, and the large egg provides this. Eggs contain stores of nutrients. **8.** apply This treatment is predicted to promote polyspermy, because there would be no release of Ca^{2+} inside the cell to trigger a block to polyspermy. **9.** understand They contain different types and/or concentrations of cytoplasmic determinants. **10.** analyze a; this is because ectodermal cells have to constrict on their dorsal margins and expand on their ventral margin to fold ectoderm into a neural tube. **11.** understand When transplanted early in development, somite cells become the cell type associated with their new location. But when transplanted later in development, somite cells become the cell type associated with the original location. These observations indicate that the same cell is not committed to a particular fate until later in development. **12.** apply More than 50,000 fibroblasts would need to be screened. This is because if 2×10^{-5} of all mRNAs and cDNAs coded for MyoD, then 50,000 cells would need to be screened on average to find one with a MyoD cDNA (50,000 comes from the quotient of $1/2 \times 10^{-5}$ MyoD cDNAs per cDNA). Since this is an average, in some groups of 50,000 cells, there may not be a MyoD cDNA. Therefore, to be reasonably sure of finding at least one MyoD cDNA, more than 50,000 cells should be screened.

✔ Test Your Problem-Solving Skills

13. analyze The interactions that allow proteins to bind to each other are extremely specific—certain amino acids have to line up in certain positions with specific charges and/or chemical groups exposed. Sperm–egg binding is species specific because each form of bindin binds to a different egg-cell receptor for sperm. **14.** evaluate Translation is not needed for cleavage to occur normally—meaning that all the proteins needed for early cleavage are present in the egg. **15.** create The yellow pigment may be a cytoplasmic determinant, or it may be only a molecule that is found in the same cells as the cytoplasmic determinant. Without isolating the pigment and adding it to cells to see if it acts as a cytoplasmic determinant, these two possibilities cannot be distinguished. **16.** apply a (See Figure 23.10 and note how the notochord is closest to the somite region that forms bone. If an additional notochord were transplanted near the top of the neural tube, signals from the notochord would be expected to convert the nearby somite into bone-producing somite, adding to the amount of bone.)

CHAPTER 24

IN-TEXT QUESTIONS AND EXERCISES

p. 434 Fig. 24.2 remember See **FIGURE A24.1**.
p. 436 CYU (1) understand Cells located on the outside of the embryo become epidermal tissue; cells in the interior become vascular tissue; cells in between become ground tissue. **(2)** apply The *MONOPTEROS* gene would be overexpressed, producing higher levels of the MONOPTEROUS transcription factor. The embryonic cells would get information indicating that they are in the shoot apex, where MONOPTEROS levels are high. As a result, the root would not develop normally.
p. 437 Fig. 24.6 analyze Many animals have three body axes analogous to the three axes of leaves: anterior–posterior (like the leaf's proximal–distal), dorsal–ventral (like the leaf's adaxial–abaxial), and a left–right axis (like the leaf's mediolateral axis). The main plant body, in contrast, has only two axes: apical–basal and radial.
p. 438 CYU (1) create Simply planting a cut stem will often produce a new root meristem. This occurs whenever the cutting produces a new plant. **(2)** create If the plant could be genetically engineered to express higher levels of the PHAN transcription factor in leaves, the likely result would be a shift in leaf type from simple to compound.
p. 440 apply Mutual inhibition between the *A* and *C* genes helps create separate regions of gene expression. If *C* gene expression is lost, then the inhibition of *A* gene expression is also lost, and *A* genes are expressed in their normal location and where they are normally inhibited by *C* gene expression.
p. 441 CYU (1) analyze Plants generate many reproductive structures—flowers—many times and in many places during the plant's life. Plant reproductive cells are created from vegetative cells, not cells that are set aside early in development as reproductive cells. In contrast, animals form reproductive structures (ovaries and testes) in set locations, produce reproductive structures only once during development and set aside specialized reproductive cells (the germ line) early in their development. **(2)** analyze Like *Hox* genes, *MADS-box* genes code for DNA-binding proteins that function as transcriptional regulators. Both Hox proteins and MADS-domain proteins are involved in regulatory transcription cascades that lead to development of specific structures in specific locations. Although they perform similar functions, *Hox* genes and *MADS-box* genes evolved independently and differ in their base sequences. Thus, these genes and their protein products are not homologous.

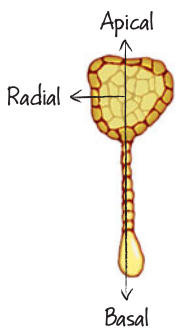
IF YOU UNDERSTAND . . .

24.1 apply If there were only one master regulatory gene for patterning, the predicted result of loss of that gene's function by mutation would be disorganization of the entire apical–basal axis, not just removal of parts of it as seen in the actual mutants. **24.2** apply Many things could be imagined, but all should point in the direction of many repeated body parts (for example, 21 wings in a variety of shapes and positions on the body) and a very large overall size (if the fly is old) due to continuous growth. **24.3** apply The prediction is that sepals would develop from every whorl. This is because when the *C* gene product is absent, *A* gene expression spreads across the flower. Since there is no *B* gene expression, only sepals would form—the structure associated with only *A* gene expression.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. understand This is because mechanisms for development evolved independently in plants and animals.
2. understand b **3.** remember b **4.** remember d **5.** remember c
6. understand a.



✔ Test Your Understanding

7. understand c. **8.** understand Animal cells that lead to sperm or egg formation are "sequestered" early in development, so that they are involved only in reproduction and undergo few rounds of mitosis. Because mutations occur in every round of mitosis, plant eggs and sperm should contain many more mutations than animal eggs and sperm. **9.** understand Meristem cells are undifferentiated and divide to produce a cell that remains in the meristem and a cell that can commit to a particular pathway of differentiation. These are properties of stem cells. **10.** understand Just like the three tissue layers in plant embryos, the tissues produced in the SAMs and RAMs of a 300-year-old oak tree can differentiate into all of the specialized cell types found in a mature plant.
11. evaluate The ABC model predicted that the *A*, *B*, and *C* genes would each be expressed in specific whorls in the developing flower. The experimental data showed that the prediction was correct. **12.** understand Cell proliferation is responsible for expansion of meristems and growth in size. Asymmetric cell division along with cell expansion is responsible for giving the adult plant a particular shape. Differentiation is responsible for generating functional tissues and organs in the adult plant. Cell–cell signals are responsible for setting up the apical–basal axis of the embryo and for guiding the pollen tube to the egg.

✔ Test Your Problem-Solving Skills

13. create Four. This is because there are four states of gene activity (in any cell, *D* can be on or off and *E* can be on or off) and therefore four structures that could be specified using this code. Sets of on–off switches are known as Boolean systems and are the basis for information storage in computers and (sometimes) in cells. **14.** analyze Because vegetative growth is continuous and occurs in all directions (unrestricted), it could be considered indeterminate. In contrast, reproductive growth produces mature reproductive organs and stops when those organs are complete. Because its duration is limited, it could be considered determinate. **15.** apply a; see Figure 24.10 to understand the reasoning. *A* and *B* together create petals, and *B* and *C* together create stamens. **16.** analyze One hundred times more likely. This is because 100 times more cell divisions were required to create the oak egg, and the rate of mutation per cell division is constant. (You don't need to consider the absolute rate of 1×10^{-6}/division, since the question asks about relative chances only).

FIGURE A24.1

CHAPTER 25

IN-TEXT QUESTIONS AND ANSWERS

p. 448 Fig. 25.4 analyze Under special creation, fossils with transitional features would be explained as separate types, unrelated to other organisms and just coincidentally having intermediate features.
p. 448 Fig. 25.5 analyze If vestigial traits result from inheritance of acquired characteristics, some individuals must have lost the traits during their own lifetimes and passed the reduced traits on to their offspring. For example, a certain monkey's long tail might have been bitten off by a predator. The new traits would then somehow have passed to the individual's eggs or sperm, resulting in shorter-tailed offspring, until humans with a coccyx resulted.
p. 453 CYU (1) evaluate If birds evolved from dinosaurs you would expect to find transitional fossil dinosaurs with feathers. Such fossils have been found. **(2)** analyze The DNA sequences of chimpanzees and humans are so similar because we share a recent common ancestor.
p. 455 (1) understand Relapse occurred because the few bacteria remaining after drug therapy were not eliminated by the patient's weakened immune system and began to reproduce quickly. **(2)** understand No—almost all of the cells present at the start of step 3 would have been resistant to the drug.
p. 456 understand When antibiotics are overused, some bacteria will be killed, including the bacteria that are harmless or beneficial to us. However, bacteria that are resistant to these antibiotics will flourish and multiply, reducing the likelihood that antibiotic treatment will be effective in the future.
p. 457 Fig. 25.16 analyze "Prediction": Beak measurements were different before and after the drought. "Prediction of null hypothesis": No difference was found in beak measurements before and after the drought.
p. 459 CYU (1) understand *Postulate 1:* Traits vary within a population. *Postulate 2:* Some of the trait variation is heritable. *Postulate 3:* There is variation in reproductive success (some individuals produce more offspring than others). *Postulate 4:* Individuals with certain heritable traits produce the most offspring. The first two postulates describe heritable variation; the second two describe differential reproductive success. **(2)** understand Beak size and shape and body size vary among individual finches, in part because of differences in their genotypes (some alleles lead to deeper or shallower beaks, for example). When a drought hit, individuals with deep beaks survived better and produced more offspring than individuals with shallow beaks.
p. 460 analyze In biology, an adaptation is any heritable trait that increases an individual's ability to produce offspring in a particular environment. In everyday English, adaptation is often used to refer to an individual's nonheritable adjustment to meet an environmental challenge, a phenomenon that biologists call acclimatization. The phenotypic changes resulting from acclimatization are not passed on to offspring.

IF YOU UNDERSTAND . . .

25.1 analyze Typological thinking is based on the idea that species are unchanging types and that variations within species are unimportant or even misleading. Population thinking recognizes the variation that occurs within a species as critically important. **25.2** remember Many answers are possible. For example, the evolution of an antibiotic-resistant TB bacterium demonstrates that species change through time. The homologous sequences in human and fruit fly genes demonstrate that these species are related by common ancestry. **25.3** analyze In biology, fitness is the ability of an individual to produce viable, fertile offspring, relative to that ability in other individuals in the population. In everyday English, fitness is a physical attribute that is acquired as a result of practice or exercise. **25.4** apply Under special creation, changes in *Mycobacterium tuberculosis* populations would be explained as individual creative events governed by an intelligent creator. Under the theory of evolution by inheritance of acquired characters, changes in *M. tuberculosis* populations would be explained by the cells trying to transcribe genes in the presence of the drug, and their *rpoB* gene becoming altered as a result. **25.5** understand Brain size in *H. sapiens* might be constrained by the need for babies to pass through the mother's birth canal, by the energy required to maintain a large brain as an adult, or by lack of genetic variation for even larger brain size. Flying speed in falcons might be constrained by loss of maneuverability (and thus less success in hunting), the energy demands of extremely rapid flight, or lack of genetic variation for even faster flight.

YOU SHOULD BE ABLE TO . . .

✓ Test Your Knowledge

1. remember b **2.** remember False **3.** remember a **4.** understand d **5.** remember homologous **6.** remember c

✓ Test Your Understanding

1. understand Mutation produces new genetic variations, at random, without any forethought as to which variations might prove adaptive in the future. Individuals with mutations that are disadvantageous won't produce many offspring, but individuals with beneficial mutations will produce many offspring. The beneficial mutations will thus increase in frequency through selection. **2.** analyze Artificial selection is determined by human choice and is goal directed, whereas natural selection is the unplanned differential reproductive success of individuals that vary in their heritable traits. **3.** analyze b (In some environments, being big and strong lowers fitness.) **4.** analyze There were 751 finches before the drought and 90 finches afterward, so only 90/751 = 0.12, or 12 percent, survived. There were more finches with deep beaks before the drought only because the population was much larger, but the *average* beak depth increased after the drought. **5.** analyze The evidence for within-patient evolution is that DNA sequences at the start and end of treatment were identical except for a single nucleotide change in the *rpoB* gene. If rifampin were banned, *rpoB* mutant strains likely would have had lower fitness in the drug-free environment and would not continue to increase in frequency in *M. tuberculosis* populations. **6.** apply (1) Traits vary within rabbit populations, such as fur color and hearing ability. (2) Some of this variation is heritable. (3) More rabbits are produced than can survive. (4) Rabbits with certain heritable traits, such as the ability to camouflage in their environment or hear the approach of foxes, produce more offspring.

✓ Test Your Problem-Solving Skills

1. analyze The theory of evolution by natural selection predicts that white and brown deer mice are descendants of an ancestral population that varied in color. The white mice had higher fitness in the beach environment, where they were more likely to escape the notice of predators. Likewise, the brown mice had a higher fitness in the shady forest environment. Over time, the average color of each population changed. Special creation claims that the two colors of mice do not change and were created by divine intervention. Evolution by inheritance of acquired characteristic predicts that the mice in the different environments needed to change color, so they did so and then passed their traits onto their offspring. **2.** analyze b (No, because changes in height due to nutrition and reduced incidence of disease are not heritable.) **3.** evaluate Evidence to support a common ancestor of humans and chimpanzees about 6–7 million years ago includes the following: fossils from Africa that date from 6–7 million years ago with primate characteristics that are common to chimps and humans, and DNA sequence comparisons showing homologies between chimps and humans (the rate of change of some genes can be used to estimate time of divergence). **4.** evaluate The theory of evolution fits the six criteria as follows: (1) and (2): It provides a common underlying mechanism responsible for puzzling observations such as homology, geographic proximity of similar species, the law of succession in the fossil record, vestigial traits, and extinctions. (3) and (4): It suggests new lines of research to test predictions about the outcome of changing environmental conditions in populations, about the presence of transitional forms in the fossil record, and so on. (5): It is a simple idea that explains the tremendous diversity of living and fossil organisms and why species continue to change today. (6): The realization that all organisms are related by common descent and that none are higher or lower than others was a surprise.

CHAPTER 26

IN-TEXT QUESTIONS AND EXERCISES

p. 467 (1) apply The frequencies of the three genotypes are shown by $p^2 + 2pq + q^2 = 1$.

$$\text{Freq}(A_1A_1) = p^2 = (0.6)^2 = 0.36.$$
$$\text{Freq}(A_1A_2) = 2pq = 2(0.6)(0.4) = 0.48.$$
$$\text{Freq}(A_2A_2) = q^2 = (0.4)^2 = 0.16.$$

(2) apply Allele frequencies in the offspring gene pool:

$$\text{Freq}(A_1) = 0.36 + 1/2(0.48) = 0.60.$$
$$\text{Freq}(A_2) = 1/2(0.48) + 0.16 = 0.40.$$

(3) apply Evolution has not occurred, because the allele frequencies have not changed.
p. 469 Table 26.1 apply The observed allele frequencies, calculated from the observed genotype frequencies, are 0.43 for *M* and 0.57 for *N*. The expected genotypes, calculated from the observed allele frequencies under the Hardy–Weinberg principle, are 0.185 for *MM*, 0.49 for *MN*, 0.325 for *NN*.
p. 470 CYU apply Given the observed genotype frequencies, the observed allele frequencies are

$$\text{Freq}(A_1) = 0.574 + 1/2(0.339) = 0.744.$$
$$\text{Freq}(A_2) = 1/2(0.339) + 0.087 = 0.256.$$

Given these allele frequencies, the genotype frequencies expected under the Hardy–Weinberg principle are A_1A_1: $0.744^2 = 0.554$; A_1A_2: $2(0.744 \times 0.256) = 0.381$; A_2A_2: $0.256^2 = 0.066$. There are 4 percent too few heterozygotes observed, relative to the expected proportion. One of the assumptions of the Hardy–Weinberg principle is not met at this gene in this population, at this time.
p. 470 apply The proportions of homozygotes should increase, and the proportions of heterozygotes should decrease, but allele frequencies will not change if no selection is occurring at this locus.
p. 474 apply There will be an excess of observed genotypes containing the favored allele compared to the proportion expected under Hardy–Weinberg proportions.
p. 478 (1) understand Sperm are small and hence relatively cheap to produce, whereas eggs are large and require a large investment of resources to produce. **(2)** understand Sperm are inexpensive to produce, so reproductive success for males depends on their ability to find mates—not on their ability to find resources to produce sperm. The opposite pattern holds for females. Sexual selection is based on variation in ability to find mates, so is more intense in males—leading to more exaggerated traits in males.
p. 479 apply If allele frequencies are changing due to drift, the populations in Table 26.1 would behave like the simulated populations in Figure 26.12—frequencies would drift up and down over time, and diverge.
p. 479 Fig. 26.12 analyze See **FIGURE A26.1**.
p. 480 Fig. 26.13 analyze The smaller the population, the greater the chance that genetic drift will cause alleles to

be fixed or lost in the population in a short time. Starting with a smaller population makes the experiment easier.

p. 481 Fig. 26.14 analyze Original population: freq(A_1) = (9 + 9 + 11)/54 = 0.54; New population: freq(A_1) = (2 + 2 + 1)/6 = 0.83. The frequency of A_1 has increased dramatically.

p. 482 CYU (1) understand When allele frequencies fluctuate randomly up and down, sooner or later the frequency of an allele will hit 0. That allele thus is lost from the population, and the other allele at that locus is fixed. **(2)** understand In small populations, sampling error is large. For example, the accidental death of a few individuals would have a large impact on allele frequencies.

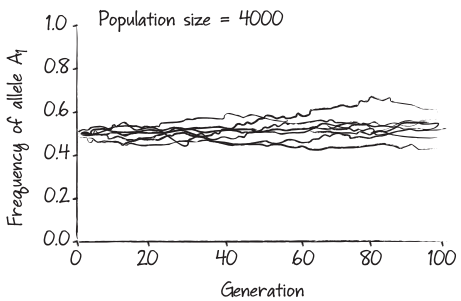
IF YOU UNDERSTAND . . .

26.1 apply The frequencies of two alleles are shown by $p + q = 1$. The frequencies of the three genotypes are shown by $p^2 + 2pq + q^2 = 1$.

$$\text{If freq}(A_1) = 0.2, \text{ then freq}(A_2) = 0.8.$$
$$\text{Freq}(A_1A_1) = p^2 = (0.2)^2 = 0.04.$$
$$\text{Freq}(A_1A_2) = 2pq = 2(0.2)(0.8) = 0.32.$$
$$\text{Freq}(A_2A_2) = q^2 = (0.8)^2 = 0.64.$$

26.2 apply It increased homozygosity of recessive alleles associated with diseases such as hemophilia. As a result, the royal families were plagued by genetic diseases. **26.3** understand The Hardy–Weinberg principle predicts that allele frequencies will stay the same over time. Natural selection favors some alleles over others, causing the frequency of those alleles to increase. **26.4** apply Genetic drift will rapidly reduce genetic variation in small populations. Thus, it is a high priority to keep the populations of endangered animals as large as possible. **26.5** apply In some cases, gene flow could be used to increase genetic variation and reduce inbreeding depression. However, gene flow can also be deleterious if the new alleles reduce the fitness of the endangered population. **26.6** apply Mutation rates themselves are too slow to affect an endangered population in a short time—unless a deleterious or beneficial mutation exposes the population to selection. (In instances where chemicals cause mutations in organisms, such as pesticides causing abnormal development in frogs, actions could be taken to remove the source of chemicals.)

YOU SHOULD BE ABLE TO . . .



✔ Test Your Knowledge

1. understand It defines what genotype and allele frequencies should be expected if evolutionary processes and nonrandom mating are *not* occurring. **2.** remember b **3.** understand a **4.** remember b **5.** remember True **6.** understand c

✔ Test Your Understanding

1. apply d; freq(A_1) = 0.9, so freq(A_2) = 0.1. Freq(A_2A_2) = $q^2 = (0.1)^2 = 0.01$. The number of babies with cystic fibrosis = 2500(0.01) = 25. **2.** apply Inbreeding causes an increase in the number of homozygotes. Individuals who are homozygous for recessive deleterious alleles are exposed to—and eliminated by—directional natural selection. **3.** evaluate This statement is false. Mutations do not occur because an organism wants or needs them. They just happen by accident and can be beneficial, neutral, or deleterious. **4.** understand Sexual selection is most intense on the sex that makes the least investment in the offspring, so that sex tends to have exaggerated traits that make individuals successful in competition for mates. In this way, sexual dimorphism evolves. **5.** analyze An allele in males, because a successful male can have as many as 100 offspring—10 times more than a successful female. **6.** create Your concept map should have linking verbs that relate the following information: Selection may decrease genetic variation or maintain it (e.g., if heterozygotes are favored). Genetic drift reduces it. Gene flow may increase or decrease it (depending on whether immigrants bring new alleles or emigrants remove alleles). Mutation increases it.

FIGURE A26.1

✔ Test Your Problem-Solving Skills

1. apply If we let p stand for the frequency of the loss-of-function allele, we know that $p^2 = 0.0001$; therefore $p = \sqrt{0.0001} = 0.01$. By subtraction, the frequency of normal alleles is 0.99. Under the Hardy–Weinberg principle, the frequency of heterozygotes is $2pq$, or $2 \times 0.01 \times 0.99$, which is 0.0198. **2.** apply c **3.** analyze If males never lift a finger to help females raise children, the fundamental asymmetry of sex is pronounced and sexual dimorphism should be high. If males invest a great deal in raising offspring, then the fundamental asymmetry of sex is small and sexual dimorphism should be low. **4.** apply Captive-bred young, transferred adults, and habitat corridors could be introduced to counteract the damaging effects of drift and inbreeding in the small, isolated populations. It is important, though, to introduce individuals only from similar habitats and connect patches of similar habitat with corridors—to avoid introducing alleles that lower fitness.

CHAPTER 27

IN-TEXT QUESTIONS AND EXERCISES

p. 493 CYU (1) understand Biological species concept: Reproductive isolation means that no gene flow is occurring. Morphological species concept: If populations are evolving independently, they may have evolved morphological differences. Phylogenetic species concept: If populations are evolving independently, they should have synapomorphies that identify them as independent twigs on the tree of life. **(2)** understand Biological species concept: It cannot be used to evaluate fossils, species that reproduce asexually, or species that do not occur in the same area and therefore never have the opportunity to mate. Morphospecies concept: It cannot identify species that differ in traits other than morphology and is subjective—it can lead to differences of opinion that cannot be resolved by data. Phylogenetic species concept: Reliable phylogenetic information exists only for a small number of organisms.

p. 494 Fig. 27.4 analyze The disruption of the salt marsh was a vicariance event that split the range of seaside sparrows into two areas (Gulf and Atlantic coasts), limiting gene flow and eventually resulting in two monophyletic groups.

p. 496 Fig. 27.7 analyze It creates genetic isolation—the precondition for divergence—by separating apple maggot flies from hawthorn flies, which mate on hawthorn fruits.

p. 497 create The difference in timing of ripening of apples and hawthorns causes divergence by separating apple flies and hawthorn flies not only in space (apple fruits versus hawthorn fruits) but also in time. The earlier ripening of apples means that apple maggots develop in relatively warm conditions in the fall compared to hawthorn maggots. Natural selection may favor traits in apple maggots that make them adapted to warmer temperatures and traits in hawthorn maggots that make them adapted to cooler temperatures.

p. 498 apply A diploid grape plant experiences a defect in meiosis resulting in the formation of diploid gametes. The individual self-fertilizes, producing tetraploid offspring. The tetraploid grape plants self-fertilize or mate with other tetraploid individuals, producing a tetraploid population.

p. 499 apply A tetraploid ($4n$) species (in this case, wheat) gives rise to diploid ($2n$) gametes, and a diploid wheat species gives rise to haploid (n) gametes. When a haploid gamete (n) fertilizes a diploid gamete ($2n$), a sterile triploid offspring results. If an error in mitosis occurs and chromosome number doubles before meiosis, then hexaploid wheat is formed.

p. 499 CYU understand Use one of the cases given in the chapter to illustrate dispersal (Galápagos finches), vicariance (snapping shrimp), or habitat specialization (apple maggot flies). In each case, drift will cause allele frequencies to change randomly. Differences in the habitats occupied by the isolated populations will cause allele frequencies to change under natural selection. Any mutation that occurs in one population will not occur in the other due to the lack, or low level, of gene flow. Or use polyploidization in maidenhair fern or *Tragopogon* to illustrate how a massive mutation can itself create immediate genetic isolation and divergence.

p. 501 Fig. 27.12 evaluate If the same processes were at work in the past that are at work in an experiment with living organisms, then the outcome of the experiment should be a valid replication of the outcome that occurred in the past.

p. 502 analyze Gene regions in the experimental hybrid would not align with those of *H. annuus* and *H. petiolaris*, meaning that the gray bar representing the DNA of the experimental hybrid could have had no orange or red regions corresponding to *H. annuus* and *H. petiolaris*.

IF YOU UNDERSTAND THAT . . .

27.1 apply Human populations would not be considered separate species under the biological concept, because human populations can successfully interbreed. They would not be considered separate species under the morphological species concept, because all human populations have the same basic morphology. Although human races differ in minor superficial attributes such as skin color and hair texture, they have virtually identical anatomy and physiology in all other regards. Nor would human populations be separate species under the phylogenetic species concept, because they all arose from a very recent common ancestor. (DNA comparisons have revealed that human races are remarkably similar genetically and do not differ enough genetically to qualify even for subspecies status.) **27.2** create (Many possibilities) Collect a group of fruit flies that are living in your kitchen, separate the individuals into different cages, and expose the two new populations to dramatically different environmental conditions—heat, lighting, food sources. In essence: Create genetic isolation and then conditions for divergence due to drift, mutation, and selection. **27.3** evaluate The sample experiment described above is an example of vicariance, because the experimenter fragmented the habitat into isolated cages. (A different mechanism of speciation may have been involved in your example.) **27.4** apply Hybrid individuals will increase in frequency, and natural selection will favor parents that hybridize. The hybrid zone will increase. The two parent populations may go extinct if hybrids live in the same environment.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. remember a **2.** remember b **3.** understand a **4.** understand a **5.** understand d **6.** remember False

✔ Test Your Understanding

1. analyze Direct observation: Galápagos finch colonization, apple maggot flies, *Tragopogon* allopolyploids, maidenhair ferns. Indirect studies: snapping shrimp, sunflowers. **2.** understand a **3.** analyze Based on biological and morphospecies criteria (breeding range and morphological traits, respectively), one species with six subspecies of seaside sparrows were recognized. However, based on phylogenetic criteria (comparison of gene sequences), biologists concluded that seaside sparrows represent only two monophyletic groups. **4.** evaluate Some flies breed on apple fruits, others breed on hawthorn fruits. This reduces gene flow. Because apple fruits and hawthorn fruits have different scents and other characteristics, selection is causing the populations to diverge. **5.** apply Decreasing. Gene flow tends to equalize allele frequencies among populations. **6.** apply c

✔ Test Your Problem-Solving Skills

1. analyze b **2.** create Sexual selection can promote divergence because it affects gene flow directly. For example, if blond women began mating only with blond men, and dark-haired women began mating only with dark-haired men, gene flow would decrease between these two populations even though they live in the same geographic area. Given enough time, these two populations would diverge due to mutation, genetic drift, and natural selection. **3.** evaluate Two things: (1) Some flies happen to have alleles that allow them to respond to apple scents; others happen to have alleles that allow them to respond to hawthorn scents. There is no "need" involved. (2) The alleles for scent response exist; they are not acquired by spending time on the fruit. **4.** analyze If the isolated populations and habitat fragments are small enough, the species is likely to dwindle to extinction due to inbreeding and loss of genetic variation or catastrophes like a severe storm or a disease outbreak. If the isolated populations survive, they are likely to diverge into new species because they are genetically isolated and because the habitats may differ.

CHAPTER 28

IN-TEXT QUESTIONS AND EXERCISES

p. 507 Fig. 28.1 apply Many trees are possible. See **FIGURE A28.1**.

p. 510 understand Because whales and hippos share SINEs 4–7 and no other species has these four, they are synapomorphies that define them as a monophyletic group. The similarity is unlikely to be due to homoplasy because the chance of four SINEs inserting in exactly the same place in two different species, independently, is very small.

p. 510 CYU analyze Hair and limb structures in humans and whales are examples of homology because they are traits that can be traced to a common ancestor. All mammals have hair and similar limb bone structure. However, extensive hair loss and advanced social behavior in whales and humans are examples of homoplasy. These traits are not common to all mammalian species and likely arose independently during the evolution of specific mammalian lineages.

p. 511 Fig. 28.4 apply See **FIGURE A28.2**. SINEs group (19, 20) identifies peccaries and pigs as a monophyletic group.

p. 513 apply Since some organisms fossilize better than others—such as mollusks with hard shells—a paleontologist would be mistaken to conclude that mollusks were more abundant than other organisms at a certain time just because mollusks are more abundant in the fossil record. Similarly, a paleontologist would be mistaken to conclude that no organisms occupied an ancient desert based on the lack of fossil evidence; organisms in deserts do not fossilize well. Several other examples are possible.

p. 517 create In habitats on the mainland, complex communities have been established for a long time, so tarweeds in California and *Anolis* lizards on the mainland experience greater competition for resources and are limited to specific niches.

p. 520 CYU understand In terms of ecological opportunity, many resources were available because no other animals (or other types of organisms) existed to exploit them. Also, the evolution of new species in new niches made new niches available for predators. Morphological innovations like limbs and complex mouthparts were important because they made it possible for animals to live in habitats other than the benthic area, and to consume new types of food.

p. 520 Fig. 28.14 analyze The dinosaurs went extinct during the end-Cretaceous. About 15 percent of families went extinct.

IF YOU UNDERSTAND . . .

28.1 apply Humans are the only mammal that walks upright on two legs, so this character is a synapomorphy that defines the hominins. **28.2** apply Snail shells are hard structures, and snails often live in marine environments that fossilize readily, so snail fossils are relatively abundant. Abundant fossils are more helpful than rare fossils for estimating changes in relative abundance over time. **28.3** analyze They could eat food that was available off the substrate. And once animals lived off (and away from) the bottom, it created an opportunity for other animals who could eat them to evolve. **28.4** evaluate This statement is false. Human-induced extinctions today are not due to poor adaptation to the normal environment. Humans are changing habitats rapidly and in unusual ways (such as clear-cutting forests), so most species cannot adapt to these changes rapidly enough to avoid going extinct. In this way, human-induced extinctions are more similar to mass extinctions than to background extinctions.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. remember c **2.** understand a **3.** understand b **4.** understand False **5.** understand d **6.** remember True

✔ Test Your Understanding

1. evaluate The fossil record is biased because recent, abundant organisms with hard parts that live underground or in environments where sediments are being deposited are most likely to fossilize. Even so, it is the only data available on what organisms that lived in the past looked like, and where they lived. **2.** create An enormous amount of animal diversity appeared in a time frame that was short compared to the sweep of earlier Earth history. The most common analogy is to an explosion, referring to the sudden and spectacular radiation of lineages. Another analogy is your hand, where one line (your arm) comes into a node (your palm) and several lineages (your fingers) come out. Many other answers are possible. **3.** understand Homoplasy is rare relative to homology, so phylogenetic trees that minimize the total change required are usually more accurate. In the case of the artiodactyl astragalus, parsimony was misleading because the astragalus was lost when whales evolved limblessness—creating two changes (a loss following a gain) instead of one (a gain). **4.** create (Many answers are possible.) Adaptive radiation of *Anolis* lizards after they colonized new islands in the Caribbean. *Hypothesis:* After lizards arrived on each new island, where there were no predators or competitors, they rapidly diversified to occupy four distinct types of habitats on each island. Adaptive radiation during the Cambrian period following a morphological innovation. *Hypothesis:* Additional *Hox* genes made it possible to organize a large, complex body; the evolution of complex mouthparts and limbs made it possible for animals to move and find food in new ways. **5.** apply About 90 percent of species went extinct during the end-Permian, so about 10 percent survived, written as 0.1 in decimals. $1880 \times 0.1 = 188$ would make it to graduation. **6.** apply d

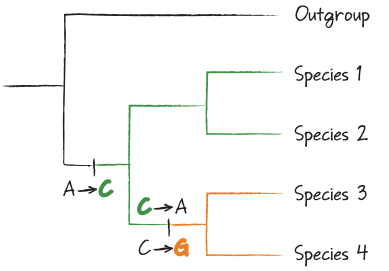
✔ Test Your Problem-Solving Skills

1. understand b **2.** evaluate Many trees are possible. See **FIGURE A28.3**. Sponges are the outgroup. The most parsimonious tree has the fewest number of changes (five in this case). Adding more characters to the matrix can improve the reliability of the results. **3.** understand It would be helpful to have (1) a large crater or other physical evidence from a major impact dated at 251 mya, (2) shocked quartz and microtektites in rock layers dating to the end-Permian era, and (3) high levels of iridium or other elements common in space rocks and rare on Earth, dated to the time of the extinctions. **4.** create Many concept map topologies are possible. Maps should follow this logic: Oxygen is an effective final electron acceptor in cellular respiration because of its high electronegativity. Organisms that use it as a final electron acceptor can produce more usable energy than organisms that do not use oxygen, but only if it is available. With more available energy, aerobic organisms can grow larger and move faster.

BIG PICTURE Evolution

p. 526 CYU (1) understand Circle = inbreeding, sexual selection, nonrandom mating, natural selection, genetic drift,

FIGURE A28.1



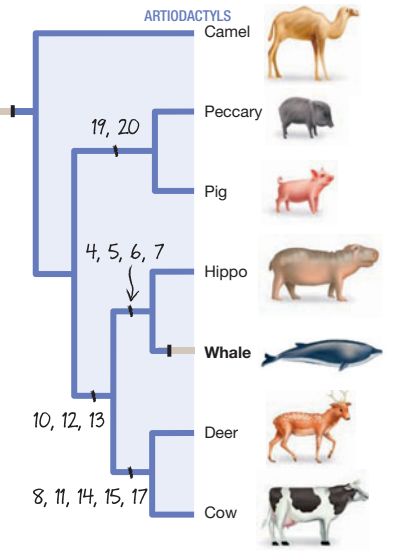


FIGURE A28.2

mutation, and gene flow. **(2)** analyze Adaptation "increases" fitness; synapomorphies "identify branches on" the tree of life. **(3)** analyze Several answers possible, e.g., adaptive radiations and mass extinctions → can be studied using → the fossil record. **(4)** analyze Genetic drift, mutation, and gene flow "are random with respect to" fitness.

CHAPTER 29

IN-TEXT QUESTIONS AND EXERCISES

p. 529 Fig. 29.1 analyze Prokaryotic—it would require just one evolutionary change, the origin of the nuclear envelope in Eukarya. If it were eukaryotic, it would require that the nuclear envelope was lost in both Bacteria and Archaea—two changes are less parsimonious (see Chapter 28).
p. 529 Table 29.1 apply See **FIGURE A29.2**.
p. 534 Fig. 29.5 analyze Weak—different culture conditions may have revealed different species.
p. 535 CYU (1) create Conditions should mimic a spill—sand or stones with a layer of crude oil, or seawater with oil floating on top. Add samples, from sites contaminated with oil, that might contain cells capable of using molecules in oil as electron donors or electron acceptors. Other conditions (temperature, pH, etc.) should be realistic. **(2)** create Use metagenomic analysis. After isolating DNA from a soil sample, fragment and sequence the DNA. Compare the sequences to those from known organisms and use the data to place the species on the tree of life.
p. 538 apply cyanobacteria—photoautotrophs; *Clostridium aceticum*—chemoorganoautotroph; *Nitrosopumilus* sp.—chemolithoautotrophs; helicobacteria— photoheterotrophs; *Escherichia coli*—chemoorganoheterotroph; *Beggitoa*—chemolithotrophic heterotrophs.
p. 539 Fig. 29.10 apply Table 29.5 contains the answers. For example, for organisms called sulfate reducers you would have H_2 as the electron donor, SO_4^{2-} as the electron acceptor, and H_2S as the reduced by-product. For humans the electron donor is glucose ($C_6H_{12}O_6$), the electron acceptor is O_2, and the reduced by-product is water (H_2O).
p. 541 understand Different species of bacteria that have different forms of bacterial chlorophyll will not absorb the same wavelengths of light and will therefore not compete.
p. 542 Fig. 29.12 apply Aerobic respiration. More free energy is released when oxygen is the final electron acceptor than when any other molecule is used, so more ATP can be produced and used for growth.
p. 543 apply If bacteria and archaea did not exist, then (1) the atmosphere would have little or no oxygen, and (2) almost all nitrogen would exist in molecular form (the gas N_2).
p. 543 Fig. 29.13 apply Add a label for "animals" in the upper right quarter of the circle, and draw arrows leading from "Organic compounds with amino groups" to "animals" and from "animals" to "NH_3."
p. 544 CYU evaluate Eukaryotes can only (1) fix carbon via the Calvin–Benson pathway, (2) use aerobic respiration with organic compounds as electron donors, and (3) perform oxygenic photosynthesis. Among bacteria and archaea, there is much more diversity in pathways for carbon fixation, respiration, and photosynthesis, along with many more fermentation pathways.
p. 545a, **p. 545b**, **p. 546a**, **p. 546b**, **p. 547** apply See **FIGURE A29.1**.
p. 548 Fig. 29.21 apply About 600,000 *N. maritimus* cells would fit end to end on a meter stick.

IF YOU UNDERSTAND . . .

29.1 analyze Eukaryotes have a nuclear envelope that encloses their chromosomes; bacteria and archaea do not. Bacteria have cell walls that contain peptidoglycan, and archaea have phospholipids containing isoprene subunits in their plasma membranes. Thus, the exteriors of a bacterium and archaeon are radically different. Archaea and eukaryotes also have similar machinery for processing genetic information. **29.2** apply After extracting and sequencing DNA from bacteria that live in an insect gut, analyze the resulting sequences for genes that are similar to known genes involved in nitrogen fixation. **29.3** understand They are compatible, and thrive in each others' presence—one species' waste product is the other species' food.

YOU SHOULD BE ABLE TO . . .

✓ Test Your Knowledge

1. understand c **2.** remember b **3.** remember d **4.** remember d **5.** remember False—the enzyme nitrogenase is poisoned by oxygen. **6.** remember peptidoglycan

✓ Test Your Understanding

1. understand c **2.** understand An electron donor provides the potential energy required to produce ATP. **3.** evaluate Yes. The array of substances that bacteria and archaea can use as electron donors, electron acceptors, and fermentation substrates, along with the diversity of ways that they can fix carbon and perform photosynthesis, allows them to live just about anywhere. **4.** apply They should get energy from reduced organic compounds "stolen" from their hosts. **5.** understand Large amounts of potential energy are released and ATP produced when oxygen is the electron acceptor, because oxygen is so electronegative.

FIGURE A28.3

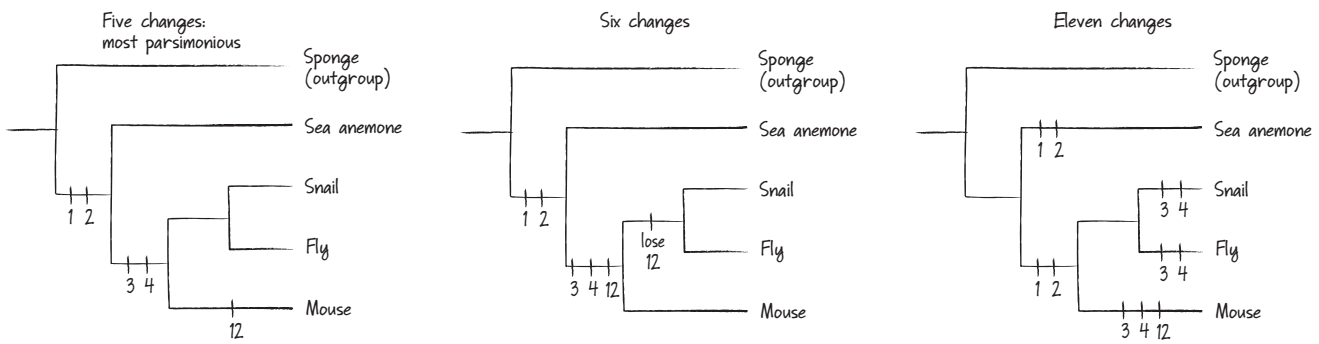

FIGURE A29.1

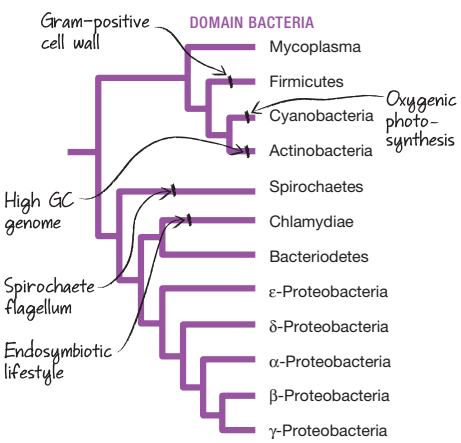

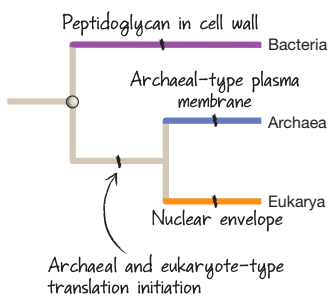

FIGURE A29.2

Large body size and high growth rates are not possible without large amounts of ATP. **6.** understand They are paraphyletic because the prokaryotes include some (bacteria and archaea) but not all (eukaryotes) groups derived from the common ancestor of all organisms living today.

✔ Test Your Problem-Solving Skills

1. understand c (It is pathogenic on a wide variety of organisms). **2.** analyze This result supports their hypothesis because the drug poisons the enzymes of the electron transport chain and prevents electron transfer to Fe^{3-}, which is required to drive magnetite synthesis. If magnetite had still formed, another explanation would have been needed. **3.** create Hypothesis: A high rate of tooth cavities in Western children is due to an excess of sucrose in the diet, which is absent from the diets of East African children. To test this hypothesis, switch a group of East African children to a diet that contains sucrose, switch a group of Western children to a diet lacking sucrose, and monitor the presence of *S. mutans* in both groups of children. **4.** create Look in waters or soil polluted with benzene-containing compounds. Put samples from these environments in culture tubes where benzene is the only source of carbon. Monitor the cultures and study the cells that grow efficiently.

CHAPTER 30

IN-TEXT QUESTIONS AND EXERCISES

p. 529 CYU (1) understand Opisthokonts have a flagellum at the base or back of the cell; alveolate cells contain unique support structures called alveoli; stramenopiles—meaning "straw hairs"—have straw-like hairs on their flagella. **(2)** understand In direct sequencing, DNA is isolated directly from the environment and analyzed to place species on the tree of life. It is not necessary to actually see the species being studied.
p. 557 CYU (1) understand *Plasmodium* species are transmitted to humans by mosquitoes. If mosquitoes can be prevented from biting people, they cannot spread the disease. **(2)** apply Iron added → primary producers (photosynthetic protists and bacteria) bloom → more carbon dioxide taken up from atmosphere during photosynthesis → consumers bloom, eat primary producers → bodies of primary producers and consumers fall to bottom of ocean → large deposits of carbon-containing compounds form on ocean floor.
p. 560 apply See **FIGURE A30.1**.
p. 560 Fig. 30.8 analyze Two—one derived from the original bacterium and one derived from the eukaryotic cell that engulfed the bacterium.
p. 561 apply A photosynthetic bacterium (e.g., a cyanobacterium) could have been engulfed by a larger eukaryotic cell. If it was not digested, it could continue to photosynthesize and supply sugars to the host cell.
p. 562 apply Membrane infoldings observed in bacterial species today support the hypothesis's plausibility—they confirm that the initial steps actually could have happened. The continuity of the nuclear envelope and ER are consistent with the hypothesis, which predicts that the two structures are derived from the same source (infolded membranes).
p. 564 apply The chloroplast genes label should come off of the branch that leads to cyanobacteria. (If you had a phylogeny of just the cyanobacteria, the chloroplast branch would be located somewhere inside.)
p. 565 analyze The acquisition of the mitochondrion and the chloroplast represent the transfer of entire genomes, and not just single genes, to a new organism.
p. 566 apply Yes—when food is scarce or population density is high, the environment is changing rapidly (deteriorating). Offspring that are genetically unlike their parents may be better able to cope with the new and challenging environment.
p. 569a understand (1) Alternation of generations refers to a life cycle in which there are multicellular haploid phases and multicellular diploid phases. A gametophyte is the multicellular haploid phase that produces gametes; the sporophyte is the multicellular diploid phase that produces spores. A spore is a cell that grows into a multicellular individual but is not produced by fusion of two cells. A zygote is a cell that grows into a multicellular individual but *is* produced by fusion of two cells (gametes). Gametes are haploid cells that fuse to form a zygote. (2) See **FIGURE A30.2**.
p. 569b apply Most likely, the two types of amoebae evolved independently. The alternative hypothesis is that the common ancestor of alveolates, stramenopiles, rhizarians, plants, opisthokonts, and amoebozoa were amoeboid and that this growth form was lost many times. See **FIGURE A30.1**.
p. 569c, p. 569d, p. 569e, p. 570a, p. 570b, p. 570c apply See **FIGURE A30.1**.
p. 571 analyze If euglenids could take in food via phagocytosis (ingestive feeding), then that would have provided a mechanism by which a smaller photosynthetic protist could have been engulfed and incorporated into the cell via secondary endosymbiosis.
p. 572a, p. 572b, p. 573, p 574. apply See **FIGURE A30.1**.

IF YOU UNDERSTAND . . .

30.1 understand Photosynthetic protists use CO_2 and light to produce sugars and other organic compounds, so they furnish the first or primary source of organic material in an ecosystem. **30.2** remember Eukaryotic cells contain many organelles, including a nucleus, endomembrane system, and an extensive cytoskeleton. Most prokaryotic cells contain few or no organelles, and no nucleus or endomembrane system and lack a complex cytoskeleton. **30.3** understand (1) Outside membrane was from host eukaryote; inside from engulfed cyanobacterium. (2) From the outside in, the four membranes are derived from the eukaryote that engulfed a chloroplast-containing eukaryote, the plasma membrane of the eukaryote that was engulfed, the outer membrane of the engulfed cell's chloroplast, and the inner membrane of its chloroplast.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. understand b **2.** remember b **3.** remember a **4.** remember b **5.** remember False. **6.** remember diatoms.

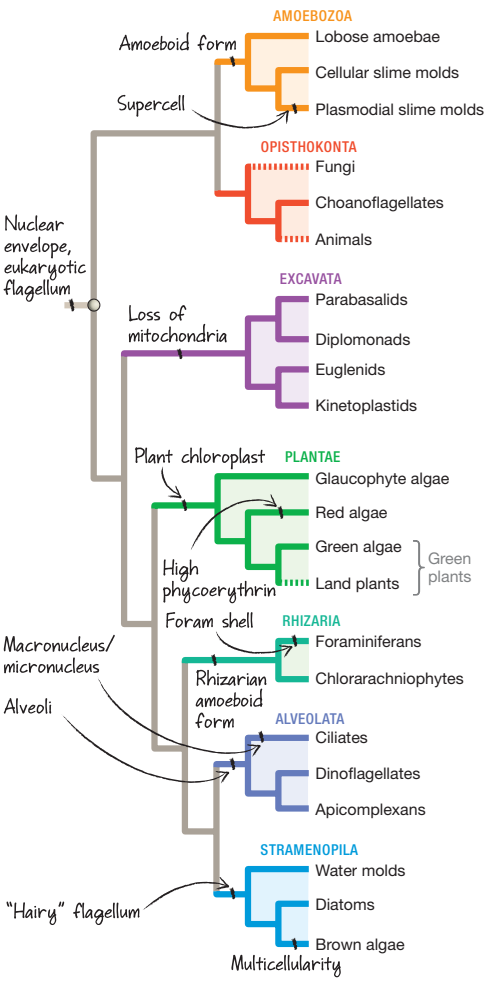
✔ Test Your Understanding

1. understand a **2.** understand Because all eukaryotes living today have cells with a nuclear envelope, it is valid to infer that their common ancestor also had a nuclear envelope. Because bacteria and archaea do not have a nuclear envelope, it is valid to infer that the trait arose in the common ancestor of eukaryotes. **3.** understand The host cell provided a protected environment and carbon compounds for the endosymbiont; the endosymbiont provided increased ATP from the carbon compounds **4.** understand It confirmed a fundamental prediction made by the hypothesis and could not be explained by any alternative hypothesis. **5.** understand All alveolates have alveoli, which are unique structures that function in supporting the cell. Among alveolates there are species that are (1) ingestive feeders, photosynthetic, or parasitic, and that (2) move using cilia, flagella, or a type of amoeboid movement.

✔ Test Your Problem-Solving Skills

1. analyze d **2.** analyze If the apicoplast that is found in *Plasmodium* (the organism that causes malaria) is genetically similar to chloroplasts, and if glyphosate poisons chloroplasts, it is reasonable to hypothesize that glyphosate will poison the apicoplast and potentially kill the *Plasmodium*. This would be a good treatment strategy for malaria because humans have no chloroplasts, provided that the glyphosate produces no other effects that would be detrimental to humans. **3.** evaluate Primary producers usually grow faster when CO_2 concentration increases, but to date they have not grown fast enough to make CO_2 levels drop—CO_2 levels have been increasing steadily over decades. **4.** analyze Given that lateral gene transfer can occur at different points in a phylogenetic history, specific genes can become part of a lineage by a different route from that taken by other genes of the organism. In the case of chlorophyll *a*, its history traces back to a bacterium being engulfed by a protist and forming a chloroplast.

FIGURE A30.1



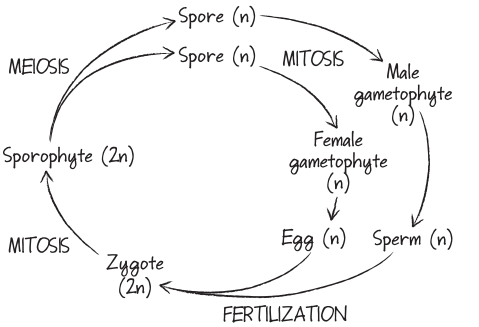


FIGURE A30.2

CHAPTER 31

IN-TEXT QUESTIONS AND EXERCISES

p. 582 CYU understand (1) Green algae and land plants share an array of morphological traits that are synapomorphies, including the chlorophylls they contain; (2) green algae appear before land plants in the fossil record; and (3) on phylogenetic trees estimated from DNA sequence data, green algae and land plants share a most recent common ancestor—green algae are the initial groups to diverge, and land plants diverge subsequently.
p. 583 Fig. 31.6 remember If you find the common ancestor of all the green algae (at the base of the Ulvophyceae), the lineages that are collectively called green algae don't include that common ancestor and all of its descendants—only some of its descendants. The same is true for non-vascular plants (the common ancestor here is at the base of the Hepaticophyta) and seedless vascular plants (the common ancestor here is at the base of the Lycophyta).
p. 586 Fig. 31.8 understand Water flows more easily through a short, wide pipe than through a long, skinny one because there is less resistance from the walls of the pipe.
p. 587 Fig. 31.9 understand To map an innovation on a phylogenetic tree, biologists determine the location(s) on the tree that is (are) consistent with all descendants from that point having the innovation (unless, in rare cases, the innovation was lost in a few descendants).
p. 589 understand Alternation of generations occurs when there are multicellular haploid individuals and multicellular diploid individuals in a life cycle. One hypothesis is that this life cycle evolved because the plants with a large sporophyte were more successful at using the wind to disperse many spores, while a small gametophyte produces gametes that can swim.
p. 590 apply In the hornwort photo, the sporophyte is the spike-like green and yellow structure; the gametophyte is the leafy-looking structure underneath. The horsetail gametophyte is the microscopic individual on the left; the sporophyte is the much larger individual on the right.
p. 590 Fig. 31.14 understand There are multicellular haploid stages and multicellular diploid stages in these plants.
p. 592 Fig. 31.18 analyze Gymnosperm gametophytes are microscopic, so they are even smaller than fern gametophytes. The gymnosperm gametophyte is completely dependent on the sporophyte for nutrition, while fern gametophytes are not. Fern gametophytes are photosynthetic and even supply nutrition to the young sporophytes.
p. 593 Fig. 31.19 analyze Consistent—the fossil data suggest that gymnosperms evolved earlier, and gymnosperms have larger gametophytes than angiosperms.
p. 595 Fig. 31.21 analyze To eliminate all other variables except for the one being tested, such as the possibility of pollination by other insects in the field. Scales differ because the two insect species visited flowers at very different frequencies.
p. 596 CYU (1) understand Cuticle prevents water loss from the plant; UV-absorbing compounds allow plants to be exposed to high light intensities without damage to their DNA; vascular tissue moves water up from the soil and moves photosynthetic products down to the roots.
(2) apply See **FIGURE A31.1**.
p. 600a, **p. 600b**, **p. 601**, **p. 603a**, **p. 603b**, **p. 604**, **p. 605**, **p. 606** apply See **FIGURE A31.1**.
p. 596 Fig. 31.23 apply See **FIGURE A31.1**.

IF YOU UNDERSTAND . . .

31.1 apply Rates of soil formation will decline; rates of soil loss will increase. **31.2** understand All green algae and land plants contain chlorophyll *a* and *b*, have similar arrangements of thylakoid membranes, and store starch.
31.3 analyze Both spores and seeds have a tough, protective coat, so they can survive while being dispersed to a new location. Seeds have the advantage of carrying a store of nutrients with them—when a spore germinates, it must make its own food via photosynthesis right away.

YOU SHOULD BE ABLE TO . . .

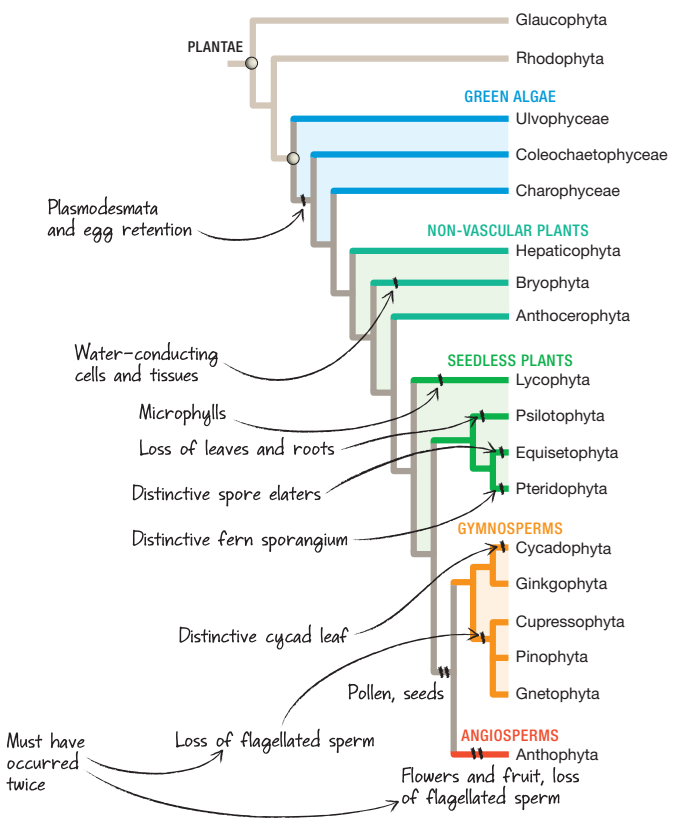
✓ Test Your Knowledge

1. remember c **2.** remember c **3.** remember a **4.** remember c **5.** remember (a) Gametangia are found in all land plant groups except angiosperms; (b) pollen is found in gymnosperms and angiosperms; (c) seeds are found in gymnosperms and angiosperms, (d) fruit is found in angiosperms. **6.** understand In a gametophyte-dominant life cycle, the gametophyte is larger and longer lived than the sporophyte and produces most of the nutrition. In a sporophyte-dominant life cycle, the sporophyte generation is the larger, longer-lived, and photosynthetic phase of the life cycle.

✓ Test Your Understanding

1. remember c **2.** understand Plants build and hold soils required for human agriculture and forestry, and they increase water supplies that humans can use for drinking, irrigation, or industrial use. Plants release oxygen that we breathe. **3.** analyze Cuticle prevents water loss from leaves but also prevents entry of CO_2 required for photosynthesis. Stomata allow CO_2 to diffuse but can close to minimize water loss. Liverwort pores allow gas exchange but cannot be closed if conditions become dry. **4.** understand They provided the support needed for plants to grow upright and not fall over in response to wind or gravity. Erect growth allowed plants to compete for light. **5.** apply Homosporous plants produce a single type of spore that develops into a gametophyte that produces both egg and sperm. Heterosporous plants produce two different types of spores that develop into two different gametophytes that produce either egg or sperm. In a tulip, the microsporangium is found within the stamen, and the megasporangium is found within the ovule. Microspores divide by mitosis to form male gametophytes (pollen grains); megaspores divide by mitosis to form the female gametophyte. **6.** understand Animal pollinators increase the efficiency of pollination so plants can save energy by making less pollen.

✓ Test Your Problem-Solving Skills



1. understand d **2.** analyze A "reversion" to wind pollination might be favored by natural selection because it is costly to produce a flower that can attract animal pollinators. Because wind-pollinated species grow in dense clusters, they can maximize the chance that the wind will carry pollen from one individual to another (less likely if the individuals are far apart). Wind-pollinated deciduous trees flower in early spring before their developing leaves begin to block the wind. **3.** create The combination represents a compromise between efficiency and safety. Tracheids can still transport water if vessels become blocked by air bubbles. **4.** create Alter one characteristic of a flower, and present the flower to the normal pollinator. As a control, present the normal (unaltered) flower to the normal pollinator. Record the amount of time the pollinator spends in the flower, the amount of pollen removed, or some other measure of pollination success. Repeat for other altered characteristics. Analyze the data to determine which altered characteristic affects pollination success the most.

CHAPTER 32

IN-TEXT QUESTIONS AND EXERCISES

p. 619 CYU (1) understand Because they are made up of a network of thin, branching hyphae, mycelia have a large surface area, which makes absorption efficient.
(2) remember Swimming spores and gametes, zygosporangia, basidia, asci.

FIGURE A31.1

p. 622 Fig. 32.10 analyze Labeled nutrient experiments identify which nutrients are exchanged and in which direction. They explain *why* plants do better in the presence of mycorrhizae, and why the fungus also benefits.
p. 625 analyze Human sperm and egg undergo plasmogamy followed by karyogamy during fertilization, but heterokaryotic cells do not occur in humans or other eukaryotes besides fungi.
p. 625 Fig. 32.12 apply The haploid mycelium.
p. 626 Fig. 32.13 analyze Mycelia produced by asexual reproduction are genetically identical to their parent; mycelia produced by sexual reproduction are genetically different from both parents (each spore has a unique genotype).
p. 628 CYU (1) understand When birch tree seedlings are grown in the presence and absence of EMF, individuals denied their normal EMF are not able to acquire sufficient nitrogen and phosphorus. **(2)** analyze Each type of fungus involves meiosis and the production of haploid spores. In a zygosporangium, meiosis occurs in a multinucleate cell; in basidia and asci, this cell has a single diploid nucleus. In asci, meiosis is followed by one round of mitosis.
p. 628, **p. 630a**, **p. 630b**, **p. 630c**, **p. 631**, **p. 632a**, **p. 632b** apply See **FIGURE A32.1**.

IF YOU UNDERSTAND . . .

32.1 apply Loss of mycorrhizal fungi would decrease nutrient delivery to plants and reduce their growth inside the experimental plots, compared to control plots with intact fungi. Also, lack of fungi would slow decay of dead plant material, causing a dramatic buildup of dead organic material. **32.2** understand Like humans, fungi are composed of eukaryotic cells. Bacteria are prokaryotic and thus have many more unique targets for antibiotics. **32.3** understand Haploid hyphae fuse, forming a heterokaryotic mycelium. When karyogamy occurs, a diploid nucleus forms—just as when gametes fuse. **32.4** understand See the diversity boxes.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. remember a **2.** remember d **3.** remember b **4.** remember b **5.** understand Pores in septa allow nutrients to move from regions of acquisition to regions of mycelial growth; **6.** remember commensal.

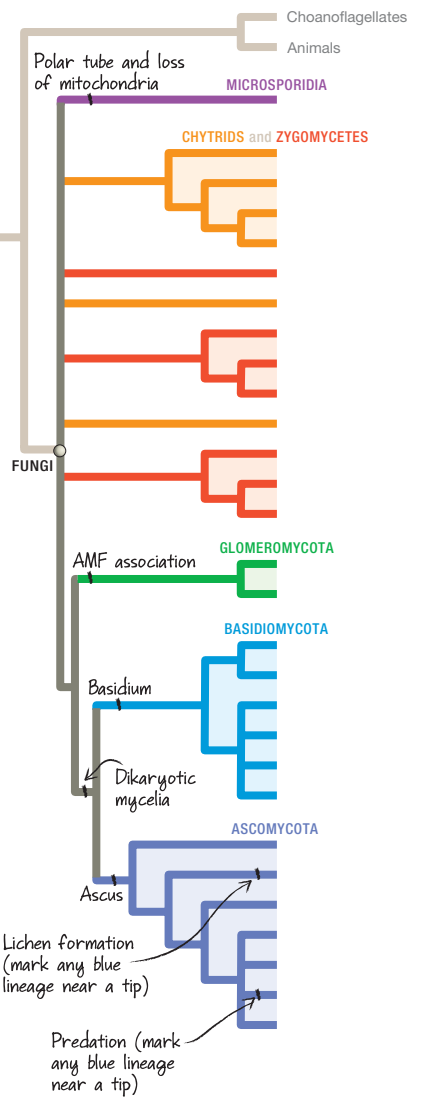
✔ Test Your Understanding

7. understand c **8.** evaluate Along with a few bacteria, fungi are the only organisms that can digest wood completely. If the wood is not digested, carbon remains trapped in wood. Without fungi, CO_2 would be tied up and unavailable for photosynthesis, and the presence of undecayed organic matter would reduce the space available for plants to grow. **9.** analyze Fungi produce enzymes that degrade cellulose and lignin. **10.** analyze Plant roots have much smaller surface area than EMF or AMF. Hyphae are much smaller than the smallest portions of plant roots so can penetrate dead material more efficiently. Extracellular digestion—which plant roots cannot do—allows fungi to break large molecules into small compounds that can be absorbed. **11.** apply DNA and RNA contain phosphorus. Mycorrhizal fungi effectively increase the volume of soil mined by root systems and can make adequate amounts of phosphorus available for supporting rapid cell division. **12.** analyze Both compounds are processed via extracellular digestion. Different enzymes are involved, however. The degradation of lignin is uncontrolled and does not yield useful products; digestion of cellulose is controlled and produces useful glucose molecules.

✔ Test Your Problem-Solving Skills

13. apply c **14.** create (1) Confirm that the chytrid fungus is found only in sick frogs and not healthy frogs. (2) Isolate the chytrid fungus and grow it in a pure culture. (3) Expose healthy frogs to the cultured fungus and see if they become sick. (4) Isolate the fungus from the experimental frogs, grow it in culture, and test whether it is the same as the original fungus. **15.** create Each of the different cellulase enzymes attacks cellulose in a different way, so producing all the enzymes together increases the efficiency of the fungus in breaking down cellulose completely. It is likely that lignin peroxidase is produced along with cellulases, so they can act in concert to degrade wood. To test this idea, you could harvest enzymes secreted from a mycelium before and after it contacts wood in a culture dish, and see if the cellulases and lignin peroxidase appear together once the mycelium begins growing on the wood. **16.** create Collect a large array of colorful mushrooms that are poisonous; also capture mushroom-eating animals, such as squirrels. Present a hungry squirrel with a choice of mushrooms that have been dyed or painted a drab color versus others treated with a solution that is identical to the dye or paint used but uncolored. Record which mushrooms the squirrel eats. Repeat the test with many squirrels and many mushrooms.

CHAPTER 33



IN-TEXT QUESTIONS AND EXERCISES

p. 639 Fig. 33.2 apply The label and bar for "Segmentation?" should go on the branch to the left of the clam shell and "Mollusca" label. The label and bar for "Toolkit genes for segmentation?" should go on the same branch as cephalization, CNS, and coelom.
p. 640 apply The genetic tool kit required for multicellularity includes genes that regulate the cell cycle, and thus cell division. When something goes wrong in this process, uncontrolled growth called cancer can result. Thus, cancer may be as ancient as multicellularity itself.
p. 642 Fig. 33.7 analyze Stained *Hox* and *dpp* gene products would either not be found in *Nematostella* at all or would not occur in the same anterior–posterior and dorsal–ventral pattern as observed in bilaterians.
p. 646 CYU (1) apply Yes, your body has a tube-within-a-tube design. Humans are vertebrates, vertebrates are chordates, chordates are bilaterians, and all bilaterians have a tube-within-a-tube design, consisting of a bilaterally symmetrical, slender body with an inner tube (gut), an outer tube (mostly skin), muscles and organs derived from mesoderm in between, and one end (head) cephalized with sensory organs and brain. **(2)** understand When an animal moves through an environment in one direction, its ability to acquire food and perceive and respond to threats is greater if its feeding, sensing, and information-processing structures are at the leading end.
p. 651 Fig. 33.14 evaluate The larva and metamorphosis arrow should be circled in the life cycle. It might be adaptive to skip the feeding larval stage if more food resources are available for the mother (who must expend energy to produce the yolk) than for the larva, if predation pressure on larvae is high, or if other environmental factors for larvae are unfavorable, resulting in high mortality of the larvae.
p. 652 CYU (1) understand The mouthparts of deposit feeders are relatively simple because these animals simply gulp relatively soft material. The mouthparts of mass feeders are more complex because they have to tear off and process chunks of relatively hard material. **(2)** create Gametes that are shed into aquatic environments can float or swim. This cannot happen on land, so internal fertilization is more common there. Also, gametes are more at risk of drying out on land, and internal fertilization eliminates that risk.
p. 653 apply The origin of cilia-powered swimming should be marked on the Ctenophora branch.
p. 654 apply The origin of cnidocytes should be marked on the Cnidaria branch.

IF YOU UNDERSTAND . . .

33.1 apply It should increase dramatically—animals would no longer be consuming plant material. **33.2** understand Your drawing should show the tube-within-a-tube design of a worm, with one end labeled head and containing the mouth and brain. From the brain, one or two major nerve tracts should run the length of the body. The gut should go from the mouth to the other end, ending in the anus. In between the gut and outer body wall, there should be blocks or layers of muscle. **33.3** apply There are many possible answers. For example, within the phylum Arthropoda: The sensory systems have diversified (e.g., eyes are important for sight in flies, antennae are important for smelling in moths); feeding strategies have diversified (e.g., butterflies are fluid feeders but caterpillars are mass feeders); ecological roles have diversified (e.g., butterflies are herbivores but spiders are carnivores); limbs have diversified (e.g., butterflies have legs and wings but caterpillars have lobe-like limbs); and some insects, like grasshoppers, have direct development whereas others, like mosquitoes, have indirect development. **33.4** remember If you see a

FIGURE A32.1

sessile, multicellular animal with no symmetry or radial symmetry, with outcurrent holes, and choanocytes, it is a sponge. If you see a radially symmetric, transparent, planktonic organism moving via rows of cilia, it is a ctenophore. If you see a diploblastic, outwardly radially symmetric animal that is either a single polyp or colony of multiple polyps, or it is a medusa, then the animal is a cnidarian.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. remember a **2.** remember True **3.** remember protostomes, deuterostomes **4.** understand a **5.** remember d **6.** remember d

✔ Test Your Understanding

1. understand Diploblasts have two types of embryonic tissue (ectoderm, endoderm); triploblasts have three (ectoderm, mesoderm, endoderm). Mesoderm made it possible for an enclosed, mesoderm-lined cavity to develop, creating a coelom. **2.** analyze Many unicellular organisms are heterotrophic, but they can consume only small bits of food. Animals are multicellular, so they are larger and can consume larger amounts of food—making them important consumers in food webs. **3.** apply There are about 18.4 named arthropods for every named species of chordate (1,160,000/63,000), about 1.3 named mollusks for every named species of chordate (85,000/63,000), and about 0.4 named species of nematode worm for every named species of chordate (25,000/63,000). These numbers are likely to be underestimates because there are probably many more arthropods, mollusks, and nematode worms than have been described, yet relatively few of the larger, more familiar chordates (including vertebrates) left to be described. **4.** understand In oviparous species, the mother adds nutrient-rich yolk to the egg that nourishes the developing embryo. In viviparous species, the mother transfers nutrients directly from her body to the growing embryo. **5.** evaluate You could stain the gene products of the segmentation genes in chordates (such as a mouse embryo) and observe whether the expression pattern correlates with the expression pattern observed in arthropods (such as a fly embryo). **6.** apply c

✔ Test Your Problem-Solving Skills

1. analyze Yes—if the same gene is found in nematodes and humans, it was likely found in the common ancestor of protostomes and deuterostomes. If so, then fruit flies should also have this gene. **2.** apply Asexual reproduction is likely to be favored when the sea anemones have plenty of resources such as space and food. Sexual reproduction is likely to be favored when the sea anemones are stressed due to lack of resources, predation, infection, or other factors. In this case, it is adaptive to reproduce in a way that enables dispersal to a new site and/or genetically diverse offspring, some of which will be more likely to survive selection than a clone of identical animals would. **3.** apply Since echinoderms evolved from bilaterally symmetric ancestors with nerve cords, they should have nerve cords too. However, the organization of the nerve cords should be more diffuse, because echinoderms need to take in and process information from multiple directions—not just one. **4.** apply d

CHAPTER 34

IN-TEXT QUESTIONS AND EXERCISES

p. 659 Fig. 34.3 apply We know that aquatic living was the ancestral trait because the outgroups (e.g., Cnidaria, Porifera) were aquatic. We also have fossil evidence that the aquatic lifestyle was ancestral.
p. 660, **p. 662**, **p. 665**, **p. 666**, **p. 667**, **p. 671**, **p. 674** apply See **FIGURE A34.1**.
p. 662 Fig. 34.6 evaluate Different phyla of worms have different feeding strategies and mouthparts, and they eat different foods, so they are not all in direct competition for food.
p. 664 CYU (1) apply Snails on land would be expected to have gills or lungs inside the body or otherwise protected from drying out, thinner shells so that they are not as heavy, and desiccation-resistant eggs. **(2)** evaluate The tentacles of the octopus could be probed during development for *Hox* genes known to be important in establishing the foot of snails. If the expression pattern is similar, homology would be supported.
p. 664 Fig. 34.10 apply You should have drawn a circle around all the tentacles.

IF YOU UNDERSTAND . . .

34.1 remember Ecological opportunity was important in the diversification of protostomes because many lineages made the transition from water to land, radiating into new niches. Genetic opportunity was important because changes in the expression of developmental tool-kit genes enabled diverse modifications of body plans based on existing genes. **34.2** understand One source of diversification is the loss of ancestral traits; just because a species does not possess a trait does not mean that its ancestor didn't. **34.3** analyze Both arthropods and vertebrates have segmented bodies, which are especially amenable to modularity since a change in the expression pattern of developmental tool-kit genes can change the number, size, and type of segments, exposing morphological diversity to the adaptive forces of natural selection.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. remember False **2.** remember a **3.** remember c **4.** understand c **5.** remember Both groups are bilaterally symmetric triploblasts with the protostome pattern of development. **6.** remember b

✔ Test Your Understanding

1. remember d **2.** apply Both annelids and arthropods have segmented bodies, unlike other protostomes such as flatworms and nematodes. **3.** evaluate Clams are relatively sessile as adults. Because larvae can swim, they provide a mechanism to disperse to new locations. To test this idea, you could measure the distance traveled by clam larvae and measure their success in recruiting to new habitats compared to larvae that are artificially limited to stay near their parents. **4.** apply Land plants would require cuticles or other mechanisms to keep their tissues from drying out, a mechanism of keeping gametes from drying out, and structural support to retain body shape despite the effects of gravity. **5.** evaluate The ability to fly allowed insects to disperse to new habitats and find new food sources efficiently. **6.** analyze It might be adaptive for juveniles of hemimetabolous individuals to use the same food source as the adults when the food source is plentiful.

✔ Test Your Problem-Solving Skills

1. analyze See **FIGURE A34.2**. **2.** analyze If the ancestors of brachiopods and mollusks lived in similar habitats and experienced natural selection that favored similar traits, then they would have evolved to have similar forms and habitats. This is called convergent evolution (see Chapter 28). **3.** evaluate This hypothesis is reasonable because simple characteristics often occur before more elaborate ones; this could be true for the radula and foot in aplacophorans. An alternate hypothesis would be that these structures' simple forms are derived characteristics that are adaptations for parasitism, but the evidence suggests that aplacophorans are carnivores and detritivores, not parasites. The position of the aplacophorans in the phylogeny could be tested by using DNA sequence data rather than morphological characters in a phylogenetic analysis. **4.** apply b

CHAPTER 35

IN-TEXT QUESTIONS AND EXERCISES

p. 682 Fig. 35.1 apply Invertebrates are a paraphyletic group. The group does not include all the descendants of the common ancestor because vertebrates are excluded.
p. 684 CYU understand If it's an echinoderm, it should have five-part radial symmetry, a calcium carbonate endoskeleton just underneath the skin, and a water vascular system (e.g., visible tube feet).
p. 684, **p. 685a**, **p. 685b** apply See **FIGURE A35.1**.

FIGURE A34.1

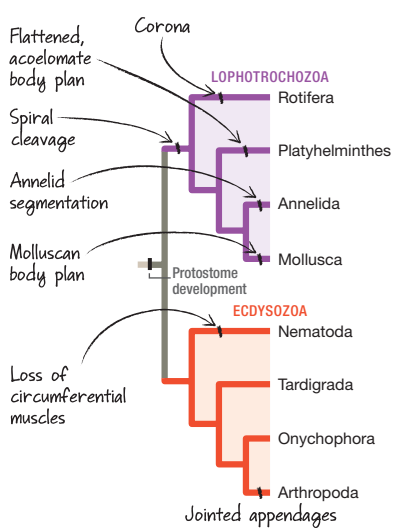


FIGURE A34.2

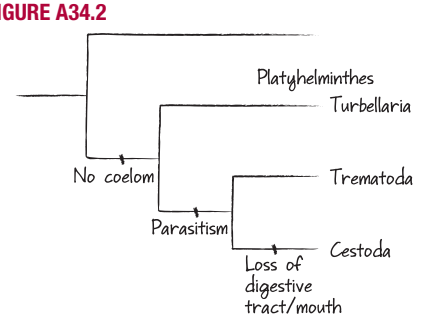

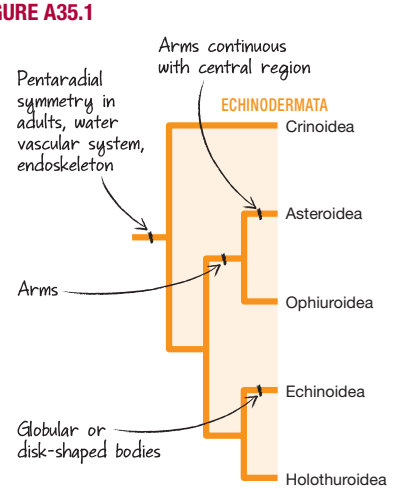

FIGURE A35.1

p. 690 Fig. 35.12 apply Mammals and birds are equally related to amphibians, because birds and mammals share a common ancestor, and this ancestor shares a common ancestor with amphibians.
p. 691 apply See **FIGURE A35.2**
p. 693 Fig. 35.16 analyze If this phylogeny were estimated on the basis of limb traits, it would be based on the *assumption* that the limb evolved from fish fins in a series of steps. But because the phylogeny was estimated from other types of data, it is legitimate to use it to analyze the evolution of the limb without making a circular argument.
p. 694 Fig. 35.18 analyze The yolk sac is smaller here—their function in an amniotic egg has been taken over by the placenta.
p. 695 CYU (1) understand Jaws allow animals to capture food efficiently and process it by crushing or tearing. The ability to process food more efficiently increased the importance of jawed vertebrates as herbivores and carnivores. The tetrapod limb enables vertebrates to locomote on land. The amniotic egg enables vertebrates to lay eggs on land; amniotic eggs are resistant to drying out. The placenta protects the growing fetus and enables the mother to be mobile. Parental care reduces the number of offspring that can be raised, but increases their survivorship. Flight enabled pterosaurs, bats, and birds to expand into new habitats. **(2)** analyze Protostomes and deuterostomes living on land both have mechanisms for preventing their eggs from drying out (e.g., thick membranes in snail and insect eggs; amniotic egg in tetrapods), preventing their skin from drying out (e.g., waxy cuticle in insects, scaly skin in reptiles), and keeping their respiratory surfaces from drying out (e.g., lungs in land snails and tracheal system in insects; lungs in tetrapods).
p. 696 apply See **FIGURE A35.3**.
p. 698a, **p. 698b**, **p. 699**, **p. 700** apply See **FIGURE A35.4**.
p. 701a, **p. 701b**, **p. 702a**, **p. 702b**, **p. 703a**, **p. 703b** apply See **FIGURE A35.3**.
p. 705 Table 35.1 analyze 44 percent, 26 percent; relative to body size, *H. floresiensis* has a smaller brain than *H. sapiens*.
p. 706 Fig. 35.37 apply Five hominin species existed 1.8 mya, and three existed 100,000 years ago.
p. 706 Fig. 35.38 analyze The forehead became much larger, and the face became "flatter"; the brow ridges are less prominent in later skulls than in earlier skulls.

IF YOU UNDERSTAND . . .

35.1 apply (1) Mussels and clams will increase dramatically; (2) kelp density will increase.
35.2 understand Your cartoon should have a dorsal hollow nerve chord along the top, dorsal edge; another line representing the notochord below the nerve cord; a tail labeled at one end; and a series of lines or bumps representing pharyngeal gill slits near the other end.
35.3 understand Like today's lungfish, the earliest tetrapods could have used their limbs for pulling themselves along the substrate in shallow-water habitats. **35.4** understand The earliest fossils of *H. sapiens* are found in Africa, and phylogenetic analyses of living human populations indicate that the most basal groups are all African.

YOU SHOULD BE ABLE TO . . .

✓ Test Your Knowledge

1. remember True **2.** remember a **3.** understand d **4.** remember mammals **5.** understand d **6.** remember b

✓ Test Your Understanding

1. understand c **2.** understand Pharyngeal gill slits function in suspension feeding. The notochord furnishes a simple endoskeleton that stiffens the body; electrical signals that coordinate movement are carried by the dorsal hollow nerve cord to the muscles in the post-anal tail, which beats back and forth to make swimming possible. Cephalochordates and Urochordates are chordates, but they are not vertebrates. **3.** analyze If jaws are derived forms of gill arches, then the same genes and the same cells should be involved in the development of the jaw and the gill arches. **4.** understand Increased parental care allows

FIGURE A35.2

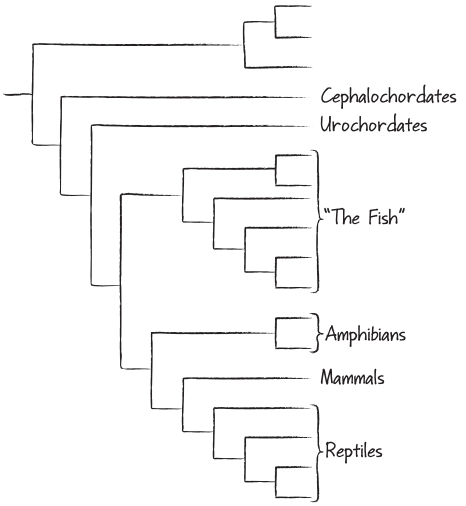

FIGURE A35.3

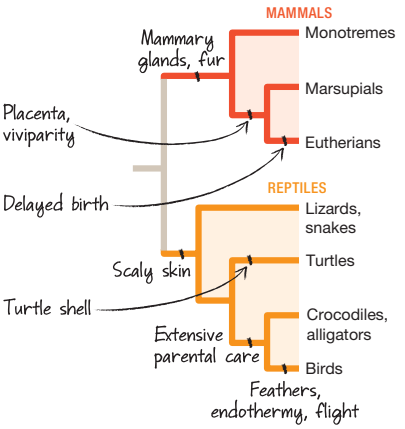

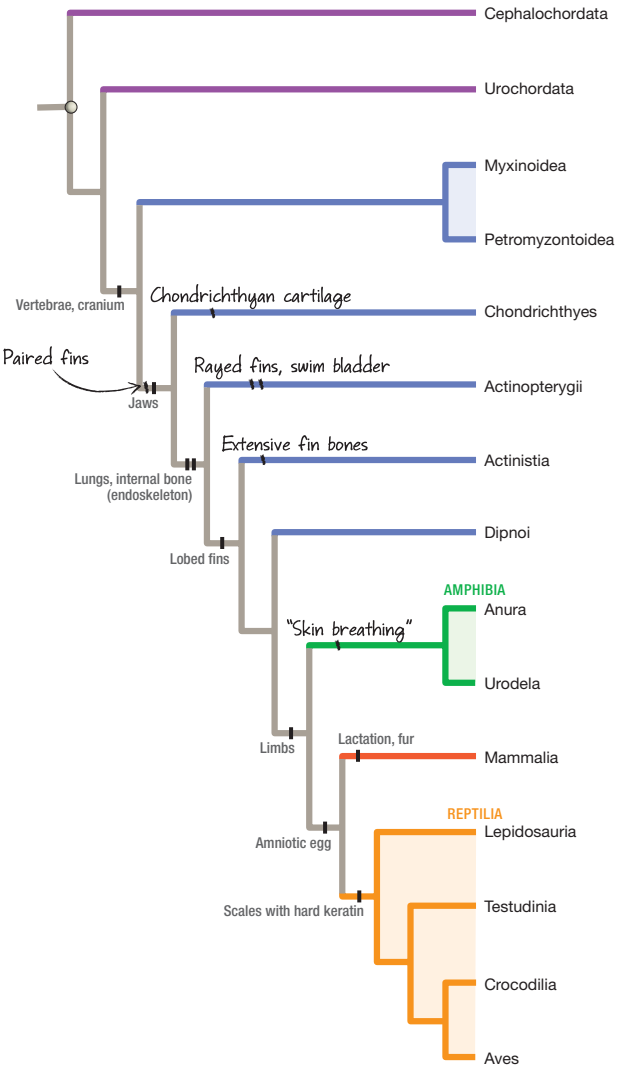

FIGURE A35.4

offspring to be better developed, and thus have increased chances of survival, before they have to live on their own. **5.** evaluate Yes: Over a short time interval, many species that occupy an array of foods and habitats evolved. Changes in tooth and jaw structure, tool use, and body size suggest that different hominin species exploited different types of food. **6.** evaluate A phylogeny of modern humans would reject the out-of-Africa hypothesis if the most ancestral lineages in the phylogeny were from any other region but Africa, such as Asia or Europe.

