Brief Contents

About the Authors iv
Improving Biology Education v
Strengthen Problem Solving Skills and Key Concept Development with Connect xiii
Using Connect and *Biology*, 4th edition xiv
Contents xxi

1 An Introduction to Biology 1

Unit I Chemistry

2 The Chemical Basis of Life I: Atoms, Molecules, and Water 23
3 The Chemical Basis of Life II: Organic Molecules 44

Unit II Cell

4 General Features of Cells 68
5 Membrane Structure, Synthesis, and Transport 100
6 An Introduction to Energy, Enzymes, and Metabolism 121
7 Cellular Respiration and Fermentation 138
8 Photosynthesis 156
9 Cell Communication 175
10 Multicellularity 194

Unit III Genetics

11 Nucleic Acid Structure, DNA Replication, and Chromosome Structure 211
12 Gene Expression at the Molecular Level 234
13 Gene Regulation 257
14 Mutation, DNA Repair, and Cancer 281
15 The Eukaryotic Cell Cycle, Mitosis, and Meiosis 300
16 Simple Patterns of Inheritance 325
17 Complex Patterns of Inheritance 347
18 Genetics of Viruses and Bacteria 364
19 Developmental Genetics 386
20 Genetic Technology 406
21 Genomes, Proteomes, and Bioinformatics 426

Unit IV Evolution

22 The Origin and History of Life on Earth 445
23 An Introduction to Evolution 467
24 Population Genetics 487
25 Origin of Species and Macroevolution 505
26 Taxonomy and Systematics 525

Unit V Diversity

27 Archaea and Bacteria 545
28 Protists 565
29 Plants and the Conquest of Land 588
30 The Evolution and Diversity of Modern Gymnosperms and Angiosperms 611
31 Fungi 633
32 An Introduction to Animal Diversity 654
33 The Invertebrates 668
34 The Vertebrates 702

Unit VI Flowering Plants

35 An Introduction to Flowering Plant Form and Function 734
36 Flowering Plants: Behavior 755
37 Flowering Plants: Nutrition 774
38 Flowering Plants: Transport 790
39 Flowering Plants: Reproduction 811

Unit VII Animals

40 Animal Bodies and Homeostasis 831
41 Neuroscience I: Cells of the Nervous System 849
42 Neuroscience II: Evolution, Structure, and Function of the Nervous System 872
43 Neuroscience III: Sensory Systems 893
44 Muscular-Skeletal Systems and Locomotion 919
45 Nutrition and Animal Digestive Systems 938
46 Control of Energy Balance, Metabolic Rate, and Body Temperature 959
47 Circulatory Systems 977
48 Respiratory Systems 999
49 Excretory Systems and the Homeostasis of Internal Fluids 1023
50 Endocrine Systems 1044
51 Animal Reproduction 1069
52 Animal Development 1089
53 Immune Systems 1107

Unit VIII Ecology

54 An Introduction to Ecology and Biomes 1131
55 Behavioral Ecology 1162
56 Ecology 1183
57 Species Interactions 1202
58 Community Ecology 1223
59 Ecosystem Ecology 1241
60 Biodiversity and Conservation Biology 1260

About the Authors

Robert J. Brooker

Rob Brooker (Ph.D., Yale University) received his B.A. in biology at Wittenberg University, Springfield, Ohio, in 1978. At Harvard, he studied lactose permease, the product of the *lacY* gene of the *lac* operon. He continued working on transporters at the University of Minnesota, where he is a Professor in the Department of Genetics, Cell Biology, and Development and the Department of Biology Teaching and Learning. At the University of Minnesota, Dr. Brooker teaches undergraduate courses in biology, genetics, and cell biology. In addition to many other publications, he has written two undergraduate genetics texts published by McGraw-Hill: *Genetics: Analysis & Principles*, 5th edition, copyright 2015, and *Concepts of Genetics*, 2nd edition, copyright 2016.

Eric P. Widmaier

Eric Widmaier received his Ph.D. in 1984 in endocrinology from the University of California at San Francisco. His research focuses on the control of body mass and metabolism in mammals, the hormonal correlates of obesity, and the effects of high-fat diets on intestinal cell function. Dr. Widmaier is currently Professor of Biology at Boston University, where he teaches undergraduate human physiology and recently received the university's highest honor for excellence in teaching. Among other publications, he is a coauthor of *Vander's Human Physiology: The Mechanisms of Body Function*, 14th edition, published by McGraw-Hill, copyright 2017.

Linda E. Graham

Linda Graham received her Ph.D. in botany from the University of Michigan, Ann Arbor. Her research explores the evolutionary origin of algae and land-adapted plants, focusing on their cell and molecular biology as well as ecological interactions with microbes. Dr. Graham is now Professor of Botany at the University of Wisconsin-Madison. She teaches undergraduate courses in microbiology and plant biology. She is the coauthor of, among other publications, *Algae*, 3rd edition, copyright 2015, a major's textbook on algal biology, and *Plant Biology*, 3rd edition, copyright 2015, both published by LJLM Press.

Left to right: Eric Widmaier, Linda Graham, Peter Stiling, and Rob Brooker

Peter D. Stiling

Peter Stiling obtained his Ph.D. from University College, Cardiff, Wales, in 1979. Subsequently, he became a postdoctoral fellow at Florida State University and later spent two years as a lecturer at the University of the West Indies, Trinidad. During this time, he began photographing and writing about butterflies and other insects, which led to publication of several books on local insects. Dr. Stiling is currently a Professor of Biology at the University of South Florida at Tampa. His research interests include plant-insect relationships, parasite-host relationships, biological control, restoration ecology, and the effects of elevated carbon dioxide levels on plant herbivore interactions. He teaches graduate and undergraduate courses in ecology and environmental science as well as introductory biology. He has published many scientific papers and is the author of *Ecology: Global Insights and Investigations*, 2nd edition, published by McGraw-Hill, copyright 2015.

The authors are grateful for the help, support,
and patience of their families, friends, and students,
Deb, Dan, Nate, and Sarah Brooker,
Maria, Rick, and Carrie Widmaier,
Jim, Michael, Shannon, and Melissa Graham, and
Jacqui, Zoe, Leah, and Jenna Stiling.

Lead Digital Author

Ian Quitadamo

Ian Quitadamo is a Professor with a dual appointment in Biological Sciences and Science Education at Central Washington University in Ellensburg, Washington. He teaches introductory and majors biology courses and cell biology, genetics, and biotechnology, as well as science teaching methods courses for future science teachers and interdisciplinary content courses in alternative energy and sustainability. Dr. Quitadamo was educated at Washington State University and holds a BA in biology, Masters degree in genetics and cell biology, and an interdisciplinary Ph.D. in science, education, and technology. Previously a researcher of tumor angiogenesis, he now investigates the behavioral and neurocognitive basis of critical thinking and has published numerous studies of factors that improve student critical thinking performance. He has received the Crystal Apple award for teaching excellence, led multiple initiatives in critical thinking and assessment, and is active nationally in helping transform university faculty practice. He served as a coauthor on *Biology*, 11th edition, by Mader and Windelspecht, copyright 2013 and is the lead digital author for *Biology*, 10th and 11th editions by Raven, copyright 2014 and 2017, *Biology*, 3rd edition, by Brooker, copyright 2014, *Understanding Biology* by Mason, copyright 2015, and *Principles of Biology* by Brooker, copyright 2015, all published by McGraw-Hill. For fun, Dr. Quitadamo practices Kyokushin full contact karate and is a 5th degree blackbelt.

Improving Biology Education: We Listened to You

A Modern Vision for Learning: Emphasizing Core Principles and Problem Solving Skills

Over the course of four editions, the ways in which biology is taught have dramatically changed. We have seen a shift away from the memorization of details, which are easily forgotten, and a movement toward emphasizing core concepts and critical thinking skills. For example, the previous edition of *Biology* put biology principles at the forefront by introducing them in Chapter 1 and then emphasizing them over and over again within the figure legends of hundreds of figures throughout the textbook. This focus on biology principles has been retained in the new edition. New to the fourth edition is a greater emphasis on skill development, thereby striking a better balance between foundational knowledge and critical thinking skills. In particular, two new features, called SciSKILLS and BioTIPS, described later, are aimed at helping students develop effective strategies for solving problems and applying their knowledge in novel situations.

Through our classroom experiences and research work, we became inspired by the prospect that the first three editions of *Biology* could move biology education forward. We are confident that this new edition of *Biology* is another step in the right direction because we listened to you. Based on our own experience and our discussions with educators and students, we continue to concentrate our efforts on these crucial areas:

Experimentation and the process of science

Modern content

Evolutionary perspective

Emphasis on visuals

Accuracy and consistency

Problem solving skills

Media—Active teaching and learning with technology

Continued feedback from instructors using this textbook and other educators in the field of biology has been extremely valuable in refining the presentation of the material. Likewise, we have used the textbook in our own classrooms. This hands-on experience has provided much insight for areas for improvement. Our textbook continues to be comprehensive and cutting-edge, featuring an evolutionary focus and an emphasis on scientific inquiry.

To help guide our revision for this fourth edition, we were able to incorporate student usage data and input, derived from thousands of our SmartBook® users. SmartBook "heat maps" provided a quick visual snapshot of chapter usage data and the relative difficulty students experienced in mastering the content. With these data, we were able to hone not only our text content but also the SmartBook probes.

- If the data indicated that the subject was more difficult than other parts of the chapter, as evidenced by a high proportion of students responding incorrectly to the probes, we revised or reorganized the content to be as clear and illustrative as possible.
- In other cases, one or more of the SmartBook probes for a section was not as clear as it might be or did not appropriately reflect the content. In these cases the *probe*, rather than the text, was edited.

A Message from the Authors

As active teachers and writers, one of the great joys of this process for us is that we have been able to meet many more educators and students during the creation of this textbook. It is humbling to see the level of dedication our peers bring to their teaching. Likewise, it is encouraging to see the energy and enthusiasm so many students bring to their studies. We hope this book and its digital resources will serve to aid both faculty and students in meeting the challenges of this dynamic and exciting course. For us, this remains a work in progress, and we encourage you to let us know what you think of our efforts and what we can do to serve you better.

Rob Brooker, Eric Widmaier, Linda Graham, Peter Stiling

KEY PEDAGOGICAL FEATURES OF THIS EDITION

The author team is dedicated to producing the most engaging and current text that is available for undergraduate students who are majoring in biology. We have listened to educators and reviewed documents, such as *Vision and Change, A Call to Action*, which includes a summary of recommendations made at a national conference organized by the American Association for the Advancement of Science (see www.visionandchange.org). We want our textbook to reflect core competencies and provide a more learner-centered approach. To achieve these goals, *Biology*, 4th edition, has the following features.

- **Principles of Biology:** Based on educational literature and feedback from biology educators, we have listed 12 Principles of Biology in Chapter 1 (see Figure 1.4). These 12 principles align with the overarching core concepts described in *Vision and Change*, with 1 to 3 principles included per core concept.
- The Principles of Biology are threaded throughout the entire textbook. This is achieved in two ways. First, the principles are explicitly stated in selected figure legends in every chapter. Such legends are given a Principle of Biology icon. In addition, a question at the end of each chapter is directly aimed at a particular principle.
- **BioTIPS:** A new feature added to *Biology*, 4th edition will help students develop their problem-solving skills. Chapters 2 through 60 contain solved problems called **BioTIPS**, which stands for **T**opic, **I**nformation, and **P**roblem-Solving **S**trategy. These solved problems follow a consistent pattern in which students are given advice on how to solve problems in biology using different types of problem-solving strategies. These strategies include: Make a drawing; Compare and contrast; Relate structure and function; Sort out the steps in a complicated process; Propose a hypothesis; Design an experiment; Predict the outcome; Interpret data; Use statistics; Make a calculation; and Search the literature.
- **SciSKILLS:** Another new feature in *Biology*, 4th edition, called **SciSKILLS**, emphasizes experimental skills needed in the study of biology. Skills such as Analyze data, Form hypotheses, Make predictions, Make calculations, are skills that scientists generally perform and students majoring in biology should be practicing. Unfortunately, students often focus on learning concepts and don't develop these important skills. SciSKILLS are incorporated in two places in *Biology*, 4th edition: as Learning Outcomes and in the Feature Investigation questions. The Learning Outcomes set expectations for student learning. Those Learning Outcomes that are designated SciSKILLS will direct students to devote time to developing certain skills associated with experimentation. Further, by including SciSKILLS questions in the Feature Investigations, students are challenged to develop scientific thinking skills.
- **Unit openers:** Each unit begins with a Unit opener that provides an overview of the chapters within that unit. They allow the student to see the big picture of the unit. In addition, the unit openers draw attention to the principles of biology that will be emphasized in that unit.
- **BioConnections:** The BioConnections inform students of how a topic in one chapter is connected to a topic in another.
- **Learning Outcomes:** As advocated in *Vision and Change*, educational materials should have well-defined learning goals. Each section of every chapter begins with a set of Learning Outcomes. These outcomes inform students of the key concepts they will learn and the skills they will acquire when mastering the material. They also provide a tangible understanding of how student learning will be assessed. The assessments in Connect were developed using these Learning Outcomes as a guide in formulating online questions, thereby linking the learning goals of the text with the assessment in Connect.

CONTENT CHANGES TO THIS EDITION

With regard to the scientific content in the textbook, the author team has worked with hundreds of faculty reviewers to refine this new edition and to update the content so that our students are exposed to the most current material. Some of the key changes that have occurred are summarized below.

- **Chapter 1. An Introduction to Biology:** Chapter 1 contains a new subsection that relates genomes and proteomes, and also explores the fascinating topic of "zombie parasites" (see Figure 1.13 and Table 1.1). It also contains a subsection that describes our new BioTIPS feature (pp. 19–20).

Chemistry Unit

- **Chapter 2. The Chemical Basis of Life I: Atoms, Molecules, and Water:** Chapter 2 contains a new BioTIPS feature that helps students to calculate molarity and to relate their calculation to a disease condition.
- **Chapter 3. The Chemical Basis of Life II: Organic Molecules:** The section on Proteins (Section 3.6) has a new figure that explains the concept of protein domains (Figure 3.20).

Cell Unit

- **Chapter 4. General Features of Cells:** This chapter has an expanded discussion of how to calculate the surface area-to-volume ratio, depending on the shape of a cell.
- **Chapter 5. Membrane Structure, Synthesis, and Transport:** The section of membrane transport has been revised to better distinguish simple diffusion from facilitated diffusion.
- **Chapter 6. An Introduction to Energy, Enzymes, and Metabolism:** This chapter has a new BioTIPS feature that helps students understand how a mutation could affect an allosteric site in an enzyme.
- **Chapter 7. Cellular Respiration and Fermentation:** The section on oxidative phosphorylation has been divided into two sections, the second of which takes a closer look at ATP synthase.
- **Chapter 8. Photosynthesis:** This chapter has a new BioTIPS feature that asks students to distinguish between the light-harvesting complex, P680, and the primary electron acceptor.
- **Chapter 9. Cell Communication:** In *Biology*, 4th edition, the topic of apoptosis has been expanded to include a discussion of how it plays a role in certain diseases (see Table 9.2).
- **Chapter 10. Multicellularity:** The section comparing animal and plant cells has been streamlined. The discussion of plasmodesmata in plants has also been revised.

Genetics Unit

- **Chapter 11. Nucleic Acid Structure, DNA Replication, and Chromosome Structure:** This chapter has a new BioTIPS feature that pertains to the role of DNA ligase during DNA replication. The illustration regarding the Avery, MacLeod, and McCarty experiment has been revised (see Figure 11.2).
- **Chapter 12. Gene Expression at the Molecular Level:** The section on RNA modification (formerly RNA processing) has been reorganized.
- **Chapter 13. Gene Regulation:** A new section has been added (Section 13.5) on Epigenetic Gene Regulation, including a new figure (Figure 13.21) and two new tables (Tables 13.1 and 13.2).
- **Chapter 14. Mutation, DNA Repair, and Cancer:** Section 14.1 that was in *Biology*, 3rd edition, is now subdivided into two sections on the Causes of Mutation and the Consequences of Mutation.
- **Chapter 15. The Eukaryotic Cell Cycle, Mitosis, and Meiosis:** The Genomes & Proteomes Connection has been changed to the topic of how mitosis in eukaryotes evolved from binary fission that occurs in prokaryotic cells (see Figure 15.10).
- **Chapter 16. Simple Patterns of Inheritance:** This chapter has a new BioTIPS feature that helps students learn how to use probability and a Punnett square to predict the outcome of crosses.
- **Chapter 17. Complex Patterns of Inheritance:** Building on the BioTIPS feature in Chapter 17, Chapter 18 has a BioTIPS feature that focuses on maternal inheritance.
- **Chapter 18. Genetics of Viruses and Bacteria:** The first part of Chapter 18 has been reorganized by adding a new section (Section 18.2) on viral reproductive cycles.
- **Chapter 19. Developmental Genetics:** In many places, the information in this chapter has been broken down into bulleted and numbered lists to make it easier for students to follow. The illustration of the effects of the bicoid mutation has been revised (see Figure 19.8).
- **Chapter 20. Genetic Technology:** In Chapter 20 of *Biology*, 4th edition, a new subsection has been added on how genetically modified organisms can make products that are useful to people (also see Table 20.1).
- **Chapter 21. Genomes, Proteomes, and Bioinformatics:** The rapidly changing information on the properties of bacterial, archaeal, and eukaryotic genomes has been updated.

Evolution Unit

- **Chapter 22. The Origin and History of Life:** This chapter has a new BioTIPS feature that helps students to learn how the calculation of radioisotope decay is used to date fossils.
- **Chapter 23. An Introduction to Evolution:** The topic of whale evolution from tetrapod mammals has been added, along with a new figure (see Figure 23.7).
- **Chapter 24. Population Genetics:** An example has been added to help students use the Hardy-Weinberg equation to calculate allele and genotype frequencies.
- **Chapter 25. Origin of Species and Macroevolution:** This chapter has a new BioTIPS feature that helps students learn how to design an experiment to determine if two populations constitute different species.
- **Chapter 26. Taxonomy and Systematics:** The information on eukaryotic supergroups has been updated. The chapter also includes an example to help students learn how to assess evolutionary trees using the principle of parsimony.

Diversity Unit

- **Chapter 27. Archaea and Bacteria:** Phylogenetic history of major lineages of Bacteria and Archaea has been updated to reflect recent progress, including identification of archaea most closely related to eukaryotes.
- **Chapter 28. Protists:** The phylogenetic history of major lineages of protists has been updated to reflect recent progress, including identification of the root of the eukaryotic tree of life. A new Feature Investigation describes an experiment that tests hypotheses of protist fossil identifications and provides results useful in industrial applications of materials produced by common protists.
- **Chapter 29. Plants and the Conquest of Land:** Table 29.1 that summarizes the features of major groups of land plants has been reorganized to enhance reader access.
- **Chapter 30. The Evolution and Diversity of Modern Gymnosperms and Angiosperms:** To emphasize the importance of whole genome duplication (WGD) events in the evolutionary history of seed plants, major WGD events have been mapped onto phylogenetic diagrams.
- **Chapter 31. Fungi:** Phylogenetic history of the fungi has been updated to reflect recent progress. Table 31.1 has been simplified to include major derived fungal lineages of most concern to human society.
- **Chapter 32. An Introduction to Animal Diversity:** The chapter opening photograph has been changed to illustrate a

naked mole rat. The introductory paragraph discusses some of the unusual features of naked mole rat biology as well as the potential value of naked mole rats to medicine. Some data in Table 32.3 have been updated.

- **Chapter 33. The Invertebrates:** The sections on both cnidarians and flatworms have been simplified. A new photograph has been provided to illustrate a molluscan veliger larva. The sections on the annelid body plan and crustacean diversity have been rewritten. The major echinoderm classes are now illustrated using five new photographs.
- **Chapter 34. The Vertebrates:** The section introducing the vertebrates has been simplified. The material on the chondrchthyans has been completely re-organized. New photographs have been used to illustrate reptile diversity.

Flowering Plants Unit

- **Chapter 38. Flowering Plants: Transport:** The Feature Investigation has been replaced. The new Feature Investigation discusses new ways to genetically modify crop plants for enhanced drought resistance. The Genomes & Proteomes feature was also replaced. The new Genomes & Proteomes feature explores the evolutionary history of plant resistance to drought. Both of these are related to the increasing need to feed populations living in arid lands and the need to cope with climate change.

Animal Unit

- **Chapter 40. Animal Bodies and Homeostasis:** A new confocal micrograph showing the complexity of nervous tissue has been added, and other figures have been modified for additional clarity. Several assessments have been added that require making predictions and analyzing data, including a new BioConnections question. A new BioTIPS feature related to body temperature homeostasis has been added.
- **Chapter 41. Neuroscience I: Cells of the Nervous System:** The material on resting membrane potential and action potentials has been subdivided into seven shorter sections to allow this challenging material to be more easily assimilated by beginning students. Several new assessments, BioConnections, and SciSKILLS have been added that require critical thinking and the ability to make predictions and perform calculations. A new figure illustrates the structural features of nerves. A new BioTIPS feature related to the ionic basis of action potentials has been added.
- **Chapter 42. Neuroscience II: Evolution, Structure, and Function of the Nervous System:** Several figures have been revised for clarity and new detail, particularly that of the structures of the human brain. Test questions have been updated to include higher Bloom's level questions. The description of the evolution of the brain has been updated, as have the discussions of the formation of memories and the effects of training on brain plasticity. The discussion of the anatomy of the vertebrate central nervous system has been reorganized and broken into smaller segments for greater clarity and manageability. A new BioTIPS feature related to the anatomical features of the vertebrate brain has been added.
- **Chapter 43. Neuroscience III: Sensory Systems:** The chapter has been reorganized by the addition of numerous subheadings to help break up complex areas of text into more manageable portions for the reader. Ten figures have been revised and updated with additional labeling and text boxes to help the reader navigate through complex topics. Many of the test questions at the end of the chapter have been revised, updated, and, where appropriate, changed to a higher Bloom's level. The chapter has been tightened to focus the reader on fundamental features of sensory biology. A new BioTIPS feature asks students to make conclusions about the relation between structure and function in different organs.
- **Chapter 44. Muscular-Skeletal Systems and Locomotion:** The chapter has been reorganized to include more subheadings and bulleted lists to assist the reader in navigating through complex material, particularly the material on the sarcomere and its bands, and material on the cross bridge cycle. Numerous figures have been revised for clarity and improved labeling and visibility. A new discussion and figure relating to myostatin have been added. Many of the test questions at the end of the chapter have been updated or revised including the addition of higher level Bloom's questions. A new BioTIPS feature asks students to make calculations and interpret graphical data related to the metabolic cost of flying.
- **Chapter 45. Nutrition and Animal Digestive Systems:** The chapter has been consolidated and shortened to focus less on feeding behavior and more on the processes of digestion and absorption. The chapter has been reorganized with eleven new subheadings for easier navigation through complex material. A new figure illustrating protein digestion and absorption in the small intestine has been added, and several figures have been improved with additional labeling and text. A new Feature Investigation (Marshall and Warren's investigation of the relation of *H. pylori* to stomach ulcers) has been added. Test questions at the end of the chapter and in the Feature Investigation have been modified to include higher order Bloom's questions. A new BioTIPS feature asks students to predict the benefits of segregated function in the alimentary canal.
- **Chapter 46. Control of Energy Balance, Metabolic Rate, and Body Temperature:** Numerous figures and test questions have been modified and updated, and the text has been reorganized to include several new subheadings. The chapter has been shortened to better focus on key, fundamental features of energy balance and thermal regulation. A new BioTIPS feature has been added that asks students to propose an hypothesis regarding the experimental effects of the hormone leptin on body mass in mice.
- **Chapter 47. Circulatory Systems:** The chapter has been shortened and consolidated to better focus on the similarities and differences between open and closed circulations, and single and double circulations. The events of the ECG have been reorganized into a bulleted list for emphasis and clarity. The table describing comparative features of mammalian hearts has been expanded. Numerous new subheadings have been added, as have several new test questions and Concept Checks. A new BioTIPS feature has been added that requires students to describe the sequence of steps in the vertebrate heart cycle.
- **Chapter 48. Respiratory Systems:** Several new subheadings have been added, as have numerous new or revised test questions, Concept Checks, BioConnections, and collaborative ques-

tions. A new figure illustrating asthma and bronchoconstriction has been added. A new Feature Investigation describing the effectiveness of surfactant in human newborns has been added. A new photomicrograph of an emphysematous lung has been added. A new BioTIPS feature has been added that requires students to make a graph and make calculations regarding the relation between altitude and oxygen pressure.

- **Chapter 49. Excretory Systems and the Homeostasis of Internal Fluids:** The title has been changed to reflect the important role of excretory systems in homeostasis. The concept of osmolarity is now introduced very early in the text, to lay the groundwork for later discussions in the chapter. Numerous bulleted lists (for example, in the discussion about individual parts of a nephron) and subheadings have been added to break up complex material and provide a useful study guide. Many of the test questions have been updated or revised, including BioConnection questions and Feature Investigation questions, in some cases where appropriate at higher Bloom's levels. A new BioTIPS feature has been added that requires students to relate the structure of a nephron to its function.
- **Chapter 50. Endocrine Systems:** Eleven figures have been revised with improved labeling and text box detail where appropriate, to better help the student work through illustrations of complex processes. Numerous subheadings and revised test questions, including Feature Investigation questions, have been added. The introductory material on the chemical nature and mechanisms of actions of hormones has been consolidated and tightened to focus on major concepts. The material on endocrine disruptors has been updated. A new BioTIPS feature has been added that requires students to predict the outcome of a scenario in which Ca^{2+} homeostasis may be compromised.
- **Chapter 51. Animal Reproduction:** New conceptual, collaborative, and multiple choice questions have been added to the end of the chapter. Several new subheadings and six revised figures have been added. A new BioTIPS feature has been added that requires students to predict what might happen in a person who takes supplements of the androgen testosterone.
- **Chapter 52. Animal Development:** New BioConnection questions, Concept Checks, and multiple choice questions have been added. The figures on fertilization, cleavage, and neurulation have been revised. The section on morphogenesis and control of development has been shortened, consolidated and reorganized to reduce redundancy and improve clarity. A new BioTIPS feature has been added that asks students to place various events in their correct stage of development.
- **Chapter 53. Immune Systems:** Eleven figures have been revised and updated (such as the latest figures on people living with HIV worldwide). New subheadings have been added to shorten complex regions of text (for example, the discussion of the production and recirculation of lymphocytes). Several new collaborative questions and Concept Checks have been added. A new figure of a micrograph of a mast cell has been added. The discussion of the different cell types of the immune system now includes a bulleted list as a visual aid to the reader and a handy study reference. A new BioTIPS feature has been added that requires students to make a prediction about immune responses in the absence of memory cells.

Ecology Unit

- **Chapter 54. An Introduction to Ecology and Biomes:** Section 54.2, Ecological Methods, has been completely rewritten. Instead of using a hypothetical example of locust ecology, we have instead used a real life example of oak winter moth ecology. We discuss how knowledge of the oak winter moth life cycle was vital in addressing control of this important apple orchard pest in the U.S. northwest and western Canada. Several new figures have been prepared to help in illustrating main points of this section. In Section 54.3, The Environment's Effect on the Distribution of Organisms, we have provided a new example of the effects of cold temperatures on organismal distribution by including a figure on how the frequency of the cyanide-producing form of white clover in Europe is affected by temperature. In the section on Global Warming, data on selected greenhouse gases have been updated in Table 54.2. Many new photographs have been included in Section 54.5 on major biomes. Finally, in Section 54.6, Continental Drift and Biogeography, we have included a new figure on the distribution of fossil land plants and animals to illustrate the concept of continental drift.
- **Chapter 55. Behavioral Ecology:** In Section 55.3, Foraging Behavior, we have illustrated the concept of optimal foraging by including new information, and a new figure, on optimal foraging by leafcutter ants, and the disruption of this foraging by parasitic flies. We have also simplified the chapter by eliminating the section on sexual selection and mate choice, which is already covered in Chapter 24.
- **Chapter 56. Ecology:** The section on Quantifying Population Density has been divided into more easily digestible parts by the use of subheadings. The section of Human Population Growth has been updated.
- **Chapter 57. Species Interactions:** The section on Predation, Herbivory, and Parasitism has been substantially rewritten and simplified. The example of cactus control by the cactus moth, *Cactoblastis cactorum*, has been added to this section. Section 57.4, on bottom-up and top-down control, has been simplified and a new figure on the nitrogen content of plants and animals has been added. In addition, a new figure illustrates the trophic interactions that can result from the effects of wolf addition, using data from Banff National Park, Canada.
- **Chapter 58. Community Ecology:** In Section 58.3, Calculating Species Diversity, we introduce the new concept of effective number of species and provide details of how to calculate it. This measure of species diversity permits easy and meaningful comparisons between different communities.
- **Chapter 59. Ecosystem Ecology:** The distinction between decomposers and detritivores has been made clearer throughout the chapter. Figure 59.19, which concerns the increase in atmosphere CO_2 levels and temperatures due to the burning of fossil fuels, has been updated.
- **Chapter 60. Biodiversity and Conservation Biology:** Section 60.2, Why Conserve Biodiversity, has been updated. Tables 60.1 and 60.2, which provide data on examples of the world's ecosystem services and the valuation of those services, have been completely rewritten and modernized using the latest data. We have also added an additional question to the Feature Investigation.

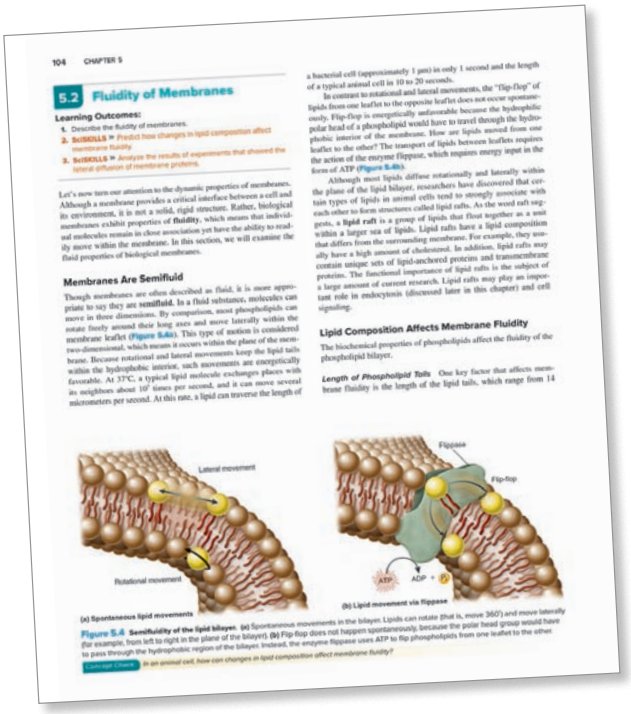
A NOTE FROM THE AUTHORS

The lives of most science-textbook authors do not revolve around an analysis of writing techniques. Instead, we are people who understand science and are inspired by it, and we want to communicate that information to our students. Simply put, we need a lot of help to get it right.

Editors are a key component that help the authors modify the content of their book so it is logical, easy to read, and inspiring. The editorial team for this *Biology* textbook has been a catalyst that kept this project rolling. The members played various roles in the editorial process. Rebecca Olson and following her, Justin Wyatt, Brand Managers (Major Biology) did outstanding jobs overseeing the fourth edition. Their insights with regard to pedagogy, content, and organization have been invaluable. Elizabeth Sievers, Lead Product Developer, has been the master organizer. Liz's success at keeping us on schedule is greatly appreciated. We would also like to acknowledge our copy editor, Jane Hoover, for keeping our grammar on track.

Another important aspect of the editorial process is the actual design, presentation, and layout of materials. It's confusing if the text and art aren't on the same page, or if a figure is too large or too small. We are indebted to the tireless efforts of Jayne Klein, Content Project Manager; and David Hash, Senior Designer at McGraw-Hill. Likewise, our production company, Lachina Publishing Services, did an excellent job with the paging, revision of existing art, and the creation of new art for the fourth edition. Their artistic talents, ability to size and arrange figures, and attention to the consistency of the figures have been remarkable.

We would like to acknowledge the ongoing efforts of the superb marketing staff at McGraw-Hill. Special thanks to Patrick Reidy, Executive Marketing Manager-Life Sciences, for his ideas and enthusiasm for this book.



Finally, other staff members at McGraw-Hill Higher Education have ensured that the authors and editors were provided with adequate resources to achieve the goal of producing a superior textbook. These include Kurt Strand, Senior Vice President, Products & Markets, and Marty Lange, Vice President, General Manager, Products & Markets, and Michael Hackett, Director for Life Sciences.

EMPHASIZING PROBLEM-SOLVING AND SKILLS DEVELOPMENT

Skills Development

At the beginning of each section, **Learning Outcomes** inform students of concepts they should understand and new to the fourth edition are skills-based Learning Outcomes. Labeled as **SciSKILLS**, these Learning Outcomes are specific to the skills students will acquire when mastering the material and provide a specific understanding of how such skills may be assessed. SciSKILLS is a mental action such as analyze data, form hypotheses, make predictions, or perform calculations. These are skills scientists generally perform and students should practice.

The emphasis on skills development continues in the ***Feature Investigations***. Feature Investigations provide a complete description of experiments, including data analysis, so students can understand how experimentation leads to an understanding of biological concepts.

104 CHAPTER 5

5.2 Fluidity of Membranes

Learning Outcomes:
1. Describe the fluidity of membranes.
2. SciSKILLS » Predict how changes in lipid composition affect membrane fluidity.
3. SciSKILLS » Analyze the results of experiments that showed the lateral diffusion of membrane proteins.

Let's now turn our attention to the dynamic properties of membranes. Although a membrane provides a critical interface between a cell and its environment, it is not a solid, rigid structure. Rather, biological membranes exhibit properties of **fluidity**, which means that individual molecules remain in close association yet have the ability to readily move within the membrane. In this section, we will examine the fluid properties of biological membranes.

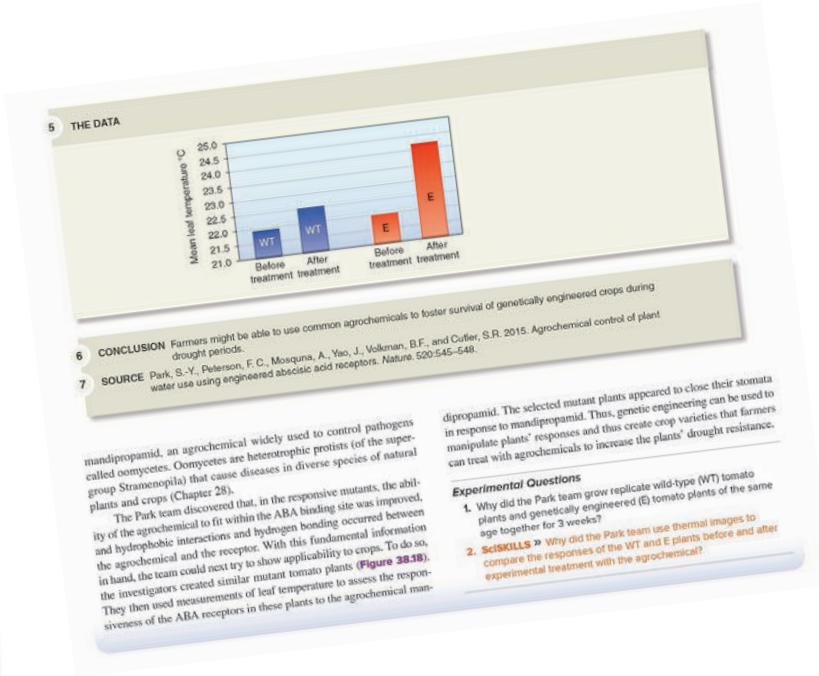
Membranes Are Semifluid

Though membranes are often described as fluid, it is more appropriate to say they are **semifluid**. In a fluid substance, molecules can move in three dimensions. By comparison, most phospholipids can rotate freely around their long axes and move laterally within the membrane leaflet (Figure 5.4a). This type of motion is considered two-dimensional, which means it occurs within the plane of the membrane. Because rotational and lateral movements keep the lipid tails within the hydrophobic interior, such movements are energetically favorable. At 37°C, a typical lipid molecule exchanges places with its neighbors about 10^7 times per second, and it can move several micrometers per second. At this rate, a lipid can traverse the length of a bacterial cell (approximately 1 μm) in only 1 second and the length of a typical animal cell in 10 to 20 seconds.

In contrast to rotational and lateral movements, the "flip-flop" of lipids from one leaflet to the opposite leaflet does not occur spontaneously. Flip-flop is energetically unfavorable because the hydrophilic polar head of a phospholipid would have to travel through the hydrophobic interior of the membrane. How are lipids moved from one leaflet to the other? The transport of lipids between leaflets requires the action of the enzyme Flippase, which requires energy input in the form of ATP (Figure 5.4b).

Although most lipids diffuse rotationally and laterally within the plane of the lipid bilayer, researchers have discovered that certain types of lipids in animal cells tend to strongly associate with each other to form structures called lipid rafts. As the word raft suggests, a **lipid raft** is a group of lipids that float together as a unit within a larger sea of lipids. Lipid rafts have a lipid composition that differs from the surrounding membrane. For example, they usually have a high amount of cholesterol. In addition, lipid rafts may contain unique sets of lipid-anchored proteins and transmembrane proteins. The functional importance of lipid rafts is the subject of a large amount of current research. Lipid rafts may play an important role in endocytosis (discussed later in this chapter) and cell signaling.

Lipid Composition Affects Membrane Fluidity



The biochemical properties of phospholipids affect the fluidity of the phospholipid bilayer.

Length of Phospholipid Tails One key factor that affects membrane fluidity is the length of the lipid tails, which range from 14

Lateral movement
Rotational movement
(a) Spontaneous lipid movements
Flippase
Flip-flop
ATP
ADP + P
(b) Lipid movement via flippase

Figure 5.4 Semifluidity of the lipid bilayer. (a) Spontaneous movements in the bilayer. Lipids can rotate (that is, move 360°) and move laterally (for example, from left to right in the plane of the bilayer). (b) Flip-flop does not happen spontaneously because the polar head group would have to pass through the hydrophobic region of the bilayer. Instead, the enzyme flippase uses ATP to flip phospholipids from one leaflet to the other.

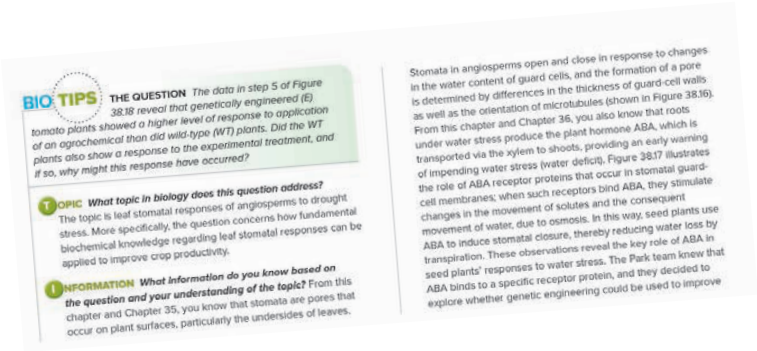
Concept Check In an animal cell, how can changes in lipid composition affect membrane fluidity?

5 THE DATA

6 CONCLUSION Farmers might be able to use common agrochemicals to foster survival of genetically engineered crops during drought periods.

7 SOURCE Park, S.-Y., Peterson, F. C., Mosquna, A., Yao, J., Volkman, B.F., and Cutler, S.R. 2015. Agrochemical control of plant water use using engineered abscisic acid receptors. *Nature*. 520:545–548.

mandipropamid, an agrochemical widely used to control pathogens called oomycetes. Oomycetes are heterotrophic protists (of the supergroup Stramenopila) that cause diseases in diverse species of natural plants and crops (Chapter 28).



The Park team discovered that, in the responsive mutants, the ability of the agrochemical to fit within the ABA binding site was improved, and hydrophobic interactions and hydrogen bonding occurred between the agrochemical and the receptor. With this fundamental information in hand, the team could next try to show applicability to crops. To do so, the investigators created similar mutant tomato plants (Figure 38.18). They then used measurements of leaf temperature to assess the responsiveness of the ABA receptors in these plants to the agrochemical mandipropamid. The selected mutant plants appeared to close their stomata in response to mandipropamid. Thus, genetic engineering can be used to manipulate plants' responses and thus create crop varieties that farmers can treat with agrochemicals to increase the plants' drought resistance.

Experimental Questions

1. Why did the Park team grow replicate wild-type (WT) tomato plants and genetically engineered (E) tomato plants of the same age together for 3 weeks?
2. SciSKILLS » Why did the Park team use thermal images to compare the responses of the WT and E plants before and after experimental treatment with the agrochemical?

Problem Solving

A new feature added to *Biology*, 4th edition, will help students develop their problem solving skills. Chapters 2 through 60 contain solved problems called **BioTIPS**, which stands for **T**opic, **I**nformation, and **P**roblem Solving **S**trategy. These solved problems follow a consistent pattern in which students are given advice on how to solve problems in biology using different types of problem solving strategies. These strategies include: Make a drawing; Compare and contrast; Relate structure and function; Sort out the steps in a complicated process; Propose a hypothesis; Design an experiment; Predict the outcome; Interpret data; Use statistics; Make a calculation; and Search the literature.

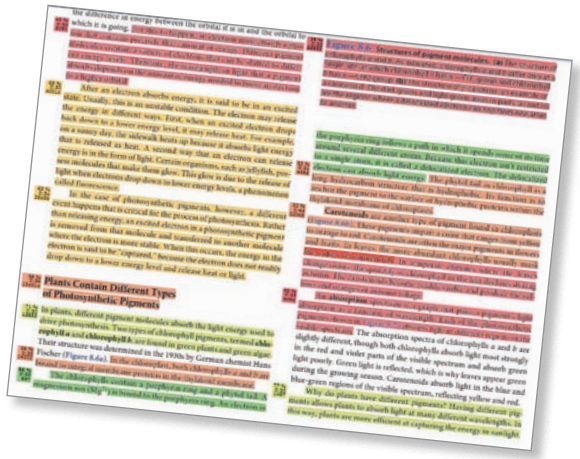
BIO TIPS

THE QUESTION *The data in step 5 of Figure 38.18 reveal that genetically engineered (E) tomato plants showed a higher level of response to application of an agrochemical than did wild-type (WT) plants. Did the WT plants also show a response to the experimental treatment, and if so, why might this response have occurred?*

TOPIC ***What topic in biology does this question address?*** The topic is leaf stomatal responses of angiosperms to drought stress. More specifically, the question concerns how fundamental biochemical knowledge regarding leaf stomatal responses can be applied to improve crop productivity.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From this chapter and Chapter 35, you know that stomata are pores that occur on plant surfaces, particularly the undersides of leaves.

Stomata in angiosperms open and close in response to changes in the water content of guard cells, and the formation of a pore is determined by differences in the thickness of guard-cell walls as well as the orientation of microtubules (shown in Figure 38.16). From this chapter and Chapter 36, you also know that roots under water stress produce the plant hormone ABA, which is transported via the xylem to shoots, providing an early warning of impending water stress (water deficit). Figure 38.17 illustrates the role of ABA receptor proteins that occur in stomatal guard-cell membranes; when such receptors bind ABA, they stimulate changes in the movement of solutes and the consequent movement of water, due to osmosis. In this way, seed plants use ABA to induce stomatal closure, thereby reducing water loss by transpiration. These observations reveal the key role of ABA in seed plants' responses to water stress. The Park team knew that ABA binds to a specific receptor protein, and they decided to explore whether genetic engineering could be used to improve



The emphasis on developing problem solving skills is carried over to the digital content, as described later.

USING STUDENT USAGE DATA TO MAKE IMPROVEMENTS

To help guide the revision for the fourth edition, student usage data and input were used, derived from thousands of SmartBook® users of the 3rd edition. SmartBook "heat maps" provided a quick visual snapshot of chapter usage data and the relative difficulty students experienced in mastering the content. These data directed the authors to evaluate text content that was particularly challenging for students. These same data were also used to revise the SmartBook probes.

- If the data indicated that the subject was more difficult than other parts of the chapter, as evidenced by a high proportion of students responding incorrectly to the probes, the authors revised or reorganized the content to be as clear and illustrative as possible by rewriting the section, providing additional examples or revised figures to assist visual learners, etc.
- In other cases, one or more of the SmartBook probes for a section was not as clear as it might be or did not appropriately reflect the content in the chapter. In these cases the *probe*, rather than the text, was edited.

Below is an example of one of the heat maps from Chapter 8. The color-coding of highlighted sections indicates the various levels of difficulty students experienced in learning the material, topics highlighted in red being the most challenging for students.

MAKING CONNECTIONS

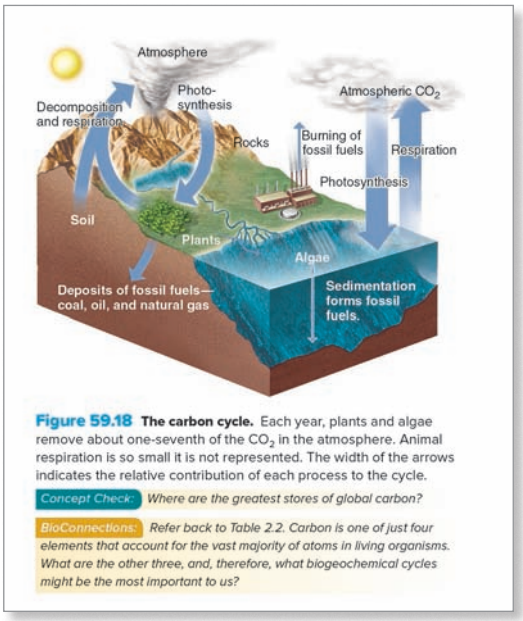


Figure 59.18 **The carbon cycle.** Each year, plants and algae remove about one-seventh of the CO_2 in the atmosphere. Animal respiration is so small it is not represented. The width of the arrows indicates the relative contribution of each process to the cycle.

Concept Check: *Where are the greatest stores of global carbon?*

BioConnections: *Refer back to Table 2.2. Carbon is one of just four elements that account for the vast majority of atoms in living organisms. What are the other three, and, therefore, what biogeochemical cycles might be the most important to us?*

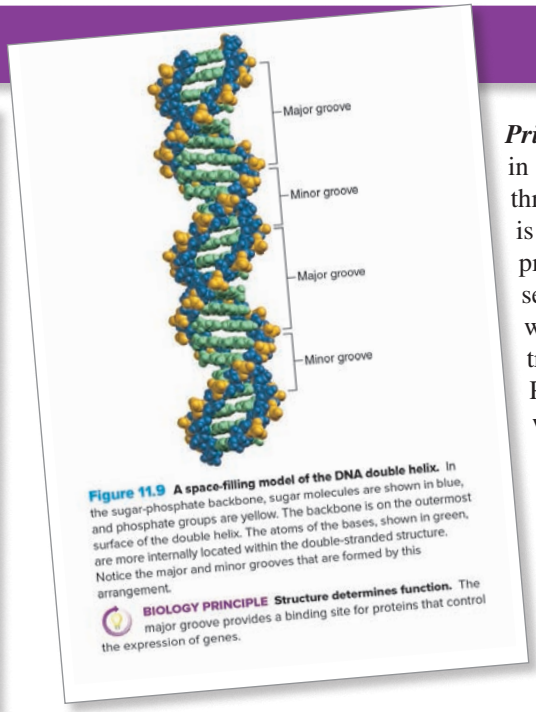

Figure 11.9 **A space-filling model of the DNA double helix.** In the sugar-phosphate backbone, sugar molecules are shown in blue, and phosphate groups are yellow. The backbone is on the outermost surface of the double helix. The atoms of the bases, shown in green, are more internally located within the double-stranded structure. Notice the major and minor grooves that are formed by this arrangement.

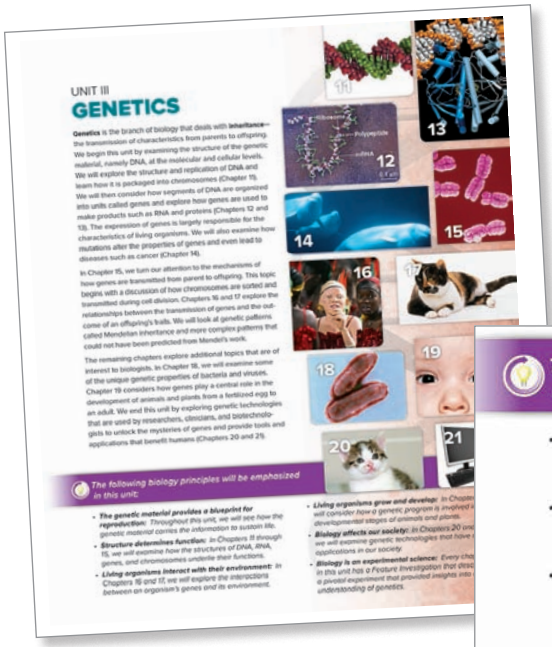
BIOLOGY PRINCIPLE **Structure determines function.** The major groove provides a binding site for proteins that control the expression of genes.



Principles of Biology are introduced in Chapter 1 and are then threaded throughout the entire textbook. This is achieved in two ways. First, the principles are explicitly stated in selected figure legends for figures in which the specific principle is illustrated. The legends that relate to a Principle of Biology are highlighted with an icon.

In addition, a Conceptual Question at the end of each chapter is directly aimed at exploring a particular principle related to the content of the chapter.

BioConnections BioConnections are questions found in selected figure legends in each chapter that help students make connections between biological concepts. BioConnections help students understand that their study of biology involves linking concepts together and building on previously learned information. Answers to the BioConnections are found in Appendix B.

Conceptual Questions

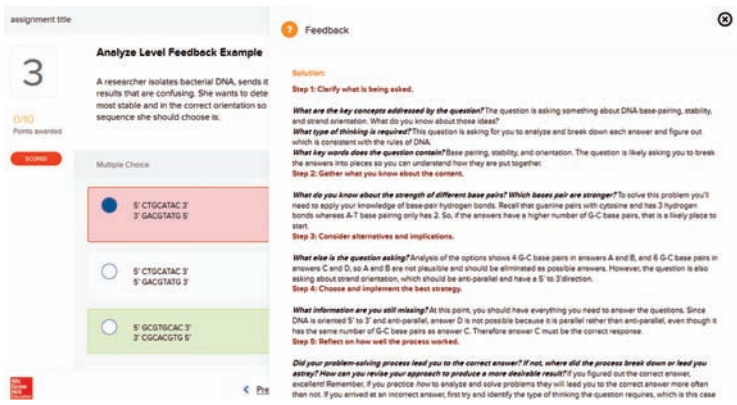
1. What are the four key criteria that the genetic material must fulfill? What was Griffith's contribution to the study of DNA, and why was it so important?
2. A double-stranded DNA molecule contains 560 nucleotides. How many complete turns occur in this double helix?
3. A principle of biology is that *structure determines function.* Discuss how the structure of DNA underlies different aspects of its function.

Unit openers serve two purposes. They allow the student to see the big picture of the unit. In addition, the unit openers draw attention to the principles of biology that will be emphasized in that unit.

The following biology principles will be emphasized in this unit:

- ***The genetic material provides a blueprint for reproduction:*** *Throughout this unit, we will see how the genetic material carries the information to sustain life.*
- ***Structure determines function:*** *In Chapters 11 through 15, we will examine how the structures of DNA, RNA, genes, and chromosomes underlie their functions.*
- ***Living organisms interact with their environment:*** *In Chapters 16 and 17, we will explore the interactions between an organism's genes and its environment.*
- ***Living organisms grow and develop:*** *In Chapter 19, we will consider how a genetic program is involved in the developmental stages of animals and plants.*
- ***Biology affects our society:*** *In Chapters 20 and 21, we will examine genetic technologies that have many applications in our society.*
- ***Biology is an experimental science:*** *Every chapter in this unit has a Feature Investigation that describes a pivotal experiment that provided insights into our understanding of genetics.*

Strengthen Problem Solving Skills and Key Concept Development with Connect®



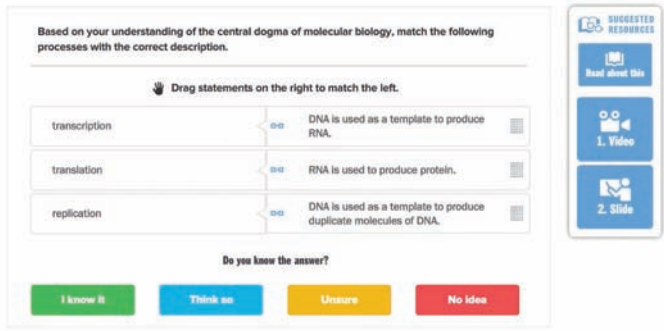
Problem Solving Skills

Detailed Feedback in Connect®

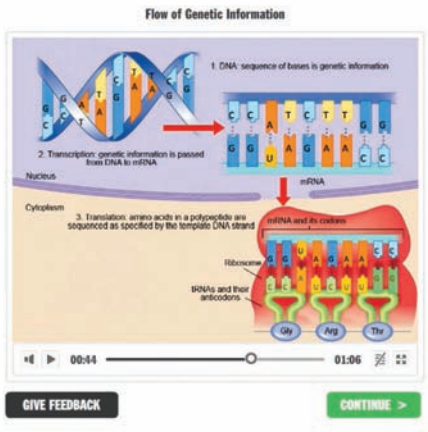
Learning is a process of iterative development, of making mistakes, reflecting, and adjusting over time. The question and test banks in Connect® for *Biology*, 4th edition, are more than direct assessments; they are self-contained learning experiences that systematically build student learning over time.

For many students, choosing the right answer is not necessarily based on applying content correctly; it is more a matter of increasing their statistical odds of guessing. A major fault with this approach is students don't learn how to process the questions correctly, mostly because they are repeating and reinforcing their mistakes rather than reflecting and learning from them. To help students develop problem solving skills, all higher level Blooms questions in Connect are supported with hints, to help students focus on important information for answering the questions, and detailed feedback that walks students through the problem solving process, using Socratic questions in a decision tree-style framework to scaffold learning, where each step models and reinforces the learning process.

The feedback for each higher level Blooms question (Apply, Analyze, Evaluate) follows a similar process: Clarify Question, Gather Content, Consider Possibilities, Choose Answer, Reflect on Process.



Unpacking the Concepts

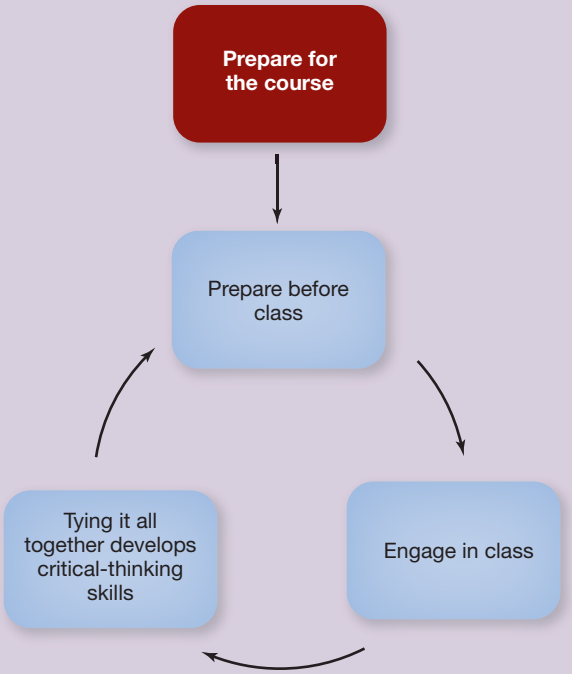


We've taken problem solving a step further. In each chapter, 3 to 5 higher level Blooms questions in the question and test banks are broken out by the steps in detailed feedback. Rather than leaving it up to the student to work through the detailed feedback, a second version of the question is presented in a stepwise format. Following the problem solving steps, students need to answer questions about earlier steps, such as "What is the key concept addressed by the question?" before proceeding to answer the question. A professor can choose which version of the question to include in the assignment based on the problem solving skills of the students.

Key Concept Development

SmartBook with Learning Resources

To help students understand key concepts, SmartBook® for *Biology*, 4th edition, is enhanced with Learning Resources. Based on student usage data, derived from thousands of SmartBook users of the third edition, concepts that proved more challenging for students are supported with Learning Resources to enhance the textbook presentation. Learning Resources, such as animations and tutorials, are indicated in Smartbook adjacent to the textbook content. If a student is struggling with a concept based on his/her performance of the SmartBook questions, the student is given an option to review the Learning Resource or the student can click on the Learning Resources at any time.



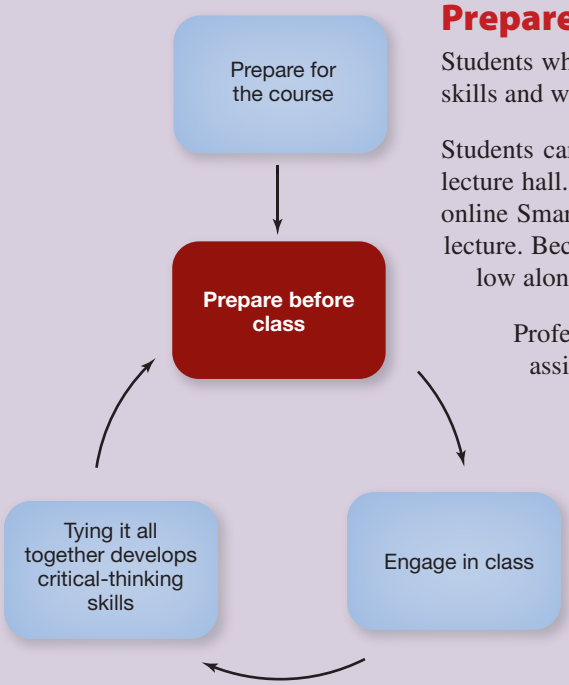
USING CONNECT AND *BIOLOGY*, 4TH EDITION

Biology, 4th edition, and its online assets have been carefully crafted to help professors and students, work efficiently and effectively through the material in the course, making the most of instructional and study time.

PREPARE FOR THE COURSE

Many biology students struggle the first few weeks of class. Many institutions expect students to start majors biology having a working knowledge of basic chemistry and cellular biology. *LearnSmart Prep* is now available in Connect. Professors can assign modules in LearnSmart Prep to help students get up to speed on core concepts or students can access LearnSmart Prep directly through the LearnSmart Prep link.

LEARNSMART PREP® LearnSmart Prep is an adaptive learning tool designed to increase student success and aid retention through the first few weeks of class. Using this digital tool, Majors Biology students can master some of the most fundamental and challenging principles of biology before they begin to struggle in the first few weeks of class



1 A diagnostic establishes your baseline comprehension and knowledge; then the program generates a learning plan tailored to your academic needs and schedule.

2 As you work through the learning plan, the program asks you questions and tracks your mastery of concepts. If you answer questions about a particular concept incorrectly, the program will provide a learning resource (ex. animation or tutorial) on that concept, then ensure that you understand the concept by asking you more questions. Didn't get it the first time? Don't worry—*LearnSmart Prep* will keep working with you!

3 Using *LearnSmart Prep*, you can identify the content you don't understand, focus your time on content you need to know but don't, and therefore improve your chances of success in your majors biology course.

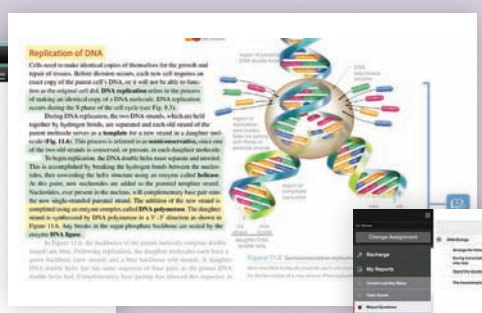
Prepare Before Class

Students who are most successful in college are those who have developed effective study skills and who use those skills, before, during, and after class.

Students can maximize time in class by previewing the material before stepping into the lecture hall. *Biology,* 4th edition, is available in two formats: the printed text as well as the online SmartBook. Students can use either of these options to preview the material before lecture. Becoming familiar with terminology and basic concepts will allow students to follow along in class and engage in the content in a way that allows for better retention.

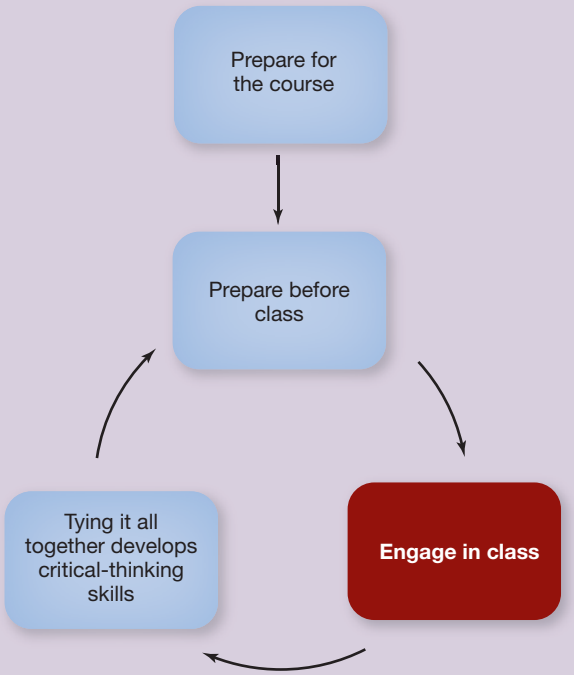
Professors can help students prepare for class by making assignments—SmartBook assignments are effective for introducing terminology and general concepts.

SmartBook provides a personalized, adaptive reading experience.



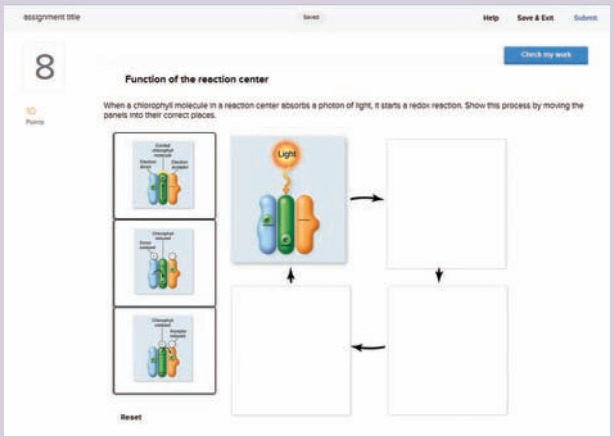
Powered by an intelligent diagnostic and adaptive engine, SmartBook facilitates the reading process by identifying what content a student knows and doesn't know through adaptive assessments.

▲ The SmartBook experience starts by previewing key concepts from the chapter and ensuring that you understand the big ideas.



▲ SmartBook asks you questions that identify gaps in your knowledge. The reading experience then continuously adapts in response to the assessments—highlighting the material you need to review based on what you don't know.

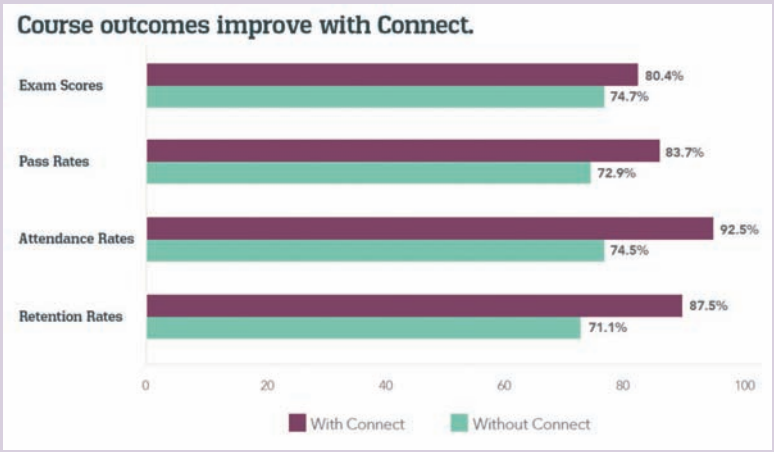
▼ The reports in SmartBook help identify topics where you need more work.



Engage in Class

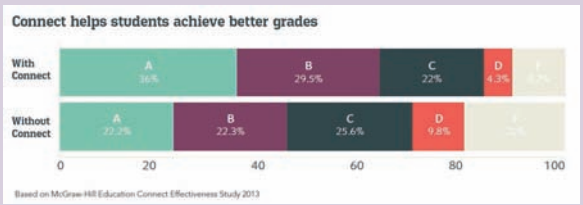
McGraw-Hill Connect provides online presentation, assignment, and assessment solutions. It connects students with the tools and resources they'll need to achieve success. A robust set of questions and activities is presented in the Question Bank and a separate set of questions to use for exams are presented in the Test Bank. Instructors can edit existing questions and author entirely new problems. Track individual student performance—by question, assignment, or in relation to the class overall—with detailed grade reports.

1 Pre-class assignments to help students engage in the content during class.

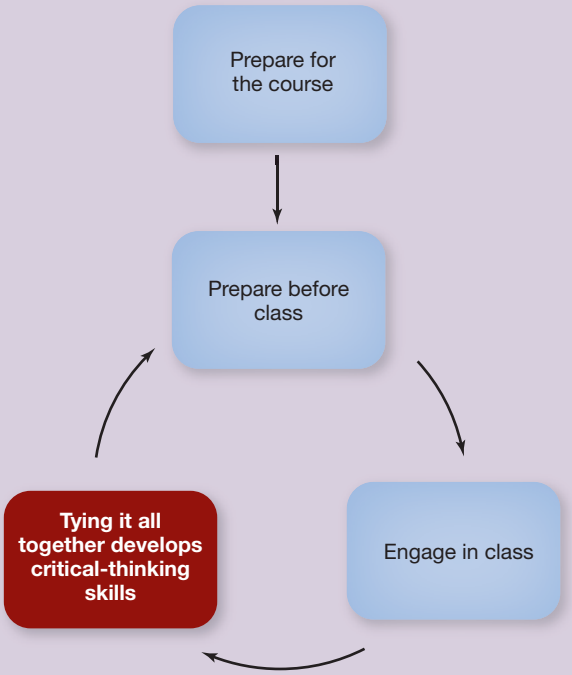


Mc Graw Hill Education connect®

Assignments are accessed through Connect and could include homework assignments, quizzes, SmartBook assignments, and other resources.



Interactive and traditional questions help assess your knowledge of the material.



2 Connect Insight is Connect's visual analytics dashboard for instructors and students.

◀ Provides at-a-glance student performance on assignments. Instructors can use the information for a just-in-time approach to teaching.

◀ Connect Insight presents data that empowers students to improve performance that is efficient and effective.

Tying It All Together

Follow up class with assessment that helps students develop problem solving skills. Set up assignments from the various assessment banks in Connect.

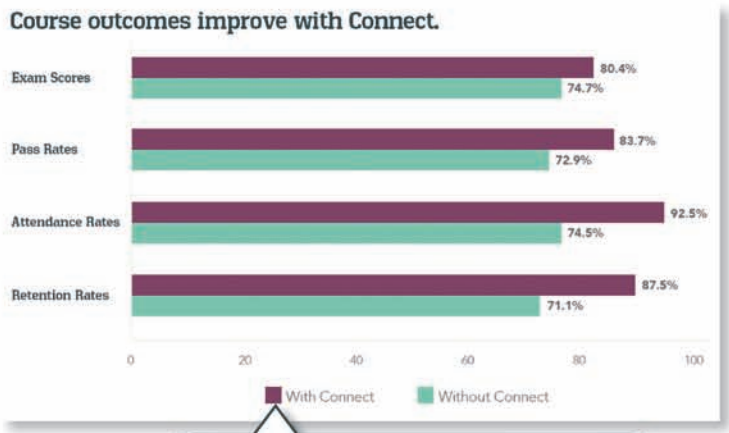
The Question and Test Banks contain higher order critical thinking questions that require students to demonstrate a more in-depth understanding of the concepts—instructors can quickly and easily filter the banks for these questions using higher level Blooms tags.

◀ **Detailed Feedback** All higher level Blooms questions, that involve problem solving, contain detailed feedback in Connect. The feedback walks students through the steps of the problem solving process and helps them evaluate their scientific thinking skills.

Many chapters also contain a **Quantitative Question Bank.** These are more challenging algorithmic questions, intended to help your students practice their quantitative reasoning skills. Hints and guided solution options step students through a problem. ▶

Mc Graw Hill Education

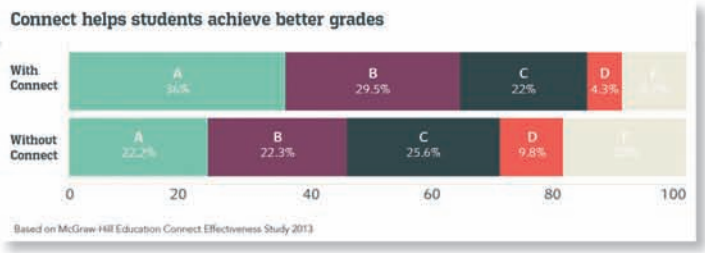
connect®



Required=Results

McGraw-Hill Connect®
Learn Without Limits

Connect is a teaching and learning platform that is proven to deliver better results for students and instructors.



Connect empowers students by continually adapting to deliver precisely what they need, when they need it, and how they need it, so your class time is more engaging and effective.

Using **Connect** improves passing rates by **10.8%** and retention by **16.4%.**

88% of instructors who use **Connect** require it; instructor satisfaction **increases** by 38% when **Connect** is required.

Analytics

Connect Insight®

Connect Insight is Connect's new one-of-a-kind visual analytics dashboard—now available for both instructors and students—that provides at-a-glance information regarding student performance, which is immediately actionable. By presenting assignment, assessment, and topical performance results together with a time metric that is easily visible for aggregate or individual results, Connect Insight gives the user the ability to take a just-in-time approach to teaching and learning, which was never before available. Connect Insight presents data that empowers students and helps instructors improve class performance in a way that is efficient and effective.

Students can view their results for any **Connect** course.

Mobile

Connect's new, intuitive mobile interface gives students and instructors flexible and convenient, anytime–anywhere access to all components of the Connect platform.

Adaptive

THE FIRST AND ONLY **ADAPTIVE READING EXPERIENCE** DESIGNED TO TRANSFORM THE WAY STUDENTS READ

More students earn **A's** and **B's** when they use McGraw-Hill Education **Adaptive** products.

SmartBook®

Proven to help students improve grades and study more efficiently, SmartBook contains the same content within the print book, but actively tailors that content to the needs of the individual. SmartBook's adaptive technology provides precise, personalized instruction on what the student should do next, guiding the student to master and remember key concepts, targeting gaps in knowledge and offering customized feedback, and driving the student toward comprehension and retention of the subject matter. Available on smartphones and tablets, SmartBook puts learning at the student's fingertips—anywhere, anytime.

Over **4 billion questions** have been answered, making McGraw-Hill Education products more intelligent, reliable, and precise.

www.learnsmartadvantage.com

STUDENTS WANT SMARTBOOK®

95% of students reported **SmartBook** to be a more effective way of reading material

100% of students want to use the Practice Quiz feature available within **SmartBook** to help them study

100% of students reported having reliable access to off-campus wifi

90% of students say they would purchase **SmartBook** over print alone

95% reported that **SmartBook** would impact their study skills in a positive way

12.1 Overview of Gene Expression 235
12.2 Transcription 238
12.3 RNA Modification in Eukaryotes 240
12.4 Translation and the Genetic Code 242
Feature Investigation: Nirenberg and Leder Found That RNA Triplets Can Promote the Binding of tRNA to Ribosomes 245
12.5 The Machinery of Translation 247
Genomes & Proteomes Connection: Comparisons of Small Subunit rRNAs Among Different Species Provide a Basis for Establishing Evolutionary Relationships 250
12.6 The Stages of Translation 251

Chapter 13

Gene Regulation 257

13.1 Overview of Gene Regulation 257
13.2 Regulation of Transcription in Bacteria 260
Feature Investigation: Jacob, Monod, and Pardee Studied a Constitutive Mutant to Determine the Function of the Lac Repressor 264
13.3 Regulation of Transcription in Eukaryotes: Roles of Transcription Factors and Mediator 269
13.4 Regulation of Transcription in Eukaryotes: Changes in Chromatin Structure and DNA Methylation 271
13.5 Epigenetic Gene Regulation 274
13.6 Regulation of RNA Modification and Translation in Eukaryotes 276
Genomes & Proteomes Connection: Alternative Splicing Tends to Be More Prevalent in Complex Eukaryotic Species 277

Chapter 14

Mutation, DNA Repair, and Cancer 281

14.1 Consequences of Mutations 281
14.2 Causes of Mutations 285
Feature Investigation: The Lederbergs Used Replica Plating to Show That Mutations Are Random Events 285
14.3 DNA Repair 289
14.4 Cancer 291
Genomes & Proteomes Connection: Mutations in Approximately 300 Human Genes May Promote Cancer 298

Chapter 15

The Eukaryotic Cell Cycle, Mitosis, and Meiosis 300

15.1 The Eukaryotic Cell Cycle 300
Feature Investigation: Masui and Markert's Study of Oocyte Maturation Led to the Identification of Cyclins and Cyclin-Dependent Kinases 305
15.2 Mitotic Cell Division 306
Genomes & Proteomes Connection: Mitosis in Eukaryotes Evolved from the Binary Fission That Occurs in Prokaryotic Cells 310
15.3 Meiosis and Sexual Reproduction 311
15.4 Variation in Chromosome Structure and Number 318

Chapter 16

Simple Patterns of Inheritance 325

16.1 Mendel's Laws of Inheritance 326
16.2 The Chromosome Theory of Inheritance 331
16.3 Pedigree Analysis of Human Traits 334
16.4 Sex Chromosomes and X-Linked Inheritance Patterns 335
Feature Investigation: Morgan's Experiments Showed a Correlation Between a Genetic Trait and the Inheritance of a Sex Chromosome in *Drosophila* 337
16.5 Variations in Inheritance Patterns and Their Molecular Basis 339
Genomes & Proteomes Connection: Recessive Alleles That Cause Diseases May Have Multiple Effects on Phenotype 340
16.6 Genetics and Probability 343

Chapter 17

Complex Patterns of Inheritance 347

17.1 Gene Interaction 348
17.2 Genes on the Same Chromosome: Linkage, Recombination, and Mapping 350
Feature Investigation: Bateson and Punnett's Cross of Sweet Peas Showed That Genes Do Not Always Assort Independently 350
17.3 Extranuclear Inheritance: Organelle Genomes 354
Genomes & Proteomes Connection: Chloroplast and Mitochondrial Genomes Are Relatively Small, but Contain Genes That Encode Important Proteins 354
17.4 Epigenetic Inheritance 357

Chapter 18

Genetics of Viruses and Bacteria 364

18.1 Genetic Properties of Viruses 365
18.2 Viral Reproductive Cycles 368
18.3 Viroids and Prions 373
18.4 Genetic Properties of Bacteria 375
18.5 Gene Transfer Between Bacteria 378

Feature Investigation: Lederberg and Tatum's Work with *E. coli* Demonstrated Gene Transfer Between Bacteria and Led to the Discovery of Conjugation 379

Genomes & Proteomes Connection: Horizontal Gene Transfer Can Occur Within a Species or Between Different Species 382

Chapter 19

Developmental Genetics 386

19.1 General Themes in Development 386
19.2 Development in Animals 391

Genomes & Proteomes Connection: A Homologous Group of Homeotic Genes Is Found in Nearly All Animals 396

Feature Investigation: Davis, Weintraub, and Lassar Identified Genes That Promote Muscle Cell Differentiation 400

19.3 Development in Plants 402

Chapter 20

Genetic Technology 406

20.1 Gene Cloning 406
20.2 Genomics: Techniques for Studying Genomes 412

Genomes & Proteomes Connection: A Microarray Can Identify Which Genes Are Transcribed by a Cell 415

20.3 Biotechnology 416

Feature Investigation: Blaese and Colleagues Performed the First Gene Therapy to Treat ADA Deficiency 422

Chapter 21

Genomes, Proteomes, and Bioinformatics 426

21.1 Bacterial and Archaeal Genomes 427

Feature Investigation: Venter, Smith, and Colleagues Sequenced the First Genome in 1995 428

21.2 Eukaryotic Genomes 430
21.3 Proteomes 435
21.4 Bioinformatics 438

UNIT IV Evolution

Chapter 22

The Origin and History of Life on Earth 445

22.1 Origin of Life on Earth 446

Feature Investigation: Bartel and Szostak Demonstrated Chemical Evolution in the Laboratory 450

22.2 The Fossil Record 453
22.3 History of Life on Earth 455

Genomes & Proteomes Connection: The Origin of Eukaryotic Cells Involved a Union Between Bacterial and Archaeal Cells 459

Chapter 23

An Introduction to Evolution 467

23.1 Overview of Evolution 468

Feature Investigation: The Grants Observed Natural Selection in Galápagos Finches 471

23.2 Evidence of Evolutionary Change 473
23.3 The Molecular Processes That Underlie Evolution 481

Genomes & Proteomes Connection: Gene Duplications Produce Gene Families 482

Chapter 24

Population Genetics 487

24.1 Genes in Populations 488

Genomes & Proteomes Connection: Genes Are Usually Polymorphic 488

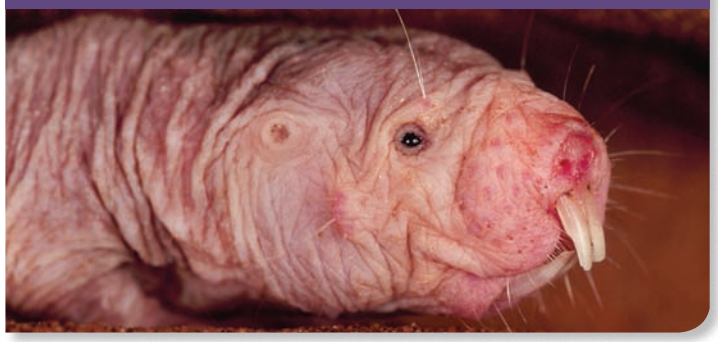
24.2 Natural Selection 491
24.3 Sexual Selection 495

Feature Investigation: Seeha and van Alphen Found That Male Coloration in African Cichlids Is Subject to Female Choice 497

24.4 Genetic Drift 499
24.5 Migration and Nonrandom Mating 501

Chapter 25

Origin of Species and Macroevolution 505



25.1 Identification of Species 506
25.2 Mechanisms of Speciation 511
Feature Investigation: Podos Found That an Adaptation for Feeding May Have Promoted Reproductive Isolation in Finches 513
25.3 The Pace of Speciation 517
25.4 Evo-Devo: Evolutionary Developmental Biology 518
Genomes & Proteomes Connection: The Study of the *Pax6* Gene Indicates That Different Types of Eyes Evolved from One Simple Form 521

Chapter 26

Taxonomy and Systematics 525

26.1 Taxonomy 526
26.2 Phylogenetic Trees 528
26.3 Cladistics 532
Feature Investigation: Cooper and Colleagues Compared DNA from Extinct Flightless Birds and Existing Species to Propose a New Phylogenetic Tree 536
26.4 Molecular Clocks 538
26.5 Horizontal Gene Transfer 540
Genomes & Proteomes Connection: Due to Horizontal Gene Transfer, the "Tree of Life" Is Really a "Web of Life" 541

UNIT V Diversity

Chapter 27

Archaea and Bacteria 545

27.1 Diversity and Evolution 545
27.2 Structure and Movement 550
27.3 Reproduction 554
27.4 Nutrition and Metabolism 556
27.5 Ecological Roles and Biotechnology Applications 557
Feature Investigation: Dantas and Colleagues Found That Many Bacteria Can Break Down and Consume Antibiotics as a Sole Carbon Source 557
Genomes & Proteomes Connection: The Evolution of Bacterial Pathogens 561

Chapter 28

Protists 565

28.1 An Introduction to Protists 565
28.2 Evolution and Relationships 568
Genomes & Proteomes Connection: Genome Sequences Reveal the Different Evolutionary Pathways of *Trichomonas vaginalis* and *Giardia intestinalis* 570
28.3 Nutritional and Defensive Adaptations 577
Feature Investigation: Cook and Colleagues Demonstrated That Cellulose Helps Green Algae Avoid Chemical Degradation 578
28.4 Reproductive Adaptations 580

Chapter 29

Plants and the Conquest of Land 588

29.1 Ancestry and Diversity of Modern Plants 588
Genomes & Proteomes Connection: Comparison of Plant Genomes Reveals Genetic Changes That Occurred During Plant Evolution 597
29.2 An Evolutionary History of Land Plants 599
29.3 The Origin and Evolutionary Importance of the Plant Embryo 602
Feature Investigation: Browning and Gunning Demonstrated That Placental Transfer Tissues Facilitate the Movement of Organic Molecules from Gametophytes to Sporophytes 603
29.4 The Origin and Evolutionary Importance of Leaves and Seeds 605

Chapter 30

The Evolution and Diversity of Modern Gymnosperms and Angiosperms 611

30.1 The Evolution and Diversity of Modern Gymnosperms 611
30.2 The Evolution and Diversity of Modern Angiosperms 617
Genomes & Proteomes Connection: Whole-Genome Duplications Influenced the Evolution of Flowering Plants 622
Feature Investigation: Hillig and Mahlberg Analyzed Secondary Metabolites to Explore Species Diversification in the Genus *Cannabis* 626

30.3 The Role of Coevolution in Angiosperm Diversification 628
30.4 Human Influences on Angiosperm Diversification 630

Chapter 31

Fungi 633

31.1 Evolution and Distinctive Features of Fungi 633
31.2 Fungal Asexual and Sexual Reproduction 637
31.3 Diversity of Fungi 639
31.4 Fungal Ecology and Biotechnology 644

Feature Investigation: Márquez and Associates Discovered That a Three-Partner Symbiosis Allows Plants to Cope with Heat Stress 648

Genomes & Proteomes Connection: Genomic Comparisons of Forest Fungi Reveal Coevolution with Plants 650

Chapter 32

An Introduction to Animal Diversity 654

32.1 Characteristics of Animals 655
32.2 Animal Classification 656

Genomes & Proteomes Connection: Changes in *Hox* Gene Expression Control Body Segment Specialization 662

32.3 Molecular Views of Animal Diversity 662

Feature Investigation: Aguinaldo and Colleagues Analyzed SSU rRNA Sequences to Determine the Taxonomic Relationships of Arthropods to Other Taxa 665

Chapter 33

The Invertebrates 668

33.1 Parazoa: Sponges, the First Multicellular Animals 669
33.2 Radiata: Jellyfish and Other Radially Symmetrical Animals 670
33.3 Lophotrochozoa: The Flatworms, Rotifers, Bryozoans, Brachiopods, Mollusks, and Annelids 672

Feature Investigation: Fiorito and Scotto's Experiments Showed That Invertebrates Can Exhibit Sophisticated Observational Learning Behavior 680

33.4 Ecdysozoa: The Nematodes and Arthropods 683

Genomes & Proteomes Connection: DNA Barcoding: A New Tool for Classification 693

33.5 Deuterostomia: The Echinoderms and Chordates 693

Chapter 34

The Vertebrates 702

34.1 Vertebrates: Chordates with a Backbone 702
34.2 Gnathostomes: Jawed Vertebrates 705
34.3 Tetrapods: Gnathostomes with Four Limbs 710

Feature Investigation: Davis and Colleagues Provided a Genetic-Developmental Explanation for Limb Length in Tetrapods 711

34.4 Amniotes: Tetrapods with a Desiccation-Resistant Egg 714
34.5 Mammals: Milk-Producing Amniotes 720

Genomes & Proteomes Connection: Comparing the Human and Chimpanzee Genetic Codes 727

UNIT VI Flowering Plants

Chapter 35

An Introduction to Flowering Plant Form and Function 734

35.1 From Seed to Seed—the Life of a Flowering Plant 734
35.2 How Plants Grow and Develop 738
35.3 The Shoot System: Stem and Leaf Adaptations 743

Feature Investigation: Sack and Colleagues Showed That Palmate Venation Confers Tolerance of Leaf Vein Breakage 744

Genomes & Proteomes Connection: Genetic Control of Guard-Cell Development 747

35.4 Root System Adaptations 751

Chapter 36

Flowering Plants: Behavior 755

36.1 Overview of Plant Behavioral Responses 755
36.2 Plant Hormones 758

Feature Investigation: An Experiment Performed by Briggs Revealed the Role of Auxin in Phototropism 760

Genomes & Proteomes Connection: Gibberellin Function Arose in a Series of Stages During Plant Evolution 762

36.3 Plant Responses to Environmental Stimuli 765

Chapter 37

Flowering Plants: Nutrition 774

37.1 Plant Nutritional Requirements 774

37.2 The Role of Soil in Plant Nutrition 778

Feature Investigation: Hammond and Colleagues Engineered Smart Plants That Can Communicate Their Phosphate Needs 782

37.3 Biological Sources of Plant Nutrients 784

Genomes & Proteomes Connection: Development of Legume-Rhizobia Symbioses 786

Chapter 38

Flowering Plants: Transport 790

38.1 Overview of Plant Transport 790

38.2 Uptake and Movement of Materials at the Cellular Level 791

38.3 Tissue-Level Transport 794

38.4 Long-Distance Transport 796

Feature Investigation: The Park Team Genetically Engineered an ABA Receptor Protein to Foster Crop Survival During Droughts 802

Genomes & Proteomes Connection: Stomatal Responses to Abscisic Acid Arose Relatively Late in Plant Evolution 806

Chapter 39

Flowering Plants: Reproduction 811

39.1 An Overview of Flowering Plant Reproduction 811

39.2 Flower Production, Structure, and Development 815

Feature Investigation: Liang and Mahadevan Used Time-Lapse Video and Mathematical Modeling to Explain How Flowers Bloom 818

39.3 Male and Female Gametophytes and Double Fertilization 820

39.4 Embryo, Seed, Fruit, and Seedling Development 823

39.5 Asexual Reproduction in Flowering Plants 827

Genomes & Proteomes Connection: The Evolution of Plantlet Production in *Kalanchoë* 827

UNIT VII Animals

Chapter 40

Animal Bodies and Homeostasis 831

40.1 Organization of Animal Bodies 831

Genomes & Proteomes Connection: Organ Development and Function Are Controlled by *Hox* Genes 835

40.2 The Relationship Between Structure and Function 838

40.3 Homeostasis 840

Feature Investigation: Pavlov Demonstrated the Relationship Between Learning and Feedforward Processes 845

Chapter 41

Neuroscience I: Cells of the Nervous System 849

41.1 Cellular Components of Nervous Systems 850

41.2 Electrical Properties of Neurons and the Resting Membrane Potential 852

41.3 Generation and Transmission of Electrical Signals Along Neurons 856

41.4 Neurons Communicate Electrically or Chemically at Synapses 860

Feature Investigation: Otto Loewi Discovered Acetylcholine 865

Genomes & Proteomes Connection: Varied Subunit Compositions of Neurotransmitter Receptors Allow Precise Control of Neuronal Regulation 867

41.5 Impact on Public Health 868

Chapter 42

Neuroscience II: Evolution, Structure, and Function of the Nervous System 872

42.1 The Evolution and Development of Nervous Systems 872

42.2 Structure and Function of the Nervous Systems of Humans and Other Vertebrates 875

Genomes & Proteomes Connection: Many Genes Have Been Important in the Evolution and Development of the Cerebral Cortex 884

42.3 Cellular Basis of Learning and Memory 884

Feature Investigation: Gaser and Schlaug Showed That the Sizes of Certain Brain Structures Differ Between Musicians and Nonmusicians 888

42.4 Impact on Public Health 889

Chapter 43

Neuroscience III: Sensory Systems 893

43.1 An Introduction to Sensation 893

43.2 Mechanoreception 895

43.3 Thermoreception and Nociception 901

43.4 Electromagnetic Reception 902

43.5 Photoreception 902

Genomes & Proteomes Connection: Color Vision Is an Ancient Adaptation in Animals 906

43.6 Chemoreception 910

Feature Investigation: Buck and Axel Discovered a Family of Olfactory Receptor Proteins That Bind Specific Odor Molecules 912

43.7 Impact on Public Health 915

Chapter 44

Muscular-Skeletal Systems and Locomotion 919

44.1 Types of Animal Skeletons 919

44.2 Skeletal Muscle Structure and the Mechanism of Force Generation 921

Genomes & Proteomes Connection: Did an Ancient Mutation in Myosin Play a Role in the Development of the Human Brain? 924

44.3 Types of Skeletal Muscle Fibers and Their Functions 928

Feature Investigation: Evans and Colleagues Activated a Gene to Produce "Marathon Mice" 930

44.4 Animal Locomotion 932

44.5 Impact on Public Health 934

Chapter 45

Nutrition and Animal Digestive Systems 938

45.1 Animal Nutrition 938

45.2 General Principles of Digestion and Absorption of Food 940

45.3 Overview of Vertebrate Digestive Systems 943

45.4 Mechanisms of Digestion and Absorption in Vertebrates 948

Genomes & Proteomes Connection: Evolution and Genetics Explains Lactose Intolerance 949

45.5 Neural and Endocrine Control of Digestion 952

45.6 Impact on Public Health 953

Feature Investigation: Marshall and Warren and Coworkers Demonstrated a Link Between Bacterial Infection and Ulcers 955

Chapter 46

Control of Energy Balance, Metabolic Rate, and Body Temperature 959

46.1 Use and Storage of Energy 959

46.2 Regulation of the Absorptive and Postabsorptive States 962

Genomes & Proteomes Connection: A Family of GLUT Proteins Transports Glucose in All Animal Cells 963

46.3 Energy Balance and Metabolic Rate 965

Feature Investigation: Coleman Revealed a Satiety Factor in Mammals 968

46.4 Regulation of Body Temperature 970

46.5 Impact on Public Health 974

Chapter 47

Circulatory Systems 977

47.1 Types of Circulatory Systems 977

Genomes & Proteomes Connection: A Four-Chambered Heart Evolved from Simple Contractile Tubes 980

47.2 The Composition of Blood 981

47.3 The Vertebrate Heart and Its Function 983

47.4 Blood Vessels 987

47.5 Relationship Among Blood Pressure, Blood Flow, and Resistance 989

Feature Investigation: Furchgott Discovered a Vasodilatory Factor Produced by Endothelial Cells 991

47.6 Adaptive Functions of Closed Circulatory Systems 994

47.7 Impact on Public Health 995

Chapter 48

Respiratory Systems 999

48.1 Physical Properties of Gases 999

48.2 Types of Respiratory Systems 1002

48.3 Structure and Function of the Mammalian Respiratory System 1006

Feature Investigation: Fujiwara and Colleagues Demonstrated the Effectiveness of Administering Surfactant to Newborns with RDS 1010

48.4 Mechanisms of Oxygen Transport in Blood 1013

Genomes & Proteomes Connection: Hemoglobin First Evolved Over 500 mya 1016
48.5 Control of Ventilation 1017
48.6 Adaptations to Extreme Conditions 1018
48.7 Impact on Public Health 1019

Chapter 49

Excretory Systems and the Homeostasis of Internal Fluids 1023

49.1 Principles of Homeostasis of Internal Fluids 1023
Feature Investigation: Cade and Colleagues Discovered Why Athletes' Performances Wane on Hot Days 1027
49.2 Excretory Systems in Different Animal Groups 1030
49.3 Structure and Function of the Mammalian Kidney 1033
Genomes & Proteomes Connection: Aquaporins Comprise a Large Family of Proteins That Are Found in All Animals 1039
49.4 Impact on Public Health 1040

Chapter 50

Endocrine Systems 1044

50.1 Types of Hormones and Their Mechanisms of Action 1045
50.2 Links Between the Endocrine and Nervous Systems 1048
50.3 Hormonal Control of Metabolism and Energy Balance 1050
Feature Investigation: Banting, Best, MacLeod, and Collip Were the First to Isolate Active Insulin 1056
50.4 Hormonal Control of Mineral Balance 1058
Genomes & Proteomes Connection: Hormones and Receptors Evolved as Tightly Integrated Molecular Systems 1061
50.5 Hormonal Control of Growth and Development 1062
50.6 Hormonal Control of Reproduction 1064
50.7 Impact on Public Health 1065

Chapter 51

Animal Reproduction 1069

51.1 Overview of Asexual and Sexual Reproduction 1069
Feature Investigation: Paland and Lynch Provided Evidence That Sexual Reproduction May Promote the Elimination of Harmful Mutations in Populations 1071
51.2 Gametogenesis and Fertilization 1072
51.3 Mammalian Reproductive Structure and Function 1075
51.4 Pregnancy and Birth in Mammals 1081
Genomes & Proteomes Connection: The Evolution of the Globin Gene Family Has Been Important for Internal Gestation in Mammals 1083
51.5 Impact on Public Health 1085

Chapter 52

Animal Development 1089

52.1 Principles of Embryonic Development 1089
52.2 General Events of Embryonic Development 1090
52.3 Control of Cell Differentiation and Morphogenesis During Animal Development 1099
Genomes & Proteomes Connection: Groups of Embryonic Cells Can Produce Specific Body Structures Even When Transplanted into Different Animals 1100
Feature Investigation: Harland and Coworkers Identified Genes Expressed Specifically in the Organizer 1101
52.4 Impact on Public Health 1103

Chapter 53

Immune Systems 1107

53.1 Types of Pathogens 1108
53.2 Innate Immunity 1108
Feature Investigation: Lemaitre and Colleagues Identify an Immune Function for Toll Protein in *Drosophila* 1111
53.3 Acquired Immunity 1113
Genomes & Proteomes Connection: Recombination and Hypermutation Produce an Enormous Number of Different Immunoglobulin Proteins 1118
53.4 Impact on Public Health 1125

UNIT VIII Ecology

Chapter 54

An Introduction to Ecology and Biomes 1131

54.1 The Scale of Ecology 1132
Feature Investigation: Callaway and Aschehoug's Experiments Showed That the Secretion of Chemicals Gives Invasive Plants a Competitive Edge Over Native Species 1132
54.2 Ecological Methods 1134
54.3 The Environment's Effect on the Distribution of Organisms 1137

Genomes & Proteomes Connection: Temperature Tolerance May Be Manipulated by Genetic Engineering 1140
54.4 Climate and Its Relationship to Biological Communities 1144
54.5 Major Biomes 1147
54.6 Continental Drift and Biogeography 1157

Chapter 55

Behavioral Ecology 1162

55.1 The Influence of Genetics and Learning on Behavior 1163
Genomes & Proteomes Connection: Some Behavior Results from Simple Genetic Influences 1163
55.2 Local Movement and Long-Range Migration 1167
Feature Investigation: Tinbergen's Experiments Showed That Digger Wasps Use Landmarks to Find Their Nests 1167
55.3 Foraging Behavior 1171
55.4 Communication 1173
55.5 Living in Groups 1175
55.6 Altruism 1176
55.7 Mating Systems 1179

Chapter 56

Ecology 1183

56.1 Understanding Populations 1183
56.2 Demography 1188
Feature Investigation: Murie's Collections of Dall Mountain Sheep Skulls Permitted the Accurate Construction of Life Tables 1189
56.3 How Populations Grow 1192
Genomes & Proteomes Connection: Hexaploidy Increases the Growth of Coast Redwood Trees 1196
56.4 Human Population Growth 1197

Chapter 57

Species Interactions 1202

57.1 Competition 1203
Feature Investigation: Connell's Experiments with Barnacle Species Revealed Each Species' Fundamental and Realized Niches 1206
57.2 Predation, Herbivory, and Parasitism 1209
Genomes & Proteomes Connection: Transgenic Plants May Be Used in the Fight Against Plant Diseases 1216
57.3 Mutualism and Commensalism 1217
57.4 Bottom-Up and Top-Down Control 1219

Chapter 58

Community Ecology 1223

58.1 Differing Views of Communities 1223
58.2 Patterns of Species Richness 1225
58.3 Calculating Species Diversity 1227
Genomes & Proteomes Connection: Metagenomics May Be Used to Measure Species Diversity 1229
58.4 Species Diversity and Community Stability 1230
58.5 Succession: Community Change 1231
58.6 Island Biogeography 1234
Feature Investigation: Simberloff and Wilson's Experiments Tested the Predictions of the Equilibrium Model of Island Biogeography 1237

Chapter 59

Ecosystem Ecology 1241

59.1 Food Webs and Energy Flow 1242
Genomes & Proteomes Connection: Using Genetically Engineered Plants to Remove Pollutants 1248
59.2 Biomass Production in Ecosystems 1248
59.3 Biogeochemical Cycles 1251
Feature Investigation: Stiling and Drake's Experiments with Elevated CO_2 Showed an Increase in Plant Growth but a Decrease in Herbivory 1254

Chapter 60

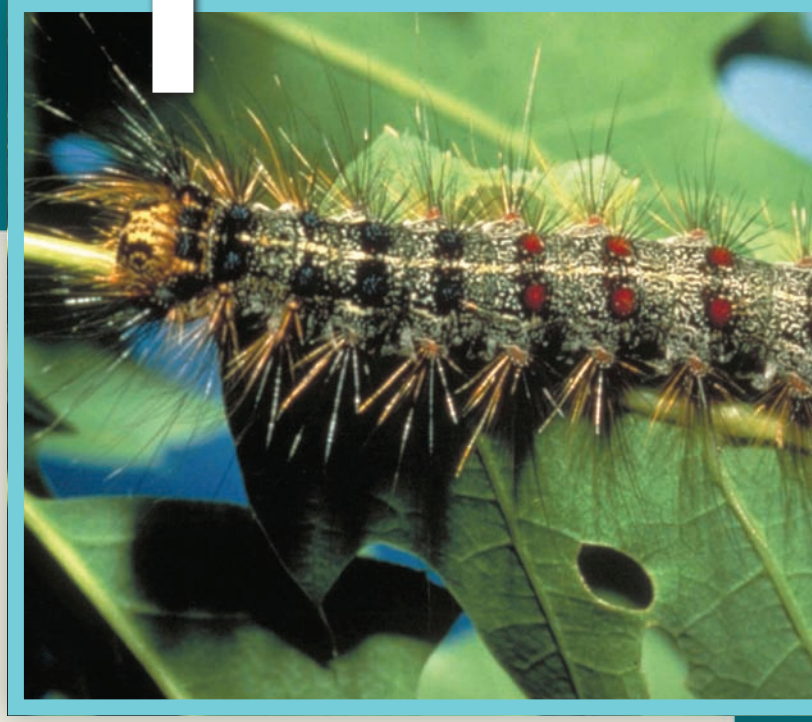
Biodiversity and Conservation Biology 1260

60.1 What Is Biodiversity? 1261
60.2 Why Conserve Biodiversity? 1261
Feature Investigation: Ecotron Experiments Showed the Relationship Between Biodiversity and Ecosystem Function 1263
60.3 The Causes of Extinction and Loss of Biodiversity 1266
60.4 Conservation Strategies 1270
Genomes & Proteomes Connection: Can Cloning Save Endangered Species? 1277

Appendix A: Periodic Table of the Elements A-1
Appendix B: Answer Key A-2
Glossary G-1
Credits C-1
Index I-1

CHAPTER OUTLINE

1.1 Principles of Biology and the Levels of Biological Organization



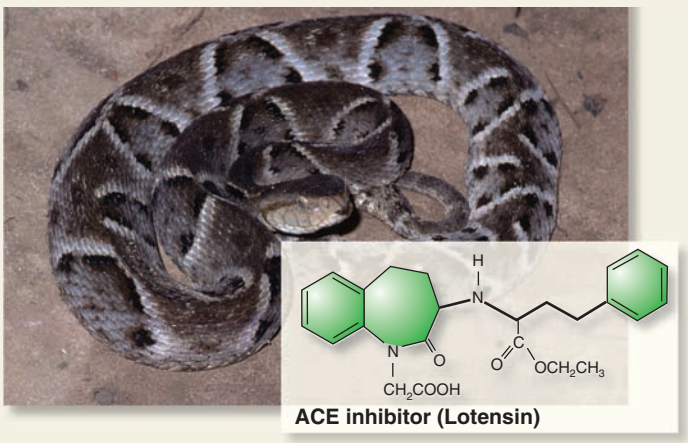
1.2 Unity and Diversity of Life

1.3 Biology as a Scientific Discipline

Summary of Key Concepts

Assess and Discuss

1 An Introduction to Biology



Gypsy moth (*Lymantria dispar*). The gypsy moth progresses through different stages, including a caterpillar, to become an adult moth. As discussed later in this chapter, the caterpillar can be infected with a virus, which alters its behavior into that of a "zombie."

Biology is the study of life. The diverse forms of life found on Earth provide biologists with an amazing array of organisms to study. In many cases, the investigation of living things leads to discoveries that no one would have imagined. For example, researchers determined that the venom from certain poisonous snakes contains a chemical that lowers blood pressure in humans. By analyzing that chemical, scientists developed drugs to treat high blood pressure (**Figure 1.1**).

Biologists have discovered that plants can communicate with each other. For example, the beautiful umbrella thorn acacia (*Vachellia tortillis*), shown in **Figure 1.2**, emits volatile organic molecules when it is attacked by herbivores. These molecules warn other nearby acacia trees that herbivores are in the area, and those trees release toxins to protect themselves.

In the 20th century, biologists studied soil bacteria that naturally produce "chemical weapons" to kill competing bacteria in their native environment. These chemicals have been characterized and used to develop antibiotics such as streptomycin to treat bacterial infections (**Figure 1.3**).

ACE inhibitor (Lotensin)

Figure 1.1 The Brazilian arrowhead viper and inhibitors of high blood pressure. Derivatives of a chemical, called an angiotensin-converting enzyme (ACE) inhibitor, are found in the venom of the Brazilian arrowhead viper and are commonly used to treat high blood pressure.

Figure 1.2 Plant communication. If attacked by herbivores, this acacia tree will emit molecules that will warn other acacia trees in the area.

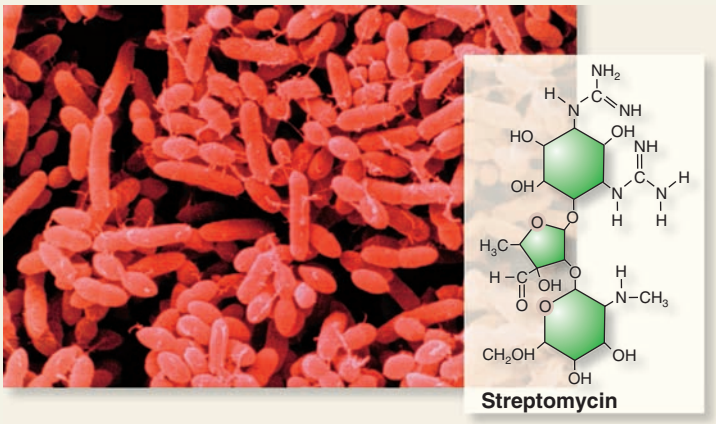


Figure 1.3 The soil bacterium *Streptomyces griseus*, which naturally produces the antibiotic streptomycin, kills competing bacteria in the soil. Doctors administer streptomycin to treat bacterial infections.

These are but a few of the many discoveries that make biology an intriguing discipline. The study of life not only reveals the fascinating characteristics of living species but also leads to the development of medicines and research tools that benefit the lives of people.

To make new discoveries, biologists view life from many different perspectives. What is the composition of living things? How is life organized? How do organisms reproduce? Sometimes the questions posed by biologists are fundamental and even philosophical in nature. How did living organisms originate? Can we live forever? What is the physical basis for memory? Can we save endangered species?

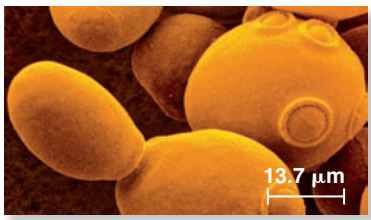
Future biologists will continue to make important advances. Biologists are scientific explorers looking for answers to some of life's most enduring mysteries. Unraveling these mysteries presents an exciting challenge to the best and brightest minds. The rewards of a career in biology include the excitement of forging into uncharted territory, the thrill of making discoveries that can improve the health and lives of people, and the impact of trying to preserve the environment and protect endangered species. For these and many other compelling reasons, students seeking challenging and rewarding careers may wish to choose biology as a lifelong pursuit.

In this chapter, we will begin our survey of biology by examining the basic principles that underlie the characteristics of all living organisms and the fields of biology. We will then take a deeper look at the process of evolution and how it has led to the development of genomes—the entire genetic compositions of living organisms—which explains the unity and diversity that we observe among living species. Finally, we will explore the general approaches that scientists follow when making new discoveries.

1.1 Principles of Biology and the Levels of Biological Organization

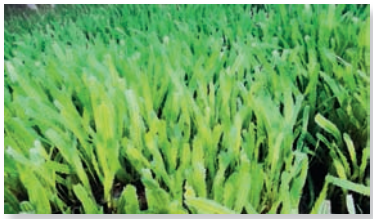
Learning Outcomes:

1. Describe the principles of biology.
2. Explain how life can be viewed at different levels of biological complexity.



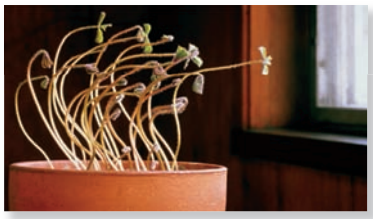
Because biology is the study of life, a good way to begin a biology textbook is to distinguish living organisms from nonliving objects. At first, the distinction might seem obvious. A person is alive, but a rock is not. However, the distinction between living and nonliving may seem less obvious when we consider microscopic entities. Is a bacterium alive? What about a virus or a chromosome? In this section, we will examine the principles that underlie the characteristics of all forms of life and explore other broad principles in biology. We will then consider the levels of organization that biologists study, ranging from atoms and small molecules to very large geographical areas.

The Study of Life Has Revealed a Set of Unifying Principles



Biologists have studied many different species and learned that a set of principles applies to all fields of biology. Twelve broad principles are described in **Figure 1.4**. The first eight principles are often used as criteria to define the basic features of life. You will see these twelve principles at many points as you progress through this textbook, and they are indicated with the icon. In particular, we will draw your attention to them at the beginning of each unit, and we will refer to them within particular figures in Chapters 3 through 60. It should be noted that the principles of biology are also governed by the laws of chemistry and physics, which are discussed in Chapters 2, 3, and 6.

Principle 1: Cells are the simplest units of life. The term **organism** can be applied to all living things. Organisms maintain an internal order that is separated from the environment (Figure 1.4a). The simplest unit of such organization is the **cell**, which we will examine in Unit II. One of the foundations of biology is the **cell theory**, which states that (1) all organisms are composed of cells, (2) cells are the smallest units of life, and (3) new cells come from pre-existing cells via cell division. Unicellular organisms are composed of one cell, whereas multicellular organisms such as plants and animals contain many cells. In plants and animals, each cell has an internal order, and the cells within the organism have specific arrangements and functions.



Principle 2: Living organisms use energy. The maintenance of organization requires energy. Therefore, all living organisms acquire energy from the environment and use that energy to maintain their internal order. Cells carry out a variety of chemical reactions that are responsible for the breakdown of nutrients. Such reactions often release energy in a process called **respiration**. The energy may be used to synthesize the components that make up individual cells and living organisms. Chemical reactions involved with the breakdown and synthesis of cellular molecules are collectively known as **metabolism**. Plants, algae, and certain bacteria can directly

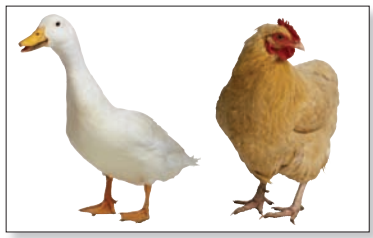
(a) Cells are the simplest units of life: Organisms maintain an internal order. The simplest unit of organization is the cell. Yeast cells are shown here.

(b) Living organisms use energy: Organisms need energy to maintain internal order. These algae harness light energy via photosynthesis. Energy is used in chemical reactions collectively known as metabolism.

(c) Living organisms interact with their environment: Organisms respond to environmental changes. These plants are growing toward the light.

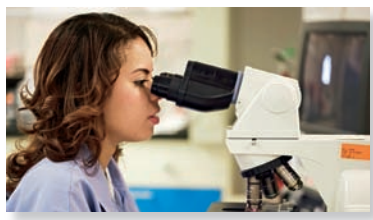
(d) Living organisms maintain homeostasis: Organisms regulate their cells and bodies, maintaining relatively stable internal conditions, a process called homeostasis. For example, this bird maintains its internal body temperature on a cold day.

(e) Living organisms grow and develop: Growth produces more or larger cells, whereas development produces organisms with a defined set of characteristics.



(f) The genetic material provides a blueprint for reproduction: To sustain life over many generations, organisms must reproduce. Due to the transmission of genetic material, offspring tend to have traits like their parents.

(g) Populations of organisms evolve from one generation to the next: Populations of organisms change over the course of many generations. Evolution results in traits that promote survival and reproductive success.



(h) All species (past and present) are related by an evolutionary history: The three mammal species shown here share a common ancestor, which was also a mammal.

(i) Structure determines function: In the example seen here, webbed feet (on ducks) function as paddles for swimming. Nonwebbed feet (on chickens) function better for walking on the ground.

(j) New properties of life emerge from complex interactions: Our ability to see is an emergent property due to interactions among many types of cells in the eye and neurons that send signals to the brain.

(k) Biology is an experimental science: The discoveries of biology are made via experimentation, which leads to theories and biological principles.

(l) Biology affects our society: Many discoveries in biology have had major effects on our society. For example, biologists developed Bt-corn, which is resistant to insect pests and widely planted by farmers.

Figure 1.4 Twelve principles of biology. The first eight principles are often used as criteria for defining the basic features of life. Note: The twelve principles described here were modeled after the themes and core competencies described in *Vision and Change in Undergraduate Biology*, a report that was published in 2009 and organized by the American Association for the Advancement of Science. *Vision and Change* proposed five themes. We have divided them into ten principles to make them more accessible to beginning biology students. The five *Vision and Change* themes are related to our principles in the following manner: 1. Evolution (principles g and h); 2. Structure and Function (principle i); 3. Information Flow, Exchange, and Storage (principles e and f); 4. Pathways and Transformations of Energy and Matter (principles b, c, and d); 5. Systems (principles a and j). The last two principles are modeled after two core competencies described in *Vision and Change*: Ability to Apply the Process of Science (principle k) and Ability to Understand the Relationship between Science and Society (principle l).

BioConnections: *Look ahead to Figure 52.11. Which of these principles is this figure emphasizing?*

harness light energy to produce their own nutrients in the process of **photosynthesis** (Figure 1.4b). They are the primary producers of food on Earth. In contrast, some organisms, such as animals and fungi, are consumers—they must use other organisms as food to obtain energy.

Principle 3: Living organisms interact with their environment. To survive, living organisms must be able to interact with their environment, which includes other organisms they may encounter. All organisms must respond to environmental changes. In the winter,

many species of mammals develop a thicker coat of fur that protects them from the cold temperatures. Plants respond to changes in the angle of the sun. If you place a plant in a window, it will grow toward the light (Figure 1.4c).

Principle 4: Living organisms maintain homeostasis. Although life is a dynamic process, living cells and organisms regulate their cells and bodies to maintain relatively stable internal conditions, a process called **homeostasis** (from the Greek, meaning to stay the same). The degree to which homeostasis is achieved varies among different organisms. For example, most mammals and birds maintain a relatively stable body temperature in spite of changing environmental temperatures (Figure 1.4d), whereas reptiles and amphibians tolerate a wider fluctuation in body temperature. By comparison, all organisms continually regulate their cellular metabolism so nutrient molecules are used at an appropriate rate and new cellular components are synthesized when they are needed.

Principle 5: Living organisms grow and develop. All living organisms grow and develop. **Growth** produces more or larger cells. In plants and animals, a fertilized egg undergoes multiple cell divisions to develop into a mature organism with many cells. Among unicellular organisms such as bacteria, new cells are relatively small, and they increase in volume by the synthesis of additional cellular components. **Development** is a series of changes in the state of a cell, tissue, organ, or organism, eventually resulting in organisms with a defined set of characteristics (Figure 1.4e).

Principle 6: The genetic material provides a blueprint for reproduction. All living organisms have a finite life span. To sustain life, organisms must **reproduce**, or generate offspring (Figure 1.4f). A key feature of reproduction is that offspring tend to have characteristics that greatly resemble those of their parent(s). How is this possible? All living organisms contain genetic material composed of **DNA (deoxyribonucleic acid)**, which provides a blueprint for the organization, development, and function of living things. During reproduction, a copy of this blueprint is transmitted from parent to offspring. DNA is **heritable**, which means that offspring inherit DNA from their parents.

As discussed in Unit III, **genes**, which are segments of DNA, govern the characteristics, or traits, of organisms. Most genes are transcribed into a type of **RNA (ribonucleic acid)** molecule called messenger RNA (mRNA) that is then translated into a **polypeptide** with a specific amino acid sequence. A **protein** is composed of one or more polypeptides. The structures and functions of proteins are largely responsible for the traits of living organisms.

Principle 7: Populations of organisms evolve from one generation to the next. The first six characteristics of life, which we have just considered, apply to individual organisms over the short run. Over the long run, another universal characteristic of life is **biological evolution**, or simply **evolution**, which refers to a heritable change in a population of organisms from generation to generation. As a result of evolution, populations become better adapted to the environment in which they live. For example, the long snout of an anteater is an adaptation that enhances its ability to obtain food, namely ants, from hard-to-reach places (Figure 1.4g). Over the course of many generations, the fossil record indicates that the long snout occurred via biological evolution in which modern anteaters evolved from populations of organisms with shorter snouts.

Principle 8: All species (past and present) are related by an evolutionary history. Principle 7 considers evolution as an ongoing process that happens from one generation to the next. Evidence from a variety of sources, including the fossil record and DNA sequences, also indicates that all organisms on Earth share a common ancestry. For example, the three species of mammals shown in Figure 1.4h shared a common ancestor in the past, which was also a mammal. We will discuss evolutionary relationships later in Section 1.2 and more thoroughly in Units IV and V.

As described later in this chapter, biologists often view evolution within the context of genomes and proteomes. The term **genome** refers to the complete genetic composition of an organism or species. Because most genes encode proteins, these genetic changes are often associated with changes in the **proteome**, which is the complete protein composition of a cell or organism. By studying how evolution affects genomes and proteomes, biologists can better understand how the changes that occur during evolution affect the characteristics of species. Because evolution is a core unifying principle in biology, we will draw your attention to it in Chapters 4 through 60 by including a brief topic that we call "Genomes & Proteomes Connection." This topic connects the principle of evolution to the subject matter in each chapter.

Principle 9: Structure determines function. In addition to the preceding eight characteristics of life, biologists have identified other principles that are important in all fields of biology. The principle "structure determines function" pertains to very tiny biological molecules and to very large biological structures. For example, at the microscopic level, a cellular protein called actin naturally assembles into structures that are long filaments. The function of these filaments is to provide support and shape to cells. At the macroscopic level, let's consider the feet of different birds (Figure 1.4i). Aquatic birds have webbed feet that function as paddles for swimming. By comparison, the feet of nonaquatic birds are not webbed and are better adapted for grasping food, perching on branches, and running along the ground. In this case, the structure of a bird's feet, webbed versus nonwebbed, is a critical feature that affects their function.

Principle 10: New properties of life emerge from complex interactions. In biology, when individual components in an organism interact with each other or with the external environment to create novel structures and functions, the resulting characteristics are called **emergent properties**. For example, the human eye is composed of many different types of cells that are organized to sense incoming light and transmit signals to the brain (Figure 1.4j). Our ability to see is an emergent property of this complex arrangement of different cell types. As discussed later in this chapter, biologists use the term **systems biology** to describe the study of how new properties of life arise by complex interactions of its components.

Principle 11: Biology is an experimental science. Biology is an inquiry process. Biologists are curious about the characteristics of living organisms and ask questions about those characteristics. For example, a cell biologist may wonder why a cell produces a specific protein when it is confronted with high temperature. An ecologist may ask herself why

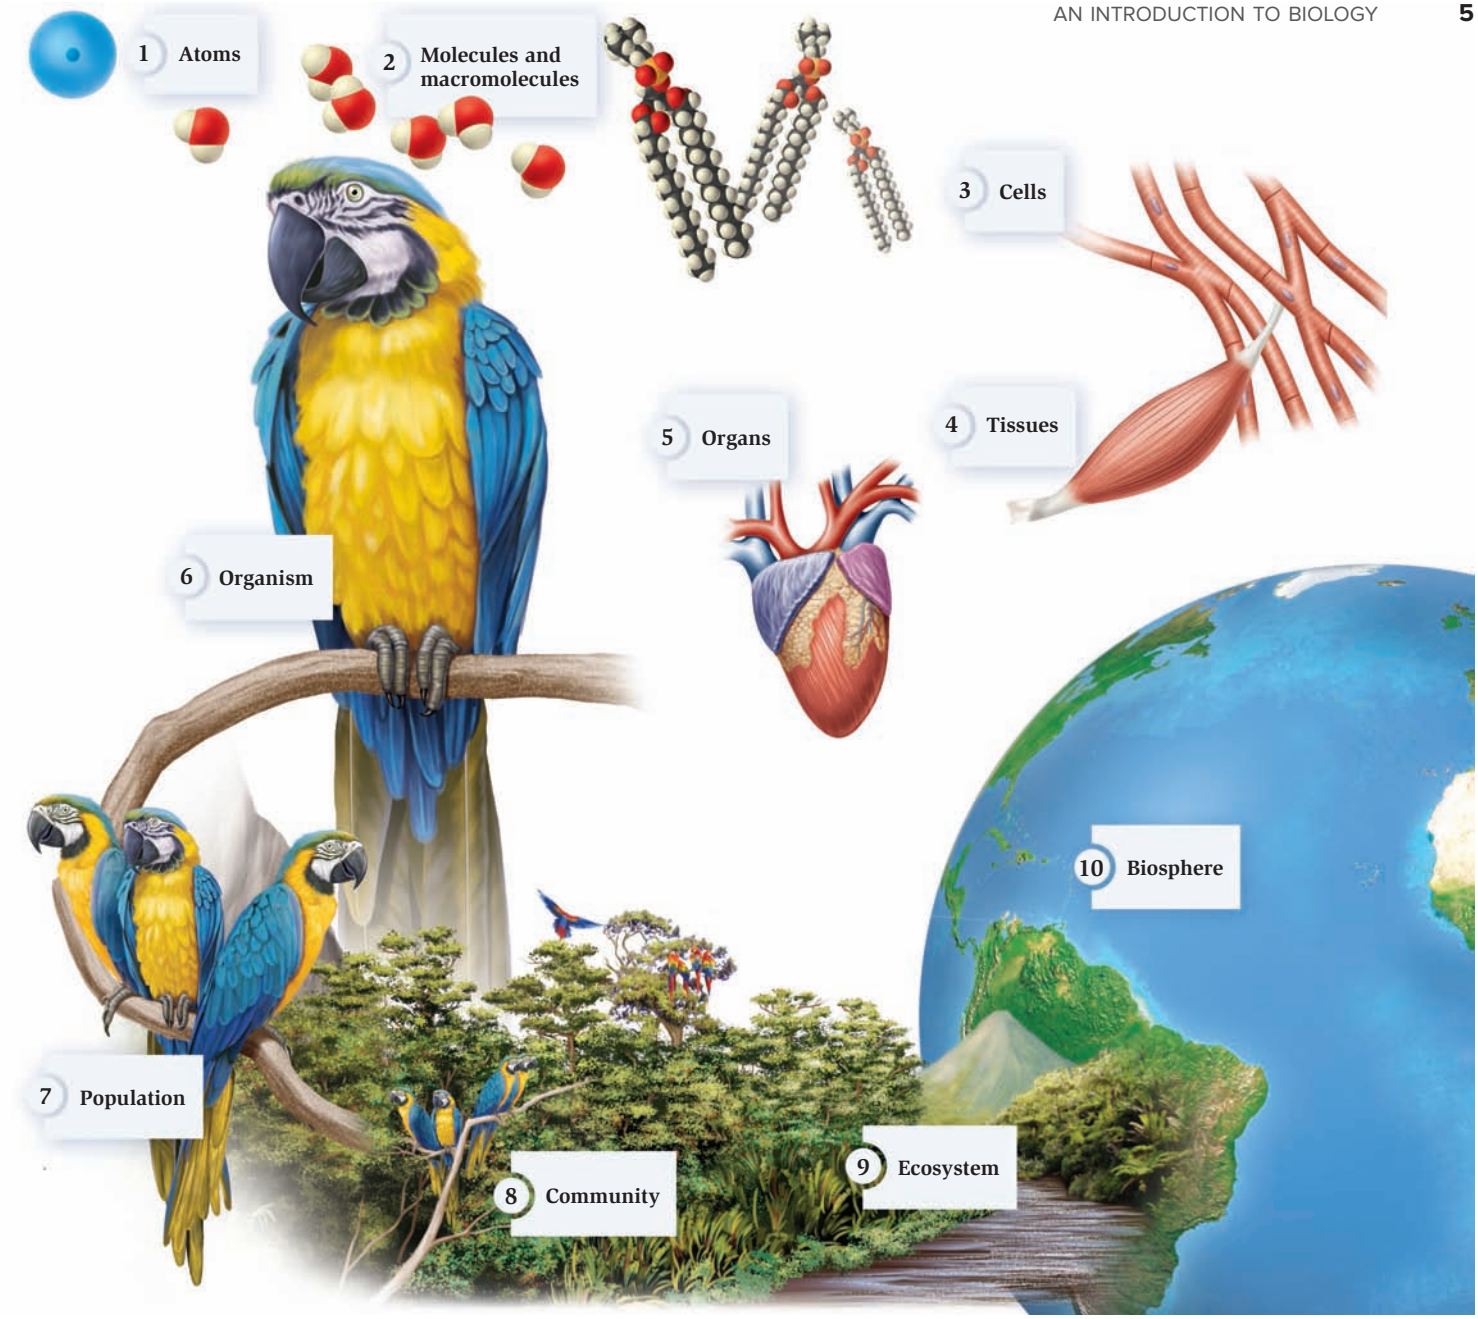


Figure 1.5 **The levels of biological organization.**

Concept Check: *At which level of biological organization would you place a herd of buffalo?*

a particular bird eats insects in the summer and seeds in the winter. To answer such questions, biologists typically gather additional information and ultimately form a hypothesis, which is a proposed explanation for a natural phenomenon. The next stage is to design one or more experiments to test the validity of a hypothesis (Figure 1.4k).

Like our emphasis on evolution, experimentation is such a key aspect of biology that the authors of this textbook have highlighted it in every chapter. As discussed later, a consistent element in Chapters 2 through 60 is a "Feature Investigation"—an actual study by current or past researchers that showcases the experimental approach.

Principle 12: Biology affects our society. The influence of biology is not confined to textbooks and classrooms. The work of biologists has far-reaching effects in our society. For example, biologists have discovered drugs that are used to treat many different human diseases. Likewise, biologists have created technologies that have many uses. Examples include the use of microorganisms to make medical products, such as human insulin, and the genetic engineering of crops to make them resistant to particular types of insect pests (Figure 1.4l).

Living Organisms Are Studied at Different Levels of Organization

The organization of living organisms can be analyzed at different levels of biological complexity, starting with the smallest level of organization and progressing to levels that are physically much larger and more complex. **Figure 1.5** depicts a scientist's view of the levels of biological organization.

1. **Atoms:** An **atom** is the smallest unit of an element that has the chemical properties of the element. All matter is composed of atoms.
2. **Molecules and macromolecules:** As discussed in Unit I, atoms bond with each other to form **molecules**. Many molecules bonded together to form a polymer such as a polypeptide is called a **macromolecule**. Carbohydrates, proteins, and nucleic acids (DNA and RNA) are important macromolecules found in living organisms.
3. **Cells:** Molecules and macromolecules associate with each other to form larger structures such as membranes. A **cell** is surrounded by a membrane and contains a variety of molecules and macromolecules. A cell is the simplest unit of life.
4. **Tissues:** In the case of multicellular organisms such as plants and animals, many cells of the same type associate with each other to form **tissues**. An example is muscle tissue.
5. **Organs:** In complex multicellular organisms, an **organ** is composed of two or more types of tissue. For example, the heart is composed of several types of tissues, including muscle, nervous, and connective tissue.
6. **Organism:** All living things can be called **organisms**. Biologists classify organisms as belonging to a particular **species**, which is a related group of organisms that share a distinctive form and set of attributes in nature. The members of the same species are closely related genetically. In Units VI and VII, we will examine plants and animals at the level of cells, tissues, organs, and complete organisms.
7. **Population:** A group of organisms of the same species that occupy the same environment is called a **population**.
8. **Community:** A biological **community** is an assemblage of populations of different species. The types of species found in a community are determined by the environment and by the interactions of species with each other.
9. **Ecosystem:** Researchers may extend their work beyond living organisms and also study the physical environment. Ecologists analyze **ecosystems**, which are formed by interactions of a community of organisms with their physical environment. Unit VIII considers biology from populations to ecosystems.
10. **Biosphere:** The **biosphere** includes all of the places on the Earth where living organisms exist. Life is found in the air, in bodies of water, on the land, and in the soil.

1.2 Unity and Diversity of Life

Learning Outcomes:

1. Explain the two basic mechanisms by which evolutionary change occurs: vertical descent with mutation and horizontal gene transfer.
2. Outline how organisms are classified (taxonomy).
3. Describe how changes in genomes and proteomes underlie evolutionary changes.

Unity and diversity are two words that often are used to describe the living world. As we have seen, all modern forms of life display a common set of characteristics that distinguish them from nonliving objects. In this section, we will explore how this unity of common traits is rooted in the phenomenon of biological evolution. Life on Earth is united by an evolutionary past in which modern organisms have evolved from populations of pre-existing organisms.

Evolutionary unity does not mean that organisms are exactly alike. The Earth has many different types of environments, ranging from tropical rain forests to salty oceans, hot and dry deserts, and cold mountaintops. Diverse forms of life have evolved in ways that help them prosper in the different environments the Earth has to offer. In this section, we will begin to examine the unity and diversity that exists within the biological world.

Modern Forms of Life Are Connected by an Evolutionary History

Life began on Earth as primitive cells about 3.5–4 billion years ago (bya). Since that time, populations of living organisms underwent evolutionary changes that ultimately gave rise to the species we see today. Understanding the evolutionary history of species can provide key insights into the structure and function of an organism's body, because evolutionary change frequently involves modifications of characteristics in pre-existing populations. Over long periods of time, populations may change so that structures with a particular function become modified to serve a new function. For example, the wing of a bat is used for flying, and the flipper of a dolphin is used for swimming. Evidence from the fossil record indicates that both structures were modified from a limb that was used for walking in a pre-existing ancestor (**Figure 1.6**).

Evolutionary change occurs by two mechanisms: vertical descent with mutation and horizontal gene transfer. Let's take a brief look at each of these mechanisms.

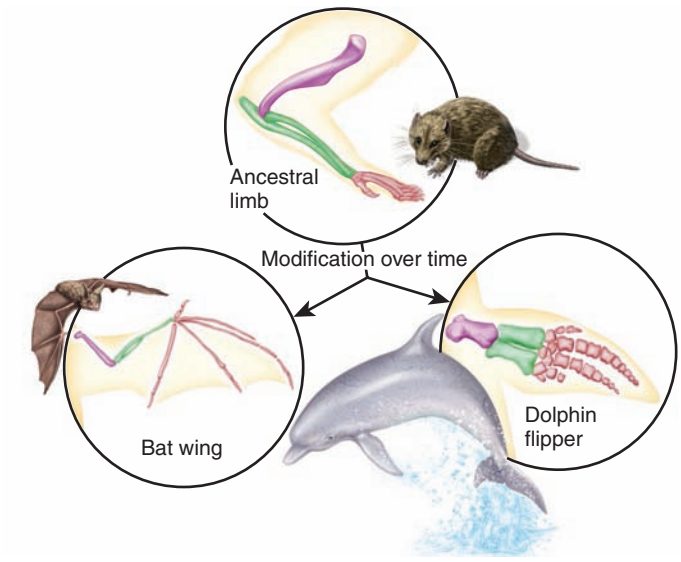

Figure 1.6 An example showing a modification that has occurred as a result of biological evolution. The wing of a bat and the flipper of a dolphin are modifications of a limb that was used for walking in a pre-existing ancestor.

Concept Check: Among mammals, give two examples of how the tail has been modified and has different purposes.

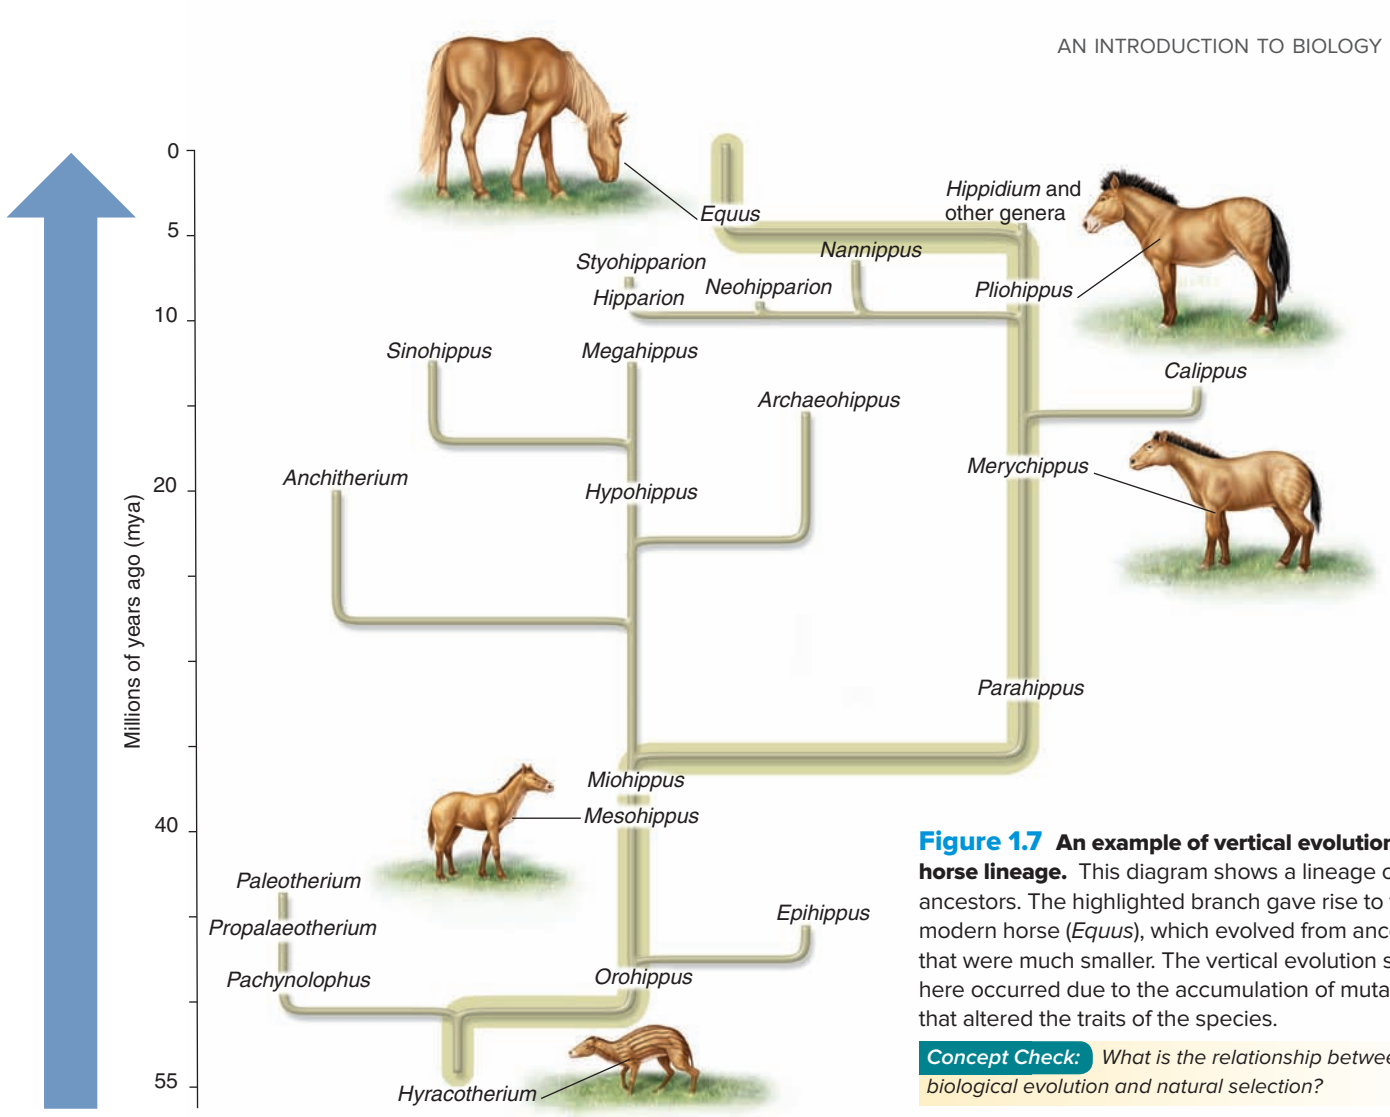

Figure 1.7 An example of vertical evolution: The horse lineage. This diagram shows a lineage of ancestors. The highlighted branch gave rise to the modern horse (*Equus*), which evolved from ancestors that were much smaller. The vertical evolution shown here occurred due to the accumulation of mutations that altered the traits of the species.

Concept Check: *What is the relationship between biological evolution and natural selection?*

Vertical Descent with Mutation The traditional way to study evolution is to examine a progression of changes in a series of ancestors. Such a series is called a **lineage**. Figure 1.7 shows a portion of the lineage that gave rise to modern horses. This type of evolution is called **vertical evolution** because it occurs in a lineage. Biologists have traditionally depicted such evolutionary change in a diagram like the one shown in Figure 1.7. In this mechanism of evolution, new species evolve from pre-existing ones by the accumulation of **mutations**, which are heritable changes in the genetic material of organisms. But why would some mutations accumulate in a population and eventually change the characteristics of an entire species? One reason is that a mutation may alter the traits of organisms in a way that increases their chances of survival and reproduction. When a mutation causes such a beneficial change, the frequency of the mutation may increase in a population from one generation to the next, a process called **natural selection**. This topic is discussed in Units IV and V. Evolution also involves the accumulation of neutral changes that do not benefit or harm a species, and evolution sometimes involves rare changes that may be harmful.

