Although different species consume a wide variety of foods, all animals require the same fundamental organic molecules (**Table 45.1**; see also Chapter 3 for a discussion of the chemical nature of organic molecules). Ingested organic molecules are used for two general purposes: to provide energy and to make new molecules. Carbohydrates supply energy-yielding glucose and the carbon required for building organic molecules. Proteins supply amino acids that, in addition to building new protein, can also be used as an energy source. Lipids supply components for membrane-building and thermal insulation and also provide energy. Nucleic acids supply some of the components required for DNA, RNA, and ATP synthesis. The other category of organic nutrients—vitamins—are required in small quantities and function as coenzymes in various reactions.

As described in Chapter 6, the bonds of organic molecules may be broken down to release energy; this energy can be used in the synthesis of ATP, a primary energy source of all cells. Indirectly, therefore, organic molecules provide the energy required for most of the chemical reactions that occur in animals' bodies. Alternatively, organic molecules serve as building blocks to synthesize new cellular molecules. For example, all animals that have muscles use amino acids obtained from food to make the specialized proteins that allow their muscle fibers to shorten.

Essential Nutrients Must Be Obtained from the Diet

Animal cells can synthesize many organic molecules, but certain compounds cannot be synthesized from any ingested or stored precursor molecule. These **essential nutrients** must be obtained in the diet in their complete form. The word essential in this context refers to the fact that these nutrients must come from food. It does not mean that other nutrients are less important, because many synthesized nutrients are required for an animal's survival. The essential nutrients can be classified into four groups: essential amino acids, essential fatty acids, vitamins, and minerals.

Essential Amino Acids Nine **essential amino acids** are required in the diet of humans and many but not all other animals—isoleucine, leucine, lysine, methionine, phenylalanine, histidine, threonine, tryptophan, and valine. These amino acids are required for building proteins but cannot be synthesized by the animal's cells, unlike the other 11 amino acids that also make up proteins. Also, animal cells do not store amino acids. Therefore, without a recurring supply of these nine amino acids, protein synthesis in each cell in an animal's body would

Table 45.1 Major Nutrients in Animals, Their Dietary Sources, and Some of Their Functions and Symptoms of Deficiency in Vertebrates

Class of nutrient	Dietary sources	Functions in vertebrates	Symptoms of deficiency in humans
Carbohydrates	All food sources, especially starchy plants	Energy source; component of some proteins; source of carbon	Muscle weakness; weight loss
Proteins	All food sources, especially meat, legumes, cereals, roots	Provide amino acids to make new proteins; build muscle; some amino acids used as energy source	Weight loss; muscle loss; weakness; weakened immune system; increased likelihood of infections
Lipids	All food sources, especially fatty meats, dairy products, plant oils	Major component of cell membranes; energy source; thermal insulator; building blocks of some hormones	Hair loss; dry skin; weight loss; hormonal and reproductive disorders
Nucleic acids	All food sources	Provide sugars, bases and phosphates that can be used to make DNA, RNA, and ATP	None; components of nucleic acids can be synthesized by cells from amino acids and sugars

slow down or stop completely. Carnivores and omnivores readily obtain all of the essential amino acids, because meat (animal muscle) contains all 20 amino acids. Unlike animal meat, most plants do not contain every essential amino acid in sufficient quantities to supply a human's nutritive requirements. Therefore, people who follow a strict vegetarian diet must find ways to balance the protein content of the plant matter they eat. By contrast, some herbivores, such as cows, have evolved the capacity to synthesize the essential amino acids, which allows them to subsist entirely on a diet of plants.

Essential Fatty Acids The **essential fatty acids** are certain unsaturated fatty acids, such as linoleic acid (see Figure 3.9), that cannot be synthesized by animal cells. Linoleic acid is vital to an animal's health because it is converted in cells to another fatty acid, called arachidonic acid. This fatty acid is the precursor required for production of several compounds that are important in many aspects of animal physiology; such compounds include the prostaglandins, which function in pain, blood clotting, and smooth muscle contraction. Some animals—such as felines—cannot synthesize arachidonic acid from linoleic acid, so arachidonic acid is an essential fatty acid in those species. Unsaturated fatty acids are found primarily in plants, which provide a dietary source of essential fatty acids for both herbivores and omnivores. Strict carnivores such as felines, however, obtain their essential fatty acids from fishes or from the adipose (fat) tissue of birds and mammals.

Vitamins **Vitamins** are important organic nutrients that serve as coenzymes for many metabolic and biosynthetic reactions. The two categories of vitamins are water-soluble and fat-soluble. Water-soluble vitamins, such as vitamin C, are not stored in the body and must be regularly ingested. Fat-soluble vitamins, such as vitamin A, are stored to some degree in adipose tissue. Not all animals require the same vitamins in their diet, however. Among vertebrates, for example, only primates and guinea pigs cannot synthesize their own vitamin C and must therefore consume it in the diet. **Table 45.2** summarizes the vitamins, their dietary sources, some of their important functions, and some health consequences associated with their deficiencies in humans.

Minerals **Minerals** are inorganic ions required by animals for normal functioning of cells. Minerals such as iron and zinc are required as cofactors or constituents of some enzymes and other proteins. Other minerals such as calcium are required for bone, muscle, and nervous system function, and still others—notably sodium and potassium—contribute to changes in electrical differences across plasma membranes and therefore are especially critical for heart, skeletal muscle, and neuronal activity. **Table 45.3** summarizes some of the most important minerals and their functions. Many minerals are required in only trace amounts, far less than 1 mg/day in a relatively large mammal such as a human. Nonetheless, without regular consumption of these small amounts, serious health problems arise.

Regardless of the type of food consumed by an animal, the useful parts of the material that is eaten must in many cases be digested into molecules that the animal's cells can absorb. Next, we will consider how animals digest their food and absorb the nutrients.

45.2 General Principles of Digestion and Absorption of Food

Learning Outcomes:

1. Compare the processes of intracellular and extracellular digestion, and explain why one is far more common than the other.
2. **SciSKILLS** » Make predictions about the function of parts of the alimentary canal based on their structural adaptations.
3. Distinguish between passive and active absorption of food.

Once food has been ingested, some of the nutrients from the food must be broken down (digested) so that they can be absorbed by the cells of the digestive tract. In this section, we will examine some of the major principles of digestion and absorption in animals, beginning with where digestion takes place.

Digestion Usually Occurs Extracellularly

Food is digested either inside cells (intracellularly) or, more commonly, outside cells (extracellularly). Intracellular digestion occurs only in some very simple invertebrates such as sponges and single-celled organisms and to a limited extent in cnidarians. It involves using

Table 45.2 Vitamins Required by Animals

Class of nutrient	Dietary sources	Functions in vertebrates	Symptoms of deficiency in humans
Water-soluble vitamins			
Biotin	Liver; legumes; soybeans; eggs; nuts; mushrooms; some green vegetables	Coenzyme for gluconeogenesis and fatty acid and amino acid metabolism	Skin rash; nausea; loss of appetite; mental disorders (depression or hallucinations)
Folic acid	Green vegetables; nuts; legumes; whole grains; organ meats (especially liver; kidney; heart)	Coenzyme required for synthesis of nucleic acids	Anemia (a lower than normal number of red blood cells in the blood); depression; birth defects
Niacin	Legumes; nuts; milk; eggs; meat	Involved in many oxidation-reduction reactions	Skin rashes; diarrhea; mental confusion; memory loss
Pantothenic acid	Nearly all foods	Part of coenzyme A, which is involved in numerous synthetic reactions, including formation of cholesterol	Burning sensation in hands and feet; GI symptoms; depression
Vitamin B_1 (thiamine)	Meats; legumes; whole grains	Coenzyme involved in metabolism of sugars and some amino acids	Beriberi (muscular weakness, anemia, heart problems, loss of weight)
Vitamin B_2 (riboflavin)	Dairy foods; meats; organ meats; cereals; some vegetables	Respiratory coenzyme; required for metabolism of fats, carbohydrates, and proteins	Seborrhea (excessive oil secretion from skin glands resulting in skin lesions)
Vitamin B_6 (pyridoxine)	Meats; liver; fish; nuts; whole grains; legumes	Coenzyme for over 100 enzymes that participate in amino acid metabolism, lipid metabolism, and heme synthesis	Seborrhea; nerve disorders; depression; confusion; muscle spasms
Vitamin B_{12}	Meats; liver; eggs; some shellfish; dairy foods	Required for red blood cell formation	Anemia; nervous system disorders leading to sensory problems; balance and gait problems; loss of bladder and bowel control
Vitamin C (ascorbic acid)	Citrus fruits; green vegetables; tomatoes; potatoes	Antioxidant and free radical scavenger; aids in iron absorption; helps maintain healthy connective tissue and gums	Scurvy (connective tissue disease associated with skin lesions, weakness, poor wound healing, tooth decay); bleeding gums
Fat-soluble vitamins			
Vitamin A (retinol)	Liver; green and yellow vegetables; some fruits in small amounts	Component of visual pigments; regulatory molecule affecting transcription; important for reproduction and immunity	Night blindness due to loss of visual ability; skin lesions; impaired immunity
Vitamin D	Fish oils; fish; egg yolk; liver; synthesized in skin via sunlight	Required for calcium and phosphorus absorption from intestine; bone growth	Rickets (weakened, deformed bones) in children; osteomalacia (weak bones) in adults
Vitamin E	Meats; vegetable oils; grains; nuts; seeds; small amounts in some fruits and vegetables	Antioxidant; inhibits prostaglandin synthesis	Unknown, possibly skeletal muscle atrophy; peripheral nerve disorders
Vitamin K	Legumes; green vegetables; some fruits; some vegetable oils (olive oil, soybean oil); liver; synthesized by hindgut bacteria	Component of blood-clotting mechanism	Reduced blood clotting ability

phagocytosis to bring food particles directly into a cell, where the food is segregated from the rest of the cytoplasm in food vacuoles. Once inside these vacuoles, hydrolytic enzymes digest the food into monomers (the building blocks of polymers), which then are moved out of the vacuole to be used directly by that cell. Intracellular digestion cannot support the metabolic demands of an active animal for long, because only tiny bits of food can be phagocytosed at one time. It also does not provide a mechanism for storing large quantities of food so that an animal can digest it slowly while going about its other activities.

Most animals digest food via extracellular digestion in a cavity of some sort. Extracellular digestion protects the interior of the cells from the actions of hydrolytic enzymes and allows animals to consume large prey or large pieces of vegetation. Food enters the digestive cavity, where it is stored, slowly digested, and absorbed gradually over long periods of time, ranging from hours (for example, after a human eats a pizza) to weeks (after a python eats a gazelle).

In the simplest form of extracellular digestion—seen in invertebrates such as flatworms and cnidarians—the digestive cavity has one opening that serves as both an entry and an exit port (**Figure 45.2**). The digestive cavity of these animals is called a **gastrovascular cavity**, because not only does digestion occur within it, but fluid movements in the cavity also serve as a circulatory—or

Table 45.3 Minerals Required by Animals

Mineral	Dietary sources	Functions in vertebrates	Symptoms of deficiency in humans
Calcium (Ca)	Dairy products; cereals; legumes; whole grains; green leafy vegetables; bones (eaten by some animals)	Bone and tooth formation; exocytosis of stored secretions in nerves and other cells; muscle contraction; blood clotting	Muscular disorders; loss of bone; reduced growth in children
Chlorine (Cl)	Meats; dairy foods; blood; natural deposits of salt	Participates in electrical, acid-base, and osmotic balance across cell membranes, notably neurons and heart cells	Muscular and nerve disorders
Chromium (Cr)	Liver; seafood; some nuts; meats; mushrooms; some vegetables	Required for proper glucose metabolism, possibly by aiding the action of the hormone insulin	Disorders of lipid and glucose balance in blood
Copper (Cu)	Fish; shellfish; nuts; legumes; liver; and other organs	Required for hemoglobin production and melanin synthesis; required for connective tissue formation; serves as oxygen-binding component in some invertebrates	Anemia; bone changes
Iodine (I)	Seaweed; seafood; milk; iodized salt	Required for formation of thyroid hormones	Inability to make thyroid hormones, resulting in enlarged thyroid gland
Iron (Fe)	Liver and other organs; some meats; eggs; legumes; leafy green vegetables	Oxygen-binding component of hemoglobin; cofactor in some enzymes	Anemia
Magnesium (Mg)	Hay; grasses; whole grains; green leafy vegetables	Cofactor for many enzymes that use ATP as a substrate	Changes in nervous system function
Manganese (Mn) and molybdenum (Mo)	Nuts; whole grains; legumes; vegetables; liver	Cofactors for many enzymes	Poor growth; abnormal skeletal formation; nervous system disorders (convulsions)
Phosphorus (P)	Dairy foods; grains; legumes; nuts; meats	Bone and tooth formation; component of DNA, RNA, and ATP	Bone loss; muscle weakness
Potassium (K)	Meats; fruits; vegetables; dairy foods; grains	Participates in electrical, acid-base, and osmotic balance across cell membranes, notably neurons and heart cells	Muscle weakness; serious heart irregularities; GI symptoms
Selenium (Se)	Seafood; eggs; chicken; soybeans; grains	Antioxidant; cofactor for some enzymes	Keshan disease (damage to and loss of heart muscle)
Sulfur (S)	Proteins from any source	Component of two amino acids (methionine and cysteine)	Inability to synthesize many proteins
Sodium (Na)	Many fruits; vegetables; meats; and natural salt deposits	Participates in electrical, acid-base, and osmotic balance across cell membranes, notably neurons and heart cells	Muscle cramps; changes in nerve activities
Zinc (Zn)	Widely found in meats; fish; shellfish (oysters); grains	Many functions related to tissue repair; sperm development; cofactor for many metabolic enzymes; required for certain transcription factors to bind to DNA	Stunted growth; loss of certain sensations like taste; impaired immune function; skin lesions

vascular—system to distribute digested nutrients throughout the animal's body. Food within a gastrovascular cavity is partially digested by enzymes that are secreted into the cavity by the cells lining the cavity. As the food particles become small enough, they are phagocytosed by the lining cells and further digested intracellularly. Undigested material that remains in the gastrovascular cavity is expelled.

Most Digestive Cavities Are Alimentary Canals with Specialized Regions and Openings at Opposite Ends

In contrast to the gastrovascular cavities of simple invertebrates, all other animals possess digestive systems that consist of a single elongated tube, or alimentary canal, with an opening at both ends through which food passes from one end to the other. Along its length, the tube usually contains smooth muscle. When the muscle contracts, it helps churn up the ingested food so that it is mechanically broken into smaller fragments. The canal is lined on its interior surface by a layer of epithelial cells. These cells synthesize and secrete digestive enzymes and other factors into the hollow cavity (or lumen, as such cavities are called) of the alimentary canal, and they secrete certain hormones into the blood that help regulate digestive processes. The cells are also involved with transporting digested material out of the canal.

Along its length, an alimentary canal has several specialized regions that vary according to species. Because of these specializations, digestive processes requiring acidic conditions can be segregated from those requiring higher pH, and undigested food can be stored in one region while digestion continues in another area. The ability of some animals to store food in the stomach, for example, allows them to eat less frequently, leaving time for other activities.

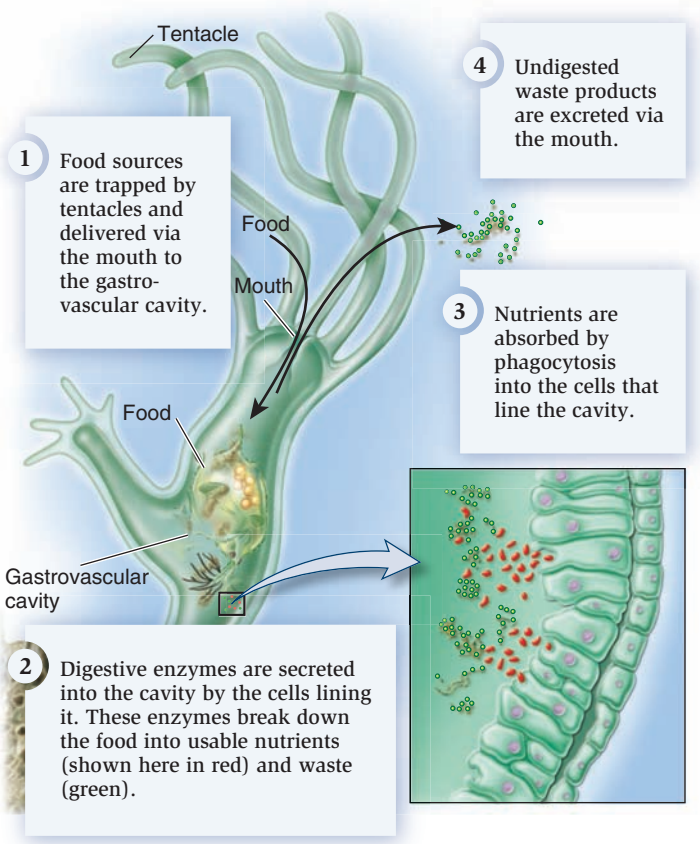

Figure 45.2 Extracellular digestion in a gastrovascular cavity. In animals with gastrovascular cavities, such as the cnidarian *Hydra* illustrated here, digestion occurs extracellularly within the cavity.

Absorption of Food May Be Passive or Active

Once food is digested, the nutrients must be absorbed by the epithelial cells that line specialized portions of the alimentary canal. This occurs in different ways, either by simple or facilitated diffusion or by active transport. Small, hydrophobic molecules such as fatty acids diffuse down concentration gradients across the epithelium. Ions and other molecules are transported by facilitated diffusion or active transport. Minerals are ions and therefore, like all polar substances, do not readily cross plasma membranes. Instead, they are usually actively transported across the membranes of the epithelial cells of the canal by ATP-driven ion pumps. In other cases, small, hydrophilic organic nutrients are transported by secondary active transport, usually with Na^+.

After nutrients enter the epithelial cells of the alimentary canal, the cells use some of the nutrients for their own requirements. Most of the nutrients, however, are transported across the basolateral surface of the epithelial cells (the side opposite the lumen), where they can enter into nearby blood or lymph vessels and circulate to the other cells of the body. Thus, nutrients enter the alimentary canal in food, are digested within the canal into monomers or other small fragments that can be transported into epithelial cells, and from there are released into the blood, where they can reach all of the body's cells. In the special case of water, osmotic gradients established by the transport of ions and other nutrients out of the epithelial cells draw water by osmosis from the canal, across the epithelial cells, and from there into the blood.

The mechanisms that activate and control the digestive and absorptive functions of the alimentary canal have been extensively studied in vertebrates and have great importance for human health. In the rest of this chapter, we will explore the structure and function of the digestive systems of vertebrates.

45.3 Overview of Vertebrate Digestive Systems

Learning Outcomes:

1. Describe the general structure of the vertebrate digestive system.
2. Describe how food moves through regions of the alimentary canal, and explain how each part contributes to the processes of digestion and absorption.
3. **SciSKILLS** » Predict problems that might arise if saliva or acid could not be secreted into the mouth or stomach, respectively.
4. Outline how microorganisms can help digest cellulose in ruminants and other herbivores.

The vertebrate **digestive system** consists of the alimentary canal—also known as the gastrointestinal (or GI) tract—plus several accessory glands and organs (**Figure 45.3**). As illustrated in Figure 45.3, the human alimentary canal consists of the oral cavity (mouth), pharynx, esophagus, stomach, small and large intestines, and anus. The accessory structures, not all of which are found in all vertebrates, are the tongue, teeth, salivary glands, liver, gallbladder, and pancreas. The differences between the digestive systems of various vertebrates reveal much about their respective diets. In this section, we will look at a few of the most important differences as we discuss the form and function of each part of the vertebrate digestive system.

The Vertebrate Alimentary Canal is Divided into Functional Regions

The alimentary canal is one continuous tube that changes in appearance and function along its length, with three general sections. The first section, at the anterior end, functions primarily in the ingestion of food. It contains the mouth (with its accessory organs, the salivary glands), pharynx (throat), and esophagus. The middle section, which functions in the storage and initial digestion of food, contains one or more food storage or digestive organs, including the crop, gizzard, and stomach, depending on the species. This section also contains the upper part of the small intestine—where most of the digestion and absorption of food takes place—and accessory structures that connect with the intestine, including the pancreas, liver, and gallbladder. The third section, the posterior part of the canal, functions in final digestion and absorption and the elimination of nondigestible wastes. It consists of the remainder of the small intestine, and in most vertebrates other than fishes, a large intestine. Undigested material is defecated through an opening called an anus, or in many amphibians, reptiles, and birds, a cloaca (a common opening for the digestive and urogenital tracts).

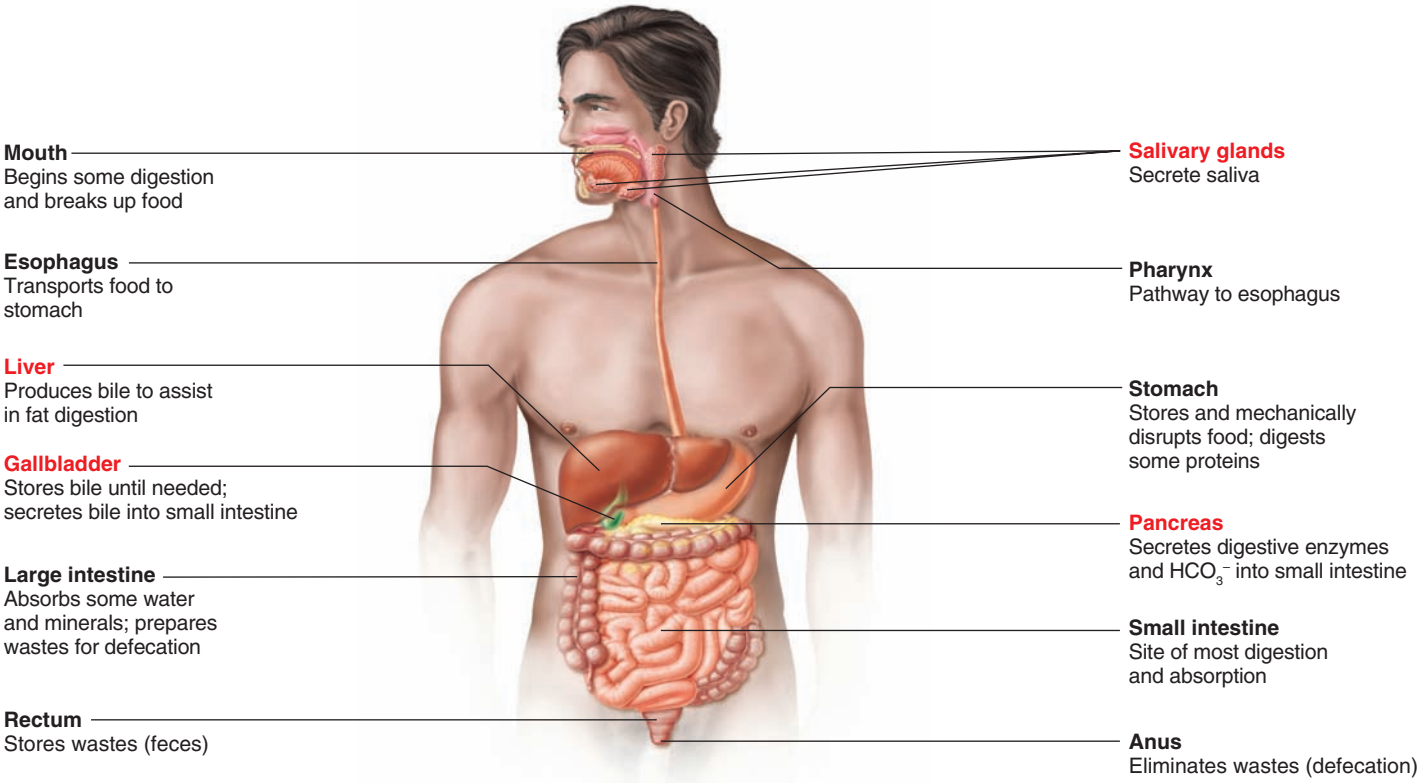

Figure 45.3 A vertebrate digestive system, as shown in the human. This figure shows the organs of the gastrointestinal tract (labeled in black) and the major accessory structures (labeled in red). Not all vertebrates share identical features of the digestive system; for example, some fishes lack a stomach, and many birds and some mammals lack a gallbladder.

From the midpoint of the esophagus to the anus or cloaca, the GI tract has the same general structure, with a lumen that is lined by a layer of epithelial and glandular cells. Included in the epithelial layer are secretory cells that release a protective coating of mucus into the lumen of the tract, and for this reason this layer of cells is also referred to as the mucosa. Other cells in the mucosal layer release hormones into the blood in response to the presence of food. Passing through the mucosal layer are ducts from secretory glands that release acid, enzymes, water, and ions into the lumen. From the stomach onward, the epithelial cells are linked along the edges of their apical surfaces by tight junctions that prevent digestive enzymes and undigested food from moving between the cells and out of the alimentary canal. In some places, such as the small intestine, the apical surface is highly convoluted, a feature that increases the surface area available for digestion and absorption.

The epithelial cell layer is surrounded by layers of tissue made of smooth muscles, neurons, connective tissue, and blood vessels. The neurons are activated by nerves coming from the central nervous system that respond to the sight and smell of food. The neurons of the alimentary canal are also activated directly by the presence of food in the tract. Contraction of the muscles is controlled by these neurons and results in mechanical mixing of the contents within the stomach and intestine. This helps speed up digestion and also brings digested foods into contact with the epithelium to facilitate absorption.

Food Processing and Carbohydrate Digestion Begin in the Mouth

Ingestion and the start of digestion begin once food enters the mouth. In terrestrial vertebrates, the presence of food stimulates salivary glands in and around the mouth, cheeks, tongue, and throat to produce a flow of saliva—a watery fluid containing proteins, mucus, and antibacterial agents that keeps the mouth moist and clean. Unlike terrestrial vertebrates, fishes, which lack true salivary glands, secrete mucus from specialized cells in their mouth and pharynx.

Saliva has several functions, not all of which pertain to all vertebrates:

- to moisten and lubricate food to facilitate swallowing
- to dissolve food particles to facilitate the ability of specialized chemical-sensing structures called taste buds to taste food
- to kill ingested bacteria with a variety of antibacterial compounds, including antibodies
- to initiate digestion of carbohydrates through the action of a secreted enzyme called **amylase**.

Digestion is the least important of these functions in most vertebrates, few of which produce salivary amylase. In humans and other primates, salivary amylase is present and accounts for only a very small percent of total carbohydrate digestion.

The other functions of saliva, however, are very important. For example, imagine trying to swallow food with a perfectly dry mouth. Also, the antibiotic properties of saliva help cleanse the mouth. In people who have had cancerous salivary glands removed, the teeth and gums often become so diseased that tooth loss occurs.

Peristalsis Moves Swallowed Food Through the Esophagus to a Storage Organ

As food is swallowed, it moves into the next segments of the alimentary canal, the **pharynx** and **esophagus**. These structures, although not contributing to digestion or absorption, serve as a pathway to storage organs.

Pharynx and Esophagus The muscles in the walls of the pharynx and esophagus contribute to swallowing. In the pharynx, swallowing begins as a voluntary action but continues in the esophagus by the process of **peristalsis**—rhythmic, spontaneous waves of smooth muscle contraction that begin near the mouth and end at the stomach. When most vertebrates eat, the mouth and stomach are roughly horizontal with respect to each other. In fact, the head of a terrestrial grazing animal is usually lower than its stomach when eating. The wavelike action of peristalsis ensures that swallowed food is moved toward the stomach and does not sit in the esophagus or even move backward into the mouth if the head is lowered.

The Crop In some animals, food moves directly from the esophagus to a storage organ called the **crop**, which is a dilation of the lower esophagus (**Figure 45.4**). Crops are found in most birds (and are also found in many invertebrates, including insects and some worms). Food is stored and softened by watery secretions in the crop, but little or no digestion occurs there. Because they process large amounts of tough food, birds that eat primarily grains and seeds have larger crops than birds that eat insects and worms. The material that birds regurgitate to their young comes from the crop. In some species, such as pigeons and doves, the cells that line the crop wall secrete a lipid-rich watery solution called crop milk or pigeon milk into the material to be regurgitated.

Food Processing Continues and Protein Digestion Begins in the Stomach

Once food passes through the esophagus (and crop, if present), it reaches a storage organ such as a stomach.

General Features of Stomachs A **stomach** is a saclike organ that most likely evolved as a means of storing food. Stomach-like organs are found in all vertebrate classes, but a true stomach (one that produces hydrochloric acid, HCl) is absent in many species of herbivorous fishes. In addition to its storage function, the muscular nature of the stomach helps it to mechanically break up large chunks of food into smaller, more easily digestible fragments. Lastly, the stomach partially digests some of the macromolecules in food and regulates the rate at which the contents empty into the small intestine. Glands within the stomach wall secrete HCl and an inactive molecule called pepsinogen into the stomach lumen. One function of the acid is to convert pepsinogen into the active enzyme **pepsin**, which is a protease and begins the digestion of protein. Why do stomach cells secrete pepsinogen instead of pepsin? The answer is that if the cells produced active pepsin, they would digest their own cellular proteins. The epithelium of the stomach is coated with a layer of alkaline mucus that protects the stomach wall from the effects of HCl.

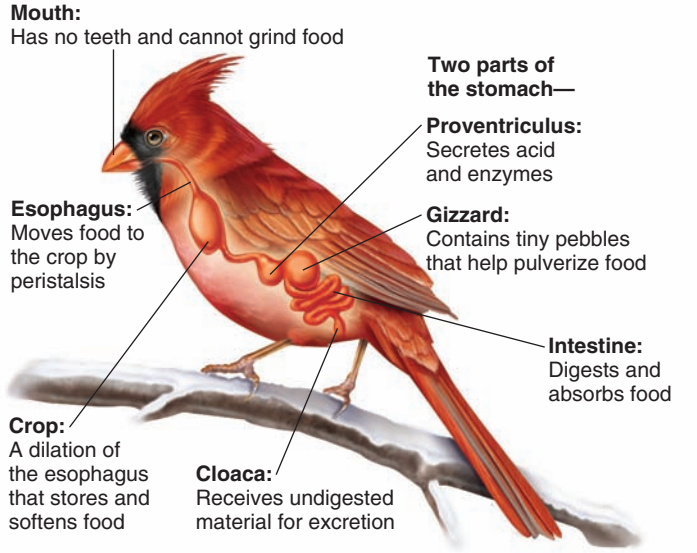

Figure 45.4 The alimentary canal of birds. The avian alimentary canal contains specialized regions for storing and softening food (the crop) and pulverizing food (the gizzard). The gizzard and proventriculus constitute the stomach. Undigested material is excreted through the cloaca.

Concept Check: Smooth, polished stones have been found in the stomach region of fossilized skeletons of ancient sauropod dinosaurs. What does this suggest about the alimentary canal of such animals?

In addition to its function in activating pepsin, HCl kills many of the microorganisms that may have been ingested with food, and also helps dissolve the particulate matter in food. In addition, the acid environment in the stomach (or gastric) lumen alters the ionization of polar molecules, especially proteins. This disrupts the structural framework of the tissues in food and makes the proteins more accessible to pepsin, which partially digests some protein into smaller polypeptide fragments. By contrast, no significant digestion of carbohydrates or lipids occurs in the stomach.

Specialization Among Vertebrates In birds, the stomach is divided into two parts: the proventriculus and the gizzard (see Figure 45.4). The **proventriculus** is the glandular portion of the stomach that secretes acid and pepsinogen. Partially digested and acidified food then moves to the **gizzard**, a muscular structure with a rough inner lining that grinds food into smaller fragments. This increases their surface area available for digestive enzymes later in the small intestine.

The gizzard contains sand or tiny stones swallowed by the bird. The gritty sand and stones take the place of teeth and help mash and grind ingested food. Eventually, the pebbles in the gizzard become smaller as they are worn away, and they are excreted. Thus, birds must occasionally restock the gizzard with new grinding stones. Grain-eating birds, particularly chickens and other fowl, many passerines

(perching birds), and pigeons and doves, generally have more muscular gizzards than do insectivorous birds, because of the difficulty in breaking down plant matter. Gizzards, incidentally, are not unique to birds. Certain reptiles that are closely related to birds, such as crocodiles, also contain muscular gizzards. In addition, some species of herbivorous fishes (for example, members of the family Acanthuridae) ingest quantities of inorganic grit with their meals, which help to grind up food in a portion of the stomach that is modified into a strong, muscular grinding organ like a gizzard.

Digestive actions of the stomach reduce food particles to **chyme**, a solution that contains water, ions, molecular fragments of proteins, nucleic acids, carbohydrates, droplets of fat, and various other small molecules. Very little of these molecules, except water, can cross the epithelium of the stomach wall; therefore, little or no absorption of organic nutrients occurs in the stomach.

Specializations in Ruminants Cellulose, the main macromolecule of plant cell walls (refer back to Figures 3.7 and 10.5), is a very important part of the diet of herbivores and many omnivores. In the human diet, cellulose is also called fiber or roughage, and is useful in eliminating solid wastes. The human digestive system is not equipped with the enzymes to digest cellulose, and it therefore passes through the system intact. Herbivores called **ruminants** (sheep, goats, llamas, and cows) also lack the enzymes, but they are able to digest cellulose with the help of microorganisms living within their digestive tract. The microorganisms break down the cellulose into monosaccharides that can be absorbed along with other by-products of microbial digestion, such as fatty acids and some vitamins. In this way, bacteria and protists predigest the food, and the animal absorbs the broken-down cellulose and uses its sugar as a food source.

Ruminants have a complex esophagus and stomach consisting of several chambers, beginning with three outpouchings of the lower esophagus composed of the rumen, reticulum, and omasum, in sequence (**Figure 45.5**). The rumen and reticulum contain the microorganisms that digest cellulose, and the omasum absorbs some of the water and ions released from the chewed and partially digested food (called the cud). The cud is occasionally regurgitated, rechewed, and swallowed again. Eventually, the partially digested food, the microorganisms, and the by-products of microbial digestion (including useful products such as fatty acids) reach the true stomach, the abomasum, which contains the acid and proteases typical of the vertebrate stomach. From the abomasum, the material passes to the intestines, where digestion and absorption are completed. The microorganisms are killed by the secreted stomach acid, and digested or eliminated. Some microorganisms remain in the rumen and quickly multiply to replenish their populations, ensuring that a well-balanced mutualistic relationship is maintained.

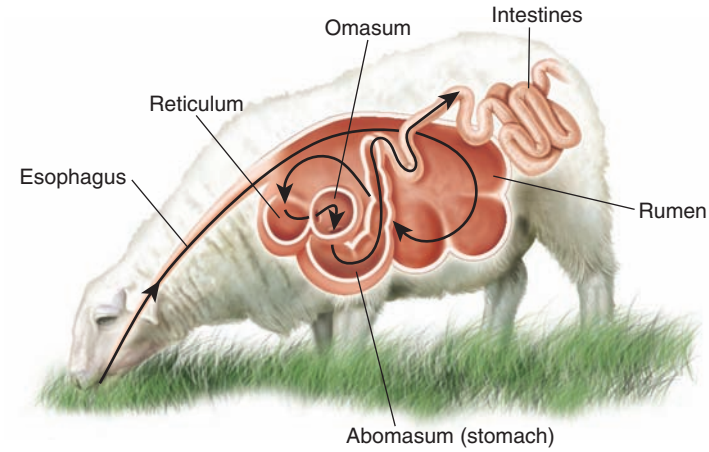

Figure 45.5 Digestive tract of a ruminant. Ruminants have a complex arrangement of three modified pouches arising from the esophagus: the rumen, reticulum, and omasum. The rumen and reticulum act as storage and processing sites (in large ruminants, the rumen may store up to 95 L of undigested food); the omasum absorbs some water and ions. Digestion by acid and pepsin takes place in the abomasum, which connects with the intestines.

Most Digestion and Absorption Occurs in the Small Intestine

Nearly all digestion of food and absorption of nutrients and water occur in the **small intestine**, the portion of the alimentary canal that leads from the stomach to the large intestine or, in some animals, directly to the anus or cloaca. Hydrolytic enzymes break down molecules of organic nutrients into fragments or monomers. Some of these hydrolytic enzymes are on the apical membrane of the intestinal epithelial cells; others are secreted by the pancreas and enter the intestinal lumen. The products of digestion are absorbed across the epithelial cells and enter the blood. Vitamins and minerals, which do not require enzymatic digestion, are also absorbed in the small intestine. Water is absorbed by osmosis from the small intestine in response to the movement of nutrients across the intestinal epithelium. We will discuss the mechanisms of digestion and absorption in more detail later.

Surface Area Specializations The ability of the small intestine to carry out the bulk of digestion and absorption is aided by mucosal infoldings and specializations along its length. Finger-like projections known as **villi** (singular, villus) extend into the lumen of the vertebrate small intestine (**Figure 45.6**). The surface of each villus is covered with a layer of epithelial cells, the plasma membranes of which form small projections called **microvilli**, known collectively as a **brush border**. The combination of folded mucosa, villi, and microvilli increases the small intestine's surface area about 600-fold above that of a flat-surfaced tube having the same length and diameter. The small intestine is small in diameter compared with the large intestine, but it is very long—3 m in an adult human (if removed from the abdomen, the small intestine can expand to almost twice as long as its normal length, because the muscles relax). This brings the total surface area of the human small intestine to about 300 m^2—roughly the size of a tennis court! This enormous surface area means that the likelihood of an ingested food particle encountering a digestive enzyme and being absorbed across the epithelium is very high, so digestion and absorption proceed rapidly.

Absorption into Blood and Lymph The center of each intestinal villus is occupied by capillaries, the smallest blood vessels in the body, and by a special type of vessel called a **lacteal**, which is part of the lymphatic system (see Figure 45.6). Most of the fat absorbed in the small intestine exists as bulky protein-bound particles that are too large to enter capillaries. Consequently, absorbed fat enters the larger,

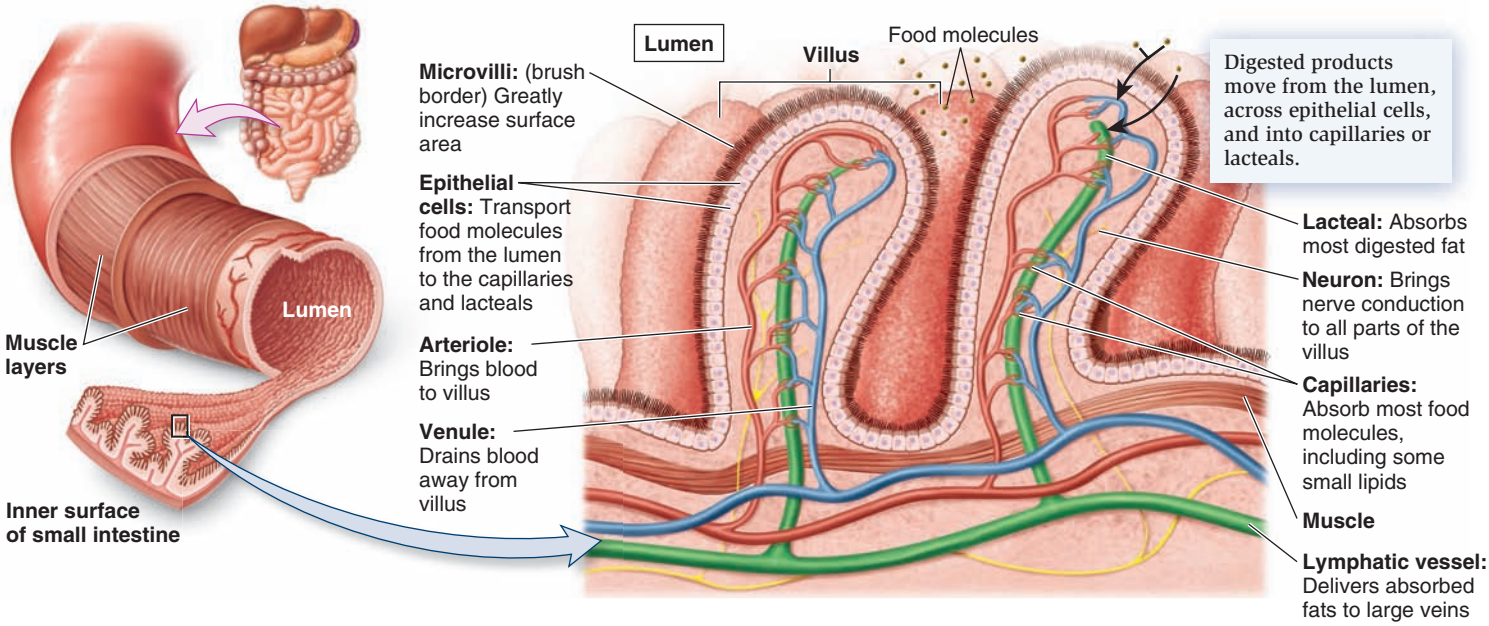

Figure 45.6 The specialized arrangement of tissues in the small intestine. The small intestine is folded into numerous villi, which increase the surface area for digestion and absorption. Within each villus are capillaries and a lymphatic vessel called a lacteal, into which absorbed nutrients are transported. The epithelial cells of the villi have extensions from their surface called microvilli. The microvilli constitute the brush border of the intestine and greatly add to the total surface area.

wider lacteals. Material absorbed by the lacteals eventually empties into the circulatory system. Other nutrients are absorbed directly into the capillaries and from there into veins.

Accessory Organs Secrete Substances into the Small Intestine That Aid Digestion

As the chyme moves through the small intestine, three organs—the pancreas, liver, and gallbladder—secrete substances that flow via ducts into the first portion of the intestine, which is called the **duodenum** (Figure 45.7).

Pancreas The **pancreas**, a complex organ located behind and below the stomach in humans (see Figure 45.3), has several functions, but in this chapter, we will focus on those that are directly involved in digestion. The gland secretes digestive enzymes and a fluid rich in bicarbonate ions (HCO_3^-). The HCO_3^- neutralizes the acidity of chyme, which would otherwise inactivate the pancreatic enzymes in the small intestine and could also damage the intestinal epithelium.

Liver The **liver** is the site of bile production. **Bile** contains HCO_3^-, cholesterol, phospholipids, a number of organic wastes, and a group of amphipathic substances that are derived from cholesterol and are known as **bile salts**. The HCO_3^-, like that from the pancreas, helps neutralize acid (H^+) from the stomach, and the phospholipids and bile salts break up dietary fat droplets, thereby increasing their accessibility to digestive enzymes.

Gallbladder The liver secretes bile into small ducts that join to form the common hepatic duct. Between meals, secreted bile is stored in the **gallbladder**, a small sac underneath the liver. During a meal, the smooth muscles in the gallbladder contract, secreting the bile solution into a connecting duct called the common bile duct (see Figure 45.7). The opening of a sphincter allows the bile to flow into the lumen of the small intestine. The gallbladder, therefore, is a storage organ that allows the release of large amounts of bile to be precisely timed to the consumption of fats. However, many animals such as horses and doves that secrete bile do not have a gallbladder. In humans, the gallbladder can be surgically removed without impairing bile secretion by the liver or its flow into the intestinal tract. People without a gallbladder can still digest fat but may need to limit the amount of fat they eat at one time because bile secretion can no longer be well timed to a meal.

The digested nutrients, along with water, are absorbed across the plasma membranes of the brush border cells. Peristalsis slowly propels the remaining contents through the posterior two portions of the small intestine, called the jejunum and the ileum, where further absorption occurs. Finally, depending on the animal, the remaining material enters the large intestine or the anus or cloaca.

The Large Intestine Concentrates Undigested Material, Which Is Then Egested via the Anus

The size of the large intestine varies greatly among different vertebrates, and the organ is vestigial or even absent in many animals, notably fishes. In humans, the large intestine is a tube about 6 cm in diameter and 1–1.5 m long. Its first portion, the **cecum**, forms a small pouch from which extends the appendix, a finger-like projection having no certain essential function but that may contribute to the body's immune defense mechanisms. The next part of the large intestine in humans and other mammals is called the **colon**. The terminal portion of the colon empties into the **rectum**, a short segment of the large intestine that ends at the **anus**, the opening at the posterior end of the alimentary canal.

The primary functions of the large intestine are to store and concentrate fecal material before defecation and to absorb some of

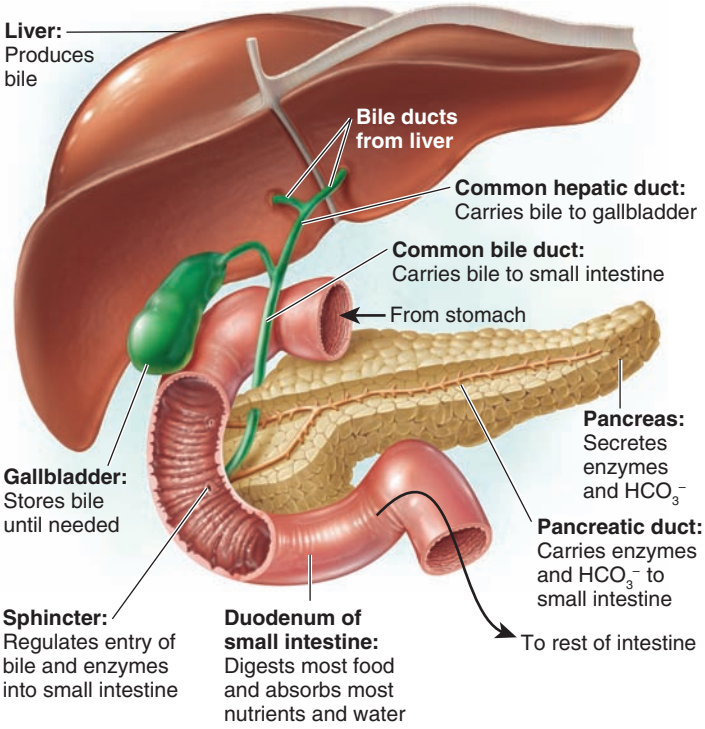

Figure 45.7 The arrangement and functions of the vertebrate liver, gallbladder, pancreas, and small intestine. Bile drains from the liver into the gallbladder through the common hepatic duct. During a meal, bile is secreted from the gallbladder and enters the duodenum of the small intestine through the common bile duct. Simultaneously, secretions from the pancreas travel through the pancreatic duct, which joins with the common bile duct from the gallbladder and empties into the small intestine. A muscular sphincter controls the entrance to the small intestine.

Concept Check: *What advantage does an animal gain by having a gallbladder?*

the remaining ions and water that were not absorbed in the small intestine. Because most substances are absorbed in the small intestine, only a small volume of water and ions, along with undigested material (feces), is passed on to the large intestine. **Defecation** occurs when contractions of the rectum and relaxation of associated sphincter muscles expel the feces through the anus (see Figure 45.3).

Located within the large intestine are large populations of various bacteria, some of which provide benefits to animals. For example, some bacteria release by-products such as certain vitamins into the lumen of the large intestine, where these substances can be absorbed across the intestinal epithelium. Although this source of vitamins generally provides only a small part of the normal daily requirement, it may make a significant contribution when dietary vitamin intake is low. Sometimes people develop a vitamin deficiency if treated with antibiotics that kill these species of bacteria. Other bacterial products include gas (flatus), which is a mixture of nitrogen, carbon dioxide, hydrogen, methane, and hydrogen sulfide. Bacterial processing of undigested polysaccharides produces these gases, except for nitrogen, which is derived from swallowed air. Certain foods (for example, beans) contain large amounts of carbohydrates that cannot be digested by intestinal enzymes but are readily metabolized by bacteria in the large intestine, producing gas.

45.4 Mechanisms of Digestion and Absorption in Vertebrates

Learning Outcomes:

1. Describe the mechanisms of digestion and absorption of carbohydrates, proteins, and fats in vertebrates, and explain the importance of enzymes in some of these processes.
2. Explain why some nutrients do not require digestion prior to being absorbed.
3. **SciSKILLS** » Propose a hypothesis explaining why most human adults are lactose-intolerant to some degree.

The preceding sections provided an overview of nutrition and the basic features of digestive systems. We turn now to a more detailed description of the mechanisms by which carbohydrates, proteins, and lipids are processed in the vertebrate digestive system and how the end products of digestion are absorbed across intestinal cells. Nucleic acids are handled via mechanisms similar to those for these other nutrients and will not be discussed further.

Carbohydrates Are Digested by Amylase and Brush Border Enzymes and Absorbed in the Small Intestine

In omnivores such as humans, most of the ingested carbohydrates are the polysaccharides (polymers of glucose) starch and cellulose from plants and glycogen from animals. The remainder consists of simple carbohydrates, such as the monosaccharides fructose and glucose in fruit, and disaccharides (combinations of two monosaccharides), such as lactose in milk. Humans also add the disaccharide sucrose (table sugar) to their food. Certain other animals consume sucrose from sources such as maple sap and sugarcane.

Although a very small amount of polysaccharide is digested in the mouth by salivary amylase, almost all polysaccharide digestion takes place in the small intestine by amylase secreted into the intestine by the pancreas. The products of starch digestion via amylase are molecules of the disaccharide maltose. Maltose, along with any ingested sucrose and lactose, is broken down into monosaccharides—fructose, glucose, and galactose—by enzymes located on the brush border of the small intestine epithelial cells (**Figure 45.8**). The monosaccharides are then absorbed into the epithelial cells. Fructose crosses the apical (luminal surface) membrane of the epithelial cells by facilitated diffusion, whereas glucose and galactose undergo secondary active transport (see Figure 5.21) coupled to Na^+. Monosaccharides then leave the epithelial cells by way of facilitated diffusion through transporters located in the basolateral membrane of the epithelial cells and enter the blood. The bloodstream distributes the monosaccharides and other absorbed nutrients to the cells of the body.

Do you feel ill after drinking milk or eating dairy products? If so, you are among the majority of people who cannot adequately digest lactose, the chief disaccharide in milk. A smaller percentage of humans, however, retain the ability to fully digest lactose throughout life. Next, we'll examine this phenomenon along with its genetic and evolutionary basis.

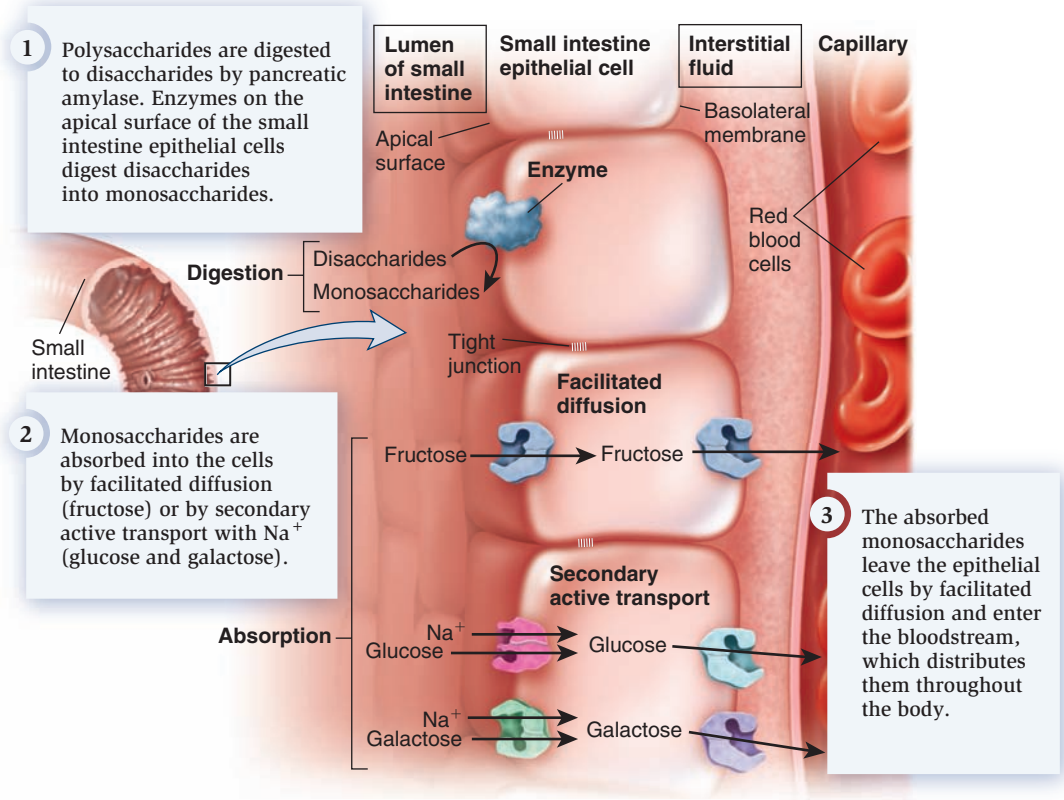

Figure 45.8 Digestion and absorption of carbohydrates in the small intestine. Digestion and absorption occur in the same cells but are shown separately here for clarity. For simplicity, the microvilli (brush border) are not shown.

Concept Check: *The absorption of many nutrients requires secondary active transport. What can we conclude from that about the energetic cost of absorption?*

BioConnections: *Are the transport processes shown here, including facilitated diffusion and secondary active transport, unique to animal cells? See Figure 38.2 for help.*

Genomes & Proteomes Connection

Evolution and Genetics Explains Lactose Intolerance

One of the defining features of mammals is that they produce and consume milk, a nutrient-rich solution containing all the macro- and micronutrients required by their offspring. With rare exceptions, the milk of all mammals contains the dissacharide lactose. Lactose is digested by the intestinal brush border enzyme lactase, which cleaves lactose into glucose and galactose. Humans with lactose intolerance cannot adequately digest lactose because their lactase is either inactive, absent, or present in small amounts.

Milk is the sole food of most mammals shortly after birth, and the primary food for various lengths of time thereafter until weaning, the transition from consuming mother's milk to eating a diet of solid foods. Once weaned, mammals never again drink milk, except, of course, for humans. The popular notion of adult cats lapping up milk from a bowl is a misconception; most adult cats are lactose-intolerant. Some visits to the veterinarian are in fact related to GI symptoms caused by well-meaning owners who regularly feed milk to their adult pets.

Because the only dietary source for lactose is milk, it is not surprising that older mammals lose the ability to digest this disaccharide. This occurs because the gene that encodes the enzyme lactase is shut off at the age of weaning or shortly thereafter. The developmental mechanisms that turn off lactase production and activity are not firmly established, but they are known to involve decreased transcription of the lactase gene.

If an adult mammal were to drink milk, the undigested lactose would remain in the intestine. As a result, water that normally would be absorbed by osmosis with the digested monosaccharides formed from lactose would also remain in the intestine. Farther along the alimentary canal, microorganisms in the large intestine digest some of the lactose for their own use and, in the process, release by-products such as hydrogen and other gases. The combination of water retention and bacterial action results in GI symptoms such as diarrhea, gas, and cramps.

An estimated 90% of the world's human population cannot fully digest lactose after early childhood. In other words, lactose intolerance is not a disorder, it is the usual condition that evolved in all mammals, including humans. Why, then, are some people able to consume dairy products without getting ill? Researchers have discovered that the ability of human adults to digest lactose is clearly linked to genetic background. Lactose intolerance is an example of a human polymorphism, a genetic trait that varies among people. Other than individuals who trace their ancestry to northern Europe and a few isolated regions in western Africa, nearly every population of humans shows a considerable degree of lactose intolerance, reaching nearly 100% in most of south and east Asia. One hypothesis for this phenomenon appears to be a behavioral and cultural change that occurred in Neolithic times, when certain populations domesticated cattle and added cow's milk to their diet. Adults who were able to digest lactose—presumably due to some mutation affecting the expression of the lactase gene—enjoyed a selective advantage and tended to thrive and pass on their genes

more frequently than those whose digestive systems could not handle milk. In other words, natural selection may have favored certain populations carrying mutations that caused the lactase gene to be expressed after weaning. Eventually, a substantial percentage of people in those regions of the world retained sufficient intestinal lactase to use milk as a staple food.

To understand how this trait was passed on, let's examine the gene that codes for lactase. Surprisingly, the coding regions of the lactase gene and the lactase core promoter are identical whether individuals are lactose tolerant or intolerant. Recently, however, Finnish investigators have uncovered two single-nucleotide changes located in presumed regulatory sites that control the expression of the lactase gene. These changes are associated with prolonged lactase expression, allowing it to continue to be active after weaning. People carrying these mutations are lactose-tolerant and can consume milk products through adulthood. By comparison, adults who lack these mutations—and are therefore lactose-intolerant—can consume dairy products only in small amounts or not at all. However, their ability to do so can be greatly improved if the product has been commercially treated with purified lactase to predigest the lactose.

Proteins Are Digested by Proteases in the Stomach and Small Intestine and Amino Acids are Absorbed in the Small Intestine

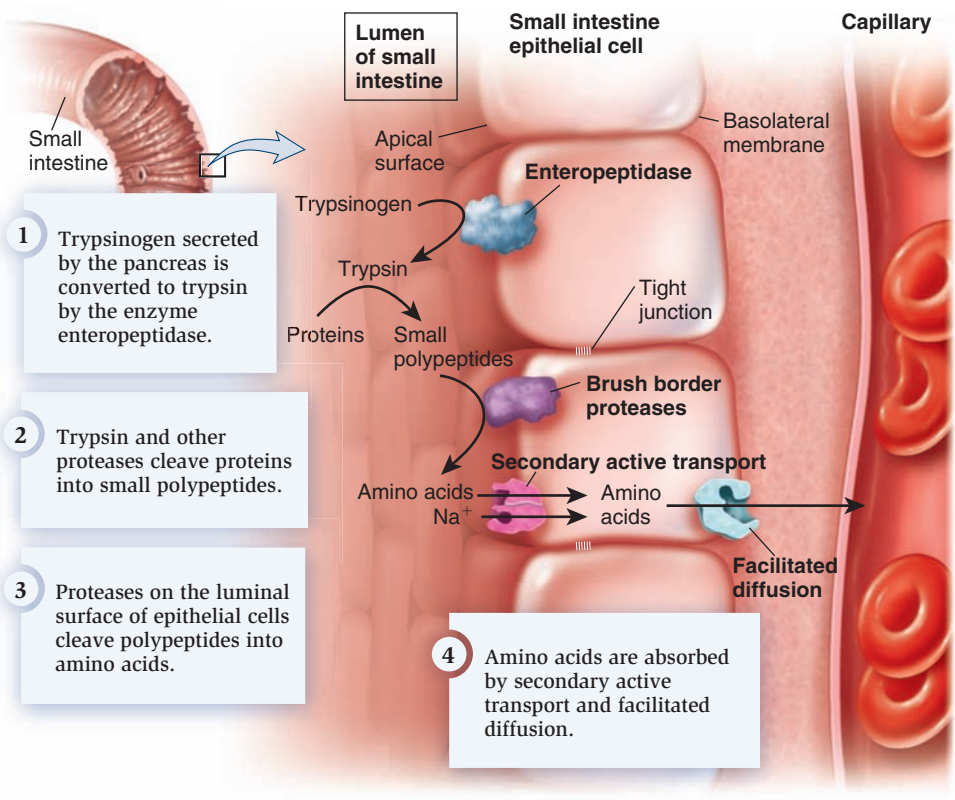
Proteins are broken down to polypeptide fragments in the stomach by pepsin, and in the small intestine by proteases such as **trypsin** (**Figure 45.9**). The pancreas secretes its enzymes as inactive precursors, which prevents the active enzymes from digesting the pancreas itself. Once the inactive form of trypsin (called trypsinogen) enters the small intestine, it is cleaved into the active molecule by the enzyme enteropeptidase (also called enterokinase), the active site of which is located on the apical membranes of intestinal epithelial cells. Trypsin then activates the inactive forms of other pancreatic enzymes.

The polypeptide fragments produced by trypsin and other proteases are further digested into individual amino acids by the actions of additional proteases located on the membranes of the brush border in the small intestine. Together, these proteases cleave off one amino acid at a time from the N-terminus and C-terminus of polypeptide fragments. Individual amino acids then enter the epithelial cells by secondary active transport coupled to Na^+. Amino acids leave these cells and enter the blood by facilitated diffusion across the basolateral membrane. As with carbohydrates, protein digestion and absorption are largely completed in the duodenum.

Lipids are Digested by Lipases and Absorbed in the Small Intestine

Most ingested lipids are in the form of triglycerides (fats). Fat digestion occurs almost entirely in the small intestine. The major digestive enzyme in this process is **lipase**, secreted by cells of the pancreas into the small intestine. The lipase reaction catalyzes the splitting of bonds in triglycerides, producing two free fatty acids and a monoglyceride:

$$\text{Triglyceride} \rightarrow 2 \text{ Free fatty acids} + 1 \text{ Monoglyceride}$$



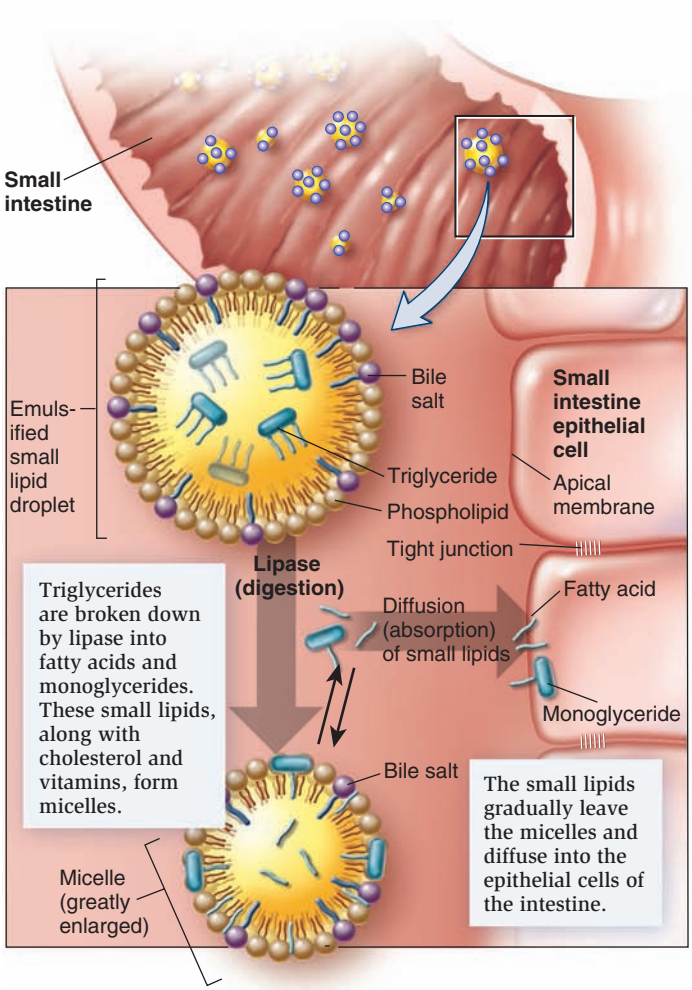


Figure 45.9 **Digestion of proteins and absorption of amino acids in the small intestine.**

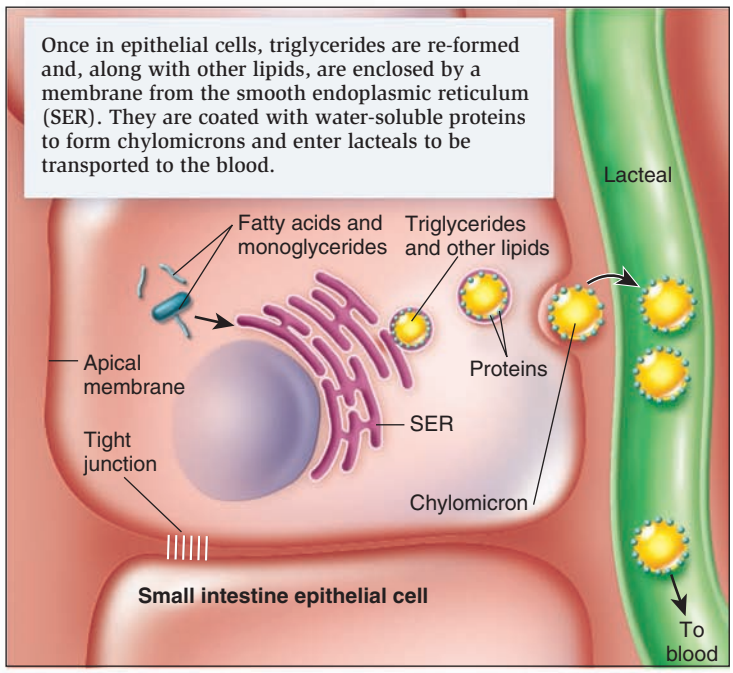
Emulsification Fats are poorly soluble in water and aggregate into large lipid droplets, as you can see if you shake a salad dressing made of oil and vinegar. Because lipase is a water-soluble enzyme, its digestive action in the small intestine can take place only at the surface layer of a lipid droplet. The rate of digestion is substantially increased by the process of **emulsification**, which disrupts the large lipid droplets into many tiny droplets, increasing their total surface area and therefore providing greater exposure to lipase (**Figure 45.10a**). Emulsification occurs in two steps. First, the muscular contractions of the stomach and small intestine mechanically break up large lipid droplets into many smaller ones. Second, the nonpolar portions of amphipathic molecules from bile (bile salts and phospholipids) dissolve in a lipid droplet; the polar (charged) regions dissolve in the surrounding watery chyme. The charged hydrophilic groups of bile salts and phospholipids repel each other; this prevents the small lipid droplets from coalescing into larger ones. The resulting suspension of small lipid droplets is called an emulsion.



Formation of Micelles Although emulsification speeds up digestion of fats, absorption of the poorly soluble products of the lipase reaction is facilitated by a second action of bile salts and phospholipids, the formation of **micelles** (see Figure 45.10a). Micelles consist of bile salts, phospholipids, fatty acids, and monoglycerides clustered together. By temporarily storing breakdown products of lipid digestion in micelles, the products remain in solution and can slowly diffuse out of the micelle and across the epithelial cell apical membrane. Thus, the micelles keep most of the insoluble fat digestion products in small soluble aggregates while gradually releasing very small quantities of lipids to diffuse into the intestinal epithelium. Note that it is not the micelle that is absorbed but rather the individual lipid molecules that are released from the micelle.

Formation of Chylomicrons During their passage through the epithelial cells, fatty acids and monoglycerides are resynthesized into triglycerides in the smooth endoplasmic reticulum (SER). This process decreases the concentration of cytosolic free fatty acids and monoglycerides in the epithelial cells, and so maintains a diffusion gradient for these molecules from the lumen into the cell. The resynthesized triglycerides aggregate into **chylomicrons**, large droplets coated with proteins that perform an emulsifying function similar to that of bile salts (**Figure 45.10b**). In addition to triglycerides, chylomicrons contain phospholipids, cholesterol, and fat-soluble vitamins that have been absorbed by the same process that led to fatty acid and monoglyceride movement into the epithelial cells of the small intestine.

Chylomicrons are released by exocytosis from the epithelial cells and enter lacteals (see Figure 45.6). The fluid from the lacteals eventually empties into the blood.

(a) Digestion of emulsified fats into micelles, and absorption into intestinal cells

(b) Absorption of triglycerides via the formation and secretion of chylomicrons

Figure 45.10 Digestion and absorption of emulsified fat in the small intestine. (Note: Fatty acids and other molecules are not drawn to scale but are enlarged for clarity.)

Vitamins, Minerals, and Water Are Not Digested and Are Absorbed Mostly in the Small Intestine

As stated earlier, vitamins, minerals, and water do not require digestion, and they are absorbed in their complete form. Most water-soluble vitamins are absorbed by diffusion or active transport in the small intestine. The fat-soluble vitamins—A, D, E, and K—follow the pathway for lipid absorption described in the previous section. Any interference with the secretion of bile or the action of bile salts in the intestine decreases the absorption of fat-soluble vitamins.

Water is the most abundant substance in chyme. Small amounts of ingested water are absorbed in the stomach, but the stomach has a small surface area available for diffusion and lacks the solute-absorbing mechanisms that create the osmotic gradients necessary for water absorption. The great majority of water absorption occurs in the small intestine. The epithelial membranes of the small intestine are very permeable to water, and water diffuses across the epithelium whenever an osmotic gradient is established by the active absorption of solutes, particularly Na^+, Cl^-, and HCO_3^-. Other minerals, such as K^+, Mg^{2+}, and Ca^{2+}, are present in smaller concentrations and are also absorbed by this mechanism, as are trace elements such as zinc and iodine. The mechanisms of absorption of these molecules generally involve transport proteins.

BIO TIPS **THE QUESTION** *What is the advantage of the structural division of the alimentary canal of animals into multiple compartments, including the stomach, small intestine, and so on?*

TOPIC ***What topic in biology does this question address?*** The topic is the anatomy of the alimentary canal. More specifically, the question concerns how it is subdivided into different structures and how such subdivisions may be advantageous for an animal.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you know that the alimentary canals of animals are compartmentalized into discrete structures, such as the stomach and small intestine, which has some advantage to the animals. From your understanding of the topic, you may recall what these structures are and what their functions are.

PROBLEM-SOLVING STRATEGY ***Sort out the steps in a complicated process. Relate structure to function.*** One way to answer this question is to think about the steps involved in the digestion of food and the absorption of nutrients along the alimentary canal. Which functions occur in which parts of the canal, and why? Next, think about the structural differences along the canal, and how those differences relate to the various functions.

ANSWER *Having discrete structures along the alimentary canal allows for the separation of functions. For example, food is acidified in the stomach, which is well suited to withstand the effects of low pH. The presence of a stomach allows for the slow processing of chyme as it enters the small intestine, allowing animals to eat large amounts of food and store much of it in the stomach without overwhelming the ability of the intestines to digest and absorb the food. Digestive enzymes can be released directly into the small intestine, where they are required, and not secreted throughout the entire canal; it would be wasteful to secrete digestive enzymes into the large intestine, where little or no digestion occurs. Absorptive structures, such as the brush border of the small intestine, are adapted for this function and possess digestive enzymes, transport proteins, and a large surface area. Such adaptations would have no value in the esophagus, for example, which acts simply to move food to the stomach.*

45.5 Neural and Endocrine Control of Digestion

Learning Outcomes:

1. Explain how the nervous system controls different features of the digestive process.
2. Name three major hormones important for the regulation of digestion in vertebrates, and describe the role of each.

The digestive systems of animals are regulated by the nervous and endocrine systems. Neurotransmitters from neurons and hormones from endocrine glands control the volume of saliva produced, the amount of acid produced in the stomach, the timing and amount of secretions from the gallbladder and pancreas, and the rate and strength of muscle contractions along the alimentary canal. In this section, we will examine the major mechanisms by which the nervous and endocrine systems control the activity of the vertebrate digestive system.

The Nervous System Controls Muscle and Secretory Activity

The nervous system can affect the activities of the digestive system in two major ways: (1) local control of muscle and glandular activity by the neurons within the alimentary canal and (2) long-distance regulation by the brain.

Within the walls along the length of the alimentary canal is a highly branched, interconnected collection of neurons that function in local control of the digestive system. These neurons interact with nearby smooth muscles, glands, and epithelial cells, and stimulation of neuronal activity at one point along the alimentary canal can lead to impulses that are transmitted up and down the length of the canal. When food enters the small intestine, for example, the intestine is expanded. This directly activates stretch-sensitive neurons in the intestinal wall. Impulses are sent from these neurons to the smooth muscles of the stomach, where they decrease the strength of the contractions of the stomach. This slows the rate at which chyme moves from the stomach into the small intestine, giving the intestine sufficient time for digestion and absorption of each bolus of chyme it receives. In this way, the alimentary canal can regulate its own function independent of the brain.

In long-distance regulation, the brain communicates with neurons in the walls of the stomach and intestines and thereby influences the movement and secretory activity of the alimentary canal. For example, emotional stress, a brain-related event, can affect digestive processes. Likewise, the sight, smell, and taste of food activate digestive functions even before food reaches the stomach. These stimuli when processed

by the nervous system act via nerves from the brain as a feedforward mechanism (see Figure 40.16), so saliva production, stomach activity, and digestion are ready to begin immediately when food is ingested.

Hormones Regulate the Rate of Digestion

Hormones are chemical messengers secreted by specialized cells into the blood, where they travel to all parts of an animal's body and act on various target cells (see Figure 9.3e). The hormones that control the digestive system are secreted mainly by cells scattered throughout the epithelium of the stomach and small intestine. One surface of each hormone-producing cell is exposed to the lumen of the alimentary canal. At this surface, chemical substances in chyme stimulate cells in the stomach epithelium to release a hormone called **gastrin**, which reaches all the parts of the stomach through the bloodstream (**Figure 45.11**). The presence of gastrin stimulates smooth muscle contraction in the stomach, which helps move chyme into the small intestine. Gastrin also stimulates acid production by stomach epithelial cells. In the small intestine, the arrival of chyme stimulates release of the hormones cholecystokinin (CCK) and secretin from intestinal epithelial cells. Cells of the pancreas respond to CCK by secreting digestive enzymes and to secretin by secreting acid-neutralizing bicarbonate ions (HCO_3^-) into the small intestine. CCK also stimulates contraction of the gallbladder and therefore bile release.

45.6 Impact on Public Health

Learning Outcomes:

1. Describe the impact of diarrhea, heartburn, and ulcers on public health.
2. Identify the primary cause of ulcers.

As we have seen, the functioning of the vertebrate digestive system is extraordinarily fine-tuned by the brain, nerves, and hormones. When people are well nourished, therefore, you might assume that digestive problems would be rare. However, each year in the U.S. alone, GI complaints account for approximately 40 million visits to doctors and 10 million visits to hospitals and emergency rooms. Among the most common GI problems registered by hospitals and physicians are diarrhea, heartburn, and ulcers.

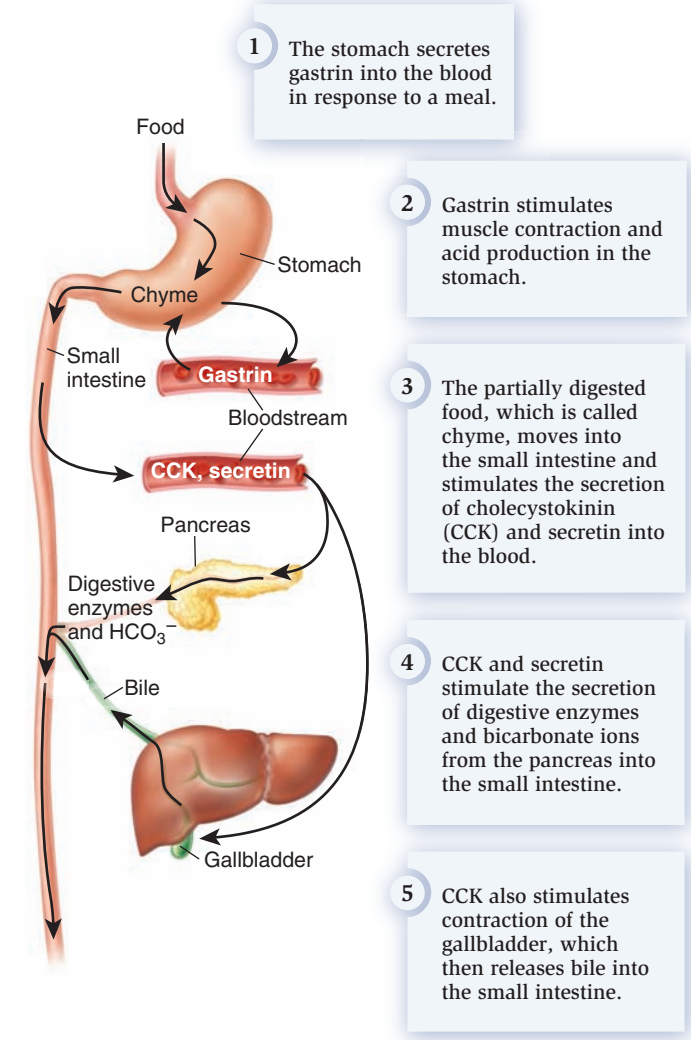


Figure 45.11 Hormonal regulation of digestion in the stomach and small intestine.

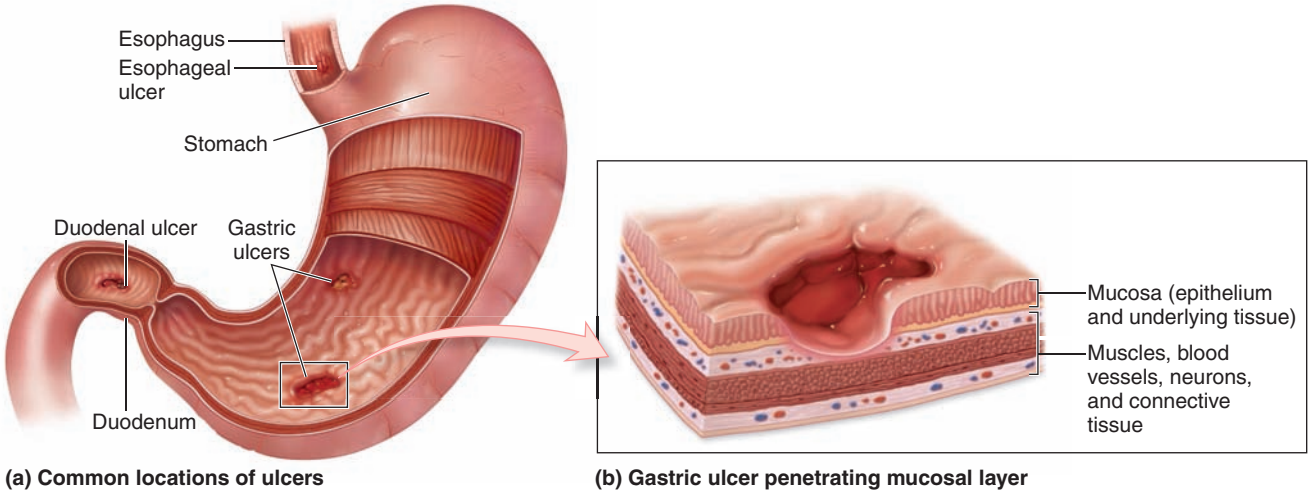
BioConnections: In Chapter 40 you learned about the process of negative feedback, which helps maintain homeostasis in animals. Can you make a prediction about the possible feedback effects, if any, of CCK on the stomach? Do you think CCK might stimulate or inhibit smooth muscle activity and acid production in the stomach?

Diarrhea Is the Most Common Gastrointestinal Disorder Worldwide

According to the World Health Organization, worldwide there are over 2 billion cases of **diarrhea**—loose, watery stools occurring at least three times per day—every year. Nearly all episodes of diarrhea resolve in a day or two. Typically they result from infection with a pathogen, such as a virus or bacterium. Other times, however, diarrhea may be caused by food sensitivities (such as lactose intolerance, discussed earlier), reactions to medications, stress-related disorders, or parasites that inhabit the rectum and colon.

Most cases of pathogen-related diarrhea in the U.S. result from exposure to one of several related types of bacteria, including those of the genera *Salmonella*, *Shigella*, and *Escherichia*. Often, these infections are handled by the body's immune system within a day or two, but sometimes medical attention is required. One cause of diarrhea stands apart as particularly dangerous, however. Cholera is a disease caused by the bacterium *Vibrio cholerae*, usually ingested by consuming contaminated food or water. Each year at least 2,000 people die of cholera worldwide, with another 100,000 people contracting the disease but surviving. Nearly all cases of cholera occur in Africa, parts of Asia (notably China), and India, although scattered outbreaks have occurred nearly everywhere except the U.S., with the most recent worldwide pandemic lasting from 1961 to 1971. *V. cholerae* releases a toxin that alters the permeability of ions in the large intestine, resulting in a massive flow of these ions, followed by water, due to osmosis, into the intestinal lumen. As with all cases of diarrhea, the chief concern with cholera is the loss of nutrients and water and the dehydration that ensues. In addition to killing the bacteria with antibiotics, therefore, the major treatment of cholera is the same as for any cause of diarrhea, which includes drinking solutions of ions and water to replace those that were lost in the feces.

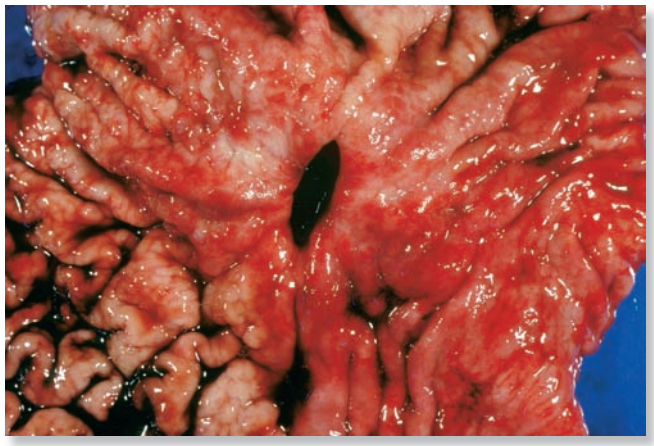
Excess Stomach Acid Production Can Lead to Heartburn



Approximately one in four people in the U.S. suffers at some time from **heartburn** (more properly called acid reflux, or gastroesophageal reflux). The term heartburn is a misnomer, because although the painful burning sensations of this disorder are felt in the vicinity of the heart, they are caused by stomach acid and arise within the esophagus, not the heart. Normally, very little of the stomach contents move backward into the esophagus, largely because of a muscular sphincter at the esophageal/stomach juncture. However, under some conditions, the sphincter either does not close entirely or is forced open by the pressure of material in the stomach. When this happens, the acid in the stomach lumen enters the esophagus and irritates neuron endings there.

Many circumstances may contribute to heartburn. Overeating, for example, enlarges the volume of the stomach to the point of forcing its contents through the esophageal sphincter. Lying down after a big meal removes the effect of gravity on food in the stomach and may allow some acid to leak backward. Heartburn is also associated with smoking and consumption of alcohol, citrus fruits (which are acidic), chocolate (which contains caffeine, an alkaloid that relaxes the esophageal sphincter), and fatty foods (which take longer to digest than other foods and therefore slow the rate at which the stomach empties). One of the most common causes is pregnancy. Toward the middle of pregnancy, the growing fetus pushes up on the abdominal contents, which tends to force material from the stomach into the esophagus.

Common antacids contain calcium carbonate, which buffers the acid in the stomach and esophagus. In severe cases, heartburn can damage the walls of the esophagus enough to cause a chronic cough and pain, or even perforate the esophagus. Antacids may not be sufficient to treat these individuals, who are instead given drugs that inhibit the stomach's ability to produce acid. These drugs are among the most widely prescribed medications in the U.S.



Erosion of the Walls of the Alimentary Canal Causes an Ulcer

Erosion of any portion of the alimentary canal due to any cause is called an **ulcer**. Most ulcers occur in the stomach (gastric ulcers) and the duodenum, but occasionally also in the lower esophagus, because these sites have the greatest exposure to acid (**Figure 45.12**). Ulcers are typically less than an inch wide; if left untreated, contents of the lumen may leak into the surrounding body cavity, where enzymes and acids from the stomach can do considerable damage. As many as 20 million Americans have an

(a) Common locations of ulcers

(b) Gastric ulcer penetrating mucosal layer

(c) Human gastric ulcer

Figure 45.12 Gastric and duodenal ulcers. **(a)** Common locations of ulcers in humans. **(b)** Illustration of a gastric ulcer eroding through the mucosal epithelium. **(c)** Photograph of an actual gastric ulcer that has penetrated through the stomach wall.

ulcer. Each year, 40,000 patients require surgery to repair tissue damaged by ulcers, and around 6,000 die due to complications from the disease.

Acid is essential for ulcer formation, but we now know that it is not usually the primary cause. Many patients with ulcers have perfectly normal rates of acid production. Contrary to popular belief, stress or spicy food is probably not a major cause of ulcers either. So what is the main cause of ulcers? In the 1980s, two Australian scientists, Barry Marshall and J. Robin Warren, proposed that most stomach ulcers arise from a bacterial infection. This idea did not gain quick acceptance because many scientists believed that bacteria could not survive the acidic conditions in the stomach. As we see next, however, Marshall and Warren were able to provide support for their hypothesis with compelling experimental data.

Feature Investigation | Marshall and Warren and Coworkers Demonstrated a Link Between Bacterial Infection and Ulcers

For many years, the conventional wisdom regarding ulcers was that they occurred as a consequence of overproduction of stomach acid, which in turn was due to factors such as stress, eating spicy foods, and smoking, among others. In the early 1980s, Barry Marshall and Robin Warren had obtained evidence that some individuals with gastritis (inflammation of the stomach lining) or ulcers had active colonies of a bacterium (initially thought to be *Campylobacter pylori* but later identified as *Heliobacter pylori*). This was a startling observation, because it had been assumed that no organism could survive the harsh pH and enzymes present in the stomach. In preliminary studies, Marshall and Warren further observed that treatment of such individuals with compounds that kill bacteria could reduce colonies of *H. pylori* and provide relief from gastritis. Based on these observations, they hypothesized that symptoms of gastritis and ulcers in certain individuals were caused by *H. pylori* infection and that eradication of the infection would cure the disease (**Figure 45.13**).

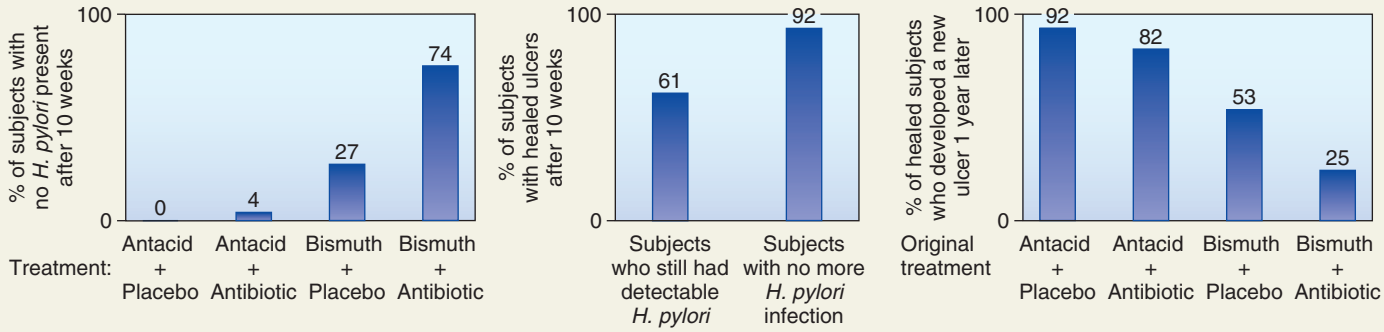


Figure 45.13 Marshall and Warren and coworkers demonstrate that *H. pylori* infection is a cause of ulcers in humans.

HYPOTHESIS *H. pylori* infection is a cause of ulcers in humans.

KEY MATERIALS Endoscope, bacterial culture plates and medium, histologic stains, biopsy instruments.

	Experimental level	Conceptual level
1 Confirm presence of ulcer and *H. pylori* in human subjects.	Use endoscopy to visualize the ulcer. Remove a tissue sample for analysis (biopsy), and check for presence of *H. pylori* by culture and enzyme analysis.	Endoscope; View through endoscope; Normal; Gastritis
	If the cultures are *H. pylori*, then extracts of them should contain enzymes known to be present specifically in this species (measurable in a sensitive assay with a spectrophotometer).	Petri dish with colonies of bacteria; *H. pylori*; 1 µm
2 Randomly assign subjects to 1 of 4 treatment groups.	Treatment Group 1: Antacid + Placebo Treatment Group 2: Antacid + Antibiotic Treatment Group 3: Bismuth + Placebo Treatment Group 4: Bismuth + Antibiotic ↓ 10 weeks Re-evaluate for ulcers and *H. pylori* ↓ 1 year Follow-up exams	Group 1 is a control, because antacids help the symptoms of ulcers, but do not cure them. A placebo is an ineffective treatment with no function. An antibiotic is a compound that kills bacteria. Bismuth is an element that also has bacteria-killing properties.

3 THE DATA

4 CONCLUSION Infection with *H. pylori* is a significant cause of ulcers in humans.

5 SOURCE Marshall, B.J., et al. 1988. Prospective double-blind trial of duodenal ulcer relapse after eradication of *Campylobacter pylori*. *The Lancet* 332:1437–1442.

To test their hypothesis, the investigators recruited individuals who were being treated for ulcers at a local clinic. First, the presence of *H. pylori* and an ulcer was confirmed using visual inspection, biopsies, enzymatic tests, and bacterial cultures in vitro. On the basis of these exams and tests, 100 patients were chosen for the study. They were assigned to one of four groups based on the treatment they were to be given: antacid plus placebo, antacid plus antibiotic, bismuth plus placebo, or bismuth plus antibiotic. Bismuth is known to have antibacterial properties, but its mechanism of action is unclear. The antacid used in the study temporarily relieves the symptoms of an ulcer by decreasing acid production; it does not cure ulcers, however, and therefore served as a control.

After 10 weeks, the patients were examined again. The results were striking: The antacid by itself or with the antibiotic had little effect on the elimination of *H. pylori* infection. Bismuth cleared the infection from 27% of patients, and bismuth plus antibiotic cleared it from 74%. Interestingly, the use of the antibiotic alone led to antibiotic-resistant strains of *H. pylori*, accounting for the failure of the antibiotic on its own to eliminate the infection. The presence of bismuth somehow prevented this resistance from developing.

A trend was observed in which patients with cured ulcers were more likely to no longer have *H. pylori* infection. As seen in the data, 92% of those individuals with no further evidence of infection had healed ulcers, compared to only 61% of those who still had signs of infection. Finally, a 1-year follow-up of those subjects whose ulcers had fully healed after 10 weeks (regardless of treatment) was performed. The bismuth-plus-antibiotic treatment given 1 year previously reduced the rate of relapse (new ulcer formation) to only 25%, compared with a high of 92% in the antacid-plus-placebo group, a statistically significant result.

The investigators concluded that *H. pylori* infection is a significant cause of ulcers in humans. The mechanism seems to involve toxic by-products released by the bacterium and the body's inflammatory reaction to the microbe. These responses erode the protective mucosal layer in the stomach and also cause acid-producing cells to become overactive. Today, patients with ulcers can be easily tested for the presence of colonies of this bacterium in the stomach, and treatment with bismuth plus one or two different antibiotics is remarkably effective at curing the disease.

Experimental Questions

1. What hypothesis was tested in this experiment, and what background information led to that hypothesis?
2. **SciSKILLS »** Did the results support the hypothesis? Do the results indicate that *H. pylori* infection is the only cause of ulcers in people?
3. **SciSKILLS »** Based on these data, propose a treatment for someone with confirmed presence of *H. pylori* and an ulcer. From the data, can you conclude that some ulcers heal on their own?

Summary of Key Concepts

45.1 Animal Nutrition

- The four phases of food use in animals are ingestion, digestion, absorption, and egestion. Animals require organic nutrients—carbohydrates, proteins, lipids, nucleic acids, and vitamins—and inorganic nutrients including water and minerals. Differences in nutritional demands reflect an animal's physiology and environment (Figure 45.1).
- Herbivores eat only plants, carnivores consume animal flesh or fluids, and omnivores eat both plant and animal products.
- Essential nutrients include nine amino acids that cannot be synthesized by humans and many other animals; vitamins, which are organic nutrients that serve as coenzymes for metabolic and biosynthetic reactions; certain fatty acids; and minerals, which are inorganic ions that serve many functions (Tables 45.1, 45.2, 45.3).

45.2 General Principles of Digestion and Absorption of Food

- Intracellular digestion occurs in single-celled organisms and simple invertebrates. Most animals digest food via extracellular digestion. Flatworms and cnidarians have a gastrovascular cavity with one opening that serves as both entry and exit port (Figure 45.2).
- Nearly all other animals have an alimentary canal, open at the mouth and anus or cloaca and segregated into specialized regions, through which food passes from one end to the other.
- Once food has been digested, the nutrients must be absorbed via simple diffusion, facilitated diffusion, or primary or secondary active transport.

45.3 Overview of Vertebrate Digestive Systems

- The vertebrate digestive system consists of the alimentary canal plus associated glands and organs. The anterior portion of the canal contains the oral cavity, pharynx (throat), and esophagus. The middle portion contains food storage or digestive organs (crop, gizzard, and/or stomach), and the upper part of the small intestine (duodenum). The posterior part of the alimentary canal contains the remainder of the small intestine, the large intestine, the rectum, and the anus or cloaca (Figure 45.3).
- Saliva facilitates swallowing, dissolves food particles, and initiates digestion. Peristalsis moves food through the pharynx and esophagus to the stomach, where digestion begins (Figure 45.4).
- The stomach stores food, partially digests proteins, and regulates the rate at which chyme empties into the small intestine. Ruminants have a complex stomach with several chambers that facilitates cellulose digestion (Figure 45.5).
- Nearly all digestion and absorption occur in the small intestine. The combination of villi and microvilli increases the small intestine's surface area and maximizes the efficiency of digestion and absorption (Figure 45.6).
- The pancreas secretes digestive enzymes and a bicarbonate-rich fluid that neutralizes the acidic chyme. The liver secretes bile acids in the digestion of fat (Figure 45.7).
- The large intestine concentrates undigested material, which is then eliminated from the anus or cloaca.

45.4 Mechanisms of Digestion and Absorption in Vertebrates

- Carbohydrate digestion occurs in the small intestine, where maltose and other disaccharides are digested into monomers by enzymes and transported across epithelial cells into the blood (Figure 45.8).
- In humans, the ability to digest lactose after childhood is linked to a genetic mutation.
- Proteins are broken down to peptide fragments in the stomach by pepsin and further broken down into amino acids in the small intestine by trypsin and other proteases (Figure 45.9).
- Lipid digestion and absorption occurs entirely in the small intestine by the action of pancreatic lipase (Figure 45.10).
- Most water-soluble vitamins are absorbed by diffusion or active transport. Fat-soluble vitamins follow the pathway for lipid absorption.

45.5 Neural and Endocrine Control of Digestion

- The digestive systems of animals are regulated primarily by the nervous and endocrine systems. The nervous system affects the digestive system in two major ways: (1) local control by the nerves in the alimentary canal and (2) long-distance regulation by the brain.
- Several hormones work together to regulate the rate of digestion. (Figure 45.11).

45.6 Impact on Public Health

- Diarrhea, heatburn, and ulcers are common disorders involving the alimentary canal. Marshall and Warren and coworkers demonstrated that many ulcers are due to bacterial infection (Figures 45.12, 45.13).

Assess and Discuss

Test Yourself

1. The process of enzymatically breaking down large molecules into smaller molecules that can be used by cells is
   a. absorption. c. ingestion. e. egestion.
   b. secretion. d. digestion.
2. The term essential nutrients refers to
   a. all the carbohydrates, proteins, and lipids ingested by an organism.
   b. nutrients that an animal cannot manufacture from other molecules.
   c. nutrients that must be obtained from the diet in their complete form.
   d. all organic nutrients.
   e. b and c, both
3. Which of the following statements is *false*?
   a. Trypsin digests proteins in the small intestine.
   b. Enzymes on the brush border of the small intestine complete the digestion of carbohydrates.
   c. Free fatty acids are absorbed across the apical membranes of small intestinal epithelial cells.

d. Approximately 10% of the world's adult population is lactose-intolerant.
e. Bile is a mixture of wastes, HCO_3^-, cholesterol, and amphipathic compounds.

4. Which of the following statements is *true*?
a. Intracellular digestion commonly occurs in vertebrates.
b. Absorption of nutrients always requires active transport.
c. Alimentary canals have two openings, whereas gastrovascular cavities have only one.
d. Extracellular, but not intracellular, digestion requires hydrolytic enzymes.
e. Most minerals are absorbed by simple diffusion.

5. To which part of the alimentary canal is the pancreas connected?
a. esophagus c. small intestine e. large intestine
b. stomach d. cecum

6. Which of the following statements regarding the vertebrate stomach is *false*?
a. Its cells secrete the protease pepsin in its active form.
b. It is a saclike organ that may have evolved to store food.
c. Its cells secrete hydrochloric acid.
d. It is the initial site of protein digestion.
e. Little or no absorption of nutrients occurs there.

7. Absorption in the small intestine is increased by
a. the many villi present on the inner surface of the small intestine.
b. the brush border formed by microvilli on the cells of the villi.
c. the presence of numerous transporter molecules on the epithelial cells.
d. all of the above.
e. a and b only.

8. In birds, the secretion of acid and pepsinogen occurs in the
a. crop. d. cloaca.
b. gizzard. e. gallbladder.
c. proventriculus.

9. Bile is produced by the _____ and stored in the _____.
a. liver, small intestine
b. gallbladder, liver
c. pancreas, small intestine
d. small intestine, gallbladder
e. liver, gallbladder

10. Which of the following is a function of the large intestine?
a. It contains microorganisms that may produce useful by-products that can be absorbed.
b. It stores and concentrates fecal material.
c. Its cells absorb ions and water that remain in chyme after it leaves the small intestine.
d. It varies considerably in size and may even be absent in some vertebrates.
e. All of the above are true of the large intestine.

Conceptual Questions

1. Distinguish between digestion and absorption.
2. Explain the functions of the crop and gizzard in birds. Why don't humans have a crop or gizzard?
3.  A principle of biology is that *structure determines function*. Describe the various structural adaptations of the vertebrate small intestine from the organ to the cellular level, and explain how each is related to the functions of digestion and absorption.

Collaborative Questions

1. Discuss the role of enzymes in digestion.
2. Define nutrient. On the basis of that definition, do you consider water a nutrient? Briefly discuss the essential nutrients, vitamins, and minerals that animals must obtain through their diet.

Control of Energy Balance, Metabolic Rate, and Body Temperature

46

A genetically obese, leptin-deficient mouse and a normal mouse.

In 1997, two young cousins being treated for extreme obesity were brought to the attention of researchers studying a newly discovered hormone called leptin. Leptin had been demonstrated to inhibit appetite in laboratory rodents. The researchers hypothesized that the children—who weighed approximately 30 kg by age 2, and in one case, 86 kg by age 9—were not producing leptin. This hypothesis was confirmed by molecular analyses and traced to a mutation in the leptin-encoding gene. Subsequently, several other individuals with mutations affecting leptin production were identified, leading in each case to extreme childhood obesity. Treatment of these individuals with leptin has proven beneficial in restoring normal body weight. Although leptin deficiency is rare and is only one of many possible causes of obesity in humans, animal models of leptin deficiency, such as the mice shown in the chapter opening photo, represent a remarkable breakthrough in our understanding of the genetic bases of the control of appetite and metabolism. How nutrients that supply energy are processed, stored, and used by animals' bodies in times of food abundance or fasting is a focus of this chapter.

In Chapter 45, we saw that all animals require nutrients to assemble the macromolecules that make up body tissues. Some of the ingested nutrients, such as carbohydrates, lipids, and proteins, also represent a form of energy that can be used to generate ATP within cells. Most animals, however, do not have a constant supply of nutrients. For example, insects, cephalopods, and all vertebrates sleep or have periods of greatly reduced activity for part of the day, during which time they do not eat. In addition, environmental changes may reduce the food supply, leading to long fasts. As a consequence of the irregular and sometimes unpredictable flow of nutrients into the body, animals have evolved an array of mechanisms to adequately maintain levels of important fuel molecules even during a fast. In the first two sections of this chapter, we will explore how ingested nutrients are stored in the body for such times of need and the mechanisms by which these stores are tapped.

Metabolism refers to all the bodily activities and chemical reactions in an organism that maintain life. **Metabolic rate** describes the rate at which an organism uses energy to power these reactions. Animals may have widely different metabolic rates, which determine the amount of nutrients they require. The greater an animal's metabolic rate, the more heat it generates as a by-product of breaking down nutrients and using the energy of their chemical bonds to synthesize ATP. Some of this heat escapes to the environment, and some is used to warm an animal's body. Metabolism and body temperature are therefore closely related, and we will examine this relationship in the next two sections of the chapter. We will also discuss energy balance, the balance between energy consumption and expenditure. We will conclude with the public health impact of human disorders associated with metabolism, including obesity.

46.1 Use and Storage of Energy

Learning Outcomes:

1. Describe the processes of absorption of glucose, triglycerides, and amino acids during the absorptive state.
2. Discuss the two major ways that vertebrates can increase their blood glucose concentrations during the postabsorptive state.
3. Define glucose sparing, and explain why it is important.

Once nutrients have been ingested, they are either used or, in many cases, stored. The handling of nutrients can be divided into two alternating states. The **absorptive state** occurs when ingested nutrients enter the blood from the alimentary canal. The **postabsorptive state** occurs when the alimentary canal is empty of nutrients and the body's own stores must supply energy. During the absorptive state, some ingested nutrients supply the immediate energy requirements of the body. The rest are added to the body's energy stores to be called upon during the next postabsorptive state. An average meal in a human requires about 4 hours for complete absorption. Therefore, our usual three-meal-a-day pattern places us in the postabsorptive state during the late morning and afternoon and part of the night. Total-body energy stores are adequate for the average human to withstand a fast of several weeks. By contrast, some animals can barely survive a single skipped meal—particularly if they have low energy reserves—because their relative metabolic requirements are much greater than our own. In this section, we will focus on nutrient absorption, use, and storage in vertebrates, with a closer look at mammals.

In the Absorptive State, Nutrients Are Absorbed and Used for Energy or Stored

The categories of nutrients that are absorbed during the absorptive state include carbohydrates, lipids, proteins, nucleic acids, vitamins, minerals, and water. We will look in depth at the first three of these; **Figure 46.1** gives an overview of what happens to these nutrients.

Digested carbohydrates are absorbed as monosaccharides, including glucose (refer back to Figure 45.8). Digested lipids (triglycerides) are absorbed after first being resynthesized into triglycerides in intestinal epithelial cells (refer back to Figure 45.10). Proteins are broken down into amino acids, which are then absorbed (refer back to Figure 45.9).

Absorbed Carbohydrates The chief carbohydrate monomer absorbed from the alimentary canal of vertebrates is glucose, which is one of the two major energy sources during the absorptive state (triglycerides being the other). Much of the absorbed glucose enters cells and is enzymatically broken down, resulting in the formation of hydrogen ions, carbon dioxide, and water and, in the process, releasing the energy required to form ATP from ADP and inorganic phosphate (Figure 46.1a). Because skeletal muscle makes up a large fraction of body mass in most vertebrates, it is a major consumer of glucose, particularly when an animal is active. In all vertebrates, skeletal muscle also incorporates some of the glucose into the polymer glycogen, which is stored in the muscle cells to be used later. If more glucose is absorbed than is required for immediate energy, a portion of the excess is incorporated into glycogen in the liver, and the remainder into triglycerides in adipose cells. The structures of glycogen and triglycerides are described in Figures 3.7 and 3.8, respectively.

Absorbed Triglycerides Triglycerides are too large to diffuse across the plasma membranes of the intestinal epithelial cells. As described in Chapter 45 (refer back to Figure 45.10), they are digested into fatty acids and monoglycerides in the lumen of the small intestine

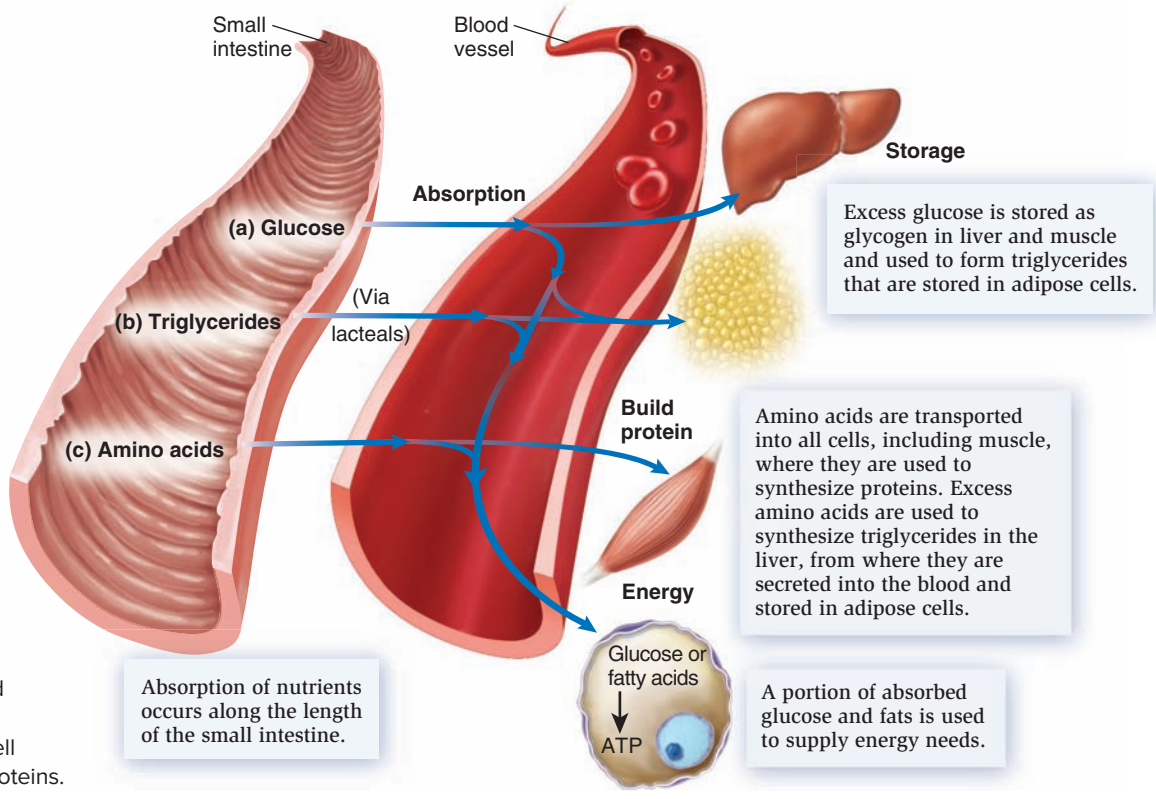

Figure 46.1 Events of the absorptive state. The products of digestion are absorbed into the blood along the length of the small intestine. (Note that triglycerides are absorbed into lacteals and from there into the blood; refer back to Figures 45.6 and 45.10 for details.) These nutrients are used for immediate energy demands, or they are deposited in cells as energy stores or as macromolecules important in cell function, such as for building proteins.

and then resynthesized into triglycerides once they diffuse into the intestinal epithelial cells. The triglycerides and other ingested lipids (for example, cholesterol) are packaged into chylomicrons, which enter lymph and from there the blood. As blood moves through adipose tissue, a blood vessel enzyme called lipoprotein lipase releases the fatty acids from the triglycerides in the chylomicrons. The released fatty acids then diffuse into adipose cells to re-form triglycerides (Figure 46.1b). These triglycerides are stored in adipose cells until the body requires additional energy.

As with glucose, some of the ingested fatty acids are not stored but are used by most organs other than the brain during the absorptive state to provide energy. The relative amounts of carbohydrate and fat used for energy during the absorptive state depend largely on the composition of a meal.

Absorbed Amino Acids Amino acids are taken up by all body cells, where they are used to synthesize proteins (Figure 46.1c). All cells require a constant supply of amino acids, because proteins are constantly being synthesized and degraded. However, unlike excess glucose and fatty acids, which are stored as glycogen and triglycerides, excess amino acids that are ingested are not stored as protein. Instead, excess amino acids are enzymatically broken down and used in the synthesis of fatty acids, which get incorporated into triglycerides. The triglycerides are then packaged and released into the blood to be taken up and stored in adipose cells. Therefore, eating large amounts of protein does not normally increase stores of body protein.

In the Postabsorptive State, Stored Nutrients Are Released and Used

As the postabsorptive state begins, synthesis of glycogen and triglycerides slows, and the breakdown of these substances begins. During this state, macromolecules formed during the absorptive state are broken down to supply monomers that can be used for energy. No glucose is available to be absorbed from the intestines during this time, yet the blood glucose concentration must be maintained because the cells of the central nervous system (CNS) normally use only glucose for energy. A large decrease in blood glucose concentration can disrupt CNS functions, ranging from subtle impairment of mental function to seizures, coma, or even death.

The events that maintain blood glucose concentration fall into two categories: (1) reactions that provide glucose to the blood and (2) cellular use of fatty acids for energy, thus sparing glucose for the CNS. Let's look at each of these.

Production of Glucose from Glycogen and Other Sources Vertebrates can increase their blood glucose concentration during the postabsorptive state in two major ways: by breaking down glycogen and by synthesizing new glucose. First, the glycogen that was formed during the absorptive state can be broken back down into molecules of glucose by hydrolysis, a process known as **glycogenolysis** (**Figure 46.2a**). This occurs primarily in the liver, after which the glucose is released into the blood, where it can travel to all cells.

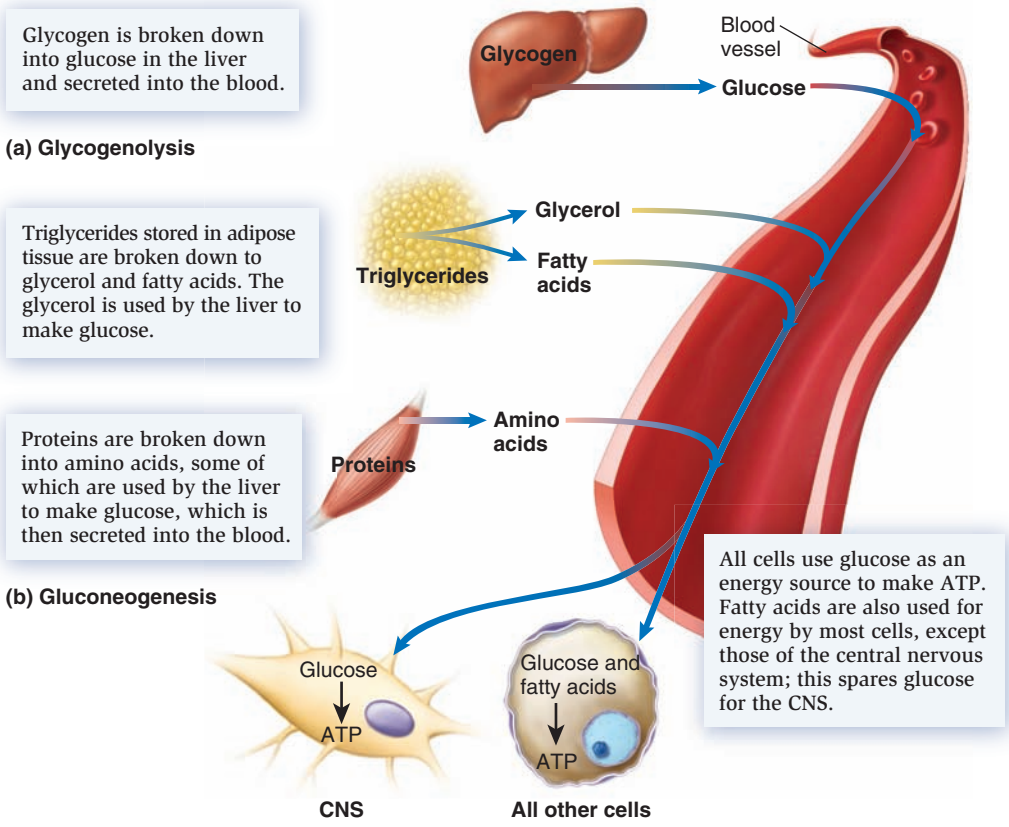

Figure 46.2 Events of the postabsorptive state. In this state, macromolecules formed during the absorptive state are broken down into smaller molecules that can be used for energy. **(a)** This begins with glycogenolysis—the breakdown of glycogen into glucose. **(b)** In gluconeogenesis, the breakdown products of triglycerides and proteins, namely, glycerol, fatty acids, and amino acids, can be used to synthesize glucose in the liver.

Table 46.1 Relative Changes in the Use and Generation of Energy Sources During the Absorptive and Postabsorptive States

	Glucose absorption from alimentary canal	Glucose use by cells	Synthesis of triglycerides	Use of fatty acids for energy by cells	Breakdown of glycogen in muscle and liver	Blood concentration of glucose
Absorptive state	High	High	High	Low/moderate	Low	Normal
Postabsorptive state	Absent	Moderate (some glucose is spared for CNS use)	Low	High	High	Normal

Muscle glycogen is also broken down into glucose by glycogenolysis, but this glucose is used exclusively by muscle cells and not secreted into the blood.

The amount of liver glycogen available to provide glucose during the postabsorptive state varies among animals, but it is generally sufficient to maintain blood glucose concentration for only a brief time, such as an overnight fast in a human. Therefore, a second mechanism for maintaining blood glucose concentration is required if the postabsorptive state continues longer. In the process of **gluconeogenesis** (literally, creation of new glucose), enzymes in the liver convert noncarbohydrates into glucose, which is then secreted into the blood (**Figure 46.2b**). This process occurs in all vertebrates but appears to be especially important in mammals.

A major precursor for gluconeogenesis is glycerol, which is released from triglycerides in adipose tissue by the breakdown process called **lipolysis**. In lipolysis, enzymes within adipose cells hydrolyze triglycerides into fatty acids and glycerol, both of which enter the bloodstream. The fatty acids diffuse into cells, where they are used as an alternate energy source to glucose (except in the CNS, which continues to require glucose). The glycerol is taken up by the liver, where enzymes process it by gluconeogenesis into glucose, which is then released back into the blood.

When the postabsorptive state continues for an extended period of time—as when an animal fails to find food—protein becomes an important source of blood glucose. Large quantities of protein in muscle and other tissues can be broken down to amino acids without serious tissue damage or loss of function. The amino acids enter the blood and are taken up by the liver. In the liver, the amino group is removed from each amino acid, and the remainder of the molecule is used for the synthesis of glucose by a stepwise series of enzyme-catalyzed reactions. This process, however, has limits. Continued protein loss can result in the death of cells throughout the body because they depend on proteins for such vital processes as plasma membrane function, enzymatic activity, and formation of organelles.

Lipid Metabolism by Other Tissues: Glucose Sparing Another way that glucose is made available to the organs and tissues that require it the most—such as the brain—is by having other organs and tissues decrease their dependence on glucose. They do this by increasing their use of fat as an energy supply during the postabsorptive state. This metabolic adjustment, called **glucose sparing**, reserves (or spares) the glucose produced by the liver by glycogenolysis and gluconeogenesis for use by the CNS.

The essential step in glucose sparing is lipolysis, the breakdown of adipose tissue triglycerides, which, as stated earlier, liberates fatty acids and glycerol into the blood. In vertebrates, the circulating fatty acids are taken up and used to provide energy by almost all tissues, excluding the nervous system, whose cells do not express the enzymes required to break down fatty acids for energy.

Of the vertebrate body's tissues and organs, the liver is unique in that most of the fatty acids entering it during the postabsorptive state are not used by that organ for energy. Instead they are processed into three small compounds collectively called **ketones**. Ketones are released into the blood during prolonged fasting. They provide an important energy source for the many tissues, including the brain, that are able to oxidize these compounds through the citric acid cycle.

The use of fatty acids and ketones during fasting provides energy for the body, sparing the available glucose for the brain. Moreover, as just mentioned, the brain can use ketones for energy, and it does so increasingly as ketones build up in the blood during the first few days of a fast. The survival value of this phenomenon is significant. When the brain decreases its glucose requirement by using ketones, much less protein breakdown is required to supply amino acids for gluconeogenesis. Protein stores last longer, enabling the animal to survive a longer fast without serious tissue damage.

The combined effects of glycogenolysis, gluconeogenesis, and glucose sparing are so efficient that, after several days of complete fasting in humans, the concentration of glucose in the blood decreases by only a small percentage. **Table 46.1** summarizes the relative changes in these and other variables during the absorptive and postabsorptive states.

46.2 Regulation of the Absorptive and Postabsorptive States

Learning Outcomes:

1. **SciSKILLS** » Predict how the blood concentration of insulin will change as the blood concentration of glucose changes, and vice versa.
2. Describe how the human body regulates the use and storage of glucose.
3. Describe the effect of exercise on energy demands and the mechanisms that are activated to meet those demands.

Tight control mechanisms are required to maintain homeostatic levels of energy-providing molecules in the blood. These controls come in two forms: endocrine and nervous. Cells of the endocrine system produce the blood-borne long-distance signaling molecules called

hormones. Several hormones work together with signals arising from cells of the nervous system in this coordination. In this section, we will see that one common function of the endocrine and nervous systems is to regulate the processes of glycogenolysis and gluconeogenesis so that glucose is made available to cells at all times.

Insulin Is a Key Regulator of Metabolism

The blood concentration of **insulin**, a hormone made by the pancreas, increases during the absorptive state and decreases during the postabsorptive state. Insulin regulates metabolism primarily by regulating the blood glucose concentration. It does this by promoting the transport of glucose from extracellular fluid into cells, where it can be used for metabolism. Glucose is a polar molecule that cannot cross plasma membranes without the aid of a transport protein. Insulin increases glucose uptake by binding to a cell-surface receptor and stimulating an intracellular signaling pathway. This pathway increases the availability of transport proteins called glucose transporters (GLUTs) in the plasma membrane (**Figure 46.3**). These GLUTs are located within preformed vesicles stored in the cytosol of cells. When these vesicles are stimulated, they fuse with the plasma membrane, making more GLUTs available to transport glucose into the cell. Consequently, insulin functions to decrease the blood glucose concentration because it increases uptake of glucose into cells.

Insulin exerts its effects mainly on skeletal and cardiac muscle cells and adipose cells, because these cells have insulin receptors in their plasma membranes. However, animal cells have many types of GLUTs, but only one requires insulin for its activity, as described next.

Genomes & Proteomes Connection

A Family of GLUT Proteins Transports Glucose in All Animal Cells

All animal cells use glucose for energy and thus require transporters to move glucose across their plasma membranes. GLUTs are evolutionarily ancient, and their structure is very similar across phyla. For example, almost 70% of the sequence of a gene that encodes a GLUT in *Drosophila* is identical to that of a gene encoding one of the GLUTs in humans. In more closely related phyla, such as birds and mammals, GLUTs are even more similar, with up to 95% of their amino acid sequences being the same. These and other considerations indicate that the GLUTs arose by accumulated mutations of a common ancestral gene.

GLUTs in mammals make up a family of at least 14 related proteins that share similar structures but are expressed in different tissues. The different GLUTs vary in their ability to bind glucose. For example, some GLUTs have high affinity for glucose, and others have low affinity. High affinity means the protein binds glucose even at very low concentrations of glucose. Let's look at the properties of three mammalian GLUTs, named GLUT1, GLUT3, and GLUT4. Muscle and adipose cells express the protein GLUT4, which has a low affinity for glucose, but one that is sufficient for the concentration of glucose normally found in blood. This is also the only GLUT whose movement to the plasma membrane requires the cell to be stimulated by insulin. Consequently, as the glucose concentration increases in the blood after a meal, insulin recruits

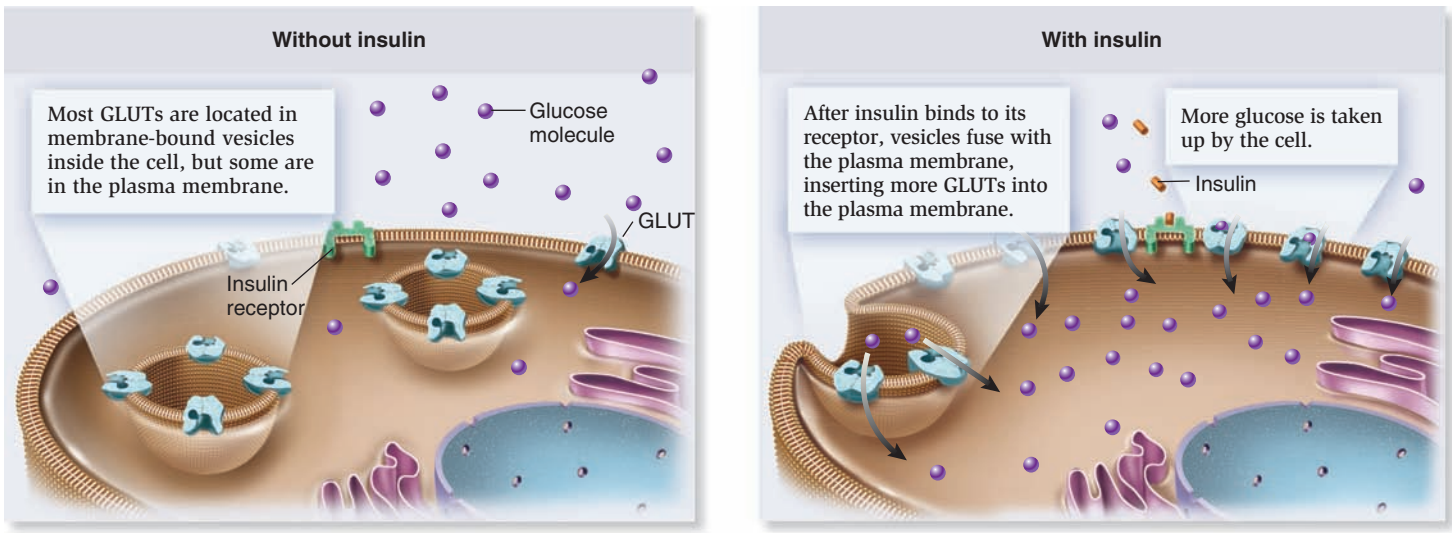

Figure 46.3 The effect of insulin on glucose transporters (GLUTs). In adipose cells and skeletal and cardiac muscle cells, the presence of insulin results in the fusion of intracellular vesicles containing GLUTs with the plasma membrane, where they facilitate glucose uptake into the cell.

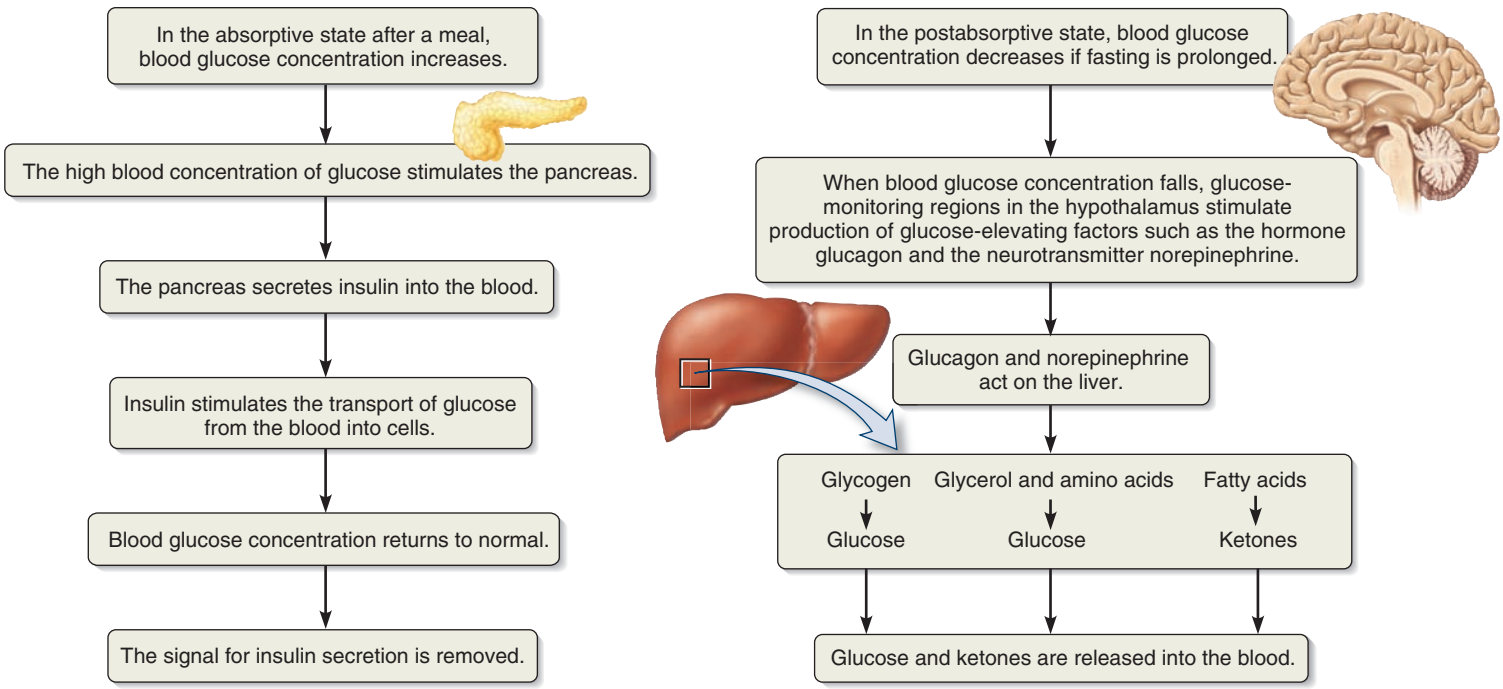
Concept Check: *What benefit is there to having GLUTs premanufactured and stored in intracellular vesicles?*

BioConnections: *In what other contexts have you learned about the fusion of intracellular vesicles with a cell's plasma membrane? (For one example, look back at Figure 5.23.)*

more GLUT4 molecules from vesicles in the cell cytosol to the plasma membrane of muscle and adipose cells.

By comparison, GLUT1 and GLUT3 are found predominantly in the vertebrate brain, where they act in concert to mediate the transport of glucose from blood vessels to the interstitial fluid of the brain, and from there into brain cells. GLUT1 and GLUT3 have much higher affinity for glucose than do other GLUTs. This means that neurons of the brain can transport glucose into their cytosol even when the concentration of glucose in the extracellular fluid is very low. In addition, insulin is not required for GLUT1 and GLUT3 to be present in the plasma membrane, unlike the situation for GLUT4. Instead, GLUT1 and GLUT3 are always present in the plasma membranes of cells expressing them. As a result of these properties of GLUT1 and GLUT3, neurons of the brain still receive adequate energy for survival even if an animal's blood glucose concentration decreases significantly, perhaps due to disease or starvation. Insulin-dependent cells, in contrast, would not be able to take up glucose under these circumstances, thus sparing glucose for the brain.



Expressing multiple types of the same functional class of protein means that different parts of an animal's body can meet their own particular metabolic demands. Moreover, these demands may change during development. For example, high-affinity GLUTs such as GLUT1 and GLUT3 are present in high numbers in the plasma membranes of many embryonic cells, which have a greater requirement for glucose, but are present in smaller numbers during other stages of life.

Because insulin, through its actions on GLUT4, is the key regulatory molecule that controls the blood glucose concentration, it is important to understand the regulation of insulin production and release, as described next.

The Blood Glucose Concentration Is Maintained Within a Normal Range

To maintain homeostasis, the blood glucose concentration is controlled by a system of checks and balances. In the absorptive state, after a meal has been eaten, the blood glucose concentration increases; in the postabsorptive state, depending on how long it lasts, the concentration may begin to decrease. What homeostatic mechanisms keep the blood glucose concentration within a normal range?

Increased Glucose in the Absorptive State The primary factor controlling the secretion of insulin from the pancreas is the blood glucose concentration (**Figure 46.4a**). An increase in an animal's blood glucose concentration directly stimulates cells of the pancreas to secrete insulin in proportion to the amount of glucose in the blood.

(a) When blood glucose concentration is high **(b) When blood glucose concentration is low**

Figure 46.4 Maintenance of blood glucose concentration within a normal range.

BIOLOGY PRINCIPLE Living organisms maintain homeostasis. Most animals cannot feed constantly and thus the ability to tap into stored reserves of energy allows them to maintain the blood concentration of glucose within a homeostatic range. This, in turn, ensures that homeostasis can be maintained, because cells are supplied with energy even when an animal has not recently ingested nutrients.

Concept Check: What are the sources of the glycerol, fatty acids, and amino acids that are used to make glucose and ketones?

Later, after insulin promotes glucose uptake into its target cells, the resulting decrease in the blood glucose concentration removes the signal for insulin secretion. This is an example of a negative feedback loop, as described in Figure 40.13.

In addition to the blood glucose concentration, inputs from the nervous system to the pancreas also play a role in the regulation of insulin secretion. During a meal, signals from the parasympathetic division of the autonomic nervous system (recall the rest-or-digest response from Chapter 42) stimulate the secretion of insulin into the blood.

Decreased Glucose in the Postabsorptive State Several factors act in concert to prevent blood glucose from decreasing below the normal homeostatic range, even during a short fast. Otherwise, glucose could decrease so much—a condition called hypoglycemia—that despite the high-affinity GLUT1 and GLUT3 in neuronal plasma membranes, there would not be enough glucose to keep these neurons alive.

If for any reason—such as a prolonged fast—the blood glucose concentration decreases below the normal homeostatic range for an animal, neurons within the hypothalamus that respond to changes in the extracellular concentration of glucose are activated (**Figure 46.4b**). Signals from the hypothalamus then stimulate the production of glucose-elevating factors. These include numerous hormones, notably **glucagon**, a protein hormone that is also secreted by the pancreas that stimulates the processes of glycogenolysis, gluconeogenesis, and ketone synthesis in the liver. In addition, certain other hormones from various endocrine glands, as well as the neurotransmitter norepinephrine released from neurons of the sympathetic division of the autonomic nervous system, stimulate adipose tissue to release fatty acids into the blood. The fatty acids diffuse across plasma membranes and provide another source of energy for the synthesis of ATP. The overall effect is to increase the blood concentrations of glucose, fatty acids, and ketones during the postabsorptive state or during a prolonged fast.

More Energy Is Required During Exercise

We think of exercise as something humans do for fun or fitness, but in its broadest sense, **exercise** can be defined as any physical activity that increases an animal's metabolic rate. Generally, an animal becomes active to seek something, such as food, shelter, or a mate, or to elude something, such as a predator or a storm. The types of exercise animals engage in, therefore, can be quite varied. When a cheetah sprints after a small antelope, for example, the activity of both predator and prey is brief and intense, perhaps lasting only a few seconds. By contrast, a tuna may never stop swimming, and a migrating bird may fly a hundred miles a day or more over a span of weeks.

For all types of activity, including exercise in humans, nutrients must be available to provide the energy required for such things as skeletal muscle contraction, increased heart and lung activity, and increased activity of the nervous system. These energy-providing nutrients include glucose and fatty acids as well as the muscle's own glycogen. The liver supplies the blood with the glucose used during exercise by breaking down its glycogen stores and by gluconeogenesis. This occurs even in the absorptive state, and thus the blood glucose concentration increases above normal when an animal exercises at such times. In addition, an increase in adipose tissue lipolysis releases fatty acids into the blood, which provides an additional source of energy for the exercising muscle.

These events are mediated by the same hormones and nerves responsible for the regulation of the postabsorptive state. For example, inputs from the sympathetic division to the pancreas inhibit insulin secretion during exercise. Consequently, glucose transport into muscle and adipose cells is decreased, which tends to increase the blood glucose concentration (this is part of the fight-or-flight response described in Chapter 42). Because the brain does not depend on insulin for glucose transport across neuronal membranes, as just described, more of the body's supply of glucose is available to the brain at such times, while other cells can use fatty acids for energy. Therefore, the body uses all available forms of energy in response to fasting or exercise.

46.3 Energy Balance and Metabolic Rate

Learning Outcomes:

1. Define basal metabolic rate (BMR), and explain how it is measured.
2. **SciSKILLS** » Predict the effects of various factors on metabolic rate.
3. Describe how hormones regulate metabolic rate and appetite.

Animals have a wide range of metabolic demands that depend on numerous factors. Active animals, such as migrating birds, use energy at a greater relative rate than inactive animals, such as hibernating mammals. Likewise, juveniles typically use energy at a greater relative rate than mature animals. Recall that the amount of energy an organism uses in a given period of time to power its metabolic requirements is called its metabolic rate.

A fundamental characteristic of energy is that it can be neither created nor destroyed, but it can be converted from one form to another (the first law of thermodynamics; see Chapter 6). The breakdown of organic molecules liberates energy in their chemical bonds, which is transferred to the bonds in ATP. This is the energy that cells use to perform various biological activities such as muscle contraction, active transport, and molecular synthesis. We refer to these functions as work. Not all of the energy is used to do work, however. Some of it appears as heat, which contributes to an animal's body temperature or is dissipated to the environment. In this section, we examine how metabolic rate is measured in animals; how metabolic rate is influenced by activity, digestion, and body mass; and how a balance is achieved between energy consumption and expenditure.

Metabolic Rate Can Be Measured by Calorimetry

The standard unit of energy is the joule (J), but biologists have historically quantified the energy of metabolism in calories. A **calorie** (equivalent to 4.187 J) is the amount of heat required to raise the temperature of 1 gram of water 1 degree Celsius. Most biological activities, however, require much greater amounts of energy than a

calorie, and consequently, the more common unit of measurement is the kilocalorie (1,000 calories, abbreviated as **kcal**). (In food labeling, a Calorie with a capital C is the same as a kilocalorie.) Biologists often measure and compare the metabolic rates of different animals to learn, for example, how some animals are capable of hibernating, how an animal's body temperature influences its metabolic rate, and how hormones and other factors alter an animal's metabolism.

The most common measure used to compare the metabolic rates of different species is the **basal metabolic rate (BMR)**. The BMR is called the metabolic cost of living, and, in vertebrates, most of it can be attributed to the routine functions of the heart, liver, kidneys, and brain. In the basal condition, the animal is at rest in the postabsorptive state and at a standard temperature. For **endotherms**—animals that generate their own internal heat through their metabolism and maintain a relatively narrow range of body temperatures—the standard temperature is within the range that causes the animal to neither generate heat (for example, by shivering) nor lose heat (for example, by perspiration). This temperature range is called an animal's thermoneutral zone. The BMR of **ectotherms**—animals that have a body temperature that changes with the environmental temperature—must be measured at a standard temperature for each species that approximates the average temperature that the species normally encounters. In this case, the term standard metabolic rate (SMR) is used instead of BMR, because the basal condition in ectotherms is harder to define than for endotherms.

The usual method for measuring metabolic rate, **indirect calorimetry**, is based on the principle that animals require oxygen to metabolize foodstuffs. The more fuel being metabolized—that is, the greater the metabolic rate—the more oxygen must be consumed by the animal. Measuring the rate at which a resting animal uses oxygen, therefore, provides a good estimate of BMR. Indirect calorimetry can also be used to compare the metabolic rates of an animal during rest and activity, when oxygen consumption increases (**Figure 46.5**). One limitation to this method is that a small percentage of fuel is metabolized anaerobically—that is, without oxygen—and thus indirect calorimetry underestimates actual metabolic rate.

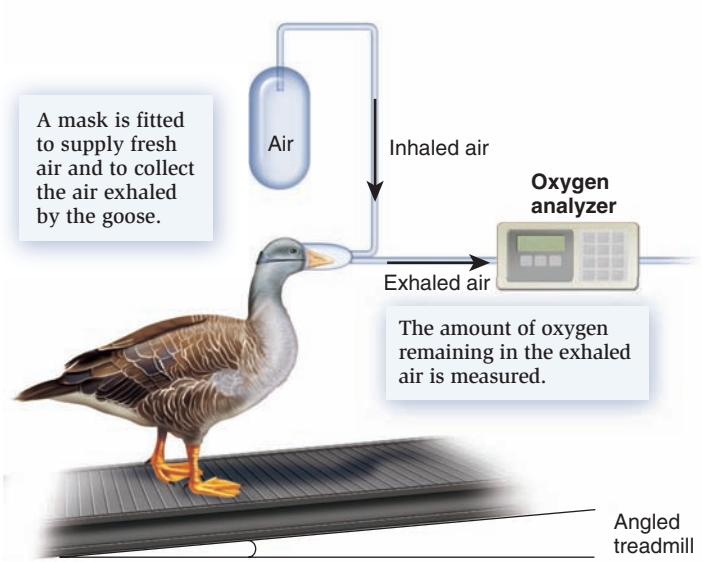


Figure 46.5 Measuring metabolic rate by indirect calorimetry. Many animals, such as this goose, can be trained to walk on a treadmill, which allows scientists to compare metabolism during rest and exercise. Oxygen consumption can be determined by sampling the air exhaled into a tightly fitting mask. One-way valves prevent inhaled and exhaled air from mixing.

BIOLOGY PRINCIPLE Biology is an experimental science. This figure illustrates how biologists can learn about general physiological principles using a variety of animal models. For example, many geese and other birds often fly for long periods at very high altitudes where oxygen availability is limited. Using experimental procedures like the one shown here allows scientists to understand how such animals can function under conditions that would be very challenging for humans.

Concept Check: If the exhaled air had been sampled from the mask just prior to starting the treadmill (while the goose was not yet exercising), would this have been a good estimate of BMR?

Activity, Digestion, and Body Mass Influence Metabolic Rate

Not all tissues in the body use oxygen and produce heat at the same rate. Some structures, such as skin, consume relatively little oxygen under resting conditions, whereas others, such as the brain, heart, and liver, have high rates of metabolism even when an animal is sleeping. Moreover, the metabolic rates of different tissues can vary depending on their activity. For example, the metabolism of the alimentary canal increases when food is being digested, and that of skeletal muscle increases during exercise.

Physical Activity The primary factor that increases metabolic rate is altered skeletal muscle activity. Even small increases in muscle contraction significantly increase metabolic rate; strenuous activity increases it even more. For example, the total daily expenditure of kilocalories may vary for a healthy adult human from approximately 1,350 kcal for a small person at rest to more than 7,000 kcal for a cyclist competing in the Tour de France. Metabolic rate is also slowed during sleep, due partly to decreased muscle activity, and increased during exposure to cold temperatures, due to increased muscle activity from shivering.

Digesting Food Eating and digesting food also increase the metabolic rate. Particularly in mammals that eat meat, this may increase metabolic rate (and associated heat production) by 10–50% for a few hours after eating. You may have noticed this **food-induced thermogenesis** after consuming a large meal. Ingested protein produces the greatest effect, whereas carbohydrate and fat produce less. The increased heat is believed to result partly from the processing of the absorbed nutrients by the liver and from the energy expended by the alimentary canal in digestion and absorption. Food-induced thermogenesis is observed in nearly all vertebrates, but it is most notable in certain reptiles such as many snakes that eat large and infrequent meals.

Body Mass Another factor affecting metabolic rate is body mass. In general, a large animal uses greater amounts of energy than does a small animal because the large animal has more mass and more cells, all of which consume fuel and generate heat. The metabolic rate and heat generation of an elephant are clearly greater than those of a mouse, for instance. However, when the metabolic rate of an elephant and a mouse are scaled to their respective body masses, we find that the energy expenditure per gram of body mass in a mouse is much higher than the comparable calculation in an elephant. **Mass-specific BMR** is the amount of energy expended per gram of body mass in the resting condition. Mass-specific BMR is a relative term that allows scientists to compare basal metabolic rates among animals of different sizes. Research has shown that the relationship between mass-specific BMR and body mass is exponential (**Figure 46.6**). One possible explanation for this phenomenon is that because the ratio of an animal's surface area to its body mass is greater in smaller animals than in larger animals, smaller animals lose heat more rapidly than larger ones. According to this hypothesis, smaller animals must generate more heat per gram of body mass than larger animals to replace their heat loss. However, although this hypothesis appears to provide an explanation for the relationship between metabolism and body size in endotherms, it does not explain the observation that the same relationship exists in almost all animals, including ectotherms.

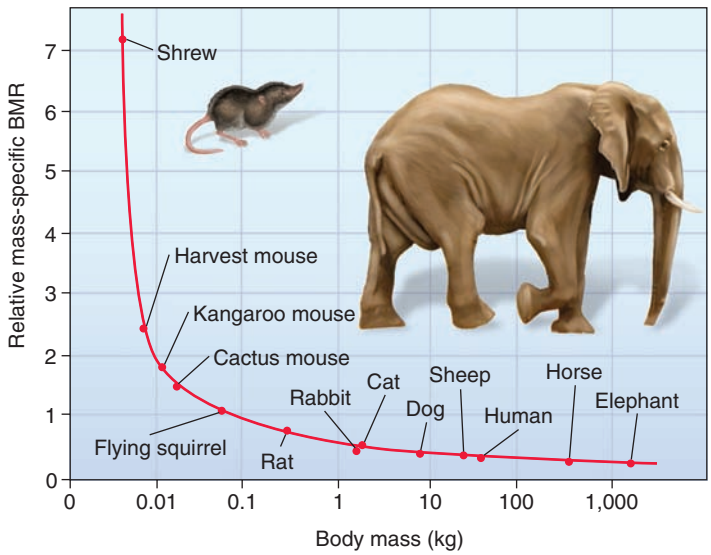

Figure 46.6 Metabolic rates of animals that differ in size. Metabolism can be scaled to body mass by measuring oxygen consumption and normalizing it to the animal's body mass (mass-specific BMR). Note that when expressed in this way, the mass-specific BMR of a shrew is greater than that of an elephant, even though the total oxygen consumption and heat output of the elephant are much greater. The values on the vertical axis are relative units of metabolism.

BIOLOGY PRINCIPLE Living organisms use energy. Many factors affect the relative energy usage by animals, including such things as an animal's life history, age, and as shown here, its body mass.

Concept Check: Can the relationship between body size and metabolic rate be used to propose hypotheses about metabolic rates of extinct animals?

Hormones and the Nervous System Control Food Intake

When the daily amount of energy an animal consumes is equal to the amount of energy it expends, the animal's body weight remains stable. Tipping the balance in either direction causes weight gain or loss, that is, the total body mass increases or decreases. Normally, energy is stored in the form of fat in adipose tissue.

Body weight in an adult animal is usually regulated around a predetermined set point that differs among species and between individuals. Body weight is maintained by adjusting caloric intake and energy expenditure in response to changes in body weight. This mechanism usually works very precisely in those animals in which it has been studied. For example, if given the opportunity a mammal that eats less one day will eat more the next day to compensate for the previous day's deficit. Similarly, if an animal is overfed one day, it may eat less the next day.

Short-term control of feeding generally involves a feeling of **satiety**, that is, fullness. As an animal's stomach and small intestine stretch to accommodate food, nerves send inhibitory signals from these structures to the appetite center in the hypothalamus. At the same time, the stomach and small intestine release into the blood hormones that reach the hypothalamus and suppress appetite. These satiety signals remove the sensation of hunger and set the time period before hunger returns again.

Long-term control of food intake is mediated by many different brain molecules, by hormones, and by emotional state, particularly in humans. One hormone that has received considerable attention in recent years for its ability to control appetite and metabolic rate is **leptin** (from the Greek *leptos*, meaning thin). Leptin has been identified in all classes of vertebrates but has been most extensively studied in mammals. In these animals, leptin is produced by adipose cells in proportion to fat mass: As more fat is stored in adipose cells, more leptin is secreted into the blood. Leptin acts on the hypothalamus to decrease appetite and increase metabolic rate (**Figure 46.7a**). In this way, the brain is made aware of how much fat is stored in the body at all times, and it can adjust appetite and metabolic rate appropriately if fat stores decline or increase. If an animal fasts for a period of time, its adipose cells shrink as they release their stored fat into the blood. The decrease in leptin secretion resulting from the decreased adipose mass results in a decrease in BMR and an increase in appetite. This may be the true evolutionary significance of leptin, namely that its disappearance from the blood lowers the BMR, consequently prolonging life during periods of starvation (**Figure 46.7b**).

Leptin was discovered in 1994, but its existence was postulated decades before that by the pioneering work of Douglas Coleman, who investigated the nature of mutations in mice that result in obesity. His observations continue to have important implications for human health today.

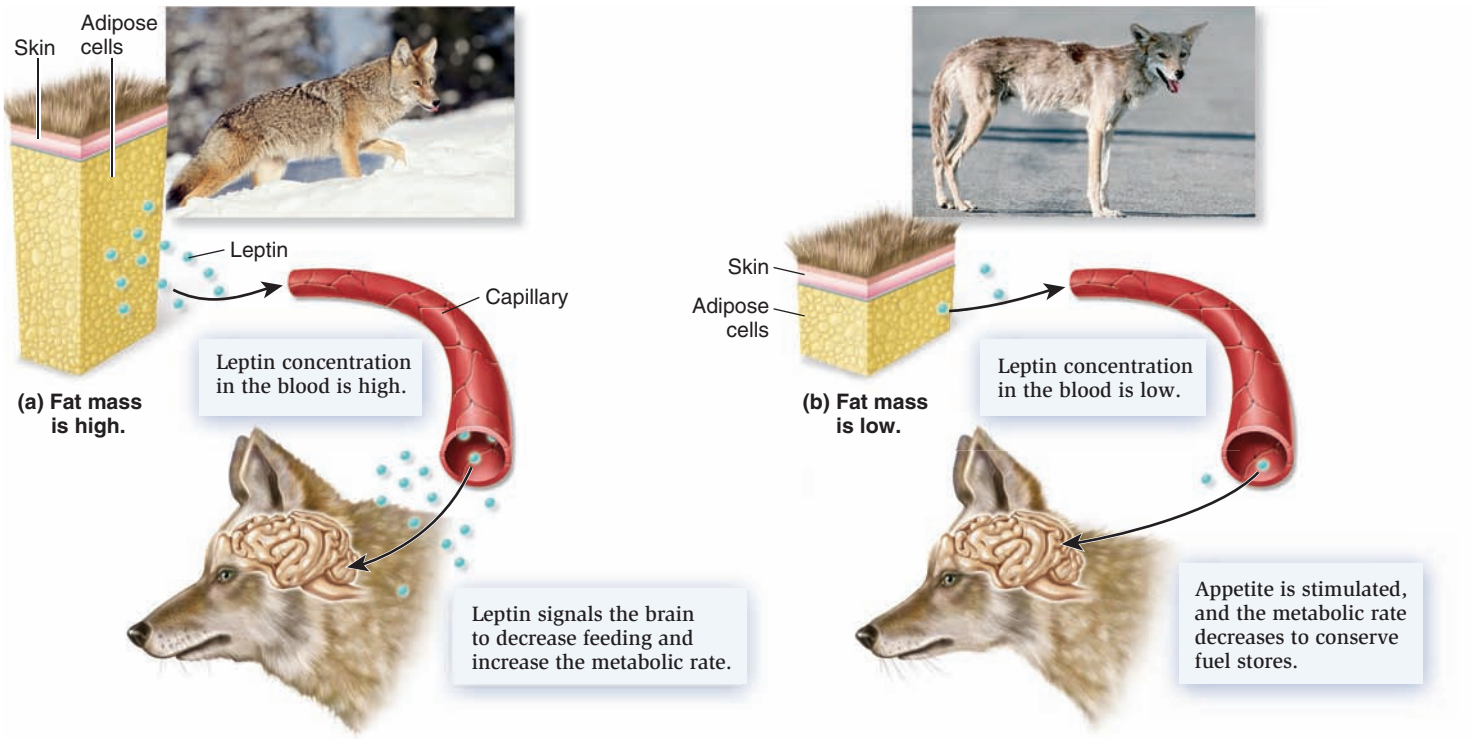

Figure 46.7 The role of leptin in regulating appetite and metabolic rate. In animals such as the coyote, changes in the blood leptin level result directly from changes in fat mass. Animals with more fat make more leptin.

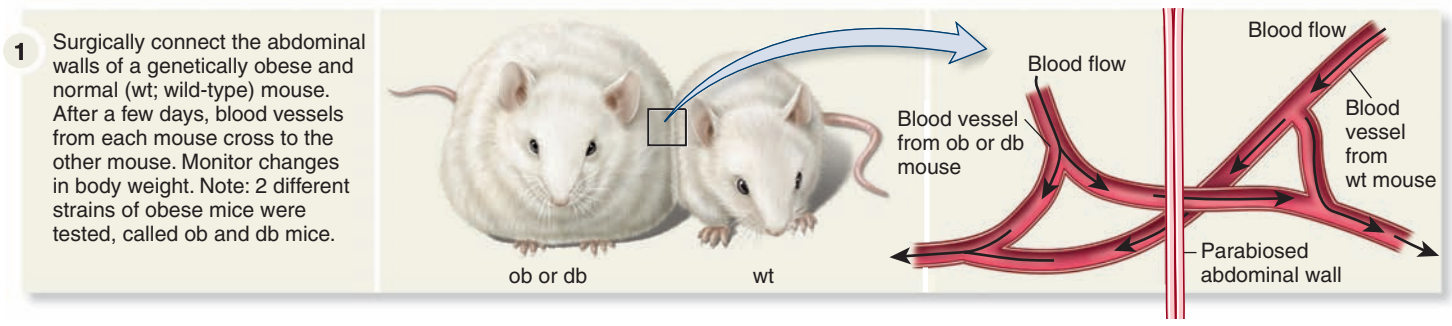
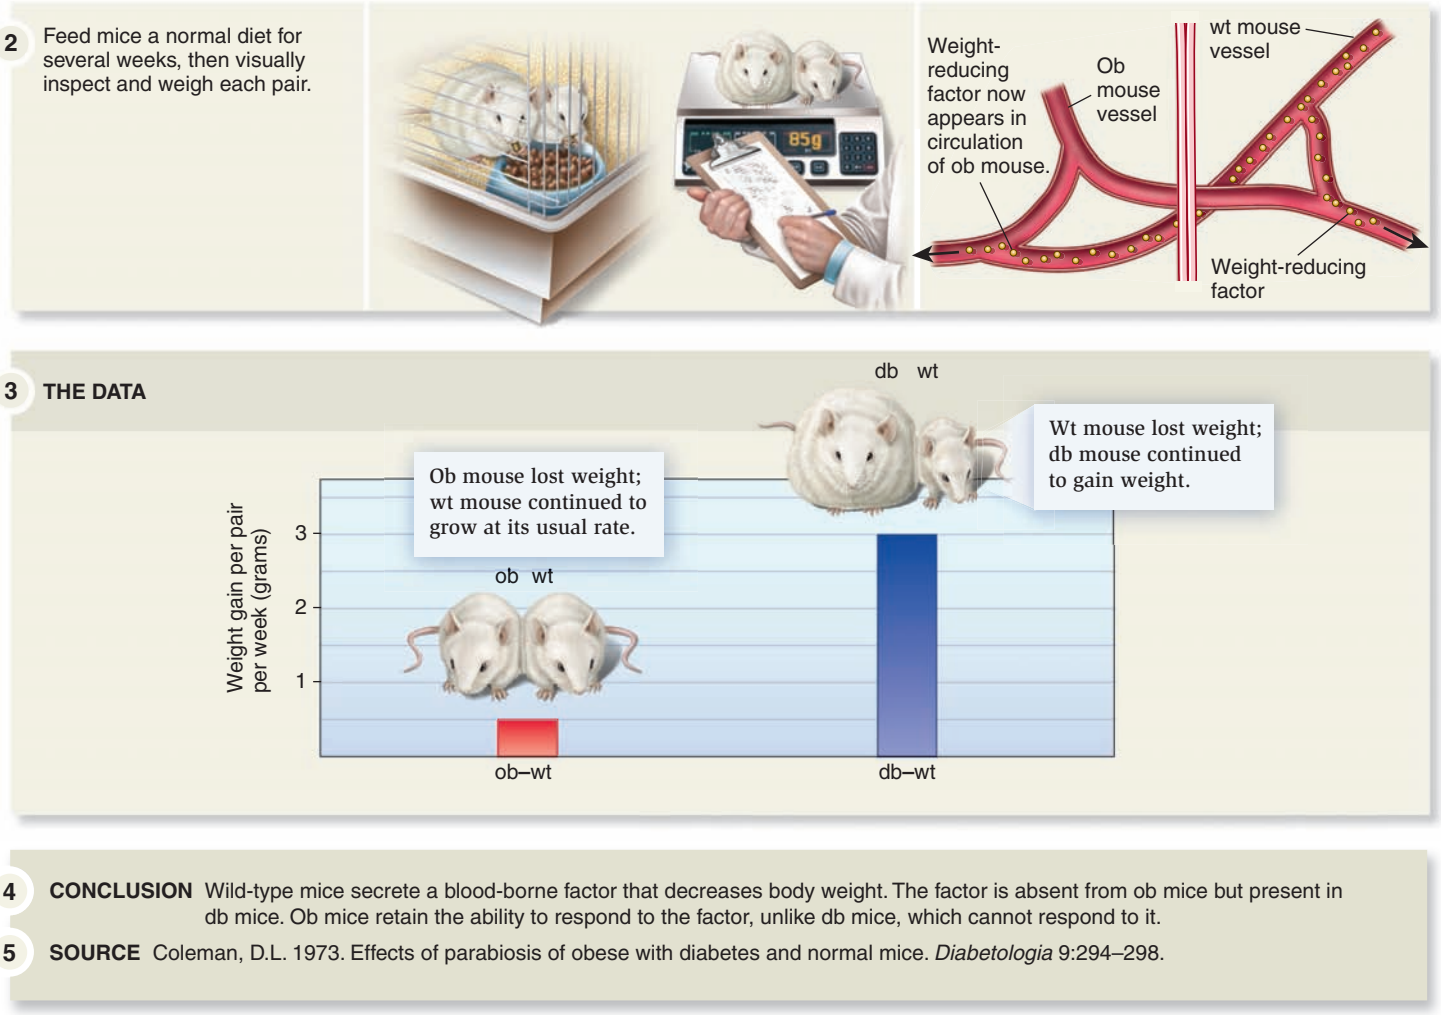
Feature Investigation | Coleman Revealed a Satiety Factor in Mammals



For many years, scientists wondered how most animals appeared to regulate their body mass around a predetermined set point, despite fluctuations in the food supply. They postulated that other parts of the body somehow communicated with the brain to signal when energy stores were above or below normal. In the 1970s, Canadian-American researcher Douglas Coleman tested this hypothesis in an experiment involving parabiosis, the surgical connection of the abdominal walls of two animals, such that the blood supply from one animal intermixes with that of the other.



Coleman used two strains of mice called ob and db mice, carrying different mutations that resulted in inherited forms of obesity, the excessive accumulation of body fat (an example of an ob mouse is shown in the chapter opening photo). Coleman first connected a wild-type (wt) mouse, one that lacked these mutations, with either an ob mouse or a db mouse, as shown in **Figure 46.8**. He discovered that when the circulatory system of the ob mouse was in contact with that of the wt mouse, the ob mouse ate less and gained less weight than usual. This suggested that the blood of the wt mouse contained

Figure 46.8 Coleman's parabiosis experiments revealed a satiety factor in wild-type mice that was absent in genetically obese mice.

HYPOTHESIS Body weight is controlled by a factor that circulates in the blood. This factor is absent in strains of mice that have an inherited form of obesity.

KEY MATERIALS Two different strains of genetically obese mice, normal (wild-type) mice.

a circulating factor that signals the brain when an animal has sufficient fat stored in its body and adjusts appetite accordingly. The ob mouse was deficient in this factor, but when exposed to it through the wt mouse's circulation, it responded in the appropriate way. The wt mouse of the parabiosis pair apparently retained a sufficient amount of the factor in its blood, because it maintained its body weight at a normal level.

Coleman noticed, however, that a db mouse continued to gain weight at an abnormally high rate even when its circulatory system was in contact with that of a wt mouse. In this case, the wt animal actually lost weight while the db animal remained obese. Coleman concluded that the db mouse must produce the same factor as the wt mouse, but for some reason, was unable to respond to it. The wt mouse that was parabiosed to the db mouse lost weight because it received the factor from the db mouse, in addition to having its own supply of the factor. Thus, whether the factor was absent as in the ob mouse, or present but unable to function as in the db mouse, the resulting phenotype was the same—obesity.

In 1994, American molecular biologist Jeffrey Friedman and coworkers at Rockefeller University identified this circulating factor as the hormone leptin. The ob mice were found to be homozygous for a mutation in the leptin gene, which produced an inactive leptin molecule, whereas db mice produced leptin but did not respond to it. In fact, the db mice were found to produce even greater amounts of leptin than wt mice, which explained why the wt mouse in Coleman's experiments lost weight when parabiosed with a db mouse. Friedman and others later showed that adipose cells produce leptin in direct proportion to the total fat mass of an animal, as stated earlier. Biologists now know that all classes of vertebrates produce leptin.

At first, the work of Coleman and Friedman generated considerable excitement that leptin might be useful to treat obesity in humans, but this has thus far proven difficult. Why? Recent research has revealed that most obese humans are more like the db mice than the ob mice. That is, they produce leptin but fail to respond adequately to it, and therefore, simply increasing the concentration of leptin in the blood may not have a significant effect on body weight. However, other studies have shown that leptin normally acts in nonobese humans in a manner much like it does in wt rodents. As noted in the chapter introduction, researchers have identified rare individuals in whom leptin is not produced due to a mutation in the leptin gene. These individuals are extremely obese and respond well to injections of leptin, losing considerable weight. The body weight disorders of such individuals, therefore, are reminiscent of ob mice.

Experimental Questions

1. What observation led to the experiments conducted by Coleman?
2. **SciSKILLS »** How did the experimental linking of the bloodstreams of the wild-type mice and the mutant mice affect the body weight of both strains? Why did the db mice fail to lose weight when parabiosed with the wt mice?
3. **SciSKILLS »** Predict what will happen to the respective body weights of ob and db mice if they are parabiosed to one another.

BIO TIPS

THE QUESTION *What do you predict will happen if a healthy mouse with a normal body weight is injected daily with a high dose of leptin?*

TOPIC ***What topic in biology does this question address?*** The topic is the control of body weight in a mouse by the hormone leptin.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you know that a mouse with a normal body weight (not obese or underweight) will be injected daily with a high dose of leptin. From your understanding of the topic, you know the effects of leptin on appetite and metabolic rate.

PROBLEM-SOLVING STRATEGY ***Propose a hypothesis.*** The best way to begin to answer this question is to consider how appetite and metabolic rate are related to body weight; then you can predict what will happen if the blood concentration of leptin is experimentally increased.

ANSWER *Leptin functions to inhibit appetite and increase metabolic rate. Daily injections of a high dose of leptin will increase the blood concentration of leptin in a mouse, perhaps to a level similar to those observed in obese mice (recall that leptin secretion increases as adiposity increases). Therefore, a logical hypothesis is that normal, healthy mice injected with leptin will lose weight; indeed, this is exactly what happens. When such an experiment is performed, the mice become underweight because their brains respond to the increased leptin as if the mice had an excess of body fat. As a result, their appetite decreases and metabolism increases.*

46.4 Regulation of Body Temperature

Learning Outcomes:

1. Provide examples of how changes in temperature affect chemical reactions, protein functions, and membrane structure.
2. List and define the four terms used to categorize organisms based on their source of heat and ability to maintain body temperature.
3. Identify the four main mechanisms animals use to exchange heat with the environment.
4. **SciSKILLS »** Identify several mechanisms by which animals can alter the rate of heat gain or loss, and describe some ways in which body structures facilitate these mechanisms.

As we have seen, metabolic rate is linked to body temperature. In this section, we will discuss why body temperature is important for the health and survival of all animals and consider mechanisms by which animals gain or lose heat.

Temperature Affects Chemical Reactions, Protein Function, and Plasma Membrane Structure

Most animals can survive only in a relatively narrow range of temperatures. Temperature has an effect on animals' bodies in three main areas: chemical reactions (and the enzymes that catalyze them), protein function, and membrane structure.

Chemical Reactions Chemical reactions depend on temperature. Heat accelerates the motion of molecules, so as an animal's temperature increases, the rates at which the molecules in its body move and contact each other also increase. Consequently, the rate of most chemical reactions in animals increases significantly with an increase in body temperature. In addition, enzymes, which catalyze many reactions in the body, including those involved in metabolism, have an optimal temperature range for their maximal catalytic function. Low temperatures slow down chemical reactions, making it harder for an animal to remain active and carry out internal functions such as digestion, reproduction, and immunity. The latter is particularly important, as many vertebrates become susceptible to disease when their body temperatures are decreased for long periods.

Protein Structure and Function A second effect of temperature is that it affects protein structure. Very high temperature causes many proteins to become denatured; that is, they lose the three-dimensional structure that is crucial to their ability to function properly. This occurs because the bonds that form tertiary and quaternary protein structures result from weak interactions, such as hydrogen bonds, and can be disrupted by heat (refer back to Figure 3.17). Denaturation of enzymes is especially serious because of the major role they play in metabolism. Most animals have an upper limit of body temperature at which they can survive. Most mammals have a resting body temperature of 35–38°C (95–100°F). In humans, a body temperature of 41°C (106°F) causes loss of protein function and breakdown of the nervous system, and a body temperature of 42–43°C (107–109°F) is fatal.

Membrane Structure A third effect of temperature is that heat alters the structures of plasma and intracellular membranes. At low temperatures, membranes become less fluid and more rigid, primarily due to changes in their phospholipids. Rigid membranes are less able to perform biological functions, such as transporting ions and binding extracellular molecules to receptors on the membrane surface. Alternatively, if the temperature becomes too high, membranes can become leaky.

Ectotherms and Endotherms May Have Fluctuating or Stable Body Temperatures

Biologists classify animals according to both the source of heat used to warm their bodies and their ability to maintain body temperature.

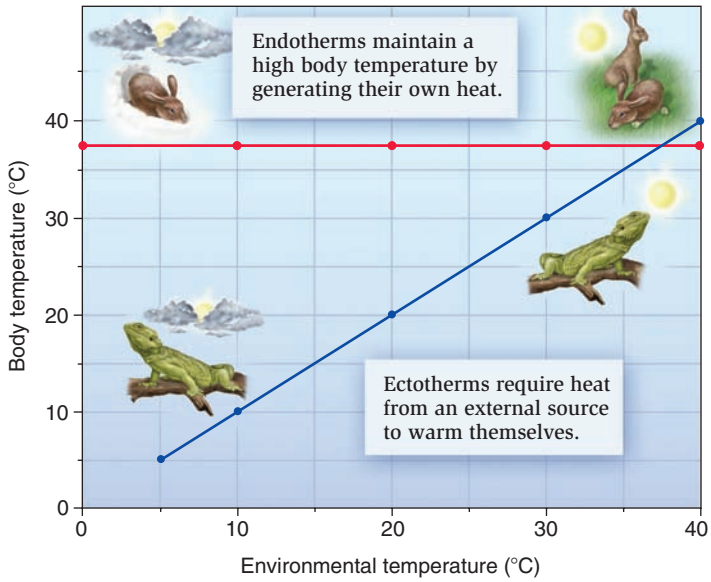


Figure 46.9 Body temperature and environmental temperature in endotherms and ectotherms. A rabbit is an endotherm but also a homeotherm because its body temperature doesn't change much; a lizard is an ectotherm but also a heterotherm because its body temperature changes considerably.

Concept Check: What thermoregulatory categories do humans fit into?

Recall that ectotherms depend on external heat sources to warm their bodies, whereas endotherms use their own metabolically generated heat to warm themselves. **Homeotherms** have body temperatures that are maintained within a narrow range, whereas **heterotherms** have body temperatures that vary widely with the environment (**Figure 46.9**). Most animals can be categorized as either endotherms or ectotherms and as either homeotherms or heterotherms. Generally, birds and mammals are endothermic and homeothermic. Other vertebrates and most invertebrates are ectothermic and heterothermic.

Not all animals, however, can be neatly classified into two categories at all times. For example, a fish swimming in deep ocean waters is an ectotherm but also homeothermic because the temperature of the water—and therefore of its body—remains essentially constant. Fishes that live in waters with fluctuating temperatures, by contrast, are ectothermic and heterothermic.

Even endothermic homeotherms do not have truly constant body temperatures. They have a narrow range of body temperatures that increases or decreases slightly in extreme climates, during exercise, or during sleep. The important feature is that birds and mammals can quickly adjust the body's mechanisms for retaining or releasing heat such that body temperature remains within the optimal narrow range. This provides the advantage that the body's chemical reactions are at optimal levels even when the environment imposes extreme challenges. The metabolic rate of a resting mammal, for example, is roughly six times greater than that of a comparably sized reptile. A suddenly awakened mammal is instantly capable of intense activity even on a winter day, but an icy-cold reptile could be at the mercy of a predator because of the time required to warm itself in order to flee.

Endothermy does have three major disadvantages, however. First, to produce sufficient heat by metabolic processes, endotherms must consume larger amounts of food to provide the nutrients used by cells in the formation of ATP, during which heat is generated. Small endotherms with high BMRs, such as shrews (see Figure 46.6), must eat almost continuously and may die if deprived of food for as little as a day. By contrast, many ectotherms, such as snakes, can go for weeks without eating. Second, endotherms have a greater risk of hyperthermia, or overheating, during periods of intense activity, even in cold weather. Third, as described shortly, because preventing body temperature from increasing often requires the evaporation of bodily fluids (and thus a need for replenishment of fluid), endotherms are often restricted to environments where water is plentiful.

Animals Exchange Heat with the Environment in Four Ways

The surface of an animal's body can lose or gain heat from the external environment via four mechanisms: radiation, evaporation, convection, and conduction (**Figure 46.10**).

- **Radiation** is the emission of electromagnetic waves by the surfaces of objects. The rate of emission is determined by the temperature of the radiating surface. Thus, if the body surface is warmer than the environment, the body loses heat at a rate that depends on the temperature difference. If the outside temperature is warmer than body temperature, the body gains heat, for instance from sunlight. We can observe radiated heat from an animal's body with imaging devices that detect infrared light (**Figure 46.11**).

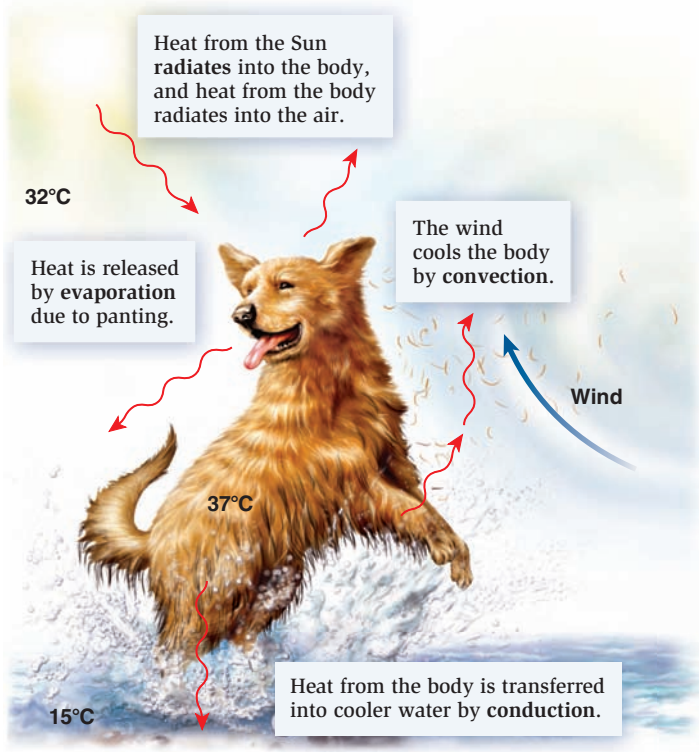

Figure 46.10 Types of heat exchange. The four ways in which animals exchange heat with the environment are radiation, evaporation, convection, and conduction.

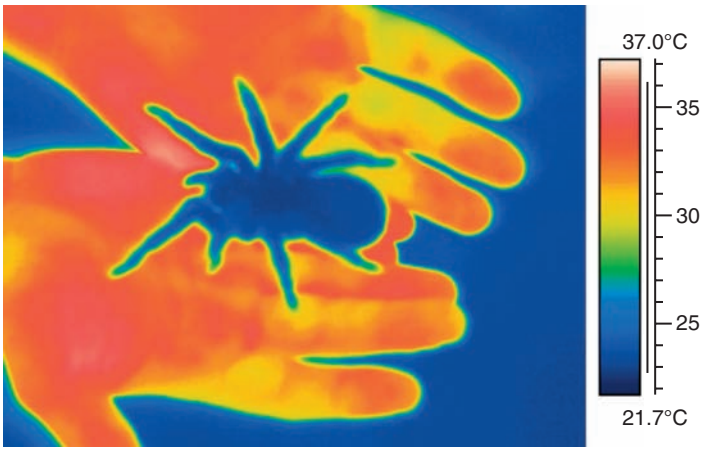

Figure 46.11 Visualization of heat exchange in an ectotherm and an endotherm. Thermal-imaging cameras can detect heat radiated from an animal's body. Note the warm skin of the endotherm (the human) and the cold body surface of the ectotherm (the tarantula), even though both animals are at the same environmental temperature of about 20–25°C.

- **Evaporation** is the conversion of water from the liquid to the gaseous state. Animals can lose body heat through evaporation of water from the skin and membranes lining the respiratory tract, including the surface of the tongue. A large amount of energy in the form of heat is required to transform water from liquid to gas. Whenever water vaporizes from the body's surface, the heat required to drive the process is conducted from the surface, thereby cooling the animal.
- **Convection** is the transfer of heat by the movement of air or fluid next to the body. For example, the air close to an endotherm's body is heated by conduction. Because warm air is less dense than cold air, the warm air near the body rises and carries away heat by convection. Convection is aided by creating currents of air around an animal's body. Humans may do this by sitting near fans, but other animals can create cooling air currents by other means such as when an elephant waves its ears.
- **Conduction** is the process by which the body surface loses or gains heat through direct contact with cooler or warmer substances. The greater the temperature difference, the greater is the rate of heat transfer. Different materials have different abilities to absorb heat, however. As we saw in Chapter 2, water has a higher specific heat than air, meaning that at any temperature, water will retain greater amounts of heat than will air. Consequently, aquatic animals in water that is 10°C lose considerably more heat in a short time than terrestrial animals lose in air that is 10°C. Indeed, on a hot day, terrestrial animals can lose heat efficiently by immersing themselves in cooler water. An animal's body surface area plays an important role in the rate of heat conduction across its body surface.

The four processes of heat transfer just described can be regulated in animals in such a way that heat is retained within the body at some times and lost at other times, as we see next.

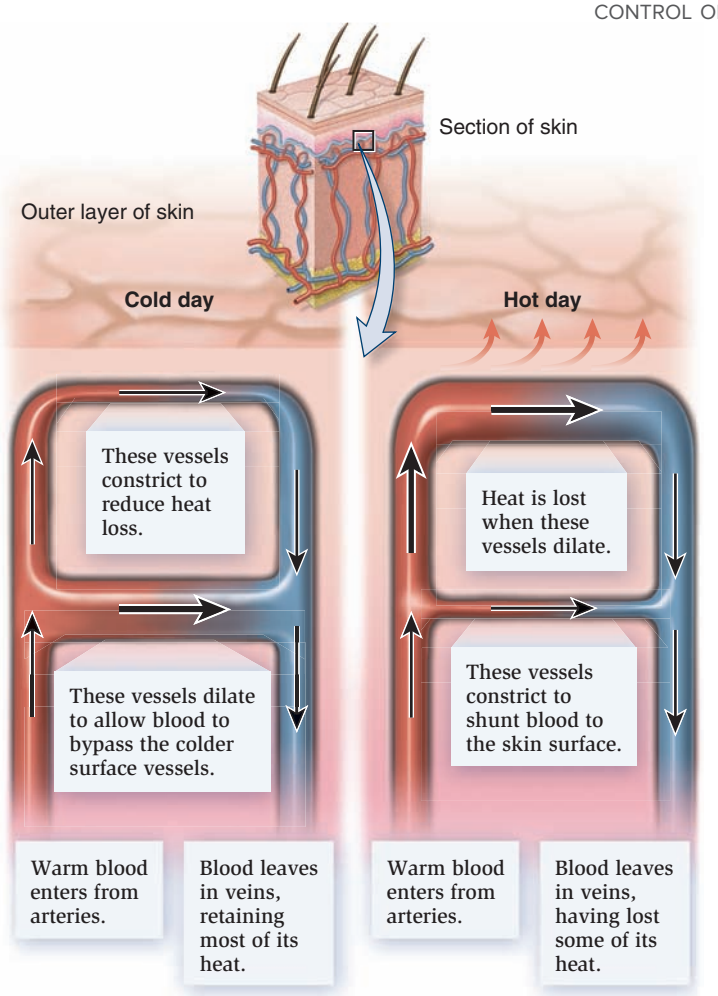
Several Mechanisms Can Alter Rates of Heat Gain or Loss in Endotherms

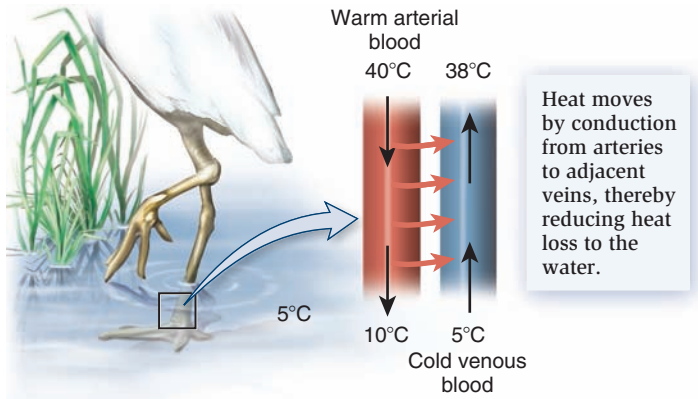
For purposes of temperature control, think of an endotherm's body as a central core surrounded by a shell consisting of skin and subcutaneous (just below the skin) tissue. Depending on the species, the temperature of the central core of endotherms is regulated at approximately 37–40°C (97–104°F), but the temperature of the outer surface of the skin varies considerably. If the skin were a perfect insulator, the body would never lose or gain heat by conduction. The skin does not insulate completely, however, so the temperature of its outer surface generally is somewhere between that of the external environment and the core. Only in animals that store large amounts of subcutaneous fat (blubber) does the body surface provide considerable insulation. In endotherms without blubber, the main form of insulation is a covering of hair, fur, or feathers, which traps heat from the body in a layer of warm air near the skin, reducing heat loss from conduction. Given these structures, then, let's take a look at four mechanisms that different endotherms use to regulate how much heat is gained or lost from their surface.

Changes in Skin Blood Flow Rather than acting as an insulator, the skin of many endotherms functions as a variable heat exchanger that can be adjusted to increase or decrease heat loss from the body. Skin surface blood vessels dilate (widen to increase blood flow) on hot days to dissipate heat to the environment, and they constrict (get narrower to decrease blood flow) on cold days to retain body heat (**Figure 46.12**). Signals from the nervous system regulate the relaxation or contraction of the smooth muscles that control the diameter of these blood vessels. Diving birds and diving mammals are good examples of animals that use this mechanism. Ducks, seals, and walruses dramatically decrease the amount of blood flowing to the skin when they dive in cold waters. This allows them to retain body heat that would otherwise be conducted into the water.

Countercurrent Exchange Many endotherms and ectotherms regulate heat loss to the environment through **countercurrent exchange**, in which heat is transferred between fluids flowing in opposite directions. Countercurrent exchange regulates heat loss to the environment by returning heat to the body's core and keeping the core much warmer than the extremities. In endotherms, countercurrent exchange occurs primarily in the extremities—the flippers of dolphins, for example, or the legs of birds and certain other terrestrial animals (**Figure 46.13a**). As warm blood travels from the core through arteries down a bird's leg, heat moves by conduction from the artery to adjacent veins carrying cooler blood in the other direction (**Figure 46.13b**). By the time the arterial blood reaches the tip of the leg, its temperature has dropped considerably, reducing the amount of heat lost to the environment and returning the heat via the veins to the body's core.

Evaporative Heat Loss Recall that some animals can lose body heat through evaporation of water from the skin and membranes lining the respiratory tract. Heat exchange in some mammals can be regulated by changing the rate of water evaporation through perspiration. Nerves to the sweat glands stimulate the production of sweat, a dilute solution containing Na^+ and Cl^-. The most important factor determining evaporation rate—and therefore heat loss—is the water





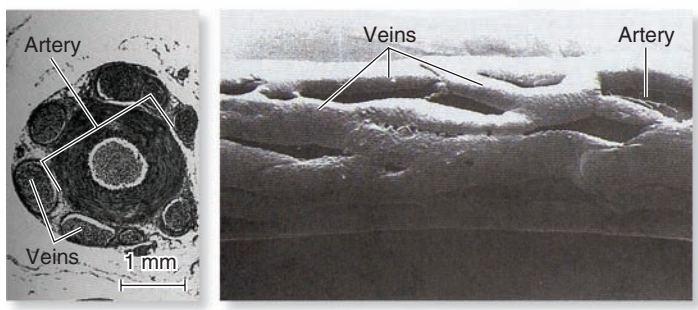


Figure 46.12 Regulation of heat exchange in the skin. As shown in this schematic illustration, the skin functions as a variable heat exchanger. The arrows in the blood vessels indicate direction of blood flow.

(a) Countercurrent heat exchange in the leg of an endotherm

(b) Cross section and surface view of veins covering an artery

Figure 46.13 Countercurrent exchange. (a) Countercurrent exchange retains heat in the leg of an endotherm such as this bird. Black arrows in vessels indicate direction of blood flow. **(b)** A micrograph of the arrangement of veins surrounding an artery in a bird's leg. The artery is almost completely covered by overlying veins, allowing efficient heat exchange between the vessels.

vapor concentration, or humidity, of the air. The discomfort you feel on a humid day is due to the failure of evaporation. Your sweat glands continue to secrete, but the sweat simply remains on your skin with body temperature remaining elevated, especially during exercise.

In endotherms that lack sweat glands, such as birds, or those that have very few glands, such as dogs and cats, panting (short, rapid breaths with the mouth open) promotes evaporation of water from the tongue surface. Panting has advantages over sweating, because no ions are lost, and panting provides the air current that promotes heat exchange by convection. However, the surface area of the mouth and tongue is relatively small, which limits the rate at which heat can be eliminated. Interestingly, many reptiles also pant on hot days, suggesting that panting evolved prior to endothermy.

Behavioral Adaptations Behavioral mechanisms can also alter heat loss by radiation, conduction, and evaporation. Two such behaviors involve changing exposed surface area and changing surroundings. On hot days, birds may ruffle their feathers and raise their wings, whereas many mammals will reduce their activity and spread their limbs; these postural changes increase the surface area available for heat transfer. Terrestrial endotherms seek shade, partially immerse themselves in water, or burrow into the ground when the sun is high. Pigs, which lack sweat glands, roll in the mud to cool down. Animals that neither sweat nor pant can still benefit from evaporative heat loss. The evaporation of fluids deposited on the body surface by licking the skin or splashing the skin with water also draws heat from the body.

Similarly, animals respond to cold temperatures with numerous behavioral adaptations. Huddling in groups, curling up into a ball, hunching the shoulders, burying the head and feet in feathers, and similar maneuvers decrease the surface area exposed to a cold environment and decrease heat loss by radiation and conduction. Changing environments is also a common strategy for coping with cold. Migration from cold to warmer regions occurs in numerous species of birds and mammals.

Muscle Activity and Brown Adipose Tissue Metabolism Increase Heat Production

We have discussed how heat is gained or lost to the environment and how heat can be retained by reducing blood flow to the skin on a cold day. Body temperature, however, is a balance between these factors and heat production. Changes in muscle activity constitute a major control of heat production for temperature regulation in endotherms.

When an endotherm is in its thermoneutral zone, no significant adjustments are necessary to maintain core body temperature. When

exposed to temperatures below the thermoneutral zone, however, core body temperature begins to decrease. The primary response to decreasing temperatures is to decrease the flow of blood to regions that permit conduction of heat. If this does not adequately decrease heat loss, skeletal muscle contraction is increased. This may lead to shivering, which consists of rapid muscle contractions without any locomotion. Virtually all of the energy liberated by the contracting muscles appears as internal heat, a process known as **shivering thermogenesis**. Many birds that remain in cold climates during the winter shiver almost continuously.

In many mammals, chronic cold exposure also induces **nonshivering thermogenesis**, an increase in the metabolic rate and therefore heat production that is not due to increased muscle activity. Nonshivering thermogenesis occurs primarily in **brown adipose tissue** (also called brown fat), a specialized tissue in small mammals such as hibernating bats, small rodents living in cold environments, and many newborn mammals, including humans. Brown adipose tissue is responsive to hormones and signals from the nervous system, which are activated when body temperature decreases. Unlike the adipose tissue discussed previously, which stores energy in the form of fat, brown adipose tissue metabolizes fat and generates heat as a by-product.

46.5 Impact on Public Health

Learning Outcome:

1. Define body mass index (BMI), and explain how it is used to assess health risks associated with overweight and obesity.

As we have seen, most animals, when provided adequate nutrients, maintain their body mass around a set point that is normal for their species. We rarely observe healthy animals in nature that are overweight. Generally, only domesticated animals become sufficiently sedentary that they gain excess, unnecessary weight (think of an overweight housecat). Humans, too, are prone to weight gain, particularly when living sedentary lives. Many people maintain a healthy body weight, but, as discussed in this section, an increasing number are unable to meet this goal.

Obesity Is a Global Health Issue

Excess body fat increases the risk of many diseases, including high blood pressure, cancer, heart disease, and diabetes mellitus. In diabetes mellitus, either insufficient insulin is available from the pancreas to control blood glucose concentrations (type 1 diabetes mellitus), or the cells of the body are less sensitive than usual to insulin (type 2 diabetes mellitus). In the U.S. alone, about 8% of the population—nearly 24,000,000 people—have diabetes mellitus. Of all diabetics in the U.S., more than 90% have type 2 diabetes mellitus. Compelling evidence has directly linked the incidence of this type of diabetes with being overweight. At what point does fat accumulation in humans start to pose a health risk? Historically, this question has been evaluated by research studies that investigate possible correlations between disease rates and some measure of body fat.

One of the currently preferred methods for assessing body fat and health risks is the **body mass index (BMI)**, a ratio of weight relative to height. A person's BMI is calculated by dividing his or her weight in kilograms by the square of his or her height in meters. For example, a 70-kg human with a height of 180 cm would have a BMI of 21.6 kg/m^2:

$$\text{BMI} = 70 \text{ kg} / (1.8)^2 \text{ m}$$
$$= 21.6 \text{ kg/m}^2$$

Current National Institutes of Health guidelines categorize BMIs of 25 or more as overweight, that is, as having increased health risk because of excess adipose tissue. BMIs of 30 or greater are considered obese, with a highly increased health risk. Data compiled by the Centers for Disease Control and Prevention in Atlanta, Georgia, and other U.S. federal agencies indicate that approximately two-thirds of U.S. adults age 20–74 are now overweight or obese (**Figure 46.14**). One of the more troubling statistics is that the percentage of adults who are overweight but not obese has remained relatively unchanged since 1960, at roughly 30–35%. However, the percentage of obese adults has risen during that time from about 13% to the current level of 33–34%. Since as recently as the early 1990s, the CDC estimates that the average body weight of Americans has risen by 10 pounds. Even more troubling, the rate of childhood obesity has also risen. In the U.S., the incidence of obesity in children age 6–11 has increased from 2–3% in 1960 to the current estimate of more than 15%.

The increase in the overweight and obesity categories is not confined to the U.S., but has become a worldwide trend. According to the World Health Organization, more than 1 billion adults globally are overweight and 300 million are obese. One ray of hope is that the incidence of obesity in the U.S. population has leveled off since 2003, suggesting that efforts at educating the public about the health consequences of obesity may be starting to have a positive result.

Some studies indicate that genetic factors play an important role in obesity. Identical twins separated soon after birth and raised in

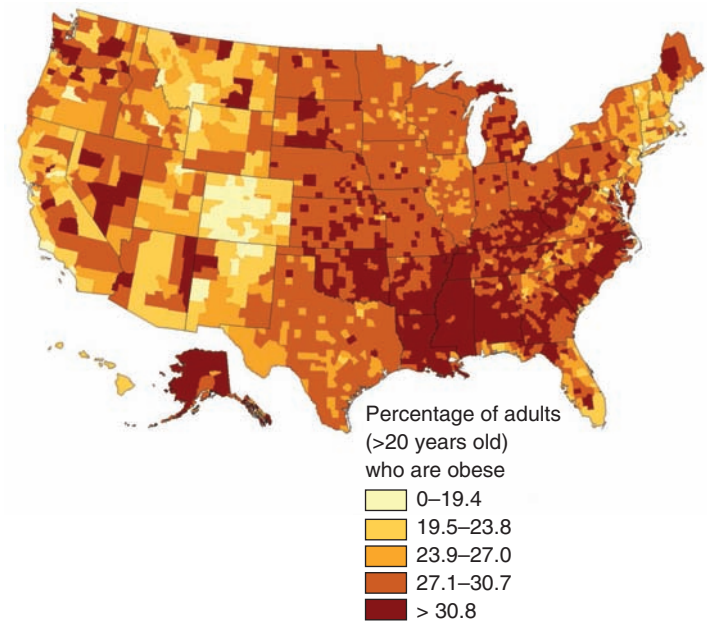

Figure 46.14 Obesity in U.S. adults. The Centers for Disease Control and Prevention estimate that many areas of the country experience obesity rates over 30% in adults (the darkest colored areas).

different households have strikingly similar body weights as adults. Researchers hypothesize that natural selection favored the evolution of so-called thrifty genes, which boosted our ancestors' ability to store fat from each feast in order to sustain them through the next famine. Given today's abundance of high-fat foods in many countries, what was once a survival mechanism may now be a liability.

The methods and goals of treating obesity are undergoing extensive rethinking. An increase in body fat is generally due to an excess of energy intake over energy expenditure, and overweight people have traditionally been advised to follow a low-calorie diet. However, such diets alone have limited effectiveness, because over 90% of obese people regain most or all of their lost weight within 5 years. This disturbing phenomenon may be related to the observation that metabolic rate decreases as the concentration of leptin in the blood decreases. Metabolic rate may decrease sufficiently to prevent further weight loss on as little as 1,000 kcal per day.

Research indicates that crash diets are not an effective long-term method for controlling weight. Instead, caloric intake should be set at a realistic level that can be maintained for the rest of one's life. This should lead to a slow, steady weight loss of no more than 1 pound per week until body weight stabilizes at a new, lower level. Most important, any program of weight loss should include increased physical activity. The exercise itself burns calories, but more importantly, it partially offsets the tendency for the metabolic rate to decrease. As a bonus, the combination of exercise and caloric restriction causes the person to lose more fat and less protein than with caloric restriction alone.

The impact of obesity on public health is enormous, accounting for many illnesses requiring hospitalization and chronic drug therapy and well over 100,000 premature deaths per year. Its impact on the economy is far-reaching as well. The economic toll of obesity-related illnesses is felt in the loss of worker-hours in the workplace, in the cost of hospital stays, physician office visits, nursing home care, and medication costs. In fact, current estimates are that as much as 10% of all U.S. health-care expenditures are directly or indirectly related to obesity! Obesity can affect society in unexpected ways. As an example, the increasing weight load of passengers forces airplanes to burn 350 million additional gallons of fuel each year, compared with just 20 years ago! This translates into nearly 4 million tons of additional pollution released into the atmosphere every year. In another recent example, for safety reasons, the U.S. Coast Guard has begun downgrading the allowable number of passengers on large state ferries due to the increasing average weight of U.S. adults.

Summary of Key Concepts

46.1 Use and Storage of Energy

- An animal's handling of nutrients has two states: the absorptive state, during which ingested nutrients are entering the blood from the alimentary canal; and the postabsorptive state, during which the GI tract is empty of nutrients and the body's own stores must supply energy.
- Glucose and fatty acids are the two major energy sources during the absorptive state. Much of the absorbed glucose immediately enters cells and is enzymatically broken down, providing energy required to synthesize ATP. Most absorbed triglycerides are stored in adipose cells until the body requires additional energy. Amino acids are taken up by all body cells and used to synthesize proteins (Figure 46.1).
- The events that maintain blood glucose concentration in the postabsorptive state fall into two categories: (1) the reactions glycogenolysis and gluconeogenesis, which provide glucose to the blood, and (2) cellular use of fatty acids for energy, which spares glucose for use by the nervous system (Figure 46.2, Table 46.1).

46.2 Regulation of the Absorptive and Postabsorptive States

- Tight control mechanisms, in the form of several hormones and the nervous system, maintain homeostatic concentrations of fuel molecules in the blood. The hormone insulin acts on certain cells to facilitate the diffusion of glucose from blood into the cell cytosol via glucose transporters (GLUTs). All animal cells use GLUTs to transport glucose across their plasma membranes (Figure 46.3).
- In vertebrates, an increase in blood glucose concentration in the absorptive state stimulates the cells of the pancreas to secrete insulin; a decrease in glucose concentration removes the signal for secretion. In the postabsorptive state, when the blood glucose concentration decreases, glucose-monitoring regions in the hypothalamus stimulate production of glucose-elevating factors such as glucagon and norepinephrine (Figure 46.4).
- Exercise or any type of physical activity increases an animal's metabolic rate. Exercise increases an animal's requirement for nutrients, including glucose and fatty acids, to provide energy.

46.3 Energy Balance and Metabolic Rate

- An animal's metabolic rate refers to the amount of energy it uses in a given period of time to power all of its metabolic requirements.
- The most common measure for comparing metabolic rates of different species is the basal metabolic rate (BMR). Most of the basal metabolism is due to the routine functions of the heart, liver, kidneys, and brain (Figure 46.5).
- Many factors affect metabolism, including skeletal muscle activity, whether an animal has recently eaten, and body mass (Figure 46.6).
- When the daily amount of energy consumed equals the amount of energy expended, body weight remains stable. Tipping the balance in either direction causes weight gain or loss by increasing or decreasing total body energy content.
- Short-term control of feeding generally involves satiety signals that remove the sensation of hunger and set the time period before hunger returns again. Experiments by Coleman and Friedman investigated the hormone leptin as a satiety factor in mammals. Leptin has since been found in all classes of vertebrates (Figures 46.7, 46.8).

46.4 Regulation of Body Temperature

- Most animals can survive only in a relatively narrow temperature range that allows chemical reactions to proceed, maintains the structures of membranes, and avoids denaturing proteins.
- Animals can be classified according to their source of heat and their ability to maintain body temperature. Ectotherms depend on external heat sources to warm their bodies, whereas endotherms use their own metabolically generated heat to warm themselves. Homeotherms maintain their body temperature within a narrow range, but heterotherms have body temperatures that vary with environmental conditions (Figure 46.9).

- The surface of an animal's body can lose or gain heat from the external environment via four mechanisms: radiation, evaporation, convection, and conduction (Figures 46.10, 46.11).
- The skin can function as a variable heat exchanger; blood vessels near the skin surface dilate to dissipate heat or constrict to retain it. Both endotherms and ectotherms regulate heat loss through countercurrent exchange, which retains heat by returning it to the body's core and keeping the core warmer than the extremities. Heat exchange can also be regulated by changing the rate of water evaporation via perspiration. Behavioral mechanisms can alter heat loss by radiation, conduction, and convection (Figures 46.12, 46.13).
- Muscle activity (shivering thermogenesis) and brown adipose tissue metabolism (nonshivering thermogenesis) increase the production of heat.

46.5 Impact on Public Health

- Excess body fat increases the risk of many diseases. A body mass index (BMI) of 25 kg/m^2 or more is considered overweight; 30 kg/m^2 is considered obese (Figure 46.14).
- Obesity can have serious health risks and is treated with caloric restriction and exercise.

Assess and Discuss

Test Yourself

1. During the absorptive state, an animal is
   a. fasting.
   b. relying entirely on stored molecules for energy.
   c. absorbing nutrients from a recently ingested meal.
   d. metabolizing lipids stored in adipose tissue to supply ATP to its cells.
   e. doing both a and b.
2. Gluconeogenesis
   a. occurs when the liver synthesizes glucose from noncarbohydrate precursors.
   b. is the process by which glycogen is broken down to glucose.
   c. occurs primarily when an animal is in the absorptive state.
   d. occurs when triglycerides are being formed and stored in adipose cells.
   e. occurs primarily in skeletal muscle.
3. In the process of _____, most tissues of the vertebrate body metabolize fat instead of glucose to ensure that _____ tissue has an adequate supply of glucose.
   a. gluconeogenesis, muscle
   b. glucose sparing, epithelial
   c. glycogenolysis, nervous
   d. glucose sparing, nervous
   e. gluconeogenesis, epithelial
4. Ketones are compounds that are derived from _____ and are synthesized primarily in the _____ state.
   a. glucose, absorptive
   b. glycogen, absorptive
   c. fatty acids, postabsorptive
   d. amino acids, postabsorptive
   e. triglycerides, absorptive
5. Insulin primarily regulates the blood glucose concentration by
   a. stimulating the recruitment of GLUTs from the cytosol to the plasma membrane for transport of glucose from extracellular to intracellular fluid.
   b. stimulating gluconeogenesis.
   c. suppressing glucose uptake by muscle tissue.
   d. stimulating the release of glucose from glycogen reserves in the liver.
   e. inhibiting the synthesis of new GLUTs.
6. The rate at which an animal uses energy is called
   a. body mass index.
   b. the animal's energy consumption.
   c. metabolic rate.
   d. nonshivering thermogenesis.
   e. shivering thermogenesis.
7. Which factor may increase metabolic rate?
   a. shivering
   b. decreased muscle activity
   c. sleeping
   d. consumption of a meal
   e. both a and d
8. Which molecule acts on brain centers to decrease appetite in mammals and other vertebrates?
   a. GLUT4
   b. glycogen
   c. leptin
   d. glucagon
   e. a ketone
9. Animals that have body temperatures that are maintained within a narrow range are
   a. endotherms.
   b. ectotherms.
   c. homeotherms.
   d. heterotherms.
   e. both b and d.
10. The rate of heat loss in a mammal is regulated by
    a. the degree of blood flow at the surface of the skin.
    b. the amount of perspiration.
    c. behavioral adaptations.
    d. air currents near the animal's body.
    e. all of the above.

Conceptual Questions

1. Explain the functions of insulin. Why do you think a hormone such as insulin is required to carry out these functions?
2. Explain how appetite is controlled by the brain. What is the benefit of having a hormone released from adipose cells in proportion to total fat mass?
3. A principle of biology is that *structure determines function*. How does this principle apply to countercurrent exchange?

Collaborative Questions

1. Discuss the differences between being ectothermic and endothermic and between being heterothermic and homeothermic.
2. Discuss four ways animals exchange heat with their environment.

Image from cardiac angiography of a human heart (dye contrast injection makes the coronary blood vessels appear red and thus easier to visualize).

In the time it takes you to read this chapter introduction, three or four people in the U.S. will have suffered a heart attack, and one or more of those individuals will likely have died as a result. Cardiovascular disease—disease of the heart or blood vessels—is the leading cause of death in the U.S. and in much of the rest of the world. In the U.S. alone, an estimated 80,000,000 or more people have one or more diseases that affect the heart and blood vessels. About 1–1.5 million of those individuals will have a heart attack in the next year, and between 400,000–600,000 of them will die as a result.

The heart is a muscular pump that works ceaselessly. Because of this constant activity, heart muscle requires a steady and large amount of blood, bringing with it the nutrients and oxygen required to sustain that muscular effort. The chapter opening photo shows the extensive network of blood vessels coursing through the human heart. Should any of those vessels become diseased, the regions of the heart supplied by those vessels can die. That is what happens during a heart attack. If a heart attack occurs, the damaged heart may not be able to pump blood forcefully enough to generate the pressure required for sufficient blood and oxygen to reach the cells of the body.

Circulatory systems transport necessary materials to all the cells of an animal's body, and transport waste products away from the cells so they can be released into the environment. In this chapter, we will examine how this occurs. Single-celled organisms are small enough that dissolved substances are able to diffuse into and out of the cell. In larger animals, however, dissolved substances must move greater distances between cells, as well as between the internal and external environments. The time required for osmosis of water and diffusion of solutes throughout the body and between environments would be too great to sustain life in such animals. In the circulatory systems of larger animals, the heart pumps a fluid such as blood through vessels throughout the body. As we will see, this is accomplished with either an open circulatory system or a closed circulatory system. An important feature of many circulatory systems is that they are capable of adjusting their activities to an animal's changing metabolic demands. For instance, we will see how physical activity increases the ability of the vertebrate heart to pump blood and enables more of it to be sent to the skeletal muscles where it is most needed. Understanding the relationships among the heart, blood, and blood pressure is a major focus of this chapter. We end by considering the major types of cardiovascular disease in humans and some of their causes, symptoms, and treatments.

47.1 Types of Circulatory Systems

Learning Outcomes:

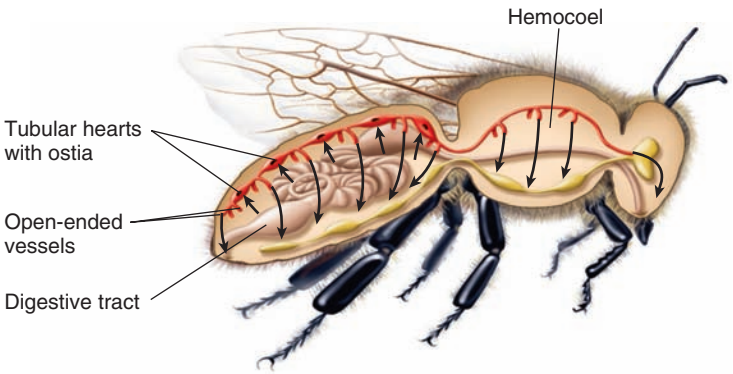
1. Relate the key structural characteristics of open and closed circulatory systems to their functions.
2. Describe single and double circulations in vertebrates.

Apart from the simple type of circulation found in certain invertebrates that have a gastrovascular cavity (refer back to Figure 45.2), two types of circulatory systems exist in animals: open systems and closed systems. Both types have three basic components: (1) a fluid containing cells and solutes; (2) a system of vessels, hollow tubes

through which the fluid travels; and (3) one or more muscular structures such as a **heart** that pump the fluid through the vessels. In this section, we will compare and contrast some of the key features of the two major types of circulatory systems found in animals.

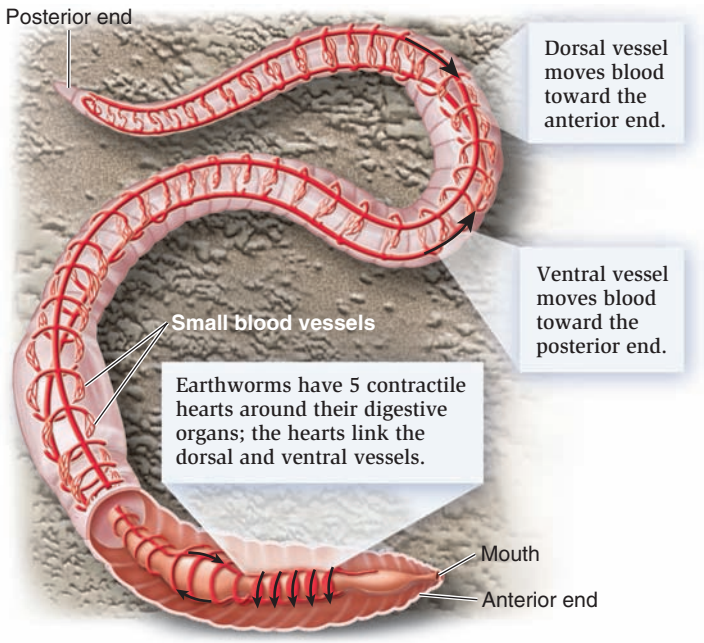
In Open Circulatory Systems, Hemolymph Enters the Body Cavity

Arthropods and some mollusks have an **open circulatory system**, the defining feature of which is that fluid is pumped by one or more hearts through vessels that open into the animal's body cavity, called the hemocoel (**Figure 47.1a**). Therefore, the fluid in the vessels and the interstitial fluid that surrounds cells mingle in one large compartment, rather than being located in separate body compartments. The mixed fluid is called **hemolymph**. Nutrients and wastes are exchanged by diffusion between the hemolymph and body cells, and the hemolymph eventually returns to the heart. In mollusks with open circulatory systems, hemolymph re-enters the heart through vessels, whereas in arthropods, it returns directly to the heart through small openings called ostia.



In insects, hemolymph primarily transports nutrients and wastes; in mollusks, it also brings oxygen to body cells. Insects have a unique oxygen-delivery system that does not involve the circulatory system, as you will learn in Chapter 48. This is a major distinction between insect circulatory systems and those of other animals.

Open circulatory systems are metabolically inexpensive because energy is not required to pump the hemolymph through an extensive network of blood vessels; recall that hemolymph simply enters the hemocoel through open vessels. In addition, open systems can adapt to changes in an animal's metabolic demands. As an insect takes flight, for example, its flight muscles contract more forcefully and rapidly, which acts to expand and compress the animal's thorax. This helps propel hemolymph more rapidly throughout the hemocoel and into and out of the hearts. In other words, as the animal's physical activity increases, its circulation becomes more efficient, recharging metabolically active cells with nutrients. The ability to adjust circulation to meet an animal's requirements is one of the most important features of any circulatory system.



Despite the phenomenal success of species with open systems, this type of circulation has certain limitations. For instance, because the hemolymph empties in bulk into the hemocoel, it cannot be selectively delivered to individual regions of the body in proportion to their metabolic demands. By contrast, during periods of increased physical activity in vertebrates, larger amounts of blood are delivered to skeletal muscles and away from less metabolically active structures, an extremely useful adaptation that results in greater endurance. This is possible because these animals have a closed circulatory system, as we see next.

In Closed Circulatory Systems, Blood Remains in Vessels at All Times

In a **closed circulatory system**, blood and interstitial fluid are physically separated and differ from each other in their components and chemical composition. Closed circulatory systems are found in

(a) An open circulatory system.

(b) A closed circulatory system.

Figure 47.1 Types of circulatory systems. **(a)** In open circulatory systems, one or more muscular, tubular hearts pump hemolymph through open-ended vessels, where it percolates through the body. In arthropods such as this honeybee, hemolymph re-enters the heart through ostia. The arrows show the movement of hemolymph. **(b)** In closed circulatory systems, such as that of the earthworm, blood remains in vessels and hearts and recirculates without emptying into the body cavity. Arrows indicate direction of blood flow.

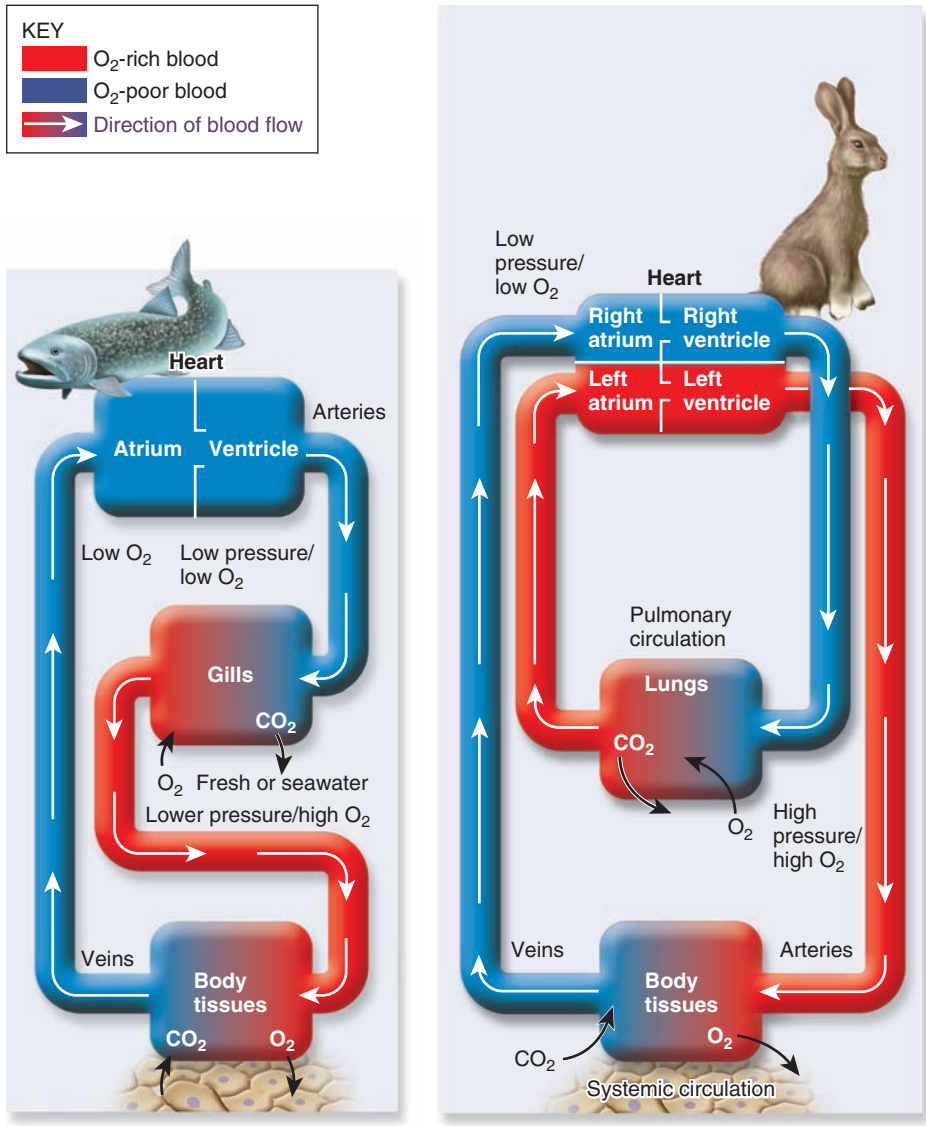
Concept Check: *It is correct to think of open circulatory systems as primitive compared with closed systems. Why or why not?*

earthworms, cephalopods (squids and octopuses), and all vertebrates (Figure 47.1b). Despite some differences in structure among taxa, closed circulatory systems share certain key features:

- **Blood**—a fluid connective tissue containing a mixture of cells and solutes to be transported throughout the body—is pumped under pressure by one or more contractile, muscular hearts.
- Blood remains within vessels that distribute it throughout the body.
- The solutes in blood can be exchanged with the environment and the body's cells.
- In most cases, blood contains disease-fighting cells and molecules.
- The activity of the closed circulatory system can be adjusted to match an animal's metabolic demands.
- Closed systems generally can heal themselves when wounded, by forming clots at the site of injury.
- These systems grow in size as an animal grows.

From this list, you can see that a closed circulatory system offers several advantages. First, animals can grow to a larger size, because blood can be directed to every cell of an animal's body, no matter how large. Nearly all body cells are within one- or two cell-widths of a blood vessel. Second, blood flow can be selectively increased or decreased to supply different parts of the body with the precise amount of blood needed at any given moment. After a meal, for example, more blood can be directed to the intestines to absorb nutrients, and on a hot day, additional blood can be routed to the skin to dissipate heat. Animals with an open circulatory system cannot make these adjustments.

The closed circulatory systems of vertebrates can be divided into two major arrangements: single circulations and double circulations. In single circulations, blood is pumped under low pressure from the heart to the respiratory surface (for example, gills), where it picks up oxygen and drops off carbon dioxide. From there, blood circulates to the tissues of the body, where it releases oxygen and picks up carbon dioxide. The blood then circulates back to the heart. In double circulations, blood is pumped under low pressure from the heart to the lungs, and then back to the heart, to be pumped under high pressure to the tissues and finally returned again to the heart. Single circulations are seen in fishes, and double circulations are seen in crocodiles, birds, and mammals. Amphibians and most reptiles have an intermediate type of circulation that combines features of both.



Single Circulation: Fishes In the single circulation of fishes, the heart has a single filling chamber called an **atrium** that collects blood from the tissues. Blood exits the atrium through a one-way valve into a single **ventricle** that pumps blood out of the heart (Figure 47.2a). Blood vessels called **arteries** carry blood away from the heart to the gills, which obtain oxygen by diffusion from the water in which the fish swims and unload carbon dioxide into the water. The freshly oxygenated blood then circulates via other arteries to the rest of the body. There, oxygen and nutrients are delivered to cells, and carbon dioxide diffuses from cells into the blood. Finally, the partially deoxygenated blood is returned to the heart via blood vessels called **veins**, where it is pumped back to the gills for another load of oxygen.

An important feature of all respiratory surfaces is that they function best when the blood flowing through them is maintained at a low pressure. Consequently, the fish heart does not generate high pressure when it pumps blood to the gills. This means that blood leaving the gills will also be under low pressure, therefore limiting the rate at which oxygenated blood can be delivered to the body's cells.

Double Circulation: Crocodiles, Birds, and Mammals In crocodiles, birds, and mammals, oxygenated and deoxygenated blood are completely separated into two distinct circuits, the **systemic circulation** and the **pulmonary circulation** (Figure 47.2b). This is made possible by a heart that has two sets of atria and ventricles connected by one-way valves. The two sides of the heart are completely separated by a septum, or wall. The crocodilian circulatory system has evolved to be somewhat different from that of birds and mammals. It allows crocodiles to spend part of their lives under water, and it reflects that they are considerably less active than birds and mammals. When resting or under water, crocodiles can divert blood between the two circuits in ways that birds and mammals cannot. Nonetheless, all animals with double circulations have a left and right atrium and a left and right ventricle.

In a double circulation, the pulmonary circulation delivers oxygenated blood from the lungs to the left atrium, which then passes it on to the left ventricle. The left ventricle pumps blood to all the body's tissues via the systemic circulation. The systemic circulation then delivers deoxygenated blood from the tissues to the right atrium, which sends it to the right ventricle. The right ventricle pumps this blood via the pulmonary circulation to the lungs, where the blood becomes oxygenated and the cycle starts again.

An advantage of a double circulation is that the two ventricles can function as if they were, in effect, two hearts, each with its own ability to pump blood under a different pressure. This means that blood from the right ventricle can be pumped under low pressure to the lungs, which, as mentioned earlier, is important for normal function of respiratory surfaces. In a double circulation, however, once the blood picks up oxygen from the lungs, it can be returned to the left side of the heart. The left ventricle is more muscular than the right ventricle and therefore generates higher pressures when pumping blood. Thus, the oxygenated blood leaving the left side of the heart has sufficiently high pressure to reach all the cells of the animal's body and deliver oxygen and nutrients at a high rate, even to regions above the heart that must contend with gravity. This is no small feat, considering the distance blood must travel in some large animals. The left ventricle of a giraffe, for example, is particularly muscular compared with that of other animals.

(a) Single circulation in fishes

(b) Double circulation in crocodiles, birds, and mammals

Figure 47.2 Representative vertebrate circulatory systems. **(a)** Fishes have a single circulation in which blood is pumped from the heart to the gills, from where it circulates to the rest of the body tissues, and finally returns to the heart. **(b)** Birds and mammals have a double circulation, in which oxygenated blood is pumped under high pressure to the body's tissues, and deoxygenated blood is pumped under low pressure to the lungs.

Genomes & Proteomes Connection

A Four-Chambered Heart Evolved from Simple Contractile Tubes

The heart is the first vertebrate organ to become functional during embryonic development, and the factors responsible for its development have been extensively studied. Interestingly, at least one of these developmental factors has also recently shed light on how a heart develops four chambers in crocodiles, birds, and mammals.

The first heartlike organ appears to have evolved at least 500 mya. Ancestral hearts may have resembled those observed today in cephalochordates and urochordates—a simple linear tube with wavelike contractile properties but no valves or chambers (refer back to Figure 33.37). A valvelike structure first appears in the tubular hearts of some arthropods, such as *Drosophila*, but such hearts do not have clearly defined chambers. Analyses of animal genomes have identified numerous genes that are critical for the development of the chambered vertebrate heart, including a core set of five genes and their proteins. Interestingly, however, one or more of these five genes are also expressed in linear tube hearts such as those just described, and even in contractile structures in animals without hearts. For example, cnidarians do not have a heart or blood vessels, but have muscle cells in their contractile bell that not only produce locomotion, but in the process circulate water through the animal's gastrovascular cavity. These muscle cells express at least three of these heart developmental genes. Nematodes also do not have a heart, but instead have a contractile pharynx that serves part of the same function; the pharyngeal muscles of these animals express four of the five key heart developmental genes that are found in all vertebrates. Thus, the genes required for the formation of a contractile, multichambered heart are ancient. This question arises, however: Why are some vertebrate hearts four-chambered, and others are not?

In a 2009 study, American researcher Benoit Bruneau and colleagues compared the expression of one of the major heart developmental genes, called *Tbx5*, in the hearts of amphibians, reptiles, birds, and mammals. They discovered that the expression of *Tbx5* became increasingly restricted in animals displaying greater separation of the ventricles into two chambers (**Figure 47.3**). In amphibians, which have a single ventricle, *Tbx5* was expressed throughout the developing ventricle. In reptiles in which an incomplete septum partially divides the ventricles, *Tbx5* expression was absent in a portion of the right half of the ventricle. In birds and mammals, *Tbx5* expression was completely absent from the developing right ventricle, but the gene was highly expressed in the left ventricle. This suggests that a gradient of *Tbx5* expression is required for the ventricle to form two chambers and thereby a complete double circulation.

The investigators also showed that if *Tbx5* expression was experimentally induced in the heart of an embryonic mouse in a pattern that mimicked that seen in lizards, the mouse heart developed only three clearly defined chambers—there was no distinction between left and right ventricle!

From these and other studies, it appears that the expression of a core set of genes is vital for the formation of a heart or heartlike structure, and a smaller set of genes like *Tbx5* is critical for the division of the heart into chambers. The most common congenital organ defects in humans are those associated with the heart. The relatively high incidence of heart-related birth defects makes an understanding of the genetic control of the growth and development of the heart a great concern in medicine today.

47.2 The Composition of Blood

Learning Outcomes:

1. List the four components of blood and the functions of each.
2. Describe the steps involved in the process of blood clotting in mammals.

Blood is the transport medium of many animals' bodies. It moves necessary materials, including nutrients and gases such as oxygen, to all cells and takes away waste products, including carbon dioxide and other breakdown products of metabolism. What are the components of blood that allow it to perform its functions?

Blood Is Composed of Cells and Water with Dissolved Solutes

Blood consists of cells and, in mammals, cell fragments suspended in a solution of water containing dissolved nutrients, proteins, gases, and other molecules. If we collect a blood sample and spin it in a centrifuge, the blood separates into three layers (**Figure 47.4**). These layers correspond to three of blood's four components: plasma, leukocytes, and erythrocytes. (A fourth component, the much less abundant platelets or thrombocytes, is not readily visible in a centrifuged sample.) Let's take a look at each of these.

Plasma The top layer of the centrifuged blood sample is a yellowish solution called **plasma** (see Figure 47.4). Plasma typically makes up about 35–60% of the total volume of blood in vertebrates. It contains water and the dissolved organic and inorganic nutrients

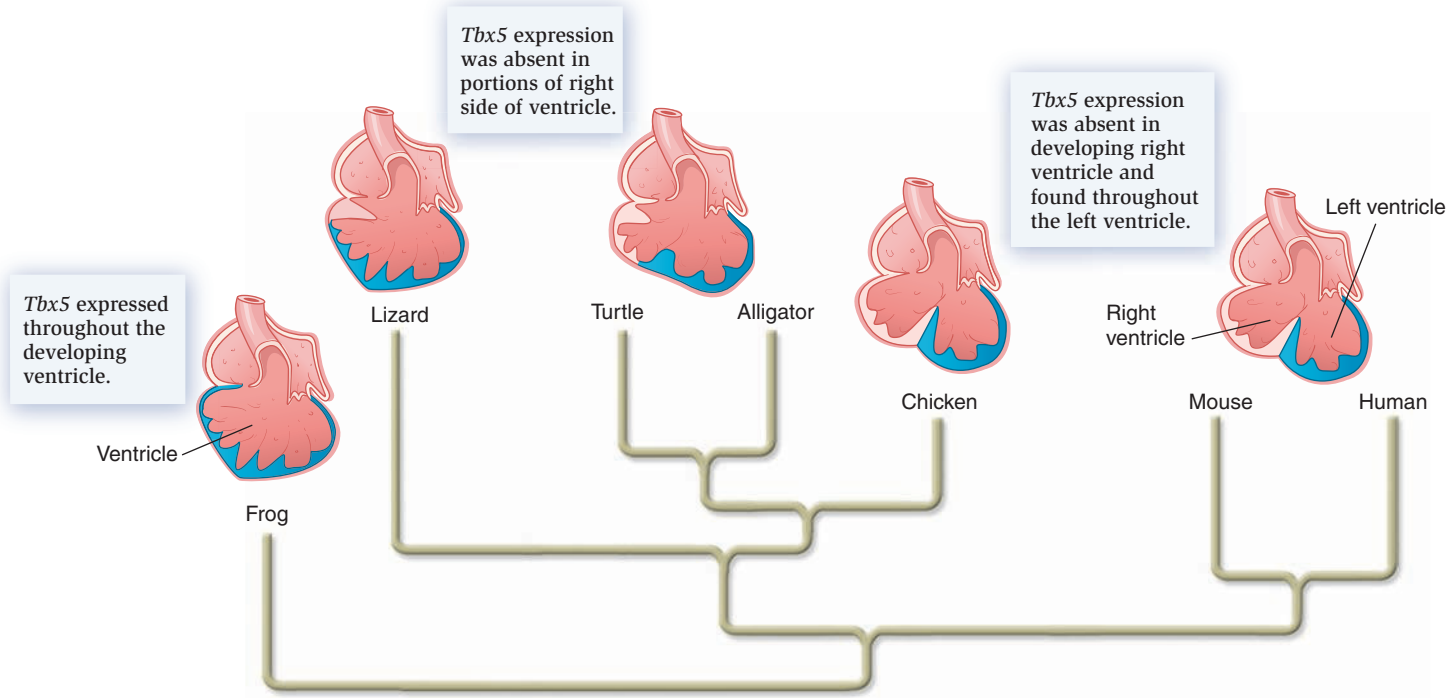


Figure 47.3 Expression of the *Tbx5* gene in embryonic vertebrate hearts. The blue color indicates where in the developing heart muscle the gene was expressed. Note: Structural details have been omitted for simplicity.

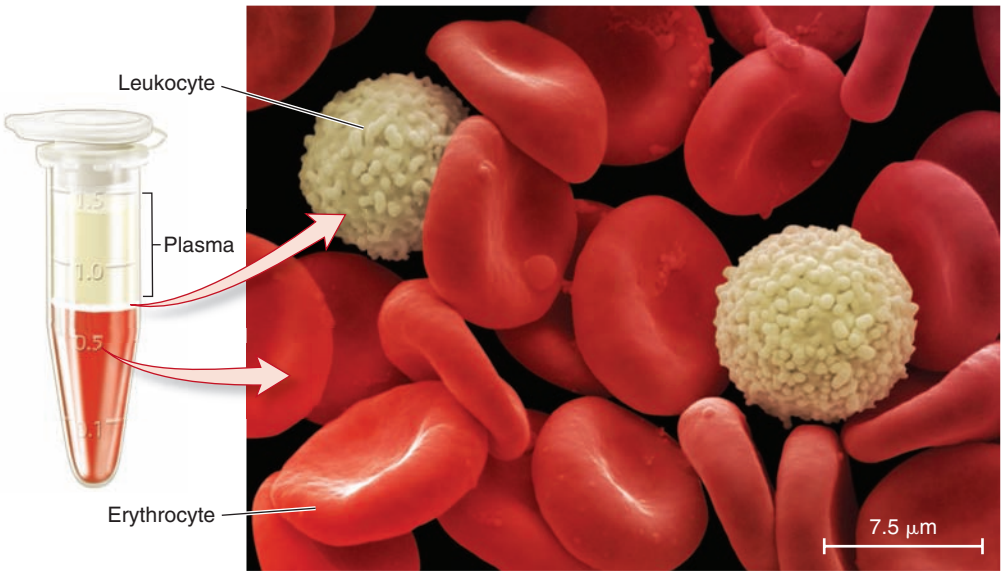

Figure 47.4 Components of blood. When a blood sample that has been prevented from clotting is centrifuged, it forms three visible layers: plasma, leukocytes, and erythrocytes. Plasma is the cell-free component of blood that contains dissolved solutes. Leukocytes, shown in the scanning electron micrograph (SEM), are the white blood cells that make up part of the immune system. Erythrocytes are red blood cells and function to carry oxygen. An additional component of blood is not visible under these conditions because of small numbers and size. These are the platelets in mammals (or thrombocytes in other vertebrates) that participate in blood clotting reactions. Note: The leukocyte layer is enlarged and not to scale, for illustrative purposes.

BioConnections: *Leukocytes are part of the immune system of animals. Are immune defenses unique to animals? (Look back at Figure 36.19 for a hint.)*

that were absorbed from the digestive tract or secreted from cells. Plasma also contains dissolved oxygen; waste products of metabolism, such as carbon dioxide; and other molecules released by cells, such as hormones. Plasma also transports cells of the immune system and cells involved in oxygen transport, as well as proteins that serve several important functions, such as forming blood clots, which seal off wounds to blood vessels.

In addition to transporting molecules throughout the body, plasma has other functions. For example, plasma contains buffers that help keep the pH of body fluids within its normal range. It is also important in maintaining the fluid balance of cells. For example, changes in the ion and protein concentrations in plasma can affect the movement of water between intracellular and extracellular fluid compartments.

Leukocytes Beneath the plasma in the centrifuged blood sample is a narrow white layer of **leukocytes**, also known as white blood cells (see Figure 47.4). Leukocytes develop from a specialized connective tissue (the marrow) of certain bones in vertebrates. Although there are several types—which we describe further in Chapter 53—all leukocytes perform vital functions that defend the body against infection and disease.

Erythrocytes The bottom visible layer of the centrifuged blood sample consists of **erythrocytes**, also called red blood cells because of their color (see Figure 47.4). The term **hematocrit** refers to the volume of blood (expressed as percentage) that is composed of erythrocytes, usually between 40% and 65% in vertebrates (the range is very wide in invertebrates and can vary between vascular and coelomic fluids, but generally is much lower than in vertebrates). Erythrocytes serve the critical function of transporting oxygen throughout the body. There are approximately a thousand times more erythrocytes than leukocytes in the circulation. Like leukocytes, erythrocytes are derived from cells in the bone marrow. In most vertebrates, mature erythrocytes retain their nuclei and other cellular organelles, but in all mammals (and a few species of fishes and amphibians), the nuclei are lost upon maturation. The lack of a nucleus and many other organelles in the mammalian red blood cell increases the cell's oxygen-carrying capacity and contributes to its characteristic biconcave shape (see Figure 47.4). The biconcave shape of the mammalian erythrocyte increases its surface area relative to the flattened disc or oval shape seen in most other vertebrates. This is believed to make gas exchange between the erythrocyte and the surrounding body fluids more efficient in mammals.

Oxygen is poorly soluble in plasma. Consequently, the amount of oxygen that dissolves in plasma usually cannot support a vertebrate's basal metabolic rate, let alone more strenuous activity. Within the cytosol of erythrocytes, however, are large amounts of the protein **hemoglobin**. Each molecule of hemoglobin reversibly binds up to four molecules of oxygen. The oxygen attached to hemoglobin greatly increases the reservoir of oxygen in the blood and enables animals to be more active. Chapter 48 describes the mechanisms by which hemoglobin binds and releases oxygen.

Platelets Vertebrate blood has a fourth component called platelets in mammals and thrombocytes in other vertebrates. **Platelets** are fragments of membrane-enclosed cytosol and lack a nucleus, whereas **thrombocytes** are intact cells; both play a crucial role in the formation of blood clots, which limit blood loss after injury (Clotting mechanisms in invertebrates are either absent or very different from the mechanisms in vertebrates). Like leukocytes and erythrocytes, platelets and thrombocytes are formed in the bone marrow. Their function in blood clotting in mammals is described next.

Blood Clotting Is a Multistep Process

The formation of a blood clot in mammals requires several steps, two of which include platelets (**Figure 47.5**). When a blood vessel is injured, platelets first secrete substances that cause the platelets to clump together and bind to collagen fibers in the surrounding connective tissue at the wound site; this forms a plug that prevents continued blood loss. Second, other platelet secretions interact with plasma

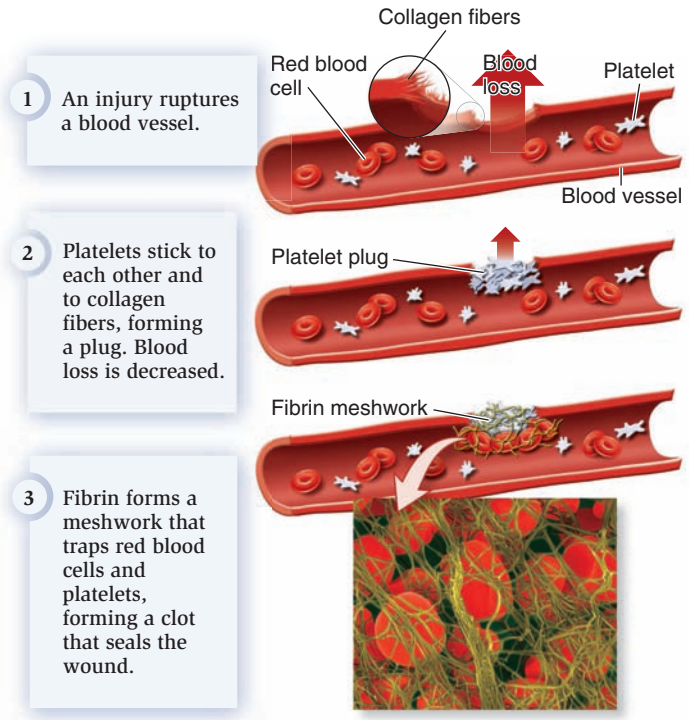

Figure 47.5 Platelets and the process of blood clot formation. A blood clot forms in two major steps: A platelet plug reduces initial blood loss, and a fibrin clot then seals the wound. An example of a fibrin clot is shown in the SEM.

BIOLOGY PRINCIPLE Living organisms maintain homeostasis. Because the blood carries the nutrients, hormones, proteins, and waste products that must circulate throughout an animal's body, a loss of blood due to injury can be catastrophic unless the wound is healed and the blood loss is stopped. Thus, blood clotting is a key feature that indirectly contributes to the ability of animals to maintain homeostasis.

proteins to cause the precipitation from solution of the fibrous protein **fibrin**. Fibrin forms a meshwork of threadlike fibers that wrap around and between platelets and erythrocytes, enlarging and thickening the plug to form a clot. Blood clotting begins within seconds and helps prevent injured animals from bleeding to death. Eventually, the body absorbs the clot as the injured vessel heals.

47.3 The Vertebrate Heart and Its Function

Learning Outcomes:

1. Explain the difference between neurogenic and myogenic hearts.
2. Describe the two phases of the excitation of the vertebrate heart.
3. **SciSKILLS »** Describe the sequence of events of the cardiac cycle, and draw conclusions regarding the functional relationship between electrical and contractile events.
4. **SciSKILLS »** Interpret the meaning of the tracings on an electrocardiogram.

As described earlier, all vertebrate hearts have at least one upper (anterior) chamber called an atrium and at least one lower (posterior) chamber called a ventricle (**Figure 47.6**). In hearts with more than one atrium or ventricle, such as the mammalian heart, which has two of each chamber, the chambers are physically separated by a thick strip of connective tissue called a septum. Each atrium is fed by either pulmonary or systemic veins; the pulmonary veins return blood from the lungs, and the systemic veins return blood from the rest of the body. Between the atria and ventricles there are one-way valves called **atrioventricular (AV) valves** that control the movement of blood between them. Each ventricle ejects blood into either the aorta or the pulmonary trunk. The **aorta** leads to the systemic circulation, and the **pulmonary trunk** divides into the pulmonary arteries that lead to the right and left lungs. One-way valves called **semilunar valves** are located between each ventricle and the artery (either the aorta or the pulmonary trunk) into which the ventricle ejects blood. Note that the blood can flow only one way through any of the valves. Let's take a closer look at the structure and function of the heart.

Vertebrates Have Myogenic Hearts Capable of Beating on Their Own

What causes the heart to beat so steadily? Animals cannot consciously initiate heart contractions. The beating of the heart is initiated either by nerves or by intrinsic activity of the heart muscle cells themselves. Many arthropods and decapod crustaceans have a **neurogenic heart** that will not beat unless it receives regular electrical impulses from the nervous system. All vertebrates, however, have a **myogenic heart**; that is, the signaling mechanism that initiates contraction resides within the cardiac muscle itself. Cardiac muscle is distinguished by the interconnectedness between individual cardiac muscle cells, or myocytes. Each myocyte has membrane extensions that form interlocking networks with other myocytes. Within these networks, or intercalated discs, as they are called, are many gap junctions (refer back to Figure 10.11) that electrically couple the myocytes. The large number of gap junctions permits the rapid spread of electric current from cell to cell so that all parts of the heart are rapidly stimulated virtually as one. This electric current is the signal that increases the cytosolic concentration of Ca^{2+} within the myocytes. The increase in Ca^{2+} concentration triggers contraction (cell shortening) in a manner that is similar in many ways to what happens in skeletal muscle cells (see Chapter 44).

Myogenic hearts are electrically excitable and generate their own action potentials. The rate and forcefulness of the beating of myogenic hearts can, however, be regulated by the nervous system. Nonetheless, myogenic hearts continue to beat on their own if dissected out of an animal and placed in a nutrient bath, even with no nerves present.

Excitation of the Vertebrate Heart Begins in the SA Node in the Atria and Spreads to the Ventricles via the AV Node

Contraction of the vertebrate heart cannot occur until the muscle is electrically stimulated. The electrical excitation of the vertebrate heart has two phases: atrial and ventricular. In atrial excitation, electrical signals are generated at the junction of the veins and single

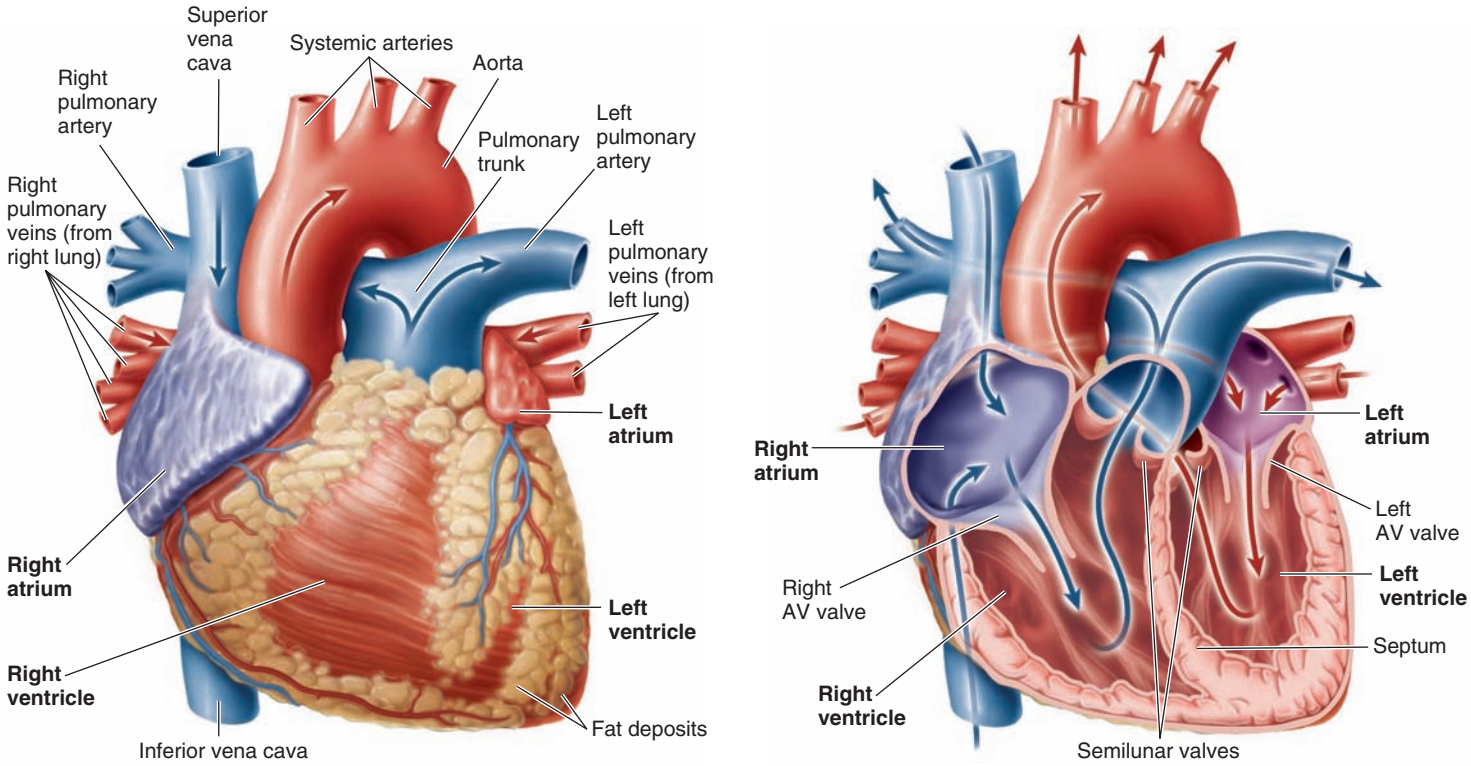

Figure 47.6 The mammalian heart and circulation. The figure shows the major blood vessels entering and leaving the heart, the locations of the valves, and the direction of blood flow through the chambers of the heart. Regions that contain oxygenated blood are shown in red, deoxygenated in blue. Note that the pulmonary veins carry oxygenated blood because they return blood from the lungs, whereas veins from the systemic circulation carry deoxygenated blood.

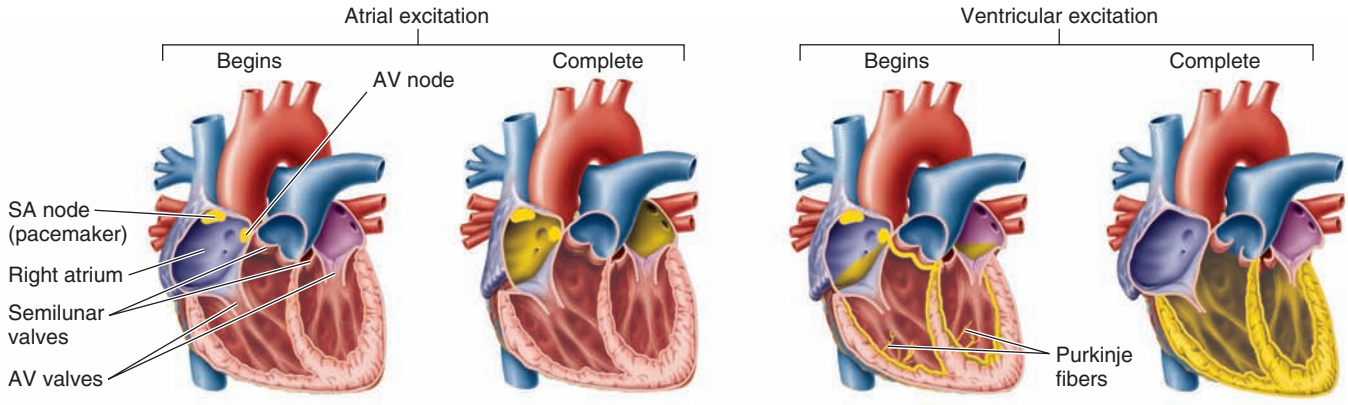
Concept Check: *Which artery or arteries shown in this figure carry (carries) oxygenated blood?*



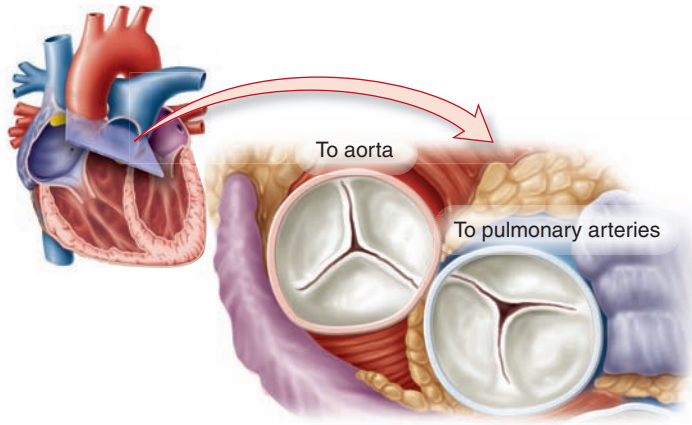
atrium in fishes, and within the wall of the right atrium in other vertebrates, at what is called the **sinoatrial (SA) node**, or **pacemaker** (**Figure 47.7**). The SA node is a collection of modified myocytes that have an inherently unstable resting membrane potential. Ion channels in the membranes of these cells are opened spontaneously and allow the influx of positively charged ions into the cytosol, thereby depolarizing the cell. These depolarizations produce action potentials in the SA node cells with a range of frequencies that are characteristic for a given species; the frequency determines an animal's heart rate. Once the SA node cells generate action potentials, the potentials quickly spread across the atria through the gap junctions described earlier. The action potentials trigger an influx of Ca^{2+} into the muscle cell cytosol, which activates contraction. Because the impulses spread very rapidly across the atria, both atria contract together almost as if they were one large muscle cell. Atrial contraction assists in moving blood through the open AV valves into the ventricles.

To begin ventricular excitation, action potentials initiated in the SA node first reach another node of specialized cardiac cells, the **atrioventricular (AV) node**. The AV node is located near the junction of the atria and ventricles and conducts the electrical signals from the atria to the ventricles. This is important, because the atria and ventricles are separated by a connective tissue septum that does not contain gap junctions. Like the SA node, the AV node is electrically excitable, but its cells require a longer time to become excited than do the cells of the atria. This allows time for the atria to contract before the ventricles do. Fibers branching from the AV node spread electrical impulses along a conducting system of myocytes called Purkinje fibers, which are specialized to rapidly conduct electricity. These fibers branch throughout the muscular walls of the ventricles, ensuring that all of the ventricular muscle gets depolarized quickly and nearly simultaneously (see Figure 47.7). In this way, the entire mass of both ventricles contracts nearly in unison in response to depolarization.

The Cardiac Cycle Has Two Phases: Diastole and Systole

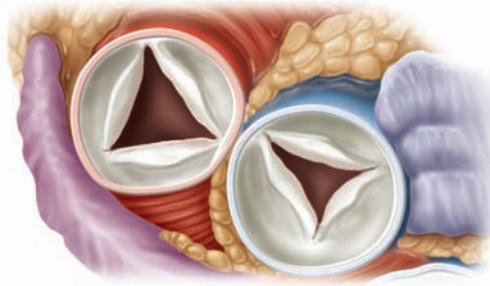
Each beat of the vertebrate heart requires coordinated actions by the atria and ventricles. The contraction and relaxation events that produce a single heartbeat are known as the **cardiac cycle**, which can be divided into two phases (see Figure 47.7). In the first phase, **diastole**, the ventricles are relaxed and fill with blood coming from the atria through the open AV valves. At the end of diastole, the atria are electrically stimulated, and therefore they contract, which provides a boost of additional blood filling the ventricles. In the second phase, **systole**, the ventricles contract and eject the blood through the open semilunar valves.

The valves open and close as a result of pressure gradients established between the atria and ventricles and between the



AV valves	OPEN	OPEN	Beginning to close	CLOSED
Semilunar valves	CLOSED	CLOSED	CLOSED	OPEN
Phase of cardiac cycle	Diastole	Diastole	Systole beginning	Systole
Atria	Relaxed	Contracted	Beginning to relax	Relaxed
Ventricles	Relaxed	Relaxed	Beginning to contract	Contracted
Chambers with highest pressure	All low pressure	Atria (slightly)	Ventricles	Ventricles

Figure 47.7 Electrical activity in the mammalian heart and the cardiac cycle. The spread of electrical activity, which is depicted in yellow, begins in the sinoatrial (SA) node and quickly spreads through the atria to the atrioventricular (AV) node. Branches from the AV node transmit electrical activity throughout the ventricles along the Purkinje fibers. The atria and ventricles do not contract until they have become electrically excited. Changes in fluid pressure gradients between the atria and ventricles and between the ventricles and the aorta and pulmonary trunk are the forces that open or close the four heart valves. Note: Most of the left semilunar valve is not visible from this perspective.



ventricles and arteries. During diastole, pressure in the ventricles is lower than in the atria and the arteries; therefore, the AV valves are open, but the semilunar valves are closed (**Figure 47.8a**). Once the ventricles are electrically excited, they begin contracting, and the pressure within the ventricles rapidly increases. This marks the beginning of systole.

Because the ventricular walls are thicker and stronger than the atrial walls, ventricular contractions generate much greater pressure. The pressure exerted by the ventricles on the blood within their cavities causes the AV valves to shut, preventing blood from flowing backward into the atria. This is why the electrical delay that is built into the AV node is important. If the atria and ventricles were excited and contracted at the same time, the AV valves would close too soon, and the ventricles would not receive their normal volume of blood. Closure of the AV valves makes the "lub" sound of the familiar "lub-dub" heard through a stethoscope.

Ventricular pressure continues to increase as the ventricles contract; when it exceeds the pressure in the arteries, the semilunar valves open (**Figure 47.8b**). Blood is ejected through the open semilunar valves into the arteries. As a result, the pressure in the arteries increases during systole. The ventricles then begin to return to their resting, unexcited state, and the pressure in the ventricles eventually decreases below that in the arteries. This pressure gradient closes the semilunar valves, which prevents blood from flowing back into the heart. Closure of the semilunar valves creates the second heart sound, “dub,” heard through a stethoscope. Throughout systole, meanwhile, the atria continue to fill with blood, which

(a) Semilunar valves in nearly closed position

(b) Semilunar valves in opened position

Figure 47.8 Appearance and function of the semilunar valves.

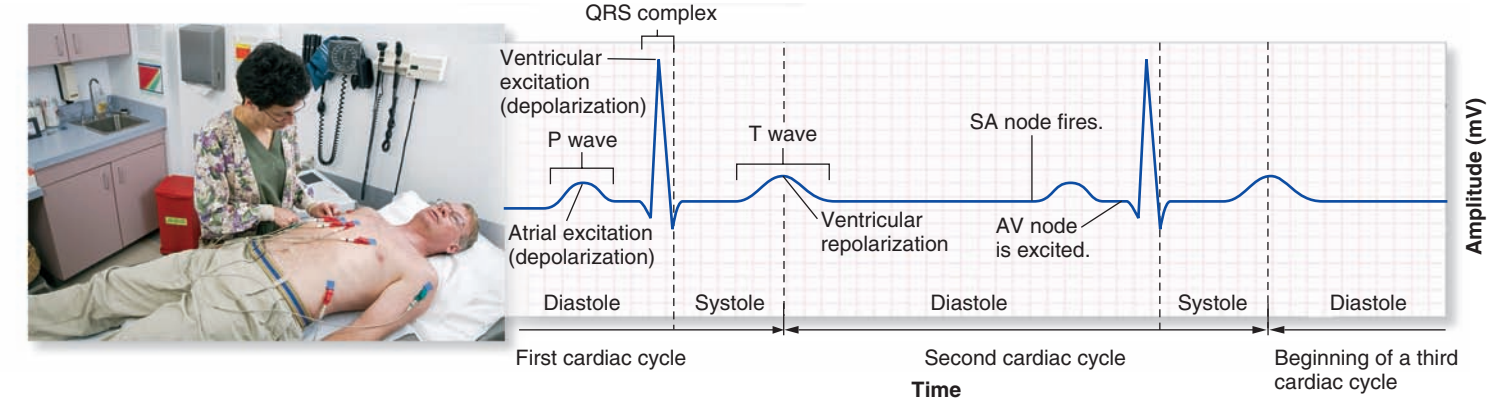


Figure 47.9 An electrocardiogram (ECG). Electrodes placed on the skin detect electrical impulses occurring in the heart, and an ECG is a recording of them. The resultant waveform is a useful indicator of cardiac health. Note that the ventricular wave (QRS complex) is taller than the atrial wave (P wave). This is because the ventricles are larger than the atria and generate more electrical activity.

Concept Check: *Why is it possible to detect electrical changes in the heart using electrodes placed on the surface of the skin? (Hint: Think about the composition of body fluids and their ability to conduct electricity.)*

increases the pressure in the atria. Soon the pressure in the atria exceeds that in the relaxed ventricles, which opens the AV valves again, bringing a new volume of blood into the ventricles and starting a new diastole.

Blood pressure, which is defined as the force exerted by blood on the walls of blood vessels, is highest in the arteries during systole and lowest during diastole. For this reason, blood pressure is measured with two numbers, the systolic and diastolic pressures. For historical reasons, the units are usually given as mmHg (millimeters of mercury). Of vertebrates, blood pressures are highest in mammals and birds, and lowest in fishes. For example, a typical blood pressure in humans is around 120/80 mmHg (systolic/diastolic).

An ECG Tracks Electrical Events During the Cardiac Cycle

An **electrocardiogram** (**ECG** or **EKG**, the latter reflecting the original German spelling) is a medical test used to investigate the function of the heart. An ECG is a record of the summed electrical potentials between various points on the body. These potentials arise from the electrical signals generated by myocytes during the cardiac cycle. Sensitive electrodes are placed on the surface of the body to monitor the wave of electricity initiated by the SA node, which spreads in sequence through the atria, AV node, and ventricles. This procedure works because the body fluids that surround the heart conduct electricity, even the very weak impulses generated by a beating heart.

The trace on an ECG reveals several waves of electrical excitation (Figure 47.9):

- The P wave begins when the SA node generates action potentials and ends when the two atria are completely depolarized. In the cardiac cycle, the P wave is followed by atrial contraction, while the ventricles are in diastole and filling with blood through the open AV valves.
- The QRS complex begins when the branches from the AV node excite the ventricles and ends when both ventricles depolarize completely. In the cardiac cycle, the QRS complex is followed by ventricular contraction during systole.
- The T wave results from the repolarization of the ventricles back to their resting state and is associated with ventricular relaxation as diastole begins again. (No wave is visible for atrial repolarization because it occurs simultaneously with the large QRS complex.)

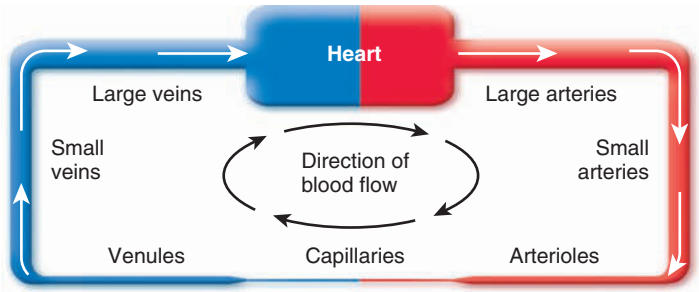
The ECG monitor displays both the amplitude (strength) of the electrical signal and the direction the signal is moving in the chest. From this information, physicians can determine whether a person's heart signals have a normal frequency, strength, duration, and pattern.

BIO TIPS **THE QUESTION** *Place the following events of the vertebrate cardiac cycle in their correct sequence: contraction of the ventricles, QRS complex on the ECG, the first heart sound, and ejection of blood into the arteries.*

TOPIC ***What topic in biology does this question address?*** The topic is the cardiac cycle of the vertebrate heart. More specifically, the question asks you to put four events from that cycle into their correct order.

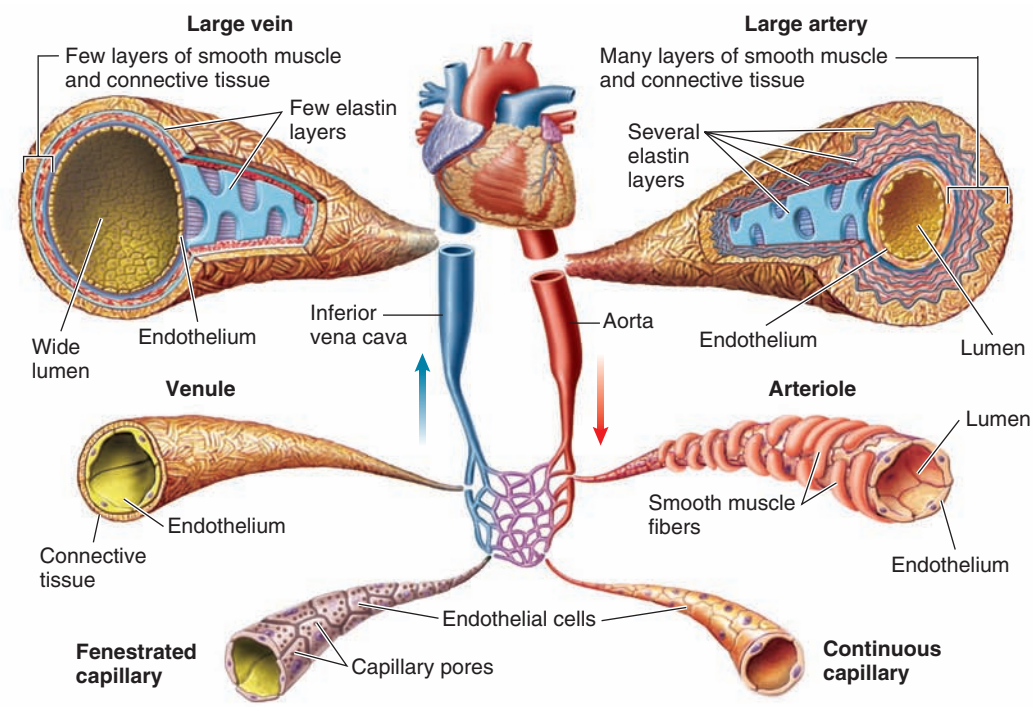
INFORMATION ***What information do you know based on the question and your understanding of the topic?*** The question lists electrical and mechanical events that must occur in a sequential way during the cardiac cycle. From your understanding of the topic, you know that the electrical events in the heart's chambers must precede mechanical ones (that is, contractions). You also know what event causes the first heart sound (closure of the AV valves).

PROBLEM-SOLVING STRATEGY ***Sort out the steps in a complicated process.*** First, look again at Figure 47.9, and then try to determine where the different waves on an ECG best fit into Figure 47.7. In other words, try to match the electrical events of Figure 47.9 with the mechanical ones in Figure 47.7.



ANSWER *The correct sequence is as follows: QRS complex on the ECG, ventricular contraction, the first heart sound, ejection of blood into the arteries. The QRS complex is the electrical event that stimulates ventricular contraction. Once that contraction begins, the pressure in the ventricles increases above that in the much smaller atria, shutting the AV valves (making the first heart sound). Very soon after that, the increasing pressure opens the semilunar valves, and blood is ejected into the arteries.*

47.4 Blood Vessels



Learning Outcomes:

1. **SciSKILLS** » Make predictions about the functions of different blood vessels based on their structures.
2. Describe the interaction of the lymphatic system with the circulatory system.

Now that we have discussed the vertebrate heart, let's examine the vessels that transport blood to and from the heart and throughout the body. **Figure 47.10a** illustrates the route that blood follows in a closed circulatory system. Blood is pumped by the heart to large arteries and then flows to branching small arteries and eventually to the smallest arteries, called arterioles. Arterioles bring blood to the smallest vessels, which are called capillaries. Gas and nutrient exchange occurs between the blood in the capillaries and the cells surrounding the

(b) The structure of blood vessels in a closed circulatory system.

Figure 47.10 Comparative features of blood vessels. **(a)** Overview of blood flow through vessels in a closed circulatory system. Regions of gas exchange with the environment (such as the lungs) have been omitted for simplicity. **(b)** Blood vessel anatomy. Sizes are not to scale. Two common types of capillaries are illustrated, but they do not actually appear together in this way. Fenestrated capillaries are typically found in secretory glands, such as the pancreas, or organs where blood is filtered, such as the kidney. Inset: Light micrograph (enlarged four times) of a medium-sized artery near a vein. Note the difference between the two vessels in wall thickness and lumen diameter.

capillaries. The blood then flows back to the heart, leaving the capillaries through venules, which empty into veins. Let's examine each of these vessels in detail.

Arteries Distribute Blood to Organs and Tissues

Arteries are thick-walled vessels that consist of layers of smooth muscle and connective tissue wrapped around a single-celled inner layer of specialized epithelial cells, called an **endothelium**, which forms a smooth lining in contact with the blood (**Figure 47.10b**). Because thick layers of tissue surround the endothelium, most dissolved substances cannot diffuse across arteries. Instead, arteries act as conducting tubes that distribute blood leaving the heart to all the organs and tissues of an animal's body.

In vertebrates, the walls of the largest arteries, such as the aorta, also contain one or more layers of elastin, a protein with elastic properties (refer back to Figure 10.3). As the aorta stretches to accommodate blood arriving from the heart, the elastin layers also stretch. The thick layers of tissue in the aorta and other large arteries prevent them from stretching more than a small amount, however. When the heart relaxes as it readies for another beat, the elastin layers in the aorta and largest arteries recoil to their original state, something like releasing a stretched rubber band. The recoiling vessels generate a force on the blood within them; this helps prevent blood pressure from decreasing too much while the heart is relaxing during diastole.

Arterioles Distribute Blood to Capillaries

As arteries carry blood away from the heart, they branch repeatedly and become narrower to penetrate to the smallest reaches of an organ or tissue (**Figure 47.11**). Eventually, the vessels are little more than a single-celled layer of endothelium surrounded by one or two layers of smooth muscle and connective tissue (see Figure 47.10). These **arterioles** distribute blood to regions of the body in proportion to metabolic demands. This is accomplished by changing the diameter of arterioles: They widen, or dilate, in areas of high metabolic activity and narrow, or constrict, in inactive regions. Arterioles dilate when the smooth muscle cells around them relax, and constrict when these cells contract.

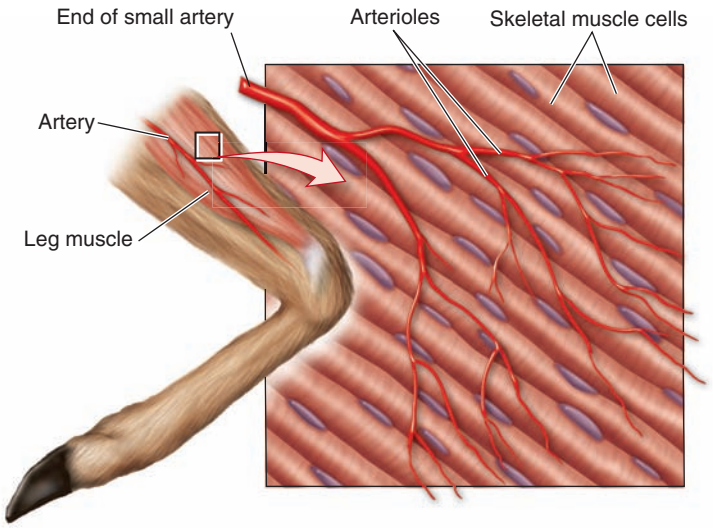

Figure 47.11 Arteries and arterioles. Arteries branch into smaller arteries, and into even smaller arterioles, in order to penetrate to all the cells of tissues and organs.

Concept Check: *What happens to the diameter of the arterioles of an animal's leg muscle when the animal is active?*

Capillaries Are the Site of Gas and Nutrient Exchange

Arterioles branch into the tiny thin-walled capillaries. **Capillaries** are tubes composed of an endothelium resting on a layer of extracellular matrix called a basal lamina. Continuous capillaries have smooth walls with a relatively small number of tiny openings that permit movement of water and solutes across the capillary. By contrast, fenestrated capillaries contain numerous larger holes in their walls that permit large quantities of fluid to move between the plasma and interstitial fluid; such capillaries are typically found in filtration organs such as the kidney (see Figure 47.10). Capillaries are the narrowest blood vessels in the body; essentially every cell in an animal's body is near one. The diameter of a capillary is about the same as the width of a red blood cell, so erythrocytes move through them in single file (**Figure 47.12**). At the capillaries, materials in the blood are delivered to the other cells of the body, and waste products and secretions from cells are delivered to the blood.

Movement of Water In and Out of the Capillaries Blood flows through capillaries under pressure that is created by the beating of the heart as blood is pumped into the arteries. This pressure forces some of the water in blood out through the fenestrations and other tiny openings in capillary walls into the interstitial fluid (**Figure 47.13**). These openings are wide enough to permit water with its solutes to leave the capillary, but not erythrocytes and most proteins. If the water that leaves a capillary were to remain in the interstitial fluid, the volume of plasma in the blood would decrease, and that of the interstitial fluid would increase. Most of the water that leaves at the beginning of a capillary, however, is recaptured at the capillary's end, due to two phenomena (see Figure 47.13). First, the blood pressure inside the capillary near the arteriole is higher than the fluid pressure of the surrounding interstitial fluid, which creates a force that moves water out of the capillary. However, by the time blood reaches the end of

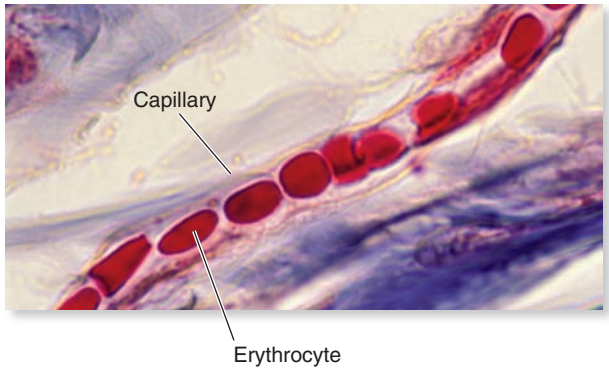

Figure 47.12 Erythrocytes moving through a capillary in single file, as seen through a light microscope. The diameter of the capillary is approximately 7 µm.

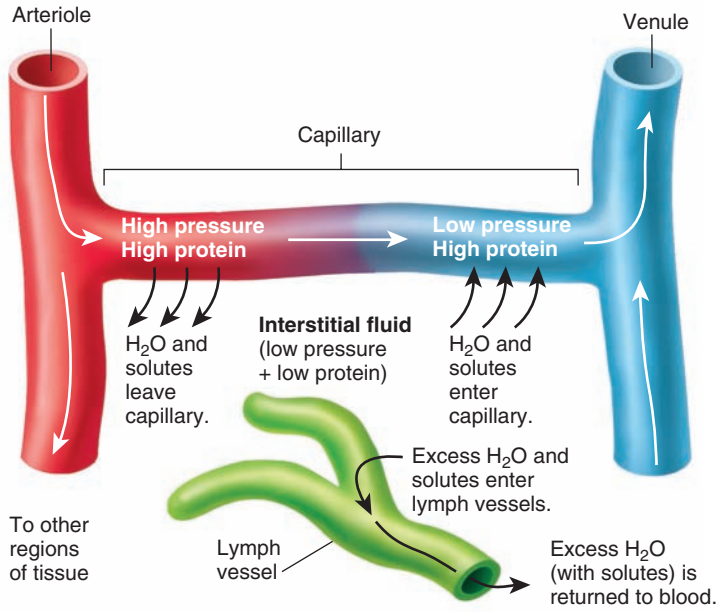

Figure 47.13 Water movement between capillaries and interstitial fluid. Water and dissolved solutes (other than proteins) exit capillaries near the arteriolar end because the capillary pressure is much greater than that of the interstitial fluid. As the volume of the water in the capillary decreases, however, the pressure within the capillary also decreases (but remains greater than that in the interstitial fluid). Proteins remaining in the capillary contribute an osmotic force that tends to draw water back into the capillary. The combination of decreased pressure within the capillary and the osmotic force due to the proteins leads to the recapture of much of the water that left the capillary. Lymph vessels drain any excess fluid from the interstitial fluid. For clarity, the system shown here contains a single capillary connecting an arteriole and venule, instead of the typical situation where capillaries divide into numerous branching vessels.

a capillary, its pressure has decreased considerably, partly as a result of the loss of water. Second, proteins are trapped within the capillary because they are too large to diffuse through the capillary walls or to leak out of the tiny openings. This creates an osmotic force that draws water back into the capillary from the interstitial fluid. Near the end of a capillary, the osmotic force drawing water into the capillary is greater than the pressure forcing water out; therefore, water and dissolved solutes reenter the capillary.

In these ways, fluid can move readily between fluid compartments. An advantage of this can be seen in situations such as dehydration or blood loss, which could lead to dangerously low blood pressure. In such cases, there is less pressure moving fluid out of capillaries but the osmotic effect of proteins is still present; consequently, there is a net movement of fluid into capillaries, which helps restore blood volume and prevent the blood pressure from continuing to fall.

Despite the ability of capillaries to recapture their own fluid, the process is not 100% effective. Another set of vessels, those of the lymphatic system, collects excess fluid and returns it to the blood. The system is also part of the immune system of animals (see Chapter 53).

Venules and Veins Return Blood to the Heart

Once blood travels through capillaries, picking up any substances secreted from the cells of the body, it enters the **venules**, which are small, thin-walled extensions of capillaries. The venules empty into the larger veins that return blood to the heart. The walls of veins are much thinner, less muscular, and more easily distended or stretched than those of arteries (see Figure 47.10).

By the time blood has been distributed through all the capillaries and reached the veins, the residual pressure of the blood is very low. Consequently, veins can fill with considerable volumes of blood, particularly veins in the lower parts of an animal's body, such as the legs, where gravity tends to cause blood to pool. However, several factors assist the blood on its way toward the heart when flowing against gravity. One factor is stimulation of the contraction of smooth muscle in leg veins by the sympathetic nervous system, which compresses the veins and helps force blood back to the heart. Another factor is the activity of skeletal muscles in the limbs that assists the return of venous blood to the heart. For example, each time the leg skeletal muscles contract, they squeeze the veins passing through them (**Figure 47.14**). This alone would not move blood upward toward the heart, though, because each time a vein is squeezed, blood could be forced both up and down. This does not happen because one-way valves inside veins ensure that blood returning from below the heart moves in only one direction, toward the heart. By contrast, veins located above the heart, like those in the necks of bipeds and some quadrupeds, lack valves because gravity is sufficient to draw blood toward the heart.

Many people can easily observe the effects of gravity on venous blood flow. When the arms are held down by their side, the veins are visible on the backs of the hands. When the arms are raised above the head, the bulging veins quickly lose blood and become less visible. When blood from the veins returns to the heart, it must travel against gravity when your arms are at your side and with gravity when your arms are elevated. Blood drains from veins much more efficiently when gravity works in its favor.

47.5 Relationship Among Blood Pressure, Blood Flow, and Resistance

Learning Outcomes:

1. **SciSKILLS** » Be able to relate blood pressure, blood flow, and resistance in a mathematical way.
2. Distinguish between the effects of vasodilation and vasoconstriction on blood flow.
3. **SciSKILLS** » Predict the effects of changes in resistance and cardiac output on blood pressure.

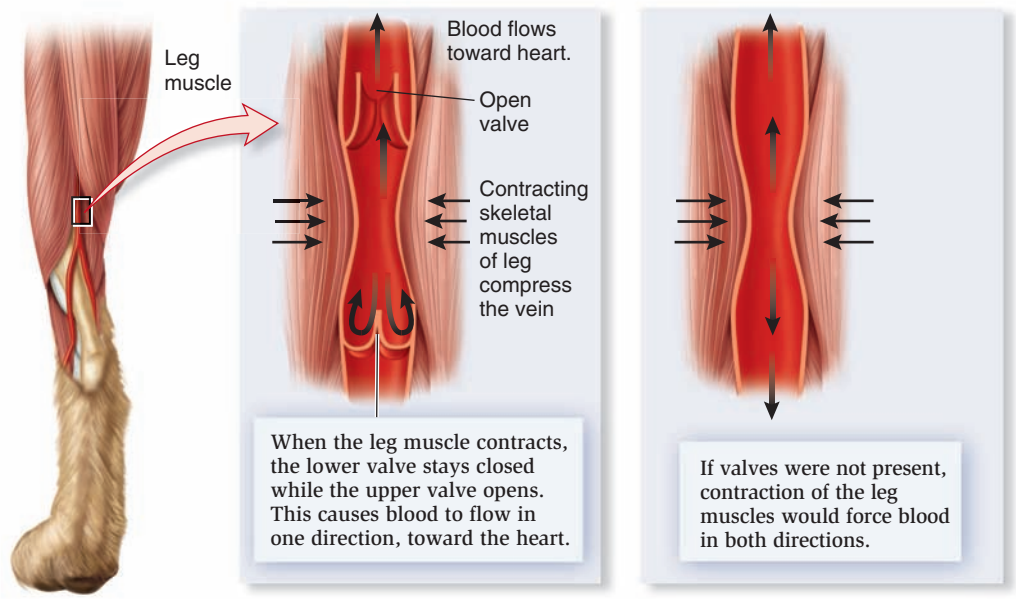

Figure 47.14 One-way valves in veins. Valves are typically present in the limbs, as shown in this dog's leg. **(a)** In some veins, one-way valves assist the return of blood to the heart against the force of gravity. **(b)** Blood moving in a vein without valves would flow in both directions.

Concept Check: *Unlike most mammals, giraffes have one-way valves in the veins of their long necks. Which way do you think the valves open, toward the heart or toward the head, and why? (Hint: Search online for a photo of a giraffe drinking from a pool of water.)*

Blood pressure is responsible for blood flow, the movement of blood through the vessels. Blood pressure and blood flow are not the same in all regions of an animal's body, however, because of resistance. **Resistance (*R*)** refers to the tendency of blood vessels to slow down the flow of blood through their lumens. As we saw earlier, the blood pressure in arteries is much higher than in veins. For this reason, we generally speak only of arterial pressure when discussing blood pressure. The relationship among blood pressure, blood flow, and resistance can be considered on two levels—local and systemic—as we see next.

Blood Pressure, Blood Flow, and Resistance Are Mathematically Related

The physical characteristics of a blood vessel determine the amount of blood that flows through it and how fast that blood flows. This affects how much blood reaches particular areas of the body at any given time. For example, the diameter of different blood vessels (particularly arterioles) can be increased or decreased to change the amount of blood flowing through them. As stated earlier, the ability to distribute blood to different parts of the body in amounts proportional to each body part's metabolic requirements is a key adaptation of closed circulatory systems.

The relationship among blood pressure, blood flow, and resistance is stated by Poiseuille's law, which was derived in the 1840s by Jean Marie Louis Poiseuille, a French physician and physiologist. His law is simplified here:

$$\text{Flow } (F) = \Delta\text{Pressure } (P)/\text{Resistance } (R)$$

Stated mathematically, blood flow through a blood vessel is directly proportional to the difference (Δ) in pressure of the blood between the beginning and end of the vessel, and inversely proportional to the resistance created by that vessel. Changes in any of these three variables determine how much blood flows through different body regions at any moment. The equation can be rearranged as $\Delta P = F \times R$, which demonstrates that blood pressure depends on both blood flow and resistance. Poiseuille's law applies to blood flow through a single vessel, an organ, or the entire body.

Resistance to Flow Depends Primarily on Three Factors

Resistance is a function of three variables: vessel radius, length, and blood viscosity. Wide, short tubes provide less resistance to flow than narrow, long tubes. Resistance is increased by the blood's viscosity, which is a measure of the blood's hematocrit. A high hematocrit increases the blood's viscosity—it makes the blood more sludge-like—and hinders the blood's smooth flow through vessels. Changes in arteriolar resistance are the major mechanism for increasing or decreasing blood flow to a region. In the short term, the length of an arteriole and the viscosity of blood do not normally change. Therefore, the radii of arterioles become the most important factor in determining minute-to-minute resistance.

The relationship between arteriolar radius and resistance is not linear. Resistance is inversely proportional to the radius of the vessel raised to the fourth power: $R \propto 1/r^4$, where $\propto$ means proportional to, and r is the radius of the arteriolar lumen. Let's consider an arteriole with a radius that increases by a factor of 2. This would occur if the smooth muscles of the arteriolar wall relaxed sufficiently to allow the vessel to dilate and double its original radius. Because resistance is inversely proportional to the fourth power of vessel radius, an increase in radius by a factor of 2 will result in a decrease in resistance of 2^4 ($2 \times 2 \times 2 \times 2$), or 16-fold.

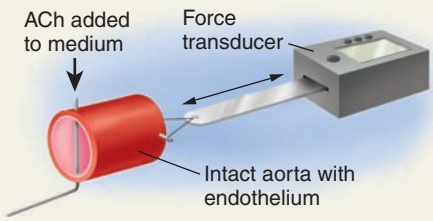
Vasodilation refers to an increase in blood vessel radius, and **vasoconstriction** refers to a decrease in blood vessel radius. The signals that control arteriolar radius come from three sources: locally produced substances, hormones, and nervous system inputs. Locally, metabolic by-products such as carbon dioxide, lactic acid, and other substances secreted by metabolically active tissues, cause nearby arterioles to vasodilate. According to Poiseuille's law, this permits more blood flow to the active region, facilitating oxygen and nutrient

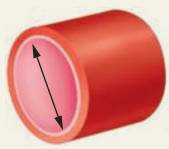
delivery and waste removal. Hormones secreted by glands throughout the body can also regulate arteriolar radius. For example, some hormones cause arterioles that deliver blood to the small intestine to vasoconstrict during the fight-or-flight response, routing blood away from the intestine and to areas of more immediate need such as the heart and skeletal muscles. Smooth muscle cells that make up the outer wall of arterioles also receive inputs from nerves that can stimulate those muscles to contract or relax. One of the most important regulators of blood vessel diameters, however, is a gas, as we see next.

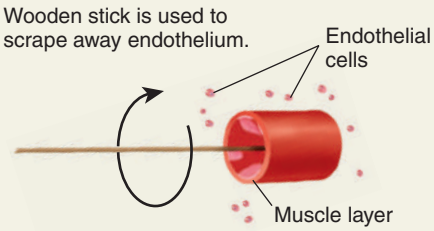
Feature Investigation | Furchgott Discovered a Vasodilatory Factor Produced by Endothelial Cells

As we have seen, the cells surrounding blood vessels can produce metabolic by-products that diffuse to arteriolar smooth muscle cells and cause these cells to relax and vasodilate. Beginning in the 1970s, American biochemist Robert Furchgott provided evidence that an unidentified substance released from within an artery—that is, from the endothelial lining of the vessel—also played a key role in regulating blood vessel radius.

For many years, Furchgott had used flattened strips of rabbit aorta in a culture bath to test whether various compounds stimulated or inhibited contraction of the smooth muscle in the artery. Although large arteries such as the aorta do not show the dramatic vasodilation and vasoconstriction that arterioles do, they were more useful in experiments because of their larger size.







One of the compounds he tested was the neurotransmitter acetylcholine (ACh). Scientists knew at the time that when ACh is injected into an animal, it causes vasodilation by relaxing smooth muscle in certain arteries and arterioles. However, in Furchgott's in vitro preparations, ACh caused the flattened strips of artery to contract instead of relaxing, as predicted. To determine if this apparent contradiction could be the result of the method in which the tissues were prepared for in vitro tests, Furchgott compared the effects of ACh in different types of preparations. He discovered that ACh produced muscle relaxation when applied to circular rings of aorta, as described in step 1 in **Figure 47.15**.

How did Furchgott explain that the muscle contracted when ACh was applied to the flattened strips of aorta? After examining the two preparations of tissue, Furchgott realized that the lining of endothelial cells along the inner wall of the vessel had been scraped away during preparation of the strips, but the endothelial lining was still present in the rings of aorta. He hypothesized that the endothelial cells must produce a factor the secretion of which was stimulated by ACh. Moreover, he further hypothesized that the factor not only prevented contraction but even caused smooth muscles surrounding the blood vessel to relax. If so, this would explain the observation that when ACh was injected into rabbits, it resulted in vasodilation, because the intact vessels of the animals contained their endothelial lining and thus resembled Furchgott's aortic rings.

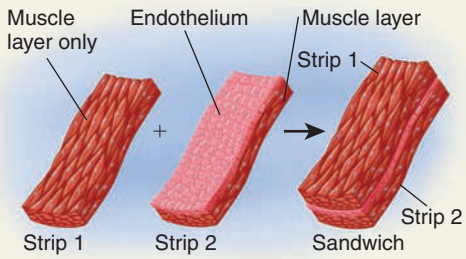


Figure 47.15 Furchgott discovered that endothelial cells produce a vasodilatory substance.