✔ Test Your Problem-Solving Skills

1. apply b **2.** evaluate Xenoturbellidans either retain traits that were present in the common ancestor of all deuterostomes, or they have lost many complex morphological characteristics. **3.** evaluate Vertebrate limbs are diverse in form and function (they can serve as arms, flippers, wings, etc.) but have homologous bones within. Molecular probes could be used to visualize the expression patterns of tool-kit genes like *Hox* in the embryonic limbs of different vertebrate species to show how changes in the expression of homologous genes can cause changes to the structure and function of limbs. **4.** analyze See **FIGURE A35.5**. It is important to use indigenous people for this study to minimize the amount of gene flow (transfer of alleles from one population to another) that occurred during the history of the study populations due to immigration and interbreeding.

CHAPTER 36

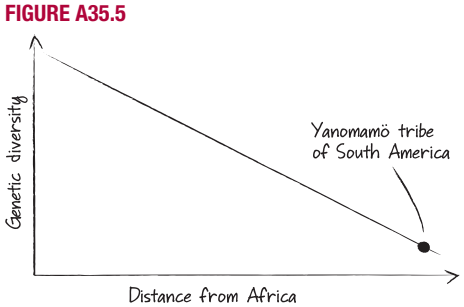
IN-TEXT QUESTIONS AND EXERCISES

p. 717 Fig. 36.7 apply Starting with 1 virion, approximately 80 virions were produced after 40 minutes. If all of these virions infected new cells, you expect each of the 80 infected cells to produce 80 virions by 90 minutes, or a total of 6400 virions. The cells appear to replicate once every 30 minutes, which means that they will have replicated 3 times during this period. The total number of cells at 90 minutes would be approximately 2^3, or 8 cells. There would be 800 times as many virions as cells.
p. 717 Fig. 36.8 analyze No—it only shows that CD4 is required. (Subsequent work showed that other proteins are involved as well.)
p. 721 analyze In T4, the viral genome is injected into the host while HIV inserts its genome via membrane fusion. HIV must first convert its genome into double-stranded DNA before replication, which is not necessary for T4, which has a DNA genome. Both viruses use double-stranded DNA to make mRNA that is translated into viral proteins. T4 virions are made in the cytosol of the cell and are released when the cell bursts. HIV virions bud from the cell surface, which does not require cell death.
p. 721 Fig. 36.12 create Budding may disrupt the integrity of the host-cell plasma membrane enough to kill the cell.
p. 722 CYU analyze Like cars in the assembly line of an automobile plant, new virions are assembled from premanufactured parts, and large numbers of progeny are produced per generation. Cells, on the other hand, reproduce by the division of a single integrated unit, resulting in only two progeny per generation.
p. 724 Fig. 36.15 apply You should have the following bars and labels: on branch to HIV-2 (sooty mangabey to human); on branch to HIV-1 strain O (chimp to human); on branch to HIV-1 strain N (chimp to human); on branch to HIV-1 strain M (chimp to human).
p. 725 CYU (1) analyze The escaped-genes and degenerate-cell hypotheses state that viruses originated from cells, while the RNA-world hypothesis suggests that viruses originated in parallel with, maybe even influenced, the origin of cells. The escaped-gene and RNA-world hypotheses state that the viruses originated from parasitic molecules. The degenerate-cell hypothesis states that viruses originated from parasitic organisms. **(2)** apply A mutation that made transmission between humans more efficient would make it more dangerous. Such mutation could occur via genomic reassortment in pigs, where an avian virus and a human virus could co-infect cells and produce recombinants.

IF YOU UNDERSTAND . . .

36.1 understand HIV infects helper T cells. These cells play a central role in the human immune response. As latently infected cells are activated by the immune response, HIV replication causes cell death. Over several years, steady decline in helper T cells leads to a compromised immune response that allows other infections to eventually kill the infected person. **36.2** understand (1) Fusion inhibitors block viral envelope proteins or host cell receptors. (2) Protease inhibitors prevent processing/assembly of viral proteins. (3) Reverse transcriptase inhibitors block reverse transcriptase, preventing replication of the genome. **36.3** apply There is heritable variation among virions, due to random changes that occur as their genomes are copied. There is also differential reproductive success among virions in their ability to successfully infect host cells. This differential success is due to the presence of certain heritable traits. **36.4** analyze Both classes have positive-sense single-stranded RNA genomes. Class IV viruses use an RNA replicase to make a negative-sense copy of the genome, which is then used as a template for producing mRNA and genomic RNAs. Class VI viruses use reverse transcriptase to convert their RNA genome into dsDNA, which is then integrated into the host genome. There it serves as a template to for transcribing viral mRNA and genomic RNAs by host-cell RNA polymerase.

YOU SHOULD BE ABLE TO . . .



✔ Test Your Knowledge

1. remember d **2.** remember b **3.** understand In class VI and VII viruses, reverse transcriptase converts positive-sense single-stranded RNA to double-stranded DNA.
4. remember b **5.** remember c **6.** remember The unique type of genetic material included in the virion (classes I–V) in addition to the manner in which the genome is replicated (compare classes VI and VII with classes IV and I, respectively).

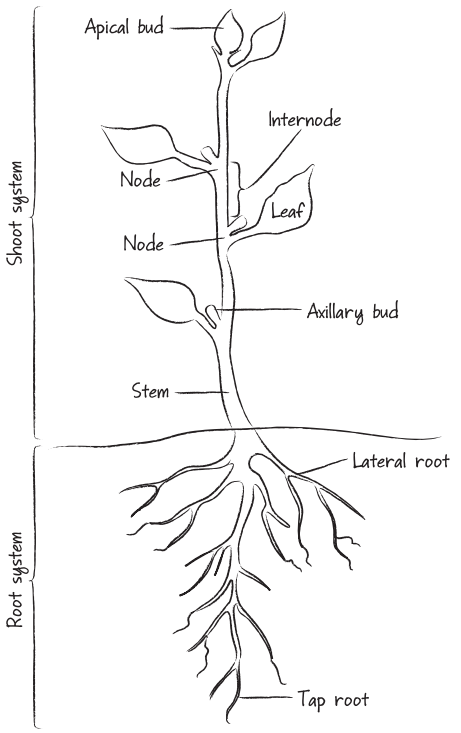
✔ Test Your Understanding

7. analyze A virus with an envelope exits host cells by budding. A virus that lacks an envelope exits host cells by lysis (or other mechanisms that don't involve budding). **8.** analyze (1) Rate of viral genome replication is much higher via the lytic cycle. In lysogeny, the viral genome can replicate only when the host cell replicates. (2) Only the lytic cycle produces virions. (3) The lytic cycle results in host cell death, while the host cell continues to survive during lysogeny. **9.** create Viruses rely on host-cell enzymes to replicate, whereas bacteria do not. Therefore, many drugs designed to disrupt the virus life cycle cannot be used, because they would kill host cells as well. Only viral-specific proteins are good targets for drug design. **10.** evaluate Each major hypothesis to explain the origin of viruses is associated with a different type of genome. Escaped genes: single- and double-stranded DNA or possibly single-stranded RNA. Degenerate cells: double-stranded DNA. RNA world: single- or double-stranded RNA. **11.** understand The phylogenies of SIVs and HIVs show that the two shared common ancestors, but that SIVs are ancestral to the HIVs. Also, there are plausible mechanisms for SIVs to be transmitted to humans through butchering or contact with pets, but fewer or no plausible mechanisms for HIVs to be transmitted to monkeys or chimps. **12.** apply a; the single-stranded positive-sense RNA genome of this virus can serve as an mRNA to produce viral proteins, while all of the other possibilities require viral enzymes to transcribe the genome into mRNA.

FIGURE A35.5

✔ Test Your Problem-Solving Skills

13. create Culture the *Staphylococcus* strain outside the human host and then add the virus to determine whether the virus kills the bacterium efficiently. Then test the virus on cultured human cells to determine whether the virus harms human cells. Then test the virus on monkeys or other animals to determine if it is safe. Finally, you could test the virus on human volunteers.
14. evaluate Prevention is currently the most cost-effective program, but it does not help people who are already infected. Treatment with effective drugs not only prolongs lives but also reduces virus loads in infected people, so that they have less chance of infecting others. **15.** apply b; by prolonging the infection in this manner, these viruses are more likely to be transmitted to a new host.
16. evaluate Viruses cannot be considered to be alive by the definition given in (1), because viruses are not capable of replicating by themselves. By the definition given in (2), it can be argued that viruses are alive because they store, maintain, replicate, and use genetic information—although they cannot perform all these tasks on their own.



CHAPTER 37

IN-TEXT QUESTIONS AND EXERCISES

p. 732 Fig. 37.1 apply New branches and leaves should develop to the right (the plant will also lean that way); new lateral roots will develop to the left.
p. 734 Fig. 37.3 analyze Lawn grasses are shallow rooted, so when the top part of soil dries out, the plants cannot grow.
p. 735 Table 37.1 understand For aerobic respiration, which generates ATP needed to keep cells alive.
p. 736 Fig. 37.5 evaluate The individuals are genetically identical—thus, any differences in size or shape in the different habitats are due to phenotypic plasticity and not genetic differences.
p. 738 Fig. 37.6 analyze Large surface area provides more area to capture photons, but also more area from which to lose water and be exposed to potentially damaging tearing forces from wind.

p. 739 CYU (1) remember See **FIGURE A37.1** **(2)** understand The generalized body of a plant has a taproot with many lateral roots and broad leaves. Examples of deviations from this generalized body structure follow. Modified roots: Unlike taproots, *fibrous roots* do not have one central root, and *adventitious roots* arise from stems. Modified stems: *Stolons* grow along the soil and grow roots and leaves at each node, and *rhizomes* grow horizontally underground. Both of these modified stems function in asexual reproduction. Modified leaves: The *needle-shaped leaves* of cacti don't lose water to transpiration compared with typical broad leaves, and they protect the plant from herbivory. *Tendrils* on climbing plants are modified leaves that do not photosynthesize, but wrap around trees or other substrates to facilitate climbing.
p. 745 Fig. 37.16 evaluate Many possible answers; for example, in leaf cells, genes encoding proteins involved in photosynthesis would be expressed. These genes wouldn't be expressed in the root cells.
p. 747 CYU (1) understand The apical meristem gives rise to the three primary meristems. The apical meristem is a single mass of cells localized at the tip of a root or shoot; the primary meristems are localized in distinctive locations behind the apical meristem. **(2)** understand Epidermal cells are flattened and lack chloroplasts; they secrete the cuticle (in shoots) or extend water and nutrient-absorbing root hairs (in roots) and protect the plant. Parenchyma cells are "metabolic workhorse cells" found throughout the plant body; they perform photosynthesis and synthesize, store, and/or transport materials. Tracheids are long, slim cells with pits in their secondary cell walls; they are found in xylem and are dead when mature, and they conduct water and solutes up the plant. Sieve-tube elements are long, thin cells found in phloem; they are alive when mature and conduct sugars and other solutes up and down the plant.
p. 750 understand Secondary growth adds cells only to the inside and outside of the vascular cambium, so the nail remains the same distance above the ground as the tree grows.

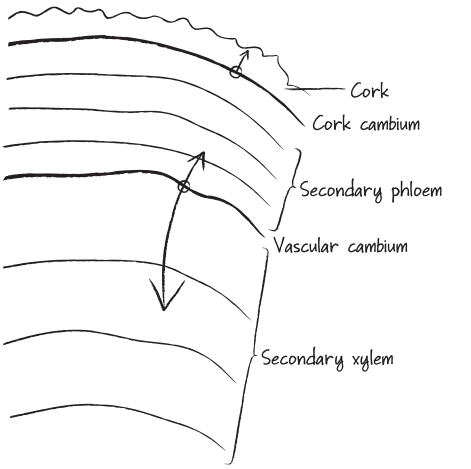
FIGURE A37.1

p. 750 Fig. 37.24 remember You should have labeled a light band as early wood, and the dark band to its right as late wood; both bands together comprise one growth ring.
p. 751 CYU (1) apply The rings are small on the shaded side and large on the sunny side. **(2)** remember See **FIGURE A37.2**.

IF YOU UNDERSTAND . . .

37.1 analyze Phenotypic plasticity is more important in (1) environments where conditions vary because it gives individuals the ability to change the growth pattern of their roots, shoots, and stems to access sunlight, water, and other nutrients as the environment changes; and (2) in long-lived species because it gives individuals a mechanism to change their growth pattern as the environment changes throughout their lifetime.
37.2 analyze The zone of cellular maturation is where root hairs emerge. Root hairs are the site where most of the water and ions are absorbed in the root system. **37.3** apply (1) In both cases, the structure would stop growing; (2) the shoot would lack epidermal cells and would die.
37.4 apply (1) The plant would not produce secondary xylem and phloem, so its girth and transport ability would be reduced, though it would still produce bark. (2) The trunk would have much wider tree rings on one side than the other side.

YOU SHOULD BE ABLE TO . . .



✔ Test Your Knowledge

1. remember b **2.** understand a **3.** remember c **4.** remember a **5.** remember Cactus spines are modified leaves; thorns are modified stems. **6.** analyze Collenchyma and sclerenchyma cells both have thickened cell walls and function in providing structural support. Unlike collenchyma cells, sclerenchyma cells have lignified cell walls and are dead at maturity.

✔ Test Your Understanding

7. remember b **8.** evaluate The general function of both systems is to acquire resources: The shoot system captures light and carbon dioxide; the root system absorbs water and nutrients. Vascular tissue is continuous throughout both the shoot and root systems. Diversity in roots and shoots enables plants of different species to live together in the same environment without directly competing for resources. **9.** analyze Continuous growth enhances phenotypic plasticity because it allows plants to grow and respond to changes or challenges in their environment (such as changes in light and water availability). **10.** apply Cuticle reduces water loss; stomata facilitate gas exchange. Plants from wet habitats should have a relatively large number of stomata and thin cuticle. Plants living in dry habitats should have relatively few stomata and thick cuticle. **11.** analyze Parenchyma cells in the ground tissue perform photosynthesis and/or synthesize and store materials. In vascular tissue, parenchyma cells in rays conduct water and solutes across the stem; other parenchyma cells differentiate into the sieve-tube elements and companion cells in phloem. **12.** understand Cells produced to the inside of the vascular cambium differentiate into secondary xylem; cells produced to the outside of the vascular cambium differentiate into secondary phloem.

FIGURE A37.2

✔ Test Your Problem-Solving Skills

13. apply c **14.** remember Asparagus—stem; Brussels sprouts—lateral buds; celery—petiole; spinach—leaf (petiole and blade); carrots—taproot; potato—modified stem. **15.** create They grow continuously, so do not have alternating groups of large and small cells that form rings. **16.** analyze Girdling disrupts transport of solutes in secondary phloem. The tree's root system starves.

CHAPTER 38

IN-TEXT QUESTIONS AND EXERCISES

p. 756 apply (1) Add a solute (e.g., salt or sugar) to the left side of the U-tube, so that solute concentration is higher than on the right side. (2) Water would move from the right side of the U-tube into the left side.
p. 757 apply Pull the plunger up.
p. 757 Fig. 38.2 apply It increases (becomes less negative), which reduces the solute potential gradient between the two sides.
p. 758 CYU (1) apply When a cell is in equilibrium with pure water, the negative solute potential of the cell will be balanced by the positive pressure potential (turgor pressure). **(2)** analyze Irrigation water contains low concentrations of salts so the solute potential will be near zero. As water evaporates, salts remain in the soil, lowering the solute potential.
p. 760 Fig. 38.7 understand See **FIGURE A38.1**.
p. 761 apply The individual would not be able to exclude toxic solutes from the xylem. If these solutes were transported throughout the plant in high enough concentrations, they could damage tissues. The mutant could also not maintain ions in the xylem and so could not generate root pressure.
p. 764 Fig. 38.12 analyze The line on the graph would go up, and large jumps would occur each time the light level was turned up, because increased transpiration rates would increase negative pressure (tension) at the leaf surface and thus increase the water-potential gradient.
p. 765 CYU (1) understand At the air–water interface under a stoma, water molecules cannot hydrogen-bond in all directions—they can bond only with water molecules below them. This creates tension at the surface. When transpiration occurs, the curvature of the meniscus increases—increasing tension. **(2)** apply When a nearby stoma closes, the humidity inside the air space increases, transpiration decreases, and surface tension on menisci decreases. The same changes occur when a rain shower starts. When air outside the leaf dries, though, the opposite occurs: The humidity inside the air space decreases, transpiration increases, and surface tension on menisci increases.
p. 768 Fig. 38.17 understand See **FIGURE A38.2**.
p. 771 CYU (1) understand In early spring, growing leaves are sinks and phloem sap moves toward them. In midsummer, leaves are sources and phlo em sap moves away from them. **(2)** create The movement of water and solutes in sieve elements is by bulk flow, so stationary organelles would provide resistance to the flow.
p. 771 Fig. 38.22 create With time the plant will metabolize the radioactive sucrose, and levels of radioactivity will decline.

IF YOU UNDERSTAND . . .

38.1 analyze Because xylem cells are dead at maturity, there are no plasma membranes for water to cross and thus no solute potential. The only significant force acting on water in xylem is pressure. **38.2** evaluate It drops, because transpiration rates from stomata decrease, reducing the water potential gradient between roots and leaves. **38.3** understand CAM plants open their stomata only at night, and thus they transpire when temperatures are cooler. **38.4** analyze To create high pressure in phloem near sources and low pressure near sinks, water has to move from xylem to phloem near sources and from phloem back to xylem near sinks. If xylem were not close to phloem, this water movement could not occur, and the pressure gradient in phloem wouldn't exist.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. understand d **2.** apply b **3.** understand a **4.** remember c **5.** remember Endodermal cells. **6.** remember Companion cells.

✔ Test Your Understanding

7. understand c **8.** apply See **FIGURE A38.3**. **9.** analyze The force responsible for root pressure is the high solute potential of root cells at night, when they continue to accumulate ions from soil and water follows by osmosis. The mechanism is active, in the sense that ions are imported against their concentration gradient. Capillarity is driven by adhesion of water molecules to the sides of xylem cells that creates a pull upward, and by cohesion with water molecules below. Cohesion-tension, generated by transpiration, is driven by the loss of water molecules from menisci in leaves, which creates a large negative pressure (tension). Both capillarity and cohesion-tension are passive processes. **10.** understand Water moves up xylem because of transpiration-induced tension created at the air–water interface under stomata, which is communicated down to the roots by the cohesion of water molecules. Sap flows in phloem because of a pressure gradient that exists between source and sink cells, driven by differences in sucrose concentration and flows of water into or out of nearby xylem. **11.** understand By pumping protons out, companion cells create a strong electrochemical gradient favoring entry of protons. A cotransport protein (a symporter) uses this proton gradient to import sucrose molecules *against* their concentration gradient. **12.** apply When it germinates—sucrose stored inside the seed is released to the growing embryo, which cannot yet make enough sucrose to feed itself.

✔ Test Your Problem-Solving Skills

13. apply b **14.** create Plants would not grow as quickly or as tall, because the taller they grew, the more energy they would need to use to transport water and thus the less they would have available for growth. **15.** analyze Because they cannot readily replace water that is lost to transpiration, they have to close stomata. During a heat wave, transpiration cannot cool the plants' tissues. The trees bake to death. **16.** create Closing aquaporins will slow or stop movement of water from cells into the xylem and out of the plant via transpiration. Because water does not leave the cells, they are able to maintain turgor (normal solute potentials).

CHAPTER 39

IN-TEXT QUESTIONS AND EXERCISES

p. 776 Fig. 39.1 evaluate To test the hypothesis that most of a plant's mass comes from CO_2 in the atmosphere, design an experiment where plants are grown in the presence or absence of CO_2 and compare growth, and/or grow plants in the presence of labeled CO_2 and document the presence of labeled carbon in plant tissues.
p. 777 Fig. 39.3 evaluate Because soil is so complex, it would be difficult to defend the assumption that the soils with and without added copper are identical except for the difference in copper concentrations. Also, it would be better to compare treatments that had no copper versus normal amounts of copper, instead of comparing with and without added copper.
p. 783 Fig. 39.10 analyze The proton gradient arrow in (b) should begin above the membrane and cross the

FIGURE A38.1

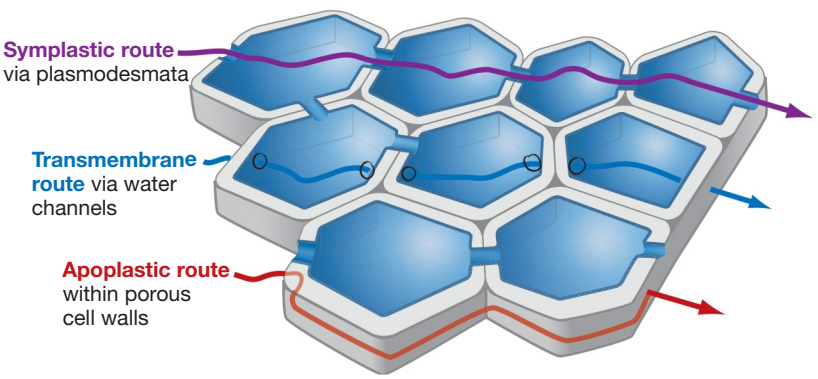


FIGURE A38.2

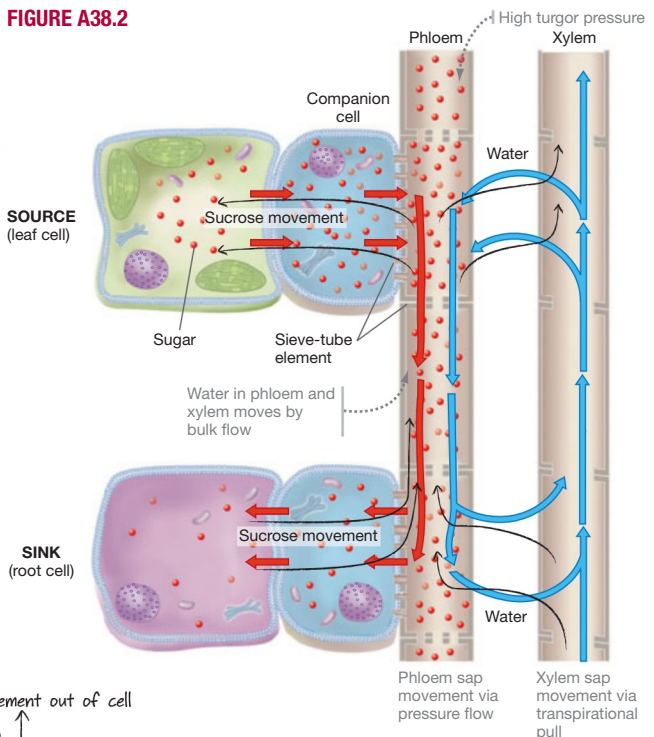

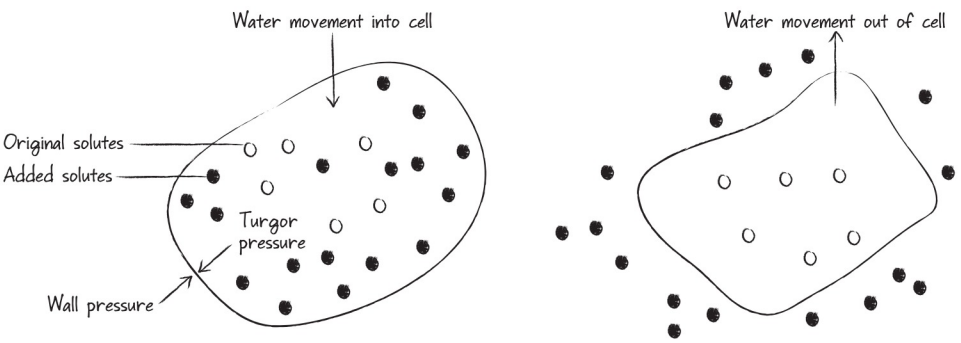

FIGURE A38.3

membrane pointing down. The electrical gradient arrow in (c) should also begin above the membrane (marked positive) and cross the membrane pointing down (toward negative).

p. 784a apply (1) If there is no voltage across the root-hair membrane, there is no electrical gradient favoring entry of cations, and absorption stops. (2) There is no route for cations to cross the root hair membrane, so absorption stops.

p. 784b apply (1) If there is no proton gradient across the root-hair membrane, there is no gradient favoring entry of protons, so symport of anions stops. (2) There is no route for anions to cross the root-hair membrane, so absorption stops.

p. 786 CYU (1) understand Proton pumps establish an electrical gradient across root-hair membranes, and the inside of the membrane is much more negative than the outside. Cations follow this electrical gradient into the cell. Anions are transported with protons via symporters. **(2)** create See **FIGURE A39.1**.

p. 788 CYU (1) analyze Many possible answers, including the following: If N-containing ions are abundant in the soil, the energetic cost of maintaining nitrogen-fixing bacteria may outweigh the benefits in terms of increased nitrogen availability. If mycorrhizal fungi provide a plant with nitrogen-containing ions, the energetic cost of maintaining nitrogen-fixing bacteria may outweigh the benefits in terms of increased nitrogen availability. Plants that grow near species with N-fixing bacteria might gain nitrogen by absorbing nitrogen-containing ions after root nodules die, or by "stealing it" (roots of different species will often grow together). There could be a genetic constraint (see Chapter 25): Plant species may simply lack the alleles required to manage the relationship. Note: To be considered correct, your hypothesis should be plausible (based on the underlying biology) and testable. **(2)** analyze Many possible answers, including: Because the bacterial cell enters root cells, it is important for the plant to have reliable signals that it is not a parasitic bacterium. It is advantageous for the plant to be able to reject nitrogen-fixing bacteria if usable nitrogen is already abundant in the soil.

p. 790 Fig. 39.17 analyze Mistletoe is parasitic (it extracts water and certain nutrients from host trees); bromeliads are not (they are epiphytes and don't affect the fitness of their host plants).

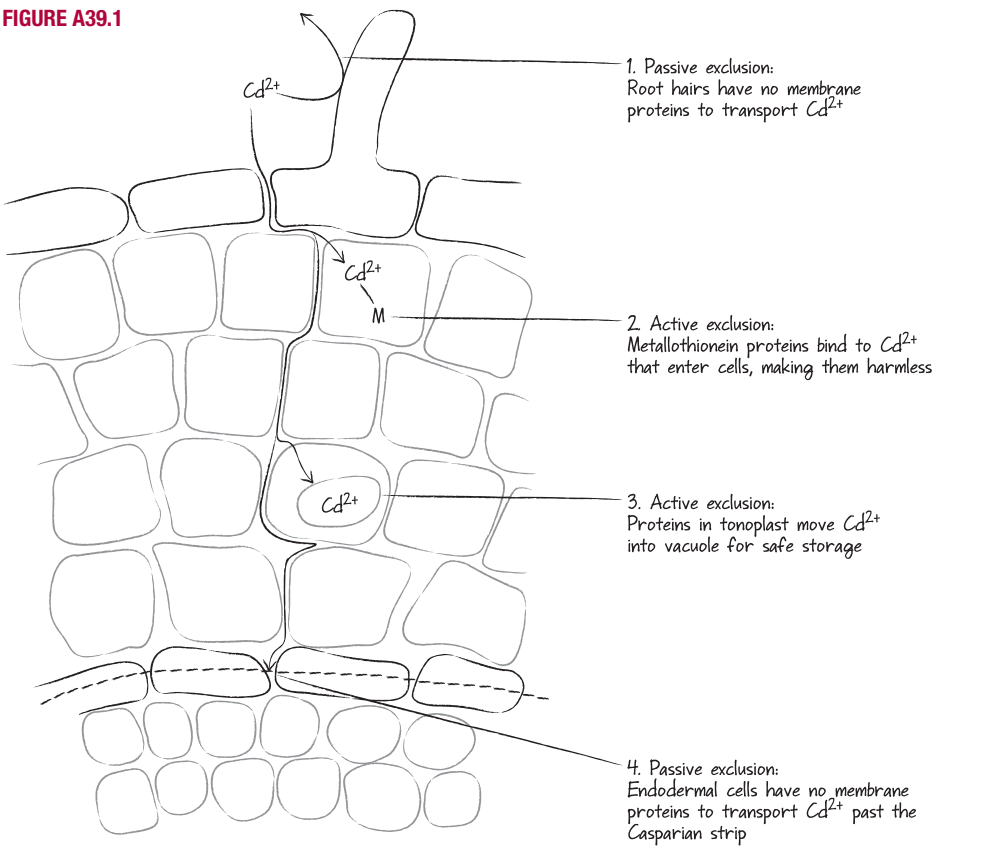
IF YOU UNDERSTAND . . .

39.1 evaluate Add nitrogen to an experimental plot and compare growth within the plot to growth of a similar plot nearby. Do many replicates of the comparison, to convince yourself and others that the results are not due to unusual circumstances in one or a few plots. **39.2** understand Loam is a mixture of sand, clay, and organic matter so it can retain water and nutrients, and provide aeration, all properties that benefit plants. **39.3** apply A higher membrane voltage would allow cations in soil to cross root-hair membranes more readily through membrane channels and would allow anions to enter more readily via symporters. Nutrient absorption should increase. **39.4** evaluate Grow pea plants in the presence of rhizobia, exposed to air with (1) N_2 containing the heavy isotope of nitrogen and (2) radioactive carbon dioxide. Allow the plant to grow and then analyze the rhizobia and plant tissues. If the rhizobia–pea plant interaction is mutualistic, then ^{15}N-containing compounds and radioactive-carbon-containing compounds should be observed in both rhizobia and plant tissues. As a control, grow pea plants in the presence of the labeled compounds but without rhizobia. If the mutualism hypothesis is correct, the plant should contain labeled carbon but no heavy nitrogen. **39.5** analyze Despite the abundance of rain in tropical rain forests, many epiphytes there have limited access to water because their roots don't reach the soil. Like desert plants, these epiphytes are adapted to conserve water.

YOU SHOULD BE able TO . . .

✔ Test Your Knowledge

1. remember b **2.** understand d **3.** remember d **4.** understand c **5.** remember Mycorrhizal fungi obtain most of their nitrogen from proteins in soil organic matter. Rhizobia obtain nitrogen from N_2 gas. **6.** remember Plant



✔ Test Your Understanding

7. remember b **8.** evaluate (1) Grow a large sample of corn plants with a solution containing all essential nutrients needed for normal growth and reproduction. Grow another set of genetically identical (or similar) corn plants in a solution containing all essential nutrients except iron. Compare growth, color, and seed production (and/or other attributes) in the two treatments. (2) Grow corn plants in solutions containing all essential nutrients in normal amounts, but with varying concentrations of iron. Determine the lowest iron concentration at which plants exhibit normal growth rates. **9.** understand If nutrients in soil are scarce, there is intense natural selection favoring alternative ways of obtaining nutrients—for example, by digesting insects or stealing nutrients. **10.** apply Higher in soils with both sand and clay. Clay fills spaces between sand grains and slows (1) passage of water through soil and away from roots, and (2) leaching of anions in soil water. Clay particles also provide negative charges that retain cations so they are available to plants. The presence of sand keeps soil loose enough to allow roots to penetrate. **11.** understand Some metal ions are poisonous to plants, and high levels of other ions are toxic. Passive mechanisms of ion exclusion—such as a lack of ion channels that allow passage into root cells—do not require an expenditure of ATP. Active mechanisms of exclusion—such as production of metallothioneins—require an expenditure of ATP. **12.** analyze (1) The amounts required and the mechanisms of absorption are different. Much larger amounts of C, H, and O are needed than mineral nutrients. CO_2 enters plants via stomata, and water is absorbed passively along a water potential gradient; mineral nutrients enter via active uptake in root hairs or via mycorrhizae. (2) Macronutrients are required in relatively large quantities and usually function as components of macromolecules; micronutrients are required in relatively small quantities and usually function as enzyme cofactors.

✔ Test Your Problem-Solving Skills

13. apply The soil lost 60 g while the tree gained 74,000 g. Dividing 60 by 74,000 and converting to a percentage equals 0.08%, far less than 4%. The water that van Helmont used may have contained many of the macro- and micronutrients that were incorporated into plant mass. To test this hypothesis, conduct an experiment of the same design but have one treatment with pure water and one treatment with water containing solutes ("hard water"). Compare the percentage of soil mass incorporated into the willow tree in both treatments. Another explanation: Willow may be unusual. To test this hypothesis, repeat the experiment with willow and several other species under identical conditions, and compare the percentage of soil mass incorporated into the plants. A third hypothesis: Van Helmont's measurements were inaccurate. Repeat the experiment. **14.** analyze Acid rain inundates the soil with protons, which bind with the negatively charged clay particles—displacing the cations that are normally bound there. Cations may then be leached away. **15.** evaluate If the hypothesis is correct, vanadate should inhibit phosphorus uptake. To test this hypothesis, grow plants in solution with radioactively labeled phosphorus without vanadate and in solution with vanadate. Measure the amount of labeled phosphorus in root cells with and without vanadate. **16.** apply Alder should decompose much faster, because it provides more nitrogen to the fungi and bacteria that are responsible for decomposition—meaning that they can grow faster.

FIGURE A39.1

CHAPTER 40

IN-TEXT QUESTIONS AND EXERCISES

p. 796 CYU (1) understand The only cells that can respond to a specific environmental signal or hormone are cells that have an appropriate receptor for that signal or hormone. **(2)** remember Once a receptor is activated, it triggers production of many second messengers or the activation of many proteins in a phosphorylation cascade.
p. 797 Fig. 40.4 evaluate Wild-type plants already have a normal *PHOT1* gene and can respond to directional blue light. Inserting a defective gene into a wild-type plant would have no effect.
p. 798 Fig. 40.5 evaluate For "Tip removed": Cut the tip and replace it, to control for the hypothesis that the wound itself influences bending (not the loss of the tip). For "Tip covered": Cover the tip with a transparent cover instead of opaque one, to control for the hypothesis that the cover itself affects bending (not excluding light).
p. 799 CYU (1) apply Using a syringe or other device, apply auxin to the west side of each stem, just below the tip. **(2)** apply Stems would become very long and would not respond to directional light.
p. 801 Table 40.1 analyze The average germination rate of lettuce seeds last exposed to red light is about 99 percent. The average for seeds last exposed to far-red light is about 50 percent. Both of these values are much higher than the germination rate of buried seeds that receive no light at all; their germination rate is only 9 percent.
p. 803 CYU (1) understand Lettuce grows best in full sunlight. If a seed receives red light, it indicates that the seed is in full sunlight—meaning that conditions for growth are good. But if a seed receives far-red light, it indicates that the seed is in shade—meaning that conditions for growth are poor. **(2)** understand Night length changes very predictably throughout the year, so it is a reliable signal for plants to perceive.
p. 803 Fig. 40.10 apply An appropriate control treatment would be to graft a leaf from a plant that had never been exposed to a short-night photoperiod onto a new plant that also had never been exposed to the correct conditions for flowering. If the hypothesis is correct, the grafted leaf should not induce flowering.
p. 804 Fig. 40.12 evaluate (One possibility) Direct pressure from a statolith changes the shape of the receptor protein. The shape change triggers a signal transduction cascade, leading to a gravitropic cell response.
p. 805 CYU (1) analyze In both roots and shoots, auxin is redistributed asymmetrically in response to a signal. In phototropism, auxin is redistributed to the shaded side of the shoot tip in response to blue light. In gravitropism, auxin is redistributed to the lower part of the root or shoot in response to gravity. **(2)** understand In root cells, auxin concentrations indicate the direction of gravity. The gravitropic response is triggered by changes in the distribution of auxin in root-tip cells.
p. 809 Fig. 40.19 analyze The dwarfed individuals can put more of their available energy into reproduction because they are using less energy for growth than taller individuals.
p. 810 Fig. 40.21 analyze Without these data, a critic could argue that the stomata closed in response to water potentials in the leaf, not a signal from the roots.
p. 813 CYU (1) analyze ABA: Stomata should close and photosynthesis should stop compared to individuals that do not receive extra ABA. GA: Their stems should elongate rapidly, compared to plants that do not receive extra GA. **(2)** understand The rotten apple produces ethylene, which, being a gas, stimulates all of the other apples in the bushel basket to ripen too fast.
p. 816 analyze Sacrificing a small number of cells due to the hypersensitive response is far less costly for the plant than death.
p. 819 CYU (1) analyze Because specific receptor proteins recognize and match specific proteins produced by pathogens, having a wide array of these proteins allows individuals to recognize and respond to a wide array of pathogens. **(2)** understand If herbivores are not present, synthesizing large quantities of proteinase inhibitors wastes resources (ATP and substrates) that could be used for growth and reproduction.

IF YOU UNDERSTAND . . .

40.1 analyze An external signal arrives at a receptor cell/protein (a person sees a barn on fire); the person calls (the receptor transduces the signal); the dispatcher rings a siren (a second messenger is produced or phosphorylation cascade occurs); the fire department members get to the pumper truck (gene expression or some other cell activity changes). **40.2** apply Sun-adapted (high-light) plants are likely to have a significant positive phototropic response (i.e., growth toward light), whereas shade-adapted (low-light) plants are less likely to respond phototropically. **40.3** evaluate They do not perform photosynthesis and therefore do not need to switch behavior based on being located in full sunlight versus shade. **40.4** understand Starch is denser than water, so it falls quickly to the bottom of cells. **40.5** understand A reduction in plant height in a windy environment might keep them upright. **40.6** evaluate Those hormones need to be transported throughout the plant, because cells throughout the body need to respond to the signal—not in a single direction. **40.7** understand In the hypersensitive response, a few cells are sacrificed to prevent a pathogen from spreading throughout the plant.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. remember d **2.** remember b **3.** remember d **4.** understand b **5.** remember hypersensitive response **6.** remember plasma membrane

✔ Test Your Understanding

7. remember a **8.**. remember The P_{fr}–P_r switch in phytochromes lets plants know whether they are in shade or sunlight, and triggers responses that allow sun-adapted plants to avoid shade. Phototropins are activated by blue light, which indicates full sunlight, and trigger responses that allow plants to photosynthesize at full capacity. **9.** analyze Transduce means to convert energy from one form to another. There are many examples: A touch may be converted to an electrochemical potential, light energy or pressure into a shape change in a protein, and so on. **10.** understand (Many possibilities) Cells or tissue involved: Auxin directs gravitropism in roots but phototropism in shoots. Developmental stage or age: GA breaks dormancy in seeds but extends stems in older individuals. Concentration: Large concentrations of auxin in stems promote cell elongation; small concentrations do not. Other hormones: The concentration of GA relative to ABA influences whether germination proceeds. **11.** apply Ethylene promotes senescence; increased ethylene sensitivity in leaves (combined with reduced auxin concentrations) causes abscission; fruits exposed to ethylene ripen faster than fruits that are not exposed to ethylene. Produce dealers can maximize profits by delaying ripening during transit of fruit by removing ethylene and then adding ethylene just before fruits are displayed. **12.** apply When one leaf on the mutant plant is chewed on by a herbivore, the damaged leaf would not be able to signal to the rest of the plant, so it would not be able to fend off future herbivore attacks.

✔ Test Your Problem-Solving Skills

13. apply a **14.** evaluate Small-seeded plants need to perform photosynthesis early in seedling development or they will starve. Therefore, they need to germinate in direct sunlight. The food reserves in large-seeded plants can support seedling growth for a relatively long time without photosynthesis. Therefore, they do not need to germinate in direct sunlight. **15.** evaluate In these seeds, (a) little or no ABA is present, or (b) ABA is easily leached from the seeds, so its inhibitory effects are eliminated. Test hypothesis (a) by determining whether ABA is present in the seeds. Test hypothesis (b) by comparing the amount of ABA present before and after running water—enough to mimic the amount of rain that falls in a tropical rain forest over a few days or weeks—over the seeds. **16.** apply New types of plant resistance provide a selective pressure for pathogens to evolve new mechanisms to evade the resistance.

CHAPTER 41

IN-TEXT QUESTIONS AND EXERCISES

p. 825 understand (1) The microsporocyte divides by meiosis to generate male spores; the megasporocyte divides by meiosis to generate female spores. (2) In angiosperms, the female gametophyte stays within the ovary at the base of the flower even after it matures and produces an egg cell. Fertilization and seed development take place in the same location.
p. 829 CYU (1) analyze Both are diploid cells that divide by meiosis to produce spores. The megasporocyte produces a megaspore (female spore); a microsporocyte produces a microspore (male spore). **(2)** analyze Both are multicellular individuals that produce gametes by mitosis. The female gametophyte is larger than the male gametophyte and produces an egg; the male gametophyte produces sperm.
p. 829 Fig. 41.8 understand A gametophyte is the multicellular individual that produces gametes by mitosis. The pollen grain is a gametophyte because it is multicellular and produces sperm by mitosis.
p. 832 CYU (1) understand Insects feed on nectar and/or pollen in flowers. Flowers provide food rewards to insects to encourage visitation. The individuals that attract the most pollinators produce the most offspring. **(2)** understand One product of double fertilization is the diploid zygote, which will eventually grow by mitosis into a mature sporophyte. The other product is the triploid endosperm nucleus, which will grow by mitosis to form a source of nutrients for the embryo.
p. 833 remember The endosperm nucleus in the central cell is triploid; the zygote is diploid; the synergid and other cells remaining from the female gametophyte are haploid.
p. 834 analyze A cotyledon and a radicle develop into organs with distinct functions, but both are composed of the same tissues: Epidermis is derived from protoderm, ground tissue is derived from ground meristem, and vascular tissue is derived from the procambium.
p. 835 Fig. 41.14 evaluate Hypothesis: Fruit changes color when it ripens as a signal to fruit eaters. The color change is advantageous because seeds are not mature in unripe fruit and are unlikely to survive. Fruit eaters disperse mature seeds in ripe fruit, which are more likely to survive.
p. 836 Fig. 41.16 evaluate Hackberries served as a control to demonstrate that animals that avoided chilies were hungry,
p. 837 Fig. 41.17 understand Beans—their cotyledons are aboveground.

IF YOU UNDERSTAND . . .

41.1 remember The sporophyte is diploid, the gametophyte is haploid, spores and gametes are haploid, and zygotes are diploid. **41.2** apply There would be four embryo sacs in each ovule, and thus four eggs. **41.3** apply Endosperm tissue is generated when two haploid, female nuclei fuse with one haploid sperm nucleus, forming a cell with three sets of chromosomes. In contrast, a zygote is formed by the fusion of one haploid sperm nucleus and one haploid egg, forming a cell with two sets of

chromosomes. **41.4** analyze A cold requirement for germination ensures that seeds from plants native to habitats that experience cold winters will not germinate in the fall and fail to become established before winter.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. remember b **2.** understand c **3.** remember a **4.** understand d
5. remember Megasporocytes (female) and microsporocytes (male) undergo meiosis to generate megaspores and microspores, respectively. These divide mitotically to give rise to female and male gametophytes—the embryo sac and pollen grain, respectively. **6.** remember Pollination is the transfer of pollen from an anther to a stigma. Fertilization is the fusion of haploid gametes.

✔ Test Your Understanding

7. understand c **8.** analyze Asexual reproduction is a quick, efficient way for a plant to produce large numbers of offspring. The disadvantage is that offspring are genetically identical to the parent and thus are vulnerable to the same diseases and able to thrive only in habitats similar to those inhabited by the parent. **9.** analyze Sepals are the outermost structures in a flower and usually protect the structures within; petals are located just inside the sepals and usually function to advertise the flower to pollinators. In wind- and bee-pollinated flowers, sepals probably do not vary much in overall function or general structure. Petals are often lacking in wind-pollinated species; they tend to be broad and flat (to provide a landing site) and colored purple, blue, or yellow in bee-pollinated species (often with ultraviolet markings).
10. analyze Outcrossing increases genetic diversity among offspring, making them more likely to thrive if environmental conditions change from the parental generation. However, outcrossing requires cross-pollination to be successful. Self-fertilization results in relatively low genetic diversity among offspring but ensures that pollination succeeds. **11.** remember The female gametophyte develops inside the ovule; the ovary develops into the pericarp of the fruit after fertilization. A mature ovule contains both gametophyte and sporophyte tissue; the ovary and carpel are all sporophyte tissue. **12.** analyze The endosperm of a corn seed and the cotyledons of a bean seed both contain nutrients needed for the seed to germinate. The bean cotyledons have absorbed the nutrients of the endosperm.

✔ Test Your Problem-Solving Skills

13. remember c **14.** apply Subtracting the number of used pollen grains per plant (600) from the number of pollen grains generated per plant (10 million) divided by 10 million reveals that 99.994% of the pollen is wasted.
15. evaluate In response to "cheater" plants, insects should be under intense selection pressure to detect and avoid species that do not offer a food reward. Individuals would have to be able to distinguish scents, colors, or other traits that identify cheaters. In response to cheater insects, plants possessing unusually thick or toxic petals or sepals that prevented insects from bypassing the anthers on their way to the nectaries would be more successful at producing seed in the next generation.
16. evaluate Acorns have a large, edible mass and are usually animal dispersed (e.g., by squirrels that store them and forget some). Cherries have an edible fruit and are animal dispersed. Burrs stick to animals and are dispersed as the animals move around. Dandelion seeds float in wind. To estimate the distance that each type of seed is dispersed from the parent, (1) set up "seed traps" to capture seeds at various distances from the parent plant; (2) sample locations at various distances from the parent and analyze young individuals—using techniques introduced in Chapter 21 to determine if they are offspring from the parent being studied; (3) mark seeds, if possible, and find them again after dispersal.

BIG PICTURE Plant and Animal Form and Function

p. 840 CYU (1) understand Plants and animals may accumulate compounds in the epidermis and skin (such as waxes and other lipids) that reduce water loss. Both plants and animals evolved closable openings in this barrier to allow regulated gas exchange. Plants and animals may also change the amount of the body exposed to the sun (in plants by moving leaves, in animals by changing posture or taking shelter) to reduce evaporative water loss.
(2) understand Many plants and animals keep their eggs inside their bodies and depend on sperm being deposited near them rather than releasing both to the environment where they could dry out. **(3)** understand Very large animals and plants need to build strong supporting structures such as thick bones or trunks to withstand the force of gravity. They also need elaborate internal transport systems to bring nutrients to each cell and carry wastes away.
(4) analyze Cellular respiration fits into one of the key functions for survival—Nutrition. Both plants and animals depend on sugar (produced by plants via photosynthesis) as their energy source to make ATP via cellular respiration.

CHAPTER 42

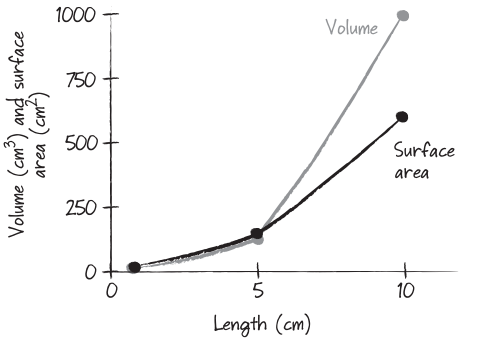
IN-TEXT QUESTIONS AND EXERCISES

p. 844 Fig. 42.2 create There would be no difference between experimental and control males.
p. 847 Fig. 42.4 analyze Based on the projections called axons that go to specific cells and tissues, neurons transmit signals to specific tissues rather than broadly throughout the body.
p. 850 CYU analyze *Connective tissues* consist of cells embedded in a matrix. The density of the matrix determines the rigidity of the connective tissue and its function in padding/protection, structural support, or transport. *Nervous tissue* is composed of neurons and support cells. Neurons have long projections that function as "biological wires" for transmitting electrical signals. *Muscle tissue* has cells that can contract and functions in movement. *Epithelial tissue* has tightly packed layers of cells with distinct apical and basal surfaces. They protect underlying tissues and regulate the entry and exit of materials into these tissues.
p. 850 apply A newborn.
p. 851 Fig. 42.10 apply The puppy has to eat relatively more because it has a higher mass-specific metabolic rate than an adult dog.
p. 852 Fig. 42.11 apply There should be no oxygen uptake on either side of the chamber.
p. 853 CYU (1) understand As three-dimensional size increases, volume increases more quickly than does surface area, so the surface area/volume ratio decreases.
(2) analyze The squirrel has a higher mass-specific metabolic rate because it is a smaller animal. It therefore needs more energy per unit body mass than a bear.
p. 858 CYU (1) analyze Endotherms can remain active during the winter and at night and sustain high levels of aerobic activities such as running or flying, but they require large amounts of food energy. Ectotherms need much less food and can devote a larger proportion of their food intake to reproduction, but they have a hard time maintaining high activity levels at night or in cold weather. **(2)** apply The whale's tongue would become colder because not as much heat would be transferred from warm arterial blood to cool venous blood with concurrent flow as with countercurrent flow, and as a result more heat from the arterial blood would be lost to the environment.

IF YOU UNDERSTAND . . .

42.1 understand Some adaptations to cold environments in mammals include the evolution of thick coats of hair, countercurrent heat exchangers in the extremities, and dark coloration to absorb radiation. Acclimatization may include further thickening and darkening of hair upon exposure to cold. **42.2** apply Loosening tight junctions would compromise the barrier between the external and internal environments. It would allow water and other substances (including toxins) to pass more readily across the epithelial boundary. **42.3** create King Kong is endothermic, and his huge mass would generate a great deal of heat. His relatively small surface area, especially as compared to a normal-sized gorilla, would not be able to dissipate the heat—especially if it were covered with fur. **42.4** create Individuals could acclimatize by normal homeostatic mechanisms (increased sweating, seeking shade, etc.). Individuals with alleles that allowed them to function better at higher temperatures would produce more offspring than individuals without those alleles. Over time, this would lead to adaptation via natural selection.
42.5 create *Apatosaurus* was likely a homeotherm because of its huge size. Because of its low surface area/volume ratio, metabolically produced heat would be trapped inside the dinosaur's body. Even if exposed to cold or warm temperatures, the dinosaur's temperature would not change much because it takes a long time for it to lose or gain heat across such a relatively small surface area.

YOU SHOULD BE ABLE TO . . .



✔ Test Your Knowledge

1. understand True **2.** remember Epithelial **3.** understand b
4. understand d **5.** understand a **6.** analyze a

✔ Test Your Understanding

7. understand It is where environmental changes are sensed first. As an effector, it has a large surface area for losing or gaining heat. **8.** analyze A warm frog can move, breathe, and digest much faster than a cold frog, because enzymes work faster (rates of chemical reactions increase) at 35°C than at 5°C. A warm frog needs much more food, though, to support this high metabolic rate. **9.** understand *Absorptive sections* have many folds and projections that increase their surface area for absorption. *Capillaries* have a high surface area because they are thin and highly branched, making exchange of fluids and gases efficient. *Beaks of Galápagos finches* have sizes and shapes that correlate with the type of food each species eats. Large beaks are used to crack large seeds; long, thin beaks are used to pick insects off surfaces; etc. *Fish gills* are thin, flattened structures with a large surface area, which facilitates the efficient exchange of gases and wastes. **10.** analyze A larger sphere has a relatively smaller surface area for its interior volume than does a smaller sphere, because surface area increases with size at a lower rate than volume does. Diffusion will be more efficient in the smaller sphere.
11. apply See **FIGURE A42.1**. The graph shows that as size (length) increases, the volume increases more rapidly than the surface area. **12.** understand c. This is an example of negative feedback because insulin is released in response to an increase in a parameter (blood sugar concentration)

FIGURE A42.1

and acts to reduce that parameter so that homeostasis is maintained. In the other examples, homeostasis is not maintained.

✔ Test Your Problem-Solving Skills

13. create Large individuals require more food, so are more susceptible to starvation if food sources can't be defended (e.g., when seeds are scattered around). They may also be slower and/or more visible to predators. **14.** create You would have to show changes in the frequencies of alleles whose products are affected by temperature—for example, increases in the frequencies of alleles for enzymes that operate best at higher temperature. **15.** create The heat-dissipating system should have a very high surface area/volume ratio. Based on biological structures, it should be flattened (thin) and highly folded and branched, and/or contain tubelike projections. **16.** understand a. Turtles are ectothermic, so they do not expend much energy to produce body heat. Mice are endothermic, and expend energy to regulate body temperature. Mice will therefore have a higher basal metabolic rate and consume more food.

CHAPTER 43

IN-TEXT QUESTIONS AND EXERCISES

p. 863 Fig. 43.1 understand The black and white molecules are moving down their concentration gradients, and the concentration of red molecules does not affect the concentration of black or white molecules.
p. 867 Fig. 43.6 understand The sodium–potassium ATPase performs primary active transport; the sodium–chloride–potassium cotransporter performs secondary active transport; the chloride and potassium channels are involved in passive transport.
p. 869 CYU apply The osmolarity of the fish's tissue would decrease because the pumps would no longer be able to import sodium.
p. 869 Fig. 43.8 analyze The underside of the abdomen is shaded by the grasshopper's body. This location is relatively cool and should reduce the loss of water during respiration.
p. 871 CYU (1) understand Uric acid is insoluble in water and can be excreted without much water loss. **(2)** understand When electrolytes are reabsorbed in the hindgut epithelia, water follows along an osmotic gradient.
p. 873 understand Blood contains cells and large molecules as well as ions, nutrients, and wastes; the filtrate contains only ions, nutrients, and wastes.
p. 876 apply (1) Less water reabsorption will occur because the osmotic gradient is not as steep. (2) Filtrate osmolarity will be lower because less water has been reabsorbed. (3) Salt reabsorption will be reduced because the concentration of NaCl in the filtrate is lower.
p. 878 apply Ethanol consumption inhibits water reabsorption, leading to a larger volume of less concentrated urine. Nicotine consumption increases water reabsorption, leading to a smaller volume of more concentrated urine.
p. 878 CYU apply Water intake increases blood pressure and filtration rate in the renal corpuscle. It leads to lowered electrolyte concentration in the blood and filtrate and the production of large volumes of dilute urine. Eating large amounts of salt results in concentrated, hyperosmotic urine. Water deprivation triggers ADH release and the production of concentrated, hyperosmotic urine.
p. 879 Fig. 43.19 create Carrying a large volume of water in the bladder may be energetically costly to the animal. The animal also might not be able to run as quickly and may have an increased predation risk.

IF YOU UNDERSTAND . . .

43.1 understand A sodium gradient establishes an osmotic gradient that moves water. It also sets up an electrochemical gradient that can move ions against their electrochemical gradient by secondary active transport through a cotransporter, or with their electrochemical gradient by passive diffusion through a channel.
43.2 analyze Cartilaginous fishes such as sharks maintain a high concentration of urea in their blood, which raises their osmolarity to about the same as seawater. Therefore, they lose very little water to the environment. Bony fishes drink seawater and maintain their osmolarity lower than that of seawater by actively transporting excess ions out of the gills. Sharks actively excrete sodium chloride through a rectal gland. **43.3** understand When comparing chloride cells in gills of salmon in the ocean versus freshwater, the cells are in different locations on the gills, different forms of Na^+/K^+-ATPase exist, and $Na^+K^+Cl^-$ transporters are located on the basolateral side of the membrane in ocean salmon and on the apical side of the membrane in freshwater salmon. **43.4** apply Aquatic insects produce more urea, and especially more ammonia, than terrestrial insects because these nitrogenous wastes are energetically less expensive to produce than uric acid. Ammonia and urea require more water to be excreted, but aquatic insects have access to plenty of water. **43.5** create The longer the loop of Henle, the steeper the osmotic gradient in the interstitial fluid in the medulla. Steep osmotic gradients allow a great deal of water to be reabsorbed as urine passes through the collecting duct, resulting in highly concentrated urine.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. remember True **2.** understand c **3.** apply a **4.** remember d **5.** understand c **6.** remember bladder

✔ Test Your Understanding

7. create b. Fishes excrete nitrogenous wastes in the form of ammonia. Although the ammonia can easily diffuse across the fish's gills into the water, freshwater ponds are often small and ammonia can build up to potentially toxic levels. **8.** analyze Ammonia is toxic and must be diluted with large amounts of water to be excreted safely. Urea and uric acid are safer and do not have to be excreted with large amounts of water but are more expensive to produce in terms of energy expenditure. Fish excrete ammonia; mammals excrete urea; insects excrete uric acid. You would expect the embryos inside terrestrial eggs to excrete uric acid, since it is the least toxic and is insoluble in water. **9.** understand Mitochondria are needed to produce ATP. A key component of salt regulation in fish is the Na^+/K^+-ATPase, which requires ATP to function. Because ATP fuels establishment of the ion gradients necessary for the cotransport mechanisms used by chloride cells as well as other epithelial cells, an abundance of mitochondria would be expected in a chloride cell. **10.** create The wax layer should be thicker in insects inhabiting dry habitats, because the animals there are under more osmotic stress (more evaporation due to low humidity; less available drinking water). Insects that live in extremely humid habitats may lack the ability to close their spiracles; animals that live in humid habitats may excrete primarily ammonia or urea and have relatively short loops of Henle. In each case, you could test these predictions by comparing individuals of closely related species that live in dry versus humid habitats. **11.** create Without a loop of Henle, there would be no concentration gradient in the medullary interstitial fluid, so water would not be absorbed from the pre-urine in the collecting duct; concentrated urine could not be formed. **12.** create Freshwater has such a low osmolarity that if invertebrates osmoconformed to it, they would lack sufficient quantities of ions to conduct electrical currents in their excitable tissues.

✔ Test Your Problem-Solving Skills

13. apply c. Without aquaporins in the collecting duct, water cannot be reabsorbed, which would result in increased urine volume and decreased urine osmolarity. **14.** create The mammal's urine volume would increase dramatically. Ouabain would poison Na^+/K^+-ATPase pumps in the nephron, which would prevent reabsorption of ions and nutrients. Without the osmotic gradient established by reabsorption of ions and nutrients, the water would remain in the nephron and exit as urine. **15.** analyze The observation that the Na^+ concentration decreased by 30 percent, even as volume also decreased, indicates that Na^+ ions were reabsorbed to a greater degree than water. The observation that the urea concentration increased by 50 percent indicates that urea was not reabsorbed. **16.** analyze The hypothesis that the mussels are osmoconformers is supported because their hemolymph is very close in osmolarity to that of the wide range of water osmolarities into which they are placed.

CHAPTER 44

IN-TEXT QUESTIONS AND EXERCISES

p. 891 understand Nutrient absorption occurs in the small intestine, but not in the esophagus or stomach, and the rate of absorption increases with available surface area.
p. 894 Fig. 44.14 understand Frog eggs don't normally make the sodium-glucose cotransporter protein, so the researchers could be confident that if the protein appeared, it was from the injected RNA. They would not be confident of this if the RNAs were injected into rabbit epithelial cells, where the protein was probably already present.
p. 896 apply (1) Decreased energy yield from foods due to reduced glucose absorption, (2) increased fecal glucose content due to the passing of unabsorbed glucose into the colon, (3) watery feces due to decreased water reabsorption in the large intestine (lower osmotic gradient). (An additional effect would be increased flatulence due to the metabolism of unabsorbed glucose by bacteria that produce gases as waste products.)
p. 896 CYU (1) understand *Mouth:* Food is taken in; teeth physically break down food into smaller particles; salivary amylase begins to break down carbohydrates; lingual lipase initiates the digestion of fats. *Esophagus:* Food is moved to the stomach via peristaltic contractions. *Stomach:* HCl denatures proteins; pepsin begins to digest them. *Small intestine:* Pancreatic enzymes complete the digestion of carbohydrates, proteins, lipids, and nucleic acids. Most of the water and all of the nutrients are absorbed here. *Large intestine:* Water is reabsorbed and feces are formed. *Anus:* Feces accumulate in the rectum and are expelled out the anus. **(2)** apply If the release of bile salts is inhibited, fats would not be digested and absorbed efficiently, and they would pass into the large intestine. The individual would likely produce fatty feces and lose weight over time. Trypsin inactivation would inhibit protein digestion and reduce absorption of amino acids, likely leading to weight loss and muscle atrophy due to protein deprivation. If the Na^+-glucose cotransporter is blocked, then glucose would not be absorbed into the bloodstream. The individual would likely become sluggish from lack of energy.
p. 897 Fig. 44.16 understand In type 2 diabetes mellitus, the top, black arrow from glucose (in the blood) to glycogen (inside liver and muscle cells) is disrupted. In type 1 diabetes mellitus, the green arrow on the top left, indicating insulin produced by the pancreas, is disrupted.
p. 898 understand Individuals with type 1 diabetes mellitus have normal insulin receptors on their liver cells but do not produce and release insulin from the pancreas. Individuals with type 2 diabetes mellitus produce and release insulin, but they have fewer insulin receptors and/or these receptors do not respond as well to insulin. In both types of diseased individuals, glucose concentrations in the blood remain high. In individuals without disease, both insulin production and insulin receptors

are normal, so liver cells respond to insulin by taking up glucose from the blood and storing it.
p. 898 Fig. 44.17 analyze The data do not prove that obesity causes type 2 diabetes mellitus. The study provides correlational data and cannot directly assign causation. However, the study provides strong evidence of an association between obesity and type 2 diabetes.
p. 899 CYU (1) understand Type 1 diabetes mellitus is an autoimmune disease, meaning that the body's immune system mistakenly kills the insulin-producing cells of the pancreas. Type 2 diabetes mellitus is caused by a combination of factors, including genetic predisposition, obesity, and poor diet. **(2)** apply When the blood sugar of individuals with type 1 diabetes mellitus gets too high, they should inject themselves with insulin, which will trigger the absorption and storage of glucose by their cells. When their blood glucose gets too low, they should eat something with a high concentration of sugar (such as orange juice or a candy bar) to increase their blood glucose levels quickly. (If glucose is dangerously low, a glucagon shot may be administered.)

IF YOU UNDERSTAND . . .

44.1 analyze One serving of skim milk has approximately 80 kcal, while whole milk has about 152 kcal. **44.2** apply Its mouth or tongue would be modified to make probing of flowers and sucking nectar efficient. It would not require teeth, and its digestive tract would be relatively simple. For example, the stomach would not have to pulverize food or digest large amounts of protein, and the large intestine would not have to process and store large amounts of bulky waste. **44.3** analyze Amylase will work best at a neutral or slightly alkaline pH (typical of mouth and small intestine), whereas pepsin will work best at a low pH (typical of the stomach). **44.4** understand Type 1 diabetes mellitus leads to high glucose because insulin is not produced, and therefore glucose cannot be moved from blood into cells. Type 2 diabetes mellitus leads to high blood glucose because insulin does not bind in sufficient amounts to its receptor, so glucose cannot be transported from blood into cells.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. remember a **2.** understand d **3.** remember d **4.** remember b **5.** remember insulin, glucagon **6.** remember False

✔ Test Your Understanding

7. understand The bird crop is an enlarged sac that can hold quickly ingested food; in leaf-eating species it is filled with symbiotic organisms and functions as a fermentation vessel. The cow rumen is an enlarged portion of the stomach; the elephant cecum is enlarged relative to other species. Both structures are filled with symbiotic organisms and function as fermentation vessels. **8.** analyze Digestive enzymes break down macromolecules (proteins, carbohydrates, nucleic acids, lipids). If they weren't produced in an inactive form, they would destroy the cells that produce and secrete them. **9.** understand b **10.** understand Pima living in the United States are genetically similar to Pima living in Mexico, but they have higher rates of type 2 diabetes. This suggests that the difference in diabetes rates is due to environmental factors such as diet and exercise. **11.** understand Humans have sharp canines and incisors, which may help to bite and tear meat. Humans also have flat molars, which help in grinding grains and other plant material. **12.** apply In a type 1 diabetic who took too much insulin, the blood glucose would become very low. The person would become sluggish and disoriented, and might slip into a diabetic coma.

✔ Test Your Problem-Solving Skills

13. create A proton pump inhibitor reduces activity of the proton pumps in parietal cells, reducing the amount of HCl produced. The contents of the stomach would therefore become less acidic, helping to prevent acid reflux. **14.** analyze b **15.** evaluate The result is still valid because the injection caused secretion—if it is also true that lack of injection led to no secretion. The criticism is also somewhat valid, however, because the researchers couldn't rule out the hypothesis that signaling from nerves plays some sort of role, too. **16.** create Terrestrial animals are exposed to increased risk of water loss, and the large intestine is where water reabsorption occurs. In most cases, fish do not need to reabsorb large amounts of water from their feces.

CHAPTER 45

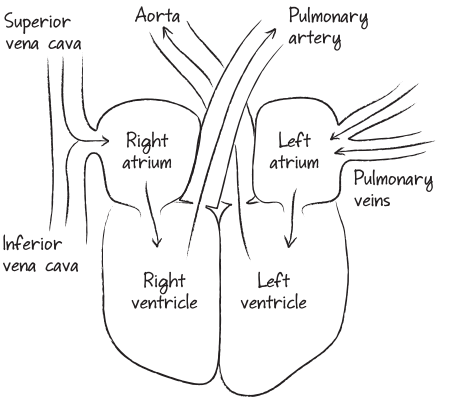
IN-TEXT QUESTIONS AND EXERCISES

p. 905 CYU (1) analyze Oxygen partial pressure is high in mountain streams because the water is cold, mixes constantly, and has a high surface area (due to white water). Oxygen partial pressure is low at the ocean bottom because that is far from the surface, where gas exchange takes place, and there is relatively little mixing. **(2)** create *Warm-water species:* Large amount of air, because the oxygen-carrying capacity of warm water is low. *Vigorous algal growth:* Small amount of air, because algae contribute oxygen to the water through photosynthesis. *Sedentary animals:* Small amount of air, because sedentary animals require relatively little oxygen.
p. 906 Fig. 45.4 analyze External gills are ventilated passively and are efficient because they are in direct contact with water. They are exposed to predators and mechanical damage, however. Internal gills are protected but have to be ventilated by some type of active mechanism for water flow.
p. 907 Fig. 45.6 apply If "concurrent flow" occurred, oxygen transfer would stop, because the partial pressure gradient driving diffusion would fall to zero partway along the length of the capillary.
p. 909 Fig. 45.7 analyze Using many animals increases confidence that the results are true for most or all members of the population and are not due to one or a few unusual individuals or circumstances.
p. 912 CYU (1) analyze Common features include large surface area, short diffusion distance (a thin gas exchange membrane), and a mechanism that keeps fresh air or water moving over the gas exchange surface. Only fish gills use a countercurrent exchange mechanism; only tracheae deliver oxygen directly to cells without using a circulatory system; only lungs (mammalian) contain "dead space"—areas that are not involved in gas exchange. **(2)** apply The P_{O_2} would go down as oxygen is used up, the P_{CO_2} would go up as CO_2 diffuses into the blood but cannot be exhaled, and pH would drop as the CO_2 dissolves in blood to form bicarbonate and H^+ ions.
p. 913 create There would be an even larger change in the oxygen saturation of hemoglobin in response to an even smaller change in the partial pressure of oxygen.
p. 914 Fig. 45.16 analyze According to the data in the figure, when the tissue P_{O_2} is 30 mm Hg, the oxygen saturation of hemoglobin is about 15 percent for blood at pH 7.2 and about 25 percent at pH 7.4. Therefore, about 85 percent of the oxygen is released from hemoglobin at pH 7.2, but only about 75 percent of the oxygen is released at pH 7.4.
p. 915 Fig. 45.18 analyze In the lungs, a strong partial pressure gradient favors diffusion of dissolved CO_2 from blood into the alveoli. As the partial pressure of CO_2 in the blood declines, hydrogen ions leave hemoglobin and react with bicarbonate to form more CO_2, which then diffuses into the alveoli and is exhaled from the lungs.
p. 916 CYU analyze The curve for Tibetans should be shifted to the left relative to people adapted to sea level—meaning that their hemoglobin has a higher affinity for oxygen at all partial pressures.
p. 921 Fig. 45.24 analyze Air from the alveoli mixes with air in the "dead space" in the bronchi and trachea on its way out of the body. This dead space air is from the previous inhalation ($P_{O_2} = 160$ mm Hg; $P_{CO_2} = 0.3$), so when the alveolar air mixes with the dead space air, the partial pressures in the exhaled air achieve levels intermediate between that of inhaled and alveolar air.
p. 922 apply Without the delay at the AV node, the ventricles would not have the chance to fully fill with blood from the atria. As a consequence, the volume of blood ejected from the ventricles would decline.
p. 924 CYU (1) understand Blood plasma that leaks out of the capillaries and is not reabsorbed into capillaries enters lymphatic vessels that eventually merge with blood vessels. **(2)** understand See **FIGURE A45.1**.

IF YOU UNDERSTAND . . .

45.1 understand Cellular respiration. **45.2** create It is harder to extract oxygen from water than it is to extract it from air. This limits the metabolic rate of water breathers. **45.3** analyze Large animals have a relatively small body surface area relative to their volume. If they had to rely solely on gas exchange across their skin, the skin surface area would not be large enough to exchange the volume of oxygen needed to meet their metabolic needs. **45.4** create Since O_2 cannot compete as well as CO for binding sites in hemoglobin, O_2 transport decreases. As oxygen levels in the blood drop, tissues (most crucially in the brain) become deprived of oxygen, and suffocation occurs. **45.5** apply Their circulatory systems should have relatively high pressures—achieved by independent systemic and pulmonary circulations powered by a four-chambered heart—to maximize the delivery of oxygenated blood to metabolically active tissues.

YOU SHOULD BE ABLE TO . . .



✔ Test Your Knowledge

1. understand b **2.** remember c **3.** understand d **4.** understand d **5.** remember c **6.** understand An open circulatory system is less efficient than a closed circulatory system because it is not capable of directing the hemolymph toward specific organs, and because the pressure is lower, resulting in slower flow of hemolymph.

✔ Test Your Understanding

7. understand During exercise, P_{O_2} decreases in the tissues and P_{CO_2} increases. The increase in P_{CO_2} lowers tissue pH. The drop in P_{O_2} and pH causes more oxygen to be released from hemoglobin. **8.** understand In blood, CO_2 is converted to carbonic acid, which dissociates into a proton and a bicarbonate ion. Because the protons bind to deoxygenated hemoglobin, they do not cause a dramatic drop in blood pH (hemoglobin acts as a buffer). Also, small decreases in blood pH trigger a homeostatic response that increases breathing rate and expulsion of CO_2. **9.** understand Because airflow through bird lungs is unidirectional, the gas exchange surfaces are

FIGURE A45.1

continuously ventilated with fresh, oxygenated air. The trachea and bronchi in a mammalian lung do not have a gas exchange surface, and bidirectional airflow in these species means that "stale" air has to be expelled before "fresh" air can be inhaled. As a result, the alveoli are not ventilated continuously. **10.** understand Lungs increase the temperature of the air and are moist to allow greater solubility of gases (increasing *k*); alveoli present a large surface area (large *A*); the epithelium of alveoli is thin (small *D*); and constant delivery of deoxygenated blood to alveoli maintains a steep partial pressure gradient, favoring diffusion of oxygen into the body ($P_2 - P_1$ is high). **11.** analyze Yes—the trait compensates for the small P_{O_2} gradient between stagnant water and the blood of the carp. **12.** analyze c

✔ Test Your Problem-Solving Skills

13. create Cold water carries more oxygen than warm water does, so icefish blood can carry enough oxygen to supply the tissues with oxygen even in the absence of hemoglobin. The oxygen and carbon dioxide are simply dissolved in the blood. **14.** analyze The insect tracheal system delivers O_2 directly to respiring cells; in humans, O_2 is first taken up by the blood of the circulatory system, which then delivers it to the cells. The human respiratory system also has specialized muscles devoted to ventilating the lungs. The open circulatory system of the insect is a low-pressure system, which makes use of pumps (hearts) and body movements to circulate hemolymph. The closed circulatory system of humans is a high-pressure system, which can respond to rapid changes in O_2 demand by tissues. **15.** understand If the pulmonary circulation were under pressure as high as that found in the systemic circulation, large amounts of fluid would be forced out of capillaries in the lungs. There is a conflict between the thin surface required for efficient gas exchange and the thickness needed in blood vessels to withstand high pressure. **16.** analyze b

CHAPTER 46

IN-TEXT QUESTIONS AND EXERCISES

p. 931 Fig. 46.3 apply No—as K^+ leaves the cell along its concentration gradient, the interior of the cell becomes more negative. As a result, an electrical gradient favoring movement of K^+ into the cell begins to counteract the concentration gradient favoring movement of K^+ out of the cell. Eventually, the two opposing forces balance out, and there is no net movement of K^+.
p. 932a apply $E_{Ca2+} = 58\ mV \times \log 1\ mM/0.0001\ mM)/(+2) = 116\ mV$.
p. 932b apply The membrane potential would be near zero because the Na^+ and K^+ would diffuse across the membrane along their concentration gradients.
p. 934 CYU (1) apply The resting potential would fall (be much less negative) because K^+ could no longer leak out of the cell. **(2)** understand The size of an action potential from a particular neuron does not vary, so it cannot contain information. Only the frequency of action potentials from the same neuron varies.
p. 934 understand See **FIGURE A46.1**.
p. 935 (1) understand Na^+ channels open when the cell membrane depolarizes, and as more channels open, more Na^+ flows into the cell, further depolarizing the cell, causing more voltage-gated Na^+ channels to open. **(2)** apply Sodium would flow inward as potassium flowed outward, and their charges would cancel each other out. The membrane would not depolarize.
p. 938 CYU (1) understand Once the threshold level of depolarization is attained, the probability that the voltage-gated sodium channels will open approaches 100 percent. But below threshold, the massive opening of Na^+ channels does not occur. This is why the action potential is all or none. **(2)** apply The membrane would depolarize and stay depolarized.
p. 938 Fig. 46.10 understand Get a solution taken from the synapse between the heart muscle and the vagus nerve *without* the nerve being stimulated. Expose a second heart to this solution. There should be no change in heart rate.
p. 940 analyze The inside of the cell becomes more positive (depolarized). This shifts the membrane potential closer to the threshold, making it more likely that the postsynaptic cell will fire an action potential.
p. 942 CYU apply The EPSP would not be as strong if an enzyme that broke down excitatory neurotransmitter increased in concentration.
p. 943 Fig. 46.16 analyze In the rest-and-digest mode, pupils take in less light stimulation, the heartbeat slows to conserve energy, liver conserves glucose, and digestion is promoted by release of gallbladder products. In the fight-or-flight mode, the pupils open to take in more light, the heartbeat increases to support muscle activity, and the liver releases glucose into the blood to fuel the fight or the flight (for example, from a predator).
p. 944 Fig. 46.18 understand Point to your forehead and top of your head for the frontal lobe, the top and top rear of your head for the parietal lobe, the back of your head for the occipital lobe, and the sides of your head (just above your ear openings) for the temporal lobes.
p. 946 Fig. 46.21 analyze No—for example, part (b) indicates that the size of the brain area devoted to the trunk is no bigger than the size of the brain area devoted to the thumb.
p. 948 CYU (1) understand One method is to study individuals with known brain lesions and correlate the location of the defect with a deficit in mental or physical function. Another is to directly stimulate brain areas in conscious patients during brain surgery and record the response. **(2)** remember Learning and memory involve changes in the number, sensitivity, and placement of synapses and neurons.

IF YOU UNDERSTAND . . .

46.1 understand See **FIGURE A46.2**. **46.2** understand Because the behavior of voltage-gated Na^+ and K^+ channels does not change. Every time a membrane depolarizes past the threshold and all of the voltage-gated Na^+ channels are open, the same amount of Na^+ will enter the cell, and the cell will depolarize to the same extent. In addition, K^+ channels open at the same time and allow the same amount of K^+ to leave the cell, so that it repolarizes to the same extent. **46.3** understand Summation means that EPSPs and IPSPs produced at various sites combine to determine the response or lack of response in a postsynaptic cell. Thus the behavior of a postsynaptic cell depends on the integration of input from many synapses. **46.4** apply The animal would likely die because its basic bodily functions (circulation, breathing, digestion, etc.) would be disrupted.

✔ Test Your Understanding

7. understand The Na^+/K^+-ATPase pumps 3 Na^+ out of the cell for every 2 K^+ it brings in. Since more positive charges leave the cell than enter it, there is a difference in charge on the two sides of the membrane and thus a voltage. **8.** analyze The ligand-gated channel opens or closes in response to binding by a small molecule (for example, a neurotransmitter); the voltage-gated channel opens or closes in response to changes in membrane potential. **9.** understand EPSPs and IPSPs are produced by flow of ions through channels in the membrane, which change the membrane potential in the postsynaptic cell. If a flow of ions at one point depolarizes the cell but a nearby flow of ions hyperpolarizes the cell, then in combination the flows of ions cancel each other out. But if two adjacent flows of ions depolarize the cell, then their effects are additive and sum to produce a total that is more likely to reach threshold. **10.** analyze The somatic system responds to external stimuli and controls voluntary skeletal muscle activity, such as movement of arms and legs. The autonomic system controls internal involuntary activities, such as digestion, heart rate, and gland activities. **11.** apply A drug that activates the sympathetic nervous system would increase heart rate. **12.** understand a

✔ Test Your Problem-Solving Skills

13. apply The neurotransmitters will stay in the synaptic cleft longer, so the amount of binding to ligand-gated channels will increase. Ion flows into the postsynaptic cell will increase dramatically, affecting its membrane potential and likelihood of firing action potentials. **14.** analyze The benefit of these approaches is that they allow the specific role of the brain region to be assessed in a living person. However, diseased or damaged brains may not respond like healthy and undamaged brains. Also, the extent of lesions and the exact location of electrical stimulation may be difficult to determine, making correlations between the regions affected and the response imprecise. **15.** analyze c (Because the current is reduced from normal levels, but not eliminated completely, there must be more than one type of potassium channel present. The venom probably knocks out just one specific type of channel.) **16.** create A reasonable hypothesis is that the new neurons arise from stem cells in the brain.

CHAPTER 47

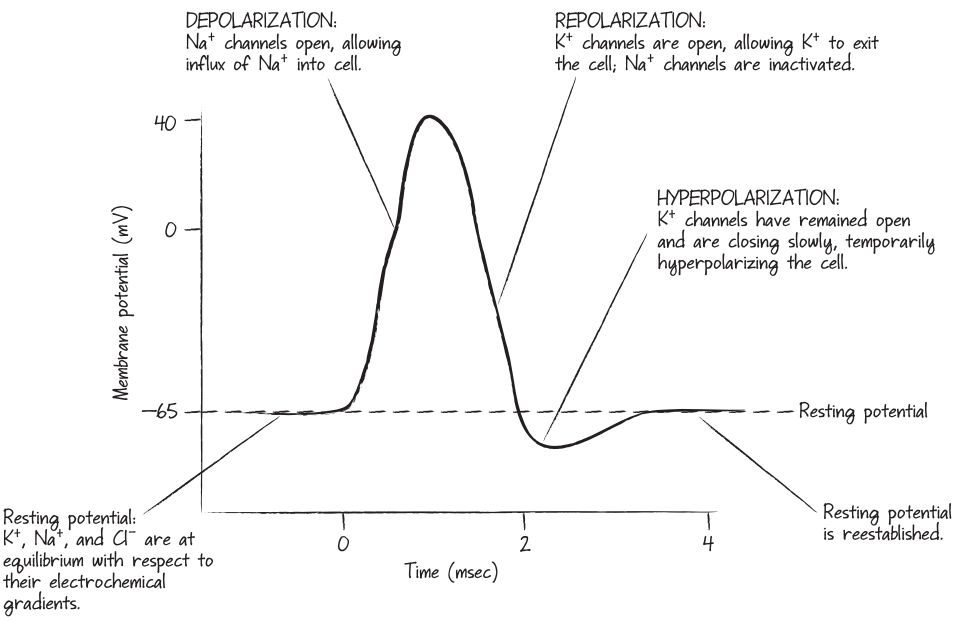
IN-TEXT QUESTIONS AND EXERCISES

p. 959 CYU (1) apply A punctured eardrum wouldn't vibrate correctly and would result in hearing loss at all frequencies in the affected ear. If the stereocilia are too short to come into contact with the tectorial membrane, vibration of the basilar membrane will not cause them to bend, and sound will not be detected. A loss in basilar membrane flexibility would result in the inability to hear lower-pitched sounds, such as human speech. **(2)** understand The lateral line system senses pressure waves in the water, allowing fishes to detect the presence of such objects as prey, predators, or potential mates. **p. 959 Fig. 47.9** create Vision could potentially be used to detect prey in diurnal catfish. To control for this, catfish could be blinded or "blindfolded" with an opaque material over their eyes to permit study of the lateral line system. **p. 961 Fig. 47.12** create The change in retinal's shape would induce a change in opsin's shape. A protein's function correlates with its shape, so opsin's function is likely to change as well. **p. 962** analyze cGMP is a second messenger in the sense that it signals the sodium channel that transducing is inactive, and it is also a ligand that opens sodium channels. Transducin is like a G protein because it switches from "off" to "on" in response to a receptor protein, activating a key protein as a result. Closing Na^+ channels stops the entry of positive charges into the cell, making the inside of the cell more negative relative to the outside. **p. 962 Fig. 47.13** understand This ion flow occurs when the photoreceptor cell is not receiving light—when the cell is in the dark. **p. 963 Fig. 47.15** create The S, M, and L opsin proteins are each different in structure. These structural differences affect the ability of retinal to absorb specific frequencies of light and change shape. **p. 964 CYU (1)** understand Retinal acts like an on–off switch that indicates whether light has fallen on a rod cell. When retinal absorbs light, it changes shape. The shape change triggers events that result in a change in action potentials, signaling that light has been absorbed. **(2)** apply Retina detachment from a jarring car accident would separate the retina from the optic nerve, resulting in blindness. The mutation would produce blue–purple color blindness, because the S opsin responds to wavelengths in that region of the spectrum. A clouded lens would reduce the amount of light that reaches the retina, reducing visual sensitivity. **p. 967 CYU (1)** understand Extremely hot food damages taste receptors, so those proteins would no longer be able to respond to their chemical triggers. **(2)** create One hypothesis to explain why the vomeronasal organ is vestigial in most primates is that primates have evolved other complex methods of communication, including gestures, facial expressions, and language, that render sensation with the vomeronasal organ less important. **p. 967** apply (1) A rattlesnake with its eyes covered will strike effectively because its pits will sense the prey. (2) A rattlesnake with its eyes and pits covered with cotton cloth will strike effectively. The cloth will block vision but the heat from the animal will penetrate the cloth to stimulate the thermoreceptors in the pits. (3) A rattlesnake with its eyes and pits covered with an opaque heat-blocking material will not be able to strike effectively, because the material blocks vision and heat energy. **p. 969 CYU (1)** create Electrogenic fishes may have a survival advantage over other fishes in murky water, where vision would be compromised. **(2)** create Female sea turtles likely use magnetic cues to locate their natal beaches.