With regard to the horses shown in Figure 1.7, the fossil record has revealed adaptive changes in various traits such as size and tooth morphology. The first horses were the size of dogs, whereas modern horses typically weigh more than a half ton. The teeth of *Hyracotherium* were relatively small compared with those of modern horses. Over the course of millions of years, horse teeth have increased in size, and a complex pattern of ridges has developed on the molars. How do evolutionary biologists explain these changes in horse characteristics? They can be attributed to natural selection, in that changing global climates favored the survival and reproduction of horses with certain types of traits. Over North America, where much of horse evolution occurred, large areas changed from dense forests to grasslands. Horses with genetic variation that made them larger were more likely to escape predators and travel greater distances in search of food. The changes seen in horses' teeth are consistent with a dietary shift from eating tender leaves to eating grasses and other vegetation that are more abrasive and require more chewing.

Horizontal Gene Transfer The most common way for genes to be transferred is in a vertical manner. This can involve the transfer of genetic material from a mother cell to daughter cells, or it can occur via gametes—sperm and egg—that unite to form a new organism. However, as discussed in later chapters, genes are sometimes transferred between organisms by other mechanisms. These other mechanisms are collectively known as **horizontal gene transfer**, which is the transfer of genetic material from one organism to another organism that is not its offspring. In some cases, horizontal gene transfer can occur between members of different species. For example, you may have heard in the news media that resistance to antibiotics among bacteria is a growing medical problem. As discussed in Chapter 18,

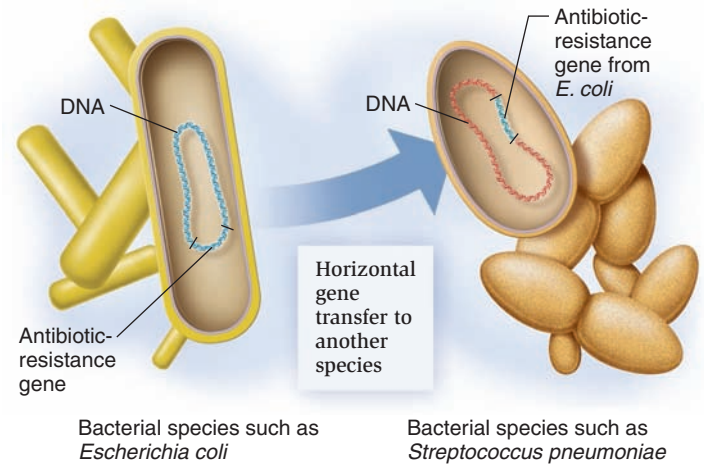

Figure 1.8 An example of horizontal gene transfer: Antibiotic resistance. One bacterial species may transfer a gene to a different bacterial species, such as a gene that confers resistance to an antibiotic.

genes that confer antibiotic resistance are sometimes transferred between different bacterial species (**Figure 1.8**).

In a lineage in which the time scale is depicted on a vertical axis, horizontal gene transfer between different species is shown as a horizontal line (**Figure 1.9**). Genes transferred horizontally may be subjected to natural selection and promote changes in an entire species. This has been an important mechanism of evolutionary change, particularly among bacterial species. In addition, during the early stages of evolution, which occurred a few billion years ago, horizontal gene transfer was an important part of the process that gave rise to all modern species.

Traditionally, biologists have described evolution using diagrams that depict the vertical evolution of species on a long time scale. This type of evolutionary tree was shown earlier in Figure 1.7. For many decades, the simplistic view held that all living organisms evolved from a common ancestor, resulting in a "tree of life" that could describe the vertical evolution that gave rise to all modern species. Now that we understand the great importance of horizontal gene transfer in the evolution of life on Earth, biologists have needed to re-evaluate the concept of evolution as it occurs over time. Rather than a tree of life, a more appropriate way to view the unity of living organisms is to describe it as a "web of life," as shown in Figure 1.9, which accounts for both vertical evolution and horizontal gene transfer.

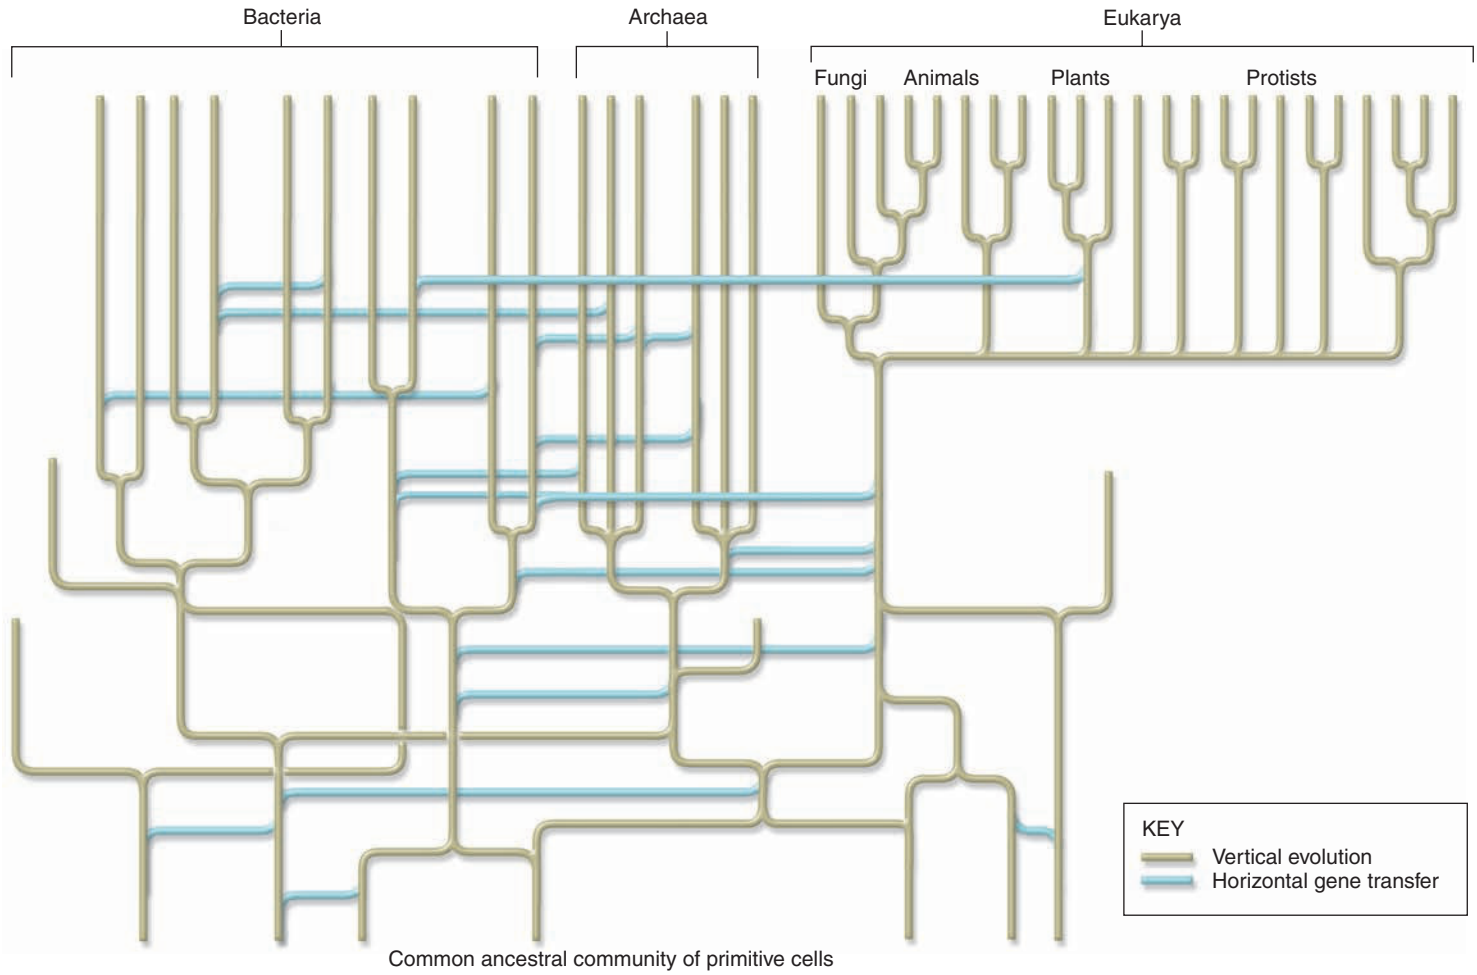

Figure 1.9 The web of life, showing both vertical evolution and horizontal gene transfer. This diagram of evolution includes both of these important mechanisms in the evolution of life on Earth. Note: Archaea are unicellular species that are similar in cell structure to bacteria.

Concept Check: *How does the concept of a tree of life differ from that of a web of life?*

The Classification of Living Organisms Allows Biologists to Appreciate the Unity and Diversity of Life

As biologists discover new species, they try to place them into groups based on their evolutionary history. This is a difficult task because researchers estimate that the Earth has between 5 and 50 million different species! The rationale for categorization is based on vertical descent. Species with a recent common ancestor are grouped together, whereas species whose common ancestor was in the very distant past are placed into different groups. The grouping of species is termed **taxonomy**.

Let's first consider taxonomy on a broad scale. You may have noticed that Figure 1.9 showed three main groups of organisms. From an evolutionary perspective, all forms of life can be placed into those three large categories, or domains, called **Bacteria**, **Archaea**, and **Eukarya** (**Figure 1.10**). Bacteria and archaea are microorganisms that are also termed **prokaryotic** because their cell structure is relatively simple. At the molecular level, bacterial and archaeal cells show significant differences in their compositions. By comparison, organisms in domain Eukarya are **eukaryotic** and have larger cells with internal compartments that serve various functions. A defining distinction between prokaryotic and eukaryotic cells is that eukaryotic cells have a **cell nucleus** in which the genetic material is surrounded by a membrane.

The organisms in domain Eukarya were once subdivided into four major categories, or kingdoms, called Protista (protists), Plantae (plants), Fungi, and Animalia (animals). However, as discussed in Chapter 26 and Unit V, this traditional view became invalid as biologists gathered new information regarding the evolutionary relationships of these organisms. We now know the protists do not form a single kingdom but instead are divided into several broad categories called supergroups.

Taxonomy involves multiple levels in which particular species are placed into progressively smaller and smaller groups of organisms that are more closely related to each other evolutionarily. Such an approach emphasizes the unity and diversity of different species. As an example, let's consider the clownfish, a popular saltwater aquarium fish (**Figure 1.11**). Several species of clownfish have been identified. One species of clownfish, which is orange with white stripes, has several common names, including Ocellaris clownfish. The broadest grouping for this clownfish is the domain, namely, Eukarya, followed by progressively smaller divisions, from supergroup (Opisthokonta), to kingdom (Animalia), and eventually to species. In the animal kingdom, clownfish are part of a phylum, Chordata, the chordates, which is subdivided into classes. Clownfish are in a class called Actinopterygii, which includes all ray-finned fishes. The common ancestor that gave rise to ray-finned fishes arose about 420 million years ago (mya). Actinopterygii is subdivided into several smaller orders. The clownfish are in the order Perciformes (bony fish). The order is, in turn, divided into families; the clownfish belong to the family of marine fish called Pomacentridae, which are often brightly colored. Families are divided into genera (singular, genus). The genus *Amphiprion* is composed of 28 different species; these are various types of clownfish. Therefore, the genus contains species that are very similar to each other in form and have evolved from a common (extinct) ancestor that lived relatively recently on an evolutionary time scale.

Biologists use a two-part description, called **binomial nomenclature**, to provide each species with a unique scientific name. The scientific name of the Ocellaris clownfish is *Amphiprion ocellaris*. The first part is the genus, and the second part is the specific epithet, or species descriptor. By convention, the genus name is capitalized, whereas the specific epithet is not. Both names are italicized. Scientific names are usually Latinized, which means they are made similar in appearance to Latin words. The origins of scientific names are typically Latin or Greek, but they can come from a variety of sources, including a person's name.

Genomes & Proteomes Connection

The Study of Genomes and Proteomes Provides an Evolutionary Foundation for Our Understanding of Biology

The unifying concept in biology is evolution. We can understand the unity of modern organisms by realizing that all living species evolved from an interrelated group of ancestors. However, from an experimental perspective, this realization presents a dilemma—we cannot take a time machine back over the course of 4 billion years to carefully study the characteristics of extinct organisms and fully appreciate the series of changes that have led to modern species. Fortunately, though, evolution has given biologists some wonderful puzzles to study, including the fossil record and the genomes of modern species.

As mentioned, the term genome refers to the complete genetic composition of an organism or species (**Figure 1.12a**). The genomes of bacteria and archaea usually contain a few thousand genes, whereas those of eukaryotes may contain tens of thousands. The genome is critical to life because it performs these functions:

- *Stores information in a stable form:* The genome of every organism stores information that provides a blueprint for producing its characteristics.
- *Provides continuity from generation to generation:* The genome is copied and transmitted from generation to generation.
- *Acts as an instrument of evolutionary change:* Every now and then, the genome undergoes a mutation that may alter the characteristics of an organism. In addition, a genome may acquire new genes by horizontal gene transfer. The accumulation of such changes from generation to generation produces the evolutionary changes that alter species and produce new species.

An exciting advance in biology over the past couple of decades has been the ability to analyze the DNA sequence of genomes, a technology called **genomics**. For instance, we can compare the genomes of a frog, a giraffe, and a petunia and discover intriguing similarities and differences. These comparisons help us to understand how new traits evolved. For example, all three types of organisms have the same kinds of genes needed for the breakdown of nutrients such as sugars. In contrast, only the petunia has genes that allow it to carry out photosynthesis.

(a) Domain Bacteria: Mostly unicellular prokaryotes that inhabit many diverse environments on Earth.

(b) Domain Archaea: Unicellular prokaryotes that often live in extreme environments, such as hot springs.

Protists: Unicellular and small multicellular organisms that are now subdivided into seven broad groups based on their evolutionary relationships.

Plants: Multicellular organisms that can carry out photosynthesis.

Fungi: Unicellular and multicellular organisms that have a cell wall but cannot carry out photosynthesis. Fungi usually survive on decaying organic material.

Animals: Multicellular organisms that usually have a nervous system and are capable of locomotion. They must eat other organisms or the products of other organisms to live.

(c) Domain Eukarya: Unicellular and multicellular organisms having cells with internal compartments that serve various functions.

Figure 1.10 The three domains of life. Two of these domains, **(a)** Bacteria and **(b)** Archaea, are prokaryotic cells. The third domain, **(c)** Eukarya, comprises species that are eukaryotes.

BioConnections: *Look ahead to Figure 26.1. Are fungi more closely related to plants or animals?*

Taxonomic group	The Ocellaris clownfish is found in	Approximate time when the common ancestor for this group arose	Approximate number of modern species in this group	Examples
Domain	Eukarya	2,000 mya	> 5,000,000	
Supergroup	Opisthokonta	2,000 mya	> 1,000,000	
Kingdom	Animalia	600 mya	> 1,000,000	
Phylum	Chordata	525 mya	50,000	
Class	Actinopterygii	420 mya	30,000	
Order	Perciformes	80 mya	7,000	
Family	Pomacentridae	~ 40 mya	360	
Genus	*Amphiprion*	~ 9 mya	28	
Species	*ocellaris*	< 3 mya	1	

Figure 1.11 **Taxonomic classification of the clownfish.**

Concept Check: *Why is it useful to place organisms into taxonomic groupings?*

An extension of genome analysis is the study of **proteomes**, which refers to all of the proteins that a cell or organism makes. The function of most genes is to encode polypeptides that become units in proteins. As shown in **Figure 1.12b**, these include proteins that form a cytoskeleton and proteins that function in cell organization and as enzymes, transport proteins, cell-signaling proteins, and extracellular proteins. The genome of each species carries the information to make its proteome—the hundreds or thousands of proteins that each cell of that species makes. Proteins are largely responsible for the structures and functions of cells and organisms. The technical approach called **proteomics** involves the analysis of the proteome of a single species and the comparison of the proteomes of different species. Proteomics helps us understand how the various levels of biology are related to one another, from the molecular level—at the level of protein molecules—to the higher levels, such as how the functioning of proteins produces the characteristics of cells and organisms and affects the ability of populations of organisms to survive in their natural environments.

In Chapters 3 through 60, we use a recurring theme in a brief topic called "Genomes & Proteomes Connection" as a concrete way of understanding the unifying concept of evolution in biology. These brief topics will allow you to appreciate how evolution produced the characteristics of modern species. These topics explore how the genomes of different species are similar to each other and how they are different. You will learn how genome changes affect the proteome and thereby control the traits of modern species. Ultimately, these concepts provide you with a way to relate information at the molecular level to the traits of organisms and their survival within ecosystems.

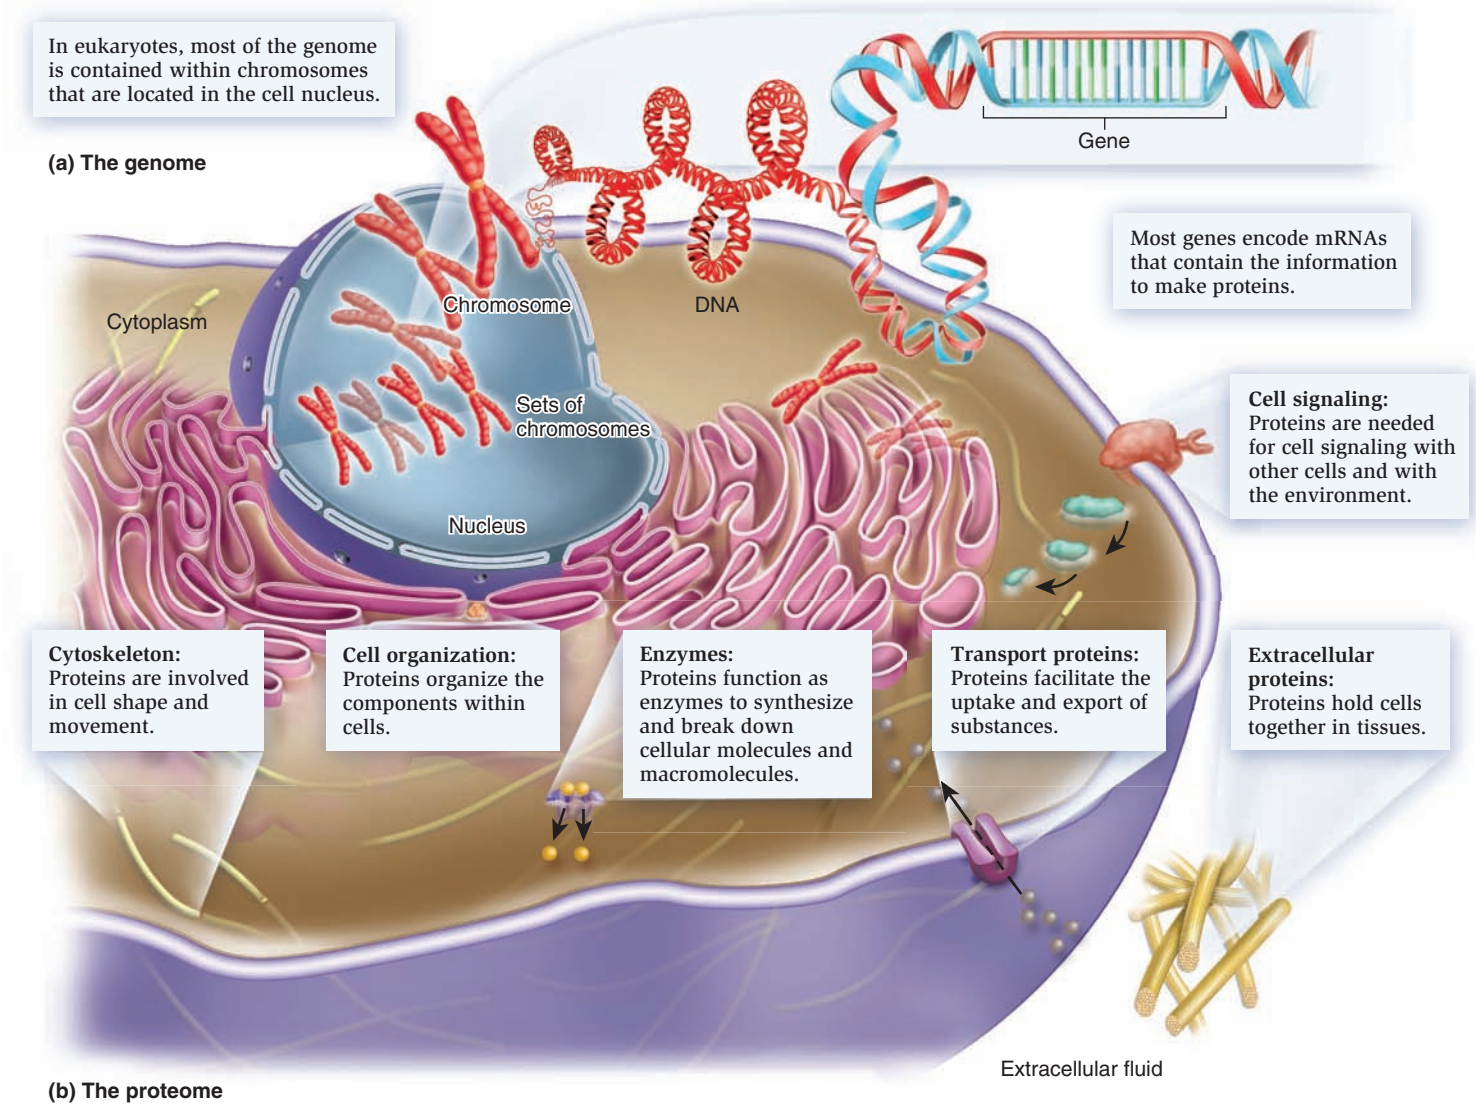

Figure 1.12 Genomes and proteomes. (a) The genome, which is composed of DNA, is the entire genetic composition of an organism. Most of the genetic material in eukaryotic cells is found in the cell nucleus. The primary function of the genome is to encode the proteome **(b)**, which is the entire protein complement of a cell or organism. Six general categories of proteins are illustrated. Proteins are largely responsible for the structure and function of cells and complete organisms.

Concept Check: *Biologists sometimes say the genome is a storage unit of life, whereas the proteome is largely the functional unit of life. Explain this statement.*

Genomes and Proteomes Affect Many Features of Living Organisms, Including Morphology and Behavior

The cover of your textbook and the chapter opening photo show a gypsy moth and a gypsy moth caterpillar (*Lymantria dispar*), found in Europe, Africa, and North America. This species provides two striking examples of how genomes and proteomes affect the traits of living organisms.

Stages of Development Multicellular species, such as plants and animals, go through different stages of development, beginning with a fertilized egg and ending with the adult (development is discussed in Chapters 19 and 52). In many insects, the various stages of development show dramatic differences in morphology. As an example, the gypsy moth exhibits four very different forms as it progresses through its development (**Figure 1.13**).

- **Egg/embryo**: The gypsy moth begins its life as a fertilized egg that is typically laid in an egg mass on a branch or trunk of a tree. The egg remains dormant during the winter months. In the spring, it develops into an embryo. After about 1 month, the embryo becomes a larva, which hatches from the egg and becomes free-living.
- **Larva** (plural, larvae): Gypsy moth larvae are called caterpillars. The caterpillars feed on leaves and can be quite destructive, often decimating large areas of forest. Over the course of 1–2 months, they go through a series of 5 or 6 molts in which they shed their outer, hard surface, called a cuticle. Molting allows the caterpillars to grow larger and larger.
- **Pupa** (plural, pupae): At the end of the larval stage, the larva undergoes a process called pupation, in which larval structures break down and adult structures form. This process, which lasts

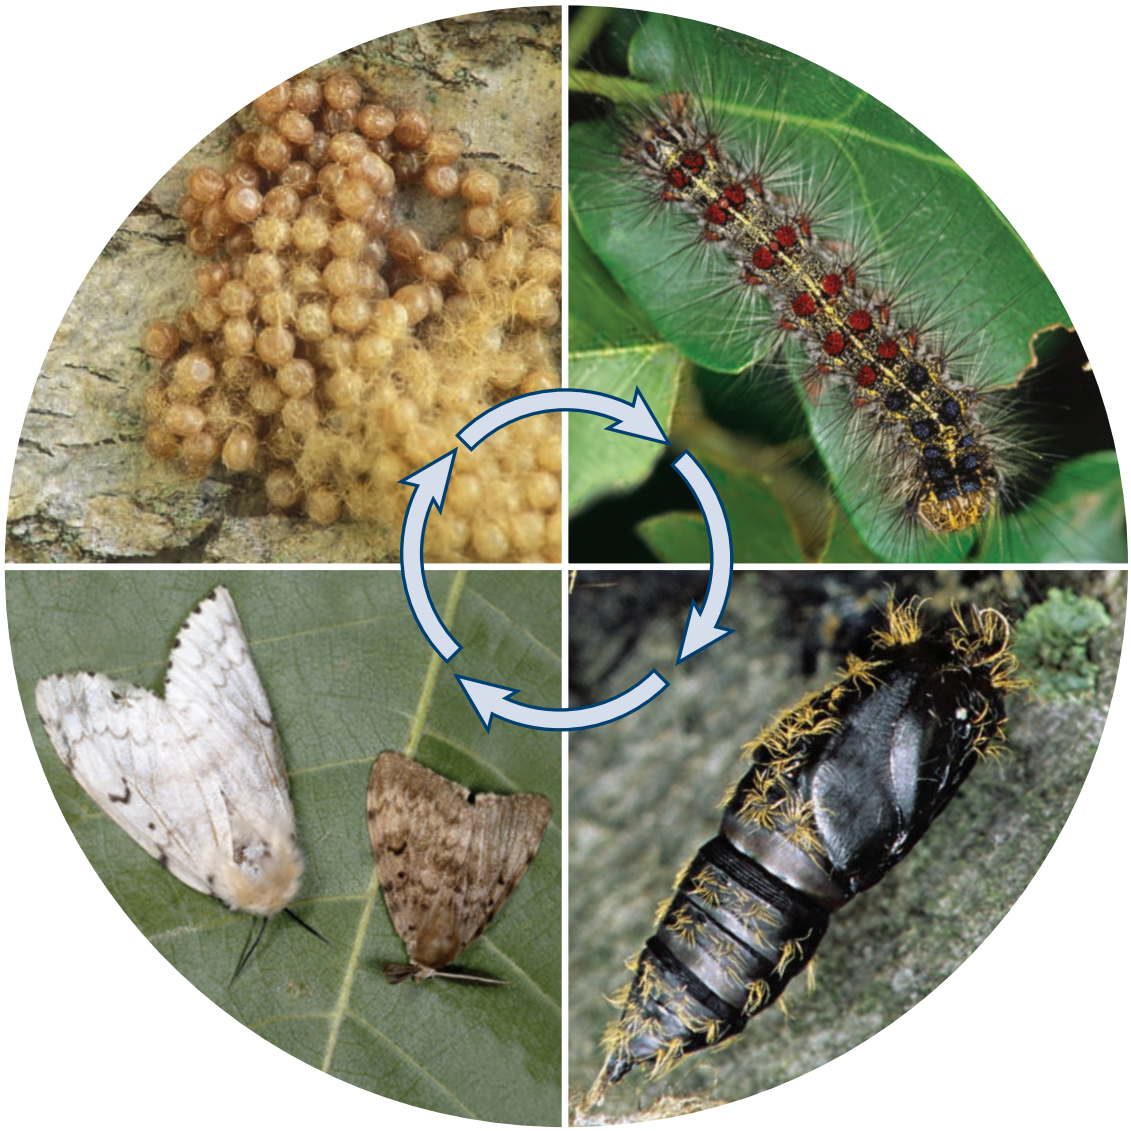

Figure 1.13 **The four stages in the life cycle of the gypsy moth (*Lymantria dispar*).** Note: the larger moth on the left is a female.

about 2 weeks, occurs within a hard outer covering that forms around the pupa and is called the pupal case.

- **Adult**: An adult moth emerges, fully formed, by splitting open the pupal case. Adults do not have a digestive system and therefore cannot feed, but they can take in moisture. Females secrete a powerful pheromone to attract males. Following mating, the female lays masses of eggs, and the cycle can begin again. Adult moths typically live only about 1 week.

How do we explain the dramatic changes in morphology during the different stages of gypsy moth development? The answer is that different genes are expressed at certain stages but not others. For example, some genes that are expressed in the caterpillar encode proteins that give the caterpillar its striking characteristics. Then, at later stages of development, these genes are turned off, and other genes are expressed, resulting in the traits seen in the adult.

Zombie Parasites Another interesting and seemingly bizarre example of how genomes and proteomes can affect the traits of organisms is a phenomenon known as **zombie parasites**. As you may know, zombies are fictional creatures most commonly depicted in horror and fantasy novels and movies, where they appear as dead creatures that are able to move because of some magical force. A zombie parasite is a parasite that infects its host and is then able to control its behavior. A relatively small group of researchers have begun to study this phenomenon, which has spawned a new field called **neuroparasitology**—the study of how parasites control the nervous systems of their hosts.

The chapter opening photo also illustrates an interesting example of zombie parasites. When gypsy moth caterpillars are infected by a virus called *Lymantria dispar* multicapsid nucleopolyhedrovirus (LdMNPV), they climb to the tops of trees during the day, die, liquefy, and release millions of infective virus particles when it next

Table 1.1 Examples of Zombie Parasites

Host	Parasite	Description
House cricket (*Acheta domesticus*)	Horsehair worm (*Paragordius varius*)	A horsehair worm larva infects a cricket and grows inside it. The cricket is terrestrial, but the adult stage of the horsehair worm is aquatic. When the larva matures into an adult, it alters the behavior of the cricket, causing it to jump into the nearest body of water! As the cricket drowns, an adult worm emerges.
Spider (*Plesiometa argyra*)	Wasp (*Hymenoepimecis argyraphaga*)	A female wasp glues an egg onto the spider's body. After the egg develops into a larva, the larva pokes a few holes in the spider's abdomen, which allows it to suck the spider's blood and also to transfer chemicals into the spider, which control its behavior. The spider stops building its normal orb-shaped web and starts building a new one. The geometry of the new web is strikingly different and is apparently designed to suspend the larva's cocoon in the air, where it will be protected from predators.
Various vertebrates, including mice and rats	Protozoan (*Toxoplasma gondii*)	*Toxoplasma gondii* is a parasite whose life cycle involves more than one vertebrate host. The definitive host is the cat, which is where *T. gondii* becomes mature and reproduces sexually. An intermediate host can be a variety of different vertebrates including mice and rats, which can ingest the parasite from cat feces. In the intermediate host, the parasite develops and reproduces asexually. To escape an intermediate host, such as a mouse or rat, and move to the definitive host, *T. gondii* dramatically alters the rodent's behavior. The infected animal becomes attracted to the smell of cat urine! This makes it more likely for the rodent to be eaten by a cat and thereby allows *T. gondii* to enter its definitive host and mature.

rains. In contrast, gypsy moth caterpillars, which are not infected with LdMNPV, never exhibit this behavior. During the day, they hide in bark crevices or climb down the tree to the soil to avoid predation by birds; these healthy caterpillars feed only at night. Researchers have discovered a gene in the virus that is responsible for controlling the caterpillars' behavior. This gene, called the *egt* gene, encodes a protein (ecdysteroid UDP–glucosyltransferase) that inactivates a molting hormone and also affects behavior. When researchers removed the gene from the virus and infected gypsy moth caterpillars with the altered virus, they no longer exhibited the unusual behavior.

During the past few decades, researchers have discovered many other examples of zombie parasites that control the behavior of their hosts. A few are described in **Table 1.1**.

1.3 Biology as a Scientific Discipline

Learning Outcomes:

1. Explain how researchers study biology at different levels, ranging from molecules to ecosystems.
2. **SciSKILLS** » Distinguish between discovery-based science and hypothesis testing, and describe the steps of the scientific method.

What is science? Surprisingly, the definition of science is not easy to state. Most people have an idea of what science is, but actually articulating that idea proves difficult. In biology, we can define **science** as the observation, identification, experimental investigation, and theoretical explanation of natural phenomena.

Science is conducted in different ways and at different levels. Some biologists study the molecules that compose life, and others try to understand how organisms survive in their natural environments. Experimentally, researchers often focus their efforts on **model organisms**—organisms studied by many different researchers so they can compare their results and determine scientific principles that apply more broadly to other species. Examples include *Escherichia coli* (a bacterium), *Saccharomyces cerevisiae* (a yeast), *Drosophila melanogaster* (fruit fly), *Caenorhabditis elegans* (a nematode worm), *Mus musculus* (mouse), and *Arabidopsis thaliana* (a flowering plant). Model organisms offer experimental advantages over other species. For example, *E. coli* is a very simple organism that can be easily grown in the laboratory. By limiting their work to a few such model organisms, researchers can gain a deeper understanding of these species. Importantly, the discoveries made using model organisms help us to understand how biological processes work in other species, including humans.

In this section, we will examine how biologists follow a standard approach, called the **scientific method**, to test their ideas. We will explore how scientific knowledge makes predictions that can be experimentally tested. Even so, not all discoveries are the result of researchers following the scientific method. Some discoveries are simply made by gathering new information. For example, as described earlier in Figures 1.1 and 1.3, the characterization of many living organisms has led to the development of important medicines. In this section, we will also consider how researchers often set out on "fact-finding missions" aimed at uncovering new information that may eventually lead to modern discoveries in biology.

Biologists Investigate Life at Different Levels of Organization

In Figure 1.5, we examined the various levels of biological organization. The study of these different levels depends not only on the scientific interests of biologists but also on the tools available to them. The study of organisms in their natural environments is a branch of biology called **ecology**, which considers populations, communities, and ecosystems (**Figure 1.14a**). In addition, researchers examine the structures and functions of plants and animals, which are disciplines called **anatomy** and **physiology** (**Figure 1.14b**). With the advent of microscopy, **cell biology**, which is the study of cells, became an important branch of biology in the early 1900s and remains so today (**Figure 1.14c**). In the 1970s, genetic tools became available for studying single genes and the proteins they encode.

This genetic technology enabled researchers to study individual molecules, such as proteins, in living cells and thereby spawned the field of **molecular biology**. Together with chemists and biochemists, molecular biologists focus their efforts on the structure and function of the molecules of life (**Figure 1.14d**). Such researchers want to understand how biology works at the molecular and even atomic levels. Overall, the 20th century saw a progressive increase in the number of biologists who used an approach to understanding biology called **reductionism**—reducing complex systems to simpler components as a way to understand how the system works. In biology, reductionists study the parts of a cell or organism as individual units.

In the 1990s, the pendulum began to swing in the other direction. Scientists have invented new tools that allow them to study groups of genes (genomic techniques) and groups of proteins (proteomic techniques). As mentioned earlier, biologists now use the term **systems biology** to describe research aimed at understanding how emergent properties arise. This term is often applied to the study of cells. In this context, systems biology may involve the investigation of groups of genes that encode proteins with a common purpose (**Figure 1.14e**). For example, a systems biologist may conduct experiments that try to characterize an entire cellular process, which is driven by dozens of different proteins. However, systems biology is not new. Animal and plant physiologists have been studying the functions of complex organ systems for centuries. Likewise, ecologists have been characterizing ecosystems for a very long time. The novelty and excitement of systems biology in recent years have been the result of new experimental tools that allow us to study complex interactions at the molecular level.

A Hypothesis Is a Proposed Idea, Whereas a Theory Is a Broad Explanation Backed by Extensive Evidence

Let's now consider the process of science. In biology, a **hypothesis** is a proposed explanation for a natural phenomenon. It is a proposition based on previous observations or experimental studies. For example, with knowledge of seasonal changes, you might hypothesize that maple trees drop their leaves in the autumn because of the shortened amount of daylight. An alternative hypothesis might be that the trees drop their leaves because of colder temperatures. In biology, a hypothesis requires more work by researchers to evaluate its validity.

A useful hypothesis must make **predictions**—expected outcomes that can be shown to be correct or incorrect. In other words, a useful hypothesis is **testable**. If a hypothesis is incorrect, it should be **falsifiable**, which means that it can be shown to be incorrect by additional observations or experimentation. Alternatively, a hypothesis may be correct, so further work will not disprove it. In such cases, we would say that the researcher(s) has failed to reject the hypothesis. Even so, in science, a hypothesis is never really proven but rather always remains provisional. Researchers accept the possibility that perhaps they have not yet conceived of the correct hypothesis. After many experiments, biologists may conclude their hypothesis is consistent with known data, but they should never say the hypothesis is proven.

Ecologists study species in their native environments.

(a) Ecology—population/community/ecosystem levels

Anatomists and physiologists study how the structures of organisms are related to their functions.

(b) Anatomy and physiology—tissue/organ/organism levels

Cell biologists often use microscopes to learn how cells function.

(c) Cell biology—cellular levels

Molecular biologists and biochemists study the molecules and macromolecules that make up cells.

(d) Molecular biology—atomic/molecular levels

Systems biologists may study groups of molecules. The microarray shown in the inset determines the expression of many genes simultaneously.

(e) Systems biology—all levels, shown here at the molecular level

Figure 1.14 **Biological investigation at different levels.**

By comparison, the term **theory**, as it is used in biology, is a broad explanation of some aspect of the natural world that is substantiated by a large body of evidence. Biological theories incorporate observations, hypothesis testing, and the laws of other disciplines such as chemistry and physics. Theories are powerful because they allow us to make many predictions about the properties of living organisms. As an example, let's consider the theory that DNA is the genetic material and that it is organized into units called genes. An overwhelming body of evidence has substantiated this theory. Thousands of living species have been analyzed at the molecular level. All of them have been found to use DNA as their genetic material and to express genes that produce the proteins that lead to their characteristics. This theory makes many valid predictions. For example, certain types of mutations in genes are expected to affect the traits of organisms. This prediction has been confirmed experimentally. Similarly, this theory predicts that genetic material is copied and transmitted from parents to offspring. By comparing the DNA of parents and offspring, this prediction has also been confirmed. Furthermore, the theory explains the observation that offspring resemble their parents. Overall, two key attributes of a scientific theory are (1) consistency with a vast amount of known data and (2) the ability to make many correct predictions.

The meaning of the term "theory" is sometimes muddled because the word is used in different situations. In everyday language, a theory is often viewed as little more than a guess. For example, a person might say, "My theory is that Professor Simpson did not come to class today because he went to the beach." However, in biology, a theory is much more than a guess. A theory is an established set of ideas that explains a vast amount of data and offers valid predictions that can be tested. Like a hypothesis, a theory can never be proven to be true. Scientists acknowledge that they do not know everything. Even so, biologists would say that theories are extremely likely to be true, based on all known information. In this regard, theories are viewed as **knowledge**, which is the awareness and understanding of information.

Discovery-Based Science and Hypothesis Testing Are Scientific Approaches That Help Us Understand Biology

The path that leads to an important discovery is rarely a straight line. Rather, scientists ask questions, make observations, ask modified questions, and may eventually conduct experiments to test their hypotheses. The first attempts at experimentation may fail, and new experimental approaches may be needed. To suggest that scientists follow a rigid scientific method is an oversimplification of the process of science. Scientific advances often occur as scientists dig deeper and deeper into a topic that interests them. Curiosity is the key phenomenon that sparks scientific inquiry. How is biology actually conducted? As discussed next, researchers typically follow two general types of approaches: discovery-based science and hypothesis testing.

Discovery-Based Science The collection and analysis of data without the need for a preconceived hypothesis is called **discovery-based science**, or simply **discovery science**. Why is discovery-based science carried out? The information gained from discovery-based science may lead to the formation of new hypotheses and, in the long run, may have practical applications that benefit people. Researchers, for example, have identified and begun to investigate newly discovered genes within the human genome without already knowing the function of the gene they are studying. The goal is to gather additional clues that may eventually allow them to propose a hypothesis that explains the gene's function. Discovery-based science often leads to hypothesis testing.

Hypothesis Testing In biological science, the scientific method, also known as **hypothesis testing**, is usually followed to formulate and test the validity of a hypothesis. This strategy may be described as a five-step method:

1. Observations are made regarding natural phenomena.
2. These observations lead to a hypothesis that tries to explain the phenomena. A useful hypothesis is one that is testable because it makes specific predictions.
3. Experimentation is conducted to determine if the predictions are correct.
4. The data from the experiment are analyzed.
5. The hypothesis is considered to be consistent with the data, or it is rejected.

The scientific method is intended to be an objective way to gather knowledge. As an example, let's return to our scenario of maple trees dropping their leaves in autumn. By observing the length of daylight throughout the year and comparing that data with the time of the year when leaves fall, one hypothesis might be that leaves fall in response to a shorter amount of daylight (**Figure 1.15**). This hypothesis makes a prediction—exposure of maple trees to shorter daylight will cause their leaves to fall. To test this prediction, researchers would design and conduct an experiment.

How is hypothesis testing conducted? Although hypothesis testing may follow many paths, certain experimental features are common to this approach. First, data are often collected in two parallel manners. One set of experiments is done on the **control group**, while another set is conducted on the **experimental group**. In an ideal experiment, the control and experimental groups differ by only one factor. For example, an experiment could be conducted in which two groups of trees are observed, and the only difference between their environments is the length of light each day. To conduct such an experiment, researchers would grow small trees in a greenhouse where they could keep other factors such as temperature, water, and nutrients the same between the control and experimental groups, while providing them with different amounts of daylight. In the control group, the number of hours of light provided by lightbulbs is kept constant each day, whereas in the experimental group, the amount of light each day becomes progressively shorter to mimic seasonal light changes. The researchers would then record the number of leaves dropped by the two groups of trees over a certain period of time.

Another key feature of hypothesis testing is data analysis. The result of experimentation is a set of data from which a biologist tries to draw conclusions. Biology is a quantitative science. When

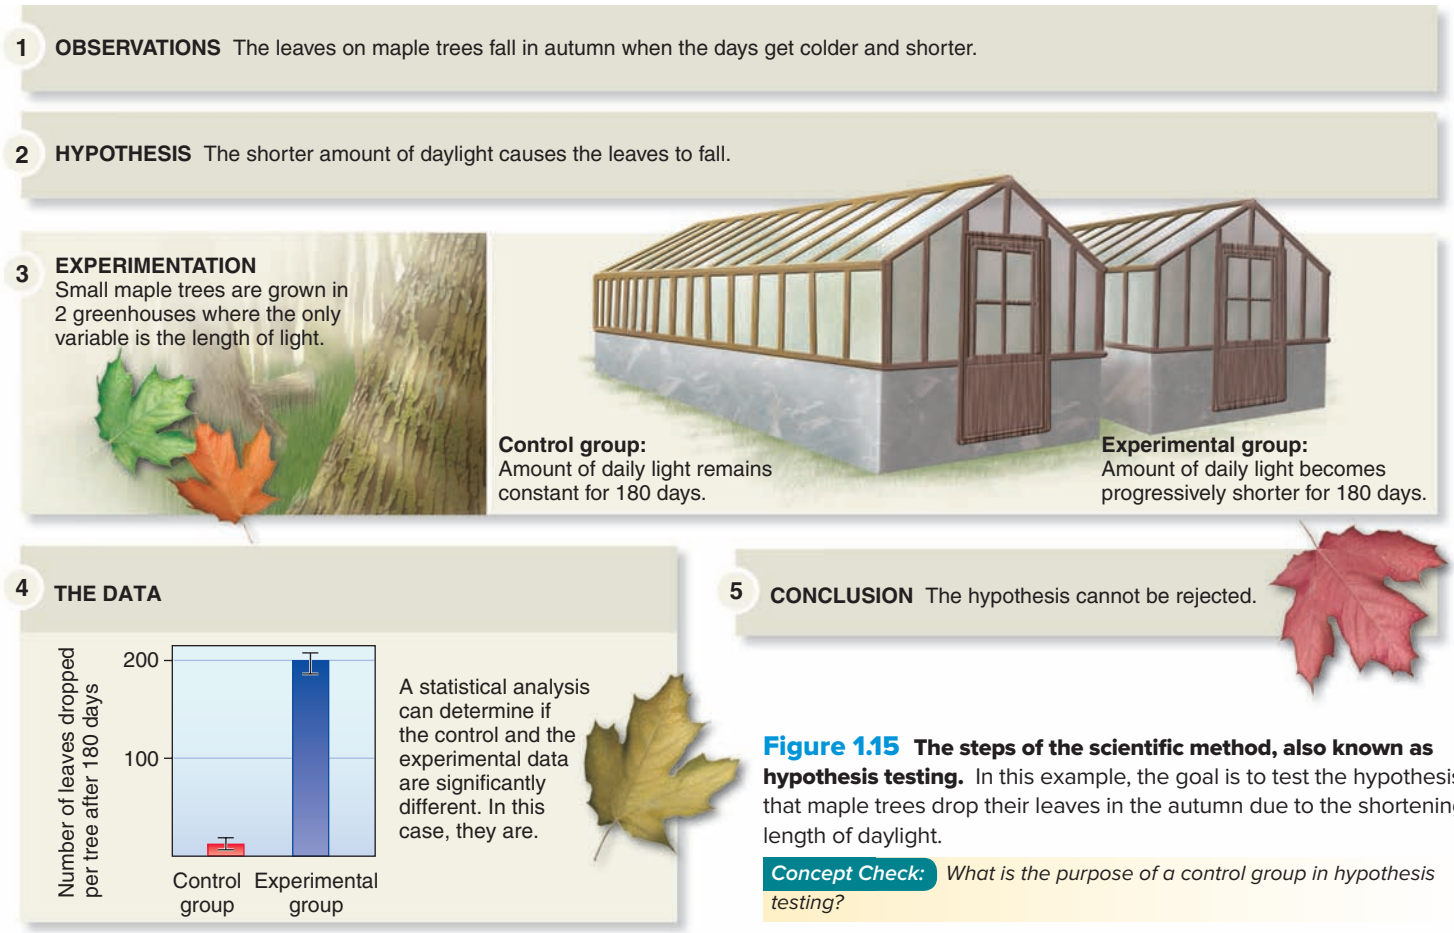

Figure 1.15 The steps of the scientific method, also known as hypothesis testing. In this example, the goal is to test the hypothesis that maple trees drop their leaves in the autumn due to the shortening length of daylight.

Concept Check: What is the purpose of a control group in hypothesis testing?

experimentation involves control and experimental groups, a common form of analysis is to determine if the data collected from the two groups are truly different from each other. Biologists apply statistical analyses to their data to determine if the control and experimental groups are likely to be different from each other because of the single variable that is different between the two groups. When they are statistically significant, the differences between the control and experimental data are not likely to have occurred as a matter of random chance.

In our tree example shown in Figure 1.15, the trees in the control group dropped far fewer leaves than did those in the experimental group. A statistical analysis could determine if the data collected from the two greenhouses are significantly different from each other. If the two sets of data are found not to be significantly different, the hypothesis would be rejected. Alternatively, if the differences between the two sets of data are significant, as shown in Figure 1.15, biologists would conclude that the hypothesis is consistent with the data, though it is not proven. A hallmark of science is that valid experiments are **repeatable**, which means that similar results are obtained when the experiment is conducted on multiple occasions. For our example in Figure 1.15, the data would be valid only if the experiment was repeatable.

As described next, discovery-based science and hypothesis testing are often used together to learn more about a particular scientific topic. As an example, let's look at how both approaches led to successes in the study of the disease called cystic fibrosis.

The Study of Cystic Fibrosis Provides Examples of Discovery-Based Science and Hypothesis Testing

Let's consider how biologists made discoveries related to the disease cystic fibrosis (CF), which affects about 1 in every 3,500 Americans. Persons with CF produce abnormally thick and sticky mucus that obstructs the lungs and leads to life-threatening lung infections. The thick mucus also blocks ducts in the pancreas, which prevents the digestive enzymes this organ produces from reaching the intestine. Without these enzymes, the intestine cannot fully absorb amino acids and fats, which can cause malnutrition. Persons with this disease may also experience liver damage because the thick mucus can obstruct the liver. On average, people with CF in the United States currently live into their late 30s. Fortunately, as more advances have been made in treatment, this number has steadily increased.

Because of its medical significance, many scientists are interested in CF and are conducting studies aimed at gaining greater information regarding its underlying cause. The hope is that knowing more about the disease may lead to improved treatment options, and perhaps even a cure. As described next, discovery-based science and hypothesis testing have been critical to gaining a better understanding of this disease.

The CFTR Gene and Discovery-Based Science In 1935, American physician Dorothy Andersen determined that cystic fibrosis

is a genetic disorder. Persons with CF have inherited two faulty *CFTR* genes, one from each parent. (We now know this gene encodes a protein named the cystic fibrosis transmembrane regulator, abbreviated CFTR.) In the 1980s, researchers used discovery-based science to identify this gene. Their search for the *CFTR* gene did not require any preconceived hypothesis regarding the function of the gene. Rather, they used genetic strategies similar to those described in Chapter 20. Research groups headed by Lap-Chee Tsui, Francis Collins, and John Riordan identified the *CFTR* gene in 1989.

The discovery of the gene made it possible to devise diagnostic testing methods to determine if a person carries a faulty *CFTR* gene. In addition, the characterization of the *CFTR* gene provided important clues about its function. Researchers observed striking similarities between the *CFTR* gene and other genes that were already known to encode proteins that function in the transport of substances across membranes. Based on this observation, as well as other kinds of data, the scientists hypothesized that the function of the normal *CFTR* gene is to encode a transport protein. In this way, the identification of the *CFTR* gene led them to conduct experiments aimed at testing a hypothesis of its function.

The CFTR Gene and Hypothesis Testing Researchers considered the characterization of the *CFTR* gene along with other studies showing that patients with the disorder have an abnormal regulation of salt balance across their plasma membranes. They hypothesized that the normal *CFTR* gene encodes a protein that functions in the transport of chloride ions (Cl^-) across the membranes of cells (**Figure 1.16**). This hypothesis led to experimentation in which they tested normal cells and cells from CF patients for their ability to transport Cl^-. The CF cells were found to be defective in chloride transport. In 1990, scientists successfully transferred the normal *CFTR* gene into CF cells in the laboratory. The introduction of the normal gene corrected the cells' defect in chloride transport. Overall, the results showed that the *CFTR* gene encodes a protein that transports Cl^- across the plasma membrane. A mutation in this gene causes it to encode a defective protein, leading to a salt imbalance that affects water levels outside the cell, which explains the thick and sticky mucus in CF patients. In this example, hypothesis testing has provided a way to evaluate a hypothesis about how a disease is caused by a genetic change.

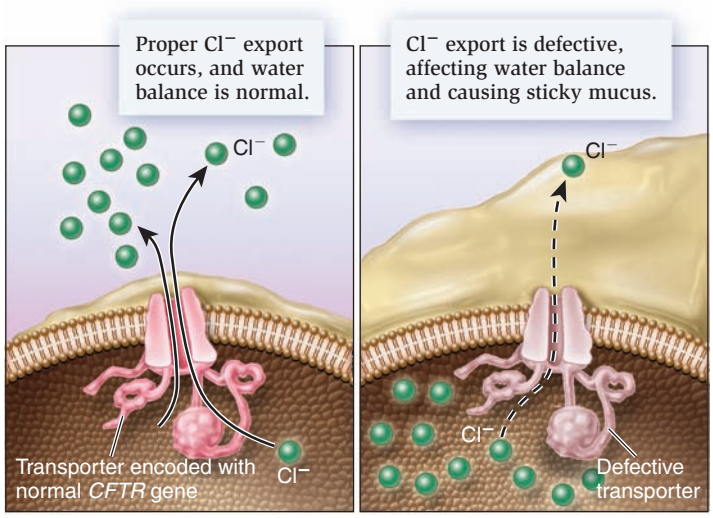

Figure 1.16 A hypothesis suggesting an explanation for the function of a gene defective in patients with cystic fibrosis. The normal *CFTR* gene, which does not carry a mutation, encodes a protein that transports chloride ions (Cl^-) across the plasma membrane to the outside of the cell. In persons with CF, this protein is defective due to a mutation in the *CFTR* gene.

Concept Check: *Explain how discovery-based science helped researchers to hypothesize that the CFTR gene encodes a transport protein.*

Feature Investigation | Observation and Experimentation Form the Core of Biology

Biology is largely about the process of discovery. Therefore, a recurring theme of this textbook is how scientists design experiments, analyze data, and draw conclusions. Although each chapter contains many examples of data collection and experiments, a consistent element is a "Feature Investigation"—which presents an actual study by current or past researchers. Some of these involve discovery-based science, in which biologists collect and interpret data in an attempt to make discoveries that are not hypothesis driven. Most Feature Investigations, however, involve hypothesis testing in which a hypothesis is stated and the experiment and resulting data are presented. Figure 1.15, which we discussed earlier, shows the general form of Feature Investigations.

The Feature Investigations allow you to appreciate the connection between science and scientific theories. As you read a Feature Investigation, you may find yourself thinking about different approaches and alternative hypotheses. Different people can view the same data and arrive at very different conclusions. As you progress through the experiments in this textbook, we hope you will try to develop your own skills at formulating hypotheses, designing experiments, and interpreting data.

Experimental Questions

1. Discuss the difference between discovery-based science and hypothesis testing.
2. What are the steps in the scientific method, also called hypothesis testing?
3. **SciSKILLS** » When conducting an experiment, explain how a control group and an experimental group differ from each other.

Figure 1.17 The social aspects of science. At scientific meetings, researchers gather together to discuss new data and discoveries. Research that is conducted by professors, students, lab technicians, and industrial participants is sometimes hotly debated.

Science as a Social Discipline

Finally, it is worthwhile to point out that biology is a social as well as a scientific discipline. Different laboratories often collaborate on scientific projects. After performing observations and experiments, biologists communicate their results in different ways. Most importantly, papers are submitted to scientific journals. Following submission, papers usually undergo a **peer-review process** in which other scientists, who are experts in the area, evaluate the paper and make suggestions regarding its quality. As a result of peer review, a paper is either accepted for publication, rejected, or the authors of the paper may be given suggestions for how to revise the work or conduct additional experiments before it is acceptable for publication.

Another social aspect of research is that biologists often attend meetings where they report their most recent work to the scientific community (**Figure 1.17**). They comment on each other's ideas and work, eventually shaping together the information that builds into scientific theories over many years. As you develop your skills at scrutinizing experiments, it is helpful to discuss your ideas with other people, including fellow students and faculty members. Importantly, you do not need to "know all the answers" before you enter into a scientific discussion. Instead, a more realistic way to view science is as an ongoing and never-ending series of questions.

BioTIPS Will Help You Improve Your Problem-Solving Skills

As you progress through this textbook, your learning will involve two general goals:

- You will gather foundational knowledge. In other words, you will be able to describe core concepts in biology. For example, you will be able to explain how photosynthesis works.
- You will develop problem-solving skills that will allow you to apply that foundational knowledge in different ways. For example, you will learn how to use statistics to determine if a hypothesis is consistent with experimental data.

The combination of foundational knowledge and problem-solving skills will enable you not only to understand biology but also to apply your knowledge in different situations. To help you develop these skills, Chapters 2 through 60 contain solved problems called **BioTIPS**, which stands for **T**opic, **I**nformation, and **P**roblem-Solving **S**trategy. These solved problems follow a consistent pattern.

BIO TIPS

THE QUESTION *All of the* **BioTIPS** *begin with a question. As an example, let's consider the following question:*

The following base sequence is found within a messenger RNA molecule:

AUG GGC CUU AGC

This segment carries the information to make a region of a polypeptide with the amino acid sequence methionine-glycine-leucine-serine. What would be the consequences if a mutation in the gene that encodes this mRNA changed the second cytosine (C) in the base sequence to an adenine (A)?

TOPIC ***What topic in biology does this question address?*** The topic is gene expression. More specifically, the question is about the relationship between a base sequence and the genetic code.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** In the question, you are given the base sequence of a short segment of an mRNA and told that one of the bases has been changed. From your understanding of the topic, you may remember that a polypeptide sequence is determined by reading the mRNA (transcribed from a gene) in groups of three bases called codons.

PROBLEM-SOLVING STRATEGY ***Compare and contrast. Predict the outcome.*** One strategy to begin to solve this problem is to compare the mRNA sequence before and after the mutation:

Original: AUG GGC CUU AGC
Mutant: AUG GGC AUU AGC
↑

ANSWER *The mutation has altered the sequence of bases in the mRNA, changing the third codon from CUU to AUU (see the arrow). Because codons specify amino acids, this may change the third amino acid to something else. Note: If you look ahead to Chapter 12 (see Table 12.1), you will see that CUU specifies leucine, whereas AUU specifies isoleucine. Therefore, you can predict that the mutation will change the third amino acid from leucine to isoleucine.*

Chapters 2 through 60 will contain one or more **BioTIPS**. Though many different problem-solving strategies exist, **BioTIPS** will focus on 11 strategies that will help you solve problems. You will see these strategies over and over again as you progress through this textbook:

1. ***Make a drawing***. Biology problems are often difficult to solve in your head. Making a drawing may make a big difference in your ability to see the solution.
2. ***Compare and contrast***. Making a direct comparison between two biological structures or processes may help you understand how they are similar and how they are different.
3. ***Relate structure and function***. A recurring theme in biology is that structure determines function. This relationship holds true at many levels of biology, including the molecular, microscopic, and macroscopic levels. For some questions, you will need to understand how certain structural features are related to their biological functions.
4. ***Sort out the steps in a complicated process***. At first, some questions may be difficult to understand because they involve mechanisms that occur in a series of several steps. Sometimes, if you sort out the steps, you will be able to identify the key step that you need to understand to solve the problem.
5. ***Propose a hypothesis***. A hypothesis is an attempt to explain an observation or data. Hypotheses may be made in many forms including statements, models, equations, and diagrams.
6. ***Design an experiment***. Experimental design lies at the heart of science. In many cases, an experiment begins with some type of starting material(s), such as strains of organisms or purified molecules, and then the starting materials are subjected to a series of steps. The Feature Investigations throughout the textbook will also help you refine the skill of designing experiments.
7. ***Predict the outcome***. Biologists may want to predict the outcome of an experiment.
8. ***Interpret data***. Experimentation involves the analysis of data. Such an analysis often involves the use of statistics to determine if the experimental and control data show significant differences. The interpretation of data allows scientists to propose models that describe what the data may mean.
9. ***Use statistics***. A variety of different statistical methods are used to analyze data and make conclusions about what they mean.
10. ***Make a calculation***. Biology is a quantitative science. Researchers have devised mathematical relationships to understand and predict biological phenomena. Becoming familiar with these mathematical relationships will help you to better understand biological concepts and to make predictions.
11. ***Search the literature.*** The goal here is to be able to read and explain a scientific article, and extract useful information.

For most problems in this textbook, one or more of these strategies may help you arrive at the correct solution. **BioTIPS** will provide you with practice at applying these problem-solving strategies.

Summary of Key Concepts

- Biology is the study of life. Discoveries in biology help us understand how life exists, and they also have many practical applications, such as the development of drugs to treat human diseases (Figures 1.1, 1.2, 1.3).

1.1 Principles of Biology and the Levels of Biological Organization

- Twelve principles of biology are the following: (1) Cells are the simplest unit of life; (2) living organisms use energy; (3) living organisms interact with their environment; (4) living organisms maintain homeostasis; (5) living organisms grow and develop; (6) the genetic material provides a blueprint for reproduction; (7) populations of organisms evolve from one generation to the next; (8) all species are connected by an evolutionary history; (9) structure determines function; (10) new properties of life emerge from complex interactions; (11) biology is an experimental science; and (12) biology influences our society (Figure 1.4).
- Living organisms can be viewed at different levels of biological organization: atoms, molecules and macromolecules, cells, tissues, organs, organisms, populations, communities, ecosystems, and the biosphere (Figure 1.5).

1.2 Unity and Diversity of Life

- Changes in species often occur as a result of modification of pre-existing structures (Figure 1.6).
- During vertical evolution, mutations in a lineage alter the characteristics of species from one generation to the next. Individuals with greater reproductive success are more likely to contribute to future generations, a process known as natural selection. Over the long run, this process alters species and may produce new species (Figure 1.7).
- Horizontal gene transfer is the transfer of genetic material from one organism to another organism that is not its offspring. Along with vertical evolution, it is an important process in biological evolution, producing a web of life (Figures 1.8, 1.9).
- Taxonomy is the grouping of species according to their evolutionary relatedness to other species. Going from broad to narrow groups, each species is placed into a domain, supergroup, kingdom, phylum, class, order, family, and genus (Figures 1.10, 1.11).
- The genome is the genetic composition of a species. It provides a blueprint for the traits of an organism, is transmitted from parents to offspring, and acts as an instrument for evolutionary change. The proteome is the collection of proteins that a cell or organism makes (Figure 1.12).
- An analysis of genomes and proteomes helps us to understand how information at the molecular level relates to the characteristics of individuals and how they survive in their native environments (Figure 1.13).

1.3 Biology as a Scientific Discipline

- Biological science is the observation, identification, experimental investigation, and theoretical explanation of natural phenomena.
- Biologists study life at different levels, ranging from ecosystems to the molecular components in cells (Figure 1.14).

- A hypothesis is a proposal to explain a natural phenomenon. A useful hypothesis makes a testable prediction. A biological theory is a broad explanation that is substantiated by a large body of evidence.
- Discovery-based science is an approach in which researchers conduct experiments and analyze data without a preconceived hypothesis.
- The scientific method, also called hypothesis testing, is a series of steps to formulate and test the validity of a hypothesis. The experimentation often involves a comparison between control and experimental groups (Figure 1.15).
- The study of cystic fibrosis provides an example in which both discovery-based science and hypothesis testing led to key insights regarding the nature of the disease (Figure 1.16).
- Each chapter in this textbook has a "Feature Investigation," an actual study by current or past researchers that highlights the experimental approach and helps you appreciate how science has led to key discoveries in biology.
- Biology is a social discipline in which scientists often work in teams. To be published, a scientific paper is usually subjected to a peer-review process in which other scientists evaluate the paper and make suggestions regarding its quality. Advances in science often occur when scientists gather and discuss their data (Figure 1.17).

Assess and Discuss

Test Yourself

1. A bird maintains a relatively stable internal body temperature on a cold day. This is an example of
   a. adaptation.
   b. evolution.
   c. metabolism.
   d. homeostasis.
   e. development.
2. Populations of organisms change over the course of many generations. Many of these changes result in increased survival and reproduction. This phenomenon is
   a. evolution.
   b. homeostasis.
   c. development.
   d. genetics.
   e. metabolism.
3. A biologist is studying the living organisms in a valley in western Colorado. She is studying
   a. an ecosystem.
   b. a community.
   c. the biosphere.
   d. a viable land mass.
   e. a population.
4. Which of the following is an example of horizontal gene transfer?
   a. the transmission of an eye color gene from father to daughter
   b. the transmission of a mutant gene causing cystic fibrosis from father to daughter
   c. the transmission of a gene conferring pathogenicity (the ability to cause disease) from one bacterial species to another
   d. the transmission of a gene conferring antibiotic resistance from a mother cell to its two daughter cells
   e. all of the above
5. The scientific name for humans is *Homo sapiens*. The name *Homo* is the _____ to which humans are classified.
   a. kingdom
   b. phylum
   c. order
   d. genus
   e. species
6. The complete genetic makeup of an organism is called its
   a. genus.
   b. genome.
   c. proteome.
   d. genotype.
   e. phenotype.
7. After observing certain desert plants in their native environment, a researcher proposes that they drop their leaves to conserve water. This is an example of
   a. a theory.
   b. a law.
   c. a prediction.
   d. a hypothesis.
   e. an assay.
8. In science, a theory should
   a. be equated with knowledge.
   b. be supported by a substantial body of evidence.
   c. provide the ability to make many correct predictions.
   d. do all of the above.
   e. b and c only
9. Conducting research without a preconceived hypothesis is called
   a. discovery-based science.
   b. the scientific method.
   c. hypothesis testing.
   d. a control experiment.
   e. none of the above.
10. What is the purpose of using a control group in scientific experiments?
    a. A control group allows the researcher to practice the experiment first before actually conducting it.
    b. A researcher can compare the results in the experimental group and control group to determine if a single variable is causing a particular outcome in the experimental group.
    c. A control group provides the framework for the entire experiment so the researcher can recall the procedures that should be conducted.
    d. A control group allows the researcher to conduct other experimental changes without disturbing the original experiment.
    e. All of the above are correct.

Conceptual Questions

1. Of the first eight principles of biology described in Figure 1.4, which apply to individuals and which apply to populations?
2. Explain how it is possible for evolution to result in unity among different species yet also produce amazing diversity.
3.  In your own words, describe the twelve principles of biology that are detailed at the beginning of this chapter.

Collaborative Questions

1. Discuss whether or not you think that theories in biology are true. Outside of biology, how do you decide if something is true?
2. In certain animals, such as alligators, sex is determined by temperature. When alligator eggs are exposed to low temperatures, most alligator embryos develop into females. Discuss how this phenomenon is related to genomes and proteomes.

UNIT I

CHEMISTRY

Living organisms are composed of chemicals, which are altered via chemical reactions. These reactions occur between atoms and molecules and may require, or in some cases release, energy. Chemical reactions and interactions between molecules play a role in virtually all aspects of a cell's activities. In order to understand how living organisms function, grow, develop, behave, and interact with their environments, therefore, we first need to understand some basic principles of atomic and molecular structure and the forces that allow them to interact with each other. We begin this unit with an overview of **inorganic chemistry**—that is, the nature of atoms and molecules, with the exception of those that contain rings or chains of carbon. Such carbon-containing molecules form the basis of **organic chemistry** and are covered in Chapter 3.

The following biology principles will be emphasized in this unit:

- ***Living organisms use energy:*** *We will see how the chemical energy stored in the bonds of molecules such as sugars and fats can be released and used by living organisms to perform numerous functions that support life, including growth, digestion, and locomotion.*
- ***Structure determines function:*** *As described in Chapter 3, the three-dimensional structure of molecules is critical in enabling them to interact specifically with each other.*
- ***The genetic material provides a blueprint for reproduction, and all species (past and present) are related by an evolutionary history:*** *Nucleic acids, the basis of inherited genetic material, are first introduced in Chapter 3.*
- ***New properties emerge from complex interactions:*** *You will learn in this unit how simple molecules are connected together to create a more complex molecule with new biological properties. The newly created molecule has properties that are different from those of its component atoms.*
- ***Biology affects our society:*** *In Chapter 2, we will see how an understanding of chemistry has transformed the ability of physicians to diagnose disease in humans. One example of an application of chemistry to medicine is the PET scan.*

Summary of Key Concepts
Assess and Discuss

The Chemical Basis of Life I: Atoms, Molecules, and Water

2

Crystals of sodium chloride (NaCl), a compound composed of two elements.

Biology—the study of life—is founded on the principles of chemistry and physics. All living organisms are a collection of atoms and molecules bound together and interacting with each other through the forces of nature. Throughout this textbook, we will see how chemistry can be applied to living organisms as we discuss the components of cells, the functions of proteins, the flow of nutrients in plants and animals, and the evolution of new genes. This chapter lays the groundwork for understanding these and other concepts. We begin with an overview of the nature of atoms and molecules, focusing on the structure of the atom and how it was discovered. We next explore the various ways that atoms combine with other atoms to create molecules, looking at the different types of chemical bonds between atoms, how these bonds form, and how they determine the structures of molecules. We end with an examination of the water molecule and the properties that make it a crucial component of living organisms and their environment.

2.1 Atoms

Learning Outcomes:

1. Describe the general structure of atoms.
2. **SciSKILLS »** Interpret the results of an experiment indicating that most of an atom is empty space.
3. Define orbital and electron shell.
4. Relate atomic structure to the periodic table of the elements.
5. **SciSKILLS »** Quantify atomic mass using units such as daltons and moles.
6. Explain how a single element may exist in two or more forms, called isotopes, and how certain isotopes have importance in human medicine.
7. List the elements that make up most of the mass of all living organisms.

All life-forms are composed of **matter**, which is defined as anything that contains mass and occupies space. In living organisms, matter may exist in any of three states: solid, liquid, or gas. All matter is composed of **atoms**, which are the smallest functional units of matter that form all chemical substances and ultimately all organisms; they cannot be further broken down into other substances by ordinary chemical or physical means. Atoms, in turn, are composed of different types of smaller, subatomic particles. Chemists study the properties of atoms and **molecules**, which are two or more atoms bonded together. A major interest of the physicist, by contrast, is to uncover the properties of subatomic particles. Chemistry and physics merge when one attempts to understand the mechanisms by which atoms and molecules interact. When atoms and molecules are studied in the context of a living organism, the science of biochemistry emerges. In this section, we explore the physical properties of atoms so we can understand how atoms combine to form molecules of biological importance.

Atoms Are Composed of Subatomic Particles

The chemicals within living organisms are composed of many different types of atoms. The simplest atom, hydrogen, is approximately 0.1 nanometer (nm) in diameter, roughly one-millionth the diameter

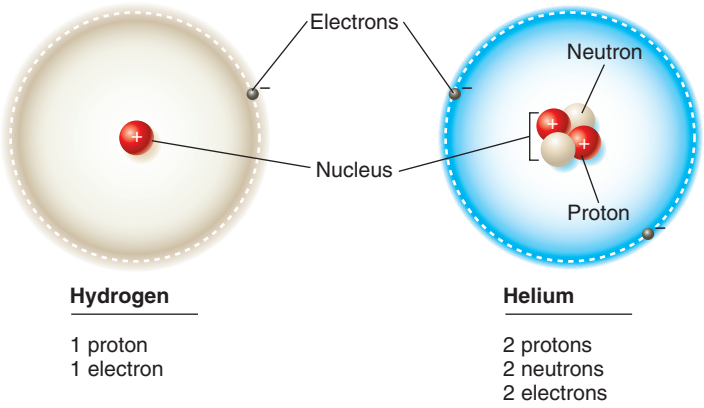

Figure 2.1 Diagrams of two simple atoms. These are models of the two simplest atoms, hydrogen and helium. The nucleus consists of protons and neutrons, and electrons are found outside the nucleus. Note: In all figures of atoms, the sizes and distances are not to scale.

of a human hair. Each specific type of atom—nitrogen, hydrogen, oxygen, and so on—is called an **element** (or chemical element), which is defined as a pure substance made up of only one kind of atom.

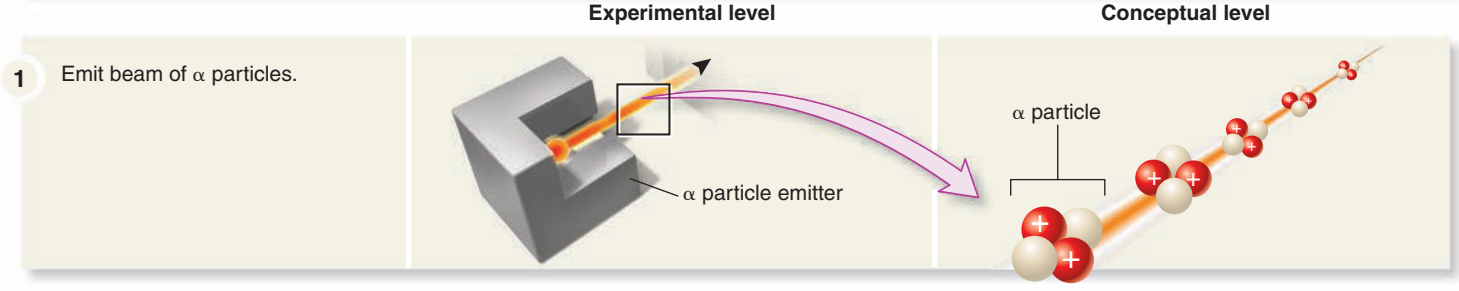
Three subatomic particles—**protons** (p^+), **neutrons** (n^0), and **electrons** (e^-)—are found within atoms (**Figure 2.1**). The protons and neutrons are confined to a very small volume at the center of an atom, the **atomic nucleus**, whereas the electrons are found in regions at various distances from the nucleus. In most atoms, the numbers of protons and electrons are identical, but the number of neutrons may vary. Each of the subatomic particles has a different electric charge. Protons have one unit of positive charge, electrons have one unit of negative charge, and neutrons are electrically neutral. Like charges repel each other, and opposite charges attract each other. The positive charges in the nucleus attract the negatively charged electrons.

Because the protons are located in the atomic nucleus, the nucleus has a net positive charge equal to the number of protons it contains. The entire atom has no net electric charge, however, because the number of negatively charged electrons around the nucleus is equal to the number of positively charged protons in the nucleus.

This basic concept of the structure of the atom was not established until a landmark experiment conducted by Ernest Rutherford during the years 1909–1911, as described next.

Feature Investigation | Rutherford Determined the Modern Model of the Atom

Nobel laureate Ernest Rutherford was born in 1871 in New Zealand, but he did his greatest work at McGill University in Montreal, Canada, and later at the University of Manchester in England. At that time, scientists knew that atoms contained charged particles but had no idea how those particles were distributed. Neutrons had not yet been discovered, and many scientists, including Rutherford, hypothesized that the positive charge and the mass of an atom were evenly dispersed throughout the atom.



In a now-classic experiment, Rutherford aimed a fine beam of positively charged α (alpha) particles at an extremely thin sheet of gold foil only 400 atoms thick (**Figure 2.2**). Alpha particles are the two protons and two neutrons that comprise the nuclei of helium atoms; you can think of them as helium atoms without their electrons (see Figure 2.1). Surrounding the gold foil were zinc sulfide screens that registered any α particles passing through or bouncing off the foil, much like film in a camera detects light. Rutherford hypothesized that if the positive charges of the gold atoms were uniformly distributed, many of the positively charged α particles would be slightly deflected, because one of the most important features of electric charge is that like charges repel each other. Due to their much smaller mass, he did not expect electrons in the gold atoms to have any effect on the ability of an α particle to move through the metal foil.

Surprisingly, Rutherford discovered that more than 98% of the α particles passed right through as if the foil was not there and only a

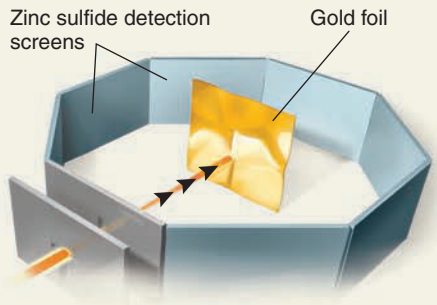


Figure 2.2 Rutherford's gold foil experiment, demonstrating that most of the volume of an atom is empty space.

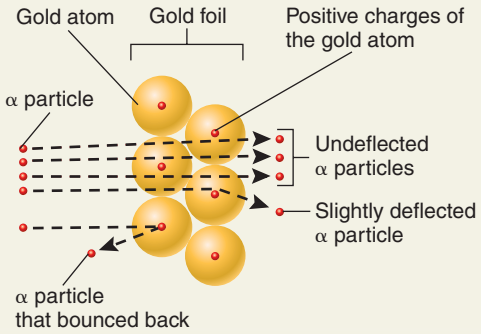
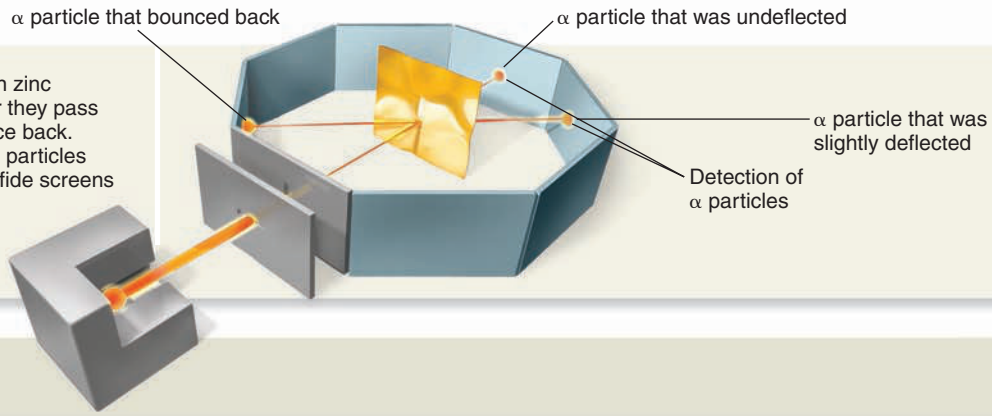


HYPOTHESIS Atoms in gold foil are composed of diffuse, evenly distributed positive charges that should usually cause α particles to be slightly deflected as they pass through.

KEY MATERIALS Thin sheet of gold foil, α particle emitter, zinc sulfide detection screen.



2 Pass beam through gold foil.

3 Detect α particles on zinc sulfide screens after they pass through foil or bounce back. Record number of α particles detected on zinc sulfide screens and their locations.

4 **THE DATA**

% of α particles detected on zinc sulfide screens	Location
98%	Undeflected
<2%	Slightly deflected
0.01%	Bounced back

5 **CONCLUSION** The hypothesis is rejected. Most of the volume of an atom is empty space, with the positive charges concentrated in a small volume.

6 **SOURCE** Rutherford, E. 1911. The scattering of α and β particles by matter and the structure of the atom. *Philosophical Magazine* 21:669–688.

small percentage was slightly deflected; a few even bounced back at a sharp angle! To explain the 98% that passed right through, Rutherford concluded that most of the volume of an atom is empty space. To explain the few α particles that bounced back at a sharp angle, he postulated that most of the atom's positive charge was localized in a highly compact area at the center of the atom. The existence of this small, dense region of highly concentrated positive charge—which today we call the atomic nucleus—explains how some α particles could be so strongly deflected by the gold foil. The α particles would bounce back on the rare occasion when they directly collided with an atomic nucleus. Therefore, based on these results, Rutherford rejected his original hypothesis that atoms are composed of diffuse, evenly distributed positive charges.

From this experiment, without being able to actually visualize an atom, Rutherford proposed a model of an atom, with its small, positively charged nucleus surrounded at relatively great distances by negatively charged electrons. Today we know that more than 99.99% of an atom's volume is outside the nucleus. The nucleus accounts for only about 1/10,000 of an atom's diameter—most of an atom is empty space!

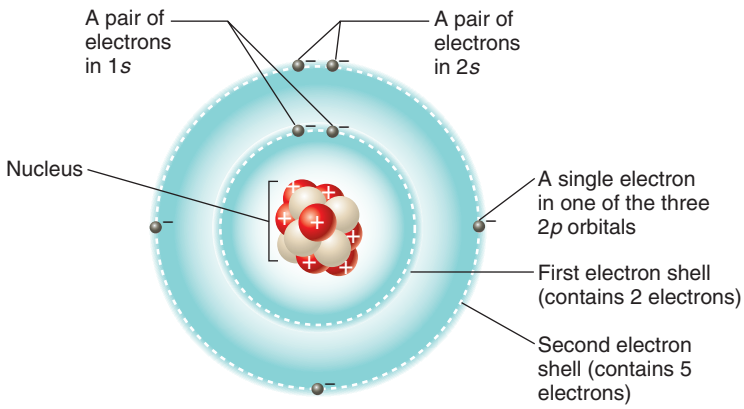
Experimental Questions

1. Before the experiment conducted by Ernest Rutherford, how did many scientists envision the structure of an atom?
2. What was the hypothesis tested by Rutherford?
3. **SciSKILLS** » The data showed that 98% of the α particles passed right through the gold foil. What is an interpretation of these results?

Electrons Occupy Orbitals Around an Atom's Nucleus

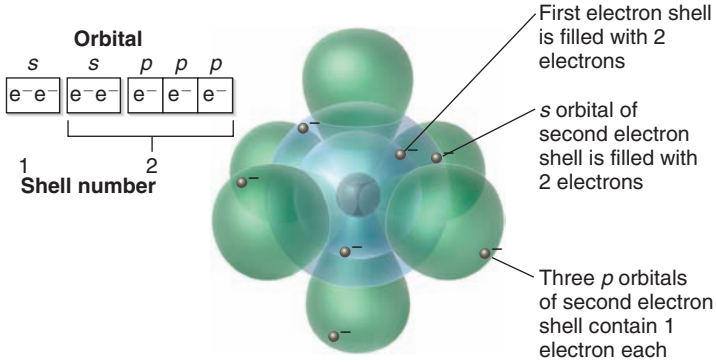
At one time, scientists visualized an atom as a mini–solar system, with the nucleus being the Sun and the electrons traveling in clearly defined orbits around it. Diagrams of the two simplest atoms—hydrogen and helium—which have the smallest numbers of protons, were shown in Figure 2.1. This model of the atom is now known to be an oversimplification, because as described shortly, electrons do not actually orbit the nucleus in a defined path like planets around the Sun. However, this depiction of an atom remains a convenient way to diagram atoms in two dimensions.

Electrons move at terrific speeds. Some estimates suggest that the electron in a typical hydrogen atom could circle the Earth in less than 20 seconds! Partly for this reason, we cannot precisely predict the exact location of a given electron. Instead, chemists view electrons as existing within orbitals. An **orbital** is the physical region of space where an electron may be found. A better model of an atom, therefore, is a central nucleus surrounded by cloudlike orbitals. Some orbitals are spherical, called *s* orbitals, whereas others assume a shape that is often described as similar to a propeller or dumbbell and are called *p* orbitals (**Figure 2.3**). An orbital can contain a maximum of two electrons. Consequently, any atom with more than two electrons must contain additional orbitals.



Orbitals are found within **electron shells**, or energy levels. **Energy** can be defined as the capacity to do work or cause a change. Electrons have kinetic energy, that is, the energy of moving matter. The electron shells are numbered, with shell number 1 being closest to the nucleus. Different electron shells may contain one or more orbitals, each orbital with up to two electrons. The innermost electron shell of all atoms has room for only two electrons, which spin in opposite directions within a spherical *s* orbital (1*s*). The second electron shell is composed of one spherical *s* orbital (2*s*) and three dumbbell-shaped *p* orbitals (2*p*). Therefore, the second shell can hold up to four pairs of electrons, or eight electrons altogether (see Figure 2.3).

Electrons vary in the amount of energy they have. The shell closest to the nucleus fills up with the lowest energy electrons first, and then each subsequent shell fills with higher and higher energy electrons, one shell at a time. Within a given shell, the energy of electrons can also vary among different orbitals. In the second shell, for example, the *s* orbital has lower energy, whereas the three *p* orbitals have slightly higher and roughly equal energies. In that case, two electrons fill the *s* orbital first. Any additional electrons fill the *p* orbitals one electron at a time.



Although electrons are found in orbitals of varying shapes, as shown in Figure 2.3, scientists often use more simplified diagrams when depicting the electron shells of atoms. **Figure 2.4a** presents an example of such a depiction of an atom of the element nitrogen. An atom of this element has seven protons and seven electrons. Two electrons fill the first shell, and five electrons are found in the outer shell.

Orbital name	1*s*	2*s*	2*p*
	Nucleus 		
Number of electrons per electron shell	2	2 per orbital; 8 total	
Orbital shape	Spherical	First orbital: spherical	Second to fourth orbital: dumbbell-shaped

Figure 2.3 Diagrams of individual electron orbitals. Electrons are found outside the nucleus in orbitals that may resemble spherical or dumbbell-shaped clouds. The orbital cloud represents a region in which the probability is high of locating a particular electron. For this illustration, only two shells are shown; the heaviest elements contain a total of seven shells.

(a) Simplified depiction of a nitrogen atom

(b) Nitrogen atom showing electrons in orbitals

Figure 2.4 Diagrams showing the multiple electron shells and orbitals of a nitrogen atom. The nitrogen atom is shown **(a)** simplified and **(b)** with all of its orbitals and shells. An atom's shells fill up one by one. In shells containing more than one orbital, the orbital with lowest energy fills first. Subsequent orbitals gain one electron at a time, shown schematically in boxes, where e^- represents an electron. Heavier elements contain additional shells and orbitals.

Concept Check: Explain the difference between an electron shell and an orbital.

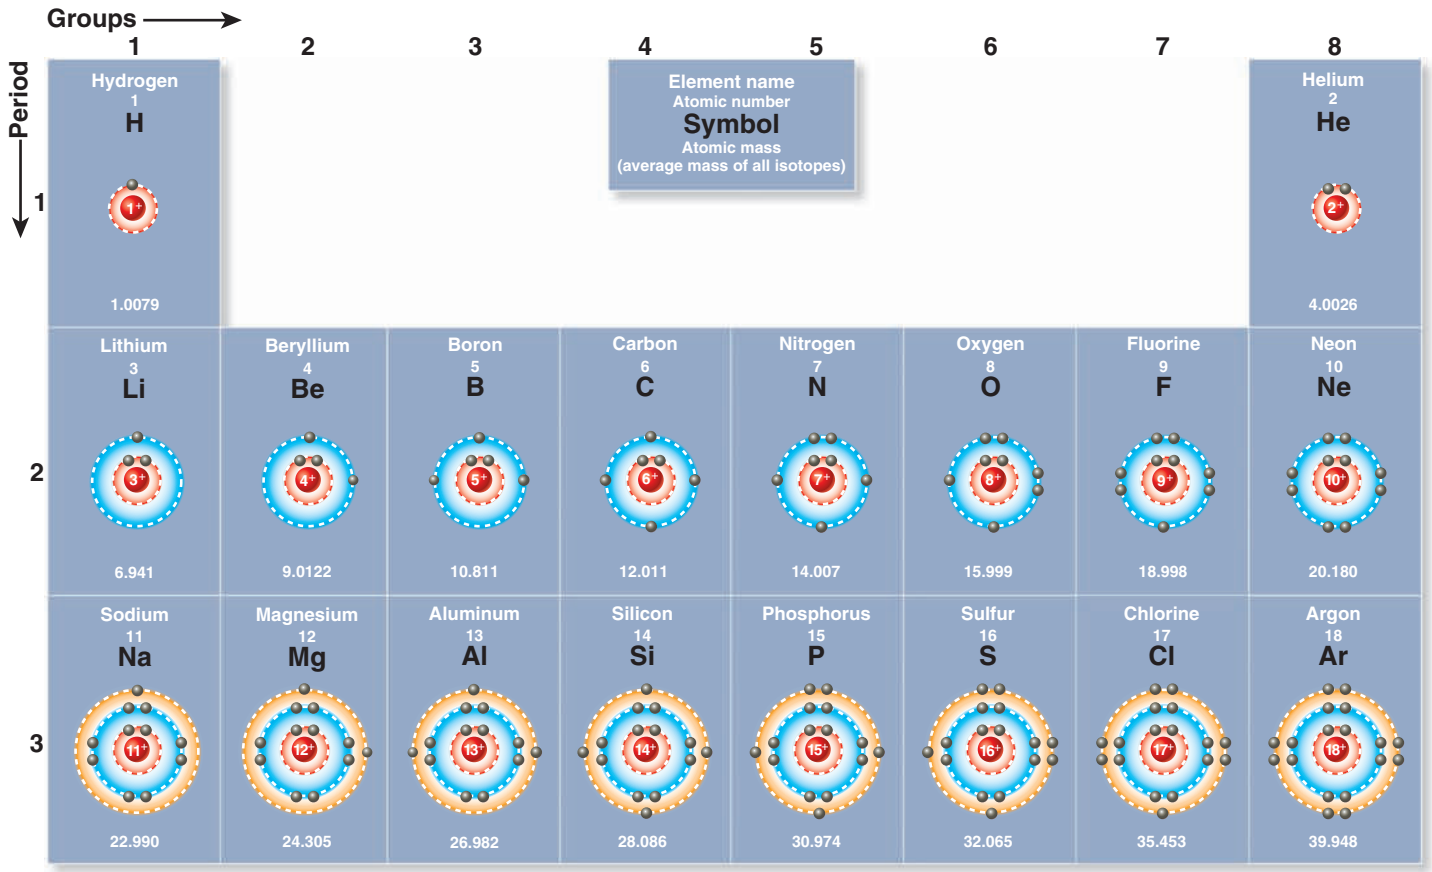


Figure 2.5 The first three rows of the periodic table of the elements. The elements are shown in models that depict the electron shells in different colors and the total number of electrons in each shell. The occupancy of orbitals is that of the elements in their pure state. The red sphere represents the nucleus of the atom, and the numerical value with the $^+$ designation represents the number of protons and, therefore, the positive charge of the nucleus. Elements are arranged in groups (columns) and periods (rows). For the complete periodic table, see Appendix A.

Two of these fill the 2*s* orbital and are shown as a pair of electrons in the second shell. The other three electrons in the second shell are found singly in each of the three *p* orbitals. The diagram in Figure 2.4a makes it easy to see whether electrons are paired within the same orbital and whether the outer shell is full. **Figure 2.4b** shows a more accurate depiction of a nitrogen atom, showing how the electrons occupy orbitals with different shapes.

Most atoms have outer shells that are not completely filled with electrons. Nitrogen, as we just saw, has a first shell filled with two electrons and a second shell with five electrons (see Figure 2.4a). Because the second shell can actually hold eight electrons, the outer shell of a nitrogen atom is not full. As discussed later in this chapter, atoms that have unfilled electron shells tend to share, release, or obtain electrons to fill their outer shell. Those electrons in the outermost shell are called the **valence electrons**. As you will learn shortly, such electrons allow atoms to form chemical bonds with each other, in which two or more atoms become joined together to create a new substance.

Each Element Has a Unique Number of Protons

Each chemical element has a specific and unique number of protons in its nucleus that distinguishes it from another element. The number of protons in an atom is its **atomic number**. For example, hydrogen, the simplest atom, has an atomic number of 1, corresponding to its single proton. Magnesium has an atomic number of 12, corresponding to its 12 protons. With the exception of ions, which are described later, the number of protons and electrons in a given atom are identical. Therefore, the atomic number is also equal to the number of electrons in the atom, resulting in a net electric charge of zero.

Figure 2.5 shows the first three rows of the periodic table of the elements, which arranges the known elements according to their atomic number and electron shells (see Appendix A for the complete periodic table). A one- or two-letter symbol is used as an abbreviation for each element. The rows (known as periods) indicate the number of electron shells. For example, hydrogen (H) has one shell, lithium (Li) has two shells, and sodium (Na) has three shells. The columns (called groups) indicate the numbers of electrons in the outer shell. As you move along the columns from left to right, the outer shell of lithium (Li) has one electron, beryllium (Be) has two, boron (B) has three, and so forth. This organization of the periodic table tends to arrange elements based on similar chemical properties. The similarities of elements within a group occur because they have the same number of valence electrons, and therefore, they have similar chemical bonding properties.

Atoms Have a Small but Measurable Mass

Atoms are extremely small and thus have very little mass. A single hydrogen atom, for example, has a mass of about 1.67×10^{-24} g (grams). Protons and neutrons are nearly equal in mass, and each has

Table 2.1 Characteristics of Major Subatomic Particles

Particle	Location	Charge	Mass relative to electron
Proton	Nucleus	+1	1,836
Neutron	Nucleus	0	1,839
Electron	Around the nucleus	–1	1

more than 1,800 times the mass of an electron (**Table 2.1**). Because of their tiny size relative to protons and neutrons, the mass of the electrons in an atom is ignored in calculations of atomic mass.

The **atomic mass** scale indicates an atom's mass relative to the mass of other atoms. By convention, the most common type of carbon atom, which has six protons and six neutrons, is assigned an atomic mass of exactly 12. On this scale, a hydrogen atom has an atomic mass of 1, indicating that it has 1/12 the mass of a carbon atom. A magnesium atom, with an atomic mass of 24, has twice the mass of a carbon atom.

The term mass is sometimes confused with weight, but these two terms refer to different features of matter. Weight is derived from the gravitational pull on a given mass. For example, a man who weighs 154 pounds on Earth would weigh only 25 pounds if he were standing on the Moon, and he would weigh 21 trillion pounds if he could stand on a neutron star. However, his mass is the same in all locations because he has the same amount of matter.

Atomic mass is measured in units called daltons, after the English chemist John Dalton, who postulated that matter is composed of tiny indivisible units he called atoms and laid the groundwork for atomic theory. One **dalton (Da)**, also known as an atomic mass unit (amu), equals 1/12 the mass of a carbon atom, or about the mass of a proton or a hydrogen atom. Therefore, the most common type of carbon atom has an atomic mass of 12 Da.

Because atoms such as hydrogen have a small mass, but atoms such as carbon have a larger mass, 1 g of hydrogen contains more atoms than 1 g of carbon. A **mole** (mol) of any substance contains the same number of particles as there are atoms in exactly 12 g of carbon. Twelve grams of carbon equals 1 mol of carbon, and 1 g of hydrogen equals 1 mol of hydrogen. As first described by Italian physicist Amedeo Avogadro, 1 mole of any element contains the same number of atoms—6.022×10^{23}. For example, 12 g of carbon contain 6.022×10^{23} atoms, and 1 g of hydrogen, whose atoms have 1/12 the mass of a carbon atom, also contains 6.022×10^{23} atoms. This number is known as Avogadro's number. To visualize the enormity of this number, imagine that people could move through a turnstile at a rate of 1 million people per second. Even at that incredible rate, it would require almost 20 billion years for 6.022×10^{23} people to move through that turnstile!

Isotopes Vary in Their Number of Neutrons

Many elements can exist in multiple forms, called **isotopes**, that differ in the number of neutrons they contain. For example, the most abundant form of the carbon atom, ^{12}C, contains six protons and six neutrons, and thus has an atomic number of 6 and an atomic mass of 12 Da. The superscript placed to the left of ^{12}C is the sum of the protons and neutrons. The rare carbon isotope ^{14}C, however, contains six protons and eight neutrons. Although ^{14}C has an atomic number of 6, it has an atomic mass of 14 Da. Nearly 99% of the carbon in living organisms is ^{12}C. Consequently, the average atomic mass of carbon is slightly greater than 12 Da because of the existence of a small amount of heavier isotopes. This explains why the atomic masses given in the periodic table do not add up exactly to the predicted masses based on the atomic number and the number of neutrons of a given atom (for example, see carbon in Figure 2.5).

Isotopes of an atom have similar chemical properties but may have very different physical properties. For example, many isotopes found in nature are inherently unstable; the length of time they persist is measured in half-lives—the time it takes for 50% of the isotope to decay. Such unstable isotopes are called **radioisotopes**. They emit radiation, which converts them to a stable form. At the very low amounts found in nature, radioisotopes usually pose no serious threat to life, but exposure of living organisms to high amounts of radioactivity can result in the disruption of cellular function, cancer, and even death.

Modern medical treatment and diagnosis make use of the special properties of radioactive compounds in many ways. For example, beams of high-energy radiation can be directed onto cancerous parts of the body to kill cancer cells. In another example, one or more atoms in a metabolically important molecule, such as the sugar glucose, can be chemically replaced with a radioactive isotope of fluorine (^{18}F) to create a molecule called fluorodeoxyglucose (FDG). ^{18}F has a half-life of about 110 minutes. When a solution containing such a modified radioactive glucose is injected into a person's bloodstream, the organs of the body take it up from the blood just as they would ordinary glucose. Special imaging techniques, such as the positron-emission tomography (PET) scan shown in **Figure 2.6**, can detect the amount of the radioactive FDG in the body's organs. In this way, it is possible to visualize whether organs such as the lungs or brain are functioning normally, or at an increased or decreased rate. For example, cancer cells tend to take up much more glucose than normal cells do. Therefore, PET scans can also reveal the presence of cancer—a disease characterized by uncontrolled cell growth. The scan of the individual shown in Figure 2.6, for example, identified numerous regions of high activity, suggestive of cancer.

The Mass of All Living Organisms Is Largely Composed of Four Elements

Just four elements—oxygen, carbon, hydrogen, and nitrogen—account for the vast majority of atoms in living organisms (**Table 2.2**). These elements typically make up about 95% of the mass of living organisms. Much of the oxygen and hydrogen occur in the form of water, which accounts for approximately 60% of the mass of most animals and up to 95% or more in some plants. Carbon is a major building block of all living matter, and nitrogen is a vital element in all proteins. Note in Table 2.2 that although hydrogen accounts for about 63% of the atoms in the body, it makes up only a small percentage of the mass of the human body. That is because the atomic mass of hydrogen is so much smaller than that of heavier elements such as oxygen.

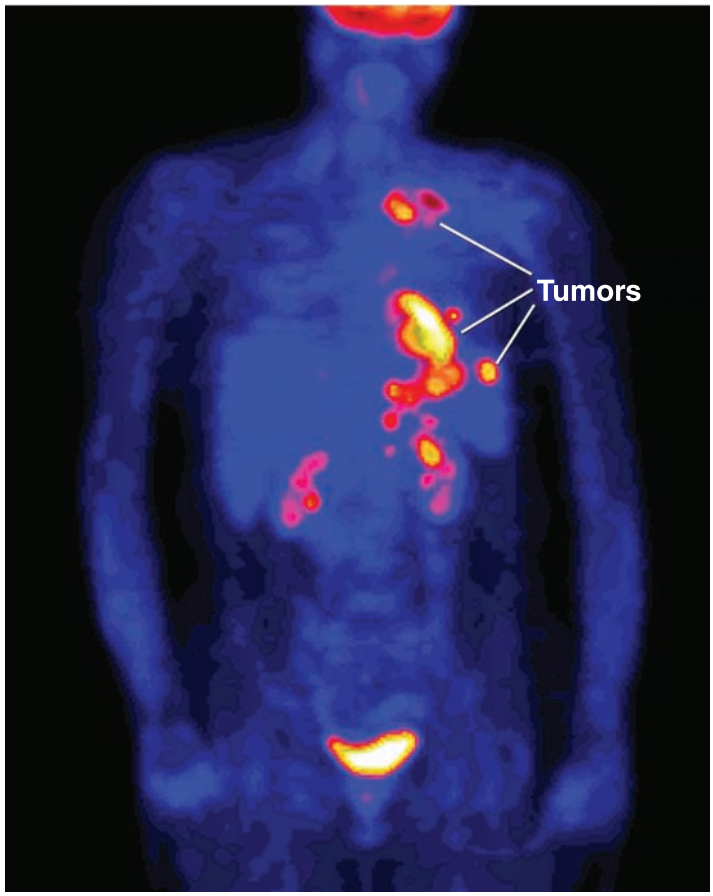

Figure 2.6 Diagnostic image of the human body using radioisotopes. A procedure called positron-emission tomography (PET) scanning highlights regions of the body that are actively using glucose, the body's major energy source. Radioactivity in this image shows up as a color. The bright patches are regions of extremely intense activity, some of which were later determined to be cancer in this patient. Note: In this PET scan, the brain, kidneys, and bladder are not cancerous. The brain naturally uses a high amount of glucose. The kidneys filter the blood, and the bladder accumulates urine, which contains some glucose.

BIOLOGY PRINCIPLE Biology affects our society. Applying an understanding of chemistry to biology has transformed the ability of physicians to diagnose diseases in humans. In the United States alone, between 1 and 2 million PET scans such as this one are performed each year, helping to localize the sites and extent of diseased structures, greatly facilitating subsequent drug or surgical treatments.

Other important elements in living organisms include the mineral elements. Calcium and phosphorus, for example, are important constituents of the skeletons and shells of animals. Minerals such as potassium and sodium are key regulators of water movement and electric currents that occur across the surfaces of many cells.

In addition, all living organisms require **trace elements**. These elements are present in extremely small quantities but still are essential for normal growth and function. For example, iron plays an important role in how vertebrates transport oxygen in their blood, and copper serves a similar role in some invertebrates.

Table 2.2 Chemical Elements Essential for Life in Many Organisms*

Element	Symbol	% Human body mass	% All atoms in human body
Most abundant in living organisms (approximately 95% of total mass)			
Oxygen	O	65	25.5
Carbon	C	18	9.5
Hydrogen	H	9	63.0
Nitrogen	N	3	1.4
Mineral elements (less than 1% of total mass)			
Calcium	Ca	Potassium	K
Chlorine	Cl	Sodium	Na
Magnesium	Mg	Sulfur	S
Phosphorus	P		
Trace elements (less than 0.01% of total mass)			
Boron	B	Manganese	Mn
Chromium	Ch	Molybdenum	Mo
Cobalt	Co	Selenium	Se
Copper	Cu	Silicon	Si
Fluorine	F	Tin	Sn
Iodine	I	Vanadium	V
Iron	Fe	Zinc	Zn

*Although these are the most common elements in living organisms, many other trace and mineral elements have reported functions. For example, aluminum is believed to be a cofactor for certain chemical reactions in animals, but it is generally toxic to plants.

2.2 Chemical Bonds and Molecules

Learning Outcomes:

1. Compare and contrast the types of atomic interactions that lead to the formation of molecules.
2. Explain the concept of electronegativity and how it contributes to the formation of polar and nonpolar covalent bonds.
3. Describe how a molecule's shape is important for its ability to interact with other molecules.
4. Relate the concepts of a chemical reaction and chemical equilibrium.

The linkage of atoms with other atoms serves as the basis for life and also gives life its great diversity. Two or more atoms bonded together make up a molecule. For example, two oxygen atoms can combine to form one oxygen molecule, represented as O_2. This representation is called a **molecular formula**. It consists of the chemical symbols for all of the atoms that are present (here, O for oxygen) and a subscript that tells you how many of those atoms are present in the molecule (in this case, two). The term **compound** refers to a molecule composed of two or more different elements. Examples include water (H_2O), with two hydrogen atoms and one oxygen atom, and the sugar glucose ($C_6H_{12}O_6$), which has 6 carbon atoms, 12 hydrogen atoms, and 6 oxygen atoms.

One of the most important features of compounds is their emergent properties. This means that the properties of a compound differ greatly from those of its elements. Let's consider sodium as an example. Pure sodium (Na) is a soft, silvery white metal that can be cut with a knife. When sodium forms a compound with chlorine (Cl), table salt (NaCl) results. NaCl is a white, relatively hard crystal (as seen in the chapter opening photo) that dissolves in water. Thus, the properties of a compound can be dramatically different from the properties of the elements that combined to form it.

The atoms in molecules are held together by chemical bonds. In this section, we will examine the different types of chemical bonds, how those bonds form, and how they determine the structures of molecules.

Covalent Bonds Are Formed When Atoms Share Electrons

Covalent bonds, in which atoms share a pair of electrons, can occur between atoms whose outer shells are not full. A fundamental principle of chemistry is the following:

Atoms tend to be most stable when their outer shells are filled with electrons.

Figure 2.7 shows this principle as it applies to the formation of hydrogen fluoride (HF), a molecule with many important industrial and medical applications such as petroleum refining, fluorocarbon formation, and pharmaceutical production. The outer shell of a hydrogen atom is full when it contains two electrons, though a hydrogen atom has only one electron. The outer shell of a fluorine atom is full when it contains eight electrons, though a fluorine atom has only seven electrons in its outer shell. When HF is made, the two atoms share a pair of electrons, which spend time in the outer shells of both nuclei. This allows both of the outer shells of those atoms to be full. Covalent bonds are strong chemical bonds, because the shared electrons behave as if they belong to each atom.

Chemists sometimes depict molecules with a **structural formula** in which each covalent bond is represented by a line indicating a pair of shared electrons. For example, HF is diagrammed as

H—F

A molecule of water (H_2O) can be diagrammed as

H—O—H

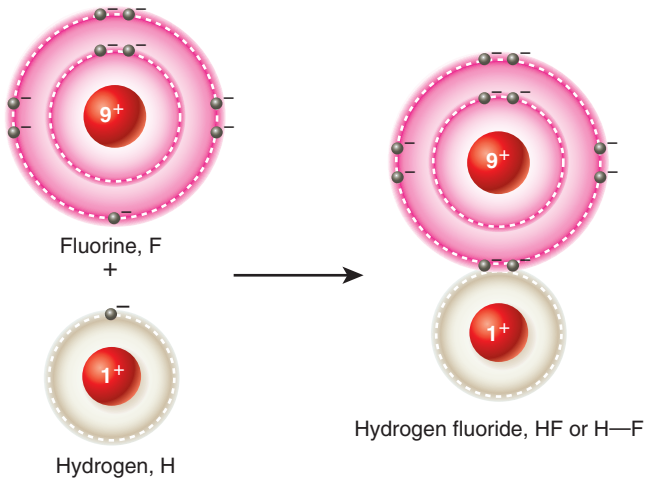

Figure 2.7 The formation of a covalent bond. In a covalent bond, electrons from the outer shell of two atoms are shared with each other in order to complete the outer shells of both atoms. This simplified illustration shows hydrogen forming a covalent bond with fluorine.

The structural formula of water indicates that the oxygen atom is covalently bonded to two hydrogen atoms.

Each atom forms a characteristic number of covalent bonds, which depends on the number of electrons required to fill the outer shell. The atoms of some elements important for life, notably carbon, form more than one covalent bond and become linked simultaneously to two or more other atoms. **Figure 2.8** shows the number of covalent bonds formed by several atoms commonly found in the molecules of living cells—hydrogen, oxygen, nitrogen, and carbon.

For many types of atoms, their outermost shell is full when they contain eight electrons, an octet. The **octet rule** states that many atoms are most stable when they have eight electrons in their outermost electron shell. This rule applies to most atoms found in living organisms, including oxygen, nitrogen, carbon, phosphorus, and sulfur. These atoms form a characteristic number of covalent bonds to make an octet in their outermost shell (see Figure 2.8). However, the octet rule does not always apply. For example, hydrogen has an outermost shell that can contain only two electrons, not eight.

Atom name	Hydrogen	Oxygen	Nitrogen	Carbon
	Nucleus, Electron, 1+	8+	7+	6+
Electron number needed to complete outer shell (typical number of covalent bonds)	1	2	3	4

Figure 2.8 The number of covalent bonds formed by common elements found in living organisms. These elements form different numbers of covalent bonds due to the electron configurations in their outer shells.

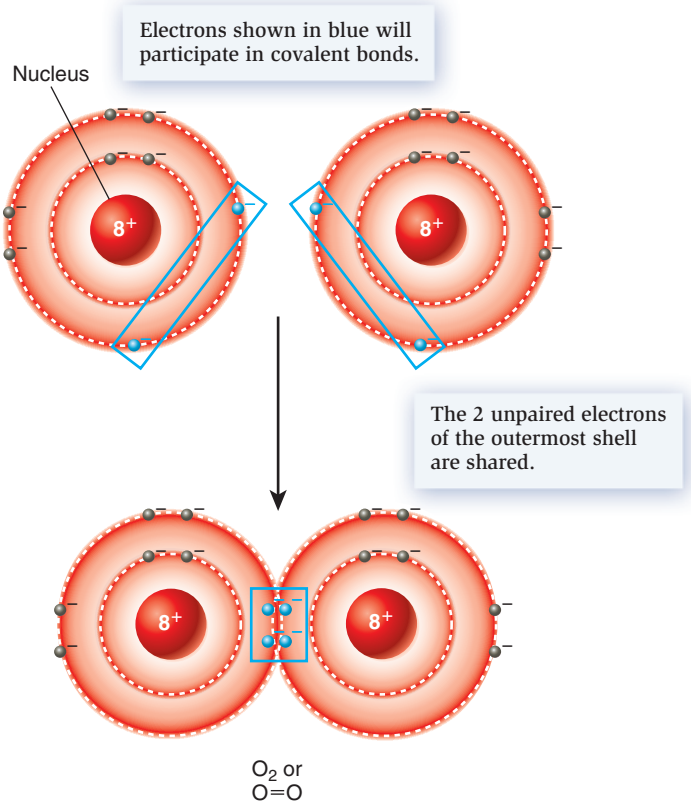

Figure 2.9 **A double bond between two oxygen atoms.**

Concept Check: *Explain how an oxygen molecule obeys the octet rule.*

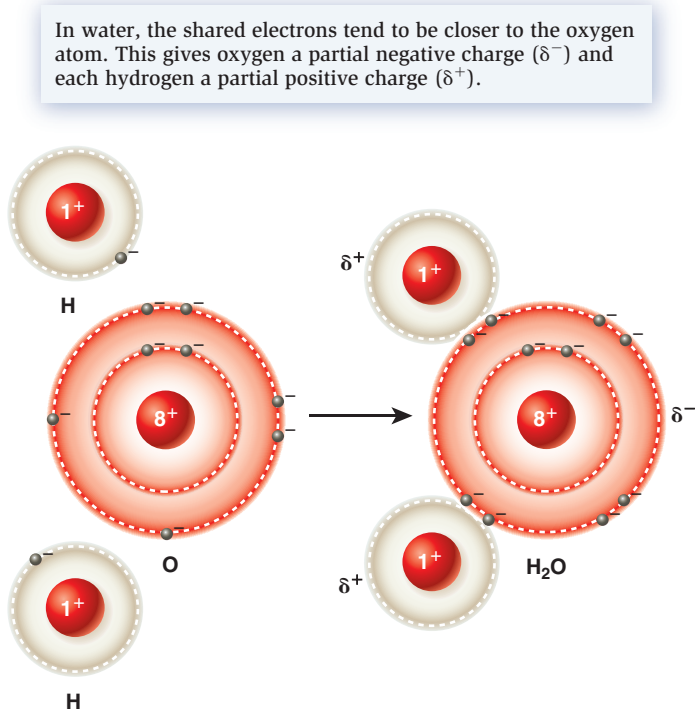

Figure 2.10 **Polar covalent bonds in water molecules.** In a water molecule, two hydrogen atoms share electrons with an oxygen atom. Because oxygen has a higher electronegativity, the shared electrons tend to be closer to oxygen. This gives oxygen a partial negative charge, designated δ^-, and each hydrogen a partial positive charge, designated δ^+.

In some molecules, a **double bond** occurs when atoms share two pairs of electrons (four electrons) rather than one pair. As shown in **Figure 2.9**, this is the case for an oxygen molecule (O_2), which can be diagrammed as

$$O{=}{=}O$$

Another common example occurs when two carbon atoms form bonds in compounds. They may share one pair of electrons (single bond) or two pairs (double bond), depending on how many other covalent bonds each carbon forms with other atoms. In rare cases, carbon can even form triple bonds, in which three pairs of electrons are shared between two atoms.

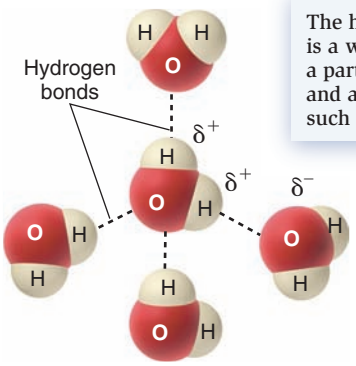
Some atoms attract shared electrons more readily than do other atoms. The **electronegativity** of an atom is a measure of its ability to attract electrons in a bond with another atom. When two atoms with different electronegativities form a covalent bond, the shared electrons are more likely to be closer to the nucleus of the atom of higher electronegativity than to the atom of lower electronegativity. Such bonds are called **polar covalent bonds**, because the distribution of electrons around the nuclei creates a polarity, or difference in electric charge, across the molecule. Water is a classic example of a molecule containing polar covalent bonds. Since oxygen is much more electronegative than hydrogen, the shared electrons tend to be pulled closer to the oxygen nucleus than to either of the hydrogens. This unequal sharing of electrons gives the molecule a region of partial negative charge (indicated by the Greek letter δ and a minus sign, δ^-) and two regions of partial positive charge (δ^+) (**Figure 2.10**).

Atoms with high electronegativity, such as oxygen and nitrogen, have a relatively strong attraction for electrons. These atoms form polar covalent bonds with hydrogen atoms, which have low electronegativity. Examples of polar covalent bonds include O—H and N—H. In contrast, bonds between atoms with similar electronegativities, for example, between two carbon atoms (C—C) or between carbon and hydrogen atoms (C—H), are called **nonpolar covalent bonds**. Polar molecules usually have one or more polar covalent bonds, whereas nonpolar molecules tend to have bonds that are mostly nonpolar covalent. A single molecule may have different regions with nonpolar bonds and polar bonds. As we will explore later, the physical characteristics of polar and nonpolar molecules, especially their solubility in water, are quite different.

Hydrogen Bonds Allow Interactions Between and Within Molecules

An important effect of certain polar covalent bonds is the ability of one molecule to loosely associate with another molecule through a weak interaction called a **hydrogen bond**. A hydrogen bond forms when a hydrogen atom from one polar molecule becomes electrically attracted to an electronegative atom, such as an oxygen or nitrogen

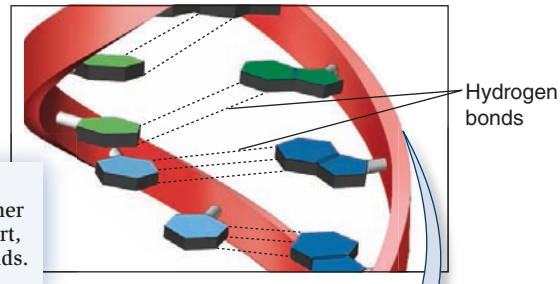
atom, in another polar molecule. Hydrogen bonds, like those between water molecules, are represented in diagrams by dashed or dotted lines to distinguish them from covalent bonds (**Figure 2.11a**). A single hydrogen bond is very weak. The strength of a hydrogen bond is only a small percentage of the strength of the polar covalent bonds linking the hydrogen and oxygen within a water molecule.



Hydrogen bonds can also occur within a single large molecule. Large molecules may have many hydrogen bonds within their structure. Collectively, many hydrogen bonds may add up to a strong force that helps maintain the three-dimensional structure of a molecule. This is particularly true in deoxyribonucleic acid (DNA)—the molecule that makes up the genetic material of living organisms. DNA exists as two long, twisting strands of many millions of atoms. The two strands are held together along their length, in part, by hydrogen bonds between different portions of the molecule (**Figure 2.11b**). Due to the large number of hydrogen bonds, it takes considerable energy to separate the strands of DNA.

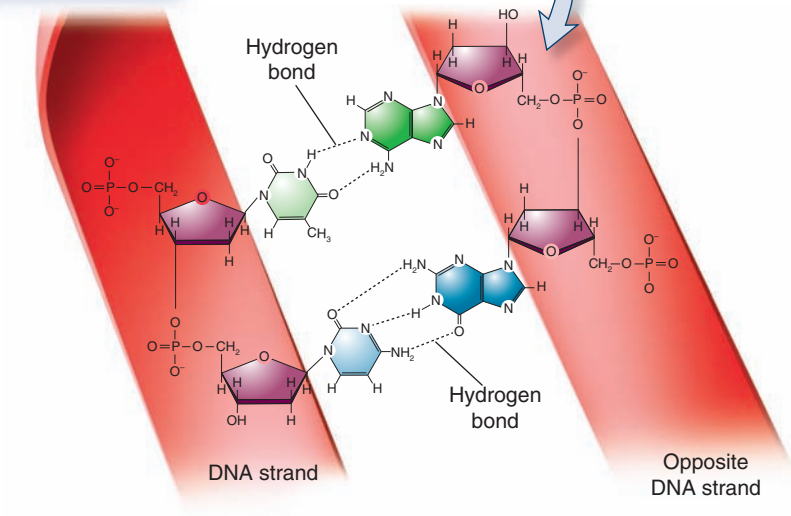
In contrast to the cumulative strength of many hydrogen bonds, the weakness of individual bonds is also important. When an interaction between two molecules involves relatively few hydrogen bonds, such an interaction tends to be weak and readily broken. The reversible nature of hydrogen bonds allows molecules to interact and then to become separated again. For example, small molecules may bind to proteins called enzymes via hydrogen bonds. **Enzymes** are molecules found in all cells that facilitate or catalyze many biologically important chemical reactions. The small molecules are later released after the enzymes have changed their structure.

In addition to hydrogen bonds, another type of weak molecular attraction is due to **van der Waals dispersion forces**. These van der Waals dispersion forces arise because electrons are located within orbitals in a random way, as described previously. At any moment, the electrons in the outer shells of the atoms in a nonpolar molecule may be evenly distributed or unevenly distributed. In the latter case, a fleeting electrical attraction may arise with other nearby molecules. As with hydrogen bonds, the collective strength of these temporary attractive forces between molecules can be quite strong.



Ionic Bonds Involve an Attraction Between Positive and Negative Ions

Atoms are electrically neutral because they contain equal numbers of negative electrons and positive protons. If an atom or molecule gains or loses one or more electrons, it acquires a net electric charge and becomes an **ion** (**Figure 2.12a**). For example, when a sodium atom (Na), which has 11 electrons, loses 1 electron, it becomes a sodium ion (Na^+) with a net positive charge. Ions that have a net positive



The hydrogen bond (H bond) is a weak attraction between a partially positive hydrogen and a partially negative atom such as oxygen.

(a) Hydrogen bonds between water molecules

A DNA molecule consists of 2 twisted strands held together along its entire length, in part, by millions of hydrogen bonds.

(b) Hydrogen bonds within a DNA molecule

Figure 2.11 Examples of hydrogen bonds. Hydrogen bonds are important because they allow for interactions between different molecules or interactions of atoms within a molecule. **(a)** This example depicts hydrogen bonds (shown as dashed lines) between water molecules. For simplicity, the partial charges are indicated on only one water molecule. In this diagram, the atoms are depicted as solid spheres, which represent the outer shell. This is called a space-filling model of an atom. **(b)** A DNA molecule is composed of two twisting strands connected to each other by hydrogen bonds (dashed lines). Although each individual bond is weak, the sum of all the hydrogen bonds in a large molecule like DNA imparts considerable stability to the molecule.

Concept Check: *In Chapter 11, you will learn that the two DNA strands must first separate into two single strands for DNA to be replicated. Do you think the process of strand separation requires energy, or do you think the strands can separate spontaneously?*

charge are called **cations**. A sodium ion still has 11 protons, but only 10 electrons. Ions such as Na^+ are depicted with a superscript that indicates the net charge of the ion. A chlorine atom (Cl), which has 17 electrons, can gain an electron and become a chloride ion (Cl^-) with a net negative charge—it still has 17 protons but now has 18 electrons. Ions with a net negative charge are called **anions**.

Table 2.3 lists the ionic forms of several elements. Hydrogen atoms and most mineral and trace elements readily form ions. The ions listed in this table are relatively stable because the outer electron shells of the ions are full. For example, a sodium atom has one electron in its third (outermost) shell. If it loses this electron to become Na^+, it no longer has a third shell, and the second shell, which is full, becomes its outermost shell (see Figure 2.12a).

Alternatively, a Cl atom has seven electrons in its outermost shell. If it gains an electron to become a chloride ion (Cl^-), its outer shell becomes full with eight electrons. Some atoms can gain or lose more than one electron. For instance, a calcium atom, which has 20 electrons, loses 2 electrons to become a calcium ion, depicted as Ca^{2+}.

An **ionic bond** occurs when a cation binds to an anion. Figure 2.12a shows an ionic bond between Na^+ and Cl^- to form NaCl, or common table salt. NaCl may form crystals in which the cations and anions form a regular array. **Figure 2.12b** shows a NaCl crystal, in which the sodium and chloride ions are held together by ionic bonds.

Table 2.3 Ionic Forms of Some Common Elements in Living Organisms

Atom	Chemical symbol	Ion	Ion symbol	Electrons gained or lost
Calcium	Ca	Calcium ion	Ca^{2+}	2 lost
Chlorine	Cl	Chloride ion	Cl^-	1 gained
Hydrogen	H	Hydrogen ion	H^+	1 lost
Magnesium	Mg	Magnesium ion	Mg^{2+}	2 lost
Potassium	K	Potassium ion	K^+	1 lost
Sodium	Na	Sodium ion	Na^+	1 lost

Molecules May Change Their Shapes

When atoms combine, they can form molecules with various three-dimensional shapes, depending on the arrangements and numbers of bonds between their atoms. As an example, let's consider the arrangements of covalent bonds in a few simple molecules, including water (**Figure 2.13**). These molecules form new orbitals that cause the atoms to have defined angles relative to each other. This gives groups of atoms very specific shapes, as shown in the three examples of Figure 2.13.

Molecules containing covalent bonds are not rigid, inflexible structures. Think of a single covalent bond, for example, as an axle around which the joined atoms can rotate. Within certain limits, the shape of a molecule can change without breaking its covalent bonds. As illustrated in **Figure 2.14a**, a molecule of six carbon atoms bonded together can assume a number of shapes as a result of rotations around various covalent bonds. The three-dimensional, flexible shape of molecules contributes to their biological properties. As shown in **Figure 2.14b**, the binding of one molecule to another may affect the shape of one of the molecules. A person can smell food, for instance, because odor molecules interact with special proteins called receptors

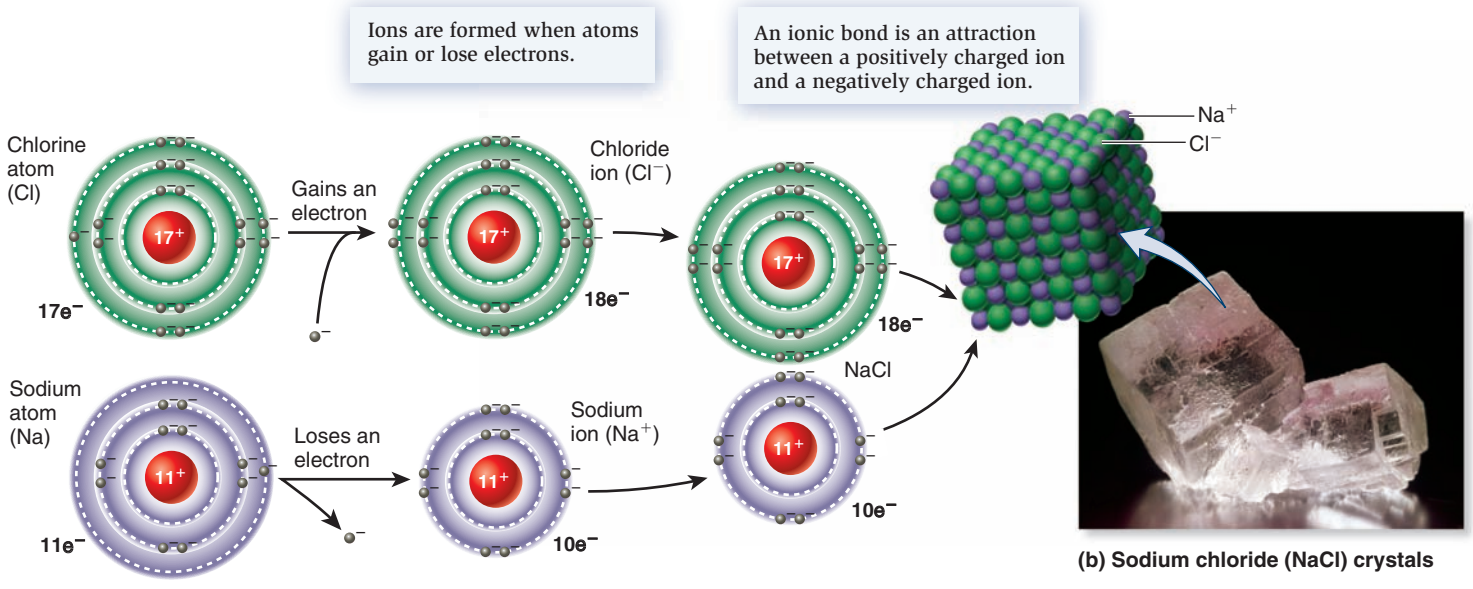


Figure 2.12 Ionic bonding in table salt (NaCl). **(a)** When a sodium atom loses an electron, a sodium ion is formed, and when a chlorine atom gains an election, a chloride ion is formed. The resulting ions are attracted to each other via an ionic bond. **(b)** In a salt crystal, a lattice is formed in which the positively charged sodium ions (Na^+) are attracted to negatively charged chloride ions (Cl^-). Note: Electrons do not exist free in solution; when an electron is removed from one atom, it must be transferred to some other atom.

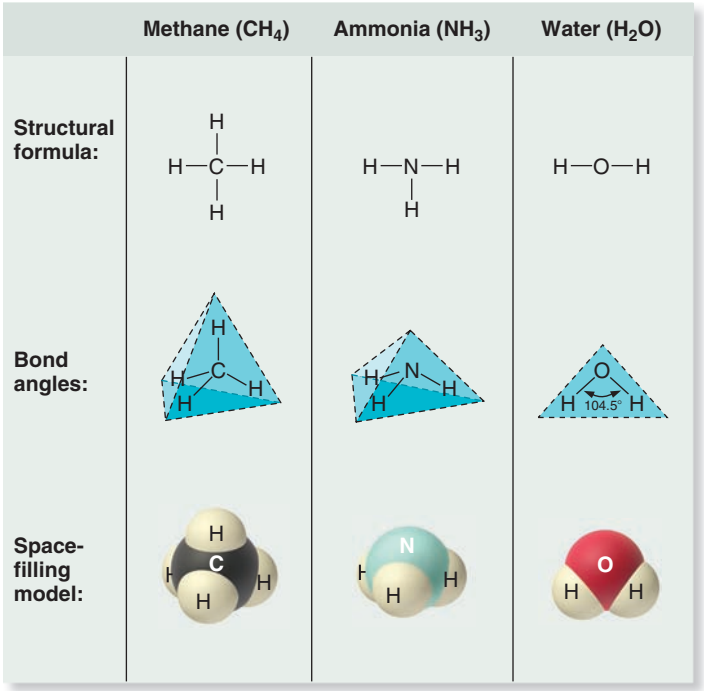

Figure 2.13 Shapes of molecules. Molecules may assume different shapes, depending on the types of bonds between their atoms. The angles between groups of atoms are well defined. For example, in liquid water at room temperature, the angle formed by the covalent bonds between the two hydrogen atoms and the oxygen atom is approximately 104.5°. This bond angle can vary slightly, depending on the temperature and degree of hydrogen bonding between adjacent water molecules.

in their nose (see Figure 43.24). When an odor molecule encounters a receptor, the two molecules recognize each other by their unique shapes, somewhat like a key fitting into a lock. As molecules in the food interact with the receptor, the shape of the receptor changes.

Free Radicals Are a Special Class of Highly Reactive Molecules

Recall that an atom or an ion is most stable when each of its orbitals is occupied by its full complement of electrons. A molecule containing an atom with a single, unpaired electron in its outer shell is known as a **free radical**. Free radicals can react with other molecules to "steal" an electron from one of their atoms, thereby filling the orbital in the free radical. In the process, this may create a new free radical in the donor molecule, setting off a chain reaction.

Free radicals can be formed in several ways, including exposure of cells to radiation and toxins. They are diagrammed with a dot (representing the unpaired electron) next to the atomic symbol. Examples of biologically important free radicals are superoxide anion, $O_2\cdot^-$; hydroxyl radical, ·OH; and nitric oxide, NO·. Note that free radicals can be either charged or neutral.

Free radicals can do considerable harm to living cells—for example, by causing a cell to rupture or by damaging the genetic material. Surprisingly, the lethal effect of free radicals is sometimes put to good use. Some cells in animals' bodies create free radicals

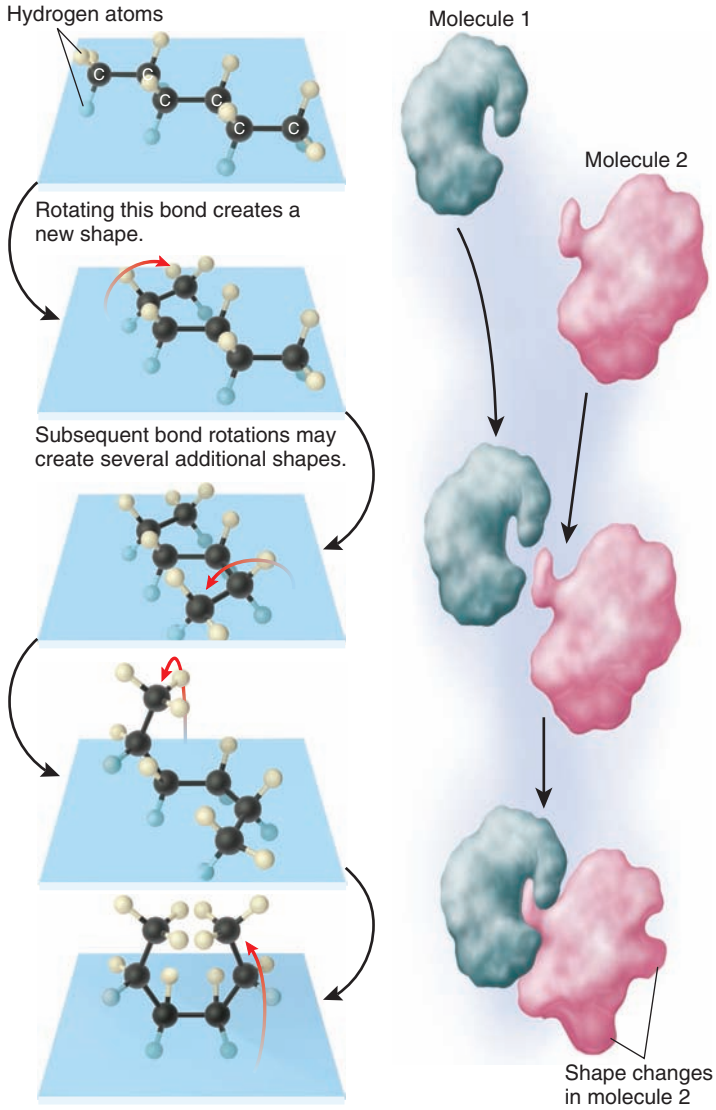

Figure 2.14 Shape changes in molecules. A single molecule may assume different three-dimensional shapes without breaking any of the covalent bonds between its atoms, as shown in **(a)** for a six-carbon molecule. Hydrogen atoms above the blue plane are shown in white; those below the blue plane are blue. **(b)** Two molecules are shown schematically as having complementary shapes that permit them to interact. Upon interacting, the flexible nature of the molecules causes molecule 2 to twist sufficiently to assume a new shape. This change in shape is often an important mechanism by which one molecule influences the activity of another.

BIOLOGY PRINCIPLE Structure determines function. The three-dimensional structure of the two molecules in Figure 2.14b is critical in ensuring that they are capable of specifically interacting with each other and not with other molecules. The function of the molecules is defined by their abilities to bind to each other, which in turn depends on their unique structures.

and use them to kill invading cells such as bacteria. Likewise, for many years people have used weak solutions of hydrogen peroxide to kill bacteria, as in a dirty skin wound. When applied to the wound, hydrogen peroxide can break down to create free radicals, which can then attack bacteria (this practice is no longer recommended because of the possibility of damage to skin cells).

Despite the exceptional case of fighting off bacteria, though, most free radicals that arise in an organism need to be inactivated so they do not kill healthy cells. Protection from free radicals is afforded by molecules that can donate electrons to the free radicals without becoming highly reactive themselves. Such protective compounds are known as antioxidants. Examples include vitamins C and E, which are found in fruits and vegetables, and the numerous plant compounds known as flavonoids. This is one reason why a diet rich in fruits and vegetables is beneficial to our health.

Chemical Reactions Change the Properties of Atoms or Molecules and Create New Molecules

A **chemical reaction** occurs when one or more substances are changed into other substances by the making or breaking of chemical bonds. This can happen when two or more elements or compounds combine to form a new compound, when one compound breaks down into two or more molecules, or when electrons are added to or removed from an atom.

Chemical reactions share similar properties.

- First, they all require a source of energy for molecules to encounter each other. The energy required for atoms and molecules to interact is provided partly by heat or thermal energy. In the complete absence of any heat (a temperature called absolute zero), atoms and molecules would be totally stationary and unable to interact. Heat causes atoms and molecules to vibrate and move, a phenomenon known as Brownian motion.
- Second, chemical reactions that occur in living organisms often require more than just Brownian motion to proceed at a reasonable rate. Such reactions need to be catalyzed. As discussed in Chapter 6, a **catalyst** is a substance that speeds up the rate of a chemical reaction. Enzymes are proteins that are found in all cells and catalyze most chemical reactions.
- Third, chemical reactions tend to proceed in a particular direction but eventually reach a state of equilibrium.

To understand what we mean by "direction" and "equilibrium," let's consider a chemical reaction between methane (a component of natural gas) and oxygen. When a single molecule of methane reacts with two molecules of oxygen, one molecule of carbon dioxide and two molecules of water are produced:

$$\underset{\text{(methane)}}{CH_4} + 2\,\underset{\text{(oxygen)}}{O_2} \rightleftharpoons \underset{\text{(carbon dioxide)}}{CO_2} + 2\,\underset{\text{(water)}}{H_2O}$$

As it is written here, methane and oxygen are the starting materials, or **reactants**, and carbon dioxide and water are the **products**. The bidirectional arrows indicate that this reaction can proceed in both directions. Whether a chemical reaction is likely to proceed in a forward (left to right) or reverse (right to left) direction depends on changes in free energy, which you will learn about in Chapter 6. If we began with only methane and oxygen, the forward reaction would be very favorable. The reaction would produce a large amount of carbon dioxide and water, as well as heat. This is why natural gas is used as a fuel to heat homes.

Chemical reactions may eventually reach **chemical equilibrium**, in which the rate of the formation of products equals the rate of the formation of reactants; in other words, the concentrations of products and reactants do not change. In the case of the reaction involving methane and oxygen, this equilibrium occurs when nearly all of the reactants have been converted to products. In biological systems, however, many reactions do not have a chance to reach chemical equilibrium. For example, the products of a reaction may immediately be converted within a cell to a different product through a second reaction, or used by a cell to carry out some function. When a product is removed from a reaction as fast as it is formed, the reactants continue to form new product until all the reactants are used up.

A final feature common to chemical reactions in living organisms is that many reactions occur in watery environments. Such chemical reactions involve reactants and products that are dissolved in water. Next, we will examine the properties of this amazing liquid and its importance to biology.

2.3 Properties of Water

Learning Outcomes:

1. Describe how hydrogen bonding determines many properties of water.
2. List the properties of water that make it a valuable solvent, and distinguish between hydrophilic and hydrophobic substances.
3. **SciSKILLS** » Calculate the molarity of a solution, and explain its meaning.
4. Discuss the properties of water that are critical for the survival of living organisms.
5. **SciSKILLS** » Calculate the concentrations of hydrogen and hydroxide ions at a given pH.
6. Give examples of how buffers maintain a stable environment in an animal's body fluids.

It would be difficult to imagine life without **water**, which is the liquid form of H_2O. People can survive for a month or more without food but usually die in less than a week without water. The bodies of all organisms are composed largely of water; most of the cells in an organism's body are filled with water and surrounded by it. Up to 95% of the weight of certain plants comes from water. In humans, typically 60–70% of body weight is from water. The brain is roughly 70% water, blood is about 80% water, and the lungs are nearly 90% water. Even our bones are about 20% water! In addition, water is an important liquid in the surrounding environments of living organisms. For example, many species are aquatic organisms that live in watery environments.

Thus far in this chapter, we have considered the features of atoms and molecules and the nature of bonds and chemical reactions between atoms and molecules. In this section, we will turn our attention to issues related to the liquid properties of living organisms and the environment in which they live. Most of the chemical reactions that occur in nature involve molecules that are dissolved in water, including those reactions that happen inside the cells of living organisms and in the spaces that surround them (**Figure 2.15**).

In this section, we will examine the properties of chemicals that influence whether they dissolve in water and consider how biologists measure the amounts of dissolved substances. In addition, we will examine some of the other special properties of water that make it a vital component of living organisms and their environments.