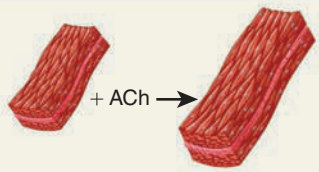
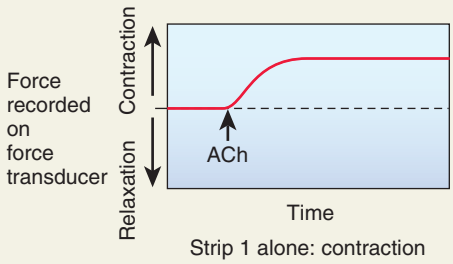


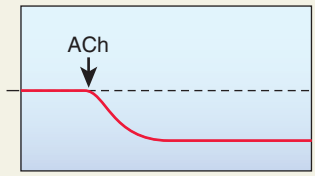
HYPOTHESIS The endothelium of arteries produces a vasodilatory substance.

KEY MATERIALS Strips or rings of rabbit aorta, force transducers, acetylcholine.

	Experimental level	Conceptual level
1 Attach a ring of aorta to a pressure gauge. Add acetylcholine (ACh) to bath medium. Record change in force (increased force = increased muscle contraction; decreased force = decreased muscle contraction).		 In the presence of endothelium, ACh relaxes the muscles of the aorta, causing the vessel to widen.
2 Denude ring of its endothelium. The muscle layer is left behind. Retest effect of ACh.	 The denuded ring is then placed in recording apparatus as before.	 In the absence of endothelium, ACh stimulates the muscles to contract, which narrows the vessel.

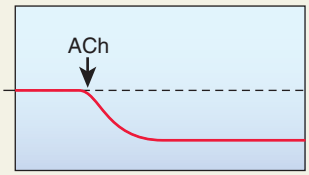
3 Perform "sandwich" experiment by combining denuded strip of aorta with an intact strip. Record effect of ACh on strip 1 alone, strip 2 alone, and strip 1 sandwiched with strip 2.





Endothelium produces a vasodilating substance following ACh treatment that diffuses from strip 2 to strip 1, and causes strip 1 to relax.

4 THE DATA



Results of sandwich experiment

Strip 1 alone: contraction

Strip 2 alone: relaxation

Strip 1 recorded while attached to strip 2: relaxation

5 CONCLUSION Endothelial cells release a factor that diffuses to the surrounding smooth muscle, causing it to relax. Relaxation of the vascular smooth muscle causes dilation of the blood vessel.

6 SOURCE Furchgott, R.F., and Zawadzki, J.V. 1980. The obligatory role of endothelial cells in relaxation of arterial smooth muscle by acetylcholine. *Nature* 288:373–376.

To test his hypothesis, Furchgott performed two experiments. As shown in step 2 of Figure 47.15, he used a wooden rod to scrape away the endothelium from circular rings of aorta and discovered that the relaxation effect of ACh was lost, as predicted. In step 3, he used a sandwich technique, in which he tested the effects of ACh on muscle contraction in a "denuded" strip of artery with the endothelium removed, and then again on the same strip, which was attached ("sandwiched") to another strip in which the endothelium remained intact. When ACh was added to the water bath before the sandwich was formed, the denuded strip contracted, as expected. When the denuded strip was attached to the intact strip in such a way that its muscle layer was exposed to the intact strip's endothelial surface, the denuded strip relaxed after ACh was added. This was consistent with the hypothesis that the endothelium released a vasodilatory factor that diffused to the denuded strip and relaxed its muscles.

Two other scientists, Americans Louis Ignarro and Ferid Murad, later determined that this vasodilatory factor was the gas nitric oxide (NO). The discovery of this function of NO revealed a new category of signaling molecules. Ignarro and Murad also revealed that nitroglycerin, which had for many years been used to treat patients with cardiovascular disease, acted by generating NO in the blood to produce vasodilation and lower blood pressure. Today, NO is considered one of the most potent and important naturally occurring vasodilators in animals. Knowledge of the NO signaling pathway has led to new therapies for treating a wide variety of health disorders associated with blood vessels, including high blood pressure, glaucoma (an eye disease; see Chapter 43), and erectile dysfunction (see Chapter 51). For their efforts, Furchgott, Ignarro, and Murad shared the 1998 Nobel Prize in Physiology or Medicine.

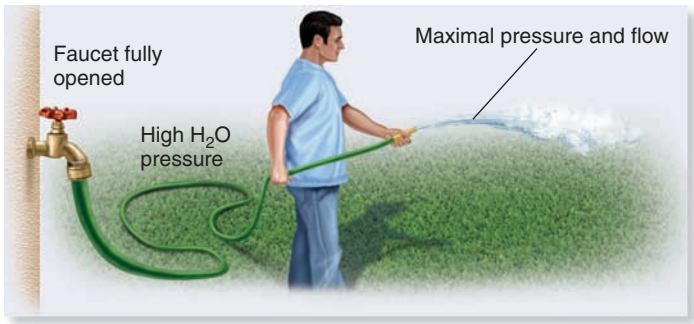
Experimental Questions

1. What observation did Furchgott make when testing the effects of ACh on different treatments of rabbit aorta? How did he explain the results?
2. **SciSKILLS** » Based on his observations of the effects of ACh on different preparations of rabbit aorta, what hypothesis did Furchgott propose to explain the relationship of ACh and vasodilation? How did he test this hypothesis?
3. **SciSKILLS** » Under what conditions do you predict endothelial cells in an arteriole of a living animal will release NO?

Together, Cardiac Output and Total Peripheral Resistance Determine Systemic Blood Pressure

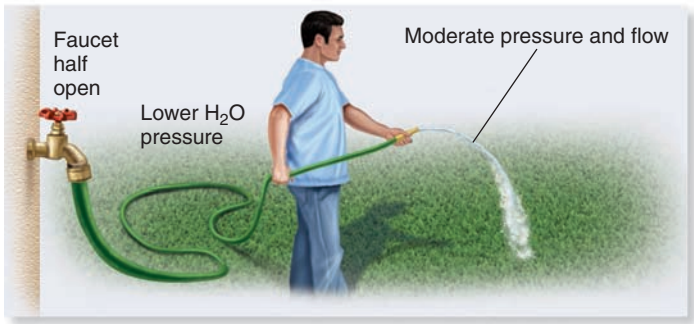
Because blood vessels provide resistance to blood flow, the heart must beat forcefully enough to overcome that resistance throughout an animal's entire body. **Cardiac output (CO)** is the amount of blood the heart pumps per unit of time, usually expressed in units of liters per minute (L/min). Poiseuille's law can be adapted to the whole body. In this case, ΔP refers to the difference between arterial and venous blood pressure (BP; however, we ignore the venous pressure as being close to zero). Flow refers to CO, and resistance refers to the sum of the resistances in all the arterioles (**total peripheral resistance**, or **TPR**). Thus, we have BP = CO × TPR. The CO and TPR determine the pressure the blood exerts in the arteries of a closed circulatory system. Let's examine these variables in more detail.

Cardiac Output The cardiac output depends on the size of an animal's heart, how often it beats each minute, and how much blood it ejects with each beat. Each beat, or stroke, of the heart ejects an amount of blood known as the **stroke volume (SV)** that is roughly proportional to the size of the heart (**Table 47.1**). Thus, if we know the stroke volume of a heart and can measure the heart rate (HR, the number of beats per minute, bpm), we can determine the CO. Simply put, CO = SV × HR.



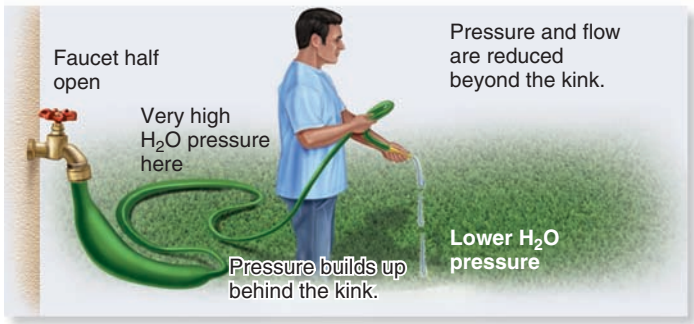
Unsurprisingly, the CO of an elephant is far greater than that of a human, a dog, or a shrew. Note in Table 47.1 that heart mass and stroke volume increase roughly in proportion with body mass. Similar relationships are observed in other vertebrates, notably birds. Smaller animals have smaller hearts and, therefore, smaller stroke volumes. The heart of a typical shrew, for example, is the size of a small pea, whereas the heart of a blue whale is as large as a cow. Their stroke volumes are similarly proportioned. However, small animals have faster heart rates than do large animals. A hummingbird's or shrew's resting heart rate may be more than 800 bpm, whereas a blue whale's heart may beat only 10 times per minute (although the amount of blood ejected with each of those beats is enormous!). Recall from Chapter 46 that metabolic rate is relatively greater in smaller animals. The higher heart rates of small animals give them a greater cardiac output than would be predicted from the size of their hearts, which helps them meet the extraordinary oxygen and nutrient demands due to their high metabolisms.

Table 47.1 Comparative Features of Representative Mammalian Hearts



Animal	Body mass* (kg)	Heart mass* (kg)	Stroke volume* (L)	Heart rate* (bpm)†
Shrew‡	0.0024 (2.4 g)	0.000035 (35 mg)	0.000008 (8 µl)	835
Rat	0.20	0.001	0.0002	360
Rabbit	2	0.012	0.0013	189
Dog	23	0.12	0.025	95
Human	75	0.38	0.075	70
Horse	450	3.50	0.90	38
Elephant	4,000	25	4.0	25
Blue whale	100,000	600	100	10

*Values are based on average body masses and resting conditions. In some cases, stroke volumes are estimates based on heart size.
†bpm = beats per minutes.
‡The shrew here is the Etruscan shrew, one of the smallest known mammals. Its heart is somewhat larger than would be predicted for its body mass. Note its heart rate; at 835 bpm, the heart beats 14 times per second!



Total Peripheral Resistance The greater the cardiac output and resistance to blood flow, the higher the blood pressure. Imagine that the circulatory system is like a faucet (the heart) connected to a garden hose (the arteries) (**Figure 47.16**). If the faucet is fully open,

(a) Maximal cardiac output with low resistance

(b) Moderate cardiac output with low resistance

(c) Moderate cardiac output with high resistance

Figure 47.16 The relationship between cardiac output, resistance, and blood pressure. A hose analogy shows the way in which cardiac output (the faucet) and resistance (constriction of the hose) affect blood pressure.

analogous to maximal cardiac output, and the hose is not blocked, analogous to low TPR, the amount of water rushing into the hose will be high and so will the water pressure, representing blood pressure. If the faucet is only partially open, the water pressure will be lower. However, now imagine that the faucet is partially open but the end of the hose is constricted, representing high TPR. In that case, the pressure of the water in the hose (the arteries) will increase between the faucet and the point where the hose is squeezed, and will decrease beyond the constriction, as will the flow of water (representing blood).

Arterial blood pressure, therefore, is a function of how hard the heart is working (CO) and how constricted or dilated the various arterioles are (TPR). Blood pressure must be high enough for blood to reach all body tissues even at the farthest extremities but not high enough to damage blood vessels or force excess plasma out of capillaries. Blood pressure is roughly similar among mammals. Although species differences exist, they are not as great as, for example, species differences in heart rates. By contrast, blood pressure is relatively low in nonmammalian vertebrates and in invertebrates.

47.6 Adaptive Functions of Closed Circulatory Systems

Learning Outcomes:

1. Explain how the circulatory system adapts to exercise.
2. Describe what a baroreceptor is, and explain why such receptors are important features in the ability to respond to a change in blood pressure.

A circulatory system must not only pump blood and return it to the heart, it must also adapt to changes, including sleep, activity, and emergencies such as blood loss or dehydration. In this section, we will examine how changes in the circulatory system help maintain cardiovascular activity during exercise and when an animal experiences a change in blood pressure.

Circulatory Function Adapts to Exercise

Nearly all animals have periods of rest and activity. Therefore, the activity of the heart must adjust to fluctuating metabolic demands. For this reason, blood must be sent to different areas in proportion to their requirements for oxygen and nutrients. Exercise provides a good illustration of rapid changes in circulatory function.

We often think of exercise as voluntary. In nature, exercise means an increase in physical activity for any reason. Typically, an animal increases its physical activity when it needs something, such as food or shelter, or when it is escaping something, such as a predator. The increased activity may be momentary and moderate, as when a fish briefly swims faster to avoid the tentacles of an anemone, or it may last longer and be more intense, as when a cheetah sprints after a gazelle. Exercise may last for very long periods of time, as when a salmon migrates from the sea to its freshwater spawning grounds or a migratory goose flies thousands of miles over several weeks. The circulatory systems of animals must quickly adapt to these increased metabolic demands and adjust to the intensity, duration, and type of exercise.

Blood Vessel Diameter We have already noted some adjustments made by circulatory systems, such as vasodilation and vasoconstriction. These are the result of changes in the radius of arterioles. During exercise, these vessels vasodilate in regions that require more energy and oxygen—for example, skeletal muscles and the heart—and vasoconstrict in areas where blood flow is less immediately essential, such as the alimentary canal.

Cardiac Output Cardiac output also increases during exercise to supply more blood to the tissues that require it. This happens by increasing stroke volume or heart rate, or both. In humans, for example, stroke volume increases from approximately 75 mL (milliliters) at rest to 110 mL during exercise, a change of 1.5-fold, and heart rate can almost triple, from about 70 bpm to nearly 200 bpm. Thus, the combined effects of increasing stroke volume and heart rate increase the cardiac output by about 4.5-fold.

One of the major mechanisms involved in increasing CO is an increase in blood concentrations of epinephrine, also known as adrenaline. **Epinephrine** is a hormone secreted by the adrenal glands, which are activated by the sympathetic nervous system during exercise. Epinephrine binds to receptors on heart ventricular muscle cells, making them contract more vigorously, thereby increasing stroke volume. In addition, epinephrine binds to receptors in the atrial SA node cells, stimulating them to initiate electrical signals at a faster rate, thereby increasing heart rate. These effects of epinephrine are enhanced by the release of the neurotransmitter **norepinephrine** (or noradrenaline) directly from sympathetic nerve endings onto cardiac myocytes.

At rest, the heart does not pump out its entire content of blood. A reservoir of blood remains in each ventricle at the end of a beat. During exercise, some of this reservoir is tapped when epinephrine and norepinephrine stimulate the heart muscles. In addition, the mechanical process of exercise itself enhances the return of blood to the heart, as skeletal muscles squeeze the veins within them and open their one-way valves. The combination of more blood getting returned to the heart and the enhanced emptying of the built-in reservoir of blood from the ventricles provides increased stroke volume during exercise.

Blood Pressure Because blood pressure equals cardiac output times total peripheral resistance (BP = CO × TPR), you might imagine that increased CO would raise BP to possibly harmful levels during exercise. Although blood pressure does increase somewhat, it does not increase as much as you might predict. This is because the blood vessels of skeletal muscles dilate (that is, resistance is decreased) to allow more blood to enter; similarly, the vessels in the skin of terrestrial animals dilate as a means of dissipating heat. Therefore, even though CO increases in exercise, the TPR decreases, negating some of the effect on BP.

Regular, long-term exercise induces additional adaptive responses in the circulatory system. For example, the thickness of the muscle of the ventricles of the human heart is greater in athletes than in sedentary individuals, which makes the athletic heart a stronger pump.

Baroreceptors Maintain Blood Pressure

How do vertebrate circulatory systems adapt to changes in blood pressure? One mechanism is by changing blood volume accordingly, which is largely the responsibility of the kidneys, as you will learn

in Chapter 49. Another mechanism, however, involves a reflex that depends on special pressure-sensitive regions within the walls of certain arteries, notably the aorta and the carotid arteries (the latter are two large blood vessels that supply the brain with blood). These regions contain the endings of neurons, known as **baroreceptors** (from the Greek *baros*, meaning weight or pressure), that are in constant electrical communication with the medulla oblongata, a region of the brainstem (**Figure 47.17**).

If blood pressure increases above the normal range, these large arteries are stretched more than normal, which makes the endings of the baroreceptors stretch, too. The stretching of the baroreceptors opens ion channels in their plasma membranes, resulting in the generation of action potentials. Nerves carry the signals to the brain, which interprets this as a signal that blood pressure is above normal. The response is a decrease in the amount of norepinephrine released from neurons of the sympathetic nervous system onto the cardiac SA node and a decrease in the secretion of epinephrine from the adrenal glands. The result is a decreased heart rate and stroke volume, resulting in lower cardiac output. In addition, nerves throughout the body release less vasoconstricting neurotransmitters from their neurons onto the smooth muscle cells of arterioles, thereby promoting vasodilation and decreasing total peripheral resistance. The combination of decreased cardiac output and decreased resistance lowers blood pressure toward normal.

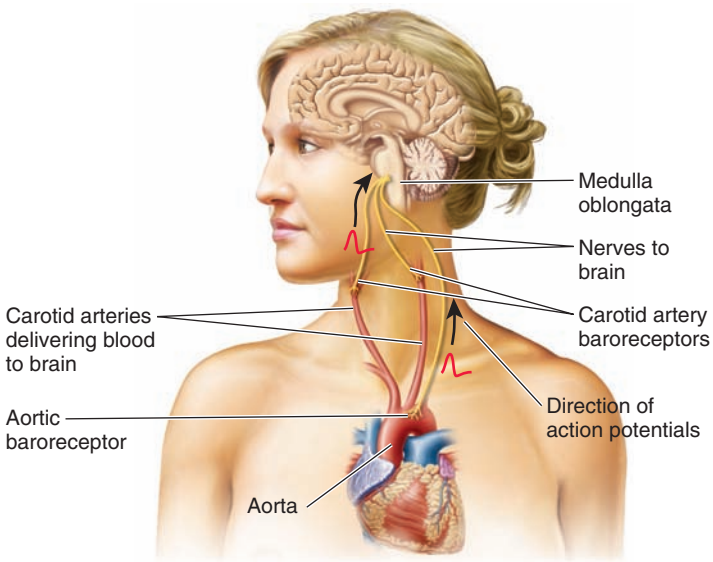


Figure 47.17 Location of the major baroreceptors. Increased blood pressure stretches arteries. This activates baroreceptors in the arteries, which send action potentials to the medulla oblongata in the brain. Nerve signals from the brain then initiate changes in heart function and total peripheral resistance that help restore blood pressure to normal.

BioConnections: In Chapters 41–43, we discussed the different types of ion channels found in neurons and the ways in which such channels open and close. What type of channels would you expect to be activated when baroreceptors are stimulated?

By contrast, if blood pressure decreases below normal, the walls of these arteries are less stretched than they normally are, and the baroreceptors send fewer action potentials to the brain. This results in a sequence of events that are opposite to those just described. More norepinephrine and epinephrine are secreted, thereby increasing cardiac output and vasoconstriction and consequently increasing blood pressure toward normal. One situation in which blood pressure can decrease is dehydration, which is a reduction in the amount of water in the body. Because blood is mostly water, dehydration decreases blood volume, and arteries—including those that contain baroreceptors—are filled with less blood than normal. Blood pressure can also decrease due to **hemorrhage**, loss of blood from a ruptured blood vessel. Dehydration is primarily a problem for terrestrial animals, but hemorrhage may occur in any animal that has been injured. In a hemorrhage, both plasma and blood cells are lost; therefore, hemorrhage may be more serious than dehydration. Like dehydration, though, hemorrhage results in decreased blood volume and therefore less baroreceptor activity.

47.7 Impact on Public Health

Learning Outcomes:

1. Describe the impact of hypertension and atherosclerosis on human health.
2. List the causes, symptoms, and current medical treatments for myocardial infarction (MI), or heart attack.

Cardiovascular disease—disease of the heart and blood vessels—accounts for more deaths each year in the U.S. than any other cause. Why is cardiovascular disease so devastating? One reason is that damage to these structures often occurs slowly, over many years, and without symptoms until the disease has reached late stages. Cardiovascular disease not only has a dramatic impact on the health of many Americans, it also has a significant impact on expenditures for health care services, medications, and lost productivity. In this section, we will consider several common cardiovascular disorders and their causes, symptoms, and treatments.

Hypertension and Atherosclerosis May Cause Heart and Blood Vessel Disease

Hypertension, or high blood pressure, refers to an arterial blood pressure that is chronically above normal. The normal range in humans varies from systolic/diastolic pressures of about 90/60 to 120/80 mmHg. A resting blood pressure above 140/90 mmHg defines hypertension, and values between 140/90 and 120/80 mmHg are considered borderline (sometimes called prehypertension). Hypertension can have many causes, including obesity, smoking, aging, kidney disease, excess male hormones, and genetic factors, although in many cases, the cause is unknown. It can often be treated with diet and exercise and with drugs that cause vasodilation, thereby reducing arterial resistance.

Hypertension rarely has any noticeable symptoms. For this reason, it is important to have blood pressure checked regularly. Without treatment, hypertension can damage arteries, contributing to the formation of **plaques**—accumulations of lipids, fibrous

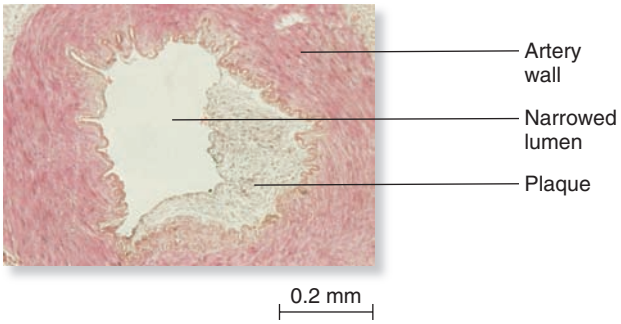

Figure 47.18 An atherosclerotic plaque in an artery. Compare this with the normal artery shown in the inset in Figure 47.10.

tissue, and smooth muscle cells—inside arterial walls that leads to a condition known as **atherosclerosis**, in which plaque causes the arteries to narrow and harden (**Figure 47.18**). Large plaques may occlude (block) the lumen of an artery entirely. In addition to hypertension, other factors are known to contribute to the formation of plaques, including Ca^{2+} and fat deposits, and plaques are correlated with obesity, high blood cholesterol concentrations, and smoking.

If plaques form in any artery, the regions of the body supplied with blood by that artery receive less oxygen and nutrients. Although atherosclerosis is dangerous anywhere, it is especially significant if it affects the **coronary arteries** (see the chapter opening photo), which carry oxygen and nutrients to the heart muscle. **Coronary artery disease** occurs when plaques form in the coronary vessels, and it can be life-threatening. One warning sign of coronary artery disease is **angina pectoris**, chest pain during exertion due to the heart being deprived of oxygen.

Myocardial Infarction Results in Death of Cardiac Muscle Cells

If a region of the heart is deprived of blood for an extended time, the result may be a **myocardial infarction (MI)**, or heart attack. This is usually caused by a blockage of one of the coronary arteries. Some heart attacks are relatively minor; in fact, the discomfort of a small heart attack may not even alarm someone enough to seek medical attention. A heart attack with no symptoms is called a silent heart attack. More serious heart attacks can lead to significant damage or death to the heart. Dead cardiac muscle tissue does not regenerate, diminishing the heart's ability to pump. Reduced pumping activity of the heart can result in congestive heart failure, in which the heart cannot pump enough blood to meet the body's needs. As noted in the chapter introduction, each year in the U.S., more than 1 million people suffer a heart attack, many of which are fatal.

Preventing a heart attack in the first place is the best way to increase survival rates. Procedures are available that allow physicians to monitor the status of the coronary vessels in people thought to have heart disease. In the procedure called **cardiac angiography**, the coronary arteries can be visualized by injecting a dye into a person's veins and then taking an X-ray image of the chest, allowing a physician to determine if the vessels are narrowed by disease.

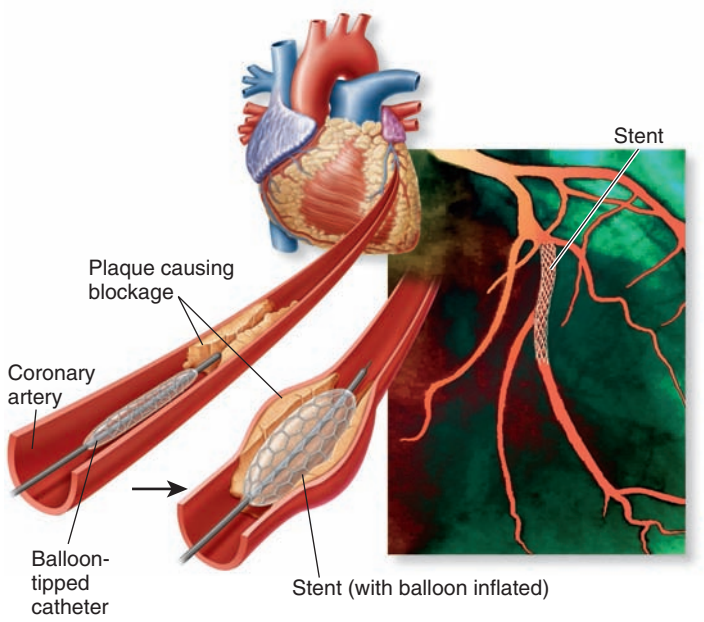

Figure 47.19 A treatment for blocked blood vessels. Balloon angioplasty can widen diseased arteries, followed by insertion of a stent. The inset shows a stent placed in a coronary artery of a human patient.

BIOLOGY PRINCIPLE Biology affects our society. Biologists investigating the mechanisms of blood flow, heart function, and blood pressure in animals can use that knowledge to develop treatments for common heart diseases in humans.

If a blockage is found, several common treatments can restore blood flow through a coronary artery. One is **balloon angioplasty**, in which a thin tube with a tiny, inflatable balloon at its tip is threaded through the artery to the diseased area. Inflating the balloon compresses the plaque against the arterial wall, widening the lumen. In most cases, a wire-mesh device called a stent is inserted into the artery after angioplasty has expanded it, providing a sort of lattice to hold the artery open (**Figure 47.19**). A treatment for more serious coronary artery disease is a **coronary artery bypass**, in which a small piece of healthy blood vessel is removed from one part of the body and surgically grafted onto the coronary circulation in such a way that blood bypasses the diseased portion of the artery.

Summary of Key Concepts

47.1 Types of Circulatory Systems

- Circulatory systems transport necessary materials to all cells of an animal's body and transport waste products away from cells. The two basic types of circulatory systems are open circulatory systems and closed circulatory systems.
- An open circulatory system contains three components: hemolymph, vessels, and one or more hearts. The vessels open into the animal's body cavity (Figure 47.1a).
- In a closed circulatory system—found in earthworms, cephalopods, and all vertebrates—blood and interstitial fluid

are physically separated by blood vessel walls and differ in their components and chemical composition (Figure 47.1b).

- The closed circulatory systems of vertebrates can be divided into single or double circulations. In the double circulation of crocodiles, birds, and mammals, oxygenated and deoxygenated blood are completely separated into the systemic circulation and pulmonary circulation (Figures 47.2, 47.3).

47.2 The Composition of Blood

- Blood is a fluid connective tissue consisting of cells and, in mammals, fragments of membrane-enclosed cytosol suspended in a solution of water containing dissolved nutrients, proteins, gases, and other molecules. Blood has four components: plasma, leukocytes, erythrocytes, and platelets or thrombocytes (Figures 47.4, 47.5).

47.3 The Vertebrate Heart and Its Function

- All vertebrate hearts have at least one atrium and one ventricle. In hearts with more than one atrium or ventricle, a septum separates these chambers. Blood enters the atria from systemic or pulmonary veins, moves down a pressure gradient through the AV valves into the ventricles, and is pumped out through the semilunar valves into the systemic and pulmonary arteries (Figure 47.6).
- Many arthropods and decapod crustaceans have a neurogenic heart that cannot beat without regular electrical impulses from the nervous system; all vertebrates have a myogenic heart, which beats on its own without electrical stimulation, but which can be regulated by the nervous system.
- The electrical signals of the vertebrate heart are generated either at the junction of the veins and the single atrium (in fishes) or at the sinoatrial (SA) node (in other vertebrates). The electrical impulses spread through the atria and ventricles and stimulate the heart muscle to contract. The cardiac cycle has two phases: diastole and systole (Figures 47.7, 47.8, 47.9).

47.4 Blood Vessels

- Arteries are thick-walled vessels that carry blood away from the heart. Arterioles distribute blood to capillaries, and capillaries are the site of gas and nutrient exchange. Blood leaving the capillaries empties into venules and then into veins, which return it to the heart. One-way venous valves help to return blood to the heart (Figures 47.10, 47.11, 47.12, 47.13, 47.14).

47.5 Relationship Among Blood Pressure, Blood Flow, and Resistance

- Blood pressure is the force exerted by blood on the walls of blood vessels, and it is responsible for moving blood through the vessels. Resistance refers to the tendency of blood vessels to slow down the flow of blood through their lumens.
- Local blood flow through a vessel is directly proportional to the pressure of the blood entering the vessel and inversely proportional to the resistance created by that vessel. Arteriolar radius is the major factor that regulates resistance. The endothelium of arteries produces a vasodilatory substance (Figure 47.15).
- Cardiac output overcomes resistance to generate systemic blood pressure and depends on the size of an animal's heart, how often it beats each minute, and how strongly it contracts with each beat (Table 47.1).
- Cardiac output (CO) and total peripheral resistance (TPR) determine blood pressure (BP): $BP = CO \times TPR$. Blood pressure must be high enough for blood to adequately reach all body tissues and cells, but not so high as to damage blood vessels (Figure 47.16).

47.6 Adaptive Functions of Closed Circulatory Systems

- The circulatory system adjusts to fluctuating metabolic requirements through changes in cardiac output, vasodilation, and vasoconstriction. Baroreceptors maintain blood pressure by relaying information about circulatory system status to the brain, which initiates compensatory mechanisms (Figure 47.17).

47.7 Impact on Public Health

- Cardiovascular disease accounts for more deaths each year in the U.S. than any other cause. Cardiovascular disorders include hypertension, atherosclerosis, coronary artery disease, angina pectoris, and myocardial infarction (MI, or heart attack) (Figure 47.18).
- Cardiovascular diagnostic techniques and treatments include cardiac angiography, balloon angioplasty, and coronary artery bypass (Figure 47.19).

Assess and Discuss

Test Yourself

1. Hemolymph differs from blood in that it
   a. does not contain blood cells.
   b. is a mixture of fluid in blood vessels and the hemocoel.
   c. circulates through closed circulatory systems only.
   d. functions only in defense of the body and not transport.
   e. does not pass through a heart.
2. The heart chamber that receives oxygenated blood from the lungs of animals with a double circulation is the
   a. left atrium.
   b. right ventricle.
   c. left ventricle.
   d. right atrium.
3. A typical hematocrit for a human is around 42%. This value means that
   a. the typical fluid portion of blood is about 42% of the blood volume.
   b. leukocytes make up 42% of the blood volume.
   c. erythrocytes make up 42% of the blood volume.
   d. leukocytes and erythrocytes together make up 58% of the blood volume.
   e. erythrocytes alone make up 58% of the blood volume.
4. A major advantage of a double circulation is that
   a. blood can be pumped to the upper portions of the body by one circuit and to the lower portions of the body by the other circuit.
   b. each circuit can pump blood at a different pressure to optimize the function of each.
   c. the oxygenated blood can mix with the deoxygenated blood before being pumped to the tissues of the body.
   d. less energy is required to provide nutrients and oxygen to the tissues of the body.
   e. All of the above are advantages of a double circulation.

5. The function of erythrocytes is to
   a. transport oxygen throughout the body.
   b. defend the body against infection and disease.
   c. transport chemical signals throughout the body.
   d. secrete the proteins that form blood clots.
   e. Both a and d are functions of erythrocytes.
6. What would happen to an animal's blood pressure if its cardiac output increased by a factor of 2 and its total peripheral resistance decreased by 50%?
   a. Blood pressure would decrease 16-fold.
   b. Blood pressure would increase 8-fold.
   c. Blood pressure would increase 1.5-fold.
   d. Blood pressure would increase 24-fold.
   e. Blood pressure would not change.
7. During systole of the cardiac cycle, the
   a. ventricles of the heart are both relaxed.
   b. ventricles of the heart are both filling.
   c. ventricles of the heart are both contracting.
   d. right ventricle is contracting while the left ventricle is at rest.
   e. left ventricle is contracting while the right ventricle is at rest.
8. Considering blood flow through a closed circulation, which is the correct sequence of vessels, beginning at the heart?
   a. arteriole, artery, capillary, vein, venule
   b. artery, capillary, arteriole, venule, vein
   c. vein, venule, capillary, arteriole, artery
   d. artery, arteriole, capillary, venule, vein
   e. artery, arteriole, capillary, vein, venule
9. Gas and nutrient exchange between the circulation and the tissues occurs primarily at the
   a. arteries.
   b. arterioles.
   c. capillaries.
   d. venules.
   e. veins.
10. Which of the following factors determines arterial blood pressure?
    a. cardiac output
    b. resistance
    c. arteriole diameter
    d. a, b, and c
    e. a and b only

Conceptual Questions

1. What are the basic components of a circulatory system?
2. Discuss the difference between closed and open circulatory systems. What advantages does a closed system provide?
3.  A principle of biology is that *living organisms maintain homeostasis*. In what ways does the circulatory system contribute to homeostasis?

Collaborative Questions

1. Describe the cardiac cycle, and explain why heart valves open in only one direction.
2. Discuss the types of closed circulatory systems found in vertebrates.

CHAPTER OUTLINE

48.1 Physical Properties of Gases
48.2 Types of Respiratory Systems
48.3 Structure and Function of the Mammalian Respiratory System
48.4 Mechanisms of Oxygen Transport in Blood

Summary of Key Concepts
Assess and Discuss

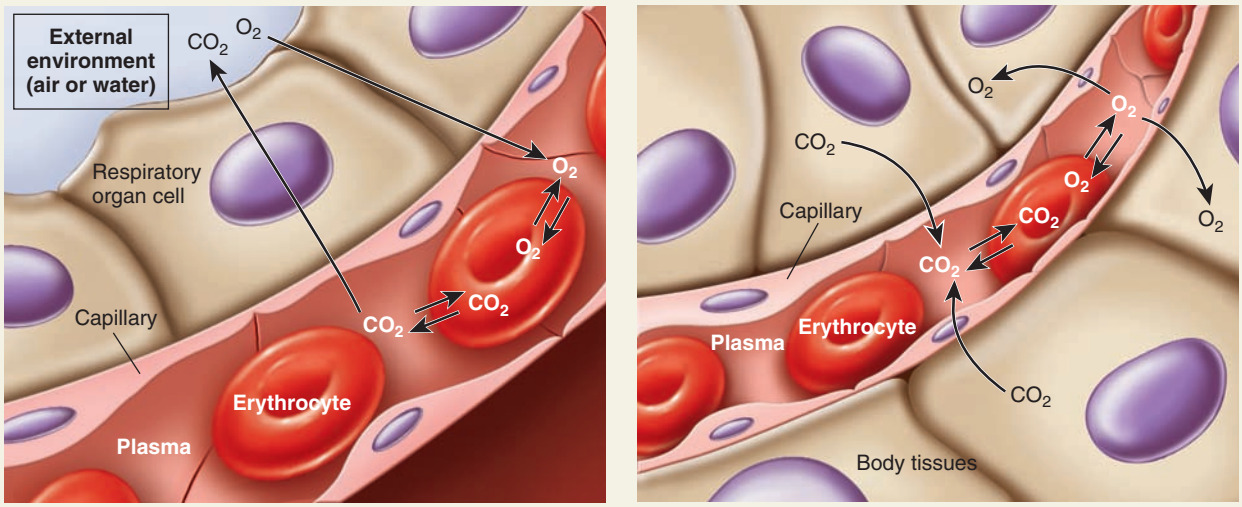
Respiratory Systems

48

Llama (*Lama glama*) in the Andes Mountains, an example of an animal adapted to conditions of low oxygen pressure.

Have you ever wondered why it is easy for an animal like the llama in the chapter opening photo to live at high altitudes, whereas most humans become ill when they ascend to such heights? What is it about the atmosphere in mountainous regions that makes it hard for us to function normally, and how do some people and animals adapt to those conditions if given sufficient time? Many such intriguing questions make the study of animal respiratory function fascinating. For example, how are you able to continue breathing while asleep? How does your breathing rate adjust to match your level of activity? If our respiratory system did not operate automatically, think how challenging, indeed impossible, life would be for us.

In Chapter 47, we saw how circulatory systems function to transport blood or hemolymph throughout an animal's body. In many animals, these fluids also carry the oxygen (O_2) that animals require. The oxygen enters the body via a respiratory (breathing) organ. It then dissolves into bodily fluids and is distributed to cells. As described in Chapter 7, O_2 is used by mitochondria in the formation of ATP. One of the waste products of that reaction is carbon dioxide (CO_2) which diffuses out of cells. CO_2 is returned by the circulatory system to the respiratory organ and is then released into the environment, either the air or water. The process of moving O_2 and CO_2 in opposite directions between the environment, bodily fluids, and cells is called **gas exchange** (**Figure 48.1**). A **respiratory system** includes all of an animal's structures that contribute to gas exchange.



This chapter deals with the mechanisms by which animals obtain and transport O_2, rid themselves of CO_2, and cope with the challenges imposed by their environments and their changing metabolic demands. We begin, however, with an overview of the properties of gases in air and water, which will help us understand how gases move between the environment and an animal's body fluids. We will conclude the chapter by looking at several human respiratory system disorders, some caused by lifestyle, others by genetics, and discuss their typical causes, possible treatments, and impact on society.

48.1 Physical Properties of Gases

Learning Outcomes:

1. List the relative amounts of each gas that make up the majority of the air we breathe.
2. Describe the relationship between altitude and atmospheric pressure.
3. **SciSKILLS** » Define partial pressure, and explain how it is calculated.
4. Explain the influence of pressure, temperature, and the presence of other solutes on the solubility of gases in water.

The exchange of O_2 and CO_2 between the environment and the fluids of an animal's body depends on the physical properties of these gases. These include such things as the solubility of the gas in water and the rate of diffusion of the gas. Air is composed of

(a) Gas exchange between the environment and a respiratory organ

(b) Gas exchange between the blood and tissues

Figure 48.1 Overview of gas exchange between the environment, blood, and cells. **(a)** In vertebrates, oxygen (O_2) diffuses from the environment across the cells of a respiratory organ into the blood (plasma and erythrocytes); carbon dioxide (CO_2) diffuses in the opposite direction and is released into the environment. **(b)** From the blood, O_2 diffuses into tissue cells, where it is used during the formation of ATP. Cells generate CO_2 as a waste product, which diffuses out of cells and into blood. Note: Interstitial fluid is omitted for simplicity.

BIOLOGY PRINCIPLE **Living organisms maintain homeostasis.** Keep this principle in mind as you read this chapter. The exchange of O_2 and CO_2 illustrated here is absolutely essential for all homeostatic processes in animals, in part because oxygen is required for the production of much of an animal's ATP. The ATP, in turn, provides the energy required to sustain processes that contribute to homeostasis.

about 21% O_2, 78% nitrogen (N_2), and roughly 1% CO_2 and other gases. From a respiratory standpoint, N_2 can usually be ignored because it plays no role in energy production nor is it created as a waste product of metabolism. In this section, we begin by examining some of the basic properties of the two major gases that are important in respiration.

Gases Exert Pressure, Which Depends on Altitude

The gases in air exert pressure on the body surfaces of animals, although the pressure is not perceptible (unless it changes suddenly, like when your ears "pop" in a descending airplane). This pressure is called **atmospheric** (or **barometric**) **pressure**. It can be measured by noting how high a column of mercury is forced upward by the air pressure in a device called a mercury manometer. The traditional unit of gas pressure, therefore, is millimeters of mercury (mmHg)—the same as for blood pressure.

At sea level, atmospheric pressure is 760 mmHg. It decreases as we ascend to higher elevations because the gravitational pull of the Earth decreases; consequently, gases expand and fewer gas molecules are in a given volume of air at a higher altitude (**Figure 48.2**). To visualize why gas pressure decreases at higher altitudes, think about how hydrostatic pressure decreases from the ocean floor to the ocean surface. Now, imagine that you are standing at the bottom of an "ocean" of air. The closer you get to the "ocean" surface (the top of the atmosphere), the lower the pressure exerted on your body. At an elevation of 1,700 m, as in Denver, the pressure is about 640 mmHg, but at the highest elevations continuously inhabited by humans—in the Andes Mountains at 5,500 m—the pressure falls to 375 mmHg.

Atmospheric pressure is the sum of the pressures exerted by each gas in air, in exact proportion to their amounts. The individual pressure of each gas is its **partial pressure**, symbolized by a capital P and a subscript depending on the gas. At sea level, the partial pressure of oxygen (P_{O_2}) in the air we breathe is 21% of the atmospheric pressure at sea level, or 160 mmHg (0.21 × 760 mmHg). The relative proportions (percentages) of oxygen and other gases in air remain the same regardless of altitude, but the lower the atmospheric pressure, the lower the partial pressure of oxygen in air. In Denver, for example, the P_{O_2} would be 21% of 640 mmHg, or 134.4 mmHg.

The partial pressure of oxygen provides the driving force for its diffusion from air or water across the respiratory surface and into the blood. All gases diffuse along pressure gradients, from

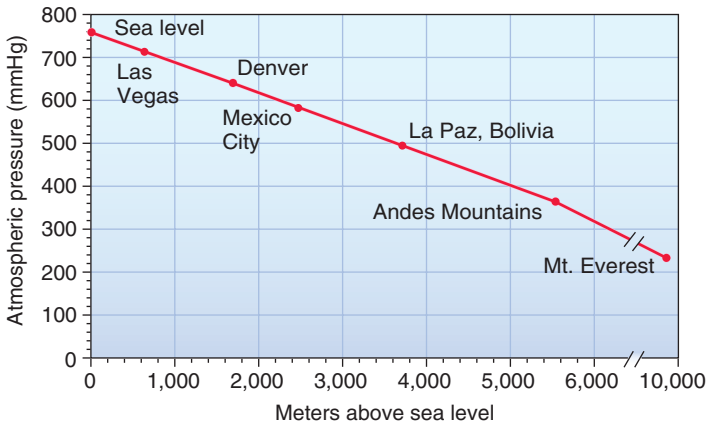


Figure 48.2 The relationship between atmospheric pressure and altitude. Atmospheric pressure decreases as altitude increases.

Concept Check: Is the percentage of oxygen in the air over Mt. Everest less than it is at sea level?

regions of high pressure to regions of lower pressure. This is analogous to the diffusion of dissolved solutes from regions of high to low concentration, or the way heat moves from hotter to cooler regions. Consequently, the rate of oxygen diffusion into the blood of a terrestrial animal decreases when the animal moves from sea level to a higher altitude, where the Po_2 is lower. This explains why humans who climb to high altitudes often need to breathe from a tank containing gas that is enriched in oxygen, to compensate for the lower Po_2.

Pressure, Temperature, and Solutes Influence the Solubility of Gases

Gases dissolve in water, including fresh water, seawater, and all body fluids. Gases such as O_2 exert their biological effects while in solution. However, most gases dissolve rather poorly in water. There is less O_2 in a given volume of water than in air, for example, which limits how active many aquatic organisms can be. Among the factors that influence the solubility of a gas in water, three are particularly important: the pressure of the gas, the temperature of the water, and the presence of other solutes.

Pressure of the Gas The greater the pressure of a gas that comes into contact with water, the more of that gas that will dissolve, up to a limit that is specific for each gas at a given temperature. Not all gases dissolve equally. O_2 is less soluble in water than is CO_2, but more soluble than N_2. The partial pressure of gas in water is given in the same units as atmospheric pressure (mmHg). For example, if a solution of water is in contact with air that contains a Po_2 of 160 mmHg, the Po_2 of the water is also 160 mmHg.

Temperature of the Water Solubility also depends on the temperature of the water: More O_2 and CO_2 dissolve in 1 L of cold water than in 1 L of warm water. You can observe this effect of temperature with the following experiment. Open two bottles of a carbonated beverage (that is, one in which CO_2 has been added) and keep one on ice and the other at room temperature. Note that the "fizz" of the room-temperature beverage disappears sooner, as CO_2 escapes due to its lower solubility at that temperature. Why does this happen? At higher temperatures, gases in solution have more thermal energy and are therefore more likely to escape the liquid. In terms of biological systems, this effect of water temperature means that animals inhabiting very warm waters generally have less O_2 available to them than do animals living in cold waters. Animals that live in shallow water such as ponds or tide pools, where water temperature can fluctuate widely over a single day, must be able to adapt to large swings in O_2 availability.

Presence of Other Solutes Finally, the presence of other solutes, namely, ions from salts such as NaCl, decreases the amount of gas that dissolves in water. Thus, warm salty blood dissolves less O_2 than does pure, cold water. Likewise, less O_2 dissolves in seawater than in fresh water at any given temperature and pressure. Animals living in cold freshwater lakes, therefore, typically have more O_2 available to them than do animals living in warm salty seas (although other factors can also influence the amount of dissolved O_2, such as the amount of aquatic plant life).

BIO TIPS

THE QUESTION *The city of Quito, Ecuador, lies at an altitude of approximately 2,800 m above sea level. What is the partial pressure of oxygen (Po_2) in Quito?*

TOPIC ***What topic in biology does this question address?*** The topic is oxygen partial pressures at different altitudes above sea level. More specifically, the question asks you to calculate a value of Po_2, given an altitude.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you know the altitude of Quito. From your understanding of the topic, you know that altitude and atmospheric pressure are related. Moreover, you know that the percentage of oxygen in the air does not change with altitude.

PROBLEM-SOLVING STRATEGY ***Make a calculation.*** Look at Figure 48.2. Find 2,800 m on the horizontal axis, and then look straight above that value to the curve. Determine what value on the vertical axis corresponds to that point on the curve. Then, calculate Po_2 at that atmospheric pressure.

ANSWER *The atmospheric pressure at 2,800 m is approximately 560 mmHg. The percentage of oxygen in air does not change with altitude and remains 21%. Therefore, the Po_2 at 2,800 m is (0.21 × 560 mmHg), or 117.6 mmHg.*

48.2 Types of Respiratory Systems

Learning Outcomes:

1. Describe some structural and functional features that are common to all gas-exchange surfaces in animals.
2. Describe the different challenges faced by water- and air-breathing animals.
3. Describe how an animal's body surface can exchange gases with the environment.
4. **SciSKILLS »** Diagram the process of countercurrent flow in gill ventilation.
5. Explain the unique aspects of the tracheal system of ventilation in insects.
6. Describe how lungs function in gas exchange in air-breathing vertebrates.

Despite their staggering array of shapes, sizes, and habitats, animals obtain oxygen from their surroundings with one of just four major types of gas-exchange organs: the body surface, gills, tracheae, or lungs. **Ventilation** is the process of bringing oxygenated water or air into contact with a gas-exchange organ. In this section, we will examine the mechanisms of ventilation used by animals with different respiratory systems.

The Structures of Respiratory Organs Are Adapted for Gas Exchange

All gas-exchange structures share certain common features. All of them have moist surfaces on which the gases can dissolve and diffuse. Further, all have adaptations that increase the amount of surface area available for gas exchange.

The extensive surface area of respiratory organs is coupled with an equally extensive blood circulation, except in the special case of insects, described later in this chapter. The density of capillaries in gills and lungs, for example, is among the highest found anywhere in an animal's body. The greater the amount of blood flowing to a respiratory surface, the more effective the delivery and removal of gases.

Thick barriers greatly slow the diffusion of a gas. As a result, respiratory organs tend to be thin, delicate structures, which also means they are easily damaged. For instance, the inner structures of fish gills are so thin that they cannot support their own weight out of water, and they collapse when exposed to air.

Water-Breathing and Air-Breathing Animals Face Different Challenges

Exchanging gases in water or in air requires respiratory organs that are suited for the challenges presented by each of those different environments. Since water-breathing animals generally have less oxygen available to them than do air-breathing animals, an active water-breathing animal requires a very efficient means of obtaining oxygen from water. In addition, unlike air-breathing animals, water-breathing animals must adapt to fluctuating oxygen availability when the temperature changes. By contrast, air-breathing animals must cope with the dryness of air. Moving dry air over the lung surfaces poses the risk of drying out the lungs, which would damage them, dehydrate the animal, and reduce the ability of gases to dissolve.

Water-breathing animals bring water, not air, over their respiratory surfaces and therefore do not usually risk dehydration in the way that air-breathing animals do. However, moving water over a gas-exchange surface has its own challenges. First, because water is denser than air, more energy (muscular work) is required to move water. Second, cold water moving over the richly vascular gills draws considerable heat from an animal's body, due to the high heat capacity of water. Third, moving either fresh or salty water over a gas-exchange surface can create osmotic movement of water across the surface, potentially resulting in water imbalances in an animal's body.

Some Animals Exchange Gases Across the Body Surface

In those invertebrates that are only a few cell layers thick, such as platyhelminthes and cnidarians, O_2 and CO_2 can diffuse directly across the body surface. In this way, O_2 reaches all the interior cells, in some cases without any specialized transport mechanism or circulatory system.

Even in some large animals, the body surface may be permeable to gases (**Figure 48.3**). Amphibians, and a few species of fishes, including eels, have unusually permeable skin. On land, amphibians rely primarily on their lungs but also on their moist skin to obtain O_2 and release CO_2. Under water, however, the lungs are no longer useful because they are not suited for obtaining O_2 from water. Although O_2 diffusion across the skin provides less O_2 than can be provided by the lungs, this secondary ability to exchange gas permits amphibians to spend prolonged times under water.

Some vertebrates spend part of their lives on land and part in water and can hold their breath under water for much longer periods than can humans. Some reptiles, such as marine iguanas, can obtain O_2 from the water across the highly permeable mucous membranes of the nose, mouth, and anus. Although this provides less O_2 than does air breathing, it nonetheless allows them to remain under water for extended periods, as when foraging for food. Other animals have highly specialized body regions with considerable surface area—like the wings of a bat—that permit some gas exchange with the environment (see Figure 48.3). Except for amphibians, however, no vertebrates can rely for long periods of time exclusively on their skin to obtain oxygen and remain active.

Water-Breathing Animals Use Gills for Gas Exchange

Most water-breathing animals use specialized respiratory structures called **gills**, which can be either external or internal. External gills are uncovered extensions from the body surface, found in many invertebrates and the larval forms of some amphibians. Internal gills, which occur in fishes, are enclosed in a protective cavity.

External Gills External gills vary widely in appearance, but all have a large surface area, often in the form of extensive projections

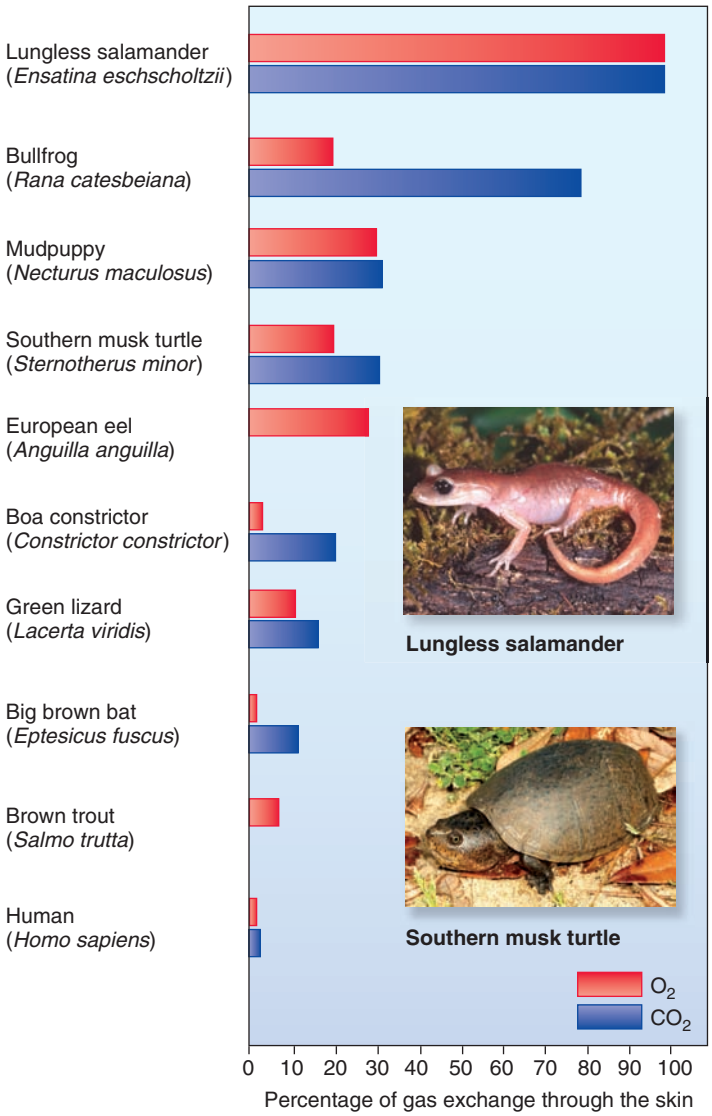

Figure 48.3 Gas exchange across body surfaces. This type of gas exchange occurs readily in amphibians, to a lesser extent in marine reptiles and some fishes, and to a negligible extent among mammals. Note: CO_2 determinations were not made in all species.

Concept Check: *What would happen to gas exchange in lungless salamanders if the animals were allowed to dry out?*

(a) Mollusk (nudibranch) with clustered external gill tufts

(b) Larval salamander with external gills

Figure 48.4 Examples of animals with external gills. The gills of these animals have extensive projections to increase surface area, which facilitates oxygen diffusion from the surrounding water.

BIOLOGY PRINCIPLE Structure determines function. Note how the gills of the nudibranch and larval salamander have extensive surface modifications to increase the total area available for gas exchange. This is not unique to external gills; indeed, all gas-exchange surfaces have one or another type of surface area structural modification to maximize their function.

(**Figure 48.4**). External gills may exist in one region of the body or be scattered over a large area. In many cases, they are ventilated by being waved back and forth through the water. The ability to move external gills is particularly important for sessile invertebrates, which must otherwise rely on sporadic local water currents or muscular efforts of their bodies to create local currents for ventilation.

Despite the success of marine invertebrates, external gills have several limitations. First, they are unprotected and therefore are susceptible to damage from the environment. Second, because water is much more dense than air, considerable energy is required to continually wave the gills back and forth through the water (think of the difference between waving your hands through air or water). Finally, their appearance and motion may draw the attention of predators.

Internal Gills By contrast, fishes have internal gills, which are covered by a bony plate called an operculum (**Figure 48.5a**). Fish gills have a more uniform appearance than external gills and are confined within the opercular cavity, the space beneath the operculum, which protects the gills and helps streamline the fish body.

The main support structure of gills are the gill arches, which contain gill filaments composed of numerous platelike structures called **lamellae** (**Figure 48.5b**). Blood vessels run the length of the filaments, with oxygen-poor blood traveling through the afferent vessel along one side of the filament and oxygen-rich blood

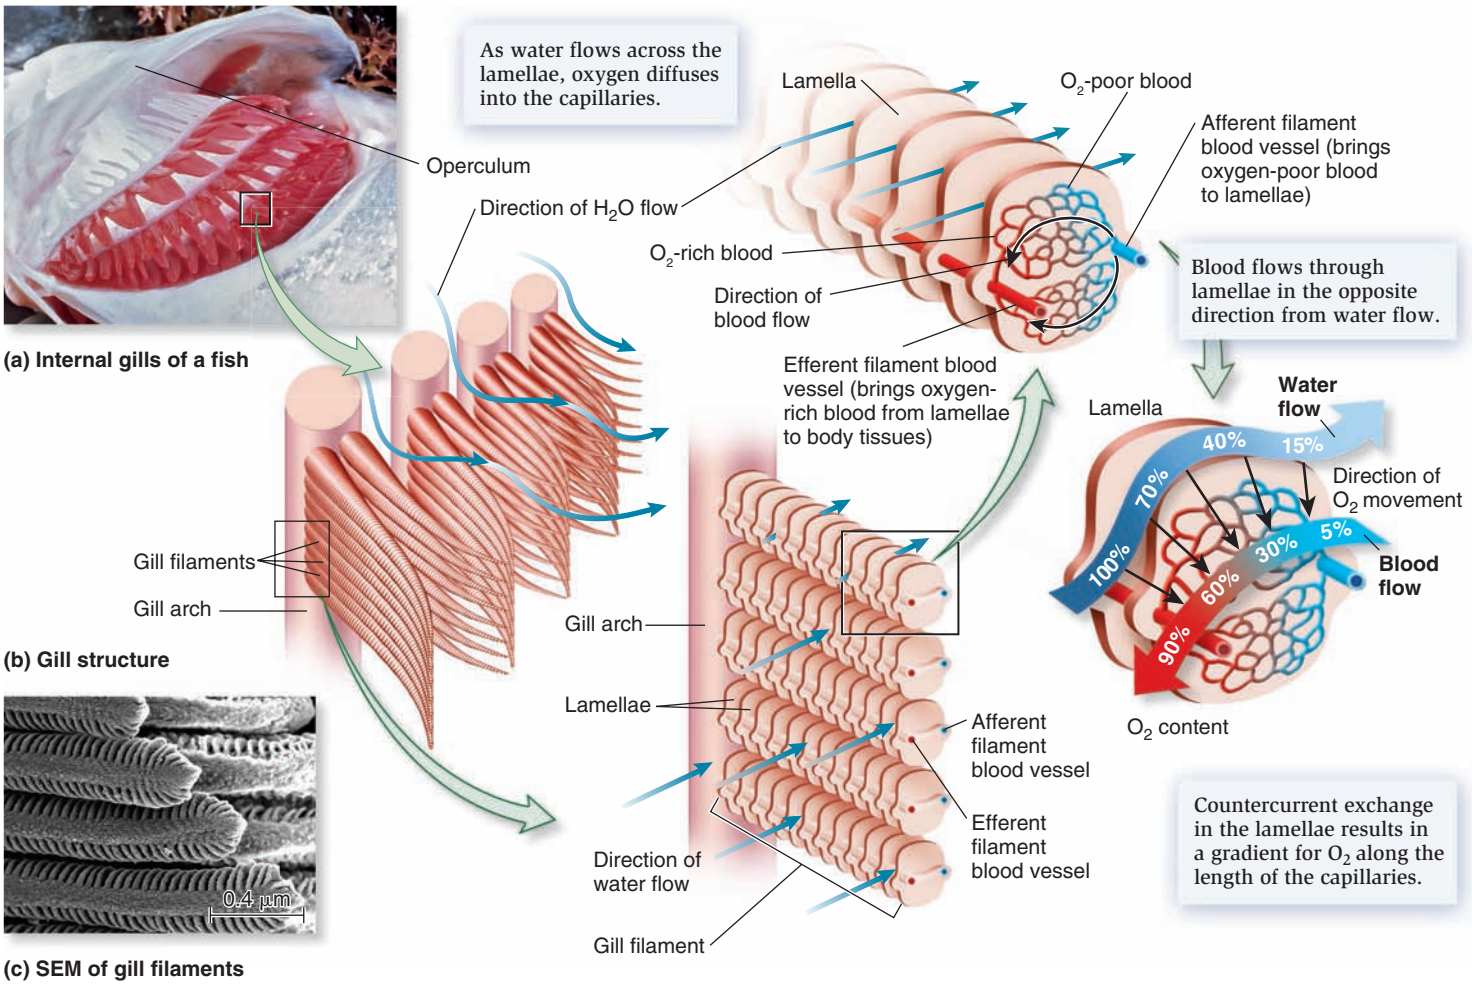

Figure 48.5 **Structure of fish gills.** **(a)** The operculum, which has been lifted open in this photo, protects the gills underneath. **(b)** The gills are composed of gill arches, from which numerous pairs of filaments arise. Thin, platelike lamellae are arrayed along the filaments. Blood flows through the capillaries of the gill filaments in the opposite direction from water flowing between lamellae, a process called countercurrent exchange. **(c)** Several filaments with their lamellae as revealed in a scanning electron micrograph.

Concept Check: *Why do fishes die when out of water? (Hint: Consider what happens if you hold two thin, wet paper towels together.)*

BioConnections: *You have already learned about countercurrent exchange (look back at Figure 46.13). How does it relate to heat exchange in vertebrates?*

traveling through the efferent vessel along the other side. Within the lamellae are numerous capillaries, all oriented with blood flowing in the same direction, from the oxygen-poor (afferent) vessel to the oxygen-rich (efferent) one.

Water enters a fish's mouth and flows between the lamellae in the opposite direction from that of the blood flowing through the lamellar capillaries. This arrangement of water and blood flow is an example of **countercurrent exchange** (refer back to Figure 46.13). As oxygenated water encounters the lamellae, it comes into close proximity with blood in the gill capillaries. Recall that oxygen diffuses along a pressure gradient from a region of high oxygen pressure to one of low oxygen pressure. Thus, oxygen diffuses from the water into the capillaries of the lamellae. As water continues to flow across the lamellar surface, it encounters regions of capillaries that have not yet picked up oxygen—in other words, even as oxygen begins to diffuse from the water into the gill capillaries, a sufficient pressure gradient remains along the lamellae to permit diffusion of more of the remaining oxygen from the water. This is an extremely efficient way to remove as much oxygen from the water as possible before the water passes out of the operculum.

Mechanisms of Internal Gill Ventilation Fishes use one of two mechanisms to ventilate their gills: buccal pumping or ram ventilation.

- **Buccal pumping** (the buccal cavity refers to the mouth) makes use of the muscles of the mouth and operculum to create a hydrostatic pressure gradient for water to flow in one direction (**Figure 48.6a**). First, the jaw is lowered, which enlarges the buccal cavity and lowers the pressure in the mouth, something like a suction pump. This draws water into the mouth, raising the water pressure again. At roughly the same time, the operculum begins to swing out from the body,

enlarging the opercular cavity and lowering the water pressure there. This second suction pump is stronger than the buccal pump, so water flows down its hydrostatic pressure gradient from the environment into the mouth, and from there into the opercular cavity. Next, the mouth closes, and the buccal cavity is compressed. This creates positive pressure that forces water across the gills and out through the open operculum. A flap of tissue at the back of the mouth helps prevent flow of water down the esophagus. Consequently, fishes do not swallow the water they inhale but instead send it on a one-way journey across their gills. With buccal pumping, a fish can remain stationary and still ventilate, even in stagnant water, by drawing water into its mouth.

- **Ram ventilation**, the second way in which fishes ventilate their gills, consists of swimming with an open mouth, in essence using their swimming muscles to bring water into their buccal cavity and from there across their gills (**Figure 48.6b**). This method of ventilation is more energy-efficient than buccal pumping. Ram ventilation still requires energy expenditure, but in this case, the energy is used for swimming or for using muscles to remain stationary while facing upstream in moving water. Many fishes employ both methods of ventilation, using buccal pumping when swimming slowly or in stagnant water and switching to ram ventilation when swimming quickly or facing upstream. Some fishes—such as tuna—can only ram ventilate and therefore rarely stop swimming.

Both buccal pumping and ram ventilation are **flow-through systems**—water moves unidirectionally in such a way that the gills are constantly in contact with fresh, oxygenated water. As we will see, many air-breathing animals use a less efficient method of ventilating their lungs, called tidal ventilation, in which fresh air is breathed in and stale air is breathed out through the same route. Despite the efficiency of flow-through systems for maximizing oxygen diffusion from water, they are energetically costly because of the work required to overcome the density of water. Fishes may devote up to 10–20% of their resting metabolic rate simply to ventilating their gills, whereas a typical air-breather may allocate only 1–2% of its total energy usage to ventilating the lungs at rest.

Insects Use Tracheal Systems to Exchange Gases with the Air

Except for terrestrial isopods such as the pill bug (*Armadillidium vulgare*; see Figure 33.31b), which breathe air through very small, moist gills, the delicate nature of gill lamellae makes them unsuitable for gas exchange in air. Air breathing probably evolved as an adaptation in aquatic animals inhabiting regions that were subject to periodic drought.

One of the major mechanisms that animals evolved to breathe air is the **tracheal system** found in insects. Running along the surface of both sides of an insect's body are tiny openings to the outside, called **spiracles**. Arising from the spiracles are **tracheae** (singular, trachea), sturdy tubes that are reinforced with the polysaccharide chitin to keep them open (**Figure 48.7**). Tracheae branch extensively into ever-smaller tubes called tracheoles, which eventually become

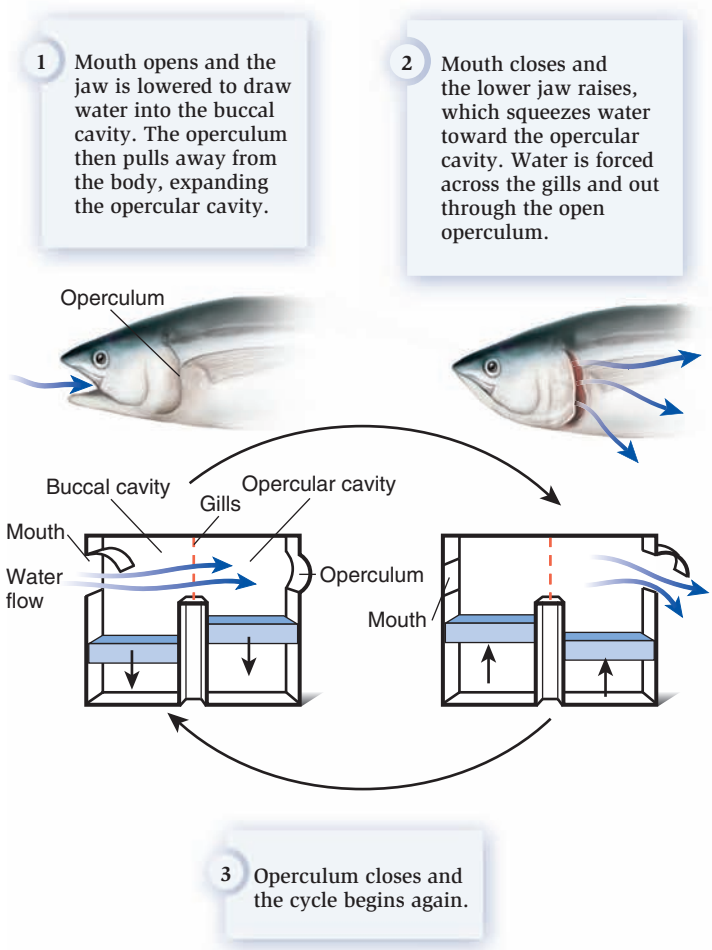

Figure 48.6 Mechanisms of gill ventilation. **(a)** Buccal pumping. The expansion of the buccal and opercular cavities acts like a suction pump, and closing these cavities acts like a pressure pump. **(b)** Ram ventilation. Many fishes ventilate their gills by swimming forward, such as this tuna, or by facing upstream in moving water with their mouths open. This allows the water to move through the mouth and opercular cavity. Some species use both buccal pumping and ram ventilation, whereas some use only one. During both types of ventilation, flaps of tissue in the mouth, throat, and operculum help prevent water from moving in the reverse direction or down the esophagus.

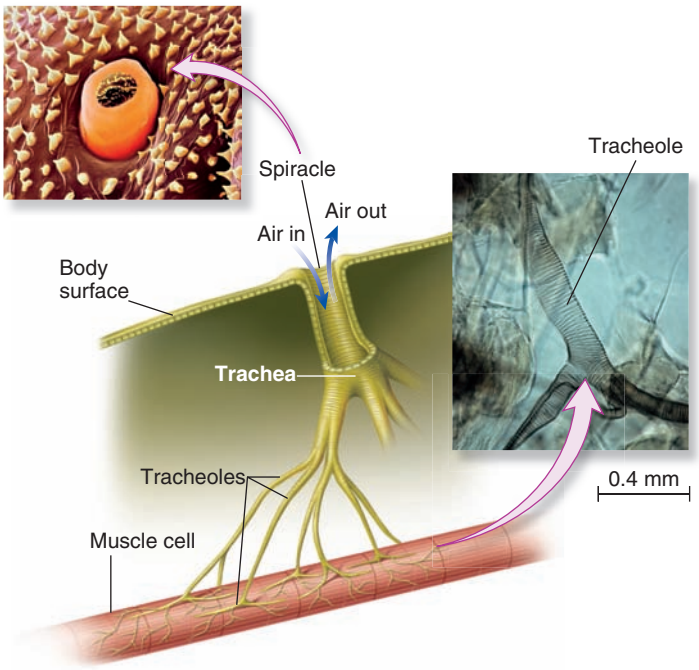

Figure 48.7 The tracheal system of insects. Air enters holes on the body surface called spiracles. Oxygen diffuses directly from the fluid-filled tracheole tips to cells that come into contact with the tips. The circulatory system has no role in gas exchange. The micrographs illustrate a single spiracle and a few branching tracheoles of an insect.

Concept Check: How might the structure of the respiratory system of insects be related to why insects tend to be small?

small enough that their tips contact virtually every cell in the body. At their tips, tracheoles are filled with a small amount of fluid. Air flowing down the tracheoles comes into contact with this fluid. Oxygen from the air dissolves in the fluid, and from there it diffuses across the tracheole and into nearby cells. Carbon dioxide diffuses in the opposite direction, from cells into the tracheoles, and from there to the environment.

When an insect's oxygen demands increase due to increased activity, muscular movements of its abdomen and thorax draw air into and out of the tracheae like a bellows, a phenomenon first demonstrated in the early 20th century by Danish physiologist and Nobel laureate August Krogh, who studied the mechanics of ventilation in locusts. Krogh showed that an insect's muscles and tracheal system match ventilation with the animal's exercise intensity and oxygen requirements. This is particularly important in flying insects, which have very great metabolic demands. The faster an insect flies, the more oxygen it uses. Likewise, the more intensely and rapidly the body wall muscles move, the more air is moved in and out of the tracheae.

As discussed in Chapter 47, the open circulatory system of insects does not participate in gas exchange. Oxygen diffuses directly from air to trachea to tracheoles and finally to body cells. This mechanism of ventilation and oxygen delivery is very effective. The metabolic rate of insect flight muscles is among the highest known of any tissue in any animal, and the tracheal system supplies enough oxygen to meet those enormous demands.

Air-Breathing Vertebrates Use Lungs to Exchange Gases

Except for some amphibians such as lungless salamanders (family Plethodontidae), all air-breathing terrestrial vertebrates use lungs to bring oxygen into the circulatory system and remove carbon dioxide from it. **Lungs** are internal paired structures that arise during embryonic life from the pharynx (throat). All lungs receive deoxygenated blood from the heart and return oxygenated blood back to the heart. Depending on the class of vertebrate, lungs may be filled using positive or negative pressure, and they may be ventilated by a tidal system or a flow-through system.

Most amphibians have lungs that are simple sacs with relatively little surface area, making them less effective surfaces for oxygen diffusion than are the lungs of other vertebrates. A lung of a 30-g mouse, for example, has nearly 50 times more gas-exchange surface per cubic centimeter of lung tissue than a lung of a 30-g frog. The method by which amphibians ventilate their lungs is similar in some ways to the buccal pumping of fishes. A frog, for example, lowers its jaw, which decreases the air pressure inside the mouth cavity. According to Boyle's law, the pressure of a gas and its volume are inversely related (**Figure 48.8**). For example, when the volume in which a gas is contained increases, the pressure of the gas in that container decreases. By expanding its mouth cavity, therefore, a frog creates a pressure gradient for air to move from the atmosphere (higher pressure) into its mouth (lower pressure). The mouth and nostrils then close, and the mouth cavity is compressed by raising the jaw. This increases the air pressure in the mouth, forcing air through a series of valves into the lungs. Thus, **positive pressure filling** means that frogs and most other amphibians gulp air and force it under pressure into the lungs, as if inflating a balloon. They may do this many times in a row before exhaling.

Except for a few species of lizards, all other terrestrial vertebrates use a different method of ventilation, called negative pressure filling. To understand how negative pressure filling works, we will first examine the anatomy of the respiratory tract in vertebrates, using the mammalian system as a model.

48.3 Structure and Function of the Mammalian Respiratory System

Learning Outcomes:

1. Describe the components of the mammalian respiratory system and the structure of the mammalian lung.
2. Describe the steps involved in the process of ventilation in mammalian lungs.
3. Explain the importance of surfactant in mammalian ventilation.

In vertebrates, the respiratory system includes all components of the body that contribute to the exchange of gas between the external environment and the blood. In this section, we will examine the structures of the mammalian respiratory system and the mechanisms by which mammals ventilate their lungs.

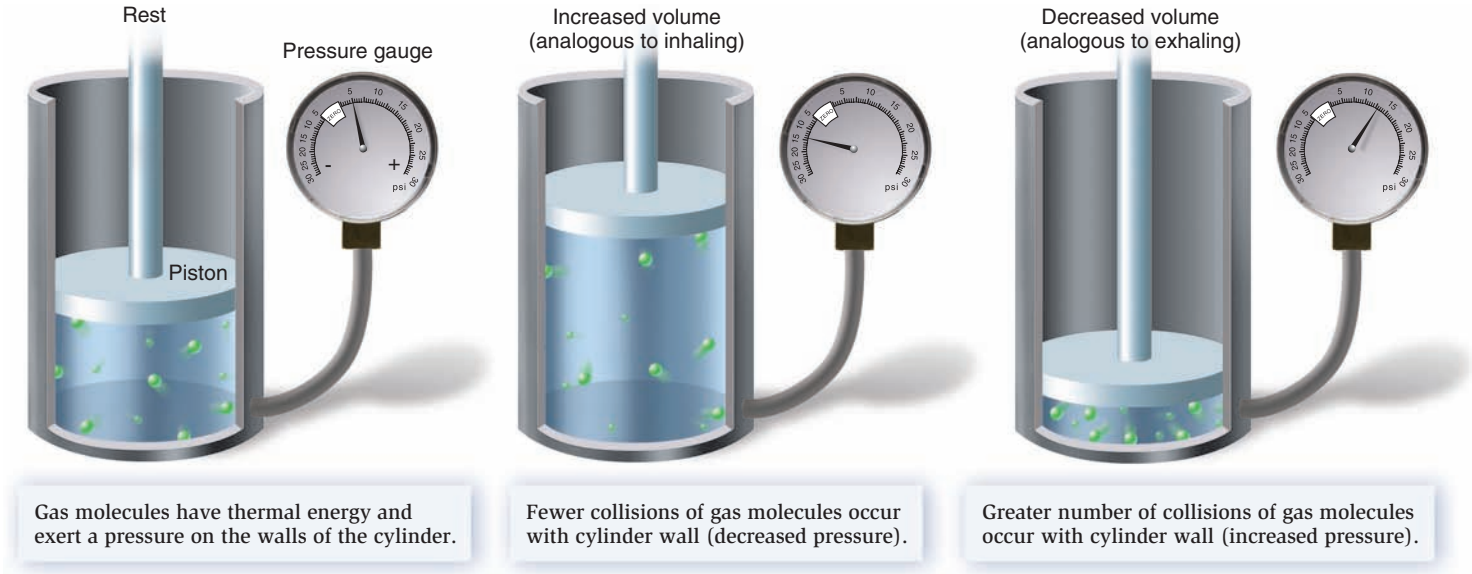

Figure 48.8 Boyle's law. The volume and pressure of a gas are inversely related. This relationship explains the gas pressure gradients that ventilate the vertebrate lungs.

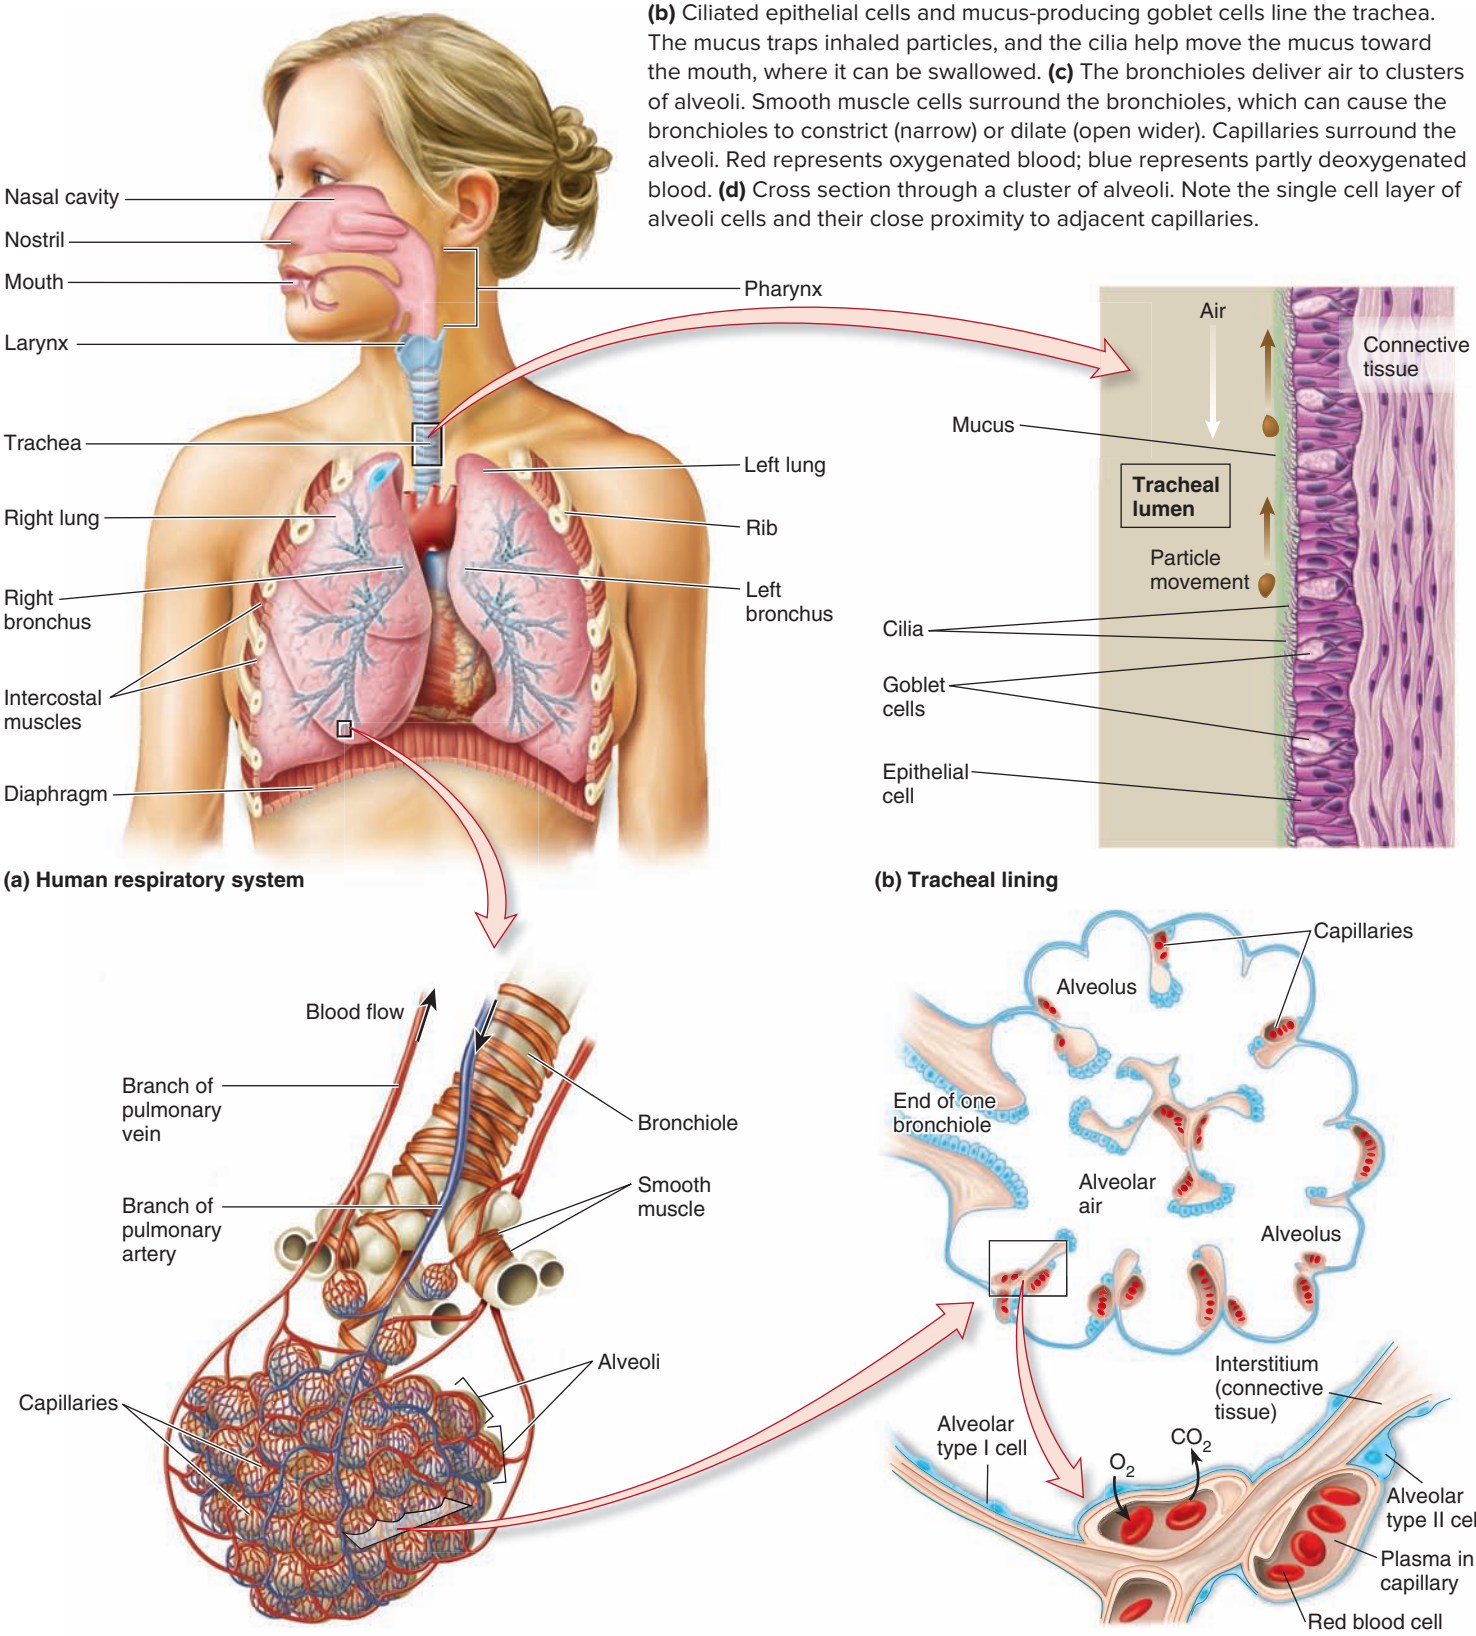
Concept Check: *As the lungs expand during inhalation, what happens to the pressure of air inside the lungs?*

During Ventilation, Air Flows Through a Series of Branching Tubes

In mammals, the respiratory system includes the nose, mouth, pharynx, larynx, trachea and branching tubes, lungs, and muscles and connective tissues that encase these structures within the thoracic (chest) cavity (**Figure 48.9a**). When humans and other mammals breathe, air first enters the nose and mouth, where it is warmed and humidified. These processes protect the lungs from drying out. While in the nose, the air is cleansed as it flows over a coating of sticky mucus in the nasal cavity. The mucus and hairs in the nasal cavity trap some of the larger dust and other particles that are inhaled with air. These are then removed by the body's defense cells or swallowed.

The inhaled air from the mouth and nose converges at the back of the throat, or **pharynx**, a common passageway for air and food. From there, air passes through the **larynx**. Within the larynx are the vocal cords, folds of tissue through which air passes to create sound. Air flows from the larynx into the **trachea**, a tube that leads to the lungs.

The trachea is partly ringed by C-shaped cartilage supports that provide rigidity and ensure that the trachea always remains open. The inner wall of the trachea is lined with cilia and cells called goblet cells (**Figure 48.9b**). These cells secrete mucus onto the inner surface of the trachea, coating the cilia. This mucous layer captures potentially harmful or irritating particles that escaped the nasal cleaning mechanism. The beating of the cilia continually moves the mucus and its trapped particles toward the mouth, where it can be expelled or swallowed. Without these active cilia, repeated coughing would be needed to force the mucus out of the trachea. This is why people who smoke develop a chronic "smoker's cough"—the smoke and its components reduce the number of cilia, causing mucus to collect in the trachea.



Inhaled air flows down the trachea as it branches into two smaller tubes, called **bronchi** (singular, bronchus), which lead to each lung. The bronchi branch repeatedly into smaller and smaller tubes, eventually becoming thin-walled **bronchioles** containing circular rings of smooth muscle (**Figure 48.9c**). Bronchioles can dilate or constrict in a manner analogous to that of arterioles (see Chapter 47). They may partially constrict when a damaging particle—such as a small bit of inhaled pollutant or dust—gets past the mucous layers of the upper airways. Constriction of a bronchiole prevents foreign particles from reaching delicate lung tissue. Once the body's defense cells have removed the particles, the bronchiole reopens to its normal diameter.

The bronchioles empty into **alveoli** (singular, alveolus), the final, saclike regions of the lungs where gas exchange occurs (see Figure 48.9c). Until now, air has flowed through the air tubes without any gas exchange taking place. The alveoli are highly adapted for gas exchange and consist of two major types of cells. Type I cells are those across which gases diffuse, whereas type II cells are secretory cells (described later). The alveoli are only one-cell thick and resemble extremely thin sacs, appearing like bunches of grapes on a stem. Deoxygenated blood pumped from the right ventricle of the heart flows to the many capillaries surrounding the alveoli. Oxygen diffuses from the lumen of each alveolus across the alveolar cells, through the interstitial space outside the cells, and into the capillaries (**Figure 48.9d**). Carbon dioxide diffuses in the opposite direction. The oxygenated blood from the lungs then flows to the left atrium of the heart and from there enters the left ventricle, where it is pumped out through the aorta to the rest of the body.

The Pleural Sacs Protect the Lungs

The lungs are soft, delicate tissues that could easily be damaged by the surrounding bone, muscle, and connective tissue of the thoracic cavity if not protected. Each lung is encased in a **pleural sac**, a double layer of thin, moist tissue. Between the two layers of tissue is a

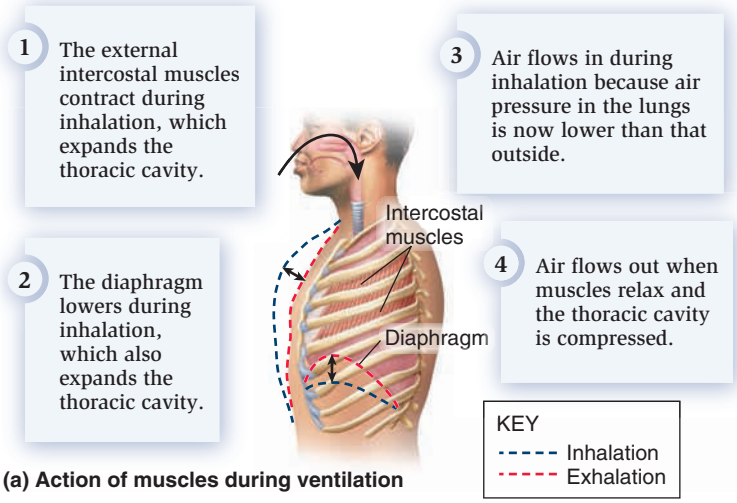
Figure 48.9 The mammalian respiratory system. **(a)** The lungs and major airways. The thoracic cavity is bounded by the ribs and intercostal muscles and the muscular diaphragm. For simplicity, external and internal intercostal muscles are not indicated separately, and the ribs have been removed in front. **(b)** Ciliated epithelial cells and mucus-producing goblet cells line the trachea. The mucus traps inhaled particles, and the cilia help move the mucus toward the mouth, where it can be swallowed. **(c)** The bronchioles deliver air to clusters of alveoli. Smooth muscle cells surround the bronchioles, which can cause the bronchioles to constrict (narrow) or dilate (open wider). Capillaries surround the alveoli. Red represents oxygenated blood; blue represents partly deoxygenated blood. **(d)** Cross section through a cluster of alveoli. Note the single cell layer of alveoli cells and their close proximity to adjacent capillaries.

microscopically thin layer of water that acts as a lubricant and makes the two tissue layers adhere to each other.

In addition to protecting the lungs, the inner pleural sac adheres to its lung, and the outer pleural sac adheres to the chest wall. In this way, movements of the chest wall result in similar movements of the lungs. This is important because the lungs are not muscular and so cannot inflate themselves. Instead, as we will see, the lungs are inflated by the expansion of the thoracic cavity, which results from the contraction of muscles in the thorax.

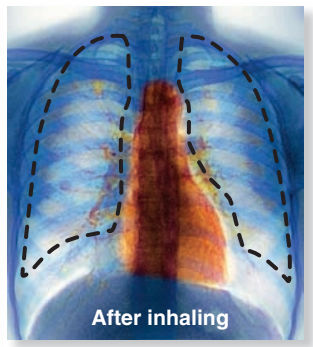
The Lungs Expand by Negative Pressure Filling

The way in which you inflate a balloon, by forcing air from your mouth into the balloon, is called positive pressure filling. It is reminiscent of how amphibians ventilate their lungs. **Negative pressure filling**, by contrast, is the mechanism by which most reptiles and all birds and mammals ventilate their lungs. In this process, the volume of the lungs expands, creating a decreased pressure (refer to Figure 48.8) that draws air into the lungs. The process differs in some ways among classes of vertebrates, but in mammals, the work is provided by the **external intercostal muscles**, which surround and connect the ribs in the chest, and a large muscle called the **diaphragm** (see Figure 48.9a), which divides the thoracic cavity from the abdomen.



Let's follow the process when a mammal ventilates its lungs (**Figure 48.10**). At the start of a breath, the diaphragm contracts, pulling downward and enlarging the thoracic cavity. Simultaneously, the external intercostal muscles contract, moving the chest upward and outward, which also helps to enlarge the thoracic cavity. Recall that the pleural sacs adhere the lungs to the chest wall, so as the chest expands, the lungs expand with it. According to Boyle's law, as the volume of the lungs increases, the pressures of the gases within them must decrease. In other words, the pressure in the lungs becomes negative with respect to the outside air. Air, therefore, flows down its pressure gradient from outside the mouth and nose, into the lungs.

Once the lungs are inflated with air, the chest muscles and diaphragm relax and recoil back to their original positions as an animal exhales. This compresses the lungs and forces air out of the airways. Whereas inhaling requires the expenditure of significant amounts of energy, exhaling is mostly passive and does not require much if any energy. The lower energy requirement for exhaling occurs because the lungs and chest have large numbers of fibers of the protein elastin which, as its name implies, has elastic properties (refer back to Figure 10.3). During physical activity, however, exhalation is assisted by contraction of another set of rib muscles, called the internal intercostal muscles. The contraction of these muscles depresses the rib cage and provides a more forceful exhalation; this increases the rate at which ventilation occurs and helps empty the larger volume of air that fills the lungs during the deeper breathing associated with physical activity.



Mammals Breathe by Tidal Ventilation

When mammals exhale, air leaves via the same route that it entered during inhalation, and no new oxygen is delivered to the airways at that time. As mentioned, this type of breathing is called **tidal ventilation** (think of air flowing in and out of the lungs like the ebb and flow of tides on the ocean). Tidal ventilation is less efficient than the unidirectional, flow-through system of fishes in which gills are always exposed to oxygenated water during all phases of the respiratory cycle; for comparison, avian lungs share features of both types of ventilation (**Figure 48.11**).

As you likely know from experience, the lungs are neither fully inflated nor fully deflated at rest. The volume of air that is normally breathed in and out at rest is the **tidal volume**, about 0.5 L in an average-sized human. Tidal volume is proportional to body size both among individuals and between species. A 6-foot-tall adult human, for example, has a larger tidal volume than a 4-foot-tall child because the adult has larger lungs. Similarly, horses have larger tidal volumes than humans, and humans have larger tidal volumes than dogs (**Table 48.1**). During exertion, the lungs can be inflated further than the resting tidal volume to provide additional oxygen. Likewise, the lungs can be deflated beyond their normal limits at rest, by exerting a strong effort during exhalation. The lungs never fully deflate, however, partly because they are held open by their adherence to the chest wall. This is important for a simple reason. Think again of our analogy of a balloon. It is much easier to fill a balloon that is already partly inflated than it is to inflate a completely empty balloon. The same is true of the lungs.

(a) Action of muscles during ventilation

(b) Change in lung volume during ventilation

Figure 48.10 Ventilation of the mammalian lung by negative pressure filling. **(a)** The external intercostal muscles contract, which expands the chest cavity by moving the ribs up and out. The diaphragm also contracts, causing it to pull downward, further expanding the cavity. The muscular efforts of inhalation require energy, whereas the return to the resting state by exhaling is primarily by recoil. **(b)** X-ray image of the chest of an adult man after inhaling. The volume of the lungs after exhaling is superimposed using dashed lines to illustrate the relative change in lung volume.

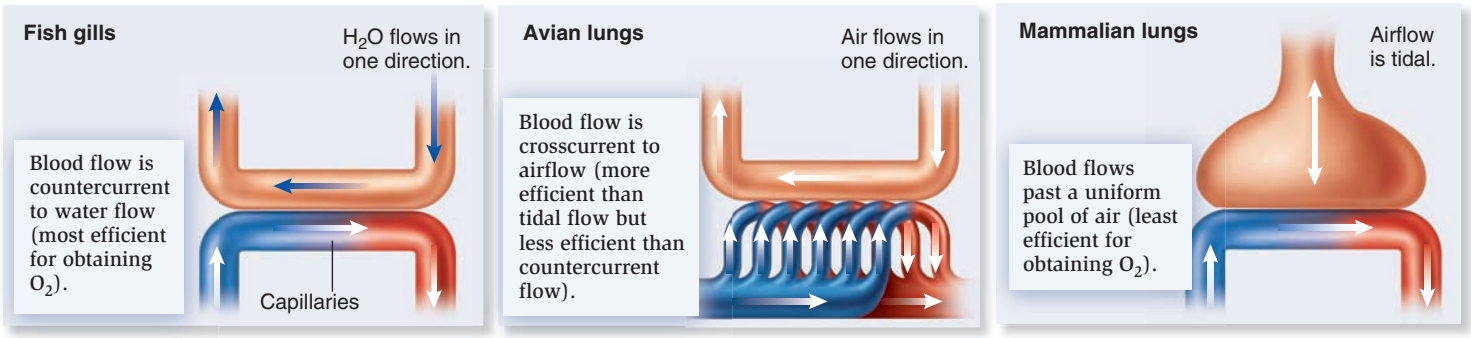


Figure 48.11 **Relationships between direction of flow of blood and water or air in the respiratory surfaces of fish and mammals.**

Concept Check: *What might you conclude about the relative amounts of oxygen available in water and air based on the differences illustrated in this figure?*

Table 48.1 **Comparative Ventilatory Characteristics of Representative Mammals**

Animal	Body mass (kg)	Breaths/min	Tidal volume
Shrew	0.0024	700	30 μL
Dog	25	20	0.27 L
Human	75	12	0.50 L
Horse	465	9	6.50 L

Note: All values are averages from resting animals. Tidal volume is the volume of air breathed in with each breath. Note that tidal volume increases as an animal's mass and lung size increase. By contrast, breathing rate is faster in smaller animals. Similar relationships occur in other vertebrates, notably birds.

The most difficult breath is the very first one that a newborn mammal takes—the only time its lungs are ever completely empty of air.

Surfactant Facilitates Lung Inflation by Decreasing Surface Tension

Like all cells, those that make up the lining of the alveoli are surrounded by extracellular fluid. This fluid layer is where gases dissolve. Unlike other internal body cells, however, alveolar cells come into contact with air, creating an air/liquid interface along the inner surface of the alveoli. This results in surface tension (look back at Figure 2.19g) within the alveoli. Surface tension results from the mutual attractive forces between water molecules (look back at Figure 2.11a) at the air/liquid interface. Within a layer of water, these attractive forces all cancel out, but at the very surface, the forces are not balanced because water molecules at the air/liquid interface do not have water molecules all around them. This imbalance creates a force along the surface of the water coating the inner surfaces of alveoli; the force pulls the alveoli inward, causing them to slowly collapse. If many or all of the alveoli collapsed, however, the amount of surface area available for gas exchange in the lungs would be greatly decreased. What prevents them from collapsing? The type II cells of the alveoli produce **surfactant**—a mixture of proteins and amphipathic lipids (that is, lipids with both polar and nonpolar regions)—and secrete it into the alveolar lumen. Surfactant forms a barrier between the air and the fluid layer inside the alveoli. This barrier reduces surface tension in the alveolar walls, allowing them to remain open.

Surface tension is particularly important in the transition from fetal to postnatal life in mammals. Most mammalian fetuses are encased in fluid within the uterus. Consequently, their lungs do not have an air/liquid interface, and they do not start producing surfactant until the final stages of pregnancy. In humans, surfactant production begins around week 26 of gestation but does not increase to final levels until after week 33 (normal pregnancy length is about 40 weeks). If a human baby is born prematurely (defined as prior to week 37 of gestation), sufficient surfactant may not be available, and consequently, many alveoli may collapse after birth. This condition, known as **respiratory distress syndrome (RDS)** of the newborn, can be partially alleviated by inserting a tube in the trachea and injecting a natural or synthetic form of surfactant. Each year in the U.S., approximately 500,000 babies are born prematurely; of those, roughly 25,000–40,000 will be born sufficiently premature as to be diagnosed with RDS.

The discovery of how surfactant could be used to treat infants with RDS was among the greatest scientific achievements of the 20th century. The treatment continues to save many thousands of lives each year, as we see next.

Feature Investigation | Fujiwara and Colleagues Demonstrated the Effectiveness of Administering Surfactant to Newborns with RDS

In the early part of the 20th century, researchers noted that isolated lungs from experimental animals were easier to inflate if they were first filled with fluid, which eliminated the air/liquid interface that exists in vivo. Later, investigators discovered the presence of substances in mammalian lungs (including those of humans) that had surface-active (surfactant) properties. A surfactant is any substance that decreases surface tension in a liquid. Surfactants typically contain amphipathic compounds; that is, a portion of such a molecule is hydrophilic (soluble in water) and another portion is hydrophobic. The hydrophilic region of an amphipathic molecule dissolves in

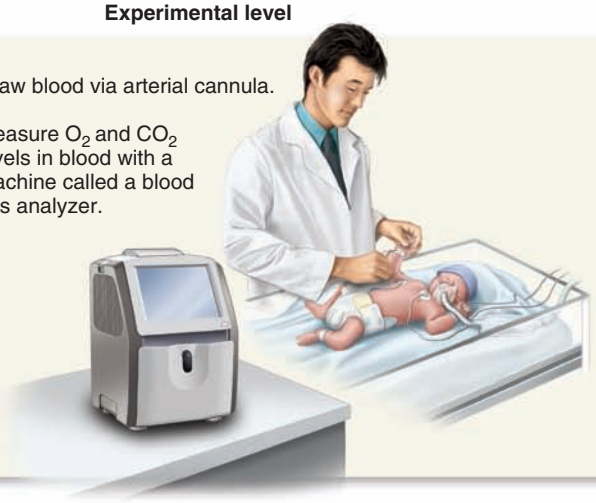
water, while the hydrophobic region is excluded from the water. One hypothesis for how surfactants work is that by intercalating between water molecules at the interface between a liquid and the air, they increase the distance between water molecules. Recall from Chapter 2 that each water molecule has a region of partial negative charge and another of partial positive charge. These charges produce an attractive force between water molecules. A principle of physics is that electrical forces decrease with the square of the distance between charges; thus, as surfactant increases the distance between water molecules at the surface of a liquid, the attractive forces between the water molecules decreases exponentially. This is what is meant when it is said that surface tension is decreased in the presence of surfactant.

As noted earlier, respiratory distress syndrome (RDS) is an extremely serious condition that occurs in many newborns born prematurely. In such infants, the lungs have not matured to the point that they produce sufficient amounts of surfactant to maintain a normal surface tension in the alveoli. The reason surfactant is not produced early in fetal life is there is no air/liquid interface in the fetal lungs; the lungs of fetuses are filled with amniotic fluid (the fluid in which a fetus is suspended within the uterus). Indeed, the lungs are not used for gas exchange at this time, because a fetus receives oxygen via the umbilical circulation. If a baby is born before sufficient surfactant is available, surface tension in the lungs will be too high to allow the alveoli to remain open, and they will all collapse within a few breaths of air. Recall that it is easier to inflate a balloon that is partially inflated than one that is fully deflated; in a premature infant with RDS, all of the millions of alveoli are analogous to deflated balloons. Under such conditions, it becomes impossible for a newborn to fully inflate the lungs with each breath, and he or she quickly becomes very ill. If surfactant can be administered to such babies, their chances of survival should be greatly increased because they will be better able to ventilate their lungs.

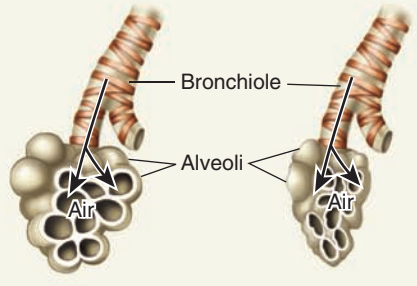
How can this be accomplished? Prior to 1980, experiments in animals suggested that administering animal lung extracts that contained surfactant to prematurely born experimental animals improved the lung function and chances of survival of those animals. In 1980, Tetsuro Fujiwara and coworkers tested this in human newborns for the first time. Their hypothesis was that administering a modified form of surfactant (obtained from cows) to very premature infants with RDS would improve lung function and increase the chances that such infants would survive. The presence of RDS was confirmed by—among other things—determining the blood O_2 and CO_2 levels of the newborns. The babies were placed in ventilators with a mixture of air that was greatly enriched in O_2 during this time as part of the standard treatment for premature infants. As shown in the data in step 4 of **Figure 48.12**, the newborns' blood O_2 levels were lower than normal despite the oxygen-rich air they were breathing, and their CO_2 levels were also higher than normal, both indicating poor lung function. The infants were then administered surfactant through a tube placed within the trachea (called an endotracheal tube). Next, their blood gases were re-examined at intervals over the next few hours. As seen in the data, the arterial Po_2 of each infant increased dramatically within an hour or so of surfactant administration! Other signs of improved overall health were also noted, such as heart, kidney, and gastrointestinal function (all of these organs are adversely affected when a baby has RDS and is not receiving sufficient oxygen). Within 3 hours after surfactant administration, the physicians were able to decrease the amount of oxygen supplied via the ventilator from approximately 80% to 38%, and eventually nearly to normal (which, you will recall, is 21%); in other words, by that time the lungs of the infants were functioning almost normally, and the requirement for oxygen supplementation was greatly reduced.

Of the 12 newborns treated, 10 survived and 2 died (but from causes not directly attributable to RDS). While it is, of course, tragic that any infant failed to survive, consider that in 1979, just prior to

Figure 48.12 The pioneering study of Fujiwara and colleagues established that treatment with surfactant greatly improved the survival rate of premature infants with RDS.



HYPOTHESIS Administration of surfactant to infants born with RDS will improve their lung function and chances for survival.

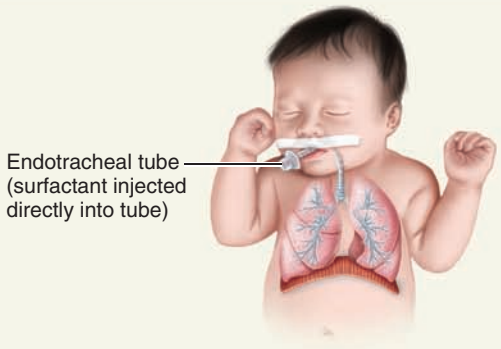


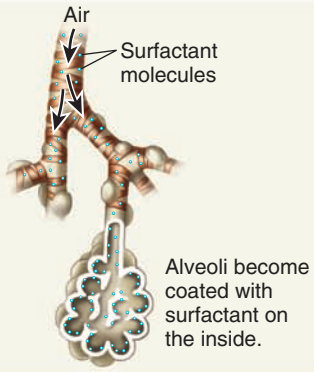
KEY MATERIALS Ventilator to supply air mixture containing up to 80% oxygen, blood gas analyzer, surfactant extracted from cow lungs.

Experimental level | **Conceptual level**

1 Once parental consent is obtained, confirm diagnosis of RDS in premature infants; initiate ventilation with enriched O_2.

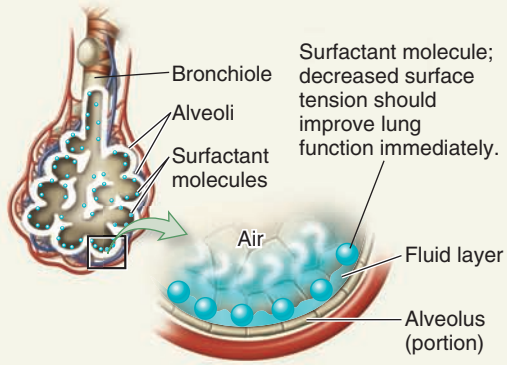
1. Draw blood via arterial cannula.
2. Measure O_2 and CO_2 levels in blood with a machine called a blood gas analyzer.





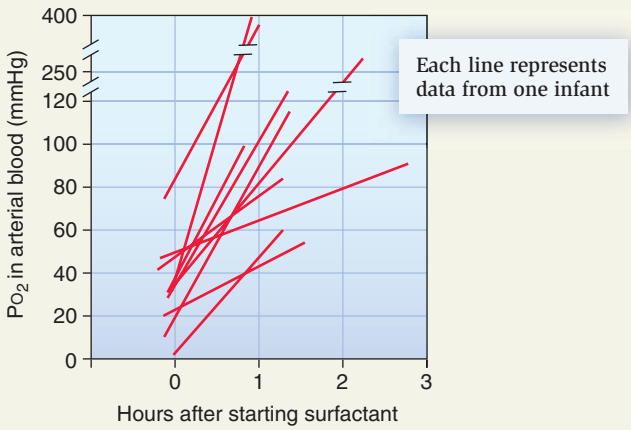
Healthy lung: Alveoli are open and have a large surface area for gas exchange.

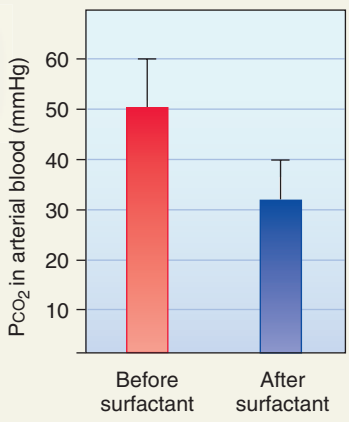
RDS lung: Alveoli are collapsed and less surface area is available for gas exchange.



2 Prepare surfactant from cow lungs. Infuse surfactant through endotracheal tube.

3 Monitor blood gases for next several hours; check overall health of infants.





4 THE DATA

Initial measurements to confirm diagnosis:

No. of infants	Arterial P_{O_2} (mean ± standard deviation)	Arterial P_{CO_2}
10	45 ± 22 mmHg (Normal for full-term infant ≈70)	50 ± 10 mmHg (Normal for full-term infant ≈35–45)

Effect of surfactant:

5 **CONCLUSION** Treatment with surfactant quickly improved lung function as evidenced by greatly increased blood O_2 levels and decreased CO_2 levels, to within the normal range. Surfactant therapy improves overall health and chances for survival in premature infants.

6 **SOURCE** Fujiwara, T., et al. 1980. Artificial surfactant therapy in hyaline-membrane disease. *The Lancet* 315: 55–59. (Note: Hyaline-membrane disease was a common earlier name for RDS.)

the advent of surfactant therapy, RDS was the second leading cause of death in infants in the U.S. Following Fujiwara's pioneering study in 1980 and subsequent improvements in the ways in which surfactant was produced and administered, RDS fell to being the fourth leading cause of death in infants by 1988, and to ninth in 2010. Prior to the 1980s, approximately 25,000 infants died from RDS in the U.S. each year; today, despite no decrease in the number of premature births annually, fewer than 900 RDS infants do not survive. Whereas that number is still tragically high, it represents an astounding improvement, and ranks the development of the surfactant treatment among the greatest scientific achievements of modern times.

Perhaps you noticed something unusual about the experimental design in Fujiwara's study. Did you notice that there were no control groups (infants who received a vehicle solution without surfactant)? Today, the gold standard for clinical studies is a randomized control trial (RCT). However, at the time of Fujiwara's study, not all clinical experiments were controlled as they are today; in some cases, this was due to practical considerations of cost and the limited availability of subjects. In others, ethical considerations may have taken precedence, such as the immediate need to save the lives of the infants in Fujiwara's study. Nonetheless, since Fujiwara's study, the results have been replicated and expanded upon many times in animal models and in humans using RCT protocols, and surfactant therapy is now routinely used in hospitals around the world to save countless lives.

Experimental Questions

1. **SciSKILLS** » Glucocorticoids are hormones made by the adrenal glands. They are known to stimulate surfactant production in the lungs. If a woman was told that due to complications of her pregnancy, she needed to have her baby delivered very prematurely, explain how our understanding of glucocorticoids could be used to help prevent RDS in the newborn of this woman.
2. **SciSKILLS** » Refer to the arterial blood Po_2 in the newborns in Fujiwara's study. A normal, healthy oxygen level in a full-term (not premature) newborn is about 70 mmHg (for various reasons, this is lower than in adults). Did some of the infants in Fujiwara's study have oxygen levels much greater than 70 mmHg after surfactant therapy? Why might this be? (Hint: How were the babies treated in addition to receiving surfactant?)
3. **SciSKILLS** » Prior to treatment, arterial blood Po_2 in the newborns in this study were very low. Propose a hypothesis to explain why the blood PCO_2 levels were greater than normal.

48.4 Mechanisms of Oxygen Transport in Blood

Learning Outcomes:

1. Describe the characteristics of respiratory pigments in the blood of vertebrates and the hemolymph of many invertebrates.
2. Write the reversible reaction between hemoglobin and oxygen.
3. **SciSKILLS** » Analyze the quantitative relationship between oxygen and hemoglobin, and explain how certain factors can modify the shape of the dissociation curve.

Gases such as oxygen are soluble in the plasma component of blood, but as with all solutes, there are limits to how much of a gas can dissolve in a volume of water. The amount of gas dissolved in the body fluids is not sufficient to sustain life in most animals. In nearly all animals, therefore, the amount of oxygen in the body fluids must be increased above that which can be physically dissolved. This is made possible because of the widespread occurrence of oxygen-binding proteins, which increase the total reservoir of oxygen available to cells. In this section, we will examine the nature, function, and evolution of these molecules.

Oxygen Binds to Respiratory Pigments

The oxygen-binding proteins that have evolved in animals are called **respiratory pigments**, because they have a color (blue or red). In vertebrates, the pigments are contained within erythrocytes, whereas many invertebrates have these pigments in their hemolymph. Respiratory pigments are proteins containing one or more metal atoms in their cores; the metal atom binds to oxygen. In vertebrates and many marine invertebrates, the metal is iron (Fe^{2+}). **Hemoglobin** is the major iron-containing pigment and gives blood a red color when oxygen is bound. In decapod crustaceans, arachnids, and many mollusks (including cephalopods and some gastropods), the metal is copper (Cu^{2+}). The copper-containing pigment, **hemocyanin**, gives the blood or hemolymph a bluish tint.

Hemoglobin gets its name because it is a globular protein—which refers to the shape and water solubility of a protein—and because it contains a chemical group called a heme in its core (**Figure 48.13**). An atom of iron is bound within the heme group. In vertebrates, hemoglobin consists of four polypeptide subunits, each with its own iron atom to which a molecule of oxygen can bind. Thus, a single hemoglobin protein can bind up to four molecules of oxygen.

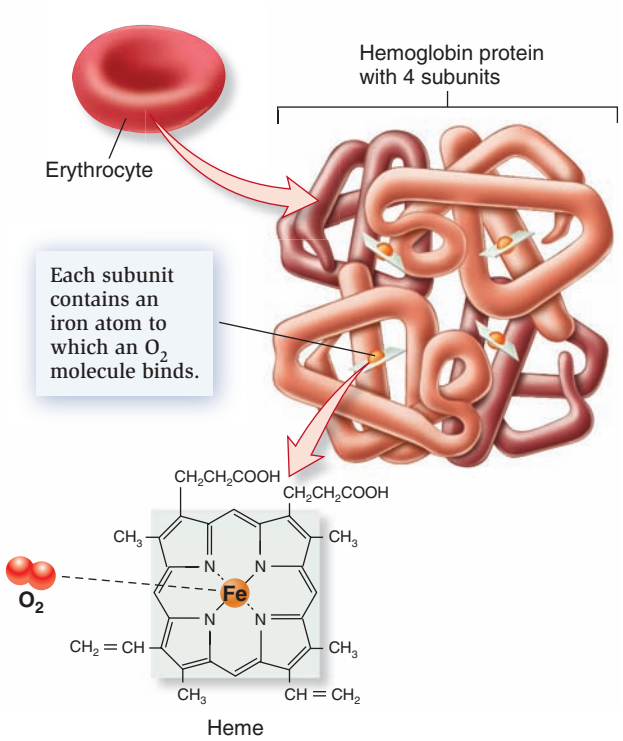


Figure 48.13 Hemoglobin. Erythrocytes contain large amounts of the protein hemoglobin. Oxygen binds reversibly to iron atoms in the heme portion of each subunit of hemoglobin.

BIOLOGY PRINCIPLE Structure determines function. The precise tertiary and quaternary structures of hemoglobin permit its association with heme groups, which contain the iron atoms that bind oxygen molecules. Without a correct protein structure, the ability of hemoglobin to bind oxygen would be greatly compromised.

Concept Check: How many atoms of oxygen can be bound to a single molecule of hemoglobin?

Respiratory pigments share certain characteristics that make them ideal for transporting O_2. First, they all have a high affinity for binding O_2. Second, the binding between the pigment and O_2 is noncovalent and reversible. Clearly, it would be of no benefit for a protein to bind O_2 if it could not later unload the O_2 to cells that need it. The binding reaction between hemoglobin (Hb) and oxygen is as follows:

$$Hb + O_2 \rightleftharpoons HbO_2$$

where HbO_2 is hemoglobin with bound O_2 (called oxyhemoglobin), and the double arrows ($\rightleftharpoons$) indicate that the reaction is reversible.

The amount of pigment present in the blood is great enough to provide sufficient O_2 to meet all but the most strenuous exertion. In humans, for example, the presence of hemoglobin gives blood about 45 times more oxygen-carrying capacity than plasma alone has. Differences exist among respiratory pigments, however, at the molecular level. For example, the amino acid sequences of hemoglobins from different species vary, in some cases considerably. Human hemoglobin is similar but not identical to that of other mammals, and mammalian hemoglobins have numerous amino acid differences from other vertebrate hemoglobins. The differences in amino acid sequences cause slight changes in the overall three-dimensional shape of hemoglobin, which alters its affinity for O_2. As a general rule, animals with the highest metabolic rates tend to have hemoglobins with lower O_2 affinity, and animals with lower metabolic rates have higher affinities. That may sound paradoxical at first, but consider the preceding reactions again. Because the hemoglobin of animals with high relative metabolic rates has lower O_2 affinity, the unloading reaction ($HbO_2 \rightarrow Hb + O_2$) will be more likely to occur when oxygen is diffusing from the blood to active cells. In other words, hemoglobin unloads its O_2 more readily in those animals whose cells use O_2 at the greatest rates.

The Amount of Oxygen Bound to Hemoglobin Depends on the Po_2 of Blood

Recall that the partial pressure of O_2 (Po_2) is a measure of its dissolved concentration. When Po_2 is high, more O_2 binds to hemoglobin, whereas fewer O_2 molecules will be bound when Po_2 is low. **Figure 48.14** shows the relationship between O_2 binding and Po_2, known as an **oxygen-hemoglobin dissociation curve**, for humans. At a Po_2 of 100 mmHg, which is found in the blood leaving the lungs, each hemoglobin protein binds four O_2 molecules (far right of graph). It is 100% saturated with O_2 at that Po_2. The Po_2 in blood leaving the tissue capillaries of other parts of the body is lower because the cells have removed some of the O_2 from blood. At rest, the Po_2 in capillaries in these other parts of the body is typically around 40 mmHg. At this Po_2, hemoglobin releases some O_2 molecules, and is about 75% saturated with O_2. During periods of physical activity or exercise, an animal uses

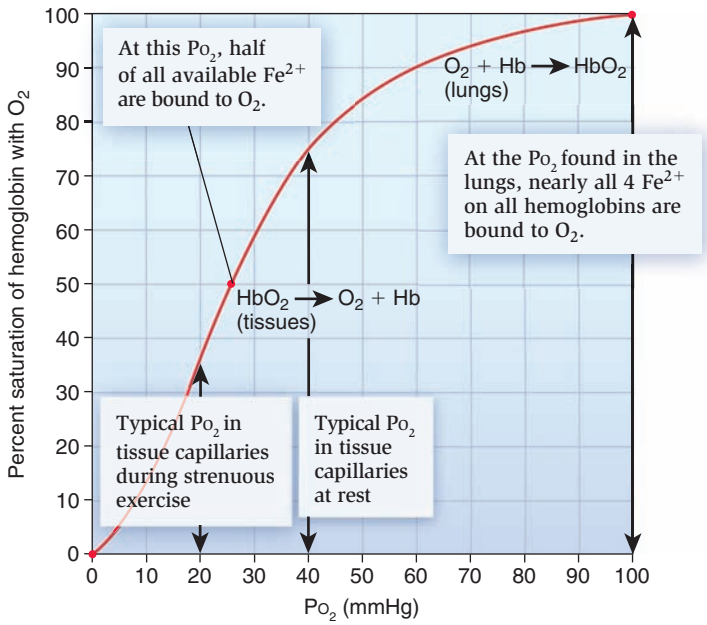

Figure 48.14 The human oxygen-hemoglobin dissociation curve. Depending on the partial pressure of oxygen (Po_2), oxygen is either loaded onto hemoglobin, as in the lungs, or unloaded from hemoglobin, as in the rest of the body tissues. When Po_2 is high, more Fe^{2+} atoms are bound to O_2, and the hemoglobin is more saturated with O_2.

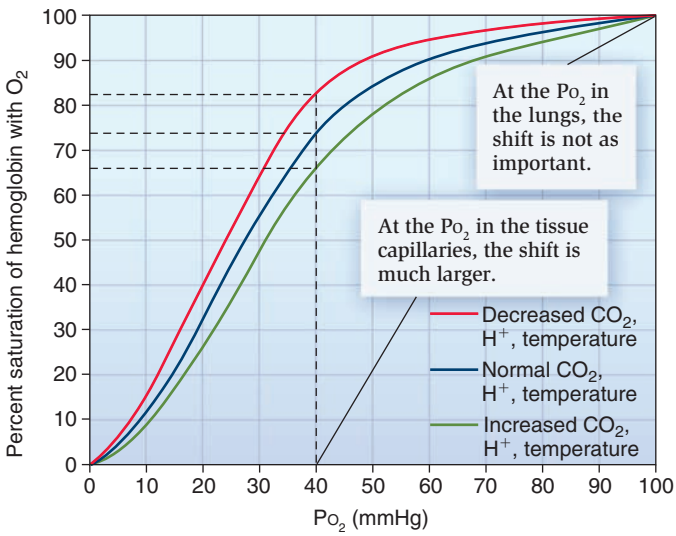
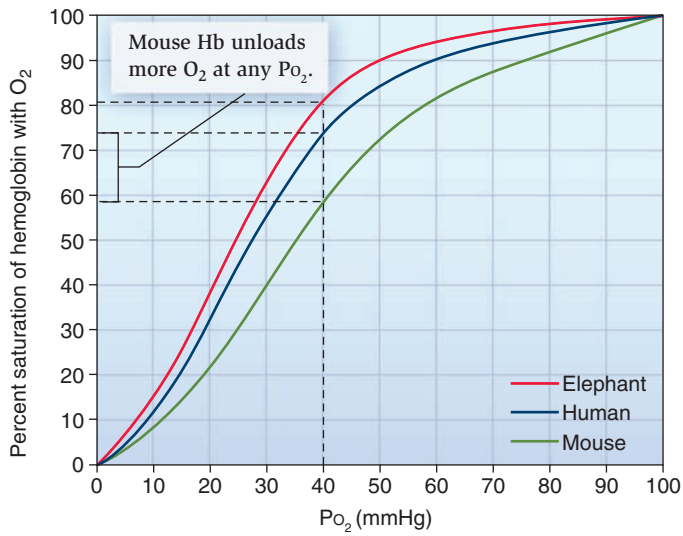
Concept Check: Members of the Channichthyidae family of Antarctic icefish are the only vertebrates that do not have erythrocytes and hemoglobin. Can you propose some mechanisms or adaptations that allow them to survive without the oxygen reservoir provided by hemoglobin? (Hint: Think about the effect of temperature on oxygen solubility and on an animal's metabolic rate.)

more O_2, and the Po_2 in the capillaries decreases even further (as low as 20 mmHg); consequently, hemoglobin releases even more O_2 and becomes less saturated. In this way, hemoglobin performs its function of delivering oxygen. In the lungs, it binds O_2, and elsewhere it releases some of the O_2 as needed.



You may have noticed that the curve in Figure 48.14 is not linear but S-shaped (sigmoidal). This is because the subunits of hemoglobin are said to cooperate with each other in binding O_2. Once a molecule of O_2 binds to one subunit's iron atom, the shape of the entire hemoglobin protein changes, making it easier for a second O_2 to bind to the next subunit, and so on. Thus, the relationship between O_2 pressure and the amount of O_2 bound to hemoglobin becomes very steep in the midrange of the curve, which represents the pressures that occur in the tissue capillaries. This steepness allows O_2 release from Hb to be very sensitive to even small decreases in Po_2 generated by the diffusion of O_2 from capillaries into cells.

Effect of Waste Products on O_2-Hb Binding (Bohr Effect) One of the remarkable features of the oxygen-hemoglobin binding relationship is that it can be influenced by metabolic waste products such as CO_2 and H^+ and also by heat (temperature). **Figure 48.15a** shows three curves, one obtained under normal resting conditions and the others in the presence of low or high levels of CO_2. About 25% of the CO_2 in blood is bound to hemoglobin. Carbon dioxide binds to amino acids in the hemoglobin protein (not to the iron, like O_2), and when it does, the ability of hemoglobin to continue binding O_2 decreases (that is, CO_2 decreases the affinity of hemoglobin for O_2). Note how an increase in CO_2 shifts the curve to the right, such that at any Po_2, less O_2 is bound to hemoglobin. Another way of saying this is that at any Po_2, more O_2 has been released from hemoglobin, thus becoming available to cells. A similar shift in the curve occurs with an increase in the concentration of H^+, which can also bind to hemoglobin; the effect of CO_2 and H^+ on the oxygen-hemoglobin dissociation curve is known as the Bohr effect, after its discoverer, the Danish physiologist Christian Bohr. Elevated temperature also decreases the affinity of hemoglobin for O_2, resulting in a right-shifted curve.



Cells generate each of these products—CO_2, H^+, and heat—when they are actively metabolizing fuel. The metabolic products enter the surrounding blood vessels, where they disrupt the normal shape of hemoglobin, causing it to release more of its O_2 than would normally occur at that Po_2. This phenomenon is a way in which individual body tissues can obtain more oxygen from the blood to match their increasing metabolic demands. Thus, when an animal increases its physical activity, the skeletal muscles generate more waste products and heat than does, say, the skin. Therefore, the oxyhemoglobin in muscle blood vessels releases more oxygen to the cells where it is immediately required.

Species Differences in O_2-Hb Binding The shift in the oxygen-hemoglobin dissociation curve occurs in all classes of vertebrates (although not in all species), but it has different magnitudes in different species. Not surprisingly, perhaps, more metabolically active animals, such as mice, show a greater shift for a given increase in CO_2, H^+, or heat than do less active animals. Recall from Chapter 47 that these same waste products of metabolism also cause local vasodilation of arterioles. The more metabolically active a tissue is, therefore, the more blood flow it receives, which means more oxygen-bound hemoglobin. Moreover, the oxygen is unloaded from hemoglobin more readily due to the shift in the curve. This is an excellent example of how adaptive changes in circulatory and respiratory functions often occur in parallel.

Regardless of their sensitivity to CO_2 and other factors, the hemoglobins of metabolically active animals have a lower affinity for oxygen (**Figure 48.15b**). For small, active animals the curves are displaced to

(a) Shifts in the oxygen-hemoglobin dissociation curve

(b) Oxygen-hemoglobin dissociation curves of different animals

Figure 48.15 Differences in oxygen-hemoglobin dissociation curves under different physiological conditions and among different species. **(a)** Increasing or decreasing the amounts of CO_2 or H^+ (pH), or the temperature of the blood, shifts the oxygen-hemoglobin dissociation curve. Metabolically active tissues generate more of these products. The change in affinity of hemoglobin for oxygen (O_2) allows different tissues to obtain O_2 in proportion to their metabolic requirements. **(b)** Oxygen-hemoglobin dissociation curves for three mammals with low (elephant), moderate (human), or high (mouse) relative metabolic rates. For any Po_2, such as the one shown (40 mmHg), which is typical of the Po_2 of tissue capillaries, less O_2 is bound to mouse hemoglobin than to human or elephant hemoglobin, and less O_2 is bound to human hemoglobin than to elephant hemoglobin. Therefore, O_2 is unloaded from hemoglobin more readily in smaller animals.

the right of the human curve. In contrast, larger animals with lower relative metabolic rates, such as the elephant, have curves shifted to the left of the human curve. At high oxygen pressures, such as those that occur in the lungs, these shifts have little relevance because nearly all the hemoglobin is bound to oxygen at those pressures. At lower Po_2, however, such as those that occur in the blood vessels of metabolically active tissues, the difference in the curves becomes significant. For example, look at the three curves at a Po_2 of 40 mmHg, a typical value found in tissues that are using oxygen at a resting rate. The mouse hemoglobin has less oxygen bound (its hemoglobin is less saturated) at that pressure than does the human hemoglobin, which, in turn, has less O_2 bound than does the elephant hemoglobin. In other words, the mouse hemoglobin has released more of its O_2 to the active tissues than have the other animal hemoglobins.

Oxygen-carrying molecules are among the most ancient proteins found in animals. The globin gene family appears to have evolved from a single ancestral globin gene. Around 500 mya, the gene for this ancient molecule duplicated, eventually resulting in one gene that coded for myoglobin, a protein that stores oxygen in muscle cells, and the other for an early form of hemoglobin (refer back to Figure 21.8). Thus, animals gained the ability not only to store O_2 in tissues but also to transport it throughout the body via the circulation. Let's take a closer look at the molecular structure and evolution of hemoglobin and how a simple mutation in the sequence of one hemoglobin gene can have devastating consequences in humans.

Genomes & Proteomes Connection

Hemoglobin First Evolved Over 500 mya

Modern hemoglobin in adult mammals contains four subunits, designated α1, α2, β1, and β2. The two α and two β subunits are identical. Early in animal evolution, hemoglobin existed only as monomers (one subunit) or dimers (two subunits), which is still observed in lampreys. Later, gene duplication created the second set of subunits, leading to the four-subunit form, which first appeared in sharks and bony fishes. As we have seen in this chapter, the subunit structure of hemoglobin enables one hemoglobin protein to bind four oxygen molecules. Equally important, the subunits of hemoglobin cooperate with each other as shown by the sigmoidal shape of the oxygen-hemoglobin dissociation curve.

As noted earlier, modern hemoglobins differ among species within the same class of vertebrates and even more so between classes. This suggests that evolution of the hemoglobin genes continued even after the four-subunit structure appeared. The mutations that arose in the hemoglobin genes affected the structure of the hemoglobin protein. One consequence is that the affinity of hemoglobin for oxygen differs among animals. The differences in affinity may result, for example, in better oxygen-capturing ability of animals living in regions of low oxygen pressure, such as the llama shown in the chapter opening photograph. They also account, at least in part, for the ability of metabolically active animals to unload oxygen from hemoglobin more readily than less metabolically active organisms.

Despite the high frequency of mutations in the hemoglobin genes in vertebrates, certain regions of the molecule have remained stable. Not surprisingly, these are regions that are critically important for the function of the molecule. For instance, the amino acids that encase the heme group and iron atom of each subunit have changed little if at all during evolution. Similarly, the amino acid sequences associated with sites of interactions between subunits have also resisted evolutionary change. Mutations that arise in these regions are typically not adaptive and may even be lethal.

Some mutations in the hemoglobin genes may appear to be detrimental because they negatively affect hemoglobin's function, and yet they provide a selective advantage under certain conditions. Consider **sickle cell disease** (also called sickle cell anemia). In this disease, substitution of a thymine for an adenine at one position in the hemoglobin gene results in a single amino acid substitution (from a glutamic acid to a valine; refer back to Figure 14.1). This produces a form of hemoglobin that tends to form polymers and precipitate under low oxygen conditions, typically in capillaries and veins. The protein forms long fibrous strands that may permanently deform an erythrocyte, making it sickle-shaped. Sickled cells are less able to move smoothly through capillaries and can block blood flow, resulting in severe pain and cell death in the surrounding tissue. The sickled cells are also fragile and easily destroyed. The loss of those cells and their hemoglobin results in anemia, meaning that people with the disease have less oxygen-carrying capacity in their blood. Only individuals who are homozygous for this mutation show the dramatic phenotype of the disease. Heterozygotes are relatively unaffected.

The sickle cell gene mutation is present in up to one-third of individuals living in malaria-prone regions of Africa, to lesser extents in the Middle East and Eastern Europe, and in roughly 8% of African Americans (refer back to Figure 24.6). Why should such an obviously harmful mutation have persisted in the human population? Recall from Chapter 24 that individuals who are heterozygous for the sickle cell allele are less likely to develop full-blown malaria than either those who are homozygous for the sickle cell allele or those who are homozygous for the normal allele, although the reason for this is uncertain. One favored hypothesis states that the parasite causing malaria lowers the oxygen pressure in erythrocytes by consuming oxygen to support its own metabolism. This may render the cells susceptible to sickling even in heterozygous individuals. The damaged cells are destroyed and removed from the circulation, which also removes the parasite and limits its ability to multiply. Another hypothesis states that the heterozygotic condition results in a more efficient immune response of the body to the presence of the parasite. Thus, although both malaria and sickle cell disease can be life-threatening, those who are heterozygous for the sickle cell allele develop neither pronounced anemia nor severe malaria and therefore have an advantage in areas where malaria is present. This phenomenon, an example of heterozygote advantage, explains why the sickle cell mutation persists among certain human populations.

48.5 Control of Ventilation

Learning Outcomes:

1. Describe the role of respiratory centers and chemoreceptors in the regulation of ventilation.
2. Explain the link between ventilation rate and H^+ concentration.
3. **SciSKILLS** » Explain how changes in the activity of the respiratory centers in the brain of vertebrates are related to an animal's metabolic rate.

In the previous sections, you saw that different species are adapted to obtaining oxygen from the environment in very different ways. Now let's look at how the mechanisms of breathing are controlled, using mammals as our example.

Lungs are neither muscles nor electrically excitable tissue. Therefore, they cannot initiate or regulate their own expansion. Nonetheless, lungs require a mechanism to rhythmically expand and recoil, because animals cannot always consciously control breathing, such as during sleep. In this section, we will examine the ways in which the nervous system and other structures control ventilation in mammals and how these control mechanisms are linked with metabolism.

The Nervous System Contains the Control Center for Ventilation

The control center that initiates rhythmic expansion of the lungs is a collection of nuclei in the central nervous system. In mammals, these **respiratory centers** are located in the brainstem (**Figure 48.16**). Neurons within certain brainstem nuclei periodically generate action potentials. These electrical impulses then travel from the brainstem through two sets of nerves. The first set stimulates the intercostal muscles, and the second set stimulates the diaphragm. When the lungs expand in response to the contraction of these muscles, stretch-sensitive neurons in the lungs and chest send signals to the respiratory centers, informing them that the lungs are inflated. This temporarily turns off the stimulating signal until the animal exhales, whereupon a new signal is sent to the breathing muscles.

Although the brainstem controls breathing automatically, it can be overridden. Animals that dive underwater—including humans when we go swimming—can temporarily hold their breath. We can also breathe faster than normal even while resting, at least for short periods of time. Normally, however, increased breathing occurs in response to physical activity. At such times, a variety of factors converge on the respiratory centers to increase the rate and strength of signals to the breathing muscles, resulting in faster and deeper breaths.

Chemoreceptors Modulate the Activity of the Respiratory Centers

The respiratory centers are influenced by the concentrations of certain substances in the blood, including the partial pressures of oxygen and carbon dioxide, and the concentration of hydrogen ions (in other words, blood pH). **Chemoreceptors**—special cells located in the aorta, carotid arteries, and the brainstem—detect the circulating levels of these substances and relay that information through nerves or interneurons to the respiratory centers.

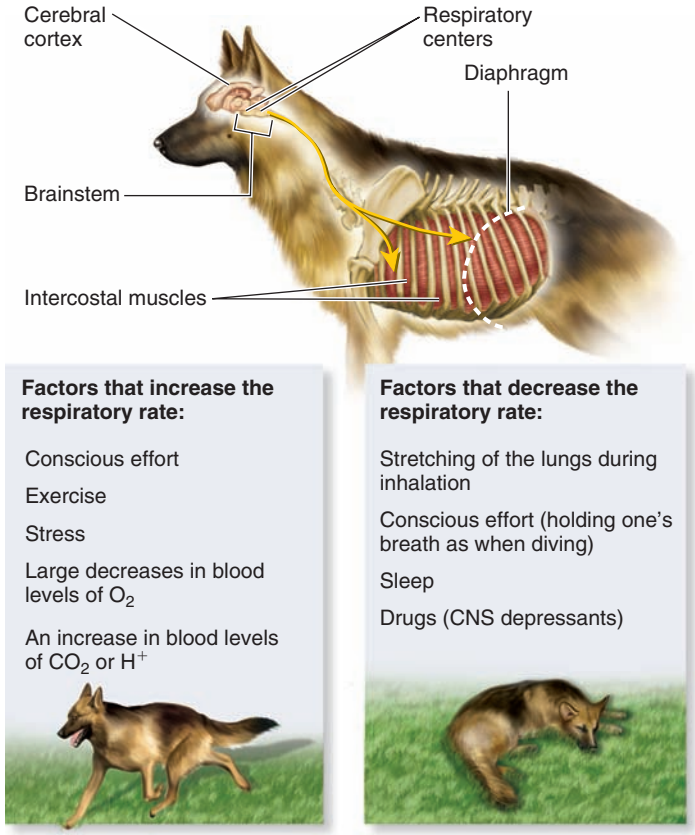


Figure 48.16 The control of breathing via respiratory centers in the mammalian brain. Neurons in the brainstem send action potentials along neurons in nerves that stimulate the intercostal muscles and diaphragm. The factors listed here can modulate the rate of action potential generation and therefore the respiratory rate.

BioConnections: The brainstem of vertebrates was described in Chapter 42. What parts of the brain are included in the brainstem?

If the arterial P_{O_2} decreases well below normal, as might occur at high altitude or in certain respiratory diseases, the chemoreceptors signal the respiratory centers to increase the rate and depth of breathing to increase ventilation of the lungs. This brings in more oxygen. Similarly, a buildup of CO_2 in the blood, which would occur if an animal's ventilation were lower than normal (again, often the result of respiratory disease), signals the respiratory centers to stimulate breathing. The increased ventilation not only brings in more O_2, it also helps eliminate more CO_2. Finally, an increased concentration of H^+ in the blood activates chemoreceptors, which signal the brain that the blood is too acidic. This leads to an increase in the rate of breathing.

What is the link between ventilation rate and H^+ concentration? The concentrations of CO_2 and H^+ in the blood are related, because the concentration of H^+ in the fluid bathing the brainstem chemoreceptors reflects the amount of CO_2 produced by cells during metabolism. This is because roughly two-thirds of the CO_2 produced during metabolism is converted into a less toxic and more soluble form, bicarbonate ions (HCO_3^-). In the process, H^+ ions are formed according to the following reaction, where H_2CO_3 is a short-lived compound called carbonic acid that immediately dissociates to a H^+ and a HCO_3^-:

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$$

This reaction is readily reversible. The first step is catalyzed in both directions by the enzyme carbonic anhydrase, which is present in high amounts in erythrocytes. As you learned in Chapter 2, reactions of this type proceed according to the concentrations of the reactants and products. For example, if the CO_2 concentration was to increase for any reason, the forward reaction (from left to right as illustrated here) would be favored, and the pH of the blood would decrease because more H^+ ions would be formed. Conversely, if the concentration of CO_2 decreased, the reactions would proceed from right to left, and the pH of the blood would increase as H^+ ions were removed from the blood by combining with HCO_3^-.

What happens when an animal increases its physical activity? During such times lactic acid—a by-product of metabolism—is released into the blood, and this decreases the pH of the blood. The increase in H^+ concentration that results from lactic acid activates chemoreceptors to stimulate increased ventilation. This, in turn, helps prevent CO_2 concentrations from increasing in the blood despite the increased metabolic rate.

The chemoreceptors in the brain are very sensitive to certain drugs that act as CNS depressants, such as ethanol (alcohol), opiates, and barbiturates. One action of these drugs is to decrease the sensitivity of chemoreceptors to CO_2, and thereby reduce ventilation to potentially life-threatening levels. Particularly when taken together, these drugs may be a lethal combination partly because of their inhibitory effects on ventilation.

Respiratory Center Activity Varies Among Mammals with Different Metabolic Rates

The respiratory centers are sensitive to a variety of other factors besides gases and hydrogen ions, such as sleep, stress, hormones, and body size. Recall that small animals tend to have higher relative metabolic rates than larger animals (refer back to Figure 46.6). Thus, small animals would be expected to require more oxygen per unit mass than larger animals. This is not achieved by having disproportionately large lungs in small animals. Instead, small animals have faster breathing rates than do large animals (see Table 48.1). The respiratory centers are set at a higher rate in smaller, active animals. For example, a typical adult human takes about 12–14 breaths per minute at rest, whereas small rodents and shrews have astonishingly high rates of breathing, up to many hundreds of breaths per minute! Thus, the respiratory activity of small, highly active animals is matched with their metabolism by increasing the resting breathing rate. This is similar to differences in heart rate among species (refer back to Table 47.1). Parallel changes in the heart and breathing rates are adaptations that allow small animals to have small hearts and lungs yet achieve relatively high metabolic rates.

48.6 Adaptations to Extreme Conditions

Learning Outcomes:

1. List adaptations of the respiratory and circulatory systems of animals living at high altitudes.
2. Describe the adaptations of the respiratory and circulatory systems of diving animals.

Many animals, including a wide range of vertebrates, are able to live permanently or temporarily in low-oxygen environments. Many humans, for instance, live in mountainous regions, and llamas and mountain goats spend most of their lives at extremely high altitudes. Other animals may only transiently encounter periods of oxygen deprivation, such as some reptiles, birds, and mammals that dive under water to forage for food. As described in this section, several adaptations allow animals to thrive in these environments, but all of them include changes in both circulatory and respiratory activities.

Life at High Altitudes Requires More Hemoglobin

Animals that live at high altitudes must have special adaptations that permit them to obtain the oxygen they require at such low atmospheric pressures. Llamas, such as the one shown in the chapter opening photo, may live at altitudes up to 4,800 m, where the P_{O_2} is only about 85 mmHg (compared with 160 mmHg at sea level; see Figure 48.2). Llama hemoglobin is quite different in amino acid sequence from that of other mammals, giving it an extraordinarily high affinity for binding oxygen even at very low atmospheric pressure. In other words, a llama's oxygen-hemoglobin dissociation curve is shifted well to the left of a human's. In addition, llamas have larger hearts and lungs than would be predicted for their body size, and a greater number of erythrocytes in a given volume of blood. These adaptations provide the oxygen-carrying capacity and cardiac output needed to deliver sufficient oxygen to the tissues, even at low partial pressures of oxygen.

When animals that normally inhabit lowland areas temporarily move to higher altitudes, they develop some of these same features. In humans, for example, the number of erythrocytes increases from about 5.1×10^{12} cells/L to about 6.4×10^{12} cells/L. This is stimulated by the hormone erythropoietin, which is secreted by the kidneys when the arterial P_{O_2} is low. This hormone acts on bone marrow to stimulate maturation of new erythrocytes. Moving to higher elevations also increases ventilation due to a higher rate of breathing. The number of capillaries in skeletal muscle increases at high altitudes, a modification that facilitates oxygen diffusion into muscle cells. Finally, myoglobin content increases in muscle cells, expanding the reservoir of oxygen in the cytosol of those cells. Consequently, after several days or weeks at high altitude, the circulatory and respiratory systems adapt together to maximize oxygen uptake, diffusion of oxygen into the blood, and the oxygen-carrying capacity of blood.

Diving Animals Have Adaptations That Permit Long Dives Under Water

Many birds, reptiles, and several species of mammals spend time under water, foraging for food or escaping predators. During that time, the animal cannot breathe. In short dives, this is not a problem. We are all familiar with our own ability to stay under water for a short time. After that time, the oxygen concentration in the blood decreases, the carbon dioxide concentration in the blood increases, and we must surface for air. Some marine mammals, however, have an astonishing ability to remain under water for very long periods—up to nearly 2 hours in beaked whales and elephant seals. During that time, they continue to be active and search for food. How do they do it?

Like high-altitude animals, many diving animals have unusually large numbers of erythrocytes, allowing them to store more oxygen in their blood than nondiving animals. In some species, such as seals, the extra blood cells are stored in the spleen until the animal dives, at which time the spleen contracts like wringing a wet washcloth and ejects the blood cells into the circulation. When seals resurface, the blood cells are sequestered again in the spleen until needed. In addition to having more erythrocytes, diving mammals typically have larger blood volumes than comparably sized mammals that live exclusively on land. The muscles of diving mammals also usually contain large quantities of myoglobin and its bound oxygen. This means that the muscles do not need to consume the precious stores of oxygen circulating in blood. Instead, the blood and its oxygen can be routed to other critical structures that lack myoglobin, such as the eyes, certain glands, the brain, and the placenta if the animal is pregnant.

Eventually, even with these adaptations, the oxygen in muscles and blood becomes so depleted that the only way to prolong the dive is for cells to depend on glycolysis for ATP (see Chapter 7). This generates less ATP than does aerobic respiration, but is sufficient to prolong the dives of such animals.

48.7 Impact on Public Health

Learning Outcomes:

1. Outline the causes, symptoms, and current treatments of several respiratory system diseases.
2. Describe the impact of smoking tobacco on respiratory health.

Respiratory diseases of all kinds (including lung cancer) afflict as many as 10% of the U.S. population and result in an estimated 300,000–400,000 deaths per year, making lung disease among the top three causes of death in the U.S. The economic impact of respiratory diseases on the U.S. economy is staggering, with recent estimates of up to $150 billion per year in health-related costs and lost productivity. Many of these diseases are chronic—once they appear, they last for the rest of a person's lifetime. Lifestyle factors, such as smoking tobacco and exposure to air pollution, cause some respiratory disorders or make existing conditions worse. In this section, we will examine a few of the most common respiratory disorders, as well as some of their causes and treatments.

Asthma Is a Disease of Hyperreactive Bronchioles

Bronchioles are thin tubes surrounded by smooth muscle cells that can contract in the presence of airborne pollutants or other potentially damaging substances, thereby protecting local alveoli. In the disease **asthma**, however, the muscles around the bronchioles are hyperexcitable and contract more than usual. Contraction of these muscles narrows the bronchioles, a process called bronchoconstriction (**Figure 48.17**). This makes it difficult to move air in and out of the lungs, because resistance to airflow increases when the diameter of the airways decreases. Often, the resistance to airflow can be so great that the movement of air creates a characteristic wheezing sound.

Asthma tends to run in families and therefore has a genetic basis. Several known triggers can elicit wheezing, including exercise, cold air, and allergic reactions. The latter is of interest because asthma is believed to be partly the result of an imbalance in the immune system (see Chapter 53), which controls inflammation and other allergic responses. During flare-ups of asthma, inflammation results in the secretion of a viscous, mucus-like fluid into the bronchioles; this inhibits air flow and worsens symptoms.

The symptoms of asthma can be alleviated by inhaling an aerosol mist containing **bronchodilators**, compounds that bind to receptors located on the plasma membranes of smooth muscle cells that make up the outer part of bronchioles. These compounds, which are related to the neurotransmitter norepinephrine, cause bronchiolar smooth muscles to relax. This, in turn, allows the bronchioles to dilate (widen). To help reduce the inflammation of the lungs, patients may inhale a mist containing hormones with anti-inflammatory actions. Currently there is no cure for asthma, but with regular treatment and the avoidance of known triggers, most people with this disease can lead normal lives.

Tobacco Smoke Causes Respiratory Health Problems and Cancer

Smoking tobacco products is one of the leading global causes of death, contributing to about 430,000 deaths each year in the U.S. alone and over 5 million per year worldwide. According to the Centers for Disease Control and Prevention and the American Lung Association, people who smoke up to one pack of cigarettes each day live on average 7 fewer years than nonsmokers, and heavy smokers lose on average 15–25 years of life. Pregnant women who smoke run a high risk of their babies being born underweight, a potentially serious condition that may affect the newborn's long-term health.

Up to 85% of all new cases of lung cancer diagnosed each year are attributable to smoking, making lung cancer the leading cause of preventable death. Equally important, however, is that smoking is estimated to be responsible for nearly 30% of *all* cancers, including cancer of the mouth and throat, esophagus, bladder, pancreas, and ovaries. Smoking is also a leading cause of cardiovascular disease, high blood pressure, and stroke. Smoking as few as three to five cigarettes per day increases the risk of heart disease.

Because the products of tobacco smoke are inhaled directly into the lungs, the chemicals in smoke can do considerable damage to lung tissue. Even adolescents who have only recently started smoking have increased mucus (phlegm) production in their airways, shortness of breath, and reduced lung growth. Thousands of chemicals, including over 40 known cancer-causing compounds, have been identified in cigarette smoke. Some of these chemicals—such as formaldehyde—are toxic to all cells. Others, like the odorless gas carbon monoxide (CO), have harmful effects on lung function in particular. CO competes with oxygen for binding sites in hemoglobin, thereby reducing hemoglobin saturation. Individuals who smoke more than a pack of cigarettes each day may have as much as 15% less oxygen-carrying capacity in their blood.

In addition to being a risk factor for lung cancer and cardiovascular disease, long-term smoking is the major cause of the serious and irreversible disease emphysema.

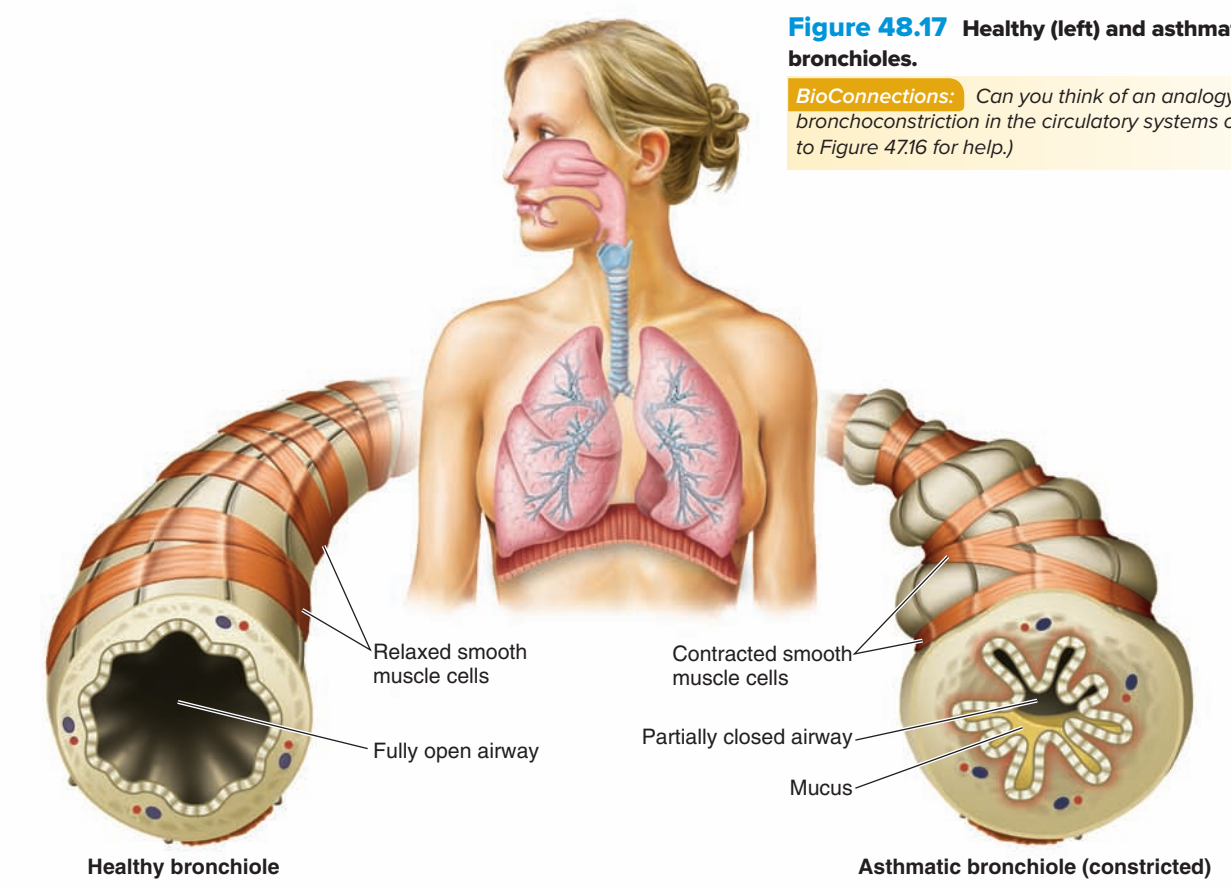

Figure 48.17 Healthy (left) and asthmatic (right) human bronchioles.

BioConnections: *Can you think of an analogy to bronchodilation and bronchoconstriction in the circulatory systems of mammals? (Refer back to Figure 47.16 for help.)*

Emphysema Causes Permanent Lung Damage

Unlike asthma, in which the major problems are inflamed airways and hyperreactive bronchioles, **emphysema** involves extensive lung damage (**Figure 48.18**). The disease reduces the elastic quality of the lungs and the total surface area of the alveoli, which significantly slows the rate of oxygen diffusion from the lungs into the circulation. Consequently, one sign of emphysema is a lower than normal Po_2 in the arteries. It is also physically harder to exhale because of the loss of elasticity, and therefore, arterial CO_2 concentrations increase. Finally, the terminal ends of the bronchioles are often damaged, which increases resistance to airflow and creates asthma-like symptoms and shortness of breath.

Reduced blood oxygen and poor lung function limit the ability of an individual with emphysema to perform ordinary daily activities, and in the late stages of the disease, the person becomes essentially bedridden. Oxygen therapy, in which the person breathes a mixture of air and pure oxygen from a portable gas tank, can provide some help. The extra oxygen increases the pressure gradient for oxygen from the alveoli to the lung capillaries, promoting oxygen diffusion into the blood.

In some cases, emphysema results from an enzyme deficiency in the lungs that destroys the protein that provides the recoil during exhalation, or it may result from chronic exposure to air pollution. However, the overwhelming majority of cases, 85%, are due to smoking. Toxins in cigarettes and other tobacco products damage the lungs by stimulating erythrocytes to release proteolytic enzymes that degrade lung tissue. The likelihood of developing emphysema is very strongly correlated with the quantity of cigarettes smoked during a person's lifetime.

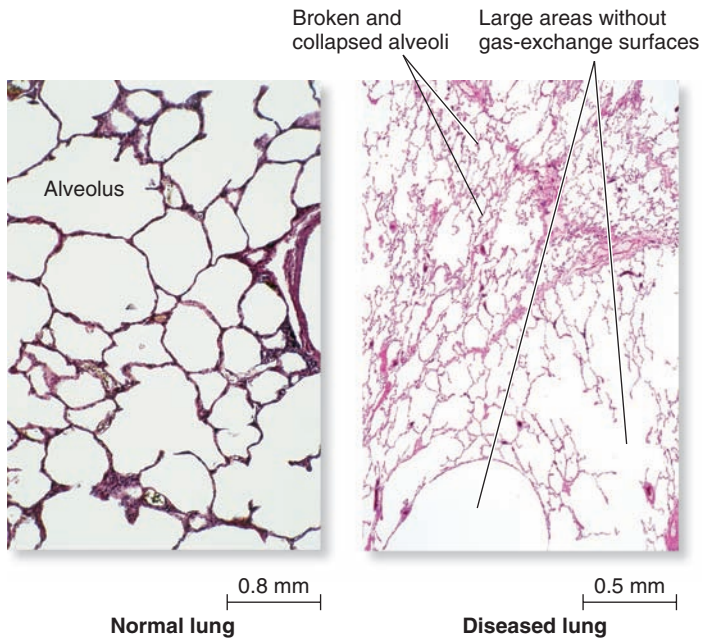

Figure 48.18 The effects of emphysema. These light micrographs compare a section of a normal lung (left) with that of a lung from a person who died of emphysema (right). The destruction of alveoli caused by this disease reduces the surface area for gas exchange in the lungs.

BIOLOGY PRINCIPLE **Biology affects society.** Lung disease affects millions of people. Biologists study the causes, mechanisms, and possible treatments of human diseases such as emphysema.

Estimating how many people have emphysema is difficult because the symptoms appear gradually, but more than 3 million people have severe cases of the disease in the U.S., and at least 15,000 people die from it each year. Emphysema is a progressive disease. As the years go by, the disease worsens; although medical care can slow the rate at which this happens, it is not curable and does not get better.

Summary of Key Concepts

48.1 Physical Properties of Gases

- Gas exchange is the process of moving oxygen and carbon dioxide in opposite directions between the environment, body fluids, and cells. The partial pressure of oxygen (P_{O_2}) in the environment provides the driving force for its diffusion from air or water across a respiratory organ and into the blood. Atmospheric pressure decreases at higher elevations (Figures 48.1, 48.2).
- Three factors—the pressure of the gas, temperature of the water, and presence of any other solutes—are particularly important in affecting the solubility of a gas in water.

48.2 Types of Respiratory Systems

- Ventilation is the process of bringing oxygenated water or air into contact with a respiratory organ. All respiratory organs have moist surfaces on which gases can dissolve and diffuse, as well as other adaptations that increase the amount of surface area and blood flow. Water-breathing and air-breathing animals face different gas-exchange challenges.
- The body surface is permeable to gases in some invertebrates and in amphibians, eels, and a few other species of fishes (Figure 48.3).
- Water-breathing animals use external or internal gills for gas exchange (Figures 48.4, 48.5, 48.6).
- Air-breathing animals have evolved two major mechanisms to exchange gas with the environment: the tracheal system in insects and lungs in terrestrial vertebrates. In insects, air moving down the tracheoles comes into contact with fluid at the tracheole tips. Oxygen from the air dissolves in this fluid and diffuses across the tracheole wall and into nearby cells (Figure 48.7).
- Air-breathing vertebrates generally use lungs to bring oxygen into the circulatory system and remove carbon dioxide. All lungs receive deoxygenated blood from the heart and return oxygenated blood to the heart.
- Frogs and most other amphibians ventilate their lungs with positive pressure filling, which follows the principles of Boyle's law (Figure 48.8).

48.3 Structure and Function of the Mammalian Respiratory System

- The mammalian respiratory system includes the nose, mouth, airways, lungs, and muscles and connective tissues that encase these structures within the thoracic (chest) cavity (Figure 48.9).
- Most reptiles and all birds and mammals ventilate their lungs by negative pressure filling. In mammals, the work is done by the intercostal muscles and diaphragm. Mammals breathe by tidal ventilation. Tidal volume is proportional to body size within and between species (Figures 48.10, 48.11, Table 48.1).
- Surfactant is a mixture of lipids and proteins secreted into the alveoli; it lowers alveolar surface tension and is critical for the survival of newborns (Figure 48.12).

48.4 Mechanisms of Oxygen Transport in Blood

- A limited amount of any gas can dissolve in water. Such limits are overcome in nearly all animals by either transporting gas molecules reversibly bound to a protein carrier or by transforming the gas into a more soluble form.
- Animals have evolved a way to carry a reservoir of oxygen on respiratory pigments. Hemoglobin is the major iron-containing pigment in vertebrates and many invertebrates; hemocyanin is the copper-containing pigment in decapod crustaceans, arachnids, and many mollusks, including cephalopods and some gastropods (Figure 48.13).
- The amount of oxygen bound to hemoglobin depends on the P_{O_2} in the blood. Metabolic waste products can influence the oxygen-hemoglobin binding relationship (Figures 48.14, 48.15).
- The evolution of the globin gene family has resulted in several specialized hemoglobin proteins.

48.5 Control of Ventilation

- In mammals, respiratory centers in the brainstem initiate the rhythmic expansion of the lungs (Figure 48.16).
- Chemoreceptors detect blood levels of H^+ and the P_{CO_2} and P_{O_2}. They relay this information through nerves to the respiratory centers, which, in turn, affect the breathing rate. The respiratory centers are also sensitive to factors such as sleep, stress, hormones, and body size.

48.6 Adaptations to Extreme Conditions

- Adaptations in respiratory and circulatory systems allow animals to exploit low-oxygen environments. Animals that inhabit high altitudes have larger hearts and lungs and have hemoglobin with a high affinity for binding oxygen. Many diving animals have unusually large numbers of erythrocytes and also have muscles that contain large amounts of the oxygen-binding protein myoglobin in their cells.

48.7 Impact on Public Health

- In asthma, the muscles of the bronchioles contract more than usual, increasing resistance to airflow (Figure 48.17).
- Smoking tobacco products is one of the leading global causes of death. Smoking is strongly linked to cancer, cardiovascular disease, stroke, and emphysema, which is a progressive disease associated with loss of elastic tissue in the lungs (Figure 48.18).

Assess and Discuss

Test Yourself

1. The driving force for diffusion of oxygen across the cells of a respiratory organ is the
   a. difference in the partial pressure of oxygen (Po_2) in the environment and in the blood.
   b. humidity.
   c. partial pressure of carbon dioxide (Pco_2) in the blood.
   d. air temperature.
   e. Pco_2 in the atmosphere.
2. Carbon dioxide is considered a harmful waste product of cellular respiration because it
   a. decreases the pH of the blood.
   b. decreases the H^+ concentration in the blood.
   c. competes with oxygen for transport in the blood.
   d. does all of the above.
   e. does a and b.
3. The process of bringing oxygenated water or air into contact with a gas-exchange surface is
   a. respiration. c. ventilation. e. exhalation.
   b. gas exchange. d. gas transport.
4. The group of vertebrates with the greatest capacity for gas exchange across the skin is the
   a. fishes. c. amphibians. e. mammals.
   b. reptiles. d. birds.
5. The countercurrent exchange mechanism in fish gills
   a. maximizes oxygen diffusion into the bloodstream.
   b. is a less efficient mechanism for gas exchange than that used in mammalian lungs.
   c. occurs because the flow of blood is in the same direction as water flowing across the gills.
   d. facilitates diffusion of CO_2 into the blood of fishes.
   e. facilitates diffusion of oxygen into the environment.
6. The tracheal system of insects
   a. consists of several tracheae that connect to multiple lungs within the different segments of the body.
   b. consists of extensively branching tubes that are in close contact with all the cells of the body.
   c. allows oxygen to diffuse directly across the thin exoskeleton of the insect to the bloodstream.
   d. cannot function without constant movement of the wings to move air into and out of the body.
   e. provides oxygen that is carried through the animal's body in hemolymph.
7. _____ is secreted by type II alveolar cells in the mammalian lungs and prevents the collapse of alveoli that would otherwise occur due to surface tension at the interface of air and extracellular fluid.
   a. Hemoglobin c. Mucus e. Surfactant
   b. Myoglobin d. Water
8. In negative pressure filling, air moves into the lungs when
   a. the volume of the thoracic cavity increases.
   b. the pressure in the thoracic cavity decreases.
   c. air is forced down the trachea by muscular contractions of the mouth and pharynx.
   d. all of the above occur.
   e. only a and b occur.
9. Which of the following factors does *not* increase the rate of breathing by influencing the chemoreceptors?
   a. an increase in the Pco_2 in the arterial blood
   b. an increase in the Po_2 in the arterial blood
   c. a decrease in the pH of arterial blood
   d. a decrease in the Po_2 in the arterial blood
   e. an increase in the H^+ concentration in the arterial blood
10. With rare exceptions, the majority of oxygen is transported in the blood of vertebrates
    a. by binding to plasma proteins.
    b. by binding to hemoglobin in erythrocytes.
    c. as dissolved gas in the plasma.
    d. as dissolved gas in the cytoplasm in the erythrocytes.
    e. by binding to myoglobin.

Conceptual Questions

1. Define countercurrent exchange as it relates to gas exchange in fishes.
2. Explain some of the special adaptations for life at high altitudes; why are such adaptations necessary?
3.  Two principles of biology are that *new properties of life emerge from complex interactions* and *structure determines function*. How are these principles related to what you have learned in this chapter about hemoglobin?

Collaborative Questions

1. Discuss two ways in which animals exchange gases in an aqueous environment. What special adaptations facilitate this exchange?
2. Identify the components of the mammalian respiratory system, and describe the major functions of each.

CHAPTER OUTLINE

49.1 Principles of Homeostasis of Internal Fluids
49.2 Excretory Systems in Different Animal Groups
49.3 Structure and Function of the Mammalian Kidney
49.4 Impact on Public Health
Summary of Key Concepts
Assess and Discuss

Excretory Systems and the Homeostasis of Internal Fluids

49

The human kidneys could filter the volume of water of this pool in a few months.

If you have ever noticed how quickly the water in an aquarium or a swimming pool becomes dirty if the filter is not functioning, you will have a good idea of the importance of filtering the wastes from an animal's body fluids. The human kidneys, for example, are remarkable filtration devices. Although each one is only about the size of a computer mouse, the kidneys are able to filter blood at a rate of 150–200 L/day. Considering that there are only 5 L or so of blood in a typical adult, that is an astonishingly effective filtration mechanism. By the time a person reaches 50 years of age, his or her kidneys have filtered roughly 3,000,000 L of blood! Along the way, the kidneys not only remove waste products of metabolism from that filtered blood, but recapture useful substances such as sodium ions and water that form part of the liquid being filtered.

The ability of organisms to maintain homeostasis is one of the principles of biology and a common theme of the previous several chapters. Excretory systems are critical not only for removing wastes from body fluids, but also for homeostasis, particularly of salt and water balance. The general term salt is used to refer to a compound formed from an attraction between a positively charged ion, such as sodium (Na^+), and a negatively charged ion, such as chloride (Cl^-). These ions are held together by ionic bonds, which are broken when the salt is dissolved in water. Changes in the concentrations of ions from dissolved salts in the extracellular and intracellular fluids have the potential to disrupt proper cellular function; for example, they may alter the difference in electrical potential across plasma membranes in the cells of the heart and brain. Ion concentrations and water volumes in the different body fluid compartments are related to each other, because a major way in which water moves between compartments is by osmosis, which, in turn, depends on the numbers of dissolved solutes in water. Consequently, changes in ion concentrations in body fluids may also affect cell volume, which then can cause cell disruption or death.

In this chapter, we examine why ion and water balance is vital for survival, how it is affected by the requirement to eliminate metabolic wastes, and how different excretory organs participate in these processes. We then highlight some of the major features of the mammalian kidney, examine how the kidney eliminates wastes and regulates ion and water balance, and conclude by considering how kidney disease affects human health.

49.1 Principles of Homeostasis of Internal Fluids

Learning Outcomes:

1. **SciSKILLS »** Predict outcomes of imbalances of water and ions on animals' function and survival.
2. List ways in which water and ions move across cell membranes and between body fluid compartments.
3. Compare and contrast osmotic adaptations of freshwater fish with those of marine fish.
4. List two ways of classifying animals according to how they adapt to osmotic challenges.

As we saw in Chapters 40 and 47, an animal's internal fluids exist in compartments within the body. In invertebrates, these fluids

include the intracellular fluid and hemolymph, whereas in vertebrates, they include the intracellular fluid and the extracellular fluid (composed of the interstitial fluid surrounding cells and the plasma component of blood). Within the internal fluids are many salts, such as NaCl, KCl, and so on. As stated earlier, salts dissociate in solution into ions. (Because ions from dissolved salts are electrically charged, they are also referred to as electrolytes.) In this section, we will examine why water and ion homeostasis is so important and how an animal's ion concentration and water volume are maintained within normal ranges.

A Balance of Water and Ions Is Critical for Survival

Maintenance of normal body water levels is of great importance for all animals. Not only is water the major portion of an animal's body mass, it is also the solvent that permits dissolved solutes to participate in chemical reactions. As described in Chapters 2 and 3, water itself participates in important chemical reactions, notably hydrolysis reactions. In addition, water is the transport vehicle that brings O_2 and nutrients to cells and removes wastes generated by metabolism.

When an animal's water volume is reduced below the normal range, we say the animal is dehydrated. In terrestrial animals, dehydration may occur if sufficient drinking water is not available or when water is lost by evaporation (perspiring or panting). Dehydration can be a serious, potentially life-threatening condition. For example, because blood is roughly 50% water (plasma), blood volume may decrease in dehydrated animals. Decreased blood volume compromises the ability of the circulatory system to move nutrients and wastes throughout the body and to assist in the regulation of body temperature on hot days (refer back to Figure 46.12).

Ion balance is also very important for animals. A change of only a few percent in the extracellular fluid concentrations of potassium ions (K^+), for example, can trigger changes in nerve, heart, and skeletal muscle function by altering membrane potentials (see Chapter 41). Other electrolytes, such as calcium (Ca^{2+}), magnesium (Mg^{2+}), phosphate (PO_4^{3-}), and sulfate (SO_4^{2-}), also participate in various biological activities. Their functions include serving as cofactors for enzyme activation, participating in bone formation, forming part of the extracellular matrices around cells, and activating cellular events such as exocytosis and muscle contraction. An imbalance in any of these ions can seriously disrupt cellular activities.

Water moves between adjacent body compartments by osmosis down an osmotic gradient (see Chapter 5; refer back to Figure 5.15). Changes in the ion concentration in one compartment will lead to changes in fluid distribution between the compartments. These changes can cause cells to shrink or swell. When, for example, the ion concentration of extracellular fluid increases, water moves by osmosis from inside cells to the extracellular fluid, causing the cells to shrink. Shrinking or swelling of cells in the brain, heart, and other vital organs can rupture plasma membranes, leading to cell death (refer back to Figure 40.8).

Whereas water moves between fluid compartments by osmosis, ions from dissolved salts such as NaCl move by different mechanisms. All ions have very limited ability to diffuse across plasma membranes, because of their high water solubility and low lipid solubility. As described in Chapter 5, ions may cross membranes by diffusion through channels formed by proteins that create a channel in the membrane (refer back to Figure 5.17). Alternatively, ions may be actively transported across epithelial cells. Active transport requires energy stored in the chemical bonds of ATP. Thus, animals that face exceptional challenges to maintaining ion balance, such as marine fishes, must expend a considerable portion of their daily energy budget transporting ions across epithelial cells.

The solute concentration of a solution is known as the solution's **osmolarity**, expressed in milliosmoles/liter (mOsm/L). The number of dissolved solute particles determines a solution's osmolarity. For example, a 150 mM NaCl solution has an osmolarity of 300 mOsm/L, because each NaCl molecule dissociates into two ions, one Na^+ and one Cl^- ($2 \times 150 = 300$). For reference, the value 300 mOsm/L is well within the range of typical osmolarities of animal body fluids.

Exchanges of Ions and Water with the Environment Are Obligatory

Many vital processes—eliminating nitrogenous wastes, obtaining O_2 and eliminating carbon dioxide (CO_2), consuming and metabolizing food, and regulating body temperature—have the potential to disturb ion and water balance. Therefore, these processes require additional energy expenditure to minimize or reverse the disturbance. Exchanges of ions and water with the environment that occur as a consequence of such vital processes are called obligatory exchanges (because the animal is "obliged" to make them) (**Figure 49.1**).

Exchanges Due to Elimination of Nitrogenous Wastes When carbohydrates and fats are metabolized by animal cells, the major waste product is CO_2, which is exhaled or diffuses across the body surface. By contrast, proteins and nucleic acids contain nitrogen; when these molecules are broken down and metabolized, nitrogenous wastes are generated. **Nitrogenous wastes** are molecules that include nitrogen from amino groups (—NH_2). These wastes are toxic at high concentrations and must be eliminated from the body but, unlike CO_2, cannot be eliminated by exhaling or diffusion. As we will see later, elimination of nitrogenous wastes is carried out by excretory organs and often requires body water.

Exchanges Due to Respiration The requirements for both respiration and water and electrolyte balance present different challenges to air- and water-breathing animals. To ventilate its lungs, an air-breathing animal moves air in and out of its airways. Water in the form of water vapor in the mouth, nasal cavity, and upper airways exits the body with each exhalation. As an animal becomes more active, it requires more O_2 and produces more CO_2. These changes are met by an increase in respiratory activity. Breathing becomes deeper and more rapid, which, in turn, increases the rate of water loss from the body. Therefore, respiration in animals with lungs is associated

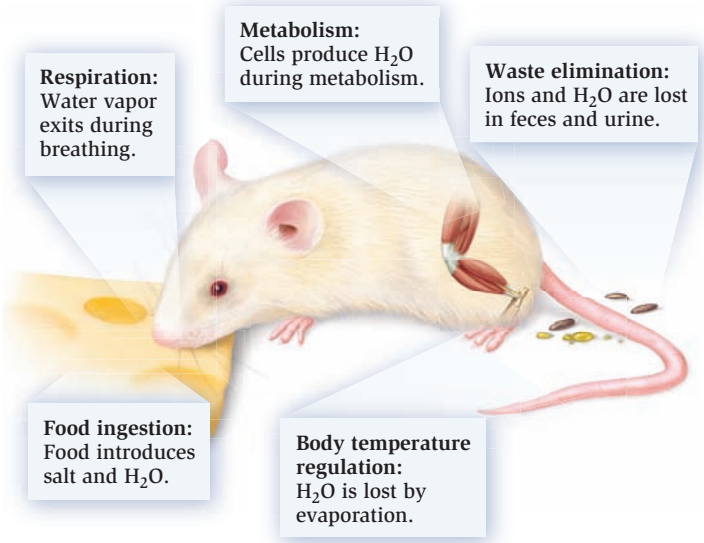

Figure 49.1 Types of obligatory salt and water exchanges in a terrestrial animal. Obligatory exchanges with the environment occur as the result of necessary life processes.

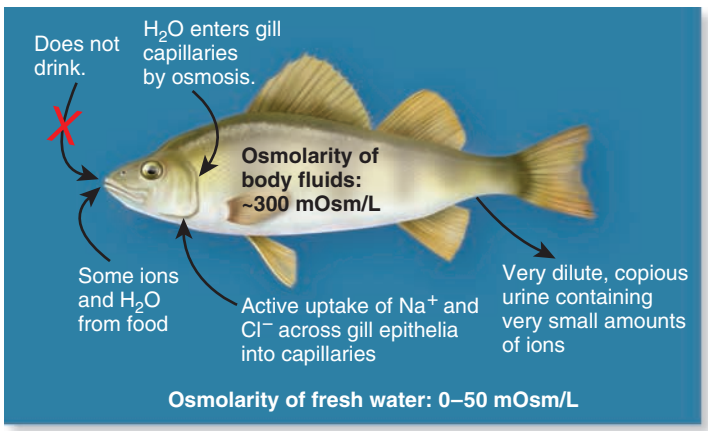
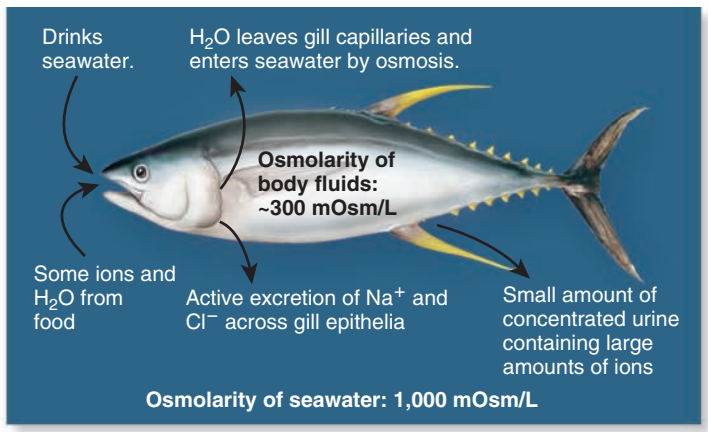
Concept Check: Can animals completely avoid all the losses resulting from obligatory exchanges?



with significant water loss, as you can observe in cold weather when you can "see your breath."

Also, as described in Chapter 48, small, active animals with high metabolic rates have faster breathing rates than do larger, less active animals. Consequently, the potential for water loss due to respiration is considerably greater in small animals, particularly in endotherms. Hummingbirds, for example, may have 15–20 times the water loss per gram of body mass than does a large goose.



In water-breathing animals, the challenge of water and ion balance is more complex, because such animals move water, not air, over their respiratory organs (gills). Recall from Chapter 48 that gills, like all respiratory organs, are thin structures with large amounts of surface area and an extensive network of capillaries. Although these features make gills ideal for gas exchange by diffusion between the capillaries and the surrounding water, they also make them ideal for ion and water movement by diffusion and osmosis, respectively.

When differences occur in ion concentration between a water-breathing animal's body fluids and the surrounding water, respiration via the gills has the potential to disrupt ion and water balance. Fishes or other water-breathing animals that live in fresh water and those that live in salt water face opposite challenges in maintaining this balance (**Figure 49.2**). The internal fluid osmolarity of most fishes is usually within the range of 225–400 mOsm/L, similar to that of most other vertebrates. Because freshwater lakes and rivers have very little ion content (usually <25 mOsm/L), a high concentration gradient for ions could promote the loss of ions from a fish's body into the fresh water. Likewise, a high osmotic gradient favors the movement of water into a freshwater fish. Freshwater fishes, therefore, gain water and lose ions when ventilating their gills (Figure 49.2a). If left uncorrected, this would cause a dangerous decrease in blood ion concentrations.

Freshwater fishes maintain water and ion balance via two different mechanisms. First, their kidneys are adapted to producing copious amounts of dilute urine—up to 30% of their body mass per day (an amount that would be equivalent to about 25 L per day in

(a) Freshwater fish

(b) Saltwater fish

Figure 49.2 Ion and water balance in water-breathers. Water-breathing creates osmoregulatory challenges due to diffusion of ions and osmosis of water across gills. These challenges differ between **(a)** freshwater and **(b)** saltwater fishes and are met by drinking or not drinking water, by active transport of ions across the gills, and by alterations in urine output.

BIOLOGY PRINCIPLE Living organisms use energy, and living organisms maintain homeostasis. Energy from the hydrolysis of ATP is required for all of the active transport processes illustrated here. This energy is required to maintain homeostatic body fluid osmolarities despite the osmotic challenges imposed by very different environments.

an average-sized human!). Second, specialized gill epithelial cells actively transport Na^+ and Cl^- from the surrounding water into the fish's capillaries. Thus, these two important ions are recaptured from the water. Freshwater fishes rarely, if ever, drink water, except for any that might be swallowed with food.

Saltwater fishes have the opposite problem. They tend to gain ions and lose water across their gills, because seawater has a much higher osmolarity (about 1,000 mOsm/L) than that of their body fluids (Figure 49.2b). The gain of ions and the loss of water from the body are only partly offset by the kidneys, which in marine fishes produce very little urine so that water can be retained in the body. The urine that is produced has a higher ion concentration than that of freshwater fishes. To prevent dehydration from occurring, marine fishes must drink. However, the only water available to them is seawater, which has a very high salt content. Paradoxically, therefore, marine fish drink seawater to replenish the water lost by osmosis through their gills. What does the fish do with all of the salt it ingested? The ingested salt must be eliminated, and this process is accomplished by gill epithelial cells. In contrast to the gills of freshwater fishes, which pump ions from the water into the fluids of the fish, the gills of marine fishes pump ions out of the fish and into the ocean. Thus, marine fishes drink seawater to replace the water lost through their gills by osmosis and then expend energy to transport the excess ions out of the body.

Exchanges Due to Feeding Because foods contain salts and water, eating also involves an obligatory exchange of these substances. Some plant products are over 95% water by weight, and other foods may contain high amounts of Na^+ or other minerals. Therefore, the type of diet an animal consumes determines how much salt and water it ingests.

Once food has been digested and absorbed, the unusable parts of food are excreted as solid wastes. Some ions and water are lost by this route in most animals, but exceptions exist. Desert-dwelling kangaroo rats such as *Dipodomys panamintensis* produce fecal pellets that are almost completely dry, which helps these animals conserve water.

When food molecules are metabolized to provide energy that will be stored in the chemical bonds of ATP, oxygen captures electrons and combines with hydrogen ions, thereby making water (refer back to Figure 7.8). This water is sometimes called metabolic water to indicate its origin.

As noted earlier, marine fishes drink seawater. Other animals besides marine fishes may also drink seawater, either because fresh water is unavailable or because they ingest some with the food they eat. Many marine reptiles and birds, for example, ingest seawater when consuming prey or, in some cases, when they spend prolonged periods at sea and have no access to fresh water for drinking. These animals have specialized epithelial cells that line structures called salt glands, located in groups around the nostrils, mouth, and eyes (**Figure 49.3**). Ions (notably Na^+ and Cl^-) move from the blood into the interstitial fluid, from where they are actively transported by the epithelial cells of the salt glands into the tubules of the gland. The ions and a small amount of fluid then collect into a central duct and are excreted as highly concentrated solutions. In general, vertebrates without salt glands cannot survive by drinking seawater, because they have no means of creating and excreting such a highly concentrated salt solution. Some marine mammals have been observed to occasionally drink small amounts of seawater, but most appear to never drink at all. These animals get their water from the food they eat.

Exchanges Due to Evaporation of Water Endotherms use body water to cool off (refer back to Figure 46.10). For example, sweating and panting are used to cool the body. These activities use the evaporation of water to draw heat out of the body. In the

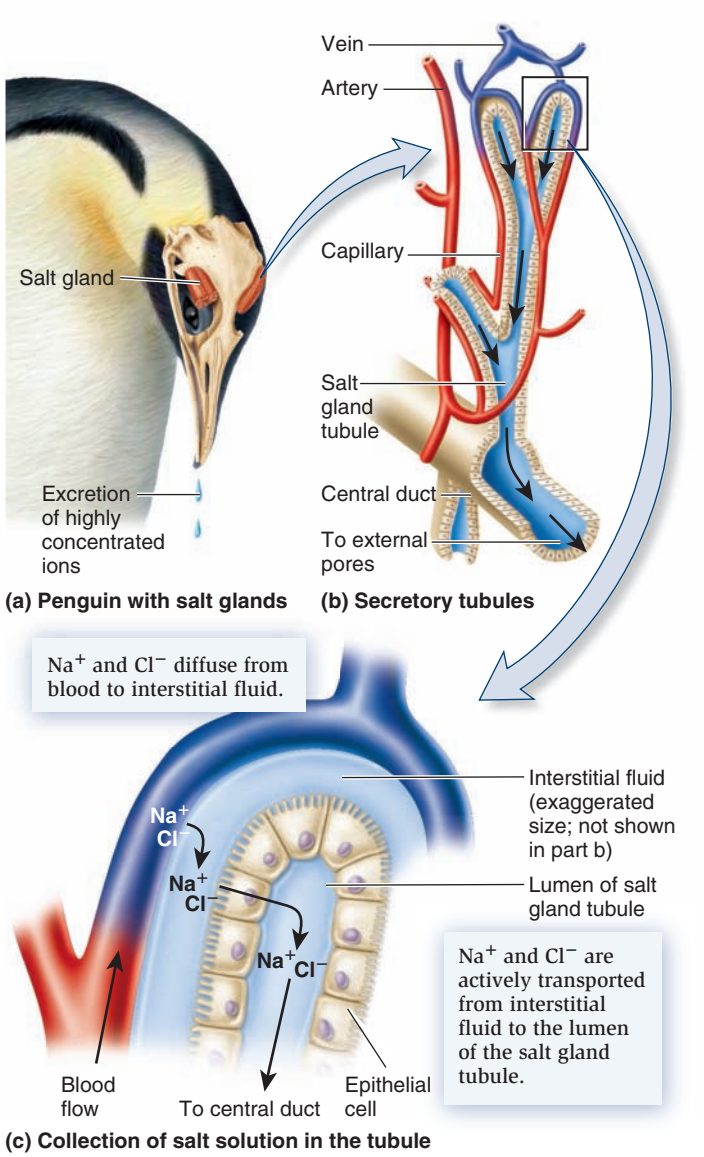


Figure 49.3 Salt glands as an adaptation for marine life. Many marine birds and reptiles have salt glands, which contain a network of secretory tubules that actively transport NaCl from the interstitial fluid into the tubule lumen. The viscous solution then moves through a central duct and to the outside environment through pores in the nose, around the eyes, and in other locations. The black arrows indicate direction of flow of blood or salt gland excretions.

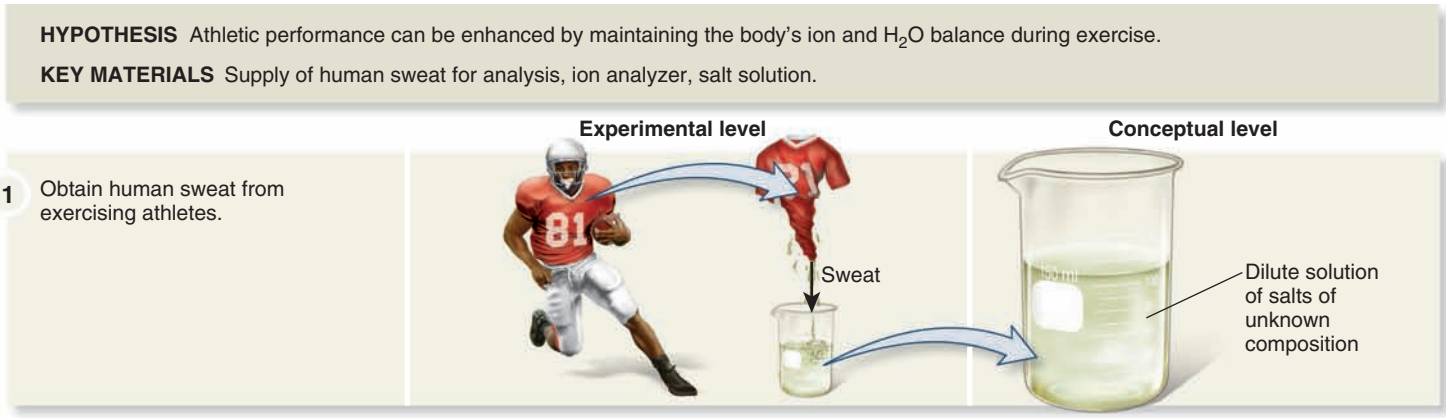
Concept Check: *Why can't humans survive by drinking seawater?*

process, however, the animal loses water and, in sweat, some ions. You know from tasting sweat that it is salty, but the saltiness of sweat and that of blood are not the same. Sweat is a hypoosmotic solution compared with blood; that is, it has a lower concentration of solutes, so the fluid left behind in the body after perspiration has both a lower volume and a higher solute concentration than normal.

Other than perspiration and panting, very little water is gained or lost directly across the body surface of most terrestrial vertebrates, because their skin is impermeable to water; exceptions include amphibians. In invertebrates, the rate of water loss across the body surface depends on whether the animal is soft-bodied, like worms, or covered in a waxy, water-impermeable cuticle, like most insects.

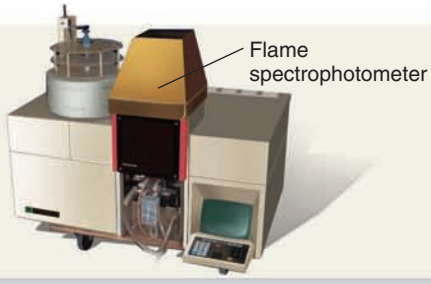
The significance of obligatory exchanges and their effects on homeostasis was dramatically illustrated by a long-term investigation by a research team at the University of Florida, as described next. Their discovery led to a revolution in our understanding of exercise physiology in humans.

Feature Investigation | Cade and Colleagues Discovered Why Athletes' Performances Wane on Hot Days



On a typically hot summer day in the mid-1960s in Gainesville, Florida, the University of Florida football team was practicing in full equipment. The players were rapidly becoming dehydrated and, unbeknownst to them, the osmolarity of their body fluids was increasing as their bodies produced copious amounts of dilute sweat in an effort to maintain body temperature. The athletes became aware of two things. First, they discovered that they did not need to urinate for long periods after a long practice session, and second, their performance on the field suffered as they became increasingly fatigued and more susceptible to severe muscle cramps. Occasionally, players would require medical treatment for their symptoms. In extreme cases, athletes exercising in these conditions have been known to occasionally develop seizures—uncontrolled activity of neurons in the brain. This situation did not escape the notice of the team physicians and, notably, university faculty member and kidney specialist Robert Cade.

Many of the symptoms experienced by the players could be readily explained. The fatigue was directly related to loss of water from the body, which put a strain on the circulatory system and reduced blood flow to muscles and other organs. It was worsened by a decrease in blood glucose concentration that was not being compensated for during the long periods of strenuous activity. The muscle cramps and even the occasional seizures arose from an imbalance in extracellular electrolytes—notably Na^+ and K^+—which are secreted out of the body by sweat glands in the process of perspiration. The resulting imbalance in extracellular ion concentrations caused a change in the electrical potential across muscle and neuronal cell membranes, which triggered the spasms. Lastly, decreased urine production is one of the body's mechanisms for reducing fluid loss when body water is decreasing.

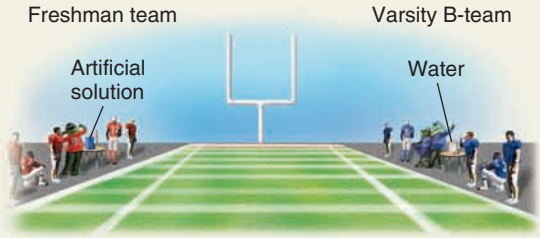


The key question was: How could these effects of strenuous exercise best be reversed or prevented? The answer was simple and clever. Cade and his colleagues rejected the prevailing view that drinking any fluids during heavy exercise somehow contributed to cramps and other problems. Instead, they hypothesized that the best way to maintain ion and water homeostasis in a profusely sweating person is to restore to the body exactly what was lost; that is, the person should drink a solution that resembles sweat!

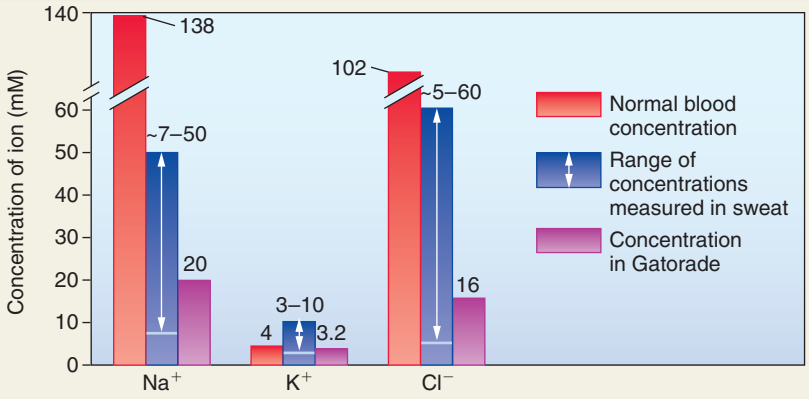
The first thing Cade needed to do was analyze precisely how much Na^+, K^+, and other ions are actually present in sweat. Fortunately, he had an abundance of human sweat at his disposal to analyze. Once the players left the field, their jerseys were wrung out, and the composition of the collected sweat was determined with an ion analyzer such as the flame spectrophotometer shown in **Figure 49.4**. The concentrations could then be compared with known values of ion

Figure 49.4 Cade and colleagues discovered a way to improve athletic performance and prevent ion and water imbalance during strenuous exercise.

2 Analyze composition of sweat using a flame spectrophotometer, which measures ion concentrations. Prepare artificial solution that mimics composition of sweat. Compare composition of both sweat and artificial solution to known ion concentration in human blood.



3 Add flavoring and sugar to artificial solution.



Sugar improves flavor and provides energy.

4 Provide freshman team with the artificial solution and varsity B-team with water. Hold scrimmage.

5 **THE DATA**

6 **CONCLUSION** Replacement of fluid with solute concentrations similar to those found in human sweat improves athletic performance compared to water replacement alone.

7 **SOURCE** Most of the original studies described here were published in expanded form in a later report. See Cade, R., et al. 1972. Effect of fluid, electrolyte and glucose replacement during exercise on performance, body temperature, rate of sweat loss, and compositional changes of extracellular fluid. *Journal of Sports Medicine and Physical Fitness* 12:150–156.

concentrations in human blood. Today, we know that the composition of human sweat can change under certain conditions and can vary among people, but Cade's results were typical. The athletes' sweat contained mostly Na^+, K^+, and Cl^- at concentrations that indicated the solution was dilute compared with blood. Once Cade completed this analysis, he simply prepared an artificial solution of a composition similar to human sweat. The next step was to have the players ingest the solution before and during the practice sessions and games. Improving its taste—adding some lemon flavoring and sugar—removed any inhibitions the players may have had about drinking it, while also providing an energy boost and helping maintain glucose homeostasis.

For the first trial, Cade gave the solution to the freshman players during an intrasquad scrimmage against the more experienced varsity B-team, whose members received only pure water to drink as a control. At first, the freshman team appeared overmatched by the B-team, as might be expected. In the second half of the scrimmage, however, the freshman team vastly outperformed the more experienced players and did not suffer the characteristic late-game fatigue the B-team experienced. Based on this test, the varsity A-team was given a similar solution to drink the next day during a game against a heavily favored opponent, whom they beat handily on a hot 39°C day.

In subsequent years, Cade and other researchers conducted carefully controlled experiments with humans and laboratory animals to confirm that a balanced solution of electrolytes similar to that present in sweat effectively improves exercise performance and reduces the possibility of dehydration and its consequences.

Because the solution was envisioned as "aid" for the team known as the University of Florida "Gators," the drink eventually came to be called Gatorade. The year after its introduction, the Gators enjoyed their most successful season. In 1965, the Kansas City Chiefs of the former American Football League became the first professional sports team to try the drink, and shortly thereafter, the team enjoyed its greatest success. Nowadays, Gatorade and similar "sports drinks" are used at sporting events around the world, and for good scientific reason.

The effectiveness of a solution like Gatorade is due to its ability to restore the correct amounts of both water and ions lost during exercise. Importantly, it is very rapidly absorbed because its osmolarity is close to that of body fluids. Many of the other sports drinks subsequently invented contain additional solutes, such as vitamins and other minerals, and many contain higher amounts of sugar. Because of the presence of these other solutes, these drinks may be very hyperosmotic (a greater concentration of solutes) relative to body fluids.

The story of Gatorade is one of good common sense based on solid scientific principles of osmolarity and ion and water homeostasis. You can now understand why drinking a dilute salt solution during strenuous exercise is better than drinking water. Although drinking pure water prevents dehydration, if drunk in excess, it will actually decrease plasma ion concentrations to below normal. In other words, it will replace one type of ion imbalance with another.

Experimental Questions

1. What symptoms are sometimes seen in athletes after prolonged, strenuous exercise, particularly in hot weather? How are these symptoms related to water loss during exercise, and what did Cade and his colleagues hypothesize about this?
2. **SciSKILLS** » How did the researchers test their hypothesis?
3. **SciSKILLS** » Propose a hypothesis: Would drinking a sports drink like Gatorade be beneficial for someone at rest or someone exercising only moderately?

Animals Adapt to Osmotic Challenges by Regulating or Conforming

Animals adapt to osmotic challenges posed by the environment in one of two major ways. Some animals regulate their internal osmolarity at a very stable level, whereas others conform to the osmolarity of their environment (for example, the sea). Animals that maintain very stable internal ion concentrations and osmolarities, even when living in water whose osmolarity is very different from that of their body fluids or on land, are called **osmoregulators**. Such animals drink or excrete water and ions as necessary to maintain an internal osmolarity that is generally about 300 mOsm/L, or about one-third that of seawater and at least 10 times that of fresh water. All terrestrial animals are osmoregulators, as are all freshwater animals and many marine animals, including bony fishes and some crustaceans. Osmoregulators maintain stable cellular levels of ions and water, but this requires considerable expenditure of energy, primarily to pump ions into and out of epithelial cells.

Most marine invertebrates and some vertebrates—notably sharks—use a different means to control body fluid composition. In this case, the osmolarity of extracellular and intracellular fluids is matched with seawater. These animals are called **osmoconformers**, because their osmolarity conforms to that of their environment. The osmolarity of blood and other fluids of marine osmoconformers is like that of seawater, around 1,000 mOsm/L. An advantage of having body fluids conform to the osmolarity of the surrounding seawater is that there is much less tendency to gain or lose water by osmosis across the skin or gills. Thus, sharks and other osmoconformers expend less energy to compensate for water gain or loss than do other aquatic animals. However, osmoconformers are generally limited to the marine environment.

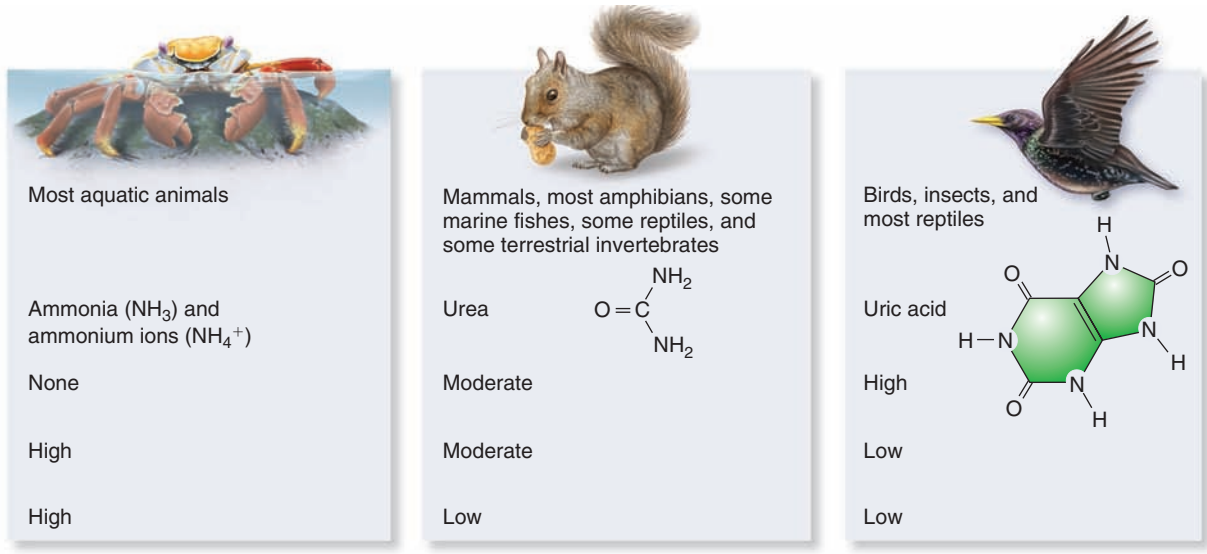
Vertebrate osmoconformers have a high concentration of uncharged molecules dissolved in their extracellular fluids. This allows the extracellular fluids and seawater to have similar osmolarities, but it prevents the excessive accumulation of ions in the body. The body fluids of sharks and other osmoconformers contain sugars, amino acids, and metabolic waste products that produce an osmolarity very similar to that of seawater, even though the concentrations of Na^+, K^+, and other critical ions in these fluids are similar to those of osmoregulators.

Vertebrate osmoconformers cannot tolerate high ion concentrations in their body fluids any better than can osmoregulators. One reason is because a proper ion balance is required for normal electrical signaling in neurons and muscle cells. In addition, very high ion concentrations tend to disrupt the three-dimensional structure of many proteins, rendering them inactive. Consequently, the body fluids of vertebrate osmoconformers are less salty—that is, they have fewer ions—than seawater, as is also the case for all osmoregulators. Therefore, vertebrate osmoconformers such as sharks tend to gain ions by diffusion across their gills. The excess ions are eliminated by the kidneys and a type of salt gland called the rectal gland.

49.2 Excretory Systems in Different Animal Groups

Learning Outcomes:

1. Describe the forms of nitrogenous wastes generated by animals.
2. Describe the general processes of filtration, reabsorption, secretion, and excretion.
3. Identify several invertebrate osmoregulatory organs, and compare and contrast the process of elimination in each.
4. Recognize the general structural and functional features of kidneys that are common to all vertebrates.



Animals make use of one or more organs to rid themselves of metabolic wastes, excess water and ions, and toxins from their environment. Most excretory organs contain tubular structures lined with epithelial cells that have the capacity to actively transport ions across their membranes. Wastes are excreted out of the body by means of these tubes.

In some cases, animals may have considerable ability to regulate the rate at which waste is secreted and how much water is lost in the process. For example, even though a thirsty mammal on a hot, sunny day must continue to rid its body of soluble waste products, it must also conserve water. In this section, we will consider the anatomy and physiology of invertebrate and vertebrate excretory organs. First, let's examine the major forms of nitrogenous wastes generated in animals.

Forms of Nitrogenous Wastes

Nitrogenous wastes are usually found in three forms—ammonia (and ammonium ions), urea, or uric acid (**Figure 49.5**). Different animal groups produce a particular form of waste, depending on the species and the environment in which they live.

- **Ammonia (NH_3) and ammonium ions (NH_4^+)** are the most toxic of the nitrogenous wastes because they disrupt pH, ion electrochemical gradients, and many chemical reactions that involve oxidations and reductions. Animals that excrete wastes in this form typically live exclusively or most of the time in water. In marine invertebrates, NH_3 and NH_4^+ are continually excreted across the skin and gills, whereas in freshwater and most saltwater fishes, these wastes are excreted via the gills and kidneys. Because NH_3 is so toxic, aquatic animals excrete it as quickly as it is formed. The chief advantage of excreting nitrogenous wastes in the forms of NH_3 and NH_4^+ is that energy is not required for their conversion to a less toxic product, as is the case for urea and uric acid.
- **Urea** is produced by all mammals, most amphibians, some marine fishes, some reptiles, and some terrestrial invertebrates by the metabolic conversion of NH_3. In addition to being less toxic than NH_3, urea does not require large volumes of water to be excreted. Animals can tolerate some accumulation of urea in their blood, tissues, and storage organs such as the urinary bladder. Thus, producing urea conserves water, removes the necessity for constant excretion, and reduces the likelihood of toxicity. One

Animal group	Most aquatic animals	Mammals, most amphibians, some marine fishes, some reptiles, and some terrestrial invertebrates	Birds, insects, and most reptiles
Major form of nitrogenous waste	Ammonia (NH_3) and ammonium ions (NH_4^+)	Urea	Uric acid
Energy required for production	None	Moderate	High
Amount of water required for excretion	High	Moderate	Low
Toxicity of waste	High	Low	Low

Figure 49.5 Nitrogenous wastes produced by different animal groups. The three forms of nitrogenous wastes, which are derived from the breakdown of proteins or nucleic acids, have different properties.

BIOLOGY PRINCIPLE Living organisms use energy. Energy from ATP is required to metabolize nitrogenous wastes into urea and uric acid. Different animals, therefore, must expend more or less energy each day to rid themselves of toxic nitrogenous wastes.

drawback of producing urea is that the enzymatic conversion of NH_3 into urea requires a moderate expenditure of ATP and thus consumes part of an animal's total daily energy budget.

- **Uric acid** or other nitrogenous compounds called purines are produced by birds, insects, and most reptiles. Like urea, these compounds are less toxic than ammonia, but they are even more energetically costly to synthesize from NH_3. However, because they are poorly soluble in water, they are not excreted in a watery urine but instead are packaged with other waste products and excess salts into a semisolid, partly dried precipitate that is excreted. The energy investment required to produce uric acid, therefore, is balanced against the water conserved by excreting nitrogenous wastes in this form.

Excretory Systems Use Four Processes to Rid Their Body Fluids of Nitrogenous and Other Wastes

Most excretory systems function by using one or more of the following processes: filtration, reabsorption, secretion, and excretion (**Figure 49.6**).

1. **Filtration.** In filtration, an organ functions like a sieve or filter, removing some of the water and its small solutes from the blood, interstitial fluid, or hemolymph, while excluding blood cells and large solutes such as proteins. A typical filtration system is that seen in the mammalian kidney, in which a portion of the plasma component of the blood is forced under pressure through leaky capillaries and into the kidney tubules. The material that passes through the filter and enters the excretory organ for further processing or excretion is called a **filtrate**.
2. **Reabsorption.** In reabsorption, some of the material in the filtrate is recaptured and returned to the blood. This is an important feature of many excretory organs, because the formation of a filtrate is not selective, apart from the exclusion of proteins and blood cells. In other words, in order to filter the blood and remove soluble wastes, necessary molecules such as ions, sugars, and amino acids also get filtered in the process. Reabsorbing these useful solutes requires active transport pumps or other transport systems. Much of the filtered water also gets reabsorbed.
3. **Secretion.** In some cases, solutes may get excreted from the body in quantities greater than those found in the filtrate. How is this possible? Some solutes are actively transported from the interstitial fluid surrounding the epithelial cells of the tubules into the tubule lumens. This process, called secretion, supplements the amount of a solute that would normally be removed by filtration alone. This is often a way in which excretory organs eliminate particularly toxic compounds from an animal's body, and it can be very effective. Some marine fishes, for example, use secretion as the sole means of cleansing the blood. These animals do not form a filtrate at all.
4. **Excretion.** The process of expelling waste or harmful materials from the body is called excretion. In animals that form a filtrate, the part of the filtrate that remains after reabsorption has been completed and that gets excreted is called **urine**.

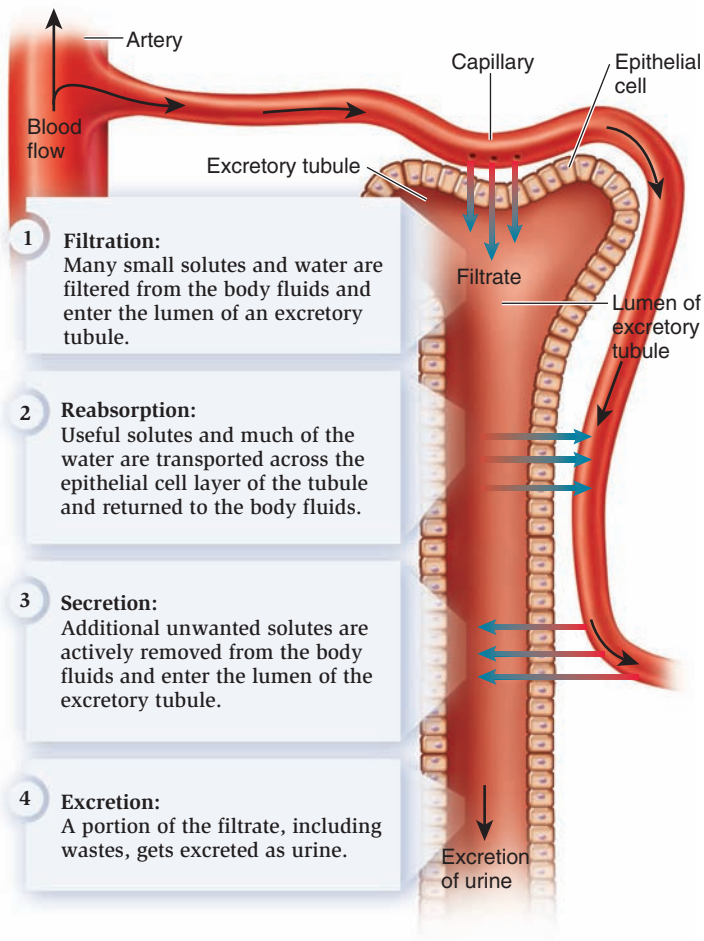


Figure 49.6 Basic features of the function of many excretory systems.

Concept Check: What is the benefit of secreting substances into the tubule?

Many Invertebrates Remove Wastes From Their Body Fluids by Filtration

Invertebrates use a variety of mechanisms to filter and purify their body fluids. The simplest filtration mechanism in invertebrates is the protonephridia system of flatworms (**Figure 49.7**). **Protonephridia** (singular, protonephridium) are a series of branching tubules that filter fluids from the body cavity by means of ciliated cells that cap the ends of the tubule branches. The beating of the cilia bears some resemblance to a flickering flame, which is why these cells are known as flame cells. As fluid is drawn through slitlike openings of the flame cells and into the lumen, it percolates through the tubule, where most solutes are reabsorbed back into the extracellular fluid. Excess water and some wastes travel through the tubules and exit the body through tiny openings in the body wall called nephridiopores. Much of the nitrogenous waste in flatworms actually diffuses across the body surface into the surrounding water; therefore, the protonephridia are primarily osmoregulatory organs. The urine of flatworms is hypoosmotic (more dilute) relative to the body fluids, an adaptation for life in fresh water.

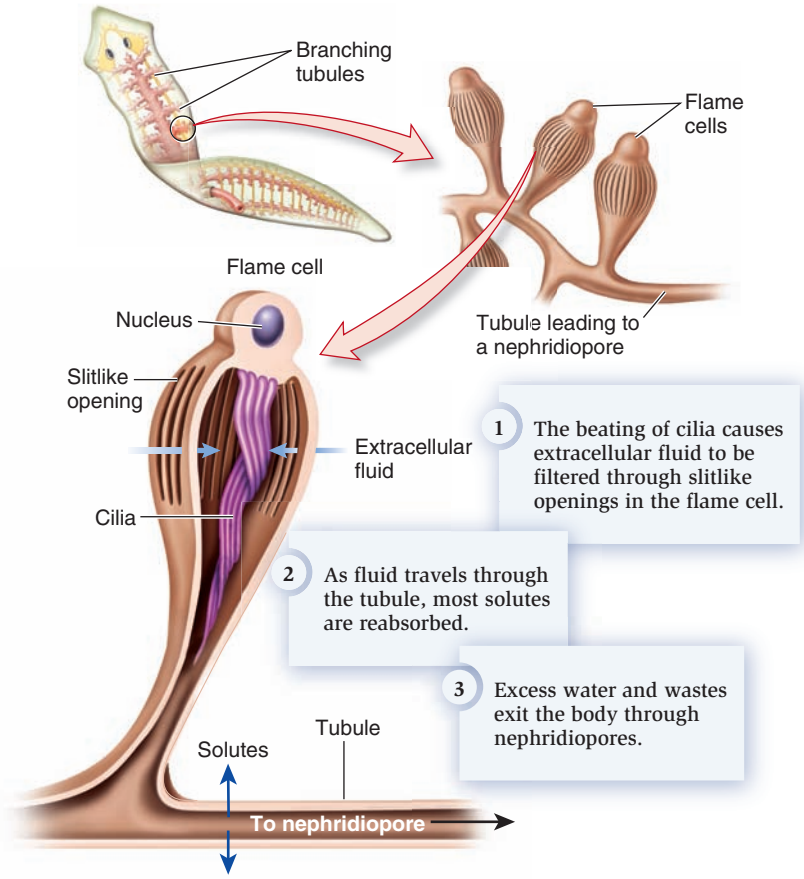

Figure 49.7 The protonephridial filtration system of flatworms. As the filtrate moves along the tubules, most solutes are reabsorbed. The final excreted fluid is usually hypoosmotic relative to body fluids, a typical adaptation found in freshwater animals that helps eliminate excess water.

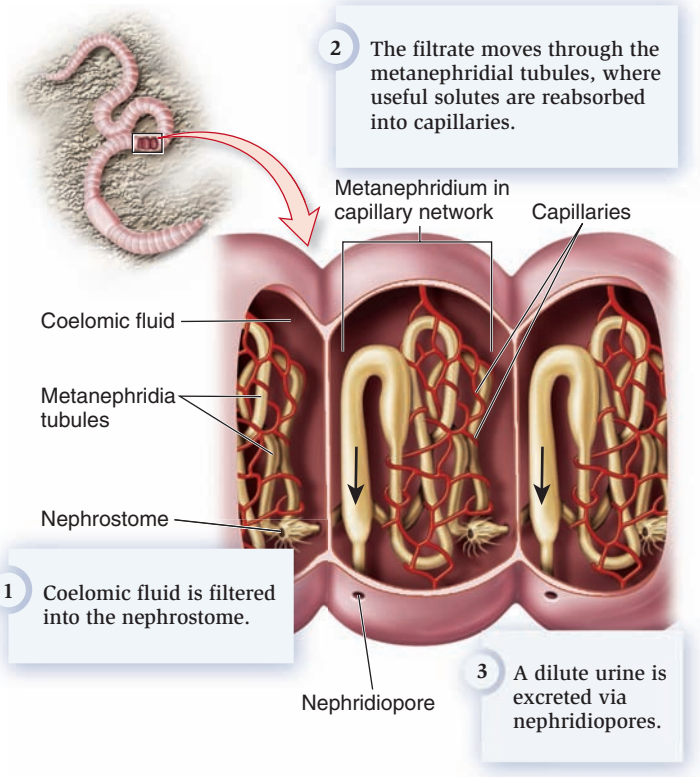

Figure 49.8 The metanephridial filtration system of annelids. Most internal body structures have been omitted for clarity. Only one of the two metanephridia in each segment is depicted; the other is located behind the one shown.

Annelids use a different filtration mechanism, called a metanephridial system (Figure 49.8). Pairs of **metanephridia** (singular, metanephridium) are located in each body segment and consist of a tubular network that begins with a funnel-like structure called a nephrostome. The nephrostomes collect coelomic fluid, which contains nitrogenous wastes, through tiny pores that exclude large solutes. Na^+, Cl^-, and other solutes are reabsorbed by active transport along the length of the tubules that extend from the nephrostomes, and then diffuse into nearby capillaries. The nitrogenous wastes remain behind in the tubules and are excreted through nephridiopores in the body wall. Many annelids live in watery environments and like flatworms, excrete hypoosmotic urine.

Insects Remove Wastes From Their Body Fluids by Secretion

The insect excretory system is quite different from that of other invertebrates, because it involves secretion rather than filtration of body fluids. In insects, a series of narrow, extensive tubes called **Malpighian tubules** arises from the midgut and extends into the surrounding hemolymph (Figure 49.9). The cells lining the tubules actively transport ions and uric acid from the hemolymph into the tubule lumen. This secretion process creates an osmotic gradient that draws water into the tubules. The fluid moves from the tubules into the hindgut—the intestine and rectum—where much of the useful solutes and water is reabsorbed. The nitrogenous wastes, any excess ions, and other waste compounds are excreted together with the feces through the anus.

Unlike other invertebrates, most terrestrial insects, apart from blood-sucking ones, excrete urine that is either isoosmotic (has the same total solute concentration) or hyperosmotic (more concentrated) relative to body fluids. This is a testament to the efficiency with which the insect hindgut reabsorbs water, and reflects the general principle that life in dry environments is associated with a risk of dehydration and a need to conserve water.

Vertebrates Remove Wastes From Their Body Fluids by Filtration and Secretion

The major excretory organ found in all vertebrates is the **kidney**. The kidneys of all vertebrates have many features in common. They typically contain specialized tubules composed of epithelial cells that participate in both ion and water homeostasis by promoting active transport of Na^+, K^+, and other ions across their membranes. In addition, all kidneys participate in the excretion of wastes. In response to an animal's changing requirements, these processes can be controlled, that is, stimulated or inhibited, by the actions of nerves and hormones. Most vertebrate kidneys are filtration kidneys, with the exception of purely secretory kidneys found in some marine fishes. Finally, filtration in the kidneys is controlled by mechanical

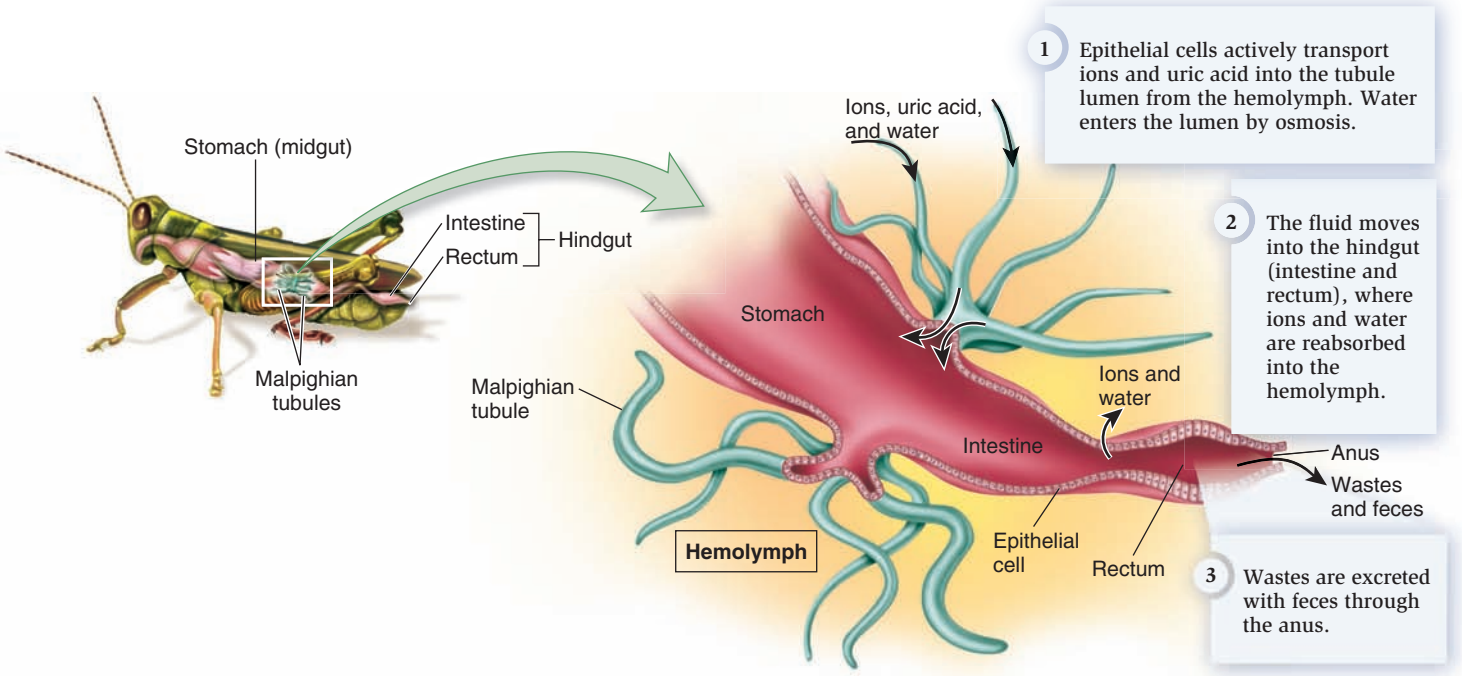

Figure 49.9 Malpighian tubules form the secretory system of an insect. The tubules, which are longer and more convoluted than shown in this simplified illustration, extend into the body cavity, where they are surrounded by hemolymph.

forces, such as the hydrostatic pressure exerted by blood entering the capillaries of the kidneys. The mammalian kidney has been especially well studied and is examined in detail in the next section.

49.3 Structure and Function of the Mammalian Kidney

Learning Outcomes:

1. Name the primary components of the urinary system in mammals and the major anatomical features of the human kidney.
2. Describe how the structural features of different parts of a nephron relate to specific functions in the formation of urine.
3. Explain how the actions of two hormones, aldosterone and antidiuretic hormone (ADH), mediate the final composition of urine.
4. **SciSKILLS** » Predict the effects of changes in the blood concentrations of aldosterone and antidiuretic hormone on the osmolarity of blood.

In mammals, the two kidneys lie in the abdominal cavity (**Figure 49.10a**). The urine formed in each kidney collects in a central area called the renal pelvis. (The adjective renal means pertaining to the kidneys.) From there, urine flows through tubes called the ureters into the urinary bladder. Urine is eliminated via the urethra. Collectively, the kidneys, ureters, urinary bladder, and urethra constitute the **urinary system**.

Each kidney has an outer portion called the renal cortex and an inner portion called the renal medulla (**Figure 49.10b**). The cortex is the primary site of blood filtration. In the medulla, the filtrate becomes concentrated by the reabsorption of water back into the blood. In this section, we will examine the structural features of the kidney that allow it to function as a filtration system.

The Functional Units of the Kidney Are Called Nephrons

Depending on its size, a mammalian kidney contains as many as several million **nephrons**, structures that are only a single cell thick. (The name of the medical specialty nephrology—the study of kidney function and disease—comes from the word nephron.) As shown in **Figure 49.10c**, the filtering process begins at a region called the **renal corpuscle**. The renal corpuscle forms a filtrate from blood that is free of cells and proteins. This filtrate then leaves the renal corpuscle and passes through three different regions of the nephron. As the filtrate does so, substances are reabsorbed from it or secreted into it. Ultimately the filtrate remaining at the end of each nephron combines in the collecting duct. When it reaches the renal pelvis, the filtrate is called urine. Let's look more closely at each part of the nephron and its associated structures.

The Renal Corpuscle Each renal corpuscle contains a cluster of capillaries called the **glomerulus** (plural, glomeruli) (**Figure 49.11a**). Each glomerulus is supplied with blood under pressure by an **afferent arteriole**, and blood exits the glomerulus via an **efferent arteriole** (afferent means toward, and efferent means away from). The glomerulus protrudes into a fluid-filled space called **Bowman's capsule** (first identified by the English physiologist William Bowman in 1841). The combination of a glomerulus and a Bowman's capsule constitutes a renal corpuscle. The glomerular capillaries contain fenestrations, tiny holes that permit rapid flow of plasma out of the capillaries. This filtration is further modified by cells called podocytes that surround the capillaries and form filtration

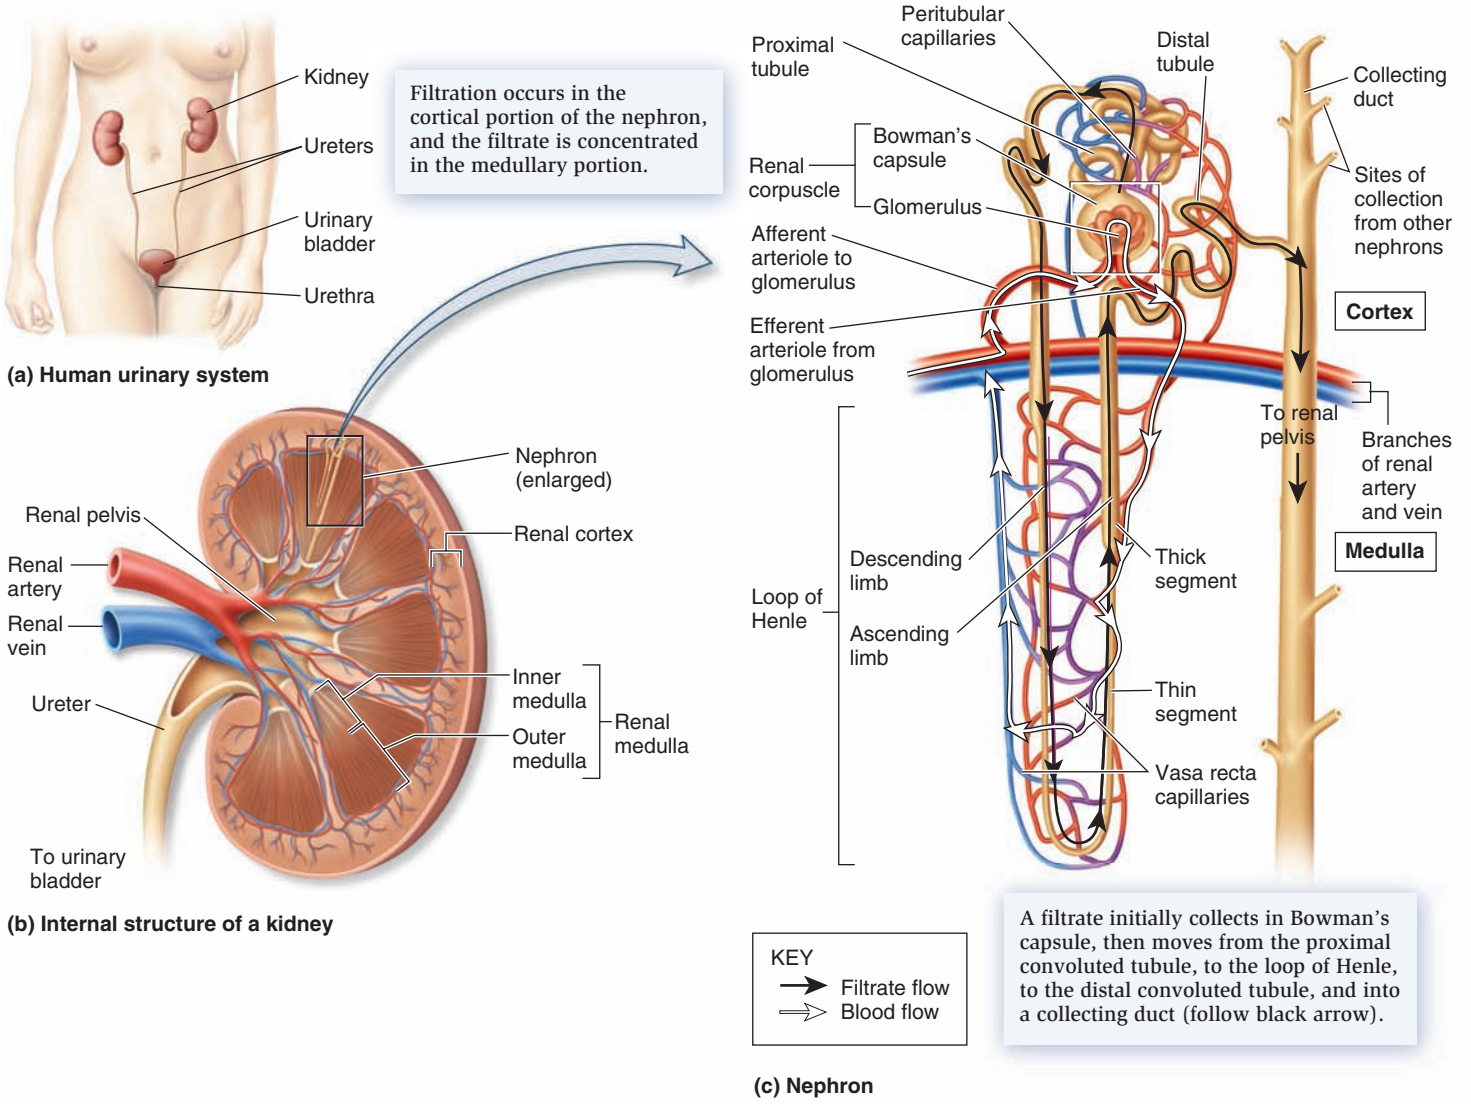

Figure 49.10 The mammalian urinary system, including the basic functional unit of the nephron. **(a)** The human urinary system in a female. In the male, the urethra passes through the penis. **(b)** View of a section through a kidney, showing the locations of the major internal structures and a single nephron (enlarged; at the scale of this illustration, nephrons would be microscopic). **(c)** Structure of a nephron. The nephron begins at Bowman's capsule and empties into a collecting duct. Many nephrons empty into a given collecting duct. Surrounding the nephron are capillaries, called peritubular capillaries in the cortex and vasa recta capillaries in the medulla.

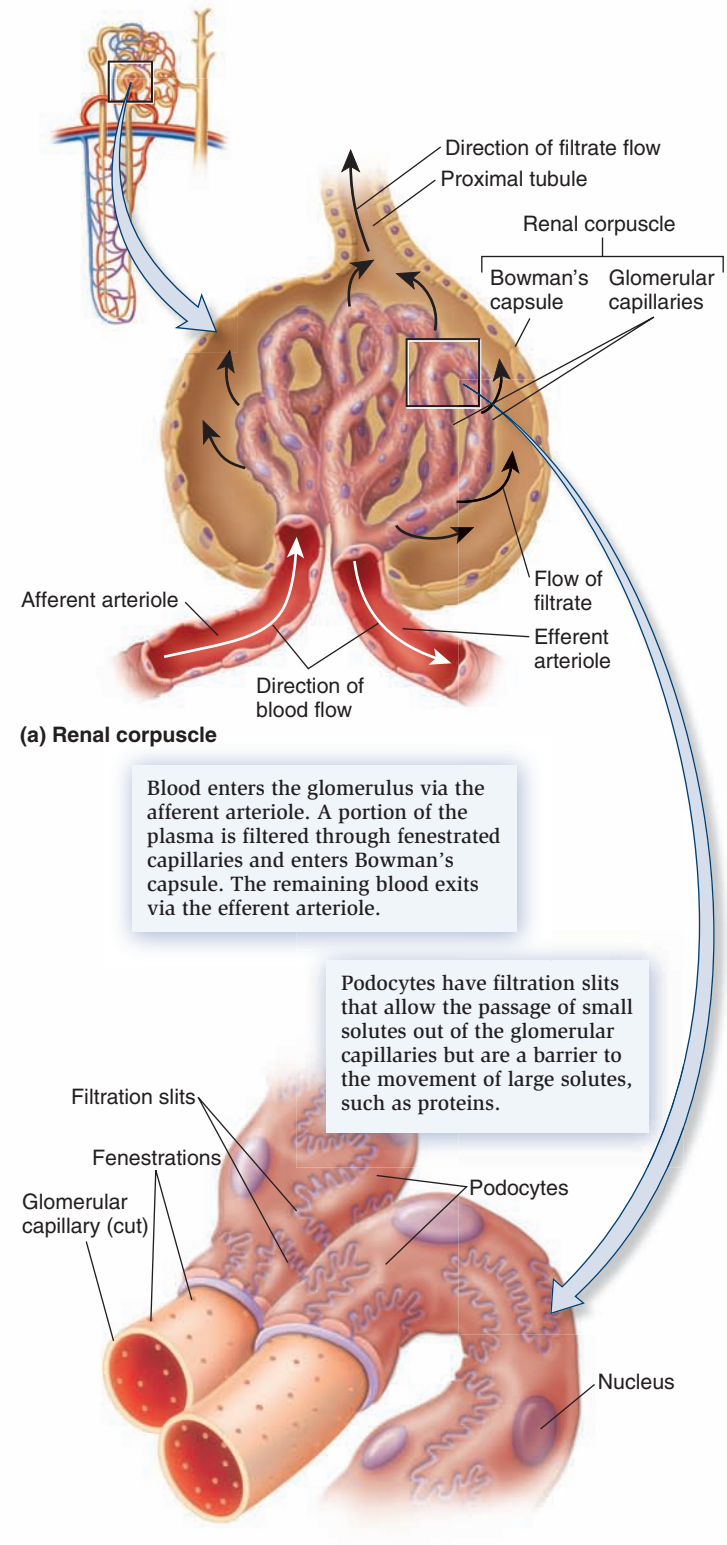
slits that allow the passage of small solutes but are believed to help prevent proteins from entering the filtrate (**Figure 49.11b**).

The Tubular Part of the Nephron The tubule of the nephron, which is continuous with Bowman's capsule, is made of a single layer of epithelial cells joined by tight junctions and resting on a basement membrane. The basolateral surfaces of the epithelial cells have numerous Na^+/K^+-ATPase pumps in their membranes. The epithelial cells differ in structure and function along the tubule's length, and three major segments are recognized:

- The **proximal tubule** is the nephron segment that drains Bowman's capsule.
- The **loop of Henle** arises from the proximal tubule; it is a long, hairpin-shaped loop consisting of a descending limb that comes from the proximal tubule and an ascending limb. The ascending limb has two segments—a thick segment and a thin segment—with different properties.
- The **distal tubule** arises from the thick segment of the loop of Henle; fluid flows from the distal tubule into one of the collecting ducts.



Capillaries of the Nephron All along its length, each tubule is surrounded by capillaries. These include the **peritubular capillaries** in the cortex and the **vasa recta capillaries** in the medulla (see Figure 49.10c). Both sets of capillaries carry away reabsorbed solutes and water from the filtrate in the nephron and return them to the bloodstream. However, only the peritubular capillaries secrete solutes into the tubules.

A Filtrate Is Produced in Bowman's Capsule

Filtration begins as blood flows through the glomerulus and a portion of the plasma leaves the glomerular capillaries and filters into Bowman's capsule. Only a small portion of the plasma is filtered from the blood as it circulates through the glomerulus. Most of the plasma, therefore, exits the glomerulus by an efferent arteriole (see Figure 49.11a). Proteins and blood cells are prevented from leaving the glomerular capillaries because of the small diameter of the fenestrations and the presumed actions of the filtration slits mentioned earlier.

The fluid that enters Bowman's capsule is called the glomerular filtrate. The rate at which the filtrate is formed is called the **glomerular filtration rate (GFR)**. GFR can be increased by dilation (widening) of the afferent arteriole. When the afferent arteriole dilates, more blood enters the glomerulus, increasing the hydrostatic pressure in its capillaries and forcing more plasma through the fenestrations in the capillaries and into Bowman's capsule. This might happen, for example, when excess water in the body must be excreted in the urine.

By contrast, constriction of the afferent arteriole will decrease the amount of blood entering the glomerular capillaries and therefore decrease GFR. This might occur during dehydration or following a loss of blood due to a severe injury. In this situation, decreasing GFR results in less urine production, which, in turn, minimizes how much water is lost from the body and helps compensate for the blood lost due to the injury. The tradeoff, however, is that the blood is less effectively cleared of wastes.

Useful Solutes Are Reabsorbed from the Filtrate in the Proximal Tubule

The filtrate flows from the renal corpuscle to the proximal tubule. Anywhere from two-thirds to all of a particular useful solute is reabsorbed from the filtrate in the proximal tubule. This includes Na^+, K^+, Cl^-, HCO_3^- (bicarbonate ion), and organic molecules such as glucose and amino acids. Some ions diffuse through channels in the membranes of the epithelial cells that form the proximal tubule. Others are actively transported across the tubule. Organic molecules generally are reabsorbed by being coupled to transport of ions such as Na^+. The reabsorption of solutes and water is enhanced by microvilli that extend into the lumen from the apical membrane of the epithelial cells of the proximal tubule. This anatomical adaptation, called a **brush border**, creates an enormous surface area for transporters and channels to be localized (**Figure 49.12**).

Most of the water in the filtrate is reabsorbed by osmosis as the ions and organic molecules are transported from the lumen of the proximal tubule to the interstitial fluid. From the interstitial fluid, the solutes and water enter peritubular capillaries to return to the blood. By contrast, some solutes that are not required by an animal or

Figure 49.11 The structure and function of the renal corpuscle. **(a)** A renal corpuscle comprises Bowman's capsule and the capillaries that make up the glomerulus. It is here that the filtrate is first formed. **(b)** The capillaries are completely encased in podocytes, specialized epithelial cells that support the glomerulus and are believed to act in part as a filtration barrier.

BIOLOGY PRINCIPLE Structure determines function. The structure of the capillaries in the renal glomerulus is suited to their function. Fenestrations permit the passage of plasma, but not blood cells, out of the capillaries. The structure of the podocytes is also suited to their function, in that filtration slits prevent the passage of plasma proteins into the filtrate. Damage to the structure of the podocytes might cause proteins to leak into the filtrate and be lost in the urine.

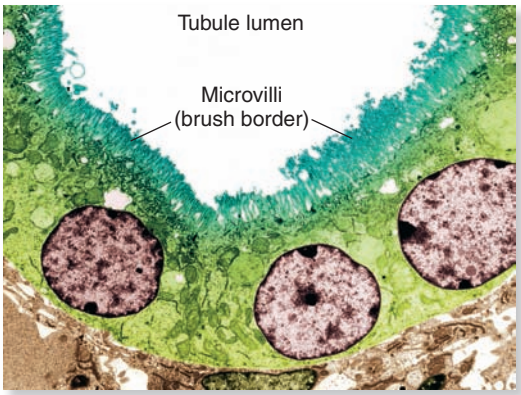


Figure 49.12 Electron micrograph of cuboidal epithelial cells of the proximal tubule of a rat nephron. Note the extensive brush border microvilli on the apical membranes of the cells.

BioConnections: In what other organ have you learned about a brush border (refer back to Figure 45.6)? What general conclusions can you draw about the function of such specialized epithelia?

that are potentially toxic at high concentrations are removed by active transport mechanisms from the blood and secreted into the interstitial fluid and then into the lumen of the proximal tubule. Examples of such substances include drugs (for example, penicillin), naturally occurring toxins, nucleoside metabolites, and ions such as K^+ and H^+ (if they are in excess). These solutes are excreted in the final urine.

By the time the filtrate leaves the proximal tubule, its volume and composition have changed considerably. The amount of solutes and water it contains is much reduced, and the organic molecules have all been removed and returned to the blood. However, the osmolarity of the filtrate at this stage is still about the same as that of blood.

Additional Water and Ions Are Reabsorbed from the Filtrate Along the Loop of Henle

In the loop of Henle, the filtrate moves down the descending limb of the loop, makes a U-turn at the bottom, and then moves back up the ascending limb of the loop. The permeabilities and transport characteristics of the epithelial cells lining the loop change over its length as it descends from the cortex into the medulla and then ascends to the cortex again (**Figure 49.13**).

The filtrate that leaves the proximal tubule has had solutes and water reabsorbed from it in about equal proportions, and its osmolarity is about 300 mOsm/L. This filtrate enters the descending limb of the loop of Henle, which is very permeable to water but not to Na^+ and Cl^-. Water leaves the filtrate by osmosis in this region because the surrounding interstitial fluid is hyperosmotic relative to the tubule contents.

The hyperosmolarity of the interstitial fluid originates from three sources:

1. First, the initial upturn of the thin segment of the ascending limb of the loop of Henle is very permeable to Na^+ and Cl^- but not to water. Therefore, these ions diffuse at high rates out of the loop into the interstitial fluid, significantly increasing the osmolarity of the inner medulla.
2. The epithelial cells of the thick segment of the ascending limb of the loop of Henle actively transport some of the remaining Na^+ and Cl^- out of the filtrate and into the interstitial fluid of the outer medulla.

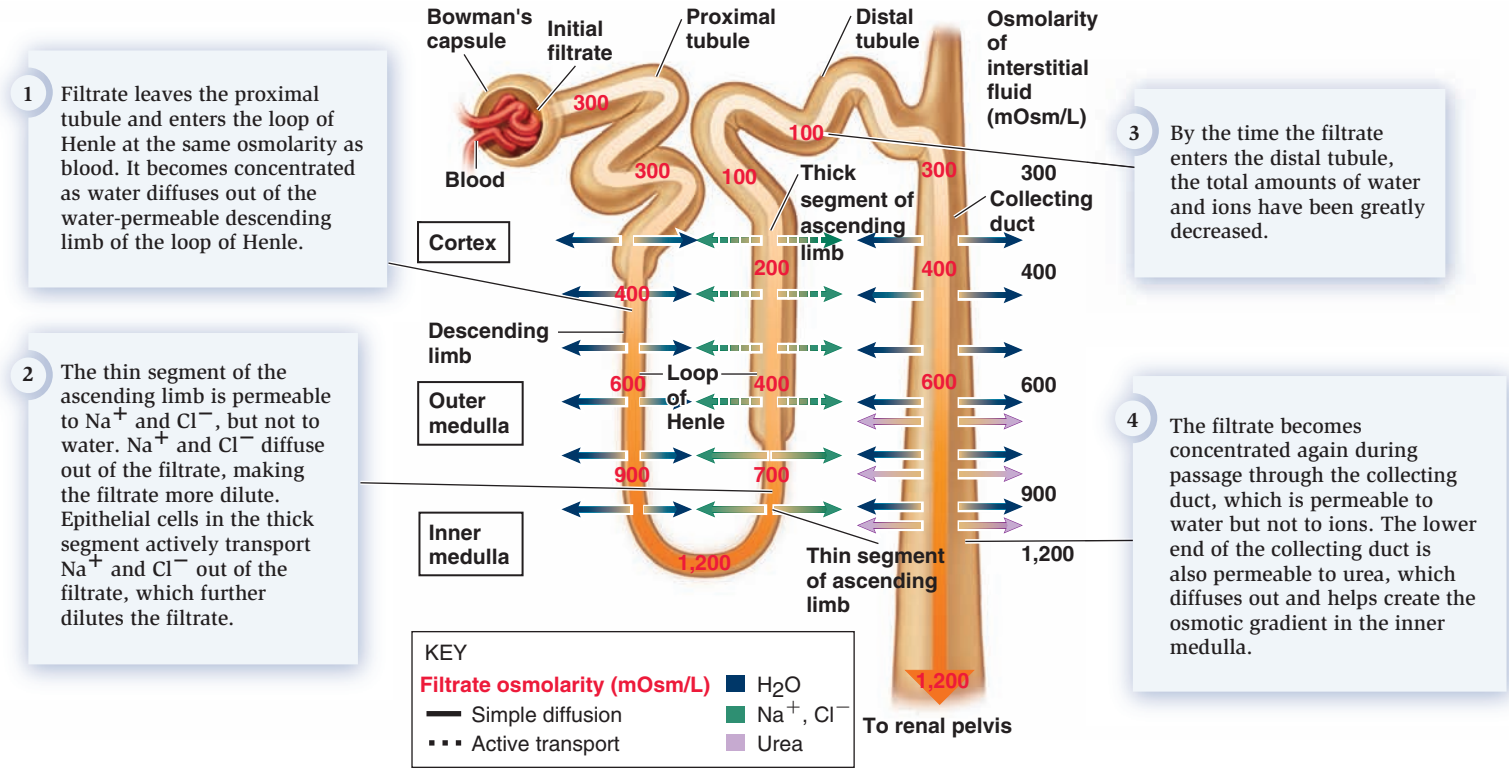

Figure 49.13 Tubule permeabilities and osmolarities of the filtrate in the nephron and collecting duct.

3. Some of the urea that is present in the filtrate does not get excreted in the urine, but instead diffuses out of the lower ends of the collecting ducts and into the inner medulla interstitial fluid.

Collectively, these solutes create the osmotic force that draws water out of the filtrate in the descending limb. The water then enters local capillaries and rejoins the blood circulation.

As water diffuses out of the filtrate in the descending limb of the loop of Henle, the osmolarity of the filtrate increases from 300 mOsm/L to about 1,200 mOsm/L (or higher in some species). During its passage up the ascending limb, however, the osmolarity of the filtrate decreases to about 200 mOsm/L as ions diffuse out and are transported out of the tubule into the interstitial fluid, as just mentioned. The ascending limb has two different segments, each with a slightly different structure. The thin segment of the ascending limb is permeable to Na^+ and Cl^-, but not water, so Na^+ and Cl^- diffuse out of the filtrate in this segment, which begins to dilute the filtrate. The thick segment is similarly not permeable to water, but in this segment, epithelial cells actively transport Na^+ and Cl^- out of the filtrate, and the filtrate becomes increasingly more dilute.

As a consequence of ion movement out of the ascending limb, the osmolarity of the kidney interstitial fluid increases in a gradient from renal cortex to inner medulla. This extracellular osmolarity gradient is what allows water to diffuse by osmosis from the descending limb of the loop of Henle all along its length. In other words, this is an example of a countercurrent exchange system, like those that operate in heat and gas exchange in some animals (refer back to Figures 46.13 and 48.5). A major difference between those countercurrent exchange systems and the one in the loop of Henle, however, is that the latter requires energy-dependent ion pumps to maintain the necessary concentration gradient. Because energy is used to increase—or multiply—the gradient, the loop of Henle system is also referred to as a **countercurrent multiplication system**.

The chief advantage provided to an animal by the loop of Henle is that the final volume of urine produced has been reduced by the reabsorption of water along the osmotic gradient. This is especially important in animals in which total body water stores are regularly in danger of being depleted. For example, desert mammals such as the kangaroo rat tend to have longer loops of Henle than other mammals. The extra length of the loop provides for a very large osmotic gradient in the medulla and, therefore, more water-reabsorbing capacity. At the other extreme, animals that generally must eliminate excess water have shorter or absent loops of Henle. Freshwater fishes, for example, do not have a loop of Henle in their nephrons. In their case, it is advantageous to excrete as much water as possible to compensate for the large amounts of water constantly entering the blood by osmosis across the gills.

The Concentrations of Ions Are Fine-Tuned in the Distal Tubule and Cortical Collecting Duct

By the time the filtrate reaches the distal tubule and cortical collecting duct (the part of the collecting duct that is in the kidney's cortex), most of the reabsorbed ions and water have already been restored to the blood, and the filtrate has been diluted to an osmolarity of about 100 mOsm/L (see Figure 49.13). However, the remaining concentrations of Na^+ and K^+ in the filtrate can still be fine-tuned to precisely match an animal's requirements for retaining or eliminating water and these ions. This process is mediated by the actions of two hormones called aldosterone and antidiuretic hormone (ADH).

Aldosterone: Na^+ Reabsorption and K^+ Secretion Aldosterone is a hormone produced by the adrenal glands. It acts on epithelial cells of the distal tubule and cortical collecting duct, stimulating the active transport of three Na^+ out of the filtrate in the tubule into the extracellular fluid (reabsorption) for every two K^+ it pumps into cells from the interstitial fluid and ultimately into the filtrate (secretion) (**Figure 49.14**). Water from the filtrate follows the Na^+ by osmosis into the extracellular fluid and blood. This makes the remaining

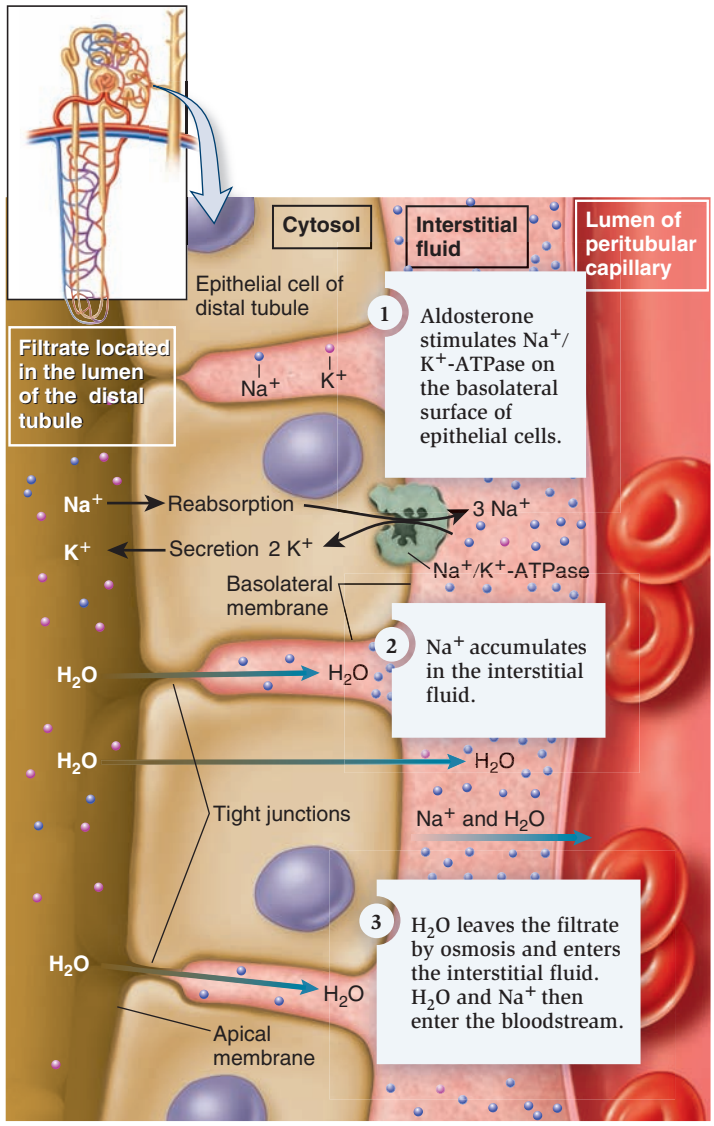

Figure 49.14 Effect of aldosterone on ion and water movement. Aldosterone stimulates Na^+/K^+-ATPase pumps in cells of the distal tubule and cortical collecting duct; these pumps are expressed only on the side of the cells facing the interstitial fluid (the basolateral surface). This activity creates an osmotic gradient, as three Na^+ are reabsorbed from the filtrate for every two K^+ secreted into it. Water then leaves the tubule by osmosis. The net effect is reabsorption of Na^+ and water, and secretion of K^+, which gets excreted in the urine. Na^+ and water enter the peritubular capillaries and are carried away in the bloodstream.

BioConnections: What special property of epithelial cells is demonstrated by the action of aldosterone? Look back to Figure 40.4 for help.

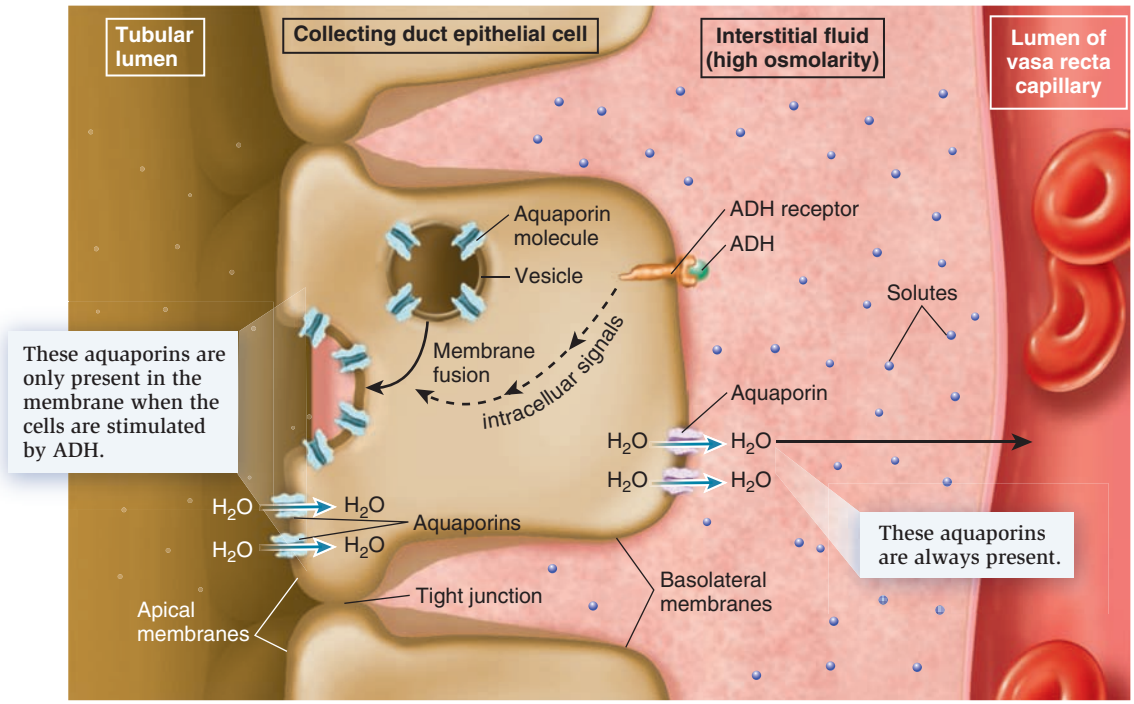

Figure 49.15 The effect of antidiuretic hormone (ADH) on water reabsorption in the collecting ducts of the kidney. Water molecules diffuse more rapidly across a membrane when the membrane contains aquaporin channels. The epithelial cells of collecting ducts express two sets of aquaporins. One set is always present on the basolateral side of the cells; the other set inserts into the apical membrane only in the presence of ADH. ADH activates cell-signaling mechanisms that stimulate the fusion of intracellular storage vesicles containing aquaporins with the apical membrane. Water moves by osmosis across the cell and into the interstitial fluid, and from there enters the vasa recta capillaries to be transported into the circulation (not shown). When ADH concentrations in the blood decrease (for example, when an animal is fully hydrated), the aquaporins on the apical membrane are returned to the intracellular storage vesicles by the process of endocytosis.

filtrate that moves on to the lower, medullary part of the collecting duct a bit more concentrated than it was before, with an osmolarity of about 400 mOsm/L. Aldosterone concentrations increase in the blood whenever the Na^+ concentration of the blood is lower than normal or the K^+ concentration is higher than normal; such imbalances might occur, for example, due to dietary changes. Through its actions on the nephron, aldosterone corrects such imbalances.

ADH: Water Reabsorption The lower part of the collecting duct, in the inner medulla, is the final place where urine composition can be altered. The osmolarity of the filtrate increases during passage along the collecting duct, which is permeable to water but not to ions, allowing water to diffuse out of the tubules by osmosis. As previously described, the cells of the collecting duct in the inner medulla are permeable to urea, which contributes to the osmotic gradient there.

In addition, however, the permeability of the epithelial cells of the collecting ducts to water (but not ions) can be regulated, depending on an animal's requirement at that moment for retaining or excreting water. This happens under the influence of **antidiuretic hormone (ADH)**, also known as vasopressin. When ADH is present in the blood, it acts to increase the number of water channels called aquaporins (from the Latin, meaning water pores; refer back to Chapter 5) in the apical membranes of the collecting duct cells (**Figure 49.15**). It does this by stimulating intracellular signaling mechanisms that promote the fusion of storage vesicles containing aquaporins with the apical membranes of the duct epithelial cells, resulting in the insertion of aquaporins into those membranes. Because the collecting ducts travel through the hyperosmotic medulla of the kidney, an osmotic gradient draws water from the filtrate in the duct into the duct epithelial cells. The water exits the cells on the other side (the basolateral surface), where another set of aquaporins is present. These latter aquaporins are always present in the basolateral membrane; unlike those on the apical side of the cells, they do not require the presence of ADH for insertion into the membrane. Once the water moves from the cells into the interstitial fluid, it enters the vasa recta capillaries and the blood. In this way, as the filtrate travels through the collecting ducts, it becomes greatly concentrated (hyperosmotic) compared to blood—as much as four to five times more concentrated in humans, for example.

ADH concentrations increase in the blood during situations where it is important to conserve water, such as when an animal is dehydrated. The ability of the kidneys to produce hyperosmotic urine is a major determinant of an animal's ability to survive in conditions where water availability is limited. By contrast, when there is excess water in the body, the concentration of ADH in the blood decreases. This results in endocytosis of portions of the apical membranes,

along with their aquaporins. This, in turn, decreases the water permeability of the collecting ducts. In such a case, urine increases in volume and becomes more dilute because less water diffuses out of the collecting ducts.

BIO TIPS **THE QUESTION** *The proximal tubule is the only region of the vertebrate nephron and collecting ducts that contains a brush border. Why?*

TOPIC ***What topic in biology does this question address?*** The topic is the purpose of a brush border, specifically one found in the kidney tubules.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you know that the proximal tubule contains a brush border but the rest of the tubules in the kidneys do not. From your understanding of the topic, you may remember that a brush border consists of epithelial cells with microvilli extending from the apical membranes into a lumen, such as that of the proximal tubules.

PROBLEM-SOLVING STRATEGY ***Relate structure to function.*** Recall the functions that are associated with the structural adaptation provided by a brush border, and then consider the different functions along a nephron.

ANSWER *Brush borders increase the surface area available for many transport processes, such as the reabsorption of solutes from the lumen of a kidney tubule into the blood. As the text mentioned, more than two-thirds of most useful solutes are reabsorbed in the proximal tubule of the nephron. The structure of the epithelial cells of the proximal tubule, therefore, reflects their major contribution to reabsorption. At distal regions of the tubule, there is very little reabsorption of solutes, and therefore a brush border did not evolve at those sites.*

Genomes & Proteomes Connection

Aquaporins Comprise a Large Family of Proteins That Are Found in All Animals

Biological membranes such as the plasma membranes of animal cells are composed of a lipid bilayer that inhibits the movement of water (refer back to Figure 5.1). The mystery of how water moves rapidly across membranes like those of the collecting ducts, and how ADH controls the amount of water reabsorption, were not solved until the early 1990s. At that time, the American physiologist Peter Agre and colleagues discovered the first of what would eventually be recognized as a new family of proteins, called aquaporins, a discovery that earned Agre the Nobel Prize in Chemistry in 2003 (see Figure 5.18). Scientists now know that aquaporins are a subfamily of an even larger family of proteins with membrane transport capabilities, found in all kingdoms of living organisms. The functions of all the members of this family are not yet known, but some aquaporins can transport other small molecules, such as glycerol and urea.

Aquaporins are proteins with six transmembrane domains and two short loops in the membrane (**Figure 49.16**). In animals, the two short loops come together to form the three-dimensional core of the water channel. The importance of the loops is reflected in the observation that the amino acid sequences of these portions are very similar among different species. Water must pass through a zone of constriction, created by the loops, that reduces the channel opening to a pore that is about 30 picometers (30×10^{-12} m), or just about the width of a water molecule. Scattered along the inner part of the channel are arginines, amino acids that are positively charged. The

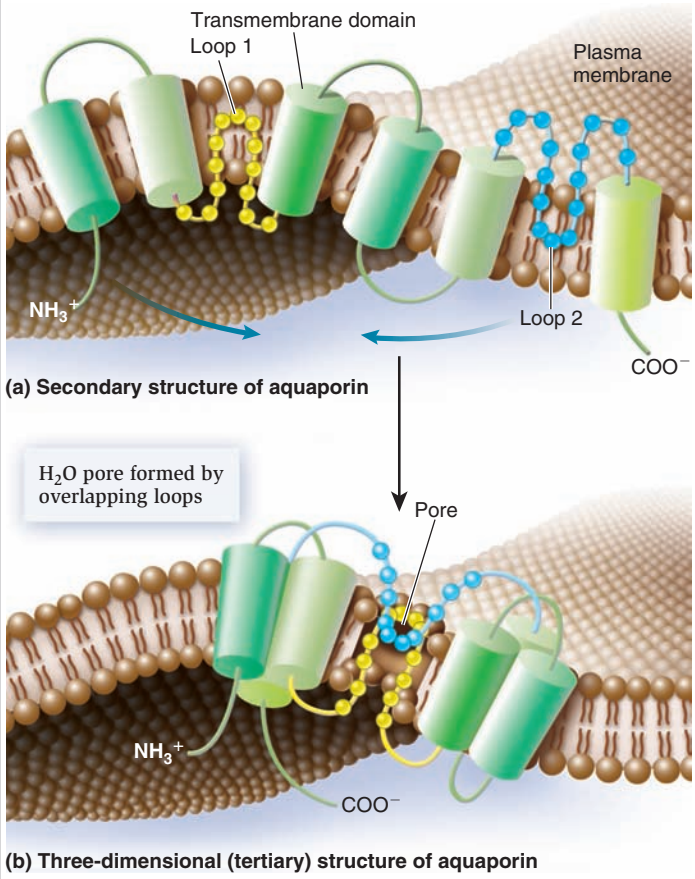

Figure 49.16 **Detailed aquaporin structure.** All proteins of the aquaporin family share a similar structure, with six membrane-spanning domains (represented as cylinders) and two loops that come together to form a water channel. **(a)** Secondary structure of aquaporin. This highly schematic representation highlights the two separate regions of the molecule that come together to form the water pore. **(b)** Tertiary structure of aquaporin showing pore formation.

charged arginines participate in hydrogen bonding with water molecules, facilitating their single-file movement through each channel at rates that have been estimated to be up to billions of water molecules per second!

Within the various extracellular and intracellular domains of aquaporin proteins are sites that can be modified by enzymes, such as protein kinases. This suggests that the opening and closing of these channels may be gated by stimuli, like the gating of ion channels in neurons and other cells. In addition, the promoter region of certain aquaporin genes contains a site that is recognized by transcriptional activator proteins that are responsive to the presence of cAMP, a common intracellular signaling molecule and one that is generated by cells stimulated by ADH. Thus, in addition to its rapid effect on aquaporin insertion into cell membranes (see Figure 49.15), another mechanism by which ADH promotes osmosis of water out of the renal collecting ducts, and thereby reducing urine volume, is by stimulating the transcription of one or more aquaporin genes.

An understanding of aquaporin function has allowed scientists to explain the molecular basis of one form of an inherited human disease called hereditary nephrogenic diabetes insipidus. People with this disease are unable to produce a concentrated urine and consequently lose large amounts of water. A mutation in an aquaporin gene (*AQP2*) results in a form of the protein expressing any of several abnormalities: improper folding, impaired ability of the molecule to enter the plasma membrane, or impaired ability of the molecule to form a channel core. AQP2 is the aquaporin that is responsive to the presence of ADH. Because of this, water reabsorption from the kidneys is greatly impaired in individuals with mutations in the *AQP2* gene.

In addition, Agre's discovery may have widespread implications for other areas of biology and human health. For example, certain types of plant diseases are associated with abnormal aquaporin expression in roots. In addition, some scientists are investigating the possibility that drugs that inhibit bacterial aquaporins may someday be useful antibiotics. The use of drugs to inhibit one class of aquaporins has even been suggested as a possible antiperspirant!

49.4 Impact on Public Health

Learning Outcomes:

1. Describe several common health issues related to diseases of the kidneys.
2. **SciSKILLS** » Diagram the process of hemodialysis, and predict its strengths and limitations.

Diseases and disorders of the kidney are a major cause of illness in humans. According to statistics released by the Centers for Disease Control and Prevention, up to 20 million people suffer from kidney disease in the U.S., with approximately 15,000–20,000 individuals receiving kidney transplants each year. This section gives an overview of kidney diseases and disorders in humans and also discusses some of the available treatments for these conditions.

Kidney Disease Disrupts Homeostasis

Many diseases affect the kidneys. Diabetes, bacterial infections, allergies, congenital defects, kidney stones (accumulation of mineral deposits in nephron tubules), tumors, and toxic chemicals are some possible sources of kidney damage or disease. A buildup of pressure due to obstruction of the urethra or a ureter may damage one or both kidneys and increase the likelihood of a bacterial infection and eventual renal failure. The symptoms of renal failure (fatigue, weakness, swollen abdomen and other regions, changes in urine amount and composition, anemia, ion imbalances, nausea, and muscle disturbances, among others) are similar regardless of the cause of the disease, and all stem from the condition known as **uremia**, the retention of urea and other waste products in the blood.

Assuming that a person with poorly functioning kidneys continues to ingest a normal diet containing the usual quantities of nutrients and electrolytes, what problems might arise? Potentially toxic waste products that would normally enter the nephron tubules in large amounts by filtration instead build up in the blood, because kidney damage significantly decreases the number of functioning nephrons. In addition, the excretion of K^+ is impaired because too few nephrons remain capable of normal tubular secretion of this ion. Increased K^+ in the blood is an extremely serious condition, because of the importance of stable extracellular concentrations of K^+ in the control of heart and nerve function.

The kidneys are still able to perform their homeostatic functions reasonably well as long as at least 20% or so of the nephrons are functioning normally. The remaining nephrons undergo alterations in function—filtration, reabsorption, and secretion—to partially compensate for the missing nephrons. For example, each remaining nephron increases its rate of K^+ secretion so that the total amount of K^+ excreted by the kidneys can be maintained at homeostatic levels. The kidneys' compensatory abilities are limited, however. If, for example, someone with severe renal disease were to eat a diet high in K^+, the remaining nephrons might not be able to secrete enough K^+ to prevent its concentration from increasing in the extracellular fluid.

Kidney Disease May Be Treated with Hemodialysis or Transplantation

Diseased kidneys may eventually reach a point where they can no longer excrete and reabsorb water and ions at rates that maintain homeostasis, nor excrete waste products as fast as they are produced. Adjusting a person's diet can help reduce the severity of these problems; for example, lowering K^+ intake decreases the amount of K^+ that must be excreted. However, such alterations may not eliminate the problems. In that case, doctors must use various procedures to artificially perform the kidneys' excretory functions.

Hemodialysis The most important of these procedures is **hemodialysis**. The general term dialysis means to separate substances in solution using a porous membrane. In hemodialysis, blood from one of the patient's arteries is purified by redirecting it through a dialysis machine, which is called a dialyzer (**Figure 49.17**). Within the dialyzer, blood flows through cellophane tubing that is surrounded by a special dialysis fluid. The tubing is highly permeable to most solutes but relatively impermeable to protein and completely impermeable to blood cells. These characteristics are designed to be similar to those of the kidneys' glomerular capillaries. The dialysis fluid has ion concentrations similar to those in plasma but contains no urea or other substances that are to be completely removed from the plasma.

As blood flows through the tubing in the dialyzer, small solutes diffuse out into the dialysis fluid until an equilibrium is reached. If, for example, the patient's plasma K^+ concentration is above normal, K^+ diffuses out of the blood across the cellophane tubing and into the dialysis fluid. Similarly, waste products and excess amounts of other substances also diffuse into the dialysis fluid and thus are eliminated from the body. Note in Figure 49.17 that blood and dialysis fluid move in opposite directions through the dialyzer. This establishes an artificial countercurrent exchange system that increases the efficiency with which waste products are removed from the blood. The dialyzed, purified blood is then returned to one of the patient's veins through another type of tubing that leaves the dialyzer.

Some patients with reversible, temporary forms of kidney disease may require hemodialysis for only days or weeks. However, patients with chronic, irreversible kidney disease require treatment for the rest of their lives, unless they receive a kidney transplant. Such patients undergo hemodialysis several times a week. Each year nearly 400,000 Americans undergo some type of dialysis.

Kidney Transplantation The treatment of choice for most patients with permanent kidney disease is kidney transplantation. Rejection of the transplanted kidney by the recipient's body is a potential problem with transplants, but great strides have been made in decreasing the frequency of rejection. Many people who might benefit from a transplant, however, do not receive one, because the number of people needing a transplant far exceeds the number of donors. Currently, the major source of kidneys for transplanting is from recently deceased persons. Improved public understanding may lead many more individuals to give permission to have their kidneys and other organs used following their death. Recently, donation from a living, related donor has become more common, particularly with improved methods for preventing rejection. As noted earlier, the mammalian kidney can perform its functions with only a fraction of its nephrons intact. Due to this large safety margin, a person who donates one of his or her kidneys can function quite normally with only one kidney.

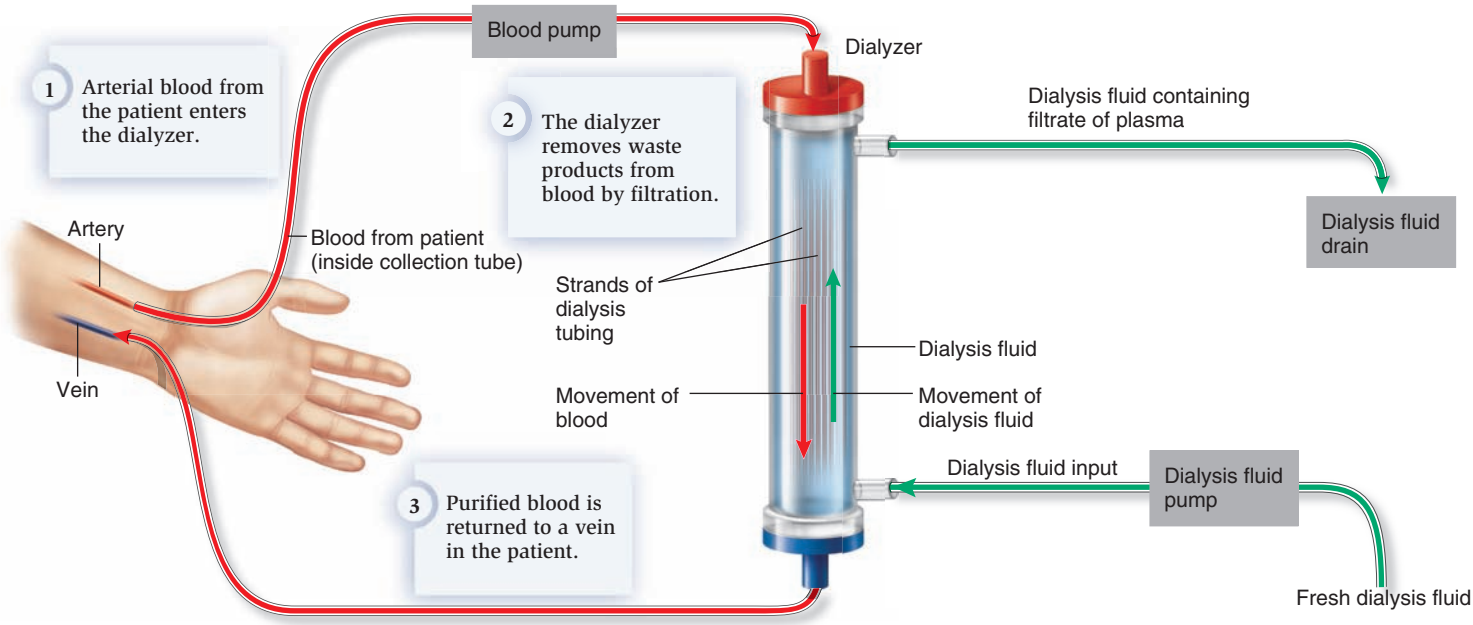

Figure 49.17 Simplified diagram of hemodialysis. The dialyzer is composed of many strands of very thin, sievelike tubing. In the dialyzer, blood within the dialysis tubing and the dialysis fluid bathing the tubing move in opposite directions (a countercurrent), which maximizes diffusion of substances out of the blood. The dialyzer provides a large surface area for diffusion of waste products out of the blood and into the dialysis fluid.

BioConnections: Note that modern medical technology is using a feature found in many animals—countercurrent exchange. What other examples of countercurrent exchange have you learned about? (Refer back to Figures 46.13, 48.5, and 49.13 for help.)

Summary of Key Concepts

49.1 Principles of Homeostasis of Internal Fluids

- Exchanges of ions and water with the environment resulting from vital processes, such as respiration, feeding, or the elimination of wastes, are called obligatory exchanges (Figure 49.1).
- The solute concentration of a solution of water is known as the solution's osmolarity. Fishes and other water-breathing animals that live in fresh water and those that live in salt water face opposite osmoregulatory challenges (Figures 49.2, 49.3).
- Robert Cade and coworkers discovered that fluid replacement during exercise is particularly beneficial if the fluid contains solutes at concentrations resembling those in sweat (Figure 49.4).
- Animals that maintain constant internal ion concentrations and osmolarities are called osmoregulators. Animals in which internal osmolarity conforms to the osmolarity of the environment are called osmoconformers.

49.2 Excretory Systems in Different Animal Groups

- Among the important products of the breakdown of proteins and nucleic acids are nitrogenous wastes, molecules that include nitrogen from amino groups ($-NH_2$). Most aquatic animals produce ammonia (NH_3) and ammonium ions (NH_4^+), which are the most highly toxic nitrogenous wastes but require no energy to produce. Many animals, including all mammals, convert ammonia into urea, which is less toxic than ammonia and requires no energy to produce. Birds, insects, and most reptiles produce uric acid or purines. These nitrogenous wastes conserve water and are less toxic but energetically costlier to produce than ammonia (Figure 49.5).
- Most excretory organs operate using one or more of the following processes: (1) filtration, the removal of water and small solutes from the body fluids; (2) reabsorption, in which useful filtered solutes are returned to the body fluids via transport systems; (3) secretion, in which unnecessary solutes are actively transported from the extracellular fluid and into the excretory tubule; and (4) excretion, in which waste is passed out of the body (Figure 49.6).
- In the protonephridial system of flatworms, a series of branching tubules filters fluids from the body cavity into the tubule lumens via the actions of ciliated flame cells (Figure 49.7).
- In the metanephridial system of annelids, pairs of metanephridia located in each body segment filter interstitial fluid and dilute urine is excreted via nephridiopores in the body wall (Figure 49.8).
- In insects, cells of Malpighian tubules secrete ions and uric acid from hemolymph into the tubule lumen; water follows by osmosis. After useful ions and water are reabsorbed into the hemolymph, wastes are excreted from the body (Figure 49.9).

49.3 Structure and Function of the Mammalian Kidney

- The urinary system in humans consists of the kidneys, ureters, urinary bladder, and urethra. Urine is excreted through the urethra. Each kidney is composed of an outer renal cortex and an inner renal medulla (Figure 49.10).
- Nephrons, the functional units of the kidney, are composed of a filtering component, called the renal corpuscle, and a tubule that empties into a collecting duct. Each renal corpuscle contains a cluster of capillaries called the glomerulus within a structure called Bowman's capsule. Each glomerulus is supplied with blood under pressure by an afferent arteriole. Each tubule of a nephron is composed of a proximal tubule, a loop of Henle, and a distal tubule. Tubules are surrounded by peritubular capillaries in the cortex and by the vasa recta capillaries in the medulla (Figure 49.11).
- Different portions of the tubule have different permeabilities to solutes and water. Most reabsorption of useful solutes occurs in the proximal tubule. Water and ion reabsorption continues along the loop of Henle, using a countercurrent exchange system. The reabsorption of solutes by the vasa recta minimizes the loss of solutes from the renal medulla. Fine-tuning of urine composition by the hormone aldosterone occurs in the distal tubule and upper collecting duct, and the final concentration of urine is determined by ADH in the lower collecting duct in the medulla (Figures 49.12, 49.13, 49.14).
- Agre and coworkers discovered that water moves through plasma membranes through protein channels called aquaporins. Aquaporins regulate water reabsorption in the kidneys (Figures 49.15, 49.16).

49.4 Impact on Public Health

- The symptoms of renal malfunction stem from uremia, the retention of urea and other waste products in the blood.
- One important treatment for kidney disease is hemodialysis, in which wastes in blood diffuse across a selectively permeable artificial membrane into a dialysis fluid (Figure 49.17).

Assess and Discuss

Test Yourself

1. A change in ion (salt) concentrations in an animal's body may result in
   a. altered membrane potentials that disrupt normal cell function.
   b. disruption of certain biochemical processes that occur in the cell.
   c. movement of water between fluid compartments.
   d. a and b only.
   e. a, b, and c.
2. Nitrogenous wastes are the by-products of the metabolism of
   a. carbohydrates. c. nucleic acids. e. both c and d.
   b. lipids. d. proteins.
3. Marine fishes avoid water balance problems by
   a. producing a large volume of dilute urine.
   b. not drinking water.
   c. having gill epithelial cells that recapture lost ions from the environment.
   d. producing small volumes of concentrated urine.
   e. doing a, b, and c.
4. The active transport of solutes into the lumen of an excretory organ is called
   a. filtration.
   b. reabsorption.
   c. secretion.
   d. excretion.

5. Which statement is *false*?
   a. Sweat has a lower solute concentration than internal body fluids such as blood.
   b. Some animals can survive without drinking water.
   c. A solution with an osmolarity of 1,000 mOsm/L is hyperosmotic relative to the body fluids of a fish.
   d. Marine fishes, but not freshwater fishes, drink the water they swim in.
   e. A 300 mOsm/L solution of NaCl contains 300 mOsm/L Na^+ and 300 mOsm/L Cl^-.
6. The excretory organs found in insects are composed of
   a. protonephridia.
   b. metanephridia.
   c. Malpighian tubules.
   d. a filtration kidney.
   e. a secretory kidney.
7. In the mammalian kidney, filtration is mainly driven by the
   a. solute concentration in the tubular filtrate.
   b. solute concentration in the blood.
   c. osmolarity of the blood.
   d. osmolarity of the filtrate in the distal tubule.
   e. hydrostatic pressure in the blood vessels of the glomerulus.
8. In the mammalian urinary system, the urine formed in the kidneys is carried to the urinary bladder by the
   a. collecting duct.
   b. nephron.
   c. renal pelvis.
   d. ureters.
   e. urethra.
9. Which of the following causes an increase in Na^+ reabsorption in the distal tubule and cortical collecting duct?
   a. an increase in aldosterone concentration
   b. an increase in antidiuretic hormone concentration
   c. a decrease in aldosterone concentration
   d. a decrease in antidiuretic hormone concentration
   e. b and c, both
10. ADH-dependent aquaporins are
    a. ion channels.
    b. water channels.
    c. receptors for ADH.
    d. small pores in the fenestrated capillaries of the glomerulus.
    e. both a and c.