IF YOU UNDERSTAND . . .

47.1 create The sensory neurons that used to serve that limb are cut, but may still fire action potentials that stimulate brain areas associated with awareness of pain in the missing limb. **47.2** analyze Each of these senses involves ion channels that open in response to application of pressure to cell membranes. **47.3.** understand Because different animal species have different sets of opsin molecules that respond to different wavelengths of light absorbed by retinal they see different colors. **47.4** create Smells are part of the sensation of flavor, and people with nasal congestion cannot smell. In addition to smell being important, the small number of taste receptors can send many different frequencies of action potentials to the brain, and the taste receptors can be stimulated in many different combinations. **47.5** understand Capsaicin binds to thermoreceptors that are also activated at high temperatures, leading to the perception of heat. It can also bind to some nociceptors.

YOU SHOULD BE ABLE TO . . .



✔ Test Your Knowledge

1. understand a **2.** remember d **3.** understand c **4.** remember b **5.** remember false **6.** remember magnetoreception

✔ Test Your Understanding

7. understand b **8.** understand The many possible examples include several blue opsins allowing coelacanths to distinguish the blue wavelengths present in their deep-sea habitat, infrasound hearing allowing elephants to hear over long distances, ultrasonic hearing allowing bats to hunt by echolocation and moths to avoid bat predators, red and yellow opsins allowing fruit-eating mammals to distinguish ripe from unripe fruit. **9.** analyze The data provide evidence that a pheromone acted to synchronize the women's menstrual cycles because the average time between onset of a woman's cycle and that of the rest of the women declined over time following move-in to the dorms in fall. It declined most rapidly after they first moved in together. The leveling of the graph over time

FIGURE A46.3

shows that the onset dates became more synchronized. **10.** understand Ion channels in hair cells are thought to open in response to physical distortion caused by the bending of stereocilia. Ion channels in taste receptors, in contrast, change shape and open when certain bitter-tasting molecules bind to them. **11.** evaluate Dalton's hypothesis was reasonable because blue fluid absorbs red light and would prevent it from reaching the retina, and this could be tested by dissecting his eyes. Although the hypothesis was rejected, it inspired a rigorous test and required researchers to think of alternative explanations. **12.** create To determine whether electric eels are electrogenic, place an eel in a tank and measure the electricity of water to determine if the eel is emitting an electric field. To determine whether they are electroreceptive, place an eel in a tank in the dark and add an object the size and shape of a prey item that emits no scent or taste. Block the lateral line system with a chemical as in Figure 47.9. If the eel locates the object, it must do so using electroreception.

✔ Test Your Problem-Solving Skills

13. understand a; vomeronasal organs evolved in tetrapods, presumably as an adaptation for communication in terrestrial habitats. **14.** analyze Both the lateral line system and electroreceptors use hair cells to sense changes in the water. Hair cells in the lateral line system contain mechanoreceptors that are depolarized in response to changes in water pressure. In contrast, electroreceptors cause hair cells to depolarize in response to changes in the electric field. **15.** evaluate It is unlikely that a perfume contains human pheromones because they have never actually been characterized, although their presence is suspected. **16.** create Block all but a few hundred ommatidia in the center of each compound eye of many dragonflies with an opaque material, and observe any differences that might occur in their ability to detect and pursue prey compared to individuals whose ommatidia had been covered by a transparent material.

CHAPTER 48

IN-TEXT QUESTIONS AND EXERCISES

p. 974 understand The trucks are the Z discs, the ropes are the thin filaments, and the burly weightlifters are the thick filaments.
p. 974 Fig. 48.2 analyze The dark band includes thin filaments and a dense concentration of bulbous structures extending from the thick filament; the light band consists of thin filaments only.
p. 977 CYU (1) understand In a sarcomere, thick myosin filaments are sandwiched between thin actin filaments. When the heads on myosin contact actin and change conformation, they pull the actin filaments toward one another, shortening the whole sarcomere. **(2)** apply Increased acetylcholine release would result in an increased rate of muscle-cell contraction. Preventing conformational changes in troponin would prevent muscle contraction. Blocking the uptake of calcium ions into the sarcoplasmic reticulum would lead to sustained muscle contraction.
p. 980 apply The breast meat of pigeons is composed of dark meat because these muscles are specialized for endurance. Their dark color is due to a high concentration of myoglobin.
p. 981 create When earthworms shorten their longitudinal muscles, the segment containing these muscles shortens and squeezes the internal fluid, which becomes pressurized and pushes in all directions, expanding the circumference of the segment and pushing laterally against the burrow.
p. 983 CYU (1) analyze Exoskeletons are made of chitin, proteins, and other substances like calcium carbonate. Endoskeletons are made of calcium phosphate, calcium carbonate, and proteins. Exoskeletons occur on the outsides of animals, whereas endoskeletons occur on the insides. Both types of skeletons are composed of rigid levers separated by joints such that motions are a result of changes in joint angles. Both types of skeletons attach to skeletal muscle and serve to transmit muscle forces. Hydrostatic skeletons also transmit muscle forces but are made of soft tissues that vary from animal to animal. Shape changes in hydrostatic skeletons occur not from changes in joint angles, but from shape changes of the bodies themselves. **(2)** apply No movement of the arm would occur, because for these antagonistic muscles to produce movement, one of them must be contracted while the other is relaxed.
p. 986 Fig. 48.16 apply Galloping at 3.5 m/s would cost about 75 percent more energy.
p. 987 Fig. 48.18 apply About 10 times more costly.

IF YOU UNDERSTAND . . .

48.1 apply Paralysis, because acetylcholine has to bind to its receptors on the membrane of postsynaptic muscle fibers for action potentials to propagate in the muscle and cause contraction. **48.2** analyze Skeletal muscle is multinucleate, unbranched, striated, and voluntary. Cardiac muscle is branched, striated, and involuntary. Smooth muscle is smooth and involuntary. **48.3** analyze When muscles contract in hydrostatic skeletons, the body deforms by becoming longer and thinner, or shorter and narrower, or by bending side to side. In vertebrates and arthropods, muscle contractions cause changes in the joint angles between rigid segments rather than shape changes in the segments themselves. **48.4** understand On land, an animal is constrained by its weight; larger animals cannot move as freely and are in greater danger of breaking than are smaller animals. In water, animals are constrained by their shapes. Some shapes would cause high drag, which would inhibit locomotion. In air, animals are constrained by their weight. Larger animals must create more lift to overcome gravity.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. remember a **2.** remember c **3.** understand d **4.** remember True **5.** understand a **6.** understand False.

✔ Test Your Understanding

7. create The key observation was that the banding pattern of sarcomeres changed during contraction. Even though the entire unit became shorter, only some portions moved relative to each other. This observation suggested that some portions of the structure slid past other portions. Muscle fibers have to have many mitochondria because large amounts of ATP are needed to power myosin heads to move along actin filaments; large amounts of calcium stored in smooth ER are needed to initiate contraction by binding to troponin. **8.** apply c **9.** analyze Acetylcholine reduces the rate and force of contraction of cardiac muscle, whereas it stimulates skeletal muscle to contract. **10.** create ATP is no longer produced after death, so calcium cannot be actively transported from the cytosol into the sarcoplasmic reticulum to enable the binding of myosin and actin. The proteins do not unbind, because this process requires ATP. **11.** apply The oxygen consumption of the runner would increase because the arches of his or her feet would no longer store as much elastic energy, which normally reduces the energetic cost of running. **12.** create Because diverse animals experience the same physical constraints where they live, natural selection favors the same kind of adaptations to those constraints, resulting in convergent evolution. For example, dolphins and ichthyosaurs are distantly related but have a similar body shape due to their similar ability to swim rapidly through water.

✔ Test Your Problem-Solving Skills

13. apply In cardiac muscle, the binding of acetylcholine to its receptors causes the heart rate to slow. Ingestion of nightshade would increase heart rate because it blocks acetylcholine receptors. **14.** apply If the sarcomere is in a stretched state before stimulation, the initial force production would be reduced because less overlap would occur between actin and myosin; thus, fewer myosin heads could engage in the pull. **15.** apply c:

$$0.5 = v^2/(9.8\ \text{m/s}^2 \times 0.9\ \text{m})$$
$$0.5 = v^2/8.8\ \text{m}^2/\text{s}^2$$
$$v^2 = 0.5 \times 8.8\ \text{m}^2/\text{s}^2$$
$$v = \text{square root of } 4.4\ \text{m}^2/\text{s}^2$$
$$v = 2.1\ \text{m/s}$$

16. evaluate The bones of *T. rex* are available and can be analyzed to determine their structural properties, such as the mechanical advantage of the leg joints and the ability of the bones to withstand the different forces that the skeleton would experience at different speeds based on data from living animals. A very close estimate could be made, but the exact speed would be hard to determine without observing the dinosaur in action, since behavior affects speed.

CHAPTER 49

IN-TEXT QUESTIONS AND EXERCISES

p. 994 apply The current temperature is analogous to the sensory input; the thermostat, to the CNS; the thermostat signal, to the cell-to-cell signal; and the furnace, to the effector. If feedback inhibition fails, hormone production will continually increase.
p. 996 Fig. 49.4 understand Injecting the dog with a liquid extract from a different part of the body, or with a solution that is similar in chemical composition to the extract from the pancreas (e.g., in pH or ions present) but lacking molecules produced by the pancreas.
p. 997 CYU (1) understand It is difficult to differentiate between the nervous and endocrine systems because some neurons secrete hormones and some endocrine glands respond to neural signals. **(2)** apply Thyroid hormone receptors are intracellular because thyroid hormones are lipid soluble.
p. 998 create The cells could differ in receptors, signal transduction systems, or response systems (genes or proteins that can be activated).
p. 1001 understand Stressed individuals would be less able to heal or to fight pathogens.
p. 1001 Fig. 49.9 understand The saline injection controlled for any stress induced by the injection procedure and for introducing additional fluids.
p. 1002 Fig. 49.11 apply Same—a defect in both signal and receptor has the same effect—no response—as a defective signal alone or a defective receptor alone.
p. 1003 CYU (1) analyze In amphibians, an increase in thyroid hormones stimulates metamorphosis from a tadpole to an adult without a resting stage. In insects, a decrease in juvenile hormone and increase in ecdysone stimulate metamorphosis during a resting (pupal) stage. **(2)** understand By reducing immune system function, promoting release of fatty acids from storage cells and use of amino acids from muscles for energy production, and preventing release of glucose in response to signals from insulin, cortisol conserves glucose supplies for use by the brain.
p. 1004 Fig. 49.12 create Inject ACTH and monitor cortisol levels. If cortisol does not increase, adrenal failure is likely.

p. 1006 CYU (1) understand ACTH triggers the release of cortisol, but cortisol inhibits ACTH release by blocking the release of CRH from the hypothalamus and suppressing ACTH production. High levels of cortisol tend to lower cortisol levels in the future. **(2)** understand Processing centers in the brain are responsible for synthesizing a wide array of sensory input. To start a response to this sensory input, they stimulate neurosecretory cells in the hypothalamus. Neurohormones from these cells travel to the anterior pituitary, where they trigger the production and release of other hormones.
p. 1010 CYU (1) apply The steroid-hormone–receptor complex would probably fail to bind to the hormone-response element. Then gene expression would not change in response to the hormone—the arrival of the hormone would have little or no effect on the target cell. **(2)** analyze The mode of action would be similar to that of a peptide—hormone binding would have to trigger a signal transduction event that resulted in production of a second messenger or a phosphorylation cascade.

IF YOU UNDERSTAND . . .

49.1 understand The production and release of hormones are often controlled, directly or indirectly, by electrical or chemical signals from the nervous system. A good example is the hypothalamic–pituitary axis, where neuroendocrine signals regulate endocrine signals. **49.2** analyze Electrical signals are short lived and localized. All of the processes listed in the question are long-term changes in the organism that require responses by tissues and organs throughout the body. **49.3** apply The hypothalamus would continue to release CRH, stimulating the pituitary to release ACTH, which in turn would stimulate continued release of cortisol from the adrenal cortex. Sustained, high circulating levels of cortisol have negative effects. **49.4** apply A cell can respond to more than one hormone at a time, because cells produce different receptors for each hormone.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. understand c **2.** understand a **3.** remember a **4.** remember c **5.** remember Mammals—eye and pineal gland; lizards—pineal gland; birds—diffuse in brain **6.** remember True

✔ Test Your Understanding

7. understand b **8.** create This is one reason that the same hormone can trigger different effects in different tissues. For example, epinephrine binds to four different types of receptors in different tissues—eliciting a different response from each. **9.** analyze The posterior pituitary is an extension of the hypothalamus; the anterior pituitary is independent—it communicates with the hypothalamus via chemical signals in blood vessels. The posterior pituitary is a storage area for hypothalamic hormones; the anterior pituitary synthesizes and releases an array of hormones in response to releasing hormones from the hypothalamus. **10.** analyze Steroid hormones act directly, and alter gene expression. They usually bind to receptors inside the cell, forming a complex that binds to DNA and activates transcription. Nonsteroid hormones act indirectly, and activate proteins. They bind to receptors on the cell surface and trigger production of a second messenger or a phosphorylation cascade, ending in activation of proteins already present in the cell. **11.** create Subject volunteers to travel and jet lag, measure ACTH and cortisol levels, and correlate these results with their perceived level of jet lag symptoms. **12.** create Studies have shown that treatment with leptin is largely ineffective in reducing food intake in obese humans.

✔ Test Your Problem-Solving Skills

13. apply c (dehydration would result, because ADH would not be present) **14.** create There are two basic strategies: (1) remove the structure from some individuals and compare their behavior and condition to untreated individuals in the same environment, or (2) make a liquid extract from the structure, inject it into some individuals, and compare their behavior and condition to individuals in the same environment that were injected with water or a saline solution. **15.** evaluate The researcher's hypothesis initially sounds unreasonable, because peptide hormones cannot enter cells to initiate gene transcription. However, a second messenger activated by the hormone could possibly lead to changes in gene transcription.**16.** evaluate The graph shows that atrazine treatment reduces the testosterone concentrations in male frogs to near the levels of females. This result supports the hypothesis that atrazine is an endocrine disruptor that feminizes male amphibians.

CHAPTER 50

IN-TEXT QUESTIONS AND EXERCISES

p. 1015 Fig. 50.3 create Isolate and identify the molecules found in "crowded" water. Test each molecule by adding it, at the same concentration found in crowded water, to clean water occupied by a single *Daphnia* and recording whether the female produces a male-containing brood. Repeat with many test females, and for each molecule identified. As a control, record the number of male-containing broods produced in clean water.
p. 1016 apply Asexual reproduction would be expected in environments where conditions change little over time.
p. 1019 Fig. 50.7 evaluate No—the data are consistent with the displacement hypothesis, but there is no direct evidence for it. There are other plausible explanations for the data.
p. 1021 CYU (1) analyze Oviparity usually requires less energy input from the mother after egg laying, and mothers do not have to carry eggs around as long—meaning that they can lay more eggs and be more mobile. However, before egg laying, mothers have to produce all the nutrition the embryo will require in the egg, and eggs may not be well protected after laying. Viviparity usually increases the likelihood that the developing offspring will survive until birth, but it limits the number of young that can be produced to the space available in the mother's reproductive tract. If viviparous young can be nourished longer than oviparous young, then they may be larger and more capable of fending for themselves. **(2)** create Divide a population of sperm into two groups. Subject one group of sperm to spermkillerene at concentrations observed in the female reproductive tract (the experimental group) but not the other group (the control). Document the number of sperm that are still alive over time in both groups.
p. 1025 Fig. 50.13 create (Note: There is more than one possible answer—this is an example.) Having two gonads is an "insurance policy" against loss or damage. To test this idea, surgically remove one gonad from a large number of male and female rats. Do a similar operation on a large number of similar male and female rats, but do not remove either gonad. Once the animals have recovered, place them in a barn or other "natural" setting and let them breed. Compare reproductive success of individuals with paired versus unpaired gonads.
p. 1026 Fig. 50.15 analyze It is similar. In both cases, the hypothalamus produces a releasing factor (GnRH or CRH) that acts on the pituitary. The releasing factor stimulates release of regulatory hormones from the anterior pituitary (LH and FSH or ACTH). These hormones travel via the bloodstream and act on the gonads or adrenals to induce the release of hormones from these glands. In both cases, the hormones are involved in negative feedback control of the regulatory hormones from the pituitary.
p. 1029 apply (1) There should be an LH spike early in the cycle, followed by early ovulation. (This might not actually occur, though, if the follicle is not yet ready to rupture.) (2) LH levels should remain low—no mid-cycle spike and no ovulation.
p. 1030 CYU (1) understand FSH triggers maturation of an ovarian follicle. Its level rises at the end of a cycle because it is no longer inhibited by progesterone, which stops being produced at high levels when the corpus luteum degenerates. **(2)** apply The drug would keep FSH levels low, meaning that follicles would not mature and would not begin producing estradiol and progesterone. The uterine lining would not thicken.
p. 1032 analyze (1) The uterine lining may not be maintained adequately—if it degenerates, a miscarriage is likely. (2) Pregnancy tests detect hCG in urine. By the third trimester, hCG is no longer being produced by the placenta.
p. 1034 Fig. 50.23 apply The birth will be more difficult, as limbs or other body parts can get caught.
p. 1034 Fig. 50.24 apply A mother's chance of dying in childbirth in 1760 was a little over 1000 in 100,000 live births, or close to 1.0 percent. If she gave birth 10 times, she would have a 10 percent chance of dying in childbirth.

IF YOU UNDERSTAND . . .

50.1 create Parasites could wipe out a population of asexually produced animals because the animals do not vary genetically. However, a population of sexually produced animals would have enough genetic variability that some individuals could present better resistance to the parasites. **50.2** create Parental care demands resources (time, nutrients) that cannot be used to produce more eggs. Sperm competition is not likely when external fertilization occurs, and most fishes use external fertilization. **50.3** create The most common methods are surgical ligation (tying off) of the fallopian tubes in a woman to stop the delivery of the egg to the uterus and cutting the vas deferens (vasectomy) in a man to stop the delivery of sperm into the semen. **50.4** apply FSH and LH levels would increase following ovariectomy, because sex steroids would no longer be present to exert negative feedback upon the anterior pituitary. **50.5** understand The placenta is highly vascularized to provide a large surface area for transfer of oxygen and nutrients from the mother's circulation to the fetus's, and of wastes from the fetus's circulation to the mother's.

YOU SHOULD BE ABLE TO . . .

1. remember a **2.** understand b **3.** remember a **4.** remember b **5.** remember Luteinizing hormone (LH) and follicle-stimulating hormone (FSH) **6.** remember True

✔ Test Your Understanding

7. remember Every offspring that is produced sexually is genetically unique; offspring that are produced asexually have DNA from their mother only and often are genetically identical to her. **8.** create *Daphnia* females produced males only when they were exposed to short day lengths *and* water from crowded populations *and* low food levels. These conditions are likely to occur in the fall. Sexual reproduction could be adaptive in fall if genetically variable offspring are better able to thrive in conditions that occur the following spring. **9.** analyze Spermatogenesis generates four haploid sperm cells from each primary spermatocyte; oogenesis produces only one haploid egg cell from each primary oocyte. Egg cells are much larger than sperm cells because they contain more cytoplasm. In males, the second meiotic division occurs right after the first meiotic division, but in females it is delayed until fertilization. **10.** understand LH triggers release of estradiol, but at low levels estradiol inhibits further release of LH. LH and FSH trigger release of progesterone, but progesterone inhibits further release of LH and FSH. High levels of estradiol trigger release of more LH. The follicle can produce high levels of estradiol only if it has

grown and matured—meaning that it is ready for ovulation to occur. **11.** analyze c **12.** apply Females should be choosier about their second mate because the sperm of the second male has an advantage in sperm competition.

✔ Test Your Problem-Solving Skills

13. create If all sheep were genetically identical, it is less likely that any individuals could survive a major adverse event (e.g., a disease outbreak or other environmental challenge) than if the population were composed of genetically diverse individuals, which are likely to vary in their ability to cope with the new conditions. **14.** apply Oviparous populations should produce larger eggs than viviparous populations. Because oviparous species deposit eggs in the environment, the eggs must contain all the nutrients and water required for the entire period of embryonic development. But because embryos in viviparous species receive nourishment directly from the mother, it is likely that their eggs are smaller. **15.** create One hypothesis might be that the shell membrane is a vestigial trait (see Chapter 25)—specifically, an "evolutionary holdover" from an ancestor of today's marsupials that laid eggs. **16.** analyze b

CHAPTER 51

IN-TEXT QUESTIONS AND EXERCISES

p. 1040 apply See **FIGURE A51.1**. Each type of Toll protein is a pattern-recognition receptor that responds to a different group of pathogens. Since bacteria and fungi are very different pathogens, you would not expect a receptor that recognizes fungi to be required for a response against bacteria, so flies lacking Toll would survive as well as the wild-type control.

p. 1041 CYU analyze (1) Applying direct pressure constricts blood vessels, mimicking the effect of histamine released from mast cells. (2) Cleaning the wound to remove dirt and debris mimics the phagocytic activity of macrophages and neutrophils to eliminate foreign cells and material. (3) Applying bandages impregnated with platelet-recruiting compounds mimics the effect of chemokines released from injured tissues and macrophages, which attract circulating leukocytes and platelets to facilitate blood clotting and wound repair.

p. 1041 Fig. 51.3 understand Rubor (reddening) is due to increased blood flow to the infected or injured area. Mast cells trigger dilation of vessels by releasing signaling molecules. Calor (heat) is the result of fever, which is activated by the release of cytokines from macrophages that are in the area of infection. Tumor (swelling) occurs due to dilation of blood vessels triggered by mast cells and macrophages.

p. 1046 apply (1) In a human, 200 different light chains are possible (see text). The recombination of the *V*, *D*, and *J* segments results in $51 \times 27 \times 6 = 8262$ possible heavy chains. Since these chains combine to produce BCRs, a total of $200 \times 8262 = 1{,}652{,}400$ are possible within a human. (2) Only one type of antibody can be produced from a single human B cell.

p. 1047 CYU (1) understand The production of BCRs and TCRs via DNA recombination is required for an effective response. Selection against self-reactive lymphocytes is required for a safe response. **(2)** understand The cell is able to make a larger number of differing variable regions per unit of DNA when the variable region is segmented. For example, 3 segments of *V* and 3 segments of *J* can randomly assemble into 8 different variable light chains, whereas only 6 light chains would be possible with the same amount of DNA if the *V* regions were preassembled.

p. 1048 understand "Clonal" refers to the cloning—producing many exact copies—of cells that are "selected" by the binding of their receptor to a specific antigen (or MHC–peptide complex, which is introduced later).

p. 1050 understand See **TABLE A51.1**.

p. 1051 CYU create Individuals who are heterozygous for MHC genes have greater variability in their MHC proteins than do individuals who are homozygous for these genes. The increased variability in MHC proteins allows a greater variety of peptides to be presented to T cells, which thus would be able to recognize, attack, and eliminate a wider range of pathogens compared with T cells in homozygotes. As a result, heterozygous individuals would likely suffer fewer infections than homozygous individuals.

p. 1054 Fig. 51.17 apply See **FIGURE A51.2**. The response to the new antigen would resemble the primary response that occurred after the first injection of the original antigen.

p. 1055 CYU analyze Attenuated viruses are able to infect the cells of a vaccinated host, but not well enough to cause disease. Inactivated viruses are not able to infect cells at all, and instead remain as extracellular particles. Since attenuated viruses can infect cells, their antigens will be processed and presented by class I MHC complexes, which will promote a stronger cell-mediated response than the inactivated viruses.

IF YOU UNDERSTAND . . .

51.1 understand Toll-like receptors recognize molecular patterns of broad groups of pathogens, such as viruses, fungi, and bacteria. Upon binding to these molecules, the receptors cause signals to be transduced that activate cellular responses directed at eliminating these types of pathogens. **51.2** analyze The BCR locus would be smaller in mature B cells compared to immature cells, since recombination between the gene segments resulted in removing sections of DNA. **51.3** understand Antigen-presenting cells activate the $CD4^+$ T cells that are required for the full activation of B cells to differentiate into plasma cells. **51.4** understand Extracellular viruses are agglutinated and inactivated by antibodies produced in the humoral response. Intracellular viruses are eliminated by the destruction of their host via cytotoxic T cells in the cell-mediated response. **51.5** apply The IgE antibodies generate hypersensitive responses. When these are severe, they can lead to anaphylactic shock. If IgE antibodies were generated against self molecules, you would expect a strong response that will lead to either anaphylactic shock or chronic inflammation.

YOU SHOULD BE ABLE TO . . .

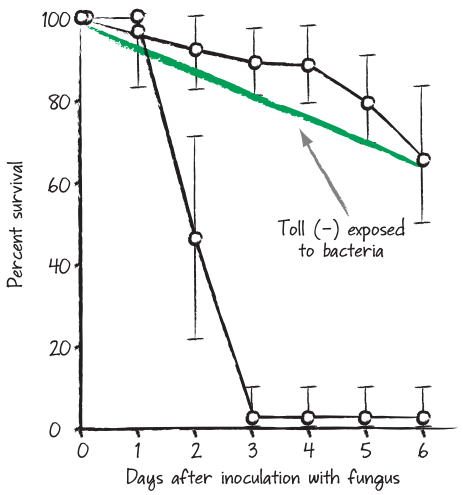
✔ Test Your Knowledge

1. remember c **2.** understand a **3.** remember b **4.** understand They are identical except that a B-cell receptor has a transmembrane domain that allows it to be located in the B-cell

TABLE A51.1

MHC type	Origin of Peptide	Type of T cell that binds	Activity stimulated
Class I MHC	Host cell cytosol	CD8+	Activates T cell to secrete molecules that kill infected cell
Class II MHC	Extracellular environment	CD4+	Activates T cell to secrete cytokines that support the immune response of other cells

FIGURE A51.1



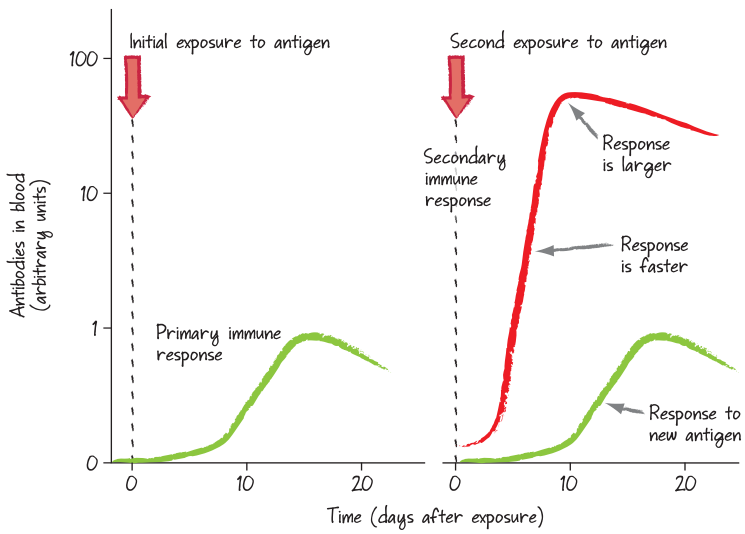


FIGURE A51.2

plasma membrane. **5.** remember c **6.** understand The hygiene hypothesis claims that immune disorders such as allergies and autoimmunity have increased in frequency due to the implementation of hygienic practices that decrease common bacterial, viral, and parasitic infections.

Test Your Understanding

7. understand B cells are first activated to divide via interactions between the BCRs and their complementary antigens. They are then fully activated to differentiate and continue to divide when their class II MCH–peptide complex interacts with an activated $CD4^+$ T cell that has a complementary TCR. **8.** analyze Both the BCR and TCR interact with epitopes of antigens via binding sites located in the variable regions of their polypeptide chains. A TCR is like one "arm" of a BCR. The BCR can interact with an antigen directly, while the TCR interacts with its epitope in the context of an MHC protein presented by another cell. **9.** analyze Vaccines have to contain an antigen that can stimulate an appropriate primary immune response. Vaccines have not worked for HIV, because the antigens on this virus are constantly changed through mutation, rendering it unrecognizable to memory cells generated following vaccination. **10.** analyze b **11.** analyze Pattern-recognition receptors on leukocytes bind to surface molecules that are present on many pathogens. BCRs and TCRs bind to particular epitopes of antigens that are pathogen specific. Pattern-recognition-receptor binding directly activates the cell, while BCRs and TCRs often require additional signals to become fully activated. **12.** understand The mixing and matching of different combinations of gene segments from the variable and joining regions of the light-chain immunoglobulin gene, along with diversity regions of the heavy-chain gene, gives lymphocytes a unique sequence in both chains of the BCR. The variable regions in the alpha and beta chains of the TCR are assembled from segments in a similar manner.

Test Your Problem-Solving Skills

13. apply d **14.** create If B cells have receptors that bind to self molecules during maturation, they would become activated during the maturation process. Instead of the signal causing the cells to divide, these immature B cells might respond to the signal by becoming permanently inactivated or might be induced to undergo apoptosis. **15.** analyze Natural selection favors individuals that can create a large array of antibodies, because the high mutation rates and rapid evolution observed in pathogens means that they will constantly present the immune system with new antigens. If these antigens were not recognized by the immune system, the pathogens would multiply freely and kill the individual. **16.** analyze Tissue from the patient's own body is marked with the major histocompatibility (MHC) proteins that the patient's immune system recognizes as self. This results in the preservation, rather than the destruction, of the transplanted tissue. Tissue from a different person is marked with MHC proteins that are unique to that individual. The body of the transplant recipient will recognize the MHC proteins (and other molecules) of the donor as foreign, resulting in a full immune response and rejection of the grafted tissue.

CHAPTER 52

IN-TEXT QUESTIONS AND EXERCISES

p. 1062 Fig. 52.1 apply It would increase, because cattle would no longer succumb to the disease carried by tsetse flies. (In Africa, cattle are limited more by biotic conditions than abiotic conditions.)
p. 1064 Fig. 52.4 apply Since there were 28 plots and four treatments, there were probably about seven replicate plots per treatment. This is important because the abiotic and biotic characteristics of individual plots are likely to vary in natural landscapes.
p. 1066 apply See **FIGURE A52.1**.
p. 1067 CYU (1) apply There is little rain at the North Pole because dense, dry air descends and absorbs moisture. **(2)** apply The highest risk of skin cancer is in the tropics where the Sun is often directly overhead, resulting in a large amount of solar radiation per unit area.
p. 1069 Fig. 52.10 analyze Most of the remaining wildlands occur in Canada, at the top of the image.
p. 1070a understand Vines and epiphytes increase productivity because they are photosynthetic organisms that fill space between small trees and large trees—they capture light and use nutrients that might not be used in a forest that lacked vines and epiphytes.
p. 1070b understand Most leaves have a large surface area to capture light. Light is abundant in deserts, however, and plants with a large surface area would be susceptible to high water loss and/or overheating.
p. 1071a understand Crop grains like wheat and corn are grasses, so they thrive in the grassland biome.
p. 1071b apply There is a continuous grass cover and scattered trees. (A biome like this is called a savanna.)
p. 1072a apply Boreal forests should move north.
p. 1072b understand High elevations present an abiotic environment (precipitation and temperature) that is similar to the conditions in arctic tundra. As a result, the plant species present will have similar adaptations to cope with these physical conditions. These similarities are the result of convergent evolution.
p. 1073 Fig. 52.17 analyze Visible wavelengths enter the chamber from the top and through the glass, warming the plants and ground inside the chamber. Some of this heat energy is retained within the mini-greenhouse.
p. 1074 CYU (1) analyze Tropical dry forests are probably less productive than tropical wet forests because they have less water available to support photosynthesis during some periods of the year. **(2)** apply Your answer will depend on where you live. For example, if global warming continues at the current projected rates, several effects can be expected. If you live in a coastal area, you can expect water levels to rise. In general, plant communities will change because average temperature and moisture—and variation in temperature and moisture—will change. Also, development is likely to increase in most areas, transforming the landscape.
p. 1077a apply The littoral zone, because light is abundant and nutrients are available from the substrate.
p. 1077b apply Bogs are nitrogen poor, so plants that are able to capture and digest insects have a large advantage. This advantage does not exist in marshes and swamps, where nutrients are more readily available.
p. 1078a apply Cold water contains more oxygen than warm water, so it can support a higher rate of cellular respiration.
p. 1078b apply Species that live in estuaries must be able to tolerate variable salinity; freshwater marsh species do not. The abiotic environment (salt concentration) is so different that few species grow well in both habitats.
p. 1079 apply No—the aphotic zone is lightless, so natural selection favors individuals that do not invest energy in developing and maintaining eyes.

IF YOU UNDERSTAND . . .

52.1 understand Populations are made up of individual organisms; communities are made up of populations of different species; ecosystems are made up of groups of communities along with the abiotic environment; the biome is made up of all the world's ecosystems. **52.2** apply The Argentine ants would likely increase their range into the moist agricultural fields, displacing native ants. **52.3** apply All latitudes would get equal amounts of sunlight all year round. There would be no seasons and no changes in climate with latitude. **52.4** apply If precipitation does not increase, then increased transpiration rates will put plants under water stress and reduce productivity. **52.5** apply Like deserts, open oceans have plenty of sunlight but very low productivity. Unlike deserts, which are water limited, open oceans are nutrient limited.

YOU SHOULD BE ABLE TO . . .

Test Your Understanding

7. create Examples of possible questions: *Organismal:* How do humans cope with extremely hot (or cold) weather conditions? *Population:* How large will the total human population be in 50 years? *Community:* How are humans affecting ocean species such as cod and tuna? *Ecosystem:* How does nitrogen runoff from agricultural fields affect the availability of oxygen in the Gulf of Mexico? *Global:* How will human-induced changes in global temperature affect sea level? **8.** apply *Biotic*: These ants compete with native ants. *Abiotic*: Argentine ants require moist conditions, not too cold, not too hot. These factors interact; Argentine ants outcompete native ants in moist environments, but competition slows down their dispersal. **9.** apply b **10.** analyze Productivity in intertidal and neritic zones is high because sunlight is readily available and because nutrients are available from estuaries and deep-ocean currents. Productivity in the oceanic zone is extremely low—even though light is available at the surface—because nutrients are scarce. The deepest part of the oceanic zone may have nutrients available from the substrate but lacks light to support photosynthesis. **11.** analyze As elevation increases, biomes often change in a similar way as increasing in latitude (e.g., you might go from temperate forest to a boreal-type forest to tundra). **12.** analyze The natural biome of Eastern North America is primarily temperate forest. However, most of this area is now occupied by human-influenced biomes such as cities, suburbs, and farmland.

FIGURE A52.1

✔ Test Your Problem-Solving Skills

13. apply a **14.** create A single population of lizards was split when South America split from Africa due to continental drift. Fossils are too old to represent animals dispersed by human travel. **15.** evaluate Yes. As average global temperatures increase, some organisms may be able to adapt by moving their range. As mountaintops warm, however, organisms adapted to cold conditions will have nowhere to go. Ecologists have good reason to be concerned about these possible extinctions. **16.** create Temperature is relatively constant in the tropics all year, whereas temperature fluctuates dramatically at higher latitudes. Organisms that are physiologically adapted to constant temperatures may not have as much genetic variation for traits that enable adaptation to higher temperatures, compared to organisms at higher latitudes, which are adapted to tolerate different temperatures at different times of the year.

CHAPTER 53

IN-TEXT QUESTIONS AND EXERCISES

p. 1086 Fig. 53.4 analyze Even though half of each plot serves as a control, the natural landscape varies within plots, so there is a chance that foraging in the two subplots could be different due to factors not measured in the experiment. By measuring foraging activity before adding owls and seeds, the researchers established an additional control and a baseline.
p. 1087 CYU apply If owls were allowed to hunt within the treatment subplots, the threat of predation would increase. A larger amount of supplementary seed would be required to compensate for the increased risk of foraging. Gerbils do not consciously calculate costs and benefits. One possible proximate explanation is that the presence of hunting owls would increase the stress level in the gerbils (e.g., the hormone cortisol), which could suppress the hunger of the gerbils or reduce their drive to find food.
p. 1088 Fig. 53.6 analyze To form a better control, bring females into the lab and give them the same food and housing conditions as the treatment groups, but expose them to artificial lighting that simulates the short daylight conditions of winter.
p. 1089 CYU (1) analyze As in lizards, a rise in sex hormones in humans is a proximate cause of sexual readiness. **(2)** analyze Humans, like lizards, tend to choose a mate who will increase their fitness. For example, women often prefer men who will be able to help provide for offspring.
p. 1090 Fig. 53.7 apply The data would either be distributed randomly around the circles, showing no preference for direction, or the turtles would swim the same direction in both cases, suggesting that they are using compass orientation rather than map orientation.
p. 1093 Fig. 53.10 apply See **FIGURE A53.1**.
p. 1095 CYU (1) analyze Auditory communication allows individuals to communicate over long distances but can be heard by predators. Olfactory communication is effective in the dark, and scents can continue to carry information long after the signaler has left, but scents do not carry long distances. Visual communication is effective during the day but can be seen by predators. **(2)** apply The ability to detect deceit protects the individual from fitness costs (e.g., being eaten, having a mate's eggs fertilized by someone else); avoiding or punishing "liars" should also lower the frequency of deceit (because it becomes less successful). Alleles associated with detecting and avoiding or punishing liars should be favored by natural selection and increase in frequency.
p. 1096 Fig. 53.14 apply Between first cousins, $r = 1/2n \times 1/2n \times 1/2n = 1/8$.
p. 1097 apply Humans often live near kin, are good at recognizing kin, and in many cases can give kin resources for protection that increase fitness.
p. 1097 Fig. 53.15 create The control would be to drag an object of similar size through the colony, at similar times of day. This would test the hypothesis that prairie dogs are reacting to the presence of the experimenter and the disturbance—not to a predator.

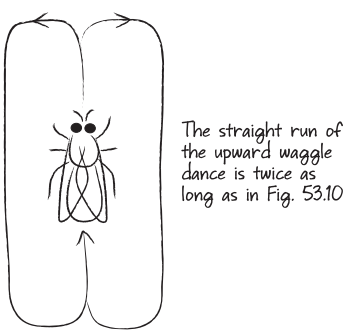
IF YOU UNDERSTAND . . .

53.1 apply At the proximate level of causation, human teens experience an increase in the sex hormones testosterone and estrogen, which increases sex drive. At the ultimate level of causation, teens with a higher sex drive will, on average, have more offspring, which will increase their fitness and pass along their alleles at a higher rate than individuals with a lower sex drive. **53.2** apply You would have to consider variables that provide costs and benefits to the web-building spiders. For example, spinning silk and building webs uses up energy, so the size of the web, the amount of material used to build the web, and the frequency of building webs should be considered, as well as the effect of web-building on vulnerability to predation. But large, well-built webs can increase prey capture, so the rate of capture of prey of various types of webs also should be considered.
53.3 create Only a bowerbird with plenty of resources could afford the time and energy to build a highly decorated bower. Thus, the decoration behavior is likely an honest signal of male fitness. **53.4** create Migration is condition-dependent in some birds. If enough food is available locally, the costs of migration outweigh the benefits, so the birds' fitness will be higher if they stay put. **53.5** apply Deceitful communication should decrease. If large males are gone, few nests are available and more female-mimic males would compete at them. Most female-mimic males would have no (or fewer) eggs to fertilize and no male to take care of the eggs they did fertilize. There would be less natural selection pressure favoring deceitful communication. **53.6** understand (1) Long-lived, so that extensive interactions with kin and nonrelatives are possible; (2) good memory, to record reciprocal interactions; (3) kin nearby, to make inclusive fitness gains possible; (4) ability to share fitness benefits (e.g., food) between individuals.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. understand c **2.** understand Adaptive significance of behavior; how behavior affects fitness **3.** remember d **4.** understand c **5.** understand d **6.** understand c



✔ Test Your Understanding

7. understand The fitness of honeybees depends on how much energy they can bring into the hive by foraging. Hives with honeybees that successfully communicate locations of food resources will be favored by natural selection such that the frequency of alleles that determine the communication behavior will increase in the population. **8.** evaluate Evolution favors organisms that forage optimally—maximizing benefits and minimizing costs—increasing the frequency of optimal foraging in populations over time. However, individuals in populations vary and environmental circumstances vary. Some individuals will forage suboptimally and suffer reduced fitness. **9.** apply Only males that are in good shape (well nourished and free of disease) have the resources required to perform their displays. **10.** understand Longer day lengths indicate the arrival of spring, when renewed plant growth and insect activity make more food available. Courtship displays from males indicate the presence of males that can fertilize eggs. **11.** analyze This statement is true; sea turtles need both a map and a compass. A map provides information about the spatial relationships of places on a landscape; a compass allows sea turtles to orient the map—so that it aligns with the actual landscape. **12.** apply c

✔ Test Your Problem-Solving Skills

13. create One possibility would be to set up a testing arena with food supplies at various distances from the food source where adult flies are originally released. Identify rover and sitter adults by genotype and test them individually; then record how far each travels during a set time interval. If the rover and sitter alleles affect foraging movements in adults, then rovers should be more likely to move (and to move farther) than sitters. **14.** analyze a, b, c, d; the howler monkeys make condition-dependent decisions about what to eat and are likely to prefer high-energy foods, when available, or foods with nutrients or compounds that would increase their fitness. Hamilton's rule could be considered if some monkeys give the highest-quality foods to close relatives rather than consuming it themselves. **15.** analyze Individuals have an r of 1/2 with full siblings and an r of 1/8 with first cousins. If the biologist will lose his life, he needs to save two siblings, or eight first cousins, to keep the "lost copy" of his altruism alleles in the population. **16.** apply People would be expected to donate blood under two conditions: (1) They either received blood before or expect to have a transfusion in the future, and/or (2) they receive some other benefit in return, such as a good reputation among people who might be able to help them in other ways.

FIGURE A53.1

CHAPTER 54

IN-TEXT QUESTIONS AND EXERCISES

p. 1105 Fig. 54.2 apply See **FIGURE A54.1** (see A:48)
p. 1106 (1) apply Compared to northern populations, fecundity should be high and survivorship low in southern populations. **(2)** apply Fecundity can be much higher if females lay eggs instead of retaining them in their bodies and giving birth to live young.
p. 1109 Fig. 54.6 create At high population density, competition for food limits the amount of energy available to female song sparrows for egg production.
p. 1112 CYU create One possibility is competition for food. To test this idea, compare carrying capacity in identical fenced-in areas that differ only in the amount of food added. (You could also test a hypothesis of space limitation by doubling the size of the enclosure but keeping the amount of food the same.)
p. 1114 Fig. 54.10 apply When the population of hares was low, the rate of increase was not density dependent on food. That is, plenty of food was available for the few rabbits, so competition for this resource was low.
p. 1117 CYU (1) understand Developed nations have roughly equal numbers of individuals in each age class because the fertility rate has been constant and survivorship high for many years. Developing countries have many more

children and young people than older people, because the fertility rate and survivorship have been increasing. **(2)** understand Because survivorship is high in most human populations, changes in overall growth rate depend almost entirely on fertility rates.

p. 1118 Fig. 54.14 apply The total population size of first-generation females in the third year = 1000; in the fourth year = 240. The total population size of first- and second-generation females in the third year = 2308; in the fourth year = 1230. The number of 1-year-olds created by third-generation females (blue) is $981 \times 0.33 = 324$. The number of newborns (green) created by these 1-year-olds is $324 \times 4.0 = 1296$. Thus, the total population size at the end of the fourth year is expected to be $200 + 792 + 1296 + 324 + 198 + 40 = 2850$.

p. 1119 apply The population appears to be increasing over time: From the original 1000 females, there are 2308 females in the third year.

IF YOU UNDERSTAND . . .

54.1 create First you would need to observe snowshoe hares to determine how many pellets one individual can produce in one day, on average. Then you could use a quadrat to measure the number of fresh pellets produced in a known area of habitat in one day and use your pellets/hare number to convert this value to hares/area. **54.2** analyze In ancient Rome, survivorship was probably low and fecundity high—women started reproducing at a young age and did not live long, on average. In Rome today, the population has high survivorship and low fecundity. **54.3** apply See **FIGURE A54.2** **54.4** apply The population density of mosquitoes would not be constant over time. Ignoring the number of predators that might be present, you would expect high densities of these short-lived insects after rains, followed by low densities during extended dry periods. **54.5** understand Fewer children are being born per female, but there are many more females of reproductive age due to high fecundity rates in the previous generation. **54.6** apply Small, isolated populations are likely to be wiped out by bad weather, a disease outbreak, or changes in the habitat. But in a metapopulation, migration between the individual small populations helps reestablish populations and maintain the overall size of the metapopulation.

YOU SHOULD BE ABLE TO . . .

1. remember b **2.** remember births, deaths, immigration, emigration **3.** remember a **4.** remember True **5.** understand d **6.** understand c

✔ Test Your Understanding

7. remember c **8.** apply See **TABLE A54.1** **9.** create The population has undergone near-exponential growth recently because advances in nutrition, sanitation, and medicine have allowed humans to live at high density without suffering from decreased survivorship and fecundity. Eventually, however, growth rates must slow as density-dependent effects such as disease and famine increase death rates and lower birth rates. **10.** understand (a) Corridors allow individuals to move between populations, increasing gene flow and making it possible to recolonize habitats where populations have been lost. (b) Maintaining unoccupied habitat makes it possible for the habitat to be recolonized. **11.** apply *Lacerta vivipara* is most vulnerable at the southern edge of its ranges, such as in the mountains of Spain. These lizards are cold adapted and may become locally extinct in areas that become too warm **12.** analyze r_{max} gives the population growth rate in the absence of density-dependent limitation; r is the actual growth rate, which is usually affected by density-dependent factors.

✔ Test Your Problem-Solving Skills

13. apply Fewer older individuals will be left in the population; there will be relatively more young individuals. If too many older individuals are taken, population growth rate may decline sharply as reproduction stops or slows. (But if relatively few older individuals are taken, more resources are available to younger individuals and their survivorship and fecundity, and the population's overall growth rate, may increase.) **14.** create The sunflowers and beetles are both metapopulations. To preserve them, you must preserve as many of the sunflower patches as possible (or plant more) and maintain corridors (that may be smaller sunflower patches) along which the beetles can migrate between the patches. **15.** apply As a sexually transmitted disease, AIDS will reduce the number of sexually active adults. If the epidemic continues unabated, the numbers of both reproductive-age adults and children will decline, causing a top-heavy age distribution dominated by older adults and the elderly. See **FIGURE A54.3**. **16.** analyze c

CHAPTER 55

IN-TEXT QUESTIONS AND EXERCISES

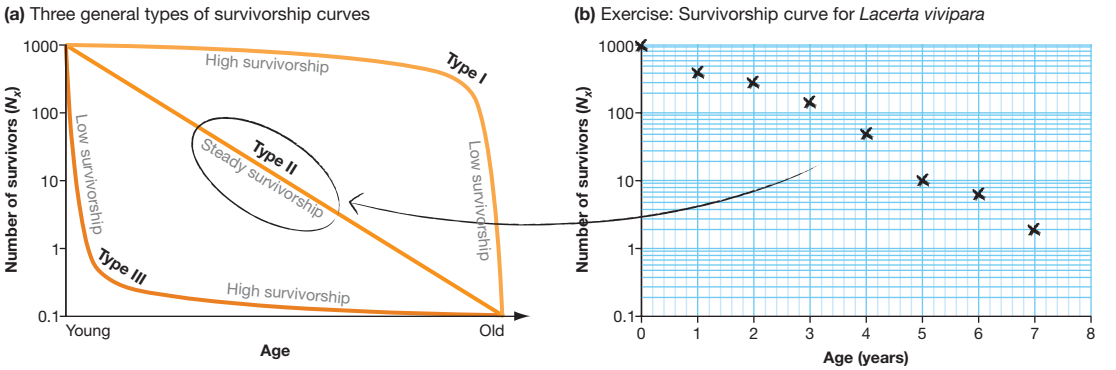
p. 1126 apply Your graph should look like Figure 55.4, with *Semibalanus* on the left, *Chthamalus* is on the right, and the *x*-axis indicating height in the intertidal zone. The realized niche of *Chthamalus* is in the upper intertidal zone.

p. 1127 Fig. 55.5 apply If Connell had done the treatments on different rocks, a critic could argue that differences in survival were due to differences in the nature of the rocks—not differences in competition.

p. 1128 apply Your graph should look like the bottom graph in Figure 55.6, showing that the niches of *Semibalanus* and *Chthamalus* are nonoverlapping with respect to height in the intertidal zone.

p. 1131 Fig. 55.10 apply This experimental design tested the hypothesis that mussels can sense the presence of crabs. If the crabs had been fed mussels, a critic could argue that the mussels detect the presence of damaged mussels—not crabs. (As it turns out, the mussels can do both. The experimenters did the same experiment with broken mussel shells in the chamber instead of a fish-fed crab.)

FIGURE A54.1



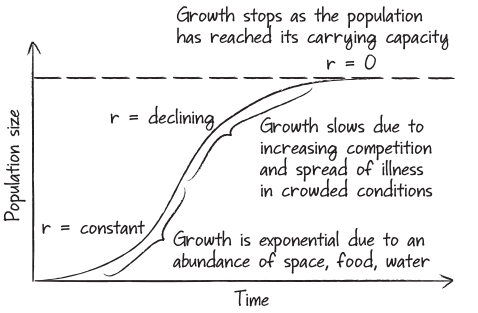


TABLE A54.1

Trait	Life-History Continuum		
	Left	Middle	Right
	High fecundity Low survivorship	Intermediate	Low fecundity High survivorship
Growth habit	Herbaceous	Shrub	Tree
Disease- and predator-fighting ability	Low	Medium	High
Seed size	Small	Medium	Large
Seed number	Many	Moderate	Few
Body size	Small	Medium	Large

FIGURE A54.2

p. 1133 Fig. 55.12 create Put equal numbers of infected and uninfected ants in a pen that includes a bird predator. Count how many of each type are eaten over time.
p. 1134 Fig. 55.13 apply Many possible answers. For example, acacia trees may expend energy in producing the large bulbs the ants live in and the food they eat. The *Crematogaster* ants may expend energy and risk injury or death in repelling herbivores. The cleaner shrimp may occasionally get injured or eaten by the fish they are cleaning, or their diets may be somewhat restricted by the association. The host fish may miss meals or be at greater risk of predation when they are undergoing cleaning by the shrimp. In both examples of mutualism, however, the overall associations are positive for both parties.
p. 1135 CYU (1) understand The individuals do not choose or try to have traits that reduce competition—they simply have those traits (or not). Resource partitioning just happens, because individuals with traits that allow them to exploit different resources produce more offspring, which also have those traits. (Recall from Chapter 25 that natural selection occurs on individuals, but adaptive responses such as resource partitioning are properties of populations.) **(2)** understand When species interact via consumption, a trait that gives one species an advantage will exert natural selection on individuals of the other species who have traits that reduce that advantage. This reciprocal adaptation will continue indefinitely. An example is the interaction of *Plasmodium* with the human immune system: The human immune system has evolved the ability to detect proteins from the *Plasmodium* and kill infected cells; in response, *Plasmodium* has evolved different proteins that the immune system does not detect.
p. 1135 Fig. 55.14 apply These steps controlled for the alternative hypothesis that differences in treehopper survival were due to differences in the plants they occupied—not the presence or absence of ants.
p. 1137 Fig. 55.15 analyze Predictable, at least to a degree.
p. 1142 CYU (1) understand The shade provided by early successional species increases humidity, and decomposition of their tissues adds nutrients and organic material to the soil. These conditions favor growth by later successional species, which can outcompete the early successional species. **(2)** understand The presence or absence of a plant species where nitrogen fixation occurs would dramatically alter nutrient conditions, and thus the speed of succession and the types of species that could become established. For example, species that require high nitrogen would be favored on sites where alder grew, and species that can tolerate low nitrogen would thrive on sites where alder is absent.
p. 1142 Fig. 55.22 apply The effect would be to make the island more remote, which would lower the rate of immigration and move the whole immigration curve downward. The rate of extinction would increase, shifting the curve upward. The overall effect would be to decrease the number of species, because the island effectively would have become more remote.
p. 1143 analyze The calculations for community 1 are as follows. (Note that your final answer is sensitive to the number of digits you use in your calculations; see BioSkills 1 in Appendix B).

Species A
$p_A = 10/18 = 0.555$
$\ln 0.555 = -0.589$
$-0.589 \times 0.555 = -0.327$

Species B
$p_B = 1/18 = 0.0555$
$\ln 0.0555 = -2.891$
$-2.891 \times 0.0555 = -0.160$

Species C
$p_C = 1/18 = 0.0555$
$\ln 0.0555 = -2.891$
$-2.891 \times 0.0555 = -0.160$

Species D
$p_D = 3/18 = 0.167$
$\ln 0.167 = -1.790$
$-1.790 \times 0.167 = -0.299$

Species E
$p_E = 2/18 = 0.111$
$\ln 0.111 = -2.198$
$-2.198 \times 0.111 = -0.244$

Species F
$p_F = 1/18 = 0.0555$
$\ln 0.0555 = -2.891$
$-2.891 \times 0.0555 = -0.160$

Summing the values of $p \times \ln p$ for each species and multiplying by -1 gives the Shannon index of species diversity for community 1:

$$(-1)[(-0.327) + (-0.160) + (-0.160) + (-0.299) + (-0.244) + (-0.160)] = 1.350$$

Similar calculations would give species diversity values of 1.794 for community 2 and 1.610 for community 3.

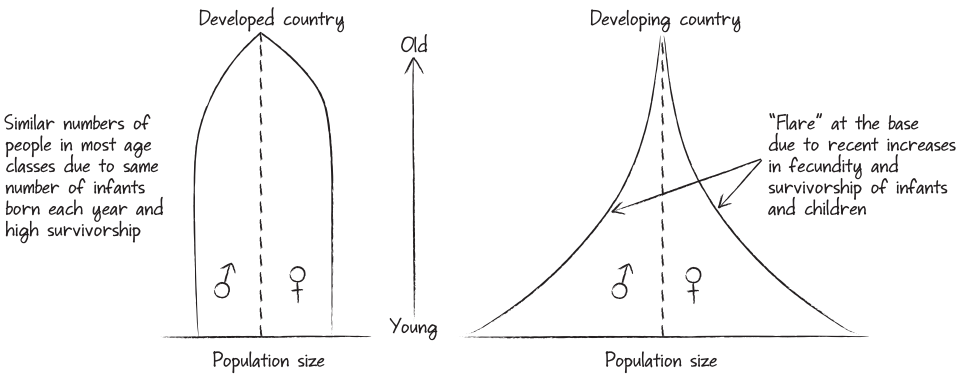
IF YOU UNDERSTAND . . .

55.1 understand A mutualistic relationship becomes a parasitic one if one of the species stops receiving a benefit. The treehopper–ant mutualism becomes parasitic in years when spiders are rare, because the treehoppers no longer derive a benefit but pay a fitness cost (producing honeydew that the ants eat). **55.2** apply An invasive species could have a large impact on community structure by replacing the dominant plant species that creates physical structure, which in turn affects other members of the community; by replacing a keystone species that has an indirect effect on many other species; or by outcompeting many species, causing a direct reduction in species richness. **55.3** apply All species at Glacier Bay must be able to survive in a cold climate with the local amount of precipitation. The species earliest in the succession must also be able to grow on rock exposed as the glacier melts. But chance, historical differences in seed sources, and presence or absence of alder (and nitrogen fixation) created differences in the species present. **55.4** apply Many national parks are surrounded by altered habitats, so they are functionally similar to islands. Species richness in the park is more likely to be preserved if it is large and located nearby other wilderness areas.

YOU SHOULD BE ABLE TO . . .

✓ Test Your Knowledge

1. remember True **2.** remember a **3.** remember d **4.** understand d **5.** remember fecundity **6.** remember c



✓ Test Your Understanding

7. evaluate Yes—the treehopper–ant mutualism is parasitic or mutualistic, depending on conditions; competition can evolve into no competition over time if niche differentiation occurs; arms races mean that the outcome of host–parasite interactions can change over time, and so forth (many other examples). **8.** understand b **9.** evaluate (a) If community composition is predictable, then the species present should not change over time. But if composition is not predictable, then that species should undergo significant changes over time. (b) If community composition is predictable, then two sites with identical abiotic factors should develop identical communities. If community composition is not predictable, then sites with identical abiotic factors should develop variable communities. In most tests, the data best match the predictions of the "not predictable" hypothesis, though communities show elements of both. **10.** analyze Disturbance is any short-lived event that changes the distribution of resources. Compared to low-frequency fires, high-frequency fires would tend to be less severe (less fuel builds up) and would tend to exert more intense natural selection for adaptations to resist the effects of fire. Compared to low-severity fires, high-severity fires would open up more space for pioneering species and would tend to exert more intense natural selection for adaptations to resist the effects of fire. **11.** apply Early successional species are adapted to disperse to new environments (small seeds) and grow and reproduce quickly (reproduce at an early age, grow quickly). They can tolerate severe abiotic conditions (high temperature, low humidity, low nutrient availability) but have little competitive ability. These species are able to enter a new environment (with no competitors) and thrive. These attributes are considered adaptations because they increase the fitness of these species. **12.** analyze The idea is that high productivity will lead to high population density of consumers, leading to competition and intense natural selection favoring niche differentiation that leads to speciation.

✓ Test Your Problem-Solving Skills

13. analyze Natural selection will favor orchid individuals that have traits that resist bee attack: thicker flower walls, nectar storage in a different position, a toxin in the flower walls, and so on. Individuals could also be favored if their anthers were in a position that accomplished pollination even if bees eat through the walls of the nectar-storage structure. **14.** apply b **15.** apply The exact answer will depend on the location of the campus. The first species to appear must possess good dispersal ability, rapid growth, quick reproductive periods, and tolerance for very harsh and severe conditions. The two-acre plot is likely to be colonized first by pioneer species that have very "weedy" characteristics. But once colonization is under way, the course of succession will depend more on how the various species interact with each other. The presence of one species can inhibit or facilitate the arrival and establishment of another. For example, an early-arriving species might provide the shade and nutrients required by a late-arriving species. The site's history and nearby ecosystems may influence which species appear at each stage; for instance, an undisturbed ecosystem nearby could be a source for native species. The pattern and rate of this succession is also influenced by the overall environmental conditions affecting it. Only species with traits appropriate to the local climate are likely to colonize the site. **16.** create One reasonable experiment would involve constructing artificial ponds and introducing different numbers of plankton species

FIGURE A54.3

to different ponds, but the same total number of individuals. (Any natural immigration to the ponds would have to be prevented.) After a period of time, remove all of the plankton and measure the biomass present. Make a graph with number of species on the *x*-axis and total biomass on the *y*-axis. If the hypothesis is correct, the line of best fit through the data should have a positive slope.

CHAPTER 56

IN-TEXT QUESTIONS AND EXERCISES

p. 1152 apply To grow a kilogram of beef, first you have to grow 10 kg of grain or grass and feed it to the cow. Only 10 percent of this 10 kg will be used for growth and reproduction—the other 9 kg is used for cellular respiration or lost as heat.
p. 1152 apply Crustaceans and fish are ectothermic, so they are much more efficient at converting primary production into the biomass in their bodies than are endothermic birds and mammals.
p. 1153 apply Tuna are top predators in marine food webs. Mercury occurs in low concentrations in the water, but accumulates in higher concentrations at each trophic level. A person who eats a lot of tuna will accumulate mercury over time, potentially causing mercury poisoning. Sardines are primary consumers, a low trophic level, and therefore are not in danger of biomagnification of mercury.
p. 1155 Fig. 56.10 apply Average NPP = 125 g/m^2/year. Area = 65%. Although NPP in the ocean is very small, the ocean is so vast that it ends up being the largest contributor to total NPP.
p. 1156 CYU (1) understand At each trophic level, most of the energy that is consumed is lost to cellular respiration and ultimately heat, metabolism, or other maintenance activities, which leaves only a small percentage of energy for biomass production (growth and reproduction).
(2) apply Since NPP depends on temperature, it is logical to predict that NPP will increase with global warming. (However, Section 56.3 explains that global warming changes precipitation patterns, ocean stratification, and other factors that can limit NPP).
p. 1157 understand When the trees of tropical rain forests are hauled away and the remnants of the forest are burned, the nutrients are exported from the site, leaving only poor soil to nourish the crops.
p. 1158 Fig. 56.13 create One logical hypothesis is that the total amount exported increases as tree roots and other belowground organic material decay and begin to wash into the stream; the amount exported should begin to decline as nitrate reserves become exhausted—eventually, there is no more nitrate to wash away.
p. 1159 Fig. 56.14 apply Much more water should evaporate. One possibility is that more water vapor will be blown over land and increase precipitation over land.
p. 1162 CYU apply **Water**: perhaps the most direct impacts concern rates of groundwater replenishment. Converting biomes into farms or suburbs decreases groundwater recharge and increases runoff. Irrigation pumps groundwater to the surface, where much of it runs off into streams. **Nitrogen**: Humans introduce huge quantities of nitrogen into ecosystems as fertilizer. **Carbon**: Humans are releasing huge quantities of stored carbon, in the form of fossil fuels, into the atmosphere as CO_2. Whereas humans are depleting supplies of freshwater below natural levels, we are increasing quantities of N and C above natural levels.
p. 1164 Fig. 56.22 analyze Photosynthesis increases in summer, resulting in removal of CO_2 from the atmosphere.
p. 1165 Fig. 56.23 apply $2 \times 7000 = 14{,}000$ million metric tons of CO_2, double the current total.
p. 1168 apply The pH of the water will fall (acidity will increase) because CO_2 from your breath reacts with water to form carbonic acid.

IF YOU UNDERSTAND . . .

56.1 apply Tofu is a plant, a primary producer at the base of the productivity pyramid. Cows are primary consumers, one level up. It would be about 10 times more efficient to eat tofu, because 10 times the quantity of plants would be necessary to provide one pound of beef.
56.2 apply Decomposition is slowest in cold, wet temperatures on land and in anoxic conditions in the ocean (or in freshwater). Stagnant water often becomes anoxic as decomposers use up available oxygen that is not replenished by diffusion from the atmosphere. **56.3** apply Many possible answers, including (1) reducing carbon dioxide emissions by finding alternatives to fossil fuels should decrease the amount of carbon dioxide released into the atmosphere, (2) recycling programs decrease carbon dioxide emissions from manufacturing plants and power plants, and (3) reforestation can tie up carbon dioxide in wood.

YOU SHOULD BE ABLE TO . . .

✓ Test Your Knowledge

1. remember True **2.** understand d **3.** understand a **4.** remember c **5.** remember c **6.** remember b

✓ Test Your Understanding

7. apply a **8.** analyze Sharks normally eat fish that eat the herbivorous fish that keep the growth of algae on corals in check. When sharks are absent, more of the intermediate fish survive, which decreases the number of herbivorous fish, causing algae to thrive on the coral reef. **9.** analyze Warmer, wetter climates speed decomposition; cool temperatures slow it. Decomposition regulates nutrient availability because it releases nutrients from detritus and allows them to reenter the food web.
10. evaluate Yes, corals would be a good choice. Corals are important ecologically because they have a high NPP, providing energy to diverse animals in reef food webs. Corals are also vulnerable to climate change from the increase in water temperature, which can cause bleaching (loss of photosynthetic algae), as well as from the effects of ocean acidification, which slows the rate of coral growth. **11.** analyze Forest fires are an example of positive feedback; drier, hotter summers increase the risk of fires, and fires release CO_2 to the atmosphere, increasing global warming and the risk of fires. Forest growth is an example of negative feedback; as CO_2 increases in the atmosphere, the rate of forest growth in some areas may increase (due to increased availability of CO_2, increased temperature, and/or increased precipitation), reducing the concentration of CO_2 in the atmosphere. **12.** analyze The open ocean has almost no nutrient input from the land and has little upwelling to supply nutrients from the deep ocean. In contrast, intertidal and coastal areas receive large inputs of nutrients from rivers as well as from upwellings from ocean depths.

✓ Test Your Problem-Solving Skills

13. create One possibility is to add radioactive nitrogen to the water of the ponds in natural concentrations (control ponds) and elevated nitrogen concentrations (treatment ponds) and then follow this isotope through the primary producers, primary consumers, and secondary consumers in the system by measuring the amount of radioisotope in the tissues of organisms, and quantity of biomass, at each trophic level in the treatment versus control ponds **14.** evaluate c **15.** apply Without herbivores, there is no link in the nitrogen cycle between primary producers and secondary consumers. All of the plant nitrogen would go to the primary decomposers and back into the soil. If decomposition is rapid enough, nitrogen would cycle quickly between primary producers, decomposers, the soil, and back to primary producers.
16. apply Atmospheric oxygen would increase due to extensive photosynthesis, but carbon dioxide levels would decrease because little decomposition was occurring. The temperature would drop because fewer greenhouse gases would be trapping heat reflected from the Earth's surface.

CHAPTER 57

IN-TEXT QUESTIONS AND EXERCISES

p. 1177 CYU create Do an all-taxon survey: organize experts and volunteers to collect, examine, and identify all species present. This could include direct sequencing studies (see Chapter 29) to document the bacteria and archaea present in different habitats on campus.
p. 1178 Fig. 57.7 apply Nearly all endangered species are threatened by more than one factor and therefore appear on the graph more than once, leading to species totals greater than 100 percent.
p. 1180 Fig. 57.9 analyze Because the treatments and study areas were assigned randomly, there is no bias involved in picking certain areas that are unusual in terms of their biomass or species diversity. They should represent a random sample of biomass and species diversity in fragments of various sizes versus intact forest.
p. 1183 Using the equation $S = (18.9)A^{0.15}$, plug in 5000 km^2 for A and solve for S such that $S = 18.9 \times 5000^{0.15} = 68$ species.
p. 1184 CYU (1) understand Fragmentation reduces habitat quality by creating edges that are susceptible to invasion and loss of species, due to changed abiotic conditions. Genetic problems occur inside fragments as species become inbred and/or lose genetic diversity via genetic drift. **(2)** create Habitat destruction and fragmentation in Borneo are obvious from the clear-cut areas. Overexploitation could be assessed by interviewing local citizens and law enforcement officers to the history of poaching orangutans for the pet trade or for other uses. Effects from invasive species could be assessed by published or local accounts of community structure over time. Pollution could be assessed by direct measurement of soil, water, air, and possibly tissue samples (in dead orangutans, feces, or blood samples). The effects of climate change could be assessed based on local weather records.
p. 1185 Fig. 57.12 analyze *Null hypothesis:* NPP is not affected by species richness or functional diversity of species. *Prediction:* NPP will be greater in plots with more species and more functional groups. *Prediction of null:* There will be no difference in NPP based on species richness or number of functional groups.
p. 1188 CYU create Establish several study plots in an area of Borneo where some of the forest has been converted to palm plantation but the adjacent forest (of similar elevation and topography) has rain forest still intact—half of the plots in the plantation and half in the rain forest. Monitor soil depth, soil nutrient levels, precipitation, and stream sediment levels regularly, and compare after several years.
p. 1191 Fig. 57.16 apply See **FIGURE A57.1**.

IF YOU UNDERSTAND . . .

57.1 apply At the genetic level, you could measure the genetic diversity of the orangutan population by comparing DNA sequences obtained from blood or feces samples. This information could help you to determine if a genetic bottleneck had occurred during the clear-cutting period. At the species level, you could monitor the increase in species richness of trees, birds, mammals, and other groups as the restoration progressed. At the

ecosystem level, you could measure the ability of the growing forest to retain nutrients in the soil, prevent erosion, trap carbon, increase the prevalence of rain, and other functions **57.2** apply Small, geographically isolated populations of orangutans have low genetic diversity due to lack of gene flow and genetic drift and can suffer from inbreeding depression. Low genetic diversity makes them vulnerable to changes in their habitat, and small population size makes them susceptible to catastrophic events such as storms, disease outbreaks, or fires. **57.3** apply If many species are present, and each uses the available resources in a unique way, then a larger proportion of all available resources should be used—leading to higher biomass production. **57.4** evaluate Twelve percent of land area is already protected, but a mass extinction event is still going on. This is because 12 percent is not sufficient to save most species, and because many or most protected areas are not located in biodiversity hotspots.

YOU SHOULD BE ABLE TO . . .

✔ Test Your Knowledge

1. remember d **2.** remember a **3.** remember b **4.** remember d **5.** understand c **6.** understand overexploitation

✔ Test Your Understanding

7. analyze b **8.** analyze By comparing the number of species estimated to reside in the park before and after the survey, biologists will have an idea of how much actual species diversity is being underestimated in other parts of the world—where research was at the level of Great Smoky Mountains National Park before the survey. The limitation is that it may be difficult to extrapolate from the data—no one knows if the situation at this park is typical of other habitats. **9.** evaluate No one correct answer; there are good arguments for both. In a case like the orangutans of Borneo, it is not possible to save the orangutans without saving their ecosystem. On the other hand, it is much easier to attract money and volunteers to help save a charismatic primate like an orangutan than to save a patch of forest. Both types of efforts are needed, their relative importance depends on the circumstance. **10.** evaluate In experiments with species native to North American grasslands, study plots that have more species produce more biomass, change less during a disturbance (drought), and recover from a disturbance faster than study plots with fewer species. **11.** understand Wildlife corridors facilitate the movement of individuals. Corridors allow areas to be recolonized if a species is lost and enable the introduction of new alleles that can counteract genetic drift and inbreeding in small, isolated populations. **12.** apply Ecosystem services are beneficial effects that ecosystems have on humans. It is rare to own or pay for these services, so no one has a vested interest in maintaining them. This is a primary reason that ecosystems are destroyed, even though the services they offer are valuable. The exception would be landowners who are paid *not* to log their forests, to maintain ecosystem functions like carbon storage.

✔ Test Your Problem-Solving Skills

13. apply d **14.** create Catalog existing biodiversity at the genetic, species, and ecosystem levels. Using these data, find areas that have the highest concentration of biodiversity at each level. Protect as many of these areas as possible, and connect them with corridors of habitat. **15.** evaluate There is no "correct" answer. One argument is that conservationists could lobby officials in Brazil and Indonesia to learn from the mistakes made in developed nations, and preserve enough forests to maintain biodiversity and keep ecosystem services intact—avoiding the expenditures that developed countries had to make to clean up pollution and restore ecosystems and endangered species. **16.** analyze Species with specialized food or habitat requirements, large size (and thus large requirements for land area), small population size, and low reproductive rate are vulnerable to extinction. A good example is the koala bear. Species that are particularly resistant to pressure from humans possess the opposite of many of these traits. A good example of a resistant species is the Norway rat.

BIG PICTURE Ecology

p. 1196 CYU (1) analyze Species interactions "are agents of" natural selection. **(2)** analyze As the human population climbs, more resources are needed to support the population. The harvesting of resources affects other species both directly (e.g. overfishing) and indirectly (e.g. climate change), resulting in decreased biodiversity. **(3)** analyze Both energy and nutrients flow through trophic levels in food webs. However, energy flows in one direction, ultimately dissipating as heat, whereas nutrients continue to cycle through ecosystems. **(4)** apply Human behavior "increases emissions of" CO_2 "causes" greenhouse effect "causes" climate change.

FIGURE BA.4

APPENDIX B BioSkills

BIOSKILL 1 the metric system and significant figures

Scientists ask questions that can be answered by observing or measuring things—by collecting data. What units are used to make measurements? When measurements are reported, how can you tell how reliable the data are?

The Metric System

The metric system is the system of units of measure used in every country of the world but three (Liberia, Myanmar, and the United States). It is also the basis of the SI system—the International System of Units (abbreviated from the French, *Système international d'unités*)—used in scientific publications.

The popularity of the metric system is based on its consistency and ease of use. These attributes, in turn, arise from the system's use of the base 10. For example, each unit of length in the system is related to all other measures of length in the system by a multiple of 10. There are 10 millimeters in a centimeter; 100 centimeters in a meter; 1000 meters in a kilometer.

Measures of length in the English system, in contrast, do not relate to each other in a regular way. Inches are routinely divided into 16ths; there are 12 inches in a foot; 3 feet in a yard; 5280 feet (or 1760 yards) in a mile.

If you have grown up in the United States and are accustomed to using the English system, it is extremely important to begin developing a working familiarity with metric units and values. **Tables B1.1** and **B1.2** (see B:2) should help you get started with this process.

As an example, consider the following question: An American football field is 120 yards long, while rugby fields are 144 meters

TABLE B1.1 Metric System Units and Conversions

Measurement	Unit of Measurement and Abbreviation	Metric System Equivalent	Converting Metric Units to English Units
Length	kilometer (km)	1 km = 1000 m = 10^3 m	1 km = 0.62 mile
	meter (m)	1 m = 100 cm	1 m = 1.09 yards = 3.28 feet = 39.37 inches
	centimeter (cm)	1 cm = 0.01 m = 10^{-2} m	1 cm = 0.3937 inch
	millimeter (mm)	1 mm = 0.001 m = 10^{-3} m	1 mm = 0.039 inch
	micrometer (μm)	1 μm = 10^{-6} m = 10^{-3} mm	
	nanometer (nm)	1 nm = 10^{-9} m = 10^{-3} μm	
Area	hectare (ha)	1 ha = 10,000 m^2	1 ha = 2.47 acres
	square meter (m^2)	1 m^2 = 10,000 cm^2	1 m^2 = 1.196 square yards
	square centimeter (cm^2)	1 cm^2 = 100 mm^2 = 10^{-4} m^2	1 cm^2 = 0.155 square inch
Volume	liter (L)	1 L = 1000 mL	1 L = 1.06 quarts
	milliliter (mL)	1 mL = 1000 μL = 10^{-3} L	1 mL = 0.034 fluid ounce
	microliter (μL)	1 μL = 10^{-6} L	
Mass	kilogram (kg)	1 kg = 1000 g	1 kg = 2.20 pounds
	gram (g)	1 g = 1000 mg	1 g = 0.035 ounce
	milligram (mg)	1 mg = 1000 μg = 10^{-3} g	
	microgram (μg)	1 μg = 10^{-6} g	
Temperature	Kelvin (K)*		K = °C + 273.15
	degrees Celsius (°C)		°C = $\frac{5}{9}$ (°F − 32)
	degrees Fahrenheit (°F)		°F = $\frac{9}{5}$°C + 32

*Absolute zero is −273.15 °C = 0 K.

TABLE B1.2 Prefixes Used in the Metric System

Prefix	Abbreviation	Definition
nano–	n	$0.000\ 000\ 001 = 10^{-9}$
micro–	μ	$0.000\ 001 = 10^{-6}$
milli–	m	$0.001 = 10^{-3}$
centi–	c	$0.01 = 10^{-2}$
deci–	d	$0.1 = 10^{-1}$
–	–	$1 = 10^{0}$
kilo–	k	$1000 = 10^{3}$
mega–	M	$1\ 000\ 000 = 10^{6}$
giga–	G	$1\ 000\ 000\ 000 = 10^{9}$

long. In yards, how much longer is a rugby field than an American football field? To solve this problem, first convert meters to yards: 144 m × 1.09 yards/m = 157 yards (note that the unit "m" cancels out). The difference in yards is thus: 157 – 120 = 37 yards. If you did these calculations on a calculator, you might have come up with 36.96 yards. Why has the number of yards been rounded off? The answer lies in significant figures. Let's take a closer look.

Significant Figures

Significant figures or "sig figs"—the number of digits used to report the measurement—are critical when reporting scientific data. The number of significant figures in a measurement, such as 3.524, is the number of digits that are known with some degree of confidence (3, 5, and 2) plus the last digit (4), which is an estimate or approximation. How do scientists know how many digits to report?

Rules for Working with Significant Figures

The rules for counting significant figures are summarized here:

- All nonzero numbers are always significant.
- Leading zeros are never significant; these zeros do nothing but set the decimal point.
- Embedded zeros are always significant.
- Trailing zeros are significant *only* if the decimal point is specified (Hint: Change the number to scientific notation. It is easier to see the "trailing" zeros.)

Table B1.3 provides examples of how to apply these rules. The bottom line is that significant figures indicate the precision of measurements.

Precision versus Accuracy

If biologists count the number of bird eggs in a nest, they report the data as an exact number—say, 3 eggs. But if the same biologists are measuring the diameter of the eggs, the numbers will be inexact. Just how inexact they are depends on the equipment used to make the measurements. For example, if you measure the width of your textbook with a ruler several times, you'll get essentially the same measurement again and again. Precision refers to how closely individual measurements agree with each other. So, you have determined the length with precision, but how do you know if the ruler was accurate to begin with?

Accuracy refers to how closely a measured value agrees with the correct value. You don't know the accuracy of a measuring device unless you calibrate it, by comparing it against a ruler that is known to be accurate. As the sensitivity of equipment used to

4. **QUANTITATIVE** Calculate how many liters of milk you would need to buy to get approximately the same volume as a gallon of milk.
5. **QUANTITATIVE** Multiply the measurements 2.8723 and 1.6. How many significant figures does your answer have? Why?

TABLE B1.3 Rules for Working with Significant Figures

Example	Number of Significant Figures	Scientific Notation	Rule
35,200	5	3.52×10^{4}	All nonzero numbers are always significant
0.00352	3	3.52×10^{-3}	Leading zeros are not significant
1.035	4	$1.035\ (\times 10^{0})$	Imbedded zeros are always significant
200	1	2×10^{2}	Trailing zeros are significant only if the decimal point is specified
200.0	4	2.000×10^{2}	Trailing zeros are significant only if the decimal point is specified

make a measurement increases, the number of significant figures increases. For example, if you used a kitchen scale to weigh out some sodium chloride, it might be accurate to 3 ± 1 g (1 significant figure); but an analytical balance in the lab might be accurate to 3.524 ± 0.001 g (4 significant figures).

In science, only the numbers that have significance—that are obtained from measurement—are reported. It is important to follow the "sig fig rules" when reporting a measurement, so that data do not appear to be more accurate than the equipment allows.

Combining Measurements

How do you deal with combining measurements with different degrees of accuracy and precision? The simple rule to follow is that the accuracy of the final answer can be no greater than the least accurate measurement. So, when you multiply or divide measurements, the answer can have no more significant figures than the least accurate measurement. When you add or subtract measurements, the answer can have no more decimal places than the least accurate measurement.

As an example, consider that you are adding the following measurements: 5.9522, 2.065, and 1.06. If you plug these numbers into your calculator, the answer your calculator will give you is 9.0772. However, this is incorrect—you must round your answer off to the nearest value, 9.08, to the least number of decimal places in your data.

It is important to nail down the concept of significant figures and to practice working with metric units and values. The Check Your Understanding questions in this BioSkill should help you get started with this process.

BIOSKILL 2 some common Latin and Greek roots used in biology

Greek or Latin Root	English Translation	Example Term
a, an	not	anaerobic
aero	air	aerobic
allo	other	allopatric
amphi	on both sides	amphipathic
anti	against	antibody
auto	self	autotroph
bi	two	bilateral symmetry
bio	life, living	bioinformatics
blast	bud, sprout	blastula
co	with	cofactor
cyto	cell	cytoplasm
di	two	diploid
ecto	outer	ectoparasite
endo	inner, within	endoparasite
epi	outer, upon	epidermis
exo	outside	exothermic
glyco	sugary	glycolysis
hetero	different	heterozygous
homo	alike	homozygous
hydro	water	hydrolysis
hyper	over, more than	hypertonic
hypo	under, less than	hypotonic
inter	between	interspecific
intra	within	intraspecific
iso	same	isotonic
logo, logy	study of	morphology
lyse, lysis	loosen, burst	glycolysis
macro	large	macromolecule
meta	change, turning point	metamorphosis

BIOSKILL 3 reading graphs

Graphs are the most common way to report data, for a simple reason. Compared to reading raw numerical values in a table or list, a graph makes it much easier to understand what the data mean.