Ions and Polar Molecules Readily Dissolve in Water

Substances dissolved in a liquid are known as **solutes**, and the liquid in which they are dissolved is the **solvent**. In all living organisms, the solvent for chemical reactions is water, which is the most abundant solvent in nature. Solutes dissolve in a solvent to form a **solution**. Solutions made with water are called **aqueous solutions**. To understand why a substance dissolves in water, we need to consider the chemical bonds in the solute molecule and those in water. As discussed earlier, the covalent bonds linking the two hydrogen atoms to the oxygen atom in a water molecule are polar. Therefore, the oxygen in water has a slight negative charge, and each hydrogen has a slight positive charge. To dissolve in water, a substance must be electrically attracted to water molecules. For example, table salt (NaCl) is a solid crystalline substance because of the strong ionic bonds between positive sodium ions (Na^+) and negative chloride ions (Cl^-). When a crystal of sodium chloride is placed in water, the partially negatively charged oxygens of water molecules are attracted to the Na^+, and the partially positively charged hydrogens are attracted to the Cl^- (**Figure 2.16**). Clusters of water molecules surround the ions, allowing the Na^+ and Cl^- to separate from each other and enter the water—that is, to dissolve.

Generally, molecules that contain ionic and/or polar covalent bonds dissolve in water. Such molecules are said to be **hydrophilic**, which literally means "water-loving." In contrast, molecules composed predominantly of carbon and hydrogen are relatively insoluble in water, because carbon-carbon and carbon-hydrogen bonds are nonpolar. These molecules do not have partial positive and negative charges and, therefore, are not attracted to water molecules. Such molecules are **hydrophobic**, or "water-fearing." Oils are a familiar example of hydrophobic molecules. Try mixing vegetable oil with water and observe the result. The two liquids separate into an oil layer and a water layer, with very little oil dissolving in the water.

Some Molecules Have Both Hydrophilic and Hydrophobic Regions

Molecules that have both hydrophilic regions at one or more sites and hydrophobic regions at other sites are called **amphipathic** (or amphiphilic, from the Greek for "both loves"). When mixed with water, long amphipathic molecules may aggregate into spheres called **micelles**, with their polar (hydrophilic) regions at the surface of the micelle, where they are attracted to the surrounding water molecules. The nonpolar (hydrophobic) ends are oriented toward the interior of the micelle (**Figure 2.17**). Such an arrangement minimizes the interaction between water molecules and the nonpolar ends of the amphipathic molecules, which face inward. Nonpolar molecules can dissolve in the central nonpolar regions of these clusters and thus exist in an aqueous environment in far higher amounts than would otherwise be possible based on their low solubility in water. Familiar examples of amphipathic molecules are those in detergents, which can form micelles that help to dissolve oils and nonpolar molecules found in dirt. The detergent molecules found in soap have polar and nonpolar ends. Oils on your skin dissolve in the nonpolar regions of the detergent micelles, and the polar ends help the detergent rinse off in water, taking the oil with it.

In addition to micelles, amphipathic molecules may form structures consisting of double layers of molecules called bilayers. Such bilayers have two hydrophilic surfaces facing outside, in contact with water, and a hydrophobic interior facing away from water. As you will learn in Chapter 5, bilayers play a key role in cellular membrane structure (look ahead to Figure 5.1).

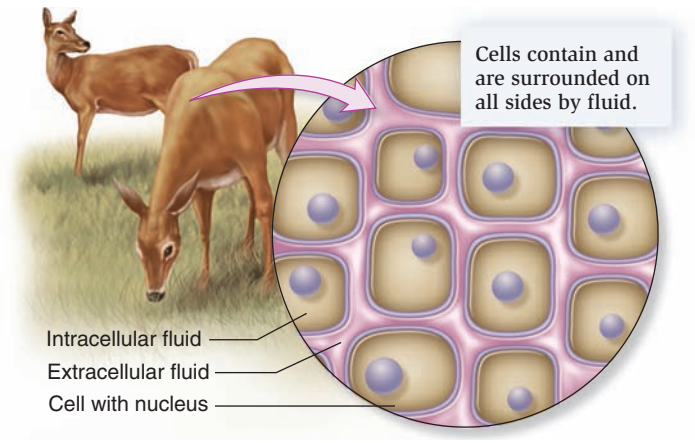

Figure 2.15 Fluids inside and outside of cells. Aqueous solutions exist in the intracellular fluid and in the extracellular fluid. Chemical reactions are always ongoing in both fluids.

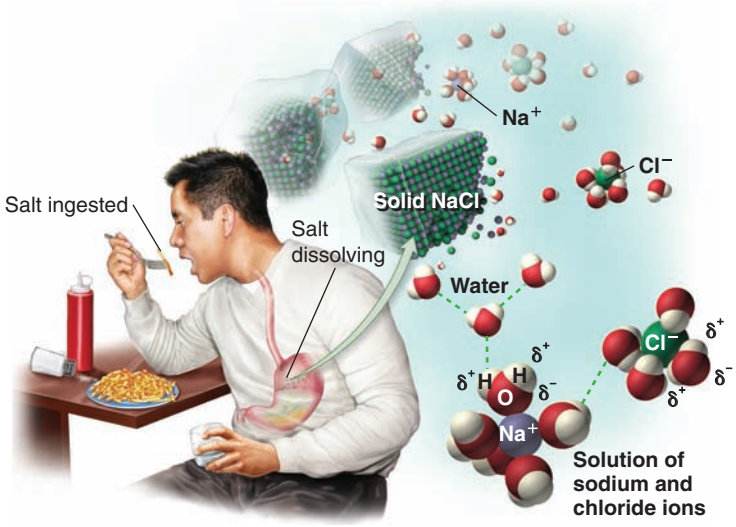

Figure 2.16 Table salt (NaCl crystals) dissolving in water. The ability of water to dissolve sodium chloride crystals depends on the electrical attraction between the polar water molecules and the charged sodium (Na^+) and chloride ions (Cl^-). Water molecules surround each ion as it becomes dissolved. For simplicity, the partial charges are indicated for only two water molecules.

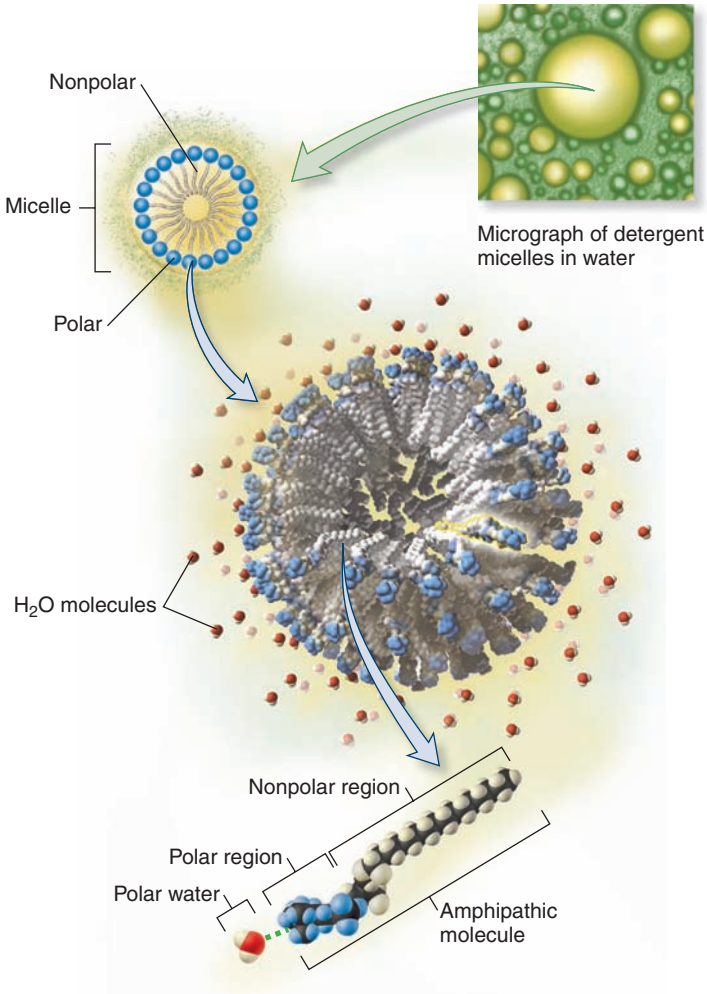

Figure 2.17 The formation of a micelle by amphipathic molecules. In water, amphipathic molecules tend to arrange themselves so their nonpolar regions are directed away from water molecules and the polar regions are directed toward the water and can form hydrogen bonds with it.

Concept Check: When oil dissolves in soap, where is the oil found?

The Amount of a Dissolved Solute per Unit Volume of Liquid Is Its Concentration

Solute **concentration** is defined as the amount of a solute dissolved in a unit volume of solution. For example, if 1 gram (g) of NaCl was dissolved in enough water to make 1 liter (L) of solution, we would say that its solute concentration is 1 g/L.

A comparison of the concentrations of two different substances on the basis of the number of grams per liter of solution does not directly indicate how many molecules of each substance are present. For example, let's compare 10 g each of glucose ($C_6H_{12}O_6$) and sodium chloride (NaCl). Because the individual molecules of glucose have more mass than those of NaCl, 10 g of glucose contains fewer molecules than 10 g of NaCl. Therefore, another way to describe solute concentration is according to the moles of dissolved solute per volume of solution. To make this calculation, we must know three things: the amount of dissolved solute, the molecular mass of the dissolved solute, and the volume of the solution.

The **molecular mass** of a molecule is equal to the sum of the atomic masses of all the atoms in the molecule. For example, glucose ($C_6H_{12}O_6$) has a molecular mass of 180 ([6 × 12] + [12 × 1] + [6 × 16] = 180).

As mentioned earlier, 1 mole (abbreviated mol) of a substance is the amount of the substance in grams equal to its atomic or molecular mass. The **molarity** of a solution is defined as the number of moles of a solute dissolved in 1 L of solution. A solution containing 180 g of glucose (1 mol) dissolved in enough water to make 1 L is a 1 **molar** solution of glucose (1 mol/L). By convention, a 1 mol/L solution is usually written as 1 M, where the capital M stands for molar and is defined as mol/L. If 90 g of glucose (half its molecular mass) were dissolved in enough water to make 1 L, the solution would have a solute concentration of 0.5 mol/L, or 0.5 M.

The concentrations of solutes dissolved in the fluids of living organisms are usually much less than 1 M. Many have concentrations in the range of millimoles per liter (1 mM = 0.001 M = 10^{-3} M), and others are present in even smaller concentrations—micromoles per liter (1 μM = 0.000001 M = 10^{-6} M), nanomoles per liter (1 nM = 0.000000001 M = 10^{-9} M), or picomoles per liter (1 pM = 0.000000000001 M = 10^{-12} M), or even less.

BIO TIPS

THE QUESTION *Insulin is a hormone that regulates the uptake of glucose into muscle and fat cells. It is composed of 51 amino acids and has a molecular mass of approximately 5,808 g/mol. In healthy individuals, insulin levels in the bloodstream rise sharply after eating a meal, which increases the ability of muscle and fat cells to take up glucose. Two individuals, Alfonzo and Gordan, had their blood insulin levels tested before and after a meal.*

	Before meal (ng/L)	After meal (ng/L)
Alfonzo	475	2,850
Gordan	399	789

Calculate the molarity of insulin in each individual's bloodstream before and after the meal, expressed in units of picomoles/L (pM). (Note: 1 mole = 10^{12} picomoles.) Which person do you think may be diabetic because he does not release enough insulin into his bloodstream?

TOPIC ***What topic in biology does this question address?*** The topic is about insulin levels in the bloodstream. More specifically, the question is about calculating the concentration of insulin (in pM) before and after a meal. You are also asked to consider if either individual may be diabetic.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you have learned that insulin increases the ability of muscle and fat cells to take up glucose and that diabetic individuals have a diminished ability to produce insulin. You are given the blood insulin levels of two individuals before and after a meal. From your understanding of the topic, you may remember

that molarity refers to the number of moles of a substance dissolved in a liter of solvent.

PROBLEM-SOLVING STRATEGY ***Make a calculation. Compare and contrast.*** To begin to solve this problem, you first need to calculate the molarities. After this is done, you can compare the concentrations between Alfonzo and Gordan.

Let's go through the calculation for Alfonzo's insulin level before a meal. We begin with his blood insulin level, which is 475 ng/L. To convert this value to g/L, remember that 1 g = 10^9 ng.

$$475 \text{ ng/L} \times \frac{1 \text{ g}}{10^9 \text{ ng}} = 475 \times 10^{-9} \text{ g/L}$$

We then divide this value by the molecular mass of insulin, which is 5,808 g/mol.

$$\frac{475 \times 10^{-9} \text{ g/L}}{5{,}808 \text{ g/mol}} = 0.082 \times 10^{-9} \text{ mol/L}$$

The question asks you to express your value in pM, where 1 mole = 10^{12} picomoles:

$$0.082 \times 10^{-9} \text{ mol/L} \times \frac{10^{12} \text{ pmol}}{\text{mol}} = 82 \text{ pmol/L, or } 82 \text{ pM}$$

ANSWER

	Before meal (pM)	After meal (pM)
Alfonzo	82	492
Gordan	69	136

Alfonzo's blood insulin level after the meal is six times higher than before the meal, whereas Gordan's is only about twice as high. Gordan may be diabetic, but this would need to be substantiated by more extensive testing of his insulin and glucose levels.

H_2O Exists in Three States

H_2O is an abundant compound on Earth that exists in all three states of matter—solid (ice), liquid (water), and gas (water vapor). At the temperatures found over most regions of the planet, H_2O is found primarily as a liquid in which the weak hydrogen bonds between molecules are continuously being formed, broken, and formed again. If the temperature rises, the rate at which hydrogen bonds break increases, and molecules of water escape into the gaseous state, becoming water vapor. If the temperature falls, hydrogen bonds are broken less frequently, so larger and larger clusters of water molecules are formed, until at 0°C water freezes into a crystalline matrix—ice. The H_2O molecules in ice tend to lie in a more orderly and open arrangement, that is, with greater intermolecular distances, which makes ice less dense than water. This is why ice floats on water (**Figure 2.18**). Compared with water, ice is also less likely to participate in most types of chemical reactions.

Changes in state, such as changes between the solid, liquid, and gaseous states of H_2O, involve an input or a release of energy. For example, when energy is supplied to make water boil, it changes from the liquid to the gaseous state—a process called vaporization. The heat required to vaporize 1 mole of any substance at its boiling point is called the substance's **heat of vaporization**. For water, this value is very high, because of the high number of hydrogen bonds between the molecules. It takes more than five times as much heat to vaporize water than it does to raise the temperature of water from 0°C to 100°C. In contrast, energy is released when water freezes to form ice. A substance's **heat of fusion** is the amount of heat that must be withdrawn or released from a substance to cause it to change from the liquid to the solid state. For water, this value is also high.

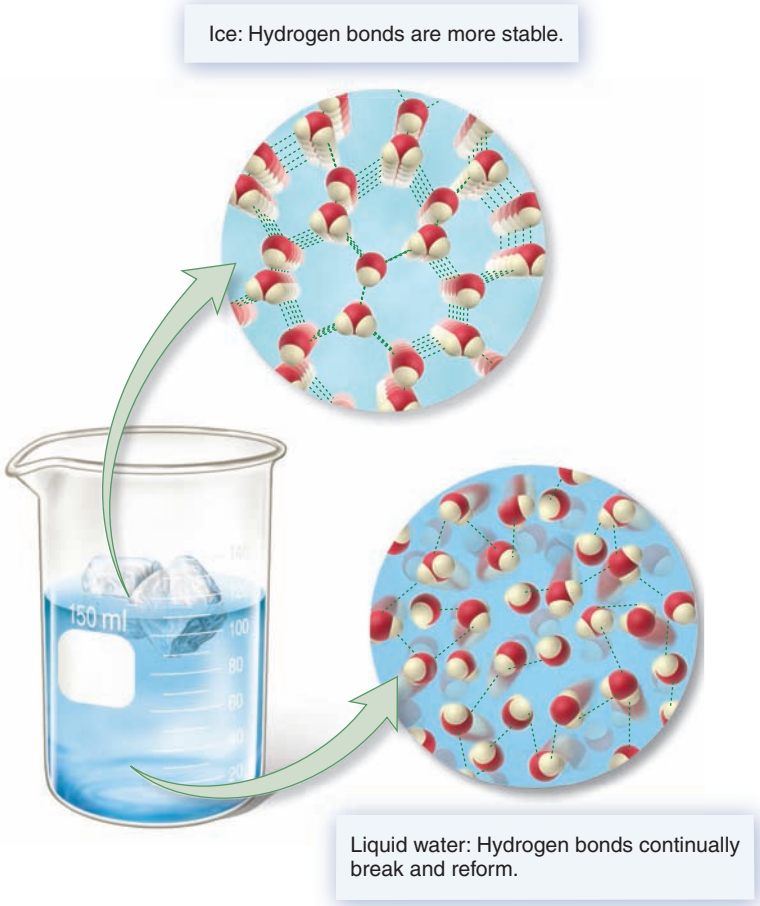

Figure 2.18 Structure of liquid water and ice. In the liquid form of H_2O, the hydrogen bonds between molecules continually form, break, and re-form, resulting in a changing arrangement of molecules from instant to instant. At temperatures at or below its freezing point, H_2O forms a crystalline matrix called ice. In this solid form, hydrogen bonds are more stable. Ice has a hexagonally shaped crystal structure. The greater space between H_2O molecules in this crystal structure causes ice to have a lower density than liquid water. For this reason, ice floats on water.

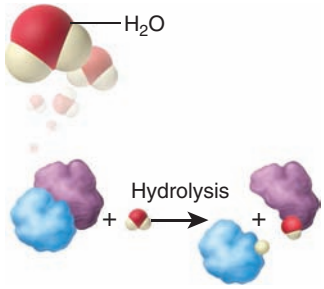
Another important feature for living organisms is that water has a very high **specific heat**, defined as the amount of heat required to raise the temperature of 1 gram of a substance by 1°C (or conversely, the amount of heat that must be lost to lower the temperature by 1°C). A high specific heat means that it takes considerable heat to raise the temperature of water. A related concept is heat capacity, which refers to the amount of heat required to raise the temperature of an entire object or substance. A large beaker of water

has a greater heat capacity than a small beaker of water, but both have the same specific heat. These properties of water contribute to the relatively stable temperatures of large bodies of water compared with inland temperatures. Large bodies of water tend to have a moderating effect on the temperature of nearby land masses. These three features—the high heats of vaporization and fusion and the high specific heat of water—mean that water is extremely stable as a liquid. Not surprisingly, therefore, living organisms have evolved to function best within a range of temperatures consistent with the liquid phase of water.

The temperature at which a solution freezes or vaporizes is influenced by the amounts of dissolved solutes. These are examples of a solution's **colligative properties**, defined as those properties that depend strictly on the total number of dissolved solutes, not on the specific type of solute. Pure water freezes at 0°C and vaporizes at 100°C. Addition of solutes to water lowers its freezing point below 0°C and raises its boiling point to above 100°C. Adding a small amount of the compound ethylene glycol—antifreeze—to the water in a car's radiator, for instance, lowers the freezing point of the water and consequently prevents it from freezing in cold weather. Similarly, the presence of large amounts of solutes partly explains why the oceans do not freeze when the temperature falls below 0°C.

Water Performs Many Important Tasks in Living Organisms

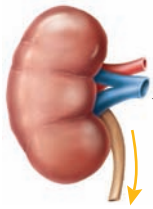


As discussed previously, water is the primary solvent in the fluids of all living organisms, from unicellular bacteria to the largest sequoia tree. Water permits atoms and molecules to interact in ways that would be impossible in their nondissolved states. In Unit II, we will consider many ions and molecules that are solutes in living cells.

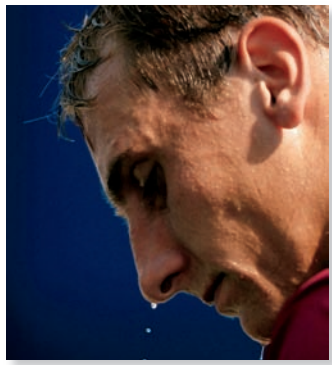
Even so, it is important to recognize that in addition to acting as a solvent, water serves many other remarkable functions that are critical for the survival of living organisms. For example, water molecules participate in many chemical reactions of this general type:

$$R_1—R_2 + H—O—H \rightarrow R_1—OH + H—R_2$$

R is a general symbol used in this case to represent a group of atoms. In this equation, R_1 and R_2 are distinct groups of atoms. On the left side, $R_1—R_2$ is a compound in which the groups of atoms are connected by a covalent bond. To be converted to products, a covalent bond is broken in each reactant, $R_1—R_2$ and H—O—H, and OH and H (from water) form covalent bonds with R_1 and R_2, respectively. Reactions of this type are known as **hydrolysis reactions** (from the Greek *hydro*, meaning water, and *lysis*, meaning to break apart), because water is used to break apart another molecule (**Figure 2.19a**). As discussed in Chapter 3 and later chapters, many large molecules are broken down into smaller, biologically important units by hydrolysis reactions.



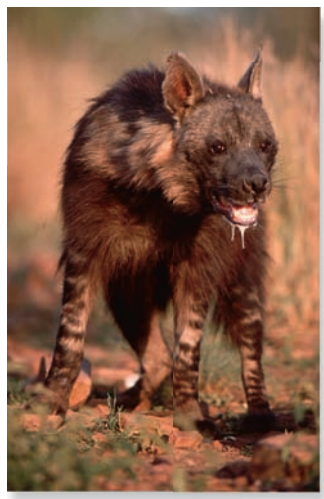
Another feature of water is that it is incompressible—its volume does not significantly decrease when subjected to high pressure. This has biological importance for many organisms that use water to provide force or support. For example, water supports the bodies of worms and some other invertebrates in a structure called a hydrostatic skeleton, and it provides turgidity (stiffness) and support for plants (**Figure 2.19b**).



(a) Water participates in chemical reactions.

(b) Water provides support. The plant on the right is wilting due to lack of water.

(c) Water is used to eliminate soluble wastes.



(d) Evaporation helps some animals dissipate body heat.

(e) The cohesive force of water molecules aids in the movement of fluid through vessels in plants.

(g) The surface tension of water explains why this water strider doesn't sink.

(f) Water in saliva serves as a lubricant during—or as shown here, in anticipation of—feeding.

Figure 2.19 Some of the amazing functions of water. In addition to acting as a solvent, water serves many crucial functions in nature.

BIOLOGY PRINCIPLE Living organisms maintain homeostasis. Healthy organisms have a normal supply of water that maintains such homeostatic functions as body temperature, salt balance, and waste levels.

Water is also the means by which unneeded and potentially toxic waste compounds are eliminated from an animal's body (**Figure 2.19c**). In mammals, for example, the kidneys filter out soluble waste products derived from the breakdown of proteins and other compounds. The filtered products remain in solution in a watery fluid, which eventually becomes urine and is excreted.

Recall from our discussion of water's properties that it takes considerable energy in the form of heat to convert water from a liquid to a gas. This feature has great biological significance. Although everyone is familiar with the phenomenon of boiling water being converted to water vapor, water can also vaporize into the gaseous state even at ordinary temperatures. This process is known as **evaporation**. The simplest way to understand this is to imagine that in any volume of water at any temperature, some vibrating water molecules have higher energy than others. Those with the highest energy break their hydrogen bonds and escape into the gaseous state. During this process, energy in the form of heat is released into the environment. Evaporation is an important mechanism by which many animals cool themselves on hot days (**Figure 2.19d**).

The hydrogen-bonding properties of water affect its ability to form droplets and to adhere to surfaces. The phenomenon of water molecules attracting each other is called **cohesion**. Water exhibits strong cohesion due to hydrogen bonding. Cohesion aids in the movement of water through the vessels of plants (**Figure 2.19e**). A property similar to cohesion is **adhesion**, which refers to the ability of water to be attracted to, and thus adhere to, a surface that is not electrically neutral. Water tends to cling to surfaces to which it can hydrogen bond, such as a paper towel. In organisms, the adhesive properties of water allow it, for example, to coat the surfaces of the digestive tract of animals and act as a lubricant for the passage of food (**Figure 2.19f**).

Surface tension is a measure of the attraction between molecules at the surface of a liquid. In the case of water, the attractive force between hydrogen-bonded water molecules at the interface between water and air is what causes water to form droplets. The surface water molecules attract each other into a configuration (roughly that of a sphere) that reduces the number of water molecules in contact with air. You can see this by slightly overfilling a glass with water; the water forms an oval shape above the rim. Likewise, surface tension allows certain insects, such as water striders, to walk on the surface of a pond without sinking (**Figure 2.19g**).

Hydrogen Ion Concentrations Are Changed by Acids and Bases

Pure water has the ability to ionize to a very small extent into **hydroxide ions (OH^-)** and hydrogen ions that exist as single protons (H^+). In pure water, the concentrations of H^+ and OH^- are both 10^{-7} mol/L, or 10^{-7} M. An inherent property of water is that the product of the concentrations of H^+ and OH^- is always 10^{-14} M at 25°C. Therefore, in pure water, $[H^+][OH^-] = [10^{-7}\ M][10^{-7}\ M] = 10^{-14}$ M. (The brackets around the symbols for the hydrogen and hydroxide ions indicate concentration.)

When certain substances are dissolved in water, they may release or absorb H^+ or OH^-, thereby altering the relative concentrations of these ions. Substances that release hydrogen ions in solution are called **acids**. Two examples are hydrochloric acid and carbonic acid:

$$\underset{\text{(hydrochloric acid)}}{HCl} \rightarrow \underset{}{H^+} + \underset{\text{(chloride ion)}}{Cl^-}$$

$$\underset{\text{(carbonic acid)}}{H_2CO_3} \rightleftharpoons \underset{}{H^+} + \underset{\text{(bicarbonate ion)}}{HCO_3^-}$$

Hydrochloric acid is called a **strong acid** because it almost completely dissociates into H^+ and Cl^- when added to water (which is why the arrow is not bidirectional in this reaction). By comparison, carbonic acid is a **weak acid** because some of it remains in the H_2CO_3 state when dissolved in water (note the bidirectional arrows $\rightleftharpoons$).

Compared with an acid, a **base** has the opposite effect when dissolved in water—it decreases the H^+ concentration. This can occur in different ways. Some bases, such as sodium hydroxide (NaOH), release OH^- when dissolved in water:

$$\underset{\text{(sodium hydroxide)}}{NaOH} \rightarrow \underset{\text{(sodium ion)}}{Na^+} + OH^-$$

Recall that the product of $[H^+]$ and $[OH^-]$ is always 10^{-14} M. When a base such as NaOH raises the OH^- concentration, some of the hydrogen ions bind to these hydroxide ions to form water. Therefore, increasing the OH^- concentration lowers the H^+ concentration.

Let's consider another example. Ammonia reacts with water to produce ammonium ion:

$$\underset{\text{(ammonia)}}{NH_3} + H_2O \rightleftharpoons \underset{\text{(ammonium ion)}}{NH_4^+} + OH^-$$

In this case, NH_3 increases the OH^- concentration by removing H^+ from H_2O. Both NaOH and ammonia have the same effect—they lower the concentration of H^+. NaOH achieves this by directly increasing the OH^- concentration, whereas NH_3 reacts with water to produce OH^-.

The pH Is a Measure of the H^+ Concentration of a Solution

The addition of acids and bases to water can greatly change the $H^+$and OH^- concentrations over a very broad range. Therefore, scientists use a log scale to describe the concentrations of these ions. The H^+ concentration is expressed as the solution's **pH**, which is defined as the negative logarithm to the base 10 of the H^+ concentration (a logarithmic scale is used because the concentrations of hydrogen ions can vary over a very wide range).

$$pH = -\log_{10}[H^+]$$

To understand what this equation means, let's consider a few examples. A solution with an H^+ concentration of 10^{-7} M has a pH of 7. A concentration of 10^{-7} M is the same as 0.1 μM. A solution in which $[H^+] = 10^{-6}$ M has a pH of 6. 10^{-6} M is the same as 1.0 μM. A solution at pH 6 is said to be **acidic**, because it contains more H^+ ions than OH^- ions. Note that as the acidity increases, the pH decreases. A solution in which the pH is 7 is said to be neutral because $[H^+]$

and [OH^-] are equal. A solution with a pH above 7 is considered to be **alkaline**. **Figure 2.20** considers the pH values of some familiar fluids. Keep in mind that each change of one pH unit represents a 10-fold difference in H^+ concentration.

Why is pH of importance to living cells? The answer lies in the observation that H^+ and OH^- can readily bind to many kinds of ions and molecules. For this reason, the pH of a solution can affect:

- the shapes and functions of molecules
- the rates of many chemical reactions
- the ability of two molecules to bind to each other
- the ability of ions or molecules to dissolve in water

Due to the various effects of pH, many biological processes function best within very narrow ranges of pH, and even small shifts can have a negative effect. In living cells, the pH ranges from about 6.5 to 7.8 and is carefully regulated to avoid major shifts in pH. The blood of the human body has a normal range of about pH 7.35–7.45 and is therefore slightly alkaline. Certain diseases, such as kidney disease, can decrease or increase blood pH by a few tenths of a unit. When this happens, the enzymes in the body that are required for normal metabolism can no longer function optimally, leading to additional illness. As described next, living organisms have molecules called buffers to help prevent such changes in pH.

Buffers Minimize Fluctuations in pH

What factors might alter the pH of an organism's fluids? In plants, external factors such as acid rain and other forms of pollution can reduce the pH of water entering the roots. In animals, exercise generates lactic acid, and certain disease states can raise or lower the pH of blood.

Organisms have several ways to cope with changes in pH. In mammals, for example, the kidneys secrete acidic or alkaline compounds into the bloodstream when the blood pH becomes imbalanced. Another mechanism by which pH balance is regulated in diverse organisms involves the actions of acid-base buffers. A **buffer** is usually a pair of substances, an acid and its related base, that minimizes pH fluctuations in the fluids of living organisms. For example, carbonic acid (H_2CO_3) and bicarbonate ions (HCO_3^-) function to keep the pH of an animal's body fluids within a narrow range:

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$$

(carbonic acid) (bicarbonate)

This buffer can affect pH in both directions. For example, if the pH of an animal's body fluids were to increase (that is, the H^+ concentration decreased), the reaction would proceed from left to right. Carbon dioxide would combine with water to make carbonic acid, and then the carbonic acid would dissociate into H^+ and HCO_3^-. This would increase the H^+ concentration and thereby decrease the pH. Alternatively, when the pH of an animal's blood decreases (that is, the H^+ concentration increases), the reaction runs in reverse. Bicarbonate combines with H^+ to make H_2CO_3, which then dissociates to CO_2 and H_2O. This process removes H^+ from the blood, restoring it to its normal pH, and the CO_2 is exhaled from the lungs. Many buffers exist in nature. Buffers found in living organisms function most efficiently at the normal range of pH values found in that organism.

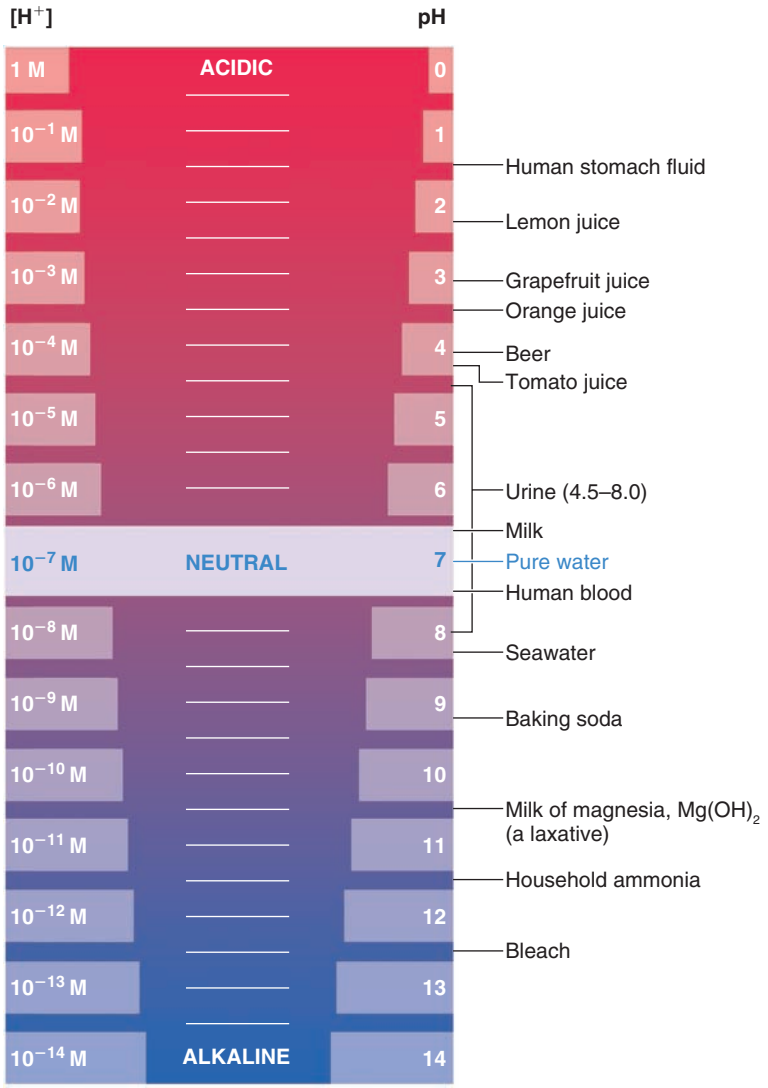


Figure 2.20 **The pH scale and the relative acidities of common substances.**

Concept Check: *What is the OH^- concentration at pH 8?*

BioConnections: *Look ahead to Figure 54.17. The plant life shown growing in part (b) of that figure is sparse because the soil is very acidic. If the pH of the soil were 5.0, what would the H^+ concentration be?*

Summary of Key Concepts

2.1 Atoms

- Atoms are the smallest functional units of matter that form all chemical elements and cannot be further broken down into other substances by ordinary chemical or physical means. Atoms are composed of protons (p^+, positive charge), electrons (e^-, negative charge), and (except for hydrogen) neutrons (n^0, electrically neutral). Electrons are found in orbitals around the nucleus (Table 2.1, Figures 2.1, 2.2, 2.3, 2.4).

- Each element contains a unique number of protons—its atomic number. The periodic table organizes all known elements by atomic number and electron shells (Figure 2.5).
- Each atom has a small but measurable mass, measured in daltons (Da). The atomic mass scale indicates an atom's mass relative to the mass of other atoms.
- Many atoms exist as isotopes, which differ in the number of neutrons they contain. Some isotopes are unstable radioisotopes and emit radiation (Figure 2.6).
- Four elements—oxygen, carbon, hydrogen, and nitrogen—account for the vast majority of atoms in living organisms. In addition, living organisms require mineral and trace elements that are essential for growth and function (Table 2.2).

2.2 Chemical Bonds and Molecules

- A molecule is two or more atoms bonded together. The properties of a molecule are different from the properties of the atoms that combined to form it. A compound is a molecule composed of two or more different elements.
- Atoms tend to form bonds that fill their outer shell with electrons. Covalent bonds, in which atoms share electrons, are strong chemical bonds. Atoms form two covalent bonds—a double bond—when they share two pairs of electrons (Figures 2.7, 2.8, 2.9).
- The electronegativity of an atom is a measure of its ability to attract bonded electrons. When two atoms with different electronegativities combine, they form a polar covalent bond because the distribution of electrons around the atoms creates a difference in electric charge across the molecule. Polar molecules, such as water, typically have one or more polar covalent bonds, whereas nonpolar molecules tend to have a predominance of nonpolar covalent bonds (Figure 2.10).
- An important result of polar covalent bonds is the ability of one molecule to loosely associate with another molecule through weak interactions called hydrogen bonds. The van der Waals dispersion forces are weak electrical attractions that arise between molecules due to the variation in the locations of electrons in atoms (Figure 2.11).
- If an atom or molecule gains or loses one or more electrons, it acquires a net electric charge and becomes an ion. The strong attraction between two oppositely charged ions forms an ionic bond (Table 2.3, Figure 2.12).
- The three-dimensional, flexible shape of molecules allows them to interact and contributes to their biological properties (Figures 2.13, 2.14).
- A free radical is an unstable molecule that can cause cellular damage by taking electrons away from other molecules.
- A chemical reaction occurs when one or more substances are changed into different substances. All chemical reactions eventually reach an equilibrium, unless the products of the reaction are continually removed.

2.3 Properties of Water

- Water is the solvent for most chemical reactions in all living organisms, both inside and outside of cells. Atoms and molecules dissolved in water interact in ways that would be impossible in their nondissolved states (Figure 2.15).
- A solute dissolves in a solvent to form a solution. Solute concentration refers to the amount of a solute dissolved in a unit volume of solution. The molarity of a solution is defined as the number of moles of a solute dissolved in 1 L of solution (Figure 2.16).
- Molecules with ionic and polar covalent bonds generally are hydrophilic, whereas nonpolar molecules, composed predominantly of carbon and hydrogen, are hydrophobic. Amphipathic molecules, such as detergents, have both hydrophilic and hydrophobic regions (Figure 2.17).
- H_2O exists as ice, liquid water, and water vapor (gas) (Figure 2.18).
- The colligative properties of water depend on the number of dissolved solutes and allow it to function as an antifreeze in certain organisms.
- Water's high heat of vaporization and high heat of fusion make it very stable in its liquid form.
- Water molecules participate in many chemical reactions in living organisms. Hydrolysis reactions break down large molecules into smaller units. In living organisms, water provides support, is used to eliminate wastes, dissipates body heat, aids in the movement of liquid through vessels, serves as a lubricant, and its surface tension allows certain insects to walk on water (Figure 2.19).
- The pH of a solution refers to its hydrogen ion concentration. The pH of pure water is 7 (a neutral solution). Alkaline solutions have a pH higher than 7, and acidic solutions have a pH lower than 7 (Figure 2.20).
- A buffer is usually a pair of substances, an acid and its related base, that minimizes pH fluctuations in the fluids of living organisms. Buffers in animals can raise or lower pH to keep the pH of body fluids within a narrow range.

Assess and Discuss

Test Yourself

1. _____ make(s) up the nucleus of an atom.
   a. Protons and electrons
   b. Protons and neutrons
   c. DNA and RNA
   d. Neutrons and electrons
   e. DNA only
2. Living organisms are composed mainly of which atoms?
   a. calcium, hydrogen, nitrogen, and oxygen
   b. carbon, hydrogen, nitrogen, and oxygen
   c. hydrogen, nitrogen, oxygen, and helium
   d. carbon, helium, nitrogen, and oxygen
   e. carbon, calcium, hydrogen, and oxygen
3. The ability of an atom to attract electrons in a bond with another atom is termed its
   a. hydrophobicity.
   b. electronegativity.
   c. solubility.
   d. valence.
   e. both a and b.

4. Hydrogen bonds differ from covalent bonds in that
   a. covalent bonds can form between any type of atom, and hydrogen bonds form only between H and O.
   b. covalent bonds involve sharing of electrons, and hydrogen bonds involve the complete transfer of electrons.
   c. covalent bonds result from equal sharing of electrons, but hydrogen bonds involve unequal sharing of electrons.
   d. covalent bonds involve sharing of electrons between atoms, but hydrogen bonds are the result of weak attractions between a hydrogen atom of a polar molecule and an electronegative atom of another polar molecule.
   e. covalent bonds are weak bonds that break easily, but hydrogen bonds are strong links between atoms that are not easily broken.
5. A free radical
   a. is a positively charged ion.
   b. is an atom with one unpaired electron in its outer shell.
   c. is a stable atom that is not bonded to another atom.
   d. can cause considerable cellular damage.
   e. both b and d.
6. Chemical reactions in living organisms
   a. require energy to begin.
   b. usually require a catalyst to speed up the process.
   c. are usually reversible.
   d. occur in liquid environments, such as water.
   e. all of the above.
7. Solutes that easily dissolve in water are said to be
   a. hydrophobic.
   b. hydrophilic.
   c. polar molecules.
   d. all of the above.
   e. b and c only.
8. The molecular mass of glucose is about 180 g/mol. If 45 g of glucose is dissolved into a final volume of 0.5 L of water, what is the molarity of the solution?
   a. 0.125 M
   b. 0.25 M
   c. 0.5 M
   d. 1.0 M
   e. 2.0 M
9. The sum of the atomic masses of all the atoms of a molecule is its
   a. atomic weight.
   b. molarity.
   c. molecular mass.
   d. concentration.
   e. polarity.
10. Reactions in which water is used to break apart other molecules are known as _____ reactions.
    a. hydrophilic
    b. hydrophobic
    c. dehydration
    d. anabolic
    e. hydrolysis

Conceptual Questions

1. Compare and contrast the different types of bonds commonly found in biological molecules.
2. What is the significance of molecular shape, and what may change the shape of molecules?
3.  A principle of biology is that *new properties emerge from complex interactions*. How is this principle evident even at the molecular level? What examples of emergent properties of molecules can you find in this chapter, in which atoms with one type of property combine to form molecules with completely different properties?

Collaborative Questions

1. Discuss the properties of the three subatomic particles of atoms.
2. Discuss several properties of water that make it possible for life to exist.

The Chemical Basis of Life II:
Organic Molecules

3

A model showing the structure of DNA—a type of organic macromolecule that stores genetic information.

In Chapter 2, we learned that all life is composed of atoms, which, in turn, combine to form molecules. Molecules may be simple in atomic composition, as in water (H_2O) or hydrogen gas (H_2), or may bind with other molecules to form larger ones. Of the countless possible molecules that can be produced from the known elements in nature, certain types contain carbon and are found in all forms of life. These carbon-containing molecules are collectively referred to as **organic molecules**, so named because they were first discovered in living organisms. Among these are lipids and large, complex compounds called **macromolecules**, which include carbohydrates, proteins, and nucleic acids. In this chapter, we will survey the structures of these molecules and examine their main functions. We begin with the element whose chemical properties are fundamental to the formation of biologically important molecules: carbon. This element provides the atomic scaffold on which life is built.

3.1 The Carbon Atom

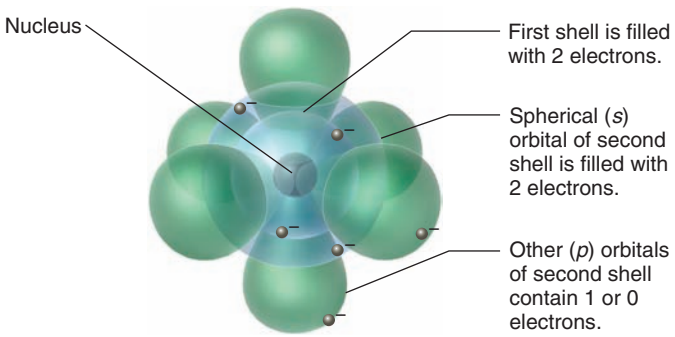
Learning Outcomes:

1. Explain the properties of carbon that make it the chemical basis of all life.
2. Describe the variety and chemical characteristics of common functional groups of organic compounds.
3. Compare and contrast different types of isomers.

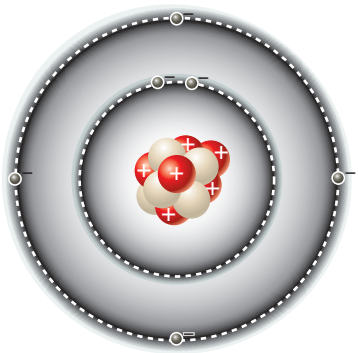
The science of carbon-containing molecules is known as **organic chemistry**. A long time ago, the study of organic molecules was considered a fruitless endeavor because of a concept called vitalism, which persisted into the 19th century. Vitalism held that organic molecules were created by, and therefore imparted with, a vital life force that was contained within a plant or an animal's body. Supporters of vitalism argued that chemists could not synthesize an organic compound, because such molecules could arise only through the intervention of mysterious qualities associated with life.

Vitalism was disproved by Friedrich Wöhler, a German physician and chemist interested in the properties of inorganic and organic compounds. He spent some time studying urea ($(NH_2)_2CO$), a natural organic molecule formed from the breakdown of proteins in an animal's body. In mammals, urea accumulates in the urine formed by the kidneys, and then is excreted from the body. During the course of his studies, Wöhler purified urea from the urine of mammals. He noted the color, size, shape, and other characteristics of the urea crystals.



In 1828, while exploring the reactive properties of ammonia and cyanic acid, Wöhler attempted to synthesize an inorganic molecule, ammonium cyanate (NH_4OCN), which is not found in living organisms. Instead, to his surprise, Wöhler discovered that ammonia and cyanic acid reacted to produce a third compound, which, when heated, formed familiar-looking crystals. After careful analysis, he concluded that these crystals were urea. No mysterious life force was required to make this organic molecule. Other scientists, such

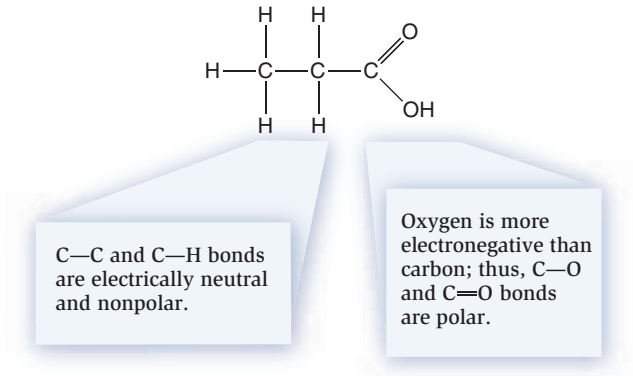
as Hermann Kolbe, would soon demonstrate that organic compounds such as acetic acid (CH_3COOH) could also be synthesized directly from simpler molecules. These studies refuted the concept of vitalism, and so began the field of organic chemistry.



Central to Wöhler's and Kolbe's reactions is the carbon atom. Urea and acetic acid, like all organic compounds, contain carbon atoms bonded to other atoms. In this section, we will consider the chemical features of carbon that make it such an important element in living organisms.

Carbon Forms Four Covalent Bonds with Other Atoms

A key property of the carbon atom is its ability to form four covalent bonds with other atoms, including other carbon atoms. This occurs because carbon has four electrons in its outer (second) shell, and it requires eight electrons, or four additional electrons, to fill this shell (**Figure 3.1**). In living organisms, carbon atoms most commonly form covalent bonds with other carbon atoms and with hydrogen, oxygen, nitrogen, and sulfur atoms. Bonds between two carbon atoms, between carbon and oxygen, or between carbon and nitrogen can be single or double, or in the case of C≡C and C≡N bonds, triple. The variation in bonding of carbon with other carbon atoms and with different elements allows a vast number of organic compounds to be formed from only a few chemical elements. Carbon bonds may occur in configurations that are linear, ringlike, or highly branched. Such molecular shapes can produce molecules with a variety of functions.



(a) Electron orbitals in carbon

(b) Simplified depiction of carbon's electron shells

Figure 3.1 Models for the electron orbitals and shells of carbon. A carbon atom has four electrons in its outer (second) electron shell. When a carbon atom forms four covalent bonds with other atoms, its outer shell is full with eight electrons, which is a stable condition.

Propionic acid

Figure 3.2 Nonpolar and polar bonds in an organic molecule. Carbon can form both nonpolar and polar bonds, and both single and double bonds, as shown here for the molecule propionic acid, a common food preservative.

Carbon and hydrogen have similar electronegativities (see Chapter 2). Therefore, carbon-carbon and carbon-hydrogen bonds are nonpolar. As a consequence, molecules with a high amount of hydrogen-carbon bonds, called **hydrocarbons**, are hydrophobic and poorly soluble in water. In contrast, when carbon forms polar covalent bonds with more electronegative atoms, such as oxygen or nitrogen, the molecule is much more soluble in water due to the electrical attraction of polar water molecules. The ability of carbon to form both polar and nonpolar bonds (**Figure 3.2**) contributes to its ability to serve as the backbone for an astonishing variety of biologically important molecules.

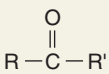
Another feature of carbon that is important to living organisms is that carbon bonds are stable within the large range of temperatures associated with life. This property arises in part because the carbon atom is very small relative to most other atoms. Therefore, the distance between carbon atoms forming a carbon-carbon bond is quite short. Shorter bonds tend to be stronger and more stable than longer bonds between two large atoms. For this reason, carbon bonds are compatible with what we observe about life-forms today; namely, living organisms can inhabit environments with a range of temperatures, from the Earth's frigid icy poles to the superheated water of deep-sea vents.

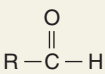
Carbon Atoms Bond to Several Biologically Important Functional Groups

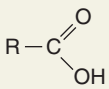
Aside from the simplest hydrocarbons, most organic molecules and macromolecules contain **functional groups**—groups of atoms with characteristic chemical structures and properties. Each type of functional group exhibits similar chemical properties in all molecules in which it occurs. For example, the amino group (—NH_2) acts like a base. At the pH found in living organisms, amino groups readily bind H^+ to become NH_3^+, thereby removing H^+ from an aqueous solution and raising the pH. As discussed later in this chapter, amino groups are found in proteins and also in other types of organic molecules. **Table 3.1** describes examples of functional groups in many different types of organic molecules. We will discuss each of these groups at numerous points throughout this textbook.

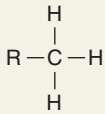
Carbon-Containing Molecules May Exist in Multiple Forms Called Isomers

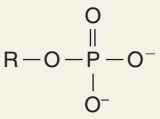
Wöhler was surprised to discover that urea ($(NH_2)_2CO$) and ammonium cyanate (NH_4OCN) contained the exact same ratio of carbon,

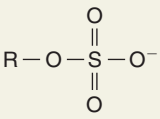






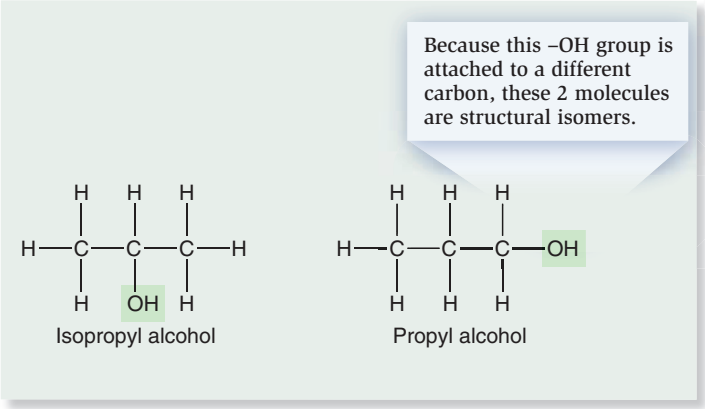






nitrogen, hydrogen, and oxygen atoms, yet they were different molecules with distinct chemical and biological properties. Two molecules with an identical chemical formula but different structures and characteristics are called **isomers**.

Figure 3.3 depicts three ways in which isomers may occur. **Structural isomers** contain the same atoms but in different bonding relationships. Urea and ammonium cyanate fall into this category. A simpler example of structural isomers (isopropyl alcohol and propyl alcohol) is illustrated in Figure 3.3a.



Stereoisomers have identical bonding relationships, but the spatial positioning of their atoms differs. Two types of stereoisomers are *cis-trans* isomers and enantiomers. In ***cis-trans* isomers**, like those shown in Figure 3.3b, the two hydrogen atoms linked to the two carbons of a C═C double bond may be on the same side of the carbons, in which case the C═C bond is called a *cis* double bond. If the hydrogens are on opposite sides, it is a *trans* double bond. *Cis-trans* isomers may have very different chemical properties from each other, most notably their stability and sensitivity to heat and light. For instance, the light-sensitive region of your eye contains a molecule called retinal, which exists in either a *cis* or *trans* form. In darkness, the *cis*-retinal form predominates. The energy of sunlight, however, causes retinal to isomerize to the *trans* form. The *trans*-retinal activates the light-capturing cells in the eye.

A second type of stereoisomer, called an **enantiomer**, exists as a pair of molecules that are mirror images. Four different atoms can bind to a single carbon atom in two possible ways, designated a left-handed and a right-handed structure. The resulting structures are not identical, but instead are mirror images of each other (Figure 3.3b). A convenient way to visualize the contrasting structures of enantiomers is to consider a pair of gloves. No matter which way you turn or hold a left-hand glove, it cannot fit properly on your right hand. Any given pair of enantiomers shares identical chemical properties, such as solubility and melting point. However, due to the different orientation of atoms in space, their ability to noncovalently bind to other molecules can be strikingly different. For example, **enzymes** are molecules that catalyze (speed up) the rates of many biologically important chemical reactions. An enzyme that recognizes one enantiomer usually does not recognize the other.

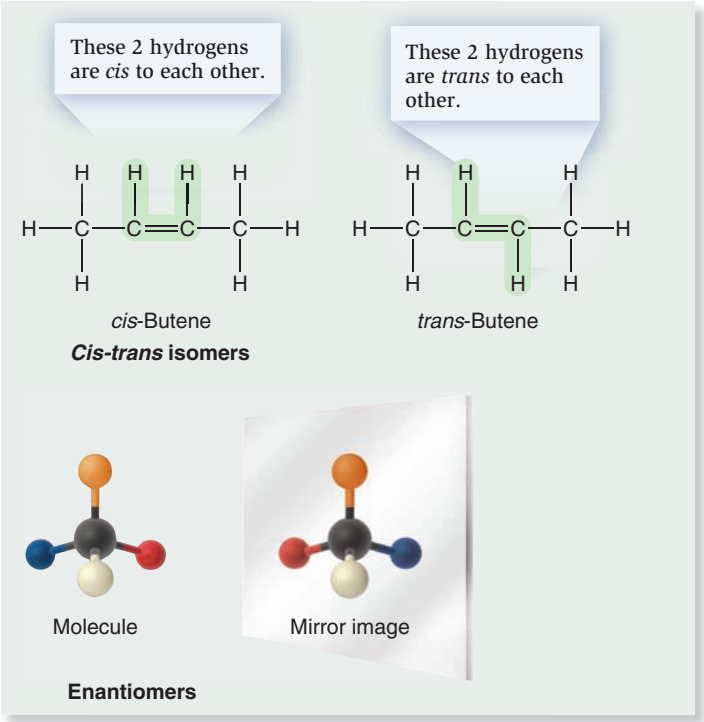


Table 3.1 Some Biologically Important Functional Groups That Bond to Carbon

Functional group* (with shorthand notation)	Formula†	Examples of where the group is found	Properties
Amino ($-NH_2$)		Amino acids (proteins)	Weakly basic (can accept H^+); polar; forms part of peptide bonds
‡Carbonyl (–CO) Ketone		Steroids, waxes, and proteins	Polar; highly chemically reactive; forms hydrogen bonds
Aldehyde (–CHO)		Linear forms of sugars and some odor molecules	Polar; highly chemically reactive; forms hydrogen bonds
Carboxyl (–COOH)		Amino acids, fatty acids	Acidic (gives up H^+ in water); forms part of peptide bonds
Hydroxyl (–OH)		Steroids, alcohol, carbohydrates, some amino acids	Polar; forms hydrogen bonds with water
Methyl ($-CH_3$)		May be attached to DNA, proteins, and carbohydrates	Nonpolar
Phosphate ($-PO_4^{2-}$)		Nucleic acids, ATP, phospholipids	Polar; weakly acidic and thus negatively charged at typical pH of living organisms
Sulfate ($-SO_4^-$)		May be attached to carbohydrates, proteins, and lipids	Polar; negatively charged at typical pH
Sulfhydryl (–SH)		Proteins that contain the amino acid cysteine	Polar; forms disulfide bridges in many proteins

*This list contains many of the functional groups that are important in biology. However, many more functional groups have been identified by biochemists.
†R and R′ represent the remainder of the molecule.
‡A carbonyl group is C═O. In a ketone, the carbon forms covalent bonds with two other carbon atoms. In an aldehyde, the carbon is linked to a hydrogen atom.

(a) Structural isomers

(b) Two types of stereoisomers

Figure 3.3 Types of isomers. Isomers are molecules with the same chemical formula but different structures. The differences in structure result in different biological properties. Isomers can be grouped into **(a)** structural isomers and **(b)** stereoisomers.

3.2 Formation of Organic Molecules and Macromolecules

Learning Outcome:

1. Diagram how small molecules are assembled into larger ones by dehydration reactions and how hydrolysis reactions reverse this process.

As we have seen, organic molecules have various shapes due to the bonding properties of carbon. During the past two centuries, biochemists have studied many organic molecules found in living organisms and determined their structures at the molecular level. Many of these molecules are relatively small molecules. However, some organic molecules are extremely large macromolecules composed of thousands or even millions of atoms. Such large molecules are formed by linking together many smaller molecules called **monomers** (meaning one part) and are known as **polymers** (meaning many parts). When a polymer is formed, two smaller molecules combine by a **condensation reaction**, which produces a larger organic molecule plus a water molecule. This specific type of condensation reaction is also called a **dehydration reaction**, because a molecule of water is removed when a monomer is added to a growing polymer.

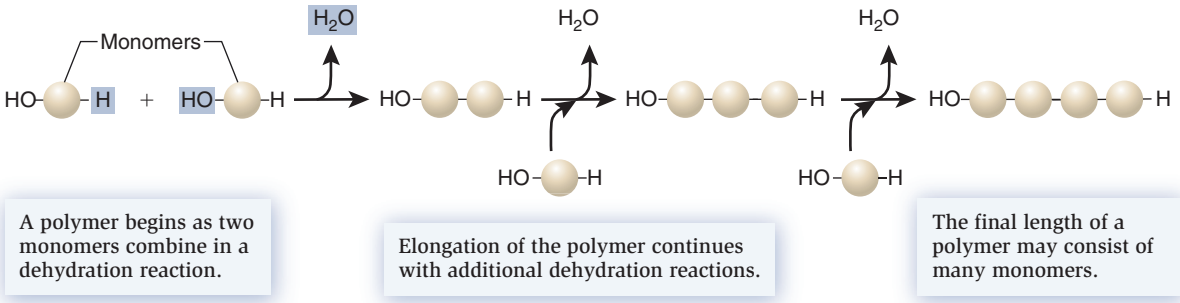
The mechanism of a dehydration reaction is illustrated in Figure 3.4a. The length of a polymer is extended with each dehydration reaction. Some polymers reach great lengths by this mechanism. For example, during the synthesis of DNA, which is described in Chapter 11, dehydration reactions produce linear strands of DNA that contain millions of monomers called nucleotides.

Although DNA is a stable polymer, other polymers, such as large carbohydrates, may be broken down. As discussed later in this chapter, a large carbohydrate in plants, which is called starch, plays a role in storing energy. When a plant cell needs that stored energy, the starch is broken down into its constituent monomers. The process by which a polymer is broken down into monomers is called a **hydrolysis reaction**, because a molecule of water is added back each time a monomer is released (Figure 3.4b).

3.3 Overview of the Four Major Classes of Organic Molecules Found in Living Cells

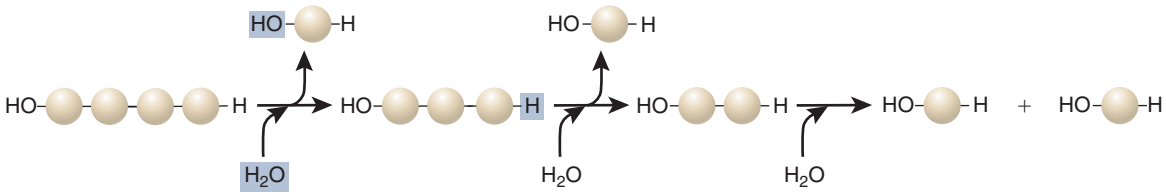
Learning Outcome:

1. Compare and contrast the structures and functions of carbohydrates, lipids, proteins, and nucleic acids.



By analyzing the cells of many different species, researchers have determined that all forms of life have organic molecules and macromolecules that fall into four broad categories, based on their chemical and biological properties: carbohydrates, lipids, proteins, and nucleic acids. Table 3.2 outlines the general structures and functions of these molecules and provides some examples. In the next sections, we will examine them in greater detail.

3.4 Carbohydrates



Learning Outcomes:

1. Distinguish among different forms of carbohydrate molecules, including monosaccharides, disaccharides, and polysaccharides.
2. Relate the functions of plant and animal polysaccharides to their structure.

Carbohydrates are composed of carbon, hydrogen, and oxygen atoms in or close to the proportions represented by the general formula $C_n(H_2O)_n$, where n is a whole number. This formula gives

(a) Polymer formation by dehydration reactions

(b) Breakdown of a polymer by hydrolysis reactions

Figure 3.4 Formation and breakdown of polymers. **(a)** Monomers combine to form polymers in living organisms by dehydration reactions, in which a molecule of water is removed each time a new monomer is added to the growing polymer. **(b)** Polymers can be broken down into their constituent monomers by hydrolysis reactions, in which a molecule of water is added each time a monomer is released.

carbohydrates their name—carbon-containing compounds that are hydrated, that is, contain water. Most of the carbon atoms in a carbohydrate are linked to a hydrogen atom and a hydroxyl functional group. However, other functional groups, such as amino and carboxyl groups, are also found in certain carbohydrates. As discussed next, sugars are relatively small carbohydrates, whereas polysaccharides are large macromolecules.

Sugars Are Small Carbohydrates That May Taste Sweet

Sugars are small carbohydrates that usually taste sweet. The simplest sugars are monomers known as **monosaccharides** (from the Greek, meaning single sugars). The most common types contain either five carbons (pentoses) or six carbons (hexoses). Important pentoses are

Table 3.2 A Comparison of the Four Types of Organic Molecules Found in Living Organisms

Type	Structure	Key Functions	Examples
Carbohydrates	The general formula is $C_n(H_20)_n$, where *n* is a whole number.	Simple carbohydrates are broken down to make ATP, which is used as a source of energy. Larger carbohydrates store energy or may play a structural role, as in plant cell walls. Some carbohydrates function as molecular tags allowing recognition of specific cells and molecules.	Simple sugars, such as glucose; larger polymers, such as starch and cellulose
Lipids	Lipids are nonpolar molecules that are primarily composed of carbon and hydrogen, with some oxygen.	Lipids are a key part of cell membranes and also function as hormones and in energy storage; in animals, they act as insulators and shock absorbers.	Phospholipids, estrogen, testosterone, triglycerides
Proteins	A polypeptide is a structural unit composed of a linear sequence of amino acids. A protein is a functional unit composed of one or more polypeptides.	Proteins play a key role in cell structure and carry out a diverse array of cellular functions; for example, there are proteins involved with gene expression and regulation, motor proteins, defense proteins, cell-signaling proteins, metabolic enzymes, structural proteins, and transporters.	See Table 3.3
Nucleic acids	A nucleic acid is a linear sequence of nucleotides; DNA is double-stranded.	DNA stores genetic information in units called genes. RNA is made from DNA and provides access to that information.	DNA and RNA

ribose ($C_5H_{10}O_5$) and the closely related deoxyribose ($C_5H_{10}O_4$), which are part of RNA and DNA molecules, respectively, and are described later in this chapter. The most common hexose is glucose ($C_6H_{12}O_6$). Like other monosaccharides, glucose is very water-soluble and circulates in the blood or fluids of animals, where it can be transported across cell membranes. Once inside a cell, enzymes can break down glucose into smaller molecules, releasing energy that was stored in the chemical bonds of glucose. This energy is then stored in the bonds of another molecule, called adenosine triphosphate, or ATP (see Chapter 7), which, in turn, powers a variety of cellular processes. In this way, sugar is often used as a source of energy by living organisms.

Figure 3.5a depicts the bonds between atoms in a monosaccharide in both linear and ring forms, with the carbon atoms numbered by convention. The ring is made from the linear structure when the oxygen atom attached to carbon 5 forms a covalent bond with carbon 1. The hydrogen atoms and the hydroxyl groups may lie above or below the plane of the ring structure. The ring structure is the predominant type of structure found in living organisms.

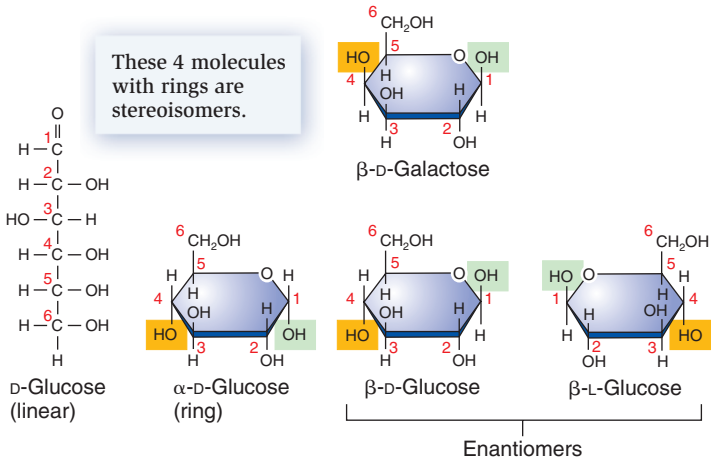


Figure 3.5 Monosaccharide structure. **(a)** A comparison of the linear and ring structures of glucose. In solution, such as the fluids of organisms, nearly all glucose is in the ring form. **(b)** Isomers of glucose. The locations of the hydroxyl groups on carbon 1 and carbon 4 are emphasized with green and orange boxes, respectively. Glucose exists as stereoisomers designated α- and β-glucose, which differ in the position of the —OH group attached to carbon atom number 1. Glucose and galactose differ in the position of the —OH group attached to carbon atom number 4. Enantiomers of glucose, called D-glucose and L-glucose, are mirror images of each other. D-Glucose is the form found in living cells.

BIOLOGY PRINCIPLE **Living organisms use energy.** The chemical energy stored in certain of the bonds of glucose molecules can be harnessed by living organisms. This energy can be used to perform numerous functions that support life, including the synthesis of new molecules, growth, digestion, locomotion, and many others.

Concept Check: With regard to their binding to enzymes, why do enantiomers such as D- and L-glucose have different biological properties?

Figure 3.5b compares different isomers of glucose. Glucose can exist as D- and L-glucose, which are mirror images of each other, or enantiomers.

D-Glucose is the isomer of glucose that is commonly found in living cells. It is recognized by enzymes that can synthesize polymers of D-glucose, such as starch. By comparison, L-glucose is rarely found in living cells, and it binds poorly to enzymes that recognize D-glucose. Other types of isomers are formed by changing the relative positions of the hydrogens and hydroxyl groups along the sugar ring. For example, glucose exists in two interconvertible forms, with the hydroxyl group attached to the number 1 carbon atom lying either above (the β form of glucose, Figure 3.5b) or below (the α form, Figure 3.5a) the plane of the ring. As another example, if the hydroxyl group on carbon atom number 4 of glucose is above the plane of the ring, the sugar called galactose is created (Figure 3.5b).

Monosaccharides can join together by dehydration to form larger carbohydrates. **Disaccharides** (meaning two sugars) are carbohydrates composed of two monosaccharides. A familiar disaccharide is sucrose, or table sugar, which is composed of the monomers glucose and fructose (**Figure 3.6**). Sucrose is the major transport form of sugar in plants. The linking together of most monosaccharides involves the removal of a hydroxyl group from one monosaccharide and a hydrogen atom from the other, giving rise to a molecule of water and covalently bonding the two sugars together through an oxygen atom. The bond formed between two sugar molecules by such a dehydration reaction is called a **glycosidic linkage**. Other disaccharides frequently found in nature are maltose, formed in animals during the digestion of large carbohydrates in the intestinal tract, and lactose, present in the milk of mammals. Maltose is α-D-glucose linked to α-D-glucose, and lactose is β-D-galactose linked to β-D-glucose.

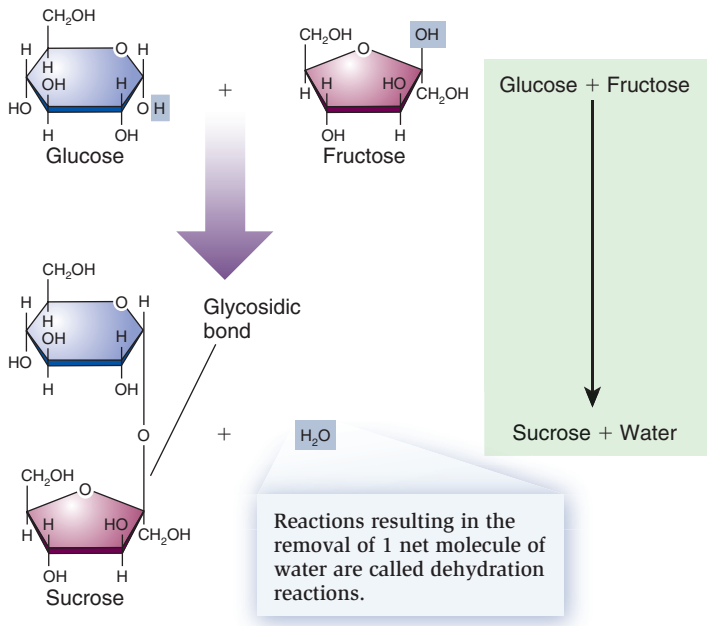

Figure 3.6 Formation of a disaccharide. Two monosaccharides can bond to each other to form a disaccharide, such as sucrose, maltose, or lactose, by a dehydration reaction.

Concept Check: What type of reaction is the reverse of the one shown here, in which a disaccharide is broken down into two monosaccharides?

Polysaccharides Are Carbohydrate Polymers That Include Starch, Glycogen, and Cellulose

When many monosaccharides are linked together to form long polymers, **polysaccharides** (meaning many sugars) are made. **Starch**, found in plant cells, and **glycogen**, in animal cells, are examples of polysaccharides (**Figure 3.7**). Both of these polysaccharides are composed of thousands of α-D-glucose molecules linked together in long, branched chains, differing only in the extent of branching along the chain. The bonds that connect the monomers are very specific. In starch and glycogen, the bonds form between carbons 1 and 4 and between carbons 1 and 6. The high degree of branching in glycogen contributes to its solubility in animal tissues, such as muscle tissue, because the extensive branching creates a more open structure in which many hydrophilic hydroxyl (—OH) side groups have access to water and can hydrogen-bond with it. Starch is less branched and less soluble, which contributes to the properties of plant structures (think of a potato or a kernel of corn).

Some polysaccharides, such as starch and glycogen, store energy in cells. Like disaccharides, polysaccharides can be hydrolyzed to yield monosaccharides, which are broken down to produce ATP, a common energy source for cells. Starch and glycogen, the polymers of α-glucose, provide an efficient means of storing energy for those times when a plant or animal cannot obtain sufficient energy from its environment or diet for its metabolic requirements.

Other polysaccharides provide a structural role, rather than storing energy. For example, cellulose is a major constituent of plant cell

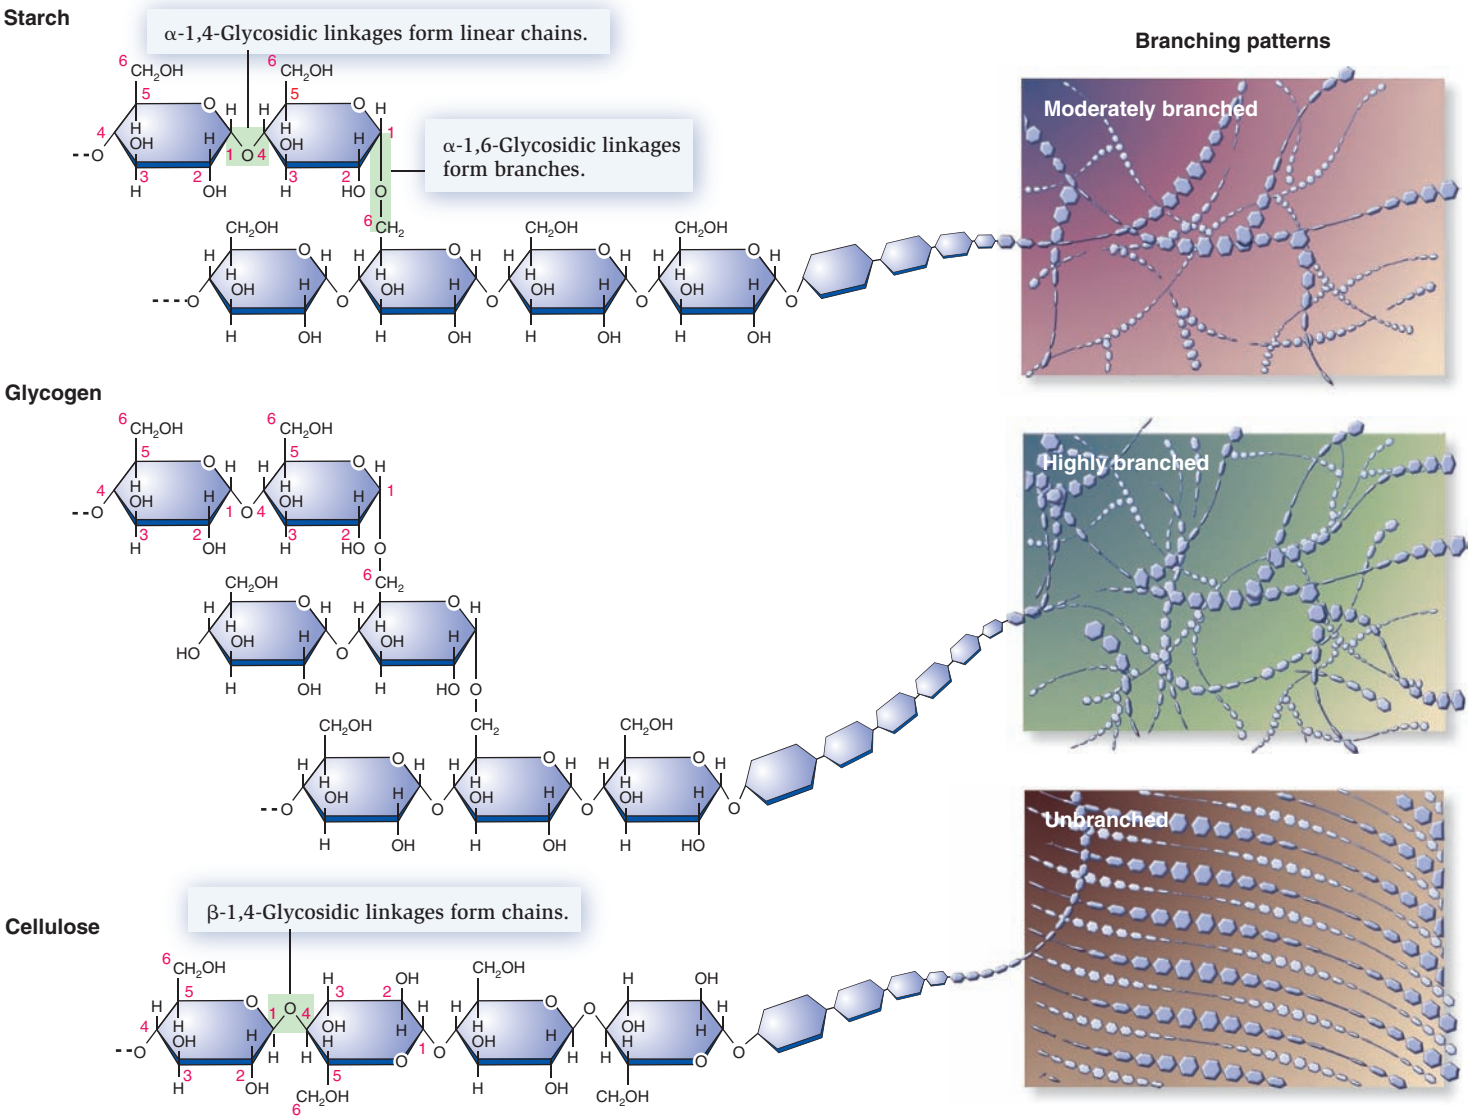

Figure 3.7 Polysaccharides that are polymers of glucose. These polysaccharides differ in their arrangement, extent of branching, and type of glucose isomer. In cellulose, the bonding arrangements cause every other glucose to be upside-down with respect to its neighbors.

BioConnections: Look ahead to Figures 10.5 and 10.6 for its role in plant structure and to Figures 35.10 and 35.11 for the role of cellulose in plant growth. Considering the amount of plant life on Earth, what might you conclude about the abundance of cellulose on the planet?

walls. **Cellulose** is a polymer of β-D-glucose, with a linear arrangement of carbon-carbon bonds and no branching (see Figure 3.7). Each glucose monomer in cellulose is in an opposite orientation from its adjacent monomers ("flipped over"), forming long chains of several thousand glucose monomers.

Linear chains of cellulose can form hydrogen bonds with each other and thereby arrange themselves in a parallel pattern (see the lower right panel in Figure 3.7). These sheets provide great strength to plant cell walls. The bond orientations in β-D-glucose prevent cellulose from being hydrolyzed for ATP production in most types of organisms. The enzymes that break the bonds between monomers of α-D-glucose in starch do not recognize the shape of the polymer made by the bonds between β-D-glucose monomers in cellulose. Therefore, plant cells can break down starch without breaking down cellulose. In this way, cellulose can be used for other functions, notably in the formation of the rigid cell-wall structure characteristic of plants.

Unlike most animals and plants, some organisms do have an enzyme capable of breaking down cellulose. For example, certain bacteria present in the gastrointestinal tracts of grass and wood eaters, such as cows and termites, respectively, can digest cellulose into usable monosaccharides because they contain an enzyme that can hydrolyze the bonds between β-D-glucose monomers. Humans lack this enzyme. Therefore, we eliminate in the feces most of the cellulose ingested in our diet. Undigestible plant matter we consume is commonly referred to as fiber.

Other polysaccharides also play structural roles. **Chitin**, a tough, structural polysaccharide, forms the external skeleton of insects and crustaceans (shrimp and lobsters) as well as the cell walls of fungi. The sugar monomers within chitin have nitrogen-containing groups attached to them. **Glycosaminoglycans** are large polysaccharides that play a structural role in animals. For example, they are abundantly found in cartilage, the tough, fibrous material found in joints and other animal structures. Glycosaminoglycans are also abundant in the extracellular matrix that provides a structural framework surrounding many of the cells in an animal's body (look ahead to Figure 10.4).

3.5 Lipids

Learning Outcomes:

1. List the several classes of lipid molecules important in living organisms.
2. Diagram the structure of a triglyceride and explain how it is affected by the presence of saturated and unsaturated fatty acids.
3. Explain why some fats are solid at room temperature, and others are liquid.
4. Discuss how fats function as energy-storage molecules.
5. Explain why phospholipids form a bilayer when dissolved in water.
6. Describe the chemical nature of steroids and give an example of their biological importance.

Lipids are hydrophobic molecules composed mainly of hydrogen and carbon atoms, and some oxygen. The defining feature of lipids is that they are nonpolar and therefore insoluble in water. Lipids account for about 40% of the organic matter in the average human body and include fats, phospholipids, steroids, and waxes.

Triglycerides Are Made from Glycerol and Fatty Acids

Triglycerides (often called fats) are formed by bonding glycerol to three fatty acids (**Figure 3.8**). Glycerol is a three-carbon molecule with one hydroxyl group (—OH) bonded to each carbon. A fatty acid is a chain of carbon and hydrogen atoms with a carboxyl group (—COOH) at one end. Each of the hydroxyl groups in glycerol is linked to the carboxyl group of a fatty acid by the removal of a molecule of water by a dehydration reaction. The resulting bond is an ester bond.

Fatty Acids May Differ in Length and Contain Double Bonds

The fatty acids found in fats and other lipids may differ with regard to their lengths and the presence of double bonds (**Figure 3.9**). Most fatty acids in nature have an even number of carbon atoms, with

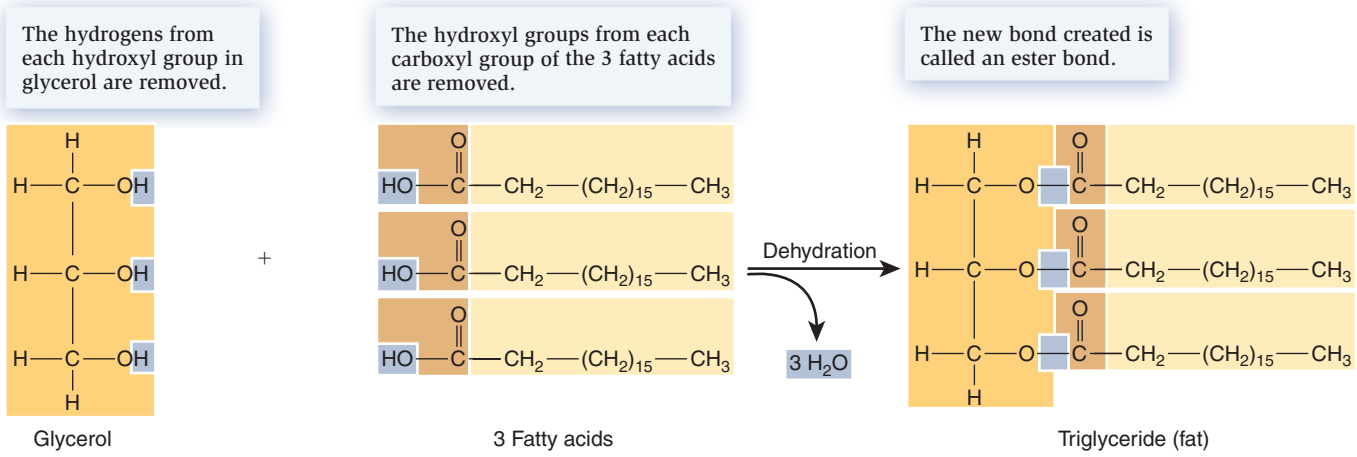

Figure 3.8 The formation of a triglyceride. The formation of a triglyceride occurs via three dehydration reactions in which fatty acids are bonded to glycerol. Note in this figure and in Figure 3.9, a common shorthand notation is used for depicting fatty acid chains, in which a portion of the CH_2 groups are illustrated as $(CH_2)_n$, where n is 2 or greater.

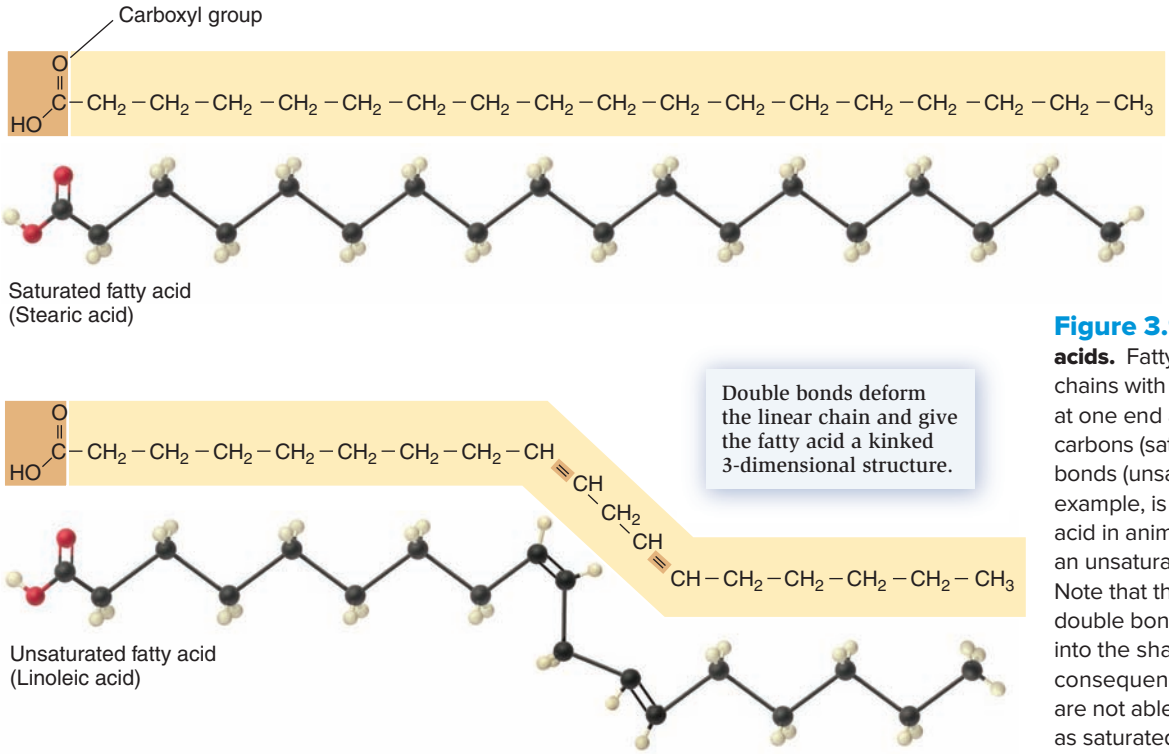

Figure 3.9 Examples of fatty acids. Fatty acids are hydrocarbon chains with a carboxyl functional group at one end and either no double-bonded carbons (saturated) or one or more double bonds (unsaturated). Stearic acid, for example, is an abundant saturated fatty acid in animals, whereas linoleic acid is an unsaturated fatty acid found in plants. Note that the presence of two C═C double bonds introduces two kinks into the shape of linoleic acid. As a consequence, unsaturated fatty acids are not able to pack together as tightly as saturated fatty acids.

16- and 18-carbon fatty acids being the most common in the cells of plants and animals.

Fatty acids also differ with regard to the presence of double bonds. When all of the carbons in a fatty acid are linked by single covalent bonds, the fatty acid is said to be a **saturated fatty acid**, because all of the carbons are saturated with covalently bound hydrogen. Alternatively, some fatty acids contain one or more C═C double bonds. These fatty acids are known as **unsaturated fatty acids**. The C═C double bond introduces a kink into the linear shape of a fatty acid. A fatty acid with one C═C bond is a monounsaturated fatty acid, whereas a fatty acid with two or more C═C bonds is a polyunsaturated fatty acid.

In organisms such as mammals, certain fatty acids are necessary for good health but cannot be synthesized by the body. Such fatty acids are called essential fatty acids, because they must be obtained in the diet; one example is linoleic acid (see Figure 3.9).

Fats (triglycerides) that contain high amounts of saturated fatty acids pack together tightly, resulting in numerous intermolecular interactions that stabilize the fat. Saturated fats have a high melting point and tend to be solid at room temperature. Animal fats generally contain a high proportion of saturated fatty acids. For example, beef fat contains high amounts of stearic acid, a saturated fatty acid with a melting point of 70°C (see Figure 3.9). When you heat a hamburger on the stove, the stearic acid and other saturated animal fats melt, and liquid grease appears in the frying pan (**Figure 3.10**). When allowed to cool to room temperature, however, the liquid grease in the pan returns to its solid form.

Because of kinks in their chains, unsaturated fatty acids do not pack together as tightly as saturated fatty acids. Fats high in unsaturated fatty acids usually have low melting points and are liquid at room temperature. Such fats are called oils. Fats derived from plants

High temperature converts solid, saturated fats to liquid.

After cooling, saturated fats return to their solid form.

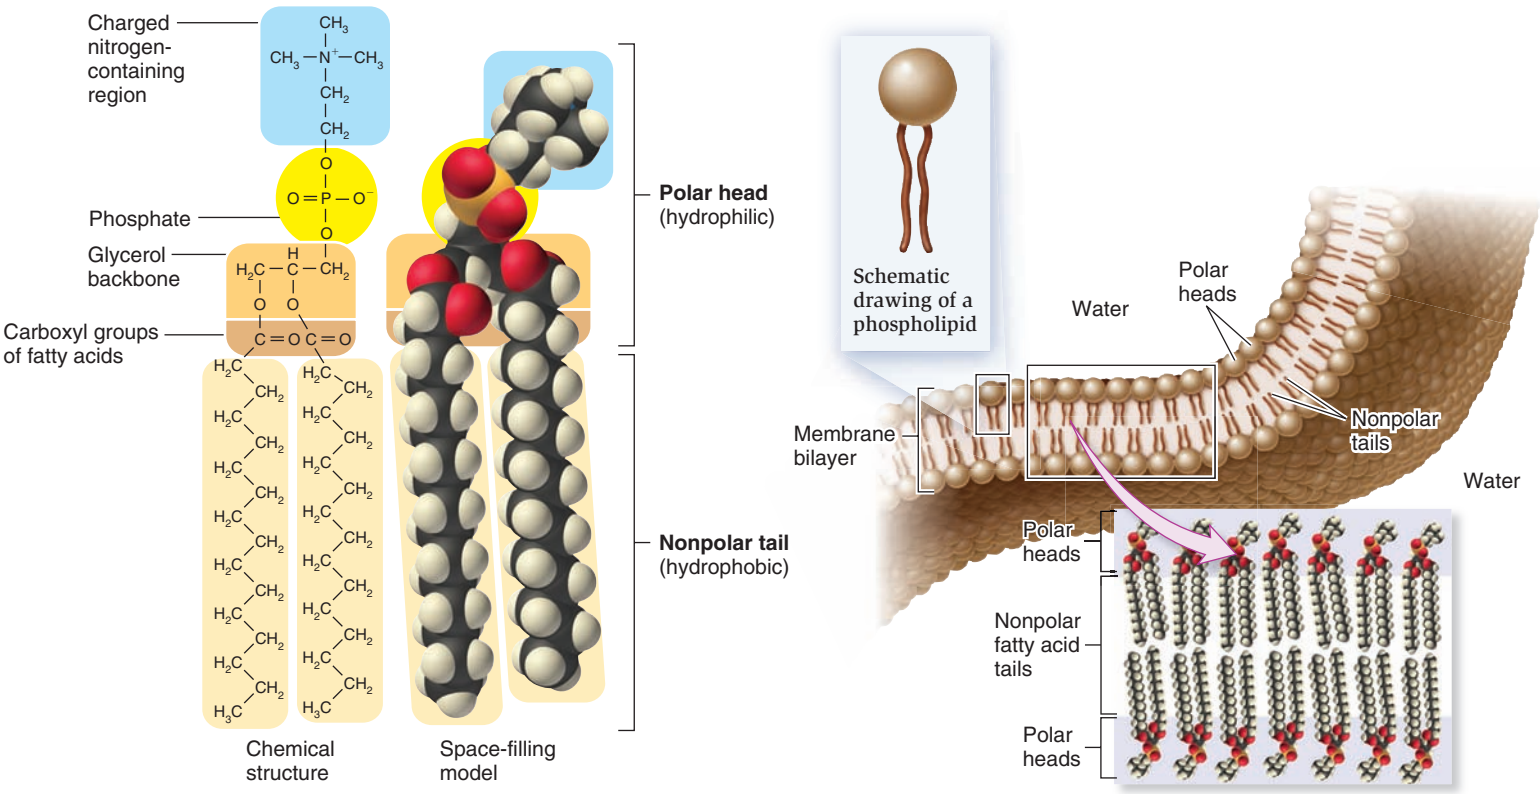
(a) Animal fats at high and low temperatures

Unsaturated fats have low melting points and are liquid at room temperature.

(b) Vegetable fats at low temperature

Figure 3.10 Fats at different temperatures. Saturated fats found in animals tend to have high melting points compared with unsaturated fats found in plants.

Concept Check: Certain types of fats used in baking are called shortenings. Shortenings are often made from vegetable oils by a process called hydrogenation, in which the addition of hydrogens causes double bonds to become single bonds. What do you think happens to such oils when they are hydrogenated?



generally contain unsaturated fatty acids. For example, olive oil contains high amounts of oleic acid, a monounsaturated fatty acid with a melting point of 16°C. Fatty acids with additional double bonds have even lower melting points. For example, linoleic acid (see Figure 3.9) has two double bonds and melts at –5°C. Safflower and sunflower oils contain high amounts of linoleic acid.

Most unsaturated fatty acids, including linoleic acid, exist in nature in the *cis* form (see Figure 3.3). Of particular concern to human health, however, are *trans* fatty acids, which are formed by an artificial process in which the natural *cis* form is altered to a *trans* configuration. This gives the fats that contain such fatty acids a more compact, linear structure and, therefore, a higher melting point. Although this process has been used for many years to produce fats with a longer shelf-life and with better characteristics for baking, research has revealed that *trans* fats are linked with human disease. Notable among these is coronary artery disease, caused by a narrowing of the blood vessels that supply the heart with blood.

Like starch and glycogen, fats are important for storing energy. The hydrolysis of triglycerides releases the fatty acids from glycerol, and these products can then be metabolized to provide energy to make ATP. Certain organisms, most notably mammals, have the ability to store large amounts of energy by accumulating fats. The number of C—H bonds in a molecule of fat or carbohydrate determines in part how much energy the molecule can yield. Fats contain many C—H bonds, whereas glucose and other carbohydrates have numerous C—OH bonds. Consequently, 1 gram of fat stores more energy than does 1 gram of starch or glycogen. Fat is therefore an efficient means of energy storage for mobile organisms in which excess body mass may be a disadvantage. In animals, fats can also play a structural role by forming cushions that support organs. In addition, fats provide insulation under the skin that helps protect many terrestrial animals during cold weather and marine mammals in cold water.

Phospholipids Are Amphipathic Lipids

Phospholipids, another class of lipids, are similar in structure to triglycerides but with one important difference. The third hydroxyl group of glycerol is linked to a phosphate group instead of a fatty acid. In most phospholipids, a small polar or charged nitrogen-containing molecule is attached to this phosphate (**Figure 3.11a**). The

(a) Structure and model of a phospholipid

(b) Arrangement of phospholipids in a bilayer

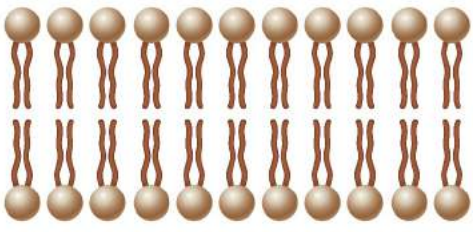
Figure 3.11 Structure of phospholipids. **(a)** Chemical structure and space-filling model of phosphatidylcholine, a common phospholipid found in living organisms. Phospholipids contain both polar and nonpolar regions, making them amphipathic. The fatty-acid tails are nonpolar. The rest of the molecule is polar. **(b)** Arrangement of phospholipids in a biological membrane, such as the plasma membrane that encloses cells. The polar regions of the phospholipids face the watery environment, whereas the nonpolar regions associate with each other in the interior of the membrane, forming a bilayer.

Concept Check: *When water and oil are added to a test tube, the two liquids form two separate layers (think of oil and vinegar in a bottle of salad dressing). If a solution of phospholipids was added to a mixture of water and oil, where would the phospholipids dissolve?*

BioConnections: *For a more detailed view of the components of cellular membranes, including the phospholipid bilayer, look ahead to Figure 5.1.*

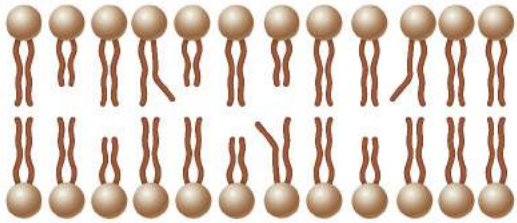
glycerol backbone, phosphate group, and a charged molecule (in this case, choline) constitute a hydrophilic head at one end of the phospholipid, whereas the fatty acid chains are hydrophobic tails at the opposite end. Recall from Chapter 2 that molecules with polar and nonpolar regions are called amphipathic molecules.

In water, phospholipids become organized into bilayers, with their polar heads interacting with the water molecules and their nonpolar tails facing the interior, where they are shielded from water. As you will learn in Chapter 5, this bilayer arrangement of phospholipids is critical for determining the structure of cellular membranes, as shown in **Figure 3.11b**.



BIO TIPS **THE QUESTION** *Biological membranes contain a phospholipid bilayer. As discussed in Chapter 5, membranes are somewhat fluid. For example, lipids move laterally within a membrane. When the lipid molecules are packed tightly together, the membrane tends to be less fluid than when they are more loosely packed.*

Let's suppose that one membrane is composed primarily of lipids with long nonpolar tails that do not have any double bonds. A second membrane has some lipids with long nonpolar tails and others with short nonpolar tails. Also, some of the longer tails in this second membrane contain double bonds. Which of these two membranes would you expect to be less fluid?



TOPIC ***What topic in biology does this question address?*** The topic is how lipid structure may affect the fluidity of a membrane.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you have learned that membranes with tightly packed lipids are less fluid than membranes in which the lipids are loosely packed. From your understanding of the topic, you may recall that the hydrophobic lipid tails associate with each other in the nonpolar region of the membrane (see Figure 3.11b). You may also remember that phospholipids vary with regard to the lengths of their nonpolar tails and that a double bond introduces a kink into the tail.

PROBLEM-SOLVING STRATEGY ***Make a drawing. Compare and contrast.*** One strategy to solve this problem is to make a drawing that shows the structures of these two types of membrane. Then compare the two structures, and decide which membrane is more tightly packed.

All long nonpolar tails

A mixture of long and short nonpolar tails, with double bonds in some of the long tails

ANSWER *When you compare the structures in the two drawings, the lipids are more tightly packed in the membrane that is composed primarily of lipids with long nonpolar tails, which is the first structure. As you can see, there is less open space in this membrane. It would be less fluid than the membrane in the second drawing.*

Steroids Contain Ring Structures

Steroids have a distinctly different chemical structure from the other types of lipid molecules discussed thus far. Four fused rings of carbon atoms form the skeleton of all steroids. One or more polar hydroxyl groups are attached to this ring structure, but they are not numerous enough to make a steroid highly water-soluble. For example, steroids with a hydroxyl group are known as sterols—one of the most well known being cholesterol (**Figure 3.12**, top). Cholesterol is found in the blood and cellular membranes of animals.

In steroids, minor differences in chemical structure lead to profoundly different biological properties. For example, all steroid hormones are derived from cholesterol and share similarities in structure, but with some important differences. Estrogen is a steroid hormone found in high amounts in female vertebrates. Estrogen differs from testosterone, a steroid hormone found largely in males, by having one less methyl group, a hydroxyl group instead of a ketone group (see Table 3.1), and additional double bonds in one of its rings (Figure 3.12, bottom). However, these small differences are sufficient to make these two molecules largely responsible for whether an animal exhibits male or female characteristics, including feather color in birds.

Waxes Are Complex Lipids That Prevent Water Loss from Organisms

Many plants and animals produce lipids called waxes that are secreted onto their surface, such as the leaves of plants and the cuticles of insects. Although any wax may contain hundreds of different compounds, all waxes contain one or more hydrocarbons and long structures that resemble a fatty acid attached by its carboxyl group to another long hydrocarbon chain. Most waxes are very nonpolar and therefore exclude water, providing a barrier to water loss. They may also be used as structural elements in colonies like those of bees, where beeswax forms the honeycomb of the hive.

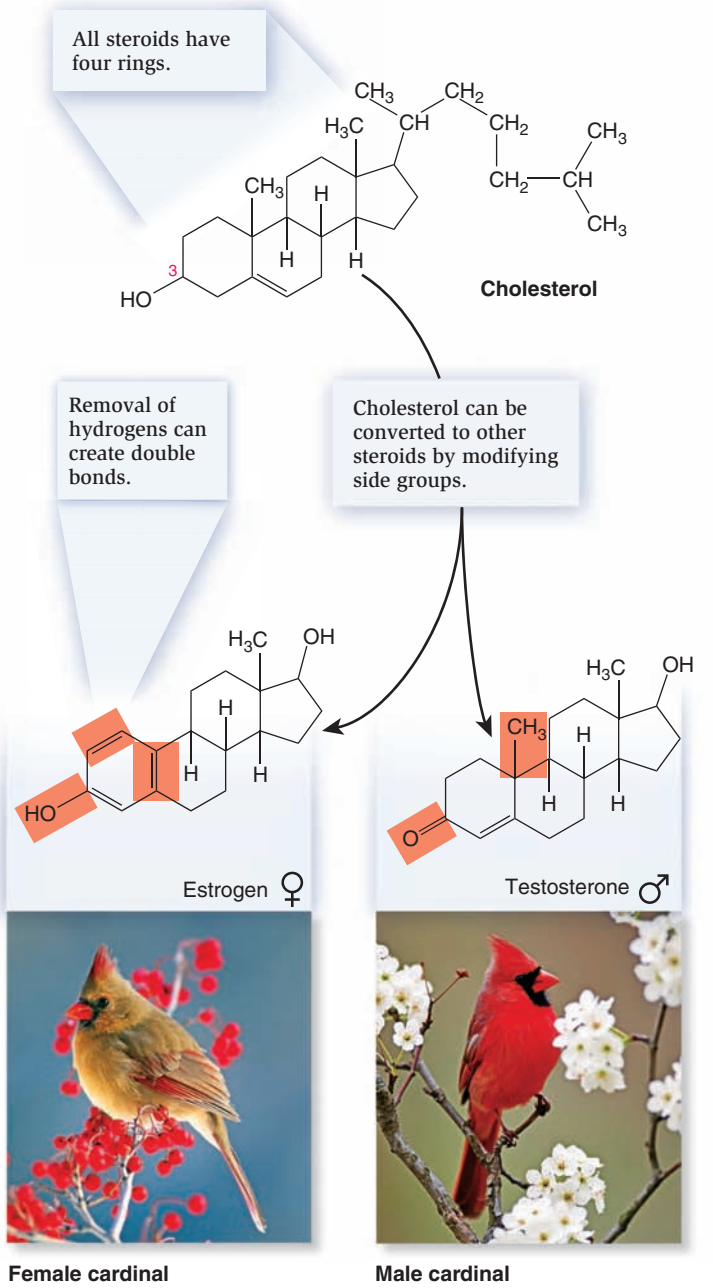


Figure 3.12 Structure of cholesterol and steroid hormones derived from cholesterol. The structure of a steroid has four rings. Steroids include cholesterol and molecules derived from cholesterol, such as steroid hormones. These include the reproductive hormones estrogen and testosterone.

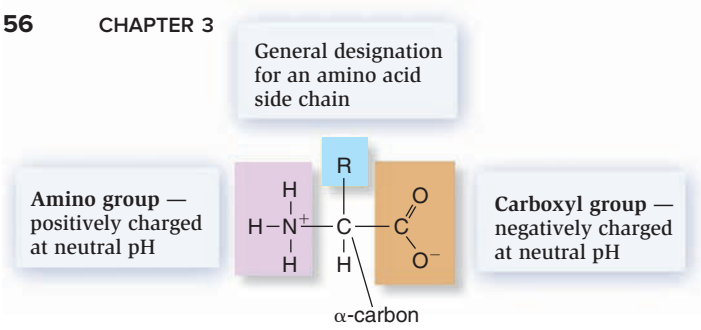
BIOLOGY PRINCIPLE Structure determines function. The minor chemical (structural) differences between estrogen and testosterone dramatically alter their biological functions. The differences between female and male cardinals are one example of sex-dependent differences in form and function in the animal world that are due to these two hormones.

3.6 Proteins

Learning Outcomes:

1. Give examples of the general functions that are carried out by different proteins.
2. Describe how amino acids are joined to form a polypeptide, and distinguish between a polypeptide and a protein.
3. Explain the four levels of protein structure.
4. Outline the factors that determine protein shape and function.
5. Define protein domain.



Proteins play critical roles in nearly all life processes (**Table 3.3**). The word protein comes from the Greek *proteios* (meaning of the first rank), which aptly describes their importance. Proteins account for about 50% of the organic material in a typical animal's body. In this section, we will survey the structure and function of proteins.

Amino Acids Are the Building Blocks of Proteins

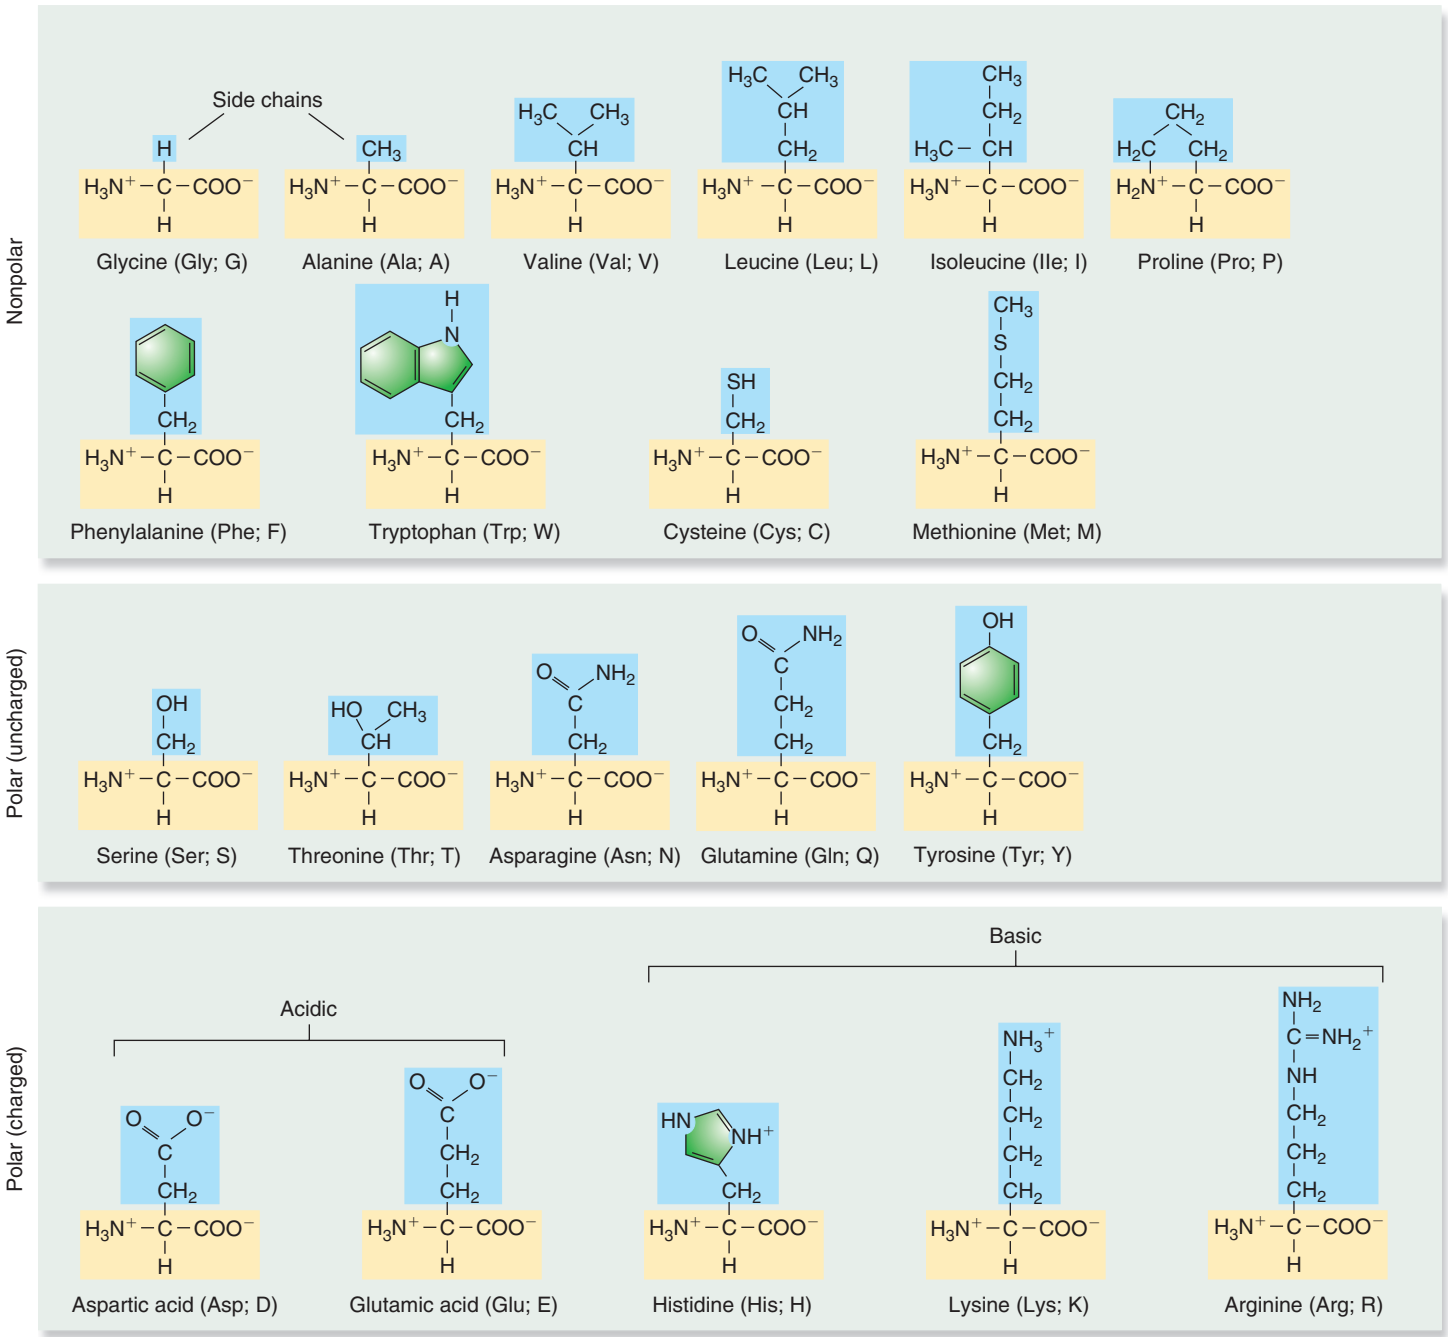
Proteins are composed of carbon, hydrogen, oxygen, nitrogen, and small amounts of other elements, notably sulfur. The monomers of proteins are **amino acids**, compounds with a structure in which a carbon atom, called the α-carbon, is linked to an amino group (—NH_2) and a carboxyl group (—COOH). The α-carbon also is linked to a hydrogen atom and a side chain, designated with the letter R. Proteins are polymers of amino acids.

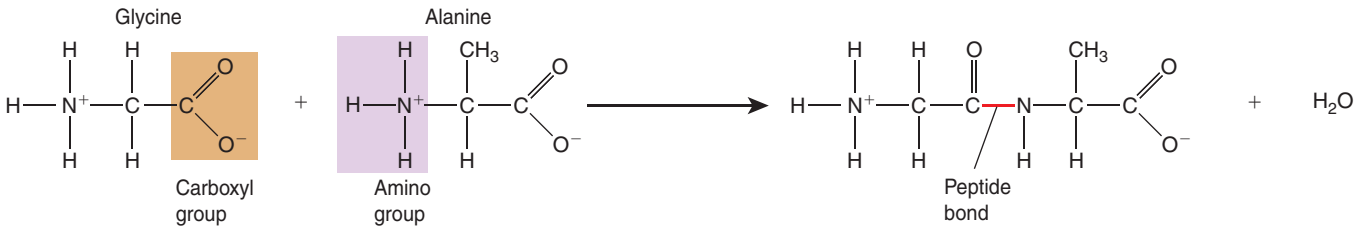
Table 3.3 Major Categories and Functions of Proteins

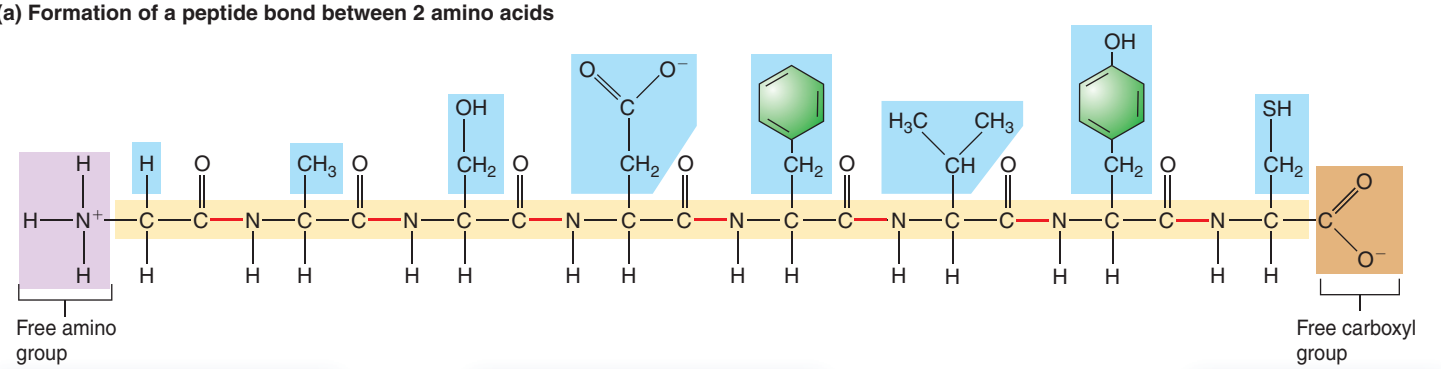
Category	Functions	Examples
Proteins involved in gene expression and regulation	Make mRNA from a DNA template; synthesize polypeptides from mRNA; regulate genes	RNA polymerase assists in synthesizing RNA from DNA.
Motor proteins	Initiate movement	Myosin provides the contractile force of muscles.
Defense proteins	Protect organisms against disease	Antibodies help destroy bacteria or viruses.
Metabolic enzymes	Increase rates of chemical reactions	Hexokinase is an enzyme involved in sugar metabolism.
Cell-signaling proteins	Enable cells to communicate with each other and with the environment	Taste receptors in the tongue allow animals to taste molecules in food.
Structural proteins	Support and strengthen structures	Actin provides shape to the cytoplasm of plant and animal cells. Collagen gives strength to tendons.
Transporters	Promote movement of solutes across membranes	Glucose transporters move glucose from outside cells to inside cells, where it can be used for energy.

When an amino acid is dissolved in water at neutral pH, the amino group accepts a hydrogen ion and is positively charged, whereas the carboxyl group loses a hydrogen ion and is negatively charged. The term amino acid is the name given to such molecules because they have an amino group and also a carboxyl group that acts as an acid.

All amino acids except glycine exist in more than one isomeric form, called the D and L forms, which are enantiomers. Only L-amino acids are found in proteins. D-amino acids are not found in most cells. An exception is the cell walls of certain bacteria, where they may play a protective role against molecules secreted by the host organism in which the bacteria live.







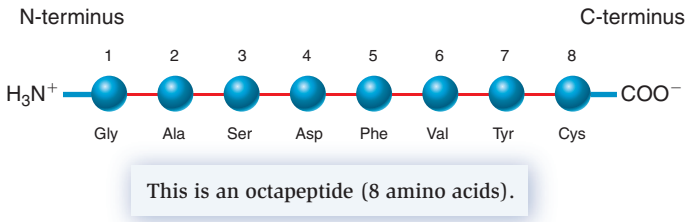


Figure 3.13 The 20 amino acids found in living organisms. Amino acids have different chemical properties (for example, nonpolar versus polar) due to the nature of their different side chains, which are highlighted in blue. These properties contribute to the differences in the three-dimensional shapes and chemical properties of proteins, which, in turn, influence their biological functions. Note: Tyrosine has both polar and nonpolar characteristics and is listed in just one category for simplicity. The common three-letter and one-letter abbreviations for each amino acid are shown in parentheses.

(a) Formation of a peptide bond between 2 amino acids

(b) Polypeptide—a linear chain of amino acids

(c) Numbering system of amino acids in a polypeptide

Figure 3.14 The chemistry of polypeptide formation.
Polypeptides are polymers of amino acids. They are formed by linking amino acids via dehydration reactions to make peptide bonds. Every polypeptide has an amino end, or N-terminus, and a carboxyl end, or C-terminus.

Concept Check: How many water molecules would be produced in making a polypeptide that is 72 amino acids long?

The 20 amino acids in proteins are distinguished by their side chains (**Figure 3.13**). The amino acids are categorized by the properties of their side chains, whether nonpolar, polar and uncharged, or polar and charged. The structures of the side chains are critical features of protein structure and function. The arrangement and chemical features of the side chains cause proteins to fold and adopt their three-dimensional shapes. In addition, certain amino acids may be critical in protein function. For example, amino acid side chains found within the active sites of enzymes are important in catalyzing chemical reactions.

Polypeptides Are Linear Sequences of Amino Acids

Amino acids are joined together by a dehydration reaction that links the carboxyl group of one amino acid to the amino group of another (**Figure 3.14a**). The covalent bond formed between a carboxyl and amino group is called a **peptide bond**. When multiple amino acids are joined by peptide bonds, the resulting molecule is called a **polypeptide** (**Figure 3.14b**). The backbone of the polypeptide in Figure 3.14 is highlighted in yellow. The amino acid side chains project from the backbone. When two or more amino acids are linked together, one end of the resulting molecule has a free amino group. This is the amino end, or **N-terminus**. The other end of the polypeptide, called the carboxyl end, or **C-terminus**, has a free carboxyl group. As shown in **Figure 3.14c**, amino acids within a polypeptide are numbered from the N-terminus to the C-terminus.

The term polypeptide refers to a structural unit composed of a linear sequence of amino acids. A **protein** is a functional unit composed of one or more polypeptides that have been folded and twisted into a precise three-dimensional shape. Many proteins also have carbohydrates (glycoproteins) or lipids (lipoproteins) attached at various points along their amino acid chain; these modifications impart unique functions to such proteins.

Proteins Have a Hierarchy of Structure

Scientists view protein structure at four progressive levels: primary, secondary, tertiary, and quaternary, shown schematically in **Figure 3.15**. Each higher level of structure depends on the preceding levels. For example, changing the primary structure may affect the secondary, tertiary, and quaternary structures. Let's now consider each level separately.

Primary Structure The **primary structure** (see Figure 3.15) of a protein is its amino acid sequence, from beginning to end. The primary structures of proteins are determined by genes. As we will

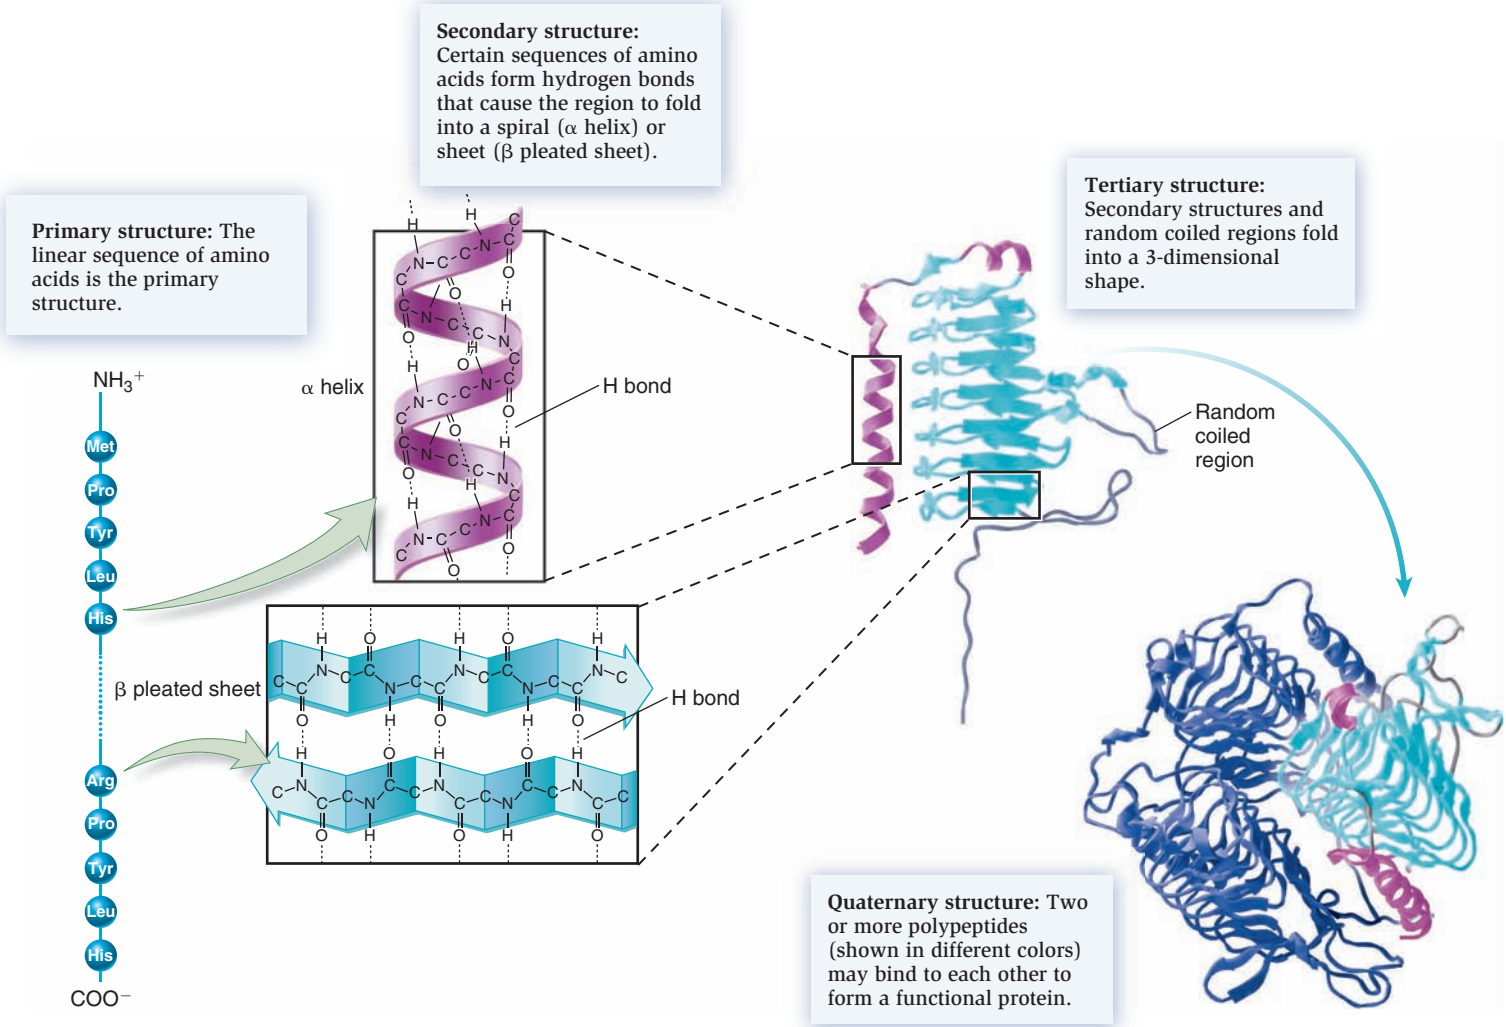

Figure 3.15 **The hierarchy of protein structure.** The R groups are omitted for simplicity.

explore in Chapter 12, genes carry the information for the production of polypeptides with specific amino acid sequences.

Figure 3.16 shows the primary structure of ribonuclease, which functions as an enzyme to degrade ribonucleic acid (RNA) molecules after they are no longer required by a cell. As described later and in Unit III, RNA carries the information for protein synthesis. Ribonuclease is composed of a relatively short polypeptide consisting of 124 amino acids. An average polypeptide is about 300 to 500 amino acids in length, but some polypeptides form proteins that are a few thousand amino acids long.

Secondary Structure The amino acid sequence of a polypeptide, together with the laws of chemistry and physics, cause a protein to fold into a more compact structure. Amino acids can rotate around bonds within a polypeptide. Consequently, proteins are flexible and can fold into a number of shapes, just as a string of beads can be twisted into many configurations. Folding can be irregular, or certain regions can have a repeating folding pattern called **secondary structure**. The two basic types of a protein's secondary structure are the α helix and the β pleated sheet.

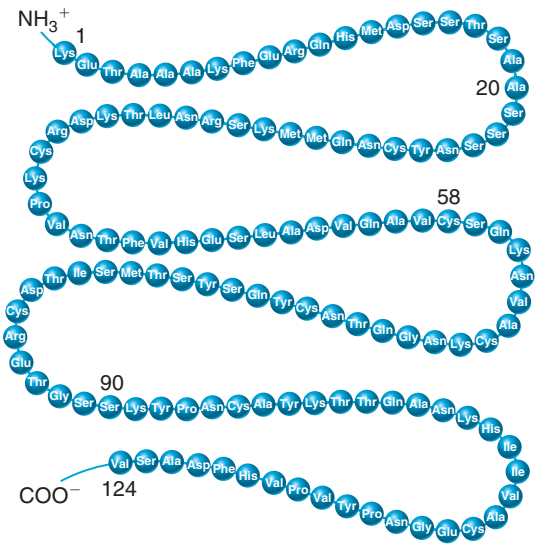

Figure 3.16 **The primary structure of ribonuclease.** The example shown here is ribonuclease from cows, which contains 124 amino acids.

In an α helix, the polypeptide backbone forms a repeating helical structure that is stabilized by hydrogen bonds along the length of the backbone. As shown in Figure 3.15, the hydrogen linked to a nitrogen atom forms a hydrogen bond with an oxygen atom that is double-bonded to a carbon atom. These hydrogen bonds occur at regular intervals within the polypeptide backbone and cause the backbone to twist into a helix.

In a β pleated sheet, regions of the polypeptide backbone lie parallel to each other. Hydrogen bonds between a hydrogen linked to a nitrogen atom and a double-bonded oxygen form between these adjacent, parallel regions. When this occurs, the polypeptide backbone adopts a repeating zigzag, or pleated, shape.

The α helices and β pleated sheets are key determinants of a protein's characteristics. For example, α helices in certain proteins are composed primarily of nonpolar amino acids. Proteins containing stretches of nonpolar amino acids tend to anchor themselves into a lipid-rich environment, such as a cell's plasma membrane. In this way, a protein whose function is required in a specific location such as a plasma membrane can be retained there. Secondary structure also contributes to the great strength of certain proteins, including the keratins found in hair and hooves; the proteins that make up the silk webs of spiders; and collagen, the chief component of cartilage in vertebrate animals.

Some regions along a polypeptide chain do not assume an α helix or β pleated sheet conformation and do not have a secondary structure. These regions are sometimes called random coiled regions. However, this term is somewhat misleading because the shapes of random coiled regions are usually very specific and important for the protein's function.

Tertiary Structure As the secondary structure of a polypeptide becomes established due to the particular primary structure, side chains of amino acids interact with each other. The polypeptide folds and refolds upon itself to assume a complex three-dimensional shape—its **tertiary structure** (see Figure 3.15). The tertiary structure is the three-dimensional shape of a single polypeptide. Tertiary structure includes all secondary structures plus any interactions involving amino acid side chains. For some proteins, such as ribonuclease, the tertiary structure is the final structure of a functional protein. However, as described next, other proteins are composed of two or more polypeptides and adopt a quaternary structure.

Quaternary Structure Most functional proteins are composed of two or more polypeptides that each adopt a tertiary structure and then assemble with each other (see Figure 3.15). The individual polypeptides are called **protein subunits**. Subunits may be identical polypeptides or they may be different. When proteins consist of more than one polypeptide, they are said to have **quaternary structure**. A common example is the oxygen-binding protein called hemoglobin, found in the red blood cells of vertebrate animals. Four protein subunits combine to form one hemoglobin protein. Each subunit can bind a single molecule of oxygen; therefore, each hemoglobin protein can carry four molecules of oxygen in the blood.

Protein Structure Is Determined by Several Factors

The amino acid sequences of polypeptides distinguish the structure of one protein from another. As polypeptides are synthesized in a cell, they fold into secondary and tertiary structures, which assemble into quaternary structures for most proteins. Several factors determine the way proteins adopt their secondary, tertiary, and quaternary structures. As shown in **Figure 3.17**, five factors are critical for protein folding and stability:

1. *Hydrogen bonds*—The large number of weak hydrogen bonds within a polypeptide and between polypeptides adds up to a collectively strong force that promotes protein folding and stability. As we already learned, hydrogen bonding is a critical determinant of protein secondary structure and also is important in tertiary and quaternary structure.
2. *Ionic bonds and other polar interactions*—Some amino acid side chains are positively or negatively charged. Positively charged side chains may bind to negatively charged side chains via ionic bonds. Similarly, uncharged polar side chains in a protein may bind to ionic amino acids. Ionic bonds and polar interactions are particularly important in tertiary and quaternary structure.
3. *Hydrophobic effect*—Some amino acid side chains are nonpolar. As a protein folds, the hydrophobic amino acids are likely to be found in the center of the protein, minimizing contact with water. As mentioned, some proteins have stretches of nonpolar amino acids that anchor them in the hydrophobic portion of membranes. The hydrophobic effect plays a major role in tertiary and quaternary structures.
4. *van der Waals dispersion forces*—Atoms within molecules have temporary weak attractions for each other if they are an optimal distance apart. This weak attraction is termed the van der Waals force (see Chapter 2). If two atoms are too close together, their electron clouds will repel each other. If they are far apart, the van der Waals dispersion forces will diminish. The van der Waals dispersion forces are important in determining tertiary structures.
5. *Disulfide bridges*—The side chain of the amino acid cysteine contains a sulfhydryl group (—SH), which can react with a sulfhydryl group in another cysteine side chain (see Figure 3.13). The result is a **disulfide bridge**, or disulfide bond, which links the two amino acid side chains together (—S—S—). Disulfide bridges are covalent bonds that can occur within a polypeptide or between different polypeptides. Though other forces are usually more important in protein folding, the covalent nature of disulfide bridges can help to stabilize the structure of a protein.

The first four factors just described are also important in the ability of different proteins to interact with each other. As discussed throughout Unit II and other parts of this textbook, many cellular processes involve steps in which two or more different proteins interact with each other. For this to occur, one protein must recognize and bind to the surface of the other. Such binding is usually very specific. The surface of one protein precisely fits into the surface of another (**Figure 3.18**). Such **protein-protein interactions** are critically important so that cellular processes can occur in a series of defined steps. In addition, protein-protein interactions are important in building complicated cellular structures that provide shape and organization to cells.

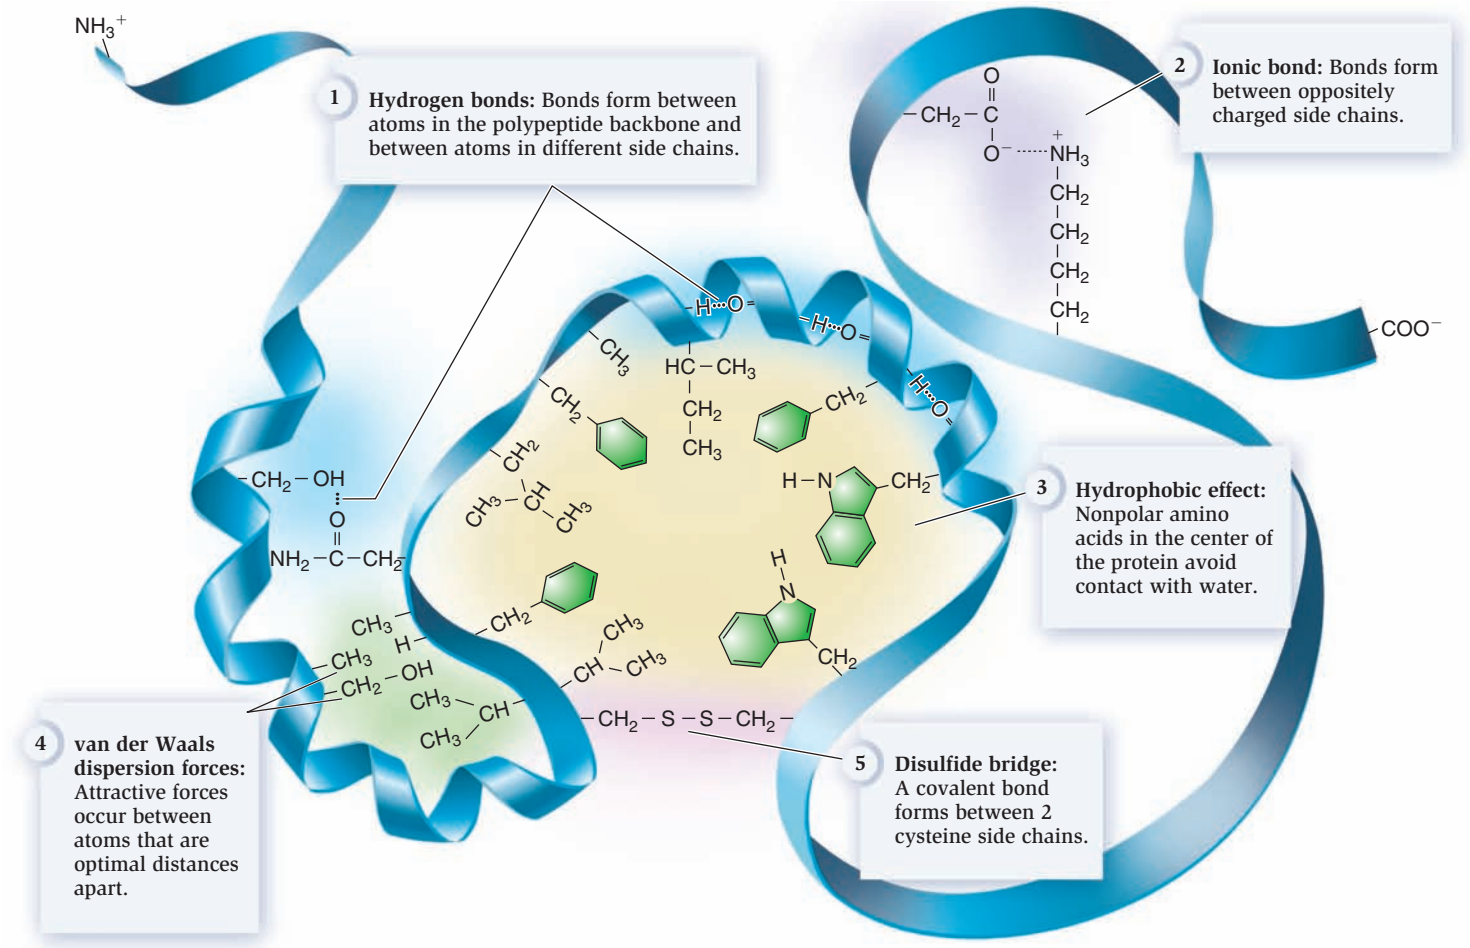

Figure 3.17 **Factors that influence protein folding and stability.**

BIOLOGY PRINCIPLE **New properties emerge from complex interactions.** This key principle of biology is apparent even at the molecular level. As seen in this figure, several distinct types of chemical interactions produce a protein with a complex shape. The three-dimensional shape of different proteins determines their functions and their ability to interact with other cellular components.

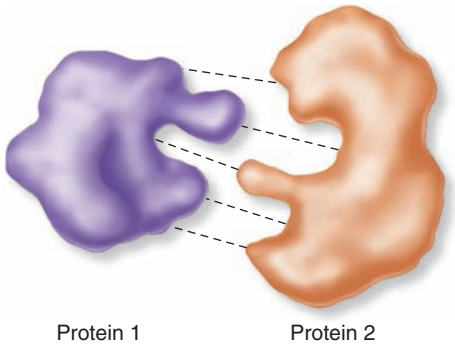

Figure 3.18 **Protein-protein interaction.** Two different proteins may interact with each other due to hydrogen bonding, ionic bonding, the hydrophobic effect, and van der Waals dispersion forces.