Conceptual Questions

1. Define nitrogenous wastes, and list the main types produced in animals. What are some advantages and disadvantages of excreting different types of nitrogenous wastes?
2. List and define the three processes involved in urine production. Do each of these processes occur for every substance that enters an excretory organ such as the kidney?
3.  A principle of biology is that *living organisms maintain homeostasis*. Explain how salt glands are a homeostatic adaptation for marine life.

Collaborative Questions

1. Describe as many mechanisms as you can by which the body fluids of animals are purified.
2. Briefly discuss the parts and functions of the nephron in the mammalian kidney. Which functions occur in multiple regions of the nephron, and which occur in only one portion?

Endocrine Systems

A section through a human brain, highlighting the pituitary gland and its connection to the hypothalamus (white). Both of these structures secrete numerous hormones. (Image is a three-dimensional MRI.)

CHAPTER OUTLINE

50.1 Types of Hormones and Their Mechanisms of Action
50.2 Links Between the Endocrine and Nervous Systems
50.3 Hormonal Control of Metabolism and Energy Balance
50.4 Hormonal Control of Mineral Balance
50.5 Hormonal Control of Growth and Development
50.6 Hormonal Control of Reproduction
50.7 Impact on Public Health
Summary of Key Concepts
Assess and Discuss

A 22-year-old man was seen by his physician because of a complaint of hair loss and the appearance of severe acne over much of his face, neck, back, and shoulders; he also reported feelings of irritability and aggression. Upon examination, the man was found to have additional symptoms, including hypertension, an increased plasma cholesterol concentration, an increased hematocrit (red blood cell count; see Chapter 47), and, alarmingly, shrunken testes. When questioned, the patient admitted that for 6 months he had been taking an oral form of the illegal drug stanozolol in an effort to improve his physique by building more muscle mass. Stanozolol is a synthetic version of a hormone known as an androgen. A **hormone** is a chemical signal produced by cells in the body, which circulates in the bloodstream and acts on one or more target tissues to alter their functions.

In males, androgens are produced by the testes, which are reproductive organs that contain endocrine glands. The most well-known androgen is testosterone. In normal amounts, androgens play a key role in the physiological events associated with puberty and reproduction, including the increase in skeletal muscle mass that accompanies male puberty. This young man hoped to increase his muscle mass by consuming large amounts of synthetic androgen. At high concentrations, however, androgens promote increased erythrocyte production, which, in turn, forces the heart to work harder and can lead to hypertension. Likewise, high concentrations of androgens increase the amount of cholesterol in the blood, promote fluid retention, damage the liver, cause hair loss, and increase the activity of the sebaceous glands. At such concentrations, androgens also strongly inhibit the activity of the testes. In this last phenomenon, the body senses that sufficient androgens are already available in the blood; the testes do not need to make more androgens and thus shrink in size.

Fortunately, this individual was educated by his doctor about the consequences of misuse of these powerful hormones, and he discontinued the practice. Had he continued to take androgens, all of his symptoms would have worsened, and he would have run the risk of serious and irreversible damage to his heart, liver, and other organs, while increasing his risk of cancer and other diseases.

Androgens and other hormones are found in all vertebrates and many invertebrates. Hormones are often produced in response to a homeostatic challenge, such as a change in an animal's blood pressure or body temperature. A chief function of hormones is to counter these challenges and maintain homeostasis. Hormones affect a wide range of body functions, including gastrointestinal activity, blood pressure regulation, cholesterol balance, fluid and mineral balance, and reproduction, among others.

Hormones are made by cells in nearly all the body's organs. In addition, hormone-producing cells are often found in specialized glands, called **endocrine glands**, the primary function of which is hormone synthesis and secretion. An example is the pituitary gland highlighted in the chapter opening photo. Collectively, all the endocrine glands and other organs with hormone-secreting cells constitute the **endocrine system**.

In this chapter, we will first learn about the chemical nature of hormones and their mechanisms of action, how the endocrine and nervous systems interact, and the ways in which hormones influence such diverse functions as metabolism, growth, and reproduction. We will conclude with a discussion of how hormones affect human health, including how synthetic hormones are misused, as in the example just described.

50.1 Types of Hormones and Their Mechanisms of Action

Learning Outcomes:

1. Define hormone.
2. List and give examples of the three different chemical classes of hormones, and describe some of their structural differences.
3. Describe the cellular location of receptors for lipid-soluble hormones and receptors for water-soluble hormones.

Figure 50.1 is an overview of the major vertebrate endocrine glands and their hormones; you should take a moment and review this figure as preparation for the rest of the chapter. In this section, we will examine some of the general characteristics of hormones, how they act, and how they are controlled. Keep in mind that endocrine signaling is just one type of cell-to-cell communication. Refer back to Figure 9.3 for a review of the different types of cell-signaling mechanisms found in animals.

Hormones Are Classified According to Their Structure

Hormones fall into three broad classes: amines, polypeptides, and steroid hormones (**Table 50.1**). The amines and the polypeptides generally share similar chemical properties and mechanisms of action, whereas the steroid hormones act very differently from the other two classes.

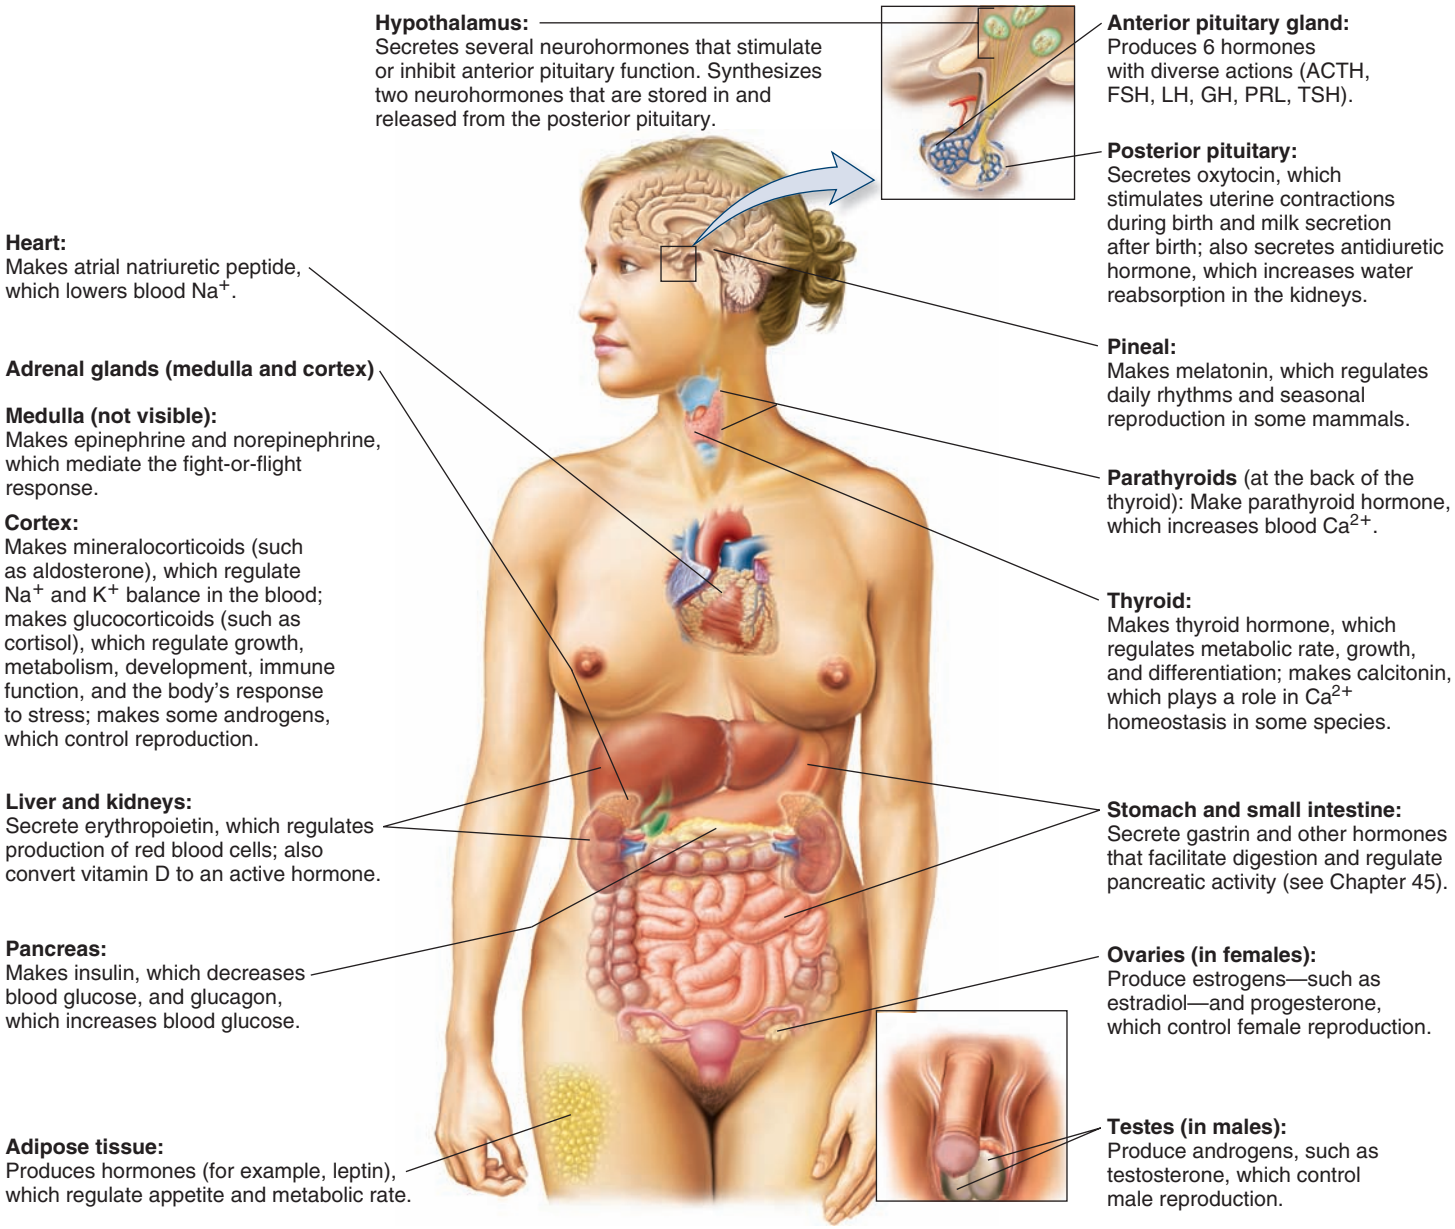

Figure 50.1 Overview of the vertebrate endocrine system. This figure shows many of the major endocrine glands and other structures that constitute the vertebrate endocrine system (as seen in a human), along with the major functions of the hormones produced by those glands.

Table 50.1 Chemical Classes of Hormones

Class	Chemical properties	Location of target cell receptor	Mechanism of action	Examples
Amines	Derived from tyrosine or tryptophan; small, water-soluble (except thyroid hormones, which are lipophilic)	Plasma membrane (except thyroid hormones, which act via intracellular receptors)	Stimulate second-messenger pathways (except thyroid hormones, which act via changes in gene transcription)	Epinephrine, norepinephrine, dopamine, thyroid hormone, melatonin
Polypeptides	Water-soluble	Plasma membrane	Stimulate second-messenger pathways	Insulin, glucagon, leptin
Steroids	Derived from cholesterol, mostly lipid-soluble	Cytosol or nucleus	Usually stimulate gene transcription directly	Aldosterone, cortisol, androgens, estrogens

The amine hormones are derived from an amino acid, either tyrosine or tryptophan. Tyrosine is the precursor for the hormones epinephrine and norepinephrine, which are produced in the adrenal medulla and are important in the body's response to stress (the fight-or-flight response; see Chapter 42), and for dopamine, a hormone made by the brain. Tyrosine is also the chemical backbone of the major hormone made by the thyroid gland, which is an important regulator of metabolic rate, growth, and development. The major hormone derived from tryptophan is melatonin, which is produced within an endocrine gland called the pineal gland located in the vertebrate brain. Melatonin is important in some species for controlling circadian rhythms, daily cycles of physiological or biochemical processes. In some mammals such as sheep and hamsters that breed only at certain times of year, melatonin controls seasonal cycles of reproduction.

Polypeptides are the most abundant hormones. These hormones participate in numerous body functions such as metabolism, mineral balance, growth, and reproduction. Examples include insulin and glucagon made by the pancreas, and leptin made by adipose tissue.

Amine and polypeptide hormones are generally synthesized and secreted at a steady rate or in a circadian rhythm in an unstimulated cell, until additional hormone is required. In that case, transcription factors within the cell direct the increased transcription of the gene coding for the hormone in question. Conversely, when less hormone is required, gene transcription is slowed or stopped. These hormones are too large and hydrophilic to diffuse from the cytosol across the plasma membrane and then into the extracellular fluid. Instead, they are packaged into secretory vesicles in much the same way as neurotransmitters are packaged in neuron axon terminals. This packaging provides a ready means of secreting the hormones by exocytosis and a reservoir of stored hormone available for immediate release when required. When a cell is stimulated to secrete its stored amine or polypeptide hormones, it also is typically stimulated to synthesize new hormone molecules to replace them.

Steroid hormones are synthesized from cholesterol as shown in **Figure 50.2**, and thus all steroid hormones are lipids, unlike the other classes of hormones. Steroid hormones, unlike water-soluble hormones, are not packaged into secretory vesicles because the steroid can diffuse out across the lipid membrane of the vesicle. Instead, steroid hormones are made on demand, and no significant amount of them is stored.

Steroids are less soluble in water than are amines or polypeptide hormones. Due to this limited solubility, steroids are usually bound to large, soluble proteins in the blood that serve as carriers. By combining with these proteins, steroids can reach high concentrations in the blood.

Hormones Act Through Plasma Membrane or Intracellular Receptors

The amine and polypeptide hormones are generally water-soluble, and the steroid hormones are lipid-soluble. Therefore, the amines and polypeptide hormones are not able to cross plasma membranes and must bind to a receptor protein on the surface of a target cell. Steroid hormones, however, being small lipids, can diffuse across the target cell's plasma membranes and bind to a receptor protein located in the cytosol or nucleus. Hormones that act through plasma membrane receptors tend to elicit fast responses, whereas those that act via intracellular receptors generally take longer.

Water-Soluble Hormones and Their Membrane Receptors All the amine and polypeptide hormones, with one exception (thyroid hormone, discussed later), act by binding to a receptor protein located in the plasma membrane (refer back to Figure 9.5). Only cells having the proper receptors on their surfaces can respond to the hormone. Thus, although a hormone travels throughout the entire circulatory system, it activates only specific cells. The hormone interacts noncovalently and reversibly with the receptor. The reversibility of the binding between hormone and receptor is one way in which cells are prevented from being permanently stimulated.

Among cells throughout the body, different receptors may recognize the same hormone. These different receptors, called subtypes, or isoforms, may be the product of different genes or may be produced by alternative splicing, described in Chapter 13 (refer back to Figure 13.22). By binding to different receptor subtypes, the same hormone is able to elicit differing, sometimes even opposite, responses, depending on where it binds in the body. In this way, most hormones are able to serve more than one function.

The binding of a water-soluble hormone to a plasma membrane receptor initiates intracellular signaling pathways that involve second messengers (refer back to Figure 9.12). Three major signaling pathways that are activated by water-soluble hormones are those involving cyclic AMP, diacylglycerol and inositol trisphosphate, and receptor tyrosine kinases. These signal transduction processes may be rapid, occurring in some cases within seconds, and involve changing the activity of enzymes. These features are important, because occasionally the rapidity of the cell response to a hormone may be critical, as may occur, for example, under fight-or-flight conditions.

Activation of signaling pathways may also lead to changes in cellular activities that occur more slowly. These slower changes usually

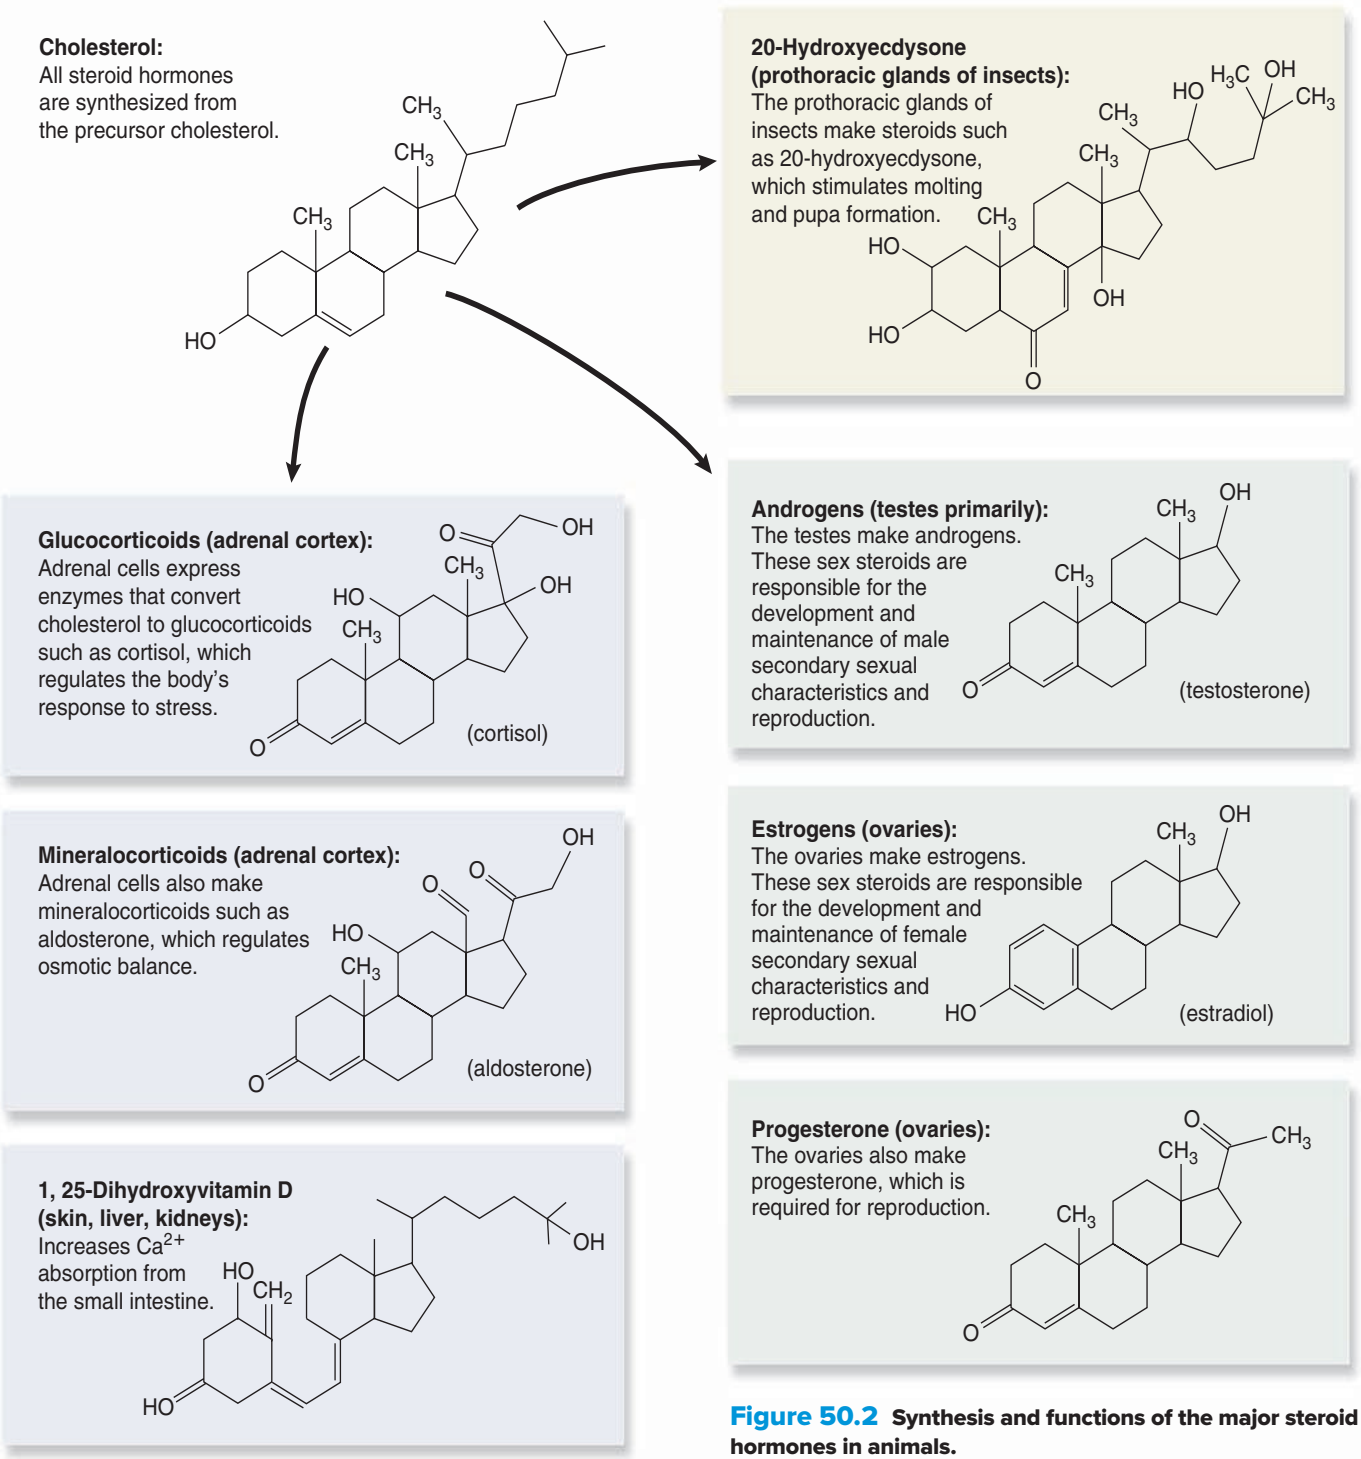

Figure 50.2 **Synthesis and functions of the major steroid hormones in animals.**

BIOLOGY PRINCIPLE **Structure determines function.** Notice how slight changes in the arrangements of side groups attached to the four-ring backbone create products with completely different functions. Keep in mind that the three-dimensional shape of a molecule may be changed much more by such chemical modifications than is visible in a two-dimensional depiction.

require activation or inhibition of genes in the nucleus, and are mediated by transcription factors (see Chapter 12) that are activated by the same signaling pathways described earlier.

Lipid-Soluble Hormones and Their Intracellular Receptors Thyroid hormone and all steroid hormones are lipophilic and bind to intracellular receptors. The complex of a steroid or thyroid hormone bound to its intracellular receptor functions as a transcriptional activator (or less frequently as an inhibitor) by binding to enhancers of particular genes (refer back to Figure 9.9). Once bound, transcription of a gene is increased, which increases the amount of that gene's protein product. These proteins may be important in a variety of cellular activities, such as regulating the number of ion pumps in membranes, and controlling cell differentiation, secretory activity, and growth.

Steroid and thyroid hormones can influence several genes within a single cell or different cells. In this way, one hormone can exert a variety of actions throughout the body. The physical changes that accompany puberty in mammals result from the actions of two steroid hormones—androgens in males and estrogens in females—and are among the most striking and commonly recognized examples of this kind of widespread action.

Generally, hormone concentrations in the blood remain within a normal range under most circumstances, but have the capacity to be increased or decreased beyond that range if required. One of the ways in which changes in hormone concentrations are initiated is through sensory input to an animal's brain. As we see next, the nervous system and endocrine system are functionally linked in many animals, including all vertebrates.

50.2 Links Between the Endocrine and Nervous Systems

Learning Outcomes:

1. Describe the anatomical connections among the hypothalamus, posterior pituitary, and anterior pituitary gland.
2. Describe the role of the hypothalamus and anterior pituitary gland in regulation of endocrine function.
3. **SciSKILLS** » Predict what would happen to the secretion of each hormone of the anterior pituitary gland if the unique blood connection between that gland and the hypothalamus was severed.
4. List some of the major functions of the hormones of the posterior pituitary.

A key feature of the endocrine system in most animals is that the concentrations of many hormones in the extracellular fluid increase and decrease with changes in an animal's environment. For this to happen, the hormone-producing cells of the endocrine system must receive signals that indicate environmental changes. This often occurs when sensory input is received by an animal's nervous system, which, in turn, modulates the activity of one or more endocrine glands.

Sensory stimuli detected by the nervous system can activate the endocrine system. For example, when an antelope detects the presence of a nearby lioness, visual and olfactory sense information is relayed to the antelope's brain. The brain initiates responses in certain endocrine glands that release hormones to prepare the antelope for the possibility of an attack. As another example, the concentrations of several hormones fluctuate in the blood of certain fishes as they migrate back and forth between feeding grounds in the sea and freshwater spawning sites. These hormones are activated by different salinities in the environment, which are detected by sensory cells of the fish's nervous system. The hormones act to prepare the gills of the fish to handle the large changes in salinity of the water.

The common feature of these examples and many others is that a sensory cue, such as a predator or the salinity of water, must be received by a sensory receptor and converted into an endocrine response. Electrical signals are transmitted from the sensory receptors to different parts of the brain, including the hypothalamus. In this section, we will explore the ways in which the hypothalamus and pituitary gland link the nervous and endocrine systems.

The Hypothalamus and Pituitary Gland Are Physically Connected

As described in Chapter 42, the **hypothalamus** is a collection of several nuclei that are located at the bottom surface of the vertebrate brain (**Figure 50.3a**). Neurons in these nuclei are connected to an endocrine gland sitting directly below the hypothalamus, called the **pituitary gland** (see the bottom part of the highlighted structure in the chapter opening photo). The pituitary gland in humans is made up of two lobes, the anterior and posterior lobes. Some vertebrate species have an intermediate lobe that is believed to be vestigial in primates.

The hypothalamus and pituitary are connected by a thin piece of tissue called the **infundibular stalk** and also by a system of blood vessels called portal veins. **Portal veins** differ from ordinary veins because not only do they collect blood from capillaries—like all veins do—but they then also form another set of capillaries, as opposed to returning the blood directly to the heart like other veins. The portal veins extend through the length of the infundibular stalk. Within the anterior lobe of the pituitary gland—often simply called the anterior pituitary gland—the portal veins empty into a second set of capillaries. This arrangement of blood vessels bypasses the general circulation and allows the hypothalamus to communicate directly with the anterior pituitary gland. Let's now explore the nature of this communication.

The Hypothalamus and Anterior Pituitary Gland Have Integrated Functions

As described in Chapter 42, the hypothalamic nuclei are vital for such diverse functions as reproduction, circadian rhythms, appetite, metabolism, and responses to stress. The hypothalamus has such wide-ranging effects in part because it acts as a master control, signaling the pituitary gland when to produce and secrete its various hormones. However, the hypothalamus communicates differently with the anterior and posterior lobes of the pituitary gland. Let's look at the interaction between the hypothalamus and anterior pituitary first.

Within the different nuclei of the hypothalamus are neurons that synthesize a class of hormones called neurohormones. A **neurohormone** is any hormone that is synthesized and secreted by neurons. All neurohormones are either amines or polypeptides. Although they are produced within neurons, these molecular signals are not referred to as neurotransmitters, because the endings of the neurons do not terminate in a synapse with another cell. Instead, the axon terminals from the hypothalamus end next to capillaries. Here, the neurons secrete their neurohormones into the capillaries, which, in turn, collect into the portal veins. This allows neurohormones to be delivered directly from the hypothalamus to the cells of the anterior pituitary gland in a quick, efficient manner (**Figure 50.3b**).

In response to the presence of these hypothalamic neurohormones, the anterior pituitary gland synthesizes several different hormones. **Table 50.2** lists the six major anterior pituitary hormones that have well-defined functions in vertebrates and the neurohormones that either stimulate or inhibit them. Recent research suggests the possibility of dual stimulatory and inhibitory control of several pituitary gland hormones, but this remains uncertain for most species.

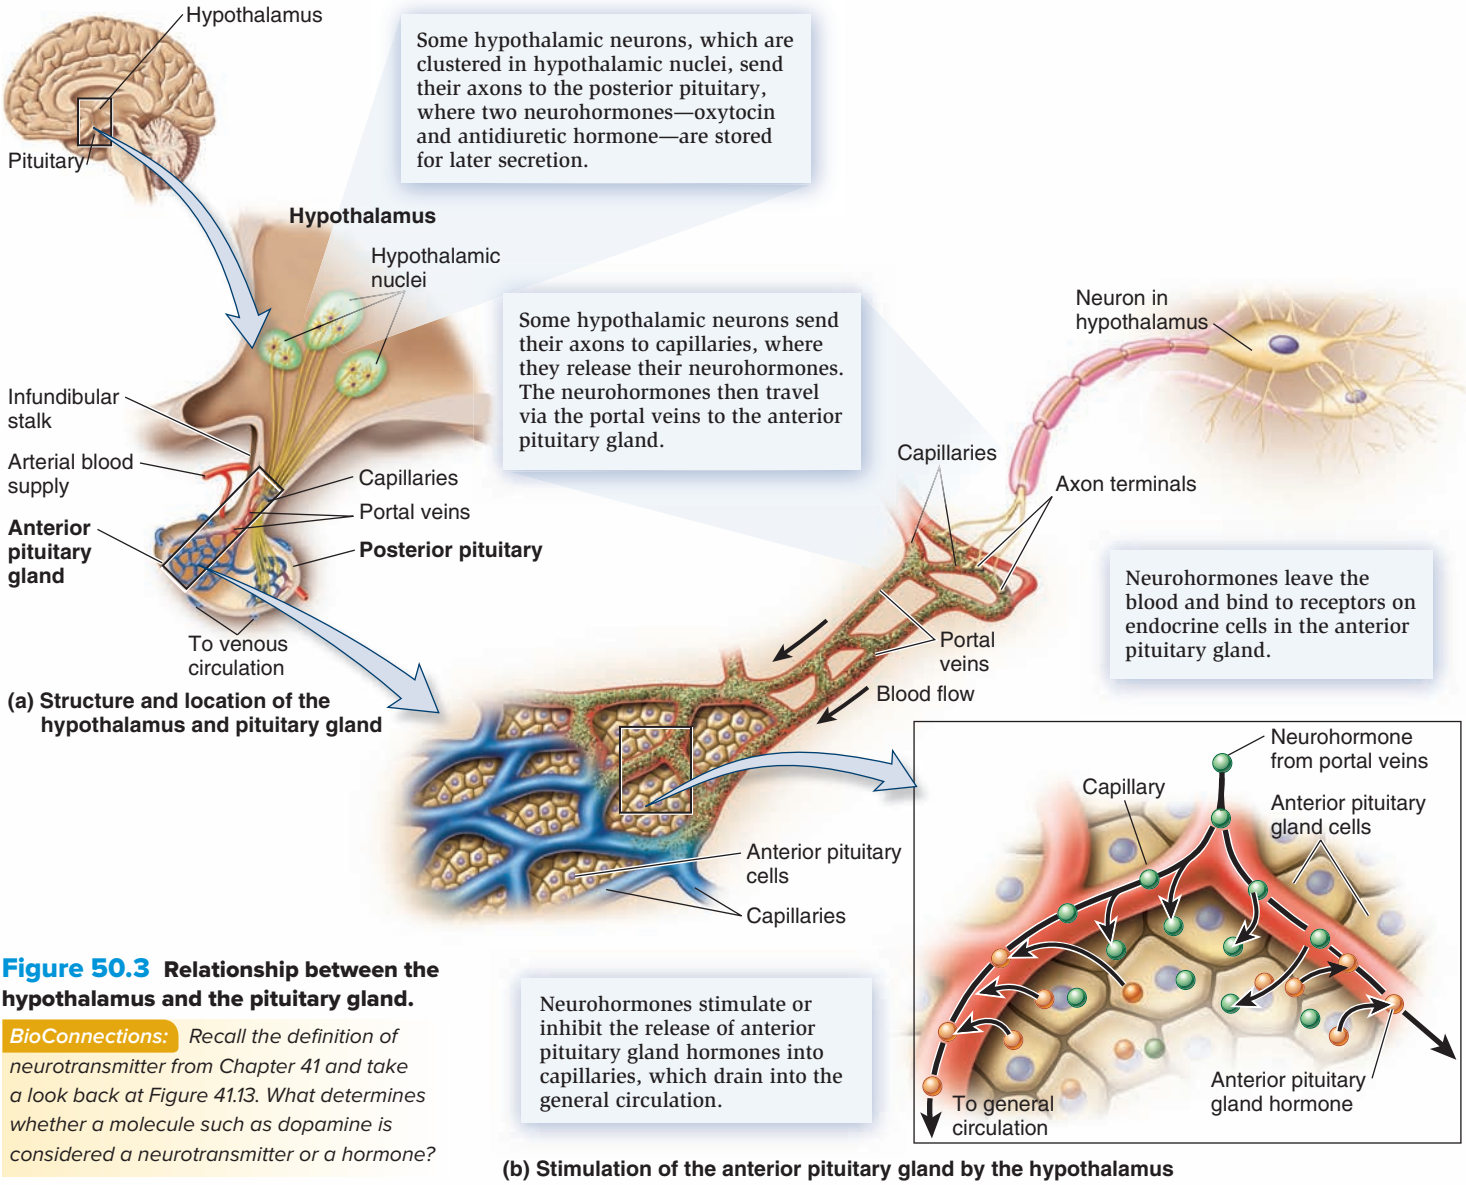

Figure 50.3 Relationship between the hypothalamus and the pituitary gland.

BioConnections: Recall the definition of neurotransmitter from Chapter 41 and take a look back at Figure 41.13. What determines whether a molecule such as dopamine is considered a neurotransmitter or a hormone?

The stimulatory action of several of the hypothalamic neurohormones has historically led to them also being known as hypothalamic-releasing hormones, because they cause the release, or secretion, of other hormones from the anterior pituitary. The six major hormones of the anterior pituitary gland are secreted into the general blood circulation, where they act on other endocrine glands or structures.

The Posterior Pituitary Contains Axon Terminals from Hypothalamic Neurons That Store and Secrete Oxytocin and Antidiuretic Hormone

The posterior pituitary has a blood supply, but, in contrast to the anterior pituitary gland, it is not connected to the hypothalamus by portal veins and does not respond to neurohormones from the hypothalamus. The posterior pituitary is not actually a gland but instead an extension of the hypothalamus that lies in close contact with the anterior pituitary gland (see Figure 50.3). Axons from neurons extend from the hypothalamus into the posterior pituitary. In mammals, the axon terminals in the posterior pituitary store one of two polypeptide hormones, oxytocin or antidiuretic hormone, that are produced by the cell bodies of those neurons. When the hypothalamus receives information that these hormones are required, they are released directly from the neuron axon terminals into the bloodstream.

Oxytocin concentrations increase in the blood of pregnant mammals just prior to birth. This hormone stimulates contractions of the smooth muscles in the uterus, which facilitates the birth process, and shortly afterward helps expel the placenta. Oxytocin also stimulates the secretion of milk from the mammary glands of lactating females. When the mother's nipples are stimulated by the suckling of a newborn, neurons transmit a signal from there to the mother's

Table 50.2 Hormones of the Anterior Pituitary Gland and Hypothalamus

Anterior pituitary gland hormone	Stimulatory neurohormone from hypothalamus	Inhibitory neurohormone from hypothalamus	Major functions
Adrenocorticotropic hormone (ACTH)	Corticotropin-releasing hormone (CRH)	None known	Stimulates adrenal cortex to make glucocorticoids
Follicle-stimulating hormone (FSH)	Gonadotropin-releasing hormone (GnRH)	None known	Stimulates germ cell development and sex steroid production in gonads
Luteinizing hormone (LH)	GnRH	None known	Stimulates release of eggs in females; stimulates sex steroid production from gonads
Growth hormone (GH)	Growth hormone-releasing hormone (GHRH)	Somatostatin	Promotes linear growth; regulates glucose and fatty acid balance in blood
Thyroid-stimulating hormone (TSH)	Thyrotropin-releasing hormone (TRH)	None known	Stimulates thyroid gland to make thyroid hormones
Prolactin (PRL)	TRH and other factors have been suggested as stimulators of PRL in some species, but this is not unequivocal	Dopamine	Stimulates milk formation in mammals; participates in mineral balance in other vertebrates

hypothalamus, which stimulates the cells that produce oxytocin. Oxytocin is released from the posterior pituitary into the blood where it travels to smooth muscle cells surrounding the secretory components of the mammary glands. This stimulates the release of milk. Thus, oxytocin has two important and different functions, one during birth and one during lactation. In both cases, the hormone stimulates contraction of muscle cells. Recent evidence also supports a role of oxytocin in maternal/infant bonding and prosocial behavior in some species; whether this is true in humans, however, is unknown.

Antidiuretic hormone (ADH) gets its name because it acts on kidney cells to decrease urine production—a process known as antidiuresis. (Diuresis is an increased loss of water in the urine, as happens, for example, when you drink large amounts of fluids.) If the fluid content of the body is low, for example during dehydration or after a significant loss of blood, ADH is secreted into the blood from the posterior pituitary. It acts to increase the number of water-channel proteins called aquaporins (refer back to Figure 49.15) present in the membranes of kidney tubule cells; water is recaptured from the forming urine through these aquaporins. Minimizing the volume of water used to form urine is an adaptation that conserves body water when necessary.

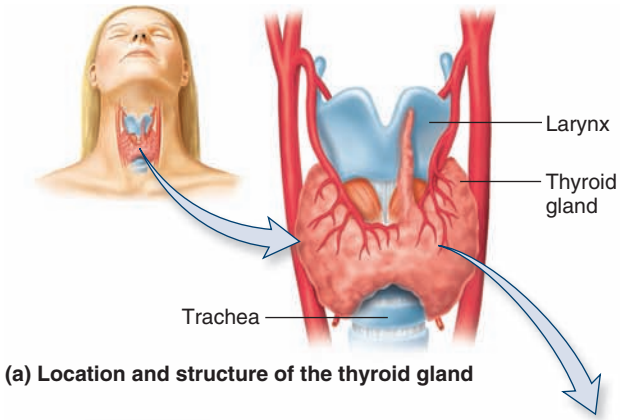
At high concentrations, ADH also increases blood pressure by stimulating vasoconstriction of blood vessels, a function that accounts for the other common name of ADH, vasopressin. Like oxytocin, therefore, ADH has more than one function. Both of the major functions of ADH are related in that they contribute to maintaining blood pressure and fluid levels in the body.

Oxytocin and ADH are well-studied examples of the evolution of hormones. Although these two hormones are found only in mammals, many invertebrates and all nonmammalian vertebrates secrete one or more polypeptides that are chemically similar to oxytocin and ADH but are not identical to the mammalian hormones. One of these is **vasotocin**, which combines some of the chemical structure of both oxytocin and ADH. Research indicates that an ancestral vasotocin gene duplicated at some point, and then the two genes evolved into the oxytocin and ADH genes found in mammals. Because only mammals lactate, the role of vasotocin in birds, fishes, and other vertebrates must be different from that of oxytocin in mammals. Research has shown that vasotocin is responsible for regulating salt and water balance in the blood of nonmammalian vertebrates. The observation that members of the vasotocin/oxytocin/ADH gene family arose early in animal evolution also suggests that oxytocin and ADH may have additional, unrecognized actions that have been retained in mammals. For example, human males have oxytocin in their blood, but its role cannot be the same as in females because, of course, only females give birth and lactate. The major physiological functions of oxytocin in male humans and other animals have not been unequivocally identified.

50.3 Hormonal Control of Metabolism and Energy Balance

Learning Outcomes:

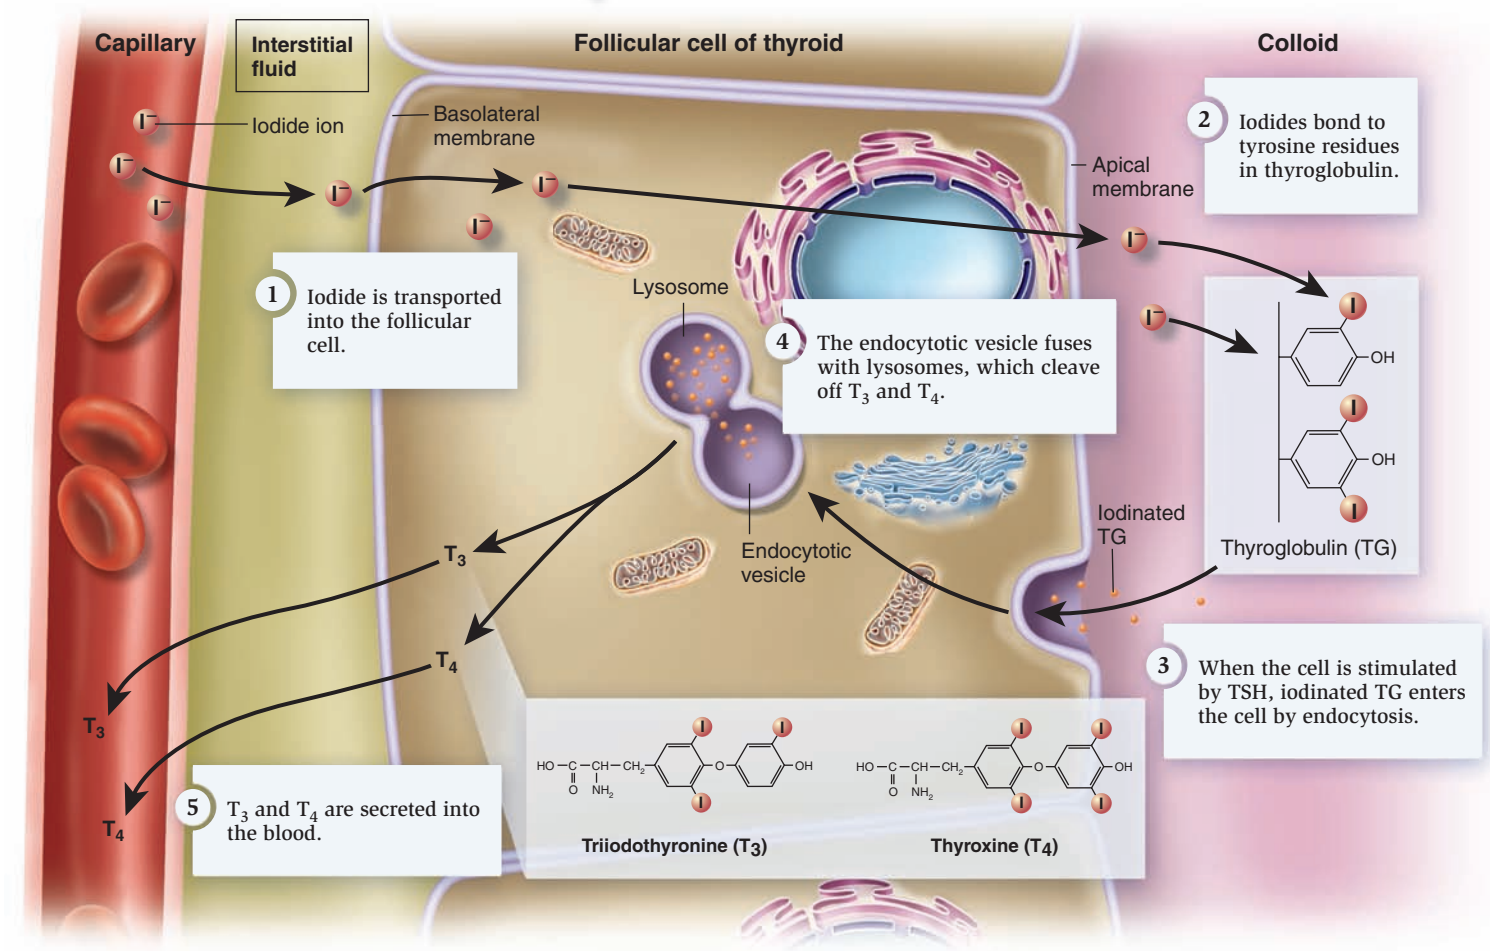
1. Explain how the structure of the thyroid gland is linked to its function (synthesis of thyroid hormone).
2. Describe the important anatomical features of the thyroid gland and the major function of thyroid hormone in adult animals.
3. List the hormones produced by the pancreas and adrenal glands, and provide a brief description of the major metabolic functions of each.
4. Explain the difference between type 1 and type 2 diabetes mellitus.



An important function of the endocrine system is to regulate the metabolic rate and energy balance. Hormones are partly responsible for regulating energy balance by modulating appetite, digestion, absorption of nutrients, and the concentration of glucose in the blood and its transport into cells. Although many hormones are involved in these processes, those from the thyroid gland, adrenal glands, pancreas, and adipose tissue have particularly important functions, as described in this section.

Thyroid Hormone Stimulates Metabolism

The thyroid gland lies within the neck of vertebrates, straddling the trachea just below the larynx in mammals (**Figure 50.4a**). It consists of many small, spherical structures called follicles, made of a shell of epithelial cells called follicular cells and a core of a gel-like substance called the colloid. The colloid consists primarily of large amounts of the protein thyroglobulin (TG), which plays a major role in the synthesis of thyroid hormone.

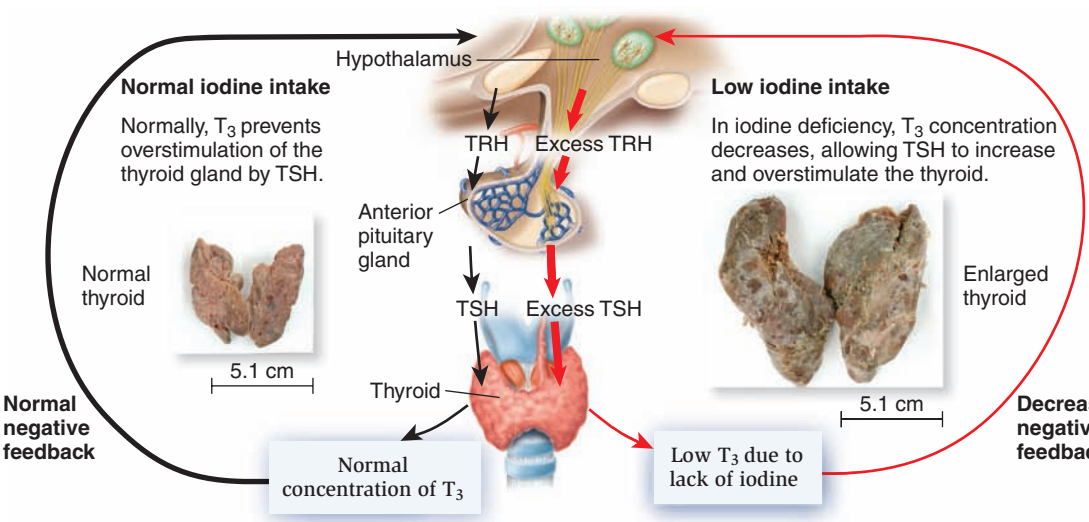


Synthesis of Thyroid Hormone Thyroid hormone is produced when the hypothalamic neurohormone thyrotropin-releasing hormone (TRH; see Table 50.2) stimulates the anterior pituitary gland to secrete thyroid-stimulating hormone (TSH) into the blood. TSH stimulates the follicular cells of the thyroid gland to begin the process of making thyroid hormone. Thyroid hormone has a negative feedback effect on the hypothalamus and anterior pituitary, preventing them from producing too much TRH and TSH, thereby keeping the circulating concentration of thyroid hormone in check.

Figure 50.4b shows the pathway leading to thyroid hormone synthesis. First, iodide—converted in the intestine from dietary iodine—diffuses from the bloodstream into the interstitial fluid, from where it is transported across the basolateral membrane of the thyroid follicular

(a) Location and structure of the thyroid gland

Figure 50.4 The thyroid gland and synthesis of thyroid hormone. **(a)** Location and structure of the gland in a human. Vertebrates contain thyroid tissue in the neck region, but it is not always consolidated into a single structure as shown here. **(b)** The steps involved in production of thyroid hormone. Shown is a cross section through a small part of a single follicle in a thyroid gland, with a nearby capillary (not to scale). The blood delivers iodide to the gland and picks up thyroid hormone secreted by the gland. Although T_4 and T_3 are both synthesized in the thryroid gland, T_3 is the active form of thyroid hormone. T_4 circulates in the blood and gets converted by cells to T_3.



(b) Synthesis of thyroid hormone

cells. The iodide then diffuses through the apical membrane and enters the colloid, where it is oxidized and bonds to tyrosine side chains in thyroglobulin. When the thyroid follicular cells are stimulated by TSH, the apical membranes undergo endocytosis, bringing colloid with its iodinated thyroglobulin into the cell. The endocytotic vesicles fuse with lysosomes; there, lysosomal enzymes cleave the iodinated tyrosines from thyroglobulin to form **thyroxine**, also called **T_4**, because it contains four iodines and **triiodothyronine**, or **T_3**, which has three iodines. Both T_4 and T_3 then diffuse out of the follicular cells across the basolateral membrane into the bloodstream. These molecules are carried throughout the body and diffuse into cells. Inside cells, most T_4 is converted by enzymes that remove one iodine, forming T_3. It is T_3 that actually binds to cellular receptor proteins. T_4 can be considered, therefore, as a circulating reservoir of the active hormone T_3. From here on, we will for simplicity refer only to T_3 as thyroid hormone.

Stimulation of Metabolism A major action of thyroid hormone in adult animals is to stimulate energy expenditure by many different cell types. This occurs in large part by increasing the number and activity of the Na^+/K^+-ATPase pumps in plasma membranes. As these pumps hydrolyze ATP, the cellular concentration of ATP decreases. This decrease is compensated for by increasing the cell's metabolism of glucose, which provides the energy to produce more ATP. Whenever metabolism is increased, heat production is increased. Consequently, a person with a hyperactive thyroid gland (hyperthyroidism; from the Greek *hyper*, meaning over or above) generally feels warm, whereas the opposite condition (hypothyroidism; from the Greek *hypo*, meaning under or below) results in a sensation of coldness. Biologists have estimated that up to 70% of the heat produced by some endotherms is attributable solely to the actions of thyroid hormone on metabolic rate. From these considerations, it is not surprising that humans with hyperthyroidism often lose weight, while weight gain is typically a problem in hypothyroidism.

Effect of Iodine Deficiency The observation that thyroid hormone cannot be made without iodine presents some interesting and unique features. The availability of iodine in the diet of most animals varies. As a consequence, the ability to store large amounts of thyroglobulin in the colloid of the thyroid was an important evolutionary adaptation. In this way, during times when iodine ingestion is high, many thyroglobulin molecules have their tyrosine residues bound to iodines, one of the first steps in forming T_3. During times of low iodine availability, this reservoir of iodinated tyrosines in thyroglobulin molecules can be tapped. Humans, for example, have at least a 2-month supply of thyroid hormones even if dietary iodine becomes unavailable. In most industrialized countries, iodine deficiency is rarely a problem since the introduction of iodized salt in the mid-20th century. However, in some regions of the world, this is still a major health problem.

The left side of **Figure 50.5a** shows the pattern of T_3 production from a healthy thyroid gland when iodine ingestion is adequate. The right side of the figure shows the consequences when T_3 is not produced in normal amounts, for example, due to a lack of iodine in the diet. In such a case, the decreased T_3 concentration exerts less negative feedback on the hypothalamus and anterior pituitary gland, resulting in increased TRH and, consequently, TSH concentrations. The thyroid gland responds to the increased TSH by increasing the cellular machinery needed to produce more and more thyroglobulin, even though in the absence of iodine, no additional T_3 can be synthesized.

(a) Thyroid function with and without normal iodine intake

(b) Woman with iodine-deficient goiter

Figure 50.5 Consequences of inadequate iodine in the diet. **(a)** With normal iodine intake, as shown on the left, T_3 controls TSH secretion by negative feedback. Without enough iodine, as shown on the right, less T_3 is synthesized; this decreases the negative feedback effect of T_3, and consequently the TSH concentration increases. This leads to the enlargement of the thyroid gland. **(b)** An extreme example of an enlarged thyroid gland, or goiter, due to iodine deficiency.

BIOLOGY PRINCIPLE **Living organisms maintain homeostasis.** Recall from Chapter 40 that a key way in which homeostasis is maintained is via negative feedback. Notice in this figure how a change in dietary intake of iodine results in decreased negative feedback and subsequent overgrowth of the thyroid gland.

What results is an overgrown gland that still lacks the resources to make T_3. This condition is known as an **iodine-deficient goiter** (**Figure 50.5b**). In humans, the problem can be alleviated either by adding iodine to the diet or by taking pills that contain thyroid hormone. Goiters are not unique to humans. Iodine deficiency is relatively common among vertebrates, and goiters are found frequently in reptiles and birds, particularly those that subsist on all-seed diets, which are generally low in iodine.

Hormones of the Adrenal Glands and Pancreas Regulate the Concentration of Energy-Yielding Molecules in the Blood

Thyroid hormone regulates an animal's metabolism. For metabolism to proceed normally, however, body cells must have adequate sources of energy available, usually in the form of glucose and fatty acids. The brain, in particular, must have a constant supply of glucose because brain cells have relatively limited storage capacity for fuel. Regulation of energy availability to cells is in large part accomplished by the hormones of the adrenal glands and the pancreas.

Adrenal Glands The adrenal glands, so named because they sit on top of the kidneys (from the Latin *ad*, meaning toward, and *renis*, meaning kidney), are multifunctional glands that contain an inner region called the adrenal medulla and an outer region called the adrenal cortex (**Figure 50.6**). These two regions produce different hormones that have widespread effects in animals, including effects on metabolism (see **Table 50.3** for a summary of many of the metabolic and nonmetabolic actions of these hormones).

When an animal is fasting, the sympathetic nervous system will stimulate the cells of the adrenal medulla to secrete the amine hormones epinephrine and norepinephrine. Together, these two hormones are responsible for most of the physiological reactions of the fight-or-flight response that were described in Chapter 42 and Table 9.1. These reactions include increased production of glucose by the liver via stimulation of glycogenolysis (release of glucose from glycogen) and gluconeogenesis (synthesis of glucose from other sources) (refer back to Figure 46.2).

The outer part of the adrenal gland, the cortex, is subdivided into three zones: the glomerulosa, the fasciculata, and the reticularis (see Figure 50.6). The outer zone, the glomerulosa, is the region that makes the hormone aldosterone, which acts to maintain Na^+, K^+, and water balance (described later). The innermost cortical zone, known as the reticularis, functions in humans to make certain androgens, but its function in other animals is not as clear. The bulk of the cortex is the middle zone, the fasciculata, which produces glucocorticoid hormones such as **cortisol**.

Glucocorticoids are catabolic hormones; that is, they promote the breakdown of molecules and macromolecules. For example, they act on bone, immune, muscle, and adipose tissue to break down proteins and lipids to provide energy for the body's organs—in particular, vital organs such as the heart and brain. This is not only important for an animal that is fasting, but also for one that is facing an acute stress (traditionally defined in biology as a real or perceived threat to homeostasis), because feeding and digestion both stop during the fight-or-flight stress response. Consequently, internal stores become

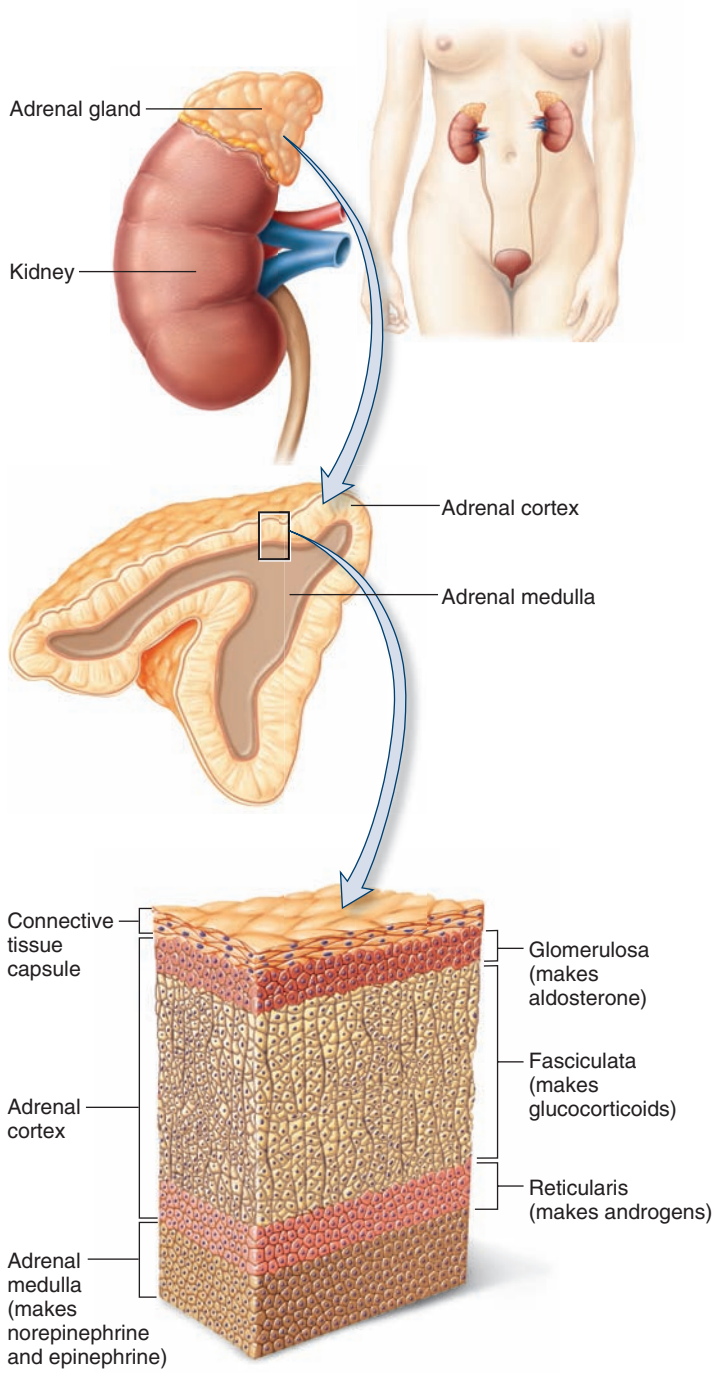


Figure 50.6 Location, structure, and function of the adrenal glands.

the only source of energy. These adrenal steroids are called glucocorticoids because one of their major actions is to promote gluconeogenesis in the liver during times of stress, thus providing glucose to the blood. Glucocorticoid release is stimulated by the anterior pituitary hormone ACTH, the release of which in turn is stimulated by the neurohormone CRH (refer back to Table 50.2).

Pancreas The pancreas is a complex organ that is both an exocrine and endocrine gland (**Figure 50.7**). An **exocrine gland** is one in which epithelial cells secrete chemicals into a duct, which carries

Table 50.3 Major Actions of Hormones Secreted by the Adrenal Glands

Site of Action	Action(s)
Epinephrine and norepinephrine (secreted by the adrenal medulla)	
Circulatory system	Increase heart rate and strength of heart contractions to maximize pumping of blood to all parts of the body; dilate blood vessels entering tissues requiring more oxygen—such as skeletal muscle—and constrict blood vessels to regions of less immediate importance—such as the gut and kidney
Respiratory system	Dilate small airways (bronchioles) to reduce resistance to airflow in mammals; increase rate and depth of breathing to maximize oxygen intake and carbon dioxide elimination
Metabolic system	Increase glycogenolysis in muscle to provide glucose for muscle cells and in the liver to provide glucose to the blood, where it can reach all body cells; increase breakdown of adipose triglycerides into usable fuel (fatty acids) that can then enter the bloodstream; stimulate glucagon secretion, which acts on the liver to promote gluconeogenesis
Nervous system	Increase arousal and alertness; inhibit nonessential functions such as appetite
Glucocorticoids (secreted by the adrenal cortex)	
Liver	Stimulate gluconeogenesis, thus providing glucose to the blood
Adipose tissue	Stimulate breakdown of triglycerides into fatty acids and glycerol for fuel
Muscle and adipose tissue	Inhibit sensitivity to insulin, making more glucose available to brain cells, which do not require insulin to move glucose across their plasma membranes
Bone	Inhibit bone growth and formation, because such processes require large amounts of nutrients that could be used to combat stress instead
Lungs	Stimulate lung maturation in the fetus
Immune	Suppress immune system function and reduce inflammation
Other	Regulate Na^+ and Cl^- balance in migratory fishes; stimulate nervous system development in most vertebrates; stimulate protein breakdown to provide amino acids to the liver for gluconeogenesis; inhibit reproduction

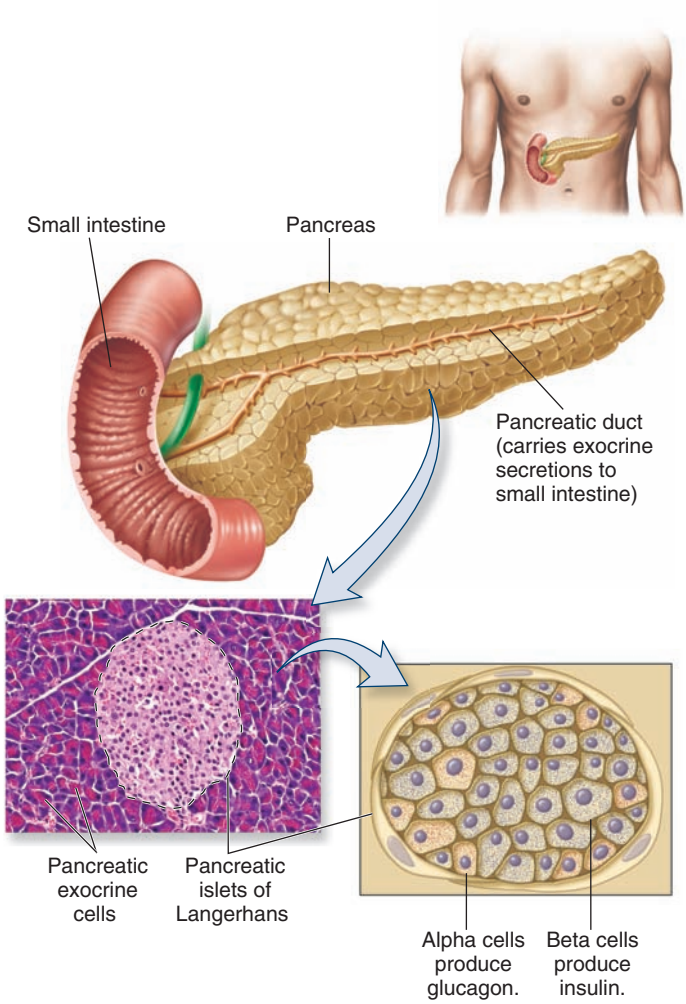

Figure 50.7 Location, appearance, and internal structure of the mammalian pancreas. Within the exocrine pancreas are scattered islets of Langerhans, which are endocrine tissue. Only the exocrine products are secreted into the intestine; the hormones from the islets of Langerhans are secreted into the blood (not shown).

BioConnections: The pancreas contains both exocrine and endocrine tissue. Is this property ever observed in other organs? (Hint: Think about the processes associated with digestion and absorption of food.)

those molecules directly to another structure or to the outside surface of the body. Familiar examples of exocrine glands include the sweat glands and salivary glands. Most of the mass of the pancreas consists of exocrine cells. The secretions of the exocrine pancreas empty into the small intestine, where they aid digestion.

The nonexocrine portion of the pancreas consists of endocrine cells that produce polypeptide hormones. Spherical clusters of endocrine cells called **islets of Langerhans** are scattered in large numbers throughout the pancreas. Within the islets are alpha cells, which make **glucagon**, and beta cells, which make **insulin**. The actions of these two hormones are antagonistic with respect to each other—insulin decreases and glucagon increases blood glucose concentrations.

Maintaining homeostatic concentrations of glucose and other nutrients in the blood is a vital process that keeps cells functioning optimally. When an animal has not eaten for some time, its energy stores become depleted, and the blood glucose concentration decreases. Under these conditions, glucagon is secreted into the blood, where it acts on the liver to stimulate glycogenolysis within seconds (**Figure 50.8**, right side). A second action of glucagon on the liver is important for responses to prolonged fasting. In that case, glucagon stimulates gluconeogenesis. Due to the combined actions of cortisol, epinephrine, and glucagon, the concentration of glucose in the blood of a fasting animal is prevented from decreasing significantly below the normal homeostatic range.

Hormonal Changes After a Meal In contrast to fasting, after an animal eats a meal, the concentrations of glucose and other nutrients in the blood become elevated. Restoring the normal blood concentrations of glucose, fats, and amino acids is almost exclusively under the control of insulin, one of the few hormones that are absolutely essential

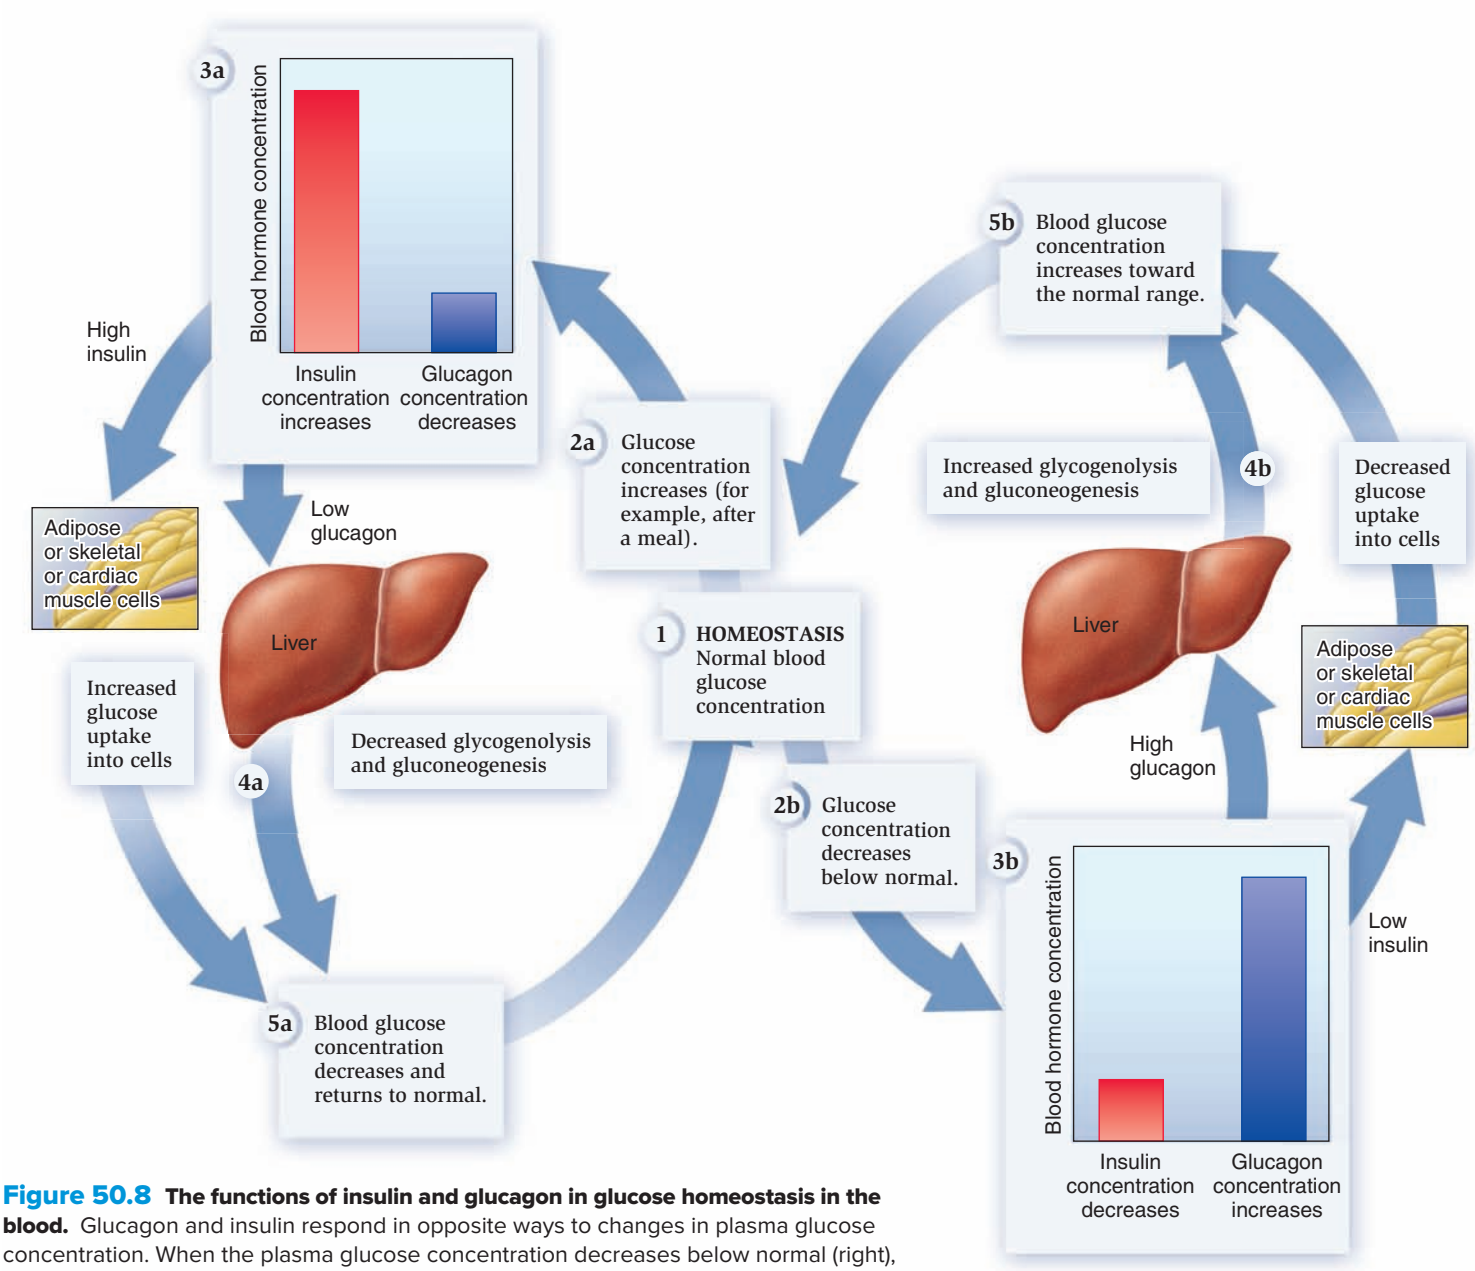

Figure 50.8 The functions of insulin and glucagon in glucose homeostasis in the blood. Glucagon and insulin respond in opposite ways to changes in plasma glucose concentration. When the plasma glucose concentration decreases below normal (right), the insulin concentration decreases, and glucagon increases. When the plasma glucose concentration increases above normal (left), the insulin concentration increases, and glucagon decreases. Both of these mechanisms return the plasma glucose concentration to normal. In addition, through their action on the liver, hormones from the adrenal medulla and adrenal cortex play significant roles in elevating glucose concentration (not shown).

for survival in animals. The secretion of insulin is directly stimulated by an increased concentration of glucose in the blood (Figure 50.8, left side). Once in the blood, insulin acts on plasma membrane receptors located primarily in cells of adipose and skeletal and cardiac muscle tissues to facilitate the transport of glucose across the plasma membrane into the cytosol. Once in the cell, glucose is metabolized for cellular functions or converted to stored energy forms such as fat. As discussed in Chapter 46, the process of glucose transport involves the actions of proteins called glucose transporters (GLUTs; refer back to Figure 46.3). These proteins are located in cytosolic membrane-bound vesicles. The major function of insulin is to stimulate fusion of the vesicles with the plasma membrane. Once a vesicle with its GLUTs fuses with the plasma membrane, the GLUTs begin transporting glucose from the extracellular fluid into the cell.

When the blood glucose concentration returns to normal, the stimulus for insulin secretion disappears, and the insulin concentration in the blood decreases. This results in a decrease in the number of GLUTs in plasma membranes, because the GLUTs are subjected to endocytosis and thereby return to membrane vesicles in the cytosol. The actions of insulin are not limited to glucose transport, however, because the hormone also stimulates transport of amino acids into cells and promotes fat deposition in adipose tissue.

In the absence of sufficient insulin, as occurs in the disease **type 1 diabetes mellitus (T1DM)**, less extracellular glucose can cross plasma membranes, and consequently, glucose accumulates to a very high concentration in the blood. T1DM occurs in many mammals and other vertebrates. It is caused when the body's immune system mistakenly attacks and destroys the insulin-producing cells of the islets of Langerhans. One consequence of the disease is that muscle and adipose cells cannot receive the normal amount of glucose to provide the ATP they require. In addition, the unusually large amount of glucose in the blood overwhelms the kidneys' ability to reabsorb it from the kidney filtrate, and glucose appears in the urine. Fortunately, this form of the disease is treatable with regular monitoring of blood glucose concentration and daily administration of insulin.

In humans, the more common form of diabetes, which accounts for roughly 90–95% of all cases (estimates range between 15 and 20 million people in the U.S. alone), is **type 2 diabetes mellitus (T2DM)**. In T2DM, the pancreas may function relatively normally and is not attacked by the immune system. However, the cells of the body lose much of their ability to respond to insulin for reasons that are still unclear. T2DM is linked to obesity and can often be prevented or reversed with weight control. Drugs are also available that improve the ability of cells to respond to insulin. Formerly, T2DM was known as adult-onset diabetes, because it usually appeared in middle age. This name is no longer used, because the rising tide of childhood obesity in developed countries like the U.S. has sparked a dramatic increase in the number of young people with the disease.

The discovery of insulin and its application to the human condition was one of the greatest and most influential achievements in the history of medical research, as described next.

Feature Investigation | Banting, Best, MacLeod, and Collip Were the First to Isolate Active Insulin

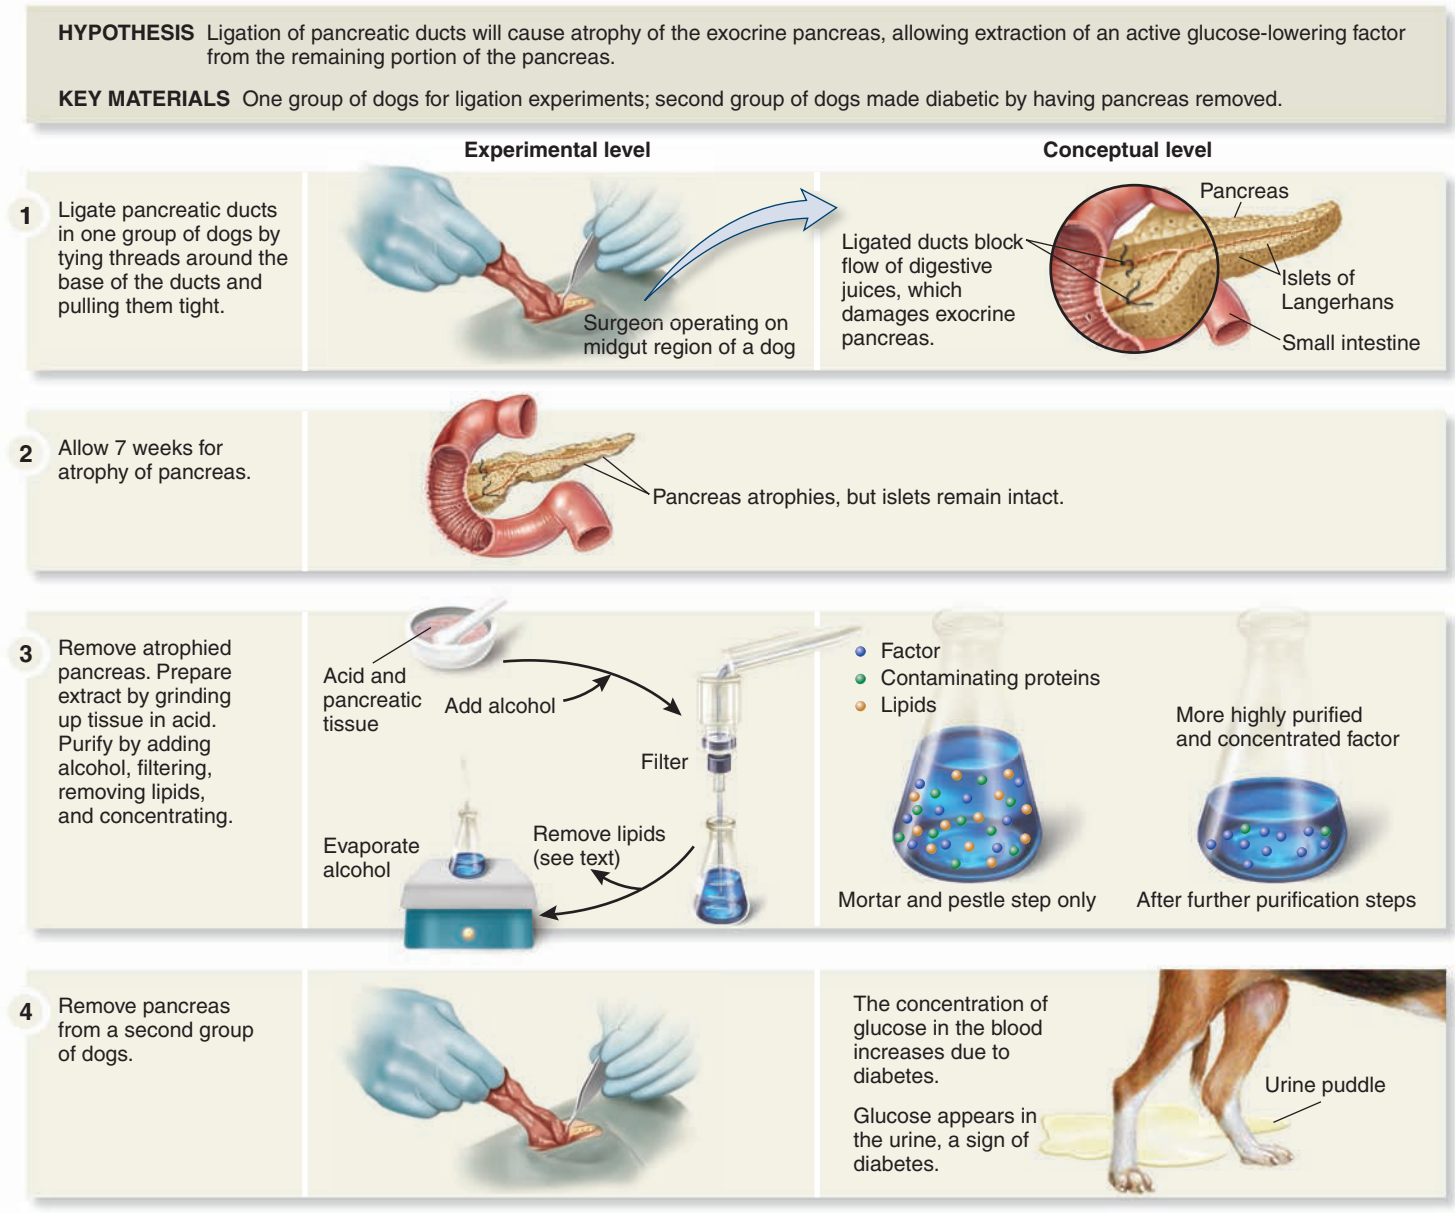
In the 19th century, scientists discovered that in addition to the exocrine part of the pancreas, the organ contains spherical clusters of cells that are not associated with its exocrine digestive functions. These clusters were called islets by their discoverer, German physiologist Paul Langerhans. By the early 20th century, German scientists had discovered that in dogs, complete removal of the pancreas resulted immediately in diabetes. Researchers assumed, therefore, that cells of the islets of Langerhans produced a factor of some kind that prevented diabetes—in other words, it helped maintain glucose homeostasis by preventing the blood glucose concentration from increasing uncontrollably. The factor, however, proved impossible to isolate using the chemical purification methods available at the time. Researchers assumed that during the process of grinding up a pancreas to produce an extract, the factor was destroyed by the digestive enzymes of the exocrine pancreas.

This problem was eventually solved in 1921 by a team of Canadian scientists working at the University of Toronto: surgeon Frederick Banting, medical student Charles Best, and biochemist James Bertram Collip. The work was performed in the laboratory of John MacLeod, a renowned expert in carbohydrate metabolism at the time. Banting had read a paper in a medical journal that described a deceased patient in whom the pancreatic duct, which carries digestive juices to the small intestine, had become clogged due to calcium deposits. The closed duct caused pressure to build up behind the blockage, which eventually caused the exocrine part of the pancreas to atrophy and die. The islets of Langerhans, however, survived intact. Banting hypothesized that if he were to tie off, or ligate, the pancreatic ducts of an animal, and then wait a sufficient time for the exocrine pancreas to die, he could more easily obtain an active glucose-lowering factor from the remaining islets without the problem of contamination by digestive enzymes.

Banting and Best proceeded to ligate the pancreatic ducts of several dogs, as shown in **Figure 50.9**. After waiting 7 weeks, an amount of time they previously had determined was sufficient for the exocrine part of the pancreas to atrophy, they prepared extracts of the remaining parts of the pancreas, including its islets of Langerhans. This was done by removing the atrophied pancreas from each dog and grinding it up with a mortar and pestle in an acid solution. The extract was then injected into a second group of dogs in which diabetes had previously been induced by surgically removing the pancreas. The researchers discovered that the extract was capable of keeping the diabetic dogs alive for a brief time. However, they were unable to isolate sufficient quantities of the active factor in the extract to keep the experiments going longer than a day or so, nor were they able to obtain sufficiently pure factor to prevent side effects such as infection and fever.

This is where Collip's expertise came in. Collip developed a method to precipitate contaminating proteins from the extract by adding alcohol to the acid (step 3, Figure 50.9). Different proteins will precipitate from a solution in response to different concentrations of alcohol. Using a concentration too low to cause the active factor to precipitate, Collip was able to remove most of the contaminating proteins, leaving behind a much more purified and safer extract. The extract was then filtered to remove debris and further extracted to remove lipids. In this step, a hydrophobic solvent was added to the partially purified extract; the lipids in the extract dissolved in the solvent, which could then be decanted and removed. This was done because the researchers correctly believed that the factor was a small protein and that by removing lipids, they would obtain a more purified preparation. Finally, the purified extract was concentrated by evaporating the alcohol, which increased its potency. When increasing amounts of this purified factor were injected into a second group of diabetic dogs, their blood glucose concentrations decreased and even returned to normal, and there was no longer any glucose in their urine. Diabetic dogs that received only a control solution that did not contain the factor continued to show a high glucose concentration in the blood and urine, compared with healthy controls.

In later experiments, two subsequent innovations enabled the researchers to obtain larger amounts of the factor and more accurately assess its potency without using the ligation procedure. First, the researchers chose the very large pancreases of cows, obtained at a local slaughterhouse, for the starting material from which to prepare the extracts. Second, Collip developed a highly sensitive assay to



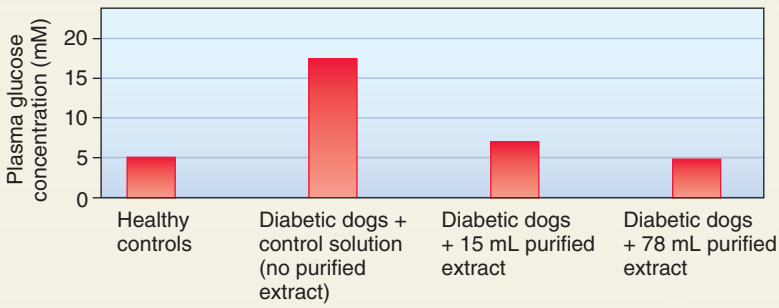
more precisely measure the concentration of glucose in the blood of an animal before and after injection of the purified factor. The combination of the improved chemical purification steps, large amounts of starting material, and improved assays for testing the extract proved to be the keys that enabled the team to test the factor, which they eventually named insulin, on human patients. The first successful test came in 1922 on a 14-year-old boy in Toronto, who was seriously ill from T1DM. The success of the team in rapidly isolating insulin and proving its effectiveness was so significant that Banting and MacLeod were awarded the 1923 Nobel Prize in Medicine or Physiology. The Nobel committee felt that Banting and MacLeod were the leaders of the project and that it was they who deserved the prize, but the two scientists disagreed. Banting shared the monetary portion of his award with Best, and MacLeod shared his with Collip.

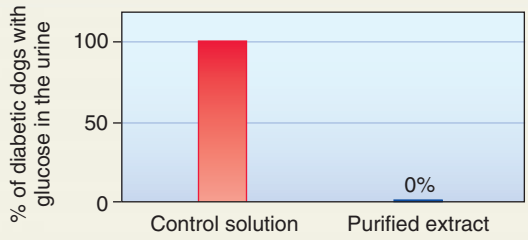
Experimental Questions

1. How did Banting and Best propose to obtain the glucose-lowering factor produced by the pancreas?
2. What was Collip's contribution to the isolation of insulin?
3. **SciSKILLS** » Propose an explanation for why glucose appears in the urine of untreated diabetic animals or humans.

Figure 50.9 The isolation of insulin by Banting, Best, MacLeod, and Collip.

BIOLOGY PRINCIPLE Biology affects our society. The discovery of insulin and the methods to manufacture it in large amounts has improved (and in many cases, saved) the lives of many millions of people. Today, dozens of human diseases, including diabetes, are treatable with the use of hormones.





5 Inject either purified extract or control solution into the diabetic dogs. Determine the levels of glucose in the blood and in the urine.

The control solution contained all of the chemicals used to prepare the extract, but did not include any material from a pancreas.

6 THE DATA

7 CONCLUSION Atrophy of the exocrine portion of the pancreas eliminated digestive enzymes that would have degraded the glucose-lowering factor (insulin) during its purification from the pancreas. Insulin was effective in reversing the major symptoms of diabetes in dogs.

Adipose Tissue Secretes the Hormone Leptin, Which Regulates Appetite

Hormones also contribute to energy balance by exerting effects on appetite and, as a consequence, on food consumption. As you might imagine from its importance as the body's major storage site for energy-yielding fat, a chief source of appetite-regulating hormones is adipose tissue. One such hormone introduced in Chapter 46 is the protein leptin, which has been observed in all vertebrate classes. Leptin is released by adipose cells into the blood in direct proportion to the amount of adipose tissue in the body, and it acts on the hypothalamus to reduce appetite and increase metabolic rate (refer back to Figure 46.7). When adipose stores are low, however, leptin secretion from adipose cells decreases, resulting in a decreased blood concentration of leptin. This removes the inhibitory effect of leptin on appetite, resulting in an increase in appetite and increased food consumption by the animal, along with a decrease in metabolic rate. In these ways, the amount of energy stored in an animal's body in the form of fat is communicated to the brain via leptin to regulate how hungry an animal feels.

We have seen that hormones influence energy homeostasis by regulating nutrient concentrations in the blood, transport of nutrients into cells, metabolic rate, and appetite. In the next section, we will consider how hormones control another feature of homeostasis, regulating concentrations of key minerals in the blood.

50.4 Hormonal Control of Mineral Balance

Learning Outcomes:

1. Describe the hormonal control of Ca^{2+} homeostasis.
2. Explain the regulation in the kidneys of Na^+ and K^+ balance by antidiuretic hormone, aldosterone, and atrial natriuretic factor.

All animals must maintain a proper balance of minerals such as calcium (Ca^{2+}), sodium (Na^+), and potassium (K^+) in their cells and extracellular fluids. These ions participate in numerous functions common throughout much of the animal kingdom. For example, the partitioning of ions across plasma membranes determines in large part the electrical properties of neurons. In this section, we will see how maintaining a homeostatic balance of these ions in an animal's body is coordinated in large part by hormones.

Vitamin D and Parathyroid Hormone Regulate Ca^{2+} Concentration in the Blood

Calcium ions have critical roles in neuronal transmission, heart function, muscle contraction, and numerous other events. Therefore, the concentration of Ca^{2+} in the blood is among the most tightly regulated variables in an animal's body.

1,25-Dihydroxyvitamin D Calcium is obtained from the diet and absorbed through the small intestine. Like all charged molecules, Ca^{2+} cannot readily cross plasma membranes, including those of the epithelial cells of the small intestine, and thus its transport must be regulated. This process is controlled by the action of a derivative of **vitamin D**. In most mammals that receive regular exposure to the Sun, skin cells produce vitamin D from a precursor called 7-dehydrocholesterol, a reaction that requires the energy of UV light (**Figure 50.10**). In addition, many animals obtain vitamin D from food, and people may obtain the vitamin from milk and other foods to which it has been added as a supplement. This is especially important for people who live at latitudes that receive little sunlight for much or part of the year.

Before it can act, vitamin D must first be modified by two enzymes that each add one hydroxyl group to specific carbon atoms, first in the liver and then in the kidney. The final active product is called 1,25-dihydroxyvitamin D. This molecule is a hormone because it is secreted into the blood by one organ—the kidneys—and then circulates in the blood and acts on a distant target tissue—the small intestine. The major function of 1,25-dihydroxyvitamin D in the intestine is to activate expression of a Ca^{2+} active transporter in the intestinal epithelium, thereby stimulating the absorption of Ca^{2+}. The Ca^{2+} then enters the blood, from where the ions are delivered to tissues for such activities as building bone and maintaining nerve, muscle, and heart functions. If the active form of vitamin D is not present in the blood, the bones lose Ca^{2+} and become weakened. In children, this results in the weight-bearing bones of the legs becoming deformed, a condition called rickets.

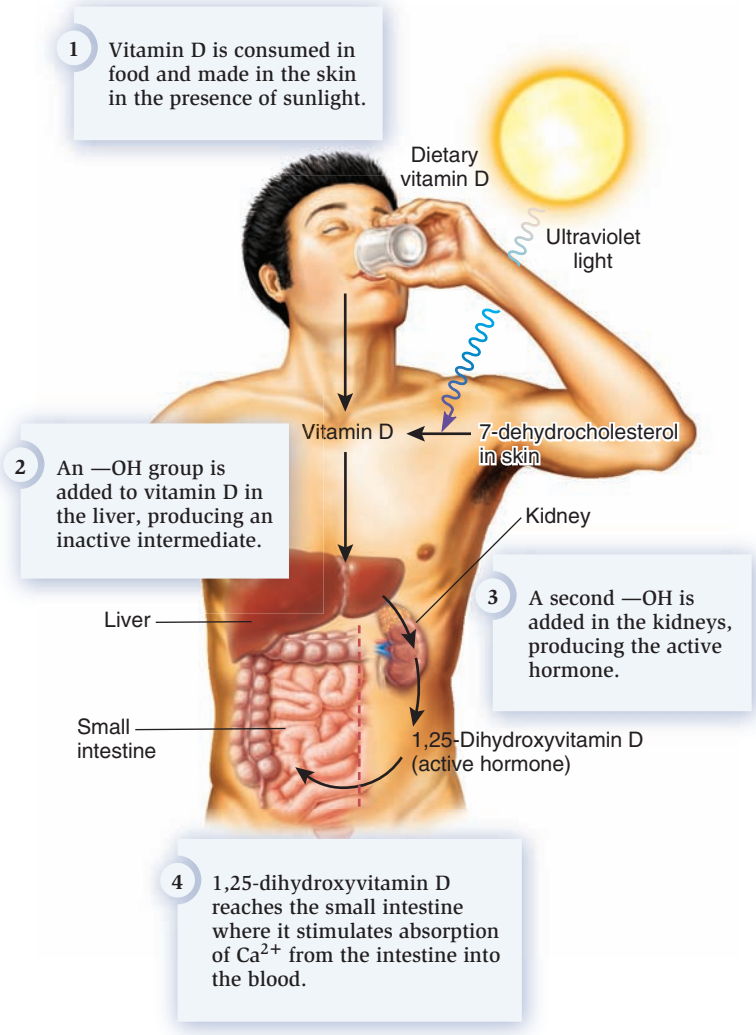

Figure 50.10 Synthesis of the active hormone formed from vitamin D or its precursor in the skin.

Concept Check: Would you predict that all mammals synthesize the active form of vitamin D using the energy of sunlight?

Parathyroid Hormone Even when Ca^{2+} is not present in the diet, or when 1,25-dihydroxyvitamin D is not formed in normal amounts because of insufficient exposure to sunlight, the blood concentration of Ca^{2+} does not normally decrease significantly, because of a hormone called **parathyroid hormone (PTH)**. This hormone is secreted from several small glands called parathyroid glands, which in humans are located behind the thyroid gland (**Figure 50.11a**). A decrease in the blood concentration of Ca^{2+} stimulates the cells of the parathyroid glands to secrete more PTH. PTH acts on bone to stimulate the activity of cells that dissolve the mineral part of bone. This releases Ca^{2+}, which then enters the blood (**Figure 50.11b**). Typically, only a very small fraction of the total Ca^{2+} in bone is removed in this way. Therefore, besides providing a skeletal framework for the vertebrate body, bone also serves as an important reservoir of Ca^{2+}. PTH also acts to increase reabsorption of Ca^{2+} from the filtrate in the kidneys, so less Ca^{2+} is excreted in the urine. If the blood Ca^{2+} concentration increases, PTH secretion is inhibited. Without PTH, Ca^{2+} homeostasis is not possible. The complete absence of PTH is fatal in humans and other mammals.

Calcitonin In addition to 1,25-dihydroxyvitamin D and PTH, another hormone called **calcitonin** functions in Ca^{2+} homeostasis in some vertebrates, notably fishes and possibly some mammals. Calcitonin is a polypeptide produced in and secreted from cells in the thyroid gland. Its function is the opposite in many respects to that of PTH. Calcitonin promotes excretion of Ca^{2+} via the kidneys and deposition of Ca^{2+} into bone, thereby decreasing blood Ca^{2+} concentrations. This is especially important in marine fishes, because of the high Ca^{2+} content of seawater and the entry of this ion into the body fluids of the animals when they drink (refer back to Figure 49.2).

BIO TIPS

THE QUESTION *What might happen to the blood concentrations of Ca^{2+} and parathyroid hormone (PTH) if the kidney enzyme responsible for the formation of 1,25-dihydroxyvitamin D was absent, nonfunctional, or inhibited for some reason?*

TOPIC ***What topic in biology does this question address?***

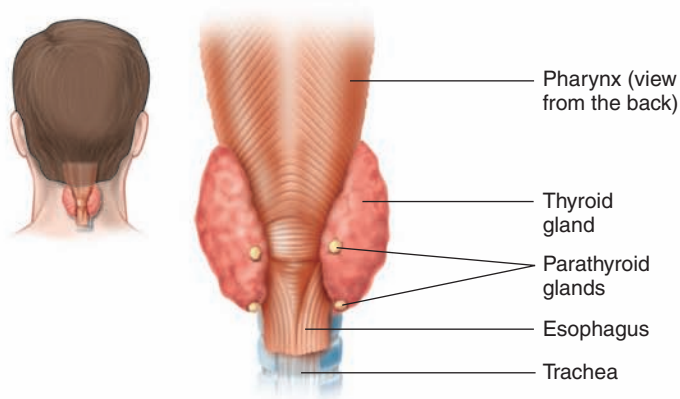
The topic is the relationship between the blood concentrations of Ca^{2+} and two hormones that are known to help regulate Ca^{2+} homeostasis. Specifically, how does a change in the amount of one hormone affect the blood concentrations of the other and of Ca^{2+}?

INFORMATION ***What information do you know based on the question and your understanding of the topic?***

From the question, you know that 1,25-dihydroxyvitamin D is not being produced in normal amounts. From your understanding of the topic, you may remember that this hormone acts in the small intestine to stimulate absorption of Ca^{2+} into the blood. You also know the function of PTH and that its secretion is controlled by the blood concentration of Ca^{2+}.

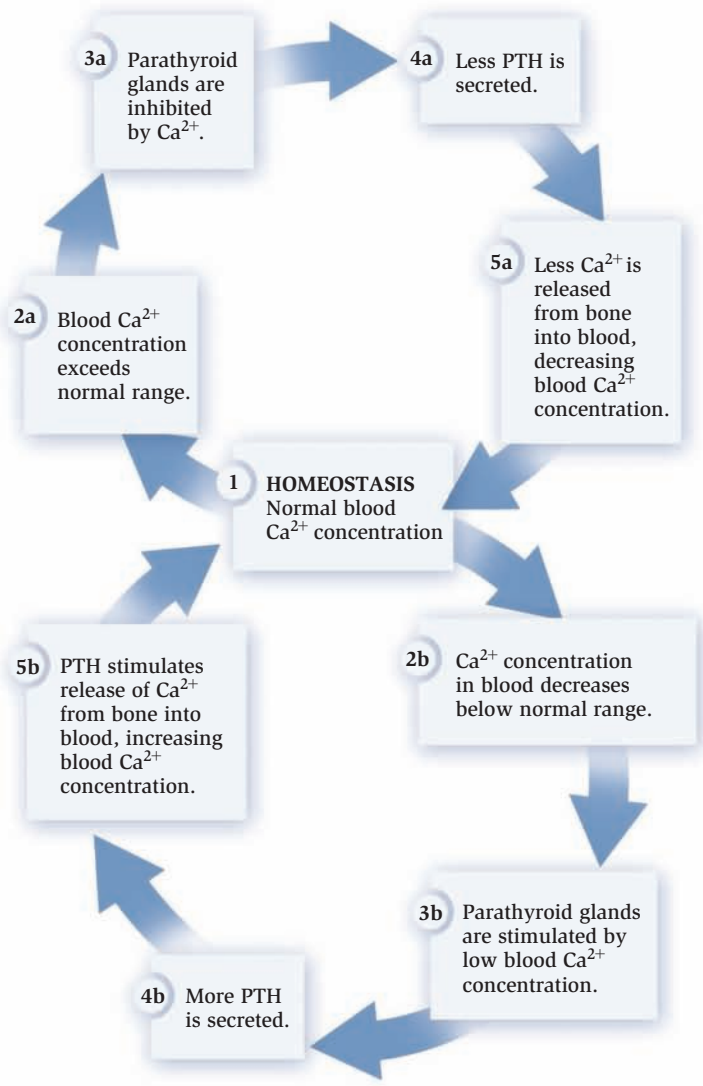
PROBLEM-SOLVING STRATEGY ***Predict the outcome.***

Based on your knowledge of the relationships among the blood concentrations of Ca^{2+}, 1,25-dihydroxyvitamin D, and PTH, you can predict the sequence of events that will follow a decrease in the concentration of 1,25-dihydroxyvitamin D.



ANSWER *The sequence of events is as follows:*

1. *If the blood concentration of 1,25-dihydroxyvitamin D is decreased, the ability to absorb Ca^{2+} from the intestine will be decreased.*
2. *This will lead to a decreased blood concentration of Ca^{2+} as most of the dietary calcium will not get absorbed.*
3. *A decrease in blood concentration of Ca^{2+} will trigger an increase in the secretion of PTH from the parathyroid glands.*
4. *PTH, in turn, will act on bone to resorb some Ca^{2+} that will then enter the blood and help to prevent the Ca^{2+} concentration from decreasing further.*



Several Hormones Regulate the Extracellular Fluid Concentrations of Na^+ and K^+ in Vertebrates

Like Ca^{2+}, concentrations of Na^+ and K^+ in the body fluids of most animals are tightly regulated, because these ions play crucial roles in membrane potential formation and action potential generation (see Chapter 41), among other functions. Like Ca^{2+}, Na^+ and $K^+$are ingested in the diet and excreted in the urine at rates that maintain homeostatic concentrations in the body fluids. Unlike Ca^{2+} in vertebrates, however, no large reservoirs exist in the body for Na^+ and K^+. One of the key mechanisms that regulates the concentrations of these ions in the blood is altering the rate of Na^+, K^+, and water reabsorption from the urine as it is being formed in the kidneys. This is accomplished in large part by the actions of three hormones: ADH, aldosterone, and atrial natriuretic peptide (**Figure 50.12**). All three of these hormones exert their effects on the kidneys.

The vertebrate kidney normally reabsorbs most Na^+ and K^+ from the fluid filtered through the glomeruli (refer back to Figures 49.13 and 49.14). However, dietary and other changes can alter the concentrations of these ions in the blood. When this happens, the kidney works to restore the ions to their normal concentrations. For example, if the blood Na^+ concentration increases above normal, the osmolarity of the blood will increase. Osmoreceptors in the brain detect this and stimulate ADH secretion from the posterior pituitary. As mentioned earlier, ADH acts on the kidney to reabsorb water from the forming urine. By increasing the amount of ADH available to act on the kidneys, less water is excreted in the urine (and more is reabsorbed into the blood). In addition, the synthesis and secretion of the adrenal steroid hormone **aldosterone** are directly inhibited in response to an increase

(a) Location of the parathyroid glands

(b) Homeostatic control of blood Ca^{2+} concentration

Figure 50.11 The role of parathyroid hormone in calcium homeostasis. **(a)** The four small parathyroid glands are located behind the thyroid. **(b)** The action of PTH: Steps 2a–5a occur when Ca^{2+} is in excess; steps 2b–5b occur when Ca^{2+} is below normal.

BIOLOGY PRINCIPLE **Living organisms maintain homeostasis.** Homeostatic control of Ca^{2+} concentration is vitally important to life in most living organisms, and in all animals. Because of hormones like PTH, the Ca^{2+} concentration in the body fluids of humans rarely changes more than slightly.

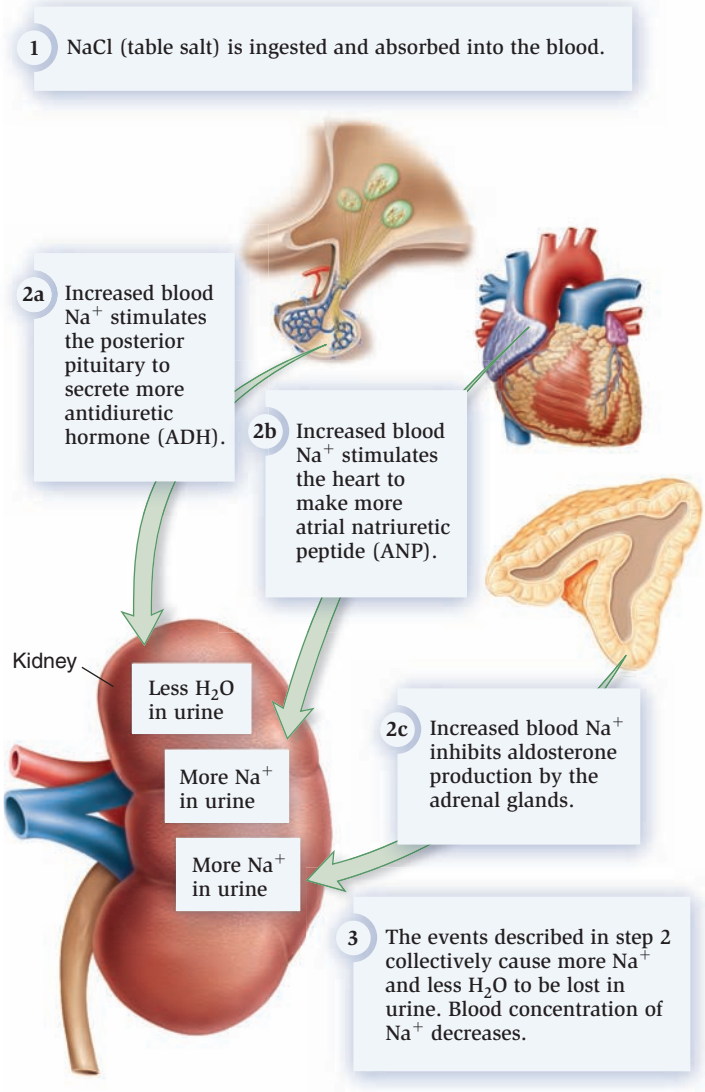


Figure 50.12 An example of Na^+ balance achieved by the coordinated actions of three hormones.

Concept Check: *Given the importance of these ions in numerous aspects of animal biology, is it surprising that there is more than one hormone that regulates Na^+ and K^+ balance?*

in Na^+concentration. Normally, aldosterone increases Na^+ reabsorption in the kidney, and therefore, its absence results in more Na^+ excretion in the urine. Last, **atrial natriuretic peptide (ANP)** is secreted from the atria of the heart whenever the blood concentration of Na^+ increases. ANP causes a natriuresis (a loss of Na^+ in the urine; from the neo-Latin *natrium*, meaning sodium) by decreasing Na^+ reabsorption. Thus, ANP and aldosterone have opposite effects on Na^+ balance in the body, which is why their concentrations in the blood tend to change in opposite directions. The combined effect of decreasing water loss in the urine and reabsorbing less Na^+ is to decrease the concentration of Na^+ in blood and other body fluids, returning its concentration to normal.

Aldosterone is a steroid hormone. Its structure is similar to, but distinct from, all the other steroid hormones (refer back to Figure 50.2). Their similarities have enabled biologists to use steroid hormones as models for understanding how hormones and their receptors may have coevolved, as described next.

Genomes & Proteomes Connection

Hormones and Receptors Evolved as Tightly Integrated Molecular Systems

We have learned that hormones act in all cases by binding to receptor proteins located on the cell surface or in the cytosol or nucleus. This raises an intriguing question: Which evolved first, a given hormone or its receptor? There would appear to be no selection pressure to evolve one without the other. Without a receptor, a hormone has no function, and without a hormone, the receptor has no function. Hormones and their receptors function as tightly integrated molecular systems. Each molecule requires the other for biological activity. How such systems could have evolved, or whether they evolved together, has long been a major puzzle. However, recent research has generated intriguing new hypotheses regarding the evolution of these signaling systems.

American biologist and environmental scientist Joseph Thornton and colleagues tackled this puzzle by examining how two structurally related steroid hormones evolved separate activities and distinct receptors. Aldosterone, as noted, is a steroid hormone made by the adrenal cortex. Because it regulates the balance of two minerals (Na^+ and K^+) in the body, it is known as a mineralocorticoid. Cortisol is another steroid hormone made by the adrenal cortex and is known as a glucocorticoid because one of its major functions is to regulate glucose balance. The actions of these hormones are mediated by intracellular receptors known as the mineralocorticoid receptor (MR) and the glucocorticoid receptor (GR), respectively. Phylogenetic analysis of the gene sequences that code for these two receptors suggests that they arose at least 450 mya, after the evolution of the first vertebrates, by duplication of an ancient corticoid receptor (CR) gene.

The researchers analyzed the known sequences of the genes for the MR and GR of many vertebrate species, including the most ancient vertebrates, to deduce a theoretical sequence of an ancestral CR. They then synthesized this CR and tested its ability to bind aldosterone and cortisol. They discovered that the CR was capable of binding both hormones, particularly aldosterone. This was surprising, because aldosterone is only present in tetrapods, which arose around 300 mya, long after the proposed gene duplication event that created the MR. Therefore, it appears that a receptor with high affinity for aldosterone was present long before animals acquired the capacity to synthesize aldosterone. The receptor seems to have evolved to bind other steroids. Around 450 mya, the gene for the CR duplicated, and then the two resulting genes seem to have further mutated such that one receptor gained high affinity primarily for mineralocorticoids and the other for glucocorticoids.

These studies suggest that the ability of an animal to respond to aldosterone evolved long before aldosterone did, because a receptor with high affinity was already in place in animals. When aldosterone evolved in tetrapods, it was able to use the MR derivative of the ancestral CR. In this example, the answer to "which came first?" appears to be that the receptor evolved first and the hormone later.

50.5 Hormonal Control of Growth and Development

Learning Outcomes:

1. List and describe the function of the polypeptide hormones involved in the regulation of growth and development in vertebrates.
2. Identify the functions of the three major hormones that control growth and development in insects.

Hormones play a nearly universal role in controlling growth and development in animals. Growth can occur slowly over long periods or in brief spurts, with some animals exhibiting both types of growth. Many mammals, for example, grow slowly but steadily until puberty, then experience a period of rapid growth, followed by slower rates of growth, and finally cessation of growth. Many insects, however, grow and develop in spurts during molting periods. Although growth is determined by many factors, notably adequate nutrition, it is regulated in large part by the endocrine system.

Growth is distinguished from development, which is the process by which cells form tissues with specific functions, and tissues develop into larger and more complex structures. In this section, we will examine how both processes depend in part on the endocrine system.

Vertebrates Require a Balance of Several Hormones for Normal Growth

Several hormones stimulate growth in vertebrates. The anterior pituitary gland produces **growth hormone (GH)**, which is under the control of the hypothalamus (see Table 50.2). GH acts on the liver to produce another hormone, called **insulin-like growth factor-1 (IGF-1)**. In mammals, IGF-1 stimulates the elongation of bones, especially during puberty, when mammals become reproductively mature. This growth is further accelerated by the steroid hormones of the gonads, leading to the rapid pubertal growth spurt. Eventually, however, the gonadal hormones cause the growth regions of bone to seal, preventing any further bone elongation.

GH, IGF-1, and gonadal steroid hormones continue to be produced in adult vertebrates—including humans—even though growth has ceased. In adulthood, GH serves metabolic functions, such as helping to regulate the concentrations of glucose and fatty acids in the blood. The gonadal steroids are important for reproduction in adults (see Chapter 51).

In rare cases, a tumor of the GH-secreting cells of the anterior pituitary gland produces excess GH. If this occurs during childhood, a person with this disorder can grow exceedingly tall and is known as a **pituitary giant**. Soon after puberty, growth stops. If a tumor causes a high GH concentration after puberty, the excess GH causes many bones, such as those of the face, hands and feet, to thicken and enlarge, a condition known as **acromegaly** (Figure 50.13). People with acromegaly are generally treated with a synthetic form of somatostatin, which is the inhibitor of GH made by the hypothalamus (see Table 50.2). In many cases, however, the tumor must be surgically removed.

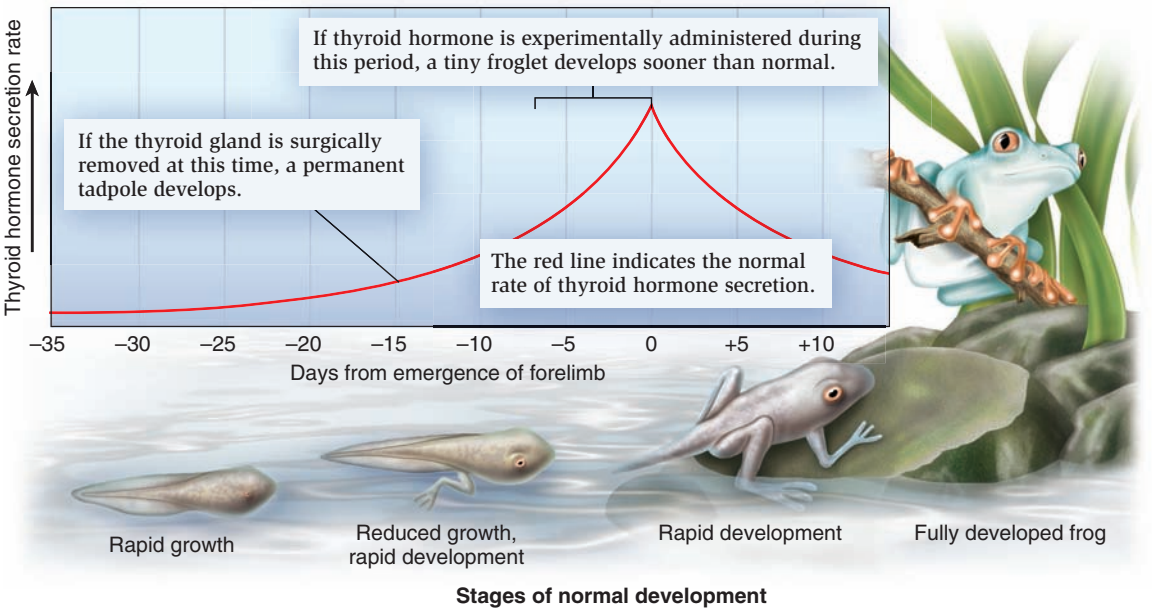

Figure 50.13 Acromegaly in one individual from a pair of identical twins. This disease is caused by a high concentration of growth hormone and insulin-like growth factor-1, which leads to increased height and enlarged bones including those of the skull, hands, and feet.

Concept Check: Did the individual on the left develop a growth hormone disorder before or after puberty?

By contrast, if the pituitary fails to make adequate amounts of GH during childhood, the concentrations of GH and IGF-1 in the blood will be lower than normal. In such cases, growth is stunted, resulting in one of the many possible causes of **short stature**. Individuals with this condition can be treated with injections of recombinant human GH and will grow to relatively normal height, as long as treatment begins before puberty is completed, so that the bones can still elongate.

Hormones are also required during fetal life, not for growth but for development of the brain, lungs, and other organs into fully mature, functional structures. For example, cortisol from the fetal adrenal gland is vital for proper lung formation. Premature babies born before the adrenal glands have matured have lungs that are not capable of expanding normally; such babies require hospitalization to survive (refer back to Figure 48.12 for details about the treatment for respiratory distress syndrome in newborns).

As another example, thyroid hormone influences development among all vertebrates. In amphibians, thyroid hormone has a critical function in metamorphosis, notably in tadpoles, where it promotes the resorption of the tail and development of the legs (Figure 50.14a). This effect can be dramatically demonstrated by experimentally decreasing or increasing a tadpole's thyroid hormone concentration, which results respectively in a tadpole that does not transform into a frog or in a tadpole in which metamorphosis occurs sooner than normal, resulting in a tiny frog. In fishes, thyroid hormone has an equally critical function in development. For example, among species of flatfish such as flounder that live on the ocean floor, thyroid hormone is responsible for the characteristic change in appearance that occurs in these species as they settle into a sedentary existence on the ocean

(a) The effect of thyroid hormones on tadpole development

(b) Japanese flounder

Figure 50.14 Effects of thyroid hormone on animal development. **(a)** Experimental manipulation of thyroid hormone concentrations can slow down or accelerate development of tadpoles. **(b)** The eyes of a bottom-dwelling flounder (*Platichthys flesus*) migrate to one side of the head during development, partly in response to thyroid hormone.

bottom. The fins and gill covers migrate to the dorsal surface facing the water; the dorsal body surface becomes pigmented; and, most remarkably, the eyes migrate to the same side of the head so that one eye is not unused on the side facing the ocean floor (**Figure 50.14b**). Each of these metamorphic events is under the direct control of thyroid hormone.

Invertebrates Grow and Develop in Spurts Under the Control of Three Major Hormones

Like vertebrate endocrine pathways, hormonal control systems in insects and other invertebrates often involve multiple glands and neural structures acting in concert. In insects, for example, the endocrine system is critical for the growth and development of larvae and their eventual development into pupae (**Figure 50.15**). In the case of larval growth and metamorphosis, specialized neurosecretory cells in the brain periodically secrete a hormone called **prothoracicotropic hormone (PTTH)**, which then stimulates a pair of endocrine glands called the prothoracic glands. These glands, located in the thorax, synthesize and secrete into the hemolymph a steroid hormone called **20-hydroxyecdysone**. This hormone is secreted only periodically. In response to each burst of secretion, the larva undergoes a rapid development and molts (sheds its cuticle). It then begins a new developmental period until it molts again in response to another episode of secretion. The molting process is known as ecdysis, from which the name of the hormone is derived (refer back to Figure 32.12).

Throughout larval development, paired neurosecretory structures behind the brain, called the corpus allata, secrete another hormone, a protein called **juvenile hormone (JH)**. JH determines the character of

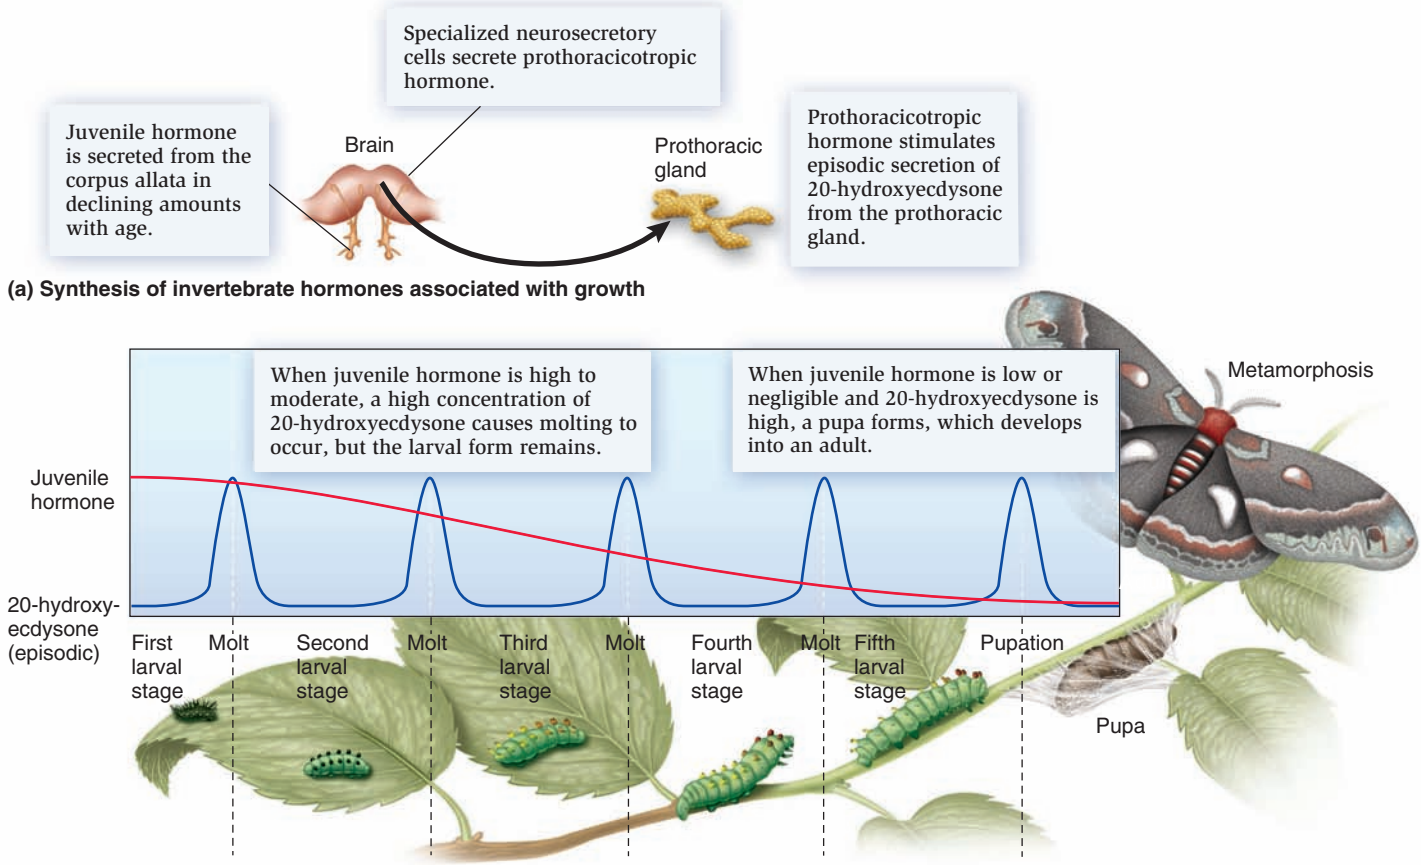

Figure 50.15 Hormonal control of insect development. Development of insects requires the coordinated actions of three hormones. Note: The relative concentrations and patterns of 20-hydroxyecdysone and juvenile hormone in this figure are schematic and not representative of all insects.

Concept Check: *In what part of a cell do you predict the receptor for the steroid 20-hydroxyecdysone is located?*

the molt that is induced by 20-hydroxyecdysone, by acting to prevent metamorphosis into an adult (hence the name juvenile, which reflects the fact that JH fosters the larval stage). As the larva ages, however, the amount of JH it produces gradually declines until the concentration is nearly zero. During this time, 20-hydroxyecdysone continues to be periodically secreted. The decline in JH below a certain concentration results in the transition from larva to pupa in response to a burst of 20-hydroxyecdysone; the near absence of JH is a prerequisite for the final step of metamorphosis into an adult.

50.6 Hormonal Control of Reproduction

Learning Outcomes:

1. List the male and female sex steroids, their sites of production, and their functions in reproductive development.
2. **SciSKILLS** » Propose a mechanism by which hormones can link nutrition with reproduction.

The topic of reproduction is covered in detail in Chapter 51, but it is worth noting here that in all vertebrates and probably most invertebrates, reproduction is closely linked with endocrine function. In this section, we will briefly discuss the most common reproductive hormones and some of their major actions in male and female animals.

The Gonads Secrete Sex Steroids That Influence Most Aspects of Reproduction

Hormones produced by the gonads of animals have vital functions in nearly all aspects of reproduction, from reproductive behaviors to the ability to produce offspring. In males, the gonads are called testes. They produce and house the gametes, called sperm cells. In addition, the testes produce several related steroid hormones collectively termed **androgens**. In many vertebrates, including humans, the primary androgen is **testosterone**. The gonads of females are called the ovaries, which contain the female gametes, or egg cells. Other cells within the ovaries secrete two major steroid hormones, **progesterone** and a family of related hormones called **estrogens**. The major estrogen in many animals, including humans, is **estradiol**. Collectively,

the male and female gonadal steroid hormones are referred to as the sex steroids.

The sex steroids are responsible for male- or female-specific reproductive changes associated with courtship and mating. In vertebrates, androgens from the developing testes are required for development of the male phenotype. Exposure of fetuses to abnormal concentrations of male or female hormones can lead to ambiguous phenotypes and sexual behavior after birth. Sex steroids are also chiefly responsible for development of secondary sex characteristics for each sex, which in humans include growth of the appropriate external genitals, growth of the breasts in women, development of facial hair in men, and distribution and amount of fat and muscle in the body. Finally, sex steroids are required for maturation of gametes, the transition of young animals to reproductive maturity, and the ability of females to produce young.

The ability of the testes and ovaries to produce sex steroids depends on the presence of the gonadotropins secreted by the anterior pituitary, which are the same in both sexes and include **follicle-stimulating hormone (FSH)** and **luteinizing hormone (LH)** (see Table 50.2). Therefore, identical anterior pituitary gland hormones control the gonads in both male and female animals.

Nutrition and Reproduction Are Linked Through Hormones

An interesting feature of the endocrine control of reproduction is the observation that puberty is delayed in mammals, including humans, that are very undernourished. Similarly, fertility—the ability to produce offspring—is reduced in women and other adult female mammals under such conditions. This makes sense, because supporting the nutritional demands of a growing fetus would be difficult without adequate nutrition and energy stores. In such a case, it is more advantageous for an animal to delay reproduction until sufficient food is available.

How does the brain of a female mammal determine when sufficient energy is stored in her body to support pregnancy? The answer appears to be partly the result of hormonal signals. For example, if the amount of fat in a woman's body decreases, so does the concentration of leptin in her blood, as described earlier. Leptin has been demonstrated to stimulate synthesis and secretion of reproductive hormones such as FSH and LH. Consequently, undernourishment that causes a decrease in leptin also results in decreased production of reproductive hormones, thereby contributing to a loss of fertility. Therefore, leptin acts as a link between adipose stores and the reproductive system.

50.7 Impact on Public Health

Learning Outcomes:

1. Name several hormones used therapeutically, and identify the disease or health problem for which they are prescribed.
2. **SciSKILLS** » Predict the risks associated with the misuse of hormones and with exposure to endocrine disruptors in the environment.

The list of endocrine-related diseases in the human population is lengthy, ranging from relatively common disorders such as diabetes and thyroid disease to rare ones that may affect only 1 in every 100,000 or more individuals. Hormones can be used to treat many of these diseases, but they can also be misused in ways that cause health problems. Also, the widespread industrial use of chemicals with hormone-like actions and their possible environmental consequences have become common topics of news reports. In this section, we will consider how hormones are used therapeutically as well as misused, and then look at an example of how environmental factors that alter the function of the human endocrine system can have important public health implications.

Hormones Are Used to Treat Millions of People

Since the advent of synthetic hormone production, doctors have been able to provide individuals with hormones that their own bodies may fail to produce. For example, millions of people self-administer insulin each day to treat diabetes or take thyroid hormone supplements to treat hypothyroidism. Many women take hormones to help induce pregnancy or control the symptoms of menopause. A growing number of men, too, are administered gonadal hormones if the levels produced by their bodies decline significantly in later life. Other examples include recombinant human growth hormone to treat abnormally short stature in prepubertal children, epinephrine inhalers to treat asthma, and glucocorticoids to treat inflammation, lung disease, and skin disorders, to name just a few.

Hormone Misuse Can Have Disastrous Consequences

As we saw at the beginning of this chapter, some individuals, typically those in competitive sports, self-administer hormones such as androgens. This practice may increase muscle mass and improve athletic performance. However, the price is steep. First, androgens exert negative feedback on FSH and LH secreted by the anterior pituitary gland. As a consequence, the anterior pituitary gland stops producing and secreting FSH and LH while the user is taking supplements containing androgens. In males, this causes the testes to shrink, as they no longer are making sperm, and the man becomes infertile; this is what happened to the young man described at the beginning of the chapter. Androgen administration has also been linked to extreme aggressive behavior, cardiovascular disease and heart attacks, skin problems, and certain cancers. Women using androgens face health risks similar to those men but, in addition, develop masculinizing traits, including increased growth of body hair and thinning scalp hair.

Another example of misuse occurs when a hormone is used to boost the number of erythrocytes in the circulation in order to increase the oxygen-carrying capacity of the blood (often called blood-doping). This has become common among athletes participating in long-distance aerobic activities, such as competitive cycling and cross-country skiing. The hormone used is **erythropoietin (EPO)**, which acts by stimulating the maturation of erythrocytes in the bone marrow and their release into the blood. EPO is normally made by the liver and kidneys as part of the homeostatic control of erythrocyte production. Its secretion is increased above normal in response to any situation where additional blood cells are required, such as following blood loss or when a person lives at high altitudes, where the oxygen

pressure is low. When EPO is used abusively, however, the number of erythrocytes can reach such a high level that the blood becomes much more viscous than normal. This puts a serious strain on the heart, which must work harder to pump the thickened blood. Since the 1990s, the international cycling community has been rocked by an alarming number of world-class European cyclists who died of heart attacks in the prime of their lives. These individuals had been using EPO to gain an unfair and, as it turns out, unwise advantage over their peers. Testing continues to detect injected EPO in the blood of some cyclists and other endurance athletes.

Synthetic Compounds May Act as Endocrine Disruptors

A recent and disturbing phenomenon is the growing amount of so-called **endocrine disruptors** found in lakes, streams, ocean water, and soil exposed to pollution runoff. These chemicals are derived in many cases from industrial waste and have molecular structures that in some cases resemble estrogen sufficiently to bind to estrogen receptors. They are also found naturally in certain plants (for example, soy) and are widespread in common household goods including nearly all plastic products. If these compounds make their way into drinking water or food, they can exert estrogen-like actions or inhibit the actions of the body's own estrogen. This can lead to dramatic consequences on fertility and on the development of embryos and fetuses. The extent of the risk from endocrine disruptors is hotly debated, but the number of mature, functional germ cells produced in animals as diverse as mollusks and human males has declined substantially during the past 50 years in the U.S. In addition, researchers throughout the world have noted feminization of freshwater fishes downstream of wastewater facilities. For example, male fishes that were exposed to such conditions during development show increased production of proteins normally made by females bearing eggs. They also show changes in gonadal structures that resemble the female appearance. Further research is being conducted to gain more information on the consequences of these contaminants for animal endocrine systems. The U.S. Environmental Protection Agency currently lists about 10,000 chemicals as recommended for screening or as already having been documented to exert endocrine disruptive actions. Other than reproductive hormones, the hormones that are most commonly affected by different types of endocrine disruptors are thyroid hormone and, to a lesser extent, glucocorticoids.

Summary of Key Concepts

50.1 Types of Hormones and Their Mechanisms of Action

- The endocrine glands and other organs with hormone-secreting cells constitute the endocrine system. Endocrine glands contain epithelial cells that secrete hormones into the bloodstream, where they circulate throughout the body. Although slower than the electrical signaling in nervous systems, chemical signaling complements nervous system regulation through its varying actions in multiple locations across widely ranging time frames (Figure 50.1).
- Hormones fall into three broad classes: amines, polypeptides and steroids. Water-soluble hormones (amines and polypeptides) act on receptor molecules located in the plasma membrane, whereas lipid-soluble hormones (steroids) act on intracellular receptors (Table 50.1).
- Synthesis of amine hormones is mediated by enzymatic conversion of either tyrosine or tryptophan into their respective hormones. The steroid hormones are derived from cholesterol (Figure 50.2).

50.2 Links Between the Endocrine and Nervous Systems

- Sensory input from an animal's nervous system modulates the activity of certain endocrine glands and influences blood concentrations of many hormones.
- The hypothalamus is physically connected to the pituitary gland, which consists of anterior and posterior lobes (Figure 50.3).
- Within the hypothalamus are numerous neurons that synthesize neurohormones and stimulate the anterior pituitary. In response, the anterior pituitary gland synthesizes six different hormones that respond to the presence of hypothalamic neurohormones. They are adrenocorticotropic hormone (ACTH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), growth hormone, prolactin, and thyroid-stimulating hormone (TSH) (Table 50.2).
- In mammals, the neuron terminals in the posterior pituitary store and secrete one of two hormones: oxytocin or antidiuretic hormone (ADH).

50.3 Hormonal Control of Metabolism and Energy Balance

- Hormones are partly responsible for regulating energy use by cells, such as modulating appetite, digestion, absorption of nutrients, and blood concentration of glucose. Although many hormones are involved in these processes, one from the thyroid gland (T_3), three from the adrenal glands (cortisol, epinephrine, and norepinephrine), two from the pancreas (insulin and glucagon), and one from adipose tissue (leptin) have especially important functions.
- The thyroid gland makes T_3, which contains iodine. A major action of T_3 in adult animals is to stimulate energy consumption by many different cell types (Figures 50.4, 50.5).
- The adrenal glands produce epinephrine and norepinephrine in the medulla and glucocorticoids in the cortex; these hormones increase the blood glucose concentration. The endocrine pancreas produces insulin and glucagon, which have opposite effects on blood glucose concentration (Figures 50.6, 50.7, Table 50.3).
- Maintaining normal glucose and other nutrient concentrations in the blood is a vital process that keeps cells functioning optimally. The combined short-term and long-term actions of insulin, glucagon, epinephrine, and cortisol help maintain normal blood glucose concentrations during fasting (Figure 50.8).
- Ground-breaking research by Banting, Best, MacLeod, and Collip isolated insulin for therapeutic use in treating diabetes mellitus (Figure 50.9).
- Adipose tissue is an important source of appetite-regulating hormones, including the protein leptin, which acts on the hypothalamus to inhibit appetite.

50.4 Hormonal Control of Mineral Balance

- Because of the important functions that Ca^{2+} has in neuronal transmission, heart function, muscle contraction, and numerous other physiological processes, the concentration of Ca^{2+} in the blood is among the most tightly regulated variables in an animal's body. Vitamin D and parathyroid hormone, produced by the parathyroid glands, regulate the blood concentration of Ca^{2+} (Figures 50.10, 50.11).
- Na^+ and K^+ play crucial roles in membrane potential formation, action potential generation, and other functions. A key mechanism that regulates blood concentrations of these ions is altering the rate of Na^+, K^+, and water reabsorption from the urine as it is being formed in the kidneys. This is accomplished in large part by the actions of ADH, aldosterone, and atrial natriuretic peptide (Figure 50.12).

50.5 Hormonal Control of Growth and Development

- Hormones play a crucial role in regulating growth and development. In vertebrates, normal growth depends on a balance between growth hormone, insulin-like growth factor 1, and gonadal hormones. Thyroid hormones affect development among all vertebrates (Figures 50.13, 50.14).
- In insects, prothoracicotropic hormone, 20-hydroxyecdysone, and juvenile hormone control the growth of larvae and their development into pupae (Figure 50.15).

50.6 Hormonal Control of Reproduction

- Hormones produced by the gonads play vital roles in nearly all aspects of reproduction. The ability of the testes and ovaries to produce the sex steroids depends on the gonadotropins, which are the same in both sexes and include follicle-stimulating hormone and luteinizing hormone.

50.7 Impact on Public Health

- Hormones are used therapeutically to treat a variety of human disorders, including diabetes, infertility, growth disorders, asthma, and inflammation.
- Androgen misuse can disrupt normal hormone concentrations and cause health risks such as cardiovascular disease, skin problems, cancer, infertility in men, and masculinizing traits in women. Blood-doping with erythropoietin can make blood dangerously thick.
- Endocrine disruptors, such as chemicals derived from industrial waste, may bind to estrogen receptors in animals' bodies. They may exert estrogen-like actions or inhibit the actions of the body's own estrogen.

Assess and Discuss

Test Yourself

1. Which is the defining feature of hormones?
   a. They are only produced in endocrine glands.
   b. They are secreted into the blood, where they may reach one or more types of distant target cells, thereby altering cell function throughout the body.
   c. They are released only by neurons.
   d. They are never released by neurons.
   e. They are secreted into ducts, where they diffuse to another nearby gland or other structure.
2. Steroid hormones are synthesized from _____ and bind to _____.
   a. proteins; membrane receptors
   b. fatty acids; membrane receptors
   c. tyrosine; intracellular receptors
   d. proteins; intracellular receptors
   e. cholesterol; intracellular receptors
3. Which of the following statements about polypeptide hormones is *false*?
   a. They bind to receptors located on the cell membrane.
   b. Most of them are lipophilic.
   c. They are the most abundant class of hormones.
   d. They normally activate second messengers.
   e. They bind noncovalently to receptors.
4. Chronic deficiency of iodine in a person's diet will lead to
   a. increased secretion of TRH, decreased secretion of TSH, decreased T_3 concentration in the blood, and a goiter.
   b. decreased secretion of TRH and TSH, decreased T_3 concentration in the blood, and a goiter.
   c. increased T_3 concentration in the blood, decreased secretion of TRH and TSH, but no goiter.
   d. decreased T_3 concentration in the blood, increased secretion of TRH and TSH, and a goiter.
   e. decreased secretion of TRH, increased secretion of TSH, decreased T_3 concentration in the blood, and a goiter.
5. The hypothalamus and the pituitary gland are physically connected by
   a. arteries.
   b. the infundibular stalk and portal veins.
   c. the adrenal medulla.
   d. the spinal cord.
   e. the intermediate lobe.
6. Antidiuretic hormone (ADH)
   a. increases water reabsorption in the kidneys.
   b. regulates blood pressure by constricting arterioles.
   c. decreases the volume of urine produced by the kidneys.
   d. increases blood pressure during times of high blood loss.
   e. does all of the above.
7. Which of the following pairs of hormones are involved in the regulation of blood Ca^{2+} concentration in vertebrates?
   a. aldosterone and ANP
   b. insulin and glucagon
   c. parathyroid hormone and 1,25-dihydroxyvitamin D
   d. prolactin and oxytocin
   e. thyroxine and TSH
8. In invertebrates, molting of larvae is stimulated by
   a. growth hormone.
   b. cortisol.
   c. juvenile hormone.
   d. 20-hydroxyecdysone.
   e. aldosterone.
9. Which of the following is *true* of the adrenal glands?
   a. They produce insulin.
   b. They produce hormones that control ion balance and maintain glucose homeostasis.
   c. They produce only steroid hormones.
   d. They are inhibited by the pituitary hormone ACTH.
   e. They chiefly regulate Ca^{2+} balance.

10. Endocrine disruptors are
    a. chemicals released by the nervous system to override the endocrine system.
    b. chemicals released by the male of a species to decrease the fertility of other males.
    c. drugs used to treat overactive endocrine structures.
    d. chemicals derived from industrial waste that may alter endocrine function.
    e. all of the above.

Conceptual Questions

1. What is the function of leptin, and what is the benefit of an adipose-derived signaling molecule in this context? Why does an animal have an appetite?
2. Distinguish between type 1 and type 2 diabetes mellitus.
3.  A principle of biology is that *living organisms maintain homeostasis*. How do the opposing actions of insulin and glucagon maintain glucose homeostasis? When are these hormones released into the blood? What might happen to a nonfasting mammal that was injected with a high dose of glucagon?

Collaborative Questions

1. Discuss the role of hormones in growth and development.
2. Discuss the functions of the different steroid hormones, and indicate where they are produced in the human body.

Animal Reproduction

51

These mud daubers, shown here mating, reproduce by sexual reproduction, which favors genetic variation in species.

Over a span of 40 years in the early 18th century, a woman known to history only as the "wife of Feodor Vassilyev," a Russian peasant, reportedly gave birth 27 times to a total of 69 children! If accurate, it is safe to say that this probably represents the uppermost realistic limit of human fertility, considering a pregnancy length of about 40 weeks, the rarity of a woman producing multiple births such as twins, and the reproductive life span of an adult woman. Impressive as such a number is, however, it is not unusual in animals. For example, many invertebrate species, such as the wasps known as mud daubers (shown in the chapter opening photo), lay anywhere from several to dozens of eggs in 1 day. As an extreme example, a single female cod fish can lay several million eggs during one spawning season (although not all the eggs will result in offspring).

Indeed, when we examine all forms of life, we discover that individuals of every species are part of an unbroken cycle of life and death. Perpetuation of all life requires **reproduction**—the processes by which organisms replicate themselves and multiply. The biological mechanisms that favor successful reproduction in the animal kingdom are extraordinarily diverse. Many of the observable differences in animal behavior and anatomy are the result of adaptations that increase an animal's chances of reproducing. Both the behaviors and the anatomical specializations that promote reproduction are under the control of a variety of factors, particularly hormones.

In this chapter, we will begin by examining the diverse means of reproduction that occur throughout the animal kingdom, including asexual and sexual reproduction. Then we will highlight some of the anatomical, hormonal, and behavioral aspects of reproduction in mammals, including humans. We will conclude with a discussion of some key issues related to fertility (the ability to reproduce) in the human population today.

51.1 Overview of Asexual and Sexual Reproduction

Learning Outcomes:

1. Describe several differences between asexual and sexual reproduction.
2. Classify the three types of asexual reproduction.
3. **SciSKILLS** » Propose an hypothesis for why most animals reproduce by sexual reproduction.

In this section, we will consider the processes of asexual and sexual reproduction, as well as their advantages and disadvantages.

Asexual Reproduction Takes Several Forms

Asexual reproduction occurs when offspring are produced from a single parent, without the fusion of genetic material from another parent. The offspring are therefore clones of the single parent. Asexual reproduction occurs in some invertebrates and in a small number of vertebrate species. These animals use one of three major forms of asexual reproduction: budding, regeneration, or parthenogenesis. **Budding**, which is seen in cnidarians, occurs when a portion of the parent organism pinches off to form a complete new individual (**Figure 51.1a**). In this process, cells from the parent undergo mitosis and differentiate into specific types of structures before the new individual breaks away. At any one time, a parent organism may have one, two, or multiple buds forming simultaneously. Budding continues throughout such an animal's lifetime.

Some animals, including certain species of sponges, echinoderms, and worms, reproduce by the **regeneration** of a complete organism from small fragments of their body. In some sea stars and starfish, for example, an arm removed by injury or predation can grow into an entirely new individual (**Figure 51.1b**). Similarly, a flatworm bisected into two pieces can regenerate two new individuals.

The asexual process called **parthenogenesis** (from the Greek, meaning virgin birth) is the development of offspring from an unfertilized egg (one that has not combined with a male gamete). It occurs in several invertebrate classes and in a few species of fishes and reptiles. Animals produced by parthenogenesis are usually haploid. Some animals—such as rotifers, social insects such as ants and bees, and the freshwater crustacean *Daphnia*—may reproduce either parthenogenically or sexually, depending on the time of year or environmental conditions.

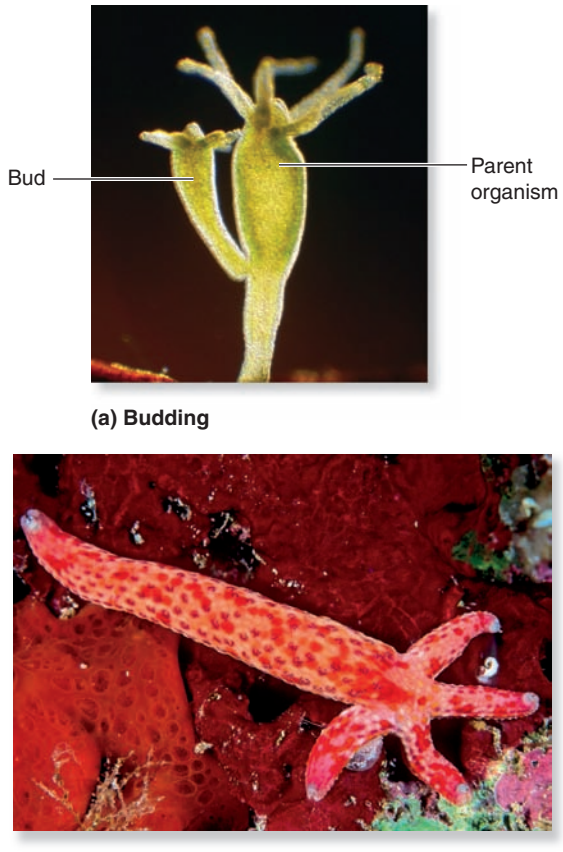

Figure 51.1 Examples of asexual reproduction. (a) *Hydra* with a single bud. **(b)** A starfish regenerating a complete new body from a single arm.

Sexual Reproduction Occurs in Most Species

Sexual reproduction is the production of a new individual by the joining of two haploid reproductive cells called **gametes**—one from each parent. This produces offspring that are genetically different from both parents. Sexual reproduction occurs in most animal species, both invertebrate and vertebrate. The gametes are spermatozoa (usually shortened to **sperm**) from the male and **egg cells**, or **ova** (singular, **ovum**), from the female. When a sperm unites with an egg—the process called **fertilization**—each haploid gamete contributes its set of chromosomes to produce a diploid cell called a fertilized egg, or **zygote**. As the zygote undergoes cell divisions and begins to develop, it is called an **embryo**.

Asexual and Sexual Reproduction Have Advantages and Disadvantages

Asexual reproduction provides a relatively simple way for an organism to produce many copies of itself, whereas sexual reproduction requires two individuals to produce offspring. What are the advantages and disadvantages of each method?

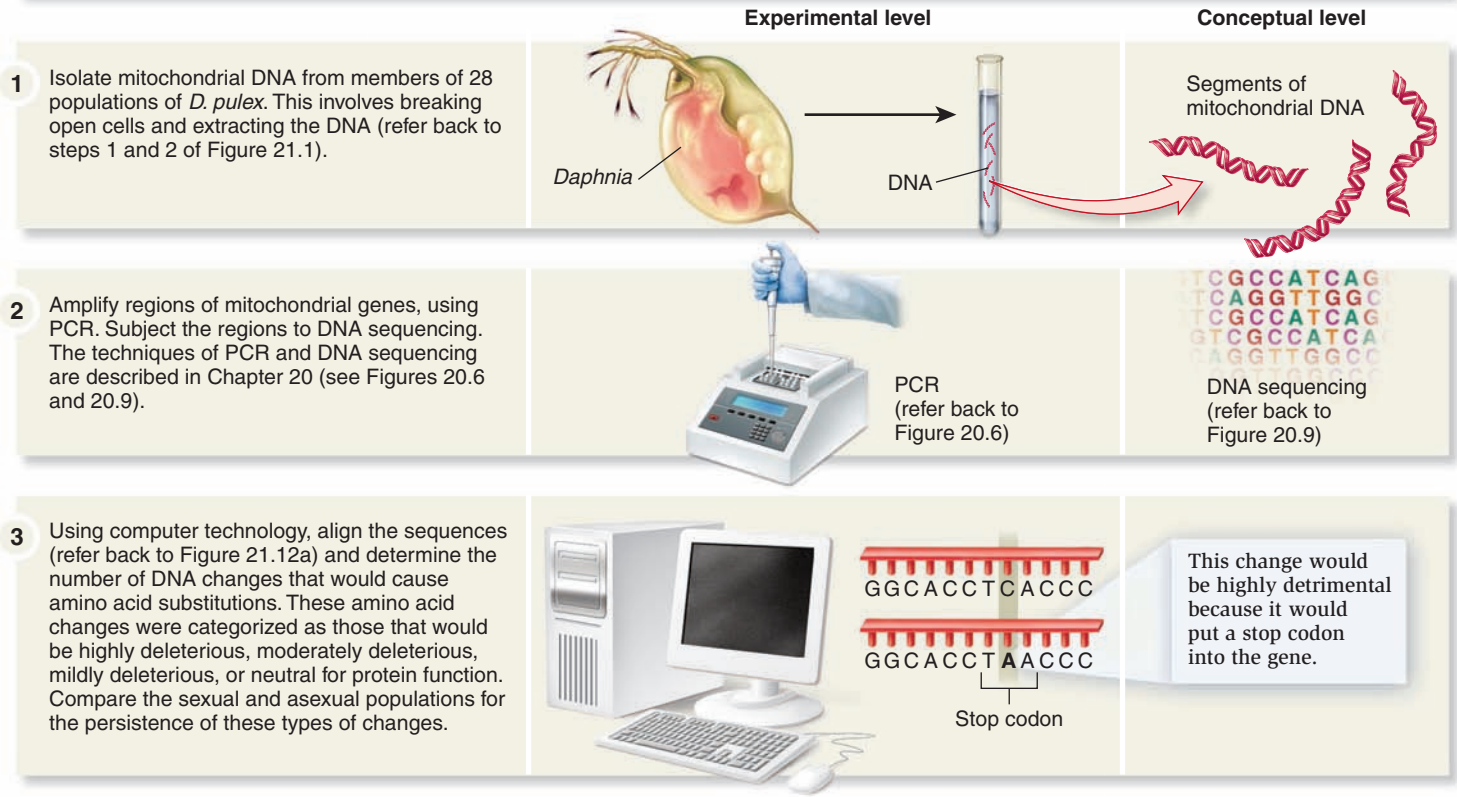
Asexual reproduction has numerous advantages over sexual reproduction. First, an animal can reproduce asexually even if it is isolated from others of its own species. Individuals can reproduce rapidly at any time because they need not seek out, attract, and mate with a member of the opposite sex. Asexual reproduction, therefore, is an effective way of generating large numbers of offspring. Although many kinds of animals reproduce asexually, it is more prevalent in species that live in very stable environments, with little selection pressure for genetic diversity in the population.

Compared with asexual reproduction, sexual reproduction is associated with unique costs. Two types of gametes (sperm and eggs) must be made, males and females require specialized body parts to mate with each other, and the two sexes must be able to find each other. Yet given that the vast majority of eukaryotic species reproduce sexually, this question has intrigued biologists since the time of Darwin: What is the advantage of sexual reproduction for the perpetuation of a species?

In the context of species survival, the major difference between asexual and sexual reproduction is that sexual reproduction allows for greater genetic variation due to genetic recombination. Only certain alleles from each parent are passed on, and when a set of genes from one parent mixes with a different set from the other parent, the offspring are never exactly like either of their parents. Thus, a hallmark of sexual reproduction is increased genetic variation between successive generations. One prevalent hypothesis about why sex evolved is that sexual reproduction allows more rapid adaptation to environmental changes than does asexual reproduction.

In particular, sexual reproduction allows alleles within a species to be redistributed via crossing over and independent assortment across many generations. As a result, some offspring carry combinations of alleles that promote survival and reproduction, whereas other offspring may carry less favorable combinations. As described in Chapter 24, natural selection can favor those combinations that promote greater reproductive success while eliminating offspring with lower fitness. By comparison, the alleles of asexual organisms are not reassorted from generation to generation. As a result, it is more difficult to accumulate potentially beneficial alleles within individuals of these species. Also, as described next, sexual reproduction may facilitate elimination of harmful alleles from a population.

Feature Investigation | Paland and Lynch Provided Evidence That Sexual Reproduction May Promote the Elimination of Harmful Mutations in Populations



Evolutionary biologists have suggested that the inability of asexual species to reassort alleles may be a key disadvantage compared with sexually reproducing species. To investigate this question, American researchers Susanne Paland and Michael Lynch studied the persistence of mutations in populations of *Daphnia pulex*, a freshwater organism commonly known as the water flea. The researchers chose this organism because some natural populations reproduce asexually, and others reproduce sexually.

In their experiment, shown in **Figure 51.2**, Paland and Lynch studied the sequences of several mitochondrial genes in 14 sexually reproducing and 14 asexually reproducing populations of *D. pulex*. The researchers hypothesized that asexual populations would be less able to eliminate harmful mutations. As discussed in Chapter 14, random gene mutations that change the amino acid sequence of the encoded protein are much more likely to be harmful than beneficial. The alleles of sexually reproducing populations

Figure 51.2 Paland and Lynch demonstrated the importance of sexual reproduction in reducing the frequency of harmful genetic mutations.

HYPOTHESIS Sexual reproduction allows for greater mixing of alleles of different genes and thereby may prevent the accumulation of detrimental alleles in a population.

KEY MATERIALS The researchers collected samples of *Daphnia pulex* from many natural populations. A total of 14 sexual populations and 14 asexual populations were studied.

4 THE DATA

Results from step 3:

Types of amino acid substitutions (The amino acid substitutions were due to rare mutations that occurred in the natural populations of *D. pulex*.)	Percentage of total mutations resulting in an amino acid substitution of mitochondrial proteins	Allowed to persist in	
		Sexual populations	Asexual populations
Highly deleterious	73.2	No	No
Moderately deleterious	13.3	No	Yes
Mildly deleterious	4.4	Yes	Yes
Neutral	9.1	Yes	Yes

5 CONCLUSION Moderately deleterious mutations are less likely to persist in populations of animals that reproduce sexually.

6 SOURCE Paland, S., and Lynch, M. 2006. Transition to asexuality results in excess amino acid substitutions. *Science* 311:990–992.

can be reassorted from generation to generation, thereby producing succeeding generations in which the detrimental alleles are lost from the population. As you can see in the data, the researchers discovered that both the sexual and asexual populations could eliminate highly deleterious mutations. Organisms having such mutations probably died rather easily. In addition, the sexual and asexual populations both retained mildly deleterious and neutral mutations. However, moderately deleterious mutations were eliminated from the sexual populations but not from the asexual ones. One interpretation of these data is that sexual reproduction allowed for the reassortment of beneficial and detrimental alleles, making it easier for sexually reproducing populations to eliminate those mutations that are moderately detrimental.

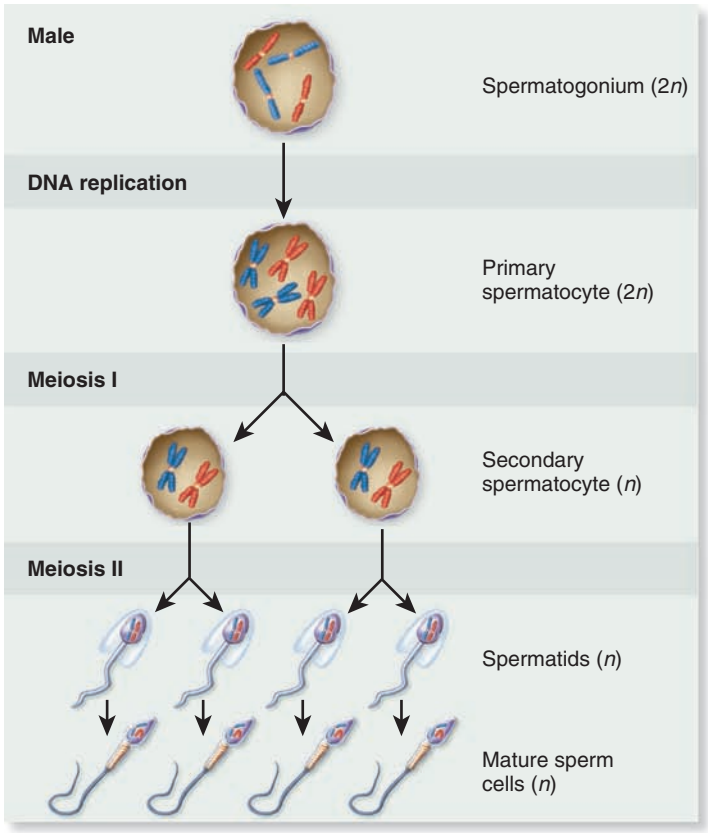
Experimental Questions

1. **SciSKILLS** » How did Paland and Lynch test the hypothesis that sexual reproduction allowed for the reduction in deleterious mutations?
2. **SciSKILLS** » Approximately how many times more often did deleterious mutations persist in the asexually reproducing populations compared to the sexually reproducing ones?
3. What is the proposed evolutionary benefit of sexual reproduction?

51.2 Gametogenesis and Fertilization

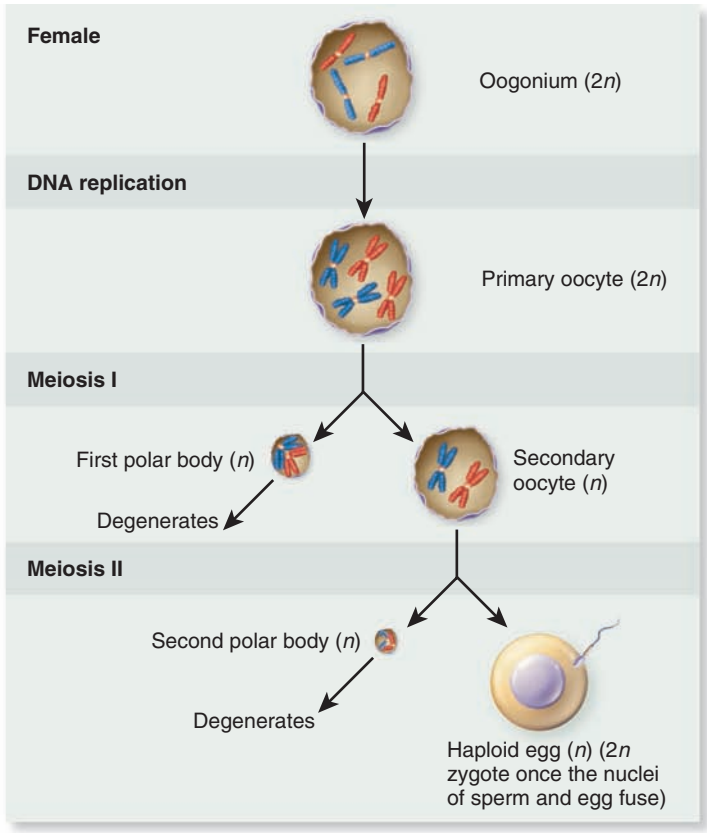
Learning Outcomes:

1. Outline the processes of spermatogenesis and oogenesis.
2. **SciSKILLS** » Propose reasons why internal fertilization is advantageous.
3. Describe the two different types of hermaphroditism.



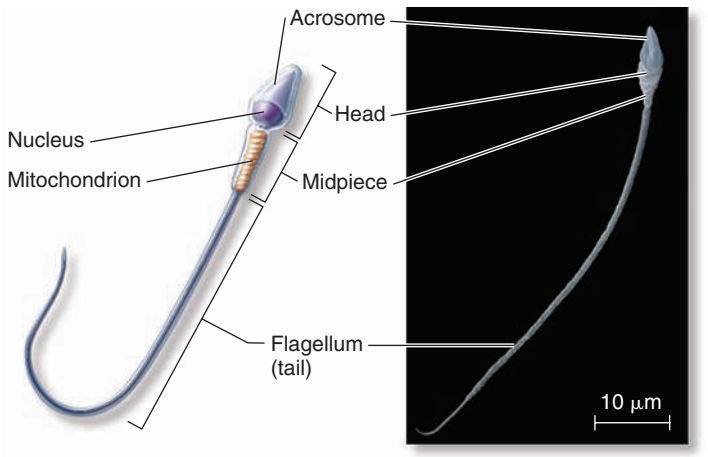
This section will discuss how and where gametes are formed and how two gametes join to form a new organism.

Sperm and Eggs Are Produced During the Process of Gametogenesis

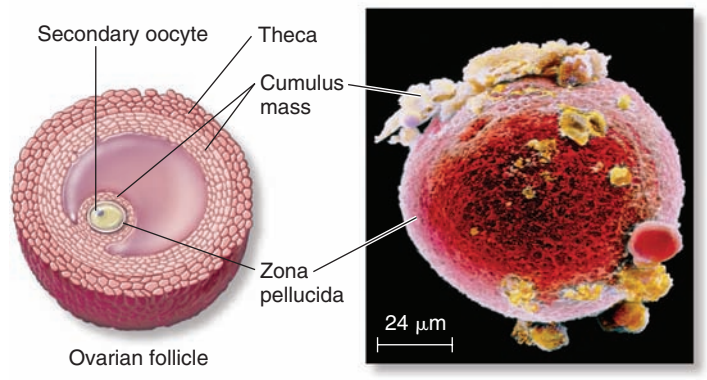


Male and female gametes are formed within the **gonads**—the **testes** (singular, testis) in males and the **ovaries** (singular, ovary) in females. Some similarities are found in the ways gametes develop in the testes and the ovaries, as well as some differences.

In both cases, **gametogenesis**—the formation of gametes—begins with cells called germ cells, which multiply by mitosis, resulting in diploid cells (carrying two copies of each gene; denoted as $2n$). These are called **spermatogonia** (singular, spermatogonium) in males and **oogonia** (singular, oogonium) in females (**Figure 51.3**). Some of these cells become **primary spermatocytes** or **primary oocytes**, respectively, that may begin the process of meiosis. Until this point, the development of sperm and eggs is similar. From then on, gametogenesis differs between the two types of gamete.



Spermatogenesis The formation of haploid sperm from the diploid germ cell is called **spermatogenesis**. As shown in Figure 51.3a, primary spermatocytes begin this process by undergoing the first of two meiotic divisions (meiosis I). (Refer back to Chapter 15 for a review of the processes of mitosis and meiosis.) In the primary spermatocyte, meiosis I produces two haploid (n) cells called **secondary spermatocytes**. These cells also undergo meiosis (meiosis II), producing four haploid **spermatids** that eventually differentiate into mature sperm cells. Gametogenesis in males, therefore, results in four gametes from each spermatogonium.



(a) Spermatogenesis

(c) Oogenesis

(b) Mature human sperm

(d) Mature human follicle and oocyte

Figure 51.3 **Gametogenesis and gametes in males and females.** **(a)** In the process of spermatogenesis, male diploid (2*n*) germ cells undergo two meiotic divisions to produce mature haploid (*n*) sperm. **(b)** The characteristic head, midpiece, and flagellum (tail) of a mature human sperm, as seen in a drawing and accompanying scanning electron micrograph (SEM; scale approximate). **(c)** The process of oogenesis in females, which produces a haploid secondary oocyte that enters but does not complete meiosis II until it is fertilized. **(d)** Mature follicle and oocyte. The drawing depicts a secondary oocyte within its follicle; the SEM shows an isolated human oocyte covered by its zona pellucida and remnants of the cumulus mass.

BIOLOGY PRINCIPLE **Structure determines function.** The structure of a sperm cell is a good example of this principle of biology at the cellular level. Notice how each of the three major structural elements of the sperm cell is suited for a particular function. When all three elements function together, the cell is capable of fertilizing an egg.

The most striking change in each spermatocyte as it differentiates into a sperm is the formation of a flagellum, also called the tail (Figure 51.3b). The movements of the tail require energy and make the sperm motile. The sperm also has a head, which contains the nucleus that carries the chromosomes. At the tip of the head is a special structure called the **acrosome**, which contains proteolytic enzymes that help break down the protective outer layers surrounding an ovum. The head and tail are separated by a midpiece containing one or more mitochondria, depending on the species, that produce the ATP required for tail movements.

Oogenesis Whereas spermatogenesis produces four gametes from each primary spermatocyte, gametogenesis in the female, called **oogenesis**, results in the production of a single gamete from each primary oocyte (Figure 51.3c). The first meiotic division (meiosis I) in oogenesis results in one large cell—a **secondary oocyte**—plus a smaller cell, called a polar body, that eventually degenerates.

Depending on the species, one or many oocytes can develop at a time. Within the ovaries, each oocyte grows and develops within a structure called a **follicle** before it leaves the ovary in the process of **ovulation**. Once ovulated, a secondary oocyte can become fertilized if sperm are available. In mammals, the secondary oocyte is surrounded by three layers: an inner layer composed of glycoproteins called the **zona pellucida**, which surrounds the surface of the secondary oocyte; a second layer of cells called the cumulus mass which provides protection and nutritive support; and an outer layer called the theca, which produces hormones that control oocyte growth (Figure 51.3d). These layers play important roles in the fertilization of the secondary oocyte.

In mammals, oogenesis begins in the female embryo before birth: A cohort of germ cells develop into primary oocytes and enter meiosis I, which is arrested partway through the process. Meiosis I does not resume until puberty, the time after which a mammal first becomes capable of reproducing. In some primary oocytes, meiosis I is completed, producing haploid secondary oocytes. These cells then begin but do not complete meiosis II. A secondary oocyte will complete meiosis II and become a haploid egg if it is fertilized by a sperm. Once the haploid egg nucleus fuses with a haploid sperm nucleus, a diploid zygote is produced.

Fertilization Involves the Union of Sperm with Egg

Fertilization is a complex series of events by which the haploid male and female gametes unite and become a diploid zygote. Several important cellular and molecular processes must occur before the nuclei of the gametes can fuse. The mechanism by which the egg and sperm make contact has been studied extensively in sea urchins, and some evidence suggests that a similar process occurs in humans and other mammals. When chemical attractant molecules emitted by sea urchin eggs bind to nearby sperm, cellular respiration (that is, the breakdown of nutrients to synthesize ATP) within the sperm increases, which helps increase sperm motility. The sperm then swim toward the egg by following the attractant's concentration gradient. The attractants are species-specific; that is, sperm will respond to the attractants produced only by eggs of their own species.

For a sperm to physically contact the egg, it must first penetrate the layers surrounding the egg's plasma membrane. In mammals, when the head of a sperm contacts the layers surrounding a secondary oocyte, chemicals in the cumulus mass stimulate the breakdown of the membrane covering the acrosome of the sperm. Proteolytic enzymes released from the acrosome digest a local area of the zona pellucida, allowing the sperm to contact the plasma membrane of the secondary oocyte. The plasma membrane of the secondary oocyte then fuses with the sperm head, facilitating its movement into the secondary oocyte's cytoplasm.

Once a sperm fuses with the secondary oocyte, other sperm must be prevented from also fusing with the fertilized egg to avoid the formation of a polyploid zygote, a condition that few zygotes survive. In most mammals, the penetration of one sperm induces metabolic changes within the egg that prevent additional sperm from penetrating the zona pellucida and entering the egg (look ahead to Chapter 52).

In a Given Species, Fertilization Occurs Either Outside or Inside the Female

For sperm to fertilize eggs, the two gametes must physically come into contact. This can occur either outside or inside the female's body. When this occurs outside of the female, the process is called **external fertilization**. This type of fertilization occurs in aquatic environments, when eggs and sperm are released into the water close enough for fertilization to occur. The aqueous environment protects the gametes from drying out. Animals that reproduce by external fertilization show species-specific behaviors that help bring the eggs and sperm together. For instance, very soon after a female fish lays her eggs, a male deposits his sperm in the water nearby, where they spread over the clump of eggs. When frogs mate, the clasping behavior of the male stimulates the female to release her eggs into the water (**Figure 51.4**); the male then releases sperm onto the eggs. The fertilized eggs then develop outside the mother's body.

Although the aqueous environment protects against desiccation, eggs can be eaten by predators, washed away by currents, or subjected to potentially lethal changes in water temperature. Such environmental challenges have led to selection for some species, including many aquatic or amphibious animals, to release very large numbers of eggs at once, as noted previously for the female cod fish.

In contrast to external fertilization, most terrestrial animals and some aquatic animals reproduce by **internal fertilization**, in which

Figure 51.4 An example of external fertilization. The male frog (*Rana temporaria*) clasps the female, which stimulates her to release her eggs. He then releases his sperm (not visible here) over the eggs. This process occurs in aquatic environments, which protect gametes from drying out.

Concept Check: What kinds of aquatic environments are most suitable for external fertilization?

sperm are deposited within the reproductive tract of the female during the act called **copulation**, as seen in the mud daubers in the chapter opening photo. Internal fertilization protects the delicate gametes from environmental hazards and predation and also guarantees that sperm are placed and remain in very close proximity to eggs. Once fertilization occurs within the female, the zygotes then develop into offspring.

The behaviors and anatomical structures involved in achieving internal fertilization are extremely varied among species. Typically, mating involves accessory sex organs, which are reproductive structures other than the gonads. The external accessory sex organs involved in copulation are the genitalia (for example, the **penis** and the **vagina**), which are used to physically join the male and female so that sperm can be deposited directly into the female's reproductive tract. A penis or analogous structure is present in most insects, reptiles, some species of birds (ratites and waterfowl), and all mammals. However, males of other vertebrate species—including most birds—that reproduce by internal fertilization lack a structure that can be inserted into the female, so they deposit sperm in the female by cloacal contact. The cloaca is a common opening for the reproductive, digestive, and excretory systems in these animals (refer back to Figure 45.4).

Another form of internal fertilization involves an indirect means of depositing sperm. In this case, males produce small packets of sperm, called spermatophores, that are deposited externally and then inserted into the female's reproductive tract by either the male or the female. During copulation in cephalopods, the male uses a tentacle to transfer a spermatophore into the mantle cavity of the female. In spiders, the male places a droplet of sperm on a web and then uses a foreleg to insert the droplet into the female's reproductive tract. Subsequently, the eggs are fertilized internally and deposited on the web or elsewhere in the environment.

Individuals of Some Hermaphroditic Species Can Fertilize Themselves or Each Other

In some species, including many gastropods, worms, and some fish and reptiles, individuals have both male and female reproductive systems for part or all of their lives. This is called **hermaphroditism** (after the male and female Greek gods, Hermes and Aphrodite). In some hermaphroditic species, individuals can fertilize their own eggs with their own sperm, but in most hermaphroditic species, individuals exchange sperm with another individual. The latter situation has the selective advantage of creating additional genetic diversity in the population. An advantage of hermaphroditism is that all individuals of a sexually reproducing species can produce offspring.

There are two main types of hermaphroditism. In one, animals are simultaneously both male and female. This type of hermaphroditism is known as synchronous hermaphroditism. Such hermaphrodites are often sessile animals or burrowing animals such as earthworms, which may live for long periods without encountering sexual partners. A single earthworm can fertilize its own eggs, or two earthworms can join together for several hours during which sperm from each worm fertilize the eggs of the other. In the latter case, individual worms act both as females (receiving sperm to fertilize their eggs) and males (giving sperm to fertilize another worm's eggs), so the offspring carry genes from both individuals.

The second type of hermaphroditism, called sequential hermaphroditism, involves sex reversal, in which a female may change into a male, or vice versa. In such animals, individuals express specific genes and therefore develop and maintain reproductive structures of either a male or a female, but not at the same time. This kind of sex reversal occurs in some species of animals with strong social hierarchies. In some reef-dwelling species of fishes, for example, a single dominant male defends a harem of several females within a specific territory. If that dominant male dies, the largest of the females reverses sex and becomes a male. Thus, these fishes are **protogynous**—that is, female first but capable of becoming males later during their life cycle. Oysters and clownfish are also sequential hermaphrodites, but they are **protandrous**; that is, they are males first and only later become females. An advantage of protandrous hermaphroditism is that males change into females when they are older and larger—and so are likely to be capable of producing a greater number of eggs.

51.3 Mammalian Reproductive Structure and Function

Learning Outcomes:

1. Describe the structure of the human male reproductive tract.
2. Outline the process of hormonal control of the male reproductive system.
3. Describe the structure of the human female reproductive tract.
4. Diagram the sequence of events of the ovarian cycle.
5. Outline the process of hormonal control of the reproductive cycle of the human female.
6. Explain how maternal hormones prepare the uterus to accept the embryo.

We turn now to a detailed look at the mammalian reproductive system, paying particular attention to the human system. We will begin with a description of the anatomy of the reproductive system, including the gonads and the accessory sex structures. We will then examine the hormones that control the production of the gametes and the preparation for and establishment of pregnancy.

The Human Male Reproductive Tract Is Specialized for Production and Ejaculation of Sperm

The external structures of the male reproductive tract—the genitalia—consist of the penis and the scrotum, the sac that contains the testes and holds them outside the body cavity (**Figure 51.5**). The testes develop within the body cavity. Just before birth in human males, they descend into the scrotum, where the temperature is approximately 2°C lower than core body temperature. The lower temperature is optimal for spermatogenesis.

Each testis is composed of tightly packed **seminiferous tubules** encased in connective tissue (see Figure 51.5). Surrounding the tubules are Leydig cells—scattered endocrine cells that secrete the steroid hormone testosterone (refer back to Figure 50.2). Spermatogenesis begins at puberty and continues throughout life. It occurs all along the walls of the seminiferous tubules. Cells at the earliest stages of

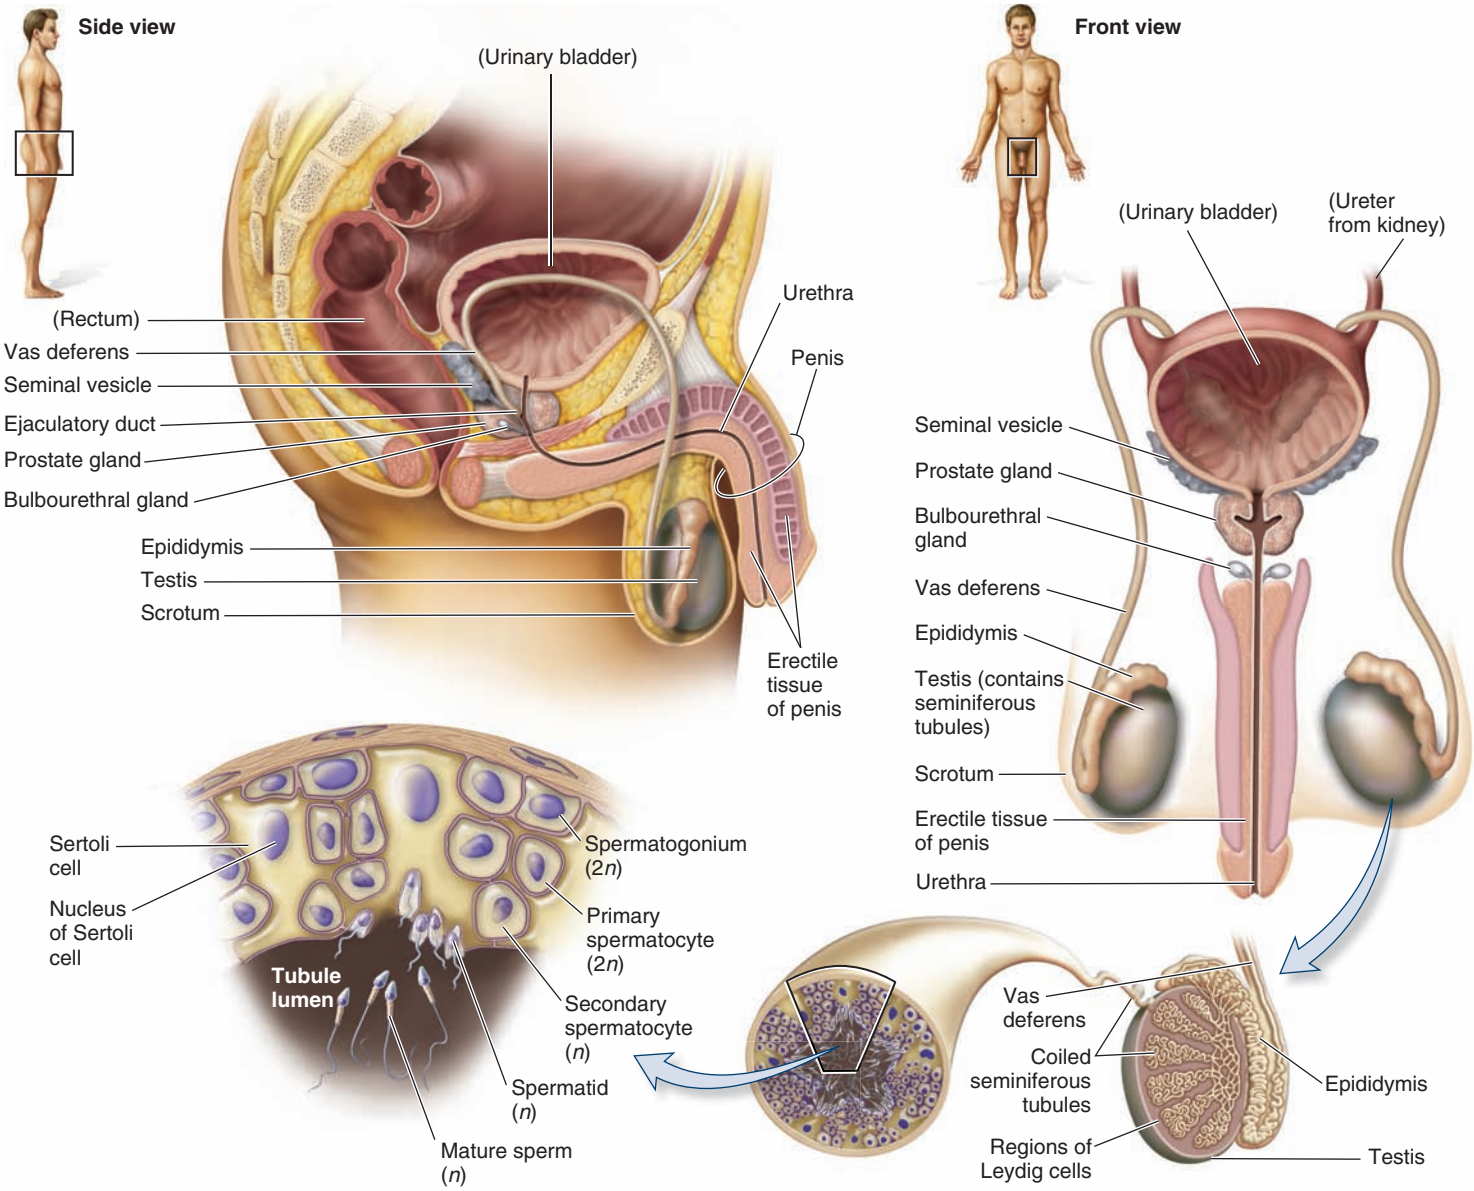


Figure 51.5 **Male reproductive structures in humans.** Side and front views of the male reproductive system (nonreproductive structures are identified in parentheses for orientation purposes). The enlargement (at bottom), showing the internal structure of a testis and associated structures, depicts the stages of spermatogenesis.

spermatogenesis, the spermatogonia, are located nearest the outer surface of the wall. Cells of more advanced stages are located progressively inward, so that the mature sperm are released into the tubule lumen. Cells within the seminiferous tubules are continuously developing from spermatogonia into spermatocytes and eventually to sperm, so at any one time, all types of cells are present along the seminiferous tubule. Support cells, called Sertoli cells, surround the developing spermatogonia and spermatocytes, providing them with nutrients and protection and playing a role in their maturation into sperm.

Sperm moving out of the seminiferous tubules are emptied into the **epididymis**, a coiled, tubular structure located on the surface of the testis (see Figure 51.5). The epididymis is very long—approximately 6 m in humans—and it takes about 2 to 12 days for new sperm to reach its end. Here the sperm complete their differentiation by becoming motile and gaining the capacity to fertilize ova.

Sperm leave the epididymis through the **vas deferens**, a muscular tube leading to the ejaculatory duct, which then connects to the urethra (see Figure 51.5). As noted in Chapter 49, the urethra originates at the bladder and extends to the end of the penis. In males, the urethra not only conducts urine but also carries **semen**, a mixture containing fluid and sperm, that is released during **ejaculation**—the movement of semen through the urethra by contraction of muscles at the base of the penis. These contractions during ejaculation contribute to the pleasurable sensation of orgasm.

The liquid components of semen are important for the survival and movement of sperm through the female reproductive tract. This liquid is formed by three accessory glands that secrete substances into the urethra to mix with the sperm. The **seminal vesicles** secrete the monosaccharide fructose, the main nutrient for sperm, as well as other factors that enhance sperm motility and survival. The **prostate gland** secretes a thin, alkaline fluid that protects sperm from acidic fluids in the urethra and within the female reproductive tract. An additional small amount of alkaline fluid is secreted by the **bulbourethral glands**. Secretions constitute about 95% of semen, and sperm make up only about 5% of total semen volume. The volume of semen released at ejaculation in humans is about 2–5 mL and contains 20–130 million sperm per milliliter. Although this seems like an excessive amount of sperm to fertilize a single egg, relatively few sperm actually reach the egg.

Introduction of sperm into the female reproductive system during copulation is made possible by erection of the penis. Erection occurs when blood fills spongy erectile tissue located along the length of the penis (see Figure 51.5). Sexual arousal stimulates release of the gaseous neurotransmitter nitric oxide (NO; refer back to Figure 47.15) in the penis, causing vasodilation of arteries. The pressure of the blood flowing into the penis compresses veins that are near the dilated arteries, causing a decrease in venous drainage from the penis, engorging it with blood. After ejaculation, NO release is decreased, causing a reversal of the vascular changes responsible for erection. Both physiological and psychological factors can result in an inability to achieve an erection, a medical condition known as erectile dysfunction (also called impotence). Orally administered drugs such as sildenafil and tadalafil (Viagra and Cialis) can increase the occurrence of erections by stimulating the same intracellular signaling events as NO in the smooth muscle cells of penile blood vessels.

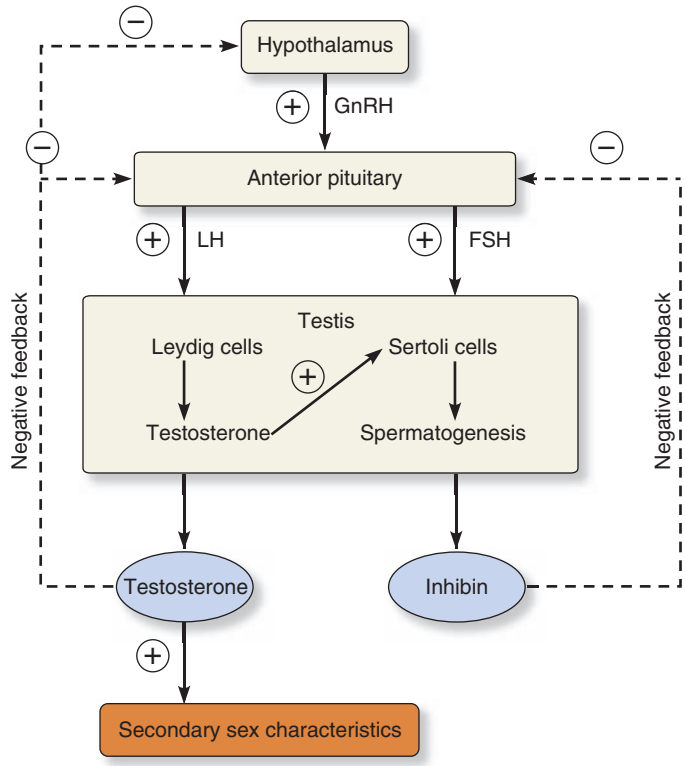

Figure 51.6 The hormonal control of male reproduction. In response to LH, Leydig cells in the testes secrete testosterone, which, along with FSH, acts on Sertoli cells to facilitate spermatogenesis. Negative signs indicate inhibitory effects via negative feedback, and plus signs indicate stimulatory effects.

Male Reproductive Function Requires the Actions of Hormones

Recall from Chapter 50 that the hypothalamus is a structure at the base of the brain that synthesizes neurohormones, including gonadotropin-releasing hormone (GnRH) (see Table 50.2 and Figure 50.3). GnRH stimulates the anterior pituitary gland to release two gonadotropins: luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

In males, LH stimulates the Leydig cells of the testes to produce androgens, particularly testosterone (**Figure 51.6**). Testosterone stimulates the growth of the male reproductive tract and the genitalia during development and puberty and the development of male secondary sex characteristics. In humans, these include facial hair growth, increased muscle size, and deepening of the voice. Examples in other male mammals include growth of the horns of a bull, enlargement of the nose of proboscis monkeys, and formation of cheek pads in some apes. Testosterone-dependent secondary sex characteristics are not unique to mammals, however. One familiar example is the bright coloration of plumage in male birds such as the peacock.

The other pituitary gonadotropin, FSH, functions along with testosterone to stimulate spermatogenesis. FSH does this by stimulating the activity of the Sertoli cells within the seminiferous tubules. The Sertoli cells provide the nutritional and structural support necessary for development of the sperm. They also respond to testosterone produced by the Leydig cells, by stimulating mitosis and meiosis of the germ cells associated with them in the tubules.

Production of sperm and testosterone is kept in check by negative feedback mechanisms that control the amount of gonadotropins produced (see Figure 51.6). Testosterone in high concentrations inhibits the secretion of GnRH from the hypothalamus, so both LH and FSH are inhibited when the blood concentration of testosterone is high. Testosterone also directly inhibits LH secretion by the anterior pituitary gland. In addition, when Sertoli cells are activated by FSH, they secrete a protein hormone called inhibin, which enters the blood and inhibits further secretion of FSH. These feedback mechanisms maintain homeostatic concentrations of FSH and LH in the blood.

Before puberty, LH is not released in sufficient amounts to stimulate significant testicular production of testosterone, and the reproductive system is quiescent—spermatogenesis does not occur. Although the mechanisms that initiate puberty in mammals are still not completely understood, research has shown that increased GnRH production at that time initiates increased LH and FSH secretion from the pituitary. The testosterone induced by LH stimulates development of adult male characteristics. Testosterone is also responsible for an increased sex drive (libido) at this time.

BIO TIPS

THE QUESTION *What will happen to spermatogenesis in a man taking supplements of testosterone to increase muscle mass and athletic performance?*

TOPIC ***What topic in biology does this question address?*** The topic concerns the effects of abnormally increased amounts of testosterone on spermatogenesis in men.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you can assume that the testosterone supplements increase the man's blood concentration of testosterone above the normal range. From your understanding of the topic, you may recall that the blood concentrations of testosterone and the hypothalamic hormone GnRH are related to spermatogenesis.

PROBLEM-SOLVING STRATEGY ***Sort out the steps in a complicated process. Predict the outcome.*** Consider the sequence of events beginning with an increase in blood concentration of testosterone. What happens next to the concentrations of GnRH and the gonadotropins? In turn, what follows from the changes in those hormones? Based on this sequence of steps, predict what happens to sperm production.

ANSWER *Let's follow the sequence of events. 1) Taking testosterone supplements will increase the blood concentration of testosterone above normal. 2) This, in turn, will inhibit the secretion of GnRH from the hypothalamus and the gonadotropins LH and FSH from the anterior pituitary. The inhibition results from increased negative feedback (see Figure 51.6). 3) The plasma concentrations of LH and FSH decrease as a consequence. 4) With decreased LH and FSH, there will be less stimulation of the Leydig and Sertoli cells of the testes.*

Thus, you can predict that spermatogenesis will decrease. This is, in fact, what happens with chronic use of androgens in men.

The Female Reproductive Tract Is Specialized for Production and Fertilization of the Egg and Development of the Embryo

The female genitalia differentiate from the same embryonic tissues as the male genitalia. The female genitalia are composed of the larger, hair-covered outer folds called the **labia majora** (from the Latin, meaning major lips), which surround the external opening of the reproductive tract, plus smaller, inner folds, called the **labia minora** (from the Latin, meaning minor lips; **Figure 51.7**). The labia majora originate from the same embryonic tissue as the scrotum of the male, whereas the labia minora originate from urethral primordial tissue.

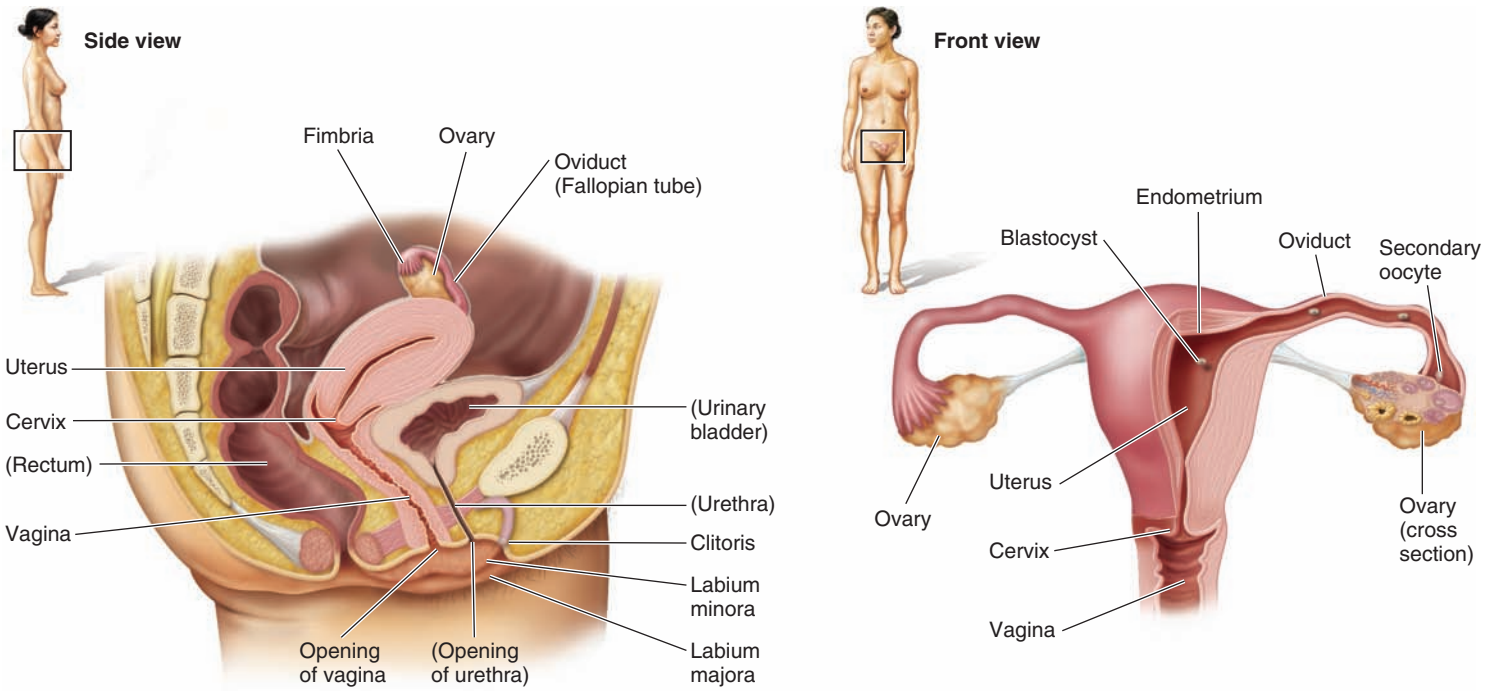

Figure 51.7 Female reproductive structure and function in humans. Side and front views of the female reproductive system (nonreproductive structures are identified in parentheses for orientation purposes). An oocyte moves from the ovary into the oviduct (Fallopian tube), where it may be fertilized and develop into a blastocyst. Subsequently, the blastocyst enters the uterus, where it may implant in the endometrium, the inner lining of the uterus.

At the anterior part of the labia minora is the **clitoris**, which is erectile tissue of the same origin as the penis. Like the penis, the clitoris becomes engorged with blood during sexual arousal and is very sensitive to sexual stimulation. Unlike males, however, the openings of the reproductive tract and the urethra are separate in females. The opening of the urethra is located between the clitoris and the opening of the reproductive tract.

In mammals alone, the external opening of the reproductive tract leads to the vagina, a tubular, smooth muscle structure into which sperm are deposited during copulation. At the end of the vagina is the **cervix**, the opening to the **uterus**, which in humans is about the size and shape of an inverted pear. Sperm pass through the cervix into the uterus, an organ specialized for carrying the developing embryo and fetus. It consists of an inner lining of glandular and secretory cells, called the endometrium, and a thick muscular layer, called the myometrium. We will discuss the functions of the uterus later in the chapter.

Oocytes develop within one of the two bilateral ovaries (see Figure 51.7), which are suspended within the abdominal cavity by connective tissue. In humans, each ovary is typically a little larger than an almond. Usually, a secondary oocyte leaves the ovary and is quickly drawn into a thin tube, the **oviduct** (also called the Fallopian tube), by the actions of undulating fimbriae (fingerlike projections) of the oviduct that extend out to the ovary.

The secondary oocyte is moved down the length of the oviduct by cilia on the oviduct's inner surface. For fertilization to take place, sperm must travel through the cervix and uterus and then into the oviduct, where fertilization typically occurs. Upon contact with a sperm, the secondary oocyte completes meiosis II, and the union of sperm and secondary oocyte creates a fertilized egg, or zygote. The zygote undergoes several cell divisions to become a **blastocyst**, a ball of approximately 32–150 cells that enters the uterus, where it will develop into an embryo (the details of this development are covered in Chapter 52).

Gametogenesis in Females Is a Cyclical Process Within the Ovaries

In contrast to males, in which spermatogenesis continues throughout postpubertal life in the testes, most female mammals appear to be born with all the primary oocytes they will ever have, although limited recent evidence suggests that new oocytes may form in mice later in life. At birth, each ovary in a human female has about 1 million primary oocytes, which are arrested in prophase of meiosis I. Most of these degenerate before the onset of puberty, when each ovary contains about 200,000 primary oocytes. Other than this degeneration, the ovaries are quiescent until puberty, when they begin to show cyclical activity.

The cells within all mammalian ovaries secrete a family of steroid hormones called estrogens (refer back to Figure 50.2). The most important estrogen is **estradiol**, which plays a critical role in ovulation and influences the secondary sex characteristics of females. In humans, the secondary sex characteristics, which begin to develop at puberty, include development of breasts, widening of the pelvis (an adaptation for giving birth), and a characteristic pattern of fat deposition.

The **ovarian cycle** involves the development of an ovarian follicle, the release of a secondary oocyte, and the formation and subsequent regression of a corpus luteum (**Figure 51.8**). During the first week of the ovarian cycle in humans, several primary oocytes that have been maturing for several months, each within their own follicle, now begin their final maturation steps. By the beginning of the second week, all but one of these growing follicles and its primary oocyte degenerate, and the single remaining follicle continues to develop and enlarge, and a new crop of immature follicles begins their slow growth period for future ovarian cycles. During that time, the primary oocyte of that follicle completes meiosis I, becomes a secondary oocyte, and begins meiosis II. The developing secondary oocyte is surrounded by cells of the cumulus mass and theca, which both protect and nurture it and which secrete estradiol. The estradiol is secreted into the blood, where it functions to control the secretion of LH and FSH from the anterior pituitary gland. Some estradiol is also secreted into the follicle, where it stimulates fluid secretion into the inner core. As the

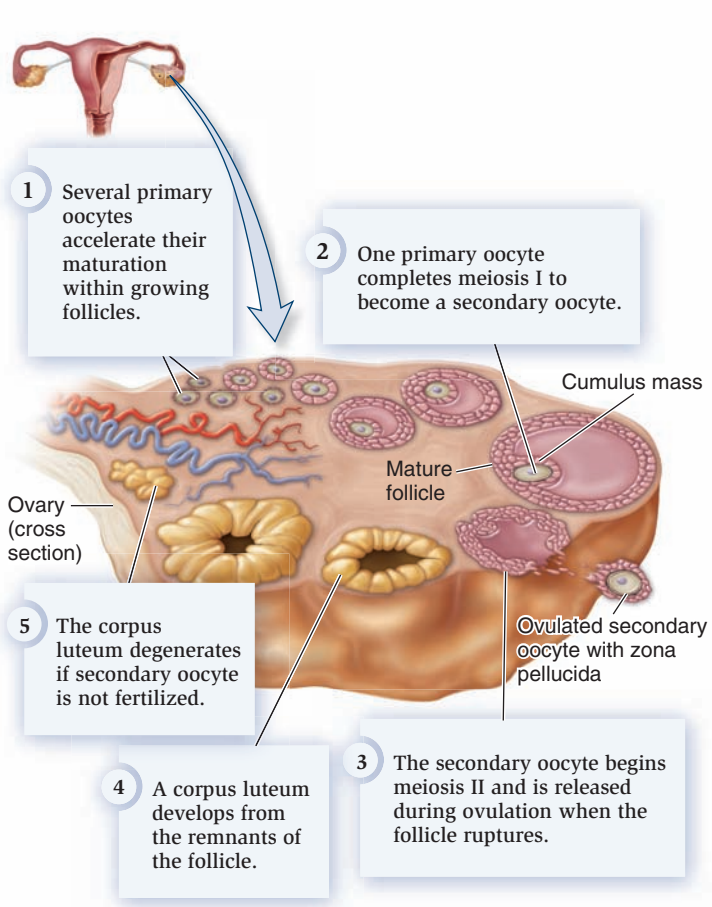

Figure 51.8 Follicle and oocyte development in the ovarian cycle. Development of an oocyte and corpus luteum within the ovary are events that occur during a single ovarian cycle.

BIOLOGY PRINCIPLE Living organisms grow and develop. This figure illustrates that growth and development do not necessarily stop in animals once they have reached maturity. Organs such as the human ovary can continue to develop throughout much of adulthood, as shown in this figure. Likewise, male gametes continue to develop throughout life in humans, as shown in Figure 51.5.

follicle grows in response to continued stimulation by LH and FSH, the fluid pressure inside the follicle increases, until it begins to form a bulge. Eventually, ovulation occurs as the follicle ruptures, and the secondary oocyte, zona pellucida, and some surrounding supportive cells of the cumulus mass are released from the ovary.

Cells in the empty follicle subsequently undergo pronounced anatomical and physiological changes, developing into a structure called the **corpus luteum**. In humans, the corpus luteum is active for approximately the second half of the ovarian cycle. It is responsible for secreting hormones that stimulate the development of the uterus that is required for sustaining the embryo in the event of a pregnancy. If pregnancy does not occur, the corpus luteum degenerates, and a new group of follicles with their primary oocytes develops.

In an adult female, the ovarian cycle may be as brief as a few days in small rodents or as lengthy as 15–16 weeks in elephants. In humans, a typical ovarian cycle lasts approximately 28 days. Ovulation and degeneration of additional primary oocytes continue throughout adulthood, with about 300–500 secondary oocytes ovulated over a woman's 30- to 40-year reproductive lifetime. Eventually, the oocytes become nearly depleted, and a woman stops having ovarian cycles, an event called **menopause**. The average onset of menopause in the U.S. is approximately 51 years of age. After menopause, a woman is no longer capable of becoming pregnant. At one time, scientists thought menopause was unique to humans, but it now appears that certain other female mammals, if they survive long enough, also become incapable of ovulation at some point.

The Ovarian Cycle Results from Changes in Hormone Secretion

We saw that in males, testosterone produced in the testes exerts a negative feedback on secretion of GnRH and LH. In females, however, the situation is more complicated. Although GnRH also stimulates release of LH and FSH in females, the resulting estradiol can have both negative and positive feedback effects on the gonadotropins. To understand this, let's examine the hormone changes that occur during the ovarian cycle in a human female (**Figure 51.9**).

The first half of the ovarian cycle is called the follicular phase of the cycle, because this is when the growth and differentiation of a cohort of follicles are occurring. The relatively low concentration of LH that exists during follicular development is sufficient to stimulate the cells of the follicle to make estradiol. The estradiol that is produced is important for enlargement and growth of the oocytes and it also is secreted into the blood, where it can influence the secretion of LH and FSH.

As these follicles develop, estradiol (and to a lesser extent, another steroid hormone called progesterone) production continues, and consequently, the concentration of estradiol in the blood slowly but steadily increases. Initially, estradiol exerts a negative feedback action on LH and FSH secretion, keeping their concentrations in check, and all but the largest of follicles die. When the remaining follicle is fully developed and ready for ovulation, its production of estradiol increases, such that the blood concentration of estradiol increases sharply. At that time, the feedback action of estradiol on LH and FSH switches from negative to positive, by mechanisms that involve increased GnRH secretion from the hypothalamus. This switch results in a sudden, sharp surge in gonadotropin concentrations in the blood, particularly LH.

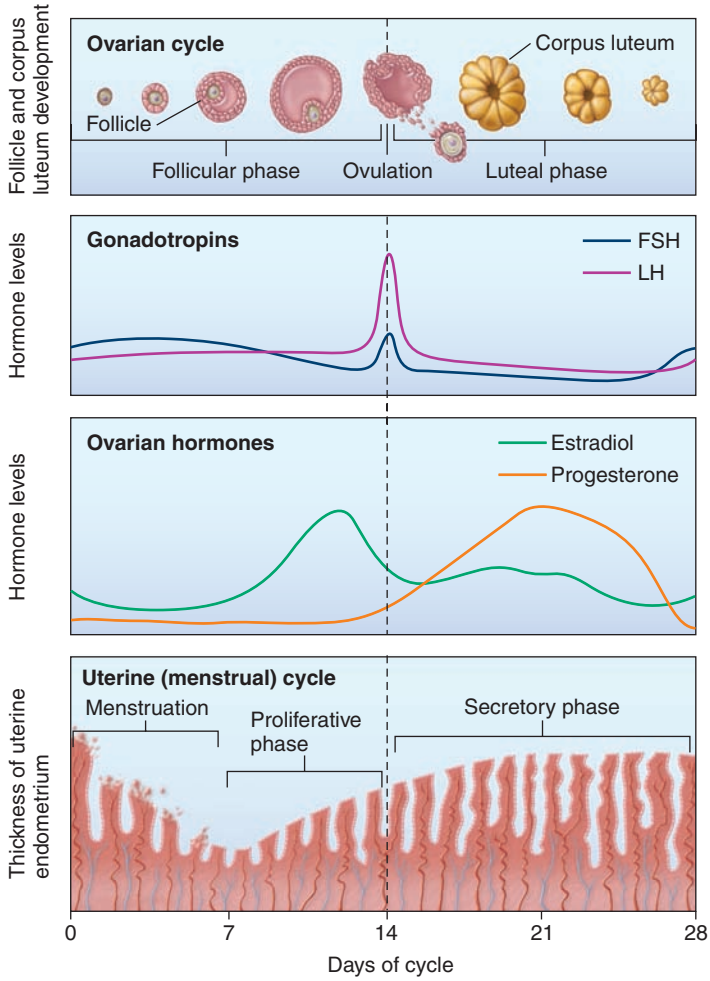

Figure 51.9 The ovarian and uterine cycles in a human female. The ovarian cycle is divided into the follicular and luteal phases. The uterine cycle is divided into menstruation and the proliferative and secretory phases.

Concept Check: Would similar surges in the concentrations of FSH and LH be expected to occur in human males?

The LH released from the pituitary as a result of positive feedback by estradiol induces rupture of the follicle and ovulation. Ovulation marks the end of the follicular phase and the beginning of the luteal phase of the ovarian cycle, named after the corpus luteum. Estradiol production decreases, and LH initiates development of the corpus luteum. The corpus luteum secretes progesterone, the dominant ovarian hormone of the luteal phase, plus some estradiol. Progesterone inhibits LH and FSH secretion, and it is essential for preparing the uterus to receive and nourish the embryo. If fertilization of the secondary oocyte does not occur, the corpus luteum degenerates after 2 weeks, allowing LH and FSH to initiate development of a new set of oocytes and their follicles. However, if fertilization does occur, the blastocyst develops a surrounding layer of cells that secrete an LH-like hormone, called **chorionic gonadotropin**, which maintains the corpus luteum and its ability to secrete progesterone. Chorionic gonadotropin is the hormone that is tested for by home pregnancy tests; it is excreted in the urine, where its presence is readily detectable.

Maternal Hormones Prepare the Uterus to Accept the Embryo

In humans, the ovarian cycle occurs in parallel with changes in the lining of the uterus called the **uterine cycle**, or **menstrual cycle**. The hormones produced by the ovarian follicle influence the development of the endometrium, the glandular inner layer of the uterus. As depicted at the bottom left of Figure 51.9, a period of bleeding called **menstruation** (from the Latin *mensis*, meaning month) marks the beginning of the uterine cycle and the follicular phase of the ovarian cycle. During menstruation, the endometrium is sloughed off and released from the body.

Menstrual cycles are found in many primates, including humans. Other mammals also have uterine cycles but often without the bleeding associated with menstruation. These cycles are called estrous cycles and are usually associated with a period of sexual receptivity in females that is timed to coincide with the ovulatory period. Cyclical changes in female sexual receptivity may be present in some primates with menstrual cycles but have never been documented to occur in humans.

By about the end of the first week of the menstrual cycle in humans, the endometrium is ready to grow again in response to the newly increasing concentration of estrogen secreted by a developing follicle. This phase of the menstrual cycle, which corresponds to the latter part of the ovarian follicular phase, is called the proliferative phase (see Figure 51.9). During this time, the endometrium becomes thicker and more vascularized. During the subsequent luteal phase of the ovarian cycle, progesterone from the corpus luteum initiates further endometrial growth, including the development of glands that secrete nutritive substances that sustain the embryo during its first 2 weeks in the uterus. This part of the menstrual cycle is called the secretory phase. If fertilization does not occur, degeneration of the corpus luteum and the associated decrease in progesterone and estrogen concentrations initiate menstruation and the beginning of the next uterine cycle. If fertilization does occur, however, and the blastocyst becomes embedded in the endometrium, pregnancy begins, as described next.

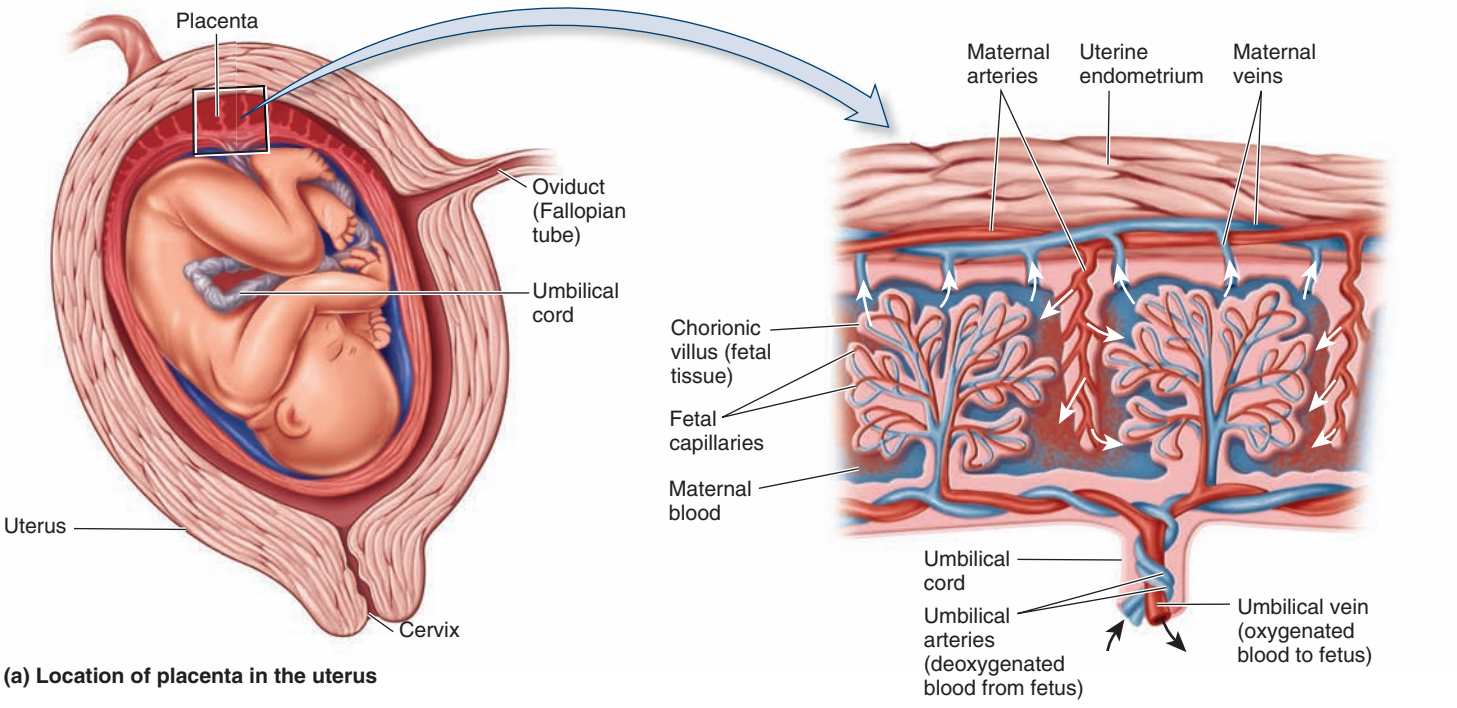
51.4 Pregnancy and Birth in Mammals

Learning Outcomes:

1. Describe the major developmental steps in the first trimester of pregnancy in mammals.
2. Explain the relationship between the fetal and maternal structures of the placenta.
3. Outline the hormonal control of the birth process.
4. **SciSKILLS** » Propose several mechanisms by which animals may synchronize the production of offspring with favorable environmental conditions.

Pregnancy, or gestation, is the time during which a developing embryo and fetus grows within the uterus of the mother. Physiologically, pregnancy is considered to begin not at fertilization but when the embryo is established in the uterine lining. This occurs within days of fertilization in animals with short gestation lengths but may take weeks in large animals with long gestations.

In mammals, gestation length varies widely and is roughly related to the size of adults in a particular species. Small animals such as hamsters and mice have gestation periods of 16–21 days, canines have longer pregnancies of about 60–65 days, humans average about 268 days, and the Asian elephant carries its fetus up to 660 days. The advantages of prolonging prenatal development are twofold: The embryo is protected while it is developing in the uterus, and the offspring can be more fully developed at birth. This is especially important for animals whose survival depends on mobility shortly after birth, such as horses and ruminants.



Gestation length is influenced not only by adult body size but also by the number of offspring in a single pregnancy. Rats, for example, which bear up to 12 or so offspring per litter, have a short gestation period and produce young that are relatively undeveloped at birth and are totally dependent on the mother. Horses, by contrast, have a long gestation period and typically give birth to a single, highly developed offspring. In this section, we will examine how mammals have evolved to retain their young in the uterus for extended periods, the structure and function of the nourishing placenta, and the role of hormones in pregnancy and birth.

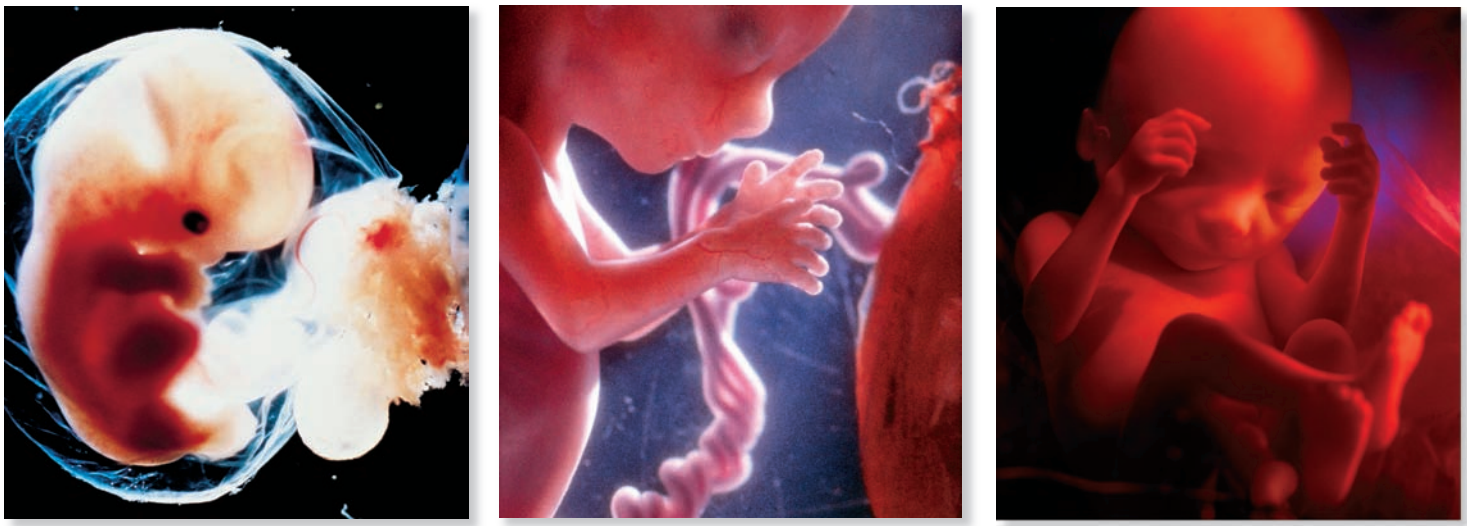
Most Mammals Retain Their Young in the Uterus and Nourish Them via a Placenta

Three types of pregnancies are found in mammals, which correspond to the three clades of mammals (refer back to Chapter 34). Monotremes such as the platypus are the only mammals that lay fertilized eggs. In marsupials such as the kangaroo, the young are born while still extremely undeveloped. They then crawl up the mother's abdomen to her pouch, where they attach to a nipple to suckle and obtain nourishment. They remain there and mature within the pouch. Compared with marsupials, humans and other eutherian mammals retain their young within the uterus for a longer period of time, and nourish them via transfer of nutrients and gases through a structure called the **placenta**.

During pregnancy, many physiological changes occur in both the embryo and the mother. The first event of pregnancy in eutherian (placental) mammals is **implantation**, when the blastocyst embeds within the uterine endometrium, which in humans typically occurs around 8–10 days after fertilization. Initially, the implanted blastocyst receives nutrients directly from endometrial glands. However, shortly after implantation, newly developing embryonic tissues merge with the endometrium to form the placenta (**Figure 51.10**), which remains in place and grows larger as the embryo matures into a **fetus**. (In humans, an embryo is called a fetus after the eighth week of gestation.) The placenta, therefore, has a maternal portion and a fetal portion.

The placenta is rich in blood vessels from both the mother and the fetus. The maternal and fetal sets of vessels lie in close proximity. The fetal portion of the placenta, called the chorion, contains convoluted structures called chorionic villi that provide a large surface area containing capillaries for exchange of nutrients, gases, and other solutes. Nutrients and oxygen from the mother are carried through maternal arteries, where her blood pools in large areas of the fetal placenta surrounding the fetal capillaries. Solutes diffuse from the maternal blood into fetal capillaries, and from there flow into the

(a) Location of placenta in the uterus



(b) Detailed view of the placenta

Figure 51.10 The structure of the placenta. In all mammals, the placenta is composed of both fetal and maternal tissues. **(a)** Location of placenta in the human. **(b)** Enlarged view of the placenta showing the relationship between fetal and maternal structures. Note that in humans, blood in the fetal and maternal circulations does not mix.

BioConnections: Note that the umbilical arteries are shown in blue to signify that they carry deoxygenated blood, and the umbilical vein is shown in red to signify it carries oxygenated blood. Normally, arteries carry oxygenated blood, and veins carry deoxygenated blood, except in the pulmonary circulation (see Figure 47.2b and Chapter 48). Why is the circulation through the placenta like that of the lungs?

umbilical vein, part of the fetal circulation. In turn, carbon dioxide and other waste products from the fetus are carried through the umbilical arteries to the placenta, where they diffuse into the mother's circulation, from which they can be excreted. Because of this placental organization, the blood of the mother and the fetus do not mix.

Prenatal development in humans is generally described arbitrarily as having three trimesters, each of which lasts about 3 months (Figure 51.11). During the first 2 months of pregnancy, the organs of the embryo develop. At the end of the first trimester, the rudiments of the organs are present, and the developing fetus is about an inch long.

(a) First-trimester human embryo (6 weeks)

(b) Second-trimester human fetus (16 weeks)

(c) Early third-trimester human fetus (about 24 weeks)

Figure 51.11 Prenatal development in humans.

The second trimester is an extremely rapid phase of growth. During the third trimester, the lungs of the fetus mature so that they are ready to function as gas-exchange organs (refer back to Figure 48.12).

Genomes & Proteomes Connection

The Evolution of the Globin Gene Family Has Been Important for Internal Gestation in Mammals

As discussed in Chapter 21 (see Figure 21.7), genes can be duplicated, which sometimes creates gene families. Gene families have been important in the evolution of complex traits because the various members of a gene family enable the expression of complex, specialized forms and functions. An interesting example is the globin gene family in animals. Globin genes encode polypeptides that are subunits of proteins that function in oxygen binding. Hemoglobin, which is made in red blood cells, carries oxygen throughout the body in all vertebrates and many invertebrates, delivering oxygen to all of the body's cells. In humans, the globin gene family is composed of several homologous genes that were originally derived from a single ancestral globin gene (refer back to Figure 21.8).

All of the globin polypeptides are subunits of proteins that function in oxygen binding, but the various family members tend to have specialized functions. For example, certain globin genes are expressed only during particular stages of embryonic development. This has particular importance in placental mammals, because the oxygen demands of a growing embryo and fetus are quite different from the demands of its mother. These different demands are met by the differential expression of hemoglobin genes during prenatal development.

Altogether, five globin genes, designated α, β, γ, ε, and ζ, encode the major subunits that are found in hemoglobin proteins at different developmental stages. During embryonic development, the ε-globin and ζ-globin genes are turned on, resulting in embryonic hemoglobin with a very high affinity for oxygen (**Table 51.1**; refer also to Figure 13.3). At the fetal stage, these genes are turned off, and the α-globin and γ-globin genes are turned on, producing fetal hemoglobin with slightly less (but still high) affinity for oxygen. Finally, just before birth, expression of the γ-globin gene decreases, and the β-globin gene is turned on, resulting in adult hemoglobin, which has a lower affinity for oxygen than either the embryonic or fetal forms. The higher affinities of embryonic and fetal hemoglobins enable the embryo and fetus to remove oxygen from the mother's bloodstream and use that oxygen to meet their own metabolic demands. Therefore, the expression of different globin genes at particular stages of development enables placental mammals to develop in the uterus without either breathing on their own or being continually exposed to atmospheric oxygen (as occurs for vertebrate embryos that develop externally within shelled eggs).

Table 51.1 Globin Gene Expression During Mammalian Development

Stage of development	Globin genes expressed	Hemoglobin composition	Oxygen affinity (P_{50})*
Embryo	ε-globin and ζ-globin	Two ε-globin and two ζ-globin subunits	5–13.5 mmHg
Fetus	γ-globin and α-globin	Two γ-globin and two α-globin subunits	19.5 mmHg
Birth to adult	β-globin and α-globin	Two β-globin and two α-globin subunits	26.5 mmHg

*P_{50} values represent the partial pressure of oxygen required to half-saturate hemoglobin (see Chapter 48): A lower P_{50} indicates a higher affinity of hemoglobin for oxygen. The value for embryos is an estimate based on in vitro experiments. All values are for human hemoglobins.

Birth Is Dependent on Hormones That Elicit a Positive Feedback Loop

Birth—also called **parturition**—is initiated by the actions of several hormones and other factors secreted by the mother and the placenta (**Figure 51.12**). Toward the end of pregnancy, hormones from the fetus stimulate the placenta to start secreting large amounts of estrogens such as estradiol into the maternal circulation. Estrogens have at least two major effects on uterine tissue at this time. First, they promote gap junction formation between uterine smooth muscle cells, which enables coordinated uterine contractions. Second, estrogens enhance uterine sensitivity to oxytocin.

Recall from Chapter 50 that oxytocin is a posterior pituitary hormone that stimulates contraction of uterine muscle. The high concentration of estradiol in the mother's blood near the end of pregnancy stimulates the production of oxytocin receptors within the cells of the smooth muscle layer of the uterus, making the uterus more sensitive to oxytocin. At the same time, the fetus usually positions itself with its head above the cervix in preparation for birth. The pressure of the fetus's head pressing on the cervix stretches the smooth muscle of the uterus and cervix. This stretch is detected by neurons in these structures. Signals from the stretch-sensitive neurons are sent to the mother's hypothalamus, triggering the release of oxytocin from the posterior pituitary.

Binding of oxytocin to its receptors initiates the strong uterine muscle contractions that are the hallmark of **labor**. In addition to its direct action on uterine muscle, oxytocin stimulates uterine secretion of small molecules called prostaglandins that act with oxytocin to increase the strength of the muscle contractions. The stronger contractions elicit more oxytocin release from the mother's pituitary, which causes yet stronger contractions, setting up a positive feedback loop that continues until the baby is born.

Labor occurs in three stages (**Figure 51.13**). The initial stage induces dilation and thinning of the cervix to allow passage of the fetus out of the uterus. As the uterine contractions get stronger and more frequent toward the end of labor, the fetus is pushed, usually headfirst, through the cervix and the vagina and out into the world; this is the second stage of labor. In the third and final stage, the contractions continue for a short while. Blood vessels within the placenta

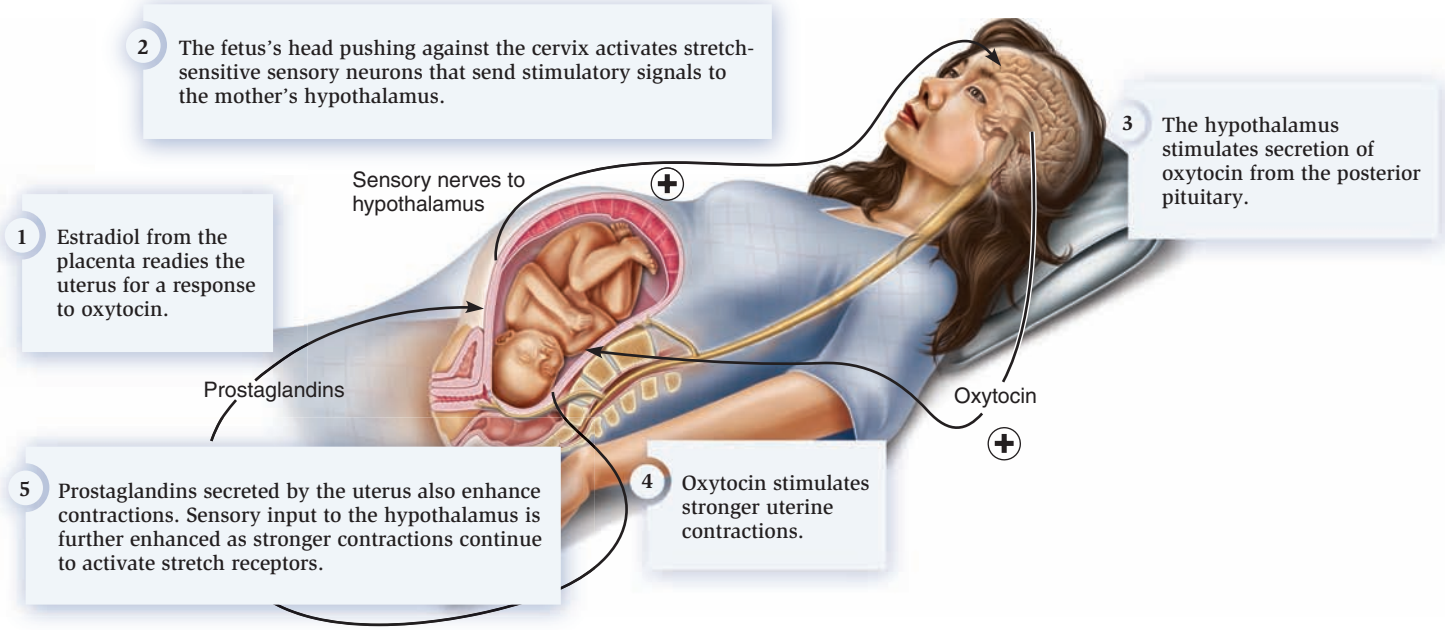


Figure 51.12 Hormonal control of parturition. Birth relies on maternal hormones that act on the uterus and neural signals from the uterus. In response to sensory neural input arising from the push of the fetus on the cervix, the maternal posterior pituitary releases oxytocin into the blood, which stimulates uterine smooth muscle contractions. The secretion of prostaglandins by the uterus also increases the strength of the contractions. Sensory receptors in the uterus detect the more forceful contractions and signal the mother's posterior pituitary to secrete more oxytocin, thus completing a positive feedback loop that further strengthens the contractions.

and umbilical cord contract and block further blood flow, making the newborn independent from the mother. As the oxytocin-induced contractions continue for a short period, the placenta detaches from the uterine wall and is delivered a few minutes after the birth of the baby.

In mammals, the young are nurtured for a period after birth by milk produced within the mother's mammary glands and secreted via the nipples. The monotremes, in which the young of some species use their pliable bills to attach to the breast of the mother and draw milk directly through the skin, are an exception. The production of milk is called **lactation**. During pregnancy, the placenta secretes progesterone. Progesterone, in turn, suppresses the secretion of the anterior pituitary hormone prolactin, which is required for milk production. In humans, lactation begins shortly after birth in response to the sudden decrease in the blood concentration of progesterone, which was previously provided by the placenta. Whereas the synthesis of milk is dependent on prolactin, the actual release of milk from the breast depends on activation of smooth muscle cells surrounding secretory ducts in the breast. These cells are stimulated to contract by the presence of oxytocin. Oxytocin, therefore, has key functions in two major and different processes: birth and lactation.

In Some Species, Reproduction Is Synchronized with Favorable Times of Year

A species' survival depends on successful production of offspring, and the likelihood that those offspring will survive to adulthood and reproduce is influenced to a large degree by the environment into which they are born. For that reason, reproductive cycles often occur at times of the year when the likelihood of reproductive success is

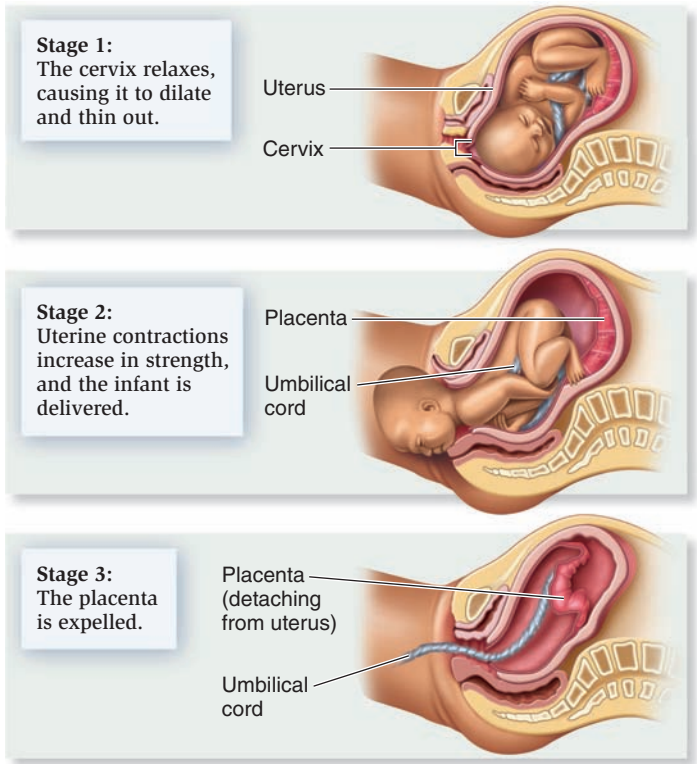

Figure 51.13 The three stages of labor.

Concept Check: Many female mammals consume the placenta after giving birth. What is the benefit of this behavior?

greatest—when the young will have sufficient nutrients to sustain them during their period of rapid growth. In general, animals that live under more uniformly favorable conditions—stable temperatures, ample rainfall, and abundant food—have less well defined cycles of reproductive activity. Many tropical species, for example, reproduce several times each year. By contrast, many temperate zone animals have seasonal reproductive cycles that reflect the large fluctuations in environmental conditions.

Animals often synchronize the production of offspring with favorable environmental conditions by several means. In **sperm storage**, females store and nourish sperm in their reproductive tract for long periods of time. For example, certain insectivorous bats such as the little brown myotis (*Myotis lucifugus*) mate in the fall, but the ovarian cycle in females is halted before ovulation, and sperm are stored and nourished in the female's uterus over the winter. Upon arousal from hibernation in the spring, the female ovulates one or more oocytes, which are fertilized by the stored sperm. This type of reproductive cycle, called **delayed ovulation**, ensures that such bats mate when they are in prime condition and that young are born when temperatures and food supplies are optimal.

Other mammals have **delayed implantation**, in which a fertilized egg reaches the uterus but does not implant until environmental conditions are more favorable for the newly produced young. This type of reproduction is common among carnivores, notably the mustelids (weasels) and some bears.

Finally, many mammals (cats, some hamsters, and sheep) and many birds have seasonal periods of mating followed immediately by implantation and pregnancy. Such seasonal breeding results from neuroendocrine changes in the hypothalamus in response to changes in the length of daylight. In some seasonal breeders with short gestation periods, such as hamsters, these neuroendocrine changes occur when day length increases in spring. The young are born in the late spring or in summer when conditions are favorable. Other seasonal breeders with long gestation times—sheep, for example—reproduce in response to shorter day length. Ewes are impregnated by rams in the fall, as the days grow shorter, and they carry the pregnancy through the winter. Lambs are born in the spring, providing a relatively long growth period before onset of the next winter. If sheep mated in summer, lambs would be born in late fall or winter, when conditions are much less favorable.

Unlike the examples just described, humans neither have a seasonal breeding cycle nor alter the timing of implantation or ovulation. Moreover, sperm can survive in a woman's reproductive tract for only a short time—2 or 3 days. Human reproduction, therefore, is far less responsive to environmental changes, day length, or other factors. However, human reproductive success can be seriously curtailed by sickness and other factors, as we see next.

51.5 Impact on Public Health

Learning Outcomes:

1. Explain the most common causes of human infertility.
2. Compare the different types of birth control and their mechanisms of pregnancy prevention.

Human reproduction can be affected by many factors, some voluntary and some not. Approximately 5–10% of individuals of reproductive age in the U.S. are not fertile; that is, they cannot reproduce. In men and women alike, fertility can be compromised by a variety of factors. In this section, we will discuss some of the common causes of **infertility**—the inability of a man to produce sufficient numbers or quality of sperm to impregnate a woman, or the inability of a woman to become pregnant or maintain a pregnancy. We will then examine the methods in use today to prevent pregnancy.

Infertility May Result from Disease, Developmental Disorders, Inadequate Nutrition, and Stress

As many as 75% of infertility cases have some identifiable cause, ranging from disease to toxin exposure.

Disease Primary among the diseases that affect fertility are sexually transmitted diseases (STDs). For example, some STDs cause blockage in the ducts of the testes, thus preventing normal sperm transport, or cause permanent damage to the Fallopian tubes, uterus, and surrounding tissues.

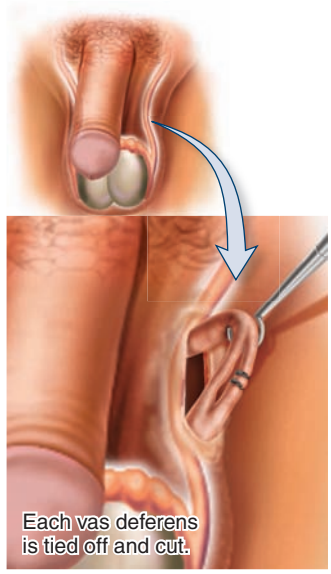
Developmental Disorders Developmental disorders are conditions that are either present at birth or arise during childhood and adolescence. In some developmental disorders that affect fertility, inherited mutations of genes that code for enzymes involved in the synthesis of reproductive hormones cause abnormal expression of those genes. The result is either too much or too little of one or more of these hormones, notably estradiol or testosterone. Other developmental disorders that compromise fertility include malformations of the cervix or oviducts.

Inadequate Nutrition Adequate nutrition is required for normal growth and development of all parts of the body, including the reproductive system. Because the reproductive system is not essential for an individual's survival, it often becomes inactive when nutrients are chronically scarce, such as during starvation. In this way, precious stores of energy in the body are preserved for vital functions, such as those of the brain and heart. Nutrition can also affect reproduction before adulthood. Undernourished children may enter puberty several years later than normal. The brains of all mammals, including humans, contain a center that monitors the body's fat stores. One of the triggers that initiate puberty in girls may be a signal—such as the hormone leptin—from adipose tissue to the brain (refer back to Figure 46.7). Very low fat stores in undernourished girls signal the brain that the body does not contain sufficient fuel to support the energetic demands of pregnancy; consequently, puberty is delayed.

Stress Starvation or poor nutrition is considered a type of stress, defined in animal biology as any real or perceived threat to an animal's homeostasis. Physical and psychological stress can and do affect fertility in humans. In the short term, stress can produce hormonal changes that are adaptive in meeting a crisis. However, long-term stress is damaging to many aspects of health, including reproductive health. Many nonessential functions, including the maintenance of

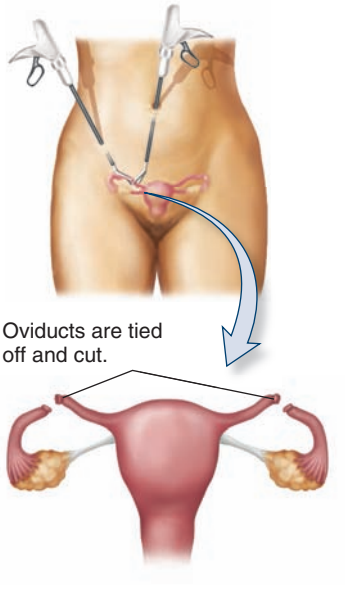
menstrual cycles in women, can be suppressed by chronic stress. The reproductive consequences of stress are much greater in females than in males, very likely because only females bear the energetic cost of pregnancy. Interestingly, from a reproduction viewpoint, the human body responds to long-term extreme exercise in a way that is similar to its response to long-term stress. This is why many young ballerinas and gymnasts experience delayed puberty and why in female marathon runners, menstrual cycles may be abnormal or absent.

Other Causes of Infertility When the causes of infertility cannot be determined, a variety of factors come under suspicion. Among these possible causes are ingestion of toxins (for example, certain heavy metals such as cadmium), tobacco smoking, marijuana use, and injuries to the gonads. Recall also that as women age, they experience a loss of fertility, an event called menopause. Although reproductive function declines with age in men, they typically do not experience complete cessation of gamete production, even at very advanced ages.



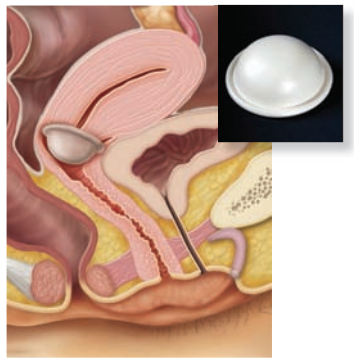
Among several currently available treatments for increasing the likelihood of pregnancy in infertile couples are hormone therapy for the woman to increase egg production and a collection of procedures known as **assisted reproductive technologies (ART)**. In the most common ART procedure, called in vitro fertilization, sperm and eggs collected from a man and a woman are placed together in culture dishes. Once the sperm have fertilized the eggs and the resulting zygotes have undergone several cell divisions, one or more embryos are inserted into a woman's uterus with the goal that one will implant. When this procedure was first used in 1978, the children born as a result came to be known as test-tube babies. Since then, over 200,000 children have been born using this technology, which is typically effective about 30–35% of the time.

Contraception Usually Prevents Pregnancy



The use of methods to prevent fertilization or the implantation of a fertilized egg is termed **contraception**. Methods of contraception can be either permanent or temporary. The permanent forms of contraception surgically prevent the transport of gametes through the reproductive tract (**Figure 51.14a**). **Vasectomy** is a surgical procedure in men that severs the vas deferens, thereby preventing the release of sperm at ejaculation (however, semen is still released). In women, **tubal ligation** involves the cutting and sealing of the oviducts. This procedure prevents the movement of the egg from the oviduct into the uterus. These procedures are considered permanent, because it is difficult—sometimes impossible—to reverse the surgery.

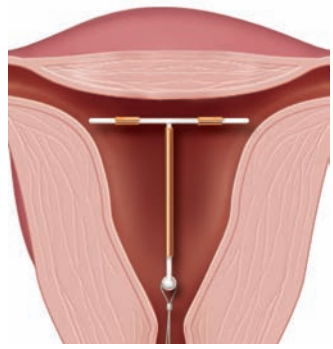
Temporary methods of preventing fertilization include barrier methods, which prevent sperm from reaching an egg (**Figure 51.14b**). Barrier methods include **vaginal diaphragms**, which are placed in the upper part of the vagina just prior to intercourse and block movement of sperm to the cervix, and **condoms**, which are sheathlike membranes worn over the penis that collect the ejaculate. In addition to their contraceptive function, condoms significantly reduce the risk of STDs such as HIV infection, syphilis, gonorrhea, chlamydia, and herpes. Other types of contraception do not reduce this risk.



Another temporary form of contraception involves synthetic hormones. Oral contraceptives (birth control pills) are synthetic forms of

Vasectomy (<1.0%)
(a) Permanent methods

Tubal ligation (<1.0%)



Diaphragm (5–20%)

Condoms (male) (2–15%)

Oral contraceptive (1–2%)
(b) Temporary methods

Intrauterine device (IUD) (1–2%)

Figure 51.14 Examples of contraceptive methods. These methods may be used by men or women to **(a)** permanently or **(b)** temporarily prevent pregnancy. The estimated first-year failure rates for each method are given in parentheses (collected from data published by the U.S. Food and Drug Administration and other organizations). A failure rate of 10% means that 10 of every 100 women using that method of contraception will become pregnant in the first year of use. The large range for use of condoms and diaphragms is due to improper use of these devices by many people. Female condoms are also available and have a failure rate of approximately 20%.

estradiol and progesterone, taken by mouth, that prevent ovulation in women by inhibiting pituitary LH and FSH release. The hormones in these pills also affect the composition of cervical mucus such that sperm cannot easily pass through it into the uterus. In addition to the oral route, hormones can be administered by injections, skin patches, and vaginal rings.

The last temporary method of contraception involves placement in the uterus of an **intrauterine device (IUD)**, a small object that interferes with the endometrial preparation required for acceptance of the blastocyst. Unlike the other forms of contraception described here, an IUD works after fertilization—by preventing implantation (although some IUDs also inhibit sperm movement and survival in the uterus). Although not as widely used as other contraceptives in the U.S., IUDs are the most commonly used means of contraception by women worldwide because of their effectiveness and simplicity of use.

In addition to the contraceptive methods used before or during intercourse, within 72 hours after intercourse, women can take a variety of drugs that typically interfere with ovulation or implantation. Approaches include a high dose of estrogen, or two large doses (12 hours apart) of a combined estrogen-progestin oral contraceptive. However, the drug RU486 (mifepristone) is more effective and produces fewer side effects; this drug antagonizes progesterone's effects on the endometrium, causing it to erode.

Used prior to the advent of modern contraception, and still in use today by individuals who prefer not to use contraceptives, is the rhythm method, which involves abstaining from sexual intercourse near the time of ovulation. Its main drawback is the difficulty in precisely pinpointing the time of ovulation. One problem with predicting the time of ovulation is that several of the detectable changes characteristic of the midpoint of the ovarian cycle—including a small rise in body temperature and changes in the cellular characteristics of the vaginal epithelium—occur only after ovulation. This problem, plus the fact that ovulation can occur any time between days 5 and 15 of the 28-day cycle, explains why the rhythm method has a relatively high failure rate.

Summary of Key Concepts

51.1 Overview of Asexual and Sexual Reproduction

- Asexual reproduction occurs when offspring are produced from a single parent, without the fusion of genetic material from two parents. Budding, regeneration, and parthenogenesis are mechanisms of asexual reproduction (Figure 51.1).
- Sexual reproduction is the production of a new individual by the joining of two haploid gametes: a sperm from the father and an egg from the mother. The union of a sperm and an egg—fertilization—produces a diploid zygote, which develops into an embryo.
- Sexual reproduction was shown by Paland and Lynch to be more effective in eliminating deleterious mutations from populations of *Daphnia* than asexual reproduction (Figure 51.2).

51.2 Gametogenesis and Fertilization

- Male and female gametes are formed within the gonads—the testes in males and the ovaries in females.
- Gametogenesis—the formation of gametes—begins with diploid primordial cells called germ cells. In spermatogenesis, one spermatogonium yields four sperm cells. In oogenesis, meiosis yields one egg. Within the ovaries, each oocyte undergoes growth and development within a structure called a follicle before it leaves the ovary in a process called ovulation (Figure 51.3).
- In external fertilization, sperm and eggs are released into an aquatic environment where they unite and avoid desiccation. Terrestrial animals use internal fertilization, in which sperm are deposited within the reproductive tract of the female during the act called copulation (Figure 51.4).
- In hermaphroditism, individuals can fertilize their own eggs with their own sperm, but in most hermaphroditic species, individuals exchange sperm with another individual.

51.3 Mammalian Reproductive Structure and Function

- Sperm produced within each testis move out of the seminiferous tubules and into the epididymis, which leads into the vas deferens, a muscular tube leading to the ejaculatory duct. The urethra conducts semen, a mixture containing fluid and sperm, during ejaculation. The fluid components of semen are produced in the seminal vesicles, the bulbourethral glands, and the prostate gland (Figures 51.5, 51.6).
- The external female genitalia are composed of the labia majora, the labia minora, and the clitoris; the internal female genitalia consist of the vagina, uterus, oviducts, and each of two ovaries. In the ovary, primary oocytes develop into secondary oocytes (the ovarian cycle). Sperm typically fertilize secondary oocytes in the oviduct. The fertilized egg undergoes several cell divisions to become a blastocyst, a ball of cells that enters the uterus, where it will develop into an embryo (Figures 51.7, 51.8).
- In females, changes in hormone secretion produce the ovarian cycle and also control the uterine cycle or menstrual cycle (Figure 51.9).
- The cessation of ovarian cycles is called menopause.

51.4 Pregnancy and Birth in Mammals

- The time during which a developing embryo and fetus grow within the uterus of the mother is termed pregnancy, or gestation. Humans and other eutherian mammals retain and nourish their young within the uterus via transfer of nutrients and gases through a structure called the placenta (Figure 51.10).
- The first event of pregnancy is implantation, when the blastocyst imbeds within the uterine endometrium. Newly developing embryonic tissues merge with the endometrium to form the placenta, which remains in place and grows larger as the embryo matures into a fetus. There are three trimesters to human pregnancy (Figure 51.11).
- The evolution of the globin gene family contributed to the ability of placental mammals to develop inside the mother's uterus (Table 51.1).
- Birth, or parturition, is initiated by the actions of hormones produced by the placenta and by the mother's endocrine system. The hormone oxytocin stimulates the strong uterine muscle contractions that are the hallmark of the three-stage process called labor (Figures 51.12, 51.13).

- In mammals, the young are nurtured for a period after birth by milk produced in the process called lactation.
- Animals synchronize the production of offspring with favorable environmental conditions by several means, including sperm storage, delayed ovulation, delayed implantation, and seasonal mating.

51.5 Impact on Public Health

- Infertility is the inability of a man to produce sufficient numbers or quality of sperm to impregnate a woman, or the inability of a woman to become pregnant or maintain a pregnancy. A primary cause of infertility is STDs.
- The use of procedures to prevent fertilization or implantation of a fertilized egg is termed contraception. Methods of contraception include vasectomy and tubal ligation, vaginal diaphragms, condoms, oral contraceptives, and IUDs (Figure 51.14).

Assess and Discuss

Test Yourself

1. The development of offspring from unfertilized eggs is
   a. budding.
   b. cloning.
   c. fragmentation.
   d. parthenogenesis.
   e. implantation.
2. Which is considered an advantage of sexual reproduction?
   a. necessity to locate a mate
   b. increased energy expenditure in producing gametes that may not be used in reproduction
   c. increased genetic variation
   d. decreased genetic variation
   e. both a and b
3. Spermatogonia
   a. are haploid germ cells.
   b. are mature haploid cells.
   c. are male gametes.
   d. have flagella.
   e. are diploid germ cells.
4. Compared with external fertilization, in internal fertilization,
   a. male gametes have a higher chance to come into close proximity to female gametes.
   b. gametes are less protected against predation or other harmful environmental factors.
   c. there is a decreased likelihood of desiccation of gametes.
   d. gametes come into contact only outside the mother's reproductive tract.
   e. Both b and c are true of internal fertilization.
5. Which of the following statements is *true*?
   a. The majority of animals reproduce by asexual reproduction.
   b. Budding, regeneration, and parthenogenesis account for reproduction in nearly all invertebrates.
   c. A zygote is the haploid structure produced by the union of a sperm and egg.
   d. Potentially beneficial alleles are more likely to accumulate in species that reproduce sexually than in species that reproduce asexually.
   e. In asexual reproduction, gametes from each parent join to form a zygote.
6. The fructose in semen is secreted by the
   a. epididymis.
   b. seminiferous tubules.
   c. seminal vesicles.
   d. prostate gland.
   e. bulbourethral glands.
7. A major function of FSH is to
   a. stimulate the development of the gonads in embryos.
   b. stimulate spermatogenesis in males and oocyte maturation in females.
   c. increase the secretion of testosterone by the testes.
   d. regulate the secretion of the bulbourethral glands.
   e. inhibit the activity of Sertoli cells in the testes.
8. During the human ovarian cycle, ovulation is stimulated by
   a. a decrease in FSH secretion.
   b. an increase in progesterone secretion.
   c. an increase in LH secretion.
   d. the presence of semen in the vagina.
   e. a decrease in estradiol concentration in the blood.
9. During the secretory phase of the menstrual cycle, endometrial glands secrete
   a. hormones that increase the likelihood of pregnancy.
   b. nutritive substances that sustain an embryo during the first 2 weeks of development.
   c. hormones that prevent ovulation.
   d. waste products into the lumen of the uterus.
   e. both a and c.
10. During the _____ stage of labor in mammals, the placenta is expelled from the uterus.
    a. first
    b. second
    c. third
    d. It is not expelled; the placenta is reabsorbed.

Conceptual Questions

1. What disadvantages are associated with external fertilization, and what is one major way in which animals overcome those disadvantages?
2. How does the hypothalamus influence vertebrate reproduction?
3. A principle of biology is that *living organisms use energy*. What are some of the energy costs associated with sexual reproduction? What outweighs those costs and accounts for the observation that most animals reproduce sexually?

Collaborative Questions

1. Define asexual reproduction and give three examples.
2. Describe the events of the ovarian and uterine cycles and their timing with respect to each other.

CHAPTER OUTLINE

52.1 Principles of Embryonic Development
52.2 General Events of Embryonic Development

Summary of Key Concepts
Assess and Discuss

Animal Development

52

How embryonic development can go wrong—a normal zebrafish embryo (top) and one experimentally exposed to a high concentration of an artificial estrogenic compound (bottom). Many animals become exposed in nature to endocrine disruptors such as the one that caused the abnormal development of this animal.

During the late 1950s and early 1960s in Europe, a drug called thalidomide was developed for use as an anticonvulsive treatment for epilepsy; it was also prescribed as a treatment for allergies. Although further testing revealed no beneficial effects on these conditions, it was noted that thalidomide seemed to calm nausea and help people sleep. This led, by 1961, to thalidomide being the most widely used sleeping medication in Europe, where it was also prescribed to combat morning sickness (nausea) in pregnant women.

Soon afterward, however, physicians in Europe noticed that babies born to mothers who had taken thalidomide sometimes had severely malformed limbs, with hands and feet often emanating directly from the body. It became clear that certain cells in human embryos, such as those that give rise to arms and legs, are selectively and adversely affected by this toxic compound. Ultimately, thousands of babies worldwide were deformed due to thalidomide. The drug was quickly eliminated from pharmaceutical markets, and the U.S. was largely spared from its effects due to prompt legislative action by the Food and Drug Administration that blocked its sale. Such tragedies underscore the importance of continued research into the mechanisms that regulate the normal development of an embryo. Environmentally or drug-induced developmental abnormalities occur throughout the animal kingdom. The chapter opening photo, for example, shows the effect of exposure to an artificial estrogen-like compound during a critical stage of development of a zebrafish embryo. (An **embryo** is an early stage of a multicellular organism during which the organization of the organism is largely formed.) Such models are helping researchers understand the effects of alcohol consumption and other environmental factors on human embryo development.

In Chapter 19, we saw how the sequential actions of genes provide a program for the development of an organism from a fertilized egg to an adult. In this chapter, we will learn about the cellular and molecular processes that lead to the formation of an animal embryo. We will first briefly review some basic principles of development from Chapter 19. Then we will consider the five general events of embryonic development in animals. Next, we will examine the cellular and molecular mechanisms that control development. We conclude with an overview of how abnormal development affects the human condition.

BIOLOGY PRINCIPLE **Living organisms interact with their environment.** As you read this chapter, consider the many environmental factors that animals such as zebrafish (*Danio rerio*) and humans are exposed to during embryonic development.

52.1 Principles of Embryonic Development

Learning Outcomes:

1. Define embryonic development and body plan.
2. Describe the process of cellular differentiation.

The process by which a fertilized egg (that is, a **zygote**) is transformed into an animal with distinct physiological systems and body parts is called **embryonic development**. The biological information

that controls embryonic development resides in both the animal's genetic material—its DNA—and in the cytoplasm of the egg. A fertilized egg first becomes transformed into a cluster of cells without specialized functions and ultimately develops into a complex organism containing organs with specific functions. Embryonic development is often accompanied by growth, but they are different processes. Development produces organisms with a defined set of characteristics, whereas growth produces more or larger cells. Let's begin by reviewing some of the fundamental features of development, first introduced in Chapter 19.

As animals develop, cells arrange themselves in coordinated ways that lead to the establishment of a **body plan**. The final, adult body plan of most animals is organized along three axes: the **dorsoventral axis**, the **anteroposterior axis**, and the **left-right axis** (refer back to Figure 19.2a). Along these axes are often separate sections, or body segments, each containing specific body parts such as wings or legs.

To establish the correct body plan, each cell in a developing animal must receive information regarding its relative position within the body. Such information determines where a cell should move to, whether or not it should divide (or die), and what types of functions it will ultimately perform. This is possible because each cell receives positional information from its neighboring cells. This information is provided in a variety of ways, including intracellular and extracellular signaling molecules and cell-to-cell contacts (refer back to Figure 19.5).

In addition to stimulating cells to divide or to die (by apoptosis), positional information may cause the migration of a cell or group of cells from one region of the embryo to another (refer back to Figure 19.3). It may also cause **cellular differentiation**—the process by which different cells within a developing organism acquire specialized forms and functions, due to the expression of cell-specific genes. (In the thalidomide cases discussed in the chapter introduction, for example, cells that should have differentiated into those capable of developing into limbs were destroyed or damaged.) Now let's look at the general events that occur during embryonic development in animals.

52.2 General Events of Embryonic Development

Learning Outcomes:

1. **SciSKILLS »** Describe the general events of embryonic development, and identify the end result of each.
2. Compare and contrast the fast block to polyspermy and the slow block to polyspermy.
3. Describe the process of cleavage, beginning at fertilization and leading to gastrulation.
4. **SciSKILLS »** Predict the fates of cells in a gastrula as they differentiate into the three major germ layers.
5. Outline the early development of the nervous system during neurulation.
6. Describe the migration and fates of neural crest cells.

Even though the adult forms of animals vary immensely in size and morphology, embryonic development follows a similar pattern in most animals. As described in Chapter 32, most modern animals are triploblastic; that is, they develop from embryos with three germ cell layers. Such triploblasts include vertebrates, arthropods, echinoderms, and mollusks. Development in these animals can be categorized into five general events: fertilization, cleavage, gastrulation, neurulation, and organogenesis (**Figure 52.1**). In this section, we will examine the key aspects of each of the five general events. However, it should be noted that many species also have an additional event called metamorphosis, which is a transition from a feeding larval form to an adult (refer back to Figures 1.13, 33.27, 50.14, and 50.15). Metamorphosis occurs after organogenesis and facilitates the rapid growth of young organisms into mature ones.

Event 1: Fertilization Involves a Union Between Sperm and Egg to Create a Zygote-Stage Embryo

The events in **fertilization**—the union of a sperm and an egg—are quite similar in all triploblasts. The description that follows summarizes some of the hallmark events following external fertilization in the sea urchin, a well-studied model organism.

Acrosomal Reaction In sea urchins, as in many animals, the sperm must penetrate a jelly-like layer consisting of glycoproteins and polysaccharides before contacting the plasma membrane of the egg. The sperm is able to do this because of the **acrosomal reaction**, in which proteases and other hydrolytic enzymes are released from the acrosome, a structure at the tip of its head, onto the jelly coat of the egg (**Figure 52.2a**). These enzymes dissolve a localized region of the jelly coat, allowing the sperm head to bind to proteins in the egg's plasma membrane. Binding is followed by fusion of the sperm head membrane with the egg membrane, and shortly thereafter by penetration of the sperm head and release of its nucleus into the egg.

Additional sperm are prevented from fusing with the egg because the fusion of sperm and egg plasma membranes depolarizes the egg. This depolarization changes the properties of the membrane of the egg, blocking other sperm from binding to egg membrane proteins; this process is known as the **fast block to polyspermy**. Without this block, a single egg could receive chromosomes from two or more sperm, resulting in a zygote that would fail to develop normally or at all. Polyspermy does occur in some animals, notably urodeles (newts and salamanders), but in such cases, the nucleus from only one sperm fuses with the nucleus of the egg, and the remaining nuclei are degraded inside the egg.

Cortical Reaction The acrosomal reaction is followed by the **cortical reaction** (**Figure 52.2b**). Normally, the cytosolic calcium ion (Ca^{2+}) concentration in eggs, as in most cells, is kept low by several mechanisms, including one in which Ca^{2+} is transported by an ATP-dependent pump out of the cytosol and into the endoplasmic reticulum. When the sperm binds to the egg, a second messenger (see Chapter 9) called inositol trisphosphate (IP_3) is released from the region of the plasma membrane nearest to the sperm entry point. IP_3 then binds to nearby sites on the endoplasmic reticulum (ER) and

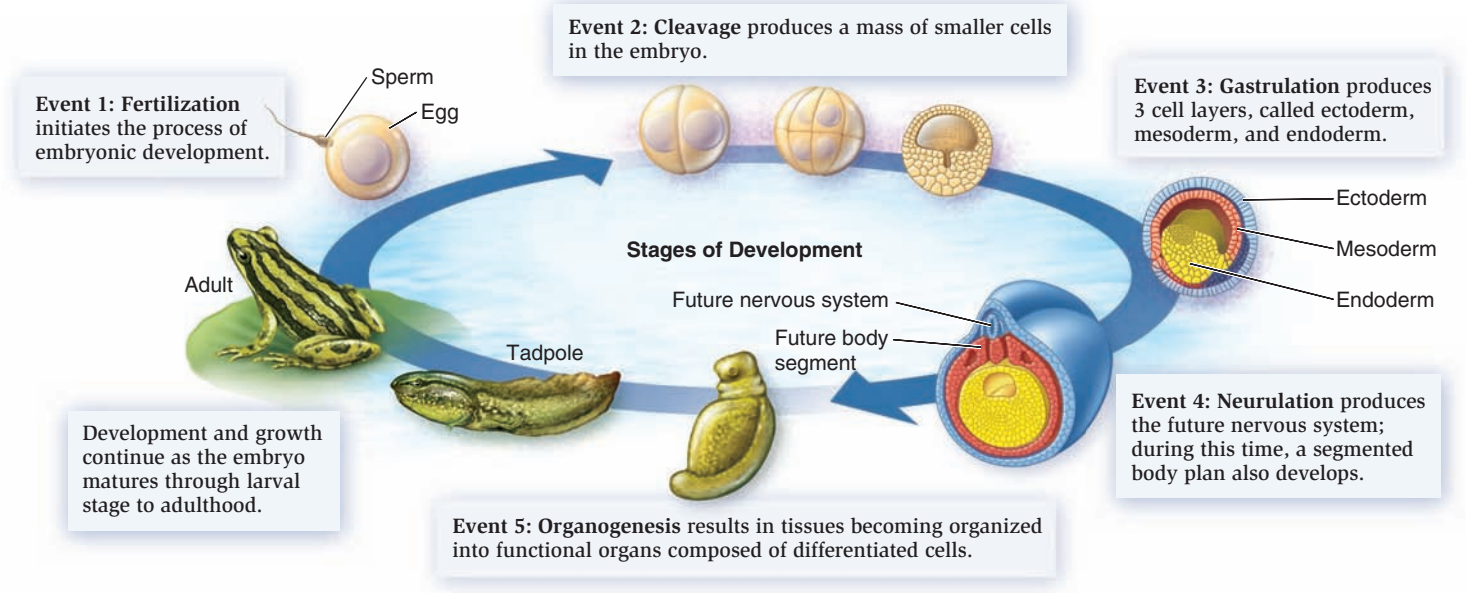

Figure 52.1 Overview of events of embryonic development. This figure shows the general events that all vertebrate embryos go through, using a frog as an example.

BioConnections: What is the final process by which a tadpole develops into an adult frog called, and is this process unique to frogs? (Refer back to Figures 1.13, 33.27, 50.14, and 50.15 for a hint.)

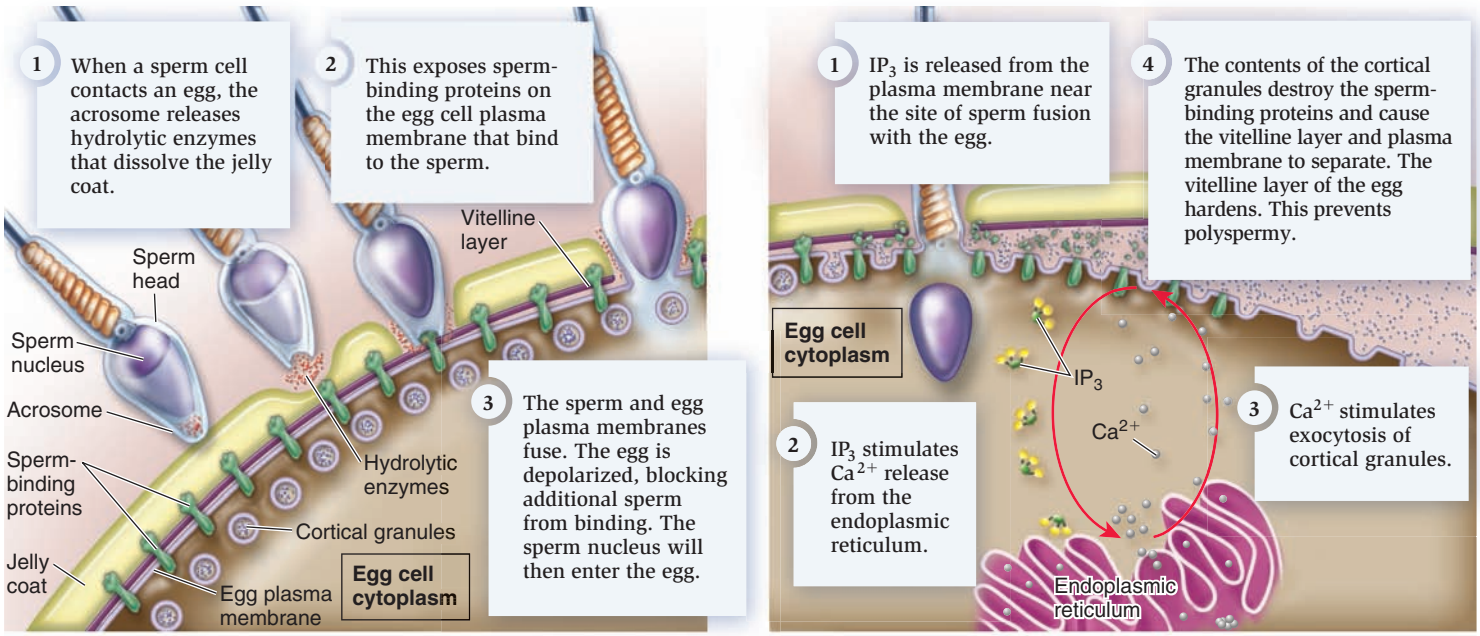

Figure 52.2 The acrosomal and cortical reactions during fertilization of an egg by a sperm. **(a)** Acrosomal reaction. The contact of a sperm with an egg initiates a series of events that permits the head of the sperm to bind to the plasma membrane of the egg. This depolarizes the egg and blocks other sperm from entering (the fast block to polyspermy). **(b)** Cortical reaction. Sperm fusion leads to an increased concentration of cytosolic Ca^{2+} that ultimately causes the vitelline layer of the egg to harden, creating the slow block to polyspermy.

opens Ca^{2+} channels. Ca^{2+} diffuses down its electrochemical gradient from the lumen of the ER into the cytosol.

The release of Ca^{2+} in the cortical reaction has several important effects. First, membrane-bound vesicles in the egg's cytosol, called cortical granules, release enzymes and other substances that inactivate the sperm-binding proteins on the plasma membrane. In addition, the outer coating of the egg cell, known as the vitelline layer in sea urchins or the zona pellucida in vertebrates, becomes hardened and begins to separate from the plasma membrane. These events create another barrier to more sperm fusing with the egg, called the **slow block to polyspermy**. Additionally, the burst of cytosolic Ca^{2+} leads to the activation of molecular signaling pathways that initiate the first cell cycle and triggers an increase in protein synthesis and metabolism within the egg cell.

Shortly afterward, the nucleus of the sperm fuses with the nucleus of the egg, creating a diploid zygote. The first cell division of the zygote occurs approximately 90 minutes after fertilization in sea urchins and amphibians, but it can take up to 24 hours in mammals.

Event 2: Cell Divisions Without Cell Growth Create a Cleavage-Stage Embryo

The initial cell cycles of embryos are unique because they involve repeated cell divisions without cell growth. The process by which these cell cycles occur is called **cleavage**. The embryonic cells repeatedly split in two, resulting in several generations of daughter cells that are roughly half the size of the cells that gave rise to them.

In most species in which development occurs outside the mother, where eggs and embryos can be eaten by predators, cell division during cleavage represents one of the fastest cell cycles found in nature. The cell cycle during cleavage in amphibians, for example, requires only 20 minutes. During each 20-minute cell cycle, complete genome replication, mitosis, and duplication of the nuclear envelope are followed by cytokinesis. In eutherian (placental) mammals, in which development occurs within the protective environment of the mother's body, cell divisions during cleavage are slower, requiring about 12 hours to complete.

The two half-size daughter cells produced by each cell division during cleavage are known as **blastomeres**. Individual blastomeres are bound together, and as cell divisions continue, the outer single-cell layer of blastomeres forms a sheet of epithelial cells that separates the embryo from its environment. After formation of the outer epithelial layer, the embryos of many animals take up water and form a cavity called a **blastocoel**. The embryo at this stage is called a **blastula**. The blastocoel provides a space into which cells will migrate to form the digestive tract and other structures of the embryo, in event 3.

Meroblastic Cleavage: Birds and Fishes Among triploblasts, cleavage-stage embryos can vary dramatically in size and appearance. This variation is in part related to whether or not the egg contained yolk and, if so, the location and amount of that yolk. Yolk is a nutrient-rich food store that is used by the developing embryo. The eggs of birds, some fishes, and some other vertebrates have large amounts of yolk. In the eggs of these species, yolk is most concentrated toward one end—or pole—of the egg, called the **vegetal pole**. Much less yolk, and much more cytoplasm, is concentrated near the opposite pole, called the **animal pole**. These poles are retained in the embryo and form the apices of the vegetal and animal hemispheres (**Figure 52.3**), which determine in part the future anteroposterior (head-tail) and dorsoventral (back-front or top-bottom, depending on the species) axes of the embryo.

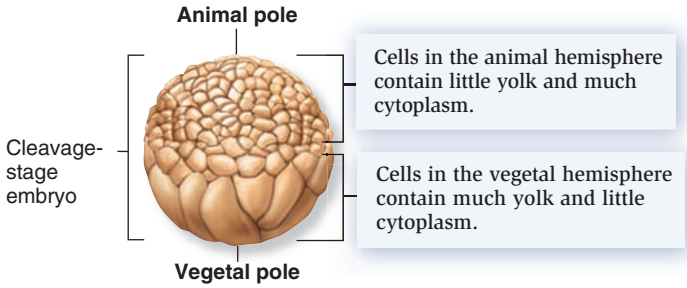

Figure 52.3 **Polarity in an amphibian cleavage-stage embryo.**

In some but not all species that exhibit animal and vegetal poles, cleavage of the zygote is called **meroblastic cleavage**, or incomplete cleavage, because only the region of the zygote and embryo containing the animal hemisphere undergoes cell division (**Figure 52.4**). Instead of forming a ball of cells (a blastula), in this type of cleavage, a flattened disc of blastomeres known as a **blastoderm** develops on top of the yolk mass.

Holoblastic Cleavage: Amphibians and Mammals In animals whose eggs have smaller amounts of yolk, cleavage during the first cell division is complete and bisects the entire zygote into two equal-sized blastomeres. Such **holoblastic cleavage** or complete cleavage occurs in amphibians and mammals (see Figure 52.4). In amphibians, cleavage-stage embryos form a blastula, as previously noted. In mammals, however, cleavage-stage embryos undergo a process called compaction, in which the amount of physical contact between cells is maximized. At this stage, the embryo in these species is called a **morula**. The resulting blastomeres in mammals then proceed to form a **blastocyst**, the mammalian counterpart of a blastula.

Cleavage and Implantation in Mammals In mammals, the events of fertilization and cleavage occur in the oviduct (**Figure 52.5**). The blastocyst has a different morphological appearance than the blastula or blastoderm in nonmammalian species, and no animal-vegetal polarity analogous to that of other chordates exists. The blastocyst consists of an outer epithelial layer called the **trophectoderm**, which gives rise to the placenta, and an inner layer called the inner cell mass, which develops into the embryo. Upon reaching the uterus, the embryo hatches from the zona pellucida, the layer of glycoproteins that surrounds the secondary oocyte and is retained up to this time to prevent premature adhesion of the embryo to the oviduct. The embryo then becomes embedded in the endometrium of the mother's uterus, a process known as implantation (see Figure 52.5). This entire process takes 4 days in mice and about 8–10 days in humans.

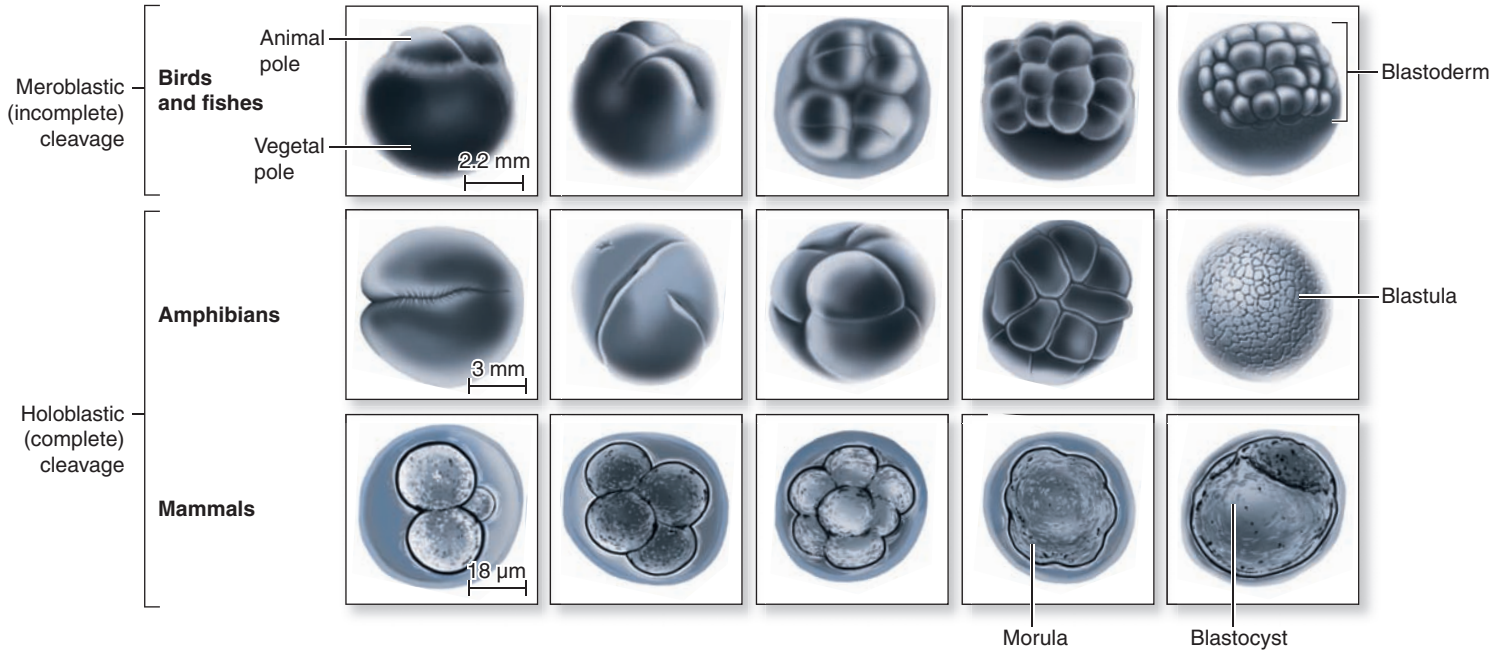

Figure 52.4 Meroblastic and holoblastic cleavage. As seen in these illustrations, early embryos of birds and many fishes undergo incomplete (meroblastic) cleavage, whereas most amphibian and mammalian embryos undergo complete (holoblastic) cleavage. The amount of yolk that was in the egg (not visible in these images) contributes to many of these morphological differences observed in various species.

Toward the end of cleavage, cell cycles become less synchronous, and the embryo begins to express its own genes. The embryo's shift from existing exclusively on maternal factors to developing in response to products derived from its own genome begins 6–24 hours after fertilization in vertebrates. This is followed by the next general event of development, called gastrulation.

Event 3: Gastrulation Establishes the Three Germ Layers in the Embryo

Gastrulation is one of the most dramatic events of embryonic development in animals because of the major cell movements that occur during this time. During gastrulation, the hollow ball of cells that

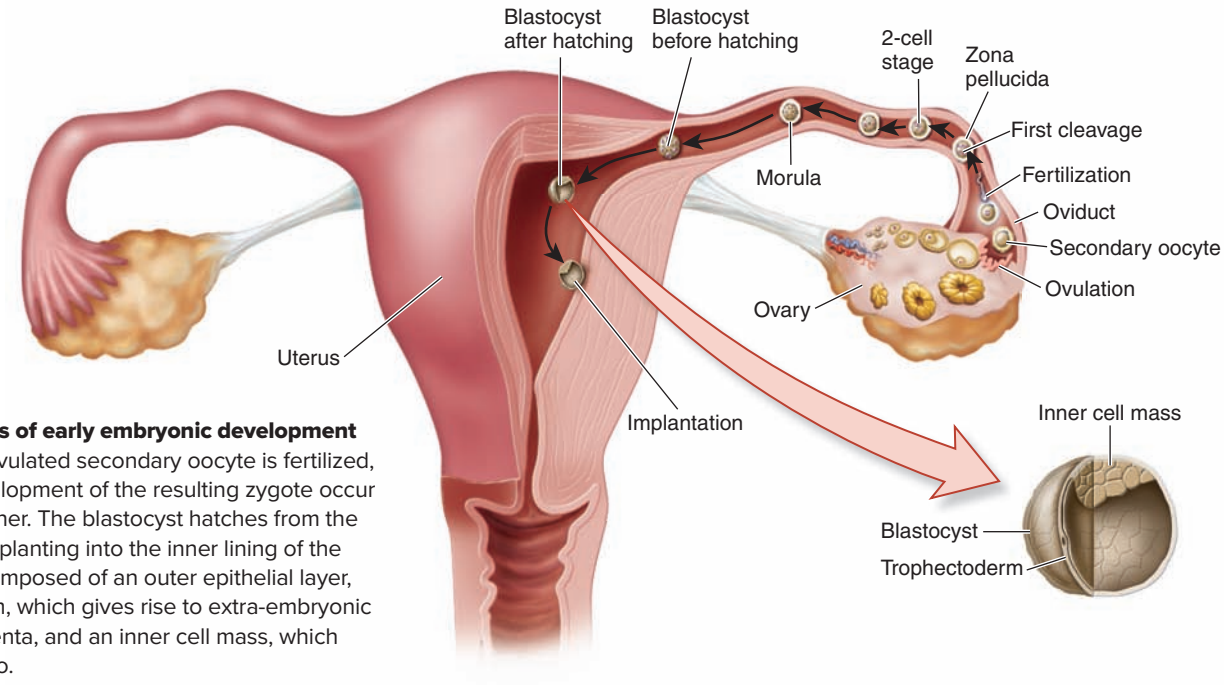

Figure 52.5 The sites of early embryonic development in mammals. After an ovulated secondary oocyte is fertilized, initial cleavage and development of the resulting zygote occur in the oviduct of the mother. The blastocyst hatches from the zona pellucida before implanting into the inner lining of the uterus. A blastocyst is composed of an outer epithelial layer, called the trophectoderm, which gives rise to extra-embryonic tissues such as the placenta, and an inner cell mass, which develops into the embryo.

BioConnections: Fertilization is internal in mammals. Is this true of all vertebrates? (You may need to refer back to Chapter 51 and Figure 51.4.)

makes up a blastula or blastocyst develops into a highly organized structure called a **gastrula** (refer back to Figure 32.6). In the gastrula-stage embryo, the three germ layers—**ectoderm**, **mesoderm**, and **endoderm**—become clearly established. These distinct germ layers are partially differentiated tissues that are easily recognized by their appearance under a light microscope. The layers occupy discrete regions of the embryo: an outer ectoderm, a middle mesoderm, and an inner endoderm. Each type of germ layer eventually gives rise to different structures. The organization that emerges during gastrulation is most evident by the clear establishment of the digestive tube and body axes. Gastrulation is the first time when both the anteroposterior and dorsoventral body axes are clearly evident in the embryo.

Fates of Germ Layers Scientists have established the ultimate fate of the three germ layers with an experimental procedure called **fate mapping**. In this technique, a single cell or a small population of cells within an embryo is specifically labeled with a harmless dye, and the fate of these labeled cells is followed to a later stage of embryonic development (**Figure 52.6**). Use of this technique in a variety of vertebrates has shown that the ectoderm in the gastrula forms the epidermis and nervous system in the later embryo (**Figure 52.7**). The mesoderm gives rise to muscles, kidneys, blood, heart, limbs, connective tissues, and notochord, which is a key feature of all chordates, described later in this section. The endoderm becomes the epithelial lining of the pancreas, thyroid, lungs, gut, liver, and urinary bladder.

Gastrulation occurs in all vertebrates. Many of the genes responsible for specifying gastrulation processes are very similar in species from all vertebrate classes. Although the developmental steps vary among vertebrate species, gastrulation usually is initiated by changes in a small number of cells within an external epithelial cell layer. This leads to a morphologically distinct structure that clearly defines the anteroposterior axis of the animal.