Learning how to read and interpret graphs is one of the most basic skills you'll need to acquire as a biology student. As when learning piano or soccer or anything else, you need to understand a few key ideas to get started and then have a chance to practice—a lot—with some guidance and feedback.

Getting Started

To start reading a graph, you need to do three things: read the axes, figure out what the data points represent—that is, where they came from—and think about the overall message of the data. Let's consider each step in turn.

What Do the Axes Represent?

Graphs have two axes: one horizontal and one vertical. The horizontal axis of a graph is also called the *x*-axis or the abscissa. The vertical axis of a graph is also called the *y*-axis or the ordinate. Each axis represents a variable that takes on a range of values. These values are indicated by the ticks and labels on the axis. Note that each axis should *always* be clearly labeled with the unit or treatment it represents.

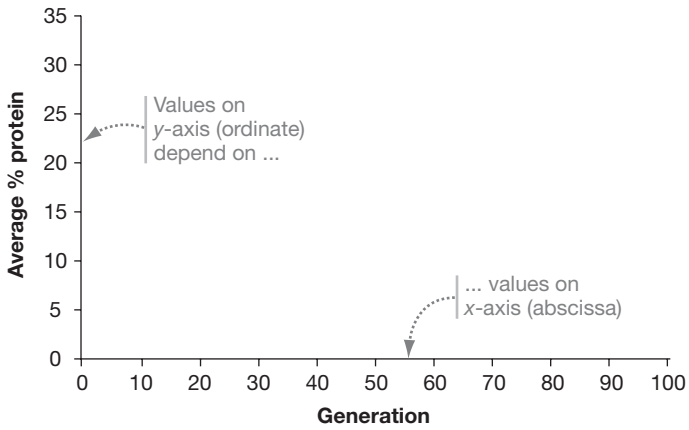

FIGURE B3.1 shows a scatterplot—a type of graph where continuous data are graphed on each axis. Continuous data can take an array of values over a range. In contrast, discrete data can take only a restricted set of values. If you were graphing the average height of men and women in your class, height is a continuous variable, but gender is a discrete variable.

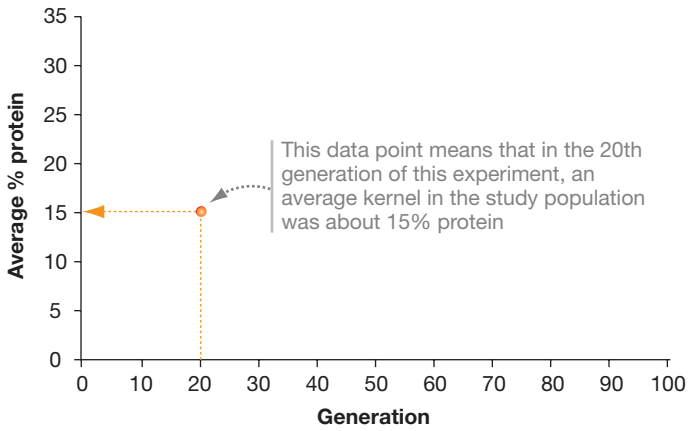
For the example in this figure, the *x*-axis represents time in units of generations of maize; the *y*-axis represents the average percentage of the dry weight of a maize kernel that is protein.



To create a graph, researchers plot the independent variable on the *x*-axis and the dependent variable on the *y*-axis (Figure B3.1a). The terms independent and dependent are used because the values on the *y*-axis depend on the *x*-axis values. In our example, the researchers wanted to show how the protein content of maize kernels in a study population changed over time. Thus, the protein concentration plotted on the *y*-axis depended on the year (generation) plotted on the *x*-axis. The value on the *y*-axis always depends on the value on the *x*-axis, but not vice versa.

In many graphs in biology, the independent variable is either time or the various treatments used in an experiment. In these cases, the *y*-axis records how some quantity changes as a function of time or as the outcome of the treatments applied to the experimental cells or organisms.

(a) Read the axes—what is being plotted?

(b) Look at the bars or data points—what do they represent?

(c) What's the punchline?

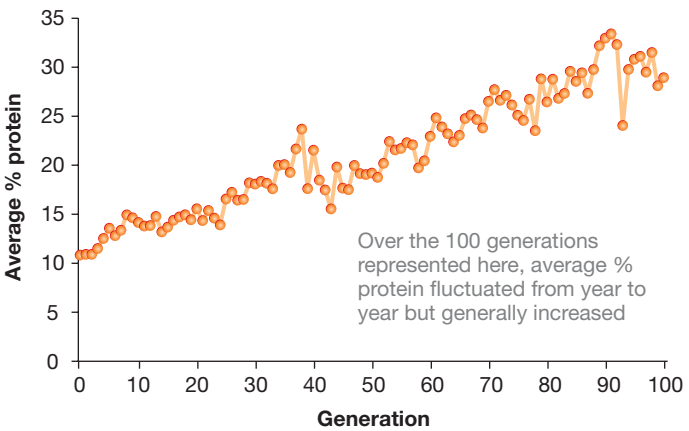


FIGURE B3.1 Scatterplots Are Used to Graph Continuous Data.

What Do the Data Points Represent?

Once you've read the axes, you need to figure out what each data point is. In our maize kernel example, the data point in Figure B3.1b represents the average percentage of protein found in a sample of kernels from a study population in a particular generation.

If it's difficult to figure out what the data points are, ask yourself where they came from—meaning, how the researchers got them. You can do this by understanding how the study was done and by understanding what is being plotted on each axis. The *y*-axis will tell you what they measured; the *x*-axis will usually tell you when they measured it or what group was measured. In some cases—for example, in a plot of average body size versus average brain size in primates—the *x*-axis will report a second variable that was measured.

In other cases, a data point on a graph may represent a relative or arbitrary unit of measurement. The data point shows the ratio of the amount of a substance, intensity, or other quantities, relative to a predetermined reference measurement. For example, the *y*-axis might show the percentage of relative activity of an enzyme—the rate of the enzyme-catalyzed reaction, scaled to the highest rate of activity observed (100 percent)—in experiments conducted under conditions that are identical except for one variable, such as pH or temperature (see Figure 8.14).

What Is the Overall Trend or Message?

Look at the data as a whole, and figure out what they mean. Figure B3.1c suggests an interpretation of the maize kernel example. If the graph shows how some quantity changes over time, ask yourself if that quantity is increasing, decreasing, fluctuating up and down, or staying the same. Then ask whether the pattern is the same over time or whether it changes over time.

When you're interpreting a graph, it's extremely important to limit your conclusions to the data presented. Don't extrapolate beyond the data, unless you are explicitly making a prediction based on the assumption that present trends will continue. For example, you can't say that the average percentage of protein content was increasing in the population before the experiment started, or that it will continue to increase in the future. You can say only what the data tell you.

Types of Graphs

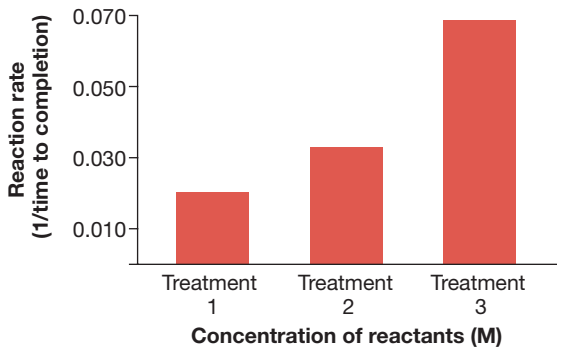
Many of the graphs in this text are scatterplots like the one shown in Figure B3.1c, where individual data points are plotted. But you will also come across other types of graphs in this text.

Scatterplots, Lines, and Curves

Scatterplots sometimes have data points that are by themselves, but at other times data points will be connected by dot-to-dot lines to help make the overall trend clearer, as in Figure B3.1c, or may have a smooth line through them.

A *smooth line* through data points—sometimes straight, sometimes curved—is a mathematical "line of best fit." A line of best fit represents a mathematical function that summarizes the relationship between the *x* and *y* variables. It is "best" in the sense of fitting the data points most precisely. The line may pass through some of the points, none of the points, or all of the points.

Curved lines often take on characteristic shapes depending on the relationships between the *x* and *y* variable. For example, a bell-shaped curve depicts a normal distribution in which most data points are clumped near the middle, while a sigmoid or S-shaped curve exhibits small changes at first, which then accelerate and approach maximal value over time. Data from studies on population growth (see Chapter 54), enzyme kinetics (see Chapter 8), and oxygen–hemoglobin dissociation (see Chapter 45) typically fall on a curved line.



Bar Charts, Histograms, and Box-and-Whisker Plots

Scatterplots, or line-of-best-fit graphs, are the most appropriate type of graph when the data have a continuous range of values and you want to show individual data points. But other types of graphs are used to represent different types of distributions:

- ***Bar charts*** plot data that have discrete or categorical values instead of a continuous range of values. In many cases the bars might represent different treatment groups in an experiment, as in **FIGURE B3.2a** (see B:6). In this graph, the height of the bar indicates the average value. Statistical tests can be used to determine whether a difference between treatment groups is significant (see **BIOSKILLS 4**).
- ***Histograms*** illustrate frequency data and can be plotted as numbers or percentages. **FIGURE B3.2b** shows an example where height is plotted on the *x*-axis, and the number of students in a population is plotted on the *y*-axis. Each rectangle indicates the number of individuals in each interval of height, which reflects the relative frequency, in this population, of people whose heights are in that interval. The measurements could also be recalculated so that the *y*-axis would report the proportion of people in each interval. Then the sum of all the bars would equal 100 percent. Note that if you were to draw a smooth curve connecting the top of the bars on this histogram, the smooth curve would represent the shape of a bell.
- ***Box-and-whisker plots*** allow you to easily see where most of the data fall. Each box indicates where half of the data numbers are. The whiskers indicate the lower extreme and the upper extreme of the data. The vertical line inside each box indicates the median—meaning that half of the data are above this value and half are below (see Figure 1.9 for an example).

When you are looking at a bar chart that plots values from different treatments in an experiment, ask yourself if these values are the same or different. If the bar chart reports averages over discrete ranges of values, ask what trend is implied—as you would for a scatterplot.

(a) Bar chart

(b) Histogram

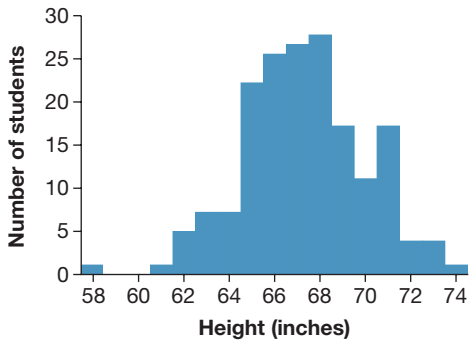


FIGURE B3.2 Bar Charts and Histograms. (a) Bar charts are used to graph data that are discontinuous or categorical. **(b)** Histograms show the distribution of frequencies or values in a population.

When you are looking at a histogram, ask whether there is a "hump" in the data—indicating a group of values that are more frequent than others. Is the hump in the center of the distribution of values, toward the left, or toward the right? If so, what does it mean?

Similarly, when you are looking at a box-and-whisker plot, ask yourself what information the graph gives you. What is the range of values for the data? Where are half the data points? Below what value is three quarters of the data?

Getting Practice

Working with this text will give you lots of practice with reading graphs—they appear in almost every chapter. In many cases we've inserted an arrow to represent your instructor's hand at the whiteboard, with a label that suggests an interpretation or draws your attention to an important point on the graph. In other cases, you should be able to figure out what the data mean on your own or with the help of other students or your instructor.

5. **QUANTITATIVE** Determine the most common height in the class graphed in Figure B3.2b.

BIOSKILL 4 using statistical tests and interpreting standard error bars

When biologists do an experiment, they collect data on individuals in a treatment group and a control group, or several such comparison groups. Then they want to know whether the individuals in the two (or more) groups are different. For example, in one experiment student researchers measured how fast a product formed when they set up a reaction with three different concentrations of reactants (introduced in Chapter 8). Each treatment—meaning, each combination of reactant concentrations—was replicated many times.

FIGURE B4.1 graphs the average reaction rate for each of the three treatments in the experiment. Note that Treatments 1, 2, and 3 represent increasing concentrations of reactants. The thin "I-beams" on each bar indicate the standard error of each average. The standard error is a quantity that indicates the uncertainty in the calculation of an average.

For example, if two trials with the same concentration of reactants had a reaction rate of 0.075 and two trials had a reaction rate of 0.025, then the average reaction rate would be 0.050. In this case, the standard error would be large. But if two trials had a reaction rate of 0.051 and two had a reaction rate of 0.049, the average would still be 0.050, but the standard error would be small.

In effect, the standard error quantifies how confident you are that the average you've calculated is the average you'd observe if

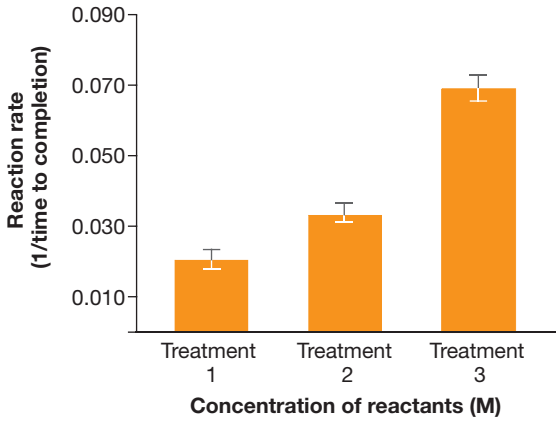

FIGURE B4.1 Standard Error Bars Indicate the Uncertainty in an Average.

you did the experiment under the same conditions an extremely large number of times. It is a measure of precision (see **BIOSKILLS 1**).

Once they had calculated these averages and standard errors, the students wanted to answer a question: Does reaction rate increase when reactant concentration increases?

After looking at the data, you might conclude that the answer is yes. But how could you come to a conclusion like this objectively, instead of subjectively?

The answer is to use a statistical test. This can be thought of as a three-step process.

1. Specify the null hypothesis, which is that reactant concentration has no effect on reaction rate.
2. Calculate a test statistic, which is a number that characterizes the size of the difference among the treatments. In this case, the test statistic compares the actual differences in reaction rates among treatments to the difference predicted by the null hypothesis. The null hypothesis predicts that there should be no difference.
3. The third step is to determine the probability of getting a test statistic at least as large as the one calculated just by chance. The answer comes from a reference distribution—a mathematical function that specifies the probability of getting various values of the test statistic if the null hypothesis is correct. (If you take a statistics course, you'll learn which test statistics and reference distributions are relevant to different types of data.)

You are very likely to see small differences among treatment groups just by chance—even if no differences actually exist. If you flipped a coin 10 times, for example, you are unlikely to get exactly five heads and five tails, even if the coin is fair. A reference distribution tells you how likely you are to get each of the possible outcomes of the 10 flips if the coin is fair, just by chance.

In this case, the reference distribution indicated that if the null hypothesis of no actual difference in reaction rates is correct, you would see differences at least as large as those observed only 0.01 percent of the time just by chance. By convention, biologists consider a difference among treatment groups to be statistically significant if there is less than a 5 percent probability of observing it just by chance. Based on this convention, the student researchers were able to claim that the null hypothesis is not correct for reactant concentration. According to their data, the reaction they studied really does happen faster when reactant concentration increases.

You'll likely be doing actual statistical tests early in your undergraduate career. To use this text, though, you only need to know what statistical testing does. And you should take care to inspect the standard error bars on graphs in this book. As a *very* rough rule of thumb, averages often turn out to be significantly different, according to an appropriate statistical test, if there is no overlap between two times the standard errors.

- Measuring the height of every student who showed up for class on a particular day to estimate the average.

BIOSKILL 5 combining probabilities

In several cases in this text, you'll need to combine probabilities from different events in order to solve a problem. One of the most common applications is in genetics problems. For example, Punnett squares work because they are based on two fundamental rules of probability. Each rule pertains to a distinct situation.

The Both-And Rule

The both-and rule—also known as the product rule or multiplication rule—applies when you want to know the probability that two or more independent events occur together. Let's use the rolling of two dice as an example. What is the probability of rolling two sixes? These two events are independent, because the probability of rolling a six on one die has no effect on the probability of rolling a six on the other die. (In the same way, the probability of getting a gamete with allele *R* from one parent has no effect on the probability of getting a gamete with allele *R* from the other parent. Gametes fuse randomly.)

The probability of rolling a six on the first die is 1/6. The probability of rolling a six on the second die is also 1/6. The probability of rolling a six on *both* dice, then, is $1/6 \times 1/6 = 1/36$. In other words, if you rolled two dice 36 times, on average you would expect to roll two sixes once.

In the case of a cross between two parents heterozygous at the *R* gene, the probability of getting allele *R* from the father is 1/2 and the probability of getting *R* from the mother is 1/2. Thus, the probability of getting both alleles and creating an offspring with genotype *RR* is $1/2 \times 1/2 = 1/4$.

The Either-Or Rule

The either-or rule—also known as the sum rule or addition rule—applies when you want to know the probability of an event happening when there are several different ways for the same event or outcome to occur. In this case, the probability that the event will occur is the sum of the probabilities of each way that it can occur.

For example, suppose you wanted to know the probability of rolling either a one or a six when you toss a die. The probability of drawing each is 1/6, so the probability of getting one or the other is $1/6 + 1/6 = 1/3$. If you rolled a die three times, on average you'd expect to get a one or a six once.

In the case of a cross between two parents heterozygous at the *R* gene, the probability of getting an *R* allele from the father and an *r* allele from the mother is $1/2 \times 1/2 = 1/4$. Similarly, the probability of getting an *r* allele from the father and an *R* allele from the mother is $1/2 \times 1/2 = 1/4$. Thus, the combined probability of getting the *Rr* genotype in either of the two ways is $1/4 + 1/4 = 1/2$.

2. **QUANTITATIVE** Calculate the probability of getting a two, a three, or a six after a single roll of a die.

BIOSKILL 6 using logarithms

You have probably been introduced to logarithms and logarithmic notation in algebra courses, and you will encounter logarithms at several points in this course. Logarithms are a way of working with powers—meaning, numbers that are multiplied by themselves one or more times.

Scientists use exponential notation to represent powers. For example,

$$a^x = y$$

means that if you multiply a by itself x times, you get y. In exponential notation, a is called the base and x is called the exponent. The entire expression is called an exponential function.

What if you know y and a, and you want to know x? This is where logarithms come in. You can solve for exponents using logarithms. For example,

$$x = \log_a y$$

This equation reads, x is equal to the logarithm of y to the base a. Logarithms are a way of working with exponential functions. They are important because so many processes in biology (and chemistry and physics, for that matter) are exponential. To understand what's going on, you have to describe the process with an exponential function and then use logarithms to work with that function.

Although a base can be any number, most scientists use just two bases when they employ logarithmic notation: 10 and e (sometimes called Euler's number after Swiss mathematician Leonhard Euler). What is e? It is a rate of exponential growth shared by many natural processes, where e is the limit of $(1 + \frac{1}{n})^n$ (as n tends to infinity). Mathematicians have shown that the base e is an irrational number (like π) that is approximately equal to 2.718. Like 10, e is just a number; $10^0 = 1$ and, likewise, $e^0 = 1$. But both 10 and e have qualities that make them convenient to use in biology (as well as chemistry and physics).

Logarithms to the base 10 are so common that they are usually symbolized in the form log y instead of $\log_{10} y$. A logarithm to the base e is called a natural logarithm and is symbolized ln (pronounced *EL-EN*) instead of log. You write "the natural logarithm of y" as ln y.

Most scientific calculators have keys that allow you to solve problems involving base 10 and base e. For example, if you know y, they'll tell you what log y or ln y are—meaning that they'll solve for x in our first example equation. They'll also allow you to find a number when you know its logarithm to base 10 or base e. Stated another way, they'll tell you what y is if you know x, and y is equal to e^x or 10^x. This is called taking an antilog. In most cases, you'll use the inverse or second function button on your calculator to find an antilog (above the log or ln key).

To get some practice with your calculator, consider this equation:

$$10^2 = 100$$

If you enter 100 in your calculator and then press the log key, the screen should say 2. The logarithm tells you what the exponent is. Now press the antilog key while 2 is on the screen. The calculator screen should return to 100. The antilog solves the exponential function, given the base and the exponent.

If your background in algebra isn't strong, you'll want to get more practice working with logarithms—you'll see them frequently during your undergraduate career. Remember that once you understand the basic notation, there's nothing mysterious about logarithms. They are simply a way of working with exponential functions, which describe what happens when something is multiplied by itself a number of times—like cells that divide and then divide again and then again.

Using logarithms will also come up when you are studying something that can have a large range of values, like the concentration of hydrogen ions in a solution or the intensity of sound that the human ear can detect. In cases like this, it's convenient to express the numbers involved as exponents. Using exponents makes a large range of numbers smaller and more manageable. For example, instead of saying that hydrogen ion concentration in a solution can range from 1 to 10^{-14}, the pH scale allows you to simply say that it ranges from 1 to 14. Instead of giving the actual value, you're expressing it as an exponent. It just simplifies things.

BIOSKILL 7 reading a phylogenetic tree

Phylogenetic trees show the evolutionary relationships among species, just as a genealogy shows the relationships among people in your family. They are unusual diagrams, however, and it can take practice to interpret them correctly.

To understand how evolutionary trees work, consider **FIGURE B7.1**. Notice that a phylogenetic tree consists of a root (the most ancestral branch in the tree), branches, nodes, and tips.

- Branches represent populations through time. In this text, branches are drawn as horizontal lines. In most cases the length of the branch is arbitrary and has no meaning, but in some cases branch lengths are proportional to time or the extent of genetic difference among populations (if so, there will be a scale at the bottom of the tree). The vertical lines on the tree represent splitting events, where one group broke into two independent groups. Their length is arbitrary—chosen simply to make the tree more readable.
- Nodes (also called forks) occur where an ancestral group splits into two or more descendant groups (see point A in Figure B7.1). Thus, each node represents the most recent common ancestor of the two or more descendant populations that emerge from it. If more than two descendant groups emerge from a node, the node is called a polytomy (see node C). A polytomy usually means that the populations split from one another so quickly that it is not possible to tell which split off earlier or later.
- Tips (also called terminal nodes) are the tree's endpoints, which represent groups living today or a dead end—a branch ending in extinction. The names at the tips can represent species or larger groups such as mammals or conifers.

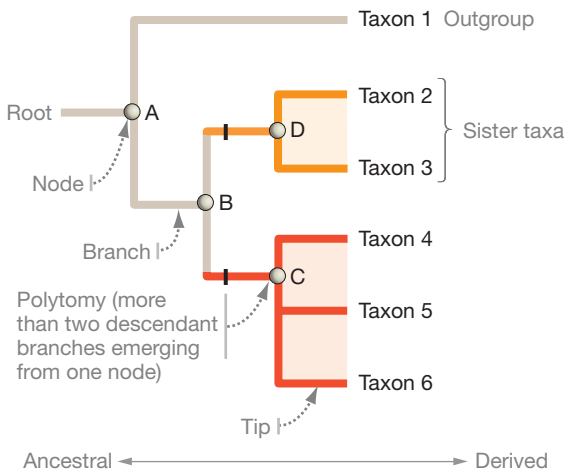

FIGURE B7.1 Phylogenetic Trees Have Roots, Branches, Nodes, and Tips.

✔**EXERCISE** Circle all four monophyletic groups present.

Recall that a taxon (plural: taxa) is any named group of organisms (see Chapter 1). A taxon could be a single species, such as *Homo sapiens*, or a large group of species, such as Primates. Tips connected by a single node on a tree are called sister taxa.

The phylogenetic trees used in this text are all rooted. This means that the first, or most basal, node on the tree—the one on the far left in this book—is the most ancient. To determine where the root on a tree occurs, biologists include one or more outgroup species when they are collecting data to estimate a particular phylogeny. An outgroup is a taxonomic group that is known to have diverged before the rest of the taxa in the study. Outgroups are used to establish whether a trait is ancestral or derived. An ancestral trait is a characteristic that existed in an ancestor; a derived trait is a characteristic that is a modified form of the ancestral trait, found in a descendant.

In Figure B7.1, Taxon 1 is an outgroup to the monophyletic group consisting of taxa 2–6. A monophyletic group consists of an ancestral species and all of its descendants. The root of a tree is placed between the outgroup and the monophyletic group being studied. This position in Figure B7.1 is node A. Note that black hash marks are used to indicate a derived trait that is shared among the red branches, and another derived trait that is shared among the orange branches.

Understanding monophyletic groups is fundamental to reading and estimating phylogenetic trees. Monophyletic groups may also be called lineages or clades and can be identified using the "one-snip test": If you cut any branch on a phylogenetic tree, all of the branches and tips that fall off represent a monophyletic group. Using the one-snip test, you should be able to convince yourself that the monophyletic groups on a tree are nested. In Figure B7.1, for example, the monophyletic group comprising node A and taxa 1–6 contains a monophyletic group consisting of node B and taxa 2–6, which includes the monophyletic group represented by node C and taxa 4–6.

To put all these new terms and concepts to work, consider the phylogenetic tree in **FIGURE B7.2**, which shows the relationships between common chimpanzees and six human and humanlike species that lived over the past 5–6 million years. Chimps functioned as an outgroup in the analysis that led to this tree, so the root was placed at node A. The branches marked in red identify a monophyletic group called the hominins.

To practice how to read a tree, put your finger at the tree's root, at the far left, and work your way to the right. At node A, the ancestral population split into two descendant populations. One of these populations eventually evolved into today's chimps; the other gave rise to the six species of hominins pictured. Now

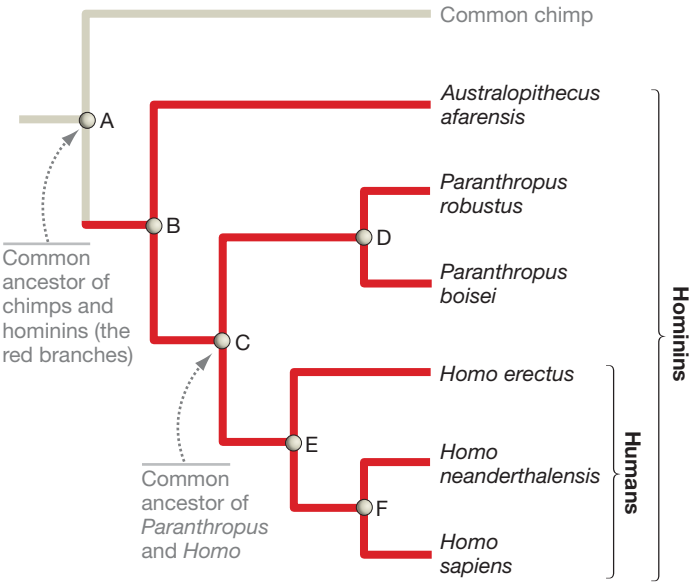

FIGURE B7.2 An Example of a Phylogenetic Tree. A phylogenetic tree showing the relationships of species in the monophyletic group called hominins.

✔**EXERCISE** All of the hominins walked on two legs—unlike chimps and all of the other primates. Add a mark on the phylogeny to show where upright posture evolved, and label it "origin of walking on two legs." Circle and label a pair of sister species. Label an outgroup to the monophyletic group called humans (species in the genus *Homo*).

continue moving your finger toward the tips of the tree until you hit node C. It should make sense to you that at this splitting event, one descendant population eventually gave rise to two *Paranthropus* species, while the other became the ancestor of humans—species in the genus *Homo*. As you study Figure B7.2, consider these two important points:

1. There are many equivalent ways of drawing this tree. For example, this version shows *Homo sapiens* on the bottom. But the tree would be identical if the two branches emerging from node E were rotated 180°, so that the species appeared in the order *Homo sapiens*, *Homo neanderthalensis*, *Homo erectus*. Trees are read from root to tips, not from top to bottom or bottom to top.
2. No species on any tree is any higher or lower than any other. Chimps and *Homo sapiens* have been evolving exactly the same amount of time since their divergence from a common ancestor—neither species is higher or lower than the other. It is legitimate to say that more ancient groups like *Australopithecus afarensis* have traits that are ancestral or more basal—meaning, that appeared earlier in evolution—compared to traits that appear in *Homo sapiens*, which are referred to as more derived.

FIGURE B7.3 presents a chance to test your tree-reading ability. Five of the six trees shown in this diagram are identical in terms of the evolutionary relationships they represent. One differs. The key to understanding the difference is to recognize that the ordering of tips does not matter in a tree—only the ordering of nodes (branch points) matters. You can think of a tree as being like a mobile: The tips can rotate without changing the underlying relationships.

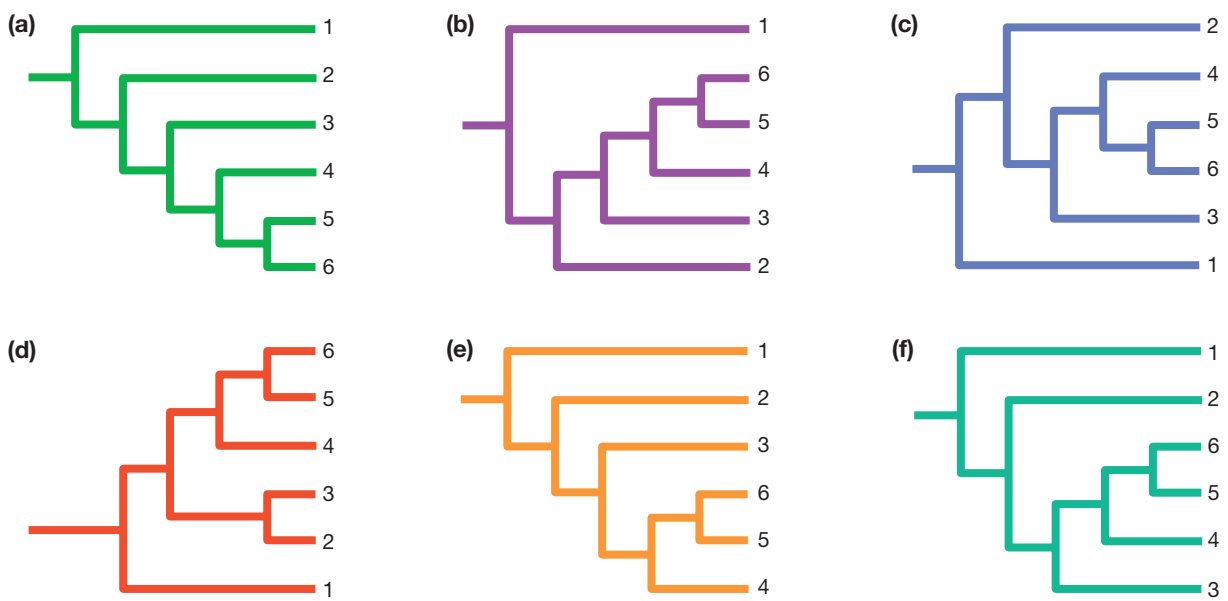

FIGURE B7.3 Alternative Ways of Drawing the Same Tree.

✔**QUESTION** Five of these six trees describe exactly the same relationships among taxa 1 through 6. Identify the tree that is different from the other five.

BIOSKILL 8 reading chemical structures

If you haven't had much chemistry yet, learning basic biological chemistry can be a challenge. One stumbling block is simply being able to read chemical structures efficiently and understand what they mean. This skill will come much easier once you have a little notation under your belt and you understand some basic symbols.

Atoms are the basic building blocks of everything in the universe, just as cells are the basic building blocks of your body. Every atom has a one- or two-letter symbol. **Table B8.1** shows the symbols for most of the atoms you'll encounter in this book. You should memorize these. The table also offers details on how the atoms form bonds as well as how they are represented in some visual models.

When atoms attach to each other by covalent bonding, a molecule forms. Biologists have a couple of different ways of representing molecules—you'll see each of these in the book and in class.

- Molecular formulas like those in **FIGURE B8.1a** simply list the atoms present in a molecule. Subscripts indicate how many of each atom are present. If the formula has no subscript, only one atom of that type is present. A methane (natural gas) molecule, for example, can be written as CH_4. It consists of one carbon atom and four hydrogen atoms.

TABLE B8.1 Some Attributes of Atoms Found in Organisms

Atom	Symbol	Number of Bonds It Can Form	Standard Color Code*
Hydrogen	H	1	white
Carbon	C	4	black
Nitrogen	N	3	blue
Oxygen	O	2	red
Sodium	Na	1	—
Magnesium	Mg	2	—
Phosphorus	P	5	orange or purple
Sulfur	S	2	yellow
Chlorine	Cl	1	—
Potassium	K	1	—
Calcium	Ca	2	—

*In ball-and-stick or space-filling models.

- Structural formulas like those in **FIGURE B8.1b** show which atoms in the molecule are bonded to each other. Each bond is indicated by a dash. The structural formula for methane in-

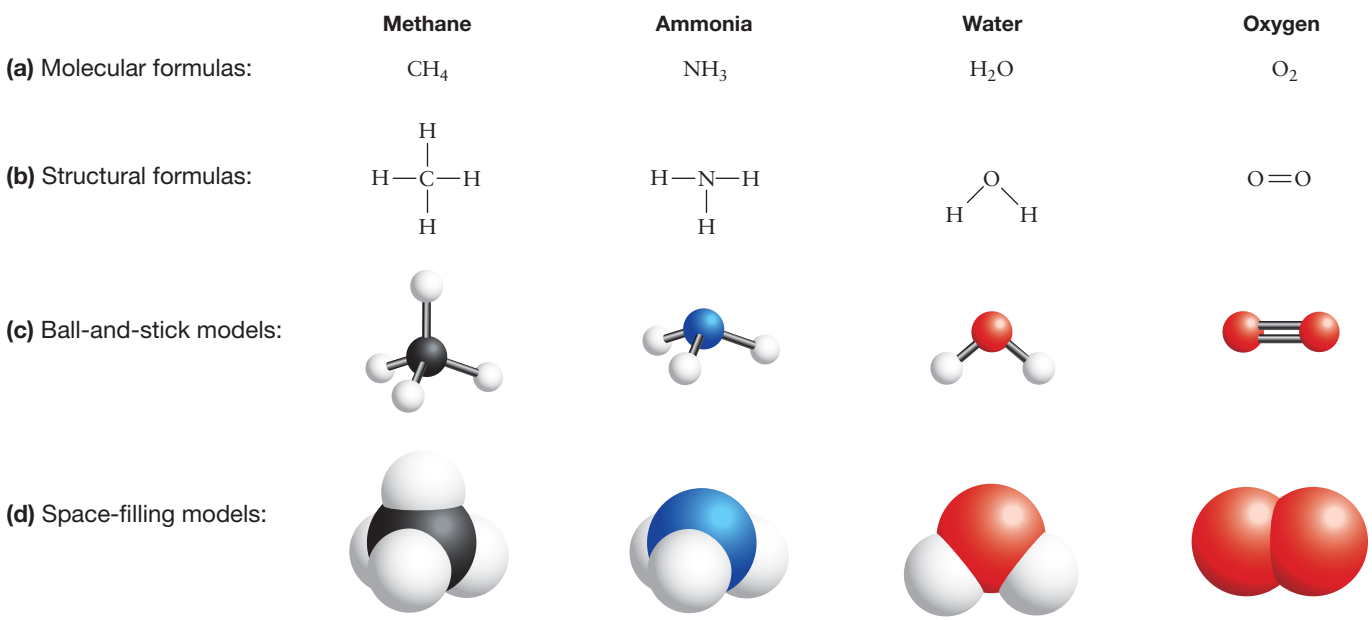

FIGURE B8.1 Molecules Can Be Represented in Several Different Ways.

✔**EXERCISE** Carbon dioxide consists of a carbon atom that forms a double bond with each of two oxygen atoms, for a total of four bonds. It is a linear molecule. Write carbon dioxide's molecular formula and then draw its structural formula, a ball-and-stick model, and a space-filling model.

dicates that each of the four hydrogen atoms forms one covalent bond with carbon, and that carbon makes a total of four covalent bonds. Single covalent bonds are symbolized by a single dash; double bonds are indicated by two dashes.

Even simple molecules have distinctive shapes, because different atoms make covalent bonds at different angles. Ball-and-stick and space-filling models show the geometry of the bonds accurately.

- In a ball-and-stick model, a stick is used to represent each covalent bond (see **FIGURE B8.1c**).
- In space-filling models, the atoms are simply stuck onto each other in their proper places (see **FIGURE B8.1d**).

To learn more about a molecule when you look at a chemical structure, ask yourself three questions:

1. ***Is the molecule polar—meaning that some parts are more negatively or positively charged than others?*** Molecules that contain nitrogen or oxygen atoms are often polar, because these atoms have such high electronegativity (see Chapter 2). This trait is important because polar molecules dissolve in water.
2. ***Does the structural formula show atoms that might participate in chemical reactions?*** For example, are there charged atoms or amino or carboxyl ($-COOH$) groups that might act as a base or an acid?
3. ***In ball-and-stick and especially space-filling models of large molecules, are there interesting aspects of overall shape?*** For example, is there a groove where a protein might bind to DNA, or a cleft where a substrate might undergo a reaction in an enzyme?

BIOSKILL 9 separating and visualizing molecules

To study a molecule, you have to be able to isolate it. Isolating a molecule is a two-step process: the molecule has to be separated from other molecules in a mixture and then physically picked out or located in a purified form. **BIOSKILLS 9** focuses on the techniques that biologists use to separate nucleic acids and proteins and then find the particular one they are interested in.

Using Electrophoresis to Separate Molecules

In molecular biology, the standard technique for separating proteins and nucleic acids is called gel electrophoresis or, simply, electrophoresis (literally, "electricity-moving"). You may be using electrophoresis in a lab for this course, and you will certainly be analyzing data derived from electrophoresis in this text.

The principle behind electrophoresis is simple. Proteins (when denatured and coated with a special detergent) and nucleic acids carry a charge. As a result, these molecules move when placed in an electric field. Negatively charged molecules move toward the positive electrode; positively charged molecules move toward the negative electrode.

To separate a mixture of macromolecules so that each one can be isolated and analyzed, researchers place the sample in a gelatinous substance. More specifically, the sample is placed in a "well"—a slot in a sheet or slab of the gelatinous substance. The "gel" itself consists of long molecules that form a matrix of fibers. The gelatinous matrix has pores that act like a sieve through which the molecules can pass.

When an electrical field is applied across the gel, the molecules in the well move through the gel toward an electrode. Molecules that are smaller or more highly charged for their size move faster than do larger or less highly charged molecules. As they move, then, the molecules separate by size and by charge. Small and highly charged molecules end up at the bottom of the gel; large, less-charged molecules remain near the top.

An Example "Run"

FIGURE B9.1 (see B:14) shows the electrophoresis setup used in an experiment investigating how RNA molecules polymerize. In this case, the investigators wanted to document how long RNA molecules became over time, when ribonucleoside triphosphates were present in a particular type of solution.

Step 1 shows how they loaded samples of macromolecules, taken on different days during the experiment, into wells at the top of the gel slab. This is a general observation: Each well holds a different sample. In this and many other cases, the researchers also filled a well with a sample containing fragments of known size, called a size standard or "ladder."

In step 2, the researchers immersed the gel in a solution that conducts electricity and applied a voltage across the gel. The molecules in each well started to run down the gel, forming a lane. After several hours of allowing the molecules to move, the researchers removed the electric field (step 3). By then, molecules of different size and charge had separated from one another. In this case, small RNA molecules had reached the bottom of the gel. Above them were larger RNA molecules, which had run more slowly.

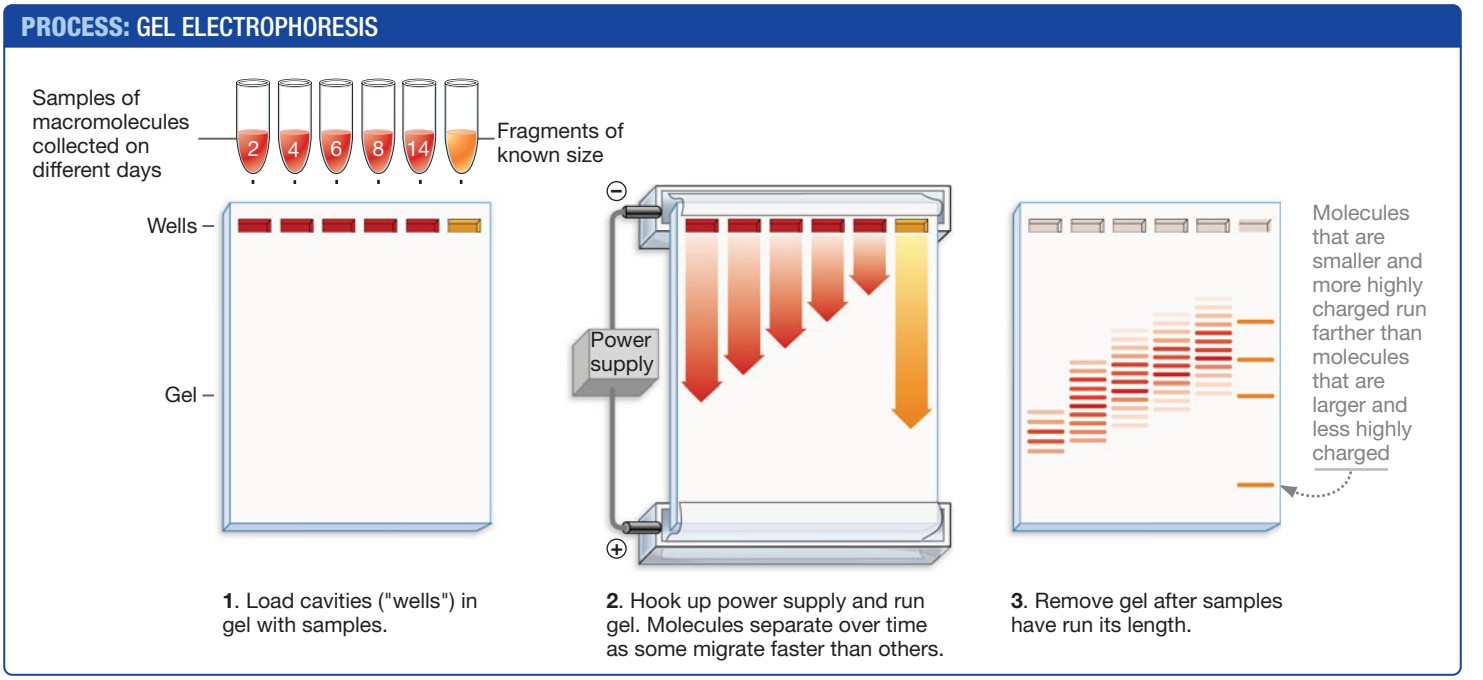

FIGURE B9.1 Macromolecules Can Be Separated via Gel Electrophoresis.

✔**QUESTION** DNA and RNA run toward the positive electrode. Why are these molecules negatively charged?

Why Do Separated Molecules Form Bands?

When researchers visualize a particular molecule on a gel, using techniques described in this section, the image that results consists of bands: shallow lines that are as wide as a lane in the gel. Why?

To understand the answer, study **FIGURE B9.2**. The left panel shows the original mixture of molecules. In this cartoon, the size of each dot represents the size of each molecule. The key is to realize that the original sample contains many copies of each specific molecule, and that these copies run down the length of the gel together—meaning, at the same rate—because they have the same size and charge.

It's that simple: Molecules that are alike form a band because they stay together.

Using Thin Layer Chromatography to Separate Molecules

Gel electrophoresis is not the only way to separate molecules. Researchers also use a method called thin layer chromatography. This method was developed in the early 1900s by botanists who were analyzing the different-colored pigments from leaves of a plant (see Chapter 10), hence the name chromatography from the Greek words khroma for "color" and graphein, "to write."

In this method, rather than loading the sample into the well of a gel, the samples are deposited or "spotted" near the bottom of a stiff support, either glass or plastic, that is coated with a thin layer of silica gel, cellulose, or a similar porous material. The coated support is placed in a solvent solution. As the solvent

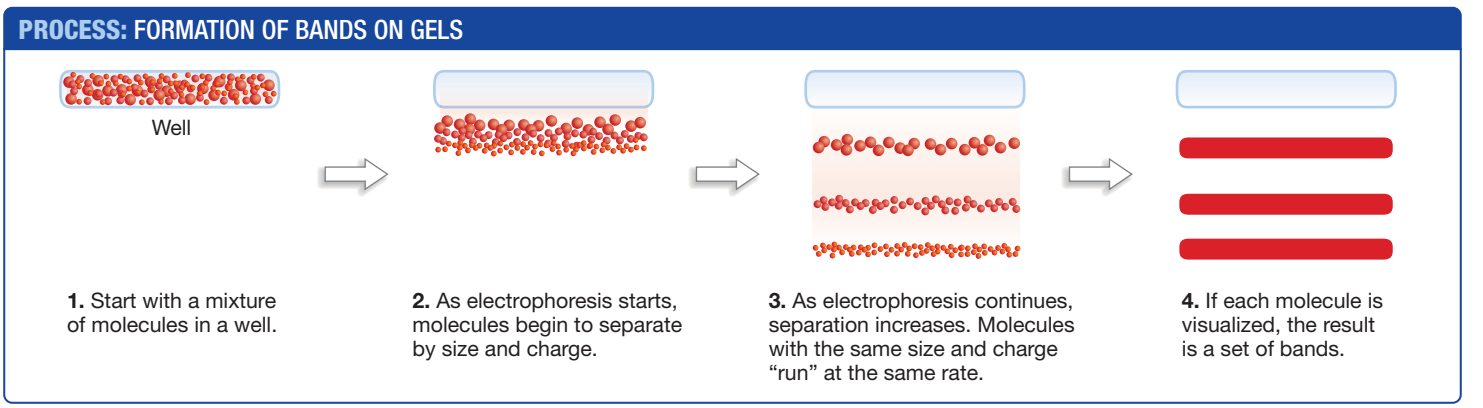

FIGURE B9.2 On a Gel, Molecules That Are Alike Form Bands.

wicks upward through the coating by capillary action, it carries the molecules in the mixture with it. Molecules are carried at different rates, based on their size and solubility in the solvent.

Visualizing Molecules

Once molecules have been separated using electrophoresis or thin layer chromatography, they have to be detected. Unfortunately, although plant pigments are colored, proteins and nucleic acids are invisible unless they are tagged in some way. Let's first look at two of the most common tagging systems and then consider how researchers can tag and visualize specific molecules of interest and not others.

Using Radioactive Isotopes and Autoradiography

When molecular biology was getting under way, the first types of tags in common use were radioactive isotopes—forms of atoms that are unstable and release energy in the form of radiation.

In the polymerization experiment diagrammed in Figure B9.1, for example, the researchers had attached a radioactive phosphorus atom to the monomers—ribonucleoside triphosphates—used in the original reaction mix. Once polymers formed, they contained radioactive atoms. When electrophoresis was complete, the investigators visualized the polymers by laying X-ray film over the gel. Because radioactive emissions expose film, a black dot appears wherever a radioactive atom is located in the gel. So many black dots occur so close together that the collection forms a dark band.

This technique for visualizing macromolecules is called autoradiography. The autoradiograph that resulted from the polymerization experiment is shown in **FIGURE B9.3**. The samples, taken on days 2, 4, 6, 8, and 14 of the experiment, are noted along the bottom. The far right lane contains macromolecules of known size; this lane is used to estimate the size of the molecules in the experimental samples. The bands that appear in each sample lane represent the different polymers that had formed.

Reading a Gel

One of the keys to interpreting or "reading" a gel, or the corresponding autoradiograph, is to realize that darker bands contain more radioactive markers, indicating the presence of many radioactive molecules. Lighter bands contain fewer molecules.

To read a gel, then, you look for **(1)** the presence or absence of bands in some lanes—meaning, some experimental samples—versus others, and **(2)** contrasts in the darkness of the bands—meaning, differences in the number of molecules present.

For example, several conclusions can be drawn from the data in Figure B9.3. First, a variety of polymers formed at each stage. After the second day, for example, polymers from 12 to 18 monomers long had formed. Second, the overall length of polymers produced increased with time. At the end of the fourteenth day, most of the RNA molecules were between 20 and 40 monomers long.

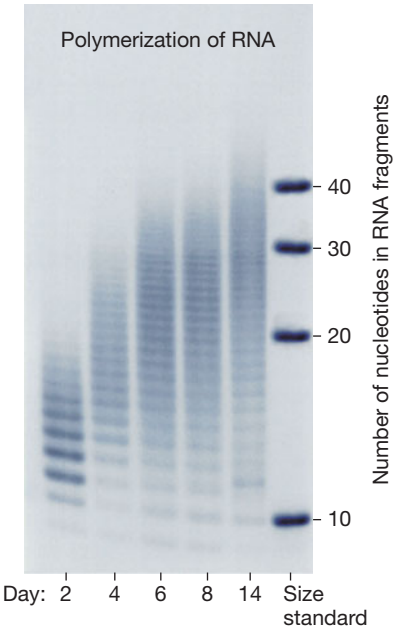

FIGURE B9.3 Autoradiography Is a Technique for Visualizing Macromolecules. The molecules in a gel can be visualized in a number of ways. In this case, the RNA molecules in the gel exposed an X-ray film because they had radioactive atoms attached. When developed, the film is called an autoradiograph.

Starting in the late 1990s and early 2000s, it became much more common to tag nucleic acids with fluorescent tags. Once electrophoresis is complete, fluorescence can be detected by exposing the gel to an appropriate wavelength of light; the fluorescent tag fluoresces or glows in response (fluorescence is explained in Chapter 10).

Fluorescent tags have important advantages over radioactive isotopes: **(1)** They are safer to handle. **(2)** They are faster—you don't have to wait hours or days for the radioactive isotope to expose a film. **(3)** They come in multiple colors, so you can tag several different molecules in the same experiment and detect them independently.

Using Nucleic Acid Probes

In many cases, researchers want to find one specific molecule—a certain DNA sequence, for example—in the collection of molecules on a gel. How is this possible? The answer hinges on using a particular molecule as a probe.

You'll learn in more detail about how probes work in this text (Chapter 20). Here it's enough to get the general idea: A probe is a marked molecule that binds specifically to your molecule of interest. The "mark" is often a radioactive atom, a fluorescent tag, or an enzyme that catalyzes a color-forming or light-emitting reaction.

If you are looking for a particular DNA or RNA sequence on a gel, for example, you can expose the gel to a single-stranded probe that binds to the target sequence by complementary base pairing. Once it has bound, you can detect the band through autoradiography or fluorescence.

- ***Southern blotting*** is a technique for making DNA fragments that have been run out on a gel single stranded, transferring them from the gel to a nylon membrane, and then probing them to identify segments of interest. The technique was named after its inventor, Edwin Southern.
- ***Northern blotting*** is a technique for transferring RNA fragments from a gel to a nylon membrane and then probing them to detect target segments. The name is a lighthearted play on Southern blotting—the protocol from which it was derived.

Using Antibody Probes

How can researchers find a particular protein out of a large collection of different proteins? The answer is to use an antibody. An antibody is a protein that binds specifically to a section of a different protein (see Chapter 51 if you want more detail on the structure of antibodies and their function in the immune system).

To use an antibody as a probe, investigators attach a tag molecule—often an enzyme that catalyzes a color-forming reaction—to the antibody and allow it to react with proteins in a mixture. The antibody will stick to the specific protein that it binds to and then can be visualized thanks to the tag it carries.

If the proteins in question have been separated by gel electrophoresis and transferred to a membrane, the result is called a western blot. The name western is an extension of the Southern and northern patterns.

Using Radioimmunoassay and ELISA to Measure Amounts of Molecules

Another important method that makes use of antibodies is called a radioimmunoassay. This method is used when investigators want to measure tiny amounts of a molecule, such as a hormone in the blood. In this case, a known quantity of a hormone is labeled with a radioactive tag. This tagged hormone is then mixed with a known amount of antibody, and the two bind to one another. Next, a sample of blood, containing an unknown quantity of that same hormone, is added. The hormone from the blood and the radiolabeled hormone compete for antibody binding sites. As the concentration of unlabeled hormone increases, more of it binds to the antibody, displacing more of the radiolabeled hormone. The amount of unbound radiolabeled hormone is then measured. Using known standards as a reference, the amount of hormone in the blood can be determined.

Another commonly used technique based on similar principles is called ELISA (enzyme-linked immunosorbent assay). In this case, the amount of a particular molecule is measured using colorimetric signals instead of a radioactive signal.

check your understanding

C Y U

If you understand BioSkill 9

✔You should be able to . . .

Interpret a gel that has been stained for "RNA X." One lane contains no bands. Two lanes have a band in the same location, even though one of the bands is barely visible and the other is extremely dark. The fourth lane has a faint band located below the bands in the other lanes.

BIOSKILL 10 separating cell components by centrifugation

Biologists use a technique called differential centrifugation to isolate specific cell components. Differential centrifugation is based on breaking cells apart to create a complex mixture and then separating components in a centrifuge. A centrifuge accomplishes this task by spinning cells in a solution that allows molecules and other cell components to separate according to their density or size and shape. The individual parts of the cell can then be purified and studied in detail, in isolation from other parts of the cell.

The first step in preparing a cell sample for centrifugation is to release the cell components by breaking the cells apart. This can be done by putting them in a hypotonic solution, by exposing them to high-frequency vibration, by treating cells with a detergent, or by grinding them up. Each of these methods breaks apart plasma membranes and releases the contents of the cells.

The resulting pieces of plasma membrane quickly reseal to form small vesicles, often trapping cell components inside. The solution that results from the homogenization step is a mixture of these vesicles, free-floating macromolecules released from the cells, and organelles. A solution like this is called a cell extract or cell homogenate.

When a cell homogenate is placed in a centrifuge tube and spun at high speed, the components that are in solution tend to move outward, along the red arrow in **FIGURE B10.1a**. The effect is similar to a merry-go-round, which seems to push you outward in a straight line away from the spinning platform. In response to this outward-directed force, the cell homogenate exerts a centripetal (literally, "center-seeking") force that pushes the homogenate away from the bottom of the tube. Larger, denser molecules or particles resist this inward force more readily than do smaller, less dense ones and so reach the bottom of the centrifuge tube faster.

To separate the components of a cell extract, researchers often perform a series of centrifuge runs. Steps 1 and 2 of

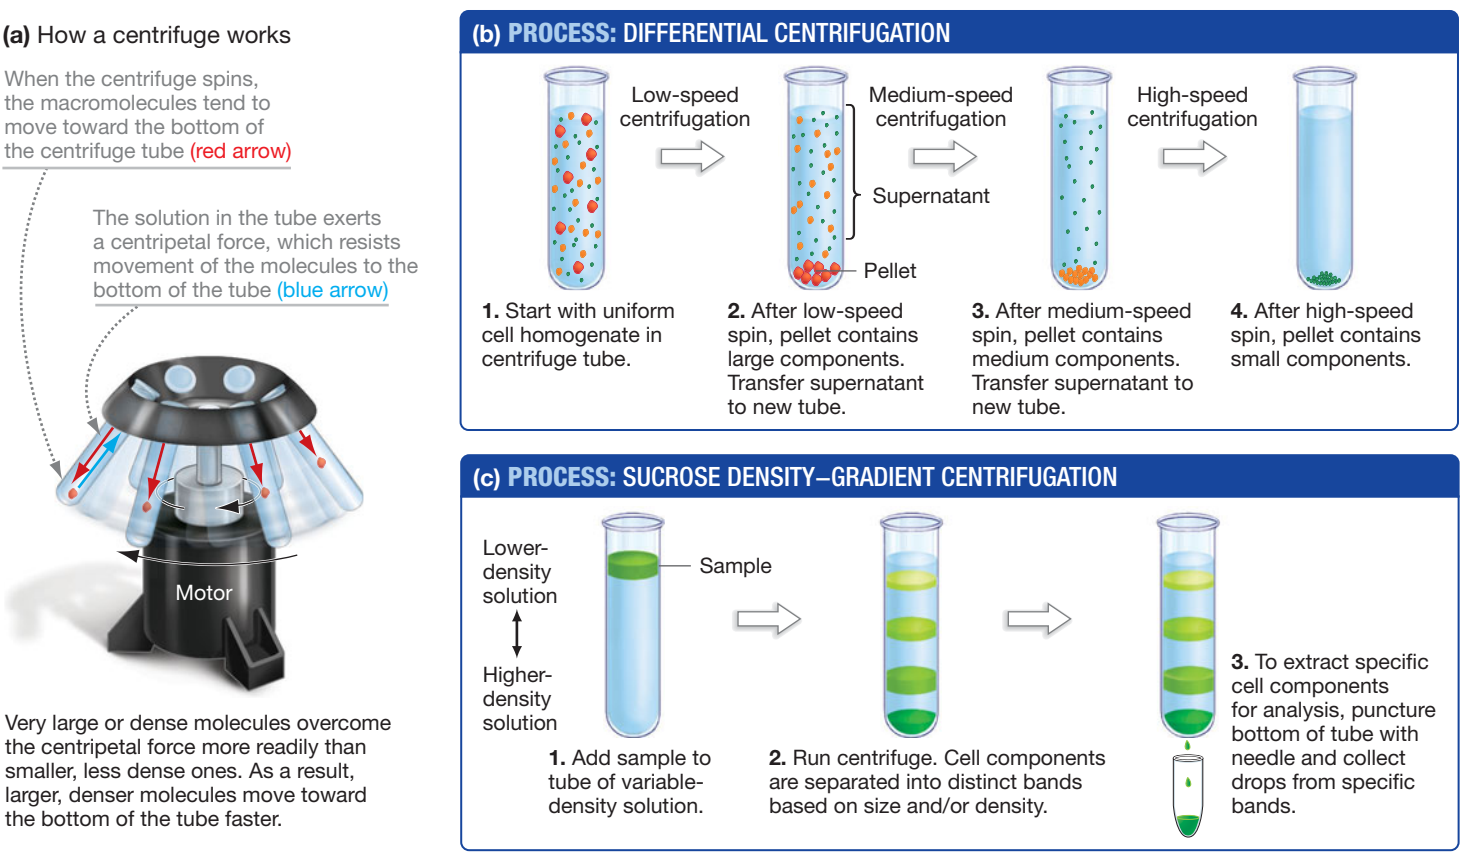

FIGURE B10.1 Cell Components Can Be Separated by Centrifugation. (a) The forces inside a centrifuge tube allow cell components to be separated. **(b)** Through a series of centrifuge runs made at increasingly higher speeds, an investigator can separate fractions of a cell homogenate by size via differential centrifugation. **(c)** A high-speed centrifuge run can achieve extremely fine separation among cell components by sucrose density–gradient centrifugation.

FIGURE B10.1b illustrate how an initial treatment at low speed causes larger, heavier parts of the homogenate to move below smaller, lighter parts. The material that collects at the bottom of the tube is called the pellet, and the solution and solutes left behind form the supernatant ("above-swimming"). The supernatant is placed in a fresh tube and centrifuged at increasingly higher speeds and longer durations. Each centrifuge run continues to separate cell components based on their size and density.

To accomplish separation of macromolecules or organelles, researchers frequently follow up with centrifugation at extremely high speeds. One strategy is based on filling the centrifuge tube with a series of sucrose solutions of increasing density (**FIGURE B10.1c**). The density gradient allows cell components to separate on the basis of small differences in size, shape, and density. When the centrifuge run is complete, each cell component occupies a distinct band of material in the tube, based on how quickly each component moves through the increasingly dense gradient of sucrose solution during the centrifuge run. A researcher can then collect the material in each band for further study.

check your understanding

If you understand BioSkill 10

✔You should be able to . . .

1. Explain the physical basis for separating molecules or cell components via centrifugation given that electrophoresis separates molecules by charge and size.
2. Determine which cell component—ribosomes or mitochondria—you would expect to find closer to the bottom of the tube if you centrifuge a cell homogenate by sucrose density–gradient centrifugation.

BIOSKILL 11 biological imaging: microscopy and x-ray crystallography

A lot of biology happens at levels that can't be detected with the naked eye. Biologists use an array of microscopes to study small multicellular organisms, individual cells, and the contents of cells. And to understand what individual macromolecules or macromolecular machines like ribosomes look like, researchers use data from a technique called X-ray crystallography.

You'll probably use dissecting microscopes and compound light microscopes to view specimens during your labs for this course, and throughout this text you'll be seeing images generated from other types of microscopy and from X-ray crystallographic data. Among the fundamental skills you'll be acquiring as an introductory student, then, is a basic understanding of how these techniques work. The key is to recognize that each approach for visualizing microscopic structures has strengths and weaknesses. As a result, each technique is appropriate for studying certain types or aspects of cells or molecules.

Light and Fluorescence Microscopy

If you use a dissecting microscope during labs, you'll recognize that it works by magnifying light that bounces off a whole specimen—often a live organism. You'll be able to view the specimen in three dimensions, which is why these instruments are sometimes called stereomicroscopes, but the maximum magnification possible is only about 20 to 40 times normal size (20× to 40×).

To view smaller objects, you'll probably use a compound microscope. Compound microscopes magnify light that is passed *through* a specimen. The instruments used in introductory labs are usually capable of 400× magnifications; the most sophisticated compound microscopes available can achieve magnifications of about 2000×. This is enough to view individual bacterial or eukaryotic cells and see large structures inside cells, like condensed chromosomes (see Chapter 12). To prepare a specimen for viewing under a compound light microscope, the tissues or cells are usually sliced to create a section thin enough for light to pass through efficiently. The section is then dyed to increase contrast and make structures visible. In many cases, different types of dyes are used to highlight different types of structures.

To visualize specific proteins, researchers use a technique called immunostaining. After preparing tissues or cells for viewing, the specimen is stained with fluorescently tagged antibodies. In this case, the cells are viewed under a fluorescence microscope. Ultraviolet or other wavelengths of light are passed through the specimen. The fluorescing tag emits visible light in response. The result? Beautiful cells that glow green, red, or blue.

Electron Microscopy

Until the 1950s, the compound microscope was the biologist's only tool for viewing cells directly. But the invention of the electron microscope provided a new way to view specimens. Two basic types of electron microscopy are now available: one that allows researchers to examine cross sections of cells at extremely high magnification, and one that offers a view of surfaces at somewhat lower magnification.

Transmission Electron Microscopy

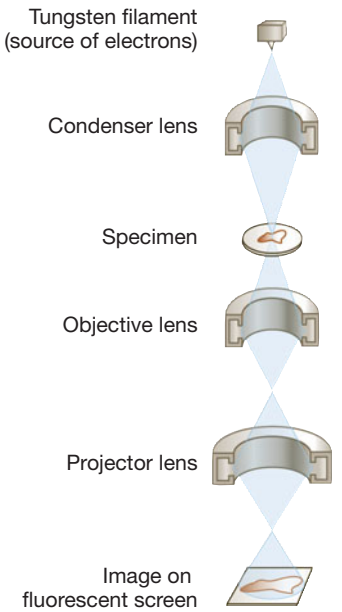
The transmission electron microscope (TEM) is an extraordinarily effective tool for viewing cell structure at high

magnification. TEM forms an image from electrons that pass through a specimen, just as a light microscope forms an image from light rays that pass through a specimen.

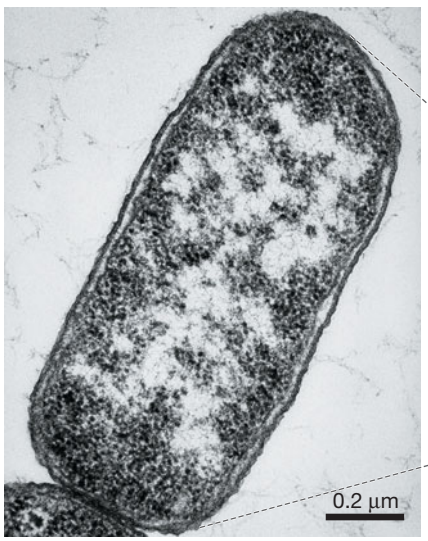
Biologists who want to view a cell under a transmission electron microscope begin by "fixing" the cell, meaning that they treat it with a chemical agent that stabilizes the cell's structure and contents while disturbing them as little as possible. Then the researcher permeates the cell with an epoxy plastic that stiffens the structure. Once this epoxy hardens, the cell can be cut into extremely thin sections with a glass or diamond knife. Finally, the sectioned specimens are impregnated with a metal—often lead. (The reason for this last step is explained shortly.)

FIGURE B11.1a outlines how the transmission electron microscope works. A beam of electrons is produced by a tungsten filament at the top of a column and directed downward. (All of the air is pumped out of the column, so that the electron beam isn't scattered by collisions with air molecules.) The electron beam passes through a series of lenses and through the specimen. The lenses are actually electromagnets, which alter the path of the beam much like a glass lens in a dissecting or compound microscope bends light. The electromagnet lenses magnify and focus the image on a screen at the bottom of the column. There the electrons strike a coating of fluorescent crystals, which emit visible light in response—just like a television screen. When the microscopist moves the screen out of the way and allows the electrons to expose a sheet of black-and-white film or to be detected by a digital camera, the result is a micrograph—a photograph of an image produced by microscopy.

The image itself is created by electrons that pass through the specimen. If no specimen were in place, all the electrons would pass through and the screen (and micrograph) would be uniformly bright. Unfortunately, cell materials by themselves would also appear fairly uniform and bright. This is because an atom's ability to deflect an electron depends on its mass. In turn, an atom's mass is a function of its atomic number. The hydrogen, carbon, oxygen, and nitrogen atoms that dominate biological molecules have low atomic numbers. This is why cell biologists must saturate cell sections with lead solutions. Lead has a high atomic number and scatters electrons effectively. Different macromolecules take up lead atoms in different amounts, so the metal acts as a "stain" that produces contrast. With TEM, areas of dense metal scatter the electron beam most, producing dark areas in micrographs.



The advantage of TEM is that it can magnify objects up to 250,000×—meaning that intracellular structures are clearly visible. The downsides are that researchers are restricted to observing dead, sectioned material, and they must take care that the preparation process does not distort the specimen.



Scanning Electron Microscopy

The scanning electron microscope (SEM) is the most useful tool biologists have for looking at the surfaces of structures. Materials are prepared for scanning electron microscopy by coating their surfaces with a layer of metal atoms. To create an image of this surface, the microscope scans the surface with a narrow beam of electrons. Electrons that are reflected back from the surface or that are emitted by the metal atoms in response to the beam then strike a detector. The signal from the detector controls a second electron beam, which scans a TV-like screen and forms an image magnified up to 50,000 times the object's size.

Because SEM records shadows and highlights, it provides images with a three-dimensional appearance (**FIGURE B11.1b**). It cannot magnify objects nearly as much as TEM can, however.

FIGURE B11.1 There Are Two Basic Types of Electron Microscopy.

Studying Live Cells and Real-Time Processes

Until the 1960s, biologists were unable to get clear, high-magnification images of living cells. But a series of innovations over the past 50 years has made it possible to observe organelles and subcellular structures in action.

The development of video microscopy, where the image from a light microscope is captured by a video camera instead of by an eye or a film camera, proved revolutionary. It allowed specimens to be viewed at higher magnification, because video cameras are more sensitive to small differences in contrast than are the human eye or still cameras. It also made it easier to keep live specimens functioning normally, because the increased light sensitivity of video cameras allows them to be used with low illumination, so specimens don't overheat. And when it became possible to digitize video images, researchers began using computers to remove out-of-focus background material and increase image clarity.

A more recent innovation was the use of a fluorescent molecule called green fluorescent protein, or GFP, which allows researchers to tag specific molecules or structures and follow their movement in live cells over time. This was a major advance over immunostaining, in which cells have to be fixed. GFP is naturally synthesized in jellyfish that fluoresce, or emit light. By affixing GFP to another protein (using genetic engineering techniques described in Chapter 20) and then inserting it into a live cell, investigators can follow the protein's fate over time and even videotape its movement. For example, researchers have videotaped GFP-tagged proteins being transported from the rough ER through the Golgi apparatus and out to the plasma membrane. This is cell biology: the movie.

GFP's influence has been so profound that the researchers who developed its use in microscopy were awarded the 2008 Nobel Prize in Chemistry.

Visualizing Structures in 3-D

The world is three-dimensional. To understand how microscopic structures and macromolecules work, it is essential to understand their shape and spatial relationships. Consider three techniques currently being used to reconstruct the 3-D structure of cells, organelles, and macromolecules.

- ***Confocal microscopy*** is carried out by mounting cells that have been treated with one or more fluorescing tags on a microscope slide and then focusing a beam of ultraviolet or other wavelengths of light at a specific depth within the specimen. The fluorescing tag emits visible light in response. A detector for this light is then set up at exactly the position where the emitted light comes into focus. The result is a sharp image of a precise plane in the cell being studied (**FIGURE B11.2a**). Note that if you viewed the same specimen under a conventional fluorescence microscope, the image would be blurry because it results from light emitted by the entire cell (**FIGURE B11.2b**). By altering the focal plane, a researcher can record images from an array of depths in the specimen; a computer can then be used to generate a 3-D image of the cell.
- ***Electron tomography*** uses a transmission electron microscope to generate a 3-D image of an organelle or other subcellular structure. The specimen is rotated around a single axis while the researcher takes many "snapshots." The individual images are then pieced together with a computer. This technique has provided a much more accurate view of mitochondrial structure than was possible using traditional TEM (see Chapter 7).
- ***X-ray crystallography, or X-ray diffraction analysis***, is the most widely used technique for reconstructing the 3-D structure of molecules. As its name implies, the procedure is based on bombarding crystals of a molecule with X-rays. X-rays are scattered in precise ways when they interact with the electrons surrounding the atoms in a crystal, producing a diffraction pattern that can be recorded on X-ray film or other types of detectors (**FIGURE B11.3**). By varying the orientation of the X-ray beam as it strikes a crystal and documenting the

1. Interpret whether the absence of mitochondria in a transmission electron micrograph of a cancerous human liver means that the cell lacks mitochondria.
2. Explain why the effort to understand the structure of biological molecules is worthwhile even though X-ray crystallography is time consuming and technically difficult. What's the payoff?

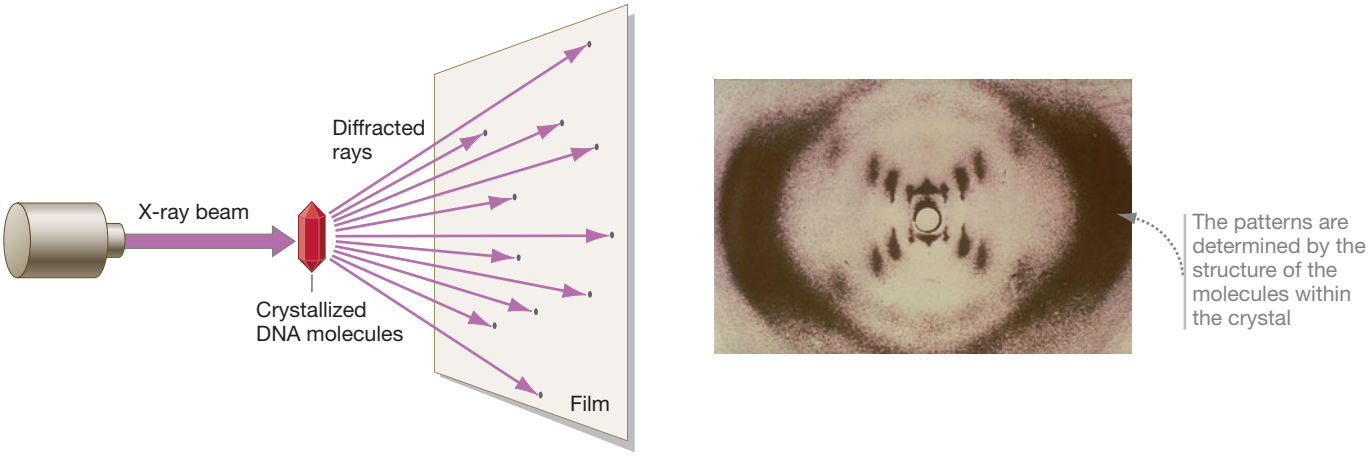

FIGURE B11.3 X-Ray Crystallography. When crystallized molecules are bombarded with X-rays, the radiation is scattered in distinctive patterns. The photograph at the right shows an X-ray film that recorded the pattern of scattered radiation from DNA molecules.

diffraction patterns that result, researchers can construct a map representing the density of electrons in the crystal. By relating these electron-density maps to information about the primary structure of the nucleic acid or protein, a 3-D model of the molecule can be built. Virtually all of the molecular models used in this book were built from X-ray crystallographic data.

BIOSKILL 12 cell and tissue culture methods

For researchers, there are important advantages to growing plant and animal cells and tissues outside the organism itself. Cell and tissue cultures provide large populations of a single type of cell or tissue and the opportunity to control experimental conditions precisely.

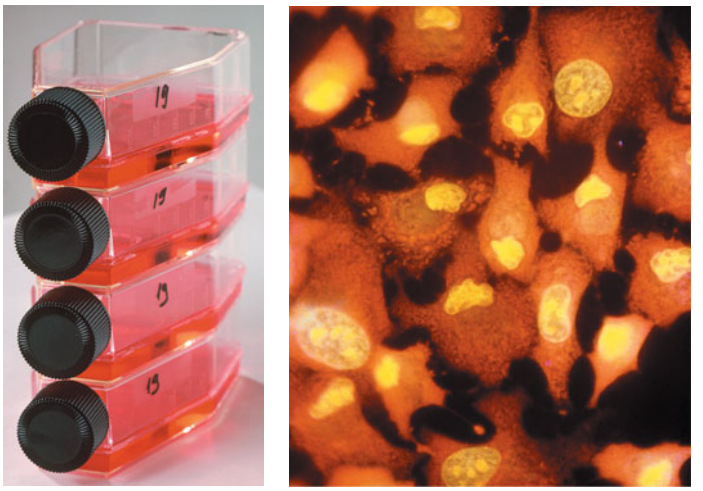
Animal Cell Culture

The first successful attempt to culture animal cells occurred in 1907, when a researcher cultivated amphibian nerve cells in a drop of fluid from the spinal cord. But it was not until the 1950s and 1960s that biologists could routinely culture plant and animal cells in the laboratory. The long lag time was due to the difficulty of re-creating conditions that exist in the intact organism precisely enough for cells to grow normally.

To grow in culture, animal cells must be provided with a liquid mixture containing the nutrients, vitamins, and hormones that stimulate growth. Initially, this mixture was serum, the liquid portion of blood; now, serum-free media are available for certain cell types. Serum-free media are preferred because they are much more precisely defined chemically than serum.

In addition, many types of animal cells will not grow in culture unless they are provided with a solid surface that mimics the types of surfaces that enable cells in the intact organisms to adhere. As a result, cells are typically cultured in flasks (**FIGURE B12.1a**, left; see B:22).

Even under optimal conditions, though, normal cells display a finite life span in culture. In contrast, many cultured cancerous cells grow indefinitely. This characteristic correlates with a key feature of cancerous cells in organisms: Their growth is continuous and uncontrolled.



Because of their immortality and relative ease of growth, cultured cancer cells are commonly used in research on basic aspects of cell structure and function. For example, the first human cell type to be grown in culture was isolated in 1951 from a malignant tumor of the uterine cervix. These cells are called HeLa cells in honor of their donor, Henrietta Lacks, who died soon thereafter from her cancer. HeLa cells continue to grow in laboratories around the world (Figure B12.1a, right).

Plant Tissue Culture

Certain cells found in plants are totipotent—meaning that they retain the ability to divide and differentiate into a complete, mature plant, including new types of tissue. These cells, called parenchyma cells, are important in wound healing and asexual reproduction. But they also allow researchers to grow complete adult plants in the laboratory, starting with a small number of parenchyma cells.

Biologists who grow plants in tissue culture begin by placing parenchyma cells in a liquid or solid medium containing all the

(a) Animal cell culture: immortal HeLa cancer cells

(b) Plant tissue culture: tobacco callus

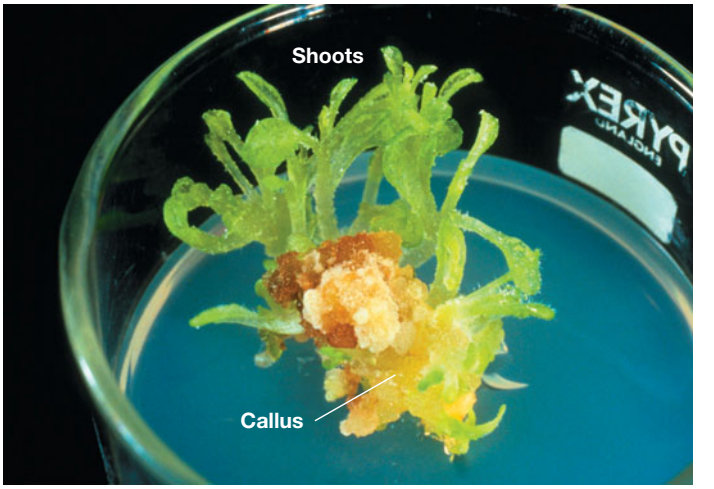


FIGURE B12.1 Animal and Plant Cells Can Be Grown in the Lab.

nutrients required for cell maintenance and growth. In the early days of plant tissue culture, investigators found not only that specific growth signals called hormones were required for successful growth and differentiation but also that the relative abundance of hormones present was critical to success.

The earliest experiments on hormone interactions in tissue cultures were done with tobacco cells in the 1950s by Folke Skoog and co-workers. These researchers found that when the hormone called auxin was added to the culture by itself, the cells enlarged but did not divide. But if the team added roughly equal amounts of auxin and another growth signal called cytokinin to the cells, the cells began to divide and eventually formed a callus, or an undifferentiated mass of parenchyma cells.

By varying the proportion of auxin to cytokinins in different parts of the callus and through time, the team could stimulate the growth and differentiation of root and shoot systems and produce whole new plants (**FIGURE B12.1b**). A high ratio of auxin to cytokinin led to the differentiation of a root system, while a high ratio of cytokinin to auxin led to the development of a shoot system. Eventually Skoog's team was able to produce a complete plant from just one parenchyma cell.

The ability to grow whole new plants in tissue culture from just one cell has been instrumental in the development of genetic engineering (see Chapter 20). Researchers insert recombinant genes into target cells, test the cells to identify those that successfully express the recombinant genes, and then use tissue culture techniques to grow those cells into adult individuals with a novel genotype and phenotype.

BIOSKILL 13 model organisms

Research in biological science starts with a question. In most cases, the question is inspired by an observation about a cell or an organism. To answer it, biologists have to study a particular species. Study organisms are often called model organisms, because investigators hope that they serve as a model for what is going on in a wide array of species.

Model organisms are chosen because they are convenient to study and because they have attributes that make them appropriate for the particular research proposed. They tend to have some common characteristics:

- ***Short generation time and rapid reproduction*** This trait is important because it makes it possible to produce offspring quickly and perform many experiments in a short amount of time—you don't have to wait long for individuals to grow.
- ***Large numbers of offspring*** This trait is particularly important in genetics, where many offspring phenotypes and genotypes need to be assessed to get a large sample size.
- ***Small size, simple feeding and habitat requirements*** These attributes make it relatively cheap and easy to maintain individuals in the lab.

The following notes highlight just a few model organisms supporting current work in biological science.

Escherichia coli

Of all model organisms in biology, perhaps none has been more important than the bacterium *Escherichia coli*—a common inhabitant of the human gut. The strain that is most commonly worked on today, called K-12 (**FIGURE B13.1a**; see B:24), was originally isolated from a hospital patient in 1922.

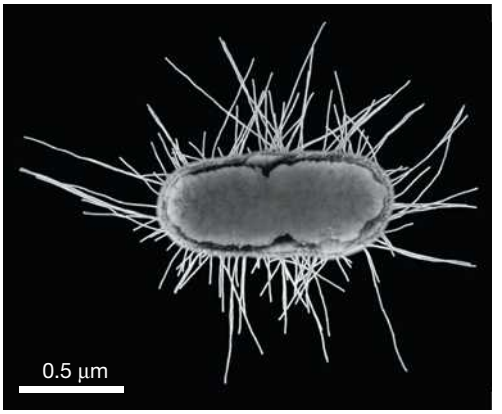
During the last half of the twentieth century, key results in molecular biology originated in studies of *E. coli*. These results include the discovery of enzymes such as DNA polymerase, RNA polymerase, DNA repair enzymes, and restriction endonucleases; the elucidation of ribosome structure and function; and the initial characterization of promoters, regulatory transcription factors, regulatory sites in DNA, and operons. In many cases, initial discoveries made in *E. coli* allowed researchers to confirm that homologous enzymes and processes existed in an array of organisms, often ranging from other bacteria to yeast, mice, and humans.

The success of *E. coli* as a model for other species inspired Jacques Monod's claim that "Once we understand the biology of *Escherichia coli*, we will understand the biology of an elephant." The genome of *E. coli* K-12 was sequenced in 1997, and the strain continues to be a workhorse in studies of gene function, biochemistry, and particularly biotechnology. Much remains to be learned, however. Despite over 60 years of intensive study, the function of about a third of the *E. coli* genome is still unknown.

In the lab, *E. coli* is usually grown in suspension culture, where cells are introduced to a liquid nutrient medium, or on plates containing agar—a gelatinous mix of polysaccharides. Under optimal growing conditions—meaning before cells begin to get crowded and compete for space and nutrients—a cell takes just 30 minutes on average to grow and divide. At this rate, a single cell can produce a population of over a million descendants in just 10 hours. Except for new mutations, all of the descendant cells are genetically identical.