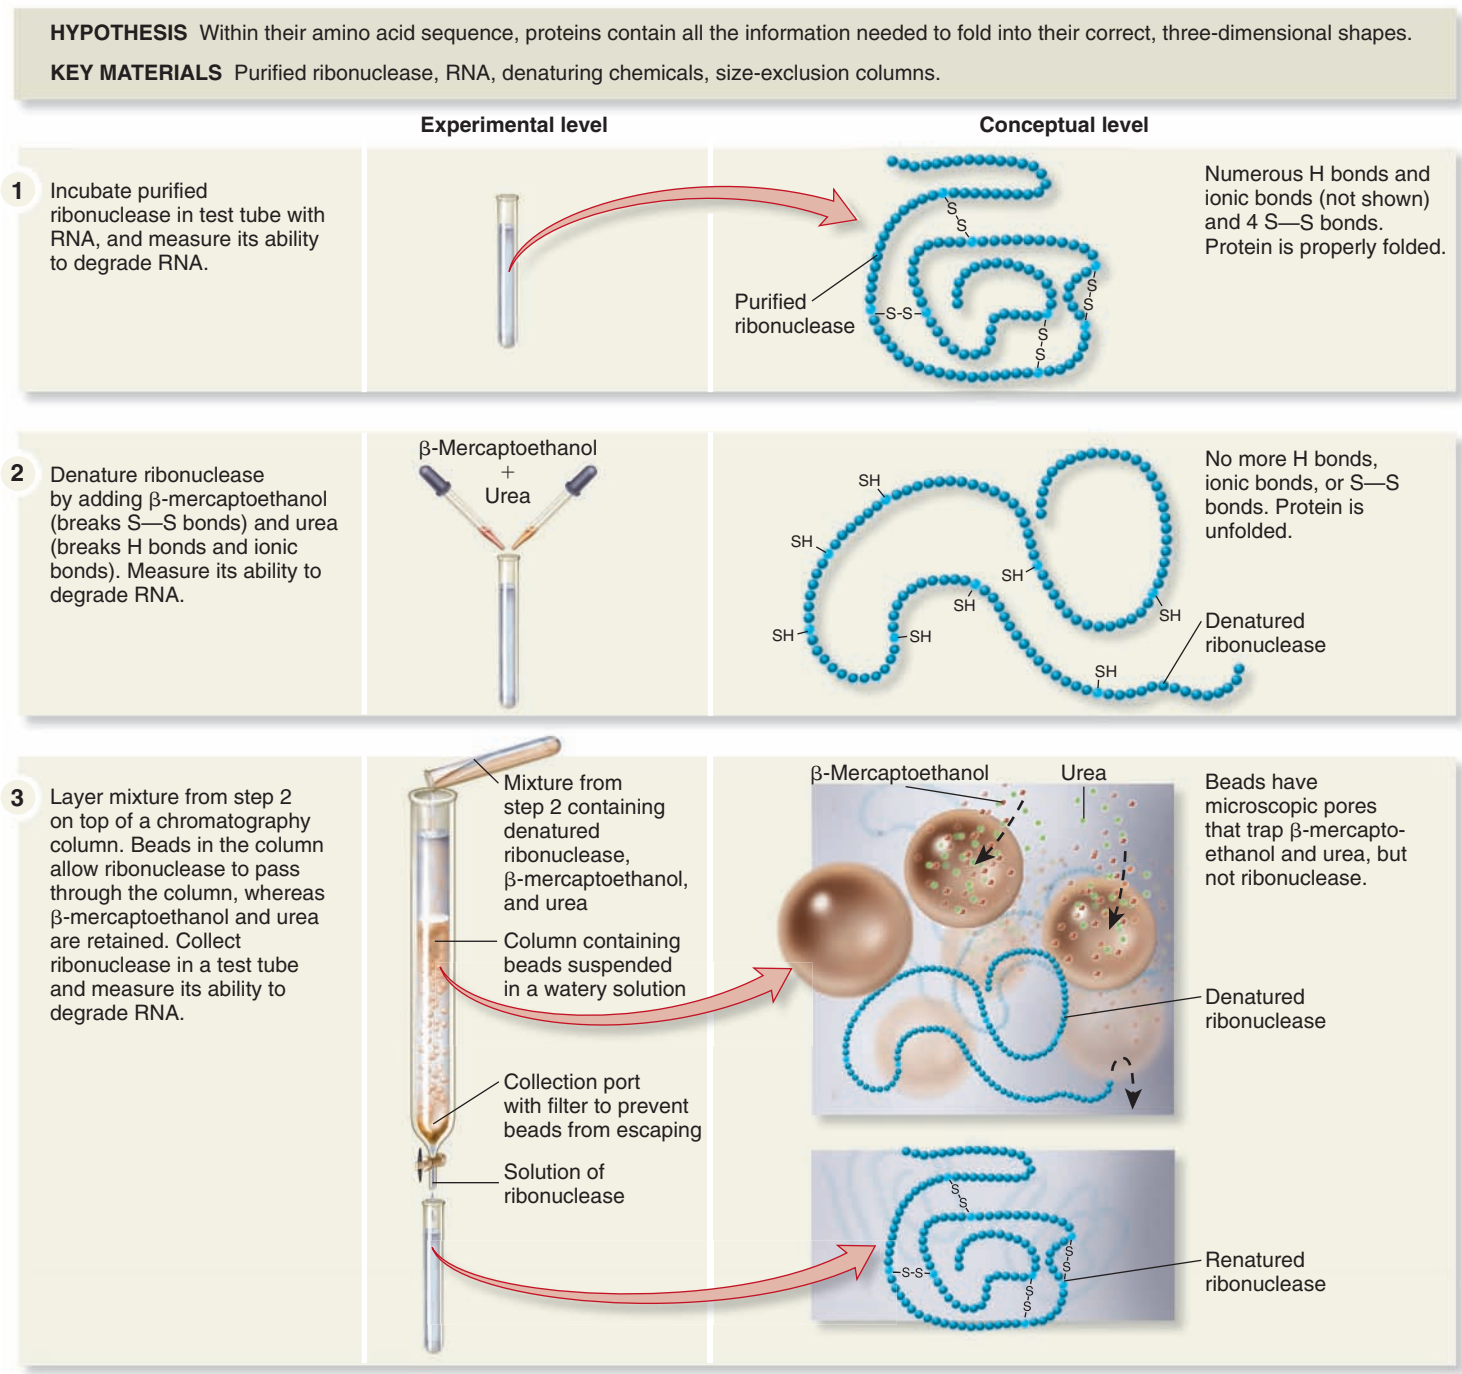
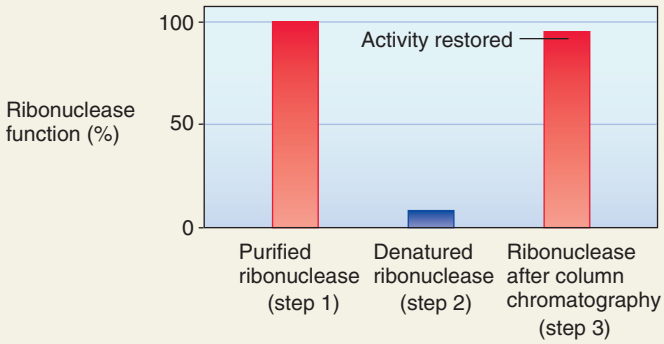
Concept Check: *If the primary structure of protein 1 in this figure was experimentally altered by the substitution of several incorrect amino acids for the correct ones, would protein 1 still be able to interact with protein 2?*



Feature Investigation | Anfinsen Showed That the Primary Structure of Ribonuclease Determines Its Three-Dimensional Structure

Prior to the 1960s, the mechanisms by which proteins assume their three-dimensional structures were not understood. Scientists hypothesized that the correct folding required cellular factors or that ribosomes, the site where polypeptides are synthesized, somehow shaped proteins as they were being made. American researcher Christian Anfinsen, however, postulated that the amino acid sequence is the primary factor that determines how proteins fold into their proper conformation. He hypothesized that proteins spontaneously assume their most stable conformation based on the laws of chemistry and physics (**Figure 3.19**).



To test this hypothesis, Anfinsen studied ribonuclease, an enzyme that degrades RNA molecules. Biochemists had already determined that ribonuclease has four disulfide bridges between eight cysteine amino acids. Anfinsen began with purified ribonuclease. The key point is that other cellular components were not present. He exposed ribonuclease to a chemical called β-mercaptoethanol, which breaks S—S bonds, and to urea, which disrupts hydrogen and ionic bonds. This treatment was expected to cause ribonuclease to unfold and become denatured. Following this treatment, he measured the ability of the enzyme to degrade RNA. The enzyme had lost nearly all of its ability to degrade RNA. Therefore, Anfinsen concluded that when ribonuclease was denatured, it was no longer functional.

Anfinsen then removed the urea and β-mercaptoethanol. Because these molecules are much smaller than ribonuclease, removing them was accomplished via a chromatography column. In this method, solutions are layered on top of a column of small beads and allowed to filter down through the column to an open collection port at the

Figure 3.19 Anfinsen's experiments with ribonuclease, demonstrating that the primary structure of a polypeptide plays a key role in protein folding.

4 THE DATA

5 CONCLUSION Certain proteins, like ribonuclease, can spontaneously fold into their final, functional shapes without assistance from other cellular structures or factors. (However, as described in the text, this is not true of many other proteins.)

6 SOURCE Haber, E., and Anfinsen, C.B. 1961. Regeneration of enzyme activity by air oxidation of reduced subtilisin-modified ribonuclease. *Journal of Biological Chemistry* 236:422–424.

bottom. The beads in the column have microscopic pores that trap small molecules like urea and mercaptoethanol but permit large molecules such as ribonuclease to pass down the length of the column and out the collection port.

Using this chromatography column, Anfinsen separated ribonuclease from β-mercaptoethanol and urea. He then retested the ribonuclease for its ability to degrade RNA. The result revolutionized our understanding of proteins. The activity of the ribonuclease was almost completely restored! Therefore, even in the complete absence of any cellular factors or organelles, this unfolded protein can refold into its correct, functional structure.

Since Anfinsen's research, we have learned that ribonuclease's ability to refold into its functional structure does not occur with all proteins. Some proteins require enzymes and other proteins to assist in their proper folding. Even so, Anfinsen's experiments provided compelling evidence that the primary structure of a polypeptide is a key determinant of a protein's tertiary structure, an observation that earned him the Nobel Prize in Chemistry for 1972.

Experimental Questions

1. What hypothesis was Anfinsen testing?
2. Why did Anfinsen use urea and β-mercaptoethanol in his experiments?
3. **SciSKILLS »** Explain the result that was crucial to the discovery that the tertiary structure of ribonuclease may depend entirely on the primary structure.

Genomes & Proteomes Connection

Proteins Contain Functional Domains

Modern research has revealed that many proteins have a modular design. This means that portions within proteins, called **domains**, have distinct structures and functions. These domains have been duplicated during evolution so the same kind of domain may be found in many different proteins. When the same domain is found in different proteins, the domain has the same three-dimensional tertiary structure and performs a function that is characteristic of that domain.

As an example, **Figure 3.20** shows two members of a family of related proteins, known as nuclear receptors, which play critical roles in regulating how certain genes are turned on in animal cells. These types of proteins are involved in animal development, reproduction, metabolism, and homeostasis. Nuclear receptors contain four or more domains within their structure:

- One domain found in nuclear receptors is a ligand-binding domain. These receptors are activated by a ligand, which is a molecule that binds to the receptor. For the two examples in Figure 3.20, the ligands are the steroid hormones estrogen and testosterone (a type of androgen), and the nuclear receptors are called the estrogen receptor and the androgen receptor, respectively. Though the ligand-binding domains in these two nuclear receptors have similar structures, slight structural differences allow one to bind estrogen and the other to bind testosterone (see the insets in Figure 3.20).
- A second domain, called the DNA-binding domain, binds to DNA once the receptor is activated by its ligand. The DNA-binding domains of these two receptors are sufficiently similar to enable both of them to bind to DNA, but dissimilar enough that they bind to different genes. Therefore, estrogen and testosterone have different effects, because they regulate different sets of genes.
- Another domain, called a nuclear localization domain, facilitates the movement of the protein into the cell nucleus, where the DNA is located.
- Once the protein binds to DNA, a fourth domain, called the activation domain, activates the transcription of the target gene.

Overall, a nuclear receptor is a single protein with multiple domains, each with a unique function.

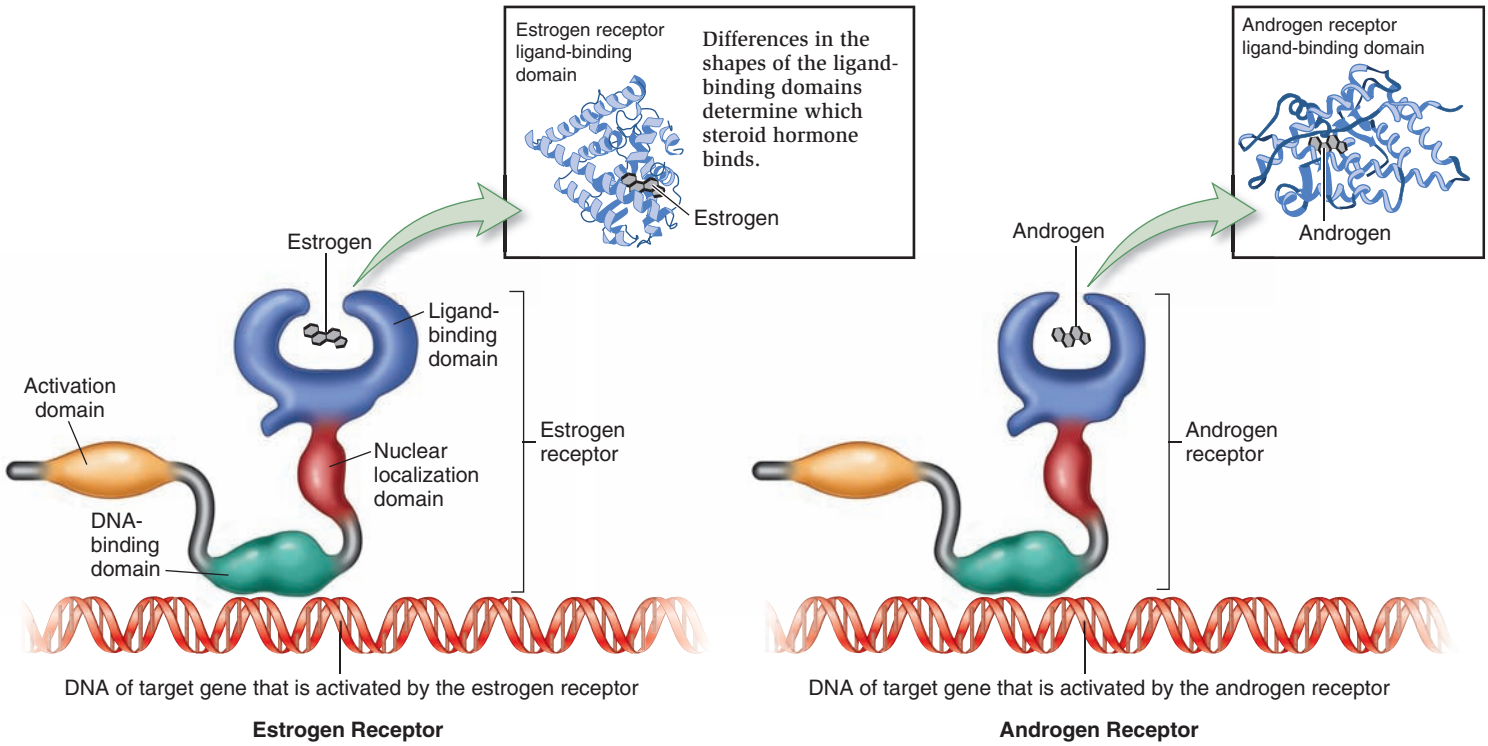


Figure 3.20 **The domain structures of two related proteins called nuclear receptors.** The schematic drawings do not depict the actual three-dimensional structures of the estrogen and androgen receptors but rather emphasize that both receptors are composed of a series of different domains. The insets show the actual structures of the ligand-binding domains for both receptors. Note: The estrogen and androgen receptors are each composed of two identical polypeptides. For simplicity, only one polypeptide is shown here.

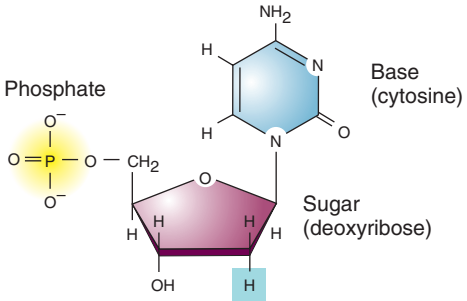
3.7 Nucleic Acids

Learning Outcomes:

1. Describe the three components of a nucleotide.
2. Distinguish between the structures of DNA and RNA.
3. Explain how certain bases pair with others in DNA and RNA.

Nucleic acids account for only about 2% of the weight of animals like humans, yet these molecules are extremely important because they are responsible for the storage, expression, and transmission of genetic information. The expression of genetic information in the form of specific proteins determines whether an organism is a human, a frog, an onion, or a bacterium. In this section, we will survey the general features of DNA and RNA, which are discussed in greater detail in Chapter 11.

Nucleotides Are the Building Blocks of DNA and RNA



The two classes of nucleic acids are **deoxyribonucleic acid (DNA)** and **ribonucleic acid (RNA)**. DNA molecules store genetic information coded in the sequence of their building blocks. RNA molecules are involved in decoding this information into instructions for linking a specific sequence of amino acids to form a polypeptide. The monomers in DNA must be arranged in a precise way so that the correct code can be read.

Like other macromolecules, DNA and RNA are polymers consisting of linear sequences of repeating monomers. Each monomer, known as a **nucleotide**, has three components: (1) a phosphate group, (2) a pentose (five-carbon) sugar (either ribose or deoxyribose), and (3) a single or a double ring of carbon and nitrogen atoms known as a base (**Figure 3.21**). A nucleotide of DNA is called a deoxyribonucleotide; that of RNA is a ribonucleotide. The nucleotides in DNA contain the five-carbon sugar **deoxyribose**. Four different nucleotides are present in DNA, corresponding to the four different bases that can be linked to deoxyribose. The **purine** bases, **adenine (A)** and **guanine (G)**, have fused double rings of carbon and nitrogen atoms, and the **pyrimidine** bases, **cytosine (C)** and **thymine (T)**, have a single-ring structure (look ahead to Figure 3.22).

DNA Is Composed of Two Strands of Nucleotides

Nucleotides are covalently linked together to form strands of DNA. The phosphates and sugar molecules form the backbone of a DNA or RNA strand, with the bases projecting from the backbone. The carbon atoms of the sugar are numbered 1′ through 5′ (**Figure 3.22**). The phosphate groups link the 3′ carbon of one nucleotide to the 5′ carbon of the next. A DNA molecule consists of two strands of nucleotides coiled around each other to form a double helix (**Figure 3.23**). The two strands are held together by hydrogen bonds between a purine base in one strand and a pyrimidine base in the opposite strand. The ring structure of each base lies in a flat plane perpendicular to the sugar-phosphate backbone, somewhat like steps on a spiral staircase.

Only certain bases can pair with each other, due to the locations of the hydrogen-bonding groups in the four bases (see Figure 3.23). In a DNA molecule, A on one strand is always paired with T on the opposite strand, and G is always paired with C. Two hydrogen bonds form

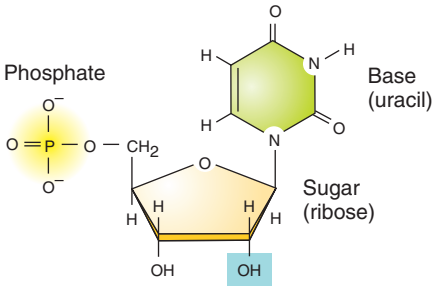


Figure 3.21 Examples of two nucleotides found in RNA or DNA. A nucleotide has a phosphate group, a five-carbon sugar, and a nitrogenous base.

between adenine and thymine (A-T pairing), whereas three hydrogen bonds are formed between guanine and cytosine (G-C pairing).

If we know the amount of one type of base in a DNA molecule, we can predict the relative amounts of each of the other three bases. For example, if a DNA molecule is composed of 20% A bases, there must also be 20% T bases. That leaves 60% of the bases that must be G and C combined. Because the amounts of G and C must be equal, this particular DNA molecule must be composed of 30% each of G and C. This specificity provides the mechanism for duplicating and transferring genetic information (see Chapter 11).

RNA Strands Have a Similar Structure to DNA Strands

RNA structure differs in only a few respects from DNA. Like DNA, RNA consists of nucleotides covalently linked together. RNA usually consists of a single strand of nucleotides. In RNA, the sugar in each nucleotide is **ribose** instead of deoxyribose. Also, the pyrimidine base thymine in DNA is replaced in RNA with the pyrimidine base **uracil (U)** (see Figure 3.21). The other three bases—adenine, guanine, and cytosine—are found in both DNA and RNA.

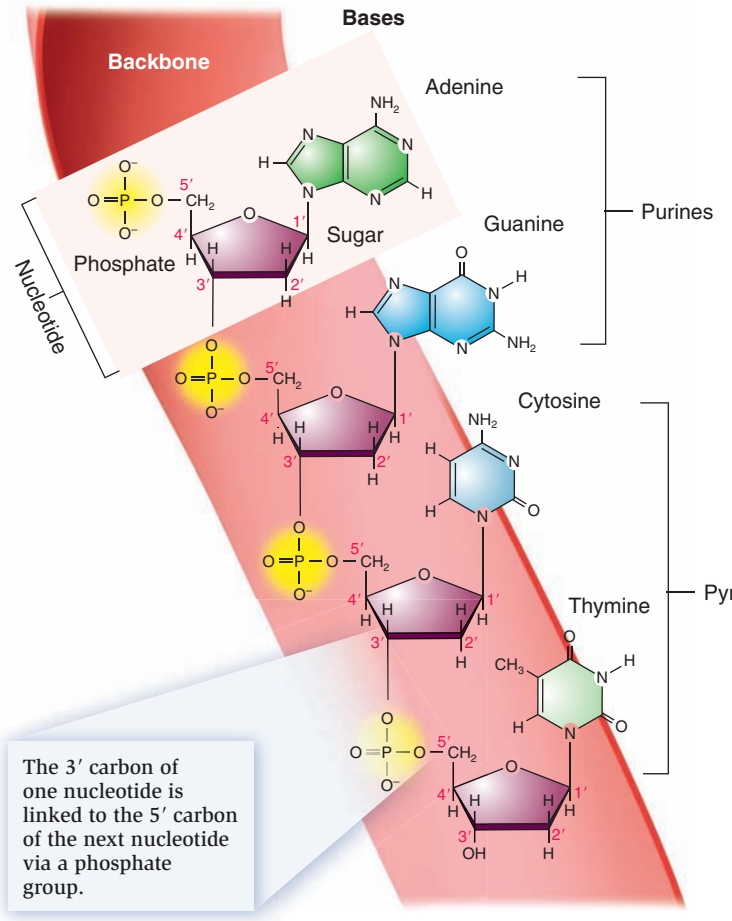

Figure 3.22 Structure of a DNA strand. Nucleotides are linked to each other to form a strand of DNA. The four bases found in DNA are shown. A strand of RNA is similar except the sugar is ribose, and uracil is substituted for thymine.

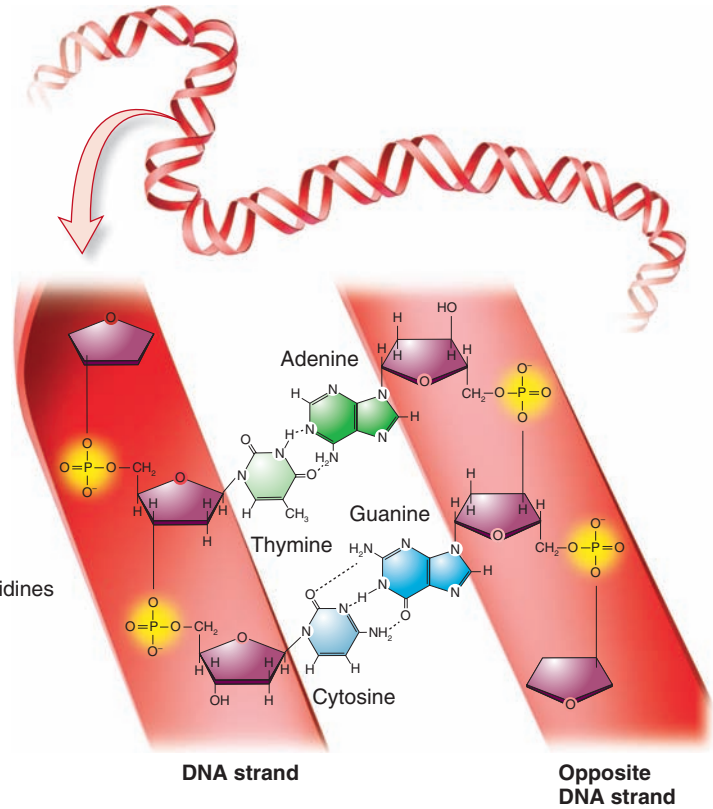

Figure 3.23 The double-stranded structure of DNA. DNA consists of two strands coiled together into a double helix. The bases form hydrogen bonds (dashed lines) in which A pairs with T, and G pairs with C.

Concept Check: If the sequence of bases in one strand of a DNA double helix is known, can the base sequence of the opposite strand be predicted?

Summary of Key Concepts

3.1 The Carbon Atom

- Organic chemistry is the science of studying carbon-containing molecules, which are found in living organisms.
- A key property of the carbon atom is its ability to form four covalent bonds (polar or nonpolar) with other atoms. The combination of different elements and different types of bonds allows a vast number of organic compounds to be formed from a relatively few chemical elements (Figures 3.1, 3.2).
- Carbon bonds are stable at the different temperatures associated with life.
- Organic compounds may contain functional groups with specific structures and chemical properties (Table 3.1).
- Carbon-containing molecules can exist as isomers, which have identical molecular composition but different structures and characteristics (Figure 3.3).

3.2 Formation of Organic Molecules and Macromolecules

- Organic molecules exist as monomers or polymers. Polymers are large macromolecules built by dehydration reactions, in which individual monomers are attached to a growing polymer. Monomers are released from polymers by hydrolysis reactions (Figure 3.4).

3.3 Overview of the Four Major Classes of Organic Molecules Found in Living Cells

- The four major classes of organic molecules are carbohydrates, lipids, proteins, and nucleic acids (Table 3.2).

3.4 Carbohydrates

- Carbohydrates are composed of carbon, hydrogen, and oxygen atoms. Cells can break down glucose, an important carbohydrate, releasing energy, which is then stored in the bonds of ATP.
- Carbohydrates include monosaccharides (the simplest sugars), disaccharides, and polysaccharides. The polysaccharides called starch (in plant cells) and glycogen (in animal cells) store energy in cells. Some polysaccharides, notably cellulose, serve a structural function (Figures 3.5, 3.6, 3.7).

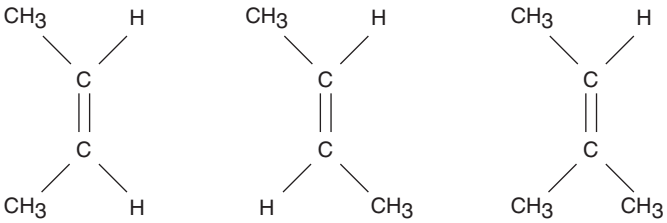
3.5 Lipids

- Lipids, composed predominantly of hydrogen and carbon atoms, are nonpolar and very insoluble in water. Major classes of lipids include fats, phospholipids, steroids, and waxes.
- Fats, also called triglycerides, are formed by bonding glycerol with three fatty acids. In a saturated fatty acid, all the carbons are linked by single covalent bonds. Unsaturated fatty acids contain one or more C═C double bonds (Figures 3.8, 3.9, 3.10).
- Phospholipids are similar in structure to triglycerides, except that one glycerol is linked to a phosphate group instead of a fatty acid. They contain both hydrophilic and hydrophobic regions, making them amphipathic (Figure 3.11).
- Steroids are constructed of four fused rings of carbon atoms. Small differences in steroid structure can lead to profoundly different biological properties, such as the differences between estrogen and testosterone (Figure 3.12).
- Waxes, another class of lipids, are nonpolar and repel water, and are often found as protective coatings on the leaves of plants and the outer surfaces of animals' bodies.

3.6 Proteins

- Proteins are composed of carbon, hydrogen, oxygen, nitrogen, and small amounts of other elements such as sulfur. Proteins are macromolecules that play critical roles in almost all life processes. The proteins of all living organisms are composed of the same set of 20 amino acids, which contain 20 different side chains (Figure 3.13, Table 3.3).
- Amino acids are joined by linking the carboxyl group of one amino acid to the amino group of another, forming a peptide bond. A polypeptide is a structural unit composed of amino acids. A protein is a functional unit composed of one or more polypeptides that have folded and twisted into precise three-dimensional shapes (Figure 3.14).
- The four levels of protein structure are primary (its amino acid sequence), secondary (α helices or β pleated sheets), tertiary (folding to assume a three-dimensional shape), and quaternary (proteins that consist of more than one polypeptide). The three-dimensional structure of a protein determines its function (Figures 3.15, 3.16, 3.17, 3.18, 3.19).
- Proteins contain regions called domains that have particular functions (Figure 3.20).

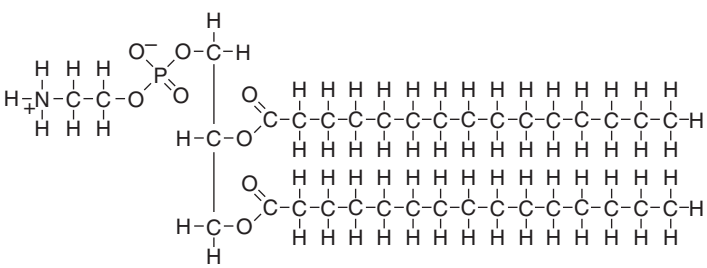
3.7 Nucleic Acids



- Nucleic acids are responsible for the storage, expression, and transmission of genetic information. The two types of nucleic acids are deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). DNA and RNA consist of repeating monomers known as nucleotides. Each nucleotide is composed of a phosphate group, a five-carbon sugar (either ribose or deoxyribose), and a single or double ring of carbon and nitrogen atoms called a base (Figure 3.21).
- Nucleotides are covalently linked together to form a strand. A DNA molecule consists of two strands of nucleotides coiled around each other to form a double helix, held together by hydrogen bonds between an A and a T or between a G and a C. DNA molecules store genetic information coded in the sequence of their bases (Figures 3.22, 3.23).
- RNA consists of a single strand of nucleotides. The sugar in each nucleotide is ribose rather than deoxyribose, and the base uracil replaces thymine. RNA molecules are involved in decoding information in DNA into instructions for linking amino acids in a specific sequence to form a polypeptide.

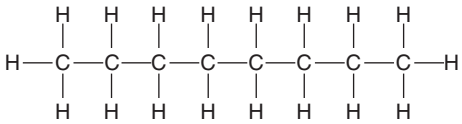
Assess and Discuss

Test Yourself



1. Molecules that are found in living cells and contain the element _____ are considered organic molecules.
   a. hydrogen
   b. carbon
   c. oxygen
   d. nitrogen
   e. calcium

2. The versatility of carbon to serve as the backbone for a variety of different molecules is due to
   a. the ability of carbon atoms to form four covalent bonds.
   b. the fact that carbon usually forms ionic bonds with many different atoms.
   c. the abundance of carbon in the environment.
   d. the ability of carbon to form covalent bonds with many different types of atoms.
   e. both a and d.
3. Which of the following type(s) of bonds are nonpolar?
   a. C—C
   b. C—O
   c. C—H
   d. both a and b
   e. both a and c
4. Which of the following molecules are isomers of each other?



(a) (b) (c)

   a. a and b
   b. a and c
   c. b and c
   d. a, b, and c
   e. None of them are isomers of each other.
5. A polysaccharide that is commonly found in animal cells and stores energy is
   a. glucose.
   b. sucrose.
   c. glycogen.
   d. starch.
   e. cellulose.
6. In contrast to other fatty acids, essential fatty acids
   a. are always saturated fats.
   b. cannot be synthesized by the organism and are necessary for survival.
   c. can act as building blocks for large, more complex macromolecules.
   d. are the simplest form of lipids found in plant cells.
   e. are structural components of plasma membranes.
7. The structures of three molecules are shown below. Which of them is (are) amphipathic?

(a)

(b)

(c)

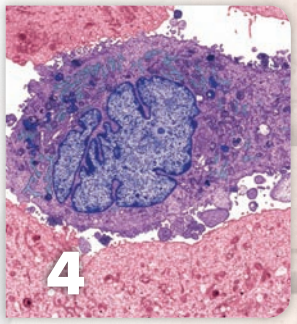
   a. a only
   b. b only
   c. c only
   d. b and c
   e. a and c
8. The monomers of proteins are _____, and these are linked by polar covalent bonds commonly referred to as _____.
   a. nucleotides, peptide bonds
   b. amino acids, ester bonds
   c. hydroxyl groups, ester bonds
   d. amino acids, peptide bonds
   e. monosaccharides, glycosidic linkages
9. A _____ is a portion of protein with a particular structure and function.
   a. peptide bond
   b. domain
   c. phospholipid
   d. wax
   e. monosaccharide
10. A DNA molecule contains 30% G. What percentage of its bases are A?
    a. 30%
    b. 20%
    c. 15%
    d. 10%
    e. none of the above

Conceptual Questions

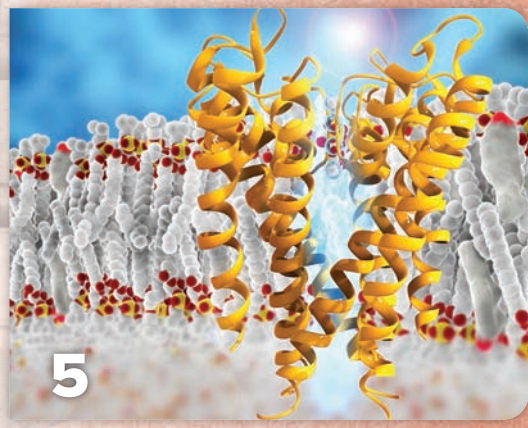
1. Explain the similarities and differences between isomers.
2. What is the difference between a saturated and an unsaturated fatty acid? How do the structural differences contribute to differences in their properties?
3. A principle of biology is that *structure determines function*. What does this mean for organic molecules such as carbohydrates, lipids, and proteins?

Collaborative Questions

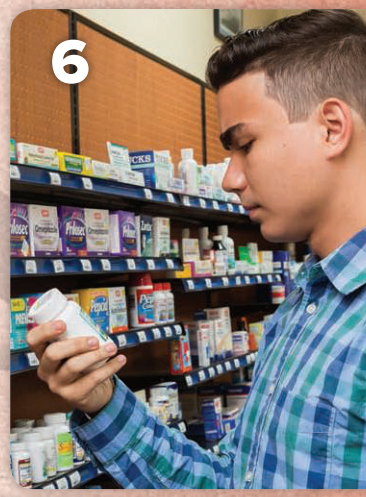
1. Discuss the differences between the various types of carbohydrates.
2. Discuss some of the roles that proteins play in organisms.



UNIT II



CELL



Cell biology is the study of life at the cellular level. Although cells are the simplest units of life, biologists have come to realize that they are wonderfully complex and interesting, providing information about all living things. In this unit, Chapter 4 begins with an overview of cell structure and function and explores the technique of microscopy. In Chapter 5, we will examine the structure and synthesis of cell membranes and the transport of substances in and out of the cell.

Chapters 6, 7, and 8 are largely devoted to metabolism, the sum of the chemical reactions in a cell or organism. Chapter 6 explores the topic of energy and considers how enzymes facilitate chemical reactions in a cell. Chapter 7 examines the pathways for carbohydrate breakdown and how those pathways are used to make an energy intermediate called ATP. In Chapter 8, we will explore the process of photosynthesis, in which the energy of sunlight drives the synthesis of carbohydrates.

Finally, Chapters 9 and 10 consider the ways that cells interact with their environment and with each other. In Chapter 9, we will examine how cells respond to signals, either those that come directly from their environment or those that are made by other cells. In Chapter 10, we will explore how cells interact with each other to produce a multicellular organism.

The following biology principles will be emphasized in this unit:

- ***Cells are the simplest units of life:*** *Throughout this unit, we will examine how life exists at the cellular level.*
- ***Living organisms use energy:*** *Chapters 6, 7, and 8 examine how cells utilize and store energy contained within organic molecules such as glucose.*
- ***Living organisms interact with their environment:*** *Chapters 5 and 9 largely focus on the plasma membrane of the cell and how it provides an interface between the cell and its environment.*
- ***Structure determines function:*** *Throughout this unit, we will see many examples in which the structure of proteins determines their cellular functions.*
- ***Biology is an experimental science:*** *Every chapter has a Feature Investigation that describes a pivotal experiment that provided insights into the workings of cells.*

A cell from the lung of a person with lung cancer. The cell in this micrograph was viewed by a technique called transmission electron microscopy, which is described in this chapter. The micrograph was artificially colored using a computer to enhance the visualization of certain cell structures.

Emily had a persistent cough ever since she started smoking cigarettes in college. However, at age 35, it seemed to be getting worse, and she was alarmed by the occasional pain in her chest. When she began to lose weight and became easily fatigued, Emily decided to see a doctor. The diagnosis was lung cancer. Despite aggressive treatment with chemotherapy and radiation therapy, she succumbed to lung cancer 14 months after the initial diagnosis. Emily was 36.

Topics such as cancer are within the field of **cell biology**—the study of individual cells and their interactions with each other. Researchers in this field want to understand the basic features of cells and apply their knowledge in the treatment of diseases such as cystic fibrosis, sickle cell disease, and lung cancer.

The idea that organisms are composed of cells originated in the mid-1800s. German botanist Matthias Schleiden studied plant material under the microscope and was struck by the presence of many similar-looking compartments, each of which contained a dark area. Today we call those compartments cells and the dark area the nucleus. In 1838, Schleiden speculated that cells are living entities and that plants are aggregates of cells arranged according to definite laws.

Schleiden was a good friend of the German physiologist Theodor Schwann. Over dinner one evening, their conversation turned to the nuclei of plant cells, and Schwann remembered having seen similar structures in animal tissue. Schwann conducted additional studies that showed animal tissue contains large numbers of nuclei that are located in cell-like compartments and occur at regular intervals. In 1839, Schwann extended Schleiden's hypothesis to animals. About two decades later, German biologist Rudolf Virchow proposed that *omnis cellula e cellula*, or "every cell originates from another cell." This idea arose from his research, which showed that diseased cells divide to produce more diseased cells.

The **cell theory**, which is credited to both Schleiden and Schwann with contributions from Virchow, has three parts.

1. All living organisms are composed of one or more cells.
2. Cells are the smallest units of life.
3. New cells come only from pre-existing cells by cell division.

Most cells are so small they cannot be seen with the unaided eye. However, as cell biologists have begun to unravel cell structure and function at the molecular level, the cell has emerged as a unit of incredible complexity and adaptability. In this chapter, we begin our examination of cells with an overview of their structures and functions. Later chapters in this unit will explore certain aspects of cell biology in greater detail. But first, let's look at the tools and techniques that allow us to observe cells.

4.1 Microscopy

Learning Outcomes:

1. **SciSKILLS »** Explain the three key parameters in microscopy: resolution, contrast, and magnification.
2. **SciSKILLS »** Compare and contrast the different types of light and electron microscopes and their uses.

The **microscope** is a magnification tool that enables researchers to visualize the structure and inner workings of cells. A **micrograph** is an image taken with the aid of a microscope. The first compound microscope—a microscope with more than one lens—was invented in 1595 by Zacharias Jansen of Holland. In 1665, an English biologist, Robert Hooke, studied cork under a primitive compound microscope he had made. He actually observed cell walls because cork cells are dead and have lost their internal components. Hooke coined the word cell, derived from the Latin word *cellula*, meaning small compartment, to describe the structures he observed.

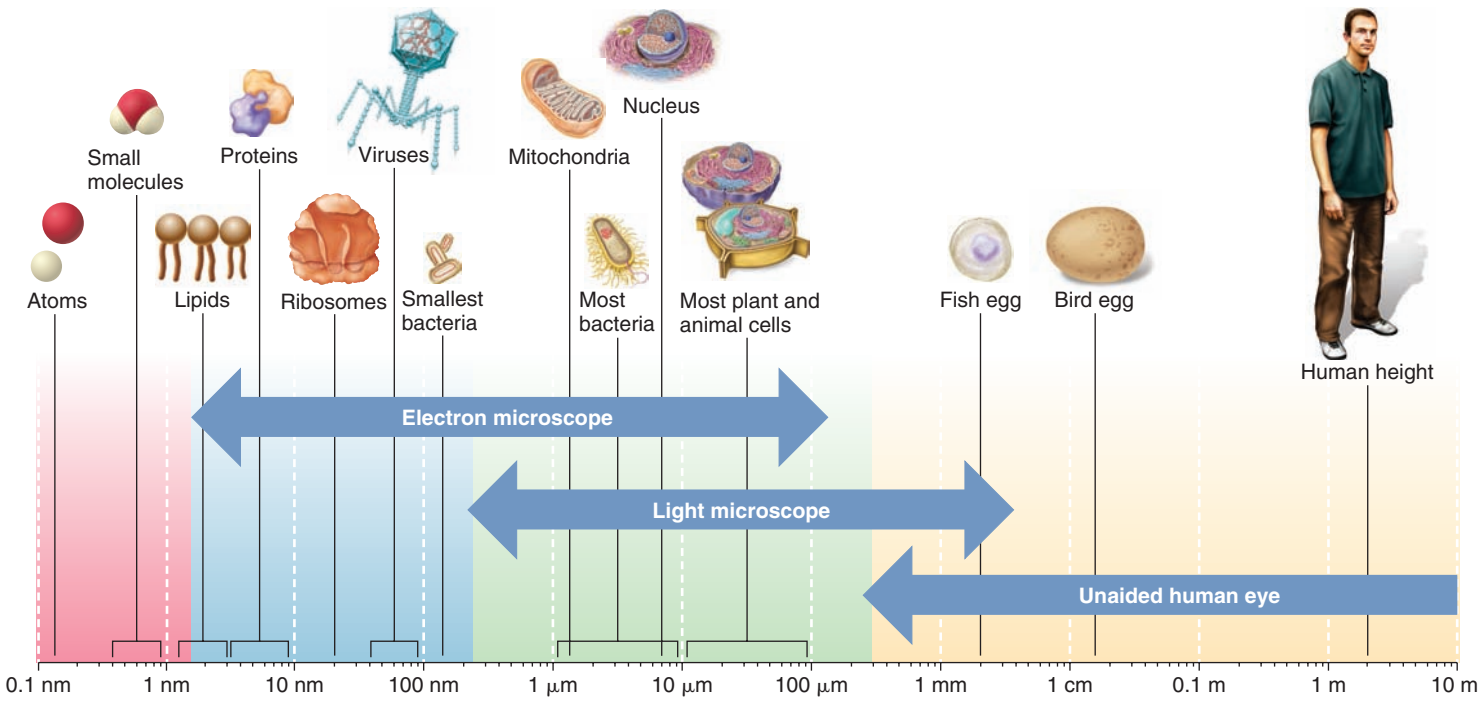
Three important parameters in microscopy are resolution, contrast, and magnification.

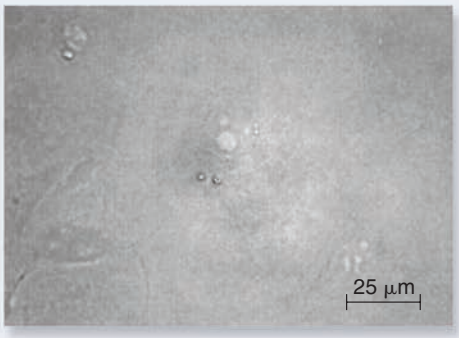
- **Resolution**, a measure of the clarity of an image, is the ability to observe two adjacent objects as distinct from one another. For example, a microscope with good resolution enables a researcher to distinguish two adjacent chromosomes as separate objects, which would appear as a single, blurry object under a microscope with poor resolution.
- The second important parameter in microscopy is **contrast**. The ability to visualize a particular cell structure may depend on how different it looks from an adjacent structure. Staining the cellular structure of interest with a dye can make viewing much easier. The application of stains, which selectively label individual components of the cell, greatly improves contrast. However, staining should not be confused with colorization. Many of the micrographs shown in this textbook are colorized, or artificially colored, to emphasize certain cellular structures, such as different parts of a cell (see the chapter opener, for example). In colorization, particular colors are added to micrographs with the aid of a computer.
- **Magnification** is the ratio between the size of an image produced by a microscope and its actual size. For example, if the image size is 100 times larger than its actual size, the magnification is designated 100×. Depending on the quality of the lens and illumination source, every microscope has an optimal range of magnification before objects appear too blurry to be readily observed.

Microscopes are categorized into two groups based on the source of illumination. A **light microscope** utilizes light for illumination, whereas an **electron microscope** uses a beam of electrons for illumination. Very good light microscopes resolve structures that are as close as 0.2 μm (micron, or micrometer) from each other.

Resolution is improved when the illumination source has a shorter wavelength. A major advance in microscopy occurred in 1931 when Max Knoll and Ernst Ruska invented the first electron microscope. Because the wavelength of an electron beam is much shorter than visible light, the resolution of the electron microscope is far better than any light microscope; the resolution limit is typically around 2 nm (nanometers), which is about 100 times better than the light microscope. **Figure 4.1** shows the range of resolving powers of the electron microscope, light microscope, and unaided eye and compares them with various cells and cell structures.

Over the past several decades, technological advances have made light microscopy a powerful research tool. Improvements in lens technology, microscope organization, sample preparation, sample illumination, and computerized image processing have enabled researchers





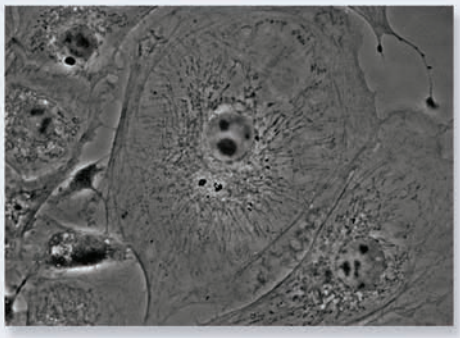


Figure 4.1 A comparison of the sizes of various chemical and biological structures, and the resolving power of the unaided eye, light microscope, and electron microscope. The scale at the bottom is logarithmic to accommodate the wide range of sizes in this drawing.

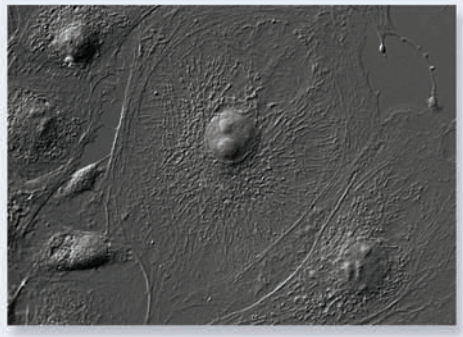
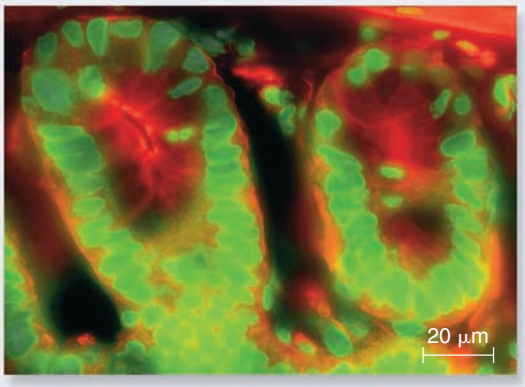
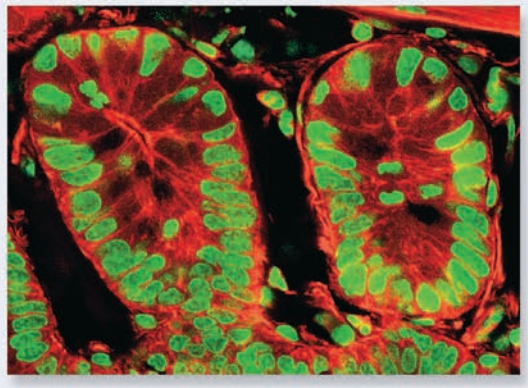


Concept Check: *Which type of microscope would you use to observe a virus?*

Standard light microscopy (bright field, unstained sample). Light is passed directly through a sample, and the light is focused using glass lenses. Simple, inexpensive, and easy to use but offers little contrast with unstained samples.



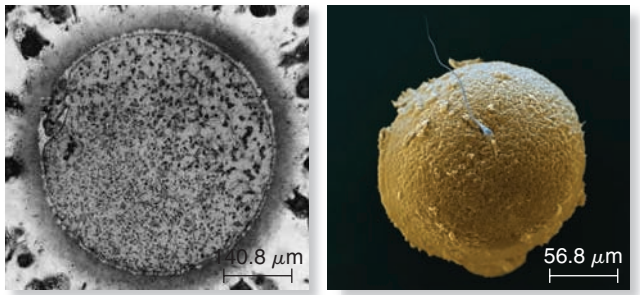
Phase contrast microscopy. As an alternative to staining, this microscope controls the path of light and amplifies differences in the phase of light transmitted or reflected by a sample. The dense structures appear darker than the background, thereby improving the contrast in different parts of the specimen. Can be used to view living, unstained cells.



Differential interference contrast (Nomarski) microscopy. Similar to a phase contrast microscope in that it uses optical modifications to improve contrast in unstained specimens. Can be used to visualize the internal structures of cells and is commonly used to view whole cells or large cell structures such as nuclei.

(a) Three different methods of light microscopy on the same unstained sample

Standard (wide-field) fluorescence microscopy. Fluorescent molecules specifically label a particular type of cellular protein or organelle. A fluorescent molecule absorbs light at a particular wavelength and emits light at a longer wavelength. This microscope has filters that illuminate the sample with the wavelength of light that a fluorescent molecule absorbs, and then only the light that is emitted by the fluorescent molecules is allowed to reach the observer. To detect their cellular location, researchers often label specific cellular proteins using fluorescent antibodies that bind specifically to a particular protein.



Confocal fluorescence microscopy. Uses lasers that illuminate various points in the sample. These points are processed by a computer to give a very sharp focal plane. In this example, this microscope technique is used in conjunction with fluorescence microscopy to view fluorescent molecules within a cell.

(b) Two different methods of fluorescence microscopy on the same sample

Figure 4.2 Examples of light microscopy. (a) These micrographs compare three microscopic techniques on the same unstained sample of endothelial cells that line the interior surface of arteries in the lungs. **(b)** These two micrographs compare standard (wide-field) fluorescence microscopy with confocal fluorescence microscopy. The sample is a section through a mouse intestine, showing two villi, projections from the small intestine that are described in Chapter 45. In this sample, the nuclei are stained green, and the actin filaments (discussed later in this chapter) are stained red.

to invent different types of light microscopes, each with its own advantages and disadvantages (**Figure 4.2**).

Similarly, improvements in electron microscopy occurred during the 1930s and 1940s, and by the 1950s, the electron microscope was playing a major role in advancing our understanding of cell structure. Two general types of electron microscopy have been developed: transmission electron microscopy and scanning electron microscopy. In **transmission electron microscopy (TEM)**, a beam of electrons is transmitted through a biological sample. To provide contrast, the sample is stained with a heavy metal, which binds to certain cellular structures

(a) Transmission electron micrograph (TEM)

(b) Scanning electron micrograph (SEM)

Figure 4.3 A comparison of transmission and scanning electron microscopy. **(a)** Section through a developing human egg cell, observed by TEM, shortly before it was released from an ovary. **(b)** An egg cell, with an attached sperm, was coated with heavy metal and observed via SEM. This SEM is colorized.

Concept Check: *What is the primary advantage of SEM?*

such as membranes. The sample is then adhered to a copper grid and placed in a transmission electron microscope. When the beam of electrons strikes the sample, some of them hit the heavy metal and are scattered, while those that pass through without being scattered are focused to form an image on a photographic plate or screen (**Figure 4.3a**). The metal-stained regions of the sample that scatter electrons appear as darker areas, due to reduced electron penetration. TEM provides a cross-sectional view of a cell and its organelles and gives the best resolution compared with other forms of microscopy. However, such microscopes are expensive and cannot be used to view living cells.

Scanning electron microscopy (SEM) is used to view the surface of a sample. A biological sample is coated with a thin layer of heavy metal, such as gold or palladium, and then is exposed to an electron beam that scans its surface. Secondary electrons are emitted from the sample, which are detected and create an image of the three-dimensional surface of the sample (**Figure 4.3b**).

4.2 Overview of Cell Structure

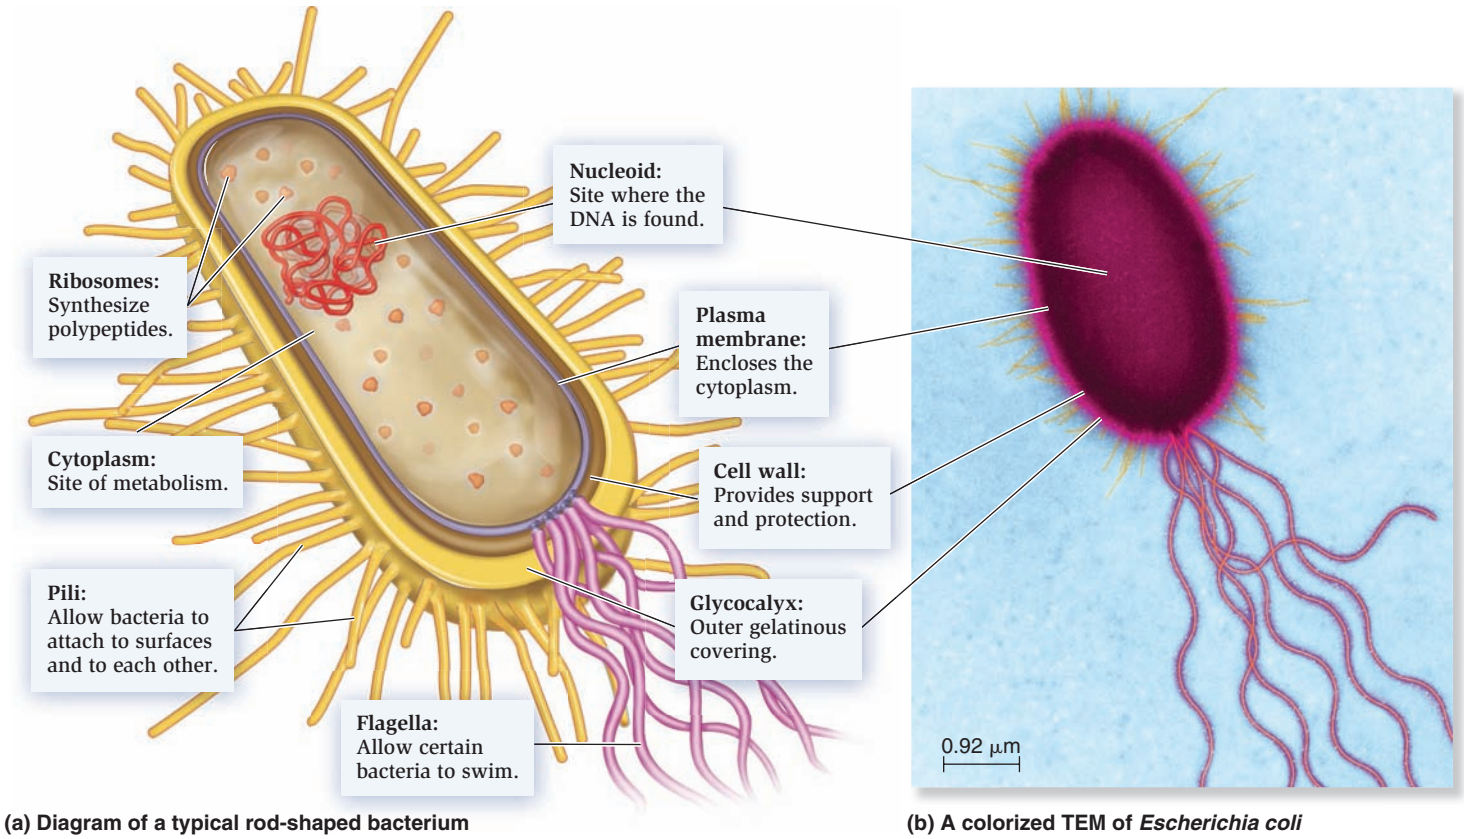
Learning Outcomes:

1. Compare and contrast the general structural features of prokaryotic and eukaryotic cells.
2. Explain how the proteome underlies the structure and function of cells.
3. **SciSKILLS »** Analyze how cell size and shape affect the surface area/volume ratio.

Cell structure is primarily determined by four factors: (1) matter, (2) energy, (3) organization, and (4) information. In Chapters 2 and 3, we considered the first factor. The matter found in living organisms is composed of atoms, molecules, and macromolecules. Each type of cell synthesizes a unique set of molecules and macromolecules that contribute to cell structure. We will discuss the second factor, energy, throughout this unit, particularly in Chapters 6 through 8. Energy is needed to produce molecules and macromolecules and to carry out many cellular functions.

The third phenomenon that underlies cell structure is organization. A cell is not a haphazard bag of components. The molecules and macromolecules that constitute cells are found at specific sites. For example, if we compare the structure of a muscle cell in two different humans, or two muscle cells within the same individual, we would see striking similarities in their overall structures. All living cells have the ability to build and maintain their internal organization. Proteins often bind to each other in much the same way that building blocks snap together. These types of **protein-protein interactions** create intricate cell structures and also facilitate processes in which proteins interact in a consistent series of steps.

The fourth critical factor of cell structure is information. Cell structure requires instructions. These instructions are found in the blueprint of life, namely, the genetic material (DNA), which is discussed in Unit III. Every species has a distinctive **genome**, the entire complement of its genetic material. Likewise, each living cell has a copy of the genome. This genetic information is passed from cell to cell and from parent to offspring to yield new generations of cells and new generations of offspring. The **genes** within each species' genome contain the information to produce cellular proteins with particular structures and functions. The proteins, in turn, are largely responsible for determining cell structure and function. In this section, we will explore the general structure of cells and examine how the genome contributes to cell structure and function.



Prokaryotic Cells Have a Simple Structure

Based on cell structure, all forms of life can be placed into two categories called prokaryotes and eukaryotes. We will first consider **prokaryotic cells**, which have a relatively simple structure. The term comes from the Greek *pro* and *karyon*, which means before a kernel—a reference to the kernel-like appearance of what would later be named the cell nucleus. Prokaryotic cells lack a membrane-enclosed nucleus.

From an evolutionary perspective, the two categories of organisms that have prokaryotic cells are **bacteria** and **archaea**. Both types are microorganisms that are relatively small, with cell sizes that usually range between 1 micrometer (μm) and 10 μm in diameter. Bacteria are abundant throughout the world, being found in soil, water, and even our digestive tracts. Most bacterial species are not harmful to humans, and they play vital roles in ecology. However, some species are pathogenic—they cause disease. Examples of pathogenic bacteria include *Vibrio cholerae*, the source of cholera, and *Bacillus anthracis*, which causes anthrax. Archaea are also widely found throughout the world, though they are less common than bacteria and often occupy extreme environments such as hot springs and deep-sea vents.

Figure 4.4 shows a typical bacterial cell. The **plasma membrane**, which is a double layer of phospholipids and embedded proteins, forms an important barrier between the cell and its external environment. The **cytoplasm** is the region of the cell contained within the plasma membrane. Certain structures in the bacterial cytoplasm are visible via microscopy. These include the **nucleoid** (not to be confused with the eukaryotic nucleus), where the genetic material is located, and **ribosomes**, which are involved in polypeptide synthesis.

Some bacterial structures are located outside the plasma membrane. Nearly all species of bacteria and archaea have a relatively

(a) Diagram of a typical rod-shaped bacterium

(b) A colorized TEM of *Escherichia coli*

Figure 4.4 Structure of a typical bacterial cell. Prokaryotic cells, which include bacteria and archaea, lack internal compartmentalization.

rigid **cell wall** that supports and protects the plasma membrane and cytoplasm. The cell-wall composition varies widely among prokaryotic cells but commonly contains peptides and carbohydrates. The cell wall, which is relatively porous, allows most nutrients in the environment to reach the plasma membrane. Many bacteria also secrete a **glycocalyx**, an outer viscous covering surrounding the bacterium. The glycocalyx traps water and helps protect bacteria from drying out. Certain strains of bacteria that invade animals' bodies produce a very thick, gelatinous glycocalyx called a **capsule** that may help them avoid being destroyed by the animal's immune (defense) system or may aid in the attachment to cell surfaces. Finally, many prokaryotic cells have appendages such as pili and flagella. **Pili** allow cells to attach to surfaces and to each other. **Flagella** provide prokaryotic cells with a way to move, also called motility.

Eukaryotic Cells Are Compartmentalized by Internal Membranes to Create Organelles

Aside from bacteria and archaea, all other species are **eukaryotes** (from the Greek, meaning true nucleus), which include protists, fungi, plants, and animals. Paramecia and algae are types of protists; yeasts and molds are types of fungi. **Figure 4.5** illustrates the morphology of a typical animal cell. Eukaryotic cells possess a true nucleus, where most of the DNA is housed. A nucleus is a type of **organelle**—a membrane-bound compartment with its own unique structure and function. In contrast to prokaryotic cells, eukaryotic cells exhibit extensive **compartmentalization**, which means they have many membrane-bound organelles that separate the cell into different regions. Cellular compartmentalization allows a cell to carry out specialized chemical reactions in different places.

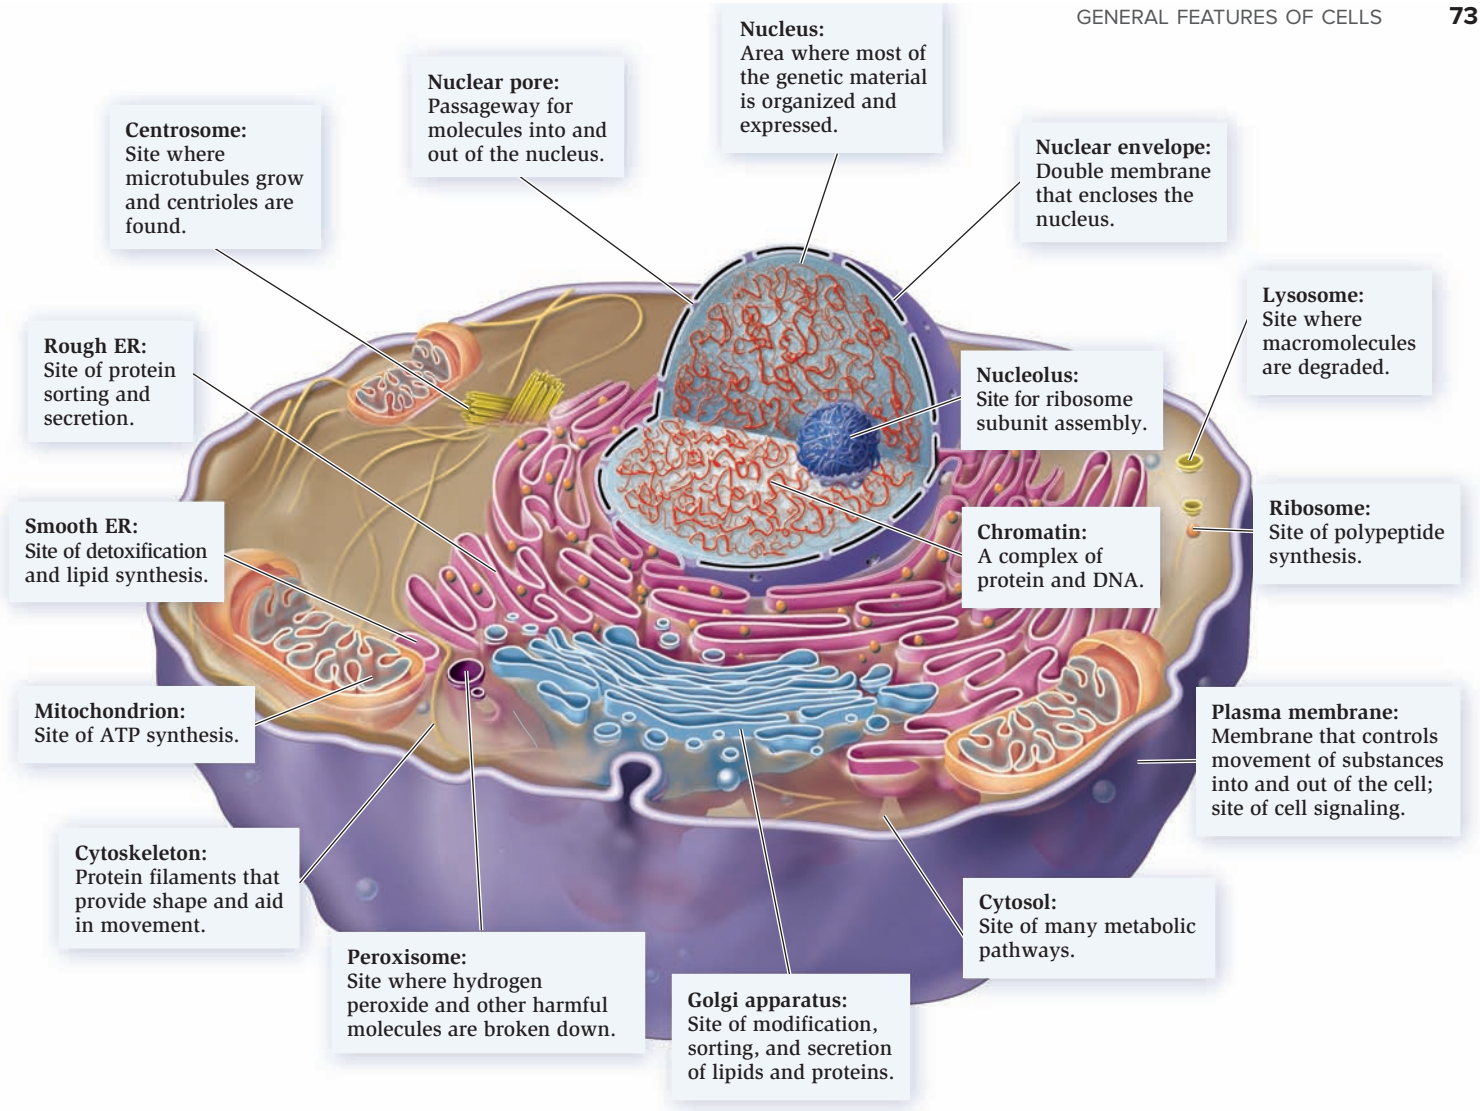
Some general features of cell organization, such as a nucleus, are found in nearly all eukaryotic cells. Even so, the shape, size, and organization of cells vary considerably among different species and even among different cell types of the same species. For example, micrographs of a human skin cell and a human neuron show that, although these cells contain the same types of organelles, their overall morphologies are quite different (**Figure 4.6**).

Plant cells possess a collection of organelles similar to animal cells (**Figure 4.7**). Additional structures found in plant cells but not animal cells include chloroplasts, a central vacuole, and a cell wall.

Genomes & Proteomes Connection

The Characteristics of a Cell Are Largely Determined by the Proteins It Makes

Many organisms, such as animals and plants, are multicellular, meaning that a single organism is composed of many cells. However, the cells of most multicellular organisms are not all identical. For example, your body contains skin cells, neurons, muscle cells, and many other types. An intriguing question, therefore, is how does a single organism produce different types of cells?



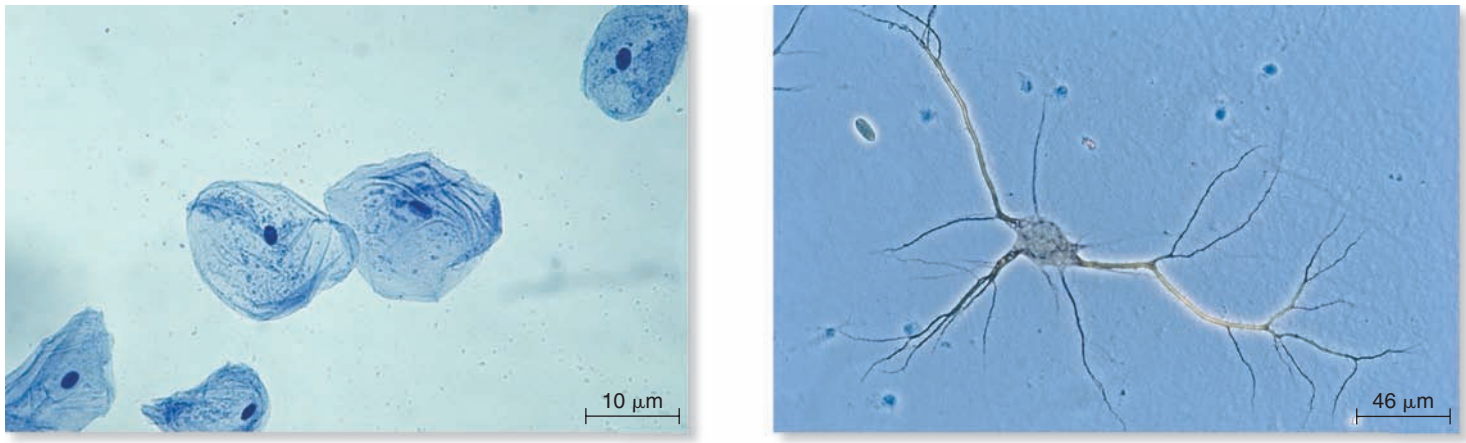


Figure 4.5 **General structure of an animal cell.**

BIOLOGY PRINCIPLE **Cells are the simplest units of life.** A cell, such as the animal cell illustrated here, is the smallest unit that satisfies all of the characteristics of living organisms. These characteristics are discussed in Chapter 1 (see Figure 1.4).

(a) Human skin cell **(b) Human neuron**

Figure 4.6 **Variation in morphology of eukaryotic cells.** Light micrographs of **(a)** a human skin cell and **(b)** a human neuron (a cell of the nervous system). Although these cells have the same genome and same types of organelles, their general morphologies are quite different.

BioConnections: *Look ahead to Figure 13.22. How does alternative splicing affect protein structure and function?*

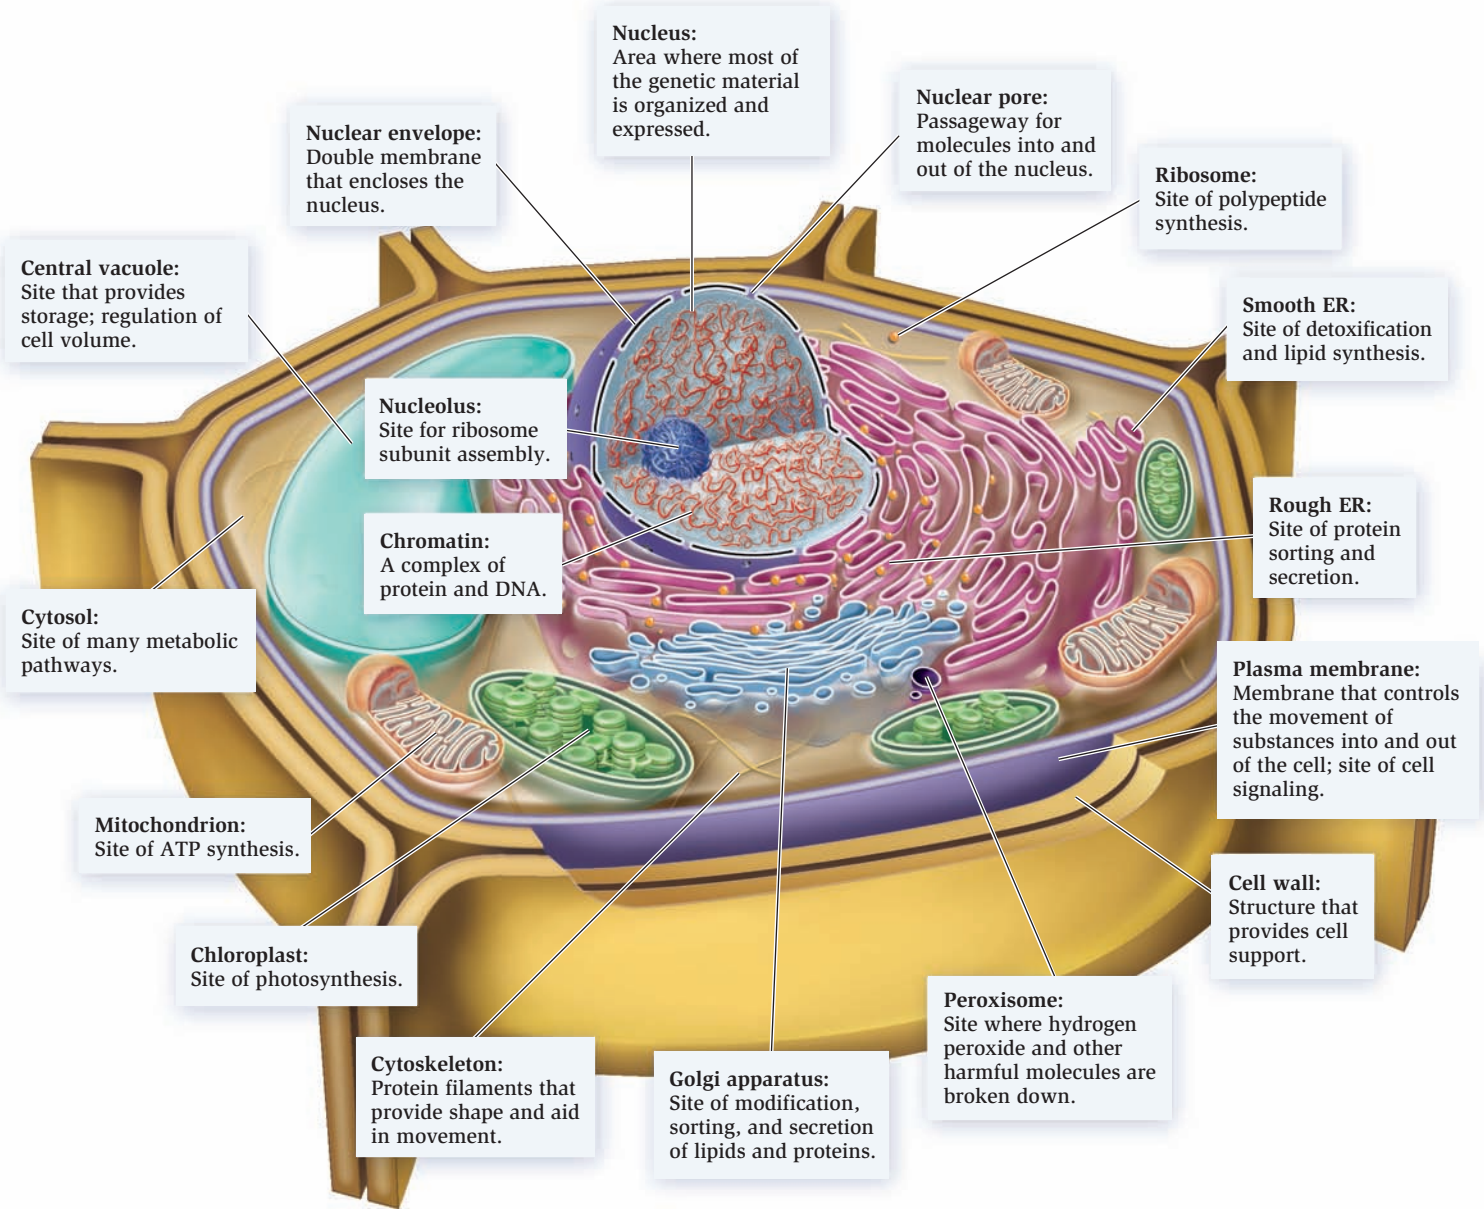

Figure 4.7 General structure of a plant cell. Plant cells lack lysosomes and centrioles. Unlike animal cells, plant cells have an outer cell wall; a large central vacuole that functions in storage and the regulation of cell volume; and chloroplasts, which carry out photosynthesis.

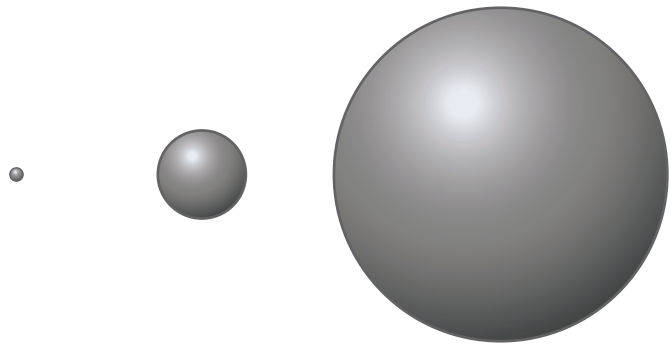
Concept Check: What are the functions of the cell structures and organelles that are (1) found in animal cells but not plant cells and (2) found in plant cells but not animal cells?

To answer this question, we need to consider the distinction between a cell's genome and its proteome. Recall that the genome constitutes all types of genetic material, namely DNA, that contains many different genes. Most genes encode the production of polypeptides, which assemble into functional proteins. The **proteome** is defined as the complete protein composition of a cell or organism. The set of proteins that is made by a given cell type is largely responsible for determining the characteristics of that cell.

The set of proteins made in one cell type is not the same as that made in a different cell type. As an example, let's consider skin cells and neurons—two cell types that have dramatically different organization and structure (see Figure 4.6). In any particular individual, the genes in a human skin cell are identical to those in a human neuron. However, their protein compositions are quite different for the following reasons:

1. *Certain proteins found in skin cells may not be produced in neurons, and vice versa.* As described in Chapter 13, genes can be regulated so they are turned on only in certain cell types.
2. *Skin cells and neurons may produce the same protein but in different amounts*. This is also due to gene regulation and to the rates at which a protein is synthesized and degraded.

3. *The amino acid sequences of particular proteins can vary in skin cells and neurons.* As discussed in Chapter 13, the mRNA from a single gene can produce two or more polypeptides with different amino acid sequences via a process called alternative splicing.
4. *Skin cells and neurons may alter their proteins in different ways.* After a protein is made, its structure may be changed in a variety of ways. These include the covalent attachment of molecules, such as phosphate and carbohydrates, and the cleavage of a protein to a smaller size, which are discussed in Chapter 21.



These four phenomena enable skin cells and neurons to produce different sets of proteins, that is, different proteomes, and therefore have different structures and functions. Likewise, the proteomes of skin cells and neurons differ from those of other cell types such as muscle and liver cells. Ultimately, the proteomes of cells are largely responsible for producing the traits of organisms, such as the color of a person's eyes.

During the last few decades, researchers have also discovered an association between proteome changes and disease. For example, the proteomes of healthy lung cells are different from the proteomes of lung cancer cells. Furthermore, the proteomes of cancer cells change as the disease progresses. A key challenge for biologists is to understand the synthesis and function of proteomes in different cell types and how proteome changes may lead to disease conditions such as cancer.

Surface Area and Volume Are Critical Parameters That Affect Cell Sizes and Shapes

As we have seen, a common feature of most cells is their small size. For example, most bacterial cells are about 1–10 µm in diameter, and a typical eukaryotic cell is 10–100 µm in diameter (see Figure 4.1). Though some exceptions are known, such as an ostrich egg, small size is a nearly universal characteristic of cells. In general, large organisms attain their large sizes by having more cells, not by having larger cells. For example, the various types of cells found in an elephant and a mouse are roughly the same sizes. However, an elephant has many more cells than a mouse.

Why are cells usually small? One key factor is the interface between a cell and its extracellular environment, which is the plasma membrane. For cells to survive, they must import substances across their plasma membranes and export waste products. If the internal volume of a cell is large, it will require a greater amount of nutrient uptake and waste export. The rate of transport of substances across the plasma membrane, however, is limited by its surface area. Therefore, a critical issue for sustaining a cell is the surface area/volume ratio. This concept is illustrated in **Figure 4.8**, which considers a simplified case in which cells are spherical. As cells get larger, the surface area of their plasma membrane increases with the square of the radius ($A = 4\pi r^2$), whereas the volume increases with the cube of the radius ($V = 4/3\pi r^3$). Therefore, as the radius of the cell gets larger, the surface area-to-volume ratio gets smaller. Biologists hypothesize that most cells are small because a high surface area/volume ratio is needed for cells to sustain an adequate level of nutrient uptake and waste export.

Radius (µm):	1	10	100
Surface area (µm²) ($A = 4\pi r^2$):	12.6	~1,260	~124,600
Volume (µm³) ($V = {}^4/_3\pi r^3$):	4.2	~4,200	~4,200,000
Surface area/volume ratio:	3.0 : 1	0.3 : 1	0.03 : 1

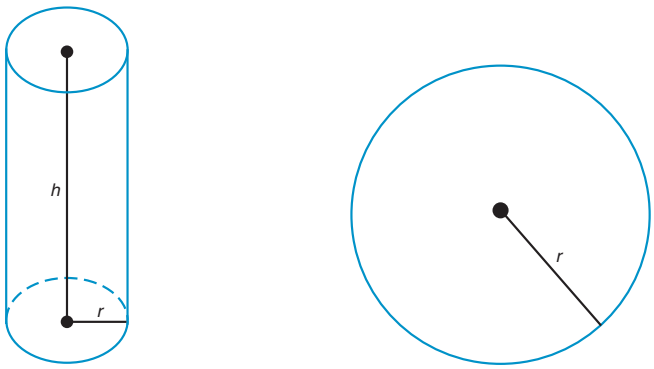
Figure 4.8 Relationship between cell size and the surface area/volume ratio. As cells get larger, the surface area/volume ratio gets smaller. Note: The three spheres shown here are not drawn precisely to scale.

BioConnections: Look ahead to Figure 40.9. How does the surface area/volume ratio affect the shapes of structures involved with gas exchange?

BIO TIPS

THE QUESTION *One way for cells to partially overcome the problem posed by the surface area/volume ratio is to be elongated and have an irregularly shaped surface. For example, look back at Figure 4.6. The skin cell is roughly spherical, whereas the neuron is very elongated and has an irregularly shaped surface. If a skin cell and a neuron cell had the same internal volume, the neuron would have a much higher surface area/volume ratio.*

Let's suppose that one cell is spherical with a radius of 21 μm. Another cell is cylindrical, with a smaller radius of 3 μm, but has a much greater length of 1,372 μm. Which of these cell types has a greater volume? Which has a greater surface area/volume ratio? Note: For a cylinder, the volume and surface area are calculated as follows:



$$\text{Volume} = \pi r^2 h$$
$$\text{Surface area} = 2\pi r^2 + 2\pi rh$$

In these equations, h (height) corresponds to cell length.

TOPIC ***What topic in biology does this question address?*** The topic is about cell volume and the surface area/volume ratio. More specifically, the question asks you to compare these parameters for two cells with different shapes.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** In the question, you are given the dimensions of two different cells and equations to calculate the volume and surface area of a cylindrical cell. From your understanding of the topic, you may remember the equations for finding the volume and surface area of a spherical cell (see Figure 4.8).

PROBLEM-SOLVING STRATEGY ***Make a drawing. Make a calculation.*** To solve this problem, you need to use the equations for calculating cell volume and surface area. It may be helpful to begin with a drawing that depicts the variables in these equations, as shown below:

Let's begin by calculating the volume for both cell types. For the cylinder, we have

$$\text{Volume} = \pi r^2 h$$
$$\text{Volume} = 3.14(3\ \mu\text{m})^2 (1372\ \mu\text{m}) = 38{,}773\ \mu\text{m}^3$$

For the sphere, we have

$$\text{Volume} = {}^4/_3\pi r^3$$
$$\text{Volume} = {}^4/_3(3.14)(21\ \mu\text{m})^3 = 38{,}773\ \mu\text{m}^3$$

Now let's calculate the surface area for both cell types. For the cylinder,

$$\text{Surface area} = 2\pi r^2 + 2\pi rh$$
$$\text{Surface area} = 2(3.14)(3\ \mu\text{m})^2 + 2(3.14)(3\ \mu\text{m})(1372\ \mu\text{m})$$
$$= 25{,}905\ \mu\text{m}^2$$

For the sphere,

$$\text{Surface area} = 4\pi r^2$$
$$\text{Surface area} = 4(3.14)(21\ \mu\text{m})^2 = 5{,}539\ \mu\text{m}^2$$

ANSWER *Though they have very different shapes, the two cell types have the same volume. The surface area/volume ratio for the cylindrical cell is 25,905/38,773 = 0.67. By comparison, the surface area/volume ratio for the spherical cell is 5,539/38,773 = 0.14. If we divide 0.67 by 0.14, we find that the cylindrical cell's surface area/volume ratio is about 4.8 times greater than that of the spherical cell.*

4.3 The Cytosol

Learning Outcomes:

1. Identify the location of the cytosol in a eukaryotic cell, and list its general functions.
2. Describe the three types of protein filaments that make up the cytoskeleton.
3. Explain how motor proteins interact with microtubules or actin filaments to promote cellular movements.

Thus far, we have focused on the general features of prokaryotic and eukaryotic cells. In the rest of this chapter, we will survey the various compartments of eukaryotic cells with a greater emphasis on structure and function. **Figure 4.9** highlights an animal and plant cell according to four different regions. We will start with the **cytosol** (shown in yellow), the region of a eukaryotic cell that is outside the membrane-bound organelles but inside the plasma membrane. The other regions of the cell, which we will examine later in this chapter, include the interior of the nucleus (blue), the endomembrane system (purple and pink), and the semiautonomous organelles (orange and green). As in prokaryotic cells, the term cytoplasm refers to the region enclosed by the plasma membrane. This includes the cytosol and the organelles.

Synthesis and Breakdown of Molecules Occur in the Cytosol

Metabolism is defined as the sum of the chemical reactions by which cells produce the materials and utilize the energy necessary to sustain life. Although many steps of metabolism also occur in cell organelles, the cytosol is a central coordinating region for many metabolic activities of eukaryotic cells. Metabolism often involves a series of steps called a metabolic pathway. Each step in a metabolic pathway is catalyzed by a specific **enzyme**—a protein that accelerates the rate of a chemical reaction. In Chapters 6 and 7, we will examine enzymes and consider a few metabolic pathways that occur in the cytosol and cell organelles.

Some pathways involve the breakdown of a molecule into smaller components, a process termed **catabolism**. Such pathways are needed

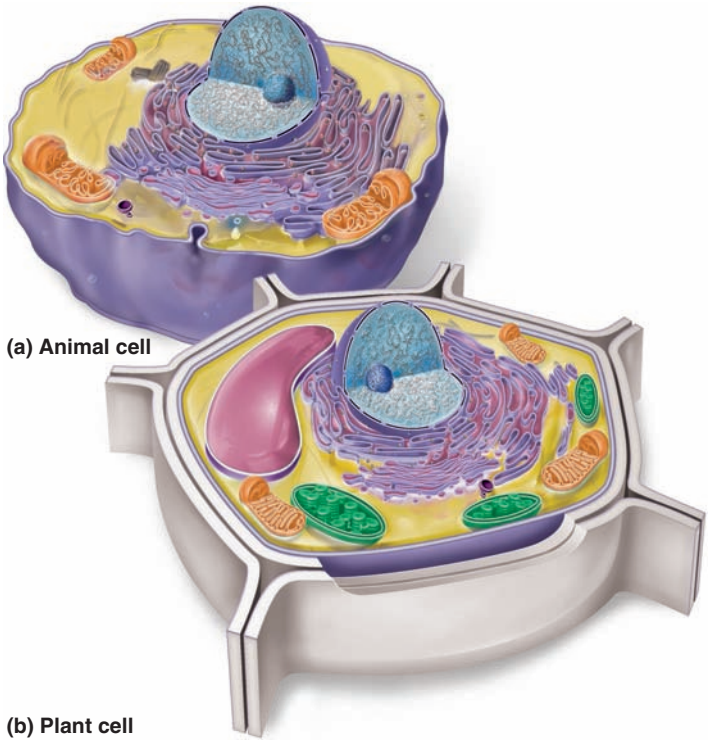


Figure 4.9 Compartments within (a) animal and (b) plant cells. The cytosol, which is outside the organelles but inside the plasma membrane, is shown in yellow. The membranes of the endomembrane system are shown in purple, and the fluid-filled interiors are pink. The peroxisome is dark purple. The interior of the nucleus is blue. Semiautonomous organelles are shown in orange (mitochondria) and green (chloroplasts).

by the cell to utilize energy and also to generate molecules that provide the building blocks to construct macromolecules. Conversely, other pathways are involved in **anabolism**, the synthesis of molecules and macromolecules. For example, polysaccharides are made by linking sugar molecules. To make proteins, amino acids are covalently connected to form a polypeptide, using the information within an mRNA (see Chapter 12). Translation occurs on ribosomes, which are found in various locations in the cell. Some ribosomes may float freely in the cytosol, others are attached to the outer membrane of the nuclear envelope and endoplasmic reticulum membrane, and still others are found within the mitochondria or chloroplasts.

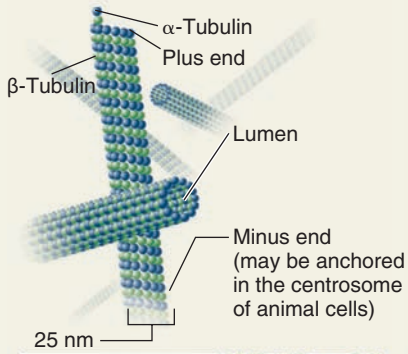
The Cytoskeleton Provides Cell Shape, Organization, and Movement

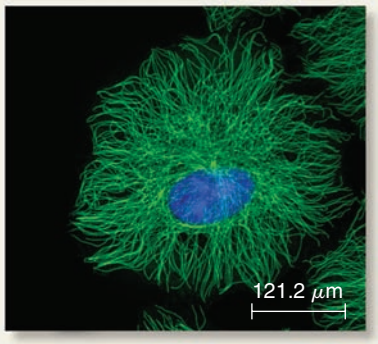
The **cytoskeleton** is a network of three different types of protein filaments: **microtubules**, **intermediate filaments**, and **actin filaments** (**Table 4.1**). Each type is constructed from many protein monomers. The cytoskeleton is a striking example of protein-protein interactions. The cytoskeleton is found primarily in the cytosol and also in the nucleus along the inner nuclear membrane. Let's first consider the structure of cytoskeletal filaments and their roles in the construction and organization of cells. Later, we will examine how they are involved in cell movement.

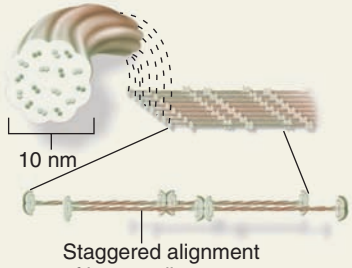
Microtubules Microtubules are long, hollow, cylindrical structures about 25 nm in diameter composed of protein subunits called α- and β-tubulin. The assembly of tubulin to form a microtubule results in a structure with a plus end and a minus end (see Table 4.1). Microtubules grow only at the plus end, but can shorten at either the plus or minus end. A single microtubule can oscillate between growing and shortening phases, a phenomenon termed **dynamic instability**. This phenomenon is important in many cellular activities, including the sorting of chromosomes during cell division.

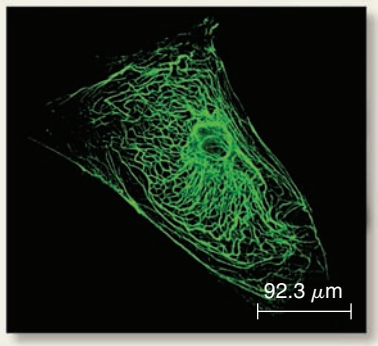
The sites where microtubules form within a cell vary among different types of organisms. Nondividing animal cells contain a single structure near their nucleus called the **centrosome**, also called a microtubule-organizing center (see Table 4.1). Within the centrosome are the **centrioles**, a conspicuous pair of structures arranged perpendicular to each other. In animal cells, microtubule growth typically starts at the centrosome in such a way that the minus end is anchored there. In contrast, most plant cells and many protists lack centrosomes and centrioles. Microtubules are created at many sites that are scattered throughout a plant cell. In plants, the nuclear membrane appears to function as a microtubule-organizing center.

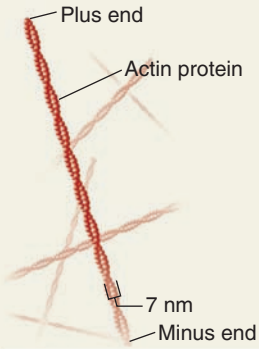
Microtubules are important for cell shape and organization. Organelles such as the Golgi apparatus are attached to microtubules. In addition, microtubules are involved in the organization and movement of chromosomes during mitosis and in the orientation of cells during cell division, events we will examine in Chapter 15.

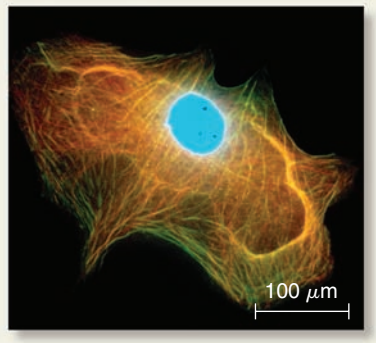


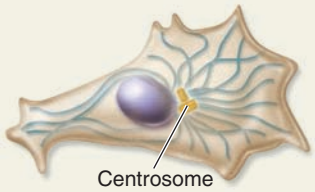


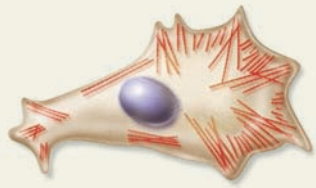












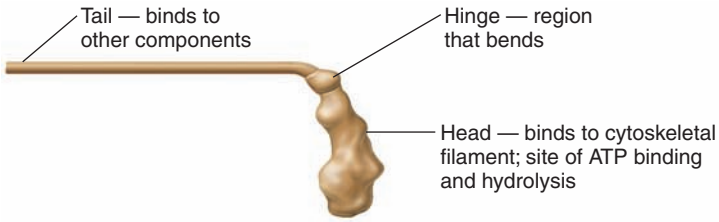
Intermediate Filaments Intermediate filaments are another class of cytoskeletal filament found in the cells of many but not all animal species. Their name is derived from the observation that they are intermediate in diameter between actin filaments and microtubules. Intermediate filament proteins bind to each other in a staggered array to form a twisted, ropelike structure with a diameter of approximately 10 nm (see Table 4.1). They function as tension-bearing fibers that help maintain cell shape and rigidity. Intermediate filaments tend to be relatively permanent. By comparison, microtubules and actin filaments readily lengthen and shorten in cells.

Several types of proteins assemble into intermediate filaments. Keratins form intermediate filaments in skin, intestinal, and kidney cells, where they are important for cell shape and mechanical strength. They are also a major constituent of hair and nails. In addition, intermediate filaments are found inside the cell nucleus. As discussed later in this chapter, nuclear lamins form a network of intermediate filaments that line the inner nuclear membrane and provide anchor points for the nuclear pores.

Actin Filaments Actin filaments are also known as **microfilaments**, because they are the thinnest cytoskeletal filaments. They are long, thin fibers approximately 7 nm in diameter (see Table 4.1). Like microtubules, actin filaments have plus and minus ends, and they are very dynamic structures in which each strand grows at the plus end by the addition of actin monomers. This assembly process produces a fiber composed of two strands of actin monomers that spiral around each other.

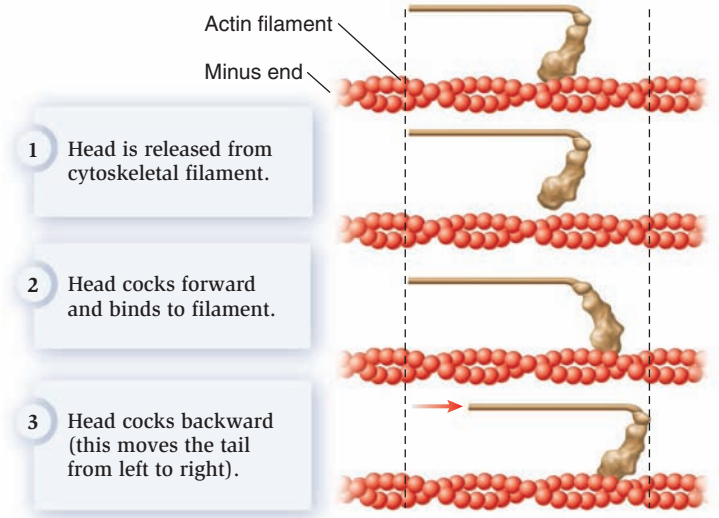
Despite their thinness, actin filaments play a key role in cell shape and strength. Although actin filaments are dispersed throughout the cytosol, they tend to be highly concentrated near the plasma

Table 4.1 Types of Cytoskeletal Filaments Found in Eukaryotic Cells



Characteristic	Microtubules	Intermediate filaments	Actin filaments
Diameter	25 nm	10 nm	7 nm
Structure	Hollow tubule  	Twisted filament  	Spiral filament  
Protein composition	Hollow tubule composed of the protein tubulin	Can be composed of different proteins including keratin, lamin, and others that form twisted filaments	Two intertwined strands composed of the protein actin
			
Common functions	Cell shape; organization of cell organelles; chromosome sorting in cell division; intracellular movement of cargo; cell motility (cilia and flagella)	Cell shape; provide cells with mechanical strength; anchorage of cell and nuclear membranes	Cell shape; cell strength; muscle contraction; intracellular movement of cargo; cell movement (amoeboid movement); cytokinesis in animal cells

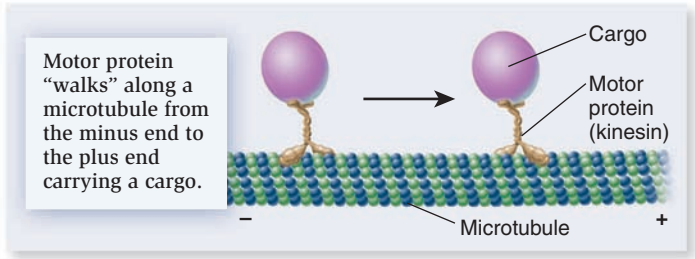
membrane. In many types of cells, actin filaments support the plasma membrane and provide shape and strength to the cell. The sides of actin filaments are often anchored to other proteins near the plasma membrane, which explains why actin filaments are typically found there. The plus ends grow toward the plasma membrane and play a key role in cell shape and movement.



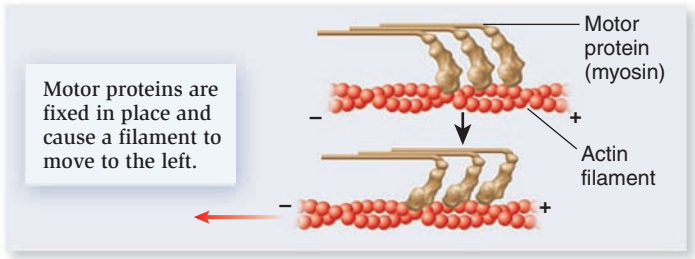
Motor Proteins Interact with Cytoskeletal Filaments to Promote Movements

Motor proteins are a category of proteins that use ATP as a source of energy to promote various types of movements. As shown in **Figure 4.10a**, a motor protein consists of three domains: the head, hinge, and tail. The head is the site where ATP binds and is hydrolyzed to adenosine diphosphate (ADP) and inorganic phosphate (P_i). ATP binding and hydrolysis cause a bend in the hinge, which results in movement. The tail region is attached to other proteins or to other kinds of cellular molecules.

To promote movement, the head region of a motor protein interacts with a cytoskeletal filament, such as an actin filament (**Figure 4.10b**). When ATP binds and is hydrolyzed, the motor protein attempts to "walk" along the filament. The head of the motor protein is initially attached to a filament. To move forward, the head detaches from the filament, cocks forward, binds to the filament, and cocks backward. To picture how this works, consider the act of walking and imagine that the ground is a cytoskeletal filament, your leg is



(a) Three-domain structure of myosin, a motor protein



(b) Movement of a motor protein along a cytoskeletal filament

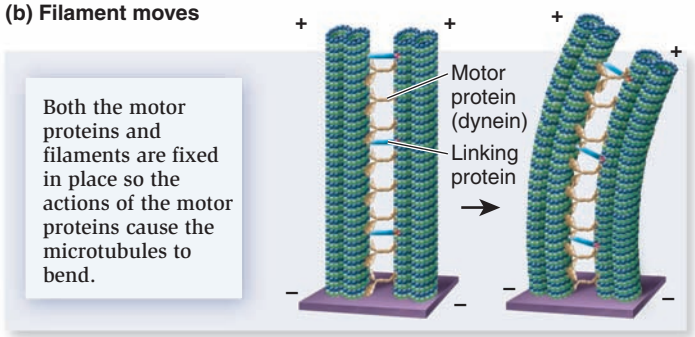


Figure 4.10 Motor proteins and their interactions with cytoskeletal filaments. The example illustrated here is the motor protein myosin (discussed in Chapter 44), which interacts with actin filaments. **(a)** Three-domain structure of myosin. **(b)** Conformational changes in a motor protein that allow it to "walk" along a cytoskeletal filament.

(a) Motor protein moves

(b) Filament moves

(c) Filaments bend

Figure 4.11 Three ways that motor proteins and cytoskeletal filaments cause movement.

BioConnections: Look ahead to Figure 44.7. Which of these three types of movements occurs during muscle contraction?

the head of the motor protein, and your hip is the hinge. To walk, you lift your leg up, you move it forward, you place it on the ground, and then you cock it backward (which propels you forward). This series of events is analogous to how a motor protein moves along a cytoskeletal filament.

Motor proteins can cause three different kinds of movements: movement of cargo via the motor protein, movement of the filament, or bending of the filament.

- In the example shown in **Figure 4.11a**, the tail region of a motor protein called kinesin is attached to a cargo, so the motor protein moves the cargo from one location to another.
- Alternatively, a motor protein called myosin can remain in place and cause the filament to move (**Figure 4.11b**). This occurs during muscle contraction, which is described in Chapter 44.
- A third possibility is that both the motor protein and filament are restricted in their movement due to the presence of linking proteins. In this case, when motor proteins called dynein attempt to walk toward the minus end, they exert a force that causes the microtubules to bend (**Figure 4.11c**).

In certain kinds of cells, microtubules and motor proteins facilitate movement involving cell appendages called **flagella** and **cilia** (singular, flagellum and cilium). The difference between the two is that flagella are usually longer than cilia and are typically found singly or in pairs.

Both flagella and cilia cause movement by generating bends that move along the length and push backwards against the surrounding fluid. A sperm cell generates bends alternatively in each direction, which begin at the head and move (propagate) toward the tip of the flagellum. (**Figure 4.12a**). Alternatively, a pair of flagella may move in a synchronized manner to pull a microorganism through the water (think of a human swimmer doing the breaststroke). Certain unicellular algae swim in this manner (**Figure 4.12b**). By comparison, cilia are often shorter than flagella and tend to cover all or part of the surface of a cell. Protists such as paramecia may have hundreds of adjacent cilia that beat in a coordinated fashion to propel the organism through the water (**Figure 4.12c**).

Despite their differences in length, flagella and cilia have the same internal structure called the **axoneme**. The axoneme contains microtubules, the motor protein dynein, and linking proteins (**Figure 4.13**). In the cilia and flagella of most eukaryotic organisms, the microtubules form an arrangement called a 9 + 2 array. The outer nine are doublet

(a) Drawing of a sperm moving its flagellum (b) *Chlamydomonas* with 2 flagella (c) *Paramecium* with many cilia

Figure 4.12 Cellular movements due to the actions of flagella and cilia. **(a)** Spermatozoa (singular, spermatozoon) are sperm cells that are motile. They swim by producing repeated bends that move along a single, long flagellum. **(b)** The swimming of *Chlamydomonas reinhardtii*, a unicellular green algae, also involves a bending motion at the base, but the motion is precisely coordinated between two flagella. This results in swimming behavior that resembles a breaststroke. **(c)** Ciliated protozoa such as this *Paramecium* swim via many shorter cilia.

Concept Check: *During the movement of a cilium or flagellum, describe the type of movements that occur between the motor proteins and microtubules.*

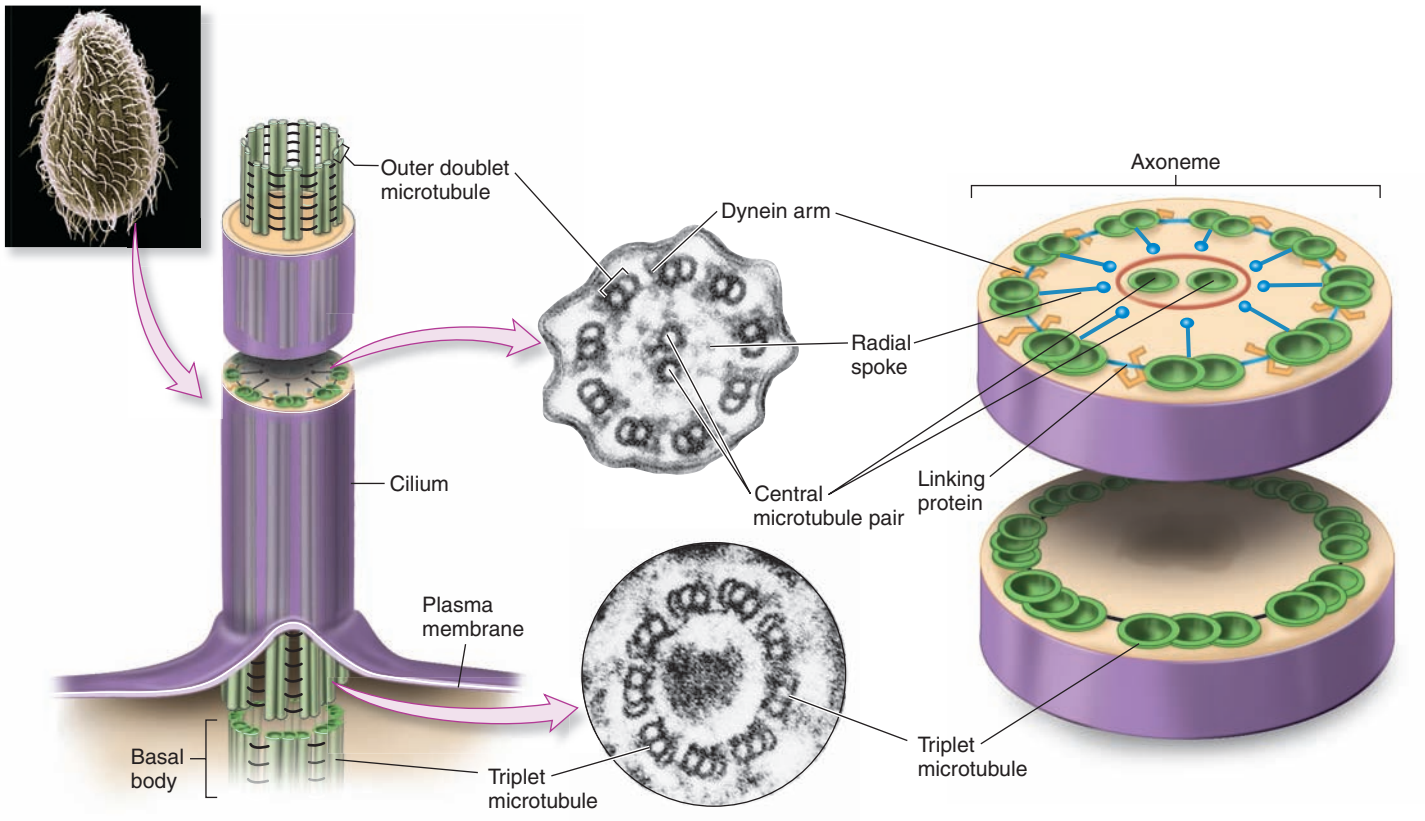

Figure 4.13 Structure of a eukaryotic cilium or flagellum. The structure of a cilium of a protist, *Tetrahymena thermophila* (see inset), consists of a 9 + 2 arrangement of nine outer doublet microtubules and two central microtubules. This structure is anchored to the basal body, which has nine triplet microtubules, in which three microtubules are fused together. Note: The structure of the basal body is very similar to centrioles in animal cells.

BioConnections: *Look ahead to Figures 28.4, 28.7, and 28.8. What are some different uses of cilia and flagella among protists?*

microtubules, which are composed of a partial microtubule attached to a complete microtubule. Each of the two central microtubules consists of a single microtubule. Radial spokes project from the outer doublet microtubules toward the central pair. The microtubules in flagella and cilia emanate from **basal bodies**, which are anchored to the cytoplasmic side of the plasma membrane. At the basal body, the microtubules form a triplet structure. Much like the centrosome of animal cells, the basal bodies provide a site for microtubules to grow.

The movement of both flagella and cilia involves the propagation of a bend, which begins at the base of the structure and proceeds toward the tip (see Figure 4.12a). The bending occurs because dynein is activated to walk toward the minus end of the microtubules. However, the microtubules and dynein are not free to move relative to each other because of linking proteins. Therefore, instead of dyneins freely walking along the microtubules, they exert a force that bends the microtubules (see Figure 4.11c). The dyneins at the base of the flagellum or cilium are activated first, followed by dyneins that are progressively closer to the tip, and the resulting movement propels the organism.

4.4 The Nucleus and Endomembrane System

Learning Outcomes:

1. Describe the structure and organization of the cell nucleus.
2. Outline the structures and general functions of the components of the endomembrane system.
3. Distinguish between the rough endoplasmic reticulum and the smooth endoplasmic reticulum.
4. **SciSKILLS** » Analyze the results of Palade's study, and explain how they indicate the existence of a secretory pathway in eukaryotic cells.
5. Identify three important functions of the plasma membrane.

In Chapter 2, we learned that the nucleus of an atom contains protons and neutrons. In cell biology, the term **nucleus** has a different meaning. It is an organelle found in eukaryotic cells that contains most of the cell's genetic material. A small amount of genetic material is also found outside the nucleus, in mitochondria and chloroplasts.

The membranes that enclose the nucleus are part of a larger network of membranes called the **endomembrane system**. This system includes not only the nuclear envelope, which encloses the nucleus, but also the endoplasmic reticulum, Golgi apparatus, lysosomes, vacuoles, and peroxisomes. The prefix endo- (from the Greek, meaning inside) originally referred only to these organelles and internal membranes. However, we now know that the plasma membrane is also part of this integrated membrane system (**Figure 4.14**). In this section, we will examine the nucleus and survey the structures and functions of the organelles and membranes of the endomembrane system.

The Eukaryotic Nucleus Contains Chromosomes

The nucleus is the compartment that is enclosed by a double-membrane structure termed the **nuclear envelope** and houses the genetic material (**Figure 4.15**). **Nuclear pores** are formed where the inner and outer nuclear membranes make contact with each other. The pores provide a passageway for the movement of molecules and macromolecules into and out of the nucleus. Although cell biologists view the nuclear envelope as part of the endomembrane system, the materials within the nucleus are not.

Inside the nucleus are the chromosomes and a filamentous network of proteins called the nuclear matrix. Each **chromosome** is composed of genetic material, namely DNA, and many types of proteins that help to compact the chromosome to fit inside the nucleus. The complex formed between DNA and such proteins is termed **chromatin**. The **nuclear matrix** consists of two parts: the nuclear lamina, which is composed of intermediate filaments that line the inner nuclear membrane, and an internal nuclear matrix, which is connected to the lamina and fills the interior of the nucleus. The nuclear matrix serves to organize the chromosomes within the nucleus. Each chromosome is located in a distinct, nonoverlapping **chromosome territory**, which is visible when cells are exposed to dyes that label specific types of chromosomes (**Figure 4.16**).

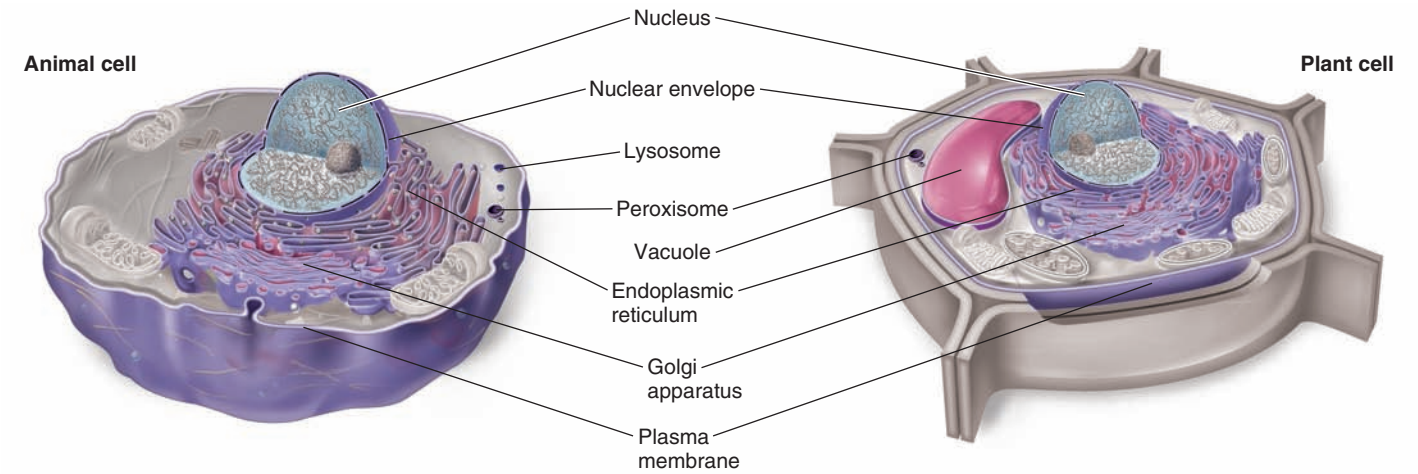

Figure 4.14 The nucleus and endomembrane system. This figure highlights the internal compartment of the nucleus (blue), the membranes of the endomembrane system (purple), and the fluid-filled interiors of the endomembrane system (pink). The nuclear envelope is part of the endomembrane system, but the interior of the nucleus is not.

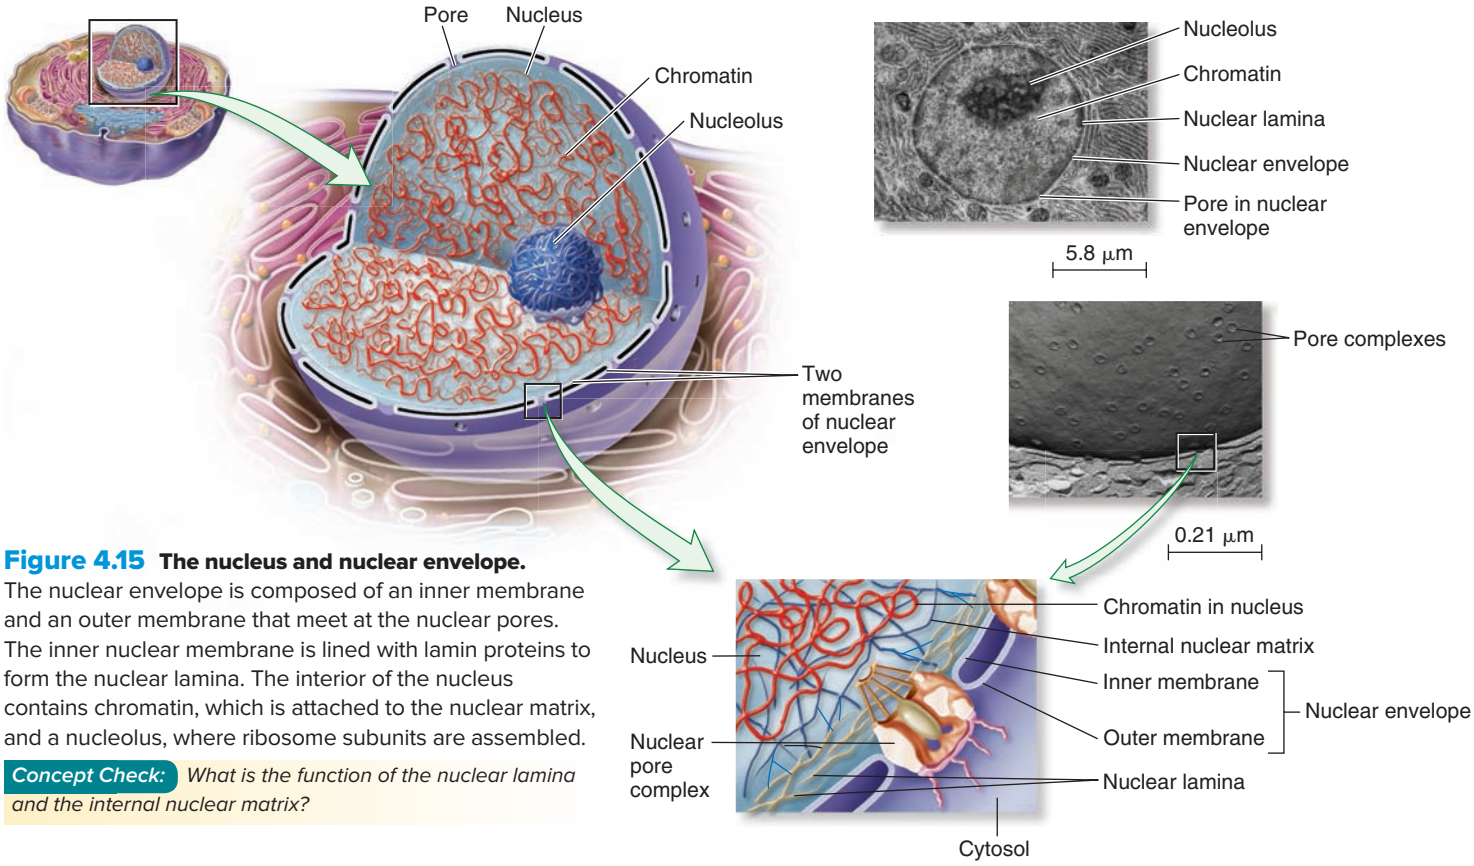

Figure 4.15 The nucleus and nuclear envelope.
The nuclear envelope is composed of an inner membrane and an outer membrane that meet at the nuclear pores. The inner nuclear membrane is lined with lamin proteins to form the nuclear lamina. The interior of the nucleus contains chromatin, which is attached to the nuclear matrix, and a nucleolus, where ribosome subunits are assembled.

Concept Check: What is the function of the nuclear lamina and the internal nuclear matrix?

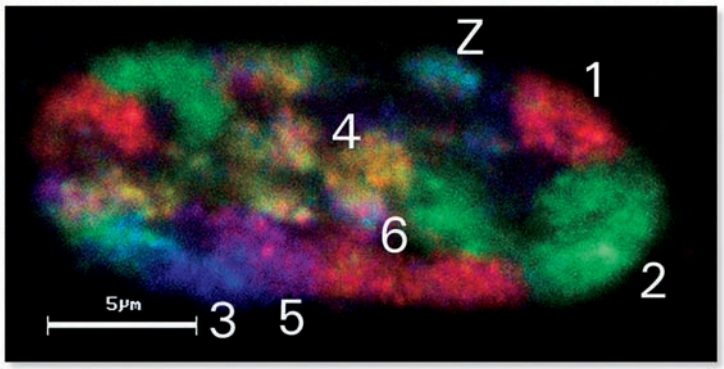

Figure 4.16 Chromosome territories in the cell nucleus.
Chromosomes from a chicken were labeled with chromosome-specific probes. Seven types of chicken chromosomes are stained with a different dye. Each chromosome occupies its own distinct, nonoverlapping territory within the cell nucleus.

BioConnections: Look ahead to Figure 15.8. What happens to chromosome territories during cell division?

The primary function of the nucleus is the protection, organization, replication, and expression of the genetic material. These topics are discussed in Unit III. Another important function is the assembly of ribosome subunits—cellular structures involved in producing polypeptides during the process of translation (look ahead to Table 12.3). The assembly of ribosome subunits occurs in the **nucleolus** (plural, nucleoli), a prominent region in the nucleus of nondividing cells. A ribosome is composed of two subunits: one small and one large. Each subunit contains one or more RNA molecules and several types of proteins. Most of the RNA molecules that are components of ribosomes are made in the vicinity of the nucleolus. By comparison, the ribosomal proteins are produced in the cytosol and then imported into the nucleus through the nuclear pores. The ribosomal proteins and RNA molecules then assemble in the nucleolus to form the ribosomal subunits. Finally, the subunits exit through the nuclear pores into the cytosol, where they are needed for protein synthesis.

The Endoplasmic Reticulum Initiates the Sorting of Some Proteins and Carries Out Metabolic Functions

The **endoplasmic reticulum (ER)** is a network of membranes that form flattened, fluid-filled tubules, or **cisternae** (Figure 4.17). The terms endoplasmic (Greek, for in the cytoplasm) and reticulum (Latin, for little net) refer to the location and shape of this organelle when viewed under a microscope. The term **lumen** describes the internal space of an organelle. The ER membrane encloses a single compartment called the **ER lumen**. There are two distinct, but continuous types of ER: rough ER and smooth ER.

Rough ER The outer surface of the **rough endoplasmic reticulum (rough ER)** is studded with ribosomes, giving it a bumpy appearance. Rough ER plays a key role in the sorting of proteins that are destined for the ER, Golgi apparatus, lysosomes, vacuoles, plasma membrane, or outside of the cell. Proteins are packaged into **membrane vesicles**—small spheres composed of membrane—and moved from one

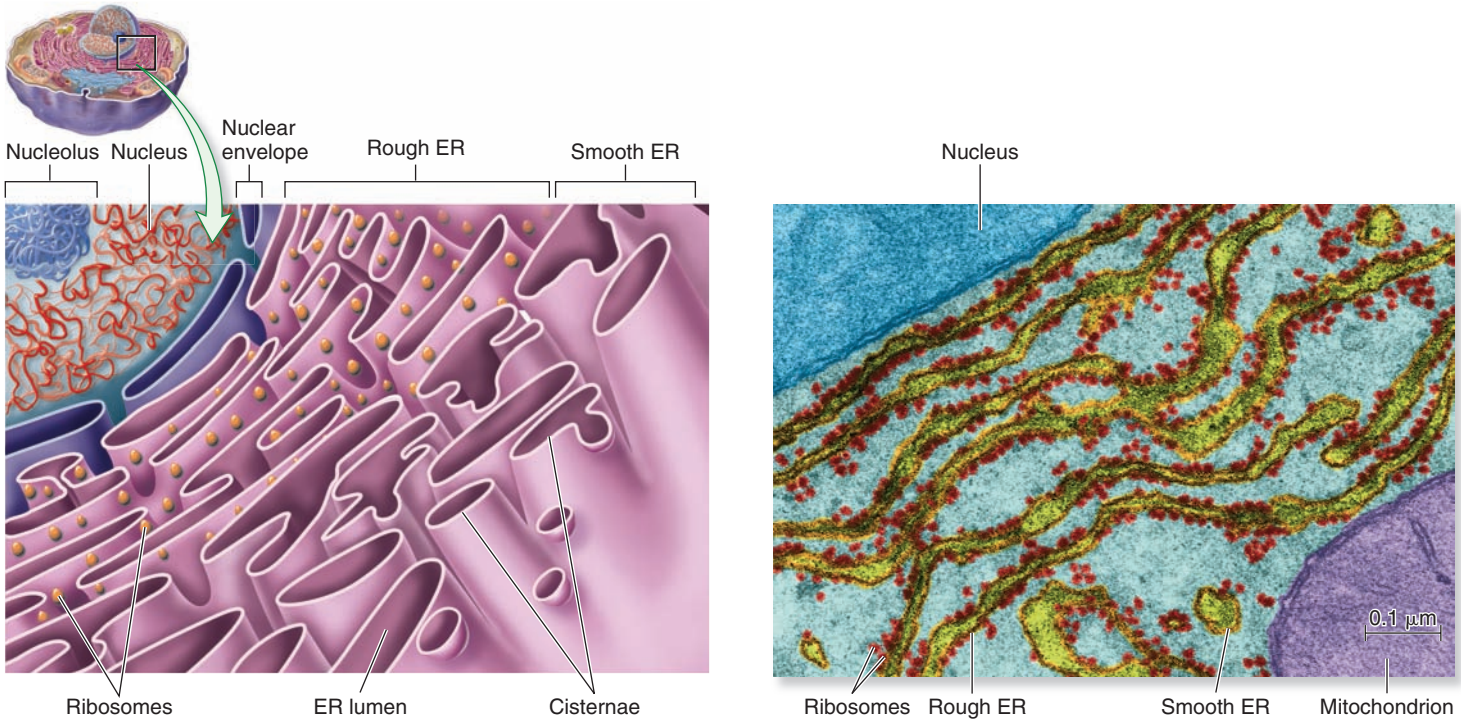

Figure 4.17 Structure of the endoplasmic reticulum. (Left side) The endoplasmic reticulum (ER) is composed of a network of flattened tubules called cisternae that enclose a continuous ER lumen. The rough ER is studded with ribosomes, whereas the smooth ER lacks ribosomes. The rough ER is continuous with the outer nuclear membrane. (Right side) A colorized TEM of the ER. The lumen of the ER is colored yellow and the ribosomes are red.

location in the endomembrane system to another. This sorting process is described later in Section 4.6. In conjunction with protein sorting, a second function of the rough ER is the insertion of certain newly made proteins into the ER membrane. A third important function of the rough ER is the attachment of carbohydrates to proteins and lipids. This process is called **glycosylation**. The topics of membrane protein insertion and protein glycosylation will be discussed in Chapter 5.

Smooth ER The **smooth endoplasmic reticulum (smooth ER)**, which lacks ribosomes, functions in diverse metabolic processes. The extensive network of smooth ER membranes provides an increased surface area for enzymes that play important metabolic roles. In liver cells, enzymes in the smooth ER detoxify many potentially harmful organic molecules, including barbiturate drugs and ethanol. These enzymes convert hydrophobic toxic molecules into more hydrophilic molecules, which are easily excreted from the body. Chronic alcohol consumption, as in alcoholics, leads to a greater amount of smooth ER in liver cells, which increases the rate of alcohol breakdown. This explains why people who consume alcohol regularly must ingest more alcohol to experience its effects. It also explains why alcoholics often have enlarged livers.

The smooth ER of liver cells also plays a role in carbohydrate metabolism. The liver cells of animals store energy in the form of glycogen, which is a polymer of glucose. Glycogen granules sit very close to the smooth ER membrane. When chemical energy is needed, enzymes are activated that break down the glycogen to glucose-6-phosphate. Then, an enzyme in the smooth ER called glucose-6-phosphatase removes the phosphate group, and glucose is exported from the cell into the bloodstream.

Another important function of the smooth ER in all eukaryotes is the accumulation of calcium ions (Ca^{2+}). The smooth ER contains calcium pumps that transport Ca^{2+} into the ER lumen. The regulated release of Ca^{2+} into the cytosol is involved in many vital cellular processes, including muscle contraction in animals.

Finally, enzymes in the smooth ER are critical in the synthesis and modification of lipids. For example, the smooth ER is the primary site for the synthesis of phospholipids, which are the main lipid component of eukaryotic cell membranes. This topic is discussed in Chapter 5. In addition, enzymes in the smooth ER are necessary for certain modifications of the lipid cholesterol that are needed to produce steroid hormones such as estrogen and testosterone.

The Golgi Apparatus Directs the Processing, Sorting, and Secretion of Cellular Molecules

The **Golgi apparatus** (also called the Golgi body, Golgi complex, or simply Golgi) was discovered by the Italian microscopist Camillo Golgi in 1898. It consists of a stack of flattened membranes, with each flattened membrane enclosing a single compartment. The Golgi compartments are named according to their orientation in the cell. The *cis* Golgi is near the ER membrane, the *trans* Golgi is closest to the plasma membrane, and the medial Golgi is found in the middle.

Two models have been proposed to explain how materials move through the Golgi apparatus:

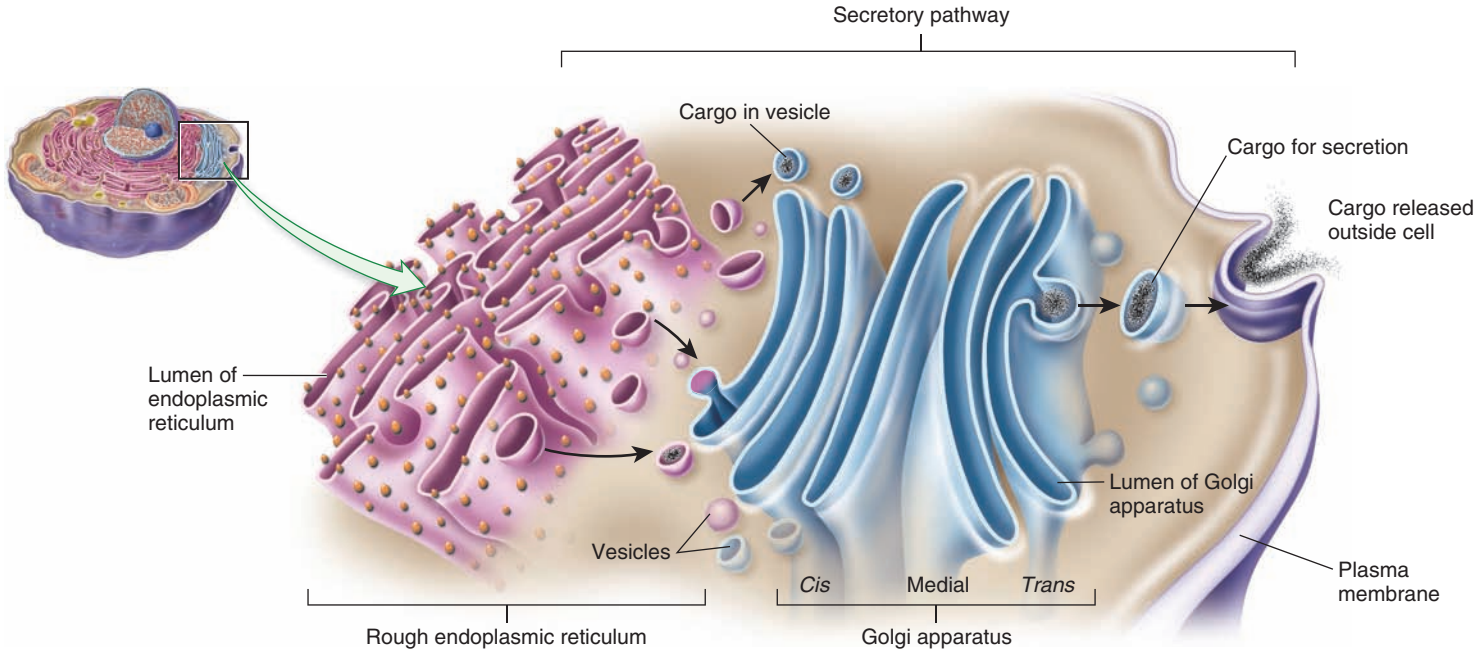

Figure 4.18 The Golgi apparatus and secretory pathway. The Golgi is composed of stacks of membranes that enclose distinct compartments. Transport to and from the Golgi compartments occurs via membrane vesicles. Vesicles bud from the ER and go to the Golgi, and vesicles from the Golgi fuse with the plasma membrane to release cargo to the outside. The pathway from the ER to the Golgi to the plasma membrane is termed the secretory pathway.

Concept Check: *If we consider the Golgi apparatus as three compartments (cis, medial, and trans), describe the compartments that a protein travels through to be secreted.*

- **Vesicular transport model:** Materials are transported between the Golgi cisternae via membrane vesicles that bud from one compartment in the Golgi (for example, the *cis* Golgi) and fuse with another compartment (for example, the medial Golgi).
- **Cisternal maturation model:** Vesicles from the ER fuse to form a cisterna at the *cis* face; the cisterna that was previously at the *cis* face becomes a medial cisterna. This addition of a cisterna moves the other medial cisternae toward the *trans* face. A cisterna at the *trans* face is lost as a result of the export of vesicles from its surface.

Further research is needed to determine the validity of these models.

The Golgi apparatus performs three overlapping functions: (1) processing, (2) protein sorting, and (3) secretion. We will discuss protein sorting in Section 4.6. Enzymes in the Golgi apparatus process, or modify, certain proteins and lipids. As mentioned earlier, carbohydrates can be attached to proteins and lipids in the endoplasmic reticulum. Glycosylation continues in the Golgi. For this to occur, a protein or lipid is transported via vesicles from the ER to the *cis* Golgi. Most of the glycosylation occurs in the medial Golgi.