Some of the most detailed descriptions of the events in gastrulation come from the study of frog embryos. Three features of amphibians make them ideal for analyzing embryonic development using nongenetic mechanisms. First, fertilization and embryonic development occur outside the mother, making it easy to observe and manipulate embryos as they develop. Second, eggs are abundant—adult females carry thousands of eggs and can be induced to lay them by injecting a specific hormone—and are easily fertilized, usually by simply placing a male in an aquarium with an ovulating female. Third, amphibian embryos develop rapidly. In frogs, for example,

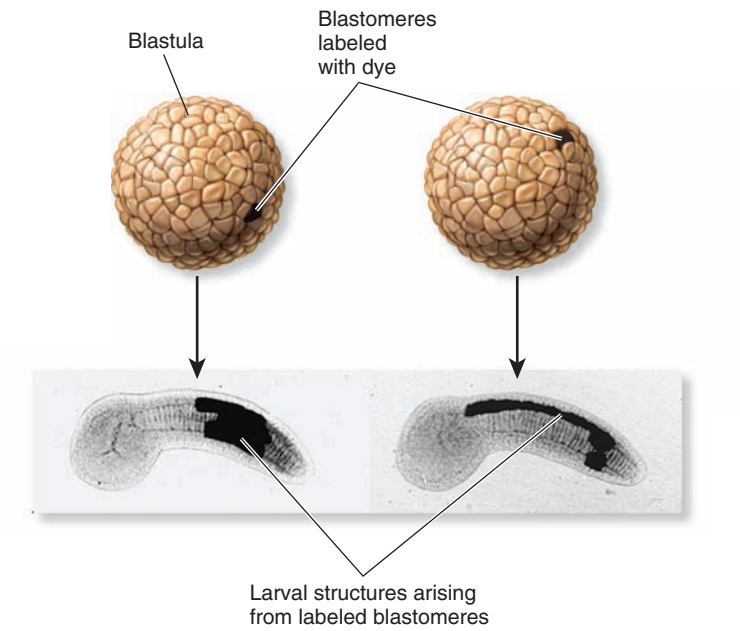

Figure 52.6 Fate mapping during embryonic development. In fate mapping, an individual embryonic cell (a blastomere) is labeled with a dye. The fate of that cell and its daughter cells can then be followed, showing that different cells in the embryo (in this case, a urochordate blastula) form different structures in the tadpole-like larva, as shown by the dark regions.

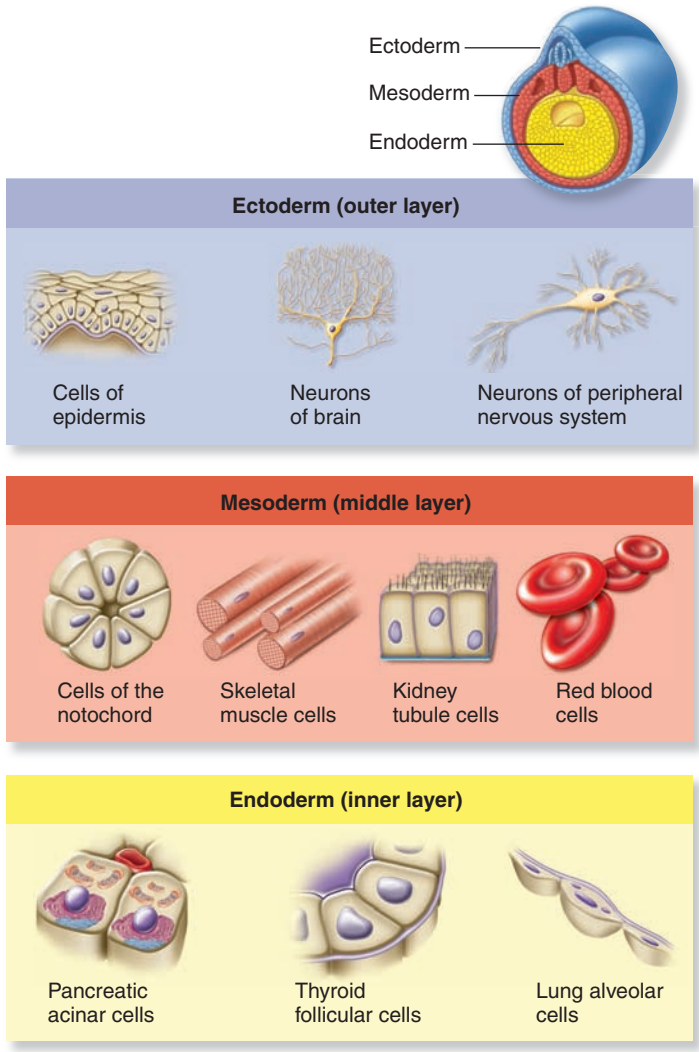

Figure 52.7 Examples of cell types derived from ectoderm, mesoderm, and endoderm.

BIOLOGY PRINCIPLE Living organisms grow and develop. The appearance of specific types of cells, such as those shown here, is an example of development; growth would entail an increase in the numbers of each of these cell types.

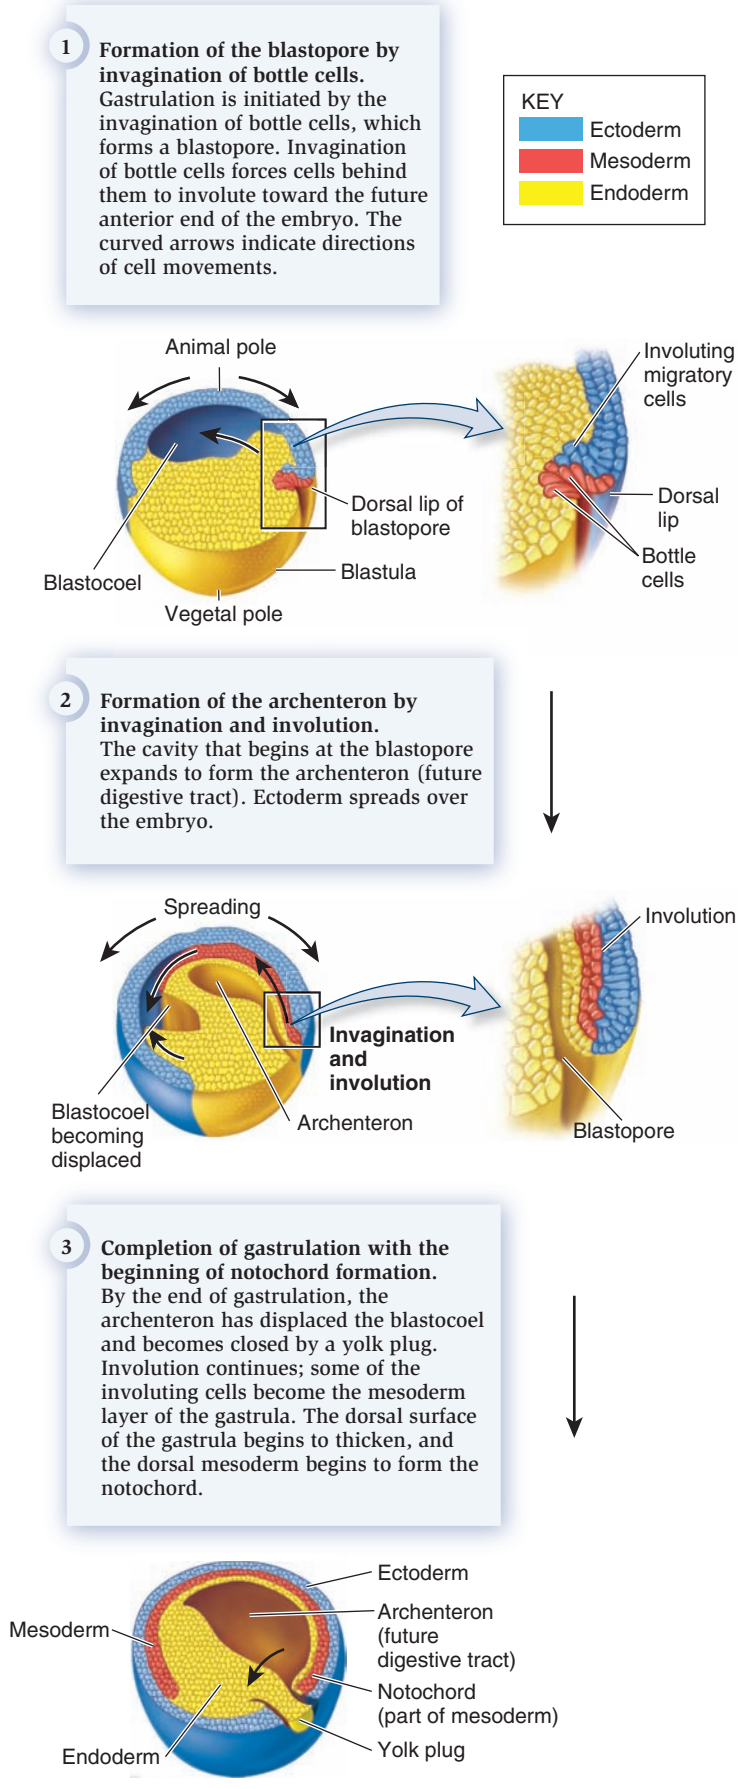
development from fertilized egg to tadpole takes only about 35 hours. The major events of gastrulation in amphibians are depicted in **Figure 52.8** and described next.

Invagination and Involution: Formation of Germ Layers and Archenteron Prior to gastrulation, the blastula is enclosed in a simple, spherical epithelial cell layer. Gastrulation begins when a band of tissue extending perpendicularly to the animal-vegetal axis at the widest part of the embryo pinches in, pushing cells from the outside of the embryo to the inside (Figure 52.8, step 1). This process—called **invagination**—creates a small opening called the **blastopore**, which defines the anteroposterior axis of the animal. Invagination begins when a few epithelial cells located at the vegetal hemisphere of the blastula—called bottle cells—undergo a change in their morphology, causing them to elongate toward their basal end and forcing the cells toward the interior of the embryo. The initiating site of invagination becomes what is called the dorsal lip of the blastopore. This change in morphology of a few key cells in the embryo initiates the gastrulation process in amphibians.

Once the bottle cells change their shape and push into the interior of the embryo, other cell movements occur, and together these orchestrated movements establish the mesoderm and endoderm of the organism, including its future digestive tract. Just before invagination begins near the equator, or midline, of the embryo, cells of the animal hemisphere spread out and move downward. The bottle cells then move in at the blastopore. Animal hemisphere cells continue to migrate downward. When they arrive at the blastopore, they too enter the opening and subsequently migrate upward along the roof of the blastocoel, toward the animal pole of the embryo. This folding back of sheets of surface cells into the interior of the embryo is called **involution** (Figure 52.8, step 2). Both endodermal and mesodermal cells involute from the blastopore toward the opposite end of the embryo. After involution, dorsal mesodermal cells migrate toward the animal pole by crawling along the roof of the blastocoel, with endoderm following closely behind.

As the opening from the blastopore extends into the embryo, a new cavity called the **archenteron** displaces the existing blastocoel (Figure 52.8, steps 2 and 3). The archenteron becomes the organism's digestive tract. The blastopore opening remains sealed with a yolk-rich piece of tissue called the yolk plug until later in development. In chordates and echinoderms, the opening formed by the blastopore ultimately becomes the anus of the organism (refer back to Figure 32.7a). Meanwhile, during involution, surface cells spread from the animal hemisphere to surround the entire vegetal hemisphere and become the ectoderm. The result of these cellular rearrangements is an embryo with three distinct germ layers.

Mechanisms for Changes in Cell Shape and Position How do cells change shape and position during the process of embryonic development? Several processes are at work. For example, bottle cells initiate gastrulation through a process called **apical constriction** (**Figure 52.9a**). As discussed in Chapter 10, some epithelial cells have a ring of actin filaments along their apical membranes (refer back to Figure 10.7). In apical constriction, the actin rings constrict, elongating the cells.



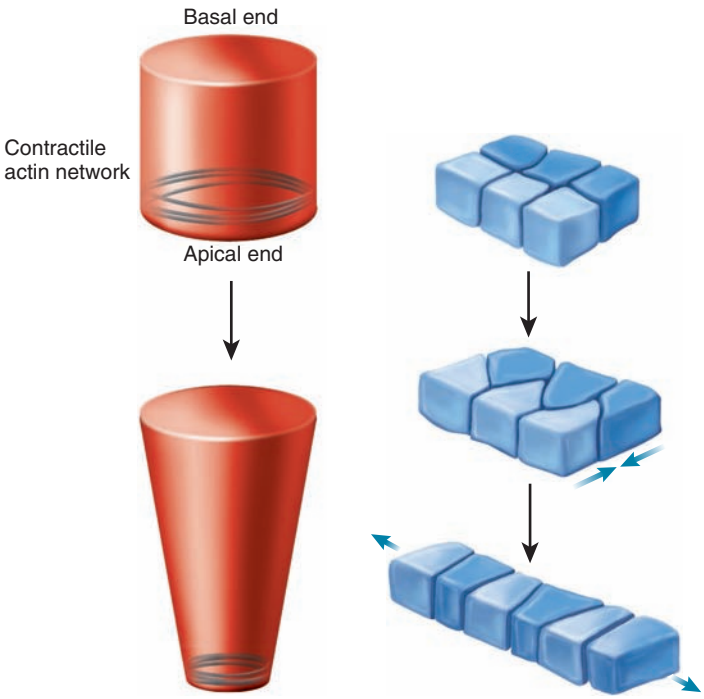


Figure 52.8 **The events of gastrulation in amphibians.**

(a) Apical constriction (b) Convergent extension

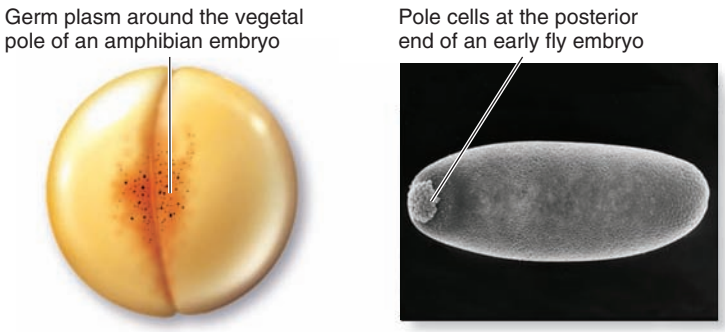

Figure 52.9 Two mechanisms that affect cell shape and movement.

BioConnections: In what other type of animal cells does actin function in significantly changing cell shape? (Hint: The shape change is reversible. Refer back to Figure 44.5.)

In a second mechanism, the spreading of ectoderm in the animal hemisphere toward the vegetal hemisphere is mediated by a cellular process called **convergent extension**. During this process, two rows of cells merge to form a single elongated layer (**Figure 52.9b**). Convergent extension produces the movement of sheets of cells.

Primordial Germ Cells During gastrulation, a specialized group of cells arise called **primordial germ cells (PGCs)**. The PGCs often arise independently of the three germ layers in the embryo. This cell lineage has two primary functions: (1) to protect and propagate the genetic content of the species and (2) to undergo meiosis and differentiate into gametes—sperm or eggs—in the adult organism. PGCs are stem cells that can divide through mitosis to make copies of themselves. Some of the resulting daughter cells can later undergo meiosis and differentiate into gametes.

The eggs and resulting embryos of some species contain certain cytoplasmic determinants—called the **germ plasm** (**Figure 52.10a**)—that help define and specify the PGCs in the gastrula stage. In amphibian eggs, for example, the germ plasm occupies a small region of cytoplasm around the vegetal pole and contains a specific subset of maternal mRNAs. These cytoplasmic determinants are inherited by a subpopulation of blastomeres during cleavage. At the beginning of gastrulation, blastomeres that inherit these cytoplasmic determinants differentiate into PGCs. At a later stage of development, the PGCs migrate to primordial gonads that eventually will form testes

(a) Germ plasm (b) Pole cells

Figure 52.10 Germ plasm and primordial germ cells (PGCs) during gastrulation. (a) Germ plasm in an amphibian embryo as it would appear by labeling an mRNA that is specifically expressed in PGCs. **(b)** In fly embryos, the PGCs are called pole cells as seen in this SEM.

or ovaries. In flies, by contrast, PGCs are the first cells to form at the posterior end of the embryo and are called pole cells (**Figure 52.10b**).

In mammals, neither germ plasm nor pole cells have been identified. Instead, a few mesoderm-like cells begin to express PGC-specific genes early during gastrulation. These cells migrate during gastrulation and, as in amphibians, eventually intermix with gonad primordial cells later in development. Thus, the establishment of PGCs occurs during the earliest phases of animal development, indicating the broad importance of this cell lineage for the propagation of species.

Notochord Formation A distinguishing anatomical feature that begins forming at the end of gastrulation in all chordates is the **notochord**—a structure derived from mesoderm that provides rigidity along the anteroposterior axis in the dorsal side of the gastrula (see Figure 52.8, step 3). The presence of a notochord defines the phylum Chordates. The notochord persists in the trunk and tail of fishes and amphibians; in birds and mammals, the notochord disappears by the time vertebrae have formed.

In the amphibian embryo, after formation of the archenteron, the dorsal surface of the gastrula begins to thicken, and the dorsal mesoderm forms the notochord. The notochord elongates through convergent extension. By the time the notochord has formed, the dorsal ectoderm overlying it begins to thicken, which initiates the next general event in development, called neurulation.

Event 4: Neurulation Involves Formation of the Central Nervous System and Segmentation of the Body

By studying development in several different vertebrate species, researchers are beginning to understand some of the fundamental steps in the formation of the central nervous system (CNS)—the brain and spinal cord—in vertebrates. The multistep embryological process responsible for initiating CNS formation is called **neurulation** (**Figure 52.11**). Neurulation occurs just after gastrulation and involves the formation of the **neural tube** from ectoderm located dorsal to the notochord. All neurons and their

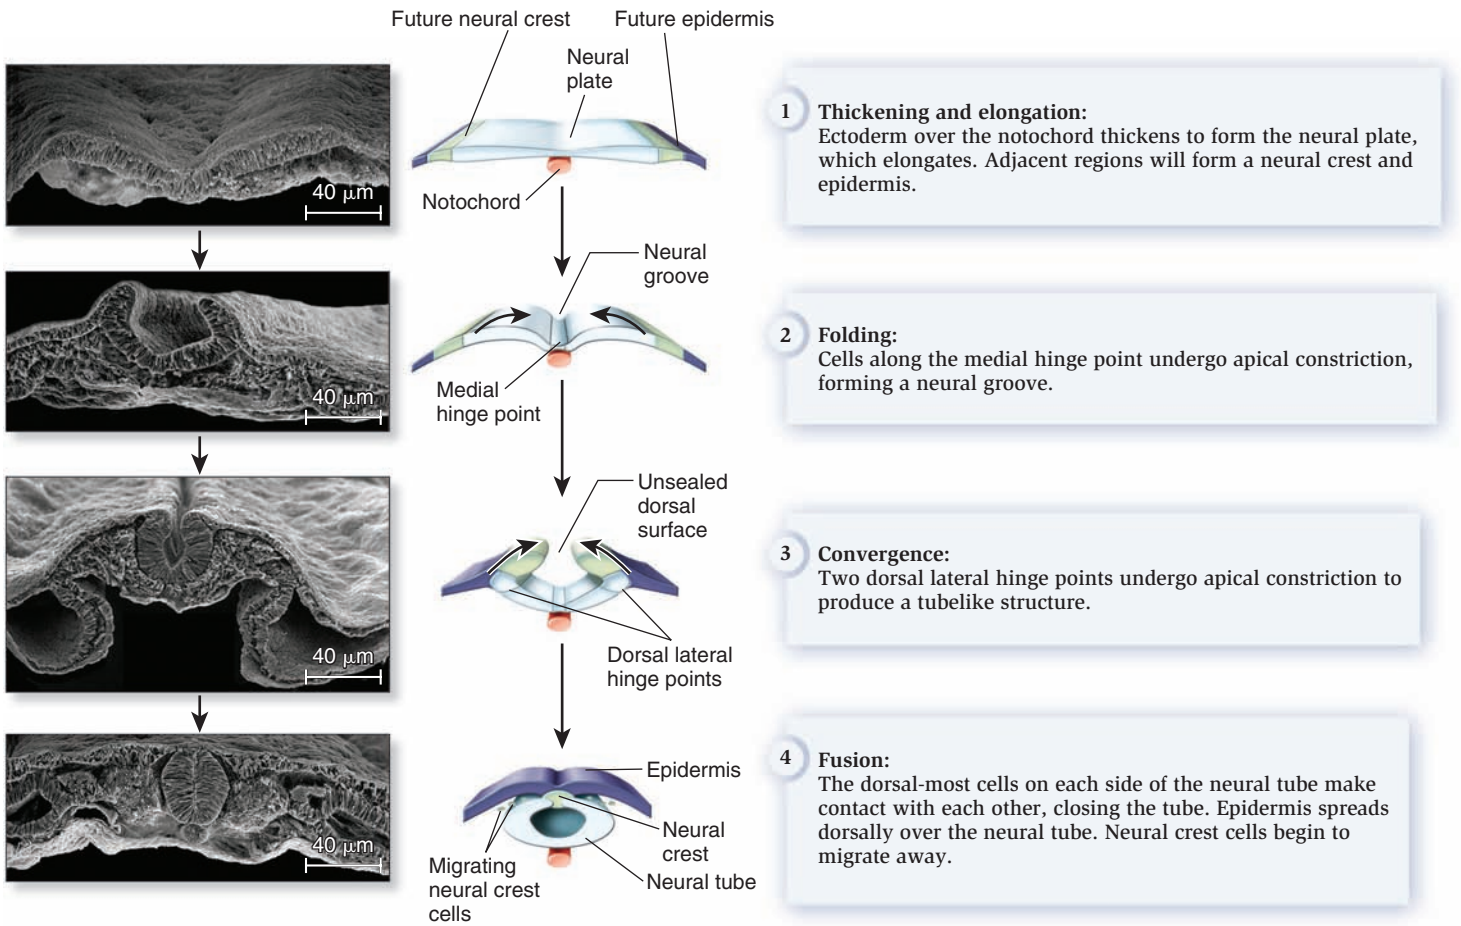

Figure 52.11 Neurulation and the beginning of neural crest formation in vertebrates. The four major steps of neurulation are (1) thickening and elongation; (2) folding, which creates the neural groove; (3) convergence, in which the neural tube begins to take shape; and (4) fusion, in which the neural tube is completed. In a later event, cells migrate away from the neural crest to form several other structures, including neurons of the peripheral nervous system. (Scale bar is approximate.)

supporting cells in the CNS originate from neural precursor cells derived from the neural tube. During neurulation, the embryo also develops segmented structures.

Neural Tube Formation Neurulation in vertebrates occurs in four major steps, as shown in Figure 52.11. In the first step, ectoderm overlaying the notochord thickens by the elongation of cells in the dorsal region to form the neural plate, with adjacent regions that will eventually form the epidermis and a structure called the neural crest (discussed shortly). The neural plate then elongates by convergent extension, resulting in the formation of a single, dorsal elongated epithelial cell layer that is aligned with the animal's anteroposterior axis.

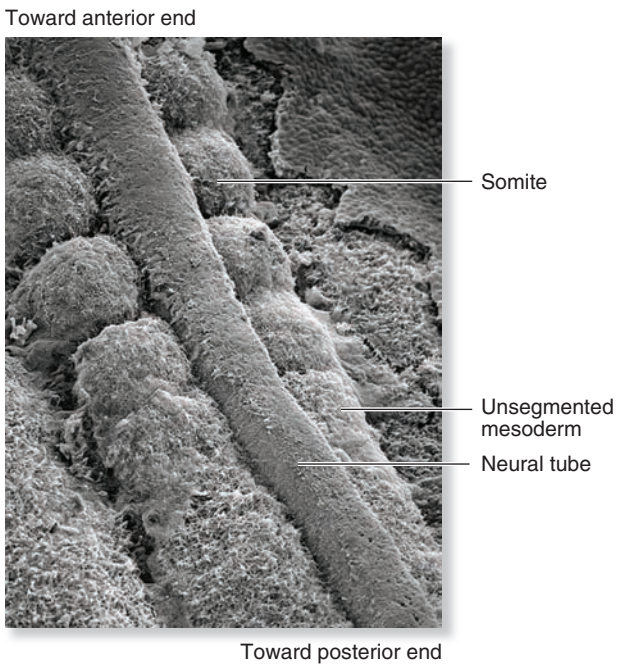
Next, the neural plate forms the neural tube through a series of apical constrictions (steps 2 and 3, Figure 52.11). In the second step, a column of cells along the midline of the neural plate—the medial hinge point—undergoes apical constriction. This initiates the folding phase of neurulation and leads to the formation of the neural groove. After folding, in the third step, bilateral columns of cells in the dorsal lateral hinge points then undergo apical constriction, leading to convergence of the two sides of the neural groove and generation of a tubelike structure that is not yet sealed on the dorsal surface.

In the fourth step of neurulation, called fusion, the dorsal-most cells on either side of the neural tube are released from adjacent ectoderm and make contact with each other, culminating in the closure of the neural tube. At the same time, ectoderm on either side of the neural tube moves toward the centerline, then up and over the neural tube, where it fuses and forms the dorsal epidermis of the embryo.

Neural Crest Formation Another important group of cells that arises during neurulation is the **neural crest**, which is unique to vertebrates. It consists of cells that originate from the ectoderm overlaying the dorsal surface of the newly formed neural tube and that migrate to other regions of the embryo. Once these cells reach their final destination in the embryo, they differentiate into a variety of cell types different from those that arise from the rest of the ectoderm. All neurons and supporting cells of the peripheral

nervous system in vertebrates are derived from neural crest cells. In addition, the neural crest gives rise to skeletal and cartilaginous structures in the head and face, melanocytes (specialized cells that provide pigmentation to the skin of vertebrates), the medulla (the inner region) of the adrenal glands, and connective tissue in numerous organs, notably the heart.

Segmentation and the Formation of Somites As embryos develop, distinct tissues acquire recognizable shapes and patterns, and the body often becomes segmented along the anteroposterior axis of the embryo. **Segmentation** allows individual body segments to have more specialized functions. In some animal taxa, such as insects, body segments are found in the adult animal. In vertebrates, the segmentation process helps define repeated structures such as vertebrae and ribs, which form later during development. Segmentation of the body along the anteroposterior axis becomes apparent during neurulation.



During neurulation, the mesoderm becomes segmented from the anterior end first, giving rise to blocklike structures of mesoderm called **somites** (Figure 52.12). Somites consist of a hollow ball enclosed by an epithelial layer. The scanning electron micrograph in Figure 52.12a shows a dorsal view of a chick embryo undergoing somite formation. The somites are located toward the anterior end, and unsegmented mesoderm can be seen extending toward the posterior end. The somites are transient structures, and the cells within them soon transform into two morphologically distinct structures that eventually form ribs and skeletal muscle or vertebrae, respectively.

Event 5: Organogenesis Is the Process of Organ Formation

As described in Chapter 40, organs are specialized structures that consist of arrangements of two or more tissue types. Most organs, such as the kidney, contain all four tissue types: nervous, muscle, epithelial, and connective tissue (refer back to Figures 10.15 and 40.1). The developmental event in which cells and tissues form organs is called **organogenesis**. Each germ layer gives rise to particular types of cells found within different organs (see Figure 52.7).

Many organs begin to form during or just after neurulation. However, these organs become functional at different times during development. For example, the lungs of mammals do not acquire the ability to function until shortly before birth. By contrast, the heart is the first functional organ to form in the vertebrate embryo. It begins to beat and pump blood before all the embryo's somites have formed (by 2.5 days after fertilization in chicks, 9 days in mice, and about 22 days in humans).

As we saw in Chapter 40, the development of different organs in animals is controlled by genes in the embryo, notably the *Hox* genes. *Hox* genes are important for establishing structures along the anteroposterior axis. Many of the genes controlling the processes of gastrulation, neurulation, and organogenesis encode secreted proteins or growth factors that induce cells in their local vicinity to differentiate along a specific developmental pathway. For example, the notochord produces many signaling proteins that help establish tissue patterns in the embryo. Proteins produced within it induce segment-specific expression of the *Hox* genes in subsequent stages of development.

BIO TIPS **THE QUESTION** *Below is a list of 10 steps that occur during embryonic development. For each step, indicate if they occur during fertilization, cleavage, gastrulation, neurulation, or organogenesis.*

1. *fusion of sperm and egg*
2. *formation of most organs in the body*
3. *establishment of the three germ layers*
4. *formation of the neural tube*
5. *creation of the blastopore*
6. *formation of the archenteron*
7. *beginning of cell divisions (without cell growth)*
8. *fast and slow blocks to polyspermy*
9. *formation of blastocoel and blastula*
10. *formation of the gastrula*

TOPIC ***What topic in biology does this question address?*** The topic is embryonic development in animals. More specifically, the question asks you to identify when specific steps occur during development.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you are given a list of 10 steps that occur during embryonic development. From your understanding of the topic, you may recall that there are five general events of embryonic development; each of these general events encompasses specific steps.

PROBLEM-SOLVING STRATEGY ***Sort out the steps in a complicated process.*** It is important to recognize that embryonic development occurs in five general events, each with several steps. Certain steps must occur before other steps may occur. Placing the steps in the correct sequence is the key to answering this question.

ANSWER *Steps 1 and 8 occur during fertilization; 7 and 9 occur during cleavage; 3, 5, 6, and 10 occur during gastrulation; 4 occurs during neurulation; and 2 occurs during organogenesis.*

52.3 Control of Cell Differentiation and Morphogenesis During Animal Development

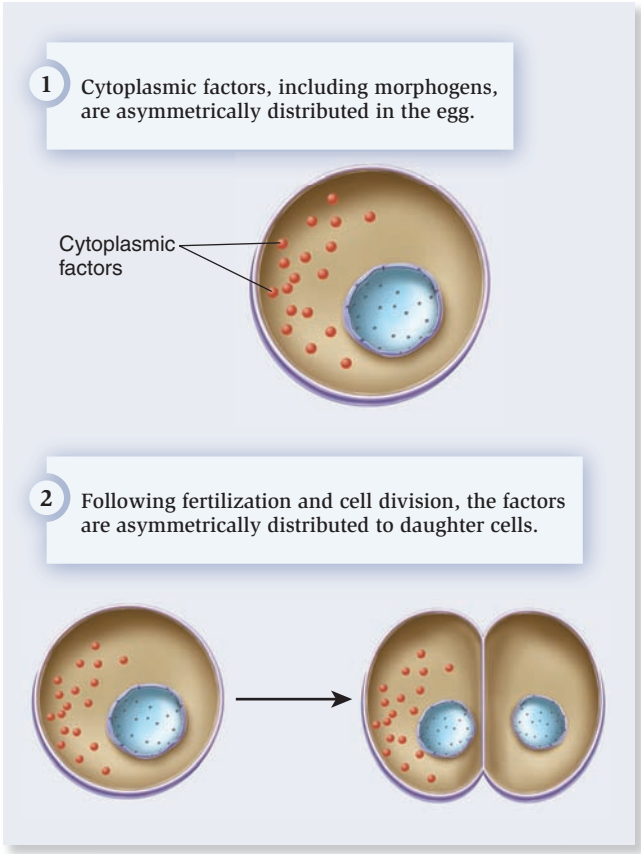
Learning Outcomes:

1. Distinguish between autonomous and conditional specification.
2. **SciSKILLS** » Propose mechanisms by which the direct contact between the plasma membranes of neighboring cells affects embryonic development.
3. Describe how organizers can influence cells to differentiate.

Thus far, we have examined the five general events of embryonic development. In this section, we will turn our attention to certain molecular mechanisms that are crucial for cell differentiation and morphogenesis.

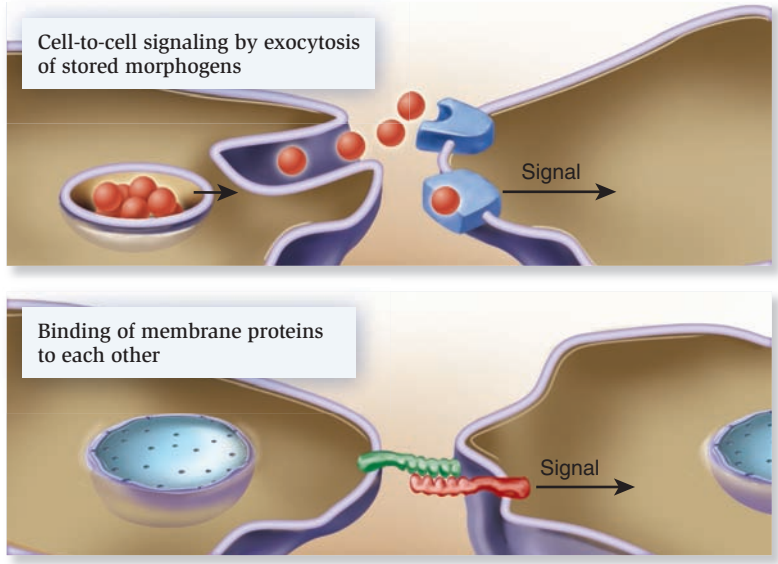
Positional Information Is Conveyed Internally and Externally to Each Cell

The process of embryonic development requires that cells divide, move to specific sites, and acquire distinct functional properties (that is, differentiate). Cells receive positional information that determines how they differentiate. There are two primary mechanisms of conveying such positional information.



The first mechanism is an internal one, which involves the unequal acquisition by daughter cells of various cytoplasmic factors during cell division, a process known as **autonomous specification** (**Figure 52.13a**). An example of autonomous specification can be found during the cleavage events of embryonic development. During early cleavage, cell cycles can be extremely rapid, such that little or no gene transcription occurs during this time. Consequently, nearly all cellular division and differentiation processes during cleavage are regulated by cytoplasmic factors that resided in the oocyte prior to fertilization. Subcellular components that were synthesized prior to fertilization are called maternal factors. These factors include many mRNAs and other factors that are stockpiled in the maturing oocyte during oogenesis to facilitate cleavage in the absence of transcription.

The second mechanism includes a variety of external cell-to-cell signaling mechanisms, a process called **conditional specification** (**Figure 52.13b**). This process may occur via secreted molecules that act as extracellular signals or via cell-to-cell contact between plasma membrane proteins. In the latter case, cells of a given germ layer, such as mesoderm, express membrane proteins that can bind with each other, but not to proteins in the membranes of other germ layers. In this way, cells can recognize other cells within a germ layer and begin to form structures. In both types of conditional specification, intracellular signals are generated that stimulate the cells to migrate or to stay together as their final positions within different regions of an embryo are established.



These two general mechanisms provide embryonic cells with a continuously changing internal and external environment, in which cells ultimately fulfill their unique spatial and functional fates. This differentiation process involves alterations of gene expression in which specific cells express a unique set of genes required for a particular function.

The molecules that impart positional information and promote developmental changes at the cellular level are called **morphogens**. Morphogens include the cytoplasmic factors involved in autonomous specification and also the secreted factors used in conditional specification as cell-to-cell signals. The actions of morphogens depend on their concentrations, with different concentrations often inducing cells to follow different developmental fates.

Throughout development, the mechanisms of autonomous and conditional specification function together so that distinct cells respond appropriately. In the rest of this section, we will look at some examples of how these mechanisms lead cells to differentiate into each of the numerous diverse cell types with unique functions in the developing organism. Such differentiation involves changes in both gene expression and subcellular organization. Identifying the precise autonomous and conditional signals that specify each cell lineage in the embryo is one of the biggest challenges facing developmental biologists in the 21st century.

(a) Autonomous specification

(b) Conditional specification

Figure 52.13 Mechanisms that convey positional information during embryonic development. **(a)** In autonomous specification, cell fate is determined through the unequal segregation of subcellular components during mitosis. **(b)** In conditional specification, cells respond to signals generated by neighboring embryonic cells or by membrane-bound proteins.

Concept Check: *In which event(s) of animal development is autonomous specification important?*

Genomes & Proteomes Connection

Groups of Embryonic Cells Can Produce Specific Body Structures Even When Transplanted into Different Animals

One of the early ideas to emerge from the study of developmental biology was the concept of the **morphogenetic field**, a group of embryonic cells that ultimately produce a specific body structure. Long before genes and their encoded proteins were identified, embryologists discovered that particular groups of embryonic cells in amphibians have a striking characteristic: They form complete body structures when transplanted to another site in the embryo. This has been observed for cells that form the eyes, limbs, and heart in vertebrates and the eyes, antennae, legs, and wings in insects.

One of the first morphogenetic fields postulated in vertebrates was the limb field. Between 1910 and 1930, two important observations were made concerning the limb field. First, removing this group of cells from either side of an early developing embryo led to an embryo that lacked a limb at the corresponding position. Second, transplanting a limb field to a new location within prelimb embryos led to the development of an additional limb at the new location. Interestingly, fate-mapping studies showed that certain cells within the field give rise to specific regions of the limb. These types of experiments suggested that cells within morphogenetic fields were uniquely specified to become particular embryonic structures before any physical evidence for the structure itself could be observed in the embryo.

In the 1920s, the German zoologists Hans Spemann and Hilde Mangold discovered a morphogenetic field with amazing properties in an early gastrula. This region of the gastrula is now known as **Spemann's organizer**. Their experiments involved dissecting a small piece of tissue from the dorsal lip of the blastopore in an early gastrula of a newt, and transplanting it to the opposite side of another gastrula (**Figure 52.14**). The result was the formation of a second notochord and neural tube during gastrulation and neurulation in the host embryo, and ultimately the formation of an entirely new body axis—the resulting embryo developed two bodies!

In their experiments, the researchers used two very closely related species of newts. *Triton taeniatus*, which is pigmented, served as the tissue donor, and *Triton cristatus*, which is nonpigmented, served as the host embryo. By transplanting a pigmented Spemann's organizer from the donor embryo into a nonpigmented host embryo, Spemann and Mangold could visually track the origin of the newly developed tissue. The results showed that the

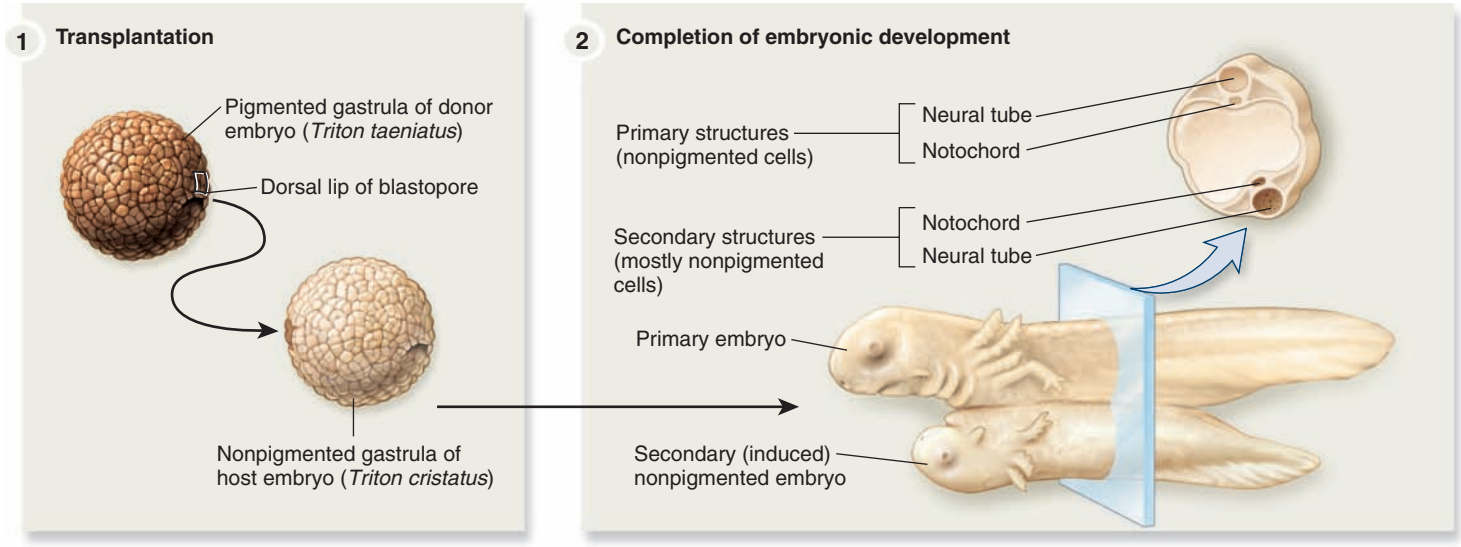


Figure 52.14 Experiment on newt embryos that led to the discovery of Spemann's organizer. Note that the secondary body axis formed by the transplanted organizer is composed of host (nonpigmented) tissue, indicating that the organizer (donor) tissue induced the host tissue to differentiate.

secondary notochord and neural tube were composed in large part of nonpigmented host cells, with some pigmented cells remaining from the transplanted tissue. This indicated that the transplanted tissue—which they named the "organizer"—had induced cells in the host to differentiate into neural tissue on the transplanted side of the embryo. More recent work has shown that the organizer secretes morphogens—unknown at the time of Spemann's experiments—responsible for inducing the formation of a new embryonic axis. In 1935, Spemann was acknowledged for his important discovery of cellular induction by receiving the first Nobel Prize (Physiology or Medicine) for studies in developmental biology.

In the past two decades, scientists have identified several genes expressed specifically in Spemann's organizer. Strikingly, many of these genes, which were first discovered in amphibians, are found in all vertebrates. These organizer-specific genes are expressed in very small regions of early gastrula embryos, allowing researchers to identify the equivalent of Spemann's organizer in other species. The names given the organizer in different species vary. In chicks, it is called Hensen's node, whereas in mice, it is simply referred to as the node. Moreover, in addition to the organizer genes, the regulatory mechanisms involved in the formation of these organizing structures appear to be conserved through vertebrate evolution as well.

With advances in molecular genetics during the 1960s and 1970s, molecular biologists began to reexamine the concept of a morphogenetic field. An important goal of this new generation of molecular biologists was to identify the specific genes transcribed within Spemann's organizer (and equivalent structures in other vertebrates) that give this region the ability to form an entirely new body structure. They thought that identifying these genes would provide key insights into the genetic control systems that govern embryonic patterning during gastrulation in vertebrates. However, identifying unknown genes and their protein products was a daunting challenge. Eventually, in 1992, the first secreted morphogen expressed specifically in the organizer was isolated, as we see next.

Feature Investigation | Harland and Coworkers Identified Genes Expressed Specifically in the Organizer

In the early 1990s, Richard Harland and his colleagues hypothesized that morphogens expressed in the organizer should promote the formation of dorsal structures such as those found in the head of embryos. To search for genes that promote the formation of dorsal structures and that are expressed in the organizer during gastrulation, Harland's group took advantage of a property of unfertilized eggs of the African clawed frog (*Xenopus laevis*). When these eggs are exposed to UV light at their vegetal hemisphere, they fail to form tadpoles after the eggs are fertilized. However, embryos derived from UV-treated eggs do form primitive mesoderm, but only ventral mesoderm forms. Dorsal mesoderm, which normally gives rise to the notochord and somites, does not form in UV-treated eggs, and the resulting ventralized embryos soon die. The embryos appear to be lacking one or more morphogens needed for proper dorsal development.

To identify genes in the organizer that encode morphogens that promote the formation of structures such as the notochord, Harland and colleagues used a strategy called expression cloning, as shown in **Figure 52.15**. First, after dissecting a frog embryo, they isolated

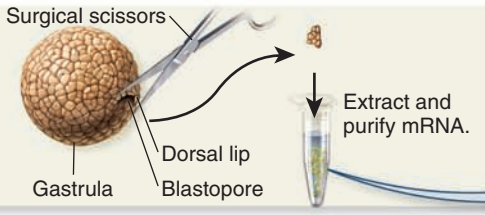

Figure 52.15 Harland and colleagues discovered the morphogen noggin using expression cloning.

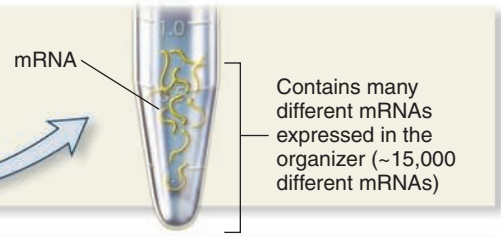
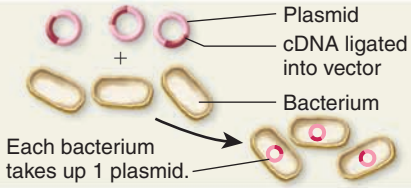
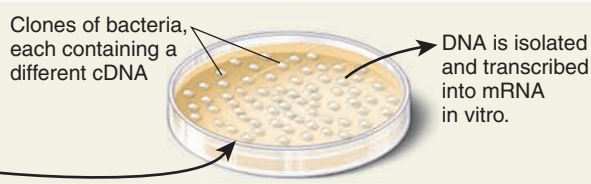


HYPOTHESIS Cells within Spemann's organizer express specific genes that encode proteins that regulate the development of dorsal structures during gastrulation.

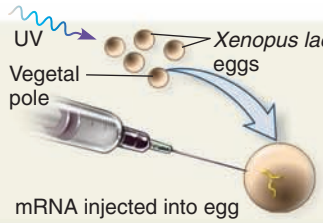
KEY MATERIALS *Xenopus laevis* gastrulas and eggs.



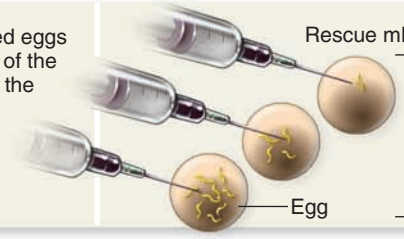
Experimental level | **Conceptual level**



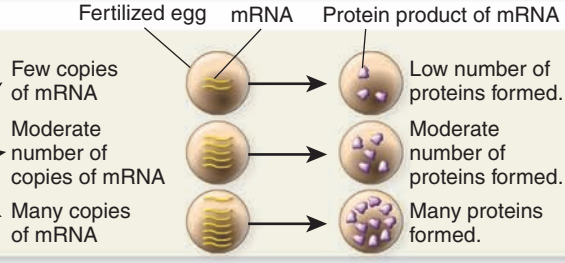
1 Isolate mRNA from dorsal lip tissue, which contains the organizer.



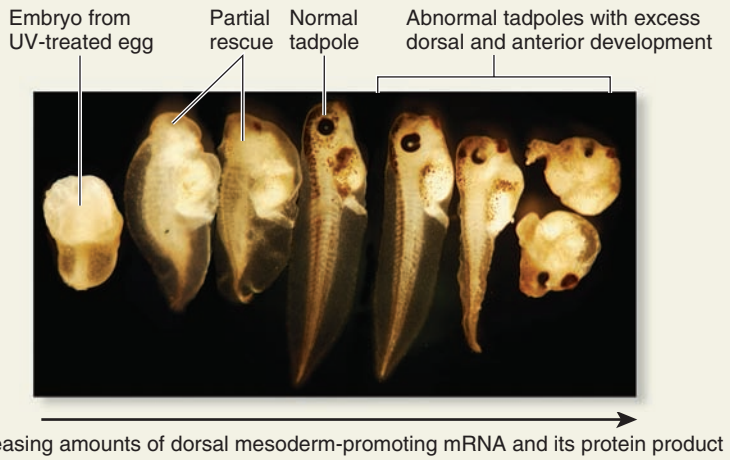
2 Create cDNA library. Use cDNA library to make 15,000 different mRNAs. (See Chapter 20 for a description of cDNA libraries.)



3 Expose unfertilized *Xenopus laevis* eggs to UV light, then inject with an mRNA. Fertilize the eggs to determine which, if any, develop. Note: Each egg was injected with a single type of mRNA.



UV light inactivates a morphogen and prevents dorsal mesoderm formation; the embryos usually die.



Most fertilized eggs formed only ventral mesoderm and died. One, however, developed into a tadpole (rescue).

4 Inject with UV-treated eggs increasing amounts of the mRNA that rescued the embryo in step 3.

5 THE DATA

6 CONCLUSION Cells in Spemann's organizer secrete a morphogen—termed noggin—that directs normal dorsal development in *Xenopus laevis* embryos.

7 SOURCE Smith, W.C., and Harland, R.M. 1992. Expression cloning of noggin, a new dorsalizing factor localized to the Spemann organizer in *Xenopus* embryos. *Cell* 70:829–840.

and purified mRNA from dorsal lip tissue containing the organizer. Second, they constructed a cDNA library (see Figure 20.4) from the purified mRNA. This resulted in approximately 15,000 different cDNAs, each of which corresponded to a single gene that had been expressed in the organizer. Their next task was to transcribe each of these cDNAs back into mRNA in vitro. In a third step, the researchers injected the different mRNAs into thousands of unfertilized UV-treated eggs, which they then fertilized. Each egg was injected with a single type of mRNA. Their idea was that any mRNA that produced a protein with dorsal mesoderm-promoting activity might "rescue" the embryos and result in free-swimming tadpoles.

Using this procedure, the researchers identified one mRNA whose protein product rescued the embryo (step 3). They then injected increasing amounts of this mRNA into UV-treated eggs, fertilized the eggs, and examined the morphology of the resultant tadpoles. They discovered that the protein product from this mRNA acted as a morphogen because it induced different embryonic structures at different concentrations. At low concentrations, it partially rescued the embryos. At moderate concentrations, it resulted in the formation of normal embryos. However, at very high concentrations, the embryos developed too much dorsal mesoderm and not enough ventral mesoderm. These abnormal embryos developed large heads and extremely small trunks. Further studies identified the gene that coded for this mRNA and verified that it was transcribed in Spemann's organizer. They named the gene *noggin* (a slang term for brain or head), because it caused embryos to develop large heads when present in abnormally high concentrations (see right side of the data).

Later work revealed that noggin protein promotes dorsal development by inhibiting ventral development. Noggin protein inhibits at least two other morphogens that are known to induce ventral, but not dorsal, mesoderm. These studies showed that antagonistically acting proteins expressed and secreted from certain cells in the organizer can specify precise structures in a concentration-dependent fashion. Further work revealed that *noggin* is expressed in the node of mice. Specific deletion of the *noggin* gene in mice leads to defects in dorsal structures. This indicates that *noggin* plays a fundamental role during gastrulation in mammals as well as amphibians.

The discovery of noggin and its mechanism of action revealed that the normal development of embryos requires a balance between stimulatory and inhibitory factors. The inhibition of developmental processes—such as the suppression of ventral mesoderm by noggin (and, as researchers have since learned, several other key gene products)—appears to be a common and important part of the mechanism by which development of an organism occurs.

Experimental Questions

1. Why were scientists interested in identifying genes expressed exclusively in Spemann's organizer?
2. What hypothesis did Harland and colleagues test?
3. **SciSKILLS** » How did the scientists identify possible genes that are important for the development of dorsal structures, and how did they test the gene products to determine their activity?

52.4 Impact on Public Health

Learning Outcome:

1. Describe three human birth defects that are due to abnormalities in embryonic development.

Given the complexity and precision of the five general developmental events described in this chapter, it may not be surprising that on occasion these processes fail to occur properly. When this happens in humans, its impact can be devastating. Many health problems in humans are caused by genetic or environmental factors that disrupt embryonic development. As we have seen, the early development of an embryo is among the most complex processes found in nature, and a number of diseases and disorders in humans stem from problems that arise during this process.

An example of a condition involving defective embryonic development is **spina bifida**, caused by the failure of the neural tube to close at either the anterior or posterior end during neurulation. Signs and symptoms of spina bifida, which occurs in about 7 of every 10,000 births in the U.S., vary depending on the degree to which the neural tube fails to close. In minor forms, gaps may occur between a few vertebrae at the bottom of the back, and impairment of motor or sensory function may not be apparent at birth. However, neurological deterioration often becomes evident during childhood or adulthood. Surgical procedures soon after birth can improve the long-term quality of life for patients with spina bifida, but prevention of this condition is much more effective. Spina bifida appears to be related to deficient concentrations of folic acid, a common B vitamin needed during the rapid growth that occurs during embryonic development. Up to 75% of spina bifida cases may be prevented if women increase their dietary intake of folic acid in the first trimester of pregnancy.

Other embryonic defects are caused by foreign chemicals introduced during pregnancy. Given the deleterious effects of certain chemical compounds on specific phases of embryonic development in humans, it is not surprising that exposure to environmental contaminants (see the chapter opening photo), or ingested or inhaled compounds such as tobacco, alcohol, and other drugs can have devastating consequences on a developing fetus. The leading overall cause of mental impairment worldwide is **fetal alcohol syndrome (FAS)**, which occurs in babies whose mothers consumed large amounts of alcohol during pregnancy. In addition to cognitive disorders, children born with FAS also show malformed facial features and joints and altered overall growth characteristics. These morphological features are likely caused by the generally detrimental effects that ethanol has on cell division. The cognitive deficits are thought to result from the death of developing CNS neurons, which are particularly susceptible to the toxic effects of ethanol.

Figure 52.16 **Child with cleft lip/palate before and at two different ages after surgeries.**

Unlike the previous conditions, which are caused by environmental conditions (inadequate nutrition or exposure to toxins), other embryonic defects are caused by genetic defects. The most common genetic disorder affecting humans is **Down syndrome**, which arises when a zygote receives three copies of chromosome 21. The effects in an embryo are complex, and multiple physical and neurological disorders are associated with this syndrome. The mechanisms that produce the many and varied developmental and later abnormalities in Down syndrome are unclear, but are related to overexpression of some of the approximately 300 genes on chromosome 21. As one example, the increased cellular and extracellular accumulation of one of the proteins encoded by these genes results in damage to the brain that is similar to that seen in brains of persons with Alzheimer's disease (refer back to Figure 42.18).

Finally, cleft lip or palate (or both combined) are relatively common (roughly 1 in 1,000 births in the U.S.) developmental disorders that appear to share both a genetic and an environmental basis. During early development in humans, the tissues of the lip and palate exist as two structures that merge around weeks 5–7 of embryonic development. In cleft lip, the tissues of the upper lip fail to fuse, whereas in cleft palate, those of the palate fail to fuse; in some cases, these two deformities occur together. In the latter case, the result is a gap or groove that extends from the mouth into the nasal cavity. Cleft lip/palate is a disfiguring condition that leads to speech impediments, difficulty eating and drinking (for example, an affected infant cannot readily produce the suction needed to drink from a bottle or nipple), and repeated infections. The only treatment for cleft lip/palate is surgical repair of the affected tissues, which is often quite successful but which usually entails numerous surgical procedures over several years (**Figure 52.16**). Despite intensive research, the causes of cleft lip/palate are still uncertain. However, certain environmental agents have been linked with an increased risk of this disorder, notably maternal ingestion of alcohol, lead, cocaine, or certain antiseizure drugs, or possibly vitamin deficiencies during pregnancy. Recently, researchers have identified several genes in which loss-of-function mutations affect the way in which the palate develops, contributing to a cleft.

The World Health Organization has compiled numbers of birth defects around the world by geographic region in order to assess the extent of the impact of developmental disorders on public health. The resulting document, entitled *The World Atlas of Birth Defects*, indicates that regional differences in the incidences of a given birth defect can be dramatic. For example, the rate of spina bifida varies from 1 in every 10,000 births in France to about 15–30 in every 10,000 births in Mexico and Ireland. The occurrence of Down syndrome, by contrast, varies from about 7 cases per 10,000 births in Cuba to 22 per 10,000 births in Chile. Together, 27 different birth defects affect 2–3% of all babies born in the world today, an astonishing number when one considers the world's population of roughly 7 billion, with annual worldwide births of nearly 150 million.

Summary of Key Concepts

52.1 Principles of Embryonic Development

- The process by which a fertilized egg is transformed into an organism with distinct physiological systems and body parts is called embryonic development. The process by which different cells within a developing organism acquire specialized forms and functions, due to the expression of cell-specific genes, is called cellular differentiation. Four responses to positional information are cell division, cell migration, cell differentiation, and apoptosis.

52.2 General Events of Embryonic Development

- Development in many animals, including vertebrates, involves five general events: fertilization, cleavage, gastrulation, neurulation, and organogenesis (Figure 52.1).
- Major events in fertilization include the acrosomal reaction and the cortical reaction. During the acrosomal reaction, the binding of a sperm with the egg membrane triggers a series of events producing the fast block to polyspermy, which prevents other sperm from binding to the egg. During the cortical reaction, an increase in cytosolic Ca^{2+} concentration leads to additional barriers to sperm, a process called the slow block to polyspermy (Figure 52.2).
- Fertilization is followed by cleavage, which involves cell divisions without cell growth, and results in daughter cells called blastomeres. In many species, when the embryo forms an outer epithelial layer and an inner cavity, it is called a blastula. The mammalian counterpart of a blastula is a blastocyst.
- Cleavage-stage embryos in triploblastic organisms have animal and vegetal hemispheres. The hemispheres determine in part the future anteroposterior and dorsoventral axes of the embryo (Figure 52.3).

- Incomplete or meroblastic cleavage occurs in birds, some fishes, and some other vertebrates whose eggs contain large amounts of yolk. Complete or holoblastic cleavage occurs in amphibians and mammals, whose eggs have smaller amounts of yolk. In mammals, cleavage occurs in the oviduct, and the embryo implants in the uterine wall (Figures 52.4, 52.5).
- In fate mapping, a small population of embryonic cells is specifically labeled with a harmless dye, and the fate of these labeled cells is followed to a later stage of embryonic development (Figure 52.6).
- During gastrulation, the hollow ball of cells that makes up the blastula or blastocyst is converted into a gastrula, containing the three germ layers: endoderm, mesoderm, and ectoderm. Each germ layer gives rise to specific structures (Figure 52.7).
- Gastrulation begins when a band of tissue invaginates, creating a small opening called the blastopore. During gastrulation, the embryo forms a cavity called the archenteron, which will become the organism's digestive tract. By the end of gastrulation, the notochord has formed in chordates (Figure 52.8).
- During gastrulation, two cellular processes are crucial to development: apical constriction, in which a reduction in the diameter of the actin rings connected to the adherens junctions causes the cells to elongate toward their basal end, and convergent extension, in which two rows of cells merge to form a single elongated layer (Figure 52.9).
- Primordial germ cells (PGCs) become established during gastrulation. Amphibian eggs contain certain cytoplasmic determinants, called the germ plasm, that help define and specify the PGCs in the gastrula stage. In flies, PGCs are the first cells to form at the posterior end of the embryo and are called pole cells (Figure 52.10).
- Neurulation is the multistep embryological process responsible for initiating CNS formation. Neurulation occurs just after gastrulation and involves the formation of the neural tube from ectoderm located dorsal to the notochord. The neural crest, which gives rise to all neurons and supporting cells of the peripheral nervous system in vertebrates, arises during neurulation. The mesoderm becomes segmented from the anterior end first, giving rise to blocklike structures of mesoderm called somites (Figures 52.11 and 52.12).
- The developmental event during which cells and tissues form organs is called organogenesis.

52.3 Control of Cell Differentiation and Morphogenesis During Animal Development

- Two mechanisms convey positional information during embryonic development: autonomous specification, which involves internal factors, and conditional specification, which involves external signals. Morphogens and cell-to-cell contacts are the molecular mechanisms behind autonomous and conditional specification (Figure 52.13).
- An extremely important region in the early gastrula is known as Spemann's organizer. The organizer secretes morphogens responsible for inducing the formation of a new embryonic axis (Figure 52.14).
- Harland and coworkers discovered the *noggin* gene in frog embryos and demonstrated that the protein it expresses acts to promote dorsal development by inhibiting ventral development (Figure 52.15).

52.4 Impact on Public Health

- Some important examples of conditions involving defective embryonic development are spina bifida, caused by the failure of the neural tube to close completely during neurulation; fetal alcohol syndrome (FAS), which occurs in babies whose mothers drink large amounts of alcohol during pregnancy; Down syndrome, the most common genetic disorder affecting humans, in which the embryo has three copies of chromosome 21; and cleft lip or palate, a developmental disorder with both genetic and environmental causes (Figure 52.16).

Assess and Discuss

Test Yourself

1. During which general event of embryonic development do the acrosomal and cortical reactions occur?
   a. fertilization
   b. cleavage
   c. gastrulation
   d. neurulation
   e. organogenesis
2. Choose the correct sequence of events in embryonic development.
   a. fertilization → cleavage → gastrulation → organogenesis → neurulation
   b. neurulation → cleavage → organogenesis → gastrulation → fertilization
   c. fertilization → cleavage → gastrulation → neurulation → organogenesis
   d. organogenesis → fertilization → neurulation → gastrulation → cleavage
   e. fertilization → organogenesis → cleavage → neurulation → gastrulation
3. Cell differentiation that results from cell-to-cell signaling is
   a. autonomous specification.
   b. conditional specification.
   c. communicative specification.
   d. gastrulation.
   e. embryogenesis.
4. The three germ layers of triploblasts are established during
   a. fertilization.
   b. cleavage.
   c. blastula formation.
   d. gastrulation.
   e. neurulation.
5. The limbs of vertebrates are formed from
   a. the endoderm.
   b. the mesoderm.
   c. the ectoderm.
   d. all of the above.
6. In vertebrates, the digestive tract forms from
   a. the blastopore.
   b. the dorsal lip.
   c. the archenteron.
   d. the mesoderm.
   e. both a and d.
7. The cells that give rise to gametes
   a. are derived from the mesoderm.
   b. often arise independently from the three germ layers.
   c. originate directly from the tissue that will develop into the gonads.
   d. are some of the last cells of the embryo to differentiate.
   e. are formed the same way in all animals.
8. Cells of the neural crest
   a. give rise to the central nervous system.
   b. originate from the ectoderm.

c. migrate to different areas of the body and differentiate into a variety of cells, including neurons of the peripheral nervous system.
d. do all of the above.
e. do only b and c.

9. Which statement is true of Spemann's organizer?
a. It is unique to amphibian embryos.
b. It arises early in cleavage-stage embryos.
c. It secretes morphogens, including the protein called noggin.
d. It is found in the dorsal lip region of early gastrula-stage embryos.
e. Both c and d are true of Spemann's organizer.

10. Morphogens
a. are present in oocytes.
b. are important signaling proteins in the process of embryonic development.
c. can elicit different cell responses at different concentrations.
d. contribute to autonomous specification.
e. All of the above are true of morphogens.

Conceptual Questions

1. What are the differences between autonomous and conditional specification?
2. During organogenesis in vertebrates, some organs develop and become functional sooner than others. Why is it important, for example, that the heart of a terrestrial vertebrate develop sooner than its lungs?
3.  A principle of biology is that *living organisms grow and develop*. Distinguish among embryonic development, cellular differentiation, and growth.

Collaborative Questions

1. Discuss the major events in animals' embryonic development, beginning with fertilization.
2. Name the three germ layers, and identify several types of structures that arise from each.

CHAPTER OUTLINE

53.1 Types of Pathogens
53.2 Innate Immunity
53.3 Acquired Immunity
53.4 Impact on Public Health
Summary of Key Concepts
Assess and Discuss

Immune Systems

53

In an immune system response, a macrophage engulfs numerous rod-shaped bacteria (false-color SEM).

In 2001, as many as 10 million domestic sheep and cattle had to be destroyed in England due to an epidemic of hoof-and-mouth disease, a viral disease that infected animals across the country. A similarly severe outbreak resulted in millions of diseased pigs and cattle being killed in South Korea and Japan in 2010–2011. Beginning in 2006, as many as 6 million bats in North America have died due to an epidemic of a fungal disease called White Nose Syndrome, reducing the populations of some species by as much as 99%. Since the 1990s, thousands of gorillas and chimpanzees have died from outbreaks of the ebola virus in parts of Africa, decimating their populations. Countless numbers of crows and other birds have died from West Nile virus in recent years, a virus that, like ebola, can be transmitted to humans. These and other epidemic illnesses highlight the importance of understanding how animals protect themselves from harmful microorganisms and their secretions. In addition, however, they must also protect against other internal threats, such as cancer.

The ability of an animal to ward off these threats—an animal's **immunity**, or immune defenses—is the subject of this chapter. The cells and organs within an animal's body that contribute to immune defenses collectively constitute that animal's **immune system**. The study of immunity is called immunology. Immunologists examine the processes by which the immune system protects an animal from foreign matter, whether living or nonliving. In these processes, the body's immune defenses recognize the body's own molecules as "self" and attack anything that is foreign, or "nonself."

Immune defenses are often divided into two types: innate and acquired. **Innate immunity** refers to the body's defenses that are present at birth and that act against foreign materials in much the same way regardless of the specific identity of the invading material. Innate immunity includes a set of cellular and chemical defenses that oppose substances that breach the external barriers (skin and mucous membranes) of an animal's body. An example of an innate immune response is seen in the chapter opening photo, in which a cell known as a macrophage is engulfing numerous bacteria. All animals have innate immune defenses.

In contrast, **acquired immunity** develops only after the body is exposed to foreign substances. This type of immunity is characterized by the ability of certain cells of the immune system to recognize a particular foreign substance and initiate a response that targets that substance specifically. Another feature distinguishing acquired immunity is that repeated exposure to a foreign substance elicits greater and greater defense responses, unlike the situation for innate immunity, in which each exposure to the foreign material elicits the same defense responses. Thus, acquired immunity is also called adaptive immunity. Acquired immune defenses have been identified in all vertebrates except for the jawless fishes, but they have not been unequivocally identified in invertebrates.

We begin the chapter with a brief overview of the different pathogens that cause disease in animals. We will then consider the mechanisms that provide animals with innate and acquired immunity against harmful pathogens. We will conclude with a discussion of the public health implications of some immunity-related conditions in humans.

53.1 Types of Pathogens

Learning Outcome:

1. List the three main types of pathogens that elicit immune responses, and briefly describe how each damages its host organism.

An animal's immune defenses must protect against a variety of foreign materials, but most important among them are disease-causing viruses and microorganisms, or **pathogens**. Pathogens exist in nearly every ecological niche on Earth. Both terrestrial and aquatic animals, including invertebrates and vertebrates, encounter each of the three major types of pathogens: certain bacteria, viruses, and eukaryotic parasites. A fourth type of infectious agent—proteins called prions—were considered in Chapter 18 (refer back to Figure 18.8) and will not be discussed here.

Bacteria As described in Chapter 27, bacteria are prokaryotic organisms that lack a true nucleus. Bacteria can either damage tissues at open wound sites or release toxins that enter the bloodstream and disrupt functions in other parts of the body. Bacteria are responsible for many diseases and infections in animals and humans, including typhoid fever, strep throat, skin infections, ear infections, anthrax, plague, cholera, and food poisoning. The major ways in which bacteria gain entry into an animal's body are through direct bodily contact, open wounds, inhalation through the respiratory tract, and ingestion via fecal contamination of food or water. This last situation may arise because many infectious bacteria enter the intestines and are excreted in feces, which may be deposited near food or water sources used by some animals.

Viruses All viruses contain nucleic acid (DNA or RNA) within a protein coat (see Chapter 18). Unlike bacteria, viruses lack the metabolic machinery to synthesize the proteins they require to replicate themselves. Instead, they must infect a host cell and use its biochemical and genetic machinery, including nucleotides and energy sources, to make more viruses. The viral nucleic acid directs the host cell to synthesize the proteins required for the virus's replication. After entering a cell, some viruses, such as the common cold virus, multiply rapidly, kill the cell, and then infect other cells. Other viruses can lie dormant within host cells before suddenly undergoing rapid replication, which causes cell damage or death. Finally, certain viruses can transform their host cells into cancerous cells. Viruses are responsible for a great variety of illnesses, including ebola, swine fever, West Nile encephalitis, hoof-and-mouth disease, influenza, and some sexually transmitted diseases. Like bacterial infections, viral infections can spread rapidly among animals and can be lethal. Viruses typically enter an animal's body through the respiratory tract or through open wounds.

Eukaryotic Parasites Eukaryotic parasites—whether protists, fungi, or worms—damage a host by using the host's nutrients for their own growth and reproduction or by secreting toxic chemicals. In humans, parasites account for an enormous number of cases of disease annually. For example, several hundred million people are infected each year with one of the mosquito-borne protists of the genus *Plasmodium* that cause malaria. Parasitic infections may enter a host through the bite of an infected insect, as in malaria; by ingestion of food or water containing parasitic organisms, such as roundworms; or in some cases, by penetrating the skin, as with blood flukes.

53.2 Innate Immunity

Learning Outcomes:

1. Identify the main innate defense mechanisms in animals, and explain why innate immunity is also called nonspecific immunity.
2. Explain how an animal's body surface provides protection from pathogens.
3. Describe the process of phagocytosis, and explain its importance in innate immune responses.
4. List the cell types involved in innate immunity and the functions of each.
5. Identify the correct sequence of the events in the inflammatory response.
6. Describe the role of Toll proteins in innate immunity.

Innate immune defenses protect against foreign cells or substances without having to recognize the invaders' specific identities. This type of defense mechanism is called innate because animals inherit the ability to perform these protective functions and because this type of immunity does not require prior exposure to invaders. Instead of distinguishing among foreign materials, innate defenses recognize some general property marking the invader as foreign, such as a particular class of carbohydrate or lipid present in the cell walls of many different kinds of microbes. For this reason, innate immunity is sometimes referred to as nonspecific immunity.

In this section, we will consider the innate immune defenses. These include the actions of phagocytic cells, the response to injury known as inflammation, and various proteins secreted by cells of the immune system that facilitate the destruction of pathogens. We begin, however, with a brief look at barrier defenses that can help prevent pathogens from entering an animal's body fluids and cells.

The Body Surface Is an Initial Line of Defense

An animal's initial defense against pathogens is the cellular, chemical, and anatomical barrier provided by a surface exposed to the external environment. Very few microorganisms can penetrate the intact skin or body surface of most animals, particularly the tough, thick, or scaly skin characteristic of many vertebrates or the rigid exoskeleton of many arthropods. In addition, glands in the body surfaces of both invertebrates and vertebrates secrete a variety of antimicrobial molecules, including mild acids and enzymes such as lysozyme that destroy bacterial cell walls.

The mucus secreted by cells in the mucous membranes lining the respiratory and upper gastrointestinal tracts of vertebrates also contains antimicrobial molecules. More importantly, mucus is sticky—microbes that become stuck in it are prevented from penetrating the mucous membrane barrier. They are either swept up by cilia into the pharynx and then swallowed, or they are engulfed by cells that are present in both tracts. Pathogens ingested with food are often destroyed by the acidic environment of an animal's stomach.

If a pathogen is able to penetrate a barrier and gain entry into an animal's internal tissues and fluids, innate defense mechanisms are activated. These mechanisms are mediated by several types of cells that reside in the body fluids and tissues, as described next.

Phagocytic Cells Defend Against Pathogens That Enter the Body

Several different types of cells in vertebrates have important functions in innate immunity (**Figure 53.1**). Many of these cells are **phagocytes**—cells capable of phagocytosis. **Phagocytosis** is a type of endocytosis in which a cell engulfs particulate matter, which usually is then destroyed by proteases or oxidizing compounds such as hydrogen peroxide. Phagocytes are found in the body fluids, such as hemolymph and blood, and also within various tissues and organs. They are present in all classes of animals and are among the most fundamental and ancestral forms of immune defenses.

In vertebrates, most phagocytes belong to the type of blood cells called **leukocytes** (see Figure 53.1). All leukocytes are derived from a common type of stem cell (adult hematopoietic stem cells; refer back to Figure 19.20), which in mammals and birds is found in the bone marrow. These stem cells give rise to several types of leukocytes and other immune cells that have specialized functions. The leukocytes involved in innate immunity include the following:

- **Neutrophils** are phagocytes and the most abundant leukocytes. They are found in blood and some may enter tissues during inflammation. After neutrophils engulf bacteria by phagocytosis, the bacteria are destroyed within endocytotic vacuoles by proteases, oxidizing compounds, and antibacterial proteins called defensins. The production and release of neutrophils from bone marrow are greatly stimulated during the course of an infection.
- **Eosinophils** are found in the blood and in the mucosal surfaces lining the gastrointestinal, respiratory, and urinary tracts, where they fight off parasitic invasions. In some cases, eosinophils act by releasing toxic chemicals that kill parasites, and in other cases by phagocytosis.
- **Monocytes** are phagocytes that circulate in the blood for a short time, after which they migrate into tissues and organs and develop into macrophages.
- **Macrophages** are strategically located where they will encounter foreign matter, including in epithelia in contact with the external environment, such as skin and the linings of respiratory and digestive tracts. Macrophages are large phagocytes capable of engulfing viruses and bacteria, as shown in the chapter opening photo.
- **Basophils** are secretory cells, not phagocytes. They secrete an anticlotting factor called heparin at the site of an infection, which helps the circulation flush out the infected site. Basophils also secrete histamine, which attracts infection-fighting cells and proteins to the site.
- **Natural killer (NK) cells** are another kind of leukocyte called lymphocytes, of which there are several types. We will discuss the other types of lymphocytes later, because they play the major role in acquired immunity. NK cells, however, participate in both innate and acquired immunity. These cells are part of an animal's innate defenses because they recognize general features on the surface of cancerous cells or virus-infected cells. NK cells arise in the bone marrow. They act by releasing chemicals into the vicinity of cancerous or virus-infected cells, thereby killing those cells.

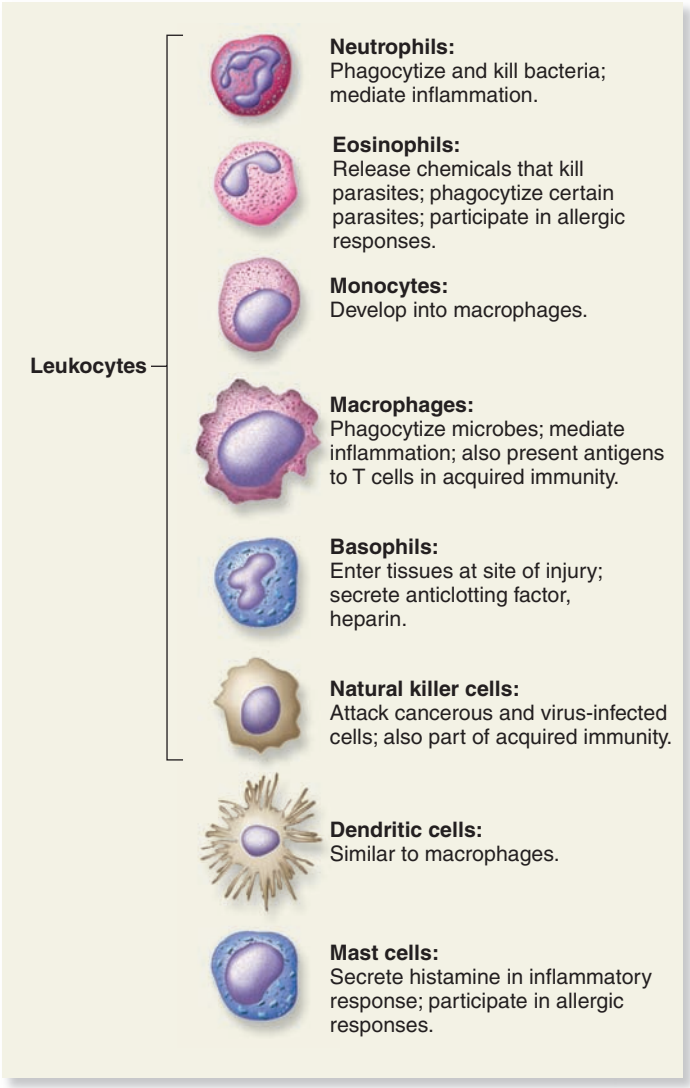


Figure 53.1 Cells involved in innate immunity in vertebrates. Six of these types of cells are leukocytes, and several are phagocytes. Some of these cells also participate in acquired immunity; a few of those actions are included here for reference.

In addition to leukocytes, two other types of cells derived from bone marrow stem cells have important functions in innate immunity. **Dendritic cells** are scattered throughout most tissues, where they perform various macrophage-like functions. **Mast cells** are found throughout connective tissues, particularly beneath the epithelial surfaces of the body. Mast cells secrete many locally acting molecules, including histamine. Histamine and other substances are involved in inflammation, a fundamental component of the innate defense mechanism, which we now examine.

Inflammation Is an Innate Response to Infection or Injury

Inflammation is an innate local response to infection or injury. The functions of inflammation are to destroy or inactivate pathogens, to clear the infected region of dead cells and other debris, and to set the stage for tissue repair. The key cellular components of this process are neutrophils, macrophages, dendritic cells, and mast cells.

The events of inflammation are induced and regulated by chemical mediators. These include a family of proteins called **cytokines** that function in both innate and acquired immune defenses. Cytokines provide a chemical communication network that synchronizes the components of the immune response. Most cytokines are secreted by more than one type of immune cell and also by certain nonimmune cells such as endothelial cells and fibroblasts.

The sequence of local events in a typical inflammatory response to a bacterial infection is summarized in **Figure 53.2**. A tissue injury such as that caused by a splinter begins the inflammatory process, which results in the familiar signs and symptoms of local redness, swelling, heat, and pain.

Substances secreted into the extracellular fluid from injured tissue cells, mast cells, and neutrophils contribute to the inflammatory response. For example, histamine from mast cells and nitric oxide from endothelial cells (Figure 53.2, step 1) cause vasodilation of the small blood vessels in the infected and damaged area, inducing the vessels to leak (step 2).

These vascular changes provide two benefits. First, the increased blood flow to the inflamed area, which accounts for the redness and heat, speeds the delivery of beneficial proteins and leukocytes and increases local metabolism to facilitate healing. Second, the increased vascular permeability ensures that the plasma proteins that participate in inflammation can gain entry to the interstitial fluid. The swelling in an inflamed area also results from this increased leakiness of blood vessels.

Once neutrophils and macrophages arrive at the site of the injury, they begin the process of phagocytizing and destroying the bacteria (Figure 53.2, step 3). The initial step in phagocytosis involves the interaction of phagocyte surface receptors with certain carbohydrates or lipids in the bacterial cell walls. Subsequently, the neutrophils and macrophages also release antimicrobial substances into the extracellular fluid that can destroy bacteria even before phagocytosis occurs. Other secreted substances such as nitric oxide function as inflammatory mediators. The result is positive feedback: Once phagocytes enter the area and encounter bacteria, they release inflammatory mediators that bring even more phagocytes into the area.

Inflammation—indeed any stage of an illness—may be accompanied by **fever**, an increase in an animal's body temperature that results from an infection. This is distinguished from hyperthermia, an increase in body temperature resulting from any number of causes, such as overexertion. In humans, a body temperature greater than 38°C (100.4°F) is considered to be a fever (normal is about 37°C [98.6°F]). The precise mechanisms by which a fever arises are not completely understood. It is clear, however, that in mammals, cytokines released into the circulation by activated macrophages act within the hypothalamus to raise the body's set point for temperature,

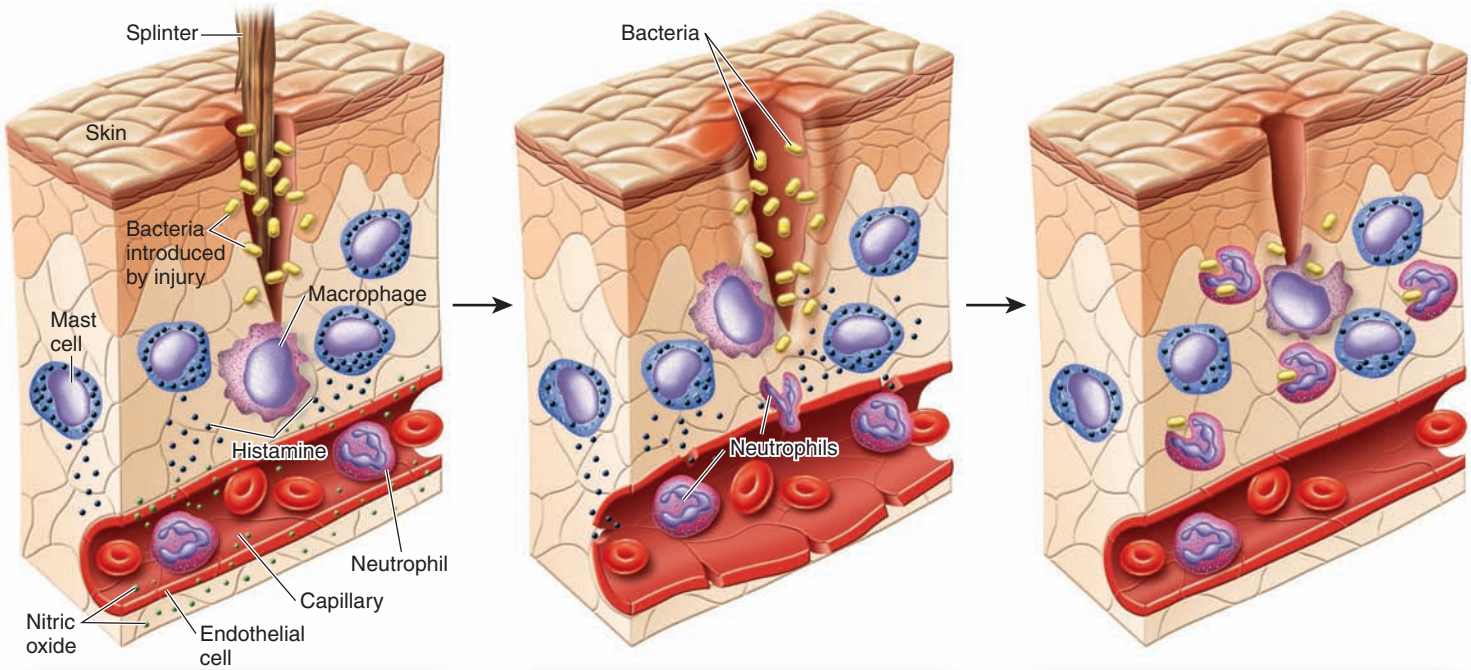

Figure 53.2 The events in inflammation. Shown are the initial stages of inflammation in response to a penetrating wound that introduces bacteria beneath the skin.

Concept Check: *Inflammation is often associated with swelling of the inflamed area. Could this swelling have an adaptive value?*

BioConnections: *In Chapter 41, you learned about another role of histamine in animals, as a neurotransmitter that increases wakefulness. Why would antihistamines (drugs that block histamine receptors) used to treat the inflammatory components of allergies cause drowsiness?*

just as when you turn up a thermostat in a room. The result is an increase in heat generation. Whereas a sustained high fever requires medical attention because of the damaging effects of high temperature on membrane function, enzyme activity, and other processes (see Chapter 46), it appears from animal models that a small or moderate increase in temperature stimulates leukocyte activity and proliferation and provides a less hospitable environment for at least some types of pathogens. For example, fever promotes the uptake of iron from the blood into the liver, thus preventing microbes from obtaining this element that is important for their survival and reproduction.

Defenses Against Pathogens Include Interferons and Complement Proteins

In addition to phagocytes and the inflammatory response, animal bodies have at least two other types of innate defenses against invading pathogens. These defenses allow for extracellular destruction of pathogens without prior exposure to them. The first of these innate defenses is used against viruses. **Interferons** are proteins that generally inhibit viral replication inside host cells. In response to viral infection, many types of cells produce interferons and secrete them into the extracellular fluid. When the interferons bind to plasma membrane receptors on the secreting cell and on other cells, each cell synthesizes a variety of proteins that interfere with the ability of the viruses to replicate. Interferons are not specific. Many kinds of viruses induce interferon synthesis, and the same interferons, in turn, can inhibit the multiplication of many different kinds of viruses.

The second type of innate defense is provided by a family of proteins present in blood and known as **complement**. Inactive complement proteins normally circulate in the blood at all times and are activated by contact with the surface of microbes. Activation of complement proteins results in a cascade of events. Among their many actions, complement proteins stimulate the release of histamine from mast cells, thereby increasing permeability of local blood vessels, as described earlier. Five of the active proteins generated in the complement cascade form a multiunit protein called the **membrane attack complex (MAC)**, which, by embedding itself in the pathogen's cell membrane or envelope (in the case of some viruses), creates porelike channels. Water and ions enter the pathogen through the channels, and the pathogen is destroyed.

Innate Immune Responses Require Proteins That Recognize Features of Many Pathogens

As we have seen, innate immunity often depends on an immune cell recognizing some general molecular feature common to many types of pathogens. These features are called **pathogen-associated molecular patterns (PAMPs)**. Until fairly recently, however, it was not known how that recognition was accomplished. In 1985, German biologist Christiane Nüsslein-Volhard and American biologist Eric Wieschaus were interested in how animal embryos differentiate into adults. In the course of their studies, they discovered a protein they named Toll (now called Toll-1) that was required for the proper dorsoventral orientation of the fruit fly (*Drosophila melanogaster*). In a landmark study in 1996, it was discovered that Toll-1 also conferred on adult flies the ability to fight off fungal infections (see the Feature Investigation). It has since become clear that a family of Toll proteins exists in animals from nematodes to mammals, including humans, and these proteins are found in the plasma membranes and endosomal membranes of macrophages and dendritic cells, among others.

One function of the Toll proteins in vertebrates is to recognize and bind to ligands with PAMPs, such as lipopolysaccharide and other common microbial lipids and carbohydrates; viral and bacterial nucleic acids; and a protein found in the flagellum of many bacteria. These PAMPs have conserved molecular features that are generally considered to be vital to the survival of the particular pathogen. When one of these ligands binds a Toll protein on the plasma membrane of an immune cell, second messengers are generated in the cell, triggering secretion of inflammatory mediators such as various cytokines. These in turn stimulate the activity of other leukocytes involved in the innate immune response. Some of these mediators also activate cells involved in the acquired immune response. Because many of the Toll proteins are plasma-membrane-bound, bind extracellular ligands, and induce second-messenger formation, they are referred to as receptors, and the family of proteins is known as **Toll-like receptors (TLRs)**. Despite this, not all TLRs generate intracellular signals when bound to a ligand; some TLRs induce attachment of a microbe to a macrophage, for example, thereby facilitating its phagocytosis and subsequent destruction.

The importance of TLRs in mammals has been demonstrated in mice with a mutated form of one member of the family called Toll-4. These mice are hypersensitive to the effects of injections of lipopolysaccharide (to mimic a bacterial infection) and are less able to ward off bacterial infection. In humans, recent studies suggest that certain naturally occurring variants in a specific TLR are associated with increased risk of certain diseases.

TLRs are currently an active area of investigation among biologists because of their immune significance. Certain domains of these receptors have also been identified in plants, where they may also be involved in disease resistance. Therefore, TLRs may be among the first immune defense mechanisms to have evolved in living organisms. For their investigations of embryonic development and discovery of Toll proteins, Nüsslein-Volhard and Wieschaus were awarded the 1995 Nobel Prize in Physiology or Medicine.

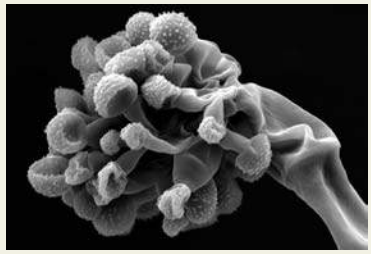
Feature Investigation | Lemaitre and Colleagues Identify an Immune Function for Toll Protein in *Drosophila*

As you've just learned, Toll protein was initially identified as a critical molecule directing the proper dorsoventral development of *Drosophila* embryos. Interestingly, however, certain aspects of the sequence and function of Toll shared similarities with at least one important immune protein found in vertebrates. For example, both Toll and the receptor for the cytokine interleukin-1 were found to be transmembrane proteins with similar cytosolic sequences; moreover, both proteins activated a similar intracellular signaling pathway once they had bound an extracellular ligand. This led to the hypothesis proposed by French researcher Bruno Lemaitre and coworkers working

in the laboratory of Jules Hoffman, that Toll protein may also function in immunity in *Drosophila*.

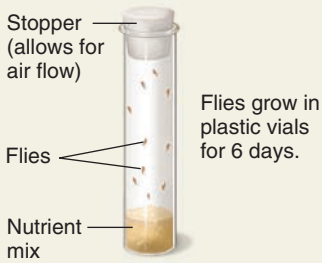
To test this hypothesis, the researchers compared wild-type to mutant flies in which the *Toll* gene was underexpressed due to a mutation (**Figure 53.3**). They then exposed the flies to a variety of pathogens, by pricking them with a needle that had been dipped into water (as a control) or a concentrated solution of fungal spores. Survival of the flies was monitored over the next several days, and compared with the survival of wild-type flies with normal Toll protein. What they found was remarkable: Within days of being infected with the fungus *Aspergillus fumigatus*, 100% of the mutant flies died, but only about 30% of the wild-type flies died (see the data in step 4 of Figure 53.3). The mutant flies were observed to be covered in germinating hyphae of the fungus, clearly demonstrating that the flies were unable to

Figure 53.3 Lemaitre and colleagues identified the importance of Toll protein in immunity in *Drosophila*.



HYPOTHESIS The Toll signaling pathway is required for the immune response in *Drosophila*.

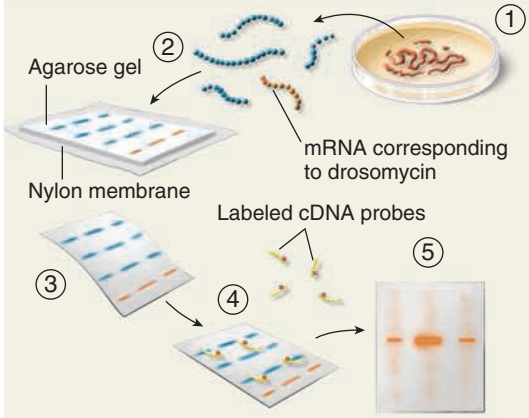
KEY MATERIALS Wild-type *Drosophila*; mutant strain of *Drosophila* that underexpresses the receptor for Toll protein; spores of the fungus *A. fumigatus*; cDNA probe to detect mRNA of antifungal polypeptide drosomycin.

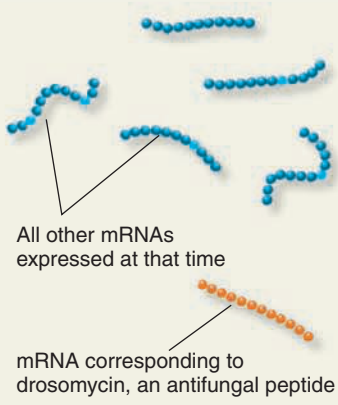


1 Prick flies with a clean needle that was previously dipped in water or a solution of *A. fumigatus* spores.

A. fumigatus is a common pathogen that *Drosophila* is normally able to defend against (approximate magnification: 3500x).

2 Follow survival rates of flies for 6 days.





3 Examine expression of antipathogen genes in wild-type and mutant flies, using Northern blot analysis:

1. Extract mRNA from flies.
2. Separate individual mRNAs by gel electrophoresis.
3. Transfer mRNAs from the gel to a nylon membrane.
4. Probe membrane with a radioactively labeled fragment of cDNA complementary to a region of the mRNA of interst.
5. Expose membrane to X-ray film.

Survival test results:

Northern blot results:

5 CONCLUSION Toll protein receptor is essential for survival in *Drosophila* exposed to a common fungal pathogen and for induction of antifungal genes.

6 SOURCE Lemaitre, B., Nicolas, E., Michaut, L., Reichhart, T., and Hoffmann, J.A. 1996. The dorsoventral regulatory gene cassette spätzle/toll/cactus controls the potent antifungal response in *Drosophila* adults. *Cell* 86:973–983.

fight the infection. Moreover, analysis of mRNA from the treated and untreated flies revealed that the mutant flies were unable to increase expression of a key antifungal gene after infection with *A. fumigatus*, unlike the situation in the wild-type animals.

Since then, these and other researchers have identified much of the mechanism by which Toll promotes immunity to certain microbes in *Drosophila* and, presumably, other insects. Activation of Toll protein induces expression of several genes that encode antimicrobial molecules. Unlike TLRs, however, in *Drosophila* Toll does not directly bind PAMPs associated with microbial membranes. Rather, microbial infection induces activation of extracellular signaling molecules in *Drosophila* that, in turn, bind to Toll that is located on cell membranes; this binding induces intracellular signals that activate gene expression. Despite this difference, the identification of an immune function of an ancestral Toll protein paved the way for a clearer understanding of TLRs and innate immunity in all animals; in 2011, Jules Hoffman received a share of the Nobel Prize in Physiology or Medicine for this pioneering research.

Experimental Questions

1. What led the investigators to hypothesize that Toll protein may serve an immune function in *Drosophila*?
2. Is *Drosophila* Toll protein a receptor that binds PAMPs?
3. **SciSKILLS** » Based on the results of their survival studies of infected flies, was the researchers' hypothesis supported?

53.3 Acquired Immunity

Learning Outcomes:

1. Describe the components of the immune system, including the major classes of lymphocytes.
2. Outline the three stages of the acquired immune response.
3. Compare and contrast the humoral immune response with the cell-mediated immune response.
4. **SciSKILLS** » Explain how the structures of different immunoglobulins allow predictions to be made about their functions.
5. Explain how genetic rearrangement creates a diverse set of antibodies in mammals.
6. Describe how B and T cells that recognize self molecules are destroyed.
7. **SciSKILLS** » Predict the benefit of secondary immune responses, and explain the function of memory cells in these responses.

In acquired (specific) immunity, cells of the immune system first encounter and later recognize a specific foreign cell or protein to be destroyed or eliminated, as opposed to recognizing some general feature of pathogens. Any molecule that can trigger a specific immune response

is called an **antigen**. An antigen, therefore, is any molecule that the host does not recognize as self. Most antigens are either proteins or very large polysaccharides. Antigens include the protein coats of viruses, bacterial surface proteins, specific macromolecules on pollens and other allergens, proteins of cancerous or transplanted cells, toxins, and vaccines.

This type of immunity is found in all classes of vertebrates except jawless fishes and was once thought to be absent in invertebrates. Recently, however, scientists who study the evolution of immune systems have uncovered several interesting features of invertebrate immune function that suggest some invertebrates have a limited ability to adapt immune activity to a specific invader. Despite this intriguing finding, however, we will consider acquired immune responses in the context in which they are best understood, the jawed vertebrates.

Acquired Immune Defense Mechanisms Include Lymphoid Organs, Tissues, and Cells

The cells of the immune system that are responsible for acquired immunity are a type of leukocyte mentioned earlier called **lymphocytes**. Like all leukocytes, lymphocytes circulate in the blood, but most of them reside in a group of organs and tissues that constitute the **lymphatic system** (Figure 53.4a). The system is composed primarily of a network of lymphatic vessels. These vessels drain the fluid known as lymph from the interstitial fluid (refer back to Figure 47.13). The lymph is transported through lymph vessels to lymph nodes, before eventually returning to the blood and circulatory system. Various lymphoid organs and tissues are located throughout the lymphatic system. They are grouped into primary and secondary lymphoid organs.

Primary Lymphoid Organs The primary lymphoid organs are the structures in which lymphocytes differentiate into mature immune cells. These are the bone marrow in birds and mammals and the thymus gland in all vertebrates. In animals without extensive bone marrow, specialized regions of other organs such as the kidney and liver serve as primary lymphoid organs. Destruction of or damage to a primary lymphoid organ usually results in a severe inability to fight off infections.

Secondary Lymphoid Organs The primary lymphoid organs supply mature lymphocytes to secondary lymphoid tissues and organs, where the lymphocytes multiply and function. These include the lymph nodes of mammals (Figure 53.4b), the spleen (found in all jawed vertebrates and the largest secondary lymphoid structure), the tonsils (small, rounded lymphoid organs in the pharyngeal region of mammals), and scattered lymphocyte accumulations in the linings of the intestinal, respiratory, genital, and urinary tracts. The loss of any of the secondary lymphoid organs, although not as serious, nevertheless increases the risk of local or systemic infections throughout an animal's life. For example, in humans, the spleen must occasionally be surgically removed due to injury or disease. Such individuals must be monitored carefully for the rest of their lives because of their increased vulnerability to infection.

Recirculation of Lymphocytes After leaving the bone marrow or thymus gland, lymphocytes circulate between the secondary lymphoid organs, blood, lymph, and all the tissues of the body. Lymphocytes from all the secondary lymphoid organs continually leave those structures and are carried to the bloodstream. Simultaneously, some circulating lymphocytes leave venules all over the body to enter interstitial

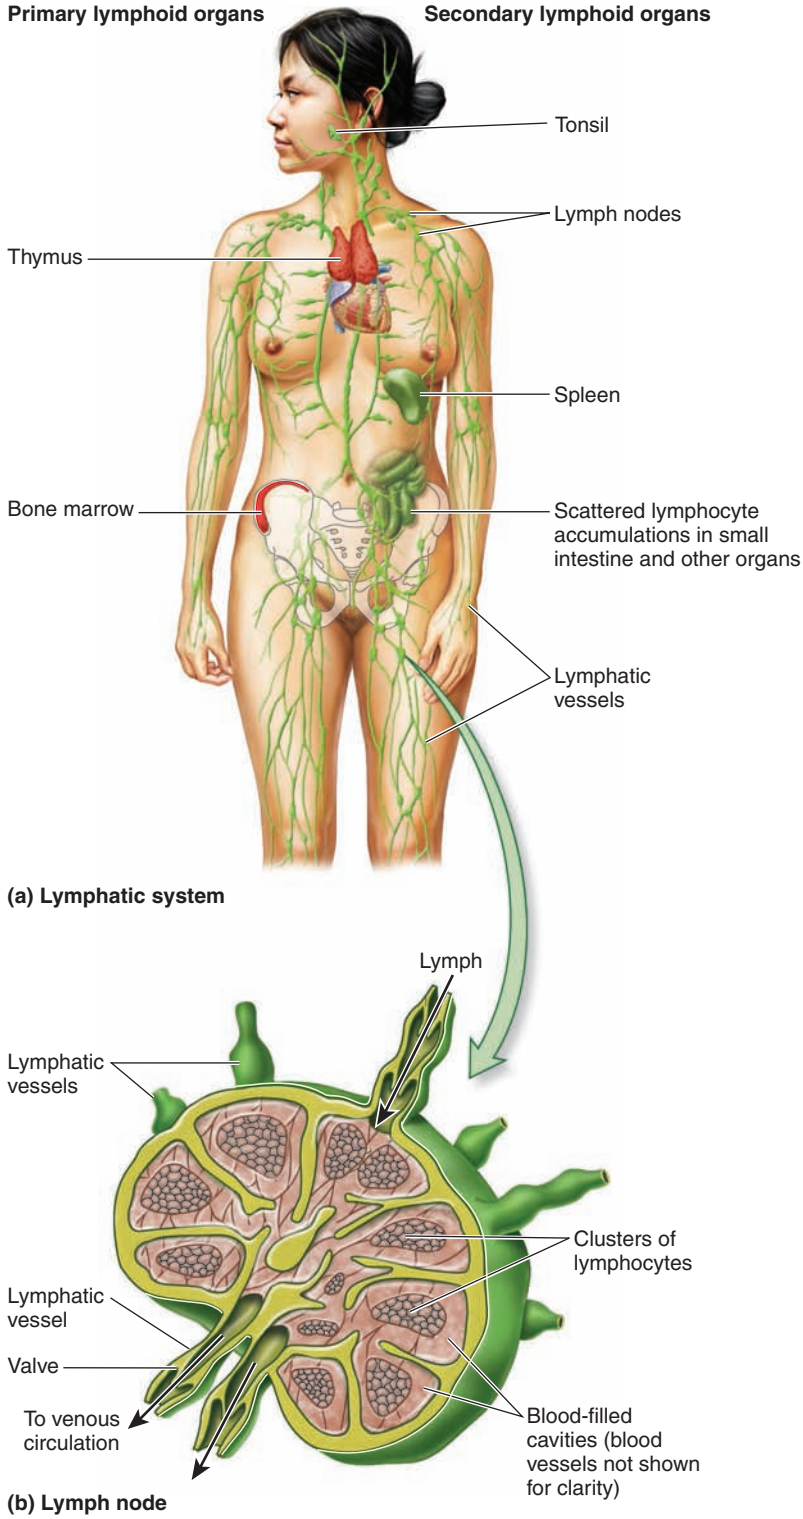

Figure 53.4 The lymphatic system in humans. **(a)** The major components of the human lymphatic system. Primary lymphoid organs are shown in red, and secondary lymphoid organs are shown in green. In adult humans, the primary lymphoid organs in bone are found in the sternum, ribs, parts of the skull, small regions of the femur and humerus, and, as shown here, the hip bones. **(b)** The structure of a lymph node. Lymph nodes occur along the course of lymphatic vessels, which drain interstitial fluid from tissues and return it to the venous circulation. Within a lymph node, lymph percolates through open cavities containing clusters of lymphocytes.

BioConnections: From where does lymph arise (refer back to Figure 47.13 for help)?

fluid. From there, they reenter lymphatic vessels and are carried back to secondary lymphoid organs. This constant recirculation of lymphocytes increases the likelihood that any given lymphocyte will encounter an antigen it is specifically programmed to recognize.

Lymphocytes Provide Specific Immunity Against Antigens in Humoral and Cell-Mediated Immunity

Different kinds of lymphocytes participate in specific coordinated immune system responses (**Figure 53.5**). In addition to NK cells, described earlier, the two major types of lymphocytes are **B cells** and **T cells**. B cells were first observed to mature in an avian organ called the bursa of Fabricius, and therefore were named B cells. In mammals, B cells mature within bone marrow. If stimulated by antigen, some B cells differentiate further into **plasma cells**, which synthesize and secrete **antibodies**, proteins that bind to and help destroy foreign molecules, as described later.

T cells may directly kill infected, mutated, or transplanted cells. They are called T cells because they mature within the thymus gland. T cells that mediate defense mechanisms include two distinct types of lymphocytes: cytotoxic T cells and helper T cells. **Cytotoxic T cells** travel to the location of their targets, bind to the targets by recognizing an antigen, and kill the targets via secreted chemicals. In addition, responses mediated by cytotoxic T cells are directed against body cells that have become cancerous or infected by pathogens. NK cells also destroy such cells by secreting toxic chemicals.

As their name implies, **helper T cells** do not themselves function as "attack" cells. Instead, they assist in the activation and function of B cells and cytotoxic T cells. With only a few exceptions, B cells and cytotoxic T cells cannot function adequately unless they are stimulated by cytokines secreted from helper T cells. An additional type of T cell that won't be considered further here is the regulatory T cell. These cells function to suppress other T cell activities and to help prevent destruction of self proteins.

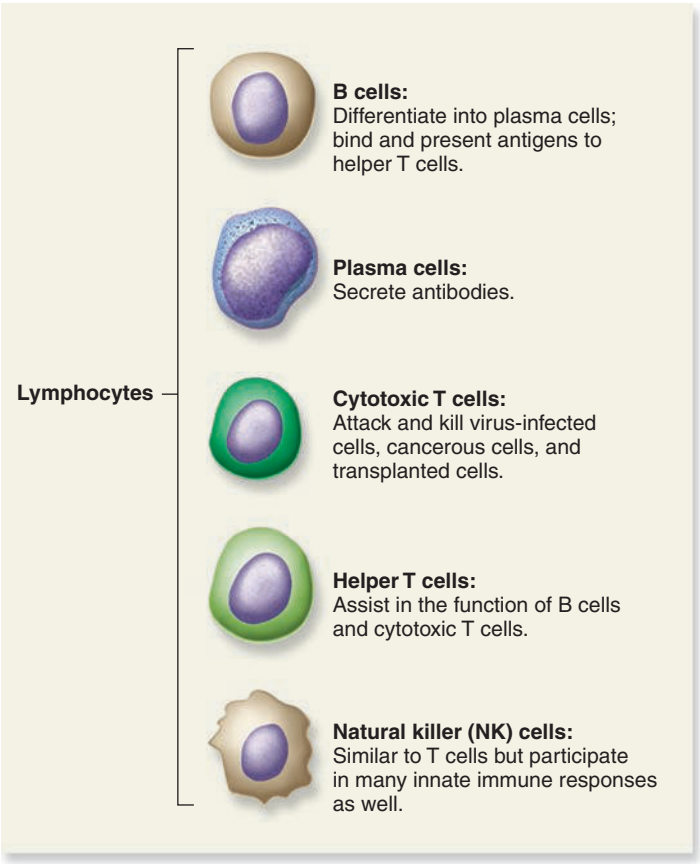

Figure 53.5 Cells involved in acquired immunity in vertebrates. Some important functions of each type of lymphocyte are included. The shape and color conventions shown in this figure will be used throughout this chapter.

Acquired Immune Responses Occur in Three Stages

Lymphocytes function by recognizing antigens such as those found on viruses, bacteria, and the surface of cancerous cells. The ability of lymphocytes to distinguish one antigen from another has a central role in acquired immunity. There are two types of acquired immunity. In **humoral immunity**, plasma cells secrete antibodies that bind to antigens. The adjective humoral denotes communication by way of soluble chemical messengers (the word humors was once used to refer to bodily fluids). In **cell-mediated immunity**, cytotoxic T cells directly encounter and destroy infected body cells, cancerous cells, or transplanted cells.

An acquired immune response can usually be divided into three stages (**Figure 53.6**): recognition of antigen, activation and proliferation of lymphocytes, and attack against the recognized antigen.

Stage 1: Recognition of Antigen During its development, each lymphocyte synthesizes a type of membrane receptor that can bind to a specific antigen. If subsequently the lymphocyte encounters that antigen, the antigen becomes bound to the receptor. This specific binding is the meaning of the word recognize in immunology. Antigens that bind to a lymphocyte receptor are said to be recognized by the lymphocyte. The ability of lymphocytes to distinguish one antigen from another, therefore, is determined by the nature of their plasma membrane receptors. Each lymphocyte is specific for just one type of antigen.

Stage 2: Activation of Lymphocytes In the second stage, the binding of an antigen to a receptor on a lymphocyte activates that lymphocyte. Upon activation, the lymphocyte undergoes multiple cycles of cell division. The result is the formation of many identical cells called clones that express the same receptor as the receptor that first recognized the antigen. The chemical nature of the antigen determines which individual lymphocytes will be activated to form clones. This process requires the function of helper T cells, which divide when activated and then secrete the cytokines that promote further cell division. Some of the cloned lymphocytes become **effector cells**, the plasma cells and cytotoxic T cells that carry out the attack response, whereas others function as **memory cells**, which remain poised to recognize the antigen if it returns in the future.

In a typical person, the size of the lymphocyte population is staggering. Over 100 million different lymphocytes, each with the ability to recognize a unique antigen, are estimated to exist in a human's immune system. This vast population explains why our bodies are able to recognize so many different antigens as foreign and eventually destroy them.

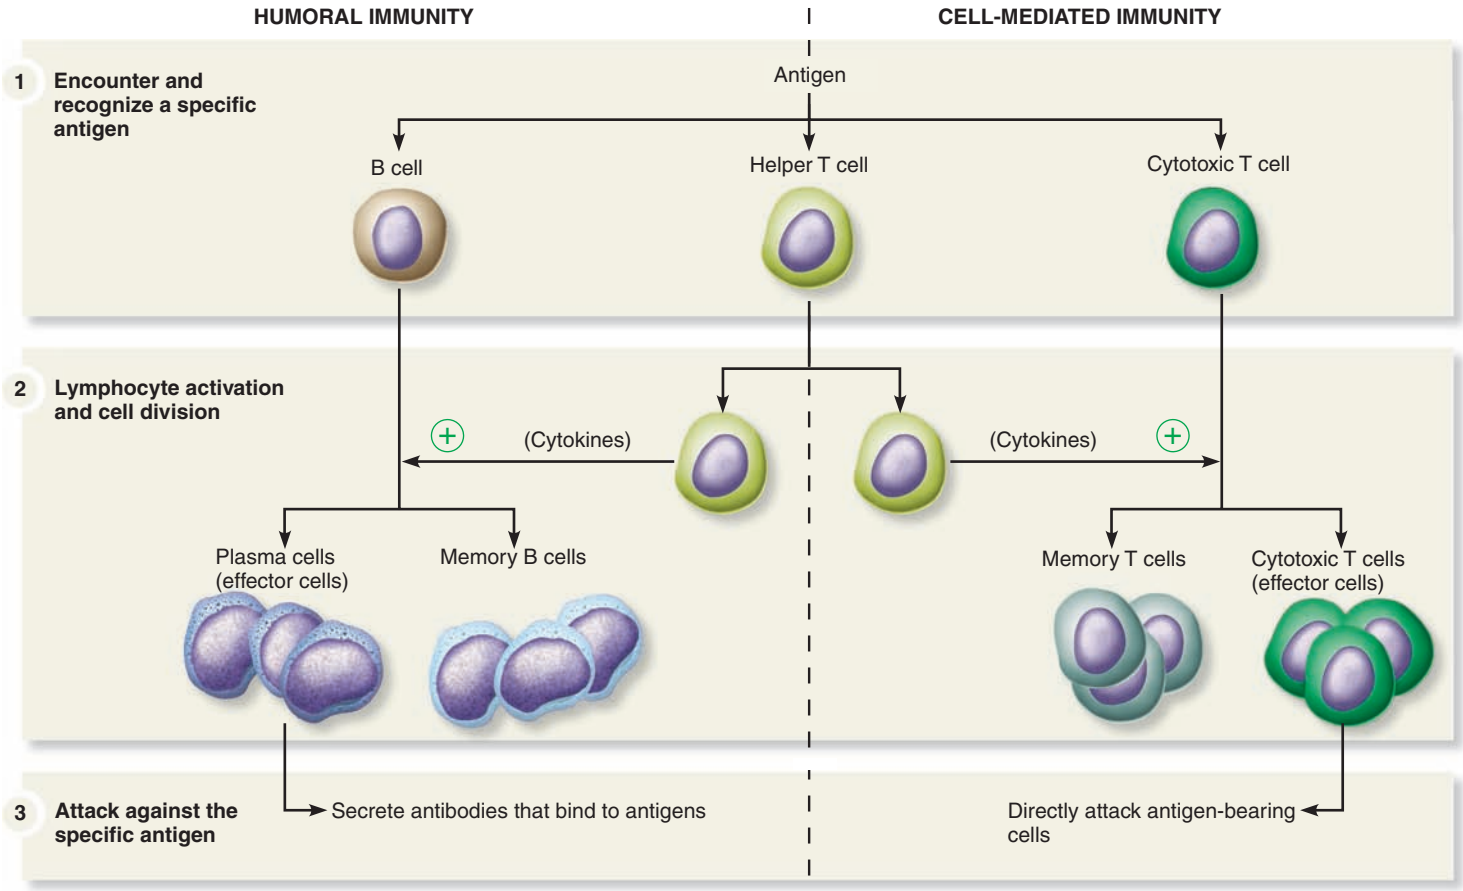

Figure 53.6 The three stages of an acquired immune response. All three cell types in step 1 recognize the same antigen. Helper T cells secrete cytokines that activate B cells and cytotoxic T cells, as indicated by the ⊕ symbols. Both B cells and T cells undergo cell division to form clones when activated, and in both cases, a portion of the cells are set aside as memory cells to fight off a future infection of the same type.

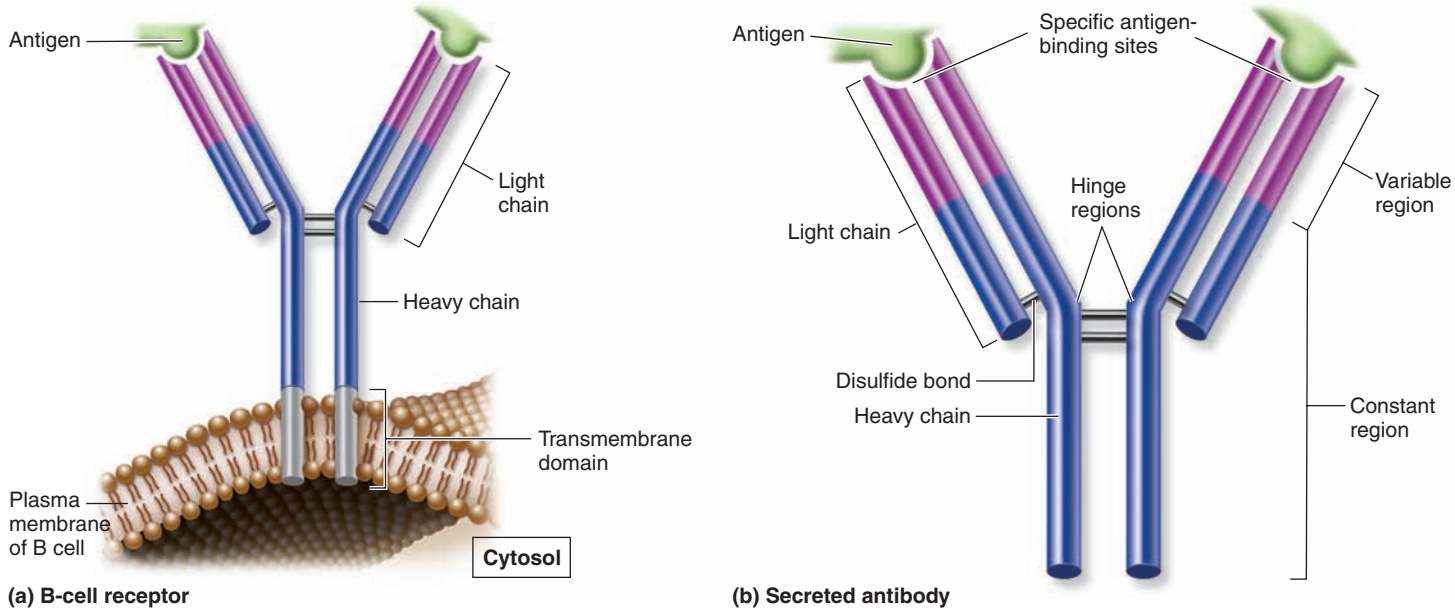
Stage 3: Attack Against Antigen In the third stage, the effector cells attack all antigens of the kind that initiated the immune response. Plasma cells carry out a humoral response by secreting antibodies into the blood. These antibodies then recruit and guide other molecules and cells that perform the actual attack. Activated cytotoxic T cells, by contrast, carry out cell-mediated immunity. They directly attack and kill the cells bearing the antigens.

Once the attack is successfully completed, the great majority of plasma cells and cytotoxic T cells that participated in it die by apoptosis. However, memory cells persist even after the immune response has been successfully completed, so they can recognize and fight off any future infection with the same type of antigen. Let's look at each of these three stages in more detail, first for humoral immunity and then cell-mediated immunity.

In Humoral Immunity, B Cells Produce Immunoglobulins That Serve as Receptors or Antibodies

In stage 1 of humoral immunity (see Figure 53.6, left side), B cells recognize antigens with the help of B-cell receptors. When B cells are activated in stage 2, they proliferate and differentiate into plasma cells, which secrete antibodies. These are proteins that travel all over the body to reach antigens identical to those that stimulated their production. In some cases, the binding of an antibody to an antigen simply prevents that antigen from infecting a host cell; this action is called neutralization. Many viruses, in particular, are prevented from infecting host cells in this way. In other cases, antibodies bound to an antigen guide an attack that eliminates the antigens or the cells bearing them, a process we will discuss in more detail later. Antibody-mediated responses are the major defense against pathogens and toxin molecules in the extracellular fluid.

B-Cell Receptors and Antibodies B-cell receptors and the antibodies secreted by plasma cells share many structural and functional similarities (**Figure 53.7**). They are both members of a family of proteins called **immunoglobulins (Ig)**. However, there are some differences between them. B-cell receptors have a transmembrane domain that anchors them in the plasma membrane of the B cell (Figure 53.7a). Antibodies are soluble proteins that are secreted from plasma cells (Figure 53.7b). Interestingly, B-cell receptors and the antibodies made by plasma cells are encoded by the same genes. In plasma cells, the pre-mRNA is alternatively spliced, a phenomenon



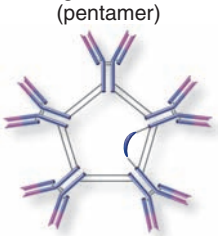


Figure 53.7 Immunoglobulins. (a) B-cell receptor and (b) secreted antibody. Immunoglobulins are composed of two heavy chains and two light chains. Disulfide bonds hold the chains together. A B-cell receptor is anchored to the plasma membrane by a transmembrane domain, whereas an antibody is secreted into the extracellular fluid. Within each immunoglobulin class, the constant regions have identical amino acid sequences. In contrast, the antigen-binding sites formed by the light- and heavy-chain variable regions have unique amino acid sequences and give each receptor or antibody its specificity for a particular antigen.

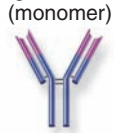
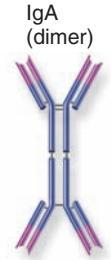
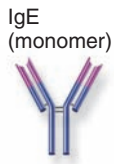


BIOLOGY PRINCIPLE Structure determines function. The amino acid sequences of the variable regions of different immunoglobulins impart highly specific three-dimensional structures. This structural distinctiveness, in turn, is what allows an immunoglobulin to specifically bind a particular antigen and not others.

described in Chapter 13, so the transmembrane domain is not present in the protein. For this reason, the B-cell receptor in a particular B cell and secreted antibodies from the resulting plasma cells recognize the exact same antigen.

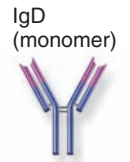


Immunoglobulin Classes and Structure Each immunoglobulin molecule is composed of four interlinked polypeptides: two long heavy chains and two short light chains (see Figure 53.7). A hinge region that provides the molecule with flexibility separates the light chains and upper parts of the heavy chains from the lower parts of the heavy chains. One portion of an immunoglobulin is called the **constant region**: The amino acid sequence of the constant region is identical for all immunoglobulins of a given class and is what distinguishes the classes from each other. The constant regions are important for the binding of antibodies to immune cells and to complement proteins, and thus contribute to the eventual destruction of antigen. A defining feature of immunoglobulins, however, is their **variable region**, which gets its name because its amino acid sequence varies among different B cells. The variable region is the site that specifically recognizes a particular antigen.



Mammals have five classes of immunoglobulins, designated IgM, IgG, IgA, IgE, and IgD. All vertebrates have IgM molecules. These pentamers (made of five Ig molecules connected by disulfide bonds and other linkages) are the first Ig class produced after antigen exposure, but their blood concentration declines afterward. Some vertebrates have only some of the other classes and also express unique immunoglobulins not found in mammals.

The most abundant immunoglobulins in mammals are IgM and IgG, the latter commonly called gamma globulin. Together these two immunoglobulin classes provide the bulk of specific immunity against bacteria and viruses in the extracellular fluid.



IgA immunoglobulins exist as dimers and are secreted as antibodies by plasma cells in the linings of the gastrointestinal, respiratory, and genitourinary tracts and in tear ducts and salivary glands. Because the antibodies are present in secretions, they act locally in the linings or on the surfaces of body structures. For example, IgA molecules secreted into saliva help keep animals' mouths relatively free of pathogens. IgA molecules are also secreted by the mammary glands of female mammals shortly after birth of their young and therefore are the major antibodies in milk.

IgE immunoglobulins are monomers that participate in defenses against multicellular eukaryotic parasites and also mediate allergic responses. Although present in blood at low concentrations, they also attach to mast cell membranes. When mast cell IgE molecules bind antigen, the mast cell secretes its

histamine into the extracellular fluid, causing vasodilation and contributing to the allergic response. In people who are particularly sensitive to allergens, this response is easily demonstrated by a pinprick injection of an antigen—such as one of the proteins associated with hay fever—into a small region under the skin, or by applying the antigen topically for an extended period of time (called patch testing). The resultant local inflammation and reddening of the skin are mediated in large part by IgE molecules.

The functions of IgD are still unclear. However, IgD molecules are present both in blood and on the surface of B cells, and they are known to bind antigen on B cells, thus possibly contributing to B-cell activation.

The amino acid sequences of the variable regions vary widely from immunoglobulin to immunoglobulin in a given Ig class. The enormous number of variable sequences results in countless unique structures within each class of immunoglobulins. Thus, each of the five classes of immunoglobulins contains up to millions of unique molecules each capable of combining with only one specific antigen or, in some cases, with several antigens with very similar structures. How does an animal's body make all of these different immunoglobulins? The genetic explanation for this remarkable array was first identified in the 1970s, as we see next.

Genomes & Proteomes Connection

Recombination and Hypermutation Produce an Enormous Number of Different Immunoglobulin Proteins

The human genome contains about 200 genes that encode immunoglobulins. This raises an intriguing question: How can an animal such as a human produce millions of different immunoglobulin proteins if there are only 200 immunoglobulin genes? The answer is that the 200 genes undergo a unique process involving gene rearrangements. This phenomenon was discovered by Japanese scientist Susumu Tonegawa and others in the 1970s; Tonegawa was recognized for this achievement in 1987 with the Nobel Prize in Physiology or Medicine.

Along the length of a typical human immunoglobulin gene are numerous gene segments that code for a piece of the final immunoglobulin protein (**Figure 53.8**). In light chains, these gene segments are of three types: variable, joining, and constant. A total of 40 variable (V) segments code for the antigen-binding site. These are next to four joining (J) segments and a single constant (C) segment. Each segment along the length of the gene is associated with recognition sequences that bind two enzymes, called RAG-1 and RAG-2 (for recombination-activating gene). These enzymes, which are expressed only in developing lymphocytes, cut randomly at the end of a V segment and at the beginning of a J segment. The intervening region is lost, and then other enzymes paste the V and J segments together. The result is a new, permanent immunoglobulin gene for that B cell. Because any V segment can be linked with any J segment, the number of possible

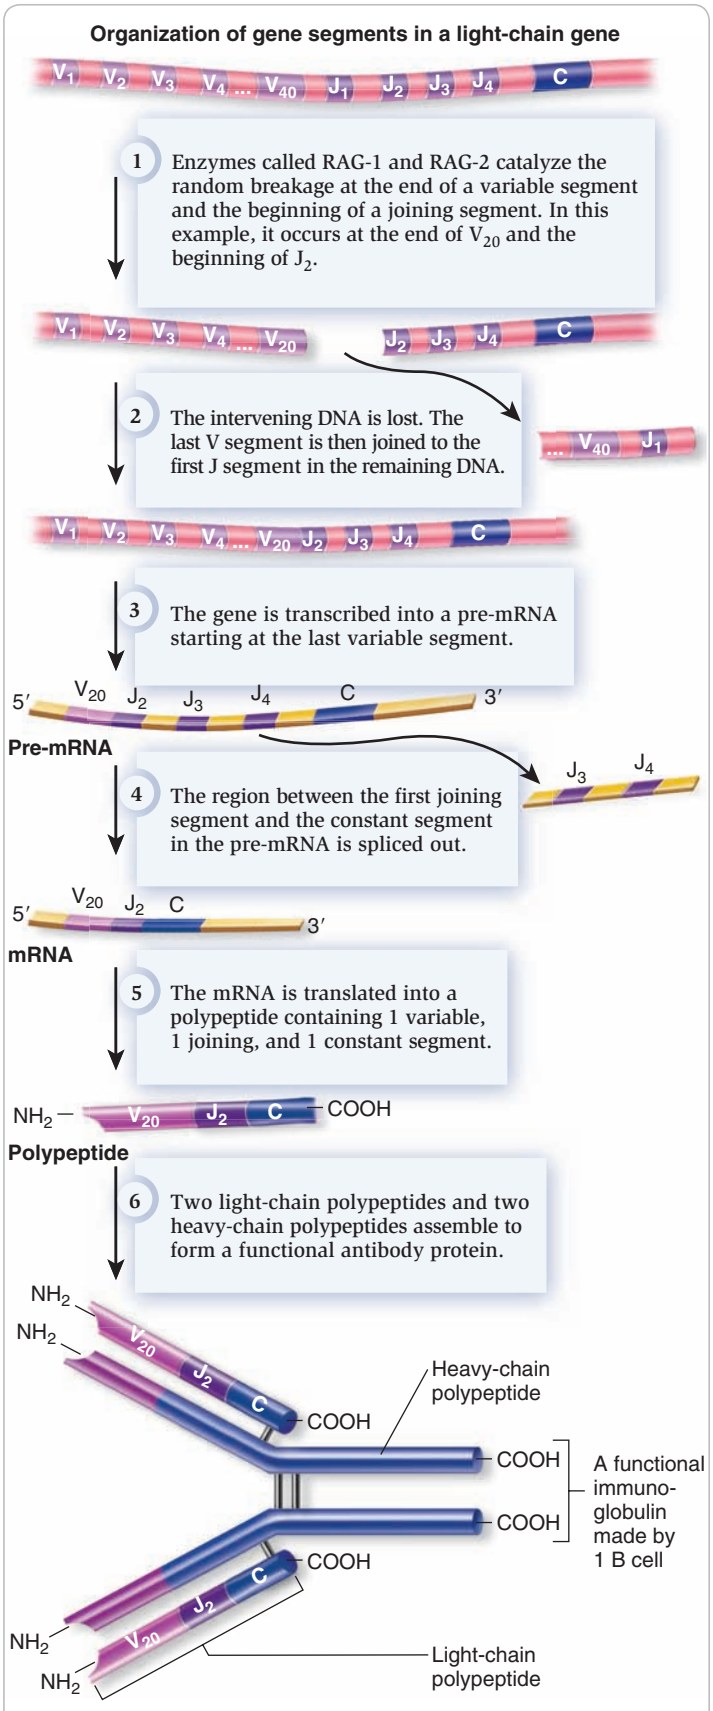


Figure 53.8 The mechanism of immunoglobulin diversity. Although this figure shows events for a light-chain gene, events similar to those depicted here also occur in the production of the heavy chains, creating even more structural diversity.

final genes among different B cells is huge. Additionally, heavy chains also have multiple segments that are spliced together in this way, except that they have yet another segment (designated D) and more V segments, yielding an even greater number of possible heavy-chain genes. Finally, any heavy chain can combine with any light chain in a given B cell, which results in an immense number of possible immunoglobulins.

The number of possible immunoglobulins is increased even further in two more important ways within B cells. First, the joining process of the V, D, and J segments is not always precise. Occasionally, a few nucleotides may be lost at a joining end, resulting in a different amino acid sequence in the immunoglobulin protein. Second, in a subset of activated B cells, the DNA coding for the variable antigen-binding sites of immunoglobulins undergoes a unique process known as hypermutation, which primarily produces point mutations. The result is a hypervariable region of the light and heavy chains of all immunoglobulins.

The three processes of gene recombination, imprecise joining of gene segments, and hypermutation cause each lymphocyte within an individual's body to produce a unique type of immunoglobulin. The immune system can produce an incredibly diverse array of immunoglobulins capable of recognizing many different antigens because an animal's body makes hundreds of millions of different lymphocytes. Nearly any foreign antigen that is taken into the body is recognized by some lymphocytes in this large population.

Activated B Cells Produce Plasma Cells That Secrete Antibodies

In stages 2 and 3 of the humoral immune response, B cells are activated and divide into plasma and memory cells. The plasma cells then secrete antibodies that bind the antigen that was detected (see Figure 53.6). Let's take a closer look at these processes.

Clonal Selection B cells are activated by a specific antigen, with the aid of a helper T cell (a process we will discuss later). When an antigen-stimulated lymphocyte divides and replicates itself, the progeny of this lymphocyte—all of which express the same receptor—are clones. The process by which these clones are formed is called **clonal selection** (**Figure 53.9**). This term emphasizes that lymphocyte proliferation is selected by exposure to an antigen.

Antibodies Facilitate the Destruction of Pathogens via Opsonization The antibodies secreted from the plasma cells circulate through the lymphatic system and the bloodstream. Eventually, the antibodies combine with the antigen that initiated the immune response. These antibodies then direct the attack against the pathogen to which they are now bound. Thus, immunoglobulins have two distinct roles in humoral immune responses. First, during antigen recognition, immunoglobulins (B-cell receptors) on the surface of B cells bind to antigen brought to them. Second, immunoglobulins (antibodies) secreted by the resulting plasma cells bind to pathogens bearing the same antigens, marking them as the targets to be attacked.

Instead of directly destroying the pathogens, antibodies bound to antigen on the pathogen surface inactivate the pathogens in various ways. Antibodies may physically link the pathogens to phagocytes (neutrophils and macrophages), complement proteins, or NK cells. This linkage—called **opsonization**—triggers the attack mechanism and ensures that only the pathogens, and not nearby body cells, are destroyed.

In a second mechanism, antibodies that recognize toxins produced by bacterial pathogens in the extracellular fluid bind to the toxins, thereby preventing them from harming susceptible body cells. The antibody-antigen complexes that are formed are then destroyed by phagocytes.

In a similar way, antibodies that recognize certain viral surface proteins bind to the viruses in the extracellular fluid, preventing them from attaching to the plasma membranes of potential host cells. As with bacterial toxins, the antibody-virus complexes that are formed are subsequently phagocytized.

In Cell-Mediated Immunity, T Cells Recognize Antigens Complexed with Self Proteins

In cell-mediated immunity, T cells recognize and are activated by antigen (see Figure 53.6). T-cell receptors for antigens have specific regions that differ from one T cell to another. As shown in **Figure 53.10**, they are composed of two polypeptides, each with a variable and a constant region, along with a transmembrane domain. The variable regions recognize an antigen. As in B-cell development, multiple DNA rearrangements occur during T-cell maturation, leading to millions of distinct types of T cells, each with a receptor of unique specificity. For T cells, this maturation occurs as they develop in the thymus.

A T-cell receptor cannot bind to an antigen unless the antigen is already complexed with a protein that is found on the surface of another cell, such as a macrophage. Such proteins are encoded by a gene family known as the **major histocompatibility complex (MHC)**, and thus the proteins are called MHC proteins. In humans, two major classes of MHC proteins are known. Class I MHC proteins are found on the surface of all human body cells except erythrocytes (that is, all nucleated cells). Class II MHC proteins are found primarily on the surface of macrophages, B cells, and dendritic cells.

The two different types of T cells have different MHC requirements. Cytotoxic T cells require antigen to be associated with class I MHC proteins, whereas helper T cells require an association with class II MHC proteins. One reason for this difference stems from the presence of different proteins on their surfaces; helper T cells can be identified by a unique membrane protein called CD4, and cytotoxic T cells are identified by a membrane protein known as CD8. CD4 binds to class II MHC proteins, whereas CD8 binds to class I MHC proteins.

Antigen Presentation to Helper T Cells How do antigens, which are foreign, end up complexed with MHC proteins on the surface of the body's own cells? The answer involves the mechanism known as antigen presentation. As previously noted, helper T cells can bind antigen only when the antigen appears on the plasma membrane of a host cell complexed with the cell's class II MHC proteins. Cells bearing these complexes, therefore, function as **antigen-presenting cells (APCs)**. Because only macrophages, B cells, and dendritic cells express class II MHC proteins, only these cells can function as APCs for helper T cells.

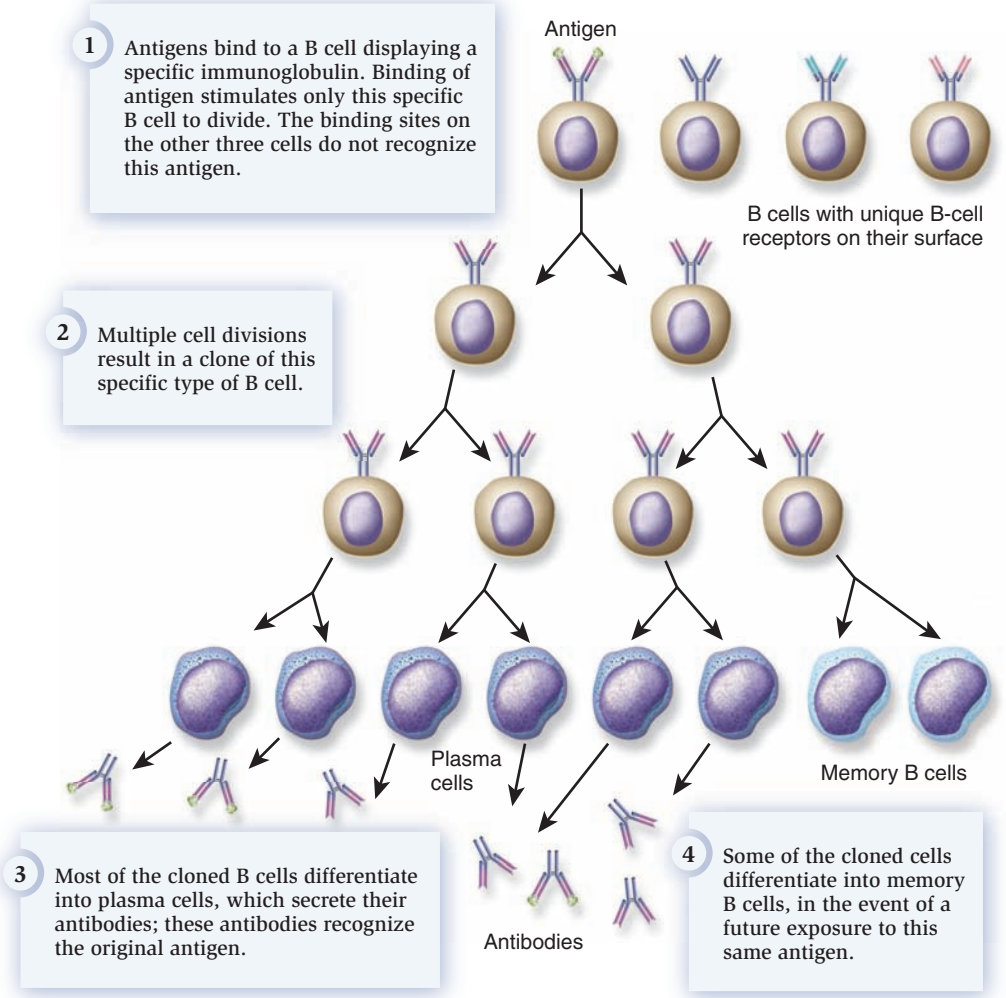

Figure 53.9 **Clonal selection.** In this example, a B cell with a specific immunoglobulin on its surface recognizes an antigen and is stimulated to divide into a clone of identical cells.

Let's consider the function of macrophages as APCs for helper T cells (**Figure 53.11**). After a microbe or noncellular antigen has been phagocytized by a macrophage in an innate immune response, antigens, such as proteins, are partially broken down into smaller polypeptide fragments by the macrophage's proteolytic enzymes within endosomes. The resulting digested fragments then bind in the endosome to class II MHC proteins synthesized by the macrophage. Each fragment-MHC complex is then transported to the cell surface, where it is displayed on the plasma membrane. A specific helper T-cell receptor then binds this entire complex on the cell surface of the macrophage. The CD4 protein helps link the two cells. What is complexed to MHC proteins and presented to the helper T cells is not the intact antigen but instead a polypeptide fragment of the antigen—called an antigenic determinant, or **epitope**. Even so, it is customary to call this antigen presentation rather than epitope presentation.

B cells process antigen and present it to helper T cells in essentially the same way as macrophages do. The ability of B cells to present antigen to helper T cells is a second function of B cells in response to antigenic stimulation, in addition to their differentiation into antibody-secreting plasma cells.

The binding between the helper T-cell receptor and antigen bound to class II MHC proteins on an APC is the essential antigen-specific event in helper T-cell activation. However, by itself, this specific binding does not result in T-cell activation. In addition, interactions occur between nonantigenic proteins on the surfaces of the attached helper T cell and the APC. These interactions provide a necessary costimulus for T-cell activation (see Figure 53.11).

Finally, the antigen-dependent binding of the APC to the T cell plus the costimulus induces the APC to secrete large amounts of two cytokines—interleukin 1 (IL-1) and tumor necrosis factor (TNF). These molecules also stimulate the attached helper T cell.

Thus, the APC participates in the activation of a helper T cell in three ways: (1) antigen presentation, (2) providing a costimulus, and (3) secretion of cytokines. Activated helper T cells then secrete additional cytokines of their own that stimulate B cells and cytotoxic T cells.

Helper T Cells and B-Cell Activation Now we can go back to B cells and understand how they are activated by the actions of helper T cells. This process begins when a helper T cell specific for a particular antigen binds to a complex of that antigen and a class II MHC

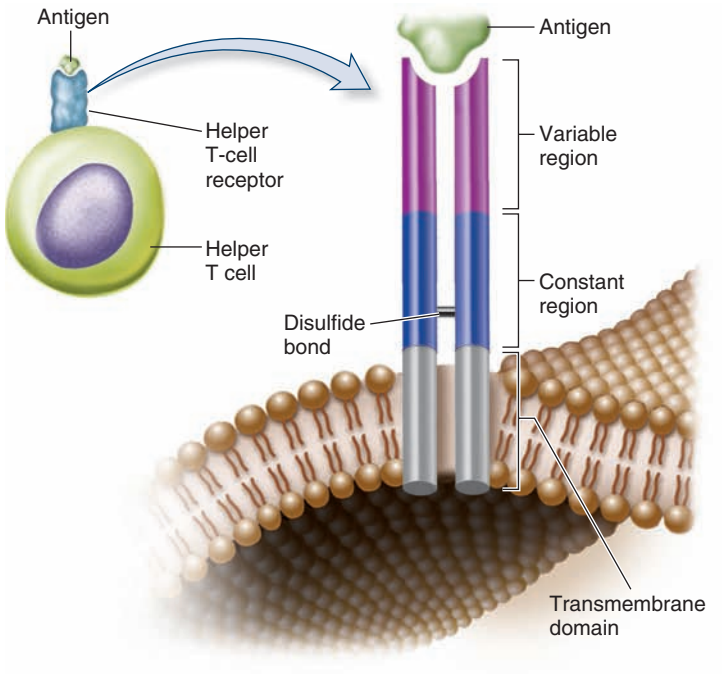

Figure 53.10 Structure of a T-cell receptor in the plasma membrane.

Concept Check: *What are some structural similarities between T-cell receptors and B-cell receptors?*

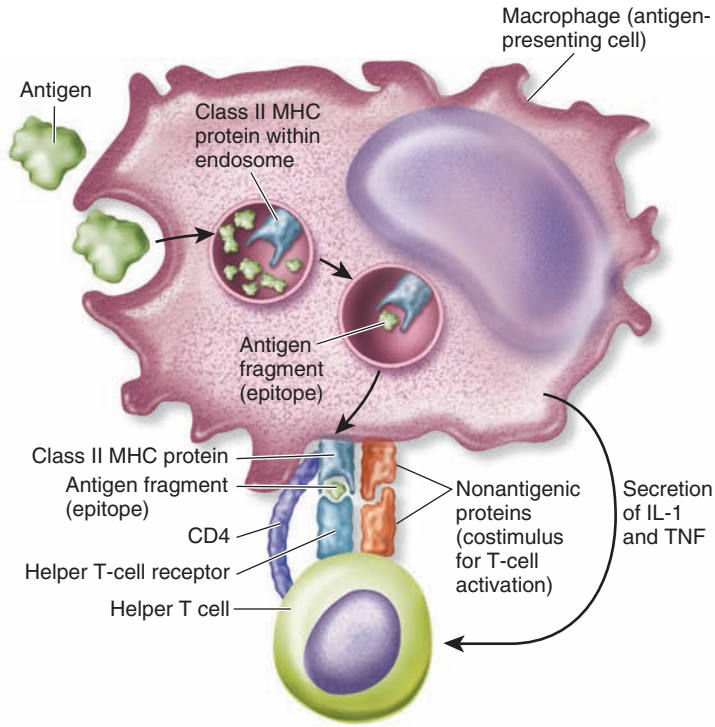

Figure 53.11 Antigen presentation and helper T-cell activation. In the initial events in helper T-cell activation, antigen fragments are complexed with a class II MHC protein within an antigen-presenting cell such as a macrophage. The complex is then displayed on the cell surface and binds to a helper T-cell receptor. Also required for T-cell activation are the binding of nonantigenic proteins between the APC and the attached helper T cell, and the actions of the cytokines interleukin 1 (IL-1) and tumor necrosis factor (TNF).

protein on an APC, activating the helper T cell. Along with other signals, this binding induces the activated helper T cell to divide. Some of the resulting activated helper T cells then bind to B cells that display the same antigen on their surfaces. This binding, along with additional cytokines, stimulates the B cell to go through the process of clonal selection. Thus, helper T cells are so named because their secretions help activate B cells that have bound antigen, in addition to their participation in activation of cytotoxic T cells and antigen presentation.

Antigen Presentation to Cytotoxic T Cells Unlike helper T cells, cytotoxic T cells require class I MHC proteins for activation. This distinction helps explain the major function of cytotoxic T cells—destruction of any of the body's own altered cells that have become cancerous or infected with viruses. The crucial point is that the antigens that complex with class I MHC proteins typically arise within body cells and are thus endogenous antigens.

How do such antigens arise? In viral infections, once a virus has entered a host cell, the expression of viral genes results in the synthesis of viral proteins, which are foreign to the cell. In cancerous cells, one or more of the cell's genes have become altered by chemicals, radiation, or other factors. The altered genes, called oncogenes, code for proteins that are not normally found in the body. Such abnormal proteins act as antigens.

In both virus-infected and cancerous cells, cytosolic enzymes hydrolyze some of the endogenously produced antigenic proteins into polypeptide fragments, which are transported into the endoplasmic reticulum. There the fragments are complexed with the host cell's class I MHC proteins and then shuttled by the secretory pathway to the plasma membrane, where a cytotoxic T cell specific for the antigen/MHC protein complex can bind to it. Once binding occurs, cytotoxic T cells release chemicals that kill the infected or cancerous cell, as discussed next.

Activated Cytotoxic T Cells Kill Infected or Cancerous Cells

The previous sections described how immune responses provide long-term defenses against bacteria, viruses, and individual foreign molecules that enter the body's extracellular fluid. We now examine how the body's own cells that have become infected by viruses or transformed into cancerous cells are destroyed by cell-mediated immune responses (see Figure 53.6).

What is the value of destroying virus-infected host cells? First, and most importantly, such destruction prevents cells from making more viruses. Second, for cells that already are making mature viruses, it results in the release of the viruses into the extracellular fluid, where they can be neutralized by circulating antibody.

Role of Cytotoxic T Cells A typical cytotoxic T-cell response triggered by viral infection of a vertebrate's body cells is summarized in **Figure 53.12**. The response triggered by a cancerous cell would be similar. A virus-infected cell produces foreign proteins, viral antigens

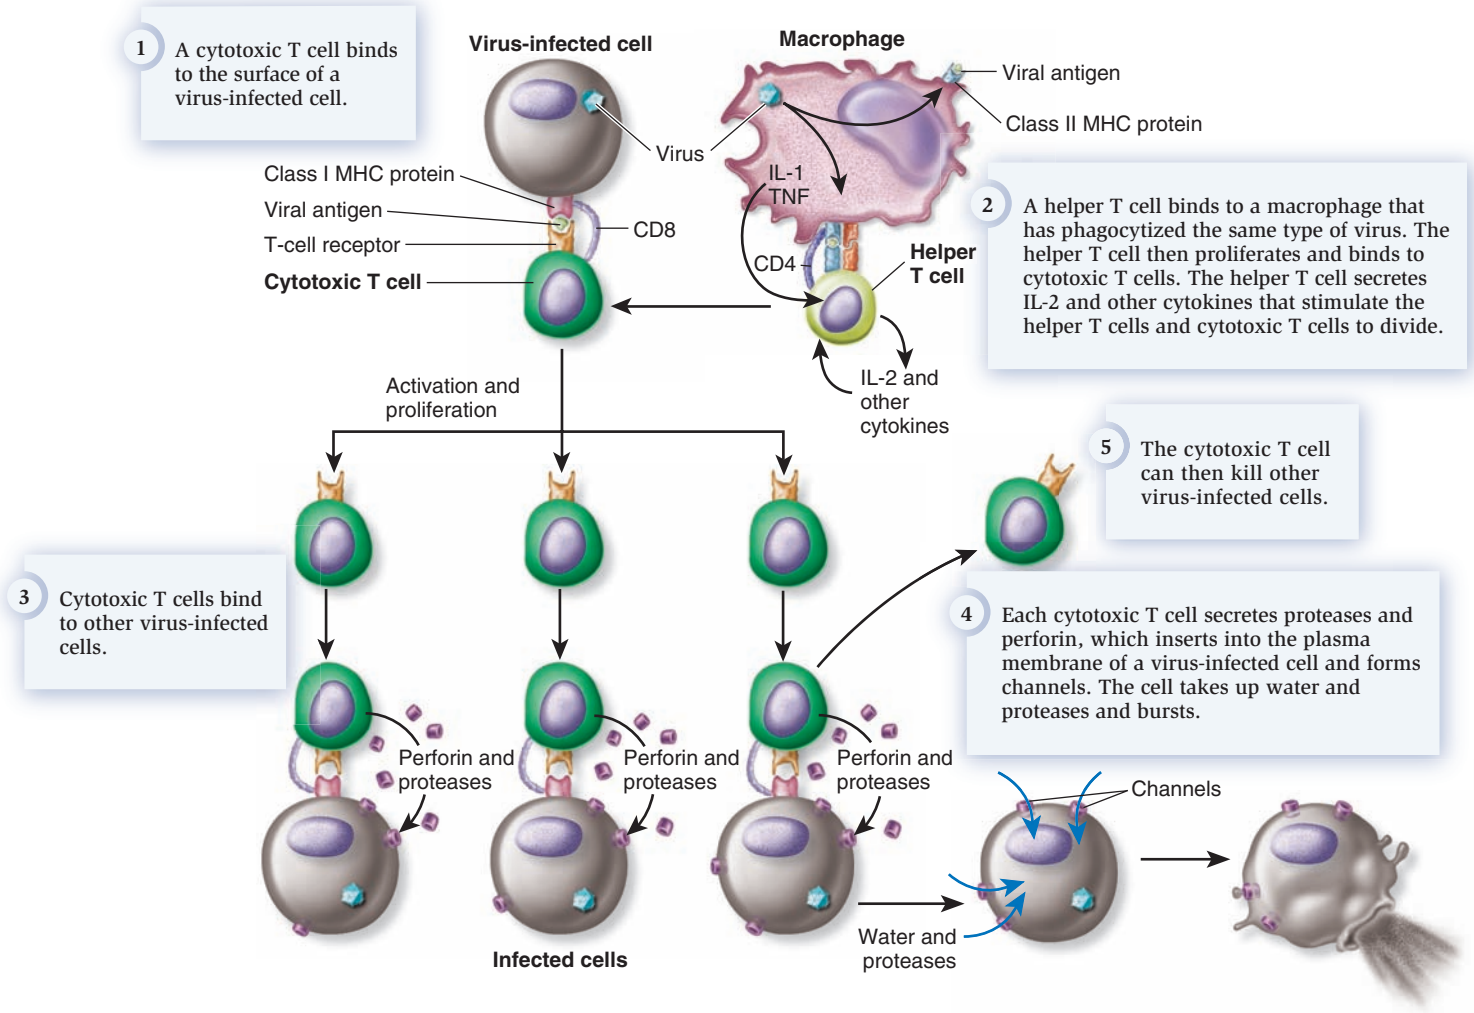

Figure 53.12 Summary of events in the killing of virus-infected cells by cytotoxic T cells. The sequence is similar for cancerous cells attacked by cytotoxic T cells.

that are processed and presented on the plasma membrane of the cell complexed with class I MHC proteins. Cytotoxic T cells specific for the particular antigen bind to the complex (Figure 53.12, step 1). As with B cells, binding to antigen alone does not cause activation of the cytotoxic T cell. Cytokines from nearby activated helper T cells are also required.

Macrophages phagocytize extracellular viruses (or, in the case of cancer, antigens released from the surface of cancerous cells) and then process and present antigen, in association with class II MHC proteins, to the helper T cells (step 2). In addition, the macrophages provide a costimulus and also secrete IL-1 and TNF. The activated helper T cell releases IL-2 and other cytokines, which stimulate proliferation of the helper T cell.

IL-2 and other cytokines also act on the cytotoxic T cell bound to the surface of the virus-infected or cancerous cell, stimulating this attack cell to proliferate. Why is proliferation important if a cytotoxic T cell has already located and bound to its target? The answer is that there is rarely just one virus-infected or cancerous cell. By expanding the population of cytotoxic T cells capable of scanning the entire body and recognizing the particular antigen, the likelihood is greater that the other virus-infected or cancerous cells will be encountered by an appropriate cytotoxic T cell.

The cytotoxic T cells specific for that virus then find and bind to other virus-infected cells (step 3). Each cytotoxic T cell releases the contents of its secretory vesicles directly into the extracellular space between itself and the target cell to which it is bound (thereby ensuring that other nearby host cells will not be killed). These vesicles contain proteases and a protein called perforin, which is similar in structure to the proteins of the complement system's membrane attack complex. Perforin is believed to insert into the target cell's membrane and form channels (perforations) through the membrane (step 4). In this manner, the proteases secreted by a cytotoxic T cell enter the attacked cell, and this is believed to be what triggers apoptosis. The cell also takes in water through the pores, which causes it to burst. The cytotoxic T cell is not harmed by this process and can then continue to kill other virus-infected cells (step 5). Target cell killing by activated cytotoxic T cells occurs by several mechanisms, but this is one of the most important.

Viruses can be eliminated from an animal's body in two ways: through the humoral actions of antibodies in body fluids and through

the cell-mediated killing of virus-infected cells by cytotoxic T cells. Although cytotoxic T cells have an important role in the attack against such cells, they are not the only mechanisms. NK cells also destroy virus-infected and cancerous cells by secreting toxic chemicals. As mentioned earlier, NK cells can recognize general features on the surface of such cells and participate in innate immunity. In addition, in a cell-mediated immune response, NK cells can be linked to such target cells by antibodies and then can destroy them by release of toxic molecules.

Summary: Example of an Acquired Immune Response

Let's bring together our discussion of the humoral immune system by looking in detail at one example. One classic humoral immune response is that which results in the destruction of bacteria. The sequence of events, which is quite similar to the humoral response to a virus in the extracellular fluid, is summarized in **Figure 53.13**. For this example, we consider the response in mammals, in which lymph nodes are present. Many features of the response, however, are similar in other vertebrates.

This process starts the same way as for innate responses, with the bacteria penetrating one of the body's linings through an injury and entering the interstitial fluid (Figure 53.13, step 1). The bacteria then move with lymph into the lymphatic system and are carried to lymph nodes (step 2). Within the lymph node, a macrophage and a B cell recognize the bacteria as foreign and bind to them.

As we have discussed, the process of B-cell activation usually requires the activation of helper T cells. The helper T cell binds to a complex of processed antigen and class II MHC protein on an APC (step 3). In this case, the APC is a macrophage that has phagocytized the bacterium, hydrolyzed its proteins into polypeptide fragments, complexed the fragments with class II MHC proteins, and displayed the complexes on its surface. Once a helper T cell specific for the complex binds to it, the helper T cell becomes activated. The macrophage helps this process in two other ways: It provides a costimulus, and it secretes the cytokines IL-1 and TNF.

IL-1 and TNF stimulate the helper T cell to secrete another cytokine, IL-2. IL-2 stimulates the activated helper T cell to divide, which leads eventually to the formation of a clone of activated helper T cells (step 4). The activated helper T cells bind to B cells that display the antigen, and also secrete IL-2 and other cytokines (step 5). Certain of these cytokines provide the additional signals that are usually required to activate nearby antigen-bound B cells to proliferate (step 6). These cells differentiate into memory cells, which help ward off possible future attacks by the same antigen, and plasma cells, which then secrete specific antibodies (step 7). The antibodies enter the bloodstream and bind to bacterial cells, which are then destroyed (step 8).

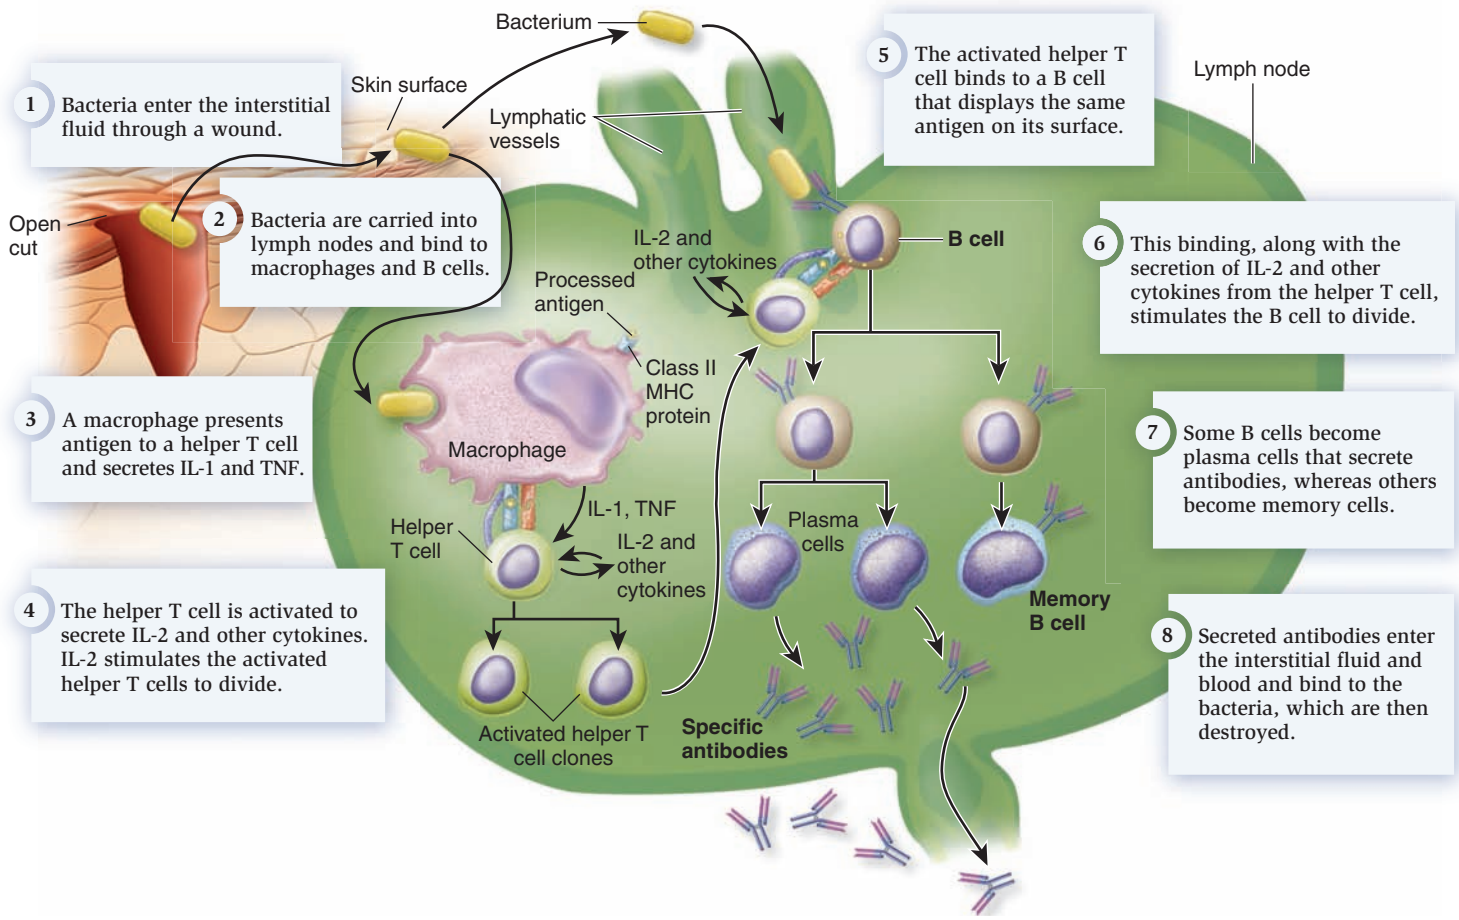

Figure 53.13 **Summary of events in a typical humoral immune response.** Most of the events depicted occur within a lymph node.

B Cells and T Cells That Recognize Self Molecules Must Be Killed or Inhibited

As we have seen, the lymphocytes responsible for the specific immune response in vertebrates are very capable killers of pathogens—so capable, in fact, that it raises a question: Why don't these cells attack and kill normal self cells? In other words, how does the body distinguish between self and nonself components and develop what is called **immune tolerance**, or tolerance of its own molecules?

Recall that the huge diversity of lymphocyte receptors is ultimately the result of multiple random DNA cutting and recombination processes. It is virtually certain, therefore, that every animal possessing specific immune defenses will have clones of lymphocytes with receptors that can bind to that individual's own proteins. The continued existence and functioning of such lymphocytes would be disastrous, because such binding would launch an immune attack against all body cells expressing these proteins.

At least two mechanisms explain why individuals normally lack active lymphocytes that respond to self components. First, during early development in vertebrates, T cells are exposed to a wide mix of self proteins in the thymus. Those T cells with receptors capable of binding self proteins are destroyed by apoptosis in a process termed **clonal deletion**. The second process, termed **clonal inactivation**, occurs outside the thymus and causes potentially self-reacting T cells to become nonresponsive. B cells undergo similar processes. The mechanisms by which these two events occur are still under investigation.

Occasionally, however, these mechanisms fail, and an animal's immune cells attack the body's own cells. When this happens, it produces autoimmune disease. **Autoimmune diseases** are conditions in which the body's normal state of immune tolerance somehow breaks down, with the result that both humoral and cell-mediated attacks are directed against the body's own cells and tissues. A growing number of human diseases are being recognized as autoimmune in origin. Examples are multiple sclerosis, in which myelin around neurons is attacked; myasthenia gravis, in which the receptors for acetylcholine on skeletal muscle cells are the targets; rheumatoid arthritis, in which joints are damaged; systemic lupus erythematosus, in which numerous organs are damaged; and type 1 diabetes mellitus, in which the insulin-producing cells of the pancreas are destroyed. Treatments for autoimmune disease range from treating the symptoms (for example, administering insulin to individuals with diabetes) to suppressing the immune system with drugs.

Immunological Memory Is an Important Feature of Acquired Immunity

As we have learned, the acquired immune response to a given antigen depends on whether or not the body has previously been exposed to that antigen. Consider, for example, the humoral immune response. In mammals, antibody production in response to the first contact with an antigen occurs slowly, over a few weeks. This response to an initial antigen exposure is termed a **primary immune response** (**Figure 53.14**). Any subsequent infection by the same pathogen elicits an immediate and heightened production of additional specific antibodies against that particular antigen, a reaction termed a **secondary immune response**.

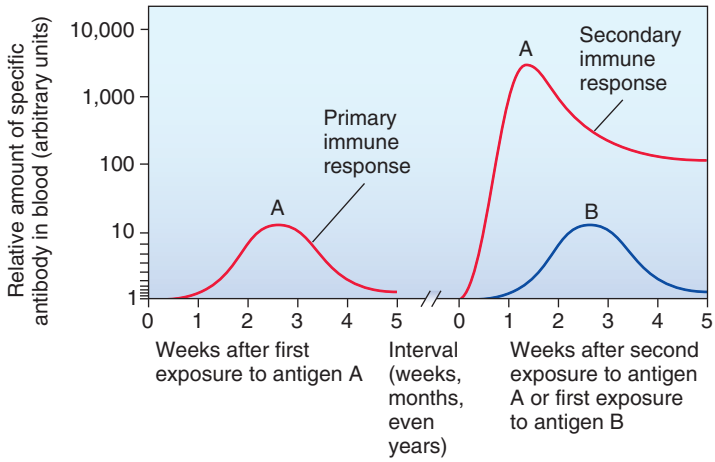

Figure 53.14 Primary and secondary immune responses. In a primary response, as shown on the left of this graph, an initial exposure to an antigen produces modest levels of specific antibody over a period of weeks. In a secondary response, subsequent exposure to the same antigen results in greater antibody production that occurs more rapidly and lasts longer than a primary response. (Note that the scale on the vertical axis of the graph is logarithmic.) The secondary response is specific for that antigen. Exposure at that time to another antigen for the first time produces the usual primary response.

Concept Check: What is the advantage of a secondary immune response?

In the case of humoral immunity, this secondary response occurs more quickly, is stronger, and lasts longer because memory B cells that were produced in response to the initial antigen exposure are quickly stimulated to multiply and differentiate into thousands of plasma cells. These cells then produce large amounts of specific antibodies. The immune system's ability to produce this secondary response is called **immunological memory**.

Immunological memory explains why humans and other animals are able to fight off many illnesses, such as many common childhood diseases, after having been previously exposed to them. The acquired response to exposure to any type of antigen is known as **active immunity**. Active immunity not only results from natural exposure to antigens, it is also the basis for the artificial exposures to antigen that occur in vaccinations. In **vaccinations**, small quantities of living, dead, or altered microbes, small quantities of toxins, or harmless antigenic molecules derived from a microorganism or its toxin are injected into the body, resulting in a primary immune response, including the production of memory cells. Subsequent natural exposure to the immunizing antigen results in a rapid, effective response that can prevent or reduce the severity of disease.

In contrast to active immunity, another type of acquired immunity, called **passive immunity**, confers protection against disease through the direct transfer of antibodies from one individual to another. Passive immunity can occur naturally, as when IgG molecules cross the mammalian placenta to protect a fetus from various pathogens, or when a newborn mammal receives antibodies from breast milk. It can also occur artificially, as when a person is given an injection of IgG molecules shortly after exposure to hepatitis

viruses. Recent advances in the creation of highly specific and pure antibodies, called **monoclonal antibodies** because they are derived from a single clone of cells prepared in a laboratory, have paved the way for the use of passive immunity to combat certain types of cancer. Because antibodies are proteins with a limited life span, the protection afforded by the transfer of antibodies in passive immunity is relatively short-lived, usually lasting only a few weeks or months.

BIO TIPS **THE QUESTION** *What might be the consequences if an animal was unable to form memory cells after being vaccinated against a particular pathogen or antigen?*

TOPIC ***What topic in biology does this question address?*** The topic is memory cells. Specifically, you are asked to predict the outcome for an animal that was unable to form memory cells following a vaccination.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you know that an animal has received a vaccination to help protect it from some disease caused by a particular pathogen or antigen. From your understanding of the topic, you may recall that vaccinations rely on the processes of active immunity. You also have learned from Figure 53.14 that acquired immunity produces a small primary response and a larger secondary response on subsequent exposure to the same antigen.

PROBLEM-SOLVING STRATEGY ***Predict the outcome.*** First, consider the function of memory cells: How do they contribute to the secondary immune response? Next, predict what might happen without that contribution.

ANSWER *Artificial exposure to small quantities of an antigen (vaccination) results in a small primary immune response, but also causes the differentiation of activated T and B cells into memory cells. These cells are activated by subsequent (natural) exposure to the same antigen, resulting in a large secondary immune response. Without the production of memory cells, the secondary immune response would be greatly diminished, resembling the blue curve labeled B on the right side in Figure 53.14.*

53.4 Impact on Public Health

Learning Outcomes:

1. **SciSKILLS** » Predict the influence of lifestyle on immunity.
2. Explain the role of the immune system in organ transplant rejection and allergic reactions.
3. Describe the effects of HIV on a human immune system, and list current methods of treating HIV infection.

In this section, we will consider a few ways in which the functioning of the immune system can be affected by lifestyle, medical interventions, allergies, and destruction of immune cells. Collectively, the effects of disorders of the immune system have an almost immeasurable impact on public health in terms of worker productivity, healthcare resources, and the economy.

Lifestyle Has an Important Influence on Immunity

Protein-calorie malnutrition is the single greatest contributor to decreased resistance to infection worldwide. When inadequate amino acids are available to synthesize essential proteins, immune function is impaired. Deficits of certain nonprotein nutrients can also lower resistance to infection.

Both stress and state of mind can affect resistance to infection and to cancer. The immune system can alter neural and endocrine function, and, in turn, neural and endocrine activity modifies immune function. For example, lymphoid tissue receives input from nerves, and immune cells have receptors for certain hormones. Conversely, immune cells release cytokines that have important effects on the brain and endocrine system. Moreover, lymphocytes secrete several hormones that are also produced by endocrine glands. The multiple mind-body interactions that affect disease resistance are the subject of a field called psychoneuroimmunology.

Of the hormones associated with stress, the adrenal hormone cortisol has received the most attention due to its powerful suppressive activity on inflammation and acquired immunity. Among other things, cortisol inhibits production of inflammatory mediators, reduces capillary permeability in injured areas, and suppresses the growth and activity of certain types of leukocytes. In this way, it acts as a sort of brake on the immune system. During chronic stress or when cortisol is used to treat certain illnesses for long periods of time, it may cause immunosuppression. This is a key link between stress and health. Chronic stress may lead to a chronically increased concentration of cortisol in the blood that, by suppressing the body's immune responses, lowers resistance to infection.

Another feature of a person's lifestyle that appears to affect immune function is exercise. The influence of physical exercise on the body's resistance to infection and cancer has been debated for decades. Evidence now indicates that the intensity, duration, regularity, and psychological stress of the exercise all have important influences, both positive and negative, on a variety of immune functions, such as the numbers of circulating NK cells. Although evidence suggests that too much intense exercise can reduce immunity, most experts currently believe that moderate exercise and physical conditioning have net beneficial effects on the immune system and on disease resistance. Recent studies suggest that exercise may be particularly beneficial in helping to ward off the onset of breast cancer, one of the most common types of cancer in women.

Organ Transplants Are Medical Procedures That Can Cause Serious Immune Reactions

Organ transplants have saved numerous lives. However, they carry the possibility of provoking immune reactions that can threaten the life of the recipient. Since the mid-20th century, organ transplants from a healthy or recently deceased donor to a recipient have become widespread. The United Network for Organ Sharing reports that approximately 28,500 organs are transplanted in the U.S. each year, with kidney (17,000), liver (6,000), heart (2,000), and lung (1,800)

accounting for most of the transplants. The major obstacle to successful transplantation of tissues and organs is a reaction called graft rejection, in which the immune system recognizes the transplant (also called a graft) as foreign and attacks it as it would any other foreign cells. Although B cells and macrophages play some role in graft rejection, cytotoxic T cells and helper T cells are mainly responsible. To minimize this possibility, transplant patients are given drugs that suppress immune function, a procedure that is associated with some risk.

Except for grafts from identical twins, the class I MHC proteins on graft cells differ from those on the recipient's cells, as do the class II MHC proteins present on macrophages in the graft cells. Consequently, the recipient's T cells recognize the MHC proteins in the graft as foreign, and cytotoxic T cells (with the aid of helper T cells) destroy the graft cells.

Allergies Affect the Quality of Life of Millions of People

An **allergy** (also known as hypersensitivity) is a condition in which immune responses to environmental antigens cause inflammation and damage to body cells. Antigens that induce allergic reactions are called allergens. Common examples of allergens include ragweed pollen and animal dander. Most allergens themselves are relatively or completely harmless. It is the immune responses to them that cause the damage. In essence, then, allergy is immunity gone awry, for the response is of inappropriate strength and duration for the stimulus. In the U.S. alone, as many as 40 million people (about 13% of the population) suffer from allergies.

For any allergy to develop, a genetically predisposed person must first be exposed to the allergen—a process called sensitization. Subsequent exposures elicit the damaging immune responses we recognize as an allergy. Hypersensitivities can be broadly classified according to the speed of the response. Allergies that take up to several days to develop are considered delayed hypersensitivities. The skin rash that appears after contact with poison ivy is an example. More common are reactions considered immediate hypersensitivities, which can develop in minutes. These allergies are also called IgE-mediated hypersensitivities because they involve IgE antibodies.

In immediate hypersensitivity, sensitization to the allergen leads to the production of specific antibodies and a clone of memory B cells. In individuals who are genetically susceptible to allergies, antigens that elicit immediate hypersensitivity reactions stimulate the production of IgE antibodies. Upon their release from plasma cells, these IgE molecules circulate throughout the body and become attached to mast cells in connective tissue (**Figure 53.15**). When the same antigen enters the body at some future time and binds with IgE that is bound to mast cells, the mast cell is stimulated to secrete many inflammatory mediators, including histamine, that then initiate an inflammatory response.

The signs and symptoms of IgE-mediated hypersensitivity reflect both the effects of inflammatory mediators and the body site in which the binding of antigen to the IgE bound to a mast cell occurs. When, for example, a previously sensitized person inhales ragweed pollen, the antigen combines with the variable region of IgE, and the constant region of IgE binds to mast cells in the airways. The mast cells release their contents, which induce increased mucus secretion,

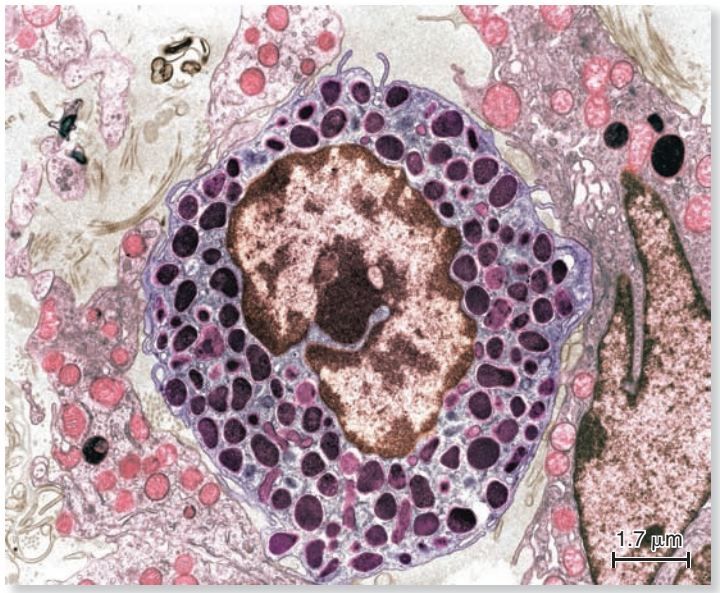

Figure 53.15 **Colorized electron micrograph of a mast cell, showing numerous secretory vesicles filled with histamine, a major mediator of allergic responses.**

increased blood flow, swelling of the epithelial lining, and contraction of the smooth muscle surrounding airways. These effects produce the congestion, runny nose, sneezing, and difficulty in breathing characteristic of hay fever. Antihistamines are drugs taken by people to block the action of histamine that is released during allergic responses. These drugs prevent histamine from binding to its receptor protein on its target cells, thereby preventing or relieving some of the symptoms of allergy.

Acquired Immunodeficiency Syndrome (AIDS) Results from HIV Infection

Acquired immunodeficiency syndrome (AIDS) is caused by the **human immunodeficiency virus (HIV)**, which incapacitates the immune response by preferentially infecting helper T cells. HIV is a retrovirus, a virus that contains RNA as its genetic material. Once inside a helper T cell, HIV uses the enzyme reverse transcriptase to transcribe its RNA into DNA, which is then integrated into the chromosomal DNA of the host's T cells (refer back to Figure 18.4b). Later, viral replication within the T cell results in the death of the cell.

HIV infects helper T cells because the CD4 protein in their plasma membranes acts as a binding protein for an HIV capsid protein. However, binding to CD4 is not sufficient to enable HIV to enter the helper T cell. Another T-cell surface protein, which normally acts as a receptor for certain cytokines, must serve as a coreceptor. Interestingly, individuals possessing a mutation in this cytokine receptor are highly resistant to HIV infection, so much research is now focused on the possible therapeutic use of chemicals that can bind to and block this coreceptor.

HIV not only directly kills helper T cells, but it also indirectly causes additional helper T-cell death by inducing cytotoxic T cells to kill HIV-infected helper T cells. In addition, by still poorly understood

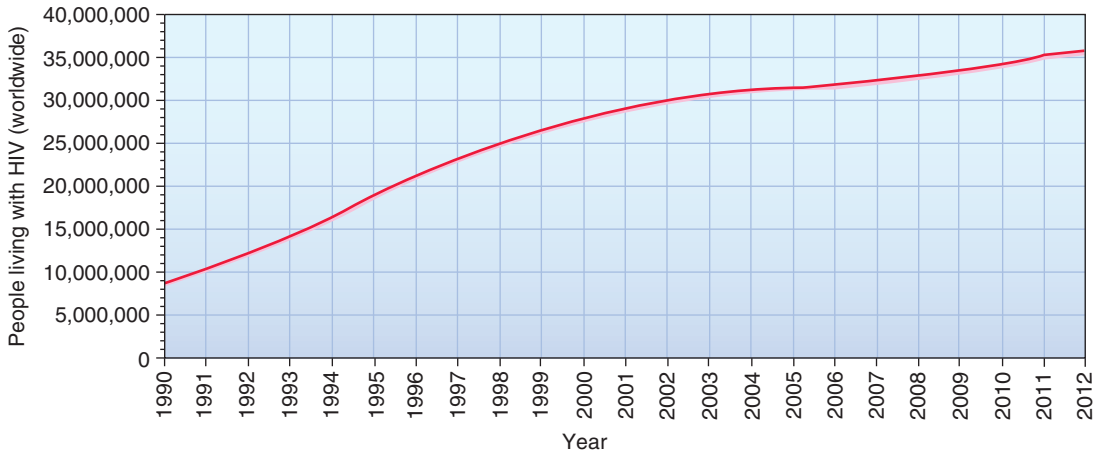

Figure 53.16 Worldwide incidence of people living with HIV/AIDS. Data are from the *2013 World AIDS Day Report* published by UNAIDS (The Joint United Nations Programme on HIV/AIDS).

mechanisms, HIV causes the death of many uninfected helper T cells by apoptosis. Without adequate numbers of helper T cells, neither B cells nor cytotoxic T cells can function normally. Both humoral and cell-mediated immunity are compromised. Many individuals with AIDS die from infections and cancers that ordinarily would be readily handled by a fully functional immune system.

AIDS, first described in 1981, has since reached pandemic proportions. About 35 million people worldwide are currently living with HIV infection, and an estimated 5,000–10,000 new infections occur in the world each day (**Figure 53.16**). The major routes of HIV transmission are (1) unprotected sexual intercourse with an infected partner; (2) transfer of contaminated blood or blood products between individuals, such as the sharing of needles among intravenous drug users, or, less commonly, as a result of a blood transfusion; (3) transfer from an infected mother to her child across the placenta or during delivery; or (4) transfer via breast milk during nursing.

The great majority of individuals now infected with HIV show no signs of AIDS. Their infections are diagnosed by the presence of anti-HIV antibodies or HIV RNA in the blood. However, if left untreated, HIV infection commonly develops into AIDS in about 10 years. During the first 5 years, killed helper T cells are typically replaced by new cells, so T-cell concentrations remain normal, and the individual remains asymptomatic. Over the next 5 years, T-cell concentrations begin to decline, until at some point, AIDS reveals itself in the form of opportunistic viral, bacterial, and fungal infections. Certain unusual cancers, such as Kaposi sarcoma, also occur with high frequency. In untreated individuals, death usually occurs within 2 years after the onset of AIDS symptoms.

Treatment for HIV-infected individuals has two components: one directed against the virus itself to delay progression of the disease, and one to prevent or treat the opportunistic infections and cancers that ultimately cause death. One current antiviral approach involves administering a combination of four drugs, known as HAART (highly active antiretroviral therapy). Two of the drugs inhibit the action of reverse transcriptase in converting viral RNA into DNA within the host cell, a third drug inhibits an HIV enzyme required for assembling new viruses, and a fourth class of drugs called fusion inhibitors prevents the virus from entering T cells. These treatments have been demonstrated to be effective in slowing the rate at which infection with HIV leads to AIDS. Unfortunately, however, the HAART regimen is associated with numerous side effects, including nausea, vomiting, diarrhea, metabolic disturbances resulting in part from insulin resistance, and liver damage. Much research is under way to find better treatments and ultimately to cure this disease. For example, drugs have been developed to block the integration of viral DNA (formed after viral RNA has been reverse transcribed into DNA) into host DNA or to increase production of new helper T cells. The possibility of using gene therapy to alter the structure of the coreceptor described earlier, thereby preventing the entry of HIV into helper T cells, is currently being investigated. Finally, the use of specific activators of a subtype of cannabinoid receptor has also shown promise as a means of inhibiting HIV replication in infected cells.

Summary of Key Concepts

- An animal's cells and organs that collectively contribute to its immunity constitute the animal's immune system.
- In innate immunity, the body's defenses are present at birth and act against foreign materials in much the same way regardless of the specific identity of the invading material. Acquired immunity develops only after the body is exposed to foreign substances and targets those foreign substances specifically.

53.1 Types of Pathogens

- Three major types of pathogens elicit an immune response: bacteria, viruses, and eukaryotic parasites.

53.2 Innate Immunity

- An important innate defense is composed of phagocytes—cells capable of phagocytosis. In vertebrates, most phagocytes belong to the blood cells called leukocytes. The leukocytes involved in innate immunity include neutrophils, eosinophils, monocytes, macrophages, basophils, and natural killer (NK) cells (Figure 53.1).
- Inflammation is an innate local response to infection or injury characterized by local redness, swelling, heat, and pain. The events of inflammation are induced and regulated by chemical mediators called cytokines (Figure 53.2).
- Antimicrobial proteins include interferons, which inhibit viral replication, and complement proteins, which kill microbes without

prior phagocytosis. Activation of the complement proteins results in the formation of a membrane attack complex (MAC), which creates water channels in the microbial plasma membrane and causes the microbe to swell and burst.

- Toll-like receptors (TLRs) are evolutionarily ancient proteins that recognize common molecular features of many pathogens (Figure 53.3).

53.3 Acquired Immunity

- A foreign molecule that the host does not recognize as self and that triggers an acquired immune response is an antigen.
- Leukocytes called lymphocytes are responsible for acquired immune responses. Most lymphocytes reside in a group of organs and tissues that constitute the lymphatic system (Figure 53.4).
- Lymphocytes responsible for acquired immunity are B and T cells. B cells differentiate into antibody-producing cells called plasma cells. T cells include cytotoxic T cells, which directly kill target cells, and helper T cells, which assist in the activation and function of B cells and cytotoxic T cells (Figure 53.5).
- Immunologists recognize two types of acquired immunity. In humoral immunity, plasma cells secrete antibodies that bind to antigens. In cell-mediated immunity, cytotoxic T cells directly attack and destroy abnormal body cells.
- Acquired immune responses occur in three stages: The first stage is recognition of antigen; the second is activation of lymphocytes; and the third is attack against antigen (Figure 53.6).
- In humoral immunity, B cells recognize antigens with B-cell receptors. When B cells are activated, they proliferate and differentiate into plasma cells, which secrete antibodies.
- Both B-cell receptors and antibodies belong to a family of proteins called immunoglobulins. Immunoglobulins contain a constant region, which is identical for all immunoglobulins of a given Ig class, and a variable region that serves as the antigen-binding site (Figures 53.7, 53.8).
- The process known as hypermutation, which primarily involves point mutations in the genes that encode immunoglobulins, is crucial in enabling plasma cells to produce a diverse array of antibodies capable of recognizing many different antigens.
- B cells that are activated by an antigen differentiate into plasma cells by a process called clonal selection. Antibodies combine with the antigen that activated the B cell and guide an attack that eliminates the antigen or the cells bearing it (Figure 53.9).
- Major histocompatibility complex (MHC) proteins are cellular "identity tags" that serve as genetic markers of self. Class I MHC proteins are found on the surface of all human body cells except erythrocytes. Class II MHC proteins are found only on the surface of macrophages, B cells, and dendritic cells.
- Antigen-presenting cells (APCs) are cells bearing fragments of antigen, called antigenic determinants, or epitopes, complexed with the cell's MHC proteins.
- The binding between a helper T-cell receptor and an antigen bound to class II MHC proteins on an APC is essential to helper T-cell activation. Once activated, helper T cells can help to activate both B cells and cytotoxic T cells (Figures 53.10, 53.11).
- Cell-mediated immune responses are mediated by cytotoxic T cells, which directly kill virus-infected and cancerous cells via secreted chemicals. Humoral immune responses are mediated by B cells and plasma cells. In both types of responses, helper T cells are required (Figures 53.12, 53.13).
- The process by which the body distinguishes between self and nonself components is called immune tolerance. Individuals normally lack active lymphocytes that respond to self components because of two mechanisms. T cells with receptors capable of binding self proteins are destroyed by apoptosis in a process termed clonal deletion. Clonal inactivation causes potentially self-reacting lymphocytes to become nonresponsive. When the body's immune cells attack the body's own cells, the result is autoimmune disease.
- Upon initial exposure to an antigen, the body produces a primary immune response. Any subsequent exposure to the same antigen elicits an immediate and heightened response termed a secondary immune response. The immune system's ability to produce this secondary response is called immunological memory (Figure 53.14).
- The acquired response to exposure to any type of antigen is known as active immunity. The artificial exposures to antigen that occur in vaccinations and immunizations also induce active immunity. In contrast, passive immunity confers protection against disease through the direct transfer of antibodies from one individual to another.

53.4 Impact on Public Health

- Factors that cause malfunction of the immune system include lifestyle; organ transplants; allergies; and acquired immune deficiency syndrome (AIDS), caused by the human immunodeficiency virus (HIV). AIDS reduces the body's immunity by killing helper T cells (Figures 53.15, 53.16).

Assess and Discuss

Test Yourself

1. Which of the following is *not* an example of a barrier defense in animals?
   a. skin
   b. secretions from skin glands
   c. exoskeleton
   d. mucus
   e. antibodies
2. The leukocytes that are found in mucosal surfaces and that play a role in defending the body against parasitic infections are
   a. neutrophils.
   b. eosinophils.
   c. basophils.
   d. monocytes.
   e. NK cells.
3. The vascular changes of inflammation
   a. lead to an increase in bacterial cells at the injury site.
   b. decrease the number of leukocytes at the injury site.
   c. allow plasma proteins to move easily from the bloodstream to the injury site.
   d. increase the number of antibodies at the injury site.
   e. activate lymphocytes.
4. Which statement about acquired immunity is correct?
   a. Acquired immunity only requires the presence of helper T cells to function properly.
   b. Acquired immunity does not require exposure to a foreign substance.
   c. Acquired immunity is triggered by contact with a particular antigen.

d. Acquired immunity includes inflammation.
e. All of the above are correct.

5. Memory B cells are
   a. cloned lymphocytes that are active in subsequent infections.
   b. cloned lymphocytes that are active during a primary infection.
   c. NK cells that recognize cancer cells and destroy them.
   d. cells that produce antibodies.
   e. macrophages that have recognized self antigens.
6. Which of the following are phagocytes?
   a. mast cells
   b. all lymphocytes
   c. all leukocytes
   d. plasma cells
   e. dendritic cells
7. The region of an antibody that is the antigen binding site is the
   a. constant region.
   b. variable region.
   c. heavy chain.
   d. light chain.
   e. hinge region.
8. A major difference between the activation of B cells and that of cytotoxic T cells is that
   a. cytotoxic T cells must interact with antigens bound to plasma membranes.
   b. B cells interact only with free antigens.
   c. B cells are not regulated by helper T cells.
   d. cytotoxic T cells produce antibodies.
   e. only cytotoxic T cells express immunoglobulins on their membranes.
9. Cells that process foreign proteins and complex them with their MHC proteins are called
   a. cytotoxic T cells.
   b. plasma cells.
   c. NK cells.
   d. antigen presenting cells.
   e. helper T cells.
10. HIV causes immune deficiency because the virus
    a. destroys all the cytotoxic T cells.
    b. preferentially destroys helper T cells that regulate the immune system.
    c. directly inactivates plasma cells.
    d. causes mutations that lead to autoimmune diseases.
    e. does all of the above.

Conceptual Questions

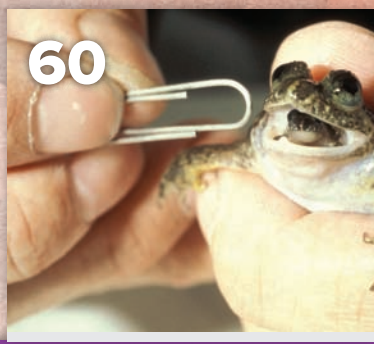
1. Distinguish between innate and acquired immunity.
2. Describe the basic structure of an immunoglobulin, and explain how the structure relates to the ability to recognize a specific antigen.
3.  A principle of biology is that *living organisms interact with their environment.* Such interactions include potentially threatening environmental factors such as pathogens. Distinguish between three types of pathogens that affect the health of animals.

Collaborative Questions

1. Explain the function of cytotoxic T cells.
2. List the different types of lymphocytes, and briefly describe a key structure or function of each type.

UNIT VIII

ECOLOGY



Ecology is the study of interactions among organisms and between organisms and their environment. These interactions govern the number of species in an area and their population densities. Ecologists work at the largest scales of any biologists.

Chapter 54 introduces the field of ecology and discusses the effects of physical variables such as temperature and moisture. At the largest scales, variation in temperature and moisture create distinct large-scale habitats, called biomes. Chapter 55 discusses behavioral ecology and how behavior contributes to the fitness of organisms. The chapter begins by investigating how different behaviors are achieved and ends by examining group behavior and mating systems. The next two chapters examine population growth and the constraints to growth provided by competitors and natural enemies. Chapter 56 introduces the demographic tools needed to study population growth, provides simple mathematical models of growth, and examines the special case of human population growth. In Chapter 57, we discuss the effects of competition, mutualism, predation, herbivory, and parasitism on populations. Chapters 58 and 59 focus on communities and ecosystems. In Chapter 58, we consider the factors that influence the number of species in a community and examine different measures of diversity. Chapter 59 addresses the flow of energy and nutrients through the living and nonliving components of the environment. Finally, Chapter 60 focuses on the conservation of life on Earth and the various strategies used to protect genetic, species, and ecosystem diversity. Throughout the unit, we'll examine the effects of humans on the environment, including pollution, global climate change, and the introduction of exotic species of plants and animals.

The following biology principles will be emphasized in this unit:

- ***Living organisms use energy:*** *Chapter 59 discusses the cycle of nutrients and energy flow in ecosystems.*
- ***Living organisms interact with their environment:*** *Chapter 54 provides examples of the influence of temperature, water, pH, salt concentration, and light on the distribution and abundance of organisms.*
- ***New properties of life emerge from complex interactions:*** *In Chapter 57, we see how the effects of natural enemies and abiotic factors can cascade through natural communities.*
- ***Biology is an experimental science:*** *Throughout the unit are numerous examples of experiments that ecologists have used to investigate how ecosystems function.*
- ***Biology affects our society:*** *Chapter 60 discusses some of the conservation efforts currently under way to save and secure life on Earth.*

Assess and Discuss

An Introduction to Ecology and Biomes

54

Diminishing and disappearing populations. Population sizes of the Panamanian golden frog (*Atelopus zeteki*) have decreased greatly over the past 20 years, and populations of many other species of harlequin frogs have disappeared entirely. Ecologists are investigating the reasons for this decline.

BioConnections: *Look ahead to Section 60.3. What are the main threats to species? Are they natural or human-induced?*

In 2006, a study led by J. Alan Pounds of the Monteverde Cloud Forest Preserve in Costa Rica reported that two-thirds of the 110 species of harlequin frogs in mountainous areas of Central and South America had become extinct over the previous 20 years. The researchers noted that populations of other species, such as the Panamanian golden frog (*Atelopus zeteki*), had been greatly reduced (see the chapter opening photo). The question was why. The culprit was identified as a disease-causing fungus, *Batrachochytrium dendrobatidis*, but Pounds's study implicated global warming—a gradual increase in the average temperature of the Earth's atmosphere—as the agent causing outbreaks of the fungus. One effect of global warming is to increase the cloud cover, which reduces daytime temperatures and raises nighttime temperatures. Researchers believe that this combination has created favorable conditions for the spread of *B. dendrobatidis* and other pathogens, which thrive in cooler daytime temperatures. Pounds, the team's lead researcher and an ecologist, was quoted as saying, "Disease is the bullet killing frogs, but climate change is pulling the trigger."

Ecology is the study of interactions among organisms and between organisms and their environments. Interactions among organisms are called **biotic** interactions, and those between organisms and their nonliving environment are termed **abiotic** interactions. These interactions, in turn, govern the numbers of species in an area and their population densities. This first chapter of the ecology unit will introduce the four broad areas of ecology: organismal, population, community, and ecosystems ecology. Next, we will explore how ecologists approach and conduct their work. We will then turn our focus to abiotic interactions and examine the effects of factors such as temperature, water, light, pH, and salt concentrations on the distributions of organisms. We will conclude with a consideration of climate and its large influence on **biomes**, the major types of habitats where organisms are found.

Before 1960, the field of ecology was dominated by taxonomy, natural history, and speculation about observed patterns. An ecologist's tools of the trade included sweep nets, quadrats (small, measured plots of land used to sample living things), and specimen jars. Since that time, the number of ecological studies has exploded, and ecologists have become active in investigating environmental change on local, regional, and global scales. Ecologists have embraced experimentation and adapted concepts and methods derived from biochemistry, genetics, mathematics, and physiology. Their tools have kept pace with technological innovations. Now an ecologist's equipment is just as likely to include laptops, satellite-generated images, and chemical autoanalyzers.

Ecological studies have important implications in the real world, as will be amply illustrated by examples discussed throughout this unit. However, there is a distinction between ecology and **environmental science**, the application of ecology to real-world problems. To use an analogy, ecology is to environmental science as physics is to engineering. Both physics and ecology provide the theoretical framework on which to pursue more applied studies. Engineers rely on the principles of physics to build bridges. Environmental scientists rely on the principles of ecology to solve environmental problems.

(a) A single organism

(b) A population of zebras

(c) An African grassland community

(d) Nutrient flow in an African grassland community

Figure 54.1 The scale of ecology. **(a)** Organismal ecology. What is the temperature tolerance of this zebra? **(b)** Population ecology. What factors influence the growth of zebra populations in Africa? **(c)** Community ecology. What factors influence the number of species in African grassland communities? **(d)** Ecosystems ecology. How do water, energy, and nutrients flow among plants, zebras, and other herbivores and carnivores in African grassland communities?

54.1 The Scale of Ecology

Learning Outcome:

1. Describe and differentiate between the different scales at which ecologists work.

Ecology ranges in scale from the study of an individual organism through the study of populations to the study of communities and ecosystems (**Figure 54.1**). This section introduces the broad areas of organismal, population, community, and ecosystem ecology and presents an investigation that helps illuminate the field of population ecology.

Organismal Ecology Investigates How Adaptations and Choices by Individuals Affect Their Reproduction and Survival

Organismal ecology is the study of the ways in which individual organisms meet the challenges of the abiotic and biotic environments. It can be divided into two subdisciplines. The first, **physiological ecology**, investigates how organisms are physiologically adapted to their environment and how the environment impacts the distribution of species. Much of this chapter discusses physiological ecology. The second subdiscipline, **behavioral ecology**, focuses on how the behavior of individual organisms contributes to their survival and reproductive success, which, in turn, eventually affects the population density of the species. This is the topic of Chapter 55.

Population Ecology Describes How Populations Grow and Interact with Other Species

Population ecology focuses on groups of interbreeding individuals, called populations. A primary goal of population ecology is to understand the factors that affect a population's growth and determine its size and density. Although the attention of a population ecologist may be aimed at studying the population of a particular species, the relative abundance of that species is often influenced by its interactions with other species. Thus, population ecology includes the study of **species interactions**, such as predation, competition, and parasitism. Knowing what factors affect populations can help us lessen species endangerment, stop extinctions, and control invasive species.

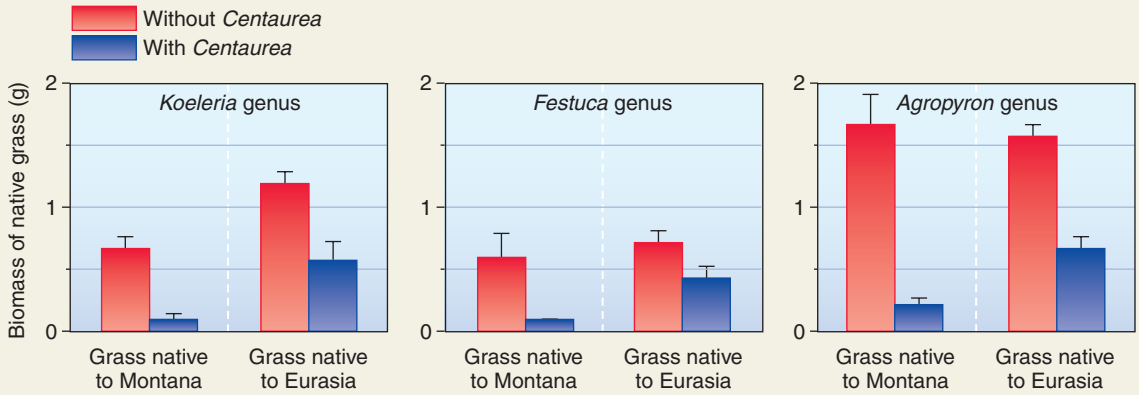
Feature Investigation | Callaway and Aschehoug's Experiments Showed That the Secretion of Chemicals Gives Invasive Plants a Competitive Edge over Native Species

One important topic in the area of population ecology concerns **introduced species** (also called exotic species), species that are moved from a native location to another location, usually by humans. Such species sometimes spread so aggressively that they crowd out native organisms, in which case they are considered **invasive species**. Of the 300 most invasive plant species in the U.S., over half were brought in for gardening, horticulture, or landscaping purposes. Invasive species have traditionally been thought to succeed because they have escaped their natural enemies, primarily insects that are in the country of origin and not in the new locale. One way of controlling these species, therefore, has been to import the plant's natural enemies. This is known as **biological control**. However, an investigation of the population ecology of diffuse knapweed (*Centaurea diffusa*), a Eurasian plant that has established itself in many areas of North America, suggests a different reason for the success of invasive species.

American researchers Ragan Callaway and Erik Aschehoug hypothesized that the roots of this particular species secrete powerful toxins, called **allelochemicals**, that kill the roots of other species, allowing *Centaurea* to proliferate. To test their hypothesis, Callaway and Aschehoug collected seeds of three native Montana grasses, *Koeleria cristata*, *Festuca idahoensis*, and *Agropyron spicata*, and grew each of them with or without the exotic *Centaurea* species (**Figure 54.2**). As hypothesized, *Centaurea* depressed the biomass of the native grasses. When the experiments were repeated with grasses native to

Figure 54.2 Experimental evidence of the effect of allelochemicals on plant production.

HYPOTHESIS Exotic plants from Eurasia outcompete native Montana grasses by secreting allelochemicals from their roots.



KEY MATERIALS Seeds of *Centaurea diffusa* from Eurasia plus seeds of native Montana grasses.

	Experimental level	Conceptual level
1 Collect seeds of native Montana grasses and plant with and without seeds of invasive *C. diffusa* from Eurasia. Three months after sowing seeds, the plants are harvested, dried, and weighed.		*C. diffusa* significantly reduces biomass of native Montana grasses.
2 Collect seeds of grasses from Eurasia of the same three genera as the Montana grasses and plant with and without *C. diffusa*. Three months after sowing seeds, the plants are harvested, dried, and weighed.		*C. diffusa* doesn't depress the biomass of grasses native to Eurasia as much.

3 **THE DATA***

*The biomass is that of the genus noted at the top of each graph.

4 **CONCLUSION** *Centaurea diffusa*, a Eurasian grass, is invasive in the U.S. because it secretes allelochemicals, which inhibit the growth of native plants.

5 **SOURCE** Callaway, R.M., and Aschehoug, E.T. 2000. Invasive plants versus their old and new neighbors. *Science* 290:521–523.

Eurasia, *Koeleria laerssenii*, *Festuca ovina*, and *Agropyron cristatum*, the growth of each species was inhibited, but to a significantly lesser degree than the growth of the Montana species.

In other experiments not described in Figure 54.2, Callaway and Aschehoug added activated carbon to the soil, which absorbs the chemical excreted by the *Centaurea* roots. With activated carbon added, the Montana grass species increased in biomass compared with the previous experiments. The researchers concluded that *C. diffusa* outcompetes Montana grasses by secreting an allelochemical and that Eurasian grasses are not as susceptible to the chemical's effect because they coevolved with it. If the reason for the success of invasive plants can be attributed to the chemicals they secrete, this calls into question the effectiveness of biological control of invasive plants by importation of their natural enemies. This study on the population biology of an invasive plant changed thinking on why such species succeed and could affect attempts to control them in the future.

Experimental Questions

1. Prior to Callaway and Aschehoug's study, what was the prevailing hypothesis on why invasive species succeed in new environments?
2. Briefly describe the evidence collected to support the allelochemical hypothesis.
3. What was the function of the activated carbon used in a subsequent test of the hypothesis?
4. **SciSKILLS** » Explain what else could have been measured in these experiments to further investigate the interactions between *C. diffusa* and native grasses.

Community Ecology Focuses on What Factors Influence the Number of Species in a Given Area

Community ecology studies how populations of species interact and form functional communities. For example, a forest is a community of trees, herbs, shrubs, grasses, the herbivores that eat them, and the carnivores that prey on the herbivores.

Community ecology focuses on why certain areas have high numbers of species (that is, are species-rich), but other areas have low numbers of species (that is, are species-poor). Although ecologists are interested in species richness for its own sake, a link also exists between species richness and community function. Ecologists generally believe that species-rich communities perform better than species-poor communities. It has also been proposed that more species make a community more stable, that is, more resistant to disturbances such as introduced species. Community ecology also considers how species composition and community structure change over time and, in particular, after a disturbance, a process called succession.

Ecosystem Ecology Describes the Flow of Energy and Chemicals Through Communities

An **ecosystem** is a system formed by the interaction between a community of organisms and its physical environment. **Ecosystem ecology** deals with the flow of energy and cycling of chemical elements within an ecosystem. Following this flow of energy and chemicals necessitates an understanding of feeding relationships between species, called food chains. In food chains, each level is called a trophic level, and many food chains interconnect to form complex food webs. As you learned in Chapter 6, the second law of thermodynamics states that in every energy transformation, free energy is reduced because heat energy is lost in the process, and the entropy of the system increases. Therefore, a unidirectional flow of energy occurs through an ecosystem, with energy dissipated at every step. An ecosystem needs a recurring input of energy from an external source—in most cases, the Sun—to sustain itself. In contrast, chemicals such as nitrogen do not dissipate and constantly cycle between abiotic and biotic components of the environment.

54.2 Ecological Methods

Learning Outcome:

1. **SciSKILLS »** Explain how the five steps of hypothesis testing discussed in Chapter 1 can be applied to an ecological research project.

How do ecologists go about studying their subject? As an example, let's consider an insect pest of apple trees. The oak winter moth, *Operophtera brumata*, is a small moth whose larvae feed on a variety of trees and shrubs in Europe and Asia. Egg hatch often coincides with the opening of buds, so young caterpillars can feed on soft new foliage. Sometimes, however, eggs hatch before leaves appear, and, rather than starve, caterpillars "balloon" away on silken threads in an attempt to reach trees whose leaves have already appeared. Although this is a risky business, being able to feed on a variety of food plants maximizes the caterpillars' chances of survival. In the early 20th century, oak winter moths were accidentally introduced into North America, where larvae became a problem in apple orchards in British Columbia and the northwestern United States, including Oregon. How could these moths be controlled? A thorough understanding of their biology was needed.

First, ecologists drew up a web of interactions between the oak winter moth and the factors that could affect its population size (**Figure 54.3**). These numerous and varied factors include the following:

- Abiotic factors such as temperature and rainfall. Warm temperatures can accelerate an egg hatch, meaning that larvae will appear before buds open and leaves are available to feed on.
- Natural enemies, including bird predators of adults and caterpillars, insect parasites, bacterial parasites, and pupal predators. Bird predators consume relatively few adult moths and caterpillars. Bacterial parasites tend to kill larvae before they pupate. Insect parasites usually lay their eggs inside the caterpillars, and the developing parasite gradually eats the caterpillar from the inside out, emerging as an adult parasite the following summer when new caterpillars are available to parasitize. Predators of pupae in the leaf litter and soil include small mammals, such as shrews, and especially predatory beetles.
- Competitors, including other insects and larger vertebrate grazers that feed on leaves. The most common competitors are other species of leaf-feeding caterpillars.
- Host plants, including increases or decreases in either the quality or quantity of the plants.

With such a vast array of factors to be investigated, where is the best place to start? As discussed in Chapter 1, hypothesis testing involves a five-stage process: (1) observations, (2) hypothesis formation, (3) experimentation, (4) data analysis, and (5) acceptance or rejection of the hypothesis.

Observations Are Made to Develop Hypotheses

In Canada, size fluctuations in populations of oak winter moths were observed for many years to determine if the population sizes were affected by fluctuations in abiotic or biotic interactions, such as levels of parasitism, predator abundance, or the quality of available leaves. It was found that such factors caused relatively little mortality among the moths. However, in the 1950s, *Cyzenis albicans*, a parasite of oak winter moth larvae, was imported from Europe and released. Within 5 years of this release, oak winter moth populations collapsed.

Ecologists noticed that in areas where the moths were more abundant, parasitism of their larvae by *C. albicans* increased (**Figure 54.4a**). In areas with few moths, such parasitism was low. This meant that the parasites were killing more caterpillars in areas where they were more common, which tended to control caterpillar numbers. Using statistical methods, ecologists may find a line of best fit, a straight line that represents a summary of the relationship between two variables, as shown in Figure 54.4a. Alternatively, if the data points had not been tightly clustered, as in **Figure 54.4b**, ecologists would have had little confidence that parasitism affects

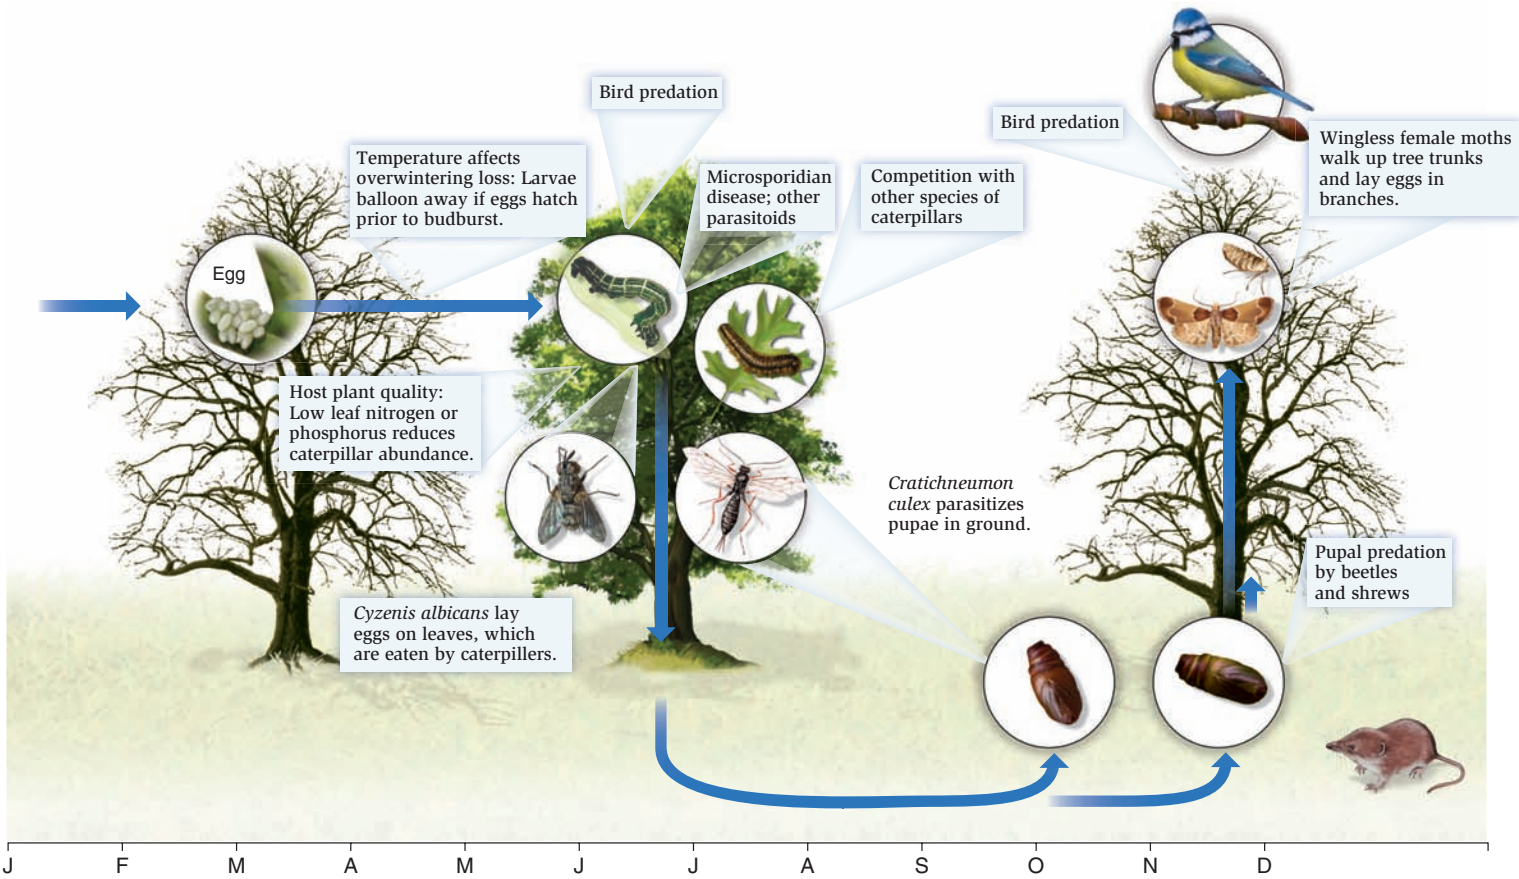


Figure 54.3 Web of interactions showing factors that might influence populations of oak winter moths. Eggs hatch in early April, coincident with bud burst. If leaves are not available, caterpillars balloon away on silken threads to try to reach trees with leaves. Caterpillars feed on leaves and may compete with other leaf feeders. Larvae of the parasite *Cyzenis albicans*, which lays its eggs on the foliage, are unwittingly devoured by the caterpillars. Caterpillars drop to the ground to pupate in the soil and leaf litter. Adult *Cratichneumon culex* directly parasitize pupae. Pupal predation is performed by soil-dwelling beetles and shrews. Adult, wingless, female oak winter moths climb up trees to lay their eggs in November and December.

the moth population size. This was not the case for parasitism by *C. albicans*.

Many statistical tests are used to determine whether or not two variables are significantly related to one another. The type of relationship shown in Figure 54.4a is called a significant correlation. Ecologists have to be cautious when forming conclusions based on correlations. For this reason, after conducting observations, ecologists usually turn to experiments to test their hypotheses.

Experiments Are Conducted to Test Hypotheses

In Canada, once oak winter moth populations collapsed due to *C. albicans*, continued control of the population sizes was thought to arise not from larval parasitism but from pupal predation. By the late 1960s, oak winter moth populations were so low that generalist beetle and shrew predators already present could keep the moths at low densities.

An experiment to test the hypothesis that pupal predation controls oak winter moth abundance might involve removing pupal predators and examining subsequent survival rates of the moth pupae. Reduced predation might be achieved by putting out traps to catch predatory beetles and small mammals or by applying a pesticide to the soil in July to kill the predators prior to the moths' pupation. Ecologists could then look at survival rates of the moth pupae over the course of a winter. If predators are having a significant effect, then removing them should cause moth pupal populations to substantially increase. The experiment would be conducted using two groups of trees, containing equal numbers of trees: a group of trees with predators denied access to pupae in the ground beneath (the experimental group), and a group of trees with predators still present (the control group). Any differences in oak winter moth pupal survival over the winter would be due solely to differences in predation.

Data Analysis Permits Rejection or Acceptance of a Hypothesis

Performing an experiment several times is called **replication**. Ecologists might replicate the experiment involving the removal of predators of the oak winter moths five or ten times, or even more. At the end of the replications, the researchers would sum the total number of emerging moths, divide the sum by the number of replications, and calculate the mean. From replications with the experimental group of trees, suppose that the surviving numbers of moth pupae per tree are 5, 4, 7, 8,

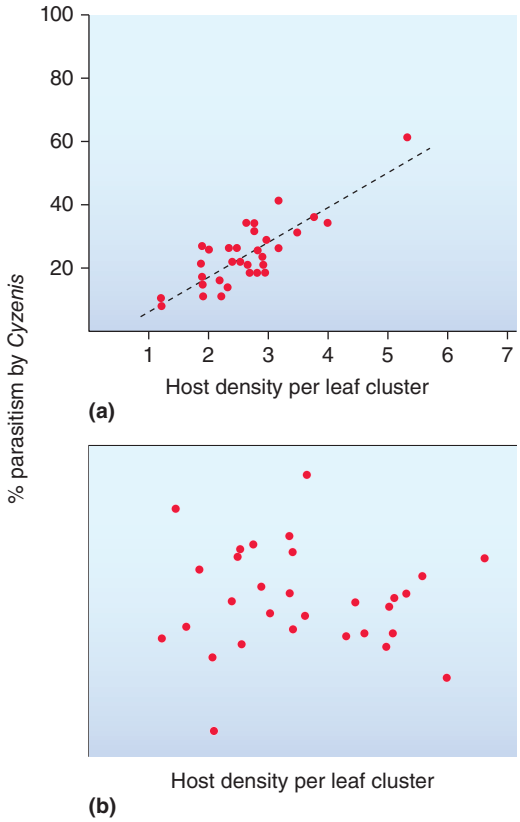

Figure 54.4 The effects of larval parasitism on oak winter moth abundance. **(a)** Percentage of parasitism of moth larvae in Nova Scotia is dependent on the number of caterpillars per leaf cluster of 4–5 leaves. Data from an apple orchard in Nova Scotia in 1983. **(b)** In this hypothetical graph, there is no apparent relationship between the two variables.

Concept Check: *What would it mean if the line of best fit in part (a) sloped in the opposite direction?*

12, 15, 13, 6, 8, and 10; the mean number of surviving pupae is then 8.8. For the control group, where predator access is allowed, the surviving numbers of pupae per tree are 2, 4, 7, 5, 3, 6, 11, 4, 1, and 3, with a mean of 4.6. Without predators, the mean number of pupae surviving is almost double the mean number surviving with predators. This data analysis would give ecologists confidence that predators were indeed the cause of the changes in oak winter moth pupal abundance.

The results of such a predator removal experiment are displayed in the bar graph in **Figure 54.5**. Researcher Jens Roland applied the pesticide Diazinon to the soil prior to oak winter moth pupation. This treatment killed larvae and adults of predator beetles but not the moth pupae, because the pesticide had been degraded by the time the moth larvae dropped to the ground. Results showed that pupal predation was indeed important in influencing the numbers of surviving moth pupa.

Ecologists use a variety of tests to determine whether the differences between experimental and control groups are statistically significant. We will not cover the mechanics of these tests, but when experimental and control groups are described in this unit as differing, the results are statistically significant differences unless stated otherwise.

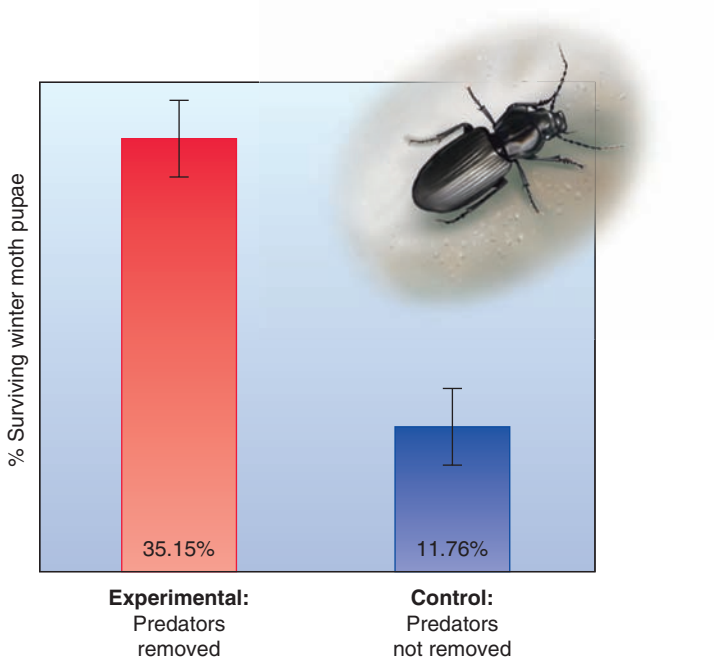

Figure 54.5 Graphic display of results of a predator removal experiment. The two bars represent the average percentages of surviving oak winter moth pupae when beetle predators are removed (experimental) and when they are not removed (control). The vertical lines with brackets (standard errors of the mean; added for illustrative purposes) give an indication of how tightly the individual replicated results are clustered around the mean. The shorter the lines, the tighter the cluster and the more confidence the researchers have in the result.

BIO TIPS **THE QUESTION** *What would it mean if a predator removal experiment yielded the opposite results from those shown in Figure 54.5—that is, numbers of surviving moths increased where predators were not removed?*

TOPIC ***What topic in biology does this question address?*** The topic is interpreting the results of field experiments, more specifically, the results of predator removal experiments.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you are reminded that beetle predators eat oak winter moth pupae. From your understanding of the topic, you may remember that most predators feed on a variety of types of prey. Thus, beetle predators likely eat a variety of insect larvae and pupae, probably including pupae of other moths whose caterpillars eat the same kind of vegetation as oak winter moth pupae.

PROBLEM-SOLVING STRATEGY ***Predict the outcome.*** Think about the web of interactions that are possible among the oak winter moth, its beetle predators, and other competing caterpillar larvae.

ANSWER *One possible explanation is that predator removal increased the number of competing moths. In turn, increased competition might then reduce the number of oak winter moth caterpillars. In this scenario, the enemy (beetle) of the moth's enemy (competing caterpillar species) is the moth's friend.*

In addition to natural enemies, physical or abiotic factors such as the availability of water often have powerful effects in most ecological systems. In the next section, we turn our attention to an examination of the effects of the physical environment on the distribution patterns of organisms.

54.3 The Environment's Effect on the Distribution of Organisms

Learning Outcomes:

1. Give examples of how extremes of temperature, both low and high, drastically affect the distribution and abundance of life on Earth.
2. Describe how global warming is gradually increasing the Earth's temperature and will likely affect species distributions.
3. Explain how other environmental factors, such as wind, water availability, light availability, salt concentration, and pH of soil and water, can affect the distributions of organisms.

Both the distribution patterns of organisms and their abundance are limited by physical features of the environment such as temperature, wind, availability of water and light, salinity, and pH (**Table 54.1**). In this section, we will examine these features of the environment.

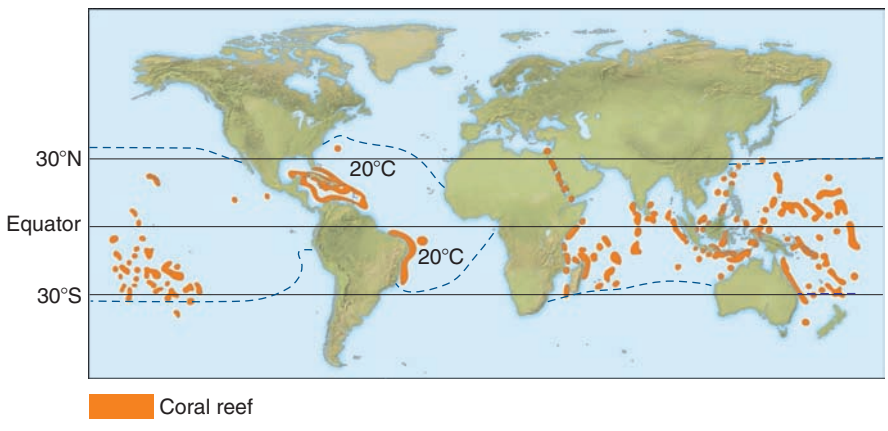

Table 54.1 Selected Abiotic Factors and Their Effects on Organisms

Factor	Effect
Temperature	Low temperatures freeze many plants; high temperatures denature proteins. Some plants require fire for germination.
Wind	Wind amplifies effects of cool temperatures (wind chill) and water loss; creates pounding waves.
Water	Insufficient water limits plant growth and animal abundance; excess water drowns plants and other organisms.
Light	Insufficient light limits plant growth, particularly in aquatic environments.
Salinity	High salinity generally reduces plant growth in terrestrial habitats; affects osmosis in marine and freshwater environments.
pH	Variations in pH affect decomposition and nutrient availability in terrestrial systems; directly influence mortality in both aquatic and terrestrial habitats.

Temperature Has an Important Effect on the Distribution of Plants and Animals

Temperature is perhaps the most important factor in the distribution of organisms because of its effect on biological processes and because of the inability of most organisms to regulate their body temperature precisely. For example, the organisms that form coral reefs secrete a calcium carbonate shell. Shell formation and coral deposition are accelerated at high temperatures but are suppressed in cold water. Coral reefs are therefore abundant only in warm water, and a close correspondence is observed between the 20°C isotherm for the average daily temperature during the coldest month of the year and the limits of the distribution of coral reefs (**Figure 54.6**). An isotherm is a line on a map connecting points of equal temperature. Coral reefs are located between the two 20°C isotherm lines that are formed above and below the equator.

Low Temperatures Frost is probably the single most important factor limiting the geographic distribution of tropical and subtropical plants. In plants, cold temperature can be lethal because cells may rupture if the water they contain freezes. Disruption of cells via freezing is especially lethal to plants that produce poisonous chemical defenses against herbivores. One form of white clover, *Trifolium repens*, produces cyanide as a defense against herbivores. However, frost injury is lethal to these plants because when cell membranes are disrupted, the toxin is released into other tissues. As a result, the cyanide-producing form is less common in colder regions of Europe (**Figure 54.7**).

(a) Worldwide distribution of coral reefs

(b) A coral reef

Figure 54.6 Worldwide locations of coral reefs. **(a)** Coral reef formation is limited to waters bounded by the 20°C isotherm (dashed line), a line where the average daily temperature is 20°C during the coldest month of the year. **(b)** Coral reef in the Pacific Ocean.

Concept Check: *Why are coral reefs limited to warm water?*

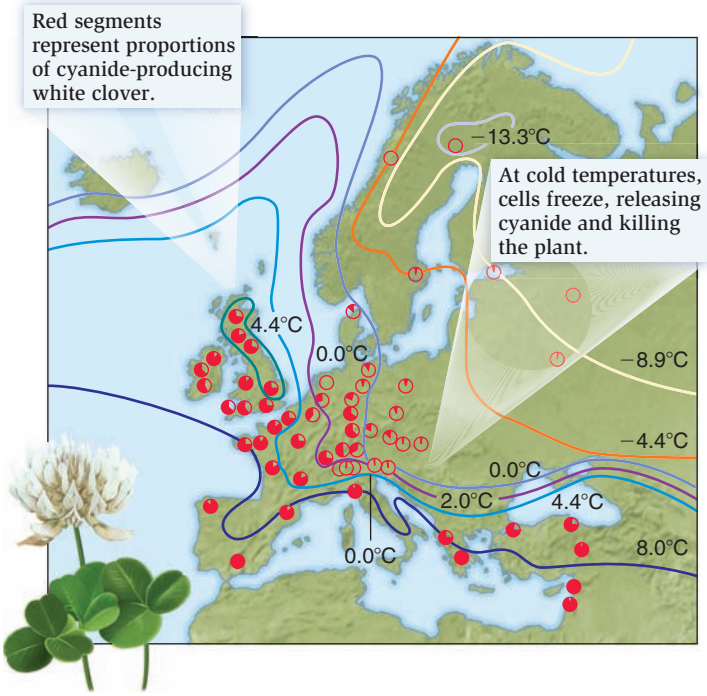

Figure 54.7 Frequency of the cyanide-producing form in populations of white clover, *Trifolium repens*, is affected by temperature. The proportion of the cyanide-producing form is represented by the red section of each circle. This form is more common in warmer regions of Europe. Lines are January isotherms.

BIOLOGY PRINCIPLE Living organisms interact with their environment. In many cases, the distributional limits of organisms are set by the physical environment.

The geographic range limits of endothermic animals are also affected by temperature. For example, the eastern phoebe (*Sayornis phoebe*), a small bird, has a northern winter range that coincides with an average minimum January temperature above 4°C. Such limits are probably related to the energy demands associated with cold temperatures. Cold temperatures mean higher metabolic costs, which are, in turn, dependent on high feeding rates. Below 4°C, the eastern phoebe cannot feed fast enough or, more likely, find enough food to keep warm.

High Temperatures High temperatures are also limiting for many plants and animals because relatively few species can survive internal temperatures more than a few degrees above their metabolic optimum. We have noted that corals are sensitive to low temperatures; however, they are sensitive to very high temperatures as well. When temperatures are too high, the symbiotic algae that live within coral die and are expelled, causing a phenomenon known as coral bleaching. Once bleaching occurs, the coral tissue loses its color and turns a pale white (**Figure 54.8**). El Niño is a weather phenomenon characterized by a major increase in the water temperature of the equatorial Pacific Ocean. In the winter of 1982–1983, an influx of warm water from the eastern Pacific raised temperatures just 2–3°C for 6 months, which was enough to kill many of the reef-building corals on the coast of Panama. By May 1983, just a few individuals of one species, *Millepora intricata*, were alive.

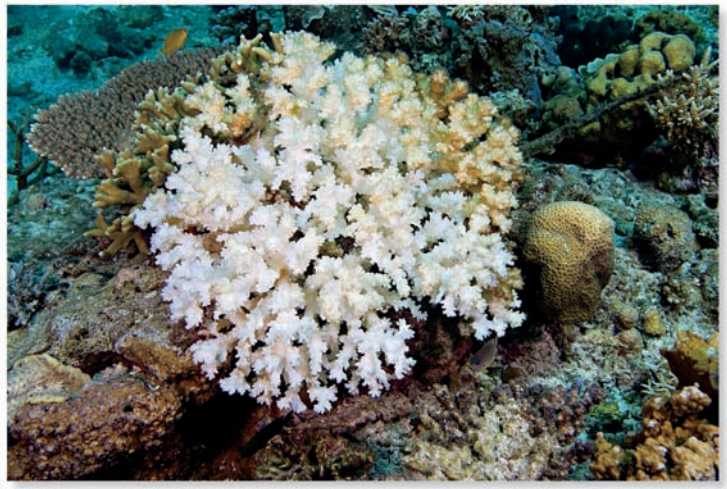

Figure 54.8 Coral bleaching. Mantanani Island, Malaysia.

The ultimate high temperatures that many terrestrial organisms face are the result of fire. However, some species depend on frequent low-intensity fires for their reproductive success. The jack pine (*Pinus banksiana*) of the northern U.S. produces serotinous cones, which remain sealed by pine resin until the heat of a fire melts them open and releases the seeds. In the west, giant sequoia trees are similarly dependent on periodic low-intensity fires for germination of their seeds. Such fires both enhance the release of seeds and clear out competing vegetation at the base of the tree so that seeds can germinate and grow. Fire-suppression practices that attempt to protect forests from fires can actually have undesirable results by preventing the regeneration of fire-dependent species. Furthermore, fire prevention can result in an accumulation of vegetation beneath the canopy (the understory) that may later fuel hotter and more damaging fires. The U.S. Forest Service uses controlled human-made fires to mimic the natural disturbance of periodic fires and maintain fire-dependent forest species (**Figure 54.9**).

The Greenhouse Effect The Earth is warmed by the **greenhouse effect**. In a greenhouse, sunlight penetrates the glass and raises temperatures, with the glass acting to trap the resultant heat inside. Similarly, solar energy in the form of short-wave radiation passes through the atmosphere to heat the surface of the Earth. At night, this energy is radiated from the Earth's warmed surface back into the atmosphere, but in the form of long-wave infrared radiation. Instead of letting it escape back into space, however, atmospheric gases absorb much of this infrared energy and radiate it back to the Earth's surface, causing the surface temperature to rise further (**Figure 54.10**). The greenhouse effect is a naturally occurring process that is responsible for keeping the Earth warm enough to sustain life. Without some type of greenhouse effect, global temperatures would be much lower than they are, perhaps averaging only −17°C compared with the existing average of +15°C.

The greenhouse effect is caused by a group of atmospheric gases that together make up less than 1% of the total volume of the

Figure 54.9 Giant sequoia. A park ranger uses a drip torch to ignite a fire at Sequoia National Park in California. Periodic, controlled human-made fires mimic the sporadic wildfires that normally burn natural areas. Such fires are vital to the health of giant sequoia populations, because they serve to open the pine cones and release the seeds.

Concept Check: *Why are some fires very destructive to natural systems?*

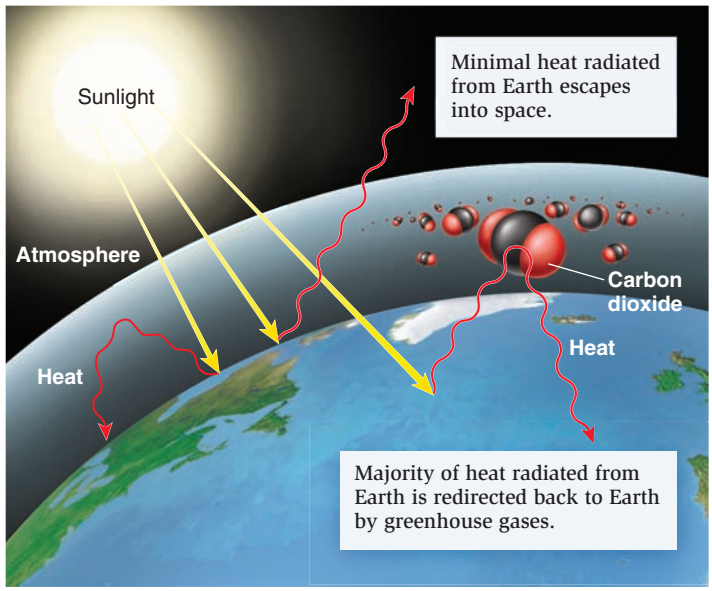

Figure 54.10 The greenhouse effect. Solar energy, in the form of short-wave radiation, passes through the atmosphere to heat the Earth's surface. Long-wave infrared radiation is redirected back into the atmosphere. Much infrared energy is absorbed by atmospheric gases, including carbon dioxide molecules, and reflected back to Earth, causing global temperatures to rise.

atmosphere. These gases—primarily water vapor, carbon dioxide, methane, nitrous oxide, and chlorofluorocarbons—are referred to as greenhouse gases (**Table 54.2**).

Global Warming Ecologists are concerned that human activities are increasing the greenhouse effect and causing **global warming** (also called global climate change), a gradual elevation of the Earth's surface temperature. According to the Intergovernmental Panel on Climate Change 2007 report, warming of the climate is unequivocal, as is now evident from observations of increases in global average air and ocean temperatures, widespread melting of snow and ice, and rising average global sea level. Most greenhouse gases have increased in atmospheric concentration since the industrial revolution in the late 18th century. Of those increasing, the most important is carbon dioxide (CO_2). As Table 54.2 shows, although CO_2 has a lower global warming potential per unit of gas (relative absorption) than any of the other major greenhouse gases, its concentration in the atmosphere

Table 54.2 Selected Greenhouse Gases and Their Contribution to Global Warming*

	Carbon dioxide (CO_2)	Methane (CH_4)	Nitrous oxide (N_2O)	Chlorofluorocarbons (CFCs)
Relative absorption in ppm of increase†	1	32	150	10,000
Atmospheric concentration (ppm‡)	400	1.75	0.315	0.0005
Contribution to global warming	73%	7%	19%	1%
Percent from natural sources; type of source	20–30%; volcanoes	70–90%; swamps, gas from termites and ruminants	90–100%; soils	0%
Major human-made sources	Fossil fuel use, deforestation	Rice paddies, landfills, biomass burning, coal and gas exploitation	Cultivated soil, fossil-fuel use, automobiles, industry	Previously manufactured products (for example, aerosol propellants) now banned in the U.S. and the E.U.

*Water vapor is not included in this table.
†Relative absorption is the warming potential per unit of gas.
‡ppm = parts per million

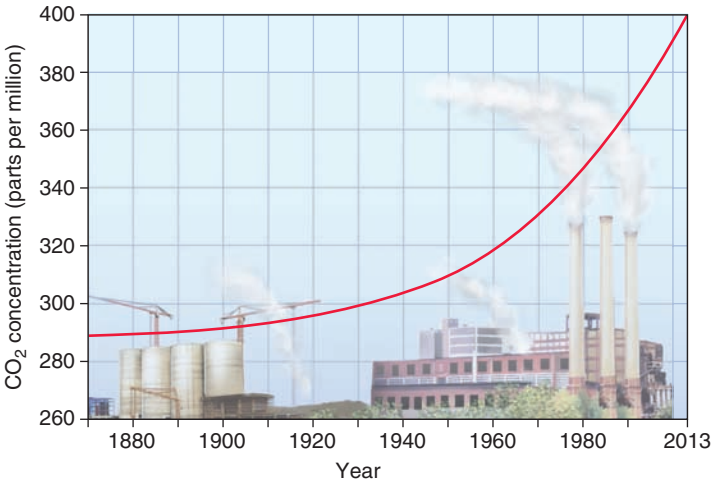

Figure 54.11 The increase of atmospheric carbon dioxide. Increases in the burning of fossil fuels have caused a steady increase in atmospheric CO_2 since the late 19th century.

is much higher. Atmospheric levels of CO_2 have increased by almost 50% from pre-industrial levels (**Figure 54.11**).

To predict the effect of global warming, most scientists focus on a future point, about 2100, when the concentration of atmospheric CO_2 will have doubled—that is, increased to about 700 ppm compared with the late-20th-century level of 350 ppm. Scientists estimate that at that time, average global temperatures will be somewhere in the range of 1–6°C (about 2–10°F) warmer than present and will increase an additional 0.5°C each decade. This increase in heat might not seem like much, but it is comparable to the warming that ended the last Ice Age. Future consequences will include a further contraction of snow cover and a decrease in sea ice extent, heat waves and drought in dry areas, heavier precipitation in moister areas, and an increase in hurricane and tornado intensity.

Assuming this scenario of gradual global warming is accurate, what might be the consequences for plant and animal life? At the beginning of the chapter, we saw how global warming is believed to be contributing to the decline and extinction of some amphibian species. Although many species can adapt to slight changes in their environment, the anticipated changes in global climate are expected to occur too rapidly to be compensated for by normal evolutionary processes such as natural selection. Plant species in particular cannot simply disperse and move north or south into the newly created climatic regions that will be suitable for them. Many tree species take hundreds, even thousands, of years for seed dispersal. American paleobotanist Margaret Davis predicted that in the event of a CO_2 doubling, the sugar maple (*Acer saccharum*), which is presently distributed throughout the midwestern and northeastern U.S. and southeastern Canada, would die back in all areas except northern Maine, northern New Brunswick, and southern Quebec (**Figure 54.12**). Of course, this contraction in the tree's distribution could be offset by the creation of new favorable habitats in central Quebec. However, most scientists believe that the climatic zones would shift toward the poles faster than trees could migrate via seed dispersal; therefore, extinctions would occur. Interestingly, scientists are beginning to be able to genetically modify organisms to change their temperature tolerances, as described next.

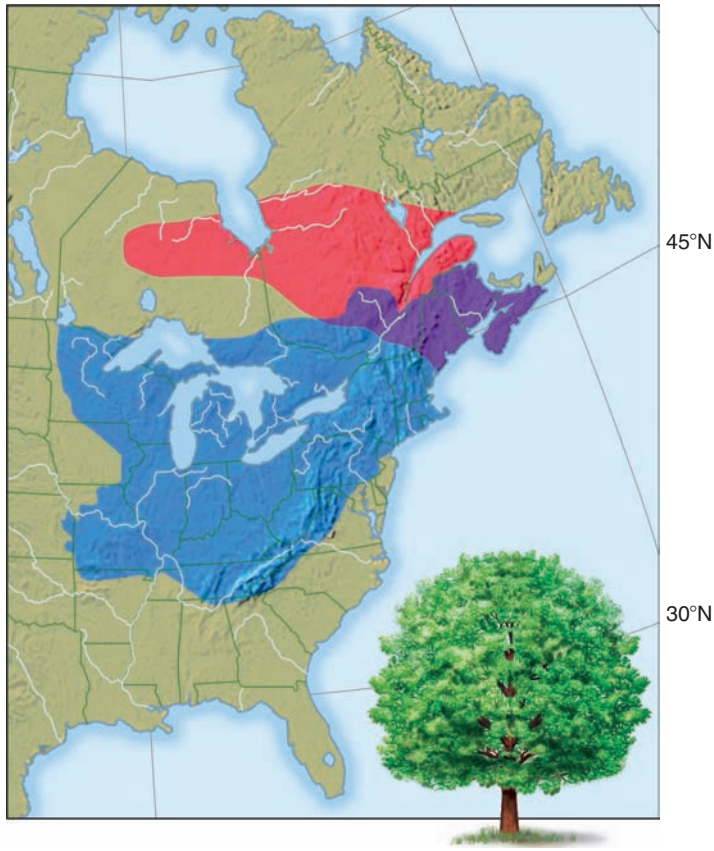

Figure 54.12 Possible changes in the range of sugar maples due to global warming. The present geographic range of the sugar maple (blue shading) and its potential range with doubled CO_2 levels (red shading) in North America. Purple shading indicates the region of overlap, which is the only area where the sugar maple would be found before it spread into its new potential range.

BIOLOGY PRINCIPLE Biology affects our society. Global warming will change the distributions of many species familiar to us.

Concept Check: What abiotic factors that influence sugar maple distribution might change in a world with elevated levels of CO_2?

Genomes & Proteomes Connection

Temperature Tolerance May Be Manipulated by Genetic Engineering

Below-freezing temperatures can be very damaging to plant tissue, either killing the plant or greatly reducing its productivity. Frost injury causes losses to agriculture of more than $1 billion annually in the U.S. Frost has been considered an unavoidable result of subfreezing temperatures, but genetic engineering is beginning to change this view.

Between 0°C and –40°C, pure water will be liquid unless provided with an ice nucleus or template on which an ice crystal can be built. Any number of ions or molecules within an organism's cells can act as a template. Researchers discovered that

some bacteria commonly found on leaf surfaces act as ice nuclei, triggering the formation of ice crystals and eventually causing frost damage. The genes that confer ice nucleation resistance have been identified, isolated, and deactivated in a genetically engineered strain of the bacteria *Pseudomonas syringae*. When this strain is allowed to colonize strawberries, frost damage is greatly reduced, and plants can withstand an additional 5°C drop in temperature before ice forms. Other techniques have been used to create cold-tolerant transgenic plants, but to date, the number of transgenic crops is relatively small and includes varieties of tomato, tobacco, rice, maize, alfalfa, cotton, canola and flax. Moreover, the techniques are not always perfect. For example, transgenic tomatoes that are less sensitive to frost may exhibit dwarfism and reduced fruit set. However, the promise of this technique for increasing agricultural yields and altering normal plant-distribution patterns is staggering.

At the other end of the temperature spectrum, heat shock proteins (HSPs) help organisms cope with the stress of high temperatures. At high temperatures, proteins may denature, that is, either unfold or bind to other proteins to form misfolded aggregations. HSPs act as molecular chaperones, proteins that help in the proper folding of other proteins, to prevent these types of events from taking place (refer back to Figure 4.31). HSPs normally constitute only about 2% of a cell's soluble protein content, but this can increase to 20% when a cell is stressed, whether by heat, cold, drought, or other conditions. The genes that encode HSPs are extremely common and are found in the genomes of all organisms, from bacteria to plants and animals. In 2006, several genes responsible for inducing the synthesis of HSPs were found in tomato and maize. As a result, transgenic tobacco plants have been produced that grow better than normal plants under higher temperatures.

In the tropics, high temperatures can substantially decrease the growth rates and productivity of many crop species. There is now substantial interest in identifying crop strains with naturally high HSP levels for use in crop-breeding programs. Given the projected continuation of global warming, such research seems particularly timely.

Wind Can Amplify the Effects of Temperature

Wind is created by temperature gradients. As air heats up, it becomes less dense and rises. As hot air rises, cooler air rushes in to take its place. For example, hot air rising in the tropics is replaced by cooler air flowing in from more temperate regions, thereby creating northerly or southerly winds.

Wind affects living organisms in a variety of ways. It increases the rate of heat loss by convection, the transfer of heat by the movement of air next to the body (the wind chill factor). Wind also contributes to water loss in organisms by increasing the rate of evaporation in animals and transpiration in plants.

Winds can also intensify oceanic wave action, with resulting effects for aquatic organisms. On the ocean's rocky shore, seaweeds survive heavy surf by a combination of holdfasts and flexible structures. The animals of this zone have powerful organic glues and muscular feet to hold them in place (**Figure 54.13**).

(a) Brown alga with a holdfast

(b) A mussel with byssal threads

Figure 54.13 Animals and plants of the intertidal zone adhering to their rocky surface. **(a)** The brown alga (*Laminaria digitata*) has a holdfast that enables it to cling to the rock surface. **(b)** The mussel (*Mytilus edulis*) attaches to the surface of a rock by proteinaceous threads (byssal threads) that extend from the animal's muscular foot.

The Availability of Water Has Important Effects on the Abundance of Organisms

Water has an important effect on the distribution of organisms. Cytoplasm is 85–90% water, and without moisture, there can be no life. As noted in Chapter 2, water performs crucial functions in all living organisms. It acts as a solvent for chemical reactions, takes part in hydrolysis and dehydration reactions, is the means by which animals eliminate wastes, and is used for support in plants and in some invertebrates as part of a hydrostatic skeleton.

The distribution patterns of many plants are limited by available water. For example, the density of creosote bushes in the Mojave Desert increases in wetter areas. In cold climates, water can be present

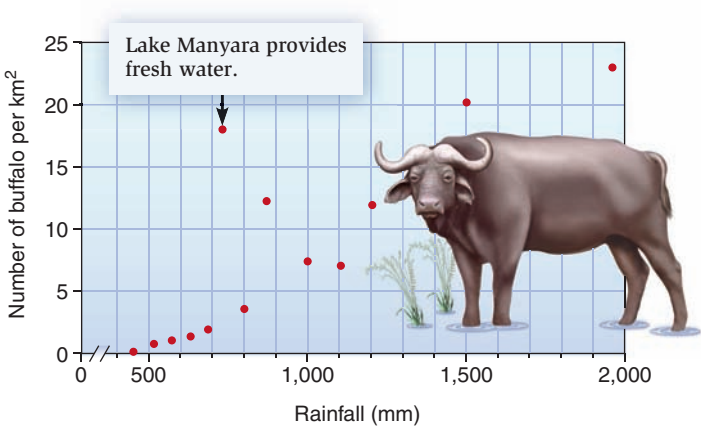

Figure 54.14 The relationship between the amount of rainfall and the density of buffalo. In the Serengeti area of Africa, buffalo density is very much dependent on grass availability, which itself depends on annual rainfall. The main exception is where there is permanent water, such as Lake Manyara. Greater water availability leads to greater grass growth and buffalo densities.

but locked up as permafrost and, therefore, unavailable. Alpine trees stop growing at a point on the mountainside where they cannot take up enough moisture to offset transpiration losses. This point, known as the timberline, is readily apparent on many mountainsides.

Animals face problems of water balance, too, and their distribution and population density can be strongly affected by water availability. Because most animals depend ultimately on plants for food, their distribution is intrinsically linked to those of their food sources. Such a phenomenon regulates the number of buffalo (*Syncerus caffer*) in the Serengeti area of Africa. In this area, grass productivity is related to the amount of rainfall in the previous month. Buffalo density is governed by grass availability, so a significant correlation is found between buffalo density and rainfall (**Figure 54.14**). The only exception occurs in the vicinity of Lake Manyara, where groundwater promotes plant growth.

Light Can Be a Limiting Resource for Plants and Algae

Because light is necessary for photosynthesis, it can be a limiting resource for plants. However, what may be sufficient light to support the growth of one plant species may be insufficient for another. Many plant species grow best in shady conditions, such as eastern hemlock (*Tsuga canadensis*). Its saplings grow in the understory below the forest canopy, reaching maximal photosynthesis at one-quarter of full sunlight. Other plants, such as sugarcane (*Saccharum officinarum*), continue to increase their photosynthetic rate as light intensity increases.

In aquatic environments, light may be an even more limiting factor because water absorbs light, preventing photosynthesis at depths greater than 100 m. Most aquatic plants and algae are limited to a fairly narrow zone close to the surface, where light is sufficient to allow photosynthesis to occur. This zone is known as the **photic zone**. In marine environments, seaweeds at greater depths have wider thalli (leaflike light-gathering structures) than those nearer the surface,

(a) Green algae at the ocean surface

(b) Red algae at a greater depth

Figure 54.15 Algae growing at different ocean depths. **(a)** In the eastern Pacific Ocean, off the coast of California, these giant kelp floating at the ocean surface are green, just like terrestrial plants. **(b)** In contrast, at 75-m depth, in the McGrail Bank off of the Gulf of Mexico, most seaweeds are pink and red because the pigments can absorb the blue-green light that reaches such depths.

because wide thalli can collect more light. In addition, in aquatic environments, plant color changes with depth. At the surface, plants and algae appear green, as they are in terrestrial conditions, because they absorb red and blue light, but not green (**Figure 54.15a**). At greater depths, red light is mostly absorbed by water, leaving predominantly blue-green light. Red algae found in deeper water possess pigments that enable them to utilize blue-green light efficiently and that reflect red light (**Figure 54.15b**).

The Concentration of Salts in Soil or Water Can Be Critical

Salt concentrations vary widely in aquatic environments and have a great effect on osmotic balance in animals. Oceans contain considerably more dissolved minerals than rivers because oceans continually receive the nutrient-rich waters of rivers, and the Sun evaporates pure water from ocean surfaces, making concentrations of minerals such as salts even higher.

The phenomenon of osmosis influences how living organisms cope with different environments. Freshwater fishes cannot live in salt water, and saltwater fishes cannot live in fresh water. Each employs different mechanisms to maintain an osmotic balance with

Figure 54.16 Plant adaptations for salty conditions. Special salt glands in the leaves of *Spartina* exude salt, enabling this grass to exist in saline intertidal conditions.

BioConnections: Look back to Section 38.2. Why can't most plants grow in salty habitats?

their environment (refer back to Figure 49.2). Freshwater fishes are hyperosmotic (having a greater concentration of solutes) relative to their environment and tend to gain water by osmosis as it diffuses through the thin tissue of the gills and mouth. To counter this, the fish continually eliminate water in the urine. However, to avoid losing all dissolved ions, many ions are reabsorbed into the bloodstream at the kidneys. Many marine fishes are hypo-osmotic (having a lower concentration of solutes) relative to their environment and tend to lose water as seawater passes over the mouth and gills. They drink water to compensate for this loss, but the water contains a higher concentration of salt, which must then be excreted at the gills and kidneys.

Salt in the soil also affects the growth of plants. In arid terrestrial regions, salt accumulates in soil where water settles and then evaporates. This can also be of great significance in agriculture, where continued watering in arid environments, together with the addition of salt-based fertilizers, greatly increases salt concentration in the soil and reduces crop yields. A few terrestrial plants are adapted to live in saline soil along seacoasts. Here the vegetation consists largely of **halophytes**, species that can tolerate higher salt concentrations in their cell sap than regular plants. Species such as mangroves and *Spartina* grasses have salt glands that excrete salt to the surface of the leaves, where it forms tiny white salt crystals (**Figure 54.16**).

The pH of Soil or Water Can Limit the Distribution of Organisms

As discussed in Chapter 2, the pH of water can be acidic, alkaline, or neutral. Variation in pH can have a major effect on the distribution of organisms. Normal rainwater has a pH of about 5.6, which is slightly acidic because the absorption of atmospheric carbon dioxide (CO_2) and sulfur dioxide (SO_2) into rain droplets forms carbonic and sulfuric acids. However, most plants grow best at a soil water pH of about 6.5, a value at which soil nutrients are most readily available to plants. Only a few genera, such as rhododendrons and azaleas (*Rhododendron*), can live in soils with a pH of 4.0 or less. Furthermore, at a pH of 5.2 or less, nitrifying bacteria do not function properly, which prevents organic matter from decomposing. In general, alkaline soils containing chalk and limestone have a higher pH and sustain a much richer flora (and associated fauna) than do acidic soils (**Figure 54.17**).

Likewise, the number of fishes and other species also decreases in acidic waters. The optimal pH for most freshwater fishes and bottom-dwelling invertebrates is between 6.0 and 9.0. Acidity in lakes increases the amount of toxic metals, such as mercury, aluminum, and lead, which can leach into the water from surrounding soil and rock. Too much mercury or too much aluminum can interfere with gill function, causing fishes to suffocate.

Acid Rain The susceptibility of both aquatic and terrestrial organisms to changes in pH explains why ecologists are so concerned about **acid rain**, precipitation with a pH of less than 5.6. Acid rain results from the burning of fossil fuels such as coal, oil, and natural gas, which releases SO_2 and nitrogen oxide (NO_2) into the atmosphere. These react with oxygen in the air to form sulfuric acid and nitric acid, which falls to the Earth's surface in rain or snow. When this precipitation falls on rivers and especially lakes, it can turn them more acidic, and they lose their ability to sustain fishes and other aquatic life. For example, lake trout disappear from lakes in Ontario and the eastern U.S. when the pH dips below about 5.2. Although this low pH does not affect survival of the adult fish, it affects the survival of juveniles.

Acid rain is important in terrestrial systems, too. For example, acid rain can directly affect forests by killing leaves or pine needles, as has happened on some of the higher mountaintops in the Great Smoky Mountains. It can also greatly lower soil pH, which can result in a loss of essential nutrients such as calcium and nitrogen. Low soil

(a) Rich flora on alkaline soil

(b) Sparse flora on acidic soil

Figure 54.17 Species-rich flora of chalk grassland compared with species-poor flora of acid soils. **(a)** At Mount Caburn, in the lime-rich chalk hills of Sussex County, England, there is a much greater variety of plant and animal species than at **(b)** a heathland site elsewhere in England. Heathlands are a product of thousands of years of human clearance of natural forest areas and are characterized by acidic, nutrient-poor soils.

Concept Check: Why do acidic soils support fewer species of plants and animals than lime-rich soils?

calcium results in calcium deficiencies in plants, in the snails that consume the plants, and in the birds that eat the snails, ultimately causing weak eggshells that break before hatching. Decreased soil pH also kills certain soil microorganisms, preventing decomposition and recycling of nitrogen in the soil. Decreases in soil calcium and nitrogen weaken trees and other plants and may make them more susceptible to insect attack.

Acid rain is a common problem in the northeastern U.S. and Scandinavia, where sulfur-rich air drifts over from the Midwest and the industrial areas of Britain, respectively, causing the deposition of highly acidic rain. The problem was particularly acute during the 1960s and 1970s, but decreased manufacturing and the use of low-sulfur coal and of sulfur-absorbing scrubbers on the smokestacks of coal-burning power plants have somewhat reduced the problem in recent years. Acid rain is clearly a problem with a wide-ranging effect on ecological systems.

54.4 Climate and Its Relationship to Biological Communities

Learning Outcomes:

1. Explain how global temperature differentials drive atmospheric circulation.
2. Explain how both mountains and large bodies of water can change local temperature and precipitation patterns.

Temperature, wind, precipitation, and light are components of **climate**, the prevailing weather pattern in a given region. As we have seen, the distribution and abundance of organisms are influenced by these factors. Therefore, to understand the patterns of abundance of life on Earth, ecologists need to study the global climate. In this section, we examine global climate patterns, focusing on how temperature variation drives atmospheric circulation and how features such as elevation and landmass can alter these patterns.

Atmospheric Circulation Is Driven by Global Temperature Differentials

Substantial differences in temperature occur over the Earth, mainly due to latitudinal variations in the incoming solar radiation. In higher latitudes, such as northern Canada and Russia, the Sun's rays hit the Earth obliquely and are spread out over more of the planet's surface than they are in equatorial areas (**Figure 54.18**). More heat is also lost in the atmosphere of higher latitudes because the Sun's rays travel a greater distance through the atmosphere, allowing more heat to be dissipated by cloud cover. The result is that 40% less solar energy strikes polar latitudes than equatorial areas. Generally, temperatures increase as the amount of solar radiation increases (**Figure 54.19**). However, at the tropics, both cloudiness and rain reduce average temperature, so temperatures do not continue to increase toward the equator.

Global patterns of atmospheric circulation and precipitation are influenced by solar energy. In 1735, English meteorologist George Hadley made the initial contribution to a model of general atmospheric circulation. In his model, high temperatures at the equator

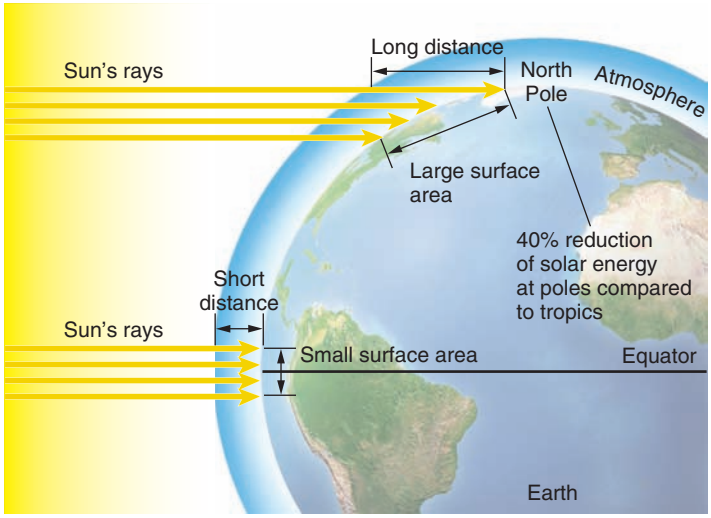

Figure 54.18 The intensity of solar radiation at different latitudes. In polar areas, the Sun's rays strike the Earth at an oblique angle and deliver less energy than at tropical locations. In tropical areas, the energy is concentrated over a smaller surface and travels a shorter distance through the atmosphere.

cause the surface equatorial air to heat up and rise vertically into the atmosphere. The vertical rising of the hot air cools the land by convection (look back to Figure 46.10). As the warm air rises away from its source of heat, it cools and becomes less buoyant, but the cool air does not sink back to the surface because of the warm air behind it. The warm air rising near the equator forms towers of cumulus clouds that provide rainfall, which, in turn, maintains the lush vegetation of the equatorial rain forests. As the upper flow of air moves toward the poles, it begins to subside, or fall back to Earth, at about 20–30° north

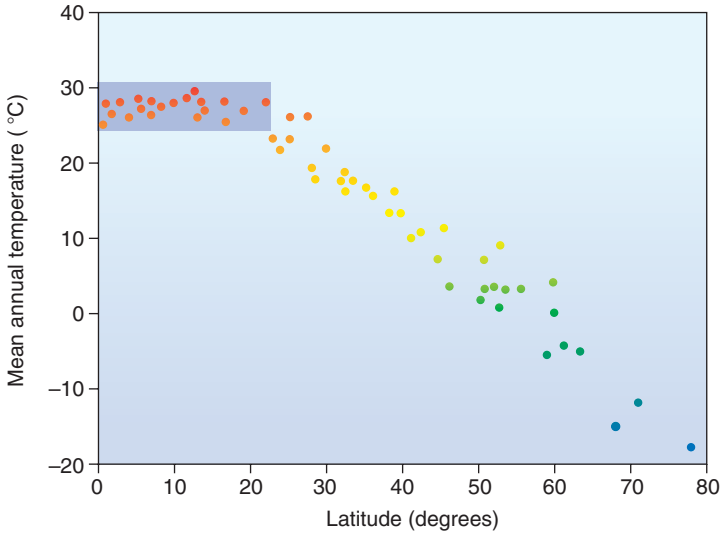

Figure 54.19 Variation of the Earth's temperature. The temperatures shown in this figure were measured at moderately moist continental locations of low elevation.

Concept Check: Why is there a wide band of similar temperatures at the tropics? (See the orange dots highlighted in the purple rectangle.)

and south of the equator. These **subsidence zones** are areas of high pressure and are the sites of the world's tropical deserts, because the subsiding air is relatively dry, having released all of its moisture over the equator (**Figure 54.20**).

From the center of the subsidence zones, the surface flow splits into two directions, one of which flows toward the poles and the other toward the equator. The equatorial flow from both hemispheres meets near the equator in a region called the intertropical convergence zone (ITCZ). In the three-cell model, the circulation between 30° and 60° latitude is opposite that of the cell nearest the equator because the net surface flow is poleward. Additional zones of high precipitation occur in this cell, usually between 45° and 55°. In the final circulation cell, at the poles, the air has cooled and descends, but it has little moisture left, explaining why many high-latitude regions are desert-like in condition. The distributions of the major biomes discussed in Section 54.5 are largely determined by temperature differences and the wind patterns they generate. Hot, tropical forest blankets the tropics, where rainfall is high. At about 20–30° latitude, the air cools and descends, but it is without moisture, so the hot deserts occur around that latitude. The middle cell of the circulation model shows us that at about 45° to 55° latitude, the air has warmed and gained moisture, so it ascends, dropping rainfall over the wet, temperate forests of the Pacific Northwest and Western Europe in the Northern Hemisphere and New Zealand and Chile in the Southern Hemisphere.

Elevation and Other Features of a Landmass Can Also Affect Climate

Thus far, we have considered how global temperatures and wind patterns affect climate. The geographic features of a landmass can also have an important effect. For example, the elevation of a region greatly influences its temperature range. On mountains, temperatures decrease with increasing elevation. This decrease is a result of a process known as **adiabatic cooling**, in which increasing elevation leads to a decrease in air pressure. When air is blown across the Earth's surface and up over mountains, it expands because of the reduced pressure. As it expands, it cools at a rate of about 10°C for every 1,000 m in elevation, as long as no water vapor or cloud formation occurs. (Adiabatic cooling is also the process applied in the function of a refrigerator, in which refrigerant gas cools as it expands coming out of the compressor.) A vertical ascent of 600 m produces a temperature change roughly equivalent to that brought about by an increase in latitude of 1,000 km. This explains why mountaintop vegetation, even in tropical areas, can have the characteristics of a colder biome.

Mountains can also influence patterns of precipitation. For example, when warm, moist air encounters the windward side of a mountain, it flows upward and cools, releasing precipitation in the form of rain or snow. On the side of the mountain sheltered from the wind (the leeward side), drier air descends, producing what is called a **rain shadow**, an area where precipitation is noticeably less

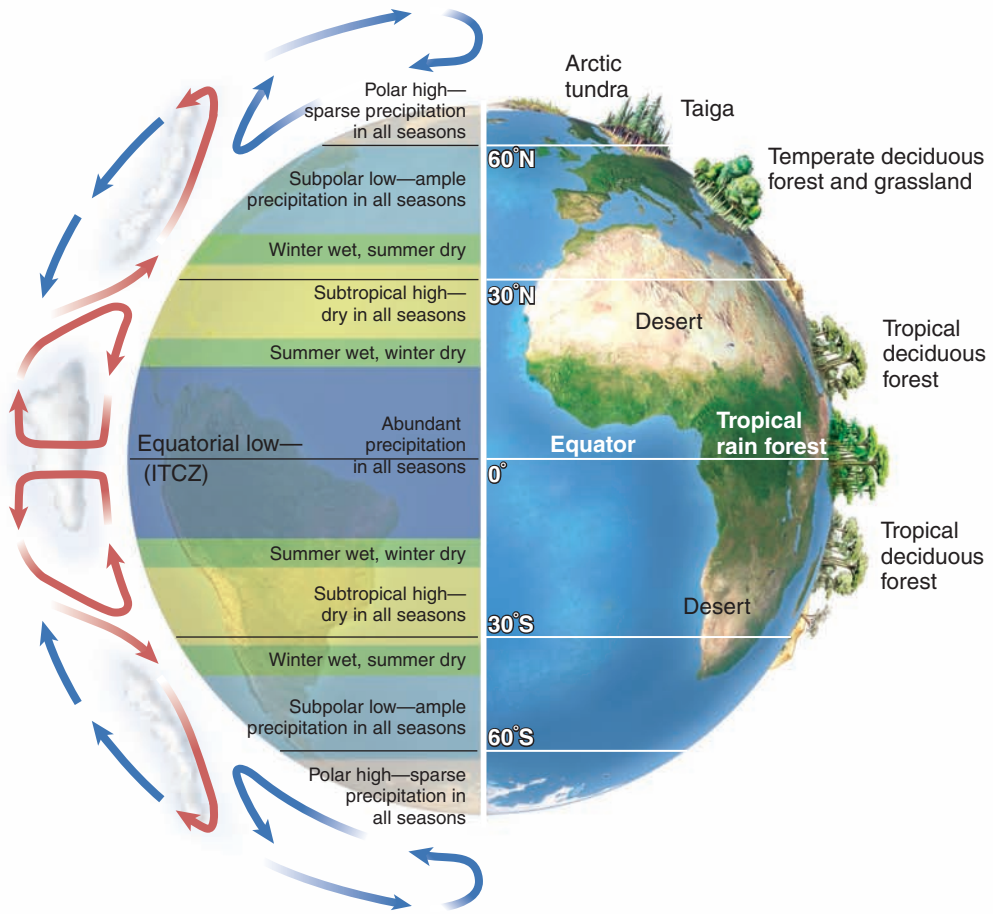

Figure 54.20 Global circulation based on a modified three-cell model. Tropical forests exist mainly in a band around the equator, where it is hot and rainy. At around 30° north and south, the air is hot and dry, and deserts exist. A secondary zone of precipitation exists at around 45° to 55° north and south, where temperate forests are located. The polar regions are generally cold and dry. The term high refers to areas of high pressure resulting from falling air. Low refers to areas of low pressure resulting from rising air.

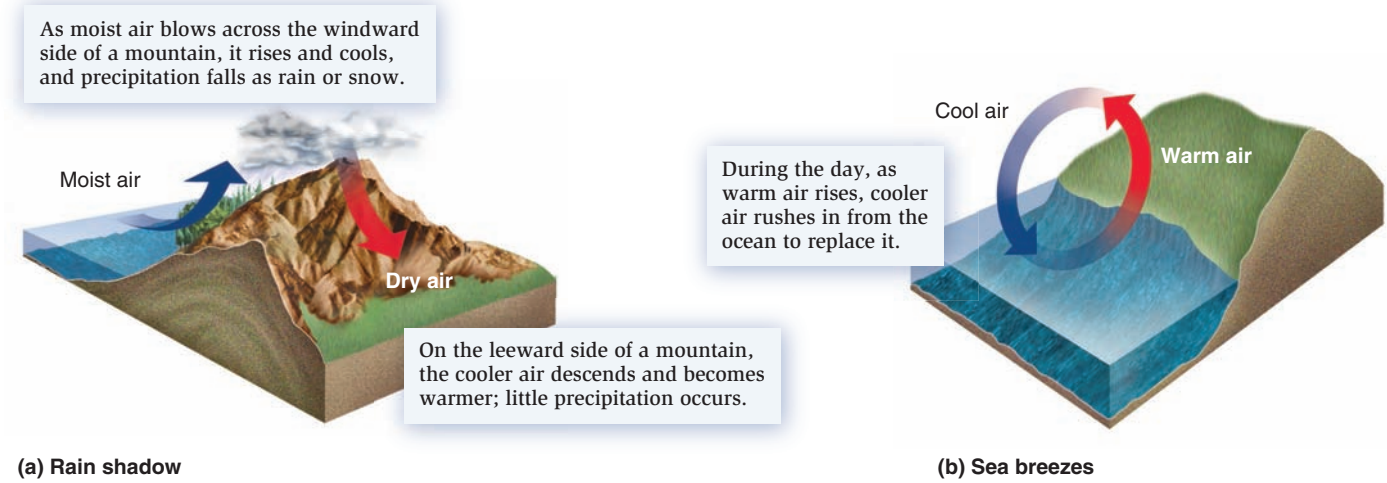

Figure 54.21 **The influence of elevation and proximity to water on climate.**

(**Figure 54.21a**). In this way, the western side of the Cascade Range in Washington State receives more than 500 cm of annual precipitation, whereas the eastern side receives only 50 cm.

The proximity of a landmass to a large body of water can affect climate because land heats and cools more quickly than the sea does. Recall from Chapter 2 that water has a very high specific heat—the amount of energy required to raise the temperature of 1 gram of a substance by 1°C. The specific heat of the land is much lower than that of the water, allowing the land to warm quicker than water. During the day, the warmed air rises and cooler air flows in to replace it. This pattern creates the familiar onshore sea breezes in coastal areas (**Figure 54.21b**). At night, the land cools quicker than the sea, and so the pattern is reversed, creating offshore breezes. The sea, therefore, has a moderating effect on the temperatures of coastal regions and especially islands. The climates of coastal regions may differ markedly from those of their climatic zones. Many never experience frost, and fog is often evident. Thus, along coastal areas, vegetation patterns may differ from those in areas farther inland. In fact, some areas of the U.S. would be deserts were it not for the warm water of the sea and the moisture-laden clouds that form above them.

Together with the rotation of the Earth, winds also create ocean currents. The major ocean currents act as "pinwheels" between continents, running clockwise in the ocean basins of the Northern Hemisphere and counterclockwise in those of the Southern Hemisphere (**Figure 54.22**). The Gulf Stream, equivalent in flow to 50 times the world's major rivers combined, brings warm water from the

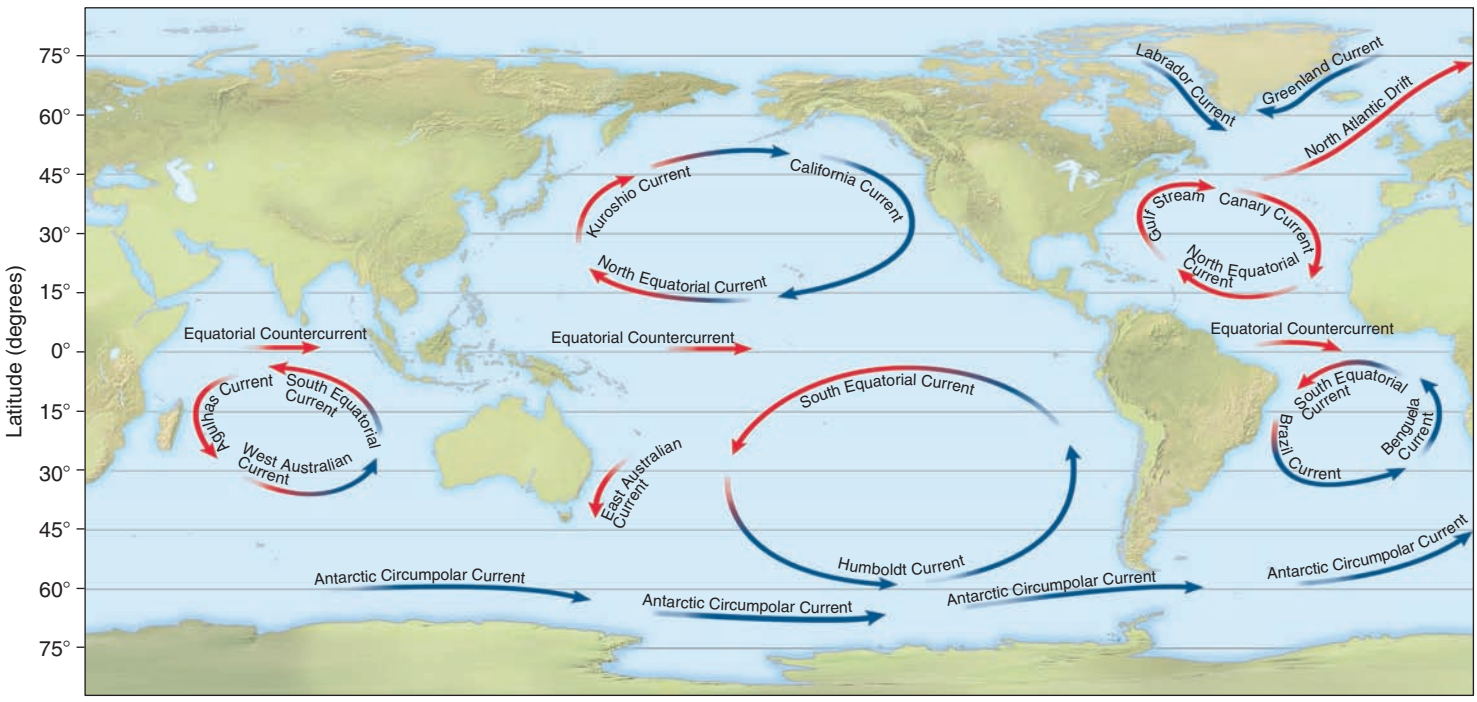

Figure 54.22 **Major ocean currents of the world.** The red arrows represent warm water; the blue arrows, cold water.

Caribbean and the U.S. coasts across the Atlantic Ocean, where it combines with the North Atlantic Drift to moderate the climate of Europe. The Humboldt Current brings cool conditions to the western coast of South America and almost to the equator, and the California Current brings cooler climate to the Hawaiian Islands.

54.5 Major Biomes

Learning Outcomes:

1. **SciSKILLS** » Predict how changes in temperature and rainfall affect the distribution patterns of terrestrial biomes.
2. Discuss how changes in water salinity, oxygen content, depth, and current affect aquatic biomes.

Differences in climate on Earth help to define its different terrestrial biomes. Many types of classification schemes are used for mapping the geographic extent of terrestrial biomes, but one of the most useful was developed by the American ecologist Robert Whittaker, who classified biomes according to the physical factors of average annual precipitation and temperature (**Figure 54.23**). This classification scheme recognizes 10 terrestrial biomes (**Figure 54.24**). Aquatic biomes are generally differentiated by water salinity, current strength, water depth, oxygen content, and light availability. In this section, we will explore the main characteristics of Earth's major terrestrial and aquatic biomes.

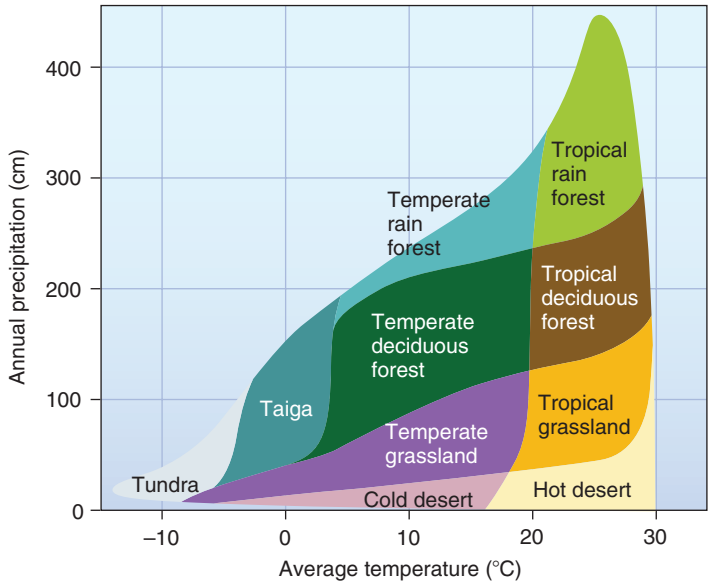

Figure 54.23 The relationship between the world's terrestrial biome types and temperature and precipitation patterns.

Concept Check: What other factors may influence biome types?

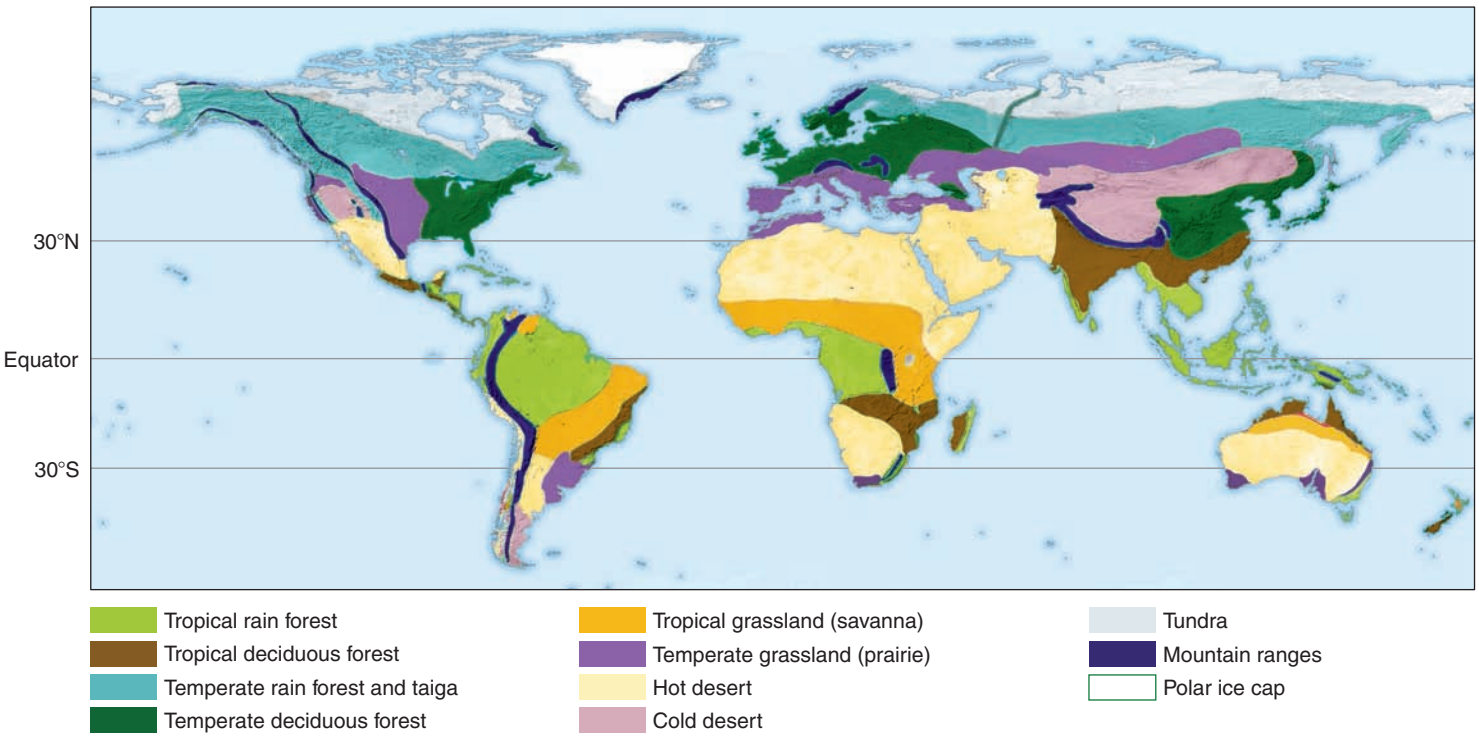

Figure 54.24 Geographic location of terrestrial biomes. The distribution patterns of taiga and temperate rain forest are combined because of their similarity in tree species and because temperate rain forest is actually limited to a very small area.