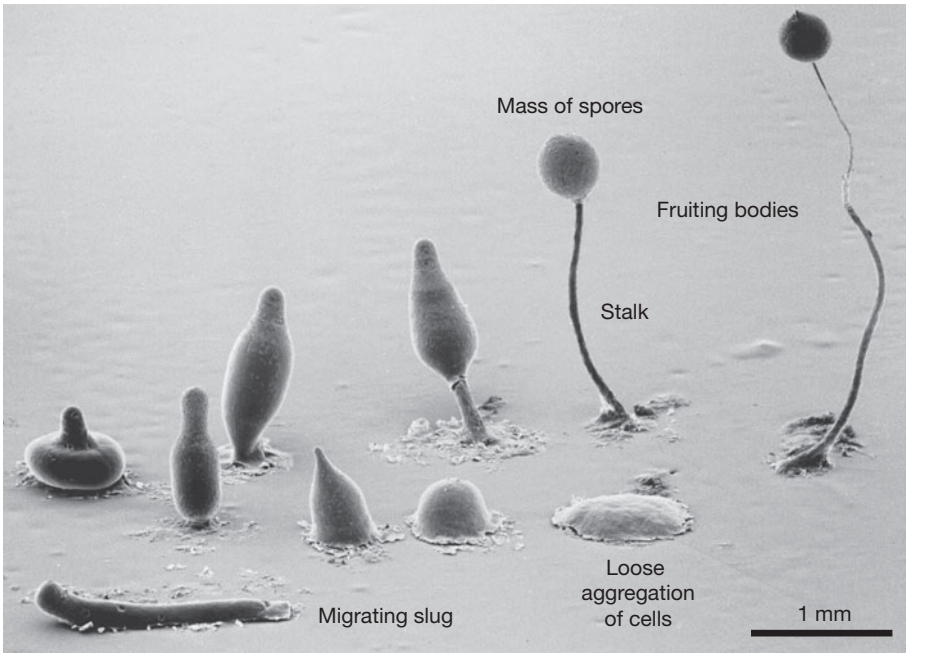
Dictyostelium discoideum

The cellular slime mold *Dictyostelium discoideum* is not always slimy, and it is not a mold—meaning a type of fungus. Instead, it is an amoeba. Amoeba is a general term that biologists use to characterize a unicellular eukaryote that lacks a cell wall and is extremely flexible in shape. *Dictyostelium* has long fascinated biologists because it is a social organism. Independent cells sometimes aggregate to form a multicellular structure.



Under most conditions, *Dictyostelium* cells are haploid (n) and move about in decaying vegetation on forest floors or other habitats. They feed on bacteria by engulfing them whole. When these cells reproduce, they can do so sexually by fusing with another cell then undergoing meiosis, or asexually by mitosis, which is more common. If food begins to run out, the cells begin to aggregate. In many cases, tens of thousands of cells cohere to form a 2-mm-long mass called a slug (**FIGURE B13.1b**). (This is not the slug that is related to snails.)

After migrating to a sunlit location, the slug stops and individual cells differentiate according to their position in the slug. Some form a stalk; others form a mass of spores at the tip of the stalk. (A spore is a single cell that develops into an adult organism, but it is not formed from gamete fusion like a zygote is.) The entire structure, stalk plus mass of spores, is called a fruiting body. Cells that form spores secrete a tough coat and represent a durable resting stage. The fruiting body eventually dries out, and the wind disperses the spores to new locations, where more food might be available.



Dictyostelium has been an important model organism for investigating questions about eukaryotes:

- Cells in a slug are initially identical in morphology but then differentiate into distinctive stalk cells and spores. Studying this process helped biologists better understand how cells in plant and animal embryos differentiate into distinct cell types.

(a) Bacterium *Escherichia coli* (strain K-12)

(d) Yeast *Saccharomyces cerevisiae*

(g) Mouse *Mus musculus*

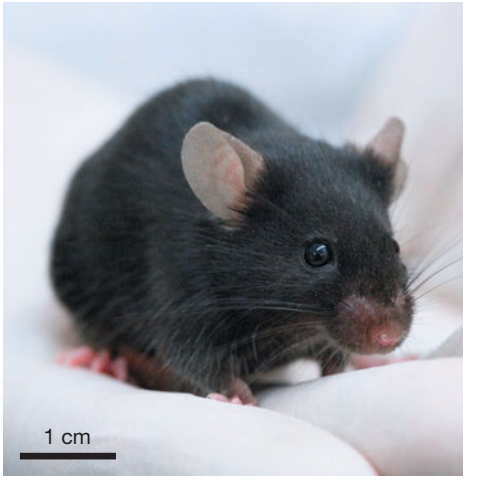

FIGURE B13.1 Model Organisms.

✔ **QUESTION** *E. coli* is grown at a temperature of 37°C. Why?

- The process of slug formation has helped biologists study how animal cells move and how they aggregate as they form specific types of tissues.
- When *Dictyostelium* cells aggregate to form a slug, they stick to each other. The discovery of membrane proteins responsible for cell–cell adhesion helped biologists understand some of the general principles of multicellular life (highlighted in Chapter 11).

Arabidopsis thaliana

In the early days of biology, the best-studied plants were agricultural varieties such as maize (corn), rice, and garden peas. When biologists began to unravel the mechanisms responsible for oxygenic photosynthesis in the early to mid-1900s, they relied on green algae that were relatively easy to grow and manipulate in the lab—often the unicellular species *Chlamydomonas reinhardii*—as an experimental subject.

Although crop plants and green algae continue to be the subject of considerable research, a new model organism emerged in the 1980s and now serves as the preeminent experimental subject in plant biology. That organism is *Arabidopsis thaliana*, commonly known as thale cress or wall cress (**FIGURE B13.1c**).

Arabidopsis is a member of the mustard family, or Brassicaceae, so it is closely related to radishes and broccoli. In nature it is a weed—meaning a species that is adapted to thrive in habitats where soils have been disturbed.

One of the most attractive aspects of working with *Arabidopsis* is that individuals can grow from a seed into a mature, seed-producing plant in just four to six weeks. Several other attributes make it an effective subject for study: It has just five chromosomes, has a relatively small genome with limited numbers of repetitive sequences, can self-fertilize as well as undergo cross-fertilization, can be grown in a relatively small amount of space and with a minimum of care in the greenhouse, and produces up to 10,000 seeds per individual per generation.

Arabidopsis has been instrumental in a variety of studies in plant molecular genetics and development, and it is increasingly popular in ecological and evolutionary studies. In addition, the entire genome of the species has now been sequenced, and studies have benefited from the development of an international "*Arabidopsis* community"—a combination of informal and formal associations of investigators who work on *Arabidopsis* and use regular meetings, e-mail, and the Internet to share data, techniques, and seed stocks.

Saccharomyces cerevisiae

When biologists want to answer basic questions about how eukaryotic cells work, they often turn to the yeast *Saccharomyces cerevisiae*.

S. cerevisiae is unicellular and relatively easy to culture and manipulate in the lab (**FIGURE B13.1d**). In good conditions, yeast cells grow and divide almost as rapidly as bacteria. As a result, the species has become the organism of choice for experiments on control of the cell cycle and regulation of gene expression in eukaryotes. For example, research has confirmed that several of the genes controlling cell division and DNA repair in yeast have homologs in humans; and when mutated, these genes contribute to cancer. Strains of yeast that carry these mutations are now being used to test drugs that might be effective against cancer.

S. cerevisiae has become even more important in efforts to interpret the genomes of organisms like rice, mice, zebrafish, and humans. It is much easier to investigate the function of particular genes in *S. cerevisiae* by creating mutants or transferring specific alleles among individuals than it is to do the same experiments in mice or zebrafish. Once the function of a gene has been established in yeast, biologists can look for the homologous gene in other eukaryotes. If such a gene exists, they can usually infer that it has a function similar to its role in *S. cerevisiae*. It was also the first eukaryote with a completely sequenced genome.

Drosophila melanogaster

If you walk into a biology building on any university campus around the world, you are almost certain to find at least one lab where the fruit fly *Drosophila melanogaster* is being studied (**FIGURE B13.1e**).

Drosophila has been a key experimental subject in genetics since the early 1900s. It was initially chosen as a focus for study by T. H. Morgan, because it can be reared in the laboratory easily and inexpensively, matings can be arranged, the life cycle is completed in less than two weeks, and females lay a large number of eggs. These traits made fruit flies valuable subjects for breeding experiments designed to test hypotheses about how traits are transmitted from parents to offspring (see Chapter 14).

More recently, *Drosophila* has also become a key model organism in the field of developmental biology. The use of flies in developmental studies was inspired largely by the work of Christianne Nüsslein-Volhard and Eric Wieschaus, who in the 1980s isolated flies with genetic defects in early embryonic development. By investigating the nature of these defects, researchers have gained valuable insights into how various gene products influence the development of eukaryotes (see Chapter 22). The complete genome sequence of *Drosophila* has been available to investigators since the year 2000.

Caenorhabditis elegans

The roundworm *Caenorhabditis elegans* emerged as a model organism in developmental biology in the 1970s, due largely to work by Sydney Brenner and colleagues. (*Caenorhabditis* is pronounced *see-no-rab-DIE-tiss*.)

C. elegans was chosen for three reasons: **(1)** Its cuticle (soft outer layer) is transparent, making individual cells relatively easy to observe (**FIGURE B13.1f**); **(2)** adults have exactly 959 nonreproductive cells; and, most important, **(3)** the fate of each cell in an embryo can be predicted because cell fates are invariant among

individuals. For example, when researchers examine a 33-cell *C. elegans* embryo, they know exactly which of the 959 cells in the adult will be derived from each of those 33 embryonic cells.

In addition, *C. elegans* are small (less than 1 mm long), are able to self-fertilize or cross-fertilize, and undergo early development in just 16 hours. The entire genome of *C. elegans* has now been sequenced.

Mus musculus

The house mouse *Mus musculus* is the most important model organism among mammals. For this reason, it is especially prominent in biomedical research, where researchers need to work on individuals with strong genetic and developmental similarities to humans.

The house mouse was an intelligent choice of model organism in mammals because it is small and thus relatively inexpensive to maintain in captivity, and because it breeds rapidly. A litter can contain 10 offspring, and generation time is only 12 weeks—meaning that several generations can be produced in a year. Descendants of wild house mice have been selected for docility and other traits that make them easy to handle and rear; these populations are referred to as laboratory mice (**FIGURE B13.1g**).

Some of the most valuable laboratory mice are strains with distinctive, well-characterized genotypes. Inbred strains are virtually homogenous genetically (see Chapter 26) and are useful in experiments where gene-by-gene or gene-by-environment interactions have to be controlled. Other populations carry mutations that knock out genes and cause diseases similar to those observed in humans. These individuals are useful for identifying the cause of genetic diseases and testing drugs or other types of therapies.

Determine which model organisms described here would be the best choice for the following studies. In each case, explain your reasoning.

1. A study of why specific cells in an embryo die at certain points in normal development. One goal is to understand the consequences for the individual when programmed cell death does not occur when it should.
2. A study of proteins that are required for cell–cell adhesion.
3. Research on a gene suspected to be involved in the formation of breast cancer in humans.

BIOSKILL 14 primary literature and peer review

As part of the process of doing science, biologists communicate their results to the scientific community through publications in scientific journals that report on their original research discoveries (see Chapter 1). These published reports are referred to, interchangeably, as the primary literature, research papers, or primary research articles.

What Is the Primary Literature?

Scientists publish "peer-reviewed" papers. This means that several experts in the field have carefully read the paper and considered its strengths and weaknesses. Reviewers write a critique of the paper and make a recommendation to the journal editor as to whether the paper should be published. Often reviewers will suggest additional experiments that need to be completed before a paper is considered acceptable for publication. The peer review process means that research discoveries are carefully vetted before they go to press.

A primary research paper can be distinguished from secondary sources—such as review articles, textbooks, and magazine articles—by looking for key characteristics. A primary research paper includes a detailed description of methods and results, written by the researchers who did the work. A typical paper contains a Title, Abstract, Introduction, Materials and Methods (or Experimental Design), Results and Discussion (**Table B14.1**), although the order and name of the sections varies among journals.

Getting Started

At first, trying to read the primary literature may seem like a daunting task. A paper may be peppered with unfamiliar terms and acronyms. If you tried to read a research paper from start to finish, like you might read a chapter in this textbook, it would be a frustrating experience. But, with practice, the scientific literature becomes approachable, and it is well worth the effort. The primary literature is the cutting edge, the place to read firsthand about the process of doing science. Becoming skilled at reading and evaluating scientific reports is a powerful way to learn how to think critically—to think like a biologist.

To get started, try breaking down reading the primary research article into a series of steps:

1. Read the authors' names. Where are they from? Are they working as a team or alone? After delving into the literature,

TABLE B14.1 Sections of a Primary Research Paper

Section	Characteristics
Title	Short, succinct, eye-catching
Abstract	Summary of Methods, Results, Discussion. Explains why the research was done and why the results are significant.
Introduction	Background information (what past work was done, why the work was important). States the objectives and hypotheses of the study and explains why the study is important.
Materials and Methods	Explains how the work was done and where it was done.
Results	Explains what the data show.
Discussion	Explains why the data show what they show, how the analysis relates to the objectives from the Introduction, and the significance of findings and how they advance the field.

certain familiar names will crop up again and again. You'll begin to recognize the experts in a particular field.

2. Read the title. It should summarize the key finding of the paper and tell you what you can expect to learn from the paper.
3. Read the abstract. The abstract summarizes the entire paper in a short paragraph. At this point, it might be tempting to stop reading. But sometimes authors understate or overstate the significance and conclusions of their work. You should never cite an article as a reference after having read only the abstract.
4. Read the Introduction. The first couple of paragraphs should make it clear what the objectives or hypotheses of the paper are; the remaining paragraphs will give you the background information you need to understand the point of the paper.
5. Flip through the article and look at the figures, illustrations, and tables, including reading the legends.
6. Read the Results section carefully. Ask yourself these questions: Do the results accurately describe the data presented in the paper? Were all the appropriate controls carried out in an experiment? Are there additional experiments that you think should have been performed? Are the figures and tables clearly labeled?
7. Consult the Materials and Methods section to help understand the research design and the techniques used.
8. Read the Discussion. The first and last paragraphs usually summarize the key findings and state their significance. The Discussion is the part of the paper where the results are explained in the context of the scientific literature. The authors should explain what their results mean.

Getting Practice

The best way to get practice is to start reading the scientific literature as often as possible. You could begin by reading some of the references cited in this textbook. You can get an electronic copy of most articles through online databases such as PubMed, ScienceDirect, or Google Scholar, or through your institution's library.

After reading a primary research paper, you should be able to paraphrase the significance of the paper in a few sentences, free of technical jargon. You should also be able to both praise and criticize several points of the paper. As you become more familiar with reading the scientific literature, you're likely to start thinking about what questions remain to be answered. And, you may even come up with "the next experiment."

C Y U

If you understand BioSkill 14

✔ **You should be able to . . .**

After choosing a primary research paper on a topic in biology that you would like to know more about, select one figure in the Results section that reports on the experiment and construct a Research box (like the ones in this textbook) that depicts this experiment.

BIOSKILL 15 making concept maps

A concept map is a graphical device for organizing and expressing what you know about a topic. It has two main elements: **(1)** concepts that are identified by words or short phrases and placed in a box or circle, and **(2)** labeled arrows that physically link two concepts and explain the relationship between them. The concepts are arranged hierarchically on a page with the most general concepts at the top and the most specific ideas at the bottom.

The combination of a concept, a linking word, and a second concept is called a proposition. Good concept maps also have cross-links—meaning, labeled arrows that connect different elements in the hierarchy as you read down the page.

Concept maps, initially developed by Joseph Novak in the early 1970s, have proven to be an effective studying and learning tool. They can be particularly valuable if constructed by a group, or when different individuals exchange and critique concept maps they have created independently. Although concept maps vary widely in quality and can be graded using objective criteria, there are many equally valid ways of making a high-quality concept map on a particular topic.

When you are asked to make a concept map in this text, you will usually be given at least a partial list of concepts to use. As an example, suppose you were asked to create a concept map on experimental design and were given the following concepts: results, predictions, control treatment, experimental treatment, controlled (identical) conditions, conclusions, experiment, hypothesis to be tested, null hypothesis. One possible concept map is shown in **FIGURE B15.1**.

Good concept maps have four qualities:

1. They exhibit an organized hierarchy, indicating how each concept on the map relates to larger and smaller concepts.
2. The concept words are specific—not vague.
3. The propositions are accurate.
4. There is cross-linking between different elements in the hierarchy of concepts.

As you practice making concept maps, go through these criteria and use them to evaluate your own work as well as the work of fellow students.

C U Y

If you understand BioSkill 15

✔ You should be able to . . .

1. Add an "Alternative hypothesis" concept to the map in Figure B15.1, along with other concepts and labeled linking arrows needed to indicate its relationship to other information on the map. (Hint: Recall that investigators often contrast a hypothesis being tested with an alternative hypothesis that does not qualify as a null hypothesis.)
2. Add a box for the concept "Statistical testing" (see **BIOSKILLS 4**) along with appropriately labeled linking arrows.

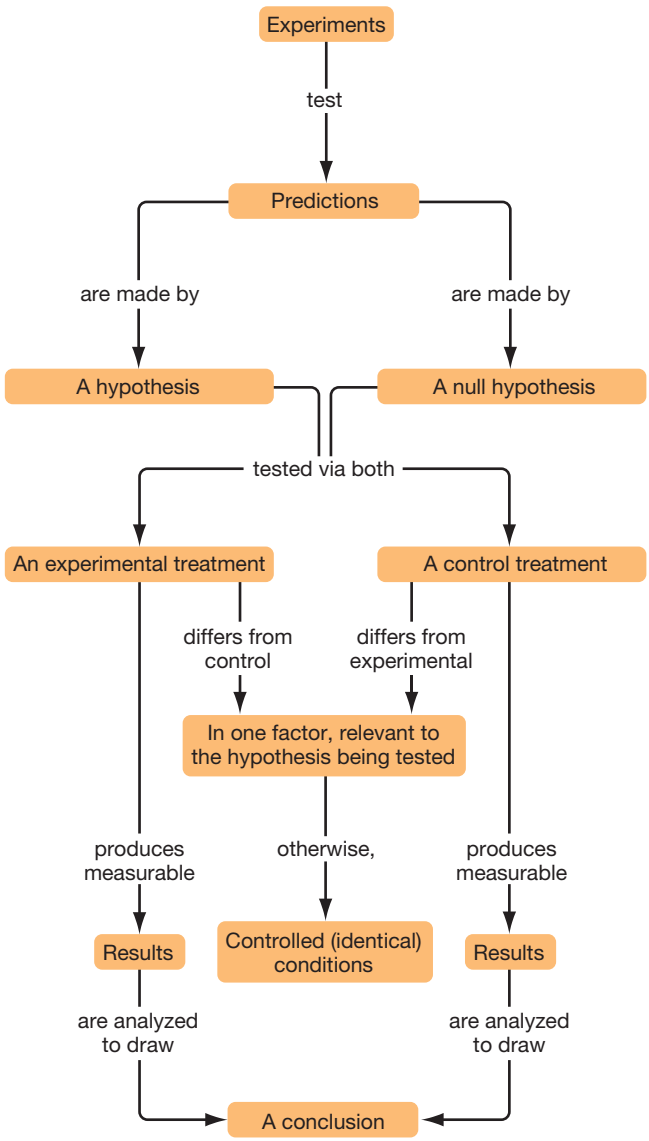

FIGURE B15.1 A Concept Map on Principles of Experimental Design.

BIOSKILL 16 using Bloom's taxonomy

Most students have at one time or another wondered why a particular question on an exam seemed so hard, while others seemed easy. The explanation lies in the type of cognitive skills required to answer the question. Let's take a closer look.

Categories of Human Cognition

Bloom's Taxonomy is a classification system that instructors use to identify the cognitive skill levels at which they are asking students to work, particularly on practice problems and exams. Bloom's Taxonomy is also a very useful tool for students to know—it can help you to figure out the appropriate level at which you should be studying to succeed in a course.

Bloom's Taxonomy distinguishes six different categories of human thinking: remember, understand, apply, analyze, evaluate, and create. One of the most useful distinctions lies not in the differences among the six categories, but rather in the difference between high-order cognitive (HOC) and low-order cognitive (LOC) skills. **FIGURE B16.1** shows how the different levels of the taxonomy can be broken into HOC and LOC skills.

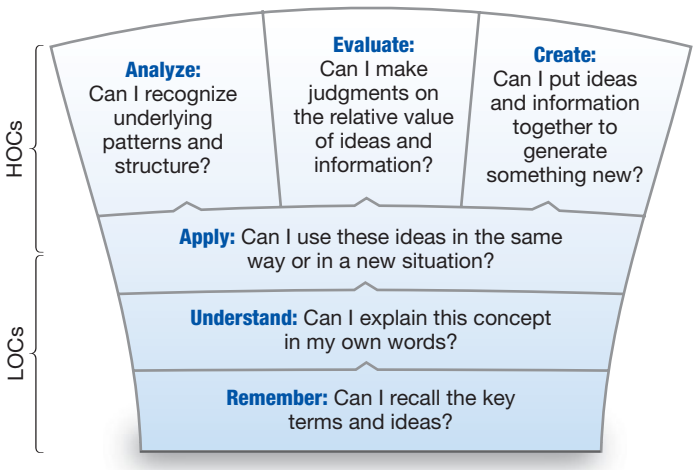
Skills that hallmark LOCs include recall, explanation, or application of knowledge in the exact way that you have before (remember, understand, apply), while skills that typify HOCs include the application of knowledge in a new way, as well as the breakdown, critique, or creation of information (analyze, evaluate, and create). Most college instructors will assume students are proficient at solving LOC questions and will expect you to frequently work at the HOC levels. HOC problems usually require use of basic vocabulary and applying knowledge—working at this level helps students to master the LOC levels.

Six Study Steps to Success

Bloom's Taxonomy provides a useful guide for preparing for an exam, using the following six steps:

1. ***Answer in-chapter questions while reading the chapter.*** All questions in this book have been assigned Bloom's levels, so you can review the question answers and the Bloom's level while you study.
2. ***Identify the Bloom's level(s) of the questions that you are having greatest difficulty answering.*** While working through the text, take note of the content and Bloom's level(s) that you find the most challenging.
3. ***Use the Bloom's Taxonomy Study Guide*** **(Table B16.1; see B:30)** ***to focus your study efforts at the appropriate Bloom's level.*** Table B16.1 lists specific study methods that can help you practice your understanding of the material at both the LOC and HOC levels, whether you are studying alone or with a study group.
4. ***Complete the end-of-chapter questions as if you're taking an exam, without looking for the answers.*** If you look at the chapter text or jump to the answers, then you really aren't testing your ability to work with the content and have reduced the questions to the lowest Bloom's level of remember.
5. ***Grade your answers and note the Bloom's level of the questions you got wrong.*** At what level of Bloom's Taxonomy were the questions you missed?
6. ***Use the Bloom's Taxonomy Study Guide to focus your study efforts at the appropriate Bloom's level.*** If you missed a lot of questions, then spend more time studying the material and find other resources for quizzing yourself.

By following these steps and studying at the HOC levels, you should succeed in answering questions on in-class exams.



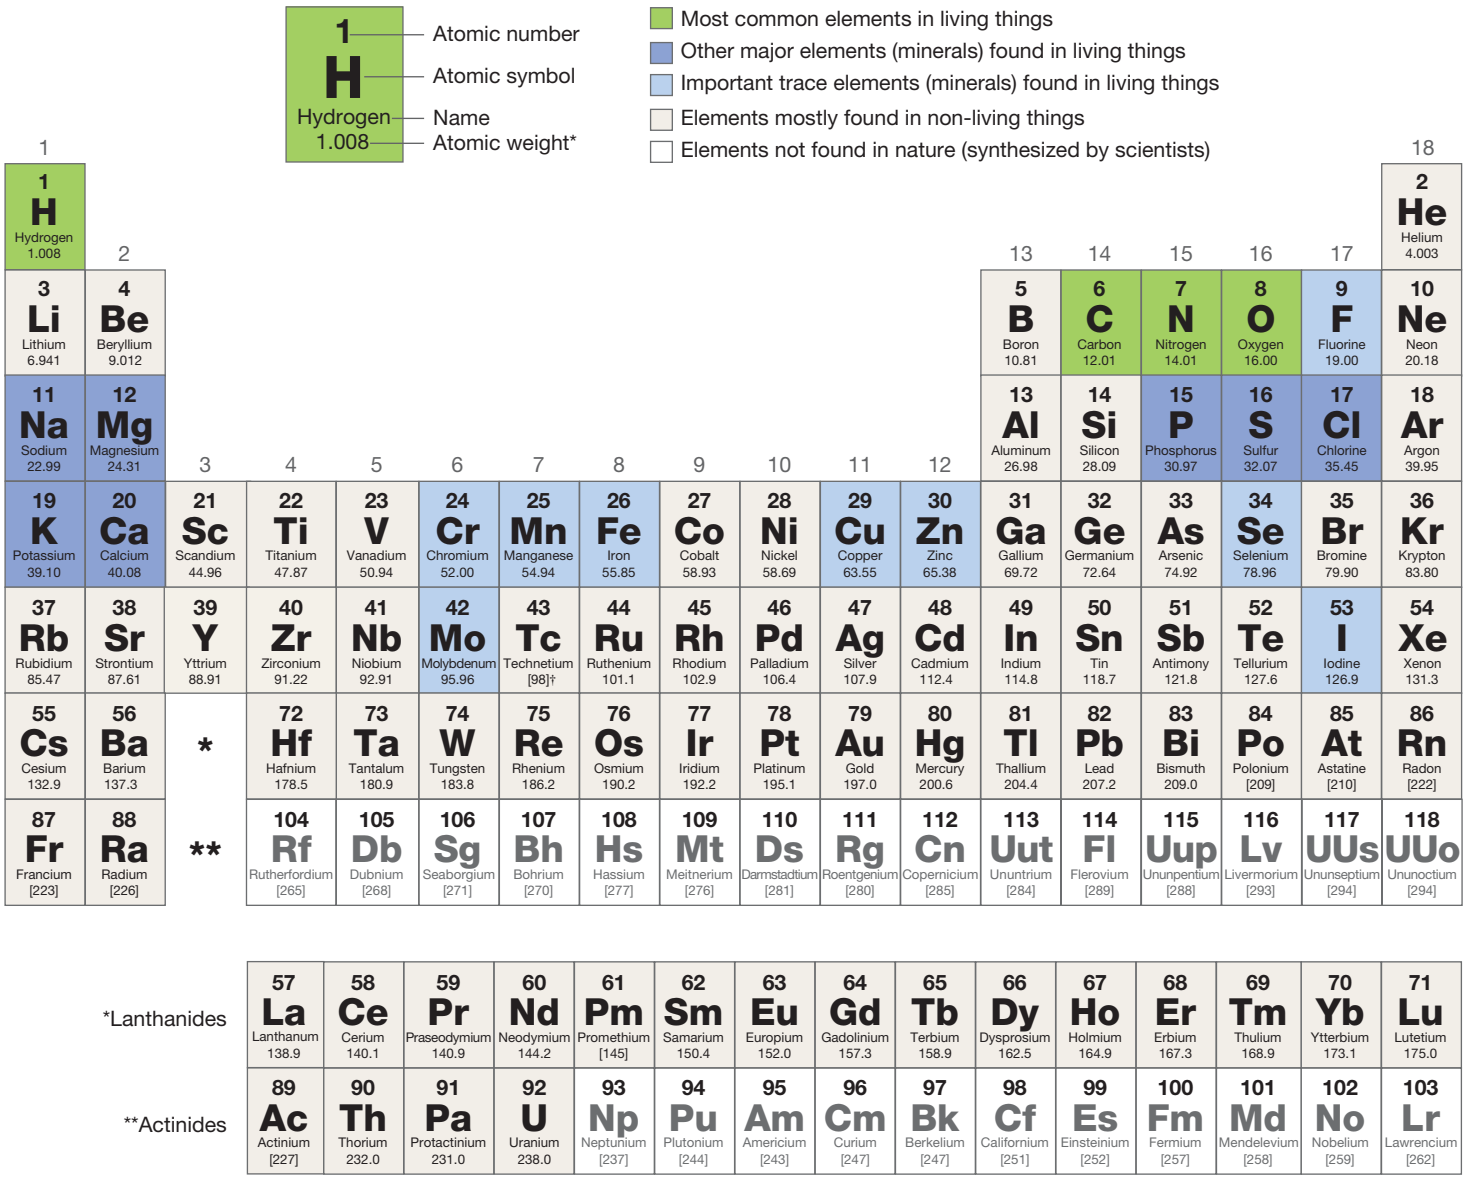


FIGURE B16.1 **Bloom's Taxonomy.**

TABLE B16.1 Bloom's Taxonomy Study Guide

	Individual Study Activities	Group Study Activities
Create (HOC) Generate something new	• Generate a hypothesis or design an experiment based on information you are studying • Create a model based on a given data set • Create summary sheets that show how facts and concepts relate to each other • Create questions at each level of Bloom's Taxonomy as a practice test and then take the test	• Each student puts forward a hypothesis about biological process and designs an experiment to test it. Peers critique the hypotheses and experiments • Create a new model/summary sheet/concept map that integrates each group member's ideas
Evaluate (HOC) Defend or judge a concept or idea	• Provide a written assessment of the strengths and weaknesses of your peers' work or understanding of a given concept based on previously determined criteria	• Provide a verbal assessment of the strengths and weaknesses of your peers' work or understanding of a given concept based on previously described criteria, and have your peers critique your assessment
Analyze (HOC) Distinguish parts and make inferences	• Analyze and interpret data in primary literature or a textbook without reading the author's interpretation and then compare the authors' interpretation with your own • Analyze a situation and then identify the assumptions and principles of the argument • Compare and contrast two ideas or concepts • Construct a map of the main concepts by defining the relationships of the concepts using one- or two-way arrows	• Work together to analyze and interpret data in primary literature or a textbook without reading the author's interpretation, and defend your analysis to your peers • Work together to identify all of the concepts in a paper or textbook chapter, construct individual maps linking the concepts together with arrows and words that relate the concepts, and then grade each other's concept maps
Apply (HOC or LOC) Use information or concepts in new ways (HOC) or in the same ways (LOC)	• Review each process you have learned and then ask yourself: What would happen if you increase or decrease a component in the system, or what would happen if you alter the activity of a component in the system? • If possible, graph a biological process and create scenarios that change the shape or slope of the graph	• Practice writing out answers to old exam questions on the board, and have your peers check to make sure you don't have too much or too little information in your answer • Take turns teaching your peers a biological process while the group critiques the content
Understand (LOC) Explain information or concepts	• Describe a biological process in your own words without copying it from a book or another source • Provide examples of a process • Write a sentence using the word • Give examples of a process	• Discuss content with peers • Take turns quizzing each other about definitions, and have your peers check your answer
Remember (LOC) Recall information	• Practice labeling diagrams • List characteristics • Identify biological objects or components from flash cards • Quiz yourself with flash cards • Take a self-made quiz on vocabulary • Draw, classify, select, or match items • Write out the textbook definitions	• Check a drawing that another student labeled • Create lists of concepts and processes that your peers can match • Place flash cards in a bag and take turns selecting one for which you must define a term • Do the preceding activities, and have peers check your answers

APPENDIX C Periodic Table of Elements

DATA: Wieser, M. E., and M. Berglund. 2009. *Pure and Applied Chemistry* 81: 2131–2156.

*Atomic weights are reported to four significant figures.

†For elements with a variable number of protons and/or neutrons, the mass number of the longest-lived isotope of the element is reported in brackets.

This page intentionally left blank

Glossary

5′ cap A modified guanine (G) nucleotide (7-methylguanylate) added to the 5′ end of eukaryotic mRNAs. Helps protect the mRNA from being degraded and promotes efficient initiation of translation.

abdomen A region of the body; in insects, one of the three prominent body regions called tagmata.

abiotic Not alive (e.g., air, water, and some components of soil). Compare with **biotic**.

aboveground biomass The total mass of living plants in an area, excluding roots.

abscisic acid (ABA) A plant hormone that inhibits growth; it stimulates stomatal closure and triggers dormancy.

abscission In plants, the normal (often seasonal) shedding of leaves, fruits, or flowers.

abscission zone The region at the base of a petiole where cell wall degradation occurs; results in the dropping of leaves.

absorption In animals, the uptake of ions and small molecules, derived from food, across the lining of the intestine and into the bloodstream.

absorption spectrum The amount of light of different wavelengths absorbed by a pigment. Usually depicted as a graph of light absorbed versus wavelength. Compare with **action spectrum**.

acclimation A change in a study organism's phenotype that occurs in response to laboratory conditions.

acclimatization A change in an individual's phenotype that occurs in response to a change in natural environmental conditions.

acetyl CoA A molecule produced by oxidation of pyruvate (the final product of glycolysis) in a reaction catalyzed by pyruvate dehydrogenase. Can enter the citric acid cycle and is used as a carbon source in the synthesis of fatty acids, steroids, and other compounds.

acetylation Addition of an acetyl group ($-COCH_3$) to a molecule. Acetylation of histone proteins is important in controlling chromatin condensation.

acetylcholine (Ach) A neurotransmitter, released by nerve cells at neuromuscular junctions, that triggers contraction of skeletal muscle cells but slows the rate of contraction in cardiac muscle cells. Also used as a neurotransmitter between neurons.

acid Any compound that gives up protons or accepts electrons during a chemical reaction or that releases hydrogen ions when dissolved in water.

acid-growth hypothesis The hypothesis that auxin triggers elongation of plant cells by increasing the activity of proton pumps, making the cell wall more acidic and leading to expansion of the cell wall and an influx of water.

acoelomate A bilaterian animal that lacks an internal body cavity (coelom). Compare with **coelomate** and **pseudocoelomate**.

acquired immune deficiency syndrome (AIDS) A human disease characterized by death of immune system cells (in particular helper T cells) and subsequent vulnerability to other infections. Caused by the human immunodeficiency virus (HIV).

acrosome A caplike structure, located on the head of a sperm cell, that contains enzymes capable of dissolving the outer coverings of an egg.

ACTH See **adrenocorticotropic hormone**.

actin A globular protein that can be polymerized to form filaments. Actin filaments are part of the cytoskeleton and constitute the thin filaments in skeletal muscle cells.

actin filament A long fiber, about 7 nm in diameter, composed of two intertwined strands of polymerized actin protein; one of the three types of cytoskeletal fibers. Involved in cell movement. Also called a *microfilament*. Compare with **intermediate filament** and **microtubule**.

action potential A rapid, temporary change in electrical potential across a membrane, from negative to positive and back to negative. Occurs in cells, such as neurons and muscle cells, that have an excitable membrane.

action spectrum The relative effectiveness of different wavelengths of light in driving a light-dependent process such as photosynthesis. Usually depicted as a graph of some measure of the process versus wavelength. Compare with **absorption spectrum**.

activation energy The amount of energy required to initiate a chemical reaction; specifically, the energy required to reach the transition state.

activator A protein that binds to a DNA regulatory sequence to increase the frequency of transcription initiation by RNA polymerase.

active site The location in an enzyme molecule where substrates (reactant molecules) bind and react.

active transport The movement of ions or molecules across a membrane against an electrochemical gradient. Requires energy (e.g., from hydrolysis of ATP) and assistance of a transport protein (e.g., pump).

adaptation Any heritable trait that increases the fitness of an individual with that trait, compared with individuals without that trait, in a particular environment.

adaptive immune response See **adaptive immunity**.

adaptive immunity Immunity to a particular pathogen or other antigen conferred by activated B and T cells in vertebrates. Characterized by specificity, diversity, memory, and self–nonself recognition. Also called *adaptive immune response.* Compare with **innate immunity**.

adaptive radiation Rapid evolutionary diversification within one lineage, producing many descendant species with a wide range of adaptive forms.

adenosine triphosphate (ATP) A molecule consisting of an adenine base, a sugar, and three phosphate groups that can be hydrolyzed to release energy. Universally used by cells to store and transfer energy.

adhesion The tendency of certain dissimilar molecules to cling together due to attractive forces. Compare with **cohesion**.

adipocyte A fat cell.

adrenal gland Either of two small endocrine glands, one above each kidney. The outer portion (cortex) secretes several steroid hormones; the inner portion (medulla) secretes epinephrine and norepinephrine.

adrenaline See **epinephrine**.

adrenocorticotropic hormone (ACTH) A peptide hormone, produced and secreted by the anterior pituitary, that stimulates release of steroid hormones (e.g., cortisol, aldosterone) from the adrenal cortex.

adult A sexually mature individual.

adventitious root A root that develops from a plant's shoot system instead of from the plant's root system.

aerobic Referring to any metabolic process, cell, or organism that uses oxygen as an electron acceptor. Compare with **anaerobic**.

afferent division The part of the nervous system that transmits information about the internal and external environment to the central nervous system. Consists mainly of sensory neurons. Compare with **efferent division**.

age class All the individuals of a specific age in a population.

age-specific fecundity The average number of female offspring produced by a female in a certain age class.

age structure The proportion of individuals in a population that are of each possible age.

agglutination Clumping together of cells or viruses by antibodies or other cross-linking molecules.

aggregate fruit A fruit (e.g., raspberry) that develops from a single flower that has many separate carpels. Compare with **multiple** and **simple fruit**.

AIDS See **acquired immune deficiency syndrome**.

albumen A solution of water and protein (particularly albumins), found in amniotic eggs, that nourishes the growing embryo. Also called *egg white*.

alcohol fermentation Catabolic pathway in which pyruvate produced by glycolysis is converted to ethanol in the absence of oxygen.

aldosterone A hormone that stimulates the kidney to conserve salt and water and promotes retention of sodium; produced in the adrenal cortex.

allele A particular version of a gene.

allergen Any molecule (antigen) that triggers an allergic response (an allergy).

allergy An IgE-mediated abnormal response to an antigen, usually characterized by dilation of blood vessels, contraction of smooth muscle cells, and increased activity of mucus-secreting cells.

allopatric speciation Speciation that occurs when populations of the same species become geographically isolated, often due to dispersal or vicariance. Compare with **sympatric speciation**.

allopatry Condition in which two or more populations live in different geographic areas. Compare with **sympatry**.

allopolyploidy (adjective: allopolyploid) The state of having more than two full sets of chromosomes (polyploidy) due to hybridization between different species. Compare with **autopolyploidy**.

allosteric regulation Regulation of a protein's function by binding of a regulatory molecule, usually to a specific site distinct from the active site, that causes a change in the protein's shape.

α-amylase See **amylase**.

α-helix (alpha-helix) A protein secondary structure in which the polypeptide backbone coils into a spiral shape stabilized by hydrogen bonding.

alternation of generations A life cycle involving alternation of a multicellular haploid stage (gametophyte) with a multicellular diploid stage (sporophyte). Occurs in most plants and some protists.

alternative splicing In eukaryotes, the splicing of primary RNA transcripts from a single gene in different ways to produce different mature mRNAs and thus different polypeptides.

altruism Any behavior that has a fitness cost to the individual (lowered survival and/or reproduction) and a fitness benefit to the recipient. See **reciprocal altruism**.

alveolus (plural: alveoli) Any of the tiny air-filled sacs of a mammalian lung.

ambisense RNA virus A ssRNA virus whose genome consists of at least one strand that contains both positive-sense and negative-sense regions.

aminoacyl tRNA A transfer RNA molecule that is covalently bound to an amino acid.

aminoacyl-tRNA synthetase An enzyme that catalyzes the addition of a particular amino acid to its corresponding tRNA molecule.

ammonia (NH_3) A small molecule, produced by the breakdown of proteins and nucleic acids, that is very toxic to cells. Is a strong base that gains a proton to form the ammonium ion (NH_4^+).

amnion The innermost of the membranes surrounding the embryo in an amniotic egg.

amniotes A major lineage of vertebrates (Amniota) that reproduce with amniotic eggs. Includes all reptiles (including birds) and mammals—all tetrapods except amphibians.

amniotic egg An egg that has a watertight shell or case enclosing a membrane-bound water supply (the amnion), food supply (yolk sac), and waste sac (allantois).

amoeboid motion See **cell crawling**.

amphibians A lineage of vertebrates, many of which breathe through their skin and feed on land but lay their eggs in water. Represent the earliest tetrapods; include frogs, salamanders, and caecilians.

amphipathic Containing hydrophilic and hydrophobic regions.

ampullae of Lorenzini Structures on the heads of sharks that contain cells with electroreceptors.

amylase Any enzyme that can break down starch by catalyzing hydrolysis of the glycosidic linkages between the glucose residues.

amyloplasts Starch-storing organelles (plastids) in plants. In root cap cells, they settle to the bottom of the cell and may be used as gravity detectors.

anabolic pathway Any set of chemical reactions that synthesizes large molecules from smaller ones. Generally requires an input of energy. Compare with **catabolic pathway**.

anadromous Having a life cycle in which adults live in the ocean (or large lakes) but migrate up freshwater streams to breed and lay eggs.

anaerobic Referring to any metabolic process, cell, or organism that uses an electron acceptor other than oxygen, including fermentation or anaerobic respiration. Compare with **aerobic**.

anaphase A stage in mitosis or meiosis during which chromosomes are moved to opposite poles of the spindle apparatus.

anatomy The study of the physical structure of organisms.

ancestral trait A trait found in the ancestors of a particular group.

aneuploidy (adjective: aneuploid) The state of having an abnormal number of copies of a certain chromosome.

angiosperm A flowering vascular plant that produces seeds within mature ovaries (fruits). The angiosperms form a single lineage. Compare with **gymnosperm**.

animal A member of a major lineage of eukaryotes (Animalia) whose members typically have a complex, large, multicellular body; eat other organisms; and are mobile.

animal model Any disease that occurs in a nonhuman animal and has parallels to a similar disease of humans. Studied by medical researchers in hopes that findings may apply to human disease.

anion A negatively charged ion.

annelids Members of the phylum Annelida (segmented worms). Distinguished by a segmented body and a coelom that functions as a hydrostatic skeleton. Annelids belong to the lophotrochozoan branch of the protostomes.

annual Referring to a plant whose life cycle normally lasts only one growing season—less than one year. Compare with **perennial**.

anoxygenic Referring to any process or reaction that does not produce oxygen. Photosynthesis in purple sulfur and purple nonsulfur bacteria, which does not involve photosystem II, is anoxygenic. Compare with **oxygenic**.

antagonistic muscle group A set of two or more muscles that reextend one another by transmitting their forces via the skeleton.

antenna (plural: antennae) A long appendage of the head that is used to touch or smell.

antenna complex Part of a photosystem, containing an array of chlorophyll molecules and accessory pigments, that receives energy from light and directs the energy to a central reaction center during photosynthesis.

anterior Toward an animal's head and away from its tail. The opposite of posterior.

anterior pituitary The part of the pituitary gland containing endocrine cells that produce and release a variety of peptide hormones in response to other hormones from the hypothalamus. Compare with **posterior pituitary**.

anther The pollen-producing structure at the end of a stamen in flowering plants (angiosperms).

antheridium (plural: antheridia) The sperm-producing structure in most land plants except angiosperms.

anthropoids One of the two major lineages of primates, including apes, humans, and all monkeys. Compare with **prosimians**.

antibiotic Any substance, such as penicillin, that can kill or inhibit the growth of bacteria.

antibody A protein produced by B cells that can bind to a specific part of an antigen, tagging it for removal by the immune system. All monomeric forms of antibodies consist of two light chains and two heavy chains, which vary between different antibodies. Also called *immunoglobulin*.

anticodon The sequence of three bases (a triplet) in a transfer RNA molecule that can bind to an mRNA codon with a complementary sequence.

antidiuretic hormone (ADH) A peptide hormone, secreted from the posterior pituitary gland, that stimulates water retention by the kidney. Also called *vasopressin*.

antigen Any foreign molecule, often a protein, that can stimulate an innate or adaptive response by the immune system.

antigen presentation Process by which small peptides, derived from ingested particulate antigens (e.g., bacteria) or intracellular antigens (e.g., viruses in infected cell) are complexed with MHC proteins and transported to the cell surface, where they are displayed and can be recognized by T cells.

antiparallel Describing the opposite orientation of nucleic acid strands that are hydrogen bonded to one another, with one strand running in the 5′→3′ direction and the other in the 3′→5′ direction.

antiporter A carrier protein that allows an ion to diffuse down an electrochemical gradient, using the energy of that process to transport a different substance in the opposite direction *against* its concentration gradient. Compare with **symporter**.

antiviral Any drug or other agent that can interfere with the transmission or replication of viruses.

aorta In terrestrial vertebrates, the major artery carrying oxygenated blood away from the heart.

aphotic zone Deep water receiving no sunlight. Compare with **photic zone**.

apical Toward the top. In plants, at the tip of a branch. In animals, on the side of an epithelial layer

that faces the environment and not other body tissues. Compare with **basal**.

apical–basal axis The shoot-to-root axis of a plant.

apical bud A bud at the tip of a stem or branch, where growth occurs to lengthen the stem or branch.

apical dominance Inhibition of lateral bud growth by the apical meristem at the tip of a plant branch.

apical meristem A group of undifferentiated plant cells, at the tip of a shoot or root, that is responsible for primary growth. Compare with **cambium**.

apodeme Any of the chitinous ingrowths of the exoskeleton to which muscles attach.

apomixis The formation of mature seeds without fertilization occurring; a type of asexual reproduction.

apoplast In plants, the region outside plasma membranes consisting of the porous cell walls and the intervening extracellular air space. Compare with **symplast**.

apoptosis Series of tightly controlled changes that lead to the self-destruction of a cell. Occurs frequently during embryological development and as part of the immune response to remove infected or cancerous cells. Also called *programmed cell death*.

appendix A blind sac (having only one opening) that extends from the cecum in some mammals.

aquaporin A type of channel protein through which water can move by osmosis across a plasma membrane.

aquifer An underground layer of porous rock, sand, or gravel that is saturated with water.

***ara* operon** A set of three genes in *E. coli* that are transcribed into a single mRNA and required for metabolism of the sugar arabinose. Transcription of the *ara* operon is controlled by the AraC regulatory protein.

araC The regulatory gene (written as *araC*) or regulatory protein (when written as AraC) of the *E. coli ara* operon.

arbuscular mycorrhizal fungi (AMF) Fungi from the Glomeromycota lineage whose hyphae enter the root cells of their host plants. Also called *endomycorrhizal fungi*.

Archaea One of the three taxonomic domains of life, consisting of unicellular prokaryotes distinguished by cell walls made of certain polysaccharides not found in bacterial or eukaryotic cell walls, plasma membranes composed of unique isoprene-containing phospholipids, and ribosomes and RNA polymerase similar to those of eukaryotes. Compare with **Bacteria** and **Eukarya**.

archegonium (plural: archegonia) The egg-producing structure in most land plants except angiosperms.

arteriole Any of the many tiny vessels that carry blood from arteries to capillaries.

arteriosclerosis Hardening and loss of elasticity of arteries.

artery Any thick-walled blood vessel that carries blood (oxygenated or not) under relatively high pressure away from the heart to organs throughout the body. Compare with **vein**.

arthropods Members of the phylum Arthropoda. Distinguished by a segmented body; a hard, jointed exoskeleton; paired, jointed appendages; and an extensive body cavity called a hemocoel. Arthropods belong to the ecdysozoan branch of the protostomes.

articulation A movable point of contact between two rigid components of a skeleton, such as between bones of a vertebrate endoskeleton or between segments of cuticle in an arthropod exoskeleton. See **joint**.

artificial selection Deliberate manipulation by humans, as in animal and plant breeding, of the genetic composition of a population by allowing only individuals with desirable traits to reproduce.

ascus (plural: asci) Specialized spore-producing cell found at the ends of hyphae in "sac fungi" (Ascomycota).

asexual reproduction Any form of reproduction where offspring inherit DNA from only one parent. Includes binary fission, budding, and parthenogenesis. Compare with **sexual reproduction**.

astral microtubules Mitotic and meiotic microtubules that have arisen from the two spindle poles and interact with proteins on the plasma membrane.

asymmetric competition Ecological competition between two species in which one species suffers a much greater fitness decline than the other. Compare with **symmetric competition**.

atomic number The number of protons in the nucleus of an atom, giving the atom its identity as a particular chemical element.

atomic weight The average mass of an element that is based on the relative proportions of all the naturally occurring isotopes.

ATP synthase A large membrane-bound protein complex that uses the energy of protons flowing through it to synthesize ATP.

ATP See **adenosine triphosphate**.

atrioventricular (AV) node A region of the heart between the right atrium and right ventricle where electrical signals from the atrium are slowed briefly before spreading to the ventricle. This delay allows the ventricle to fill with blood before contracting. Compare with **sinoatrial (SA) node**.

atrium (plural: atria) A thin-walled chamber of the heart that receives blood from veins and pumps it to a neighboring chamber (the ventricle).

autocrine Relating to a chemical signal that affects the same cell that produced and released it.

autoimmunity A pathological condition in which the immune system attacks self cells or tissues of an individual's own body.

autonomic nervous system The part of the peripheral nervous system that controls internal organs and involuntary processes, such as stomach contraction, hormone release, and heart rate. Includes parasympathetic and sympathetic nerves. Compare with **somatic nervous system**.

autophagy The process by which damaged organelles are surrounded by a membrane and delivered to a lysosome to be recycled.

autopolyploidy (adjective: autopolyploid) The state of having more than two full sets of chromosomes (polyploidy) due to a mutation that doubled the chromosome number. All the chromosomes come from the same species. Compare with **allopolyploidy**.

autosomal inheritance The inheritance patterns that occur when genes are located on autosomes rather than on sex chromosomes.

autosome Any chromosome other than a sex chromosome (i.e,. any chromosome other than the X or Y in mammals).

autotroph Any organism that can synthesize reduced organic compounds from simple inorganic sources such as CO_2 or CH_4. Most plants and some bacteria and archaea are autotrophs. Also called *primary producer*. Compare with **heterotroph**.

auxin Indoleacetic acid (IAA), a plant hormone that stimulates phototropism and cell elongation.

axillary bud A bud that forms at a node and may develop into a lateral (side) branch. Also called *lateral bud*.

axon A long projection of a neuron that can propagate an action potential.

axon hillock The site in a neuron where an axon joins the cell body and where action potentials are first triggered.

axoneme A structure found in eukaryotic cilia and flagella and responsible for their motion; composed of two central microtubules surrounded by nine doublet microtubules (9 + 2 arrangement).

B cell A type of lymphocyte that matures in the bone marrow and, with T cells, is responsible for adaptive immunity. Produces antibodies and also functions in antigen presentation. Also called *B lymphocyte*.

B-cell receptor (BCR) An immunoglobulin protein embedded in the plasma membrane of mature B cells and to which antigens bind. Apart from the transmembrane domain, it is identical in structure to antibodies.

BAC library A collection of all the sequences found in the genome of a species, inserted into **bacterial artificial chromosomes (BACs)**.

background extinction The average rate of low-level extinction that has occurred continuously throughout much of evolutionary history. Compare with **mass extinction**.

Bacteria One of the three taxonomic domains of life, consisting of unicellular prokaryotes distinguished by cell walls composed largely of peptidoglycan, plasma membranes similar to those of eukaryotic cells, and ribosomes and RNA polymerase that differ from those in archaeans or eukaryotes. Compare with **Archaea** and **Eukarya**.

bacterial artificial chromosome (BAC) An artificial version of a bacterial chromosome that can be used as a cloning vector to produce many copies of large DNA fragments.

bacteriophage Any virus that infects bacteria.

baculum A bone inside the penis; usually present in mammals with a penis that lacks erectile tissue.

balancing selection A mode of natural selection in which no single allele is favored in all populations of a species at all times. Instead, there is a balance among alleles in terms of fitness and frequency.

ball-and-stick model A representation of a molecule where atoms are shown as balls—colored and scaled to indicate the atom's identity—and covalent bonds are shown as rods or sticks connecting the balls in the correct geometry.

bar coding The use of well-characterized gene sequences to identify species.

bark The protective outer layer of woody plants, composed of cork cells, cork cambium, and secondary phloem.

baroreceptors Specialized nerve cells in the walls of the heart and certain major arteries that detect changes in blood pressure and trigger appropriate responses by the brain.

basal Toward the base. In plants, toward the root or at the base of a branch where it joins the stem. In animals, on the side of an epithelial layer that abuts underlying body tissues. Compare with **apical**.

basal body The microtubule organizing center for cilia and flagella in eukaryotic cells. Consists of nine triplets of microtubules arranged in a circle and establishes the structure of axonemes. Structurally identical with a centriole.

basal lamina A thick, collagen-rich extracellular matrix that underlies most epithelial tissues in animals and connects it to connective tissue.

basal metabolic rate (BMR) The total energy consumption by an organism at rest in a comfortable environment. For aerobes, often measured as the amount of oxygen consumed per hour.

basal transcription factor Proteins, present in all eukaryotic cells, that bind to promoters and help initiate transcription. Compare with **regulatory transcription factor**.

base Any compound that acquires protons or gives up electrons during a chemical reaction or accepts hydrogen ions when dissolved in water.

basidium (plural: basidia) Specialized spore-producing cell at the ends of hyphae in club fungi, members of the Basidiomycota.

basilar membrane The membrane on which the bottom portion of hair cells sits in the vertebrate cochlea.

basolateral Toward the bottom and sides. In animals, the side of an epithelial layer that faces other body tissues and not the environment.

Batesian mimicry A type of mimicry in which a harmless or palatable species resembles a dangerous or poisonous species. Compare with **Müllerian mimicry**.

beak A structure that exerts biting forces and is associated with the mouth; found in birds, cephalopods, and some insects.

behavior Any action by an organism, often in response to a stimulus.

behavioral ecology The study of how organisms respond to particular abiotic and biotic stimuli from their environment.

beneficial In genetics, referring to any mutation, allele, or trait that increases an individual's fitness.

benign tumor A mass of abnormal tissue that appears due to unregulated growth but does not spread to other organs. Benign tumors are not cancers. Compare with **malignant tumor**.

benthic Living at the bottom of an aquatic environment.

benthic zone The area along the bottom of an aquatic environment.

β-pleated sheet (beta-pleated sheet) A protein secondary structure in which the polypeptide backbone folds into a sheetlike shape stabilized by hydrogen bonding.

bilateral symmetry An animal body pattern in which one plane of symmetry divides the body into a left side and a right side. Typically, the body is long and narrow, with a distinct head end and tail end. Compare with **radial symmetry**.

bilaterian A member of a major lineage of animals (Bilateria) that are bilaterally symmetrical at some point in their life cycle, have three embryonic germ layers, and have a coelom. All protostomes and deuterostomes are bilaterians.

bile A complex solution produced by the liver, stored in the gallbladder, and secreted into the intestine. Contains steroid derivatives called bile salts that are responsible for emulsification of fats during digestion.

binary fission The process of cell division used for asexual reproduction of many prokaryotic cells. The genetic material is replicated and partitioned to opposite sides of a growing cell, which is then divided in half to create two genetically identical cells.

biodiversity The diversity of life considered at three levels: genetic diversity (variety of alleles and/or genes in a population, species, or group of species); species diversity (variety and relative abundance of species present in a certain area); and ecosystem diversity (variety of communities and abiotic components in a region).

biodiversity hotspot A region that is extraordinarily rich in species.

biofilm A complex community of bacteria enmeshed in a polysaccharide-rich, extracellular matrix that allows them to attach to a surface.

biogeochemical cycle The pattern of circulation of an element or molecule among living organisms and the environment.

biogeography The study of how species and populations are distributed geographically.

bioinformatics The field of study concerned with managing, analyzing, and interpreting biological information, particularly DNA sequences.

biological species concept The definition of a species as a population or group of populations that are reproductively isolated from other groups. Members of a species have the potential to interbreed in nature to produce viable, fertile offspring but cannot interbreed successfully with members of other species. Compare with **morphospecies** and **phylogenetic species concepts**.

bioluminescence The emission of light by a living organism via an enzyme-catalyzed reaction.

biomagnification In animal tissues, an increase in the concentration of particular molecules that may occur as those molecules are passed up a food chain.

biomass The total mass of all organisms in a given population or geographical area; usually expressed as total dry weight.

biome A large terrestrial or marine region characterized by distinct abiotic characteristics and dominant types of vegetation.

biomechanics A field of biology that applies the principles of physics and engineering to analyze the mechanical structure and function of organisms.

bioprospecting The effort to find commercially useful compounds by studying organisms—especially species that are poorly studied to date.

bioremediation The use of living organisms, usually bacteria or archaea, to degrade environmental pollutants.

biosphere The thin zone surrounding the Earth where all life exists; the sum of all terrestrial and aquatic ecosystems.

biotechnology The application of biological techniques and discoveries to medicine, industry, and agriculture.

biotic Living, or produced by a living organism. Compare with **abiotic**.

bipedal Walking primarily on two legs; characteristic of hominins.

bipolar cell A type of cell in the vertebrate retina that receives information from one or more photoreceptors and passes it to other bipolar cells or ganglion cells.

bivalent The structure formed by synapsed homologous chromosomes during prophase of meiosis I. Also known as a *tetrad*.

bivalves A lineage of mollusks that have shells made of two parts, or valves, such as clams and mussels.

bladder A mammalian organ that holds urine until it can be excreted.

blade The wide, flat part of a plant leaf.

blastocoel Fluid-filled cavity in the blastula of many animal species.

blastocyst The mammalian blastula. A roughly spherical structure composed of trophoblast cells on the exterior and a cluster of cells (the inner cell mass) that fills part of the interior space.

blastomere A cell created by cleavage divisions in early animal embryos.

blastopore An opening (pore) in the surface of some early embryos, through which cells move during gastrulation.

blastula In vertebrate development, a ball of cells (blastomere cells) typically surrounding a fluid-filled cavity (the blastocoel). The blastula is formed by cleavage of a zygote and undergoes gastrulation. See **blastocyst**.

blood A type of connective tissue consisting of red blood cells and leukocytes suspended in a fluid portion, an extracellular matrix called plasma. Transports materials throughout the vertebrate body.

body mass index (BMI) A mathematical relationship of weight and height used to assess obesity in humans. Calculated as weight (kg) divided by the square of height (m^2).

body plan The basic architecture of an animal's body, including the number and arrangement of limbs, body segments, and major tissue layers.

bog A freshwater wetland that has no or almost no water flow, resulting in very low oxygen levels and acidic conditions.

Bohr shift The rightward shift of the oxygen–hemoglobin equilibrium curve that occurs with decreasing pH. It results in hemoglobin being more likely to release oxygen in the acidic environment of exercising muscle.

bone A type of vertebrate connective tissue consisting of living cells and blood vessels within a hard extracellular matrix composed of calcium phosphate ($CaPO_4$) and small amounts of calcium carbonate ($CaCO_3$) and protein fibers.

bone marrow The soft tissue filling the inside of large bones; contains stem cells that develop into red blood cells and leukocytes throughout life.

Bowman's capsule The hollow, double-walled, cup-shaped portion of a nephron that surrounds a glomerulus in the vertebrate kidney.

brain A large mass of neurons, located in the head region of an animal, that is involved in information processing; may also be called the cerebral ganglion.

brain stem The most posterior portion of the vertebrate brain, connecting to the spinal cord and responsible for autonomic body functions such as heart rate, respiration, and digestion.

braincase See **cranium**.

branch (1) A part of a phylogenetic tree that represents populations through time. (2) Any extension of a plant's shoot system.

brassinosteroids A family of steroid hormones found in plants; stimulate growth.

bronchiole Any of the small tubes in mammalian lungs that carry air from the bronchi to the alveoli.

bronchus (plural: bronchi) In mammals, one of a pair of large tubes that lead from the trachea to each lung.

bryophyte See **non-vascular plants**.

budding Asexual reproduction in which an outgrowth from the parent breaks free as an independent individual; occurs in yeasts and some invertebrates.

buffer A substance that, in solution, acts to minimize changes in the pH of that solution when acid or base is added.

bulbourethral gland In male mammals, either of a small pair of glands at the base of the urethra that secrete an alkaline mucus (part of semen), which lubricates the tip of the penis and neutralizes acids in the urethra during copulation. In humans, also called *Cowper's glands*.

bulk flow The directional mass movement of a fluid due to pressure differences, such as movement of water through plant xylem and phloem, and movement of blood in animals.

bulk-phase endocytosis Nonspecific uptake of extracellular fluid by pinching off the plasma membrane to form small membrane-bound vesicles; considered to be a means of retrieving membrane from the surface following exocytosis. Compare with **receptor-mediated endocytosis**.

bundle-sheath cell A type of cell found around the vascular tissue (veins) of plant leaves.

C_3 pathway The most common form of photosynthesis in which atmospheric CO_2 is fixed by rubisco to form 3-phosphoglycerate, a three-carbon molecule. Used in first phase of the Calvin cycle.

C_4 pathway A variant type of photosynthesis in which atmospheric CO_2 is first fixed by PEP carboxylase into four-carbon acids, rather than the three-carbon molecules of the classic C_3 pathway. Used to concentrate CO_2 to reduce photorespiration in the Calvin cycle while stomata are closed.

C_4 photosynthesis A variant type of photosynthesis in which atmospheric CO_2 is first fixed into four-carbon sugars, rather than the three-carbon sugars of classic C_3 photosynthesis. Enhances photosynthetic efficiency in hot, dry environments by reducing loss of oxygen due to photorespiration.

cadherin Any of a class of cell-surface proteins involved in selective cell–cell adhesion. Important for coordinating movements of cells and the establishment of tissues during embryological development.

callus In plants, a mass of undifferentiated cells that can generate roots and other tissues necessary to create a mature plant.

Calvin cycle In photosynthesis, the set of reactions that use NADPH and ATP formed in the light-dependent reactions to drive the fixation of CO_2, reduction of the fixed carbon to produce sugar, and the regeneration of the substrate used to fix CO_2. Also called *light-independent reactions*.

calyx All of the sepals of a flower.

CAM See **crassulacean acid metabolism**.

cambium (plural: cambia) In woody plants, tissue that consists of two types of cylindrical meristems that increase the width of roots and shoots through the process of secondary growth. See **vascular cambium** and **cork cambium**.

Cambrian explosion The rapid diversification of animal body types and lineages that occured between the species present in the Doushantuo faunas (around 570 mya), Ediacaran faunas (565–542 mya), and the Early Cambrian faunas (525–515 mya).

cancer General term for any tumor whose cells grow in an uncontrolled fashion, invade nearby tissues, and spread to other sites in the body.

capillarity The tendency of water to move up a narrow tube due to adhesion, cohesion, and surface tension (also called capillary action).

capillary Any of the many small, thin-walled blood vessels that permeate all tissues and organs, and allow exchange of gases and other molecules between blood and body cells.

capillary bed A thick network of capillaries.

capsid A shell of protein enclosing the genome of a virus particle.

carapace In crustaceans, a large platelike section of the exoskeleton that covers and protects the cephalothorax (e.g., a crab's "shell").

carbohydrate Any of a class of molecules that contain a carbonyl group, several hydroxyl groups, and several to many carbon-hydrogen bonds. See **monosaccharide** and **polysaccharide**.

carbon cycle, global The worldwide movement of carbon among terrestrial ecosystems, the oceans, and the atmosphere.

carbon fixation The process of converting gaseous carbon dioxide into an organic molecule, often associated with photosynthesis. See also **PEP carboxylase** and **rubisco**.

carbonic anhydrase An enzyme that catalyzes the formation of carbonic acid (H_2CO_3) from carbon dioxide and water.

carboxylic acids Organic acids with the form R-COOH (a carboxyl group).

cardiac cycle One complete heartbeat cycle, including systole and diastole.

cardiac muscle The muscle tissue of the vertebrate heart; responsible for pumping blood. Consists of long, branched fibers that are electrically connected and that initiate their own contractions; not under voluntary control. Compare with **skeletal** and **smooth muscle**.

cardiovascular disease A group of diseases of the heart and blood vessels caused by poor diet, obesity, inactivity, genetics, tobacco use, age, and other factors.

carnivore (adjective: carnivorous) An animal whose diet consists predominantly of meat, or other animals. Most members of the mammalian taxon Carnivora are carnivores. Some plants are carnivorous, trapping and killing small animals and then absorbing nutrients from the prey's body. Compare with **herbivore** and **omnivore**.

carotenoid Any of a class of accessory pigments, found in chloroplasts, that absorb wavelengths of light not absorbed by chlorophyll; typically appear yellow, orange, or red. Includes carotenes and xanthophylls.

carpel The female reproductive organ in a flower. Consists of the stigma, to which pollen grains adhere; the style, through which the pollen tube grows; and the ovary, which houses the ovule. Compare with **stamen**.

carrier protein A membrane protein that facilitates diffusion of a small molecule (e.g., glucose) across a membrane by a process involving a reversible change in the shape of the protein. Also called *carrier* or *transporter*. Compare with **channel protein**.

carrier A heterozygous individual carrying a normal allele and a recessive allele for an inherited trait; does not display the phenotype of the recessive trait but can pass the recessive allele to offspring.

carrying capacity (*K*) The maximum population size of a certain species that a given habitat can support.

cartilage A type of vertebrate connective tissue that consists of relatively few cells scattered in a stiff matrix of polysaccharides and protein fibers. Provides structural support.

Casparian strip In plant roots, a waxy layer containing suberin, a water-repellent substance that prevents movement of water through the walls of endodermal cells, thus blocking the apoplastic pathway of water and ion movement into the vascular tissue.

cast A type of fossil, formed when the decay of a body part leaves a void that is then filled with minerals that later harden.

catabolic pathway Any set of chemical reactions that breaks down large, complex molecules into smaller ones, releasing energy in the process. Compare with **anabolic pathway**.

catalysis (verb: catalyze) Acceleration of the rate of a chemical reaction due to a decrease in the free energy of the transition state, called the activation energy.

catalyst Any substance that increases the rate of a chemical reaction without itself undergoing any permanent chemical change.

catecholamines A class of small compounds, derived from the amino acid tyrosine, that are used as hormones or neurotransmitters. Include epinephrine, norepinephrine, and dopamine.

cation A positively charged ion.

cation exchange The release (displacement) of cations, such as magnesium and calcium from soil particles, by protons in acidic soil water. The released cations are available for uptake by plants.

CD4 A membrane protein on the surface of some T cells in humans. $CD4^+$ T cells can give rise to helper T cells.

CD8 A membrane protein on the surface of some T cells in humans. $CD8^+$ T cells can give rise to cytotoxic T cells.

Cdk See **cyclin-dependent kinase**.

cDNA See **complementary DNA**.

cDNA library A set of cDNAs from a particular cell type or stage of development. Each cDNA is carried by a plasmid or other cloning vector and can be separated from other cDNAs. Compare with **genomic library**.

cecum A blind sac between the small intestine and the colon. Is enlarged in some species (e.g., rabbits) that use it as a fermentation vat for digestion of cellulose.

cell A highly organized compartment bounded by a thin, flexible structure (plasma membrane) and containing concentrated chemicals in an aqueous (watery) solution. The basic structural and functional unit of all organisms.

cell body The part of a neuron that contains the nucleus; where incoming signals are integrated. Also called the *soma*.

cell crawling A form of cellular movement involving actin filaments in which the cell produces bulges (pseudopodia) that stick to the substrate and pull the cell forward. Also called *amoeboid motion*.

cell cycle Ordered sequence of events in which a eukaryotic cell replicates its chromosomes, evenly partitions the chromosomes to two daughter cells, and then undergoes division of the cytoplasm.

cell-cycle checkpoint Any of several points in the cell cycle at which progression of a cell through the cycle can be regulated.

cell division Creation of new cells by division of preexisting cells.

cell-mediated (immune) response The type of immune response that involves generation of cytotoxic T cells from $CD8^+$ T cells. Defends against pathogen-infected cells, cancer cells, and transplanted cells. Compare with **humoral (immune) response**.

cell membrane See **plasma membrane**.

cell plate A flattened sac-like structure formed in the middle of a dividing plant cell from Golgi-derived vesicles containing cell wall material; ultimately divides the cytoplasm into two separate cells.

cell sap An aqueous solution found in the vacuoles of plant cells.

cell theory The theory that all organisms are made of cells and that all cells come from preexisting cells.

cell wall A fibrous layer found outside the plasma membrane of most bacteria and archaea and many eukaryotes.

cellular respiration A common pathway for production of ATP, involving transfer of electrons from compounds with high potential energy through an electron transport chain and ultimately to an electron acceptor (often oxygen).

cellulase An enzyme that can break down cellulose by catalyzing hydrolysis of the glycosidic linkages between the glucose residues.

cellulose A structural polysaccharide composed of glucose monomers joined by β-1,4-glycosidic linkages. Found in the cell wall of algae, plants, and some bacteria and fungi.

Cenozoic era The most recent interval of geologic time, beginning 65.5 million years ago, during which mammals became the dominant vertebrates and angiosperms became the dominant plants.

central dogma The scheme for information flow in the cell: DNA → RNA → protein.

central nervous system (CNS) Large numbers of neurons aggregated into clusters called ganglia in bilaterian animals. In vertebrates, the central nervous system consists of the brain and spinal cord. Compare with **nerve net** and **peripheral nervous system (PNS)**.

centriole One of two small cylindrical structures found together within the centrosome near the nucleus of a eukaryotic cell (not found in plants). Consists of microtubule triplets and is structurally identical with a basal body.

centromere Constricted region of a replicated chromosome where the two sister chromatids are joined and the kinetochore is located.

centrosome Structure in animal and fungal cells, containing two centrioles, that serves as a microtubule organizing center for the cell's cytoskeleton and for the spindle apparatus during cell division.

cephalization The formation in animals of a distinct anterior region (the head) where sense organs and a mouth are clustered.

cephalochordates One of the three major chordate lineages (Cephalochordata), comprising small, mobile organisms that live in marine sands and suspension feed; also called *lancelets* or *amphioxus*. Compare with **urochordates** and **vertebrates**.

cephalopods A lineage of mollusks including the squid, octopuses, and nautiluses. Distinguished by large brains, excellent vision, tentacles, and a reduced or absent shell.

cerebellum Posterior section of the vertebrate brain; involved in coordination of complex muscle movements, such as those required for locomotion and maintaining balance.

cerebrum The most anterior section of the vertebrate brain. Divided into left and right hemispheres and four lobes: frontal lobe, involved in complex decision making (in humans); occipital lobe, receives and interprets visual information; parietal lobe, involved in integrating sensory and motor functions; and temporal lobe, functions in memory, speech (in humans), and interpreting auditory information.

cervix The bottom portion of the uterus, containing a canal that leads to the vagina.

chaetae (singular: chaeta) Bristle-like extensions found in some annelids.

channel protein A protein that forms a pore in a cell membrane. The structure of most channels allows them to admit just one or a few types of ions or molecules. Compare with **carrier protein**.

character Any genetic, morphological, physiological, or behavioral characteristic of an organism to be studied.

character displacement The evolutionary tendency for the traits of similar species that occupy overlapping ranges to change in a way that reduces interspecific competition.

chelicerae A pair of clawlike appendages found around the mouth of certain arthropods called chelicerates (spiders, mites, and allies).

chemical bond An attractive force binding two atoms together. Covalent bonds, ionic bonds, and hydrogen bonds are types of chemical bonds.

chemical energy The potential energy stored in covalent bonds between atoms.

chemical equilibrium A dynamic but stable state of a reversible chemical reaction in which the forward reaction and reverse reactions proceed at the same rate, so that the concentrations of reactants and products remain constant.

chemical evolution A The theory that simple chemical compounds in the early atmosphere and ocean combined via chemical reactions to form larger, more complex substances, eventually leading to the origin of life and the start of biological evolution.

chemical reaction Any process in which one compound or element is combined with others or is broken down; involves the making and/or breaking of chemical bonds.

chemiosmosis An energetic coupling mechanism whereby energy stored in an electrochemical proton gradient is used to drive an energy-requiring process such as production of ATP.

chemokine Any of a subset of cytokines that acts as a chemical signal attracting leukocytes to a site of tissue injury or infection.

chemolithotroph An organism (bacteria or archaea) that produces ATP by oxidizing inorganic molecules with high potential energy such as ammonia (NH_3) or methane (CH_4). Also called *lithotroph*. Compare with **chemoorganotroph**.

chemoorganotroph An organism that produces ATP by oxidizing organic molecules with high potential

energy such as sugars. Also called *organotroph*. Compare with **chemolithotroph**.

chemoreception A sensory system in which receptors are activated in response to the binding of chemicals.

chemoreceptor A sensory cell or organ specialized for detection of specific molecules or classes of molecules.

chiasma (plural: chiasmata) The X-shaped structure formed during meiosis by crossing over between non-sister chromatids in a pair of homologous chromosomes.

chitin A structural polysaccharide composed of *N*-acetyl-glucosamine (NAG) monomers joined end to end by β-1,4-glycosidic linkages. Found in cell walls of fungi and many algae, and in external skeletons of insects and crustaceans.

chitons A lineage of marine mollusks that have a protective shell formed of eight calcium carbonate plates.

chlorophyll Any of several closely related green pigments, found in chloroplasts, that absorb light during photosynthesis.

chloroplast A chlorophyll-containing organelle, bounded by a double membrane, in which photosynthesis occurs; found in plants and photosynthetic protists. Also the location of starch, amino acid, fatty acid, purine, and pyrimidine synthesis.

choanocyte A specialized, flagellated feeding cell found in choanoflagellates (protists that are the closest living relatives of animals) and sponges (the most ancient animal phylum).

cholecystokinin A peptide hormone secreted by cells in the lining of the small intestine. Stimulates the secretion of digestive enzymes from the pancreas and of bile from the liver and gallbladder.

chordate Any member of the phylum Chordata. Chordates are deuterostomes distinguished by a dorsal hollow nerve cord, pharyngeal gill slits, a notochord, and a post-anal tail. Includes vertebrates, cephalochordata, and urochordata.

chromatid One of the two identical double-stranded DNAs composing a replicated chromosome that is connected at the centromere to the other strand.

chromatin The complex of DNA and proteins, mainly histones, that compose eukaryotic chromosomes. Can be highly compact (heterochromatin) or loosely coiled (euchromatin).

chromatin remodeling The process by which the DNA in chromatin is unwound from its associated proteins to allow transcription or replication. May involve chemical modification of histone proteins or reshaping of the chromatin by large multiprotein complexes in an ATP-requiring process.

chromatin remodeling complexes Sets of enzymes that use energy from ATP hydrolysis shift nucleosomes on DNA to expose regulatory sequences to transcription factors.

chromosome theory of inheritance The principle that genes are located on chromosomes and that patterns of inheritance are determined by the behavior of chromosomes during meiosis.

chromosome Gene-carrying structure consisting of a single long molecule of double-stranded DNA and associated proteins (e.g., histones). Most prokaryotic cells contain a single, circular chromosome; eukaryotic cells contain multiple noncircular (linear) chromosomes located in the nucleus.

cilium (plural: cilia) One of many short, filamentous projections of some eukaryotic cells, containing a core of microtubules. Used to move the cell as well as to circulate fluid or particles around the surface of a stationary cell. See **axoneme**.

circadian clock An internal mechanism found in most organisms that regulates many body processes (sleep–wake cycles, hormonal patterns, etc.) in a roughly 24-hour cycle.

circulatory system The system responsible for moving oxygen, carbon dioxide, and other materials (hormones, nutrients, wastes) within the animal body.

cisternae (singular: cisterna) Flattened, membrane-bound compartments that make up the Golgi apparatus.

cisternal maturation The process of cargo movement through the Golgi apparatus by residing in cisternae that mature from *cis* to *trans* via the import and export of different Golgi enzymes.

citric acid cycle A series of eight chemical reactions that start with citrate (deprotonated citric acid) and ends with oxaloacetate, which reacts with acetyl CoA to form citrate—forming a cycle that is part of the pathway that oxidizes glucose to CO_2. Also known as the *Krebs cycle* or *tricarboxylic acid* (*TCA*) *cycle*.

clade See **monophyletic group**.

cladistic approach A method for constructing a phylogenetic tree that is based on identifying the unique traits (shared, derived characters, called synapomorphies) of each monophyletic group.

Class I MHC protein A type of MHC protein that is present on the plasma membrane of virtually all nucleated cells and functions in presenting antigen to $CD8^+$ T cells.