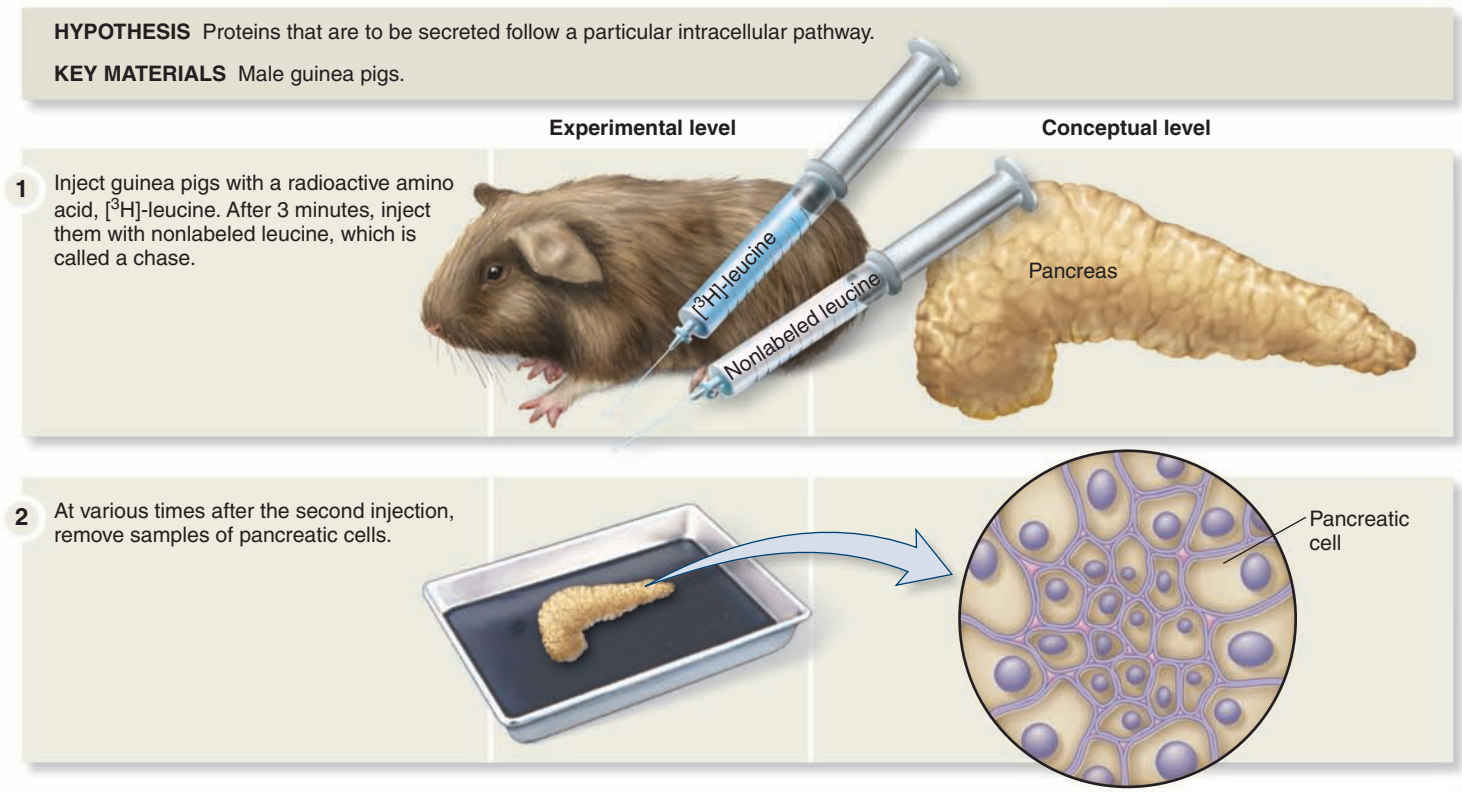
A second type of processing event is **proteolysis**, whereby enzymes called **proteases** make cuts in polypeptides. For example, the hormone insulin is first made as a large precursor termed proinsulin. In the Golgi apparatus, proinsulin is packaged with proteases into vesicles. The proteases cut out a portion of the proinsulin to create a smaller insulin polypeptide that is a functional hormone. This happens just prior to secretion, which is described next.

The Golgi apparatus packages different types of materials (cargo) into **secretory vesicles** that fuse with the plasma membrane, thereby releasing their contents outside the cell. Proteins destined for secretion are synthesized into the ER, travel to the Golgi, and then are transported by vesicles to the plasma membrane. The vesicles then fuse with the plasma membrane, and the proteins are secreted to the outside of the cell. The entire route is called the **secretory pathway** (**Figure 4.18**). In addition to secretory vesicles, the Golgi also produces vesicles that travel to other parts of the cell, such as the lysosomes.

Feature Investigation | Palade Discovered That Proteins Destined for Secretion Move Sequentially Through Organelles of the Endomembrane System

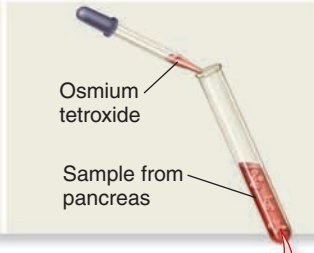
As we have seen, a key function of the endomembrane system is protein secretion. The identification of the secretory pathway came from studies of George Palade and his colleagues in the 1960s. He hypothesized that proteins follow an intracellular pathway to be secreted. Palade's team conducted pulse-chase experiments, in which the researchers administered a pulse of radioactive amino acids to cells

so they made radioactive proteins. A few minutes later, the cells were given a large amount of nonradioactive amino acids. This is called a "chase" because it chases away the ability of the cells to make any more radioactive proteins. In this way, radioactive proteins were produced only briefly. Because they were labeled with radioactivity, the fate of these proteins could be monitored over time. The goal of a pulse-chase experiment is to determine where the radioactive proteins are produced and the pathway they take as they travel through a cell.



Palade chose to study the cells of the pancreas. This organ secretes enzymes and protein hormones that play a role in digestion and metabolism. Therefore, these cells were chosen because their primary activity is protein secretion. To study the pathway for protein secretion, Palade and colleagues injected a radioactive version of the amino acid leucine into the bloodstream of male guinea pigs. The radiolabeled leucine traveled in the bloodstream and was quickly taken up by cells of the body, including those in the pancreas. Three minutes later, the researchers injected nonradioactive leucine (**Figure 4.19**). At various times after the second injection, samples of pancreatic cells were removed from the animals. The cells were then prepared for transmission electron microscopy (TEM). The sample was stained with osmium tetroxide, a heavy metal that became bound to membranes and showed the locations of the cell organelles. In addition, the sample was coated with a radiation-sensitive emulsion containing silver. When radiation was emitted from radioactive proteins, it interacted with the emulsion in a way that caused the precipitation of silver, which became tightly bound to the sample. In this way, the precipitated silver marked the location of the radiolabeled proteins. Unprecipitated silver in the emulsion was later washed away. Because silver atoms are electron dense, they produce dark spots in a TEM. Therefore, dark spots revealed the locations of radioactive proteins.

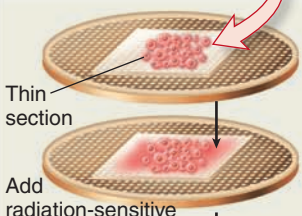
The schematic drawings shown in the data indicate the path of the proteins as they moved through the secretory pathway. Very dark objects, namely radioactive proteins, were first observed in the rough ER. Observations made at later times indicated that the radioactive proteins moved from the ER to the Golgi, and then to secretory vesicles near the plasma membrane. In this way, Palade followed the intracellular pathway of protein movement. His experiments provided the first evidence that secreted proteins are synthesized into the rough ER and move through a series of cellular compartments before they are secreted.



Experimental Questions

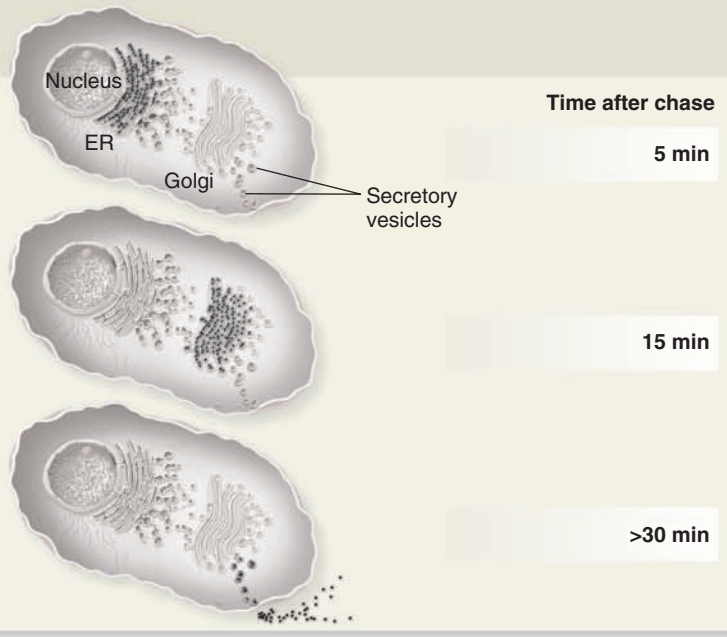
1. **SciSKILLS** » Explain the procedure of a pulse-chase experiment. What is the pulse, and what is the chase? What was the purpose of the approach?
2. Why were pancreatic cells used for this investigation?
3. **SciSKILLS** » Analyze the results of the experiment of Figure 4.19. What did the researchers conclude?

Figure 4.19 **Palade's use of the pulse-chase method to study protein secretion.**



3 Stain the sample with osmium tetroxide, which is a heavy metal that binds to membranes.

4 Cut thin sections of the samples, and place a thin layer of radiation-sensitive emulsion over the sample. Allow time for radioactive emission from radiolabeled proteins to precipitate silver atoms in the emulsion.



5 Observe the sample under a transmission electron microscope.

6 **THE DATA**

Schematic drawings of transmission electron micrographs

7 **CONCLUSION** To be secreted, proteins move from the ER to the Golgi to secretory vesicles and then to the plasma membrane, where they are released to the outside of the cell.

Lysosomes Are Involved in the Intracellular Digestion of Macromolecules

We now turn to another organelle of the endomembrane system, **lysosomes**, which are small organelles found in animal cells that break down macromolecules. Lysosomes contain many **acid hydrolases**, which are hydrolytic enzymes that use a molecule of water to break a covalent bond. This type of chemical reaction is called hydrolysis:

$$R_1\text{—}R_2 + H_2O \xrightarrow{\text{Acid hydrolase}} R_1\text{—}OH + R_2\text{—}H$$

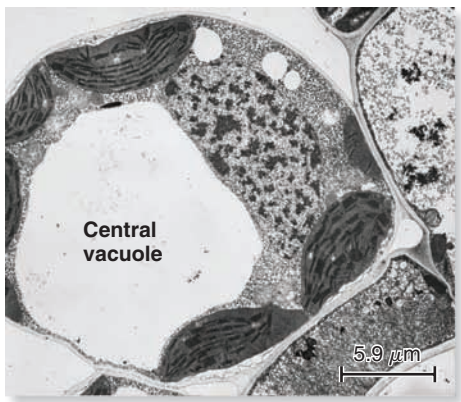
The acid hydrolases in a lysosome function optimally at an acidic pH. The fluid-filled interior of a lysosome has a pH of approximately 4.8. If a lysosomal membrane breaks, releasing acid hydrolases into the cytosol, the enzymes are not very active because the cytosolic pH is neutral (approximately pH 7.2) and buffered. This prevents significant damage to the cell from lysosome breakage.

Lysosomes contain many different types of acid hydrolases that break down carbohydrates, proteins, lipids, and nucleic acids. This enzymatic function enables lysosomes to break down complex materials. One function of lysosomes involves the digestion of substances that are taken up from outside the cell via a process called endocytosis (see Chapter 5). In addition, lysosomes break down intracellular molecules and macromolecules to recycle their building blocks to make new molecules and macromolecules in a process called autophagy (see Chapter 6).

Vacuoles Function in Storage, Regulation of Cell Volume, and Degradation

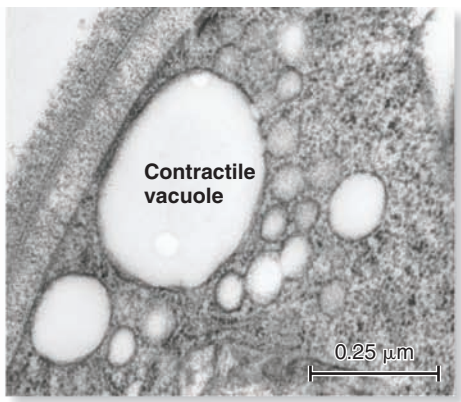
Vacuoles are prominent organelles in plant cells, fungal cells, and certain protists. The term vacuole (Latin, for empty space) came from early microscopic observations of these compartments. We now know that vacuoles are not empty but instead contain fluid and sometimes even solid substances. Most vacuoles are made from the fusion of many smaller membrane vesicles. Vacuoles in animal cells tend to be smaller than those in plants and are more commonly used to temporarily store materials or transport substances. Such vacuoles are sometimes called storage vesicles.

The functions of vacuoles are extremely varied, and they differ among cell types and even environmental conditions. The best way to appreciate vacuole function is to consider a few examples. Mature plant cells usually have a large **central vacuole** that occupies 80% or more of the cell volume (**Figure 4.20a**). The central vacuole serves two important purposes. First, it stores a large amount of water, enzymes, and inorganic ions such as calcium. It also stores other materials including proteins and pigments. Second, it performs a space-filling function. The large, fluid-filled vacuole exerts a pressure on the cell wall, called turgor pressure. If a plant becomes dehydrated and this pressure is lost, a plant will wilt. Turgor pressure is important in maintaining the structure of plant cells and the plant itself, and it helps to drive the expansion of the cell wall, which is necessary for growth.



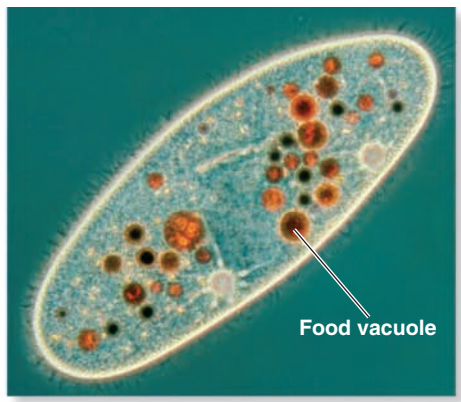
Certain species of protists use vacuoles to maintain cell volume. Freshwater organisms such as the alga *Chlamydomonas reinhardtii* have small, water-filled **contractile vacuoles** that expand as water enters the cell (**Figure 4.20b**). Once they reach a certain size, the vacuoles fuse with the plasma membrane, expelling their contents to the exterior of the cell (look ahead to Figure 5.16). This mechanism is necessary to remove excess water that continually enters the cell by diffusion across the plasma membrane.

Another function of vacuoles is degradation. Some protists engulf their food into large food vacuoles in the process of phagocytosis (**Figure 4.20c**). Food vacuoles contain hydrolytic enzymes that break down macromolecules within food. Macrophages, a type of cell found in animals' immune systems, engulf bacterial cells into phagocytic vacuoles, which then fuse with lysosomes, where the bacteria are destroyed.



Peroxisomes Catalyze Detoxifying Reactions

Peroxisomes, discovered by Christian de Duve in 1965, are small organelles found in all eukaryotic cells. Peroxisomes consist of a single membrane that encloses a fluid-filled lumen. A typical eukaryotic cell contains several hundred of them.



Peroxisomes catalyze a variety of chemical reactions, including some reactions that break down organic molecules and others that are biosynthetic. In mammals, large numbers of peroxisomes are found in

(a) Central vacuole in a plant cell

(b) Contractile vacuoles in an algal cell

(c) Food vacuoles in a paramecium

Figure 4.20 Examples of vacuoles. These are TEMs. Part (c) is colorized.

liver cells, where toxic molecules accumulate and are broken down. A common by-product of the breakdown of toxins is hydrogen peroxide, H_2O_2:

$$\underset{\text{(toxin)}}{RH_2} + O_2 \longrightarrow R + H_2O_2$$

Hydrogen peroxide has the potential to damage cellular components. In the presence of metals such as iron (Fe^{2+}), which are found naturally in living cells, H_2O_2 is broken down to form a hydroxide ion (OH^-) and a molecule called a hydroxide free radical (·OH):

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^- + \cdot OH \text{ (hydroxide free radical)}$$

The ·OH is highly reactive and can damage proteins, lipids, and DNA. Therefore, it is beneficial for cells to break down H_2O_2 in an alternative manner that does not form a ·OH. Peroxisomes contain an enzyme called **catalase** that breaks down H_2O_2 to make water and oxygen gas (hence the name peroxisome):

$$2\,H_2O_2 \xrightarrow{\text{Catalase}} 2\,H_2O + O_2$$

Aside from detoxification, peroxisomes usually contain enzymes involved in the metabolism of fats and amino acids. For example, plant seeds contain specialized organelles called **glyoxysomes**, which are similar to peroxisomes. Seeds often store fats instead of carbohydrates. Because fats have higher energy per unit mass, a plant can make seeds that are smaller and less heavy. Glyoxysomes contain enzymes that are needed to convert fats to sugars. These enzymes become active when a seed germinates and the seedling begins to grow.

A general model for peroxisome formation is shown in **Figure 4.21**, though the details may differ among animal, plant, and fungal cells. To initiate peroxisome formation, vesicles bud from the ER membrane and form a premature peroxisome. Following the import of additional proteins, the premature peroxisome becomes a mature peroxisome. Once the mature peroxisome has formed, it may then divide to further increase the number of peroxisomes in the cell.

The Plasma Membrane Is the Interface Between a Cell and Its Environment

The cytoplasm of eukaryotic cells is surrounded by a plasma membrane, which is part of the endomembrane system and provides a boundary between a cell and the extracellular environment. Proteins in the plasma membrane perform many important functions that affect the activities inside the cell (**Figure 4.22**).

Membrane Transport First, many plasma membrane proteins are involved in **membrane transport**. Some of these proteins function to transport essential nutrients or ions into the cell, and others are involved in the export of substances. Due to the functioning of these protein transporters, the plasma membrane is selectively permeable; it allows only certain substances in and out. We will examine the structure and function of the plasma membrane, as well as a variety of transporters, in Chapter 5.

Cell Signaling A second vital function of the plasma membrane is **cell signaling**. To survive and adapt to changing conditions, cells must be able to sense changes in their environment. In addition, the cells of a multicellular organism need to communicate with each other to coordinate their activities. The plasma membrane of all cells contains receptors that recognize signals—either environmental agents or molecules secreted by other cells. When a signaling molecule binds to a receptor, it activates a signal transduction pathway—a series of steps that cause the cell to respond to the signal. For example, when you eat

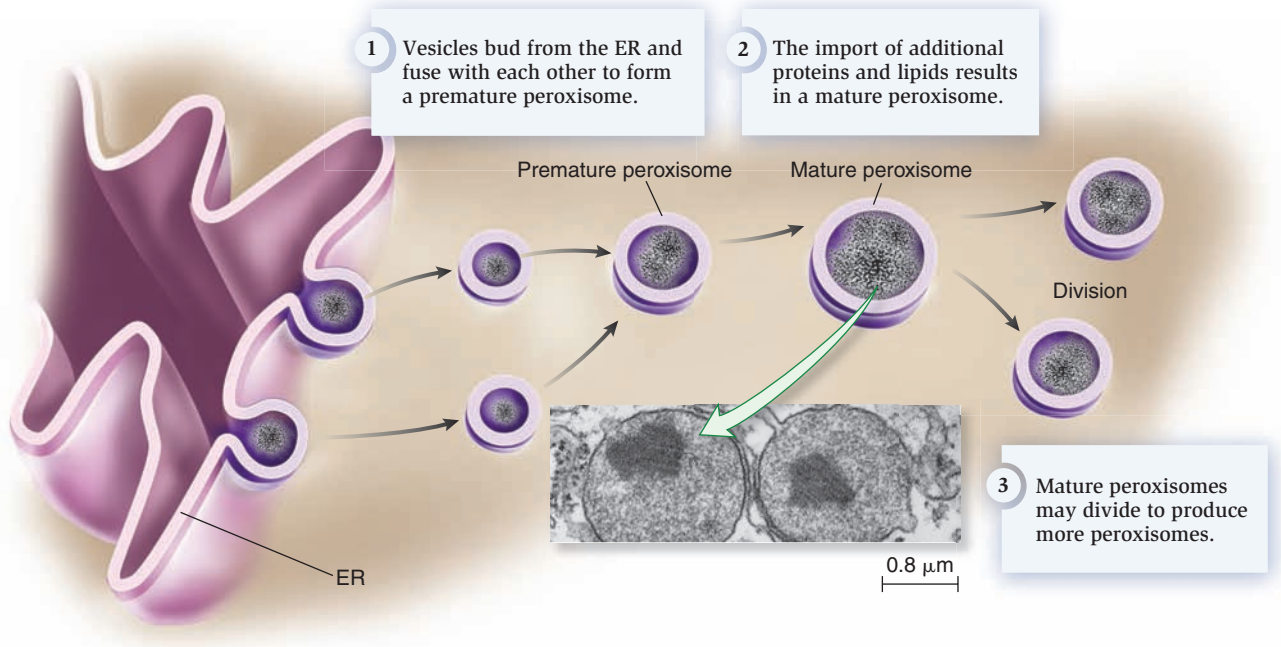


Figure 4.21 Formation of peroxisomes. The inset is a TEM of mature peroxisomes.

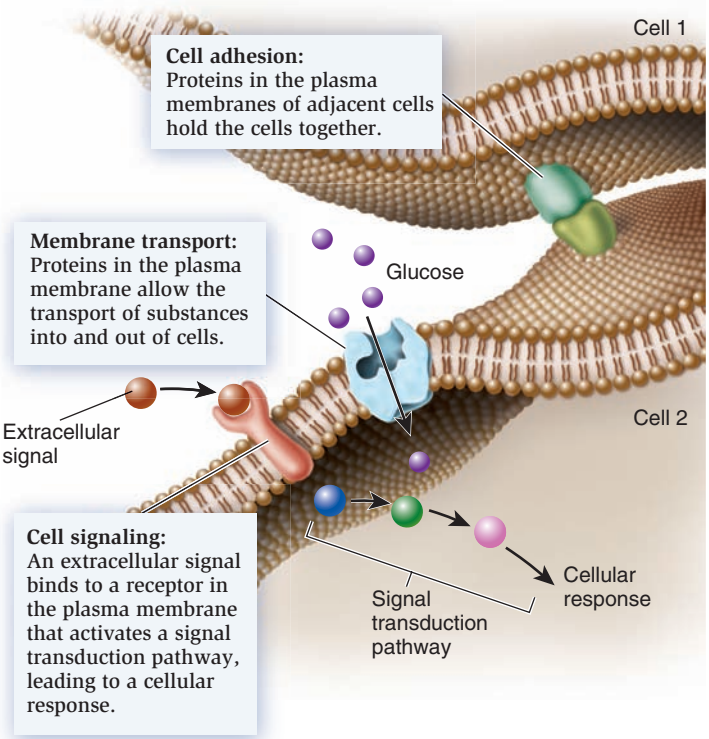

Figure 4.22 Major functions of the plasma membrane. Three important roles are membrane transport, cell signaling, and cell adhesion.

Concept Check: Which of these three functions do you think is the most important for cell metabolism?

a meal, the hormone insulin is secreted into your bloodstream. This hormone binds to receptors in the plasma membranes of your cells, which results in a cellular response that allows your cells to increase their uptake of certain molecules found in food, such as glucose. We will explore the details of cell signaling in Chapter 9.

Cell Adhesion A third important role of the plasma membrane in animal cells is **cell adhesion**. Protein-protein interactions among proteins in the plasma membranes of adjacent cells promote cell-to-cell adhesion. This phenomenon is critical for animal cells to properly interact to form a multicellular organism and allows cells to recognize each other. The structures and functions of proteins involved in cell adhesion will be examined in Chapter 10.

4.5 Semiautonomous Organelles

Learning Outcomes:

1. Outline the structures and general functions of mitochondria and chloroplasts.
2. **SciSKILLS** » Evaluate the evidence for the endosymbiosis theory.

We now turn to those organelles in eukaryotic cells that are considered semiautonomous: mitochondria and chloroplasts. These organelles grow and divide, but they are not completely autonomous because

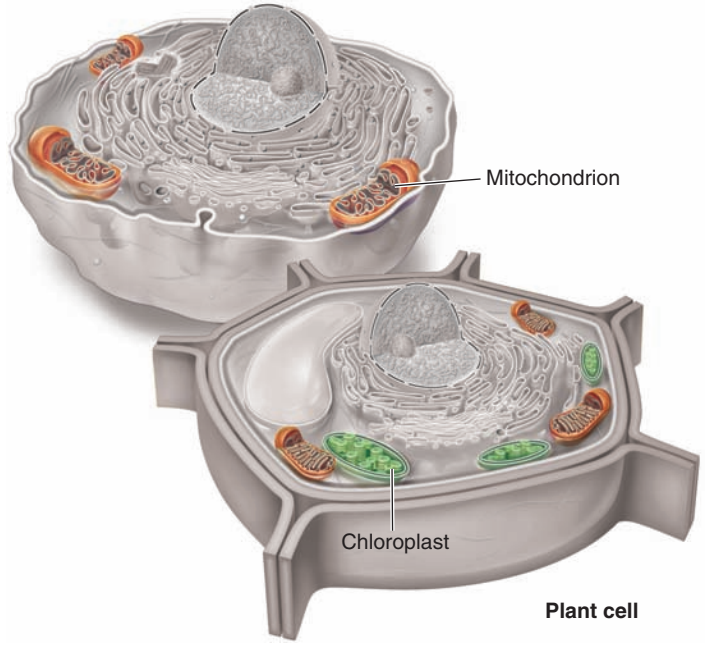

Figure 4.23 Semiautonomous organelles. These are the mitochondria and chloroplasts.

BIOLOGY PRINCIPLE Living organisms use energy. Chloroplasts capture light energy and synthesize organic molecules. Mitochondria break down organic molecules and make ATP that is used as an energy source to drive many different cellular processes.

they depend on other parts of the cell for their internal components (**Figure 4.23**). For example, most of the proteins found in mitochondria are imported from the cytosol. In this section, we will survey the structures and functions of the semiautonomous organelles in eukaryotic cells and consider their evolutionary origins. In Chapters 7 and 8, we will explore the functions of mitochondria and chloroplasts in greater depth.

Mitochondria Supply Cells with Most of Their ATP

Mitochondrion (plural, mitochondria) literally means thread granule, which is what mitochondria look like under a light microscope—either threadlike or granular-shaped. They are similar in size to bacteria. A typical cell may contain a few hundred to a few thousand mitochondria. Cells with particularly heavy energy demands, such as muscle cells, have more mitochondria than other cells. Research has shown that regular exercise increases the number and size of mitochondria in human muscle cells to meet the expanded demand for energy.

A mitochondrion has an outer membrane and an inner membrane separated by a region called the intermembrane space (**Figure 4.24**). The inner membrane is highly invaginated (folded) to form projections called **cristae**. The cristae greatly increase the surface area of the inner membrane, which is the site where ATP is made. The compartment enclosed by the inner membrane is the **mitochondrial matrix**.

The primary role of mitochondria is to make ATP. Even though mitochondria produce most of a cell's ATP, mitochondria do not create energy. Rather, their primary function is to convert chemical energy that is stored within the covalent bonds of organic molecules

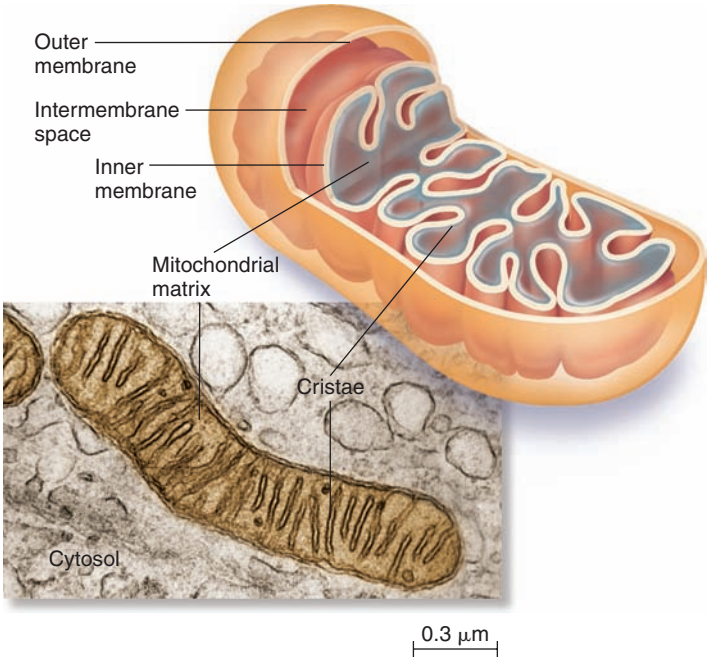

Figure 4.24 **Structure of a mitochondrion.** This figure emphasizes the membrane organization of a mitochondrion, which has an outer and inner membrane. The invaginations of the inner membrane are called cristae. The mitochondrial matrix lies inside the inner membrane. The micrograph is a colorized TEM.

Concept Check: *What is the advantage of having a highly invaginated inner membrane?*

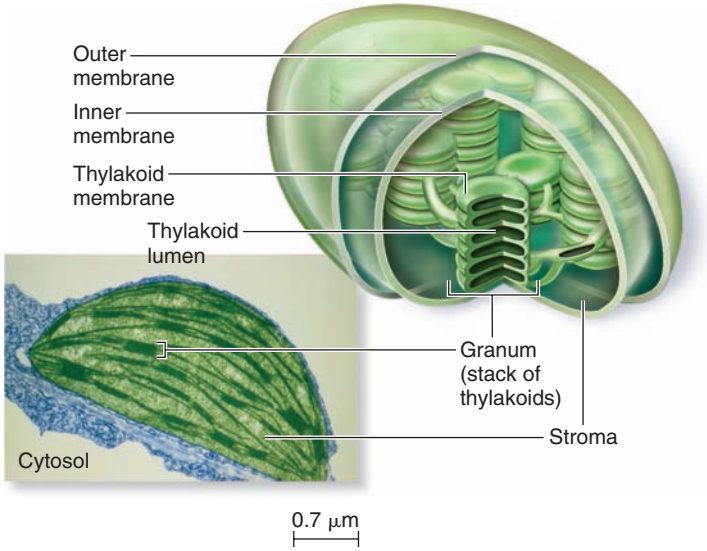

Figure 4.25 **Structure of a chloroplast.** Like a mitochondrion, a chloroplast is enclosed in a double membrane. In addition, it has an internal thylakoid membrane system that forms flattened compartments. These compartments stack on each other to form grana. The stroma is located inside the inner membrane but outside the thylakoid membrane. This micrograph is a colorized TEM.

into a form that can be readily used by cells. Covalent bonds in sugars, fats, and amino acids store a large amount of energy. The breakdown of these molecules into simpler molecules releases energy that is used to make ATP. Many proteins in living cells use ATP as a source of energy to carry out their functions, such as muscle contraction, the uptake of nutrients, cell division, and many other cellular processes.

Mitochondria perform other functions as well. They are involved in the synthesis, modification, and breakdown of several types of cellular molecules. For example, the synthesis of certain hormones requires enzymes that are found in mitochondria. Another interesting role of mitochondria is to generate heat in specialized fat cells known as brown fat cells. Groups of brown fat cells serve as "heating pads" that help to revive hibernating animals and protect sensitive areas of young animals from the cold.

Chloroplasts Carry Out Photosynthesis

Chloroplasts are organelles that capture light energy and use some of that energy to synthesize organic molecules such as glucose. This process, called **photosynthesis**, is described in Chapter 8. Chloroplasts are found in nearly all species of plants and algae. **Figure 4.25** shows the structure of a typical chloroplast. Like a mitochondrion, a chloroplast contains an outer and inner membrane. An intermembrane space lies between these two membranes. A third system of membranes, the **thylakoid membrane**, forms many flattened, fluid-filled tubules that enclose a single, convoluted compartment called the thylakoid lumen. These tubules tend to stack on top of each other to form a structure called a **granum** (plural, grana). The **stroma** is the compartment of the chloroplast that is enclosed by the inner membrane but outside the thylakoid membrane.

Chloroplasts are a specialized version of plant organelles that are more generally known as **plastids**. All plastids are derived from unspecialized **proplastids**. The various types of plastids are distinguished by their synthetic abilities and the types of pigments they contain. Chloroplasts, which carry out photosynthesis, contain the green pigment chlorophyll. The abundant number of chloroplasts in the leaves of plants gives them their green color. Chromoplasts, a second type of plastid, function in synthesizing and storing the yellow, orange, and red pigments known as carotenoids. Chromoplasts give many fruits and flowers their colors. In autumn, the chromoplasts also give many leaves their yellow, orange, and red colors. A third type of plastid, leucoplasts, typically lacks pigment molecules. An amyloplast is a leucoplast that synthesizes and stores starch. Amyloplasts are common in underground structures such as roots and tubers.

Mitochondria and Chloroplasts Contain Their Own Genetic Material and Divide by Binary Fission

To fully appreciate the structure and organization of mitochondria and chloroplasts, we also need to briefly examine their genetic properties. In 1951, Yasutane Chiba exposed plant cells to Feulgen stain, a DNA-specific dye, and discovered that the chloroplasts became stained. Based on this observation, he was the first to suggest that chloroplasts contain their own DNA. Researchers in the 1970s and 1980s isolated DNA from both chloroplasts and mitochondria. These studies revealed that the DNA of these organelles resembled smaller versions of bacterial chromosomes.

The chromosomes found in mitochondria and chloroplasts are referred to as the **mitochondrial genome** and **chloroplast genome**,

respectively, whereas the chromosomes found in the nucleus of the cell constitute the **nuclear genome**. Like bacteria, the genomes of most mitochondria and chloroplasts are composed of a single circular chromosome. Compared with the nuclear genome, they are very small. For example, the amount of DNA in the human nuclear genome (about 3 billion base pairs) is about 200,000 times greater than the mitochondrial genome. In terms of genes, the human genome has approximately 22,000 different genes, whereas the human mitochondrial genome has only a few dozen. Chloroplast genomes tend to be larger than mitochondrial genomes, and they have a correspondingly greater number of genes. Depending on the particular species of plant or algae, a chloroplast genome is about 10 times larger than the mitochondrial genome of human cells.

Just as the genomes of mitochondria and chloroplasts resemble bacterial genomes, the production of new mitochondria and chloroplasts bears a striking resemblance to the division of bacterial cells. Like their bacterial counterparts, mitochondria and chloroplasts increase in number via **binary fission**, or splitting in two. **Figure 4.26** illustrates the process for a mitochondrion. The mitochondrial chromosome, which is found in a region called the nucleoid, is duplicated, and the organelle divides into two separate organelles. Mitochondrial and chloroplast divisions are needed to maintain a full complement of these organelles when cell growth occurs following cell division.

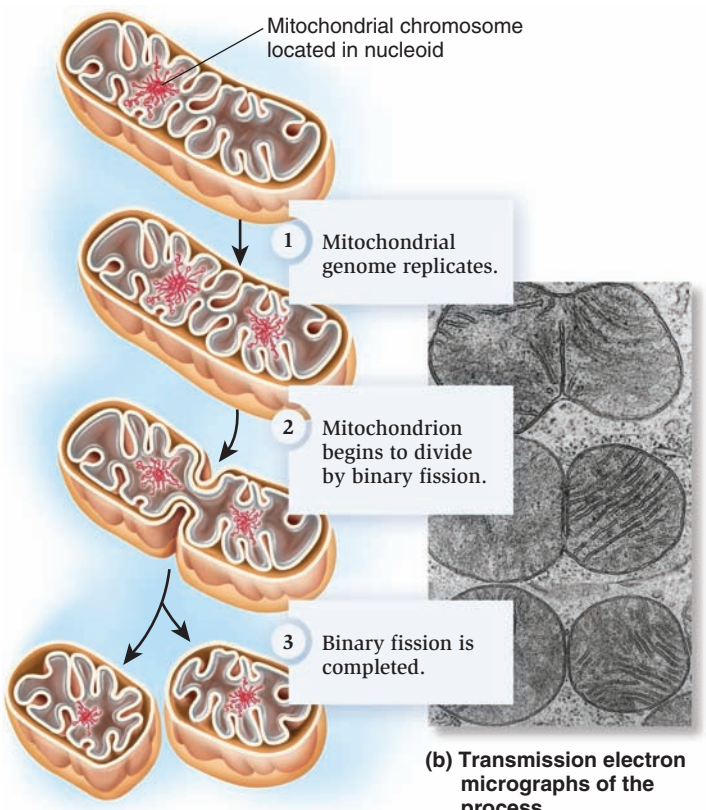

Figure 4.26 **Division of mitochondria by binary fission.**

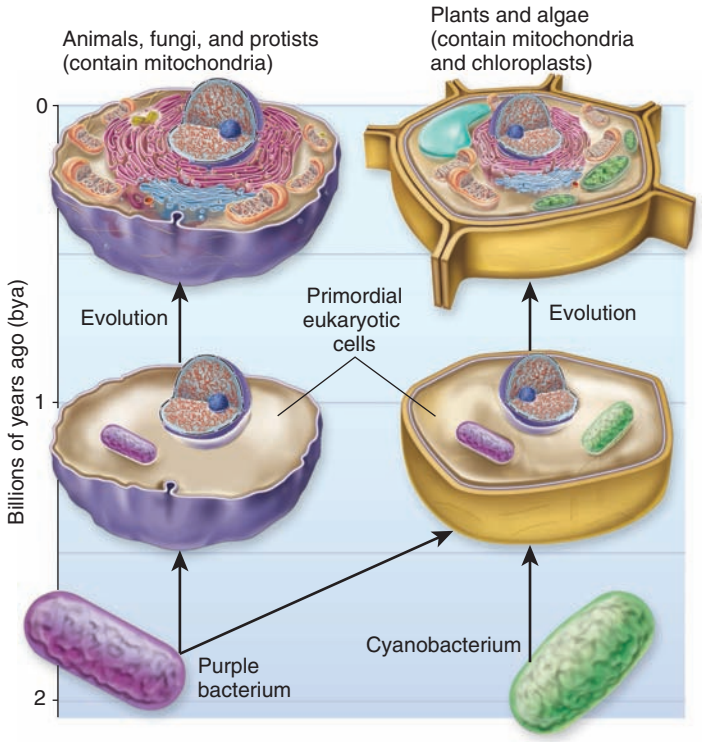
BioConnections: *Look ahead to Figure 18.13. How is this process similar to bacterial cell division, and how is it different?*

In addition, environmental conditions may influence the sizes and numbers of these organelles. For example, when plants are exposed to more sunlight, the number of chloroplasts in leaf cells increases.

Mitochondria and Chloroplasts Are Derived from Ancient Symbiotic Relationships



The observation that mitochondria and chloroplasts contain their own genetic material may seem puzzling. Perhaps you might think that it would be simpler for a eukaryotic cell to have all of its genetic material in one place—the nucleus. The distinct genomes of mitochondria and chloroplasts can be traced to their evolutionary origin, which involved an ancient symbiotic association.

A symbiotic relationship occurs when two different species live in direct contact with each other. **Endosymbiosis** describes a symbiotic relationship in which the smaller species—the symbiont—actually lives inside the larger species. In 1883, Andreas Schimper proposed that chloroplasts were descended from an endosymbiotic relationship between cyanobacteria (a bacterium capable of photosynthesis) and eukaryotic cells. In 1922, Ivan Wallin also hypothesized an endosymbiotic origin for mitochondria.

In spite of these interesting ideas, the question of endosymbiosis was largely ignored until the discovery that mitochondria and chloroplasts contain their own genetic material. In 1970, the issue of endosymbiosis as the origin of mitochondria and chloroplasts was revived by Lynn Margulis in her book *Origin of Eukaryotic Cells*. During the 1970s and 1980s, the advent of molecular genetic techniques allowed researchers to analyze genes from mitochondria, chloroplasts, bacteria, and eukaryotic nuclear genomes. Researchers discovered that genes in mitochondria and chloroplasts are very similar to bacterial genes. Likewise, mitochondria and chloroplasts are strikingly similar in size and shape to certain bacterial species. These observations provided strong support for the **endosymbiosis theory**, which proposes that mitochondria and chloroplasts originated from bacteria that took up residence within a primordial eukaryotic cell (**Figure 4.27**). Over the next 2 billion years, the characteristics of these intracellular bacterial cells gradually changed to those of a mitochondrion or chloroplast. The origin of eukaryotic cells is discussed in more detail in Chapter 22.

Symbiosis occurs because the relationship is beneficial to one or both species. According to the endosymbiosis theory, this relationship provided eukaryotic cells with useful cellular characteristics. Chloroplasts, which were derived from cyanobacteria, have the ability to carry out photosynthesis. This benefits plant cells by giving them the ability to use the energy from sunlight. By comparison, mitochondria are thought to have been derived from a different type of bacteria known as purple bacteria, or α-proteobacteria. In this case, the endosymbiotic relationship enabled eukaryotic cells to synthesize greater amounts of ATP. How the relationship would have been beneficial to a cyanobacterium or purple bacterium is less clear, though the cytosol of a eukaryotic cell may have provided a stable environment with an adequate supply of nutrients.

During the evolution of eukaryotic species, many genes that were originally found in the genomes of the primordial purple bacteria and cyanobacteria have been transferred from the organelles to the nucleus. This has occurred many times throughout evolution, so modern mitochondria and chloroplasts have lost most of the genes

(a) Mitochondria originated from endosymbiotic purple bacteria.

(b) Chloroplasts originated from endosymbiotic cyanobacteria.

Figure 4.27 A simplified view of the endosymbiosis theory. **(a)** According to this concept, modern mitochondria were derived from purple bacteria, also called α-proteobacteria. Over the course of evolution, their characteristics changed into those found in mitochondria today. **(b)** A similar phenomenon occurred for chloroplasts, which were derived from cyanobacteria (blue-green bacteria), a bacterium that is capable of photosynthesis.

Concept Check: *Discuss the similarities and differences between modern bacteria and mitochondria.*

that still exist in present-day purple bacteria and cyanobacteria. Some researchers speculate that the movement of genes into the nucleus makes it easier for the cell to control the structure, function, and division of mitochondria and chloroplasts. In modern cells, hundreds of different proteins that make up these organelles are encoded by genes that have been transferred to the nucleus. These proteins are made in the cytosol and then taken up into mitochondria or chloroplasts. We will discuss this topic next.

4.6 Protein Sorting to Organelles

Learning Outcomes:

1. List which categories of proteins are sorted cotranslationally and which are sorted post-translationally.
2. Describe the steps that occur during the cotranslational sorting of proteins to the endoplasmic reticulum.
3. Explain how proteins are moved through the endomembrane system.
4. Outline the steps of post-translational sorting of proteins to mitochondria.

As we have seen, eukaryotic cells contain a variety of membrane-bound organelles. Each protein that a cell makes usually functions within one cellular compartment or is secreted from the cell. How does each protein reach its appropriate destination? For example, how does a mitochondrial protein get sent to the mitochondrion rather than to a different organelle such as a lysosome? In eukaryotes, most proteins contain short stretches of amino acid sequences that direct them to their correct cellular location. These sequences are called **sorting signals**, or **traffic signals**. Each sorting signal is recognized by specific cellular components that facilitate the proper movement of that protein to its correct location.

Most eukaryotic proteins begin their synthesis on ribosomes in the cytosol, using messenger RNA (mRNA) that contains the information for polypeptide synthesis (**Figure 4.28**). The cytosol provides amino acids, which are used as building blocks to make these proteins during translation. Cytosolic proteins lack any sorting signal, so they remain there. By comparison, the synthesis of proteins destined for the ER, Golgi, lysosomes, vacuoles, or secretory vesicles begins in the cytosol and then halts temporarily until the ribosome has become bound to the ER membrane. After this occurs, translation resumes and the polypeptide is synthesized into the ER. Proteins that are destined for the ER, Golgi, lysosome, vacuole, plasma membrane, or secretion are first directed to the ER. This is called **cotranslational sorting** because the first step in the sorting process begins while translation is occurring. Finally, the uptake of most proteins into the nucleus, mitochondria, chloroplasts, and peroxisomes occurs after the protein is completely made (that is, completely translated) in the cytosol. This is called **post-translational sorting** because sorting does not happen until translation is finished. In this section, we will consider how cells carry out cotranslational and post-translational sorting.

The Cotranslational Sorting of Some Proteins Occurs at the Endoplasmic Reticulum Membrane

The concept of sorting signals in proteins was first proposed by Günter Blobel in the 1970s. Blobel and colleagues discovered a sorting signal in proteins that sends them to the ER membrane, which is the first step in cotranslational sorting (**Figure 4.29**). To be directed to the rough ER membrane, a polypeptide must contain a sorting signal called an **ER signal sequence**, which is a sequence of about 6–12 amino acids that are predominantly hydrophobic and usually located near the N-terminus. As the ribosome is making the polypeptide in the cytosol, the ER signal sequence emerges from the ribosome and is recognized by a protein-RNA complex called **signal recognition particle (SRP)**. SRP has two functions. First, it recognizes the ER signal sequence and pauses translation. Second, SRP binds to an SRP receptor in the ER membrane, which docks the ribosome over a channel. At this stage, SRP is released and translation resumes. The growing polypeptide is threaded through the channel to cross the ER membrane. If the protein is not a membrane protein, it will be released into the lumen of the ER. In most cases, the ER signal sequence is removed by an enzyme, signal peptidase. In 1999, Blobel won the Nobel Prize in Physiology or Medicine for his discovery of sorting signals in proteins. The process shown in Figure 4.29 illustrates another important role of protein-protein interactions—a series of interactions causes the steps of a process to occur in a specific order.

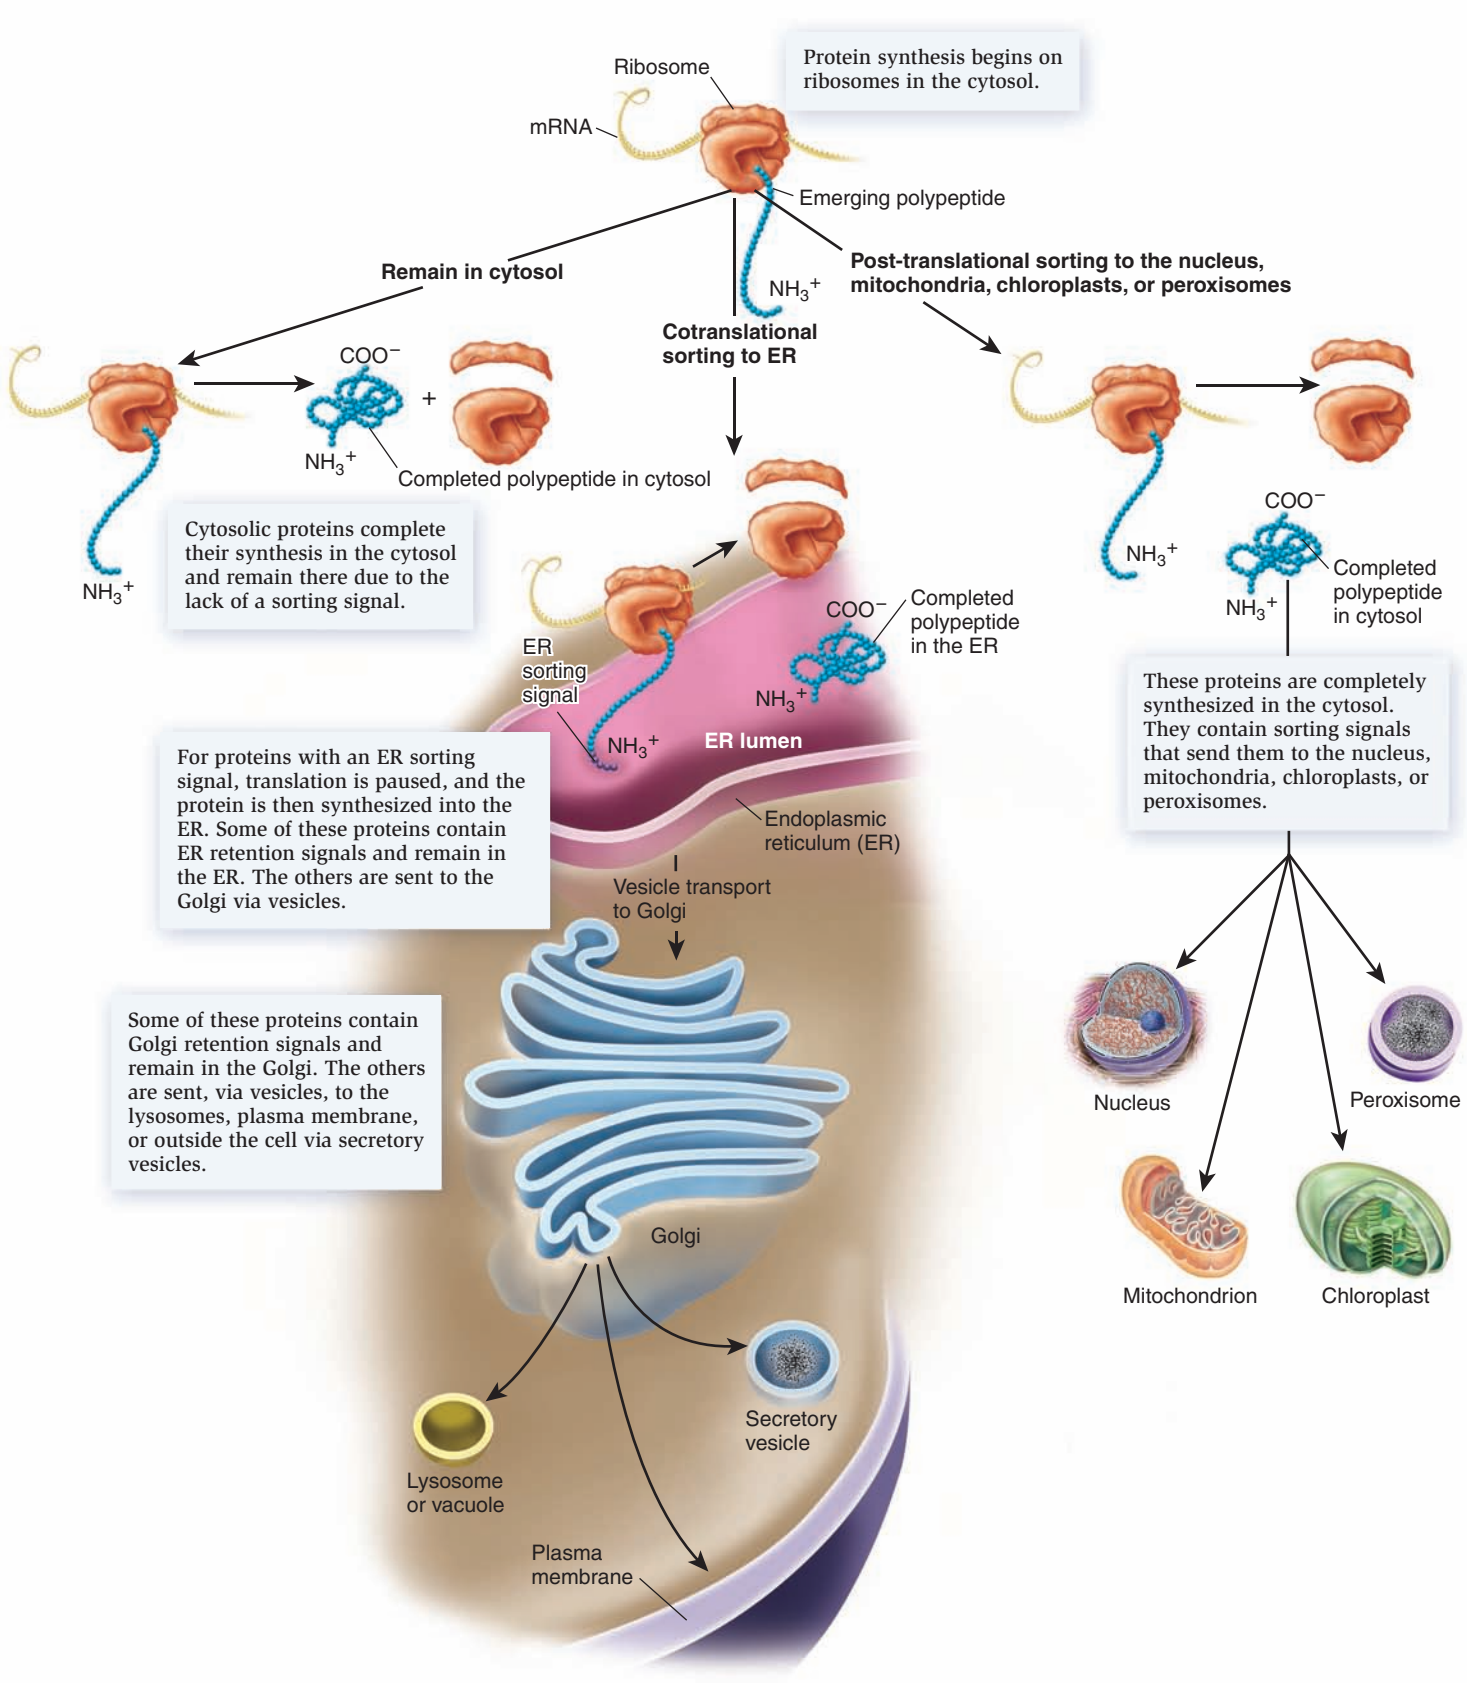


Figure 4.28 **Three pathways for protein sorting in a eukaryotic cell.** Proteins either remain in the cytosol, are sorted to the ER (cotranslational sorting), or are sorted after the protein is completely made (post-translational sorting).

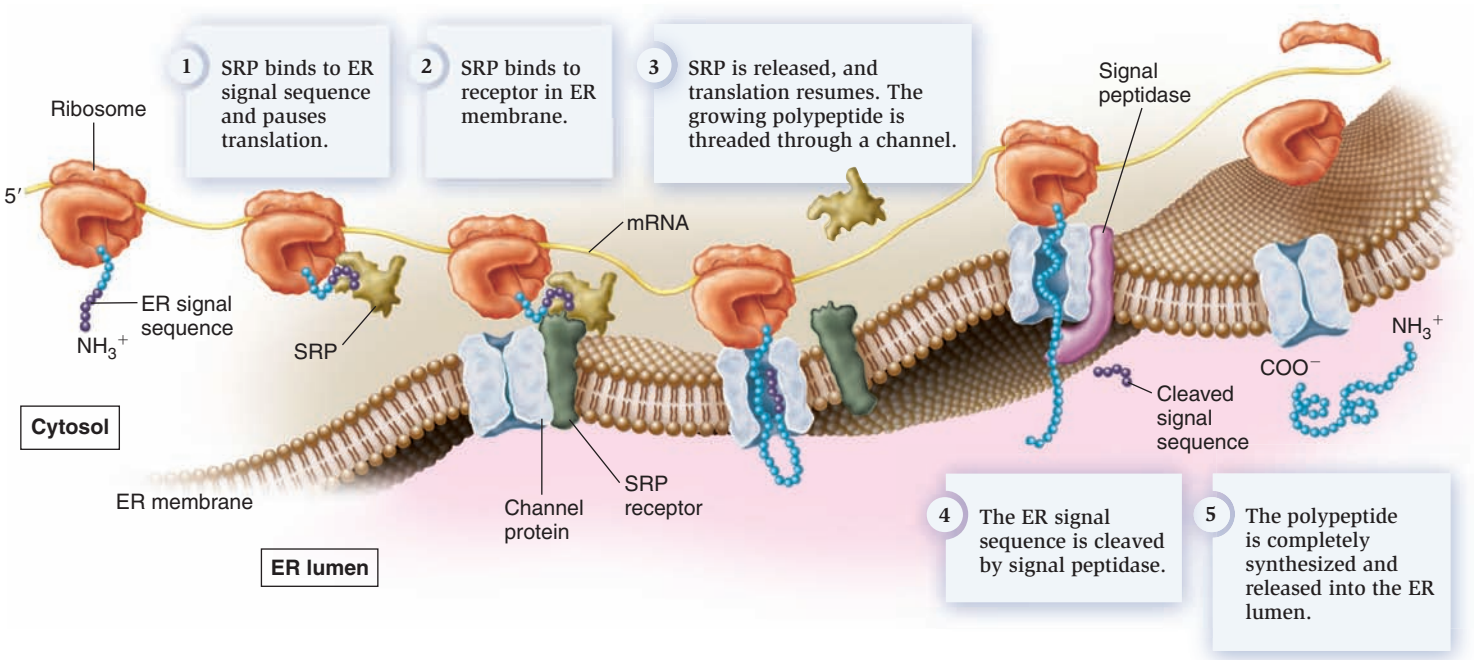

Figure 4.29 **First step in cotranslational sorting: sending proteins to the ER.**

Concept Check: *What prevents an ER protein from being completely synthesized in the cytosol?*

Some proteins are meant to function in the ER. Such proteins contain ER retention signals in addition to the ER signal sequence. Alternatively, other proteins that are destined for the Golgi, lysosomes, vacuoles, plasma membrane, or secretion leave the ER and are transported to their correct location (see Figure 4.28). This transport process occurs via vesicles that are formed from one compartment and then move through the cytosol and fuse with another compartment. Vesicles from the ER may go to the Golgi, and then vesicles from the Golgi may go to the lysosomes, vacuoles, or plasma membrane. Sorting signals within proteins' amino acid sequences are responsible for directing them to the correct location.

Figure 4.30 describes the second step in cotranslational sorting, vesicle transport from the ER to the Golgi. A cargo, such as protein molecules, is loaded into a developing vesicle by binding to cargo receptors in the ER membrane. Vesicle formation is facilitated by the binding of coat proteins, which, by shaping the surrounding membrane into a sphere, helps a vesicle to bud from a given membrane.

As a vesicle forms, other proteins called V-snares are incorporated into the vesicle membrane (hence the name V-snare). Many types of V-snares are known to exist. The particular V-snare that is found in a vesicle membrane depends on the type of cargo it carries. After a vesicle is released from one compartment, such as the ER, the coat is shed. The vesicle then travels through the cytosol. But how does the vesicle know where to go? The answer is that the V-snares in the vesicle membrane are recognized by T-snares in a target membrane. After V-snares recognize T-snares, the vesicle fuses with the membrane containing the T-snares. The recognition between V-snares and T-snares ensures that a vesicle carrying a specific cargo moves to the correct target membrane in the cell. Like the sorting of proteins to the ER membrane, the formation and sorting of vesicles also involves a series of protein-protein interactions that cause the steps to occur in a defined manner.

Proteins Are Sorted Post-Translationally to the Nucleus, Peroxisomes, Mitochondria, and Chloroplasts

The organization and function of the nucleus, peroxisomes, mitochondria, and chloroplasts depend on the uptake of proteins from the cytosol. Most of their proteins are synthesized in the cytosol and then taken up into their respective organelles. For example, most proteins involved in ATP synthesis are made in the cytosol and taken up into mitochondria after they have been completely synthesized. For this to occur, a protein must have the appropriate sorting signal as part of its amino acid sequence.

As one example of post-translational sorting, let's consider how a protein is directed to the mitochondrial matrix. Such a protein has a short amino acid sequence at the N-terminus called a matrix-targeting sequence. As shown in **Figure 4.31**, the process of protein import into the matrix involves a series of intricate protein-protein interactions. A protein destined for the mitochondrial matrix is first made in the cytosol, where proteins called **chaperones** keep it in an unfolded state. A receptor protein in the outer mitochondrial membrane recognizes the matrix-targeting sequence. The protein is released from the chaperone as it is transferred to a channel in the

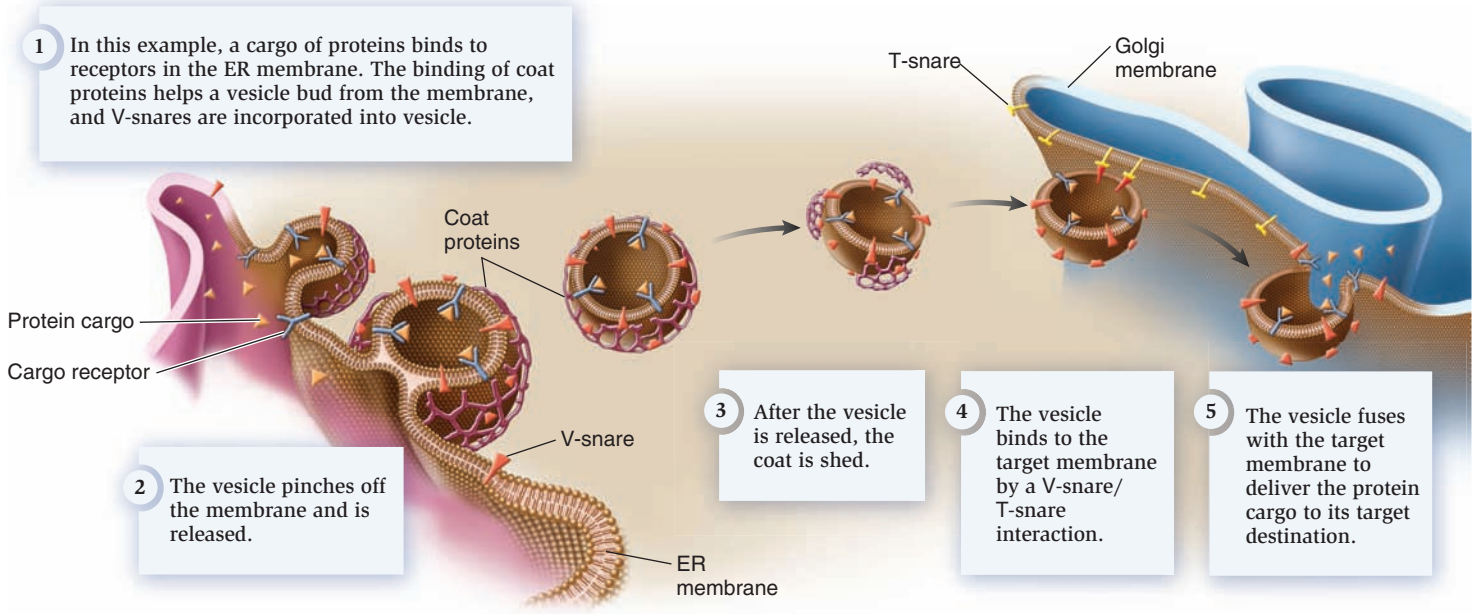

Figure 4.30 **Second step in cotranslational sorting: vesicle transport from the ER to the Golgi.**

outer mitochondrial membrane. Because it is in an unfolded state, the mitochondrial protein can be threaded through this channel, and then through another channel in the inner mitochondrial membrane. These channels lie close to each other at contact sites between the outer and inner membranes. As the protein emerges in the matrix, other chaperone proteins already in the matrix continue to keep it unfolded. Eventually, the matrix-targeting sequence is cleaved, and the entire protein is threaded into the matrix. At this stage, the chaperone proteins are released, as the protein folds into its three-dimensional active structure.

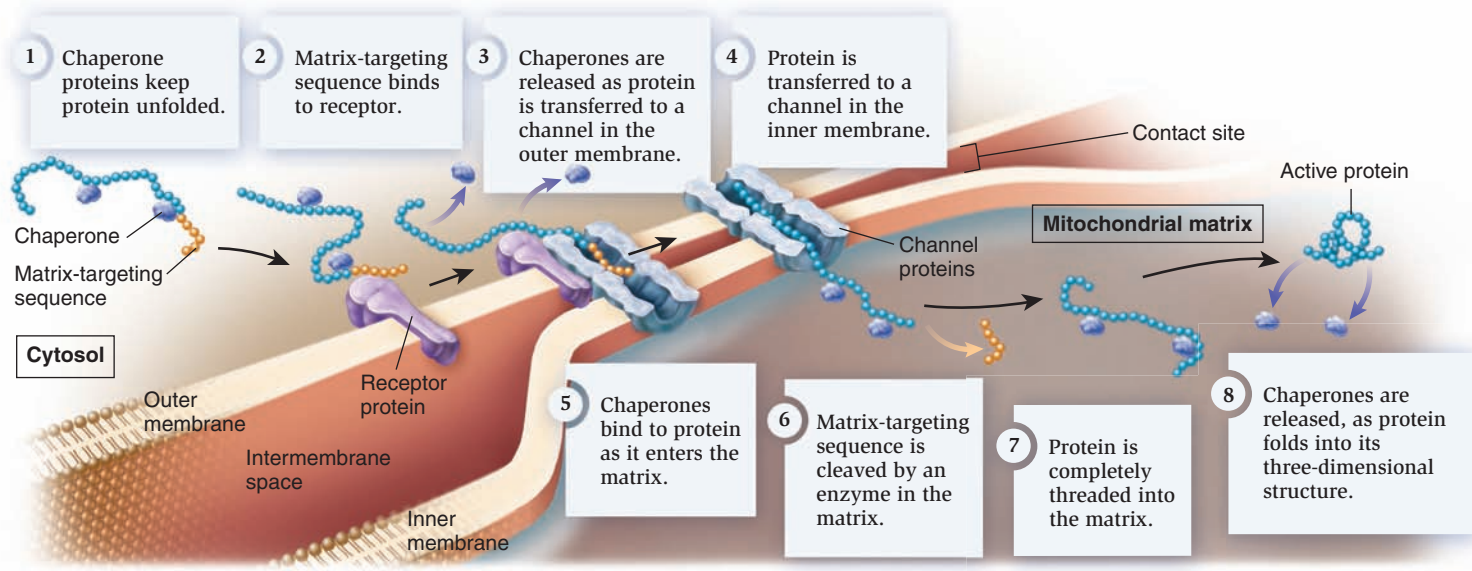

Figure 4.31 **Post-translational sorting of a protein to the mitochondrial matrix.**

Concept Check: *What do you think would happen if chaperone proteins did not bind to a mitochondrial matrix protein before it was imported into the mitochondrion?*

4.7 Systems Biology of Cells: A Summary

Learning Outcomes:

1. Outline the differences in complexity among bacteria, animal, and plant cells.
2. Describe how a eukaryotic cell can be viewed as four interacting systems: the nucleus, cytosol, endomembrane system, and semiautonomous organelles.

We will conclude this chapter by reviewing cell structure and function from a perspective called **systems biology**, the study of how new properties of life arise by complex interactions of its components. The system being studied can be anything from a metabolic pathway to a cell, an organ, or even an entire organism. In this section, we view the cell as a system. First, we will compare prokaryotic and eukaryotic cells as systems, and then examine the four interconnected parts that make up the system that is the eukaryotic cell.

Bacterial Cells Are Relatively Simple Systems Compared to Eukaryotic Cells

Bacterial cells are relatively small and lack the extensive internal compartmentalization characteristic of eukaryotic cells (**Table 4.2**). On the outside, bacterial cells are surrounded by a cell wall, and many species have flagella. Animal cells lack a cell wall, and only certain cell types have flagella or cilia. Like bacteria, plant cells also have cell walls but their chemical composition is different from that of bacterial cells. Plant cells rarely have flagella.

As mentioned earlier in this chapter, the cytoplasm is the region of the cell enclosed by the plasma membrane. Ribosomes are found in the cytoplasm of all cell types. In bacteria, the cytoplasm is a single compartment. The bacterial genetic material, usually a single chromosome, is found in the nucleoid, which is not surrounded by a membrane. By comparison, the cytoplasm of eukaryotic cells is highly compartmentalized. The cytosol is the area that surrounds many different types of membrane-bound organelles. For example, eukaryotic chromosomes are found in the nucleus, which is surrounded by a double membrane. In addition, all eukaryotic cells have an endomembrane system and mitochondria, and plant cells also have chloroplasts.

A Eukaryotic Cell Is a System with Four Interacting Parts

We can view a eukaryotic cell as a system with four interacting parts: the interior of the nucleus, the cytosol, the endomembrane system, and the semiautonomous organelles. These four regions have their own structure and organization, while also playing a role in the structure and organization of the entire cell. The structures and functions of these four interacting parts are described in **Figure 4.32**.

Table 4.2 A Comparison of Cell Complexity Among Bacterial, Animal, and Plant Cells

Structures	Bacteria	Animal cells	Plant cells
Extracellular structures			
Cell wall*	Present	Absent	Present
Flagella/cilia	Flagella sometimes present	Cilia or flagella present on certain cell types	Rarely present†
Plasma membrane	Present	Present	Present
Interior structures			
Cytoplasm	Usually a single compartment inside the plasma membrane	Composed of membrane-bound organelles that are surrounded by the cytosol	Composed of membrane-bound organelles that are surrounded by the cytosol
Ribosomes	Present	Present	Present
Chromosomes and their location	Typically one circular chromosome per nucleoid; a nucleoid is not a separate compartment.	Multiple linear chromosomes in the nucleus; nucleus is surrounded by a double membrane. Mitochondria also have chromosomes.	Multiple linear chromosomes in the nucleus; nucleus is surrounded by a double membrane. Mitochondria and chloroplasts also have chromosomes.
Endomembrane system	Absent	Present	Present
Mitochondria	Absent	Present	Present
Chloroplasts	Absent	Absent	Present

*Note that the biochemical composition of bacterial cell walls is very different from plant cell walls.
†Some plant species produce sperm cells with flagella, but flowering plants produce sperm within pollen grains that lack flagella.

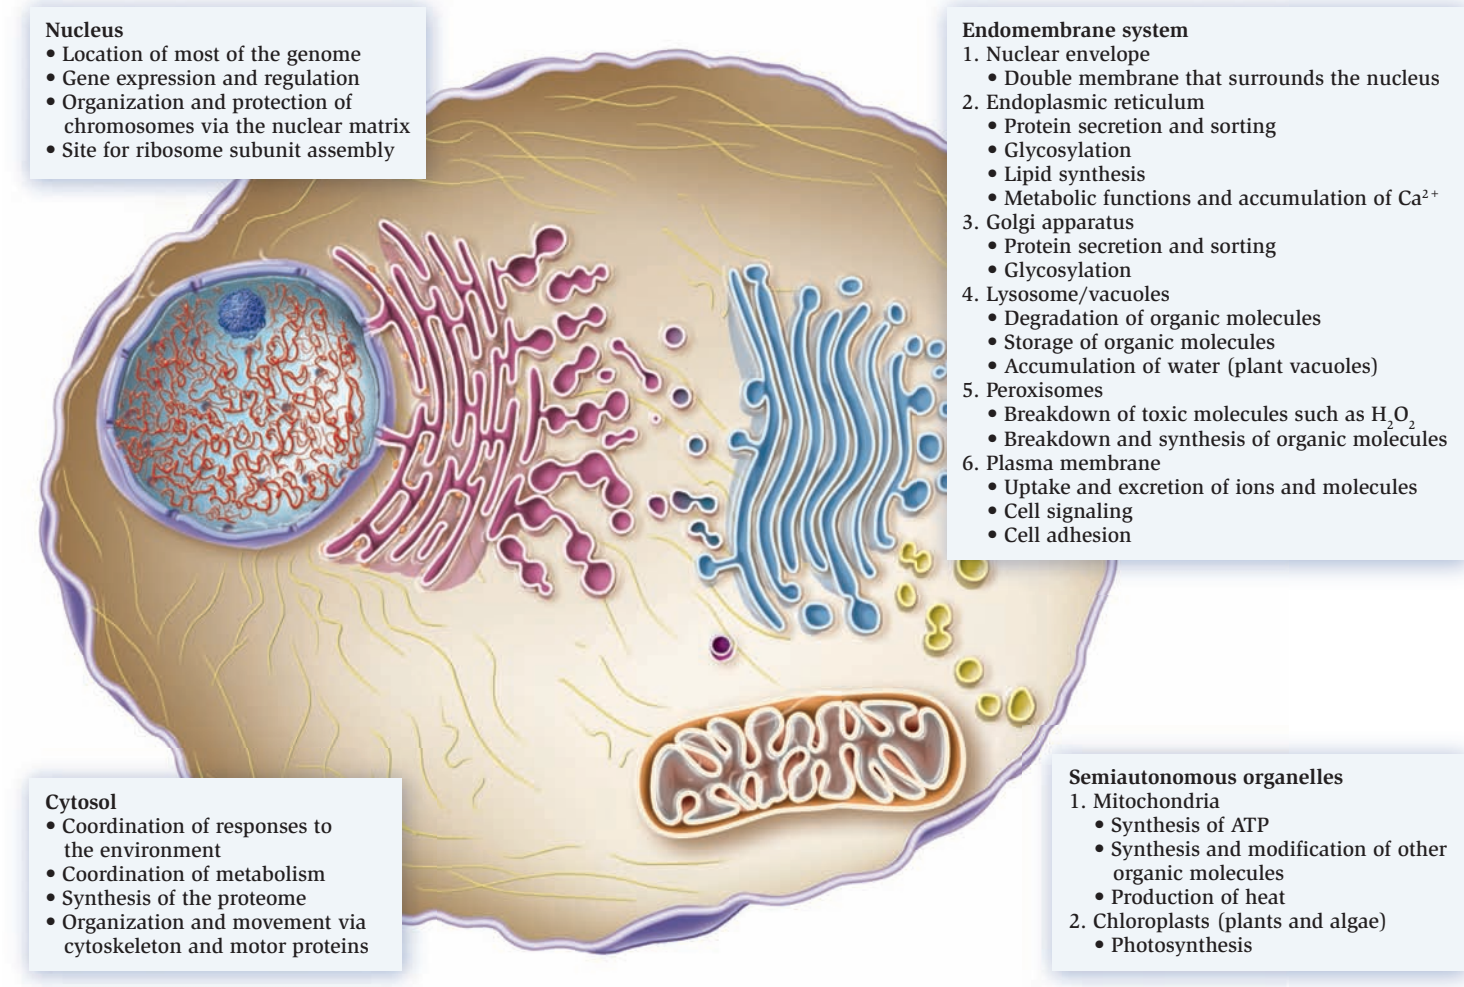

Figure 4.32 The four interacting parts of eukaryotic cells: nucleus, cytosol, endomembrane system, and semiautonomous organelles. An animal cell is illustrated here.

Summary of Key Concepts

4.1 Microscopy

- Three important parameters in microscopy are magnification, resolution, and contrast. A light microscope utilizes light for illumination, whereas an electron microscope uses an electron beam. Transmission electron microscopy (TEM) provides the best resolution of any form of microscopy, and scanning electron microscopy (SEM) produces an image of a three-dimensional surface (Figures 4.1, 4.2, 4.3).

4.2 Overview of Cell Structure

- Cell structure is determined by four factors: matter, energy, organization, and information. Every living organism has a genome. The genes within the genome contain the information to produce cells with particular structures and functions.
- We can classify all forms of life into two categories based on cell structure: prokaryotes and eukaryotes.
- Bacteria and archaea have prokaryotic cells with a relatively simple structure that lacks a membrane-enclosed nucleus. Structures in prokaryotic cells include the plasma membrane, cytoplasm, nucleoid, and ribosomes. Prokaryotic cells also have a cell wall and many have a glycocalyx (Figure 4.4).
- Eukaryotic cells are compartmentalized into organelles and contain a nucleus that houses most of the DNA. The surface area/volume ratio is thought to limit cell size (Figures 4.5, 4.6, 4.7, 4.8).
- The proteome of a cell determines its structure and function.

4.3 The Cytosol

- The cytosol is a central coordinating region for many metabolic activities of eukaryotic cells, including polypeptide synthesis (Figure 4.9).
- The cytoskeleton is a network of three different types of protein filaments: microtubules, intermediate filaments, and actin filaments. Microtubules are important for cell shape, organization, and movement. Intermediate filaments help maintain cell shape, rigidity,

and strength. Actin filaments support the plasma membrane and play a key role in cell strength, shape, and movement (Table 4.1, Figures 4.10, 4.11, 4.12, 4.13).

4.4 The Nucleus and Endomembrane System

- The primary function of the nucleus is the organization and expression of the genetic material. A second important function is the assembly of ribosomal subunits in the nucleolus (Figures 4.14, 4.15, 4.16).
- The endomembrane system includes the nuclear envelope, endoplasmic reticulum (ER), Golgi apparatus, lysosomes, vacuoles, peroxisomes, and plasma membrane. The rough endoplasmic reticulum (rough ER) plays a key role in the initial sorting of proteins. The smooth endoplasmic reticulum (smooth ER) functions in metabolic processes such as detoxification, carbohydrate metabolism, accumulation of calcium ions, and synthesis and modification of lipids. The Golgi apparatus performs three overlapping functions: processing, protein sorting, and secretion. Lysosomes degrade macromolecules and help digest substances taken up from outside the cell (endocytosis) and inside the cell (autophagy) (Figures 4.17, 4.18).
- Palade's pulse-chase experiments demonstrated that secreted proteins move sequentially through the ER and Golgi apparatus (Figure 4.19).
- Types of vacuoles include central vacuoles; contractile vacuoles; and phagocytic, or food, vacuoles (Figure 4.20).
- Peroxisomes catalyze a variety of chemical reactions, including those involved with the breakdown of toxic molecules such as hydrogen peroxide, and also typically contain enzymes involved in the metabolism of fats and amino acids. Peroxisomes are made via budding from the ER, followed by maturation and division (Figure 4.21).
- Proteins in the plasma membrane perform many important roles that affect activities inside the cell, including membrane transport, cell signaling, and cell adhesion (Figure 4.22).

4.5 Semiautonomous Organelles

- Mitochondria and chloroplasts are considered semiautonomous because they grow and divide, but they still depend on other parts of the cell for their internal components (Figure 4.23).
- Mitochondria produce most of a cell's ATP, which is utilized by many proteins to carry out their functions. Other mitochondrial functions include the synthesis, modification, and breakdown of cellular molecules and the generation of heat in specialized fat cells (Figure 4.24).
- Chloroplasts, which are found in nearly all species of plants and algae, carry out photosynthesis (Figure 4.25).
- Mitochondria and chloroplasts contain their own genetic material and divide by binary fission (Figure 4.26).
- According to the endosymbiosis theory, mitochondria and chloroplasts originated from bacteria that took up residence in early eukaryotic cells (Figure 4.27).

4.6 Protein Sorting to Organelles

- Eukaryotic proteins are sorted to their correct cellular destination (Figure 4.28).
- The cotranslational sorting of ER, Golgi, lysosomal, vacuolar, plasma membrane, and secreted proteins begins in the cytosol, while translation is occurring, and involves sorting signals and vesicle transport (Figures 4.29, 4.30).
- Most proteins of the nucleus, mitochondria, chloroplasts, and peroxisomes are synthesized in the cytosol and taken up after the protein is completely made; this is called post-translational sorting (Figure 4.31).

4.7 Systems Biology of Cells: A Summary

- Systems biology is the study of how new properties of life arise by complex interactions of its components. In systems biology, the cell is viewed in terms of its structural and functional connections, rather than its individual molecular components.
- Prokaryotic and eukaryotic cells differ in their levels of organization. In eukaryotic cells, four parts—the nucleus, cytosol, endomembrane system, and semiautonomous organelles—work together to produce dynamic organization (Table 4.2, Figure 4.32).

Assess & Discuss

Test Yourself

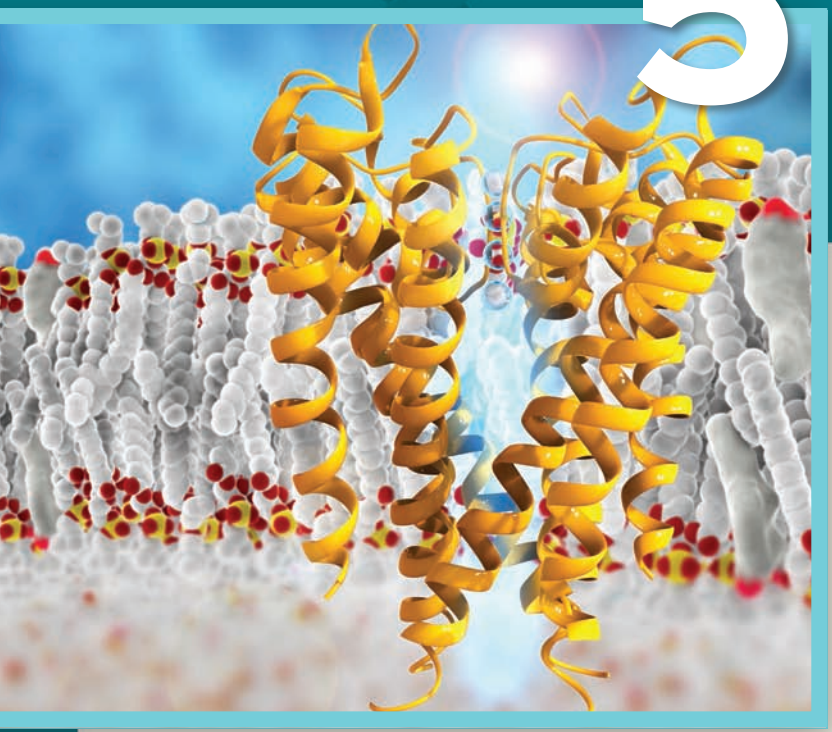
1. The cell theory states that
   a. all living things are composed of cells.
   b. cells are the smallest units of living organisms.
   c. new cells come from pre-existing cells by cell division.
   d. all of the above.
   e. a and b only.
2. When using microscopes, the resolution refers to
   a. the ratio between the size of the image produced by the microscope and the actual size of the object.
   b. the degree to which a particular structure looks different from other structures around it.
   c. how well a structure takes up certain dyes.
   d. the ability to observe two adjacent objects as being distinct from each other.
   e. the degree to which the image is magnified.
3. A spherical cell has a radius of 34 μm. What is its surface area/volume ratio?
   a. 0.088
   b. 0.12
   c. 11.3
   d. 55.7
   e. 127
4. If a motor protein was held in place and a cytoskeletal filament was free to move, what type of motion would occur when the motor protein was active?
   a. The motor protein would "walk" along the filament.
   b. The filament would move.
   c. The filament would bend.
   d. All of the above would happen.
   e. Only b and c would happen.
5. Each of the following is part of the endomembrane system except
   a. the nuclear envelope.
   b. the endoplasmic reticulum.
   c. the Golgi apparatus.
   d. lysosomes.
   e. mitochondria.

6. Vesicle transport occurs between the ER and the Golgi in both directions. Let's suppose a researcher added a drug to cells that inhibited vesicle transport from the Golgi to the ER but did not affect vesicle transport from the ER to the Golgi. If you observed cells microscopically after the drug was added, what would you expect to see happen over the course of 1 hour?
   a. The ER would get smaller, and the Golgi would get larger.
   b. The ER would get larger, and the Golgi would get smaller.
   c. The ER and Golgi would stay the same size.
   d. Both the ER and Golgi would get larger.
   e. Both the ER and Golgi would get smaller.
7. Functions of the smooth endoplasmic reticulum include
   a. detoxification of harmful organic molecules.
   b. metabolism of carbohydrates.
   c. protein sorting.
   d. all of the above.
   e. a and b only.
8. The central vacuole in many plant cells is important for
   a. storage.
   b. photosynthesis.
   c. structural support.
   d. all of the above.
   e. a and c only.
9. Let's suppose an abnormal protein contains three targeting sequences: an ER signal sequence, an ER retention sequence, and a mitochondrial matrix-targeting sequence. The ER retention sequence is supposed to keep proteins within the ER. Where would you expect this abnormal protein to go? Note: Think carefully about the timing of events in protein sorting and which events occur cotranslationally and which occur post-translationally.
   a. It would go to the ER.
   b. It would go the mitochondria.
   c. It would go to both the ER and mitochondria equally.
   d. It would remain in the cytosol.
   e. It would be secreted.
10. Which of the following observations would *not* be considered evidence for the endosymbiosis theory?
   a. Mitochondria and chloroplasts have genomes that resemble smaller versions of bacterial genomes.
   b. Mitochondria, chloroplasts, and bacteria all divide by binary fission.
   c. Mitochondria, chloroplasts, and bacteria all have ribosomes.
   d. Mitochondria, chloroplasts, and bacteria all have similar sizes and shapes.
   e. All of the above are considered evidence for the theory.

Conceptual Questions

1. Describe two specific ways that protein-protein interactions are involved with cell structure or cell function.
2. Explain how motor proteins and cytoskeletal filaments interact to promote three different types of movements: movement of a cargo, movement of a filament, and bending of a filament.
3.  A principle of biology is that *structure determines function*. Explain how the invaginations of the inner mitochondrial membrane are related to mitochondrial function.

Collaborative Questions



1. Discuss the roles of the genome and proteome in determining cell structure and function.
2. Discuss and draw the structural relationship between the nucleus, the rough endoplasmic reticulum, and the Golgi apparatus.

Membrane Structure, Synthesis, and Transport

Summary of Key Concepts
Assess and Discuss

This is a model showing a membrane in which a protein (shown in yellow) is embedded in a bilayer of lipids. The protein functions as a channel that allows ions to cross the membrane.

When he was 28, Andrew began to develop a combination of symptoms that included fatigue, joint pain, abdominal pain, and a loss of sex drive. His doctor conducted some tests and discovered that Andrew had abnormally high levels of iron in his body. Iron is a mineral found in many foods. Andrew was diagnosed with a genetic disease called hemochromatosis, which caused him to absorb more iron than he needed. This was due to an overactive protein involved in the transport of iron through the membranes of intestinal cells and into the bloodstream. Unfortunately, when the human body takes up too much iron, it is stored in body tissues, especially the liver, heart, pancreas, and joints. The extra iron can damage a person's organs. In Andrew's case, the disease was caught relatively early, and treatment—which includes a modification in diet along with medication that inhibits the absorption of iron—prevented more severe symptoms. Without treatment, however, hemochromatosis can cause organ failure. Later signs and symptoms include skin discoloration, arthritis, liver disease, diabetes mellitus, and heart failure.

The disease hemochromatosis illustrates the importance of membranes in regulating the traffic of ions and molecules into and out of cells. Cellular membranes, also known as biological membranes, are an essential characteristic of all living cells. The **plasma membrane** separates the internal contents of a cell from its external environment. With such a role, you might imagine that the plasma membrane would be thick and rigid. Remarkably, the opposite is true. All cellular membranes, including the plasma membrane, are thin (typically 5–10 nm) and somewhat fluid. It would take 5,000–10,000 membranes stacked on top of each other to equal the thickness of the page you are reading! Despite their thinness, however, membranes are impressively dynamic structures that effectively maintain the separation between a cell and its surroundings. Membranes provide an interface to carry out many vital cellular activities (**Table 5.1**).

In this chapter, we will begin by considering the components that provide the structure and fluid properties of membranes and then explore how they are synthesized. Finally, we will examine one of a membrane's primary functions—membrane transport. Biological membranes regulate the traffic of substances into and out of the cell and its organelles. As you will learn, this occurs via transport proteins and via exocytosis and endocytosis.

Table 5.1 Important Functions of Cellular Membranes

Function
Selective uptake and export of ions and molecules
Cell compartmentalization
Protein sorting
Anchoring of the cytoskeleton
Production of energy intermediates such as ATP and NADPH
Cell signaling
Cell and nuclear division
Adhesion of cells to each other and to the extracellular matrix

5.1 Membrane Structure

Learning Outcomes:

1. Describe the fluid-mosaic model of membrane structure.
2. Identify the three different types of membrane proteins.
3. **SciSKILLS** » Describe the technique of freeze fracture electron microscopy, and explain why it is used.

An important biological principle is that *structure determines function*. Throughout this chapter, we will see how the structure of cellular membranes enables them to compartmentalize the cell while selectively importing and exporting vital substances. The two primary components of membranes are phospholipids, which form the basic matrix of a membrane, and proteins, which are embedded in the membrane or loosely attached to its surface. A third component is carbohydrate, which may be attached to membrane lipids and proteins. In this section, we will examine the organization of these components to form a biological membrane and how they are important in the overall function of membranes.

Biological Membranes Are a Mosaic of Lipids, Proteins, and Carbohydrates

Figure 5.1 shows the biochemical organization of a membrane, which is similar in composition among all living organisms. The framework of the membrane is the **phospholipid bilayer**, which consists of two layers of phospholipids. Recall from Chapter 3 that phospholipids are **amphipathic** molecules. They have a hydrophobic (water-fearing) or nonpolar region, and also a hydrophilic (water-loving) or polar region. The hydrophobic tails of the lipids are found in the interior of the membrane, and the hydrophilic heads are on the surface. Biological membranes also contain proteins, and most membranes have carbohydrates attached to lipids and proteins. Overall, the membrane is considered a mosaic of lipid, protein, and carbohydrate molecules. The membrane structure illustrated in Figure 5.1 is referred to as the **fluid-mosaic model**, originally proposed by S. Jonathan Singer and Garth Nicolson in 1972. As discussed later, the membrane exhibits properties that resemble a fluid because lipids and proteins can move relative to each other within the membrane.

Half of a phospholipid bilayer is termed a **leaflet**. Each leaflet faces a different region. For example, the plasma membrane contains a cytosolic leaflet and an extracellular leaflet (see Figure 5.1). With regard to lipid composition, the two leaflets of cellular membranes are asymmetrical. Certain types of lipids may be more abundant in one leaflet compared to the other. A striking asymmetry occurs with glycolipids—lipids with carbohydrate attached. These are found primarily in the extracellular leaflet. The carbohydrate portion of a glycolipid protrudes into the extracellular medium.

Proteins Associate with Membranes in Three Different Ways

Although the phospholipid bilayer forms the basic foundation of cellular membranes, the protein component carries out many key functions. Some of these functions were considered in Chapter 4. For example, we saw how membrane proteins in the smooth ER membrane function as enzymes that break down glycogen. Later in this chapter, we will explore how membrane proteins are involved in transporting ions and molecules across membranes. In later chapters, we will examine

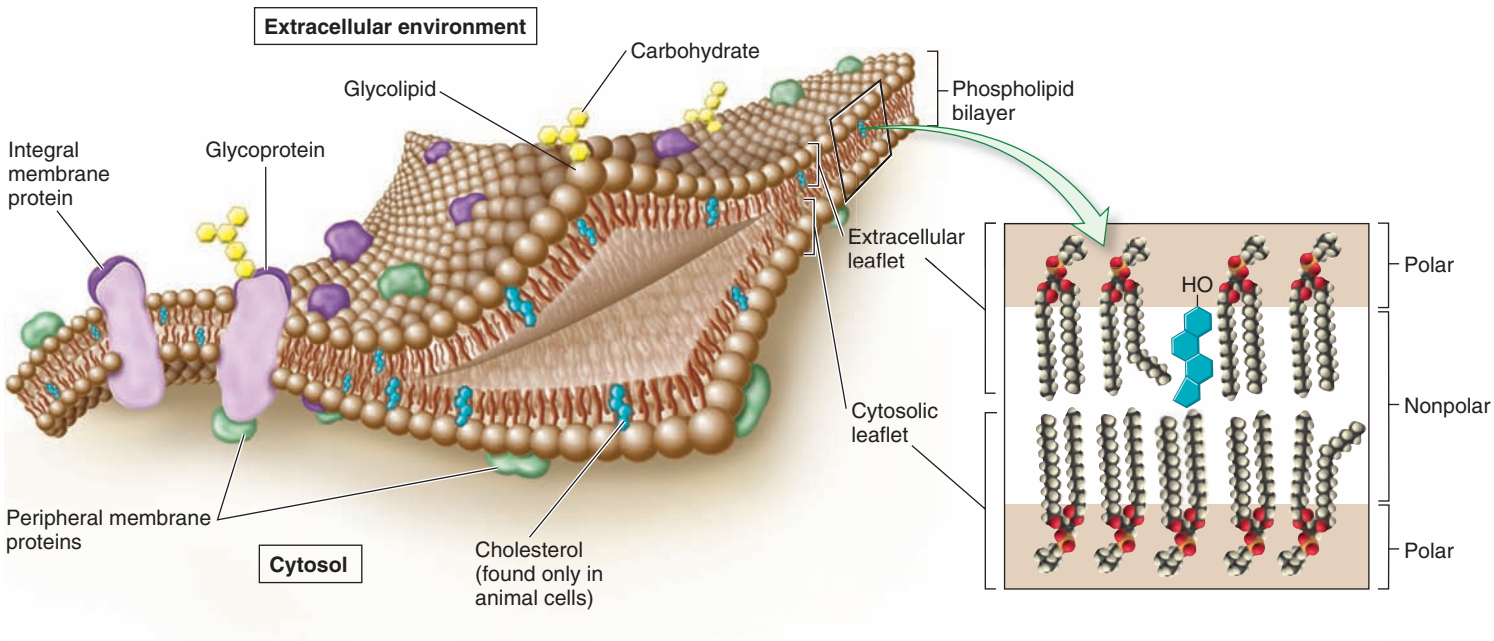

Figure 5.1 Fluid-mosaic model of membrane structure. The basic framework of a plasma membrane is a phospholipid bilayer. Proteins may span the membrane and may be bound on the surface to other proteins or to lipids. Proteins and lipids that have covalently bound carbohydrates are called glycoproteins and glycolipids, respectively. The inset shows nine phospholipids and one cholesterol molecule in a bilayer, and it emphasizes the two leaflets and the polar and nonpolar regions of the bilayer.

how membrane proteins are responsible for other functions, including ATP synthesis (Chapter 7), photosynthesis (Chapter 8), cell signaling (Chapter 9), and cell-to-cell adhesion (Chapter 10).

Membrane proteins have three different ways of associating with a membrane (**Figure 5.2**).

Transmembrane Proteins **Transmembrane proteins** have one or more regions that are physically inserted into the hydrophobic interior of the phospholipid bilayer. These regions, the transmembrane segments, are stretches of nonpolar amino acids that span or traverse the membrane from one leaflet to the other. In most transmembrane proteins, each transmembrane segment is folded into an α helix structure. Such a segment is stable in a membrane because the nonpolar amino acids interact favorably with the hydrophobic lipid tails.

Lipid-Anchored Proteins A **lipid-anchored protein** associates with a membrane because it has a lipid molecule that is covalently attached to an amino acid side chain within the protein. The lipid tails are inserted into the hydrophobic portion of the membrane and thereby keep the protein firmly attached to the membrane. Both lipid-anchored proteins and transmembrane proteins are considered to be **integral membrane proteins** because they cannot be released from the membrane unless the membrane is dissolved with an organic solvent or detergent. In other words, they cannot be removed without disrupting the integrity of the membrane.

Peripheral Membrane Proteins **Peripheral membrane proteins**, also called extrinsic proteins, represent a third way that proteins can associate with membranes. They do not interact with the hydrophobic interior of the phospholipid bilayer. Instead, they are noncovalently bound to regions of integral membrane proteins that project out from the membrane (see Figure 5.2), or they are bound to the polar head groups of phospholipids. Peripheral membrane proteins are typically attached to the membrane by hydrogen and/or ionic bonds.

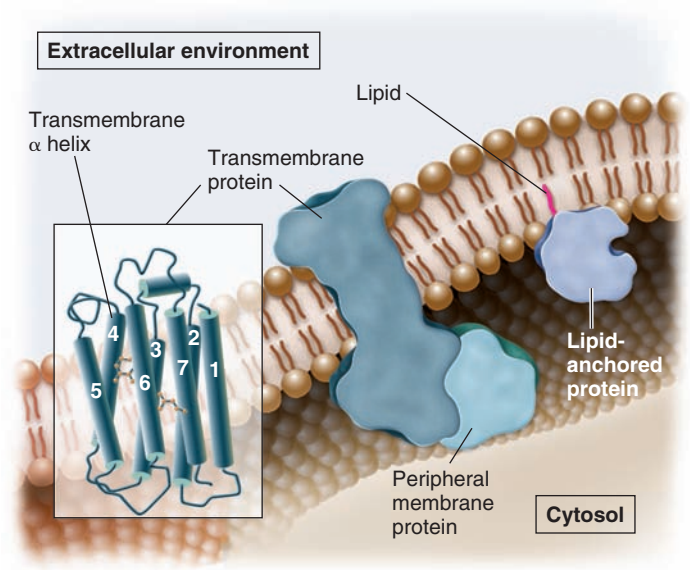

Figure 5.2 **Types of membrane proteins.** Integral membrane proteins are of two types: transmembrane proteins and lipid-anchored proteins. Peripheral membrane proteins are noncovalently bound to the hydrophilic regions of integral membrane proteins or to the polar head groups of lipids. Inset: The protein bacteriorhodopsin contains seven transmembrane segments, depicted as cylinders, each having an α helix structure. Bacteriorhodopsin is found in halophilic (salt-loving) archaea.

Genomes & Proteomes Connection

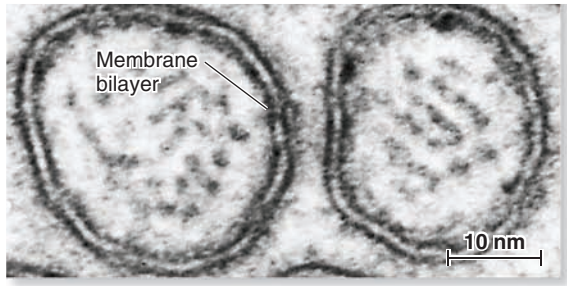
Approximately 20–30% of All Genes Encode Transmembrane Proteins

Membrane proteins participate in some of the most important cellular processes, including transport, energy transduction, cell signaling, secretion, cell recognition, metabolism, and cell-to-cell contact. Research studies have revealed that cells devote a sizeable fraction of their energy and metabolic machinery to the synthesis of membrane proteins. These proteins are particularly important in human medicine—approximately 70% of all medications exert their effects by binding to membrane proteins. Examples include the drugs aspirin, ibuprofen, and acetaminophen, which are widely used to relieve pain and inflammatory conditions such as arthritis. These drugs bind to cyclooxygenase, a protein in the ER membrane that is necessary for the synthesis of chemicals that play a role in pain sensation and inflammation.

Because membrane proteins are so important biologically and medically, researchers have analyzed the genomes of many species and asked the question "What percentage of genes encode transmembrane proteins?" To answer this question, they have developed tools to predict the likelihood that a gene encodes a transmembrane protein. For example, the occurrence of transmembrane α helices can be predicted from the amino acid sequence of a protein. All 20 amino acids can be ranked according to their tendency to enter a hydrophobic or hydrophilic environment. With these values, the amino acid sequence of a protein can be analyzed using computer software to determine the average hydrophobicity of short amino acid sequences within the protein. A stretch of 18–20 amino acids in an α helix is long enough to span the membrane. If such a stretch contains a high percentage of hydrophobic amino acids, it is predicted to be a transmembrane α helix. However, such computer predictions must eventually be verified by experimentation.

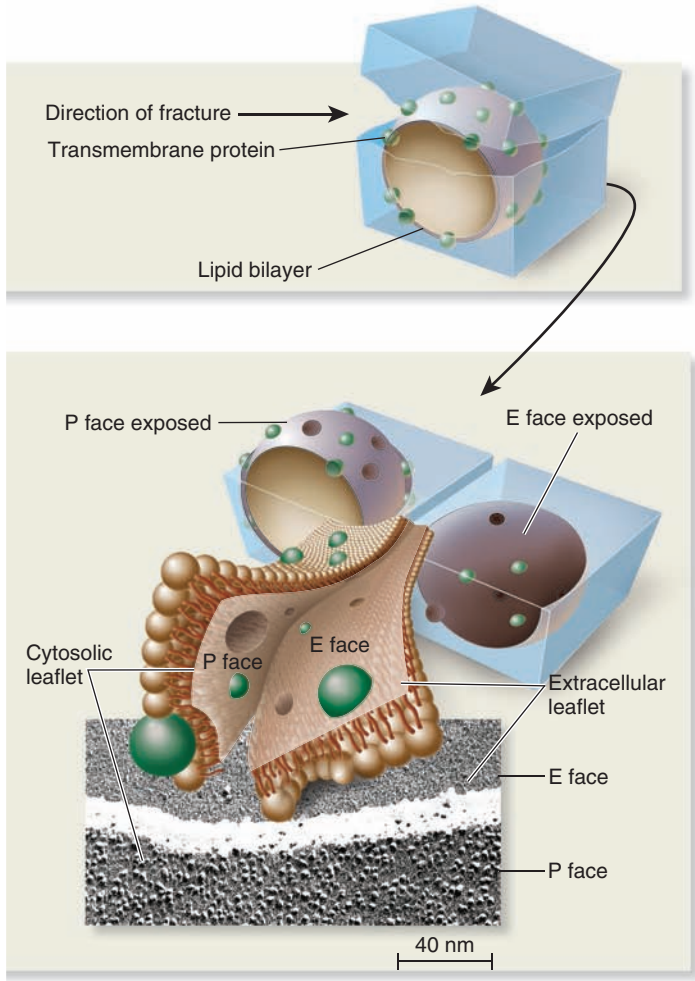
Using a computer approach, many research groups have attempted to calculate the percentage of genes that encode transmembrane proteins in various species. **Table 5.2** shows the results of one such study. The estimated percentage of transmembrane proteins is substantial: 20–30% of all genes may encode transmembrane proteins. This trend is found throughout all domains of life, including archaea, bacteria, and eukaryotes. For example, about 30% of human genes encode transmembrane proteins. With a genome size of about 22,000 different genes, the total number of human genes that encode transmembrane proteins is estimated to be 6,600. The functions of many of them have yet to be determined. Identifying their functions will help researchers gain a better understanding of human biology. Likewise, medical researchers and pharmaceutical companies are interested in the identification of new transmembrane proteins that could be targets for effective new medications.

Table 5.2 Estimated Percentage of Genes That Encode Transmembrane Proteins*



Organism	Percentage of genes that encode transmembrane proteins
Archaea	
Archaeoglobus fulgidus	24.2
Methanococcus jannaschii	20.4
Pyrococcus horikoshii	29.9
Bacteria	
Escherichia coli	29.9
Bacillus subtilis	29.2
Haemophilus influenzae	25.3
Eukaryotes	
Homo sapiens	29.7
Drosophila melanogaster	24.9
Arabidopsis thaliana	30.5
Saccharomyces cerevisiae	28.2

* Data from Stevens and Arkin (2000) Do more complex organisms have a greater proportion of membrane proteins in their genomes? *Proteins* 39: 417–420. Although the numbers may vary due to different computer programs and estimation techniques, the same general trends have been observed in other similar studies.



Membrane Structure Can Be Viewed with an Electron Microscope

Electron microscopy, discussed in Chapter 4, is a valuable tool to probe membrane structure and function. In transmission electron microscopy (TEM), a biological sample is thin sectioned and stained with heavy-metal dyes such as osmium tetroxide. This compound binds tightly to the polar head groups of phospholipids, but it does not bind well to the lipid tails. As shown in **Figure 5.3a**, membranes stained with osmium tetroxide resemble a railroad track. Two thin dark lines, which are the stained polar head groups, are separated by a uniform light space about 2 nm thick. This railroad track morphology is seen when cell membranes are subjected to electron microscopy.

A specialized form of TEM, freeze fracture electron microscopy (FFEM), is used to analyze the interiors of phospholipid bilayers. Russell Steere invented this method in 1957. In FFEM, a sample is frozen in liquid nitrogen and split with a knife (**Figure 5.3b**). The knife does not actually cut through the bilayer, but it fractures the frozen sample. Due to the weakness of the central membrane region, the leaflets separate into a P face (the protoplasmic face that was next to the cytosol) and the E face (the extracellular face). Most transmembrane proteins do not break in half. They remain embedded within one of the leaflets, usually in the P face. The samples, which are under a vacuum, are then sprayed with a heavy metal such as platinum, which coats the sample and reveals architectural features within each leaflet. When viewed with an electron microscope, membrane proteins are visible as bumps that provide significant three-dimensional detail about their form and shape.

(a) Transmission electron microscopy (TEM)

(b) Freeze fracture electron microscopy (FFEM)

Figure 5.3 Electron micrographs of a biological membrane. **(a)** In the standard form of TEM, a membrane appears as two dark parallel lines. These lines are the lipid head groups, which stain darkly with osmium tetroxide. The lipid tails do not stain well and appear as a light region sandwiched between the dark lines. **(b)** In the technique of freeze fracture electron microscopy (FFEM), a sample is frozen in liquid nitrogen and fractured. The sample is then coated with metal and viewed under the electron microscope.

Concept Check: *If a heavy metal labeled the lipid tails rather than the polar head groups (as osmium tetroxide does), do you think you would see a bilayer (that is, a railroad track) under TEM?*

5.2 Fluidity of Membranes

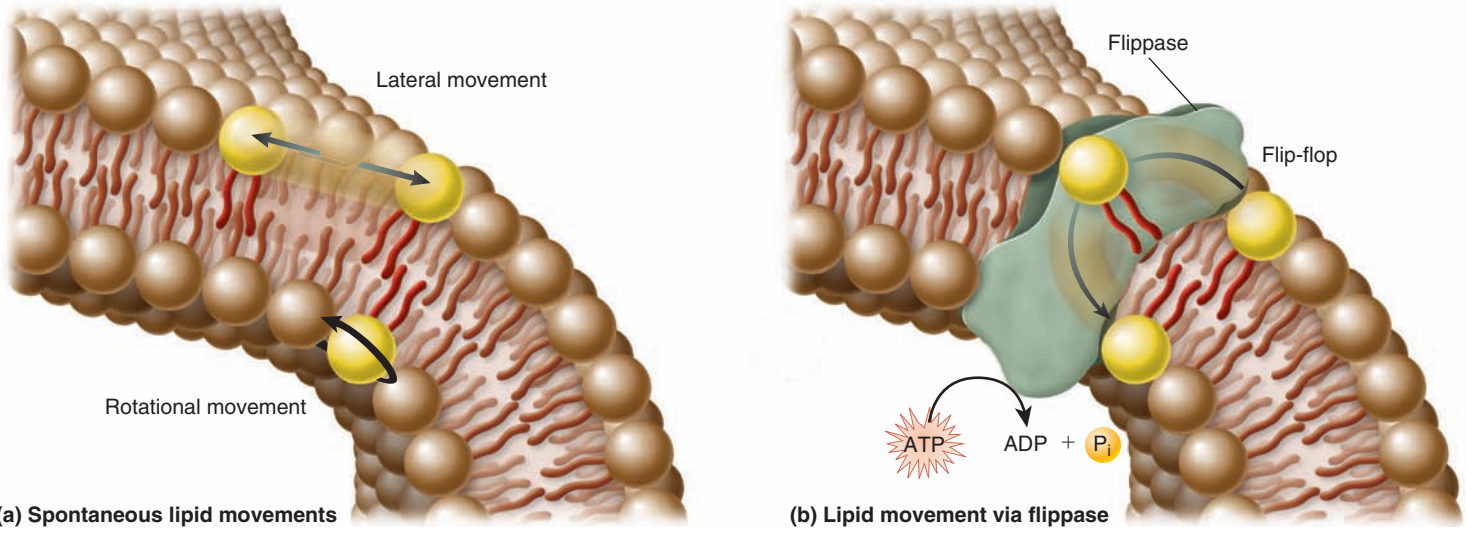
Learning Outcomes:

1. Describe the fluidity of membranes.
2. **SciSKILLS »** Predict how changes in lipid composition affect membrane fluidity.
3. **SciSKILLS »** Analyze the results of experiments that showed the lateral diffusion of membrane proteins.

Let's now turn our attention to the dynamic properties of membranes. Although a membrane provides a critical interface between a cell and its environment, it is not a solid, rigid structure. Rather, biological membranes exhibit properties of **fluidity**, which means that individual molecules remain in close association yet have the ability to readily move within the membrane. In this section, we will examine the fluid properties of biological membranes.

Membranes Are Semifluid

Though membranes are often described as fluid, it is more appropriate to say they are **semifluid**. In a fluid substance, molecules can move in three dimensions. By comparison, most phospholipids can rotate freely around their long axes and move laterally within the membrane leaflet (**Figure 5.4a**). This type of motion is considered two-dimensional, which means it occurs within the plane of the membrane. Because rotational and lateral movements keep the lipid tails within the hydrophobic interior, such movements are energetically favorable. At 37°C, a typical lipid molecule exchanges places with its neighbors about 10^7 times per second, and it can move several micrometers per second. At this rate, a lipid can traverse the length of a bacterial cell (approximately 1 μm) in only 1 second and the length of a typical animal cell in 10 to 20 seconds.



In contrast to rotational and lateral movements, the "flip-flop" of lipids from one leaflet to the opposite leaflet does not occur spontaneously. Flip-flop is energetically unfavorable because the hydrophilic polar head of a phospholipid would have to travel through the hydrophobic interior of the membrane. How are lipids moved from one leaflet to the other? The transport of lipids between leaflets requires the action of the enzyme flippase, which requires energy input in the form of ATP (**Figure 5.4b**).

Although most lipids diffuse rotationally and laterally within the plane of the lipid bilayer, researchers have discovered that certain types of lipids in animal cells tend to strongly associate with each other to form structures called lipid rafts. As the word raft suggests, a **lipid raft** is a group of lipids that float together as a unit within a larger sea of lipids. Lipid rafts have a lipid composition that differs from the surrounding membrane. For example, they usually have a high amount of cholesterol. In addition, lipid rafts may contain unique sets of lipid-anchored proteins and transmembrane proteins. The functional importance of lipid rafts is the subject of a large amount of current research. Lipid rafts may play an important role in endocytosis (discussed later in this chapter) and cell signaling.

Lipid Composition Affects Membrane Fluidity

The biochemical properties of phospholipids affect the fluidity of the phospholipid bilayer.

Length of Phospholipid Tails One key factor that affects membrane fluidity is the length of the lipid tails, which range from 14

(a) Spontaneous lipid movements (b) Lipid movement via flippase

Figure 5.4 Semifluidity of the lipid bilayer. **(a)** Spontaneous movements in the bilayer. Lipids can rotate (that is, move 360°) and move laterally (for example, from left to right in the plane of the bilayer). **(b)** Flip-flop does not happen spontaneously, because the polar head group would have to pass through the hydrophobic region of the bilayer. Instead, the enzyme flippase uses ATP to flip phospholipids from one leaflet to the other.

Concept Check: In an animal cell, how can changes in lipid composition affect membrane fluidity?

to 24 carbon atoms, with 16 to 18 carbons being the most common. Shorter tails are less likely to interact with each other, which makes the membrane more fluid.

Double Bonds in Phospholipid Tails A second important factor is the presence of double bonds in the lipid tails. When a double bond is present, the lipid is said to be **unsaturated** with respect to the number of hydrogens that are bound to the carbon atoms (refer back to Figure 3.9). A double bond creates a kink in a lipid tail (see inset to Figure 5.1), making it more difficult for neighboring tails to interact and making the bilayer more fluid. As described in Chapter 3, unsaturated lipids tend to be more liquid than saturated lipids, which often form solids at room temperature (refer back to Figure 3.10).

Cholesterol A third factor affecting fluidity is the presence of cholesterol, a short and rigid molecule produced by animal cells (see inset to Figure 5.1). Plant cell membranes contain phytosterols that resemble cholesterol in their chemical structure. Cholesterol tends to stabilize membranes; its effects depend on temperature. At higher temperatures, such as those observed in mammals that maintain a constant body temperature, cholesterol makes the membrane less fluid. At lower temperatures, such as icy water, cholesterol has the opposite effect. It makes the membrane more fluid and prevents it from freezing.

An optimal level of bilayer fluidity is essential for normal cell function, growth, and division. If a membrane is too fluid, which may occur at higher temperatures, it can become leaky. However, if a membrane becomes too solid, which may occur at lower temperatures, the functioning of membrane proteins will be inhibited. How can organisms cope with changes in temperature? The cells of many species adapt to changes in temperature by altering the lipid composition of their membranes. For example, when the water temperature drops, the cells of certain fish will incorporate more cholesterol in their membranes, making the membrane more fluid. If a plant cell is exposed to high temperatures for many hours or days, it will alter its lipid composition to have longer lipid tails and fewer double bonds, which will make the membrane less fluid.

Many Transmembrane Proteins Can Rotate and Move Laterally, but Some Are Restricted in Their Movement

Like lipids, many transmembrane proteins may rotate and move laterally throughout the plane of a membrane. Because transmembrane proteins are larger than lipids, they move within the membrane at a much slower rate. Flip-flop of transmembrane proteins does not occur, because the proteins also contain hydrophilic regions that project out from the phospholipid bilayer, and it would be energetically unfavorable for the hydrophilic regions of membrane proteins to pass through the hydrophobic portion of the phospholipid bilayer.

In 1970, Larry Frye and Michael Edidin conducted an experiment that verified the lateral movement of transmembrane proteins (**Figure 5.5**). Mouse and human cells were mixed together and exposed to agents that caused them to fuse with each other to produce mouse-human cell hybrids. Some cells were cooled to 0°C, while others were incubated at 37°C before being cooled. Both sets of cells were then exposed to fluorescently labeled antibodies that became specifically bound to a mouse transmembrane protein called H-2. The fluorescent label was observed with a fluorescence microscope. If the cells were maintained at 0°C, a temperature that greatly inhibits lateral movement, the fluorescence was seen on only one side of the fused cell. However, if the cells were incubated for several hours at 37°C and then cooled to 0°C, the fluorescence was distributed throughout the plasma membrane of the fused cell. This occurred because the higher temperature allowed the lateral movement of the H-2 protein throughout the fused cell.

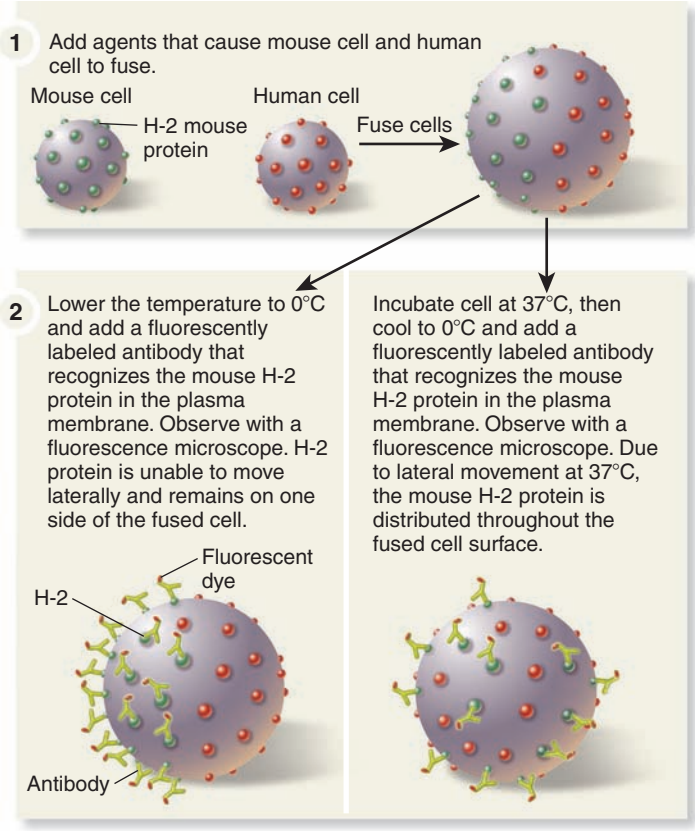


Figure 5.5 A method to measure the lateral movement of membrane proteins.

BIOLOGY PRINCIPLE Biology is an experimental science. This experiment verified that membrane proteins can diffuse laterally within the plane of the lipid bilayer.

Concept Check: Explain why the H-2 proteins were found on only one side of the cell when the cells were incubated at 0°C.

Unlike the example shown in Figure 5.5, not all transmembrane proteins are capable of rotational and lateral movement. Depending on the cell type, 10–70% of membrane proteins may be restricted in their movement. Transmembrane proteins may be bound to components of the cytoskeleton, which restricts the proteins from moving (**Figure 5.6**), or may be attached to molecules that are outside the cell, such as the interconnected network of proteins that forms the extracellular matrix of animal cells (see Chapter 10).

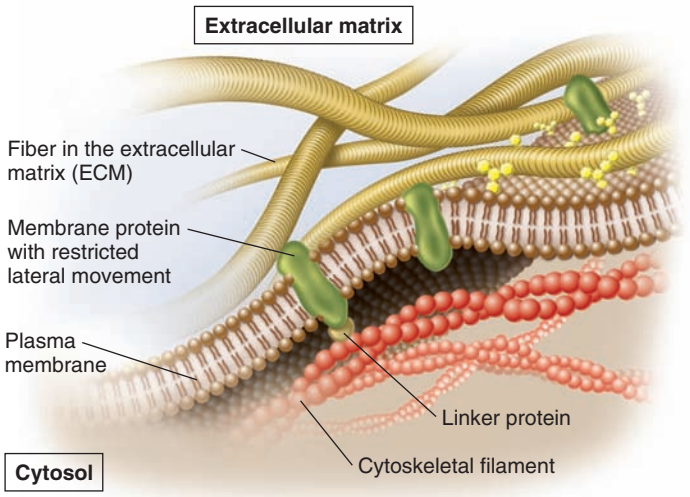

Figure 5.6 Attachment of transmembrane proteins to the cytoskeleton and extracellular matrix of an animal cell. Some transmembrane proteins have regions that extend into the cytosol and are anchored to large cytoskeletal filaments via linker proteins. Being bound to these large filaments restricts the movement of these proteins. Similarly, some transmembrane proteins are bound to large, immobile fibers in the extracellular matrix, which restricts their movements.

BioConnections: Look ahead to Figure 10.8. Discuss how transmembrane proteins are important in the binding of cells to each other and the binding of cells to the extracellular matrix.

5.3 Synthesis of Membrane Components in Eukaryotic Cells

Learning Outcomes:

1. Outline the synthesis of lipids at the ER membrane.
2. Explain how transmembrane proteins are inserted into the ER membrane.
3. Describe the process of glycosylation and its functional consequences.

As we have seen, cellular membranes are composed of lipids, proteins, and carbohydrates. Most of the membrane components of eukaryotic cells are made at the endoplasmic reticulum (ER). In this section, we will begin by considering how phospholipids are synthesized at the ER membrane. We will then examine the process by which transmembrane proteins are inserted into the ER membrane and explore how carbohydrates are attached to some proteins.

Lipid Synthesis Occurs at the ER Membrane

In eukaryotic cells, the cytosol and endomembrane system work together to synthesize most lipids. This process occurs at the cytosolic leaflet of the smooth ER membrane. **Figure 5.7** shows a simplified pathway for the synthesis of phospholipids. The building blocks for a phospholipid are two fatty acids, each with a long tail, one glycerol

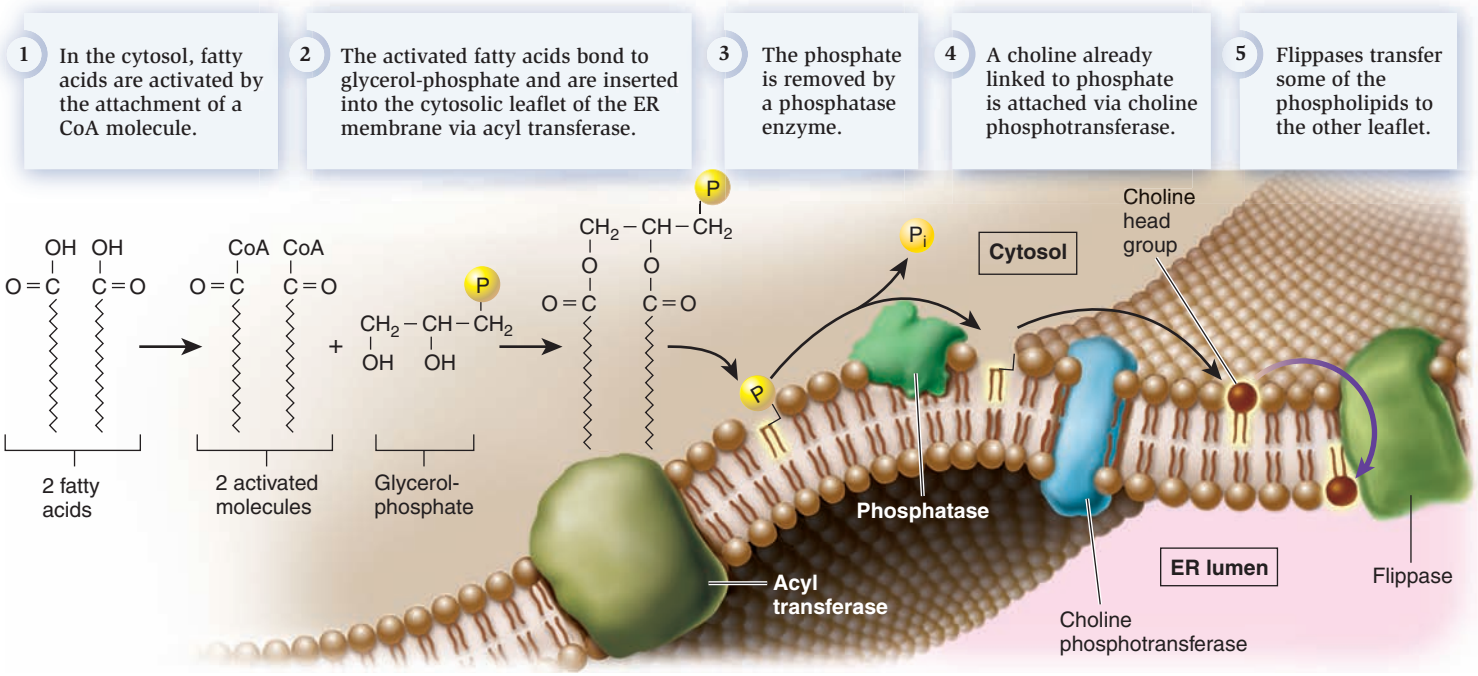

Figure 5.7 A simplified pathway for the synthesis of membrane phospholipids at the ER membrane. Note: Phosphate is abbreviated P when it is attached to an organic molecule and P_i when it is unattached. The subscript i refers to the inorganic form of phosphate.

Concept Check: How are phospholipids transferred to the leaflet of the ER membrane that faces the ER lumen?

molecule, one phosphate, and a polar head group. These building blocks are made via enzymes in the cytosol, or they are taken into cells from food. To begin the process of phospholipid synthesis, the fatty acids are activated by attachment to an organic molecule called coenzyme A (CoA). This activation promotes the bonding of the two fatty acids to a glycerol-phosphate molecule, and the resulting molecule is inserted into the cytosolic leaflet of the ER membrane. The phosphate is removed from glycerol, and then a polar molecule already linked to phosphate is attached to glycerol. In the example shown in Figure 5.7, the polar head group contains choline, but many other types of head groups are possible. Phospholipids are initially inserted into the cytosolic leaflet. Flippases in the ER membrane transfer some of the newly made lipids to the other leaflet so similar amounts of lipids are found in both leaflets.

The lipids made in the ER membrane are transferred to other membranes in the cell by a variety of mechanisms. Phospholipids in the ER can diffuse laterally to the nuclear envelope. In addition, lipids are transported via vesicles to the Golgi, lysosomes, vacuoles, or plasma membrane. A third mode of lipid transfer involves **lipid exchange proteins**, which extract a lipid from one membrane, diffuse through the cell, and insert the lipid into another membrane. Such transfer can occur between any two membranes, even between the endomembrane system and semiautonomous organelles. For example, lipid exchange proteins transfer lipids between the ER and mitochondria. In addition, chloroplasts and mitochondria synthesize certain types of lipids that are transferred from these organelles to other cellular membranes via lipid exchange proteins.

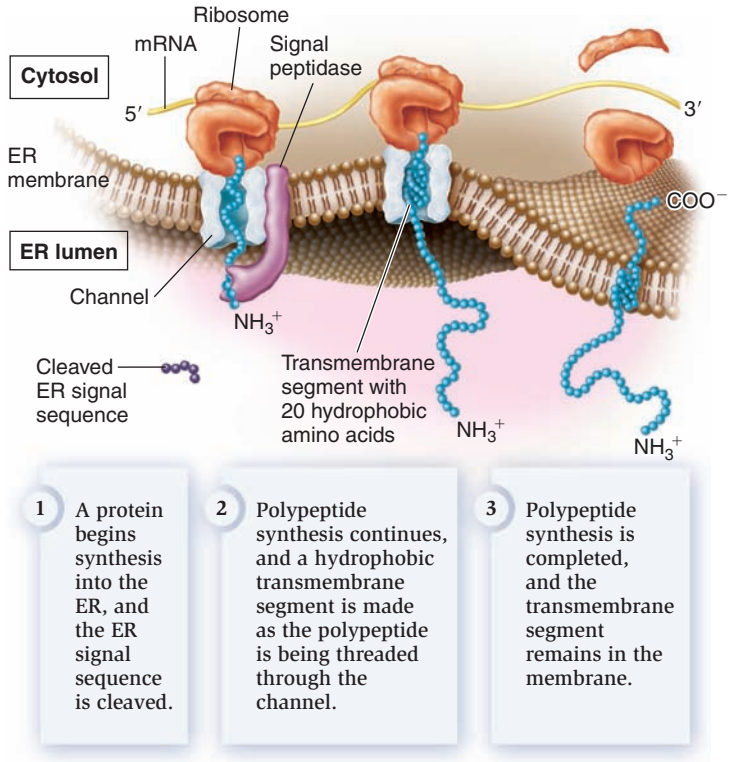

Figure 5.8 Insertion of membrane proteins into the ER membrane.

Concept Check: What structural feature of a protein causes a region to form a transmembrane segment?

Most Transmembrane Proteins Are First Inserted into the ER Membrane

In Chapter 4, we learned that eukaryotic proteins contain sorting signals that direct them to their proper destination (see Figure 4.28). With the exception of proteins destined for semiautonomous organelles, most transmembrane proteins contain an ER signal sequence that directs them to the ER membrane. If a polypeptide also contains a stretch of 20 amino acids that are mostly hydrophobic and form an α helix, this region will become a transmembrane segment. In the example shown in **Figure 5.8**, the polypeptide contains one such sequence. After the ER signal sequence is removed by signal peptidase (refer back to Figure 4.29), a membrane protein with a single transmembrane segment is the result. Other polypeptides may contain more than one transmembrane segment. Each time a polypeptide sequence contains a region of 20 amino acids that are mostly hydrophobic and form an α helix, an additional transmembrane segment is synthesized into the membrane. From the ER, membrane proteins can be transferred via vesicles to other regions of the cell, such as the Golgi, lysosomes, vacuoles, or plasma membrane.

The Attachment of Carbohydrates to Proteins Occurs in the ER and Golgi Apparatus

Glycosylation refers to the process of covalently attaching a carbohydrate to a lipid or protein. When a carbohydrate is attached to a lipid, a **glycolipid** is created, whereas attachment of a carbohydrate to a protein produces a **glycoprotein**.

What is the function of glycosylation? Though the roles of carbohydrates in cell structure and function are not entirely understood, some functional consequences of glycosylation have emerged. Glycolipids and glycoproteins often play a role in cell surface recognition. When glycolipids and glycoproteins are found in the plasma membrane, the carbohydrate portion is located in the extracellular region. During embryonic development in animals, significant cell movement occurs. Layers of cells slide over each other to create body structures such as the spinal cord and internal organs. The proper migration of individual cells and cell layers relies on the recognition of cell types via the carbohydrates on their cell surfaces.

Carbohydrates often have a protective effect. The carbohydrate-rich zone on the surface of certain animal cells shields the cell from mechanical and physical damage. Similarly, the carbohydrate portion of glycosylated proteins protects them from the harsh conditions of the extracellular environment and degradation by extracellular proteases, which are enzymes that digest proteins.

Two forms of protein glycosylation occur in eukaryotes: N-linked and O-linked. N-linked glycosylation, which also occurs in archaea, involves the attachment of a carbohydrate to the amino acid asparagine in a polypeptide. It is called N-linked because the carbohydrate is attached to a nitrogen atom of the asparagine side chain. For this to occur, a group of 14 sugar molecules, called a carbohydrate tree, is first built onto a lipid found in the ER membrane (**Figure 5.9**). An enzyme in the ER, oligosaccharide transferase, transfers the carbohydrate tree from the lipid to an asparagine in the polypeptide. N-linked glycosylation commonly occurs on membrane proteins that are transported to the cell surface.

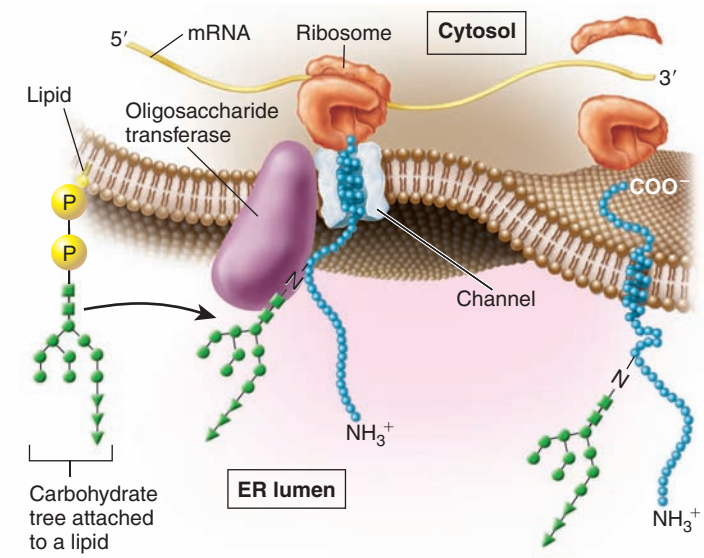

Figure 5.9 **N-linked glycosylation in the endoplasmic reticulum.**

The second form of glycosylation, O-linked glycosylation, occurs only in the Golgi apparatus. This form involves the addition of a string of sugars to the oxygen atom of serine or threonine side chains in polypeptides. In animals, O-linked glycosylation is important for the production of proteoglycans, which are highly glycosylated proteins that are secreted from cells and help to organize the extracellular matrix that surrounds cells. Proteoglycans are also a component of mucus, a slimy material that coats many cell surfaces and is secreted into fluids such as saliva. High concentrations of carbohydrates give mucus its slimy texture.

5.4 Overview of Membrane Transport

Learning Outcomes:

1. Compare and contrast simple diffusion, facilitated diffusion, passive transport, and active transport.
2. Explain the process of osmosis and how it affects cell structure.
3. **SciSKILLS** » Predict the direction of water movement in response to solute gradients.

We now turn to one of the key functions of membranes, **membrane transport**—the movement of ions and molecules across biological membranes. All cells contain a plasma membrane that exhibits **selective permeability**, allowing the passage of some ions and molecules but not others. As a protective envelope, its structure ensures that essential molecules such as glucose and amino acids enter the cell, metabolic intermediates remain in the cell, and waste products exit. The selective permeability of the plasma membrane allows the cell to maintain a favorable internal environment.

Substances can move directly across a membrane in three general ways (**Figure 5.10**). **Simple diffusion** occurs when a substance moves from a region of high concentration to a region of lower concentration. Some substances can move directly through a biological membrane via simple diffusion. In **facilitated diffusion**, a transport protein provides a passageway for a substance to diffuse across a membrane. Simple diffusion and facilitated diffusion are examples of **passive transport**—the transport of a substance across a membrane that does not require an input of energy. In contrast, a third mode of transport, called **active transport**, moves a substance from an area of low concentration to one of high concentration with the aid of a transport protein. Active transport requires an input of energy from a source such as ATP.

In this section, we will begin with a discussion of how the phospholipid bilayer presents a barrier to the movement of ions and molecules across membranes. We will then consider the concept of gradients across membranes and how such gradients affect the movement of water.

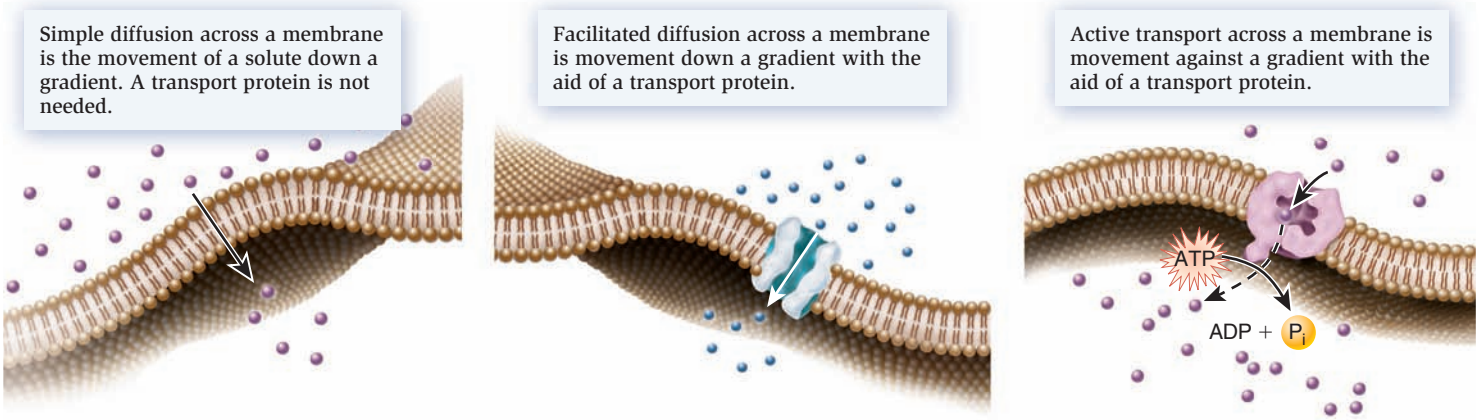

Figure 5.10 **Three general types of membrane transport.**

The Phospholipid Bilayer Is a Barrier to the Movement of Hydrophilic Solutes

Because of their hydrophobic interiors, phospholipid bilayers are a barrier to the movement of ions and hydrophilic molecules. Such ions and molecules are called **solutes**; they are dissolved in water, which is a solvent. The rate of movement across a phospholipid bilayer depends on the chemistry of the solute and its concentration. **Figure 5.11** compares the relative permeabilities of an artificial phospholipid bilayer to various solutes. This artificial bilayer does not contain any proteins or carbohydrates. Gases and a few small, uncharged molecules can readily cross the bilayer by simple diffusion. However, the permeability of the bilayer to ions and larger polar molecules, such as sugars, is relatively low, and the permeability to macromolecules, such as proteins and polysaccharides, is even lower.

When we consider how different solutes cross a lipid bilayer by simple diffusion, the greatest variation occurs in the ability of solutes to enter the hydrophobic interior of the bilayer. As an example, let's compare urea and diethylurea. Diethylurea is much more

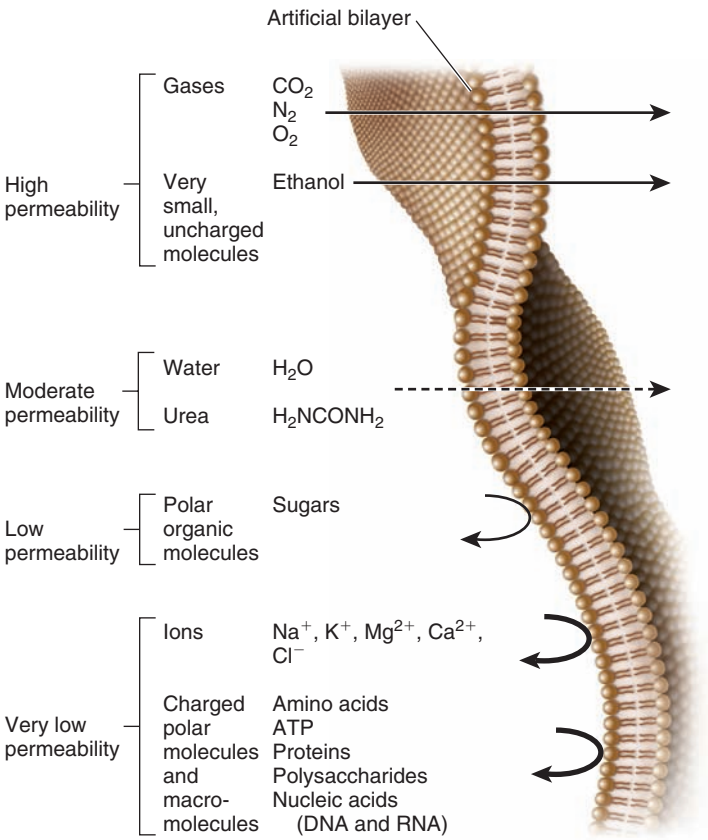

Figure 5.11 Relative permeability of an artificial phospholipid bilayer to a variety of solutes. Solutes that easily penetrate are shown with a straight arrow that passes through the bilayer. The dashed arrow indicates solutes for which the bilayer is moderately permeable. Permeability is low to very low for the remaining solutes toward the bottom of the figure.