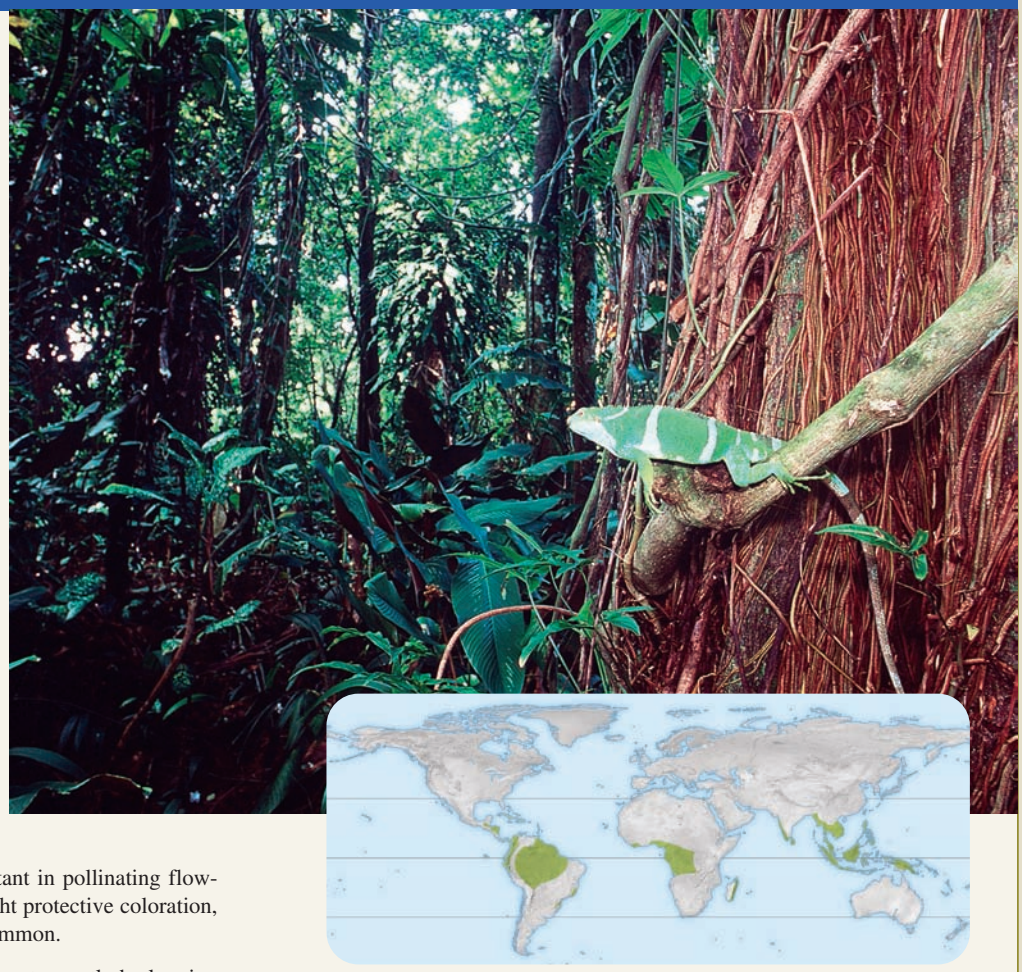


Concept Check: In a globally warmed world, what biome might expand into areas currently occupied by tundra?

Terrestrial Biomes

Figure 54.25a–j illustrates the 10 major terrestrial biomes and identifies their main characteristics. Although broad terrestrial biomes are a useful way of defining the main types of communities on Earth, ecologists acknowledge that not all communities fit neatly into 1 of these 10 major biome types. Also, one biome type often grades into another, as seen on mountain ranges (**Figure 54.25k**). Soil conditions can also influence biome type. In California, serpentine soils, which are dry and nutrient-poor, support only sparse vegetation. In the eastern U.S., most of New Jersey's coastal plain, called the Pine Barrens, consists of sandy, nutrient-poor soil that cannot support the surrounding deciduous forest and instead contains grasses and low shrubs growing among open stands of pygmy pitch pine and oak trees.

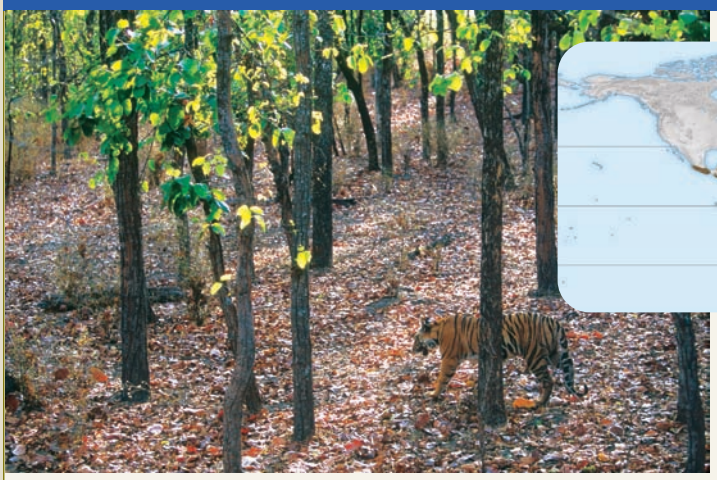
Tropical Rain Forest

Figure 54.25a

Tropical rain forest in Fiji

Physical Environment: Rainfall exceeds 230 cm per year, and the temperature is hot year round, averaging 25–29°C. Soils are often shallow and nutrient-poor.

Location: This biome is found in equatorial regions. Tropical forests cover much of northern South America, Central America, western and central Africa, Southeast Asia, and various islands in the Indian and Pacific oceans.



Plant Life: The numbers of plant species found in tropical forests can be staggering, often reaching as many as 100 tree species per square kilometer. Leaves often narrow to "drip-tips" at the apex so that rainwater drains quickly. Many trees have large buttresses that help support their shallow root systems. Little light penetrates the **canopy**, the uppermost layer of tree foliage, and the ground cover is often sparse. Vines and epiphytes, plants that live perched on trees and are not rooted in the ground, are common.

Animal Life: Animal life in the tropical rain forests is diverse; insects, reptiles, amphibians, and mammals are well represented. Large mammals, however, are not common. Because many of the plant species are widely scattered in tropical forests, plants do not typically rely on wind for pollination or to disperse their seed. Instead, animals are important in pollinating flowers and dispersing fruits and seeds. Mimicry and bright protective coloration, warning of bad taste or the existence of toxins, are common.

Effects of Humans: Humans are affecting tropical forests greatly by logging and by clearing the land for agriculture. Many South American tropical forests are cleared to create grasslands for cattle.

Tropical Deciduous Forest

Figure 54.25b

Tropical deciduous forest in Bandhavgarh National Park, India

Physical Environment: Rainfall is substantial, at around 130–280 cm a year, and temperatures are hot year round, averaging 25–39°C. This biome experiences a distinct dry season that often lasts 2–3 months or longer. Soil water shortages can occur in the dry season.

Location: This biome exists in equatorial regions where rainfall is more seasonal than in tropical rain forests. Much of India consists of tropical deciduous forest, containing teak trees. Brazil, Thailand, and Mexico also contain tropical deciduous forest. At the wet edges of this biome, it may grade into tropical rain forests; at the dry edges, it may grade into tropical grasslands or savannas.

Plant Life: Because of the biome's distinct dry season, many of the trees in tropical deciduous forests shed their leaves, just as they do in temperate forests, and an understory of herbs and grasses may grow during this time. Where the dry season is 6–7 months long, tropical deciduous forests may contain shorter, thorny plants such as acacia trees, whose thorns deter moisture-seeking animals, and the forest is then referred to as a tropical thorn forest.

Animal Life: The diversity of animal life is high, and species such as monkeys, antelopes, wild pigs, and tigers are present. However, as with plant diversity, animal diversity is less than that of tropical rain forests. Tropical thorn forests may contain more browsing mammals; hence, the evolution of plant thorns as a defense.

Effects of Humans: The soil of tropical deciduous forests is more fertile than that of tropical rain forests. Land is increasingly being logged and cleared for agriculture and a growing human population.

Temperate Rain Forest

Figure 54.25c

Hoh Rain Forest in Olympic National Park, Washington

Physical Environment: Rainfall is abundant, usually exceeding 200 cm a year. The condensation of water from dense coastal fogs augments the normal rainfall. Temperatures seldom drop below freezing in the winter, and summer temperatures rarely exceed 27°C.

Location: The area of this biome type is small, consisting of a thin strip along the northwest coast of North America from northern California through Washington State, British Columbia, and into southeastern Alaska (where it is called tongass). It also exists in southwestern South America along the Chilean coast. It is found only in coastal locales because of the moderating influence of the ocean on air temperature.

Plant Life: The dominant vegetation type, especially in North America, consists of large evergreen trees such as western hemlock, Douglas fir, and Sitka spruce. The high moisture content allows epiphytes to thrive. Cool temperatures slow the activity of decomposers, so the litter layer is thick and spongy.

Animal Life: In North America, the temperate rain forest is rich in species such as mule deer, elk, squirrels, and numerous birds such as jays and nuthatches. Because of the abundant moisture and moderate temperatures, reptiles and amphibians are also common.

Effects of Humans: This biome is a prolific producer of wood and supplies much timber; logging threatens the survival of the forest in some areas.

Terrestrial Biomes (continued)

Temperate Deciduous Forest

Figure 54.25d

Temperate deciduous forest in Minnesota

Physical Environment: Annual rainfall is generally between 75 and 200 cm. Temperatures fall below freezing each winter but not usually below –12°C.

Location: Large tracts of temperate deciduous forest are evident in the eastern U.S., Western Europe, and eastern Asia. In the Southern Hemisphere, eucalyptus forests occur in Australia, and stands of southern beech are found in southern South America, New Zealand, and Australia.

Plant Life: Species diversity is much lower in temperate deciduous forests than in the tropical forests, with about only three to four tree species per square kilometer, and several tree genera may be dominant in a given locality—for example, oaks, hickories, and maples are usually dominant in the eastern U.S. Commonly, leaves are shed in the fall and reappear in the spring. Many herbaceous plants flower in spring before the trees leaf out and block the light. Even in the summer, though, the forest is not as dense as in tropical forests, so ground cover is abundant.

Animal Life: Animals are adapted to the vagaries of the climate; many mammals hibernate during the cold months, birds migrate, and insects enter diapause, a condition of dormancy passed usually as a pupa. Reptiles, which depend on solar radiation for heat, are relatively uncommon. Mammals include squirrels, wolves, bobcats, foxes, bears, and mountain lions.

Effects of Humans: Logging has eliminated much of the temperate deciduous forest from populated portions of Europe and North America. Because the annual leaf drop promotes high soil nutrient levels, soils are rich and easily converted to agriculture. Much of the human population lives in the regions where temperate deciduous forest is found, and both agriculture and development are threats to the biome.

Temperate Coniferous Forest (Taiga)

Figure 54.25e

Temperate coniferous forest in Canada

Physical Environment: Precipitation is generally between 30 and 100 cm and often occurs in the form of snow. Temperatures are very cold, often below freezing for long periods of time.

Location: The biome of temperate coniferous forest, known commonly by its Russian name, taiga, lies north of the temperate-zone forests and grasslands. Vast tracts of taiga exist in North America and Russia. In the Southern Hemisphere, little land area occurs at latitudes at which extensive taiga could exist.

Plant Life: Most of the trees are evergreens or conifers with tough needles, hence the similarity of taiga to temperate rain forest. In this biome, spruces, firs, and pines generally dominate, and the number of tree species is relatively low. Many of the conifers have conical shapes to reduce bough breakage from heavy loads of snow. As in tropical forests, the understory is sparse because the dense year-round canopies prevent sunlight from penetrating. Soils are poor because the fallen needles decay so slowly in the cold temperatures that a layer of needles builds up and acidifies the soil, reducing the numbers of understory species.

Animal Life: Reptiles and amphibians are rare because of the low temperatures. Insects are strongly periodic but may often reach outbreak proportions in times of warm temperatures. Mammals that inhabit this biome, such as bears, lynxes, moose, beavers, and squirrels, are heavily furred.

Effects of Humans: Humans have not extensively settled these areas, but they have been quite heavily logged. Exploration and development of oil and natural gas reserves are also a threat.

Tropical Grassland (Savanna)

Figure 54.25f

Tropical grassland of the Masai Mara Game Reserve in Kenya

Physical Environment: This biome includes hot, tropical areas, with a low or seasonal rainfall between 50 and 130 cm per year. There is often an extensive dry season. Temperatures average 24–29°C.

Location: Extensive savannas occur in Africa, South America, and northern Australia.

Plant Life: Wide expanses of grasses dominate savannas, but occasional thorny trees, such as acacias, may occur. Fire is prevalent in this biome, so most plants have well-developed root systems that enable them to resprout quickly after a fire.

Animal Life: The world's greatest assemblages of large mammals occur in the savanna biome. Herds of antelope, zebra, and wildebeest are found, together with their associated predators: cheetah, lion, leopard, and hyena. Termite mounds dot the landscape in some areas. The extensive herbivory of large grazers, together with frequent fires, may help maintain savannas and prevent their development into forests.

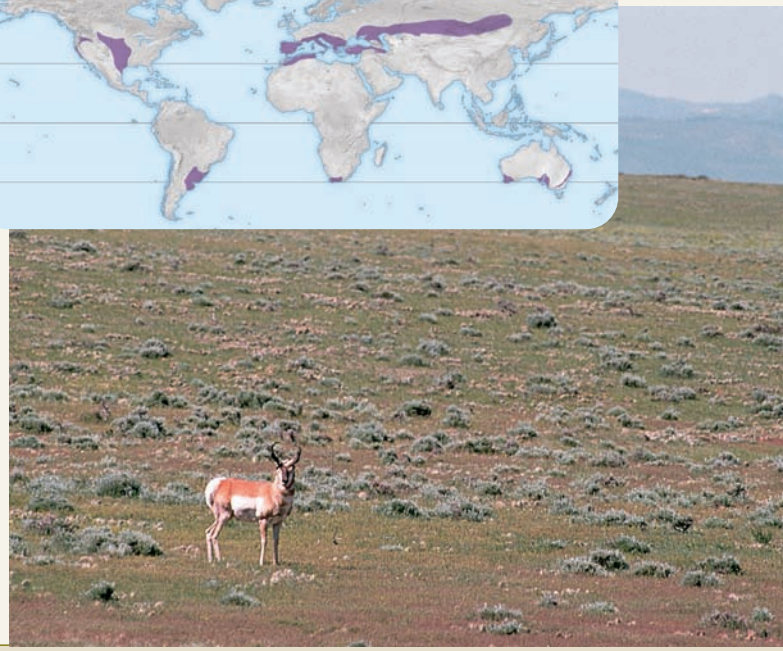
Effects of Humans: Savanna soils are often poor because the occasional rain leaches nutrients. Nevertheless, conversion of this biome to agricultural land is rampant, especially in Africa. Overstocking of land for pasturage of domestic animals can greatly reduce grass coverage through overgrazing, turning the area desert-like. This process is known as **desertification**.

Temperate Grassland (Prairie)

Figure 54.25g

Temperate grassland in Wyoming

Physical Environment: Annual rainfall is generally between 25 and 100 cm, too low to support a forest but higher than that in deserts. Temperatures in the winter sometimes fall below –10°C, whereas summers may be very hot, approaching 30°C.



Location: Temperate grasslands include the prairies of North America, the steppes of Russia, the pampas of Argentina, and the veldt of South Africa. In addition to the limiting amounts of rain, fire and grazing animals may also prevent the establishment of trees in the temperate grasslands. Where temperatures rarely fall below freezing and most of the rain falls in the winter, chaparral, a fire-adapted community featuring shrubs and small trees, occurs. Chaparral is seen at around 30° latitude, where cool ocean waters moderate the climate, as along the coasts of California, South Africa, Chile, and southwest Australia and in countries surrounding the Mediterranean Sea. Some ecologists recognize chaparral as a distinct biome type.

Plant Life: From east to west in North America and from north to south in Asia, grasslands show differentiation along moisture gradients. In Illinois, with an annual rainfall of 80 cm, tall prairie grasses such as big bluestem and switchgrass grow to about 2 m high. Along the eastern base of the Rockies, 1,300 km to the west, where rainfall is only 40 cm, prairie grasses such as buffalo grass and blue grama rarely exceed 0.5 m in height. Similar gradients occur in South Africa and Argentina.

Animal Life: Where the grasslands remain, large mammals are the most prominent members of the fauna: bison and pronghorn in North America, wild horses in Eurasia, and large kangaroos in Australia. Burrowing animals such as North American gophers and African mole rats are also common.

Effects of Humans: Prairie soil is among the richest in the world, having 12 times the humus layer of a typical forest soil. Worldwide, most prairies have been converted to agriculture, and original temperate grassland habitats are among the rarest biomes in the world.

Terrestrial Biomes (continued)

Hot Desert

Figure 54.25h

The Namib Desert, Namibia

Physical Environment: Rainfall is generally less than 30 cm per year. Temperatures are variable, from below freezing at night to as high as 50°C in the day.

Location: Hot deserts are found around latitudes of 20–30° north and south. Prominent deserts include the Sahara of North Africa, the Kalahari and Namib of southern Africa, the Atacama of Chile, the Sonoran of northern Mexico and the southwest U.S., and the Simpson of Australia.

Plant Life: Three forms of plant life are adapted to deserts: annuals, succulents, and desert shrubs. Annuals circumvent drought by growing only when there is rain. Succulents, such as the saguaro cactus and other barrel cacti of the southwestern deserts, store water. Desert shrubs, such as the spraylike ocotillo, have short trunks, numerous branches, and small, thick leaves that can be shed in prolonged dry periods. In many plants, spines or volatile chemical compounds serve as a defense against water-seeking herbivores.

Animal Life: To conserve water, desert plants produce many small seeds, and animals that eat those seeds, such as ants, birds, and rodents, are common. Reptiles are numerous, because high temperatures permit these ectothermic animals to maintain a warm body temperature. Lizards and snakes are important predators of seed-eating mammals.

Effects of Humans: Ambitious irrigation schemes and the prolific use of underground water have allowed humans to develop deserts and grow crops there. Salinization, a buildup in the salt content of the soil that results from irrigation in areas of low rainfall, is prevalent. Off-road vehicles can disturb the fragile desert communities.

Cold Desert

Figure 54.25i

The Gobi Desert of Mongolia

Physical Environment: Precipitation is less than 25 cm a year and is often in the form of snow. Rainfall usually comes in the spring. In the daytime, temperatures can be high in the summer, 21–26°C, but average around freezing, –2 to 4°C, in the winter.

Location: Cold deserts are found in dry regions at middle to high latitudes, especially in the interiors of continents and in the rain shadows of mountains. Cold deserts are found in North America (the Great Basin Desert), in eastern Argentina (the Patagonian Desert), and in central Asia (the Gobi Desert).

Plant Life: Cold deserts are relatively poor in terms of numbers of plant species. Most plants are small in stature, being only between 15 and 120 cm tall. Many species are deciduous and spiny. The Great Basin Desert in Nevada, Utah, and bordering states is a cold desert dominated by sagebrush.

Animal Life: As in hot deserts, large numbers of plants produce small seeds on which numerous ants, birds, and rodents feed. Many species live in burrows to escape the cold. In the Great Basin Desert, pocket mice, jackrabbits, kit foxes, and coyotes are common.

Effects of Humans: Agriculture is hampered because of low temperatures and low rainfall, and human populations are not extensive. If the top layer of soil is disturbed by human intrusions, such as by off-road vehicles, erosion occurs rapidly and even less vegetation can exist.

Tundra

Figure 54.25j

Denali National Park in Alaska

Physical Environment: Precipitation is generally less than 25 cm per year and is often locked up as snow and unavailable for plants. Deeper water can be locked away for a large part of the year in **permafrost**, a layer of permanently frozen soil. The growing season is short, only 50–60 days. Summer temperatures are only 3–12°C, and even during the long summer days, the ground thaws to less than 1 m in depth. Midwinter temperatures average –32°C.

Location: Tundra (from the Finnish *tunturia*, meaning treeless plain) exists mainly in the Northern Hemisphere, north of temperate coniferous forest, because very little land area is in the Southern Hemisphere at the latitude where tundra would occur.

Plant Life: With so little available water, trees cannot grow. Vegetation occurs in the form of fragile, slow-growing lichens, mosses, grasses, sedges, and occasional shrubs, which grow close to the ground. Plant diversity is very low. In some places, desert conditions prevail because so little moisture falls.

Animal Life: Animals of the arctic tundra have adapted to the cold by having good insulation. Many birds, especially shorebirds and waterfowl, migrate. The fauna is much richer in summer than in winter. Many insects spend the winter at immature stages of growth, which are more resistant to cold than the adult forms. Larger animals include such herbivores as musk oxen and caribou in North America, called reindeer in Europe and Asia. Smaller animals include hares and lemmings. Common predators include arctic fox, wolves, and snowy owls, and polar bears near the coast.

Effects of Humans: Though this area is sparsely populated, mineral extraction, especially of oil, has the potential to significantly affect this biome. Ecosystem recovery from such damage would be very slow.

Mountain Ranges

Figure 54.25k

Rocky Mountains of Colorado

Physical Environment: Mountain ranges must be viewed differently from other biomes. On mountains, temperature decreases with increasing elevation through adiabatic cooling, as discussed previously. Thus, precipitation and temperature may change dramatically, depending on elevation and whether the mountainside is to windward or leeward.

Location: Mountain ranges exist in many areas of the world, but among the largest are the Himalayas in Asia, the Rockies in North America, and the Andes in South America.

Plant Life: A variety of biomes can be found on a single mountain range. Biome type may change from temperate forest through taiga and into tundra on an elevation gradient in the Rocky Mountains, and even from tropical forest to tundra on the highest peaks of the Andes in tropical South America. In tropical regions, daylight averages 12 hours per day throughout the year. Instead of a period of intense productivity seen in arctic tundra, vegetation in the tropical alpine tundra exhibits slow but steady rates of photosynthesis and growth all year.

Animal Life: The animals of this biome are as varied as the number of habitats they contain. Generally, more species of plants and animals are found at lower elevations than at higher ones. At higher elevations, animals such as bighorn sheep and mountain goats climb the craggy slopes and have skidproof pads on their hooves. Birds of prey, such as eagles, are frequent predators of the furry rodents found at higher elevations, including guinea pigs and marmots.

Effects of Humans: Logging and agriculture at lower elevations can cause habitat degradation. Because of the steep slopes, mountain soils are often well drained, thin, and especially susceptible to erosion following agriculture.

Aquatic Biomes

Aquatic Biomes Consist of Marine and Freshwater Regions

Within aquatic environments, several different biome types are also recognized, including marine aquatic biomes (intertidal zone, coral reef, and open ocean) and freshwater habitats (lakes, rivers, and wetlands). These biomes are distinguished primarily by differences in salinity, oxygen content, depth, current strength, and availability of light (**Figure 54.26a–f**). Freshwater habitats are traditionally divided into **lentic**, or standing-water habitats (from the Latin *lenis*, meaning calm), and **lotic**, or running-water habitats (from the Latin *lotus*, meaning washed).

Intertidal Zone

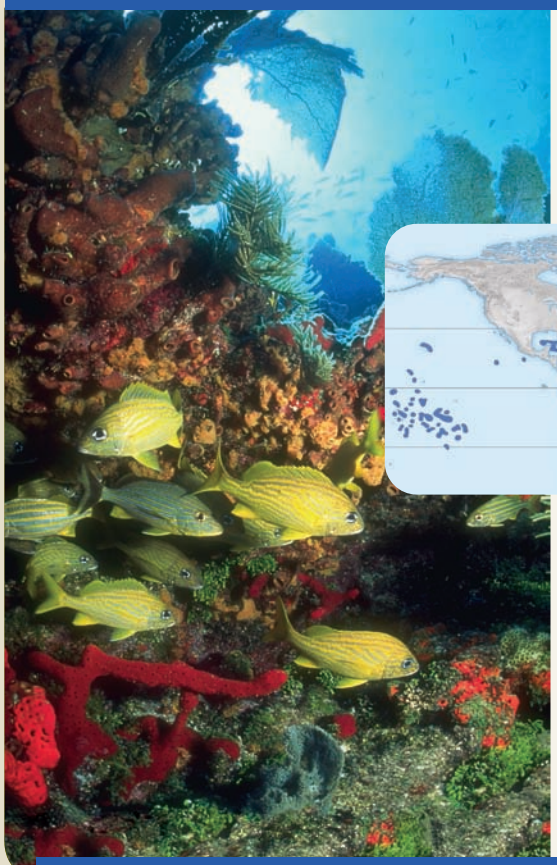
Figure 54.26a

Olympic Coast National Marine Sanctuary in Washington State

Physical Environment: The **intertidal zone**, the area where the land meets the sea, is alternately submerged and exposed by the daily cycle of tides. The resident organisms are subject to huge daily variations in temperature, light intensity, and availability of seawater.

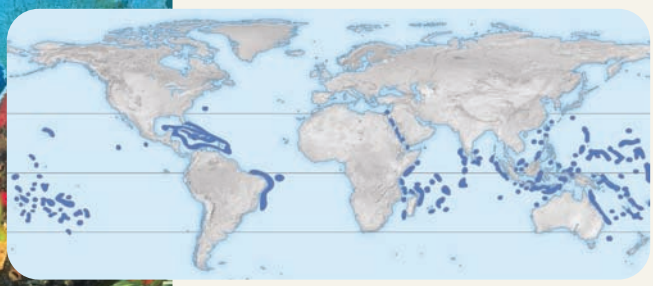
Location: Throughout the world, the area where the land meets the sea consists of sandy shore, mudflats, or rocky shore.

Plant Life: Plant life may be quite limited because the sand or mud is constantly shifted by the tide. Mangroves may colonize mudflats in tropical areas, and salt marsh grasses may colonize mudflats in temperate locations. On the rocky shore, green algae and seaweeds predominate.



Animal Life: Animal life may be quite diverse. On the rocky shore, sea anemones, snails, hermit crabs, and small fishes live in tide pools. On the rock face, there may be a variety of limpets, mussels, sea stars, sea urchins, snails, sponges, tube worms, whelks, isopods, and chitons. At low tides, organisms may be dry and vulnerable to predation by a variety of animals, including birds and mammals. High tides bring predatory fishes. Sandy or muddy shores may contain burrowing marine worms, crabs, and small isopods.

Effects of Humans: Human development has greatly reduced the beach area available to shorebirds and breeding turtles. Oil spills have greatly affected some rocky intertidal areas.



Coral Reef

Figure 54.26b

Caribbean coral reef

Physical Environment: Corals need warm water of at least 20°C but less than 30°C (refer back to Figure 54.6). They are also limited to the photic zone, where light penetrates and allows photosynthesis to occur. Sunlight is important because many corals harbor symbiotic algae, or dinoflagellates, that contribute nutrients to the animals and that require light to live.

Location: Coral reefs exist in warm tropical waters where there are solid substrates for attachment and water clarity is good. The largest coral reef in the world is the Great Barrier Reef off the Australian coastline, but other coral reefs are found in the Atlantic Ocean, the Red Sea, and the Pacific and Indian Oceans.

Plant Life: Dinoflagellate algae live within the coral tissue, and a variety of red and green algae live on the coral reef surface.

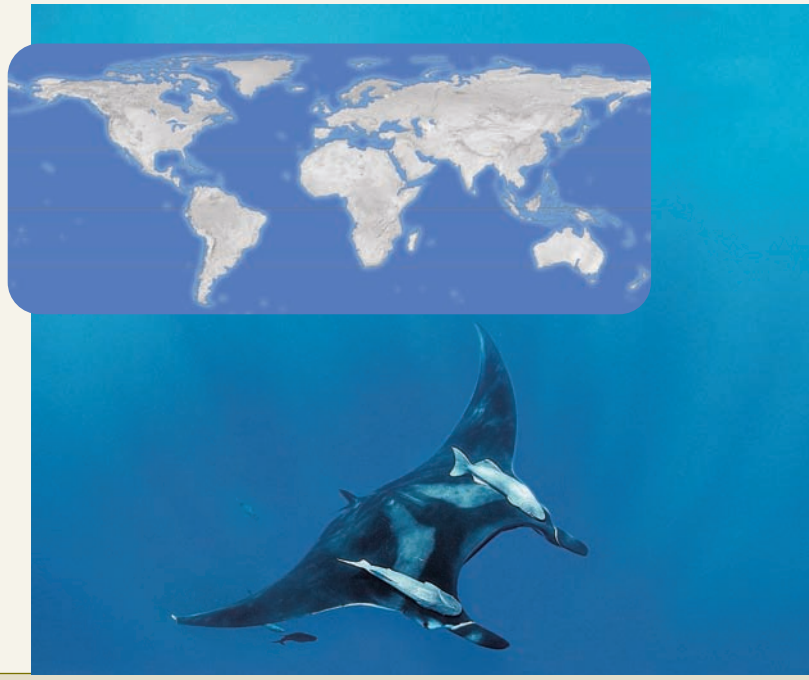
Animal Life: An immense variety of microorganisms, invertebrates, and fishes live among the coral, making the coral reef one of the most interesting and species-rich biomes on Earth. Probably 30–40% of all fish species on Earth are found on coral reefs. Prominent herbivores include snails, sea urchins, and fishes. These are consumed by octopuses, sea stars, and carnivorous fishes. Many species are brightly colored, warning predators of their toxic nature.

Effects of Humans: Collectors have removed many corals and fishes for the aquarium trade, and marine pollution threatens water clarity in some areas. Perhaps the greatest threat to coral reefs is global warming. Water temperatures that are too high (over 30°C) and high pH caused by elevated CO_2 levels both contribute to coral bleaching.

The Open Ocean

Figure 54.26c

Manta ray in the open ocean

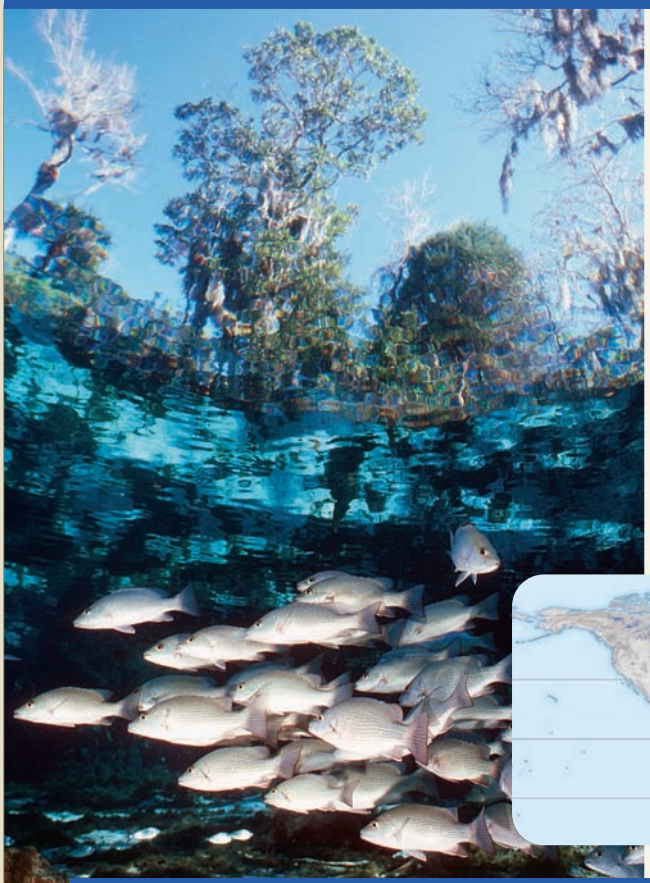


Physical Environment: In the open ocean, sometimes called the **pelagic zone**, water depth averages 4,000 m. Nutrient concentrations are typically low, though the waters may be periodically enriched by ocean **upwelling**, the circulation of cold, mineral-rich nutrients from deeper water to the surface. Pelagic waters are mostly cold, only warming near the surface.

Location: Across the globe, covering 70% of the Earth's surface.

Plant Life: In the photic zone, many microscopic photosynthetic organisms **(phytoplankton)** grow and reproduce while drifting in ocean currents. Phytoplankton account for nearly half the photosynthetic activity on Earth and produce much of the world's oxygen.

Animal Life: Open-ocean organisms include **zooplankton**, minute drifting animal organisms consisting of some worms, copepods (tiny shrimplike creatures), small jellyfish, and small invertebrate and fish larvae that graze on the phytoplankton. The open ocean also includes free-swimming animals collectively called **nekton**, which can swim against the currents to locate food. Nekton includes large squids, fishes, sea turtles, and marine mammals. Only a few of these organisms live at any great depth. In some areas, a unique assemblage of animals is associated with deep-sea hydrothermal vents that spew hot (350°C) water rich in hydrogen sulfide. Large worms and other chemoautotrophic organisms exist together in this dark, oxygen-poor environment (refer back to Figure 22.3).



Effects of Humans: Oil spills and a long history of garbage disposal have polluted the ocean floors of many areas. Overfishing has caused many fish populations to crash, and the whaling industry has greatly reduced the numbers of most species of whales.

Aquatic Biomes (continued)

Lentic Habitats

Figure 54.26d

Everglades National Park, Florida

Physical Environment: The lentic habitat consists of still, often deep water. Its physical characteristics depend greatly on the surrounding land, which dictates what nutrients collect in the lake. Young lakes often start off clear and with little plant life. Such lakes are called **oligotrophic**. With age, the lake becomes richer in dissolved nutrients from erosion and runoff from surrounding land, with the result that cyanobacteria and algae spread, reducing the water clarity. Such lakes are termed **eutrophic**. The process of eutrophication occurs naturally but can be sped up by human activities (see Chapter 59).

Location: Throughout all the continents of the world.

Plant Life: In addition to phytoplankton, lentic habitats may have rooted vegetation, which often extends above the water surface (emergent vegetation), such as cattails, plus deeper-dwelling aquatic plants and algae.

Animal Life: Animals include fishes, frogs, turtles, crayfish, insect larvae, and many species of insects. In tropical and subtropical lakes, alligators and crocodiles are common.

Effects of Humans: Agricultural runoff, including fertilizers and sewage, can greatly increase lake nutrient levels and speed up the process of eutrophication, resulting in phytoplankton blooms and fish kills. In some areas, invasive species of invertebrates and fishes are outcompeting native species.

Lotic Habitats

Figure 54.26e

Fast-flowing river in the Pacific Northwest

Physical Environment: In lotic habitats, flowing water prevents nutrient accumulations and phytoplankton blooms. The current also mixes water thoroughly, providing a well-aerated habitat of relatively uniform temperature. The current, oxygen level, and clarity are greater at the source of a stream (its headwaters) than in the lower reaches of rivers. Nutrient levels are generally less in headwaters.

Location: On all continents except Antarctica.

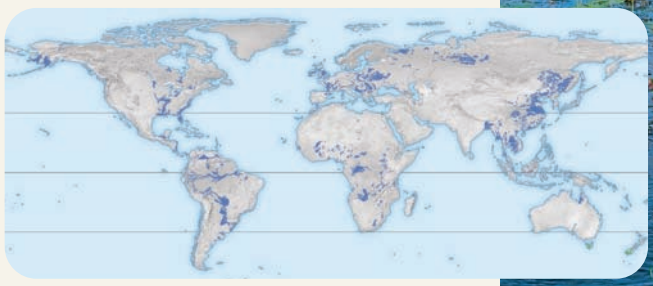
Plant Life: In slow-moving streams and rivers, algae and rooted plants may be present; in faster-moving rivers, leaves from surrounding forests are the primary food source for animals.

Animal Life: Lotic habitats have a fauna completely different from that of lentic waters. Animals are adapted to stay in place despite an often-strong current. Many of the smaller organisms are flat and attach themselves to rocks to avoid being swept away. Others live on the underside of large boulders, where the current is much reduced. Fish such as trout may be present in rivers with cool temperatures, high oxygen, and clear water. In warmer, murkier waters, catfish and carp may be abundant.

Effects of Humans: Animals of lotic systems are not well adapted for low-oxygen environments and thus are particularly susceptible to oxygen-reducing pollutants such as sewage. Dams across rivers have prevented the passage of migratory species such as salmon.

Wetlands

Figure 54.26f



Yellow Waters River, Kakadu National Park, Northern Territory, Australia

Physical Environment: At the margins of both lentic and lotic habitats, wetlands may develop. Wetlands are areas regularly saturated by surface water or groundwater. They range from marshes (treeless areas where herbaceous species predominate), to swamps (wet areas dominated by trees), and bogs (depressions dominated by marshes). Many wetlands are seasonally flooded when rivers overflow their banks or lake levels rise. Some wetlands also develop along estuaries, areas where river water merges with ocean water, and high tides can flood the land. Because of generally high nutrient levels, oxygen levels are fairly low. Temperatures vary substantially with location.

Location: Worldwide, except in Antarctica.

Plant Life: Wetlands are among the most productive, species-rich areas in the world. In North America, floating plants such as lilies and rooted species such as sedges, cattails, cypress, and gum trees predominate.

Animal Life: Most wetlands are rich in animal species. Wetlands are a prime habitat for wading and diving birds. In addition, they are home to a profusion of insects, from mosquitoes to dragonflies. Vertebrate predators include many amphibians, reptiles, otters, and alligators.

Effects of Humans: Long mistakenly regarded as wasteland by humans, many wetlands have been drained and developed for housing and industry. Wetlands play a valuable role in protecting coastal communities from hurricanes, and the loss of wetlands in Louisiana contributed to the severity of effects of Hurricane Katrina in 2005.

54.6 Continental Drift and Biogeography

Learning Outcomes:

1. Describe how the distribution of species on Earth may result from continental drift.
2. Explain the concept of biogeographical regions.

A knowledge of biomes does not tell us everything about the distribution of plant and animal life on Earth. An understanding of evolution and geological change over large scales and time periods helps explain some of the patterns we see. **Biogeography**, the study of the geographic distribution of extinct and living species, is an important part of the field of ecology. For example, South America, Africa, and Australia all have similar biomes, ranging from tropical to temperate, yet each continent has distinctive animal life. South America is inhabited by sloths, anteaters, armadillos, and monkeys with prehensile tails. Africa possesses a wide variety of antelopes, zebras, giraffes, lions, baboons, the okapi, and the aardvark. Australia, which has no native placental mammals except bats, is home to a variety of marsupials such as kangaroos, koala bears, Tasmanian devils, and wombats, as well as the egg-laying monotremes, namely, the duck-billed platypus and four species of echidnas. Most continents also have distinct species of plants; for example, eucalyptus trees are native only in Australia. In South American deserts, succulent plants belong to the family Cactaceae, the cacti. In Africa, they belong to the genus *Euphorbia*, the spurges. In North America, the pines, *Pinus* spp., and firs, *Abies* spp., are common, but they do not occur south of the mountains of central Mexico. In contrast, palms are common in South America and do not generally occur north of the mountains of central Mexico, except for several genera in southern California and Florida.

A plausible explanation for these species distributions is that abiotic factors are of paramount importance and that each region supports the fauna best adapted to it. However, the spread of introduced species has proved this explanation incorrect: European rabbits introduced into Australia proliferated rapidly, and eucalyptus from Australia grows well in California. The best explanation is that different floras and faunas are the result of the independent evolution of separate, unconnected populations, which have generated different species in different places. A knowledge of biogeography, continental drift, and evolution is therefore of great importance in understanding the contemporary distributions of species.

The relative location of the landmasses on Earth has changed enormously over time as a result of **continental drift**, the slow movement of the Earth's surface plates (refer back to Figure 22.10). Continental drift explains the occurrences of similar living plant

and animal species, and fossils, in South America, Africa, India, Antarctica, and Australia. Many of these fossils were of large land animals, such as the Triassic reptiles *Lystrosaurus* and *Cynognathus*, that could not have easily dispersed among continents, or of plants whose seeds were not likely to be dispersed far by wind, such as the fossil fern *Glossopteris*. Also, the discovery of abundant fossils in Antarctica was proof that this presently frozen land must have been situated much closer to temperate areas in earlier geological times (**Figure 54.27**).

Continental drift is not the only mechanism that creates widely separate populations of closely related species, called disjunct distributions. The distributions of many present-day species are relics of once much broader distributions. For example, currently four living species of tapir are known: three in Central and South America and one in Malaysia (**Figure 54.28**). Fossil records reveal a much more widespread distribution over much of Europe, Asia, and North America. The oldest fossils of the ancestral *Paleotapirus* were identified in Europe, making it likely that this was the center of origin of tapirs. Migrations of later-evolving *Protapirus* resulted in a more widespread distribution. Cooling resulted in the demise of tapirs in all areas except the tropical locations.

Another well-known example of a disjunct distribution is the restricted distribution of monotremes and marsupials. These animals were once plentiful over North America and Europe. They spread into the rest of the world, including South America and Australia, at the end of the Cretaceous period when, although the continents were separated, land bridges existed between them. Later, placental mammals evolved in North America and displaced the marsupials there, apart from a few species such as the opossum. However, placental mammals could not invade Australia because by then the land bridge was broken.

Elephants and camels also have disjunct distributions. Elephants evolved in Africa and subsequently dispersed through Eurasia and across the Bering land bridge from Siberia to North America, where many are found as fossils. They subsequently became extinct everywhere except Africa and India. Camels evolved in North America and made the reverse trek across the Bering land bridge into Eurasia; they also crossed into South America via the Central American isthmus. They have since become extinct everywhere except Asia, North Africa, and South America.

Alfred Russel Wallace was one of the earliest scientists to realize that certain plant and animal taxa were restricted to certain geographic areas of the Earth. For example, the distribution patterns of guinea pigs, anteaters, and many other groups are confined to Central and South America, from central Mexico southward. The whole area was distinct enough for Wallace to proclaim it the Neotropical region. Wallace went on to divide the world's biota into six major **biogeographic regions**: Nearctic, Palearctic, Neotropical, Ethiopian,

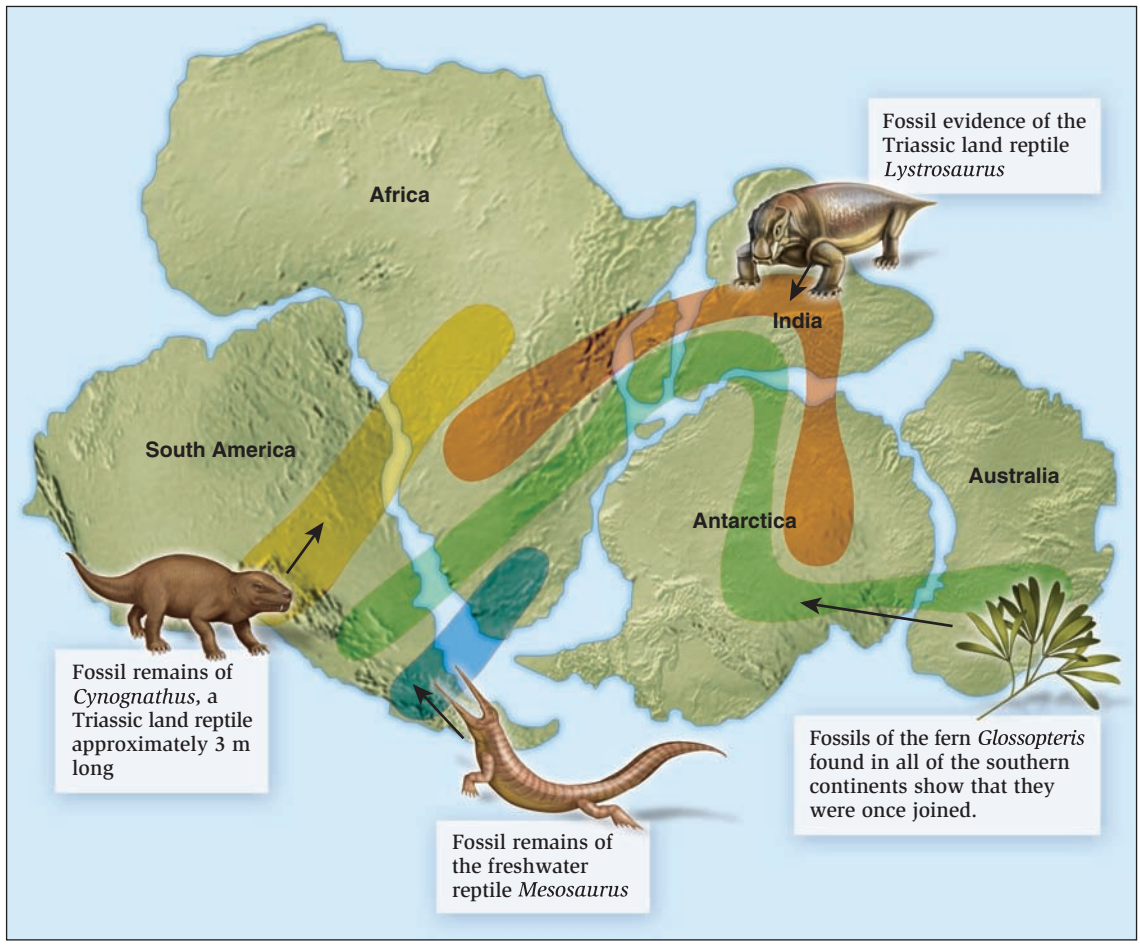


Figure 54.27 The locations of fossil plants and animals on present-day continents can be explained by continental drift. The fossil remains of dinosaurs and ancient plants are spread across regions of South America, Africa, India, Antarctica, and Australia, all of which were once united as Gondwana.

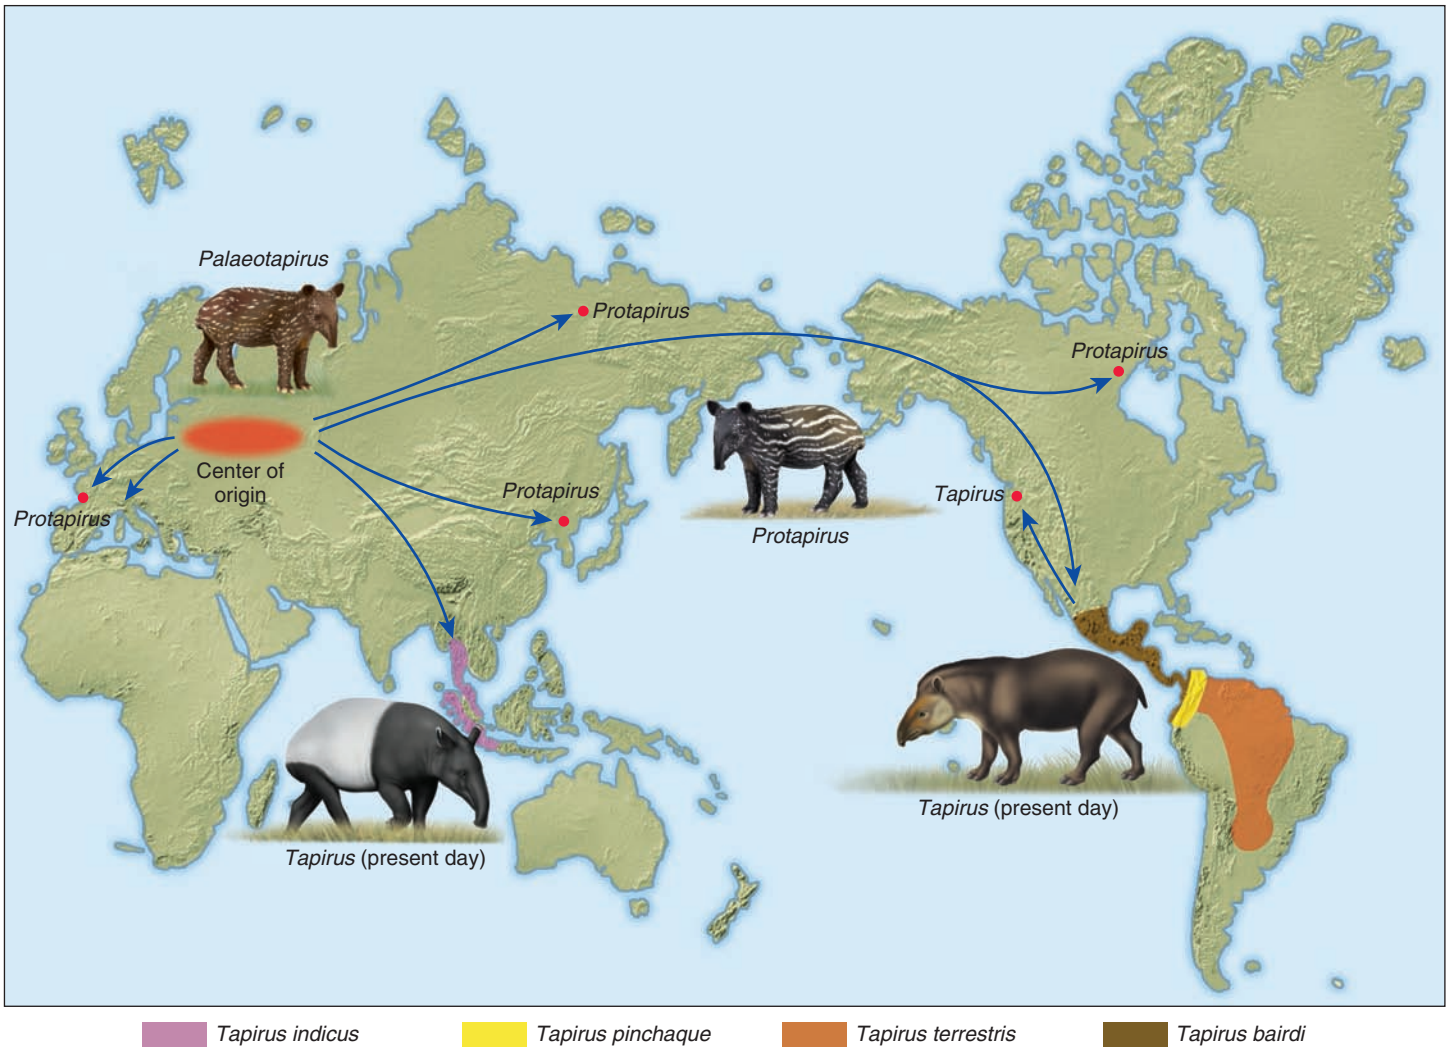

Figure 54.28 Tapir distribution. Of the four living tapir species, three are in Central and South America and one is in Malaysia. Fossil evidence suggests a European origin of the ancestral *Paleotapirus* and a dispersal of later-evolving *Protapirus.* A more widespread distribution followed, with tapirs dying out in other regions (marked with a red dot) possibly due to climate change.

BIOLOGY PRINCIPLE **All life is related by an evolutionary history.** Knowing that all tapir species share a common European ancestor makes it easier to explain their current distribution pattern.

Oriental, and Australian (**Figure 54.29**). These regions are still widely accepted today, though debate continues about the exact locations of the boundary lines.

Biogeographical regions correspond largely to continents but more exactly to areas bounded by major barriers to dispersal, like the Himalayas and the Sahara Desert. Within these regions, areas of similar climates are often inhabited by species with similar appearance and habits but from different taxonomic groups. For example, the kangaroo rats of North American deserts, the jerboas of central Asian deserts, and the hopping mice of Australian deserts look similar and occupy similar hot, arid environments, but they arose from different lineages, belonging to the families Heteromyidae, Dipodidae, and Muridae, respectively. As noted in Chapter 23, this phenomenon, called convergent evolution, has led to the emergence of similar species that have evolved from different ancestors.

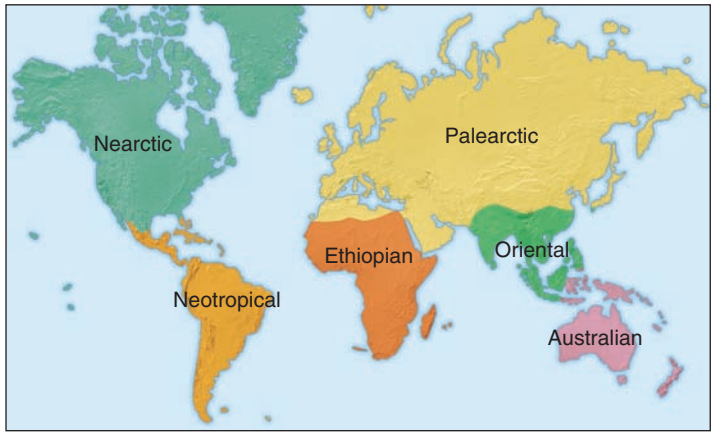

Figure 54.29 The biogeographic regions proposed by A. R. Wallace. Note that the borders do not always demarcate continents.

Summary of Key Concepts

54.1 The Scale of Ecology

- Ecologists study the interactions among organisms and between organisms and their environments. The field of ecology is subdivided into broad areas of organismal, population, community, and ecosystem ecology (Figure 54.1).
- Organismal ecology considers how individuals are adapted to their environment and how the behavior of an individual organism contributes to its survival and reproductive success and the population density of the species. Population ecology explores those factors that influence a population's growth, size, and density. Community ecology studies how populations of species interact and form functional communities. Ecosystem ecology examines the flow of energy and cycling of nutrients among organisms within a community and between organisms and the environment (Figure 54.2).

54.2 Ecological Methods

- Ecological methods focus on observation and experimentation. Interactions among species are often observed and analyzed graphically, and a hypothesis is formed (Figures 54.3, 54.4).
- Ecologists test their hypotheses using well-replicated experiments. The results are often presented graphically and analyzed via a variety of statistical tests (Figure 54.5).

54.3 The Environment's Effect on the Distribution of Organisms

- Abiotic factors such as temperature, wind, water, light, salinity, and pH have powerful effects on ecological systems (Table 54.1).
- Temperature exerts important effects on the distribution of organisms because of its effect on biological processes and the inability of many organisms to regulate their body temperature (Figures 54.6, 54.7, 54.8, 54.9).
- The greenhouse effect is the process in which short-wave solar radiation passes through the atmosphere to warm the Earth and is radiated back into the atmosphere as long-wave infrared radiation. Much of this radiation is absorbed by atmospheric gases and radiated back to the Earth's surface, causing its temperature to rise (Figure 54.10, Table 54.2).
- An increase in atmospheric gases is intensifying the greenhouse effect, causing global warming—a gradual elevation of the Earth's surface temperature (Figure 54.11). Ecologists expect that global warming will have a large effect on the distribution of the world's organisms (Figure 54.12).
- Wind amplifies the effects of temperature and modifies wave action (Figure 54.13).
- The availability of water has an important effect on the abundance of organisms (Figure 54.14).
- Light can be a limiting resource for plants in both terrestrial and aquatic environments (Figure 54.15).
- The concentration of salts and the pH of soil and water can limit the distribution of organisms (Figures 54.16, 54.17).

54.4 Climate and Its Relationship to Biological Communities

- Global temperature differentials are caused by variations in incoming solar radiation and patterns of atmospheric circulation (Figures 54.18, 54.19, 54.20).
- Elevation and the proximity between a landmass and large bodies of water can similarly affect climate (Figures 54.21, 54.22).

54.5 Major Biomes

- Climate has a large effect on biomes, major types of habitats characterized by distinctive plant and animal life (Figures 54.23, 54.24).
- Terrestrial biomes are generally named for their climate and vegetation type and include tropical rain forest, tropical deciduous forest, temperate rain forest, temperate deciduous forest, temperate coniferous forest (taiga), tropical grassland (savanna), temperate grassland (prairie), hot and cold deserts, and tundra. In mountain ranges, biome type may change on an elevation gradient (Figure 54.25).
- Within aquatic environments, biomes include marine aquatic biomes (the intertidal zone, coral reef, and open ocean) and freshwater lakes, rivers, and wetlands. These are distinguished by differences in salinity, oxygen content, depth, current strength (lentic versus lotic), and availability of light (Figure 54.26).

54.6 Continental Drift and Biogeography

- The location of many fossils and living organisms can be explained by evolution in one supercontinent followed by subsequent continental drift (Figure 54.27).
- Other distinct distribution patterns are relics of once much broader distributions (Figure 54.28).
- Six major biogeographical regions—Nearctic, Palearctic, Neotropical, Ethiopian, Oriental, and Australian—each of which contains distinct fauna and flora, are recognized today (Figure 54.29).

Assess and Discuss

Test Yourself

1. Which of the following is probably the most important factor in the distribution of organisms in the environment?
   a. light
   b. temperature
   c. salinity
   d. water availability
   e. pH
2. The greenhouse effect is
   a. a new phenomenon resulting from industrialization.
   b. due to the absorption of solar radiation by atmospheric gases.
   c. responsible for the natural warming of the Earth.
   d. all of the above.
   e. b and c only.
3. Which ecological subdiscipline would be most likely to study the temperature tolerance of zebras?
   a. organismal ecology
   b. population ecology
   c. community ecology
   d. ecosystem ecology
   e. both a and b

4. Physics is to engineering as ecology is to
   a. biology.
   b. environmental science.
   c. chemistry.
   d. mathematics.
   e. statistics.
5. The most common biome type, by area occupied, is the
   a. open ocean.
   b. tropical rainforest.
   c. tundra.
   d. hot desert.
   e. lentic habitats.
6. What is the driving force that determines the circulation of the atmospheric air?
   a. temperature differences of the Earth
   b. winds
   c. ocean currents
   d. mountain ridges
   e. all of the above
7. In this biome, rainfall is between 25 cm and 100 cm and temperatures vary between –10°C in winter and 30°C in summer. Where are you?
   a. tropical rainforest
   b. tropical deciduous forest
   c. savanna
   d. prairie
   e. temperate deciduous forest
8. What characteristics are commonly used to identify the terrestrial biomes of the Earth?
   a. temperature
   b. precipitation
   c. vegetation
   d. all of the above
   e. a and b only
9. Young lakes are often clear and with little plant life. Such lakes are called
   a. oligotrophic.
   b. eutrophic.
   c. lotic.
   d. lentic.
   e. pelagic.
10. Which gas contributes most to human-caused global warming?
    a. carbon dioxide
    b. nitrous oxide
    c. sulfur dioxide
    d. methane
    e. chlorofluorocarbons

Conceptual Questions

1. If mountains are closer to the Sun than valleys, why aren't they hotter?
2. Why are fires generally more frequent in prairies than in hotter, drier deserts?
3. A principle of biology is that *living organisms interact with their environment*. In most locations on Earth at about 20–30° latitude, air cools and descends, and hot deserts occur. Florida is situated between 31°N and 24°N. Why does it not support a desert biome?

Collaborative Questions

1. The so-called Telegraph fire, near Yosemite National Park, in 2008, was one of the worst in California that year, burning more than 46 square miles covered by timber that had not burned in over 100 years. What could be done to prevent such a catastrophic fire in the park itself?
2. Based on your knowledge of biomes, identify the biome in which you live. In your discussion, list and describe the organisms that you have observed in your biome. Why might your observations not fit the biome predicted to occur from temperature/precipitation profiles?

Behavioral Ecology

Killdeer (*Charadrius vociferus*) removing an eggshell from its nest. What is the selective advantage of this behavior?

CHAPTER OUTLINE

55.1 The Influence of Genetics and Learning on Behavior
55.2 Local Movement and Long-Range Migration
55.3 Foraging Behavior
55.4 Communication
55.5 Living in Groups
55.6 Altruism
55.7 Mating Systems
Summary of Key Concepts
Assess and Discuss

After their young hatch, nesting birds often pick up the empty eggshells and carry them away from the nest. One might think that they are being neat and tidy or are minimizing the risk of bacterial infection to the chicks, but there is more to the behavior than this. The chicks and unhatched eggs are well camouflaged in the nest, but the white color of the empty eggshell quickly attracts the attention of predators such as crows that would kill and eat the chicks or remaining eggs. By removing the old eggshells, the parents are increasing the chances that their offspring—and thus their genes—will survive. Although this behavior is likely to be an instinctive activity, it is promoted because birds that performed this activity likely have a higher rate of chick survival than those that don't, ensuring that the genes that code for this behavior are passed on.

Behavior is the observable response of organisms to external or internal stimuli. In this chapter, we focus our attention on the field of **behavioral ecology**, the study of how behavior contributes to the differential survival and reproduction of organisms. Contemporary behavioral ecology builds on earlier work that focused primarily on how organisms behave. In the early 20th century, scientific studies of animal behavior, termed **ethology** (from the Greek *ethos*, meaning habit or manner), focused on the specific genetic and physiological mechanisms of behavior. These factors are called **proximate causes**. For example, we could hypothesize that male deer rut or fight with other males in the fall because a change in day length stimulates the eyes, brain, and pituitary gland and triggers hormonal changes in their bodies. The founders of ethology, ethologists Karl von Frisch, Konrad Lorenz, and Niko Tinbergen, shared the 1973 Nobel Prize in Physiology or Medicine for their pioneering discoveries concerning the proximate causes of behavior.

However, we could also hypothesize that male deer fight to determine which deer get to mate with the most female deer and pass on their genes. This hypothesis leads to a different answer than the one that is concerned with changes in day length. This answer focuses on the adaptive significance of fighting to the deer, that is, on the effect of a particular behavior on reproductive success. These factors are called **ultimate causes** of behavior. Since the 1970s, behavioral ecologists have focused more on understanding the ultimate causes of behavior.

In this chapter, we will explore the role of both proximate and ultimate causes of behavior. We begin by investigating how behavior is achieved, examining the roles of both genetics and the environment. In doing so, we will examine the important contributions of von Frisch, Lorenz, and Tinbergen. We will consider how different behaviors are involved in movement, gathering food, and communication. Later, we will investigate how organisms interact in groups, whether an organism can truly behave in a way that benefits others at a cost to itself, and how behavior shapes different mating systems. The chapter focuses on animal behavior, because the behavior of other organisms is more limited and less well understood.

55.1 The Influence of Genetics and Learning on Behavior

Learning Outcomes:

1. Describe the differences among innate behavior, conditioning, and learning.
2. Distinguish between classical conditioning and operant conditioning.
3. Give examples of how genetics and learning influence most behaviors.

Behavior is controlled by both genetics and the environment, and in this chapter, we will discuss the influence of both. Determining to what degree a behavior is influenced by genes versus the environment depends on the particular genes and environment examined. However, in a few cases, changes in behavior may be caused by variation in just one gene. Even if a given behavior is influenced by many genes, if one gene is altered, it is possible that the entire behavior can change. To use the analogy of baking a cake, a change in one ingredient of the recipe may change the taste of the cake, but that does not mean that the one ingredient is responsible for the entire cake.

In this section, we begin by examining how genes can affect behavior and consider several examples of simple genetically programmed behaviors. Later, we will explore several types of learned behavior, including classical and operant conditioning and cognitive learning, and conclude by exploring an example of the interaction of genetics and learning on behavior.

Genes for behavior act on the development of the nervous system and musculature—physical traits that evolve through natural selection. Many genes are needed for the proper development and function of the nervous system and musculature. Even so, as revealed by Rothenbuhler's and Richmond's work (see the Genomes & Proteomes Connection), variation in a single gene can have a dramatic influence on behavior.

Fixed Action Patterns Are Genetically Programmed

Behaviors that seem to be genetically programmed are referred to as **innate** (also called instinctual). Although the expression of genes varies, often in response to environmental stimuli, some behavior patterns evidently are genetically quite fixed. Most individuals will exhibit the same behavior regardless of the environment. A spider will spin a specific web without ever seeing a member of its own species build one. The courtship behaviors of many bird species are so stereotyped as to be virtually identical.

A classic example of innate behavior is the egg-rolling response in geese (**Figure 55.1**). If an incubating goose notices an egg out of the nest, she will extend her neck toward the egg, get up, and then roll the egg back to the nest using her beak. Such behavior functions to improve fitness because it increases the survival of offspring. Eggs that roll out of the nest get cold and fail to hatch. Geese that fail to exhibit the egg-rolling response would pass on fewer of their genes to future generations.

Egg-rolling behavior is an example of what ethologists term a **fixed action pattern (FAP)**, a behavior that, once initiated, continues until completed. For example, if the egg is removed while the goose is in the process of rolling it back toward the nest, the goose still completes the FAP, as though she were rolling back the now-absent egg to the nest. The stimulus to initiate this behavior is obviously a strong one, which ethologists term a **sign stimulus**. The sign stimulus for the goose is that an egg has rolled out of the nest. According to ethologists, this stimulus acts on the goose's central nervous system, which provides a neural stimulus to initiate the motor program or FAP. Interestingly, any round object, from a wooden egg to a volleyball, can elicit the egg-rolling response. Although sign stimuli usually have certain key components, they are not necessarily very specific.

Niko Tinbergen's study of male stickleback fish provides another classic example of an FAP. Male sticklebacks, which have a characteristic red belly, will attack other male sticklebacks that invade their territory. Tinbergen found that sticklebacks attacked small, unrealistic model fish having a red ventral surface (the sign stimulus), while ignoring a realistic male stickleback model that lacked a red underside (**Figure 55.2**).

Genomes & Proteomes Connection

Some Behavior Results from Simple Genetic Influences

An example of the effect of genes on behavior was demonstrated in biologist W. C. Rothenbuhler's 1964 work on honeybees. Some strains of bees are termed hygienic; that is, they detect and remove

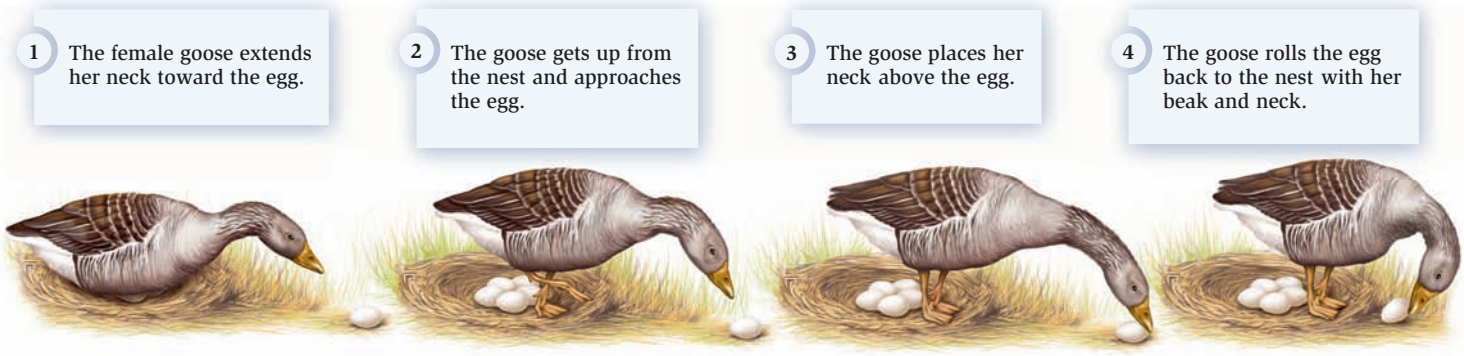

Figure 55.1 A fixed action pattern as an example of innate behavior. Female geese retrieve eggs that have rolled outside the nest through a set sequence of movements. The goose completes this entire sequence even if a researcher takes the egg away before the goose has rolled it back to the nest.

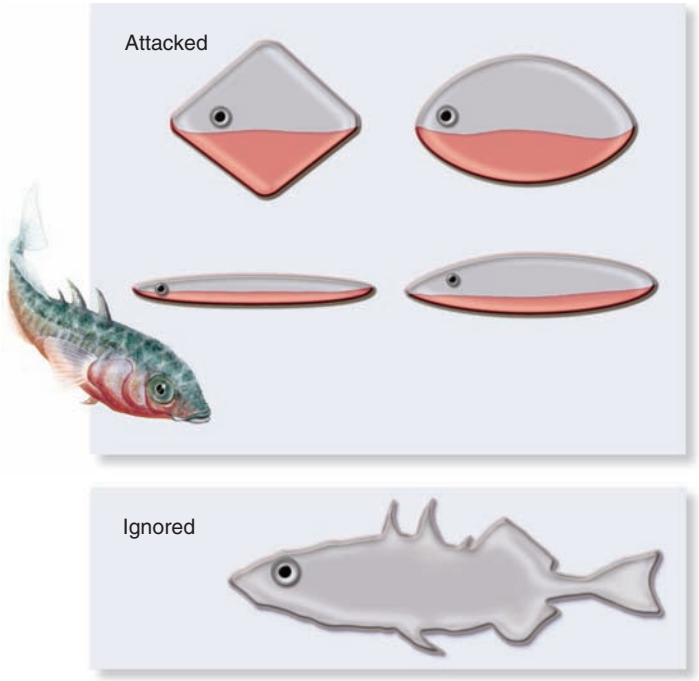

Figure 55.2 A fixed action pattern elicited by a sign stimulus. The sign stimulus for male sticklebacks to attack other males entering their territory is a red ventral surface. In experiments, male sticklebacks attacked all models that had a red underside, while ignoring a realistic model of a stickleback that lacked the red belly.

diseased larvae from the nest. This behavior involves two distinct maneuvers: uncapping the wax cells and then discarding the dead larvae. Other strains are not hygienic and do not exhibit such behavior. Using genetic crosses, Rothenbuhler demonstrated that one recessive gene (*u*) controls cell uncapping and another recessive gene (*r*) controls larval removal. Double recessives (*uurr*) are hygienic strains, and double dominants (*UURR*) are nonhygienic strains. When the two strains were crossed, all the F_1 hybrids were nonhygienic (*UuRr*). When the F_1 hybrids were crossed with the pure hygienic strain (*uurr*), four different genotypes were produced: one-quarter of the offspring were hygienic (*uurr*), one-quarter were nonhygienic and showed neither behavior (*UuRr*), one-quarter uncapped the cells but failed to remove the larvae (*uuRr*), and one-quarter removed the larvae but only if the cells were uncapped for them (*Uurr*).

More recently, in 2004, American neuroscientist Barry Richmond and colleagues showed how the work ethic of monkeys is affected by a gene expressed in a region of the brain called the rhinal cortex. Most primates, humans and monkeys included, tend to work harder when a deadline looms. Richmond's team trained four monkeys to release a lever at the exact moment a spot on a computer screen changed color from red to green. The monkeys had to complete this task three times and only on the third trial did they receive a food reward, regardless of how they performed on the first two trials. As an indication of how many trials were left, the monkeys could see a gray bar on the screen. As the bar became brighter, the monkeys knew they were reaching the last trial, and they worked more diligently for the reward. In the first two trials, the monkeys made more errors than in the last trial. Next, the team switched off the gene known to be involved in processing reward signals. To do this, the researchers injected a short strand of DNA into the monkey's brain. The effects were only temporary, 10–12 weeks, but during that time the monkeys were unable to determine how many trials were left before the reward was given, and they worked vigilantly to receive the reward on every trial, making few errors even on trials one and two. Could such studies be performed with humans? Sufferers of obsessive-compulsive disorders and people with bipolar disease (manic-depression) also work for little personal reward.

Conditioning Occurs When a Relationship Between a Stimulus and a Response Is Learned

Although many of the behavioral patterns exhibited by animals are largely innate, sometimes animals can make modifications to their behavior based on previous experience, a process that involves learning. Perhaps the simplest form of learning is **habituation**, in which an organism learns to ignore a repeated stimulus. For example, animals in African safari parks become habituated to the presence of vehicles containing tourists; these vehicles are neither a threat nor a benefit to them. Birds can become habituated to the presence of a scarecrow, resulting in damage to crops. Habituation can be a problem at airports, where birds eventually ignore the alarm calls designed to scare them away from the runways.

Habituation is a form of nonassociative learning, a change in response to a repeated stimulus without association with a positive or negative reinforcement. Alternatively, an association may gradually develop between a stimulus and a response. Such a change in behavior is termed **associative learning**. In associative learning, a behavior is changed or conditioned through the association. The two main types of associative learning are termed classical conditioning and operant conditioning.

In **classical conditioning**, an involuntary response comes to be associated positively or negatively with a stimulus that did not originally elicit the response. This type of learning is generally associated with the Russian psychologist Ivan Pavlov. In his original experiments in the 1920s, Pavlov restrained a hungry dog in a harness and presented small portions of food at regular intervals (refer back to Figure 40.16). The dog would salivate whenever it smelled the food. Pavlov then began to sound a metronome when presenting the food. Eventually the dog would salivate at the sound of the metronome, whether or not the food was present. Classical conditioning is widely observed in animals. For example, many insects quickly learn to associate certain flower odors with nectar rewards and other flower odors with no rewards. In humans, the sound of a dentist's drill is enough to produce a feeling of uneasiness, tension, and sweaty palms.

In **operant conditioning**, an animal's behavior is reinforced by a consequence, either a reward or a punishment. The classic example of operant conditioning is associated with the American psychologist B. F. Skinner, who placed laboratory animals, usually rats, in a

specially devised cage with a lever that came to be known as a Skinner box. If the rat pressed on the lever, a small amount of food would be dispensed. At the beginning of the experiment, the rat would often bump into the lever by accident, eat the food, and continue exploring its cage. Later, it would learn to associate the lever with obtaining food. Eventually, if it was hungry, the rat would almost continually press the lever. Operant conditioning, also called trial-and-error learning, is common in animals. Often it is associated with negative rather than positive reinforcement. For example, toads eventually refuse to strike at insects that sting, such as wasps and bees, and birds will learn to avoid bad-tasting butterflies (**Figure 55.3**). In humans, giving children a reward for completing homework is a positive reinforcer.

(a) Blue jay eating monarch

(b) Vomiting reaction

Figure 55.3 Operant conditioning, also known as trial-and-error learning. **(a)** A young blue jay will eat a monarch butterfly, not knowing that it is noxious. **(b)** After the first experience of vomiting after eating a monarch, a blue jay will avoid the insects in the future.

Concept Check: What's the difference between operant conditioning and classical conditioning?

BioConnections: Look forward to Figure 57.9e. How might operant conditioning be related to the similar appearance of king snakes and coral snakes?

Cognitive Learning Involves Conscious Thought

Cognitive learning refers to the ability to solve problems with conscious thought and includes activities such as perception, analysis, judgment, recollection, and imagining. In the 1920s, German psychologist Wolfgang Köhler conducted a series of classic experiments with chimpanzees that suggested animals could exhibit cognitive learning. In the experiments, a chimpanzee was left in a room with bananas hanging from the ceiling and out of reach (**Figure 55.4**). Also present in the room were several wooden boxes. At first, the chimp tried in vain to jump up and grab the bananas. After a while, however, it began to arrange the boxes one on top of another underneath the fruit. Eventually, the chimp climbed the boxes and retrieved the fruit.

Many other examples of such behavior have been observed. Chimps strip leaves off twigs and use the twigs to poke into ant nests, withdrawing the twig and licking the ants off. Captive ravens have been shown to retrieve meat suspended from a branch by a string, even though they have never encountered the problem before. They pull up on the string, step on it, and then pull up on the string again, repeating the process until the meat is within reach.

Both Genetics and Learning Influence Most Behaviors

Much of the behavior we have discussed so far has been presented as either innate or learned, but the behavior we observe in nature is usually a mixture of both. Bird songs provide a good example. Many birds learn their songs as juveniles, when they hear their parents sing.

Figure 55.4 Cognitive behavior involving problem-solving ability. This chimp has devised a solution to the problem of retrieving bananas that were initially out of its reach.

BioConnections: Look back at Figure 42.17. Does learning affect brain structure?

If juvenile white-crowned sparrows are raised in isolation, their adult songs do not resemble the typical species-specific song (**Figure 55.5**). If they hear only the song of a different species, such as the song sparrow, they again sing a poorly developed adult song. However, if they hear the song of the white-crowned sparrow, they will learn to sing a fully developed white-crowned sparrow song. The birds are genetically programmed to learn, but they will sing the correct song only if the appropriate instructive program is in place to guide learning.

Another example of how innate behavior interacts with learning can occur during a limited time period of development, called a **critical period**. At this time, many animals develop irreversible species-specific behavior patterns. This process is called **imprinting**. One of the best examples of imprinting was demonstrated by the Austrian ethologist Konrad Lorenz in the 1930s. Lorenz noted that young birds of some species imprint on their mother during a critical period that is usually within a few hours after hatching. This behavior serves them well, because in many species of ducks and geese, it would be hard for the mother to keep track of all her offspring as they walk or swim. After imprinting takes place, the offspring keep track of the mother.

The survival of the young ducks requires that they quickly learn to follow their mother's movements. Lorenz raised greylag geese from eggs, and soon after they hatched, he used himself as the model for imprinting. As a result, the young goslings imprinted on Lorenz and followed him around (**Figure 55.6**). For the rest of their life, they preferred the company of Lorenz and other humans to geese. Studies have shown that even an object as foreign as a black box, watering can, or flashing light can be imprinted on if it is the first moving object the chick sees during the critical period. In nature, if young geese are not provided with any stimulus during the critical period, they will fail to imprint on anything, and without parental care, they will almost certainly die.

Other animals imprint in different ways. Newborn shrews imprint on the scent of their mother. Mothers also can imprint on their own young within a few hours. For example, a relatively common trick used in sheep farming is to disguise a lamb whose mother has died or abandoned it by wrapping it in the fleece of another ewe's stillborn lamb. That second ewe will then care for the abandoned lamb because it smells like her own. In these situations, the innate behavior is the ability to imprint soon after birth, and the factors in the environment are the stimulus to which the imprinting is directed.

Figure 55.6 Konrad Lorenz being followed by his imprinted geese. Newborn geese follow the first object they see after hatching and later will follow that particular object only. They normally follow their mother but can be induced to imprint on humans. The first thing these young geese saw after hatching was ethologist Konrad Lorenz.

Innate behavior can interact with learning during animal migration. Inexperienced juvenile birds migrate in a particular direction but fail to correct for deviations if they are blown off course. Experienced adult birds, on the other hand, can often correct for storm-induced displacement, indicating they have developed more complex navigational skills. Many complex behaviors are involved in movement and migration, as we will explore in the next section.

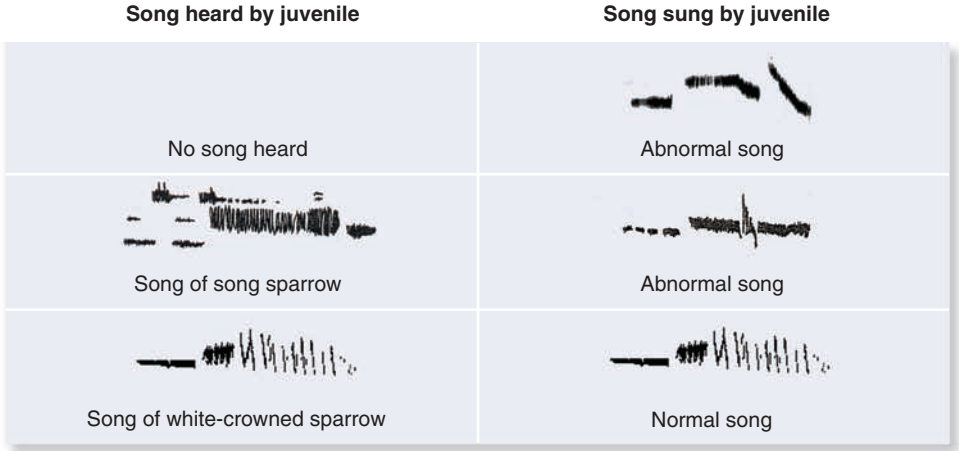

Figure 55.5 The interaction between genetics and learning. The lines represent the different sound frequencies produced by the birds over a short time interval. The juvenile white-crowned sparrow will sing an abnormal song if it is kept in isolation or hears only the song of a different species. However, the juvenile will sing the normal white-crowned sparrow song if exposed to it.

Concept Check: *Cuckoos lay their eggs in other birds' nests, so their young are reared by parent birds of a different species. However, unlike the white-crowned sparrow, adult cuckoos always sing their own distinctive song, not that of the host species they hear as juveniles. How is this possible?*

55.2 Local Movement and Long-Range Migration

Learning Outcomes:

1. Distinguish between kinesis and taxis, two different types of local movement.
2. Describe the three mechanisms animals use during migration.
3. **SciSKILLS** » Analyze experiments that determine whether animals learn using visual or olfactory clues.

Organisms need to find their way, both locally and over what can be extremely long distances. Locally, organisms continually need to locate sources of food, water, mates, and perhaps nesting sites. Migration involves the longer-distance seasonal movement of animals, usually between overwintering areas and summer breeding sites; these are often hundreds or even thousands of kilometers apart. Several different types of behavior may be involved in these movements.

In this section, we begin by exploring local movement and animals' use of landmarks to guide their movements. We will then consider migration and examine the possible mechanisms used by migrating animals to find their way.

Local Movement Can Involve Kinesis, Taxis, and Memory

The simplest forms of movement are mere responses to stimuli. A **kinesis** is a movement in response to a stimulus, but one that is not directed toward or away from the source of the stimulus. A simple experiment often done in classrooms is to observe the activity levels of woodlice, sometimes called sow bugs or pill bugs, in dry areas and moist areas. The woodlice move faster in drier areas, and they slow down when they reach moist environments. This behavior tends to keep them in damper areas, which they prefer in order to avoid desiccation.

A **taxis** is a more directed type of response either toward (positive taxis) or away from (negative taxis) an external stimulus. Cockroaches exhibit negative phototaxis, meaning they tend to move away from light. Under low-light conditions, the photosynthetic unicellular flagellate *Euglena gracilis* shows positive phototaxis and moves toward a light source. Sea turtle hatchings are also strongly attracted to light. On emerging from their nests, they crawl toward the brightest location, traditionally the reflected moonlight on the ocean's surface. Lighted houses on the shore can disorient the hatchlings, however, and lead them to wander away from the ocean and succumb to dehydration, exhaustion, and predation. This is why beachfront property owners are requested to turn their lights down in turtle-hatching season. Male silk moths orient themselves in relation to wind direction (anemotaxis). If the air current carries the scent of a female moth, they will move upwind to locate it. Some freshwater fishes orient themselves to the currents of streams. Many fishes exhibit positive rheotaxis (from the Greek *rheos*, meaning current), in that they swim against the water current to prevent being washed downstream.

Sometimes memory and landmarks may be used to aid in local movements. Dutch-born ethologist Niko Tinbergen showed how the female digger wasp uses landmarks to relocate her nests, as described next.

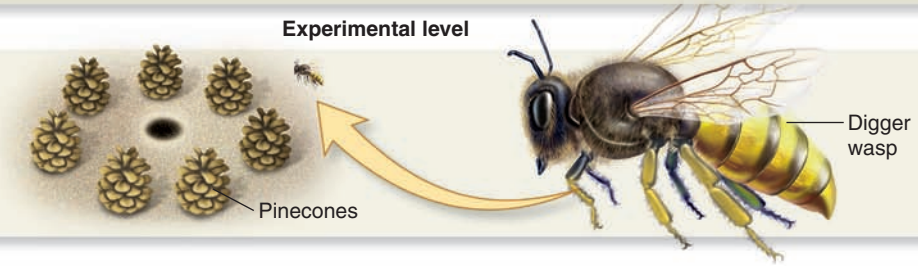
Feature Investigation | Tinbergen's Experiments Showed That Digger Wasps Use Landmarks to Find Their Nests

In the sandy, dry soils of Europe, the solitary female digger wasp (*Philanthus triangulum*) digs four to five nests in which to lay her eggs. Each nest stretches obliquely down into the ground for 40–80 cm. The wasp follows this by performing a sequence of apparently genetically programmed events. She catches and stings a honeybee, which paralyzes it; returns to the nest; drags the bee into the nest; and lays an egg on it. The egg hatches into a larva, which feeds on the paralyzed bee. However, the larva needs to ingest five to six bees before it is fully developed. This means the wasp must catch and sting four to five more bees for each larva. She can carry only one bee at a time. After each visit, the wasp must seal the nest with soil, find a new bee, relocate the nest, open it, and add the bee. How does the wasp relocate the nest after spending considerable time away? Niko Tinbergen observed the wasps hover and fly around the nest each time they took off. He hypothesized that they were learning the nest position by creating a mental map of the landmarks in the area.

To test his hypothesis, Tinbergen experimentally adjusted the landmarks around the burrow that the wasps might be using as cues (**Figure 55.7**). First, he put a ring of pinecones around the nest entrance to train the wasp to associate the pinecones with the nest. Then, when the wasp was out hunting, he moved the circle of pinecones a distance from the real nest and constructed a sham nest, making a slight depression in the sand and mimicking the covered entrance of the burrow. On returning, the wasp flew straight to the sham nest and tried to locate the entrance. Tinbergen chased it away. When it returned, it again flew to the sham nest. Tinbergen repeated this nine times, and every time the wasp chose the sham nest. Tinbergen got the same result with 16 other wasps, and not once did they choose the real nest.

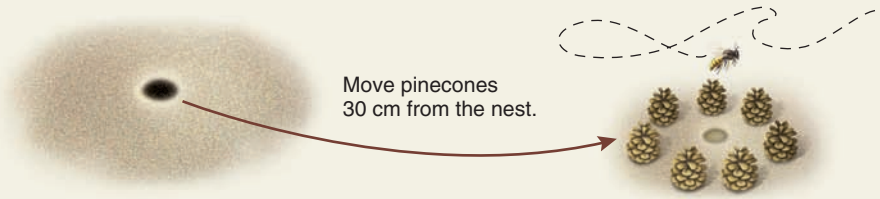
Next Tinbergen investigated the type of stimulus that might be eliciting the learning. He hypothesized that the wasps could be responding to the distinctive scent of the pinecones rather than their appearance. He trained the wasps by placing a circle of pinecones that had no scent and two small pieces of cardboard coated in pine oil around the real nest. He then moved the cones to surround a sham nest and left the scented cardboard around the real nest. The returning wasps again ignored the real nest with the scented cardboard and flew to the sham. He concluded that for the wasps, sight was apparently more important than smell in determining landmarks.

Figure 55.7 How Niko Tinbergen discovered the digger wasp's nest-locating behavior.



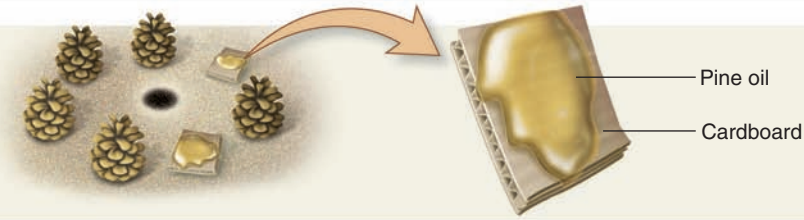
Concept Check: *How would you test what type of spatial landmarks are used by female digger wasps?*

HYPOTHESIS Digger wasps (*Philanthus triangulum*) use visual landmarks to locate their nests.

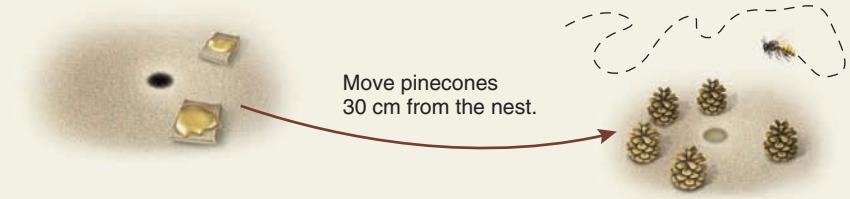


STARTING LOCATION The female digger wasp excavates an underground nest, to which she returns daily, bringing food to the larvae located inside.

Experimental level



1 Place a ring of pinecones around the nest to train the wasp to associate pinecones with the nest.



2 After the wasp leaves the nest to hunt, move the pinecones 30 cm from the real nest. The wasp returns and flies to the center of the pinecone circle instead of the real nest. Repeated experiments yield similar results (see data), indicating that the wasp uses landmarks as visual cues.

3 To test whether it is the shape or the smell of the pinecones that elicits the response, perform the same experiment as above, except use pinecones with no scent and add 2 small pieces of cardboard coated with pine oil.

4 After the wasp leaves the nest, move the pinecones 30 cm from the nest, but leave the scented cardboard at the nest. The wasps again fly to the pinecone nest (see data), indicating that it is the arrangement of cones, not their smell, that elicits the learning.

5 **THE DATA***

Results from steps 1 and 2:

Wasp #	Number of return visits per wasp to real nest without pinecones	Number of return visits per wasp to sham nest with pinecones
1–17	0	~9

Results from steps 3 and 4:

Wasp #	Number of return visits per wasp to real nest with scented cardboard	Number of return visits per wasp to sham nest with pinecones
18–22	0	~6

*Seventeen wasps, numbered 1–17, were studied as described in steps 1 and 2. Five wasps, numbered 18–22, were studied as described in steps 3 and 4.

6 **CONCLUSION** Digger wasps remember the positions of visual landmarks and use them as aids in local movements.

7 **SOURCE** Tinbergen, N. 1951. The study of instinct. Clarendon Press, Oxford.

Experimental Questions

1. What observations were important for the development of Tinbergen's hypothesis explaining how digger wasps located their nests?
2. **SciSKILLS** » How did Tinbergen test the hypothesis that the wasps were using landmarks to relocate the nest? What were the results?
3. **SciSKILLS** » Did the Tinbergen experiment rule out any other cue the wasps may have been using besides the sight of pinecones?

BIO TIPS

THE QUESTION *Tinbergen also investigated whether digger wasps used visual and/or olfactory means to locate their honeybee prey. He attached a number of dead bees to thread tethers so that they blew in the wind, descented some of these with alcohol, tethered bee-sized pieces of twigs to threads, scented some of these by shaking them with dead bees, and tied dead bees to twigs. Note: The first 4 types moved in the wind, but the dead bees tied to twigs did not. He presented these 5 types of "dummies" to digger wasps and observed their behavior. The wasps either ignored the "prey," hovered in placed before it, pounced on or grasped it, or attempted to sting or capture it. The resultant numbers of events in 100 hours of observing are shown in the table below. Do digger wasps rely on visual or olfactory cues, or both, to locate their prey?*

Experimental treatment	Hover	Pounce or grasp	Sting or capture
Tethered bees	26	14	26
Alcohol-treated tethered bees	20	9	0
Bee-sized tethered twigs	14	3	0
Bee-sized scented, tethered twigs	34	20	9
Bees tied to twigs	0	0	0

TOPIC ***What topic in biology does this question address?*** The topic is animal behavior. More specifically, the question concerns how digger wasps locate suitable prey.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you know that digger wasps may use visual or olfactory cues, or both, to locate their prey. From your understanding of the topic that you gained in the Feature Investigation, you know that digger wasps use visual landmarks to locate their nests.

PROBLEM-SOLVING STRATEGY ***Interpret data.*** Add two columns to the table of results, with one column labeled "Movement" and the other "Scent." Place a check mark or an X in each of these columns if the results of the experiment indicate that digger wasps are likely responding to bee movement or to bee scent.

ANSWER

Experimental	Hover	Pounce or grasp	Sting or capture	Movement	Scent treatment
Tethered bees	26	14	26	✓	✓
Alcohol-treated tethered bees	20	9	0	✓	×
Bee-sized tethered twigs	14	3	0	✓	×
Bee-sized scented, tethered twigs	34	20	9	✓	✓
Bees tied to twigs	0	0	0	×	✓

Bee scent alone does not attract digger wasps (see the results for bees tied to twigs). Movement of bees or of bee-sized twigs was sufficient to make some of the wasps hover and attack (pounce or grasp) the "prey." However, without any bee scent, the wasps did not attempt to sting or capture the prey. Thus, both visual and olfactory cues are used by digger wasps to locate their prey.

Migration Involves Long-Range Movement and More Complex Spatial Navigation

As well as navigating over short-range distances, many animal species undergo **migration**, long-range seasonal movement. Migrations usually involve a movement away from a birth area to feed and a return to the birth area to breed, with the movement generally being linked to seasonal availability of food. For example, nearly half the bird species of North America migrate to South America to escape the cold winters and feed, returning to North America in the spring to breed. Arctic terns that breed in Arctic Canada and Asia in summer migrate to the Antarctic to feed in the winter and then return to breed. This staggering journey involves up to a 40,000-km (25,000-mile) round-trip, most of it over the open ocean, during which the birds must stay airborne for days at a time!

Many mammals, including wildebeest and caribou, make migrations that track the appearance of new vegetation on which they feed. The monarch butterfly of North America migrates to overwinter in California, Mexico, and possibly south Florida and Cuba

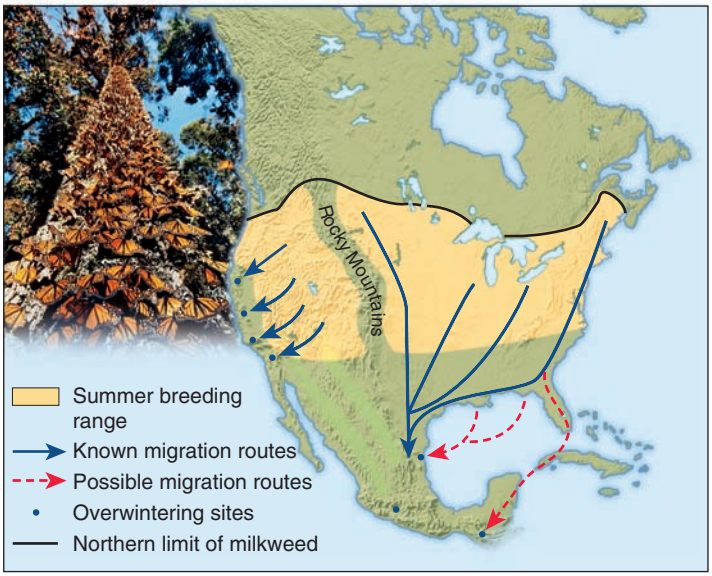


Figure 55.8 Monarch butterfly migration. Many monarch butterflies east of the Rocky Mountains migrate to a small area in Mexico to avoid the cold northern weather. Here they roost together in large numbers in fir trees (inset). Some butterflies may stay in Florida and Cuba. Butterflies west of the Rockies overwinter in mild coastal California locations.

Concept Check: *Why is this an unusual example of migration?*

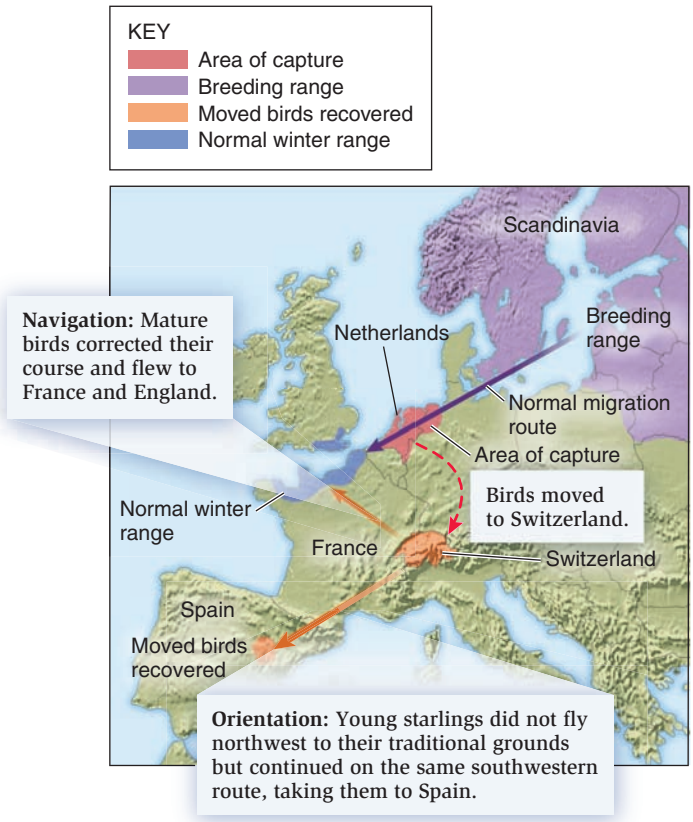

Figure 55.9 Orientation versus navigation. Starlings normally migrate from breeding grounds in Scandinavia and northeastern Europe through the Netherlands and northern Germany to overwintering sites in France and England. This involves a southwest flight. When juveniles were captured in the Netherlands and moved to Switzerland, they continued on in a southwestern direction and ended up in Spain. When adult birds were captured and moved, they changed course and flew to the normal overwintering areas.

(**Figure 55.8**). An interesting point about the northward journey of the monarch is that it involves several generations of butterflies to complete. On their way back to the northern U.S. and Canada, the butterflies lay eggs and die. The caterpillars develop on milkweed plants, and the resultant adults continue to journey farther north. This cycle happens several times in the course of the return journey. The northward and southward migrations are unique in that none of the individuals has ever been to the destinations before; therefore, the ability to migrate must be an innate behavior.

How do migrating animals find their way? Three mechanisms may be involved: piloting, orientation, and navigation. In **piloting**, an animal moves from one familiar landmark to the next. For example, many whale species migrate between summer feeding areas and winter calving grounds. Gray whales migrate between the Bering Sea near Alaska to coastal areas of Mexico. Features of the coastline, including mountain ranges, and rivers, may aid in navigation. In **orientation**, animals have the ability to follow a compass bearing and travel in a straight line. **Navigation** involves the ability not only to follow a compass bearing but also to set or adjust it.

An experiment with starlings helps illuminate the difference between orientation and navigation (**Figure 55.9**). European starlings breed in Scandinavia and northeastern Europe and migrate in a southwest direction toward coastal France and southern England to spend the winter. Migrating starlings were captured and tagged in the Netherlands and then transported south to Switzerland and released. Juvenile birds, which had never made the trip before, flew southwest in their migration and were later recaptured in Spain. Adult birds, with more experience, returned to their normal wintering range by adjusting their course by approximately 90°. This implies that the adult birds can actually navigate, whereas the juveniles rely on orientation.

Many species use a combination of navigational reference points, including the position of the Sun, the stars (for nighttime travel), and Earth's magnetic field. Homing pigeons have magnetite in their beaks that acts as a compass to indicate direction (refer back to Section 43.4 on electromagnetic reception). Navigation by the Sun or the stars also requires the use of a timing device to compensate for the ever-changing position of these reference points. Many migrants, therefore, possess the equivalent of an internal clock. Pigeons integrate their internal clock with the position of the Sun. Researchers have altered the internal clock of pigeons by keeping them under artificial lights for certain periods of time. When the pigeons are released, they display predictable deviations in their flight. For every hour that their internal clock is shifted, the orientation of the birds shifts about 15°.

Not all examples of animal migration are well understood. Green sea turtles feed off the coast of Brazil yet swim east for 2,300 km (1,429 miles) to lay their eggs on Ascension Island, an 8-km-wide island in the center of the Atlantic Ocean between Brazil and Africa. It is not known why the turtles lay their eggs on this speck of an island or how they succeed in finding it. Perhaps fewer predators exist on Ascension than on other beaches. A combination of magnetic orientation and chemical cues may help them find it. Thus, although scientists have made many discoveries about animal navigation, much remains to be learned about how animals acquire a map sense.

To a large extent, local and long-distance movement involves searching for food. In the next section, we will investigate how such foraging decisions are made.

55.3 Foraging Behavior

Learning Outcomes:

1. Describe and give examples of optimal foraging.
2. Explain how the risk of predation prevents optimal foraging in some species.
3. Outline the costs and benefits of defending a territory.

Food gathering, or foraging, often involves decisions about whether to remain at a resource patch and look for more food or look for a completely new patch. The analysis of these decisions is often performed in terms of **optimality theory**, which predicts that an animal should behave in a way that maximizes the benefits of a behavior minus its costs. In this case, the benefits are the nutritional or caloric value of the food items, and the costs are the energetic or caloric costs of movement. When the difference between the energetic benefits of food gathering and the energetic costs of food gathering is maximized, an organism is said to be optimizing its foraging behavior. Optimality theory can also be used to investigate other behavioral issues such as how large a territory to defend. Too small a territory would contain insufficient resources, such as food and mates, and too large a territory would be too energetically costly to defend. Theoretically, then, there is an optimal territory size for a given individual.

Optimal Foraging Entails Maximizing the Benefits and Minimizing the Costs of Food Gathering

Optimal foraging proposes that in a given circumstance, an animal seeks to obtain the most energy possible with the least expenditure of energy. The underlying assumption of optimal foraging is that natural selection favors animals that are maximally efficient at propagating their genes and at performing all other functions that serve this purpose. In this model, the more net energy an individual gains in a limited time, the greater the reproductive success.

Shore crabs (*Carcinus maenas*) eat many different-sized mussels but tend to feed preferentially on intermediate-sized mussels, which give them the highest rate of energy return (**Figure 55.10**). Very large mussels yield more energy, but they take so long for the crab to open that they are actually less profitable, in terms of energy yield per unit time spent, than smaller sizes. Very small mussels are easy to crack open but contain so little flesh that they are not worth the effort. This leaves intermediate-sized mussels as the preferred size. Of course, the intermediate-sized mussels may take a longer time to locate, because more crabs are looking for them, so crabs eat some less profitable but more frequently encountered sizes of mussels. The result is that the diet consists of mussels in a range of sizes around the preferred optimal size.

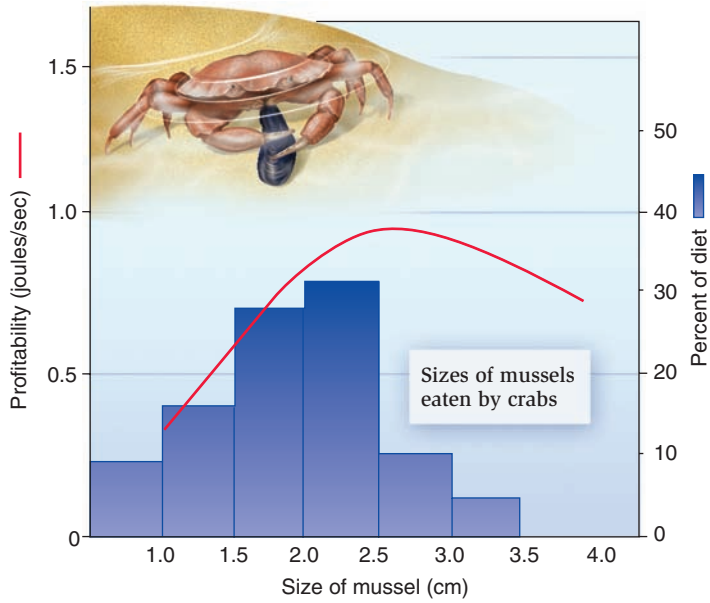

Figure 55.10 Optimal foraging behavior in shore crabs. When offered a choice of equal numbers of each size mussel, shore crabs (*Carcinus maenas*) prefer intermediate-sized mussels that provide the highest rate of energy return. Profitability is the energy yield (joules) per second of time used in breaking open the shell.

In some cases, animals do not forage optimally. For example, animals seek not only to maximize food intake but also to minimize the risk of predation. Some species may only dart out to take food from time to time. Many species of ants are attacked by parasitic flies that lay eggs on an ant's head. These flies hover around ant colonies or at the nest entrances. Ants are relatively quick themselves but cannot easily avoid these fast-flying parasites. Once the parasite's eggs hatch, the larvae bore their way into the ant's head, eventually killing it. In the tropics, leafcutter ants, *Atta cephalotes*, are subject to attack by the fly *Neodohrniphora curvinervis* (**Figure 55.11a**). Only the larger workers are attacked, because smaller workers' heads are too small to allow proper development of the fly. When Matthew Orr compared the size distributions of the leafcutter ants that foraged during the day versus those that foraged at night, he discovered a large difference in the size distributions (**Figure 55.11b**). Most foraging by larger workers is done at night, when it is too dark for the flies to see properly and their activity ceases. The lesser amount of foraging in the day is performed by smaller ants that are less susceptible to fly attack. Orr extended the activity of *N. curvinervis* by positioning lights outside the leafcutter nests. In these cases, the foraging activities of the

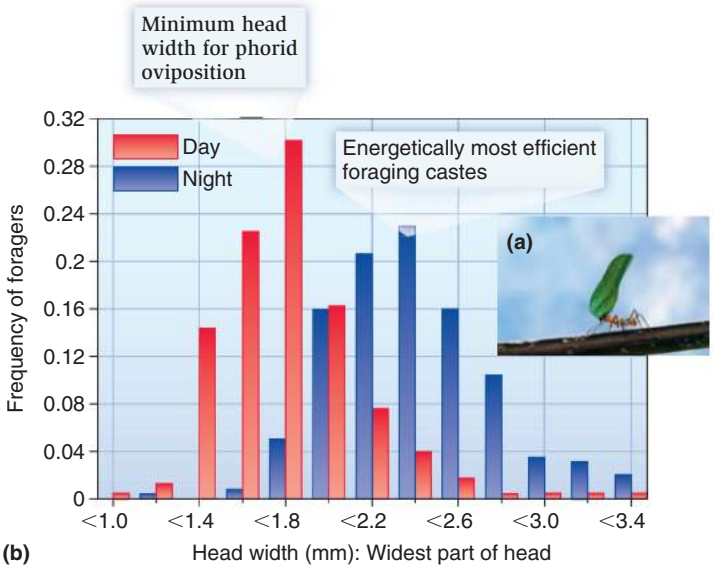

Figure 55.11 Changes in foraging strategies in the presence of parasites. **(a)** The tropical leafcutter ant, *Atta cephalotes*. **(b)** The most efficient leafcutter ants are larger individuals. However, larger individuals are restricted to foraging at night because of the activity of parasitic flies during the day. During the day, only small ants forage, as these are not subject to the same levels of parasitism.

leafcutters were thrown into disarray. Ants were backed up around the nest, many rising on their hind legs to snap at the flies which, with the extended light, continued to try to parasitize the ants. Foraging activity is influenced not only by energetic efficiency, but also by the threat of natural enemies.

Many animals also maintain territories to minimize competition with other individuals and control resources, whether food, mates, or nesting sites. As we will see, defending these territories also has an energetic cost.

Defending Territories Has Costs and Benefits

Many animals or groups of animals, such as a pride of lions, actively defend a **territory**, a fixed area in which an individual or group excludes other members of its own species, and sometimes other species, by aggressive behavior or territory marking. Optimality theory predicts that territory owners tend to optimize territory size according to the costs and benefits involved. The primary benefit of a territory is that it provides exclusive access to a particular resource—food, mates, or sheltered breeding sites. Large territories provide more of a resource but may be costly to defend, while small territories that are less costly to defend may not provide enough.

In studies of the territorial behavior of the golden-winged sunbird (*Nectarinia reichenowi*) in East Africa, American ornithologists Frank Gill and Larry Wolf measured the energy content of nectar as the benefit of maintaining a territory and compared it to the energy costs of activities such as perching, flying, and fighting (**Figure 55.12a**). Defending the territory ensured that other sunbirds did not take nectar from available flowers, thus increasing the amount of nectar in each flower. In defending a territory, the sunbird gained 780 Calories (kilocalories) a day in extra nectar content. However, the sunbird also spent 728 Calories in defense of the territory, yielding a net gain of 52 Calories a day and making territorial defense advantageous.

Territory size differs considerably among species. Because cheetahs need large areas to be able to hunt successfully, they establish large territories relative to their size (**Figure 55.12b**). In contrast, territories set up solely to defend areas for mating or nesting are often relatively small. For example, male sea lions defend small areas of beach. The preferred areas contain the largest number of females and are controlled by the largest breeding bulls. The size of the territory of some nesting birds, such as gannets, is determined by how far the bird can reach to peck its neighbor without leaving its nest (**Figure 55.12c**).

(a) Golden-winged sunbird

(b) Cheetah

(c) Nesting gannets

Figure 55.12 Differing territory sizes among animals. **(a)** The golden-winged sunbird of East Africa (*Nectarinia reichenowi*) has a medium territory size that depends on the number of flowers it can obtain resources from and defend. **(b)** Cheetahs (*Acinonyx jubatus*) hunt over large areas and can have extensive territories. This male is urine-marking part of his territory in the southern Serengeti, near Ndutu, Tanzania. **(c)** Nesting gannets (*Morus bassanus*) have much smaller territories, in which each bird is just beyond the pecking range of its neighbor.

Territories may be held for a season, a year, or the entire lifetime of the individual. Ownership of a territory needs to be periodically proclaimed; thus, communication between individuals is necessary for territory owners. This may involve various types of signaling, which we discuss next.

55.4 Communication

Learning Outcome:

1. Give examples of how animals use chemical, auditory, visual, and tactile communication.

Communication is the use of specially designed signals or displays to modify the behavior of others. It may be used for many purposes, including defining territories, maintaining contact with offspring, courtship, and contests between males. The use of different forms of communication between organisms depends on the environment in which they live. For example, visual communication plays little role in the signals of nocturnal animals. Similarly, for animals in dense forests, sounds are of prime importance. Sound, however, is a temporary signal. Scent can last longer and is often used to mark the large territories of some mammals. In this section, we outline the various types of communication—chemical, auditory, visual, and tactile—that occur among animals.

Chemical Communication Is Often Used to Mark Territories or Attract Mates

The chemical marking of territories is common among animals, especially among members of the canine and feline families (see Figure 55.12b). Scent trails are often used by social insects to recruit workers to help bring prey to the nest. Fire ants (genus *Solenopsis*) attack large, living prey, and many ants are needed to drag the prey back to the nest. The scout that finds the prey lays down a scent trail from the prey back to the nest. The scent excites other workers, which follow the trail to the prey. The scent marker is very volatile, and the trail effectively disappears in a few minutes to avoid mass confusion over old trails.

Animals frequently use chemicals to attract mates. Female moths attract males by powerful chemical attractants called **pheromones**. Male moths have receptors that can detect as little as a single molecule. Among social organisms, some individuals use pheromones to manipulate the behavior of others. For example, a queen bee releases pheromones that suppress the reproductive system of workers, which ensures that she is the only reproductive female in the hive.

Auditory Communication Is Often Used to Attract Mates and to Deter Competitors

Many organisms communicate by making sound. Because the ground can absorb sound waves, sound travels farther in the air, which is why many birds and insects perch on branches or leaves when singing. Air is on average 14 times less turbulent at dawn and dusk than during the rest of the day, so sound carries farther then, which helps explain the preference of most animals for calling at these times. Some insects utilize the very plants on which they feed as a medium of song transmission. Many male leafhopper and planthopper insects vibrate their abdomens on leaves and create species-specific courtship songs that are transmitted by adjacent vegetation and are picked up by nearby females of the same species.

Although many males use auditory communication to attract females, some females use calls to attract the attention of males. Female elephant seals scream loudly when approached by a nondominant male. This attracts the attention of the dominant male, which drives the nondominant male away. In this way, the female is guaranteed a mating with the strongest male. Sound production can attract predators as well as mates. Some bats listen for the mating calls of male frogs to find their prey. Parasitic flies detect and locate chirping male crickets and then deposit larvae on or near them. The larvae latch onto and penetrate the cricket and eventually kill it. Sound may also be used by males during competition over females. In many animals, lower-pitched sounds come from larger males, so by calling to one another, males can gauge the size of their opponents and decide whether it is worth fighting.

Visual Communication Is Often Used in Courtship and Aggressive Displays

In courtship, animals use a vast number of visual signals to identify and select potential mates. Competition among males with the most impressive displays to attract females has led to elaborate coloration and extensive ornamentation in some species. For example, peacocks and males of many bird species have developed elaborate plumage to attract females.

Male fireflies have developed light flashes that are species specific with regard to number and duration of flashes (**Figure 55.13a**). Females respond with a flash of their own. Such bright flashes are also bound to attract predators. Some female fireflies use mimicry to their advantage. Female fireflies of the species *Photuris versicolor* mimic the flashing responses normally given by females of other species, such as *Photinus tanytoxus*, in order to lure the males of those species close enough to eat them.

Visual signals are also used to resolve disputes over territories or mates. Deer and antelope have antlers or horns that they use to display and spar over territory and females. Most of these matches never develop into outright fights, because the males gauge their opponent's strength by the size of these ornaments (look ahead to Figure 55.22b). Among insects, the "horns" of rhinoceros beetles and the eye stems of stalk-eyed flies send similar signals (**Figure 55.13b**).

Tactile Communication Is Used to Strengthen Social Bonds and to Convey Information About Food

Animals often use tactile communication to establish bonds between group members. Primates frequently groom one another, and canines and felines may nuzzle and lick each other. Many insects use tactile communication to convey information on the whereabouts of food. Members of the ant genus *Leptothorax* feed on immobile prey such as dead insects. When a scouting ant encounters such prey, it usually

Figure 55.13 Visual communication. **(a)** Communication between fireflies is conducted by species-specific light flashes emitted by organs located on the underside of the abdomen. **(b)** The horns of these hercules beetles provide a signal about the strength of their owners.

BIOLOGY PRINCIPLE Structure determines function. In both these cases, morphological features influence animal behavior.

(a) Firefly flashing

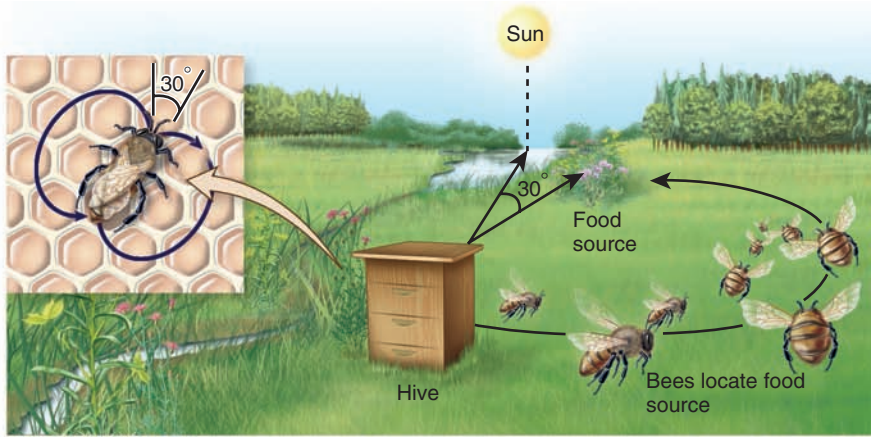
needs an additional worker to help bring it back to the nest. Rather than laying a scent trail, which is energetically costly, the scout ant recruits a helper and physically leads it to the food source. The helper runs in tandem with the scout, its antennae touching the scout's abdomen.

One of the most fascinating example of tactile communication among animals is the dance of the honeybee, elegantly studied by German ethologist Karl von Frisch in the 1940s. Bees commonly live in large hives; in the case of the European honeybee (*Apis mellifera*), the hive consists of 30,000–40,000 individuals. The flowering plants on which the bees forage can be located miles from the hive and are distributed in a patchy manner, with any given patch usually containing many flowers that store more nectar and pollen than an individual bee can carry back to the nest. The scout bee that locates a resource patch returns to the hive and recruits more workers to join it (**Figure 55.14a**). Because it is dark inside the hive, the scout uses a tactile signal. The scout dances on the vertical side of a honeycomb, and the dance is monitored by other bees, which follow and touch her to interpret the message. If the food is relatively close to the hive, less than 50 m away, the scout performs a round dance, rapidly moving in a circle, first in one direction and then the other. The other bees know the food is relatively close at hand, and the smell of the scout tells them what flower species to look for (**Figure 55.14b**).

If the food is more than 50 m away, the scout will perform a different type of dance, called a waggle dance. In this dance, the scout traces a figure 8, in the middle of which she waggles her abdomen and produces bursts of sound. Again, the other bees maintain contact with her. Occasionally, the scout regurgitates a small sample of nectar so the bees know the type of food source they are looking for. The truly amazing part of the waggle dance is that the angle at which the central part of the figure 8 deviates from the vertical direction of the comb represents the same angle at which the food source deviates from the point at which the Sun hits the horizon (**Figure 55.14c**). The direction is always up-to-date, because the bee adjusts the dance as the Sun moves across the sky.



Communication occurs not only to defend territories but also to communicate information to other individuals in the population, including potential mates. Although living on your own and

(a) Bees clustering around a recently returned scout, shown on the right

(c) Waggle dance: The angle of the waggle to the vertical orientation of the honeycomb corresponds to the angle of the food source from the Sun.

Figure 55.14 Tactile communication among honeybees regarding food sources. **(a)** Bees gather around a newly returned scout to receive information about nearby food sources. **(b)** If the food is less than 50 m away, the scout performs a round dance. **(c)** If the food is more than 50 m away, the scout performs a waggle dance, which conveys information about its location. If the dance is performed at a 30° angle to the right of the hive's vertical plane, then the food source is located at a 30° angle to the right of the Sun.

maintaining a territory has advantages, living in a group also has its benefits, including ready availability of mates and increased protection from predators. In the following section, we will examine group living and the behavior it engenders.

55.5 Living in Groups

Learning Outcome:

1. Outline the costs and benefits of living in groups.

As we have seen, much of animal behavior is directed at other animals. Some of the more complex behavior occurs when animals live together in groups such as flocks or herds. A central concern of ecology is to explain the distribution patterns of organisms, and a very important related task is to understand the reason for variation in the degree of group living. One way to approach this question is to assess the costs and benefits involved. Although group living increases competition for food and the spread of disease, it also has benefits that compensate for the costs involved. Many of these benefits relate to locating food sources, assistance in rearing offspring, access to mates, and group defense against predators. Group living can reduce predator success in at least two ways: through increased vigilance and through protection in numbers.

Living in Large Groups May Reduce the Risk of Predation Because of Increased Vigilance

For many predators, success depends on the element of surprise. If an individual is alerted to an attack, the predator's chance of success is lowered. A woodpigeon (*Columba palumbus*) in a flock takes to the air when it spots a goshawk (*Accipiter gentilis*). Once one pigeon takes flight, the other members of the flock are alerted and follow suit. If each individual in a group occasionally scans the environment for predators, the larger the group, the less time an individual forager needs to devote to vigilance and the more time it can spend feeding. This is referred to as the **many-eyes hypothesis** (Figure 55.15). Of course, cheating is a possibility, because some birds might never look up, relying on others to keep watch while they keep feeding. However, the individual that happens to be scanning when a predator approaches is most likely to escape, a fact that tends to discourage cheating.

Living in Groups Offers Protection by the Selfish Herd

Group living also provides protection in sheer numbers. Typically, predators take one prey animal per attack. In any given attack, an individual antelope in a herd of 100 has a 1 in 100 chance of being selected, whereas a single individual has a 1 in 1 chance. Large herds may be attacked more frequently than a solitary individual, but a herd is unlikely to attract 100 times more attacks than an individual, often because of the territorial nature of predators. Furthermore, large numbers of prey are able to defend themselves better than single individuals,

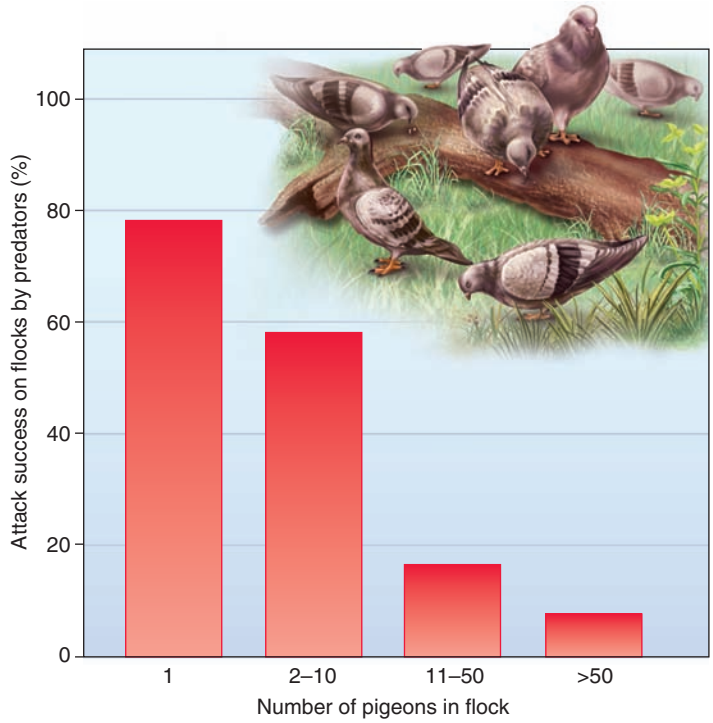

Figure 55.15 Living in groups and the many-eyes hypothesis. The larger the number of woodpigeons, the less likely an attack will be successful.

Concept Check: What other advantages do large groups have when being attacked by a predator?

which usually choose to flee. For example, groups of nesting black-headed gulls mob a crow, thereby reducing the crow's ability to steal the gulls' eggs.

Research has shown that within a group, each individual can minimize the danger to itself by choosing the location that is as close to the center of the group as possible. This was the subject of a famous paper, "The Geometry of the Selfish Herd," by the British evolutionary biologist W. D. Hamilton. The explanation of this type of defense is that predators are likely to attack prey on the periphery because they are easier to isolate visually. Many animals in herds tend to bunch close together when they are under attack, making it physically difficult for the predator to get to the center of the herd.

Overall, group size may be the result of a trade-off between the costs and benefits of group living. Although much group behavior serves to reduce predation, other complex behavior occurs in groups, including grooming behavior and behavior that appears to benefit the group at the expense of the individual. For example, a honeybee stings a potential hive predator to discourage it. The bee's stinger is barbed, and once it has penetrated the predator's skin, the bee cannot withdraw it. The bee's only means of escape is to tear away part of its abdomen, leaving the stinger behind and dying in the process. In the next section, we will explore the reasons for such apparent altruistic behavior, in which an individual incurs costs to itself for the benefit of others.

55.6 Altruism

Learning Outcomes:

1. **SciSKILLS »** Evaluate the arguments for and against the concept of group selection.
2. Describe how the concept of kin selection can explain altruistic behavior.
3. **SciSKILLS »** Predict which types of relatives are more or less likely to be the recipients of apparent altruistic acts.
4. Explain why eusociality is a form of altruism.

In Chapter 23, we learned that natural selection is a process in which certain individuals are more likely to pass on their genes, yet we see many instances in which some individuals forego reproducing altogether, apparently to benefit the group. How do ecologists explain **altruism**, a behavior that appears to benefit others at a cost to oneself? In this section, we begin by discussing whether such behavior evolved for the good of the group or for the good of the individual. As we will see, most altruistic acts serve to benefit the individual's close relatives. We will explore the concept of kin selection, which argues that acts of self-sacrifice indirectly promote the spread of an organism's genes, and see how this plays out in an extreme form in the genetics of social insect colonies. Last, we will examine reciprocal altruism, instances of altruism among nonkin.

In Nature, Individual Selfish Behavior Is More Likely Than Altruism

One of the first attempts to explain the existence of altruism was called **group selection**, the premise that natural selection produces outcomes beneficial for the whole group or species. In 1962, the British ecologist V. C. Wynne-Edwards argued that a group containing altruists, each willing to subordinate its interests for the good of the group, would have a survival advantage over a group composed of selfish individuals. In concept, the idea of group selection seemed straightforward and logical: A group that consisted of selfish individuals would overexploit its resources and die out, but the fitness of a group with altruists would be enhanced.

In the late 1960s, idea of group selection came under severe attack. Leading the charge was American evolutionary biologist George C. Williams, who argued that evolution acts through the individual; that is, adaptive traits generally are selected for because they benefit the survival and reproduction of the individual rather than the group. Some of Williams's arguments against group selection follow.

Mutation Mutant individuals that readily use resources for themselves or their offspring have an advantage in a population in which individuals limit their resource use. Consider a species of bird in which a pair lays only two eggs; that is, it has a clutch size of two, and the resources are not overexploited for the good of the group. Laying two eggs ensures a replacement of the parent birds but prevents a population explosion. Suppose a mutant bird that lays three eggs arises. If the population is not overexploiting its resources, sufficient food may be available for all three young to survive. If this happens, the three-egg genotype eventually becomes more common than the two-egg genotype.

Immigration Even in a population in which all pairs laid two eggs and no mutations occurred to increase clutch size, selfish individuals that laid more could still immigrate from other areas. In nature, populations are rarely sufficiently isolated to prevent immigration of selfish mutants from other populations.

Resource Prediction Group selection assumes that individuals are able to assess and predict future food availability and population density within their own habitat. There is little evidence that they can. For example, it is difficult to imagine that songbirds would be able to predict the future supply of the caterpillars that they feed to their young and adjust their clutch size accordingly.

Most ecologists accept individual gain as a more plausible result of natural selection than group selection. Population size is more often controlled by competition in which individuals strive to command as much of a resource as they can. Such selfishness can cause some seemingly surprising behaviors. For example, male Hanuman langurs (*Semnopithecus entellus*) kill infants when they take over groups of females from other males (**Figure 55.16**). The reason for the behavior is that when they are not nursing their young, females become sexually receptive much sooner, hastening the day when the male can father his own offspring. Infanticide ensures that the male can father more offspring, and the genes governing this tendency spread by natural selection.

Apparent Altruistic Behavior in Nature Is Often Associated with Kin Selection

If individual selfishness is more common than group selection, how do we account for what appear to be examples of altruism in

Figure 55.16 Infanticide as selfish behavior. Male Hanuman langurs (*Semnopithecus entellus*) may act aggressively toward the young of another male, even killing them, hastening the day the females become sexually receptive and thus the time when the males can father their own offspring. Note that the mother is running with the infant.

nature? Some propose that the answer lies in a concept known as **kin selection**, selection for behavior that lowers an individual's own fitness but enhances the reproductive success of a relative. Because relatives share many of the same genes, altruist individuals ensure that their genes are passed along to future generations by increasing the reproductive success of their relatives.

The probability that any two individuals will share a copy of a particular gene is a quantity, *r*, called the **coefficient of relatedness**. During meiosis in a diploid species, any given copy of a gene has a 50% chance of segregating into an egg or sperm. A mother and father are on average related to their children by an amount $r = 0.5$, because half of a child's genes come from its mother and half from its father. By similar reasoning, brothers or sisters are related by an amount $r = 0.5$ (they share half their mother's genes and half their father's); grandchildren and grandparents, by 0.25; and cousins, by 0.125 (**Figure 55.17**). In 1964, ecologist W. D. Hamilton realized the implication of the coefficient of relatedness for the evolution of altruism. An organism not only can pass on its genes by having offspring, but also can pass them on through ensuring the survival of siblings, nieces, nephews, and cousins. This means an organism has a vested interest in protecting its brothers and sisters, and even their offspring.

The term **inclusive fitness** is used to designate the total number of copies of genes passed on through one's relatives, as well as one's own reproductive output. Hamilton proposed that an altruistic gene is favored by natural selection when

$$rB > C$$

where *r* is the coefficient of relatedness of donor (the altruist) to the recipient, *B* is the benefit received by the recipient of the altruism, and *C* is the cost incurred by the donor. This relationship is known as **Hamilton's rule**.

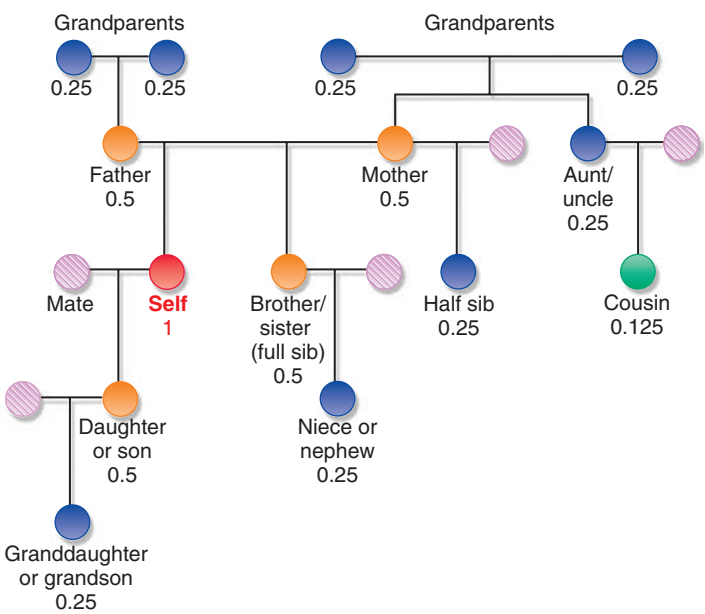

Figure 55.17 Degree of genetic relatedness to self in a diploid organism. Pink hatched circles represent completely unrelated individuals.

Figure 55.18 Altruistic behavior or kin selection? *Datana ministra* caterpillars exhibit a bright, striped warning pattern to advertise their bad taste to predators.

Concept Check: *Why do these caterpillars congregate in clusters?*

Let's examine a situation involving altruism within a group of animals. Many insect larvae, especially caterpillars, are soft-bodied creatures. They rely on a bad taste or toxin to deter predators and advertise this condition with bright warning colors. For example, noxious *Datana ministra* caterpillars, which feed on oaks and other trees, have bright red and yellow stripes and adopt a specific posture with head and tail ends upturned when threatened (**Figure 55.18**). Unless it is born with an innate avoidance of this prey type, a predator has to kill and eat one of the caterpillars in order to learn to avoid similar individuals in the future. It is of no personal use to the unlucky caterpillar to be killed. However, animals with warning colors often aggregate in kin groups because they hatch from the same egg mass. In this case, the death of one individual is likely to benefit its siblings, which are less likely to be attacked by the same predator in the future, and thus its genes are more likely to be passed on to the next generation. This explains why the genes for bright color and a warning posture are passed on from generation to generation. In a case where $r = 0.5$, *B* might be 50, and $C = 1$, the benefit of 25 is greater than 1, so the genes for this behavior are favored by natural selection.

A common example of altruism in social animals occurs when a sentry raises an alarm call in the presence of a predator. This behavior has been observed in Belding's ground squirrels (*Spermophilus beldingi*). The squirrels feed in groups, with certain individuals acting as sentries and watching for predators. As a predator approaches, the sentry typically gives an alarm call, and the group members retreat into their burrows. Similar behavior occurs in prairie dogs (*Cynomys* spp.) (**Figure 55.19**). In drawing attention to itself, the sentry is at a higher risk of being attacked by the predator. However, in many groups, those closest to the sentry are most likely to be offspring or brothers or sisters; thus, the altruistic act of alarm calling is thought to be favored by kin selection. Supporting this is the observation that most alarm calling is done by females, because they are more likely to stay in the colony where they were born and have kin nearby, whereas the males are more apt to disperse far from the colony.

BIO TIPS

THE QUESTION *From the perspective of natural selection, should you sacrifice your life to save two sisters or nine cousins?*

TOPIC ***What topic in biology does this question address?*** The topic is animal behavior. More specifically, the question concerns how the genetic relatedness of individuals influences apparently altruistic behavior.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you know that you have to compare the relatedness between you and a sister with that between you and a cousin. From your understanding of the topic and from Figure 55.17, you know that the coefficent of relatedness for a full sibling (a sister) is $r = 0.5$. The coefficient of relatedness for a cousin is $r = 0.125$. You also may remember how to use Hamilton's rule ($rB > C$) to calculate the answer (where r is the coefficient of relatedness of donor to recipient, B is the benefit received by the recipient of the altruism, and C is the cost incurred by the donor).

PROBLEM-SOLVING STRATEGY ***Make a calculation. Compare and contrast.*** Use Hamilton's rule to determine for which set of relatives it would be more beneficial (from the perspective of natural selection) to sacrifice your life. In the first case, because $r = 0.5$, $B = 2$ (sisters), and $C = 1$ (your life), rB is not greater than C. In the second case, $r = 0.125$, $B = 9$, and $C = 1$, so rB is greater than C.

ANSWER *From the perspective of natural selection, you should sacrifice your life to save nine cousins but not two sisters.*

Altruism in Eusocial Animals Arises Partly from Genetics and Partly from Lifestyle

Perhaps the most extreme form of altruism is the evolution of sterile castes in social animals, in which the vast majority of females, known as workers, do not reproduce but instead help one reproductive female (the queen) to raise offspring, a phenomenon called **eusociality**. In insects, the explanation of eusociality lies partly in the genetics of most social insect reproduction. Females develop from fertilized eggs and are diploid, the product of fertilization of an egg by a sperm. Males develop from unfertilized eggs and are haploid.

Such a system of sex determination is called the **haplodiploid system** (refer back to Figure 16.14d). If they have the same parents, each daughter receives an identical set of genes from her haploid father. The other half of a female's genes comes from her diploid mother. The coefficient of relatedness (r) of sisters is 0.50 (from father) + 0.25 (from mother) = 0.75. The result is that females are more related to their sisters (0.75) than they would be to their own offspring (0.50). From the perspective of natural selection, these numbers suggest that it is evolutionarily advantageous for females to stay in the nest or hive and care for other female offspring of the queen, which are their full sisters.

Elegant though these types of explanations are, they do not explain the whole picture. Large eusocial colonies of termites exist, but termites are diploid, not haplodiploid. In this case, how do we account for the existence of eusociality? In the 1970s, American evolutionary biologist

Figure 55.19 Alarm calling, a possible example of kin selection. This prairie dog sentry is emitting an alarm call to warn other individuals, which are often close kin, of the presence of a predator. It is believed that by doing so, the sentry draws attention away from the others but becomes an easier target itself.

BIOLOGY PRINCIPLE **The genetic material provides a blueprint for sustaining life.** The similarities in DNA between kin promote behavior whereby some animals act to save the lives of their close relatives.

Richard Alexander suggested it was the particular lifestyle of these animals, rather than genetics, that promoted eusociality. He argued that in a normal diploid organism, females are related to their daughters by 0.50 and to their sisters by 0.50, so it should matter little to them whether they rear siblings or daughters of their own. He predicted, well before eusociality was discovered to occur in mammals, that a eusocial mammalian species could exist when certain conditions were met, including that the nests or burrows be enclosed and subterranean, in order to house a large colony, and that the colony have a food supply such as large tubers and roots. In addition, the soil would need to be hard, dry clay to keep the colony safe from digging predators. He proposed that the colony would be defended by a few members of the colony willing to give their lives in defense of others, and he posited the existence of mechanisms by which a queen could manipulate other individuals.

At the time, Alexander had no idea that a mammal with such characteristics existed. Surprisingly, subsequent discoveries confirmed the existence of a eusocial mammal that satisfied all of the predictions of Alexander's model: the naked mole rat (*Heterocephalus glaber*). Naked mole rats are diploid species that live in arid areas of Africa in large underground colonies where only one female, the queen, produces offspring (**Figure 55.20**). A renewable food supply is present in the form of tubers of the plant *Pyrenacantha kaurabassana*. These weigh up to 50 kg and can provide food for a whole colony. Because the burrows are hard packed, there are few ways to attack them, and a heroic effort by a mole rat blocking the entrance can effectively stop a predator (commonly a rufous-beaked snake). The queen mole rat does indeed manipulate the colony members; she suppresses reproduction in other females by producing a pheromone in her urine that is passed around the colony by grooming. Hence, the mole rats seem to have evolved the appropriate behavior to exploit this ecological niche. As Alexander argued, lifestyle characteristics can provide an explanation for the evolution of eusociality in species such as termites and naked mole rats, in which both sexes are diploid.

Figure 55.20 A naked mole rat colony (*Heterocephalus glaber*). In this mammalian species, most females do not reproduce; only the queen has offspring.

Unrelated Individuals May Engage in Altruistic Acts If the Altruism Is Likely to Be Reciprocated

Even though we have argued that kin selection can explain instances of apparent altruism, cases of altruism are known to exist between unrelated individuals. What drives this type of behavior appears to be a "You scratch my back, I'll scratch yours" type of reciprocal altruism, in which the cost to the animal of behaving altruistically is offset by the likelihood of a return benefit. This occurs in nature, for example, when unrelated chimps groom each other.

American biologist Gerald Wilkinson has noted that female vampire bats exhibit reciprocal altruism via food sharing. Vampire bats can die after 60 hours without a blood meal, because they can no longer maintain their correct body temperature. Adult females share their food with their young, the young of other females, and other unrelated females that have not fed. The females and their dependent young roost together in groups of 8 to 12. A hungry female will solicit food from another female by approaching and grooming her. The female being groomed then regurgitates part of her blood meal for the other. The roles of blood donor and recipient are often reversed, and Wilkinson showed that unrelated females are more likely to share with those that had recently shared with them. The probability of a female getting a free lunch is decreased because the roost consists of individuals that remain associated with each other for long periods of time.

55.7 Mating Systems

Learning Outcomes:

1. Compare and contrast promiscuous, monogamous, polygynous, and polyandrous mating systems.
2. **SciSKILLS »** Predict the circumstances that favor polygyny.

In nature, males produce millions of sperm, but females produce far fewer eggs. It would seem that the majority of males are superfluous because one male could easily fertilize all the females in a local area. If one male can mate with many females, why in most species does the sex ratio remain at approximately 1 to 1? The answer lies with natural selection. Let's consider a hypothetical population that contains 10 females

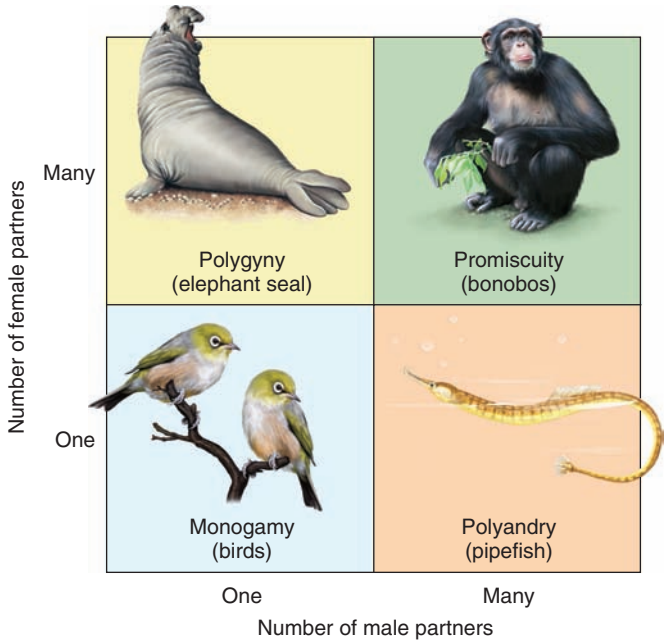

Figure 55.21 The four different animal mating strategies.

to every male; each male mates, on average, with 10 females. A parent whose children were exclusively sons could expect to have 10 times the number of grandchildren of a parent with the same number of daughters. Under such conditions, natural selection would favor the spread of genes for male-producing tendencies, and males would become prevalent in the population. If the population were mainly males, females would be at a premium, and natural selection would favor the spread of genes for female-producing tendencies. Such constraints operate on the numbers of both male and female offspring, keeping the sex ratio at about 1:1. This idea was developed in 1930 by the British geneticist Ronald Fisher and has come to be known as Fisher's principle.

Even though the sex ratio is fairly even in most species, that doesn't mean that one female always mates with one male or vice versa. Four different types of mating systems occur in nature (**Figure 55.21**). In some species, mating is promiscuous, with each female and each male mating with multiple partners within a breeding season. In monogamy, each individual mates exclusively with one partner over at least a single breeding cycle and sometimes for longer. In contrast, polygamy is a system in which either males or females mate with more than one partner in a breeding season. There are two types of polygamy. In polygyny (Greek for many females), one male mates with more than one female, but females mate only with one male. In polyandry (Greek for many males), one female mates with several males, but males mate with only one female.

In Promiscuous Mating Systems, Each Male or Female Mates with Multiple Partners

Chimpanzees and bonobos are somewhat **promiscuous**; each male mates with many females, and vice versa. Here sex alleviates conflict within the social group, but sometimes promiscuity is favored in unpredictable environments. Females that maximize the genetic diversity of their offspring are more likely to have at least some offspring that will survive in a changing world. Intertidal and terrestrial mollusks are also usually promiscuous. Individuals copulate with several partners,

and eggs are fertilized with sperm from several different individuals. These mollusks are slow moving and risk desiccation when searching for a mate. The risk of not finding a mate is believed to promote promiscuous mating. Humpback whales, *Megaptera novaeangliae*, are widely scattered throughout their breeding range, and genetic studies suggest that they have a promiscuous mating system.

In Monogamous Mating Systems, Males and Females Are Paired for at Least One Reproductive Season

In **monogamy**, each individual mates exclusively with one partner over at least a single breeding cycle and sometimes for longer. Males and females do not exhibit much **sexual dimorphism**, a pronounced difference in the morphologies of the two sexes within a species, and are generally similar in body size and structure (**Figure 55.22a**). Several hypotheses explain the existence of monogamy. The first is the **mate-guarding hypothesis**, which suggests that males stay with a female to protect her from being fertilized by other males. Such a strategy may be advantageous when receptive females are widely scattered and difficult to find.

The **male-assistance hypothesis** maintains that males remain with females to help them rear their offspring. Monogamy is common among birds, about 70% of which are socially monogamous; that is, the pairings remain intact during at least one breeding season. According to the male-assistance hypothesis, monogamy is prevalent in birds because eggs and chicks take a considerable amount of parental care. Most eggs need to be incubated continuously if they are to hatch, and chicks require almost continual feeding. It is therefore in the male's best interest to help raise his young, because he would have few surviving offspring if he did not.

The **female-enforced monogamy hypothesis** suggests that females stop their male partners from being polygynous. Male and female burying beetles (*Nicrophorus defodiens*) work together to bury small, dead animals, which provide a food resource for their developing offspring. Males release pheromones to attract other females to the site. However, while an additional female might increase the male's fitness, the additional developing offspring might compete with the offspring of the first female, decreasing her fitness. As a result, on smelling these pheromones, the first female interferes with the male's attempts at signaling, preserving the monogamous relationship.

Recent research by American neuroscientists Larry Young and Elizabeth Hammock has shown that social behavior such as fidelity may have a genetic basis. These researchers found that fidelity of male voles depends on the length of a short tandem repeat sequence (STR) in a gene that codes for a key hormone receptor. Adult male voles with the long version of the STR were more apt to form pair bonds with female partners and nurture their offspring than were voles with the short version.

In Polygynous Mating Systems, One Male Mates with Many Females

In **polygyny** (Greek, meaning many females), one male mates with more than one female in a single breeding season. Physiological constraints often dictate that female organisms must care for the young. Because of these constraints, at least in many organisms with internal fertilization, such as mammals and some fishes, males are able to mate with and then desert several females. Polygynous systems are therefore associated with uniparental care of young, with males contributing little. Sexual dimorphism is typical in polygynous mating systems, with males developing a larger body size to boost success in competition over mates (**Figure 55.22b**). Sexual maturity is often delayed in males that fight because of the considerable time it takes to reach a sufficiently large size to compete for females.

Polygyny is influenced by the temporal or spatial distribution of breeding females and by the availability of resources. In cases when all females are sexually receptive within the same narrow period of time, little opportunity exists for a male to garner all the females for himself. When female reproductive receptivity is spread out over weeks or months, there is much more opportunity for males to mate with more than one female. Where some critical resource is patchily distributed and in short supply, certain males may dominate the resource and breed with more than one visiting female. The major source of nestling death in the lark bunting (*Calamospiza melanocorys*), which lives in North American grasslands, is overheating from

(a) Monogamous species (b) Polygynous species (c) Polyandrous species

Figure 55.22 Sexual dimorphism in body size and mating system. **(a)** In monogamous species, such as these Manchurian cranes, *Grus japonensis*, males and females do not exhibit pronounced sexual dimorphism and appear very similar. **(b)** In polygynous species, such as elk, *Cervus canadensis*, males are bigger than females and have large horns with which they engage in combat over females. **(c)** In polyandrous species, females are usually bigger, as with these golden silk spiders, *Nephila clavipes*.

Figure 55.23 Male birds at a lek. Black grouse (*Tetrao tetrix*) congregate at a moorland lek in Scotland in April. Females visit the leks, and males display to them.

too much exposure to the Sun. Prime territories are therefore those with abundant shade, and some males with shaded territories attract two females, even though the second female can expect no help from the male in the process of rearing young. Males in some exposed territories remain bachelors for the season. From the dominant male's point of view, polygyny is advantageous; from the female's point of view, there may be costs. Although by choosing dominant males, a female may be gaining access to good resources, she will have to share these resources with other females.

Sometimes males defend a group of females without commanding a resource-based territory. This pattern is more common when females naturally congregate in groups or herds, perhaps to avoid predation, as with horses, zebras, and some deer, and where space is limited, as with southern elephant seals. Usually the largest and strongest males command most of the matings, but being a dominant male is usually so exhausting that males may only manage to remain the strongest male for a year or two.

Polygynous mating can occur where neither resources nor groups of females are defended. In some instances, particularly in birds and mammals, males display in designated communal courting areas called **leks** (**Figure 55.23**). Females come to these areas specifically to find a mate, and they choose a prospective mate after the males have performed elaborate displays. Most females seek to mate with the best male, so a few of the flashiest males perform the vast majority of the matings. At a lek of the white-bearded manakin (*Manacus manacus*) of South America, one male accounted for 75% of the 438 matings when there were as many as 10 males. A second male mated 56 times (13% of matings), but six others mated only a total of 10 times.

In Polyandrous Mating Systems, One Female Mates with Many Males

Polyandry (Greek, meaning many males), in which one female mates with several males, is more rare than polygyny. Nevertheless, it occurs in some species of birds, fishes, and insects. Sexual dimorphism is present, with the females being the larger of the sexes (see **Figure 55.22c**). In the Arctic tundra, the summer season is short but very productive, providing a bonanza of insect food for 2 months. The productivity of the breeding grounds of the spotted sandpiper (*Actitis macularia*) is so high that the female becomes rather like an egg factory, laying up to five clutches of four eggs each in 40 days. Her reproductive success is limited not by food but by the number of males she can find to incubate the eggs, and females compete for males, defending territories where the males sit.

Polyandry is also seen in some species where egg predation is high, and males are needed to guard the nests. For example, in the pipefish (*Syngnathus typhle*), males have brood pouches that provide eggs with safety and a supply of oxygen- and nutrient-rich water. Females produce enough eggs to fill the brood pouches of two males and may mate with more than one male.

Ultimately, as we have seen, most behaviors have evolved to maximize an individual's reproductive output. In a successful group of individuals, this leads to population growth. But we are not knee-deep in elk or Manchurian cranes, so there must be some constraints on reproductive output. In Chapter 56, we will turn to the realm of population ecology to explore how populations grow and what factors limit their growth.

Summary of Key Concepts

55.1 The Influence of Genetics and Learning on Behavior

- Behavior is usually due to the interaction of an organism's genes and the environment.
- Genetically programmed behaviors are termed innate and often involve a sign stimulus that initiates a fixed action pattern (FAP) (Figures 55.1, 55.2).
- Organisms can often make modifications to their behavior based on previous experience, a process called learning. Some forms of learning include habituation, classical conditioning, operant conditioning, and cognitive learning (Figures 55.3, 55.4).
- Much behavior is a mixture of innate and learned behaviors. A good example of this occurs in a process called imprinting, in which animals develop strong attachments that influence subsequent behavior (Figures 55.5, 55.6).

55.2 Local Movement and Long-Range Migration

- The simplest forms of local movement involve kinesis, taxis, and memory (Figure 55.7).
- Many animals undergo long-range seasonal movement called migration in order to feed or breed. They do this using three mechanisms: piloting (the ability to move from one landmark to the next), orientation (the ability to follow a compass bearing), and navigation (the ability to set, follow, and adjust a compass bearing) (Figures 55.8, 55.9).

55.3 Foraging Behavior

- Animals use complex behavior in food gathering or foraging. Optimality theory views foraging behavior as a compromise between the costs and benefits involved. The theory of optimal foraging assumes that animals modify their behavior to keep the ratio of their energy uptake to energy expenditure high. The risk of predation has an influence on foraging behavior (Figures 55.10, 55.11).
- The size of a territory, a fixed area in which an individual or group excludes other members of its own species, tends to be optimized according to the costs and benefits involved (Figure 55.12).

55.4 Communication

- Communication is a form of behavior. The use of different forms of communication between organisms depends on the environment in which they live.

- Chemical communication often involves marking territories; auditory and visual forms of communication are often used to attract mates. A fascinating form of tactile communication involves the dance of the honeybee (Figures 55.13, 55.14).

55.5 Living in Groups

- Many benefits of group living relate to defense against predators, offering protection through sheer numbers and through what is called the many-eyes hypothesis or the geometry of the selfish herd (Figure 55.15).

55.6 Altruism

- Altruism is behavior that benefits others at a cost to oneself. One of the first hypotheses to explain altruism, called group selection, suggested that natural selection produced outcomes beneficial for the group. Biologists now believe that most apparently altruistic acts are often associated with outcomes beneficial to those most closely related to the individual, a concept termed kin selection (Figures 55.16, 55.17, 55.18, 55.19).
- Altruism among eusocial animals may arise partly from the unique genetics of the animals and partly from lifestyle (Figure 55.20).
- Altruism is known to exist among nonrelated individuals that live in close proximity for long periods of time.

55.7 Mating Systems

- Four types of mating systems are found among animals: promiscuity, monogamy, polygyny, and polyandry. Relative body size of males and females depends on the species' mating system (Figures 55.21, 55.22).
- Polygynous mating can often occur in situations when males dominate a resource, defend groups of females, or display in common courting areas called leks (Figure 55.23).

Assess and Discuss

Test Yourself

1. What is the proximate cause of male deer fighting over females?
   a. to determine their supremacy over other males
   b. to injure other males so that these other males cannot mate with females
   c. to maximize the number of genes they pass on
   d. because changes in day length stimulate this behavior
   e. because fighting helps rid the herd of weaker individuals
2. Geotaxis is a response to the force of gravity. Fruit flies placed in a vial will move to the top of the vial. This is an example of _____ geotaxis.
   a. positive
   b. neutral
   c. innate
   d. negative
   e. learned
3. Certain behaviors seem to have very little environmental influence. Such behaviors are the same in all individuals regardless of the environment and are referred to as _____ behaviors.
   a. genetically programmed
   b. instinctual
   c. innate
   d. all of the above
   e. b and c only
4. Patrick has decided to teach his puppy a few new tricks. Each time the puppy responds correctly to Patrick's command, the puppy is given a treat. This is an example of
   a. habituation.
   b. classical conditioning.
   c. operant conditioning.
   d. imprinting.
   e. orientation.
5. Whales have magnetite in their retinas, which aids in navigation during migration by
   a. piloting.
   b. locating the position of the Sun.
   c. use of the Earth's magnetic fields.
   d. locating the positions of the stars.
   e. none of the above.
6. For group living to evolve, the benefits of living in a group must be greater than the costs. Which of the following is an example of a benefit of living in a group?
   a. reduced spread of disease and/or parasites
   b. increased food availability
   c. reduced competition for mates
   d. decreased risk of predation
   e. all of the above
7. The modification of behavior based on prior experience is called
   a. a fixed action pattern.
   b. learning.
   c. navigation.
   d. adjustment behavior.
   e. innate.
8. When an individual behaves in a way that reduces its own fitness but increases the fitness of others, the organism is exhibiting
   a. kin selection.
   b. group selection.
   c. altruism.
   d. selfishness.
   e. ignorance.
9. In ants, which employ a haplodiploid mating system, the coefficient of relatedness for fathers and sons is $r =$
   a. 0.
   b. 0.125.
   c. 0.25.
   d. 0.5.
   e. 0.75.
10. In a polygynous mating system,
    a. one male mates with one female.
    b. one female mates with many different males.
    c. one male mates with many different females.
    d. many different females mate with many different males.

Conceptual Questions

1. Some male spiders are eaten by the females after copulation. How can this act be seen to benefit the males?
2. Male parental care occurs in only 7% of fishes and amphibian species with internal fertilization but in 69% of species with external fertilization. Propose an explanation for why this is so.
3.  A principle of biology is that *new properties emerge from complex interactions*. Male brown bears (*Ursus arctos*) can be infanticidal, killing cubs when they move into a new territory. Explain why bear hunting may have severe consequences for bear populations.

Collaborative Questions

1. Whooping cranes (*Grus americana*) are an endangered species that is bred in captivity to increase its numbers. One problem with this approach is that these cranes are migratory. In the absence of other cranes, can you think of an innovative way human researchers might have used crane behavior to ensure safe passage of the birds to overwintering sites?
2. Discuss several ways in which organisms communicate with each other.

CHAPTER OUTLINE

56.1 Understanding Populations
56.2 Demography
56.3 How Populations Grow
56.4 Human Population Growth
Summary of Key Concepts
Assess and Discuss

A population of black-footed ferrets in Meeteetse, Wyoming.

The last known population of black-footed ferrets, *Mustela nigripes*, was discovered in 1981 near Meeteetse, Wyoming. Shortly thereafter, all but 18 of the 100 known ferrets in Meeteetse died of canine distemper. The remainder were captured between 1985 and 1987, inoculated against distemper, and bred in captivity, with the intent of reestablishing the population in the wild later on. Since then, populations have been established in Arizona, Colorado, Montana, South Dakota, Utah, Wyoming, and Chihuahua, Mexico.

In Wyoming, an area called Shirley Basin was one of those targeted for reintroductions of captive-born animals. From 1991 to 1994, Shirley Basin received 228 ferrets, but distemper again triggered a decline in the population size. By 1997, only 5 ferrets were found. Extinction seemed imminent. Monitoring efforts, which might disturb the animals, decreased. Surprisingly, by 2003, a total of 52 animals were found, and by 2006, 223 were present. How did the number of ferrets increase this fast?

A **population** can be defined as a group of interbreeding individuals occupying the same area at the same time. Thus, we can think of a population of water lilies in a particular lake, the lion population in the Ngorongoro crater in Africa, or the human population of New York City. The boundaries of a population can be a little difficult to define, though they may correspond to geographic features such as the boundaries of a lake or forest or be contained within a mountain valley or a certain island. Individuals may enter or leave a population, such as the human population of New York City or the deer population in North Carolina. Thus, populations are often fluid entities, with individuals moving into (immigrating) or out of (emigrating) an area.

This chapter explores **population ecology**, the study of the factors that affect population size and how these factors change over space and time. To study populations, ecologists need to employ some of the tools of **demography**, the study of birth rates, death rates, age distributions, and the sizes of populations. We begin our discussion by examining the ways that ecologists measure and categorize populations. We will explore characteristics of populations and how growth rates are determined by the number of reproductive individuals in the population and their fertility rate. These data are used to construct simple mathematical models that allow ecologists to analyze population growth, such as that of the black-footed ferrets, and predict future growth. We will also look at the factors that limit the growth of populations and will conclude by using the population concepts and models to explore the growth of human populations.

56.1 Understanding Populations

Learning Outcomes:

1. List the different techniques ecologists use to measure population density.
2. **SciSKILLS** » Calculate population size using mark-recapture data, and understand the limitations of this technique.
3. Identify the three main patterns of dispersion observed in nature.
4. Describe the difference between semelparity and iteroparity—two different reproductive strategies.

Within their areas of distribution, organisms occur in varying numbers. We recognize this pattern by saying a plant or animal is rare in one place and common in another. For added precision, ecologists quantify distribution further and talk in terms of population **density**—the numbers of organisms in a given unit area or volume. Population growth affects population density, and knowledge of both can help in making decisions about the management of species. How long will it take for a population of an endangered species to recover to a healthy level if we protect it from its most serious threats? For example, how quickly will the black-footed ferret populations increase in Wyoming? A knowledge of population growth rates and population densities would allow us to predict future ferret population sizes.

In this section, we will examine techniques that are used to measure population sizes and densities and other characteristics of populations within their habitats. We will also discuss the different reproductive strategies organisms use and see how ecologists assign individuals to different groups called age classes.

Ecologists Use Many Different Methods to Quantify Population Size and Density

The simplest method for measuring population size is to visually count the number of organisms in a given area. We can reasonably do this only if the area is small and the organisms are relatively large. For example, we can readily determine the number of gumbo limbo trees (*Bursera simaruba*) on a small island in the Florida Keys. Normally, however, population ecologists calculate the density of plants or animals in a small area and use this figure to estimate the total abundance over a larger area.

For plants, algae, or other sessile organisms such as intertidal animals, it is fairly easy to count numbers of individuals per square meter or, for larger organisms such as trees, numbers per hectare (an area of land equivalent to 2.471 acres). However, many plant individuals are clonal; that is, they grow in patches of genetically identical individuals, so that rather than count individuals, ecologists can also use the amount of ground covered by plants as an estimate of vegetation density.

Quadrats Can Be Used to Quantify Population Densities of Sessile Species Plant ecologists use a sampling device called a **quadrat**, a square frame that often, but not always, measures 50×50 cm and encloses an area of 0.25 m^2 (**Figure 56.1a**). They then count the numbers of plants of a given species inside the quadrat to obtain a density estimate per square meter. For example, if you counted densities of 20, 35, 30, and 15 plants in four quadrats, you could reliably say that the density of this species was 25 individuals per 0.25 m^2, or 100/m^2. For larger plants, such as trees, a quadrat would be ineffective. To count such organisms, many ecologists perform a **line transect**, in which a long piece of string is stretched out and any tree along its length is counted. For example, to count tree species on larger islands in the Florida Keys, we could lay out a 100-m line transect and count all the trees within 1 m on either side of the transect. In effect, this transect is little more than a long, thin quadrat encompassing 200 m^2. By performing five such transects, we could obtain estimates of tree density per 1,000 m^2 and then extrapolate that to a number per hectare or per island.

Traps are Used to Study More Mobile Species Several different sampling methods exist for quantifying the population density of animals, which are more mobile than plants. Suction traps, like giant aerial vacuum cleaners, can suck flying insects from the sky. Pitfall traps set into the ground can catch species such as spiders, lizards, or beetles wandering over the surface (**Figure 56.1b**). Sweep nets can be passed over vegetation to dislodge and capture the insects feeding there. Mist nets—very fine netting spread between trees—can entangle flying birds and bats (**Figure 56.1c**). Baited snap traps, such as mouse traps, or live traps can snare terrestrial animals (**Figure 56.1d**). Population density can thus be estimated as the number of animals caught per trap or per unit area where a given number of traps are set, for example, 10 traps per 100 m^2 of habitat.

The Mark-Recapture Technique Can Be Used to Estimate Population Sizes Sometimes population biologists capture animals and then tag and release them (**Figure 56.2**). The rationale behind

(a) Quadrat (b) Pitfall trap (c) Mist net (d) Live trap

Figure 56.1 Sampling techniques. **(a)** Quadrats are frequently used to count the number of plants per unit area. **(b)** Pitfall traps set into the ground catch wandering species such as beetles and spiders. **(c)** Mist nets consist of very fine mesh to entangle birds or bats. **(d)** Baited live traps catch terrestrial animals, including this lion tamarin, *Leontopithecus rosalia*, in Brazil.

Figure 56.2 The mark-recapture technique for estimating population size. An ear tag identifies this Rocky Mountain goat (*Oreamnos americanus*) in Olympic National Park, Washington. Recapture of such marked animals permits estimates of population size.

the **mark-recapture technique** is that after the tagged animals are released, they mix freely with unmarked individuals and within a short time are randomly mixed within the population. The population is resampled, and the numbers of marked and unmarked individuals are recorded. We assume that the ratio of marked to unmarked individuals in the second sample is the same as the ratio of marked individuals in the first sample to the total population size. Thus,

$$\frac{\text{Number of individuals marked in first catch}}{\text{Total population size, } N} = \frac{\text{Number of marked recaptures in second catch}}{\text{Total number of second catch}}$$

Let's say we catch 50 largemouth bass in a lake and mark them with colored fin tags. A week later, we return to the lake and catch 40 fish and 5 of them were previously tagged fish. If we assume no immigration or emigration has occurred, which is quite likely in a closed system like a lake, and we assume there have been no births or deaths of fish, then the total population size is given by rearranging the equation:

$$\text{Total population size, } N = \frac{\text{Number of marked individuals in first catch} \times \text{Total number of second catch}}{\text{Number of marked recaptures in second catch}}$$

Using the data,

$$N = \frac{50 \times 40}{5} = \frac{2{,}000}{5} = 400$$

From this calculation, we estimate that the lake has a total population size of 400 largemouth bass. This could be useful information for game and fish personnel who wish to know the total size of a fish population in order to set catch limits.

However, the mark-recapture technique can have drawbacks. Some animals that have been marked may learn to avoid the traps. Recapture rates will then be low, resulting in an overestimate of population size. Imagine that instead of 5 tagged fish out of 40 recaptured fish, we get only 2 tagged fish. Now our population size estimate is 2,000/2 = 1,000, a dramatic increase in our population size estimate. On the other hand, some animals can become "trap-happy," particularly if the traps are baited with food. This would result in an underestimate of the population size.

Because of the limitations of the mark-recapture technique, ecologists also use other methods to estimate population density. For some larger terrestrial or marine species, captured animals can be fitted with radio collars and followed remotely, using an antennal tracking device. Their home ranges can be determined and population estimates developed based on the area of available habitat. For many species with valuable pelts, ecologists can track population densities through time by examining pelt records taken from trading stations. They can also estimate relative population density by examining catch per unit effort, which is especially valuable in commercial fisheries. They can't easily expect to count the number of fishes in an area of ocean, but can count the number caught, say, per 100 hours of trawling. For some species that leave easily recognizable fecal pellets, like rabbits or deer, ecologists can count pellet numbers, and, if they know the pellet production per individual and how long pellets last in the environment, can estimate population size. For frogs or birds, they can count chorusing or singing individuals. Ecologists can also count leaf scars or chewed leaves and, if they know the responsible herbivores and the rates of herbivory, use these to estimate the density of the animals that damage them.

BIO TIPS

THE QUESTION *Suppose we mark 110 Rocky Mountain goats in a population and later recapture 100 goats, 20 of which have ear tags. What is the estimate of the total population size?*

TOPIC ***What topic in biology does this question address?*** The topic is estimating population size, specifically, using the mark-recapture technique.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you know how many goats were marked, how many were recaptured, and how many of the recaptured goats were also marked. From your understanding of the mark-recapture technique, you may recall the formula used to estimate population size.

PROBLEM-SOLVING STRATEGY ***Make a calculation.*** Insert the relevant data into the formula given in the text:

$$\text{Total population size, } N = \frac{\text{Number of marked individuals in first catch} \times \text{Total number of second catch}}{\text{Number of marked recaptures in second catch}}$$

$$N = \frac{110 \times 100}{20} = 550$$

ANSWER *The estimated total population size is 550 goats.*

(a) Clumped (b) Uniform (c) Random

Figure 56.3 Three types of dispersion. **(a)** A clumped distribution pattern, as for these plants clustered around an oasis, often results from the uneven distribution of a resource, in this case, water. **(b)** A uniform distribution pattern, as for these nesting black-browed albatrosses (*Diomedea melanophris*) on the Falkland Islands, may be a result of competition or social interactions. **(c)** A random distribution pattern, as for these bushes at Leirhnjukur Volcano in Iceland, is the least common form of spacing.

Concept Check: *What is the distribution pattern of students in a half-empty classroom?*

BioConnections: *Look back to Figure 55.12b. What is the likely dispersion pattern of cheetahs in the wild?*

Populations Show Different Degrees of Spacing Among Individuals

Individuals within a population show different patterns of **dispersion**; that is, they can be clustered together or spread out to varying degrees. The three basic kinds of dispersion patterns are clumped, uniform, and random.

The type of dispersion observed in nature can tell us a lot about what processes shape group structure. The most common dispersion pattern is **clumped**, because resources in nature tend to be clustered. For example, certain plants may do better in moist conditions, and moisture is greater in low-lying areas (**Figure 56.3a**). Social behavior among animals that aggregate into flocks or herds reflects a clumped pattern.

On the other hand, competition may cause a **uniform** dispersion pattern among individuals, as among trees in a forest. At first, the pattern of trees and seedlings may appear random as seedlings develop from seeds dropped at random, but competition among roots may cause some trees to be outcompeted by others, causing a thinning out and resulting in a relatively uniform distribution. Thus, the dispersion pattern starts out random but ends up uniform. Uniform dispersions may also result from social interactions, as among some nesting birds, which tend to keep an even distance from one other (**Figure 56.3b**).

Perhaps the rarest dispersion pattern is **random**, in which the probability of finding an individual at any point in an area is equal, because resources in nature are rarely randomly spaced. Where resources are common and abundant, as in moist, fertile soil, the dispersion patterns of plants may lack a pattern as plants germinate from randomly dispersed wind-blown seeds (**Figure 56.3c**).

Reproductive Strategies May Differ Among Species

To better understand how populations grow in size, let's consider their reproductive strategies. Some organisms produce all of their offspring in a single reproductive event. This pattern, called **semelparity** (from the Latin *semel*, meaning once, and *parere*, meaning to bear), is common in insects and invertebrates and also occurs in organisms such as salmon, bamboo grasses, and agave plants (**Figure 56.4a**). These individuals reproduce once only and die. Semelparous organisms, like agaves, may live for many years before reproducing, or they may be annual plants that develop from seed, flower, and drop their own seed within a year.

Other organisms reproduce in successive years or breeding seasons. The pattern of repeated reproduction at intervals throughout the life cycle is called **iteroparity** (from the Latin *itero*, meaning to repeat). It is common in most vertebrates, perennial plants, and trees. Among iteroparous organisms, much variation occurs in the number of reproductive events and in the number of offspring per event. Many species, such as birds or trees in temperate areas, have distinct breeding seasons (seasonal iteroparity) that lead to distinct generations (**Figure 56.4b**). For a few species, individuals reproduce repeatedly and at any time of the year. This is termed continuous iteroparity and is exhibited by some tropical species, many parasites, and many primates (**Figure 56.4c**).

Why do species reproduce in a semelparous or iteroparous mode? The answer may lie in part in environmental uncertainty. If survival of juveniles is very low and unpredictable, then selection favors repeated reproduction and a long reproductive life to increase the chance that juveniles will survive in at least some years. If the environment is stable, then selection favors a single act of reproduction, because the organism can devote all its energy to making offspring, not maintaining its own body. Under favorable circumstances, annual plants produce more seeds per unit biomass than trees, which have to invest a lot of energy in maintenance. However, when the environment becomes stressful, annuals run the risk of their seeds not germinating. They must rely on some seeds successfully lying dormant and germinating after the environmental stress has ended.

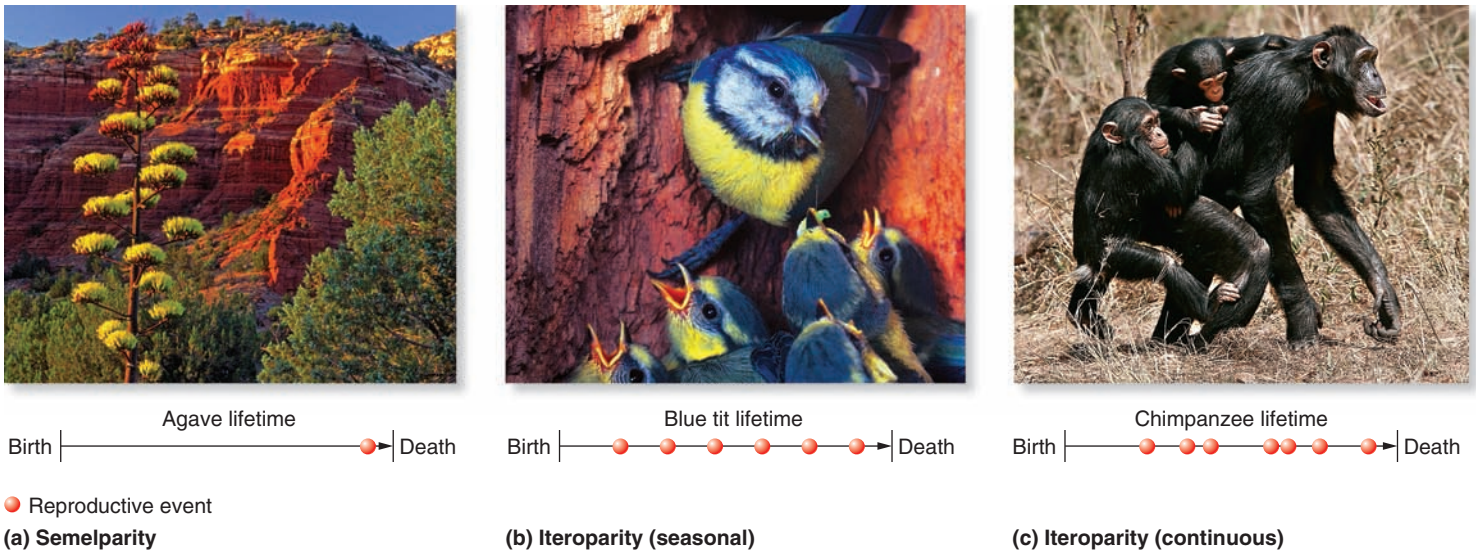

Figure 56.4 **Differences in reproductive strategies.** Species such as **(a)** agave plants (*Agave shawii*) are semelparous, meaning they breed once in their lifetime and then die. This contrasts with **(b)** blue tits (*Parus caeruleus*) and **(c)** chimpanzees (*Pan troglodytes*), which are iteroparous and breed more than once in their lifetime.

The Size of an Age Class Can Indicate How Quickly a Population Might Grow

The reproductive strategy employed by an organism has a strong effect on the subsequent age classes of a population. Semelparous organisms often produce groups of same-aged young called **cohorts** that grow at similar rates. Iteroparous organisms generally have many young of different ages because the parents reproduce frequently. The age classes of populations can be characterized by specific categories, such as years in mammals, stages (eggs, larvae, or pupae) in insects, or size in plants.

We expect that a population that is increasing should have a large number of young, whereas a decreasing population should have few young. An imbalance in age classes can have a profound influence on a population's future. For example, in an overexploited fish population, the larger, older reproductive age classes are often removed. If the population is overfished for several years, there will be no young fish to move into the reproductive age class to replace the removed fish, and the population may collapse. Other populations experience removal of younger age classes. In the Florida Keys, populations of Key deer overgraze young gumbo limbo trees, leaving mostly older trees, whose foliage is too tall for them to reach (**Figure 56.5**). This can have disastrous

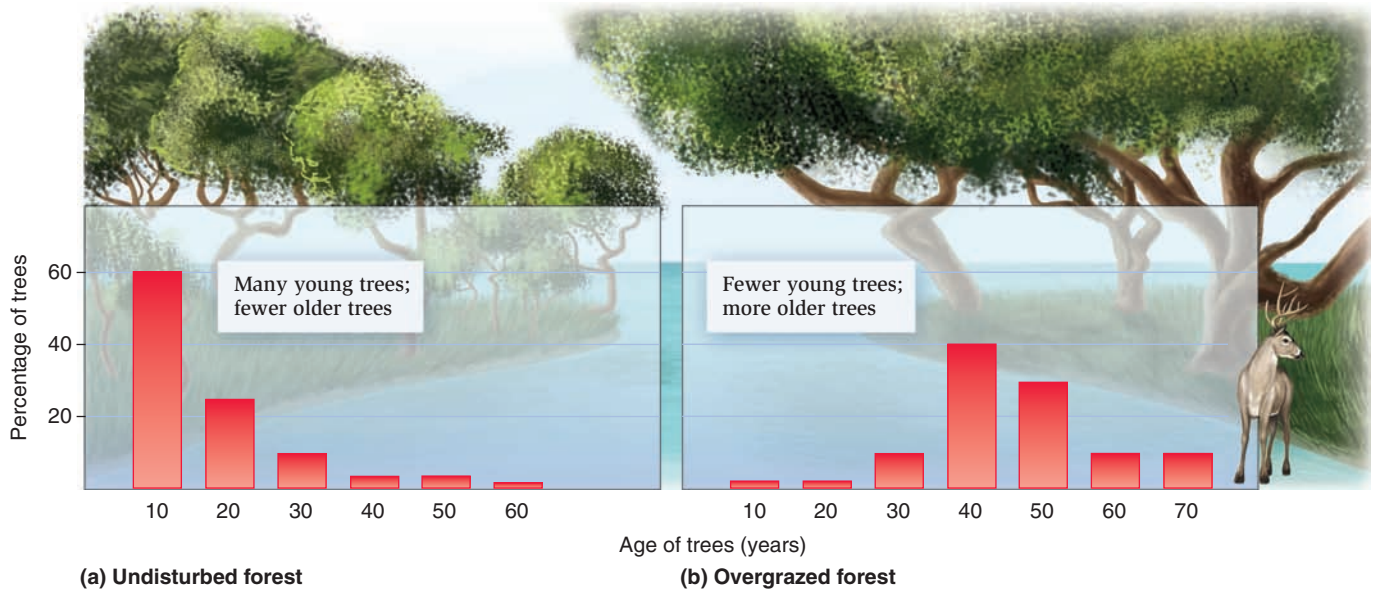

Figure 56.5 **Theoretical age distribution of two populations of gumbo limbo trees in the Florida Keys.** **(a)** Age distribution of an island with no Key deer with numerous young trees, many of which die as the trees age and compete with one another for resources, leaving relatively few big, older trees. **(b)** Age distribution of a forest where overgrazing by Key deer has reduced the abundance of young trees, leaving mostly trees in the older age classes.

effects on the future population of trees, for although the forest might consist of healthy mature trees, when these die, there will be no replacements. To accurately examine how populations grow, we need to examine and understand the demography of the population.

56.2 Demography

Learning Outcomes:

1. Describe the difference between information summarized in a life table and in a survivorship curve.
2. Differentiate among type I, II, and III survivorship curves, and give examples of organisms that exhibit those survivorship curves.
3. **SciSKILLS** » Use survivorship and age-specific fertility data to predict a population's growth.

One way to determine how a population will change is to examine a cohort of individuals from birth to death. For most animals and plants, this involves marking a group of individuals in a population as soon as they are born or germinate and following their fate through their lifetime. For some long-lived organisms, such as tortoises, elephants, or trees, this is impractical, so a snapshot approach is used, in which researchers examine the age structure of a population at one point in time. Recording the presence of juveniles and mature individuals, researchers use this information to construct a **life table**—a table that provides data on the number of individuals alive in each particular age class. Age classes can be created for any time period, but they often represent 1 year. Only females are included in these tables because only females produce offspring. In this section, we will see how to construct life tables and plot survivorship curves, which show at a glance the general pattern of population survival over time.

Life Tables and Survivorship Curves Summarize Survival Patterns

Let's examine a life table for the North American beaver (*Castor canadensis*). Prized for their pelts, by the mid-19th century, these animals had been hunted and trapped to near extinction. Beavers began to be protected by laws in the 20th century, and populations recovered in many areas, often growing to what some considered to be nuisance status. In Newfoundland, Canada, legislation supported trapping as a management technique. From 1964 to 1971, trappers provided mandibles from which teeth were extracted for age classification. If many mandibles were obtained from, say, 1-year-old beavers, then such animals were probably common in the population. If the number of mandibles from 2-year-old beavers was low, then we know there was high mortality for the 1-year-old age class. From the mandible data, researchers constructed a life table (**Table 56.1**). The number of individuals alive at the start of the time period (in this case, a year) is referred to as n_x, where n is the number and x refers to the particular age class. By subtracting the value of n_x from the number alive at the start of the previous year, we can calculate the number dying in a given age class or year, d_x. Thus, $d_x = n_x - n_x + 1$. For example, in Table 56.1, 273 beavers were alive at the start of their sixth year (n_5), and only 205 were alive at the start of the seventh year (n_6); thus, 68 died during the sixth year: $d_5 = n_5 - n_6$, or $d_5 = 273 - 205 = 68$.

A simple but informative exercise is to plot numbers of surviving individuals at each age, creating a **survivorship curve** (**Figure 56.6**). The value of n_x, the number of individuals, is typically expressed on a log scale. Ecologists use a log scale to examine rates of change with time, not change in absolute numbers. Although they could accomplish the same thing with a linear scale, the use of logs makes it easier to examine a wide range of population sizes.

Table 56.1 Life Table for the Beaver (*Castor canadensis*) in Newfoundland, Canada

Age (years), x	Number alive at start of year, n_x	Number dying during year, d_x	Proportion alive at start of year, l_x	Age-specific fertility, m_x	$l_x m_x$
0–1	3,695	1,995	1.000	0.000	0
1–2	1,700	684	0.460	0.315	0.145
2–3	1,016	359	0.275	0.400	0.110
3–4	657	286	0.178	0.895	0.159
4–5	371	98	0.100	1.244	0.124
5–6	273	68	0.074	1.440	0.107
6–7	205	40	0.055	1.282	0.071
7–8	165	38	0.045	1.280	0.058
8–9	127	14	0.034	1.387	0.047
9–10	113	26	0.031	1.080	0.033
10–11	87	37	0.024	1.800	0.043
11–12	50	4	0.014	1.080	0.015
12–13	46	17	0.012	1.440	0.017
13–14	29	7	0.007	0.720	0.005
14+	22	22	0.006	0.720	0.004

Net reproductive rate, $\Sigma l_x m_x = 0.938$

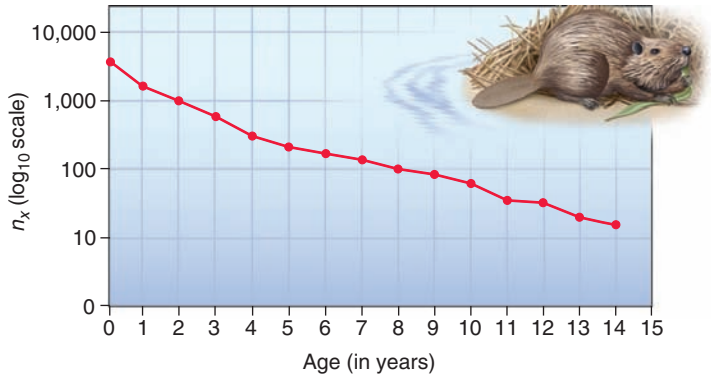

Figure 56.6 Survivorship curve for the North American beaver. The survivorship curve is generated by plotting the number of surviving individuals, n_x, from any given cohort of young, usually measured on a log scale, against age. This survivorship curve shows a fairly uniform rate of decline through time.

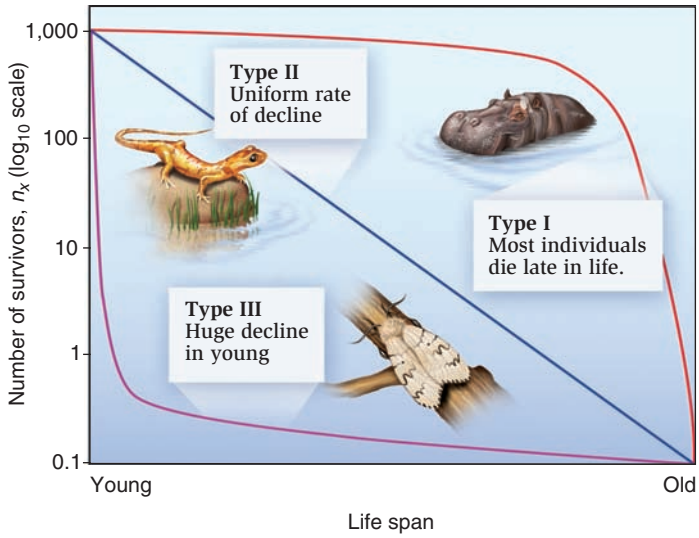

Figure 56.7 Idealized survivorship curves.

Concept Check: *Which type of survivorship curve would you expect for (a) mussels and (b) turtles?*

For example, if we start with 1,000 individuals and 500 are lost in year 1, the log of the decrease is

$$\log_{10} 1{,}000 - \log_{10} 500 = 3.0 - 2.7 = 0.3 \text{ per year}$$

If we start with 100 individuals and 50 are lost, the log of the decrease is similarly

$$\log_{10} 100 - \log_{10} 50 = 2.0 - 1.7 = 0.3 \text{ per year}$$

In both cases, the rates of change are identical, even though the absolute numbers are different. Plotting the n_x data on a log scale ensures that regardless of the size of the starting population, the rate of change of one survivorship curve can easily be compared with that of another species.

Survivorship curves generally fall into one of three patterns (**Figure 56.7**). With a type I curve, the rate of loss for juveniles is relatively low, and most individuals are lost later in life, as they become older and more prone to sickness and predators (see the Feature Investigation). Organisms that exhibit type I survivorship curves have relatively few offspring but invest much time and resources in raising their young. Many large mammals, including humans, exhibit type I curves. At the other end of the scale is a type III curve, in which the rate of loss for juveniles is relatively high, and the survivorship curve flattens out for those organisms that have avoided early death. Many fishes and marine invertebrates fit this pattern. Most of the juveniles die or are eaten, but a few reach a favorable habitat and thrive. For example, once they find a suitable rock face on which to attach themselves, barnacles grow and survive very well. Many insects and plants also fit the type III survivorship curve, because they lay many eggs or release hundreds of seeds, respectively. Type II curves represent a middle ground, with fairly uniform death rates over time. Species with type II survivorship curves include many birds, small mammals, reptiles, and some annual plants. The North American beaver population exhibits this survivorship curve. Keep in mind, however, that these are generalized curves and that few populations fit them exactly.

Feature Investigation | Murie's Collections of Dall Mountain Sheep Skulls Permitted the Accurate Construction of Life Tables

The Dall mountain sheep (*Ovis dalli*) lives in mountainous regions, including the Arctic and sub-Arctic regions of Alaska. In the late 1930s, the U.S. National Park Service was bombarded with public concerns that wolves were responsible for a sharp decline in the population of Dall mountain sheep in Denali National Park (then Mt. McKinley National Park). Shooting the wolves was advocated as a way of increasing the number of sheep. Because meaningful data on sheep mortality were nonexistent, the Park Service enlisted American biologist Adolph Murie to determine whether the wolves killed enough sheep to justify controlling the wolf population. In addition to spending many hours observing interactions between wolves and sheep, Murie also collected sheep skulls, determining the sheep's age at death by counting annual growth rings on the horns.

In 1947, American ecologist Edward Deevey put Murie's data in the form of a life table that listed each age class and the number of skulls in it (**Figure 56.8**). Although Murie had collected 608 skulls, Deevey expressed the data per 1,000 individuals to allow for comparison with other life tables. From the data, Deevey constructed a survivorship curve. For the Dall mountain sheep in Denali National Park, there was a slight initial decline in survivorship as young lambs were lost; then the survivorship curve flattened out, indicating that the sheep survived well through about age 7 or 8. Then the number of sheep declined rapidly as they aged. These data underlined what

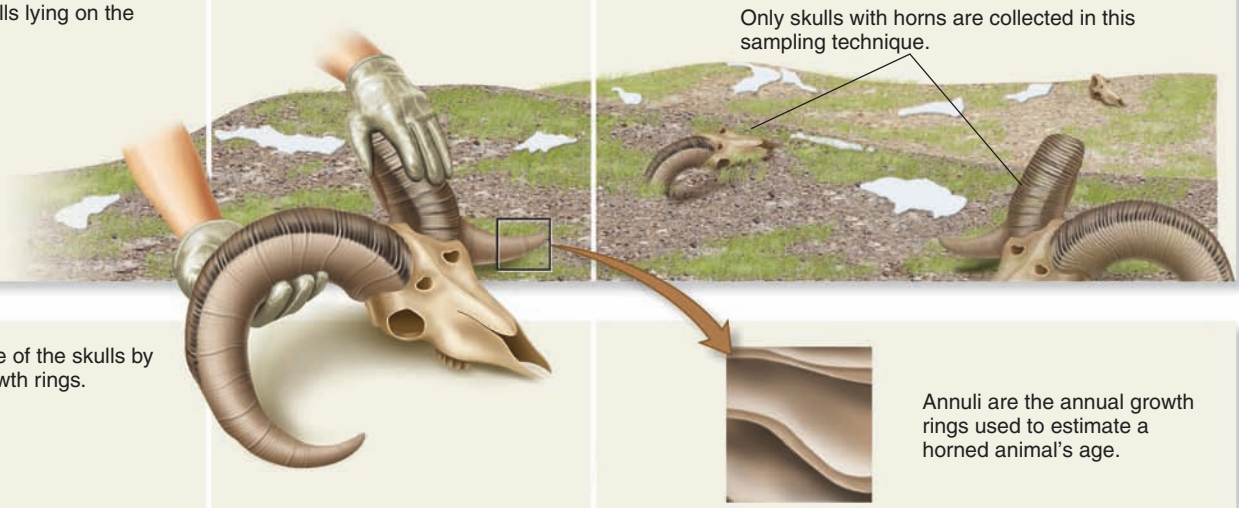

Figure 56.8 Examining the survivorship curve of a Dall mountain sheep population reveals information on the cause of death.

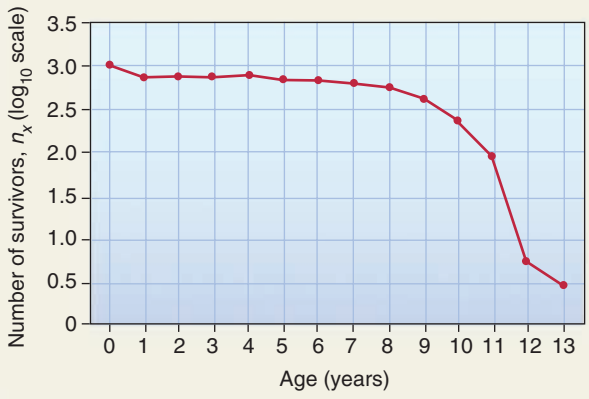
HYPOTHESIS Culling the wolf population would protect reproductively active adults in the Dall mountain sheep population.

STARTING LOCATION Denali National Park (formerly known as Mt. McKinley National Park) in Alaska, where wolf predation of sheep is common.

Experimental level | **Conceptual level**



1 Collect sheep skulls lying on the ground.

2 Determine the age of the skulls by counting their growth rings.

Annuli are the annual growth rings used to estimate a horned animal's age.

3 Organize the data into a life table (see step 4), and construct a survivorship curve using the data.

Survivorship curve for the Dall mountain sheep shows the number of sheep alive in each age class on a log scale, plotted against age in years.

4 **THE DATA**

Results used in step 3:

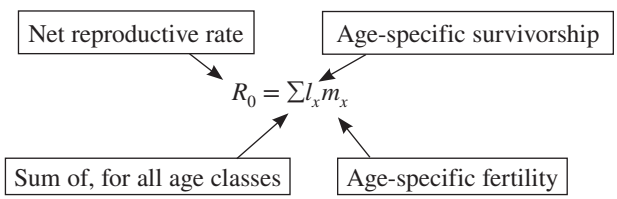
Age class	Number alive, n_x	$\log_{10} n_x$	Age class	Number alive, n_x	$\log_{10} n_x$
0–1	1,000	3.00	7–8	640	2.81
1–2	801	2.90	8–9	571	2.76
2–3	789	2.90	9–10	439	2.64
3–4	776	2.89	10–11	252	2.40
4–5	764	2.88	11–12	96	1.98
5–6	734	2.86	12–13	6	0.78
6–7	688	2.84	13–14	3	0.48

5 **CONCLUSION** Most Dall mountain sheep die when very young or very old. Culling the wolf population would not greatly increase sheep survival.

6 **SOURCE** Deevey, E.S., Jr. 1947. Life tables for natural populations of animals. *Quarterly Review of Biology* 22:283–314.

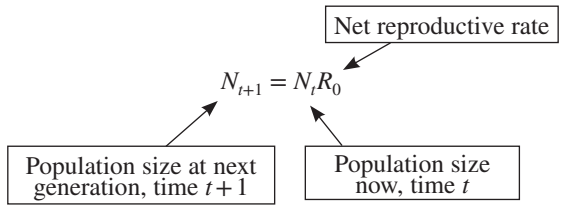
Murie had previously observed, which was that wolves preyed primarily on the most vulnerable members of the sheep population—the youngest and the oldest. Such predation would not be expected to dramatically reduce the sheep population because the reproductively active adults were not being taken. The Park Service ultimately ended their limited wolf-control program.

Experimental Questions



1. What problem led to the study conducted by Murie on the Dall mountain sheep population of Denali National Park?
2. Describe the survivorship curve developed by Deevey based on Murie's data.
3. **SciSKILLS** » How did Murie's data and Deevey's analysis affect the decision of the Park Service on the control of the wolf population?

Age-Specific Fertility Data Help to Predict Population Growth



To calculate how a population grows, we need information on birth rates as well as mortality and survivorship rates. For any given age, we can determine the proportion of female offspring that are born to females of reproductive age. Using these data, we can determine an **age-specific fertility rate**, called m_x. For example, if 100 females of a given age produce 75 female offspring, $m_x = 0.75$. With this additional information, we can calculate the growth rate of a population.

First, we use the survivorship data to find the proportion of individuals alive at the start of any given age class. This age-specific survivorship rate, termed l_x, equals n_x/n_0, where n_0 is the number alive at time 0, the start of the study, and n_x is the number alive at the beginning of age class x. Let's return to the beaver life table in Table 56.1. The proportion of the original beaver population still alive at the start of the sixth age class, l_5, equals $n_5/n_0 = 273/3{,}695$, or 0.074. This means that 7.4% of the original beaver population survived to age 5. Next we multiply the data in the two columns, l_x and m_x, for each row, to give us a column $l_x m_x$, an average number of offspring per female age class. This column represents the contribution of each age class to the overall population growth rate. An examination of the beaver age-specific fertility rates illustrates a couple of general points. First, for this beaver population in particular, and for many organisms in general, there are no babies born to young females. As females mature sexually, age-specific fertility goes up, and it remains fairly high until later in life, when females reach postreproductive age.

The number of offspring born to females of any given age class depends on two things: the number of females in that age class and their age-specific fertility rate. Thus, although fertility of young beavers is very low, there are so many females in the age class that $l_x m_x$ for 1-year-olds is quite high. Age-specific fertility for older beavers is much higher, but the relatively few females in these age classes cause $l_x m_x$ to be low. Maximum values of $l_x m_x$ occur for females of an intermediate age, 3–4 years old in the case of the beaver. The overall growth rate per generation is the number of offspring born to all females of all ages, where a generation is defined as the mean period between birth of females and birth of their offspring. Therefore, to calculate the generational growth rate, we sum all the values of $l_x m_x$, that is, $\sum l_x m_x$, where the $\sum$ symbol means "sum of." This summed value, R_0, is called the **net reproductive rate**.

To calculate the future size of a population, we simply multiply the number of individuals in the population by the net reproductive rate. Thus, the population size in the next generation, N_{t+1}, is determined by the number in the population now, at time t, which is given by N_t, multiplied by R_0.

Let's consider an example in which the number of beavers alive now, N_t, is 1,000, and $R_0 = 1.1$. This means the beaver population is reproducing at a rate that is 10% greater than simply replacing itself. The size of the population next generation, N_{t+1}, is given by

$$N_{t+1} = N_t R_0$$
$$N_{t+1} = 1{,}000 \times 1.1$$
$$= 1{,}100$$

Therefore, the number of beavers in the next generation is 1,100, and the population will have grown larger.

In determining population growth, much depends on the value of R_0. If $R_0 > 1$, then the population will grow. If $R_0 < 1$, the population is in decline. If $R_0 = 1$, the population size stays the same, and we say it is at **equilibrium**. In the case of the beavers, Table 56.1 reveals that $R_0 = 0.938$, which is less than 1, and, therefore, the population is declining. This is valuable information, because it tells us that at that time, the beaver population in Newfoundland needed some form of protection (perhaps bans on trapping and hunting) in order to attain a population level at equilibrium.

Because of the effort involved in calculating R_0, the net reproductive rate, ecologists sometimes use a shortcut to predict population growth. Imagine a bird species that breeds annually. To measure population growth, ecologists count the number of birds in the population, N_0. Let's say $N_0 = 100$. The next year, ecologists count 110 birds in the same population, so $N_1 = 110$. The **finite rate of increase**, λ, is the ratio of the population size from one year to the next, calculated as

$$\lambda = N_1/N_0$$

In this case, $\lambda = 1.10$, or 10%. λ is often given as percent annual growth, and t is a number of years.

Let's consider a population of birds growing at a rate of 5% per year. To calculate the size of the population after 5 years, we substitute λ for R_0:

$$N_t = 100,\ \lambda = 1.05, \text{ and } t = 5$$
$$\text{therefore, } N_{t+5} = 100(1.05)^5 = 127.6$$

What's the difference between R_0 and λ? R_0 represents the net reproductive rate per generation. λ represents the finite rate of population change over some time interval, often a year. When species are annual breeders that live 1 year, such as annual plants, $R_0 = \lambda$. For species that breed for multiple years, $R_0 \neq \lambda$. Just as

$$N_t = N_0 R_0^t, \text{ where } t = \text{a number of generations}$$
$$\text{so } N_t = N_0 \lambda^t, \text{ where } t = \text{a number of time intervals}$$

Populations grow when R_0 or $\lambda > 1$; populations decline when R_0 or $\lambda < 1$; and they are at equilibrium when R_0 or $\lambda = 1$.

56.3 How Populations Grow

Learning Outcomes:

1. **SciSKILLS »** Calculate the population growth of continuously breeding organisms using the per capita growth rate (*r*).
2. Distinguish between exponential growth and logistic growth.
3. Explain how density-dependent factors and density-independent factors regulate population size.
4. Compare and contrast life history strategies of *r*-selected and *K*-selected species.

Life tables can provide accurate information about how populations grow from generation to generation. However, other population growth models can provide valuable insights into how populations grow over shorter time periods. The simplest of these assumes that populations grow if, for any given time interval, the number of births is greater than the number of deaths. In this section, we will examine two different types of these simple models. The first assumes resources are not limiting, and it results in prodigious growth. The second, and perhaps more biologically realistic, assumes resources are limiting, and it results in limits to growth and eventual stable population sizes. We will then consider how other factors, such as natural enemies, might limit population growth and discuss the overall life history strategies exhibited by different species.

Knowing the Per Capita Growth Rate Helps Predict How Populations Will Grow

The change in population size over any time period can be written as the number of births per unit time interval minus the number of deaths per unit time interval.

For example, if in a population of 1,000 rabbits, there were 100 births and 50 deaths over the course of 1 year, then the population would grow in size to 1,050 the next year. We can write this formula mathematically as

$$\frac{\text{Change in numbers}}{\text{Change in time}} = \text{Births} - \text{Deaths}$$

or

$$\frac{\Delta N}{\Delta t} = B - D$$

The Greek letter delta, Δ, indicates change, so ΔN is the change in number and Δt is the change in time; B is the number of births per time unit; and D is the number of deaths per time unit.

Often, the numbers of births and deaths are expressed per individual in the population, so the birth of 100 rabbits to a population of 1,000 would represent a per capita birth rate, b, of 100/1,000, or 0.10. Similarly, the death of 50 rabbits in a population of 1,000 would be a per capita death rate, d, of 50/1,000, or 0.05. Now we can rewrite our equation giving the rate of change in a population.

$$\frac{\Delta N}{\Delta t} = bN - dN$$

For our rabbit example,

$$\frac{\Delta N}{\Delta t} = 0.10 \times 1{,}000 - 0.05 \times 1{,}000 = 50$$

so if $\Delta t = 1$ year, the rabbit population would increase by 50 individuals in a year.

Ecologists often simplify this formula by representing $b - d$ as r, the **per capita growth rate**. Thus, $bN - dN$ can be written as rN. Because ecologists are also interested in population growth rates over very short time intervals, so-called instantaneous growth rates, instead of writing

$$\frac{\Delta N}{\Delta t}$$

they write

$$\frac{dN}{dt}$$

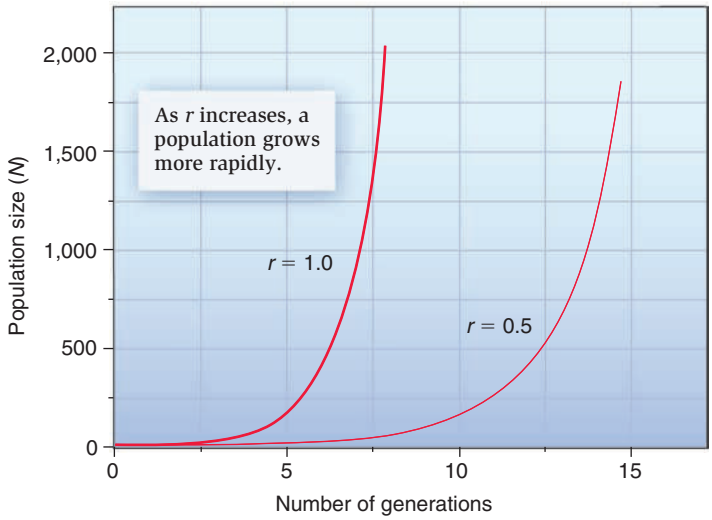
which is the notation of differential calculus. The equations essentially mean the same thing, except that dN/dt reflects very short time intervals. Thus, for the rabbit population,

$$\frac{dN}{dt} = rN = (0.10 - 0.05)N = 50$$

Exponential Growth Occurs When the Per Capita Growth Rate Remains Above Zero

How do populations grow? Clearly, much depends on the value of the per capita growth rate, r. When $r < 0$, the population decreases; when $r = 0$, the population remains constant; and when $r > 0$, the population increases. When $r = 0$, the population is often referred to as being at equilibrium, where no changes in population size will occur and there is **zero population growth**.

Even if r is only fractionally above 0, population increase is rapid, and when plotted graphically, a characteristic J-shaped curve results (**Figure 56.9**). We refer to this type of population growth as **exponential growth**, also known as geometric growth. When



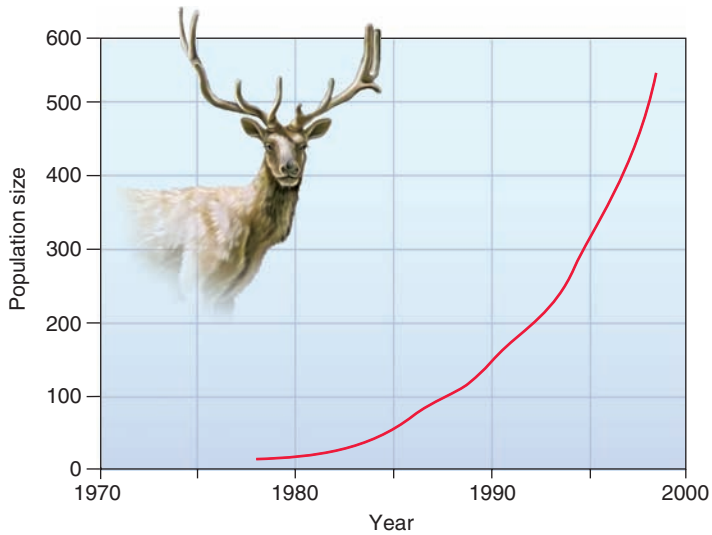


Figure 56.9 Exponential population growth. As the value of *r* increases, the slope of the curve gets steeper. In theory, a population with unlimited resources could grow indefinitely.

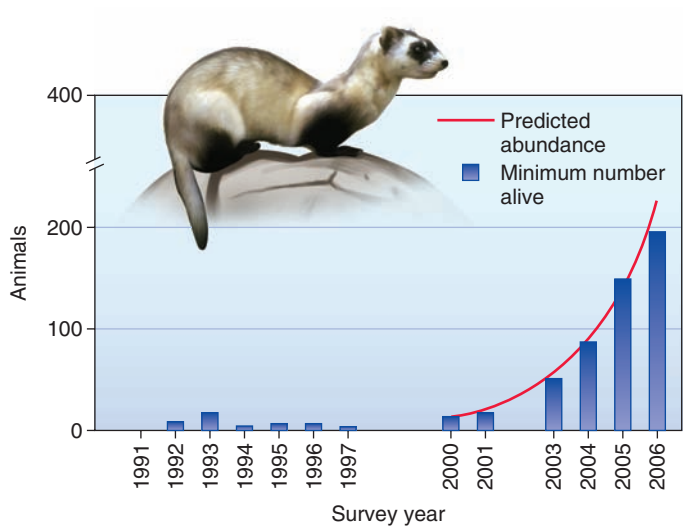
conditions are optimal for the population, *r* is at its maximum rate and is called the **intrinsic rate of increase** (denoted r_{max}). Thus, the rate of population growth under optimal conditions is $dN/dt = r_{max}N$. The larger the value of r_{max}, the steeper the slope of the curve. Because population growth depends on the value of *N* as well as the value of *r*, the population increase is even greater as time passes.

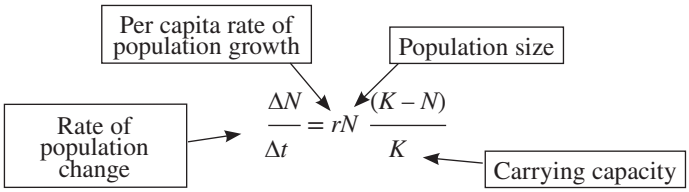


How do field data fit this simple model for exponential growth? Population growth cannot go on forever, as envisioned with the exponential growth model. But initially at least, in a new and expanding population when resources are not limited, exponential growth is often observed. Let's look at a few examples. Tule elk (*Cervus elaphus nannodes*) is a subspecies of elk that is native to California. Hunted nearly to extinction in the 19th century, less than a dozen individuals survived on a private ranch. In the 20th century, reintroductions resulted in the recovery of tule elk to around 3,500 individuals. One reintroduction was made in March 1978 at Point Reyes National Seashore in California, where 10 animals—2 males and 8 females—were released. By 1993, the herd had reached 214 individuals, and it continued to grow in an exponential fashion until 1998, when the herd size stood at 549 (**Figure 56.10a**). This was deemed an excessive number for the size of the available habitat, and animals were removed to begin herds in other locations. Since then, herd size at Point Reyes has been maintained at around 350.

The growth of the recovering black-footed ferret population in Wyoming mentioned at the beginning of the chapter also fits the exponential growth pattern (**Figure 56.10b**). The ferrets had been reintroduced in 1991, but the population declined and languished for many years, so that by 1997, only five were living. However, from 2000 to 2006, the population grew in an exponential fashion. A value of $r = 0.47$ was calculated for the increase in population size of the ferrets during those years. Ecologists have noted that in some cases, populations seem to languish at low levels before conditions become favorable for population growth.

The growth of some introduced species also seems to fit the pattern of exponential growth. The rapid expansion of rabbits after their introduction into southern Australia in the late 19th century is a case in point. In 1859, British immigrant Thomas Austin received two dozen European rabbits from England. Rabbit gestation lasts a mere 31 days, and in southern Australia, each female rabbit could produce up to 10 litters of at least six young each year. The rabbits had essentially no enemies and ate the grass used by sheep and other grazing animals. Even when two-thirds of the population was shot for sport, which was the purpose of the initial introduction, the population grew into the millions within a few short years. By 1875, rabbits were reported on the west coast of Australia, having moved over 1,760 km across the continent despite the deployment of huge, thousand-kilometer-long fences (rabbit-proof fences) meant to contain them.

(a) Tule elk



(b) Black-footed ferret

Figure 56.10 Exponential growth following reintroduction of a population into a habitat. (a) A population of tule elk (*Cervus elaphus nannodes*) reintroduced to Point Reyes National Seashore in 1978 fits a pattern of exponential growth. **(b)** Black-footed ferrets (*Mustela nigripes*) reintroduced to Shirley Basin, Wyoming, since 2000. No survey was conducted in 2002.

Finally, one of the most prominent examples of exponential growth is the growth of the global human population, which, because of its great importance, we will examine separately in Section 56.4.

Logistic Growth Occurs in Populations in Which Resources Are Limited

Despite its applicability to rapidly growing populations, the exponential growth model is not appropriate in many situations. The model assumes unlimited resources, which is not typically the case in the real world. For most species, resources eventually become limiting as populations grow, and the per capita growth rate decreases. The upper boundary for the population size is known as the **carrying capacity (*K*)**. A more realistic equation to explain population growth, one that takes into account the amount of available resources, is

where $(K - N)/K$ represents the proportion of the carrying capacity that is unused by the population. This equation is called the **logistic equation**.

As the population size, N, grows, it moves closer to the carrying capacity, K, with fewer available resources for population growth. At large values of N, the value of $(K - N)/K$ becomes small, and population growth is small. If $K = 1{,}000$, $N = 900$, and $r = 0.1$, then

$$\frac{dN}{dt} = (0.1)(900) \times \frac{(1{,}000 - 900)}{1{,}000}$$

$$\frac{dN}{dt} = 9$$

In this instance, population growth is 9 individuals per unit of time.

Let's consider how an ecologist would use the logistic equation. First, the value of K would come from intense field and laboratory work from which researchers would determine the amount of resources, such as food, needed by each individual and then determine the amount of available food in the wild. Field censuses determine N, and field censuses of births and deaths per unit time provide r. When this type of population growth is plotted over time, an S-shaped growth curve results (**Figure 56.11**). This pattern, in which the growth of a population slows down as it approaches K, is called **logistic growth**.

Does the logistic growth model provide a better fit to growth patterns of plants and animals in the wild than the exponential model? In some instances, such as laboratory cultures of bacteria and yeasts, the logistic growth model provides a very good fit (**Figure 56.12**). In nature, however, variations in temperature, rainfall, or resources can cause changes in carrying capacity and thus in population size. The uniform conditions of temperature, moisture, and resource levels of the laboratory do not usually exist. In addition, time lags may occur between changes in carrying capacity and changes in reproduction. For instance, pregnant females are still likely to give birth even when resources are declining. This can lead to temporary overshoots of population density beyond the carrying capacity. Therefore, relatively few exact fits of the logistic growth model to population growth have been documented in the field. Instead, populations tend to fluctuate around the limits suggested by the logistic model, with frequent overshoots and undershoots.

Is the logistic model of little value because it fails to describe population growth accurately? Not really. It is a useful starting point for thinking about how populations grow, and it seems intuitively correct. However, the carrying capacity is a difficult feature of the environment to identify for most species, and it also varies with time and

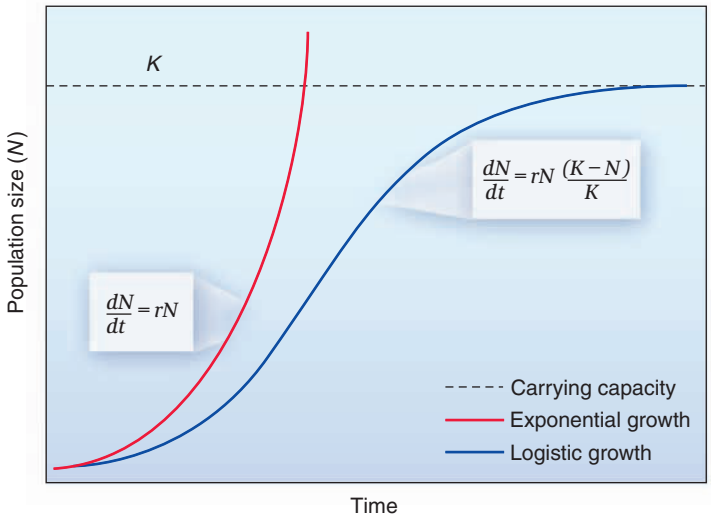


Figure 56.11 Exponential versus logistic growth. Exponential (J-shaped) growth occurs in an environment with unlimited resources, whereas logistic (S-shaped) growth occurs in an environment with limited resources.

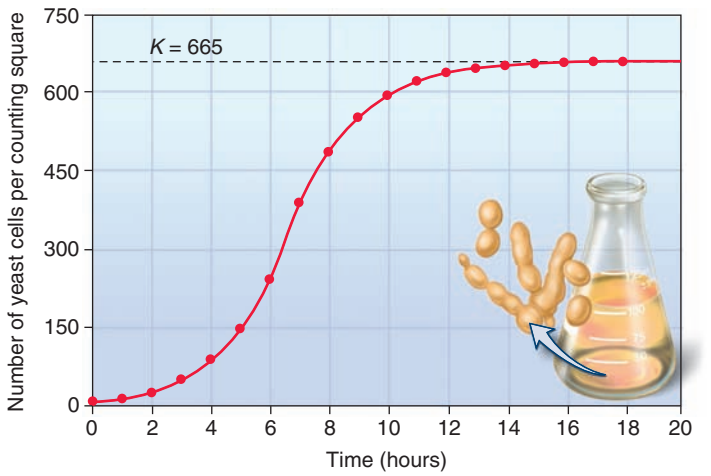

Figure 56.12 Logistic growth of yeast cells in culture. Early tests of the logistic growth curve were validated by growth of yeast cells in laboratory cultures. These populations showed the typical S-shaped growth curve.

BIOLOGY PRINCIPLE Biology is an experimental science. Tests of population growth models are more accurately performed using manipulative experiments than by simple field observations.

according to local climate patterns. For these reasons, logistic growth is difficult to measure accurately.

Also, as we will discover, populations are affected by interactions with other species. In Chapter 57, we will examine how predators, parasites, and competitors affect population densities and explore situations in which species interactions commonly limit population growth. As described next, such population limitations are often influenced by a process known as density dependence.

Density-Dependent Factors May Regulate Population Sizes

A **density-dependent factor** is a mortality factor whose influence increases with the density of the population. Parasitism, predation, and competition are some of the many density-dependent factors that may reduce the population densities of living organisms and stabilize them at equilibrium levels. Such factors can be density-dependent in that their effect depends on the density of the population; they kill relatively more of a population when densities are higher and less of a population when densities are lower. For example, many predators develop a visual search image for a particular prey. When a prey is rare, predators tend to ignore it and kill relatively few. When a prey is common, predators key in on it and kill relatively more. In England, for example, predatory shrews kill proportionately more moth pupae in leaf litter when the pupae are common compared with when they are rare. Density-dependent mortality may also occur as population densities increase and competition for scarce resources increases, reducing offspring production or survival. Parasitism may also act in a density-dependent manner. Parasites are able to pass from host to host more easily as the host's population density increases.

Density dependence can be detected by plotting mortality, expressed as a percentage, against population density (**Figure 56.13**). If a positive slope results and mortality increases with density, the factor tends to have a greater effect on dense populations than on sparse ones and is clearly acting in a density-dependent manner.

A **density-independent factor** is a mortality factor whose influence is not affected by changes in population size or density. When mortality is plotted against density, a flat line results. In general, density-independent factors are physical factors, including weather, drought, freezes, floods, and disturbances such as fire. For example, in hard freezes, the same proportion of organisms such as birds or plants are usually killed, no matter how large the population size.

Finally, a mortality factor that decreases with increasing population size is considered an **inverse density-dependent factor**. In this case, a negative slope results when mortality is plotted against density. For example, if a territorial predator such as a lion always killed the same number of wildebeest prey, regardless of wildebeest density, it is acting in an inverse density-dependent manner, because it is taking a smaller proportion of the population at higher density. Some mammalian predators, being highly territorial, often act in this manner on herbivore density.

Determining which factors act in a density-dependent or density-independent fashion has large practical implications. Foresters, game managers, and conservation biologists alike are interested in maintaining populations. For example, if a specific disease were to act in a density-dependent manner on white-tailed deer, there wouldn't be much point in game managers attempting to kill off predators such as mountain lions to increase herd sizes for hunters, because proportionately more deer would be killed by disease.

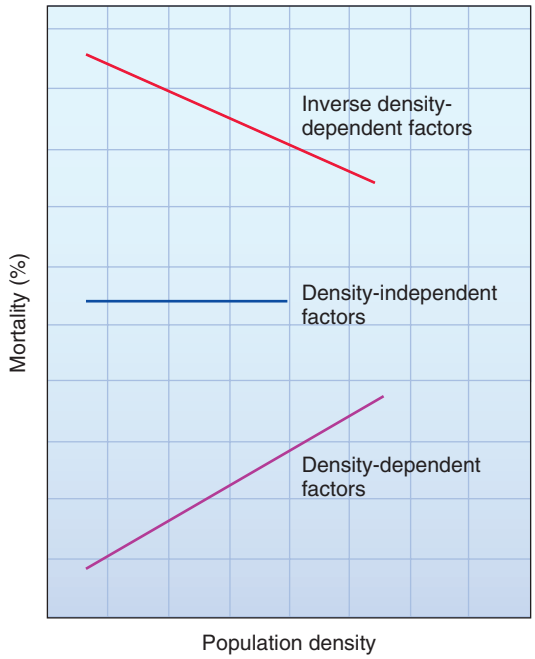

Figure 56.13 Three ways that factors affect mortality in response to changes in population density. For a density-dependent factor, mortality increases with population density; for a density-independent factor, mortality remains unchanged. For an inverse density-dependent factor, mortality decreases as a population increases in size.

Concept Check: Which types of factors tend to stabilize populations at equilibrium levels?

Life History Strategies Incorporate Traits Relating to Survival and Competitive Ability

The population parameters we have discussed—including iteroparity versus semelparity, exponential versus logistic growth, and density-dependent versus density-independent factors—have important implications for how populations grow and for the reproductive success of populations and species. These reproductive strategies can be viewed in the context of a much larger picture of life history strategies, sets of physiological and behavioral features that incorporate not only reproductive traits but also survivorship and length of life characteristics, habitat type, and competitive ability.

When comparing many different species, life history strategies follow a continuum. At the one end are species, termed ***r*-selected species**, that have a high rate of per capita population growth (r), but poor competitive ability. An example is a dandelion, which produces huge numbers of tiny seeds and therefore has a high value of r (**Figure 56.14a**). Weeds exist in disturbed habitats such as gaps in a forest canopy where trees have blown down, and also in areas disturbed by humans such as agricultural fields or backyard gardens. An *r*-selected species such as a weed grows quickly and reaches reproductive age early, devoting much energy to producing a large number of seeds that disperse widely. These weed species generally remain small, and individuals do not live long. In the animal world, insects are mostly *r*-selected species that produce many young and have short life cycles.

At the other end of the continuum are species, termed ***K*-selected species**, that have more or less stable populations adapted to exist at or near the carrying capacity (K), of the environment. An example is an oak tree that exists in a mature forest (**Figure 56.14b**). Oak trees grow slowly and reach reproductive age late, having to devote much energy to growth and maintenance. A *K*-selected species like a tree grows large and shades out *r*-selected species like weeds, eventually outcompeting them. Such trees live a long time and produce seeds repeatedly every year when mature. These seeds are bigger than those of *r*-selected species, but do not disperse widely. Acorns contain a large food reserve that helps them grow, whereas dandelion seeds must rely on whatever nutrients they can gather from the soil where they land. Mammals, such as elephants, that grow slowly, have few young, and reach large sizes are typical of *K*-selected animal species. **Table 56.2** compares the general characteristics of *r*- and *K*-selected species.

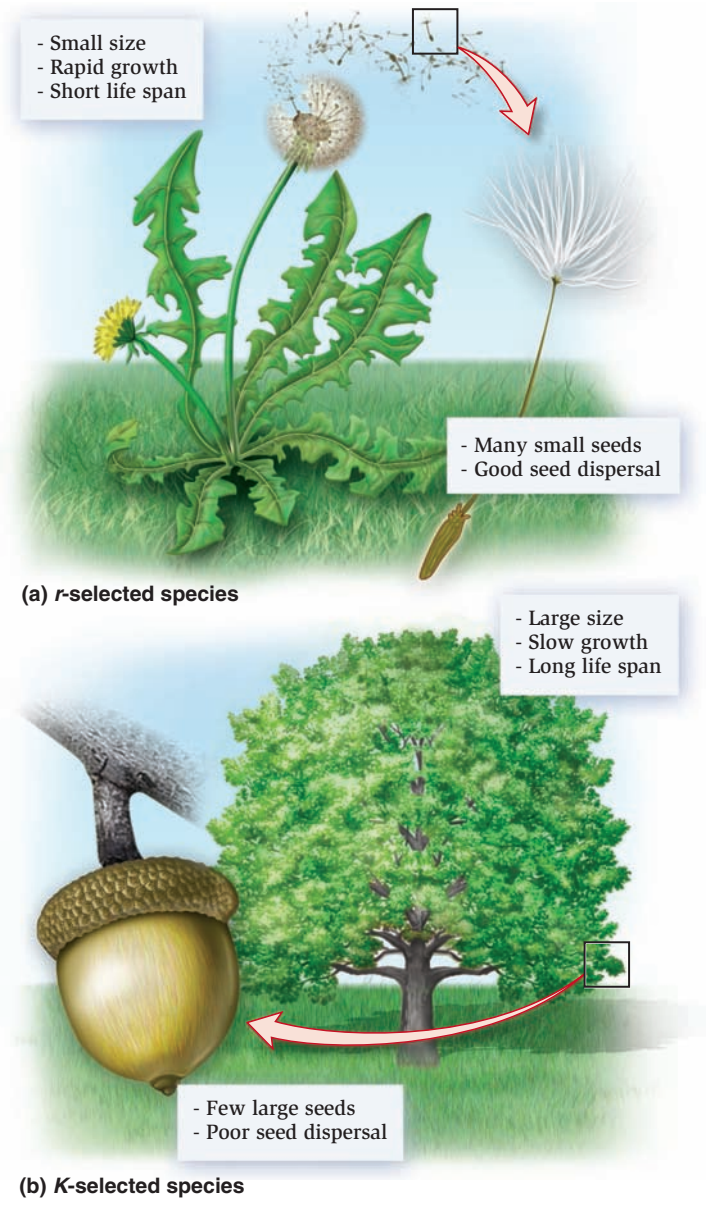

Figure 56.14 Life history strategies. Differences in traits of a dandelion **(a)** and an oak tree **(b)** illustrate some of the differences between *r*- and *K*-selected species.

BioConnections: Look back at Figure 39.21. What is unusual about the reproductive strategy of the mother of thousands plant?

Table 56.2 Characteristics of *r*- and *K*-Selected Species

Life history feature	*r*-selected species	*K*-selected species
Development	Rapid	Slow
Reproductive rate	High	Low
Reproductive age	Early	Late
Body size	Small	Large
Length of life	Short	Long
Competitive ability	Weak	Strong
Survivorship	Type III	Type I
Population size	Variable	Fairly constant
Dispersal ability	Good	Poor
Habitat type	Disturbed	Not disturbed
Parental care	Low	High

In a human-dominated world, almost every life history attribute of a *K*-selected species sets it at risk of extinction. First, *K*-selected species tend to be larger, so they need more habitat in which to live. For example, Florida panthers need huge tracts of land to establish their territories and hunt for deer (look ahead to Figure 60.15c). *K*-selected species tend to have fewer offspring, so their populations cannot recover as fast from disturbances such as fire or overhunting. California condors, for example, produce only a single chick every other year. *K*-selected species breed at a later age, and the time they require to grow from a small population to a larger population is long. Gestation time in elephants is 22 months, and elephants take at least 7 years to become sexually mature. Large trees, such as the giant sequoia; large terrestrial mammals, such as elephants, rhinoceroses, and grizzly bears; and large marine mammals, such as blue whales and sperm whales, all run the risk of extinction. Interestingly, the coast redwood seems to be an exception, a fact perhaps attributable to its unusual genome (see the Genomes & Proteomes Connection).

What are the advantages to being a *K*-selected species? In a world not disturbed by humans, *K*-selected species would fare well. However, in a human-dominated world, many *K*-selected species are selectively logged or hunted, or their habitat is altered, and the resulting small population sizes make extinction a real possibility.

Genomes & Proteomes Connection

Hexaploidy Increases the Growth of Coast Redwood Trees

Besides being home to the world's most massive tree, the giant sequoia (*Sequoiadendron giganteum*), California is also the location of the world's tallest tree, the coast redwood (*Sequoia sempervirens*), a towering giant that can grow to over 90 m and can live for up to 2,000 years (**Figure 56.15**). These trees are currently confined to a relatively small 700-km strip along the Pacific coast from California to southern Oregon, an area characterized by year-long moderate temperatures, heavy winter rains,

Figure 56.15 The coast redwood (*Sequoia sempervirens*)—a hexaploid conifer. The coast redwood can grow to over 90 m, and the oldest living trees are over 2,000 years old. Their great genetic variation may help explain their incredible growth and longevity.

BIOLOGY PRINCIPLE The genetic material provides a blueprint for reproduction. Despite being large, *K*-selected species, coast redwoods grow faster than any other known conifer and this is due to their unusual hexaploid genome.

and dense summer fog. Interestingly, because this climate was far more common in an earlier era, these trees were once dispersed throughout the Northern Hemisphere.

How is this huge species different from other tree species? In 1948, researchers made the startling discovery that the tree is a hexaploid; that is, each of its cells contains six sets of chromosomes, with 66 chromosomes in total. (Keep in mind that humans have two sets of chromosomes in every cell.) Although hexaploidy is not unknown in grasses and shrubs, it is unusual in trees, particularly gymnosperms. The coast redwood is the only known hexaploid conifer. Hexaploidy means that each tree may have several different alleles for any given gene, which leads to a very genetically diverse population. American molecular biologist Chris Brinegar has found that hardly any two trees have exactly the same genetic constitution. Such genetic diversity allows greater adaptation to environmental conditions and more adaptations against insect or fungal pests. Indeed, living redwoods have no known lethal diseases, and pests do not cause significant damage. What's more, with six sets of genes, trees also have the potential for great variety in their gene products, the proteins, which may help explain their prodigious growth. The coast redwood grows faster than any conifer on Earth, and this is why it is an exception to most *K*-selected species.

56.4 Human Population Growth

Learning Outcomes:

1. Describe the pattern of human population growth.
2. Explain how the demographic transition affects birth rate, death rate, and population size.
3. Detail the differences in age structure and human fertility across different countries.
4. Explain the concept of an ecological footprint.

In 2011, the world's population was estimated to be increasing at the rate of 145 people every minute: 2 per minute in developed nations and 143 in less-developed nations. Based on this rate, one of the United Nations' 2010 projections pointed to a world population reaching 10 billion near the year 2100. In this section, we will examine human population growth trends in more detail and discuss how knowledge of the human population's age structure can help predict its future growth. We will then investigate the carrying capacity of the Earth for humans and explore how the concept of an ecological footprint, which measures human resource use, can help us determine this carrying capacity.

Human Populations Show Extremely Rapid Recent Growth

Until the beginning of agriculture and the domestication of animals, about 10,000 B.C.E., the average rate of human population growth was very low. With the establishment of agriculture, the world's population grew to about 300 million by 1 C.E. and to 800 million by the year 1750. Between 1750 and 2011, a relatively tiny period of human history, the world's human population surged from 800 million to 7 billion (**Figure 56.16**). In 2014, the number of humans was estimated at 7.1 billion. If the population reaches 10 billion by 2100, as the U.N. projects, when and at what level will the human population level off?

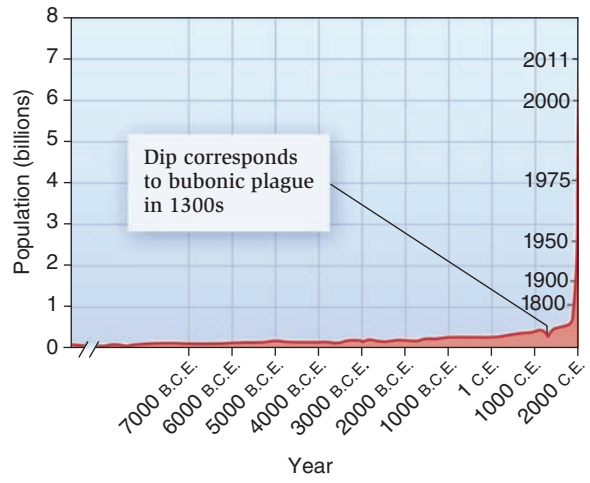

Figure 56.16 The growth pattern of the human population through history. If, and when, human population growth will level off is the focus of considerable debate.

Human populations can exist at equilibrium densities in one of two ways:

1. *High birth and high death rates.* Before 1750, this was often the case, with high birth rates offset by deaths from wars, famines, and epidemics.
2. *Low birth and low death rates.* In Western Europe, beginning in the 18th century, better health and living conditions reduced the death rate. Eventually, social changes such as increasing education for women and marriage at a later age reduced the birth rate.

The shift in birth and death rates that accompanies development is known as the **demographic transition** (**Figure 56.17**). In the first stage of the transition, birth and death rates are both high, and the population is in equilibrium. In the second stage of this transition, the death rate declines first, but the birth rate remains high. High rates of population growth result. In the third stage, the birth rates drop and death rates stabilize, so population growth rates become lower. In the fourth stage, both birth and death rates are low, and the population is again at equilibrium.

The pace of the demographic transition differs among countries, depending on culture, economics, politics, and religion. This is illustrated by comparing the demographic transitions in Sweden and Mexico (**Figure 56.18**). In Mexico, the demographic transitions occurred more recently and was typified by a faster decline in the death rate, reflecting rapid improvements in public health. A relatively longer lag occurred between the decline in the death rate and the decline in the birth rate, however, with the result that Mexico's population growth rate is still well above Sweden's, perhaps reflecting differences in culture or the fact that in Mexico, the demographic transition is not yet complete.

Knowledge of a Population's Age Structure Can Help Predict Its Future Growth

Changes in the age structure of a population also characterize the demographic transition. In all populations, **age structure** refers to the relative numbers of individuals of each defined age group. This information is commonly displayed as a population pyramid (**Figure 56.19**). In West Africa, for example, children younger than age 15 make up nearly half of the population, creating a pyramid with a wide base and narrow top. Even if fertility rates decline, there will still be a huge increase in the population as these young people move into childbearing age. The age structure of Western Europe is much more balanced. Even if the fertility rate of young women in Western Europe increased to a level higher than that of their mothers, the annual numbers of births would still be relatively low because of the low number of women of childbearing age.

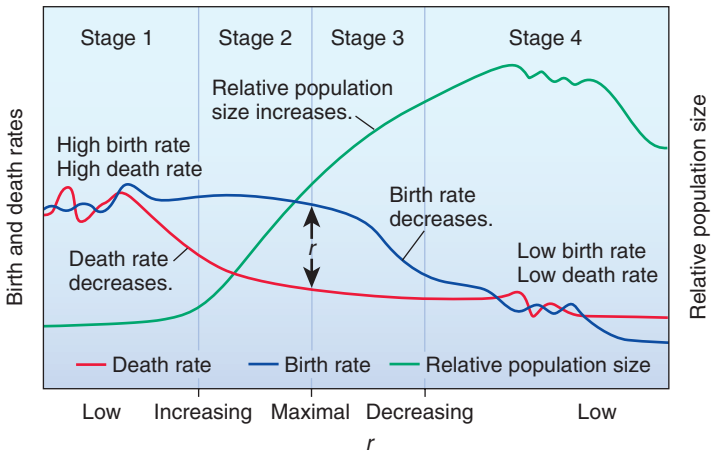

Figure 56.17 The classic stages of the demographic transition. The difference between the birth rate and the death rate determines the rate of population increase or decrease.

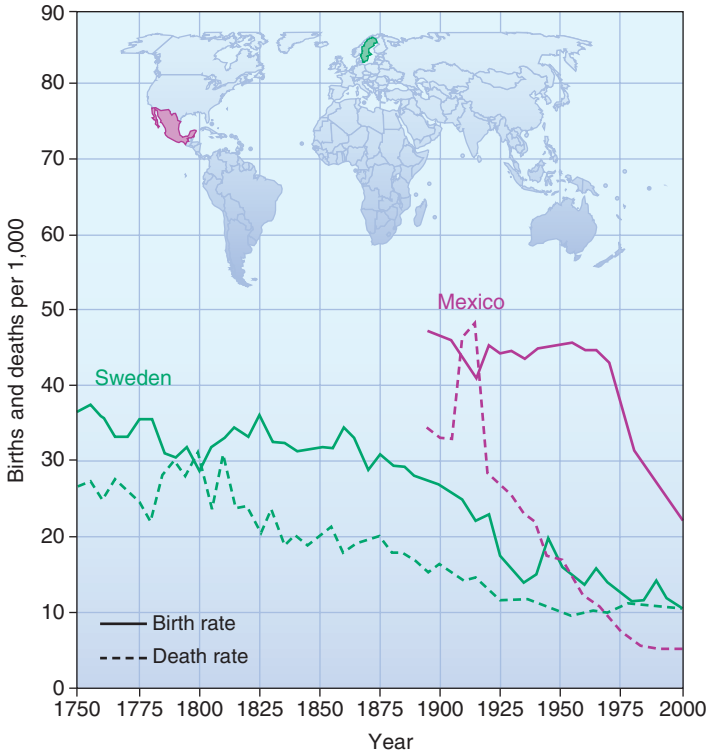

Figure 56.18 The demographic transitions in Sweden and Mexico. Although the demographic transition began earlier in Sweden than it did in Mexico, the transition was more rapid in Mexico, and the overall rate of population increase remains higher. (The spike in the death rate in Mexico prior to 1920 is attributed to the turbulence surrounding the Mexican Revolution.)

Human Population Fertility Rates Vary Widely Around the World

Most estimates propose that the human population will grow to between 10 and 11 billion people by the middle of the 22nd century. Global population growth can be examined by looking at the **total fertility rate (TFR)**, the average number of live births a woman has during her lifetime (**Figure 56.20**). The total fertility rate differs considerably between geographic areas. In Africa, the total fertility rate of 4.6 in 2010 has declined substantially since the 1970s, when it was around 6.7 children per woman. In Latin America and Southeast Asia, the rates have declined considerably from the 1970s and are now at around 2.3. Canada and most countries in Europe have a TFR of less than 2.0 (it is slightly above 2.0 in the U.S.); in Russia, fertility rates have dropped to 1.34. In China, although the TFR is only 1.7, the population there will still continue to increase until at least 2025 because of the large number of women of reproductive age. Although

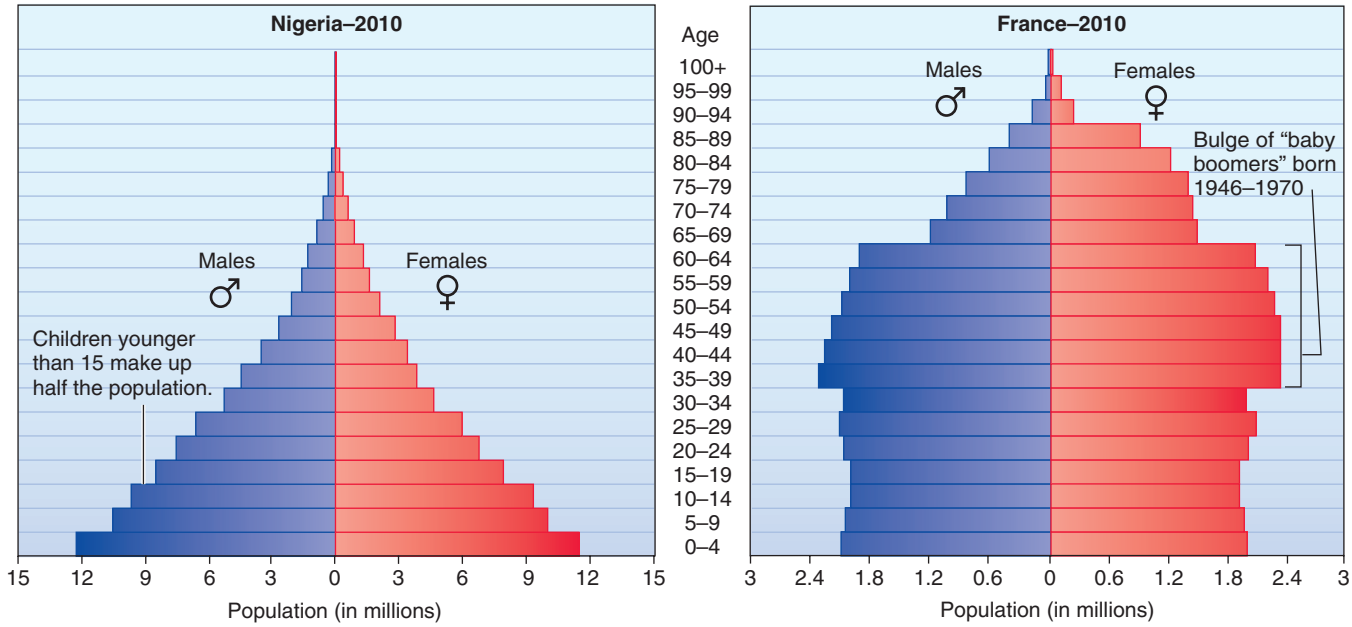

Figure 56.19 **The age structure of human populations in Nigeria and France, as of 2010.** **(a)** In developing areas of the world such as Nigeria, there are far more children than any other age group. Population growth is rapid. **(b)** In the developed countries of Western Europe, the age structure is more evenly distributed. The bulge represents those born in the post-World War II "baby boom," when birth rates climbed due to stabilization of political and economic conditions. Population growth is close to zero.

Concept Check: *If the population pyramid in part (a) was inverted, what would you conclude about the age structure of the population?*

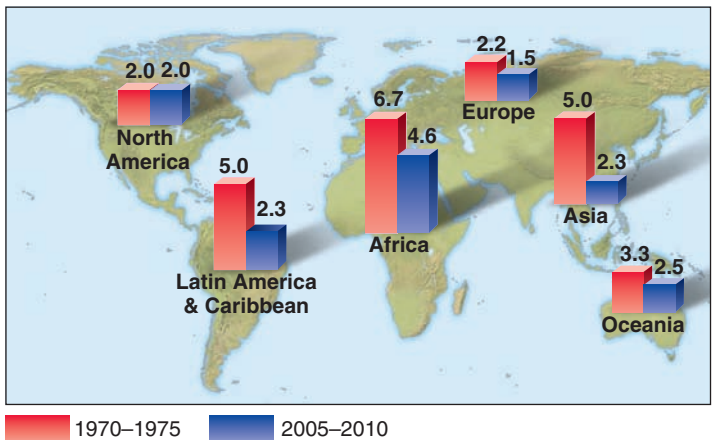

Figure 56.20 **Total fertility rates (TFRs) among major regions of the world.** Data refer to the average number of children born to a woman during her lifetime.

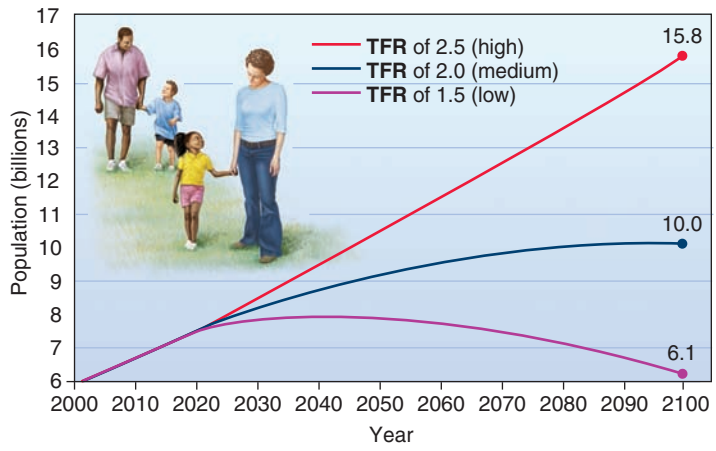

Figure 56.21 **Population predictions for 2000–2100, using three different total fertility rates (TFRs).**

BIOLOGY PRINCIPLE **Biology affects our society.** How TFR is calculated has a great influence on assumptions about how human global population size will change over the next 85 years.

the global TFR has declined from 4.47 in the 1970s to 2.52 in 2010, this is still greater than the average of 2.3 needed for zero population growth. The replacement rate is slightly higher than 2.0, which would replace mother and father, due to natural mortality prior to reproduction. The replacement rate varies globally, from 2.1 in developed countries to between 2.5 and 3.3 in developing countries.

The wide variation in fertility rates makes it difficult to predict future population growth. The 2010 United Nations report shows world population projections to the year 2100 for three different growth scenarios: low, medium, and high (**Figure 56.21**). The three scenarios are based on three different assumptions about fertility rate. Using a low fertility rate estimate of only 1.5 children per woman, the population would reach a maximum of about 8 billion people by 2050. A more realistic assumption may be to use the fertility rate estimate of 2.0 or even 2.5, in which case the population would continue to rise to 10 or 16 billion, respectively.

The Concept of an Ecological Footprint Helps Estimate Carrying Capacity

What is the Earth's carrying capacity for the human population and when will it be reached? Estimates vary widely. Much of the speculation on the upper boundary of the world's population size centers

on lifestyle. To use a simplistic example, if everyone on the planet ate meat extensively and drove large cars, then the carrying capacity would be a lot less than if people were vegetarians and used bicycles as their main means of transportation.

In the 1990s, Swiss researcher Mathis Wackernagel and coworkers calculated how much land is needed for the support of each person on Earth. Everybody has an effect on the Earth, because each person consumes the land's resources, including crops, wood, fossil fuels, minerals, and so on. Thus, each person has an **ecological footprint**, the aggregate total of productive land needed for survival in a sustainable world. The average footprint size for everyone on the planet is about 3 hectares (1 ha = 10,000 m^2), but a wide variation is found around the globe (**Figure 56.22**). The ecological footprint of the average Canadian is 7.5 hectares versus about 10 hectares for the average American.

In most developed countries, the largest component of productive land is needed for energy, followed by food and then forestry. Much of the land needed for energy serves to absorb the CO_2 emitted by the use of fossil fuels. If everyone required 10 hectares, as the average American does, humans would need three Earths to provide the needed resources. Many people in less-developed countries are much more frugal in their use of resources. However, globally humans are already beyond the Earth's carrying capacity even if we all lived in a sustainable manner. This has happened because many people currently live in an unsustainable manner, using more resources than can be regenerated in any given year.

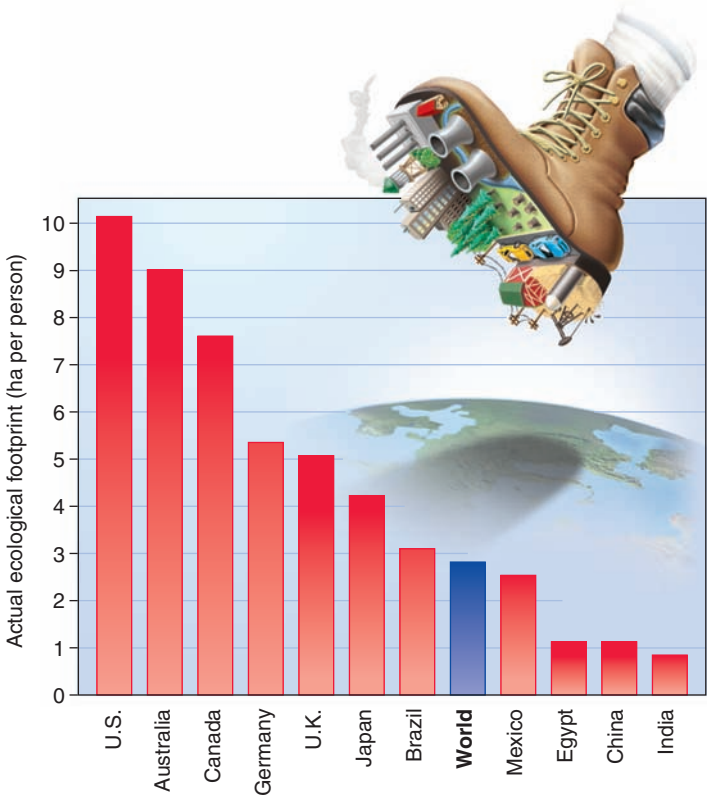

Figure 56.22 Ecological footprints of different countries. The term ecological footprint refers to the amount of productive land needed to support the average individual of that country.

Concept Check: What is your ecological footprint?

What's your personal ecological footprint? Several different calculations are available on the Internet that you can use to find out. A rapidly growing human population combined with an increasingly large per capita ecological footprint makes it increasingly difficult to preserve other species on the planet, a subject we will examine further in our discussion of conservation biology (Chapter 60).

Summary of Key Concepts

56.1 Understanding Populations

- Population ecology studies how populations grow and what factors promote and limit growth. Ecologists measure population density, the numbers of organisms in a given unit area, in many ways (Figures 56.1, 56.2).
- Individuals within populations show different patterns of dispersion, including clumped (the most common), uniform, and random. Individuals also exhibit different reproductive strategies, and populations have different age classes (Figures 56.3, 56.4, 56.5).

56.2 Demography

- Life tables summarize the survival pattern of a population. Survivorship curves illustrate life tables by plotting the numbers of surviving individuals at different ages. Age-specific fertility and survivorship data help determine the overall growth rate per generation, or the net reproductive rate (R_0) (Figures 56.6, 56.7, 56.8, Table 56.1).

56.3 How Populations Grow

- The per capita growth rate (r) helps determine how populations grow over any time period. When r is > 0, exponential (J-shaped) growth occurs. Exponential growth can be observed in an environment where resources are not limited. Logistic (S-shaped) growth takes into account the upper boundary for a population, called the carrying capacity, and occurs in an environment where resources are limited (Figures 56.9, 56.10, 56.11, 56.12). Density-dependent factors are mortality factors whose influence varies with population density. Density-independent factors are those whose influence does not vary with population density (Figure 56.13).
- Life history strategies are a set of features including reproductive traits, survivorship and length of life characteristics, and competitive ability. Life history strategies can be viewed as a continuum, with *r*-selected species (those with a high rate of population growth but poor competitive ability) at one end and *K*-selected species (those with a lower rate of population growth but better competitive ability) at the other (Figures 56.14, 56.15, Table 56.2).

56.4 Human Population Growth

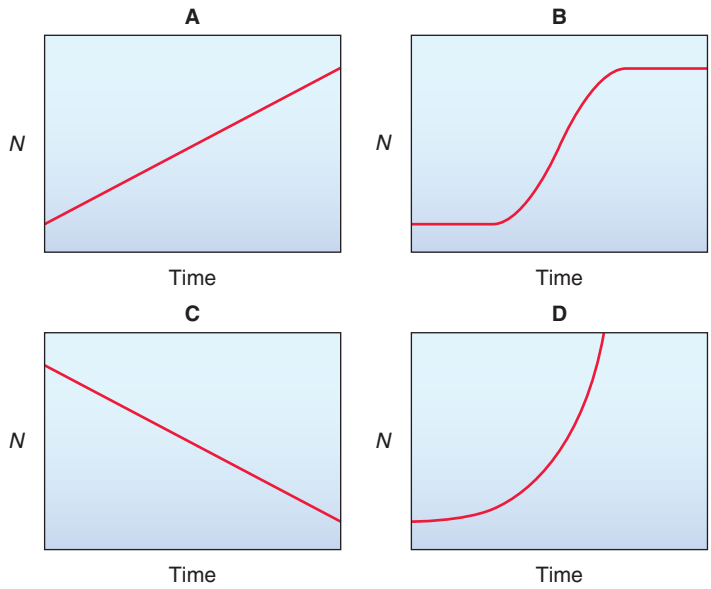
- Over the past 300 years, human populations have shown prodigious growth. Human populations have been moving from states of high birth and death rates to low birth and death rates, a shift called the demographic transition (Figures 56.16, 56.17, 56.18).
- Differences in the age structure of a population, the numbers of individuals in each age group, are also characteristic of the demographic transition (Figure 56.19).
- Although they have been declining worldwide, total fertility rates (TFRs) differ markedly between less-developed and

more-developed countries. Predicting the growth of the human population depends on the total fertility rate that is projected (Figures 56.20, 56.21).

- The ecological footprint refers to the amount of productive land needed to support each person on Earth. Because people in many countries live in a nonsustainable manner, overall humans are already in an ecological deficit (Figure 56.22).

Assess and Discuss

Test Yourself



1. A student decides to use the mark-recapture technique to estimate the population size of mosquitofish in a small pond near his home. In the first catch, he marked 45 individuals. Two weeks later, he captured 62 individuals, of which 8 were marked. What is the estimated size of the population based on these data?
   a. 134 c. 558 e. 22,320
   b. 349 d. 1,016

Questions 2–4 refer to the following table:

Age	n_x	d_x	l_x	m_x	$l_x m_x$
0	100	35	1.00	0	0
1	65	?	0.65	0	0
2	45	15	?	3	1.35
3	30	20	0.30	1	?
4	10	10	0.10	1	0.10
5	0	0	0.00	1	0.0

2. How many individuals die between their first and second birthday?
   a. 65 c. 35 e. 20
   b. 45 d. 25
3. What proportion of newborns survive to age 2?
   a. 0.55 c. 0.35 e. 0.15
   b. 0.45 d. 0.20
4. What is the net reproductive rate?
   a. 5 c. 1.75 e. 0.80
   b. 2.5 d. 1.45
5. _____ survivorship curves are usually associated with organisms that have high mortality rates in the early stages of life.
   a. type I c. type III e. types II and III
   b. type II d. types I and II
6. If the net reproductive rate (R_0) is equal to 0.5, what assumption can we make about the population?
   a. This population is essentially not changing in numbers.
   b. This population is in decline.
   c. This population is growing.
   d. This population is in equilibrium.
   e. None of the above is correct.
7. The maximum number of individuals a certain area can sustain is known as the
   a. intrinsic rate of growth.
   b. resource limit.
   c. carrying capacity.
   d. logistic equation.
   e. equilibrium size.

Questions 8 and 9 refer to the following generalized growth patterns, plotted on arithmetic scales. In each case, choose the correct pattern from the four options.

Each pattern may be used once, more than once, or not at all.

8. Which pattern is found when a population exhibits a constant per capita growth rate?
   a. A
   b. B
   c. C
   d. D
   e. none of the above
9. Which pattern is found when a population is heading toward extinction?
   a. A d. D
   b. B e. none of the above
   c. C
10. The amount of land necessary for survival for each person in a sustainable world is known as
    a. the sustainability level. b. an ecological impact.
    c. an ecological footprint. d. survival needs.
    e. all of the above.

Conceptual Questions

1. As a researcher, you are using the mark-recapture technique (see Figure 56.2) with largemouth bass. Say you do a poor job tagging the fish, and 20% of the tags fall off. How does this influence your estimate of population size? Does it increase or decrease?
2. Using the logistic equation, calculate population growth when $K = 1{,}000$, $N = 100$, and $r = 0.1$. Compare the result with that shown in Section 56.3, where $K = 1{,}000$, $N = 900$, and $r = 0.1$, and with the result when $K = 1{,}000$, $N = 500$, and $r = 0.1$.
3. A principle of biology is that *living organisms interact with their environment*. Imagine two types of ponds. One type dries out when there is little rain, and the other type has a water level that fluctuates but there is always some water present. Contrast the reproductive strategies of organisms that might live in each pond.

Collaborative Questions

1. Discuss what might limit human population growth in the future.
2. Describe where students on campus might show each type of dispersion pattern, and explain why these patterns might occur.

Species Interactions

57

CHAPTER OUTLINE

57.1 Competition
57.2 Predation, Herbivory, and Parasitism
57.3 Mutualism and Commensalism
57.4 Bottom-Up and Top-Down Control
Summary of Key Concepts
Assess and Discuss

In this species interaction, a shark is feeding on a ray, which in turn feeds on bay scallops.

In 2007, marine biologist Ransom Myers and his colleagues showed that overfishing severely depleted the numbers of 11 shark species that occurred along the eastern seaboard of the U.S. Several shark species had declined by over 99% since the 1950s. Because of strong interactions between the sharks and other marine species, this drastic reduction of the shark population had at least two other effects. First, there was a large increase in the main prey species of the sharks, rays and skates. Second, the increase in rays and skates reduced the densities of their prey—bay scallops (*Argopecten irradians*). Such losses contributed to the closure of the bay scallop industry in North Carolina.

In this chapter, we turn from considering populations on their own to investigating how they interact with populations of other species that live in the same locality. Such species interactions can take a variety of forms (Table 57.1). **Competition** can be defined as an interaction that affects both species negatively (–/–), as when both species compete over food or other resources. Sometimes an interaction is one-sided, being detrimental to one species and neutral to the other, an interaction called **amensalism** (–/0). **Predation, herbivory,** and **parasitism** all have a positive effect on one species and a negative effect on the other (+/–). **Mutualism** is an interaction in which both species benefit (+/+), whereas **commensalism** benefits one species and leaves the other unaffected (+/0).

Table 57.1 Summary of the Types of Species Interactions

Nature of interaction	Species 1*	Species 2*
Competition	–	–
Amensalism	–	0
Predation, herbivory, parasitism	+	–
Mutualism	+	+
Commensalism	+	0

*+ = positive effect; – = negative effect; 0 = no effect.

To illustrate how species interact in nature, let's consider a rabbit population in a woodland community (Figure 57.1). To determine what factors influence the size and density of the rabbit population, we need to understand each of the possible species interactions. For example, the rabbit population could be limited by the quality of available food. It is also likely that other species, such as deer, use the same resource and thus compete with the rabbits. The rabbit population could be limited by predation from foxes or by the virus that causes the disease myxomatosis, which is usually spread by fleas and mosquitoes. It is also possible that other associations, such as mutualism or commensalism, may occur.

This chapter examines each of these species interactions in turn, beginning with competition, an important interaction among species. We will conclude with a discussion of bottom-up and top-down effects, both of which are influential in controlling population densities within ecological systems.

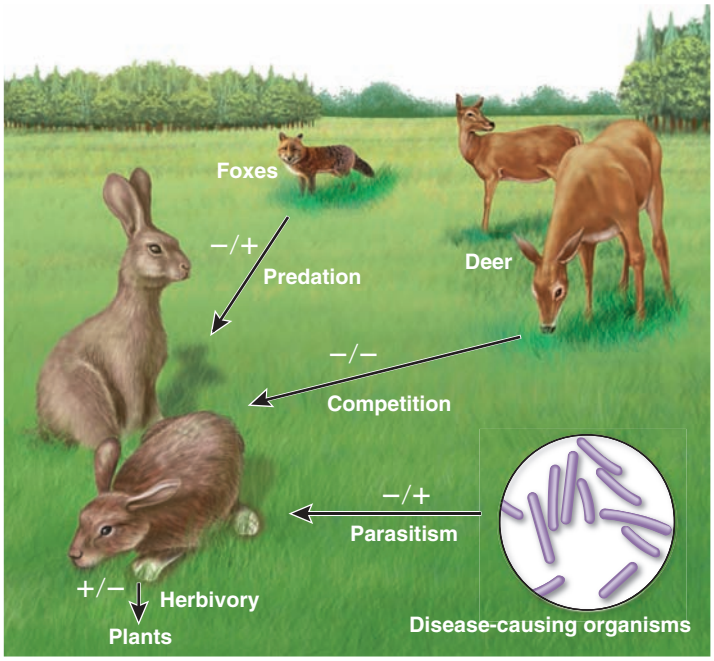


Figure 57.1 Species interactions. These rabbits can interact with a variety of species, experiencing predation by foxes, competition with deer for food, and parasitism from various disease-causing organisms. Herbivory occurs when rabbits feed on various plants. The effects of each species on the other are identified by the labels associated with the arrows, as discussed in the text.

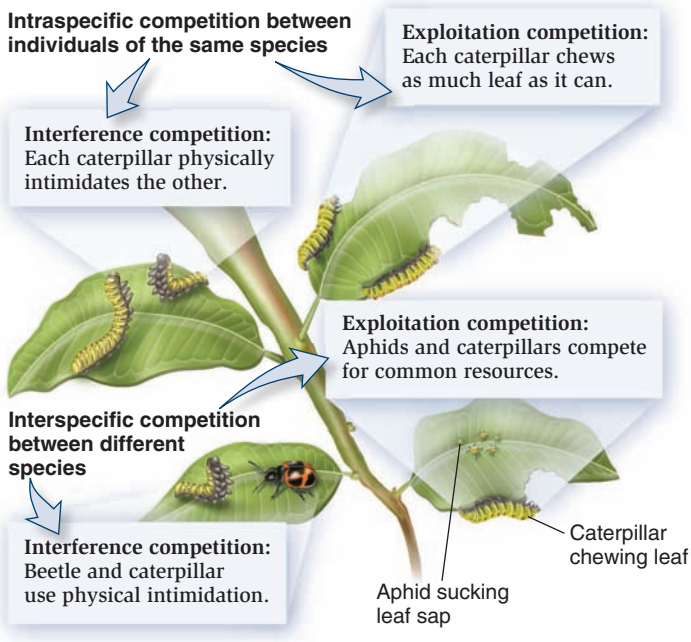

Figure 57.2 The different types of competition in nature.

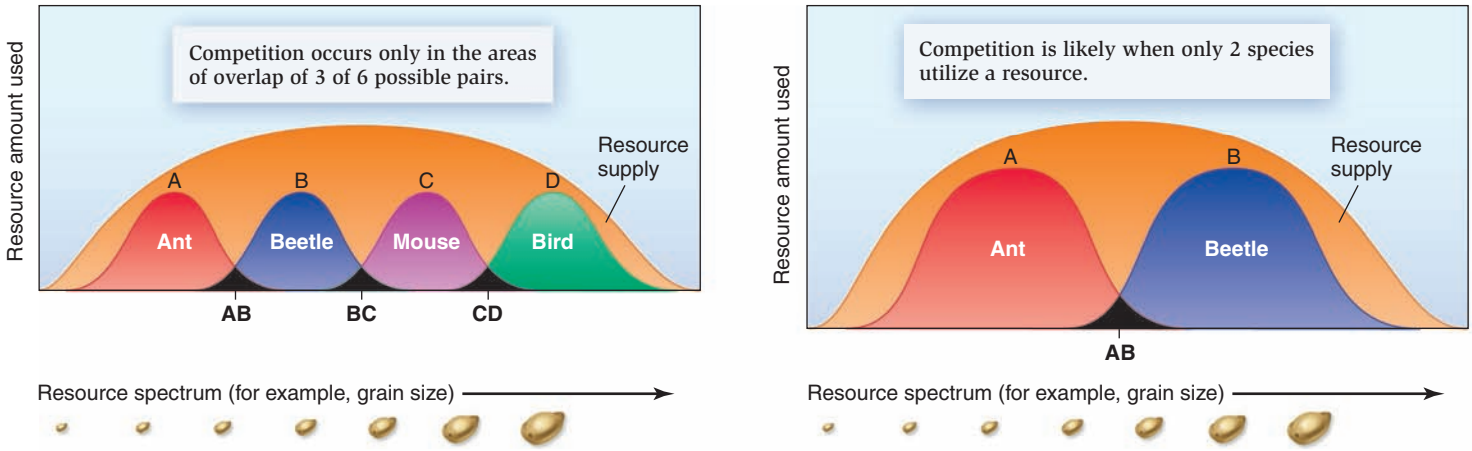
Concept Check: *How would you classify competition between vultures feeding on roadkill?*

57.1 Competition

Learning Outcomes:

1. Describe the different types of competition that occur in nature.
2. **SciSKILLS** » Predict how the competitive exclusion principle can lead to resource partitioning among species.
3. Give examples of how morphological differences may allow species to coexist.

In this section, we will see how ecologists have studied different types of competition and how they have shown that the competitive effects of one species on another can change as the environment changes. Although species may compete for resources, we will also learn how sufficient differences in lifestyle or morphology can reduce the overlap in their habitat use, thus allowing them to coexist.



Several Different Types of Competition Occur in Nature

Several different types of competition are found in nature (**Figure 57.2**). Competition may be **intraspecific** (between individuals of the same species) or **interspecific** (between individuals of different species). Competition can also be characterized by the mechanism by which it occurs. In **exploitation competition**, organisms compete indirectly through the consumption of a limited resource, with each obtaining as much as it can. For example, when fly maggots compete in a mouse carcass, not all the individuals can command enough of the resource to survive and become adult flies. In **interference competition**, individuals interact directly with one another by physical force or intimidation. Often this force is ritualized into aggressive behavior associated with territoriality. In these cases, strong individuals survive and take the bulk of the resources, and weaker ones perish or, at best, survive under suboptimal conditions.

Competition between species is not always equal. An extreme asymmetric competition can be observed between plants, in which one species secretes and produces chemicals from its roots that inhibit the growth of another species. Chapter 54's Feature Investigation revealed that diffuse knapweed, an introduced species, secretes root chemicals called allelochemicals into the surrounding environment that kill the roots of native grass species—a phenomenon called **allelopathy**.

Field Studies Show That Competition Occurs Frequently in Nature

By reviewing studies that have investigated competition in nature, we can see how frequently it occurs and in what particular circumstances it is most important. In a 1983 review of field studies by American ecologist Joseph Connell, competition was found in 55% of 215 species surveyed, demonstrating that it is indeed frequent in nature. Generally in studies of single pairs of species utilizing the same resource, competition is almost always reported (90%), whereas in studies involving more species, the frequency of competition drops to 50%. Why should this be the case? Imagine a resource such as a series of different-sized grains with four species—ants, beetles, mice, and birds—feeding on it (**Figure 57.3a**). The ants

(a) Competition among 4 species for a resource

(b) Competition among 2 species for a resource

Figure 57.3 The frequency of competition according to the number of species involved. **(a)** Resource supply and utilization curves of four species, A, B, C, and D, along the spectrum of a hypothetical resource such as grain size. If competition occurs only between species with adjacent resource utilization curves, competition is expected between three of the six possible pairings: A and B; B and C; and C and D. **(b)** When only two species utilize a resource set, competition is nearly always expected between them.

feed on the smallest grain, the beetles and mice on the intermediate sizes, and the birds, on the largest. If only adjacent species competed with each other, competition would be expected only between the ant–beetle, beetle–mouse, and mouse–bird. Thus, competition would be found in only three out of the six possible species pairs (50%). Naturally, the percentage would vary according to the number of species on the resource spectrum. If only three species occur along the spectrum, we would expect competition in two of the three pairs (67%). If just two species utilized the resource spectrum, however, we would expect competition in almost 100% of the cases (**Figure 57.3b**).

Some other general patterns were evident from Connell's review. Plants showed a high degree of competition, perhaps because they are rooted in the ground and cannot easily escape or perhaps because they are competing for the same set of limiting nutrients—water, light, and minerals. Marine organisms tended to compete more than terrestrial ones, perhaps because many of the species studied lived in the intertidal zone and were attached to the rock face, in a manner similar to that of plants. Because the area of the rock face is limited, competition for space is quite important.

BIO TIPS **THE QUESTION** *If 5 species utilized the resource set in Figure 57.3(a), what percentage of the interactions would be competitive?*

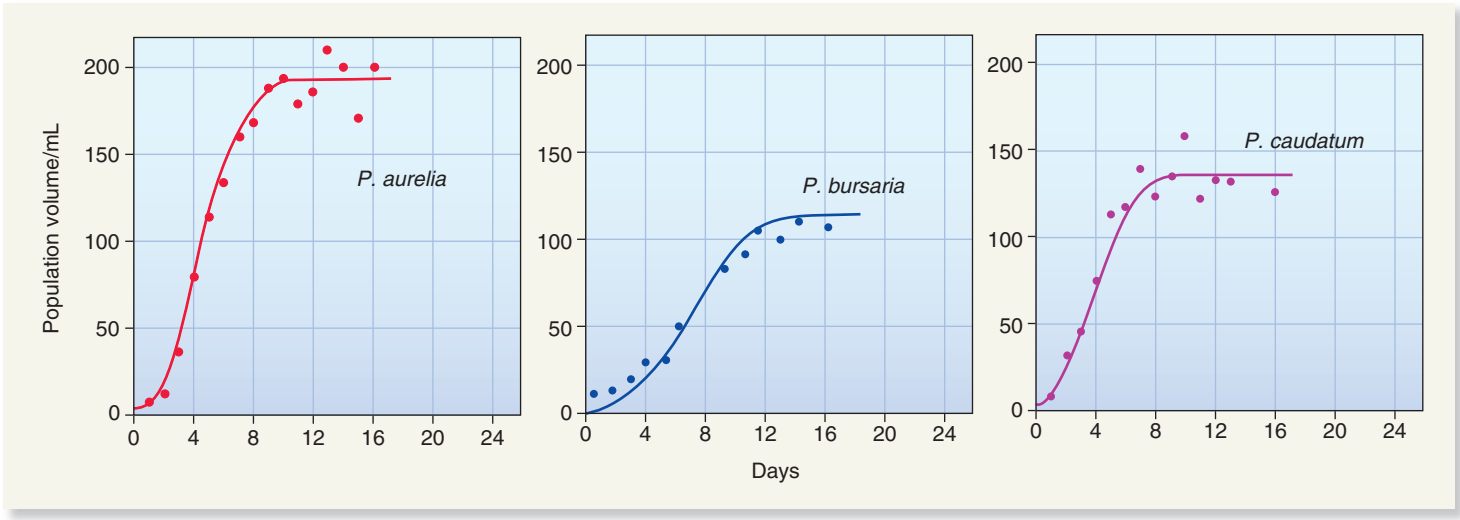
TOPIC ***What topic in biology does this question address?*** The topic is species interactions. More specifically, the question asks you to determine what proportion of species that utilize a resource set are likely to compete.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you know that there are 5 species utilizing the same resource set. From Figure 57.3(a) and the text discussion, you may recall that only adjacent species compete.

PROBLEM-SOLVING STRATEGY ***Make a calculation. Interpret data.*** A good way to start to solve this problem is to construct a table of possible species interactions, with first competing species in columns and second competing species in rows, as shown below.

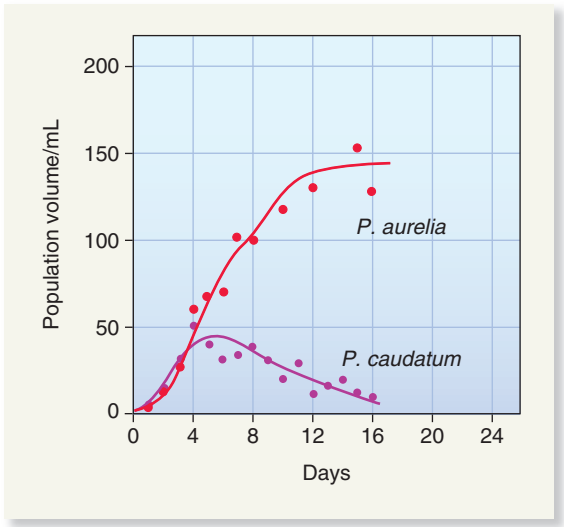
First potential competing species	Second potential competing species				
	A	B	C	D	E
A	X	AB	AC	AD	AE
B		X	BC	BD	BE
C			X	CD	CE
D				X	DE
E					X

Next, determine the total number of possible species interactions (which is 10). Then, divide the number of cases where adjacent species compete (for example, A and B or B and C) by the total number of possible species interactions and multiply that result by 100.



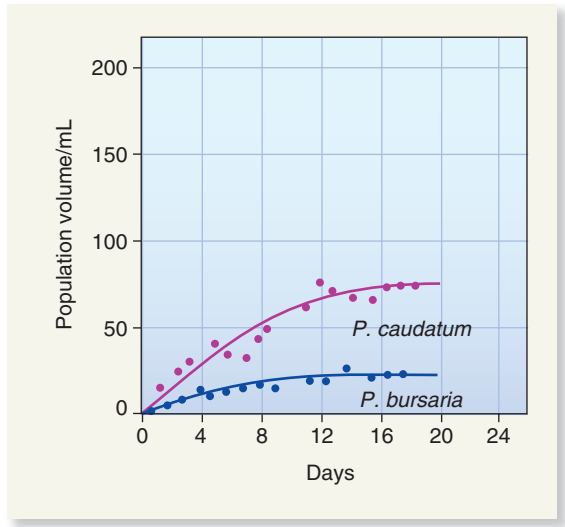
ANSWER *For this group of species, the percentage of interactions that would be competitive is 40%.*

Species May Coexist If They Do Not Occupy Identical Niches



Although competition is common, researchers have proposed several mechanisms by which two competing species can coexist. One states that similar species can coexist if they occupy different niches. A **niche**

is often thought of as the area where an organism can be found, but it also can convey what an organism does in a community, including how it feeds. In 1934, the Russian microbiologist Georgyi Gause began to study competition between three protist species, *Paramecium aurelia*, *Paramecium bursaria*, and *Paramecium caudatum*, all of which fed on bacteria and yeast, which, in turn, fed on an oatmeal medium in a culture tube in the laboratory. The bacteria occurred more in the oxygen-rich upper part of the culture tube, and the yeast in the oxygen-poor lower part of the tube. Because each species was a slightly different size, Gause calculated population growth as a combination of numbers of individuals per milliliter of solution multiplied by their unit volume to give a population volume for each species. When grown separately, population volume of all three *Paramecium* species followed a logistic growth pattern (**Figure 57.4a**; refer back to Figure 56.11). When Gause cultured *P. caudatum* and *P. aurelia* together, *P. caudatum* went extinct (**Figure 57.4b**). Both species utilized bacteria as food, but *P. aurelia* grew at a rate six times faster than *P. caudatum*.



However, when Gause cultured *P. caudatum* and *P. bursaria* together, neither went extinct (**Figure 57.4c**). The population volume of each was much less than when they were grown alone, because some competition occurred between them. Gause discovered, however, that *P. bursaria* was better able to utilize the yeast in the lower part of the culture tubes. *P. bursaria* have tiny green algae inside them, which produce oxygen and allow *P. bursaria* to thrive in the lower oxygen levels at the bottom of the tubes. From these experiments, Gause concluded that two species with exactly the same requirements cannot live together in the same place and use the same resources, that is, occupy the same niche. His conclusion was later termed the **competitive exclusion principle**.

(a) Each *Paramecium* species grown alone

(b) Competition between *P. aurelia* and *P. caudatum*

(c) Competition between *P. caudatum* and *P. bursaria*

Figure 57.4 Competition among *Paramecium* species. **(a)** When grown alone, each of three species, *Paramecium aurelia, Paramecium bursaria*, and *Paramecium caudatum*, grows according to the logistic model. **(b)** When *P. aurelia* is grown with *P. caudatum*, the density of *P. aurelia* is lower than when grown alone, and *P. caudatum* goes extinct. **(c)** When *P. caudatum* is grown with *P. bursaria*, the population densities of both are lowered, but they coexist.

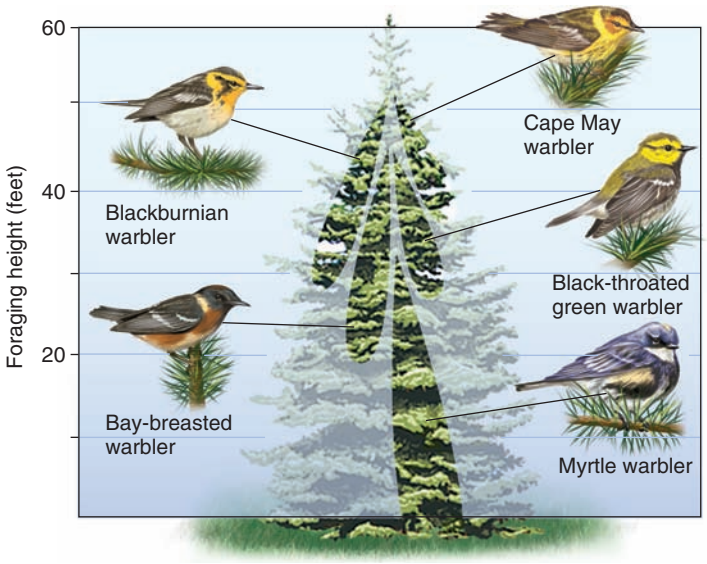


Figure 57.5 Resource partitioning. Among five species of warblers feeding in North American spruce trees, each species prefers to feed at a different height and portion of the tree, thus reducing competition.

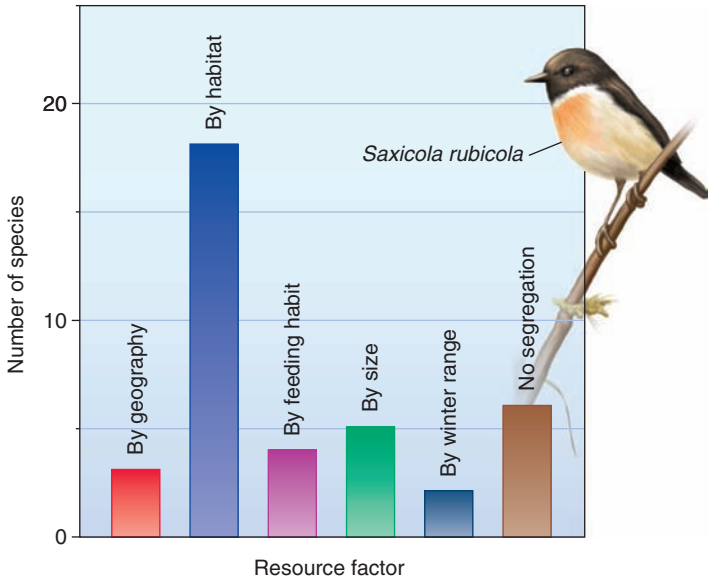

Figure 57.6 Segregation of 40 bird species according to resource factor. Among 40 species of passerine birds, most segregation was by habitat, followed by size, feeding habit, geography, and type of winter range they forage in. In about 15% of cases, no obvious segregation was observed. More than half of all bird species, including *Saxicola rubicola*, are passerines, also known as perching birds.

Concept Check: Do you think these results for passerine birds are typical for most other species? For example, do most other species segregate by habitat?

Resource Partitioning Promotes Coexistence If complete competitors drive one species to local extinction, at least in the laboratory, how different must two species be to coexist, and in what features do they usually differ? To address such questions, in 1958, American ecologist Robert MacArthur examined coexistence between five species of warblers feeding within spruce trees in New England. All belonged to the genus *Dendroica*, so these closely related bird species would be expected to compete strongly, possibly sufficiently strongly to cause extinctions. MacArthur found that the species occupied different heights and portions in the tree, and therefore, each probably fed on a different range of insects (**Figure 57.5**). In addition, the Cape May warbler fed on flying insects and tended to remain on the outside of the trees.

The term **resource partitioning** describes the differentiation of niches, both in space and time, that enables similar species to coexist in a community, just as the five species of warblers feeding in different parts of a spruce tree. We can think of resource partitioning as reflecting the results of past competition, in which competition leads the inferior competitor to eventually occupy a different niche.

British ornithologist David Lack examined competition and coexistence among about 40 species of British passerines, or perching birds (**Figure 57.6**). As a group, these birds had fairly similar lifestyles. Most segregated according to some resource factor, with habitat being the most common one. For example, although all the passerines fed on insects, some would feed exclusively in grasslands, others in forests, some low to the ground, and others high in trees, where the insects present would likely be different. Birds also segregated by size—so bigger species would take different-sized food from that used by smaller species—and by feeding habit—with some feeding on insects on foliage, others on tree trunks, and so on. Some species also fed in different winter ranges, whereas others occurred in different parts of the country (separation by geography). About 15% of bird species showed no segregation at all.

Most species perform best over a physiologically optimal range of conditions called the **fundamental niche**. However, if some part of the fundamental niche is occupied by competitors, the range of an organism may be limited to an area known as the **realized niche**, where the competitor is absent. Researchers have established that one of the best methods of determining an organism's fundamental niche is to temporarily remove one of the competing species and examine the effect on the other species. A now-classic example of this method involved a study of the interactions between two species of barnacles conducted on the west coast of Scotland, described next.

Feature Investigation | Connell's Experiments with Barnacle Species Revealed Each Species' Fundamental and Realized Niches

Chthamalus stellatus and *Semibalanus balanoides* (formerly known as *Balanus balanoides*) are two species of barnacles that dominate the Scottish coastline. Each organism's realized niche on the intertidal zone is well defined. *Chthamalus* occurs in the upper intertidal zone, and *Semibalanus* is restricted to the lower intertidal zone. Joseph Connell sought to determine what the range of *Chthamalus* adults might be in the absence of competition from *Semibalanus* (**Figure 57.7**).

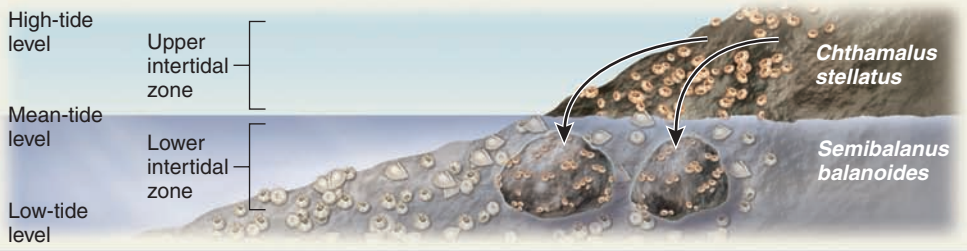

Figure 57.7 Connell's experimental manipulation of species indicated the presence of competition.

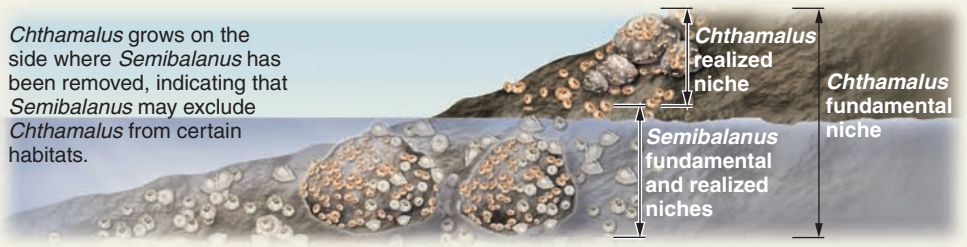
HYPOTHESIS *Chthamalus stellatus* is being competitively excluded from the lower intertidal zone by the species *Semibalanus balanoides*.

STARTING LOCATION The intertidal zone of the rocky shores of the Scottish coast, where the two species of barnacles occur.

Experimental level

1 Transfer rocks containing young and mature *Chthamalus* from the upper intertidal zone to the lower intertidal zone, and fasten them down in the new location with screws.

2 Allow *Semibalanus* to colonize the rocks.



3 After the colonization period is over, remove *Semibalanus* from half of each rock with a needle (leaving the other half undisturbed). Return the rocks to the lower intertidal zone, and fasten them down once again.