Class II MHC protein A type of MHC protein that is present only on the plasma membrane of certain cells in the immune response, such as dendritic cells, macrophages, and B cells. It functions in presenting epitopes of antigens to $CD4^+$ T cells.

cleavage In animal development, the series of rapid mitotic cell divisions, with little cell growth, that produces successively smaller cells (blastomeres) and transforms a zygote into a multicellular blastula.

cleavage furrow A pinching in of the plasma membrane that occurs as cytokinesis begins in animal cells and deepens until the cytoplasm is divided into two daughter cells.

climate The prevailing, long-term weather conditions in a particular region.

climax community The stable, final community that develops from ecological succession.

clitoris A rod of erectile tissue in the external genitalia of female mammals. Is formed from the same embryonic tissue as the male penis and has a similar function in sexual arousal.

cloaca In a few mammals and many nonmammalian vertebrates, a body cavity opening to the outside and used by both the excretory and reproductive systems.

clonal selection theory The dominant explanation of the generation of an adaptive immune response. According to the theory, the immune system retains a vast pool of inactive lymphocytes, each with a unique receptor for a unique epitope. Lymphocytes that encounter their complementary epitopes are stimulated to divide (selected and cloned), producing daughter cells that combat infection and confer immunity.

clone (1) An individual that is genetically identical to another individual. (2) A lineage of genetically identical individuals or cells. (3) As a verb, to make one or more genetic replicas of a cell or individual.

cloning vector A plasmid or other agent used to transfer recombinant genes into cultured host cells. Also called simply *vector*.

closed circulatory system A circulatory system in which the circulating fluid (blood) is confined to blood vessels and flows in a continuous circuit. Compare with **open circulatory system**.

cnidocyte A specialized stinging cell found in cnidarians (e.g., jellyfish, corals, and anemones) and used in capturing prey.

co-receptor Any membrane protein that acts with some other membrane protein in a cell interaction or cell response.

cochlea The organ of hearing in the inner ear of mammals, birds, and crocodilians. A coiled, fluid-filled tube containing specialized pressure-sensing neurons (hair cells) that detect sounds of different pitches.

coding strand See **non-template strand**.

codominance An inheritance pattern in which heterozygotes exhibit both of the traits seen in each type of homozygous individual.

codon A sequence of three nucleotides in DNA or RNA that codes for an amino acid or a start or stop signal for protein synthesis.

coefficient of relatedness (*r*) A measure of how closely two individuals are related. Calculated as the probability that an allele in two individuals is inherited from the same ancestor.

coelom An internal, usually fluid-filled body cavity that is completely or partially lined with mesoderm.

coelomate An animal that has a true coelom, completely lined with mesoderm. Compare with **acoelomate** and **pseudocoelomate**.

coenocytic Containing many nuclei and a continuous cytoplasm through a filamentous body, without the body being divided into distinct cells. Some fungi are coenocytic.

coenzyme A small organic molecule that is a required cofactor for an enzyme-catalyzed reaction. Often donates or receives electrons or functional groups during the reaction.

coenzyme A (CoA) A molecule that is required for many cellular reactions and that is often transiently linked to other molecules, such as acetyl groups (see **acetyl CoA**).

coenzyme Q A nonprotein molecule that shuttles electrons between membrane-bound complexes in the mitochondrial electron transport chain. Also called **ubiquinone** or *Q*.

coevolution A pattern of evolution in which two interacting species reciprocally influence each other's adaptations over time.

coevolutionary arms race A series of adaptations and counter-adaptations observed in species that interact closely over time and affect each other's fitness.

cofactor An inorganic ion, such as a metal ion, that is required for an enzyme to function normally. May be bound tightly to an enzyme or associate with it transiently during catalysis.

cohesion The tendency of certain like molecules (e.g., water molecules) to cling together due to attractive forces. Compare with **adhesion**.

cohesion-tension theory The theory that water movement upward through plant vascular tissues is due to loss of water from leaves (transpiration), which pulls a cohesive column of water upward.

cohort A group of individuals that are the same age and can be followed through time.

coleoptile A modified leaf that covers and protects the stems and leaves of grass seedlings.

collagen A fibrous, pliable, cable-like glycoprotein that is a major component of the extracellular matrix of animal cells. Various subtypes differ in their tissue distribution, some of which are assembled into large fibrils in the extracellular space.

collecting duct In the vertebrate kidney, a large straight tube that receives filtrate from the distal tubules of several nephrons. Involved in the regulated reabsorption of water.

collenchyma cell In plants, an elongated cell with cell walls thickened at the corners that provides support to growing plant parts; usually found in strands along leaf veins and stalks. Compare with **parenchyma cell** and **sclerenchyma cell**.

colon The portion of the large intestine where feces are formed by compaction of wastes and reabsorption of water.

colony An assemblage of individuals. May refer to an assemblage of semi-independent cells or to a breeding population of multicellular organisms.

commensalism (adjective: commensal) A symbiotic relationship in which one organism (the commensal) benefits and the other (the host) is not harmed. Compare with **mutualism** and **parasitism**.

communication In ecology, any process in which a signal from one individual modifies the behavior of another individual.

community All of the species that interact with each other in a certain area.

companion cell In plants, a cell in the phloem that is connected via many plasmodesmata to adjacent sieve-tube elements. Companion cells provide materials to maintain sieve-tube elements and function in the loading and unloading of sugars into sieve-tube elements.

compass orientation A type of navigation in which movement occurs in a specific direction.

competition In ecology, the interaction of two species or two individuals trying to use the same limited resource (e.g., water, food, living space). May occur between individuals of the same species (intraspecific competition) or different species (interspecific competition).

competitive exclusion principle The principle that two species cannot coexist in the same ecological niche in the same area because one species will outcompete the other.

competitive inhibition Inhibition of an enzyme's ability to catalyze a chemical reaction via binding of a nonreactant molecule that competes with the substrate(s) for access to the active site.

complement system A set of proteins that circulate in the bloodstream and can destroy bacteria by forming holes in the bacterial plasma membrane.

complementary base pairing The association between specific nitrogenous bases of nucleic acids stabilized by hydrogen bonding. Adenine pairs only with thymine (in DNA) or uracil (in RNA), and guanine pairs only with cytosine.

complementary DNA (cDNA) DNA produced in the laboratory using an RNA transcript as a template and reverse transcriptase; corresponds to a gene but lacks introns. Also produced naturally by retroviruses.

complementary strand A newly synthesized strand of RNA or DNA that has a base sequence complementary to that of the template strand.

complete digestive tract A digestive tract with two openings, usually called a mouth and an anus.

complete metamorphosis See **holometabolous metamorphosis**.

compound eye An eye formed of many independent light-sensing columns (ommatidia); occurs in arthropods. Compare with **simple eye**.

concentration gradient Difference across space (e.g., across a membrane) in the concentration of a dissolved substance.

condensation reaction A chemical reaction in which two molecules are joined covalently with the removal of an $-OH$ from one and an $-H$ from another to form water. Also called a *dehydration reaction*. Compare with **hydrolysis**.

conduction (1) Direct transfer of heat between two objects that are in physical contact. Compare with **convection**. (2) Transmission of an electrical impulse along the axon of a nerve cell.

cone cell A photoreceptor cell with a cone-shaped outer portion that is particularly sensitive to bright light of a certain color. Also called simply *cone*. Compare with **rod cell**.

connective tissue An animal tissue consisting of scattered cells in a liquid, jellylike, or solid extracellular matrix. Includes bone, cartilage, tendons, ligaments, and blood.

conservation biology The effort to study, preserve, and restore threatened genetic diversity, populations, communities, and ecosystems.

constant (*C*) region The invariant amino acid sequence in polypeptides that are used to make antibodies, B-cell receptors, and T-cell receptors. Apart from antibody class types (IgG, IgM, etc.), this region remains constant within an individual. Compare with **variable (*V*) region**.

constitutive Always occurring; always present. Commonly used to describe enzymes and other proteins that are synthesized continuously or mutants in which one or more genetic loci are constantly expressed due to defects in gene control.

constitutive defense A defensive trait that is always manifested even in the absence of a predator or pathogen. Also called *standing defense*. Compare with **inducible defenses**.

constitutive mutant An abnormal (mutated) strain that produces a product at all times, instead of under certain conditions only.

consumer See **heterotroph**.

consumption Predation or herbivory.

continental shelf The portion of a geologic plate that extends from a continent under seawater.

continuous strand See **leading strand**.

contraception Any of several methods to prevent pregnancy.

control In a scientific experiment, a group of organisms or samples that do not receive the experimental treatment but are otherwise identical to the group that does.

convection Transfer of heat by movement of large volumes of a gas or liquid. Compare with **conduction**.

convergent evolution The independent evolution of similar traits in distantly related organisms due to adaptation to similar environments and a similar way of life.

cooperative binding The tendency of the protein subunits of hemoglobin to affect each other's oxygen binding such that each bound oxygen molecule increases the likelihood of further oxygen binding.

coprophagy The eating of feces.

coral reef A large assemblage of colonial marine corals that usually serves as shallow-water, sunlit habitat for many other species as well.

co-receptor Any membrane protein that acts with some other membrane protein in a cell interaction or cell response.

core enzyme The enzyme responsible for catalysis in a multipart holoenzyme.

cork cambium One of two types of cylindrical meristem, consisting of a ring of undifferentiated plant cells found just under the cork layer of woody stems and roots; produces new cork cells on its outer side. Compare with **vascular cambium**.

cork cell A cell in the protective outermost layer of a woody stem and root that produces and accumulates waxes that make the cell less permeable to water and gases.

corm A rounded, thick underground stem that can produce new plants via asexual reproduction.

cornea The transparent sheet of connective tissue at the very front of the eye in vertebrates and some other animals. Protects the eye and helps focus light.

corolla All of the petals of a flower.

corona The cluster of cilia at the anterior end of a rotifer; in many species it facilitates suspension feeding.

corpus callosum A thick band of neurons that connects the two hemispheres of the cerebrum in the mammalian brain.

corpus luteum A yellowish structure that secretes progesterone in an ovary. Is formed from a follicle that has recently ovulated.

cortex (1) In animals, the outermost region of an organ, such as the kidney or adrenal gland. (2) In plants, a layer of ground tissue found outside the vascular bundles of roots and outside the pith of a stem.

corticotropin-releasing hormone (CRH) A peptide hormone, produced and secreted by the hypothalamus, that stimulates the anterior pituitary to release ACTH.

cortisol A steroid hormone, produced and secreted by the adrenal cortex, that increases blood glucose and prepares the body for stress. The major glucocorticoid hormone in some mammals. Also called *hydrocortisone*.

cost–benefit analysis Decisions or analyses that weigh the fitness costs and benefits of a particular action.

cotransporter A transmembrane protein that facilitates diffusion of an ion down its previously established electrochemical gradient and uses the energy of that process to transport some other substance, in the same or opposite direction, *against* its concentration gradient. Also called *secondary active transporter*. See **antiporter** and **symporter**.

cotyledon The first leaf, or seed leaf, of a plant embryo. Used for storing and digesting nutrients and/or for early photosynthesis.

countercurrent exchanger In animals, any anatomical arrangement that allows the maximum transfer of heat or a soluble substance from one fluid to another. The two fluids must be flowing in opposite directions and have a heat or concentration gradient between them.

covalent bond A type of chemical bond in which two atoms share one or more pairs of electrons. Compare with **hydrogen bond** and **ionic bond**.

cranium A bony, cartilaginous, or fibrous case that encloses and protects the brain of vertebrates. Forms part of the skull. Also called *braincase*.

crassulacean acid metabolism (CAM) A variant type of photosynthesis in which CO_2 is fixed and stored in organic acids at night when stomata are open and then released to feed the Calvin cycle during the day when stomata are closed. Helps reduce water loss and CO_2 loss by photorespiration.

cristae (singular: crista) Sac-like invaginations of the inner membrane of a mitochondrion. Location of the electron transport chain and ATP synthase.

Cro-Magnon A prehistoric European population of modern humans (*Homo sapiens*) known from fossils, paintings, sculptures, and other artifacts.

crop A storage organ in the digestive system of certain vertebrates.

cross A mating between two individuals that is used for genetic analysis.

cross-pollination Pollination of a flower by pollen from another individual, rather than by self-fertilization. Also called *crossing*.

cross-talk Interactions among signaling pathways, triggered by different signals, that modify a cellular response.

crossing over The exchange of segments of nonsister chromatids between a pair of homologous chromosomes that occurs during meiosis I.

crosstalk Interactions among signaling pathways that modify a cellular response.

crustaceans A lineage of arthropods that includes shrimp, lobster, and crabs. Many have a carapace (a platelike portion of the exoskeleton covering the cephalothorax) and mandibles for biting or chewing.

cryptic species A species that cannot be distinguished from similar species by easily identifiable morphological traits.

culture In cell biology, a collection of cells or a tissue growing under controlled conditions, usually in suspension or on the surface of a dish of solid growth medium.

Cushing's disease A human endocrine disorder caused by loss of feedback inhibition of cortisol on ACTH secretion. Characterized by high ACTH and cortisol levels and wasting of body protein reserves.

cuticle A protective coating secreted by the outermost layer of cells of an animal or a plant; often functioning to reduce evaporative water loss.

cyanobacteria A lineage of photosynthetic bacteria formerly known as blue-green algae. Likely the first life-forms to carry out oxygenic photosynthesis.

cyclic AMP (cAMP) Cyclic adenosine monophosphate; a small molecule, derived from ATP, that is widely used by cells in signal transduction and transcriptional control.

cyclic electron flow Path of electrons in which excited electrons of photosystem I are transferred back to plastoquinone (PQ), the start of the electron transport chain normally associated with photosystem II. Instead of reducing $NADP^+$ to make NADPH, the electron energy is used to make ATP via photophosphorylation. Compare with **noncyclic electron flow**.

cyclin One of several regulatory proteins whose concentrations fluctuate cyclically throughout the cell cycle. Involved in the control of the cell cycle via cyclin-dependent kinases.

cyclin-dependent kinase (Cdk) Any of several related protein kinases that are functional only when bound to a cyclin and are activated by other modifications. Involved in control of the cell cycle.

cytochrome *c* (cyt *c*) A soluble protein that shuttles electrons between membrane-bound complexes in the mitochondrial electron transport chain.

cytokine Any of a diverse group of signaling proteins, secreted largely by cells of the immune system, whose effects include stimulating leukocyte production, recruiting cells to the site of infection, tissue repair, and fever. Generally function to regulate the type, intensity, and duration of an immune response.

cytokinesis Division of the cytoplasm to form two daughter cells. Typically occurs immediately after division of the nucleus by mitosis or meiosis.

cytokinins A class of plant hormones that stimulate cell division and retard aging.

cytoplasm All the contents of a cell, excluding the nucleus, bounded by the plasma membrane.

cytoplasmic determinant A regulatory transcription factor or signaling molecule that is distributed unevenly in the cytoplasm of the egg and that directs early pattern formation in an embryo.

cytoplasmic streaming The directed flow of cytosol and organelles that facilitates distribution of materials within some large plant and fungal cells. Occurs along actin filaments and is powered by myosin.

cytoskeleton In eukaryotic cells, a network of protein fibers in the cytoplasm that are involved in cell shape, support, locomotion, and transport of materials within the cell. Prokaryotic cells have a similar but much less extensive network of fibers.

cytosol The fluid portion of the cytoplasm, excluding the contents of membrane-enclosed organelles.

cytotoxic T cell A type of $CD8^+$ effector T cell that induces apoptosis in infected and cancerous cells. Recognizes target cells via interactions with complementary class I MHC–peptide complexes. Also called *cytotoxic T lymphocyte (CTL)* and *killer T cell*. Compare with **helper T cell**.

dalton (Da) A unit of mass equal to 1/12 the mass of one carbon-12 atom; about the mass of 1 proton or 1 neutron.

daughter strand The strand of DNA that is newly replicated from an existing template strand of DNA.

day-neutral plant A plant whose flowering time is not affected by the relative length of day and night (the photoperiod). Compare with **long-day** and **short-day plant**.

dead space Air passages that are not involved in gas exchange with the blood; examples are the trachea and bronchi.

deciduous Describing a plant that sheds leaves or other structures at regular intervals (e.g., each autumn).

decomposer See **detritivore**.

decomposer food chain An ecological network of detritus, decomposers that eat detritus, and predators and parasites of the decomposers.

deep sequencing A method to learn the types of mRNAs or DNA sequences present in cells, and their relative amounts, involving the preparation and sequencing of cDNA libraries.

definitive host The host species in which a parasite reproduces sexually. Compare with **intermediate host**.

dehydration reaction See **condensation reaction**.

deleterious In genetics, referring to any mutation, allele, or trait that reduces an individual's fitness.

deletion In genetics, refers to the loss of part of a chromosome.

demography The study of factors that determine the size and structure of populations through time.

dendrite A short extension from a neuron's cell body that receives signals from other neurons.

dendritic cell A type of leukocyte that ingests and digests foreign antigens, moves to a lymph node, and presents the antigens' epitopes, in the context of MHC proteins on its membrane, to $CD4^+$ and $CD8^+$ T cells.

dense connective tissue A type of connective tissue, distinguished by having an extracellular matrix dominated by collagen fibers. Found in tendons and ligaments.

density dependent In population ecology, referring to any characteristic that varies depending on population density.

density independent In population ecology, referring to any characteristic that does not vary with population density.

deoxyribonucleic acid (DNA) A nucleic acid composed of deoxyribonucleotides that carries the genetic information of a cell. Generally occurs as two intertwined strands, but these can be separated. See also **double helix**.

deoxyribonucleoside triphosphate (dNTP) A monomer used by DNA polymerase to polymerize DNA. Consists of the sugar deoxyribose, a base (A, T, G, or C), and three phosphate groups.

deoxyribonucleotide See **nucleotide**.

depolarization A change in membrane potential from its resting negative state to a less negative or a positive state; a normal phase in an action potential. Compare with **hyperpolarization**.

depolarization Change in membrane potential from its resting negative state to a less negative or to a positive state; a normal phase in an action potential. Compare with **hyperpolarization**.

deposit feeder An animal that eats its way through a food-containing substrate.

derived trait A trait that is clearly homologous with a trait found in an ancestor of a particular group, but that has a new form.

dermal tissue system The tissue forming the outer layer of a plant; also called *epidermis*.

descent with modification The phrase used by Darwin to describe his hypothesis of evolution by natural selection.

desmosome A type of cell–cell attachment structure, consisting of cadherin proteins, that is anchored to intermediate filaments. Serves to link the cytoskeletons of adjacent animal cells and form strong cell–cell attachments throughout a tissue. Compare with **gap junction** and **tight junction**.

detergent A type of small amphipathic molecule used to solubilize hydrophobic molecules in aqueous solution.

determination In development, the commitment of a cell to a particular differentiated fate. Once a cell is fully determined, it can differentiate only into a particular cell type (e.g., liver cell, brain cell).

detritivore An organism whose diet consists mainly of dead organic matter (detritus). Various bacteria, fungi, protists, and animals are detritivores. Also called *decomposer*.

detritus A layer of dead organic matter that accumulates at ground level or on seafloors and lake bottoms.

deuterostomes A major lineage of bilaterian animals that share a pattern of embryological development, including formation of the anus earlier than the mouth, and formation of the coelom by pinching off of layers of mesoderm from the gut. Includes echinoderms and chordates. Compare with **protostomes**.

developmental homology A similarity in embryonic form, or in the fate of embryonic tissues, that is due to inheritance from a common ancestor.

diabetes mellitus A disease caused by defects in insulin production (type 1) or in the response of cells to insulin (type 2). Characterized by abnormally high blood glucose levels and huge amounts of glucose-containing urine.

diaphragm An elastic, sheetlike structure. In mammals, the muscular sheet of tissue that separates the chest and abdominal cavities. It contracts and moves downward during inhalation, expanding the chest cavity.

diastole The portion of the cardiac cycle during which the atria or ventricles of the heart are relaxed. Compare with **systole**.

diastolic blood pressure The force exerted by blood against artery walls during relaxation of the heart's left ventricle. Compare with **systolic blood pressure**.

dicot Any flowering plant (angiosperm) that has two cotyledons (embryonic leaves) upon germination. The dicots do not form a monophyletic group. Also called *dicotyledonous plant*. Compare with **eudicot** and **monocot**.

dideoxy sequencing A laboratory technique for determining the exact nucleotide sequence of DNA. Relies on the use of dideoxynucleoside triphosphates (ddNTPs), which terminate DNA replication.

diencephalon The part of the mammalian brain that relays sensory information to the cerebellum and functions in maintaining homeostasis.

differential centrifugation Procedure for separating cellular components according to their size and density by spinning a cell homogenate in a series of centrifuge runs. After each run, the supernatant is removed from the deposited material (pellet) and spun again at progressively higher speeds.

differential gene expression Expression of different sets of genes in cells with the same genome. Responsible for creating different cell types.

differentiation The process by which any unspecialized cell becomes a distinct specialized cell type (e.g., liver cell, brain cell), usually by changes in gene expression. Also called *cell differentiation*.

diffusion Spontaneous movement of a substance from one region to another, often with a net movement from a region of high concentration to one of low concentration (i.e., down a concentration gradient).

digestion The physical and chemical breakdown of food into molecules that can be absorbed into the body of an animal.

digestive tract The long tube that begins at the mouth and ends at the anus. Also called *alimentary canal* or *gastrointestinal (GI) tract*.

dihybrid cross A mating between two parents that are heterozygous for two different genes.

dikaryotic Describing a cell or fungal mycelium having two haploid nuclei that are genetically distinct.

dimer An association of two molecules that may be identical (homodimer) or different (heterodimer).

dioecious Describing an angiosperm species that has male and female reproductive structures on separate plants. Compare with **monoecious**.

diploblast (adjective: diploblastic) An animal whose body develops from two basic embryonic cell layers or tissues—ectoderm and endoderm. Compare with **triploblast**.

diploid (1) Having two sets of chromosomes ($2n$). (2) A cell or an individual organism with two sets of chromosomes, one set inherited from the mother and one set from the father. Compare with **haploid**.

direct sequencing A technique for identifying and studying microorganisms that cannot be grown in culture. Involves detecting and amplifying copies of certain specific genes in the microorganisms' DNA, sequencing these genes, and then comparing the sequences with the known sequences from other organisms.

directional selection A mode of natural selection that favors one extreme phenotype with the result that the average phenotype of a population changes in one direction. Generally reduces overall genetic variation in a population. Compare with **disruptive selection** and **stabilizing selection**.

disaccharide A carbohydrate consisting of two monosaccharides (sugar residues) linked together.

discontinuous strand See **lagging strand**.

discrete trait An inherited trait that exhibits distinct phenotypes rather than the continuous variation characteristic of a quantitative trait such as body height.

dispersal The movement of individuals from their place of origin (birth, hatching) to a new location.

disruptive selection A mode of natural selection that favors extreme phenotypes at both ends of the range of phenotypic variation. Maintains overall genetic variation in a population. Compare with **stabilizing selection** and **directional selection**.

distal tubule In the vertebrate kidney, the convoluted portion of a nephron into which filtrate moves from the loop of Henle. Involved in the regulated reabsorption of sodium and water. Compare with **proximal tubule**.

disturbance In ecology, any strong, short-lived disruption to a community that changes the distribution of living and/or nonliving resources.

disturbance regime The characteristic disturbances that affect a given ecological community.

disulfide bond A covalent bond between two sulfur atoms, typically in the side chains of certain amino acids (e.g., cysteine). Often contributes to tertiary and quaternary levels of protein structure.

DNA See **deoxyribonucleic acid**.

DNA cloning Any of several techniques for producing many identical copies of a particular gene or other DNA sequence.

DNA fingerprinting Any of several methods for identifying individuals by unique features of their genomes. Commonly involves using PCR to produce many copies of certain short tandem repeats (microsatellites) and then analyzing their lengths.

DNA helicase An enzyme that breaks hydrogen bonds between nucleotides of DNA, "unzipping" a double-stranded DNA molecule.

DNA library See **cDNA library** and **genomic library**.

DNA ligase An enzyme that joins pieces of DNA by catalyzing the formation of a phosphodiester bond between the pieces.

DNA methylation The addition of a methyl group ($-CH_3$) to a DNA molecule.

DNA methyltransferase A class of eukaryotic enzymes that add a methyl group to cytosines in DNA. Methylation of DNA leads to chromatin condensation and is an important means of regulating gene expression in eukaryotes.

DNA microarray A set of single-stranded DNA fragments, representing thousands of different genes that are permanently fixed to a small glass slide. Can be used to determine which genes are expressed in different cell types, under different conditions, or at different developmental stages.

DNA polymerase Any enzyme that catalyzes synthesis of DNA from deoxyribonucleotide triphosphates (dNTPs).

domain (1) A taxonomic category, based on similarities in basic cellular biochemistry, above the kingdom level. The three recognized domains are Bacteria, Archaea, and Eukarya. (2) A section of a protein that has a distinctive tertiary structure and function.

dominant Referring to an allele that determines the same phenotype when it is present in homozygous or heterozygous form.. Compare with **recessive**.

dormancy A temporary state of greatly reduced metabolic activity and growth in plants or plant parts (e.g., seeds, spores, bulbs, and buds).

dorsal Toward an animal's back and away from its belly. The opposite of ventral.

dorsal hollow nerve chord See **nerve chord**.

double fertilization An unusual form of reproduction seen in flowering plants, in which one sperm cell fuses with an egg to form a zygote and the other sperm cell fuses with two polar nuclei to form the triploid endosperm.

double helix The secondary structure of DNA, consisting of two antiparallel DNA strands wound around each other.

Down syndrome A human developmental disorder caused by trisomy of chromosome 21.

downstream In genetics, the direction in which RNA polymerase moves along a DNA strand. Compare with **upstream**.

duplication In genetics, refers to an additional copy of part of a chromosome.

dynein A class of motor proteins that uses the chemical energy of ATP to "walk" toward the minus end of a microtubule. Dyneins are responsible for bending of cilia and flagella, play a role in chromosome movement during mitosis, and can transport vesicles and organelles.

early endosome A small transient organelle that is formed by the accumulation of vesicles from receptor-mediated endocytosis and is an early stage in the formation of a lysosome.

ecdysone An insect hormone that triggers either molting (to a larger larval form) or metamorphosis (to the adult form), depending on the level of juvenile hormone.

ecdysozoans A major lineage of protostomes (Ecdysozoa) that grow by shedding their external skeletons (molting) and expanding their bodies. Includes arthropods, nematodes, and other groups. Compare with **lophotrochozoans**.

echinoderms A major lineage of deuterostomes (Echinodermata) distinguished by adult bodies with five-sided radial symmetry, a water vascular system, and tube feet. Includes sea urchins, sand dollars, and sea stars.

echolocation The use of echoes from vocalizations to obtain information about locations of objects in the environment.

ecological selection Also known as environmental selection. A type of natural selection that favors individuals with heritable traits that enhance their ability to survive and reproduce in a certain physical and/or biological environment, excluding their ability to obtain a mate. Compare with **sexual selection**.

ecology The study of how organisms interact with each other and with their surrounding environment.

ecosystem All the organisms that live in a geographic area, together with the nonliving (abiotic) components that affect or exchange materials with the organisms; a community and its physical environment.

ecosystem diversity The variety of biotic components in a region along with abiotic components, such as soil, water, and nutrients.

ecosystem function The sum of biological and chemical processes that are characteristic of a given ecosystem—such as primary production, nitrogen cycling, and carbon storage.

ecosystem services All of the benefits that humans derive, directly or indirectly, from ecosystem functions.

ecotourism Tourism that is based on observing wildlife or experiencing other aspects of natural areas.

ectoderm The outermost of the three basic cell layers (germ layers) in most animal embryos; gives rise to the outer covering and nervous system. Compare with **endoderm** and **mesoderm**.

ectomycorrhizal fungi (EMF) Fungi whose hyphae form a dense network that covers their host plant's roots but do not enter the root cells.

ectoparasite A parasite that lives on the outer surface of the host's body.

ectotherm An animal that gains most of its body heat from external sources as opposed to metabolic processes. Compare with **endotherm**.

effector Any cell, organ, or structure with which an animal can respond to external or internal stimuli. Usually functions, along with a sensor and integrator, as part of a homeostatic system.

efferent division The part of the nervous system that carries commands from the central nervous system to the body. Consists primarily of motor neurons.

egg A mature female gamete and any associated external layers (such as a shell). Larger and less mobile than the male gamete. In animals, also called *ovum*.

ejaculation The release of semen from the copulatory organ of a male animal.

ejaculatory duct A short duct through which sperm move during ejaculation; connects the vas deferens to the urethra.

electric current A flow of electrical charge past a point. Also called *current*.

electrical potential Potential energy created by a separation of electrical charges between two points. Also called *voltage*.

electrocardiogram (EKG) A recording of the electrical activity of the heart, as measured through electrodes on the skin.

electrochemical gradient The combined effect of an ion's concentration gradient and electrical (charge) gradient across a membrane that affects the diffusion of ions across the membrane.

electrogenic fish Any of various kinds of fishes having specialized electric organs that emit a current into the water to detect objects.

electrolyte Any compound that dissociates into ions when dissolved in water. In nutrition, any of the major ions necessary for normal cell function.

electromagnetic spectrum The entire range of wavelengths of radiation extending from short wavelengths (high energy) to long wavelengths (low energy). Includes gamma rays, X-rays, ultraviolet, visible light, infrared, microwaves, and radio waves (from short to long wavelengths).

electron acceptor A reactant that gains an electron and is reduced in a reduction–oxidation reaction.

electron carrier Any molecule that readily accepts electrons from and donates electrons to other molecules. Protons may be transferred with the electrons in the form of hydrogen atoms.

electron donor A reactant that loses an electron and is oxidized in a reduction–oxidation reaction.

electron shell A group of orbitals of electrons with similar energies. Electron shells are arranged in roughly concentric layers around the nucleus of an atom, and electrons in outer shells have more energy than those in inner shells. Electrons in the outermost shell, the valence shell, often are involved in chemical bonding.

electron transport chain (ETC) Any set of membrane-bound protein complexes and mobile electron carriers involved in a coordinated series of redox reactions in which the potential energy of electrons is successively decreased and used to pump protons from one side of a membrane to the other.

electronegativity A measure of the ability of an atom to attract electrons toward itself from an atom to which it is bonded.

electroreception A sensory system in which receptors are activated by electric fields.

electroreceptor A sensory cell or organ specialized to detect electric fields.

element A substance, consisting of atoms with a specific number of protons. Elements preserve their identity in chemical reactions.

elongation (1) The process by which RNA lengthens during transcription. (2) The process by which a polypeptide chain lengthens during translation.

elongation factors Proteins involved in the elongation phase of translation, assisting ribosomes in the synthesis of the growing peptide chain.

embryo A young, developing organism; the stage after fertilization and zygote formation.

embryo sac The female gametophyte in flowering plants.

embryogenesis The production of an embryo from a zygote. Embryogenesis is an early event in development of animals and plants.

Embryophyta An increasingly popular name for the lineage called land plants; reflects their retention of a fertilized egg.

embryophyte A plant that nourishes its embryos inside its own body. All land plants are embryophytes.

emergent property A property that stems from the interaction of simpler elements and that is impossible to predict from the study of individual elements.

emergent vegetation Any plants in an aquatic habitat that extend above the surface of the water.

emerging disease Any infectious disease, often a viral disease, that suddenly afflicts significant numbers of humans for the first time; often due to changes in the host species for a pathogen or to radical changes in the genetic material of the pathogen.

emigration The migration of individuals away from one population to other populations. Compare with **immigration**.

emulsification (verb: emulsify) The dispersion of fat into an aqueous solution. Usually requires the aid of an amphipathic substance such as a detergent or bile salts, which can break large fat globules into microscopic fat droplets.

endangered species A species whose numbers have decreased so much that it is in danger of extinction throughout all or part of its range.

endemic species A species that lives in one geographic area and nowhere else.

endergonic Referring to a chemical reaction that requires an input of energy to occur and for which the Gibbs free-energy change (ΔG) is greater than zero. Compare with **exergonic**.

endocrine Relating to a chemical signal (hormone) that is released into the bloodstream by a producing cell and acts on a distant target cell.

endocrine disruptor An exogenous chemical that interferes with normal hormonal signaling.

endocrine gland A gland that secretes hormones directly into the bloodstream or interstitial fluid instead of into ducts. Compare with **exocrine gland**.

endocrine system All of the glands and tissues that produce and secrete hormones into the bloodstream.

endocytosis General term for any pinching off of the plasma membrane that results in the uptake of material from outside the cell. Includes phagocytosis, pinocytosis, and receptor-mediated endocytosis. Compare with **exocytosis**.

endoderm The innermost of the three basic cell layers (germ layers) in most animal embryos; gives rise to the digestive tract and organs that connect to it (liver, lungs, etc.). Compare with **ectoderm** and **mesoderm**.

endodermis In plant roots, a cylindrical layer of cells that separates the cortex from the vascular tissue and location of the Casparian strip.

endomembrane system A system of organelles in eukaryotic cells that synthesizes, processes, transports, and recycles proteins and lipids. Includes the endoplasmic reticulum (ER), Golgi apparatus, and lysosomes.

endomycorrhizal fungi See **arbuscular mycorrhizal fungi (AMF)**.

endoparasite A parasite that lives inside the host's body.

endophyte (adjective: endophytic) A fungus that lives inside the aboveground parts of a plant in a symbiotic relationship. Compare with **epiphyte**.

endoplasmic reticulum (ER) A network of interconnected membranous sacs and tubules found inside eukaryotic cells. See **rough** and **smooth endoplasmic reticulum**.

endoskeleton Bony and/or cartilaginous structures within the body that provide support. Examples are the spicules of sponges, the plates in echinoderms, and the bony skeleton of vertebrates. Compare with **exoskeleton**.

endosperm A triploid ($3n$) tissue in the seed of a flowering plant (angiosperm) that serves as food for the plant embryo. Functionally analogous to the yolk in some animal eggs.

endosymbiont An organism that lives in a symbiotic relationship inside the body of its host.

endosymbiosis An association between organisms of two different species in which one lives inside the cell or cells of the other.

endosymbiosis theory The theory that mitochondria and chloroplasts evolved from prokaryotes that were engulfed by host cells and took up a symbiotic existence within those cells, a process termed primary endosymbiosis. In some eukaryotes, chloroplasts may have originated by secondary endosymbiosis; that is, when a cell engulfed a chloroplast-containing protist and retained its chloroplasts.

endotherm An animal whose primary source of body heat is internally generated. Compare with **ectotherm**.

endothermic Referring to a chemical reaction that absorbs heat. Compare with **exothermic**.

energetic coupling In cellular metabolism, the mechanism by which energy released from an exergonic reaction (commonly, hydrolysis of ATP) is used to drive an endergonic reaction.

energy The capacity to do work or to supply heat. May be stored (potential energy) or available in the form of motion (kinetic energy).

enhancer A regulatory sequence in eukaryotic DNA that may be located far from the gene it controls or within introns of the gene. Binding of specific proteins to an enhancer enhances the transcription of certain genes.

enrichment culture A method of detecting and obtaining cells with specific characteristics by placing a sample, containing many types of cells, under a specific set of conditions (e.g., temperature, salt concentration, available nutrients) and isolating those cells that grow rapidly in response.

enthalpy (H) A quantitative measure of the amount of potential energy, or heat content, of a system plus the pressure and volume it exerts on its surroundings.

entropy (S) A quantitative measure of the amount of disorder of any system, such as a group of molecules.

envelope (viral) A membrane that encloses the capsids of some viruses. Normally includes specialized proteins that attach to host-cell surfaces.

environmental sequencing See **metagenomics**.

enzyme A protein catalyst used by living organisms to speed up and control biological reactions.

epicotyl In some embryonic plants, a portion of the embryonic stem that extends above the cotyledons.

epidemic The spread of an infectious disease throughout a population in a short time period. Compare with **pandemic**.

epidermis The outermost layer of cells of any multicellular organism.

epididymis A coiled tube wrapped around each testis in reptiles, birds, and mammals. The site of the final stages of sperm maturation.

epigenetic inheritance Pattern of inheritance involving differences in phenotype that are not due to differences in the nucleotide sequence of genes.

epinephrine A catecholamine hormone, produced and secreted by the adrenal medulla, that triggers rapid responses related to the fight-or-flight response. Also called *adrenaline*.

epiphyte (adjective: epiphytic) A nonparasitic plant that grows on the trunks or branches of other plants and is not rooted in soil.

epithelial tissues See **epithelium**.

epithelium (plural: epithelia) An animal tissue consisting of sheetlike layers of tightly packed cells that line an organ, a gland, a duct, or a body surface. Also called *epithelial tissue*.

epitope A small region of a particular antigen to which an antibody, B-cell receptor, or T-cell receptor binds.

equilibrium potential The membrane potential at which there is no net movement of a particular ion into or out of a cell.

ER signal sequence A short amino acid sequence that marks a polypeptide for transport to the endoplasmic reticulum, where synthesis of the polypeptide chain is completed and the signal sequence removed. See **signal recognition particle**.

erythropoietin (EPO) A peptide hormone, released by the kidney in response to low blood-oxygen levels, that stimulates the bone marrow to produce more red blood cells.

esophagus The muscular tube that connects the mouth to the stomach.

essential amino acid Any amino acid that an animal cannot synthesize and must obtain from the diet. May refer specifically to one of the eight essential amino acids of adult humans: isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine.

essential nutrient Any chemical element, ion, or compound that is required for normal growth, reproduction, and maintenance of a living organism and that cannot be synthesized by the organism.

EST See **expressed sequence tag**.

ester linkage The covalent bond formed by a condensation reaction between a carboxyl group and a hydroxyl group. Ester linkages join fatty acids to glycerol to form a fat or phospholipid.

estradiol The major estrogen produced by the ovaries of female mammals and many other vertebrates. Stimulates development of the female reproductive tract, growth of ovarian follicles, and growth of breast tissue in mammals.

estrogens A class of steroid hormones, including estradiol, estrone, and estriol, that generally promote female-like traits. Secreted by the gonads, fat tissue, and some other organs.

estrous cycle A female reproductive cycle in which the uterine lining is reabsorbed rather than shed in the absence of pregnancy and the female is sexually receptive only briefly during mid-cycle (estrus). It is seen in all mammals except Old World monkeys and apes (including humans). Compare with **menstrual cycle**.

ethylene A gaseous plant hormone associated with senescence that induces fruits to ripen and flowers to fade.

eudicot A member of a monophyletic group (lineage) of angiosperms that includes complex flowering plants and trees (e.g., roses, daisies, maples). All eudicots have two cotyledons, but not all dicots are members of this lineage. Compare with **dicot** and **monocot**.

Eukarya One of the three taxonomic domains of life, consisting of unicellular organisms (most protists, yeasts) and multicellular organisms (fungi, plants, animals) distinguished by a membrane-bound cell nucleus, numerous organelles, and an extensive cytoskeleton. Compare with **Archaea** and **Bacteria**.

eukaryote A member of the domain Eukarya; an organism whose cells contain a nucleus, numerous membrane-bound organelles, and an extensive cytoskeleton. May be unicellular or multicellular. Compare with **prokaryote**.

eusociality A complex social structure in which workers sacrifice most or all of their direct reproduction to help rear the queen's offspring. Common in insects such as ants, bees, wasps, and termites.

eutherians A lineage of mammals (Eutheria) whose young develop in the uterus and are not housed in an abdominal pouch. Also called *placental mammals*.

evaporation The energy-absorbing phase change from a liquid state to a gaseous state. Many organisms evaporate water as a means of heat loss.

evo-devo Popular term for evolutionary developmental biology, a research field focused on how changes in developmentally important genes have led to the evolution of new phenotypes.

evolution (1) The theory that all organisms on Earth are related by common ancestry and that they have changed over time, and continue to change, via natural selection and other processes. (2) Any change in the genetic characteristics of a population over time, especially, a change in allele frequencies.

ex situ conservation Preserving species outside of natural areas (e.g., in zoos, aquaria, or botanical gardens).

excitable membrane A plasma membrane that is capable of generating an action potential. Neurons, muscle cells, and some other cells have excitable membranes.

excitatory postsynaptic potential (EPSP) A change in membrane potential, usually depolarization, at a neuron dendrite that makes an action potential more likely.

exergonic Referring to a chemical reaction that can occur spontaneously, releasing heat and/or increasing entropy, and for which the Gibbs free-energy change (ΔG) is less than zero. Compare with **endergonic**.

exocrine gland A gland that secretes some substance through a duct into a space other than the circulatory system, such as the digestive tract or the skin surface. Compare with **endocrine gland**.

exocytosis Secretion of intracellular molecules (e.g., hormones, collagen), contained within membrane-bound vesicles, to the outside of the cell by fusion of vesicles to the plasma membrane. Compare with **endocytosis**.

exon A transcribed region of a eukaryotic gene or region of a primary transcript that is retained in the mature RNA. Except for 5′ and 3′ UTRs, mRNA exons code for amino acids. Compare with **intron**.

exoskeleton A hard covering secreted on the outside of the body, used for body support, protection, and muscle attachment. Prominent in arthropods. Compare with **endoskeleton**.

exothermic Referring to a chemical reaction that releases heat. Compare with **endothermic**.

exotic species A nonnative species that is introduced into a new area. Exotic species often are competitors, pathogens, or predators of native species.

expansins A class of plant proteins that break hydrogen bonds between components in the primary cell wall to allow it to expand for cell growth.

exponential population growth The accelerating increase in the size of a population that occurs when the growth rate is constant and density independent. Compare with **logistic population growth**.

expressed sequence tag (EST) A portion of a transcribed gene (synthesized from an mRNA in a cell), used to find the physical location of that gene in the genome.

extant species A species that is living today.

extensor A muscle that pulls two bones farther apart from each other, increasing the angle of the joint, as in the extension of a limb or the spine. Compare with **flexor**.

extinct species A species that has died out.

extracellular digestion Digestion that takes place outside of an organism, as occurs in many fungi that make and secrete digestive enzymes.

extracellular matrix (ECM) A complex meshwork in which animal cells are embedded, consisting of proteins (e.g., collagen, proteoglycan, laminin) and polysaccharides produced by the cells.

extremophile A bacterium or archaean that thrives in an "extreme" environment (e.g., high-salt, high-temperature, low-temperature, or low-pressure).

F_1 generation First filial generation. The first generation of offspring produced from a mating (i.e., the offspring of the parental generation).

facilitated diffusion Passive movement of a substance across a membrane with the assistance of transmembrane carrier proteins or channel proteins.

facilitation In ecological succession, the phenomenon in which early-arriving species make conditions more favorable for later-arriving species. Compare with **inhibition** and **tolerance**.

facultative anaerobe Any organism that can survive and reproduce by performing aerobic respiration when oxygen is available or fermentation when it is not.

FAD/$FADH_2$ Oxidized and reduced forms, respectively, of flavin adenine dinucleotide. A nonprotein electron carrier that functions in the citric acid cycle and oxidative phosphorylation.

fallopian tube A narrow tube connecting the uterus to the ovary in humans, through which the egg travels after ovulation. Site of fertilization and cleavage. In nonhuman animals, called *oviduct*.

fast muscle fiber Type of skeletal muscle fiber that is white in color, generates ATP by glycolysis, and contracts rapidly but fatigues easily. Also called *fast glycolytic*, or *Type IIb*, *fiber*.

fat A lipid consisting of three fatty acid molecules joined by ester linkages to a glycerol molecule. Also called *triacylglycerol* or *triglyceride*.

fatty acid A lipid consisting of a hydrocarbon chain bonded at one end to a carboxyl group. Used by many organisms to store chemical energy; a major component of animal and plant fats and phospholipids.

fauna All the animal species characteristic of a particular region, period, or environment.

feather A specialized skin outgrowth, composed of β-keratin, present in all birds as well as in some nonavian dinosaurs. Used for flight, insulation, display, and other purposes.

feces The waste products of digestion.

fecundity The average number of female offspring produced by a single female in the course of her lifetime.

feedback inhibition A type of control in which high concentrations of the product of a metabolic pathway inhibit one of the enzymes early in the pathway. A form of negative feedback.

fermentation Any of several metabolic pathways that regenerate oxidizing agents, such as NAD^+, by transferring electrons to a final electron acceptor in the absence of an electron transport chain. Allows pathways such as glycolysis to continue to make ATP.

ferredoxin In photosynthetic organisms, an iron- and sulfur-containing protein in the electron transport chain of photosystem I. Can transfer electrons to the enzyme $NADP^+$ reductase, which catalyzes formation of NADPH.

fertility The average number of surviving children that each woman has during her lifetime.

fertilization Fusion of the nuclei of two haploid gametes to form a zygote with a diploid nucleus.

fertilization envelope A physical barrier that forms around a fertilized egg in many animals. The fertilization envelope prevents fertilization by more than one sperm (polyspermy).

fetal alcohol syndrome (FAS) A condition marked by hyperactivity, severe learning disabilities, and depression. Thought to be caused by exposure of an

individual to high blood alcohol concentrations during embryonic development.

fetus In live-bearing animals, the unborn offspring after the embryonic stage. It usually is developed sufficiently to be recognizable as belonging to a certain species.

fiber In plants, a type of elongated sclerenchyma cell that provides support to vascular tissue. Compare with **sclereid**.

Fick's law of diffusion A mathematical relationship that describes the rates of diffusion of gases.

fight-or-flight response Rapid physiological changes that prepare the body for emergencies. Includes increased heart rate, increased blood pressure, and decreased digestion.

filament Any thin, threadlike structure, particularly (1) the threadlike extensions of a fish's gills or (2) part of a stamen: the slender stalk that bears the anthers in a flower.

filter feeder See **suspension feeder**.

filtrate Any fluid produced by filtration, in particular the fluid ("pre-urine") in the Malpighian tubules of insects and the nephrons of vertebrate kidneys.

filtration A process of removing large components from a fluid by forcing it through a filter. Occurs in a renal corpuscle of the vertebrate kidney, allowing water and small solutes to pass from the blood into the nephron.

fimbria (plural: fimbriae) A long, needlelike projection from the cell membrane of prokaryotes that is involved in attachment to nonliving surfaces or other cells.

finite rate of increase (λ) The rate of increase of a population over a given period of time. Calculated as the ending population size divided by the starting population size. Compare with **intrinsic rate of increase**.

first law of thermodynamics The principle of physics that energy is conserved in any process. Energy can be transferred and converted into different forms, but it cannot be created or destroyed.

fission (1) A form of asexual reproduction in which a prokaryotic cell divides to produce two genetically similar daughter cells by a process similar to mitosis of eukaryotic cells. Also called *binary fission*. (2) A form of asexual reproduction in which an animal splits into two or more individuals of approximately equal size; common among invertebrates.

fitness The ability of an individual to produce viable offspring relative to others of the same species.

fitness trade-off See **trade-off**.

fixed action pattern (FAP) Highly stereotyped behavior pattern that occurs in a certain invariant way in a certain species. A form of innate behavior.

flaccid Limp as a result of low internal (turgor) pressure (e.g., a wilted plant leaf). Compare with **turgid**.

flagellum (plural: flagella) A long, cellular projection that undulates (in eukaryotes) or rotates (in prokaryotes) to move the cell through an aqueous environment. See **axoneme**.

flatworms Members of the phylum Platyhelminthes. Distinguished by a broad, flat, unsegmented body that lacks a coelom. Flatworms belong to the lophotrochozoan branch of the protostomes.

flavin adenine dinucleotide See **FAD/FADH$_2$**.

flexor A muscle that pulls two bones closer together, decreasing the joint angle, as in the flexing of a limb or the spine. Compare with **extensor**.

floral meristem A group of undifferentiated plant stem cells that can give rise to the four organs making up a flower.

florigen In plants, a protein hormone that is synthesized in leaves and transported to the shoot apical meristem, where it stimulates flowering.

flower In angiosperms, the part of a plant that contains reproductive structures. Typically includes a calyx, a corolla, and one or more stamens and/or carpels. See **perfect** and **imperfect flower**.

fluid connective tissue A type of connective tissue, distinguished by having a liquid extracellular matrix; includes blood.

fluid feeder Any animal that feeds by sucking or mopping up liquids such as nectar, plant sap, or blood.

fluid-mosaic model The widely accepted hypothesis that the plasma membrane and organelle membranes consist of proteins embedded in a fluid phospholipid bilayer.

fluorescence The spontaneous emission of light from an excited electron falling back to its normal (ground) state.

follicle In a mammalian ovary, a sac of supportive cells containing an egg cell.

follicle-stimulating hormone (FSH) A peptide hormone, produced and secreted by the anterior pituitary; it stimulates (in females) growth of eggs and follicles in the ovaries or (in males) sperm production in the testes.

follicular phase In a menstrual cycle, the first major phase, during which follicles grow and estradiol levels increase; ends with ovulation.

food Any nutrient-containing material that can be consumed and digested by animals.

food chain A relatively simple pathway of energy flow through a few species, each at a different trophic level, in an ecosystem. Might include, for example, a primary producer, a primary consumer, a secondary consumer, and a decomposer. A subset of a **food web**.

food web The complex network of interactions among species in an ecosystem formed by the transfer of energy and nutrients among trophic levels. Consists of many food chains.

foot One of the three main parts of the mollusk body; a muscular appendage, used for movements such as crawling and/or burrowing into sediment.

foraging Searching for food.

forebrain One of the three main regions of the vertebrate brain; includes the cerebrum, thalamus, and hypothalamus. Compare with **hindbrain** and **midbrain**.

fossil Any physical trace of an organism that existed in the past. Includes tracks, burrows, fossilized bones, casts, and so on.

fossil record All of the fossils that have been found anywhere on Earth and that have been formally described in the scientific literature.

founder effect A change in allele frequencies that often occurs when a new population is established from a small group of individuals (founder event) due to sampling error (i.e., the small group is not a representative sample of the source population).

fovea In the vertebrate eye, a portion of the retina where incoming light is focused; contains a high proportion of cone cells.

frameshift mutation The addition or deletion of a nucleotide in a coding sequence that shifts the reading frame of the mRNA.

free energy The energy of a system that can be converted into work. It may be measured only through the change in free energy in a reaction. See **Gibbs free-energy change**.

free radicals Any substance containing one or more atoms with an unpaired electron. Unstable and highly reactive.

frequency The number of wave crests per second traveling past a stationary point. Determines the pitch of sound and the color of light.

frequency-dependent selection A pattern of selection in which certain alleles are favored only when they are rare; a form of balancing selection.

fronds The large leaves of ferns.

frontal lobe In the vertebrate brain, one of the four major areas in the cerebrum.

fruit In flowering plants (angiosperms), a mature, ripened plant ovary (or group of ovaries), along with the seeds it contains and any adjacent fused parts; often functions in seed dispersal. See **aggregate**, **multiple**, and **simple fruit**.

fruiting body A structure formed in some prokaryotes, fungi, and protists for spore dispersal; usually consists of a base, a stalk, and a mass of spores at the top.

functional genomics The study of how a genome works; that is, when and where specific genes are expressed and how their products interact to produce a functional organism.

functional group A small group of atoms bonded together in a precise configuration and exhibiting particular chemical properties that it imparts to any organic molecule in which it occurs.

fundamental niche The total theoretical range of environmental conditions that a species can tolerate. Compare with **realized niche**.

fungi A lineage of eukaryotes that typically have a filamentous body (mycelium) and obtain nutrients by absorption.

fungicide Any substance that can kill fungi or slow their growth.

G protein Any of various proteins that are activated by binding to guanosine triphosphate (GTP) and inactivated when GTP is hydrolyzed to GDP. In G-protein-coupled receptors, signal binding directly triggers the activation of a G protein, leading to production of a second messenger or initiation of a phosphorylation cascade.

G_1 phase The phase of the cell cycle that constitutes the first part of interphase before DNA synthesis (S phase).

G_2 phase The phase of the cell cycle between synthesis of DNA (S phase) and mitosis (M phase); the last part of interphase.

gallbladder A small pouch that stores bile from the liver and releases it as needed into the small intestine during digestion of fats.

gametangium (plural: gametangia) (1) The gamete-forming structure found in all land plants except angiosperms. Contains a sperm-producing antheridium and an egg-producing archegonium. (2) The gamete-forming structure of some chytrid fungi.

gamete A haploid reproductive cell that can fuse with another haploid cell to form a zygote. Most multicellular eukaryotes have two distinct forms of gametes: egg cells (ova) and sperm cells.

gametogenesis The production of gametes (eggs or sperm).

gametophyte In organisms undergoing alternation of generations, the multicellular haploid form that arises from a single haploid spore and produces gametes. Compare with **sporophyte**.

ganglion (plural: ganglia) A mass of neurons in a centralized nervous system.

ganglion cell In the retina, a type of neuron whose axons form the optic nerves.

gap junction A type of cell–cell attachment structure that directly connects the cytosolic components of adjacent animal cells, allowing passage of water, ions, and small molecules between the cells. Compare with **desmosome** and **tight junction**.

gastrin A hormone produced by cells in the stomach lining in response to the arrival of food or to a neural signal from the brain. Stimulates other stomach cells to release hydrochloric acid.

gastropods A lineage of mollusks distinguished by a large, muscular foot and a unique feeding structure, the radula. Include slugs and snails.

gastrulation The process of coordinated cell movements, including the moving of some cells from the outer surface of the embryo to the interior, that results in the formation of three germ layers (endoderm, mesoderm, and ectoderm) and the axes of the embryo.

gated channel A channel protein that opens and closes in response to a specific stimulus, such as the binding of a particular molecule or a change in voltage across the membrane.

gemma (plural: gemmae) A small reproductive structure that is produced asexually in some plants during the gametophyte phase and can grow into a mature gametophyte; most common in non-vascular plants, particularly liverworts and club mosses, and in ferns

gene A section of DNA (or RNA, for some viruses) that encodes information for building one or more related polypeptides or functional RNA molecules along with the regulatory sequences required for its transcription.

gene duplication The formation of an additional copy of a gene, typically by misalignment of chromosomes during crossing over. Thought to be an important evolutionary process in creating new genes.

gene expression The set of processes, including transcription and translation, that convert information in DNA into aproduct of a gene, most commonly a protein.

gene family A set of genetic loci whose DNA sequences are extremely similar. Thought to have arisen by duplication of a single ancestral gene and subsequent mutations in the duplicated sequences.

gene flow The movement of alleles between populations; occurs when individuals leave one population, join another, and breed.

gene pool All the alleles of all the genes in a certain population.

gene therapy The treatment of an inherited disease by introducing a normal form of the gene.

generation The average time between a mother's first offspring and her daughter's first offspring.

genetic bottleneck A reduction in allelic diversity resulting from a sudden reduction in the size of a large population (population bottleneck) due to a random event.

genetic code The set of all codons and their meaning.

genetic correlation A type of evolutionary constraint in which selection on one trait causes a change in another trait as well; may occur when the same gene(s) affect both traits.

genetic diversity The diversity of alleles or genes in a population, species, or group of species.

genetic drift Any change in allele frequencies due to random events. Causes allele frequencies to drift up and down randomly over time, and eventually can lead to the fixation or loss of alleles.

genetic equivalence Having all different cell types of a multicellular individual possess the same genome.

genetic homology Similarity in DNA nucleotide sequences, RNA nucleotide sequences, or amino acid sequences due to inheritance from a common ancestor.

genetic map A list of genes on a chromosome that indicates their position and relative distances from one another. Also called a *linkage map*. Compare with **physical map**.

genetic marker A genetic locus that can be identified and traced in populations by laboratory techniques or by a distinctive visible phenotype.

genetic recombination A change in the combination of alleles on a given chromosome or in a given individual. Also called *recombination*.

genetic screen Any technique that identifies individuals with a particular type of mutation.

genetic variation (1) The number and relative frequency of alleles present in a particular population. (2) The proportion of phenotypic variation in a trait that is due to genetic rather than environmental influences in a certain population in a certain environment.

genetics The study of the inheritance of traits.

genital (plural: genitalia) Any external copulatory organ.

genome All the hereditary information in an organism, including not only genes but also stretches of DNA that do not contain genes.

genome annotation The process of analyzing a genome sequence to identify key features such as genes, regulatory sequences, and splice sites.

genomic library A set of DNA segments representing the entire genome of a particular organism. Each segment is carried by a plasmid or other cloning vector and can be separated from other segments. Compare with **cDNA library**.

genomics The field of study concerned with sequencing, interpreting, and comparing whole genomes from different organisms.

genotype All the alleles of every gene present in a given individual. Often specified only for the alleles of a particular set of genes under study. Compare with **phenotype**.

genus (plural: genera) In Linnaeus' system, a taxonomic category of closely related species. Always italicized and capitalized to indicate that it is a recognized scientific genus.

geologic time scale The sequence of eons, eras, and periods used to describe the geologic history of Earth.

germ cell In animals, any cell that can potentially give rise to gametes. Also called *germ-line cells*.

germ layer In animals, one of the three basic types of tissue formed during gastrulation; gives rise to all other tissues. See **endoderm**, **mesoderm**, and **ectoderm**.

germ line In animals, any of the cells that are capable of giving rise to reproductive cells (sperm or egg). Compare with **germ cell**.

germ theory of disease The theory that infectious diseases are caused by bacteria, viruses, and other microorganisms.

germination The process by which a seed becomes a young plant.

gestation The period of development inside the mother, from implantation to birth, in those species that have live birth.

gibberellins A class of hormones, found in plants and fungi, that stimulate growth. Gibberellic acid (GA) is one of the major gibberellins.

Gibbs free-energy change (ΔG) A measure of the change in enthalpy and entropy that occurs in a given chemical reaction. ΔG is less than 0 for spontaneous reactions and greater than 0 for nonspontaneous reactions.

gill Any organ in aquatic animals that exchanges gases and other dissolved substances between the blood and the surrounding water. Typically, a filamentous outgrowth of a body surface.

gill arch In aquatic vertebrates, a curved region of tissue between the gills. Gills are suspended from the gill arches.

gill filament In fish, any of the many long, thin structures that extend from gill arches into the water and across which gas exchange occurs.

gill lamella (plural: gill lamellae) Any of hundreds to thousands of sheetlike structures, each containing a capillary bed, that make up a gill filament.

gland An organ whose primary function is to secrete some substance, either into the blood (endocrine gland) or into some other space such as the gut or skin (exocrine gland).

glia Collective term for several types of cells in nervous tissue that are not neurons and do not conduct electrical signals but perform other functions, such as providing support, nourishment, or electrical insulation. Also called *glial cells*.

global carbon cycle See **carbon cycle, global**.

global climate change The global sum of all the local changes in temperature and precipitation patterns that accompany global warming (or in some past events, global cooling).

global gene regulation The regulation of multiple bacterial genes that are not part of one operon.

global nitrogen cycle See **nitrogen cycle, global**.

global warming A sustained increase in Earth's average surface temperature.

global water cycle See **water cycle, global**.

glomalin A glycoprotein that is abundant in the hyphae of arbuscular mycorrhizal fungi; when hyphae decay, it is an important component of soil.

glomerulus (plural: glomeruli) (1) In the vertebrate kidney, a ball-like cluster of capillaries, surrounded by Bowman's capsule, at the beginning of a nephron. (2) In the brain, a ball-shaped cluster of neurons in the olfactory bulb.

glucagon A peptide hormone produced by the pancreas in response to low blood glucose. Raises blood glucose by triggering breakdown of glycogen and stimulating gluconeogenesis. Compare with **insulin**.

glucocorticoids A class of steroid hormones, produced and secreted by the adrenal cortex, that increase blood glucose and prepare the body for stress. Include cortisol and corticosterone. Compare with **mineralocorticoids**.

gluconeogenesis Synthesis of glucose, often from non-carbohydrate sources (e.g., proteins and fatty acids). In plants, used to produce glucose from products of the Calvin cycle. In animals, occurs in the liver in response to low insulin levels and high glucagon levels.

glucose Six-carbon monosaccharide whose oxidation in cellular respiration is the major source of ATP in animal cells.

glyceraldehyde-3-phosphate (G3P) The phosphorylated three-carbon compound formed as the result of carbon fixation in the first step of the Calvin cycle.

glycerol A three-carbon molecule that forms the "backbone" of phospholipids and most fats.

glycogen A highly branched storage polysaccharide composed of glucose monomers joined by α-1,4- and α-1,6-glycosidic linkages. The major form of stored carbohydrate in animals.

glycolipid Any lipid molecule that is covalently bonded to a carbohydrate group.

glycolysis A series of 10 chemical reactions that oxidize glucose to produce pyruvate, NADH, and ATP. Used by organisms as part of fermentation or cellular respiration.

glycoprotein Any protein with one or more covalently bonded carbohydrates, typically oligosaccharides.

glycosidic linkage The covalent linkage formed by a condensation reaction between two sugar monomers; joins the residues of a polysaccharide.

glycosylation Addition of a carbohydrate group to a molecule.

glyoxysome Specialized type of peroxisome found in plant cells and packed with enzymes for processing the products of photosynthesis.

gnathostomes Animals with jaws. Most vertebrates are gnathostomes.

Golgi apparatus A eukaryotic organelle, consisting of stacks of flattened membranous sacs (cisternae), that functions in processing and sorting proteins and lipids destined to be secreted or directed to other organelles. Also called *Golgi complex*.

gonad An organ, such as a testis or an ovary, that produces reproductive cells.

gonadotropin-releasing hormone (GnRH) A peptide hormone, produced and secreted by the hypothalamus, that stimulates release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the anterior pituitary.

grade In taxonomy, a group of species that share some, but not all, of the descendants of a common ancestor. Also called a *paraphyletic group*.

Gram-negative Describing bacteria that look pink when treated with a Gram stain. These bacteria have a cell wall composed of a thin layer of peptidoglycan and an outer phospholipid layer. Compare with **Gram-positive**.

Gram-positive Describing bacteria that look purple when treated with a Gram stain. These bacteria have cell walls composed of a thick layer of peptidoglycan and no outer phospholipid later. Compare with **Gram-negative**.

Gram stain A dye that distinguishes the two general types of cell walls found in bacteria. Used to routinely classify bacteria as Gram-negative or Gram-positive.

granum (plural: grana) In chloroplasts, a stack of flattened, membrane-bound thylakoid discs where the light reactions of photosynthesis occur.

gravitropism The growth or movement of a plant in a particular direction in response to gravity.

grazing food chain The ecological network of herbivores and the predators and parasites that consume them.

great apes See **hominids**.

green algae A paraphyletic group of photosynthetic organisms that contain chloroplasts similar to those in green plants. Often classified as protists, green algae are the closest living relatives of land plants and form a monophyletic group with them.

greenhouse gas An atmospheric gas that absorbs and reflects infrared radiation, so that heat radiated from Earth is retained in the atmosphere instead of being lost to space.

gross primary productivity In an ecosystem, the total amount of carbon fixed by photosynthesis (or more rarely, chemosynthesis), including that used for cellular respiration, over a given time period. Compare with **net primary productivity**.

ground meristem The middle layer of a young plant embryo. Gives rise to the ground tissue system.

ground tissue An embryonic tissue layer that gives rise to parenchyma, collenchyma, and sclerenchyma—tissues other than the epidermis and vascular tissue. Also called *ground tissue system*.

groundwater Any water below the land surface.

growth factor Any of a large number of signaling molecules that are secreted by certain cells and that stimulate other cells to grow, divide, or differentiate.

growth hormone (GH) A peptide hormone, produced and secreted by the mammalian anterior pituitary, that promotes lengthening of the long bones in children and muscle growth, tissue repair, and lactation in adults. Also called *somatotropin*.

guanosine triphosphate (GTP) A nucleotide consisting of guanine, a ribose sugar, and three phosphate groups. Can be hydrolyzed to release free energy. Commonly used in RNA synthesis and also functions in signal transduction in association with G proteins.

guard cell One of two specialized, crescent-shaped cells forming the border of a plant stoma. Guard cells can change shape to open or close the stoma. See also **stoma**.

gustation The perception of taste.

guttation Excretion of water droplets from plant leaves; visible in the early morning. Caused by root pressure.

gymnosperm A vascular plant that makes seeds but does not produce flowers. The gymnosperms include five lineages of green plants (cycads, ginkgoes, conifers, redwoods, and gnetophytes). Compare with **angiosperm**.

H^+-ATPase See **proton pump**.

habitat degredation The reduction of the quality of a habitat.

habitat destruction Human-caused destruction of a natural habitat, replaced by an urban, suburban, or agricultural landscape.

habitat fragmentation The breakup of a large region of a habitat into many smaller regions, separated from others by a different type of habitat.

Hadley cell An atmospheric cycle of large-scale air movement in which warm equatorial air rises, moves north or south, and then descends at approximately 30° N or 30° S latitude.

hair cell A pressure-detecting sensory cell that has tiny "hairs" (stereocilia) jutting from its surface. Found in the inner ear, lateral line system, and ampullae of Lorenzini.

hairpin A secondary structure in RNA consisting of a stable loop formed by hydrogen bonding between purine and pyrimidine bases on the same strand.

Hamilton's rule The proposition that an allele for altruistic behavior will be favored by natural selection only if $Br\ C$, where B = the fitness benefit to the recipient, C = the fitness cost to the actor, and r = the coefficient of relatedness between recipient and actor.

haploid (1) Having one set of chromosomes (1*n* or *n* for short). (2) A cell or an individual organism with one set of chromosomes. Compare with **diploid**.

haploid number The number of different types of chromosomes in a cell. Symbolized as *n*.

Hardy–Weinberg principle A principle of population genetics stating that genotype frequencies in a large population do not change from generation to generation in the absence of evolutionary processes (e.g., mutation, gene flow, genetic drift, and selection), and nonrandom mating.

haustorium (plural: haustoria) Highly modified stem or root of a parasitic plant. The haustorium penetrates the tissues of a host and absorbs nutrients and water.

hearing The sensation of the wavelike changes in air pressure called sound.

heart A muscular pump that circulates blood throughout the body.

heart murmur A distinctive sound caused by backflow of blood through a defective heart valve.

heartwood The older xylem in the center of an older stem or root, containing protective compounds and no longer functioning in water transport.

heat Thermal energy that is transferred from an object at higher temperature to one at lower temperature.

heat of vaporization The energy required to vaporize 1 gram of a liquid into a gas.

heat-shock proteins Proteins that facilitate refolding of proteins that have been denatured by heat or other agents.

heavy chain The larger of the two types of polypeptide chains in an antibody or B-cell receptor molecule; composed of a variable (*V*) region, which contributes to the antigen-binding site, and a constant (*C*) region. Differences in heavy-chain constant regions determine the different classes of immunoglobulins (IgA, IgE, etc.). Compare with **light chain**.

helper T cell A $CD4^+$ effector T cell that secretes cytokines and in other ways promotes the activation of other lymphocytes. Activated by interacting with complementary class II MHC–peptide complexes on the surface of antigen-presenting cells such as dendritic cells.

heme A small molecule that binds to each of the four polypeptides that combine to form hemoglobin; contains an iron ion that can bind oxygen.

hemimetabolous metamorphosis A type of metamorphosis in which the animal increases in size from one stage to the next, but does not dramatically change its body form. Also called *incomplete metamorphosis*.

hemocoel A body cavity, present in arthropods and some mollusks, containing a pool of circulatory fluid (hemolymph) bathing the internal organs. Unlike a coelom, a hemocoel is not lined in mesoderm.

hemoglobin An oxygen-binding protein consisting of four polypeptide subunits, each containing an oxygen-binding heme group. The major oxygen carrier in mammalian blood.

hemolymph The circulatory fluid of animals with open circulatory systems (e.g., insects) in which the fluid is not confined to blood vessels.

herbaceous Referring to a plant that is not woody.

herbivore (adjective: herbivorous) An animal that eats primarily plants and rarely or never eats meat. Compare with **carnivore** and **omnivore**.

herbivory The practice of eating plant tissues.

heredity The transmission of traits from parents to offspring via genetic information.

heritable Referring to traits that can be transmitted from one generation to the next.

hermaphrodite An organism that produces both male and female gametes.

heterokaryotic Describing a cell or fungal mycelium containing two or more haploid nuclei that are genetically distinct.

heterospory (adjective: heterosporous) In seed plants, the production of two distinct types of spores: microspores, which become the male gametophyte, and megaspores, which become the female gametophyte. Compare with **homospory**.

heterotherm An animal whose body temperature varies markedly. Compare with **homeotherm**.

heterotroph Any organism that cannot synthesize reduced organic compounds from inorganic sources and that must obtain them from other organisms. Some bacteria, some archaea, and virtually all fungi and animals are heterotrophs. Also called *consumer*. Compare with **autotroph**.

heterozygote advantage A pattern of natural selection that favors heterozygous individuals compared with homozygotes. Tends to maintain genetic variation in a population, thus is a form of balancing selection.

heterozygous Having two different alleles of a gene.

hexose A monosaccharide (simple sugar) containing six carbon atoms.

hibernation An energy-conserving physiological state, marked by a decrease in metabolic rate, body temperature, and activity, that lasts for a prolonged period (weeks to months). Occurs in some animals in response to winter cold and scarcity of food. Compare with **torpor**.

hindbrain One of the three main regions of the vertebrate brain, responsible for balance and sometimes hearing; includes the cerebellum and medulla oblongata. Compare with **forebrain** and **midbrain**.

histamine A molecule released from mast cells during an inflammatory response that, at high concentrations, causes blood vessels to constrict to reduce blood loss from tissue damage.

histone One of several positively charged (basic) proteins associated with DNA in the chromatin of eukaryotic cells.

histone acetyltransferases (HATs) A class of eukaryotic enzymes that loosen chromatin structure by adding acetyl groups to histone proteins.

histone code The hypothesis that specific combinations of chemical modifications of histone proteins contain information that influences chromatin condensation and gene expression.

histone deacetylases (HDACs) A class of eukaryotic enzymes that condense chromatin by removing acetyl groups from histone proteins.

holoenzyme A multipart enzyme consisting of a core enzyme (containing the active site for catalysis) along with other required proteins.

holometabolous metamorphosis A type of metamorphosis in which the animal completely changes its form; includes a distinct larval stage. Also called *complete metamorphosis*.

homeobox A DNA sequence of about 180 base pairs that codes for a DNA binding motif called the homeodomain in the resulting protein. Genes containing a homeobox usually play a role in controlling development of organisms from fruit flies to humans.

homeostasis (adjective: homeostatic) The array of relatively stable chemical and physical conditions in an animal's cells, tissues, and organs. May be achieved by the body's passively matching the conditions of a stable external environment (conformational homeostasis) or by active physiological processes (regulatory homeostasis) triggered by variations in the external or internal environment.

homeotherm An animal that has a constant or relatively constant body temperature. Compare with **heterotherm**.

homeotic mutation A mutation that causes one body part to be substituted for another.

hominids Members of the family Hominidae, which includes humans and extinct related forms, chimpanzees, gorillas, and orangutans. Distinguished by large body size, no tail, and an exceptionally large brain. Also called *great apes*.

hominins Any extinct or living species of bipedal apes, such as *Australopithecus africanus*, *Homo erectus*, and *Homo sapiens*.

homologous See **homology**.

homologous chromosomes In a diploid organism, chromosomes that are similar in size, shape, and gene content. Also called *homologs*.

homology (adjective: homologous) Similarity among organisms of different species due to their inheritance from a common ancestor. Features that exhibit such similarity (e.g., DNA sequences, proteins, body parts) are said to be homologous. Compare with **homoplasy**.

homoplasy (adjective: homoplastic) Similarity among organisms of different species due to reasons other than common ancestry, such as convergent evolution. Features that exhibit such similarity (e.g., the wings of birds and bats) are said to be homoplastic, or convergent. Compare with **homology**.

homospory (adjective: homosporous) In seedless vascular plants, the production of just one type of spore. Compare with **heterospory**.

homozygous Having two identical alleles of a gene.

hormone Any of many different signaling molecules that circulate throughout the plant or animal body and can trigger characteristic responses in distant target cells at very low concentrations.

hormone-response element A specific sequence in DNA to which a steroid hormone–receptor complex can bind and affect gene transcription.

host An individual that has been invaded by an organism such as a parasite or a virus, or that provides habitat or resources to a commensal organism.

host cell A cell that has been invaded by a parasitic organism or a virus and provides an environment that is conducive to the pathogen's growth and reproduction.

***Hox* genes** A class of genes found in several animal phyla, including vertebrates, that are expressed in a distinctive pattern along the anterior–posterior axis in early embryos and control formation of specific structures. *Hox* genes code for transcription factors with a DNA-binding sequence called a homeobox.

human Any member of the genus *Homo,* which includes modern humans (*Homo sapiens*) and several extinct species.

human chorionic gonadotropin (hCG) A glycoprotein hormone produced by a human embryo and placenta from about week 3 to week 14 of pregnancy. Maintains the corpus luteum, which produces hormones that preserve the uterine lining.

Human Genome Project The multinational research project that sequenced the human genome.

human immunodeficiency virus (HIV) A retrovirus that causes acquired immune deficiency syndrome (AIDS) in humans.

humoral (immune) response The type of immune response that is mediated through the production and secretion of antibodies, complement proteins, and other soluble factors that eliminate extracellular pathogens. Compare with **cell-mediated (immune) response**.

humus The decayed organic matter in soils.

hybrid The offspring of parents from two different strains, populations, or species.

hybrid zone A geographic area where interbreeding occurs between two species, sometimes producing fertile hybrid offspring.

hydrocarbon An organic molecule that contains only hydrogen and carbon atoms.

hydrogen bond A weak interaction between two molecules or different parts of the same molecule resulting from the attraction between a hydrogen atom with a partial positive charge and another atom (usually O or N) with a partial negative charge. Compare with **covalent bond** and **ionic bond**.

hydrogen ion (H^+) A single proton with a charge of 1+; typically, one that is dissolved in solution or that is being transferred from one atom to another in a chemical reaction.

hydrolysis A chemical reaction in which a molecule is split into smaller molecules by reacting with water. In biology, most hydrolysis reactions involve the splitting of polymers into monomers. Compare with **condensation reaction**.

hydrophilic Interacting readily with water. Hydrophilic compounds are typically polar compounds containing partially or fully charged atoms. Compare with **hydrophobic**.

hydrophobic Not readily interacting with water. Hydrophobic compounds are typically nonpolar compounds that lack partially or fully charged atoms. Compare with **hydrophilic**.

hydrophobic interactions Very weak interactions between nonpolar molecules, or nonpolar regions of the same molecule, when exposed to an aqueous solvent. The surrounding water molecules support these interactions by interacting with one another and encapsulating the nonpolar molecules.

hydroponic growth Growth of plants in liquid cultures instead of soil.

hydrostatic skeleton A system of body support involving a body wall in tension surrounding a fluid or soft tissue under compression.

hydroxide ion (OH^-) An oxygen atom and a hydrogen atom joined by a single covalent bond and carrying a negative charge; formed by dissociation of water.

hygiene hypothesis The claim that immune disorders arise in individuals less likely to have been exposed to pathogens and parasites, especially in early childhood. Provides an explanation for the increased risk of allergies and autoimmune disease in countries with high levels of sanitation.

hyperosmotic Comparative term designating a solution that has a greater solute concentration, and therefore a lower water concentration, than another solution. Compare with **hyposmotic** and **isosmotic**.

hyperpolarization A change in membrane potential from its resting negative state to an even more negative state; a normal phase in an action potential. Compare with **depolarization**.

hypersensitive reaction An intense allergic response by cells that have been sensitized by previous exposure to an allergen.

hypersensitive response In plants, the rapid death of a cell that has been infected by a pathogen, thereby reducing the potential for infection to spread throughout a plant. Compare with **systemic acquired resistance**.

hypertension Abnormally high blood pressure.

hypertonic Comparative term designating a solution that, if inside a cell or vesicle, results in the uptake of water and swelling or even bursting of the membrane-bound structure. This solution has a greater solute concentration than the solution on the other side of the membrane. Used when the solute is unable to pass through the membrane. Compare with **hypotonic** and **isotonic**.

hypha (plural: hyphae) One of the long, branching strands of a fungal mycelium (the mesh-like body of a fungus). Also found in some protists.

hypocotyl The stem of a very young plant; the region between the cotyledon (embryonic leaf) and the radicle (embryonic root).

hyposmotic Comparative term designating a solution that has a lower solute concentration, and therefore a higher water concentration, than another solution. Compare with **hyperosmotic** and **isosmotic**.

hypothalamic–pituitary axis The functional interaction of the hypothalamus and the anterior pituitary gland, which are anatomically distinct but work together to regulate most of the other endocrine glands in the body.

hypothalamus A part of the brain that functions in maintaining the body's internal physiological state by regulating the autonomic nervous system, endocrine system, body temperature, water balance, and appetite.

hypothesis A testable statement that explains a phenomenon or a set of observations.

hypotonic Comparative term designating a solution that, if inside a cell or vesicle, results in the loss of water and shrinkage of the membrane-bound structure. This solution has a lower solute concentration than the solution on the other side of the membrane. Used when the solute is unable to pass through the membrane. Compare with **hypertonic** and **isotonic**.

immigration The migration of individuals into a particular population from other populations. Compare with **emigration**.

immune system The system whose primary function is to defend the host organism against pathogens. Includes several types of cells (e.g., leukocytes). In vertebrates, several organs are also involved where specialized cells develop or reside (e.g., lymph nodes and thymus).

immunity (adjective: immune) State of being protected against infection by disease-causing pathogens.

immunization The conferring of immunity to a particular disease by artificial means.

immunoglobulin (Ig) Any of the class of proteins that are structurally related to antibodies.

immunological memory The ability of the immune system to "remember" an antigen and mount a rapid, effective adaptive immune response to a pathogen encountered years or decades earlier. Based on the formation of memory lymphocytes.

impact hypothesis The hypothesis that a collision between the Earth and an asteroid caused the mass extinction at the K–P boundary, 65 million years ago.

imperfect flower A flower that contains male parts (stamens) *or* female parts (carpels) but not both. Compare with **perfect flower**.

implantation The process by which an embryo buries itself in the uterine or oviductal wall and forms a placenta. Occurs in mammals and some other viviparous vertebrates.

in situ hybridization A technique for detecting specific DNAs and mRNAs in cells and tissues by use of labeled complementary probes. Can be used to determine where and when particular genes are expressed in embryos.

inbreeding Mating between closely related individuals. Increases homozygosity of a population and often leads to a decline in the average fitness via selection (inbreeding depression).

inbreeding depression In inbred offspring, fitness declines due to deleterious recessive alleles that are homozygous, thus exposed to selection.

inclusive fitness The combination of (1) direct production of offspring (direct fitness) and (2) extra production of offspring by relatives in response to help provided by the individual in question (indirect fitness).

incomplete digestive tract A digestive tract that has just one opening.

incomplete dominance An inheritance pattern in which the heterozygote phenotype is in between the homozygote phenotypes.

incomplete metamorphosis See **hemimetabolous metamorphosis**.

independent assortment, principle of The concept that each pair of hereditary elements (alleles of the same gene) segregates (separates) independently of alleles of other genes during meiosis. One of Mendel's two principles of genetics.

indeterminate growth A pattern of growth in which an individual continues to increase its overall body size throughout its life.

induced fit Change in the shape of the active site of an enzyme, as the result of initial weak binding of a substrate, so that it binds substrate more tightly.

inducer A small molecule that triggers transcription of a specific gene, often by binding to and inactivating a repressor protein.

inducible defense A defensive trait that is manifested only in response to the presence of a consumer (predator or herbivore) or pathogen. Compare with **constitutive defense**.

infection thread An invagination of the plasma membrane of a root hair through which beneficial nitrogen-fixing bacteria enter the roots of their host plants (legumes).

inflammatory response An aspect of the innate immune response, seen in most cases of infection or tissue injury, in which the affected tissue becomes swollen, red, warm, and painful.

ingestion The act of bringing food into the digestive tract.

inhibition In ecological succession, the phenomenon in which early-arriving species make conditions less favorable for the establishment of certain later-arriving species. Compare with **facilitation** and **tolerance**.

inhibitory postsynaptic potential (IPSP) A change in membrane potential, usually hyperpolarization, at a neuron dendrite that makes an action potential less likely.

initiation (1) In an enzyme-catalyzed reaction, the stage during which enzymes orient reactants precisely as they bind at specific locations within the enzyme's active site. (2) In DNA transcription, the stage during which RNA polymerase and other proteins assemble at the promoter sequence and open the strands of DNA to start transcription. (3) In translation, the stage during which a complex consisting of initiation factor proteins, a ribosome, an mRNA, and an aminoacyl tRNA corresponding to the start codon is formed.

initiation factors A class of proteins that assist ribosomes in binding to a messenger RNA molecule to begin translation.

innate behavior Behavior that is inherited genetically, does not have to be learned, and is typical of a species.

innate immune response See **innate immunity**.

innate immunity A set of barriers to infection and generic defenses against broad types of pathogens. Produces an immediate response that involves many different leukocytes, which often activate an inflammatory response. Compare with **acquired immunity**.

inner cell mass (ICM) A cluster of cells, in the interior of a mammalian blastocyst, that eventually develop into the embryo. Contrast with **trophoblast**.

inner ear The innermost portion of the mammalian ear, consisting of a fluid-filled system of tubes that includes the cochlea (which receives sound vibrations from the middle ear) and the semicircular canals (which function in balance).

insects A terrestrial lineage of arthropods distinguished by three tagmata (head, thorax, abdomen), a single pair of antennae, and unbranched appendages.

insulin A peptide hormone produced by the pancreas in response to high levels of glucose (or amino acids) in blood. Enables cells to absorb glucose and coordinates synthesis of fats, proteins, and glycogen. Compare with **glucagon**.

integral membrane protein Any membrane protein that spans the entire lipid bilayer. Also called *transmembrane protein*. Compare with **peripheral membrane protein**.

integrated pest management In agriculture or forestry, systems for managing insects or other pests that include carefully controlled applications of toxins, introduction of species that prey on pests, planting schemes that reduce the chance of a severe pest outbreak, and other techniques.

integrator A component of an animal's nervous system that functions as part of a homeostatic system by evaluating sensory information and triggering appropriate responses. See **effector** and **sensor**.

integrin Any of a class of cell-surface proteins that bind to laminins and other proteins in the extracellular matrix, thus holding cells in place.

intercalated disc A type of specialized connection between adjacent heart muscle cells that contains gap junctions, allowing electrical signals to pass between the cells.

intermediate filament A long fiber, about 10 nm in diameter, composed of one of various proteins (e.g., keratins, lamins); one of the three types of cytoskeletal fibers. Used to form networks that help maintain cell shape and hold the nucleus in place. Compare with **actin filament** and **microtubule**.

intermediate host The host species in which a parasite reproduces asexually. Compare with **definitive host**.

intermediate muscle fiber Type of skeletal muscle fiber that is pink in color, generates ATP by both glycolysis and aerobic respiration, and has contractile properties that are intermediate between slow fibers and fast fibers. Also called fast oxidative fiber.

interneuron A neuron that passes signals from one neuron to another. Compare with **motor neuron** and **sensory neuron**.

internode The section of a plant stem between two nodes (sites where leaves attach).

interphase The portion of the cell cycle between one M phase and the next. Includes the G_1 phase, S phase, and G_2 phase.

intersexual selection The sexual selection of an individual of one gender for mating by an individual of the other gender (usually by female choice).

interspecific competition Competition between members of different species for the same limited resource. Compare with **intraspecific competition**.

interstitial fluid The plasma-like fluid found in the region (interstitial space) between cells.

intertidal zone The region between the low-tide and high-tide marks on a seashore.

intrasexual selection Competition among members of one gender for an opportunity to mate (usually male–male competition).

intraspecific competition Competition between members of the same species for the same limited resource. Compare with **interspecific competition**.

intrinsic rate of increase (r_{max}) The rate at which a population will grow under optimal conditions (i.e., when birthrates are as high as possible and death rates are as low as possible). Compare with **finite rate of increase**.

intron A region of a eukaryotic gene that is transcribed into RNA but is later removed. Compare with **exon**.

invasive species An exotic (nonnative) species that, upon introduction to a new area, spreads rapidly and competes successfully with native species.

inversion A mutation in which a segment of a chromosome breaks from the rest of the chromosome, flips, and rejoins in reversed orientation.

invertebrates A paraphyletic group composed of animals without a backbone; includes about 95 percent of all animal species. Compare with **vertebrates**.

involuntary muscle Muscle that contracts in response to stimulation by involuntary (parasympathetic or sympathetic), but not voluntary (somatic), neural stimulation.

ion An atom or a molecule that has lost or gained electrons and thus carries an electric charge, either positive (cation) or negative (anion), respectively.

ion channel A type of channel protein that allows certain ions to diffuse across a plasma membrane down an electrochemical gradient.

ionic bond A chemical bond that is formed when an electron is completely transferred from one atom to another so that the atoms remain associated due to their opposite electric charges. Compare with **covalent bond** and **hydrogen bond**.

iris A ring of pigmented muscle just behind the cornea in the vertebrate eye that contracts or expands to control the amount of light entering the eye through the pupil.

isosmotic Comparative term designating a solution that has the same solute concentration and water concentration as another solution. Compare with **hyperosmotic** and **hyposmotic**.

isotonic Comparative term designating a solution that, if inside a cell or vesicle, results in no net uptake or loss of water and thus no effect on the volume of the membrane-bound structure. This solution has the same solute concentration as the solution on the other side of the membrane. Compare with **hypertonic** and **hypotonic**.

isotope Any of several forms of an element that have the same number of protons but differ in the number of neutrons.

joint A place where two components (bones, cartilages, etc.) of a skeleton meet. May be movable (an articulated joint) or immovable (e.g., skull sutures).

juvenile An individual that has adult-like morphology but is not sexually mature.

juvenile hormone An insect hormone that prevents larvae from metamorphosing into adults.

karyogamy Fusion of two haploid nuclei to form a diploid nucleus. Occurs in many fungi, and in animals and plants during fertilization of gametes.

karyotype The distinctive appearance of all of the chromosomes in an individual, including the number of chromosomes and their length and banding patterns (after staining with dyes).

keystone species A species that has an exceptionally great impact on the other species in its ecosystem relative to its abundance.

kidney In terrestrial vertebrates, one of a paired organ situated at the back of the abdominal cavity that filters the blood, produces urine, and secretes several hormones.

kilocalorie (kcal) A unit of energy often used to measure the energy content of food. A kcal of energy raises 1 kg of water 1°C.

kin selection A form of natural selection that favors traits that increase survival or reproduction of an individual's kin at the expense of the individual.

kinesin A class of motor proteins that uses the chemical energy of ATP to "walk" toward the plus end of a microtubule. Used to transport vesicles, particles, organelles and chromosomes.

kinetic energy The energy of motion. Compare with **potential energy**.

kinetochore A protein complex at the centromere where microtubules attach to the chromosome. Contains motor proteins and microtubule-binding proteins that are involved in chromosome segregation during M phase.

kinetochore microtubules Microtubules in the spindle formed during mitosis and meiosis that are attached to the kinetochore on a chromosome.

kinocilium (plural: kinocilia) A single cilium that juts from the surface of many hair cells and functions in detection of sound or pressure.

knock-out allele A mutant allele that does not produce a functional product. Also called a *null allele* or *loss-of-function allele*.