BioConnections: *Which amino acid, described in Chapter 3 (see Figure 3.13), would you expect to cross an artificial membrane more quickly, leucine or lysine?*

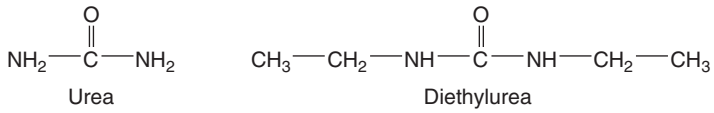

Figure 5.12 Structures of urea and diethylurea.

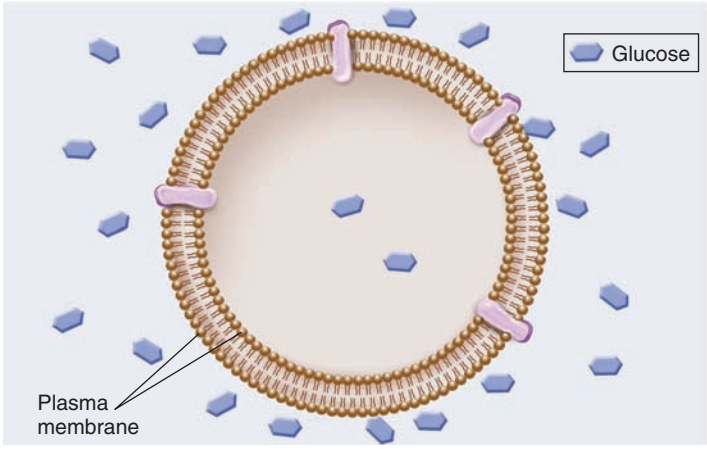
Concept Check: *Which molecule would you expect to pass through a phospholipid bilayer more quickly, methanol (CH_3OH) or methane (CH_4)?*

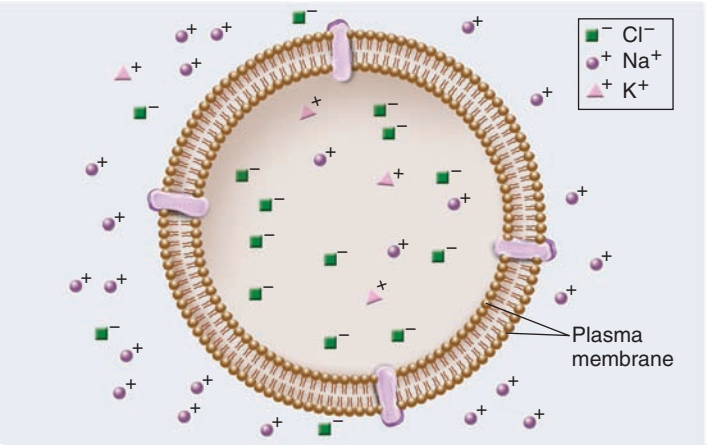
hydrophobic because it contains two nonpolar ethyl groups (—CH_2CH_3) (**Figure 5.12**). For this reason, it can pass more quickly through the hydrophobic region of the bilayer. The rate of simple diffusion of diethylurea through a phospholipid bilayer is about 50 times faster than that of urea.

Cells Maintain Gradients Across Their Membranes



A hallmark of living cells is their ability to maintain a relatively constant internal environment that is distinctively different from their external environment. Solute gradients are formed across the plasma membrane and across organellar membranes. When we speak of a **transmembrane gradient** or **concentration gradient**, we mean the concentration of a solute is higher on one side of a membrane than the other. Transmembrane gradients of solutes are a universal feature of all living cells. For example, immediately after you eat a meal containing carbohydrates, a higher concentration of glucose is found outside your cells than inside; this is an example of a chemical gradient (**Figure 5.13a**).

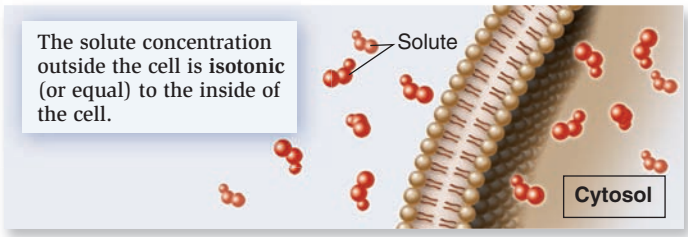
Gradients involving ions have two components—electrical and chemical. An **electrochemical gradient** is a dual gradient with both electrical and chemical components (**Figure 5.13b**). It occurs with solutes that have a net positive or negative charge. For example, let's consider a gradient involving Na^+. An electrical gradient can exist in which the amount of net positive charge outside a cell is greater than inside. In Figure 5.13b, an electrical gradient is due to differences in the amounts of different types of ions across the membrane, including sodium, potassium, and chloride (Na^+, K^+, and Cl^-). At the same time, a chemical gradient—a difference in Na^+ concentration across the membrane—could exist in which the concentration of Na^+ outside is greater than inside. The Na^+ electrochemical gradient is composed of both an electrical gradient due to charge differences across the membrane and a chemical gradient for Na^+.



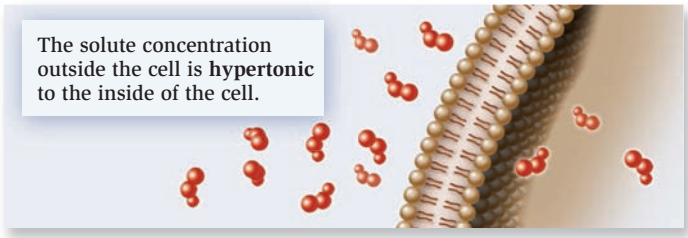
One way to view the transport of solutes across membranes is to consider how the transport process affects the pre-existing gradients across membranes. Passive transport tends to dissipate a pre-existing gradient. Such a process is energetically favorable and does not require an input of energy. As mentioned, passive transport can occur in two ways, via simple diffusion or facilitated diffusion (see Figure 5.10a,b). By comparison, active transport produces a chemical gradient or electrochemical gradient. The formation of a gradient requires an input of energy.

Osmosis Is the Movement of Water Across Membranes to Balance Solute Concentrations

Let's now turn our attention to how gradients affect the movement of water across membranes. When the concentrations of dissolved particles (solutes) on both sides of the plasma membrane are equal, the two

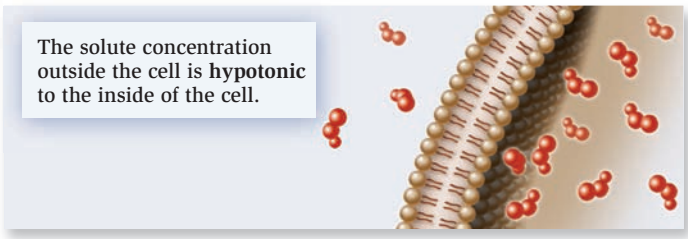


(a) Chemical gradient for glucose—a higher glucose concentration outside the cell



(b) Electrochemical gradient for Na^+—more positive charges outside the cell and a higher Na^+ concentration outside the cell

Figure 5.13 **Gradients across cell membranes.**



BioConnections: *Look ahead to Figure 41.9. What types of ion gradients are important for the conduction of an action potential across the plasma membrane of a neuron?*

(a) Outside isotonic

(b) Outside hypertonic

(c) Outside hypotonic

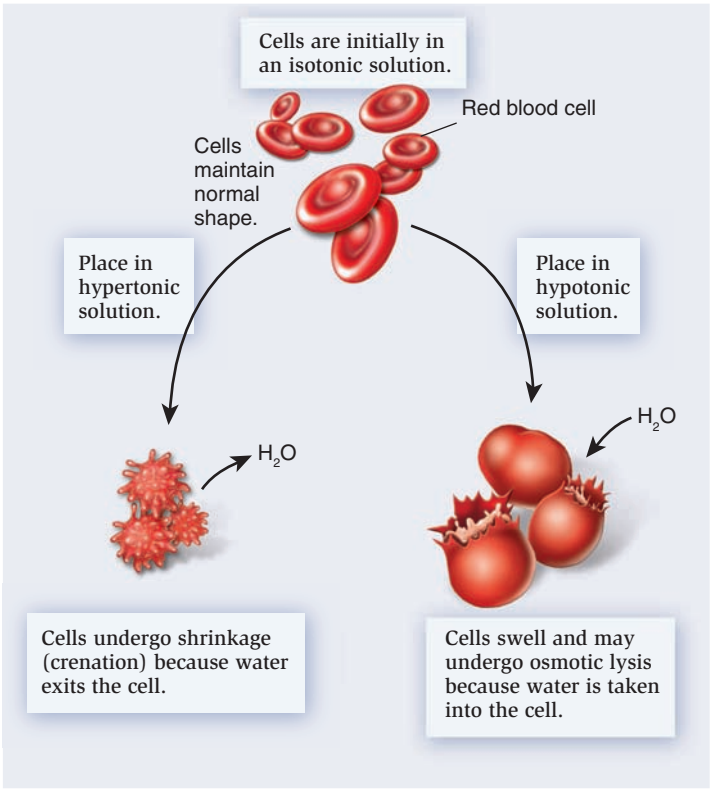


Figure 5.14 **Relative solute concentrations outside and inside cells.**

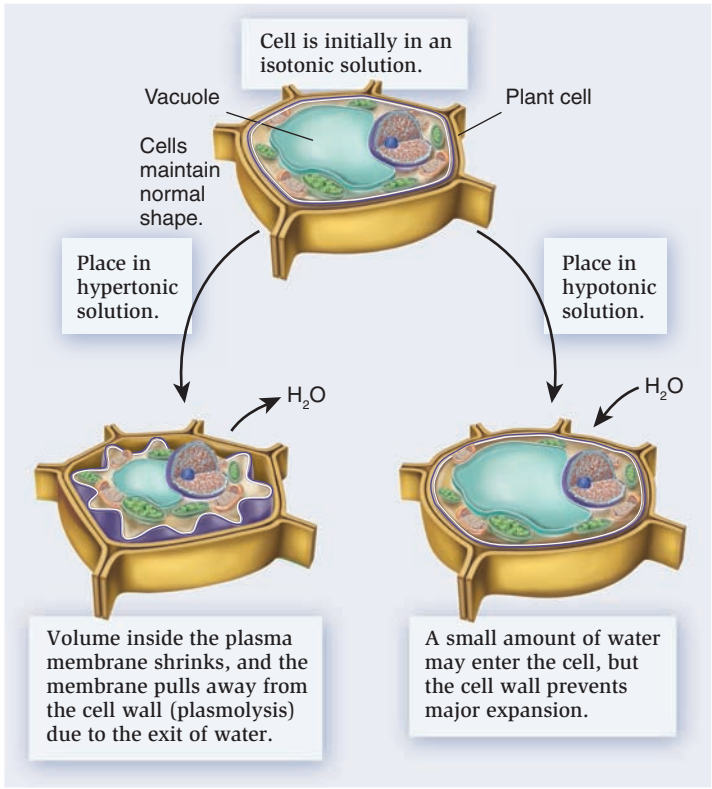
solutions are said to be **isotonic** (Figure 5.14a). However, we have also seen that transmembrane gradients commonly exist across membranes. When the concentration of solutes outside the cell is higher, it is said to be **hypertonic** relative to the inside of the cell (Figure 5.14b). Alternatively, the outside of the cell could be **hypotonic**—have a lower concentration of solutes relative to the inside (Figure 5.14c).



If solutes cannot readily move across the membrane, water will move and tend to balance the solute concentrations. In this process, called **osmosis**, water moves across a membrane from the hypotonic compartment (with a lower concentration) into the hypertonic compartment (with a higher concentration). Animal cells, which are not surrounded by a rigid cell wall, must maintain a balance between the extracellular and intracellular solute concentrations; the two solutions need to be isotonic. Animal cells contain a variety of transport proteins that sense changes in cell volume and allow the necessary movements of solutes across the membrane to prevent osmotic changes and maintain normal cell shape. However, if an animal cell is placed in a hypotonic medium, water will enter the cell to equalize solute concentrations on both sides of the membrane. In extreme cases, a cell may take up so much water that it ruptures, a phenomenon called osmotic lysis (Figure 5.15a). Alternatively, if an animal cell is placed in a hypertonic medium, water will exit the cell via osmosis and equalize solute concentrations on both sides of the membrane, causing the cell to shrink in a process called crenation.

How does osmosis affect cells with a rigid cell wall, such as bacteria, fungi, algae, and plant cells? If the extracellular fluid is hypotonic, a plant cell will take up a small amount of water, but the cell wall prevents osmotic lysis from occurring (Figure 5.15b). Alternatively, if the extracellular fluid surrounding a plant cell is hypertonic, water will exit the cell and the plasma membrane will pull away from the cell wall, a process called **plasmolysis**.

Some freshwater microorganisms, such as amoebae and paramecia, are found in extremely hypotonic environments where the external solute concentration is always much lower than the concentration of solutes in their cytosol. Because of the great tendency for water to move into the cell by osmosis, such organisms contain one or more contractile vacuoles to prevent osmotic lysis. A contractile vacuole takes up water from the cytosol and periodically discharges it by fusing with the plasma membrane (Figure 5.16).

(a) Osmosis in animal cells

(b) Osmosis in plant cells

Figure 5.15 The phenomenon of osmosis. **(a)** In cells that lack a cell wall, such as animal cells, osmosis may promote cell shrinkage (crenation) or swelling. **(b)** In cells that have a rigid cell wall, such as plant cells, a hypertonic medium causes the plasma membrane to pull away from the cell wall, whereas a hypotonic medium causes only a minor amount of expansion.

Concept Check: *Let's suppose the inside of a cell has a solute concentration of 0.3 M, and the outside is 0.2 M. If the membrane is impermeable to solutes, in which direction will water move?*

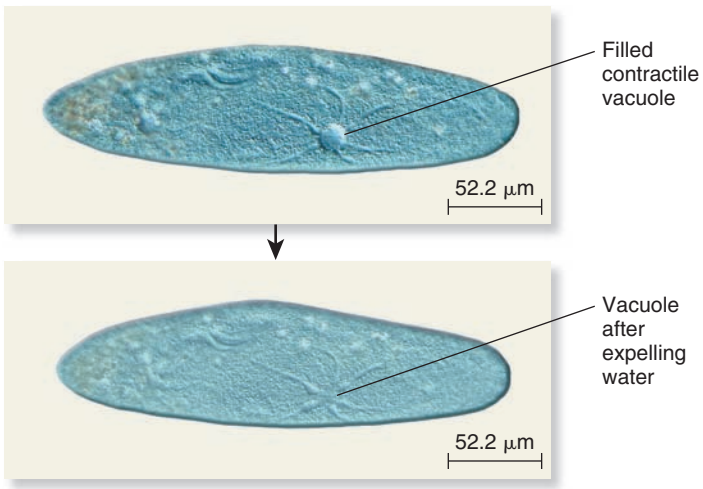


Figure 5.16 The contractile vacuole in *Paramecium caudatum*. In the upper photo, a contractile vacuole is filled with water from radiating canals that collect fluid from the cytosol. The lower photo shows the cell after the contractile vacuole has fused with the plasma membrane (which would be above the plane of this page) and released the water from the cell.

BIOLOGY PRINCIPLE Living organisms maintain homeostasis. In this example, the paramecium maintains a relatively constant internal volume by using contractile vacuoles to remove excess water.

5.5 Transport Proteins

Learning Outcomes:

1. Outline the functional differences between channels and transporters.
2. Compare and contrast uniporters, symporters, and antiporters.
3. **SciSKILLS** » Analyze the results of Agre, and explain how they indicated the presence of a water channel.
4. Explain the difference between primary active transport and secondary active transport.
5. Describe the structure and function of pumps.

Because the phospholipid bilayer is a physical barrier to the diffusion of most hydrophilic molecules and ions, cells can separate their internal contents from the external environment. However, this barrier also poses a potential problem because cells must take up nutrients from the environment and export waste products. How do cells overcome this dilemma? Over the course of millions of years, species have evolved a multitude of **transport proteins**—transmembrane proteins that provide passageways for the movement of ions and hydrophilic molecules across the phospholipid bilayer. Transport proteins play a central role in the selective permeability of biological membranes. In this section, we will examine the two categories of transport proteins—channels and transporters—based on the manner in which they move solutes across the membrane.

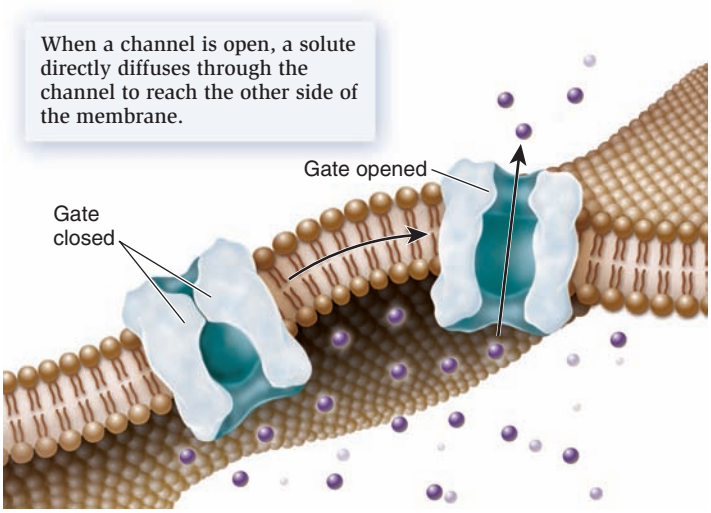

Figure 5.17 **Mechanism of transport by a channel protein.**

Concept Check: *What is the purpose of gating?*

Channels Provide Open Passageways for Solute Movement

A **channel** is a transmembrane protein that forms an open passageway for the facilitated diffusion of ions or molecules across the membrane (**Figure 5.17**). Solutes move directly through a channel to get to the other side. When a channel is open, the transmembrane movement of solutes can be extremely rapid, up to 100 million ions or molecules per second!

Most channels are **gated**, which means they open to allow the diffusion of solutes and close to prohibit diffusion. The phenomenon of gating allows cells to regulate the movement of solutes. For example, gating may involve the direct binding of a molecule to the channel protein itself. These gated channels are controlled by the noncovalent binding of small molecules—called ligands—such as hormones or neurotransmitters. The ligands are often important in the transmission of signals between neurons and muscle cells or between two neurons.

Feature Investigation | Agre Discovered That Osmosis Occurs More Quickly in Cells with a Channel That Allows the Facilitated Diffusion of Water

As discussed earlier in this chapter, osmosis is the movement of water to balance solute concentrations. Water can slowly cross biological membranes by simple diffusion through the phospholipid bilayer. However, in the 1980s, researchers discovered that certain cell types allow water to move across the plasma membrane at a much faster rate than would occur with simple diffusion alone. For example, water moves very quickly across the membrane of red blood cells, which causes them to shrink and swell in response to changes in extracellular solute concentrations. Likewise, bladder and kidney cells, which play a key role in regulating water balance in the bodies of vertebrates, allow the rapid movement of water across their membranes. Based on these observations, researchers speculated that certain cell types might have channel proteins in their plasma membranes that enable the rapid movement of water.

One approach to characterizing a new protein is to first identify a protein based on its relative abundance in a particular cell type and then attempt to determine the protein's function. This rationale was applied to the discovery of proteins that allow the rapid movement of water across membranes. Peter Agre and his colleagues first identified a protein that was abundant in red blood cells and kidney cells but not found in high amounts in many other cell types. Though they initially did not know the function of the protein, its physical structure was similar to other proteins that were already known to function as channels. They named this protein CHIP28, which stands for channel-forming integral membrane protein with a molecular mass of 28,000 daltons. During the course of their studies, they also identified and isolated the gene that encodes CHIP28.

In 1992, Agre and his colleagues conducted experiments to determine if CHIP28 functions in the transport of water across membranes (**Figure 5.18**). Because they already had isolated the gene that encodes CHIP28, they could make many copies of this gene in a test tube (in vitro) using gene cloning techniques (see Chapter 20). Starting with many copies of the gene in vitro, they added an enzyme to transcribe the gene into mRNA that encodes the CHIP28 protein. This mRNA was then injected into frog oocytes, chosen because frog oocytes are large, easy to inject, and lack pre-existing proteins in their plasma membranes that allow the rapid movement of water. Following injection, the mRNA was translated into CHIP28 proteins that were inserted into the plasma membrane of the oocytes. After allowing sufficient time for this to occur, the oocytes were placed in a hypotonic medium. As a control, oocytes that had not been injected with CHIP28 mRNA were also exposed to a hypotonic medium.

As you can see in the data, a striking difference was observed between oocytes that expressed CHIP28 versus the control. Within minutes, oocytes that contained the CHIP28 protein were seen to swell due to the rapid uptake of water. Three to five minutes after being placed in a hypotonic medium, they actually lysed! By comparison, the control oocytes did not swell as rapidly, and they did not rupture even after 1 hour. Taken together, these results are consistent with the hypothesis that CHIP28 functions as a channel that allows the facilitated diffusion of water across the membrane. Many subsequent studies confirmed this observation. Later, CHIP28 was renamed **aquaporin** to indicate its newly identified function of allowing water to diffuse through a channel in the membrane. In 2003, Agre was awarded the Nobel Prize in Chemistry for this work.

Experimental Questions

1. What observations about particular cell types in the human body led to the experimental strategy of Figure 5.18?
2. What were the characteristics of CHIP28 that made Agre and associates speculate that it may transport water? In your own words, briefly explain how they tested the hypothesis that CHIP28 has this function.
3. **SciSKILLS** » Explain how the results of the experiment of Figure 5.18 support the proposed hypothesis.

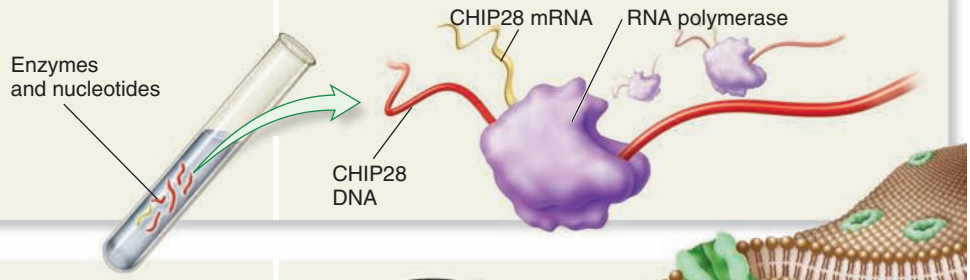

Figure 5.18 The discovery of water channels (aquaporins) by Agre.

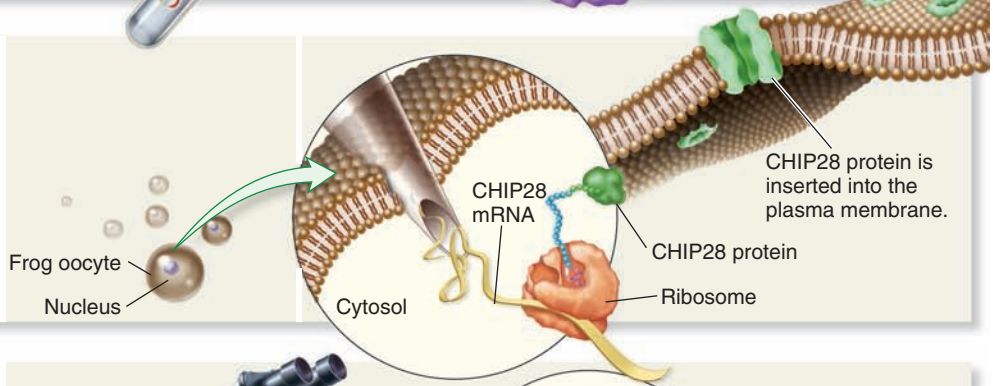
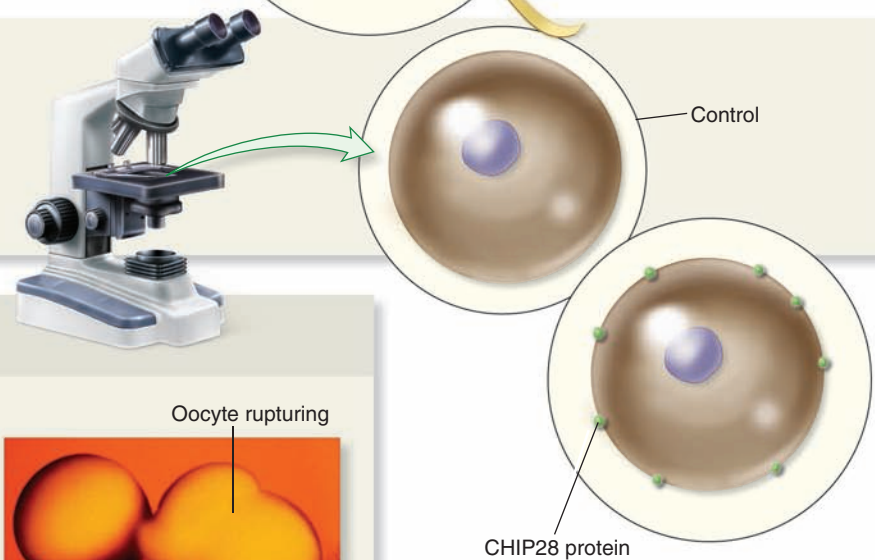
HYPOTHESIS CHIP28 may function as a water channel.

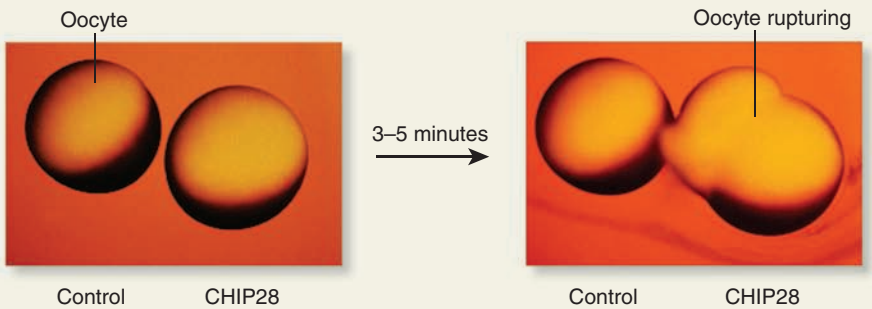


KEY MATERIALS Prior to this work, a protein called CHIP28 was identified that is abundant in red blood cells and kidney cells. The gene that encodes this protein was cloned, which means that many copies of the gene were made in a test tube.

Experimental level **Conceptual level**



1 Add an enzyme (RNA polymerase) and nucleotides to a test tube that contains many copies of the CHIP28 gene. This results in the synthesis of many copies of CHIP28 mRNA.



2 Inject the CHIP28 mRNA into frog eggs (oocytes). Wait several hours to allow time for the mRNA to be translated into CHIP28 protein at the ER membrane and then moved via vesicles to the plasma membrane.

3 Place oocytes into a hypotonic medium and observe under a light microscope. As a control, also place oocytes that have not been injected with CHIP28 mRNA into a hypotonic medium and observe by microscopy.

4 **THE DATA**

5 **CONCLUSION** The CHIP28 protein, now called aquaporin, allows the rapid movement of water across the membrane.

6 **SOURCE** Preston, G.M., Carroll, T.P., Guggino, W.B., and Agre, P. 1992. Appearance of water channels in *Xenopus* oocytes expressing red cell CHIP28 protein.

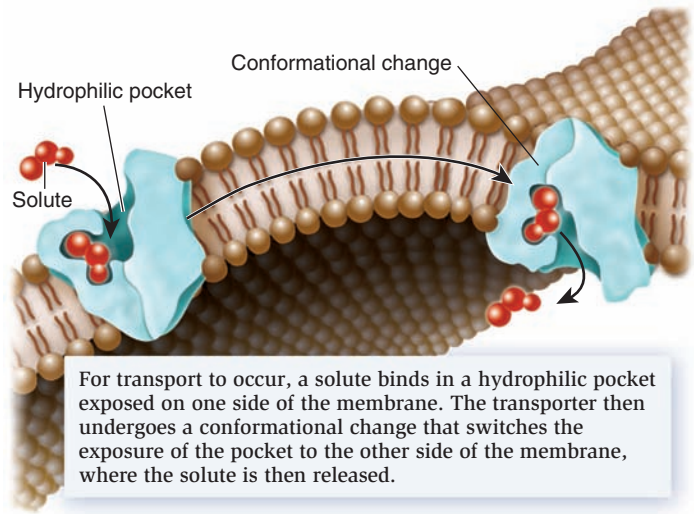


Figure 5.19 Mechanism of transport by a transporter, also called a carrier.

BIOLOGY PRINCIPLE Structure determines function. Two structural features—a hydrophilic pocket and the ability to wobble back and forth between two conformations—allow transporters to move ions and molecules across the membrane.

Transporters Bind Their Solutes and Undergo Conformational Changes

Let's now turn our attention to a second category of transport proteins known as **transporters**.* These transmembrane proteins bind their solutes in a hydrophilic pocket and undergo a conformational change that switches the exposure of the pocket from one side of the membrane to the other side (Figure 5.19). For example, in 1995, American biologist Robert Brooker and colleagues proposed that a transporter called lactose permease, which is found in the bacterium *E. coli*, has a hydrophilic pocket that binds lactose. They further proposed that the two halves of the transporter protein come together at an interface that moves in such a way that the lactose-binding site alternates between an outwardly accessible pocket and an inwardly accessible pocket, as shown in Figure 5.19. This idea was later confirmed by studies that determined the structure of the lactose permease and related transporters.

Transporters provide the principal pathway for the uptake of organic molecules, such as sugars, amino acids, and nucleotides. In animals, they also allow cells to take up certain hormones and neurotransmitters. In addition, many transporters play a key role in export. Waste products of cellular metabolism must be released from cells before they reach toxic levels. For example, a transporter removes lactic acid, a by-product of muscle cells during exercise. Other transporters, which are involved with ion transport, play an important role in regulating internal pH and controlling cell volume. Transporters tend to be much slower than channels. Their rate of transport is typically 100 to 1,000 ions or molecules per second.

* Transporters are also called carriers. However, this term is misleading because transporters do not physically carry their solutes across the membrane.

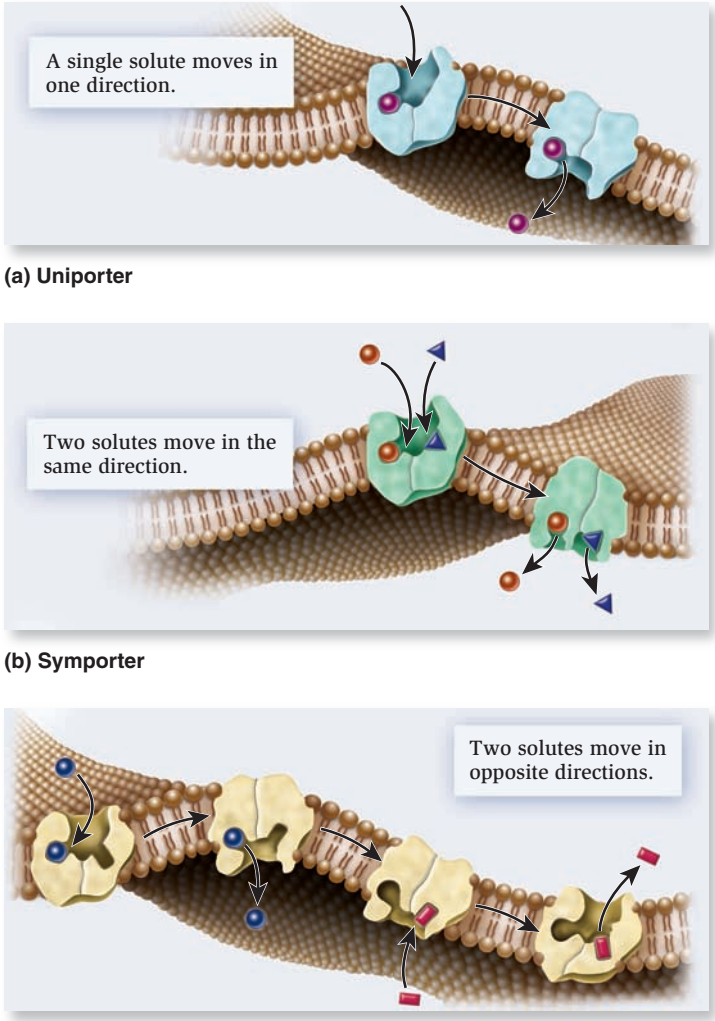

Figure 5.20 Types of transporters based on the direction of transport.

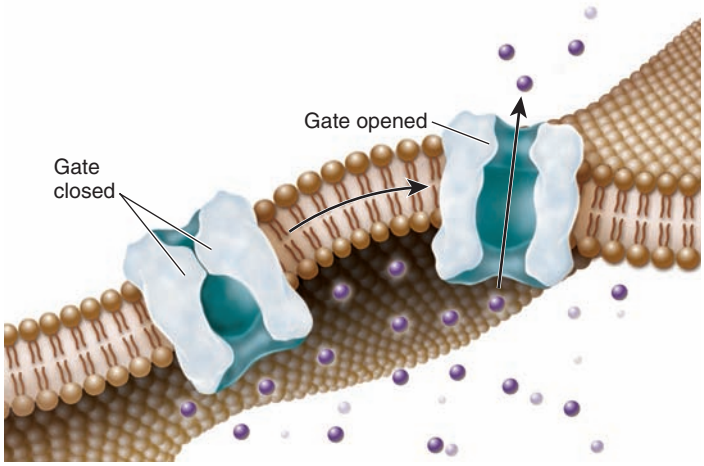
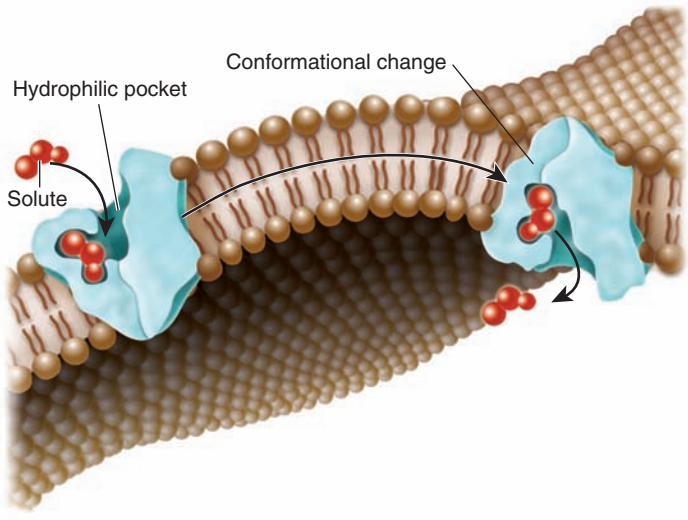
Transporters are named according to the number of solutes they bind and the direction in which they transport those solutes (Figure 5.20). **Uniporters** bind a single ion or molecule and transport it across the membrane. **Symporters** bind two or more ions or molecules and transport them in the same direction. **Antiporters** bind two or more ions or molecules and transport them in opposite directions.



BIO TIPS

THE QUESTION *Channels and transporters allow the passage of solutes across membranes. However, at the molecular level, they work in fundamentally different ways. Explain how each type can transport solutes across a membrane.*



TOPIC ***What topic in biology does this question address?*** The topic is membrane transport. More specifically, the question is about comparing the mechanisms of transport used by channels and transporters.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you know that channels and transporters allow solutes to move across membranes. From your understanding of the topic, you may remember that channels and transporters are transmembrane proteins with different structures.

PROBLEM-SOLVING STRATEGY ***Make a drawing. Relate structure and function.*** One strategy to solve this problem is to make a drawing that compares the structures of channels and transporters and shows their abilities to transport solutes across membranes.

Channel

Transporter

ANSWER *When its gate is open, a channel provides a direct passageway for the movement of a solute across a membrane. A transporter does not provide a direct passageway for such movement. Instead, a solute must first enter a hydrophilic pocket on one side of the membrane. The transporter then undergoes a conformational change that exposes the pocket on the other side of the membrane, where the solute is released.*

Active Transport Is the Movement of Solutes Against a Gradient

As mentioned, active transport is the movement of a solute across a membrane against its concentration gradient—that is, from a region of low concentration to higher concentration. Active transport is energetically unfavorable and requires an input of energy. **Primary active transport** involves the functioning of a **pump**—a type of transporter that directly uses energy to transport a solute against a concentration gradient. **Figure 5.21a** shows a pump that uses ATP to transport H^+ against a gradient. Such a pump can establish an H^+ electrochemical gradient across a membrane.

Secondary active transport involves the use of a pre-existing gradient to drive the active transport of another solute. For example, an H^+/sucrose symporter uses an H^+ electrochemical gradient, established by a pump, to move sucrose against its concentration gradient (**Figure 5.21b**). In this case, only sucrose is actively transported. Hydrogen ions move down their electrochemical gradient. H^+/solute symporters are more common in bacteria, fungi, algae, and plant cells, because H^+ pumps are found in their plasma membranes. In animal cells, a pump that exports Na^+ maintains a Na^+ gradient across the plasma membrane. Na^+/solute symporters are prevalent in animal cells.

Symporters enable cells to actively import nutrients against a gradient. These proteins use the energy stored in the electrochemical gradient of H^+ or Na^+ to power the uphill movement of organic solutes such as sugars, amino acids, and other needed molecules. Therefore, with symporters in their plasma membrane, cells can scavenge nutrients from the extracellular environment and accumulate them to high levels within the cytoplasm.

ATP-Driven Ion Pumps Generate Ion Electrochemical Gradients

The phenomenon of active transport was discovered in the 1940s based on the study of the transport of sodium ions (Na^+) and potassium ions (K^+). In animal cells, the concentration of Na^+ is lower inside the cell than outside, whereas the concentration of K^+ is higher inside the cell than outside. After analyzing the movement of these ions across the plasma membrane of muscle cells, neurons, and red blood cells, researchers determined that the export of Na^+ is coupled to the import of K^+. In the late 1950s, Danish biochemist Jens Skou proposed that a single transporter is responsible for this phenomenon. He was the first to describe an ATP-driven ion pump, which was later named Na^+/K^+-ATPase. This pump actively transports Na^+ and K^+ against their gradients by using the energy from ATP hydrolysis. The plasma membrane of a typical animal cell contains thousands of Na^+/K^+-ATPase pumps that maintain large concentration gradients in which the concentration of Na^+ is higher outside the cell and the concentration of K^+ is higher inside the cell.

Let's take a closer look at the Na^+/K^+-ATPase that Skou discovered. Every time one ATP is hydrolyzed, the Na^+/K^+-ATPase functions as an antiporter that pumps three Na^+ into the extracellular environment and two K^+ into the cytosol (**Figure 5.22a**). Because one cycle of pumping results in the net export of one positive charge,

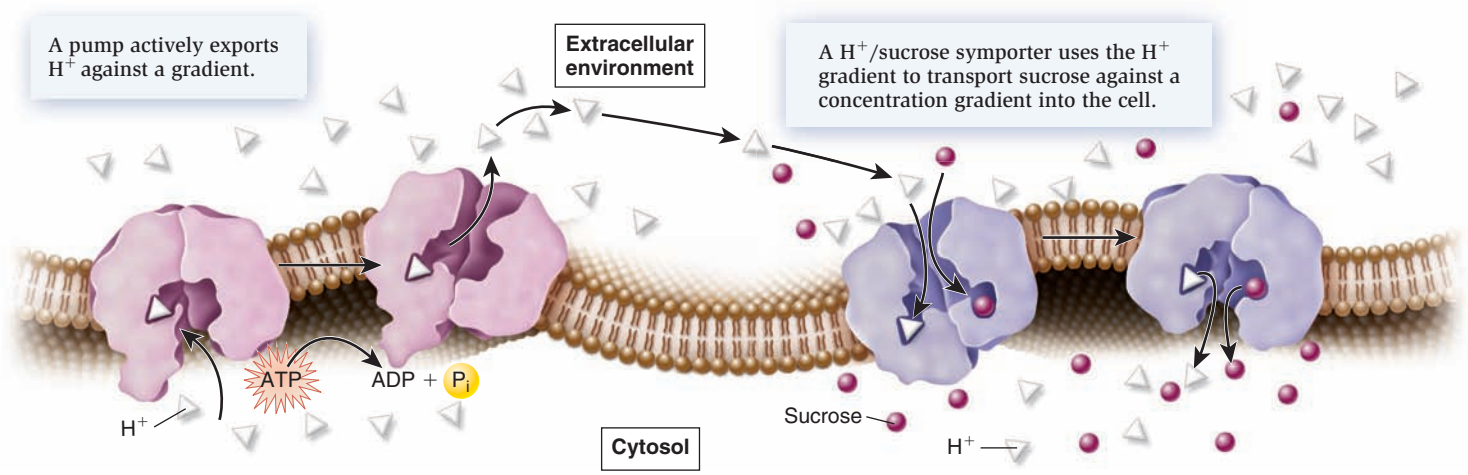


Figure 5.21 Types of active transport. **(a)** During primary active transport, a pump directly uses energy, in this case from ATP, to transport a solute against a concentration gradient. The pump shown here uses ATP to establish an H^+ electrochemical gradient. **(b)** Secondary active transport via symport involves the use of this gradient to drive the active transport of a solute, such as sucrose.

the Na^+/K^+-ATPase also produces an electrical gradient across the membrane. For this reason, it is called an **electrogenic pump**, because it generates an electrical gradient.

By studying the interactions of Na^+, K^+, and ATP with the Na^+/K^+-ATPase, researchers have pieced together a molecular road map of the steps that direct the pumping of ions across the membrane (**Figure 5.22b**). The Na^+/K^+-ATPase alternates between two conformations, designated E1 and E2. In E1, the ion-binding sites are accessible from the cytosol—Na^+ binds tightly to this conformation, whereas K^+ has a low affinity. In E2, the ion-binding sites are accessible from the extracellular environment—Na^+ has a low affinity, and K^+ binds tightly.

To examine the pumping mechanism of the Na^+/K^+-ATPase, let's begin with the E1 conformation. Three Na^+ bind to the Na^+/K^+-ATPase

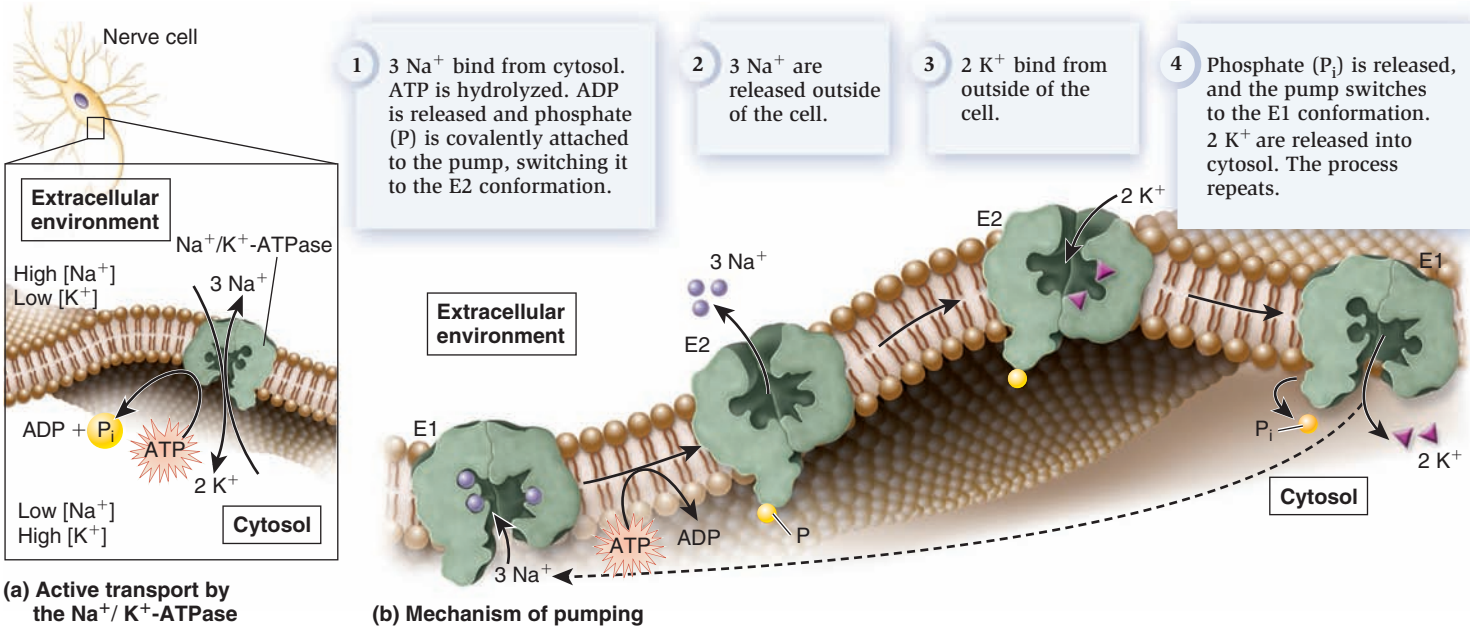

Figure 5.22 Structure and function of the Na^+/K^+-ATPase. **(a)** Active transport by the Na^+/K^+-ATPase. Each time this protein hydrolyzes one ATP molecule, it pumps out three Na^+ and pumps in two K^+. **(b)** Pumping mechanism. This figure illustrates the protein conformational changes between E1 and E2. As this occurs, ATP is hydrolyzed to ADP and phosphate. During the process, phosphate is covalently attached to the protein but is released after two K^+ bind.

Concept Check: *If a cell contained ATP and Na^+, but K^+ was missing from the extracellular medium, how far through these steps could the Na^+/K^+-ATPase proceed?*

Table 5.3 Important Functions of Ion Electrochemical Gradients

Function	Description
Transport of ions and molecules	Symporters and antiporters use H^+ and Na^+ gradients to take up nutrients and export waste products (see Figure 5.21).
Production of energy intermediates	In the mitochondrion and chloroplast, H^+ gradients are used to synthesize ATP.
Osmotic regulation	Animal cells control their internal volume by regulating ion gradients between the cytosol and extracellular fluid.
Neuronal signaling	Na^+ and K^+ gradients are involved in conducting action potentials, the signals transmitted by neurons.
Muscle contraction	Ca^{2+} gradients regulate the ability of muscle fibers to contract.
Bacterial swimming	H^+ gradients drive the rotation of bacterial flagella.

from the cytosol (Figure 5.22b). When this occurs, ATP is hydrolyzed to ADP and phosphate. Temporarily, the phosphate is covalently bound to the pump, an event called phosphorylation. The pump then switches to the E2 conformation. The three Na^+ are released into the extracellular environment, because they have a lower affinity for the E2 conformation. In this conformation, two K^+ bind from the outside. The binding of two K^+ causes the release of phosphate, which, in turn, causes a switch to E1. Because the E1 conformation has a low affinity for K^+ the two K^+ are released into the cytosol. The Na^+/K^+-ATPase is now ready for another round of pumping.

The Na^+/K^+-ATPase is a critical ion pump in animal cells because it maintains Na^+ and K^+ gradients across the plasma membrane. Many other types of ion pumps are also found in the plasma membrane and in organellar membranes. Ion pumps play the primary role in the formation and maintenance of ion gradients that drive many important cellular processes (**Table 5.3**). ATP is commonly the source of energy to drive ion pumps, and cells typically use a substantial portion of their ATP to keep them working. For example, neurons use up to 70% of their ATP just to operate ion pumps!

5.6 Exocytosis and Endocytosis

Learning Outcome:

1. Describe the steps in exocytosis and endocytosis.

We have seen that most small substances are transported via membrane proteins such as channels and transporters, which provide a passageway for the movement of ions and molecules directly across the membrane. Eukaryotic cells have two other mechanisms, exocytosis and endocytosis, to transport larger molecules such as proteins and polysaccharides, and even very large particles. Both mechanisms involve the packaging of the transported substance, sometimes called the cargo, into a membrane vesicle or vacuole. **Table 5.4** describes some examples.

Exocytosis During **exocytosis**, material inside the cell is packaged into vesicles and then excreted into the extracellular environment (**Figure 5.23**). These vesicles are usually derived from the Golgi apparatus. As the vesicles form, a specific cargo is loaded into their interior. The budding process involves the formation of a protein coat around the emerging vesicle. The assembly of coat proteins on the surface of the Golgi membrane causes the bud to form. Eventually, the bud separates from the membrane to form a vesicle. After the vesicle is released, the coat is shed. Finally, the vesicle fuses with the plasma membrane and releases the cargo into the extracellular environment.

Endocytosis During **endocytosis**, the plasma membrane invaginates, or folds inward, to form a vesicle that brings substances into the cell. Three types of endocytosis are receptor-mediated endocytosis, pinocytosis, and phagocytosis.

Receptor-Mediated Endocytosis In **receptor-mediated endocytosis**, a receptor in the plasma membrane is specific for a given cargo (**Figure 5.24**). Cargo molecules binding to their specific receptors stimulate many receptors to aggregate, and then coat proteins bind to the membrane. The protein coat causes the membrane to invaginate and form a vesicle. Once it is released into the cell, the vesicle sheds its coat. In most cases, the vesicle fuses with an internal membrane organelle,

Table 5.4 Examples of Exocytosis and Endocytosis

Exocytosis	Description
Hormones	Certain hormones, such as insulin, are composed of polypeptides. To exert its effect, insulin is secreted via exocytosis into the bloodstream from beta cells of the pancreas.
Digestive enzymes	Digestive enzymes that function in the lumen of the small intestine are secreted via exocytosis from exocrine cells of the pancreas.
Endocytosis	**Description**
Uptake of vital nutrients	Many important nutrients are very insoluble in the bloodstream. Therefore, they are bound to proteins in the blood and then taken into cells via endocytosis. Examples include the uptake of lipids (bound to low-density lipoprotein) and iron (bound to transferrin protein).
Root nodules	Nitrogen-fixing root nodules found in certain species of plants, such as legumes, are formed by the endocytosis of bacteria. After endocytosis, the bacterial cells are contained within a membrane-enclosed compartment in the nitrogen-fixing tissue of root nodules.
Immune system	Cells of the immune system, known as macrophages, engulf and destroy bacteria via phagocytosis.

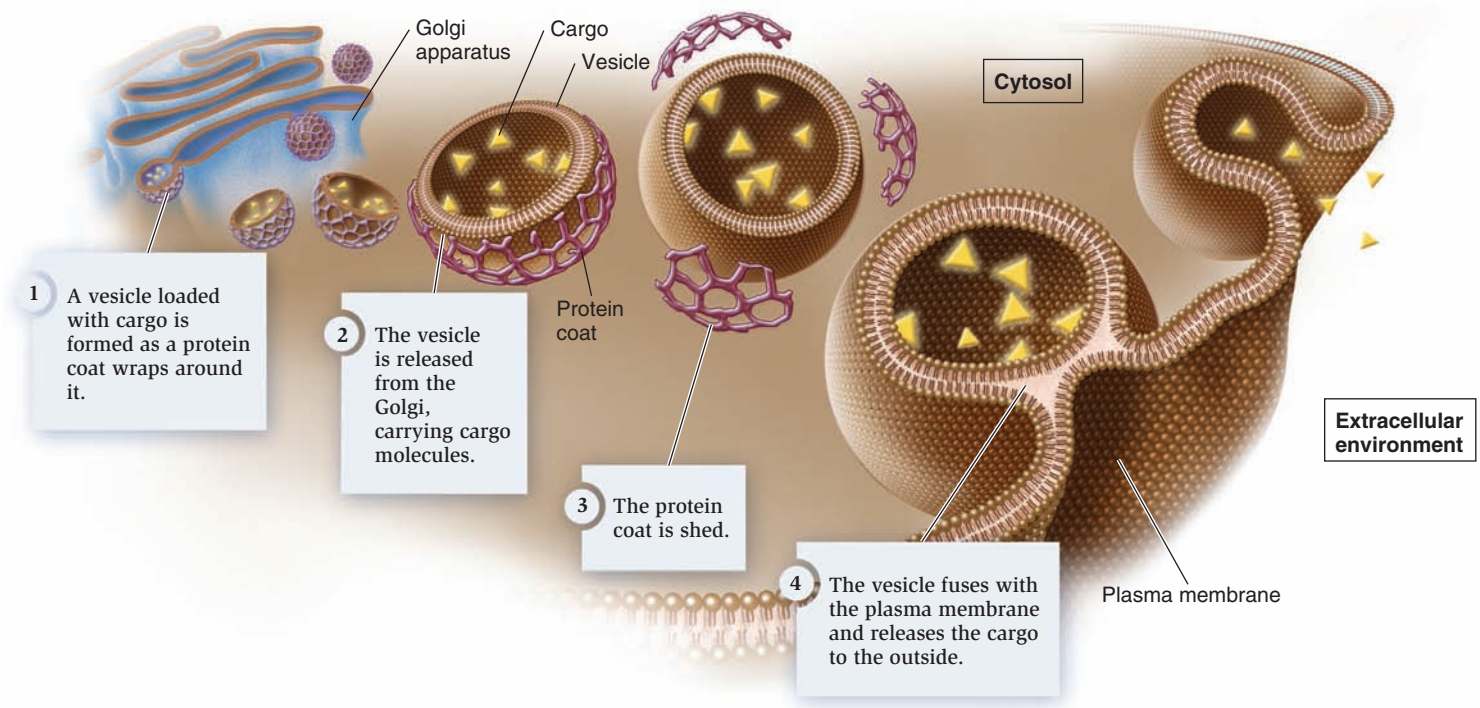

Figure 5.23 **Exocytosis.**

Concept Check: *What is the function of the protein coat?*

such as a lysosome, and the receptor releases its cargo. Depending on the cargo, the lysosome may release it directly into the cytosol or digest it into simpler building blocks before releasing it.

Pinocytosis Other specialized forms of endocytosis occur in certain types of cells. **Pinocytosis** (from the Greek, meaning cell-drinking) involves the formation of membrane vesicles from the plasma membrane as a way for cells to internalize the extracellular fluid. This allows cells to sample the extracellular solutes. Pinocytosis is particularly important in cells that are actively involved in nutrient absorption, such as cells that line the intestine in animals.

Phagocytosis **Phagocytosis** (from the Greek, meaning cell-eating) involves the formation of an enormous membrane vesicle called a

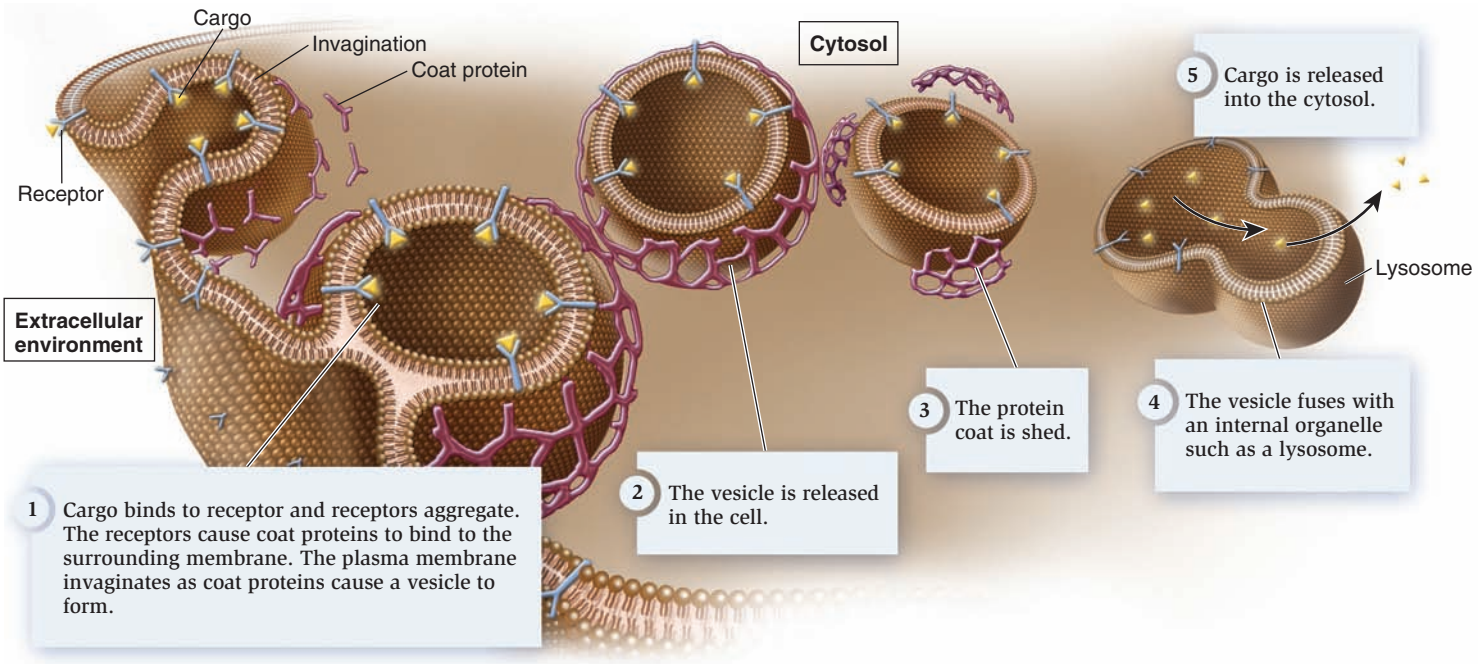

Figure 5.24 **Receptor-mediated endocytosis.**

phagosome, or phagocytic vacuole, which engulfs a large particle such as a bacterium. Only certain kinds of cells can carry out phagocytosis. For example, macrophages, which are cells of the immune system in mammals, kill bacteria via phagocytosis. Macrophages engulf bacterial cells into phagosomes. Once inside the cell, the phagosome fuses with a lysosome, and the digestive enzymes within the lysosome destroy the bacterium.

Summary of Key Concepts

5.1 Membrane Structure

- A plasma membrane separates a cell from its surroundings. The plasma membrane and organellar membranes provide interfaces for carrying out vital cellular activities (Table 5.1).
- The accepted model of membranes is the fluid-mosaic model, and its basic framework is the phospholipid bilayer. Cellular membranes also contain proteins, and most membranes have attached carbohydrates (Figure 5.1).
- The three main types of membrane proteins are transmembrane proteins, lipid-anchored proteins, and peripheral membrane proteins. Transmembrane proteins and lipid-anchored proteins are classified as integral membrane proteins. Researchers are working to identify new membrane proteins and their functions because these proteins are important biologically and medically (Figure 5.2, Table 5.2).
- Electron microscopy is a valuable tool for studying membrane structure and function. Freeze fracture electron microscopy (FFEM) is used to analyze the interiors of phospholipid bilayers (Figure 5.3).

5.2 Fluidity of Membranes

- Bilayer semifluidity is essential for normal cell function, growth, and division. Lipids and many proteins can move rotationally and laterally, but the flip-flop of lipids from one leaflet to the opposite does not occur spontaneously. Some membrane proteins are restricted in their movements (Figures 5.4, 5.5, 5.6).
- The chemical properties of phospholipids—such as tail length and the presence of double bonds—and the amount of cholesterol affect the fluidity of membranes.

5.3 Synthesis of Membrane Components in Eukaryotic Cells

- In eukaryotic cells, most membrane phospholipids are synthesized at the cytosolic leaflet of the smooth ER membrane. Flippases move some phospholipids to the other leaflet (Figure 5.7).
- Most transmembrane proteins are first inserted into the ER membrane (Figure 5.8).
- Glycosylation of proteins occurs in the ER and Golgi apparatus (Figure 5.9).

5.4 Overview of Membrane Transport

- Biological membranes exhibit selective permeability. Simple diffusion occurs when a solute moves from a region of high concentration to a region of lower concentration without the aid of a transport protein, whereas facilitated diffusion involves the use of a transport protein. Passive transport of a solute across a membrane can occur via simple diffusion or facilitated diffusion. Active transport is the movement of a substance against a gradient (Figure 5.10).
- The phospholipid bilayer is relatively impermeable to many hydrophilic substances (Figures 5.11, 5.12).
- Living cells maintain an internal environment that is separated from their external environment. Transmembrane gradients are established across the plasma membrane and across organellar membranes (Figure 5.13).
- In the process of osmosis, water moves through a membrane from a solution that is hypotonic (lower concentration of dissolved particles) into a solution that is hypertonic (higher concentration of dissolved particles). Solutions with identical concentrations are isotonic. Some microorganisms have contractile vacuoles to eliminate excess water (Figures 5.14, 5.15, 5.16).

5.5 Transport Proteins

- Two classes of transport proteins are channels and transporters.
- Channels provide open passageways for the facilitated diffusion of solutes across the membrane. One example is aquaporin, which allows the movement of water. Most channels are gated, which allows cells to regulate the movement of solutes (Figures 5.17, 5.18).
- Transporters, which tend to be slower than channels, bind their solutes in a hydrophilic pocket and undergo a conformational change that switches the exposure of the pocket to the other side of the membrane. They can be uniporters, symporters, or antiporters (Figures 5.19, 5.20).
- Primary active transport involves pumps that directly use energy to generate a solute gradient. Secondary active transport uses a pre-existing gradient (Figure 5.21).
- The Na^+/K^+-ATPase is an electrogenic pump that uses energy in the form of ATP to transport ions across the membrane. Ion gradients perform several important cellular functions (Figure 5.22, Table 5.3).

5.6 Exocytosis and Endocytosis

- In eukaryotes, exocytosis and endocytosis are used to transport large molecules and particles. Exocytosis is a process in which material inside the cell is packaged into vesicles and excreted into the extracellular environment. During endocytosis, the plasma membrane folds inward to form a vesicle that brings substances into the cell. Receptor-mediated endocytosis, pinocytosis, and phagocytosis are forms of endocytosis (Figures 5.23, 5.24, Table 5.4).

Assess and Discuss

Test Yourself

1. Which of the following statements best describes the chemical composition of biological membranes?
   a. Biological membranes are bilayers of proteins with associated lipids and carbohydrates.
   b. Biological membranes are composed of two layers—one layer of phospholipids and one layer of proteins.
   c. Biological membranes are bilayers of phospholipids with associated proteins and carbohydrates.

d. Biological membranes are composed of equal numbers of phospholipids, proteins, and carbohydrates.
e. Biological membranes are composed of lipids with proteins attached to the outer surface.

2. Which of the following events in a biological membrane can never be energetically favorable and therefore will not occur spontaneously?
a. the rotation of phospholipids
b. the lateral movement of phospholipids
c. the flip-flop of phospholipids to the opposite leaflet
d. the rotation of membrane proteins
e. the lateral movement of membrane proteins

3. Let's suppose an insect, which doesn't maintain a constant body temperature, was exposed to a shift in temperature from 60°F to 80°F. Which of the following types of membrane changes would be the most beneficial to help this animal cope with the temperature shift?
a. increase the number of double bonds in the lipid tails of phospholipids
b. increase the length of the lipid tails of phospholipids
c. decrease the amount of cholesterol in the membrane
d. decrease the amount of carbohydrate attached to membrane proteins
e. decrease the amount of carbohydrate attached to phospholipids

4. Carbohydrates of the plasma membrane
a. are bonded to a protein or lipid.
b. are located on the outer surface of the plasma membrane.
c. can function as cell markers for recognition by other cells.
d. all of the above
e. a and c only

5. A transmembrane protein in the plasma membrane is glycosylated at two sites in the polypeptide sequence. Where in this protein would you expect these two sites to be found?
a. in transmembrane segments
b. in hydrophilic regions that project into the extracellular environment
c. in hydrophilic regions that project into the cytosol
d. could be anywhere
e. b and c only

6. The tendency for Na^+ to move into the cell can be due to
a. the higher numbers of Na^+ outside the cell, resulting in a chemical concentration gradient.
b. the net negative charge inside the cell attracting the positively charged Na^+.
c. the attractive force of K^+ inside the cell pulling Na^+ into the cell.
d. all of the above.
e. a and b only.

7. Let's suppose the solute concentration inside the cells of a plant is 0.3 M and outside is 0.2 M. If we assume that the solutes do not readily cross the membrane, which of the following statements best describes what will happen?
a. The plant cells will lose water, and the plant will wilt.
b. The plant cells will lose water, which will result in a higher turgor pressure.
c. The plant cells will take up a lot of water and undergo osmotic lysis.
d. The plant cells will take up a little water and have a higher turgor pressure.
e. Both a and b are correct.

8. What features of a membrane are major contributors to its selective permeability?
a. phospholipid bilayer
b. transport proteins
c. glycolipids on the outer surface of the membrane
d. peripheral membrane proteins
e. both a and b

9. What is the name given to the process in which solutes are moved across a membrane against their concentration gradient?
a. simple diffusion
b. facilitated diffusion
c. osmosis
d. passive diffusion
e. active transport

10. Large particles or large volumes of fluid can be brought into the cell by
a. facilitated diffusion.
b. active transport.
c. endocytosis.
d. exocytosis.
e. all of the above.

Conceptual Questions

1. With your textbook closed, draw and describe the fluid-mosaic model of membrane structure.
2. Describe two different ways that integral membrane proteins associate with a membrane. How do peripheral membrane proteins associate with a membrane?
3.  A principle of biology is that *living organisms interact with their environment*. Discuss how lipid bilayers, channels, and transporters influence the ability of cells to interact with their environment.

Collaborative Questions

1. Proteins in the plasma membrane are often the target of medicines. Discuss why you think this is the case. How would you determine experimentally that a specific membrane protein was the target of a drug?
2. With regard to bringing solutes into the cell across the plasma membrane, discuss the advantages and disadvantages of simple diffusion, facilitated diffusion, active transport, and endocytosis.

Assess and Discuss

An Introduction to Energy, Enzymes, and Metabolism

6

Common drugs that act as enzyme inhibitors. Drugs such as aspirin and ibuprofen exert their effects by inhibiting an enzyme that speeds up a chemical reaction in the cell.

Have you ever taken aspirin or ibuprofen to relieve a headache or reduce a fever? Do you know how these medications work? If you answered "no" to the second question, you're not alone. Over 2,000 years ago, humans began treating pain with powder from the bark and leaves of the willow tree, which contains a compound called salicylic acid. Modern aspirin is composed of a derivative of salicylic acid called acetylsalicylic acid, which is gentler to the stomach. Only recently, however, have we learned how these drugs work. Aspirin and ibuprofen are examples of drugs that inhibit a specific enzyme called cyclooxygenase. This enzyme is needed to synthesize molecules called prostaglandins, which play a role in inflammation, pain, and fever. Aspirin and ibuprofen exert their effects by inhibiting cyclooxygenase, thereby blocking the production of prostaglandins and in turn relieving pain and fever.

Enzymes are proteins that act as critical catalysts to speed up thousands of different reactions in cells. As discussed in Chapter 2, a **chemical reaction** is a process in which one or more substances are changed into other substances. Such reactions may involve molecules attaching to each other to form larger molecules, molecules breaking apart to form two or more smaller molecules, rearrangements of atoms within molecules, or the transfer of electrons from one atom to another. Every living cell continuously performs thousands of such chemical reactions to sustain life. **Metabolism** is the sum total of all chemical reactions that occur within an organism. Metabolism also refers to a specific set of chemical reactions occurring at the cellular level. For example, biologists may speak of sugar metabolism or fat metabolism. Most types of metabolism involve the breakdown or synthesis of organic molecules. Cells maintain their structure by using organic molecules. Such molecules provide the building blocks for constructing cells, and the chemical bonds within organic molecules store energy that is used to drive cellular processes.

In this chapter, we begin with a general discussion of energy and chemical reactions. We will examine what factors control the direction of a chemical reaction and what determines its rate, paying particular attention to the role of enzymes. We then consider metabolism at the cellular level, examining how chemical reactions are often coordinated with each other in metabolic pathways. We will also explore the variety of ways in which metabolic pathways are regulated and how organic molecules are recycled.

6.1 Energy and Chemical Reactions

Learning Outcomes:

1. Define energy, and distinguish between potential and kinetic energy.
2. State the first and second laws of thermodynamics, and discuss how they relate to living things.
3. Explain how the change in free energy determines the direction of a chemical reaction and how chemical reactions eventually reach a state of equilibrium.
4. Distinguish between exergonic and endergonic reactions in terms of the energy of the reactants and products and the free energy change.
5. Describe how cells use the energy released by ATP hydrolysis to drive endergonic reactions.

Two general factors govern the fate of a given chemical reaction in a living cell—its direction and rate. To illustrate this point, let's consider this generalized chemical reaction:

$$aA + bB \rightleftharpoons cC + dD$$

where A and B are the reactants, C and D are the products, and *a*, *b*, *c*, and *d* are the number of moles of reactants and products. This reaction is reversible, which means that A + B could be converted to C + D, or C + D could be converted to A + B. The direction of the reaction, whether C + D are made (the forward direction) or A + B are made (the reverse direction), depends on energy and on the concentrations of A, B, C, and D. In this section, we will begin by examining the interplay of energy and the concentrations of reactants as they govern the direction of a chemical reaction. You will learn that cells use energy intermediate molecules, such as ATP, to drive chemical reactions in a desired direction.

Energy Exists in Different Forms

To understand why a chemical reaction occurs, we first need to consider **energy**, which is the ability to promote change or do work. Physicists often consider energy in two general forms: kinetic energy and potential energy (**Figure 6.1**). **Kinetic energy** is energy associated with movement, such as the movement of a baseball bat from one location to another. By comparison, **potential energy** is the energy that a substance or object possesses due to its structure or location. An electron in an atom has potential energy based on its position relative to other electrons and the positively charged nucleus. As you may recall from Chapter 2, electrons occupy orbitals of different shapes and sizes, which are found within electron shells, or energy levels (refer back to Figure 2.4). An electron in an outer shell has a higher amount of potential energy than one in an inner shell. If an electron drops to a lower shell, some of its potential energy is converted to kinetic energy.

The energy that is stored in atoms and in the bonds between atoms is called chemical potential energy (or simply, chemical energy). This energy can be released during chemical reactions. Organic molecules, such as glucose, store a great deal of potential energy. As discussed in Chapter 7, the breakdown of glucose releases energy that is harnessed to make energy intermediate molecules such as ATP. **Table 6.1** summarizes chemical potential energy and other forms of energy that are common in biological systems.

(a) Kinetic energy (b) Potential energy

Figure 6.1 Examples of energy. **(a)** Kinetic energy, such as that of a swinging bat, is energy associated with motion. **(b)** Potential energy is stored energy, as in a bow that is ready to fire an arrow.

An important issue in biology is the ability of energy to be converted from one form to another. The study of energy interconversions is called **thermodynamics**. Physicists have determined that two laws govern energy interconversions:

1. **The first law of thermodynamics**—The first law of thermodynamics, also called the law of conservation of energy, states that energy cannot be created or destroyed. However, energy can be transferred from one place to another and can be transformed from one type to another (as when, for example, chemical energy is transformed into heat).
2. **The second law of thermodynamics**—The second law states that any energy transfer or transformation from one form to another increases the degree of disorder of a system, called **entropy** (**Figure 6.2**). Entropy is a measure of the randomness of molecules in a system. When a physical system becomes more disordered, the entropy increases. As the energy becomes more evenly distributed, that energy is less able to promote change or do work. When energy is converted from one form to another, some energy may become unusable by living organisms. For example, a chemical reaction may release unusable heat.

Table 6.1 Types of Energy That Are Important in Biology

Energy type	Description	Biological example
Light	Light is a form of electromagnetic radiation that is visible to the eye. The energy of light is packaged in photons.	During photosynthesis, light energy is captured by pigments in chloroplasts (described in Chapter 8). Ultimately, this energy is used to produce organic molecules.
Heat	Heat is the transfer of kinetic energy from one object to another or from an energy source to an object. In biology, heat is often viewed as kinetic energy that can be transferred due to a difference in temperature between two objects or locations.	Many organisms, including humans, maintain their bodies at a constant temperature. This is achieved, in part, by chemical reactions that generate heat.
Mechanical	Mechanical energy is the energy possessed by an object due to its motion or its position relative to other objects.	In animals, mechanical energy is associated with movements due to muscle contraction such as walking.
Chemical potential	Chemical potential energy is potential energy stored in the electrons of molecules. When bonds are broken and rearranged, energy may be released.	The covalent bonds in organic molecules, such as glucose and ATP, store large amounts of energy. When bonds are broken in larger molecules to form smaller molecules, the chemical energy that is released can be used to drive cellular processes.
Electrical/ion gradient	The movement of charge or the separation of charge can provide energy. Also, a difference in ion concentration across a membrane constitutes an electrochemical gradient, which is a source of potential energy.	During a stage of cellular respiration called oxidative phosphorylation (described in Chapter 7), an H^+ gradient provides the energy to drive ATP synthesis.

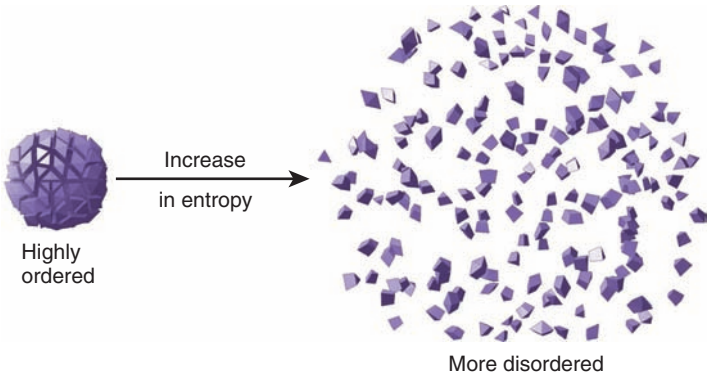

Figure 6.2 Entropy, a measure of the disorder of a system. An increase in entropy means an increase in disorder.

Concept Check: Which do you think has more entropy, a NaCl crystal at the bottom of a beaker of water or the same beaker of water after the Na^+ and Cl^- in the crystal have dissolved in the water?

Next, we will see how the two laws of thermodynamics place limits on the ways that living cells use energy for their own needs.

The Change in Free Energy Determines the Direction of a Chemical Reaction

Energy is required for many cellular processes, including chemical reactions, cellular movements such as those occurring in muscle contraction, and the maintenance of cell organization. To understand how organisms use energy, we need to distinguish between the energy that can be used to promote change or do work (usable energy) and the energy that cannot (unusable energy).

$$\text{Total energy} = \text{Usable energy} + \text{Unusable energy}$$

Why is some energy unusable? The main culprit is entropy. As stated by the second law of thermodynamics, energy transfers or transformations involve an increase in entropy, a degree of disorder that cannot be harnessed in a useful way. The total energy is termed **enthalpy (*H*)**, and the usable energy—the amount of available energy that can be used to promote change or do work—is called the **free energy (*G*)**. The letter *G* is in recognition of the American physicist J. Willard Gibbs, who proposed the concept of free energy in 1878. The unusable energy is the system's entropy (*S*). Gibbs proposed that these three factors are related to each other in the following way:

$$H = G + TS$$

where *T* is the absolute temperature in kelvins (K). Because our focus is on free energy, we can rearrange this equation as

$$G = H - TS$$

A critical issue in biology is whether a process does or does not occur spontaneously. For example, will glucose be broken down into carbon dioxide and water? Another way of framing this question is to ask: "Is the breakdown of glucose a spontaneous reaction?" A spontaneous reaction or process is one that occurs without being driven by an input of energy. However, a spontaneous reaction does not necessarily proceed quickly. In some cases, the rate of a spontaneous reaction can be quite slow. For example, the breakdown of sugar is a spontaneous reaction, but the rate at which sugar in a sugar bowl breaks down into CO_2 and H_2O is very slow.

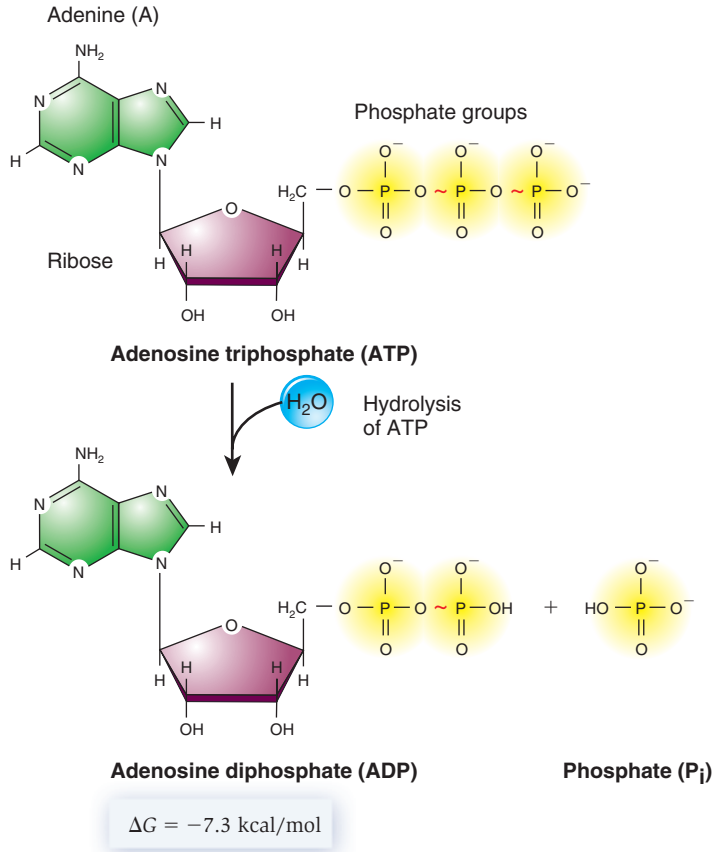

Figure 6.3 The hydrolysis of ATP to ADP and P_i. As shown in this figure, ATP has a net charge of –4, while ADP and P_i are shown with net charges of −2 each. When these compounds are shown in chemical reactions with other molecules, the net charges are also indicated. Otherwise, these compounds are simply designated ATP, ADP, and P_i. At neutral pH, ADP^{2-} dissociates to ADP^{3-} and H^+.

BIOLOGY PRINCIPLE Living organisms use energy. The hydrolysis of ATP is an exergonic reaction that is used to drive many cellular reactions.

The key way to evaluate if a chemical reaction is spontaneous is to determine the free-energy change that occurs as a result of the reaction:

$$\Delta G = \Delta H - T\Delta S$$

where the symbol Δ (the Greek letter delta) indicates a change, such as before and after a chemical reaction. If a chemical reaction has a negative free-energy change ($\Delta G < 0$), the products have less free energy than the reactants, and, therefore, free energy is released during product formation. Such a reaction is said to be **exergonic**. Exergonic reactions are spontaneous. Alternatively, if a reaction has a positive free-energy change ($\Delta G > 0$), requiring the addition of free energy, it is termed **endergonic**. An endergonic reaction is not a spontaneous reaction.

If ΔG for a chemical reaction is negative, the reaction favors the conversion of reactants to products, whereas a reaction with a positive ΔG favors the formation of reactants. Chemists have determined free-energy changes for a variety of chemical reactions, which allows them to predict their direction. As an example, let's consider **adenosine triphosphate (ATP)**, which is a molecule that is a common energy source for all cells. ATP is broken down to adenosine diphosphate (ADP) and inorganic phosphate (HPO_4^{2-}, abbreviated P_i). Because water is used to remove a phosphate group, chemists refer to this reaction as the hydrolysis of ATP (**Figure 6.3**). In converting

1 mole of ATP to 1 mole of ADP and P_i, ΔG equals −7.3 kcal/mol. Because this is a negative value, the reaction strongly favors the formation of products. As discussed later, the energy liberated by the hydrolysis of ATP is used to drive a variety of cellular processes.

Chemical Reactions Eventually Reach a State of Equilibrium

Even when a chemical reaction is associated with a negative free-energy change, not all of the reactants are converted to products. The reaction reaches a state of **chemical equilibrium** in which the rate of formation of products equals the rate of formation of reactants. Let's consider the generalized reaction

$$aA + bB \rightleftharpoons cC + dD$$

where A and B are the reactants, C and D are the products, and a, b, c, and d are the number of moles of reactants and products. An equilibrium occurs, such that

$$K_{eq} = \frac{[C]^c[D]^d}{[A]^a[B]^b}$$

where K_{eq} is the equilibrium constant. Each type of chemical reaction has a specific value for K_{eq}. When K_{eq} is greater than 1, the reaction favors the formation of products; when it is less than 1, the reaction favors the formation of reactants.

Cells Use ATP to Drive Endergonic Reactions

In living organisms, many vital processes require the addition of free energy; that is, they are endergonic and do not occur spontaneously. How do cells overcome this problem? Cells often couple exergonic reactions with endergonic reactions. If an exergonic reaction is coupled with an endergonic reaction, the endergonic reaction will proceed spontaneously if the net free-energy change for both processes combined is negative. For example, consider the following reactions:

$$\text{Glucose} + \text{Phosphate}^{2-} \rightarrow \text{Glucose-6-phosphate}^{2-} + H_2O$$
$$\Delta G = +3.3 \text{ kcal/mol}$$

$$ATP^{4-} + H_2O \rightarrow ADP^{2-} + P_i^{2-}$$
$$\Delta G = -7.3 \text{ kcal/mol}$$

Coupled reaction:

$$\text{Glucose} + ATP^{4-} \rightarrow \text{Glucose-6-phosphate}^{2-} + ADP^{2-}$$
$$\Delta G = -4.0 \text{ kcal/mol}$$

The first reaction, in which phosphate is covalently attached to glucose, is endergonic, and by itself is not spontaneous. The second, the hydrolysis of ATP, is exergonic. If the two reactions are coupled, however, the net free-energy change for both reactions combined is negative ($\Delta G = -4.0$ kcal/mol), and the coupled reaction is exergonic. In the coupled reaction, a phosphate is directly transferred from ATP to glucose, in a process called **phosphorylation**. This coupled reaction proceeds spontaneously because the net free-energy change is negative. Exergonic reactions, such as the breakdown of ATP, are commonly coupled to chemical reactions and other cellular processes that would otherwise be endergonic.

Genomes & Proteomes Connection

Many Proteins Use ATP as a Source of Energy

Over the past several decades, researchers have studied the functions of many proteins and discovered numerous examples in which a protein uses the hydrolysis of ATP to drive a chemical reaction or cellular process (**Table 6.2**). In humans, a typical cell uses millions of ATP molecules per second. At the same time, the breakdown of food molecules to form smaller molecules (an exergonic reaction) releases energy that allows cells to make more ATP from the phosphorylation of ADP (an endergonic reaction).

The recycling of ATP occurs at a remarkable pace. An average person hydrolyzes about 100 pounds of ATP per day, yet at any given time we do not have 100 pounds of ATP in our bodies. For this to happen, each molecule of ATP undergoes about 10,000 cycles of hydrolysis and regeneration during an ordinary day (**Figure 6.4**).

By studying the structures of many proteins that use ATP, biochemists have discovered that particular amino acid sequences within proteins function as ATP-binding sites. This information has allowed researchers to predict whether a newly discovered protein uses ATP or not. When an entire genome sequence of a species has been determined, the genes that encode proteins can be analyzed to find out if the encoded proteins have ATP-binding sites in their amino acid sequences. Using this approach, researchers have been able to analyze **proteomes**—all of the proteins that a given cell makes—and estimate the percentage of proteins that are able to bind ATP. This approach has been applied to the proteomes of bacteria, archaea, and eukaryotes.

Table 6.2 Examples of Proteins That Use ATP for Energy

Type	Description
Metabolic enzymes	Many enzymes use ATP to catalyze endergonic reactions. For example, hexokinase uses ATP to attach phosphate to glucose, producing glucose-6-phosphate.
Transporters	Ion pumps, such as the Na^+/K^+-ATPase, use ATP to pump ions against a gradient (see Chapter 5).
Motor proteins	Motor proteins, such as myosin, use ATP to facilitate cellular movement, as in muscle contraction (see Chapter 44).
Chaperones	Chaperones are proteins that use ATP to aid in the folding and unfolding of cellular proteins (see Chapter 4).
DNA-modifying enzymes	Many proteins such as helicases and topoisomerases use ATP to modify the conformation of DNA (see Chapter 11).
Aminoacyl-tRNA synthetases	These enzymes use ATP to attach amino acids to tRNAs (transfer RNAs; see Chapter 12).
Protein kinases	Protein kinases are regulatory proteins that use ATP to attach a phosphate to proteins, thereby phosphorylating the protein and affecting its function (see Chapter 9).

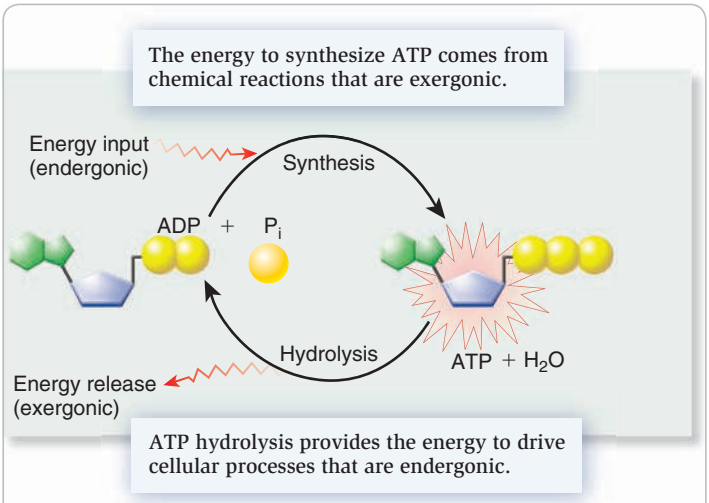

Figure 6.4 The ATP cycle. Living cells continuously recycle ATP. The energy released from the breakdown of food molecules into smaller molecules is used to synthesize ATP from ADP and P_i. The hydrolysis of ATP to ADP and P_i is used to drive many different endergonic reactions and processes that occur in cells.

Concept Check: If a large amount of ADP was broken down in the cell, how would this affect the ATP cycle?

On average, over 20% of all proteins bind ATP. However, this number is likely an underestimate because all of the types of ATP-binding sites in proteins may not have been identified. In humans, who have an estimated genome size of 22,000 different genes, a minimum of 4400 of those genes encode proteins that use ATP. From these numbers, we can see the enormous importance of ATP as a source of energy for living cells.

6.2 Enzymes and Ribozymes

Learning Outcomes:

1. Explain how enzymes increase the rates of chemical reactions by lowering the activation energy.
2. Describe how enzymes bind their substrates with high specificity and undergo induced fit.
3. **SciSKILLS** » Analyze the velocity of chemical reactions and evaluate the effects of competitive and noncompetitive inhibitors.
4. Explain how additional factors, such as nonprotein molecules or ions, temperature, and pH, influence enzyme activity.
5. Identify the unique feature of ribozymes.

For most chemical reactions in cells to proceed at a rapid pace, a catalyst is needed. A **catalyst** is an agent that speeds up the rate of a chemical reaction without being permanently changed or consumed by it. In living cells, the most common catalysts are **enzymes**, which are proteins. The term was coined in 1876 by a German physiologist, Wilhelm Kühne, who discovered trypsin, an enzyme in pancreatic juice that is needed for the digestion of food proteins. In this section, we will explore how enzymes increase the rates of chemical reactions. Interestingly, some biological catalysts are RNA molecules called ribozymes. We will examine a few examples in which RNA molecules carry out catalytic functions.

Enzymes Increase the Rates of Chemical Reactions

If a chemical reaction has a negative free-energy change, the reaction will be spontaneous; it will tend to proceed in the direction of reactants to products. Although thermodynamics governs the direction of an energy transformation, it does not determine the rate of a chemical reaction. For example, the breakdown of the molecules in gasoline to smaller molecules is an exergonic reaction. Even so, we could place gasoline and oxygen in a container and nothing much would happen (provided it wasn't near a flame). If we came back several days later, we would expect to see the gasoline still sitting there. Perhaps if we came back in a few million years, the gasoline would have been broken down. On a timescale of months or a few years, however, the chemical reaction would proceed very slowly.

In living cells, the rates of enzyme-catalyzed reactions typically occur millions of times faster than the corresponding uncatalyzed reactions. A dramatic example involves the enzyme catalase, which catalyzes the breakdown of hydrogen peroxide (H_2O_2) into water and oxygen. Catalase speeds up this reaction 10^{15}-fold faster than the uncatalyzed reaction!

Why are catalysts necessary to speed up a chemical reaction? Chemical reactions between molecules involve bond breaking and bond forming. When a covalent bond is broken or formed, this process initially involves the straining or stretching of one or more bonds in the starting molecule(s), and/or it may involve the positioning of two molecules so they interact with each other properly. Enzymes help to facilitate these kinds of events.

As an example, let's consider the reaction in which ATP is used to phosphorylate glucose:

$$\text{Glucose} + \text{ATP}^{4-} \rightarrow \text{Glucose-6-phosphate}^{2-} + \text{ADP}^{2-}$$

For a reaction to occur between glucose and ATP, the molecules must collide in the correct orientation and possess enough energy so the chemical bonds can be changed. As glucose and ATP approach each other, electrons in the outer shells of their atoms repel each other. To overcome this repulsion, an initial input of energy, called the **activation energy**, is required (**Figure 6.5**). Activation energy (E_A) allows the molecules to get close enough to cause a rearrangement of bonds. With the input of activation energy, glucose and ATP can achieve a **transition state** in which the original bonds have stretched to their limit. Once the reactants have reached the transition state, the chemical reaction can readily proceed to the formation of products, which in this case is glucose-6-phosphate and ADP.

The activation energy required to achieve the transition state is a barrier to the formation of products. This barrier is the reason why the rate of many chemical reactions is very slow. Enzymes lower the activation energy to a point where a small amount of available heat can push the reactants to a transition state.

How do enzymes lower the activation energy barrier of chemical reactions? Let's consider two common ways that enzymes exert their effects.

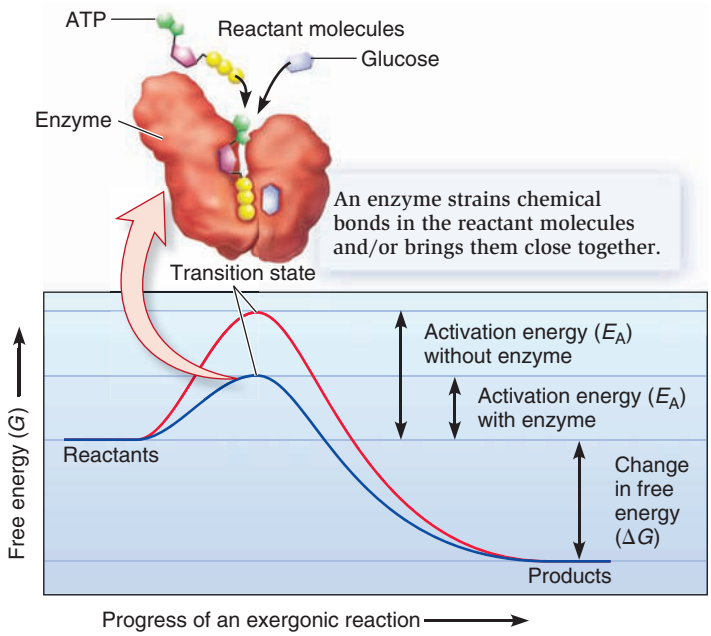

Figure 6.5 Activation energy of a chemical reaction. This figure depicts an exergonic reaction. The activation energy (E_A) is needed for molecules to achieve a transition state. One way that enzymes lower the activation energy is by straining chemical bonds in the reactants so less energy is required to attain the transition state. A second way is by binding two reactants so they are close to each other and in a favorable orientation.

Concept Check: How does lowering the activation energy affect the rate of a chemical reaction? How does it affect the direction?

- Enzymes are proteins that bind relatively small reactants. When bound to an enzyme, the bonds in the reactants can be strained, thereby making it easier for them to achieve the transition state (see Figure 6.5).
- In addition, when a chemical reaction involves two or more reactants, the enzyme provides a site in which the reactants are positioned very close to each other in an orientation that facilitates the formation of new covalent bonds. This also lowers the necessary activation energy for a chemical reaction.

Enzymes Recognize Their Substrates with High Specificity and Undergo Conformational Changes

Thus far, we have considered how enzymes lower the activation energy of a chemical reaction, and thereby increase its rate. Let's consider some other features of enzymes that enable them to serve as effective catalysts in chemical reactions. The **active site** is the location in an enzyme where the chemical reaction takes place. The **substrates** for an enzyme are the reactant molecules that bind to an enzyme at the active site and participate in the chemical reaction. For example, hexokinase is an enzyme whose substrates are glucose and ATP (**Figure 6.6**). The binding between an enzyme and substrate produces an **enzyme-substrate complex**.

A key feature of nearly all enzymes is their ability to bind their substrates with a high degree of specificity. For example, hexokinase recognizes glucose but does not recognize other similar sugars, such as fructose and galactose, very well. In 1894, the German chemist Emil Fischer proposed that the recognition of a substrate by an enzyme resembles the interaction between a lock and key: Only the

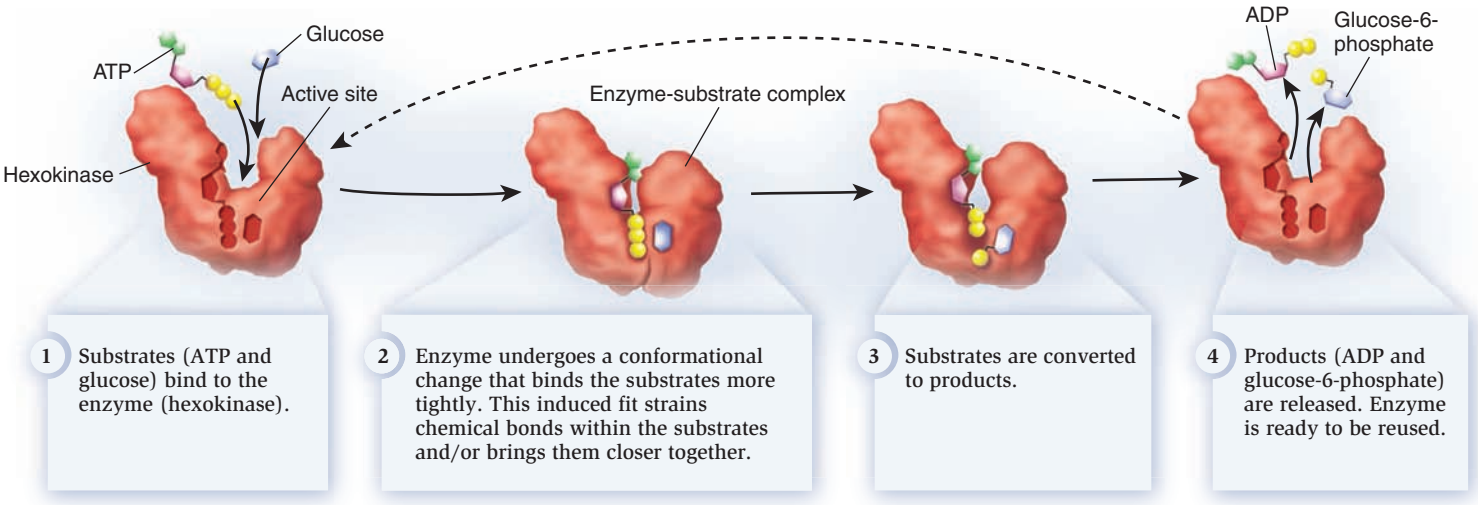

Figure 6.6 The steps of an enzyme-catalyzed reaction. The example shown here involves the enzyme hexokinase, which binds glucose and ATP. The products are glucose-6-phosphate and ADP, which are released from the enzyme.

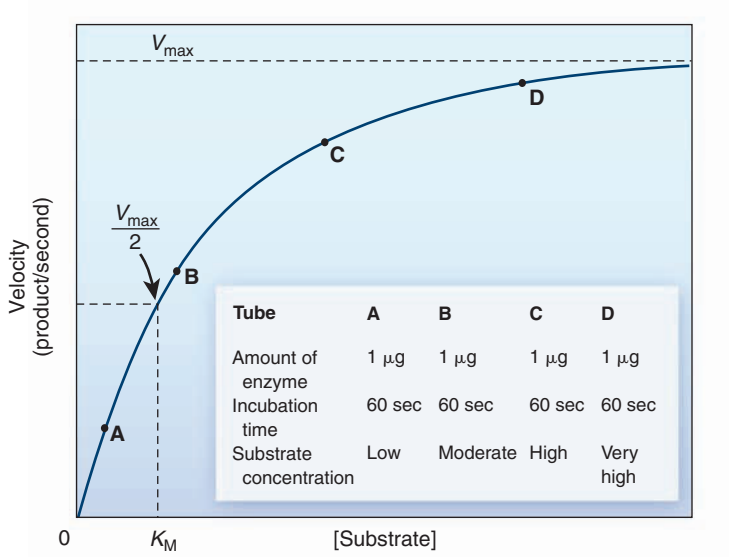
BIOLOGY PRINCIPLE Structure determines function. A key function of enzymes is their ability to bind their substrates with high specificity. This is due to the structure of the enzyme's active site.

Concept Check: During which step is the activation energy lowered?

right-sized key (the substrate) will fit into the keyhole (active site) of the lock (the enzyme). Further research revealed that the interaction between an enzyme and its substrates also involves movements or conformational changes in the enzyme itself. As shown in step 2 in Figure 6.6, these conformational changes cause the substrates to bind more tightly to the enzyme, a phenomenon called **induced fit**, which was proposed by American biochemist Daniel Koshland in 1958. Only after this induced fit takes place does the enzyme catalyze the conversion of reactants to products. Induced fit is a key phenomenon that lowers the activation energy.

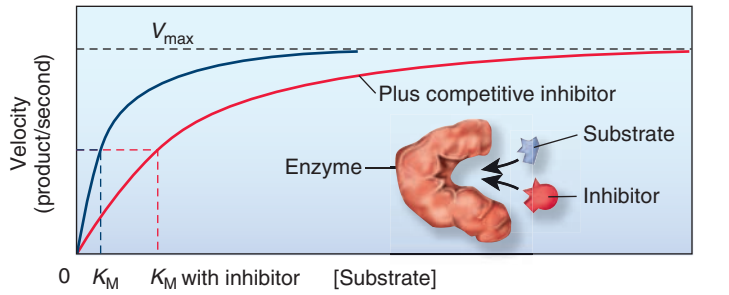
Enzyme Function Is Influenced by the Substrate Concentration and by Inhibitors

The degree of attraction between an enzyme and its substrate(s) is called the **affinity** of the enzyme for its substrate(s). Some enzymes recognize their substrates with very high affinity, which means they have a strong attraction for their substrates. Such enzymes bind their substrates even when the substrate concentration is relatively low. Other enzymes recognize their substrates with lower affinity; the enzyme-substrate complex is likely to form when the substrate concentration is higher.



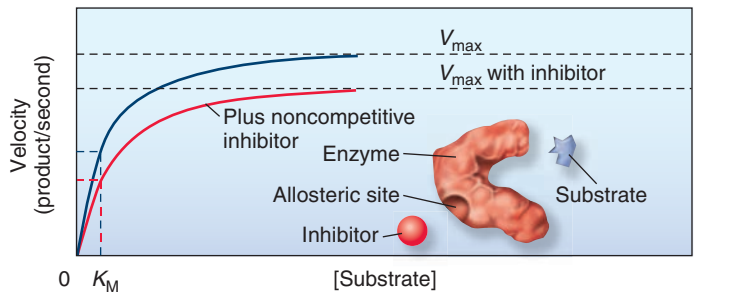
Let's consider how biologists analyze the relationship between substrate concentration and enzyme function. In the experiment of **Figure 6.7a**, tubes labeled A, B, C, and D each contained 1 μg of enzyme, but they varied in the amount of substrate that was added. This enzyme recognizes a single substrate and converts it to a product. The samples were incubated for 60 seconds, and then the amount of product in each tube was measured. The velocity or rate of the chemical reaction is expressed as the amount of product produced per second. As we see in Figure 6.7a, the velocity increases as the substrate concentration increases, but eventually reaches a plateau. Why does the plateau occur? At high substrate concentrations, nearly all of the active sites of the enzyme are occupied with substrate, so increasing the substrate concentration further has a negligible effect. At this point, the enzyme is saturated with substrate, and the velocity of the chemical reaction is near its maximal rate, called its V_{max}.

Figure 6.7a also helps us understand the relationship between substrate concentration and velocity. The K_M is the substrate concentration at which the velocity is half its maximal value. The K_M is also called the Michaelis constant in honor of the German biochemist Leonor Michaelis, who carried out pioneering work with the Canadian biochemist Maud Menten on the study of enzymes. The K_M is a measure of the substrate concentration required for a chemical reaction to occur. An enzyme with a high K_M requires a higher substrate concentration to achieve a particular reaction velocity compared to an enzyme with a lower K_M.



For an enzyme-catalyzed reaction, we can view the formation of product as occurring in two steps: (1) binding or release of substrate and (2) formation of product:

$$E + S \rightleftharpoons ES \rightarrow E + P$$



where E is the enzyme, S is the substrate, ES is the enzyme-substrate complex, and P is the product.

(a) Reaction velocity in the absence of inhibitors

(b) Competitive inhibition

(c) Noncompetitive inhibition

Figure 6.7 The relationship between velocity and substrate concentration in an enzyme-catalyzed reaction, and the effects of inhibitors. **(a)** In the absence of an inhibitor, the maximal velocity (V_{max}) is achieved when the substrate concentration is high enough to be saturating. The K_M value is the substrate concentration at which the velocity is half the maximal velocity. **(b)** A competitive inhibitor binds to the active site of an enzyme and raises the K_M for the substrate. **(c)** A noncompetitive inhibitor binds to an allosteric site outside the active site and lowers the V_{max} for the reaction.

Concept Check: *Enzyme A has a K_M of 0.1 mM, whereas enzyme B has a K_M of 1.0 mM. They both have the same V_{max}. If the substrate concentration was 0.5 mM, which reaction—the one catalyzed by enzyme A or B—would have the higher velocity?*

If the second step—the rate of product formation—is much slower than the rate of substrate release, the K_M is inversely related to the affinity between the enzyme and substrate. For example, let's consider an enzyme that breaks down ATP into ADP and P_i. If the rate of formation of ADP and P_i is much slower than the rate of ATP release, the K_M and affinity show an inverse relationship. Enzymes with a high K_M have a low affinity for their substrates—they bind them more weakly. By comparison, enzymes with a low K_M have a high affinity for their substrates—they bind them more strongly.

Now that we understand the relationship between substrate concentration and the velocity of an enzyme-catalyzed reaction, we can explore how inhibitors may affect enzyme function. These can be categorized as reversible inhibitors that bind noncovalently to an enzyme or irreversible inhibitors that usually bind covalently to an enzyme and permanently inactivate its function.

Reversible Inhibitors Cells often use reversible inhibitors to modulate enzyme function. **Competitive inhibitors** are molecules that bind noncovalently to the active site of an enzyme and inhibit the ability of the substrate to bind. Such inhibitors compete with the substrate for the ability to bind to the enzyme. Competitive inhibitors usually have a structure or a portion of their structure that mimics the structure of the enzyme's substrate. As seen in **Figure 6.7b**, when competitive inhibitors are present, the apparent K_M for the substrate increases—a higher concentration of substrate is needed to achieve the same rate of the chemical reaction. In this case, the effects of the competitive inhibitor can be overcome by increasing the concentration of the substrate.

By comparison, **Figure 6.7c** illustrates the effects of a **noncompetitive inhibitor**. This type of inhibitor lowers the V_{max} for the reaction without affecting the K_M. A noncompetitive inhibitor binds noncovalently to an enzyme at a location outside the active site, called an **allosteric site**, and inhibits the enzyme's function.

Irreversible Inhibitors Irreversible inhibitors usually bind covalently to an enzyme to inhibit its function. For example, some irreversible inhibitors bind covalently to an amino acid at the active site of an enzyme, thereby preventing it from catalyzing a chemical reaction. An example of an irreversible inhibitor is diisopropyl phosphorofluoridate (DIFP). DIFP is a type of nerve gas that was developed as a chemical weapon. This molecule covalently reacts with the enzyme acetylcholinesterase, which is important for the proper functioning of neurons.

Irreversible inhibition is not a common way for cells to control enzyme function. Why do cells usually control enzymes via reversible inhibitors? The answer is that a reversible inhibitor allows an enzyme to be used again, when the inhibitor concentration becomes lowered. Being able to reuse an enzyme is energy efficient. In contrast, irreversible inhibitors permanently inactivate an enzyme, thereby preventing its further use.

Additional Factors Influence Enzyme Function

Enzymes, which are proteins, sometimes require nonprotein molecules or ions to carry out their functions.

- **Prosthetic groups** are small molecules that are permanently attached to the surface of an enzyme and aid in enzyme function.
- **Cofactors** are usually inorganic ions, such as Fe^{3+} or Zn^{2+}, that temporarily bind to the surface of an enzyme and promote a chemical reaction.
- Some enzymes use **coenzymes**, organic molecules that temporarily bind to an enzyme and participate in the chemical reaction, but are left unchanged after the reaction is completed.

The ability of enzymes to increase the rate of a chemical reaction is also affected by their environment. In particular, the temperature, pH, and ionic conditions play an important role in the proper functioning of enzymes. Most enzymes function maximally in a narrow range of temperature and pH. For example, many human enzymes work best at 37°C (98.6°F), which is the normal body temperature. If the temperature is several degrees above or below an enzyme's optimum temperature due to infection or environmental causes, the function of many enzymes is greatly inhibited (**Figure 6.8**). Very high temperatures may denature a protein, causing it to unfold and lose its three-dimensional shape, thereby inhibiting its function.

Enzyme function is also sensitive to pH. Certain enzymes in the stomach function best at the acidic pH found in this organ. For example, pepsin is a protease—an enzyme that digests proteins into peptides—that is released into the stomach. The optimal pH for pepsin function is around pH 2.0, which is extremely acidic. By comparison, many cytosolic enzymes function optimally at a more neutral pH, such as pH 7.2, which is the pH normally found in the cytosol of human cells. If the pH was significantly above or below this value, enzyme function would be decreased for cytosolic enzymes.

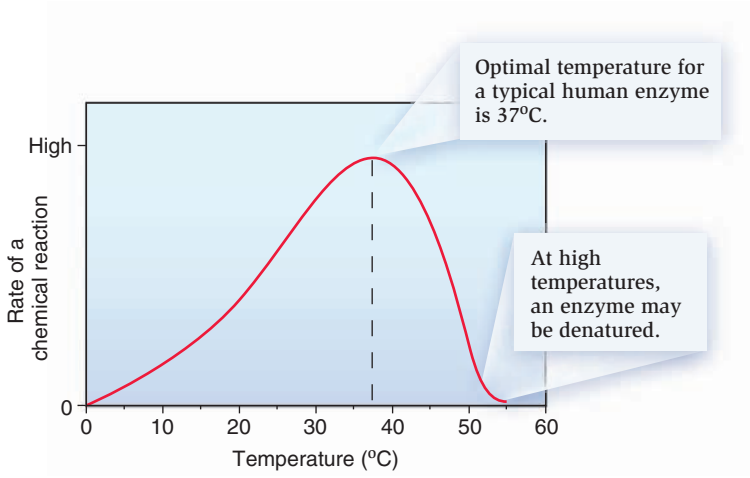


Figure 6.8 Effects of temperature on a typical human enzyme. Most enzymes function optimally within a narrow range of temperature. Many human enzymes function best at 37°C, which is normal body temperature.

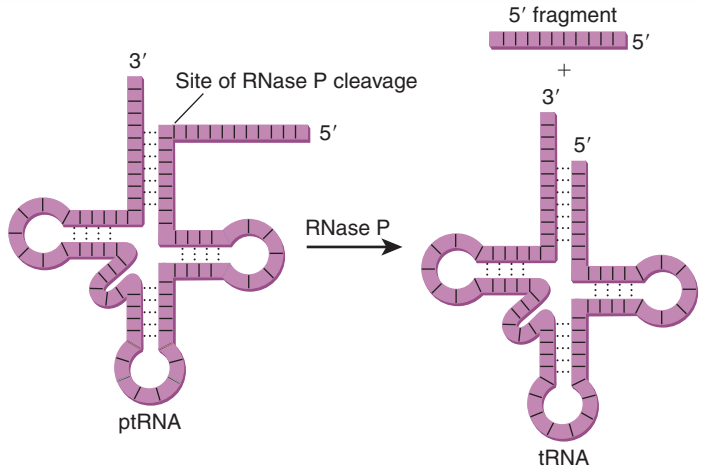
Feature Investigation | The Discovery of Ribozymes by Sidney Altman Revealed That RNA Molecules May Also Function as Catalysts

Until the 1980s, scientists thought that all biological catalysts are proteins. An avenue of study that dramatically changed this view came from the analysis of ribonuclease P (RNase P), a catalyst involved in the processing of tRNA molecules—a type of molecule required for protein synthesis. tRNA molecules are synthesized as longer precursor molecules called ptRNAs, which have 5′ and 3′ ends. (The 5′ and 3′ directionality of RNA molecules is described in Chapter 11.) RNase P breaks a covalent bond at a specific site in precursor tRNAs, which releases a fragment at the 5′ end and makes them shorter (**Figure 6.9**).

Sidney Altman and his colleagues became interested in the processing of tRNA molecules and turned their attention to RNase P in *E. coli*. During the course of their studies, they purified this enzyme and, to their surprise, discovered it has two subunits—one is an RNA molecule that contains 377 nucleotides, and the other is a small protein with a mass of 14 kDa. In the 1980s, the finding that a catalyst has an RNA subunit was very unexpected. Even so, a second property of RNase P would prove even more exciting.

Altman and colleagues were able to purify RNase P and study its properties in vitro. Cecilia Guerrier-Takada in Altman's laboratory determined that magnesium ion (Mg^{2+}) has a stimulatory effect on RNase P function. In the experiment described in **Figure 6.10**, the effects of Mg^{2+} were studied in greater detail. The researchers analyzed the effects of low (10 mM $MgCl_2$) and high (100 mM $MgCl_2$) magnesium concentrations on the processing of a ptRNA. At low or high magnesium concentrations, the ptRNA was incubated without RNase P (as a control); with the RNA subunit alone; or with intact RNase P (RNA subunit and protein subunit). Following incubation, they performed gel electrophoresis on the samples to determine if the ptRNAs had been cleaved into two pieces—the tRNA and a 5′ fragment. Gel electrophoresis separates molecules on the basis of their masses.



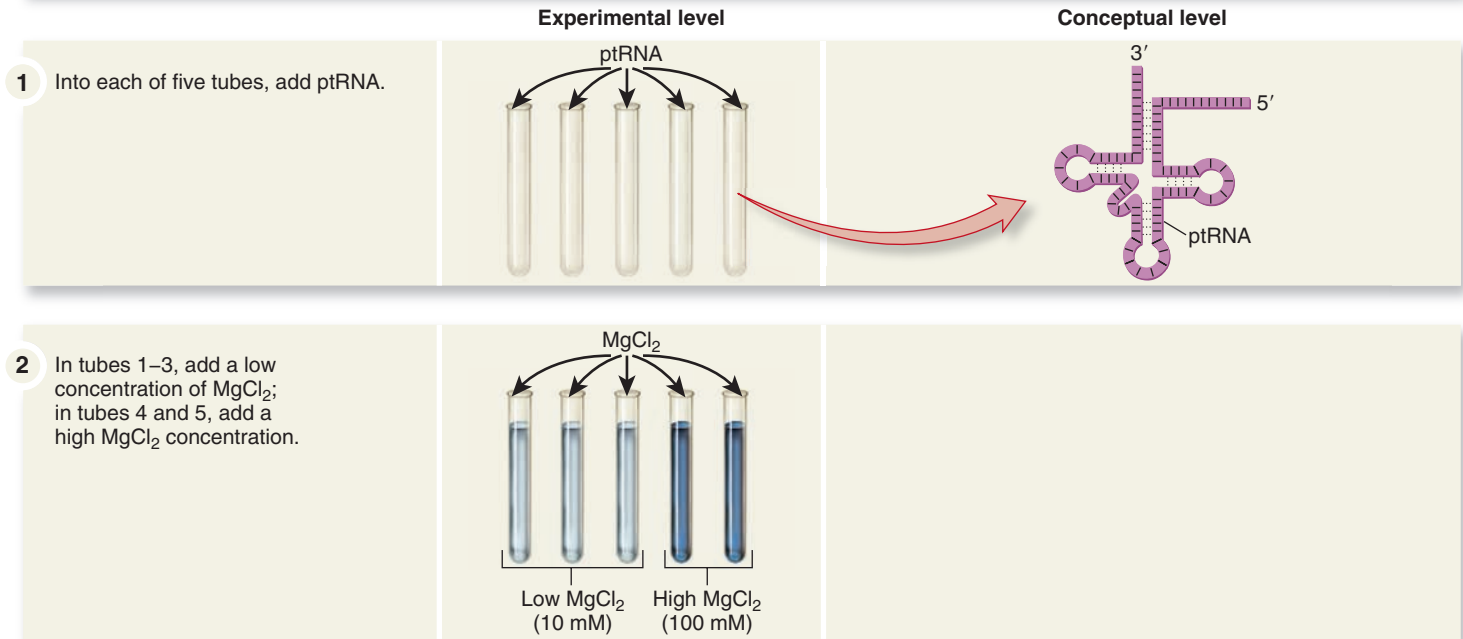


Figure 6.9 The function of RNase P. A specific bond in a precursor tRNA (ptRNA) is cleaved by RNase P, which releases a small fragment at the 5′ end. This results in the formation of a mature tRNA.

BioConnections: Look ahead to Figure 12.20. How do you imagine translation would be affected if RNase P did not work properly?

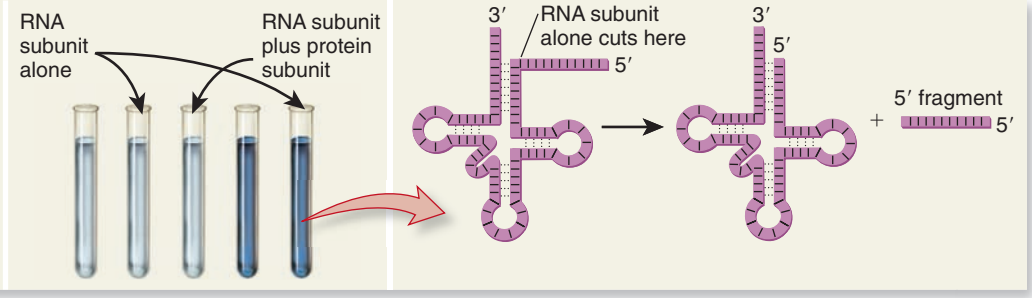

Figure 6.10 The discovery that the RNA subunit of RNase P is a catalyst.

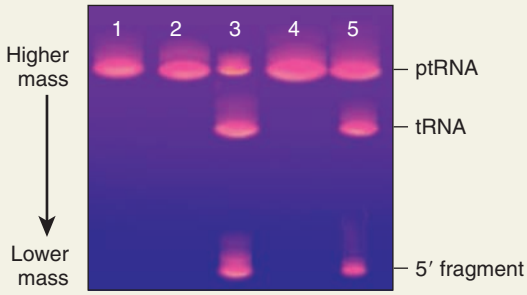
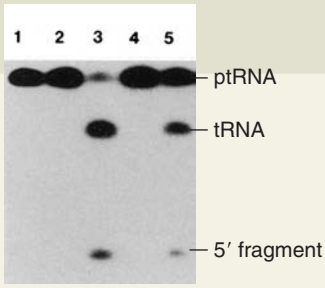
HYPOTHESIS The catalytic function of RNase P is carried out by its RNA subunit or by its protein subunit.



KEY MATERIALS Purified precursor tRNA (ptRNA) and purified RNA and protein subunits of RNase P from *E. coli*.

3 Into tubes 2 and 5, add the RNA subunit of RNase P alone; into tube 3, add both the RNA subunit and the protein subunit of RNase P. Incubate to allow digestion to occur. Note: Tubes 1 and 4 are controls that have no added subunits of RNase P.



4 Carry out gel electrophoresis on each sample. In this technique, samples are loaded into a well on a gel. They move toward the bottom of the gel and are separated according to their masses: Molecules with higher masses are closer to the top of the gel. The gel is exposed to ethidium bromide, which stains RNA.

Catalytic function will result in the digestion of ptRNA into tRNA and a smaller 5′ fragment.

5 THE DATA

6 CONCLUSION The RNA subunit alone catalyzes the breakage of a covalent bond in ptRNA at high $MgCl_2$ concentrations. It is a ribozyme.

7 SOURCE Altman, S. 1990. Enzymatic cleavage of RNA by RNA. *Bioscience Reports* 10:317–337.

Let's now look at the data. As a control, ptRNAs were incubated with low (lane 1) or high (lane 4) concentrations of $MgCl_2$ in the absence of RNase P. As expected, no processing to a lower molecular mass tRNA was observed. When the RNA subunit alone was incubated with ptRNA molecules in the presence of low $MgCl_2$ (lane 2), no processing occurred, but it did occur if the protein subunit was also included (lane 3).

The surprising result is shown in lane 5, in which the ptRNA was incubated with the RNA subunit alone in the presence of a high concentration of $MgCl_2$. The RNA subunit by itself was sufficient to cleave the ptRNA to a smaller tRNA and a 5′ fragment! Presumably, the high $MgCl_2$ concentration helps to keep the RNA subunit in a conformation that is catalytically active. Alternatively, the protein subunit plays a similar role in a living cell.

Subsequent work confirmed these observations and showed that the RNA subunit of RNase P is a true catalyst—it accelerates the rate of a chemical reaction and is not permanently altered by it. Around the same time, Thomas Cech and colleagues determined that a different RNA molecule found in the protist *Tetrahymena thermophila* also has catalytic activity. The term **ribozyme** is now used to describe an RNA molecule that catalyzes a chemical reaction. In 1989, Altman and Cech received the Nobel Prize in Chemistry for their discovery of ribozymes.

Since the pioneering work of Altman and Cech, researchers have discovered that ribozymes play key catalytic roles in cells (**Table 6.3**). They are primarily involved in the processing of RNA molecules from precursor to mature forms. In addition, a ribozyme in ribosomes catalyzes the formation of covalent bonds between adjacent amino acids during polypeptide synthesis.

Table 6.3 Types of Ribozymes

General function	Biological examples
Processing of RNA molecules	1. RNase P: As described in this chapter, RNase P cleaves precursor tRNA molecules (ptRNAs) to mature tRNAs.
	2. Spliceosomal RNA: As described in Chapter 12, eukaryotic pre-mRNAs often have regions called introns that are later removed. These introns are removed by a spliceosome that is composed of RNA and protein subunits. The RNA within the spliceosome is believed to function as a ribozyme that removes the introns from pre-mRNA.
	3. Certain introns found in mitochondrial, chloroplast, and bacterial RNAs are removed by a self-splicing mechanism.
Synthesis of polypeptides	The ribosome has an RNA component that catalyzes the formation of covalent bonds between adjacent amino acids during polypeptide synthesis.

Experimental Questions

1. Briefly explain why it was necessary to purify the individual subunits of RNase P to show that it is a ribozyme.
2. **SciSKILLS »** Explain why the researchers conducted experiments in which they measured the formation of mature tRNA without adding the protein subunit or without adding the RNA subunit.
3. **SciSKILLS »** Analyze the results of Altman and colleagues, and explain how they indicated that RNase P is a ribozyme. How does the concentration of Mg^{2+} affect the function of the RNA in RNase P?

6.3 Overview of Metabolism

Learning Outcomes:

1. Explain the concept of a metabolic pathway, and distinguish between catabolic and anabolic reactions.
2. Describe how catabolic reactions are used to generate building blocks to make larger molecules and to produce energy intermediates.
3. Define redox reaction.
4. Compare and contrast three ways that metabolic pathways are regulated.

In the previous sections, we examined the underlying factors that govern individual chemical reactions and explored the properties of enzymes and ribozymes. In living cells, chemical reactions are coordinated with each other and often occur in **metabolic pathways**, with each step catalyzed by a specific enzyme (**Figure 6.11**). These pathways are categorized according to whether the reactions lead to the breakdown or synthesis of substances. **Catabolic reactions** result in the breakdown of larger molecules into smaller ones. Such reactions are often exergonic. By comparison, **anabolic reactions** involve the synthesis of larger molecules from smaller precursor molecules. These reactions usually are endergonic and, in living cells, must be coupled to an exergonic reaction. In this section, we will survey the general features of catabolic and anabolic reactions and explore the ways in which metabolic pathways are controlled.

Catabolic Reactions Recycle Organic Building Blocks and Produce Energy Intermediates Such as ATP

Catabolic reactions result in the breakdown of larger molecules into smaller ones. Such catabolic reactions have two advantages.

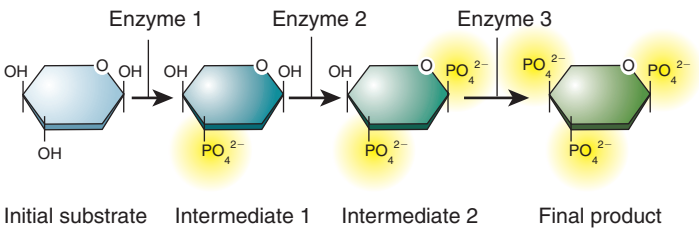


Figure 6.11 A metabolic pathway. In this metabolic pathway, a series of different enzymes catalyze the attachment of phosphate groups at several positions on a sugar molecule, beginning with a starting substrate and ending with a final product.

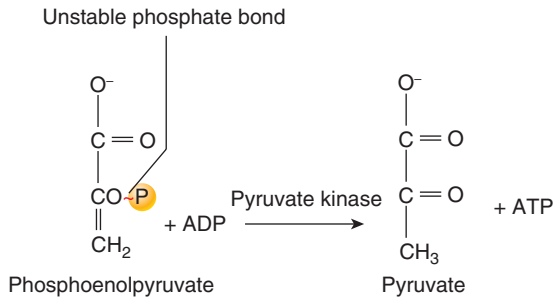


Recycling of Organic Building Blocks One reason for the breakdown of macromolecules is to recycle their organic molecules, which are used as building blocks to construct new molecules and macromolecules. For example, polypeptides, which make up proteins, are composed of a linear sequence of amino acids. When a protein is improperly folded or is no longer needed by a cell, the peptide bonds between the amino acids in the protein are broken by enzymes called proteases. This generates amino acids that can be used in the construction of new proteins.

$$\text{Protein} \xrightarrow{\text{Proteases}} \text{Many individual amino acids}$$

We will consider the mechanisms of recycling later in Section 6.4.

Breakdown of Organic Molecules to Obtain Energy A second reason for the breakdown of macromolecules into smaller organic molecules is to obtain energy that is used to drive endergonic processes in the cell. Covalent bonds store a large amount of energy. However, when cells break covalent bonds in organic molecules such as glucose, they do not directly use the energy released in this process. Instead, the released energy is stored in **energy intermediates**, molecules such as ATP, which are directly used to drive endergonic reactions in cells.

As an example, let's consider the breakdown of glucose into two molecules of pyruvate. As discussed in Chapter 7, the breakdown of glucose to pyruvate involves a catabolic pathway called glycolysis. Some of the energy released during the breakage of covalent bonds in glucose is harnessed to synthesize ATP. Glycolysis involves a series of steps in which covalent bonds are broken and rearranged. This process produces molecules that readily donate a phosphate group to ADP, thereby producing ATP. For example, phosphoenolpyruvate has a phosphate group attached to pyruvate. Due to the arrangement of bonds in phosphoenolpyruvate, this phosphate bond is unstable and easily broken. Therefore, the phosphate can be readily transferred from phosphoenolpyruvate to ADP:

This is an exergonic reaction ($\Delta G = -7.5$ kcal/mol) and therefore favors the formation of products. In this step of glycolysis, the breakdown of an organic molecule, namely phosphoenolpyruvate, results in the formation of pyruvate and the synthesis of an energy intermediate molecule, ATP, which can then be used by a cell to drive endergonic reactions. This way of synthesizing ATP, termed **substrate-level phosphorylation**, occurs when an enzyme directly transfers a phosphate from an organic molecule to ADP, thereby making ATP.

Another way to make ATP is via **chemiosmosis**. In this process, energy stored in an ion electrochemical gradient is used to make ATP from ADP and P_i. We will consider this other mechanism in Chapter 7.

Redox Reactions Involve the Transfer of Electrons

During the breakdown of small organic molecules, **oxidation**—the removal of one or more electrons from an atom or molecule—may occur. This process is called oxidation because oxygen is frequently involved in chemical reactions that remove electrons from other molecules. By comparison, **reduction** is the addition of electrons to an atom or molecule. Reduction is so named because the addition of a negatively charged electron reduces the net charge of a molecule.

Electrons do not exist freely in solution. When an atom or molecule is oxidized, the electron that is removed must be transferred to another atom or molecule, which becomes reduced. This type of reaction is termed a **redox reaction**, which is short for a reduction-oxidation reaction. As a generalized equation, an electron may be transferred from molecule A to molecule B as follows:

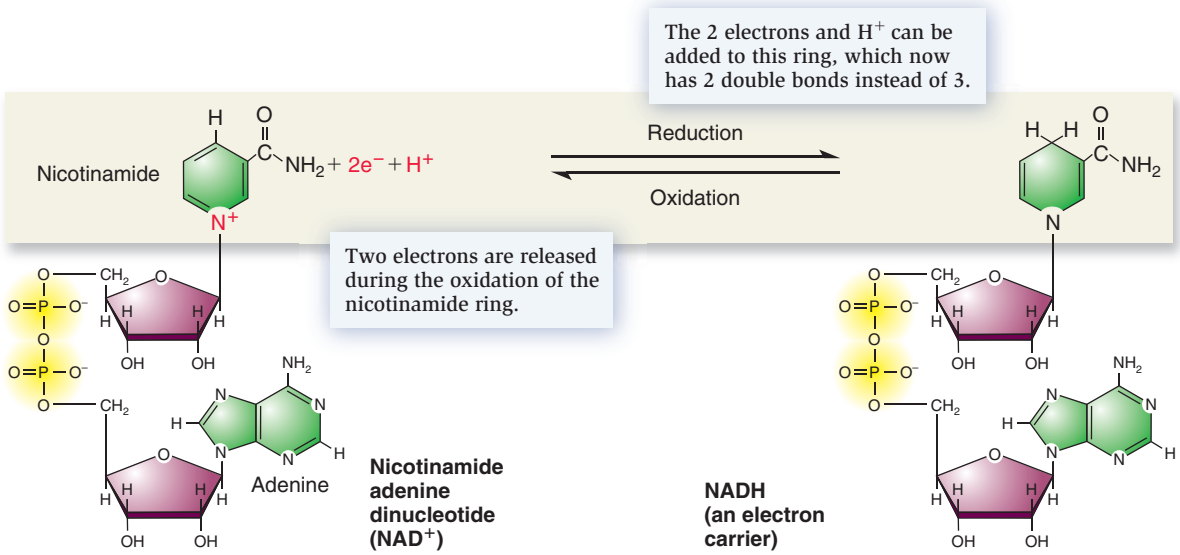
$$\underset{}{Ae^-} + B \rightarrow \underset{\text{(oxidized)}}{A} + \underset{\text{(reduced)}}{Be^-}$$

As shown on the right side of this reaction, A has been oxidized (that is, had an electron removed), and B has been reduced (that is, had an electron added). In general, a substance that has been oxidized has less energy, whereas a substance that has been reduced has more energy.

During the oxidation of organic molecules such as glucose, the electrons may be used to produce energy intermediates such as NADH (**Figure 6.12**). In this process, an organic molecule has been oxidized, and **NAD^+** (**nicotinamide adenine dinucleotide**) has been reduced to NADH. Cells use NADH in two common ways. First, as we will see in Chapter 7, the oxidation of NADH is a highly exergonic reaction that can be used to make ATP. Second, NADH can donate electrons to other organic molecules and thereby energize them. Such energized molecules can more readily form covalent bonds. Therefore, as described next, NADH is often needed in reactions that involve the synthesis of larger molecules through the formation of covalent bonds between smaller molecules.

Anabolic Reactions Require an Input of Energy to Make Larger Molecules

Anabolic reactions are also called **biosynthetic reactions**, because they are necessary to make larger molecules and macromolecules. We will examine the synthesis of macromolecules in several chapters of this textbook. For example, RNA and protein biosynthesis are described in Chapter 12. Cells also need to synthesize small organic molecules, such as amino acids and fats, if they are not readily available from food sources. Such molecules are made by the formation of covalent linkages between precursor molecules. For example, glutamate



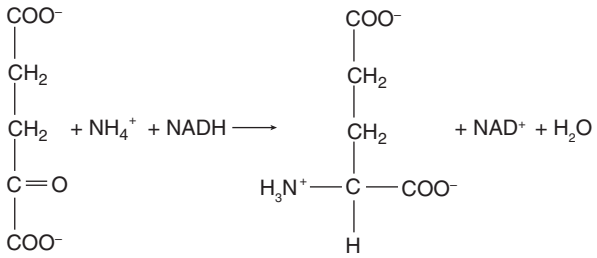


Figure 6.12 The reduction of NAD^+ to produce NADH. NAD^+ is composed of two nucleotides, one with an adenine base and one with a nicotinamide base. The oxidation of organic molecules releases electrons that bind to NAD^+ (and along with a hydrogen ion) result in the formation of NADH. The two electrons and H^+ are incorporated into the nicotinamide ring. Note: The actual net charges of NAD^+ and NADH are −1 and −2, respectively. They are designated NAD^+ and NADH to emphasize the net charge of the nicotinamide ring, which is involved in reduction-oxidation reactions.

Concept Check: *Which is the oxidized form, NAD^+ or NADH?*

(an amino acid) is made by the covalent linkage between α-ketoglutarate (a product of sugar metabolism) and ammonium (NH_4^+).

α-Ketoglutarate Ammonium Glutamate

In this reaction, an energy intermediate molecule, NADH, is needed to drive the reaction forward.

Metabolic Pathways Are Regulated in Three General Ways

The regulation of metabolic pathways is important for a variety of reasons. Catabolic pathways are regulated so organic molecules are broken down only when they are no longer needed or when the cell requires energy. During anabolic reactions, regulation ensures that a cell synthesizes molecules only when they are needed. The regulation of catabolic and anabolic pathways occurs at the genetic, cellular, and biochemical levels.

Gene Regulation Enzymes are protein molecules that are encoded by genes. One way that cells control metabolic pathways is via gene regulation. For example, if a bacterial cell is not exposed to a particular sugar in its environment, it will turn off the genes that encode the enzymes that are needed to break down that sugar. Alternatively, if the sugar becomes available, the genes are switched on. Chapter 13 examines the steps of gene regulation in detail.

Cellular Regulation Metabolism is also coordinated at the cellular level. Cells integrate signals from their environment and adjust their metabolic pathways to adapt to those signals. As discussed in Chapter 9, cell-signaling pathways often lead to the activation of protein kinases—enzymes that covalently attach a phosphate group to target proteins. For example, when people are frightened, they secrete a hormone called epinephrine into their bloodstream. This hormone binds to the surface of muscle cells and stimulates an intracellular pathway that leads to the phosphorylation of specific enzymes involved in carbohydrate metabolism. These activated enzymes promote the breakdown of carbohydrates, an event that supplies the frightened individual with more energy. Epinephrine is sometimes called the "fight-or-flight" hormone because the added energy prepares an individual to either stay and fight or run away quickly. After a person is no longer frightened, hormone levels drop, and other enzymes called phosphatases remove the phosphate groups from enzymes, thereby restoring the original level of carbohydrate metabolism.

Biochemical Regulation A third and very prominent way that metabolic pathways are controlled is at the biochemical level. In this case, the noncovalent binding of a molecule to an enzyme directly regulates its function. As discussed earlier, one form of biochemical regulation involves the binding of molecules such as competitive or noncompetitive inhibitors (see Figure 6.7). An example of noncompetitive inhibition is a type of regulation called **feedback inhibition**, in which the product of a metabolic pathway inhibits an enzyme that acts early in the pathway, thus preventing the overaccumulation of the product (**Figure 6.13**).

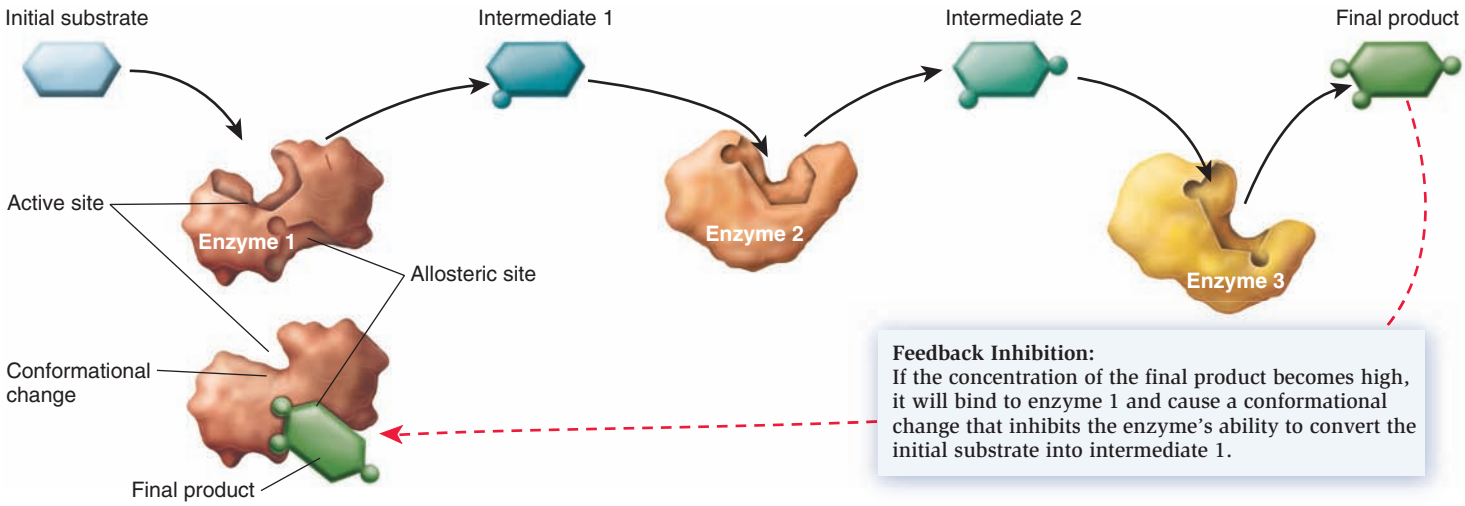

Figure 6.13 **Feedback inhibition.** In this process, the final product of a metabolic pathway inhibits an enzyme that functions in the pathway, thereby preventing the overaccumulation of the product.

BIOLOGY PRINCIPLE **Living organisms maintain homeostasis.** In this example, feedback inhibition prevents the formation of too much product of a metabolic pathway.