4 Monitor the survival of *Chthamalus* on both sides of the rocks.

Chthamalus grows on the side where *Semibalanus* has been removed, indicating that *Semibalanus* may exclude *Chthamalus* from certain habitats.

5 THE DATA

Rock No.	Side of rock	% *Chthamalus* mortality over 1 year	
		Young barnacles	Mature barnacles
13b	*Semibalanus* removed	35	0
	Semibalanus not removed	90	31
12a	*Semibalanus* removed	44	37
	Semibalanus not removed	95	71
14a	*Semibalanus* removed	40	36
	Semibalanus not removed	86	75

6 **CONCLUSION** The data from this study indicate that *Chthamalus* is not found on the lower rock face because of competition with *Semibalanus*. Other studies indicate that *Chthamalus* occupies the upper rock face because it is more resistant to desiccation.

7 **SOURCE** Connell, J.H. 1961. The influence of interspecific competition and other factors on the distribution of the barnacle *Chthamalus stellatus*. *Ecology* 42:710–732.

To do this, Connell obtained rocks from high on the rock face, just below the high-tide level, where only *Chthamalus* grew. These rocks already contained young and mature *Chthamalus*. He then moved the rocks into the *Semibalanus* zone, fastened them down with screws, and allowed *Semibalanus* to also colonize them. Once *Semibalanus* had colonized these rocks, he took the rocks out, removed all the *Semibalanus* organisms from one side of the rocks with a needle, and then returned the rocks to the lower intertidal zone, screwing them down once again. As seen in the data, the mortality of *Chthamalus* on rock halves with *Semibalanus* was fairly high. On the *Semibalanus*-free halves, however, *Chthamalus* survived well.

In other studies, Connell also monitored survival of natural patches of both barnacle species where both occurred on the intertidal zone at the upper margin of the *Semibalanus* distribution. In a period of unusually low tides and warm weather, when no water reached any barnacles for several days, desiccation became a real threat to both species' survival. During this time, young *Semibalanus* suffered a 92% mortality rate, and older individuals, a 51% mortality rate. At the same time, young *Chthamalus* experienced a 62% mortality rate compared with a rate of only 2% for more-resistant older individuals. Clearly, *Semibalanus* is not as resistant to desiccation as *Chthamalus* and could not survive in the upper intertidal zone where *Chthamalus* occurs. *Chthamalus* is more resistant to desiccation than *Semibalanus* and can be found higher in the intertidal zone. Thus, whereas the lower limit of *Chthamalus* was set by competition with *Semibalanus*, the upper limit was controlled by desiccation. Although the potential distribution, the fundamental niche, of *Chthamalus* extends over the entire intertidal zone, its actual distribution, the realized niche, is restricted to the upper zone.

Experimental Questions

1. Describe the realized niches for the two species of barnacles used in Connell's experiment.
2. Outline the procedure Connell used in the experiments.
3. **SciSKILLS »** How can you explain the presence of *Chthamalus* in the upper intertidal zone if *Semibalanus* was shown to outcompete the species in the first experiment?

Morphological Differences May Allow Species to Coexist

Although the competitive exclusion principle acknowledges that competitors with exactly the same requirements cannot coexist, some partial level of competition may exist that is not severe enough to drive one of the competitors to extinction or to a different niche. In 1959, British-born American biologist G. Evelyn Hutchinson examined the sizes of mouthparts or other body parts important in feeding and compared their sizes across species when they were **sympatric** (occurring in the same geographic area) and **allopatric** (occurring in different geographic areas). Hutchinson's hypothesis was that when species were sympatric, each species tended to specialize on different types of food. This was reflected by differences in the size of body parts associated with feeding, also called feeding characters. The tendency for two species to diverge in morphology and thus resource use because of competition is called **character displacement**. Alternatively, in areas where species were allopatric, there was no need to specialize on a particular prey type, so the size of the feeding character did not evolve to become larger or smaller; rather it retained a "middle of the road" size that allowed species to exploit the largest range of prey size distribution.

One of the classic cases of character displacement involves a study of Galápagos finches, several closely related species of finches Charles Darwin discovered on the Galápagos Islands (refer back to Table 23.1). When two species, *Geospiza fortis* and *Geospiza fuliginosa*, are sympatric, their beak sizes (bill depths) are different: *G. fortis* has a larger bill depth, which enables it to feed on bigger seeds, whereas *G. fuliginosa* has a smaller bill depth, which enables it to crack small seeds more efficiently. However, when both species are allopatric, that is, existing on different islands, their bills are more similar in depth. Researchers studying *Geospiza* concluded that the bill depth differences evolved in ways that minimized competition.

How great must differences between characters be in order to permit coexistence? Hutchinson noted that the ratio between feeding characters when species were sympatric (and thus competed) averaged about 1.3 (**Table 57.2**). In contrast, the ratio between feeding characters when species were allopatric (and did not compete) was closer to 1.0. Hutchinson proposed that the value of 1.3, a roughly 30% difference, could be used as an indication of the amount of difference necessary to permit two species to coexist.

Table 57.2 Comparison of Feeding Characters of Sympatric and Allopatric Species

		Measurement (mm) when		Ratio* when	
Animal (character)	**Species**	**Sympatric**	**Allopatric**	**Sympatric**	**Allopatric**
Weasels (skull)	*Mustela erminea*	50.4	46.0	1.28	1.07
	Mustela nivalis	39.3	42.9		
Mice (skull)	*Apodemus flavicollis*	27.0	26.7	1.09	1.04
	Apodemus sylvaticus	24.8	25.6		
Nuthatches (beak)	*Sitta tephronota*	29.0	25.5	1.23	1.02
	Sitta neumayer	23.5	26.0

57.2 Predation, Herbivory, and Parasitism

Learning Outcomes:

1. List and describe strategies animals use to avoid predation.
2. Give examples of the effects of predators on prey populations.
3. Explain why plants and herbivores are said to be in an "evolutionary arms race."
4. Describe variations on the parasitic lifestyle.

Predation, herbivory, and parasitism are interactions that have a positive effect for one species and a negative effect for the other. These categories of species interactions can be classified according to how lethal they are for the prey and the length of association between the consumer and prey (**Figure 57.8**). Each has particular characteristics that set it apart. Herbivory usually involves nonlethal predation on plants, whereas predation generally results in the death of the prey. Parasitism, like herbivory, is typically nonlethal and differs from predation in that the adult parasite typically lives and reproduces for long periods in or on the living host (refer back to Figure 33.8). Parasitoids, insects that lay eggs in living hosts, have features in common with both predators and parasites. They always kill their prey, as predators do, but unlike predators, which immediately kill their prey, parasitoids kill the host more slowly. Parasitoids are common in the insect world and include parasitic wasps and flies that feed on many other insects.

In this section, we begin by looking at antipredator strategies and will see how, despite such strategies, predation remains a factor affecting the density of prey. We will survey the strategies plants use to deter herbivores and in turn, the strategies herbivores use to overcome host plant defenses. Finally, we will investigate parasitism, which may be the predominant lifestyle on Earth, and explore the growing role of genomics in the fight against parasites.

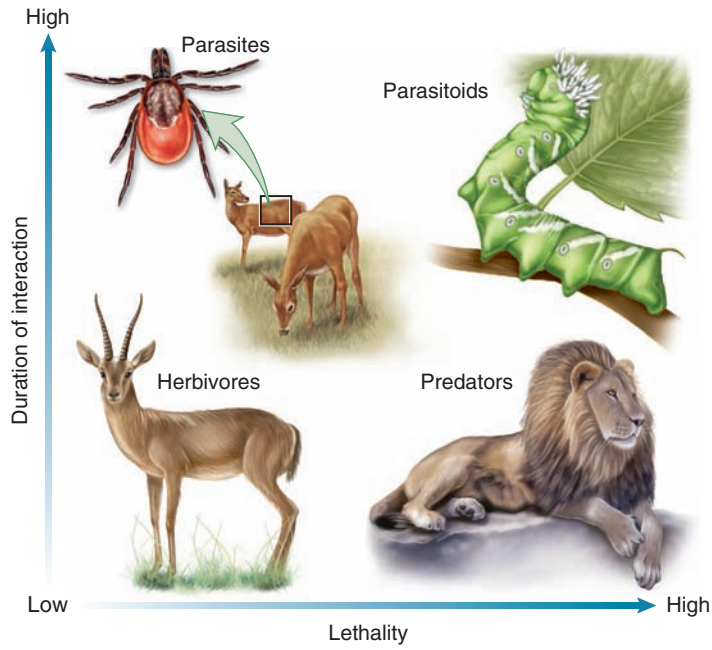

Figure 57.8 Possible interactions between populations. Lethality represents the probability that an interaction results in the death of the prey. Duration represents the length of the interaction between the consumer and the prey.

Concept Check: *Where might omnivores fit in this figure?*

Animals Have Evolved Many Antipredator Strategies

The variety of strategies that animals have evolved to avoid being eaten suggests that predation is a strong selective force. Common strategies include chemical defense, camouflage (including cryptic coloration and catalepsis), mimicry, displays of intimidation, and armor and weaponry.

Chemical Defense A great many species have evolved chemical defenses against predation. One of the classic examples of a chemical defense involves the bombardier beetle (*Stenaptinus insignis*), which has been studied by German-born American entomologist Tom Eisner and coworkers. These beetles possess a reservoir of hydroquinone and hydrogen peroxide in their abdomen. When threatened, they eject the chemicals into an "explosion chamber," where the subsequent release of oxygen causes the whole mixture to be violently ejected as a hot spray (about 88°C, or 190°F) that can be directed at the beetle's attackers (**Figure 57.9a**). Many other arthropods, such as millipedes, also have chemical sprays, and the phenomenon is also found in vertebrates, as anyone who has had a close encounter with a skunk can testify.

Often associated with a chemical defense is an **aposematic coloration**, or warning coloration, which advertises an organism's unpalatable taste. For instance, the ladybird beetle's bright red color warns of the toxic defensive chemicals it exudes when threatened, and

(a) This bombardier beetle (*Stenaptinus insignis*) directs its hot, stinging spray at a forceps "attacker."

(d) Müllerian mimicry. Viceroy (left) and monarch (right) butterflies are both noxious and have similar color patterns.

(b) Aposematic coloration advertises the poisonous nature of this blue poison arrow frog (*Dendrobates azureus*) from South America.

(e) In this example of Batesian mimicry, an innocuous scarlet king snake (*Lampropeltis elapsoides*) (left) mimics the poisonous coral snake (*Micrurus fulvius*) (right).

(c) Camouflage allows this Pygmy sea horse (*Hippocampus bargibanti*) from Bali to blend in with its background.

(f) In a display of intimidation, this porcupine fish (*Diodon hystrix*) puffs itself up to look threatening to its predators.

(g) This juvenile ornate box turtle, *Terrapene ornata*, has a strong shell that can deter predators much larger than itself.

Figure 57.9 Antipredator adaptations.

Concept Check: *According to the classification of species interactions in Table 57.1, how would you classify Batesian and Müllerian mimicry?*

BioConnections: *Refer back to Figure 33.12. Which types of antipredator adaptations are possessed by mollusks?*

many tropical frogs have bright warning coloration that calls attention to their skin's lethality (**Figure 57.9b**). Monarch butterfly caterpillars feed exclusively on milkweed, which contains toxic chemicals called cardiac glycosides that pass into the caterpillars. In the 1960s, American entomologist Lincoln Brower and coworkers showed that after inexperienced blue jays ate a monarch butterfly and suffered a violent vomiting reaction, they learned to associate the striking orange-and-black appearance of the butterfly with a noxious reaction (refer back to Figure 55.3).

Camouflage **Camouflage** is the blending of an organism with the background of its habitat. Cryptic coloration is a common method of avoiding detection by predators. For example, many grasshoppers are green and blend in with the foliage on which they feed. Stick insects mimic branches and twigs with their long, slender bodies. In most cases, these animals stay perfectly still when threatened, because movement alerts a predator. Maintenance of a fixed body posture is referred to as catalepsis. Camouflage is prevalent in the vertebrate world, too. Many sea horses adopt a body shape and color pattern similar to the environment in which they are found (**Figure 57.9c**).

Mimicry **Mimicry**, the resemblance of a species (the mimic) to another species (the model), also secures protection from predators. There are two major types of mimicry. In **Müllerian mimicry**, two or more toxic species converge to look the same, thus reinforcing the basic distasteful design. One example is the black-and-yellow-striped bands of several different types of bees and wasps. Müllerian mimicry is also found among noxious Amazonian butterflies. The viceroy butterfly (*Limenitis archippus*) and the monarch butterfly (*Danaus plexippus*) are examples of Müllerian mimicry. Both species are unpalatable and look similar, but the viceroy can be distinguished from the monarch by a black line that crosses its wings (**Figure 57.9d**).

Batesian mimicry is the mimicry of an unpalatable species (the model) by a palatable one (the mimic). Some of the best examples involve flies, especially hoverflies of the family Syrphidae, which are striped black and yellow and resemble stinging bees and wasps but are themselves harmless. Among vertebrates, the nonvenomous scarlet king snake (*Lampropeltis elapsoides*) mimics the venomous coral snake (*Micrurus fulvius*), thereby gaining protection from would-be predators (**Figure 57.9e**).

Displays of Intimidation Some animals put on displays of intimidation in an attempt to discourage predators. For example, a cat arches its back, a frilled lizard extends its collar, and a porcupine fish inflates itself when threatened in order to appear larger (**Figure 57.9f**). All of these animals use displays to deceive potential predators about the ease with which they can be eaten.

Armor and Weaponry Physical defenses that prey use against predators are varied and numerous. The shells of tortoises and freshwater turtles are an effective means of defense against most predators (**Figure 57.9g**). Though many animals developed horns and antlers for sexual selection, they can also be used in defense against predators (refer back to Figure 34.24). Invertebrate species often have powerful claws, pincers, or, in the case of scorpions, venomous stingers that can be used in defense as well as offense.

How common is each of these types of defenses? No one has done an extensive survey of the entire animal kingdom. However, in 1989, American biologist Brian Witz surveyed studies that documented antipredator mechanisms in arthropods, mainly insects. By far the most common antipredator mechanisms were chemical defenses and associated aposematic coloration, noted in 51% of the examples. Other types of defense mechanisms occurred with considerably less frequency.

Despite the Impressive Array of Defenses, Predators Can Still Affect Prey Densities

Research studies have shown that predators can have a significant effect on prey populations. Considerable data exist on the interaction of the Canada lynx (*Lynx canadensis*) and its prey, snowshoe hares (*Lepus americanus*), because of the value of the pelts of both animals. In 1942, British ecologist Charles Elton analyzed the records of furs traded by trappers to the Hudson's Bay Company in Canada over a 100-year period. Analysis of the records showed that a dramatic 9- to 11-year cycle existed for as long as records had been kept (**Figure 57.10**). As hare density increases, there is an increase in density of the lynx, which then depresses hare numbers. This is followed by a decline in the number of lynx, and the cycle begins again. Using radio collars to track individual hares, researchers were able to determine that 90% of individuals died of predation.

Invasive species provide further evidence of the effects of predators. The brown tree snake (*Boiga irregularis*) was inadvertently introduced by humans to the island of Guam, in Micronesia, shortly after World War II. The growth and spread of its population over the next 40 years closely coincided with a precipitous decline in the island's forest birds. On Guam, the snake had no natural predators to control it. Because the birds on Guam did not evolve with the snake, they had no defenses against it. Eight of the island's 11 native species of forest birds, such as the Guam rail and Micronesian kingfisher, were extinct by the 1980s (**Figure 57.11**).

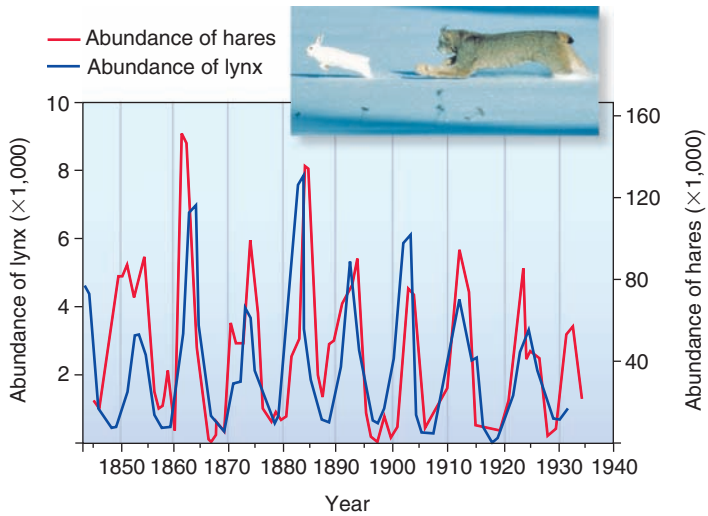

Figure 57.10 Effect of predator on prey populations. The 9- to 11-year oscillation in the abundance of the snowshoe hare (*Lepus americanus*) and the Canada lynx (*Lynx canadensis*) was revealed from pelt trading records of the Hudson's Bay Company.

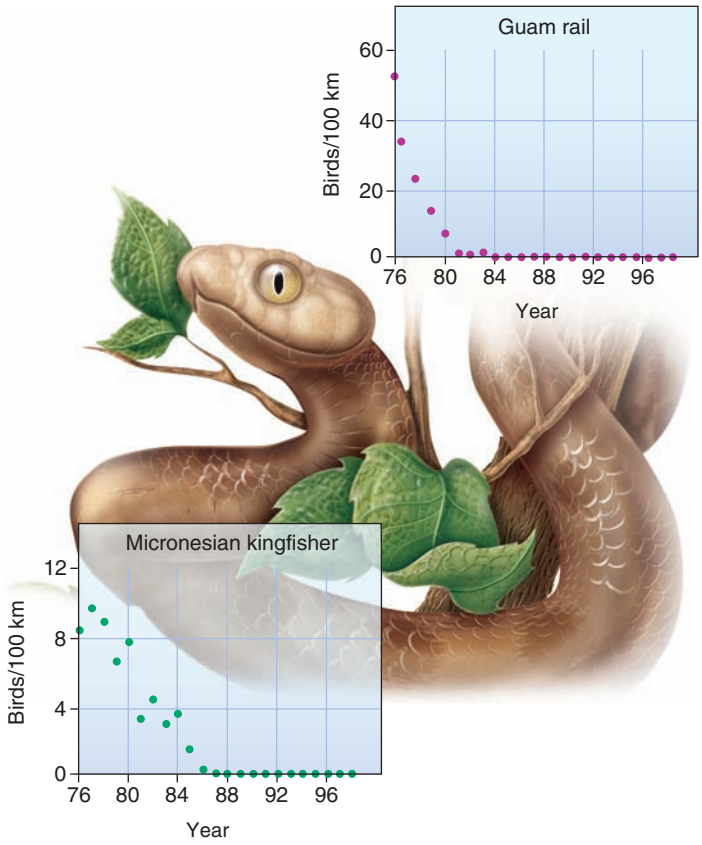

Figure 57.11 Predation by an invasive species. Population trends for two native Guam birds, as indicated by 100-km roadside surveys conducted from 1976 to 1998, show a precipitous decline because of predation by the introduced brown tree snake.

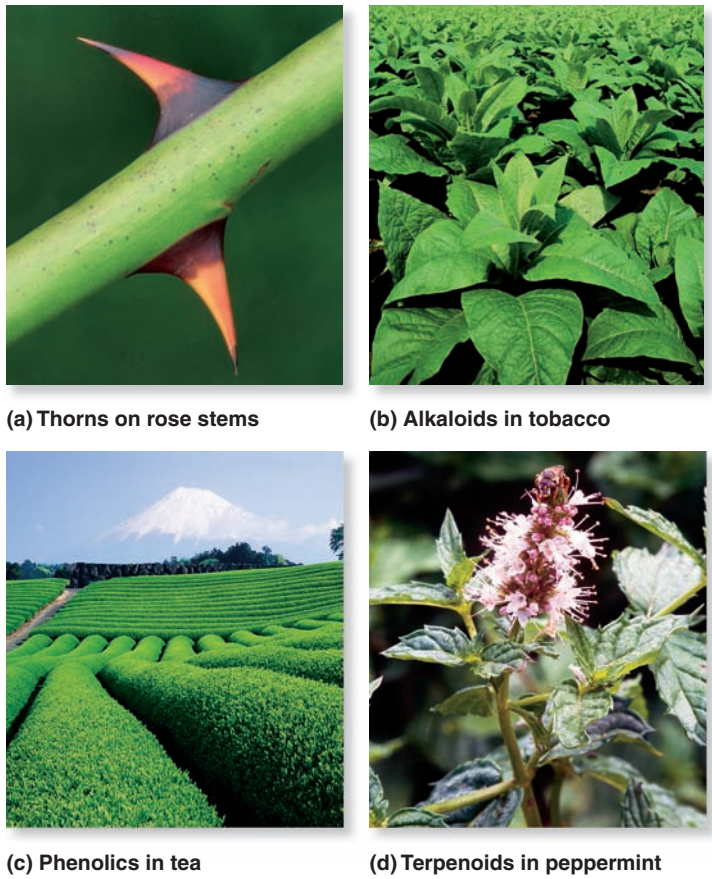

Concept Check: *Why can invasive predators have such strong effects on native prey?*

Ecologists have found that in nearly 1,500 predator-prey studies, over two-thirds (72%) showed a large depression of prey density by predators. Thus, we can conclude that in the majority of cases, predators influence the abundance of their prey in their native environment. The variety of antipredator mechanisms discussed earlier also shows how predation is important enough to select for the evolution of chemical defenses, camouflage, and mimicry in prey. Taken together, these data indicate that predation is a powerful force in nature.

Plants and Herbivores May Be Engaged in an Evolutionary Arms Race

Herbivory involves the predation of plants or similar life forms such as algae. Such predation can be lethal to the plants, especially for small species, but often it is nonlethal, because many plant species, particularly larger ones, can regrow. Plants present a luscious green world to any organism versatile enough to use them, so why don't herbivores eat more of the food available to them? After all, unlike most animals, plants cannot move to escape being eaten. Two hypotheses have been proposed to answer the question of why more plant material is not eaten. First, predators and parasites may keep herbivore numbers low, thereby sparing the plants. The many examples of the strength of predation provide evidence for this view. Second, the plant world is not as helpless as it appears. The sea of green is armed with defensive spines, tough cuticles, noxious chemicals, and more. Let's take a closer look at plant defenses against herbivores and the ways herbivores attempt to overcome them.

Plant Defenses Against Herbivores A plant's first line of defense is mechanical. Many plants have effective mechanical defenses, such as thorns and spines (**Figure 57.12a**). In addition, tough fibers discourage herbivore feeding and grasses and palms sequester silica, making their foliage difficult to chew. Furthermore, an array of unusual and powerful chemicals is present in plants, including alkaloids (nicotine in tobacco, morphine in poppies, cocaine in coca, and

(a) Thorns on rose stems **(b) Alkaloids in tobacco**

(c) Phenolics in tea **(d) Terpenoids in peppermint**

Figure 57.12 Defenses against herbivory. **(a)** Mechanical defenses include plant spines and thorns, as on this shrub, *Rosa multiflora*. Plants also possess an array of unusual and powerful chemicals, including **(b)** alkaloids, such as nicotine in tobacco, **(c)** phenolics, such as tannins in tea leaves (near Mount Fuji, Japan), and **(d)** terpenoids in peppermint leaves.

Concept Check: *Of the defenses shown here, which type would be most effective in deterring invertebrate herbivores?*

BioConnections: *Which species of plant produces the alkaloid capsaicin? Refer back to Figure 30.22.*

caffeine in coffee), phenolics (lignin in wood and tannin in leaves), and terpenoids (in peppermint) (**Figure 57.12b–d**). Such compounds are not part of the primary metabolic pathway that plants use to obtain energy and are therefore referred to as **secondary metabolites**. Most of these chemicals are bitter tasting or toxic, thereby deterring herbivores from feeding. The staggering variety of secondary metabolites in plants, over 25,000, may be testament to the large number of organisms that feed on plants. In an interesting twist, many of these compounds have medicinal properties that have proved to be beneficial to humans.

An understanding of plant defenses is of great use to agriculturalists. The better crops can defend themselves against pests, the higher the crop yield. The ability of plants to prevent herbivory via either chemical or mechanical defenses is also known as **host plant resistance**. One serious problem associated with commercial development of host plant resistance is that it may take a long time to breed into plants—between 10 and 15 years. This is because of the long time it takes to identify the responsible chemicals and develop the resistant genetic lines. Also, resistance to one pest may come at the cost of increasing susceptibility to other pests. Finally, some pest strains can overcome the plant's mechanisms of resistance.

Despite these problems, host plant resistance is a good tactic for the farmer. Host plant resistance reduces the need for chemical insecticides and is less environmentally harmful, generally having few side effects on other species in the community. About 75% of cropland in the U.S. utilizes pest-resistant plant varieties, most of these being resistant to plant pathogens. Bt corn is a variety of corn that has been genetically modified to incorporate a gene from the soil bacterium *Bacillus thuringiensis* (Bt) that encodes a protein, Bt toxin, that is toxic to some insects (refer back to Figure 20.14). Genetic engineers have also produced Bt cotton, Bt tomato, and genetically modified varieties of many other crop species.

Overcoming Plant Resistance Herbivores can sometimes overcome plant defenses. They can detoxify many poisons, mainly by two chemical pathways: oxidation and conjugation. Oxidation, the most important of these mechanisms, occurs in the liver of mammals and in the midgut of insects. It involves catalysis of the secondary metabolite to a corresponding alcohol by a group of enzymes known as mixed-function oxidases (MFOs). Conjugation, often the next step in detoxification, occurs by uniting the harmful compound or its oxidation product with another molecule to create an inactive and readily excreted product.

The Effects of Herbivores on Plant Populations A good method for estimating the effects of herbivory on plant populations is to remove the herbivores and examine subsequent growth and reproductive output. Analyses of hundreds of such experiments have yielded several interesting generalizations. For example, invertebrate herbivores such as insects have a stronger effect on plants than vertebrate herbivores such as mammals, at least in terrestrial systems. Thus, although large grazers like bison in North America or antelopes in Africa might be considered to be of huge importance in grasslands, it is more likely that grasshoppers are the more significant herbivores because of their sheer weight of numbers. In forests, invertebrate grazers such as caterpillars have greater access to canopy leaves than vertebrates and are also likely to have a greater effect.

(a) Before biological control (b) After biological control

Figure 57.13 The effects of an insect herbivore on an invasive plant pest. The prickly pear cactus, *Opuntia stricta*, in Chinchilla, Australia, **(a)** before control by the cactus moth, *Cactoblastis cactorum*, in 1928, and **(b)** after control, in 1929.

BIOLOGY PRINCIPLE Biology affects our society. Control of prickly pear by the cactus moth cleared the cacti from hundreds of thousands of hectares of rangeland, allowing sheep to graze the area and farming to thrive.

An example of the strong effects of insect herbivores on host plants was provided by the introduction of the cactus moth into Australia to control invasive cacti. In 1839, the prickly pear cactus, *Opuntia stricta*, was imported from the Americas to Australia to start a dye industry. Small cochineal insects, which fed on the cactus, could be crushed to collect a red dye. Unfortunately, the cactus spread and became a serious pest. By 1925, it occupied 240,000 km^2 of rangeland, which was rendered useless for sheep and cattle grazing. In 1925, control measures were initiated by introducing the cactus moth, *Cactoblastis cactorum*, from South America. By 1932, the stands of prickly pear had been destroyed (**Figure 57.13**).

Parasitism Might Be the Predominant Lifestyle on Earth

When one organism feeds on another but does not normally kill it outright, the organism is termed a **parasite**, and the prey, a **host**. Some parasites remain attached to their hosts for most of their life. For example, tapeworms spend their entire adult life inside the host's alimentary canal and even reproduce within their host. Others, such as the lancet fluke, have more complex life cycles that require multiple hosts (**Figure 57.14**). To facilitate transmission, many parasites induce changes in the behavior of one host, making that host more susceptible to being eaten by a second host. Notice in Figure 57.14 that the parasitic flukes cause a change in the ant's behavior, so that it climbs to the tip of the blade of grass, where it is exposed and likely to be ingested by a cow.

Great variation exists in parasites and their lifestyle. Some parasites, such as ticks and leeches, drop off their hosts after prolonged periods of feeding. Others, like mosquitoes, remain attached for

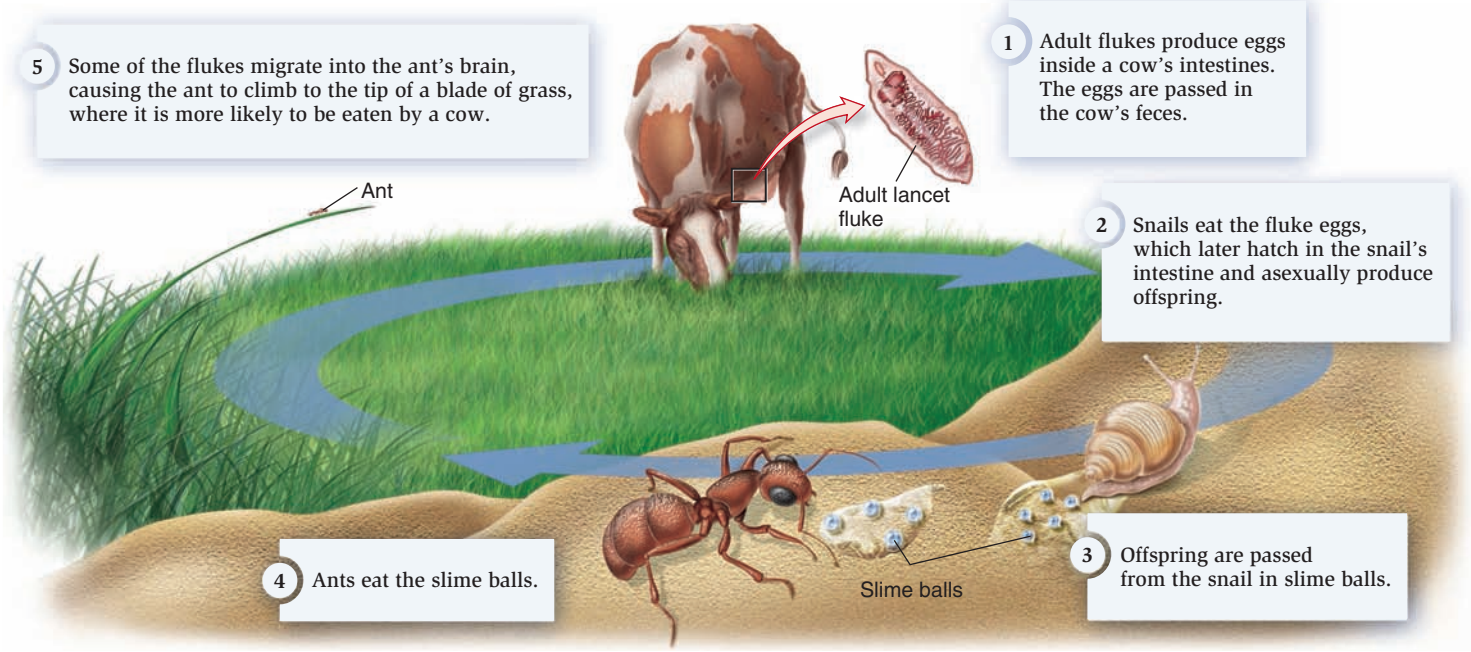

Figure 57.14 The life cycle of the lancet fluke. The lancet fluke (*Dicrocoelium dendriticum*) causes behavioral changes in ants (one of its three hosts) that increase its transmission rate.

relatively short periods. Even parasites with a short attachment period can manipulate the feeding behavior of their hosts. The malaria parasite, a single-celled species in the genus *Plasmodium*, has a complex life cycle involving two hosts, mosquitoes and vertebrates (refer back to Figure 28.29). *Plasmodium* interferes with the ability of the mosquito to draw blood from its vertebrate hosts. This increases the number of attacks the infected mosquitoes make in order to try and obtain enough blood. Increased attack rates maximize the transmission rates of the *Plasmodium* itself. British epidemiologist Jacob Koella and colleagues showed that most uninfected mosquitoes generally fed on just one human host at night, and only 10% bit more than one person. Multiple biting of different hosts increased to 22% in malaria-infected mosquitoes. In addition, the saliva of the infected mosquitoes was changed, making the host's blood flow less freely into the mouthparts. Similar behavior is exhibited by leishmaniasis parasites in sand flies and bubonic plague parasites in fleas.

Some flowering plants are parasitic on other plants. **Holoparasites** lack chlorophyll and are totally dependent on the host plant for their water and nutrients. One famous holoparasite is *Rafflesia arnoldii*, which lives most of its life within the body of its host, a *Tetrastigma* vine, which grows in tropical rain forests (**Figure 57.15**). Only the *Rafflesia* flower develops externally. It is a massive flower, 1 m in diameter, and the largest known in the world. **Hemiparasites** generally photosynthesize, but depend on their hosts for water and mineral nutrients. Mistletoe (*Viscum album*) is a hemiparasite that grows on the stems of trees. Hemiparasites usually have a broader range of hosts than do holoparasites, which may be confined to a single or a few host species.

Parasites that feed on one species or just a few closely related hosts are termed **monophagous**. By contrast, **polyphagous** species can feed on many different host species, often from more than one

Figure 57.15 A holoparasite. *Rafflesia arnoldii*, the world's biggest flower, lives as a holoparasite in Indonesian rain forests.

BioConnections: More than 4,500 species of plants live as complete or partial parasites. What is an example of another important parasitic plant discussed in Chapter 37? Refer back to Figure 37.20.

family. We can also distinguish parasites as **microparasites** (for example, pathogenic bacteria), which multiply within their hosts, sometimes within the cells, and **macroparasites** (such as schistosomes), which live in the host but release infective juvenile stages outside the host's body. Usually, the host has a strong immunological response to microparasitic infections. For macroparasitic infections, however, the immunological response is short-lived. Such infections tend to be persistent, and the hosts are subject to continual reinfection.

Last, we can distinguish **ectoparasites**, such as ticks and fleas, which live outside of the host's body, from **endoparasites**, such as pathogenic bacteria and tapeworms, which live inside the host's body. Problems of definition arise with regard to plant parasites, which seem to straddle both camps. For example, some parasitic plants, such as mistletoe, exist partly outside of the host's body and partly inside. Outgrowths called haustoria penetrate inside the host plant to tap into nutrients. Being endoparasitic on a host seems to require greater specialization than ectoparasitism. Therefore, ectoparasitic animals such as leeches feed on a wider variety of hosts than do endoparasites such as liver flukes.

As we have seen throughout this textbook, parasitism is a common way of life. There are vast numbers of species of parasites, including bacteria, protozoa, flatworms (flukes and tapeworms), nematodes, and various arthropods (ticks, mites, and fleas). Parasites may outnumber free-living species by four to one. Most plant and animal species harbor many parasites. For example, on average, each mammal species hosts two cestode species, two trematodes, four nematodes, and one acanthocephalan. For birds, the figures are even higher. A free-living organism that does not harbor parasitic individuals of a number of species is a rarity.

Parasitism Has Strong Effects on Host Populations

As with studies of other species interactions, a direct method for determining the effect of parasites on their host population is to remove the parasites and to reexamine the population. However, this is difficult to do, primarily because of the small size and unusual life histories of many parasites, which make them difficult to remove from a host completely. The few cases of experimental removal confirm that parasites can reduce host population densities. The nests of birds such as blue tits are often infested with parasitic blowfly larvae that feed on the blood of nestlings. In 1997, French biologist Sylvie Hurtrez-Bousses and colleagues experimentally reduced blowfly larval parasites of young blue tits in nests in Corsica. Parasite removal was cleverly achieved by taking the nests from 145 nest boxes, removing the young, microwaving the nests to kill the parasites, and then returning the nests and chicks to the wild. The success of chicks in microwaved nests was compared with that in nonmicrowaved (control) nests. The parasite-free blue tit chicks had greater body mass at fledging, the time when feathers first grow (**Figure 57.16**). Perhaps more important was the fact that complete nest failure, that is, death of all chicks, was much higher in control nests than in treated nests.

Because parasite removal studies are difficult to do, ecologists have also examined the strength of parasitism as a mortality factor by studying introduced parasite species. Evidence from natural populations suggests that introduced parasites have substantial effects on their hosts. For example, chestnut blight (*Cryphonectria parasitica*), a fungus from Asia, was accidentally introduced to New York around 1904. At that time, the American chestnut tree (*Castanea dentata*), was one of the most common trees in the eastern United States. It was said that a squirrel could jump from one chestnut to another all the way from Maine to Georgia without touching the ground. By the 1950s, the airborne fungus had significantly reduced the density of American chestnut trees in North Carolina (**Figure 57.17**). Eventually,

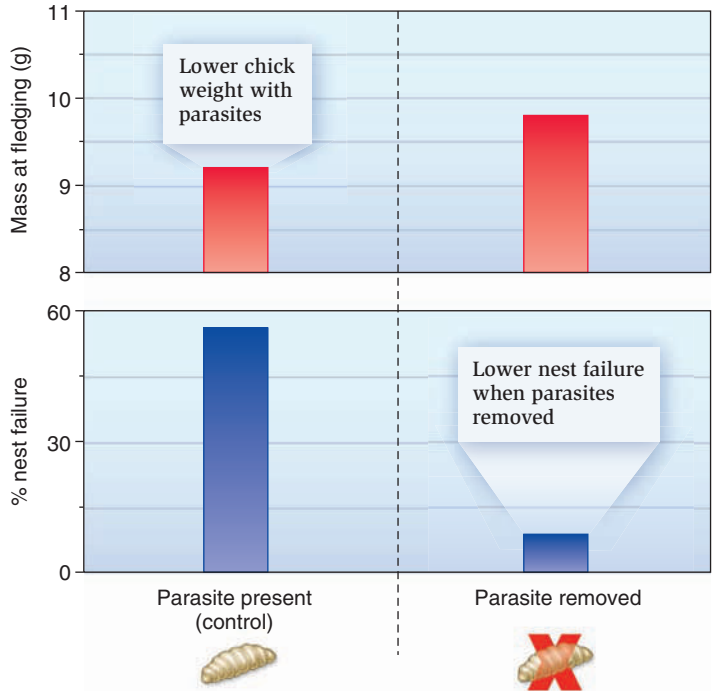

Figure 57.16 Parasite removal experiments. The left side shows the results when blowfly larvae were present in the nests of blue tits. The right side shows the results when these parasites were removed.

BIOLOGY PRINCIPLE Biology is an experimental science. In ecology, the best tests of hypotheses are usually provided by experiments, in this case performed in the field rather than in the laboratory.

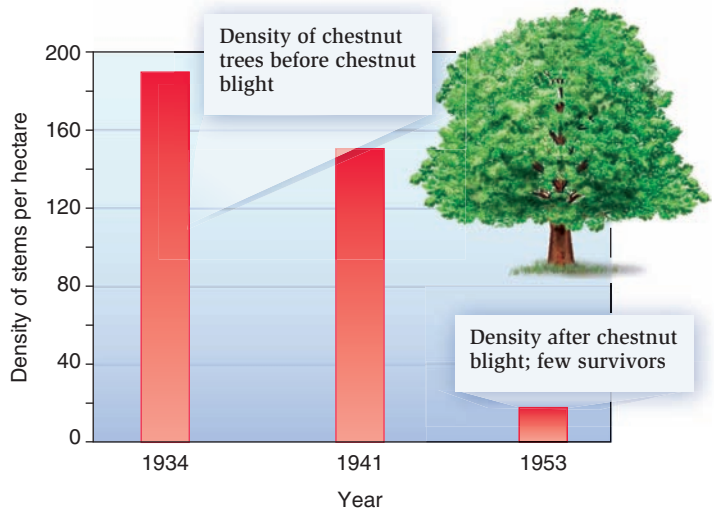

Figure 57.17 Effects of introduced parasites on American chestnut trees. The reduction in density of American chestnut trees in North Carolina following the 1904 introduction of chestnut blight from Asia shows the severe effect that parasites can have on their hosts. By the 1950s, this once-widespread species was virtually eliminated.

it eliminated nearly all chestnut trees across North America. In Europe and North America, Dutch elm disease has similarly devastated populations of elms (*Ulmus*). The disease wiped out 25 million of Britain's original 30 million elm trees between the 1960s and the 1990s. The creation of transgenic plants through recombinant DNA methods is a recent development in the fight against plant diseases.

Genomes & Proteomes Connection

Transgenic Plants May Be Used in the Fight Against Plant Diseases

Many important native forest trees, which are also grown in urban landscapes, have been almost entirely wiped out by diseases spread by the importation of exotic plants. Sudden oak death is a disease that is killing tens of thousands of oak trees and other plant species in California. The symptoms vary between species but include leaf spots, oozing of a dark sap through the bark, and twig dieback. Although sudden oak death is a forest disease, the organism causing this disease is known to infect many woody ornamental plants, such as rhododendrons, that are commonly sold by nurseries. In March 2004, a California nursery was found to have unknowingly shipped plants infected with sudden oak death to all 50 states. Following this discovery, California nurseries halted shipments of trees to other states in an attempt to stop the spread of the disease, originally thought to have been imported on rhododendrons. In 2004, scientists mapped out the genome sequence of the disease-carrying protist, *Phytophthora ramorum*. Identifying the genes and their proteins may help scientists develop specific diagnostic tests to quickly detect the presence of sudden oak death in trees, which is currently impossible to detect until a year or more after the tree is infected.

Scientists hope for much from the field of genomics in their fight against disease-causing plant parasites. Many scientists have suggested limited, cautious transfer of resistance genes from the original host species in the source regions of the disease to newly threatened species. Original host species have usually evolved over millions of years of exposure to these diseases and have acquired genes that provide resistance. In the regions of recent introduction of parasites, there has been no selection for resistance, so the host plants are often killed en masse. Transgenic trees that have received pathogen-resistance-enhancing genes could be produced and then be replanted in forests or urban areas. An advantage of this technique over traditional cross-breeding strategies involving two different species is that transgenic methods involve the introduction of fewer genes to the native species. Also, fewer tree generations would be required to develop resistance. For example, using traditional breeding technology, Asian chestnut trees (*Castanea mollissima*) are being bred with American chestnut trees (*C. dentata*) to reduce the susceptibility of the latter to chestnut blight. The resultant hybrid is often significantly altered in appearance from the traditional American chestnut, and the process takes more than a decade to produce trees that are ready to plant. Transgenic technology could minimize these drawbacks. American biologist William Powell and colleagues have worked to enhance the American chestnut's resistance by inserting a gene taken from wheat. The gene, which encodes an enzyme called oxalate oxidase, destroys a toxin produced by the fungus that causes chestnut blight. The whole process takes up to 2 years to produce plants ready to be transplanted back to the wild. The first two transgenic chestnuts were planted in New York in 2006 and 17 more followed in 2007 (**Figure 57.18**). In 2009, 500 blight-resistant trees were planted in Virginia, Tennessee, and North Carolina, but it will take many years to determine how successful these transplants will be.

Figure 57.18 Newly planted transgenic American chestnut trees in New York.

BIOLOGY PRINCIPLE The genetic material provides a blueprint for sustaining life. Even a relatively small amount of new genetic material may make the difference between life and death for American chestnut trees.

57.3 Mutualism and Commensalism

Learning Outcomes:

1. Distinguish between the different types of mutualism in nature.
2. Give examples of the species interaction called commensalism.

In this section, we will examine interactions that are beneficial to at least one of the species involved. In mutualism, both species gain from the interaction. For example, in mutualistic pollination systems, the plant benefits by the transfer of pollen, and the pollinator typically gains a nectar meal. In commensalism, one species benefits, and the other remains unaffected. For example, in some forms of seed dispersal, barbed seeds are transported to new germination sites in the fur of mammals. The seeds benefit, but the mammals are generally unaffected.

It is interesting to note that humans have entered into mutualistic relationships with many species. For example, the association of humans with plants has resulted in some of the most far-reaching ecological changes on Earth. Humans have planted huge areas of the Earth with crops, allowing these plant populations to reach densities they never would attain on their own. In return, the crops have led to expanded human populations because of the increased amounts of food they provide.

Mutualism Is an Association Between Two Species That Benefits Both

Different types of mutualisms occur in nature. In **resource-based mutualisms**, both species receive a benefit in the form of resources transfer energy and nutrients. In **defensive mutualisms**, one species receives food or shelter in return for defending another species; they often involve an animal defending a plant or an herbivore. **Dispersive mutualisms** are interactions in which a species receives food in return for transporting the pollen or seeds of its partner.

Resource-Based Mutualism Leafcutter ants of the group Attini, of which there are about 210 species, enter into a mutualistic relationship with a fungus. A typical colony of about 9 million ants has the collective biomass of a cow and harvests the equivalent of a cow's daily requirement of fresh vegetation. Instead of consuming the leaves directly, however, the ants chew them into a pulp, which they store underground as a substrate on which the fungus grows (**Figure 57.19a**). The ants shelter and tend the fungus, helping it reproduce and grow and weeding out competing fungi. In turn, the fungus produces specialized structures known as gongylidia, which serve as food for the ants (**Figure 57.19b**). In this way, the ants circumvent the chemical defenses of the leaves, which are digested by the fungus.

Defensive Mutualism One of the most commonly observed mutualisms occurs between ants and aphids. Aphids are fairly defenseless creatures and are easy prey for most predators. The aphids feed on plant sap and have to process a significant amount of it to get their required nutrients. In doing so, they excrete a lot of fluid, and some of the sugars still remain in the excreted fluid, which is called "honeydew." The ants drink the honeydew and, in return, protect the aphids from an array of predators, such as ladybird beetle larvae, by driving the predators away. In some cases, the ants herd the aphids like cattle, moving them from one area to another (**Figure 57.20a**).

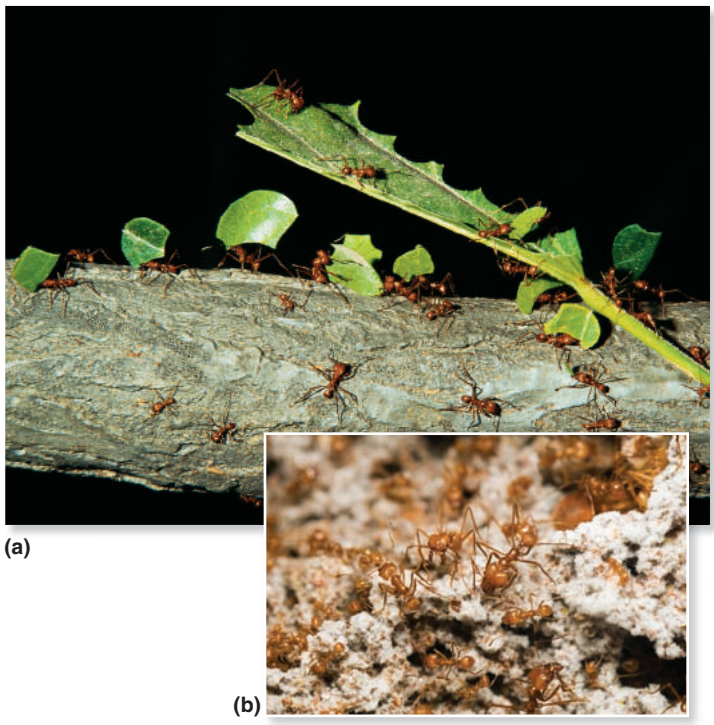

Figure 57.19 Resource-based mutualism. (a) Leafcutter ants, *Atta cephalotes*, cut leaves and chew them to a pulp underground. **(b)** The ants feed on fungi, which develop in the pulp.

In other cases, ants enter into a mutualistic relationship with a plant itself. One of the most famous cases involves acacia trees in Central America, whose large thorns provide food and nesting sites for ants (**Figure 57.20b**). In return, the ants bite and discourage both insect and vertebrate herbivores from feeding on the trees. They also trim away foliage from competing plants and kill neighboring plant shoots, ensuring more light, water, and nutrient supplies for the acacias.

Dispersive Mutualism Many examples of plant-animal mutualisms involve pollination and seed dispersal. In these cases, neither species can live without the other, a concept called **obligatory mutualism**. This contrasts with **facultative mutualism**, in which the interaction is beneficial but not essential to the survival and reproduction of either species. From a plant's perspective, an ideal pollinator would be a specialist, moving quickly among individuals but retaining a high fidelity to a plant species. Two ways that plant species in an area promote the pollinator's species fidelity is by synchronized flowering within a species and by sequential flowering of different species through the year. The plant should provide just enough nectar to attract a pollinator's visit. From the pollinator's perspective, it would be best to be a generalist and obtain nectar and pollen from as many flowers as possible in a small area, thus minimizing the energy spent on flight between patches. This suggests that although dispersive mutualisms are beneficial to both species, the species' optimal needs are quite different.

Mutualistic interactions are also highly prevalent in the seed-dispersal systems of plants. Fruits provide a balanced diet of proteins, fats, and vitamins. In return for this juicy meal, animals unwittingly disperse the enclosed seeds, which pass through the digestive tract unharmed. Fruits eaten by birds and mammals often have attractive colors (**Figure 57.21**); those that attract nocturnal bats are not brightly colored but instead give off a pungent odor.

Ants defending an acacia plant in exchange for food and shelter

Figure 57.20 Defensive mutualism. **(a)** This red carpenter ant, *Camponotus pennsylvanicus*, tends aphids feeding on a twig. The ants consume the sugar-rich honeydew produced by the aphids and in return protect the aphids from predators. **(b)** Ants, usually *Pseudomyrmex ferruginea*, make nests inside the large, hornlike thorns of the bull's horn acacia and defend the plant against insects and mammals. In return, the acacia (*Acacia collinsii*) provides two forms of food to the ants: protein-rich granules called Beltian bodies and nectar from extrafloral nectaries (nectar-producing glands that are physically apart from the flower).

Concept Check: Is the relationship between ants and bull's horn acacia an example of facultative or obligatory mutualism?

BioConnections: Refer back to Figure 31.26. What is the name given to the association between the hyphae of certain fungi and the roots of most plants which engage in a resource-based mutualism?

In Commensalism, One Partner Receives a Benefit While the Other Is Unaffected

Commensalism is an interaction between species in which one benefits and the other is neither helped nor harmed. Such is the case when orchids or other epiphytes grow in forks of tropical trees. The tree is unaffected, but the orchid gains support and increased exposure to sunlight and rain. Cattle egrets feed in pastures and fields among cattle, whose movements stir up insect prey for the birds. The egrets benefit from the association, but the cattle generally do not. One of the best examples of commensalism involves **phoresy**, in which one organism uses a second organism for transportation. Hummingbird flower mites feed on the pollen of flowers and travel between flowers in the nostrils (nares) of hummingbirds. The flowers the mites inhabit live only a short while before dying, so the mites relocate by

Figure 57.21 Dispersive mutalism. This blackbird (*Turdus merula*) is an effective seed disperser.

BioConnections: Refer back to Table 30.2. Birds have excellent color vision and are also involved in the pollination of flowers. What is a common color of the flowers of bird-pollinated plants?

scuttling into the nares of visiting hummingbirds and hitching a ride to the next flower. When the hummingbird visits a new flower, the mites disembark. Presumably, the hummingbirds are unaffected.

Some commensalisms involve one species "cheating" on the other without harming it. In the bogs of Maine, the grass-pink orchid (*Calopogon pulchellus*) produces no nectar, but it mimics the nectar-producing rose pogonia (*Pogonia ophioglossoides*) and is therefore still visited by bees. Another example involves bee orchids (*Ophrys apifera*) that mimic the appearance and scent of female bees. Males try to copulate with the flowers and in the process pick up and transfer pollen (**Figure 57.22a**). The stimuli of the bee orchid flowers are so effective that male bees prefer to mate with them even in the presence of actual female bees! Many plants have essentially cheated their potential mutualistic seed-dispersal agents out of a meal by developing seeds with barbs or hooks that lodge in the animals' fur or feathers rather than their stomachs (**Figure 57.22b**). In these cases, the plants receive free seed dispersal, and the animals receive nothing, except perhaps minor annoyance. This type

(a) An orchid without nectar mimicking a female bee

(b) Seed dispersal via hooked seeds

Figure 57.22 Commensalisms. **(a)** Bee orchids (*Ophrys apifera*) mimic the shape of a female bee. Male bees copulate with the flowers, transferring pollen but getting no nectar reward. **(b)** Hooked seeds of burdock (*Arctium minus*) have lodged in the fur of a white-footed mouse (*Peromyscus leucopus*). The plant benefits from the relationship by the dispersal of its seeds, and the animal is not affected.

of relationship is fairly common; most hikers and dogs have at some time gathered spiny or sticky seeds as they wandered through woods or fields.

57.4 Bottom-Up and Top-Down Control

Learning Outcome:

1. Explain the differences between bottom-up control and top-down control as conceptual models of how species interactions limit population size.

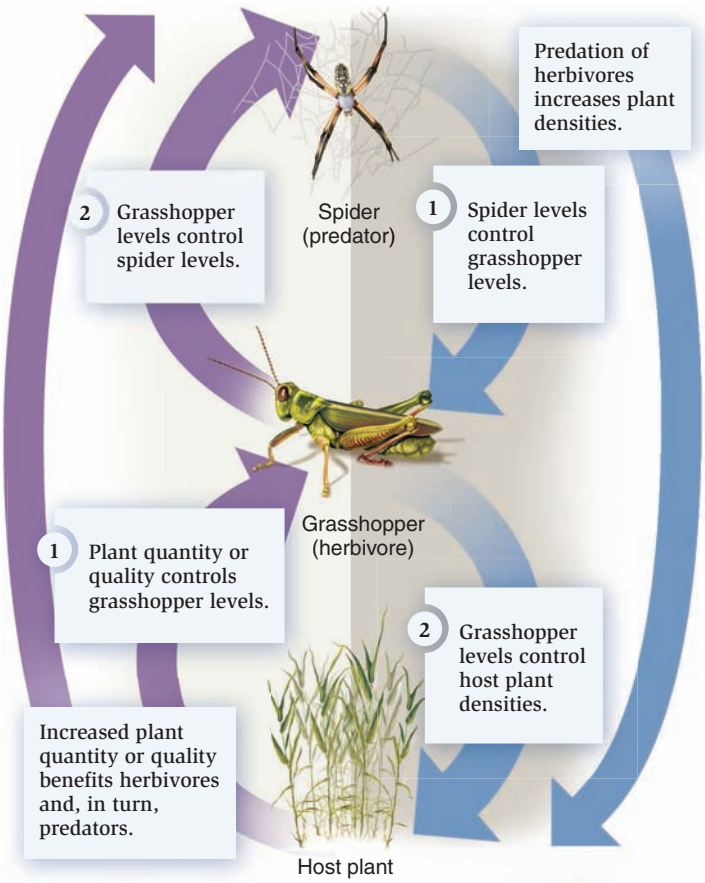

Figure 57.23 Bottom-up control versus top-down control. **(a)** Bottom-up control proposes that host plant quantity or quality limits the density of herbivores, such as grasshoppers, which, in turn, sets limits on the abundance of predators, such as spiders. Taken together, this means that high quantity and quality of host plants would result in increased numbers of predators because of higher densities of the herbivores they prey on. **(b)** Top-down control proposes that predators limit the number of herbivores, which, in turn, increases host plant density. Taken together, this means that high levels of predation would result in high densities of host plants because there would be fewer herbivores.

Concept Check: You add fertilizer to a bush, and this increases spider density on the bush. What type of control is this an example of?

In this chapter, we have seen that interactions between species, such as competition, predation, and parasitism, are important in nature. Let's return to a question posed in Chapter 56: How can ecologists determine which factors, along with abiotic factors such as temperature and moisture, are the most important in affecting population size? The question is also asked by many applied biologists, such as foresters, marine biologists, and conservation biologists, who are interested in managing a population's size.

Some ecologists stress the importance of so-called bottom-up factors, such as plant quality and abundance in controlling herbivores and the predators that feed on them. Others stress the importance of top-down factors, such as predators and parasites, acting to control herbivore or plant prey (**Figure 57.23**). In the beginning of the chapter, we noted how a decline in the size of shark populations along the east coast had led to an increase in their main prey, rays and skates, and thereby a decrease in bay scallops, the prey of rays and skates. This is a top-down effect known as a trophic cascade, because its effects cascade down to all feeding levels of the system. In this section, we will briefly discuss some of the evidence for the importance of bottom-up versus top-down control.

Bottom-Up Control Suggests Food Limitation Influences Population Densities

At least two lines of evidence suggest that bottom-up effects are important in limiting population sizes. First, we know there is a progressive lessening of available energy passing from plants through herbivores to carnivores and to secondary carnivores (carnivores that eat other carnivores). Energy conversions are never 100% efficient, and much useful energy is lost in the form of heat before it can be transferred to higher trophic levels. This line of evidence, based on the thermodynamic properties of energy transfer, suggests that the quantity and quality of plants regulates the population size of all other species that rely on them.

Second, much evidence supports the **nitrogen-limitation hypothesis** that organisms select food in terms of the nitrogen content of the tissue. This is largely due to the different proportions of nitrogen in plants and animals (**Figure 57.24**). Animal tissue generally

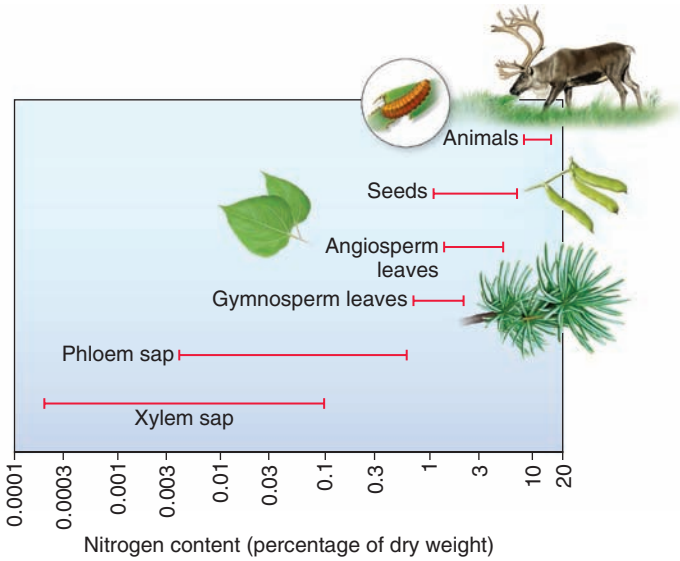

Figure 57.24 Nitrogen content of plants and animals.

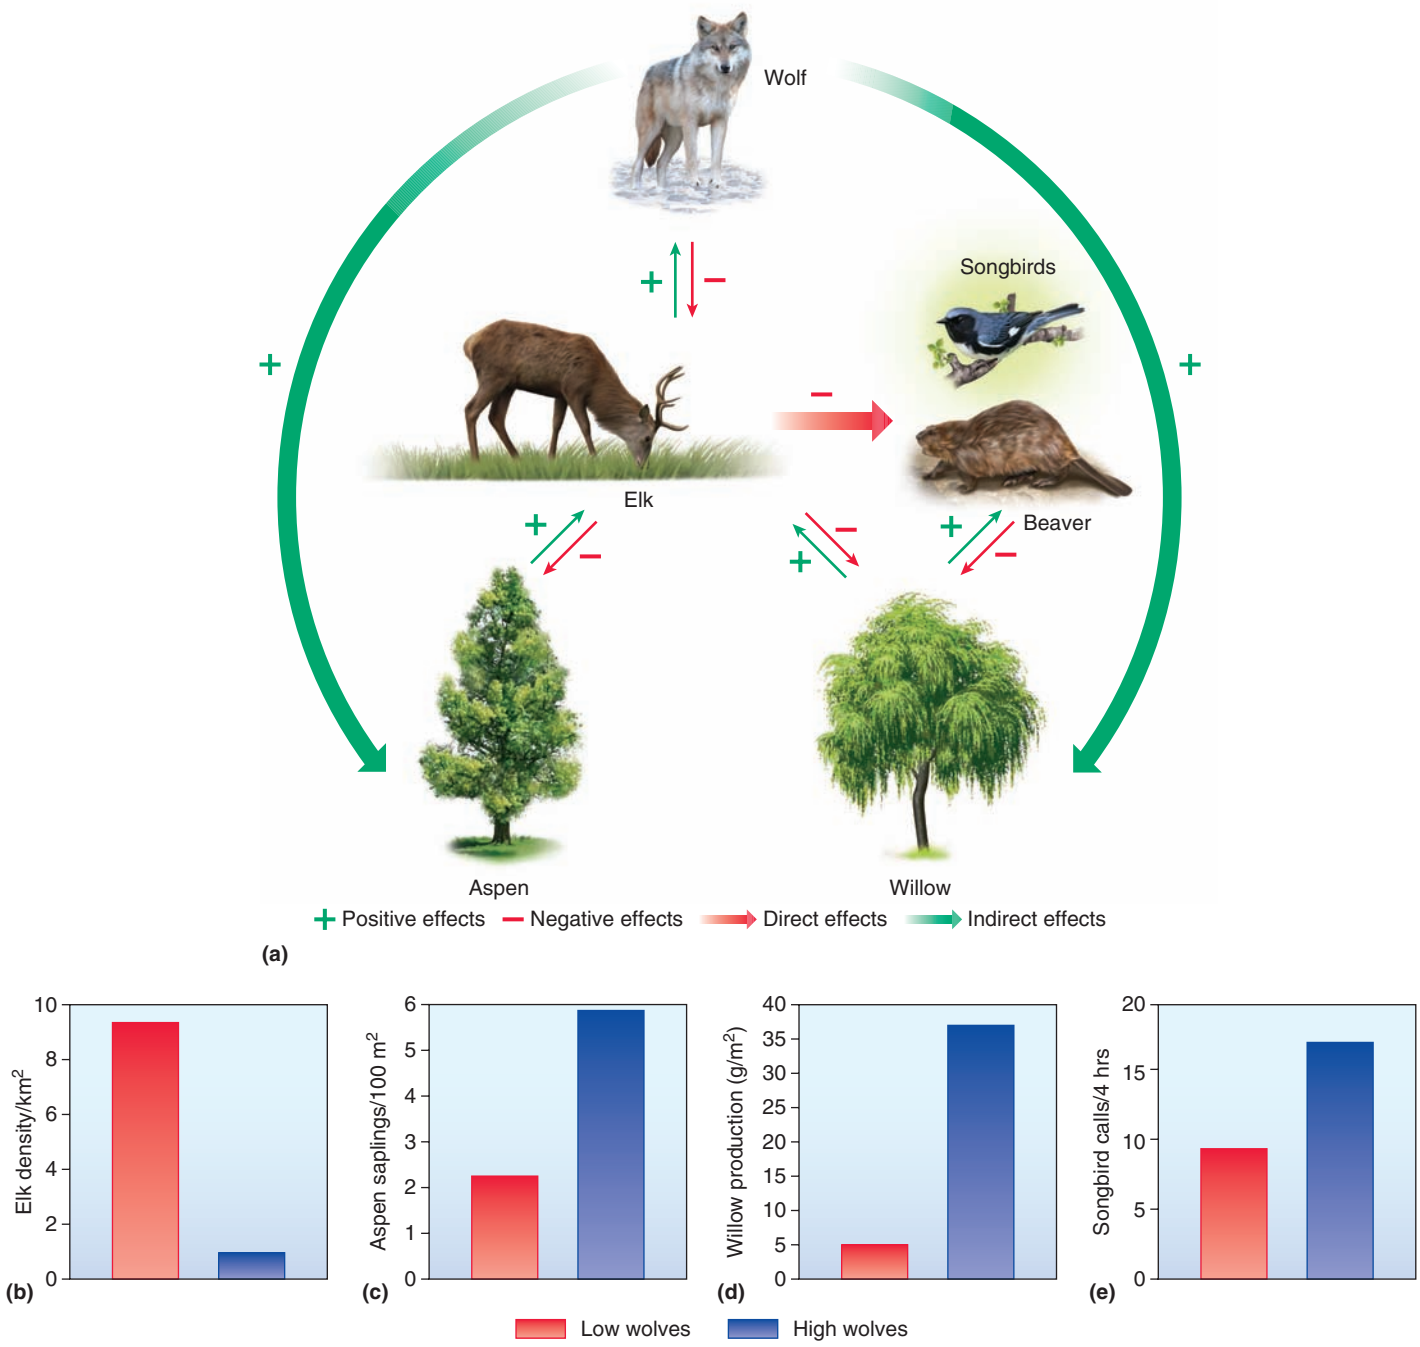

Figure 57.25 Studies on wolf addition provide support for the top-down model. **(a)** The simplified trophic interactions of wolves, elk, plants, and other organisms in Banff National Park, Canada. Increased wolf abundance caused **(b)** decreased elk abundance, **(c)** increased abundance of aspen trees and **(d)** willow trees, and **(e)** increased songbird abundance.

contains about 10 times as much nitrogen as plant tissue. For this reason, animals favor high-nitrogen plants. The addition of nitrogen-containing fertilizer has repeatedly been shown to benefit herbivores. Nearly 60% of 186 studies investigating the effects of fertilization on herbivores reported that increasing a plant's tissue nitrogen concentration through fertilization had strong positive effects on herbivore population sizes, survivorship, growth, and fecundity. Taken together, these lines of evidence indicate that plant densities influence herbivore densities, which in turn influence densities at higher trophic levels.

Top-Down Control Suggests Natural Enemies Influence Population Densities

Top-down models suggest that predators control populations of their prey (ultimately, herbivores) and that these herbivores control plant populations. Supporting evidence comes from studies of top predator removal and addition. Wolves, *Canus lupus*, are being reintroduced into many areas of the United States, and their populations are growing. In a 2005 study, Mark Hebblewhite and colleagues observed colonization of certain areas in Banff National Park in

Canada by wolves and compared these areas to those closer to human settlements, which wolves avoid. The wolves reduce the density of elk, *Cervus elaphus*, which in turn promotes growth of two major elk food plants: aspen, *Populus tremuloides*, and willow, *Salix* spp. (**Figure 57.25a**). However, the effects of wolf addition are more widespread (**Figure 57.25b–e**). Increased plant availability also increases the abundance of songbirds, especially obligate willow specialists, such as the American redstart, *Setophaga ruticilla*. Beaver abundance also increases.

Current thinking is that both bottom-up and top-down control are important in affecting population size, with their degrees of importance varying from community to community. Species interactions can clearly be very important in influencing both the growth of individual populations and the structure of communities—groups of species living in a particular area. What factors determine the numbers of species in a given area? What factors influence the stability of a community, and what are the effects of disturbances on community structure? In the next chapter, on community ecology, we will explore these and other questions.

Summary of Key Concepts

57.1 Competition

- Species interactions can take a variety of forms that differ based on their effect on the species involved (Figure 57.1, Table 57.1).
- Competition can be categorized as intraspecific (between individuals of the same species) or interspecific (between individuals of different species), and as exploitation competition or interference competition (Figure 57.2).
- Laboratory and field experiments show that competition occurs frequently in nature (Figures 57.3, 57.4).
- The competitive exclusion hypothesis states that two species with the same resource requirements cannot occupy the same niche. Resource partitioning and morphological differences between species allow them to coexist in a community (Figures 57.5, 57.6, 57.7, Table 57.2).

57.2 Predation, Herbivory, and Parasitism

- The most common antipredator strategies are chemical defense and aposematic coloration (Figures 57.8, 57.9).
- Despite these defenses, oscillations in predator-prey cycles and the effect of introduced species illustrate that predators can have a large effect on prey densities (Figures 57.10, 57.11).
- Plants have also evolved an array of defenses against herbivores, including chemical defenses, such as secondary metabolites, and mechanical defenses, such as thorns and spines. However, herbivores can sometimes circumvent these defenses and greatly reduce plant population densities (Figures 57.12, 57.13).
- Parasitism is a common lifestyle on Earth, and some parasites have complex life cycles involving multiple hosts (Figures 57.14, 57.15).
- Evidence from experimental removal of parasites and from the study of introduced plant and animal parasites confirms that parasites can greatly reduce prey densities (Figures 57.16, 57.17, 57.18).

57.3 Mutualism and Commensalism

- Mutualism is an association between two species that benefits both. In resource-based mutualisms, both species receive a benefit in the form of resources; defensive mutualisms typically involve an animal defending either a plant or herbivore; and dispersive mutualisms involve animals that disperse a plant's pollen or seeds (Figures 57.19, 57.20, 57.21).
- In commensal relationships, one partner receives a benefit while the other is not affected (Figure 57.22).

57.4 Bottom-Up and Top-Down Control

- Bottom-up models propose that plant quality or quantity regulates the abundance of all herbivore and predator species; top-down models propose that the abundance of predators controls herbivore and plant densities (Figures 57.23, 57.24, 57.25).

Assess and Discuss

Test Yourself

1. A species interaction in which one species benefits but the other species is unharmed is called
   a. mutualism.
   b. amensalism.
   c. parasitism.
   d. commensalism.
   e. mimicry.
2. Two species of birds feed on similar types of insects and nest in the same tree species. This is an example of
   a. intraspecific competition.
   b. interference competition.
   c. exploitation competition.
   d. mutualism.
   e. none of the above.
3. According to the competitive exclusion hypothesis,
   a. two species that use the exact same resources show very little competition.
   b. two species with the same niche cannot coexist.
   c. one species that competes with several different species for resources will be excluded from the community.
   d. all competition between species results in the extinction of at least one of the species.
   e. none of the above is correct.
4. In Lack's study of British passerine birds, different species seem to segregate based on resource factors, such as location of prey items. This differentiation among the niches of these passerine birds is known as
   a. competitive exclusion.
   b. intraspecific competition.
   c. character displacement.
   d. resource partitioning.
   e. allelopathy.
5. Divergence in morphology that is a result of competition is termed
   a. competitive exclusion.
   b. resource partitioning.
   c. character displacement.
   d. amensalism.
   e. mutualism.

6. Tapeworms have
   a. low lethality and low duration of interaction.
   b. low lethality and high duration of interaction.
   c. high lethality and low duration of interaction.
   d. high lethality and high duration of interaction.
   e. none of the above.
7. Ticks are regarded as
   a. monophagous endoparasites.
   b. monophagous ectoparasites.
   c. polyphagous endoparasites.
   d. polyphagous ectoparasites.
   e. none of the above.
8. Batesian mimicry differs from Müllerian mimicry in that
   a. in Batesian mimicry, both species possess the chemical defense.
   b. in Batesian mimicry, one species possesses the chemical defense.
   c. in Müllerian mimicry, one species has several different mimics.
   d. in Müllerian mimicry, one species has several different chemical defenses.
   e. in Batesian mimicry, cryptic coloration is always found.
9. Poppies are protected from herbivores by the
   a. alkaloid nicotine
   b. alkaloid morphine
   c. phenolic tannin
   d. phenolic lignin
   e. terpenoid caffeine
10. Parasitic plants that rely solely on their host for nutrients are called
    a. hemiparasites.
    b. fungi.
    c. holoparasites.
    d. monophagous.
    e. polyphagous.

Conceptual Questions

1. Can the removal of ectoparasites from the coat of one primate by another primate (grooming) be viewed as selfish behavior, as discussed in Chapter 55? Why or why not?
2.  A principle of biology is that *biology affects our society*. Crop pests cost millions of dollars to control annually. What factors do you think might limit such losses?

Collaborative Questions

1. Explain how the reintroduction of wolves in Yellowstone National Park might be beneficial.
2. Detail several antipredator strategies that animals have evolved.
3. Can you think of examples of mimicry used by predators to catch prey rather than used by prey to avoid being eaten? Look back to Figure 55.13 and the associated text.

Assess and Discuss

Community Ecology

58

Many of the species formerly present on Krakatau have returned following the 1883 eruption that covered the island in volcanic dust.

A massive volcanic explosion in 1883 on the island of Krakatau in Indonesia destroyed two-thirds of the island, originally 11 km long and covered in tropical rain forest. Life on the remaining part was eradicated, suffocated by tens of meters of red-hot ash. Nine months after the eruption, however, the first reported sign of life was a spider spinning its web. By 1896, there were 11 species of ferns and 15 species of flowering plants, mainly grasses. Most plant species at that time had been wind- or sea-dispersed. By the 1920s, 40 years after the original eruption, birds had become abundant and had dispersed additional plant species by excreting their seeds. Ecologists have been examining the return of different species to the island ever since.

So far in this unit, we have examined ecology in terms of abiotic factors such as temperature and moisture, the behavior of individual organisms, the growth of populations, and interactions between species. Most populations, however, exist not on their own, but together with populations of many other species. An assemblage of many populations that live in the same place at the same time is known as a **community**. For example, a tropical forest community consists of not only tree species, vines, and other vegetation, but also the insects that pollinate them, the herbivores that feed on the plants, and the predators and parasites of the herbivores. Communities occur on a wide range of scales, and one community can be nested within another. For example, the tropical forest community also encompasses smaller communities, such as the water-filled recesses of bromeliads, which form a microhabitat for different species of insects and their larvae. Both of these entities—the tropical forest and the bromeliad tank—are viable communities, existing at different levels of scale.

Community ecology is the study of how groups of species interact and form functional communities. In Chapter 57, we considered the interactions between individual species. In this chapter, we widen our focus to explore the factors that influence the number and abundance of species in a community. We will begin by examining the nature of ecological communities. Are communities loose assemblages of species that happen to live in the same place at the same time, or are they more tightly organized groups of mutually dependent species? Community ecology also addresses the factors that influence the number of species in a community. We will explore why, on a global scale, the number of species is usually greatest in the tropics and declines toward the poles. However, ecologists recognize that communities may change, for example, following a disturbance such as a fire or a volcanic eruption. This recovery tends to occur in a predictable way, which ecologists have termed succession. In certain situations—for example, on islands recovering from physical disturbance—the structure of the community tends toward an equilibrium determined by the balance between the rates of immigration and extinction.

58.1 Differing Views of Communities

Learning Outcomes:

1. Distinguish between Clements's organismic model and Gleason's individualistic model to explain the nature of an ecological community.
2. Explain the principle of species individuality.

Ecologists have long held differing views on the nature of an ecological community and its structure and functions. Some of the initial work in the field of community ecology considered a community to be equivalent to a superorganism, in much the same way that the body of an animal is more than just a collection of organs. In this view, individuals, populations, and communities have a stable relationship with one another that resembles the associations found between cells, tissues, and organs. American botanist Frederic Clements, the champion of this viewpoint, suggested in 1905 that ecology was to the study of communities what physiology was to the study of individual organisms. This view of community, with predictable and integrated associations of species separated by sharp boundaries, is termed the **organismic model**.

Clements's ideas were challenged in 1926 by American botanist Henry Allan Gleason. Gleason proposed an **individualistic model**, which described a community as an assemblage of species coexisting primarily because of similarities in their physiological requirements and tolerances. Although acknowledging that some assemblages of species were fairly uniform and stable over a given region, Gleason suggested that distinctly structured ecological communities usually do not exist. Instead, communities are loose assemblages of species distributed independently along an environmental gradient. Viewed in this way, communities do not necessarily have sharp boundaries, and associations of species are much less predictable and integrated than in Clements's organismic model.

By the 1950s, many ecologists had abandoned Clements's view in favor of Gleason's. In particular, American plant ecologist Robert Whittaker's studies proposed the **principle of species individuality**, which states that each species is distributed according to its physiological needs and population dynamics and that most communities intergrade, or merge into one another gradually. For example, let's consider an environmental gradient such as a moisture gradient on an uninterrupted slope of a mountain. Whittaker proposed that four hypotheses could explain the distribution patterns of plants and animals on the gradient (**Figure 58.1**):

1. Competing species, including dominant plants, exclude one another along sharp boundaries. Other species evolve toward a close, perhaps mutually beneficial association with the dominant species. Communities thus develop along the gradient, each zone containing its own group of interacting species giving way at a sharp boundary to another assemblage of species. This corresponds to Clements's organismic model.
2. Competing species exclude one another along sharp boundaries but do not become organized into groups of species with parallel distributions.
3. Competition does not usually result in sharp boundaries between species. However, the adaptation of species to similar physical variables results in the appearance of groups of species with similar distributions.
4. Competition does not usually produce sharp boundaries between species, and the adaptation of species to similar physical variables does not produce well-defined groups of species with similar distributions. The centers and boundaries of species populations are scattered along the environmental gradient. This corresponds to Gleason's individualistic model.

To test these possibilities, Whittaker examined the vegetation on various mountain ranges in the western U.S. He sampled plant populations along an elevation gradient from the tops of the mountains to the bases and collected data on physical variables, such as soil moisture.

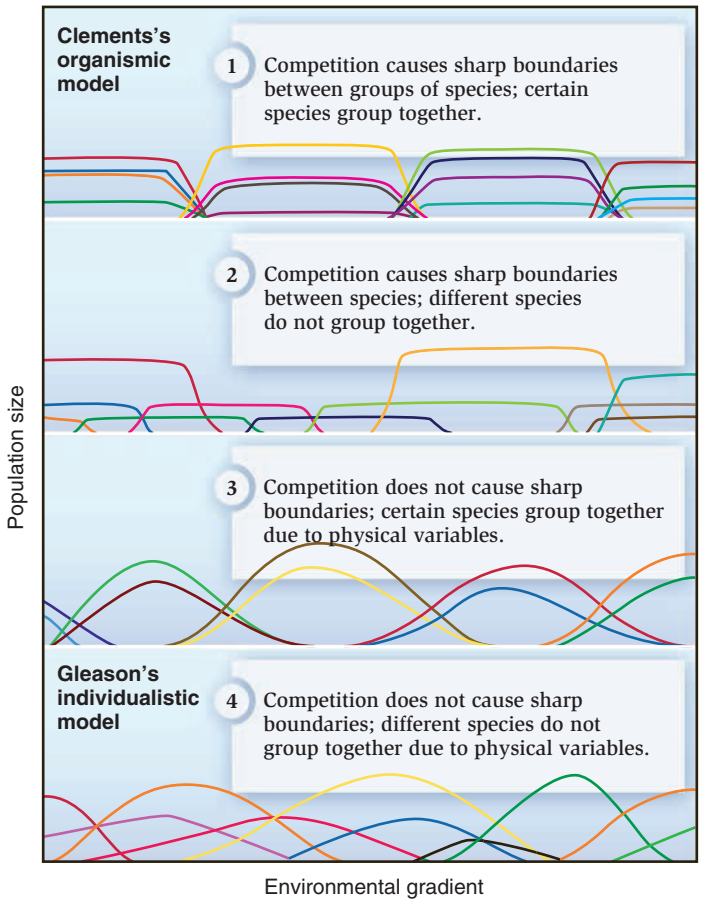

Figure 58.1 Four hypotheses for the distribution patterns of plants and animals along an environmental gradient. Each curve in each part of the figure represents one species and the way its population might be distributed along an environmental gradient.

BioConnections: Look back to Section 1.3. What's the difference between a hypothesis and a theory?

The results supported the fourth hypothesis, that competition does not produce sharp boundaries between species and that adaptation to physical variables does not result in defined groups of species. Whittaker concluded that his observations agreed with Gleason's predictions that (1) each species is distributed in its own way, according to its genetic, physiological, and life cycle characteristics; and (2) most communities grade into each other continuously rather than form distinct, clearly separated groups. The composition of species at any one point on an environmental gradient is largely determined by abiotic factors such as temperature, water, light, pH, and salt concentrations (refer back to Chapter 54).

Even though most communities intergrade along environmental gradients such as a mountain slope, ecologists recognize distinct differences between communities. The community at the top of a mountain is quite different from that at the bottom, so distinguishing between communities on a broad scale is useful. Also, sharp boundaries between groups of species sometimes do exist, especially related to physical differences such as water quality and soil type that cause distinct communities to develop. For example, serpentine soils are rich in metals, including magnesium, iron, and nickel,

Figure 58.2 An example of a sharp boundary between two communities. In New Zealand's Dun Mountain area, the sparse vegetation on the serpentine soil on the left contrasts with that of the beech forest on the nonserpentine soil on the right.

BIOLOGY PRINCIPLE Living organisms interact with their environment. Serpentine soil is nutrient-poor, and relatively few plants species are adapted to live in it.

but poor in plant nutrients. The species that have adapted to these harsh conditions form a unique community restricted to this area (**Figure 58.2**). Such sharp boundaries are not common between neighboring communities.

58.2 Patterns of Species Richness

Learning Outcomes:

1. Identify the latitudinal gradient of species richness.
2. List and describe four hypotheses for observed patterns of species richness.

Community ecology addresses the factors that influence the number of species in a community, or **species richness**. Globally, the number of species of most taxa varies according to latitudinal gradient, generally increasing from polar to temperate areas and reaching a maximum in the tropics. For example, the species richness of North American birds increases from Arctic Canada to Panama (**Figure 58.3**). A similar pattern exists for mammals, amphibians, reptiles, and plants. Although the latitudinal gradient of species richness is an important pattern, species richness is also influenced by topographical variation. More mountains mean more hilltops, valleys, and differing habitats; thus, the number of bird species is greater in the mountainous areas of the western U.S. than in areas of lower elevation. Species richness is also reduced by the peninsular effect, in which the number of species decreases as a function of distance from the main body of land. Ecologists have noted that species richness also depends on the degree to which an environment is disturbed, with more species richness observed in environments with an intermediate disturbance level.

Many hypotheses for the variation in species richness have been advanced. We will consider several hypotheses for patterns of species richness. Although they are treated separately here, these hypotheses are not mutually exclusive. All can contribute to patterns of species richness.

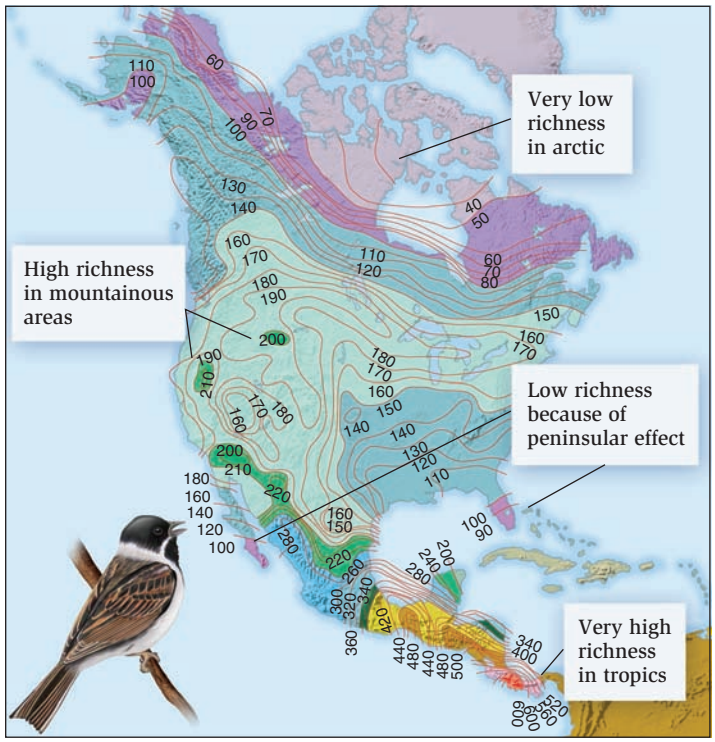

Figure 58.3 Species richness of birds in North America. The values indicate the numbers of different species in a given area. Contour lines show equal numbers of bird species, with colors indicating incremental changes. Note the pronounced latitudinal gradient toward the tropics and the high diversity in California and northern Mexico, regions of considerable topographical variation and habitat diversity.

The Time Hypothesis Suggests That Communities Diversify with Age

Many ecologists argue that communities diversify, or gain species, with time. Therefore temperate regions have less rich communities than tropical ones because they are younger and have only more recently (relatively speaking) recovered from glaciations and severe climatic disruptions. The time hypothesis proposes that resident species of the temperate zone have not yet evolved new forms to exploit vacant niches. In addition, it suggests that species that could possibly live in temperate regions have not migrated back from the unglaciated areas into which the Ice Ages drove them.

In support of the time hypothesis, ecologists compared the species richness of bottom-dwelling invertebrates, such as worms, in historically glaciated (covered with ice) and unglaciated lakes in the Northern Hemisphere that occur at similar latitudes. Lake Baikal in Siberia is an ancient, unglaciated temperate lake and contains a very diverse fauna. For example, 580 species of invertebrates are found in the bottom zone. Great Slave Lake, a comparably sized lake that was once glaciated at the same latitude in northern Canada, contains only four species in the same zone.

However, ecologists recognize drawbacks to the time hypothesis. For example, this hypothesis may help explain variations in the species richness of terrestrial organisms, but it has limited applicability to marine organisms. Although we might not expect terrestrial species, particularly plants, to redistribute themselves quickly following a

glaciation, there seems to be no reason that marine organisms couldn't relatively easily shift their distribution patterns during glaciations, yet the latitudinal gradient of species richness exists in marine habitats.

The Area Hypothesis Suggests That Large Areas Support More Species

The **area hypothesis** proposes that larger areas contain more species than smaller areas because they can support larger populations and a greater range of habitats. Much evidence supports the area hypothesis. For example, in 1974, American ecologist Donald Strong showed that species richness of insects found on tree species in Britain was better correlated with the area over which a tree species could be found than with time of habitation since the last Ice Age (**Figure 58.4**). The relationship between the amount of available area and the number of species present is called the **species-area effect**. Some introduced tree species, such as apple and lime, were relatively new to Britain, but they bore many different insect species, an observation that Strong argued did not support the time hypothesis. The species-area effect means that, on average, an individual willow tree standing next to an individual maple tree in the same location would support an order of magnitude more insect species because of the willow trees' greater abundance in that habitat.

The large, climatically similar area of the tropics has been proposed as a reason why the tropics have high species richness. However, the area hypothesis seems unable to explain why, if increased richness is linked to increased area, more species are not found in certain regions such as the vast contiguous landmass of Asia. Furthermore, although tundra may be the world's largest biome in terms of land mass, it has low species richness. Finally, the largest marine system, the open ocean, which has the greatest volume of any habitat, has fewer species than tropical nearshore waters, which have a relatively small volume.

The Productivity Hypothesis Suggests That More Energy Permits the Existence of More Species

The **productivity hypothesis** proposes that greater production by plants results in greater overall species richness. An increase in plant productivity, the total weight of plant material produced over time, leads to an increase in the number of herbivores and hence an increase in the number of predator, parasite, and scavenger species. Production itself is influenced by factors such as temperature and rainfall, because many plants grow better where it is warm and wet. For example, in 1987, Canadian biologist David Currie and colleagues showed that the species richness of trees in North America is best predicted by the **evapotranspiration rate**, the rate at which water moves into the atmosphere through the processes of evaporation from the soil and transpiration of plants, both of which are influenced by the amount of solar energy (**Figure 58.5**).

Once again, however, there are exceptions to this rule. In 1993, American researchers Robert Latham and Robert Ricklefs showed that although patterns of tree richness in North America support the productivity hypothesis, the pattern does not hold for broad comparisons between continents. For example, the temperate forests of eastern Asia support substantially higher numbers of tree species (729) than do climatically similar areas of North America (253) or Europe (124). These three areas have different evolutionary histories and different neighboring areas from which species might have invaded.

Some tropical seas, such as the southeast Pacific off Colombia and Ecuador, have low productivity but high species richness. On the other hand, the sub-Antarctic Ocean has a high productivity but low species richness. Estuarine areas, where rivers empty into the sea, are similarly very productive yet low in species, presumably because they represent stressful environments for many organisms that are alternately inundated by fresh water and salt water with daily changes in the tide. Some lakes that are polluted with fertilizers also have high productivity but low species richness.

The Intermediate-Disturbance Hypothesis Proposes That Moderately Disturbed Communities Contain More Species

American ecologist Joseph Connell has argued that the highest numbers of species are maintained in communities with intermediate

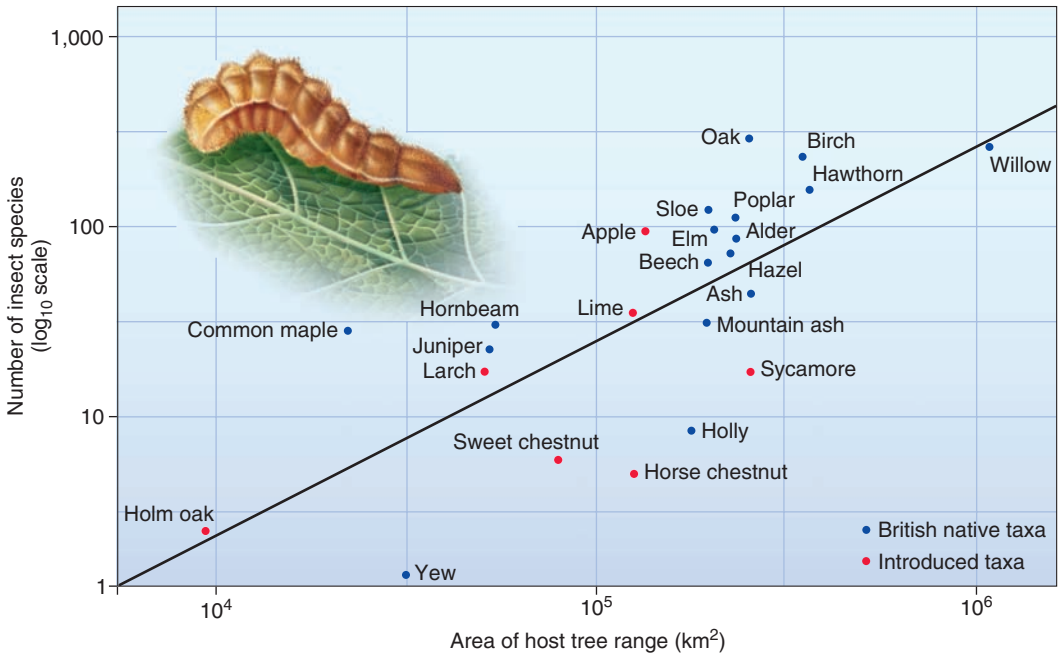

Figure 58.4 Relationship between species richness on British host trees and area. A positive correlation is found between insect species richness and the host tree's present range, in square kilometers (km^2).

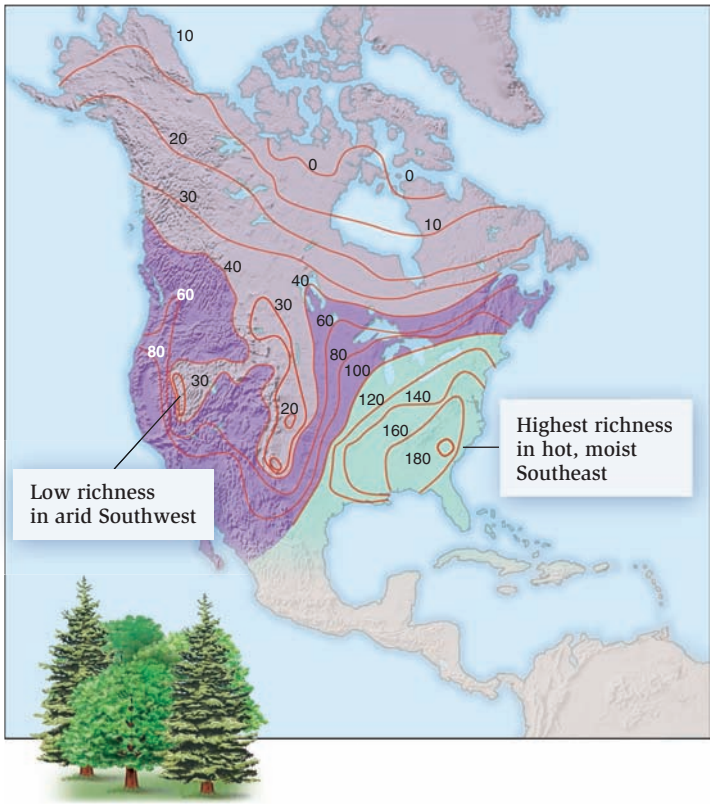

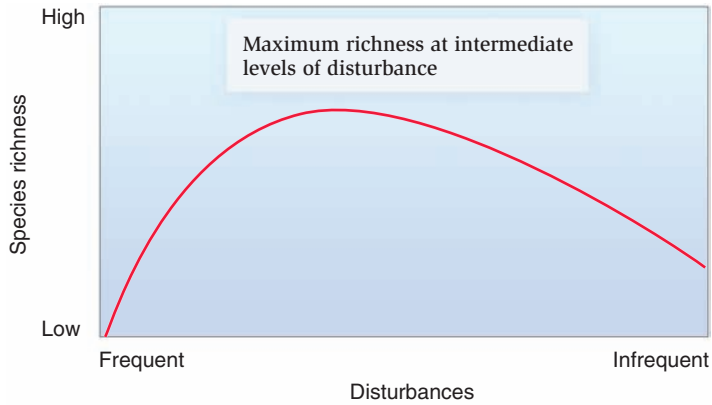

Figure 58.5 Tree species richness in North America. Contour lines show equal numbers of tree species, with colors indicating incremental changes. Tree species richness and evapotranspiration rates are highest in the southeast.

Concept Check: *Why doesn't the species richness of trees increase in mountainous areas of the West, as it does for birds?*

(a) Relationship between species richness and disturbances

(b) Light gap in a tropical rain forest

Figure 58.6 The intermediate-disturbance hypothesis of community organization. **(a)** This hypothesis proposes that species richness is highest at intermediate levels of disturbances caused by events such as fires or windstorms. **(b)** A light gap in a tropical rain forest in Costa Rica promotes the growth of small herbaceous species until trees colonize the light gap and gradually grow over and outcompete the smaller species.

Concept Check: *According to the intermediate-disturbance hypothesis, why are there so many species in the tropics?*

levels of environmental disturbance, a concept called the **intermediate-disturbance hypothesis** (Figure 58.6a). Disturbance in communities may be brought about by many different phenomena such as droughts, fires, floods, and hurricanes or by species interactions such as herbivory, predation, or parasitism. Recall from Chapter 56 that some species, termed *r*-selected species, are better dispersers than other species, and that *K*-selected species are better competitors (refer back to Figure 56.14). Connell reasoned that at high levels of disturbance, only colonists that were *r*-selected species would survive, giving rise to low species richness. This is because these species would be the only ones able to disperse quickly to a highly disturbed area. At low rates of disturbance, competitively dominant *K*-selected species would outcompete all other species, which would also yield low species richness. The most species-rich communities would lie somewhere in between.

Connell argued that natural communities fit into this model fairly well. Tropical rain forests and coral reefs are both examples of communities with high species richness. Coral reefs exhibit highest species richness in areas disturbed by hurricanes, and the richest tropical forests occur where disturbance by storms causes landslides and tree falls. The fall of a tree creates a hole in the rain forest canopy known as a light gap, where direct sunlight is able to reach the rain forest floor. The light gap is rapidly colonized by *r*-selected species, such as small herbaceous plants, which are well adapted for rapid growth. Although these pioneering species grow rapidly, they are eventually overtaken by *K*-selected species, such as mature trees, which fill in the gap in the canopy (Figure 58.6b). Although environmental events such as hurricanes and tree falls are fairly frequent events in these communities, their occurrence in any one area is usually of intermediate frequency.

58.3 Calculating Species Diversity

Learning Outcomes:

1. Define species diversity.
2. **SciSKILLS** » Calculate the Shannon diversity index.
3. **SciSKILLS** » Calculate the effective number of species.

So far, we have discussed communities in terms of variations in species richness. However, ecologists need to take into account not only the number of species in a community but also their frequency of occurrence, or **relative abundance**. For example, consider two hypothetical communities, A and B, both with two species and 100 total individuals.

	Number of individuals of species 1	Number of individuals of species 2
Community A	99	1
Community B	50	50

The species richness of community B equals that of community A, because they both contain two species. However, community B is considered more diverse than A because the distribution of individuals between species is more even. One would be much more likely to encounter both species in community B than in community A, where one species dominates. **Species diversity** is a measure of the diversity of an ecological community that incorporates both species number and relative abundance.

To measure the species diversity of a community, ecologists calculate what is known as a diversity index. Although many different indices are available, the most widely used is the **Shannon diversity index (H_S)**, which is calculated as

$$H_S = -\Sigma p_i \ln p_i$$

where p_i is the proportion of individuals belonging to species i in a community, ln is the natural logarithm, and Σ indicates summation. For example, for a species in which there are 50 individuals out of a total of 100 in the community, p_i is 50/100, or 0.5. The natural log of 0.5 is −0.693. For this species, $p_i \ln p_i$ is then $0.5 \times -0.693 = -0.347$. For a hypothetical community with 5 species and 100 total individuals, the Shannon diversity index is calculated as follows:

	Species	Abundance	p_i	$p_i \ln p_i$
	1	50	0.5	–0.347
	2	30	0.3	–0.361
	3	10	0.1	–0.230
	4	9	0.09	–0.217
	5	1	0.01	–0.046
Total	5	100	1.00	$\Sigma p_i \ln p_i$ –1.201

In this example, even the rarest species, species 5, contributes some value to the index. If a community had many rare species, their contributions would accumulate. This makes the Shannon diversity index very valuable to conservation biologists, who often study rare species and their importance to the community. Remember, too, that in the equation, the negative sign in front of the summation changes these values to positive, so the index actually becomes 1.201, not –1.201.

Values of the Shannon diversity index for real communities often fall between 1.5 and 3.5, with the higher the value, the greater the diversity. **Table 58.1** calculates the diversity of two bird communities in Indonesia with similar species richness but differing species abundance. The bird communities were surveyed in a pristine unlogged forest or in a selectively logged lowland forest. To document diversity, British biologist Stuart Marsden established census stations in the two forests and recorded the type and number of all bird species for a number of 10-minute periods. Although a greater number of individual birds was seen in the logged areas (2,358) than in the unlogged ones (1,824), a high proportion of the individuals in the logged areas

Total	**1,824**	**1.0**		**2,358**	1.0	
Shannon diversity index			**2.284**			**2.037**

(0.386) belonged to just one species, *Nectarinia jugularis*. Although only one more bird species was found in the unlogged area than in the logged area, calculation of the Shannon diversity index showed a higher diversity of birds in the unlogged area, 2.284 versus 2.037.

A problem with diversity indices is that the results are not always easy to compare. For example, imagine that a hypothetical community has 5 species, each represented by 20 individuals ($n = 100$). The Shannon diversity index is 1.609, which is 34% greater than the value of 1.201 calculated earlier for the hypothetical community with 5 species of varying abundances (also with $n = 100$). A better comparison is obtained by calculating the **effective number of species**, which converts values from species diversity indices into equivalent numbers of species. To find the effective number of species, we take the exponential of the Shannon diversity index: for example, $e^{1.609}$. Thus, the value 1.609 becomes 5.0, which is the same as the actual number of species. For the Shannon diversity index value of 1.201, the effective number of species is 3.323, which means that this hypothetical community is 33.5% less diverse than the hypothetical community with an effective number of species equal to 5.0. If we consider effective numbers of species for Marsden's data from the forests of Indonesia, we find the unlogged areas have an effective number of species of 9.816 compared to 7.668 for the logged areas, a difference of 28.0%. This is greater than the difference between the values of the Shannon diversity index for the two areas.

BIO TIPS **THE QUESTION** *Which community has the larger effective number of species: community A with 50 individuals of species 1 and 50 individuals of species 2, or community B with 80 individuals of species 1, 10 individuals of species 2, and 10 individuals of species 3?*

TOPIC ***What topic in biology does this question address?*** The topic is how to measure species diversity, more specifically, how to calculate the effective number of species.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you know the distributions of individuals and species within two communities. Community A has 2 species, and community B has 3 species. From your understanding of the topic, you may remember that the effective number of species is the best indicator of species diversity and that it is calculated using the Shannon diversity index, $H_s = -\Sigma p_i \ln p_i$.

PROBLEM-SOLVING STRATEGY ***Make a calculation.*** First, find the Shannon diversity index of both communities.

Community A: $H_s = -[(0.5 \ln 0.5) + (0.5 \ln 0.5)] = 0.693$

Community B: $H_s = -[(0.8 \ln 0.8) + (0.1 \ln 0.1) + (0.1 \ln 0.1)] = 0.638$

Next, take the exponential of each of these values to calculate the effective numbers of species.

Community A: $e^{0.693} = 2.000$

Community B: $e^{0.638} = 1.893$

ANSWER *Community A has a larger effective number of species than community B.*

An accurate determination of species diversity depends on detailed knowledge of which and how many of each species are present. This is relatively easy to determine for communities of vertebrates and some invertebrates, but it is much more difficult for microbial communities. Yet knowledge of microbial communities is of great importance, because microbes carry out vital functions such as nitrogen fixation and decomposition. As described next, the advent of modern molecular tools is expanding our knowledge of the species diversity of microbial communities.

Genomes & Proteomes Connection

Metagenomics May Be Used to Measure Species Diversity

Bacteria are abundant members of all communities and are vital to their functioning. They serve as food sources for other organisms and participate in the decomposition process. However, most microorganisms are taxonomically unknown, mainly because they cannot be cultivated on known culture media. The field of **metagenomics** seeks to identify and analyze the collective genetic material contained in a community of organisms, including those that are not easily cultured in the laboratory. Metagenomics techniques have been in existence only since the early 1990s, but significant progress has already been made in providing data that have advanced our understanding of which bacteria are present in various communities and how they function.

The process involves four main steps (**Figure 58.7**). First, an environmental sample containing an unknown number of bacterial species is collected, and its DNA is isolated from the cells using chemical or physical methods. Because the genomic DNA of each species is relatively large, it is cut up into fragments with restriction enzymes (refer back to Figures 20.1 to 20.4, which detail the steps used to clone genes and create a DNA library). Second, the fragments are combined with vectors, small units of DNA that can be inserted into a model laboratory organism, usually a bacterium. The third step begins with transformation, in which the DNA from step 2 is taken up into bacterial cells. Individual bacteria are then grown on a selective medium so that only the transformed cells survive. Each cell grows into a colony of cloned cells. A collection of thousands of clones, each containing a different piece of microbial DNA, is called a DNA library. Lastly, the DNA from the DNA library is analyzed. In some cases, expression of the new DNA results in the synthesis of a new protein that changes the phenotype of the host, for example, a new enzyme that is detected by a chemical technique or an unusual color or shape in the model organism.

In 2004, Australian earth scientist Jill Banfield and colleagues used metagenomics techniques to identify the five dominant species of bacteria living at temperatures of 42°C (107°F) and pH 0.8 in the acidic wastewater (the same pH as battery acid) from a mine in California. They detected 2,033 proteins from these species. This represented the first large-scale proteomics-level expression of a natural microbial community. One of the proteins, a cytochrome, oxidizes iron and probably influences the rate of

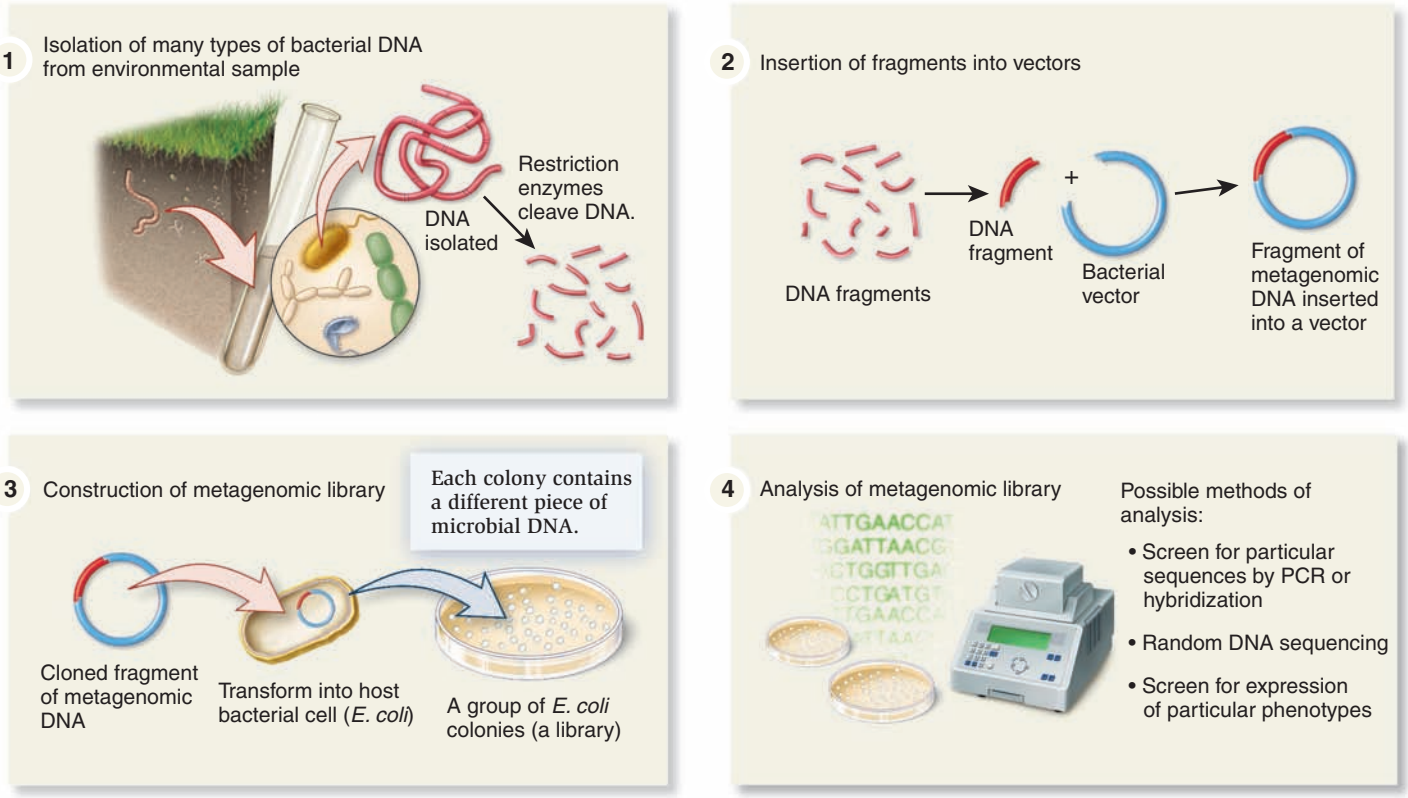

Figure 58.7 The standard protocol of a metagenomics experiment. **(1)** Isolation and fragmentation of DNA from the sample; **(2)** insertion of fragments into bacterial vectors; **(3)** insertion of cloned DNA into host bacterial cell (here, *Escherichia coli*), and culturing in selective growth media to create a DNA library; and **(4)** analysis of DNA sequences and protein expression.

breakdown of acid mine drainage products. Many other proteins appear responsible for defending against free radicals, suggesting that this is an important metabolic trait for persistence in the acidic environment. The team wants to identify enzymes and metabolic pathways that can help in the cleanup of this and other environmentally contaminated sites in the future.

Metagenomic sequencing is also being used to characterize the microbial communities of humans. There is a belief that a core human microbiome exists which, when changed, may have effects on human health. Most of these microbial partners live in our intestines, extracting nutrients from otherwise indigestible parts of our diet. Many of these also detoxify potentially harmful chemicals from our food. Other microbes defend us against pathogens. Using metagenomics to gain a better understanding of our microbial community could be of immense medical value.

58.4 Species Diversity and Community Stability

Learning Outcome:

1. Describe the diversity-stability hypothesis, and evaluate the evidence supporting it.

In this section, we will consider the relationship between species diversity and community stability. A community is often seen as stable when little to no change can be detected in the number of species and their abundance over a given time period. The community may then be said to be in equilibrium. Community stability is an important consideration to ecologists. A decrease in the stability of a community over time may alert ecologists to a possible problem. In the 1950s, the populations of many bird species in the U.S. and Europe declined precipitously (look ahead to Figure 59.8). Raptor species such as peregrine falcons, bald eagles, and osprey were particularly hard hit. Eventually, the decline was traced to use of the pesticide DDT (dichlorodiphenyltrichloroethane), which caused eggshells to become thin and break before the birds could hatch. After DDT was banned later in the 1970s, raptor species began to recover.

We begin our discussion by exploring the question of whether communities with more species are more stable than communities with fewer species. We then examine the link between diversity and stability, using evidence from the field. Finally, we will look at the relationship from a different angle and consider whether or not stable communities are more species-rich than communities that have been disturbed.

The Diversity-Stability Hypothesis States That Species-Rich Communities Are More Stable Than Those with Fewer Species

Community stability may be viewed in several different ways. Some communities, such as extreme deserts, are considered stable because they are resistant to change by anything other than water. Other communities, such as river communities, are considered stable because they can recover quickly after a disturbance, such as pollution, being cleansed by the rapid flow of fresh water. Lake communities, on the

other hand, may be seen as less stable because there is often no drainage outlet, and pollutants can accumulate quickly.

Because maintaining community stability is seen as important, much research has gone into understanding the factors that enhance it. In general, research shows that species-rich communities are more stable than species-poor communities. Even so, ecologists debate the effects of species richness. For example, are species-rich communities more resistant to invasion by introduced species, such as weeds, than species-poor communities?

The link between species richness and stability was first explicitly proposed by the English ecologist Charles Elton in the 1950s. He suggested that a disturbance in a species-rich community would be cushioned by large numbers of interacting species and would not produce as drastic an effect as it would in a species-poor community. Thus, an introduced predator or parasite could cause extinctions in a species-poor system but possibly not in a more diverse system, where its effects would be buffered by interactions with more species in the community. Elton argued that outbreaks of pests are often found on cultivated land or land disturbed by humans, both of which are species-poor communities with few naturally occurring species. His argument became known as the **diversity-stability hypothesis**.

However, some ecologists began to challenge Elton's association of diversity with stability. Ecologists pointed out many examples of introduced species that have assumed pest proportions in species-rich areas, including rabbits in Australia and pigs in North America. They noted that disturbed or cultivated land may suffer from pest outbreaks not because of its simple nature but because individual species, including introduced species, often have no natural enemies in the new environment, in contrast to the long associations between native species and their natural enemies. For example, in Europe, coevolved predators such as foxes prevent rabbit populations from increasing to pest proportions. What was needed was research to determine if a link existed between diversity and stability.

Field Studies Have Linked Stability to Diversity

In 1996, American ecologist David Tilman reported the relationship between species diversity and stability from an 11-year study of 207 grassland plots in Minnesota that varied in their species richness. He measured the biomass of every species of plant, in each plot, at the end of every year and obtained the average species biomass. He then calculated how much this biomass varied from year to year through a statistical measure called the coefficient of variation. Less variation in biomass signified community stability. Year-to-year variation in plant community biomass was significantly lower in plots with greater plant species richness (**Figure 58.8**). The results showed that greater diversity enhances community stability.

Tilman suggested that diversity stabilizes communities because they are more likely to contain disturbance-resistant species that, in the event of a disturbance, could grow and compensate for the loss of disturbance-sensitive species. For example, when a change in climate such as drought decreased the abundance of competitively dominant species that thrived in normal conditions, unharmed drought-resistant species increased in mass and replaced them. Such declines in the number of susceptible species and compensatory increases in other species acted to stabilize total community biomass.

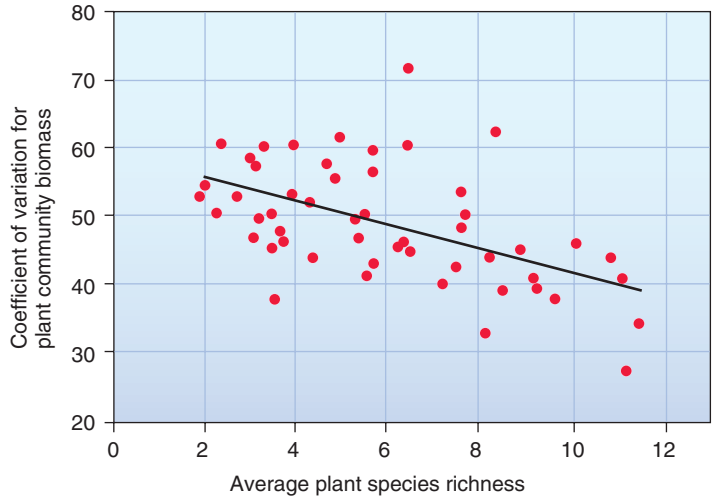

Figure 58.8 Biomass variation and species richness. Tilman's 11-year study of grassland plots in Minnesota revealed that year-to-year variability in community biomass was lower in species-rich plots. Each dot represents an individual plot. Only the plots from one field are graphed.

Although ecologists recognize a link between species diversity and community stability, they are also aware that, over long periods of time, communities may experience severe disturbances. The change in composition and structure of communities that follows occurs in a predictable way termed succession, which is described next.

58.5 Succession: Community Change

Learning Outcomes:

1. Explain the difference between primary and secondary succession.
2. Compare and contrast facilitation, inhibition, and tolerance as mechanisms of succession.

At 8:32 a.m. on May 18, 1980, Mount St. Helens, a previously little-studied peak in the Washington Cascades, erupted. The blast felled trees over a 600-km^2 area, and the landslide that followed—the largest in recorded history—destroyed everything in its path, killing nearly 60 people and millions of animals. However, since the 1980 eruption, much of the area has experienced a relatively rapid recovery of plant and animal communities (**Figure 58.9**).

Ecologists have developed several terms to describe how community change occurs. The term **succession** describes the gradual and continuous change in species composition of a community following a disturbance. **Primary succession** refers to succession on a newly exposed site that has no biological legacy in terms of plants, animals, or microbes, such as bare ground caused by a volcanic eruption or the sediment created by the retreat of glaciers. In primary succession on land, the plants must often build up the soil, and thus a long time—even hundreds of years—may be required for the process. Only a tiny proportion of the Earth's surface is currently undergoing primary succession, for example, around Mount St. Helens and the volcanoes in Hawaii and off the coast of Iceland, and behind retreating glaciers in Alaska and Canada.

(a) 1980 (b) 1997

Figure 58.9 Succession on Mount St. Helens. **(a)** The initial blast occurred on May 18, 1980. **(b)** By 2006, many of the areas initially flattened by the blast and covered in ash developed low-lying vegetation, and new trees appeared.

Secondary succession refers to succession on a site that has already supported life but has undergone a disturbance such as a fire, tornado, hurricane, or flood (as in the 2004 tsunami in Indonesia). In terrestrial areas, soil is already present. Clearing a natural forest and farming the land for several years is an example of a severe forest disturbance that does not kill all native species. Some plants and many soil bacteria, nematodes, and insects are still present. Secondary succession occurs if farming is ended. The secondary succession in abandoned farmlands (also called old fields) can lead to a pattern of vegetation quite different from one that develops after primary succession following glacial retreat. For example, the plowing and added fertilizers, herbicides, and pesticides may have caused substantial changes in the soil of an old field, allowing species that require a lot of nitrogen to colonize. These species would not be present for many years in newly created glacial soils.

Frederic Clements is often viewed as the founder of successional theory. His work in the early 20th century emphasized succession as proceeding through several stages (called seres) to a distinct end point, or **climax community**. Although disturbance can return a community from a later stage to an earlier stage, generally the community progresses in one direction. Clements's depiction of succession focused on a process termed facilitation, but two other mechanisms of succession—inhibition and tolerance—have since been described. Let's examine the evidence for each of them.

Facilitation Assumes Each Invading Species Creates a More Favorable Habitat for Succeeding Species

A key assumption of Clements is that each colonizing species makes the environment a little different—a little shadier or a little richer in soil nitrogen—so that it becomes more suitable for other species, which then invade and outcompete the earlier residents. This process, known as **facilitation**, continues until the most competitively dominant species has colonized, when the community is at climax. The composition of the climax community for any given region is thought to be determined by climate and soil conditions.

Succession following the gradual retreat of Alaskan glaciers is often used as a specific example of facilitation as a mechanism of succession. Over the past 200 years, the glaciers in Glacier Bay have undergone a dramatic retreat of nearly 100 km (**Figure 58.10**). Succession in

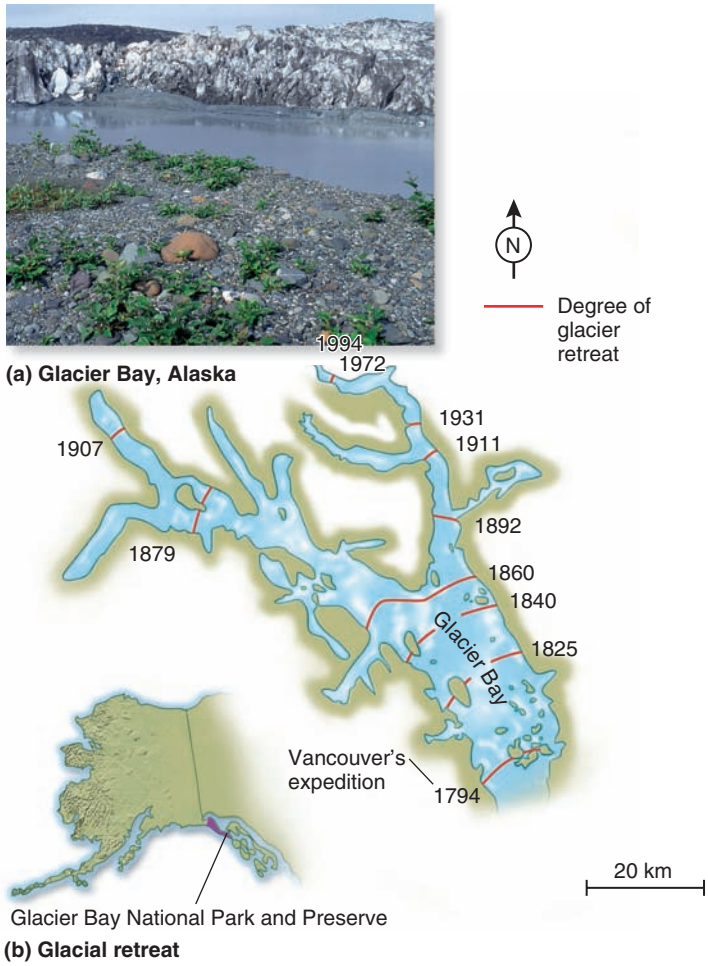

Figure 58.10 The degree of glacier retreat at Glacier Bay, Alaska, since 1794. **(a)** Primary succession begins on the bare rock and soil evident at the edges of the retreating glacier. **(b)** The lines reflect the position of the glacier in 1794 and its subsequent retreat northward.

Concept Check: *Why do ecologists sometimes view walking through Glacier Bay as the equivalent of being in a time machine?*

Glacier Bay follows a distinct pattern of vegetation. As glaciers retreat, they leave moraines—deposits of stones, pulverized rock, and debris that serve as soil. In Alaska, the bare soil has a low nitrogen content and scant organic matter. In the pioneer stage, the soil is first colonized by a black crust of cyanobacteria, mosses, lichens, horsetails (*Equisetum variegatum*), and the occasional river beauty (*Epilobium latifolium*) (**Figure 58.11a**). Because the cyanobacteria are nitrogen fixers (refer back to Figure 37.17), the soil nitrogen increases a little, but soil depth and litterfall (fallen leaves, twigs, and other plant material) are still minimal. At this stage, there may be a few seeds and seedlings of dwarf shrubs of the rose family commonly called mountain avens (*Dryas drummondii*), alders (*Alnus sinuata*), and spruce, but they are rare. After about 40 years, mountain avens dominates the landscape (**Figure 58.11b**). Soil nitrogen increases, as does soil depth and litterfall, and alder trees begin to invade.

At about 60 years, alders form dense, close thickets (**Figure 58.11c**). Alders have nitrogen-fixing bacteria that live mutualistically in their roots and convert nitrogen from the air into a biologically useful form. Soil nitrogen dramatically increases, as does litterfall. Spruce trees (*Picea sitchensis*) begin to invade at about this time. After about 75 to 100 years, the spruce trees begin to overtop the alders, shading them out. The litterfall is still high, and the large volume of needles turns the soil acidic. The shade causes competitive exclusion of many of the original understory species, including alder, and only mosses carpet the ground. At this stage, seedlings of western hemlock (*Tsuga heterophylla*) and mountain hemlock (*Tsuga mertensiana*) may also occur. After 200 years, a mixed spruce-hemlock climax forest results (**Figure 58.11d**).

What other evidence is there of facilitation? Experimental studies of early primary succession on Mount St. Helens, which show that decomposition of fungi allows mosses and other fungi to colonize the soil, provide evidence of facilitation. In New England salt marshes, *Spartina* grass facilitates the establishment of beach plant communities by stabilizing the rocky substrate and reducing water velocity, which enables other seedlings to emerge. Succession on sand dunes also supports the facilitation model, in that pioneer plant species stabilize the sand dunes and facilitate the establishment of subsequent plant species. The foredunes, those nearest the shoreline, are the most frequently disturbed and are maintained in a state of early succession, whereas more stable communities develop farther away from the shoreline.

Succession also occurs in aquatic communities. Although soils do not develop in marine environments, facilitation may still be encountered when one species enhances the quality of settling and establishment sites for another species. When experimental test plates used to

measure settling rates of marine organisms were placed in the Delaware Bay, researchers discovered that certain cnidarians enhanced the attachment of tunicates, and both facilitated the attachment of mussels, the dominant species in the community. In this experiment, the smooth surface of the test plates prevented many species from colonizing, but once the surface became rougher, because of the presence of the cnidarians, many other species were able to colonize. In a similar fashion, early colonizing bacteria, which create biofilms on rock surfaces, can facilitate succession of other organisms.

Inhibition Implies That Early Colonists Prevent Later Arrivals from Replacing Them

Although data on succession in some communities fit the facilitation model, researchers have proposed alternative hypotheses of how succession may operate. In the process known as **inhibition**, early colonists prevent colonization by other species. For example, removing the litter of *Setaria faberi*, an early successional plant species in New Jersey old fields, causes an increase in the biomass of a later species, *Erigeron annuus*. The release of toxic compounds from decomposing *Setaria* litter or physical obstruction by the litter itself blocks the establishment of *Erigeron*. Without the litter present, however, *Erigeron* dominates and reduces the biomass of *Setaria*. Plant species, such as some grasses, ferns, vines, pine trees, and bamboo, that grow in dense thickets can inhibit succession, as can many introduced plant species.

Inhibition has been seen as the primary method of succession in the marine intertidal zone, where space is limited. In this habitat, early successional species are at a great advantage in maintaining possession of valuable space. In 1974, American ecologist Wayne Sousa created an environment for testing how succession works in the intertidal zone by scraping rock faces clean of all algae or putting out fresh boulders or concrete blocks. The first colonists of these areas were the green algae *Ulva*. By removing *Ulva* from the substrate, Sousa showed that the large red alga *Chondracanthus canaliculatus* was able to colonize more quickly (**Figure 58.12**). The results of Sousa's study indicate that early colonists can inhibit rather than facilitate the invasion of subsequent colonists. Succession may eventually occur because early colonizing species, such as *Ulva*, are more susceptible than later successional species, such as *Chondracanthus*, to the rigors of the physical environment and to attacks by herbivores, such as crabs (*Pachygrapsus crassipes*).

Tolerance Suggests That Early Colonists Neither Facilitate nor Inhibit Later Colonists

In 1977, researchers Joseph Connell and Australian ecologist Ralph Slatyer proposed a third mechanism of succession, which they termed **tolerance**. In this process, any species can start the succession, but the eventual climax community is reached in a somewhat orderly fashion. The species that establish and remain do not change the environment in ways that either facilitate or inhibit subsequent colonists. Species have differing tolerances to the intensity of competition that results as more species accumulate. Relatively competition-intolerant species are more successful early in succession when the intensity of competition is low and resources are abundant. Relatively competition-tolerant species appear later in succession and at climax. Connell and Slatyer found the best evidence for the tolerance model in American plant ecologist Frank

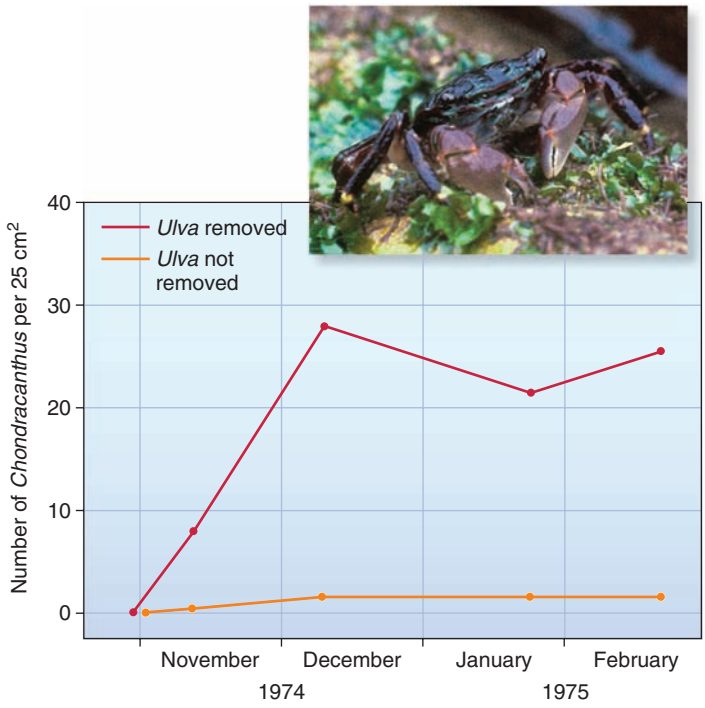

Figure 58.12 Inhibition as a primary method of succession in the marine intertidal zone. Removing *Ulva* from intertidal rock faces allowed colonization by *Chondracanthus*. The inset shows *Ulva* on a rock face with the striped shore crab *Pachygrapsus crassipes*, a herbivore.

BIOLOGY PRINCIPLE Biology is an experimental science. Waiting for ecological disturbance and following succession is unpredictable and time-consuming. Experimentally creating disturbances provides a better starting point for such studies.

Egler's earlier work on floral succession. In the 1950s, Egler showed that succession in plant communities is determined largely by species that already exist in the ground as buried seeds or old roots. Whichever species germinates first or regenerates from roots initiates the succession sequence. Germination or root regeneration, in turn, depends on the timing of a disturbance. For example, an early-season tree fall would promote early-germinating species to grow in the subsequent light gap, whereas a late-season tree fall would promote the growth of late-germinating species. As succession proceeds, earlier germinating or regenerating species may be outcompeted by different species.

The key distinction between the three models is in the manner in which succession proceeds. In the facilitation model, species replacement is facilitated by previous colonists; in the inhibition model, it is inhibited by the action of previous colonists; and in the tolerance model, species may be affected by previous colonists, but they do not require them (**Figure 58.13**).

58.6 Island Biogeography

Learning Outcomes:

1. **SciSKILLS** » Use a graph to illustrate the equilibrium model of island biogeography.
2. List the predictions of the model, and evaluate whether the evidence supports all the predictions.

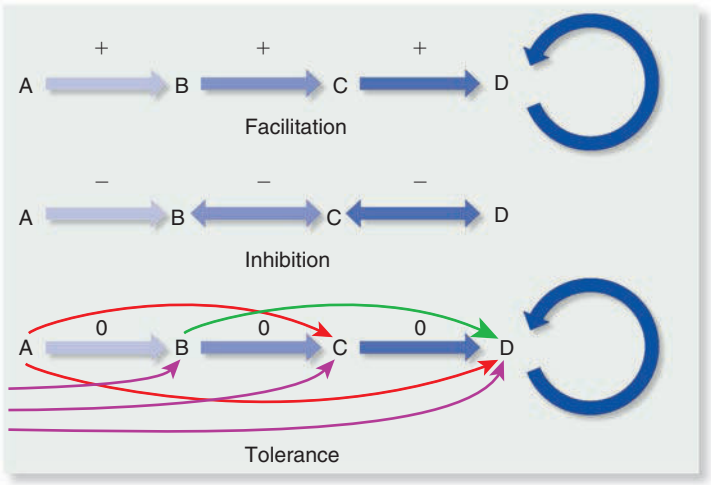

Figure 58.13 Three models of succession. A, B, C, and D represent four stages, or seres. D represents the climax community. An arrow indicates "is replaced by," and + = facilitation, – = inhibition, and 0 = no effect. The facilitation model is the classic model of succession. In the inhibition model, early-arriving species outcompete later-arriving species. The tolerance model much depends on which species gets there first. The colored arrows show that succession may bypass some stages in the tolerance model.

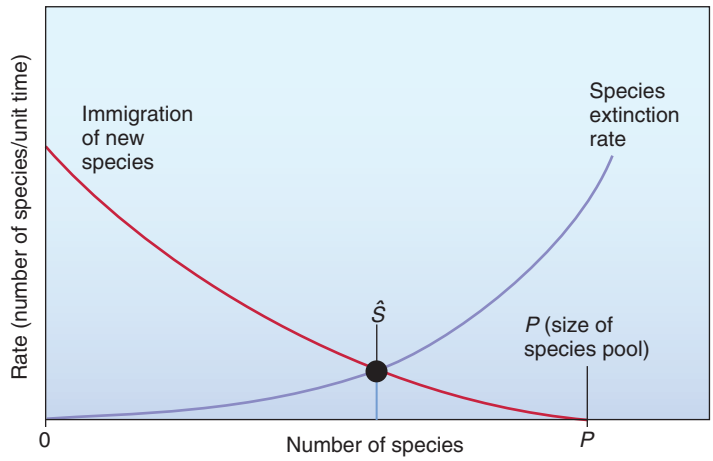
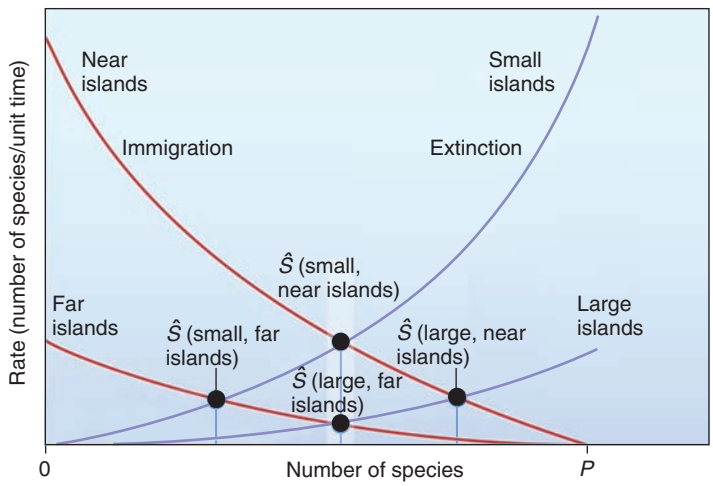


Concept Check: Inhibition implies that competition exists between species, with early-arriving species tending to outcompete later arrivals, at least for a while. Does competition or mutualism feature more prominently in facilitation?

In some newly formed habitats such as volcanic islands, succession may be affected not only by facilitation, inhibition, or tolerance, but also by the ability of species to colonize isolated areas. In such cases, species richness is affected by the distance of the habitat from a **source pool** of colonists, the pool of potential species available to colonize the island, and the size of the area to be colonized. In the 1960s, two eminent American ecologists, Robert MacArthur and E. O. Wilson, developed a comprehensive model to explain the process of succession on new islands, where a gradual buildup of species proceeds from a sterile beginning. Their model, termed the **equilibrium model of island biogeography**, holds that the number of species on an island tends toward an equilibrium number that is determined by the balance between two factors: immigration rates and extinction rates. In this section, we will explore island biogeography and see how well the model's predictions are supported by experimental data.



The Island Biogeography Model Suggests That During Succession, Gains by Immigration Are Balanced by Losses from Extinction

MacArthur and Wilson's model of island biogeography suggests that species repeatedly arrive on an island and either thrive or become extinct. The rate of immigration of new species is highest when no species are present on the island. As the number of species accumulates, the immigration rate decreases, because subsequent immigrants are more likely to represent species already present on the island. The rate of extinction is low at the time of first colonization, because few species are present and many have large populations. With the addition of new species, the populations of some species diminish, so the probability of extinction by chance alone increases. Over time, the number of species tends toward an equilibrium, $\hat{S}$, at which the rates of immigration and extinction are equal. Species may continue to arrive and go extinct, but the number of species on the island remains approximately the same.

MacArthur and Wilson reasoned that when plotted graphically, both the immigration and extinction lines would be curved, for several reasons (**Figure 58.14a**). First, species arrive on islands at different rates. Some organisms, including plants with seed-dispersal mechanisms and winged animals, are more mobile than others and arrive quickly. Other organisms arrive more slowly. This pattern causes the immigration curve to start off steep but get progressively shallower.

(a) Effects of immigration and extinction on species number

(b) Added effects of island size and proximity to the mainland on species number

Figure 58.14 MacArthur and Wilson's equilibrium model of island biogeography. (a) The interaction of immigration rate and extinction rate produces an equilibrium number of species on an island, $\hat{S}$. The value of $\hat{S}$ can vary from 0 species to *P* species, the total number of species available to colonize. **(b)** $\hat{S}$ varies according to the island's size and distance from the mainland. An increase in distance (near to far) lowers the immigration rate. An increase in island area (small to large) lowers the extinction rate.

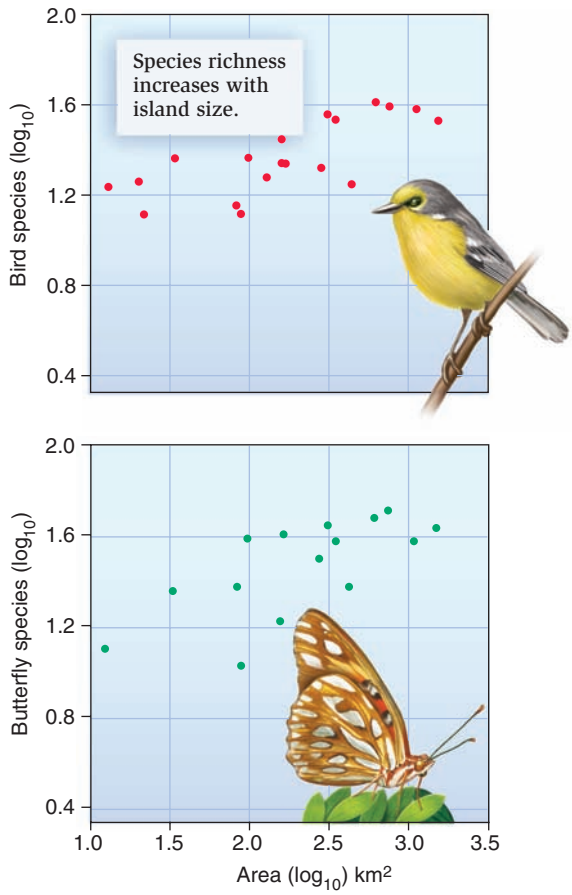
Concept Check: Can you think of a scenario where there would be large numbers of species on a small island?

BioConnections: Look forward to Figure 60.12. How might the model of island biogeography be useful in the design of nature reserves?

On the other hand, extinctions rise at accelerating rates, because as later species arrive, competition increases and more species are likely to go extinct. As noted previously, earlier-arriving species tend to be *r*-selected species, which are better dispersers, whereas later-arriving species are generally *K*-selected species, which are better competitors. Later-arriving species usually outcompete earlier-arriving ones, causing an increase in extinctions.

The strength of the island biogeography model was that it generated several testable predictions:

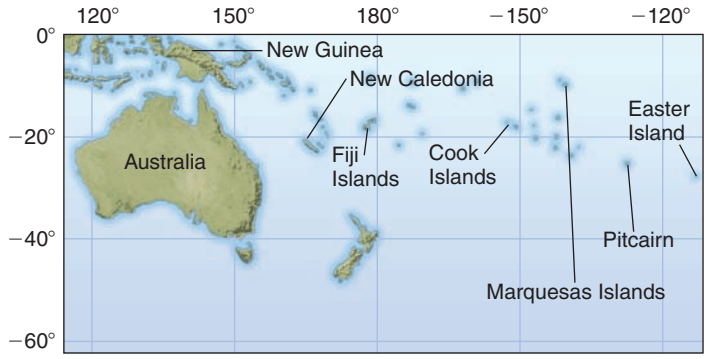
1. The number of species should increase with increasing island size (area), a concept known as the species-area effect (see Figure 58.4). Extinction rates would be greater on smaller islands because population sizes would be smaller and more susceptible to extinction (**Figure 58.14b**).
2. The number of species should decrease with increasing distance of the island from the mainland, or the source pool, Immigration rates would be greater on islands near the source pool because species do not have as far to travel (see Figure 58.14b).
3. The turnover of species should be considerable. The number of species on an island might remain relatively constant, but the composition of the species should vary over time as new species colonize the island and others become extinct.



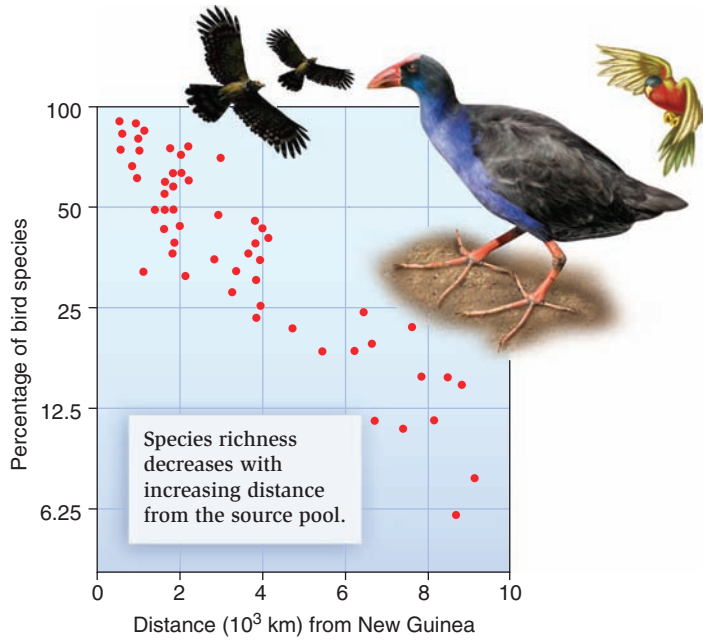
Let's examine the predictions of the island biogeography model one by one and see how well the data support them.

Species-Area Relationships The West Indies has traditionally been a key location for ecologists studying island biogeography. The physical geography and the plant and animal life of the islands are well known. Furthermore, the Lesser Antilles, from Anguilla in the north to Grenada in the south, enjoy a similar climate and are surrounded by deep water (**Figure 58.15a**). In 1999, Robert Ricklefs and American ornithologist Irby Lovette summarized the available data on the richness of species of four groups of animals—birds, bats, reptiles and amphibians, and butterflies—across 19 islands that varied in area over two orders of magnitude (13 km^2 to 1,510 km^2). In each case, a positive correlation occurred between area and species richness (**Figure 58.15b**).

Species-Distance Relationships In studies of the numbers of lowland forest bird species in Polynesia, MacArthur and Wilson found that the number of species decreased with the distance from



(a) Lesser Antilles Islands



(b) Relationship between species richness and island size

Figure 58.15 Species richness and island size. **(a)** The Lesser Antilles extend from Anguilla in the north to Grenada in the south. **(b)** On these islands, the number of bird and butterfly species increases with the area of an island. Note that these relationships are traditionally plotted on a double logarithmic scale, a so-called log-log plot, in which the horizontal axis is the logarithm to the base 10 of the area and the vertical axis is the logarithm to the base 10 of the number of species. A linear plot of the area versus the number of species would be difficult to produce, because of the wide range of area and richness of species involved. Logarithmic scales condense this variation to manageable limits.

Concept Check: *How large is the change in bird species richness across islands in the Lesser Antilles?*

(a) New Guinea and neighboring islands

(b) Relationship between species richness and distance from source

Figure 58.16 Species richness and distance from the source pool. **(a)** Map of Australia, New Guinea, and these Polynesian Islands: New Caledonia, Fiji Islands, Cook Islands, Marquesas Islands, Pitcairn, and Easter Island. **(b)** The numbers of bird species on the islands decreases with increasing distance from the source pool, New Guinea. The species richness is expressed as the percentage of bird species on New Guinea.

the source pool of New Guinea (**Figure 58.16**). They expressed the richness of bird species on the islands as a percentage of the number of bird species found on New Guinea. A significant decline in this percentage was observed with increasing distance. More distant islands contained lower numbers of species than nearer islands. This research substantiated the prediction of species richness declining with increasing distance from the source pool.

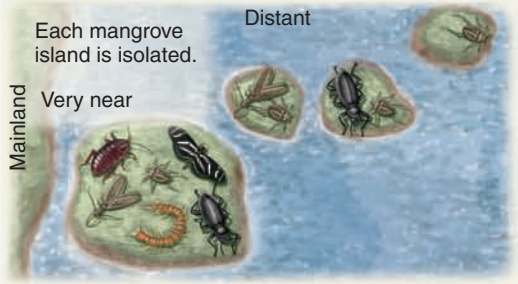
Species Turnover Studies involving species turnover on islands are difficult to perform because detailed and complete species lists are needed over long periods of time, usually many years and often decades. The lists that do exist are often compiled in a casual way and are not usually suitable for comparison with more modern data. In 1980, British researcher Francis Gilbert reviewed 25 investigations carried out to demonstrate turnover and found a lack of this type of rigor in nearly all of them. Furthermore, most of the observed turnover in these studies, usually less than 1% per year, or less than one species per year, appeared to be due to immigrants that never became established rather than to the extinction of well-established species. More recent studies have revealed similar findings, suggesting that the rates of turnover are low rather than high, giving little conclusive support to the third prediction of the equilibrium model of island biogeography. Even the most rigorous study, by E. O. Wilson and his student Daniel Simberloff, showed negligible turnover, as described next.

Feature Investigation | Simberloff and Wilson's Experiments Tested the Predictions of the Equilibrium Model of Island Biogeography

In the 1960s, American ecologists Daniel Simberloff and E. O. Wilson conducted possibly the best test of the equilibrium model of island biogeography ever performed, using islands in the Florida Keys. They surveyed small red mangrove (*Rhizophora mangle*) islands, 11–25 m in diameter, for all terrestrial arthropods. They then enclosed each island with a plastic tent and had the islands fumigated with methyl bromide, a short-acting insecticide, to remove all arthropods on them. The tents were removed, and periodically thereafter Wilson and Simberloff surveyed the islands to examine recolonization rates. At each survey, they counted all the arthropod species present, noting any species not there at the previous census and the absence of others that were previously there but had presumably gone extinct (results for four of the islands are shown in **Figure 58.17**). In this way, they estimated turnover of species on islands.

After 250 days, all but one of the islands had a similar number of arthropod species to that before fumigation, even though population densities were still low. The data indicated that recolonization rates were higher on islands nearer to the mainland than on far islands—as the island biogeography model predicts. However, the data, which consisted of lists of species on islands before and after extinctions, provided little support for the prediction of substantial turnover. Rates of turnover were low, only 1.5 extinctions per year, compared with the 15–40 species found on the islands within a year. Simberloff and

Figure 58.17 **Simberloff and Wilson's experiments on the equilibrium model of biogeography.**



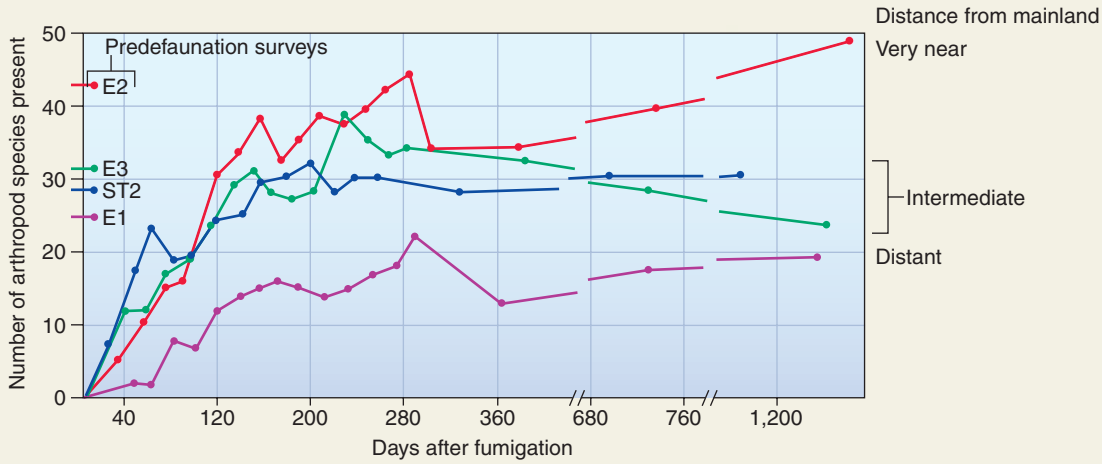
HYPOTHESIS Island biogeography model predicts higher species richness for islands closer to the mainland and significant turnover of species on islands.

STARTING LOCATION Mangrove islands in the Florida Keys.

Experimental level **Conceptual level**

1 Take initial census of all terrestrial arthropods on 4 mangrove islands. Erect a framework over each mangrove island.

2 Cover the framework with tents and fumigate with methyl bromide to kill all arthropod species.



3 Remove the tents and conduct censuses every month to monitor recolonization of arthropods and to determine extinction rates.

4 **THE DATA** Island E2 was closest to the mainland and supported the highest number of species both before and after fumigation. E3 and ST2 were at an intermediate distance from the mainland, and E1 was the most distant.

5 **CONCLUSION** Island distance from the mainland influences species richness on mangrove islands in the Florida Keys. However, species turnover is minimal, and species richness changes little following initial recolonization.

6 **SOURCE** Simberloff, D.S. 1978. Colonization of islands by insects: immigration, extinction and diversity. pp. 139–153 in L.A. Mound and N. Waloff (eds.). Diversity of insect faunas. *Blackwell Scientific Publications*, Oxford, U.K.

Wilson concluded that turnover probably involves only a small subset of transient or less important species, with the more important species remaining permanent after colonization.

Experimental Questions

1. What was the purpose of Simberloff and Wilson's study?
2. **SciSKILLS** » Explain why the researchers conducted a thorough species survey of arthropods before experimental removal of all the arthropod species.
3. What did the researchers conclude about the relationship between island proximity to the mainland and species richness and turnover?

The equilibrium model of island biogeography has stimulated much research confirming the strong effects of area and distance on species richness. However, species turnover appears to be low rather than considerable, which suggests that succession on most islands is a fairly orderly process. This means that colonization is not a random process and that the same species seem to colonize first and other species gradually appear in the same order.

It is also important to note that the principles of island biogeography have been applied to wildlife preserves, which are essentially islands in a sea of developed land consisting of agricultural fields or urban sprawl. Conservationists have therefore utilized the model of island biogeography in the design of nature preserves, a topic we will explore in Chapter 60.

Summary of Key Concepts

58.1 Differing Views of Communities

- Community ecology studies how groups of species interact and form functional communities. Ecologists have differing views on the nature of a community. In one view, communities are tightly organized groups of mutually dependent species; in another, they are loose assemblies of species that happen to live in the same place at the same time (Figure 58.1).
- Although many observations support the idea that communities are loose assemblages of species, sharp boundaries between groups of species do exist, especially related to physical differences that cause distinct communities to develop (Figure 58.2).

58.2 Patterns of Species Richness

- The number of species of most taxa varies according to geographic location, generally increasing from polar areas to tropical areas (Figure 58.3).
- Different hypotheses for the variations in species richness have been advanced, including the time hypothesis, the area hypothesis, the productivity hypothesis, and the intermediate-disturbance hypothesis (Figures 58.4, 58.5, 58.6).

58.3 Calculating Species Diversity

- The most widely used measure of the species diversity of a community, called the Shannon diversity index, takes into account both species richness and species abundance (Table 58.1). Calculating the effective number of species converts values from species diversity indices into equivalent numbers of species.
- The field of metagenomics seeks to identify and analyze the genomes contained in a community of microorganisms (Figure 58.7).

58.4 Species Diversity and Community Stability

- Community stability is an important consideration in ecology. The diversity-stability hypothesis maintains that species-rich communities are more stable than communities with fewer species. Tilman's field experiments, which showed that year-to-year variation in plant biomass decreased with increasing species diversity, established a link between diversity and stability (Figure 58.8).

58.5 Succession: Community Change

- Succession describes the gradual and continuous change in community structure over time. Primary succession refers to succession on a newly exposed site with no prior biological legacy; secondary succession refers to succession on a site that has already supported life but has undergone a disturbance (Figures 58.9, 58.10).
- Three mechanisms have been proposed for succession. In facilitation, each species facilitates or makes the environment more suitable for subsequent species. In inhibition, initial species inhibit later colonists. In tolerance, any species can start the succession, and species replacement is unaffected by previous colonists (Figures 58.11, 58.12, 58.13).

58.6 Island Biogeography

- In the equilibrium model of island biogeography, the number of species on an island tends toward an equilibrium number

determined by the balance between immigration rates and extinction rates (Figure 58.14).

- The model predicts that the number of species increases with increasing island size; that the number of species decreases with distance from the source pool; and that turnover is high (Figures 58.15, 58.16).
- Simberloff and Wilson's experiments on mangrove islands in the Florida Keys provided support for the first tenet of the island biogeography model but refuted the third tenet (Figure 58.17).

Assess and Discuss

Test Yourself

1. A community with many individuals but few different species exhibits
   a. low abundance and high species complexity.
   b. high stability.
   c. low species richness and high abundance.
   d. high species diversity.
   e. high abundance and high species richness.
2. Which of the following statements best represents the productivity hypothesis regarding species richness?
   a. The larger the area, the greater the number of species that will be found there.
   b. Temperate regions have a lower species richness due to the lack of time available for migration after the last Ice Age.
   c. The number of species in a particular community is directly related to the amount of available energy.
   d. As invertebrate productivity increases, species richness will increase.
   e. Species richness is not related to primary productivity.
3. Ecologists began to question Elton's link of increased stability to increased diversity because
   a. cultivated land undergoes few outbreaks of pests.
   b. highly disturbed areas have high numbers of species.
   c. pest outbreaks are caused by lack of long associations with natural enemies, not because they occur in simple systems.
   d. of all of the above.
4. Metagenomics is a field of study that
   a. is the analysis of a collection of genome sequences obtained from an environmental site.
   b. focuses on the microbial genomes contained in a community.
   c. compares the genomes of similar species in different communities.
   d. does none of the above.
   e. does both a and b.
5. Extreme fluctuations in species abundance
   a. lead to more diverse communities.
   b. are usually seen in early stages of community development.
   c. may increase the likelihood of extinction.
   d. have very little effect on species richness.
   e. are characteristic of stable communities.
6. Which of the following statements best represents the relationship between species diversity and community disturbance?
   a. Species diversity and community stability have no relationship.
   b. Communities with high levels of disturbance are more diverse.
   c. Communities with low levels of disturbance are more diverse.
   d. Communities with intermediate levels of disturbance are more diverse.
   e. Communities with intermediate levels of disturbance are less diverse.
7. The process of primary succession occurs
   a. around a recently erupted volcano.
   b. on a newly plowed field.
   c. on a hillside that has suffered a mudslide.
   d. on a recently flooded riverbank.
   e. on none of the above.
8. Early colonizers excluding subsequent colonists from moving into a community is referred to as
   a. facilitation.
   b. competitive exclusion.
   c. secondary succession.
   d. inhibition.
   e. natural selection.
9. A tree falls in a forest in spring and flowers germinate in the light gap. Following a tree fall in autumn, different species of flowers germinate in the light gap. This illustrates the principle of
   a. facilitation.
   b. tolerance.
   c. inhibition.
   d. primary succession.
   e. climax communities.
10. On which type(s) of island would you expect species richness to be greatest?
    a. small, near mainland
    b. small, distant from mainland
    c. large, near mainland
    d. large, distant from mainland
    e. Species richness is equal on all these types of islands.

Conceptual Questions

1. Re-examine Figure 58.4. How does the relationship shown relate to the discussion in Chapter 57 about the influence of secondary metabolites on herbivores?
2. List some possible ecological disturbances, their likely frequency in natural communities, and the severity of their effects.
3.  A principle of biology is that *biology is an experimental science*. In the nutrient-poor heathlands of Europe, scotch heather (*Calluna vulgaris*) and cross-leaved heath (*Erica tetralix*) are gradually replaced by variegated purple moor grass (*Molinia caerulea*) and wavy hair grass (*Deschampsia flexuosa*). Adding *Calluna* litter or nitrogen fertilizer speeds up this process. Explain this phenomenon, and state which mechanism of succession is supported.

Collaborative Questions

1. Distinguish between the time hypothesis, area hypothesis, and productivity hypothesis as explanations for the latitudinal gradient in species richness.
2. Calculate the species diversity of the following four communities. Which community has the highest diversity? What is the maximum diversity each community could have?

	Relative abundance of species				
Community	Species 1	Species 2	Species 3	H_S	Maximum possible diversity
1	90	10	—		
2	50	50	—		
3	80	10	10		
4	33.3	33.3	33.3

59.3 Biogeochemical Cycles
Summary of Key Concepts
Assess and Discuss

Ecosystem Ecology

59

Mandara Lake Oasis, Libya, an example of a large-scale ecosystem.

Familiar backyard earthworms are known for their ability to convert organic matter such as dead leaves into rich humus, improving soil fertility. However, earthworms are not native everywhere. North American glaciations exterminated earthworms from hardwood forests in Wisconsin and Minnesota some 11,000 to 14,000 years ago. In the absence of earthworms to break up litter into small pieces, slower acting fungi and bacteria were the main decomposers. A thick forest floor formed, and carbon built up in the soil. Earthworms from Europe and Asia initially were introduced into Wisconsin and Minnesota by European settlers and have continued to be transported to the area through a range of human activities, including the dumping of fishing bait. Organisms that are beneficial in one location can be destructive when introduced to another, however, and earthworms are no exception. In northern forests, the worms accelerate the cycling of nutrients through the soil, drastically altering the structure of the forest floor soil and releasing soil carbon into the atmosphere. According to Cindy Hale, an American biologist who has been studying the effect of earthworms on northern hardwood forests, "They have a cascading effect on plants, animals, and soil organisms. And we know they're causing significant damage to some forests. Their effect could be really profound."

The term **ecosystem** was coined in 1935 by the British plant ecologist A. G. Tansley to describe the system formed by the interaction between a community of organisms and its physical environment. **Ecosystem ecology** deals with the flow of energy and cycling of chemical elements within an ecosystem. Like the concept of a community, the ecosystem concept can be applied at any scale. A small pond inhabited by protozoa and insect larvae is an ecosystem, and an oasis with its plants, frogs, fishes, and birds constitutes another. Most ecosystems cannot be regarded as having definite boundaries. Even in a clearly defined pond ecosystem, species may be moving in and out (**Figure 59.1**). Nevertheless, studying ecosystem ecology allows us to use the common currency of energy and chemicals to compare the functions between and within ecosystems.

In investigating the dynamics of an ecosystem, at least three major constituents can be measured: flow of energy, production

Figure 59.1 A small ecosystem. Even in this pond ecosystem, frogs or other species such as birds may move in and out, importing or exporting nutrients and energy with them.

of biomass, and cycling of elements through the ecosystem. We begin the chapter by exploring **energy flow**, the movement of energy through an ecosystem. Examining energy flow mainly entails documenting the complex networks of feeding relationships and measuring the efficiency of energy transfer between organisms in an ecosystem. Next, we will focus on the measurement of **biomass**, the total mass of living matter in a given area, usually measured in grams or kilograms per square meter. We will examine the amount of biomass produced through photosynthesis, termed primary production, and the amount of biomass produced by the organisms that are the consumers of primary production. In the last section, we will examine **biogeochemical cycles**, the movement of chemicals through ecosystems, and explore the cycling of elements, such as phosphorus, carbon, and nitrogen, and the effects that human activities are having on these ecosystem-wide processes.

59.1 Food Webs and Energy Flow

Learning Outcomes:

1. Distinguish between autotrophs and heterotrophs and among primary, secondary, and tertiary consumers.
2. **SciSKILLS** » Use two ways to calculate the efficiency of consumers as energy transformers.
3. List and describe the different types of ecological pyramids.
4. Explain how the process of biomagnification can occur at higher trophic levels.

Most organisms either make their own food using energy from sunlight or feed on other organisms. Simple feeding relationships between organisms can be characterized by an unbranched **food chain**, a linear depiction of energy flow, with each organism feeding on and deriving energy from the preceding organism. Each feeding level in the chain is called a **trophic level** (from the Greek *trophos*, meaning feeder), and different species feed at different levels. In a food-chain diagram, an arrow connects each trophic level with the one above it (**Figure 59.2**).

In this section, we will consider the flow of energy in a food chain and examine a food web, a more complex model of interconnected food chains. We will then explore two of the most important features of food webs—chain length and the pyramid of numbers—and learn how the passage of nutrients through food webs can result in the accumulation of harmful chemicals in the tissues of organisms at higher trophic levels.

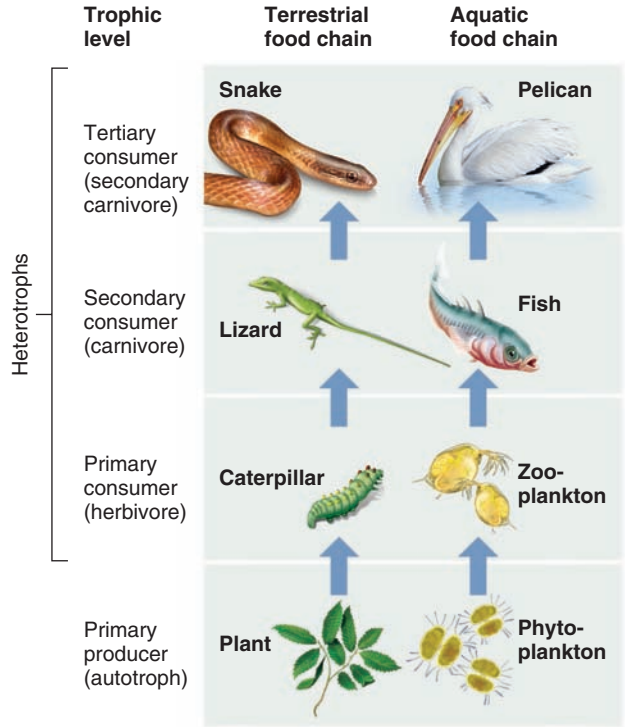

Figure 59.2 Food chains. Two examples of the flow of food energy up the trophic levels: a terrestrial food chain and an aquatic food chain.

BioConnections: In these two food chains, plants and protists (phytoplankton) are the producers. Look back at Section 27.5. What other organisms are producers and can also support food chains?

The Main Trophic Levels Within Food Chains Consist of Primary Producers, Primary Consumers, and Secondary Consumers

Food chains typically consist of organisms that obtain energy in different ways. **Autotrophs** harvest light or chemical energy and store that energy in carbon compounds. Most autotrophs, including plants, algae, and photosynthetic bacteria, use sunlight for this process. These organisms, called **producers**, form the base of the food chain. They produce the energy-rich organic molecules on which nearly all other organisms depend.

Organisms in trophic levels above the primary producers are termed **heterotrophs**. These organisms must consume organic molecules from their environment to sustain life and thus receive their nutrition by feeding on other organisms. Organisms that obtain their food from primary producers are termed **primary consumers** and include most protists, most animals, and even some plants such as mistletoe, which is parasitic on other plants. Animals that eat plants are also called **herbivores**. Organisms that eat primary consumers are **secondary consumers**. Animals that eat other animals are also called **carnivores** (from the Latin *carn*, meaning flesh). Organisms that feed on secondary consumers are **tertiary consumers**, and so on. Thus, energy enters a food chain through producers, via photosynthesis, and is passed up the food chain to primary, secondary, and tertiary consumers (see Figure 59.2).

At each trophic level, many organisms die before they are eaten. Much energy from the first trophic level, such as the plants, goes

unconsumed by herbivores. Instead, unconsumed plants die and decompose in place. This material, along with dead remains of animals and waste products, is called **detritus**. Consumers that get their energy from detritus are called **detritivores**. Some detritivores, which do not ingest their food but live by absorbing it on a molecular scale, are known as decomposers (**Figure 59.3**). In terrestrial systems,

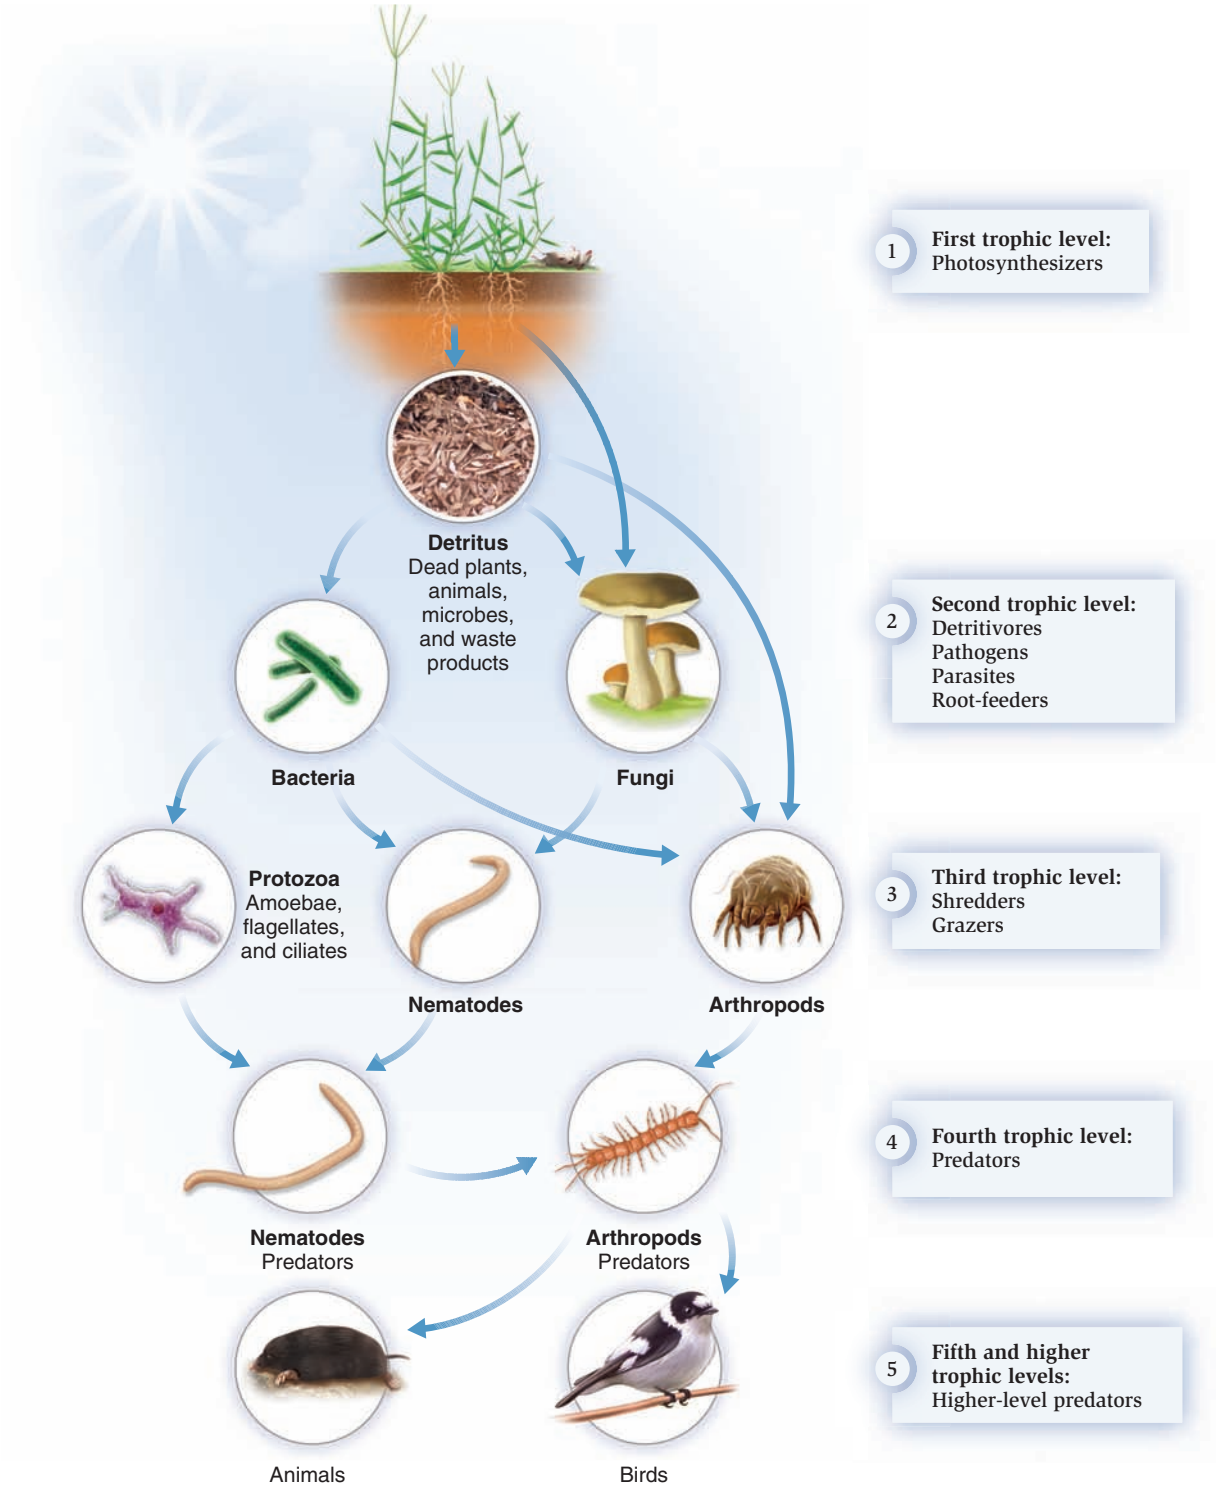

Figure 59.3 A food chain based on detritus. Many dead plants and animals are eaten by a variety of organisms. Here, bacteria and fungi feed on rotting plant material. These may, in turn, support a variety of predators, including centipedes or larger predators such as mammals and birds, which will also feed on the animal carcass.

Concept Check: *At which trophic level do detritivores feed?*

BioConnections: *Name two fungal phyla that are active in decomposition. (Hint: Refer back to Table 31.1.)*

detritivores probably carry out 80–90% of the consumption of plant matter, with different species working in concert to extract most of the energy. Detritivores may, in turn, support a community of predators that feed on them. As noted at the beginning of the chapter, changes in the detritivore community can lead to changes in nutrient cycling.

In Most Food Webs, Chain Lengths Are Short

In nature, the branching of food chains occurs widely. For example, many different herbivore species may feed on the same plant species. Also, each species of herbivore may feed on several different plant species. Such branching of food chains also occurs at other trophic levels. For instance, on the African savanna, cheetahs, lions, and hyenas all eat a variety of prey, including wildebeest, impala, and Thompson's gazelle. These, in turn, eat a variety of trees and grasses. It is more correct, then, to draw relationships between these plants and animals not as a simple chain but as a **food web**, a complex model of interconnected food chains in which there are multiple links among species (**Figure 59.4**).

Let's examine some of the characteristics of food webs in more detail. The concept of chain length refers to the number of links between the trophic levels involved. For example, if a lion feeds on a zebra, and a zebra feeds on grass, the chain length is two. In many food webs, chain lengths tend to be short, usually fewer than six levels, even including parasites and detritivores. The main reason they are short arises from the laws of chemistry and physics, discussed in Chapters 2 and 6. The second law of thermodynamics states that energy conversions are never 100% efficient. In any transfer process, some useful energy, which can do work, is lost, often in the form of heat. This decreases the amount of available energy at higher trophic levels. We can construct energy budgets for food webs that trace energy flow from green plants to tertiary consumers (and if needed beyond) (**Figure 59.5**). In each trophic level, some energy is lost to maintenance, for example, to maintain body temperature. Because energy transfer between trophic levels is not 100% efficient, energy is also lost in the passage from one trophic level to another.

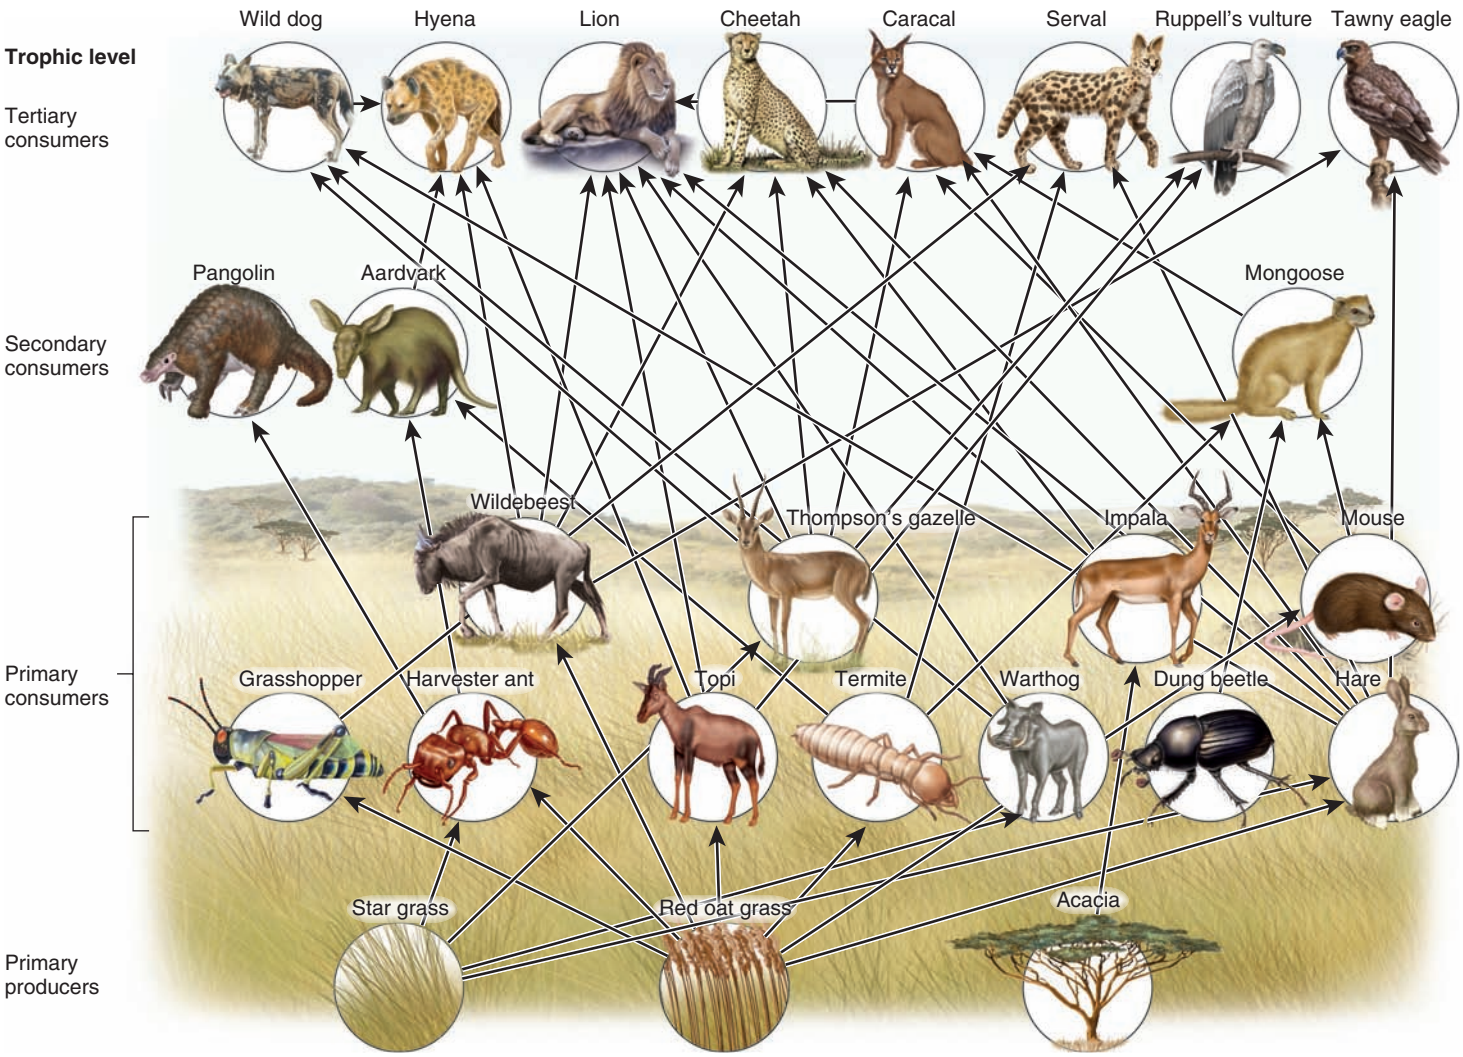

Figure 59.4 A food web from an African savanna ecosystem. Each trophic level is occupied by different species. Generally, each species feeds on, or is fed on by, more than one species.

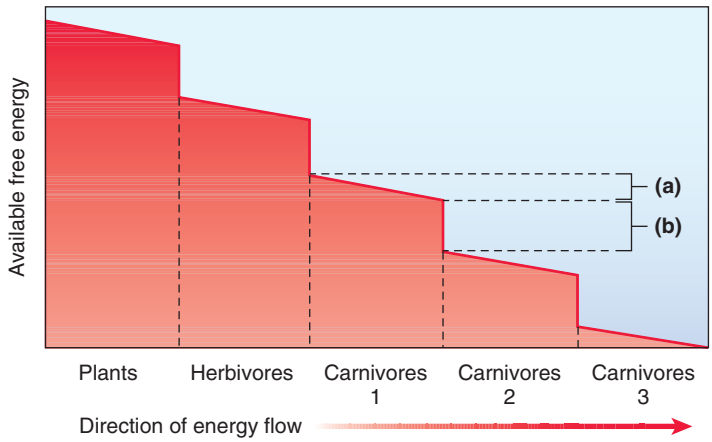

Figure 59.5 **Energy flow through a food web.** In this food web there are five trophic levels and four links between the trophic levels. **(a)** Energy lost as heat in a single trophic level. **(b)** Energy lost in the passage from one trophic level to another.

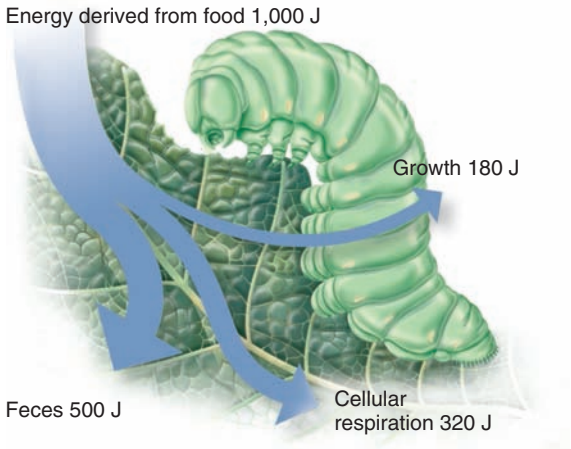
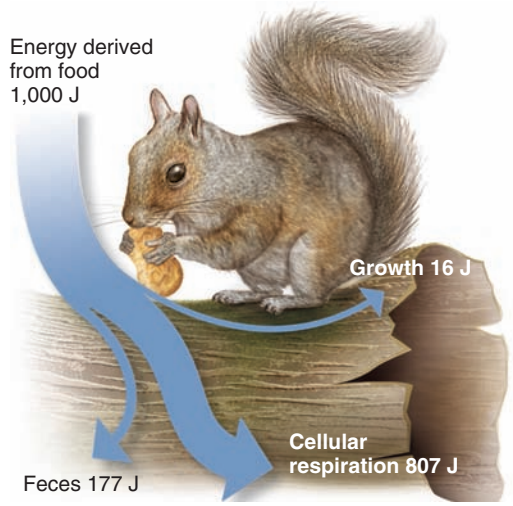
BIOLOGY PRINCIPLE **Living organisms use energy.** Within trophic levels, energy is lost to maintenance, and between trophic levels, energy is lost to imperfect efficiency of transfer.



As described next, two ways that ecologists use to evaluate the efficiency of consumers as energy transformers are production efficiency and trophic-level transfer efficiency.

Production Efficiency **Production efficiency** is defined as the percentage of energy assimilated by an organism that becomes incorporated into new biomass.



$$\text{Production efficiency} = \frac{\text{Net productivity}}{\text{Assimilation}} \times 100$$

Here, net productivity is the energy, stored in biomass, that has accumulated over a given time span, and assimilation is the total amount of energy taken in by an organism over the same time span. Invertebrates generally have high production efficiencies that average about 10–40% (**Figure 59.6a**). Microorganisms also have relatively high production efficiencies. Vertebrates tend to have lower production efficiencies than invertebrates, because they devote more energy to sustaining their metabolism than to new biomass production. Even within vertebrates, much variation occurs. Fishes, which are ectotherms, typically have production efficiencies of around 10%, and birds and mammals, which are endotherms, have production efficiencies in the range of 1–2% (**Figure 59.6b**). In large part, the difference reflects the energy cost of maintaining a constant body temperature. Production efficiencies are higher in young animals, which are rapidly accruing biomass, than in older animals, which are not. This is the main reason behind the practice of harvesting young animals for meat, at about the time when they first attain adult mass.

One consequence of differing production efficiencies is that sparsely vegetated deserts can support populations of ectotherms such as snakes and lizards, whereas mammals might easily starve. The largest living lizard known, the Komodo dragon, eats the equivalent of its own weight every 2 months, whereas a cheetah consumes approximately four times its own weight in the same period.

(a) High production efficiency of an invertebrate

(b) Low production efficiency of a vertebrate

Figure 59.6 **Production efficiencies.** **(a)** This caterpillar, an invertebrate, chews leaves to obtain its energy. If a mouthful of food contains 1,000 joules (J) of energy, about 320 J is used in cellular respiration to fuel metabolic processes (32%), and 500 J (50%) is lost in feces. As a result, about 180 J of the 500 g is assimilated to be converted into insect biomass, a production efficiency of 36%. **(b)** The production efficiency of this squirrel, a mammal, is much lower.

BIOLOGY PRINCIPLE **Living organisms maintain homeostasis.** For the squirrel, maintaining a constant body temperature reduces its production efficiency.

BIO TIPS **THE QUESTION** *What is the production efficiency of the squirrel in Figure 59.6b?*

TOPIC ***What topic in biology does this question address?*** The topic is the production efficiency of a consumer. More specifically, the question asks you to calculate the production efficiency of a squirrel.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From Figure 59.6b, you know that if a squirrel eats food that provides 1,000 J of energy, 177 J is lost in feces, 807 J is used in cellular

respiration, and 16 J is used in growth. From your understanding of the topic, you may recall that the production efficiency is calculated using this formula:

$$\text{Production efficiency} = \frac{\text{Net productivity}}{\text{Assimilation}} \times 100$$

PROBLEM-SOLVING STRATEGY ***Interpret data. Make a calculation.*** Insert the data given in the figure into the formula: Net productivity is the amount of energy used in growth, or 16 J. Assimilation is the energy used in growth plus the energy used in cellular respiration, or 807 J + 16 J = 823 J.

$$\text{Production efficiency} = \frac{16\ \text{J}}{823\ \text{J}} \times 100 = 1.9$$

ANSWER *The squirrels' production efficiency is 1.9%.*

Trophic-Level Transfer Efficiency The second measure of efficiency of consumers as energy transformers is **trophic-level transfer efficiency**, which is the amount of energy at one trophic level that is acquired by the trophic level above and incorporated into biomass. This provides a way of examining energy flow between trophic levels, not just in an individual species. Trophic-level transfer efficiency is calculated as follows:

$$\text{Trophic-level transfer efficiency} = \frac{\text{Production at trophic level } n}{\text{Production at trophic level } n-1} \times 100$$

For example, recall from Chapter 54 that zooplankton are minute drifting animal organisms that graze on microscopic photosynthetic organisms called phytoplankton. If a lake contained 14 g/m^2 of zooplankton (trophic level n) and 100 g/m^2 of phytoplankton production (trophic level $n - 1$), the trophic-level efficiency would be 14%. Trophic-level transfer efficiency tends to average around 10%, though there is much variation. Trophic-level transfer efficiency is generally low for two reasons. First, many organisms cannot digest all of their prey. They take only the easily digestible plant leaves or animal tissue such as muscles and guts, leaving the hard wood or energy-rich bones behind. Second, much of the energy assimilated by animals is used in maintenance, so most energy is lost from the system as heat. The 10% average transfer rate of energy from one trophic level to another also necessitates short food webs of no more than four or five levels. Relatively little energy is available for the higher levels.

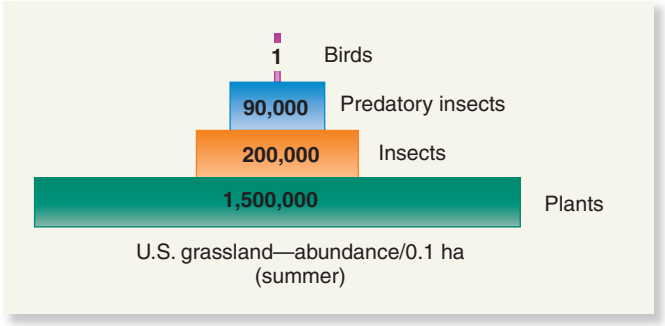
Ecological Pyramids Describe the Distribution of Numbers, Biomass, or Energy Between Trophic Levels

Trophic-level transfer efficiencies can be expressed in a graphical form called an ecological pyramid. One of the best-known pyramids, described by British ecologist Charles Elton in 1927, is the **pyramid of numbers**, in which the number of individuals decreases at each trophic level, with a large number of individuals at the base and fewer individuals at the top. Elton used a small pond as an example, in which the numbers of protozoa may run into the millions and those of *Daphnia*, their predators, number in the hundreds of thousands. Hundreds of beetle larvae may feed on *Daphnia*, and tens of fishes feed on the beetles. Many other examples of this type of pyramid are known. For example, in a grassland, there may be hundreds of individual plants per square meter, dozens of insects that feed on the plants, a few spiders feeding on the insects, and an occasional bird that feeds on the spiders (**Figure 59.7a**).

Ecologists have, however, discovered many exceptions to this pyramid. One single producer such as an oak tree can support hundreds of herbivorous beetles, caterpillars, and other primary consumers, which, in turn, may support thousands of predators. This is called an inverted pyramid of numbers (**Figure 59.7b**).

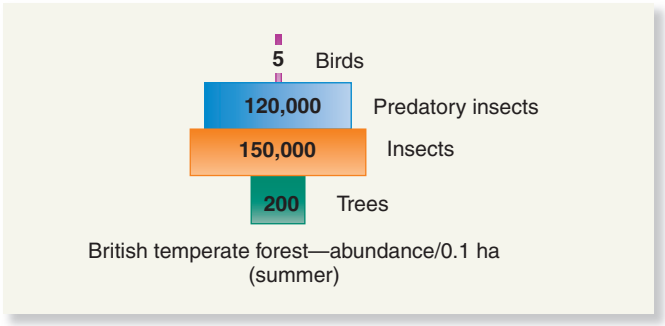
One way to reconcile this apparent exception is to weigh the organisms in each trophic level, creating a **pyramid of biomass**. For example, an oak tree weighs more than all its herbivores and predators combined. At the bottom of the pyramid is the **standing crop**, the total autotroph biomass in an ecosystem present at any one point in time.

Looking at the biomass at each trophic level rather than at numbers of organisms shows an upright pyramid. In 1957, American ecologist Howard Odum measured the pyramid of biomass for a freshwater ecosystem, Silver Springs, Florida (**Figure 59.7c**). Beds of eelgrass (genus *Sagittaria*) and attached algae make up most of the producers. Insects, snails, herbivorous fishes, and turtles eat the producers. Other fishes are the secondary and tertiary consumers. Odum also noted the presence of fungi and bacteria, which were involved in decomposition on all trophic levels.



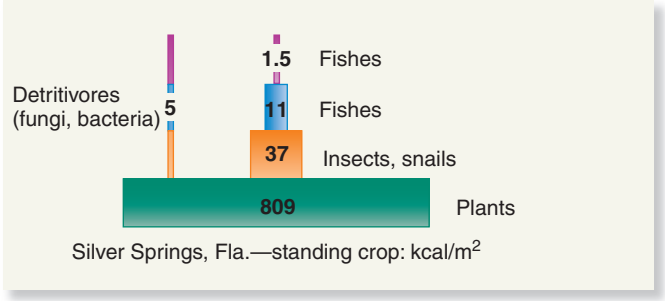
Even when biomass is used as the measure, inverted pyramids can still occur, albeit rarely. In some marine and lake systems, the biomass of phytoplankton supports a higher biomass of zooplankton (**Figure 59.7d**). This is possible because the rate of production of phytoplankton biomass is much higher than that of zooplankton, and the small phytoplankton standing crop processes large amounts of energy.

However, if the pyramid is expressed in terms of production rate, it is no longer inverted. A **pyramid of energy**, which shows the rate of energy production rather than standing crop, is never inverted (**Figure 59.7e**). The laws of thermodynamics ensure that the highest amounts of free energy are found at the lowest trophic levels. The energy pyramid for Silver Springs also shows that large amounts of energy pass through detritivores, despite their relatively small biomass.



Biomagnification Can Occur in Higher Trophic Levels

The tendency of certain chemicals to concentrate in higher trophic levels in food chains, a process called **biomagnification**, presents a problem for certain organisms. The passage of DDT in food chains provides a startling example.



Dichlorodiphenyltrichloroethane (DDT) was first synthesized by chemists in 1874. In 1939, its insecticidal properties were recognized by Paul Müller, a Swiss scientist who won the 1948 Nobel Prize in Physiology or Medicine for his discovery and subsequent research on the uses of the chemical. The first important application of DDT was in human health programs during and after World War II, particularly as a means of controlling mosquito-borne malaria; at that time, its

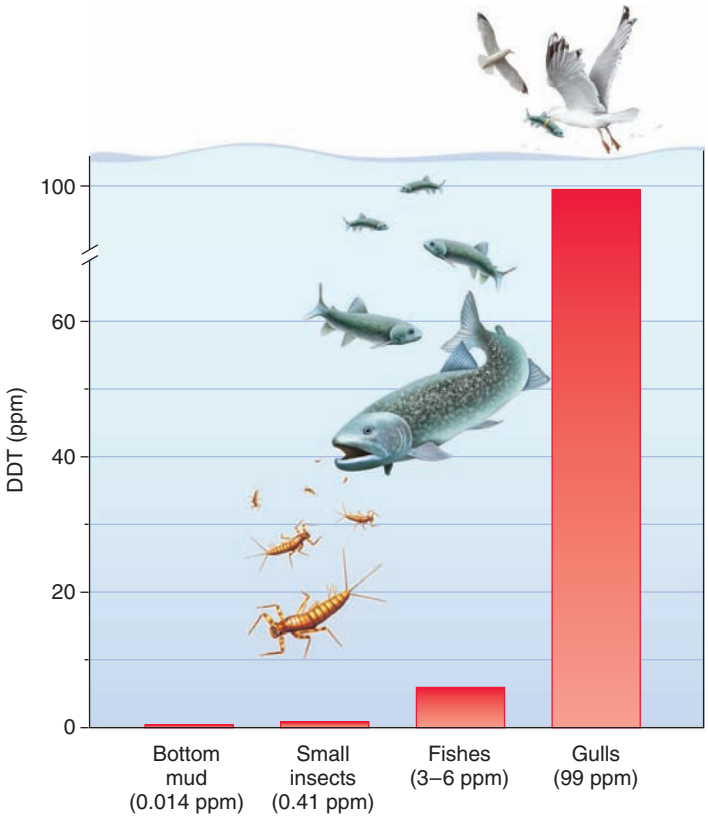
Note the large energy production of detritivores, despite their small biomass.

use in agriculture also began. The global production of DDT peaked in 1970, when 175 million kg of the insecticide was manufactured.

DDT has several chemical and physical properties that profoundly influence the nature of its ecological effect. First, DDT is persistent in the environment. It is not rapidly degraded to other, less toxic chemicals by microorganisms or by physical agents such as light and heat. The typical persistence in soil of DDT is about 10 years, which is two to three times longer than the persistence of most other insecticides. Another important characteristic of DDT is its low solubility in water and its high solubility in fats or lipids. In the environment, most lipids are present in living tissue. Therefore, because of its high lipid solubility, DDT tends to concentrate in biological tissues.

Because biomagnification occurs at each step of the food chain, organisms at higher trophic levels can accumulate very high concentrations of DDT in their lipids. A typical pattern of biomagnification is illustrated in **Figure 59.8**, which shows the relative amounts of DDT found in a Lake Michigan food chain. The highest concentration of the insecticide was found in gulls, tertiary consumers that feed on fishes, which are the secondary consumers that eat small insects. An unanticipated effect of DDT on bird species was its interference with the process of eggshell formation. The result was thin-shelled eggs that often broke under the weight of incubating birds (**Figure 59.9**). DDT was responsible for a dramatic decrease in the populations of many birds due to failed reproduction. Relatively high levels of the chemical were also found to be present in some game fishes, which became unfit for human consumption.

Because of growing awareness of the adverse effects of DDT, most industrialized countries, including the U.S., had banned the use of the chemical by the early 1970s. The good news is that following the outlawing of DDT, populations of the most severely affected bird species have recovered. However, had scientists initially possessed a more thorough knowledge of how DDT accumulated in food chains, some



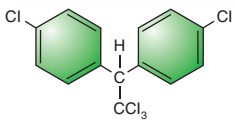


Figure 59.8 Biomagnification in a Lake Michigan food chain. The DDT tissue concentration in gulls, tertiary consumers, was about 240 times that in the small insects sharing the same ecosystem. The biomagnification of DDT causes its concentration in lipids to increase at each successive link in the food chain.

of the damage to the bird populations might have been prevented. Next, we see how scientists are taking advantage of the ability of some organisms to absorb and concentrate certain chemicals to help clean up the environment.

DDT (dichlorodiphenyltrichloroethane)
- Persists in environment
- High solubility in lipids
- Found in high concentrations at higher trophic levels

Genomes & Proteomes Connection

Using Genetically Engineered Plants to Remove Pollutants

Trichloroethylene, commonly known as TCE, has been commonly used as an industrial solvent and has become a widespread environmental contaminant. Forty percent of all abandoned hazardous waste sites are contaminated with TCE. Until recently, TCE was widely used in a range of applications, including as a dry cleaning solvent and anesthetic, and it continues to be used as a degreasing agent for metal parts. It is a human carcinogen and causes a range of neurological effects.

Scientists have been searching for safe ways to remove TCE and other toxic chemicals from hazardous waste sites. One approach, termed bioremediation, involves the use of plants that take up pollutants. After taking up the chemicals, the plants are harvested and the site replanted until pollutants have been reduced to environmentally safe levels. Recently, scientists have genetically engineered poplar trees to efficiently remove TCE from the environment. Gene products of mammalian cytochrome genes oxidize a range of compounds, including TCE. In a 2007 study, American ecologist Sharon Doty and colleagues incorporated the gene that produces cytochrome in rabbit livers into poplar trees. These genetically engineered trees were found to metabolize TCE and other pollutants nearly 100 times faster than unaltered poplars. If used in the field, the trees would be cut down before flowering so there would be no chance of pollination with wild relatives.

59.2 Biomass Production in Ecosystems

Learning Outcomes:

1. **SciSKILLS** » Be able to calculate biomass production.
2. Explain the different ways in which primary production is influenced in terrestrial and aquatic ecosystems.
3. Describe the factors that limit secondary production in ecosystems.

In this section, we will take a closer look at biomass production in ecosystems. Because the bulk of the Earth's biosphere, 99.9% by mass, consists of producers, when we measure ecosystem biomass production, we are primarily interested in plants, algae, or cyanobacteria. Because these photosynthetic organisms represent the first, or primary, trophic level, their production is called **gross primary production (GPP)**. Gross primary production is equivalent to the carbon fixed during photosynthesis. **Net primary production (NPP)** is GPP minus the energy used during cellular respiration (R) of photosynthetic organisms.

$$NPP = GPP - R$$

NPP is thus the amount of energy available to primary consumers. Unless otherwise noted, the term **primary production** refers to NPP.

Primary Production in Terrestrial Ecosystems Is Influenced by Water, Temperature, and Nutrient Availability

In terrestrial systems, water is a major determinant of primary production, and primary production shows an almost linear increase with annual precipitation, at least in arid regions. Likewise, temperature, which affects production primarily by slowing or accelerating plant metabolic rates, is also important. American ecologist Michael Rosenzweig noted that, on a logarithmic scale, the evapotranspiration rate could predict the aboveground primary production with good accuracy in North America (**Figure 59.10**). Recall from Chapter 58 that the evapotranspiration rate measures the amount of water entering the atmosphere through the processes of evaporation from the soil and transpiration of plants, so it is a measure of both temperature and available water. For example, a desert will have a low evapotranspiration rate because water availability is low despite high temperature. The evapotranspiration rate is maximized when both temperature and moisture are at high levels, as in tropical rain forests.

A lack of **nutrients**, key elements in usable form, particularly nitrogen and phosphorus, can also limit primary production in terrestrial ecosystems, as farmers know only too well. Fertilizers are commonly used to boost the production of annual crops. In 1984, Susan Cargill and Robert Jefferies showed how a lack of both nitrogen and phosphorus was limiting to salt marsh sedges and grasses in subarctic conditions in Hudson Bay, Canada (**Figure 59.11**). Of the two nutrients, nitrogen was the **limiting factor**, the one in the shortest supply for growth; without it, the addition of phosphorus did not increase production. However, once

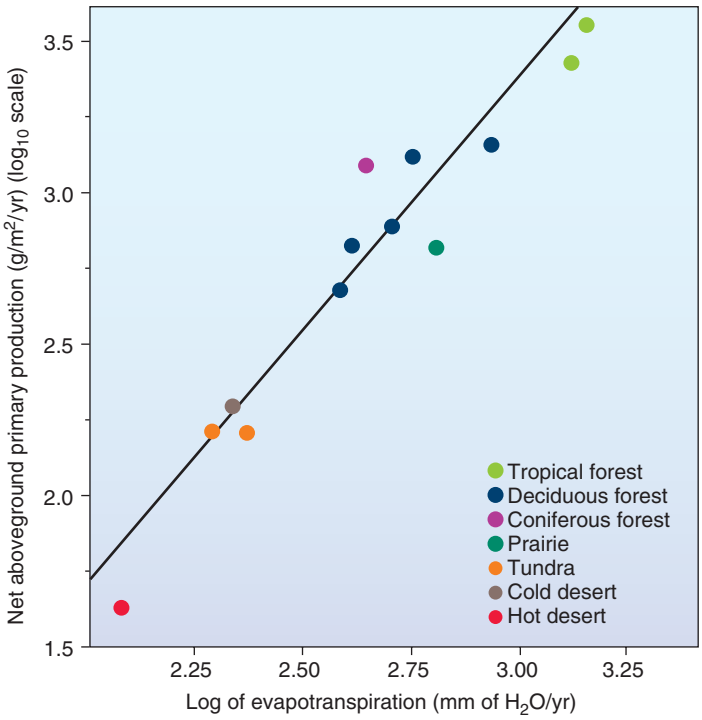

Figure 59.10 Positive correlation between the evapotranspiration rate and primary production. The evapotranspiration rate is a measure of both temperature and available water. Warm, humid environments are ideal for plant growth. Dots represent different ecosystems.

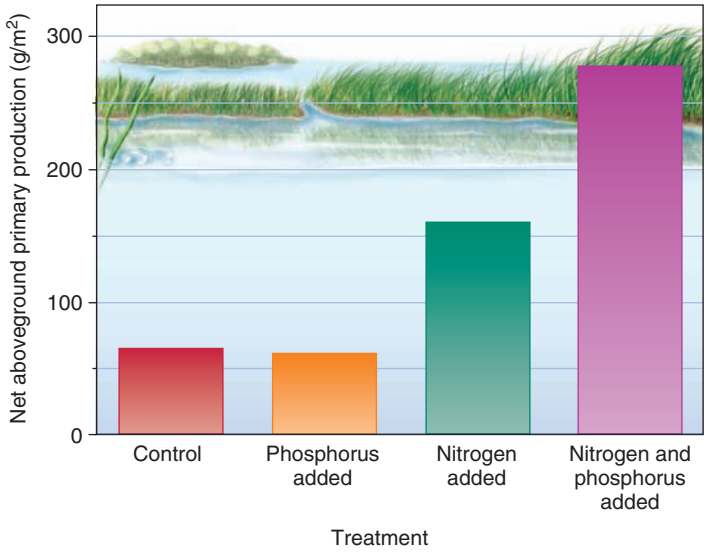

Figure 59.11 Limitation of primary production by nitrogen and phosphorus. Net aboveground primary production of a salt marsh sedge (*Carex subspathacea*) in response to nutrient addition. Nitrogen is the limiting factor. After nitrogen is added, phosphorus becomes the limiting factor.

nitrogen was added and was no longer limiting, phosphorus became the limiting factor. The addition of nitrogen and phosphorus together increased production the most. This result supports a principle known as **Liebig's law of the minimum**, named for Justus von Liebig, a 19th-century German chemist, which states that species biomass or abundance is limited by the scarcest factor. This factor can change, as the Hudson Bay experiment showed. When sufficient nitrogen is available, phosphorus becomes the limiting factor. Once phosphorus becomes abundant, then productivity will be limited by another nutrient.

Primary Production in Aquatic Ecosystems Is Limited Mainly by Light and Nutrient Availability

Of the factors limiting primary production in aquatic ecosystems, the most important are available light and available nutrients. Light is particularly likely to be in short supply because water readily absorbs light. At a depth of 1 m, more than half the solar radiation has been absorbed. By 20 m, only 5–10% of the radiation remains. The decrease in light is what limits the depth of algal growth.

The most important nutrients affecting primary production in aquatic systems are nitrogen and phosphorus, because they occur in very low concentrations. Whereas soil contains about 0.5% nitrogen, seawater contains only 0.00005% nitrogen. Enrichment of the aquatic environment by the addition of nitrogen and phosphorus occurs naturally in areas of upwellings, where cold, deep, nutrient-rich water containing sediment from the ocean floor is brought to the surface by strong currents, resulting in very productive ecosystems and plentiful fishes. Some of the largest areas of upwelling occur in the Antarctic and along the coasts of Peru and California. However, as noted in Section 37.2, too much nutrient supply can be harmful to aquatic systems, resulting in large, unchecked growths of algae called algal blooms. When the algae die, they are consumed by bacteria that, as they respire, deplete

the surrounding water of oxygen, causing dead zones with little oxygen to support other aquatic life. Such dead zones are prominent along coastal areas where fertilizer-rich rivers discharge into the oceans.

Primary Production Is Greatest in Areas of Abundant Warmth and Moisture

Knowing which factors limit primary production helps ecologists understand why the mean net primary production varies across the different biomes on Earth. Modern methods of estimating productivity use orbiting satellites to measure differences in the electromagnetic radiation reflected back from the vegetation of different ecosystems on Earth (**Figure 59.12**). When we look at the oceans, bright greens, yellows, and reds indicate high chlorophyll concentrations. Some of the highest marine chlorophyll concentrations occur at continental margins, where river nutrients pour into the oceans. Upwellings along coasts also bring nutrient-rich water to the surface. Northern oceans, and to a lesser extent southern oceans, are also very productive because seasonal temperature variations allow vertical mixing of all layers, bringing nutrient-rich water to the surface. In the spring, the high light and nutrients permit rapid phytoplankton growth until the nutrients are all used up. Many other marine areas, including tropical oceans, are highly unproductive.

Over land, productivity is measured as the normalized difference vegetation index, or NDVI, which is an estimate of the photosynthetically absorbed radiation over land surfaces. Plants absorb much visible light but reflect light at near-infrared wavelengths. This difference in absorption allows scientists to estimate photosynthetic rates and hence primary production. The productivity of forests from all parts of the world, from the tropics to northern temperate areas, is similar, but production is often higher in temperate than in tropical habitats. This matches the pattern of productivity observed in the oceans. Although tropical forests enjoy warm temperatures and abundant rainfall, such conditions weather soils rapidly. Tropical soils are low in available forms of most plant nutrients because of loss through leaching. In contrast, temperate soils tend to have much greater concentrations of essential nutrients because of lower rates of nutrient loss and more frequent grinding of fresh minerals by the cycles of continental glaciations over the past 3 million years. Prairies and savannas are also highly productive because their plant biomass usually dies and decomposes each year, returning a portion of the nutrients to the soil, and temperatures and rainfall are not limiting. Deserts and tundra have low productivity because of lack of water and low temperatures, respectively. Wetlands tend to be extremely productive, primarily because water is not limiting and nutrient levels are high.

Secondary Production Is Generally Limited by Available Primary Production

What factors control **secondary production**—the productivity of herbivores, carnivores, and detritivores? This is a complex question, but it is generally thought to be limited largely by available primary production. A strong relationship exists between primary production in a variety of biomes and the biomass of herbivores (**Figure 59.13**). This means that more plant biomass, and thus more primary production, leads to an increased biomass of consumers. This is not such a trivial answer as might be assumed; for example, secondary production could be limited by the availability of a particular nutrient or by the presence of natural enemies.

As noted before, trophic-level transfer efficiency averages about 10%. Thus, after one link in the food web, only 1/10 of the energy captured by plants is transferred to herbivores, and after two links in the food web, only 1/100 of the energy fixed by plants goes to carnivores. Thus, secondary production is generally much smaller than primary production. In 1962, American ecologist John Teal examined energy flow in a Georgia salt marsh (**Figure 59.14**). In salt marshes, most of the energy from the Sun goes to two types of organisms: *Spartina* plants and marine algae. The *Spartina* plants are rooted in the ground, whereas the algae float on the water surface or live on the mud or on *Spartina* leaves at low tide. These photosynthetic organisms absorb about 6% of the sunlight. Most of the plant energy, 77.6%, is used in plant and algal cellular respiration. Of the energy that is accumulated in plant biomass, 22.4%, most dies in place and rots on the muddy ground, to be consumed by bacteria. Bacteria are the major detritivores in this system, followed distantly by nematodes and crabs, which feed on tiny food particles as they sift through the mud. Some of this dead material is also removed from the system (exported) by the tide. The herbivores take very little of the plant production, around 0.6%, eating only a small proportion of the *Spartina* and none of the algae. A fraction of

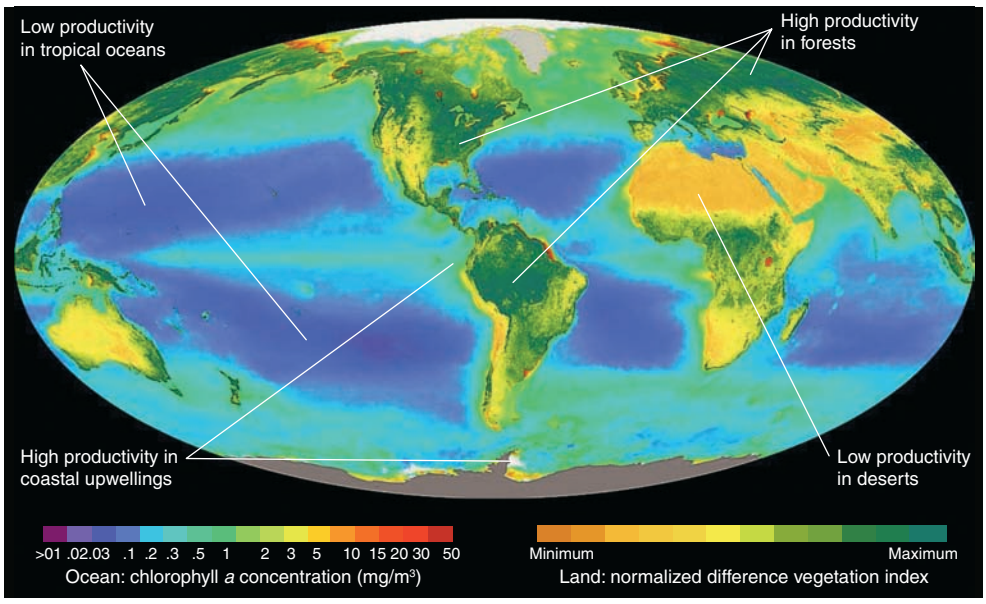

Figure 59.12 Primary productivity measured by satellite imagery. Ocean chlorophyll concentrations and the normalized difference vegetation index (NDVI) on land provide good data on marine and terrestrial productivity, respectively.

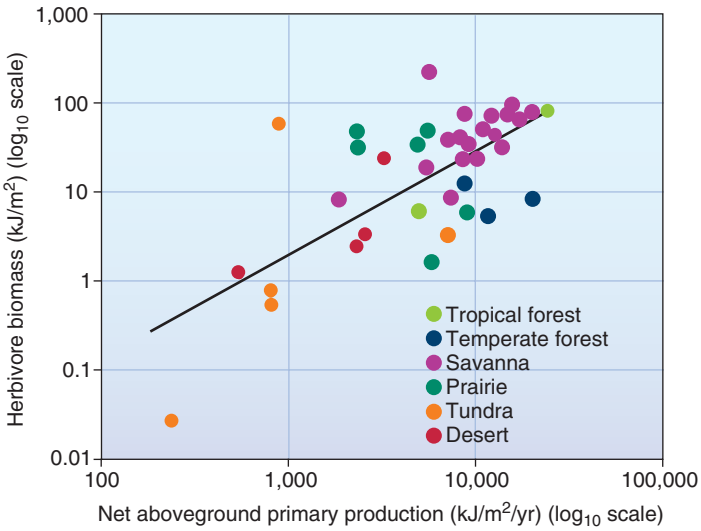

Figure 59.13 A positive correlation between herbivore biomass and net aboveground primary production. These data are taken from a variety of case studies from different biomes. Herbivore biomass can be considered an indicator of secondary production.

Concept Check: What does this relationship imply about the effects of plant secondary metabolites, many of which taste bad and some of which are toxic, on secondary production?

herbivore biomass is then consumed by spiders. Overall, if we view the species in ecosystems as transformers of energy, then plants and algae are by far the most important organisms on the planet, bacteria are next, and animals are a distant third.

59.3 Biogeochemical Cycles

Learning Outcomes:

1. Describe the phosphorus cycle, and explain the causes of eutrophication.
2. Outline the steps of the carbon cycle, and identify the environmental effects of elevated atmospheric concentrations of CO_2.
3. List the five main steps of the nitrogen cycle, and describe the human influences on it.
4. Describe the processes of the water cycle, and explain how they are affected by humans.

As we have seen, a unit of energy moves through an ecosystem only once, passing through the trophic levels of a food web from producer to consumer and dissipating as heat. In contrast, chemical elements such as carbon or nitrogen are recycled, moving from the physical environment to organisms and back to the environment, where the cycle begins again. Whereas an ecosystem constantly receives energy in the form of light, chemical elements are available in limited amounts and are recycled. Because the movements of chemicals through ecosystems involve biological, geological, and chemical transport mechanisms, they are termed **biogeochemical cycles**. Biological mechanisms involve the absorption of chemicals by living organisms and their subsequent release back into the environment. Geological mechanisms include weathering and erosion of rocks and transporting of elements by surface and subsurface drainage. Chemical transport mechanisms include dissolved matter in rain and snow, atmospheric gases, and dust blown by the wind.

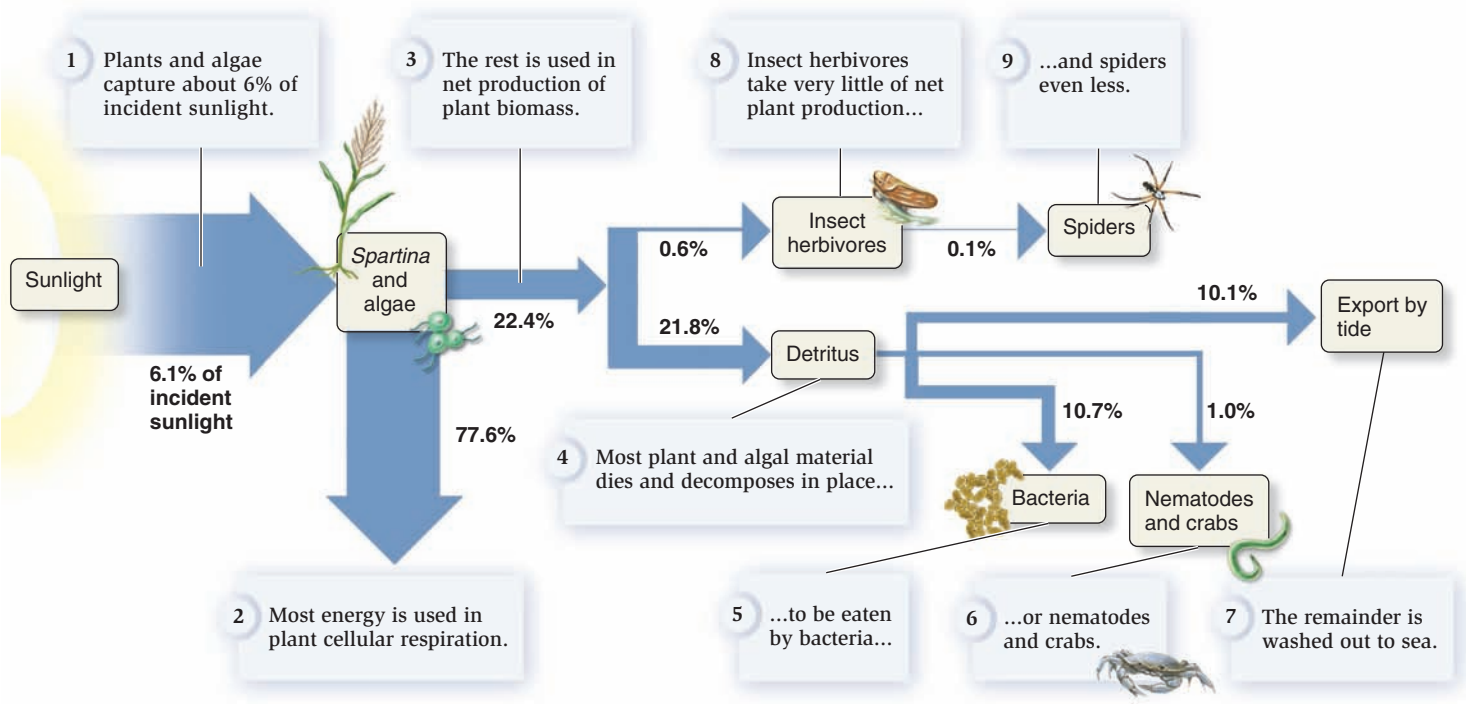

Figure 59.14 Energy-flow diagram for a Georgia salt marsh. Numbers represent the percentage of gross primary production that flows into different trophic levels or is used in plant respiration.

In addition to the basic building blocks of hydrogen, oxygen, and carbon, the elements required in the greatest amounts by living organisms are phosphorus and nitrogen. In this section, we will look closely at the cycles of these nutrients. These cycles can be divided into two broad types: (1) local cycles, such as the phosphorus cycle, which involve elements with no atmospheric mechanism for long-distance transfer; and (2) global cycles, which involve an interchange between the atmosphere and the ecosystem. Global nutrient cycles, such as the carbon and nitrogen cycles, unite the Earth and its living organisms into one giant interconnected ecosystem called the **biosphere**. Most biogeochemical cycles involve assimilation of nutrients from the soil by plants and animals and decomposition of plants and animals, which releases nutrients back into the soil. A generalized and simplified biogeochemical cycle involves both biotic and abiotic components (**Figure 59.15**). In our discussion of biogeochemical cycles, we will take a particular interest in the alteration of these cycles through human activities, such as the burning of fossil fuels, that increase nutrient inputs.

Phosphorus Cycles Locally Between Geological and Biological Components of Ecosystems

All living organisms require phosphorus, which becomes incorporated into ATP, the compound that provides energy for most metabolic processes. Phosphorus is a key component of other biological molecules such as DNA and RNA, and it is also an essential mineral that helps maintain a strong, healthy skeleton in many animals.

The phosphorus cycle is a relatively simple cycle (**Figure 59.16**). Phosphorus has no gaseous phase and thus no atmospheric component; that is, it is not moved by wind or rain. As a result, phosphorus tends to cycle only locally. The Earth's crust is the main storehouse for this element. Weathering and erosion of rocks release phosphorus into the soil. Plants have the metabolic means to absorb dissolved ionized forms of phosphorus, the most important of which occurs as phosphate (HPO_4^{2-} or $H_2PO_4^-$). Herbivores obtain their phosphorus only from eating plants, and carnivores obtain it by eating herbivores. When plants and animals excrete wastes or die, the phosphorus becomes available to detritivores, which release it back to the soil.

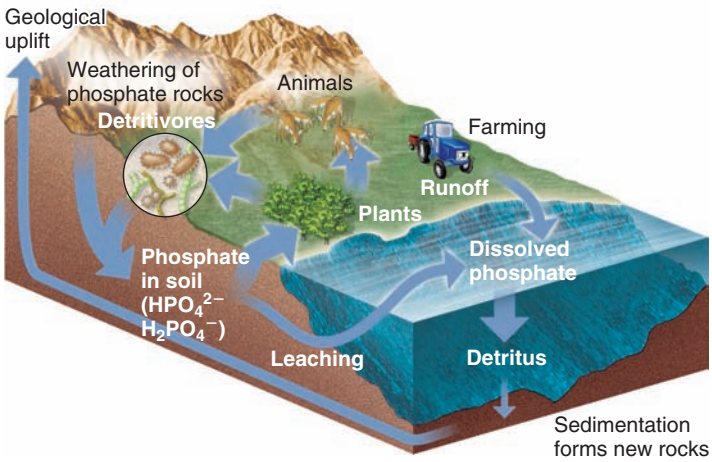

Figure 59.16 The phosphorus cycle. Unlike other major biogeochemical cycles, the phosphorus cycle does not have an atmospheric component and thus occurs only locally. The widths of the lines indicate the relative contribution of each process to the cycle.

Leaching and runoff eventually wash much phosphate into aquatic systems, where plants and algae utilize it. Phosphate that is not taken up into the food chain settles to the ocean floor or lake bottom, forming sedimentary rock. Phosphorus can remain locked in sedimentary rock for millions of years, becoming available again through the geological process of uplift.

Human Influences on the Phosphorus Cycle Plants can take up phosphate so rapidly and efficiently that they often reduce soil concentrations of phosphorus to extremely low levels, so phosphorus becomes a limiting factor (see Figure 59.11). As more phosphorus is added to an aquatic ecosystem, the production of algae and aquatic plants increases. In a pivotal 1974 study, Canadian biologist David Schindler showed that an overabundance of phosphorus caused the rapid growth of algae and plants in an experimental lake in Canada (**Figure 59.17**). What is the consequence of the rapid growth of

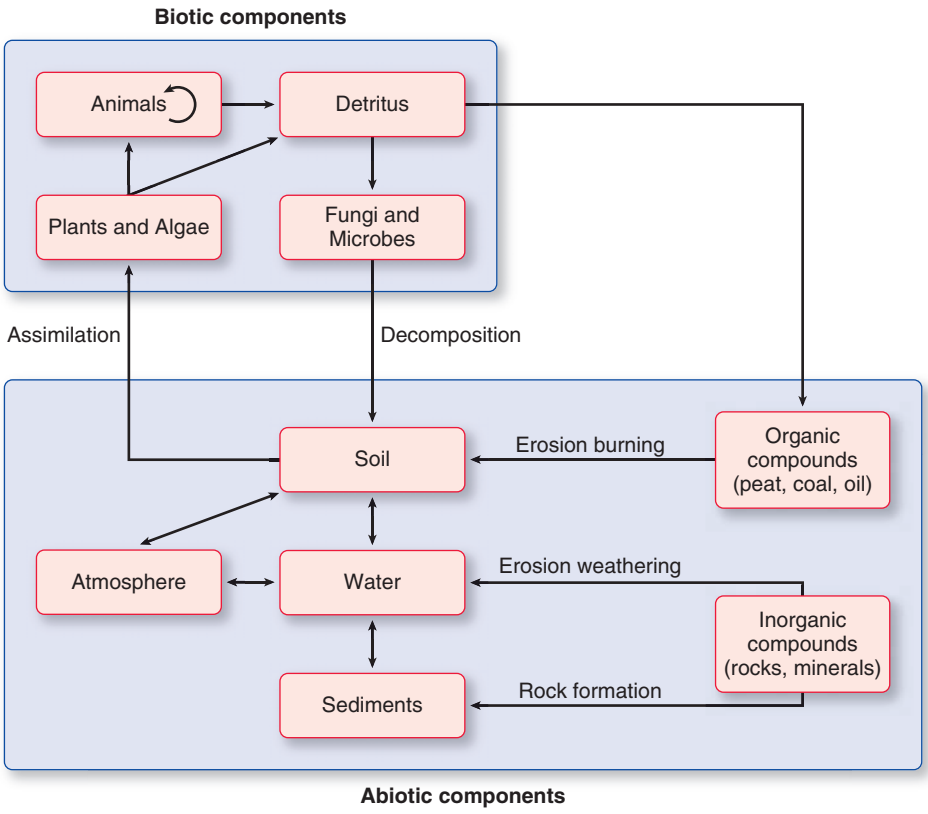

Figure 59.15 A generalized and simplified model of a biogeochemical cycle.

BIOLOGY PRINCIPLE Living organisms interact with their environment. The biomass of organisms is affected by the availability of nutrients in the soil.

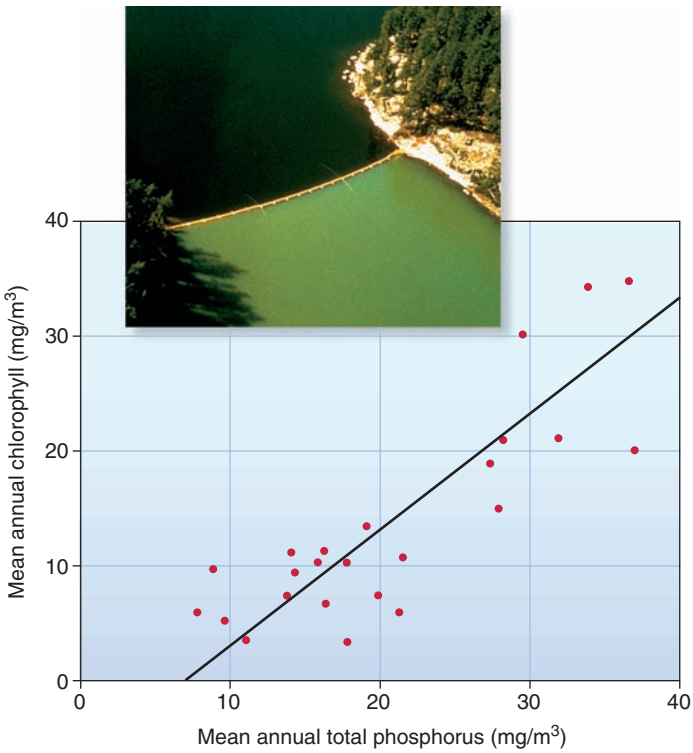

Figure 59.17 The relationship between primary production and total phosphorus concentration. As shown in this graph, primary production (measured by chlorophyll concentration) increases linearly with an increase in phosphorus. Each dot represents a different lake. The aerial photograph shows the contrast in water quality of two basins of an experimental lake in Canada separated by a plastic curtain. Carbon and nitrogen were added to the upper basin, and carbon, nitrogen, and phosphorus were added to the lower basin. The bright green color is from a surface film of algae that resulted from the added phosphorus.

algae and plants? When the algae and plants die, they sink to the bottom, where bacteria decompose them and consume the dissolved oxygen in the water. Dissolved oxygen concentrations can drop too low for fishes to breathe, killing them. The process by which elevated nutrient levels lead to an overgrowth of algae and the subsequent depletion of water oxygen concentrations is known as **eutrophication**. Cultural eutrophication refers to the enrichment of water with nutrients derived from human activities, such as fertilizer use and sewage dumping.

Lake Erie became eutrophic in the 1960s due to the runoff of fertilizer rich in phosphorus from farms and to the industrial and domestic pollutants released from the many cities along its shores. Fish species such as whitefish and lake trout became severely depleted. Based on research such as Schindler's that showed the dramatic effect of phosphorus on a lake system, the U.S. and Canada teamed together to reduce the levels of discharge by 80%, primarily through eliminating phosphorus in laundry detergents and maintaining strict controls on the phosphorus content of wastewater from sewage treatment plants. Fortunately, lake systems have great potential for recovery after phosphorous inputs are reduced, and Lake Erie has experienced fewer algal blooms, clearer water, and a restoration of fish populations.

Carbon Cycles Among Biological, Geological, and Atmospheric Pools

The movement of carbon from the atmosphere into organisms and back again is known as the carbon cycle (**Figure 59.18**). Carbon dioxide (CO_2) is present in the atmosphere at a level of about 400 parts per million (ppm), or about 0.04%. Autotrophs, primarily plants, algae, and cyanobacteria, acquire CO_2 from the atmosphere or water and incorporate it into the organic matter of their own biomass via photosynthesis. Each year, plants, algae, and cyanobacteria remove approximately one-seventh of the CO_2 from the atmosphere. At the same time, respiration and the decomposition of plants recycle a similar amount of carbon back into the atmosphere as CO_2. Much material from primary producers is also transformed into deposits of coal, gas, and oil, which are collectively known as **fossil fuels**. Herbivores can return some CO_2 to the atmosphere, eating plants and breathing out CO_2, but the amount flowing through this part of the cycle is minimal. Chemical processes such as diffusion and absorption of CO_2 into and out of oceans also contribute to changes in atmospheric CO_2.

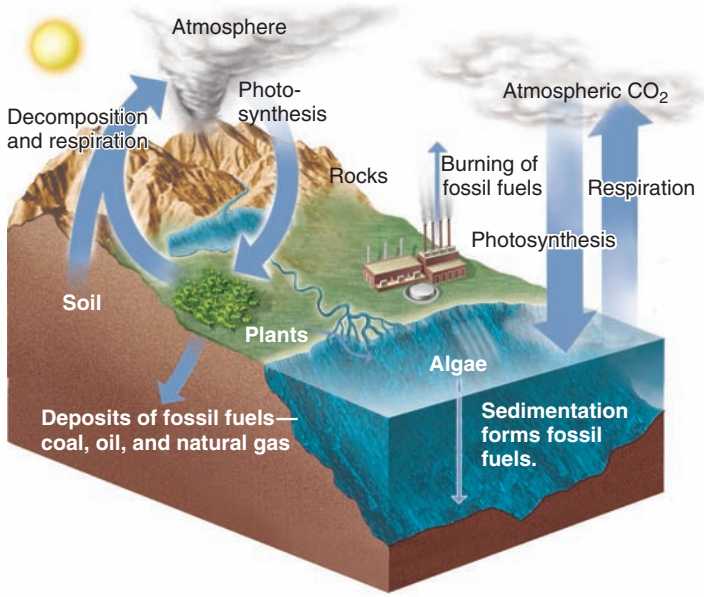

Figure 59.18 The carbon cycle. Each year, plants and algae remove about one-seventh of the CO_2 in the atmosphere. Animal respiration is so small it is not represented. The width of the arrows indicates the relative contribution of each process to the cycle.

Concept Check: *Where are the greatest stores of global carbon?*

BioConnections: *Refer back to Table 2.2. Carbon is one of just four elements that account for the vast majority of atoms in living organisms. What are the other three, and, therefore, what biogeochemical cycles might be the most important to us?*

Over time, much carbon is also incorporated into the shells of marine organisms, which eventually form huge limestone deposits on the ocean floor or in terrestrial rocks, where turnover is extremely low. As a result, rocks and fossil fuels contain the largest reserves of carbon. Natural sources of CO_2 such as volcanoes, hot springs, and fires release large amounts of CO_2 into the atmosphere. In addition, human activities, primarily deforestation and the burning of fossil fuels, are increasingly causing large amounts of CO_2 to enter the atmosphere together with large volumes of particulate matter.

Human Influences on the Carbon Cycle Direct measurements over the past five decades show a steady rise in atmospheric CO_2 (**Figure 59.19**), a pattern that shows no sign of slowing. Because of its increasing concentration in the atmosphere, CO_2 is the most troubling of the greenhouse gases, which are a primary cause of global warming (refer back to Table 54.2). Elevated atmospheric CO_2 has other dramatic environmental effects, boosting plant growth but lowering the amount of herbivory (see the Feature Investigation).

The amount of CO_2 in the atmosphere shows a seasonal variation, as can be seen in Figure 59.19 (blue line). Concentrations of atmospheric CO_2 are lowest during the Northern Hemisphere's summer and highest during the winter, when photosynthesis is minimal. This phenomenon occurs in both of the Earth's hemispheres. Because more land is in the Northern than in the Southern Hemisphere, and therefore more vegetation, concentrations of atmospheric CO_2 are lowest during the Northern Hemisphere's summer. The vegetation has a maximum photosynthetic activity during the summer, reducing the global amount of CO_2. During the Northern Hemisphere's winter, photosynthesis is low, and decomposition is relatively high, causing a global increase in the gas.

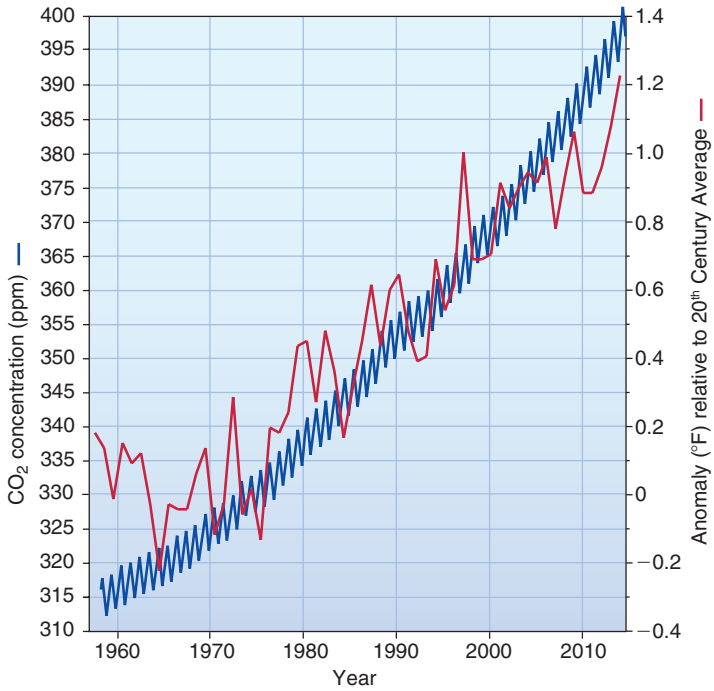

Figure 59.19 The increase in atmospheric CO_2 levels and temperatures due to the burning of fossil fuels. From 1958 to 2015, atmospheric CO_2 showed an increase of over 25%. In addition, the graph shows a seasonal variation in CO_2 (shown in blue). Temperatures are annual deviations from a 20th-century average from a variety of land and ocean monitoring stations around the globe (shown in red). CO_2 measurements were recorded at Mauna Loa Observatory in Hawaii.

Concept Check: Why does the amount of CO_2 fluctuate seasonally in the graph?

BioConnections: Refer back to Figures 29.17 and 22.9. The Earth's atmospheric CO_2 concentration has fluctuated dramatically over time. At what point, and in which period, was it highest?

Feature Investigation | Stiling and Drake's Experiments with Elevated CO_2 Showed an Increase in Plant Growth but a Decrease in Herbivory

How will forests of the future respond to elevated CO_2? To begin to answer such a question, ecologists ideally would enclose large areas of forests with chambers, increase the CO_2 content within the chambers, and measure the responses. This has proven to be difficult for two reasons. First, it is hard to enclose large trees in chambers, and second, it is expensive to increase CO_2 levels over such a large area. However, in a discovery-based investigation, ecologists Peter Stiling and Bert Drake were able to increase CO_2 levels around small patches of forest at the Kennedy Space Center in Cape Canaveral, Florida. In much of Florida's forests, trees are small, only 3–5 m when mature, because frequent lightning-initiated fires prevent the growth of larger trees. In the 1990s, Stiling and Drake teamed up with NASA engineers to create 16 circular, open-top chambers (**Figure 59.20**). In eight of these, they increased atmospheric CO_2 to double the ambient levels, from 360 ppm to 720 ppm, the latter of which is the atmospheric concentration predicted by the end of the 21st century. The experiments commenced in 1996 and lasted until 2007. Plants produced more biomass in elevated CO_2, because CO_2 is limiting to plant growth, but the data revealed much more.

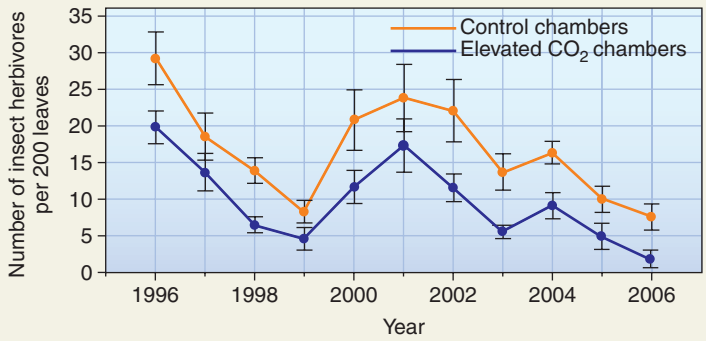
Because the chambers were open-top, insect herbivores could come and go. Insect herbivores cause the largest amount of herbivory in North American forests, because most vertebrate herbivores cannot access the high foliage. Censuses were conducted of all damaged leaves, but focused on leaves damaged by leaf miners, the most common type of herbivore at this site. Leaf miners are small moths whose larvae are small enough to burrow between the surfaces of plant leaves and mine tunnels through the leaves.

Densities of damaged leaves, including those damaged by leaf miners, were lower in elevated CO_2 in every year studied. Part of the reason for the decline was that even though plants increased in mass, the existing soil nitrogen was diluted over a greater volume of plant material, so the nitrogen level in leaves decreased. This increased insect mortality by two means. First, poorer leaf quality directly increased insect death because leaf nitrogen levels may

Figure 59.20 The effects of elevated atmospheric CO_2 on insect herbivory.

GOAL To determine the effects of elevated CO_2 on a forest ecosystem; effects on herbivory are highlighted here.

STUDY LOCATION Patches of forest at the Kennedy Space Center in Cape Canaveral, Florida.



Experimental level | **Conceptual level**

1 Erect 16 open-top chambers around native vegetation. Increase CO_2 levels from 360 ppm to 720 ppm in half of them.

Expected atmospheric CO_2 level is 720 ppm by end of the 21st century. Open-top chambers allow movement of herbivores in and out of chambers.

2 Conduct a yearly count of numbers of insect herbivores per 200 leaves in each chamber.

3 Count number of herbivores that died due to nutritional inadequacy. Monitor attack rates on insect herbivores by natural enemies such as predators and parasitoids.

Elevated CO_2 reduces foliar nitrogen, inhibits normal insect development, and prolongs the feeding time of herbivores, allowing natural enemies greater opportunities to attack them.

4 THE DATA

Source of mortality*	Elevated CO_2 (% mortality)	Control (% mortality)
Nutritional inadequacy	10.2	5.0
Predators	2.4	2.0
Parasitoids	10.0	3.2

*Data refer only to mortality of larvae within leaves and do not sum to 100%. Mortality of eggs on leaves, pupae in the soil, and flying adults is unknown.

5 CONCLUSION Elevated CO_2 decreases insect herbivory in a Florida forest.

6 SOURCE Stiling, P., and Cornelissen, T. 2007. How does elevated carbon dioxide (CO_2) affect plant-herbivore interactions? A field experiment and meta-analysis of CO_2-mediated changes on plant chemistry and herbivore performance. *Global Change Biology* 13:1823–1842.

have been too low to support the normal development of the leaf miners. Second, lower leaf quality increased the amount of time insects needed to feed to gain sufficient nitrogen. Increased feeding times, in turn, led to increased exposure to natural enemies, such as predatory spiders and ants, and parasitoids, so top-down mortality also increased (see the data in step 4 of Figure 59.20). Thus, in a world of elevated CO_2, plant growth may increase, and herbivory could decrease.

Experimental Questions

1. What was the hypothesis of Stiling and Drake's experiment?
2. **SciSKILLS** » Explain the purpose of increasing the CO_2 levels in only half of the chambers in the experiment and not all of them.
3. What were the results of the experiment?

The Nitrogen Cycle Is Strongly Influenced by Biological Processes That Transform Nitrogen into Usable Forms

Nitrogen is an essential component of proteins, nucleic acids, and chlorophyll. Because 78% of the Earth's atmosphere consists of nitrogen gas (N_2), it may seem that nitrogen should not be in short supply for organisms. However, nitrogen is often a limiting factor in ecosystems because N_2 molecules must be broken apart before the individual nitrogen atoms are available to combine with other elements. Because of its triple bond, N_2 is very stable, and only certain bacteria can break it apart and incorporate its atoms into usable forms such as ammonia (NH_3). This process, called nitrogen fixation, is a critical component of the five-part nitrogen cycle (**Figure 59.21**):

1. A few species of bacteria can accomplish **nitrogen fixation**, that is, convert atmospheric N_2 to forms usable by other organisms (refer back to Figure 37.18). The bacteria that fix nitrogen are fulfilling their own metabolic needs, but in the process, they release ammonia (NH_3) or ammonium (NH_4^+), which can be used by some plants. An important group of nitrogen-fixing bacteria, known as rhizobia, live in nodules on the roots of legumes, including peas, beans, lentils, and peanuts and some woody plants. In more natural systems, such as forests and savannas, nitrogen-fixing bacteria such as *Frankia* form a symbiosis with actinorhizal plants. Cyanobacteria are important nitrogen fixers in aquatic systems.
2. In the process of **nitrification**, soil bacteria convert NH_3 or NH_4^+ to nitrate (NO_3^-), a form of nitrogen commonly used by plants. The bacteria *Nitrosomonas* and *Nitrococcus* first oxidize the ammonia or ammonium to nitrite (NO_2^-), after which the bacteria *Nitrobacter* converts NO_2^- to NO_3^-.
3. **Assimilation** is the process by which inorganic substances are incorporated into organic molecules. In the nitrogen cycle, organisms assimilate nitrogen by taking up the NH_3, NH_4^+, and NO_3^- formed through nitrogen fixation and nitrification and incorporating them into other molecules. Plant roots take up these forms of nitrogen through their roots, and animals assimilate nitrogen from plant tissue.
4. Ammonia can also be formed in the soil through the decomposition of plants and animals and the release of animal waste. **Ammonification** is the conversion of organic nitrogen to NH_3 and NH_4^+. This process is carried out by bacteria and fungi. Most soils are slightly acidic and, because of an excess of H^+, the NH_3 rapidly gains an additional H^+ to form NH_4^+. Because many soils lack nitrifying bacteria, ammonification is the most common pathway for nitrogen to enter the soil.
5. **Denitrification** is the reduction of NO_3^- to N_2. Denitrifying bacteria, which are anaerobic and use NO_3^- in their metabolism instead of O_2, perform the reverse of their nitrogen-fixing counterparts by delivering N_2 to the atmosphere. This process delivers only a relatively small amount of nitrogen to the atmosphere.

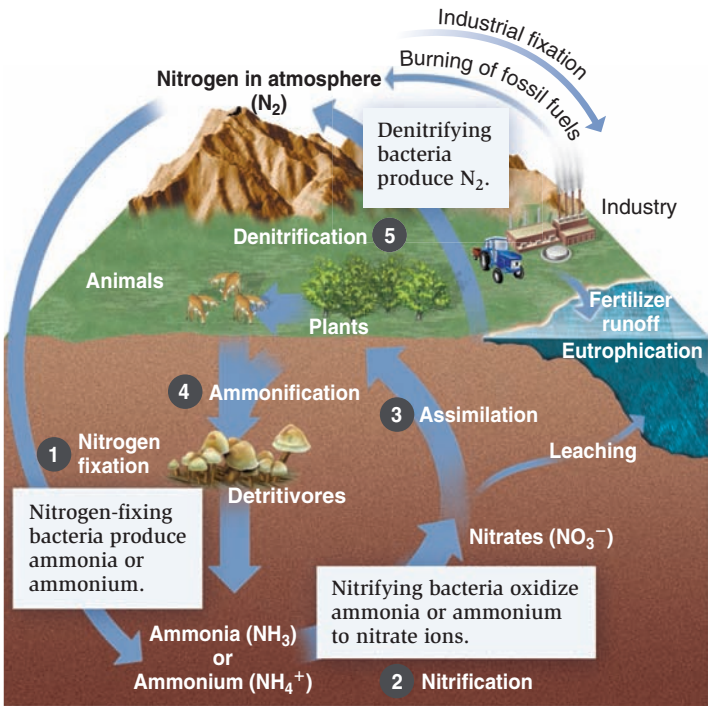


Figure 59.21 The nitrogen cycle. The five main parts of the nitrogen cycle are (1) nitrogen fixation, (2) nitrification, (3) assimilation, (4) ammonification, and (5) denitrification. The recycling of nitrogen from dead plants and animals into the soil and then back into plants is of paramount importance because this is the main pathway for nitrogen to enter the soil. The width of the arrows indicates the relative contribution of each process to the cycle.

Human Influences on the Nitrogen Cycle Human alterations of the nitrogen cycle have approximately doubled the rate of nitrogen input to the cycle. Industrial fixation of nitrogen for the production of fertilizer makes a significant contribution to the pool of nitrogen-containing material in the soils and waters of agricultural regions. Fertilizer runoff can cause eutrophication of rivers and lakes, and, as the algae die, decomposition by bacteria depletes the oxygen level of the water, resulting in fish kills. Excess NO_3^- in surface or groundwater systems used for drinking water is also a health hazard, particularly for infants. In the body, NO_3^- is converted to NO_2^-, which then combines with hemoglobin to form methemoglobin, a type of hemoglobin that does not carry oxygen. In infants, the production of large amounts of NO_2^- can cause methemoglobinemia, a dangerous condition in which the level of O_2 carried through the body decreases. Finally, burning fossil fuels releases not

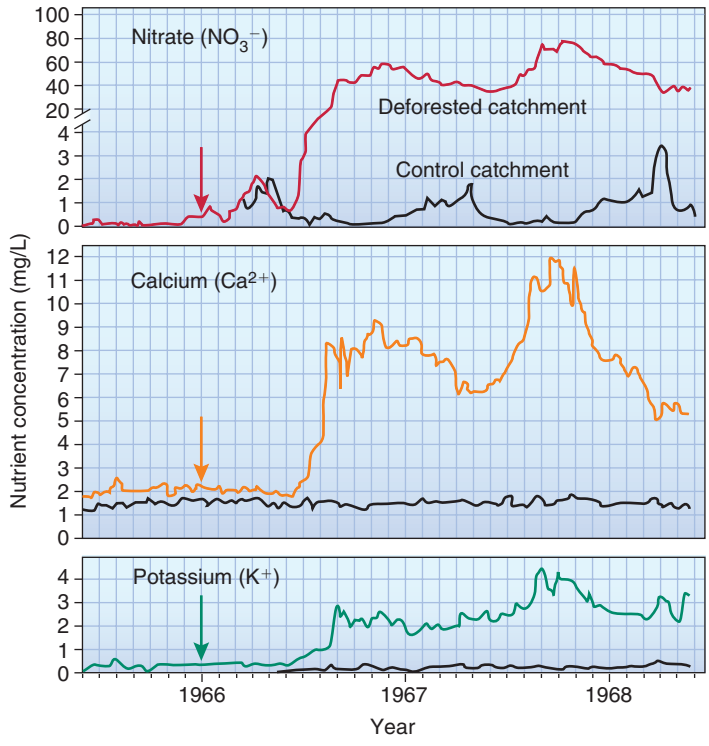
only carbon but also nitrogen in the form of nitrous oxide (N_2O), which contributes to air pollution. N_2O can also react with rainwater to form nitric acid (HNO_3), a component of acid rain, which decreases the pH of lakes and streams and increases fish mortality (see Chapter 54).

The dramatic effects of human activities on nutrient cycles in general and the nitrogen cycle in particular were illustrated by a famous long-term study by American ecosystem ecologists Gene Likens, Herbert Bormann, and their colleagues at Hubbard Brook Experimental Forest in New Hampshire in the 1960s. Hubbard Brook is a 3,160-hectare reserve that consists of six catchments along a mountain ridge. A catchment is an area of land where all water eventually drains to a single outlet. In Hubbard Brook, each outlet is fitted with a permanent concrete dam that enables researchers to monitor the outflow of water and nutrients (**Figure 59.22a**). In this large-scale experiment, researchers felled all of the trees in one of the Hubbard Brook catchments (**Figure 59.22b**). The catchment was then sprayed with herbicides for 3 years to prevent regrowth of vegetation. An untreated catchment was used as a control.

Researchers monitored the concentrations of key nutrients in the flow of water exiting the two catchments for over 3 years. Their results revealed that the overall export of nutrients from the disturbed catchment rose to many times the normal rate (**Figure 59.22c**). The researchers determined that two phenomena were responsible. First, the enormous reduction in plants reduced water uptake by vegetation and led to 40% more runoff discharged to the streams. This increased outflow caused greater rates of chemical leaching and rock and soil weathering. Second, and more significantly, in the absence of nutrient uptake in spring, when the deciduous trees would have resumed photosynthesis, the inorganic nutrients released by decomposer activity were simply leached in the drainage water. Similar processes operate in terrestrial ecosystems where clearance of forests is significant.

The Water Cycle Is Largely a Physical Process of Evaporation and Precipitation

The water cycle, also called the hydrological cycle, differs from the cycles of other nutrients in that very little of the water that cycles through ecosystems is chemically changed by any of the cycle's components (**Figure 59.23**). This cycle is a physical process, fueled by the Sun's energy, rather than a chemical one, because it consists of essentially two phenomena: evaporation and precipitation. Even so, the water cycle has important biological components. Over land, 90% of the water that reaches the atmosphere is moisture that has passed through plants and exited from the leaves via evapotranspiration. Only about 2% of the total volume of Earth's water is found in the bodies of organisms or is held frozen or in the soil. The rest cycles between bodies of water, the atmosphere, and the land.



Human Influences on the Water Cycle As we noted in Chapter 54, water is limiting to the abundance of many organisms, including humans. It takes 228 L of water to produce a pound of dry wheat, and 9,500 L of water to support the necessary vegetation to produce a pound of meat. Industry is also a heavy user of water, with commodities such as oil, iron, and steel requiring up to 20,000 L of water per ton of product. To increase the amount of available water and also to create hydroelectric power, humans have interrupted the hydrological cycle in many ways, most prominently through the use of dams to create reservoirs. Dams, such as those on the Columbia River in Washington State, can greatly interfere with the migration of fishes

(a) Hubbard Brook dam and weir

(b) Hubbard Brook Experimental Forest, New Hampshire

(c) Nutrient concentrations in deforested and control catchments

Figure 59.22 The effects of deforestation on nutrient concentrations. **(a)** Concrete dam, which concentrates water flow and permits accurate measurement of discharge rate, used to monitor nutrient flow from a Hubbard Brook catchment. **(b)** Deforested catchment at Hubbard Brook. **(c)** Nutrient concentrations in stream water from the experimentally deforested catchment and a control catchment at Hubbard Brook. The timing of deforestation is indicated by arrows. The control catchments are shown with black lines.

BIOLOGY PRINCIPLE Biology is an experimental science. Although many experiments are performed in the laboratory, some ecological experiments are done on a large scale in the field.

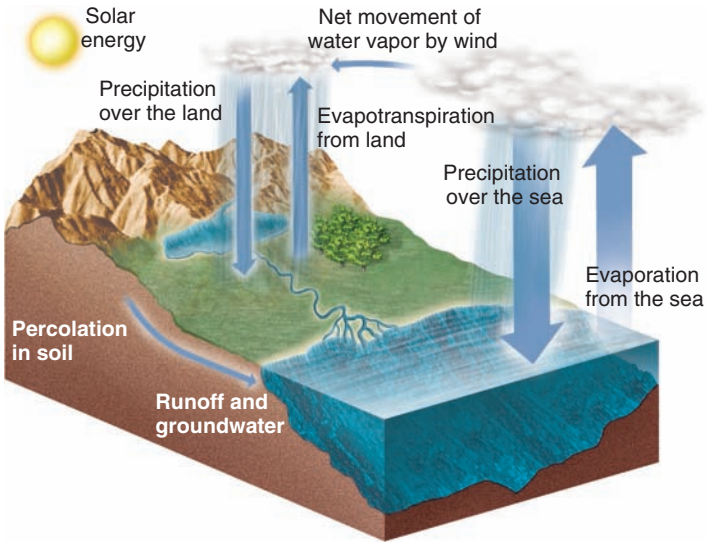


Figure 59.23 The water cycle. This cycle is primarily a physical process, not a chemical one. Solar energy drives the water cycle, causing evaporation of water from the ocean and evapotranspiration from the land. This is followed by condensation of water vapor into clouds and precipitation. The width of the arrows indicates the relative contribution of each step to the cycle.

Figure 59.24 Severe erosion following deforestation in Madagascar. After clearing and a few years of farming, the shallow soil can no longer support crops and is susceptible to erosion by rainfall.

BIOLOGY PRINCIPLE Biology affects our society. Interruptions in biogeochemical cycles, such as changes in the water cycle, can have severe repercussions for human societies. such as salmon and affect their ability to reproduce and survive. Other activities, such as tapping into underground water supplies, or **aquifers**, for drinking water removes more water than is put back by rainfall and can cause shallow ponds and lakes to dry up and sinkholes to develop.

Deforestation can also significantly alter the water cycle. When forests are cut down, less moisture transpires into the atmosphere. This reduces cloud cover and diminishes precipitation, subjecting the area to drought. Reestablishing the forests, which calls for increased water, then becomes nearly impossible. This problem has occurred on the island of Madagascar, located off the east coast of Africa. In this country, clearing of the forests in order to plant cash crops such as cotton, coffee, and tobacco has been so rapid and extensive that areas have become devoid of vegetation (**Figure 59.24**). In Madagascar, as in so many other areas on Earth, deforestation and other environmental degradations are having a deleterious effect on much of the natural habitat. Appropriately, in the following chapter, Chapter 60, we finish our study of ecology in particular, and biology in general, with a discussion of what we gain from ecosystem diversity and how best to conserve the diversity of ecosystems for future generations.

Summary of Key Concepts

59.1 Food Webs and Energy Flow

- Ecosystem ecology concerns the movement of energy and materials through organisms and their communities (Figure 59.1).
- Simple feeding relationships between organisms can be characterized by an unbranched food chain, and each feeding level in the chain is called a trophic level (Figure 59.2).
- Organisms that obtain energy from light or chemicals are called autotrophs and are primary producers. Organisms that feed on other organisms are called heterotrophs. Those that feed on primary producers are called primary consumers. Animals that eat plants are also called herbivores. Secondary consumers feed on primary consumers. Animals that eat other animals are called carnivores. Consumers that get their energy from the remains and waste products of organisms are called detritivores (Figure 59.3).
- Food webs are a more complex model of interconnected food chains in which multiple links occur between species. Food webs tend to have five or fewer levels. Energy conversions are not 100% efficient, and usable energy is lost within each trophic level and from one trophic level to the next (Figures 59.4, 59.5).
- Production efficiency measures the percentage of energy assimilated that becomes incorporated into new biomass. Trophic-level transfer efficiency measures the energy available at one trophic level that is acquired by the level above. These efficiencies can be expressed in the form of ecological pyramids, the best known being the pyramid of numbers (Figures 59.6, 59.7).
- The increase in the concentration of a substance in living organisms, called biomagnification, can occur at each trophic level of the food web (Figures 59.8, 59.9).

59.2 Biomass Production in Ecosystems

- Plant production can be measured as gross primary production, and net primary production is gross primary production minus the energy released during respiration via photosynthetic organisms.
- Net primary production in terrestrial ecosystems is limited primarily by temperature and the availability of water and

nutrients. Net primary production in aquatic ecosystems is limited mainly by availability of light and nutrients (Figures 59.10, 59.11).

- Ecosystems differ in their net primary production. Secondary production is limited by available primary production (Figures 59.12, 59.13, 59.14).

59.3 Biogeochemical Cycles

- Elements such as phosphorus, carbon, and nitrogen recycle from the physical environment to organisms and back in what are called biogeochemical cycles (Figure 59.15).
- The phosphorus cycle lacks an atmospheric component and thus is a local cycle. An overabundance of phosphorus can cause the overgrowth of algae and subsequent depletion of oxygen levels, called eutrophication (Figures 59.16, 59.17).
- In the carbon cycle, autotrophs incorporate CO_2 from the atmosphere into their biomass; decomposition of plants and respiration recycles most of this CO_2 back to the atmosphere. Human activities, primarily the burning of fossil fuels, are causing increased amounts of CO_2 to enter the atmosphere. Experiments have shown that elevated levels of CO_2 result in an increase in plant growth but a decrease in herbivory (Figures 59.18, 59.19, 59.20).
- The nitrogen cycle has five parts: nitrogen fixation, nitrification, assimilation, ammonification, and denitrification. In the nitrogen cycle, atmospheric nitrogen is unavailable for use by most organisms and must be converted to usable forms by certain bacteria. The activities of humans, including fertilizer use, fossil fuel use, and deforestation, have dramatically altered the nitrogen cycle (Figures 59.21, 59.22).
- The water cycle is a physical rather than a chemical process because it consists of essentially two phenomena: evaporation and precipitation. Alteration of the water cycle by deforestation can result in regional climatic changes because a reduction in transpiration causes a decrease in cloud cover and precipitation (Figures 59.23, 59.24).

Assess and Discuss

Test Yourself

1. The amount of energy that is fixed during photosynthesis is known as
   a. net primary production.
   b. biomagnification.
   c. trophic-level transfer efficiency.
   d. gross primary production.
   e. production efficiency.
2. Chemoautotrophic bacteria are
   a. primary consumers.
   b. secondary consumers.
   c. tertiary consumers.
   d. primary producers.
   e. detritivores.
3. When considering the average food chain, which of the following statements is true?
   a. Secondary consumers are the most abundant organisms in an ecosystem.
   b. The longer the food chain, the more stable the ecosystem.
   c. Biomass decreases moving up the food chain.
   d. The trophic level with the highest species abundance is usually the primary producers.
   e. All of the above are true.
4. Which organisms are the most important consumers of energy in a Georgia salt marsh?
   a. *Spartina* grass and algae
   b. insects
   c. spiders
   d. crabs
   e. bacteria
5. The concentration of certain chemicals, such as DDT, in higher trophic levels is known as:
   a. eutrophication
   b. biomagnification
   c. biogeochemical cycling
   d. energy transfer
   e. turnover
6. Primary production in aquatic systems is limited mainly by
   a. temperature and moisture.
   b. temperature and light.
   c. temperature and nutrients.
   d. light and nutrients.
   e. light and moisture.
7. The evapotranspiration rate
   a. can be used as a predictor for primary production.
   b. is increased when temperature decreases.
   c. is not affected by temperature.
   d. is highest in deserts.
   e. can be predicted by measuring only the water content of the soil.
8. Eutrophication is
   a. caused by an overabundance of nitrogen, which leads to an increase in bacteria populations.
   b. caused by an overabundance of nutrients, which leads to an increase in algal populations.
   c. the normal breakdown of algal plants following a pollution event.
   d. normally seen in dry, hot regions of the world.
   e. none of the above.
9. Terrestrial primary producers acquire the carbon necessary for photosynthesis from
   a. decomposing plant material.
   b. carbon monoxide released from the burning of fossil fuels.
   c. carbon dioxide in the atmosphere.
   d. carbon sources in the soil.
   e. both a and d.
10. Nitrogen fixation is the process
    a. that converts organic nitrogen to NH_3.
    b. by which plants and animals take up NO_3^-.
    c. by which bacteria convert NO_3^- to N_2.
    d. by which N_2 is converted to NH_3 or NH_4^+.
    e. All of the above are true of nitrogen fixation.

Conceptual Questions

1. At what trophic level does a carrion beetle feed?
2. Explain why chain lengths are short in food webs.
3. A principle of biology is that *living organisms use energy*. What is a fundamental difference between the passage of energy and the passage of nutrients through ecosystems?

Collaborative Questions

1. What might the atmospheric concentration of CO_2 be in 2100? Discuss the effects this might have on the environment.
2. The Earth's atmosphere consists of 78% nitrogen. Why is nitrogen a limiting nutrient, and how can we increase the supply of nitrogen to plants?

Biodiversity and Conservation Biology

60

The gastric brooding frog of Queensland, Australia. Discovered only in 1973, the species became extinct by the mid-1980s.

CHAPTER OUTLINE

60.1 What Is Biodiversity?
60.2 Why Conserve Biodiversity?
60.3 The Causes of Extinction and Loss of Biodiversity
60.4 Conservation Strategies
Summary of Key Concepts
Assess and Discuss

In 2009, Jeff Corwin, an American conservationist and host of programs on *Animal Planet* and other television networks, published a book entitled *100 Heartbeats: The Race to Save the Earth's Most Endangered Species.* The Hundred Heartbeat Club was created earlier by biologist E. O. Wilson to highlight the plight of animal species, such as Spix's macaw *(Cyanopsitta spixii*) in Brazil, the Chinese river dolphin (*Lipotes vexillifer*), and the Philippine eagle (*Pithecophaga jefferyi*), that have 100 or fewer individuals left alive (and hence that number of heartbeats away from extinction). Corwin's book was a result of 2 years' work traveling and researching such issues as the amphibian-killing fungus (refer back to the chapter opening photo of Chapter 54), the killing of elephants for their tusks, and the destruction of Indonesia's rain forests. Sadly, many of the species in the Hundred Heartbeat Club are still headed toward extinction or have recently become extinct.

The café marron (*Ramosmania rodriguesii*), a wild relative of the coffee plant that is native to a tiny island off the coast of Mauritius, was assumed to be extinct until 1979, when one surviving tree was identified. Today, cuttings from the tree are being cultured in London's Kew Gardens. The plant may contain genes that would allow coffee to be grown in a wider range of soils and elevations. The gastric brooding frog of Australia (*Rheobatrachus* spp.) incubated its young in its stomach and gave birth to froglets through its mouth. In the brooding period, females were thought to be able to switch off digestive acid production. Scientists were interested in how this may have been accomplished because it could have had a bearing in the treatment of gastric ulcers in humans. In the 1980s, however, not long after its discovery, the frog became extinct.

Biological diversity, or **biodiversity**, encompasses the genetic diversity of species, the variety of different species, and the different ecosystems they form. The field of **conservation biology** uses principles and knowledge from molecular biology, genetics, and ecology to protect and sustain the biological diversity of life. Because it draws from nearly all chapters of this textbook, a discussion of conservation biology is an apt way to conclude our study of biology. In this chapter, we begin by examining the questions of why biodiversity should be conserved and how much diversity is needed for ecosystems to function properly. We will then survey the main threats to the world's biodiversity. For many species, multiple threats result from human activities, ranging from habitat loss, overexploitation, and the effects of introduced species to climate change and pollution. Even if species are not exterminated, many may exist only in very small population sizes. We will see how small populations face special problems such as inbreeding, genetic drift, and limited mating, emphasizing the importance of genetics in conservation biology.

Last, we will consider what is being done to help conserve the world's endangered plant and animal life. This includes identifying global areas rich in species and establishing parks and refuges of the appropriate size, number, and connectivity. We will also discuss conservation of particularly important types of species and outline how ecologists have been active in restoring damaged habitats to a more natural condition. We will then examine how captive-breeding programs have been useful in building up populations of rare species prior to their release back into the wild. Some programs have also used modern genetic techniques such as cloning to help breed and perhaps eventually increase populations of endangered species.

60.1 What Is Biodiversity?

Learning Outcome:

1. Identify and describe the three levels of biodiversity.

Biodiversity can be examined on three levels: genetic diversity, species diversity, and ecosystem diversity. Each level of biodiversity provides valuable benefits to humanity.

Genetic diversity consists of the amount of genetic variation occurring within and between populations. Maintaining genetic variation in the wild relatives of crops may be vital to the continued success of crop-breeding programs. For example, in 1977, Rafael Guzman, a Mexican biologist, discovered a previously unknown wild relative of corn, *Zea diploperennis*, that is resistant to many of the viral diseases that infect domestic corn, *Zea mays*. Genetic engineers believe that this relative has valuable genes that can improve current corn crops. Because corn is the third-largest crop on Earth, the discovery of *Z. diploperennis* may well turn out to be critical to the global food supply.

The second level of biodiversity concerns species diversity, the number and relative abundance of species in a community (refer back to Chapter 58). Species diversity is an area on which much public attention is focused. In 1973, the U.S. Endangered Species Act (ESA) was enacted, which was designed to protect both endangered and threatened species. **Endangered species** are those species that are in danger of extinction throughout all or a significant portion of their range. **Threatened species** are those likely to become endangered in the future. Many species are currently threatened. According to the International Union for Conservation of Nature and Natural Resources (IUCN), more than 25% of the fish species that live on coral reefs and 22% of all mammals, 12% of birds, and 31% of amphibians are threatened with extinction.

The last level of biodiversity is ecosystem diversity, the diversity of structure and function within an ecosystem. Conservation at the level of species diversity has largely focused attention on species-rich ecosystems such as tropical rain forests. Some scientists have argued that other relatively species-poor ecosystems are also highly threatened and need to be conserved. In North America, many of the native prairies have been converted to agricultural use, especially in Midwestern states such as Illinois and Iowa. In some counties, remnants of prairie exist only inside cemetery plots, which have been spared from the plow (**Figure 60.1**).

Figure 60.1 Ecosystem biodiversity. This small cemetery in Bureau County, Illinois, contains the remains of a natural prairie ecosystem. Most of the prairie has been plowed under for agriculture.

60.2 Why Conserve Biodiversity?

Learning Outcomes:

1. Detail the benefits of biological diversity to human welfare.
2. **SciSKILLS** » Graph possible relationships between biodiversity level and ecosystem function.
3. Describe experimental evidence that shows how species diversity and ecosystem function are linked.

Why should biodiversity be a concern? American biologists Paul Ehrlich and E. O. Wilson have suggested that the loss of biodiversity should be an area of great concern for at least three reasons. First, humans depend on plants, animals, and microorganisms for a wide range of food, medicine, and industrial products. The second reason focuses on preserving the array of essential services provided by ecosystems, such as clean air and water. Finally, Ehrlich and Wilson propose that we have an ethical responsibility to protect what are our only known living companions in the universe. In this section, we will examine some of the primary reasons why preserving biodiversity matters and explore the link between biodiversity and ecosystem function.

Human Society Benefits Economically from Increased Biodiversity

During the latter half of the 20th century, the reduction of the Earth's biological diversity emerged as a critical issue, one with implications for public policy. A major concern was that loss of plant and animal resources would impair future development of important products and processes in agriculture, medicine, and industry. For example, as previously noted, *Z. diploperennis*, the wild relative of corn discovered in Mexico, is resistant to many corn viruses. Its genes are currently being used to develop virus-resistant types of corn. However, *Z. diploperennis* occurs naturally in only a few small areas of Mexico and could easily have been destroyed by development or cultivation of the land. If we allow such species to go extinct, we may unknowingly threaten the health of the food supply on which much of the world depends.

The pharmaceutical industry is heavily dependent on plant products. An estimated 50,000–70,000 plant species are used in traditional and modern medicine. About 25% of the prescription drugs in the U.S. alone are derived from plants, and the 2014 market value of such drugs was estimated to be $259 billion, accounting for a little less than half the global pharmaceutical market. Many medicines come from plants found only in tropical rain forests. These include quinine, a drug from the bark of the cinchona tree (*Cinchona officinalis*) (**Figure 60.2**), which is used for treating malaria, and vincristine, a drug derived from rosy periwinkle (*Catharanthus roseus*), which is a treatment for leukemia and Hodgkin disease. Many chemicals of therapeutic importance are likely to be found in the numerous rain forest plant species that have not yet been fully analyzed. The continued destruction of rain forests thus could mean the loss of potential lifesaving medical treatments.

Individual species are valuable for research purposes. The blood of the horseshoe crab (*Limulus polyphemus*) clots when exposed to toxins produced by some bacteria. Pharmaceutical industries use the blood enzyme responsible for this clotting to ensure that their products are free of bacterial contamination. Desert pupfishes, in the

Figure 60.2 The value of biodiversity. Bark of the cinchona tree (*Cinchona officinalis*), found only in tropical rain forests, is used to produce quinine, an effective treatment for malaria.

BioConnections: Is malaria caused by a bacterium, a protist, or an insect? Refer back to Figure 28.29.

Table 60.1 Examples of the World's Ecosystem Services

Service	Example(s)
Atmospheric gas supply	Regulation of carbon dioxide, ozone, and oxygen levels
Climate regulation	Regulation of carbon dioxide, nitrogen dioxide, and methane levels
Disturbance regulation	Storm protection, flood control
Water regulation	Regulation of hydrological flow
Water supply	Irrigation, water for industry
Erosion control	Retention of topsoil, reduction of sediment accumulation in lakes
Soil formation	Soil formation processes
Nutrient cycling	Nitrogen, phosphorus, and carbon cycles
Waste treatment	Sewage purification
Pollination	Pollination of crops
Biological control	Regulation of pest populations
Habitat for wildlife	Wilderness and refuges
Food production	Crops, livestock
Raw materials	Fossil fuels, timber
Genetic resources	Medicines, genes for plant resistance
Recreation	Ecotourism, outdoor recreation
Cultural	Aesthetic and educational value

genus *Cyprinodon*, found in isolated desert springs in the U.S. Southwest, tolerate salinity twice that of seawater and are valuable models for research on human kidney diseases.

Natural Ecosystems Provide Essential Services to Humans

Beyond the direct economic gains from biodiversity, humans benefit enormously from the essential services that natural ecosystems provide (**Table 60.1**). Forests soak up carbon dioxide, maintain soil fertility, and retain water, preventing floods; estuaries provide water filtration and protect rivers and coastal shores from excessive erosion. The loss of biodiversity can disrupt an ecosystem's ability to carry out such functions. Other ecosystem functions include the maintenance of populations of natural predators to regulate pest outbreaks and reservoirs of pollinators to pollinate crops and other plants.

A 2014 paper in the journal *Global Environmental Change* by economist Robert Costanza and colleagues made an attempt to calculate the monetary value (in 2007 dollars) of ecosystems to various economies. They came to the conclusion that the world's ecosystems were worth more than $124 trillion a year, nearly twice the gross national product of the world's economies combined ($75.2 trillion in 2007 dollars) (**Table 60.2**). Terrestrial ecosystems have greater value than marine ecosystems. Another way to view ecosystem value is its dollar value per hectare. From this perspective, shallow aquatic ecosystems, such as coral reefs, tidal marshes, estuaries, seagrass beds, and swamps, are extremely valuable because of their role in nutrient cycling, water supply, and disturbance regulation. They also serve as nurseries for aquatic life. These habitats, once thought of as useless wastelands, are among the ecosystems most endangered by pollution and development. The loss of ecosystem services due to such land use changes was estimated at $20.2 trillion per year for the period from 1997 to 2011.

There Are Ethical Reasons for Conservation of Biodiversity

Arguments can also be made against the loss of biodiversity on ethical grounds. As only one of many species, it has been argued that humans have no right to destroy other species and the environment around us. American philosopher Tom Regan suggests that animals should be treated with respect because they have a life of their own and therefore have value apart from anyone else's interests. American law professor Christopher Stone, in an influential 1972 article titled "Should Trees Have Standing?" argued that entities such as nonhuman natural objects like trees or lakes should be given legal rights just as corporations are treated as individuals for certain purposes. And, in 1984, E. O. Wilson proposed in a concept known as biophilia: that humans have innate attachments with species and natural habitats because of close association with them over millions of years.

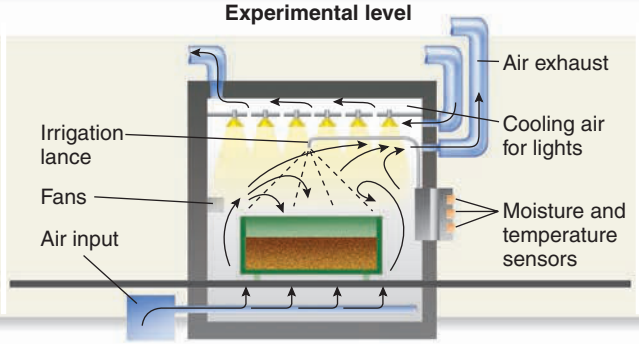
Although these benefits of species diversity may seem obvious to us now, it was only relatively recently that the link between ecosystem services and biodiversity was uncovered.

Table 60.2 Valuation of the World's Ecosystem Services*

Ecosystem type	Value (in dollars/ha/yr)	Total global value (in trillions of dollars)	Main ecosystem services
Marine	1,368	49.7	—
Open ocean	660	21.9	Nutrient cycling, food production, recreation
Estuaries	28,916	5.2	Nutrient cycling, erosion control, food production
Seagrass/algal beds	28,916	6.8	Nutrient cycling, erosion control, food production
Coral reefs	352,249	9.9	Disturbance regulation, habitat, raw materials, genetic resources
Coastal shelf	2,222	5.9	Nutrient cycling
Terrestrial	4,901	75.1	—
Tropical forest	5,382	6.8	Genetic resources, recreation, raw materials, climate regulation, nutrient cycling
Temperate forest	3,137	9.4	Food production, recreation, habitat, raw materials
Grasslands/rangelands	4,166	18.4	Habitat, food production, genetic resources
Tidal marsh/mangroves	193,843	24.8	Disturbance regulation, recreation, waste treatment, erosion control
Swamps/floodplains	25,681	1.5	Disturbance regulation, waste treatment, erosion control
Lakes/rivers	12,512	2.5	Water supply, waste treatment, recreation
Cropland	5,567	9.3	Food production, genetic resources, soil formation
Urban	6,661	2.3	Recreation

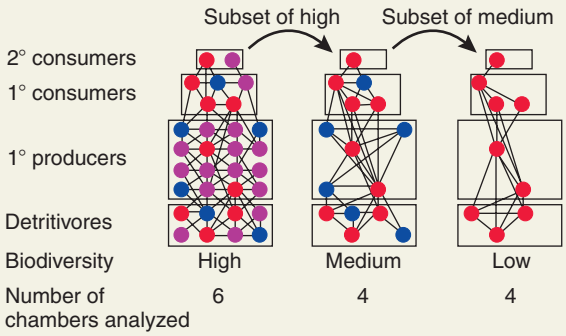
*Values are given in 2007 dollars.

Feature Investigation | Ecotron Experiments Showed the Relationship Between Biodiversity and Ecosystem Function



In the early 1990s, American ecologist Shahid Naeem and colleagues used a series of 14 environmental chambers in a facility termed the Ecotron, at Silwood Park, England, to determine how biodiversity affects ecosystem functioning. These chambers contained terrestrial communities that differed only in their level of biodiversity (**Figure 60.3**). The number of species in each chamber was manipulated to create high-, medium-, and low-diversity ecosystems, each with four trophic levels. The trophic levels consisted of primary producers (annual plants), primary consumers (insects, snails, and slugs), secondary consumers (parasitoids that fed on the herbivores), and detritivores (earthworms and soil insects). The experiment ran for just over 6 months, and species were added only after the trophic

Figure 60.3 Ecotron experiments comparing species diversity and ecosystem function.



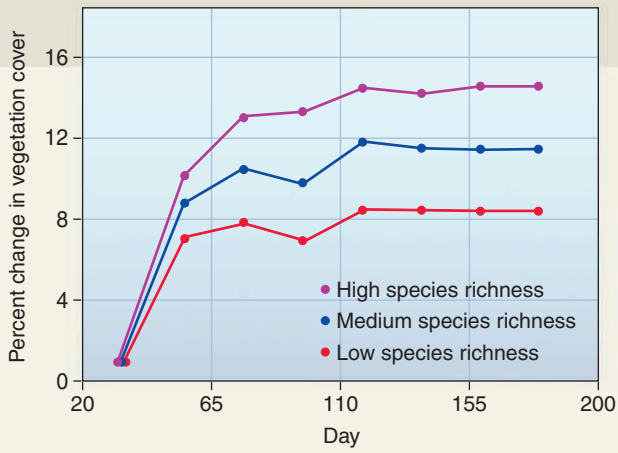
Concept Check: *What is one of the dangers in interpreting these results?*

HYPOTHESIS Reduced biodiversity can lead to reduced ecosystem functioning.

STARTING LOCATION Ecotron, a controlled environment facility at the Natural Environment Research Council (NERC) Centre for Population Biology, in Silwood Park, England.

	Experimental level	Conceptual level
1 Construct 14 identical experimental chambers.		Temperature- and humidity-controlled chambers are used to control environmental conditions and allow identical starting conditions in all chambers.

2 Add different combinations of species to the 14 chambers. The species added were based on 3 types of model communities (food webs), each with 4 trophic levels but with varying degrees of species richness.



The three diagrams to the left each represent a single chamber. Circles represent species, and lines connecting them represent biotic interactions among the species. Note that each lower-biodiversity community is a subset of its higher-diversity counterpart and that all community types have 4 trophic levels.

3 Measure and analyze a range of processes, including vegetation cover and nutrient uptake.

Measurements help determine how each different type of community functions.

4 THE DATA

Plant productivity is linked to community diversity as measured by the percent change in vegetation cover from initial conditions.

Data reveal that low-diversity communities have lower vegetation cover and thus are less productive than high-diversity communities.

5 CONCLUSION Increases in biodiversity lead to increases in ecosystem function. In this case, increased plant diversity results in greater vegetation cover.

6 SOURCE Naeem, S., et al. 1994. Declining biodiversity can alter the performance of ecosystems. *Nature* 368:734–737.

level below them was established. For example, parasitoids were not added until herbivores were abundant.

Researchers monitored and analyzed a range of measures of ecosystem function, including community respiration, decomposition, nutrient retention rates, and community productivity. The data shown in step 4 of Figure 60.3 focus only on community productivity. The result was that community productivity, expressed as percent change in vegetation cover (the amount of ground covered

by leaves of plants), increased as species richness increased. This occurred because of a greater variety of plant growth forms that could utilize light at different levels of the plant canopy. A larger ground cover also meant a larger plant biomass and greater community productivity, and increased decomposition and nutrient uptake rates. For the first time, ecologists provided an experimental demonstration that the loss of biodiversity can alter or impair the functioning of an ecosystem.

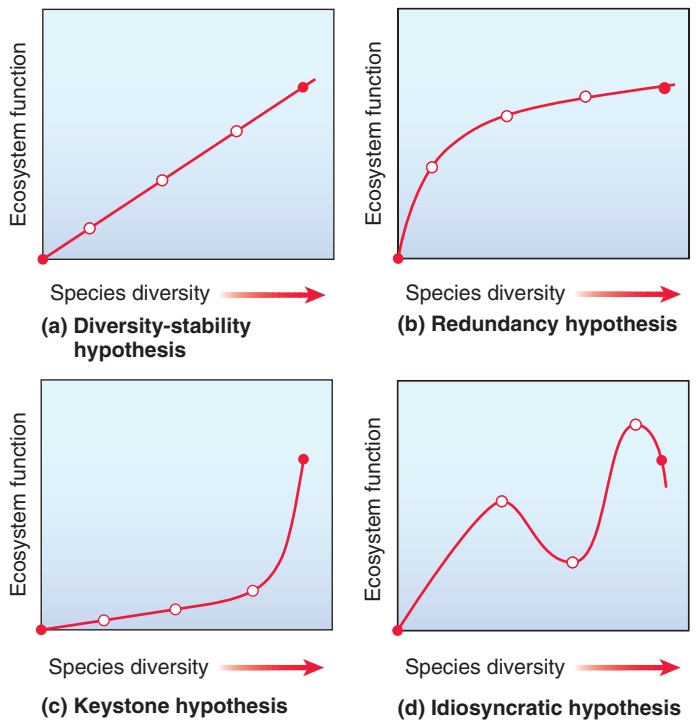
Experimental Questions

1. What was the goal of Naeem and colleagues in their experiment at Silwood Park, England?
2. What was the hypothesis tested by the researchers?
3. **SciSKILLS** » How did the researchers test for ecosystem functioning?
4. **SciSKILLS** » Which relationship between diversity and ecosystem function do these results support? (Look ahead to Figure 60.4.)