Koch's postulates Four criteria used to determine whether a suspected infectious agent causes a particular disease.

labium majus (plural: labia majora) One of two outer folds of skin that surround the labia minora, clitoris, and vaginal opening of female mammals.

labium minus (plural: labia minora) One of two folds of skin inside the labia majora and surrounding the opening of the urethra and vagina.

labor The strong muscular contractions of the uterus that expel the fetus during birth.

***lac* operon** A set of three genes in *E. coli* that are transcribed into a single mRNA and required for lactose metabolism. Studies of the *lac* operon revealed many insights about gene regulation.

lactation (verb: lactate) Production of milk to feed offspring, from mammary glands of mammals.

lacteal A small lymphatic vessel extending into the center of a villus in the small intestine. Receives chylomicrons containing fat absorbed from food.

lactic acid fermentation Catabolic pathway in which pyruvate produced by glycolysis is converted to lactic acid in the absence of oxygen.

lagging strand In DNA replication, the strand of new DNA that is synthesized discontinuously in a series of short pieces that are later joined. Also called *discontinuous strand*. Compare with **leading strand**.

laminins An abundant protein in the extracellular matrix that binds to other ECM components and to integrins in plasma membranes; helps anchor cells in place. Predominantly found in the basal lamina; many subtypes function in different tissues.

large intestine The distal portion of the digestive tract, consisting of the cecum, colon, and rectum. Its primary function is to compact the wastes delivered from the small intestine and absorb enough water to form feces.

larva (plural: larvae) An immature stage of an animal species in which the immature and adult stages have different body forms.

late endosome A membrane-bound vesicle that arises from an early endosome, accepts lysosomal enzymes from the Golgi, and matures into a lysosome.

latency In viruses that infect animals, the ability to coexist with the host cell in a dormant state without producing new virions. The viral genetic material is replicated as the host cell replicates. Genetic material may or may not be integrated in the host genome, depending on the virus.

lateral bud A bud that forms at the nodes of a stem and may develop into a lateral (side) branch. Also called *axillary bud*.

lateral gene transfer Transfer of DNA between two different species.

lateral line system A pressure-sensitive sensory organ found in many aquatic vertebrates.

lateral root A plant root that extends horizontally from another root.

leaching Loss of nutrients from soil via percolating water.

leading strand In DNA replication, the strand of new DNA that is synthesized in one continuous piece. Also called *continuous strand*. Compare with **lagging strand**.

leaf The main photosynthetic organ of vascular plants.

leak channel Ion channel that allows ions to leak across the membrane of a neuron in its resting state.

learning An enduring change in an individual's behavior that results from specific experience(s).

leghemoglobin An iron-containing protein similar to hemoglobin. Found in infected cells of legume root nodules where it binds oxygen, preventing it from poisoning a bacterial enzyme needed for nitrogen fixation.

legumes Members of the pea plant family. Many form symbiotic associations with nitrogen-fixing bacteria in their roots.

lens A transparent structure that focuses incoming light onto a retina or other light-sensing apparatus of an eye.

lenticel Spongy segment in bark that allows gas exchange between cells in a woody stem and the atmosphere.

leptin A hormone produced and secreted by fat cells (adipocytes) that acts to stabilize fat-tissue mass partly by inhibiting appetite and increasing energy expenditure.

leukocyte Any of several types of blood cells, including neutrophils, macrophages, and lymphocytes, that reside in tissues and circulate in blood and lymph. Functions in tissue repair and defense against pathogens. Also called *white blood cell*.

lichen A symbiotic association of a fungus, often in the Ascomycota lineage, and a photosynthetic alga or cyanobacterium.

life cycle The sequence of developmental events and phases that occurs during the life span of an organism, from fertilization to offspring production.

life history The sequence of events in an individual's life from birth to reproduction to death, including how an individual allocates resources to growth, reproduction, and activities or structures that are related to survival.

life table A data set that summarizes the probability that an individual in a certain population will survive and reproduce in any given year over the course of its lifetime.

ligament Connective tissue that joins bones of an endoskeleton together.

ligand Any molecule that binds to a specific site on a receptor molecule.

ligand-gated channel An ion channel that opens or closes in response to binding by a certain molecule. Compare with **voltage-gated channel**.

light chain The smaller of the two types of polypeptide chains in an antibody or B-cell receptor molecule; composed of a variable (*V*) region, which contributes to the antigen-binding site, and a constant (*C*) region. Compare with **heavy chain**.

lignin A substance, found in the secondary cell walls of some plants, that is exceptionally stiff and strong; a complex polymer built from six-carbon rings. Most abundant in woody plant parts.

limiting nutrient Any essential nutrient whose scarcity in the environment significantly reduces growth and reproduction of organisms.

limnetic zone Open water (not near shore) that receives enough sunlight to support photosynthesis.

lineage See **monophyletic group**.

LINEs (long interspersed nuclear elements) The most abundant class of transposable elements in human genomes; can create copies of itself and insert them elsewhere in the genome. Compare with **SINEs**.

lingual lipase An enzyme produced by glands in the tongue. It breaks down fat molecules into fatty acids and monoglycerides.

linkage In genetics, a physical association between two genes because they are on the same chromosome; the inheritance patterns resulting from this association.

linkage map See **genetic map**.

lipid Any organic substance that does not dissolve in water, but dissolves well in nonpolar organic solvents. Lipids include fatty acids, fats, oils, waxes, steroids, and phospholipids.

lipid bilayer The basic structural element of all cellular membranes; consists of a two-layer sheet of phospholipid molecules with their hydrophobic tails oriented toward the inside and their hydrophilic heads toward the outside. Also called *phospholipid bilayer*.

littoral zone Shallow water near shore that receives enough sunlight to support photosynthesis. May be marine or freshwater; often flowering plants are present.

liver A large, complex organ of vertebrates that performs many functions, including storage of glycogen, processing and conversion of food and wastes, and production of bile.

lobe-finned fish Fish with fins supported by bony elements that extend down the length of the structure.

locomotion Movement of an organism under its own power.

locus (plural: loci) A gene's physical location on a chromosome.

logistic population growth The density-dependent decrease in growth rate as population size approaches the carrying capacity. Compare with **exponential population growth**.

long interspersed nuclear elements See **LINEs**.

long-day plant A plant that blooms in response to short nights (usually in late spring or early summer in the Northern Hemisphere). Compare with **day-neutral** and **short-day plant**.

loop of Henle In the vertebrate kidney, a long U-shaped loop in a nephron that extends into the medulla. Functions as a countercurrent exchanger to set up an osmotic gradient that allows reabsorption of water from the collecting duct.

loose connective tissue A type of connective tissue consisting of fibrous proteins in a soft matrix. Often functions as padding for organs.

lophophore A specialized feeding structure found in some lophotrochozoans and used in suspension (filter) feeding.

lophotrochozoans A major lineage of protostomes (Lophotrochozoa) that grow by extending the size of their skeletons rather than by molting. Many phyla have a specialized feeding structure (lophophore) and/or ciliated larvae (trochophore). Includes rotifers, flatworms, segmented worms, and mollusks. Compare with **ecdysozoans**.

loss-of-function allele See **knock-out allele**.

LUCA The *l*ast *u*niversal *c*ommon *a*ncestor of cells. This theoretical entity is proposed to be the product of chemical evolution and provided characteristics of life that are shared by all living organisms on Earth today.

lumen The interior space of any hollow structure (e.g., the rough ER) or organ (e.g., the stomach).

lung Any respiratory organ used for gas exchange between blood and air.

luteal phase The second major phase of a menstrual cycle, after ovulation, when the progesterone levels are high and the body is preparing for a possible pregnancy.

luteinizing hormone (LH) A peptide hormone, produced and secreted by the anterior pituitary, that stimulates estrogen production, ovulation, and formation of the corpus luteum in females and testosterone production in males.

lymph The mixture of fluid and white blood cells that circulates through the ducts and lymph nodes of the lymphatic system in vertebrates.

lymph node Any of many small, oval structures that lymph moves through in the lymphatic system. Filters the lymph and screens it for pathogens and other antigens. Major sites of lymphocyte activation.

lymphatic system In vertebrates, a body-wide network of thin-walled ducts (or vessels) and lymph nodes, separate from the circulatory system. Collects excess fluid from body tissues and returns it to the blood; also functions as part of the immune system.

lymphocyte A cell that circulates through the bloodstream and lymphatic system and is responsible for the development of adaptive immunity. In most cases belongs to one type of leukocyte—either B cells or T cells.

lysogeny In viruses that infect bacteria (bacteriophages), the ability to coexist with the host cell in a dormant state without producing new virions. The viral genetic material is integrated in the host chromosome and is replicated as the host cell replicates. Compare with **lytic cycle**.

lysosome A small, acidified organelle in an animal cell containing enzymes that catalyze hydrolysis reactions and can digest large molecules. Compare with **vacuole**.

lysozyme An enzyme that functions in innate immunity by digesting bacterial cell walls. Occurs in lysosomes of phagocytes and is secreted in saliva, tears, mucus, and egg white.

lytic cycle A type of viral replicative growth in which the production and release of virions kills the host cell. Compare with **lysogeny**.

M phase The phase of the cell cycle during which cell division occurs. Includes mitosis or meiosis and often cytokinesis.

M-phase-promoting factor (MPF) A complex of a cyclin and cyclin-dependent kinase that, when activated, phosphorylates a number of specific proteins needed to initiate mitosis in eukaryotic cells.

macromolecular machine A group of proteins that assemble to carry out a particular function.

macromolecule Any very large organic molecule, usually made up of smaller molecules (monomers) joined together into a polymer. The main biological macromolecules are proteins, nucleic acids, and polysaccharides.

macronutrient Any element (e.g., nitrogen) that is required in large quantities for normal growth, reproduction, and maintenance of a living organism. Compare with **micronutrient**.

macrophage A type of leukocyte in the innate immune system that participates in the inflammatory response by secreting cytokines and phagocytizing invading pathogens and apoptotic cells. Also serves as an antigen-presenting cell to activate lymphocytes.

MADS box A DNA sequence that codes for a DNA-binding motif in proteins; present in floral organ identity genes in plants. Functionally similar sequences are found in some fungal and animal genes.

magnetoreception A sensory system in which receptors are activated in response to magnetic fields.

magnetoreceptor A sensory cell or organ specialized for detecting magnetic fields.

major histocompatibility protein See **MHC protein**.

maladaptive Describing a trait that lowers fitness.

malaria A human disease caused by five species of the protist *Plasmodium* and passed to humans by mosquitoes.

malignant tumor A tumor that is actively growing and disrupting local tissues or is spreading to other organs. Cancer consists of one or more malignant tumors. Compare with **benign tumor**.

Malpighian tubules A major excretory organ of insects, consisting of blind-ended tubes that extend from the gut into the hemocoel. Filter hemolymph to form "pre-urine" and then send it to the hindgut for further processing.

mammals One of the two lineages of amniotes (vertebrates that produce amniotic eggs) distinguished by hair (or fur) and mammary glands. Includes the monotremes (platypuses), marsupials, and eutherians (placental mammals).

mammary glands Specialized exocrine glands that produce and secrete milk for nursing offspring. A diagnostic feature of mammals.

mandibles Any mouthpart used in chewing. In vertebrates, the lower jaw. In insects, crustaceans, and myriapods, the first pair of mouthparts.

mantle One of the three main parts of the mollusk body; the thick outer tissue that protects the visceral mass and may secrete a calcium carbonate shell.

marsh A wetland dominated by grasses and other nonwoody plants.

marsupials A lineage of mammals (Marsupiala) that nourish their young in an abdominal pouch after a very short period of development in the uterus.

mass extinction The extinction of a large number of diverse evolutionary groups during a relatively short period of geologic time (about 1 million years). May occur due to sudden and extraordinary environmental changes. Compare with **background extinction**.

mass feeder An animal that ingests chunks of food.

mass number The total number of protons and neutrons in an atom.

mast cell A type of leukocyte that is stationary (embedded in tissue) and helps trigger the inflammatory response, including secretion of histamine, to infection or injury. Particularly important in allergic responses and defense against parasites.

maternal chromosome A chromosome inherited from the mother.

mechanical advantage The ratio of force exerted on a load to the muscle force of the effort. A measure of the force efficiency of a mechanical system.

mechanoreception A sensory system in which receptors are activated in response to changes in pressure.

mechanoreceptor A sensory cell or organ specialized for detecting distortions caused by touch or pressure. One example is hair cells in the cochlea.

mediator Regulatory proteins in eukaryotes that form a physical link between regulatory transcription factors that are bound to DNA, the basal transcription complex, and RNA polymerase.

medium A liquid or solid that supports the growth of cells.

medulla The innermost part of an organ (e.g., kidney or adrenal gland).

medulla oblongata In vertebrates, a region of the brain stem that along with the cerebellum forms the hindbrain.

medusa (plural: medusae) The free-floating stage in the life cycle of some cnidarians (e.g., jellyfish). Compare with **polyp**.

megapascal (MPa) A unit of pressure (force per unit area) equivalent to 1 million pascals (Pa).

megasporangium (plural: megasporangia) In heterosporous species of plants, a spore-producing structure that produces megaspores, which go on to develop into female gametophytes.

megaspore In seed plants, a haploid (n) spore that is produced in a megasporangium by meiosis of a diploid ($2n$) megasporocyte; develops into a female gametophyte. Compare with **microspore**.

meiosis In sexually reproducing organisms, a special two-stage type of cell division in which one diploid ($2n$) parent cell produces haploid (n) cells (gametes); results in halving of the chromosome number. Also called *reduction division*.

meiosis I The first cell division of meiosis, in which synapsis and crossing over occur and homologous chromosomes are separated from each other, producing daughter cells with half as many chromosomes (each composed of two sister chromatids) as the parent cell.

meiosis II The second cell division of meiosis, in which sister chromatids are separated from each other. Similar to mitosis.

melatonin A hormone, produced by the pineal gland, that regulates sleep–wake cycles and seasonal reproduction in vertebrates.

membrane potential A difference in electric charge across a cell membrane; a form of potential energy. Also called *membrane voltage*.

memory Retention of learned information.

memory cells A type of lymphocyte responsible for maintaining immunity for years or decades after an infection. Descended from a B cell or T cell activated during a previous infection or vaccination.

meniscus (plural: menisci) The concave boundary layer formed at most air–water interfaces due to adhesion and surface tension.

menstrual cycle A female reproductive cycle seen in Old World monkeys and apes (including humans) in which the uterine lining is shed (menstruation) if no pregnancy occurs. Compare with **estrous cycle**.

menstruation The periodic shedding of the uterine lining through the vagina that occurs in females of Old World monkeys and apes, including humans.

meristem (adjective: meristematic) In plants, a group of undifferentiated cells, including stem cells, which can divide and develop into various adult tissues throughout the life of a plant. See also **apical meristem** and **ground meristem**.

mesoderm The middle of the three basic cell layers (germ layers) in most animal embryos; gives rise to muscles, bones, blood, and some internal organs (kidney, spleen, etc.). Compare with **ectoderm** and **endoderm**.

mesoglea A gelatinous material, containing scattered ectodermal cells, that is located between the ectoderm and endoderm of cnidarians (e.g., jellyfish, corals, and anemones).

mesophyll cell A type of cell, found near the surfaces of plant leaves, that is specialized for the light-dependent reactions of photosynthesis.

Mesozoic era The interval of geologic time, from 251 million to 65.5 million years ago, during which gymnosperms were the dominant plants and dinosaurs the dominant vertebrates. Ended with extinction of the dinosaurs (except birds).

messenger RNA (mRNA) An RNA molecule transcribed from DNA that carries information (in codons) that specifies the amino acid sequence of a polypeptide.

meta-analysis A comparative analysis of the results of many smaller, previously published studies.

metabolic pathway A linked series of biochemical reactions that build up or break down a particular molecule; the product of one reaction is the substrate of the next reaction.

metabolic rate The total energy use by all the cells of an individual. For aerobic organisms, often measured as the amount of oxygen consumed per hour.

metabolic water The water that is produced as a by-product of cellular respiration.

metagenomics The inventory of all the genes in a community or ecosystem by sequencing, analyzing, and comparing the genomes of the component organisms. Also called *environmental sequencing*.

metagenomics The inventory of all the genes in a community or ecosystem by sequencing, analyzing, and comparing the genomes of the component organisms. Sequencing of all or most of the genes present in an environment directly (also called *environmental sequencing*).

metallothioneins Small plant proteins that bind to and prevent excess metal ions from acting as toxins.

metamorphosis Transition from one developmental stage to another, such as from the larval to the adult form of an animal.

metaphase A stage in mitosis or meiosis during which chromosomes line up in the middle of the cell.

metaphase plate The plane along which chromosomes line up in the middle of the spindle during metaphase of mitosis or meiosis; not an actual structure.

metapopulation A population made up of many small, physically isolated populations connected by migration.

metastasis The spread of cancerous cells from their site of origin to distant sites in the body where they may establish additional tumors.

methanogen A prokaryote that produces methane (CH_4) as a by-product of cellular respiration.

methanotroph An organism (bacteria or archaea) that uses methane (CH_4) as its primary electron donor and source of carbon.

methyl salicylate (MeSA) A molecule that is hypothesized to function as a signal, transported among tissues, that triggers systematic acquired resistance in plants—a response to pathogen attack.

MHC protein Any of a large set of mammalian cell-surface glycoproteins involved in marking cells as self and in antigen presentation to T cells. Also called *MHC molecule*. Compare with **Class I** and **Class II MHC protein**.

microbe Any microscopic organism, including bacteria, archaea, and various tiny eukaryotes.

microbiology The field of study concerned with microscopic organisms.

microfibril Bundled strands of cellulose that serve as the fibrous component in plant cell walls.

microfilament See **actin filament**.

micronutrient Any element (e.g., iron, molybdenum, magnesium) that is required in very small quantities for normal growth, reproduction, and maintenance of a living organism. Compare with **macronutrient**.

micropyle The tiny pore in a plant ovule through which the pollen tube reaches the embryo sac.

microRNA (miRNA) A small, single-stranded RNA associated with proteins in an RNA-induced silencing complex (RISC). Processed from a longer premiRNA gene transcript. Can bind to complementary sequences in mRNA molecules, allowing the associated proteins of RISC to degrade the bound mRNA or inhibit its translation. See **RNA interference**.

microsatellite A noncoding stretch of eukaryotic DNA consisting of a repeating sequence 2 to 6 base pairs long. Also called *short tandem repeat* or *simple sequence repeat*.

microsporangium (plural: microsporangia) In heterosporous species of plants, a spore-producing structure that produces microspores, which go on to develop into male gametophytes.

microspore In seed plants, a haploid (n) spore that is produced in a microsporangium by meiosis of a diploid ($2n$) microsporocyte; develops into a male gametophyte. Compare with **megaspore**.

microtubule A long, tubular fiber, about 25 nm in diameter, formed by polymerization of tubulin protein dimers; one of the three types of cytoskeletal fibers. Involved in cell movement and transport of materials within the cell. Compare with **actin filament** and **intermediate filament**.

microtubule organizing center (MTOC) General term for any structure (e.g., centrosome and basal body) that organizes microtubules in cells.

microvilli (singular: microvillus) Tiny protrusions from the surface of an epithelial cell that increase the surface area for absorption of substances.

midbrain One of the three main regions of the vertebrate brain; includes sensory integrating and relay centers. Compare with **forebrain** and **hindbrain**.

middle ear The air-filled middle portion of the mammalian ear, which contains three small bones (ossicles) that transmit and amplify sound from the tympanic membrane to the inner ear. Is connected to the throat via the eustachian tube.

migration (1) In ecology, a seasonal movement of large numbers of organisms from one geographic location or habitat to another. (2) In population genetics, movement of individuals from one population to another.

millivolt (mV) A unit of voltage equal to 1/1000 of a volt.

mimicry A phenomenon in which one species has evolved (or learns) to look or sound like another species. See **Batesian mimicry** and **Müllerian mimicry**.

mineral One of various inorganic substances that are important components of enzyme cofactors or of structural materials in an organism.

mineralocorticoids A class of steroid hormones, produced and secreted by the adrenal cortex, that regulate electrolyte levels and the overall volume of body fluids. Aldosterone is the principal one in humans. Compare with **glucocorticoids**.

minisatellite A noncoding stretch of eukaryotic DNA consisting of a repeating sequence that is 6 to 100 base pairs long. Also called *variable number tandem repeat (VNTR)*.

mismatch repair The process by which mismatched base pairs in DNA are fixed.

missense mutation A point mutation (change in a single base pair) that changes one amino acid for another within the sequence of a protein.

mitochondrial matrix Central compartment of a mitochondrion, which is lined by the inner membrane; contains mitochondrial DNA, ribosomes, and the enzymes for pyruvate processing and the citric acid cycle.

mitochondrion (plural: mitochondria) A eukaryotic organelle that is bounded by a double membrane and is the site of aerobic respiration and ATP synthesis.

mitogen-activated protein kinases (MAPK) Enzymes that are involved in signal transduction pathways that often lead to the induction of cell replication. Different types are organized in a series, where one kinase activates another via phosphorylation. See also **phosphorylation cascade**.

mitosis In eukaryotic cells, the process of nuclear division that results in two daughter nuclei genetically identical with the parent nucleus. Subsequent cytokinesis (division of the cytoplasm) yields two daughter cells.

mode of transmission The type of inheritance observed as a trait is passed from parent to offspring. Some common types are autosomal recessive, autosomal dominant, and X-linked recessive.

model organism An organism selected for intensive scientific study based on features that make it easy to work with (e.g., body size, life span), in the hope that findings will apply to other species.

molarity A common unit of solute concentration equal to the number of moles of a dissolved solute in 1 liter of solution.

mole The amount of a substance that contains 6.022×10^{23} of its elemental entities (e.g., atoms, ions, or molecules). This number of molecules of a compound will have a mass equal to the molecular weight of that compound expressed in grams.

molecular chaperone A protein that facilitates the folding of newly synthesized proteins into their correct three-dimensional shape. Usually works by an ATP-dependent mechanism.

molecular formula A notation that indicates only the numbers and types of atoms in a molecule, such as H_2O for the water molecule. Compare with **structural formula**.

molecular weight The sum of the atomic weights of all of the atoms in a molecule; roughly, the total number of protons and neutrons in the molecule.

molecule A combination of two or more atoms held together by covalent bonds.

molting A method of body growth, used by ecdysozoans, that involves the shedding of an external protective cuticle or skeleton, expansion of the soft body, and growth of a new external layer.

monocot Any flowering plant (angiosperm) that has a single cotyledon (embryonic leaf) upon germination. Monocots form a monophyletic group. Also called a monocotyledonous plant. Compare with **dicot**.

monoecious Describing an angiosperm species that has both male and female reproductive structures on each plant. Compare with **dioecious**.

monohybrid cross A mating between two parents that are both heterozygous for one given gene.

monomer A small molecule that can covalently bind to other similar molecules to form a larger macromolecule. Compare with **polymer**.

monophyletic group An evolutionary unit that includes an ancestral population and all of its descendants but no others. Also called a *clade* or *lineage*. Compare with **paraphyletic group** and **polyphyletic group**.

monosaccharide A molecule that has the molecular formula $(CH_2O)_n$ and cannot be hydrolyzed to form any smaller carbohydrates. Also called *simple sugar*. Compare with **oligosaccharide** and **polysaccharide**.

monosomy The state of having only one copy of a particular type of chromosome in an otherwise diploid cell.

monotremes A lineage of mammals (Monotremata) that lay eggs and then nourish the young with milk. Includes just five living species: the platypus and four species of echidna, all with leathery beaks or bills.

morphogen A molecule that exists in a concentration gradient and provides spatial information to embryonic cells.

morphology The shape and appearance of an organism's body and its component parts.

morphospecies concept The definition of a species as a population or group of populations that have measurably different anatomical features from other groups. Also called *morphological species concept*. Compare with **biological species concept** and **phylogenetic species concept**.

motor neuron A nerve cell that carries signals from the central nervous system (brain and spinal cord) to an effector, such as a muscle or gland. Compare with **interneuron** and **sensory neuron**.

motor protein A class of proteins whose major function is to convert the chemical energy of ATP into motion. Includes dynein, kinesin, and myosin.

MPF See **M-phase-promoting factor**.

mRNA See **messenger RNA**.

mucosal-associated lymphoid tissue (MALT) Collective term for lymphocytes and other leukocytes associated with skin cells and mucus-secreting epithelial tissues in the gut and respiratory tract. Plays an important role in preventing entry of pathogens into the body.

mucous cell A type of cell found in the epithelial layer of the stomach; responsible for secreting mucus into the stomach.

mucus (adjective: mucous) A slimy mixture of glycoproteins (called mucins) and water that is secreted in many animal organs for lubrication. Serves as a barrier to protect surfaces from infection.

Müllerian inhibitory substance A peptide hormone, secreted by the embryonic testis, that causes regression (withering away) of the female reproductive ducts.

Müllerian mimicry A type of mimicry in which two (or more) harmful species resemble each other. Compare with **Batesian mimicry**.

multicellularity The state of being composed of many cells that adhere to each other and do not all express the same genes, with the result that some cells have specialized functions.

multiple allelism The existence of more than two alleles of the same gene.

multiple fruit A fruit (e.g., pineapple) that develops from many separate flowers and thus many carpels. Compare with **aggregate** and **simple fruit**.

multiple sclerosis (MS) A human autoimmune disease in which the immune system attacks the myelin sheaths that insulate axons of neurons.

muscle fiber A single muscle cell.

muscle tissue An animal tissue consisting of bundles of long, thin, contractile cells (muscle fibers). Functions primarily in movement.

mutagen Any physical or chemical agent that increases the rate of mutation.

mutant An individual that carries a mutation, particularly a new or rare mutation.

mutation Any change in the hereditary material of an organism (DNA in most organisms, RNA in some viruses). The only source of new alleles in populations.

mutualism (adjective: mutualistic) A symbiotic relationship between two organisms (mutualists) that benefits both. Compare with **commensalism** and **parasitism**.

mutualist Organism that is a participant and partner in a mutualistic relationship. See **mutualism**.

mycelium (plural: mycelia) A mass of underground filaments (hyphae) that form the body of a fungus. Also found in some protists and bacteria.

mycorrhiza (plural: mycorrhizae) A mutualistic association between certain fungi and the roots of most vascular plants, sometimes visible as nodules or nets in or around plant roots.

myelin sheath Multiple layers of myelin, derived from the cell membranes of certain glial cells, wrapped around the axon of a neuron and providing electrical insulation.

myocardial infarction Death of cardiac muscle cells when deprived of oxygen.

myoD A transcription factor that is a master regulator of muscle cell differentiation (short for "*myo*blast *d*etermination").

myofibril Long, slender structure composed of contractile proteins organized into repeating units (sarcomeres) in vertebrate heart muscle and skeletal muscle.

myosin Any one of a class of motor proteins that use the chemical energy of ATP to move along actin filaments in muscle contraction, cytokinesis, and vesicle transport.

myriapods A lineage of arthropods with long segmented trunks, each segment bearing one or two pairs of legs. Includes millipedes and centipedes.

NAD^+/NADH Oxidized and reduced forms, respectively, of nicotinamide adenine dinucleotide. A nonprotein electron carrier that functions in many of the redox reactions of metabolism.

$NADP^+$/NADPH Oxidized and reduced forms, respectively, of nicotinamide adenine dinucleotide phosphate. A nonprotein electron carrier that is reduced during the light-dependent reactions in photosynthesis and extensively used in biosynthetic reactions.

natural experiment A situation in which a natural change in conditions enables comparisons of groups, rather than a manipulation of conditions by researchers.

natural selection The process by which individuals with certain heritable traits tend to produce more surviving offspring than do individuals without those traits, often leading to a change in the genetic makeup of the population. A major mechanism of evolution.

nauplius A distinct planktonic larval stage seen in many crustaceans.

Neanderthal A recently extinct European species of hominin, *Homo neanderthalensis*, closely related to but distinct from modern humans.

nectar The sugary fluid produced by flowers to attract and reward pollinating animals.

nectary A nectar-producing structure in a flower.

negative control Of genes, when a regulatory protein shuts down expression by binding to DNA on or near the gene.

negative feedback A self-limiting, corrective response in which a deviation in some variable (e.g., concentration of some compound) triggers responses aimed at returning the variable to normal. Represents a means of maintaining homeostasis. Compare with **positive feedback**.

negative pressure ventilation Ventilation of the lungs by expanding the rib cage so as to "pull" air into the lungs. Compare with **positive pressure ventilation**.

negative-sense RNA virus An ssRNA virus whose genome contains sequences complementary to those in the mRNA required to produce viral proteins. Compare with **ambisense virus** and **positive-sense virus**.

nematodes See **roundworms**.

nephron One of many tiny tubules inside the kidney that function in the formation of urine.

neritic zone Shallow marine waters beyond the intertidal zone, extending down to about 200 meters, where the continental shelf ends.

nerve A long, tough strand of nervous tissue, typically containing thousands of axons, wrapped in connective tissue; carries impulses between the central nervous system and some other part of the body.

nerve cord In chordate animals, a hollow bundle of nerves extending from the brain along the dorsal (back) side of the animal, with cerebrospinal fluid inside a central channel. One of the defining features of chordates.

nerve net A nervous system in which neurons are diffuse instead of being clustered into large ganglia or tracts; found in cnidarians and ctenophores.

nervous tissue An animal tissue consisting of nerve cells (neurons) and various supporting cells.

net primary productivity (NPP) In an ecosystem, the total amount of carbon fixed by photosynthesis over a given time period minus the amount oxidized during cellular respiration. Compare with **gross primary productivity**.

net reproductive rate (R_0) The growth rate of a population per generation; equivalent to the average number of female offspring that each female produces over her lifetime.

neural tube A folded tube of ectoderm that forms along the dorsal side of a young vertebrate embryo; gives rise to the brain and spinal cord.

neuroendocrine Referring to nerve cells (neurons) that release hormones into the blood or to such hormones themselves.

neurogenesis The birth of new neurons from central nervous system stem cells.

neurohormones Hormones produced by neurons.

neuron A cell that is specialized for the transmission of nerve impulses. Typically has dendrites, a cell body, and a long axon that forms synapses with other neurons. Also called *nerve cell*.

neurosecretory cell A nerve cell (neuron) that produces and secretes hormones into the bloodstream. Principally found in the hypothalamus. Also called *neuroendocrine cell*.

neurotoxin Any substance that specifically destroys or blocks the normal functioning of neurons.

neurotransmitter A molecule that transmits signals from one neuron to another or from a neuron to a muscle or gland. Examples are acetylcholine, dopamine, serotonin, and norepinephrine.

neutral In genetics, referring to any mutation or mutant allele that has no effect on an individual's fitness.

neutrophil A type of leukocyte, capable of moving through body tissues, that engulfs and digests pathogens and other foreign particles; also secretes various compounds that attack bacteria and fungi.

niche The range of resources that a species can use and the range of conditions that it can tolerate. More broadly, the role that species plays in its ecosystem.

niche differentiation The evolutionary change in resource use by competing species that occurs as the result of character displacement.

nicotinamide adenine dinucleotide See **NAD^+/NADH**.

nitrogen cycle, global The movement of nitrogen among terrestrial ecosystems, the oceans, and the atmosphere.

nitrogen fixation The incorporation of atmospheric nitrogen (N_2) into ammonia (NH_3), which can be used to make many organic compounds. Occurs in only a few lineages of bacteria and archaea.

nociceptor A sensory cell or organ specialized to detect tissue damage, usually producing the sensation of pain.

Nod factors Molecules produced by nitrogen-fixing bacteria that help them recognize and bind to roots of legumes.

node (1) In animals, any small thickening (e.g., a lymph node). (2) In plants, the part of a stem where leaves or leaf buds are attached. (3) In a phylogenetic tree, the point where two branches diverge, representing the point in time when an ancestral group split into two or more descendant groups. Also called *fork*.

node of Ranvier One of the unmyelinated sections that occurs periodically along a neuron's axon and serves as a site where an action potential can be regenerated.

nodule Globular structure on roots of legume plants that contain symbiotic nitrogen-fixing bacteria.

noncyclic electron flow Path of electron flow in which electrons pass from photosystem II, through an electron transport chain, to photosystem I, and ultimately to $NADP^+$ during the light-dependent reactions of photosynthesis. See also **Z scheme**.

nondisjunction An error that can occur during meiosis or mitosis, in which one daughter cell receives two copies of a particular chromosome and the other daughter cell receives none.

nonpolar covalent bond A covalent bond in which electrons are equally shared between two atoms of the same or similar electronegativity. Compare with **polar covalent bond**.

nonsense mutation A point mutation (change in a single base pair) that converts an amino-acid-specifying codon into a stop codon.

non-sister chromatids The chromatids of a particular type of chromosome (after replication) with respect to the chromatids of its homologous chromosome. Crossing over occurs between non-sister chromatids. Compare with **sister chromatids**.

non-template strand The strand of DNA that is not transcribed during synthesis of RNA. Its sequence corresponds to that of the mRNA produced from the other strand. Also called *coding strand*.

non-vascular plants A paraphyletic group of land plants that lack vascular tissue and reproduce using spores. The non-vascular plants include three lineages of green plants (liverworts, mosses, and hornworts). These lineages are sometimes called *bryophytes*.

norepinephrine A catecholamine used as a neurotransmitter in the sympathetic nervous system. Also is produced by the adrenal medulla and functions as a hormone that triggers rapid responses relating to the fight-or-flight response.

notochord A supportive but flexible rod that occurs in the back of a chordate embryo, ventral to the developing spinal cord. Replaced by vertebrae in most adult vertebrates. A defining feature of chordates.

nuclear envelope The double-layered membrane enclosing the nucleus of a eukaryotic cell.

nuclear lamina A lattice-like sheet of fibrous nuclear lamins, which are one type of intermediate filament. Lines the inner membrane of the nuclear envelope, stiffening the envelope and helping to organize the chromosomes.

nuclear lamins Intermediate filaments that make up the nuclear lamina layer—a lattice-like layer inside the nuclear envelope that stiffens the structure.

nuclear localization signal (NLS) A short amino acid sequence that marks a protein for delivery to the nucleus.

nuclear pore An opening in the nuclear envelope that connects the inside of the nucleus with the cytoplasm and through which molecules such as mRNA and some proteins can pass.

nuclear pore complex A large complex of dozens of proteins lining a nuclear pore, defining its shape and regulating transport through the pore.

nuclease Any enzyme that can break down RNA or DNA molecules.

nucleic acid A macromolecule composed of nucleotide monomers. Generally used by cells to store or transmit hereditary information. Includes ribonucleic acid and deoxyribonucleic acid.

nucleoid In prokaryotic cells, a dense, centrally located region that contains DNA but is not surrounded by a membrane.

nucleolus In eukaryotic cells, a specialized structure in the nucleus where ribosomal RNA processing occurs and ribosomal subunits are assembled.

nucleosome A repeating, bead-like unit of eukaryotic chromatin, consisting of about 200 nucleotides of DNA wrapped twice around eight histone proteins.

nucleotide excision repair The process of removing a damaged region in one strand of DNA and replacing it with the correct sequence using the undamaged strand as a template.

nucleotide A molecule consisting of a five-carbon sugar (ribose or deoxyribose), a phosphate group, and one of several nitrogen-containing bases. DNA and RNA are polymers of nucleotides containing deoxyribose (deoxyribonucleotides) and ribose (ribonucleotides), respectively. Equivalent to a nucleoside plus one phosphate group.

nucleus (1) The center of an atom, containing protons and neutrons. (2) In eukaryotic cells, the large organelle containing the chromosomes and surrounded by a double membrane. (3) A discrete clump of neuron cell bodies in the brain, usually sharing a distinct function.

null allele See **knock-out allele**.

null hypothesis A hypothesis that specifies what the results of an experiment will be if the main hypothesis being tested is wrong. Often states that there will be no difference between experimental groups.

nutrient Any substance that an organism requires for normal growth, maintenance, or reproduction.

occipital lobe In the vertebrate brain, one of the four major areas in the cerebrum.

oceanic zone The waters of the open ocean beyond the continental shelf.

odorant Any volatile molecule that conveys information about food or the environment.

oil An unsaturated fat that is liquid at room temperature.

Okazaki fragment Short segment of DNA produced during replication of the lagging strand template. Many Okazaki fragments make up the lagging strand in newly synthesized DNA.

olfaction The perception of odors.

olfactory bulb A bulb-shaped projection of the brain just above the nose. Receives and interprets odor information from the nose.

oligodendrocyte A type of glial cell that wraps around axons of some neurons in the central nervous system, forming a myelin sheath that provides electrical insulation. Compare with **Schwann cell**.

oligopeptide A chain composed of fewer than 50 amino acids linked together by peptide bonds. Often referred to simply as *peptide*.

oligosaccharide A linear or branched polymer consisting of less than 50 monosaccharides joined by glycosidic linkages. Compare with **monosaccharide** and **polysaccharide**.

ommatidium (plural: ommatidia) A light-sensing column in an arthropod's compound eye.

omnivore (adjective: omnivorous) An animal whose diet regularly includes both meat and plants. Compare with **carnivore** and **herbivore**.

oncogene Any gene whose protein product stimulates cell division at all times and thus promotes cancer development. Often is a mutated form of a gene involved in regulating the cell cycle. See **proto-oncogene**.

one-gene, one-enzyme hypothesis The hypothesis that each gene is responsible for making one enzyme. This hypothesis has expanded to include genes that produce proteins other than enzymes or that produce RNAs as final products.

oogenesis The production of egg cells (ova).

oogonium (plural: oogonia) In an ovary, any of the diploid cells that can divide by mitosis to create primary oocytes (which can undergo meiosis) and more oogonia.

open circulatory system A circulatory system in which the circulating fluid (hemolymph) is not confined to blood vessels. Compare with **closed circulatory system**.

open reading frame (ORF) Any DNA sequence, ranging in length from several hundred to thousands of base pairs long, that is flanked by a start codon and a stop codon. ORFs identified by computer analysis of DNA may be functional genes, especially if they have other features characteristic of genes (e.g., promoter sequence).

operator In prokaryotic DNA, a binding site for a repressor protein; located near the start of an operon.

operculum The stiff flap of tissue that covers the gills of teleost fishes.

operon A region of prokaryotic DNA that codes for a series of functionally related genes and is transcribed from a single promoter into one mRNA.

opsin A transmembrane protein that is covalently linked to retinal, the light-detecting pigment in rod and cone cells.

optic nerve A bundle of neurons that runs from the eye to the brain.

optimal foraging The concept that animals forage in a way that maximizes the amount of usable energy they take in, given the costs of finding and ingesting their food and the risk of being eaten while they're at it.

orbital The region of space around an atomic nucleus in which an electron is present most of the time.

organ A group of tissues organized into a functional and structural unit.

organ system Groups of tissues and organs that work together to perform a function.

organelle Any discrete, membrane-bound structure within a cell (e.g., mitochondrion) that has a characteristic structure and function.

organic For a compound, containing carbon and hydrogen and usually containing carbon–carbon bonds. Organic compounds are widely used by living organisms.

organism Any living entity that contains one or more cells.

organogenesis A stage of embryonic development that follows gastrulation and that creates organs from the three germ layers.

origin of replication The site on a chromosome at which DNA replication begins.

osmoconformer An animal that does not actively regulate the osmolarity of its tissues but conforms to the osmolarity of the surrounding environment.

osmolarity The concentration of dissolved substances in a solution, measured in osmoles per liter.

osmoregulation The process by which a living organism controls the concentration of water and salts in its body.

osmoregulator An animal that actively regulates the osmolarity of its tissues.

osmosis Diffusion of water across a selectively permeable membrane from a region of low solute concentration (high water concentration) to a region of high solute concentration (low water concentration).

ossicles, ear In mammals, three bones found in the middle ear that function in transferring and amplifying sound from the outer ear to the inner ear.

ouabain A plant toxin that poisons the sodium–potassium pumps of animals.

out-of-Africa hypothesis The hypothesis that modern humans (*Homo sapiens*) evolved in Africa and spread to other continents, replacing other *Homo* species without interbreeding with them.

outcrossing Reproduction by fusion of the gametes of different individuals, rather than by self-fertilization.

outer ear The outermost portion of the mammalian ear, consisting of the pinna (ear flap) and the ear canal. Funnels sound to the tympanic membrane.

outgroup A taxon that is closely related to a particular monophyletic group but is not part of it.

oval window A membrane separating the fluid-filled cochlea from the air-filled middle ear; sound vibrations pass through it from the middle ear to the inner ear in mammals.

ovary The egg-producing organ of a female animal, or the fruit- and seed-producing structure in the female part of a flower.

overexploitation Unsustainable removal of wildlife from the natural environment for use by humans.

oviduct See **fallopian tube**.

oviparous In animals, producing eggs that are laid outside the body where they develop and hatch. Compare with **ovoviviparous** and **viviparous**.

ovoviviparous In animals, producing eggs that are retained inside the body until they are ready to hatch. Compare with **oviparous** and **viviparous**.

ovulation The release of an egg from an ovary of a female vertebrate. In humans, an ovarian follicle releases an egg at the end of the follicular phase of the menstrual cycle.

ovule In flowering plants, the structure inside an ovary that contains the female gametophyte and eventually (if fertilized) becomes a seed.

ovum (plural: ova) See **egg**.

oxidation The loss of electrons from an atom or molecule during a redox reaction, either by donation of an electron to another atom or molecule, or by the shared electrons in covalent bonds moving farther from the atomic nucleus.

oxidative phosphorylation Production of ATP molecules by ATP synthase using the proton gradient established via redox reactions of an electron transport chain.

oxygen–hemoglobin equilibrium curve The graphed depiction of the percentage of hemoglobin in the blood that is bound to oxygen at various partial pressures of oxygen.

oxygenic Referring to any process or reaction that produces oxygen. Photosynthesis in plants, algae, and cyanobacteria, which involves photosystem II, is oxygenic. Compare with **anoxygenic**.

oxytocin A peptide hormone, secreted by the posterior pituitary, that triggers labor and milk production in females and that stimulates pair bonding, parental care, and affiliative behavior in both sexes.

p53 A tumor-suppressor protein (molecular weight of 53 kilodaltons) that responds to DNA damage by stopping the cell cycle, turning on DNA repair machinery, and, if necessary, triggering apoptosis. Encoded by the *p53* gene.

pacemaker cell Any of a group of specialized cardiac muscle cells in the sinoatrial (SA) node of the vertebrate heart that have an inherent rhythm and can generate an electrical impulse that spreads to other heart cells.

paleontologists Scientists who study the fossil record and the history of life.

Paleozoic era The interval of geologic time, from 542 million to 251 million years ago, during which fungi, land plants, and animals first appeared and diversified. Began with the Cambrian explosion and ended with the extinction of many invertebrates and vertebrates at the end of the Permian period.

pancreas A large gland in vertebrates that has both exocrine and endocrine functions. Secretes digestive enzymes into a duct connected to the intestine and secretes several hormones (notably, insulin and glucagon) into the bloodstream.

pancreatic amylase An enzyme produced by the pancreas that breaks down glucose chains by catalyzing hydrolysis of the glycosidic linkages between the glucose residues.

pancreatic lipase An enzyme that is produced in the pancreas and acts in the small intestine to break bonds in complex fats, releasing small lipids.

pandemic The spread of an infectious disease in a short time period over a wide geographic area and affecting a very high proportion of the population. Compare with **epidemic**.

parabiosis An experimental technique for determining whether a certain physiological phenomenon is regulated by a hormone; consists of surgically uniting two individuals so that hormones can pass between them.

paracrine Relating to a chemical signal that is released by one cell and affects neighboring cells.

paraphyletic group A group that includes an ancestral population and *some* but not all of its descendants. Compare with **monophyletic group**.

parapodia (singular: parapodium) Appendages found in some annelids from which bristle-like structures (chaetae) extend.

parasite An organism that lives on a host species (ectoparasite) or in a host species (endoparasite) and that damages its host.

parasitism (adjective: parasitic) A symbiotic relationship between two organisms that is beneficial to one organism (the parasite) but detrimental to the other (the host). Compare with **commensalism** and **mutualism**.

parasitoid An organism that has a parasitic larval stage and a free-living adult stage. Most parasitoids are insects that lay eggs in the bodies of other insects.

parasympathetic nervous system The part of the autonomic nervous system that stimulates responses for conserving or restoring energy, such as reduced heart rate and increased digestion. Compare with **sympathetic nervous system**.

parenchyma cell In plants, a general type of cell with a relatively thin primary cell wall. These cells, found in leaves, the centers of stems and roots, and fruits, are involved in photosynthesis, storage, and transport. Compare with **collenchyma cell** and **sclerenchyma cell**.

parental care Any action by which an animal expends energy or assumes risks to benefit its offspring (e.g., nest building, feeding of young, defense).

parental generation The adults used in the first experimental cross of a breeding experiment.

parental strand A strand of DNA that is used as a template during DNA synthesis.

parietal cell A cell in the stomach lining that secretes hydrochloric acid.

parietal lobe In the vertebrate brain, one of the four major areas in the cerebrum.

parsimony The logical principle that the most likely explanation of a phenomenon is the most economical or simplest. When applied to comparison of alternative phylogenetic trees, it suggests that the one requiring the fewest evolutionary changes is most likely to be correct.

parthenogenesis Development of offspring from unfertilized eggs; a type of asexual reproduction.

partial pressure The pressure of one particular gas in a mixture of gases; the contribution of that gas to the overall pressure.

particulate inheritance The observation that genes from two parents do not blend together in offspring, but instead remain separate or particle-like.

pascal (Pa) A unit of pressure (force per unit area).

passive transport Diffusion of a substance across a membrane. When this event occurs with the assistance of membrane proteins, it is called *facilitated diffusion*.

patch clamping A technique for studying the electrical currents that flow through individual ion channels by sucking a tiny patch of membrane to the hollow tip of a microelectrode.

paternal chromosome A chromosome inherited from the father.

pathogen (adjective: pathogenic) Any entity capable of causing disease, such as a microbe, virus, or prion.

pattern formation The series of events that determines the spatial organization of an entire embryo or parts of an embryo, for example, setting the major body axes early in development.

pattern-recognition receptor On leukocytes, a class of membrane proteins that bind to molecules commonly associated with foreign cells and viruses and signal responses against broad types of pathogens. Part of the innate immune response.

peat Semi-decayed organic matter that accumulates in moist, low-oxygen environments such as *Sphagnum* (moss) bogs.

pectin A gelatinous polysaccharide found in the primary cell wall of plant cells. Attracts and holds water, forming a gel that resists compression forces and helps keep the cell wall moist.

pedigree A family tree of parents and offspring, showing inheritance of particular traits of interest.

penis The copulatory organ of male mammals, used to insert sperm into a female.

pentose A monosaccharide (simple sugar) containing five carbon atoms.

PEP carboxylase An enzyme that catalyzes addition of CO_2 to phosphoenolpyruvate, a three-carbon compound, forming a four-carbon organic acid. See also **C_4 pathway** and **crassulacean acid metabolism (CAM)**.

pepsin A protein-digesting enzyme present in the stomach.

peptide See **oligopeptide**.

peptide bond The covalent bond formed by a condensation reaction between two amino acids; links the residues in peptides and proteins.

peptidoglycan A complex structural polysaccharide found in bacterial cell walls.

perennial Describing a plant whose life cycle normally lasts for more than one year. Compare with **annual**.

perfect flower A flower that contains both male parts (stamens) and female parts (carpels). Compare with **imperfect flower**.

perforation In plants, a small hole in the primary and secondary cell walls of vessel elements that allows passage of water.

pericarp The part of a fruit, formed from the ovary wall, that surrounds the seeds and protects them. Corresponds to the flesh of most edible fruits and the hard shells of most nuts.

pericycle In plant roots, a layer of cells just inside the endodermis that give rise to lateral roots.

peripheral membrane protein Any membrane protein that does not span the entire lipid bilayer and associates with only one side of the bilayer. Compare with **integral membrane protein**.

peripheral nervous system (PNS) All the components of the nervous system that are outside the central nervous system (the brain and spinal cord). Includes the somatic nervous system and the autonomic nervous system.

peristalsis Rhythmic waves of muscular contraction. In the digestive tract, pushes food along. In animals with hydrostatic skeletons, enables crawling.

permafrost A permanently frozen layer of icy soil found in most tundra and some taiga.

permeability The tendency of a structure, such as a membrane, to allow a given substance to diffuse across it.

peroxisome An organelle found in most eukaryotic cells that contains enzymes for oxidizing fatty acids and other compounds, including many toxins, rendering them harmless. See **glyoxysome**.

petal Any of the leaflike organs arranged around the reproductive organs of a flower. Often colored and scented to attract pollinators.

petiole The stalk of a leaf.

pH A measure of the concentration of protons in a solution and thus of acidity or alkalinity. Defined as the negative of the base-10 logarithm of the proton concentration: $pH = -\log[H^+]$.

phagocytosis Uptake by a cell of small particles or cells by invagination and pinching off of the plasma membrane to form small, membrane-bound vesicles; one type of **endocytosis**.

pharyngeal gill slits A set of parallel openings from the throat to the outside that function in both feeding and gas exchange. A diagnostic trait of chordates.

pharyngeal jaw A secondary jaw in the back of the throat; found in some fishes, it aids in food processing. Derived from modified gill arches.

phenology The timing of events during the year, in environments where seasonal changes occur.

phenotype The detectable traits of an individual. Compare with **genotype**.

phenotypic plasticity Within-species variation in phenotype that is due to differences in environmental conditions. Occurs more commonly in plants than animals.

pheophytin The molecule in photosystem II that accepts excited electrons from the reaction center chlorophyll and passes them to an electron transport chain.

pheromone A chemical signal, released by an individual into the external environment, that can trigger changes in the behavior or physiology or both of another member of the same species.

phloem A plant vascular tissue that conducts sugars between roots and shoots; contains sieve-tube elements and companion cells. Primary phloem develops from the procambium of apical meristems; secondary phloem, from the vascular cambium. Compare with **xylem**.

phosphatase An enzyme that removes phosphate groups from proteins or other molecules. Phosphatases are often used in the inactivation of signaling pathways that involve the phosphorylation and activation of proteins.

phosphodiester linkage Chemical linkage between adjacent nucleotide residues in DNA and RNA. Forms when the phosphate group of one nucleotide condenses with the hydroxyl group on the sugar of another nucleotide. Also known as *phosphodiester bond*.

phosphofructokinase The enzyme that catalyzes synthesis of fructose-1,6-bisphosphate from fructose-6-phosphate, a key reaction in glycolysis (step 3). Also called *6-phosphofructokinase*.

phospholipid A class of lipid having a hydrophilic head (including a phosphate group) and a hydrophobic tail (consisting of two hydrocarbon chains). Major components of the plasma membrane and organelle membranes.

phosphorylase An enzyme that breaks down glycogen by catalyzing hydrolysis of the α-glycosidic linkages between the glucose residues.

phosphorylation (verb: phosphorylate) The addition of a phosphate group to a molecule.

phosphorylation cascade A series of enzyme-catalyzed phosphorylation reactions commonly used in signal transduction pathways to amplify and convey a signal inward from the plasma membrane.

photic zone In an aquatic habitat, water that is shallow enough to receive some sunlight (whether or not it is enough to support photosynthesis). Compare with **aphotic zone**.

photon A discrete packet of light energy; a particle of light.

photoperiod The amount of time per day (usually in hours) that an organism is exposed to light.

photoperiodism Any response by an organism to the relative lengths of day and night (i.e., photoperiod).

photophosphorylation Production of ATP molecules by ATP synthase using the proton-motive force generated as light-excited electrons flow through an electron transport chain during photosynthesis.

photoreception A sensory system in which receptors are activated by light.

photoreceptor A molecule, a cell, or an organ that is specialized to detect light.

photorespiration A series of light-driven chemical reactions that consumes oxygen and releases carbon dioxide, basically undoing photosynthesis. Usually occurs when there are high O_2 and low CO_2 concentrations inside plant cells; often occurs when stomata must be kept closed to prevent dehydration.

photoreversibility A change in conformation that occurs in certain plant pigments when they are exposed to the particular wavelengths of light that they absorb; triggers responses by the plant.

photosynthesis The complex biological process that converts the energy of light into chemical energy stored in glucose and other organic molecules. Occurs in most plants, algae, and some bacteria.

photosystem One of two types of units, consisting of a central reaction center surrounded by antenna complexes, that is responsible for the light-dependent reactions of photosynthesis.

photosystem I A photosystem that contains a pair of P700 chlorophyll molecules and uses absorbed light energy to reduce $NADP^+$ to NADPH.

photosystem II A photosystem that contains a pair of P680 chlorophyll molecules and uses absorbed light energy to produce a proton-motive force for the synthesis of ATP. Oxygen is produced as a by-product when water is split to obtain electrons.

phototroph An organism (most plants, algae, and some bacteria) that produces ATP through photosynthesis.

phototropins A class of plant photoreceptors that detect blue light and initiate various responses.

phototropism Growth or movement of an organism in a particular direction in response to light.

phylogenetic species concept The definition of a species as the smallest monophyletic group in a phylogenetic tree. Compare with **biological species concept** and **morphospecies concept**.

phylogenetic tree A branching diagram that depicts the evolutionary relationships among species or other taxa.

phylogeny The evolutionary history of a group of organisms.

phylum (plural: phyla) In Linnaeus' system, a taxonomic category above the class level and below the kingdom level. In plants, sometimes called a *division*.

physical map A map of a chromosome that shows the number of base pairs between various genetic markers. Compare with **genetic map**.

physiology The study of how an organism's body functions.

phytochrome A specialized plant photoreceptor that exists in two shapes depending on the ratio of red to far-red light and is involved in the timing of certain

physiological processes, such as flowering, stem elongation, and germination.

pigment Any molecule that absorbs certain wavelengths of visible light and reflects or transmits other wavelengths.

piloting A type of navigation in which animals use familiar landmarks to find their way.

pineal gland An endocrine gland, located in the brain, that secretes the hormone melatonin.

pioneering species Those species that appear first in recently disturbed areas.

pit In plants, a small hole in the secondary cell walls of tracheids and vessel elements that allows passage of water.

pitch The sensation produced by a particular frequency of sound. Low frequencies are perceived as low pitches; high frequencies, as high pitches.

pith In the shoot systems of plants, ground tissue located to the inside of the vascular bundles.

pituitary gland A small gland located directly under the brain and physically and functionally connected to the hypothalamus. Produces and secretes an array of hormones that affect many other glands and organs.

placenta A structure that forms in the pregnant uterus from maternal and fetal tissues. Delivers oxygen to the fetus, exchanges nutrients and wastes between mother and fetus, anchors the fetus to the uterine wall, and produces some hormones. Occurs in most mammals and in a few other vertebrates.

placental mammals See **eutherians**.

plankton Drifting organisms (animals, plants, archaea, or bacteria) in aquatic environments.

Plantae The monophyletic group that includes red, green, and glaucophyte algae, and land plants.

plasma The non-cellular portion of blood.

plasma cell A B cell that produces large quantities of antibodies after being activated by interacting with antigen and a $CD4^+$ T cell via peptide presentation. Also called an *effector B cell*.

plasma membrane A membrane that surrounds a cell, separating it from the external environment and selectively regulating passage of molecules and ions into and out of the cell. Also called *cell membrane*.

plasmid A small, usually circular, supercoiled DNA molecule independent of the cell's main chromosome(s) in prokaryotes and some eukaryotes.

plasmodesmata (singular: plasmodesma) Physical connections between two plant cells, consisting of membrane-lined gaps in the cell walls through which the two cells' plasma membranes, cytoplasm, and smooth ER can connect directly. Functionally similar to gap junctions in animal cells.

plasmogamy Fusion of the cytoplasm of two individuals. Occurs in many fungi.

plastocyanin A small protein that shuttles electrons originating from photosystem II to the reaction center of photosystem I during photosynthesis.

plastoquinone (PQ) A nonprotein electron carrier in the chloroplast electron transport chain. Receives excited electrons from photosystem II (noncyclic) or photosystem I (cyclic) and passes them to more electronegative molecules in the chain. Also transports protons from the stroma to the thylakoid lumen, generating a proton-motive force.

platelet A small membrane-bound cell fragment in vertebrate blood that functions in blood clotting. Derived from large cells in the bone marrow.

pleiotropy (adjective: pleiotropic) The ability of a single gene to affect more than one trait.

ploidy The number of complete chromosome sets present. *Haploid* refers to a ploidy of 1; *diploid,* a ploidy of 2; *triploid,* a ploidy of 3; and *tetraploid,* a ploidy of 4.

point mutation A mutation that results in a change in a single base pair in DNA.

polar (1) Asymmetrical or unidirectional. (2) Carrying a partial positive charge on one side of a molecule and a partial negative charge on the other. Polar molecules are generally hydrophilic.

polar body Any of the tiny, nonfunctional cells that are made as a by-product during meiosis of a primary oocyte, due to most of the cytoplasm going to the ovum.

polar covalent bond A covalent bond in which electrons are shared unequally between atoms differing in electronegativity, resulting in the more electronegative atom having a partial negative charge and the other atom, a partial positive charge. Compare with **nonpolar covalent bond**.

polar microtubules Mitotic and meiotic microtubules that have arisen from the two spindle poles and overlap with each other in the middle of the spindle apparatus.

polar nuclei In flowering plants, the nuclei in the female gametophyte that fuse with one sperm nucleus to produce the endosperm. Most species have two.

pollen grain In seed plants, a male gametophyte enclosed within a protective coat of sporopollenin.

pollen tube In flowering plants, a structure that grows out of a pollen grain after it reaches the stigma, extends down the style, and through which two sperm cells are delivered to the ovule.

pollination The process by which pollen reaches the carpel of a flower (in flowering plants), transferred from anther to stigma, or reaches the ovule directly (in conifers and their relatives).

pollination syndrome Suites of flower characters that are associated with certain types of pollinators and that have evolved through natural selection imposed by the interaction between flowers and pollinators.

poly(A) signal In eukaryotes, a short sequence of nucleotides near the 3′ end of pre-mRNAs that signals cleavage of the RNA and addition of the poly(A) tail.

poly(A) tail In eukaryotes, a sequence of about 100–250 adenine nucleotides added to the 3′ end of newly transcribed messenger RNA molecules.

polygenic inheritance Having many genes influence one trait.

polymer Any long molecule composed of small repeating units (monomers) bonded together. The main biological polymers are proteins, nucleic acids, and polysaccharides.

polymerase chain reaction (PCR) A laboratory technique for rapidly generating millions of identical copies of a specific stretch of DNA. Works by incubating the original DNA sequence of interest with primers, nucleotides, and DNA polymerase.

polymerization (verb: polymerize) The process by which many identical or similar small molecules (monomers) are covalently bonded to form a large molecule (polymer).

polymorphic species A species that has two or more distinct phenotypes in the same interbreeding population at the same time.

polymorphism (adjective: polymorphic) (1) The occurrence of more than one allele at a genetic locus in a population. (2) The occurrence of more than two distinct phenotypes of a trait in a population.

polyp The immotile (sessile) stage in the life cycle of some cnidarians (e.g., jellyfish). Compare with **medusa**.

polypeptide A chain of 50 or more amino acids linked together by peptide bonds. Compare with **oligopeptide** and **protein**.

polyphyletic group An unnatural group based on convergent (homoplastic) characteristics that are not present in a common ancestor. Compare with **monophyletic group**.

polyploidy (adjective: polyploid) The state of having more than two full sets of chromosomes, either from the same species (autopolyploidy) or from different species (allopolyploidy).

polyribosome A messenger RNA molecule along with more than one attached ribosome and their growing peptide strands.

polysaccharide A linear or branched polymer consisting of many monosaccharides joined by glycosidic linkages. Compare with **monosaccharide** and **oligosaccharide**.

polytomy A node in a phylogenetic tree that depicts an ancestral branch dividing into three or more descendant branches; usually indicates that insufficient data were available to resolve which taxa are more closely related.

population A group of individuals of the same species living in the same geographic area at the same time.

population density The number of individuals of a population per unit area.

population dynamics Changes in the size and other characteristics of populations through time and space.

population ecology The study of how and why the number of individuals in a population changes over time and space.

population thinking The ability to analyze trait frequencies, event probabilities, and other attributes of populations of molecules, cells, or organisms.

pore In land plants, an opening in the epithelium that allows gas exchange. See also **stoma**.

positive control Of genes, when a regulatory protein triggers expression by binding to DNA on or near the gene.

positive feedback A physiological mechanism in which a change in some variable stimulates a response that increases the change. Relatively rare in organisms but is important in generation of the action potential. Compare with **negative feedback**.

positive pressure ventilation Ventilation of the lungs by using positive pressure in the mouth to "push" air into the lungs. Compare with **negative pressure ventilation**.

positive-sense RNA virus An ssRNA virus whose genome contains the same sequences as the mRNA required to produce viral proteins. Compare with **ambisense virus** and **negative-sense virus**.

posterior Toward an animal's tail and away from its head. The opposite of anterior.

posterior pituitary The part of the pituitary gland that contains the ends of hypothalamic neurosecretory cells and from which oxytocin and antidiuretic hormone are secreted. Compare with **anterior pituitary**.

postsynaptic neuron A neuron that receives signals, usually via neurotransmitters, from another neuron at a synapse. Compare with **presynaptic neuron**.

post-translational control Regulation of gene expression by modification of proteins (e.g., addition of a phosphate group or sugar residues) after translation.

postzygotic isolation Reproductive isolation resulting from mechanisms that operate after mating of individuals of two different species occurs. The most common mechanisms are the death of hybrid embryos or reduced fitness of hybrids.

potential energy Energy stored in matter as a result of its position or molecular arrangement. Compare with **kinetic energy**.

prebiotic soup model Hypothetical explanation for chemical evolution whereby small molecules reacted with one another in a mixture of organic molecules condensed into a body of water, typically in reference to the early oceans.

Precambrian The interval between the formation of the Earth, about 4.6 billion years ago, and the appearance of most animal groups about 542 million years ago. Unicellular organisms were dominant for most of this era, and oxygen was virtually absent for the first 2 billion years.

pre-mRNA In eukaryotes, the primary transcript of protein-coding genes. Pre-mRNA is processed to form mRNA.

predation The killing and eating of one organism (the prey) by another (the predator).

predator Any organism that kills other organisms for food.

prediction A measurable or observable result of an experiment based on a particular hypothesis. A correct prediction provides support for the hypothesis being tested.

pressure-flow hypothesis The hypothesis that sugar movement through phloem tissue is due to differences in the turgor pressure of phloem sap.

pressure potential (ψ_P) A component of the potential energy of water caused by physical pressures on a solution. It can be positive or negative. Compare with **solute potential** (ψ_S).

presynaptic neuron A neuron that transmits signals, usually by releasing neurotransmitters, to another neuron or to an effector cell at a synapse.

prezygotic isolation Reproductive isolation resulting from any one of several mechanisms that prevent individuals of two different species from mating.

primary active transport A form of active transport in which a source of energy like ATP is directly used to move ions against their electrochemical gradients.

primary cell wall The outermost layer of a plant cell wall, made of cellulose fibers and gelatinous polysaccharides, that defines the shape of the cell and withstands the turgor pressure of the plasma membrane.

primary consumer An herbivore; an organism that eats plants, algae, or other primary producers. Compare with **secondary consumer**.

primary decomposer A decomposer (detritivore) that consumes detritus from plants.

primary growth In plants, an increase in the length of stems and roots due to the activity of apical meristems. Compare with **secondary growth**.

primary immune response An adaptive immune response to a pathogen that the immune system has not encountered before. Compare with **secondary immune response**.

primary meristem In plants, three types of partially differentiated cells that are produced by apical meristems, including protoderm, ground meristem, and procambium. Compare with **apical meristem** and **cambium**.

primary oocyte Any of the large diploid cells in an ovarian follicle that can initiate meiosis to produce a haploid secondary oocyte and a polar body.

primary producer Any organism that creates its own food by photosynthesis or from reduced inorganic compounds and that is a food source for other species in its ecosystem. Also called *autotroph*.

primary spermatocyte Any of the diploid cells in the testis that can initiate meiosis I to produce two secondary spermatocytes.

primary structure The sequence of amino acid residues in a peptide or protein; also the sequence of nucleotides in a nucleic acid. Compare with **secondary**, **tertiary**, and **quaternary structure**.

primary succession The gradual colonization of a habitat of bare rock or gravel, usually after an environmental disturbance that removes all soil and previous organisms. Compare with **secondary succession**.

primary transcript In eukaryotes, a newly transcribed RNA molecule that has not yet been processed to a mature RNA. Called *pre-mRNA* when the final product is a protein.

primase An enzyme that synthesizes a short stretch of RNA to use as a primer during DNA replication.

primates The lineage of mammals that includes prosimians (lemurs, lorises, etc.), monkeys, and great apes (including humans).

primer A short, single-stranded RNA molecule that base-pairs with a DNA template strand and is elongated by DNA polymerase during DNA replication.

probe A radioactively or chemically labeled single-stranded fragment of a known DNA or RNA sequence that can bind to and detect its complementary sequence in a sample containing many different sequences.

proboscis A tubular, often extensible feeding appendage with which food can be obtained.

procambium A primary meristem tissue that gives rise to the vascular tissue.

product Any of the final materials formed in a chemical reaction.

progesterone A steroid hormone produced and secreted by the corpus luteum in the ovaries after ovulation and by the placenta during gestation; protects the uterine lining.

programmed cell death Regulated cell death that is used in development, tissue maintainance, and destruction of infected cells. Can occur in different ways; apoptosis is the best-known mechanism.

prokaryote A member of the domain Bacteria or Archaea; a unicellular organism lacking a nucleus and containing relatively few organelles or cytoskeletal components. Compare with **eukaryote**.

prolactin A peptide hormone, produced and secreted by the anterior pituitary, that promotes milk production in female mammals and has a variety of effects on parental behavior and seasonal reproduction in other vertebrates.

prometaphase A stage in mitosis or meiosis during which the nuclear envelope breaks down and microtubules attach to kinetochores.

promoter A short nucleotide sequence in DNA that binds a sigma factor (in bacteria) or basal transcription factors (in eukaryotes) to enable RNA polymerase to begin transcription. In bacteria, several contiguous genes are often transcribed from a single promoter. In eukaryotes, each gene generally has its own promoter.

promoter-proximal element In eukaryotes, regulatory sequences in DNA that are close to a promoter and that can bind regulatory transcription factors.

proofreading The process by which a DNA polymerase recognizes and removes a wrong base added during DNA replication and then continues synthesis.

prophase The first stage in mitosis or meiosis during which chromosomes become visible and the spindle apparatus forms. Synapsis and crossing over occur during prophase of meiosis I.

prosimians One of the two major lineages of primates, a paraphyletic group including lemurs, pottos, and lorises. Compare with **anthropoids**.

prostate gland A gland in male mammals that surrounds the base of the urethra and secretes a fluid that is a component of semen.

prosthetic group A non-amino acid atom or molecule that is permanently attached to an enzyme or other protein and is required for its function.

protease An enzyme that can break up proteins by cleaving the peptide bonds between amino acid residues.

proteasome A macromolecular machine that destroys proteins that have been marked by the addition of ubiquitin.

protein A macromolecule consisting of one or more polypeptide chains composed of 50 or more amino acids linked together. Each protein has a unique sequence of amino acids and generally possesses a characteristic three-dimensional shape.

protein kinase An enzyme that catalyzes the addition of a phosphate group to another protein, typically activating or inactivating the substrate protein.

proteinase inhibitors Defense compounds, produced by plants, that induce illness in herbivores by inhibiting digestive enzymes.

proteoglycan A type of highly glycosylated protein found in the extracellular matrix of animal cells that attracts and holds water, forming a gel that resists compression forces.

proteome The complete set of proteins produced by a particular cell type.

proteomics The systematic study of the interactions, localization, functions, regulation, and other features of the full protein set (proteome) in a particular cell type.

protist Any eukaryote that is not a green plant, animal, or fungus. Protists are a diverse paraphyletic group. Most are unicellular, but some are multicellular or form aggregations called colonies.

protocell A hypothetical pre-cell structure consisting of a membrane compartment that encloses replicating macromolecules, such as ribozymes.

protoderm The exterior layer of a young plant embryo that gives rise to the epidermis.

proto-oncogene Any gene that encourages cell division in a regulated manner, typically by triggering specific phases in the cell cycle. Mutation may convert it into an oncogene. See **oncogene**.

proton pump A membrane protein that can hydrolyze ATP to power active transport of protons (H^+ ions) across a membrane against an electrochemical gradient. Also called *H^+-ATPase*.

proton-motive force The combined effect of a proton gradient and an electric potential gradient across a membrane, which can drive protons across the membrane. Used by mitochondria and chloroplasts to power ATP synthesis via the mechanism of chemiosmosis.

protostomes A major lineage of animals that share a pattern of embryological development, including formation of the mouth earlier than the anus, and formation of the coelom by splitting of a block of mesoderm. Includes arthropods, mollusks, and annelids. Compare with **deuterostomes**.

proximal tubule In the vertebrate kidney, the convoluted section of a nephron into which filtrate moves from Bowman's capsule. Involved in the largely unregulated reabsorption of electrolytes, nutrients, and water. Compare with **distal tubule**.

proximate causation In biology, the immediate, mechanistic cause of a phenomenon (how it happens), as opposed to why it evolved. Also called *proximate explanation*. Compare with **ultimate causation**.

pseudocoelomate An animal that has a coelom that is only partially lined with mesoderm. Compare with **acoelomate** and **coelomate**.

pseudogene A DNA sequence that closely resembles a functional gene but is not transcribed. Thought to have arisen by duplication of the functional gene followed by inactivation due to a mutation.

pseudopodium (plural: pseudopodia) A temporary bulge-like extension of certain protist cells used in cell crawling and ingestion of food.

puberty The various physical and emotional changes that an immature human undergoes in reaching reproductive maturity. Also the period when such changes occur.

pulmonary artery A short, thick-walled artery that carries oxygen-poor blood from the heart to the lungs.

pulmonary circulation The part of the circulatory system that sends oxygen-poor blood to the lungs. It is separate from the rest of the circulatory system (the systemic circulation) in mammals and birds.

pulmonary vein A short, thin-walled vein that carries oxygen-rich blood from the lungs to the heart. Humans have four such veins.

pulse–chase experiment A type of experiment in which a population of cells or molecules at a particular moment in time is marked by means of a labeled molecule (pulse) and then their fate is followed over time (chase).

pump Any membrane protein that can hydrolyze ATP and change shape to power active transport of a specific ion or small molecule across a plasma membrane against its electrochemical gradient. See **proton pump**.

pupa (plural: pupae) A metamorphosing insect that is enclosed in a protective case.

pupil The hole in the center of the iris through which light enters a vertebrate or cephalopod eye.

pure line In animal or plant breeding, a strain that produces offspring identical with themselves when self-fertilized or crossed to another member of the same population. Pure lines are homozygous for most, if not all, genetic loci.

purifying selection Selection that lowers the frequency of or even eliminates deleterious alleles.

purines A class of small, nitrogen-containing, double-ringed bases (guanine, adenine) found in nucleotides. Compare with **pyrimidines**.

pyrimidines A class of small, nitrogen-containing, single-ringed bases (cytosine, uracil, thymine) found in nucleotides. Compare with **purines**.

pyruvate dehydrogenase A large enzyme complex, located in the mitochondrial matix, that is responsible for converting pyruvate to acetyl CoA during cellular respiration.

quantitative trait A trait that exhibits continuous phenotypic variation (e.g., human height), rather than the distinct forms characteristic of discrete traits.

quaternary structure In proteins, the overall three-dimensional shape formed from two or more polypeptide chains (subunits); determined by the number, relative positions, and interactions of the subunits. In single stranded nucleic acids, the hydrogen bonding between two or more distinct strands will form this level of structure through hydrophobic interactions between complementary bases. Compare with **primary**, **secondary**, and **tertiary structures**.

quorum sensing Cell–cell signaling in unicellular organisms, in which cells of the same species communicate via chemical signals. It is often observed that cell activity changes dramatically when the population reaches a threshold size, or quorum.

radial symmetry An animal body pattern that has at least two planes of symmetry. Typically, the body is in the form of a cylinder or disk, and the body parts radiate from a central hub. Compare with **bilateral symmetry**.

radiation Transfer of heat between two bodies that are not in direct physical contact. More generally, the emission of electromagnetic energy of any wavelength.

radicle The root of a plant embryo.

radioactive isotope A version of an element that has an unstable nucleus, which will release radiation energy as it decays to a more stable form. Decay often results in the radioisotope becoming a different element.

radioimmunoassay A competitive binding assay in which the quantity of hormone in a sample can be estimated. Uses radioactively labeled hormones that compete with the unknown hormone to bind with an antibody.

radula A rasping feeding appendage in mollusks such as gastropods (snails, slugs).

rain shadow The dry region on the side of a mountain range away from the prevailing wind.

range The geographic distribution of a species.

Ras protein A type of G protein that is activated by enzyme-linked cell-surface receptors, including receptor tyrosine kinases. Activated Ras then initiates a phosphorylation cascade, culminating in a cell response.

ray-finned fishes Members of the Actinopterygii, a diverse group of fishes with fins supported by bony rods arranged in a ray pattern.

rays In plant shoot systems with secondary growth, a lateral row of parenchyma cells produced by vascular cambium. Transport water and nutrients laterally across the stem.

Rb protein A tumor suppressor protein that helps regulate progression of a cell from the G_1 phase to the S phase of the cell cycle. Defects in Rb protein are found in many types of cancer.

reactant Any of the starting materials in a chemical reaction.

reaction center Centrally located component of a photosystem containing proteins and a pair of specialized chlorophyll molecules. It is surrounded by antenna complexes that transmit resonance energy to excite the reaction center pigments.

reading frame A series of non-overlapping, three-base-long sequences (potential codons) in DNA or RNA. The reading frame for a polypeptide is set by the start codon.

realized niche The portion of the fundamental niche that a species actually occupies given limiting factors such as competition with other species. Compare with **fundamental niche**.

receptor-mediated endocytosis Uptake by a cell of certain extracellular macromolecules, bound to specific receptors in the plasma membrane, by pinching off the membrane to form small membrane-bound vesicles.

receptor tyrosine kinase (RTK) Any of a class of enzyme-linked cell-surface signal receptors that

undergo phosphorylation after binding a signaling molecule. The activated, phosphorylated receptor then triggers a signal transduction pathway inside the cell.

recessive Referring to an allele whose phenotypic effect is observed only in homozygous individuals. Compare with **dominant**.

reciprocal altruism Altruistic behavior that is exchanged between a pair of individuals at different times (i.e., sometimes individual A helps individual B, and sometimes B helps A).

reciprocal cross A cross in which the mother's and father's phenotypes are the reverse of that examined in a previous cross.

recombinant Possessing a new combination of alleles. May refer to a single chromosome or DNA molecule, or to an entire organism.

recombinant DNA technology A variety of techniques for isolating specific DNA fragments and introducing them into different regions of DNA or a different host organism.

rectal gland A salt-excreting gland in the digestive system of sharks, skates, and rays.

rectum The last portion of the digestive tract. It is where feces are held until they are expelled.

red blood cell A hemoglobin-containing cell that circulates in the blood and delivers oxygen from the lungs to the tissues.

redox reaction Any chemical reaction that involves either the complete transfer of one or more electrons from one reactant to another, or a reciprocal shift in the position of shared electrons within one or more of the covalent bonds of two reactants. Also called *reduction–oxidation reaction*.

reduction The gain of electrons by an atom or molecule during a redox reaction, either by acceptance of an electron from another atom or molecule, or by the shared electrons in covalent bonds moving closer to the atomic nucleus.

reduction–oxidation reaction See **redox reaction**.

reflex An involuntary response to environmental stimulation. May involve the brain (conditioned reflex) or not (spinal reflex).

refractory No longer responding to stimuli that previously elicited a response. An example is the tendency of voltage-gated sodium channels to remain closed immediately after an action potential.

regulatory sequence Any segment of DNA that is involved in controlling transcription of a specific gene by binding a regulatory transcription factor protein.

regulatory transcription factor General term for proteins that bind to DNA regulatory sequences (eukaryotic enhancers, silencers, and promoter-proximal elements), but not to the promoter itself, leading to an increase or decrease in transcription of specific genes. Compare with **basal transcription factor**.

regulon A large set of genes in bacteria that are controlled by a single type of regulatory molecule. Regulon genes are transcribed in response to environmental cues and allow cells to respond to changing environments.

reinforcement In evolutionary biology, the natural selection for traits that prevent interbreeding between recently diverged species.

release factors Proteins that trigger termination of translation when a ribosome reaches a stop codon.

renal corpuscle In the vertebrate kidney, the ball-like structure at the beginning of a nephron, consisting of a glomerulus and the surrounding Bowman's capsule. Acts as a filtration device.

replacement rate The number of offspring each female must produce over her entire life to "replace" herself and her mate, resulting in zero population growth. The actual number is slightly more than 2 because some offspring die before reproducing.

replica plating A method of identifying bacterial colonies that have certain mutations by transferring cells from each colony on a master plate to a second (replica) plate and observing their growth when exposed to different conditions.

replication fork The Y-shaped site at which a double-stranded molecule of DNA is separated into two single strands for replication.

replicative growth The process by which viruses produce new virions.

replisome The macromolecular machine that copies DNA; includes DNA polymerase, helicase, primase, and other enzymes.

repolarization Return to a resting potential after a membrane potential has changed; a normal phase in an action potential.

repressor (1) In bacteria, a protein that binds to an operator sequence in DNA to prevent transcription when an inducer is not present and that comes off DNA to allow transcription when an inducer binds to the repressor protein. (2) In eukaryotes, a protein that binds to a silencer sequence in DNA to prevent or reduce gene transcription.

reproductive development The phase of plant development that involves development of the flower and reproductive cells. Follows vegetative development and occurs when a shoot apical meristem (SAM) transitions to a flower-producing meristem.

reptiles One of the two lineages of amniotes (vertebrates that produce amniotic eggs) distinguished by adaptations for life and reproduction on land. Living reptiles include turtles, snakes and lizards, crocodiles and alligators, and birds. Except for birds, all are ectotherms.

resilience, community A measure of how quickly a community recovers following a disturbance.

resistance, community A measure of how much a community is affected by a disturbance.

respiratory system The collection of cells, tissues, and organs responsible for gas exchange between an animal and its environment.

resting potential The membrane potential of a cell in its resting, or normal, state.

restriction endonucleases Bacterial enzymes that cut DNA at a specific base-pair sequence (restriction site). Also called *restriction enzymes*.

retina A thin layer of light-sensitive cells (rods and cones) and neurons at the back of a simple eye, such as that of cephalopods and vertebrates.

retinal A light-absorbing pigment that is linked to the protein opsin in rods and cones of the vertebrate eye.

retrovirus A virus with an RNA genome that reverse-transcribes its RNA into a double-stranded DNA sequence, which is then inserted into the host's genome as part of its replicative cycle.

reverse transcriptase An enzyme that can synthesize double-stranded DNA from a single-stranded RNA template.

rhizobia (singular: rhizobium) Members of the bacterial genus *Rhizobium;* nitrogen-fixing bacteria that live in root nodules of members of the pea family (legumes).

rhizoid The hairlike structure that anchors a nonvascular plant to the substrate.

rhizome A modified stem that runs horizontally underground and produces new plants at the nodes (a form of asexual reproduction). Compare with **stolon**.

rhodopsin A transmembrane complex that is instrumental in detection of light by rods of the vertebrate eye. Is composed of the transmembrane protein opsin covalently linked to retinal, a light-absorbing pigment.

ribonucleic acid (RNA) A nucleic acid composed of ribonucleotides that usually is single stranded. Functions include structural components of ribosomes (rRNA), transporters of amino acids (tRNA), and messages of the DNA code required for protein synthesis (mRNA), among others.

ribonucleotide See **nucleotide**.

ribosomal RNA (rRNA) An RNA molecule that forms part of the ribosome.

ribosome A large macromolecular machine that synthesizes proteins by using the genetic information encoded in messenger RNA. Consists of two subunits, each composed of ribosomal RNA and proteins.

ribosome binding site In a bacterial mRNA molecule, the sequence just upstream of the start codon to which a ribosome binds to initiate translation. Also called the *Shine–Dalgarno sequence*.

ribozyme Any RNA molecule that can act as a catalyst, that is, speed up a chemical reaction.

ribulose bisphosphate (RuBP) A five-carbon compound that combines with CO_2 in the first step of the Calvin cycle during photosynthesis.

RNA See **ribonucleic acid**.

RNA interference (RNAi) Degradation of an RNA molecule or inhibition of its translation following its binding by a short RNA (microRNA) whose sequence is complementary to a portion of the mRNA.

RNA polymerase An enzyme that catalyzes the synthesis of RNA from ribonucleotides using a DNA template.

RNA processing In eukaryotes, the changes that a primary RNA transcript undergoes to become a mature RNA molecule. For pre-mRNA it includes the addition of a 5′ cap and poly(A) tail and splicing to remove introns.

RNA replicase A viral enzyme that can synthesize RNA from an RNA template. Also called an *RNA-dependent RNA polymerase*.