BioConnections: *Look ahead to Figure 7.3, which describes a metabolic pathway called glycolysis. Feedback inhibition occurs such that high levels of ATP inhibit phosphofructokinase, an enzyme that catalyzes the conversion of fructose-6-phosphate and ATP to fructose-1,6-bisphosphate and ADP. How is this beneficial to the cell?*

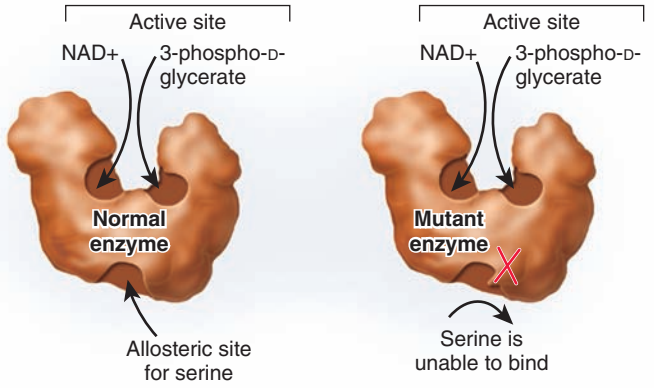
Many metabolic pathways use feedback inhibition as a form of biochemical regulation. In such cases, the inhibited enzyme has two binding sites. One site is the active site, where the reactants are converted to products. In addition, enzymes controlled by feedback inhibition also have an allosteric site, where a molecule can bind noncovalently and affect the function of the active site. The binding of a molecule to an allosteric site causes a conformational change in the enzyme that inhibits its catalytic function. Allosteric sites are often found in the enzymes that catalyze the early steps in a metabolic pathway. Such allosteric sites typically bind molecules that are the products of the metabolic pathway. When the products bind to these sites, they inhibit the function of these enzymes, thereby preventing the formation of too much product.

Regulation of the Rate-Limiting Step Cellular regulation and biochemical regulation are important and rapid ways to control chemical reactions in a cell. For a metabolic pathway composed of several enzymes, which enzyme in a pathway should be controlled? In many cases, a metabolic pathway has a **rate-limiting step**, which is the slowest step in the pathway. If the rate-limiting step is inhibited or enhanced, such changes will have the greatest influence on the formation of the product of the metabolic pathway. Rather than affecting all of the enzymes in a metabolic pathway, cellular or biochemical regulation is often directed at the enzyme that catalyzes the rate-limiting step. This is an efficient and rapid way to control the amount of product of a pathway.

BIO TIPS

THE QUESTION *The enzyme called 3-phosphoglycerate dehydrogenase catalyzes the following chemical reaction:*

3-phospho-D-glycerate + NAD^+ $\rightleftharpoons$
3-phosphonooxypyruvate + NADH + H^+



This reaction is the rate-limiting step in a metabolic pathway that synthesizes serine, which is an amino acid. Serine inhibits 3-phosphoglycerate dehydrogenase by binding to an allosteric site on the enzyme, thereby preventing the overaccumulation of serine in a cell. This is an example of feedback inhibition. Researchers have identified a mutant version of 3-phosphoglycerate dehydrogenase that does not exhibit feedback inhibition. Cells that make the mutant enzyme tend to overaccumulate serine. Make a drawing that depicts how the mutant enzyme is different from the normal one. Your drawing should include binding sites for 3-phospho-D-glycerate, NAD^+, and serine.

TOPIC ***What topic in biology does this question address?*** The topic is about enzymes and feedback inhibition. More specifically, the question is about a mutant version of 3-phosphoglycerate dehydrogenase that does not exhibit feedback inhibition.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you know that 3-phosphoglycerate dehydrogenase catalyzes the rate-limiting step in a metabolic pathway that produces serine. Serine causes feedback inhibition in the normal version of the enzyme but does not inhibit a mutant version. From your understanding of the topic, you may recall that feedback inhibition occurs via an allosteric site.

PROBLEM-SOLVING STRATEGY ***Compare and contrast. Make a drawing.*** To solve this problem, you could begin by comparing the properties of the normal and mutant enzyme. The mutant enzyme does not exhibit feedback inhibition. However, because cells harboring the mutant version of the enzyme overaccumulate serine, you know that the catalytic properties of the enzyme must be functioning normally. In other words, the active site is functional. When making the drawing, you need to remember that the enzyme has two sites: an active site and an allosteric site.

ANSWER *The mutation, designated by an X in the enzyme on the right, is altering the structure of the allosteric site in a way that prevents serine from binding.*

6.4 Recycling of Organic Molecules

Learning Outcomes:

1. Explain the relationship between the recycling of organic molecules and cellular efficiency.
2. Outline how the building blocks of proteins are recycled.
3. Describe how the components of cellular organelles are recycled via autophagy.

As mentioned earlier in this chapter, another important feature of metabolism is the recycling of organic molecules, such as amino acids, which are the building blocks of proteins. Except for DNA, which is stably maintained and inherited from cell to cell, other large molecules such as RNA, proteins, lipids, and polysaccharides typically exist for a relatively short period of time. Biologists often speak of the **half-life** of molecules, which is the time it takes for 50% of the molecules to be broken down and recycled. For example, a population of messenger RNA molecules in bacteria has an average half-life of about 5 minutes, whereas mRNAs in eukaryotes tend to exist for longer periods of time, on the order of 30 minutes to 24 hours or even several days.

Why is recycling important? To compete effectively in their native environments, all living organisms must efficiently use and recycle the organic molecules that are needed as building blocks to construct larger molecules and macromolecules. Otherwise, they would waste a great deal of energy making such building blocks from smaller molecules. For example, organisms conserve an enormous amount of energy by reusing the amino acids that are needed to construct proteins. In this section, we will explore how amino acids are recycled and consider a mechanism for the recycling of materials found in an entire organelle.

Proteins in Eukaryotes and Archaea Are Broken Down in the Proteasome

Cells continually degrade proteins that are faulty or no longer needed. To be degraded, proteins are recognized by **proteases**—enzymes that cleave the bonds between adjacent amino acids. The primary pathway for protein degradation in archaea and eukaryotic cells is via a protein complex called a **proteasome**. The core of the proteasome consists of four stacked rings, each composed of seven protein subunits (**Figure 6.14a**). The proteasomes of eukaryotic cells also contain caps at each end that control the entry of proteins into the proteasome.

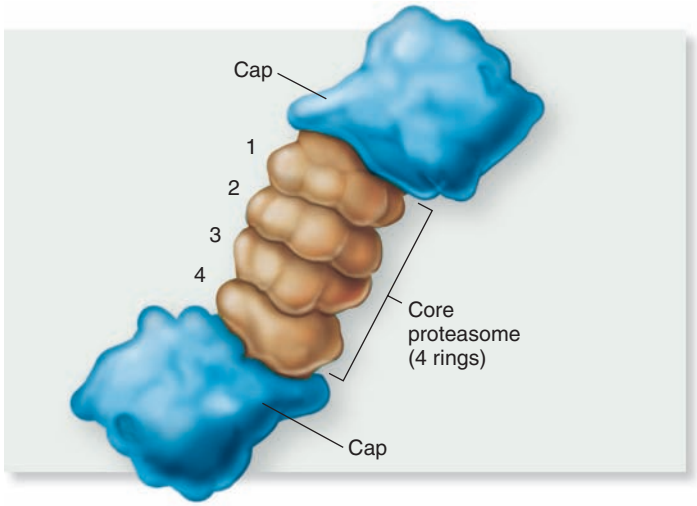


Figure 6.14b describes the steps of protein degradation via eukaryotic proteasomes. A string of small proteins called **ubiquitin** is covalently attached to the target protein. This event directs the target protein to a proteasome cap, which has binding sites for ubiquitin. The cap also has enzymes that unfold the protein and inject it into the internal cavity of the proteasome core. The ubiquitins are removed during entry and released to the cytosol for reuse. Inside the proteasome, proteases degrade the target protein into small peptides and amino acids. The process is completed when the peptides and amino acids are recycled back into the cytosol. The amino acids are reused to make new proteins.

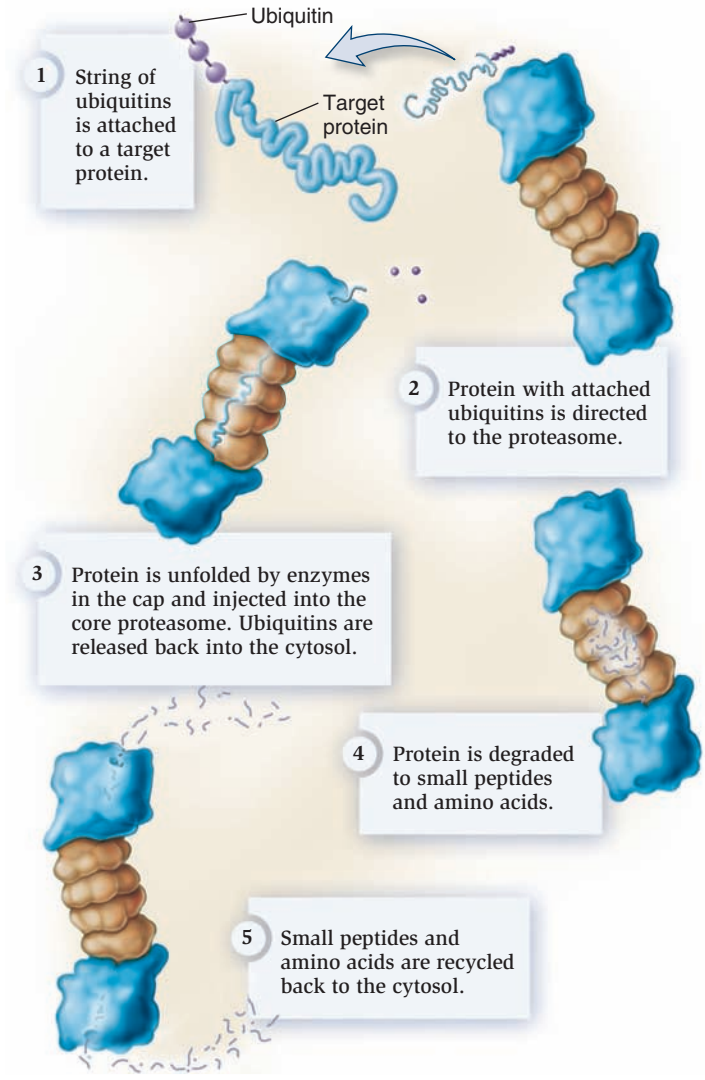
Ubiquitin targeting has two functions.



- First, the enzymes that attach ubiquitins to its target recognize improperly folded proteins, allowing cells to identify and degrade nonfunctional proteins.
- Second, changes in cellular conditions may warrant the rapid breakdown of particular proteins. For example, cell division requires a series of stages called the cell cycle, which depends on the degradation of specific proteins. After these proteins perform their functions in the cycle, ubiquitin targeting directs them to the proteasome for degradation.

Autophagy Recycles the Contents of Entire Organelles

As described in Chapter 4, lysosomes contain many different types of acid hydrolases that break down proteins, carbohydrates, nucleic acids, and lipids. This enzymatic function enables lysosomes to break down complex materials. One function of lysosomes involves the digestion of substances that are taken up from outside the cell. This process, called endocytosis, is described in Chapter 5. In addition, lysosomes help digest intracellular materials. In a process known as **autophagy** (from the Greek, meaning eating one's self), cellular

Concept Check: *What are advantages of protein degradation?*

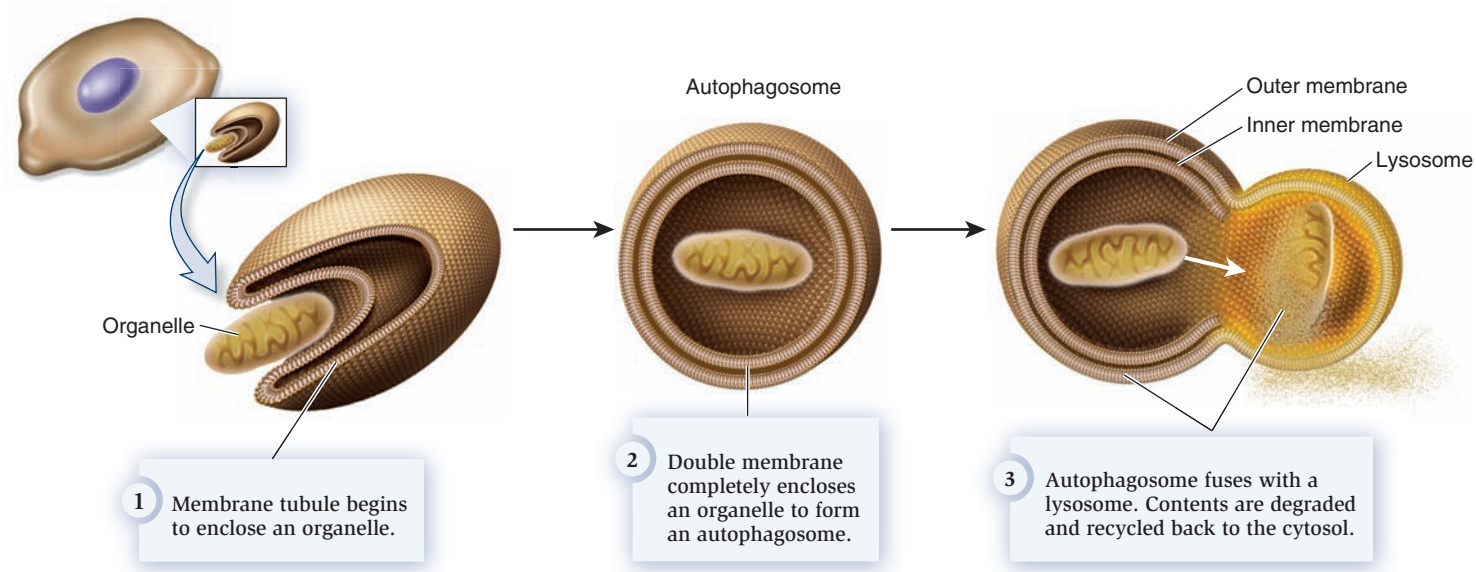

Figure 6.15 **Autophagy.**

material, such as a worn-out organelle, becomes enclosed in a double membrane (**Figure 6.15**). This double membrane is formed from a tubule that elongates and eventually wraps around the organelle to form an **autophagosome**. The autophagosome then fuses with one or more lysosomes, and the material inside the autophagosome is digested. The small molecules released from this digestion are recycled back into the cytosol.

Summary of Key Concepts

6.1 Energy and Chemical Reactions

- The fate of a chemical reaction is determined by its direction and rate.
- Energy, the ability to promote change or do work, exists in many forms. According to the first law of thermodynamics, energy cannot be created or destroyed, but it can be converted from one form to another. The second law of thermodynamics states that energy interconversions involve an increase in entropy (Figures 6.1, 6.2, Table 6.1).
- Free energy is the amount of available energy that can be used to promote change or do work. Spontaneous or exergonic reactions, which release free energy, have a negative free-energy change, whereas endergonic reactions have a positive change (Figure 6.3).
- Chemical reactions proceed until they reach a state of chemical equilibrium, where the rate of formation of products equals the rate of formation of reactants.
- Exergonic reactions, such as the hydrolysis of ATP, are commonly coupled to cellular processes that would otherwise be endergonic.
- Cells continuously synthesize ATP from ADP and P_i and then hydrolyze it to drive endergonic reactions. Estimates from genome analysis indicate that over 20% of all proteins bind ATP (Table 6.2, Figure 6.4).

6.2 Enzymes and Ribozymes

- Enzymes are proteins that speed up the rate of a chemical reaction by lowering the activation energy (E_A) needed to achieve a transition state (Figure 6.5).
- Enzymes recognize reactant molecules, also called substrates, with a high specificity. Conformational changes cause substrates to bind more tightly to enzymes, called induced fit (Figure 6.6).
- Each enzyme-catalyzed reaction exhibits a maximal velocity (V_{max}). The K_M is the substrate concentration at which the velocity of the chemical reaction is half of the V_{max} value. Competitive inhibitors raise the apparent K_M for the substrate, whereas noncompetitive inhibitors lower the V_{max} (Figure 6.7).
- Enzyme function may be affected by a variety of other factors, including prosthetic groups, cofactors, coenzymes, temperature, and pH (Figure 6.8).
- Altman and colleagues discovered that the RNA subunit within RNase P is a ribozyme, an RNA molecule that catalyzes a chemical reaction. Other ribozymes play key roles in the cell (Figures 6.9, 6.10, Table 6.3).

6.3 Overview of Metabolism

- Metabolism is the sum of the chemical reactions in a living organism. Metabolic pathways consist of chemical reactions that occur in steps and are catalyzed by specific enzymes (Figure 6.11).
- Catabolic reactions involve the breakdown of larger molecules into smaller ones. These reactions recycle organic molecules that are used as building blocks to make new molecules. The organic molecules are also broken down to make energy intermediates such as ATP.
- Some chemical reactions are redox reactions in which electrons are transferred from one molecule to another. These can be used to make energy intermediates such as NADH (Figure 6.12).
- Anabolic reactions require an input of energy to synthesize larger molecules and macromolecules.

- Metabolic pathways are controlled by gene regulation, cellular regulation, and biochemical regulation. An example of biochemical regulation is feedback inhibition. The enzyme that catalyzes the rate-limiting step in a pathway is often the target of cellular or biochemical regulation (Figure 6.13).

6.4 Recycling of Organic Molecules

- Recycling of organic molecules saves a great deal of energy for living organisms.
- Proteins in eukaryotes and archaea are degraded by proteasomes (Figure 6.14).
- Lysosomes digest intracellular material through the process of autophagy (Figure 6.15).

Assess and Discuss

Test Yourself

1. Reactions that release free energy are
   a. exergonic.
   b. spontaneous.
   c. endergonic.
   d. endothermic.
   e. both a and b.
2. Enzymes speed up reactions by
   a. providing chemical energy to fuel a reaction.
   b. lowering the activation energy necessary to initiate the reaction.
   c. causing an endergonic reaction to become an exergonic reaction.
   d. substituting for one of the reactants necessary for the reaction.
   e. none of the above.
3. For the idealized reaction $aA + bB \rightleftharpoons cC + dD$, suppose that the equilibrium constant, K_{eq}, is 0.01. If the starting concentrations for A, B, C, and D are 1 M each, what would you predict will happen based on the value of K_{eq}?
   a. The forward reaction is favored.
   b. The reverse reaction is favored.
   c. The forward reaction is fast.
   d. The reverse reaction is fast.
   e. Both b and d are correct.
4. Researchers analyzed a cell extract—a mixture of molecules isolated from cells—and studied a chemical reaction in which a carbohydrate was broken down into smaller molecules. When they added a protease to the cell extract, they discovered that the protease greatly inhibited the rate of the reaction. Based on this observation, you could conclude that the reaction is
   a. exergonic.
   b. endergonic.
   c. catalyzed by an enzyme.
   d. catalyzed by a ribozyme.
   e. Both b and c are true of this reaction.
5. In biological systems, ATP functions by
   a. providing the energy to drive endergonic reactions.
   b. acting as an enzyme and lowering the activation energy of certain reactions.
   c. adjusting the pH of solutions to maintain optimal conditions for enzyme activity.
   d. regulating the speed at which endergonic reactions proceed.
   e. interacting with enzymes as a cofactor to stimulate chemical reactions.
6. In a chemical reaction, NADH is converted to $NAD^+ + H^+$. We say that NADH has been
   a. reduced.
   b. phosphorylated.
   c. oxidized.
   d. decarboxylated.
   e. methylated.
7. Currently, scientists are identifying proteins that use ATP as an energy source by
   a. determining whether those proteins function in anabolic or catabolic reactions.
   b. determining if the protein has a known ATP-binding site.
   c. predicting the free energy necessary for the protein to function.
   d. determining if the protein has an ATP synthase subunit.
   e. all of the above.
8. For a particular chemical reaction, an inhibitor raises the K_M but does not affect the V_{max}. This inhibitor
   a. is a competitive inhibitor.
   b. is a noncompetitive inhibitor.
   c. binds to the active site of the enzyme.
   d. binds to an allosteric site of the enzyme.
   e. is a competitive inhibitor and binds to the active site of the enzyme.
9. Which of the following is (are) key benefits of catabolic reactions?
   a. Recycling of organic building blocks
   b. Breakdown of organic molecules to obtain energy
   c. Synthesis of important polymers, such as polypeptides
   d. All of the above
   e. a and b only
10. Autophagy provides a way for cells to
    a. degrade entire organelles and recycle their components.
    b. control the level of ATP.
    c. engulf bacterial cells.
    d. export unwanted organelles out of the cell.
    e. inhibit the first enzyme in a metabolic pathway.

Conceptual Questions

1. With regard to rate and direction, discuss the differences between endergonic and exergonic reactions.
2. Describe the mechanism and purpose of feedback inhibition in a metabolic pathway.
3. A principle of biology is that *living organisms use energy*. Discuss how the recycling of amino acids and nucleotides is energy efficient.

Collaborative Questions

1. Living cells are highly ordered units, yet the universe is heading toward higher entropy. Discuss how life can maintain its order in spite of the second law of thermodynamics. Are we defying this law?
2. What is the advantage of using ATP as a common energy source? Another way of asking this question is, "Why does ATP provide an advantage over using a bunch of different food molecules?" For example, instead of just having a Na^+/K^+-ATPase in a cell, why not have many different ion pumps, each driven by a different food molecule, like a Na^+/K^+-glucosase (a pump that uses glucose), a Na^+/K^+-sucrase (a pump that uses sucrose), a Na^+/K^+-fatty acidase (a pump that uses fatty acids), and so on?

Cellular Respiration and Fermentation

7

Physical endurance. Conditioned athletes, like these marathon runners, metabolize organic molecules such as glucose very efficiently.

CHAPTER OUTLINE

7.1 Overview of Cellular Respiration

Summary of Key Concepts
Assess and Discuss

Carmen became inspired while watching the 2008 Summer Olympics and set a personal goal to run a marathon—a distance of 42.2 kilometers, or 26.2 miles. Although she was active in volleyball and downhill skiing in high school, she had never attempted distance running. At first, running an entire mile was pure torture. She was out of breath, overheated, and unhappy, to say the least. However, she became committed to endurance training and within a few weeks discovered that running a mile was a "piece of cake." Two years later, Carmen participated in her first marathon and finished with a time of 4 hours and 11 minutes—not bad for someone who had previously struggled to run a single mile!

How had Carmen's training allowed her to achieve this goal? Perhaps the biggest factor is that the training had altered the metabolism in her leg muscles. For example, the network of small blood vessels supplying oxygen to her leg muscles became more extensive, providing more efficient delivery of oxygen and removal of wastes. Second, her muscle cells developed more mitochondria. Recall from Chapter 4 that the primary role of mitochondria is to make ATP, which is used as a source of energy. With these changes, Carmen's leg muscles were better able to break down organic molecules in her food and utilize them to make ATP.

The cells in Carmen's leg muscles had become more efficient at **cellular respiration**, which comprises the metabolic reactions that a cell uses to get energy from food molecules and release waste products. When we eat food, we are using much of that food for energy. People often speak of "burning calories." Although metabolism does generate some heat, the chemical reactions that take place in the cells of living organisms are uniquely different from those that occur, say, in a fire. When wood is burned, the reaction produces enormous amounts of heat in a short period of time—the reaction lacks control. In contrast, the metabolism that occurs in living cells is extremely controlled. The food molecules from which we harvest energy give up that energy in a very restrained manner rather than all at once, as in a fire. An underlying theme in metabolism is the remarkable control that cells possess when they coordinate chemical reactions. A key emphasis of this chapter is how cells use the energy stored within the chemical bonds of organic molecules.

We will begin by surveying a group of chemical reactions that accomplish the breakdown of carbohydrates, namely, the sugar glucose. As you will learn, cells carry out an intricate series of reactions so that glucose can be "burned" in a very controlled fashion when oxygen is available. We will then examine how cells use organic molecules in the absence of oxygen via processes known as anaerobic respiration and fermentation.

7.1 Overview of Cellular Respiration

Learning Outcome:

1. List and briefly describe the four metabolic pathways that are needed to break down glucose to CO_2 and H_2O.

Cellular respiration is a process by which living cells obtain energy from organic molecules and release waste products. A primary aim of cellular respiration is to make adenosine triphosphate, or ATP.

When oxygen (O_2) is used, this process is termed **aerobic respiration**. During aerobic respiration, O_2 is consumed, and carbon dioxide (CO_2) is released via the oxidation of organic molecules. When we breathe, we inhale the oxygen needed for aerobic respiration and exhale CO_2, a by-product of the process. For this reason, the term respiration has a second meaning, which is the act of breathing.

Different types of organic molecules, such as carbohydrates, proteins, and fats, are used as energy sources to drive aerobic respiration. In this chapter, we will largely focus on the use of glucose as an energy source for cellular respiration.

$$\underset{\text{(Glucose)}}{C_6H_{12}O_6} + 6\,O_2 \rightarrow 6\,CO_2 + 6\,H_2O$$

$$\Delta G = -685 \text{ kcal/mol}$$

We will focus on the breakdown of glucose in a eukaryotic cell in the presence of oxygen. Certain covalent bonds within glucose store a large amount of chemical potential energy. When glucose is broken down via oxidation, ultimately to CO_2 and water, a tremendous amount of free energy is released (−685 kcal/mol). Some of the energy is lost as heat, but much of it is used to make three energy intermediates: ATP, NADH, and $FADH_2$. This process involves four metabolic pathways: (1) glycolysis, (2) the breakdown of pyruvate, (3) the citric acid cycle, and (4) oxidative phosphorylation (**Figure 7.1**):

1. **Glycolysis:** In glycolysis, glucose (a compound with six carbon atoms) is broken down to two pyruvate molecules (with three carbons each), producing a net energy yield of two ATP molecules and two NADH molecules. The two ATP are synthesized via **substrate-level phosphorylation**, which occurs when an enzyme directly transfers a phosphate from an organic molecule to ADP. In eukaryotes, glycolysis occurs in the cytosol.

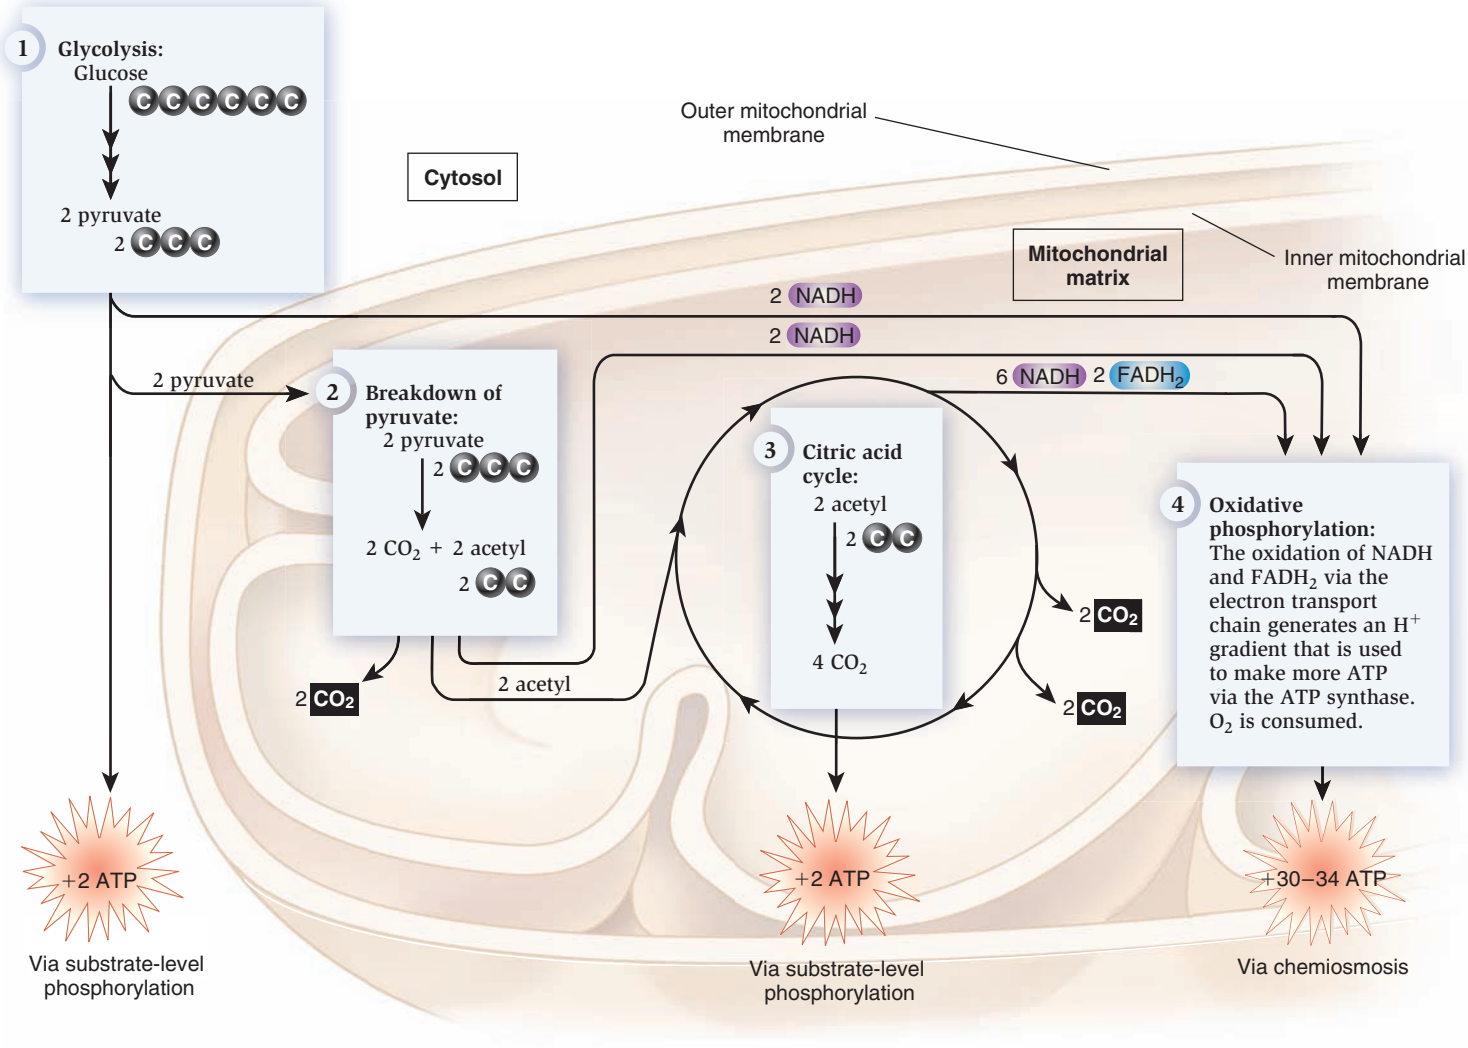

Figure 7.1 **An overview of cellular respiration.** The 30–34 ATP molecules produced via chemiosmosis is the maximum number possible. As described later in this chapter, mitochondria may use NADH, $FADH_2$, and the H^+ gradient for purposes other than ATP synthesis.

BIOLOGY PRINCIPLE **Living organisms use energy.** Molecules such as glucose store a large amount of energy. The breakdown of glucose is used to make energy intermediates, such as ATP molecules, which drive many types of cellular processes.

2. **Breakdown of pyruvate:** The two pyruvate molecules enter the mitochondrial matrix, where each one is broken down to an acetyl group (with two carbons each) and one CO_2 molecule. For each pyruvate broken down via oxidation, one NADH molecule is made by the reduction of NAD^+.
3. **Citric acid cycle:** Each acetyl group is incorporated into an organic molecule, which is later oxidized to liberate two CO_2 molecules. One ATP, three NADH, and one $FADH_2$ are made in this process. Because there are two acetyl groups (one from each pyruvate), the total yield is four CO_2, two ATP via substrate-level phosphorylation, six NADH, and two $FADH_2$. This process occurs in the mitochondrial matrix.
4. **Oxidative phosphorylation:** The NADH and $FADH_2$ made in the three previous stages contain high-energy electrons that can be readily transferred in a redox reaction to other molecules. Once removed from NADH or $FADH_2$, these high-energy electrons release some energy, and through an electron transport chain, that energy is harnessed to produce an H^+ electrochemical gradient. In **chemiosmosis**, energy stored in the H^+ electrochemical gradient is used to synthesize ATP from ADP and P_i. The overall process of electron transport and ATP synthesis is called oxidative phosphorylation because NADH or $FADH_2$ have been oxidized and ADP has become phosphorylated to make ATP. Approximately 30–34 ATP molecules are made via oxidative phosphorylation.

In eukaryotes, oxidation phosphorylation occurs along the **cristae**, which are invaginations of the inner mitochondrial membrane. The invaginations greatly increase the surface area of the inner membrane and thereby increase the amount of ATP that can be made. In bacteria and archaea, oxidative phosphorylation occurs along the plasma membrane.

7.2 Glycolysis

Learning Outcomes:

1. Outline the three phases of glycolysis and the net products.
2. Describe the series of enzymatic reactions that constitute glycolysis.
3. Explain the underlying basis for the use of positron-emission tomography to detect cancer.

Thus far, we have examined the general features of the four metabolic pathways that are involved in the breakdown of glucose. We will now turn our attention to a more detailed understanding of the pathways for glucose metabolism, beginning with glycolysis.

Glycolysis Is a Metabolic Pathway That Breaks Down Glucose to Pyruvate

Glycolysis (from the Greek *glykos*, meaning sweet, and *lysis*, meaning splitting) involves the breakdown of glucose, a simple sugar, into two molecules of a compound called pyruvate. This process can occur in the presence of oxygen, that is, under aerobic conditions, and it can also occur in the absence of oxygen. During the 1930s, the efforts of several German biochemists, including Gustav Embden, Otto Meyerhof, and Jacob Parnas, determined that glycolysis involves 10 steps, each one catalyzed by a different enzyme. The elucidation of these steps was a major achievement in the field of **biochemistry**—the study of the chemistry of living organisms. Researchers have since discovered that glycolysis is the common pathway for glucose breakdown in bacteria, archaea, and eukaryotes. Remarkably, the steps of glycolysis are virtually identical in nearly all living species, suggesting that glycolysis arose very early in the evolution of life on our planet.

The 10 steps of glycolysis can be grouped into three phases (**Figure 7.2**).

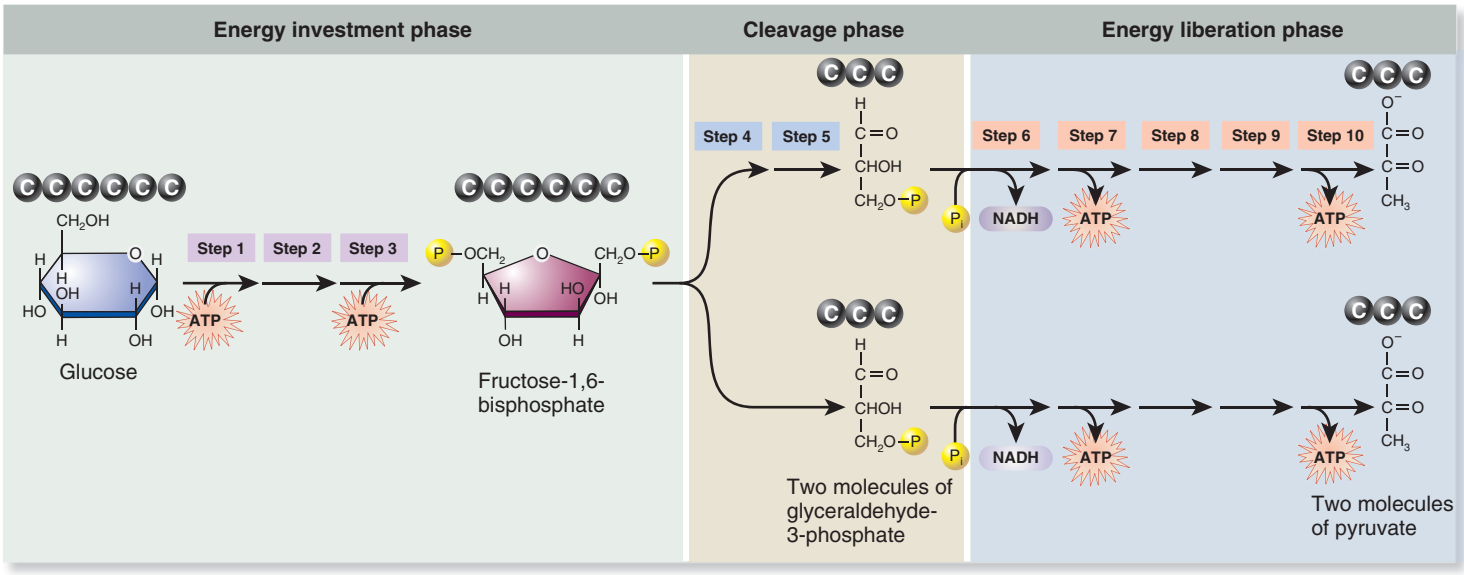

Figure 7.2 Overview of glycolysis.

Concept Check: *Explain why the three phases are named the energy investment phase, the cleavage phase, and the energy liberation phase.*

BioConnections: *Look ahead to Table 44.1. With regard to oxygen needs, what is an advantage of glycolytic muscle fibers?*

- The first phase (steps 1–3) involves an energy investment. Two ATP molecules are hydrolyzed, and the phosphates from those ATP molecules are attached to glucose, which is converted to fructose-1,6-bisphosphate. The energy investment phase raises the free energy of glucose, thereby allowing later reactions to be exergonic.
- The cleavage phase (steps 4–5) breaks this six-carbon molecule into two molecules of glyceraldehyde-3-phosphate.
- The energy liberation phase (steps 6–10) produces four ATP, two NADH, and two molecules of pyruvate. Because two molecules of ATP are used in the energy investment phase, the net yield is two molecules of ATP.

Figure 7.3 describes the details of the 10 reactions of glycolysis. The net reaction of glycolysis is as follows:

$$\underset{\text{Glucose}}{C_6H_{12}O_6} + 2\,NAD^+ + 2\,ADP^{2-} + 2\,P_i^{2-} \rightarrow$$

$$2\,\underset{\text{Pyruvate}}{CH_3(C{=}O)COO^-} + 2\,H^+ + 2\,NADH + 2\,ATP^{4-} + 2\,H_2O$$

Regulation of Glycolysis How do cells control glycolysis? The rate of glycolysis is regulated by the availability of substrates, such as glucose, and by feedback inhibition. A key control point involves the enzyme phosphofructokinase, which catalyzes the third step in glycolysis, the step believed to be the slowest, or rate-limiting, step. When a cell has a sufficient amount of ATP, feedback inhibition occurs. At high concentrations, ATP binds to an allosteric site in phosphofructokinase, causing a conformational change that renders the enzyme functionally inactive. This prevents the further breakdown of glucose and thereby inhibits the overproduction of ATP.

BIO TIPS **THE QUESTION** *During the process of glycolysis, glucose is broken down into two pyruvate molecules. As shown in Figure 7.3, this metabolic pathway consists of 10 consecutive chemical reactions. Describe the three major phases of glycolysis.*

TOPIC ***What topic in biology does this question address?*** The topic is glycolysis. More specifically, the question asks you to describe the three major phases of this process.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** In the question, you are reminded that glycolysis consists of 10 consecutive chemical reactions. From your understanding of the topic, you may remember that different types of chemical reactions are occurring.

PROBLEM-SOLVING STRATEGY ***Sort out the steps in a complicated process.*** To solve this problem, it may be helpful to examine the process in a step-by-step manner to identify the key events.

ANSWER *First phase: During steps 1–3 of glycolysis, ATP is used to phosphorylate two different sites in the glucose molecule. This stage is called the energy investment phase because ATP is used to fuel the process. The energy investment phase prepares the glucose molecule for the next two phases.*

Second phase: During steps 4 and 5, glucose is cleaved into two three-carbon molecules, and then one of those is isomerized to glyceraldehyde-3-phosphate. This phase is called the cleavage phase because a six-carbon molecule has been split (cleaved) into two three-carbon molecules.

Third phase: During steps 6–10, ATP and NADH are made, which are energy intermediate molecules. ATP is made by substrate-level phosphorylation, in which a phosphate is removed from 1,3-bisphosphoglycerate or phosphoenol-pyruvate and directly transferred to ADP. NADH is made when glyceraldehyde-3-phosphate is oxidized. This last phase is called the energy liberation phase because energy that was stored in organic molecules was released (liberated) and used to make energy intermediates (ATP and NADH).

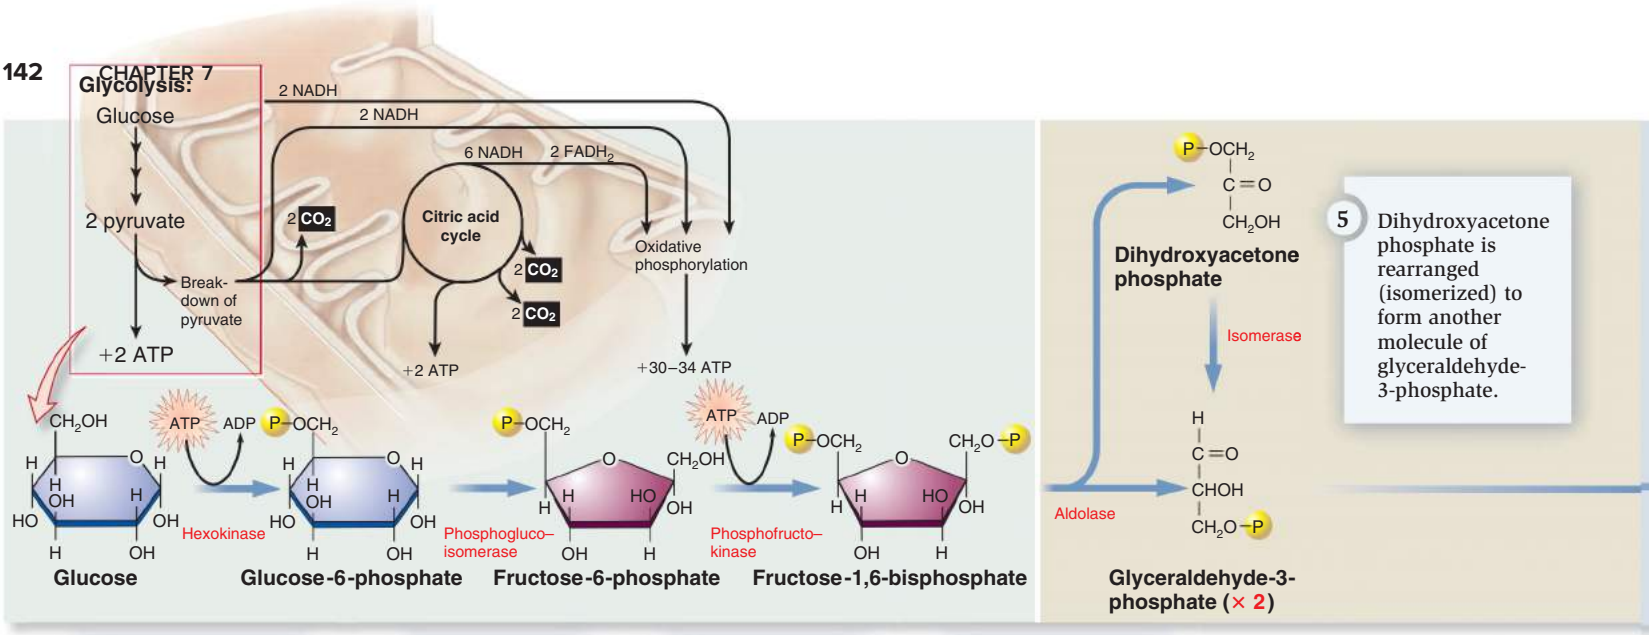
Genomes & Proteomes Connection

Cancer Cells Usually Exhibit High Levels of Glycolysis

In 1931, the German physiologist Otto Warburg discovered that certain cancer cells preferentially use glycolysis for ATP production, in contrast to healthy cells, which mainly generate ATP from oxidative phosphorylation. This phenomenon, termed the Warburg effect, is very common among different types of tumors. The Warburg effect is the basis for the detection of cancer via a procedure called positron-emission tomography (PET, see Figure 2.6). In this technique, patients are injected with a radioactive glucose analogue called [^{18}F]-fluorodeoxyglucose (FDG). FDG is taken up by high-glucose-using cells such as cancer cells. The scanner detects regions of the body that accumulate high amounts of FDG, which are visualized as bright spots on the PET scan.

Figure 7.4 shows a PET scan of a patient with lung cancer. The bright regions next to the arrows are tumors that show abnormally high levels of glycolysis. This result occurred because the genome found in cancer cells exhibits an increased expression of genes that encode enzymes involved with glycolysis. Research has shown that the enzymes of glycolysis are overexpressed in approximately 80% of all types of cancer, including lung, skin, colon, liver, pancreatic, breast, ovarian, and prostate cancers. The three enzymes of glycolysis whose overexpression is most commonly associated with cancer are glyceraldehyde-3-phosphate dehydrogenase, enolase, and pyruvate kinase (shown in Figure 7.3). In many cancers, all 10 glycolytic enzymes are overexpressed!

How does the overexpression of glycolytic enzymes affect tumor growth? While the genetic changes associated with tumor growth are complex, researchers have speculated that an increase in glycolysis favors the growth of tumors due to changes in oxygen levels. As a tumor grows, the internal regions of the tumor tend to become hypoxic, or deficient in oxygen. The hypoxic state inside



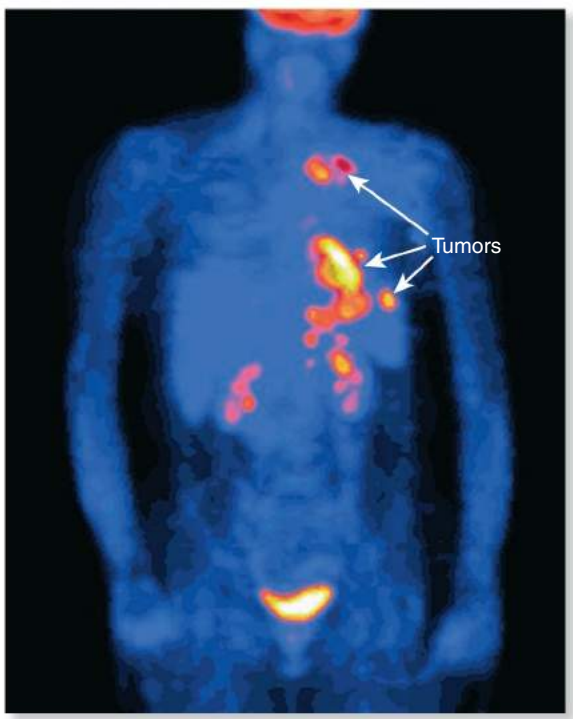


Figure 7.3 A detailed look at the steps of glycolysis. The pathway begins with a six-carbon molecule (glucose) that is broken down into two molecules that contain three carbons each. The notation **x 2** in the figure indicates that two of these three-carbon molecules are produced from each glucose molecule.

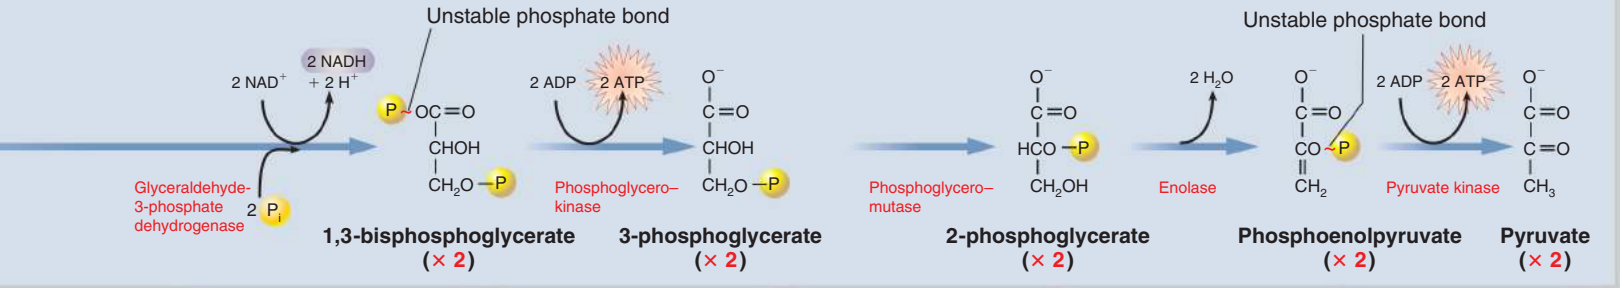
BIOLOGY PRINCIPLE Living organisms maintain homeostasis. To maintain a relatively constant level of ATP in the cytosol, the activity of phosphofructokinase is controlled by feedback inhibition. A high level of ATP inhibits its function.



Concept Check: *Which of these organic molecules donate a phosphate group to ADP during substrate-level phosphorylation?*

a tumor may contribute to the overexpression of glycolytic genes and lead to a higher level of glycolytic enzymes within the cancer cells. This favors glycolysis as a means of making ATP, because it does not require oxygen. Making ATP via glycolysis is an advantage to cancer cells, because such cells would have trouble making ATP via oxidative phosphorylation, which requires oxygen. Based on these findings, some current research is aimed at discovering drugs that inhibit glycolysis in cancer cells as a way to prevent their growth.

Figure 7.4 A PET scan of a patient with lung cancer. The bright regions in the lungs are tumors (see arrows). The brain, which is not cancerous in this patient, appears bright because it performs high levels of glucose metabolism. Also, the kidneys and bladder appear bright because they filter and accumulate FDG. (Note: FDG is taken up by cells and converted to FDG-phosphate by hexokinase, the first enzyme in glycolysis. However, because FDG lacks an —OH group, it is not metabolized further. Therefore, FDG-phosphate accumulates in metabolically active cells.)

BioConnections: *Look back at Figure 2.6. Why is FDG radiolabeled?*

6 Glyceraldehyde-3-phosphate is oxidized to 1,3-bisphosphoglycerate. NADH is produced. In 1,3-bisphosphoglycerate, the phosphate group in the upper left is destabilized, meaning that the bond will break in a highly exergonic reaction.

7 A phosphate is removed from 1,3-bisphosphoglycerate to form 3-phosphoglycerate. The removed phosphate is transferred to ADP to make ATP via substrate-level phosphorylation.

8 The phosphate group in 3-phosphoglycerate is moved to a new location, creating 2-phosphoglycerate.

9 A water molecule is removed from 2-phosphoglycerate to form phosphoenol-pyruvate. In phosphoenol-pyruvate, the phosphate group is destabilized, meaning that the bond will break in a highly exergonic reaction.

10 A phosphate is removed from phosphoenolpyruvate to form pyruvate. The removed phosphate is transferred to ADP to make ATP via substrate-level phosphorylation.

7.3 Breakdown of Pyruvate

Learning Outcome:

1. Describe how pyruvate is broken down and acetyl CoA is made.

In eukaryotes, glycolysis produces pyruvate in the cytosol, which is then transported into the mitochondria. Once in the mitochondrial matrix, pyruvate molecules are broken down (oxidized) by an enzyme complex called pyruvate dehydrogenase (**Figure 7.5**). A molecule of CO_2 is removed from pyruvate, and the remaining acetyl group is attached to an organic molecule called coenzyme A (CoA) to produce acetyl CoA. (In chemical equations, CoA is depicted as CoA—SH to emphasize how the SH group participates in the chemical reaction.) During this process, two high-energy electrons are removed from pyruvate and transferred to NAD^+ and together with H^+ produce a molecule of NADH. For each pyruvate, the net reaction is as follows:

$$\underset{\text{Pyruvate}}{^-O{-}C(=O){-}C(=O){-}CH_3} + \underset{\text{CoA}}{CoA{-}SH} + NAD^+ \rightarrow$$

$$\underset{\text{Acetyl CoA}}{CoA{-}S{-}C(=O){-}CH_3} + CO_2 + NADH$$

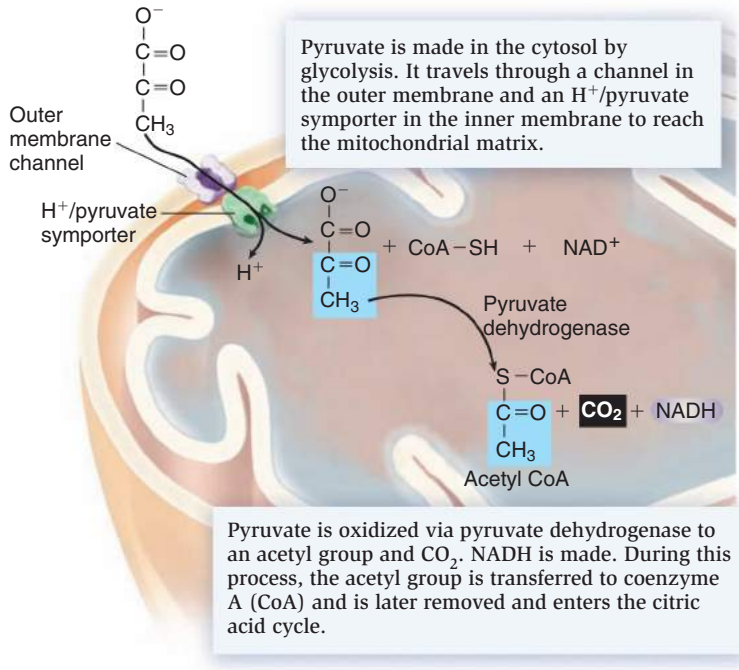


Figure 7.5 Breakdown of pyruvate and the attachment of an acetyl group to CoA.

The acetyl group is attached to CoA via a covalent bond to a sulfur atom. The hydrolysis of this bond releases a large amount of free energy, making it possible for the acetyl group to be transferred to other organic molecules. As described next, the acetyl group is removed from CoA and enters the citric acid cycle.

7.4 Citric Acid Cycle

Learning Outcomes:

1. Explain the concept of a metabolic cycle.
2. Describe how an acetyl group enters the citric acid cycle, and list the net products of the cycle.

The third stage of glucose metabolism introduces a new concept, that of a **metabolic cycle**. During a metabolic cycle, particular molecules enter the cycle while others leave. The process is cyclical because it involves a series of organic molecules that are regenerated with each turn of the cycle. The idea of a metabolic cycle was first proposed in the early 1930s by the German biochemist Hans Krebs. While studying carbohydrate metabolism in England, he analyzed cell extracts from pigeon muscle and determined that citric acid and other organic molecules participated in a cycle that resulted in the breakdown of carbohydrates to carbon dioxide. This cycle is called the **citric acid cycle**, or the Krebs cycle, in honor of Krebs, who was awarded the Nobel Prize in Physiology or Medicine in 1953.

An overview of the citric acid cycle is shown in **Figure 7.6**. In the first step of the cycle, the acetyl group (with two carbons) is removed from acetyl CoA and attached to oxaloacetate (with four carbons) to form citrate (with six carbons), also called citric acid. Then, in a series of several steps, two CO_2 molecules are released. As this occurs, three molecules of NADH, one molecule of $FADH_2$, and one molecule of guanine triphosphate (GTP) are made. The GTP, which is made via substrate-level phosphorylation, is used to make ATP. After a total of eight steps, oxaloacetate is regenerated so the cycle can begin again, provided acetyl CoA is available. **Figure 7.7** shows a more detailed view of the citric acid cycle. For each acetyl group attached to CoA, the net reaction of the citric acid cycle is as follows:

$$\text{Acetyl-CoA} + 2\,H_2O + 3\,NAD^+ + FAD + GDP^{2-} + P_i^{2-} \rightarrow$$

$$\text{CoA—SH} + 2\,CO_2 + 3\,NADH + FADH_2 + GTP^{4-} + 3\,H^+$$

Regulation of the Citric Acid Cycle How is the citric acid cycle controlled? The rate of the cycle is largely regulated by the

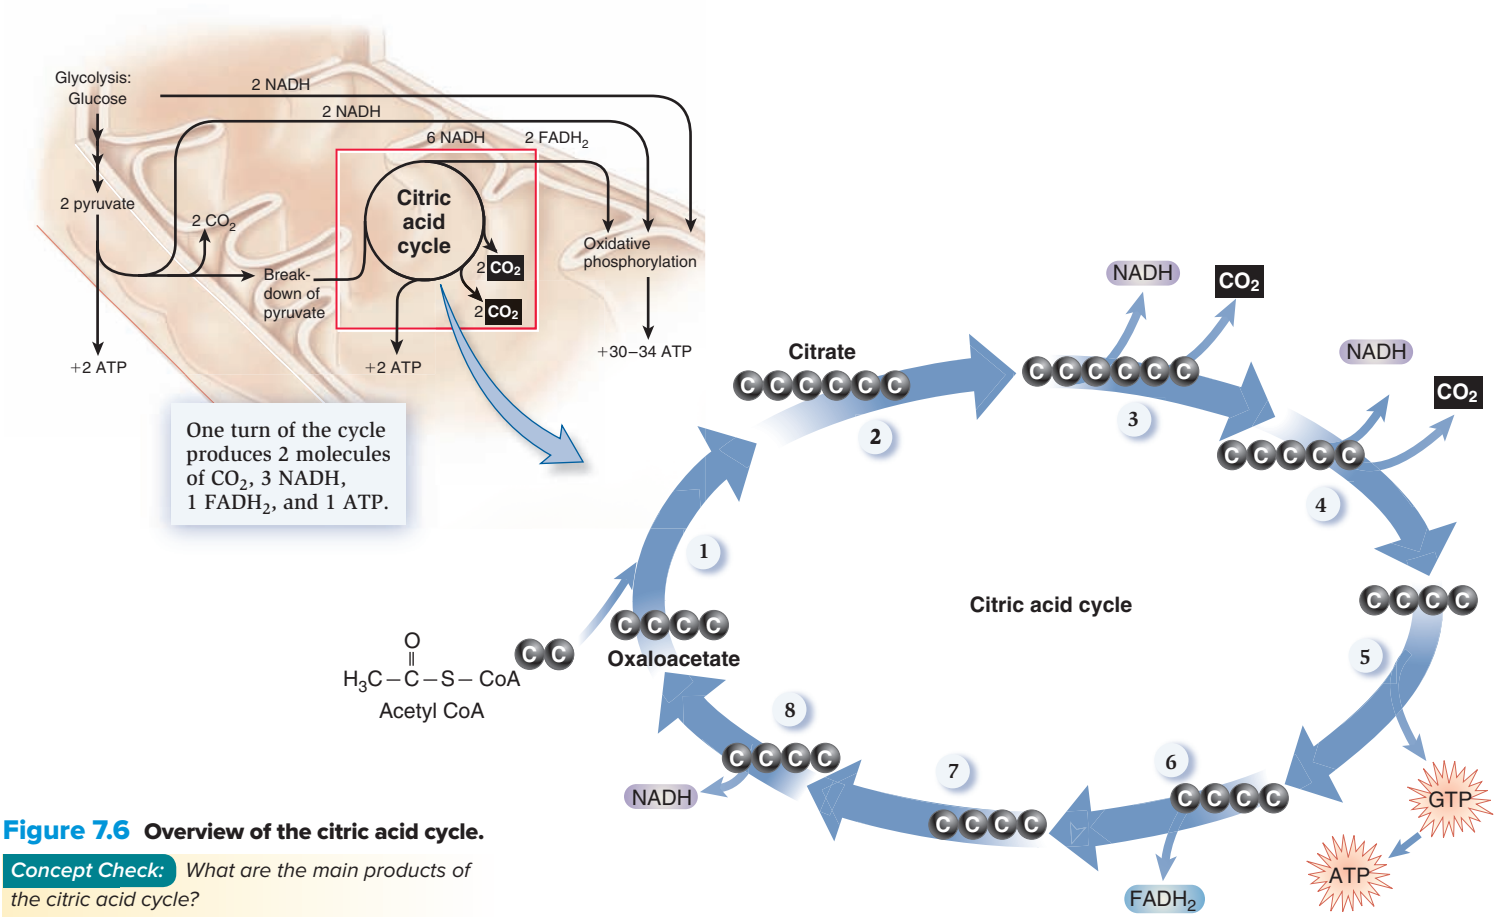

Figure 7.6 Overview of the citric acid cycle.

Concept Check: *What are the main products of the citric acid cycle?*

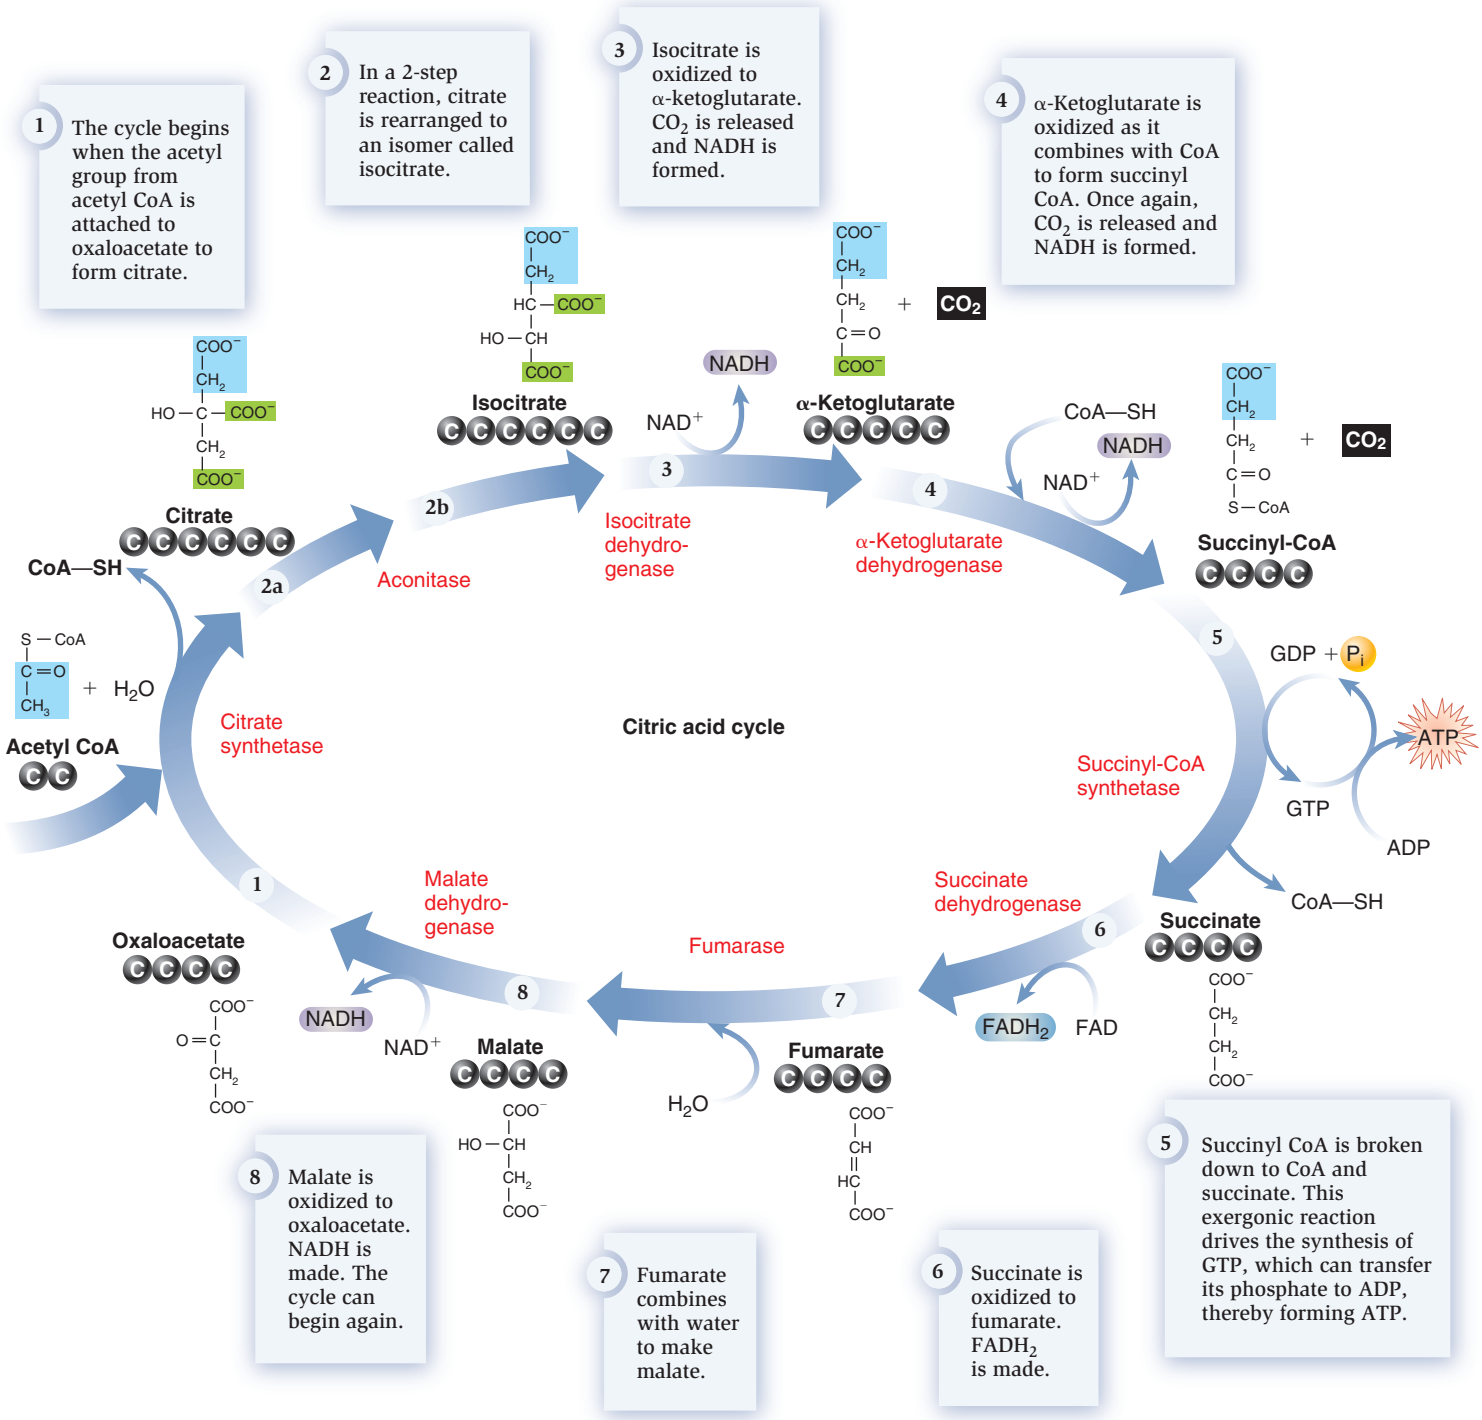

Figure 7.7 A detailed look at the steps of the citric acid cycle. The blue boxes indicate the location of the acetyl group, which is oxidized at step 6. (It is oxidized again in step 8.) The green boxes indicate the locations where CO_2 molecules are removed.

availability of substrates, such as acetyl-CoA and NAD^+, and by feedback inhibition. The three steps in the cycle that are highly exergonic are those catalyzed by citrate synthase, isocitrate dehydrogenase, and α-ketoglutarate dehydrogenase (see Figure 7.7). Each of these steps is rate-limiting under certain circumstances, and the way that each enzyme is regulated varies among different species. Let's consider an example. In mammals, NADH and ATP act as feedback inhibitors of isocitrate dehydrogenase, whereas NAD^+ and ADP act as activators. In this way, the citric acid cycle is inhibited when NADH and ATP levels are high, but it is stimulated when NAD^+ and ADP levels are high.

7.5 Overview of Oxidative Phosphorylation

Learning Outcomes:

1. Describe how the electron transport chain produces an H^+ electrochemical gradient.
2. Explain how ATP synthase utilizes the H^+ electrochemical gradient to synthesize ATP.

During the first three stages of glucose metabolism, the oxidation of glucose yields 6 molecules of CO_2, 4 molecules of ATP, 10 molecules of NADH, and 2 molecules of $FADH_2$. Let's now consider how high-energy electrons are removed from NADH and $FADH_2$ to produce more ATP. This process is called **oxidative phosphorylation**. As mentioned earlier, the term refers to the observation that electrons are removed from NADH and $FADH_2$, that is, these molecules are oxidized, and ATP is made by the phosphorylation of ADP. In this section, we will examine how the oxidative process involves the electron transport chain, whereas the phosphorylation of ADP occurs via ATP synthase.

The Electron Transport Chain Establishes an Electrochemical Gradient

The **electron transport chain (ETC)** consists of a group of protein complexes and small organic molecules embedded in the inner mitochondrial membrane. These components are referred to as an electron transport chain because electrons are passed from one component to the next in a series of redox reactions (**Figure 7.8**). Most members of the ETC are protein complexes (designated I–IV) that have prosthetic groups, which are small molecules permanently attached to the surface of proteins that aid in their function. For example, cytochrome oxidase contains two prosthetic groups, each with an iron atom. The iron in each prosthetic group can readily accept and release an electron. One member of the ETC, ubiquinone (Q), is not a protein. Rather, ubiquinone is a small organic molecule that can accept and release an electron.

The red line in Figure 7.8 shows the path of electron flow. The electrons, which are originally located on NADH or $FADH_2$, are transferred to components of the ETC. The electron path is a series of redox reactions in which electrons are transferred to components with increasingly higher electronegativity. At the end of the chain is oxygen, which is the most electronegative component and the final electron acceptor. The ETC is also called the **respiratory chain** because the oxygen we breathe is used in this process.

NADH and $FADH_2$ donate their electrons at different points in the ETC. Two high-energy electrons from NADH are first transferred one at a time to NADH dehydrogenase (complex I). They are then transferred to ubiquinone (Q), cytochrome b-c_1 (complex III), cytochrome c, and cytochrome oxidase (complex IV). The final electron acceptor is O_2. By comparison, $FADH_2$ transfers electrons to succinate reductase (complex II), then to ubiquinone, and the rest of the chain.

As shown in Figure 7.8, some of the energy that is released during the movement of electrons is used to pump H^+ across the inner mitochondrial membrane into the intermembrane space. This active transport establishes a large **H^+ electrochemical gradient**, in which the concentration of H^+ is higher outside of the matrix than inside and an excess of positive charge exists outside the matrix.

Chemicals that inhibit the flow of electrons along the ETC can have lethal effects. For example, one component of the ETC, cytochrome oxidase (complex IV), is inhibited by cyanide. The deadly effects of cyanide ingestion occur because the ETC is shut down, preventing cells from making enough ATP for survival.

ATP Synthase Makes ATP via Chemiosmosis

The second event of oxidative phosphorylation is the synthesis of ATP by an enzyme called **ATP synthase**. The H^+ electrochemical gradient across the inner mitochondrial membrane is a source of potential energy. How is this energy used? The passive flow of H^+ back into the matrix is an exergonic process. The lipid bilayer is relatively impermeable to H^+. However, H^+ can pass through the membrane-embedded portion of ATP synthase. This enzyme harnesses some of the free energy that is released as the H^+ ions flow through its membrane-embedded region to synthesize ATP from ADP and P_i (see bottom of Figure 7.8). This is an example of an energy conversion: Energy in the form of an H^+ gradient is converted to chemical potential energy in ATP. The synthesis of ATP that occurs as a result of pushing H^+ across a membrane is called chemiosmosis (from the Greek *osmos*, meaning to push). The theory behind it was proposed by Peter Mitchell, a British biochemist who was awarded the Nobel Prize in Chemistry in 1978.

Regulation of Oxidative Phosphorylation How is oxidative phosphorylation controlled? This process is regulated by a variety of factors, including the availability of ETC substrates, such as NADH and O_2, and by the ATP/ADP ratio. When ATP levels are high, ATP binds to a subunit of cytochrome oxidase (complex IV), thereby inhibiting the ETC and oxidative phosphorylation. By comparison, when ADP levels are high, oxidative phosphorylation is stimulated for two reasons: (1) ADP stimulates cytochrome oxidase, and (2) ADP is a substrate that is used (with P_i) to make ATP.

NADH Oxidation Makes a Large Proportion of a Cell's ATP

For each molecule of NADH that is oxidized and each molecule of ATP that is made, the two chemical reactions of oxidative phosphorylation can be represented as follows:

$$NADH + H^+ + {}^1/_2\, O_2 \rightarrow NAD^+ + H_2O$$

$$ADP^{2-} + P_i^{2-} \rightarrow ATP^{4-} + H_2O$$

When we add up the maximal amount of ATP that can be made by oxidative phosphorylation, most researchers agree it is in the range of 30–34 ATP molecules for each glucose molecule that is broken down to CO_2 and H_2O. However, the maximum amount of ATP is rarely achieved, for two reasons.

- First, although 10 NADH and 2 $FADH_2$ are available to make the H^+ electrochemical gradient across the inner mitochondrial membrane, a cell uses some of these molecules for anabolic

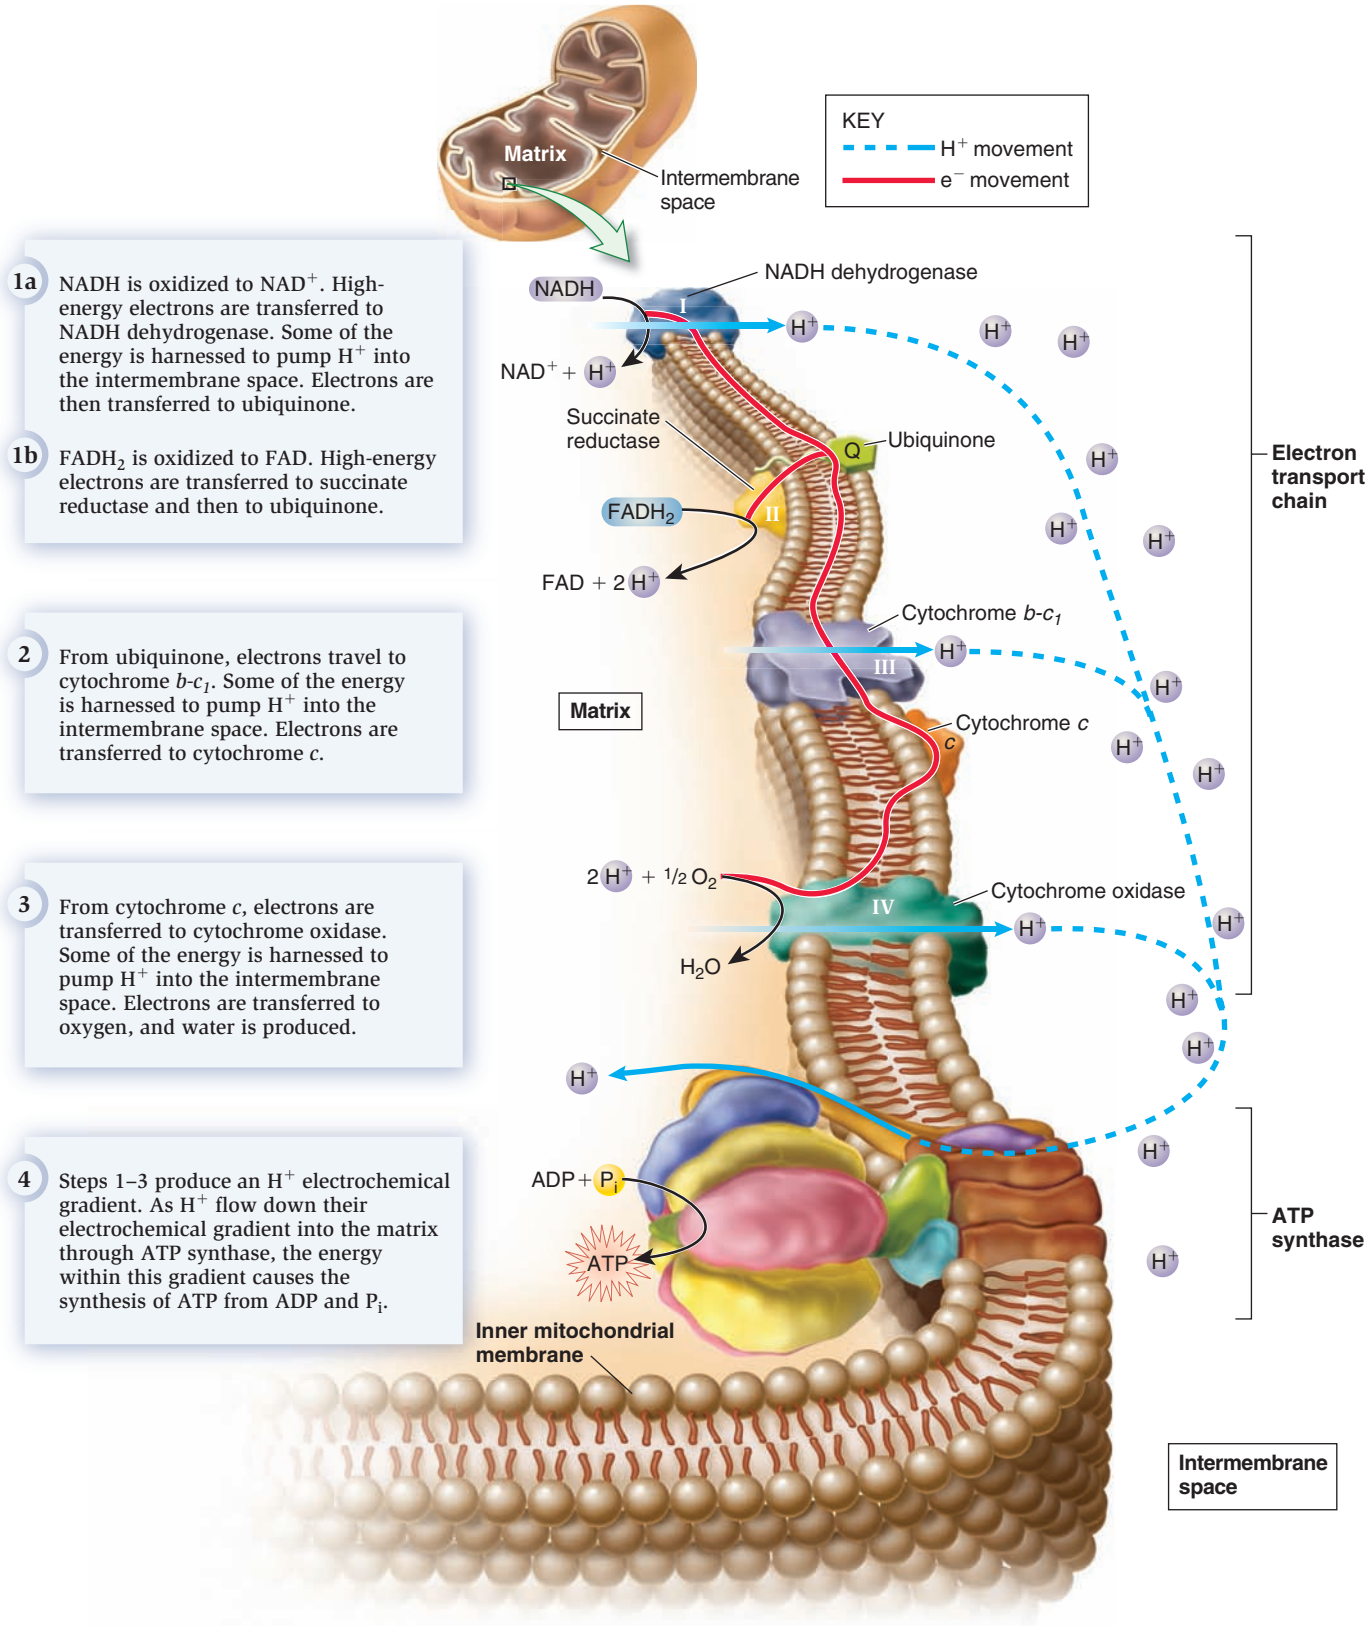

Figure 7.8 **Oxidative phosphorylation.** This process consists of two distinct events: the electron transport chain (ETC) and ATP synthesis. The ETC oxidizes, or removes electrons from, NADH or $FADH_2$ and pumps H^+ across the inner mitochondrial membrane. In chemiosmosis, ATP synthase uses the energy in this H^+ electrochemical gradient to phosphorylate ADP, thereby synthesizing ATP. In this figure, an oxygen atom is represented as $^1/_2\,O_2$ to emphasize that the ETC reduces oxygen when it is in its molecular (O_2) form.

Concept Check: *Can you explain the name of cytochrome oxidase?*

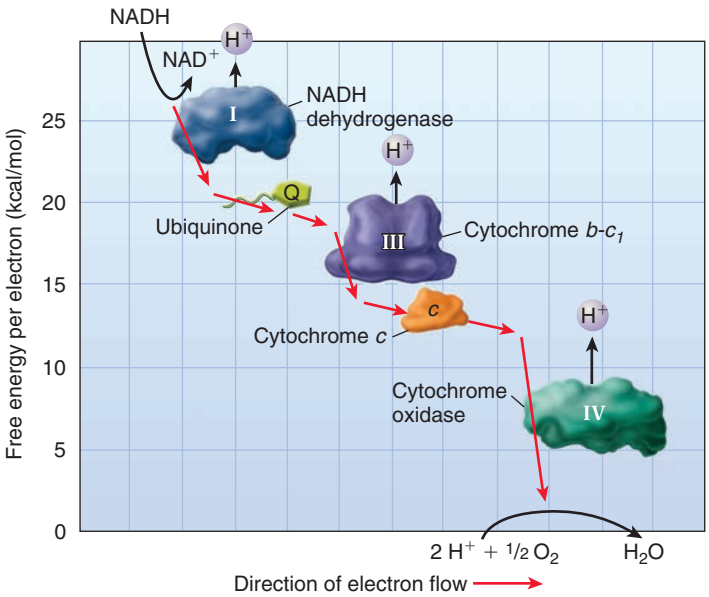

Figure 7.9 The relationship between free energy and electron movement along the electron transport chain. As electrons hop from one site to another along the electron transport chain, they release energy. Some of this energy is harnessed to pump H^+ across the inner mitochondrial membrane. The total energy released by a single electron is approximately −25 kcal/mol.

pathways. For example, NADH is used in the synthesis of organic molecules such as glycerol (a component of phospholipids).

- Second, the mitochondrion may use some of the H^+ electrochemical gradient for other purposes. For example, the gradient is used for the uptake of pyruvate into the matrix via an H^+/pyruvate symporter (see Figure 7.5).

Therefore, the actual amount of ATP synthesis is usually a little less than the maximum number of 30 to 34. Even so, when we compare the amount of ATP that is made by glycolysis (2), the citric acid cycle (2), and oxidative phosphorylation (30–34), we see that oxidative phosphorylation provides a cell with a much greater capacity to make ATP.

Free-Energy Changes Drive Oxidative Phosphorylation and Other Stages of Glucose Breakdown

Thus far, we have considered (1) glycolysis, (2) the breakdown of pyruvate, (3) the citric acid cycle, and (4) oxidative phosphorylation. All four of these stages are ultimately driven by the oxidation of glucose, which is a highly exergonic process that releases free energy. However, the energy is not released in one big blast, as in an explosion, but rather in small step-wise increments. Releasing the energy in small increments allows cells to couple the breakdown of glucose with useful chemical processes. For example, as we saw earlier in this chapter, the breakdown of glucose to pyruvate is coupled to the synthesis of ATP. **Figure 7.9** shows how free energy is released as electrons move along the electron transport chain. At particular points along the ETC, some of the energy is used to pump H^+ across the inner mitochondrial membrane and establish an H^+ electrochemical gradient. This gradient is then used to power ATP synthesis.

7.6 A Closer Look at ATP Synthase

Learning Outcomes:

1. **SciSKILLS »** Analyze the results of an experiment that verified that ATP synthase uses an H^+ electrochemical gradient to make ATP.
2. Describe the structure of ATP synthase.
3. Explain how a series of three conformational changes enables ATP synthase to make ATP.
4. **SciSKILLS »** Analyze the results of an experiment that showed that ATP synthase is a rotary machine.

The structure and function of ATP synthase are particularly intriguing and have received much attention over the past few decades. In this section, we will consider experiments that were aimed at elucidating this enzyme's function and explore, in greater depth, how it is able to synthesize ATP.

Experiments with Purified Proteins in Membrane Vesicles Verified Chemiosmosis

To show experimentally that ATP synthase directly uses an H^+ electrochemical gradient to make ATP, researchers needed to purify the enzyme and study its function in vitro. In 1974, Efraim Racker and Walther Stoeckenius purified ATP synthase and another protein called bacteriorhodopsin, which is found in certain species of archaea. Previous research had shown that bacteriorhodopsin is a light-driven H^+ pump. Racker and Stoeckenius took both purified proteins and inserted them into membrane vesicles (**Figure 7.10**). ATP synthase was oriented so its ATP-synthesizing region was on the outside of the vesicles. Bacteriorhodopsin was oriented so it would pump H^+ into the vesicles. The researchers added ADP and P_i on the outside of the vesicles. In the dark, no ATP was made. However, when they shone light on the vesicles, a substantial amount of ATP was synthesized. Because bacteriorhodopsin was already known to be a light-driven H^+ pump, these results convinced the researchers that ATP synthase uses an H^+ electrochemical gradient as an energy source to make ATP.

ATP Synthase Is a Rotary Machine That Makes ATP as It Spins

ATP synthase is a rotary machine (**Figure 7.11**). The region embedded in the membrane is composed of three types of subunits called *a*, *b*, and *c*. Approximately 10–14 *c* subunits form a ring in the membrane. One *a* subunit is bound to this ring, and two *b* subunits are attached to the *a* subunit and protrude from the membrane. The nonmembrane-embedded subunits are designated with Greek letters. One ε and one γ subunit bind to the ring of *c* subunits. The γ subunit forms a long stalk that pokes into the center of another ring of three α and three β subunits. Each β subunit contains a catalytic site where ATP is made. Finally, the δ subunit forms a connection between the ring of α and β subunits and the two *b* subunits.

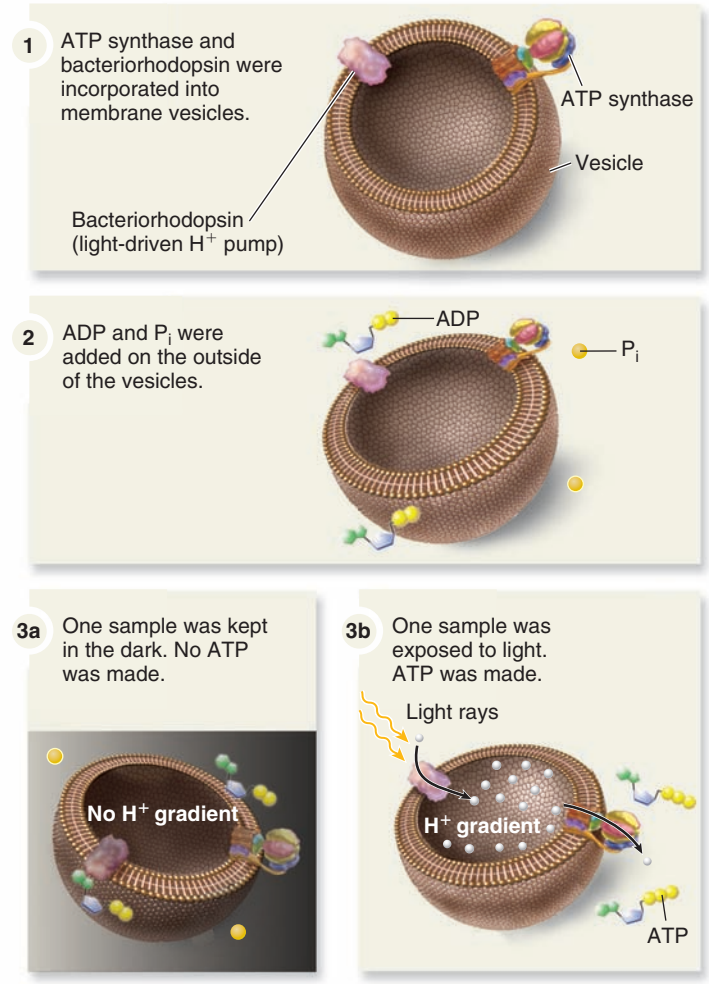

Figure 7.10 The Racker and Stoeckenius experiment. In this experiment, bacteriorhodopsin pumped H^+ into vesicles, and the resulting H^+ electrochemical gradient was sufficient to drive ATP synthesis via ATP synthase.

Concept Check: *Is the functioning of the electron transport chain always needed to make ATP via ATP synthase?*

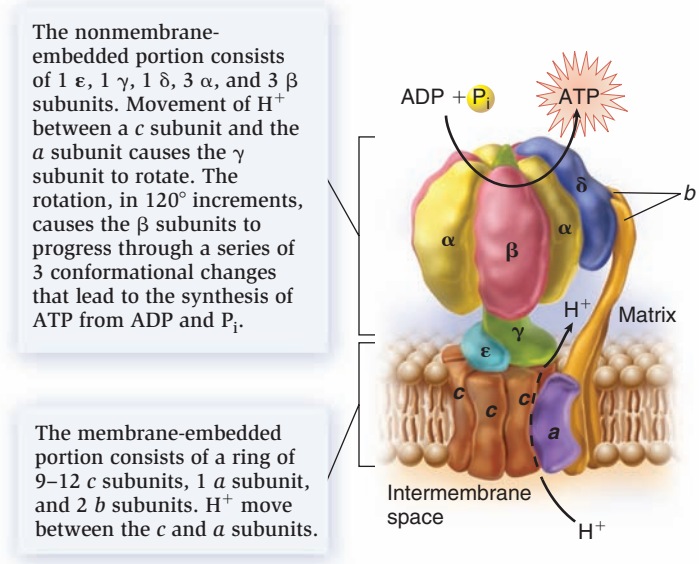

Figure 7.11 The subunit structure and function of ATP synthase.

Concept Check: *If the β subunit in the front center of this figure is in conformation 2, what are the conformations of the β subunit on the left and the β subunit on the back right?*

When hydrogen ions pass through a narrow channel at the contact site between a *c* subunit and the *a* subunit, a conformational change causes the γ subunit to turn clockwise (when viewed from the intermembrane space). Each time the γ subunit turns 120°, it changes its contacts with the three β subunits, which, in turn, causes the β subunits to change their conformations. How do these conformational changes promote ATP synthesis? The answer is that the conformational changes occur in a way that favors ATP synthesis and release. As shown in **Figure 7.12**, the conformational changes in the β subunits happen in the following order:

- Conformation 1: ADP and P_i bind with good affinity.
- Conformation 2: ADP and P_i bind so tightly that ATP is made.
- Conformation 3: ATP (and ADP and P_i) bind very weakly, and ATP is released.

Each time the γ subunit turns 120°, it causes a β subunit to change to the next conformation. After conformation 3, a 120° turn

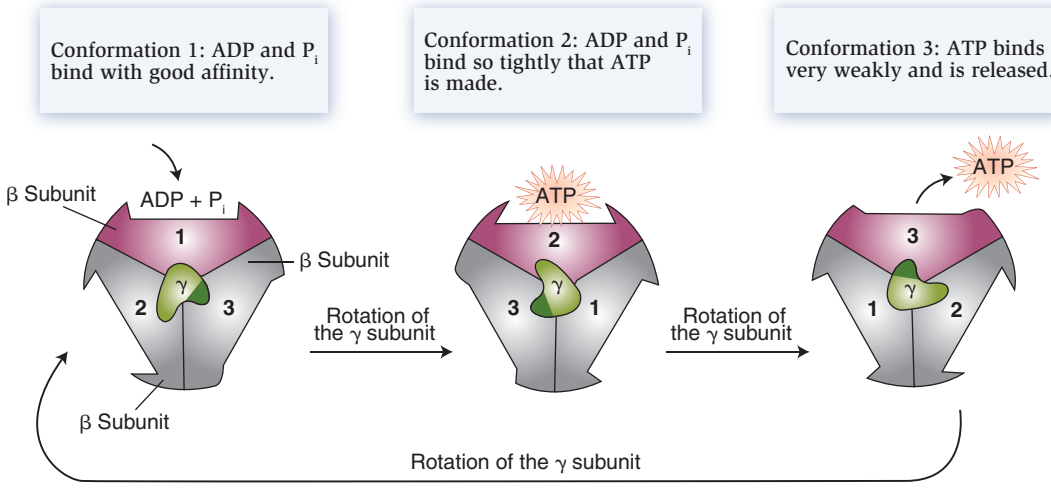

Figure 7.12 Conformational changes that result in ATP synthesis. For simplicity, the α subunits are not shown. This drawing emphasizes the conformational changes in the β subunit shown at the top. The other two β subunits also make ATP. All three β subunits alternate between three conformational states due to their interactions with the γ subunit.

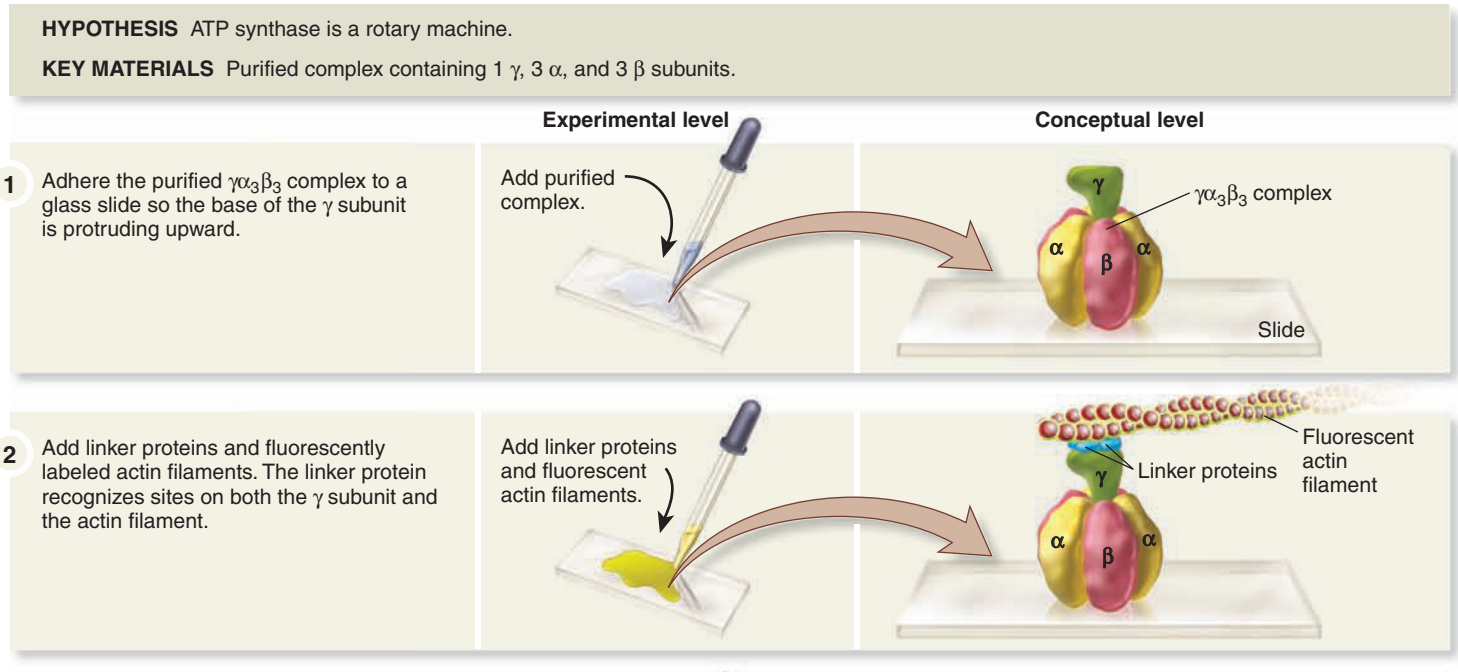
by the γ subunit returns a β subunit back to conformation 1, and the cycle of ATP synthesis can begin again. Because ATP synthase has three β subunits, each subunit is in a different conformation at any given time.

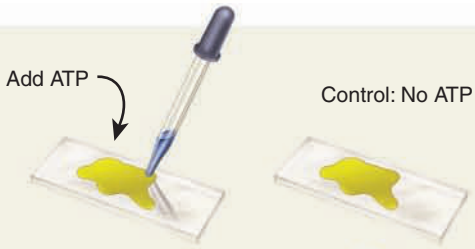
American biochemist Paul Boyer proposed the concept of a rotary machine in the late 1970s. In his model, the three β subunits alternate between three conformations, as described previously. Boyer's original idea was met with great skepticism, because the concept that part of an enzyme could spin was very novel, to say the least. In 1994, British biochemist John Walker and his colleagues determined the three-dimensional structure of the nonmembrane-embedded portion of the ATP synthase. The structure revealed that each of the three β subunits had a different conformation—one with ADP bound, one with ATP bound, and one without any nucleotide bound. This result supported Boyer's model. In 1997, Boyer and Walker shared the Nobel Prize in Chemistry for their work on ATP synthase. As described next in the Feature Investigation, other researchers subsequently visualized the rotation of the γ subunit.

Feature Investigation | Yoshida and Kinosita Demonstrated That the γ Subunit of ATP Synthase Spins



In 1997, Japanese biochemist Masasuke Yoshida, physicist Kazuhiko Kinosita, and colleagues set out to experimentally visualize the rotary nature of ATP synthase (**Figure 7.13**). The membrane-embedded region of ATP synthase can be separated from the rest of the protein by treatment of mitochondrial membranes with a high concentration of salt, releasing the portion of the protein containing one γ, three α, and three β subunits. The researchers adhered the $\gamma\alpha_3\beta_3$ complex to a glass slide so the γ subunit was protruding upward. Because the γ subunit is too small to be seen with a light microscope, the rotation of the γ subunit cannot be visualized directly. To circumvent this problem, the researchers attached a large, fluorescently labeled actin filament to the γ subunit via linker proteins. The fluorescently labeled actin filament is very long compared to the γ subunit and can be readily seen with a fluorescence microscope.

Because the membrane-embedded portion of the protein is missing, you may be wondering how the researchers could get the γ subunit to rotate. The answer is they added ATP. Although the normal function of the ATP synthase is to make ATP, it can also hydrolyze ATP. In other words, ATP synthase can run backwards. As shown in the data in Figure 7.13, when the researchers added ATP, they observed that the fluorescently labeled actin filament rotated in a counterclockwise direction, which is opposite to the direction that the γ subunit rotates when ATP is synthesized. Actin filaments were observed to rotate for more than 100 revolutions in the presence of ATP. These results convinced the scientific community that ATP synthase is a rotary machine.



Experimental Questions

1. **SciSKILLS** » The components of ATP synthase are too small to be visualized by light microscopy. For the experiment of Figure 7.13, how did the researchers observe the movement of ATP synthase?
2. **SciSKILLS** » In the experiment of Figure 7.13, what observation did the researchers make that indicated ATP synthase is a rotary machine? What was the control of this experiment? What did it indicate?
3. **SciSKILLS** » Were the rotations seen by the researchers in the data of Figure 7.13 in the same direction as expected in the mitochondria during ATP synthesis? Why or why not?

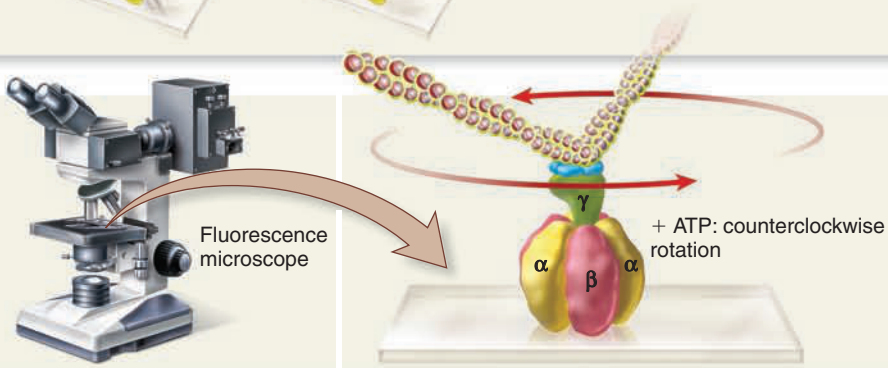


Figure 7.13 Yoshida and Kinosita provide evidence that ATP synthase is a rotary machine.

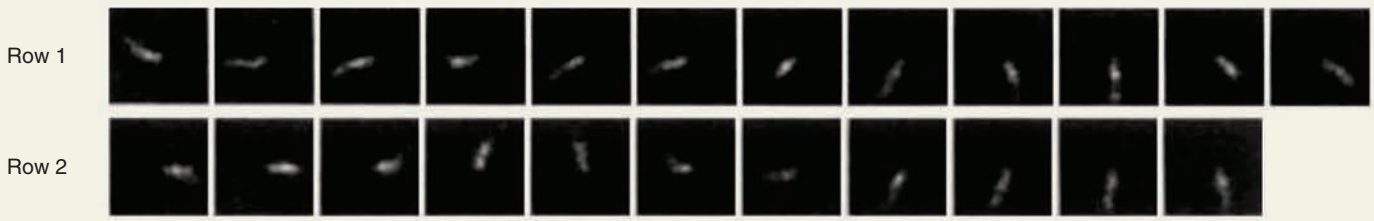
3 Add ATP. As a control, do not add ATP.



4 Observe under a fluorescence microscope. The method of fluorescence microscopy is described in Chapter 4.

5 THE DATA

Results from step 4:

ATP	Rotation
No ATP added	No rotation observed.
ATP added	Rotation was observed as shown below. This is a time-lapse view of the rotation in action.

6 CONCLUSION The γ subunit rotates counterclockwise when ATP is hydrolyzed. It would be expected to rotate clockwise when ATP is synthesized.

7.7 Connections Among Carbohydrate, Protein, and Fat Metabolism

Learning Outcome:

1. Explain how carbohydrate, protein, and fat metabolism are interconnected.

When you eat a meal, it usually contains not only carbohydrates (including glucose) but also proteins and fats. These molecules are broken down by some of the same enzymes involved with glucose metabolism. By using the same pathways for the breakdown of sugars, amino acids, and fats, cellular metabolism is more efficient because the same enzymes are used for the breakdown of different starting molecules.

As shown in **Figure 7.14**, proteins and fats can enter into glycolysis or the citric acid cycle at different points.

- Proteins are first acted on by enzymes, either in digestive juices or within cells, that cleave the bonds connecting individual amino acids. Because the 20 amino acids differ in their side chains, amino acids and their breakdown products can enter at different points in the pathway. Breakdown products of some amino acids can enter at later steps of glycolysis, or an acetyl

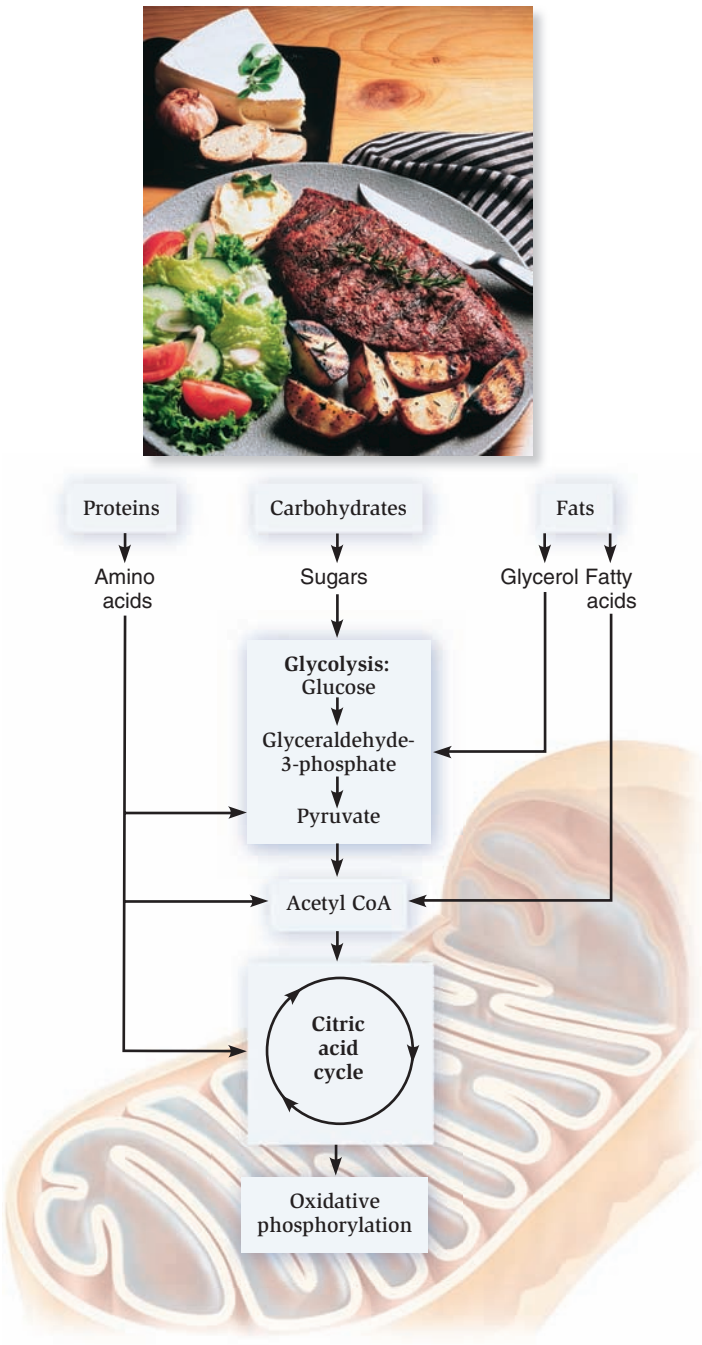

Figure 7.14 Integration of carbohydrate, protein, and fat metabolism. Breakdown products of proteins and fats are used as fuel for cellular respiration, entering the same pathways used to break down carbohydrates.

Concept Check: *What is a cellular advantage of integrating protein, carbohydrate, and fat metabolism?*

group can be removed from certain amino acids and become attached to CoA and then enter the citric acid cycle (see Figure 7.14). Other amino acids are modified and enter the citric acid cycle.

- Fats are typically broken down to glycerol and fatty acids. Glycerol can be modified to glyceraldehyde-3-phosphate and enter glycolysis. Lipid tails can have two carbon acetyl units removed, which bind to CoA and enter the citric acid cycle.

7.8 Anaerobic Respiration and Fermentation

Learning Outcomes:

1. Describe how certain microorganisms make ATP using a final electron acceptor of an electron transport chain that is not oxygen.
2. Explain how muscle and yeast cells use fermentation to synthesize ATP under anaerobic conditions.

Thus far, we have surveyed catabolic pathways that result in the complete breakdown of glucose in the presence of oxygen. Cells also commonly metabolize organic molecules in the absence of oxygen. The term **anaerobic** is used to describe an environment that lacks oxygen. Many bacteria and archaea and some fungi exist in anaerobic environments but still have to oxidize organic molecules to obtain sufficient amounts of energy. Examples include microbes living in your intestinal tract and those living deep in the soil. Similarly, when a person exercises strenuously, the rate of oxygen consumption by muscle cells may greatly exceed the rate of oxygen delivery—particularly at the start of strenuous exercise. Under these conditions, muscle cells become anaerobic and must obtain sufficient energy in the absence of oxygen to maintain their level of activity.

Two different strategies may be used by cells to metabolize organic molecules in the absence of oxygen. One mechanism is to use a substance other than O_2 as the final electron acceptor of an electron transport chain, a process called **anaerobic respiration**. A second approach is to produce ATP only via substrate-level phosphorylation without any net oxidation of organic molecules, a process called **fermentation**. In this section, we will consider examples of both strategies.

Some Microorganisms Carry Out Anaerobic Respiration

At the end of the ETC presented earlier in Figure 7.8, cytochrome oxidase recognizes O_2 and catalyzes its reduction to H_2O. The final electron acceptor of the chain is O_2. Many species of bacteria that live under anaerobic conditions have evolved enzymes that function similarly to cytochrome oxidase but recognize molecules other than O_2 and use them as the final electron acceptor.

For example, under anaerobic conditions *Escherichia coli*, a bacterial species found in your intestinal tract, produces an enzyme called nitrate reductase. This enzyme uses nitrate (NO_3^-) as the final electron acceptor of an electron transport chain. **Figure 7.15** shows a simplified ETC in *E. coli* in which nitrate is the final electron acceptor. In *E. coli* and other bacterial species, the ETC is in the plasma membrane that surrounds the cytoplasm. Electrons travel from NADH to NADH dehydrogenase to ubiquinone (Q) to cytochrome *b* and then to nitrate reductase. At the end of the chain, NO_3^- is converted to nitrite (NO_2^-). This process generates an H^+ electrochemical gradient in three ways. First, NADH dehydrogenase pumps H^+ out of the cytoplasm. Second, ubiquinone picks up H^+ in the cytoplasm and carries it to the other side of the membrane. Third, the reduction of nitrate to nitrite consumes H^+ in the cytoplasm. The generation of an H^+ gradient via these three processes allows *E. coli* cells to make ATP via chemiosmosis under anaerobic conditions.

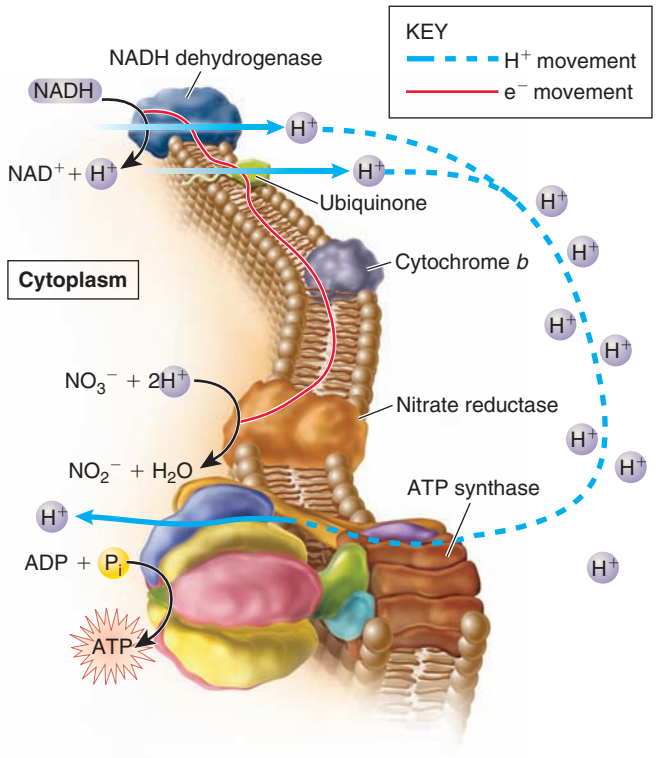

Figure 7.15 An example of anaerobic respiration in *E. coli*. When oxygen is absent, *E. coli* can use nitrate instead of oxygen as the final electron acceptor of an electron transport chain. This generates an H^+ electrochemical gradient that is used to make ATP via chemiosmosis. Note: As shown in this figure, ubiquinone (Q) picks up H^+ on one side of the membrane and deposits it on the other side. A similar event happens during aerobic respiration in mitochondria (see Figure 7.8), except that ubiquinone transfers H^+ to cytochrome *b*-c_1, which pumps it into the intermembrane space.

Fermentation Is the Breakdown of Organic Molecules Without Net Oxidation

Many organisms, including animals and yeast, use only O_2 as the final electron acceptor of their ETCs. When confronted with anaerobic conditions, these organisms must have a different way of producing sufficient ATP. One strategy is to make ATP via glycolysis, which can occur under both anaerobic or aerobic conditions. Under anaerobic conditions, cells do not use the citric acid cycle or the ETC, but make ATP only via glycolysis.

A key issue is that glycolysis requires NAD^+ and generates NADH. Under aerobic conditions, NADH is oxidized to NAD^+ to make more ATP. However, this cannot occur under anaerobic conditions in yeast and animals, and, as a result, NADH builds up and NAD^+ decreases. This is a potential problem for two reasons:

- First, at high concentrations, NADH haphazardly donates its electrons to other molecules and promotes the formation of free radicals, highly reactive chemicals that damage DNA and cellular proteins. For this reason, yeast and animal cells exposed to anaerobic conditions must have a way to remove the excess NADH generated from the breakdown of glucose.
- The second problem is the decrease in NAD^+. Cells need to regenerate NAD^+ to keep glycolysis running and make ATP via substrate-level phosphorylation.

Fermentation in Muscle Cells How do muscle cells cope with the buildup of NADH and decrease in NAD^+? When a muscle is working strenuously and becomes anaerobic, as in high-intensity exercise, the pyruvate from glycolysis is reduced to make lactate. (The uncharged, or protonated, form is called lactic acid.) The electrons to reduce pyruvate are derived from NADH, which is oxidized to NAD^+ (**Figure 7.16a**). Therefore, this process decreases NADH and reduces its potentially harmful effects. It also increases the level of NAD^+, thereby allowing glycolysis to continue. The lactate is secreted from muscle cells. Once sufficient oxygen is restored, the lactate produced during strenuous exercise can be taken up by cells, converted back to pyruvate, and used for energy, or this lactate may be used by the liver and other tissues to make glucose.

Fermentation in Yeast Cells Yeast cells cope with anaerobic conditions differently. During wine making, a yeast cell metabolizes sugar under anaerobic conditions. The pyruvate is broken down to CO_2 and a two-carbon molecule called acetaldehyde. The acetaldehyde is then reduced by NADH to make ethanol, while NADH is oxidized to NAD^+ (**Figure 7.16b**). Similar to lactate production in muscle cells, this decreases NADH and increases NAD^+, thereby preventing the harmful effects of NADH and allowing glycolysis to continue.

The term fermentation is used to describe the breakdown of organic molecules to harness energy without any net oxidation (that is, without any removal of electrons). The pathways of breaking down glucose to lactate or ethanol are examples of fermentation. Although electrons are removed from an organic molecule such as glucose to make pyruvate and NADH, the electrons are donated back to an organic molecule in the production of lactate or ethanol. Therefore, there is no net removal of electrons from an organic molecule. Compared with oxidative phosphorylation, fermentation produces far less ATP, for two reasons. First, glucose is not oxidized completely to CO_2 and H_2O. Second, the NADH made during glycolysis cannot be used to make more ATP. Overall, the complete breakdown of glucose in the presence of oxygen yields 34–38 ATP molecules. By comparison, the anaerobic breakdown of glucose to lactate or ethanol yields only 2 ATP molecules.

Summary of Key Concepts

7.1 Overview of Cellular Respiration

- Cells obtain energy via cellular respiration, which involves the breakdown of organic molecules and the export of waste products.
- The breakdown of glucose occurs in four stages: glycolysis, pyruvate breakdown, citric acid cycle, and oxidative phosphorylation (Figure 7.1).

7.2 Glycolysis

- During glycolysis, which occurs in the cytosol, glucose is split into two molecules of pyruvate, with a net yield of two ATP and

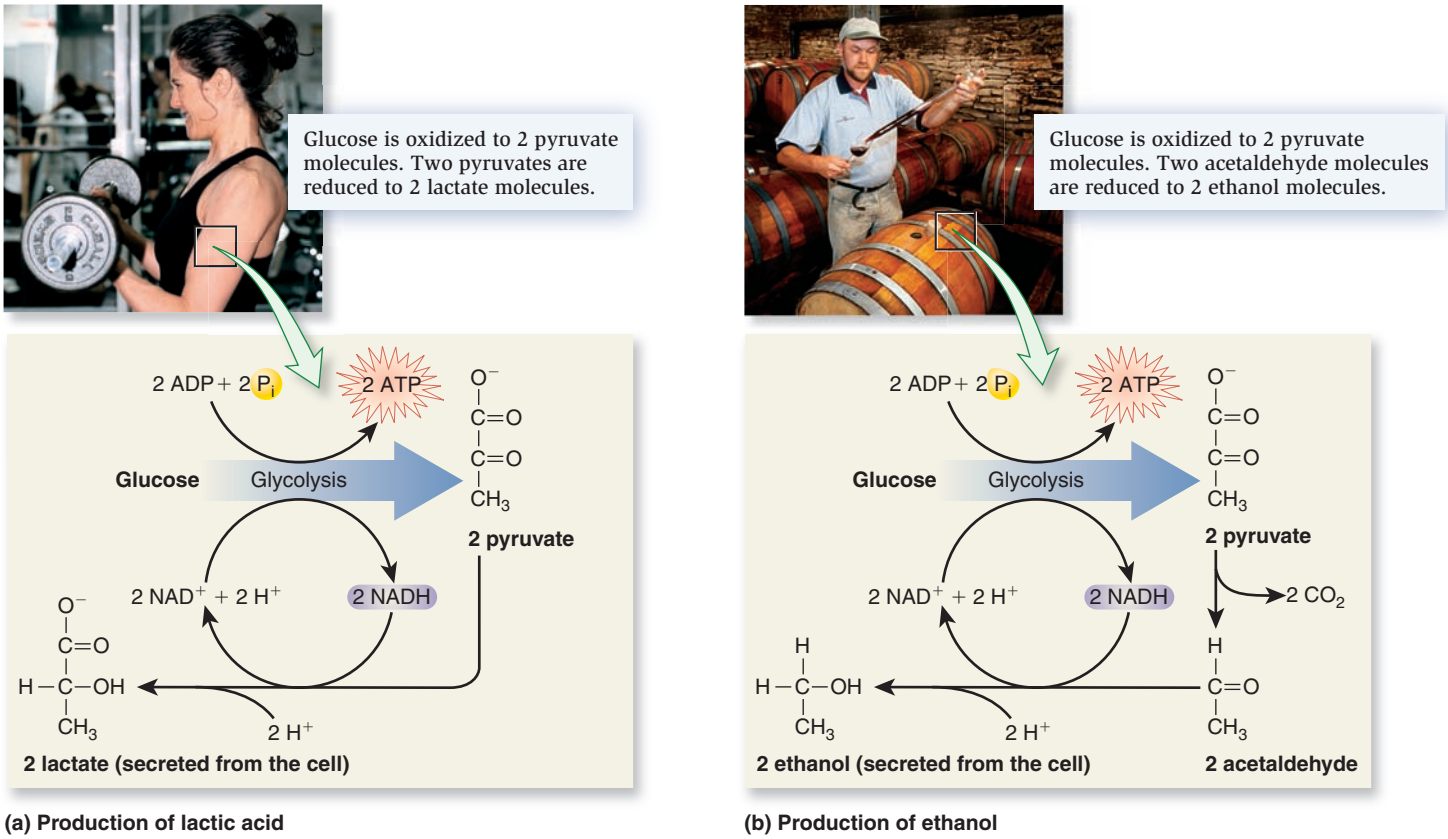

Figure 7.16 Examples of fermentation. In these examples, NADH is produced by the oxidation of an organic molecule, and then the NADH is converted back to NAD^+ when it donates electrons to a different organic molecule such as pyruvate **(a)** or acetaldehyde **(b)**.

BIOLOGY PRINCIPLE Biology affects our society. Fermentation by microorganisms is used in wine making, beer brewing, and bread making.

two NADH. The ATP is made by substrate-level phosphorylation (Figures 7.2, 7.3).

- Cancer cells preferentially carry out glycolysis, which enables the detection of tumors via a procedure called positron-emission tomography (PET) (Figure 7.4).

7.3 Breakdown of Pyruvate

- Pyruvate is broken down to CO_2 and an acetyl group that becomes attached to CoA. NADH is made during this process (Figure 7.5).

7.4 Citric Acid Cycle

- During the citric acid cycle, an acetyl group is removed from acetyl CoA and attached to oxaloacetate to make citrate. In a series of steps, two CO_2 molecules, three NADH, one $FADH_2$, and one ATP are made, after which the cycle begins again (Figures 7.6, 7.7).

7.5 Overview of Oxidative Phosphorylation

- Oxidative phosphorylation involves two events: (1) The electron transport chain (ETC) oxidizes NADH or $FADH_2$ and generates an H^+ electrochemical gradient, and (2) this gradient is used by ATP synthase to make ATP via chemiosmosis (Figures 7.8, 7.9).

7.6 A Closer Look at ATP Synthase

- Racker and Stoeckenius showed that ATP synthase uses an H^+ gradient by reconstituting ATP synthase with a light-driven H^+ pump (Figure 7.10).
- ATP synthase is a rotary machine. The rotation is triggered by the passage of H^+ through a channel between a *c* subunit and the *a* subunit that causes the γ subunit to spin, resulting in three conformational changes in the β subunits that promote ATP synthesis (Figures 7.11, 7.12).
- Yoshida and Kinosita demonstrated rotation of the γ subunit of ATP synthase by attaching a fluorescently labeled actin filament and observing its movement during the hydrolysis of ATP (Figure 7.13).

7.7 Connections Among Carbohydrate, Protein, and Fat Metabolism

- Proteins and fats can enter into glycolysis or the citric acid cycle at different points (Figure 7.14).

7.8 Anaerobic Respiration and Fermentation

- Anaerobic respiration occurs in the absence of oxygen. Certain microorganisms carry out anaerobic respiration in which the final

electron acceptor of the ETC is a substance other than oxygen, such as nitrate (Figure 7.15).

- During fermentation, organic molecules are broken down without any net oxidation (that is, without any net removal of electrons). Examples include lactic acid production in muscle cells and ethanol production in yeast cells (Figure 7.16).

Assess and Discuss

Test Yourself

1. Which of the following pathways occurs in the cytosol?
   a. glycolysis
   b. breakdown of pyruvate to an acetyl group
   c. citric acid cycle
   d. oxidative phosphorylation
   e. all of the above
2. The net products of glycolysis are
   a. 6 CO_2, 4 ATP, and 2 NADH.
   b. 2 pyruvate, 2 ATP, and 2 NADH.
   c. 2 pyruvate, 4 ATP, and 2 NADH.
   d. 2 pyruvate, 2 GTP, and 2 CO_2.
   e. 2 CO_2, 2 ATP, and glucose.
3. During glycolysis, ATP is produced by
   a. oxidative phosphorylation.
   b. substrate-level phosphorylation.
   c. redox reactions.
   d. all of the above.
   e. both a and b.
4. Which organic molecule supplies a two-carbon group to start the citric acid cycle?
   a. ATP
   b. NADH
   c. acetyl CoA
   d. oxaloacetate
   e. both a and b
5. The ability to diagnose tumors using [^{18}F]-fluorodeoxyglucose (FDG) is based on the phenomenon that most types of cancer cells exhibit higher levels of
   a. glycolysis.
   b. pyruvate breakdown.
   c. citric acid metabolism.
   d. oxidative phosphorylation.
   e. all of the above.
6. In the experiment of Racker and Stoeckenius, bacteriorhodopsin was oriented in such a way that it pumped H^+ into a vesicle. Each vesicle actually contained many molecules of bacteriorhodopsin. How would the results have been affected if 50% of the bacteriorhodopsin molecules pumped H^+ into the vesicle and 50% pumped H^+ out of the vesicles?
   a. The same amount of ATP would be made in the presence of light, and no ATP would be made in the dark.
   b. More ATP would be made in the presence of light, and no ATP would be made in the dark.
   c. No ATP would be made in the presence of light, and no ATP would be made in the dark.
   d. No ATP would be made in the presence of light, but some ATP would be made in the dark.
   e. Some ATP would be made in the presence of light, and some ATP would be made in the dark.
7. Certain drugs act as ionophores that cause the mitochondrial membrane to be highly permeable to H^+. How would such drugs affect oxidative phosphorylation?
   a. Movement of electrons down the ETC would be inhibited.
   b. ATP synthesis would be inhibited.
   c. ATP synthesis would be unaffected.
   d. ATP synthesis would be stimulated.
   e. Both a and b are correct.
8. The source of energy that *directly* drives the synthesis of ATP during oxidative phosphorylation is the
   a. oxidation of NADH.
   b. oxidation of glucose.
   c. oxidation of pyruvate.
   d. H^+ gradient.
   e. reduction of O_2.
9. Compared with oxidative phosphorylation in mitochondria, a key difference of anaerobic respiration in bacteria is that
   a. more ATP is made.
   b. ATP is made only via substrate-level phosphorylation.
   c. O_2 is converted to H_2O_2 rather than H_2O.
   d. something other than O_2 acts as a final electron acceptor of the ETC.
   e. b and d.
10. When a muscle becomes anaerobic during strenuous exercise, why is it necessary to convert pyruvate to lactate?
    a. to decrease NAD^+ and increase NADH
    b. to decrease NADH and increase NAD^+
    c. to increase NADH and increase NAD^+
    d. to decrease NADH and decrease NAD^+
    e. to keep oxidative phosphorylation running

Conceptual Questions

1. The electron transport chain is so named because electrons are transported from one component to another. Describe the purpose of the ETC.
2. What causes the rotation of the γ subunit of the ATP synthase? How does this rotation promote ATP synthesis?
3. A principle of biology is that *living organisms maintain homeostasis*. How is glucose breakdown regulated to maintain homeostasis? What would be some potentially harmful consequences if glucose metabolism was not regulated properly?

Collaborative Questions

1. Discuss the advantages and disadvantages of aerobic respiration, anaerobic respiration, and fermentation.
2. Read more about PET scans from other sources. Which types of cancers are most easily detected by this procedure, and which types are not readily detected? Is the ability to detect cancer via a PET scan related to the state of hypoxia?

Photosynthesis

8.2 Reactions That Harness Light Energy
8.3 Molecular Features of Photosystems
8.4 Synthesizing Carbohydrates via the Calvin Cycle
8.5 Variations in Photosynthesis
Summary of Key Concepts
Assess and Discuss

A tropical rain forest in the Amazon. Plant life in tropical rain forests carries out a large amount of the world's photosynthesis and supplies the atmosphere with a sizeable fraction of its oxygen.

Take a deep breath. Nearly all of the oxygen in every breath you take is made by the abundant plant life, algae, and cyanobacteria on Earth. More than 20% of the world's oxygen is produced in the Amazon rain forest in South America alone (see chapter opening photo). Biologists are alarmed about the rate at which such forests are being destroyed by human activities such as logging, mining, and oil extraction. Rain forests once covered 14% of the Earth's land surface, but they now occupy less than 6%. At their current rate of destruction, rain forests may be nearly eliminated in less than 40 years. Such an event may lower the level of oxygen in the atmosphere and thereby have a harmful effect on living organisms on a global scale.

In rain forests and across all of the Earth, the most visible color on land is green. The green color of plants is due to a pigment called chlorophyll. This pigment provides the starting point for the process of **photosynthesis**, in which the energy from light is captured and used to synthesize glucose and other organic molecules. Nearly all living organisms ultimately rely on photosynthesis for their nourishment, either directly or indirectly. Photosynthesis is also responsible for producing the oxygen that makes up a large portion of the Earth's atmosphere. Therefore, all aerobic organisms rely on photosynthesis for cellular respiration.

We begin this chapter with an overview of photosynthesis as it occurs in green plants and algae. We will then explore the two stages of photosynthesis in more detail. In the first stage, called the **light reactions**, light energy is absorbed by chlorophyll and converted to chemical energy in the form of two energy intermediates: ATP and NADPH. During the second stage, known as the **Calvin cycle**, ATP and NADPH are used to drive the synthesis of carbohydrates. We will conclude with a consideration of the variations in photosynthesis that occur in plants existing in hot and dry conditions.

8.1 Overview of Photosynthesis

Learning Outcomes:

1. Write the general equations that represent the process of photosynthesis.
2. Explain how photosynthesis powers the biosphere.
3. Describe the general structure of chloroplasts.
4. Compare and contrast the two phases of photosynthesis: the light reactions and the Calvin cycle.

In the mid-1600s, a Flemish physician, Jan Baptista Van Helmont, conducted an experiment in which he transplanted the shoot of a young willow tree into a bucket of soil and allowed it to grow for 5 years. After this time, the willow tree had added 164 pounds to its original weight, but the soil had lost only 2 ounces. Van Helmont correctly concluded that the willow tree did not get most of its nutrients from the soil. He also hypothesized that the mass of the tree came from the water he had added over the 5 years. This hypothesis was partially correct, but we now know that CO_2 from the air is also a major contributor to the growth and mass of plants.

In the 1770s, Jan Ingenhousz, a Dutch physician, immersed green plants under water and discovered they released bubbles of

oxygen. Ingenhousz determined that sunlight was necessary for oxygen production. During this same period, Jean Senebier, a Swiss botanist, found that CO_2 is required for plant growth. With this accumulating information, Julius von Mayer, a German physicist, proposed in 1845 that plants convert light energy from the Sun into chemical energy.

For the next several decades, plant biologists studied photosynthesis in plants, algae, and bacteria. Researchers discovered that some photosynthetic bacteria use hydrogen sulfide (H_2S) instead of water (H_2O) for photosynthesis, and these organisms release sulfur instead of oxygen. In the 1930s, based on this information, Dutch-American microbiologist Cornelis van Niel proposed a general equation for photosynthesis that applies to plants, algae, and photosynthetic bacteria alike.

$$CO_2 + 2\ H_2A + \text{Light energy} \rightarrow CH_2O + A_2 + H_2O$$

where A is oxygen (O) or sulfur (S) and CH_2O is the general formula for a carbohydrate. This is a redox reaction in which CO_2 is reduced and H_2A is oxidized.

In green plants, A is oxygen and A_2 is a molecule of oxygen that is designated O_2. Therefore, this equation becomes

$$CO_2 + 2\ H_2O + \text{Light energy} \rightarrow CH_2O + O_2 + H_2O$$

When the carbohydrate produced is glucose ($C_6H_{12}O_6$), we multiply each side of the equation by 6 to obtain:

$$6\ CO_2 + 12\ H_2O + \text{Light energy} \rightarrow C_6H_{12}O_6 + 6\ O_2 + 6\ H_2O$$

$$\Delta G = +685 \text{ kcal/mol}$$

In this redox reaction, CO_2 is reduced during the formation of glucose, and H_2O is oxidized during the formation of O_2. Notice that the free-energy change required for the production of 1 mole of glucose from carbon dioxide and water is a whopping +685 kcal/mol! As we learned in Chapter 6, endergonic reactions are driven forward by coupling the reaction with an exergonic process that releases free energy. In this case, the energy from sunlight ultimately drives the synthesis of glucose.

In this section, we will survey the general features of photosynthesis as it occurs in green plants and algae. Later sections will examine the various steps in this process.

Photosynthesis Powers the Biosphere

The term **biosphere** describes the regions on the surface of the Earth and in the atmosphere where living organisms exist. Organisms can be categorized as heterotrophs and autotrophs. **Heterotrophs** must consume food—organic molecules from their environment—to sustain life. Most species of bacteria and protists, as well as all species of fungi and animals, are heterotrophs. By comparison, **autotrophs** sustain themselves by producing organic molecules from inorganic sources such as CO_2 and H_2O. **Photoautotrophs** are autotrophs that use light as a source of energy to make organic molecules. These include green plants, algae, and some bacterial species such as cyanobacteria.

Life in the biosphere is largely driven by the photosynthetic power of green plants, algae, and cyanobacteria. The existence of most species relies on a key energy cycle that involves the interplay between organic molecules (such as glucose) and inorganic molecules, namely, O_2, CO_2, and H_2O (**Figure 8.1**). Photoautotrophs make a large proportion of the Earth's organic molecules via photosynthesis, using light energy, CO_2, and H_2O. During this process, they also produce O_2. To supply their energy needs, both photoautotrophs and heterotrophs metabolize organic molecules via cellular respiration. As described in Chapter 7, cellular respiration generates CO_2 and H_2O and is used to make ATP. The CO_2 is released into the atmosphere and can be reused by photoautotrophs to make more organic molecules such as glucose. In this way, an energy cycle between photosynthesis and cellular respiration sustains life on our planet.

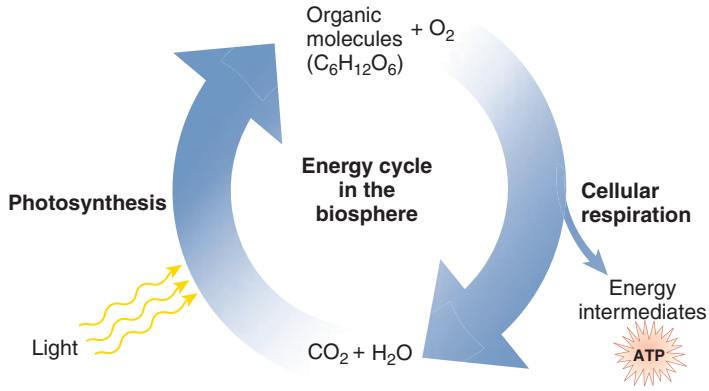

Figure 8.1 An important energy cycle between photosynthesis and cellular respiration. Photosynthesis uses light, CO_2, and H_2O to produce O_2 and organic molecules. The organic molecules are broken down to CO_2 and H_2O via cellular respiration to supply energy in the form of ATP; O_2 is reduced to H_2O.

BIOLOGY PRINCIPLE Living organisms use energy. Photosynthetic species capture light energy and store it in organic molecules, which are used by photosynthetic and nonphotosynthetic species as sources of energy.

Concept Check: Which types of organisms carry out cellular respiration? Is it heterotrophs, autotrophs, or both?

In Plants and Algae, Photosynthesis Occurs in the Chloroplast

Chloroplasts are organelles found in plant and algal cells that carry out photosynthesis. These organelles contain large quantities of **chlorophyll**, which is a pigment that gives plants their green color. All green parts of a plant contain chloroplasts and can perform photosynthesis, although the majority of photosynthesis occurs in the leaves (**Figure 8.2**). The tissue in the internal part of the leaf, called the **mesophyll**, contains cells with chloroplasts. For photosynthesis to occur, the mesophyll cells must receive light, and also obtain water and carbon dioxide. The water is taken up by the roots of the plant and is transported to the leaves by small veins. Carbon dioxide gas enters the leaf, and oxygen exits, via pores called stomata (singular, stoma or stomate; from the Greek, meaning mouth).