Ecologists Have Described Several Relationships Between Ecosystem Function and Biodiversity

Because biodiversity affects the health of ecosystems, ecologists have explored the question of how much diversity is needed for ecosystems to function properly. In doing so, they have described several possible relationships between biodiversity and ecosystem function. In the 1950s, ecologist Charles Elton proposed the **diversity-stability hypothesis** in which species-rich communities are more stable than those with fewer species (refer back to Chapter 58). If we use stability as a measure of ecosystem function, Elton's hypothesis suggests a linear correlation between diversity and ecosystem function (**Figure 60.4a**). Australian ecologist Brian Walker proposed an alternative to this idea, termed the **redundancy hypothesis** (**Figure 60.4b**). According to this hypothesis, ecosystem function levels off at fairly low levels of diversity, so most additional species are functionally redundant. Two other alternatives relating species richness and ecosystem services have been proposed. The first, termed the **keystone hypothesis** (**Figure 60.4c**), supposes ecosystem function plummets as soon as biodiversity declines from its natural levels. Lastly, the **idiosyncratic hypothesis** addresses the possibility that ecosystem function changes as the number of species increases or decreases but that the amount and direction of change are unpredictable (**Figure 60.4d**).

Determining which model is most correct is very important, as our understanding of the effect of species loss on ecosystem function can greatly affect the way we manage our environment.



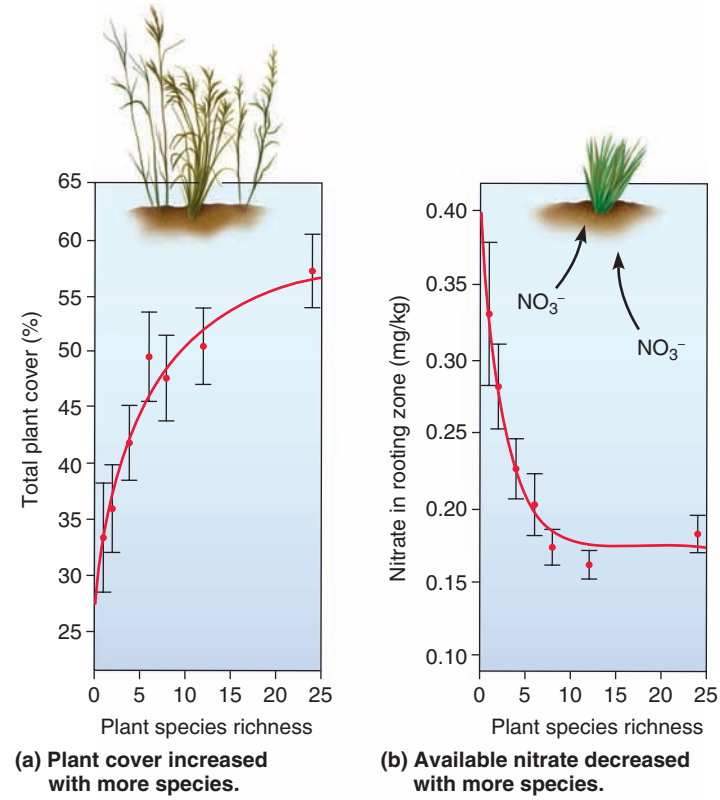


Figure 60.4 Graphical representations of possible relationships between ecosystem function and biodiversity. The two solid dots represent the end points of a continuum of species richness. The first dot is at the origin, where there are no species and no ecosystem services. The second dot represents natural levels of species diversity. The relationship is strongest in (a) and weakest in (d).

Field Experiments Have Been Used to Determine How Much Diversity Is Needed for Normal Ecosystem Function

In the mid-1990s, David Tilman and colleagues performed experiments in the field to determine how much biodiversity was necessary for proper ecosystem functioning. Tilman's previous experiments had suggested that species-rich grasslands were more stable; that is, they were more resistant to the ravages of drought and recovered from drought more quickly than species-poor grasslands (refer back to Figure 58.8). In the more recent experiments, Tilman's group sowed plots, each 3 m × 3 m and on comparable soils, with seeds of 1, 2, 4, 6, 8, 12, or 24 species of prairie plants. Exactly which species were sown into each plot was determined randomly from a pool of 24 native species. The treatments were replicated 21 times, for a total of 147 plots. The results showed that more diverse plots had increased productivity and used more nutrients, such as nitrate (NO_3^-), than less diverse plots (**Figure 60.5a** and **b**). Furthermore, the frequency of invasive plant species (species not originally planted in the plots) decreased with increased plant species richness (**Figure 60.5c**). In a separate experiment, where plots were planted with 1, 2, 4, 8, or 16 species, Tilman and colleagues showed that increased diversity also reduced the severity of attack by foliar fungal diseases (**Figure 60.5d**).

Although Tilman's experiments show a relationship between species diversity and ecosystem function, they also suggest that most of the advantages of increasing diversity come with the first 5 to 10 species, beyond which adding more species appears to have little to no effect. This supports the redundancy hypothesis (compare Figure 60.5a with Figure 60.4c). For example, uptake of nitrogen remains relatively unchanged as the number of species increases beyond 6. This is also observed on a larger scale. The productivity of temperate forests in different continents is roughly the same despite different numbers of tree species present—729 in East Asia, 253 in North America, and

(a) Plant cover increased with more species.

(b) Available nitrate decreased with more species.

(c) Invasive species decreased with more species.

(d) Fungal disease decreased with more species.

Figure 60.5 **Increased species richness improves community function.**

124 in Europe. The presence of more tree species may ensure a supply of "backups" should some of the most productive species die off from insect attack or disease. This can happen, as was seen in the demise of American chestnut and elm trees. Diseases devastated both of these species, and their presence in forests dramatically decreased by the mid-20th century (refer back to Figure 57.17). The forests filled in with other species and continued to function as before in terms of nutrient cycling and gas exchange. However, although the forests continued to function without these species, some important changes occurred. For example, the loss of chestnuts deprived bears and other animals of an important source of food and may have affected their reproductive capacity and hence the size of their populations.

60.3 The Causes of Extinction and Loss of Biodiversity

Learning Outcomes:

1. List and describe the four main human-induced threats to species.
2. Explain why the genetic diversity of small populations is threatened by inbreeding, genetic drift, and limited mating.

In light of research showing that the loss of species influences ecosystem function, the importance of understanding and preventing species loss takes on particular urgency. As we saw in Chapter 22, **extinction**—the process by which species die out—has been a natural phenomenon throughout the history of life on Earth. In fact, it has been estimated that most of all species that have ever lived on Earth are now extinct.

In the past 100 years, approximately 20 species of mammals and over 40 species of birds have gone extinct (**Figure 60.6**). The rates of

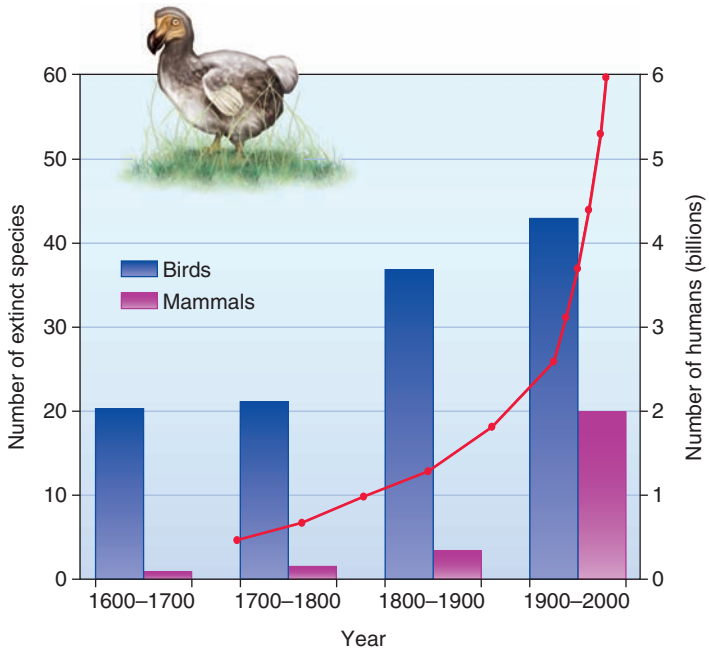

Figure 60.6 **Animal extinctions since the 17th century in relation to human population growth.** Increasing numbers of known extinctions in birds and mammals are concurrent with the exponential increase in the global human population. These data suggest that as the human population increases, more and more species will go extinct. The inset depicts a dodo bird, which went extinct within 100 years after contact with humans.

Concept Check: *Why might the increasing human population result in an increase in the extinction rate of other species?*

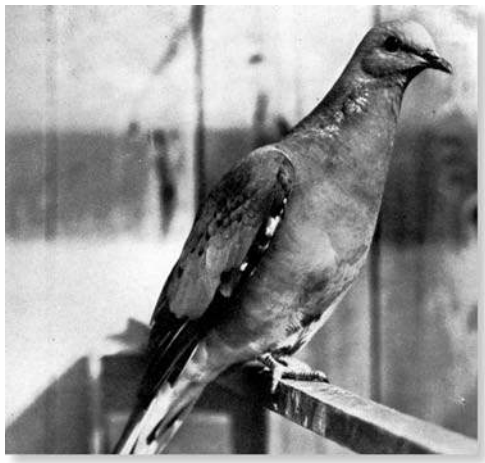
species extinctions on islands in the past confirm the dramatic effects of human activity. The Polynesians, who colonized Hawaii in the 4th and 5th centuries, appear to have been responsible for the extinction of half of the 100 or so species of land birds in the period between their arrival and that of the Europeans in the late 18th century. A similar effect was felt in New Zealand, which was colonized by settlers some 500 years later than Hawaii. In New Zealand, an entire avian megafauna, consisting of huge land birds, was exterminated over the course of a century, probably through a combination of hunting and large-scale habitat destruction through burning.

The term **biodiversity crisis** is often used to describe this elevated loss of species. Many scientists believe that the rate of loss is higher now than during most of geological history, and most suggest that the growth in the human population has led to the increase in the number of extinctions of other species. In fact, most scientists believe that we are in the middle of a sixth mass extinction.

To understand the process of extinction in more modern times, ecologists need to examine the role of human activities and their environmental consequences. In this section, we will examine why species have gone extinct in the past and look at the factors that are currently threatening species with extinction.

The Main Threats to Species Are Human-Induced

Although all causes of extinctions are not known, introduced species, direct exploitation, and habitat destruction have been identified as the most important human-induced threats. In addition, climate change is increasingly being viewed as a significant human-induced threat to species.



Introduced Species **Introduced species** are those species moved by humans from a native location to another location. Most often the species are transported for agricultural purposes or as sources of timber, meat, or wool. Others, such as plants, insects, or marine organisms, are sometimes unintentionally transported in the cargo of ships or planes. Regardless of their method of introduction, some introduced species become **invasive species**, spreading and outcompeting native species for space and resources.

We can categorize the interactions between introduced and native species as competition, predation, and disease. Competition can eliminate local populations and cause huge reductions in the densities of native species, but it has not yet been clearly shown to exterminate entire species. On the other hand, many recorded cases of extinction have been due to predation. Introduced predators such as rats, cats, and mongooses have accounted for at least 43% of recorded extinctions of birds on islands. Lighthouse keepers' cats have annihilated populations of ground-nesting birds on small islands around the world. The brown tree snake, which was accidentally introduced onto the island of Guam, has decimated the country's native bird populations (refer back to Figure 57.11). Parasites and diseases carried by introduced organisms have also been important in causing extinctions, as in the case of the American chestnut. Avian malaria in Hawaii, spread by introduced mosquito species, is believed to have contributed to the demise of up to 50% of native Hawaiian birds (**Figure 60.7a**).

Direct Exploitation Direct exploitation, particularly the hunting of animals, has been the cause of many extinctions in the past. Two remarkable North American bird species, the passenger pigeon (*Ectopistes migratorius*) and the Carolina parakeet (*Conuropsis carolinensis*), were hunted to extinction by the early 20th century. *E. migratorius* was once the most common bird in North America, probably accounting for over 40% of the entire bird population (**Figure 60.7b**). Its total population size was estimated to be over 3 billion birds. Habitat loss because of deforestation was a contributing factor in their demise, but hunting as a cheap source of meat was the main factor. The flocking behavior of the birds made them relatively easy targets for hunters, who used special firearms to harvest the birds in quantity. In 1876, in Michigan alone, over 1.6 million

(a) Introduced species

(b) Direct exploitation

(c) Habitat destruction

Figure 60.7 **Causes of extinction.** **(a)** Many Hawaiian honeycreepers such as this o'u (*Psittirostra psittacea*) were exterminated by avian malaria from introduced mosquito species. **(b)** The passenger pigeon (*Ectopistes migratorius*), which may have once been among the most abundant bird species on Earth, was hunted to extinction for its meat. **(c)** The ivory-billed woodpecker (*Campephilus principalis*), the third-largest woodpecker in the world, was long thought to be extinct in the southeastern U.S. because of habitat destruction, but possible sightings have been reported since 2004. This nestling was photographed in Louisiana in 1938.

birds were killed and sent to markets in the eastern U.S. *C. carolinensis*, the only species of parrot native to the eastern U.S., was similarly hunted to extinction by the early 1900s.

Many whale species were driven to the brink of extinction prior to the 1988 moratorium on commercial whaling. Steller's sea cow (*Hydrodamalis gigas*), a 9-m-long manatee-like mammal, was hunted to extinction in the Bering Strait only 27 years after its discovery by humans in 1740. A poignant example of human excess in hunting was the dodo (*Raphus cucullatus*), a flightless bird native only to the island of Mauritius that had no known predators (see Figure 60.6). A combination of overexploitation, habitat destruction, and introduced species led to its extinction within 100 years of the arrival of humans. Sailors hunted it for its meat; rats, pigs, and monkeys brought to the island by humans destroyed the dodo's eggs and chicks in their ground nests; and forest destruction reduced its habitat.

Habitat Destruction Habitat destruction through **deforestation**, the conversion of forested areas to nonforested land, has historically been a prime cause of the extinction of species. About one-third of the world's land surface is covered with forests, and much of this area is at risk of deforestation through human activities such as development, farming, animal grazing, or logging. Although tropical forests are probably the most threatened forest type, with rates of deforestation in Africa, South America, and Asia varying between 0.6% and 0.9% per year, the destruction of forests is a global phenomenon. The ivory-billed woodpecker (*Campephilus principalis*), the largest woodpecker in North America and an inhabitant of wetlands and forests of the southeastern U.S., was widely assumed to have gone extinct in the 1950s due to destruction of its habitat by heavy logging (**Figure 60.7c**). Since 2004, the woodpecker has been purportedly sighted in the Big Woods area of eastern Arkansas, though this has not been confirmed, despite concerted efforts.

Deforestation is not the only form of habitat destruction. Prairies are often replaced by agricultural crops. The average area of land under cultivation worldwide averages about 11%, with an additional 24% given over to rangeland; however, this amount varies tremendously between regions. For example, Europe uses 28% of its land for crops and pasturelands, with the result that many of its native species went extinct long ago. Wetlands also have been drained for agricultural purposes. Others have been filled in for urban or industrial development. In the U.S., as much as 90% of the freshwater marshes and 50% of the estuarine marshes have disappeared. Urbanization, the development of cities on previously natural or agricultural areas, is the most human-dominated and fastest-growing type of land use worldwide and devastates the land more severely than practically any other form of habitat degradation.

Climate Change As mentioned at the beginning of Chapter 54, human-induced climate change, or global warming, has been implicated in the dramatic decrease in the population sizes of frog species in Central and South America. Further, the distribution of trees would also change as climate zones shifted, with such shifts occurring faster than many plants could migrate via seed dispersal (refer back to Figure 54.12).

Other ecological properties of species, not just range limits, may change with global warming, including population densities and phenology (the timing of periodic plant and animal life-cycle events, such as flowering, egg laying, and migration). In 2003, American ecologist Terry Root and colleagues examined the phenologies of 694 species over the past 30 years. Over an average decade, the estimated mean number of days changed in spring phenology was 5.1 days earlier. For example, the North American common murre (*Uria aalge*) bred, on average, 24 days earlier per decade, and Fowler's toad (*Bufo fowleri*) bred 6.3 days earlier. Potentially more critical than the absolute change in phenology is the possible disruption of timing between associated species such as herbivores and host plants or predators and prey. If the phenologies of all species are sped up by global warming at the same rate, there is no problem. However, limited evidence suggests that this is not the case. Only 11 systems have been examined in detail, but in 7 of them, interacting species responded differently enough to temperature changes to put them more out of synchrony than they were earlier. For example, in the Colorado Rockies, yellow-bellied marmots (*Marmota flaviventris*) now emerge from hibernation 23 days earlier than they did in 1975, changing the relative phenology of the marmots with the emergence of their food plants and causing food shortages.

Small Populations Are Threatened by the Loss of Genetic Diversity

Even if habitats are not destroyed, many become fragmented, leading to the development of small, isolated populations. Such populations are more vulnerable to the loss of genetic diversity resulting from three factors: inbreeding, genetic drift, and limited mating.

Inbreeding **Inbreeding**, which is a form of mating among genetically related relatives, is more likely to take place in nature when population size becomes very small and the number of potential mates shrinks drastically (see Chapter 24). In many species, the health and survival of offspring decline as populations become more inbred. This is because inbreeding produces homozygotes, which because of an increase in recessive genes are less fit, thereby decreasing the reproductive success of the population.

One of the most striking examples of the effects of inbreeding in conservation biology involves the greater prairie chicken (*Tympanuchus cupido*). The male birds have a spectacular mating display that involves inflating the bright orange air sacs on their throat, stomping their feet, and spreading their tail feathers. The prairies of the Midwest were once home to millions of these birds, but as the prairies were converted to farmland, the population sizes of the bird shrank dramatically. The population of prairie chickens in Illinois decreased from 25,000 in 1933 to less than 50 in 1989. At that point, according to studies by Ronald Westemeier and colleagues, only 10 to 12 males existed. Because of the decreasing numbers of males, inbreeding in the population had increased. This was reflected in the steady reduction in the hatching success of eggs (**Figure 60.8**). The prairie chicken population had entered a downward spiral toward extinction from which it could not naturally recover. In the early 1990s, conservation biologists began trapping prairie chickens in Kansas and Nebraska, where populations remained larger and more genetically diverse, and moved them to Illinois, bringing an infusion of new genetic material into the population. This transfer resulted in a rebound of the egg-hatching success rate to over 90% by 1993.

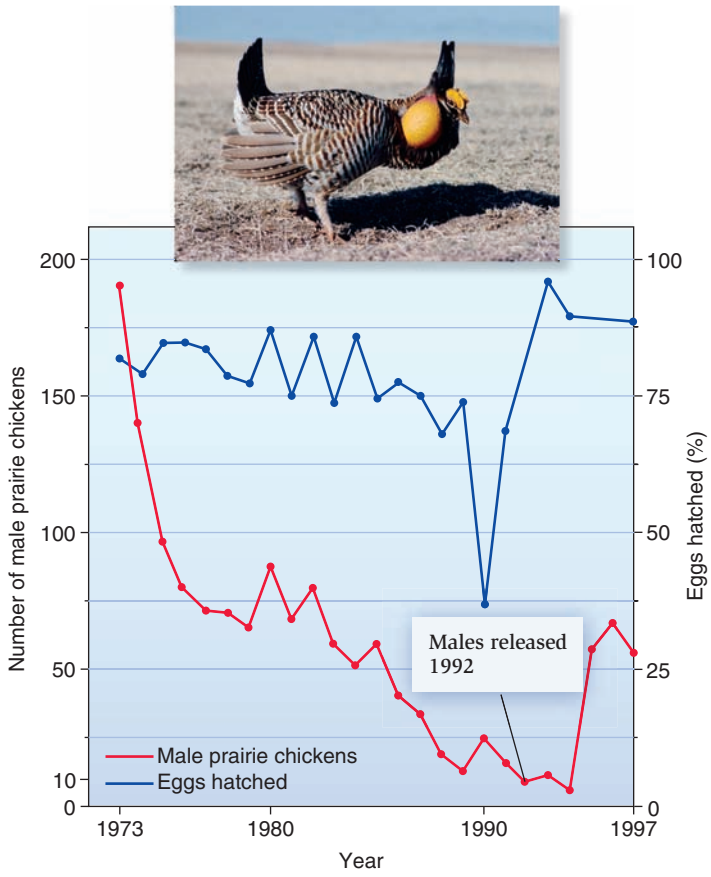


Figure 60.8 Changes in the abundance and egg-hatching success rate of prairie chickens. As the number of males decreased, inbreeding increased, resulting in a decrease in fertility, as indicated by a reduced egg-hatching rate. An influx of males in the early 1990s increased the egg-hatching success rate dramatically.

BIOLOGY PRINCIPLE **New properties of life emerge from complex interactions.** The conversion of prairies to farmland reduced the available prairie chicken habitat in Illinois, and populations of the bird decreased dramatically. The consequent increase in inbreeding led to a path toward extinction that was difficult to reverse.

Concept Check: *Is the fitness of all organisms decreased by inbreeding?*

Genetic Drift In small populations, the chance is greater that some individuals will fail to mate successfully purely by chance. For example, finding a mate may be increasingly difficult as population size decreases. If an individual that fails to mate possesses a rare gene, that genetic information will not be passed on to the next generation, resulting in a loss of genetic diversity from the population. **Genetic drift** refers to the random change in allele frequencies attributable to chance (refer back to Figure 24.10). Because the likelihood of an allele being represented in just one or a few individuals is higher in small populations than in large populations, small, isolated populations are particularly vulnerable to this type of reduction in genetic diversity. Such isolated populations will lose a percentage of their original diversity over time, approximately at the rate of $1/(2N)$ per generation, where N = population size. This has a greater effect in smaller versus larger populations:

If $N = 500$, then $\frac{1}{2N} = 1/1{,}000 = 0.001$, or 0.1% genetic diversity lost per generation

If $N = 50$, then $\frac{1}{2N} = 1/100 = 0.01$, or 1.0% genetic diversity lost per generation

As with inbreeding, the effects of genetic drift can be countered by immigration of individuals into a population. Even relatively low immigration rates of about one immigrant per generation (or one individual moved from one population to another) can be sufficient to counter genetic drift in a population of 100 individuals.

BIO TIPS

THE QUESTION *How much genetic diversity will populations of 200 individuals and 20 individuals retain after 10 generations?*

TOPIC ***What topic in biology does this topic address?*** The topic is loss of genetic diversity over time in small populations, specifically, loss due to genetic drift.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you know that one population has 200 individuals and another population has 20 individuals. You also know that there will be a loss of genetic diversity after 10 generations. From your understanding of the topic, you may recall that small populations lose genetic diversity at the rate of approximately $1/(2N)$ per generation.

PROBLEM-SOLVING STRATEGY ***Make a calculation.*** Put the given data for each population into the formula, and extend the calculation over 10 generations. For the larger population of 200 individuals, loss of genetic diversity per generation is approximately 1/400 = 0.0025, or 0.25%. Over 10 generations, this loss will be about 2.5%. For the smaller population of 20 individuals, loss of genetic diversity per generation is approximately 1/40 = 0.025, or 2.5%. For 10 generations this loss will be about 25%. (In reality, because the genetic diversity is reduced each year, the actual loss is closer to 22.4% over a 10-year period.)

ANSWER *After 10 generations, a population of 200 individuals will retain about 97.5% of its genetic diversity, whereas a population of 20 individuals will retain only about 75% (or perhaps a little more).*

Limited Mating In many populations, the **effective population size**, the number of individuals that contribute genes to future populations, may be smaller than the number of individuals in the population, particularly in animals with a harem mating structure in which only a few dominant males breed. For example, dominant elephant seal bulls control harems of females, and a few males command all the matings.

If a population consists of breeding males and breeding females, the effective population size is given by

Effective population size

Number of breeding males

Number of breeding females

$$N_e = \frac{4N_mN_f}{N_m + N_f}$$

In a population of 500, with a 50:50 sex ratio and all individuals breeding, the effective population size $N_e = (4 \times 250 \times 250)/(250 + 250) = 500$, or 100% of the actual population size. However, if 10 males breed with 250 females, $N_e = (4 \times 10 \times 250)/(10 + 250) = 38.5$, or 8% of the actual population size.

Knowledge of effective population size is vital to ensuring the success of conservation projects. One notable project in the U.S. involved planning the sizes of reserves designed to protect grizzly bear populations in the 48 contiguous states. The grizzly bear (*Ursus arctos*) has declined in numbers from an estimated 50,000 in 1800 to around 1,800 at present. The range of the species is now less than 1% of its historical range and is restricted to six separate populations in four states (**Figure 60.9**). Research by American biologist Fred Allendorf has indicated that the effective population size of grizzly populations is generally only about 25% of the actual population size because not all bears breed. Thus, even fairly large, isolated populations, such as the 500 bears in Yellowstone National Park, are vulnerable to the harmful effects of loss of genetic variation because the effective population size may be as small as 125 individuals. Allendorf and his colleagues proposed that an exchange of grizzly bears between populations or zoo collections would help tremendously in promoting genetic variation. Even an exchange of two bears per generation between populations would greatly reduce the loss of genetic variation.

Figure 60.9 Past and current ranges of the grizzly bear. The range of the grizzly bear is currently less than 1% of its historical range. The current range in the 48 contiguous states of the U.S. has contracted to just six populations in four states, as the population size has shrunk from 50,000 before the West was settled to about 1,800 today.

Concept Check: *If 900 male and 900 female grizzlies exist today, but only 25% of the males breed, what is the effective population size?*

60.4 Conservation Strategies

Learning Outcomes:

1. Detail the different criteria that conservation biologists use to target areas for protection.
2. Explain how the principles of the model of island biogeography and landscape ecology are used to create nature preserves.
3. Describe different approaches conservation biologists use to protect individual species.
4. Define restoration ecology, and describe the approaches used to restore degraded ecosystems and populations of species.

In their efforts to maintain the diversity of life on Earth, conservation biologists are currently active on many fronts. How do they decide on which areas or species to focus and which strategies to employ to protect diversity? We begin this section by discussing how conservation biologists identify the global habitats richest in species. Next, we will explore the concept of nature reserves and consider questions such as how large conservation areas should be and how far apart they should be situated. These questions are within the realm of landscape ecology, which studies the spatial arrangement of communities and ecosystems in a geographic area. Then, we will discuss how conservation efforts often focus on certain species that can have a disproportionate influence on their ecosystem. We will also examine the field of restoration ecology, focusing on how wildlife habitats can be established from degraded areas and how captive breeding programs have been used to reestablish populations of threatened species in the wild. We will conclude by returning to the theme of genomes and proteomes to show how modern molecular techniques of cloning can contribute to the fight to save critically endangered species.

Conservation Seeks to Establish Protected Areas

Currently, about 12.85% of the global land area is under some form of protection. There are more than 160,000 separate protected areas, with more added daily. Conservation biologists often must make decisions regarding which habitats should be protected. Many conservation efforts have focused on saving habitats in so-called megadiversity countries, because they often have the greatest number of species. However, more recent strategies have promoted preservation of certain key areas with the highest levels of unique species or the preservation of representative areas of all types of habitat, even relatively species-poor areas.

Megadiversity Countries One method of targeting areas for conservation is to identify those countries with the greatest numbers of species, the **megadiversity countries**. Using the number of plants, vertebrates, and selected groups of insects as criteria, American biologist Russell Mittermeier and colleagues have determined that just 17 countries are home to nearly 70% of all known species. Brazil, Indonesia, and Colombia top the list, followed by Australia, Peru, Mexico, Madagascar, China, and nine other countries. The megadiversity country approach suggests that conservation efforts should be focused on the most biologically rich countries. However, although megadiversity areas may contain the most species, they do not necessarily contain the greatest number of unique species. The mammal species list for Peru is 344, and for Ecuador, it is 271; of these, however, 208 species are common to both.

Areas Rich in Endemic Species Another method of setting conservation priorities, one adopted by the organization Conservation International, takes into account the number of species that are **endemic**, or found only in a particular place or region and nowhere else. This approach suggests that conservationists focus their efforts on geographic **hot spots**. To qualify as a hot spot, a region must meet two criteria: It must contain at least 1,500 species of vascular plants as endemic species and have lost at least 70% of its original habitat. Vascular plants were chosen as the primary group of organisms to determine whether or not an area qualifies as a hot spot, mainly because most other terrestrial organisms depend on them to some extent.

Conservationists Norman Myers, Russell Mittermeier, and colleagues identified 34 hot spots that together occupy a mere 2.3% of the Earth's surface but contain 150,000 endemic plant species, or 50% of the world's total (**Figure 60.10**). Of these areas, the tropical Andes and Sundaland (the region including Malaysia, Indonesia, and surrounding islands) have the most endemic plant species (**Table 60.3**). This approach proposes that protecting geographic hot spots will prevent the extinction of a larger number of endemic species than would protecting areas of a similar size elsewhere. The main argument against using hot spots as the criterion for targeting conservation efforts is that the areas richest in endemic species—tropical rain forests—would receive the majority of attention and funding, perhaps at the expense of protecting other areas.

Representative Habitats In a third approach to prioritizing areas for conservation, scientists have recently argued that we need to conserve representatives of all major habitats. Prairies, such as some of those in the U.S., are a case in point. An example is the Pampas region of South America, which is arguably the most threatened habitat on the continent because of conversion of its natural grasslands to ranch land and agriculture. The Pampas does not compare well in richness or endemic species with the rain forests, but it is a unique area that without preservation could disappear (**Figure 60.11**). By selecting habitats that are most distinct from those already preserved, many areas that are threatened but not biologically rich may be preserved in addition to the less immediately threatened, but richer, tropical forests.

Ecologists are divided as to which is the best way to identify areas for habitat conservation. Some ecologists feel that the best

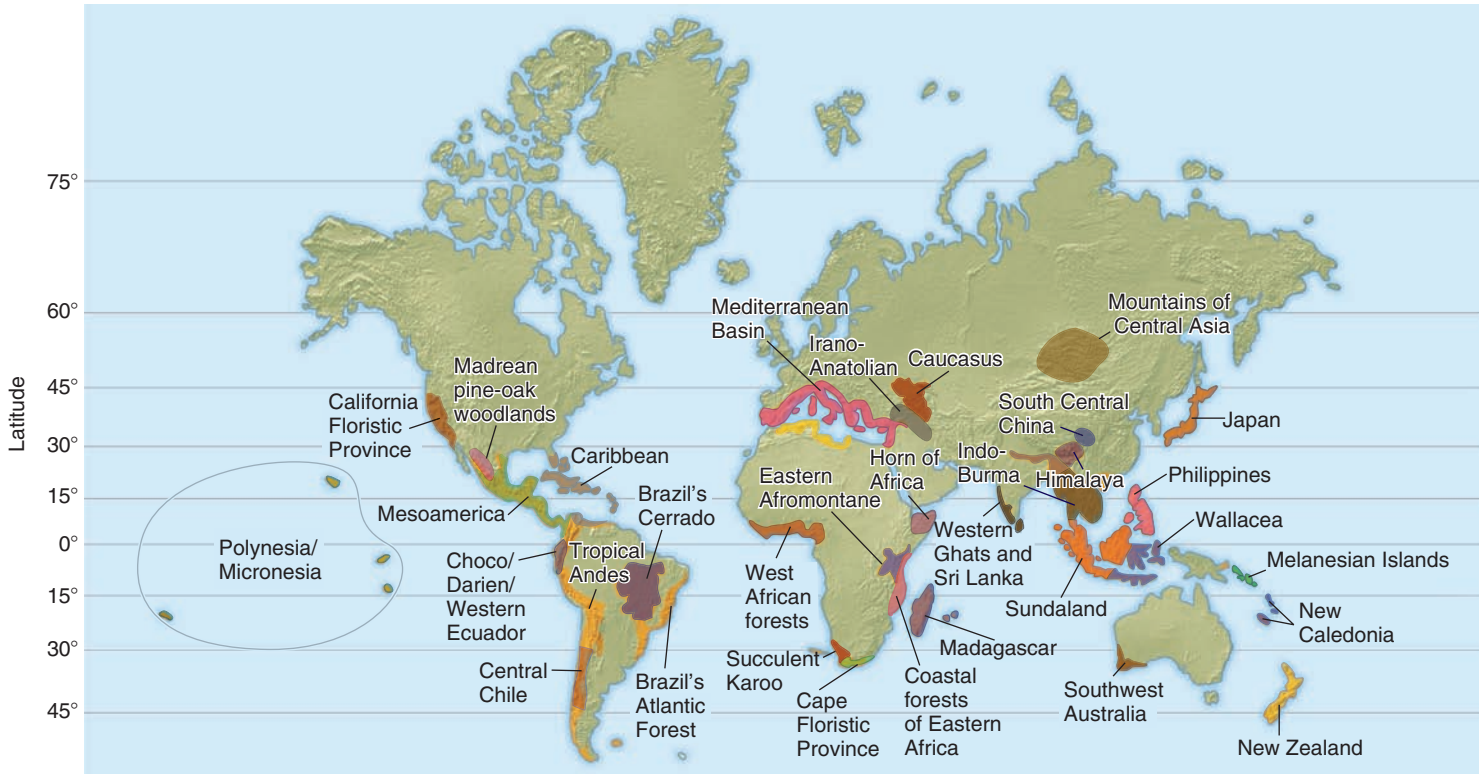

Figure 60.10 Location of major biodiversity hot spots around the world. Hot spots have high numbers of endemic species.

Table 60.3 Numbers of Endemic Species Present in the Top 10 Hot Spots of the World, Ranked by the Numbers of Endemic Plants

Rank	Hot spot	Plants	Birds	Mammals	Reptiles	Amphibians	Freshwater fishes
1	Tropical Andes	15,000	584	75	275	664	131
2	Sundaland	15,000	146	173	244	172	350
3	Mediterranean Basin	11,700	32	25	77	27	63
4	Madagascar	11,600	183	144	367	226	97
5	Brazil's Atlantic Forest	8,000	148	71	94	286	133
6	Indo-Burma	7,000	73	73	204	139	553
7	Caribbean	6,550	167	41	468	164	65
8	Cape Floristic Province	6,210	6	4	22	16	14
9	Philippines	6,091	185	102	160	74	67
10	Brazil's Cerrado	4,400	16	14	33	26	200

approach might be one that creates a "portfolio" of areas to conserve, containing some areas of high species richness, others with large numbers of endemic species, and some with various habitat types.

The Theory and Practice of Reserve Design Incorporate Principles of Island Biogeography and Landscape Ecology

After identifying areas to preserve, conservationists must determine the size, arrangement, and management of the protected land. Among the questions conservationists ask is whether one large reserve is preferable to an equivalent area composed of smaller reserves. Ecologists also need to determine whether parks should be close together or far apart and whether or not they should be connected by strips of suitable habitat to allow the movement of plants and animals between them. Conservationists also need to consider that park design is often contingent on economic factors. Let's examine some of the many issues that conservationists address in the creation and management of protected land.

Figure 60.11 The Pampas, Argentina. This habitat is not rich in species but is threatened due to conversion to ranch land and agriculture. The guanaco, shown here, is a characteristic grazer of pampas grass.

The Role of Island Biogeography In exploring the equilibrium model of island biogeography (refer back to Chapter 58), we noted that nature reserves and sanctuaries are, in essence, islands in a sea of human-altered habitat. Seen this way, the tenets of the equilibrium model of island biogeography can be applied not only to a body of land surrounded by water but also to nature reserves. One question for conservationists is how large a protected area should be (**Figure 60.12a**). According to island biogeography, the number of species should increase with increasing area (the species-area effect). Thus, the larger the area, the greater the number of species protected. In addition, larger parks have other benefits. For example, they are beneficial for organisms that require large spaces, including migrating species and species with extensive territories, such as lions and tigers.

A related question is whether it is preferable to protect a single, large reserve or several smaller ones (**Figure 60.12b**). This is called the **SLOSS debate** (for single large or several small). Proponents of the single, large reserve claim that a larger reserve is better able to preserve more and larger populations than an equal area divided into small areas. According to island biogeography, a larger block of habitat should support more species than several smaller blocks.

However, many empirical studies suggest that multiple small sites of equivalent area will contain more species, because a series of small sites is more likely to contain a broader variety of habitats than one large site. Looking at a variety of sites, American researchers Jim Quinn and Susan Harrison concluded that animal life was richer in collections of small parks than in a smaller number of larger parks. In their study, having more habitat types outweighed the effect of area on biodiversity. In addition, another benefit of a series of smaller parks is a reduction of extinction risk by a single event such as a wildfire or the spread of disease.

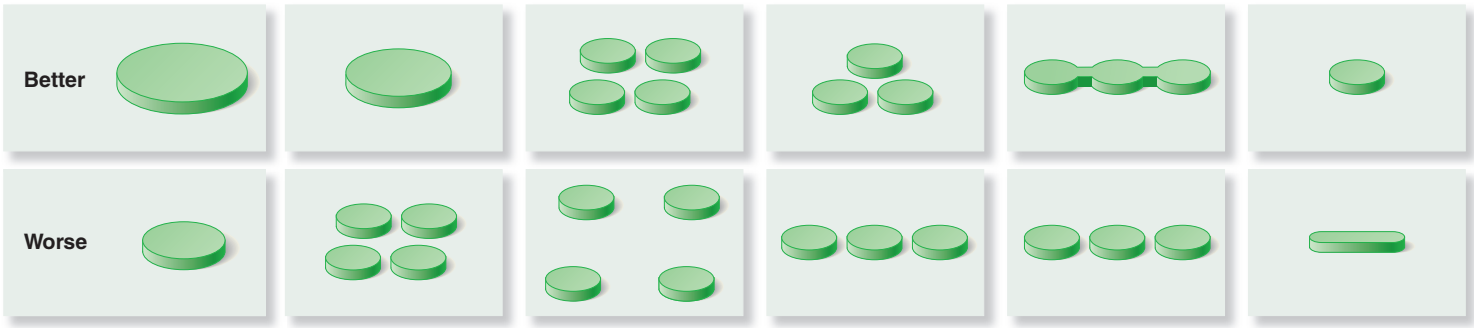

Figure 60.12 The theoretical design of nature reserves. **(a)** A larger reserve will hold more species and have low extinction rates. **(b)** A given area should be fragmented into as few pieces as possible. **(c)** If an area must be fragmented, the pieces should be as close as possible to permit dispersal. **(d)** To enhance dispersal, a cluster of fragments is preferable to a linear arrangement. **(e)** Maintaining or creating corridors between fragments may also enhance dispersal. **(f)** Circular-shaped areas minimize the amount of edge effects. The labels "Better" and "Worse" refer to theoretical principles generated by the equilibrium model of island biogeography, but empirical data have not supported all the predictions.

Concept Check: *What are some of the potential risks in connecting areas via movement corridors?*

Landscape Ecology Landscape ecology is an area of ecology that examines the spatial arrangement of communities and ecosystems in a geographic area. In the design of nature reserves, one question that needs to be addressed is how close to situate reserves to each other, such as whether to place three or four small reserves close to each other or farther apart. A similar question is whether to have a linear or a cluster arrangement of small reserves. Island biogeography suggests that if an area must be fragmented, the sites should be as close as possible to permit dispersal (Figure 60.12c and d). In practice, however, having small sites far apart may preserve more species than having them close together, because once again, distant sites are likely to incorporate slightly different habitats and species.

Landscape ecologists have also suggested that small reserves should be linked together by **movement corridors**, thin strips of land that may permit the movement of species between patches (Figure 60.12e). Such corridors ideally facilitate movements of organisms that are vulnerable to predation outside of their natural habitat or that have poor powers of dispersal between habitat patches. In this way, if a disaster befalls a population in one small reserve, immigrants from neighboring populations can more easily recolonize it. This avoids the need for humans to physically move new plants or animals into an area.

Several types of habitat may function as movement corridors, including hedgerows in Europe, which facilitate movement and dispersal of species between forest fragments (Figure 60.13). In China, corridors of habitat have been established to link small, adjacent populations of giant pandas. Riparian habitats, vegetated corridors bordering streams or rivers, are thought to facilitate movement of species between habitats. In Florida, debate continues about whether to establish a movement corridor to allow bears to move between the Ocala and Osceola National Forests. However, disadvantages are associated with movement corridors. First, corridors also can facilitate the spread of disease, invasive species, and fire between small reserves. Second, it is not yet clear if species would actually use such corridors.

Finally, parks are often designed to minimize **edge effects**, the special physical conditions that exist at the boundaries or edges of ecosystems. Habitat edges, particularly those between natural habitats such as forests and developed land, are often different in physical characteristics from the habitat core. For example, the center of a forest is shaded by trees and has less wind and light than the forest edge, which is unprotected. Many forest-adapted species therefore shy away from forest edges and prefer forest centers. Because the amount of edge is minimized, circular parks are generally preferable to oblong parks (Figure 60.12f).

Figure 60.13 Movement corridors.

Concept Check: *How would these European hedgerows act as movement corridors?*

Economic Considerations in Conservation Although the principles of the model of island biogeography and landscape ecology are useful in illuminating conservation issues, in reality, there is often little choice as to the location, size, shape, and extent of nature reserves. Management practicalities, such as costs of acquisition and maintenance, and politics may override ecological considerations, especially in developing countries, where costs for large reserves may be relatively high. Economic considerations often enter into the choice of which areas to preserve. Many countries protect areas in those regions that are the least economically valuable rather than choosing areas to ensure a balanced representation of the country's biota. In the U.S., most national parks were historically chosen for their scenic beauty, not because they preserve the richest habitat for wildlife.

When designing nature reserves, countries need to consider how to finance their management. Interestingly, the amount of money spent to protect nature reserves may better determine species extinction rates than reserve size. Theoretically, large areas minimize the risk of extinctions because they contain sizable populations. In Africa, several parks, such as Serengeti and Selous in Tanzania, Tsavo in Kenya, and Luangwa in Zambia, are large enough to fulfill this theoretical ideal. However, in the 1980s, populations of black rhinoceroses and elephants declined dramatically within these areas because of poaching—the illegal killing of animals or removing of plants. A larger park is also more difficult to patrol. Research has shown that the rates of decline of rhinos and elephants, largely a result of poaching, have been related directly to conservation efforts and spending (**Figure 60.14**). Populations of the remaining black rhinos, lowland gorillas, and pygmy chimpanzees in Africa, and the vicuna, a llama-like animal in South America, have all shown the greatest stabilization in areas that have been heavily patrolled and where economic resources have been concentrated.

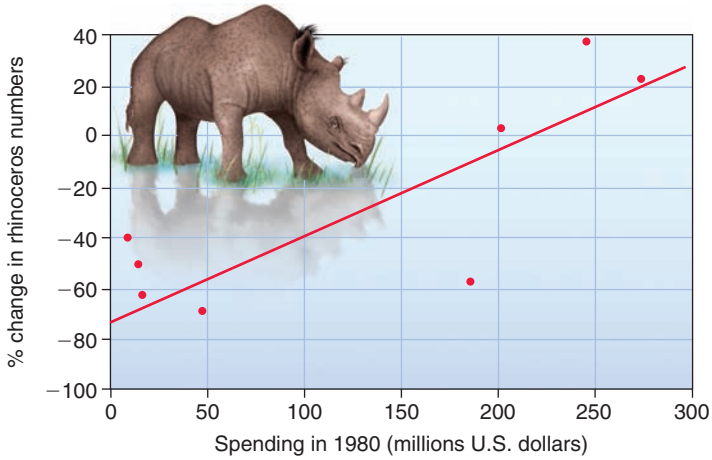

Figure 60.14 The economics of conservation. A positive relationship is seen between the percent change in the number of black rhinoceros and conservation spending in various African countries between 1980 and 1984.

The Single-Species Approach Focuses Conservation Efforts on Particular Types of Species

Much public awareness of the biodiversity crisis results from efforts to preserve individual species that are at risk of extinction. The single-species approach to conservation focuses on saving species that are deemed particularly important. As with habitat conservation, different approaches are used to identify which ecologically important species to focus effort on.

Indicator Species Some conservation biologists have suggested that certain organisms can be used as **indicator species**, those species whose status provides information on the overall health of an ecosystem. Corals are good indicators of marine processes such as siltation, the accumulation of sediments transported by water. Because siltation reduces the availability of light, the abundance of many marine organisms decreases in such situations, with corals among the first to display a decline in health. Coral bleaching is also an indicator of climate change (refer back to Figure 54.8). A proliferation of the dark variety of the peppered moth (*Biston betularia*) has been shown to be a good indicator of air pollution. The darker-colored moths flourish because predators are less able to detect them on trees darkened by soot. Polar bears (*Ursus maritimus*) are thought to be a mammalian indicator species for global climate change (**Figure 60.15a**). Scientists believe that global warming is causing the ice in the Arctic to melt earlier in the spring than in the past. Because polar bears rely on the ice to hunt for seals, the earlier breakup of the ice is leaving the bears less time to feed and build the fat that enables them to sustain themselves and their young. A U.S. Geological Survey concluded that future reduction of arctic ice could result in a loss of two-thirds of the world's polar bear population within 50 years. In May 2008, the polar bear was listed as a threatened species under the U.S. Endangered Species Act (ESA).

Umbrella Species **Umbrella species** are species whose habitat requirements are so large that protecting them would protect many other species existing in the same habitat. The northern spotted owl (*Strix occidentalis*) of the Pacific Northwest is considered to be an important umbrella species (**Figure 60.15b**). A pair of birds needs at least 800 hectares of old-growth forest for survival and reproduction, so maintaining healthy owl populations is thought to help ensure survival of many other forest-dwelling species. In the southeast area of the U.S., the red-cockaded woodpecker (*Picoides borealis*) is often seen as the equivalent of the spotted owl, because it requires large tracts of old-growth long-leaf pine (*Pinus palustris*), including old diseased trees in which it can excavate its nests.

Flagship Species In the past, conservation resources were often allocated to a **flagship species**, a single large or instantly recognizable species. Such species were typically chosen because they were attractive and thus more readily engendered support from the public for their conservation. The concept of the flagship species, typically a charismatic vertebrate such as the American buffalo (*Bison bison*), has often been used to raise awareness for conservation in general. The giant panda (*Ailuropoda melanoleuca*) is the World Wildlife Fund's emblem for endangered species, and the Florida panther (*Puma concolor*) has become a symbol of the state's conservation campaign (**Figure 60.15c**).

(a) Indicator species: polar bear

(b) Umbrella species: northern spotted owl

(c) Flagship species: Florida panther

Figure 60.15 Indicator, umbrella, and flagship species. **(a)** Polar bears have been called an indicator species of global climate change. **(b)** The northern spotted owl is considered an umbrella species for the old-growth forest in the Pacific Northwest. **(c)** The Florida panther has become a flagship species for Florida.

Keystone Species A different conservation strategy focuses on **keystone species**, species within a community that have a role out of proportion to their abundance or biomass. The beaver, a relatively small animal, can completely alter the composition of a community by building a dam and flooding an entire river valley (**Figure 60.16**). The resultant lake may become a home to fish species, wildfowl, and aquatic vegetation. A decline in the number of beavers could have serious ramifications for the remaining community members, promoting fish die-offs, waterfowl loss, and the death of vegetation adapted to waterlogged soil. In the southeastern U.S., gopher tortoises (*Gopherus polyphemus*) can be regarded as keystone species because the burrows they create provide homes for an array of other animals, including mice, opossums, frogs, snakes, and insects. Many of these creatures depend on the gopher tortoise burrows and would be unable to survive without them.

American tropical ecologist John Terborgh considers palm and fig trees to be keystone species because they produce fruit during otherwise fruitless times of the year and are thus critical resources for tropical forest fruit-eating animals, including primates, rodents, and many birds. Together, these fruit eaters account for as much as three-quarters of the tropical forest animal biomass. Without the fruit trees, wholesale extinction of these animals could occur. Note that a keystone species is not the same as a **dominant species**, one that has a large effect in a community because of its abundance or high biomass. For example, *Spartina* cordgrass is a dominant species in a salt marsh because of its large biomass, but it is not a keystone species. The American chestnut was another dominant species before it was greatly reduced in abundance by an introduced parasite (refer back to Figure 57.17).

Figure 60.16 Keystone species. The American beaver creates large dams across streams, and the resultant lakes provide habitats for a great diversity of species.

Restoration Ecology Attempts to Rehabilitate Degraded Ecosystems and Populations

Although the preservation of umbrella, flagship, or keystone species is a valuable conservation strategy, another approach is to rehabilitate previously degraded habitat. **Restoration ecology** is the full or partial repair or replacement of biological habitats and/or their populations that have been degraded or destroyed. It can focus on restoring or rehabilitating a habitat, or it can involve reintroducing species or returning species to the wild following captive breeding. Following open-pit mining for coal or phosphate, huge tracts of disturbed land must be replenished with topsoil, and a large number of species such as grasses, shrubs, and trees must be replanted. Aquatic habitats can be restored by reducing human impacts and replanting vegetation. In Florida, where seagrass beds are vulnerable to damage by motor-driven boat propellers, efforts have focused on closing off areas to motorboats and replanting previously damaged beds.

Habitat Restoration The three basic approaches to habitat restoration are complete restoration, rehabilitation, and ecosystem replacement. In complete restoration, conservationists attempt to return a habitat to its condition prior to the disturbance. Under the leadership of American ecologist Aldo Leopold, the University of Wisconsin pioneered the restoration of prairie habitats as early as 1935, converting agricultural land back to species-rich prairies (**Figure 60.17a**). The second approach aims to return the habitat to something similar

(a) Complete restoration

(b) Rehabilitation

(c) Ecosystem replacement

Figure 60.17 Habitat restoration. **(a)** The University of Wisconsin pioneered the practice of complete restoration of agricultural land to native prairies. **(b)** In Florida, phosphate mines are so degraded that complete restoration is not possible. After topsoil is replaced, some exotic species such as cogongrass often invade, allowing only habitat rehabilitation. **(c)** These old open-pit mines in Middlesex, England, have been converted to valuable freshwater habitats, replacing the wooded area that was originally present.

BIOLOGY PRINCIPLE **Biology affects our society.** Restoration of human-degraded habitats can lead to recovery of habitat and biodiversity.

to, but a little less than, full restoration, a goal called rehabilitation. In Florida, phosphate mining involves removing a layer of topsoil or overburden, mining the phosphate-rich layers, returning the overburden, and replanting the area. Exotic species such as cogongrass (*Imperata cylindrica*), an invasive Southeast Asian species, often invade these disturbed areas, and the biodiversity of the restored habitat is usually not comparable to that of unmined areas (**Figure 60.17b**). The third approach, ecosystem replacement, makes no attempt to restore what was originally present but instead replaces the original ecosystem with a different one. The replacement could be an ecosystem that is simpler but more productive, as when deciduous forest is replaced after mining by grassland to be used for public recreation.

Although any of these approaches can be employed in the habitat restoration process, complete restoration is not always the desired endpoint. In some cases, it is appropriate, but in many cases complete restoration is so difficult or expensive as to be impractical. Ecosystem replacement is particularly useful for land that has been significantly damaged by past activities. It would be nearly impossible to re-create the original landscape of an area that was mined for stone or gravel. In these situations, however, wetlands or lakes may be created in the open pits (**Figure 60.17c**).

Bioremediation Restoration can also involve **bioremediation**, the use of living organisms, usually microorganisms or plants, to degrade sewage or detoxify polluted habitats such as dump sites or oil spills.

In 1975, a leak from a military fuel storage facility released 80,000 gallons of jet fuel into the sandy soil at Hanahan, South Carolina. Soon the groundwater contained toxic chemicals such as benzene. By the 1980s, it was found that naturally occurring microorganisms in the soil were actively consuming many of these toxic compounds and converting them into carbon dioxide. In 1992, nutrients were delivered in pipes to the contaminated soils to speed up the action of the natural microbial community. By the end of 1993, contamination had been reduced by 75%. The increasing interest in bacterial genomes is providing opportunities for understanding the genetic and molecular bases of degradation of organic pollutants. Many novel biochemical reactions have been discovered.

Heavy metals such as cadmium or lead are not readily absorbed by microorganisms. Phytoremediation, a form of bioremediation that involves the use of plants, is valuable in these cases. Plants absorb contaminants in the root system and store them in root biomass or transport them to stems and leaves. After plants are removed from the area, a lower level of soil contamination will remain. Several growth/harvest cycles may be needed to achieve cleanup. Sunflower (*Helianthus annuus*) has been used to extract arsenic and uranium from soils. Pennycress (*Thalsphi caenilescens*) is an accumulator of zinc and cadmium, and lead may be removed by Indian mustard (*Brassica juncea*) and ragweed (*Ambrosia artemisifolia*). Some polychlorinated biphenyls (PCBs) have been removed by transgenic plants containing genes for bacterial enzymes. As discussed in Chapter 59, poplar trees are being genetically engineered to better degrade the chemical trichloroethylene (TCE).

Reintroductions and Captive Breeding Reintroducing species to areas where they previously existed is a valuable conservation strategy. As noted in Chapter 56, both black-footed ferrets and tule elk have been successfully reintroduced into areas where they once occurred (refer back to Figure 56.10). Reintroductions may increase genetic diversity and reduce the effects of inbreeding (see Figure 60.8). In some cases, organisms are bred in captivity before being released back into the wild. **Captive breeding**, the propagation of animals and plants outside their natural habitat to produce stock for subsequent release into the wild, has proved valuable in reestablishing breeding populations following extinction or near extinction. Zoos, aquariums, and botanical gardens often play a key role in captive breeding, propagating species that are highly threatened in the wild. They also play an important role in public education about the loss of biodiversity and the use of restoration programs.

Several classic programs illustrate the value of captive breeding and reintroduction. The peregrine falcon (*Falco peregrinus*) became extinct in nearly all of the eastern U.S. by the mid-1960s, a decline

Figure 60.18 Captive-breeding programs. The California condor (*Gymnogyps californicus*), the largest bird in the U.S., with a wingspan of nearly 3 m, has been bred in captivity in California. **(a)** A researcher at the San Diego Wild Animal Park feeds a chick with a puppet so that the bird will not become habituated to the presence of humans. **(b)** This captive-bred condor soars over the Grand Canyon. Note the tag on the underside of its wing.

(a) A condor chick being fed using a puppet **(b) A released captive-bred condor**

that was linked to the effects of DDT (refer back to Figure 59.9). In 1970, American biologist Tom Cade gathered falcons from other parts of the country to start a captive breeding program at Cornell University. Since then, the program has released thousands of birds into the wild, and in 1999, the peregrine falcon was removed from the list of endangered species. A captive breeding program is also helping save the California condor (*Gymnogyps californicus*) from extinction. At a cost of $35 million, this is the most expensive species conservation project ever undertaken in the U.S. In the 1980s, there were only 22 known condors, some in captivity and some in the wild. Scientists made the decision to capture the remaining wild birds in order to protect and breed them (**Figure 60.18a**). By 2014, the captive population numbered 204 individuals, and 225 birds were living in the Grand Canyon area of Arizona; Zion National Park, Utah; the western coastal mountains of California; and northern Baja California, Mexico (**Figure 60.18b**). A milestone was reached in 2003, when a pair of captive-reared California condors bred in the wild.

Because the number of individuals in any captive-breeding program is initially small, care must be exercised to avoid inbreeding. Matings are usually carefully arranged to maximize resultant genetic variation in offspring. The use of genetic engineering to clone endangered species is a new area that may eventually help bolster populations of captive-bred species.

Genomes & Proteomes Connection

Can Cloning Save Endangered Species?

In 1997, geneticist Ian Wilmut and colleagues at Scotland's Roslin Institute announced to the world that they had cloned a now-famous sheep, Dolly, from mammary cells of an adult ewe (refer back to Figure 20.15). Since then, interest has arisen among conservation biologists about whether the same technology might be used to save species on the verge of extinction. Scientists were encouraged that in January 2001, an Iowa farm cow called Bessie gave birth to a cloned Asian gaur (*Bos gaurus*), an endangered species. The gaur, an oxlike animal native to the jungles of India and Burma, was cloned from a single skin cell taken from a dead animal. To clone the gaur, scientists removed the nucleus from a cow's egg and replaced it with a nucleus from the gaur's cell. The treated egg was then placed into the cow's womb. Unfortunately, the gaur died from dysentery two days after birth, although scientists believe this was unrelated to the cloning procedure. In 2003, another type of endangered wild cattle, the Javan banteng (*Bos javanicus*), was successfully cloned (**Figure 60.19**). In 2005, clones of the African wildcat (*Felis libyca*) successfully produced wildcat kittens. This is the first time that clones of a wild species

Figure 60.19 Cloning an endangered species. In 2004, this 8-month-old cloned Javan banteng (*Bos javanicus*) made its public debut at the San Diego Zoo.

BIOLOGY PRINCIPLE The genetic material provides a blueprint for sustaining life. Genetic cloning utilizes a somatic cell, which contains the complete DNA or genetic blueprint of the animal that is to be cloned.

BioConnections: Livestock and even pets have been cloned as well as endangered species (refer back to Figure 20.15 and the chapter opening photograph of Chapter 20). What are some of the arguments in favor and against genetic cloning of endangered species?

have bred. In 2009, a cloned Pyrenean ibex (*Capra pyrenaica*) was born but lived only 7 minutes due to physical defects in the lungs. The last wild Pyrenean ibex had died in Spain in 2000. Other candidates for cloning include the Sumatran tiger (*Panthera tigris*) and the giant panda. Cloning extinct animals such as the woolly mammoth (*Mammuthus primigenius*) or Tasmanian tiger (*Thylacinus cynocephalus*) would be more difficult due to a lack of preserved DNA.

Despite the promise of cloning, a number of issues remain unresolved:

1. Scientists would have to develop an intimate knowledge of different species' reproductive cycles. For sheep and cows, this was routine, based on the vast experience in breeding these species, but eggs of different species, even if they could be harvested, often require different nutritive media in laboratory cultures.
2. Because it is desirable to leave natural mothers available for breeding, scientists will have to identify surrogate females of similar but more common species that can carry the fetus to term.
3. Some argue that cloning does not address the root causes of species loss, such as habitat fragmentation or poaching, and that resources would be better spent elsewhere, for example, in preserving the remaining habitat of endangered species.
4. Cloning might not be able to increase the genetic variability of the population. However, if it were possible to use cells from deceased animals, for example, from their skin, these clones could theoretically reintroduce lost genes back into the population.

Many biologists believe that while cloning may have a role in conservation, it is only part of the solution and that we should address what made the species go extinct before attempting to restore it.

Conservation is clearly a matter of great importance, and a failure to value and protect our natural resources adequately could be a grave mistake. Some authors, most recently the American ecologist and geographer Jared Diamond, have investigated why many societies of the past—including Angkor Wat, Easter Island, and the Mayans—collapsed or vanished, leaving behind monumental ruins. Diamond has concluded that the collapse of these societies occurred partly because people inadvertently destroyed the ecological resources on which their societies depended. Modern nations such as Rwanda face similar issues. The country's population density is the highest in Africa, and it has a limited amount of land that can be used for growing crops. By the late 1980s, the need to feed a growing population led to the wholesale clearing of Rwanda's forests and wetlands, with the result that little additional land was available to farm. Increased population pressure, along with food shortages fueled by environmental scarcity, were likely contributing factors in igniting the genocide of 1994.

As we hope you have seen throughout this textbook, an understanding of biology is vital to comprehending and helping to solve many of society's problems. Within this large field, genomics and proteomics may have a huge potential for improving people's lives and society at large. These disciplines offer the opportunity to unlock new diagnoses and treatments for diseases, to improve nutrition and food production, and even to help restore biological diversity.

Summary of Key Concepts

60.1 What Is Biodiversity?

- Biodiversity represents diversity at three levels: genetic diversity, species diversity, and ecosystem diversity. Conservation biology uses knowledge from molecular biology, genetics, and ecology to protect the biological diversity of life (Figure 60.1).

60.2 Why Conserve Biodiversity?

- The preservation of biodiversity has been justified because of its economic value, because of the value of ecosystem services, and on ethical grounds (Tables 60.1, 60.2, Figure 60.2).
- Four hypotheses attempt to explain the relationship between biodiversity and ecosystem function: diversity-stability, redundancy, keystone, and idiosyncratic (Figure 60.3).
- Experiments both in the laboratory and in the field have shown that increased biodiversity results in increased ecosystem function (Figures 60.4, 60.5).

60.3 The Causes of Extinction and Loss of Biodiversity

- Extinction—the process by which species die out—has been a natural phenomenon throughout the history of life on Earth. Extinction rates in recent times, however, have been much higher than in the past, a phenomenon called the biodiversity crisis (Figure 60.6).
- The main causes of extinctions have been and continue to be introduced species, direct exploitation, and habitat destruction (Figure 60.7).
- Reduced population size can lead to a reduction of genetic diversity through inbreeding, genetic drift, and limited mating, which reduces effective population size. Inbreeding, mating among genetically related relatives, can lead to a reduction in fertility (Figure 60.8).
- Knowledge of a species' effective population size is vital to ensure the success of conservation projects (Figure 60.9).

60.4 Conservation Strategies

- Habitat conservation strategies commonly target megadiversity countries, countries with the largest number of species; biodiversity hot spots, areas with the largest number of endemic species, those unique to the area; and representative habitats, areas that represent the major habitats (Figures 60.10, 60.11, Table 60.3).
- Conservation biologists employ many strategies in protecting biodiversity. Principles of the equilibrium model of island biogeography and landscape ecology are used in the theory and practice of park reserve design to determine, for example, whether the park should take the form of one single or several small reserves (Figures 60.12, 60.13).

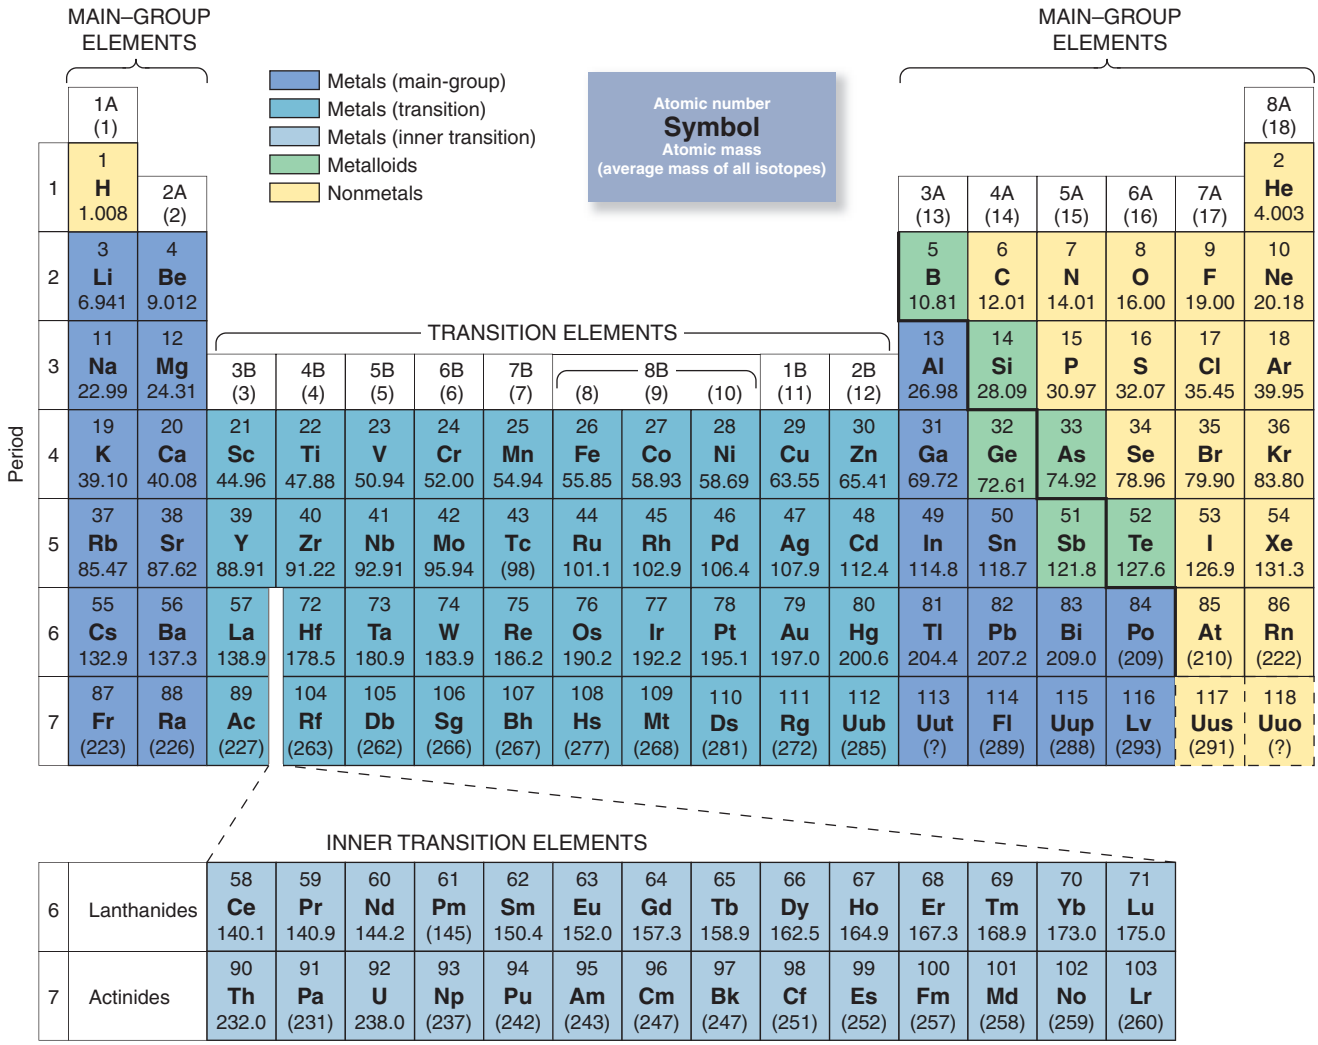
- Economic considerations also play an important role in reserve creation, and it has been shown that conservation spending is positively related to population size (Figure 60.14).
- The single-species approach focuses conservation efforts on indicator species, umbrella species, flagship species, and keystone species (Figures 60.15, 60.16).
- Restoration ecology seeks to repair or replace populations and their habitats. Three basic approaches to habitat restoration are complete restoration, rehabilitation, and ecosystem replacement (Figure 60.17).
- Captive breeding is the propagation of animals outside their natural habitat and reintroducing them to the wild (Figure 60.18).
- Cloning of endangered species has been accomplished on a very small scale, and despite its limitations may have a role in conservation biology (Figure 60.19).

Assess and Discuss

Test Yourself

1. Which of the following statements best describes an endangered species?
   a. a species that is likely to become extinct in a portion of its range
   b. a species that has disappeared in a particular community but is present in other natural environments
   c. a species that is extinct
   d. a species that is in danger of becoming extinct throughout all or a significant portion of its range
   e. both b and d
2. Biological diversity is important and should be preserved because
   a. food, medicines, and industrial products are all benefits of biodiversity.
   b. ecosystems provide valuable services to us in many ways.
   c. many species can be used as valuable research tools.
   d. we have an ethical responsibility to protect our environment.
   e. of all of the above.
3. The research conducted by Tilman and colleagues demonstrated that
   a. as diversity increases, productivity increases.
   b. as diversity decreases, productivity increases.
   c. areas with higher diversity demonstrate less efficient use of nutrients.
   d. species-richness increases lead to an increase in invasive species.
   e. increased diversity results in increased susceptibility to disease.
4. Approximately what percentage of genetic variation remains in a population of 25 individuals after three generations?
   a. 98% c. 94% e. 84%
   b. 96% d. 92%
5. What is the effective population size of an island population of parrots consisting of 30 males and 30 females, in which only 10 of the males breed?
   a. 10 c. 30 e. 60
   b. 20 d. 40
6. Saving endangered habitats, such as the Pampas of Argentina, focuses on
   a. saving genetic diversity.
   b. saving keystone species.
   c. conservation in a megadiversity country.
   d. preserving an area rich in endemic species.
   e. preservation of a representative habitat.
7. Geographic hotspots are those areas rich in
   a. species.
   b. habitats.
   c. rare species.
   d. biodiversity.
   e. endemic species.
8. A new canine distemper pathogen that decimates a population of black-footed ferrets is known as a(n):
   a. keystone species.
   b. dominant species.
   c. indicator species.
   d. umbrella species.
   e. flagship species.
9. Small strips of land that connect and allow organisms to move between small patches of natural habitat are called
   a. biological conduits.
   b. edge effects.
   c. movement corridors.
   d. migration pathways.
   e. landscape breaks.
10. Bioremediation is
    a. a process that restores a disturbed habitat to its original state.
    b. a process that uses microbes or plants to detoxify contaminated habitats.
    c. the legislation requiring rehabilitation of a disturbed habitat.
    d. a process of capturing all of the living individuals of a species for breeding purposes.
    e. the process of removing tissue from a dead organism in the hopes of cloning it.

Conceptual Questions



1. Why do managers go to the expense of keeping stud books and moving males and females between zoos to produce offspring?
2. Which types of species are most vulnerable to extinction?
3.  A principle of biology is that *biology affects our society.* What is the value of increased biodiversity for human society?

Collaborative Questions

1. Discuss several causes of species extinction.
2. You are asked to design a park to maximize biodiversity in a tropical country. What are your recommendations?

Appendix A

Periodic Table of the Elements

The complete Periodic Table of the Elements. Group numbers are different in some cases from those presented in Figure 2.5, because of the inclusion of transition elements. In some cases, the average atomic mass has been rounded to one or two decimal places, and in others only an estimate is given in parentheses due to the short-lived nature or rarity of those elements. The symbols and names of some of the elements between 112–118 are temporary until the chemical characteristics of these elements become better defined. Element 117 is currently not confirmed as a true element, and little is known about element 118. The International Union of Pure and Applied Chemistry (IUPAC) has recently proposed adopting the name copernicium (Cp) for element 112 in honor of scientist and astronomer Nicolaus Copernicus.

Concept Checks

Figure 1.5 It would be at the population level.

Figure 1.6 In monkeys, the tail has been modified to grasp onto things, such as tree branches. In skunks, the tail is modified with a bright stripe; the tail can stick up and act as a warning signal to potential predators. In cattle, the tail has long hairs and is used to swat insects. Many more examples are possible.

Figure 1.7 Natural selection is a process that causes evolution to happen.

Figure 1.9 A tree of life suggests that all living organisms evolved from a single ancestor by vertical evolution with mutation. A web of life assumes that both vertical evolution with mutation and horizontal gene transfer were important mechanisms in the evolution of new species.

Figure 1.11 Taxonomy helps us appreciate the unity and diversity of life. Organisms that are closely related evolutionarily are placed in smaller groups.

Figure 1.12 The genome stores the information to make an organism's proteins. In and of itself, the genome is merely DNA. The traits of cells and organisms are largely determined by the structures and functions of the hundreds or thousands of different proteins they make.

Figure 1.15 A researcher can compare the results in the experimental group and control group to determine if a single variable is causing a particular outcome in the experimental group.

Figure 1.16 After the *CF* gene was identified by discovery-based science, researchers realized that the *CF* gene was similar to other genes that encoded proteins that were already known to be transport proteins. This provided an important clue that the *CF* gene also encodes a transport protein.

BioConnections

Figure 1.4 This figure is emphasizing that living organisms grow and develop.

Figure 1.10 Fungi are more closely related to animals.

Feature Investigation Questions

1. In discovery-based science, a researcher does not need to have a preconceived hypothesis. Experimentation is conducted in the hope that it may have practical applications or may provide new information that will lead to a hypothesis. By comparison, hypothesis testing occurs when a researcher forms a hypothesis that makes certain predictions. Experiments are conducted to see if those predictions are correct. In this way, the hypothesis may be accepted or rejected.
2. This strategy may be described as a five-stage process:
    1. Observations are made regarding natural phenomena.
    2. These observations lead to a hypothesis that tries to explain the phenomena. A useful hypothesis is one that is testable because it makes specific predictions.
    3. Experimentation is conducted to determine if the predictions are correct.
    4. The data from the experiment are analyzed.
    5. The hypothesis is accepted or rejected.
3. In an ideal experiment, the control and experimental groups differ by only one factor. Biologists apply statistical analyses to their data to determine if the control and experimental groups are likely to be different from each other because of the single variable that is different between the two groups. This provides an objective way to accept or reject a hypothesis.

Test Yourself

1. d 2. a 3. b 4. c 5. d 6. b 7. d 8. d 9. a 10. b

Conceptual Questions

1. Principles (a) through (f) apply to individuals whereas (g) and (h) apply to populations.
2. The unity among different species occurs because modern species have evolved from a group of related ancestors. Some of the traits in those ancestors are also found in modern species, which thereby unites them. The diversity is due to the variety of environments on the Earth. Each species has evolved to occupy its own unique environment. For every species, many traits are evolutionary adaptations to survival in a specific environment. For this reason, evolution also promotes diversity.
3. The principles are outlined in Figure 1.4. Students can rephrase these principles in their own words.

Chapter 2

Concept Checks

Figure 2.4 An energy shell is a region outside the nucleus of an atom occupied by electrons of a given energy level. More than one orbital can be found within an electron shell. An orbital may be spherical or dumbbell-shaped and contains up to two electrons.

Figure 2.9 The octet rule states that atoms are stable when they have eight electrons in their outermost shell. Oxygen has six electrons in its outer shell. When two oxygen atoms share two pairs of electrons, each atom has eight electrons in its outer shell, at least part of the time.

Figure 2.11 Strand separation requires energy, because the DNA strands are held together by a large number of hydrogen bonds. Although each hydrogen bond is weak, collectively the vast number of such bonds in a molecule of DNA adds up to a considerable strength.

Figure 2.17 The oil would be in the center of the soap micelles.

Figure 2.20 It is 10^{-6} M. Since $[H^+][OH^-]$ always equals 10^{-14} M, if $[H^+] = 10^{-8}$ M (that is, pH 8.0), then $[OH^-]$ must be 10^{-6} M.

BioConnections

Figure 2.20 At a pH of 5.0, the H^+ concentration would be 10^{-5} M, as can be seen from the figure but which can also be calculated by the equation $pH = -\log_{10}[H^+]$. (From this information, you can also determine that the OH^- concentration must be 10^{-9} M, because the product of the H^+ and OH^- concentrations must be equal to 10^{-14} M).

Feature Investigation Questions

1. Scientists were aware that atoms contained charged particles. Many believed that the positive charges and mass were evenly distributed throughout the atom.
2. Rutherford was testing the hypothesis that atoms are composed of positive charges evenly distributed throughout the atom. Based on this model of the structure of the atom, alpha particles, which are positively charged nuclei of helium atoms, should be deflected as they pass through the foil, due to the presence of positive charges spread throughout the gold foil.
3. Instead of detecting slight deflection of most alpha particles as they passed through the gold foil, the majority, 98%, of the alpha particles passed directly through the gold foil without deflection. A much smaller percentage either deflected or bounced back from the gold foil. Rutherford suggested that since

most of the alpha particles passed unimpeded through the gold foil, most of the volume of atoms is empty space. Rutherford also proposed that the bouncing back of some of the alpha particles indicated that most of the positively charged particles were concentrated in a compact area. These results ran counter to the hypothesized model.

Test Yourself

1. b 2. b 3. b 4. d 5. e 6. e 7. e 8. c 9. c 10. e

Conceptual Questions

1. Covalent bonds are bonds in which atoms share electrons. A nonpolar covalent bond is one between two atoms of similar electronegativities, such as two carbon atoms. A hydrogen bond is a weak interaction that forms when a hydrogen atom from one polar molecule becomes electrically attracted to an electronegative atom. The van der Waal dispersion forces are temporary, weak interactions, resulting from random electrical forces generated by the changing distributions of electrons in the outer shells of nearby atoms. The strong attraction between two oppositely charged atoms forms an ionic bond.
2. Within limits, bonds within molecules can rotate and thereby change the shape of a molecule. This is important because it is the shape of a molecule that determines, in part, the ability of that molecule to interact with other molecules. Also, when two molecules do interact through such forces as hydrogen bonds, the shape of one or both molecules may change as a consequence. The change in shape is often part of the mechanism by which signals are sent within and between cells.
3. A good example of emergent properties at the molecular level is that of the formation of sodium chloride (NaCl), a solid white crystalline compound that is very important for most living organisms. In their elemental states, sodium is a soft, highly reactive metal and chlorine is a toxic gas. When they combine through ionic bonds, the two elements produce a completely new and harmless substance found in all the world's oceans and soils. Another example described in this chapter is water, a liquid that is vital for all life but which is formed from two gases, hydrogen and oxygen, with very different properties.

Chapter 3

Concept Checks

Figure 3.5 One reason is that the binding of a molecule to an enzyme depends on the spatial arrangements of the atoms in that molecule. Enantiomers have different spatial relationships that are mirror images of each other. Therefore, one may bind very tightly to an enzyme and the other may not be recognized at all.

Figure 3.6 Recall from Figure 3.4 that the reverse of a dehydration reaction is called a hydrolysis reaction, in which a molecule of water is added to the molecule being broken down, resulting in the formation of monomers.

Figure 3.10 Hydrogenation is the addition of hydrogens to double-bonded carbon atoms, changing them from unsaturated to saturated. This causes them to be solid at room temperature.

Figure 3.11 The phospholipids would be oriented such that their polar regions dissolved in the water layer and the nonpolar regions dissolved in the oil. Thus, the phospholipids would form a layer at the interface between the water and oil.

Figure 3.14 71; one less than the number of amino acids in the polypeptide.

Figure 3.18 If the primary structure of protein 1 were altered in some way, this would, in turn, most likely alter the secondary and tertiary structures of protein 1. Therefore, it is possible that the precise fit between proteins 1 and 2 would be lost and that the two proteins would lose the ability to interact.

Figure 3.23 Yes. The opposite strand must be complementary to the first strand, because pairs can form only between A and T, and G and C. For instance, if a portion of the first strand is AATGCA, the opposite strand along that region would be TTACGT.

BioConnections

Figure 3.7 Cellulose is believed to be the most abundant organic molecule on earth. In addition to being part of plant cells, it is also found in many other organisms, including many protists.

Feature Investigation Questions

1. Anfinsen was testing the hypothesis that the information necessary for determining the three-dimensional shape of a protein is contained within the protein itself. In other words, the chemical characteristics of the amino acids that make up a protein determines the three-dimensional shape.
2. The urea disrupts hydrogen bonds and ionic interactions that are necessary for protein folding. The mercaptoethanol disrupted the S−S bonds that also form between certain amino acids of the same polypeptide chains. Both substances essentially allow the polypeptide chain to unfold, disrupting the three-dimensional shape.
3. Anfinsen removed the urea and mercaptoethanol from the protein solution by size-exclusion chromatography. After removing the urea and mercaptoethanol, Anfinsen discovered that the protein refolded into its proper three-dimensional shape and became functional again. This was important because the solution contained only the protein and lacked any other cellular material that could possibly assist in protein folding. This demonstrated that the protein could refold into the functional conformation.

Test Yourself

1. b 2. e 3. e 4. a 5. c 6. b 7. e 8. d 9. b 10. b

Conceptual Questions

1. Isomers are two structures with an identical molecular formula but with different structures and arrangements of atoms within the molecule. There are two major types of isomers: structural and stereoisomers. Because many chemical reactions in biology depend on the actions of enzymes, which are often highly specific for the spatial arrangement of atoms in a molecule, one isomer of a pair may have biological functions, and the other may not.
2. Saturated fatty acids are saturated with hydrogen and have only single (C−C) bonds, whereas unsaturated fatty acids have one or more double (C=C) bonds. The double bonds in unsaturated fatty acids alters their shape, resulting in a kink in the structure. Saturated fatty acids are unkinked and are better able to stack tightly together. Fats containing saturated fatty acids have a higher melting point than those containing mostly unsaturated fatty acids; consequently, saturated fats tend to be solids at room temperatures, and unsaturated fatty acids are usually liquids at room temperature.
3. The structures of macromolecules in all cases determines their function. For example, the structure of a protein determines its three-dimensional shape. This, in turn, allows a protein to interact specifically with certain other molecules. Also, protein domains have specific structures that determine their functions. A single protein may have multiple domains, allowing that protein to perform a fairly complex function, such as activating genes in response to hormone binding. Likewise, the structure of different lipids determines such functional characteristics as male/female differences, cellular membrane formation, and energy storage. The different structures of polysaccharides determine their usefulness as energy stores, or as components of plant cell walls.

Chapter 4

Concept Checks

Figure 4.1 You would use transmission electron microscopy. The other methods do not have good enough resolution.

Figure 4.3 The primary advantage is that it gives an image of the 3-D surface of an object.

Figure 4.7 Centrioles: Not found in plant cells; their role is not entirely clear, but they are found in the centrosome, which is where microtubules are anchored.

Chloroplasts: Not found in animal cells; function in photosynthesis.

Cell wall: Not found in animal cells; important in cell shape.

Figure 4.12 Both dynein and microtubules are anchored in place. Using ATP as a source of energy, dynein tugs on microtubules. Because the microtubules are anchored, they bend in response to the force exerted by dynein.

Figure 4.15 The nuclear lamina organizes the nuclear envelope and also helps to organize/anchor the chromosomes. The nuclear matrix is inside the nucleus and helps to organize the chromosomes into chromosome territories.

Figure 4.18 The protein begins its synthesis in the cytosol and then is further synthesized into the ER. It travels to the *cis*-, *medial*-, and *trans*-Golgi and then is secreted.

Figure 4.22 Of these three choices, membrane transport is probably the most important because it regulates which molecules can enter the cell and participate in metabolism and which products of metabolism are exported from the cell. Cell

signaling may affect metabolism, but its overall effect is probably less important than membrane transport.

Figure 4.24 It increases the surface area where ATP synthesis takes place, thereby making it possible to increase the amount of ATP synthesis.

Figure 4.27 Bacteria and mitochondria are similar in size; they both have circular chromosomes; they both divide by binary fission; and they both make ATP. Bacterial chromosomes are larger, and they make all of their own cellular proteins. Mitochondria chromosomes are smaller, and they import most of their proteins from the cytosol.

Figure 4.29 The signal sequence of an ER protein is recognized by SRP, which halts translation. The emerging protein and its ribosome are then transferred to the ER membrane, where translation resumes.

Figure 4.31 If chaperone proteins were not found in the cytosol, the mitochondrial matrix protein would start to fold, which might prevent it from being able to pass through the channel in the outer and inner mitochondrial membrane. Normally, a protein is threaded through this channel in an unfolded state.

BioConnections

Figure 4.6 Alternative splicing produces proteins with slightly different structures, because they have certain regions that have different amino acid sequences. The functions of such proteins are often similar, but specialized for the cell type in which they are expressed.

Figure 4.8 The surfaces of cells involved with gas exchange are highly convoluted. This provides a much greater surface area, thereby facilitating the movement of gases across the membrane.

Figure 4.11 The type of movement shown in part (b) occurs during muscle contraction.

Figure 4.13 Cilia carry out a variety of functions, including motility, moving food particles into a feeding groove, and dispersing across moist surfaces.

Figure 4.16 During cell division, the chromosomes condense and form more compact structures.

Figure 4.26 These processes are very similar in that DNA replication occurs and then mitochondria or bacterial cells split in two. They are different in that bacteria have cell walls and septa must form between the two daughter cells, which does not occur when mitochondria divide.

Feature Investigation Questions

1. In a pulse-chase experiment, radioactive material is provided to cells. This is referred to as the pulse, or single administration of the radioactive material to the cells. After a few minutes, a large amount of nonradioactive material is provided to the cells to out compete or "chase away" any of the remaining radioactive material.

   The researchers were attempting to determine the movement of proteins through the different compartments of a cell. Radioactive amino acids were used to label the proteins and enable the researchers to visualize where the proteins were at different times.
2. Pancreatic cells produce large numbers of proteins that are secreted from the cell. The number and final location of the proteins would allow the researchers an ideal system for studying protein movement through the cell.
3. Using electron microscopy, the researchers found that the proteins, indicated by radioactivity, were first found in the ER of the cells. Later the radioactivity moved to the Golgi and then into vesicles near the plasma membrane.

   The researchers concluded that secreted proteins move through several cellular compartments before they are secreted from the cell. Also, the movement of proteins through these compartments is not random but follows a particular pathway: ER, Golgi, secretory vesicles, plasma membrane, and, finally, secreted.

Test Yourself

1. d 2. d 3. a 4. b 5. e 6. a 7. e 8. e 9. a It would go there first, because targeting to the ER occurs cotranslationally. 10. c It is true they carry out metabolism, but so do eukaryotic cells.

Conceptual Questions

1. There are a lot of possibilities. The interactions between a motor protein (dynein) and cytoskeletal filaments (microtubules) cause a flagellum to bend. The interaction between V-snares and T-snares causes a vesicle to fuse with the correct target membrane.
2. If the motor is bound to a cargo and the motor can walk along a filament that is fixed in place, this will cause the movement of the cargo when the motor is activated. If the motor is fixed in place and the filament is free to move, this will cause the filament to move when the motor is activated. If both the motor and filament are fixed in place, the activation of the motor will cause the filament to bend.
3. ATP synthesis occurs along the inner mitochondrial membrane. The invaginations of this membrane greatly increase its surface area, thereby allowing for a greater amount of ATP synthesis.

Chapter 5

Concept Checks

Figure 5.3 Probably not. The hydrophobic tails of both leaflets touch each other, so the heavy metal would probably show a single, thick dark line. Osmium tetroxide shows two parallel lines because it labels the polar head groups, which are separated by the hydrophobic interior of the membrane.

Figure 5.4 More double bonds and shorter fatty acyl tails make the membrane more fluid. Changing the cholesterol concentration can also affect fluidity, but that depends on the starting level of cholesterol. If cholesterol was at a level that maximized stability, increasing the cholesterol concentration would probably increase fluidity.

Figure 5.5 The low temperature prevents lateral diffusion of membrane proteins. Therefore, after fusion, all of the mouse proteins would stay on one side of the fused cell, and all of the human proteins would remain on the other.

Figure 5.7 Lipids are transferred to the other leaflet of the ER via enzymes called flippases.

Figure 5.8 The most common way for a transmembrane segment to form is that it contains a stretch (about 20) of amino acids that mostly have hydrophobic (nonpolar) side chains.

Figure 5.12 Although both of these molecules penetrate the bilayer fairly quickly, methanol has a polar $-$OH group and therefore crosses a bilayer more slowly than methane.

Figure 5.15 Water will move from outside to inside, from the hypotonic medium into the hypertonic medium.

Figure 5.17 The purpose of gating is to regulate the function of channels, allowing them to be open or closed.

Figure 5.22 The Na^+/K^+-ATPase could reach the point where the protein was covalently phosphorylated and Na^+ was released on the outside. At that stage, the reaction would stop, because it needs K^+ to proceed through the rest of the cycle.

Figure 5.23 The protein coat is needed for the membrane to bud from its site and form a vesicle.

BioConnections

Figure 5.6 Transmembrane proteins called cell adhesion molecules bind to each other to promote cell-to-cell adhesion. In addition, they can bind to molecules in the extracellular matrix, such as collagen fibers, thereby causing a cell to adhere to the extracellular matrix.

Figure 5.11 Leucine would cross an artificial membrane more easily because it is more hydrophobic than lysine.

Figure 5.13 Gradients of sodium and potassium ions are important for the conduction of action potentials.

Feature Investigation Questions

1. Most cells allow movement of water across the cell membrane by passive diffusion. However, it was noted that certain cell types had a much higher rate of water movement, indicating that something different was occurring in these cells.
2. The researchers identified water channels by characterizing proteins that are present in red blood cells and kidney cells but not other types of cells. Red blood cells and kidney cells have a faster rate of water movement across the membrane than other cell types. These cells are more likely to have water channels. By identifying proteins that are found in both of these types of cells but not in other cells, the researchers were identifying possible candidate proteins that function as water channels. In addition, CHIP28 had a structure that resembled other known channel proteins.

   Agre and his associates experimentally created multiple copies of the gene that produces the CHIP28 protein and then artificially transcribed the genes

to produce many mRNAs. The mRNAs were injected into frog oocytes where they could be translated to make the CHIP28 proteins. After altering the frog oocytes by introducing the CHIP28 mRNAs, they compared the rate of water transport in the altered oocytes versus normal frog oocytes. This procedure allowed them to introduce the candidate protein into a cell type that normally does not have the protein present.

3. After artificially introducing the candidate protein into the frog oocytes, the researchers found that the experimental oocytes took up water at a much faster rate in a hypotonic solution as compared to the control oocytes. The results indicated that the presence of the CHIP28 protein did increase water transport into cells.

Test Yourself

1. c 2. c 3. b 4. d 5. b 6. e 7. d 8. e 9. e 10. c

Conceptual Questions

1. See Figure 5.1 for the type of drawing you should have made. The membrane is considered a mosaic of lipid, protein, and carbohydrate molecules. The membrane exhibits properties that resemble a fluid because lipids and proteins can move relative to each other within the membrane.
2. Integral membrane proteins can contain transmembrane segments that cross the membrane, or they may contain lipid anchors. Peripheral membrane proteins are noncovalently bound to integral membrane proteins or to the polar heads of phospholipids.
3. Lipid bilayers, channels, and transporters cause the plasma membrane to be selectively permeable. This allows a cell to take up needed nutrients from its extracellular environment and to export waste products into the environment.

Chapter 6

Concept Checks

Figure 6.2 The solution of dissolved Na^+ and Cl^- has more entropy. A salt crystal is very ordered, whereas the ions in solution are much more disordered.

Figure 6.4 If a large amount of ADP was broken down, it would be more difficult for the cell to make ATP, which is made by the attachment of a phosphate group to ADP. The ATP cycle would be inhibited.

Figure 6.5 It speeds up the rate. When the activation energy is lower, it takes less time for reactants to reach a transition state where a chemical reaction can occur. It does not affect the direction of a reaction.

Figure 6.6 The activation energy is lowered during the second step when the substrates undergo induced fit.

Figure 6.7 At a substrate concentration of 0.5 mM, enzyme A would have a higher velocity. Enzyme A would be very near its V_{max}, whereas enzyme B would be well below its V_{max}.

Figure 6.12 The oxidized form is NAD^+.

Figure 6.14 Protein degradation eliminates proteins that are worn out, misfolded, or no longer needed by the cell. Such proteins could interfere with normal cell function. In addition, the recycling of amino acids saves the cell energy.

BioConnections

Figure 6.9 Without RNase P, the tRNAs could not be converted to their mature forms. The pre-tRNAs would be too large to fit into the ribosome. Therefore, translation would be inhibited.

Figure 6.13 Feedback inhibition prevents the excessive breakdown of carbohydrates and thereby prevents the excessive synthesis of ATP. Cells don't waste energy making ATP if they don't need it.

Feature Investigation Questions

1. RNase P has both a protein and RNA subunit. To determine which subunit has catalytic function, it was necessary to purify them individually and then see which one is able to cleave ptRNA.
2. The experimental strategy was to incubate RNase P or subunits of RNase P with ptRNA and then run a gel to determine if ptRNA had been cleaved to a mature tRNA and a 5′ fragment. The control without protein was to determine if the RNA alone could catalyze the cleavage. The control without RNA was to determine if some other factor in the experiment (for instance, Mg^{2+} or protein) was able to cleave the ptRNA.
3. The critical results occurred when the researchers incubated the purified RNA subunit at high Mg^{2+} concentrations with the ptRNA. Under these conditions, the ptRNA was cleaved. These results indicate that the RNA subunit has catalytic activity. A high Mg^{2+} concentration is needed to keep it catalytically active in the absence of a protein subunit.

Test Yourself

1. e 2. b 3. b 4. c 5. a 6. c 7. b 8. e 9. e 10. a

Conceptual Questions

1. Exergonic reactions are spontaneous. They proceed in a particular direction. An exergonic reaction could be slow or fast. By comparison, an endergonic reaction is not spontaneous. It will not proceed in a particular direction unless free energy is supplied. An endergonic reaction can be fast or slow.
2. During feedback inhibition, the product of a metabolic pathway binds to an allosteric site on an enzyme that acts earlier in the pathway. The product inhibits this enzyme, thereby preventing the overaccumulation of the product.
3. Recycling of amino acids and nucleotides is important because it conserves a great deal of energy. Cells don't have to remake these building blocks, which would require a large amount of energy. Eukaryotes primarily use the proteasome to recycle amino acids.

Chapter 7

Concept Checks

Figure 7.2 The first phase is named the energy investment phase because some ATP is used up. The second phase is called the cleavage phase because a 6-carbon molecule is broken down into two 3-carbon molecules. The energy liberation phase is so named because NADH and ATP are made.

Figure 7.3 The molecules that donate phosphates are 1,3-bisphosphoglycerate and phosphoenolpyruvate.

Figure 7.6 For each acetyl group that is oxidized, the main products are 2 CO_2, 3 NADH, 1 $FADH_2$, and 1 GTP.

Figure 7.8 It is called cytochrome oxidase because it removes electrons from (oxidizes) cytochrome *c*. Another possible name would be oxygen reductase because it reduces oxygen.

Figure 7.10 No. The role of the electron transport chain is to make an H^+ electrochemical gradient. It is the H^+ electrochemical gradient that drives ATP synthase. If the H^+ electrochemical is made another way, such as by bacteriorhodopsin, the ATP synthase still makes ATP.

Figure 7.11 The γ subunit turns clockwise, when viewed from the intermembrane space. The β subunit in the back right is in conformation 3, and the one on the left is in conformation 1.

Figure 7.14 The advantage is that the cell can use the same enzymes to metabolize different kinds of organic molecules. This saves the cell energy because it is costly to make a lot of different enzymes, which are composed of proteins.

BioConnections

Figure 7.2 Glycolytic muscle fibers rely on glycolysis for their ATP needs. Because glycolysis does not require oxygen, such muscle fibers can function without oxygen.

Figure 7.4 FDG is radiolabeled so it can be specifically detected by a PET scan.

Feature Investigation Questions

1. The researchers attached an actin filament to the γ subunit of ATP synthase. The actin filament was fluorescently labeled so the researchers could determine if the actin filament moved when viewed under the fluorescence microscope.
2. When functioning in the hydrolysis of ATP, the actin filament was seen to rotate. The actin filament was attached to the γ subunit of ATP synthase. The rotational movement of the filament was the result of the rotational movement of the enzyme. In the control experiment, no ATP was added to stimulate enzyme activity. In the absence of ATP, no movement was observed.
3. No, the observation of counterclockwise rotation is the opposite of what would be expected inside the mitochondria. During the experiment, the enzyme was not functioning in ATP synthesis but instead was running backwards and hydrolyzing ATP.

Test Yourself

1. a 2. b 3. b 4. c 5. a 6. c 7. b 8. d 9. d 10. b

Conceptual Questions

1. The purpose of the electron transport chain is to pump H^+ across the inner mitochondrial membrane to establish a H^+ electrochemical gradient. When the H^+ flows back across the membrane through ATP synthase, ATP is synthesized.
2. The movement of H^+ through the *c* subunits causes the γ subunit to rotate. As it rotates, it sequentially alters the conformation of the subunits, where ATP is made. This causes (1) ADP and P_i to bind with moderate affinity, (2) ADP and P_i to bind very tightly such that ATP is made, and (3) ATP to be released.
3. As discussed in this chapter, the phases of glucose metabolism are regulated in a variety of ways. For example, key enzymes in glycolysis and the citric acid cycle are regulated by the availability of substrates and by feedback inhibition. The electron transport chain is regulated by the ATP/ADP ratio. Such regulation ensures that a cell does not waste energy making ATP when it is in sufficient supply. Also, the production of too much NADH is potentially harmful because at high levels it has the potential to haphazardly donate its electrons to other molecules and promote the formation of free radicals, highly reactive chemicals that damage DNA and cellular proteins.

Chapter 8

Concept Checks

Figure 8.1 Both heterotrophs and autotrophs carry out cellular respiration.

Figure 8.3 The Calvin cycle can occur in the dark as long as there is sufficient CO_2, ATP, and NADPH.

Figure 8.4 Gamma rays have higher energy than radio waves.

Figure 8.5 To drop down to a lower orbital at a lower energy level, an electron could release energy in the form of heat, release energy in the form of light, or transfer energy to another electron by resonance energy transfer.

Figure 8.7 By having different pigment molecules, plants can absorb a wider range of wavelengths of light.

Figure 8.8 ATP and NADPH are made in the stroma. O_2 is made in the thylakoid lumen.

Figure 8.9 Noncyclic electron flow produces equal amounts of ATP and NADPH. However, plants usually need more ATP than NADPH. Cyclic photophosphorylation allows plants to make just ATP, thereby increasing the relative amount of ATP.

Figure 8.10 Because these two proteins are homologous, this means that the genes that encode them were derived from the same ancestral gene. Therefore, the amino acid sequences of these two proteins are expected to be very similar, though not identical. Because the amino acid sequence of a protein determines its structure, two proteins with similar amino acid sequences would be expected to have similar structures.

Figure 8.12 An electron has its highest amount of energy just after it has been boosted by light in PSI.

Figure 8.13 NADPH reduces organic molecules and makes them more able to form C−C and C−H bonds.

Figure 8.16 The arrangement of cells in C_4 plants makes the level of CO_2 high and the level of O_2 low in the bundle sheath cells.

Figure 8.17 When there is plenty of moisture and it is not too hot, C_3 plants are more efficient. However, under hot and dry conditions, C_4 and CAM plants have the advantage because they lose less water and avoid photorespiration.

BioConnections

Figure 8.2 Two guard cells make up one stoma.

Figure 8.16 Water is taken up by the roots of plants and moves via the vascular system to the leaves.

Feature Investigation Questions

1. The researchers were attempting to determine the biochemical pathway of the process of carbohydrate synthesis in plants. The researchers wanted to identify different molecules produced in plants over time to determine the steps of the biochemical pathway.
2. The purpose for using ^{14}C was to label the different carbon molecules produced during the biochemical pathway. The researchers could "follow" the carbon molecules from CO_2 that were incorporated into the organic molecules during photosynthesis. The radioactive isotope provided the researchers with a method of labeling the different molecules.

   The purpose of the experiment was to determine the steps in the biochemical pathway of photosynthesis. By examining samples from different times after the introduction of the labeled carbon source, the researchers would be able to determine which molecules were produced first and, thus, products of the earlier steps of the pathway versus products of later steps of the pathway.

   The researchers used two-dimensional paper chromatography to separate the different molecules from each other. Afterward, the different molecules were identified by different chemical methods. The text describes the method of comparing two-dimensional paper chromatography results of unknown molecules to known molecules and identifying the unknown with the known molecule it matched.
3. The researchers were able to determine the biochemical process that plants use to incorporate CO_2 into organic molecules. The researchers were able to identify the biochemical steps and the molecules produced at these steps in what is now called the Calvin cycle.

Test Yourself

1. c 2. c 3. c 4. a 5. b 6. b 7. c 8. b 9. e 10. c

Conceptual Questions

1. The two stages of photosynthesis are the light reactions and the Calvin cycle. The key products of the light reactions are ATP, NADPH, and O_2. The key product of the Calvin cycle is carbohydrate. The initial product is G3P, which is used to make sugars and other organic molecules.
2. NADPH is used during the reduction phase of the Calvin cycle. It donates its electrons to 1,3-BPG.
3. At the level of the biosphere, the role of photosynthesis is to incorporate carbon dioxide into organic molecules. These organic molecules can then be broken down, by autotrophs and by heterotrophs, to make ATP. The organic molecules made during photosynthesis are also used as starting materials to synthesize a wide variety of organic molecules and macromolecules that are made by cells.

Chapter 9

Concept Checks

Figure 9.1 It is glucose.

Figure 9.3 Endocrine signals are more likely to exist for a longer period of time. This is necessary because endocrine signals called hormones travel relatively long distances to reach their target cells. Therefore, the hormone must exist long enough to reach its target cells.

Figure 9.4 The effect of a signaling molecule is to cause a cellular response. Most signaling molecules do not enter the cell. Therefore, to exert an effect, they must alter the conformation of a receptor protein, which, in turn, stimulates an intracellular signal transduction pathway that leads to a cellular response.

Figure 9.6 Phosphorylation of a protein via a kinase involves ATP hydrolysis, which is an exergonic reaction. The energy from this reaction usually alters the conformation of the phosphorylated protein, thereby influencing its function. Phosphorylation is used to regulate protein function.

Figure 9.7 The α subunit has to hydrolyze its GTP to GDP. This changes the conformation of the α subunit so that it can reassociate with the β and γ subunits.

Figure 9.12 The signal transduction pathway begins with the G protein and ends with protein kinase A being activated. The cellular response involves the phosphorylation of target proteins. The phosphorylation of target proteins will change their function in some way, which is how the cell is responding.

Figure 9.13 Depending on the protein involved, phosphorylation can activate or inhibit protein function. Phosphorylation of phosphorylase kinase and glycogen phosphorylase activates their function, whereas it inhibits glycogen synthase.

Figure 9.14 Signal amplification allows a single signaling molecule to affect many proteins within a cell, thereby amplifying a cellular response.

Figure 9.18 The initiator caspase is part of the death-inducing signaling complex. It is directly activated when a cell receives a death signal. The initiator caspase then activates the executioner caspases, which degrade various cellular proteins and thereby cause the destruction of the cell.

BioConnections

Figure 9.2 Auxin causes cells to elongate. The cells on the nonilluminated side accumulate more auxin, which causes this side to grow faster and bend toward the light.

Figure 9.5 Most receptors and enzymes bind their ligands noncovalently and with high specificity. Enzymes, however, convert their ligands (which are reactants) into products, whereas receptors undergo a conformation change after a ligand binds.

Figure 9.10 The GTP-bound form of Ras is active and promotes cell division. To turn the pathway off, Ras hydrolyzes GTP to GDP. If this cannot occur due to a mutation, the pathway will be continuously on, and uncontrolled cell division will result.

Feature Investigation Questions

1. Compared with control rats, those injected with prednisolone alone would be expected to have a decrease in the number of cells because it suppresses ACTH synthesis. Therefore, apoptosis would be higher. By comparison, prednisolone + ACTH would have a normal number of cells because the addition of ACTH would compensate for the effects of prednisolone. ACTH alone would be expected to have a greater number of cells; apoptosis would be inhibited.
2. Yes, when injected with ACTH, prednisolone probably inhibited the ability of the rats to make their own ACTH. Even so, they were given ACTH by injection, so they didn't need to make their own ACTH to prevent apoptosis.
3. The lowest level of apoptosis would occur in the ACTH alone group, because they could make their own ACTH plus they were given ACTH. With such high levels of ACTH, they probably had the lowest level of apoptosis; it was already known that ACTH promotes cell division.

Test Yourself

1. d 2. c 3. d 4. e 5. a 6. c 7. e 8. e 9. e 10. b

Conceptual Questions

1. Cells need to respond to a changing environment, and cells need to communicate with each other.
2. In the first stage, a signaling molecule binds to a receptor, causing receptor activation. In the second stage, one type of signal is transduced or converted to a different signal inside the cell. In the third stage, the cell responds in some way to the signal, possibly by altering the activity of enzymes, structural proteins, or transcription factors. When the estrogen receptor is activated, the second stage, signal transduction, is not needed because the estrogen receptor is an intracellular receptor that directly activates the transcription of genes to elicit a cellular response.
3. Cell signaling allows cells to respond to environmental changes. For example, if a yeast cell is exposed to glucose, cell signaling will allow it to adapt to that change and utilize glucose more readily. Likewise, cell signaling allows plants to grow toward light. In addition, cells in a multicellular organism respond to changes in signaling molecules, such as hormones, and thereby coordinate their activities.

Chapter 10

Concept Checks

Figure 10.1 The four functions of the ECM in animals are strength, structural support, organization, and cell signaling.

Figure 10.2 The extension sequences of procollagen prevent fibers from forming intracellularly.

Figure 10.3 The proteins would become more linear, and the fiber would come apart.

Figure 10.4 GAGs are highly negatively charged molecules that tend to attract positively charged ions and water. Their high water content gives GAGs a gel-like character, which makes them difficult to compress.

Figure 10.6 Because the secondary cell wall is usually rigid, it prevents cell growth. If it were made too soon, it might prevent a cell from attaining its proper size.

Figure 10.7 Adherens junctions and desmosomes are cell-to-cell junctions, whereas hemidesomosomes and focal adhesions are cell-to-ECM junctions.

Figure 10.9 Tight junctions in your skin prevent harmful things like toxins and viruses from entering your body. They also prevent materials like nutrients from leaking out of your body.

Figure 10.10 As opposed to the results shown in Figure 10.10, the dye would be on the side of the cell layer facing the intestinal tract. You would see dye up to the tight junction on this side of the cells, but not on the side of the tight junction facing the blood.

Figure 10.13 Middle lamellae are similar to anchoring junctions and desmosomes in that they all function in cell-to-cell adhesion. However, their structures are quite different. Middle lamellae are composed primarily of carbohydrates that involve linkages between negatively charged carbohydrates and divalent cations. By comparison, anchoring junctions and desmosomes hold cells together via proteins such as cadherins and integrins.

Figure 10.15 Connective tissue would have the most extensive ECM.

Figure 10.17 Dermal tissue would be found on the surfaces of leaves, stems, and roots.

BioConnections

Figure 10.9 If tight junctions did not exist, substances in the lumen of your intestine might directly enter your blood. This could be potentially harmful if you consumed something with a toxic molecule in it. Likewise, materials from blood could be lost by diffusing into the lumen of your small intestine.

Figure 10.14 Plasmodesmata facilitate the movement of nutrients in a cell-to-cell manner. This is called symplastic transport.

Feature Investigation Questions

1. The purpose of this study was to determine the sizes of molecules that can move through gap junctions from one cell to another.
2. The researchers used fluorescent dyes to visibly monitor the movement of material from one cell to an adjacent cell through the gap junctions. First, single layers of rat liver cells were cultured. Next, fluorescent dyes with molecules of various masses were injected into particular cells. The researchers then used fluorescence microscopy to determine whether or not the dyes were transferred from one cell to the next.
3. The researchers found that molecules of masses less than 1,000 daltons (Da) could pass through the gap junction channels. Molecules of masses larger than 1,000 Da could not pass through the gap junctions. Further experimentation revealed variation in gap junction channel size of different cell types. However, the upper limit of the gap junction channel size was determined to usually be around 1,000 Da.

Test Yourself

1. e 2. c 3. b 4. e 5. e 6. d 7. e 8. d 9. e 10. a

Conceptual Questions

1. The primary cell wall is synthesized first between the two newly made daughter cells. It is relatively thin and allows cells to expand and grow. The secondary cell wall is made in layers by the deposition of cellulose fibrils and other components. In many cell types, it is relatively thick.
2. Cadherins and integrins are both membrane proteins that function as cell adhesion molecules. They also can function in cell signaling. Cadherins bind one cell to another cell, whereas integrins bind a cell to the extracellular matrix. Cadherins require calcium ions to function, but integrins do not.
3. Cell junctions are important in the proper arrangement of cells in a multicellular organism. In animals, for example, cells junctions allow cells to recognize and bind to each other. This is very important during embryonic development. In addition, cell junctions adhere cells to the extracellular matrix. Likewise, in plants, the cell wall and middle lamella are important in forming connections between plant cells that gives plants their correct morphology and function.

Chapter 11

Concept Checks

Figure 11.4 Cytosine is found in both DNA and RNA.

Figure 11.5 The phosphate is attached to the number 5′ carbon in a single nucleotide. In a DNA strand, it is attached to both the 5′ carbon and 3′ carbon.

Figure 11.6 A phosphoester bond is a single covalent bond between a phosphorus atom and an oxygen atom. A phosphodiester linkage involves two phosphoester bonds. This linkage occurs along the backbone of DNA and RNA strands.

Figure 11.8 Because it is antiparallel and obeys the AT/GC rule, it would be 3′–CTAAGCAAG–5′.

Figure 11.11 It would be 1/8 half-heavy and 7/8 light.

Figure 11.15 The oxygen in a new phosphoester bond comes from the sugar.

Figure 11.17 The lagging strand is made discontinuously in the direction opposite to the movement of the replication fork.

Figure 11.18 When primase is synthesizing a primer in the lagging strand, it moves from left to right in this figure. After it is done making a primer, it needs to hop to the opening of the replication fork to make a new primer. This movement is from right to left in this figure.

Figure 11.20 Telomerase uses a short strand of RNA as template to make the DNA repeat sequence.

Figure 11.23 Proteins hold the bottoms of the loops in place.

Figure 11.24 Proteins that compact the radial loop domains are primarily responsible for the X shape.

BioConnections

Figure 11.1 When a bacterium dies, it may release some of its DNA into the environment. Such DNA can be taken up via transformation by living bacteria, even bacteria of other species. If the DNA that is taken up encodes an antibiotic resistance gene, such a gene may be incorporated into the genome of the living bacterium and make it resistant to an antibiotic.

Figure 11.24 If chromosomes did not become compact, they might get tangled up with others during cell division, which would prevent the even segregation of chromosomes into the two daughter cells.

Feature Investigation Questions

1. Previous studies had indicated that mixing different strains could lead to transformation or the changing of a strain into a different one. Griffith had shown that mixing heat-killed type S with living type R would result in the transformation of the type R to type S. Though mutations could cause the changing of the identity of certain strains, the type R to type S transformation was not due to mutation but was more likely due to the transmission of a biochemical substance between the two strains. Griffith recognized this and referred to the biochemical substance as the "transformation principle." If Avery, MacCleod, and McCarty could determine the biochemical identity of this "transformation principle," they could identify the genetic material for this organism.
2. A DNA extract contains DNA that has been purified from a sample of cells.
3. The researchers could not verify that the DNA extract was completely pure and did not have small amounts of contaminating molecules, such as proteins and RNA. The researchers were able to treat the extract with enzymes to remove proteins (using protease), RNA (using RNase), or DNA (using DNase). Removing the proteins or RNA did not alter the transformation of the type R to type S strains. Only the enzymatic removal of DNA disrupted the transformation, indicating that DNA is the genetic material.

Test Yourself

1. a 2. b 3. d 4. d 5. b 6. c 7. b 8. d 9. d 10. c

Conceptual Questions

1. The genetic material must contain the information necessary to construct an entire organism. The genetic material must be accurately copied and transmitted from parent to offspring and from cell to cell during cell division in multicellular organisms. The genetic material must contain variation that can account for the known variation within each species and among different species.

   Griffith discovered something called the transformation principle, and his experiments showed the existence of biochemical genetic information. In addition, he showed that this genetic information can move from one individual to another of the same species. In his experiments, Griffith took heat-killed type S bacteria and mixed them with living type R bacteria and injected them into a live mouse, which died after the injection. By themselves, these two strains would not kill the mouse, but when they were put together, the genetic information from the heat-killed type S bacteria was transferred into the living type R bacteria, thus transforming the type R bacteria into type S.
2. Remember that DNA is double stranded, so 560 nucleotides would be 280 bp. With 10 bp per turn, this DNA molecule would have 28 complete turns.
3. In a DNA double helix, the two strands hydrogen-bond with each other according to the AT/GC rule. This provides the basis for DNA replication. In addition, as described in later chapters, hydrogen bonding between complementary bases is the basis for the transcription of RNA, which is needed for gene expression.

Chapter 12

Concept Checks

Figure 12.1 A person with two defective copies of phenylalanine hydroxylase would have phenylketonuria.

Figure 12.2 The ability to convert ornithine into citrulline is missing.

Figure 12.3 The usual direction of flow of genetic information is from DNA to RNA to protein, though exceptions occur.

Figure 12.4 If a terminator was removed, transcription would occur beyond the normal stopping point. Eventually, RNA polymerase would encounter a terminator from an adjacent gene, and transcription would end.

Figure 12.9 The ends of structural genes do not have a poly T region that acts as a template for the synthesis of a poly A tail. Instead, the poly A tail is added after the pre-mRNA is made by an enzyme that attaches many adenine nucleotides in a row.

Figure 12.11 A structural gene would still be transcribed into RNA if the start codon was missing. However, it would not be translated properly into a polypeptide.

Figure 12.12 It would bind to a 5′–UGG–3′codon, and it would carry tryptophan.

Figure 12.14 The function of the anticodon in tRNA is to recognize a codon in an mRNA.

Figure 12.17 Each mammal is closely related to the other mammals, and *E. coli* and *Serratia marcescens* are also closely related. The mammals are relatively distantly related to the bacterial species.

Figure 12.19 A region near the 5′ end of the mRNA is complementary to a region of rRNA in the small subunit. These complementary regions hydrogen-bond with each other to promote the binding of the mRNA to the small ribosomal subunit.

BioConnections

Figure 12.5 Both DNA and RNA polymerase use DNA strands as a template and connect nucleotides to each other in a 5′ to 3′ direction based on the complementarity of base pairing. One difference is that DNA polymerase needs a pre-existing strand, such as a RNA primer, to begin DNA replication, whereas RNA polymerase can begin the synthesis of RNA on a bare template strand. Another key difference is that DNA polymerase connects deoxyribonucleotides, whereas RNA polymerase connects ribonucleotides.

Figure 12.15 The attachment of an amino acid to a tRNA is an endergonic reaction. ATP provides the energy to catalyze this reaction.

Feature Investigation Questions

1. A triplet mimics mRNA because it can cause a specific tRNA to bind to the ribosome. This was useful to Nirenberg and Leder because it allowed them to correlate the binding of a tRNA carrying a specific amino acid with a triplet sequence.
2. The researchers were attempting to match codons with appropriate amino acids. By labeling one amino acid in each of the 20 tubes for each codon, the researchers were able to identify the correct relationship by detecting which tube resulted in radioactivity on the filter.
3. The AUG triplet would have shown radioactivity in the methionine test tube. Even though AUG acts as the start codon, it also codes for the amino acid methionine. The other three codons act as stop codons and do not code for an amino acid. In these cases, the researchers would not have found radioactivity trapped on filters.

Test Yourself

1. b 2. a 3. d 4. e 5. e 6. e 7. d 8. d 9. d 10. b

Conceptual Questions

1. Beadle and Tatum had the insight from their studies that a single gene controlled the synthesis of a single enzyme. In later years, it became apparent that genes code for all proteins and that some proteins consist of more than one polypeptide. So the modern statement is one gene codes for each polypeptide.

   Confirmation of their hypothesis came from studies involving arginine biosynthesis. Biochemists had already established that particular enzymes are involved in a pathway to produce arginine. Intermediates in this pathway are ornithine and citrulline. Mutants in single genes disrupted the ability of cells to catalyze just one reaction in this pathway, thereby suggesting that a single gene encodes a single enzyme.

2. Each of these 20 enzymes catalyzes the attachment of a specific amino acid to a specific tRNA molecule.
3. During transcription, a DNA strand is used as a template for the synthesis of RNA. Most genes encode mRNAs, which contain the information to make polypeptides. During translation, an mRNA binds to a ribosome and a polypeptide is made, which becomes a unit within a functional protein.

Chapter 13

Concept Checks

Figure 13.2 Gene regulation causes each cell type to express its own unique set of proteins, which, in turn, are largely responsible for the morphologies and functions of cells.

Figure 13.6 The *lacZ*, *lacY*, and *lacA* genes are under the control of the *lac* promoter.

Figure 13.7 Negative control refers to the action of a repressor protein, which inhibits transcription when it binds to the DNA. Inducible refers to the action of a small effector molecule. When it is present, it promotes transcription.

Figure 13.11 In this case, the repressor keeps the *lac* operon turned off unless lactose is present in the environment. The activator allows the bacterium to choose between glucose and lactose.

Figure 13.12 Both proteins are similar in that they repress transcription. They prevent RNA polymerase from transcribing the operons. They are different with regard to the effects of their small effector molecules. For the lac repressor, the binding of allolactose causes a conformational change that prevents the repressor from binding to its operator site. In contrast, the binding of tryptophan to the trp repressor allows it to bind to its operator site. Another difference is that the lac repressor binds to the DNA sequence found in the *lac* operator site, whereas the trp repressor recognizes a different DNA sequence that is found in the *trp* operator site.

Figure 13.16 When an activator interacts with mediator, it causes RNA polymerase to proceed to the elongation phase of transcription.

Figure 13.18 Some histone modifications may promote a loosening of chromatin structure, whereas others cause the chromatin to become more compact.

Figure 13.22 The advantage of alternative splicing is that it allows a single gene to encode two or more polypeptides. This enables organisms to have smaller genomes, which is more efficient and easier to package into a cell.

Figure 13.24 When iron levels rise in the cell, the iron binds to IRP and removes it from the mRNA that encodes ferritin. This results in the rapid translation of ferritin protein, which can store excess iron. Unfortunately, ferritin storage does have limits, so iron poisoning can occur if too much is ingested.

BioConnections

Figure 13.10 In eukaryotic cells, cAMP acts as a second messenger in signal transduction pathways.

Figure 13.19 A nucleosome is composed of DNA wrapped around an octamer of histone proteins.

Feature Investigation Questions

1. The first observation was the identification of rare bacterial strains that had constitutive expression of the *lac* operon. Normally, the genes are expressed only when lactose is present. These mutant strains expressed the genes all the time. The researchers also observed that some of these strains had mutations in the *lacI* gene. These two observations were key to the development of hypotheses explaining the relationship between the *lacI* gene and the regulation of the *lac* operon.
2. The correct hypothesis is that the *lacI* gene encodes a repressor protein that inhibits the operon.
3. The researchers used an F′ factor to introduce the wild-type *lacI* gene into the cell. In this case, the cells that contained the F′ factor had both a mutant copy of the gene and a normal copy of the gene. By creating a merozygote with an F′ factor with a normal copy of the *lacI* gene, regulation of the *lac* operon was restored. The researchers concluded that the normal *lacI* gene produced adequate amounts of a diffusible protein that could interact with the operator on the chromosomal DNA as well as the F′ factor DNA and regulate transcription.

Test Yourself

1. d 2. b 3. c 4. c 5. c 6. d 7. c 8. c 9. d 10. c

Conceptual Questions

1. In an inducible operon, the presence of a small effector molecule causes transcription to occur. An example is the *lac* operon, which is induced with allolactose. In repressible operons, a small effector molecule inhibits transcription. An example is the *trp* operon, which is represssed by high levels of tryptophan. The effects of these small molecules are mediated through regulatory proteins that bind to the DNA. Repressible operons usually encode anabolic enzymes, and inducible operons encode catabolic enzymes.
2. a. regulatory protein; b. small effector molecule; c. segment of DNA; d. small effector molecule; and e. regulatory protein.
3. Gene regulation offers key advantages such as (1) proteins are made only when they are needed; (2) proteins are made in the correct cell type; and (3) proteins are made at the correct stage of development. These advantages are important for reproduction and sustaining life.

Chapter 14

Concept Checks

Figure 14.1 At neutral pH, glutamic acid is negatively charged. Perhaps the negative charges repel each other and prevent hemoglobin proteins from aggregating into fiber-like structures.

Figure 14.2 Only germ-line cells give rise to gametes (sperm or egg cells). A somatic cell cannot give rise to a gamete and therefore cannot be passed to offspring.

Figure 14.3 This is a mutation that occurred in a somatic cell, so it cannot be transmitted to an offspring.

Figure 14.6 A thymine dimer is harmful because it can cause errors in DNA replication that result in mutations.

Figure 14.7 If we divide 44 by 2 million, the rate is 2.2×10^{-5}.

Figure 14.8 UvrC and UvrD are responsible for removing the damaged DNA. UvrC makes cuts on both sides of the damage, and then UvrD removes the damaged region.

Figure 14.9 The Sun has UV rays and other harmful radiation that could damage the DNA. This person has a defect in the nucleotide excision repair pathway. Therefore, her DNA is more likely to suffer mutations, which can cause pigmentation changes and other growths on the skin.

Figure 14.11 Growth factors turn on a signaling pathway that ultimately leads to cell division.

Figure 14.14 The type of cancer associated with this fusion is leukemia, which is a cancer of blood cells. The gene fusion produces a chimeric gene that is expressed in blood cells because it has the *bcr* promoter. The abnormal fusion protein promotes cancer in these cells.

Figure 14.15 Checkpoints prevent cell division if a genetic abnormality is detected. This helps to properly maintain the genome, thereby minimizing the possibility that a cell harboring a mutation will divide to produce two daughter cells.

Figure 14.16 Cancer would not occur if both copies of the *Rb* gene and both copies of the *E2F* gene were rendered inactive due to mutations. An active copy of the *E2F* gene is needed to promote cell division.

BioConnections

Figure 14.11 Drugs that inhibit protein kinases may be used to combat cancer if they target the protein kinases that are overactive in certain forms of cancer.

Feature Investigation Questions

1. Some biologists believed that heritable traits may be altered by physiological events. This suggests that mutations may be stimulated by certain needs of the organism. Others believed that mutations are random. If a mutation had a beneficial effect that improved survival and/or reproductive success, these mutations would be maintained in the population through natural selection.
2. The Lederbergs were testing the hypothesis that mutations are random events. By subjecting the bacteria to an environmental agent, the bacteriophage, the researchers would be able to see if the agent induced mutations or if mutations occurred randomly.
3. When looking at the number and location of colonies that were resistant to viral infection, the pattern was the same on the two secondary plates. This indicates that the mutation that allowed the colonies to be resistant to viral infection occurred on the master plate. The secondary plates introduced the selective agent that allowed the resistant bacteria colonies to survive and reproduce while the other colonies were destroyed. Thus, mutations occurred randomly in the absence of any selective agent.

Test Yourself

1. d 2. d 3. d 4. e 5. d 6. b 7. b 8. b 9. c 10. e

Conceptual Questions

1. Random mutations are more likely to be harmful than beneficial. The genes within each species have evolved to work properly. They have functional promoters, coding sequences, terminators, and so on, that allow the genes to be expressed. Mutations are more likely to disrupt these sequences. For example, mutations within the coding sequence may produce early stop codons, frameshift mutations, and missense mutations that result in a nonfunctional polypeptide. On rare occasions, however, mutations are beneficial; they may produce a gene that is expressed better than the original gene or produce a polypeptide that functions better.
2. A spontaneous mutation originates within a living cell. It may be due to spontaneous changes in nucleotide structure, errors in DNA replication, or products of normal metabolism that may alter the structure of DNA. The causes of induced mutations originate from outside the cell. They may be physical agents, such as UV light or X-rays, or chemicals that act as mutagens. Both spontaneous and induced mutations may cause a harmful phenotype such as a cancer. In many cases, induced mutations are avoidable if the individual can prevent exposure to the environmental agent that acts as a mutagen.
3. Mutations may alter the expression of a gene and/or alter the function of a protein encoded by a gene. In many cases, such changes are harmful because a gene may not be expressed at the correct level, or the protein may not function as well as the normal (nonmutant) protein.

Chapter 15

Concept Checks

Figure 15.1 Chromosomes are readily seen when they are compacted in a dividing cell. By adding such a drug, you increase the percentage of cells that are actively dividing.

Figure 15.2 Interphase consists of the G_1, S, and G_2 phases of the cell cycle.

Figure 15.6 As shown in the inset, each object is a pair of sister chromatids.

Figure 15.7 The astral microtubules, which extend away from the chromosomes, are important for positioning the spindle apparatus within the cell. The polar microtubules project into the region between the two poles. Polar microtubules that overlap with each other play a role in the separation of the two poles. Kinetochore microtubules are attached to kinetochores at the centromeres and are needed to sort the chromosomes.

Figure 15.9 Cytokinesis in both animal and plant cells separates a mother cell into two daughter cells. In animal cells, cytokinesis involves the formation of a cleavage furrow, which constricts like a drawstring to separate the cells. In plants, the two daughter cells are separated by the formation of a cell plate, which forms a cell wall between the two daughter cells.

Figure 15.13 The mother cell is diploid with two sets of chromosomes, whereas the four resulting cells are haploid with one set of chromosomes.

Figure 15.14 The reason for meiosis in animals is to produce gametes. These gametes combine during fertilization to produce a diploid organism. Following fertilization, the purpose of mitosis is to produce a multicellular organism.

Figure 15.16 Inversions and the translocations shown here do not affect the total amount of genetic material.

BioConnections

Figure 15.3 Checkpoints prevent cancer by checking the integrity of the genome. If abnormalities in DNA structure are detected or if a chromosome is not properly attached to the spindle, the checkpoint will delay cell division until the problem is fixed. If it cannot be fixed, the checkpoint will initiate the process of apoptosis, thereby killing a cell that may harbor mutations. This prevents the proliferation of cells that have the potential to be cancerous.

Figure 15.10 Though the process is not entirely understood, myosin motor proteins tug on the actin filaments. Actin monomers are gradually released during this process, which makes the contractile ring get smaller and smaller.

Feature Investigation Questions

1. Researchers had demonstrated that the binding of progesterone to receptors in oocytes caused the cells to progress from the G_2 phase of the cell cycle to mitosis. It appeared that progesterone acted as a signaling molecule for the progression through the cell cycle.
2. The researchers proposed that progesterone acted as a signaling molecule that led to the synthesis of molecules that cause the cell to progress through the cell cycle. These changes led to the maturation of the oocyte.

   To test their hypothesis, donor eggs were exposed to progesterone for either 2 or 12 hours. Control donor oocytes were not exposed to progesterone. Cytosol from each treatment was then transferred to recipient oocytes. The researchers recorded whether or not the recipient oocytes underwent maturation.
3. The oocytes that were exposed to the progesterone for only 2 hours did not induce maturation in the recipient oocytes, whereas the oocytes that were exposed to progesterone for 12 hours did induce maturation in the recipient oocytes. The researchers suggested that a time span greater than 2 hours is needed to accumulate the proteins that are necessary to promote maturation.

Test Yourself

1. b 2. e 3. b 4. e 5. c 6. a 7. c 8. d 9. b 10. c

Conceptual Questions

1. In diploid species, chromosomes are present in pairs, one from each parent, and contain similar gene arrangements. Such chromosomes are homologous. When DNA is replicated, two identical copies are created, and these are sister chromatids.
2. There are four copies. A karyotype shows homologous chromosomes that come in pairs. Each member of the pair has replicated to form a pair of sister chromatids. Therefore, four copies of each gene are present. See the inset to Figure 15.1.
3. Mitosis is a process that produces two daughter cells with the same genetic material as the original daughter cell. In the case of plants and animals, this allows a fertilized egg to develop into a multicellular organism composed of many, genetically identical cells.

Chapter 16

Concept Checks

Figure 16.2 Having blue eyes is a variant (also called a trait). A character is a more general term, which in this case would refer to eye color.

Figure 16.4 In this procedure, stamens are removed from the purple flower to prevent self-fertilization.

Figure 16.5 The reason why offspring of the F_1 generation exhibit only one variant of each character is because one trait is dominant over the other.

Figure 16.6 The ratio of alleles (*T* to *t*) is 1:1. The reason why the phenotypic ratio is 3:1 is because *T* is dominant to *t*.

Figure 16.7 It was *Pp*. To produce white offspring, which are *pp*, the original plant had to have at least one copy of the *p* allele. Because it had purple flowers, it also had to have one copy of the *P* allele. So, its genotype must be *Pp*.

Figure 16.8 If the linked hypothesis had been correct, the ratio would have been 3 round, yellow to 1 wrinkled, green.

Figure 16.11 There would be four possible ways of aligning the chromosomes, and eight different types of gametes (*ABC*, *abc*, *ABc*, *abC*, *Abc*, *aBC*, *AbC*, *aBc*) could be produced.

Figure 16.12 No. If two parents are affected with the disease, they must be homozygous for the mutant allele if it's recessive. Two homozygous parents would have to produce all affected offspring barring rare mutations. If they don't, then the inheritance pattern is not recessive.

Figure 16.13 All affected offspring having at least one affected parent suggests a dominant pattern of inheritance.

Figure 16.14 The person would be a female. In mammals, the presence of the Y chromosome causes maleness. Therefore, without a Y chromosome, a person with a single X chromosome would develop into a female.

Figure 16.18 No. You need a genetically homogenous population to study the norm of reaction. A wild population of squirrels is not genetically homogenous, so it could not be used.

BioConnections

Figure 16.9 Sexual reproduction is the process in which two haploid gametes (for example, sperm and egg) combine with each other to begin the life of a new individual. Each gamete contributes one set of chromosomes. The resulting zygote has chromosomes that occur in pairs (one from each parent). The members of each pair are called homologs of each other; they carry the same types of genes.

Figure 16.10 Alleles segregate from each other during the process of meiosis. Meiosis begins with a diploid mother cell that has pairs of genes, which may be found in different alleles. During meiosis, these pairs of genes separate and end up in different haploid cells. Therefore, each haploid cell has only one copy of each gene. In other words, each haploid cell has only one allele of a given gene.

Feature Investigation Questions

1. Morgan was testing the hypothesis of use and disuse. This hypothesis suggests that if a structure is not used, over time, it will diminish and/or disappear. In Morgan's experiments, originally he was testing to see if flies reared in the dark would lose some level of eye development.
2. When the F_1 individuals were crossed, only male F_2 offspring expressed the white eye color. At this time, Morgan was aware of sex chromosome differences between male and female flies. He realized that because males only possess one copy of X-linked genes, this would explain why only F_2 males exhibited the recessive trait.
3. In a cross between a white-eyed male and a female that is heterozygous for the white and red alleles, 1/2 of the female offspring would have white eyes. Also, a cross between a white-eyed male and a white-eyed female would yield all offspring with white eyes.

Test Yourself

1. c 2. b Mendel's law of segregation refers to the separation of the two alleles into separate cells. Meiosis is the nuclear division process that produces haploid cells. During the first meiotic division, a diploid cell divides to produce haploid cells. This is the phase in which the two alleles segregate, or separate, from each other. 3. d 4. c 5. e 6. d 7. d 8. d 9. d 10. c

Conceptual Questions

1. Two affected parents having an unaffected offspring would rule out recessive inheritance. If two unaffected parents had an affected offspring, dominant inheritance is ruled out. However, it should be noted that this answer assumes that no new mutations are happening. In rare cases, a new mutation could cause or alter these results. For recessive inheritance, two affected parents could have an unaffected offspring if the offspring had a new mutation that converted the recessive allele to the dominant allele. Similarly for dominant inheritance, two unaffected parents could have an affected offspring if the offspring inherited a new mutation that was dominant. Note: New mutations are expected to be very rare.
2. The individual probabilities are as follows: $AA = 0.25$; $bb = 0.5$; $CC = 0.5$; and $Dd = 0.5$. These are determined by making small Punnett squares. We use the product rule to calculate the probability of $AAbbCCDd = (0.25)(0.5)(0.5)(0.5) = 0.03125$, or 3.125%.
3. The environment is needed so that genes can be expressed. For example, organic molecules and energy are needed for transcription and translation. In addition, environmental factors influence the outcome of traits. For example, sunlight can cause a tanning response, thereby affecting the darkness of the skin.

Chapter 17

Concept Checks

Figure 17.1 The recessive allele is the result of a loss-of-function mutation. In a *Ccpp* individual, the enzyme encoded by the *P* gene is defective.

Figure 17.4 Crossing over occurred during oogenesis in the heterozygous female of the F_1 generation to produce the recombinant offspring of the F_2 generation.

Figure 17.5 One strategy would be to begin with two true-breeding parental strains: *alal dpdp* and al^+al^+ dp^+dp^+ and cross them together to get F_1 heterozygotes al^+al dp^+dp. Then testcross female F_1 heterozygotes to male *alal dpdp* homozygotes. In the F_2 generation, the recombinant offspring would be al^+al *dpdp* and *alal* dp^+dp, and the nonrecombinants would be al^+al dp^+dp, and *alal dpdp*.

Figure 17.7 The gene is located in the chloroplast DNA. In this species, chloroplasts are transmitted from parent to offspring via eggs but not via sperm.

Figure 17.9 The Barr body is much more compact than the other X chromosome in the cell. This compaction prevents most of the genes on the Barr body from being expressed.

Figure 17.11 Only the male genes are transcriptionally active in the offspring. In this case, half the offspring would be normal size, and half would be dwarf. The normal size offspring would have inherited the *Igf 2* allele from their father.

BioConnections

Figure 17.4 Crossing over occurs during prophase of meiosis I.

Figure 17.6 The evolutionary origin of these organelles is an ancient endosymbiotic relationship. Mitochondria are derived from purple bacteria, and chloroplasts are derived from cyanobacteria.

Feature Investigation Questions

1. Bateson and Punnett were testing the hypothesis that the gene pairs that influence flower color and pollen shape would assort independently of each other. The two traits were expected to show a pattern consistent with Mendel's law of independent assortment.
2. The expected results were a phenotypic ratio of 9:3:3:1. The researchers expected 9/16 of the offspring would have purple flowers and long pollen, 3/16 of the offspring would have purple flowers and round pollen, 3/16 of the offspring would have red flowers and long pollen, and 1/16 of the offspring would have red flowers and round pollen.
3. Though all four of the expected phenotype groups were seen, they were not in the predicted ratio of 9:3:3:1. The number of individuals with the phenotypes found in the parental generation (purple flowers and long pollen or red flowers and round pollen) was much higher than expected. Bateson and Punnett suggested that the gene controlling flower color was somehow coupled with the gene that controls pollen shape. This would explain why these traits did not always assort independently.

Test Yourself

1. d 2. c 3. d 4. c 5. d 6. b 7. a 8. d 9. a 10. a

Conceptual Questions

1. The correct answer is 6%. Individuals that are *Aabb* are recombinants that occurred as a result of crossing over. Because the genes are 12 map units apart, we expect that 12% will be recombinants. However, there are two types of recombinants: *Aabb* and *aaBb*, which would occur in equal amounts. Therefore, we expect 6% to be *Aabb*.
2. This may happen due to X-chromosome inactivation. As a matter of bad luck, a female embryo may preferentially inactivate the X chromosome carrying the normal allele in the embryonic cells that will give rise to the eyes. If the X chromosome carrying the allele for color blindness is preferentially expressed, one or both eyes may show color blindness to some degree.
3. When genes are linked along the same chromosome, researchers can set up testcrosses and determine the percentage of recombinant offspring that results from those testcrosses. This percentage can be used as a map distance between genes.

Chapter 18

Concept Checks

Figure 18.3 Viruses vary with regard to their structure and their genomes. Genome variation is described in Table 18.1.

Figure 18.5 The advantage of the lytic cycle is that the virus can make many copies of itself and proliferate. However, sometimes the growth conditions may not be favorable to make new viruses. The advantage of the lysogenic cycle is that the virus can remain latent until conditions become favorable to make new viruses.

Figure 18.9 There appears to be two nucleoids in the bacterial cell at the top.

Figure 18.10 The loop domains are held in place by proteins that bind to the DNA at the bottoms of the loops. The proteins also bind to each other.

Figure 18.11 Bacterial chromosomes and plasmids are similar in that they typically contain circular DNA molecules. However, bacterial chromosomes are usually much longer than plasmids and carry many more genes. Also, bacterial chromosomes tend to be more compacted due to the formation of loop domains and supercoiling.

Figure 18.12 16 hours is the same as 32 doublings. So, 2^{32} = 4,294,967,296. (The actual number would be much less because the cells would deplete the growth media and grow more slowly than the maximal rate.)

Figure 18.15 Yes. The two strains would have mixed together, allowing them to conjugate. Therefore, there would have been colonies on the plates.

Figure 18.16 During conjugation, only one strand of the DNA from an F factor is transferred from the donor to the recipient cell. The single-stranded DNA in both cells is then used as a template to create double-stranded F factor DNA in both cells.

Figure 18.18 Transduction is not a normal part of the phage life cycle. It is a mistake in which a piece of the bacterial chromosome is packaged into a phage coat and is then transferred to another bacterial cell.

BioConnections

Figure 18.4 Viral release occurs as a budding process in which a membrane vesicle is formed that surrounds the capsid. Similarly, exocytosis involves the formation of a membrane vesicle that encloses some type of cargo.

Figure 18.9 A nucleoid is not a membrane-bound organelle. It is simply a region where a bacterial chromosome is found. A cell nucleus in a eukaryotic cell has an envelope with a double membrane.

Figure 18.17 Griffiths was able to show that genetic material was transferred to type R bacteria, which converted them to type S. This occurred via transformation. Later, Avery, MacLeod, and McCarty determined that DNA was the material that was being transferred.

Feature Investigation Questions

1. Lederberg and Tatum were testing the hypothesis that genetic material could be transferred from one bacterial strain to another.
2. The experimental growth medium lacked particular amino acids and biotin. The mutant strains were unable to synthesize these particular amino acids or biotin. Therefore, they were unable to grow due to the lack of the necessary nutrients. The two strains used in the experiment each lacked the ability to make two essential nutrients necessary for growth. The appearance of colonies growing on the experimental growth medium indicated that some bacterial cells had acquired the normal genes for the two mutations they carried. By acquiring these normal genes, the ability to synthesize the essential nutrients was restored.
3. Bernard Davis placed samples of the two bacterial strains in different arms of a U-tube. A filter allowed the free movement of the liquid in which the bacterial cells were suspended, but prevented the actual contact between the bacterial cells. After incubating the strains in this environment, Davis found that genetic transfer did not take place. He concluded that physical contact between cells of the two strains was required for genetic transfer.

Test Yourself

1. c 2. e 3. c 4. b 5. e 6. a 7. d 8. d 9. b 10. c

Conceptual Questions

1. Viruses are similar to living cells in that they contain a genetic material that provides a blueprint to make new viruses. However, viruses are not composed of cells, and by themselves, they do not carry out metabolism, use energy, maintain homeostasis, or even reproduce. A virus or its genetic material must be taken up by a living cell to replicate.
2. Conjugation—The process involves a direct physical contact between two bacterial cells in which a donor cell transfers a strand of DNA to a recipient cell.
   Transformation—This occurs when a living bacteria takes up genetic information that has been released from a dead bacteria.
   Transduction—When a virus infects a donor cell, it incorporates a fragment of bacterial chromosomal DNA into a newly made virus particle. The virus then transfers this fragment of DNA to a recipient cell.
3. Horizontal gene transfer is the transfer of genes from another organism without being the offspring of that organism. These acquired genes sometimes increase survival and therefore may have an evolutionary advantage. Such genes may even promote the formation of new species. From a medical perspective, an important example of horizontal gene transfer is when one bacterium acquires antibiotic resistance from another bacterium and then itself becomes resistant to that antibiotic. This phenomenon is making it increasingly difficult to treat a wide variety of bacterial diseases.

Chapter 19

Concept Checks

Figure 19.3 Cell division and cell migration are common in the earliest stages of development, whereas cell differentiation and apoptosis are more common as tissues and organs start to form.

Figure 19.4 If apoptosis did not occur, the fingers would be webbed.

Figure 19.5 During development, positional information may a cause a cell to respond in one of four ways: cell division, cell migration, cell differentiation, and cell death.

Figure 19.6 Cell division and migration would be the most prevalent in the early phases of development, such as phase 1 and 2.

Figure 19.8 The larva would have anterior structures at both ends and would lack posterior structures such as a spiracle.

Figure 19.9 The Bicoid protein functions as a transcription factor that promotes the formation of anterior structures. Its function is highest in the anterior end of the embryo.

Figure 19.11 This embryo has 15 pink stripes, each of which corresponds to a portion of the 15 segments in the embryo.

Figure 19.14 The last abdominal segment would have legs!

Figure 19.18 Stem cells can divide, and they can differentiate into specific cell types.

Figure 19.20 Hematopoietic stem cells are multipotent.

Figure 19.23 Most stem cells in plants are found in meristems, which are located at the tips of roots and shoots.

Figure 19.24 The pattern would be sepal, petal, stamen, stamen.

BioConnections

Figure 19.3 First, the nucleus and cell shrink. Next, multiple extensions (blebs) are formed from the plasma membrane. Finally, this blebbing continues to occur until the cell is broken up into small fragments.

Figure 19.5 Some receptors recognize signals that convey positional information. After the signal binds to this type of receptor, a signal transduction pathway is activated that may cause a cell to divide, migrate, differentiate, or undergo apoptosis.

Figure 19.17 As the number of *Hox* genes increases, the body plans of animals become more complex.

Feature Investigation Questions

1. The researchers were interested in the factors that cause cells to differentiate. For this particular study, the researchers were attempting to identify genes involved in the differentiation of muscle cells.
2. Using genetic technology, the researcher compared the gene expression in cells that could differentiate into muscle cells with the gene expression in cells that could not differentiate into muscle cells. Though many genes were expressed in both, the researchers were able to isolate three genes that were expressed in muscle cell lines that were not expressed in the nonmuscle cell lines.
3. Again, using genetic technology, each of the candidate genes was introduced into a cell that normally did not give rise to skeletal muscle. This procedure was used to test whether or not these genes played a key role in muscle cell differentiation. If the genetically engineered cell gave rise to muscle cells, the researchers would have evidence that a particular candidate gene was involved in muscle cell differentiation. Of the three candidate genes, only one was shown to be involved in muscle cell differentiation. When the *MyoD* gene was expressed in fibroblasts, these cells differentiated into skeletal muscle cells.

Test Yourself

1. c 2. d 3. e 4. b 5. c 6. e 7. a 8. a 9. b 10. d

Conceptual Questions

1. a. This would be consistent with a defect in a segmentation gene, such as a gap gene.

   b. This would be consistent with a mutation in a homeotic gene because the characteristics of a particular segment have been changed.
2. Both types of genes encode transcription factors that bind to the DNA and regulate the expression of other genes. The effects of *Hox* genes are to

determine the characteristics of certain regions of the body, whereas the *myoD* gene is cell specific—it causes a cell to become a skeletal muscle cell.

3. Maternal effect genes control the formation of body axes, such as the anteroposterior and dorsoventral axes. Next, the segmentation genes divide the embryo into segments, though visible segments are lost in many animal species at later stages of development. Finally, the homeotic genes determine the characteristics of each segment.

Chapter 20

Concept Checks

Figure 20.2 No. A recombinant vector has been made, but it has not been cloned. In other words, many copies of the recombinant vector have not been made yet.

Figure 20.3 The insertion of chromosomal DNA into the vector disrupts the *lacZ* gene, thereby preventing the expression of β-galactosidase. The functionality of *lacZ* can be determined by providing the growth medium with a colorless compound, X-Gal, which is cleaved by β-galactosidase into a blue dye. Bacterial colonies containing recircularized vectors form blue colonies, whereas colonies containing recombinant vectors carrying a segment of chromosomal DNA will be white.

Figure 20.5 The 600-bp piece would be closer to the bottom. Smaller pieces travel faster through the gel.

Figure 20.6 The primers are complementary to sequences at each end of the DNA region to be amplified.

Figure 20.7 It means that part of their inserts are exactly the same, but other regions are not.

Figure 20.9 If a dideoxynucleotide ddNTP is added to a growing DNA strand, the strand can no longer grow because the 3′−OH group, the site of attachment for the next nucleotide, is missing.

Figure 20.10 A fluorescent spot identifies a cDNA that is complementary to a particular DNA sequence. Because the cDNA was generated from mRNA, this technique identifies a gene that has been transcribed in a particular cell type under a given set of conditions.

Figure 20.11 The reason why the A and B chains are made as fusion proteins is because the A and B chains are rapidly degraded when expressed in bacterial cells by themselves. The fusion proteins, however, are not.

Figure 20.13 Only the T DNA within the Ti plasmid is transferred to a plant cell.

Figure 20.15 Not all of Dolly's DNA came from a mammary cell. Her mitochondrial DNA came from the oocyte donor.

Figure 20.16 The bands match suspect 2.

BioConnections

Figure 20.2 Plasmids are small, circular molecules of DNA that exist independently of the bacterial chromosome. They have their own origin of replication. Many plasmids carry genes that convey some type of selective advantage to the host cell, such as antibiotic resistance.

Figure 20.6 Primers are needed in a PCR experiment because DNA polymerase cannot begin DNA replication on a bare template strand.

Figure 20.17 The genetic material of a retrovirus is reverse transcribed into DNA via reverse transcriptase. Then it is integrated into a host cell chromosome via integrase.

Feature Investigation Questions

1. Gene therapy is the introduction of cloned genes into living cells to correct genetic mutations. The hope is that the cloned genes will correct or restore the normal gene function, thereby eliminating the clinical effects of the disease.

   ADA deficiency is a recessive genetic disorder in which an enzyme, adenosine deaminase, is not functional. The absence of this enzyme causes a buildup of deoxyadenosine, which is toxic to lymphocytes. When lymphocytes are destroyed, a person's immune system begins to fail, leading to a severe combined immunodeficiency disease (SCID).

2. The researchers introduced normal copies of the ADA gene into lymphocytes, restoring normal cell metabolism. The researchers isolated lymphocytes from the patient and used a viral vector to introduce the gene into the lymphocytes. These lymphocytes were then reintroduced back into the patient.

3. Following several rounds of treatment with gene therapy, researchers were able to document continued production of the correct enzyme by the lymphocytes over the course of 4 years. However, because the patients were also receiving other forms of treatment, it was not possible to determine if the gene therapy reduced the negative effects of the genetic disease.

Test Yourself

1. e 2. d 3. b 4. b 5. b 6. c 7. d 8. b 9. e 10. e

Conceptual Questions

1. The restriction enzyme cuts the plasmid at a specific site, leaving sticky ends. The gene of interest, cut with the same enzyme, has complementary sticky ends that allow hydrogen bonding between the gene of interest and the plasmid. The connections are then made permanent, using DNA ligase that connects the DNA backbones.
2. A ddNTP is missing an oxygen at the 3′ position. This prevents the further growth of a DNA strand, thereby causing chain termination.
3. One example is Bt corn in which corn plants carry genes that make it herbicide- and pest-resistant. These types of strains have become very popular among farmers. A similar approach was used to create Bt cotton. You may find other examples by searching the web.

Chapter 21

Concept Checks

Figure 21.2 One reason is that more complex species tend to have more genes. A second reason is that species vary with regard to the amount of repetitive DNA present in their genome.

Figure 21.5 For DNA transposons, inverted repeats are recognized by transposase, which cleaves the DNA and inserts the transposon into a new location.

Figure 21.6 Retrotransposons. A single retrotransposon can be transcribed into multiple copies of RNA, which can be converted to DNA by reverse transcriptase, and inserted into multiple sites in the genome.

Figure 21.9 Differential gene regulation. Genes that encode metabolic enzymes are highly expressed in liver cells, whereas those same genes are expressed in lower amounts in muscle cells. Conversely, genes that encode cytoskeletal and motor proteins are highly expressed in muscle cells, but less so in liver cells.

Figure 21.11 The two main advantages of having a computer program translate a genetic sequence are that it's faster and probably more accurate.

Figure 21.12 It is possible for orthologs to have exactly the same DNA sequence if neither of them has accumulated any new mutations that would cause their sequences to become different. This is likely only for closely related species that have diverged relatively recently from each other.

BioConnections

Figure 21.8 The family members that are expressed at early stages of development (embryonic and fetal stages) have a higher affinity for oxygen than the adult form. This allows the embryo and fetus to obtain oxygen from its mother's bloodstream.

Figure 21.10 Reversible post-translational covalent modifications provide a way to modulate protein function. Certain types can turn off protein function, whereas others can turn on protein function. These modifications provide a rapid way for a cell to control protein function.

Feature Investigation Questions

1. The goal of the experiment was to sequence the entire genome of *Haemophilus influenzae*. By conducting this experiment, the researchers would have information about genome size and the types of genes the bacterium has.
2. One strategy requires mapping the genome prior to sequencing. After mapping is completed, each region of the genome is then sequenced. The shotgun approach does not require mapping of the genome prior to sequencing. Instead, many fragments are randomly sequenced.

   The advantage of the shotgun approach is the speed at which the sequencing can be conducted because the researchers do not have to spend time mapping the genome first. The disadvantage is that because the researchers are sequencing random fragments, some fragments may be sequenced more than necessary.
3. The researchers were successful in sequencing the entire genome of the bacterium. The genome size was determined to be 1,830,137 base pairs, with a predicted 1,743 structural genes. The researchers were also able to predict the function of many of these genes. More importantly, the results were the first complete genomic sequence of a living organism.

Test Yourself

1. c 2. e 3. a 4. c 5. e 6. b 7. b 8. d 9. c 10. c

Conceptual Questions

1. a. yes

   b. No, it's only one chromosome in the nuclear genome.

   c. yes

   d. yes

2. The two main reasons why the proteomes of eukaryote species are usually much larger than their genomes are alternative splicing and post-translational covalent modifications. During alternative splicing, a pre-mRNA is spliced in two or more different ways to yield two or more different polypeptides. Post-translational covalent modifications can affect protein structure in a variety of ways, including proteolytic processing; disulfide bond formation; the attachment of prosthetic group, sugars, or lipids; phosphorylation; acetylation; and methylation.
3. The genome contains the information for the production of cellular proteins; it is a blueprint. The production of proteins is largely responsible for determining cellular characteristics, which, in turn, determine an organism's traits.

Chapter 22

Concept Checks

Figure 22.2 Organic molecules form the chemical foundation for the structure and function of living organisms. Modern organisms can synthesize organic molecules. However, to explain how life got started, biologists need to explain how organic molecules were made prior to the existence of living cells.

Figure 22.3 These vents release hot gaseous substances from the interior of the Earth. Organic molecules can form in the temperature gradient between the extremely hot vent water and the cold water that surrounds the vent.

Figure 22.4 A liposome is more similar to real cells, which are surrounded by a membrane that is composed of a phospholipid bilayer.

Figure 22.5 Certain chemicals, such as RNA molecules, have properties that provide advantages and therefore cause them to increase in number relative to other molecules.

Figure 22.7 In a sedimentary rock formation, the layer at the bottom is usually the oldest.

Figure 22.8 For this time frame, you could analyze the relative amounts of potassium-40 and argon-40, rubidium-87 and strontium-87, uranium-235 and lead-207, or uranium-238 and lead-206.

Figure 22.14 Most animal species, including fruit flies, fishes, and humans, exhibit bilateral symmetry.

BioConnections

Figure 22.4 Phospholipids are amphipathic molecules; they have a polar end (the head groups) and a nonpolar end (the two fatty acyl tails). Phospholipids form a bilayer such that the heads interact with water, whereas the tails are shielded from the water. This is an energetically favorable structure.

Figure 22.12 First, the process of membrane invagination created the nuclear envelope. Second, endocytosis may have enabled an ancient archaeon to take up a bacterial cell. Over time, bacterial genes were transferred to the nucleus, which gave rise to the eukaryotic nuclear genome. An engulfed bacterial cell eventually became a mitochondrion, and an engulfed cyanobacterial cell became a chloroplast in algae and plants.

Figure 22.18 Two key features are mammary glands and hair. They also have specialized teeth, external ears, and enlarged skulls that harbor highly developed brains. Mammals are typically endothermic.

Feature Investigation Questions

1. Chemical selection occurs when a particular chemical in a mixture has advantageous properties that allow it to increase in number compared to the other chemicals in the mixture. Bartel and Szostak hypothesized that variation in the catalytic abilities of RNA molecules would allow for chemical selection in the laboratory. Bartel and Szostak proposed to select for RNA molecules with higher catalytic abilities.
2. The short RNA molecules allowed the researchers to physically separate the mixture of longer RNA molecules based on catalytic properties. Long RNA molecules with catalytic abilities would covalently bond with the short RNA molecules. The short RNA molecules had a specific region that caused them to be attracted to column beads in the experimental apparatus. The long RNA molecules that did not have catalytic abilities passed through the column and therefore could be separated from the ones that had catalytic activity and became bound to the column beads.
3. The researchers found that with each round of selection, the enzymatic activity of the selected pool of RNA molecules increased. These results provided evidence that chemical selection could improve the functional characteristics of a group of molecules. Much of the explanation of the evolution of life on Earth is theoretical, meaning it is based on scientific principles but has not been experimentally verified. Researchers are attempting to develop laboratory experiments that test the explanations of the evolution of life. The experiment conducted by Bartel and Szostak provided experimental data to support the hypothesis of chemical selection as a possible mechanism for the early evolutionary process that led to living cells.

Test Yourself

1. b 2. e 3. b 4. c 5. e 6. a 7. d 8. c 9. b 10. d

Conceptual Questions

1. Nucleotides and amino acids were produced prior to the existence of cells.

   Nucleotides and amino acids became polymerized to form DNA, RNA, and proteins.

   Polymers became enclosed in membranes.

   Polymers enclosed in membranes evolved cellular properties.
2. The relative ages of fossils can be determined by the locations in sedimentary rock formation. Older fossils are found in lower layers. A common way to determine the ages of fossils is via radioisotope dating, which is often conducted using a piece of igneous rock from the vicinity of the fossil. A radioisotope is an unstable isotope of an element that decays spontaneously, releasing radiation at a constant rate. The half-life is the length of time required for a radioisotope to decay to exactly one-half of its initial value. To determine the age of a rock (and that of a nearby fossil), scientists can measure the amount of a given radioisotope as well as the amount of the decay product.
3. Several examples are described in this chapter. In some cases, catastrophic events like volcanic eruptions and glaciers caused mass extinctions, which allowed new species to evolve and flourish. In other cases, changing environmental conditions (for example, changes in temperature and moisture) played key roles. One interesting example is adaptation to terrestrial environments. Plant species evolved seeds that are dessication resistant, whereas animal species evolved eggs. Mammalian species evolved internal gestation.

Chapter 23

Concept Checks

Figure 23.2 A single organism does not evolve. Populations may evolve from one generation to the next.

Figure 23.7 Due to a changing global climate, the island fox became isolated from the mainland species. Over time, natural selection resulted in adaptations for the population on the island and eventually resulted in a new species with characteristics that are somewhat different from the mainland species.

Figure 23.8 Many answers are possible. One example is the wing of a bird and the wing of a bat.

Figure 23.11 The magnitude of traits are changing. For example, in dogs, the lengths of legs, body size, and so on, are quite different. Artificial selection is often aimed at changing the relative sizes of body parts or the amount of something, such as oil content.

Figure 23.13 Rhesus and green monkeys = 0, Congo puffer fish and European flounder = 2, and Rhesus monkey and Congo puffer fish = 10. Pairs that are closely related evolutionarily have fewer differences than do pairs that are more distantly related.

Figure 23.14 Orthologs have similar gene sequences because they are derived from the same ancestral gene. The sequences are not identical because after the species diverged, each one accumulated different random mutations that changed their sequences.

Figure 23.16 Humans have one large chromosome 2, but this chromosome is divided into two separate chromosomes in the other three species. In chromosome 3, the

banding patterns among humans, chimpanzees, and gorillas are very similar, but the orangutan has a large inversion that flips the arrangement of bands in the centromeric region.

BioConnections

Figure 23.2 Both natural selection and chemical selection involve processes in which the relative proportions of something in a population increases compared with something else. In natural selection, it is the relative proportions of individuals with certain traits that increases. In chemical selection, molecules with certain characteristics increase their relative numbers compared with other molecules.

Figure 23.13 When comparing homologous genes or proteins, species that are closely related evolutionarily have more similar sequences than do more distantly related species.

Figure 23.15 The three mechanisms of horizontal gene transfer between bacterial species are conjugation, transformation and transduction.

Feature Investigation Questions

1. The island has a moderate level of isolation but is located near enough to the mainland to have some migrants. The island is an undisturbed habitat, so the researchers would not have to consider the effects of human activity on the study. Finally, the island had an existing population of ground finches that would serve as the study organism over many generations.
2. First, the researchers were able to show that beak depth is a genetic trait that has variation in the population. Second, the depth of the beak is an indicator of the types of seeds the birds can eat. The birds with larger beaks can eat larger and drier seeds; therefore, changes in the types of seeds available could act as a selective force on the bird population.

   During the study period, annual changes in rainfall occurred, which affected the seed sizes produced by the plants on the island. In the drier year, fewer small seeds were produced, so the birds would have to eat larger, drier seeds.
3. The researchers found that following the drought in 1978, the average beak depth in the finch population increased. This indicated that birds with larger beaks were better able to adapt to the environmental changes due to the drought and produce more offspring. This is direct evidence of the phenomenon of natural selection.

Test Yourself

1. d 2. d 3. b 4. b 5. b 6. d 7. c 8. d 9. d 10. e

Conceptual Questions

1. Some random mutations result in a phenotype with greater reproductive success. If so, natural selection results in a greater proportion of such individuals in succeeding generations. These individuals are more likely to survive and reproduce, which means they have evolved to be better adapted to their environment.
2. The process of convergent evolution produces two different species from different lineages that show similar characteristics because they occupy similar environments. An example is the long snout and tongue of both the giant anteater, found in South America, and the echidna, found in Australia. This enables these animals to feed on ants, but the two structures evolved independently. These observations support the idea that evolution results in adaptations to particular environments.
3. Homologous structures are two or more structures that are similar because they are derived from a common ancestor. An example is the same set of bones that is found in the human arm, turtle arm, bat wing, and whale flipper. The forearms in these species have been modified to perform different functions. This supports the idea that all of these animals evolved from a common ancestor by descent with modification.

Chapter 24

Concept Checks

Figure 24.2 If C^R is 0.4, then C^W must be 0.6, because the allele frequencies add up to 1.0. The heterozygote ($2pq$) equals 2(0.4)(0.6), which equals 0.48, or 48%.

Figure 24.3 Over the short run, alleles that confer better fitness would be favored and increase in frequency, perhaps enhancing diversity. Over the long run, however, an allele that confers high fitness in the homozygous state may become monomorphic, thereby reducing genetic diversity.

Figure 24.4 Stabilizing selection eliminates alleles that give phenotypes that deviate significantly from the average phenotype. For this reason, it tends to decrease genetic diversity.

Figure 24.6 If malaria was eradicated, there would be no selective advantage for the heterozygote. The H^S allele would eventually be eliminated because the H^SH^S homozygote has a lower fitness. Directional selection would occur.

Figure 24.7 This is likely to be a form of intersexual selection. Such traits are likely to be involved in mate choice.

Figure 24.11 The bottleneck effect decreases genetic diversity. This may eliminate adaptations that promote survival and reproductive success. Therefore, the bottleneck effect makes it more difficult for a population to survive.

Figure 24.13 Migration results in gene flow, which tends to make the allele frequencies in neighboring populations more similar to each other. It also promotes genetic diversity by introducing new alleles into populations.

BioConnections

Figure 24.12 There are lots of possibilities. The idea is that you are changing one codon to another codon that specifies the same amino acid. For example, changing a codon from GGA to GGG is likely to be neutral because both codons specify glycine.

Figure 24.14 Inbreeding favors homozygotes. Initially, inbreeding would result in more homozygotes in a population. Over the long run, however, if a homozygote has a lower fitness, inbreeding would accelerate the elimination of the allele from the population.

Feature Investigation Questions

1. The two species of cichlids used in the experiment are distinguishable by coloration, and the researchers were testing the hypothesis that the females make mate choices based on this variable.
2. Individual females were placed in tanks that contained one male from each species. The males were held in small glass tanks to limit their movement but allowed the female to see each of the males. The researchers recorded the courtship behavior between the female and males and the number of positive encounters between the female and each of the different males. This procedure was conducted under normal lighting and under monochromatic lighting that obscured the coloration differences between the two species. Comparing the behavior of the females under normal light conditions and monochromatic light conditions allowed the researchers to determine the importance of coloration in mate choice.
3. The researchers found that the female was more likely to select a mate from her own species in normal light conditions. However, under monochromatic light conditions, the species-specific mate choice was not observed. Females were as likely to choose males of the other species as they were males of their own species. This indicated that coloration is an important factor in mate choice in these species of fish.

Test Yourself

1. d 2. c 3. c 4. e 5. b 6. c 7. b 8. d 9. b 10. a

Conceptual Questions

1. The frequency of the disease is a genotype frequency because it represents individuals with the disease. If we let q^2 represent the genotype frequency, then q equals the square root of 0.04, which is 0.2. If $q = 0.2$, then $p = 1 - q$, which is 0.8. The frequency of heterozygous carriers is $2pq$, which is 2(0.8)(0.2) = 0.32, or 32%.
2. Directional selection—This is when natural selection favors an extreme phenotype that makes the organism better suited to survive and reproduce in its environment. As a result, the extreme phenotype will become predominant in the population. This can occur either through new mutation or through a prolonged environmental change. In addition to selecting for a certain phenotype, the opposite end of the extreme is removed from the gene pool.
   - Stabilizing selection—In this type of selection, natural selection favors individuals with intermediate phenotypes, whereas organisms with extreme phenotypes are less likely to reproduce. This selection tends to prevent major changes in the phenotypes of populations.
   - Disruptive selection—This type of selection favors both extremes and removes the intermediate phenotype. It is also known as diversifying selection.
   - Balancing selection—This type of selection results in a balanced polymorphism in which two or more alleles are stably maintained in a population. Examples

include heterozygote advantage, as in the sickle cell allele, and negative frequency-dependent selection, as in certain prey.
- Sexual selection—This is a type of natural selection that is directly aimed at reproductive success. It can occur by any of the previous four mechanisms. Male coloration in African cichlids is an example.

3. Genetic drift involves random changes in the genetic composition of a population from one generation to the next. Neutral changes in DNA sequences may happen randomly, and these are most likely to accumulate in a population due to genetic drift. This is evolution at the level of DNA, but it does not act upon phenotype.

Chapter 25

Concept Checks

Figure 25.1 There are a lot of possibilities. Certain grass species look quite similar. Elephant species look very similar. And so on.

Figure 25.3 Temporal isolation is an example of a prezygotic isolating mechanism. Because the species breed at different times of the year, hybrid zygotes are not formed between the two species.

Figure 25.5 Hybrid sterility is a type of postzygotic isolating mechanism. A hybrid forms between the two species, but it is sterile.

Figure 25.11 The offspring would inherit 16 chromosomes from *Galeopsis tetrahit*, and from the hybrid, it would inherit anywhere from 8 to 16. So the answer is 24 to 32. The hybrid parent would always pass the 8 chromosomes that are found in pairs. With regard to the 8 chromosomes not found in pairs, it could pass 0 to 8 of them.

Figure 25.12 The insects on different host plants would tend to breed with each other, and natural selection would favor the development of traits that are an advantage for feeding on that host. Over time, the accumulation of genetic changes may lead to reproductive isolation between the populations of insects.

Figure 25.14 If the *Gremlin* gene was underexpressed, less Gremlin protein would be produced. Because Gremlin protein inhibits apoptosis, more cell death would occur, and the result would probably be smaller feet, and maybe they would not be webbed.

Figure 25.15 By comparing the number of *Hox* genes in many different animal species, a general trend is observed that animals with more complex body structures have a greater number of *Hox* genes.

Figure 25.17 The tip of the mouse's tail might have a mouse eye!

BioConnections

Figure 25.2 Female choice is a prezygotic isolating mechanism.

Figure 25.7 The Hawaiian Islands have many different ecological niches that can be occupied by birds. The first founding bird inhabitants evolved to occupy those niches, thereby evolving into many different species.

Figure 25.15 The *Hox* genes expressed along the anteroposterior axis during early embryonic development are homeotic genes. In insects that contain discrete body segments, each *Hox* gene determines the structures that will ultimately form in those segments. Although more complex animals such as mammals do not display discrete segments, the expression of the *Hox* genes controls what structures will form along the anteroposterior axis.

Feature Investigation Questions

1. Podos hypothesized that the morphological changes in the beak would also affect the birds' songs. A bird's song is an important component for mate choice. If changes in the beak alter the song of the bird, reproductive ability would be affected. Podos suggested that changes in the beak morphology could thus lead to reproductive isolation among the birds.
2. Podos first caught male birds in the field and collected data on beak size. The birds were banded for identification and released. Later, the banded birds' songs were recorded and analyzed for range of frequencies and trill rates. The results were then compared with similar data from other species of birds to determine if beak size constrained the frequency range and trill rate of the song.
3. The results of the study did indicate that natural selection on beak size due to changes in diet could lead to changes in song. Considering the importance of bird song to mate choice, the changes in the song could also lead to reproductive isolation.

   The phrase "by-product of adaptation" refers to changes in the phenotype that are not directly acted on by natural selection. In the case of the Galápagos finches, the changes in beak size were directly related to diet; however, as a consequence of that selection, the song pattern was also altered. The change in song pattern was a by-product.

Test Yourself

1. b 2. b 3. e 4. d 5. c 6. a 7. b 8. d 9. c 10. c

Conceptual Questions

1. Prezygotic isolating mechanisms prevent the formation of the zygote. An example is mechanical isolation, the incompatibility of genitalia. Postzygotic isolating mechanisms act after the formation of the zygote. An example is inviability of the hybrid that is formed. (Other examples shown in Figure 25.2 would also be correct.) Postzygotic mechanisms are more costly because some energy is spent in the formation of a zygote and its subsequent growth.
2. The concept of gradualism suggests that each new species evolves continuously over long spans of time (Figure 25.13a). The principal idea is that large phenotypic differences that produce new species are due to the accumulation of many small genetic changes. According to the punctuated equilibrium model, species exist relatively unchanged for many generations. During this period, the species is in equilibrium with its environment. These long periods of equilibrium are punctuated by relatively short periods during which evolution occurs at a far more rapid rate. This rapid evolution is caused by relatively few genetic changes.
3. One example involves the *Hox* genes, which control morphological features along the anteroposterior axis in animals. An increase in the number of *Hox* genes during evolution is associated with an increase in body complexity and may have spawned many different animal species.

Chapter 26

Concept Checks

Figure 26.2 A phylum is broader than a family.

Figure 26.3 Yes. They can have many common ancestors, depending on how far back you go in the tree. For example, dogs and cats have a common ancestor that gave rise to mammals, and an older common ancestor that gave rise to vertebrates. The most recent common ancestor is the point at which two species diverged from each other.

Figure 26.4 An order is a smaller taxon that would have a more recent common ancestor.

Figure 26.9 A hinged jaw is the character common to the salmon, lizard, and rabbit, but not to the lamprey.

Figure 26.10 Changing the second G to an A is common to species A, B, and C, but not to species G.

Figure 26.12 The kiwis are found in New Zealand. Even so, the kiwis are more closely related to Australian and African flightless birds than they are to the moas, which were found in New Zealand.

Figure 26.14 Gorillas and humans would be expected to have fewer genetic differences because their common ancestor (named C) is more recent than that of orangutans and gorillas, which is ancestor B.

Figure 26.15 Monophyletic groups are based on the concept that a particular group of species descended from a common ancestor. When horizontal gene transfer occurs, not all of the genes in a species were inherited from the common ancestor, so this muddles the concept of monophyletic groups.

BioConnections

Figure 26.1 The domains Bacteria and Archaea have organisms with prokaryotic cells.

Figure 26.13 There are lots of possibilities. The idea is that you are changing one codon to another codon that specifies the same amino acid. For example, changing a codon from GGA to GGG is likely to be neutral because both codons specify glycine.

Feature Investigation Questions

1. Molecular paleontology is the sequencing and analysis of DNA obtained from extinct species. Tissue samples from specimens of extinct species may contain DNA molecules that can be extracted, amplified, and sequenced. The DNA sequences can then be compared with living species to study evolutionary relationships between modern and extinct species.

   The researchers extracted DNA from tissue samples of moas, extinct flightless birds that lived in New Zealand. The DNA sequences from the

moas were compared with the DNA sequences of modern species of flightless birds to determine the evolutionary relationships of this particular group of organisms.

2. The researchers compared the DNA sequences of the extinct moas and modern kiwis of New Zealand to the emu and cassowary of Australia and New Guinea, the ostrich of Africa, and rheas of South America. All of the birds are flightless. With the birds selected, the researchers could look for similarities between birds over a large geographic area.
3. The sequences were very similar among the different species of flightless birds. Interestingly, the sequences of the kiwis of New Zealand were more similar to those of the modern species of flightless birds found on other land masses than they were to those of the moas found in New Zealand.

   The researchers constructed a new evolutionary tree that suggests that kiwis are more closely related to the emu, cassowary, and ostrich. Also, based on the results of this study, the researchers suggested that New Zealand was colonized twice by ancestors of flightless birds. The first ancestor gave rise to the now-extinct moas. The second ancestor gave rise to the kiwis.

Test Yourself

1. c 2. d 3. e 4. d 5. b 6. d 7. b 8. b 9. c 10. e

Conceptual Questions

1. The scientific name of every species has two parts, which are the genus name and the species epithet. The genus name is always capitalized, but the species name is not. Both names are italicized. An example is *Canis lupus*.
2. If neutral mutations occur at a relatively constant rate, they act as a molecular clock on which to measure evolutionary time. Genetic diversity between species that is due to neutral mutation gives an estimate of the time elapsed since the last common ancestor. A molecular clock can provide a timescale to a phylogenetic tree.
3. Morphological analysis focuses on morphological features of extinct and modern species. Many traits are analyzed to obtain a comprehensive picture of two species' relatedness. Convergent evolution leads to similar traits that arise independently in different species as they adapt to similar environments. Convergent evolution can, therefore, cause errors if a researcher assumes that a particular trait arose only once and that all species having the trait have the same common ancestor.

Chapter 27

Concept Checks

Figure 27.5 The cell will tend to float because it is full of intact gas vesicles.

Figure 27.11 The motion of the stiff filament of a prokaryotic flagellum is more like that of a propeller shaft than the flexible arms of a human swimmer.

Figure 27.13 Cells having pili tend to move with a twitching or gliding motion.

Figure 27.14 When DNA sequencing studies show that samples contain many uncultured bacterial species, the fluorescence method is preferred, though it requires the use of a fluorescence microscope. Under such conditions, the culture method will underestimate the bacterial numbers. But when the goal is to estimate numbers of bacteria whose culture preferences are known, the culture method may provide good estimates.

Figure 27.15 Endospores allow bacterial cells to survive treatments and environmental conditions that would kill ordinary cells.

Figure 27.18 Structural similarities to bacterial pili indicate that these types of attack systems evolved from these structures.

BioConnections

Figure 27.6 Like the bacterium *Magnetospirillum magnetotacticum*, birds such as homing pigeons and migratory fishes such as rainbow trout have the capacity to sense and respond to magnetic fields.

Figure 27.12 The microscopic protist *Giardia intestinalis* likewise uses flagella to move within the human small intestine.

Figure 27.14 Two.

Feature Investigation Questions

1. Many bacteria are known to produce organic compounds that function as antibiotics, and are potential food sources for chemoheterotrophic bacteria.
2. Researchers isolated and cultivated bacteria from different types of soils, then grew the cultured bacteria on media that contained one of several common types of antibiotics as the only source of organic food.

Test Yourself

1. c 2. b 3. c 4. d 5. a 6. a 7. b 8. e 9. d 10. d

Conceptual Questions

1. Small cell size and simple division processes allow many bacteria to divide much more rapidly than eukaryotes. This helps to explain why food can spoil so quickly and why infections can spread very rapidly within the body. Other factors also influence these rates.
2. Pathogen populations naturally display genetic variation in their susceptibility to antibiotics. When such populations are exposed to antibiotics, even if initially only a few cells are resistant, the numbers of resistant cells will eventually increase and could come to dominate natural populations.
3. Humans. When humans pollute natural waters with high levels of fertilizers originating from sewage effluent or crop field runoff, cyanobacterial populations are able to grow large enough to produce harmful blooms.

Chapter 28

Concept Checks

Figure 28.7 After particles are ingested via feeding grooves, particles are enclosed by membrane vesicles and then digested by enzymes.

Figure 28.8 The intestinal parasite *Giardia intestinalis* is transmitted from one person to another via fecal wastes, whereas the urogenital parasite *Trichomonas vaginalis* can be transmitted by sexual activity.

Figure 28.17 Flagellar hairs function like oars, helping to pull cells through the water.

Figure 28.18 Kelps are harvested for the production of industrially useful materials. In addition, they nurture fishes and other wildlife of economic importance.

Figure 28.21 Genes that encode cell adhesion and extracellular matrix proteins are likely essential to modern choanoflagellates' ability to attach to surfaces, where they feed. Similar proteins are involved in the formation of multicellular tissues in animals. Evolutionary biologists would say that ancient choanoflagellates were preadapted for the later evolution of multicellular tissues in early animals.

Figure 28.24 Cysts allow protists to survive conditions that are not suitable for growth. One such condition would be the dry or cold environment outside a parasitic protist's warm, moist host tissues.

Figure 28.29 Gametes of *Plasmodium falciparum* undergo fusion to produce zygotes while in the mosquito host.

BioConnections

Figure 28.5 The amoebocytes of sponges, which carry food to other cells, move similarly to amoeboid protists.

Figure 28.25 Because the only cell in the *Chlamydomonas* life cycle that is diploid is the zygote, other phases of the life cycle are haploid, and therefore homologous copies do not affect gene expression.

Figure 28.27 The life cycle of diatoms is similar to that of animals.

Feature Investigation Questions

1. Natural collections of the algae were already known to resist microbial attack and breakdown.
2. This process is commonly used to release tough fossils from rock.
3. Microfibrils of this algal cellulose are almost 30 times the thickness of plant cellulose microfibrils.

Test Yourself

1. c 2. a 3. b 4. b 5. e 6. b 7. e 8. d 9. b 10. c

Conceptual Questions

1. Protists are amazingly diverse, reflecting the occurrence of extensive adaptive radiation after the origin of eukaryotic cells, widespread occurrence of endosymbiosis, and adaptation to many types of moist habitats, including the

tissues of animals and plants. As a result of this extensive diversity, protists cannot be classified into a single kingdom or phylum.

2. Several protists, including the apicomplexans *Cryptosporidium parvum* and *Plasmodium falciparum* and the kinetoplastids *Leishmania major* and *Trypanosoma brucei*, cause many cases of illness around the world, but few treatments are available, and organisms often evolve drug resistance. Genomic data allow researchers to identify metabolic features of these parasites that are not present in humans and are therefore good targets for development of new drugs. An example is provided by metabolic pathways of the apicoplast, a reduced plastid that is present in cells of the genus *Plasmodium*. Because the apicoplast plays essential metabolic roles in the protist but is absent from humans, drugs that disable apicoplast metabolism would kill the parasite without harming the human host.
3. Most protist cells cannot survive outside moist environments, but cysts have tough walls and dormant cytoplasm that allow them to persist in habitats that are unfavorable for growth. While cysts play important roles in the asexual reproduction and survival of many protists, they also allow protist parasites such as *Entamoeba histolytica* (the cause of amoebic dysentery) to spread to human hosts who consume food or water that have been contaminated with cysts. Widespread contamination can sicken thousands of people at a time.

Chapter 29

Concept Checks

Figure 29.3 Liverworts grow very close to surfaces such as soil or tree trunks. Raising their sporophytes off the surface helps to disperse spores into air currents.

Figure 29.4 Wind speed varies, so if the moss released all the spores at the same time into a weak air current, the spores would not travel very far and might have to compete with the parent plant for scarce resources. By releasing spores gradually, some spores may enter strong gusts of wind that carry them long distances, reducing competition with the parent.

Figure 29.8 Larger sporophytes are able to capture more resources for use in producing larger numbers of progeny and therefore have greater fitness than do smaller sporophytes.

Figure 29.13 The capacity to produce both wood and seeds are key features of lignophytes. Part of a woody stem can be seen and parts of seeds can be observed extending from beneath cone scales.

Figure 29.15 The polyester cutin found in cuticle, sporopollenin on spore walls, and lignin on water-conducting tracheids of vascular tissues are resistant to decay and thus help plants fossilize.

Figure 29.16 During the Carboniferous period (Coal Age), atmospheric oxygen levels reached historic high levels that were able to supply the large needs of giant insects, which obtain oxygen by diffusion.

Figure 29.21 Because the veins of fern leaves reflect the vascular systems of branched-stem systems, you might infer that leaves evolved from more highly branched stem systems would be more densely veined, that is, have more veins per unit area than fern leaves. This is actually the case for leaves of seed plants.

Figure 29.22 Although some angiosperm seeds, such as those of corn and coconut, contain abundant endosperm, many angiosperm embryos consume most or all of the nutritive endosperm during their development.

Figure 29.24 Because the lacy integument of *Runcaria* does not completely enclose the megasporangium, it probably did not function to protect the megasporangium before fertilization nor as an effective seed coat after fertilization, as do the integuments of modern seed plants. However, the lacy integument of *Runcaria* might have retained the megasporangium on the parent sporophyte during the period of time when nutrients flowed from parent to developing ovule and seed. That function would prevent megasporangia from dropping off the parent plant before fertilization occurred, allow the parent plant to provide nutrients needed during embryo development, and allow seeds time to absorb and store more nutrients from the parent. Such a function would illustrate how one mutation having a positive reproductive benefit can lay the foundation for subsequent mutations that confer additional fitness. *Runcaria* illustrates a first step in the multistage evolutionary process that gave rise to modern seeds.

BioConnections

Figure 29.19 Microvilli characteristic of the animal placenta and small intestine, like the transfer cell-wall protrusions that occur in the plant placenta, vastly increase cell membrane area, thereby providing space for many transport proteins, resulting in relatively high flux of materials across the cell membrane.

Figure 29.23 The amniotic egg characteristic of many animals, like the seeds of plants, provides protection and nutrients to the developing embryo.

Feature Investigation Questions

1. The experimental goals were to determine the rate at which organic molecules produced by gametophyte photosynthesis were able to move into sporophytes and to investigate the effect of sporophyte size on the amount of organic molecules transferred from the gametophyte.
2. The investigators shaded sporophytes with black glass covers to ensure that all of the radioactive organic molecules detected in sporophytes at the end of the experiment came originally from the gametophyte.
3. The investigators measured the amount of radioactivity in gametophytes and sporophytes, and in sporophytes of different sizes. These measurements indicated the relative amounts of labeled organic compounds that were present in different plant tissues.

Test Yourself

1. c 2. d 3. d 4. e 5. b 6. a 7. c 8. e 9. c 10. b

Conceptual Questions

1. Charophycean algae, particularly the complex genera *Chara* and *Coleochaete*, share many features of structure, reproduction, and biochemistry with land plants. Examples include cell division similarities and plasmodesmata and sexual reproduction by means of flagellate sperm and eggs.
2. Bryophytes are well adapted for sexual reproduction when water is available for fertilization. Their green gametophytes efficiently transfer nutrients to developing embryos, enhancing their growth into sporophytes. Their sporophytes are able to produce many genetically diverse spores as the result of meiosis and effectively disperse these spores by means of wind.
3. Vascular tissues allow tracheophytes to effectively conduct water from roots to stems and to leaves. Waxy cuticle helps prevent loss of water by evaporation through plant surfaces. Stomata allow plants to achieve gas exchange under moist conditions and help them avoid losing excess water under arid conditions.

Chapter 30

Concept Checks

Figure 30.4 The nitrogen-fixing cyanobacteria that often occur within the coralloid roots of cycads are photosynthetic organisms that require light. If coralloid roots occurred underground, symbiotic cyanobacteria would not receive enough light to survive.

Figure 30.10 Ways in which conifer leaves are adapted to resist water loss include low surface area/volume, needle- or scale-shape, thick surface coating of waxy cuticle, and stomata that are sunken into the leaf and are therefore less exposed to drying winds.

Figure 30.12 Wide vessels are commonly present in the water transport tissues of angiosperms and much less commonly in other plants. The vessels occasionally found in nonangiosperms are thought to have evolved independently from those of angiosperms.

Figure 30.20 A large, showy perianth would not be useful to grass plants because they are wind pollinated; such a perianth would interfere with pollination in grasses. By not producing a showy perianth, grasses increase the chances of successful pollination and save resources that would otherwise be consumed during perianth development.

Figure 30.24 The flower characteristics of *Brighamia insignis* shown in this figure (white color and deep, narrow nectar tubes) are consistent with pollination by a moth (see Table 30.1).

Figure 30.26 Importantly, ears of modern *Zea mays* do not readily shatter when the fruits are mature, as do those of teosinte. This feature enables human harvesting of the fruits.

BioConnections

Figure 30.2 Modern forests are dominated by seed plants, gymnosperms and angiosperms, whereas nonseed plants dominated *Archaeopteris* forests.

Figure 30.8 The wind-dispersed seeds of the gymnosperm pine resemble the wind-dispersed seeds of the flowering plant maple in bearing winglike structures that enhance transport in air.

Feature Investigation Questions

1. The investigators obtained many samples from around the world because they wanted to increase their chances of finding as many species as possible.
2. Although cannabinoids are produced in glandular hairs that cover the plant surface, these compounds are most abundant on leaves near the flowers. Collecting such leaves reduces the chances that compounds might be missed by the analysis.

Test Yourself

1. d 2. a 3. e 4. e 5. b 6. d 7. e 8. c 9. d 10. e

Conceptual Questions

1. Consult Figure 30.15 to see how plant biologists think stamens and pistils might have evolved from leaves that bore sporangia. Then consider how green leaves surrounding stamens and pistils might have been transformed into petals, sepals, or tepals.
2. Apple, strawberry, and cherry plants coevolved with animals that use the fleshy, sweet portion of the fruits as food and excrete the seeds, thereby dispersing them. Humans have sensory systems similar to those of the target animals and likewise are attracted by the same colors, odors, and tastes.
3. A sunflower is not a single flower, but rather is an inflorescence, a group of flowers. A pollinator visiting a compact inflorescence such as a sunflower head may be able to pollinate many flowers at the same time, thereby potentially producing many seeds per pollinator visit. Likewise, a seed disperser agent might be able to disperse more seeds per plant.

Chapter 31

Concept Checks

Figure 31.4 Fungal hyphae growing into a substrate having a much higher solute concentration will tend to lose cell water to the substrate, a process that could inhibit fungal growth. This process explains how salting or drying foods helps to protect them from fungal degradation and thus are common preservation techniques.

Figure 31.6 You might filter the air entering the patient's room and limit the entry of visitors and materials that could introduce fungal spores from the outside environment.

Figure 31.27 Modern AM (arbuscular mycorrhizal fungi), also known as Glomeromycota, do not generally occur separately from plant hosts.

Figure 31.28 Ectomycorrhizal fungi provide their plant partners with water and minerals absorbed from a much larger area of soil than plant roots can exploit on their own.

BioConnections

Figure 31.7 The *Saccharomyces cerevisiae* genome is only 12 million base pairs in size, relatively small for a eukaryote.

Figure 31.10 The amanitin toxin, by interfering with the function of RNA polymerase II, inhibits transcription in eukaryotic cells.

Feature Investigation Questions

1. Plants growing on soils up to 65°C would be expected to have fungal endophytes that aid in heat stress tolerance.
2. The investigators cured some of their *Curvularia protuberata* cultures of an associated virus; then they compared the survival of plants infected with fungal endophytes that had virus versus endophytes lacking virus under conditions of heat stress. Only plants having fungal endophytes that possessed the virus were able to survive growth on soils of high temperature.
3. The fungus *C. protuberata* might be used to confer heat stress tolerance to crop plants, as the investigators demonstrated in tomato.

Test Yourself

1. c 2. b 3. e 4. b 5. a 6. d 7. e 8. b 9. e 10. a

Conceptual Questions

1. Fungi are like animals in being heterotrophic, having absorptive nutrition, and storing surplus organic compounds in their cells as glycogen. Fungi are like plants in having rigid cell walls and reproducing by means of walled spores that are dispersed by wind, water, or animals.
2. Toxic or hallucinogenic compounds likely help to protect the fungi from organisms that would consume them.
3. Some fungi partner with algae or cyanobacteria to form lichens. Some fungi associate with plant roots to form mycorrhizae. Some fungi grow as endophytes within the bodies of plants. In all cases, the heterotrophic fungi receive photosynthetic products from the autotrophic partner.

Chapter 32

Concept Checks

Figure 32.4 Simple choanoflagellates are single-celled organisms. Only later, when such organisms became colonial and groups of cells acquired specialized functions, as in sponges, can we consider them early animals.

Figure 32.8 The coelom functions as a hydrostatic skeleton, which aids in movement. This feature permitted increased burrowing activity and contributed to the development of a profusion of wormlike body shapes.

Figure 32.12 The main members of the Ecdysozoa are the arthropods (insects, spiders, and crustaceans) and the nematodes.

BioConnections

Figure 32.6 A shared derived character.

Figure 32.11 Yellow.

Feature Investigation Questions

1. The researchers sequenced the complete gene that encodes small subunit rRNA from a variety of representative taxa of animals to determine their phylogenetic relationships, particularly the relationships of arthropods to other animal taxa.
2. The results indicated a monophyletic clade containing arthropods and nematodes, plus several other smaller phyla. This clade was called the Ecdysozoa. The results of this study indicated that nematodes were more closely related to the arthropods than previously believed.
3. The fruit fly, *Drosophila melanogaster*, and the nematode, *Caenorhabditis elegans*, have been widely studied to understand early development. Under the traditional phylogeny, these two species were not considered to be closely related, so similarities in development were assumed to have arisen early in animal evolution. With the closer relationship indicated by this study, these similarities may have evolved after the divergence of the Ecdysozoan clade. This puts into question the applicability of studies of these organisms to the understanding of human biology.

Test Yourself

1. b 2. c 3. e 4. c 5. c 6. d 7. d 8. d 9. b 10. e

Conceptual Questions

1. (1) Absence or existence of different tissue types. (2) Type of body symmetry. (3) Patterns of embryonic development.
2. The evolution of a coelom cushioned the internal organs in fluid, preventing injury from external forces. In addition, the coelom enabled the internal organs to grow and move independently of the outer body wall. Finally, in some invertebrates, the coelom acts as a hydrostatic skeleton that supports the body and permits movement.
3. Polyphyletic.

Chapter 33

Concept Checks

Figure 33.2 Sponges aren't eaten by other organisms because they produce toxic chemicals and contain needle-like silica spicules that are hard to digest.

Figure 33.4 Cnidocytes are not reused. New ones form to replace the old used ones.

Figure 33.6 Having no specialized respiratory or circulatory system, flatworms obtain oxygen by diffusion. A flattened shape ensures no cells are too far from the body surface.

Figure 33.10 (1) A ciliary feeding device, and (2) a respiratory device are the two main functions of the lophophore.

Figure 33.11 Technically, most mollusks pump hemolymph into vessels and then into tissues. The hemolymph collects in open, fluid-filled cavities called sinuses, which flow into the gills and then back to the heart. This is known as an open circulatory system. Only closed circulatory systems pump blood, as occurs in the cephalopods.

Figure 33.17 Some advantages of segmentation are organ duplication, minimization of body distortion during movement, and specialization of some segments.

Figure 33.19 An annelid is segmented and possesses a true coelom, whereas a nematode is unsegmented and has a pseudocoelom. In addition, nematodes molt, but annelids do not.

Figure 33.25 All arachnids have a body consisting of two tagmata: a cephalothorax and an abdomen. Insects have three tagmata: a head, thorax, and abdomen.

Figure 33.26 Two key insect adaptations are the development of wings and an exoskeleton that reduced water loss and aided in the colonization of land.

Figure 33.32 In embryonic development, deuterostomes have radial cleavage, indeterminate cleavage, and the blastopore becomes the anus. (In protostomes, cleavage is spiral and determinate, and the blastopore becomes the mouth.)

BioConnections

Figure 33.14 Mollusks arose in the Cambrian period, 543–490 mya. Three hundred million years later ammonites flourished, yet none are alive today.

Figure 33.21 Because most species can excrete urine that is isoosmotic or hyperosmotic to the body fluids.

Figure 33.26 Some insects, such as flies, have chemoreceptors on their feet, whereas others, such as moths, smell through their antennae.

Figure 33.29 These organs, called statocysts, are located at the base of the antennules.

Feature Investigation Questions

1. The researchers tested the hypothesis that an octopus can learn by observing the behavior of another octopus.
2. The results indicated that the observer learned by watching the training of the other octopus. The observer was much more likely to choose the same color ball that the demonstrator was trained to attack. These results seem to support the hypothesis that octopuses can learn by observing the behavior of others.
3. The untrained octopuses had no prior exposure to the demonstrators. The results indicated that these octopuses were as likely to attack the white ball as the red ball. No preference for either color was indicated. The untrained octopuses acted as a control. This is an important factor to ensure the results from the trials using observers indicate response to learning and not an existing preference for a certain color.

Test Yourself

1. b 2. d 3. d 4. d 5. b 6. c 7. b 8. a 9. c 10. a

Conceptual Questions

1. The five main feeding methods used by animals are (1) suspension feeding, (2) decomposition, (3) herbivory, (4) predation, and (5) parasitism. Suspension feeding is usually used to filter out food particles from the water column. A great many phyla, including sponges, rotifers, lophophorates, some mollusks and echinoderms and tunicates, are filter feeders. Decomposers usually feed on dead material such as animal carcasses or dead leaves. For example, many fly and beetle larvae feed on dead animals, and earthworms consume dead leaves from the surface of the Earth. Earthworms and crabs also sift through soil or mud, eating the substrate and digesting the soil-dwelling bacteria, protists, and dead organic material. Herbivores eat plants or algae and are especially common in the arthropoda. Adult moths and butterflies also consume nectar. Snails are also common plant feeders. Predators feed on other animals, killing their prey, and may be active hunters or sit-and-wait predators. Many scorpions and spiders actively pursue their prey, whereas web-spinning spiders ambush their prey using webs. Parasites also feed on other animals but do not normally kill their hosts. Endoparasites, which includes flukes, tapeworms, and nematodes, live inside their hosts. Ectoparasites (ticks and lice) live on the outside of their hosts.
2. Gametes dry out on land, and internal fertilization prevents this from happening. Also, water facilitates movement of gametes, reducing the need for internal fertilization.
3. Complete metamorphosis has four stages: egg, larva, pupa, and adult. The larval stage is often spent in an entirely different habitat from that of the adult, and larval and adult forms utilize different food sources. Incomplete metamorphosis has only three stages: egg, nymph, and adult. Young insects, called nymphs, look like miniature adults when they hatch from their eggs.

Chapter 34

Concept Checks

Figure 34.1 Vertebrates (but not invertebrates) usually possess a (1) notochord; (2) dorsal hollow nerve chord; (3) pharyngeal slits; (4) postanal tail, exhibited by all chordates; (5) vertebral column; (6) cranium; and (7) endoskeleton of cartilage or bone.

Figure 34.7 Ray-finned fishes (but not sharks) have a (1) bony skeleton; (2) mucus-covered skin; (3) swim bladder; and (4) operculum covering the gills.

Figure 34.8 Both lungfishes and coelocanths are Sarcopterygians, having lobe fins.

Figure 34.10 The advantages to animals that moved onto land included an oxygen-rich environment and a bonanza of food in the form of terrestrial plants and the insects that fed on them.

Figure 34.13 No. Caecilians and some salamanders give birth to live young.

Figure 34.14 Besides the amniotic egg, other critical innovations in amniotes are thoracic breathing; internal fertilization; a thicker, less permeable skin; and more efficient kidneys.

Figure 34.16 Snakes evolved from tetrapod ancestors but subsequently lost their limbs. Some species have tiny vestigial limbs.

Figure 34.20 Adaptations in birds to reduce body weight for flight include a lightweight skull; reduction of organ size; and a reduction of organs outside of breeding season. Also female birds have one ovary and relatively few eggs, and no urinary bladder.

Figure 34.28 Defining features of primates are grasping hands; eyes situated on the front of the head to facilitate binocular vision; a large brain; and digits with flat nails instead of claws.

BioConnections

Figure 34.5 No, an examination of Figure 34.1 shows that "fishy" organisms include an ancestral population and some of its descendants, but not all of them. The "fish" are thus a paraphyletic group. To be a monophyletic group the fish would have to include the tetrapods as well. Therefore, there is no true monophyletic group that corresponds to the popular name "fish."

Figure 34.12 Yes, the blood vessels to the lungs close and those to skin open wider. The opposite occurs when on land and frogs breathe air.

Figure 34.17 Both classes have four-chambered hearts and care for their young.

Figure 34.26 None. The bloodstreams of fetus and mother are brought into close contact in the placenta, but they do not mix.

Feature Investigation Questions

1. The researchers were interested in determining the method in which *Hox* genes controlled limb development.
2. The researchers bred mice that were homozygous for certain mutations in specific *Hox* genes. This allowed the researchers to determine the function of individual genes.
3. The researchers found that homozygous mutants would develop limbs of shorter lengths compared to the wild-type mice. The reduced length was due to the lack of development of particular bones in the limb, specifically, the radius, ulna, and some carpels. These results indicated that simple mutations in a few genes could lead to dramatic changes in limb development.

Test Yourself

1. b 2. d 3. a 4. d 5. d 6. c 7. c 8. a 9. c 10. d

Conceptual Questions

1. Both taxa have external limbs that move when the attached muscles contract or relax. The difference is that arthropods have external skeletons with the

muscles attached internally, whereas vertebrates have internal skeletons with the muscles attached externally.

2. Endothermy (warm-bloodedness) probably evolved independently in both birds and mammals. If the common ancestor of reptiles and birds were endothermic, the chances are that all reptiles would be endothermic.
3. Possibly. Both birds and reptiles lay amniotic eggs and possess scales, though these only cover the legs in birds. Birds and crocodilians also share a four-chambered heart. Finally, birds share many skeletal similarities with certain dinosaurs.

Chapter 35

Concept Checks

Figure 35.6 As in the case of shoots, the capacity to divide the root into two equal pieces by means of a line drawn from the circular edges through the center would indicate that a root has superficial radial symmetry. In order to determine that an organ has radial symmetry at the cellular level, you would have to compare the microscopic views of randomly chosen, wedge-shaped pieces of cross slices. If the structure of the wedges is similar, the organ has radial symmetry at the microscopic level.

Figure 35.8 Locating stomata on the darker and cooler lower leaf surface helps reduce water loss from the leaf.

Figure 35.12 A twig having five sets of bud scale scars is likely to be approximately 6 years old.

Figure 35.17 Cactus stems are green and photosynthetic, playing the role served by the leaves of most plants.

Figure 35.21 A woody stem builds up a thicker layer of wood than inner bark in part because older tracheids and vessel element walls are not lost during shedding of bark, which is the case for secondary phloem. In addition, plants typically produce a greater volume of xylem than phloem tissue per year, in part because vessel elements are relatively wide. A large volume of water-conducting tissue helps plants maintain a large amount of internal water.

Figure 35.25 Lateral roots are produced from internal meristematic tissue because roots do not produce axillary buds like those from which shoot branches develop. Internal production of branch roots helps to prevent them from shearing off as the root tip grows through abrasive soil.

BioConnections

Figure 35.5 Apical-basal polarity of the plant body resembles anterior-posterior polarity in the animal body.

Figure 35.9 Plant cells often possess a large vacuole, whereas animal cell vacuoles are relatively small.

Figure 35.11 There is no difference in microtubule structure among eukaryotes.

Feature Investigation Questions

1. The advantages of using natural plants include the opportunity to avoid influencing plants with unnatural environmental factors, such as artificial light, and the exposure of all experimental plants to similar growth conditions. In addition, the investigators studied the leaves of some large trees, which would be hard to accommodate in a greenhouse.
2. Pinnately veined leaves were splinted to prevent their breaking, since they were cut at the single main vein, which has both support and conducting functions.
3. Sack and associates measured leaf water conduction at two or more places on each leaf because the effect of cutting a vein might have affected some portions of leaves more than others.

Test Yourself

1. d 2. c 3. b 4. a 5. c 6. a 7. d 8. e 9. b 10. d

Conceptual Questions

1. If overall plant architecture were bilaterally symmetrical, plants would be shaped like higher animals, with a distinct front (ventral surface) and back (dorsal surface). By comparison with radially symmetrical organisms, bilaterally symmetrical plants would have reduced ability to deploy branches and leaves in a way that would fill available lighted space and would thus be unable to take optimal photosynthetic advantage of their habitats.
2. If leaves were generally radially symmetrical (shaped like spheres or cylinders), leaves would not have maximal ability to absorb sunlight, and they would not be able to optimally disperse excess heat from their surfaces.
3. Although tall herbaceous plants exist (palms and bamboo are examples), the additional support and water-conducting capacity that are provided by secondary xylem allow woody plants to grow tall.

Chapter 36

Concept Checks

Figure 36.4 Auxin efflux carriers could be located on the upper sides of root cells, thereby allowing auxin to move upward in roots.

Figure 36.6 Once a callus has been established from a single plant having desirable characteristics using plant tissue culture, the callus can be divided into many small calluses. A grower could transfer these to separate containers having the appropriate hormone mixtures to induce root and shoot growth, then transplant the young plant clones to soil. This would allow the grower to produce many identical plants.

Figure 36.9 The triple response of dicot seedlings to internally produced ethylene allows them to protect the delicate apical meristem from damage as the seedling emerges through the soil.

Figure 36.10 The active conformation of phytochrome absorbs far-red light. Such absorption causes the active conformation of phytochrome to change to the inactive conformation and to move out of the nucleus and into the cytosol.

Figure 36.11 The inactive conformation of phytochrome would absorb the red portion of sunlight, thereby converting phytochrome into the active conformation.

Figure 36.12 Exposing plants to brief periods of darkness during the daytime will have no effect on flowering because flowering is determined by night length.

Figure 36.14 Yes, just as shoots exhibit negative gravitropism in upward growth, roots are capable of using negative phototropism to grow downward, because light decreases with depth in the soil.

Figure 36.16 In some plants, aerenchyma development is genetically determined and occurs even in the absence of flooding. In other cases, aerenchyma develops only under flooding conditions as a result of controlled cell death.

Figure 36.19 The immunity effect is relatively long-lasting in both cases.

BioConnections

Figure 36.3 The defense hormone/plasma membrane receptor is the plant signaling system most similar to the general diagram shown in Figure 9.4.

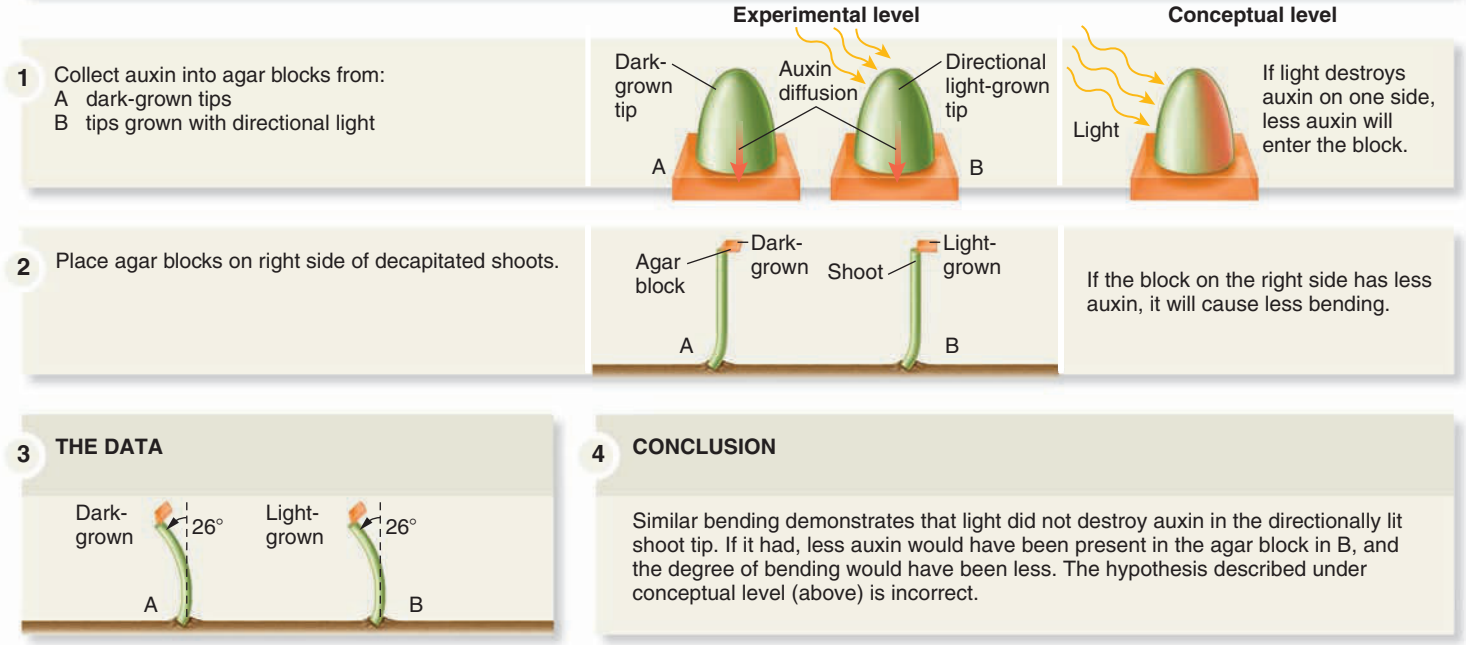
Figure 36.18 The lipopolysaccharide envelope characteristic of Gram-negative bacteria is a feature by which plants recognize pathogens.

Feature Investigation Questions

1. Hypothetically, auxin enhances the rate at which cell membrane proton pumps acidify the plant cell wall, thereby allowing cells to extend. Although the evidence for acid effects on cell-wall extension is strong, the molecular basis of possible auxin effects on proton pumps is not as yet clear.
2. A small number of seedling tips could display atypical responses for a variety of reasons. The investigators actually performed the experiment with many replicate seedling tips (coleoptiles), in order to gain confidence that the responses are general.

Test Yourself

1. c 2. c 3. a 4. e 5. d 6. d 7. c 8. d 9. d 10. d



Conceptual Questions

1. Behavior is defined as the responses of living things to a stimulus. Therefore, because plants display many kinds of responses to diverse stimuli, they display behavior.
2. Many kinds of disease-causing bacteria and fungi occur in nature, and these organisms evolve very quickly, producing diverse elicitors. Thus, plants must maintain a stock of resistance genes, each having many alleles.
3. Talking implies a conversation with "listeners" who detect a message and respond to it. Thus, plants that exude volatile compounds that attract enemies of herbivores could be interpreted as "talking" to those enemies. The message is "Hey, you guys, there's food for you over here." In addition, research has revealed that some plants near those under attack respond to volatile compounds by building up defenses. "Talking" to other plants does not enhance the "talker's" fitness. But the ability to "listen" enhances the "listener's" fitness, because it can take preemptive actions to prevent attack.

BioTIPS page 762

HYPOTHESIS Light destroys auxin on lit side of shoot tips, causing unequal auxin distribution. Unlit side should grow more than lit side.

STARTING MATERIALS Corn seedlings.

APPENDIX B

Chapter 37

Concept Checks

Figure 37.5 Plastids that occur in a cluster near the nucleus would have more rubisco than plastids at the periphery.

Figure 37.6 Chlorosis is not always a sign of iron deficiency; it can be a deficiency symptom for several mineral nutrients, including zinc in corn.

Figure 37.10 Mineral leaching occurs more readily from sandy soils than from clay soils.

Figure 37.12 Soil crusts containing nitrogen-fixing cyanobacteria increase soil fertility, fostering the growth of larger plants that stabilize soils against erosion and provide forage for animals.

Figure 37.13 Oxygen, which makes up 21% of Earth's present atmosphere, can bind to the active site of nitrogenase, thereby inactivating it.

BioConnections

Figure 37.7 Land whose topsoil has been damaged will likely not function normally to support a wild community or agriculture; rehabilitation might be accomplished by restoring topsoil and planting vegetation that holds the soil in place and increases its fertility.

Figure 37.20 Both the tapeworm and the dodder obtain organic food from a host, an animal or plant, respectively.

Feature Investigation Questions

1. *SDQ1* expression is induced by phosphorus deficiency. This gene fosters replacement of plastid phospholipids with sulfur-containing lipids, thereby reducing the plant's phosphorus requirement.
2. They used genetic engineering techniques to place a reporter gene under the control of the *SQD1* promoter, so that when *SQD1* was expressed, the reporter gene was expressed also. After growing plants in nutrient solutions containing various levels of phosphorus, they removed sample leaves and treated them with a compound that turns blue when the reporter gene is expressed. When they saw blue leaves, the investigators could infer (1) that the plants from which those leaves had been taken were beginning to experience phosphorus deficiency, and (2) that application of fertilizer at this point could prevent damage to the plants.

Test Yourself

1. e 2. a 3. c 4. b 5. e 6. c 7. d 8. d 9. a 10. b

Conceptual Questions

1. Agricultural experts are concerned that adding excess fertilizer to crop fields increases the costs of crop production. Ecologists are concerned that excess fertilizers will wash from crop fields into natural waters and cause harmful overgrowths of cyanobacteria, algae, and aquatic plants. Methods for closely monitoring crop nutrient needs so that only the appropriate amount of fertilizer is applied would help to allay both groups' concerns.
2. Use Figure 37.10 as a reference. A first arrow could be drawn from a root to rhizobia in the soil, and the arrow labeled "flavonoids." A second arrow could be drawn from rhizobia to roots and labeled "Nod factors." A third arrow from rhizobia to roots could be labeled "infection proteins." A fourth arrow from roots to rhizobia could be labeled "nodulins" and the resulting nodule environmental conditions, which influence the formation of bacterioids. A fifth arrow could represent the flow of fixed nitrogen from bacterioids to plant. A sixth arrow could represent the flow of organic compounds from plant to bacteroids.

Chapter 38

Concept Checks

Figure 38.5 When placed in pure water, a turgid cell having a water potential of 1.0 will lose water, because 1 is greater than 0. When placed in pure water, a plasmolyzed cell having a water potential of –1.0 MPa will gain water. When placed in pure water, a flaccid cell having a water potential of –0.5 MPa will gain water. This is because water moves from a region of higher water potential to a region of lower water potential, and 0 is greater than –0.5.

Figure 38.11 You would likely see stained rings or helical ribbons extending up the insides of the long walls of extensible tracheids. You would not see staining at the ends of tracheids, where they connect to form cell files.

Figure 38.12 The large perforations in vessel element end walls allow an air bubble to extend from one element to another, thereby clogging vessels and preventing water flow through them. In contrast, the much smaller pores in the end walls of tracheids do not allow water to flow as efficiently as it does through vessels, but these smaller

pores also retard the movement of air bubbles. As a result, air bubbles are confined to a single tracheid where they do little harm.

Figure 38.13 Root pressure can help to reverse embolism, thereby aiding water flow through xylem.

Figure 38.15 The evaporation of water has a powerful cooling effect because it disperses heat so effectively. Water has the highest heat of vaporization of any known liquid.

Figure 38.16 You could model a stomatal guard cell with an elongate balloon by partially inflating it, then attaching thick tape along one side to represent thickened inner walls and circles of string or thin tape to represent radial cellulose, then adding more air to the balloon. The balloon should curve as it expands, just as a guard cell does when the stomatal pore opens. Two such balloons could be used to model both guard cells and the stomatal pore.

Figure 38.19 In its desert habitat, times of drought and contrasting availability of water sufficient to support the development and photosynthetic function of leaves do not occur as predictably as for temperate forests. For this reason, ocotillo leaf abscission is not amenable to the evolution of genetic mechanisms that allow leaf drop to be precisely timed in anticipation of the onset of drought.

BioConnections

Figure 38.8 Tight junctions of intestinal epithelium and Casparian strips of endodermal cells of plant roots both incorporate materials that form a tight seal, preventing movement of materials from one location to another.

Figure 38.21 Stomatal guard cell and phloem companion cell development both begin with an unequal cell division.

Feature Investigation Questions

1. Replicates provide reproducibility, and controlled growth conditions reduce the effects of environment.
2. Plant temperature indicates degree of evaporation through open stomata.

Test Yourself

1. c 2. b 3. e 4. d 5. a 6. e 7. d 8. e 9. a 10. c

Conceptual Questions

1. In the case of plant fertilizers, more is not better, because the ion concentration of overfertilized soil may become so high as to draw water from plant cells. In this case, the cells would be bathed in a hypertonic solution and would likely lose water to the solution. If plant cells lose too much water, they will die.
2. When the natural vegetation is removed, transpiration stops, so water is not transported from the ground to the atmosphere, where it may be an important contributor to local rainfall. Extensive removal of plants actually changes local climates in ways that reduce agricultural productivity and human survival.
3. You cannot assume that an ocotillo plant lacking leaves is dead, because this plant responds to drought by shedding its leaves, and living plants can produce new leaves when the drought stress is relieved. However, if the ocotillo plants do not produce new leaves after normal rainstorms, you might suspect that they have died.

Chapter 39

Concept Checks

Figure 39.2 Because gametophytes are haploid, they lack the potential for allele variation at each gene locus that is present in diploid sporophytes. Hence, gametophytes are more vulnerable to environmental stresses. By living within the diploid tissues of flowers, flowering plant gametophytes are protected to some extent, and the plant does not lose its gamete-producing life cycle stage.

Figure 39.3 Some flowers lack some of the major flower parts.

Figure 39.4 By clustering its stamens around the pistil, the hibiscus flower increases the chance that a pollinator will both pick up pollen and deliver pollen from another hibiscus flower on the same trip.

Figure 39.7 The absence of showy petals often correlates with wind pollination, because large petals would interfere with the shedding of pollen in the wind.

Figure 39.10 The rim flowers of *Gerbera* inflorescences have bilateral symmetry, conferred by expression of a *CYCLOIDEA*-like gene. Rim flowers also possess showy petals that attract pollinators, but lack pollen-producing stamens. By contrast, central flowers display radial symmetry, lack showy petals, and possess pollen-producing stamens.

Figure 39.12 The maximum number of cells in a mature male gametophyte of a flowering plant is three: a tube cell and two sperm cells.

Figure 39.14 Female gametophytes are not photosynthetic and cannot produce their own food. Enclosed within ovules, female gametophytes lack direct access to the outside environment. Carpels contain veins of vascular tissue that bring nutrients from sporophytic tissue to ovules.

Figure 39.16 An embryo in which the TOPLESS genes were nonfunctional would have two roots and no shoots.

Figure 39.17 During their maturation, the cotyledons of eudicot seeds absorb the nutrients originally present in endosperm.

BioConnections

Figure 39.15 The plant pollen tube is analogous in function to a human penis in that both structures accomplish internal fertilization. The plant pollen tube grows long enough to deposit sperm at the micropyle within the body of the female gametophyte, much as an animal penis deposits sperm within the female's body. In both cases, sperm are more likely to survive and accomplish fertilization than if they were deposited outside the female body.

Feature Investigation Questions

1. The large flowers of this lily enabled investigators to more easily mark petals and record the positions of marks over time.
2. Time-lapse video reduced the amount of time investigators would have to spend recording changes in the positions of petal marks.

Test Yourself

1. a 2. b 3. d 4. b 5. d 6. e 7. b 8. c 9. d 10. c

Conceptual Questions

1. Pollen grains are vulnerable to mechanical damage and microbial attack during the journey through the air from the anthers of a flower to a stigma. Sporopollenin is an extremely tough polymer that helps to protect pollen cells from these dangers. The function of the beautiful sculptured patterns of sporopollenin on pollen surfaces is unclear.
2. The embryos within seeds are vulnerable to mechanical damage and microbial attack after they are dispersed. Seed coats protect embryos from these dangers and also help to prevent seeds from germinating until conditions are favorable for seedling survival and growth.
3. Flower diversity is an evolutionary response to diverse pollination circumstances. For example, plants such as oak and corn that are wind-pollinated produce flowers having a poorly developed perianth. If such wind-pollinated flowers had large, showy perianths, they would get in the way of pollen dispersal or acquisition. On the other hand, flowers that are pollinated by animals often have diverse shapes and attractive petals of differing colors or fragrances that have coevolved with different types of animal pollinators.

Chapter 40

Concept Checks

Figure 40.2 Locomotion is the movement of an animal's body from one place to another. This is achieved by the actions of skeletal muscle. However, smooth muscle contraction promotes movement of internal structures, like those of the digestive system, and contraction of cardiac muscle causes movement (beating) of the heart.

Figure 40.6 No. The brain, for example, does not contain muscle tissue (although the blood vessels supplying the brain do contain smooth muscle).

Figure 40.7 Blood, including plasma and blood cells, would leak out of the blood vessel into the interstitial space. The fluid level of the bloodstream would decrease, and that of the interstitial space near the site of the injury would increase. Eventually the blood that entered the interstitial space would be degraded by enzymes, resulting in the characteristic skin appearance of a bruise. If the injury were very severe, the fluid level in the blood could decrease to a point where the various tissues and organs of the body would not receive sufficient nutrients and oxygen to function normally.

Figure 40.8 A decrease in intracellular fluid volume, like that shown in the cell in this figure, would result in an increase in intracellular solute concentration (likewise, an increase in intracellular fluid volume would decrease intracellular solute concentrations). This may have drastic consequences on cell function. For example, some solutes, like Ca^{2+} and certain other ions, are toxic to cells at high concentrations.

Figure 40.10 Surface area is important to any living organism that needs to exchange materials with the environment. A good example of a high surface area/volume ratio is that of most tree leaves. This makes leaves ideally suited for such processes as light absorption (required for photosynthesis; see Chapter 8) and the exchange of gases and water with the environment.

Figure 40.12 No, not necessarily. Body temperature, for example, is maintained at different set points in birds and mammals. Other vertebrates and most invertebrates do not have temperature set points; their body temperature simply conforms close to that of the environment. As another example, a giraffe has a set point for blood pressure that is higher than that of a human being, because a giraffe's circulatory system must generate enough pressure to pump blood up its long neck to its brain.

Figure 40.15 In nature, an animal such as a horse would have the same type of responses shown here if threatened by a predator. Upon sensing the presence of the predator, the horse's respiratory and circulatory systems would begin increasing their activities in preparation for the possibility that the horse might have to flee or defend itself. This would occur even before the horse began to flee.

BioConnections

Figure 40.6 Note that both the stomach and the intestine depicted in Figures 40.6 and 45.9 contain layers of muscle wrapped around the lumen. Although you will learn later that the stomach and intestine have many different functions, this similarity in anatomy suggests that both of these organs may perform the similar activity of mechanically breaking apart chunks of food, and propelling the contents from one region to another.

Figure 40.13 Negative feedback may occur at the molecular level. It is a common feature of some enzymatic pathways, such as the metabolic one depicted in Figure 6.13.

Feature Investigation Questions

1. Feedforward regulation decreases the time required for a biological response to a potential homeostatic challenge. In the example demonstrated by Pavlov's experiments, this is typically beneficial but could theoretically be counterproductive. Imagine, for example, the situation of fasting (or dieting), when a person is hungry for very long periods of time. In such a situation, people are prone to think about food frequently, if not constantly, and in this way their digestive systems are repeatedly activated by feedforward processes despite the fact that no food is available. This is energetically wasteful, and could even produce negative consequences (for example, the regular accumulation of stomach acid in the absence of food).
2. Pavlov remained outside the room where the dog was housed when the conditioning stimulus—a metronome—was started. In addition, the room was carefully sealed to prevent any other stimuli, including smells, sights, and sounds, from interfering with the conditioning response.
3. Pavlov's hypothesis was supported; conditioned dogs clearly learned to associate two stimuli, triggering a feedforward response to an irrelevant stimulus. That the irrelevant stimulus could be generalized was evident by the measures taken by the investigators to eliminate other possible conditioning stimuli, and by their initial observations that the dogs salivated whenever they saw their usual food-provider. From your own experience, you may be able to think of several stimuli that you have at one time been conditioned to. For example, certain phobias and taste aversions may arise from conditioning. Classical conditioning of this kind is also employed by professional pet trainers.

Test Yourself

1. c 2. c 3. d 4. b 5. c 6. c 7. d 8. b 9. d 10. e

Conceptual Questions

1. Structure and function are related in that the function of a given organ, for example, depends in part on the organ's size, shape, and cellular and tissue arrangement. Clues about a physical structure's function can often be obtained by examining the structure's form. For example, the extensive surface area of a moth's antennae suggests that the antennae are important in detecting the presence of airborne chemicals. Likewise, any structure that contains a large surface area for its volume is likely involved in some aspect of signal detection, cell-cell communication, or transport of materials within the animal or between the animal and the environment. Surface area increases by a power of 2, and volume increases by a power of 3 as an object enlarges; this means that in order to greatly increase surface area of a structure such as an antenna, without occupying enormous volumes, specializations must be present (such as folds) to package the structure in a small space.
2. Homeostasis is the ability of animals to maintain a stable internal environment by adjusting physiological processes, despite changes in the external environment. Examples include maintenance of salt and water balance, pH of body fluids, and body temperature. Some animals conform to their external environment to achieve homeostasis, but others regulate their internal environment themselves.
3. Maintaining homeostasis requires continual supplies of energy. Animals consume food, and the energy from that food helps sustain activities that maintain variables such as body temperature and pH, and synthesis of complex molecules. Without this energy, it would be difficult or impossible for animals to maintain many important biological processes within a narrow range despite changes in the environment.

Chapter 41

Concept Checks

Figure 41.4 Many reflexes, such as the knee-jerk reflex, cannot be prevented once started. Others, however, can be controlled to an extent. Open your eyes widely and gently touch your eyelashes. A reflex that protects your eye will tend to make you close your eyelid. However, you can overcome this reflex with a bit of difficulty if you need to, for example, when you are putting in contact lenses.

Figure 41.6 Yes, the flow of K^+ down its chemical gradient does create an electrical gradient because K^+ is electrically charged. The net flow of K^+ will stop when the chemical gradient balances the electrical gradient. This occurs at the equilibrium potential.

Figure 41.9 When the K^+ channels open (at 1 msec), the Na^+ channels would still be opened, so the part of the curve that slopes downward would not occur as rapidly, and perhaps the cell would not be able to restore its resting potential.

Figure 41.11 The action potential can move faster down an axon. This is especially important for long axons, such as those that carry signals from the spinal cord to distant muscles.

Figure 41.13 In the absence of such enzymes, neurotransmitters would remain in the synapse for too long, and the postsynaptic cell could become overstimulated. In addition, the ability of the postsynaptic cell to respond to multiple, discrete inputs from the presynaptic cell would be compromised.

BioConnections

Figure 41.1 This is an example of a feedforward response, most famously demonstrated by the conditioning experiments of Ivan Pavlov. In this case, the peripheral and central nervous systems interact to prepare the hyena for feeding.

Figure 41.6 Electrochemical ion gradients function in neuronal signaling, ATP synthesis, muscle contraction, osmotic regulation, and transport of organic molecules across membranes.

Figure 41.7 Water molecules move through membrane channels called aquaporins.

Feature Investigation Questions

1. Loewi was aware that electrical stimulation of the vagus nerve associated with heart muscle would slow down the rate of heart contractions in a frog. Also, he knew that electrical stimulation of other nerves associated with the frog heart produced opposite results. If the effects of the different nerves on heart muscle were mediated directly by electrical activity only, the heart muscle cells would have no way to distinguish between stimulatory and inhibitory signals. Loewi hypothesized that nerves released chemicals onto heart muscle cells and that it was these different chemicals that produced the varied effects on the heart.
2. The results could also have been explained as a chemical having been released into the bathing medium from heart 1. The stimulated vagus nerve might have caused the muscle cells to release a chemical that was then capable of inhibiting heart 2. This may have been unlikely, but Loewi's experiment did not rule it out. A control experiment might have been to electrically stimulate heart 1 directly, by applying current to the muscle itself and not indirectly via the vagus nerve. If Loewi's hypothesis was correct, this control experiment would result in no effect on heart 2.
3. If the vagus nerve released acetylcholine, and it was this neurotransmitter that slowed the rate of beating of heart 2 in Loewi's experiment, then simply adding acetylcholine to the medium of a resting heart should produce the same effect as Loewi observed in his experiment. Alternatively, repeating Loewi's experiment but with the addition of an acetylcholine receptor blocker to heart 2, should decrease or eliminate the response.

Conceptual Questions

1. In a graded potential, a weak stimulus causes a small change in the membrane potential, whereas a strong stimulus produces a greater change. Graded potentials occur along the dendrites and cell body. If a graded potential reaches the threshold potential at the axon hillock, an action potential results. This is a change in the membrane potential that is of a constant value and is propagated from the axon hillock to the axon terminal.
2. An increase in extracellular Na^+ concentration would slightly depolarize neurons, thereby changing the resting membrane potential. This effect would be minimal, however, because the resting membrane is not very permeable to Na^+. However, the shape of the action potentials in such neurons would be a little steeper, and the peak a little higher, because the electrochemical gradient favoring Na^+ entry into the cell through voltage-gated channels would be greater.
3. Neurons are among the most highly complex cells in an animal's body, with numerous extensions of the cell body. These extensions provide considerable surface area that allows for an extraordinary number of cell-to-cell contacts with other neurons, making them ideally suited for intercellular communication. In addition, myelin sheaths provide a structure that speeds up electric signaling along the axon, facilitating communication even more.

Chapter 42

Concept Checks

Figure 42.4 Not necessarily. Brain mass is not the sole determinant of intelligence or the ability to perform complex tasks. The degree of folding of the cerebral cortex is also important.

Figure 42.6 A spinal nerve is composed of both afferent and efferent neurons.

Figure 42.7 The major symptom experienced by patients undergoing a lumbar puncture is headache, in part because the brain is no longer cushioned adequately by CSF. Within 24–48 hours, however, the CSF is replenished to normal levels.

Figure 42.9 Damage to the cerebellum would result in loss of balance and a lack of fine motor control, such as picking up small objects or making graceful, smooth movements.

Figure 42.11 It was in her right hand.

Figure 42.16 Thinking requires energy! Even daydreaming requires energy; imagine how much energy the brain uses when you concentrate for 60 minutes on a difficult exam. In fact, you just expended energy thinking about this question!

BioConnections

Figure 42.1 As defined in Chapter 32, animals are multicellular heterotrophs (cannot make their own food) whose cells lack a cell wall. Most animals have a nervous system, muscles, the ability to move about during at least some phase of their life cycle, and to reproduce sexually.

Feature Investigation Questions

1. Gaser and Schlaug hypothesized that repeated exposure to musical training would increase the size of certain areas of the brain associated with motor, auditory, and visual skills. All three skills are commonly used in reading and performing musical pieces. The researchers used MRI to examine the areas of the brain associated with motor, auditory, and visual skills in three groups of individuals: professional musicians, amateur musicians, and nonmusicians. The researchers found that certain areas of the brain were larger in the professional musicians compared to the other groups, and larger in the amateur musicians compared to the nonmusicians.
2. Schmithorst and Holland found that, when exposed to music, certain regions of the brains of musicians were activated differently compared with the brains of nonmusicians. This study supports the hypothesis that there is a difference in the brains of musicians versus nonmusicians.

   The experiment conducted by Gaser and Schlaug compared the size of certain regions of the brain among professional musicians, amateur musicians, and nonmusicians. Schmithorst and Holland, however, were also able to detect functional differences between musicians and nonmusicians.
3. A trained athlete might be expected to show greater development of brain areas devoted to motor skills. For example, athletes who engage in repetitive activities such as tennis and badminton have been found to have greater volumes of motor and balance regions including the cerebellum. Someone deaf from birth might be predicted to have decreased development of auditory regions such as those in the temporal lobe. However, it is not necessarily this simple. For example, MRI studies sometimes but not always reveal differences in cell number in the temporal lobes of deaf versus hearing subjects, but there is generally significantly less development of fiber tracts (white matter) in this region in the brains of deaf persons. Therefore, the size of a brain structure (that is, the number of neurons) by itself may not always be predictive of function.

Test Yourself

1. b 2. a 3. e 4. c 5. c 6. b 7. e 8. b 9. a 10. d

Conceptual Questions

1. All animals with nervous systems have reflexes, which allow rapid behavioral responses to changes in the environment. When a cnidarian senses a tactile stimulus, its nerve net responds immediately and the animal reflexively contracts nearly all of its muscles, making the animal a smaller target. This behavior protects the animal from predators. When you hear a loud, unexpected, and frightening sound (such as a firecracker), you hunch your shoulders and slightly lower your head; this reflex protects you from danger by minimizing exposure of your neck and head to danger. Dilation of the pupils of the eyes in darkness, and constriction of the pupils in bright light, are reflexes that help us see in the dark and protect our retinas in bright light. Reflexes are particularly adaptive because they occur rapidly, typically with very few synapses involved, and without the need for conscious thought.
2. White matter consists of the myelinated axons that are bundled together in large tracts in the central nervous system and which connect different CNS regions. The lipid-rich myelin gives the tracts a whitish appearance. It is distinguished from gray matter, which are the cell bodies, dendrites, and some unmyelinated axons of neurons in the CNS.
3. The activities of animal nervous systems are replete with examples of new properties emerging from complex interactions. For example, you learned about reflexes in this chapter, which are behaviors that emerge from interactions between individual neurons that form communication circuits between the peripheral and central nervous systems. You also learned about such "higher" properties such as conscious thought, which also emerges from the interactions between many individual cells, each of which is in communication with up to hundreds of thousands of other cells. Individually, the cells cannot "think," but networked together in elaborate ways, a person like yourself can think, remember, plan ahead, and interpret your environment.

Chapter 43

Concept Checks

Figure 43.3 To think about what types of touch you are aware of, let's take the example of sitting in a chair reading this textbook while holding it on your lap. You are aware of the constant weight of the book, the brush of the pages on your fingertips as you turn a page, a gentle breeze that may be circulating in your environment, the deep pressure from regularly adjusting your posture in your chair, an itch you may have on your skin, and the heat or cold of the room. Even a simple exercise such as this one is filled with stimuli of numerous types and durations.

Figure 43.7 Waves of fluid (perilymph) movement caused by sound pressure on the tympanic membrane result in vibration of the basilar membrane.

Figure 43.9 This orientation permits animals to detect circular or angular movement of the head in three different planes. The fluid in a canal that is oriented in the same plane as the plane of movement will respond maximally to the movement. For example, the canal that is oriented horizontally would respond greatest to horizontal movements, while the other two canals would not. Overall, by comparing the signals from the three canals, the brain can interpret the motion in three dimensions.

Figure 43.11 By comparing the arrival of signals from each side of its head, a pit viper can determine the direction of the signal.

Figure 43.18 Because red-green color blindness is a sex-linked recessive gene, males require only a single defective allele on an X chromosome, whereas females require two defective alleles, one on each X chromosome.

Figure 43.21 Photoreceptors synapse with bipolar cells, which in turn form synapses with ganglion cells.

Figure 43.26 Salt is a vital nutrient needed to maintain plasma membrane potentials and fluid balance in animals' bodies. Sugar provides glucose and other monosaccharides, important energy-yielding compounds. Sour (acidic) foods, like citrus fruits, provide

nutrients and important antioxidants (vitamin C, for example) that protect against disease. Bitter substances are often toxic, and their bad taste discourages animals from eating them.

BioConnections

Figure 43.1 The term sensory receptor refers to a type of cell that can respond to a particular type of stimulus. The term membrane receptor refers to a protein within a cell membrane that binds a ligand, thereby generating signals that initiate a cellular response.

Figure 43.4 Cilia are cell extensions that contain in their internal structure microtubules and motor proteins that cause the cilia to beat, or move, in a coordinated fashion. Stereocilia are membrane projections that are not motile, but instead are deformed by the movements of surrounding fluids.

Figure 43.8 Statoliths are also found in the roots and shoots of plants. They serve as a gravity-detection mechanism that results in roots growing downward, and shoots upward.

Feature Investigation Questions

1. One possibility is that many different types of odor molecules might bind to one or just a few types of receptor proteins, with the brain responding differently depending on the number or distribution of the activated receptors. The second hypothesis is that organisms can make a large number of receptor proteins, each type binding a particular odor molecule or group of odor molecules. According to this hypothesis, it is the *type* of receptor protein, and not the number or distribution of receptors, that is important for olfactory sensing.

   The researchers extracted RNA molecules from the olfactory receptor cells of the nasal epithelium. They then used this RNA to identify genes that encoded G-protein-coupled receptor proteins.
2. The results of the experiment conducted by Buck and Axel support the hypothesis that animals discriminate between different odors based on having a variety of receptor proteins that recognize different odor molecules. Current research suggests that each olfactory receptor cell has a single type of receptor protein that is specific to particular odor molecules. Because most odors are due to multiple chemicals that activate many different types of odor receptor proteins, the brain detects odors based on the combination of the activated receptor proteins. Odor seems to be discriminated by many olfactory receptor proteins, which are in the membrane of separate olfactory receptor cells.
3. Among other things, animals use odors to detect potential sources of food, shelter, mates, and danger. Discerning between the odors of food versus potentially toxic material is key to the survival of many animals (think, for example, how we recognize fresh milk and spoiled milk). Many animals also use olfaction in finding shelter; some birds, for example, can distinguish the odors produced by particular beneficial plants that they use to build their nests. These plants have natural pathogen-killing properties and help maintain a healthier nest site. Odor preference also plays an important role in animals finding mates via the release of pheromones, particularly animals that live in dark environments such as nocturnal animals. The ability to discern the odors of different predators even when the predator may not be close enough to hear, or may not be in sight, is a huge survival advantage for many animals, who generally can differentiate such odors from those of nonthreatening species.

Test Yourself

1. d 2. c 3. b 4. c 5. e 6. e 7. b 8. b 9. d 10. b

Conceptual Questions

1. Sensory transduction—The process by which incoming stimuli are converted into neural signals. An example would be the signals generated in the retina when a photon of light strikes a photoreceptor.

   Perception—An awareness of the sensations that are experienced. An example would be an awareness of what a particular visual image is.
2. Structurally, single-lens and compound eyes both have a lens, photoreceptors, light-absorbing pigmented cells, and surface area elaborations. Functionally, both types of eye are capable of sensing the intensity of light, as well as distinguishing between wavelengths of light (color). In both cases, also, information from the eye is sent to the brain.
3. Of the various senses, the sense of olfaction (smell) is least important for the survival of humans. As diurnal animals, we rely largely on our visual sense. Sounds are a critical way to learn about impending danger, such as a car horn, but also is our major means of communication. Other senses, such as the ability to sense pain, have acutely important functions from time to time. Olfaction, though often a pleasurable sense and at times a protective one (think of the smell of spoiled food), nonetheless provides little survival advantage to us. In fact, many people spend much of their lives with greatly diminished olfactory abilities, whether from chronic allergies or other problems, and are not hindered in any significant way. The story is very different for animals such as nocturnal mammals, which rely very heavily on olfaction to find food, locate mates, and avoid predators.

Chapter 44

Concept Checks

Figure 44.1 Yes. In addition to not having a requirement to shed their skeletons periodically, animals with endoskeletons can use their skin as an efficient means of heat transfer (and, to an extent in amphibians, water transfer). In addition, the body surface of such animals is often a highly sensitive sensory organ.

Figure 44.3 If a tendon is torn, its ability to link a muscle to bone is reduced or lost. Therefore, when a muscle such as the one shown in this illustration contracts, it will not be able to move the bone from which the tendon has become dislodged.

Figure 44.8 The ATP concentration in cells becomes depleted after death, because oxygen and nutrients are not being provided to cells. Consequently, the cross-bridge cycle becomes locked before step 3. Without ATP, the cross-bridges cannot dissociate until many hours later, when the muscle tissue sufficiently decomposes.

Figure 44.11 Na^+ enters the muscle cell because all cells have an electrochemical gradient for Na^+ that favors diffusion of Na^+ from extracellular to intracellular fluid (see Chapter 41). This is because cells have a negative membrane potential and because Na^+ concentrations are higher in the extracellular fluid. The acetylcholine receptor on skeletal muscle cells is also a ligand-gated ion channel; when acetylcholine binds the receptor, it induces a shape change that opens the channel. This allows the entry of Na^+ into the cell.

BioConnections

Figure 44.10 Voltage-gated Ca^{2+} channels exist in the terminals of all axons that communicate by chemical signaling (neurotransmitter release). In those cases, depolarization of the axon terminal opens Ca^{2+} channels, allowing Ca^{2+} to enter the terminal and trigger exocytosis of stored vesicles containing neurotransmitter molecules.

Figure 44.11 As described in Figures 41.2 and 41.11, myelin is a lipid-rich membrane sheath that speeds up conduction of action potentials along an axon. Action potentials are regenerated at discrete lengths along the axon wherever the myelin sheath is interrupted by a node of Ranvier. This is known as saltatory conduction.

Feature Investigation Questions

1. PPAR-δ is a nuclear receptor that regulates the expression of genes that enable cells to more efficiently burn fat instead of glucose for energy.
2. Evans hypothesized that if PPAR-δ were highly activated in mice, the mice would lose weight because of the high level of fat metabolism. Evans and his coworkers developed transgenic mice with highly activated PPAR-δ. Then they fed the transgenic mice and a strain of normal mice high-fat diets. They then compared the weights of the two strains of mice to determine if the change in PPAR-δ activity affected weight. The weights of the transgenic mice were considerably lower than those of the normal mice. These results supported the hypothesis that highly activated PPAR-δ would lead to lower weight gain due to fat metabolism. Interestingly, the researchers also discovered that the transgenic mice could perform prolonged exercise for a much longer time than the normal mice. The muscle tissue of the transgenic mice was more specialized for long-term exercise.
3. Based on the body weight data, the wild type and transgenic mice would have weighed approximately 49–50 and 33–34 grams, respectively, at the conclusion of the study. Current dietary recommendations suggest that people consume no more than about 30% of their daily calories from fat, and that most of that fat should be in the form of unsaturated fat. According to the Centers for Disease Control and Prevention, the average consumption of fat in the U.S. diet amounts to roughly 33% of daily calories; however, that is an average and many individuals consume far more fat than that each day.

Test Yourself

1. b 2. e 3. d 4. b 5. e 6. c 7. a 8. e 9. c 10. e

Conceptual Questions

1. Exoskeletons are on the outside of an animal's body, and endoskeletons are inside the body. Both function in support and protection, but only exoskeletons protect an animal's outer surface. Exoskeletons must be shed when an animal grows, whereas endoskeletons grow with an animal.
2. a. The cycle begins with the binding of an energized myosin cross-bridge to an actin molecule on a thin filament.

   b. The cross-bridge moves, and the thin filaments slide past the thick filaments.

   c. The ATP binds to myosin, causing the cross-bridge to detach.

   d. The ATP bound to myosin is hydrolyzed by ATPase, re-forming the energized state of myosin.
3. The use of energy released by the hydrolysis of ATP is fundamental to skeletal muscle function and locomotion. Recall that ATP must be hydrolyzed during the cross-bridge cycle for skeletal muscle cells to shorten. Energy is also used to maintain calcium ion balance in the sarcoplasmic reticulum and is used in all forms of locomotion. The amount of energy expended by an animal during locomotion reflects how well they are adapted to the environment in which they must move.

Chapter 45

Concept Checks

Figure 45.4 Sauropod dinosaurs were herbivores that probably contained a gizzard-type stomach in which stones helped to grind coarse vegetation. Such stones would have become smooth after months or even years of rumbling around in the gizzard. Some of these sauropods are known to have lacked the sort of grinding teeth characteristic of modern mammalian herbivores, and thus a gizzard would have aided in their digestion much as it does in modern birds.

Figure 45.7 By having bile stored in a gallbladder, bile can be released precisely when needed in response to a meal, which is particularly useful for animals that consume large or infrequent meals. In the absence of a gallbladder, bile flows into the intestine continuously and cannot be increased to match the amount or timing of food intake.

Figure 45.8 Secondary active transport requires energy provided by ATP. Thus, absorption of nutrients by this mechanism is an energy-requiring event, and some portion of an animal's regular nutrient consumption is used to provide the energy required to absorb the nutrients.

BioConnections

Figure 45.8 Transmembrane transport processes are not unique to animals, and one or more types are found in virtually all cells.

Figure 45.11 CCK inhibits stomach activity. This is an example of negative feedback. The arrival of chyme in the small intestine stimulates CCK, which promotes digestion as shown in the figure. At the same time, CCK inhibits contraction of the smooth muscles of the stomach so that the entry of chyme into the small intestine is slowed down. This allows time for controlled digestion and absorption of nutrients in the intestine, without the intestine becoming overfilled with chyme. Simultaneously, CCK inhibits acid production by the stomach so that the pH of the intestine does not become dangerously low before bicarbonate ions are able to neutralize it.

Feature Investigation Questions

1. The surprising observation that some people with gastritis or ulcers have living bacteria (*H. pylori*) in their stomachs, and that administering bacteria-killing compounds provided some relief from the symptoms, led to the hypothesis that *H. pylori* infection is a cause of ulcers in humans.
2. The results did support the hypothesis; however, the results also clearly indicated that not all ulcers are due to *H. pylori* infection.
3. A combined treatment with bismuth and an antibiotic would be the most effective treatment. It is apparent, however, that even in individuals with continued *H. pylori* infections, some ulcers will heal on their own. In the absence of bismuth/antibiotic therapy, though, the likelihood of a recurrence of a new ulcer is much greater.

Test Yourself

1. d 2. e 3. d 4. c 5. c 6. a 7. d 8. c 9. e 10. e

Conceptual Questions

1. Digestion is the breakdown of large molecules into smaller ones by the action of enzymes and acid. Absorption is the transport of digested molecules and small molecules that do not require digestion, across the epithelial cells of the alimentary canal and from there into the extracellular fluid of an animal.
2. The crop is a dilation of the esophagus, which stores and softens food. The gizzard contains swallowed pebbles that help pulverize food. Both of these functions are adaptations that assist digestion in birds, which do not have teeth and therefore do not chew food. Humans, like many animals, can chew food before swallowing.
3. The small intestine contains layers of smooth muscle that help mix the contents of the intestine; this facilitates digestion by bringing enzymes and food molecules into contact. Tight junctions along the apical membranes of the epithelium prevent enzymes from leaking out of the intestine. The surface area available for absorption is greatly increased by folds of the epithelium into villi, and the presence of microvilli forming a brush border. The epithelial cells contain digestive enzymes on their apical membranes; this ensures that the final steps of digestion will release products at the cell surface, where they can be quickly absorbed. The small intestine also contains neurons that, when activated by stretching of the intestine, signal the stomach to temporarily relax so that the intestine can process chyme in small amounts.

Chapter 46

Concept Checks

Figure 46.3 The time required for the vesicles to move to the plasma membrane and fuse with it is much shorter than the time required for new GLUTs to be synthesized by activation of GLUT genes. Thus, the action of insulin on cells is very quick, because the GLUTs are already synthesized.

Figure 46.4 The glycerol and fatty acids used to make glucose or ketones are the breakdown products of triglycerides that were stored in adipose tissue during the absorptive period. The amino acids used to make glucose are derived from the breakdown of protein in muscle and other tissue.

Figure 46.5 Even though the goose was resting, sampling the air from the mask would be only a rough estimate of BMR. That is because the artificial setting and the placement of the mask would be enough of a stimulus to affect the activity and behavior of the goose, thereby increasing its metabolism.

Figure 46.6 Nearly all animals today show a similar relationship between body mass and metabolic rate, and there is no reason why it should not always have been true. Thus, the tiny 1-foot-tall ancestral horse *Eohippus* most likely had a higher BMR than do today's larger horses.

Figure 46.9 Humans are homeothermic endotherms. We maintain our body temperature within a very narrow range, and we supply our own body heat.

BioConnections

Figure 46.3 Exocytosis, a feature characteristic of animal cells, involves the fusion of intracellular vesicles with the plasma membrane, resulting in the release of the vesicle contents into the extracellular fluid. See Figure 5.23 for a general description, and Figure 41.13 for a specific example unique to animal cells.

Feature Investigation Questions

1. Scientists were interested in knowing why animals seemed to regulate their body mass around a particular level, even though many animals experience changes in food supply throughout the year. This seemed to indicate that a mechanism existed within the body that monitored when fuel stores were higher or lower than normal, and that initiated changes in behavior and metabolism to compensate.
2. The ob mice lost weight and ate less during the experimental procedure. This confirmed that something in the bloodstream of the wild-type mice was regulating body weight but was missing in the obese mice. When the unknown factor crossed into the bloodstream of the obese mice, it caused them to lose weight. In another group of parabiosed mice, however, the wild-type mice lost weight, but the obese (db) mice did not. Coleman concluded that these obese mice were not able to respond to the chemical signal that regulates body weight, even though they made the signal themselves and it was active in their parabiosed wild-type partners. It is now known that db mice produce leptin and ob mice do not; however, db mice are not sensitive to leptin and consequently they failed to lose weight in Coleman's experiment.
3. When parabiosed, leptin from db mice will enter the circulation of ob mice. The ob mice will lose weight as a consequence. The db mice will continue to gain weight because they remain insensitive to leptin.

Test Yourself

1. c 2. a 3. d 4. c 5. a 6. c 7. e 8. c 9. c 10. e

Conceptual Questions

1. Insulin acts on adipose and skeletal muscle cells to facilitate the diffusion of glucose from extracellular fluid into the cell cytosol. This is accomplished by increasing the translocation of glucose-transporter (GLUT) proteins from the cytosol to sites within the plasma membrane of insulin-sensitive cells. Insulin also inhibits glycogenolysis and gluconeogenesis in the liver, which decreases the amount of glucose secreted into the blood by the liver. Insulin is required for glucose transport because like many other polar molecules, glucose cannot move across the lipid bilayer of a plasma membrane by simple diffusion. The inhibitory effects of insulin on liver function help to ensure that liver glycogen stores will be spared for the postabsorptive period.
2. Appetite is controlled by a satiety center in the brain that receives signals from the stretched stomach and intestines after a meal. When digestion and absorption are complete, the stomach and intestines return to their original size, and the brain no longer senses that an animal feels "full." In addition, appetite is controlled by leptin, a hormone secreted by adipose cells in direct proportion to the amount of fat stored in an animal's body. When leptin concentrations in the blood are high, appetite is suppressed. When leptin concentrations are low, as occurs when an animal is losing weight, appetite is increased. The presence of a hormone that is released into the blood in proportion to fat mass in the body allows the brain to monitor the amount of energy stored in the body. A decrease in the concentration of leptin in the blood, for example, is the mechanism that communicates to the brain that fat stores are lower than normal. This initiates the sensation of hunger, which encourages an animal to seek food.
3. Countercurrent heat exchange is a mechanism for retaining body heat. The physical arrangement (structure) of arteries and veins in an animal's body can contribute to the very important function of thermoregulation. As warm blood travels through arteries down a bird's leg, for example, heat moves by conduction from the artery to adjacent veins carrying cooler blood in the other direction, toward the heart. By the time the arterial blood reaches the tip of the leg, its temperature has dropped considerably, decreasing the amount of heat loss to the environment, while the heat is returned to the body's core via the warmed veins.

Chapter 47

Concept Checks

Figure 47.1 Open circulatory systems evolved prior to closed systems. However, this does not mean that open systems are in some way inferior to closed circulatory systems. It is better to think of open systems as being ideally suited to the needs of those animals that have them. Arthropods are an incredibly successful order of animals, with the greatest number of species, and inhabiting virtually every ecological niche on the planet. Clearly, their type of circulatory system has not prevented arthropods from achieving their great success.

Figure 47.6 The aorta and systemic arteries carry blood that is fully oxygenated.

Figure 47.9 Body fluids, both extracellular and intracellular, contain large amounts of charged ions, which are capable of conducting electricity. The slight electric currents generated by the beating heart muscle cells are conducted through the surrounding body fluids by the movements of ions in those fluids. This is recorded by the surface electrodes and amplified by the recording machine.

Figure 47.11 When the animal is active, the arterioles of its leg muscle would dilate, bringing more blood and, consequently, nutrients and oxygen to the active muscle tissue.

Figure 47.14 The valves open toward the heart. When the head is upright, the valves are open, and blood drains from the head to the right atrium by gravity. When the giraffe lowers its head to drink, however, gravity would prevent the venous blood from reaching the heart; instead, blood would pool in the head and could raise pressure in the head and brain. The valves in the neck veins work the same way as those in the legs of other animals, helping to propel blood against gravity to the heart.

BioConnections

Figure 47.4 Immune defenses are found in most living organisms. Many bacteria produce antibacterial secretions that kill other bacteria. Plants, as shown in Figure 36.19, have a wide array of pathogen-fighting mechanisms.

Figure 47.17 Baroreceptors are mechanoreceptors. Like all mechanoreceptors (for example, those in distensible or deformable structures such as the urinary bladder and stomach), their ion channels are opened by physical deformation or stretching of the plasma membrane. They are, therefore, mechanically gated ion channels.

Feature Investigation Questions

1. Furchgott noted that acetylcholine had different effects on the rabbit aorta depending on the manner in which the aorta was isolated and prepared. When applied to flattened strips of the aorta, acetylcholine caused contraction of the aorta smooth muscle; however, when applied to circular rings of the aorta, acetylcholine caused relaxation. Furchgott suggested that the difference was due to the absence of the endothelial layer of tissue in the flattened strips of aorta.
2. Furchgott hypothesized that acetylcholine stimulated the endothelial cells to secrete a substance that functioned as a vasodilator, causing the muscle layer to relax. Furchgott performed several experiments to test his hypothesis. He compared the effects of acetylcholine on circular rings of aorta that either had the endothelial layer intact or experimentally removed. The results of this experiment demonstrated that when the endothelial layer was present, relaxation occurred in the presence of acetylcholine. Removal of the endothelial layer, however, resulted in contraction of muscle in the presence of acetylcholine. In a second experiment, a strip of the aorta with the endothelial layer removed was put in contact with a strip of aorta with an intact endothelial layer. When this "sandwiched" treatment was exposed to acetylcholine, both muscle layers relaxed.
3. You might expect NO to be released in any region of the body that requires additional blood flow for any reason. One common example is exercising muscle; dilation of arterioles supplying muscle tissue provides additional oxygen and nutrients to the cells. Another example occurs when animals such as humans need to increase heat loss, such as when we are overheated on a hot day or during strenuous exercise. In such situations, release of NO from skin vessels dilates those vessels, bringing more warm blood near the body surface and facilitating heat transfer to the environment (refer back to Figure 46.12).

Test Yourself

1. b 2. a 3. c 4. b 5. a 6. e 7. c 8. d 9. c 10. d

Conceptual Questions

1. The main components of a circulatory system are (1) blood or hemolymph, an internal body fluid containing dissolved solutes; (2) blood vessels, a system of hollow tubes within the body through which blood travels; and (3) one or more hearts, muscular structures that pump blood through the blood vessels.
2. ***Closed circulatory system***—In a closed circulatory system, the blood and interstitial fluid are contained within tubes called blood vessels and are transported by a pump called the heart. All of the nutrients and oxygen that tissues require are delivered directly to them by the blood vessels. Advantages of closed circulatory systems are that different parts of an animal's body can receive blood flow in proportion to that body part's metabolic requirements at any given time. Due to its efficiency, a closed circulatory system allows organisms to become larger.

   Open circulatory system—In an open circulatory system, the organs are bathed in hemolymph that ebbs and flows into and out of the heart(s) and body cavity, rather than blood being directed to all cells. Like a closed circulatory system, there are a pump and blood vessels, but these two structures are less developed and less complex compared to a closed circulatory system. Partly as a result, organisms such as mollusks and arthropods are generally limited to being relatively small, although exceptions do exist.
3. A circulatory system permits delivery of the nutrients and oxygen required by cells to maintain energy-demanding processes, such as pumping ions across cellular membranes, contracting muscle cells including those of the heart, cell division, protein synthesis, and many others. In addition, the circulatory system removes soluble waste products, which, if allowed to accumulate, would be toxic to cells. Many circulatory systems are capable of adapting to changing metabolic requirements, thus ensuring that homeostasis is maintained whether an animal is resting or active.

Chapter 48

Concept Checks

Figure 48.2 Regardless of whether the atmosphere is measured on Mt. Everest or at sea level, the percentage of gas molecules that are oxygen remains close to 21%. However, the pressure exerted by those gas molecules decreases as one ascends in elevation.

Figure 48.3 If a lungless salamander were to dry out, its capacity for gas exchange would be greatly reduced. Gases diffuse into and out of the body of the salamander by dissolving in the moist fluid layer on the skin.

Figure 48.5 Imagine holding several thin sheets of a wet substance, such as paper. If you wave them in the air, what happens? The sheets stick to one another because of surface tension and other properties of moist surfaces. This is what happens to the lamellae in gills when they are in air. When the lamellae stick to each other, the surface area available for gas exchange is reduced and the fish suffocates.

Figure 48.7 Several factors probably limit insect body size, but the respiratory system most likely is one such factor. If an insect grew to the size of a human, for example, the trachea and tracheoles would be so large and extensive that there would be little room for any other internal organs in the body! Also, the mass of the animal's body and the forces generated during locomotion would probably collapse the tracheoles. Finally, diffusion of oxygen from the surface of the body to the deepest regions of a human-sized insect would take far too long to support the metabolic demands of internal structures.

Figure 48.8 As explained by Boyle's Law, as the lungs expand (that is, increase their volume), the pressure of gas within them decreases.

Figure 48.11 Because fishes have the most efficient means of extracting oxygen from their environment, one might conclude that this is an adaptation to cope with low environmental oxygen. Based on that logic, you would conclude that the oxygen content of water was less than that of air, which is indeed correct.

Figure 48.13 Each molecule of hemoglobin contains four polypeptide subunits, each of which can bind one molecule of oxygen. Since there are two atoms of oxygen in a molecule of O_2, each hemoglobin can hold up to eight atoms of oxygen.

Figure 48.14 The waters off the coast of Antarctica are extremely cold, rarely warmer than 0.30°C. As we saw earlier in this chapter, more oxygen dissolves in cold water than in warm water, and therefore icefish have the potential to obtain more oxygen across their gills. Cold temperatures also decrease the metabolic rate of the animals, because all chemical reactions slow down at low temperature. Thus, the oxygen demands of icefish are lower than those of warm-water fish. Several other adaptations have evolved to enable these animals to live without hemoglobin. Large gills with exceptionally high surface area facilitate diffusion of oxygen into the animal's blood. In addition, cardiovascular adaptations evolved to help increase the total amount of oxygen in the blood and its ability to be pumped to all body tissues. For example, icefish have larger blood volumes and a larger heart than warm-water fish of a similar size. Also, the absence of red blood cells makes the blood less viscous (makes it "thinner") and therefore easier to pump through the body.

BioConnections

Figure 48.5 Countercurrent exchange is employed by many vertebrates to retain heat within their bodies, such as when wading birds stand in cold water. Warm blood traveling away from the heart in arteries transfers heat to colder blood traveling toward the heart in nearby veins, thus minimizing heat loss to the environment.

Figure 48.16 The brainstem includes the midbrain, pons and medulla oblongata. See Figure 42.9 for an illustration of the major parts of the human brain.

Figure 48.17 Bronchoconstriction and bronchodilation of bronchioles is analogous to vasoconstriction and vasodilation that occurs in arterioles. Both bronchioles and arterioles are very thin tubes with smooth muscle in their walls that wraps around the tube. Contraction or relaxation of the smooth muscle leads to narrowing or opening, respectively, of the lumen of the tube. The flow of blood and the flow of air through tubes are both determined by the same factors of pressure and resistance.

Feature Investigation Questions

1. Since glucocorticoids stimulate production of surfactant by lung tissues, injections of glucocorticoids to a pregnant woman should induce surfactant production by the lungs of the fetus. This indeed happens; the glucocorticoids cross into the fetal circulation from the mother, and stimulate surfactant in the fetus. Once born, even though the baby is premature, it's lungs are relatively more mature and are able to remain open.
2. The oxygen levels achieved after surfactant therapy were all improved compared to the pre-treatment levels, but some babies actually had far higher values than is normal for a healthy baby. This was because at first all the babies were being ventilated with a mixture of gas that was very high in oxygen (much higher than is found in air); when their lung function improved, this mixture resulted in very high blood oxygen levels until the oxygen mixture was reduced. The differences in outcomes between babies likely reflected the degree of overall health of the individual babies; some were born slightly less prematurely than others.
3. Blood CO_2 levels were increased in the sick infants because lung ventilation is important not just for obtaining O_2, but for eliminating CO_2. If ventilation is compromised in any person, for any reason, blood levels of CO_2 inevitably increase.

Test Yourself

1. a 2. a 3. c 4. c 5. a 6. b 7. e 8. e 9. b 10. b

Conceptual Questions

1. Countercurrent exchange maximizes the amount of oxygen that can be obtained from the water in fishes. Oxygenated water flows across the lamellae of a fish gill in the opposite direction in which deoxygenated blood flows through the capillaries of the lamellae. In this way, a diffusion gradient for oxygen is maintained along the entire length of the lamellae, facilitating diffusion of oxygen even when much of it has already entered the blood.
2. Animals that live at high altitudes face the special challenge of obtaining oxygen where the atmospheric pressure is low. When atmospheric pressure is low, the partial pressure of oxygen in the air is also low. This means that there is less of a driving force for the diffusion of oxygen from the air into the body of the animal. Several adaptations have arisen that help animals cope with such habitats. For example, many high-altitude animals have more red blood cells and have hemoglobin with a higher affinity for oxygen than that of sea-level animals. This means their hemoglobin can bind oxygen even at the low partial pressures of high altitudes, thereby saturating their blood with oxygen. In addition, such animals generally have larger hearts and lungs for their body size than animals that live at lower altitudes. Animals that move to high altitude show increases in the number of red blood cells in their circulation and in respiratory rates. The number of capillaries in skeletal muscle increases to facilitate oxygen diffusion into the muscle cells. Myoglobin content of muscle cells also increases, expanding the reservoir of oxygen in the cytosol.
3. Hemoglobin is a protein with quaternary structure (see Chapter 3) in which the different subunits cooperate to bind up to a total of four oxygen molecules. It is the structure of the subunits and their relationship to each other that contributes to their ability to bind O_2 and to the nonlinear relationship of the oxygen-hemoglobin dissociation curve. In addition, however, interactions of hemoglobin with other molecules, such as CO_2, change the structure of hemoglobin in such a way that its properties change. Under such conditions, hemoglobin is less able to bind O_2 and consequently it releases the gas. Any molecule that binds to hemoglobin will alter its structure and change its properties; these revert to the original state once the bound molecules are released. A particularly dramatic example of the structure and function of hemoglobin being related is that which occurs in sickle cell disease, due to a mutation.

Chapter 49

Concept Checks

Figure 49.1 No, obligatory exchanges must always occur, but animals can minimize obligatory losses through modifications in behavior. For example, terrestrial animals that seek shade on a hot, sunny day reduce evaporative water loss. As another example, reducing activity minimizes water loss due to respiration.

Figure 49.3 Humans cannot survive by drinking seawater because we do not possess specialized salt glands to rid ourselves of the excess sodium and other ions ingested with seawater. The human kidneys cannot eliminate that much salt. The high blood concentrations of sodium and other ions would cause changes in cellular membrane potentials, disrupting vital functions of electrically excitable tissue such as cardiac muscle and nerve tissue.

Figure 49.6 Secretion of substances into excretory organ tubules is advantageous because it increases the amount of a substance that gets removed from the body by the excretory organs. This is important, because many substances that get secreted are potentially toxic. Filtration, though efficient, is limited by the volume of fluid that can leave the capillaries and enter the excretory tubule.

BioConnections

Figure 49.12 A brush border composed of microvilli is also present along the epithelial cell layer of the vertebrate small intestine (see Chapter 45). In the intestine, the brush border serves to increase the absorption of nutrients. In both the intestine and the proximal tubule of nephrons, therefore, a brush border provides extensive surface area for the transport of substances between a lumen and the epithelial cells (and from there to extracellular fluid).

Figure 49.14 Epithelial cells like those in the kidney tubules can distribute proteins between the apical and basolateral sides of the plasma membrane. In this way, the Na^+/K^+-ATPase pumps that are stimulated by aldosterone are present and active only on one side of the cell, the basolateral surfaces. If the pumps were activated on the apical surface of the cell, aldosterone would not be able to promote reabsorption of Na^+ and water, because Na^+ would also be transported from the cell into the tubule lumen.

Figure 49.17 Countercurrent exchange is important in heat regulation in endotherms, in oxygen diffusion from the water into the blood across the gills of fishes, and in solute and water reabsorption in the loop of Henle in the mammalian kidney.

Feature Investigation Questions

1. Symptoms of prolonged, heavy exercise include fatigue, muscle cramps, and even occasionally seizures. Fatigue results from the reduction in blood flow to muscles and other organs. Muscle cramps and seizures are the results of imbalances in plasma electrolyte concentrations. Cade and his colleagues hypothesized that maintaining proper water and electrolyte concentrations would prevent these problems, and that if water and electrolyte concentrations were maintained, athletic performance should not decrease as rapidly with prolonged exercise.
2. To test their hypothesis, the researchers created a drink that would restore the correct proportions of lost water and electrolytes within the athletes. If the athletes consumed the drink during exercise, they should not experience as much fatigue or muscle cramping, and thus their performance should be enhanced compared with a control group of athletes that drank only water.
3. Gatorade or many similar sports drinks are beneficial in replacing the ions and water lost in perspiration during exercise. These drinks also typically contain sugar that is meant to provide energy for someone who is being very active. Given that a person at rest, or one who is only exercising moderately, would not be expected to perspire very much, a logical hypothesis would be that sports drinks are not beneficial in such cases. A small degree of perspiration will not create a significant electrolyte imbalance. Also, as a rule, consuming sugary drinks should be avoided because of their links to weight gain and dental disease. Thus, at rest or with only light to moderate exercise, the benefits of such drinks are minimal and are outweighed by their potential negative effects.

Test Yourself

1. e 2. e 3. d 4. c 5. e 6. c 7. e 8. d 9. a 10. b

Conceptual Questions

1. Nitrogenous wastes are the breakdown products of the metabolism of proteins and nucleic acids. They consist of ammonia, ammonium ions, urea, and uric acid. The predominant type of waste excreted depends in part on an animal's environment. For example, aquatic animals typically excrete ammonia and ammonium ions, whereas many terrestrial animals excrete primarily urea and uric acid. Urea and uric acid are less toxic than the other types but require energy to be synthesized. Urea and uric acid also result in less water excreted, an adaptation that is especially useful for organisms that must conserve water, such as many terrestrial species.
2. During filtration, an organ acts like a sieve or filter, removing some of the water and its small solutes from the blood, interstitial fluid, or hemolymph, while retaining blood cells and large solutes such as proteins. Reabsorption is the process whereby epithelial cells of an excretory organ recapture useful solutes that were filtered. Secretion is the process whereby epithelial cells of an excretory organ transport unneeded or harmful solutes from the blood to the excretory tubules for elimination. Some substances such as glucose and amino acids are reabsorbed but not secreted, while some other substances such as toxic compounds are not reabsorbed and are secreted. Still other substances, namely proteins, are not filtered at all.
3. Salt glands contain a network of secretory tubules that actively transport NaCl from the extracellular fluid into the tubule lumen. This solution then moves through a central duct and to the outside environment through pores in the nose, around the eyes, and in other locations. The ability to remove salt from body fluids is an adaptation for many marine reptiles and birds, which do not have ready access to fresh water and would otherwise run the risk of having very high concentrations of ions (from ingested salts) in their blood and other body fluids.

Chapter 50

Concept Checks

Figure 50.10 Not all mammals use the energy of sunlight to synthesize vitamin D. Many animals, such as those that inhabit caves or that are strictly nocturnal, rarely are exposed to sunlight. Some of these animals get their vitamin D from dietary sources. How others maintain Ca^{2+} balance without dietary or sunlight-derived active vitamin D remains uncertain.

Figure 50.12 Na^+ and K^+ balance is of vital importance for most animals because of the critical role these ions play in nervous system and muscle function. It is more the rule than the exception that such important physiological variables are under multiple layers of control. This grants a high degree of fine-tuning capability such that these ions—and other similarly important molecules—rarely exceed or fall below the normal range of concentrations for a given animal.

Figure 50.13 The great height of the twin on the left in Figure 50.13 clearly indicates that his condition arose prior to puberty. The enlarged bones further suggest that the disease continued for a time after puberty, when further linear bone growth was no longer possible.

Figure 50.15 Because 20-hydroxyecdysone is a steroid hormone, you would predict that its receptor would be intracellular. All steroid hormones interact with receptors located either in the cytosol or, more commonly, in the nucleus. The hormone-receptor complex then acts to promote or inhibit transcription of one or more genes. The receptor for 20-hydroxyecdysone is indeed found in cell nuclei.

BioConnections

Figure 50.3 When dopamine is secreted from an axon terminal into a synapse where it diffuses to a postsynaptic cell, it is considered a neurotransmitter. When it is secreted from an axon terminal into the extracellular fluid, from where it diffuses into the blood, it is considered a hormone.

Figure 50.7 In addition to the pancreas, certain other organs in an animal's body may contain both exocrine and endocrine tissue or cells. For example, you learned in Chapters 45 and 46 that the vertebrate alimentary canal is composed of several types of secretory cells. Some of these cells release hormones into the blood that regulate the activities of the pancreas and other structures, such as the gallbladder. Other cells of the alimentary canal secrete exocrine products such as acids or mucus into the gut lumen that directly aid in digestion or act as a protective coating, respectively.

Feature Investigation Questions

1. Banting and Best based their procedure on a medical condition that results when pancreatic ducts are blocked. The exocrine cells will deteriorate in a pancreas that has obstructed ducts; however, the islet cells are not affected. The researchers proposed to experimentally replicate the condition to isolate the cells suspected of secreting the glucose-lowering factor. From these cells, they assumed they would be able to extract the substance of interest without contamination or degradation due to exocrine products.
2. The extracts obtained by Banting and Best did contain insulin, the glucose-lowering factor, but were of low strength and purity. Collip developed a procedure to obtain a more purified extract with higher concentrations of insulin.
3. Normally, the concentration of glucose in a mammal's blood is never high enough to exceed the ability of the kidneys to reabsorb it all from the filtrate (refer back to Chapter 49 for details about filtration). However, like all transport processes, reabsorption of glucose from the kidney filtrate has a finite capacity that depends upon the number of transporter molecules and their inherent rate of activity. In untreated diabetes, the blood concentration of glucose becomes so high that it exceeds the capacity of the kidney nephrons to fully reabsorb it from the filtrate. Consequently, the non-reabsorbed glucose appears in the urine.

Test Yourself

1. b 2. e 3. b 4. d 5. b 6. e 7. c 8. d 9. b 10. d

Conceptual Questions

1. Leptin acts in the hypothalamus to reduce appetite and increase metabolic rate. Because adipose tissue is typically the most important and abundant source of stored energy in an animal's body, the ability to relay information to the appetite and metabolism centers of the brain about the amount of available adipose tissue is a major benefit. In this way, the brain's centers can indirectly monitor the minute-to-minute energy status in the body. A decrease in leptin, for example, would indicate that a decrease in adipose tissue existed—as might occur during a fast. Removal of the leptin signal would cause appetite to increase and metabolism to decrease, thereby conserving energy. The presence of an appetite and the subjective sensations associated with hunger is a motivation that drives an animal to seek food at the expense of other activities, such as seeking shelter, finding a mate, and so on.
2. Type 1 DM is characterized by insufficient production of insulin due to the immune system destroying the insulin-producing cells of the pancreas. In type 2 DM, insulin is still produced by the pancreas, but adipose and muscle cells do not respond normally to insulin.
3. Insulin acts to lower blood glucose concentrations, for example, after a meal, whereas glucagon elevates blood glucose, for example, during fasting. Insulin acts by stimulating the insertion of glucose transporter proteins into the cell membrane of muscle and fat cells. Glucagon acts by stimulating glycogenolysis in the liver. If a high dose of glucagon were injected into an animal, including humans, the blood concentration of glucagon would increase rapidly. This would stimulate increased glycogenolysis, resulting in blood glucose concentrations that were above normal.

Chapter 51

Concept Checks

Figure 51.4 Aquatic environments in which the water is stagnant or only gently moving, as shown in this figure, are generally best for external fertilization. Fast-moving bodies of water reduce the likelihood of a sperm contacting an egg and increase the chances that gametes will be washed away in the current. Many river-dwelling fishes lay eggs in gently moving streams, and many marine fishes do so in relatively shallow waters.

Figure 51.9 FSH and LH concentrations do not surge in males, but instead remain fairly steady, because the testes do not show cyclical activity. Sperm production in males is constant throughout life after puberty.

Figure 51.13 Pregnancy and subsequent lactation require considerable energy and, therefore, nutrient ingestion. Consuming the placenta provides the female with a rich source of protein and other important nutrients.

BioConnections

Figure 51.10 In addition to its other functions, the placenta must serve the function of the lungs for the fetus, because the fetus' lungs are not breathing air during this time. Arteries always carry blood away from the heart; veins carry blood to the heart. Consequently, blood leaving the heart of the fetus and traveling through arteries to the placenta is deoxygenated. As blood leaves the placenta and returns to the heart, the blood has become oxygenated as oxygen diffuses from the maternal blood into fetal blood. That oxygenated blood then gets pumped from the fetal heart through other arteries to the rest of the fetus' body.

Feature Investigation Questions

1. Using *Daphnia*, Paland and Lynch compared the accumulation of mitochondrial mutations between sexually reproducing populations and asexually reproducing populations.
2. Of all the mutations observed in the populations, 17.7% were either moderately or mildly deleterious and all of these persisted in the asexually reproducing species, whereas only 4.4% persisted in sexually reproducing species. Thus, asexually reproducing species were about 4 times more likely to retain a deleterious mutation.
3. Sexual reproduction allows for mixing of the different alleles of genes with each generation, thereby increasing genetic variation within the population. This could prevent the accumulation of deleterious alleles in the population.

Test Yourself

1. d 2. c 3. e 4. a 5. d 6. c 7. b 8. c 9. b 10. c

Conceptual Questions

1. External fertilization results in exposure of gametes to predation and other environmental dangers. It also decreases the likelihood of male and female gametes coming into contact. Many animals that reproduce in this way have evolved the ability to lay enormous numbers of eggs to compensate for these dangers or challenges.
2. Cells of the hypothalamus produce two important hormones that regulate reproduction. GnRH stimulates the anterior pituitary gland to release two gonadotropic hormones, LH and FSH. These two hormones regulate the production of gonadal hormones and development of gametes in both sexes. In addition, increased secretion of GnRH contributes to the initiation of puberty. The hypothalamus also produces oxytocin, a hormone that is stored in the posterior pituitary gland and that acts to stimulate milk release during lactation. Finally, changes in neuroendocrine activity in the hypothalamus are linked to seasonal changes in day length and therefore contribute to seasonal breeding in certain mammals.
3. Sexual reproduction requires that males and females of a species produce different gametes and that these gametes come into contact with each other. This requires males and females to expend energy to locate mates. It also may require specialized organs for copulation and in some cases requires the production of very large numbers of gametes to increase the likelihood that the eggs are fertilized. These costs are outweighed by the genetic diversity afforded by sexual reproduction.

Chapter 52

Concept Checks

Figure 52.13 Autonomous specification is most important during cleavage, when intracellular molecules first get segregated into different cells.

BioConnections

Figure 52.1 The process by which a tadpole develops into an adult frog is called metamorphosis. This process is widespread in animals and occurs in many arthropods, certain fishes, numerous marine invertebrates such as gastropods, and amphibia.

Figure 52.5 No, all vertebrates do not use internal fertilization. External fertilization is common in fishes and amphibia; these animals lay unfertilized eggs, over which males deposit sperm (see Chapter 51).

Figure 52.9 Actin is present in all animal cells and is part of the cell cytoskeleton. It is present in particularly large amounts in muscle cells, where it functions with myosin and other proteins to cause shortening of a muscle and its individual cells.

Feature Investigation Questions

1. Knowing the genes expressed in this region of a developing embryo would provide important information about the control of the patterning of embryonic tissues and structures.
2. Harland and colleagues tested the hypothesis that cells within the Spemann organizer expressed certain genes important in the development of dorsal structures, such as the notochord.
3. The scientists used a procedure called expression cloning. In this process, they isolated the various mRNAs that were present in the tissue of the dorsal lip of the embryo. After purifying these mRNAs, they produced a cDNA library. This library contained all the genes expressed in the particular tissue at that particular time of development. The scientists then transcribed the different genes in the cDNA library into mRNAs and injected these into UV-damaged eggs, which were subsequently fertilized. UV-damaged fertilized eggs fail to develop dorsal structures. The scientists were interested in any mRNA that "rescued" the developing embryo and restored some level of normal development. One protein, noggin, was found to rescue the embryos and acted as a morphogen.

Test Yourself

1. a 2. c 3. b 4. d 5. b 6. c 7. b 8. e 9. e 10. e

Conceptual Questions

1. Autonomous specification results from the asymmetrical distribution of intracellular proteins and mRNAs during the cleavage events of embryonic development. The resulting daughter cells will contain different amounts of these cytoplasmic determinants, and this will direct these cells into different developmental fates. Conditional specification results from the interactions of proteins on the extracellular surface of the cell membranes of different cells or from proteins secreted from one cell and acting on another cell. This type of specification determines where a cell ends up within the embryo and what type of cell develops.
2. The timing of the final development of an embryo's organs is typically linked with the requirement for that organ's function. In mammals, for example, the heart is required early in development to pump blood through the embryonic and fetal circulation, thereby delivering nutrients and removing wastes. Fully functional lungs, however, are not required until the animal is born and begins breathing air for the first time.
3. Embryonic development is the process by which a fertilized egg is transformed into an organism with distinct physiological systems and body parts. Cell differentiation is the process by which different cells within a developing organism acquire specialized forms and functions, due to the expression of cell-specific genes. Growth is the enlargement of an embryo, as cells divide and/or enlarge.

Chapter 53

Concept Checks

Figure 53.2 Although swelling is one of the most obvious manifestations of inflammation, it has no significant adaptive value of its own. It is a consequence of fluid leaking out of blood vessels into the interstitial space. It can, however, contribute to pain sensations, because the buildup of fluid may cause distortion of connective tissue structures such as tendons and ligaments. Pain, while obviously unpleasant, is an important signal that alerts many animals to the injury and serves as a reminder to protect the injured site.

Figure 53.10 Both B and T cell receptors have transmembrane domains, a constant region, and a variable region that binds a specific antigen.

Figure 53.14 Because an animal may encounter the same type of pathogen many times during its life, having a secondary immune response means that future infections will be fought off much more efficiently.

BioConnections

Figure 53.2 When histamine receptors are blocked by antihistamines, histamine cannot promote wakefulness and thus drowsiness ensues. Some antihistamines are designed such that they cannot get into the extracellular fluid of the brain; these drugs are still effective in inhibiting allergic reactions but do not cause drowsiness.

Figure 53.4 Recall from Chapter 47 that as blood circulates, a portion of the plasma—the fluid part of blood—exits venules and capillaries and enters the interstitial fluid. Most of the plasma is reabsorbed back into the capillaries, but a portion gets left behind. That excess fluid is drained away by lymph vessels and becomes lymph. Without lymph vessels, fluid would accumulate outside of the blood, in the interstitial fluid.

Feature Investigation Questions

1. The amino acid sequence of Toll protein shared similarities with a portion of a protein known to be involved in immune responses in vertebrates. In addition, activation of Toll protein and the vertebrate immune protein (a cytokine receptor) resulted in the generation of some of the same intracellular signals. This suggested that in addition to its characterized role in embryonic development, Toll may also be important in immune functions in flies.
2. No, Toll protein is not a receptor that recognizes pathogen-associated molecular patterns (PAMPs) expressed on microbial surfaces, and thus it is distinguishable from Toll-like receptors in vertebrates. Toll is, however, a transmembrane protein that binds to extracellular signals; these signals arise, however, not from the microbes themselves but rather from proteins that are endogenous to flies and that are generated during infections.
3. Yes, the results of the survival study clearly implicated Toll as a protein required for the induction of antimicrobial proteins and the ability to withstand fungal infection. Thus, the investigators' hypothesis was supported.