RNA world hypothesis Proposal that chemical evolution produced RNAs that could catalyze key reactions involved in their own replication and basic

metabolism, which led to the evolution of proteins and the first life-form.

rod cell A photoreceptor cell with a rod-shaped outer portion that is particularly sensitive to dim light but not used to distinguish colors. Also called simply *rod*. Compare with **cone cell**.

root (1) An underground part of a plant that anchors the plant and absorbs water and nutrients. (2) The most ancestral branch in a phylogenetic tree.

root apical meristem (RAM) A group of undifferentiated plant stem cells at the tip of a plant root that can differentiate into mature root tissue.

root cap A small group of cells that covers and protects the root apical meristem. Senses gravity and determines the direction of root growth.

root hair A long, thin outgrowth of the epidermal cells of plant roots, providing increased surface area for absorption of water and nutrients.

root pressure Positive pressure of xylem sap in the vascular tissue of roots. Generated during the night as a result of the accumulation of ions from the soil and subsequent osmotic movement of water into the xylem.

root system The belowground part of a plant.

rotifer Member of the phylum Rotifera. Distinguished by a cluster of cilia, called a corona, used in suspension feeding in marine and freshwater environments. Rotifers belong to the lophotrochozoan branch of the protostomes.

rough endoplasmic reticulum (rough ER) The portion of the endoplasmic reticulum that is dotted with ribosomes. Involved in synthesis of plasma membrane proteins, secreted proteins, and proteins localized to the ER, Golgi apparatus, and lysosomes. Compare with **smooth endoplasmic reticulum**.

roundworms Members of the phylum Nematoda. Distinguished by an unsegmented body with a pseudocoelom and no appendages. Roundworms belong to the ecdysozoan branch of the protostomes. Also called *nematodes*.

rubisco The enzyme that catalyzes the first step of the Calvin cycle during photosynthesis: the addition of a molecule of CO_2 to ribulose bisphosphate. See also **carbon fixation**.

ruminant Member of a group of hoofed mammals (e.g., cattle, sheep, deer) that have a four-chambered stomach specialized for digestion of plant cellulose. Ruminants regurgitate cud, a mixture of partially digested food and cellulose-digesting bacteria, from the largest chamber (the rumen) for further chewing.

salinity The proportion of solutes dissolved in water in natural environments, often designated in grams of solute per kilogram of water (cited as parts per thousand).

salivary amylase An enzyme that is produced by the salivary glands and that can break down starch by catalyzing hydrolysis of the glycosidic linkages between the glucose residues.

salivary gland A type of vertebrate gland that secretes saliva (a mixture of water, mucus-forming glycoproteins, and digestive enzymes) into the mouth.

sampling error The selection of a nonrepresentative sample from some larger population, due to chance.

saprophyte An organism that feeds primarily on dead plant material.

sapwood The younger xylem in the outer layer of wood of a stem or root, functioning primarily in water transport.

sarcomere The repeating contractile unit of a skeletal muscle cell; the portion of a myofibril located between adjacent Z disks.

sarcoplasmic reticulum Sheets of smooth endoplasmic reticulum in a muscle cell. Contains high concentrations of calcium, which can be released into the cytoplasm to trigger contraction.

saturated Referring to lipids in which all the carbon-carbon bonds are single bonds. Such compounds have relatively high melting points. Compare with **unsaturated**.

scanning electron microscope (SEM) A microscope that produces images of the surfaces of objects by reflecting electrons from a specimen coated with a layer of metal atoms. Compare with **transmission electron microscope**.

scarify To scrape, rasp, cut, or otherwise damage the coat of a seed. Necessary in some species to trigger germination.

Schwann cell A type of glial cell that wraps around axons of some neurons outside the brain and spinal cord, forming a myelin sheath that provides electrical insulation. Compare with **oligodendrocyte**.

scientific name The unique, two-part name given to each species, with a genus name followed by a species name—as in *Homo sapiens*. Scientific names are always italicized, and are also known as Latin names.

sclereid In plants, a relatively short type of sclerenchyma cell that usually functions in protection, such as in seed coats and nutshells. Compare with **fiber**.

sclerenchyma cell In plants, a cell that has a thick secondary cell wall and provides support; typically contains the tough structural polymer lignin and usually is dead at maturity. Includes fibers and sclereids. Compare with **collenchyma cell** and **parenchyma cell**.

scrotum A sac of skin containing the testes and suspended just outside the abdominal body cavity of many male mammals.

second law of thermodynamics The principle of physics that the entropy of the universe or any closed system always increases.

second-male advantage The reproductive advantage, in some species, of a male who mates with a female last, after other males have mated with her.

second messenger A nonprotein signaling molecule produced or activated inside a cell in response to stimulation at the cell surface. Commonly used to relay the message of a hormone or other extracellular signaling molecule.

secondary active transport Transport of an ion or molecule in a defined direction that is often against its electrochemical gradient, in company with an ion or molecule being transported along its electrochemical gradient. Also called *cotransport*.

secondary cell wall The thickened inner layer of a plant cell wall formed by certain cells as they mature and have stopped growing; in water-conducting cells, contains lignin. Provides support or protection.

secondary consumer A carnivore; an organism that eats herbivores. Compare with **primary consumer**.

secondary growth In plants, an increase in the width of stems and roots due to the activity of cambium. Compare with **primary growth**.

secondary immune response The adaptive immune response to a pathogen that the immune system has encountered before. Normally much faster and more efficient than the primary response, due to immunological memory. Compare with **primary immune response**.

secondary metabolites Molecules that are closely related to compounds in key synthetic pathways and that often function in defense.

secondary oocyte A cell produced by meiosis I of a primary oocyte in the ovary. If fertilized, will complete meiosis II to produce an ootid (which develops into an ovum) and a polar body.

secondary spermatocyte A cell produced by meiosis I of a primary spermatocyte in the testis. Can undergo meiosis II to produce spermatids.

secondary structure In proteins, localized folding of a polypeptide chain into regular structures (i.e., alpha-helix and beta-pleated sheet) stabilized by hydrogen bonding between atoms of the peptide backbone. In nucleic acids, elements of structure (e.g., helices and hairpins) stabilized by hydrogen bonding and hydrophobic interactions between complementary bases. Compare with **primary**, **tertiary**, and **quaternary structures**.

secondary succession Gradual colonization of a habitat after an environmental disturbance (e.g., fire, windstorm, logging) that removes some or all previous organisms but leaves the soil intact. Compare with **primary succession**.

secretin A peptide hormone produced by cells in the small intestine in response to the arrival of food from the stomach. Stimulates secretion of bicarbonate (HCO_3^-) from the pancreas.

sedimentary rock A type of rock formed by gradual accumulation of sediment, particularly sand and mud, as in riverbeds and on the ocean floor. Most fossils are found in sedimentary rocks.

seed A plant reproductive structure consisting of an embryo, associated nutritive tissue (endosperm), and an outer protective layer (seed coat). In angiosperms, develops from the fertilized ovule of a flower.

seed bank A repository where seeds, representing many different varieties of domestic crops or other species, are preserved.

seed coat A protective layer around a seed that encases both the embryo and the endosperm.

segment A well-defined, repeated region of the body along the anterior–posterior body axis, containing structures similar to other nearby segments.

segmentation Division of the body or a part of it into a series of similar structures; exemplified by the body segments of insects and worms and by the somites of vertebrates.

segmentation genes A group of genes that control the formation and patterning of body segmentation in embryonic development. Includes maternal genes, gap genes, pair-rule genes, and segment polarity genes.

segregation, principle of The concept that each pair of hereditary elements (alleles of the same gene) separate from each other during meiosis. One of Mendel's two principles of genetics.

selective adhesion The tendency of cells of one tissue type to adhere to other cells of the same type.

selective permeability The property of a membrane that allows some substances to diffuse across it much more readily than other substances.

selectively permeable membrane Any membrane across which some solutes can move more readily than others.

self-fertilization The fusion of two gametes from the same individual to form offspring. Also called *selfing*.

self molecule A molecule that is synthesized by an organism and is a normal part of its cells and/or body; as opposed to nonself, or foreign, molecules.

semen The combination of sperm and accessory fluids that is released by male mammals and reptiles during ejaculation.

semiconservative replication The way DNA replicates, in which each strand of an existing DNA molecule serves as a template to create a new complementary DNA strand. It is called semiconservative because each newly replicated DNA molecule conserves one of the parental strands and contains another, newly replicated strand.

seminal vesicle In male mammals, either of a pair of reproductive glands that secrete a sugar-containing fluid into semen, which provides energy for sperm movement.

senescence The genetically programmed, active process of aging.

sensor Any cell, organ, or structure with which an animal can sense some aspect of the external or internal environment. Usually functions, along with an integrator and effector, as part of a homeostatic system.

sensory neuron A nerve cell that carries signals from sensory receptors to the central nervous system. Compare with **interneuron** and **motor neuron**.

sepal One of the protective leaflike organs enclosing a flower bud and later part of the outermost portion of the flower.

septum (plural: septa) Any wall-like structure. In fungi, septa divide the filaments (hyphae) of mycelia into cell-like compartments.

serotonin A neurotransmitter involved in many brain functions, including sleep, pleasure, and mood.

serum The liquid that remains when cells and clot material are removed from clotted blood. Contains water, dissolved gases, growth factors, nutrients, and other soluble substances. Compare with **plasma**.

sessile Permanently attached to a substrate; not capable of moving to another location.

set point A normal or target value for a regulated internal variable, such as body heat or blood pH.

sex chromosome Chromosomes that differ in shape or in number in males and females. For example, the X and Y chromosomes of many animals. Compare with **autosome**.

sex-linked inheritance Inheritance patterns observed in genes carried on sex chromosomes. In this case, females and males have different numbers of alleles of a gene. Often creates situations in which a trait appears more often in one sex. Also called *sex-linkage*.

sexual dimorphism Any trait that differs between males and females.

sexual reproduction Any form of reproduction in which genes from two parents are combined via fusion of gametes, producing offspring that are genetically distinct from both parents. Compare with **asexual reproduction**.

sexual selection A type of natural selection that favors individuals with traits that increase their ability to obtain mates. Acts more strongly on males than females. (Compare with **ecological selection**.)

shell A hard, protective outer structure.

Shine–Dalgarno sequence See **ribosome binding sequence**.

shoot In a plant embryo, the combination of hypocotyl and cotyledons, which will become the aboveground portions of the plant.

shoot apical meristem (SAM) A group of undifferentiated plant stem cells at the tip of a plant stem that can differentiate into mature shoot tissues.

shoot system The aboveground part of a plant comprising stems, leaves, and flowers (in angiosperms).

short-day plant A plant that blooms in response to long nights (usually in late summer or fall in the Northern Hemisphere). Compare with **day-neutral** and **long-day plant**.

short tandem repeats (STRs) Relatively short DNA sequences that are repeated, one after another, down the length of a chromosome. See **microsatellite**.

shotgun sequencing A method of sequencing genomes that is based on breaking the genome into small pieces, sequencing each piece separately, and then figuring out how the pieces are connected.

sieve plate In plants, a pore-containing structure at each end of a sieve-tube element in phloem.

sieve-tube element In plants, an elongated sugar-conducting cell in phloem that lacks nuclei and has sieve plates at both ends, allowing sap to flow to adjacent cells.

sigma A bacterial protein that associates with the core RNA polymerase to allow recognition of promoters.

signal In behavioral ecology, any information-containing behavior or characteristic.

signal receptor Any cellular protein that binds to a particular signaling molecule (e.g., a hormone or neurotransmitter) and triggers a response by the cell. Receptors for lipid-insoluble signals are transmembrane proteins in the plasma membrane; those for many lipid-soluble signals (e.g., steroid hormones) are located inside the cell.

signal recognition particle (SRP) An RNA–protein complex that binds to the ER signal sequence in a polypeptide as it emerges from a ribosome and transports the ribosome–polypeptide complex to the ER membrane, where synthesis of the polypeptide is completed.

signal transduction The process by which a stimulus (e.g., a hormone, a neurotransmitter, or sensory information) outside a cell is converted into an intracellular signal required for a cellular response. Usually involves a specific sequence of molecular events, or signal transduction pathway, that may lead to amplification of the signal.

signal transduction cascade See **phosphorylation cascade**.

silencer A regulatory sequence in eukaryotic DNA to which repressor proteins can bind, inhibiting gene transcription.

silent mutation A point mutation that changes the sequence of a codon without changing the amino acid that is specified.

simple eye An eye with only one light-collecting apparatus (e.g., one lens), as in vertebrates and cephalopods. Compare with **compound eye**.

simple fruit A fruit (e.g., apricot) that develops from a single flower that has a single carpel or several fused carpels. Compare with **aggregate** and **multiple fruit**.

simple sequence repeat See **microsatellite**.

SINEs (short interspersed nuclear elements) The second most abundant class of transposable elements in human genomes; can create copies of itself and insert them elsewhere in the genome. Compare with **LINEs**.

single nucleotide polymorphism (SNP) A site on a chromosome where individuals in a population have different nucleotides. Can be used as a genetic marker to help track the inheritance of nearby genes.

single-strand DNA-binding proteins (SSBP) A protein that attaches to separated strands of DNA during replication or transcription, preventing them from re-forming a double helix.

sink Any tissue, site, or location where an element or a molecule is consumed or taken out of circulation (e.g., in plants, a tissue where sugar exits the phloem). Compare with **source**.

sinoatrial (SA) node In the right atrium of the vertebrate heart, a cluster of cardiac muscle cells that initiates the heartbeat and determines the heart rate. Compare with **atrioventricular (AV) node**.

siphon A tubelike appendage of many mollusks, often used for feeding or propulsion.

sister chromatids The paired strands of a recently replicated chromosome, which are connected at the centromere and eventually separate during anaphase of mitosis and meiosis II. Compare with **non-sister chromatids**.

sister species Closely related species that occupy adjacent branches in a phylogenetic tree.

skeletal muscle The muscle tissue attached to the bones of the vertebrate skeleton. Consists of long, unbranched muscle fibers with a characteristic striped (striated) appearance; controlled voluntarily. Compare with **cardiac** and **smooth muscle**.

sliding-filament model The hypothesis that thin (actin) filaments and thick (myosin) filaments slide past each other, thereby shortening the sarcomere. Shortening of all the sarcomeres in a myofibril results in contraction of the entire myofibril.

slow muscle fiber Type of skeletal muscle fiber that is red in color due to the abundance of myoglobin,

generates ATP by oxidative phosphorylation, and contracts slowly but does not fatigue easily. Also called *slow oxidative*, or *Type I*, *fiber*.

small intestine The portion of the digestive tract between the stomach and the large intestine. The site of the final stages of digestion and of most nutrient absorption.

small nuclear ribonucleoproteins See **snRNPs**.

smooth endoplasmic reticulum (smooth ER) The portion of the endoplasmic reticulum that does not have ribosomes attached to it. Involved in synthesis and secretion of lipids. Compare with **rough endoplasmic reticulum**.

smooth muscle The unstriated muscle tissue that lines the intestine, blood vessels, and some other organs. Consists of tapered, unbranched cells that can sustain long contractions. Not voluntarily controlled. Compare with **cardiac** and **skeletal muscle**.

snRNPs (small nuclear ribonucleoproteins) Complexes of proteins and small RNA molecules that function as components of spliceosomes during splicing (removal of introns from pre-mRNAs).

sodium–potassium pump A transmembrane protein that uses the energy of ATP to move sodium ions out of the cell and potassium ions in. Also called *Na^+/K^+-ATPase*.

soil organic matter Organic (carbon-containing) compounds found in soil.

solute Any substance that is dissolved in a liquid.

solute potential (ψ_S) A component of the potential energy of water caused by a difference in solute concentrations at two locations. Can be zero (pure water) or negative. Compare with **pressure potential (ψ_P)**.

solution A liquid containing one or more dissolved solids or gases in a homogeneous mixture.

solvent Any liquid in which one or more solids or gases can dissolve.

soma See **cell body**.

somatic cell Any type of cell in a multicellular organism except eggs, sperm, and their precursor cells. Also called *body cells*.

somatic hypermutation Mutation that occurs in the variable regions of immunoglobulin genes when B cells are first activated and in memory cells, resulting in novel variation in the receptors that bind to antigens.

somatic nervous system The part of the peripheral nervous system (outside the brain and spinal cord) that controls skeletal muscles and is under voluntary control. Compare with **autonomic nervous system**.

somatostatin A hormone secreted by the pancreas and hypothalamus that inhibits the release of several other hormones.

somite A block of mesoderm that occurs in pairs along both sides of the developing neural tube in a vertebrate embryo. Gives rise to muscle, vertebrae, ribs, and the dermis of the skin.

sori In ferns, a cluster of spore-producing structures (sporangia) usually found on the underside of fronds.

source Any tissue, site, or location where a substance is produced or enters circulation (e.g., in plants, the tissue where sugar enters the phloem). Compare with **sink**.

space-filling model A representation of a molecule where atoms are shown as balls—color-coded and scaled to indicate the atom's identify—attached to each other in the correct geometry.

speciation The evolution of two or more distinct species from a single ancestral species.

species An evolutionarily independent population or group of populations. Generally distinct from other species in appearance, behavior, habitat, ecology, genetic characteristics, and so on.

species–area relationship The mathematical relationship between the area of a certain habitat and the number of species that it can support.

species diversity The variety and relative abundance of the species present in a given ecological community.

species richness The number of species present in a given ecological community.

specific heat The amount of energy required to raise the temperature of 1 gram of a substance by 1°C; a measure of the capacity of a substance to absorb energy.

sperm A mature male gamete; smaller and more mobile than the female gamete.

sperm competition Competition between the sperm of different males to fertilize eggs inside the same female.

spermatid An immature sperm cell.

spermatogenesis The production of sperm. Occurs continuously in a testis.

spermatogonium (plural: spermatogonia) Any of the diploid cells in a testis that can give rise to primary spermatocytes.

spermatophore A gelatinous package containing sperm cells that is produced by males of species that have internal fertilization without copulation.

sphincter A muscular valve that can close off a tube, as in a blood vessel or a part of the digestive tract.

spicule Stiff spike of silica or calcium carbonate that provides structural support in the body of many sponges.

spindle apparatus The array of microtubules responsible for moving chromosomes during mitosis and meiosis; includes kinetochore microtubules, polar microtubules, and astral microtubules.

spines In plants, modified leaves that are stiff and sharp and that function in defense.

spiracle In insects, a small opening that connects air-filled tracheae to the external environment, allowing for gas exchange.

spleen A dark red organ, found near the stomach of most vertebrates, that filters blood, stores extra red blood cells in case of emergency, and plays a role in immunity.

spliceosome In eukaryotes, a large, complex assembly of snRNPs (small nuclear ribonucleoproteins) that catalyzes removal of introns from primary RNA transcripts.

splicing The process by which introns are removed from primary RNA transcripts and the remaining exons are connected together.

sporangium (plural: sporangia) A spore-producing structure found in seed plants, some protists, and some fungi (e.g., chytrids).

spore (1) In bacteria, a dormant form that generally is resistant to extreme conditions. (2) In eukaryotes, a single haploid cell produced by mitosis or meiosis (not by fusion of gametes) that is capable of developing into an adult organism.

sporophyte In organisms undergoing alternation of generations, the multicellular diploid form that arises from two fused gametes and produces haploid spores. Compare with **gametophyte**.

sporopollenin A watertight material that encases spores and pollen of modern land plants.

stabilizing selection A mode of natural selection that favors phenotypes near the middle of the range of phenotypic variation. Reduces overall genetic variation in a population. Compare with **disruptive selection** and **directional selection**.

stamen The male reproductive structure of a flower. Consists of an anther, in which pollen grains are produced, and a filament, which supports the anther. Compare with **carpel**.

standing defense See **constitutive defense**.

stapes The last of three small bones (ossicles) in the middle ear of vertebrates. Receives vibrations from the tympanic membrane and by vibrating against the oval window passes them to the cochlea.

starch A mixture of two storage polysaccharides, amylose and amylopectin, both formed from α-glucose monomers. Amylopectin is branched, and amylose is unbranched. The major form of stored carbohydrate in plants.

start codon The AUG triplet in mRNA at which protein synthesis begins; codes for the amino acid methionine.

statocyst A sensory organ of many arthropods that detects the animal's orientation in space (e.g., whether the animal is flipped upside down).

statolith A tiny stone or dense particle found in specialized gravity-sensing organs in some animals such as lobsters, and in gravity-sensing tissues of plants.

statolith hypothesis The hypothesis that amyloplasts (dense, starch-storing plant organelles) serve as statoliths in gravity detection by plants.

stem cell Any relatively undifferentiated cell that can divide to produce a daughter cell that remains a stem cell and a daughter cell that can differentiate into specific cell types.

stems Vertical, aboveground structures that make up the shoot system of plants.

stereocilium (plural: stereocilia) One of many stiff outgrowths from the surface of a hair cell that are involved in detection of sound by terrestrial vertebrates or of waterborne vibrations by fishes.

steroid A class of lipid with a characteristic four-ring hydrocarbon structure.

sticky ends The short, single-stranded ends of a DNA molecule cut by a restriction endonuclease. Tend to form hydrogen bonds with other sticky ends that have complementary sequences.

stigma The sticky tip at the end of a flower carpel to which pollen grains adhere.

stolon A modified stem that runs horizontally over the soil surface and produces new plants at the nodes (a form of asexual reproduction). Compare with **rhizome**.

stoma (plural: stomata) Generally, a pore or opening. In plants, a microscopic pore, surrounded by specialized cells that open the pore, on the surface of a leaf or stem through which gas exchange occurs. See also **guard cells**.

stomach A tough, muscular pouch in the vertebrate digestive tract between the esophagus and small intestine. Physically breaks up food and begins digestion of proteins.

stop codon Any of three mRNA triplets (UAG, UGA, or UAA) that cause termination of protein synthesis. Also called a *termination codon*.

strain The lowest, most specific level of taxonomy that refers to a population of individuals that are genetically very similar or identical.

striated muscle Muscle tissue containing protein filaments organized into repeating structures that give the cells and tissues a banded appearance.

stroma The fluid matrix of a chloroplast in which the thylakoids are embedded. Site where the Calvin cycle reactions occur.

structural formula A two-dimensional notation in which the chemical symbols for the constituent atoms are joined by straight lines representing single (–), double (=), or triple (≡) covalent bonds. Compare with **molecular formula**.

structural homology Similarities in adult organismal structures (e.g., limbs, shells, flowers) that are due to inheritance from a common ancestor.

style The slender stalk of a flower carpel connecting the stigma and the ovary.

suberin Waxy substance found in the cell walls of cork tissue and in the Casparian strip of endodermal cells.

subspecies A population that has distinctive traits and some genetic differences relative to other populations of the same species but that is not distinct enough to be classified as a separate species.

substrate (1) A reactant that interacts with a catalyst, such as an enzyme or ribozyme, in a chemical reaction. (2) A surface on which a cell or organism sits.

substrate-level phosphorylation Production of ATP or GTP by the transfer of a phosphate group from an intermediate substrate directly to ADP or GDP. Occurs in glycolysis and in the citric acid cycle.

succession In ecology, the gradual colonization of a habitat after an environmental disturbance (e.g., fire, flood), usually by a series of species. See **primary** and **secondary succession**.

sucrose A disaccharide formed from glucose and fructose. One of the two main products of photosynthesis.

sugar Synonymous with carbohydrate, though usually used in an informal sense to refer to small carbohydrates (monosaccharides and disaccharides).

summation The additive effect of different postsynaptic potentials on a nerve or muscle cell, such that several subthreshold stimulations can cause or inhibit an action potential.

supporting connective tissue A type of connective tissue distinguished by having a firm extracellular matrix. Includes bone and cartilage.

surface metabolism model Hypothetical explanation for chemical evolution whereby small molecules reacted with one another through catalytic activity associated with a surface, such as the mineral deposits found in deep-sea hydrothermal vents.

surface tension The cohesive force that causes molecules at the surface of a liquid to stick together, thereby resisting deformation of the liquid's surface and minimizing its surface area.

survivorship On average, the proportion of offspring that survive to a particular age.

survivorship curve A graph depicting the percentage of a population that survives to different ages.

suspension feeder Any organism that obtains food by filtering small particles or small organisms out of water or air. Also called *filter feeder*.

sustainability The planned use of environmental resources at a rate no faster than the rate at which they are naturally replaced.

sustainable agriculture Agricultural techniques that are designed to maintain long-term soil quality and productivity.

swamp A wetland that has a steady rate of water flow and is dominated by trees and shrubs.

swim bladder A gas-filled organ of many ray-finned fishes that regulates buoyancy.

symbiosis (adjective: symbiotic) Any close and prolonged physical relationship between individuals of two different species. See **commensalism**, **mutualism**, and **parasitism**.

symmetric competition Ecological competition between two species in which both suffer similar declines in fitness. Compare with **asymmetric competition**.

sympathetic nervous system The part of the autonomic nervous system that stimulates fight-or-flight responses, such as increased heart rate, increased blood pressure, and decreased digestion. Compare with **parasympathetic nervous system**.

sympatric speciation The divergence of populations living within the same geographic area into different species as the result of their genetic (not physical) isolation. Compare with **allopatric speciation**.

sympatry Condition in which two or more populations live in the same geographic area, or close enough to permit interbreeding. Compare with **allopatry**.

symplast In plants, the space inside the plasma membranes. The symplast of adjacent cells is often connected through plasmodesmata. Compare with **apoplast**.

symporter A cotransport protein that allows an ion to diffuse down an electrochemical gradient, using the energy of that process to transport a different substance in the same direction *against* its concentration gradient. Compare with **antiporter**.

synapomorphy A shared, derived trait found in two or more taxa that is present in their most recent common ancestor but is missing in more distant ancestors. Useful for inferring evolutionary relationships.

synapse The interface between two neurons or between a neuron and an effector cell.

synapsis The physical pairing of two homologous chromosomes during prophase I of meiosis. Crossing over is observed during synapsis.

synaptic cleft The space between two communicating nerve cells (or between a neuron and effector cell) at a synapse, across which neurotransmitters diffuse.

synaptic plasticity Long-term changes in the responsiveness or physical structure of a synapse that can occur after particular stimulation patterns. Thought to be the basis of learning and memory.

synaptic vesicle A small neurotransmitter-containing vesicle at the end of an axon that releases neurotransmitter into the synaptic cleft by exocytosis.

synaptonemal complex A network of proteins that holds non-sister chromatids together during synapsis in meiosis I.

synthesis (S) phase The phase of the cell cycle during which DNA is synthesized and chromosomes are replicated.

system A defined set of interacting chemical components under observation.

systemic acquired resistance (SAR) A slow, widespread response of plants to a localized infection that protects healthy tissue from invasion by pathogens. Compare with **hypersensitive response**.

systemic circulation The part of the circulatory system that sends oxygen-rich blood from the lungs out to the rest of the body. It is separate from the pulmonary circulation in mammals and birds.

systemin A peptide hormone, produced by plant cells damaged by herbivores, that initiates a protective response in undamaged cells.

systems biology The study of the structure of networks and how interactions between individual network components such as genes or proteins can lead to emergent biological properties.

systole The portion of the cardiac cycle during which the heart muscles are contracting. Compare with **diastole**.

systolic blood pressure The force exerted by blood against artery walls during contraction of the heart's left ventricle. Compare with **diastolic blood pressure**.

T cell A type of lymphocyte that matures in the thymus and, with B cells, is responsible for adaptive immunity. Involved in activation of B cells ($CD4^+$ helper T cells) and destruction of infected cells ($CD8^+$ cytotoxic T cells). Also called *T lymphocytes*.

T-cell receptor (TCR) A type of transmembrane protein found on T cells that can bind to antigens displayed on the surfaces of other cells. Composed of two polypeptides, called the alpha chain and beta chain, that consist of variable and constant regions. See **antigen presentation**.

T tubule Any of the membranous tubes that extend into the interior of muscle cells, propagating action

potentials throughout the cell and triggering release of calcium from the sarcoplasmic reticulum.

tagmata (singular: tagma) Prominent body regions in arthropods, such as the head, thorax, and abdomen in insects.

taiga A vast forest biome throughout subarctic regions, consisting primarily of short coniferous trees. Characterized by intensely cold winters, short summers, and high annual variation in temperature.

taproot A large, vertical main root of a plant's root system.

taste bud A sensory structure, found chiefly in the mammalian tongue, containing spindle-shaped cells that respond to chemical stimuli.

TATA-binding protein (TBP) A protein that binds to the TATA box in eukaryotic promoters and is a component of the basal transcription complex.

TATA box A short DNA sequence in many eukaryotic promoters about 30 base pairs upstream from the transcription start site.

taxon (plural: taxa) Any named group of organisms at any level of a classification system.

taxonomy The branch of biology concerned with the classification and naming of organisms.

tectorial membrane A membrane, located in the vertebrate cochlea, that takes part in the transduction of sound by bending the stereocilia of hair cells in response to sonic vibrations.

telomerase An enzyme that adds DNA to the ends of chromosomes (telomeres) by catalyzing DNA synthesis from an RNA template that is part of the enzyme.

telomere The end of a linear chromosome that contains a repeated sequence of DNA.

telophase The final stage in mitosis or meiosis during which daughter chromosomes (homologous chromosomes in meiosis I) have separated and new nuclear envelopes begin to form around each set of chromosomes.

temperate Having a climate with pronounced annual fluctuations in temperature (i.e., warm summers and cold winters) but typically neither as hot as the tropics nor as cold as the poles.

temperature A measurement of thermal energy present in an object or substance, reflecting how much the constituent molecules are moving.

template strand An original nucleic acid strand used to make a new, complementary copy based on hydrogen bonding between nitrogeneous bases.

temporal lobe In the vertebrate brain, one of the four major areas in the cerebrum.

tendon A band of tough, fibrous connective tissue that connects a muscle to a bone.

tentacle A long, thin, muscular appendage typically used for feeling and feeding. Occurs in different forms in diverse animals such as cephalopod mollusks and sea anemones.

termination (1) In enzyme-catalyzed reactions, the final stage in which the enzyme returns to its original conformation and products are released. (2) In transcription, the dissociation of RNA polymerase from DNA. (3) In translation, the dissociation of a ribosome from mRNA when it reaches a stop codon.

territory An area that is actively defended by an animal from others of its species and that provides exclusive or semi-exclusive use of its resources by the owner.

tertiary consumers In a food chain or food web, organisms that feed on secondary consumers. Compare with **primary consumer** and **secondary consumer**.

tertiary structure The overall three-dimensional shape of a single polypeptide chain, resulting from multiple interactions among the amino acid side chains and the peptide backbone. In single-stranded nucleic acids, the three-dimensional shape is formed by hydrogen bonding and hydrophobic interactions between complementary bases. Compare with **primary**, **secondary**, and **quaternary structure**.

testcross The breeding of an individual that expresses a dominant phenotype but has an unknown genotype with an individual having only recessive alleles for the traits of interest. Used to order to infer the unknown genotype from observation of the phenotypes seen in offspring.

testis (plural: testes) The sperm-producing organ of a male animal.

testosterone A steroid hormone, produced and secreted by the testes, that stimulates sperm production and various male traits and reproductive behaviors.

tetrad The structure formed by synapsed homologous chromosomes during prophase of meiosis I. Also known as a *bivalent*.

tetrapod Any member of the lineage that includes all vertebrates with two pairs of limbs (amphibians, mammals, and reptiles, including birds).

texture A quality of soil, resulting from the relative abundance of different-sized particles.

theory An explanation for a broad class of phenomena that is supported by a wide body of evidence. A theory serves as a framework for the development of new hypotheses.

thermal energy The kinetic energy of molecular motion.

thermocline A steep gradient (cline) in environmental temperature, such as occurs in a thermally stratified lake or ocean.

thermophile A bacterium or archaean that thrives in very hot environments.

thermoreception A sensory system in which receptors are activated by changes in heat energy.

thermoreceptor A sensory cell or an organ specialized for detection of changes in temperature.

thermoregulation Regulation of body temperature.

thick filament A filament composed of bundles of the motor protein myosin; anchored to the center of the sarcomere. Compare with **thin filament**.

thigmotropism Growth or movement of an organism in response to contact with a solid object.

thin filament A filament composed of two coiled chains of actin and associated regulatory proteins; anchored at the Z disk of the sarcomere. Compare with **thick filament**.

thorax A region of the body; in insects, one of the three prominent body regions, along with the head and abdomen, called tagmata.

thorn A modified plant stem shaped as a sharp, protective structure. Helps protect a plant against feeding by herbivores.

threshold potential The membrane potential that will trigger an action potential in a neuron or other excitable cell. Also called simply *threshold*.

thylakoid A membrane-bound network of flattened sac-like structures inside a plant chloroplast that functions in converting light energy to chemical energy. A stack of thylakoid discs is a granum.

thymus An organ, located in the anterior chest or neck of vertebrates, in which immature T cells that originated in the bone marrow undergo maturation.

thyroid gland A gland in the neck that releases thyroid hormone (which increases metabolic rate) and calcitonin (which lowers blood calcium).

thyroid hormones Either of two hormones, triiodothyronine (T_3) or thyroxine (T_4), produced by the thyroid gland. See **triiodothyronine** and **thyroxine**.

thyroid-stimulating hormone (TSH) A peptide hormone, produced and secreted by the anterior pituitary, that stimulates release of thyroid hormones from the thyroid gland.

thyroxine (T_4) A lipid-soluble hormone, derived from the amino acid tyrosine, containing four iodine atoms and produced and secreted by the thyroid gland. Acts primarily to increase cellular metabolism. In mammals, T_4 is converted to the more active hormone triiodothyronine (T_3) in the liver.

Ti plasmid A plasmid carried by *Agrobacterium* (a bacterium that infects plants) that can integrate into a plant cell's chromosomes and induce formation of a gall.

tight junction A type of cell–cell attachment structure that links the plasma membranes of adjacent animal cells, forming a barrier that restricts movement of substances in the space between the cells. Most abundant in epithelia (e.g., the intestinal lining). Compare with **desmosome** and **gap junction**.

tip The end of a branch on a phylogenetic tree. Represents a specific species or larger taxon that has not (yet) produced descendants—either a group living today or a group that ended in extinction. Also called *terminal node*.

tissue A group of cells that function as a unit, such as muscle tissue in an animal or xylem tissue in a plant.

tolerance In ecological succession, the phenomenon in which early-arriving species do not affect the probability that subsequent species will become established. Compare with **facilitation** and **inhibition**.

tonoplast The membrane surrounding a plant vacuole.

tool-kit genes A set of key developmental genes that establishes the body plan of animals and plants; present at the origin of the multicellular lineages and elaborated upon over evolutionary time by a process of duplication and divergence. Includes *Hox* genes.

top-down control The hypothesis that population size is limited by predators or herbivores (consumers).

topoisomerase An enzyme that prevents the twisting of DNA ahead of the advancing replication fork by

cutting the DNA, allowing it to unwind, and rejoining it.

torpor An energy-conserving physiological state, marked by a decrease in metabolic rate, body temperature, and activity, that lasts for a short period (overnight to a few days or weeks). Occurs in some small mammals when the ambient temperature drops significantly. Compare with **hibernation**.

totipotent Capable of dividing and developing to form a complete, mature organism.

toxin A poison produced by a living organism, such as a plant, animal, or microorganism.

trachea (plural: tracheae) (1) In insects, any of the small air-filled tubes that extend throughout the body and function in gas exchange. (2) In terrestrial vertebrates, the airway connecting the larynx to the bronchi. Also called *windpipe*.

tracheid In vascular plants, a long, thin, water-conducting cell that has pits where its lignin-containing secondary cell wall is absent, allowing water movement between adjacent cells. Compare with **vessel element**.

trade-off In evolutionary biology, an inescapable compromise between two traits that cannot be optimized simultaneously. Also called *fitness trade-off*.

trait Any observable characteristic of an individual.

transcription The process that uses a DNA template to produce a complementary RNA.

transcription factor General term for a protein that binds to a DNA regulatory sequence to influence transcription. It includes both regulatory and basal transcription factors.

transcriptional activator A eukaryotic regulatory transcription factor that binds to regulatory DNA sequences in enhancers or promoter-proximal elements to promote the initiation of transcription.

transcriptional control Regulation of gene expression by various mechanisms that change the rate at which genes are transcribed to form messenger RNA. In negative control, binding of a regulatory protein to DNA represses transcription; in positive control, binding of a regulatory protein to DNA promotes transcription.

transcriptome The complete set of genes transcribed in a particular cell.

transduction The conversion of information from one mode to another. For example, the process by which a stimulus outside a cell is converted into a response by the cell.

transfer RNA (tRNA) An RNA molecule that has an anticodon at one end and an amino acid attachment site at the other. Each tRNA carries a specific amino acid and binds to the corresponding codon in messenger RNA during translation.

transformation (1) Incorporation of external DNA into a cell. Occurs naturally in some bacteria; can be induced in the laboratory. (2) Conversion of a normal mammalian cell to one that divides uncontrollably.

transgenic A plant or animal whose genome contains DNA introduced from another individual, often from a different species.

transition state A high-energy intermediate state of the reactants during a chemical reaction that must be achieved for the reaction to proceed. Compare with **activation energy**.

transitional feature A trait that is intermediate between a condition observed in ancestral (older) species and the condition observed in derived (younger) species.

translation The process by which a polypeptide (a string of amino acids joined by peptide bonds) is synthesized from information in codons of messenger RNA.

translational control Regulation of gene expression by various mechanisms that alter the life span of messenger RNA or the efficiency of translation.

translocation (1) In plants, the movement of sugars and other organic nutrients through the phloem by bulk flow. (2) A type of mutation in which a piece of a chromosome moves to a nonhomologous chromosome. (3) The movement of a ribosome down a messenger RNA during translation.

transmembrane protein See **integral membrane protein**.

transmission The passage or transfer of (1) a disease from one individual to another or (2) electrical impulses from one neuron to another.

transpiration Loss of water vapor from aboveground plant parts. Occurs primarily through stomata.

transporter See **carrier protein**.

transposable elements Any of several kinds of DNA sequences that are capable of moving themselves, or copies of themselves, to other locations in the genome. Include LINEs and SINEs.

tree of life The phylogenetic tree that includes all organisms.

trichome A hairlike appendage that grows from epidermal cells in the shoot system of some plants. Trichomes exhibit a variety of shapes, sizes, and functions depending on species.

triiodothyronine (T_3) A lipid-soluble hormone, derived from the amino acid tyrosine, containing three iodine atoms and produced and secreted by the thyroid gland. Acts primarily to increase cellular metabolism. In mammals, T_3 has a stronger effect than does the related hormone thyroxine (T_4).

triose A monosaccharide (simple sugar) containing three carbon atoms.

triplet code A code in which a "word" of three letters encodes one piece of information. The genetic code is a triplet code because a codon is three nucleotides long and encodes one amino acid.

triploblast (adjective: triploblastic) An animal whose body develops from three basic embryonic cell layers or tissues: ectoderm, mesoderm, and endoderm. Compare with **diploblast**.

trisomy The state of having three copies of one particular type of chromosome in an otherwise diploid cell.

tRNA See **transfer RNA**.

trochophore A larva with a ring of cilia around its middle that is found in some lophotrochozoans.

trophic cascade A series of changes in the abundance of species in a food web, usually caused by the addition or removal of a key predator.

trophic level A feeding level in an ecosystem.

trophoblast The exterior of a blastocyst (the structure that results from cleavage in embryonic development of mammals).

tropomyosin A regulatory protein present in thin (actin) filaments that blocks the myosin-binding sites on these filaments in resting muscles, thereby preventing muscle contraction.

troponin A regulatory protein, present in thin (actin) filaments, that can move tropomyosin off the myosin-binding sites on these filaments, thereby triggering muscle contraction. Activated by high intracellular calcium.

true navigation The type of navigation by which an animal can reach a specific point on Earth's surface. Also called *map orientation*.

trypsin A protein-digesting enzyme present in the small intestine that activates several other protein-digesting enzymes.

tube foot One of the many small, mobile, fluid-filled extensions of the water vascular system of echinoderms; the part extending outside the body is called a podium, while the bulb within the body is the ampulla. Used in locomotion, feeding, and respiration.

tuber A modified plant rhizome that functions in storage of carbohydrates.

tuberculosis A disease of the lungs caused by infection with the bacterium *Mycobacterium tuberculosis*.

tumor A mass of cells formed by uncontrolled cell division. Can be benign or malignant.

tumor suppressor A protein (e.g., p53 or Rb) that prevents cell division, such as when the cell has DNA damage. Mutant genes that code for tumor suppressors are associated with cancer.

tundra The treeless biome in polar and alpine regions, characterized by short, slow-growing vegetation, permafrost, and a climate of long, intensely cold winters and very short summers.

turbidity Cloudiness of water caused by sediments and/or microscopic organisms.

turgid Swollen and firm as a result of high internal pressure (e.g., a plant cell containing enough water for the cytoplasm to press against the cell wall). Compare with **flaccid**.

turgor pressure The outward pressure exerted by the fluid contents of a living plant cell against its cell wall.

turnover In lake ecology, the complete mixing of upper and lower layers of water of different temperatures; occurs each spring and fall in temperate-zone lakes.

tympanic membrane The membrane separating the middle ear from the outer ear in terrestrial vertebrates, or similar structures in insects. Also called the *eardrum*.

ubiquinone See **coenzyme Q**.

ulcer A hole in an epithelial layer, exposing the underlying tissues to damage.

ultimate causation In biology, the reason that a trait or phenomenon is thought to have evolved; the adaptive advantage of that trait. Also called *ultimate explanation*. Compare with **proximate causation**.

umami The taste of glutamate, responsible for the "meaty" taste of most proteins and of monosodium glutamate.

umbilical cord The cord that connects a developing mammalian embryo or fetus to the placenta and through which the embryo or fetus receives oxygen and nutrients.

unequal crossover An error in crossing over during meiosis I in which the two non-sister chromatids match up at different sites. Results in gene duplication in one chromatid and gene loss in the other.

unsaturated Referring to lipids in which at least one carbon-carbon bond is a double bond. Double bonds produce kinks in hydrocarbon chains and decrease the compound's melting point. Compare with **saturated**.

upstream In genetics, opposite to the direction in which RNA polymerase moves along a DNA strand. Compare with **downstream**.

urea The major nitrogenous waste of mammals, adult amphibains, and cartilaginous fishes. Compare with **ammonia** and **uric acid**.

ureter In vertebrates, a tube that transports urine from one kidney to the bladder.

urethra The tube that drains urine from the bladder to the outside environment. In male vertebrates, also used for passage of semen during ejaculation.

uric acid A whitish excretory product of birds, reptiles, and terrestrial arthropods. Used to remove from the body excess nitrogen derived from the breakdown of amino acids. Compare with **ammonia** and **urea**.

urochordates One of the three major chordate lineages (Urochordata), comprising sessile or floating, filter-feeding animals that have a polysaccharide covering (tunic) and two siphons through which water enters and exits; include tunicates and salps. Compare with **cephalochordates** and **vertebrates**.

uterus The organ in which developing embryos are housed in mammals and some other viviparous vertebrates.

vaccination Artificially producing immunological memory against a pathogen by using isolated antigens or altered versions of the pathogen to stimulate an adaptive immune response in the absence of disease.

vaccine A preparation designed to stimulate an immune response against a particular pathogen without causing illness. Vaccines consist of inactivated (killed) pathogens, live but weakened (attenuated) pathogens, or parts of a pathogen (subunit vaccine).

vacuole A large organelle in plant and fungal cells that usually is used for bulk storage of water, pigments, oils, or other substances. Some vacuoles contain enzymes and have a digestive function similar to lysosomes in animal cells.

vagina The birth canal of female mammals; a muscular tube that extends from the uterus through the pelvis to the exterior.

valence The number of unpaired electrons in the outermost electron shell of an atom; often determines how many covalent bonds the atom can form.

valence electron An electron in the outermost electron shell, the valence shell, of an atom. Valence electrons tend to be involved in chemical bonding.

valence shell The outermost electron shell of an atom.

valve In circulatory systems, any of the flaps of tissue that prevent backward flow of blood, particularly in veins and in the heart.

van der Waals interactions A weak electrical attraction between two nonpolar molecules that have been brought together through hydrophobic interactions. Often contributes to tertiary and quaternary structures in proteins.

variable number tandem repeat See **minisatellite**.

variable (*V*) region The amino acid sequence that changes in polypeptides used to make antibodies, B-cell receptors, and T-cell receptors, This portion of the protein is highly variable within an individual and forms the epitope-binding site. Compare with **constant (C) region**.

vas deferens (plural: vasa deferentia) A muscular tube that stores and transports semen from the epididymis to the ejaculatory duct. Also called the *ductus deferens*.

vasa recta In the vertebrate kidney, a network of blood vessels that runs alongside the loop of Henle of a nephron. Functions in reabsorption of water and solutes from the filtrate.

vascular bundle In a plant stem, a cluster of xylem and phloem strands that run the length of the stem.

vascular cambium One of two types of cylindrical meristem, consisting of a ring of undifferentiated plant cells in the stem and root of woody plants; produces secondary xylem (wood) and secondary phloem. Compare with **cork cambium**.

vascular tissue In plants, tissue that transports water, nutrients, and sugars. Made up of the complex tissues xylem and phloem, each of which contains several cell types. Also called *vascular tissue system*.

vector A biting insect or other organism that transfers pathogens from one species to another. See also **cloning vector**.

vegetative development The phase of plant development that involves growth and the the production of all plant strucutures except the flower.

vein Any blood vessel that carries blood (oxygenated or not) under relatively low pressure from the tissues toward the heart. Compare with **artery**.

veliger A distinctive type of larva, found in mollusks.

vena cava (plural: venae cavae) Either of two large veins that return oxygen-poor blood to the heart.

ventral Toward an animal's belly and away from its back. The opposite of dorsal.

ventricle (1) A thick-walled chamber of the heart that receives blood from an atrium and pumps it to the body or to the lungs. (2) Any of several small fluid-filled chambers in the vertebrate brain.

venule Any of the body's many small veins (blood vessels that return blood to the heart).

vertebrae (singular: vertebra) The cartilaginous or bony elements that form the backbones of vertebrate animals.

vertebrates One of the three major chordate lineages (Vertebrata), comprising animals with a dorsal column of cartilaginous or bony structures (vertebrae) and a skull enclosing the brain. Includes fishes, amphibians, mammals, and reptiles (including birds). Compare with **cephalochordates** and **urochordates**.

vessel element In vascular plants, a short, wide, water-conducting cell that has gaps through both the primary and secondary cell walls, allowing unimpeded passage of water between adjacent cells. Compare with **tracheid**.

vestigial trait A reduced or incompletely developed structure that has no function or reduced function, but is clearly similar to functioning organs or structures in closely related species.

vicariance The physical splitting of a population into smaller, isolated populations by a geographic barrier.

villi (singular: villus) Small, fingerlike projections (1) of the lining of the small intestine or (2) of the fetal portion of the placenta adjacent to maternal arteries. Function to increase the surface area available for absorption of nutrients and gas exchange.

virion The infectious extracellular particle that is produced from a viral infection; used for transmitting the virus between hosts. It consists of a DNA or RNA genome enclosed within a protein shell (capsid) that may be further enveloped in a phospholipid bilayer. Compare with **virus**.

virulence (adjective: virulent) Referring to the ability of pathogens to cause severe disease in susceptible hosts.

virus An obligate, intracellular parasite that is acellular, but uses host-cell biosynthetic machinery to replicate. Compare with **virion**.

visceral mass One of the three main parts of the mollusk body; contains most of the internal organs and external gill.

visible light The range of wavelengths of electromagnetic radiation that humans can see, from about 400 to 700 nanometers.

vitamin Any of various organic micronutrients that usually function as coenzymes.

vitelline envelope A fibrous sheet of glycoproteins that surrounds mature egg cells in many vertebrates. Surrounded by a thick gelatinous matrix (the jelly layer) in some aquatic species. In mammals, called the *zona pellucida*.

viviparous Producing live young (instead of eggs) that develop within the body of the mother before birth. Compare with **oviparous** and **ovoviviparous**.

volt (V) A unit of electrical potential (voltage).

voltage Potential energy created by a separation of electric charges between two points. Also called *electrical potential*.

voltage clamping A technique for imposing a constant membrane potential on a cell. Widely used to investigate ion channels.

voltage-gated channel An ion channel that opens or closes in response to changes in membrane voltage. Compare with **ligand-gated channel**.

voluntary muscle Muscle that contracts in response to stimulation by voluntary (somatic), but not involuntary (parasympathetic or sympathetic), neural stimulation.

vomeronasal organ A paired sensory organ, located in the nasal region, containing chemoreceptors that bind odorants and pheromones.

wall pressure The inward pressure exerted by a cell wall against the fluid contents of a living plant cell.

Wallace line A line in the Indonesian region that demarcates two areas, each of which is characterized by a distinct set of animal species.

water potential (ψ) The potential energy of water in a certain environment compared with the potential energy of pure water at room temperature and atmospheric pressure. In living organisms, ψ equals the solute potential (ψ_S) plus the pressure potential (ψ_P).

water-potential gradient A difference in water potential in one region compared with that in another region. Determines the direction that water moves, always from regions of higher water potential to regions of lower water potential.

water table The upper limit of the underground layer of soil that is saturated with water.

water vascular system In echinoderms, a system of fluid-filled tubes and chambers that functions as a hydrostatic skeleton.

watershed The area drained by a single stream or river.

Watson–Crick pairing See **complementary base pairing**.

wavelength The distance between two successive crests in any regular wave, such as light waves, sound waves, or waves in water.

wax A class of lipid with extremely long, saturated hydrocarbon tails. Harder and less greasy than fats.

weather The specific short-term atmospheric conditions of temperature, moisture, sunlight, and wind in a certain area.

weathering The gradual wearing down of large rocks by rain, running water, temperature changes, and wind; one of the processes that transform rocks into soil.

weed Any plant that is adapted for growth in disturbed soils.

white blood cell Any of several types of blood cells, including neutrophils, macrophages, and lymphocytes, that circulate in blood and lymph and function in defense against pathogens.

wild type The most common phenotype seen in a wild population.

wildlife corridor Strips of wildlife habitat connecting populations that otherwise would be isolated by human-made development.

wilt To lose turgor pressure in a plant tissue.

wobble hypothesis The hypothesis that some tRNA molecules can pair with more than one mRNA codon by tolerating some non-standard base pairing in the third base, so long as the first and second bases are correctly matched.

wood Xylem resulting from secondary growth; forms strong supporting material. Also called *secondary xylem*.

worm An animal with a long, thin, tubelike body lacking limbs.

Woronin body A dense organelle in certain fungi that plugs pores in damaged septa to prevent leakage of cytoplasm.

X-linked inheritance Inheritance patterns for genes located on the mammalian X chromosome. Also called *X-linkage*.

X-ray crystallography A technique for determining the three-dimensional structure of large molecules, including proteins and nucleic acids, by analysis of the diffraction patterns produced by X-rays beamed at crystals of the molecule.

xenoestrogens Foreign chemicals that bind to estrogen receptors or otherwise induce estrogen-like effects.

xeroderma pigmentosum (XP) A human disease characterized by extreme sensitivity to ultraviolet light. Caused by an autosomal recessive allele that inactivates the nucleotide excision DNA repair system.

xylem A plant vascular tissue that conducts water and ions; contains tracheids and/or vessel elements. Primary xylem develops from the procambium of apical meristems; secondary xylem, or wood, from the vascular cambium. Compare with **phloem**.

Y-linked inheritance Inheritance patterns for genes located on the mammalian Y chromosome. Also called *Y-linkage*.

yeast Any fungus growing as a single-celled form. Also, a specific lineage of Ascomycota.

yolk The nutrient-rich cytoplasm inside an egg cell; used as food for the growing embryo.

Z disk The structure that forms each end of a sarcomere. Contains a protein that binds tightly to actin, thereby anchoring thin filaments.

Z scheme Model for changes in the potential energy of electrons as they pass from photosystem II to photosystem I and ultimately to $NADP^+$ during the light-dependent reactions of photosynthesis. See also **noncyclic electron flow**.

zero population growth (ZPG) A state of stable population size due to fertility staying at the replacement rate for at least one generation.

zona pellucida The gelatinous layer around a mammalian egg cell. In other vertebrates, called the *vitelline envelope*.

zone of (cellular) division In plant roots, a group of apical meristematic cells just behind the root cap where cells are actively dividing.

zone of (cellular) elongation In plant roots, a group of young cells, derived from primary meristem tissues and located behind the apical meristem, that are increasing in length.

zone of (cellular) maturation In plant roots, a group of plant cells, located several millimeters behind the root cap, that are differentiating into mature tissues.

zygosporangium (plural: zygosporangia) The distinctive spore-producing structure in fungi that are members of the Zygomycota.

zygote The cell formed by the union of two gametes; a fertilized egg.

  giraffe necks as, 9–11
  to global climate change, 1166*t*, 1167
  in metamorphosis, 672
  mutations and (*see* Mutation[s])
  natural selection, fitness, and, 6, 454, 465 (*see also* Fitness; Fitness trade-offs; Natural selection)
  plant nutritional, 789–90
  of plants to salty or dry habitats, 757–58, 765–66
  terrestrial, by protostomes, 659–60
  thermoregulation, 855–57
Adaptive immune response, **1041**–55. *See also* Immune systems
  activation and function of cells of, 1054*t*
  activation phase of, 1047–51
  adaptive immunity vs. innate immunity and, 1038
  B-cell activation and antibody secretion in, 1050–51
  B-cell receptors and T-cell receptors in antigen recognition by, 1044–46, 1047*f*
  B cells and T cells as lymphocytes in, 1042–43
  cell-mediated response in, 1051, 1052–53
  characteristics of, 1038, 1041–42
  clonal-selection theory on, 1048
  distinguishing self from nonself in, 1046–47
  extracellular pathogen elimination by, 1052
  humoral response in, 1051–52
  immunological memory in, 1053–55
  intracellular pathogen elimination by, 1052–53
  recognition phase of, 1041–47
  response phase of, 1051–53
  T-cell activation in, 1048–50
Adaptive immunity, **1038**. *See also* Adaptive immune response
Adaptive radiations, **516**, **596**, **884**
  angiosperm, 595–97*f*
  Cambrian explosion as animal, 518–20, 636–37
  of cichlids, 884–86
  ecological opportunity as trigger for, 516–17
  green plant, 582
  of Hawaiian silverswords, 736
  of humans, 707–8
  as major patterns in history of life, 516 (*see also* History of life)
  morphological innovation as trigger for, 517
  of ray-finned fishes, 692
  seed plant, 592
Adaxial-abaxial leaf axis, 436–37*f*
Addition rule, probability, B:8
Adenine, 58–59, 61–63, 65–66, 287, 318, 326
Adenosine diphosphate (ADP). *See* ADP (adenosine diphosphate)
Adenosine monophosphate (AMP), 162
Adenosine triphosphate (ATP). *See* ATP (adenosine triphosphate)
Adenoviruses, 715
Adhesion, 26, **26**, **761**
Adhesion proteins, 206–7
Adipocytes, **1000**–1001
Adipose tissue, 1000–1001
Adjacent cells. *See* Cell–cell attachments; Cell–cell gaps; Intercellular connections
ADP (adenosine diphosphate)
  in ATP synthesis, 81
  in glycolysis, 158*f*–59*f*, 160*f*
  in muscle contraction, 974–76
  phosphorylation of, in cellular respiration, 155–56
  photophosphorylation of, 186
  synthesis of ATP from, 128, 169–70
Adrenal glands, 994*f*, **995**–97, 1000
Adrenaline. *See* Epinephrine (adrenaline)
Adrenocorticotropic hormone (ACTH), **1004**
Adult mortality, endangered species, 1118
Adults, **651**
Adventitious roots, **734**–35, 807
Aerobic respiration, **171**, **542**
  anaerobic respiration vs., 170–71
  Cambrian explosion and, 519
  efficiency of, 171–72
  fermentation vs., 172–73
  in muscle contraction, 979–80
Afferent division, PNS, **942**
Aflatoxin, 298
Africa, human evolution out of, 707–8
African elephants, 392
African wild dogs, 1098
Agar, B:23
Age class, **1104**, 1115–16
Age pyramids, 1115–16
Age-specific fecundity, **1105**
Age structure, **1103**–4, 1115–16

Aguinaldo, Anna Marie, 638, 645

AIDS (acquired immune deficiency syndrome), 309, **712**–14, **1056**. *See also* HIV (human immunodeficiency virus)
Air
  animal locomotion in, 984
  animal olfaction (smell) and, 965–66
  behavior of oxygen and carbon dioxide in, 903–4
  circulation patterns of, 1065–66
  lichens and quality of, 631 (*see also* Atmosphere)
  nitrogen fixation from, 787–89
  plant essential nutrients from, 780*t*
  water potential in, 758–59
Alarm calling, prairie dog, 1095–97
Albino sea turtle, 465*f*
Albumen, **693**
Alcohol fermentation, **172**–73*f*
Alcohol use, 1033
Alcohols, 37*t*
Aldehydes, 37*t*, 73
Aldoses, 73
Aldosterone, **877**, **1003**
Alexander, R. McNeill, 984, 986
Algae
  blooms of, 555–56, 1148*f*, 1160
  brown, 7, 552*f*, 557, 568–69, 574
  green (*see* Green algae)
  in lichens, 623, 631
  photosynthesis in, 180–81*f*, 184, 190–91
  protist lineages of, 569, 572, 574
  red, 572
  rRNA sequences for, 7
Alkaline mucus, 1023*t*
Alkaline soil, 781–82
Alkalinity, pH scale of, 29
Allantois membrane, 694
All-cells-from-cells hypothesis, 3–5
All-taxa surveys, 1175
Alleles, **238**, **261**
  in central dogma of molecular biology, 308–9
  codominance and incomplete dominance of, 272, 273*f*
  female choice for good, 475–76
  foraging, 1085
  frequencies of, in populations, 465–71*f*
  genes and, 238, 239*f*, 247 (*see also* Genes)
  genetic bottlenecks and, 481–82
  genetic drift and, 479
  in human inheritance, 277–79
  linkage, crossing over, and recombination of, 270–71, 274*f*
  in Mendelian genetics, 258*t*, 277*t*
  multiple alleleism and, 271–72
  mutations and, 305, 313, 483–84, 486
  in particulate inheritance, 261–63
  plant pathogen resistance, 815
  wild-type, 267–69
Allergens, **1055**–56
Allergies, **1055**–56
Alligators, 703
Allolactose, 341
Allopatric speciation, **494**–95
Allopatry, **494**–95, 500
Allopolyploids, **498**–99
Allosteric regulation, **149**, **343**
Aloe vera, 739*f*
α-amylase, **809**
α-glucose, 74, 75*f*, 76
α-glycosidic linkages, 75*f*–76
α-helix (alpha helix), **48**–49
α-tubulin, 129
Alpine skypilots, 831
ALS (Lou Gehrig's disease), 408
Alternate leaves, 738*f*
Alternation of generations, **567**, **588**, **823**
  fungal, 625–26*f*
  in land plants, 588–89, 823–25
  in protists, 567–69
Alternative splicing, RNA, 357–**58**, 360–61, **400**
Altman, Sidney, 67–68
Altruism, **1095**–98
Alvarez, Luis and Walter, 521
Alveolata, 558*t*, 570, 573
Alveoli, 570, **909**, 910*f*
Amazon rain forest, 1168, 1179, 1180. *See also* Tropical wet forests
Ambisense RNA viruses, **716**
American chestnut trees, 815
American elm trees, 613
Amines, 37*t*
Amino acids, **42**. *See also* Proteins
  amphipathic proteins and, 94, 95*f*
  as animal nutrients, 883
  carbohydrates and, 78
  in central dogma of molecular biology, 308
  functional groups and, 38
  genetic code for, 310–12
  hormones as derivatives of, 995–96
  major, found in organisms, 43*t*
  in metabolic pathways, 157
  as neurotransmitters, 941*t*
  in one-gene, one-enzyme hypothesis on gene expression, 305–7
  Oparin–Haldane theory on chemical evolution of, 41–42
  in peptidoglycan, 76
  in point mutations, 313–14
  polymerization of, to form proteins, 44–47
  ribosomal polypeptide synthesis from, in translation, 328–31
  sequences of, in genetic homologies, 450–51
  sequences of, in protein primary structure, 47–48
  side chains (R-groups) of, 42–44
  specification of, in translation, 325–26
  structure of, 42
  transfer of, to proteins by tRNAs, 326–28
Aminoacyl tRNAs, 326–**27**, 328–31
Aminoacyl-tRNA synthetases, **327**, 328*f*
Amino functional group, 37*t*–38, 42, 46, 48–49*f*
Amino-terminus, 46, 328
Ammonia, **865**
  in archaea metabolism, 539*t*
  molecular structure of, B:12*f*
  in nitrogen fixation, 542–44, 787
  as nitrogenous waste, 865, 866*t*
  in origin-of-life experiments, 33–34
  simple molecules of, 23*f*, 24*f*
Amnion, **1032**
Amniotes, **689**
Amniotic eggs, **689**–91, 693–94
Amniotic fluid, 1032
Amoeba, as model organism, B:23–B:25
Amoebic dysentery, 555*t*
Amoeboid motion, **565**
Amoebozoa, 558*t*, 569, 570
AMP (adenosine monophosphate), 162
Amphibians, **696**
  fungal parasites of, 629
  hormones in metamorphosis of, 997–98
  impacts of global climate change on, 1167
  lineages of, 696, 700
  mechanoreception by lateral line system of, 958–59
Amphioxus, 686, 687
Amphipathic compounds, **87**, 87, 94, 95*f*
Amplification
  cell–cell signal, 211–12
  chemical signal, 1010
  sensory signal, 953
Ampullae of Lorenzini, **967**–68
Amylases, **81**, 895*t*
Amylopectin, 76
Amyloplasts, **804**
Amylose, 76
Anabolic pathways, **151**–52, 157–58. *See also* Catabolic pathways
Anadromous organisms, **697**
Anaerobic respiration, 170–**71**, **542**. *See also* Aerobic respiration; Fermentation
Analyze (Bloom's taxonomy skill), B:29*f*–B:30*t*
Anaphase, **225**–27, 245*f*
Anaphase I, 242*f*, 243–44, 245*f*
Anaphase II, 243*f*, 244
Anaphylactic shock, 1056
Anatomy, **843**. *See also* Animal form and function
Anatomy, levels of organization, 849*f*
Ancestral groups, phylogenetic trees and, B:10–B:11
Ancestral traits, 491–92, **506**–10, B:10–B:11. *See also* Common ancestry
Anchor roots, 734–35*f*
Anemones, 653–54, 887*f*
Anfinson, Christian, 52
Angiosperms, **581**. *See also* Plant(s); Seed plants
  adaptive radiation of, 517, 595–97*f*
  Anthophyta lineage of, 608–9*f*
  in Cenozoic era, 515
  characteristics of, 581
  diversification of, 582
  flowers in, 592–93, 595*f*
  form and function of, 732 (*see also* Plant form and function)
  fruits in, 594–95
  life cycle of, 824*f*–25
  molecular phylogeny of, 583
  parasitic, 789, 790*f*
  pollination in, 593–94, 608–9*f*
  reproduction in, 823 (*see also* Plant reproduction)
Anguilla, 481
Anhydrite, 522
Animal(s), **637**. *See also* Animal cells; Animal development; Animal form and function; Animal movement; Animal nutrition; Animal reproduction
  appearance of, in Paleozoic era, 515
  biological methods for studying, 637–38
  Cambrian explosion and adaptive radiation of, 518–20, 636–37
  carbohydrate hydrolysis by digestive enzymes in, 80–81
  cell–cell attachments in, 204–7
  chemical signals of, 992–93
  chitin as structural polysaccharide in, 76, 78
  cloning of, 409
  cytokinesis in, 228
  electrolytes of, 862
  endocrine systems and hormones of, 991–92, 993, 994*f*–95 (*see also* Hormones, animal)
  evolutionary innovations of, 637–46
  food sources and feeding strategies of, 646–49
  gap junctions in tissues of, 207–8
  gas exchange and circulation in, 902–3 (*see also* Circulatory systems; Respiratory systems)
  glycogen as storage polysaccharide in, 76
  as heterotrophs, 176
  immune systems of (*see* Immune systems)
  impact of global warming on, 1166–68
  key lineages of non-bilaterian, 652–54
  life cycles of, 651–52

Phylogenies, **6**, **107**, **506**. *See also* Phylogenetic trees
animal, 637*f*, 638, 639*f*, 640*f*
of animal locomotion, 986
annelid, 667*f*
cetacean, 452–53, 510–11*f*
chelicerate, 678*f*
chordate, 690*f*
crustacean, 677*f*
deuterostome, 682*f*
developing, of all living organisms from rRNA sequences, 6–8
domains in, 106–7
echinoderm, 684*f*
of emerging viruses, 724–25
endosymbiosis and, 561
estimation of, 506–8
eukaryote, 558, 559*f*
as evolutionary history, 107
of fungi, 618–19
green plant, 582–83, 586, 587*f*
of hearts, 920*f*
history of life and, 505–6 (*see also* History of life)
human, 707–8
of pollination, 831*f*
primate, 704*f*
prokaryotic, 535–36
protist, 558, 559*f*
protostome, 658–59*f*
taxonomy and, 8–9
vertebrate, 691
whale, 510–11*f*
Physical isolation, 494–95, 1144
Physical maps, **379**. *See also* Genetic maps
Physiology, **843**, 849*f*. *See also* Animal form and function
Physiology, levels of organization, 849*f*
Phytochromes, **801**–2
Phytophthora infestans, 554, 555*t*, 574
Phytoplankton, 556
Pigments, **796**
lateral gene transfer and, 485
lipids as, 87
in mice, 308, 309*f*
phototropins as, 796–97
phytochromes as, 801–2
prokaryotic, 541
in vacuoles, 115
Pigments, photosynthetic, **178**–84
Piloting, **1089**
Pineal eye, 999, 1000*f*
Pineal gland, **999**
Pines, 592, 607
Pinophyta (pines, spruces, firs), 607
Pioneering species, **1140**
Pitches, sound, **955**
Pith, **742**
Pits, **746**
Pituitary dwarfism, 369–74
Pituitary gland, **1004**
hormones of, 994*f*, 995–96, 999
hormones of, in menstrual cycle, 1027–30
hormones of, in puberty, 1026–27
pituitary dwarfism and, 369
regulation of hormone production by, 1004–6
Placenta, **424**, **694**, 915, **1017**, 1031–32
Placental mammals, **701**
Plankton, **556**, **1077**, **1136**
community structure of, 1136–37
ctenophores as, 653
green algae and, 598
impacts of global climate change on, 1167
in lakes and ponds, 1077
protists as, 556, 573
protostomes and, 665
Plant(s). *See also* Plant cells; Plant development; Plant form and function; Plant nutrition; Plant reproduction
as autotrophs, 176
Devonian explosion radiation of, 520
as green plants (*see* Green algae; Green plants)
impact of global warming on, 1166–68
mutualisms with, 1133
photosynthesis by (*see* Photosynthesis)
Plantae and, 558*t*, 569, 572
sensory systems of (*see* Sensory systems, plant)
survivorship curves for, 1105
sympatric speciation by polyploidy in, 497–99
transgenic (*see* Transgenic plants)
types of (*see* Angiosperms; Gymnosperms; Land plants; Seed plants)
water absorption and loss in, 754–55, 765–66
Plantae, 558*t*, **569**, 572
Plant cells. *See also* Eukaryotic cells
animal cells vs., 110*f*, 742–43
cellulose as structural polysaccharide in, 72*f*, 76, 78
cell walls in, 201–2
cultures of, B:21–B:22 (*see also* Cultures, cell and tissue)
cytokinesis in, 228
cytoplasmic streaming in, 129
development processes of, 406–8
differentiation and de-differentiation of, 438
glyoxysomes and peroxisomes in, 115
middle lamella in cell–cell attachments of, 204
plasmodesmata in, 208–9
signal transduction in, 794–95
starch as storage polysaccharide in, 72*f*, 76
stem cells, 407
in tissue systems (*see* Tissue systems, plant)
vacuoles in, 114–15
Plant development, 432–43
animal development vs., 432–33, 438
embryogenesis in, 433–36
reproductive development in, 438–41
stages of, 433*f*
vegetative development in, 436–38
Plant form and function, 731–53
brassinosteroids in body size, 812
flowers, 826–29
indeterminate growth in angiosperm, 731–32
leaves in, 737–40
primary growth in, 740–42
primary plant body cells and tissues, 742–48*t*
root systems in, 733–35
secondary growth in, 748–51
shoot systems in, 735–37
surface area/volume relationships in, 732–33
Plant nutrition, 775–92
adaptations for, 789–90
nitrogen fixation and, 787–89
nutrient requirements for, 774–78, 780*t*
nutrient uptake and, 782–87
soil and, 778–82
starch in, 76
translocation (sugar transport) in, 766–72
water and sugar transport in, 754–55 (*see also* Translocation; Water transport, plant)
water transport in, 759–66
Plant reproduction, 586–95, 822–41
alternation of generations in, 588–89
asexual, 825–26
embryophyte retention of offspring in, 587–88
in energy flow, 1149
evolution from gametophyte-dominant to sporophyte-dominant life cycles in, 589–90
fertilization in, 832–33

Plant reproduction (*continued*)
flowers as reproductive structures of, 592–93, 826–29
fruits in, 594–95
heterospory in, 590, 591*f*, 592*f*
importance of, 822–23
plant life cycle and, 823–25
pollen in, 590–91
pollination in, 593–94, 608–9*f*, 830–32
seeds in, 591–92, 833–37
sexual, 586–87, 823
Plasma, **912**
Plasma cells, **1050**–51, 1054*t*
Plasma membranes, **84**–103
artificial, 88–89
carbohydrates in cell identity functions of, 78–80
cell walls and, 116
in characteristics of domains of life, 529*t*
crossing of, by hormones, 996
in cytokinesis, 228
diffusion and osmosis across, 91–94
electron transport chain and ATP synthase in, 171
eukaryotic, 117*t*
excitable, 934
exocytosis and, 126
extracellular layers and, 201
fluidity of, 90, 91*f*
importance of, to cells, 84–85, 100–101
lipids and, 85–91, 529 (*see also* Lipid bilayers)
lipid-soluble vs. lipid-insoluble hormones and, 209
membrane proteins and fluid-mosaic model for, 94–101
movement of electrolytes and water across, 864–65
nuclear envelope and, 561–62
plant passive exclusion at, 785
in polyspermy prevention, 422–23
prokaryotic, 109, 536–38
selective permeability of (*see* Selective permeability, plasma membrane)
smooth ER and, 114
transport of solutes across, in plants, 769–71
Plasmids, **108**, **370**
in DNA cloning, 370
in genetic engineering, 380*t*
inserting genes into, 370, 371*f*
introducing recombinant, into bacterial cells for transformation, 372
lateral gene transfer and, 395
origin of viruses in, 723
prokaryotic, 108
prokaryotic vs. eukaryotic, 110*f*
in transgenic plant development, 385–86
Plasmodesmata, **208**–9, **600**, **743**, **806**
Plasmodial slime molds, 570
Plasmodium, 554–55, 573, 1132
Plasmogamy, **624**–26*f*
Plastocyanin, **187**–88
Plastoquinone (PQ), **185**–88
Platelets, **912**, **1040**–41*f*
Platyhelminthes, 638*t*, 666
Platypuses, 392, 700
Pleiotropic genes, **272**–73, 277*t*, 461–62
Ploidy, 238–**39**, 240*t*, 241–42
Pneumatophore roots, 734–35*f*
Point mutations, 483
types of, **313**–14
Poisons. *See* Toxins
Polar bears, 1166*t*, 1167
Polar bodies, **1017**
Polar climate, 1066, 1165
Polar covalent bonds, **21**–23*f*
Polar microtubules, **224**
Polar nuclei, **828**
Polar transport, auxin, **807**
Polarity, 21–23*f*, 25, 43*f*, 44, B:13
Polio virus, 727, 1055
Pollen grains, **591**, **829**
fossilized, 512*f*
germination of, 832
in plant reproduction, 433*f*, 590–91
seed plants and, 599
stamens and production of, 827, 828–29
Pollen tube, **832**
Pollination, **593**, **830**
of angiosperms, 593–94, 608–9*f*
animal speciation and, 831–32
as ecosystem supporting service, 1188
evolution of, 830–31
fertilization after, 832–33
flower petals and, 826–27
photoreception of UV light in, 964
phylogenetic tree of, 831*f*
in plant development, 433
self-fertilization vs. cross-fertilization in, 258 (*see also* Crosses; Self-fertilization)
selfing vs. outcrossing in, 830
syndromes, 830
Pollination syndromes, **594**, **830**, 831*f*
Pollinators, 593–94, 608–9*f*, 831–32
Pollution
biomagnification of pollutants in, 1152–53
bioremediation of, using fungi, 632
bioremediation of, using prokaryotes, 533
ecology and, 1059–61
nitrogen, 1160
nutrient, 1148*f*
prokaryotes and nitrate, 543–44
soil, 785–87
as threat to biodiversity, 1178, 1181*t*, 1182
Polychaetes, 667
Polygenic inheritance, 275–**76**, 277*t*, 458–59*f*
Polymerase chain reaction (PCR), **374**
amplification of fossil DNA with, 376
in DNA fingerprinting, 397–98*f*
extremophiles and, 531
in genetic engineering, 381*t*
in next-generation sequencing technologies, 378
requirements of, 374–76
uses of, in genetic testing, 382
Polymerases. *See* DNA polymerases; RNA polymerase
Polymerization, **44**
of amino acids to form proteins, 44–47
chemical evolution and, 78
of monosaccharides to form polysaccharides, 75–76
of nucleotides to form nucleic acids, 59–61
in origin-of-life experiments, 68–69
Polymers, **44**. *See also* Polymerization
polysaccharides as, 72, 75–78
proteins as, 44–47
Polymorphic genetic markers, **379**
Polymorphic species, **491**
Polymorphic traits, **272**, 277*t*, 485
Polypeptides, **46**. *See also* Proteins
as hormones, 995–96, 999
peptide bonds in formation of proteins and, 45–46
synthesis of, by ribosomes, 119
synthesis of, in translation, 324–26, 328–31 (*see also* Translation)
Polyphenylalanine, 311
Polyphyletic groups, 508*t*
Polyplacophorans, 669
Polyploid organisms, **239**, 240*t*
Polyploidy, 314, **497**–99
Polyps, **653**–54
Polyribosomes, 324*f*–**25**
Polysaccharides, **72**–73, 75–81, 117, 202–3
Poly(A) signal, **320**
Poly(A) tail, mRNA, **323**–24
Polyspermy prevention, 421–23
Polytomy, 506*t*, **618**, B:10
Polyunsaturated fats, 85, 86
Ponds, **1077**
Population(s), **5**, **446**, **466**, **1061**, **1102**
analyzing changes in frequencies of alleles in, 466–70
conservation of, 1189–91
contemporary evolution of, 449
contemporary speciation in, 451
evolution of, by natural selection, 2, 5–6, 444, 446, 459 (*see also* Evolution; Natural selection)
genetic diversity of, 1173–74
genetic drift in, 478, 479, 480*f*, 481–82
genetic variation in, 472, 475*t*
growth of (*see* Population growth)
Hardy–Weinberg principle and, 466
human (*see* Human population)
monophyletic, 491–92
in phylogenetic trees, B:10–B:11
population ecology and, 1060*t*, 1061, 1102 (*see also* Population ecology)
population viability analysis for, 1182, 1190
size and structure of (*see* Demography)
speciation in, 494–502
Population cycles, 1113–15
Population density, 216, 1015, **1102**–3, 1108–12
Population dynamics, **1112**–15
Population ecology, **1102**. *See also* Population(s)
in conservation of biodiversity, 1118–20
demography in, 1103–7
geographic distribution and abundance of species in, 1102–3
human population growth in, 1115–18
population dynamics in, 1112–15
population growth in, 1107–12
populations and, 1060*t*, 1061, 1101–2
Population growth, 1106*f*, 1107–12, 1118, 1119*f*
Population pyramids, 1115–16
Population thinking, **446**
Population viability analysis (PVA), 1182, 1190
Pore-like proteins, 98
Pores, **584**–85, **744**
Porifera, 638–41, 652
Positive control, **341**, 344, 345*f*
Positive feedback, **935**, 1164–66
Positive pressure ventilation, **909**
Positive-sense single-stranded RNA viruses, **716**, 727
Post-anal tails, 686
Posterior body axis, **410**
Posterior pituitary, **1004**, 1005–6
Postsynaptic neurons, **939**
Postsynaptic potentials, 940–42
Post-transcriptional control, bacterial, 360–61
Post-transcriptional control, eukaryotic, 356–61
Post-translational control, **337**–38*f*
Post-translational modification, 360, 361*t*
Postzygotic isolation, **490**, 491*t*, 499–500
Potassium
channels for, 98, 931, 934, 935
electrolytes as, 862
as human nutrient, 885*t*
as plant nutrient, 777
potassium leak channels, 931
Potatoes, 554, 555*t*, 574, 815
Potential energy, **31**, **137**
aerobic respiration and, 171
in ATP, 143–44, 154–55
in chemical reactions, 31–32, 137–39
phosphate functional group and, 60
in storage polysaccharides, 80
water potential and, 755
Prairie dogs, 1095–97
Prairies, 1071, 1191
Prebiotic soup, 57–61, 68–69, 93–94
Prebiotic soup model, chemical evolution, **33**–35, 41–42, 44–45, 55
Precambrian, **513**–14
Precipitation
global climate change and, 1073, 1163, 1166
in global water cycle, 1159
rain shadows and, 1066–67
in terrestrial biomes, 1068–72
in tropical wet forests, 1065–66
Precision
accuracy vs., B:2–B:3
standard error and, B:7
Predation, **1128**. *See also* Predators
in animal diversification, 646
by ascomycete fungi, 632
deceitful communication and, 1094–95
efficiency of animal, 1130–31
foraging and, 1086–87
by keystone species, 1137–38
lateral line system in fishes and, 958–59
in population cycles, 1114–15
as threat to biodiversity, 1178
top-down control in, and trophic cascades, 1153, 1154*f*
in triggering of Cambrian explosion, 519–20
Predators, **647**. *See also* Predation
animals as, 647–48
deuterostomes as, 681*f*
echinoderm, 685
noxious compounds in vacuoles and, 115
predator-removal programs and, 1130–31
sharks as, 698
top-down control by, and trophic cascades, 1153, 1154*f*
Predictability, community structure, 1135–37
Predictions, **3**
biodiversity, 1182–84
experimental design and, 13

Boldface page numbers indicate a glossary entry; page numbers followed by an *f* indicate a figure; those followed by *t* indicate a table.

hypothesis testing and, 3–5, 10–11
inheritance hypotheses and, 257
Punnett squares and, for segregation principle, 262–63
testcrosses and, for independent assortment principle, 265–66
Prefixes, metric system, B:2*t*
Pregnancy, animal, 1017, 1029–34
Pre-mRNA, **321**
Preservation, fossil, 512
Pressure, 138. *See also* Mechanoreception

Ribosomal RNAs (rRNAs), **119**, **328**
  developing tree of life from sequences of, 6–8
  in gene families, 398
  phylogenies based on, 535–36
  in ribosomes, 328, 330
Ribosome binding sites, **329**–30
Ribosomes, **108**, **324**
  in cracking of genetic code, 311
  elongation of polypeptides during translation in, 330–31
  eukaryotic, 112, 113
  initiation of translation in, 329–30
  mitochondria and, 115–16
  polypeptide synthesis by, 119
  post-translational modifications of proteins in, 331–32
  prokaryotic, 108
  protein synthesis by free, 123–24
  ribosomal RNA and structure of, 328–29*f*

Ribosomes (*continued*)
as ribozymes, 330–31
structure and function of, 117*t*
termination of translation in, 331, 332*f*
in translation, 323–25, 328–32
in translocation of mRNA, 331
Ribozymes, **67**–69, 330–31
Ribulose bisphosphate (RuBP), **191**–92
Rice, 368*f*, 385, 392. *See also* Golden rice
Rickets, vitamin D–resistant, 279
Rieseberg, Loren, 501–2
Rifampin, 455–56
Ring structures, 74, 181*f*
Rings, tree growth, 751
Ripening, fruit, 812–13*f*
Ripple, William, 1153
Rivers, 1078, 1155
RNA (ribonucleic acid), **58**, 65–69. *See also* DNA (deoxyribonucleic acid); Messenger RNAs (mRNAs); Nucleic acids; Ribosomal RNAs (rRNAs); Transfer RNAs (tRNAs)
as catalytic molecule, 67–68
in central dogma of molecular biology, 308–9
codons in synthesis of, 311
components of, 58–59
directionality of strands of, 59–60
discovery of variety of types of, 309
DNA structure vs. structure of, 66*t*
in DNA synthesis, 292–94*t*, 295–97
electron micrograph of, 317*f*
as first self-replicating molecule, 68–69
gel electrophoresis of, B:13–B:14
genes and, 220
in genetic code, 310–12
genetic homologies and, 450–51
as genetic information-containing molecule, 67
as intermediary between genes and proteins in gene expression, 307–8
metabolic pathways and, 157
nucleolus and eukaryotic, 112
polymerization of ribonucleotides to form, 59–61
ribonuclease enzyme and, 52
RNA world hypothesis on, as first self-replicating molecule, 57–58
structure of, 65–66
sugar-phosphate backbone of, 60*f*
synthesis of, 67, 119–20
versatility of, 66–67
visualizing, B:15–B:16
RNA-induced silencing complex (RISC), 359
RNA interference, **358**–59, 361*t*
RNA polymerase, **292**, **307**, **318**
chromatin remodeling and, 349
in DNA synthesis, 292
in eukaryotic transcription initiation, 356, 357*f*
in recombinant DNA technology, 373–74
in RNA interference, 359
in RNA processing, 325*t*
in RNA synthesis, 307–8, 318–20
RNA processing, **324**, **349**
bacterial vs. eukaryotic, 361*t*
eukaryotic, 321–24, 325*t*, 356–59
RNA replicases, **719**–20
RNA reverse-transcribing viruses. *See* Retroviruses
RNA splicing, 322–23
RNA transcripts, 390
RNA viruses, 715–16, 719–20, 726*f*, 727–28