Test Yourself

1. e 2. b 3. c 4. c 5. a 6. e 7. b 8. a 9. d 10. b

Conceptual Questions

1. Innate immunity is present at birth and is found in all animals. These defenses recognize general, conserved features common to a wide array of pathogens and include external barriers, such as the skin, and internal defenses involving phagocytes and other cells. Acquired immunity develops *after* an animal has been exposed to a *particular* antigen. The responses include humoral and cell-mediated defenses. Acquired immunity appears to be largely restricted to vertebrates. Unlike innate immunity, in acquired immunity, the response to an antigen is greatly increased if an animal is exposed to that antigen again at some future time.
2. Immunoglobulins are made of four interlinked polypeptides, two heavy chains and two light chains held together by disulfide bonds. Each immunoglobulin contains within its structure a constant region that is the same from one molecule to another within a given immunoglobulin class, and a variable region. The amino acid sequence of the variable region is what distinguishes one immunoglobulin from another, and results in a tertiary structure of the molecule that specifically binds a particular antigen.
3. Pathogens are disease-causing microorganisms and include bacteria, viruses, and eukaryotic parasites such as certain protists, fungi and small worms. Bacteria are single-celled prokaryotes that lack a true nucleus but are capable of reproducing on their own, whereas viruses are nucleic acids packaged in a protein coat that require a host cell to reproduce.

Chapter 54

Concept Checks

Figure 54.4 Higher predation would occur where winter moth numbers are highest. This means that predators would be responding to an increase in prey density by eating more individuals.

Figure 54.6 Cold water suppresses the ability of the coral-building organisms to secrete their calcium carbonate shell.

Figure 54.9 In some areas when fire is prevented, fuel, in the form of old leaves and branches, can accumulate. When a fire eventually occurs, it can be so large and hot that it destroys everything in its path, even reaching high into the tree canopy.

Figure 54.12 Temperature and rainfall.

Figure 54.17 Acid soils are low in essential plant and animal nutrients such as calcium and nitrogen and are lethal to some soil microorganisms that are important in decomposition and nutrient cycling.

Figure 54.19 This occurs because increasing cloudiness and rain at the tropics maintain fairly constant temperatures across a wide latitudinal range.

Figure 54.23 Soil conditions can also influence biome type. Nutrient-poor soils, for example, may support vegetation different from that of the surrounding area.

Figure 54.24 Taiga.

BioConnections

Chapter Opener The main causes of extinctions are introduced species, direct exploitation, habitat destruction, and climate change. All are human-induced.

Figure 54.16 Plants cannot readily absorb salty water because of its highly negative water potential.

Feature Investigation Questions

1. Most believe that invasive species succeed in new environments due to the lack of natural enemies and that diseases and predators present in the original environment controlled the growth of the population. When these organisms are introduced into a novel environment, the natural enemies are usually absent. This allows for an unchecked increase in the population of the invasive species.
2. Callaway and Aschehoug were able to demonstrate through a controlled experiment that the presence of *Centaurea*, an invasive species, reduced the biomass of three other native species of grasses by releasing allelochemicals. Similar experiments using species of grasses that are found in the native region of *Centaurea* indicate that these species have evolved defenses against the allelochemicals.
3. The activated charcoal helps to remove the allelochemical from the soil. The researchers conducted this experiment to provide further evidence that the chemical released by the *Centaurea* was reducing the biomass of the native Montana grasses. With the removal of the chemicals by the addition of the charcoal, the researchers showed an increase in biomass of the native Montana grasses compared with the experiments lacking the charcoal.
4. You could measure the biomass of *C. diffusa*. Because *C. diffusa* is invasive in the U.S., you would expect weak effects of native North American grasses on *C. diffusa*. Conversely, *C. diffusa* is not invasive in Eurasia so you expect strong effects of Eurasian grasses on *C. diffusa*, and this is what researchers found.

Test Yourself

1. b 2. e 3. a 4. b 5. a 6. a 7. d 8. d 9. a 10. a

Conceptual Questions

1. Mountains are cooler than valleys because of adiabatic cooling. Air at higher altitudes expands because of decreased pressure. As it expands, air cools, at a rate of 10°C for every 1,000 m in elevation. As a result, mountain tops can be much cooler than the plains or valleys that surround them.
2. For several reasons. First, lightning strikes from electrical storms are usually more frequent in prairies than in deserts. Second, the vegetation in a prairie is more continuous and the biomass more extensive than in a desert, so fires burn more frequently and for longer.
3. Florida is a peninsula that is surrounded by the Atlantic Ocean and the Gulf of Mexico. Differential heating between the land and the sea creates onshore sea breezes on both the east and west coasts. These breezes often drift across the whole peninsula, bringing heavy rain.

Chapter 55

Concept Checks

Figure 55.3 In classical conditioning, an involuntary response comes to be associated with a stimulus that did not originally elicit the response, as with Pavlov's dogs salivating at the sound of a metronome.

Figure 55.5 The ability to sing the same distinctive song must be considered innate behavior because the cuckoo has had no opportunity to learn its song from its parents.

Figure 55.7 Tinbergen manipulated pinecones, but not all digger wasp nests are surrounded by pinecones. You could manipulate branches, twigs, stones, and leaves to determine the necessary size and dimensions of objects that digger wasps use as landmarks.

Figure 55.8 This is an unusual example because the return trip involves several different generations to complete: One generation overwinters in Mexico, but these individuals lay eggs and die on the return journey, and their offspring continue the return trip.

Figure 55.15 The individuals in the center of the group are less likely to be attacked than those on the edge of the group. This is referred to as the geometry of the selfish herd.

Figure 55.18 All the larvae in the group are likely to be the progeny of one egg mass from one adult female moth. The death of the one caterpillar teaches a predator to avoid the pattern and benefits the caterpillar's close kin.

BioConnections

Figure 55.3 Toxic or bad-tasting prey species converge on the same color patterns to reinforce the basic distasteful design.

Figure 55.4 According to studies of humans and other animals, learning a task increases the size of the brain regions that are associated with learning and memory.

Feature Investigation Questions

1. Tinbergen observed the activity of digger wasps as they prepared to leave the nest. Each time, the wasp hovered and flew around the nest for a period of time before leaving. Tinbergen suggested that during this time, the wasp was making a mental map of the nest site. He hypothesized that the wasp was using characteristics of the nest site, particularly landmarks, to help relocate it.
2. Tinbergen placed pinecones around the nest of the wasps. When the wasps left the nest, he removed the pinecones from the nest site and set them up in the same pattern a distance away, constructing a sham nest. For each trial, the wasps would go directly to the sham nest, which had the pinecones around it. This indicated to Tinbergen that the wasps identified the nest based on the pinecone landmarks.
3. No. Tinbergen also conducted an experiment to determine if the wasps were responding to the visual cue of the pinecones or the chemical cue of the pinecone scent. The results of this experiment indicated that the wasps responded to the visual cue of the pinecones and not their scent.

Test Yourself

1. d 2. d 3. d 4. c 5. c 6. d 7. b 8. c 9. a 10. c

Conceptual Questions

1. The donation of the male's body to the female is the ultimate nuptial gift. It is possible that this meal enables the females to produce more eggs. In this way, the male's genes will be passed on to future generations.
2. Certainty of paternity influences degree of parental care. With internal fertilization, certainty of paternity is relatively low. With external fertilization, eggs and sperm are deposited together, and paternity is more certain. This explains why males of some species, such as mouth-breeding cichlid fish, are more likely to engage in parental care.
3. As male bears are killed by hunters, new males move into a territory and kill existing cubs. Thus, not only are bears killed directly by hunters, but population growth is also slowed as cubs are killed and population recovery is prolonged.

Chapter 56

Concept Checks

Figure 56.3 In a half-empty classroom, the distribution is often clumped because friends sit together.

Figure 56.7 (a) type III, (b) type II

Figure 56.13 Only density-dependent factors operate in this way.

Figure 56.19 There were very few juveniles in the population and many mature adults. The population would be in decline.

Figure 56.22 Many different ecological footprint calculators are available on the Internet. Does altering inputs such as type of transportation, amount of meat eaten, or amount of waste generated make a difference?

BioConnections

Figure 56.3 Uniform. Territorial marking is likely to keep cheetahs well separated from each other.

Figure 56.14 It has lost the ability to produce viable seeds but it makes thousands of fully formed plantlets, borne on its leaves.

Feature Investigation Questions

1. It became apparent that the sheep population was declining. Some individuals felt that the decline in the population was due to increased wolf predation having a negative effect on population growth. This led to the suggestion of culling the wolf population to reduce the level of predation on the sheep population.
2. The survivorship curve is very similar to a typical type I survivorship curve. This suggests that survival is high among young and reproductively active members of the population and that mortality rates are higher for older members of the population. One difference between the actual survivorship curve and a typical type I curve is that the mortality rate of very young sheep was higher in the actual curve, and then it leveled off after the second year. This suggests that very young and older sheep are more at risk for predation.
3. It was concluded that wolf predation was not the primary reason for the drop in the sheep population. It appeared that wolves prey on the vulnerable members of the population and not on the healthy, reproductively active members. The Park Service determined that several cold winters may have had a more important effect on the sheep population than wolf predation did. Based on these conclusions, the Park Service ended a wolf population control program.

Test Yourself

1. b 2. e 3. b 4. c 5. c 6. b 7. c 8. d 9. c 10. c

Conceptual Questions

1. Increase. Instead of recapturing 5 tagged fish, we only recapture 4. Population size is now estimated as $50 \times 40/4 = 2000/4 = 500$. Our population estimate has increased to 500 when in fact it is more likely that 400 fish occur in the lake.
2. When population sizes are low ($N = 100$), $(K - N)/K$ is so small that growth is low.

$$\frac{dN}{dt} = (0.1)(100) \times \frac{(1{,}000 - 100)}{1{,}000}$$

$$\frac{dN}{dt} = 9$$

At medium values of N, $(K - N)/K$ is closer to a value of 1, and population growth is relatively large. If $K = 1{,}000$, $N = 500$, and $r = 0.1$, then

$$\frac{dN}{dt} = (0.1)(500) \times \frac{(1{,}000 - 100)}{1{,}000}$$

$$\frac{dN}{dt} = 25$$

By comparing these two examples with that shown in Section 56.3, we see that growth is small at high and low values of N and is greatest at immediate values of N. Growth is greatest when $N = K/2$. However, when expressed as a percentage, growth is greatest at low population sizes. Where $N = 100$, percentage growth $= 9/100 = 9\%$. Where $N = 500$, percentage growth $= 25/500 = 5\%$, and where $N = 900$, percentage growth $= 9/100 = 1\%$.

3. In the ponds that dry out, species would tend to be semelparous, producing all their offspring in a single reproductive rate while water is present. In the permanently wet ponds, species would be iteroparous, reproducing repeatedly over the course of the year.

Chapter 57

Concept Checks

Figure 57.2 Individual vultures often fight one another over small carcasses. These interactions would constitute intraspecific interference competition.

Figure 57.6 A 1974 review by Tom Schoener examined segregation in a more wide-ranging literature review of over 80 species, including slime molds, mollusks, and insects, as well as birds. He found segregation by habitat occurred in the majority of the examples, 55%. The other most common form of segregation was by food type, 40%.

Figure 57.8 Omnivores, such as bears, can feed on both plant material, such as berries, and animals, such as salmon. As such, omnivores may act as both predators and herbivores depending on what they are feeding on.

Figure 57.9 Batesian mimicry has a positive effect for the mimic, and the model is unaffected, so it is a +/0 relationship, like commensalism. Müllerian mimicry has a positive effect on both species, so it is a +/+ relationship, like mutualism.

Figure 57.11 Because there is no evolutionary history between invasive predators and native prey, the native prey often have no defenses against these predators and are very easily caught and eaten.

Figure 57.12 Invertebrate herbivores can eat around mechanical defenses; therefore, chemical defenses are probably most effective against invertebrate herbivores.

Figure 57.20 It's an example of facultative mutualism, because in this case, both species can live without the other.

Figure 57.23 Fertilizer increases plant quality and hence herbivore density, which, in turn, increases the density of spiders. This is a bottom-up effect.

BioConnections

Figure 57.9 Most mollusks are heavily armored. However, sea slugs have lost their shells. These species are aposematically colored, advertising a poisonous body. In addition, some octopuses are poisonous, and most can eject an inky chemical smoke screen.

Figure 57.12 Red hot chili peppers.

Figure 57.15 Dodder, *Cuscuta pentagona*.

Figure 57.20 Mycorrhizae.

Figure 57.21 Red.

Feature Investigation Questions

1. The two species of barnacles can be found in the same intertidal zone, but there is a distinct difference in niche of each species. *Chthamalus stellatus* is found only in the upper intertidal zone. *Semibalanus balanoides* is found only in the lower tidal zone.
2. Connell moved rocks with young *Chthamalus* from the upper intertidal zone into the lower intertidal zone to allow *Semibalanus* to colonize the rocks. After the rocks were colonized by *Semibalanus*, he removed *Semibalanus* from one side of each rock and returned the rocks to the lower intertidal zone. This allowed Connell to observe the growth of *Chthamalus* in the presence and the absence of *Semibalanus*.
3. Connell observed that *Chthamalus* was more resistant to desiccation than *Semibalanus*. Though *Semibalanus* was the better competitor in the lower intertidal zone, the species was at a disadvantage in the upper intertidal zone when water levels were low. This allowed *Chthamalus* to flourish and outcompete *Semibalanus* in a different region of the intertidal zone.

Test Yourself

1. d 2. c 3. b 4. d 5. c 6. b 7. d 8. b 9. b 10. c

Conceptual Questions

1. Yes, it is possible that by removing parasites from a neighbor, an individual may be reducing the likelihood of the parasite spreading. You scratch my back, I'll scratch yours, and together we will both be better off.
2. There are at least three reasons why we don't see more herbivory in nature. First, plants possess an array of defensive chemicals, including alkaloids, phenolics, and terpenes. Second, many herbivore populations are reduced by the action of natural enemies. Third, the low nutritive value of plants ensures herbivore populations remain low and unlikely to affect plant populations. While we can't easily increase the levels of defensive chemicals in many plants, nor reduce their nutritive value, we can introduce more natural enemies of plant pests. We see evidence for this in the world of biological control.

Chapter 58

Concept Checks

Figure 58.5 Species richness of trees doesn't increase because rainfall in the western United States is low compared with that in the east.

Figure 58.6 Hurricanes, tropical storms, heavy rainfall, and mudslides are disturbances that maintain a mosaic of disturbed and undisturbed habitats, favoring high species richness in the tropics.

Figure 58.10 As we walk forward from the edge of the glacier to the mouth of the inlet, we are walking backward in ecological time to communities that originated hundreds of years ago.

Figure 58.11 No, competition is also important. For example, the shade from later-arriving species, such as spruce trees, causes competitive exclusion of some of the original understory species.

Figure 58.13 Competition features more prominently. Although early colonists tend to make the habitat more favorable for later colonists, it is the later colonists who outcompete the earlier ones, and this fuels species change.

Figure 58.14 If a small island was extremely close to the mainland, it could continually receive migrating species from the source pool. Even though these species could not complete their life cycle on such a small island, extinctions would rarely be recorded because of this continual immigration.

Figure 58.15 At first glance, the change looks small, but the data are plotted on a log scale. On this scale, an increase in bird richness from 1.2 to 1.6 equals an increase from 16 to 40 species, a change of over 100%.

BioConnections

Figure 58.1 A hypothesis is a proposed idea, whereas a theory is a broad explanation backed by extensive evidence.

Figure 58.11 *Frankia*.

Figure 58.14 The model helps conservationists design the best shaped and optimally placed nature reserves.

Feature Investigation Questions

1. Simberloff and Wilson were testing the three predictions of the theory of island biogeography. One prediction suggested that the number of species should increase with increasing island size. Another prediction suggested that the number of species should decrease with increasing distance of the island from the source pool. Finally, the researchers were testing the prediction that the turnover of species on islands should be considerable.
2. Simberloff and Wilson used the information gathered from the species survey to determine whether the same types of species recolonized the islands or if colonizing species were random.
3. The data suggested that species richness did increase with island size. Also, the researchers found that in all but one of the islands, the number of species was similar to the number of species before fumigation.

Test Yourself

1. c 2. c 3. d 4. b 5. c 6. d 7. a 8. d 9. b 10. c

Conceptual Questions

1. Much of what we learned about secondary metabolites in Chapter 57 related to how these chemicals reduced herbivory. This graph shows that a tree's range influences species richness of herbivores. As such it suggests a reduced role for secondary metabolites in influencing herbivore species richness, although abundance of individual herbivore species may still be influenced by the presence of secondary metabolites.

2.

Disturbance	Frequency	Severity of Effects
Forest fire	Low to high, depending on lightning frequency	High to low, depending on frequency
Hurricane	Low	Severe
Tornado	Very low	Severe
Floods	Medium to high in riparian areas	Fairly low; many communities can recover quickly
Disease epidemics	Low	High; may cause catastrophic losses of species
Droughts	Low	Potentially severe
High winds	High	May kill large trees and create light gaps
Hard freezes	Low	May cause deaths to tropical species, such as mangroves

3. Facilitation. *Calluna* litter enriches the soil with nitrogen, facilitating the growth of the grasses. Adding fertilizer also increases soil nitrogen.

Chapter 59

Concept Checks

Figure 59.3 It depends on the trophic level of their food, whether dead vegetation or dead animals. Many decomposers feed at multiple trophic levels.

Figure 59.13 On a population level, plant secondary metabolites can deter herbivores from feeding. However, on an ecosystem level, these effects are not as important because higher primary production tends to result in higher secondary production.

Figure 59.18 The greatest stores are in rocks and fossil fuels.

Figure 59.19 It fluctuates because less CO_2 is emitted from vegetation in the summer and more is emitted in the winter. This pattern is driven by the large land masses of the Northern Hemisphere relative to the smaller land masses of the Southern Hemisphere.

BioConnections

Figure 59.2 Cyanobacteria.

Figure 59.3 Basidiomycetes and Zygomycetes.

Figure 59.18 Oxygen, hydrogen, and nitrogen.

Figure 59.19 About 450 mya, in the Ordovician period.

Feature Investigation Questions

1. The researchers were testing the effects of increased carbon dioxide levels on the forest ecosystem. The researchers were testing the effects of increased CO_2 levels on primary production as well as other trophic levels in the ecosystem.
2. By increasing the CO_2 levels in only half of the chambers, the researchers were maintaining the control treatments necessary for all scientific studies. By maintaining equal numbers of control and experimental treatments, the researchers could compare data to determine what effects the experimental treatment had on the ecosystem.
3. The increased CO_2 levels led to an increase in primary productivity, as expected. Since photosynthetic rate is limited by CO_2 levels, increases in the available CO_2 should increase photosynthetic rates. Interestingly, though, the increase in primary productivity did not lead to an increase in herbivory. The results indicated that herbivory actually decreased with increased CO_2 levels.

Test Yourself

1. d 2. d 3. d 4. a 5. b 6. d 7. a 8. b 9. c 10. d

Conceptual Questions

1. Carrion beetles are decomposers. They feed on dead animals such as mice, at trophic level 3 or 4. Mice generally feed on vegetative material (trophic level 1) or crawling arthropods (trophic level 2), so mice themselves feed at trophic level 2 or 3.
2. Chain lengths are short in food webs because there is low production efficiency and only a 10% rate of energy transfer from one level to another, so only a few links can be supported.
3. A unit of energy passes through a food web only once and energy is lost at each transfer between trophic levels. In contrast, chemicals cycle repeatedly through food webs and may become more concentrated at higher trophic levels.

Chapter 60

Concept Checks

Figure 60.3 It is possible that the results are driven by what is known as a sampling effect. As the numbers of species in the community increase, so does the likelihood of including a "superspecies," a species with exceptionally large individuals that would use up resources. In communities with higher diversity, care has to be taken that increased diversity is driving the results, not the increased likelihood of including a superspecies.

Figure 60.6 The extinction rate could increase because an increasing human population requires more space to live, work, and grow food, resulting in less available habitat and resources for other species.

Figure 60.8 No, some species, such as self-fertilizing flowers, appear to be less affected by inbreeding.

Figure 60.9 The effective population size (N_e) would be = $(4 \times 225 \times 900) / (225 + 900)$, or 720.

Figure 60.12 Corridors might also promote the movement of invasive species or the spread of fire between areas.

Figure 60.13 They act as habitat corridors because they permit movement of species between forest fragments.

BioConnections

Figure 60.2 A protist. Mosquitoes are the vectors.

Figure 60.19 Genetic cloning could be used to save threatened species or even to resurrect recently extinct species. Cloning may theoretically be able to increase genetic variability of populations if it were possible to use cells from deceased animals. However, cloning is not a panacea because habitat loss, poaching, or invasive species may still prevent reintroductions of species back into the wild.

Feature Investigation Questions

1. The researchers hoped to replicate terrestrial communities that differed only in their level of biodiversity. This would allow the researchers to determine the relationship between biodiversity and ecological function.
2. The hypothesis was that ecological function was directly related to biodiversity. If biodiversity increased, the hypothesis suggested that ecological function should increase.
3. The researchers tested for ecosystem function by monitoring community respiration, decomposition, nutrient retention rates, and productivity. All of these indicate the efficiency of nutrient production and use in the ecosystem.
4. The redundancy hypothesis.

Test Yourself

1. d 2. e 3. a 4. c 5. c 6. e 7. e 8. a 9. c 10. b

Conceptual Questions

1. To reduce the risks associated with inbreeding in especially small populations.
2. The most vulnerable are those with small population sizes, low rates of population growth, *K*-selected (Chapter 56), with inbreeding and possible harem mating structure, tame and unafraid of humans, possibly limited to islands, flightless, possibly valuable to humans as timber, a source of meat or fur, or desirable by collectors (Chapter 60).
3. Increased species diversity increases ecosystem function. Ecosystem functions such as nutrient cycling, regulation of atmospheric gases, pollination of crops, pest regulation, water purity, storm protection, and sewage purification are all likely to be increased by increased species diversity. In addition, increased plant species diversity increases likely availability of new medicines for humans.

Glossary

A

A band A wide, dark band in a myofibril produced by the orderly parallel arrangement of the thick filaments in the middle of each sarcomere.

abiotic The term used to describe interactions between organisms and their nonliving environment.

abortion A procedure or circumstance that causes the death of an embryo or fetus after implantation.

abscisic acid One of several plant hormones that help a plant cope with environmental stress.

abscission The process by which plants drop their leaves.

absolute refractory period The period during an action potential when the inactivation gate of the voltage-gated sodium channel is closed; during this time, it is impossible to generate another action potential.

absorption The process in which digested nutrients are transported from the digestive cavity into an animal's circulatory system.

absorption spectrum A diagram that depicts the wavelengths of electromagnetic radiation that are absorbed by a pigment.

absorptive nutrition The process whereby an organism uses enzymes to digest organic materials and absorbs the resulting small food molecules into its cells.

absorptive state One of two alternating phases in the utilization of nutrients; occurs when ingested nutrients enter the blood from the gastrointestinal tract. The other phase is the postabsorptive state.

acclimatization A long-term and persistent physiological adaptation to an extreme environment.

accommodation In the vertebrate eye, the process in which contraction and relaxation of the ciliary muscles adjust the lens according to the angle at which light enters the eye.

acetylcholinesterase An enzyme located on membranes of postsynaptic cells that respond to the neurotransmitter acetylcholine, such as in muscle fibers in a neuromuscular junction; breaks down excess acetylcholine released into the synaptic cleft.

acid A molecule that releases hydrogen ions (H^+) in solution.

acid hydrolase A hydrolytic enzyme found in lysosomes that functions at acidic pH and uses a molecule of water to break a covalent bond.

acid rain Precipitation with a pH of less than 5.6; results from the burning of fossil fuels.

acidic A solution that has a pH below 7.

acoelomate An animal that lacks a fluid-filled body cavity.

acquired antibiotic resistance The common phenomenon of a previously susceptible strain of bacteria becoming resistant to a specific antibiotic.

acquired immunity A specific immune defense that develops only after an animal is exposed to a foreign substance; believed to be unique to vertebrates.

acquired immunodeficiency syndrome (AIDS) A disease caused by the human immunodeficiency virus (HIV) that leads to a defect in the immune system of infected individuals.

acrocentric A chromosome in which the centromere is near one end.

acromegaly A condition in which a person's growth hormone level is abnormally elevated, causing many bones to thicken and enlarge.

acrosomal reaction An event in fertilization in which enzymes released from a sperm's acrosome break down the outer layers of an egg cell, allowing the entry of the sperm cell's nucleus into the egg cell.

acrosome A special structure at the tip of a sperm's head containing proteolytic enzymes that break down the protective outer layers of the egg cell at fertilization.

actin A cytoskeletal protein.

actin filament A thin type of protein filament composed of actin proteins that forms part of the cytoskeleton and supports the plasma membrane; plays a key role in cell strength, shape, and movement.

action potential An electrical signal along a cell's plasma membrane; occurs in animal neuron axons and muscle cells and in some plant cells.

action spectrum The rate of photosynthesis plotted as a function of different wavelengths of light.

activation energy An initial input of energy in a chemical reaction that allows the molecules to get close enough to cause a rearrangement of bonds.

activator A transcription factor that binds to DNA and increases the rate of transcription.

active immunity An animal's ability to fight off a pathogen to which it has been previously exposed. Active immunity can develop as a result of natural infection or artificial immunization.

active site The location in an enzyme where a chemical reaction takes place.

active transport The transport of a solute across a membrane against its gradient (from a region of low concentration to a region of higher concentration). Active transport requires an input of energy.

adaptations The processes and structures by which organisms adjust to changes in their environment.

adaptive radiation The process whereby a single ancestral species evolves into a wide array of descendant species that differ greatly in their habitat, form, or behavior.

adenine (A) A purine base found in DNA and RNA.

adenosine triphosphate (ATP) A molecule that is a common energy source for all cells.

adenylyl cyclase An enzyme in the plasma membrane that synthesizes cAMP from ATP.

adherens junction A mechanically strong cell junction between animal cells that typically occurs in bands. The cells are connected to each other via cadherins, and the cadherins are linked to actin filaments on the inside of the cells.

adhesion The ability of two different substances to bind to each other; the ability of water to be attracted to, and thereby adhere to, a surface that is not electrically neutral.

adiabatic cooling The process in which increasing elevation leads to a decrease in air temperature.

adventitious root A root that is produced on the surfaces of stems (and sometimes leaves) of vascular plants; also, roots that develop at the bases of stem cuttings.

aerenchyma Spongy plant tissue with large air spaces.

aerobe An organism that requires oxygen to survive.

aerobic respiration A type of cellular respiration in which O_2 is consumed and CO_2 is released.

aerotolerant anaerobe A microorganism that does not use oxygen but is not poisoned by it either.

afferent arterioles Blood vessels that provide a pathway for blood into the glomeruli of the vertebrate kidney.

affinity The degree of attraction between an enzyme and its substrate.

aflatoxins Fungal toxins that cause liver cancer and are a major health concern worldwide.

age-specific fertility rate The rate of offspring production for females of a certain age; used to calculate how a population grows.

age structure The relative numbers of individuals of each defined age group in a population.

AIDS *See* acquired immunodeficiency syndrome.

air sac A component of the avian respiratory system; air sacs—not lungs—expand when a bird inhales and shrink when it exhales. They do not participate in gas exchange, but help direct air through the lungs.

akinete A thick-walled, food-filled cell produced by certain bacteria or protists that enables them to survive unfavorable conditions in a dormant state.

aldosterone A steroid hormone made by the adrenal glands that regulates salt and water balance in vertebrates.

algae (singular, **alga**) A term that applies to about 10 phyla of protists, including both photosynthetic and nonphotosynthetic species; often also includes cyanobacteria.

alimentary canal In animals, the single elongated tube of a digestive system, with an opening at either end through which food and eventually wastes pass from one end to the other.

alkaline A solution with a pH above 7.

alkaloids A group of secondary metabolites that contain nitrogen and usually have a cyclic, ringlike structure. Examples include caffeine and nicotine.

allantois One of the four extraembryonic membranes in the amniotic egg. It serves as a disposal sac for metabolic wastes.

Allee effect The phenomenon that some individuals will fail to mate successfully purely by chance, for example, because of the failure to find a mate.

allele A variant form of a gene.

allele frequency The number of copies of a particular allele in a population divided by the total number of alleles in that population.

allelochemical A powerful plant chemical, often a root exudate, that kills other plant species.

allelopathy The suppressed growth of one species due to the release of toxic chemicals by another species.

allergy Hypersensitivity reaction to a harmless substance.

allopatric The term used to describe species occurring in different geographic areas.

allopatric speciation A form of speciation that occurs when a population becomes geographically isolated from other populations and evolves into one or more new species.

alloploid An organism having at least one set of chromosomes from two or more different species.

alloploidy *See* alloploid.

allosteric site A site on an enzyme where a molecule can bind noncovalently and affect the function of the active site.

alpha (α) helix A type of protein secondary structure in which a polypeptide forms a repeating helical structure stabilized by hydrogen bonds.

alternation of generations The phenomenon that occurs in plants and some protists in which the life cycle alternates between multicellular diploid organisms, called sporophytes, and multicellular haploid organisms, called gametophytes.

alternative splicing The splicing of pre-mRNA in more than one way to create two or more different polypeptides.

altruism Behavior that appears to benefit others at a cost to oneself.

alveolus (plural, **alveoli**) 1. Saclike structures in the lungs where gas exchange occurs. 2. Saclike cellular features of the protists known as alveolates.

Alzheimer disease (AD) The leading worldwide cause of dementia; characterized by a loss of memory and intellectual and emotional function (formerly called Alzheimer's disease).

AM fungi A phylum of fungi that forms mycorrhizal associations with plants.

amensalism One-sided competition between species, in which the interaction is detrimental to one species but not to the other.

Ames test A test that helps ascertain whether or not an agent is a mutagen by using a strain of a bacterium, *Salmonella typhimurium*.

amino acid The building blocks of proteins. Amino acids have a common structure in which a carbon atom, called the α-carbon, is linked to an amino group (NH_2) and a carboxyl group (COOH). The α-carbon also is linked to a hydrogen atom and a particular side chain.

aminoacyl site (A site) One of three sites for tRNA binding in the ribosome during translation; the other two are the peptidyl site (P site) and the exit site (E site). The A site is where incoming tRNA molecules bind to the mRNA (except for the initiator tRNA).

aminoacyl tRNA *See* charged tRNA.

aminoacyl-tRNA synthetase An enzyme that catalyzes the attachment of amino acids to tRNA molecules.

amino terminus *See* N-terminus.

ammonia (NH_3) A highly toxic nitrogenous waste typically produced by many aquatic animal species.

ammonification The conversion of organic nitrogen to NH_3 and NH_4^+ during the nitrogen cycle.

amnion The innermost of the four extraembryonic membranes in the amniotic egg. It protects the developing embryo in a fluid-filled sac called the amniotic cavity.

amniotes A group of tetrapods with amniotic eggs that includes turtles, lizards, snakes, crocodiles, birds, and mammals.

amniotic egg A type of egg produced by amniotic animals that contains the developing embryo and the four separate extraembryonic membranes that it produces: the amnion, the yolk sac, the allantois, and the chorion.

amoeba (plural, **amoebae)** A protist that moves by pseudopodia, which involves extending cytoplasm into filaments or lobes.

amoebocyte A mobile cell within a sponge's mesophyl that absorbs food from choanocytes, digests it, and carries the nutrients to other cells.

amphibian An ectothermic, vertebrate animal that metamorphoses from a water-breathing to an air-breathing form but must return to the water to reproduce.

amphipathic Molecules containing a hydrophobic (water-fearing) region and a hydrophilic (water-loving) region.

ampulla (plural, **ampullae)** 1. A muscular sac at the base of each tube foot of an echinoderm; used to store water. 2. A bulge in the walls of the semicircular canals of the mammalian inner ear; important for sensing circular motions of the head.

amygdala An area of the vertebrate forebrain known to be critical for understanding and remembering emotional situations.

amylase A digestive enzyme in saliva and the pancreas involved in the digestion of starch.

anabolic reaction A metabolic pathway that involves the synthesis of larger molecules from smaller precursor molecules. Such reactions usually require an input of energy.

anabolism A metabolic pathway that results in the synthesis of cellular molecules and macromolecules; requires an input of energy.

anaerobic Refers to a process that occurs in the absence of oxygen; a form of metabolism that does not require oxygen.

anaerobic respiration The breakdown of organic molecules in the absence of oxygen.

anagenesis The pattern of speciation in which a single species is transformed into a different species over the course of many generations.

analogous structure A structure that is the result of convergent evolution. Such structures have arisen independently, two or more times, because species have occupied similar types of environments on Earth.

anaphase The phase of mitosis during which the sister chromatids separate from each other and move to opposite poles; the poles themselves also move farther apart.

anchoring junction A type of junction between animal cells that attaches cells to each other and to the extracellular matrix (ECM).

androecium The aggregate of stamens that forms the third whorl of a flower.

androgens Steroid hormones produced by the male testes (and, to a lesser extent, the adrenal glands) that affect most aspects of male reproduction.

anemia A condition characterized by lower than normal levels of hemoglobin, which reduces the amount of oxygen that can be stored in the blood.

aneuploidy An alteration in the number of particular chromosomes so that the total number of chromosomes is not an exact multiple of a set.

angina pectoris Chest pain during exertion due to the heart being deprived of oxygen.

angiosperm A flowering plant. The term means enclosed seed, which reflects the presence of seeds within fruits.

animal cap assay A type of experiment used to identify proteins secreted by embryonic cells that induce cells in the animal pole to differentiate into mesoderm.

animal pole In triploblast organisms, the pole of the egg with less yolk and more cytoplasm.

Animalia A eukaryotic kingdom of the domain Eukarya.

animals Multicellular heterotrophs with cells that lack cell walls. Most animals have nerves, muscles, the capacity to move at some point in their life cycle, and the ability to reproduce sexually, with sperm fusing directly with eggs.

anion An ion that has a net negative charge.

annual A plant that dies after producing seed during its first year of life.

anorexia nervosa An eating disorder characterized by aversion to food, starvation, and illness secondary to malnourishment.

antagonist A muscle or group of muscles that produces oppositely directed movements at a joint.

antenna complex *See* light-harvesting complex.

anterior Refers to the end of an animal where the head is found.

anteroposterior axis In bilateral animals, one of the three axes along which the adult body pattern is organized; the others are the dorsoventral axis and the right-left axis.

anther The uppermost part of a flower stamen, consisting of a cluster of microsporangia that produce and release pollen.

antheridia Round or elongate gametangia that produce sperm in plants.

anthropoidea A member of a group of primates that includes the monkeys and the hominoidea; these species are larger-brained and diurnal.

antibiotic A chemical, usually made by microorganisms, that inhibits the growth of certain other microorganisms.

antibody A protein secreted by plasma cells that is part of the immune response; antibodies travel all over the body to reach antigens identical to those that stimulated their production, combine with these antigens, then guide an attack that eliminates the antigens or the cells bearing them.

anticodon A three-nucleotide sequence in tRNA that is complementary to a codon in mRNA.

antidiuretic hormone (ADH) A hormone secreted by the posterior pituitary gland that acts on kidney cells to decrease urine production.

antigen Any foreign molecule that the host does not recognize as self and that triggers a specific immune response.

antigen-presenting cell (APC) Cells bearing fragments of antigen, called antigenic determinants or epitopes, complexed with the cell's major histocompatibility complex (MHC) proteins.

antiparallel The arrangement in DNA where one strand runs in the 5′ to 3′ direction while the other strand is oriented in the 3′ to 5′ direction.

antiporter A type of transporter that binds two or more ions or molecules and transports them in opposite directions across a membrane.

anus The final portion of the alimentary canal through which solid wastes are expelled.

aorta In vertebrates, a large blood vessel that exits a ventricle of the heart and leads to the systemic circulation.

apical-basal-patterning genes A category of genes that are important in early stages of plant development during which the apical and basal axes are formed.

apical-basal polarity An architectural feature of plants in which they display an upper, apical pole and a lower, basal pole; shoot apical meristem occurs at the apical pole, and root apical meristem occurs at the basal pole.

apical constriction A cellular process during gastrulation that occurs in bottle cells, where a reduction in the diameter of the actin rings connected to the adherens junctions causes the cells to elongate toward their basal end.

apical meristem In plants, a group of actively dividing cells at a growing tip.

apical region The region of a plant seedling that produces the leaves and flowers.

apomixis A natural asexual reproductive process in which plant fruits and seeds are produced in the absence of fertilization.

apoplast The continuum of water-soaked cell walls and intercellular spaces in a plant.

apoplastic transport The movement of solutes through cell walls and the spaces between cells.

apoptosis Programmed cell death.

aposematic coloration Warning coloration that advertises an organism's unpalatable taste.

aquaporin A transport protein in the form of a channel that allows the rapid diffusion of water across the cell membrane.

aqueous humor A thin liquid in the anterior cavity behind the cornea of the vertebrate eye.

aqueous solution A solution made with water.

aquifer An underground water supply.

arbuscular mycorrhizae Symbiotic associations between AM fungi and the roots of vascular plants.

Archaea One of the three domains of life; the other two are Bacteria and Eukarya.

archaea When not capitalized, refers to a cell or species within the domain Archaea.

archegonia Flask-shaped plant gametangia that enclose an egg cell.

archenteron A cavity formed in an animal embryo during gastrulation that will become the organism's digestive tract.

area hypothesis The proposal that larger areas contain more species than smaller areas because they can support larger populations and a greater range of habitats.
arteriole A single-celled layer of endothelium surrounded by one or two layers of smooth muscle and connective tissue that delivers blood to the capillaries and distributes blood to regions of the body in proportion to metabolic demands.
artery A blood vessel that carries blood away from the heart.
artificial selection *See* selective breeding.
asci (singular, **ascus)** Fungal sporangia shaped like sacs that produce and release sexual ascospores.
ascocarp The type of fruiting body produced by ascomycete fungi.
ascomycetes A phylum of fungi that produce sexual spores in saclike asci located at the surfaces of fruiting bodies known as ascocarps.
ascospore The type of sexual spore produced by the ascomycete fungi.
aseptate The condition of not being partitioned into smaller cells; usually refers to fungal cells.
asexual reproduction A reproductive strategy that occurs when offspring are produced from a single parent, without the fusion of gametes from two parents. The offspring are therefore clones of the parent.
A site *See* aminoacyl site.
assimilation During the nitrogen cycle, the process by which plants and animals incorporate the ammonia and NO_3^- formed through nitrogen fixation and nitrification.
assisted reproductive technologies (ART) Any of a group of methods used to produce a pregnancy by artificial mechanisms.
associative learning A change in behavior due to an association between a stimulus and a response.
asthma A disease in which the smooth muscles around the bronchioles contract more than usual, decreasing airflow in the lungs.
AT/GC rule Refers to the phenomenon that an A in one DNA strand always hydrogen-bonds with a T in the opposite strand, and a G in one strand always bonds with a C.
atherosclerosis The condition in which large plaques may occlude (block) the lumen of an artery.
atmospheric (barometric) pressure The pressure exerted by the gases in air on the body surfaces of animals.
atom The smallest functional unit of matter that forms all chemical substances and cannot be further broken down into other substances by ordinary chemical or physical means.
atomic mass An atom's mass relative to the mass of other atoms. By convention, the most common form of carbon, which has six protons and six neutrons, is assigned an atomic mass of exactly 12.
atomic nucleus The center of an atom; contains protons and neutrons.
atomic number The number of protons in an atom.
ATP *See* adenosine triphosphate.
ATP-dependent chromatin remodeling enzyme An enzyme that catalyzes a change in the positions of nucleosomes.
ATP synthase An enzyme that utilizes the energy stored in a H^+ electrochemical gradient for the synthesis of ATP via chemiosmosis.
atrial natriuretic peptide (ANP) A peptide secreted from the atria of the heart whenever blood levels of sodium increase; ANP causes a natriuresis by decreasing sodium reabsorption in the kidney tubules.
atrioventricular (AV) node Specialized cardiac cells in most vertebrates that sit near the junction of the atria and ventricles and conduct the electrical events from the atria to the ventricles.
atrioventricular (AV) valve A one-way valve into the ventricles of the vertebrate heart through which blood moves from the atria.
atrium In the heart, a chamber to collect blood from the tissues.
atrophy A reduction in the size of a structure, such as a muscle.
audition The ability to detect and interpret sound waves; present in vertebrates and arthropods.
autoimmune disease In humans and many other vertebrates, a disorder in which the body's normal state of immune tolerance breaks down, with the result that attacks are directed against the body's own cells and tissues.
autonomic nervous system The division of the peripheral nervous system that regulates homeostasis and organ function.
autonomous specification The unequal acquisition of cytoplasmic factors during cell division in a developing vertebrate embryo.
autophagosome A double-membrane structure enclosing cellular material destined to be degraded; produced by the process of autophagy.
autophagy A process whereby cellular material, such as a worn-out organelle, becomes enclosed in a double membrane and is degraded.
autopolyploidy The condition of having more than two copies of the entire nuclear genome, which may result when all homologous chromosome pairs do not separate during meiosis.
autosomes All of the chromosomes found in the cell nucleus of eukaryotes except for the sex chromosomes.
autotomy In echinoderms, the ability to detach a body part, such as a limb, that will later regenerate.
autotroph An organism that has metabolic pathways that use energy from either inorganic molecules or light to make organic molecules.
auxin One of several types of hormones considered to be "master" plant hormones because they influence plant structure, development, and behavior in many ways.
auxin efflux carrier One of several types of PIN proteins, which transport auxin out of plant cells.
auxin influx carrier A plasma membrane protein that transports auxin into plant cells.
auxin-response genes Plant genes that are regulated by the hormone auxin.
avirulence gene (*Avr* gene) A gene in a plant pathogen that encodes a virulence-enhancing elicitor, which causes plant disease.
Avogadro's number As first described by Italian physicist Amedeo Avogadro, 1 mole of any element contains the same number of atoms—6.022×10^{23}.
axillary bud A bud that occurs in the axil, the upper angle where a twig or leaf emerges from a stem.
axillary meristem A meristem produced in the axil, the upper angle where a twig or leaf emerges from a stem. Axillary meristems generate axillary buds, which can produce flowers or branches.
axon An extension of the plasma membrane of a neuron that is involved in sending signals to neighboring cells.
axon hillock The part of the axon closest to the cell body; typically where an action potential begins.
axon terminal The end of the axon that sends electrical or chemical messages to other cells.
axoneme The internal structure of eukaryotic flagella and cilia consisting of microtubules, the motor protein dynein, and linking proteins.

B

bacilli (singular, **bacillus)** Rod-shaped prokaryotic cells.
backbone The linear arrangement of phosphates and sugar molecules in a DNA or RNA strand.
Bacteria One of the three domains of life; the other two are Archaea and Eukarya.
bacteria (singular, **bacterium)** When not capitalized, refers to a cell or species within the domain Bacteria.
bacterial artificial chromosome (BAC) A cloning vector derived from F factors that can contain large DNA inserts.
bacterial colony A clone of genetically identical cells formed from a single cell.
bacteriophage A virus that infects bacteria.
bacteroid A modified bacterial cell of the type known as rhizobia present in mature root nodules of some plants.
balanced polymorphism The phenomenon in which two or more alleles are kept in balance and maintained in a population over the course of many generations.
balancing selection A type of natural selection that maintains genetic diversity in a population.
balloon angioplasty A common treatment to restore blood flow through a blood vessel. A thin tube with a tiny, inflatable balloon at its tip is threaded through the artery to the diseased area; inflating the balloon compresses the plaque against the arterial wall, widening the lumen.
barometric pressure *See* atmospheric pressure.
baroreceptor A pressure-sensitive region within the walls of certain arteries that contains the endings of nerve cells; these regions sense and help to maintain blood pressure in the normal range for an animal.
Barr body A highly condensed X chromosome present in female mammals.
basal body A site at the base of flagella or cilia from which microtubules grow. Basal bodies are anchored on the cytosolic side of the plasma membrane.
basal metabolic rate (BMR) The metabolic rate of an animal under resting conditions, in a postabsorptive state, and at a standard temperature.
basal nuclei Clusters of neuronal cell bodies in the vertebrate forebrain that surround the thalamus and lie beneath the cerebral cortex; involved in planning and learning movements.
basal region The region of a plant seedling that produces the roots.
basal transcription A low level of transcription resulting from just the core promoter.
basal transcription apparatus In a eukaryotic structural gene, refers to the complex of RNA polymerase II, general transcription factors (GTFs), and a DNA sequence containing a TATA box.
base 1. A molecule that when dissolved in water lowers the H^+ concentration. 2. A component of nucleotides that is a single or double ring of carbon and nitrogen atoms.
base pair The structure in which two bases in opposite strands of DNA hydrogen-bond with each other.
base substitution A mutation that involves the substitution of a single base in the DNA for another base.
basic local alignment search tool (BLAST) *See* BLAST.
basidia Club-shaped cells that produce sexual spores in basidiomycete fungi.
basidiocarp The type of fruiting body produced by basidiomycete fungi.
basidiomycetes A phylum of fungi whose sexual spores are produced on the surfaces of club-shaped structures (basidia).
basidiospore A sexual spore of the basidiomycete fungi.

basilar membrane A component of the mammalian ear that vibrates back and forth in response to sound and bends the stereocilia in one direction and then the other.
basophil A type of leukocyte that secretes the anticlotting factor heparin at the site of an infection, which helps flush out the infected site; basophils also secrete histamine, which attracts infection-fighting cells and proteins.
Batesian mimicry The mimicry of an unpalatable species (the model) by a palatable one (the mimic).
Bayesian method One method used to evaluate a phylogenetic tree based on an evolutionary model.
B cell A type of lymphocyte responsible for specific immunity.
behavior The observable response of organisms to external or internal stimuli.
behavioral ecology A subdiscipline of organismal ecology that focuses on how the behavior of an individual organism contributes to its survival and reproductive success, which, in turn, eventually affects the population density of the species.
benign tumor A precancerous mass of abnormal cells.
beta (β) pleated sheet A type of protein secondary structure in which regions of a polypeptide lie parallel to each other and are held together by hydrogen bonds to form a repeating zigzag shape.
bidirectional replication The process in which DNA replication proceeds outward from the origin in opposite directions.
biennial A plant that does not reproduce during the first year of life but may reproduce within the following year.
bilateral symmetry An architectural feature in which the body or organ of an organism can be divided along a vertical plane at the midline to create two halves.
Bilateria Bilaterally symmetric animals.
bile A substance produced by the liver that contains bicarbonate ions, cholesterol, phospholipids, a number of organic wastes, and a group of substances collectively termed bile salts. Bile emulsifies fats so they can be absorbed by the small intestine.
bile salts A group of substances produced in the liver that solubilize dietary fat and increase its accessibility to digestive enzymes.
binary fission The process of cell division in bacteria and archaea in which one cell divides into two cells.
binocular (or stereoscopic) vision A type of vision in animals having two eyes located at the front of the head; the overlapping images coming into both eyes are processed together in the brain to form one perception. Binocular vision enables depth perception.
binomial nomenclature The standard method for naming species. Each species has a genus name and species epithet.
biochemistry The study of the chemistry of living organisms.
biodiversity The diversity of life forms in a given location.
biodiversity crisis The idea that there is currently an elevated loss of species on Earth, far beyond the normal historical extinction rate of species.
biofilm An aggregation of microorganisms that secrete adhesive mucilage, thereby gluing themselves to surfaces.
biogeochemical cycle The continuous movement of nutrients such as nitrogen, carbon, sulfur, and phosphorus from the physical environment to organisms and back.
biogeographic region One of six geographic regions which divide up the world's biota: Nearctic, Palearctic, Neotropical, Ethopian, Oriental, and Australian.
biogeography The study of the geographic distribution of extinct and modern species.
bioinformatics A field of study that uses computers to study biological information.
biological control The use of an introduced species' natural enemies to control its proliferation.
biological diversity *See* biodiversity.
biological nitrogen fixation Nitrogen fixation that is performed in nature by certain prokaryotes.
biological species concept An approach used to distinguish species, which states that a species is a group of individuals whose members have the potential to interbreed with one another in nature to produce viable, fertile offspring but cannot successfully interbreed with members of other species.
biology The study of life.
bioluminescence A phenomenon in living organisms in which chemical reactions give off light rather than heat.
biomagnification The increase in the concentration of a substance in living organisms from lower to higher trophic levels in a food web.
biomass A quantitative estimate of the total mass of living matter in a given area, usually measured in grams or grams per square meter.
biome A major type of habitat characterized by distinctive plant and animal life.
bioremediation The use of living organisms, usually microbes or plants, to detoxify polluted habitats such as dump sites or oil spills.
biosphere The regions on the surface of the Earth and in the atmosphere where living organisms exist.
biosynthetic reaction Also called an anabolic reaction; a chemical reaction in which small molecules are used to synthesize larger molecules.
biotechnology The use of living organisms or the products of living organisms for human benefit.
biotic The term used to describe interactions among organisms.
biparental inheritance An inheritance pattern in which both the male and female gametes contribute organellar genes to the offspring.
bipedal Having the ability to walk on two feet.
bipolar cells Cells in the vertebrate eye that make synapses with photoreceptors and relay responses to the ganglion cells.
bivalent Homologous pairs of sister chromatids associated with each other, lying side by side.
blade The flattened portion of a leaf.
BLAST (basic local alignment search tool) A computer program that can identify homologous genes that are found in a database.
blastocoel A cavity formed in a cleavage-stage vertebrate embryo (blastula); provides a space into which cells of the future digestive tract will migrate.
blastocyst The mammalian counterpart of a blastula.
blastoderm A flattened disc of dividing cells in the embryo of animals that undergo incomplete cleavage; occurs in birds and some fishes.
blastomere The two half-size daughter cells produced by each cell division during cleavage.
blastopore A small opening created when a band of tissue invaginates during gastrulation. It forms the primary opening of the archenteron to the outside.
blastula An animal embryo at the stage when it forms an outer epithelial layer and an inner cavity.
blending inheritance An early hypothesis of inheritance that stated that the genetic material that dictates hereditary traits blends together from generation to generation, and the blended traits are then passed to the next generation.
blood A fluid connective tissue in animals consisting of cells and (in mammals) cell fragments suspended in a solution of water containing dissolved nutrients, proteins, gases, and other molecules.
blood-doping An example of hormone misuse in which the number of red blood cells in the circulation is boosted to increase the oxygen-carrying capacity of the blood.
blood pressure The force exerted by blood on the walls of blood vessels; blood pressure is responsible for moving blood through the vessels.
body mass index (BMI) A method of assessing body fat and health risk that involves calculating the ratio of weight compared with height; weight in kilograms is divided by the square of the height in meters.
body plan The organization of cells, tissues, and organs within a multicellular organism; also known as a body pattern.
bone A relatively hard component of the vertebrate skeleton; a living, dynamic tissue composed of organic molecules and minerals.
bottleneck effect A situation in which a population size is dramatically reduced and then rebounds. While the population is small, genetic drift may rapidly reduce the genetic diversity of the population.
Bowman's capsule A saclike structure that houses the glomerulus at the beginning of the tubular component of a nephron in the mammalian kidney.
brain Organ of the central nervous system of animals that functions to process and integrate information.
brainstem The part of the vertebrate brain composed of the medulla oblongata, the pons, and the midbrain.
brassinosteroid One of several plant hormones that help a plant to cope with environmental stress.
bronchi (singular, **bronchus**) Tubes branching from the trachea and leading into the lungs.
bronchiole A thin-walled, small tube branching from the bronchi and leading to the alveoli in mammalian lungs.
bronchodilator A compound that binds to the muscles of the bronchioles of the lung and causes them to relax, thereby widening the bronchioles and easing breathing.
brown adipose tissue A specialized tissue in small mammals such as hibernating bats, small rodents living in cold environments, and many newborn mammals, including humans, that can help to generate heat and maintain body temperature.
brush border The collective name for the microvilli in the vertebrate small intestine.
bryophytes Liverworts, mosses, and hornworts, the modern nonvascular land plants.
buccal pumping A form of breathing in which animals take in water or air into their mouths, then raise the floor of the mouth, creating a positive pressure that pumps water or air across the gills or into the lungs; found in fishes and amphibians.
bud A miniature plant shoot having a dormant shoot apical meristem.
budding A form of asexual reproduction in which a portion of the parent organism pinches off to form a complete new individual.
buffer A compound that acts to minimize pH fluctuations in the fluids of living organisms. Buffer systems can raise or lower pH as needed.
bulbourethral gland Paired accessory glands in the human male reproductive system that secrete an alkaline mucus that protects sperm by neutralizing the acidity in the urethra.
bulimia nervosa An eating disorder characterized by cycles of binge eating followed by purging and vomiting to reduce body weight.
bulk feeders Animals that eat food in large pieces.
bulk flow The mass movement of liquid in a plant caused by pressure, gravity, or both.

C

C_3 plant A plant that incorporates CO_2 into organic molecules via RuBP to make 3PG, a three-carbon molecule.

C_4 plant A plant that uses PEP carboxylase to initially fix CO_2 into a four-carbon molecule and later uses rubisco to fix CO_2 into simple sugars; an adaptation to hot, dry environments.

cadherin A cell adhesion molecule found in animal cells that promotes cell-to-cell adhesion.

calcitonin A hormone that plays a role in Ca^{2+} homeostasis in some vertebrates.

calcium wave A brief increase in cytosolic Ca^{2+} concentrations in an egg that has been penetrated by a sperm cell; the change in Ca^{2+} moves through the cell and contributes to the slow block to polyspermy.

callose A carbohydrate that plays crucial roles in plant development and plugging wounds in plant phloem.

calorie The amount of heat required to raise the temperature of 1 gram of water 1°C. The Calorie (dietary unit) is equivalent to a kilocalorie, or 1,000 calories.

Calvin cycle The second stage in the process of photosynthesis. During this cycle, ATP is used as a source of energy, and NADPH is used as a source of high-energy electrons so that CO_2 can be incorporated into carbohydrate.

calyx The sepals that form the outermost whorl of a flower.

Cambrian explosion An event during the Cambrian period (543–490 mya) in which there was an abrupt increase (on a geological scale) in the diversity of animal species.

cAMP *See* cyclic adenosine monophosphate.

CAM (crassulacean acid metabolism) plants C_4 plants that open their stomata at night to take up CO_2.

cancer A disease caused by gene mutations that lead to uncontrolled cell growth.

canopy The uppermost layer of tree foliage.

capillary A tiny thin-walled vessel that is the site of gas and nutrient exchange between the blood and interstitial fluid.

capping The process in which a 7-methylguanosine is covalently attached at the 5′ end of mature mRNAs of eukaryotes.

capsid A protein coat enclosing a virus's genome.

CAP site One of two regulatory sites near the *lac* promoter; this site is a DNA sequence recognized by the catabolite activator protein (CAP).

capsule A very thick, gelatinous glycocalyx produced by certain strains of bacteria that may help them avoid being destroyed by an animal's immune (defense) system.

carapace The hard protective cuticle covering the cephalothorax of a crustacean.

carbohydrate An organic molecule often with the general formula, $C(H_2O)$; a carbon-containing compound that includes starches, sugars, and cellulose.

carbon fixation A process in which carbon from inorganic CO_2 is incorporated into an organic molecule such as a carbohydrate.

carboxyl terminus *See* C-terminus.

carcinogen An agent that increases the likelihood of developing cancer, usually a mutagen.

carcinoma A cancer of epithelial cells.

cardiac cycle The events that produce a single heartbeat, which can be divided into two phases, diastole and systole.

cardiac muscle A type of muscle tissue found only in hearts in which physical and electrical connections between individual cells enable many of the cells to contract simultaneously.

cardiac output (CO) The amount of blood the heart pumps per unit time, usually expressed in units of L/min.

cardiovascular disease Diseases affecting the heart and blood vessels.

carnivore An animal that consumes animal flesh or fluids.

carotenoid A type of photosynthetic or protective pigment found in plastids that imparts a color that ranges from yellow to orange to red.

carpel A flower shoot organ that produces ovules that contain female gametophytes.

carrier *See* transporter.

carrying capacity (*K*) The upper boundary for a population size.

Casparian strips Suberin ribbons on the walls of endodermal cells of plant roots; prevent apoplastic transport of ions into vascular tissues.

caspase An enzyme that is activated during apoptosis.

catabolic reaction A metabolic pathway in which a molecule is broken down into smaller components, usually releasing energy.

catabolism A metabolic pathway that results in the breakdown of larger molecules into smaller molecules. Such reactions are often exergonic.

catabolite activator protein (CAP) An activator protein for the *lac* operon.

catabolite repression In bacteria, a process whereby transcriptional regulation is influenced by the presence of glucose.

catalase An enzyme within peroxisomes that breaks down hydrogen peroxide to water and oxygen gas.

catalyst An agent that speeds up the rate of a chemical reaction without being consumed during the reaction.

cataract An accumulation of protein in the lens of the eye; causes blurring and poor night vision.

cation An ion that has a net positive charge.

cation exchange With regard to soil, the process in which hydrogen ions are able to replace mineral cations on the surfaces of humus or clay particles.

cDNA *See* complementary DNA.

cDNA library A type of DNA library in which the inserts are derived from cDNA.

cecum The first portion of a vertebrate's large intestine.

cell The simplest unit of a living organism.

cell adhesion A vital function of the cell membrane that allows cells to bind to each other. Cell adhesion is critical in the formation of multicellular organisms and provides a way to convey positional information between neighboring cells.

cell adhesion molecule (CAM) A membrane protein found in animal cells that promotes cell adhesion.

cell biology The study of individual cells and their interactions with each other.

cell body A part of a neuron that contains the cell nucleus and other organelles.

cell coat Also called the glycocalyx, the carbohydrate-rich zone on the surface of animal cells that shields the cell from mechanical and physical damage.

cell communication The process through which cells can detect and respond to signals in their extracellular environment. In multicellular organisms, cell communication is also needed to coordinate cellular activities within the whole organism.

cell cycle The series of phases a eukaryotic cell progresses through from its origin until it divides by mitosis.

cell differentiation The phenomenon by which cells become specialized into particular cell types.

cell division The process in which one cell divides into two cells.

cell doctrine *See* cell theory.

cell junctions Specialized structures that adhere cells to each other and to the ECM.

cell-mediated immunity A type of specific immunity in which cytotoxic T cells directly attack and destroy infected body cells, cancer cells, or transplanted cells.

cell nucleus The membrane-bound area of a eukaryotic cell in which the genetic material is found.

cell plate In plant cells, a structure that forms a cell wall between the two daughter cells during cytokinesis.

cell signaling A vital function of the plasma membrane that involves cells sensing changes in their environment and communicating with each other.

cell surface receptor A receptor found in the plasma membrane that enables a cell to respond to different kinds of signaling molecules.

cell theory A theory that states that all organisms are made of cells, cells are the smallest units of living organisms, and new cells come from pre-existing cells by cell division.

cell-to-cell communication A form of cell communication that occurs between two different cells.

cellular differentiation The process by which different cells within a developing organism acquire specialized forms and functions due to the expression of cell-specific genes.

cellular respiration A process by which living cells obtain energy from organic molecules and release waste products.

cellular response Adaptation at the cellular level that involves a cell responding to signals in its environment.

cellulose The main macromolecule of the primary cell wall of plants and many algae; a polymer made of repeating molecules of glucose attached end to end.

cell wall A relatively rigid, porous structure located outside the plasma membrane of prokaryotic, plant, fungal, and certain protist cells; provides support and protection.

centiMorgan (cM) *See* map unit (mu).

central cell In the female gametophyte of a flowering plant, a large cell that contains two nuclei; after double fertilization, it forms the first cell of the nutritive endosperm tissue.

central dogma Refers to the steps of gene expression at the molecular level. DNA is transcribed into mRNA, and mRNA is translated into a polypeptide.

central nervous system (CNS) In vertebrates, the brain and spinal cord.

central region The region of a plant seedling that produces stem tissue.

central vacuole An organelle that often occupies 80% or more of the cell volume of plant cells and stores a large amount of water, enzymes, and inorganic ions.

central zone The area of a plant shoot meristem where undifferentiated stem cells are maintained.

centrioles A pair of structures within the centrosome of animal cells. Most plant cells and many protists lack centrioles.

centromere The region where the two sister chromatids are tightly associated; the centromere is an attachment site for kinetochore proteins.

centrosome A single structure often near the cell nucleus of eukaryotic cells that forms a nucleating site for the growth of microtubules; also called the microtubule-organizing center.

cephalization The localization of a brain and sensory structures at the anterior end of the body of animals.

cephalothorax The fused head and thorax structure in species of the class Arachnida and Crustacea.

cerebellum The part of the vertebrate hindbrain, along with the pons, responsible for monitoring and coordinating body movements.

cerebral cortex The surface layer of gray matter that forms the outer part of the cerebrum of the vertebrate brain.

cerebral ganglia A paired structure in the head of invertebrates that receives input from sensory cells and controls motor output.
cerebrospinal fluid Fluid that exists in ventricles within the central nervous system and surrounds the exterior of the brain and spinal cord; it absorbs physical shocks to the brain resulting from sudden movements or blows to the head.
cerebrum A region of the vertebrate forebrain that is responsible for the higher functions of conscious thought, planning, and emotion, as well as control of motor function.
cervix A fibrous structure at the end of the female vagina that forms the opening to the uterus.
channel A transmembrane protein that forms an open passageway for the direct diffusion of ions or molecules across a membrane.
chaperone A protein that keeps other proteins in an unfolded state during the process of post-translational sorting.
character A characteristic of an organism, such as the appearance of seeds, pods, flowers, or stems.
character displacement The tendency for two species to diverge in morphology and thus resource use because of competition.
character state A particular variant of a given character.
charged tRNA A tRNA with its attached amino acid; also called aminoacyl tRNA.
charophyceans The lineages of freshwater green algae that are most closely related to the land plants.
checkpoint One of three critical regulatory points found in the cell cycle of eukaryotic cells. At these checkpoints, a variety of proteins act as sensors to determine if a cell is in the proper condition to divide.
checkpoint protein A protein that senses if a cell is in the proper condition to divide and prevents a cell from progressing through the cell cycle if it is not.
chemical energy The potential energy contained within covalent bonds in molecules.
chemical equilibrium A state in a chemical reaction in which the rate of formation of products equals the rate of formation of reactants.
chemical mutagen A chemical that causes mutations.
chemical reaction The formation and breaking of chemical bonds, resulting in a change in the composition of substances.
chemical selection Occurs when a chemical within a mixture has special properties or advantages that cause it to increase in amount. May have played a key role in the formation of an RNA world.
chemical synapse A synapse in which a chemical called a neurotransmitter is released from the axon terminal of a neuron and acts as a signal from the presynaptic to the postsynaptic cell.
chemiosmosis A process for making ATP in which energy stored in an ion electrochemical gradient is used to make ATP from ADP and P_i.
chemoautotroph An organism able to use energy obtained by chemical modifications of inorganic compounds to synthesize organic compounds.
chemoheterotroph An organism that must obtain organic molecules both for energy and as a carbon source.
chemoreceptor A sensory receptor in animals that responds to specific chemical compounds.
chiasma The connection at a crossover site of two chromosomes.
chimeric gene A gene formed from the fusion of two gene fragments to each other.
chitin A tough, nitrogen-containing polysaccharide that forms the external skeleton of many insects and the cell walls of fungi.
chlorophyll A photosynthetic green pigment found in the chloroplasts of plants, algae, and some bacteria.
chlorophyll *a* A type of chlorophyll pigment found in plants, algae, and cyanobacteria.
chlorophyll *b* A type of chlorophyll pigment found in plants, green algae, and some other photosynthetic organisms.
chloroplast A semiautonomous organelle found in plant and algal cells that carries out photosynthesis.
chloroplast genome The chromosome found in chloroplasts.
chlorosis The yellowing of plant leaves caused by various types of mineral deficiencies.
choanocyte A specialized cell of sponges that functions to trap and eat small particles.
chondrichthyans Members of the class Chondrichthyes, including sharks, skates, and rays.
chordate An organism that has or at some point in its life has had a notochord and a hollow dorsal nerve cord; includes all vertebrates and some invertebrates.
chorion One of the four extraembryonic membranes in the amniotic egg. It exchanges gases between the embryo and the surrounding air.
chorionic gonadotropin A luteinizing hormone (LH)-like hormone made by the blastocyst and placenta that maintains the corpus luteum.
chromatin Refers to the biochemical composition of chromosomes, which contain DNA and many types of proteins.
chromosome A discrete unit of genetic material composed of DNA and associated proteins. Eukaryotes have chromosomes in their cell nuclei and in plastids and mitochondria.
chromosome territory A distinct, nonoverlapping area where each chromosome is located within the cell nucleus of eukaryotic cells.
chromosome theory of inheritance An explanation of how the steps of meiosis account for the inheritance patterns observed by Mendel.
chylomicron Large fat droplet coated with amphipathic proteins that perform an emulsifying function similar to that of bile salts; chylomicrons are formed in intestinal epithelial cells from absorbed fats in the diet.
chyme A solution of water and partially digested food particles in the stomach and small intestine.
chymotrypsin A protease involved in the breakdown of proteins in the small intestine.
chytrids Simple, early-diverging phyla of fungi; commonly found in aquatic habitats and moist soil, where they produce flagellate reproductive cells.
cilia (singular, **cilium**) Cell appendages that have the same internal structure as flagella and function like flagella to facilitate cell movement; cilia are shorter and more numerous on cells than are flagella.
ciliate A protist that moves by means of cilia, which are tiny hairlike extensions that occur on the outside of cells and have the same internal structure as flagella.
circadian rhythm Internal biological clock system that can be found in plants, animals, and other organisms.
circulatory system A system that transports necessary materials to all cells of an animal's body and transports waste products away from cells. Three basic types are gastrovascular cavities, open systems, and closed systems.
***cis*-acting element** *See cis*-effect.
***cis*-effect** A DNA segment that must be adjacent to the gene(s) that it regulates. The *lac* operator site is an example of a *cis*-acting element.
cisternae Flattened, fluid-filled tubules of the endoplasmic reticulum.
***cis/trans* isomers** Organic molecules with the same chemical composition but existing in two different configurations determined by the positions of hydrogen atoms on the two carbons of a CC double bond. When the hydrogen atoms are on the same side of the double bond, it is called a *cis* isomer; when on the opposite sides of the double bond, it is a *trans* isomer.
citric acid cycle A cycle that results in the breakdown of carbohydrates to CO_2; also known as the Krebs cycle.
clade A group of species derived from a single common ancestor.
cladistic approach An approach used to construct a phylogenetic tree by comparing primitive and shared derived characters.
cladogenesis A pattern of speciation in which a species is divided into two or more species.
cladogram A phylogenetic tree constructed by using a cladistic approach.
clamp connection In basidiomycete fungi, a structure that helps distribute nuclei during cell division.
clasper An extension of the pelvic fin of a chondrichthyan, used by the male to transfer sperm to the female.
class In taxonomy, a subdivision of a phylum.
classical conditioning A type of associative learning in which an involuntary response comes to be associated positively or negatively with a stimulus that did not originally elicit the response.
cleavage A succession of rapid cell divisions with no significant growth that produces a hollow sphere of cells called a blastula.
cleavage furrow In animal cells, an area that constricts like a drawstring to separate the cells during cytokinesis.
climate The prevailing weather pattern of a given region.
climax community A distinct end point of succession.
clitoris Located at the anterior part of the female labia minora, erectile tissue that becomes engorged with blood during sexual arousal and is very sensitive to sexual stimulation.
clonal deletion One of two mechanisms that explain why normal individuals lack active lymphocytes that respond to self components; T cells with receptors capable of binding self proteins are destroyed by apoptosis.
clonal inactivation One of two mechanisms that explain why normal individuals lack active lymphocytes that respond to self components; the process occurs outside the thymus and causes potentially self-reacting T cells to become nonresponsive.
clonal selection The process by which an antigen-stimulated lymphocyte divides and forms a clone of cells, each of which recognizes that particular antigen.
cloning Making many copies of something such as a DNA molecule.
closed circulatory system A circulatory system in which blood flows throughout an animal entirely within a series of vessels and is kept separate from the interstitial fluid.
closed conformation Tightly packed chromatin that cannot be transcribed into RNA.
clumped The most common pattern of dispersion within a population, in which individuals are gathered in small groups.
cnidocil On the surface of a cnidocyte, a hairlike trigger that detects stimuli.
cnidocyte A characteristic feature of cnidarians; a stinging cell that functions in defense or the capture of prey.
coacervates Droplets that form spontaneously from the association of charged polymers such as proteins, carbohydrates, or nucleic acids surrounded by water.
coactivator A protein that increases the rate of transcription but does not directly bind to the DNA itself.
coat protein A protein that surrounds a membrane vesicle and facilitates vesicle formation.

cocci Sphere-shaped prokaryotic cells.
cochlea A coiled structure in the inner ear of mammals that contains the auditory receptors (organ of Corti).
coding sequence The region of a gene or a DNA molecule that encodes the information for the amino acid sequence of a polypeptide.
coding strand The DNA strand opposite to the template (or noncoding strand).
codominance The phenomenon in which a single individual expresses two alleles.
codon A sequence of three nucleotide bases that specifies a particular amino acid or a stop codon; codons function during translation.
coefficient of relatedness (*r*) The probability that any two individuals will share a copy of a particular gene.
coelom A fluid-filled body cavity in an animal.
coelomate An animal with a true coelom.
coenzyme An organic molecule that participates in a chemical reaction with an enzyme but is left unchanged after the reaction is completed.
coevolution The process by which two or more species of organisms influence each other's evolutionary pathway.
cofactor Usually an inorganic ion that temporarily binds to the surface of an enzyme and promotes a chemical reaction.
cognitive learning The ability to solve problems with conscious thought and without direct environmental feedback.
cohesion The ability of like molecules to noncovalently bind to each other; the attraction of water molecules for each other.
cohesion-tension theory The explanation for long-distance water transport as the combined effect of the cohesive forces of water and evaporative tension.
cohort A group of organisms of the same age.
coleoptile A protective sheath that encloses the first bud of the epicotyl in a mature monocot embryo.
coleorhiza A protective envelope that encloses the young root of a monocot.
colinearity rule The phenomenon whereby the order of homeotic genes along the chromosome correlates with their expression along the anteroposterior axis of the body.
collagen A protein secreted from animal cells that forms large fibers in the extracellular matrix.
collecting duct A tubule in the mammalian kidney that collects urine from nephrons.
collenchyma cells Flexible cells that make up collenchyma tissue.
collenchyma tissue A plant ground tissue that provides support to plant organs.
colligative property A property of a solution that depends only on the concentration of solute molecules.
colloid A gel-like substance in the follicles of the thyroid gland.
colon A part of a vertebrate's large intestine consisting of three relatively straight segments—the ascending, transverse, and descending portions. The terminal portion of the descending colon is S-shaped, forming the sigmoid colon, which empties into the rectum.
colony hybridization A method that uses a labeled probe to identify bacterial colonies that contain a desired gene.
combinatorial control The phenomenon whereby a combination of many factors determines the expression of any given gene.
commensalism An interaction that benefits one species and leaves the other unaffected.
communication The use of specially designed visual, chemical, auditory, or tactile signals to modify the behavior of others.
community An assemblage of populations of different species that live in the same place at the same time.
community ecology The study of how populations of species interact and form functional communities.
compartmentalization A characteristic of eukaryotic cells in which many organelles separate the cell into different regions. Cellular compartmentalization allows a cell to carry out specialized chemical reactions in different places.
competent The term used to describe bacterial strains that have the ability to take up DNA from the environment.
competition An interaction that affects two or more species negatively, as they compete over food or other resources.
competitive exclusion principle The proposal that two species with the same resource requirements cannot occupy the same niche.
competitive inhibitor A molecule that binds to the active site of an enzyme and inhibits the ability of the substrate to bind.
complement The family of plasma proteins that provides a means for extracellular killing of microbes without prior phagocytosis.
complementary Describes the specific base pairing that occurs between strands of nucleic acids; A pairs only with T (in DNA) or U (in RNA), and G pairs only with C.
complementary DNA (cDNA) DNA molecules that are made from mRNA as a starting material.
complete flower A flower that possesses all four types of flower organs.
complete metamorphosis During development in the majority of insects, a dramatic change in body form from larva to a very different looking adult.
compound A molecule composed of two or more different elements.
compound eye A type of image-forming eye in arthropods and some annelids consisting of several hundred to several thousand light detectors called ommatidia.
computational molecular biology An area of study that uses computers to characterize the molecular components of living things.
concentration The amount of a solute dissolved in a unit volume of solution.
condensation reaction A chemical reaction in which two or more molecules are combined into one larger molecule by covalent bonding, with the loss of a small molecule.
conditional specification The acquisition by cells of specific properties through a variety of cell-to-cell signaling mechanisms in a developing vertebrate embryo.
conditioned response The learned response that is elicited by a newly conditioned stimulus.
conditioned stimulus A new stimulus that is delivered at the same time as an old stimulus, and that over time, is sufficient to elicit the same response.
condom A sheathlike membrane worn over the penis; in addition to their contraceptive function, condoms significantly reduce the risk of contracting and transmitting sexually transmitted diseases.
conduction The process in which the body surface loses or gains heat through direct contact with cooler or warmer substances.
cone pigment Any of several types of visual pigments found in the cones of the vertebrate eye.
cones 1. Photoreceptors found in the vertebrate eye; they are less sensitive to low levels of light but can detect color. 2. The reproductive structures of coniferous plants.
congenital hypothyroidism A condition characterized by poor differentiation of the central nervous system due to a failure of neurons to become myelinated in fetal development; results in profound mental defects.
congestive heart failure The condition resulting from the failure of the heart to pump blood normally; results in fluid buildup in the lungs (congestion).
conidia A type of asexual reproductive cell produced by many fungi.
conifers A phylum of gymnosperm plants, Coniferophyta.
conjugation A type of genetic transfer between bacteria that involves a direct physical interaction between two bacterial cells.
connective tissue Clusters of cells that connect, anchor, and support the structures of an animal's body; includes blood, adipose (fat-storing) tissue, bone, cartilage, loose connective tissue, and dense connective tissue.
connexon A channel that forms gap junctions consisting of six connexin proteins in one cell aligned with six connexin proteins in an adjacent cell.
conservation biology The study that uses principles and knowledge from molecular biology, genetics, and ecology to protect the biological diversity of life.
conservative mechanism In this incorrect model for DNA replication, both parental strands of DNA remain together (are conserved) following DNA replication. The two newly made daughter strands also occur together.
consortia A community of many microbial species.
constant region The portions of amino acid sequences in the heavy and light chains that are identical for all immunoglobulins of a given class.
constitutive gene An unregulated gene that has constant levels of expression in all conditions over time.
contig A series of clones that contain overlapping pieces of chromosomal DNA.
continental drift The process by which, over the course of billions of years, the major landmasses, known as the continents, have shifted their positions, changed their shapes, and, in some cases, have become separated from each other.
contraception The use of birth control procedures to prevent fertilization or implantation of a fertilized egg.
contractile vacuole A small, membrane enclosed, water-filled compartment that eliminates excess liquid from the cells of certain protists.
contrast In microscopy, relative differences in the lightness, darkness, or color between adjacent regions in a sample.
control group The sample in an experiment that is treated just like an experimental group except that it is not subjected to one particular variable.
convection The transfer of heat by the movement of air or water next to the body.
convergent evolution The process whereby two different species from different lineages show similar characteristics because they occupy similar environments.
convergent extension A cellular process during gastrulation that is crucial to development; two rows of cells merge to form a single elongated layer.
convergent trait *See* analogous structure.
coprophagy The practice of certain birds and mammals in which feces are consumed to maximize absorption of water and nutrients.
copulation The process of sperm being deposited within the reproductive tract of the female.
corepressor A small effector molecule that binds to a repressor protein to inhibit transcription.
core promoter Refers to the TATA box and the transcriptional start site of a eukaryotic structural gene.
Coriolis effect The effect of the Earth's rotation on the surface flow of wind.

cork cambium A secondary meristem in a plant that produces cork tissue.
cornea A thin, clear layer on the front of the vertebrate eye.
corolla The petals of a flower, which occur in the whorl to the inside of the calyx and the outside of the stamens.
corona The ciliated crown of members of the phylum Rotifera.
coronary artery An artery that carries oxygen and nutrients to the heart muscle.
coronary artery bypass A common treatment to restore blood flow through a coronary artery. A small piece of healthy blood vessel is removed from one part of the body and surgically grafted onto the coronary circulation in order to bypass the diseased artery.
coronary artery disease A condition that occurs when plaques form in the coronary arteries.
corpus callosum The major tract that connects the two hemispheres of the cerebrum.
corpus luteum A structure that develops from a ruptured follicle following ovulation; it is responsible for secreting hormones that stimulate the development of the uterus during pregnancy.
correlation A meaningful relationship between two variables.
cortex The area of a plant stem or root beneath the epidermis that is largely composed of parenchyma tissue.
cortical reaction An event in fertilization in which IP_3 and calcium signaling produces barriers to more than one sperm cell binding to and uniting with an egg; called the slow block to polyspermy.
cortisol A steroid hormone made by the adrenal cortex.
cotranslational sorting The sorting process in which the synthesis of certain eukaryotic proteins begins in the cytosol and then halts temporarily until the ribosome has become bound to the ER membrane.
cotransporter *See* symporter.
cotyledon An embryonic seed leaf.
countercurrent exchange 1. An arrangement of water and blood flow in which water enters a fish's mouth and flows between the lamellae of the gills in the opposite direction to blood flowing through the lamellar capillaries. 2. An arrangement of blood vessels under the skin of vertebrates that contributes to heat retention.
countercurrent multiplication system The mechanism by which the vertebrate loop of Henle reabsorbs salts and water along it length.
covalent bond A chemical bond in which two atoms share a pair of electrons.
CpG island A cluster of CpG sites. CG refers to the nucleotides of C and G in DNA, and p refers to a phosphodiester linkage.
cranial nerve A nerve in the peripheral nervous system that is directly connected to the brain.
cranium A protective bony or cartilaginous housing that encases the brain of a craniate.
crenation The process of cell shrinkage that occurs if animal cells are placed in a hypertonic medium.
cristae Projections of the highly invaginated inner membrane of a mitochondrion.
critical innovations New features that foster the diversification of phyla.
critical period A limited period of time in which many animals develop species-specific patterns of behavior.
crop A storage organ that is a dilation of the lower esophagus; found in most birds and many invertebrates, including insects and some worms.
cross-bridge A region of myosin molecules that extend from the surface of the thick filaments toward the thin filaments in skeletal muscle.
cross-bridge cycle During muscle contraction, the sequence of events that occurs between the time when a cross-bridge binds to a thin filament and when it is set to repeat the process.
cross-fertilization Fertilization that involves the union of a female gamete and a male gamete from different individuals.
crossing over The exchange of genetic material between homologous chromosomes during meiosis; allows for increased variation in the genetic information that each parent may pass to the offspring.
cross-pollination The process in which a stigma receives pollen from a different plant of the same species.
cryptic coloration The blending of an organism with the background color of its habitat; also known as camouflage.
cryptochrome A type of blue-light receptor in plants and protists.
cryptomycota A newly discovered group of eukaryotes proposed to be an early-diverging lineage of fungi.
C-terminus The location of the last amino acid in a polypeptide; also known as the carboxyl terminus.
CT scan Computerized tomography, which is an X-ray technique used to examine the structure of bones and soft tissues, including the brain.
cupula A gelatinous structure within the lateral line organ of fishes that detects changes in water movement.
cuticle A coating of wax and cutin that helps to reduce water loss from plant surfaces. Also, a nonliving covering that serves to both support and protect an animal.
cycads A phylum of gymnosperm plants, Cycadophyta.
cyclic adenosine monophosphate (cAMP) A small effector molecule that acts as a second messenger and is produced from ATP.
cyclic AMP (cAMP) *See* cyclic adenosine monophosphate.
cyclic electron flow *See* cyclic photophosphorylation.
cyclic photophosphorylation During photosynthesis, a pattern of electron flow in the thylakoid membrane that is cyclic and generates ATP alone.
cyclin A protein responsible for advancing a cell through the phases of the cell cycle by binding to a cyclin-dependent kinase.
cyclin-dependent kinase (cdk) A protein responsible for advancing a cell through the phases of the cell cycle. Its function is dependent on the binding of a cyclin.
cyst A one-to-few celled structure that often has a thick, protective wall and can remain dormant through periods of unfavorable climate or low food availability.
cytogenetics The field of genetics that involves the microscopic examination of chromosomes.
cytokines A family of proteins that function in both nonspecific and specific immune defenses by providing a chemical communication network that synchronizes the components of the immune response.
cytokinesis The division of the cytoplasm to produce two distinct daughter cells.
cytokinin A type of plant hormone that promotes cell division.
cytoplasm The region of the cell that is contained within the plasma membrane.
cytoplasmic inheritance *See* extranuclear inheritance.
cytosine (C) A pyrimidine base found in DNA and RNA.
cytoskeleton In eukaryotes, a network of three different types of protein filaments in the cytosol called microtubules, intermediate filaments, and actin filaments.
cytosol The region of a eukaryotic cell that is inside the plasma membrane and outside the organelles.
cytotoxic T cell A type of lymphocyte that travels to the location of its target, binds to the target by combining with an antigen on it, and directly kills the target via secreted chemicals.

D

dalton (Da) A measure of atomic mass. One dalton equals one-twelfth the mass of a carbon atom.
data mining The extraction of useful information and often previously unknown relationships from sequence files and large databases.
database A large number of computer data files that are collected, stored in a single location, and organized for rapid search and retrieval.
daughter strand The newly made strand in DNA replication.
day-neutral plant A plant that flowers regardless of the night length, as long as day length meets the minimal requirements for plant growth.
deafness Hearing loss, usually caused by damage to the hair cells within the cochlea.
death-inducing signaling complex (DISC) A complex consisting of death receptors, adaptor proteins, and procaspase that initiates apoptosis via the extrinsic pathway.
death receptor A type of receptor found in the plasma membrane of eukaryotic cells that can promote apoptosis when it becomes activated.
decomposer A consumer that gets its energy from the remains and waste products of other organisms.
defecation The expulsion of feces that occurs through the anus of an animal's digestive canal.
defensive mutualism A mutually beneficial interaction often involving an animal defending a plant or herbivore in return for food or shelter.
deforestation The conversion of forested areas by humans to nonforested land.
degenerate In the genetic code, the observation that more than one codon can specify the same amino acid.
dehydration A reduction in the amount of water in the body.
dehydration reaction A type of condensation reaction in which a molecule of water is lost.
delayed implantation A reproductive cycle in which a fertilized egg reaches the uterus but does not implant until later, when environmental conditions are more favorable for the newly produced young.
delayed ovulation A reproductive cycle in which the ovarian cycle in females is halted before ovulation and sperm are stored and nourished in the female's uterus over the winter. Upon arousal from hibernation in the spring, the female ovulates one or more eggs, which are fertilized by the stored sperm.
deletion A type of mutation in which a segment of genetic material is missing.
demographic transition The shift in birth and death rates accompanying human societal development.
demography The study of birth rates, death rates, age distributions, and the sizes of populations.
dendrite A treelike extension of the plasma membrane of a neuron that receives electrical signals from other neurons.
dendritic cell A type of cell derived from bone marrow stem cells that plays an important role in nonspecific immunity; these cells are scattered throughout most tissues, where they perform various macrophage functions.
denitrification The reduction of nitrate (NO_3^-) to gaseous nitrogen (N_2).
density In the context of populations, the numbers of organisms in a given unit area.
density-dependent factor A mortality factor whose influence increases with the density of the population.

density-independent factor A mortality factor whose influence is not affected by changes in population density.
deoxynucleoside triphosphates Individual nucleotides with three phosphate groups.
deoxyribonucleic acid (DNA) One of two classes of nucleic acids; the other is ribonucleic acid (RNA). A DNA molecule consists of two strands of nucleotides coiled around each other to form a double helix, held together by hydrogen bonds according to the AT/GC rule.
deoxyribose A five-carbon sugar found in DNA.
depolarization The change in the membrane potential that occurs when a cell becomes less polarized, that is, less negative relative to the surrounding fluid.
dermal tissue The covering on various parts of a plant.
descent with modification Darwin's theory that existing life-forms on our planet are the product of the modification of pre-existing life-forms.
desertification The overstocking of land with domestic animals that can greatly reduce grass coverage through overgrazing, turning the area more desert-like.
desmosome A mechanically strong cell junction between animal cells that typically occurs in spotlike rivets.
determinate cleavage In animals, a characteristic of protostome development in which the fate of each embryonic cell is determined very early.
determinate growth A type of growth in plants that is of limited duration, such as the growth of flowers.
determined The term used to describe a cell that is destined to differentiate into a particular cell type.
detritivore *See* decomposer.
detritus Unconsumed plants that die and decompose, along with the dead remains of animals and animal waste products.
deuterostome An animal whose development exhibits radial, indeterminate cleavage and in which the blastopore becomes the anus; includes echinoderms and vertebrates.
development In biology, a series of changes in the state of a cell, tissue, organ, or organism; the underlying process that gives rise to the structure and function of living organisms.
developmental genetics A field of study aimed at understanding how gene expression controls the process of development.
diaphragm A large muscle that subdivides the thoracic cavity from the abdomen in mammals; contraction of the diaphragm enlarges the thoracic cavity during inhalation.
diarrhea A common intestinal disorder arising from ingested microbes or other causes; usually runs its course within one or two days but, in serious cases, can require hospitalization.
diastole The phase of the cardiac cycle in which the ventricles fill with blood coming from the atria through the open AV valves.
diazotroph A bacterium that fixes nitrogen.
dideoxy chain-termination method The most common method of DNA sequencing; utilizes dideoxynucleotides as a reagent.
differential gene regulation The phenomenon in which the expression of genes differs under various environmental conditions and in specialized cell types.
diffusion In a solution, the process that occurs when a solute moves from a region of high concentration to a region of lower concentration.
digestion The process of breaking down nutrients in food into smaller molecules that can be absorbed across the intestinal epithelia and directly used by cells.
digestive system In animals, the long tube through which food is processed. In a vertebrate, this system consists of the alimentary canal plus several associated structures.
dihybrid An offspring that is a hybrid with respect to two traits.
dihybrid cross A cross in which the inheritance of two different traits is followed.
dikaryotic The occurrence of two genetically distinct nuclei in the cells of fungal hyphae after mating has occurred.
dikaryotic mycelium A fungal body that is made of cells that each possess two genetically distinct nuclei.
dimorphic fungi Fungi that can exist in two different morphological forms.
dinosaur A term, meaning "terrible lizard," used to describe some of the extinct fossil reptiles.
dioecious The term to describe plants that produce staminate and carpellate flowers on separate plants.
diploblastic Having two distinct germ layers—ectoderm and endoderm—but not mesoderm.
diploid Refers to cells containing two sets of chromosomes; designated as $2n$.
diploid-dominant species Species in which the diploid organism is the prevalent organism in the life cycle. Animals are an example.
direct calorimetry A method of determining basal metabolic rate that involves quantifying the amount of heat generated by the animal.
direct repair Refers to a DNA repair system in which an enzyme finds an incorrect structure in the DNA and directly converts it back to the correct structure.
directionality In a DNA or RNA strand, refers to the orientation of the sugar molecules within that strand. Can be 5′ to 3′ or 3′ to 5′.
directional selection A pattern of natural selection that favors individuals at one extreme of a phenotypic distribution.
disaccharide A carbohydrate composed of two monosaccharides.
discovery-based science The collection and analysis of data without the need for a preconceived hypothesis; also called discovery science.
discrete trait A trait with clearly defined phenotypic variants.
dispersion A pattern of spacing in which individuals in a population are clustered together or spread out to varying degrees.
dispersive mechanism In this incorrect model for DNA replication, segments of parental DNA and newly made DNA are interspersed in both strands following the replication process.
dispersive mutualism A mutually beneficial interaction often involving plants and pollinators that disperse their pollen, and plants and fruit eaters that disperse the plant's seeds.
dissociation constant An equilibrium constant between a ligand and a protein, such as a receptor or an enzyme.
distal tubule The segment of the tubule of the nephron through which fluid flows into one of the many collecting ducts in the kidney.
disulfide bridge Covalent chemical bond formed between two cysteine residues in a protein; important in the tertiary structure of proteins.
diversifying selection A pattern of natural selection that favors the survival of two or more different genotypes that produce different phenotypes.
diversity-stability hypothesis The proposal that species-rich communities are more stable than those with fewer species.
DNA (deoxyribonucleic acid) The genetic material that provides a blueprint for the organization, development, and function of living things.
DNA fingerprinting A technology that identifies particular individuals using properties of their DNA.
DNA helicase An enzyme that uses ATP to separate DNA strands during DNA replication.
DNA library A collection of recombinant vectors, each containing a particular fragment of chromosomal DNA (cDNA).
DNA ligase An enzyme that catalyzes the formation of a covalent bond between nucleotides in adjacent DNA fragments to complete the replication process.
DNA methylase An enzyme that attaches methyl groups to bases in DNA.
DNA methylation A process in which methyl groups are attached to bases in DNA.
DNA microarray A technology used to monitor the expression of thousands of genes simultaneously.
DNA polymerase An enzyme responsible for covalently linking nucleotides together during DNA replication.
DNA primase An enzyme that synthesizes a primer for DNA replication.
DNA repair systems One of several systems to reverse DNA damage before a permanent mutation can occur.
DNA replication The process by which DNA is copied.
DNase An enzyme that digests DNA.
DNA sequencing A method to determine the base sequence of DNA.
DNA supercoiling A method of compacting chromosomes through the formation of additional coils around the long, thin DNA molecule.
DNA topoisomerase An enzyme that alleviates DNA supercoiling during DNA replication.
DNA transposon A type of transposable element that moves as a DNA molecule.
domain 1. A defined region of a protein with a distinct structure and function. 2. One of the three major categories of life: Bacteria, Archaea, and Eukarya.
domestication A process that involves artificial selection of plants or animals for traits desirable to humans.
dominant A term that describes the displayed trait in a heterozygote.
dominant species A species that has a large effect in a community because of its high abundance or high biomass.
dormancy A phase of metabolic slowdown in a plant.
dorsal Refers to the upper side of an animal.
dorsoventral axis In bilateral animals, one of the three axes along which the adult body pattern is organized; the others are the anteroposterior axis and the right-left axis.
dosage compensation The phenomenon that gene dosage is compensated between males and females. In mammals, the inactivation of one X chromosome in the female reduces the number of expressed copies (doses) of X-linked genes from two to one.
double bond A bond that occurs when the atoms of a molecule share two pairs of electrons.
double fertilization In angiosperms, the process in which two different fertilization events occur, producing both a zygote and the first cell of a nutritive endosperm tissue.
double helix Two strands of DNA hydrogen-bonded with each other. In a DNA double helix, two DNA strands are twisted together to form a structure that resembles a spiral staircase.
Down syndrome A human disorder caused by the inheritance of three copies of chromosome 21.
Duchenne muscular dystrophy An inherited, X-linked disorder of humans causing muscle weakness and muscle degeneration.
duodenum The first part of the vertebrate small intestine arising from the stomach.

duplication A type of mutation in which a section of a chromosome occurs two or more times.
dynamic instability The oscillation of a single microtubule between growing and shortening phases; important in many cellular activities, including the sorting of chromosomes during cell division.

E

Ecdysis The process by which an animal molts, or breaks out of its old exoskeleton, and secretes a newer, larger one.
Ecdysozoa A clade of molting animals that encompasses primarily the arthropods and nematodes.
echolocation The phenomenon in which certain species listen for echoes of high-frequency sound waves in order to determine the distance and location of an object.
ECM *See* extracellular matrix.
ecological footprint The amount of productive land needed to support each person on Earth.
ecological species concept An approach used to distinguish species; considers a species within its native environment and states that each species occupies its own ecological niche.
ecology The study of interactions among organisms and between organisms and their environments.
ecosystem The biotic community of organisms in an area as well as the abiotic environment affecting that community.
ecosystem engineer A keystone species that creates, modifies, and maintains habitats.
ecosystems ecology The study of the flow of energy and cycling of nutrients among organisms within a community and between organisms and the environment.
ecotypes Genetically distinct populations adapted to their local environments.
ectoderm In animals, the outermost layer of cells formed during gastrulation that covers the surface of the embryo and differentiates into the epidermis and nervous system.
ectomycorrhizae Beneficial interactions between temperate forest trees and soil fungi that coat their roots.
ectoparasite A parasite that lives on the outside of the host's body.
ectotherm An animal that largely depends on the environment to warm its body.
ectothermic Referring to an animal that is an ectotherm.
edge effect A special physical condition that exists at the boundary or edge of an area.
effective population size The number of individuals that contribute genes to future populations, often smaller than the actual population size.
effector A molecule that directly influences cellular responses.
effector cell A cloned lymphocyte that carries out the attack response during specific immunity.
efferent arteriole A blood vessel that carries blood away from a glomerulus of the vertebrate kidney.
egestion In animals, the process of undigested material passing out of the body.
egg The mature female gamete; also called an ovum.
ejaculation The movement of semen through the urethra by contraction of muscles at the base of the penis.
ejaculatory duct The structure in the male reproductive system through which sperm leave the vas deferens and enter the urethra.
elastin A protein that makes up elastic fibers in the extracellular matrix of animals.
electrical synapse A synapse that directly passes electric current from the presynaptic to the postsynaptic cell via gap junctions.
electrocardiogram (ECG) A record of the electrical impulses generated by the cells of the heart during the cardiac cycle.
electrochemical gradient The combined effect of both an electrical and chemical gradient across a membrane; determines the direction that an ion will move.
electrogenic pump A pump that generates an electrical gradient across a membrane.
electromagnetic receptor A sensory receptor in animals that detects radiation within a wide range of the electromagnetic spectrum, including visible, ultraviolet, and infrared light, as well as electrical and magnetic fields in some animals.
electromagnetic spectrum All possible wavelengths of electromagnetic radiation, from relatively short wavelengths (gamma rays) to much longer wavelengths (radio waves).
electron A negatively charged particle found in orbitals around an atomic nucleus.
electron microscope A microscope that uses an electron beam for illumination.
electron shell The region around an atom's nucleus where electrons reside; larger atoms have more electron shells than smaller atoms.
electron transport chain (ETC) A group of protein complexes and small organic molecules within the inner membranes of mitochondria and chloroplasts and the plasma membrane of prokaryotes. The components accept and donate electrons to each other in a linear manner and produce a H^+ electrochemical gradient.
electronegativity A measure of an atom's ability to attract electrons to its outer shell from another atom.
element A substance composed of specific types of atoms that cannot be further broken down by ordinary chemical or physical means.
elicitor A compound produced by bacterial and fungal pathogens that promotes virulence.
elongation factor A protein that is needed for the growth of a polypeptide during translation.
elongation stage The second step in transcription or translation where RNA strands or polypeptides are made, respectively.
embryo The early stages of development in a multicellular organism during which the organization of the organism is largely formed.
embryogenesis The process by which embryos develop from single-celled zygotes by mitotic divisions.
embryonic development The process by which a fertilized egg is transformed into an organism with distinct physiological systems and body parts.
embryonic germ cell (EG cell) A cell in the early mammalian embryo that later gives rise to sperm or egg cells. These cells are pluripotent.
embryonic stem cell (ES cell) A cell in the early mammalian embryo that can differentiate into almost every cell type of the body. These cells are pluripotent.
embryophyte A synonym for the land plants.
emerging virus A newly arising virus.
emphysema A progressive disease characterized by a loss of elastic recoil ability of the lungs, usually resulting from chronic tobacco smoking.
empirical thought Thought that relies on observation to form an idea or hypothesis, rather than trying to understand life from a nonphysical or spiritual point of view.
emulsification A process during digestion that disrupts large lipid droplets into many tiny droplets, thereby increasing their total surface area and exposure to lipase action.
enantiomer One of a pair of stereoisomers that exist as mirror images.
endangered species Those species that are in danger of extinction throughout all or a significant portion of their range.
endemic The term to describe organisms that are naturally found only in a particular location.
endergonic Refers to chemical reactions that require an addition of free energy and do not proceed spontaneously.
endocrine disruptor A chemical found in polluted water and soil that resembles a natural hormone; a common example are chemicals that resemble estrogen and can bind to estrogen receptors in animals.
endocrine glands Structures that contain epithelial cells that secrete hormones into the bloodstream, where they circulate throughout the body.
endocrine system All the endocrine glands and other organs containing hormone-secreting cells.
endocytosis A process in which the plasma membrane invaginates, or folds inward, to form a vesicle that brings substances into the cell.
endoderm In animals, the innermost layer of cells formed during gastrulation; lines the gut and gives rise to many internal organs.
endodermis In vascular plants, a thin cylinder of root tissue that forms a barrier between the root cortex and the central core of vascular tissue.
endomembrane system A network of membranes that includes the nuclear envelope, the endoplasmic reticulum, Golgi apparatus, lysosomes, vacuoles, and plasma membrane.
endomycorrhizae Partnerships between plants and fungi in which the fungal hyphae grow into the spaces between root cell walls and plasma membranes.
endoparasite A parasite that lives inside the host's body.
endophyte A mutualistic fungus that lives compatibly within the tissues of various types of plants.
endoplasmic reticulum (ER) A convoluted network of membranes in a cell's cytoplasm that forms flattened, fluid-filled tubules or cisternae.
endoskeleton An internal hard skeleton covered by soft tissue; present in echinoderms and vertebrates.
endosperm A nutritive tissue that increases the efficiency with which food is stored and used in the seeds of flowering plants.
endospore A cell with a tough coat that is produced in certain bacteria and then released when the enclosing bacterial cell dies and breaks down.
endosporic gametophyte A plant gametophyte that grows within the confines of microspore or megaspore walls.
endosymbiont A smaller species that lives within a larger species in a symbiotic relationship.
endosymbiosis A symbiotic relationship in which the smaller species—the symbiont—lives inside the larger species.
endosymbiosis theory A theory that mitochondria and chloroplasts originated from bacteria that took up residence within a primordial eukaryotic cell.
endosymbiotic Describes a relationship in which one organism lives inside the other.
endothelium The single-celled inner layer of a blood vessel; forms a smooth lining in contact with the blood.
endotherm An animal that generates most of its body heat by metabolic processes.
endothermic Referring to an animal that is an endotherm.
energy The ability to promote change or to do work.
energy flow The movement of energy through an ecosystem.
energy intermediate A molecule such as ATP or NADH that stores energy and is used to drive endergonic reactions in cells.

energy shell In an atom, an energy level of electrons occupied by one or more orbitals; each energy level is a characteristic distance from the nucleus, with outer shells having more energy than inner shells.
enhancement effect The phenomenon in which maximal activation of the pigments in photosystems I and II is achieved when organisms are exposed to two wavelengths of light.
enhancer A response element in eukaryotes that increases the rate of transcription.
enthalpy (*H*) The total energy of a system.
entomology The study of insects.
entropy The degree of disorder of a system.
environmental science The application of ecology to real-world problems.
enzyme A protein that acts as a catalyst to speed up a chemical reaction in a cell.
enzyme-linked receptor A receptor found in all living species that typically has two important domains: an extracellular domain, which binds a signaling molecule, and an intracellular domain, which has a catalytic function.
enzyme-substrate complex The binding between an enzyme and its substrate.
eosinophil A type of phagocyte found in large numbers in mucosal surfaces lining the gastrointestinal, respiratory, and urinary tracts, where they fight off parasitic infections.
epicotyl The portion of an embryonic plant stem with two tiny leaves in a first bud; located above the point of attachment of the cotyledons.
epidermis A layer of dermal tissue that helps protect a plant from damage.
epididymis A coiled, tubular structure located on the surface of the testis in which sperm complete their differentiation.
epigenetic inheritance An inheritance pattern in which modification of a gene or chromosome during egg formation, sperm formation, or early stages of embryonic growth alters gene expression in a way that is fixed during an individual's lifetime.
epinephrine A hormone secreted by the adrenal glands; also known as adrenaline.
episome A plasmid that can integrate into a bacterial chromosome.
epistasis A gene interaction in which the alleles of one gene mask the expression of the alleles of another gene.
epithalamus A region of the vertebrate forebrain that includes the pineal gland.
epithelial tissue In animals, a sheet of densely packed cells that covers the body, covers individual organs, and lines the walls of various cavities inside the body.
epitope Antigenic determinant; the peptide fragments of an antigen that are complexed to MHC proteins and presented to a helper T cell.
equilibrium 1. In a chemical reaction, occurs when the rate of the forward reaction is balanced by the rate of the reverse reaction. 2. In a population, the situation in which the population size stays the same.
equilibrium model of island biogeography A model to explain the process of succession on new islands; states that the number of species on an island tends toward an equilibrium number that is determined by the balance between immigration rates and extinction rates.
equilibrium potential In membrane physiology, the membrane potential at which the flow of an ion is at equilibrium, with no net movement in either direction.
ER lumen A single compartment enclosed by the ER membrane.
ER signal sequence A sorting signal in a polypeptide usually located near the amino terminus that is recognized by SRP (signal recognition particle) and directs the polypeptide to the ER membrane.
erythrocyte A cell that serves the critical function of transporting oxygen throughout an animal's body; also known as a red blood cell.
erythropoietin (EPO) A hormone made by the liver and kidneys in response to any situation where additional red blood cells are required.
E site *See* exit site.
esophagus In animals, the tubular structure that forms a pathway from the pharynx to the stomach.
essential amino acid An amino acid that is required in the diet of particular organisms.
essential fatty acid A polyunsaturated fatty acid, such as linoleic acid, that cannot be synthesized by animal cells and must therefore be consumed in the diet.
essential element In plants, a chemical element that is required for metabolism, sometimes by functioning as an enzyme cofactor.
essential nutrient In animals, a compound that cannot be synthesized from any ingested or stored precursor molecule and so must be obtained in the diet in its complete form. In plants, those substances needed to complete reproduction while avoiding the symptoms of nutrient deficiency.
estradiol The major estrogen in many vertebrates, including humans.
estrogens Steroid hormones produced by the ovaries that affect most aspects of female reproduction.
ethology Scientific studies of animal behavior.
ethylene A plant hormone that is particularly important in coordinating plant developmental and stress responses.
euchromatin The less condensed regions of a chromosome; areas that are capable of gene transcription.
eudicots One of the two largest lineages of flowering plants in which the embryo possesses two seed leaves.
Eukarya One of the three domains of life; the other two are Bacteria and Archaea.
eukaryote One of the two categories into which all forms of life can be placed. The distinguishing feature of eukaryotes is cell compartmentalization, including a cell nucleus; includes protists, fungi, plants, and animals.
eukaryotic Refers to organisms having cells with internal compartments that serve various functions; includes all members of the domain Eukarya.
Eumetazoa A subgroup of animals having more than one type of tissue and, for the most part, different types of organs.
euphyll A leaf with branched veins.
euphyllophytes The clade that includes pteridophytes and seed plants.
euploid An organism that has a chromosome number that is a multiple of a chromosome set (1*n*, 2*n*, 3*n*, etc.).
eusociality An extreme form of altruism in social insects in which the vast majority of females, known as workers, do not reproduce. Instead, they help one reproductive female (the queen) raise offspring.
Eustachian tube In mammals, a connection from the middle ear to the pharynx; maintains the pressure in the middle ear at atmospheric pressure.
eustele In plants, a ring of vascular tissue arranged around a central pith of nonvascular tissue; typical of progymnosperms, gymnosperms, and angiosperms.
eutherian A placental mammal and member of the subclass Eutheria.
eutrophic Waters that contain relatively high levels of nutrients such as phosphate or nitrogen and typically exhibit high levels of primary productivity and low levels of biodiversity.
eutrophication The process by which elevated nutrient levels in a body of water lead to an overgrowth of algae or aquatic plants and a subsequent depletion of water oxygen levels when these photosynthesizers decay.
evaporation The transformation of water from the liquid to the gaseous state at normal temperatures. Animals use evaporation as a means of losing excess body heat.
evapotranspiration rate The rate at which water moves into the atmosphere through the processes of evaporation from the soil and transpiration of plants.
evolution The phenomenon that populations of organisms change from one generation to the next. As a result, some organisms become more successful at survival and reproduction.
evolutionarily conserved The term used to describe homologous DNA sequences that are very similar or identical between different species.
evolutionary developmental biology (evo-devo) A field of biology that compares the development of different organisms in an attempt to understand ancestral relationships between organisms and the developmental mechanisms that bring about evolutionary change.
evolutionary lineage concept An approach used to distinguish species; states that a species is derived from a single distinct lineage and has its own evolutionary tendencies and historical fate.
excitable cell The term used to describe neurons and muscle cells because they have the capacity to generate electrical signals.
excitation-contraction coupling The sequence of events by which an action potential in the plasma membrane of a muscle fiber leads to cross-bridge activity.
excitatory postsynaptic potential (EPSP) The response from an excitatory neurotransmitter that depolarizes the postsynaptic membrane; the depolarization brings the membrane potential closer to the threshold potential that would trigger an action potential.
excretion In animals, the process of expelling waste or harmful materials from the body.
exercise Any physical activity that increases an animal's metabolic rate.
exergonic Refers to chemical reactions that release free energy and occur spontaneously.
exit site (E site) One of three sites for tRNA binding in the ribosome during translation; the other two are the peptidyl site (P site) and the aminoacyl site (A site). The uncharged tRNA exits from the E site.
exocrine gland A gland in which epithelial cells secrete chemicals into a duct, which carries those molecules directly to another structure or to the outside surface of the body.
exocytosis A process in which material inside a cell is packaged into vesicles and excreted into the extracellular medium.
exon A portion of RNA that is found in the mature mRNA molecule after splicing is finished.
exon shuffling A form of mutation in which exons and their flanking introns are inserted into genes and thereby create proteins with additional functional domains.
exonuclease An enzyme that cleaves off nucleotides, one at a time, from the end of a DNA or RNA molecule.
exoskeleton An external skeleton made of chitin and protein that surrounds and protects most of the body surface of animals such as insects.
exosome A multiprotein complex that degrades mRNA.
expansin A protein that occurs in the plant cell wall and fosters cell enlargement.
experimental group The sample in an experiment that is subjected to some type of variation that does not occur for the control group.

exploitation competition Competition in which organisms compete indirectly through the consumption of a limited resource.
exponential growth Rapid population growth that occurs when the per capita growth rate remains above zero.
extensor A muscle that straightens a limb at a joint.
external fertilization Fertilization that occurs in aquatic environments, when eggs and sperm are released into the water in close enough proximity for fertilization to occur.
external intercostal muscles Muscles of the rib cage that contract during inhalation, thereby expanding the chest.
extinction The end of the existence of a species or a group of species.
extinction vortex A downward spiral toward extinction from which a species cannot naturally recover.
extracellular fluid The fluid in an organism's body that is outside of the cells.
extracellular matrix (ECM) A network of material that is secreted from animal cells and forms a complex meshwork outside of cells. The ECM provides strength, support, and organization.
extranuclear inheritance In eukaryotes, the transmission of genes that are located outside the cell nucleus.
extremophile An organism that occurs primarily in extreme habitats.
eye The visual organ in animals that detects light and sends signals to the brain.
eyecup An eye in planaria that detects light and its direction but which does not form an image.

F

facilitated diffusion A method of passive transport of solutes down a concentration gradient that involves the aid of a transport protein.
facilitation A mechanism for succession in which a species facilitates or makes the environment more suitable for subsequent species.
facultative anaerobe A microorganism that can use oxygen in aerobic respiration, obtain energy via anaerobic fermentation, or use inorganic chemical reactions to obtain energy.
facultative mutualism An interaction between mutualistic species that is beneficial but not essential to the survival and reproduction of either species.
family In taxonomy, a subdivision of an order.
fast block to polyspermy A depolarization of the egg that blocks other sperm from binding to the egg membrane proteins.
fast fiber A skeletal muscle fiber containing myosin with a high rate of ATP hydrolysis.
fast-glycolytic fiber A skeletal muscle fiber that has high myosin ATPase activity but cannot make as much ATP as oxidative fibers because its source of ATP is glycolysis; best suited for rapid, intense actions.
fast-oxidative fiber A skeletal muscle fiber that has high myosin ATPase activity and can make large amounts of ATP; used for long-term activities.
fate The ultimate morphological features that a cell or a group of cells will adopt.
fate mapping A technique in which a small population of cells within an embryo is specifically labeled with a harmless dye, and the fate of these labeled cells is followed to a later stage of embryonic development.
feedback inhibition A form of regulation in which the product of a metabolic pathway inhibits an enzyme that acts early in the pathway, thus preventing the overaccumulation of the product.
feedforward regulation The process by which an animal's body begins preparing for a change in some variable before it even occurs.
female-enforced monogamy hypothesis The hypothesis that a male is monogamous due to various actions employed by his female mate.
female gametophyte A haploid multicellular plant generation that produces one or more eggs but does not produce sperm cells.
fermentation The breakdown of organic molecules to produce energy without any net oxidation of an organic molecule.
fertilization The union of two gametes, such as an egg cell with a sperm cell, to form a zygote.
fertilizer A soil addition that enhances plant growth by providing essential elements.
fetal alcohol syndrome The physical and mental defects that may arise in a child born to a woman who consumes alcohol during pregnancy.
fetus The maturing embryo after the eighth week of gestation in humans.
fever An increase in an animal's temperature, typically due to infection.
F factor A type of bacterial plasmid called a fertility factor that plays a role in bacterial conjugation.
F_1 generation The first generation in a genetic cross.
F_2 generation The second generation in a genetic cross.
fiber A type of tough-walled plant cell that provides support.
fibrin A protein that forms a meshwork of threadlike fibers that wrap around and between platelets and blood cells, enlarging and thickening a blood clot.
fibrous root system The root system of monocots, which consists of multiple adventitious roots that grow from the stem base.
fight-or-flight The response of vertebrates to real or perceived danger; associated with increased activity of the sympathetic branch of the autonomic nervous system.
filament 1. The elongate portion of a flower's stamen; contains vascular tissue that delivers nutrients from parental sporophytes to anthers. 2. In fishes, a part of the gills.
filtrate In the process of filtration in an excretory system, the material that passes through the filter and enters the excretory organ for either further processing or excretion.
filtration The passive removal of water and small solutes from the blood during the production of urine.
finite rate of increase In ecology, the ratio of a population size from one year to the next.
first law of thermodynamics States that energy cannot be created or destroyed; also called the law of conservation of energy.
fitness The relative likelihood that a genotype will contribute to the gene pool of the next generation as compared with other genotypes.
5′ cap The 7-methylguanosine cap structure at the 5′ end of most mature mRNAs in eukaryotes.
fixed action pattern (FAP) An animal behavior that, once initiated, will continue until completed.
fixed nitrogen Atmospheric nitrogen that has been combined with other elements into a form of nitrogen that can be used by plants. An example is ammonia, NH_3.
flaccid A plant cell in which the concentration of solutes is the same as that in the external fluid environment. A flaccid cell has a water content higher than a plasmolyzed cell, but lower than a turgid cell.
flagella (singular, **flagellum**) Relatively long cell appendages that facilitate cellular movement or the movement of extracellular fluids.
flagellate A protist that uses one or more flagella to move in water or cause water motions useful in feeding.
flagship species A single large or instantly recognizable species.
flame cell A cell that exists primarily to maintain osmotic balance between an organism's body and surrounding fluids; present in flatworms.
flavonoid A type of phenolic secondary metabolite that provides plants with protection from ultraviolet damage or imparts color to flowers.
flexor A muscle that bends a limb at a joint.
florigen The hypothesized flowering hormone, now identified as the FT (flowering time) protein that moves from leaves, where it is produced, into the shoot apex.
flower A reproductive shoot; a short stem that produces reproductive organs instead of leaves.
flowering plants The angiosperms, which produce ovules within the protective ovaries of flowers. The ovules develop into seeds, and the ovaries develop into fruits, which function in seed dispersal.
flow-through system The method of ventilation in fishes in which water moves unidirectionally such that the gills are constantly in contact with fresh, oxygenated water. Buccal pumping and ram ventilation are examples.
fluid-feeder An animal that licks or sucks fluid from plants or animals and does not need teeth except to puncture an animal's skin.
fluidity A property of biomembranes in which individual molecules remain in close association yet have the ability to move rotationally or laterally within the plane of the membrane. Membranes are semifluid.
fluid-mosaic model The accepted model of the plasma membrane; its basic framework is the semifluid phospholipid bilayer with a mosaic of proteins. Carbohydrates may be attached to the lipids or proteins.
fMRI *See* functional magnetic resonance imaging.
focal adhesion A mechanically strong cell junction that connects an animal cell to the extracellular matrix (ECM).
follicle A structure within an animal ovary where each ovum undergoes growth and development before it is released.
follicle-stimulating hormone (FSH) A gonadotropin that stimulates follicle development.
food chain A linear depiction of energy flow between organisms, with each organism feeding on and deriving energy from the preceding organism.
food-induced thermogenesis A rise in metabolic rate for a few hours after eating that produces heat.
food vacuole *See* phagocytic vacuole.
food web A complex model of interconnected food chains in which there are multiple links between species.
foot In mollusks, a muscular structure usually used for movement.
forebrain One of three major divisions of the vertebrate brain; the other two divisions are the midbrain and hindbrain.
fossil Recognizable preserved remains of past life on Earth.
fossil fuel A fuel formed in the Earth from protist, plant, or animal remains, such as coal, petroleum, and natural gas.
founder effect Genetic drift that occurs when a small group of individuals separates from a larger population and establishes a colony in a new location.
fovea A small area on the retina directly behind the lens, where an image is most sharply focused.
frameshift mutation A mutation that involves the addition or deletion of a number of nucleotides that are not in multiples of three.
free energy (*G*) In living organisms, the amount of available energy that can be used to do work.

free radical A molecule containing an atom with a single, unpaired electron in its outer shell. A free radical is unstable and interacts with other molecules by removing electrons from their atoms.
frequency In regard to sound, the number of complete wavelengths that occur in 1 second, measured in hertz (Hz).
frontal lobe One of four lobes of the cerebral cortex of the human brain; important in a variety of functions, including judgment and conscious thought.
fruit A structure that develops from flower organs, encloses seeds, and fosters seed dispersal in the environment.
fruiting bodies The visible fungal reproductive structures that are composed of densely packed hyphae that typically grow out of the substrate.
functional genomics Genomic methods aimed at studying the expression of a genome.
functional group A group of atoms with chemical features that are functionally important. Each functional group exhibits the same properties in all molecules in which it occurs.
functional magnetic resonance imaging (fMRI) A technique used to determine changes in brain activity while a person is performing specific tasks.
fundamental niche The optimal range in which a particular species best functions.
fungi A eukaryotic kingdom of the domain Eukarya.
fungus-like protists Heterotrophic protists that often resemble true fungi in having threadlike, filamentous bodies and absorbing nutrients from their environment.

G

G_0 A phase in which cells exit the cell cycle and postpone making the decision to divide.
G_1 The first gap phase of the cell cycle.
G_2 The second gap phase of the cell cycle.
gallbladder In many vertebrates, a small sac underneath the liver that is a storage site for bile; allows the release of large amounts of bile to be precisely timed to the consumption of fats.
gametangia Specialized structures produced by many land plants in which developing gametes are protected by a jacket of tissue.
gamete A haploid cell that is involved with sexual reproduction, such as a sperm or egg cell.
gametic life cycle A type of life cycle where all cells except the gametes are diploid, and gametes are produced by meiosis.
gametogenesis The formation of gametes.
gametophyte In plants and many multicellular protists, the haploid stage that produces gametes by mitosis.
ganglion A group of neuronal cell bodies in the peripheral nervous system that is involved in a similar function.
ganglion cells Cells in the vertebrate eye that send their axons into the optic nerve.
gap gene A type of segmentation gene; a mutation in this type of gene may cause several adjacent segments to be missing in the larva.
gap junction A type of junction between animal cells that provides a passageway for intercellular transport.
gas exchange The process of moving oxygen and carbon dioxide in opposite directions between the environment and blood and between blood and cells.
gas vesicle A cytoplasmic structure used to adjust buoyancy in cyanobacteria and certain other bacteria that live in aquatic habitats.
gastrin A hormone secreted by cells of the vertebrate stomach that stimulates acid production by stomach cells.
gastrovascular cavity In certain invertebrates such as cnidarians, a body cavity with a single opening to the outside; it functions as both a digestive system and circulatory system.
gastrula A stage of an animal embryo that is the result of gastrulation and has three cellular layers: the ectoderm, endoderm, and mesoderm.
gastrulation In animals, a process in which an area in the blastula invaginates and folds inward, creating different embryonic cell layers called germ layers.
gated A property of many channels that allows them to open and close to control the diffusion of solutes through a membrane.
gel electrophoresis A technique used to separate macromolecules by using an electric field that causes them to pass through a gel matrix.
gene A unit of heredity that contributes to the characteristics or traits of an organism. At the molecular level, a gene is composed of organized sequences of DNA.
gene addition The insertion of a cloned gene into the genome of an organism.
gene amplification An increase in the copy number of a gene.
gene cloning The process of making multiple copies of a gene of interest.
gene expression Gene function both at the level of traits and at the molecular level.
gene family A group of homologous genes within a single species.
gene flow Occurs when individuals migrate between different populations and results in changes in the genetic composition of the resulting populations.
gene interaction A situation in which a single trait is controlled by two or more genes.
gene knockout An organism in which both copies of a functional gene have been replaced with nonfunctional copies. Experimentally, this can occur via gene replacement.
gene mutation A relatively small change in DNA structure that alters a particular gene.
gene pool All of the genes in a population.
genera (singular, **genus**) In taxonomy, a subdivision of a family.
general lineage concept A widely accepted approach used to distinguish species; states that each species is a population of an independently evolving lineage.
general transcription factors (GTFs) Five different proteins that play a role in initiating transcription at the core promoter of structural genes in eukaryotes.
generative cell In a seed plant, one of the cells resulting from the division of a microspore; a generative cell divides to produce two sperm cells.
gene regulation The ability of cells to control their level of gene expression.
gene replacement The phenomenon in which a cloned gene recombines with the normal gene on a chromosome and replaces it.
gene therapy The introduction of cloned genes into living cells in an attempt to cure disease.
genetic code A code that specifies the relationship between the sequence of nucleotides in the codons found in mRNA and the sequence of amino acids in a polypeptide.
genetic drift The random change in a population's allele frequencies from one generation to the next that is attributable to chance. It occurs more quickly in small populations.
genetic engineering The direct manipulation of genes for practical purposes.
genetic map A chart that shows the linear arrangement of genes along a chromosome.
genetic mapping The use of genetic crosses to determine the linear order of genes that are linked to each other along the same chromosome.
genetically modified organisms (GMOs) *See* transgenic.
gene transfer The process by which genetic material is transferred from one bacterial cell to another.
genome The complete genetic composition of a cell or a species.
genomic imprinting A phenomenon in which a segment of DNA is imprinted, or marked, in a way that affects gene expression throughout the life of the individual who inherits that DNA.
genomic library A type of DNA library in which the inserts are derived from chromosomal DNA.
genomics Techniques that are used in the molecular analysis of the entire genome of a species.
genotype The genetic composition of an individual.
genotype frequency In a population, the number of individuals with a given genotype divided by the total number of individuals.
geological timescale A time line of the Earth's history from its origin about 4.55 bya to the present.
germination In plants, the process in which an embryo absorbs water, becomes metabolically active, and grows out of the seed coat, producing a seedling.
germ layer An embryonic cell layer such as ectoderm, mesoderm, or endoderm.
germ line Cells that give rise to gametes such as egg and sperm cells.
germ plasm Cytoplasmic determinants that help define and specify the primordial germ cells in the gastrula stage of animal development.
gestation *See* pregnancy.
giant axon A very large axon in certain species such as squids that facilitates high-speed neuronal conduction and rapid responses to stimuli.
gibberellic acid A type of gibberellin.
gibberellin A plant hormone that stimulates both cell division and cell elongation.
gills Specialized filamentous organs in aquatic animals that are used to obtain oxygen and eliminate carbon dioxide.
ginkgos A phylum of gymnosperms; Ginkgophyta.
gizzard The muscular portion of the stomach of birds and some reptiles that is capable of grinding food into smaller fragments.
glaucoma A condition in which drainage of aqueous humor in the eye becomes blocked and the pressure inside the eye increases. If untreated, this pressure damages cells in the retina and leads to irreversible loss of vision.
glia Cells that surround the neurons; a major class of cells in nervous systems that perform various functions.
global warming A gradual elevation of the Earth's surface temperature caused by an increasing greenhouse effect.
glomerular filtration rate (GFR) The rate at which a filtrate of plasma is formed in all the glomeruli of the vertebrate kidneys.
glomerulus A cluster of interconnected, fenestrated capillaries in the renal corpuscle of the kidney; the site of filtration in the kidney.
glucagon A hormone found in animals that stimulates the processes of glycogenolysis, gluconeogenesis, and the synthesis of ketones in the liver.
glucocorticoid A steroid hormone that regulates glucose balance and helps prepare the body for stress situations.
gluconeogenesis A mechanism for maintaining blood glucose level; enzymes in the liver convert noncarbohydrate precursors into glucose, which is then secreted into the blood.

glucose sparing A metabolic adjustment that reserves the glucose produced by the liver for use by the nervous system.
glycocalyx 1. An outer viscous covering surrounding a bacterium that traps water and helps protect bacteria from drying out. 2. A carbohydrate-rich zone on the surface of animal cells; also called a cell coat.
glycogen A polysaccharide found in animal cells (especially liver and skeletal muscle) and sometimes called animal starch; also, the major carbohydrate storage of fungi.
glycogenolysis A mechanism for maintaining blood glucose level; stored glycogen can be broken down into molecules of glucose which are then secreted into the blood.
glycolipid A lipid that has carbohydrate attached to it.
glycolysis A metabolic pathway that breaks down glucose to pyruvate.
glycolytic fiber A skeletal muscle fiber that has few mitochondria but possesses both a high concentration of glycolytic enzymes and large stores of glycogen.
glycoprotein A protein that has carbohydrate attached to it.
glycosaminoglycan The most abundant type of polysaccharide in the extracellular matrix (ECM) of animals, consisting of repeating disaccharide units that give a gel-like character to the ECM of animals.
glycosidic bond A bond formed between two sugar molecules.
glycosylation The attachment of carbohydrate to a protein or lipid, producing a glycoprotein or glycolipid.
glyoxysome A specialized organelle within plant seeds that contains enzymes needed to convert fats to sugars.
gnathostomes All vertebrate species that possess jaws.
gnetophytes A phylum of gymnosperms; Gnetophyta.
Golgi apparatus A stack of flattened, membrane-bound compartments that performs three overlapping functions: secretion, processing, and protein sorting.
gonadotropins Hormones secreted by the anterior pituitary gland that are the same in both sexes; gonadotropins influence the ability of the testes and ovaries to produce the sex steroids.
gonads The testes in males and the ovaries in females, where the gametes are formed.
G protein An intracellular protein that binds guanosine triphosphate (GTP) and guanosine diphosphate (GDP) and participates in intracellular signaling pathways.
G-protein-coupled receptors (GPCRs) A common type of receptor found in the cells of eukaryotic species that interacts with G proteins to initiate a cellular response.
graded potential A depolarization or hyperpolarization in a neuron that varies with the strength of a stimulus.
gradualism A concept suggesting that species evolve continuously over long spans of time.
grain The characteristic single-seeded fruit of cereal grasses such as rice, corn, barley, and wheat.
Gram stain A staining process that can help to identify bacteria and predict their responses to antibiotics.
granum A structure composed of stacked membrane-bound thylakoids within a chloroplast.
gravitropism Plant growth in response to the force of gravity.
gray matter Brain tissue that consists of neuronal cell bodies, dendrites, and some unmyelinated axons.
greenhouse effect The process in which short-wave solar radiation passes through the atmosphere to warm the Earth but is radiated back to space as long-wave infrared radiation. Much of this radiation is reflected by atmospheric gases back to Earth's surface, causing its temperature to rise.
groove In the DNA double helix, an indentation where the atoms of the bases make contact with the surrounding water.
gross primary production (GPP) The measure of biomass production by photosynthetic organisms; equivalent to the carbon fixed during photosynthesis.
ground meristem In plants, a type of primary plant tissue meristem that gives rise to ground tissue.
ground tissue Most of the body of a plant, which has a variety of functions, including photosynthesis, storage of carbohydrates, and support. Ground tissue can be subdivided into three types: parenchyma, collenchyma, and sclerenchyma.
group selection A premise that attempts to explain altruism. States that natural selection produces outcomes beneficial for the whole group or species rather than for individuals.
growth An increase in weight or size.
growth factors Proteins in animals that stimulate certain cells to grow and divide.
growth hormone (GH) A hormone produced in vertebrates by the anterior pituitary gland; GH acts on the liver to produce insulin-like growth factor-1 (IGF-1).
guanine (G) A purine base found in DNA and RNA.
guard cell A specialized plant cell that allows epidermal pores (stomata) to close when conditions are too dry and to open under moist conditions, allowing the entry of CO_2 needed for photosynthesis.
gustation The sense of taste.
gut The gastrointestinal (GI) tract of an animal.
guttation Droplets of water at the edges of leaves that are the result of root pressure.
gymnosperm A plant that produces seeds that are exposed rather than seeds enclosed in fruits.
gynoecium The aggregate of carpels that forms the innermost whorl of a flower.

H

habituation The form of nonassociative learning in which an organism learns to ignore a repeated stimulus.
hair cell A mechanoreceptor in animals that is a specialized epithelial cell with deformable stereocilia.
half-life 1. In the case of organic molecules in a cell, refers to the time it takes for 50% of the molecules to be broken down and recycled. 2. In the case of radioisotopes, the time it takes for 50% of the molecules to decay and emit radiation.
halophile A bacterium or archaeon that can live in an extremely salty environment.
halophyte A plant that can tolerate higher than normal salt concentrations and can occupy coastal salt marshes or saline deserts.
Hamilton's rule The proposal that an altruistic gene will be favored by natural selection when $rB > C$, where r is the coefficient of relatedness of the donor (the altruist) to the recipient, B is the benefit received by the recipient, and C is the cost incurred by the donor.
haplodiploid system A genetic system in which females develop from fertilized eggs and are diploid but males develop from unfertilized eggs and are haploid.
haploid Containing one set of chromosomes; designated as $1n$.
haploid-dominant species Species in which the haploid organism is the prevalent organism in the life cycle. Examples include fungi and some protists.
haplorrhini Larger-brained diurnal species of primates; includes monkeys, gibbons, orangutans, gorillas, chimpanzees, and humans.
Hardy-Weinberg equation An equation ($p^2 + 2pq + q^2 = 1$) that relates allele and genotype frequencies; the equation predicts an equilibrium if no new mutations are formed, no natural selection occurs, the population size is very large, the population does not migrate, and mating is random.
heart A muscular structure that pumps blood through blood vessels.
heart attack *See* myocardial infarction (MI).
heartburn More properly called gastroesophageal reflux; the movement of acidic stomach contents upward into the esophagus, typically causing pain.
heat of fusion The amount of heat energy that must be withdrawn or released from a substance to cause it to change from the liquid to the solid state.
heat of vaporization The heat required to vaporize 1 mole of any substance at its boiling point under standard pressure.
heavy chain A part of an immunoglobulin molecule.
H^+ electrochemical gradient A transmembrane gradient for H^+ composed of both a membrane potential and a concentration difference for H^+ across a membrane.
helper T cell A type of lymphocyte that assists in the activation and function of B cells and cytotoxic T cells.
hematocrit The volume of blood that is composed of red blood cells, usually between 40 and 65% in vertebrates.
hemidesmosome A mechanically strong cell junction that connects an animal cell to the extracellular matrix (ECM).
hemiparasite A parasitic organism that photosynthesizes, but lacks a root system to draw water and thus depends on its host for that function.
hemispheres The two halves of the cerebrum.
hemizygous The term used to describe the single copy of an X-linked gene in a male.
hemocyanin A copper-containing pigment that binds oxygen and gives blood or hemolymph a bluish tint.
hemodialysis A medical procedure used to artificially perform the kidneys' function.
hemoglobin An iron-containing protein that binds oxygen and is found within the cytosol of red blood cells.
hemolymph Blood and interstitial fluid combined in one fluid compartment; present in many invertebrates.
hemophilia An inherited disorder characterized by the deficiency of a specific blood clotting factor.
hemorrhage A loss of blood from a ruptured blood vessel.
herbaceous plant A plant that produces little or no wood and is composed mostly of primary vascular tissues.
herbivore An animal that eats only plants.
herbivory Refers to herbivores feeding on plants.
hermaphrodite In animals, an individual that can produce both sperm and eggs.
hermaphroditism A form of sexual reproduction in which individuals have both male and female reproductive systems.
heterochromatin The highly compacted regions of chromosomes that are usually transcriptionally inactive because of their tight conformation.
heterochrony Evolutionary changes in the rate or timing of developmental events.
heterocyst A specialized cell of some cyanobacteria in which nitrogen fixation occurs.
heterospory In plants, the formation of two different types of spores: microspores and megaspores; microspores produce male gametophytes, and megaspores produce female gametophytes.
heterotherm An animal that has a body temperature that is not constant; both ectotherms and endotherms may be heterotherms.
heterotroph Organisms that cannot produce their own organic molecules and thus must obtain organic food from other organisms.

heterotrophic Requiring organic food from the environment.
heterozygote advantage A phenomenon in which a heterozygote has a higher Darwinian fitness than either corresponding homozygote.
heterozygous An individual with two different alleles of the same gene.
hibernation The state of torpor in an animal that can last for months.
highly repetitive sequence A DNA sequence found tens of thousands or even millions of times throughout a genome.
hindbrain One of three major divisions of the vertebrate brain; the other two divisions are the midbrain and forebrain.
hippocampus The area of the vertebrate forebrain that functions in establishing memories for spatial locations, facts, and the sequence of events.
histone acetyltransferase An enzyme that loosens the compaction of chromatin by attaching acetyl groups to histone proteins.
histone code hypothesis Refers to the pattern of histone modification recognized by particular proteins. The pattern of covalent modifications of amino terminus tails provides binding sites for proteins that subsequently affect the degree of chromatin compaction.
histones A group of proteins involved in the formation of nucleosomes that aid in the compaction of eukaryotic DNA.
HIV *See* human immunodeficiency virus.
holoblastic cleavage A complete type of cell cleavage in certain animals in which the entire zygote is bisected into two equal-sized blastomeres.
holoparasite A parasitic organism that lacks chlorophyll and is totally dependent on a host plant for its water and nutrients.
homeobox A 180-bp sequence within the coding sequence of homeotic genes.
homeodomain A region of a homeotic protein that functions in binding to the DNA.
homeostasis The process whereby living organisms regulate their cells and bodies to maintain relatively stable internal conditions.
homeostatic control system A system designed to regulate particular variables in an animal's body, such as body temperature; consists of a set point, sensor, integrator, and effectors.
homeotherm An animal that maintains its body temperature within a narrow range.
homeotic gene A gene that controls the developmental fate of particular segments or regions of an animal's body.
hominin Either an extinct or modern species of humans.
hominoidea (hominoid) A member of a group of primates that includes gibbons, orangutans, gorillas, chimpanzees, and humans.
homologous genes Genes derived from the same ancestral gene that have accumulated random mutations that make their sequences slightly different.
homologous structures Structures that are similar to each other because they are derived from the same ancestral structure.
homolog A member of a pair of chromosomes in a diploid organism.
homology A fundamental similarity that occurs due to descent from a common ancestor.
homozygous An individual with two identical copies of an allele.
horizontal gene transfer A process in which an organism incorporates genetic material from another organism without being the offspring of that organism.
hormone A chemical messenger that is produced in a gland or other structure and acts on distant target cells in one or more parts of an animal or plant.
hornworts A phylum of bryophytes; Anthocerophyta.
host The prey organism in a parasitic association.
host cell 1. A cell that is infected by a virus, fungus, or a bacterium. 2. A eukaryotic cell that contains photosynthetic or nonphotosynthetic endosymbionts.
host plant resistance The ability of plants to prevent herbivory.
host range The number of species and cell types that a virus or bacterium can infect.
hot spot A human-impacted geographic area with a large number of endemic species. To qualify as a hot spot, a region must contain at least 1,500 species of endemic vascular plants and have lost at least 70% of its original habitat.
***Hox* genes** In animals, a class of genes involved in pattern formation in early embryos.
Human Genome Project A 13-year international effort coordinated by the U.S. Department of Energy and the National Institutes of Health that characterized and sequenced the entire human genome.
human immunodeficiency virus (HIV) A retrovirus that is the causative agent of acquired immune deficiency syndrome (AIDS).
humoral immunity A type of specific immunity in which plasma cells secrete antibodies that bind to antigens.
humus A collective term for the organic constituents of soils.
hybridization A situation in which two individuals with different characteristics are mated or crossed to each other; the offspring are referred to as hybrids.
hybrid zone An area where two populations can interbreed.
hydrocarbon Molecules with predominantly hydrogen–carbon bonds.
hydrogen bond A weak chemical attraction between a partially positive hydrogen atom of a polar molecule and a partially negative atom of another polar molecule.
hydrolysis reaction A chemical reaction that utilizes water to break apart molecules.
hydrophilic Refers to ions and molecules that contain polar covalent bonds and will dissolve in water.
hydrophobic Refers to molecules that do not have partial charges and therefore are not attracted to water molecules. Such molecules are composed predominantly of carbon and hydrogen and are relatively insoluble in water.
hydrostatic skeleton A fluid-filled body cavity in certain soft-bodied invertebrates that is surrounded by muscles and provides support and shape.
hydroxide ion An anion with the formula, OH^-.
hypermutation A process that primarily involves numerous C to T point mutations that are crucial to enabling lymphocytes to produce a diverse array of immunoglobulins capable of recognizing many different antigens.
hyperpolarization The change in the membrane potential that occurs when the cell becomes more polarized.
hypersensitive response (HR) A plant's local defensive response to pathogen attack.
hypertension High blood pressure.
hyperthermophile An organism that thrives in extremely hot temperatures.
hyperthyroidism A medical condition resulting from a hyperactive thyroid gland.
hypertonic Any solution that causes a cell to shrink due to osmosis of water out of the cell.
hypha A microscopic, branched filament of the body of a fungus.
hypocotyl The portion of an embryonic plant stem located below the point of attachment of the cotyledons.
hypothalamus A part of the vertebrate brain located below the thalamus; it controls functions of the gastrointestinal and reproductive systems, among others, and regulates many basic behaviors such as eating and drinking.
hypothesis In biology, a proposed explanation for a natural phenomenon based on previous observations or experimental studies.
hypothesis testing Also known as the scientific method, a strategy for testing the validity of a hypothesis.
hypothyroidism A medical condition resulting from an underactive thyroid gland.
hypotonic Any solution that causes a cell to swell when placed in that solution.
H zone In a myofibril, a narrow, light region in the center of the A band that corresponds to the space between the two sets of thin filaments in each sarcomere.

I

I band In a myofibril, a light band that lies between the A bands of two adjacent sarcomeres.
idiosyncratic hypothesis The possibility that ecosystem function changes as the number of species increases or decreases but that the amount and direction of change is unpredictable.
immune system The cells and organs within an animal's body that contribute to immune defenses.
immune tolerance The process by which the body distinguishes between self and nonself components.
immunity The ability of an animal to ward off internal threats, including harmful microorganisms, foreign molecules, and abnormal cells such as cancer cells.
immunoglobulin A Y-shaped protein with two heavy chains and two light chains that provides immunity to foreign substances; antibodies are a type of immunoglobulin.
immunological memory The immune system's ability to produce a secondary immune response.
imperfect flower A flower that lacks either stamens or carpels.
implantation The first event of pregnancy, when the blastocyst embeds within the uterine endometrium.
imprinting 1. The development of a species-specific pattern of behavior that occurs during a critical period; a form of learning, with a large innate component. 2. In genetics, the marking of DNA that occurs differently between males and females.
inactivation gate A string of amino acids that juts out from a channel protein into the cytosol and blocks the movement of ions through the channel.
inborn error of metabolism A genetic defect in the ability to metabolize certain compounds.
inbreeding Mating among genetically related relatives.
inbreeding depression The phenomenon whereby inbreeding produces homozygotes that are less fit, thereby decreasing the reproductive success of a population.
inclusive fitness The term used to designate the total number of copies of genes passed on through one's relatives, as well as one's own reproductive output.
incomplete dominance The phenomenon in which a heterozygote that carries two different alleles exhibits a phenotype that is intermediate between the corresponding homozygous individuals.
incomplete flower A flower that lacks one or more of the four flower organ types.
incomplete metamorphosis During development in some insects, a gradual change in body form from a nymph into an adult.
incurrent siphon A structure in a tunicate used to draw water through the mouth.

indeterminate cleavage In animals, a characteristic of deuterostome development in which each cell produced by early cleavage retains the ability to develop into a complete embryo.
indeterminate growth Growth in which plant shoot apical meristems continuously produce new stem tissues and leaves, as long as conditions remain favorable.
indicator species A species whose status provides information on the overall health of an ecosystem.
indirect calorimetry A method of determining basal metabolic rate in which the rate at which an animal uses oxygen is measured.
individualistic model A view of the nature of a community that considers it to be an assemblage of species coexisting primarily because of similarities in their physiological requirements and tolerances.
individual selection The proposal that adaptive traits generally are selected for because they benefit the survival and reproduction of the individual rather than the group.
induced fit Occurs when a substrate(s) binds to an enzyme and the enzyme undergoes a conformational change that causes the substrate(s) to bind more tightly to the enzyme.
induced mutation A mutation brought about by environmental agents that enter the cell and then alter the structure of DNA.
inducer In transcription, a small effector molecule that increases the rate of transcription.
inducible operon In this type of operon, the presence of a small effector molecule causes transcription to occur.
induction 1. In development, the process by which a cell or group of cells governs the developmental fate of neighboring cells. 2. In molecular genetics, refers to the process by which transcription has been turned on by the presence of a small effector molecule.
industrial nitrogen fixation The human activity of producing nitrogen fertilizers.
infertility The inability to produce viable offspring.
inflammation An innate local response to infection or injury characterized by local redness, swelling, heat, and pain.
inflorescence A cluster of flowers on a plant.
infundibular stalk The structure that physically connects the hypothalamus to the pituitary gland.
ingestion In animals, the act of taking food into the body.
ingroup In a cladogram, a group of interest.
inheritance The acquisition of traits by their transmission from parent to offspring.
inheritance of acquired characteristics Jean-Baptiste Lamarck's incorrect hypothesis that species change over the course of many generations by adapting to new environments.
inhibition A mechanism for succession in which early colonists exclude subsequent colonists.
inhibitory postsynaptic potential (IPSP) The response from an inhibitory neurotransmitter that hyperpolarizes the postsynaptic membrane; this hyperpolarization reduces the likelihood of an action potential.
initiation factor A protein that facilitates the interactions between mRNA, the first tRNA, and the ribosomal subunits during the initiation stage of translation.
initiation stage The first step in the process of transcription or translation.
initiator tRNA A specific tRNA that recognizes the start codon AUG in mRNA and binds to it, initiating translation.
innate The term used to describe behaviors that seem to be genetically programmed.
innate immunity The body's defenses that are present at birth and act against foreign materials in much the same way regardless of their specific identity; includes the skin and mucous membranes, plus various cellular and chemical defenses.
inner bark The thin layer of secondary phloem that carries out most of the sugar transport in a woody stem.
inner ear One of the three main compartments of the mammalian ear. The inner ear is composed of the bony cochlea and the vestibular system, which plays a role in balance.
inner segment The part of the vertebrate photoreceptors (rods and cones) that contains the cell nucleus and cytoplasmic organelles.
inorganic chemistry The study of the nature of atoms and molecules, with the exception of those that contain rings or chains of carbon.
insulin A hormone found in animals that regulates metabolism in several ways, primarily by regulating the blood glucose concentration.
insulin-like growth factor-1 (IGF-1) A hormone in mammals that stimulates the elongation of bones, especially during puberty.
integral membrane protein A protein that cannot be released from the membrane unless it is dissolved with an organic solvent or detergent. Includes transmembrane proteins and lipid-anchored proteins.
integrase An enzyme, sometimes encoded by viruses, that catalyzes the integration of the viral genome into a host-cell chromosome.
integrator The part of a homeostatic control system in which a variable is compared to a set point; typically a nucleus in the brain.
integrin A cell adhesion molecule found in animal cells that connects cells to the extracellular matrix.
integument In plants, a structure that encloses the megasporangium to form an ovule.
interference competition Competition in which organisms interact directly with one another by physical force or intimidation.
interferon A protein that generally inhibits viral replication inside host cells.
intermediate-disturbance hypothesis The proposal that moderately disturbed communities are more diverse than undisturbed or highly disturbed communities.
intermediate filament A type of protein filament of the cytoskeleton that helps maintain cell shape and rigidity.
internal fertilization Fertilization that occurs in terrestrial animals in which sperm are deposited within the reproductive tract of the female during copulation.
interneuron A type of neuron that forms interconnections between other neurons.
internode The region of a plant stem between adjacent nodes.
interphase The G_1, S, and G_2 phases of the cell cycle. It is the portion of the cell cycle during which the chromosomes are decondensed and found in the nucleus.
intersexual selection Sexual selection between members of the opposite sex.
interspecies hybrid The offspring resulting from the mating of two different species.
interspecific competition Competition between individuals of different species.
interstitial fluid The fluid that surrounds cells.
intertidal zone The area where the land meets the sea, which is alternately submerged and exposed by the daily cycle of tides.
intracellular fluid The fluid inside cells.
intranuclear spindle A spindle that forms within an intact nuclear envelope during nuclear division in fungi and some protists.
intrasexual selection Sexual selection between members of the same sex.
intraspecific competition Competition between individuals of the same species.
intrauterine device (IUD) A small object that is placed in the uterus and interferes with the endometrial preparation required for acceptance of the blastocyst; used as a form of contraception.
intrinsic rate of increase The situation in which conditions are optimal for a population and the per capita growth rate is at its maximum rate.
introduced species A species moved by humans from a native location to another location.
intron Intervening DNA sequences that are found in between the coding sequences of genes.
invaginate The act of pinching inward, as during early embryonic development in animals.
invasive cell A cancer cell that can invade healthy tissues.
invasive species Introduced species that spread on their own, often outcompeting native species for space and resources.
inverse density-dependent factor A mortality factor whose influence decreases as population size or density increases.
inversion A type of mutation that involves a change in the direction of the genetic material along a single chromosome.
invertebrate An animal that lacks vertebrae.
in vitro Meaning, "in glass" as in a test tube. An alternative to studying a process in a living organism that involves studying components outside of their natural locations. This can involve studying cells or components of cells in the laboratory.
in vivo Meaning, "in life." Studying a process in living organisms.
involution During embryogenesis, the folding back of sheets of surface cells into the interior of an embryo.
iodine-deficient goiter An overgrown thyroid gland that is incapable of making thyroid hormone due to a lack of dietary iodine.
ion An atom or molecule that gains or loses one or more electrons and acquires a net electric charge.
ion electrochemical gradient A dual gradient for an ion that is composed of both an electrical gradient and a chemical gradient for that ion.
ionic bond The bond that occurs when a cation binds to an anion.
ionotropic receptor One of two types of postsynaptic receptors, the other being a metabotropic receptor. Consists of a ligand-gated ion channel that opens in response to binding of a neurotransmitter.
iris The circle of pigmented smooth muscle and connective tissue that is responsible for eye color.
iron regulatory element (IRE) A response element within the ferritin mRNA to which the iron regulatory protein binds.
iron regulatory protein (IRP) An RNA-binding protein that regulates the translation of the mRNA that encodes ferritin.
islets of Langerhans Spherical clusters of endocrine cells that are scattered throughout the pancreas; the cells secrete insulin or glucagon, among other hormones.
isomers Two structures with an identical molecular formula but different structures and characteristics.
isotonic Condition in which the solute concentrations on both sides of a plasma membrane are equal, which does not cause a cell to shrink or swell.
isotope An element that exists in multiple forms that differ in the number of neutrons they contain.

iteroparity The pattern of repeated reproduction at intervals throughout an organism's life cycle.

J

joint The juncture where two or more bones of a vertebrate endoskeleton come together.
juvenile hormone A hormone made in arthropods that inhibits maturation from a larva into a pupa.

K

karyogamy The process of nuclear fusion.
karyotype A photographic representation of the chromosomes in an actively dividing cell.
K_d The dissociation constant between a ligand and its receptor.
ketones Small compounds generated from fatty acids. Ketones are made in the liver and released into the blood to provide an important energy source during prolonged fasting for many tissues, including the brain.
keystone hypothesis The idea that ecosystem function plummets as soon as biodiversity declines from its natural levels.
keystone species A species within a community that has a role out of proportion to its abundance.
kidney The major excretory organ found in all vertebrates.
kcal (kilocalorie) One thousand calories; the amount of heat energy required to raise the temperature of 1 kg of water by 1°C.
kinesis A movement in response to a stimulus, but one that is not directed toward or away from the source of the stimulus.
kinetic energy Energy associated with movement.
kinetic skull A characteristic of lizards and snakes in which the joints between various parts of the skull are extremely mobile.
kinetochore A group of proteins that bind to a centromere and are necessary for sorting each chromosome.
kingdom A taxonomic group; the second largest division after domain.
kin selection Selection for behavior that lowers an individual's own fitness but enhances the reproductive success of a relative.
K_M The substrate concentration at which an enzyme-catalyzed reaction is half of its maximal value.
knowledge The awareness and understanding of information.
Koch's postulates A series of steps used to determine whether a particular organism causes a specific disease.
***K*-selected species** A type of life history strategy where species have a low rate of per capita population growth but good competitive ability.
K/T event An ancient cataclysm that involved at least one large meteorite or comet that crashed into the Earth near the present-day Yucatán Peninsula in Mexico about 65 mya.

L

labia majora In the female mammalian genitalia, large outer folds that surround the external opening of the reproductive tract.
labia minora In the female mammalian genitalia, smaller, inner folds near the external opening of the reproductive tract.
labor The strong rhythmic contractions of the uterus that serve to deliver a fetus during childbirth.
***lac* operon** An operon in the genome of *E. coli* that contains the genes for the enzymes that allow it to metabolize lactose.
lac repressor A repressor protein that regulates the *lac* operon.
lactation In mammals, a period after birth in which the young are nurtured by milk produced by the mother.
lacteal A lymphatic vessel in the center of each intestinal villus; lipids are absorbed by the lacteals, which eventually empty into the circulatory system.
lagging strand During DNA replication, a DNA strand made as a series of small Okazaki fragments that are eventually connected to each other to form a continuous strand.
lamellae (singular, **lamella**) Platelike structures in the internal gills of fishes that branch from structures called filaments; gas exchange occurs here.
larva A free-living organism that is morphologically very different from the embryo and adult.
larynx The segment of the respiratory tract that contains the vocal cords.
latent The term used to describe a prophage or provirus that remains inactive for a long time.
lateral line system Microscopic sensory organs in fishes and some toads that allows them to detect movement in surrounding water.
lateral meristem *See* secondary meristem.
law of independent assortment States that the alleles of different genes assort independently of each other during gamete formation.
law of segregation States that two copies of a gene segregate from each other during gamete formation and during transmission from parent to offspring.
leaching The dissolution and removal of inorganic ions as water percolates through materials such as soil.
leading strand During DNA replication, a DNA strand made in the same direction that the replication fork is moving. The strand is synthesized as one long continuous molecule.
leaf abscission The process by which a leaf drops after the formation of an abscission zone.
leaflet 1. Half of a phospholipid bilayer. 2. A portion of a compound leaf.
leaf primordia Small outgrowths that occur at the sides of a shoot apical meristem and develop into young leaves.
leaf vein In plants, a bundle of vascular tissue in a leaf.
learning The ability of an animal to make modifications to a behavior based on previous experience; the process by which new information is acquired.
leaves Flattened plant organs that emerge from stems and function in photosynthesis.
left-right axis In bilaterally symmetric animals, the left and right sides of the body.
leghemoglobin A protein found in legume plants that helps to regulate local oxygen concentrations around rhizobial bacteroids in root nodules.
legume A member of the pea (bean) family; also their distinctive fruits.
lek A designated communal courting area in certain species of birds.
lens 1. A structure of the eye that focuses light. 2. The glass components of a light microscope or the electromagnetic parts of an electron microscope that allow the production of magnified images of microscopic structures.
lentic Refers to a freshwater habitat characterized by standing water.
lenticels Passages in the outer bark of a woody plant stem that allow inner stem tissues to accomplish gas exchange.
leptin A hormone produced by adipose cells in proportion to fat mass; controls appetite and metabolic rate.
leukocyte A cell that develops from the marrow of certain bones of vertebrates; all leukocytes (also known as white blood cells) perform vital functions that defend the body against infection and disease.
lichens The mutualistic association between particular fungi and certain photosynthetic green algae or cyanobacteria. This association results in a body form distinctive from that of either partner alone.
Liebig's law of the minimum States that species' biomass or abundance is limited by the scarcest factor.
life cycle The sequence of events that characterize the steps of development of the individuals of a given species.
life table A table that provides data on the number of living individuals in a population in particular age classes.
ligand An ion or molecule that binds to a protein, such as an enzyme or a receptor.
ligand-gated ion channel A type of cell surface receptor that binds a ligand and functions as an ion channel. Ligand binding either opens or closes a channel.
ligand-receptor complex The structure formed when a ligand and its receptor noncovalently bind.
light chain 1. A part of an immunoglobulin molecule. 2. Two of the polypeptides that make up each myosin molecule.
light-harvesting complex A component of photosystem II and photosystem I composed of several dozen pigment molecules that are anchored to proteins in the thylakoid membranes of a chloroplast. The role of these complexes is to absorb photons of light.
light microscope A microscope that utilizes light for illumination.
light reactions The first of two stages in the process of photosynthesis. During the light reactions, photosystem II and photosystem I absorb light energy and produce ATP, NADPH, and O_2.
lignin A tough polymer that adds strength and decay resistance to cell walls of tracheids, vessel elements, and other cells of plants.
lignophytes Modern and fossil seed plants and seedless ancestors that produced wood.
limbic system In the vertebrate forebrain, the areas involved in the formation and expression of emotions; also plays a role in learning, memory, and the perception of smells.
limiting factor A factor whose amount or concentration limits the rate of a biological process or a chemical reaction.
lineage A progression of changes in a series of ancestors.
line transect A sampling technique used by plant ecologists in which the number of plants located along a length of string are counted.
linkage The phenomenon that two genes close together on the same chromosome are transmitted as a unit.
linkage group A group of genes that usually stay together during meiosis.
lipase The major fat-digesting enzyme from the pancreas.
lipid A molecule composed predominantly of hydrogen and carbon atoms. Lipids are nonpolar and therefore very insoluble in water. They include fats (triglycerides), phospholipids, waxes, and steroids.
lipid-anchored protein A type of integral membrane protein that is attached to the membrane via a lipid molecule.
lipid-exchange protein A protein that extracts a lipid from one membrane, diffuses through the cell, and inserts the lipid into another membrane.
lipid raft In a membrane, a group of lipids and proteins that float together as a unit in a larger sea of lipids.
lipolysis The enzymatic breakdown of triglycerides into fatty acids and either monoglycerides or glycerol.
lipopolysaccharides Lipids with covalently bound carbohydrates; prevalent in the thin, outer envelope that encloses the cell walls of Gram-negative bacteria.

liposome A vesicle surrounded by a lipid bilayer.
liver An organ in vertebrates that performs diverse metabolic functions and is the site of bile production.
liverworts A phylum of bryophytes; formally called Hepatophyta.
loam A type of soil that contains a mixture of sand, silt, and clay and is ideal for plant cultivation.
lobe fins The Actinistia (coelacanths), Dipnoi (lungfishes), and tetrapods; also called Sarcopterygii.
lobe-finned fishes Fishes in which the fins are part of the body; the fins are supported by skeletal extensions of the pectoral and pelvic areas.
locomotion The movement of an animal from place to place.
locus The physical location of a gene on a chromosome.
logistic equation An equation that relates the growth of populations to their carrying capacity, *K*.
logistic growth The pattern in which the growth of a population typically slows down as it approaches the carrying capacity.
long-day plant A plant that flowers in spring or early summer, when the night period is shorter (and thus the day length is longer) than a defined period.
long-term potentiation (LTP) The long-lasting strengthening of the connection between neurons that is believed to be part of the mechanism of learning and memory.
loop domain In bacteria, a chromosomal segment that is folded into loops by the attachment to proteins; a method of compacting bacterial chromosomes.
loop of Henle A segment of the tubule of the nephron of the kidney containing a sharp hairpin-like loop that contributes to reabsorption of ions and water. It consists of a descending limb coming from the proximal tubule and an ascending limb leading to the distal tubule.
lophophore A horseshoe-shaped crown of tentacles used for feeding in several invertebrate species.
Lophotrochozoa A clade of animals that encompasses the mollusks, annelids, and several other phyla; they are distinguished by two morphological features: the lophophore, a crown of tentacles used for feeding, and the trochophore larva, a distinct larval stage.
lotic Refers to a freshwater habitat characterized by running water.
lumen The internal space or hollow cavity of an organelle or an organ, such as the stomach or a blood vessel.
lungfishes The Dipnoi; fish with primitive lungs that live in oxygen-poor freshwater swamps and ponds.
lung In terrestrial vertebrates, internal paired structures used to bring O_2 into the circulatory system and remove CO_2.
luteinizing hormone (LH) A gonadotropin that controls the production of sex steroids in both males and females.
lycophyll A relatively small leaf having a single unbranched vein; produced by lycophytes.
lycophytes Members of a phylum of vascular land plants whose leaves are lycophylls, Lycopodiophyta.
lymphatic system A system of vessels along with a group of organs and tissues where most leukocytes reside. The lymphatic vessels collect excess interstitial fluid and return it to the blood.
lymphocyte A type of leukocyte that is responsible for specific immunity; the two types are B cells and T cells.
lysogenic cycle The growth cycle of a bacteriophage consisting of integration, prophage replication, and excision.
lysosome A small organelle found in animal cells that contains acid hydrolases that degrade macromolecules.
lytic cycle The growth cycle of a bacteriophage in which the production and release of new viruses lyses the host cell.

M

macroalgae Photosynthetic protists that can be seen with the unaided eye; also known as seaweeds.
macroevolution Evolutionary changes that create new species and groups of species.
macromolecule Many molecules bonded together to form a polymer. Carbohydrates, proteins, and nucleic acids (for example, DNA and RNA) are important macromolecules found in living organisms.
macronutrient An element required by plants in amounts of at least 1 g/kg of plant dry matter.
macroparasite A parasite that lives in a host but releases infective juvenile stages outside the host's body.
macrophage A type of phagocyte capable of engulfing viruses and bacteria.
macular degeneration An eye condition in which photoreceptor cells in and around the fovea of the retina are lost; one of the leading causes of blindness in the U.S.
madreporite A sievelike plate on the surface of an echinoderm where water enters the water vascular system.
magnetic resonance imaging (MRI) An imaging method that relies on the use of magnetic fields and radio waves to visualize the internal structure of an organism's body.
magnification The ratio between the size of an image produced by a microscope and a sample's actual size.
major depressive disorder A neurological disorder characterized by feelings of despair and sadness, resulting from an imbalance in neurotransmitter levels in the brain.
major groove A groove that spirals around the DNA double helix; provides a location where a protein can bind to a particular sequence of bases and affect the expression of a gene.
major histocompatibility complex (MHC) A gene family that encodes the plasma membrane self proteins that must be complexed with an antigen for T-cell recognition to occur.
male-assistance hypothesis A hypothesis to explain the existence of monogamy that maintains that males remain with females to help them rear their offspring.
male gametophyte A haploid multicellular plant life cycle stage that produces sperm.
malignant tumor A growth of cells that has progressed to the cancerous stage.
Malpighian tubules Delicate projections from the digestive tract of insects and some other taxa that function as an excretory organ.
mammal A vertebrate that is a member of the class Mammalia that nourishes its young with milk secreted by the female's mammary glands. Another distinguishing feature is hair.
mammary gland A gland in female mammals that secretes milk.
manganese cluster A site where the oxidation of water occurs in photosystem II during photosynthesis.
mantle In mollusks, a fold of skin draped over the visceral mass that secretes a shell in those species that form shells.
mantle cavity The chamber in a mollusk mantle that houses delicate gills.
many-eyes hypothesis The idea that increased group size decreases predators' success because of increased detection of predators.
map distance The distance between genes along chromosomes, which is calculated as the number of recombinant offspring divided by the total number of offspring times 100.
mapping The process of determining the relative locations of genes or other DNA segments along a chromosome.
map unit (mu) A unit of distance on a chromosome equivalent to a 1% recombination frequency.
mark-recapture technique The capture and tagging of animals so they can be released and recaptured, allowing an estimate of population size.
marsupial A member of a group of seven mammalian orders and about 280 species found in the subclass Metatheria.
mass extinction When many species become extinct at the same time.
mass-specific BMR The amount of energy expended per gram of body mass.
mastax The circular muscular pharynx in the mouth of rotifers.
mast cell A type of cell derived from bone marrow stem cells that plays an important role in nonspecific immunity.
mate-guarding hypothesis The hypothesis that a male is monogamous to prevent his mate from being fertilized by other males.
maternal effect An inheritance pattern in which the genotype of the mother determines the phenotype of her offspring.
maternal effect gene A gene that follows a maternal effect inheritance pattern.
maternal inheritance A phenomenon in which offspring inherit particular genes only from the female parent (through the egg).
matrotrophy In plants, the phenomenon in which zygotes remain enclosed within gametophyte tissues, where they are sheltered and fed.
matter Anything that has mass and takes up space.
maturation-promoting factor (MPF) A factor, now known to be a complex of cyclin and cyclin-dependent kinase, important in the division of all types of eukaryotic cells.
mature mRNA In eukaryotes, transcription produces a long RNA, pre-mRNA, which undergoes certain processing events before it exits the nucleus; mature mRNA is the final functional product.
maximum likelihood One method used to evaluate a phylogenetic tree based on an evolutionary model.
mean fitness of the population The average reproductive success of members of a population.
mechanoreceptor A sensory receptor in animals that transduces mechanical energy such as pressure, touch, stretch, movement, and sound.
mediator A large protein complex that plays a role in initiating transcription at the core promoter of structural genes in eukaryotes.
medulla oblongata The part of the vertebrate hindbrain that coordinates many basic reflexes and bodily functions, such as breathing.
medusa A type of cnidarian body form that is motile and usually floats mouth down.
megadiversity country Those countries with the greatest numbers of species; used in targeting areas for conservation.
megaspore In seed plants and some seedless plants, a large spore that produces a female gametophyte within the spore wall.
meiosis The process by which haploid cells are produced from a cell that was originally diploid.
meiosis I The first division of meiosis in which the homologs are separated into different cells.
meiosis II The second division of meiosis in which sister chromatids are separated into different cells.
Meissner's corpuscle Structures that sense touch and light pressure and lie just beneath the skin surface of an animal.
melatonin A hormone produced by the pineal gland of vertebrates; plays a role in light-dependent behaviors such as seasonal reproduction and daily rhythms.

membrane attack complex (MAC) A multiunit protein formed by the activation of complement proteins; the complex creates water channels in the microbial plasma membrane and causes the microbe to swell and burst.
membrane potential The difference between the electric charges outside and inside a cell; also called a potential difference (or voltage).
membrane transport The movement of ions or molecules across a cell membrane.
memory The retention of information over time.
memory cell A cloned lymphocyte that remains poised to recognize a returning antigen; a component of specific immunity.
Mendelian inheritance The inheritance patterns of genes that segregate and assort independently.
meninges Three layers of sheathlike membranes that cover and protect the brain and spinal cord.
meningitis A potentially life-threatening infectious disease in which the meninges become inflamed.
menopause The event during which a woman permanently stops having ovarian cycles.
menstrual cycle The cyclical changes that occur in the uterus in parallel with the ovarian cycle in a female mammal. Also called the uterine cycle.
menstruation A period of bleeding at the beginning of the menstrual cycle in a female mammal.
meristem In plants, an organized tissue that includes actively dividing cells and a reservoir of stem cells.
meroblastic cleavage An incomplete type of cell cleavage in which only the region of the egg containing cytoplasm at the animal pole undergoes cell division. Occurs in birds and some fishes.
merozygote A strain of bacteria containing an F′ factor.
mesoderm In animals, a layer of cells formed during gastrulation that develops between the ectoderm and endoderm; gives rise to the skeleton, muscles, and much of the circulatory system.
mesoglea A gelatinous substance between the epidermis and the gastrodermis in the Radiata.
mesohyl A gelatinous, protein-rich matrix in between the choanocytes and the epithelial cells of a sponge.
mesophyll The internal tissue of a plant leaf; the site of photosynthesis.
messenger RNA (mRNA) RNA that contains the information to specify a polypeptide with a particular amino acid sequence.
metabolic cycle A biochemical cycle in which particular molecules enter while others leave; the process is cyclical because it involves a series of organic molecules that are regenerated with each turn of the cycle.
metabolic pathway In living cells, a series of chemical reactions in which each step is catalyzed by a specific enzyme.
metabolic rate The total energy expenditure of an organism per unit of time.
metabolism The sum total of all chemical reactions that occur within an organism. Also, a specific set of chemical reactions occurring at the cellular level.
metabotropic receptor A G-protein-coupled receptor that initiates a signaling pathway in response to a neurotransmitter. One of two types of postsynaptic receptors, the other being an ionotropic receptor.
metacentric A chromosome in which the centromere is near the middle.
metagenomics A field of study that seeks to identify and analyze the collective microbial genomes contained in a community of organisms, including those not easily cultured in the laboratory.
metamorphosis The process in which a pupal or juvenile organism changes into a mature adult with very different characteristics.
metanephridia Excretory filtration organs found in a variety of invertebrates.
metaphase The phase of mitosis during which the chromosomes are aligned along the metaphase plate.
metaphase plate A plane halfway between the poles of the spindle apparatus on which the sister chromatids align during the metaphase stage of mitosis.
metastasis The process by which cancer cells spread from their original location to distant parts of the body.
Metazoa The collective term for animals.
methanogens Several groups of anaerobic archaea that convert CO_2, methyl groups, or acetate to methane, and release it from their cells.
methanotroph An aerobic bacterium that consumes methane.
methyl-CpG-binding protein A protein that binds methylated sequences and inhibits transcription.
micelle The sphere formed by long amphipathic molecules when they are mixed with water. In animals, micelles aid in the absorption of poorly soluble products during digestion.
microbiome All of the microorganisms in a particular environment.
microclimate Local variations of the climate within a given area.
microevolution Changes in a population's gene pool from generation to generation.
microfilament *See* actin filament.
micrograph An image taken with the aid of a microscope.
micronutrient An element required by plants in amounts at, or less than, 0.1 g/kg of plant dry matter; also known as a trace element.
microparasite A parasite that multiplies within its host, usually within the cells.
micropyle A small opening in the integument of a seed plant ovule through which a pollen tube grows.
microRNAs (miRNAs) Small RNA molecules, typically 22 nucleotides in length, that silence the expression of specific mRNAs by inhibiting translation.
microscope A magnification tool that enables researchers to study very small structures such as cells.
microspore In seed plants and some seedless plants, a relatively small spore that produces a male gametophyte within the spore wall.
microsporidia Single-celled fungi that parasitize animal cells.
microtubule A type of hollow protein filament composed of tubulin proteins that is part of the cytoskeleton and is important for cell shape, organization, and movement.
microtubule-organizing center *See* centrosome.
microvillus (plural **microvilli**) Small projections in the surface membranes of epithelial cells in the small intestine and many other absorptive cells.
midbrain One of three major divisions of the vertebrate brain; the other two divisions are the hindbrain and the forebrain.
middle ear One of the three main compartments of the mammalian ear; contains three small bones called ossicles that connect the eardrum with the oval window.
middle lamella An extracellular layer in plants composed primarily of carbohydrate; cements adjacent plant cell walls together.
migration Long-range seasonal movement among animals in order to feed or breed.
mimicry The resemblance of an organism (the mimic) to another organism (the model).
mineral An inorganic ion or inorganic molecule required by a living organism.
mineralization The general process by which phosphorus, nitrogen, CO_2, and other minerals are released from organic compounds.
mineralocorticoid A steroid hormone such as aldosterone that regulates the balance of sodium and potassium ions in the body.
minor groove A smaller groove that spirals around the DNA double helix.
miRNA *See* microRNAs.
missense mutation A base substitution that changes a single amino acid in a polypeptide sequence.
mitochondrial genome The chromosome found in mitochondria.
mitochondrial matrix A compartment inside the inner membrane of a mitochondrion.
mitochondrion A semiautonomous organelle found in eukaryotic cells that supplies most of a cell's ATP.
mitogen-activated protein kinase (MAP kinase) A type of protein kinase that is involved with promoting cell division.
mitosis In eukaryotes, the process in which nuclear division results in two nuclei, each of which receives the same complement of chromosomes.
mitotic cell division A process whereby a eukaryotic cell divides to produce two new cells that are genetically identical to the original cell.
mitotic spindle The structure responsible for organizing and sorting the chromosomes during mitosis; also called the mitotic spindle apparatus.
mixotroph An organism that is able to use autotrophy as well as phagotrophy or osmotrophy to obtain organic nutrients.
M line In a myofibril, a narrow, dark band in the center of the H zone where proteins link the central regions of adjacent thick filaments.
model organism An organism studied by many different researchers so they can compare their results and determine scientific principles that apply more broadly to other species.
moderately repetitive sequence A DNA sequence found a few hundred to several thousand times in a genome.
molar A term used to describe a solution's molarity; a 1 molar solution contains 1 mole of a solute in 1 L of water.
molarity The number of moles of a solute dissolved in 1 L of water.
mole The amount of any substance that contains the same number of particles as there are atoms in exactly 12 g of carbon.
molecular biology A field of study spawned largely by genetic technology that looks at the structure and function of the molecules of life.
molecular clock A method for estimating evolutionary time; based on the observation that neutral mutations occur at a relatively constant rate.
molecular evolution The molecular changes in genetic material that underlie the phenotypic changes associated with evolution.
molecular formula A representation of a molecule that consists of the chemical symbols for all of the atoms present and subscripts that indicate how many of those atoms are present.
molecular homologies Similarities at the molecular level that indicate that living species evolved from a common ancestor or interrelated group of common ancestors.
molecular mass The sum of the atomic masses of all the atoms in a molecule.
molecular pharming An avenue of research that involves the production of medically important proteins in agricultural crops or animals.
molecular systematics A field of study that involves the analysis of genetic data, such as DNA sequences, to identify and study genetic homology and construct phylogenetic trees.
molecule Two or more atoms that are connected by chemical bonds.

monoclonal antibodies Antibodies of a specific type that are derived from a single clone of cells.
monocots One of the two largest lineages of flowering plants in which the embryo produces a single seed leaf.
monocular vision A type of vision in animals that have eyes on the sides of the head; the animal sees a wide area at one time, though depth perception is reduced.
monocyte A type of phagocyte that circulates in the blood for only a few days, after which it takes up permanent residence in various organs as a macrophage.
monoecious The term to describe plants that produce carpellate and staminate flowers on the same plant.
monogamy A mating system in which one male mates with one female, and most individuals have mates.
monohybrid The F_1 offspring, also called single-trait hybrids, of true-breeding parents that differ with regard to a single trait.
monohybrid cross A cross in which the inheritance of only one trait is followed.
monomer An organic molecule that can be used to form larger molecules (polymers) consisting of many repeating units of the monomer.
monomorphic gene A gene that exists predominantly as a single allele in a population.
monophagous The term used to describe parasites that feed on one or a few closely related species.
monophyletic group A group of species, a taxon, consisting of the most recent common ancestor and all of its descendants.
monosaccharide A simple sugar.
monosomic An aneuploid organism that has one too few chromosomes.
monotreme A member of the mammalian order Monotremata, which consists of three species found in Australia and New Guinea: the duck-billed platypus and two species of echidna.
morphogen A molecule that imparts positional information and promotes developmental changes at the cellular level.
morphogenetic field A group of cells believed to differentiate into a single body structure.
morphology The structure or form of a body part or an entire organism.
morula An early stage in a mammalian embryo in which physical contact between cells is maximized by compaction.
mosaic An individual with somatic cells that are genetically different from each other.
mosses A phylum of bryophytes; Bryophyta.
motor end plate The region of a skeletal muscle cell that lies beneath an axon terminal at the neuromuscular junction.
motor neuron A neuron that sends signals away from the central nervous system and elicits some type of response from a gland, muscle or other structure.
motor protein A category of cellular proteins that uses ATP as a source of energy to promote movement; consists of three domains called the head, hinge, and tail.
movement corridor Thin strips of habitat that may permit the movement of individuals between larger habitat patches.
M phase The sequential events of mitosis and cytokinesis.
mRNA *See* messenger RNA.
Müllerian mimicry A type of mimicry in which many noxious species converge to look the same, thus reinforcing the basic distasteful design.
multicellular Describes an organism consisting of more than one cell, particularly when cell-to-cell adherence and signaling processes and cellular specialization can be demonstrated.
multimeric protein A protein with more than one polypeptide chain; also said to have a quarternary structure.
multiple alleles Refers to the occurrence of a gene that exists as three or more alleles in a population.
multiple sclerosis (MS) A disease in which the patient's own body attacks and destroys myelin as if it were a foreign substance; impairs the function of myelinated neurons that control movement, speech, memory, and emotion.
multipotent A term used to describe a stem cell that can differentiate into several cell types, but far fewer than pluripotent cells.
muscle A grouping of muscle cells (fibers) bound together by a succession of connective tissue layers.
muscle fiber Individual cell within a muscle.
muscle tissue Bundles of muscle fibers that are specialized to contract when stimulated.
muscular dystrophy A group of diseases associated with progressive degeneration of skeletal and cardiac muscle fibers.
mutagen An agent known to cause mutation.
mutant allele An allele that has been altered by mutation.
mutation A heritable change in the genetic material of an organism.
mutualism A symbiotic interaction in which both species benefit.
myasthenia gravis A disease characterized by loss of acetylcholine receptors on skeletal muscle, due to the body's own immune system destroying the receptors.
mycelium A fungal body composed of microscopic branched filaments known as hyphae.
mycorrhizae (singular, **mycorrhiza**) Associations between the hyphae of certain fungi and the roots of plants.
myelin sheath In the nervous system, an insulating layer made up of specialized glial cells wrapped around the axons.
myocardial infarction (MI) The death of cardiac muscle cells, which can occur if a region of the heart is deprived of blood for an extended time.
myofibril Rodlike collection of myofilaments within a muscle fiber (cell); contains thick and thin filaments.
myogenic heart A heart in which the signaling mechanism that initiates contraction resides within the cardiac muscle itself.
myoglobin An oxygen-binding protein that provides an intracellular reservoir of oxygen for muscle fibers.
myosin A motor protein found abundantly in muscle cells and also in other cell types.

N

NAD^+ Nicotinamide adenine dinucleotide; a dinucleotide that functions as an energy intermediate molecule. It combines with two electrons and H^+ to form NADH.
NADPH Nicotinamide adenine dinucleotide phosphate; an energy intermediate that provides the energy and electrons to drive the Calvin cycle during photosynthesis.
natural killer (NK) cell A type of leukocyte that participates in both nonspecific and specific immunity; recognizes general features on the surface of cancer cells or any virus-infected cells.
natural selection The process that eliminates those individuals that are less likely to survive and reproduce in a particular environment, while allowing other individuals with traits that confer greater reproductive success to increase in numbers.
nauplius The first larval stage in a crustacean.
navigation A mechanism of migration that involves the ability not only to follow a compass bearing but also to set or adjust it.
negative control Transcriptional regulation by repressor proteins.
negative feedback loop A homeostatic system in animals in which a change in the variable being regulated brings about responses that move the variable in the opposite direction.
negative frequency-dependent selection A pattern of natural selection in which the fitness of a genotype decreases when its frequency becomes higher; the result is a balanced polymorphism.
negative pressure filling The mechanism by which reptiles, birds, and mammals ventilate their lungs.
nekton Free-swimming animals in the open ocean that can swim against currents to locate food.
nematocyst In a cnidarian, a powerful capsule with an inverted coiled and barbed thread that functions to immobilize small prey.
neocortex The layer of the brain that evolved most recently in mammals.
nephron One of several million single-cell-thick tubules that are the functional units of the mammalian kidney.
Nernst equation The formula that gives the equilibrium potential for an ion at any given concentration gradient: $E = 60 \text{ mV } \log_{10}([X_{\text{extracellular}}]/[X_{\text{intracellular}}])$.
nerve A structure found in the peripheral nervous system that is composed of multiple myelinated neurons bound by connective tissue; carries information to or from the central nervous system.
nerve cord In many invertebrates, a ventral structure that extends from the anterior end of the animal to the tail; a dorsal nerve cord is found in chordates.
nerve net Interconnected neurons with no central control organ.
nervous system Groups of cells that sense internal and environmental changes and transmit signals that enable an animal to respond in an appropriate way.
nervous tissue Clusters of cells that initiate and conduct electrical signals from one part of an animal's body to another part.
net primary production (NPP) Gross primary production minus the energy lost in plant cellular respiration.
net reproductive rate The population growth rate per generation.
neural crest In vertebrates, a group of embryonic cells derived from ectoderm that disperse throughout the embryo and contribute to the development of the skeleton and other structures, including peripheral nerves.
neural tube In chordates, a structure formed from ectoderm located dorsal to the notochord; all neurons and their supporting cells in the central nervous system originate from neural precursor cells derived from the neural tube.
neurogenesis The production of new neurons by cell division.
neurogenic heart A heart that will not beat unless it receives regular electrical impulses from the nervous system.
neurohormone A hormone made in and secreted by neurons whose cell bodies are in the hypothalamus.
neuromodulator Another term for a neuropeptide, which is a neurotransmitter that can alter or modulate the response of a postsynaptic neuron to other neurotransmitters.
neuromuscular junction The junction between a motor neuron's axon and a skeletal or cardiac muscle fiber.
neuron A highly specialized cell found in nervous systems of animals that communicates with other cells by electrical or chemical signals.
neuroscience The scientific study of nervous systems.
neurotransmitter A small signaling molecule that is released from an axon terminal and diffuses to a postsynaptic cell where it elicits a response.

neurulation The embryological process responsible for initiating central nervous system formation.
neutral theory of evolution States that most genetic variation is due to the accumulation of neutral mutations that have attained high frequencies in a population via genetic drift.
neutral variation Genetic variation in which natural selection does not favor any particular genotype.
neutron A neutral particle found in the center of an atom.
neutrophil A type of phagocyte and the most abundant type of leukocyte. Neutrophils engulf bacteria by endocytosis.
niche The unique set of habitat resources a species requires as well as its effect on the ecosystem.
nitrification The conversion by soil bacteria of ammonia (NH_3) or ammonium (NH_4^+) to nitrate (NO_3^-), a form of nitrogen commonly used by plants.
nitrogen fixation A specialized metabolic process in which certain prokaryotes use the enzyme nitrogenase to convert inert atmospheric nitrogen gas (N_2) into ammonia (NH_3); also, the industrial process by which humans produce NH_3 fertilizer from N_2.
nitrogenase An enzyme used in the biological process of fixing nitrogen.
nitrogen-limitation hypothesis The proposal that organisms select food based on its nitrogen content.
nitrogenous waste Degradation product of proteins and nucleic acids that are toxic at high concentrations and must be eliminated from the body.
nociceptor A sensory receptor in animals that responds to extreme heat, cold, and pressure, as well as to certain molecules such as acids; also known as a pain receptor.
node The region of a plant stem from which one or more leaves, branches, or buds emerge.
nodes of Ranvier Exposed areas in the axons of myelinated neurons that contain many voltage-gated Na^+ channels and are the sites of regeneration of action potentials.
Nod factor Nodulation factor; a substance produced by nitrogen-fixing bacteria in response to flavonoids secreted from the roots of potential host plants. Nod factors bind to receptors in plant root membranes, starting a process that allows the bacteria to invade roots.
nodule A small swelling on a plant root that contains nitrogen-fixing bacteria.
nodulin One of several plant proteins that foster root nodule development.
noncoding strand *See* template strand.
noncompetitive inhibitor A molecule that binds to an enzyme at a location that is outside the active site and inhibits the enzyme's function.
noncyclic electron flow The combined action of photosystem II and photosystem I in which electrons flow in a linear manner to produce NADPH.
non-Darwinian evolution The idea that much of the modern variation in gene sequences is explained by neutral variation rather than adaptive variation.
nondisjunction An event in which the chromosomes do not sort properly during cell division.
nonpolar covalent bond A strong bond formed between two atoms of similar electronegativities in which electrons are shared between the atoms.
nonpolar molecule A molecule composed predominantly of nonpolar bonds.
nonrandom mating The phenomenon that individuals choose their mates based on their genotypes or phenotypes.
nonrecombinant An offspring whose combination of traits has not changed from the parental generation.
nonsense codon *See* stop codon.
nonsense mutation A mutation that changes a normal codon into a stop codon; this causes translation to be terminated earlier than expected, producing a truncated polypeptide.
nonshivering thermogenesis An increase in an animal's metabolic rate that is not due to increased muscle activity; occurs primarily in brown adipose tissue.
nonspecific immunity *See* innate immunity.
nonvascular plant A plant that does not produce lignified vascular tissue; includes the bryophytes.
norepinephrine A type of neurotransmitter; also known as noradrenaline.
norm of reaction A description of how a trait may change depending on environmental conditions.
notochord A defining characteristic of all chordate embryos; consists of a flexible rod that lies between the digestive tract and the nerve cord.
N-terminus The location of the first amino acid in a polypeptide; also known as the amino terminus.
nuclear envelope A double-membrane structure that encloses the cell's nucleus.
nuclear genome The chromosomes found in the nucleus of a eukaryotic cell.
nuclear lamina A collection of filamentous proteins that line the inner nuclear membrane; part of the nuclear matrix.
nuclear matrix A filamentous network of proteins that is found inside the nucleus and lines the inner nuclear membrane. The nuclear matrix serves to organize the chromosomes.
nuclear pore A passageway for the movement of molecules and macromolecules into and out of the nucleus; formed where the inner and outer nuclear membranes make contact with each other.
nucleic acid An organic molecule composed of nucleotides. The two types of nucleic acids are deoxyribonucleic acid (DNA) and ribonucleic acid (RNA).
nucleoid region A site in a bacterial cell where the genetic material (DNA) is located.
nucleolus A prominent region in the nucleus of nondividing cells where ribosome assembly occurs.
nucleosome A structural unit of eukaryotic chromosomes composed of an octamer of histones (eight histone proteins) wrapped with DNA.
nucleotide An organic molecule having three components: one or more phosphate groups, a five-carbon sugar (either deoxyribose or ribose), and a single or double ring of carbon and nitrogen atoms known as a base.
nucleotide excision repair (NER) A common type of DNA repair system that removes (excises) and repairs a region of the DNA where damage has occurred.
nucleus (plural, **nuclei)** 1. In cell biology, an organelle found in eukaryotic cells that contains most of the cell's genetic material. 2. In chemistry, the region of an atom that contains protons and neutrons. 3. In neurobiology, a group of neuronal cell bodies in the brain that are devoted to a particular function.
nutrient Any substance taken up by a living organism that is needed for survival, growth, development, repair, or reproduction.
nutrition The means of providing nutrients for cell survival.

O

obese According to current National Institutes of Health guidelines, a person having a body mass index (BMI) of 30 kg/m^2 or more.
obligate aerobes Microorganisms that require oxygen.
obligate anaerobes Microorganisms that are poisoned by oxygen.
obligatory mutualism An interaction in which two mutualistic species cannot live without each other.
occipital lobe One of four lobes of the cerebral cortex of the human brain; controls aspects of vision and color recognition.
ocelli Photosensitive organs in some animal species.
octet rule The phenomenon that some atoms are most stable when their outer shell is full with eight electrons.
Okazaki fragments Short segments of DNA synthesized in the lagging strand during DNA replication.
olfaction The sense of smell.
olfactory bulbs Part of the limbic system of the forebrain of vertebrates; the olfactory bulbs carry information about odors to the brain.
oligodendrocytes Glial cells that produce the myelin sheath around neurons in the central nervous system.
oligotrophic The term used to describe aquatic systems that are low in nutrients such as phosphate and combined nitrogen and are consequently low in primary productivity and biomass, but typically high in species diversity.
ommatidium (plural, **ommatidia)** An independent visual unit in the eye of insects that functions as a separate photoreceptor capable of forming an independent image.
omnivore An animal that can survive on plants and animals for food and which typically consumes both.
oncogene A type of mutant gene derived from a proto-oncogene. An oncogene is overactive, thus contributing to uncontrolled cell growth and promoting cancer.
one-gene/one-enzyme hypothesis An early hypothesis by Beadle and Tatum that suggested that one gene encodes one enzyme. It was later modified to the one-gene/one-polypeptide theory.
one-gene/one-polypeptide theory The concept that one structural gene codes for one polypeptide.
oogenesis Gametogenesis in a female animal resulting in the production of an egg cell.
oogonium (plural, **oogonia)** In animals, diploid germ cells that give rise to the female gametes, the eggs.
open circulatory system In animals, a circulatory system in which hemolymph, which is not different than the interstitial fluid, flows throughout the body and is not confined to special vessels.
open complex Also called the transcription bubble; a small bubble-like structure between two DNA strands that occurs during transcription.
open conformation Loosely packed chromatin that can be transcribed into RNA.
operant conditioning A form of behavior modification; a type of associative learning in which an animal's behavior is reinforced by a consequence, either a reward or a punishment.
operator A DNA sequence in bacteria that is recognized by activator or repressor proteins that regulate the level of gene transcription.
operculum A protective flap that covers the gills of a bony fish.
operon An arrangement of two or more genes in bacteria that are under the transcriptional control of a single promoter.
opsin A protein that is a component of visual pigments in the vertebrate eye.
opsonization The process by which an antibody binds to a pathogen and provides a means to link the pathogen with a phagocyte.
optic disc In vertebrates, the point on the retina where the optic nerve leaves the eye.
optic nerve A structure of the vertebrate eye that carries electrical signals to the brain.

optimal foraging The concept that in a given circumstance, an animal seeks to obtain the most energy possible with the least expenditure of energy.
optimality theory The theory that predicts an animal should behave in a way that maximizes the benefits of a behavior minus its costs.
orbital The region surrounding the nucleus of an atom where the probability is high of finding a particular electron.
order In taxonomy, a subdivision of a class.
organ Two or more types of tissue combined to perform a common function.
organelle A subcellular structure or membrane-bound compartment with its own unique structure and function.
organic chemistry The study of carbon-containing molecules.
organic farming The production of crops without the use of commercial inorganic fertilizers, growth substances, and pesticides.
organic molecule A carbon-containing molecule, so named because they are found in living organisms.
organism A living thing that maintains an internal order that is separated from the environment.
organismal ecology The investigation of how adaptations and choices by individuals affect their reproduction and survival.
organismic model A view of the nature of a community that considers it to be equivalent to a superorganism; individuals, populations, and communities have a relationship to each other that resembles the associations found between cells, tissues, and organs.
organizing center A group of cells in a plant shoot meristem that ensures the proper organization of the meristem and preserves the correct number of actively dividing stem cells.
organ of Corti Coiled structure in the vertebrate ear responsible for detecting sound.
organogenesis The developmental stage during which cells and tissues form organs in animal embryos.
organ system Different organs that work together to perform an overall function in an organism.
orientation A mechanism of migration in which animals have the ability to follow a compass bearing and travel in a straight line.
origin of replication A site within a chromosome that serves as a starting point for DNA replication.
ortholog A homologous gene in different species.
osmoconformer An animal whose osmolarity conforms to that of its environment.
osmolarity The solute concentration of a solution of water, expressed as milliosmoles/liter (mOsm/L).
osmoregulator An animal that maintains stable internal salt concentrations and osmolarities, even when living in water with very different osmolarities than its body fluids.
osmosis The movement of water across membranes to balance solute concentrations. Water diffuses from a solution that is hypotonic (lower solute concentration) into a solution that is hypertonic (higher solute concentration).
osmotic adjustment The process by which a plant cell modifies the solute concentration of its cytosol.
osmotic lysis Occurs when a cell in a hypotonic environment takes up so much water that it ruptures.
osmotic pressure The hydrostatic pressure required to stop the net flow of water across a membrane due to osmosis.
osmotroph An organism that relies on osmotrophy (uptake of small organic molecules) as a form of nutrition.
osteichythan A clade that includes all vertebrates with a bony skeleton.
osteomalacia Bone deformation in adults due to inadequate mineral intake or absorption from the intestines.
osteoporosis A disease in which the mineral and organic components of bone are reduced.
otolith Granules of calcium carbonate found in the gelatinous substance that embeds hair cells in the vertebrate ear.
outer bark Protective layers of mostly dead cork cells that cover the outside of woody stems and roots.
outer ear One of the three main compartments of the mammalian ear; consists of the external ear, or pinna, and the auditory canal.
outer segment The highly convoluted plasma membranes found in the rods and cones of the eye.
outgroup In a cladogram, a species or group of species that does not exhibit one or more shared derived characters found in the ingroup.
ovarian cycle The events beginning with the development of an ovarian follicle, followed by release of a secondary oocyte, and concluding with formation and subsequent degeneration of a corpus luteum.
ovary 1. In animals, the female gonad where eggs are formed. 2. In plants, the lowermost portion of the pistil that encloses and protects the ovules.
oviduct A thin tube with undulating fimbriae (finger-like structures) that is connected to the uterus and extends out to the ovary; also called the Fallopian tube.
oviparity Development of an embryo outside the mother, usually in a protective shell or other structure from which the young hatch.
oviparous An animal whose young hatch from eggs laid outside the mother's body.
ovoviparous An animal that retains fertilized eggs covered by a protective sheath or other structure within the body, where the young hatch.
ovoviviparity Development of an embryo involving aspects of both viviparity and oviparity; fertilized eggs covered with a protective sheath are produced and hatch inside the mother's body, but the offspring receive no nourishment from the mother.
ovulation The process by which a mature oocyte is released from an ovary.
ovule In a seed plant, a megaspore-producing megasporangium and enclosing tissues known as integuments.
ovum (plural, **ova**) *See* egg.
oxidation A process that involves the removal of electrons; occurs during the breakdown of small organic molecules.
oxidative fiber A skeletal muscle fiber that contains numerous mitochondria and has a high capacity for oxidative phosphorylation.
oxidative phosphorylation A process during which NADH and $FADH_2$ are oxidized to make more ATP via the phosphorylation of ADP.
oxygen-hemoglobin dissociation curve A curve that represents the relationship between the partial pressure of oxygen and the binding of oxygen to hemoglobin proteins.
oxytocin A hormone secreted by the posterior pituitary gland that stimulates contractions of the smooth muscles in the uterus of a pregnant mammal, facilitating the birth process; after birth, it is important in milk secretion.

P

pacemaker *See* sinoatrial (SA) node.
Pacinian corpuscle Structure located deep beneath the surface of an animal's skin that responds to deep pressure or vibration.
paedomorphosis The retention of juvenile traits in an adult organism.
pair-rule gene A type of segmentation gene; a mutation in this gene may cause alternating segments or parts of segments to be deleted.
paleontologist A scientist who studies fossils.
palisade parenchyma Photosynthetic ground tissue of the plant leaf mesophyll that consists of closely packed, elongate cells adapted to efficiently absorb sunlight.
palmate A type of leaf vein pattern in which veins radiate outward, resembling an open hand.
pancreas In vertebrates, an elongated gland located behind the stomach that secretes digestive enzymes and a fluid rich in bicarbonate ions.
parabronchi In birds, a series of parallel air tubes that make up the lungs and are the regions of gas exchange.
paracrine Refers to a type of cellular communication in which molecules are released into the interstitial fluid and act on nearby cells.
paralogs Homologous genes within a single species.
paraphyletic group A group of organisms that contains a common ancestor and some, but not all, of its descendants.
parapodia Fleshy, footlike structures in the polychaetes that are pushed into the substrate to provide traction during movement.
parasite A predatory organism that feeds off another organism but does not normally kill it.
parasitism A symbiotic association in which one organism feeds off another but does not normally kill it.
parasympathetic division The division of the autonomic nervous system that is involved in maintaining and restoring body functions.
parathyroid hormone (PTH) A hormone that acts on bone to stimulate the activity of cells that dissolve the mineral part of bone.
Parazoa A subgroup of animals lacking specialized tissue types or organs, although they may have several distinct types of cells; the one phylum in this group is the Porifera (sponges).
parenchyma cell A type of plant cell that is thin-walled and alive at maturity.
parenchyma tissue A plant ground tissue that is composed of parenchyma cells.
parental strand The original strand in DNA replication.
parietal lobe One of four lobes of the cerebral cortex of the human brain; receives and interprets sensory input from visual and somatic pathways.
parthenogenesis An asexual process in which an offspring develops from an unfertilized egg.
partial pressure The individual pressure of each gas in the air; the sum of these pressures is known as atmospheric pressure.
particulate inheritance The idea that the determinants of hereditary traits are transmitted intact from one generation to the next.
parturition The birth of an organism.
passive diffusion Diffusion through a membrane without the aid of a transport protein.
passive immunity A type of acquired immunity that confers protection against disease through the direct transfer of antibodies from one individual to another.
passive transport The diffusion of a solute across a membrane in a process that is energetically favorable and does not require an input of energy.
paternal inheritance A pattern in which only the male gamete contributes particular genes to the offspring.
pathogen A microorganism that causes disease symptoms in its host.

pathogen associated molecular pattern (PAMP) Common molecules found in many pathogens that trigger an innate immune response.
pattern formation The process that gives rise to a plant or animal with a particular body structure.
pedal glands Glands in the foot of a rotifer that secrete a sticky substance that aids in attachment to the substrate.
pedicel 1. A flower stalk. 2. A narrow, waistlike point of attachment between the body parts of spiders and some insects.
pedigree analysis An examination of the inheritance of human traits in families.
pedipalps In spiders, a pair of appendages that have various sensory, predatory, or reproductive functions.
peer-review process A procedure in which experts in a particular area evaluate papers submitted to scientific journals.
pelagic zone The open ocean, where the water depth averages 4,000 m and nutrient concentrations are typically low.
penis A male external accessory sex organ found in many animals that is involved in copulation.
pentadactyl limb A limb ending in five digits.
PEP carboxylase An enzyme in C_4 plants that adds CO_2 to phosphoenolpyruvate (PEP) to produce the four-carbon compound oxaloacetate.
pepsin An active enzyme in the stomach that begins the digestion of protein.
peptide bond The covalent bond that links amino acids in a polypeptide.
peptidoglycan A polymer composed of carbohydrates crosslinked with peptides that is an important component of the cell walls of most bacteria.
peptidyl site (P site) One of three sites for tRNA binding in the ribosome during translation; the other two are the aminoacyl site (A site) and the exit site (E site). The P site holds the tRNA carrying the growing polypeptide chain.
peptidyl transfer reaction During translation, the transfer of the polypeptide from the tRNA in the P site to the amino acid at the A site.
per capita growth rate The per capita birth rate minus the per capita death rate; the rate that determines how populations grow over any time period.
perception An awareness of the sensations that are experienced.
perennial A plant that lives for more than 2 years, often producing seeds each year after it reaches reproductive maturity.
perfect flower A flower that has both stamens and carpels.
perianth The term that refers to flower petals and sepals collectively.
pericarp The wall of a plant's fruit.
pericycle A cylinder of plant tissue having cell division (meristematic) capacity that encloses the root vascular tissue.
periderm The outer layers of a woody stem, composed of cork cambium, layers of cork tissue produced by the cork cambium, and associated parenchyma cells, together forming outer bark.
peripheral membrane protein A protein that is noncovalently bound to regions of integral membrane proteins that project out from the membrane, or they are noncovalently bound to the polar head groups of phospholipids.
peripheral nervous system (PNS) In vertebrates, all nerves and ganglia outside the brain and spinal cord.
peripheral zone The area of a plant shoot meristem that contains dividing cells that will eventually differentiate into plant structures.
periphyton Communities of microorganisms that are attached by mucilage to underwater surfaces such as rocks, sand, and plants.
peristalsis In animals, the rhythmic, spontaneous waves of muscle contractions that propel food through the digestive system.
peritubular capillary A capillary near the junction of the cortex and medulla that surrounds the nephron of the mammalian kidney.
permafrost A layer of permanently frozen soil found in tundra.
peroxisome A relatively small organelle found in all eukaryotic cells that catalyzes detoxifying reactions.
personalized medicine A medical practice in which information about a patient's genotype is used to individualize their medical care.
petal A flower organ that usually serves to attract insects or other animals for pollen transport.
petiole A stalk that connects a leaf to the stem of a plant.
P generation The parental generation in a genetic cross.
pH The mathematical expression of a solution's hydrogen ion (H^+) concentration, defined as the negative logarithm to the base 10 of the H^+ concentration.
phage *See* bacteriophage.
phagocyte A cell capable of phagocytosis; phagocytes provide nonspecific defense against pathogens that enter the body.
phagocytic vacuole A vacuole that functions in the degradation of food particles or bacteria; also called a food vacuole.
phagocytosis A form of endocytosis that involves the formation of a membrane vesicle, called a phagocytic vacuole, which engulfs a particle such as a bacterium.
phagotroph An organism that specializes in phagotrophy (particle feeding) by means of phagocytosis as a form of nutrition.
pharyngeal slit A defining characteristic of all chordate embryos. In early-diverging chordates, pharyngeal slits develop into a filter-feeding device, and in some advanced chordates, they form gills.
pharynx A portion of the vertebrate alimentary canal; also known as the throat.
phenolics A group of secondary metabolites that contain a benzene ring covalently linked to a single hydroxyl group. Includes tannins, lignins, and flavonoids.
phenotype The characteristics of an organism that are the result of the expression of its genes.
pheromone A powerful chemical attractant used to manipulate the behavior of others.
phloem A specialized conducting tissue in a plant's stem.
phloem loading The process of conveying sugars to sieve-tube elements for long-distance transport.
phoresy A form of commensalism in which individuals of one species use individuals of a second species for transportation.
phosphodiesterase An enzyme that breaks down cAMP into AMP.
phosphodiester linkage Refers to a double linkage (two phosphoester bonds) that holds together adjacent nucleotides in DNA and RNA strands.
phospholipid A class of lipids that are similar in structure to triglycerides, but the third hydroxyl group of glycerol is linked to a phosphate group instead of a fatty acid; a key component of biological membranes.
phospholipid bilayer The basic framework of the cellular membrane, consisting of two layers of lipids.
phosphorylation The attachment of a phosphate to a molecule.
photic zone A fairly narrow zone close to the surface of an aquatic environment, where light is sufficient to allow photosynthesis to exceed respiration.
photoautotroph An organism that uses the energy from light to make organic molecules from inorganic sources.
photoheterotroph An organism that is able to use light energy to generate ATP but must take in organic compounds from the environment.
photon A discrete particle that makes up light. A photon is massless and travels in a wavelike pattern.
photoperiodism A plant's ability to measure and respond to amounts of light; used as a way of detecting seasonal change.
photopsin A protein in the cone cell of an animal's eye; detects color vision.
photoreceptor A specialized cell in an animal that responds to visible light energy; in plants, molecules that respond to light.
photorespiration The metabolic process occurring in C_3 plants that occurs when the enzyme rubisco combines with O_2 instead of CO_2 and produces only one molecule of 3PG instead of two, thereby reducing photosynthetic efficiency.
photosynthesis The process whereby light energy is captured by plant, algal, or bacterial cells and is used to synthesize organic molecules from CO_2 and H_2O (or H_2S).
photosystem I (PSI) A distinct complex of proteins and pigment molecules in chloroplasts that absorbs light during the light reactions of photosynthesis.
photosystem II (PSII) A distinct complex of proteins and pigment molecules in chloroplasts that generates oxygen from water during the light reactions of photosynthesis.
phototropin The main blue-light sensor involved in phototropism in plants.
phototropism The tendency of a plant to grow toward a light source.
phylogenetic tree A diagram that describes a phylogeny; such a tree is a hypothesis of the evolutionary relationships among various species, based on the information available to and gathered by systematists.
phylogeny The evolutionary history of a species or group of species.
phylum (plural, **phyla**) In taxonomy, a subdivision of a kingdom.
physical mutagen A physical agent, such as ultraviolet light, that causes mutations.
physiological ecology A subdiscipline of organismal ecology that investigates how organisms are physiologically adapted to their environment and how the environment impacts the distribution of species.
phytochrome A red and far-red-light receptor in plants.
phytoplankton Microscopic photosynthetic protists that float in the water column or actively move through water.
phytoremediation The process of removing harmful metals from soils by growing hyperaccumulator plants on metal-contaminated soils, then harvesting and burning the plants to ashes for disposal and/or metal recovery.
pigment A molecule that can absorb light energy.
pili (singular, **pilus**) Threadlike surface appendages that allow bacteria to attach to each other during conjugation or to move across surfaces.
piloting A mechanism of migration in which an animal moves from one familiar landmark to the next.
pinnate A type of leaf vein pattern in which veins appear feather-like.
pinocytosis A form of endocytosis that involves the formation of membrane vesicles from the plasma membrane as a way for cells to internalize the extracellular fluid.
pistil A flower structure that may consist of a single carpel or multiple, fused carpels and is differentiated into stigma, style, and ovary.

pit A thin-walled circular area in a plant cell wall where secondary wall materials such as lignin are absent and through which water moves.
pitch The tone of a sound wave that depends on its length and frequency.
pituitary giant A person who has a tumor of the GH-secreting cells of the anterior pituitary gland and thus produces excess GH during childhood and, if untreated, during adulthood; the person can grow very tall before growth ceases after puberty.
pituitary gland A multilobed endocrine gland sitting directly below the hypothalamus of the brain.
placenta A structure through which humans and other eutherian mammals retain and nourish their young within the uterus via the transfer of nutrients and gases.
placental transfer tissue In plants, a nutritive tissue that aids in the transfer of nutrients from maternal parent to embryo.
plant A multicellular eukaryotic organism that is photosynthetic, generally lives on land, and is adapted in many ways to cope with the environmental stresses of life on land.
Plantae A eukaryotic kingdom of the domain Eukarya.
plant tissue culture A laboratory process to produce thousands of identical plants having the same desirable characteristics.
plaques 1. Deposits of lipids, fibrous tissue, and smooth muscle cells that may develop inside arterial walls. 2. A bacterial biofilm that may form on the surfaces of teeth.
plasma The fluid part of blood that contains water and dissolved solutes.
plasma cell A cell that synthesizes and secretes antibodies.
plasma membrane The biomembrane that separates the internal contents of a cell from its external environment.
plasmid A small circular piece of DNA found naturally in many strains of bacteria and occasionally in eukaryotic cells; can be used as a vector in cloning experiments.
plasmodesma (plural, **plasmodesmata**) A membrane-lined, ER-containing channel that connects the cytoplasm of adjacent plant cells.
plasmogamy The fusion of the cytoplasm between two gametes.
plasmolysis The shrinkage of algal or plant cytoplasm that occurs when water leaves the cell by osmosis, with the result that the plasma membrane no longer presses on the cell wall.
plastid A general name given to organelles found in plant and algal cells that are bound by two membranes and contain DNA and large amounts of either chlorophyll (in chloroplasts), carotenoids (in chromoplasts), or starch (in amyloplasts).
platelets Cell fragments in the blood of mammals that play a crucial role in the formation of blood clots.
pleiotropy The phenomenon in which a mutation in a single gene can have multiple effects on an individual's phenotype.
pleural sac A double layer of moist sheathlike membranes that encases each lung.
pluripotent Refers to the ability of embryonic stem cells to differentiate into almost every cell type of the body.
point mutation A mutation that affects only a single base pair within DNA or that involves the addition or deletion of a single base pair to a DNA sequence.
polar cell The highest latitude cell in the three-cell model of atmospheric circulation.
polar covalent bond A covalent bond between two atoms that have different electronegativities; the shared electrons are closer to the atom of higher electronegativity than the atom of lower electronegativity. This distribution of electrons around the atoms creates a polarity, or difference in electric charge, across the molecule.
polarized 1. In cell biology, refers to cells that have different sides, such as the apical and basal sides of epithelial cells. 2. In neuroscience, refers to the electrical gradient across a neuron's plasma membrane.
polar molecule A molecule containing significant numbers of polar bonds.
polar transport The process whereby auxin flows primarily downward in shoots.
pole A structure of the spindle apparatus defined by each centrosome.
pollen In seed plants, tiny male gametophytes enclosed by sporopollenin-containing microspore walls.
pollen coat A layer of material that covers the sporopollenin-rich pollen wall.
pollen grain The immature male gametophyte of a seed plant.
pollen tube In seed plants, a long, thin tube produced by a pollen grain that delivers sperm to the ovule.
pollen wall A tough, sporopollenin wall at the surface of a pollen grain.
pollination The process in which pollen grains are transported to an angiosperm flower or a gymnosperm cone primarily by means of wind or animal pollinators.
pollination syndromes The pattern of coevolved traits between particular types of flowers and their specific pollinators.
pollinator An animal that carries pollen between angiosperm flowers or cones of gymnosperms.
polyandry A mating system in which one female mates with several males, but males mate with only one female.
poly A tail A string of adenine nucleotides at the 3′ end of most mature mRNAs in eukaryotes.
polycistronic mRNA An mRNA that contains the coding sequences for two or more structural genes.
polycythemia A condition of increased hemoglobin due to increased hematocrit.
polygenic A trait in which several or many genes contribute to the outcome of the trait.
polygyny A mating system in which one male mates with several females in a single breeding season, but females mate with only one male.
polyketides A group of secondary metabolites produced by diverse organisms. Examples include streptomycin, erythromycin, and tetracycline.
polymer A large molecule formed by linking many smaller molecules called monomers.
polymerase chain reaction (PCR) A technique to make many copies of a gene in vitro; primers are used that flank the region of DNA to be amplified.
polymorphic gene A gene that commonly exists as two or more alleles in a population.
polymorphism The phenomenon that many traits or genes may display variation within a population.
polyp A type of cnidarian body form that is sessile and occurs mouth up.
polypeptide A linear sequence of amino acids; the term denotes structure.
polyphagous Parasites that feed on many host species.
polyphyletic group A group of organisms that consists of members of several evolutionary lines and does not include the most recent common ancestor of the included lineages.
polyploid An organism that has three or more sets of chromosomes.
polyploidy In an organism, the state of having three or more sets of chromosomes.
polysaccharide Many monosaccharides linked to form long polymers.
pons The part of the vertebrate hindbrain, along with the cerebellum, responsible for monitoring and coordinating body movements.
population A group of individuals of the same species that occupy the same environment and can interbreed with one another.
population ecology The study of how populations grow and what factors promote or limit growth.
population genetics The study of genes and genotypes in a population.
portal vein A vein that not only collects blood from capillaries—like all veins—but also forms another set of capillaries, as opposed to returning the blood directly to the heart.
positional information Molecules that are provided to a cell that allow it to determine its position relative to other cells.
positive control Transcriptional regulation by activator proteins.
positive feedback loop In animals, the acceleration of a process, leading to what is sometimes called an explosive system.
positive pressure filling The method by which amphibians ventilate their lungs. The animals gulp air and force it under pressure into the lungs, as if inflating a balloon.
postabsorptive state One of two alternating phases in the utilization of nutrients; occurs when the gastrointestinal tract is empty of nutrients and the body's own stores must supply energy. The other phase is the absorptive state.
postanal tail A defining characteristic of all chordate embryos; consists of a tail of variable length that extends posterior to the anal opening.
posterior Refers to the rear (tail-end) of an animal.
postsynaptic cell The cell that receives the electrical or chemical signal sent from a neuron.
post-translational covalent modification A process of changing the structure of a protein, usually by covalently attaching functional groups; this process greatly increases the diversity of the proteome.
post-translational sorting The uptake of proteins into the nucleus, mitochondria, chloroplasts, or peroxisomes that occurs after the protein is completely made in the cytosol (that is, completely translated).
postzygotic isolating mechanism A mechanism that prevents interbreeding by blocking the development of a viable and fertile individual after fertilization has taken place.
potential energy The stored energy that a substance possesses due to its structure or location.
power stroke In muscle, a conformation change in the myosin cross-bridge that results in binding between myosin and actin and the movement of the actin filament.
P protein Phloem protein; the proteinaceous material used by plant phloem as a response to wounding.
prebiotic soup The medium formed by the slow accumulation of organic molecules in the early oceans over a long period of time prior to the existence of life.
predation An interaction in which the action of a predator results in the death of its prey.
predator An animal that kills its prey.
prediction An expected outcome based on a hypothesis that can be shown to be correct or incorrect through observation or experimentation.
pregnancy The time during which a developing embryo and fetus grows within the uterus of the mother. The period of pregnancy is also known as gestation.
preinitiation complex The structure of the completed assembly of RNA polymerase II and GTFs at the TATA box prior to transcription of eukaryotic structural genes.

pre-mRNA In eukaryotes, the mRNA transcript prior to any processing.

pressure-flow hypothesis Explains sugar translocation in plants as a process driven by differences in turgor pressure between cells of a sugar source, where sugar is produced, and cells of a sugar sink, where sugar is consumed.

pressure potential (P) The component of water potential due to hydrostatic pressure.

presynaptic cell The neuron that sends an electrical or chemical signal to another cell.

prezygotic isolating mechanism A mechanism that stops interbreeding by preventing the formation of a zygote.

primary active transport A type of transport that involves pumps that directly use energy to transport a solute against a gradient.

primary cell wall In plants, a relatively thin and flexible cell wall that is synthesized first between two newly made daughter cells.

primary consumer An organism that obtains its food by eating primary producers; also called a herbivore.

primary electron acceptor The molecule to which a high-energy electron from an excited pigment molecule such as P680* is transferred during photosynthesis.

primary endosymbiosis The process by which a eukaryotic host cell acquires prokaryotic endosymbionts. Mitochondria and the plastids of green and red algae are examples of organelles that originated with primary endosymbiosis.

primary growth Plant growth that occurs from primary meristems and produces primary tissues and organs of diverse types.

primary immune response The response to an initial exposure to an antigen.

primary meristem A meristematic tissue that increases plant length and produces new organs.

primary metabolism The synthesis and breakdown of molecules and macromolecules that are found in all forms of life and are essential for cell structure and function.

primary oocyte In animals, a cell that undergoes meiosis to begin the process of egg production.

primary plastid A plastid that originated from a prokaryote as the result of primary endosymbiosis.

primary production Production by autotrophs, normally green plants.

primary spermatocyte In animals, a cell that undergoes meiosis to begin the process of sperm production.

primary structure The linear sequence of amino acids of a polypeptide; one of four levels of protein structure.

primary succession Succession on newly exposed sites that were not previously occupied by soil and vegetation.

primary vascular tissue Plant tissue composed of primary xylem and phloem, which is the conducting tissue of nonwoody plants.

primer A short segment of RNA, typically 10 to 12 nucleotides in length, that is needed to begin DNA replication.

primordial germ cells (PGCs) In animals, the embryonic cells that eventually give rise to gametes.

principle of parsimony The concept that the preferred hypothesis is the one that is the simplest.

principle of species individuality A view of the nature of a community in which each species is distributed according to its physiological needs and population dynamics; most communities intergrade continuously, and competition does not create distinct vegetational zones.

prion An infectious protein that causes disease by inducing the abnormal folding of other protein molecules.

probability The chance that an event will have a particular outcome.

proboscis The coiled tongue of a butterfly or moth, which can be uncoiled, enabling it to drink nectar from flowers.

procambium In plants, a type of primary tissue meristem that produces vascular tissue.

producer An organism that synthesizes the organic compounds used by other organisms for food.

product The end result of a chemical reaction.

production efficiency The percentage of energy assimilated by an organism that becomes incorporated into new biomass.

productivity hypothesis The proposal that greater production by plants results in greater overall species richness.

product rule The probability that two or more independent events will occur is equal to the product of their individual probabilities.

progesterone A hormone secreted by the female ovaries that plays a key role in pregnancy.

progymnosperms An extinct group of plants having wood but not seeds, which evolved before the gymnosperms.

prokaryote One of the two categories into which all forms of life can be placed. Prokaryotes lack a nucleus and include bacteria and archaea.

prokaryotic Refers to organisms having cells lacking a membrane-enclosed nucleus and cell compartmentalization; includes all members of the domains Bacteria and Archaea.

prometaphase The phase of mitosis during which the mitotic spindle is completely formed.

promiscuous In ecology, a term for animals that have different sexual mates every year or breeding season.

promoter The site in the DNA where transcription begins.

proofreading The ability of DNA polymerase to identify a mismatched nucleotide and remove it from the daughter strand.

prophage Refers to the DNA of a phage that has become integrated into a bacterial chromosome.

prophase The phase of mitosis during which the chromosomes condense and the nuclear membrane begins to vesiculate.

proplastid Unspecialized structures that form plastids.

prostate gland A structure in the male reproductive system that secretes a thin fluid that protects sperm once they are deposited within the female reproductive tract.

prosthetic group Small molecules that are permanently attached to the surface of an enzyme and aid in catalysis.

protandrous Describes an animal that is born male but that may become phenotypically female under certain conditions.

protease An enzyme that cuts proteins into smaller polypeptides.

proteasome A molecular machine that is the primary pathway for protein degradation in archaea and eukaryotic cells.

protein A functional unit composed of one or more polypeptides. Each polypeptide is composed of a linear sequence of amino acids.

protein kinase An enzyme that transfers phosphate groups from ATP to a protein.

protein kinase cascade The sequential activation of multiple protein kinases.

protein phosphatase An enzyme responsible for removing phosphate groups from proteins.

protein-protein interactions The specific interactions between proteins that occur during many critical cellular processes.

protein subunit An individual polypeptide within a functional protein; most functional proteins are composed of two or more polypeptides.

proteoglycan A glycosaminoglycan in the extracellular matrix linked to a core protein.

proteolysis A processing event within a cell in which enzymes called proteases cut proteins into smaller polypeptides.

proteome The complete complement of proteins that a cell or organism can make.

proteomics Techniques used to identify and study groups of proteins.

prothoracicotropic hormone (PTTH) A hormone produced in certain invertebrates that stimulates a pair of endocrine glands called the prothoracic glands.

protist A eukaryotic organism that is not a member of the animal, plant, or fungal kingdoms; lives in moist habitats and is typically microscopic in size.

Protista Formerly a eukaryotic kingdom. Protists are now placed into seven eukaryotic supergroups.

protobiont The term used to describe the first nonliving structures that evolved into living cells.

protoderm In plants, a type of primary tissue meristem that generates the outermost dermal tissue.

protogynous Describes an hermaphroditic animal born female but which is capable of assuming a male phenotype at some point in its life history.

proton A positively charged particle found in the nucleus of an atom. The number of protons in an atom is called the atomic number and defines each type of element.

protonephridia Simple excretory organs found in flatworms that are used to filter out wastes and excess water.

proton-motive force *See* H^+ electrochemical gradient.

proto-oncogene A normal gene that, if mutated, can become an oncogene.

protostome An animal whose development exhibits spiral determinate cleavage and in which the blastopore becomes the mouth; includes mollusks, annelid worms, and arthropods.

protozoa A term commonly used to describe diverse heterotrophic protists.

proventriculus The glandular portion of the stomach of a bird.

provirus Refers to viral DNA that has become incorporated into a eukaryotic chromosome.

proximal tubule The segment of the tubule of the nephron in the kidney that drains Bowman's capsule.

proximate cause A specific genetic and physiological mechanism of behavior.

pseudocoelomate An animal with a pseudocoelom.

P site *See* peptidyl site.

pteridophytes A phylum of vascular plants having euphylls, but not seeds; Pteridophyta.

pulmocutaneous circulation The routing of blood from the heart to the gas exchange organs (lungs and skin) of frogs and some other amphibians.

pulmonary circulation The pumping of blood from the right side of the heart to the lungs to pick up oxygen from the atmosphere and release carbon dioxide.

pulmonary hypertension A condition that usually results from a diseased or damaged left ventricle that fails to pump out the usual amount of blood with each beat of the heart. This causes blood to back up in the pulmonary vessels, raising their pressure.

pulmonary trunk A major artery leaving the heart of some air-breathing vertebrates including humans that splits into the left and right pulmonary arteries and brings blood to the lungs.

pulse-chase experiment A procedure in which researchers administer a pulse of radioactively labeled materials to cells so that they make radioactive products. This is followed by the addition of nonlabeled materials called a chase.

pump A transporter that directly couples its conformational changes to an energy source, such as ATP hydrolysis.

punctuated equilibrium A concept that suggests that the tempo of evolution is more sporadic than gradual. Species rapidly evolve into new species followed by long periods of equilibrium with little evolutionary change.
Punnett square A common method for predicting the outcome of simple genetic crosses.
pupa A developmental stage in some insects that undergo metamorphosis; occurs between the larval and adult stages.
pupil A small opening in the eye of a vertebrate that transmits different patterns of light emitted from images in the animal's field of view.
purine The bases adenine (A) and guanine (G), with double rings of carbon and nitrogen atoms.
pyramid of biomass A measure of trophic-level transfer efficiency in which the organisms at each trophic level are weighed.
pyramid of energy A measure of trophic-level transfer efficiency in which rates of energy production are used rather than biomass.
pyramid of numbers An expression of trophic-level transfer efficiency in which the number of individuals decreases at each trophic level, with a huge number of individuals at the base and fewer individuals at the top.
pyrimidine The bases thymine (T), cytosine (C), and uracil (U) with a single ring of carbon and nitrogen atoms.

Q

quadrat A sampling device used by plant ecologists consisting of a square frame that often encloses 0.25 m^2.
quantitative trait A trait that shows continuous variation over a range of phenotypes.
quaternary structure The association of two or more polypeptides to form a protein; one of four levels of protein structure.
quorum sensing A mechanism by which prokaryotic cells are able to communicate by chemical means when they reach a critical population size.

R

radial cleavage A mechanism of animal development in which the cleavage planes are either parallel or perpendicular to the vertical axis of the embryo.
radial loop domain A loop of chromatin, often 25,000 to 200,000 base pairs in size, that is anchored to the nuclear matrix.
radial pattern A characteristic of the body pattern of plants.
radial symmetry 1. In plants, an architectural feature in which embryos display a cylindrical shape, which is retained in the stems and roots of seedlings and mature plants. In addition, new leaves or flower parts are produced in circular whorls, or spirals, around shoot tips. 2. In animals, an architectural feature in which the body can be divided into symmetrical halves by many different longitudinal planes along a central axis.
Radiata Radially symmetric animals; includes cnidarians and ctenophores.
radiation The emission of electromagnetic waves by the surfaces of objects; a method of heat exchange in animals.
radicle An embryonic root, which extends from the plant hypocotyl.
radioisotope An isotope found in nature that is inherently unstable and usually does not exist for long periods of time. Such isotopes decay and emit energy in the form of radiation.
radioisotope dating A common way to estimate the age of a fossil by analyzing the elemental isotopes within the accompanying rock.
radula A unique, protrusible, tonguelike organ in a mollusk that has many teeth and is used to eat plants, scrape food particles off of rocks, or bore into shells of other species.
rain shadow An area on the side of a mountain that is sheltered from the wind and experiences less precipitation.
ram ventilation A mechanism used by fishes to ventilate their gills; fishes swim or face upstream with their mouths open, allowing water to enter into their buccal cavity and across their gills.
random The rarest pattern of dispersion within a population, in which the location of individuals lacks a pattern.
random sampling error The deviation between the observed and the expected outcomes.
rate-limiting step The slowest step in a pathway.
ray-finned fishes The Actinopterygii, which includes all bony fishes except the coelacanths and lungfishes.
reabsorption In the production of urine, the process in which useful solutes in the filtrate are recaptured and transported back into the body fluids of an animal.
reactant A substance that participates in a chemical reaction and becomes changed by that reaction.
realized niche The actual range of an organism in nature.
reading frame Refers to the way in which codons are read during translation, in groups of three bases beginning with the start codon.
receptacle The enlarged region at the tip of a flower peduncle to which flower parts are attached.
receptor 1. A cellular protein that recognizes a signaling molecule. 2. A structure capable of detecting changes in the environment of an animal, such as a touch receptor.
receptor-mediated endocytosis A common form of endocytosis in which a receptor is specific for a given cargo.
receptor potential The membrane potential in a sensory receptor cell of an animal.
receptor tyrosine kinase A type of enzyme-linked receptor found in animal cells that can attach phosphate groups onto tyrosines that are found in the receptor itself or in other cellular proteins.
recessive A term that describes a trait that is masked by the presence of a dominant trait in a heterozygote.
reciprocal translocation A type of mutation in which two different types of chromosomes exchange pieces, thereby producing two abnormal chromosomes carrying translocations.
recombinant An offspring that has a different combination of traits from the parental generation.
recombinant DNA technology The use of laboratory techniques to isolate and manipulate fragments of DNA.
recombinant vector A vector containing a piece of chromosomal DNA.
recombination frequency The frequency of crossing over between two genes.
rectum The last segment of the large intestine of animals that empties into the anus, the posterior opening of the alimentary canal to the external environment.
red blood cell *See* erythrocyte.
redox reaction A type of reaction in which an electron that is removed during the oxidation of an atom or molecule is transferred to another atom or molecule, which becomes reduced; short for a reduction-oxidation reaction.
reduction A process that involves the addition of electrons to an atom or molecule.
reductionism An approach that involves reducing complex systems to simpler components as a way to understand how the system works. In biology, reductionists study the parts of a cell or organism as individual units.
redundancy hypothesis A biodiversity proposal that is an alternative to the rivet hypothesis. In this model, most species are said to be redundant because they could simply be eliminated or replaced by others with no effect.
reflex arc A simple circuit that allows an organism to respond rapidly to inputs from sensory neurons and consists of only a few neurons.
regeneration A form of asexual reproduction in which a complete organism forms from small fragments of its body.
regulatory element In eukaryotes, a DNA sequence that is recognized by regulatory transcription factors and regulates the expression of genes.
regulatory gene A gene whose function is to regulate the expression of other genes.
regulatory sequence In the regulation of transcription, a DNA sequence that functions as a binding site for genetic regulatory proteins. Regulatory sequences control whether a gene is turned on or off.
regulatory transcription factor A protein that binds to DNA in the vicinity of a promoter and affects the rate of transcription of one or more nearby genes.
relative abundance The frequency of occurrence of species in a community.
relative refractory period The period near the end of an action potential when voltage-gated potassium channels are still open; during this time a new action potential can be generated if a stimulus is sufficiently strong to raise the membrane potential to threshold.
relative water content (RWC) The property often used to gauge the water content of a plant organ or entire plant; RWC integrates the water potential of all cells within an organ or plant and is thus a measure of relative turgidity.
release factor A protein that recognizes a stop codon in the termination stage of translation and promotes the termination of translation.
renal corpuscle A filtering component in the nephron of the kidney.
repetitive sequence Short DNA sequences that are present in many copies in a genome.
replica plating A technique in which a replica of bacterial colonies is transferred from one petri plate to a new petri plate.
replication 1. The copying of DNA strands. 2. The performing of experiments several or many times.
replication fork The area where two DNA strands have separated and new strands are being synthesized.
repressible operon In this type of operon, a small effector molecule inhibits transcription.
repressor A transcription factor that binds to DNA and inhibits transcription.
reproduction The generation of offspring by sexual or asexual means.
reproductive cloning The cloning of a multicellular organism, such as a plant or animal.
reproductive isolating mechanisms Mechanisms that prevent interbreeding between different species.
reproductive isolation Refers to the concept that a species cannot successfully interbreed with other species.
reproductive success The likelihood of contributing fertile offspring to the next generation.
resistance (R) The tendency of blood vessels to slow down the flow of blood through their lumens.
resistance gene (*R* gene) A plant gene that has evolved as part of a defense system in response to pathogen attack.

resolution In microscopy, the ability to observe two adjacent objects as distinct from one another; a measure of the clarity of an image.
resonance energy transfer The process by which energy (not an electron itself) can be transferred to adjacent pigment molecules during photosynthesis.
resource partitioning The differentiation of niches, both in space and time, that enables similar species to coexist in a community.
respiration Metabolic reactions that a cell uses to get energy from food molecules and release waste products.
respiratory centers Several regions of the brainstem in vertebrates that initiate expansion of the lungs.
respiratory chain *See* electron transport chain.
respiratory distress syndrome of the newborn The situation in which a human baby is born prematurely, before sufficient surfactant is produced in the lungs, causing the collapse of many alveoli.
respiratory pigment A large protein that contains one or more metal atoms that bind to oxygen.
respiratory system All components of the body that contribute to the exchange of gas between the external environment and the blood; in mammals, includes the nose, mouth, airways, and lungs and the muscles and connective tissues that encase these structures within the thoracic (chest) cavity.
resting potential The difference in charges across the plasma membrane in an unstimulated neuron.
restoration ecology The full or partial repair or replacement of biological habitats and/or their populations that have been damaged.
rest-or-digest The response of vertebrates to situations associated with nonstressful states, such as feeding; mediated by the parasympathetic branch of the autonomic nervous system.
restriction enzyme An enzyme that recognizes particular DNA sequences and cleaves the DNA backbone at two sites.
restriction point A point in the cell cycle in which a cell has become committed to divide.
restriction sites The base sequences recognized by restriction enzymes.
reticular formation An array of nuclei in the brainstem of vertebrates that plays a major role in controlling states such as sleep and arousal.
retina A sheetlike layer of photoreceptors at the back of the vertebrate eye.
retinal A derivative of vitamin A that is capable of absorbing light energy; a component of visual pigments in the vertebrate eye.
retroelement A type of transposable element that moves via an RNA intermediate.
retrovirus An RNA virus that utilizes reverse transcription to produce viral DNA that can be integrated into the host cell genome.
reverse transcriptase A viral enzyme that catalyzes the synthesis of viral DNA starting with viral RNA as a template.
rhizobia The collective term for proteobacteria involved in nitrogen-fixation symbioses with plants.
rhodopsin The visual pigment in the rods of the vertebrate eye.
ribonucleic acid (RNA) One of two classes of nucleic acids; the other is deoxyribonucleic acid (DNA). RNA consists of a single strand of nucleotides.
ribonucleoprotein A complex between an RNA molecule and a protein.
ribose A five-carbon sugar found in RNA.
ribosomal RNA (rRNA) An RNA that forms part of ribosomes, which provide the site where translation occurs.
ribosome A structure composed of proteins and rRNA that provides the site where polypeptide synthesis occurs.
ribozyme A biological catalyst that is an RNA molecule.
rickets A condition in children characterized by bone deformations due to inadequate mineral intake or malabsorption in the intestines.
right-left axis In bilateral animals, one of the three axes along which the adult body pattern is organized; the others are the dorsoventral axis and the anteroposterior axis.
ring canal A central disc in the water vascular system of echinoderms.
RNA *See* ribonucleic acid.
RNA-induced silencing complex (RISC) A complex consisting of miRNA or siRNA and proteins; mediates RNA interference.
RNA interference (RNAi) Refers to a type of mRNA silencing; miRNA or siRNA interferes with the proper expression of an mRNA.
RNA polymerase The enzyme that synthesizes strands of RNA during gene transcription.
RNA processing A step in gene expression between transcription and translation in eukaryotes; the RNA transcript, termed pre-mRNA, is modified in ways that make it a functionally active mRNA.
RNase An enzyme that digests RNA.
RNA world A hypothetical period on primitive Earth when both the information needed for life and the enzymatic activity of living cells were contained solely in RNA molecules.
rod Type of photoreceptor found in the vertebrate eye; they are very sensitive to low-intensity light but do not readily discriminate different colors. Rods are utilized mostly at night, and they send signals to the brain that generate a black-and-white visual image.
root A plant organ that provides anchorage in the soil and also fosters efficient uptake of water and minerals.
root apical meristem (RAM) The region of rapidly dividing cells at plant root tips.
root hair A specialized, long, thin root epidermal cell that functions to absorb water and minerals, usually from soil.
root meristem The collection of cells at the root tip that generate all of the tissues of a plant root.
root pressure Osmotic pressure within roots that causes water to rise for some distance through a plant stem, under conditions of high soil moisture or low transpiration.
root-shoot axis The general body pattern of plants in which the root grows downward and the shoot grows upward.
root system The collection of roots and root branches produced by root apical meristems.
rough endoplasmic reticulum (rough ER) The part of the ER that is studded with ribosomes; this region plays a key role in the initial synthesis and sorting of proteins that are destined for the ER, Golgi apparatus, lysosomes, vacuoles, plasma membrane, or outside of the cell.
rRNA *See* ribosomal RNA.
***r*-selected species** A type of life history strategy, where species have a high rate of per capita population growth but poor competitive ability.
rubisco The enzyme that catalyzes the first step in the Calvin cycle in which CO_2 is incorporated into an organic molecule.
Ruffini corpuscle Tactile (touch) receptors in the skin of mammals that respond to deep pressure and vibration.
ruminants Animals such as sheep, goats, llamas, and cows that have complex stomachs consisting of several chambers.

S

saltatory conduction The conduction of an action potential along an axon in which the action potential is regenerated at each node of Ranvier instead of along the entire length of the axon.
sarcoma A tumor of connective tissue such as bone or cartilage.
sarcomere One complete unit of the repeating pattern of thick and thin filaments within a myofibril.
sarcoplasmic reticulum A cellular organelle that provides a muscle fiber's source of the calcium involved in muscle contraction; a specialized form of the endoplasmic reticulum.
satiety A feeling of fullness.
saturated fatty acid A fatty acid in which all the carbons are linked by single covalent bonds.
scanning electron microscopy (SEM) A type of microscopy that utilizes an electron beam to produce an image of the three-dimensional surface of biological samples.
scavenger An animal that eats the remains of dead animals.
Schwann cells The glial cells that form myelin on axons that travel outside the brain and spinal cord.
science In biology, the observation, identification, experimental investigation, and theoretical explanation of natural phenomena.
scientific method A series of steps to test the validity of a hypothesis. This approach often involves a comparison between control and experimental groups.
sclera The white of the vertebrate eye; a strong outer sheath that in the front is continuous with a thin, clear layer known as the cornea.
sclereid Star- or stone-shaped plant cells having tough, lignified cell walls.
sclerenchyma tissue A rigid plant ground tissue composed of tough-walled fibers and sclereids.
secondary active transport A type of membrane transport that involves the utilization of a pre-existing gradient to drive the active transport of another solute.
secondary cell wall A thick rigid plant cell wall that is synthesized and deposited between the plasma membrane and the primary cell wall after a plant cell matures and has stopped increasing in size.
secondary consumer An organism that eats primary consumers; also called a carnivore.
secondary endosymbiosis A process that occurs when a eukaryotic host cell acquires a eukaryotic endosymbiont having a primary plastid.
secondary growth Plant growth that occurs from secondary meristems and increases the girth of woody plant stems and roots.
secondary immune response An immediate and heightened production of additional specific antibodies against the particular antigen that previously elicited a primary immune response.
secondary meristem A meristem in woody plants forming a ring of actively dividing cells that encircle the stem.
secondary metabolism The synthesis of chemicals that are not essential for cell structure and growth and are usually not required for cell survival but are advantageous to the organism.
secondary metabolite Molecules that are produced by secondary metabolism.
secondary oocyte In animals, the large haploid cell that is produced when a primary oocyte undergoes meiosis I during oogenesis.
secondary phloem The inner bark of a woody plant.
secondary plastid A plastid that has originated by the endosymbiotic incorporation of a eukaryotic cell containing a primary plastid into a eukaryotic host cell.
secondary production The measure of production of heterotrophs and decomposers.
secondary spermatocytes In animals, the haploid cells produced when a primary spermatocyte undergoes meiosis I during spermatogenesis.

secondary structure The bending or twisting of proteins into α helices or β sheets; one of four levels of protein structure.
secondary succession Succession on a site that has previously supported life but has undergone a disturbance.
secondary xylem In plants, a type of secondary vascular tissue that is also known as wood.
second law of thermodynamics States that the transfer of energy or the transformation of energy from one form to another increases the entropy, or degree of disorder, of a system.
second messengers Small molecules or ions that relay signals inside the cell.
secretion 1. The export of a substance from a cell. 2. In the production of urine, the process in which some solutes are actively transported into the tubules of the excretory organ; this supplements the amount of a solute that would normally be removed by filtration alone.
secretory pathway A pathway for the movement of larger substances, such as carbohydrates and proteins, out of a cell.
secretory vesicle A membrane vesicle carrying different types of materials that fuses with the cell's plasma membrane to release the contents extracellularly.
seed A reproductive structure having specialized tissues that enclose plant embryos; produced by gymnosperms and flowering plants, usually as the result of sexual reproduction.
seed coat A hard and tough covering that develops from the ovule's integuments and protects a plant embryo.
seed plant The informal name for gymnosperms and angiosperms.
segmentation The division of an animal's body into clearly defined regions.
segmentation gene A gene that controls the segmentation pattern of an animal embryo.
segment-polarity gene A type of segmentation gene; a mutation in this gene causes portions of segments to be missing either an anterior or a posterior region and for adjacent regions to become mirror images of each other.
segregate To separate, as in chromosomes during mitosis.
selectable marker A gene whose presence can allow organisms (such as bacteria) to grow under a certain set of conditions. For example, an antibiotic-resistance gene is a selectable marker that allows bacteria to grow in the presence of the antibiotic.
selective breeding Programs and procedures designed to modify traits in domesticated species.
selectively permeable The property of membranes that allows the passage of certain ions or molecules but not others.
selective serotonin reuptake inhibitors Drugs used to treat major depressive disorder that act by increasing concentrations of serotonin in the brain.
self-compatible The reproductive state of plants that can serve as both mother and father to their progeny.
self-fertilization Fertilization that involves the union of a female gamete and male gamete from the same individual.
self-incompatibility (SI) Rejection of pollen that is genetically too similar to the pistil of a plant.
selfish DNA hypothesis The hypothesis that transposable elements exist because they have the characteristics that allow them to insert themselves into the host cell DNA but do not provide any advantage.
self-pollination The process in which pollen from the anthers of a flower is transferred to the stigma of the same flower or between flowers of the same plant.
self-splicing The phenomenon that RNA itself can catalyze the removal of its own intron(s); occurs in rRNA and tRNA.
SEM *See* scanning electron microscopy.
semelparity A reproductive pattern in which organisms produce all of their offspring in a single reproductive event.
semen A mixture containing fluid and sperm that is released during ejaculation.
semicircular canal Structures of the vertebrate ear that can detect a range of motions of the head.
semiconservative mechanism The correct model for DNA replication; double-stranded DNA is half conserved following replication, resulting in new double-stranded DNA containing one parental strand and one daughter strand.
semifluid A type of motion within biomembranes; considered two-dimensional because movement occurs only within the plane of the membrane.
semilunar valves One-way valves into the systemic and pulmonary arteries through which blood is pumped from the ventricles.
seminal vesicles Paired accessory glands in the male reproductive system that secrete fructose, the main nutrient for sperm, into the urethra.
seminiferous tubule A tightly packed tubule in the testis, where spermatogenesis takes place.
senescent Cells that have doubled many times and have reached a point where they have lost the capacity to divide any further.
sense A system in an animal that consists of sensory cells that respond to a specific type of chemical or physical stimulus and send signals to the central nervous system, where the signals are received and interpreted.
sensor A structure such as a sensory receptor or a nucleus in the brain that detects a signal in a homeostatic control system.
sensory neuron A neuron that detects or senses information from the outside world, such as light, sound, touch, and heat; sensory neurons also detect internal body conditions such as blood pressure and body temperature.
sensory receptor In animals, a specialized cell whose function is to receive sensory inputs.
sensory transduction The process by which incoming stimuli are converted into neural signals.
sepal A flower organ that occurs in a whorl located outside whorls of petals of eudicot plants.
septum (plural, septa) A cross wall; examples include the cross walls that divide the hyphae of most fungi into many small cells and the structure that separates the old and new chambers of a nautilus.
sere Each phase of succession in a community; also called a seral stage.
setae Chitinous bristles in the integument of many invertebrates.
set point The normal value for a controlled variable, such as blood pressure, in an animal.
sex chromosomes A distinctive pair of chromosomes that are different in males and females.
sex-influenced inheritance The phenomenon in which an allele is dominant in one sex but recessive in the other.
sex linked Refers to genes that are found on one sex chromosome but not on the other.
sex pili Hairlike structures made by bacterial F^+ cells that bind specifically to other F^- cells.
sexual dimorphism A pronounced difference in the morphologies of the two sexes within a species.
sexual reproduction A process that requires a fertilization event in which two gametes unite to produce a cell called a zygote.
sexual selection A type of natural selection that is directed at certain traits of sexually reproducing species that make it more likely for individuals to find or choose a mate and/or engage in successful mating.
Shannon diversity index (H_S) A means of measuring the diversity of a community; $H_S = -\Sigma p_i \ln p_i$.
shared derived character A trait that is shared by a group of organisms but not by a distant common ancestor.
shared primitive character A trait shared with a distant ancestor.
shattering The process by which ears of wild grain crops break apart and disperse seeds.
shell A tough, protective covering on an amniotic egg that is impermeable to water and prevents the embryo from drying out.
shivering thermogenesis Rapid muscle contractions in an animal, without any locomotion, in order to raise body temperature.
shoot The portion of a plant comprised of stems and leaves.
shoot apical meristem (SAM) The region of rapidly dividing plant cells at plant shoot apices.
shoot meristem The tissue that produces all aerial parts of the plant, which include the stems as well as lateral structures such as leaves and flowers.
shoot system The collection of plant organs produced by shoot apical meristems.
short-day plant A plant that flowers only when the night length is longer than a defined period.
short stature A condition characterized by stunted growth; formerly called pituitary dwarfism.
short tandem repeat sequences (STRs) Short sequences repeated many times in a row and found in multiple sites in the genome of humans and other species; often vary in length among different individuals.
shotgun DNA sequencing A strategy for sequencing an entire genome by randomly sequencing many different DNA fragments.
sickle cell disease A disease due to a genetic mutation in a hemoglobin gene in which sickle-shaped red blood cells are less able to move smoothly through capillaries and can block blood flow, resulting in severe pain and cell death of the surrounding tissue.
sieve plate The perforated end wall of a mature sieve-tube element.
sieve plate pore One of many perforations in a plant's sieve plate.
sieve-tube elements A component of the phloem tissues of flowering plants; thin-walled cells arranged end to end to form transport pipes.
sigma factor A protein that plays a key role in bacterial promoter recognition and recruits RNA polymerase to the promoter.
signal Regarding cell communication, an incoming or outgoing agent that influences the properties of cells.
signal recognition particle (SRP) A protein/RNA complex that recognizes the ER signal sequence of a polypeptide, pauses translation, and directs the ribosome to the ER to complete translation.
signal transduction pathway A group of proteins that convert an initial signal to a different signal inside a cell.
sign stimulus In animals, a trigger that initiates a fixed-action pattern of behavior.
silencer A regulatory element in eukaryotes that prevents transcription of a given gene.
silencing RNAs (siRNAs) Small RNA molecules, typically 22 nucleotides in length, that silence the expression of specific mRNAs by promoting their degradation.
silent mutation A gene mutation that does not alter the amino acid sequence of the polypeptide, even though the nucleotide sequence has changed.

simple Mendelian inheritance The inheritance pattern of traits affected by a single gene that is found in two variants, one of which is completely dominant over the other.
simple translocation A type of mutation in which a single piece of chromosome is attached to another chromosome.
single-factor cross *See* monohybrid cross.
single lens eye Type of eye found in vertebrates and some invertebrates with only one lens, as opposed compound eyes of insects with many lenses.
single nucleotide polymorphism (SNP) A type of genetic variation in a population in which a particular gene sequence varies at a single nucleotide.
single-strand binding protein A protein that binds to both of the single strands of parental DNA and prevents them from re-forming a double helix during DNA replication.
sinoatrial (SA) node A collection of modified cardiac cells in the right atrium of most vertebrates that spontaneously and rhythmically generates action potentials that spread across the entire atria; also known as the pacemaker of the heart.
siRNAS *See* silencing RNAs.
sister chromatids The two duplicated chromatids that are still joined to each other after DNA replication.
skeletal muscle A type of muscle tissue that is attached by tendons to bones in vertebrates and to the exoskeleton of invertebrates.
skeleton A structure or structures that serve one or more functions related to support, protection, and locomotion.
sliding filament mechanism The way in which a muscle fiber shortens during muscle contraction.
SLOSS debate In conservation biology, the debate over whether it is preferable to protect one single, large reserve or several smaller ones.
slow block to polyspermy Events initiated by the release of Ca^{2+} that produce barriers to more sperm penetrating an already fertilized egg.
slow fiber A skeletal muscle fiber containing myosin with a low rate of ATP hydrolysis.
slow-oxidative fiber A skeletal muscle fiber that has a low rate of myosin ATP hydrolysis but has the ability to make large amounts of ATP; used for prolonged, regular activity.
small effector molecule With regard to transcription, refers to a molecule that exerts its effects by binding to a regulatory transcription factor, causing a conformational change in the protein.
small intestine In vertebrates, a tube that leads from the stomach to the large intestine where nearly all digestion of food and absorption of food nutrients and water occur.
smooth endoplasmic reticulum (smooth ER) The part of the ER that is not studded with ribosomes. This region is continuous with the rough ER and functions in diverse metabolic processes such as detoxification, carbohydrate metabolism, accumulation of calcium ions (Ca^{2+}), and synthesis and modification of lipids.
smooth muscle A type of muscle tissue that surrounds hollow tubes and cavities inside the body's organs; it is not under conscious control.
soil horizon Layers of soil, ranging from topsoil to bedrock.
solute A substance dissolved in a liquid.
solute potential (S) The component of water potential due to the presence of solute molecules.
solution A liquid that contains one or more dissolved solutes.
solvent The liquid in which a solute is dissolved.
somatic cell The type of cell that constitutes all cells of an animal or plant body except those that give rise to gametes.
somatic embryogenesis The production of plant embryos from body (somatic) cells.
somatic nervous system The division of the peripheral nervous system that senses the external environmental conditions and controls skeletal muscles.
somites Blocklike structures resulting from the segmentation of mesoderm during neurulation.
soredia An asexual reproductive structure produced by lichens consisting of small clumps of hyphae surrounding a few algal cells that can disperse in wind currents.
sorting signal A short amino acid sequence in a protein that directs the protein to its correct location; also known as a traffic signal.
source pool The pool of species on the mainland that is available to colonize an island.
spatial summation Occurs when two or more postsynaptic potentials are generated at one time along different regions of the dendrites and their depolarizations and hyperpolarizations sum together.
speciation The formation of new species.
species A group of related organisms that share a distinctive form in nature and (for sexually reproducing species) are capable of interbreeding.
species-area effect The relationship between the amount of available area and the number of species present.
species concepts Different approaches for distinguishing species.
species diversity A measure of biological diversity that incorporates both the number of species in an area and the relative distribution of individuals among species.
species interactions A part of the study of population ecology that focuses on interactions such as predation, competition, parasitism, mutualism, and commensalism.
species richness The numbers of species in a community.
specific heat The amount of energy required to raise the temperature of 1 gram of a substance by 1°C.
specific immunity *See* acquired immunity.
specificity Refers to the concept that enzymes recognize specific substrates.
Spemann's organizer An extremely important morphogenetic field in the early gastrula; the organizer secretes morphogens responsible for inducing the formation of a new embryonic axis.
sperm Refers to a male gamete that is generally smaller than the female gamete (egg).
spermatid In animals, a haploid cell produced when the secondary spermatocytes undergo meiosis II; these cells eventually differentiate into sperm cells.
spermatogenesis Gametogenesis in a male animal resulting in the production of sperm.
spermatogonium In animals, a diploid germ cell that gives rise to the male gametes, the sperm.
spermatophytes All of the living and fossil seed plant phyla.
sperm storage A method of synchronizing the production of offspring with favorable environmental conditions in which female animals store and nourish sperm in their reproductive tract for long periods of time.
S phase The DNA synthesis phase of the cell cycle.
spicules Needle-like structures that are usually made of silica and form lattice-like skeletons in sponges, possibly helping to reduce predation.
spina bifida A developmental abnormality of the neural tube, which fails to close.
spinal cord In chordates, the structure that connects the brain to all areas of the body and together with the brain constitutes the central nervous system.
spinal nerve A nerve that connects the peripheral nervous system and the spinal cord.
spiracle One of several pairs of pores on the body surface of insects through which air enters and exits the body.
spiral cleavage A mechanism of animal development in which the planes of cell cleavage are oblique to the axis of the embryo.
spirilli Rigid, spiral-shaped prokaryotic cells.
spirochaetes Flexible, spiral-shaped prokaryotic cells.
spliceosome A complex of several subunits known as snRNPs that removes introns from eukaryotic pre-mRNA.
splicing The process whereby introns are removed from RNA and the remaining exons are connected to each other.
spongin A tough protein that lends skeletal support to a sponge.
spongocoel A central cavity in the body of a sponge.
spongy parenchyma Photosynthetic ground tissue of the plant leaf mesophyll that contains round cells separated by abundant air spaces.
spontaneous mutation A mutation resulting from abnormalities in biological processes.
sporangia Structures that produce and disperse the spores of plants, fungi, or protists.
sporangium Singular of sporangia.
spore A haploid, typically single-celled reproductive structure of fungi and plants that is dispersed into the environment and is able to grow into a new fungal mycelium or plant gametophyte in a suitable habitat.
sporic life cycle *See* alternation of generations.
sporophyte The diploid generation of plants or multicellular protists that have a sporic life cycle; this generation produces haploid spores by the process of meiosis.
sporopollenin The tough material that composes much of the walls of plant spores and helps to prevent cellular damage during transport in air.
stabilizing selection A pattern of natural selection that favors the survival of individuals with intermediate phenotypes.
stamen A flower organ that produces the male gametophyte, pollen.
standard metabolic rate (SMR) The metabolic rate of ectotherms measured at a standard temperature for each species—one that approximates the average temperature that a species normally encounters.
standing crop The total biomass in an ecosystem at any one point in time.
starch A polysaccharide composed of repeating glucose units that is produced by the cells of plants and some algal protists.
start codon A three-base sequence—usually AUG—that specifies the first amino acid in a polypeptide.
statocyst An organ of equilibrium found in many invertebrate species.
statolith 1. Tiny granules of sand or other dense objects located in a statocyst that aid equilibrium in many invertebrates. 2. In plants, a starch-heavy plastid that allows both roots and shoots to detect gravity.
stem A plant organ that produces buds, leaves, branches, and reproductive structures.
stem cell A cell that divides so that one daughter cell remains a stem cell and the other can differentiate into a specialized cell type. Stem cells construct the bodies of all animals and plants.
stereocilia Deformable projections from epithelial cells called hair cells that are bent by movements of fluid or other stimuli.
stereoisomers Isomers with identical bonding relationships, but different spatial positioning of their atoms.
sternum The breastbone of a vertebrate.

steroid A lipid containing four interconnected rings of carbon atoms; functions as a hormone in animals and plants.
steroid receptor A transcription factor that recognizes a steroid hormone and usually functions as a transcriptional activator.
sticky ends Single-stranded ends of DNA fragments that will hydrogen-bond to each other due to their complementary sequences.
stigma In a flower, the topmost portion of the pistil, which receives and recognizes pollen of the appropriate species or genotype.
stomach A saclike organ in some animals that most likely evolved as a means of storing food; it partially digests some of the macromolecules in food and regulates the rate at which the contents empty into the small intestine.
stomata Surface pores on plant surfaces that can be closed to retain water or open to allow the entry of CO_2 needed for photosynthesis and the exit of O_2 and water vapor.
stop codon One of three three-base sequences—UAA, UAG, and UGA—that signals the end of translation; also called termination codon or nonsense codon.
strain Within a given species, a lineage that has genetic differences compared to another lineage.
strand A structure of DNA (or RNA) formed by the covalent linkage of nucleotides in a linear manner.
strepsirrhini Smaller species of primates; includes bush babies, lemurs, and pottos.
streptophyte Land pants (embryophytes) and close relatives among the green algae.
streptophyte algae The green algae that are closely related to land plants (embryophytes).
stretch receptor A type of mechanoreceptor found widely in an animal's organs and muscle tissues that can be distended.
striated muscle Skeletal and cardiac muscle with a series of light and dark bands perpendicular to the muscle's long axis.
stroke The condition that occurs when blood flow to part of the brain is disrupted.
stroke volume (SV) The amount of blood ejected with each beat, or stroke, of the heart.
stroma The fluid-filled region of the chloroplast between the thylakoid membrane and the inner membrane.
stromatolite A layered calcium carbonate structure in an aquatic environment generally produced by cyanobacteria.
strong acid An acid that completely ionizes in solution.
structural gene Refers to most genes, which produce an mRNA molecule that contains the information to specify a polypeptide with a particular amino acid sequence.
structural isomers Isomers that contain the same atoms but in different bonding relationships.
style In a flower, the elongate portion of the pistil through which the pollen tube grows.
stylet A sharp, piercing organ in the mouth of nematodes and some insects.
submetacentric A chromosome in which the centromere is off center.
subsidence zones Areas of high pressure that are the sites of the world's tropical deserts because the subsiding air is relatively dry, having released all of its moisture over the equator.
subspecies A subdivision of a species; this designation is used when two or more geographically restricted groups of the same species differ, but not enough to warrant their placement into separate species.
substrate 1. The reactant molecules and/or ions that bind to an enzyme at the active site and participate in a chemical reaction. 2. The organic compounds such as soil or rotting wood that fungi use as food.
substrate-level phosphorylation A method of synthesizing ATP that occurs when an enzyme directly transfers a phosphate from an organic molecule to ADP.
succession The gradual and continuous change in species composition and community structure over time.
sugar sink The plant tissues or organs in which more sugar is consumed than is produced by photosynthesis.
sugar source The plant tissues or organs that produce more sugar than they consume in respiration.
sum rule The probability that one of two or more mutually exclusive outcomes will occur is the sum of the probabilities of the possible outcomes.
supergroup One of the seven subdivisions of the domain Eukarya.
surface area-to-volume (SA/V) ratio The ratio between a structure's surface area and the volume in which the structure is contained.
surface tension A measure of how difficult it is to break the interface between a liquid and air.
surfactant A mixture of proteins and amphipathic lipids produced in certain alveolar cells that prevents the collapse of alveoli by reducing surface tension in the lungs.
survivorship curve A graphical plot of the numbers of surviving individuals at each age in a population.
suspension feeder An aquatic animal that sifts water, filtering out the organic matter and expelling the rest.
suspensor A short chain of cells at the base of an early angiosperm embryo that provides anchorage and nutrients.
swim bladder A gas-filled, balloon-like structure that helps a fish to remain buoyant in the water even when the fish is completely stationary.
symbiosis An intimate association between two or more organisms of different species.
symbiotic Describes a relationship in which two or more different species live in direct contact with each other.
sympathetic division The division of the autonomic nervous system that is responsible for rapidly activating body systems to provide immediate energy in response to danger or stress.
sympatric The term used to describe species occurring in the same geographic area.
sympatric speciation A form of speciation that occurs when members of a species that initially occupy the same habitat within the same range diverge into two or more different species.
symplast All of a plant's protoplasts (the cell contents without the cell walls) and plasmodesmata.
symplastic transport The movement of a substance from the cytosol of one cell to the cytosol of an adjacent cell via membrane-lined channels called plasmodesmata.
symplesiomorphy *See* shared primitive character.
symporter A type of transporter that binds two or more ions or molecules and transports them in the same direction across a membrane; also called a cotransporter.
synapomorphy *See* shared derived character.
synapse A junction where a nerve terminal meets a target neuron, muscle cell, or gland and through which an electrical or chemical signal passes.
synapsis The process of forming a bivalent.
synaptic cleft The extracellular space between a neuron and its target cell.
synaptic plasticity The formation of additional synaptic connections that occurs as a result of learning.
synaptic signaling A specialized form of paracrine signaling that occurs in the nervous system of animals.
synergids In the female gametophyte of a flowering plant, the two cells adjacent to the egg cell that help to import nutrients from maternal sporophyte tissues.
syntrophy The phenomenon in which one species lives off the products of another species.
systematics The study of biological diversity and evolutionary relationships among organisms, both extinct and modern.
systemic acquired resistance (SAR) A whole-plant defensive response to pathogenic microorganisms.
systemic circulation The pumping of blood from the left side of an animal's heart to the body to drop off O_2 and nutrients and pick up CO_2 and wastes. The blood then returns to the right side of the heart.
systemic hypertension An arterial blood pressure above normal; in humans, normal blood pressure ranges from systolic/diastolic pressures of about 90/60 to 120/80 mmHg; often called hypertension or high blood pressure.
systems biology A field of study in which researchers investigate living organisms in terms of their underlying networks—groups of structural and functional connections—rather than their individual molecular components.
systole The second phase of the cardiac cycle, in which the ventricles contract and eject the blood through the open semilunar valves.

T

tagmata The fusion of body segments into functional units.
taproot system The root system of eudicots, consisting of one main root with many branch roots.
taste buds Structures located in the mouth and tongue of vertebrates that contain the sensory cells, supporting cells, and associated neuronal endings that contribute to taste sensation.
TATA box One of three features found in most eukaryotic promoters; the others are the transcriptional start site and regulatory elements.
taxis A directed type of response to a stimulus that is either toward or away from the stimulus.
taxon A group of species that are evolutionarily related to each other. In taxonomy, each species is placed into several taxons that form a hierarchy from large (domain) to small (genus).
taxonomy The field of biology that is concerned with the theory, practice, and rules of classifying living and extinct organisms and viruses.
T cells A type of lymphocyte that directly kills infected, mutated, or transplanted cells.
telocentric A chromosome in which the centromere is at the end.
telomerase An enzyme that catalyzes the replication of the telomere.
telomere A region at the ends of eukaryotic chromosomes where a specialized form of DNA replication occurs.
telophase The phase of mitosis during which the chromosomes decondense and the nuclear membrane re-forms.
TEM *See* transmission electron microscopy.
temperate phage A bacteriophage that may spend some of its time in the lysogenic cycle.
template strand The DNA strand that is used as a template for RNA synthesis or DNA replication.
temporal lobe One of four lobes of the cerebral cortex of human brain; necessary for language, hearing, and some types of memory.
temporal summation Occurs when two or more postsynaptic potentials arrive at the same location in a dendrite in quick succession and their depolarizations and hyperpolarizations sum together.

tepal A flower perianth part that cannot be distinguished by appearance as a petal or a sepal.
termination codon *See* stop codon.
termination stage The final stage of transcription or translation in which the process ends.
terminator A sequence that specifies the end of transcription.
terpenoids A group of secondary metabolites synthesized from five-carbon isoprene units. An example is β-carotene, which gives carrots their orange color.
territory A fixed area in which an individual or group excludes other members of its own species, and sometimes other species, by aggressive behavior or territory marking.
tertiary consumer An organism that feeds on secondary consumers.
tertiary endosymbiosis The acquisition by eukaryotic protist host cells of plastids from cells that possess secondary plastids.
tertiary plastid A plastid acquired by the incorporation into a host cell of an endosymbiont having a secondary plastid.
tertiary structure The three-dimensional shape of a single polypeptide; one of four levels of protein structure.
testcross A cross to determine if an individual with a dominant phenotype is a homozygote or a heterozygote. Also, a cross to determine if two different genes are linked.
testis (plural, **testes**) In animals, the male gonad, where sperm are produced.
testosterone The primary androgen in many vertebrates, including humans.
tetrad *See* bivalent.
tetraploid An organism or cell that has four sets of chromosomes.
tetrapod A vertebrate animal having four legs or leglike appendages.
thalamus A region of the vertebrate forebrain that plays a major role in relaying sensory information to appropriate parts of the cerebrum and, in turn, sending outputs from the cerebrum to other parts of the brain.
theory In biology, a broad explanation of some aspect of the natural world that is substantiated by a large body of evidence. Biological theories incorporate observations, hypothesis testing, and the laws of other disciplines such as chemistry and physics. A theory makes valid predictions.
thermodynamics The study of energy interconversions.
thermoreceptor A sensory receptor in animals that responds to cold and heat.
theropods A group of bipedal saurischian dinosaurs.
thick filament A section of the repeating pattern in a myofibril composed almost entirely of the motor protein myosin.
thigmotropism Touch responses in plants.
thin filament A section of the repeating pattern in a myofibril that contains the cytoskeletal protein actin, as well as two other proteins—troponin and tropomyosin—that play important roles in regulating contraction.
30-nm fiber Nucleosome units organized into a more compact structure that is 30 nm in diameter.
thoracic breathing Breathing in which coordinated contractions of muscles expand the rib cage, creating a negative pressure to suck air in and then forcing it out later; found in amniotes.
threatened species Those species that are likely to become endangered in the future.
threshold concentration The concentration above which a morphogen will exert its effects but below which it is ineffective.
threshold potential The membrane potential, typically around –50 to –55 mV, which is sufficient to trigger an action potential in an electrically excitable cell such as a neuron.
thrifty genes Genes that boosted our ancestors' ability to store fat from each feast in order to sustain them through the next famine.
thrombocyte Intact cell in the blood of vertebrates other than mammals that plays a crucial role in the formation of blood clots; in mammals, cell fragments called platelets serve this function.
thylakoid A flattened, platelike membranous region found in cyanobacterial cells and the chloroplasts of photosynthetic protists and plants; the location of the light reactions of photosynthesis.
thylakoid lumen The fluid-filled compartment within the thylakoid.
thylakoid membrane A membrane within the chloroplast that forms many flattened, fluid-filled tubules that enclose a single, convoluted compartment. It contains chlorophyll and is the site where the light-dependent reactions of photosynthesis occurs.
thymine (T) A pyrimidine base found in DNA.
thymine dimer In DNA, a type of pyrimidine dimer that can cause a mutation; a site where two adjacent thymine bases become covalently crosslinked to each other.
thyroglobulin A protein found in the colloid of the thyroid gland that is involved in the formation of thyroid hormones.
thyroxine (T_4) A weakly active thyroid hormone that contains iodine and helps regulate metabolic rate; it is converted by cells into the more active triiodothyronine (T_3).
tidal ventilation A type of breathing in mammals in which the lungs are inflated with air and then the chest muscles and diaphragm relax and recoil back to their original positions as an animal exhales. During exhalation, air leaves via the same route that it entered during inhalation, and no new oxygen is delivered to the airways at that time.
tidal volume The volume of air that is normally breathed in and out at rest.
tight junction A type of junction between animal cells that forms a tight seal between adjacent epithelial cells and thereby prevents molecules from leaking between cells; also called an occluding junction.
Ti plasmid Tumor-inducing plasmid found in *Agrobacterium tumefaciens*; it is used as a cloning vector to transfer genes into plant cells.
tissue The association of many cells of the same type, for example, muscle tissue.
tolerance A mechanism for succession in which any species can start the succession, but the eventual climax community is reached in a somewhat orderly fashion; early species neither facilitate nor inhibit subsequent colonists.
Toll-like receptor Receptor proteins that recognize nonspecific antigens in microbes; key part of the innate immune system.
tonoplast The membrane of the central vacuole in a plant or algal cell.
topsoil The uppermost layer of a soil.
torpor The strategy in endotherms of lowering internal body temperature to just a few degrees above that of the environment in order to conserve energy.
torus The nonporous, flexible central region of a conifer pit that functions like a valve.
total fertility rate The average number of live births a female has during her lifetime.
total peripheral resistance (TPR) The sum of all the resistance in all arterioles.
totipotent The ability of a fertilized egg to produce all of the cell types in the adult organism; also the ability of unspecialized plant cells to regenerate an adult plant.
toxins Compounds that have adverse effects in living organisms; often produced by various protist and plant species.
trace element An element that is essential for normal function in living organisms but is required in extremely small quantities.
trachea 1. A sturdy tube arising from the spiracles of an insect's body; involved in respiration. 2. The name of the tube leading to the lungs of air-breathing vertebrates.
tracheal system The respiratory system of insects consisting of a series of finely branched air tubes called tracheae; air enters and exits the tracheae through spiracles, which are pores on the body surface.
tracheary elements Water-conducting cells in plants that, when mature, are always dead and empty of cytosol; include tracheids and vessel elements.
tracheid A type of dead, lignified plant cell in xylem that conducts water, along with dissolved minerals; also provides structural support.
tracheophytes A term used to describe vascular plants.
tract A parallel bundle of myelinated axons in the central nervous system.
traffic signal *See* sorting signal.
trait An identifiable characteristic; usually refers to a variant.
transcription The use of a gene sequence to make a copy of RNA.
transcriptional start site The site in a eukaryotic promoter where transcription begins.
transcription factor A protein that influences the ability of RNA polymerase to transcribe genes.
transduction A type of genetic transfer between bacteria in which a virus infects a bacterial cell and then subsequently transfers some of that cell's DNA to another bacterium.
***trans*-effect** In both prokaryotes and eukaryotes, a form of genetic regulation that can occur even though two DNA segments are not physically adjacent. The action of the lac repressor on the *lac* operon is a *trans*-effect.
transepithelial transport The process of moving solutes across an epithelium, such as in the gut of animals.
transfer RNA (tRNA) An RNA that carries amino acids and is used to translate mRNA into polypeptides.
transformation A type of genetic transfer between bacteria in which a segment of DNA from the environment is taken up by a competent cell and incorporated into the bacterial chromosome.
transgenic The term used to describe an organism that carries genes that were introduced using molecular techniques such as gene cloning.
transitional form An organism that provides a link between earlier and later forms in evolution.
transition state In a chemical reaction, a state in which the original bonds have stretched to their limit; once this state is reached, the reaction can proceed to the formation of products.
translation The process of synthesizing a specific polypeptide on a ribosome.
translocation 1. A type of mutation in which one segment of a chromosome becomes attached to a different chromosome. 2. A process in plants in which phloem transports substances from a source to a sink.
transmembrane gradient A situation in which the concentration of a solute is higher on one side of a membrane than on the other.

transmembrane protein A protein that has one or more regions that are physically embedded in the hydrophobic region of a cell membrane's phospholipid bilayer.
transmembrane segment A region of a membrane protein that is a stretch of nonpolar amino acids that spans or traverses the membrane from one leaflet to the other.
transmembrane transport The export of material from one cell into the intercellular space and then into an adjacent cell.
transmission electron microscopy (TEM) A type of microscopy in which a beam of electrons is transmitted through a biological sample to form an image on a photographic plate or screen.
transpiration The evaporative loss of water from plant surfaces into sun-heated air.
transporter A membrane protein that binds a solute and undergoes a conformational change to allow the movement of the solute across a membrane; also called a carrier.
transport protein Proteins embedded within the phospholipid bilayer that allow plasma membranes to be selectively permeable by providing a passageway for the movement of some but not all substances across the membrane.
transposable element (TE) A segment of DNA that can move from one site to another.
transposase An enzyme that facilitates transposition.
transposition The process in which a short segment of DNA moves within a cell from its original site to a new site in the genome.
transverse tubules (T-tubules) Invaginations of the plasma membrane of skeletal muscle cells that open to the extracellular fluid and conduct action potentials from the outer surface to the myofibrils.
triacylglycerol *See* triglyceride.
trichome A projection, often hairlike, from the epidermal tissue of a plant that offers protection from excessive light, ultraviolet radiation, extreme air temperature, or attack by herbivores.
triglyceride A molecule composed of three fatty acids linked by ester bonds to a molecule of glycerol; also known as a triacylglycerol.
triiodothyronine (T_3) A thyroid hormone that contains iodine and helps regulate metabolic rate.
triplet A group of three bases that function as a codon.
triploblastic Having three distinct germ layers: endoderm, ectoderm, and mesoderm.
triploid An organism or cell that has three sets of chromosomes.
trisomic An aneuploid organism that has one too many chromosomes.
tRNA *See* transfer RNA.
trochophore larva A distinct larval stage of many invertebrate phyla.
trophectoderm The outer layer of cells in a developing mammalian blastocyst; continuous with the ectoderm layer.
trophic level Each feeding level in a food chain.
trophic-level transfer efficiency The amount of energy at a trophic level that is acquired by the trophic level above and incorporated into biomass.
trophic mutualism A mutually beneficial interaction between two species in which both species receive the benefit of resources.
tropism In plants, a growth response that is dependent on a stimulus that occurs in a particular direction.
tropomyosin A rod-shaped protein that plays an important role in regulating muscle contraction.
troponin A small globular-shaped protein that plays an important role in regulating muscle contraction through its ability to bind Ca^{2+}.
***trp* operon** An operon of *E. coli* that encodes enzymes required to make the amino acid tryptophan, a building block of cellular proteins.
true-breeding line A strain that continues to exhibit the same trait after several generations of self-fertilization or inbreeding.
trypsin A protease involved in the breakdown of proteins in the small intestine.
T-snare A protein in a target membrane that recognizes a V-snare in a membrane vesicle.
tubal ligation A means of contraception that involves the cutting and sealing of the fallopian tubes in a woman, thereby preventing movement of a fertilized egg into the uterus.
tube cell In a seed plant, one of the cells resulting from the division of a microspore; stores proteins and forms the pollen tube.
tube feet Echinoderm structures that function in movement, gas exchange, feeding, and excretion.
tumor An abnormal overgrowth of cells.
tumor-suppressor gene A gene that when normal (that is, not mutant) encodes a protein that prevents cancer; however, when a mutation eliminates its function, cancer may occur.
tunic A nonliving structure that encloses a tunicate, made of protein and a cellulose-like material called tunicin.
turgid The term used to describe a plant cell whose cytosol is so full of water that the plasma membrane presses right up against the cell wall; as a result, turgid cells are firm or swollen.
turgor pressure *See* osmotic pressure.
20-hydroxyecdysone A hormone produced by the prothoracic glands of arthropods that stimulates molting.
two-factor cross *See* dihybrid cross.
type 1 diabetes mellitus (T1DM) A disease in which the pancreas does not produce sufficient insulin; as a result, extracellular glucose cannot cross plasma membranes, and glucose accumulates to very high concentrations in the blood.
type 2 diabetes mellitus (T2DM) A disease in which the pancreas produces sufficient insulin, but the cells of the body lose much of their ability to respond to insulin.

U

ubiquitin A small protein in eukaryotic cells that directs unwanted proteins to a proteasome by its covalent attachment.
ulcer An erosion of the mucosal surface of the alimentary canal; typically occurs in the lower esophagus, stomach, or duodenum.
ultimate cause The reason a particular behavior evolved, in terms of its effect on reproductive success.
umbrella species A species whose habitat requirements are so large that protecting them would protect many other species existing in the same habitat.
unconditioned response An action that is elicited by an unconditioned stimulus.
unconditioned stimulus A trigger that elicits an original response.
uniform A pattern of dispersion within a population in which individuals maintain a certain minimum distance between themselves to produce an evenly spaced distribution.
uniporter A type of transporter that binds a single ion or molecule and transports it across a membrane.
unipotent A term used to describe a stem cell found in the adult that can produce daughter cells that differentiate into only one cell type.
unsaturated The quality of certain lipids containing one or more CwC double bonds.
unsaturated fatty acid A fatty acid that contains one or more CwC double bonds.
upwelling In the ocean, a process that carries mineral nutrients from the bottom waters to the surface.
uracil (U) A pyrimidine base found in RNA.
urea A nitrogenous waste commonly produced in many terrestrial species, including mammals.
uremia A condition characterized by the presence of nitrogenous wastes, such as urea, in the blood; typically results from kidney disease.
ureter A structure in the mammalian urinary system through which urine flows from the kidney into the urinary bladder.
urethra The structure in the mammalian urinary system through which urine is eliminated from the body.
uric acid A nitrogenous waste produced by birds, insects, and reptiles.
urinary bladder The structure in the mammalian urinary system that collects urine before it is eliminated.
urinary system The structures that collectively act to filter blood or hemolymph and excrete wastes, while recapturing useful compounds.
urine The part of the filtrate formed in the kidney that remains after all reabsorption of solutes and water is complete.
uterine cycle *See* menstrual cycle.
uterus A small, pear-shaped organ capable of enlarging and specialized for carrying a developing fetus in female mammals.

V

vaccination The injection into the body of small quantities of weakened or dead pathogens, resulting in the development of immunity to those pathogens without causing disease.
vacuole Specialized compartments found in eukaryotic cells that function in storage, the regulation of cell volume, and degradation.
vagina The birth canal of female mammals; also functions to receive sperm during copulation.
vaginal diaphragm A barrier method of preventing fertilization in which a diaphragm is placed in the upper part of the vagina just prior to intercourse; blocks movement of sperm to the cervix.
valence electron An electron in the outer shell of an atom that is available to combine with other atoms. Such electrons allow atoms to form chemical bonds with each other.
van der Waals forces Attractive forces between molecules in close proximity to each other, caused by the variations in the distribution of electron density around individual atoms.
variable region A unique domain within an immunoglobulin that serves as the antigen-binding site.
vasa recta capillaries Capillaries in the medulla in the nephron of the kidney.
vascular bundle Primary plant vascular tissues that occur in a cluster.
vascular cambium A secondary meristematic tissue of plants that produces both wood and inner bark.
vascular plant A plant that contains vascular tissue. Includes all modern plant species except liverworts, hornworts, and mosses.
vascular tissue Plant tissue that provides both structural support and conduction of water, minerals, and organic compounds.
vas deferens A muscular tube through which sperm leave the epididymis.
vasectomy A surgical procedure in men that severs the vas deferens, thereby preventing the release of sperm at ejaculation.
vasoconstriction A decrease in blood vessel radius; an important mechanism for directing blood flow away from specific regions of the body.
vasodilation An increase in blood vessel radius; an important mechanism for directing blood flow to specific regions of the body.

vasotocin A peptide hormone that is responsible for regulating salt and water balance in the blood of nonmammalian vertebrates.
vector A type of DNA that acts as a carrier of a DNA segment that is to be cloned.
vegetal pole In triploblast organisms, the pole of the egg where the yolk is most concentrated.
vegetative growth The production of new nonreproductive tissues by the shoot apical meristem and root apical meristem during seedling development and growth of mature plants.
vein 1. In animals, a blood vessel that returns blood to the heart. 2. In plants, a bundle of vascular tissue in a leaf.
veliger In mollusks, a free-swimming larva that has a rudimentary foot, shell, and mantle.
ventilation The process of bringing oxygenated water or air into contact with a respiratory surface such as gills or lungs.
ventral Refers to the lower side of an animal.
ventricle In the heart, a chamber that pumps blood out of the heart.
venule A small, thin-walled extension of a capillary that empties into larger vessels called veins that return blood to the heart for another trip around the circulation.
vertebrae A bony or cartilaginous column of interlocking structures that provides support and also protects the nerve cord, which lies within its tubelike structure.
vertebrate An organism with a backbone.
vertical evolution A process in which species evolve from pre-existing species by the accumulation of mutations.
vesicle A small membrane-enclosed sac within a cell.
vessel In a plant, a pipeline-like file of dead, water-conducting vessel elements.
vessel element A type of plant cell in xylem that conducts water, along with dissolved minerals and certain organic compounds.
vestibular system The organ of balance in vertebrates, located in the inner ear next to the cochlea.
vestigial structure An anatomical feature that has no apparent function but resembles a structure of a presumed ancestor.
vibrios Comma-shaped prokaryotic cells.
villus (plural, **villi**) Finger-like projections extending from the luminal surface into the lumen of the small intestine; these are specializations that aid in digestion and absorption.
viral envelope A structure enclosing a viral capsid that consists of a membrane derived from the plasma membrane of the host cell; is embedded with virally encoded spike glycoproteins.
viral genome The genetic material of a virus.
viral reproductive cycle The series of steps that result in the production of new viruses during a viral infection.
viral vector A type of vector used in cloning experiments that is derived from a virus.
viroid An RNA particle that infects plant cells.
virulence The ability of a microorganism to cause disease.
virulent phage A phage that follows only the lytic cycle.
virus A small infectious particle that consists of nucleic acid enclosed in a protein coat.
visceral mass In mollusks, a structure that rests atop the foot and contains the internal organs.
vitamin An organic nutrient that serves as a coenzyme for metabolic and biosynthetic reactions.
vitamin D A vitamin that is converted into a hormone in the body; regulates the calcium level in the blood through an effect on intestinal transport of calcium ions.
vitreous humor A thick liquid in the large posterior cavity of the vertebrate eye, which helps maintain the shape of the eye.
viviparity Development of an embryo within the mother, resulting in a live birth.
viviparous The term used to describe an animal whose embryos develop within the uterus, receiving nourishment from the mother via a placenta.
V_{max} The maximal velocity of an enzyme-catalyzed reaction.
volt A unit of measurement of potential difference in charge (electrical force) such as the difference between the interior and exterior of a cell.
voltage-gated ion channels Ion channels that open and close in response to changes in the amount of electric charge across a membrane.
V-snare A protein incorporated into a vesicle membrane during vesicle formation that is recognized by a T-snare in a target membrane.

W

water potential The potential energy of water.
water vascular system A network of canals powered by water pressure generated by the contraction of muscles; enables extension and contraction of the tube feet, allowing echinoderms to move slowly.
wavelength The distance from the peak of one sound wave or light wave to the next.
waxy cuticle A protective, waterproof layer of polyester and wax present on most surfaces of vascular plant sporophytes.
weak acid An acid that only partially ionizes in solution.
weathering The physical and chemical breakdown of rock.
white blood cell *See* leukocyte.
white matter Brain tissue that consists of myelinated axons that are bundled together in large numbers to form tracts.
whorls In a flower, concentric rings of sepals and petals (or tepals), stamens, and carpels.
wild-type allele One or more prevalent alleles in a population.
wood A secondary plant tissue composed of numerous pipelike arrays of dead, empty, water-conducting cells whose walls are strengthened by an exceptionally tough secondary metabolite known as lignin.
woody plant A type of plant that produces both primary and secondary vascular tissues.

X

X inactivation The phenomenon in which one X chromosome in the somatic cells of female mammals is inactivated, meaning that its genes are not expressed.
X inactivation center (Xic) A short region on the X chromosome known to play a critical role in X inactivation.
X-linked gene A gene found on the X chromosome but not on the Y.
X-linked inheritance The pattern displayed by pairs of dominant and recessive alleles located on X chromosomes.
X-ray crystallography A technique in which researchers purify molecules and cause them to form a crystal. When a crystal is exposed to X-rays, the resulting pattern can be analyzed mathematically to determine the three-dimensional structure of the crystal's components.
xylem A specialized conducting tissue in plants that transports water, minerals, and some organic compounds.
xylem loading The process by which root xylem parenchyma cells transport ions and water across their membranes into the long-distance conducting cells of the xylem, which include the vessel elements and tracheids.

Y

yeast A fungus that can occur as a single cell and that reproduces by budding.
yolk sac One of the four extraembryonic membranes in the amniotic egg. The yolk sac encloses a stockpile of nutrients, in the form of yolk, for the developing embryo.

Z

zero population growth The situation in which no changes in population size occur.
Z line A network of proteins in a myofibril that anchors thin filaments at the ends of each sarcomere.
zona pellucida The glycoprotein covering that surrounds a mature oocyte.
zone of elongation The area above the root apical meristem of a plant where cells extend by water uptake, thereby dramatically increasing root length.
zone of maturation The area above the zone of elongation in a plant root where root cell differentiation and tissue specialization occur.
zooplankton Aquatic organisms drifting in the open ocean or fresh water; includes minute animals consisting of some worms, copepods, tiny jellyfish, and the small larvae of invertebrates and fishes.
Z scheme A model depicting the series of energy changes of an electron during the light reactions of photosynthesis. The electron absorbs light energy twice, resulting in an energy curve with a zigzag shape.
zygomycete A phylum of fungi that produces distinctive, large zygospores as the result of sexual reproduction.
zygospore A dark-pigmented, thick-walled spore that matures within the zygosporangium of zygomycete fungi during sexual reproduction.
zygote A diploid cell formed by the fusion of two haploid gametes.
zygotic life cycle The type of life cycle of most unicellular protists in which haploid cells develop into gametes. Two gametes then fuse to produce a diploid zygote.