Like a mitochondrion, a chloroplast contains an outer and inner membrane, with an intermembrane space lying between the two. A third membrane, called the **thylakoid membrane**, contains pigment molecules, including chlorophyll. The thylakoid membrane forms many flattened, fluid-filled tubules called **thylakoids**, which enclose

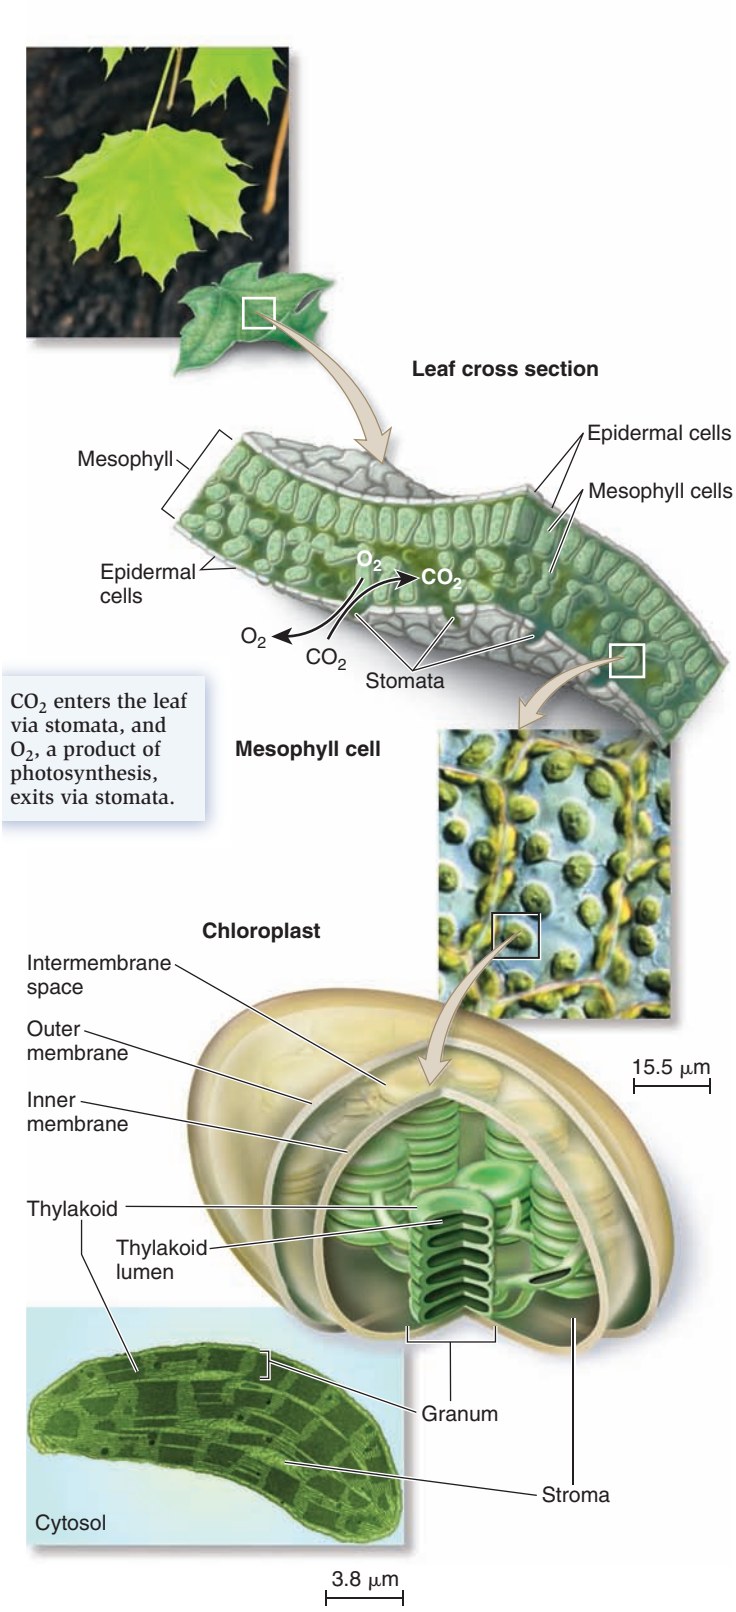

Figure 8.2 **Leaf organization.** Leaves are composed of layers of cells. The epidermal cells are on the outer surface, both top and bottom, with mesophyll cells sandwiched in the middle. The mesophyll cells contain chloroplasts and are the primary sites of photosynthesis in most plants.

BioConnections: *Look ahead to Figure 38.17. How many guard cells make up a stoma (plural, stomata)?*

a single, convoluted compartment known as the **thylakoid lumen**. Thylakoids stack on top of each other to form a structure called a **granum** (plural, grana). The **stroma** is the fluid-filled region of the chloroplast between the thylakoid membrane and the inner membrane (see Figure 8.2).

Photosynthesis Occurs in Two Stages: Light Reactions and the Calvin Cycle

How does photosynthesis take place? As mentioned, the process of photosynthesis occurs in two stages called the light reactions and the Calvin cycle. The term photosynthesis is derived from the association between these two stages: Photo refers to the light reactions that capture the energy from sunlight needed for the synthesis of carbohydrates that occurs in the Calvin cycle. The light reactions take place at the thylakoid membrane, and the Calvin cycle occurs in the stroma (**Figure 8.3**).

The light reactions involve an amazing series of energy conversions, starting with light energy and ending with chemical energy that is stored in the form of covalent bonds. The light reactions produce three chemical products: ATP, NADPH, and O_2. ATP and NADPH are energy intermediates that provide the needed energy and electrons to drive the Calvin cycle. Like NADH, **NADPH (nicotinamide adenine dinucleotide phosphate)** is an electron carrier that can accept two electrons. Its structure differs from NADH by the presence of an additional phosphate group. The structure of NADH is described in Chapter 6 (see Figure 6.12).

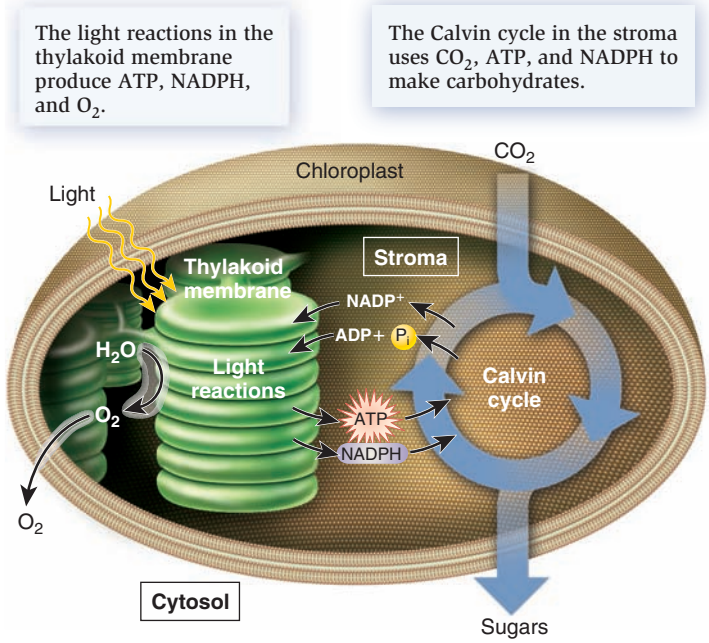

Figure 8.3 **An overview of the two stages of photosynthesis: light reactions and the Calvin cycle.** The light reactions, through which ATP, NADPH, and O_2 are made, occur at the thylakoid membrane. The Calvin cycle, in which enzymes use ATP and NADPH to incorporate CO_2 into carbohydrate, occurs in the stroma.

Concept Check: *Can the Calvin cycle occur in the dark?*

8.2 Reactions That Harness Light Energy

Learning Outcomes:

1. Define the general properties of light.
2. Describe how pigments absorb light energy, and list the types of pigments found in plants and green algae.
3. Outline the steps in which photosystems II and I capture light energy and produce O_2, ATP, and NADPH.
4. Explain the process of cyclic photophosphorylation, in which only ATP is made.

According to the first law of thermodynamics discussed in Chapter 6, energy cannot be created or destroyed, but it can be transferred from one place to another and transformed from one form to another. During photosynthesis, energy in the form of light is transferred from the Sun, some 92 million miles away, to a pigment molecule in a photosynthetic organism such as a plant. What follows is an interesting series of energy transformations in which light energy is transformed into electrochemical energy and then into energy stored within chemical bonds.

In this section, we will explore this series of transformations, collectively called the light reactions of photosynthesis. We begin by examining the properties of light and then consider the features of chloroplasts that allow them to capture light energy. The remainder of this section focuses on how the light reactions of photosynthesis generate three important products: ATP, NADPH, and O_2.

Light Energy Is a Form of Electromagnetic Radiation

Light is essential to support life on Earth. Light is a type of electromagnetic radiation, so named because it consists of energy in the form of electric and magnetic fields. Electromagnetic radiation travels as waves caused by the oscillation of the electric and magnetic fields. The **wavelength** is the distance between the peaks in a wave pattern. The **electromagnetic spectrum** encompasses all possible wavelengths of electromagnetic radiation, from relatively short wavelengths (gamma rays) to much longer wavelengths (radio waves) (**Figure 8.4**). Visible light is the range of wavelengths detected by the human eye, commonly between 380 and 740 nm. As discussed later, visible light provides the energy to drive photosynthesis.

Physicists have also discovered that light has properties that are characteristic of particles. Albert Einstein formulated the photon theory of light in which he proposed that light is composed of discrete particles called **photons**—massless particles traveling in a wavelike pattern and moving at the speed of light (about 300 million m/sec). Each photon contains a specific amount of energy. An important difference between the various types of electromagnetic radiation, shown in Figure 8.4, is the amount of energy found in the photons. Shorter wavelength radiation carries more energy per unit of time than longer wavelength radiation. For example, the photons of gamma rays carry more energy than those of radio waves.

The Sun radiates the entire spectrum of electromagnetic radiation, but the atmosphere prevents much of this radiation from reaching the Earth's surface. For example, the ozone layer forms a thin shield in the upper atmosphere, protecting life on Earth from much of the Sun's ultraviolet (UV) radiation. Even so, a substantial amount of electromagnetic radiation does reach the Earth's surface. The effect of light on living organisms is critically dependent on the energy of the photons that reach them. The photons found in gamma rays, X-rays, and UV radiation have very high energy. When molecules in cells absorb such energy, the effects can be devastating. Such radiation can cause mutations in DNA and even lead to cancer. By comparison, the energy of photons found in visible light is much milder. Molecules can absorb this energy in a way that does not cause damage. Next, we will consider how molecules in living cells absorb the energy within visible light.

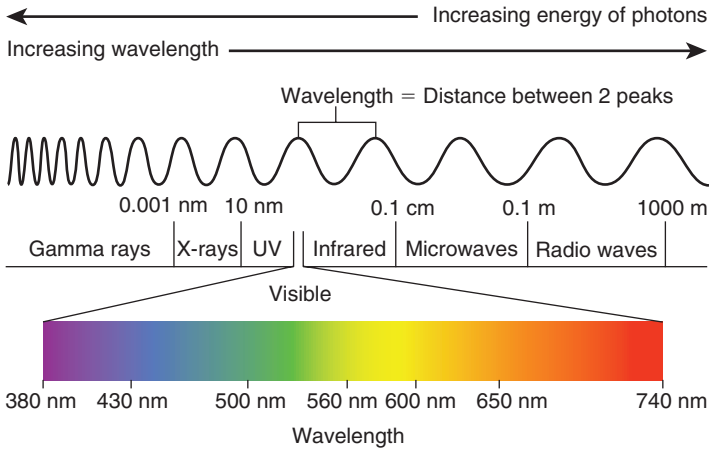

Figure 8.4 The electromagnetic spectrum. The bottom portion of this figure emphasizes visible light—the wavelengths of electromagnetic radiation visible to the human eye. Light in the visible portion of the electromagnetic spectrum drives photosynthesis.

Concept Check: Which has higher energy, gamma rays or radio waves?

Pigments Absorb Light Energy

When light strikes an object, one of three things happens. First, light may simply pass through the object. Second, the object may change the path of light toward a different direction. A third possibility is that the object may absorb the light. The term **pigment** is used to describe a molecule that can absorb light energy. When light strikes a pigment, some of the wavelengths of light energy are absorbed, while others are reflected. For example, leaves look green to us because they reflect radiant energy of the green wavelength. Various pigments in the leaves absorb the energy of other wavelengths. At the extremes of color reflection are white and black. A white object reflects nearly all of the visible light energy falling on it, whereas a black object absorbs nearly all of the light energy. This is why it is coolest to wear white clothes on a sunny, hot day.

What do we mean when we say that light energy is absorbed? In the visible spectrum, light energy may be absorbed by boosting electrons to higher energy levels (**Figure 8.5**). Recall from Chapter 2 that electrons are located around the nucleus of an atom (refer back to Figure 2.4). The region in which an electron is found is called its orbital. Electrons in different orbitals possess different amounts of energy. For an electron to absorb light energy and be boosted to an orbital with a higher energy, it must overcome the difference in

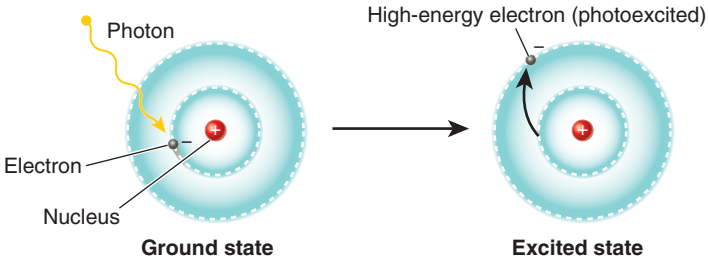

Figure 8.5 Absorption of light energy by an electron. When a photon of light of the correct amount of energy strikes an electron, the electron is boosted from the ground (unexcited) state to a higher energy level (an excited state). When this occurs, the electron occupies an orbital that is farther away from the nucleus of the atom. At this farther distance, the electron is held less firmly and is considered unstable.

Concept Check: Describe the three things that could happen to enable a photoexcited electron to become more stable.

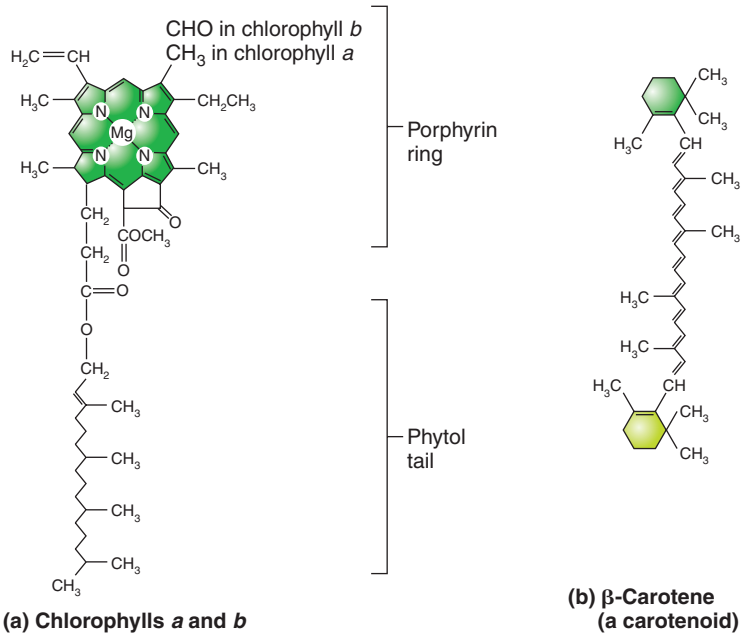
energy between the orbital it is in and the orbital to which it is going. For this to happen, an electron must absorb a photon that contains precisely that amount of energy. Different pigment molecules contain a variety of electrons that can be shifted to different energy levels. Therefore, the wavelength of light that a pigment absorbs depends on the amount of energy needed to boost an electron to a higher orbital.

After an electron absorbs energy, it is said to be in an excited state. Usually, this is an unstable condition. The electron may release the energy in different ways.

- First, when an excited electron drops back down to a lower energy level, it may release heat. For example, on a sunny day, the sidewalk heats up because it absorbs light energy that is released as heat.
- A second way that an electron can release energy is in the form of light. Certain organisms, such as jellyfish, possess molecules that make them glow. This glow is due to the release of light when electrons drop down to lower energy levels, a phenomenon called fluorescence.
- In the case of photosynthetic pigments, however, a different event happens that is critical for the process of photosynthesis. Rather than releasing energy, an excited electron in a photosynthetic pigment is removed from that molecule and transferred to another molecule where the electron is more stable. When this occurs, the energy in the electron is said to be "captured," because the electron does not readily drop down to a lower energy level and release heat or light.

Plants Contain Different Types of Photosynthetic Pigments

In plants, different pigment molecules absorb the light energy used to drive photosynthesis. Two types of chlorophyll pigments, termed **chlorophyll *a*** and **chlorophyll *b***, are found in green plants and green algae. Their structure was determined in the 1930s by German chemist Hans Fischer (**Figure 8.6a**). In the chloroplast, both chlorophylls *a* and *b* are bound to integral membrane proteins in the thylakoid membrane.



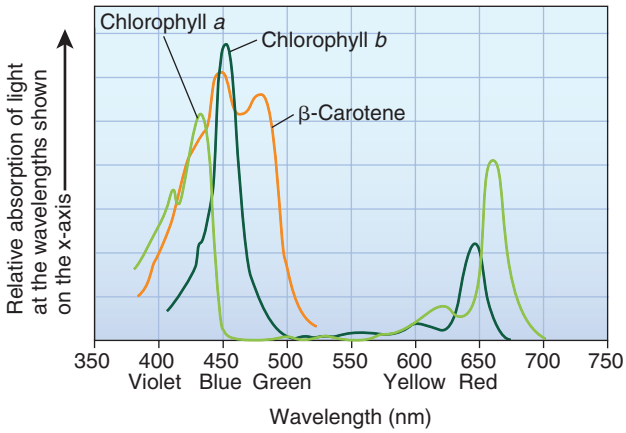


Figure 8.6 Structures of pigment molecules. (a) The structure of chlorophylls *a* and *b*. As indicated, chlorophylls *a* and *b* differ only at a single site, at which chlorophyll *a* has a —CH_3 group and chlorophyll *b* has a —CHO group. **(b)** The structure of β-carotene, an example of a carotenoid. The dark green and light green areas in parts (a) and (b) are the regions where a delocalized electron can hop from one atom to another.

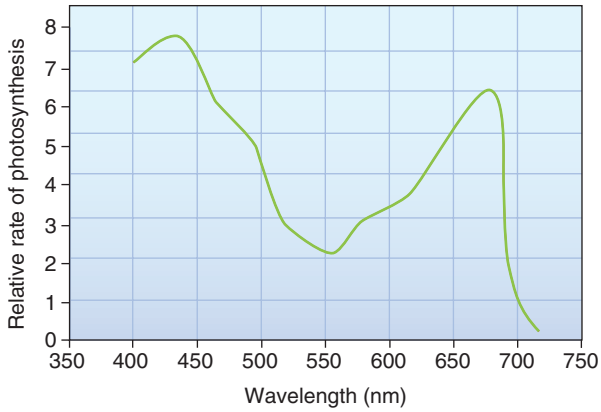
The chlorophylls contain a porphyrin ring and a phytol tail. A magnesium ion (Mg^{2+}) is bound to the porphyrin ring. An electron in the porphyrin ring follows a path in which it spends some of its time around several different atoms. Because this electron isn't restricted to a single atom, it is called a delocalized electron. The delocalized electron can absorb light energy. The phytol tail in chlorophyll is a long hydrocarbon chain that is hydrophobic. Its function is to anchor the pigment to the surface of hydrophobic proteins within the thylakoid membrane of chloroplasts.



Carotenoids are another type of pigment found in chloroplasts (**Figure 8.6b**). These pigments impart a color that ranges from yellow to orange to red. Carotenoids are often the major pigments in flowers and fruits. In leaves, the more abundant chlorophylls usually mask the colors of carotenoids. In temperate climates where the leaves change colors, the quantity of chlorophyll in the leaf declines during autumn. The carotenoids become readily visible and produce the yellows and oranges of autumn foliage.

An **absorption spectrum** is a graph that plots a pigment's light absorption as a function of wavelength. Each of the photosynthetic pigments shown in **Figure 8.7a** absorbs light in different regions of the visible spectrum. The absorption spectra of chlorophylls *a* and *b* are slightly different, though both chlorophylls absorb light most strongly in the red and violet parts of the visible spectrum and absorb green light poorly. Green light is reflected, which is why leaves appear green during the growing season. Carotenoids absorb light in the blue and blue-green regions of the visible spectrum, reflecting yellow and red.

Why do plants have different pigments? Having different pigments allows plants to absorb light at many different wavelengths. In

(a) Absorption spectra

(b) Action spectrum

Figure 8.7 Properties of pigment function: absorption and action spectra. (a) These absorption spectra show the absorption of light by chlorophyll *a*, chlorophyll *b*, and β-carotene. **(b)** An action spectrum of photosynthesis depicting the relative rate of photosynthesis in green plants at different wavelengths of light.

Concept Check: What is the advantage of having different pigment molecules?

this way, plants are more efficient at capturing the energy in sunlight. This phenomenon is highlighted in an **action spectrum**, which plots the rate of photosynthesis as a function of wavelength (**Figure 8.7b**). The highest rates of photosynthesis in green plants correlate with the wavelengths that are strongly absorbed by the chlorophylls and carotenoids. Photosynthesis is poor in the green region of the spectrum, because these pigments do not readily absorb this wavelength of light.

Photosystems II and I Work Together to Produce ATP and NADPH

A key feature of photosynthesis is the ability of pigments to capture light energy and transfer it to other molecules that can hold on to the energy in a stable fashion and ultimately produce energy-intermediate molecules that can do cellular work. Let's now consider how chloroplasts capture light energy. The thylakoid membranes of the chloroplast contain two distinct complexes of proteins and pigment molecules called **photosystem I (PSI)** and **photosystem II (PSII)** (**Figure 8.8**). Photosystem I was discovered before photosystem II, but photosystem II is the initial step in photosynthesis. We will consider the structure and function of PSII in greater detail later in this chapter.

As described in steps 1 and 2 of Figure 8.8, light excites electrons in pigment molecules, such as chlorophylls, which are located in regions of PSII and PSI called light-harvesting complexes. Rather than releasing their energy in the form of heat, the excited electrons follow a path shown by the red arrow. The combined action of photosystem II and photosystem I is termed **linear electron flow** because the electrons move linearly from PSII to PSI and ultimately reduce $NADP^+$ to NADPH. Let's consider the main events of the light reactions.

Events within Photosystem II Initially, the excited electrons move from a pigment molecule called P680 in PSII to other electron carriers called pheophytin (Pp), Q_A, and Q_B. The excited electrons are moved out of PSII by Q_B. PSII also oxidizes water, which generates O_2 and adds H^+ into the thylakoid lumen. The electrons released from the oxidized water molecules are used to replenish the electrons that leave PSII via Q_B.

Electron Transport Chain After a pair of electrons reaches Q_B, each one enters an electron transport chain (ETC)—a series of electron carriers—located in the thylakoid membrane. This ETC functions similarly to the one found in mitochondria. From Q_B, an electron goes to a cytochrome complex; then to plastocyanin (Pc), a small protein; and then to photosystem I. Along its journey from photosystem II to photosystem I, the electron releases some of its energy at particular steps and is transferred to the next component that has a higher electronegativity. The energy released is harnessed to pump H^+ into the thylakoid lumen.

Photosystem I and NADPH Synthesis A key role of photosystem I is to make NADPH (see Figure 8.8, step 3). When light strikes the light-harvesting complex of photosystem I, this energy is also transferred to a reaction center, where a high-energy electron is removed from a pigment molecule, designated P700, and transferred to a primary electron acceptor. A protein called ferredoxin (Fd) can accept two high-energy electrons, one at a time, from the primary electron acceptor. Fd then transfers the two electrons to the enzyme $NADP^+$ reductase. This enzyme transfers the two electrons to $NADP^+$ and together with an H^+ produces NADPH. The formation of NADPH results in fewer H^+ in the stroma.

A key difference between PSII and PSI lies in the source of the electrons received by their respective pigment molecules. An oxidized pigment in PSII called P680 receives an electron from water. By comparison, an oxidized pigment in PSI called P700 receives an electron from Pc. Therefore, PSI does not need to split water to reduce this pigment and does not generate oxygen.

Synthesis of ATP The synthesis of ATP in chloroplasts is achieved by a chemiosmotic mechanism called **photophosphorylation**, which is similar to that used to make ATP in mitochondria. In chloroplasts, ATP synthesis is driven by the flow of H^+ from the thylakoid lumen

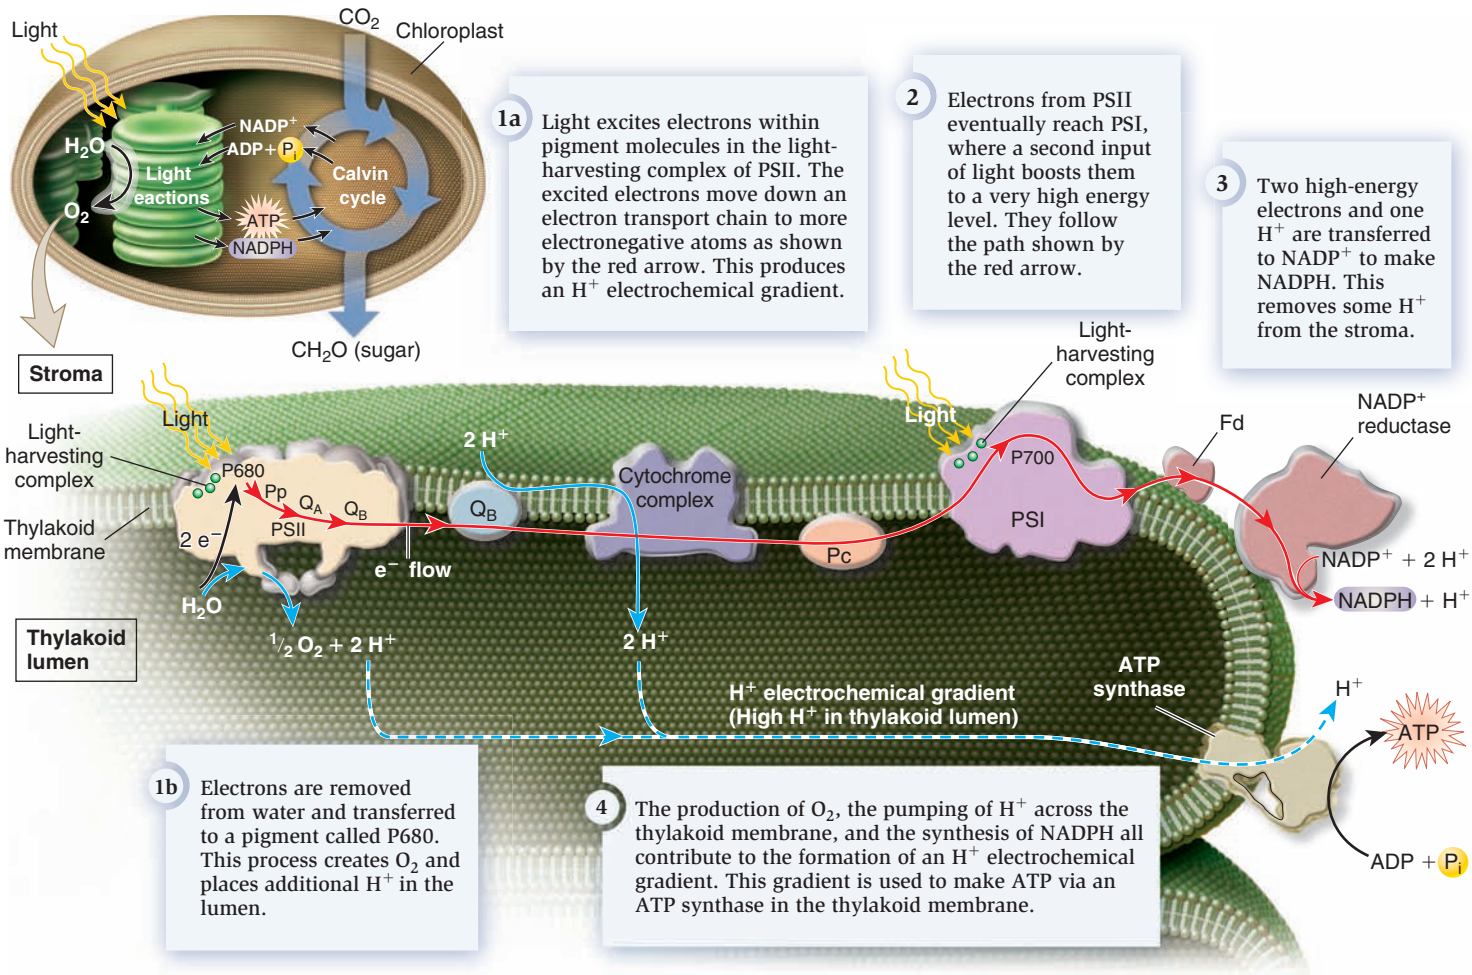


Figure 8.8 The synthesis of ATP, NADPH, and O_2 by the concerted actions of photosystems II and I. The movement of electrons from photosystem II to photosystem I to NADPH is called linear electron flow.

Concept Check: *Are ATP, NADPH, and O_2 produced in the stroma or in the thylakoid lumen?*

into the stroma via ATP synthase (Figure 8.8, step 4). An H^+ electrochemical gradient is generated via three events: (1) the splitting of water, which places H^+ in the thylakoid lumen; (2) the movement of high-energy electrons along the ETC from photosystem II to photosystem I, which pumps H^+ into the thylakoid lumen; and (3) the formation of NADPH, which consumes H^+ in the stroma.

Products of Photosynthesis In summary, the steps of the light reactions of photosynthesis produce three chemical products: O_2, NADPH, and ATP:

1. O_2 is produced in the thylakoid lumen by the oxidation of water by photosystem II. Two electrons are removed from water, which produces 2 H^+ and $^1/_2$ O_2. The two electrons are transferred to P680 molecules.
2. NADPH is produced in the stroma using high-energy electrons that start in photosystem II and are boosted a second time in photosystem I. Two high-energy electrons and one H^+ are transferred to $NADP^+$ to produce NADPH.
3. ATP is produced in the stroma via ATP synthase that uses an H^+ electrochemical gradient.

Cyclic Electron Flow Produces Only ATP

The mechanism of harvesting light energy described in Figure 8.8 is called linear electron flow because it is a linear process. This electron flow produces ATP and NADPH in roughly equal amounts. However, as we will see later, the Calvin cycle uses more ATP than NADPH. How can plant cells avoid making too much NADPH and not enough ATP? In 1959, Daniel Arnon discovered a pattern of electron flow that is cyclic and generates only ATP (**Figure 8.9**). Arnon termed the process **cyclic photophosphorylation** because (1) the path of electrons is cyclic, (2) light energizes the electrons, and (3) ATP is made via the phosphorylation of ADP. Due to the path of electrons, the mechanism is also called **cyclic electron flow**.

When light strikes photosystem I, high-energy electrons are sent to the primary electron acceptor and then to ferredoxin (Fd). The key difference in cyclic photophosphorylation is that the high-energy electrons are transferred from Fd to Q_B. From Q_B, the electrons then go to the cytochrome complex, then to plastocyanin (Pc), and back to photosystem I. As the electrons travel along this cyclic route, they release energy, and some of this energy is used to transport H^+ into the thylakoid lumen. The resulting H^+ gradient drives the synthesis of ATP via ATP synthase.

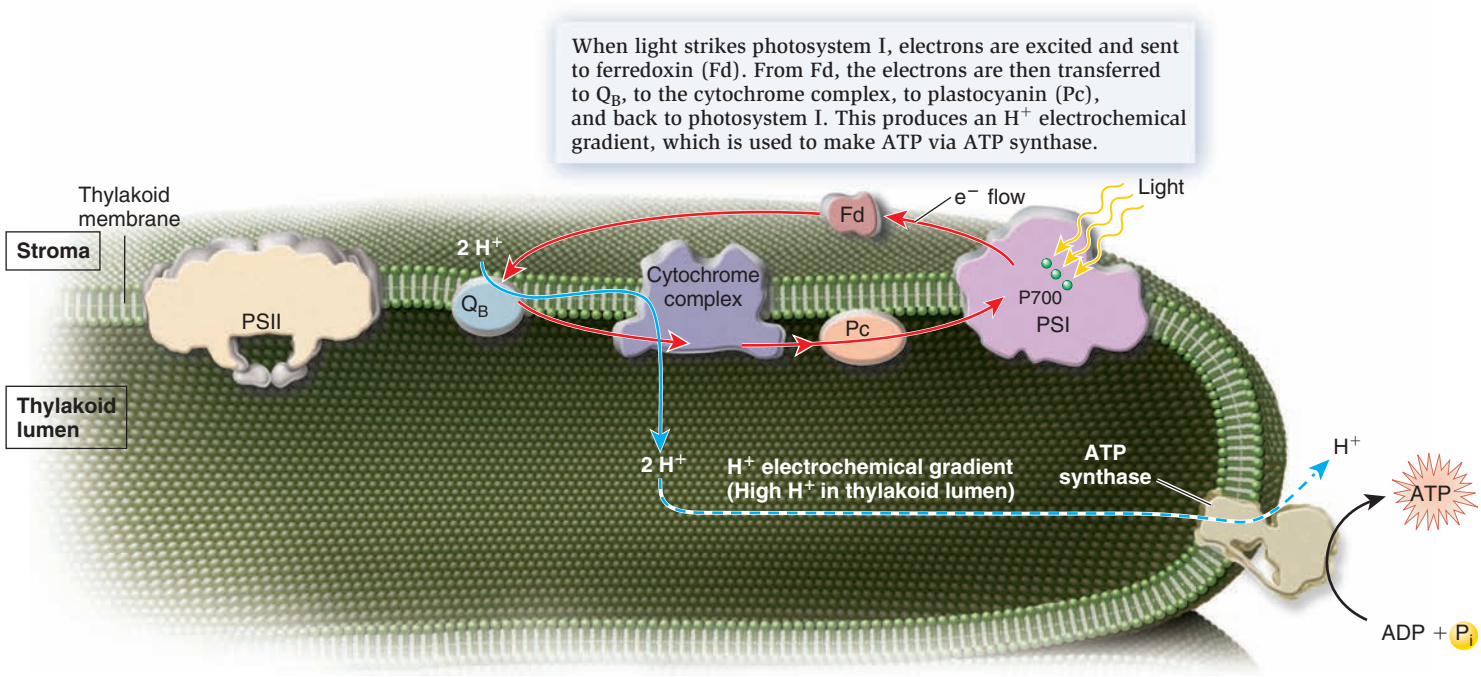

Figure 8.9 Cyclic photophosphorylation. In this process, electrons follow a cyclic path that is powered by photosystem I (PSI). This contributes to the formation of an H^+ electrochemical gradient, which is then used to make ATP by ATP synthase.

Concept Check: *Why is using cyclic photophosphorylation an advantage to a plant over using only linear electron flow?*

Cyclic electron flow is favored when the level of $NADP^+$ is low and NADPH is high. Under these conditions, there is sufficient NADPH to run the Calvin cycle, which is described later. Alternatively, when $NADP^+$ is high and NADPH is low, linear electron flow is favored, so more NADPH can be made. Cyclic electron flow is also favored when ATP levels are low.

Genomes & Proteomes Connection

The Cytochrome Complexes of Mitochondria and Chloroplasts Contain Evolutionarily Related Proteins

A recurring theme in cell biology is that evolution has resulted in groups of genes that encode proteins that play similar but specialized roles in cells—an example of descent with modification. When two or more genes are similar because they are derived from the same ancestral gene, they are called **homologous genes**. As discussed in Chapter 23, homologous genes encode proteins that have similar amino acid sequences and often perform similar functions.

A comparison of the electron transport chains of mitochondria and chloroplasts reveals homologous genes. In particular, let's consider the cytochrome complex found in the thylakoid membrane of plants and algae, called cytochrome b_6-f (**Figure 8.10a**), and cytochrome b-c_1, which is found in the ETC of mitochondria (**Figure 8.10b**; also refer back to Figure 7.8). Both cytochrome complexes b_6-f and b-c_1 are composed of several proteins. One of them is called cytochrome b_6 in cytochrome b_6-f and cytochrome b in cytochrome b-c_1.

By analyzing the sequences of the genes that encode these proteins, researchers discovered that cytochrome b_6 and cytochrome b are homologous proteins. These proteins carry out similar functions: Both of them accept electrons from a quinone (Q_B or ubiquinone), and both donate an electron to another protein within their respective complexes (cytochrome f or cytochrome c_1). Likewise, both proteins function as H^+ pumps that capture some of the energy that is released from electrons to transport H^+ across the membrane. In this way, evolution has produced a family of cytochrome b-type proteins that play similar but specialized roles.

8.3 Molecular Features of Photosystems

Learning Outcomes:

1. Explain how PSII absorbs and captures light energy and how it produces O_2.
2. Describe how the energy of an electron varies as it moves from PSII to PSI to $NADP^+$.

The previous section provided an overview of how chloroplasts absorb light energy and produce ATP, NADPH, and O_2. As you have learned, two photosystems—PSI and PSII—play critical roles in two aspects of photosynthesis. First, both PSI and PSII absorb light energy

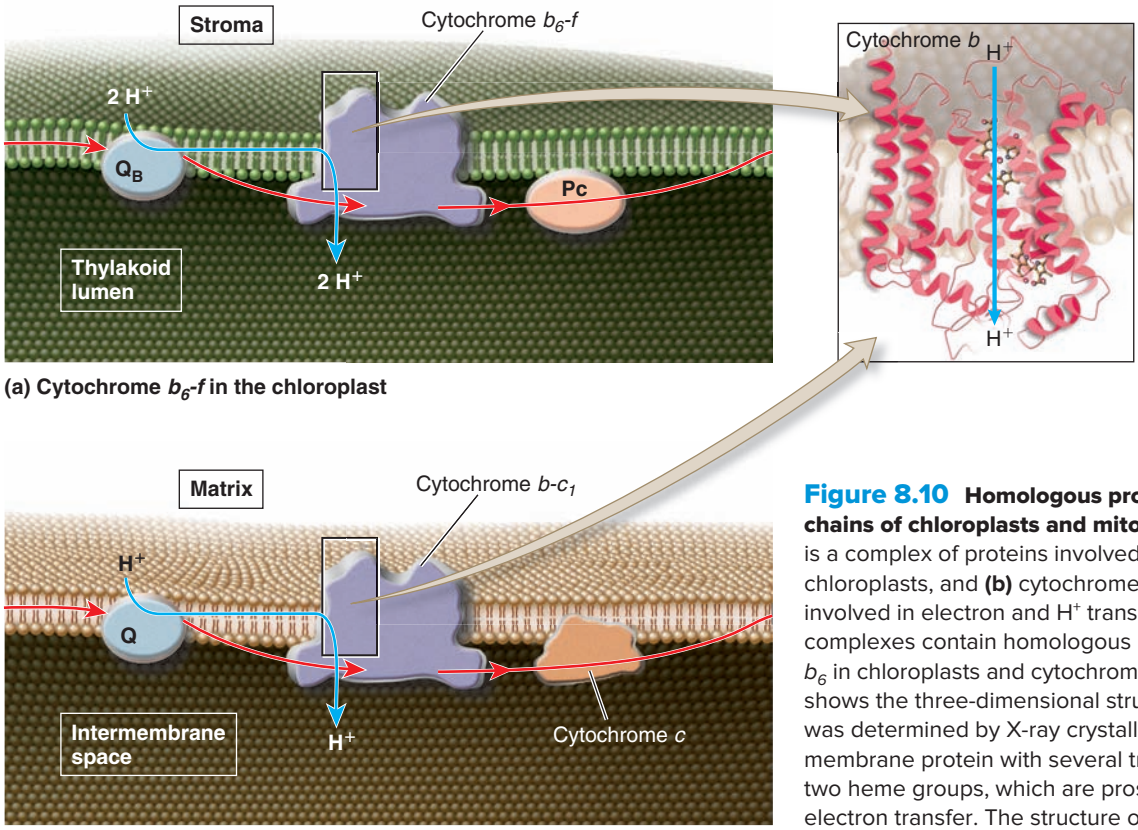

Figure 8.10 Homologous proteins in the electron transport chains of chloroplasts and mitochondria. (a) Cytochrome b_6-f is a complex of proteins involved in electron and H^+ transport in chloroplasts, and **(b)** cytochrome b-c_1 is a complex of proteins involved in electron and H^+ transport in mitochondria. These complexes contain homologous proteins designated cytochrome b_6 in chloroplasts and cytochrome b in mitochondria. The inset shows the three-dimensional structure of cytochrome b, which was determined by X-ray crystallography. It is an integral membrane protein with several transmembrane helices and two heme groups, which are prosthetic groups involved in electron transfer. The structure of cytochrome b_6 has also been determined and found to be very similar.

BIOLOGY PRINCIPLE Populations of organisms evolve from one generation to the next. Evolution has resulted in proteins with similar but specialized functions.

Concept Check: *Explain why the three-dimensional structures of cytochrome b and cytochrome b_6 are very similar.*

and capture that energy in the form of excited electrons. Second, PSII oxidizes water, thereby producing O_2. In this section, we will take a closer look at how these events occur at the molecular level.

Photosystem II Captures Light Energy and Produces O_2

PSI and PSII have two main components: a light-harvesting complex and a reaction center. **Figure 8.11** shows how these components function in PSII.

Absorption of Energy by the Light-Harvesting Complex and Its Transfer to P680 via Resonance Energy Transfer In 1932, American biologist Robert Emerson and an undergraduate student, William Arnold, originally discovered the **light-harvesting complex** in the thylakoid membrane. It is composed of several dozen pigment molecules that are anchored to transmembrane proteins. The role of the complex is to directly absorb photons of light. When a pigment molecule absorbs a photon, an electron is boosted to a higher energy level. As shown in Figure 8.11, the energy (not the electron itself) is transferred to adjacent pigment molecules by a process called **resonance energy transfer**. The energy may be transferred among multiple pigment molecules until it is eventually transferred to a special pigment molecule designated P680, which is located within the reaction center of PSII. The P680 pigment is so named because it can directly absorb light at a wavelength of 680 nm. However, P680 is more commonly excited by resonance energy transfer from another chlorophyll pigment. In either case, when an electron in P680 is excited, the molecule is designated P680*. The light-harvesting complex is also called the antenna complex because it acts like an antenna that absorbs energy from light and funnels that energy to P680 in the reaction center.

Rapid Transfer of a High-Energy Electron from P680* to the Primary Electron Acceptor A high-energy (photoexcited) electron in a pigment molecule is relatively unstable. It may abruptly release its energy by giving off heat or light. Unlike the pigments in the light-harvesting complex that undergo resonance energy transfer, P680* can actually release its high-energy electron and become $P680^+$.

$$P680^* \rightarrow P680^+ + e^-$$

The role of the reaction center is to quickly remove the high-energy electron from P680* and transfer it to another molecule, where the electron is more stable. This molecule is called the **primary electron acceptor** (see Figure 8.11). The transfer of the electron from P680* to the primary electron acceptor is remarkably fast. It occurs in less than a few picoseconds! (One picosecond equals one-trillionth of a second, also written 10^{-12} sec.) Because this occurs so quickly, the excited electron does not have much time to release its energy in the form of heat or light.

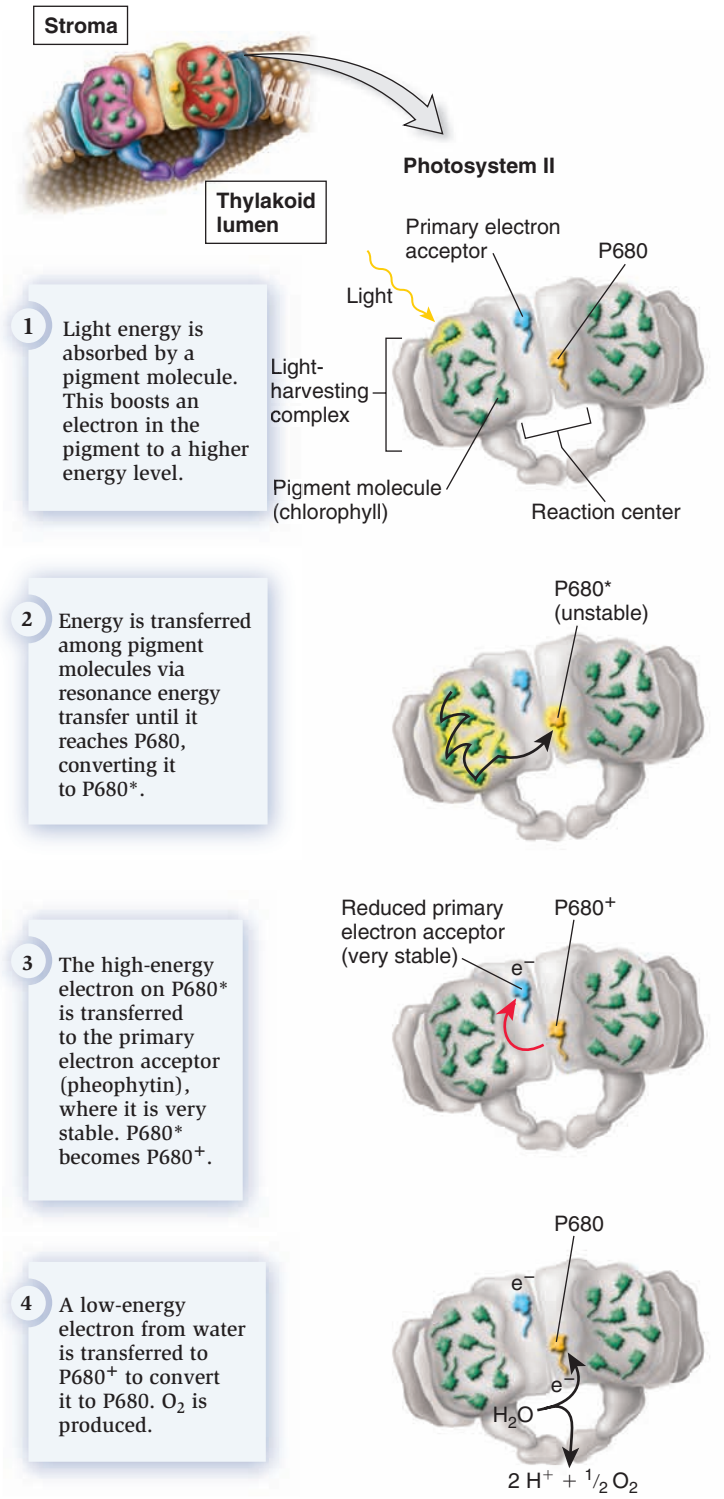

Figure 8.11 A closer look at how photosystem II harvests light energy and oxidizes water. Note: Two electrons are released during the oxidation of water, but they are transferred one at a time to $P680^+$.

After the primary electron acceptor (pheophytin) has received this high-energy electron, the light energy has been captured and can be used to perform cellular work. As discussed earlier, the work it performs is to synthesize the energy intermediates ATP and NADPH (look back at Figure 8.8).

Transfer of a Low-Energy Electron from Water to $P680^+$ Let's now consider what happens to $P680^+$, which has given up its high-energy electron. After $P680^+$ is formed, it is necessary to replace the electron so that P680 can function again. Therefore, another role of the reaction center is to replace the electron that is removed when P680* becomes $P680^+$. This missing electron of $P680^+$ is replaced with a low-energy electron from water (see Figure 8.11).

$$H_2O \rightarrow 2\,H^+ + {}^1/_2\,O_2 + 2\,e^-$$

$$2\,P680^+ + 2\,e^- \rightarrow 2\,P680$$
(from water)

The oxidation of water results in the formation of oxygen gas (O_2), which is used by many organisms for cellular respiration. Photosystem II is the only known protein complex that can oxidize water, resulting in the release of O_2 into the atmosphere.

BIO TIPS **THE QUESTION** *Describe the roles of the light-harvesting complex, P680, and the primary electron acceptor during the absorption of light energy by photosystem II (PSII). At which step is the light energy captured?*

TOPIC ***What topic in biology does this question address?*** The topic is the absorption of light by PSII. More specifically, the question asks you to describe the various roles played by the light-harvesting complex, P680, and the primary electron acceptor.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** In the question, you are reminded that PSII has a light-harvesting complex, P680, and a primary electron acceptor. From your understanding of the topic, you may remember that light absorption begins at the light-harvesting complex, which funnels energy to P680. The energy transforms P680 to P680*, which then transfers a high-energy electron to the primary electron acceptor.

PROBLEM-SOLVING STRATEGY ***Sort out the steps in a complicated process. Compare and contrast.*** To begin to solve this problem, it may be helpful to review the steps of the light-absorption process shown in Figure 8.11. As you do so, compare and contrast the roles of the light-harvesting complex, P680, and the primary electron acceptor.

ANSWER *Light-harvesting complex: The role of the light-harvesting complex is to absorb light. Because it is composed of many pigment molecules (chlorophylls and β-carotene), the light-harvesting complex is the most likely place for visible light to be absorbed. When a pigment molecule absorbs light, an electron is boosted to a higher energy level, and that energy is transferred via resonance energy transfer to P680.*

P680: The role of P680 is to provide a link between the light-harvesting complex and the primary electron acceptor. Although P680 can directly absorb light, P680 is far more likely to gain energy from the light-harvesting complex, which converts it to

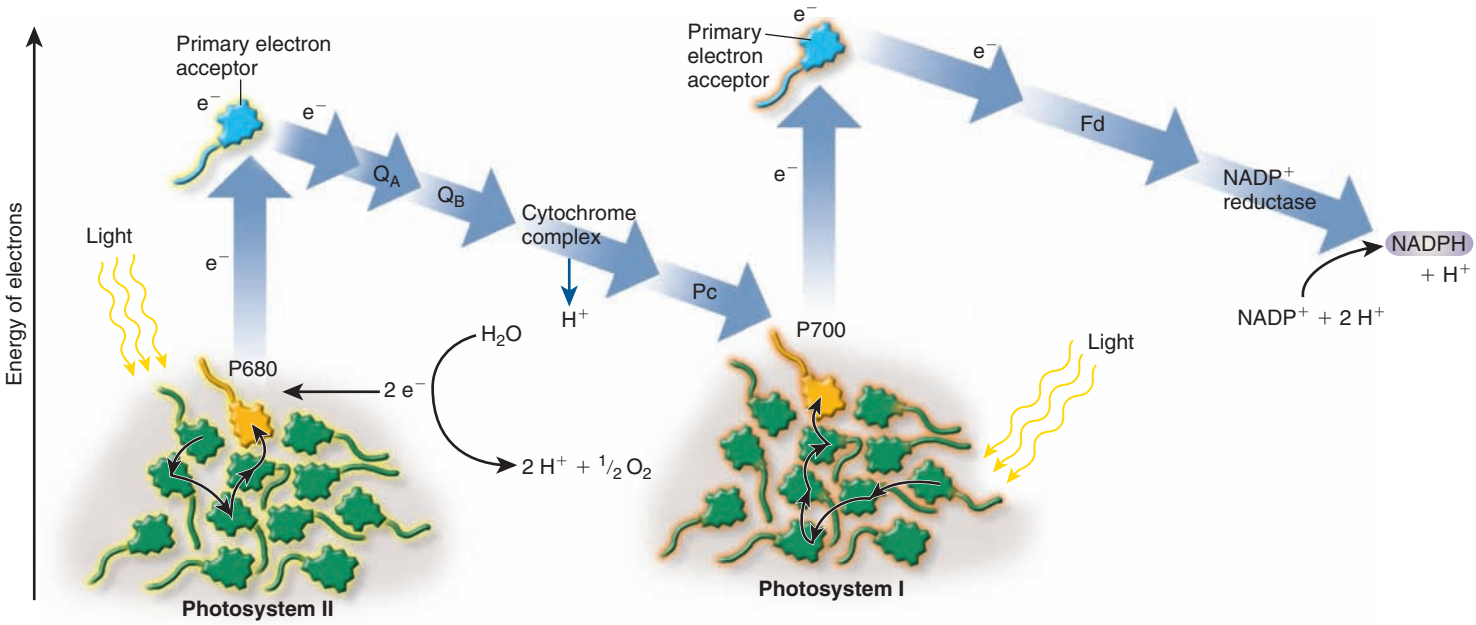

Figure 8.12 The Z scheme, showing the energy of an electron moving from photosystem II to NADP⁺. The oxidation of water releases two electrons that travel one at a time from photosystem II to NADP⁺. As seen here, the input of light boosts the energy of the electron twice. At the end of the pathway, two electrons are used to make NADPH.

Concept Check: *During its journey from photosystem II to NADP⁺, at what point does an electron have the highest amount of energy?*

P680. The high-energy electron of P680* is then transferred to the primary electron acceptor.*

Primary electron acceptor: The role of the primary electron acceptor is to capture the light energy. The high-energy electron of P680 is unstable. However, when it is transferred to the primary electron acceptor, the electron becomes more stable, meaning that it will not drop down to a lower energy level.*

Electrons Vary in Energy as They Move from Photosystem II to Photosystem I to NADP⁺

In 1960, Robin Hill and Fay Bendal proposed that the light reactions of photosynthesis involve two photoactivation events. According to their model, known as the **Z scheme**, an electron proceeds through a series of energy changes during photosynthesis (**Figure 8.12**). The Z refers to the zigzag shape of this energy curve. Based on our modern understanding of photosynthesis, we now know these events involve increases and decreases in the energy of an electron as it moves from photosystem II through photosystem I to NADP⁺ during linear electron flow.

- An electron on a nonexcited pigment molecule in photosystem II has the lowest energy.
- In photosystem II, light boosts an electron to a much higher energy level.
- As the electron travels from photosystem II to photosystem I, some of the energy is released.
- The input of light in photosystem I boosts the electron to an even higher energy than it attained in photosystem II.
- The electron releases a little energy before it is eventually transferred to NADP⁺.

8.4 Synthesizing Carbohydrates via the Calvin Cycle

Learning Outcomes:

1. Outline the three phases of the Calvin cycle.
2. **SciSKILLS** » Analyze the results of Calvin and Benson, and explain how they identified the components of the Calvin cycle.

In the previous sections, we learned how the light reactions of photosynthesis produce ATP, NADPH, and O_2. We will now turn our attention to the second phase of photosynthesis, the Calvin cycle, in which ATP and NADPH are used to make carbohydrates. The Calvin cycle consists of a series of steps that occur in a metabolic cycle. In plants and algae, it occurs in the stroma of chloroplasts. In cyanobacteria, the Calvin cycle occurs in the cytoplasm of the bacterial cells.

The Calvin cycle takes CO_2 from the atmosphere and incorporates the carbon into organic molecules, namely, carbohydrates. As mentioned earlier, carbohydrates are critical for two reasons. First, they provide the precursors to make the organic molecules and macromolecules of nearly all living cells. The second key reason is the storage of energy. The Calvin cycle produces carbohydrates, which store energy. These carbohydrates are accumulated inside plant cells. When a plant is in the dark and not carrying out photosynthesis, the stored carbohydrates are used as a source of energy. Similarly, when an animal consumes a plant, it uses the carbohydrates as an energy source.

In this section, we will examine the three phases of the Calvin cycle. We will also explore the experimental approach of Melvin Calvin and his colleagues that enabled them to elucidate the steps of this cycle.

The Calvin Cycle Incorporates CO_2 into Carbohydrate

The Calvin cycle, also called the Calvin-Benson cycle, was determined by chemists Melvin Calvin and Andrew Adam Benson and their colleagues in the 1940s and 1950s. This cycle requires a massive input of energy. For every 6 carbon dioxide molecules that are incorporated into a carbohydrate such as glucose ($C_6H_{12}O_6$), 18 ATP molecules are hydrolyzed and 12 NADPH molecules are oxidized:

$$6\ CO_2 + 12\ H_2O \rightarrow C_6H_{12}O_6 + 6\ O_2 + 6\ H_2O$$

$$18\ ATP + 18\ H_2O \rightarrow 18\ ADP + 18\ P_i$$

$$12\ NADPH \rightarrow 12\ NADP^+ + 12\ H^+ + 24\ e^-$$

Although biologists commonly describe glucose as a product of photosynthesis, glucose is not directly made by the Calvin cycle. Instead, molecules of glyceraldehyde-3-phosphate, which are products of the Calvin cycle, are used as starting materials for the synthesis of glucose and other molecules, including sucrose. After glucose molecules are made, they may be linked together to form a polymer of glucose called starch, which is stored in the chloroplast for later use. Alternatively, the disaccharide sucrose may be made and transported out of the leaf to other parts of the plant.

The Calvin cycle can be divided into three phases: carbon fixation, reduction and carbohydrate production, and regeneration of ribulose bisphosphate (RuBP) (**Figure 8.13**).

Carbon Fixation (Phase 1) During **carbon fixation**, CO_2 is incorporated into RuBP, a five-carbon sugar. The term fixation means that the carbon has been removed from the atmosphere and fixed into an organic molecule that is not a gas. More specifically, the product of the reaction is a six-carbon intermediate that immediately splits in

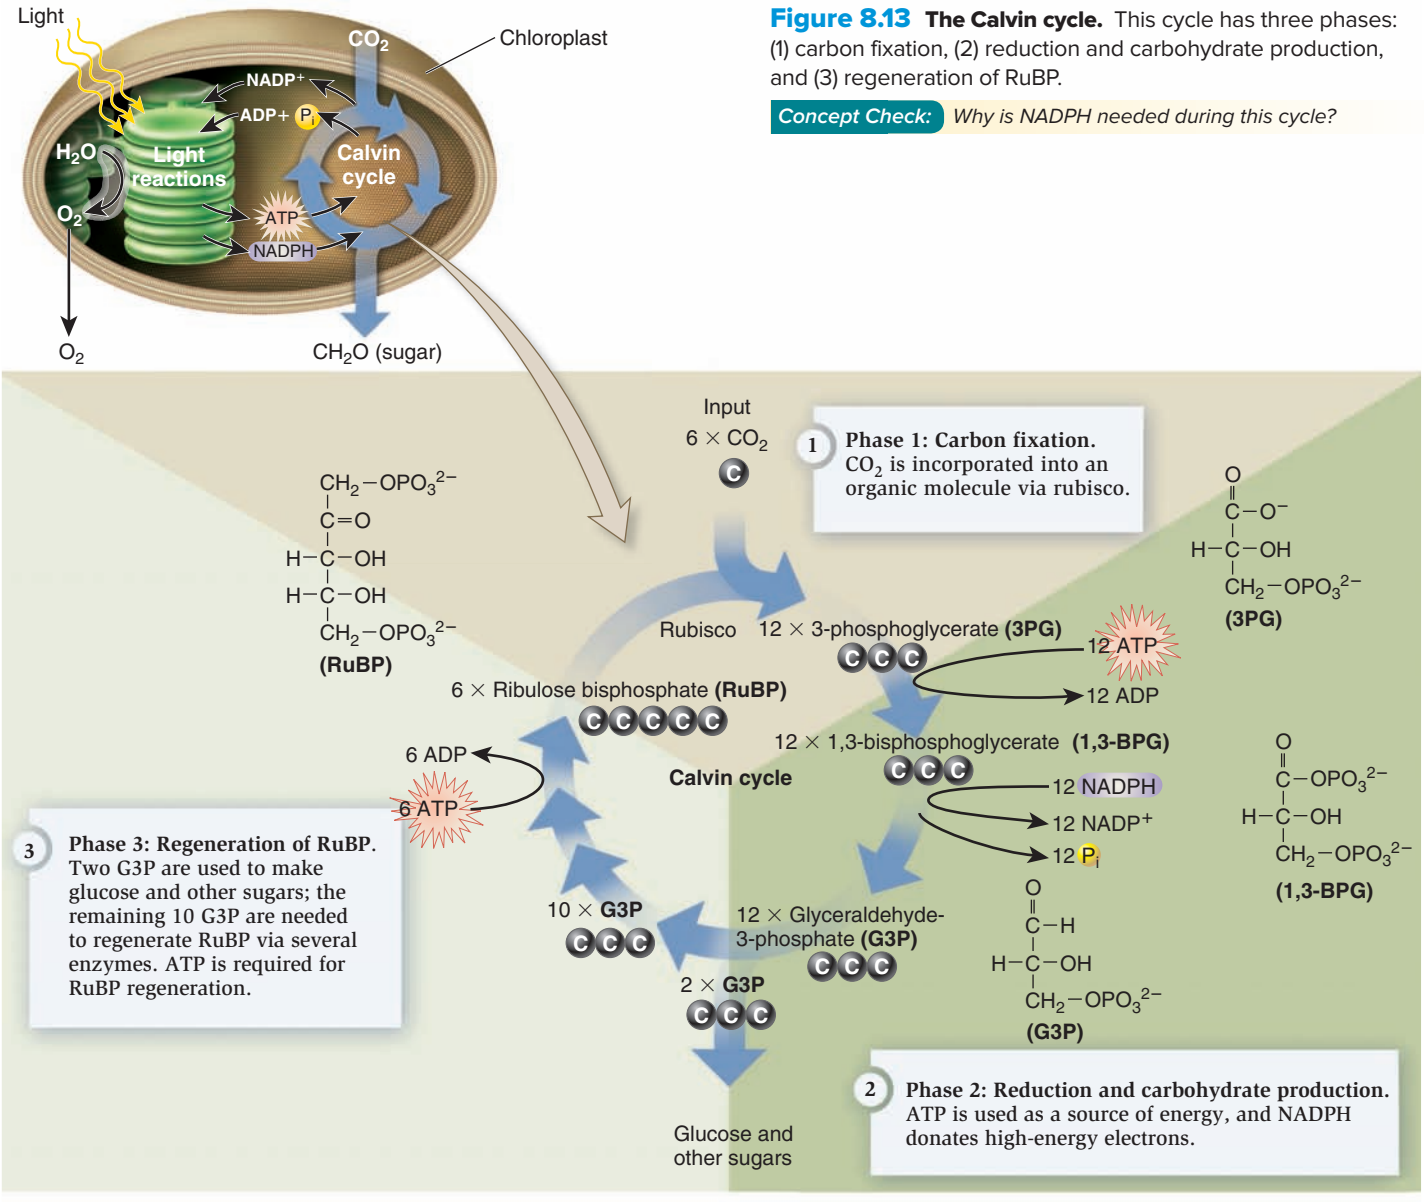

Figure 8.13 The Calvin cycle. This cycle has three phases: (1) carbon fixation, (2) reduction and carbohydrate production, and (3) regeneration of RuBP.

Concept Check: *Why is NADPH needed during this cycle?*

half to form two molecules of 3-phosphoglycerate (3PG). The enzyme that catalyzes this step is named RuBP carboxylase/oxygenase, or **rubisco**. It is the most abundant protein in chloroplasts and perhaps the most abundant protein on Earth! This observation underscores the massive amount of carbon fixation that happens in the biosphere.

Reduction and Carbohydrate Production (Phase 2) In the second phase, ATP is used to convert 3PG to 1,3-bisphosphoglycerate (1,3-BPG). Next, electrons from NADPH reduce 1,3-BPG to glyceraldehyde-3-phosphate (G3P). G3P is a carbohydrate with three carbon atoms. The key difference between 3PG and G3P is that 3PG has a C—O bond, whereas the analogous carbon in G3P has a C—H bond (see Figure 8.13). The C—H bond occurs because the G3P molecule has been reduced by the addition of two electrons from NADPH. Compared with 3PG, the bonds in G3P store more energy and enable G3P to readily form larger organic molecules such as glucose.

As shown in Figure 8.13, only some of the G3P molecules are used to make glucose or other carbohydrates. Phase 1 begins with 6 RuBP molecules and 6 CO_2 molecules. Twelve G3P molecules are made at the end of phase 2, and only 2 of these G3P molecules are used in carbohydrate production. As described next, the other 10 G3P molecules are needed to keep the Calvin cycle turning by regenerating RuBP.

Regeneration of RuBP (Phase 3) In the last phase of the Calvin cycle, a series of enzymatic steps converts the 10 G3P molecules into 6 RuBP molecules, using 6 molecules of ATP. After the RuBP molecules are regenerated, they serve as acceptors for CO_2, thereby allowing the cycle to continue.

As we have just seen, the Calvin cycle begins by using carbon from an inorganic source, that is, CO_2, and ends with organic molecules that will be used by the plant to make other molecules. You may be wondering why CO_2 molecules cannot be directly linked to form these larger molecules. The answer lies in the number of electrons that are around the carbon atoms. In CO_2, the carbon atom is considered electron poor. Oxygen is a very electronegative atom that monopolizes the electrons it shares with other atoms. In a covalent bond between carbon and oxygen, the shared electrons are closer to the oxygen atom.

By comparison, in an organic molecule, the carbon atom is electron rich. During the Calvin cycle, ATP provides energy and NADPH donates high-energy electrons, so the carbon originally in CO_2 has been reduced. The Calvin cycle combines less electronegative atoms with carbon atoms so that C—H and C—C bonds are formed. This allows the eventual synthesis of larger organic molecules, including glucose, amino acids, and so on. In addition, the covalent bonds within these molecules are capable of storing large amounts of energy.

Feature Investigation | The Calvin Cycle Was Determined by Isotope-Labeling Methods

The steps in the Calvin cycle involve the conversion of one type of molecule to another, eventually regenerating the starting material, RuBP. In the 1940s and 1950s, Calvin and his colleagues used ^{14}C, a radioisotope of carbon, to label and trace molecules produced during the cycle (**Figure 8.14**). They injected ^{14}C-labeled CO_2 into cultures of the green alga *Chlorella pyrenoidosa* grown in an apparatus called a "lollipop" (because of its shape). The *Chlorella* cells were given different lengths of time to incorporate the ^{14}C-labeled carbon, ranging from fractions of a second to many minutes. After this incubation period, the cells were abruptly placed into a solution of alcohol to inhibit enzymatic reactions and thereby stop the cycle.

The researchers separated the newly made radiolabeled molecules by a variety of methods. The most commonly used method was two-dimensional paper chromatography. In this approach, a sample containing radiolabeled molecules was spotted onto a corner of the paper at a location called the origin. The edge of the paper was placed in a solvent, such as phenol-water. As the solvent rose through the paper, so did the radiolabeled molecules. The rate at which they rose depended on their structures, which determined how strongly they interacted with the paper. This step separated the mixture of molecules spotted onto the paper at the origin.

The paper was then dried, turned 90°, and then the edge was placed in a different solvent, such as butanol-propionic acid-water. Again, the solvent rose through the paper (in a second dimension), thereby separating molecules that may not have been adequately separated during the first separation step. After this second separation step, the paper was dried and exposed to X-ray film, a procedure called autoradiography. Radioactive emission from the ^{14}C-labeled molecules caused dark spots to appear on the film.

The pattern of spots changed depending on the length of time the cells were incubated with ^{14}C-labeled CO_2. When the incubation period was short, only molecules that were made in the first steps of the Calvin cycle were seen—3-phosphoglycerate (3PG) and 1,3-bisphosphoglycerate (1,3-BPG). Longer incubations revealed molecules synthesized in later steps—glyceraldehyde-3-phosphate (G3P) and ribulose bisphosphate (RuBP).

A challenge for Calvin and his colleagues was to identify the chemical nature of each spot. They achieved this by a variety of chemical methods. For example, a spot could be cut out of the paper, the molecule within the paper could be washed out or eluted, and then the eluted molecule could be subjected to the same procedure that included a radiolabeled molecule whose structure was already known. If the unknown molecule and known molecule migrated to the same spot in the paper, this indicated they were likely to be the same molecule. During the late 1940s and 1950s, Calvin and his coworkers identified all of the ^{14}C-labeled spots and the order in which they appeared. In this way, they determined the series of reactions of what we now know as the Calvin cycle. For this work, Calvin was awarded the Nobel Prize in Chemistry in 1961.

Experimental Questions

1. What was the purpose of the study conducted by Calvin and his colleagues?
2. **SciSKILLS »** In Calvin's experiment shown in Figure 8.14, why did the researchers use ^{14}C? Why did they examine samples at several different time periods? How were the different molecules in the samples identified?
3. **SciSKILLS »** Interpret the results of Calvin's study.

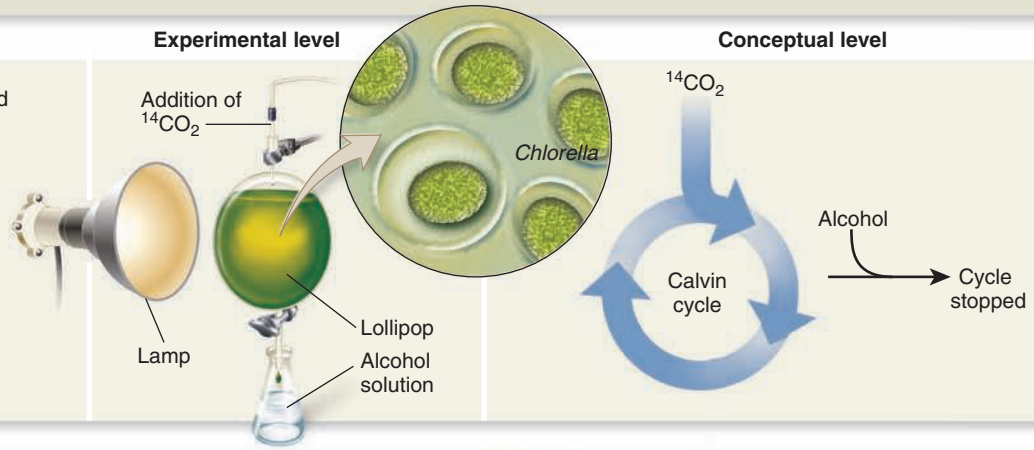

Figure 8.14 The determination of the Calvin cycle using ^{14}C-labeled CO_2 and paper chromatography.

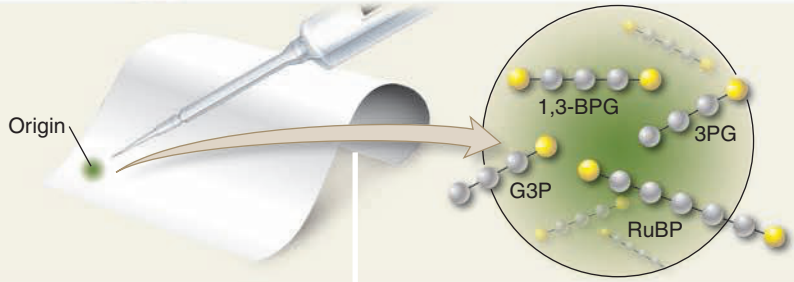
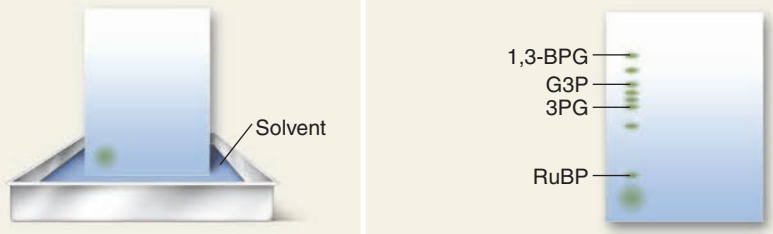
GOAL The incorporation of CO_2 into carbohydrate involves a biosynthetic pathway. The aim of this experiment was to identify the steps.



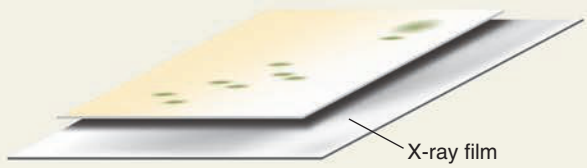
KEY MATERIALS The green alga *Chlorella pyrenoidosa* and ^{14}C-labeled CO_2.

Experimental level **Conceptual level**

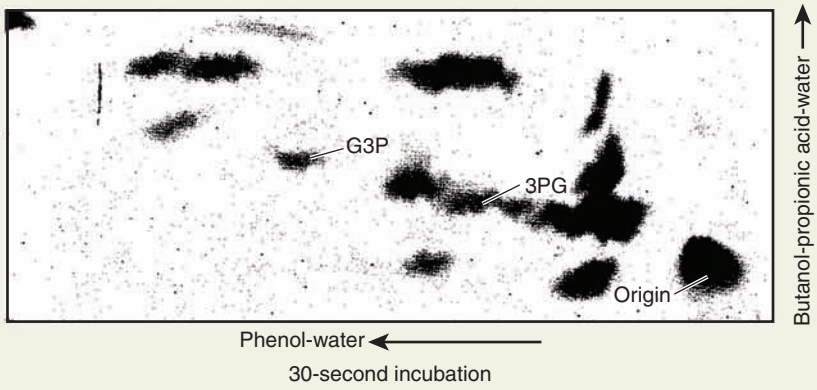


1 Grow *Chlorella* in an apparatus called a "lollipop." Add ^{14}C-labeled CO_2 and incubate for various lengths of time (from fractions of a second to many minutes). Stop the Calvin cycle by placing a sample of cells into a solution of alcohol.

2 Take a sample of the internal cell contents and spot on the corner of chromatography paper. This spot is called the origin.



3 Place edge of paper in a solvent, such as phenol-water, and allow time for solvent to rise and separate the mixture of molecules that were spotted at the origin.



4 Dry paper, turn 90°, and then place the edge in a different solvent such as butanol-propionic acid-water. Allow time for solvent to rise.

5 Dry paper and place next to X-ray film. The developed film reveals dark spots where ^{14}C-labeled molecules were located. This procedure is called autoradiography.

6 THE DATA*

*An autoradiograph from one of Calvin's experiments.

7 CONCLUSION The identification of the molecules in each spot elucidated the steps of the Calvin cycle.

8.5 Variations in Photosynthesis

Learning Outcomes:

1. Explain the concept of photorespiration.
2. Compare and contrast how C_4 and CAM plants avoid photorespiration and conserve water.

Thus far, we have considered photosynthesis as a two-stage process in which the light reactions produce ATP, NADPH, and O_2, and the Calvin cycle uses the ATP and NADPH for the synthesis of carbohydrates. This two-stage process is a universal feature of photosynthesis in all green plants, algae, and cyanobacteria. However, certain environmental conditions such as temperature, water availability, and light intensity alter the way in which the Calvin cycle operates. In this section, we begin by examining how hot and dry conditions may reduce the output of photosynthesis. We will then explore two adaptations that certain plant species have evolved that conserve water and help to maximize photosynthetic efficiency in such environments.

Photorespiration Decreases the Efficiency of Photosynthesis

In the previous section, we learned that rubisco adds a CO_2 molecule to an organic molecule, RuBP, to produce two molecules of 3-phosphoglycerate (3PG):

$$\text{RuBP} + CO_2 \rightarrow 2\ \text{3PG}$$

For most species of plants, the incorporation of CO_2 into RuBP is the only way for carbon fixation to occur. Because 3PG is a three-carbon molecule, these plants are called **C_3 plants**. Examples of C_3 plants include wheat and oak trees (**Figure 8.15**). About 90% of the plant species on Earth are C_3 plants.

Researchers have discovered that the active site of rubisco can also add O_2 to RuBP, although its affinity for CO_2 is over 10-fold better than that for O_2. Even so, when CO_2 levels are low and O_2 levels are high, rubisco adds an O_2 molecule to RuBP. This produces only one molecule of 3PG and a two-carbon molecule called phosphoglycolate. The phosphoglycolate is then dephosphorylated to glycolate, which is released from the chloroplast. In a series of several steps, the two-carbon glycolate is eventually oxidized in peroxisomes and mitochondria to produce an organic molecule plus a molecule of CO_2:

$$\text{RuBP} + O_2 \rightarrow \text{3PG} + \text{Phosphoglycolate}$$

$$\text{Phosphoglycolate} \rightarrow \text{Glycolate} \rightarrow \rightarrow \text{Organic molecule} + CO_2$$

This process, called **photorespiration**, uses O_2 and liberates CO_2. Photorespiration is considered wasteful because it releases CO_2, thereby limiting plant growth.

Photorespiration is more likely to occur when plants are exposed to a hot and dry environment. To conserve water, the stomata of the leaves close, inhibiting the uptake of CO_2 from the air and trapping the O_2 that is produced by photosynthesis. When the level of CO_2 is low and O_2 is high, photorespiration is favored. If C_3 plants are subjected to hot and dry environmental conditions, as much as 25–50% of their photosynthetic work is reversed by the process of photorespiration.

Why do plants carry out photorespiration? The answer is not entirely clear. One common view is that photorespiration is an evolutionary relic. When rubisco first evolved some 3 billion years ago, the atmospheric oxygen level was low, so photorespiration would not have been a problem. Another view is that photorespiration may have a protective advantage. On hot and dry days when the stomata are closed, CO_2 levels within the leaves fall, and O_2 levels rise. Under these conditions, highly toxic oxygen-containing molecules such as free radicals may be produced that could damage the plant. Therefore, plant biologists have hypothesized that the role of photorespiration may be to protect the plant against the harmful effects of such toxic molecules by consuming O_2 and releasing CO_2.

(a) Wheat plants

(b) Oak leaves

Figure 8.15 Examples of C_3 plants. The structures of **(a)** wheat and **(b)** oak leaves are similar to that shown in Figure 8.2.

C_4 Plants Have Evolved a Mechanism to Minimize Photorespiration

Certain species of plants have developed a way to minimize photorespiration. In the early 1960s, Hugo Kortschak discovered that the first product of carbon fixation in sugarcane is not 3GP but instead is a molecule with four carbon atoms. Species such as sugarcane are called **C_4 plants** because of this four-carbon molecule. Later, Marshall Hatch and Roger Slack confirmed this result and identified the molecule as oxaloacetate. For this reason, the pathway is sometimes called the Hatch-Slack pathway.

Some C_4 plants have a unique leaf anatomy that allows them to avoid photorespiration (**Figure 8.16**). An interior layer in the leaves of many C_4 plants has a two-cell organization composed of mesophyll cells and bundle-sheath cells. CO_2 from the atmosphere enters the mesophyll cells via stomata. Once inside, the enzyme PEP carboxylase

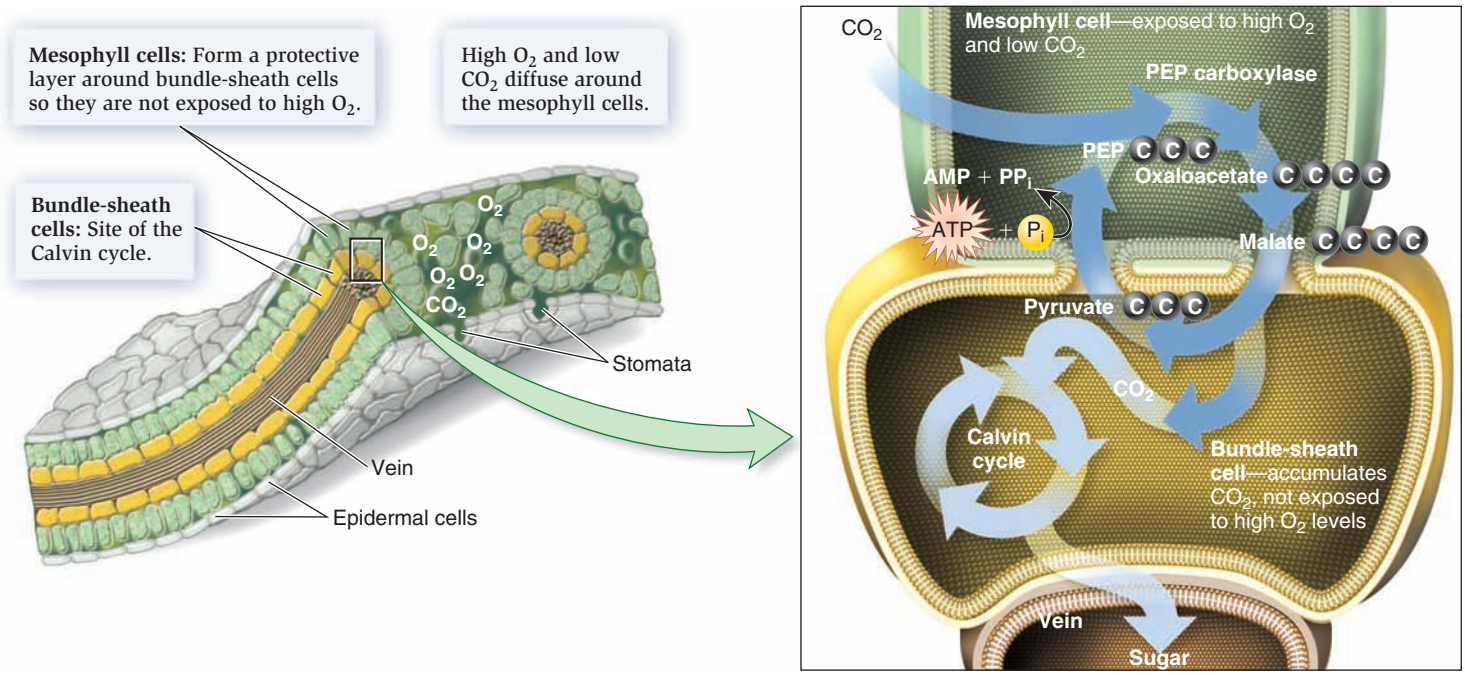

Figure 8.16 Leaf structure and its relationship to the C_4 cycle. C_4 plants have mesophyll cells, which initially take up CO_2, and bundle-sheath cells, where much of the carbohydrate synthesis occurs. Compare this leaf structure with the structure of C_3 leaves shown in Figure 8.2.

Concept Check: *How does this cellular arrangement minimize photorespiration?*

BioConnections: *Look ahead to Figure 38.9. How do plants get water needed for photosynthesis into their leaves?*

adds CO_2 to phosphoenolpyruvate (PEP), a three-carbon molecule, to produce oxaloacetate, a four-carbon molecule. PEP carboxylase does not recognize O_2. Therefore, unlike rubisco, PEP carboxylase does not promote photorespiration when CO_2 is low and O_2 is high. Instead, PEP carboxylase continues to fix CO_2.

As shown in Figure 8.16, oxaloacetate is converted to the four-carbon molecule malate, which is transported into the bundle-sheath cell. Malate is then broken down into pyruvate and CO_2. The pyruvate returns to the mesophyll cell, where it is converted to PEP via ATP, and the cycle in the mesophyll cell can begin again. The CO_2 enters the Calvin cycle in the chloroplasts of the bundle-sheath cells. Because the mesophyll cell supplies the bundle-sheath cell with a steady supply of CO_2, the concentration of CO_2 remains high in the bundle-sheath cell. Also, the mesophyll cells shield the bundle-sheath cells from high levels of O_2. This strategy minimizes photorespiration, which requires low CO_2 and high O_2 levels to proceed.

Which is better—being a C_3 or a C_4 plant? The answer is that it depends on the environment. In warm and dry climates, C_4 plants have an advantage. During the day, they can keep their stomata partially closed to conserve water. Furthermore, they minimize photorespiration. Examples of C_4 plants are sugarcane, crabgrass, and corn. In cooler climates, C_3 plants have the edge because they use less energy to fix CO_2. The process of carbon fixation that occurs in C_4 plants uses ATP to regenerate PEP from pyruvate (see Figure 8.16), which C_3 plants do not have to expend.

CAM Plants Are C_4 Plants That Take Up CO_2 at Night

We have just learned that certain C_4 plants prevent photorespiration by providing CO_2 to the bundle-sheath cells, where the Calvin cycle occurs. This mechanism spatially separates the processes of carbon fixation and the Calvin cycle. Another strategy followed by other C_4 plants, called **CAM plants**, separates these processes in time. CAM stands for crassulacean acid metabolism, because the process was first studied in members of the plant family Crassulaceae. Most CAM plants are water-storing succulents such as cacti, bromeliads (including pineapple), and sedums. To avoid water loss, CAM plants keep their stomata closed during the day and open them at night, when it is cooler and the relative humidity is higher.

How, then, do CAM plants carry out photosynthesis? **Figure 8.17** compares CAM plants with the other type of C_4 plants we considered in Figure 8.16. Photosynthesis in CAM plants occurs entirely within mesophyll cells, but the synthesis of a C_4 molecule and the Calvin cycle occur at different times. During the night, the stomata of CAM plants open, thereby allowing the entry of CO_2 into mesophyll cells. CO_2 is joined with PEP to form the four-carbon molecule oxaloacetate. This is then converted to malate, which accumulates during the night in the central vacuoles of the cells. In the morning, the stomata close to conserve moisture. The accumulated malate in the mesophyll cells leaves the vacuole and is broken down to release CO_2, which then drives the Calvin cycle during the daytime.

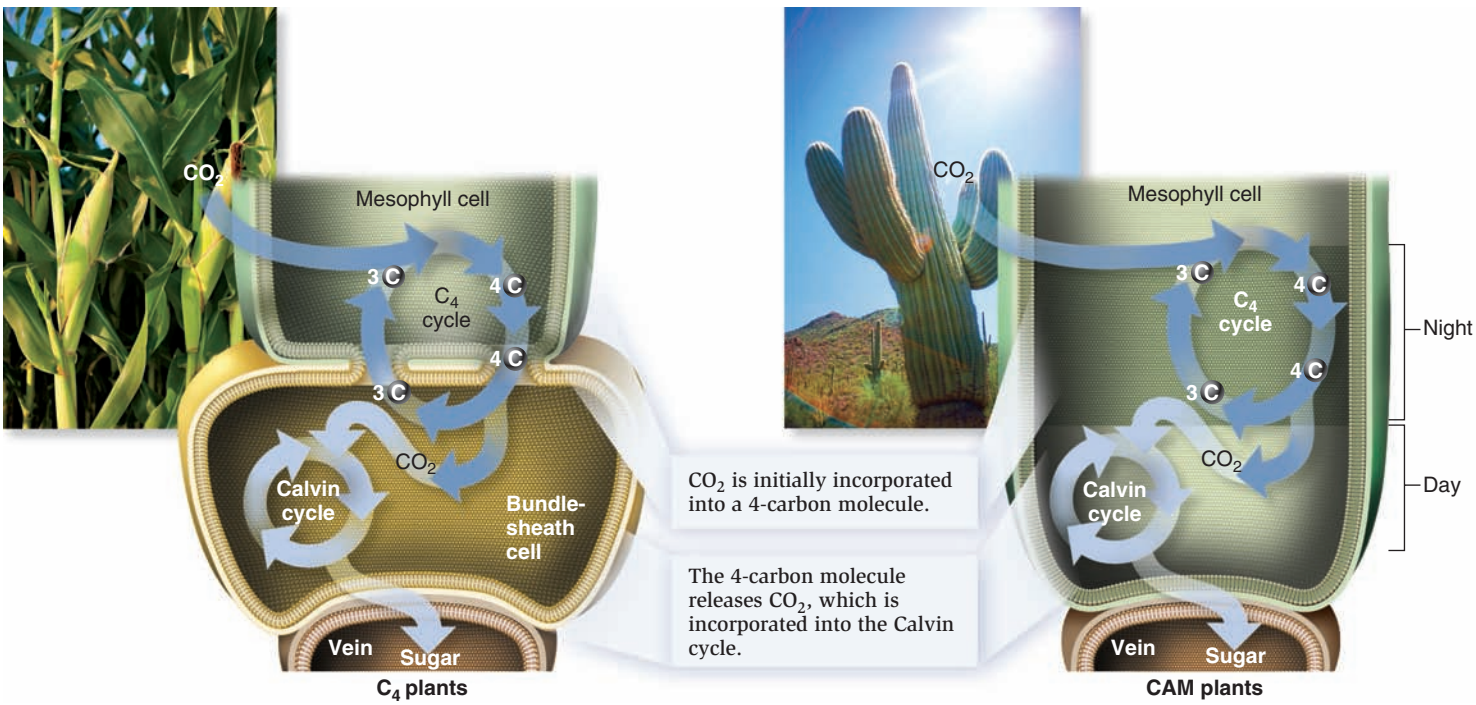

Figure 8.17 A comparison of C_4 and CAM plants. The name C_4 plant describes those plants in which the first organic product of carbon fixation is a four-carbon molecule. Using this definition, CAM plants are a type of C_4 plant. CAM plants, however, do not separate the functions of making a four-carbon molecule and the Calvin cycle into different types of cells. Instead, they make a four-carbon molecule at night and break down that molecule during the day so the CO_2 can be incorporated into the Calvin cycle.

Concept Check: *What are the advantages and disadvantages for C_3, C_4, and CAM plants?*

Summary of Key Concepts

8.1 Overview of Photosynthesis

- Photosynthesis is the process by which plants, algae, and cyanobacteria capture light energy that is used to synthesize carbohydrates.
- During photosynthesis, carbon dioxide, water, and energy are used to make carbohydrates and oxygen.
- Heterotrophs must obtain organic molecules in their food, whereas autotrophs make organic molecules from inorganic sources. Photoautotrophs use the energy from light to make organic molecules.
- An energy cycle occurs in the biosphere in which photosynthesis uses light, CO_2, and H_2O to make organic molecules, and the organic molecules are broken back down to CO_2 and H_2O via cellular respiration to supply energy in the form of ATP (Figure 8.1).
- In plants and algae, photosynthesis occurs within chloroplasts, organelles with an outer membrane, inner membrane, and thylakoid membrane. The stroma is the fluid-filled region between the thylakoid membrane and inner membrane. In plants, the leaves are the major site of photosynthesis (Figure 8.2).
- The light reactions of photosynthesis capture light energy to make ATP, NADPH, and O_2. These reactions occur at the thylakoid membrane. Carbohydrate synthesis via the Calvin cycle uses ATP and NADPH from the light reactions and happens in the stroma (Figure 8.3).

8.2 Reactions That Harness Light Energy

- Light is a form of electromagnetic radiation that travels in waves and is composed of photons with discrete amounts of energy (Figure 8.4).
- Electrons can absorb light energy and be boosted to a higher energy level—an excited state (Figure 8.5).
- Photosynthetic pigments include chlorophylls *a* and *b* and carotenoids. These pigments absorb light energy in the visible spectrum to drive photosynthesis (Figures 8.6, 8.7).
- During linear electron flow, electrons from photosystem II (PSII) follow a pathway along an electron transport chain (ETC) in the thylakoid membrane. This pathway generates an H^+ gradient that is used to make ATP. In addition, light energy striking photosystem I (PSI) boosts electrons to a very high energy level that allows the synthesis of NADPH (Figure 8.8).
- During cyclic photophosphorylation, electrons are activated in PSI and flow through the ETC back to PSI. This cyclic electron flow produces an H^+ gradient that is used to make ATP (Figure 8.9).
- Cytochrome b_6 in chloroplasts and cytochrome *b* in mitochondria are homologous proteins involved in electron transport and H^+ pumping (Figure 8.10).

8.3 Molecular Features of Photosystems

- In the light-harvesting complex of PSII, pigment molecules absorb light energy that is transferred to the reaction center via resonance energy transfer. A high-energy electron from P680* is transferred to a primary electron acceptor. An electron from water is then used to replenish the electron lost from P680* (Figure 8.11).
- The Z scheme proposes that an electron absorbs light energy twice, at both PSII and PSI, losing some of that energy as it flows along the ETC in the thylakoid membrane (Figure 8.12).

8.4 Synthesizing Carbohydrates via the Calvin Cycle

- The Calvin cycle is composed of three phases: carbon fixation, reduction and carbohydrate production, and regeneration of ribulose bisphosphate (RuBP). In the cycle, ATP is used as a source of energy, and NADPH is used as a source of high-energy electrons to incorporate CO_2 into carbohydrate (Figure 8.13).
- Calvin and Benson determined the steps in the Calvin cycle by isotope-labeling methods in which the products of the Calvin cycle were separated by chromatography (Figure 8.14).

8.5 Variations in Photosynthesis

- C_3 plants incorporate CO_2 only into RuBP to make 3PG, a three-carbon molecule (Figure 8.15).
- Photorespiration occurs when the level of O_2 is high and CO_2 is low, which happens under hot and dry conditions. During this process, some O_2 is used and CO_2 is liberated. Photorespiration is inefficient because it reverses the incorporation of CO_2 into an organic molecule.
- Some C_4 plants avoid photorespiration because the CO_2 is first incorporated, via PEP carboxylase, into a four-carbon molecule, which is pumped from mesophyll cells into bundle-sheath cells. This maintains a high concentration of CO_2 in the bundle-sheath cells, where the Calvin cycle occurs. The high CO_2 concentration minimizes photorespiration (Figure 8.16).
- CAM plants, a type of C_4 plant, prevent photorespiration by fixing CO_2 into a four-carbon molecule at night and then running the Calvin cycle during the day with their stomata closed to reduce water loss (Figure 8.17).

Assess and Discuss

Test Yourself

1. The water necessary for photosynthesis
   a. is split into H_2 and O_2.
   b. is directly involved in the synthesis of carbohydrates.
   c. provides the electrons to replace lost electrons in photosystem II.
   d. provides H^+ needed to synthesize G3P.
   e. does none of the above.
2. In PSII, P680 differs from the other pigment molecules of the light-harvesting complex in that it
   a. is a carotenoid.
   b. absorbs light energy and transfers that energy to other molecules without the transfer of electrons.
   c. transfers an excited electron to the primary electron acceptor.
   d. does not transfer an excited electron to the primary electron acceptor.
   e. acts as an ATP synthase to produce ATP.
3. The cyclic electron flow that occurs via photosystem I produces
   a. NADPH.
   b. oxygen.

c. ATP.
d. all of the above.
e. a and c only.

4. During linear electron flow, the high-energy electron from P680*
   a. eventually moves to $NADP^+$.
   b. becomes incorporated in water molecules.
   c. is pumped into the thylakoid space to drive ATP production.
   d. provides the energy necessary to split water molecules.
   e. falls back to the low-energy state in photosystem II.

5. During the first phase of the Calvin cycle, carbon dioxide is incorporated into ribulose bisphosphate (RuBP) by
   a. oxaloacetate.
   b. rubisco.
   c. RuBP.
   d. quinone.
   e. G3P.

6. The NADPH produced during the light reactions is necessary for
   a. the carbon fixation phase, which incorporates carbon dioxide into an organic molecule of the Calvin cycle.
   b. the reduction phase, which produces carbohydrates in the Calvin cycle.
   c. the regeneration of RuBP of the Calvin cycle.
   d. all of the above.
   e. a and b only.

7. The majority of the G3P produced during the reduction and carbohydrate production phase is used to produce
   a. glucose.
   b. ATP.
   c. RuBP to continue the cycle.
   d. rubisco.
   e. all of the above.

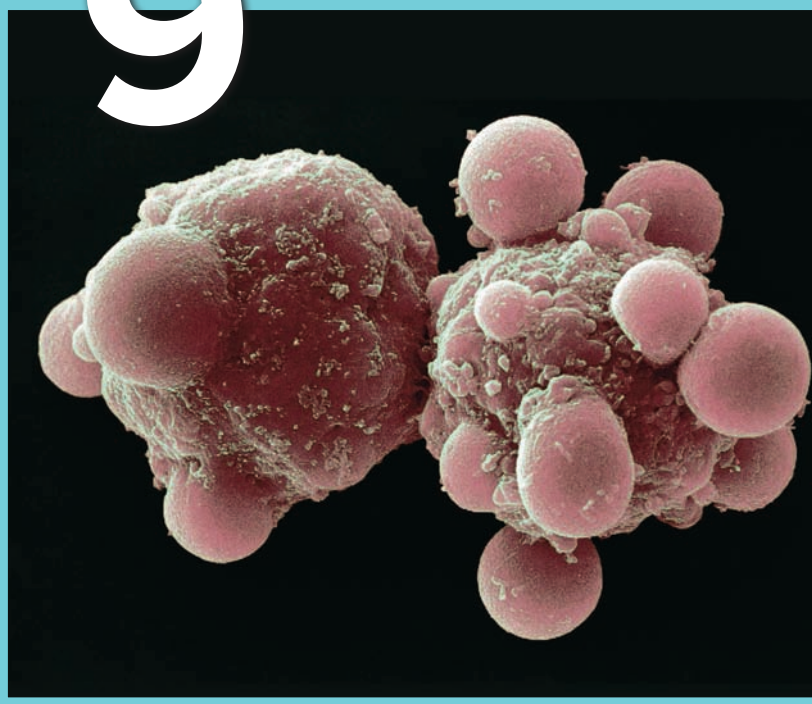
8. Photorespiration
   a. is the process where plants use sunlight to make ATP.
   b. is an inefficient way plants can produce organic molecules and in the process use O_2 and release CO_2.
   c. is a process that plants use to convert light energy to NADPH.
   d. occurs in the thylakoid lumen.
   e. is the normal process of carbohydrate production in cool, moist environments.

9. Photorespiration is avoided in C_4 plants because
   a. these plants separate the formation of a four-carbon molecule from the rest of the Calvin cycle in different cells.
   b. these plants carry out only anaerobic respiration.
   c. the enzyme PEP carboxylase functions to maintain high CO_2 concentrations in the bundle-sheath cells.
   d. all of the above.
   e. a and c only.

10. Plants commonly found in hot and dry environments that carry out carbon fixation at night are
    a. oak trees.
    b. C_3 plants.
    c. CAM plants.
    d. all of the above.
    e. a and b only.

Conceptual Questions

1. What are the two stages of photosynthesis? What are the key products of each stage?
2. What is the function of NADPH in the Calvin cycle?
3.  A principle of biology is that *living organisms use energy*. At the level of the biosphere, what is the role of photosynthesis in the utilization of energy by living organisms?



Collaborative Questions

1. Discuss the advantages and disadvantages of being a heterotroph or a photoautotroph.
2. Biotechnologists are trying to genetically modify C_3 plants to convert them to C_4 or CAM plants. Why would this be useful? What genes might you introduce into C_3 plants to convert them to C_4 or CAM plants?

CHAPTER OUTLINE

9.1 General Features of Cell Communication
9.2 Cellular Receptors and Their Activation
9.3 Signal Transduction and the Cellular Response
9.4 Hormonal Signaling in Multicellular Organisms
9.5 Apoptosis: Programmed Cell Death
Summary of Key Concepts
Assess and Discuss

9 Cell Communication

Programmed cell death. The two cells shown here are breaking apart because signaling molecules initiated a pathway that programmed their death.

Over 2 billion cells will die in your body during the next hour. In an adult human body, approximately 50–70 billion cells die each day due to programmed cell death—the process in which a cell breaks apart into small fragments (see chapter opening photo). In a year, your body produces and purposely destroys a mass of cells that is equal to your own body's weight! Though this may seem like a scary process, it's actually keeping you healthy. Programmed cell death, also called apoptosis, ensures that your body maintains a proper number of cells. It also eliminates cells that are worn out or potentially harmful, such as cancer cells. Programmed cell death can occur via signals that intentionally cause particular cells to die, or it can result from a failure of proper cell communication. It may also happen when environmental agents cause damage to a cell. Programmed cell death is one example of a response that involves **cell communication**—the process through which cells can detect, interpret, and respond to signals in their environment. A **signal** is an agent that can influence the properties of cells.

In this chapter, we will examine how cells detect environmental signals and also how they produce signals that enable them to communicate with other cells. Communication at the cellular level involves not only receiving and sending signals but also their interpretation. For this to occur, a signal must be recognized by a cellular protein called a **receptor**. When a signal and a receptor interact, the receptor changes shape, or conformation, thereby changing the way the receptor interacts with cellular factors. These interactions eventually lead to some type of response in the cell. We begin the chapter with the general features of cell communication, and then discuss the main ways in which cells receive, process, and respond to signals sent by other cells. As you will learn, cell communication involves an amazing diversity of signaling molecules and cellular proteins that are devoted to this process. We conclude by looking at the role of cell communication in apoptosis, in which a cell becomes programmed to die.

9.1 General Features of Cell Communication

Learning Outcomes:

1. Describe the two general reasons for cell signaling: responding to environmental changes and cell-to-cell communication.
2. Compare and contrast the five ways that cells communicate with each other based on the distance between cells.
3. Outline the three-stage process of cell signaling.

All living cells, including bacteria, archaea, protists, fungi, and plant and animal cells, conduct and require cell communication to survive. Cell communication, also known as cell signaling, involves both incoming and outgoing signals. For example, on a sunny day, cells can sense their exposure to ultraviolet (UV) light—a physical signal—and respond accordingly. In humans,

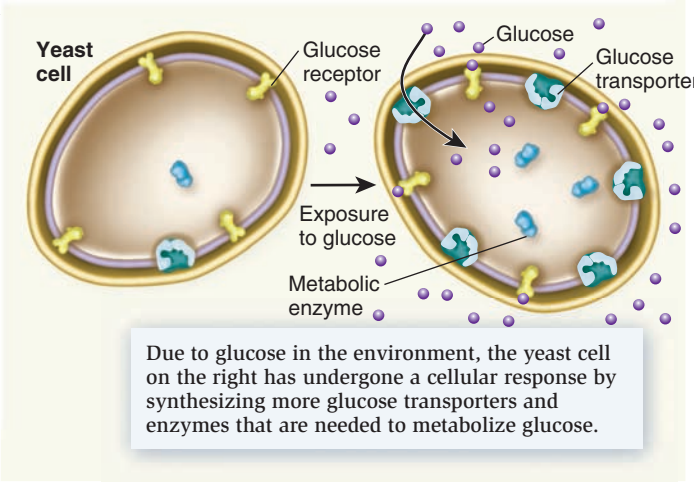


Figure 9.1 Response of a yeast cell to glucose. When glucose is absent from the extracellular environment, the cell is not well prepared to take up and metabolize this sugar. However, when glucose is present, some of that glucose binds to receptors in the membrane, which leads to changes in the amounts and properties of intracellular and membrane proteins so the cell can readily use glucose.

BIOLOGY PRINCIPLE Living organisms interact with their environment. In this example, cell signaling allows yeast cells to respond to the presence of glucose in their environment.

Concept Check: What is the signaling molecule in this example?

UV light acts as an incoming signal to promote the synthesis of melanin, a protective pigment that helps to prevent the harmful effects of UV radiation. In addition, cells produce outgoing signals that influence the behavior of neighboring cells. Plant cells, for example, produce hormones that influence the pattern of cell elongation so the plant grows toward light. Cells of all living organisms both respond to incoming signals and produce outgoing signals. Cell communication is a two-way street.

In this section, we begin by considering why cells need to respond to signals. We will then examine various forms of signaling that are based on the distance between the cells that communicate with each other. Finally, we will examine the main steps that occur when a cell is exposed to a signal and elicits a response to it.

Cells Detect and Respond to Signals from Their Environment and from Other Cells

Before getting into the details of cell communication, let's take a general look at why cell communication is necessary.

Responding to Changes in the Environment The first reason is that cells need to respond to a changing environment. Changes in the environment are a persistent feature of life, and living cells are continually faced with alterations in temperature and availability of nutrients, water, and light. A cell may even be exposed to a toxic chemical in its environment. Being able to respond to change at the cellular level is called a **cellular response**.

As an example, let's consider the response of a yeast cell to glucose in its environment (**Figure 9.1**). Some of the glucose acts as a signaling molecule that binds to a receptor and causes a cellular response. In this case, the cell responds by increasing the number of glucose transporters needed to take glucose into the cell and also by increasing the number of metabolic enzymes required to utilize glucose once it is inside. The cellular response allows the cell to use glucose efficiently.

Cell-to-Cell Communication A second reason for cell signaling is the need for cells to communicate with each other—a type of cell communication called **cell-to-cell communication**. In one of the earliest experiments demonstrating cell-to-cell communication, Charles Darwin and his son Francis Darwin studied phototropism, the phenomenon in which plants grow toward light (**Figure 9.2**). The Darwins observed that the actual bending occurs in a zone below the growing shoot tip. They concluded that a signal must be transmitted from the growing tip to lower parts of the shoot. Later research revealed that the signal is a molecule called auxin, which is transmitted from cell to cell. A higher amount of auxin accumulates on the nonilluminated side of the shoot and promotes cell elongation on that side of the shoot only, thereby causing the shoot to bend toward the light source.

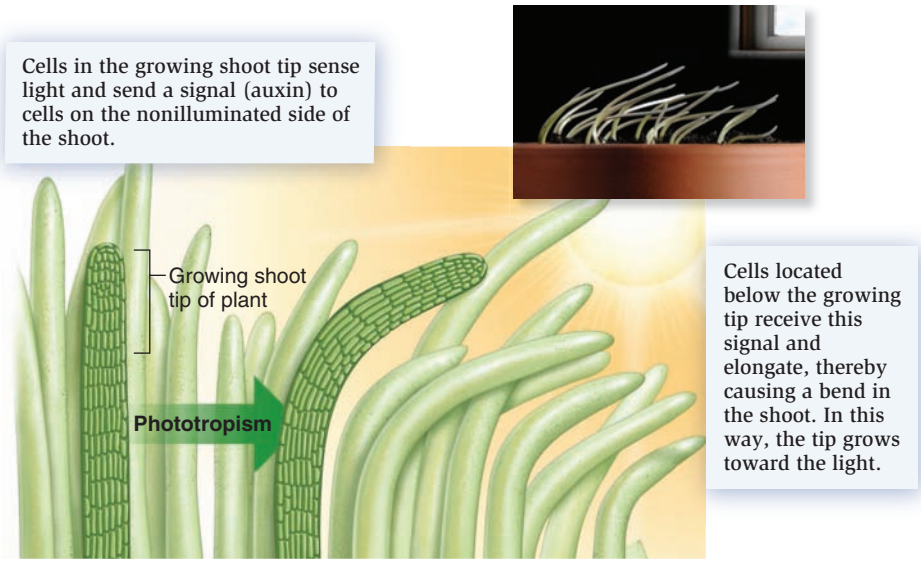

Figure 9.2 Phototropism in plants. This process involves cell-to-cell communication that leads to a shoot bending toward light just beneath its actively growing tip.

BioConnections: Look ahead to Figure 36.5. How does light affect the distribution of auxin produced by a plant's growing shoot tip?

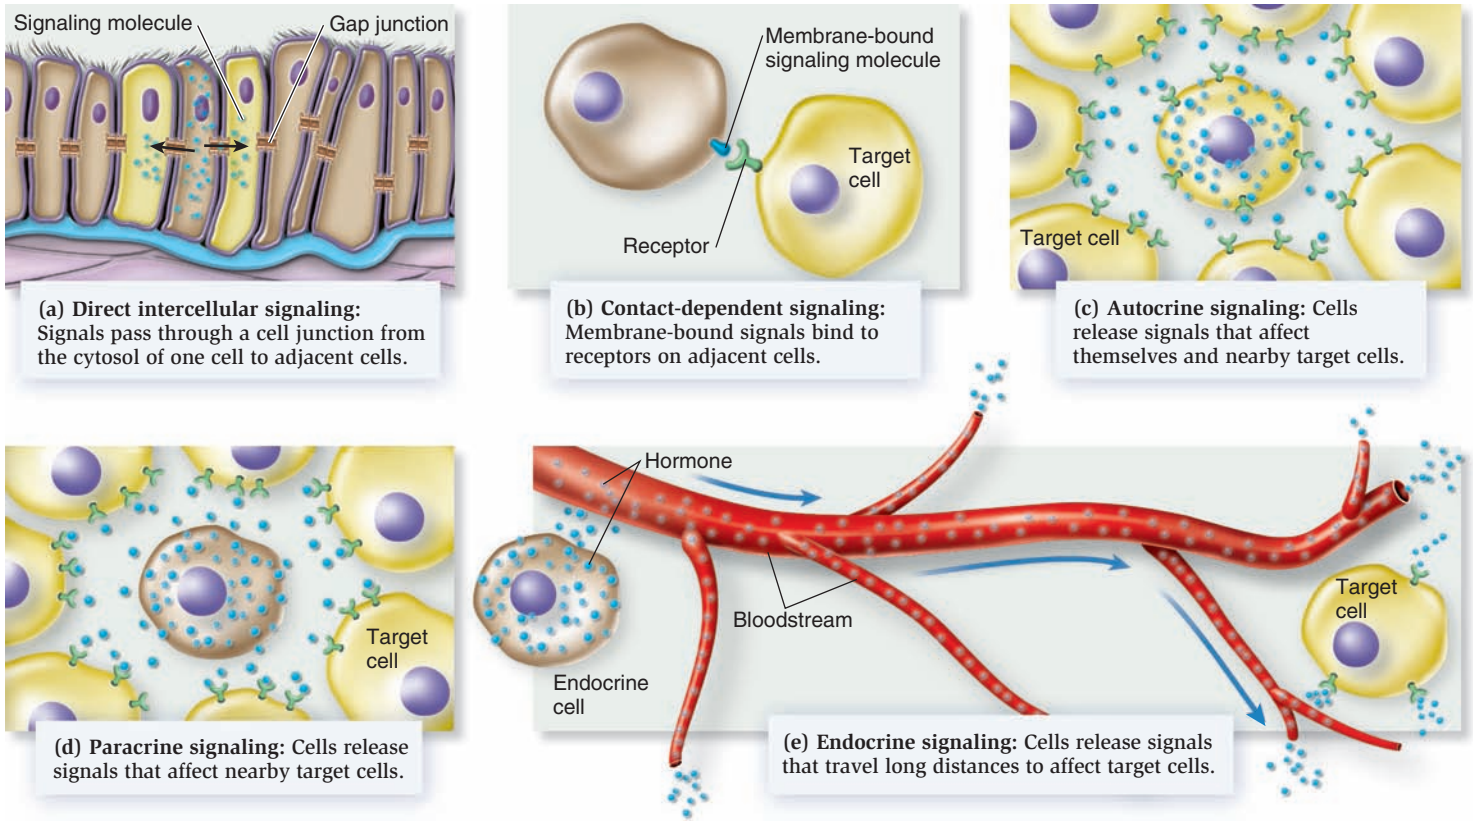

Figure 9.3 **Types of cell-to-cell communication based on the distance between cells.**

Concept Check: *Which type of signal, paracrine or endocrine, is likely to exist for a longer period of time? Explain why this is necessary.*

Cell-to-Cell Communication Can Occur Between Adjacent Cells and Between Cells That Are Long Distances Apart

Organisms have a variety of different mechanisms to achieve cell-to-cell communication. The mode of communication depends, in part, on the distance between the cells that need to communicate with each other. Let's first examine the various ways in which signals are transferred between cells. Later in this chapter, we will learn how such signals elicit a cellular response.

One way to categorize cell signaling is by the manner in which the signal is transmitted from one cell to another. Signals are relayed between cells in five common ways, all of which involve a cell that produces a signal and a target cell that receives the signal (**Figure 9.3**).

Direct Intercellular Signaling In a multicellular organism, cells adjacent to each other may have contacts, called cell junctions, that enable them to pass ions, signaling molecules, and other materials between the cytosol of one cell and the cytosol of another (Figure 9.3a). For example, cardiac muscle cells, which cause your heart to beat, have intercellular connections called gap junctions that allow the passage of ions needed for the coordinated contraction of cardiac muscle cells. We will examine how gap junctions work in Chapter 10.

Contact-Dependent Signaling Not all signaling molecules diffuse from one cell to another. Some molecules are bound to the surface of cells and provide a signal to other cells that make contact with the surface of that cell (Figure 9.3b). In this case, one cell has a membrane-bound signaling molecule that is recognized by a receptor on the surface of another cell. This occurs, for example, when portions of neurons (nerve cells) grow and make contact with other neurons. This is important for the formation of the proper connections between neurons.

Autocrine Signaling In autocrine signaling, a cell secretes signaling molecules that bind to receptors on its own cell surface and on neighboring cells of the same cell type, stimulating a response (Figure 9.3c). What is the purpose of autocrine signaling? It is often important for groups of cells to sense cell density. When cell density is high, the concentration of autocrine signals is also high. In some cases, such signals inhibit further cell growth, thereby limiting cell density.

Paracrine Signaling In paracrine signaling, a specific cell secretes a signaling molecule that does not affect the cell secreting the signal but instead influences the behavior of target cells in close proximity (Figure 9.3d). Paracrine signaling is typically of short duration. Usually, the signal is broken down too quickly to be carried to other parts of the body and affect distant cells. A specialized form of paracrine signaling occurs in the nervous systems of animals. Neurotransmitters—molecules made in neurons that transmit a signal to an adjacent cell—are released at the end of the neuron and traverse a narrow space called the synapse (see Chapter 41). The neurotransmitter then binds to a receptor in a target cell.

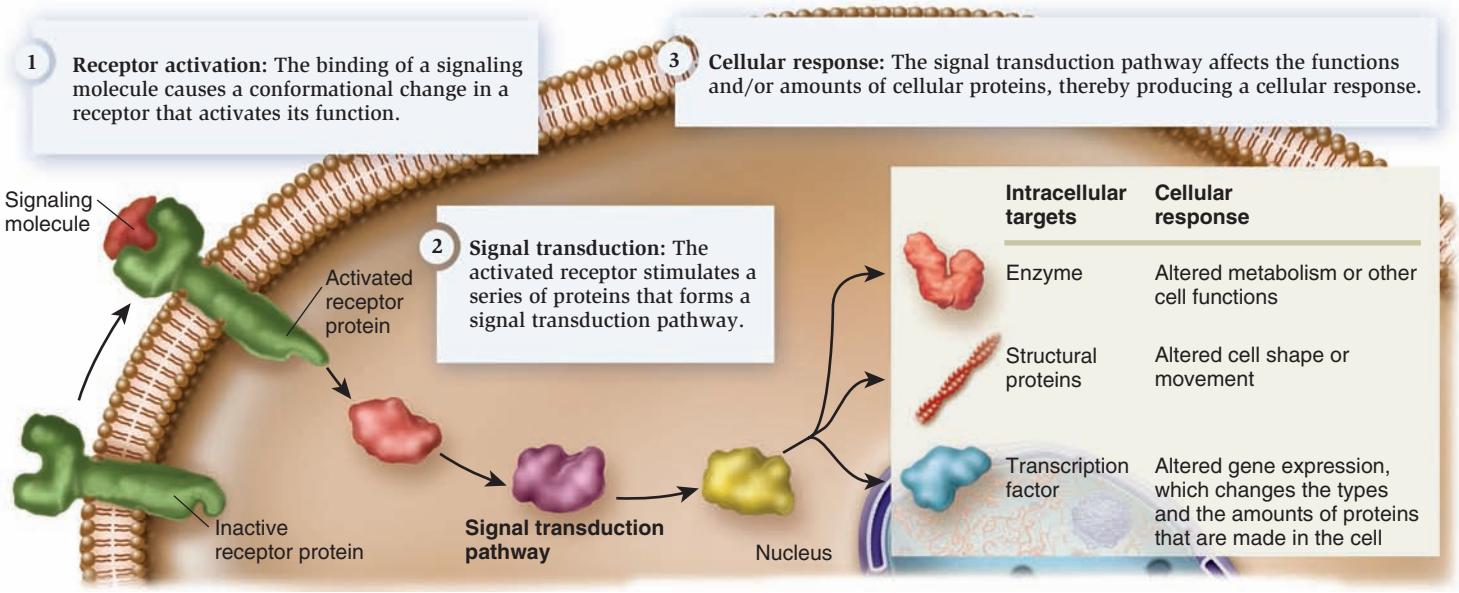

Figure 9.4 **The three stages of cell signaling: receptor activation, signal transduction, and a cellular response.**

Concept Check: *For most signaling molecules, explain why a signal transduction pathway is necessary.*

Endocrine Signaling In contrast to the previous mechanisms of cell signaling, endocrine signaling occurs over relatively long distances (Figure 9.3e). In both animals and plants, molecules involved in long-distance signaling are called **hormones**. They usually last longer than signaling molecules involved in autocrine and paracrine signaling. In mammals, endocrine signaling involves the secretion of hormones into the bloodstream, which may affect virtually all cells of the body, including those that are far from the cells that secrete the signaling molecules. In flowering plants, hormones move through the plant vascular system and also move through adjacent cells. Some hormones are even gases that diffuse into the air. Ethylene, a gas given off by plants, plays a variety of roles, such as accelerating the ripening of fruit.

Cells Usually Respond to Signals via a Three-Stage Process

Up to this point, we have learned that signals influence the behavior of cells in close proximity or at long distances, interacting with receptors to elicit a cellular response. What events occur when a cell encounters a signal? In most cases, the binding of a signaling molecule to a receptor causes the receptor to activate a signal transduction pathway, which then leads to a cellular response. **Figure 9.4** diagrams the three common stages of cell signaling: receptor activation, signal transduction, and a cellular response.

Stage 1: Receptor Activation In the initial stage, a signaling molecule binds to a receptor in the target cell, causing a conformational change in the receptor that activates its function. In most cases, the activated receptor initiates a response by causing changes in a series of proteins that collectively forms a signal transduction pathway, as described next.

Stage 2: Signal Transduction During signal transduction, the initial signal is converted—or transduced—to a different signal inside the cell. This process is carried out by a group of proteins that form a **signal transduction pathway**. These proteins undergo a series of changes that may result in the production of an intracellular signaling molecule. However, some receptors are intracellular and do not activate a signal transduction pathway. As discussed later, certain types of intracellular receptors directly cause a cellular response.

Stage 3: Cellular Response Cells respond to signals in several different ways. Figure 9.4 shows three common categories of proteins that are controlled by cell signaling: enzymes, structural proteins, and transcription factors.

Many signaling molecules exert their effects by altering the activity of one or more enzymes. For example, certain hormones provide a signal that the body needs energy. These hormones activate enzymes that are required for the breakdown of molecules such as carbohydrates.

Cells also respond to signals by altering the functions of structural proteins in the cell. For example, when animal cells move during embryonic development or when an amoeba moves toward food, signals play a role in the rearrangement of actin filaments, which are components of the cytoskeleton. The coordination of signaling and changes in the cytoskeleton enables a cell to move in the correct direction.

Cells may also respond to signals by affecting the function of **transcription factors**—proteins that regulate the transcription of genes. Some transcription factors activate gene expression. For example, when cells are exposed to sex hormones, transcription factors activate genes that change the properties of cells, which can lead to changes in the sexual characteristics of entire organisms. As discussed in Chapter 51 (see Section 51.3), estrogens and androgens are

responsible for the development of secondary sex characteristics in humans, including breast development in females and beard growth in males, respectively.

9.2 Cellular Receptors and Their Activation

Learning Outcomes:

1. **SciSKILLS »** Calculate the affinity, measured as a dissociation constant, that a receptor has for its signaling molecule, or ligand.
2. Explain how a signaling molecule activates a receptor.
3. Identify three general types of cell surface receptors.
4. Describe intracellular receptors, using estrogen receptors as an example.

In this section, we will take a closer look at receptors and how they interact with signaling molecules. We will compare receptors based on whether they are located on the cell surface or inside the cell. In this chapter, our focus will be on receptors that respond to chemical signaling molecules. Other receptors discussed in Units VI and VII respond to mechanical motion (mechanoreceptors), temperature changes (thermoreceptors), and light (photoreceptors).

Signaling Molecules Bind to Receptors

The ability of cells to respond to a signal usually requires precise recognition between a signal and its receptor. In many cases, the signal is a molecule, such as a steroid or a protein, that binds to the receptor. A signaling molecule binds to a receptor in much the same way that a substrate binds to the active site of an enzyme, as described in Chapter 6. The signaling molecule, which is called a **ligand**, binds noncovalently to the receptor with a high degree of specificity. The binding occurs when the ligand and receptor happen to collide in the correct orientation with enough energy to form a **ligand•receptor complex**.

$$[\text{Ligand}] + [\text{Receptor}] \underset{k_{off}}{\overset{k_{on}}{\rightleftharpoons}} [\text{Ligand•Receptor complex}]$$

Brackets [ ] refer to concentration. The value k_{on} is the rate at which binding occurs. After a complex forms between the ligand and its receptor, the noncovalent interaction between ligand and receptor remains stable for a finite period of time. The term k_{off} is the rate at which the ligand•receptor complex falls apart or dissociates.

In general, the binding and release between a ligand and its receptor are relatively rapid, and therefore an equilibrium is reached when the rate of formation of new ligand•receptor complexes equals the rate at which existing ligand•receptor complexes dissociate:

$$k_{on}\,[\text{Ligand}][\text{Receptor}] = k_{off}\,[\text{Ligand•Receptor complex}]$$

Rearranging,

$$\frac{[\text{Ligand}][\text{Receptor}]}{[\text{Ligand•Receptor complex}]} = \frac{k_{off}}{k_{on}} = K_d$$

K_d is called the **dissociation constant** between a ligand and its receptor. The K_d value is inversely related to the affinity between the ligand and receptor. A low K_d value indicates that a receptor has a high affinity for its ligand.

Let's look carefully at the left side of this equation and consider what it means. At a ligand concentration at which half of the receptors are bound to a ligand, the concentration of the ligand•receptor complex equals the concentration of receptor that doesn't have ligand bound. At this ligand concentration, [Receptor] and [Ligand•Receptor complex] cancel out of the equation because they are equal. Therefore, at a ligand concentration at which half of the receptors have bound ligand:

$$K_d = [\text{Ligand}]$$

When the ligand concentration is above the K_d value, most of the receptors are likely to have ligand bound to them. In contrast, if the ligand concentration is substantially below the K_d value, most receptors will not be bound by their ligand. The K_d values for many different ligands and their receptors have been experimentally determined. How is this information useful? It allows researchers to predict when a signaling molecule is likely to cause a cellular response. If the concentration of a signaling molecule is far below the K_d value, a cellular response is not likely because relatively few receptors form a complex with the signaling molecule.

Receptors Undergo Conformational Changes

Unlike enzymes, which convert their substrates into products, receptors do not usually alter the structure of their ligands. Instead, the ligands alter the structure of their receptors, causing a conformational change (**Figure 9.5**). In this case, the binding of the ligand to its receptor changes the receptor in a way that activates its ability to initiate a cellular response.

Because the binding of a ligand to its receptor is a reversible process, the ligand and receptor also dissociate. Once the ligand is released, the receptor is no longer activated.

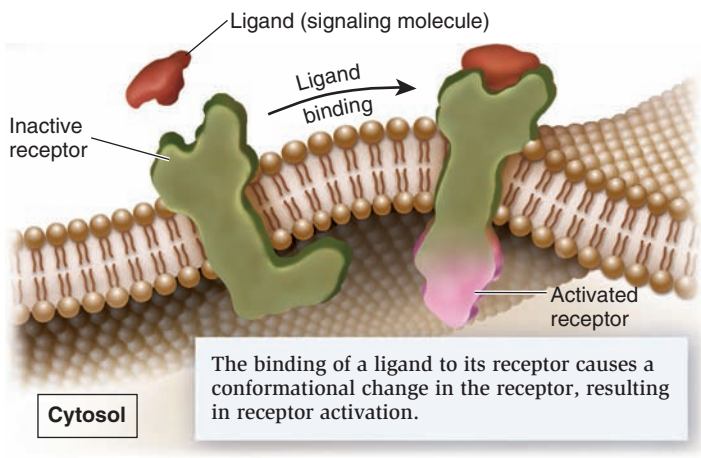

Figure 9.5 Receptor activation.

BioConnections: Look back at Figure 6.6. How is the binding of a ligand to its receptor similar to the binding of a substrate to an enzyme? How are they different?

Cells Contain a Variety of Cell Surface Receptors That Respond to Extracellular Signals

Most signaling molecules are either small hydrophilic molecules or large molecules that do not readily pass through the plasma membrane of cells. Such extracellular signals bind to **cell surface receptors**—receptors found in the plasma membrane. A typical cell is expected to contain dozens or even hundreds of different cell surface receptors that enable the cell to respond to different kinds of extracellular signaling molecules. By analyzing the functions of cell surface receptors from many different organisms, researchers have determined that most fall into one of three categories: enzyme-linked receptors, G-protein-coupled receptors, and ligand-gated ion channels, which are described next.

Enzyme-Linked Receptors Receptors known as **enzyme-linked receptors** are found in all living species. Many human hormones bind to this type of receptor. For example, when insulin binds to an enzyme-linked receptor in muscle cells, it enhances the ability of those cells to use glucose. Enzyme-linked receptors typically have two important domains: an extracellular domain, which binds a signaling molecule, and an intracellular domain, which has a catalytic function (**Figure 9.6a**). When a signaling molecule binds to the extracellular domain, a conformational change is transmitted through the membrane-embedded portion of the protein and affects the conformation of the intracellular catalytic domain. In most cases, this conformational change causes the intracellular catalytic domain to become functionally active.

Most types of enzyme-linked receptors function as **protein kinases**, enzymes that transfer a phosphate group from ATP to specific amino acids in a protein (**Figure 9.6b**). For example, tyrosine kinases attach phosphate to the amino acids serine and threonine. In the example shown in Figure 9.6b, the catalytic domain of the receptor remains inactive when no signaling molecule is present. However, when a signal binds to the extracellular domain, the catalytic domain is activated. Under these conditions, the receptor may phosphorylate itself, or it may phosphorylate intracellular proteins. The attachment of a negatively charged phosphate changes the structure of a protein and thereby alters its function. Later in this chapter, we will explore how this event leads to a cellular response, such as the activation of enzymes that affect cell function.

G-Protein-Coupled Receptors Receptors called **G-protein-coupled receptors (GPCRs)** are found in the cells of all eukaryotic species and are particularly common in animals. GPCRs typically contain seven transmembrane segments that wind back and forth through the plasma membrane. The receptors interact with intracellular proteins called **G proteins**, which are so named because of their ability to bind guanosine triphosphate (GTP) and guanosine diphosphate (GDP). GTP is similar in structure to ATP except it has guanine as a base instead of adenine. In the 1970s, the existence of G proteins was first proposed by Martin Rodbell and colleagues, who found that GTP is needed for certain hormone receptors to cause an intracellular response. Later, Alfred Gilman and coworkers used genetic and biochemical techniques to identify and purify a G protein. In 1994, Rodbell and Gilman won the Nobel Prize in Physiology or Medicine for their pioneering work.

Figure 9.7 shows how a GPCR and a G protein interact. At the cell surface, a signaling molecule binds to a GPCR, causing a conformational change that activates the receptor, enabling it to bind to a G protein. The G protein, which is a lipid-anchored protein, releases GDP and binds GTP instead. GTP binding changes the conformation of the G protein, causing it to dissociate into an α subunit and

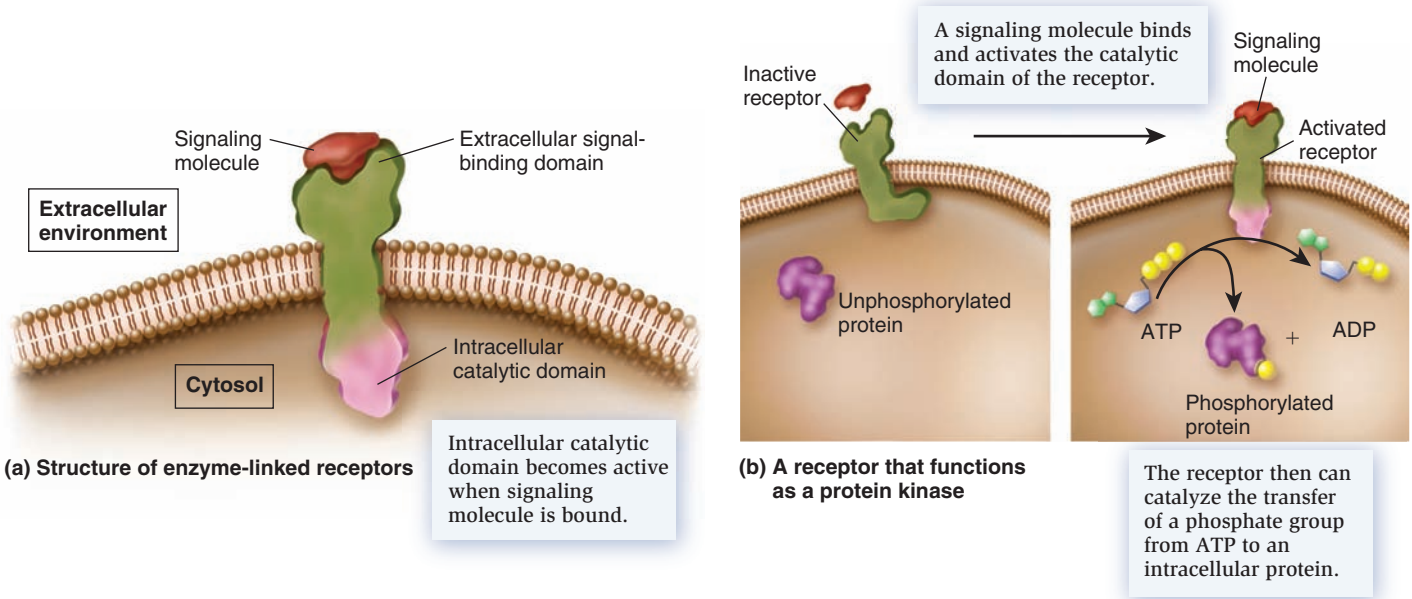

Figure 9.6 **Enzyme-linked receptors.**

Concept Check: *Based on your understanding of ATP as an energy intermediate, is the phosphorylation of a protein via a protein kinase an exergonic or endergonic reaction? How is the energy of protein phosphorylation used—what does it accomplish?*

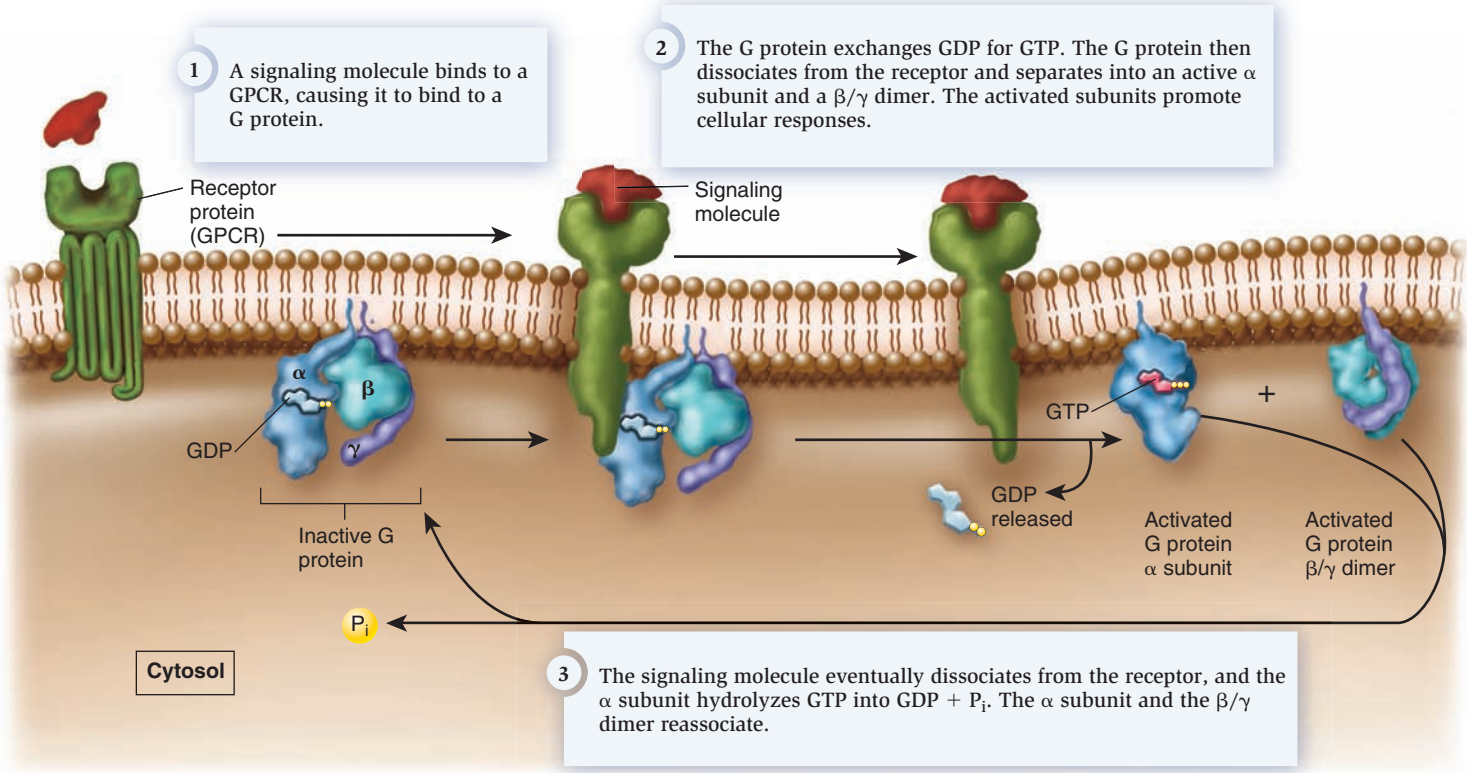

Figure 9.7 The activation of G-protein-coupled receptors (GPCRs) and G proteins. Note: All three receptors shown in this figure are meant to be the same receptor, but the one on the left is drawn with greater detail to emphasize that it has seven transmembrane segments.

Concept Check: *What has to happen for the α and β/γ subunits of the G protein to reassociate with each other?*

a β/γ dimer. Later in this chapter, we will examine how the α subunit interacts with other proteins in a signal transduction pathway to elicit a cellular response. The β/γ dimer also plays a role in signal transduction. For example, it can regulate the function of ion channels in the plasma membrane.

When a signaling molecule and a GPCR dissociate, the GPCR is no longer activated, and the cellular response is reversed. For the G protein to return to the inactive state, the α subunit first hydrolyzes its bound GTP to GDP and P_i. After this occurs, the α and β/γ subunits reassociate with each other to form an inactive G protein.

Ligand-Gated Ion Channels As described in Chapter 5, ion channels are proteins that allow the diffusion of ions across cell membranes. **Ligand-gated ion channels** are a third type of cell surface receptor found in the plasma membrane of animal, plant, and fungal cells. When signaling molecules (ligands) bind to this type of receptor, the channel opens and allows the flow of ions through the membrane, changing the concentration of the ions in the cell (**Figure 9.8**).

In animals, ligand-gated ion channels are important in the transmission of signals between neurons and muscle cells and between two neurons. In addition, ligand-gated ion channels in the plasma membrane allow the influx of Ca^{2+} into the cytosol. Changes in the cytosolic concentration of Ca^{2+} often play a role in signal transduction.

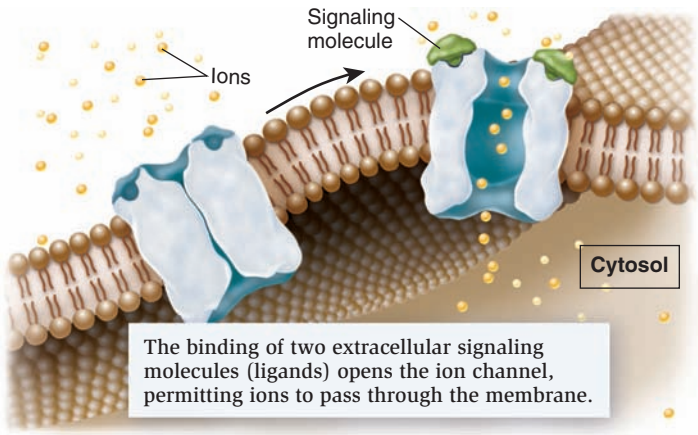

Figure 9.8 The function of a ligand-gated ion channel.

Cells Also Have Intracellular Receptors Activated by Signaling Molecules That Pass Through the Plasma Membrane

Although most receptors for signaling molecules are located in the plasma membrane, some are found inside the cell. In these cases, an extracellular signaling molecule must diffuse through the plasma membrane to gain access to its receptor.

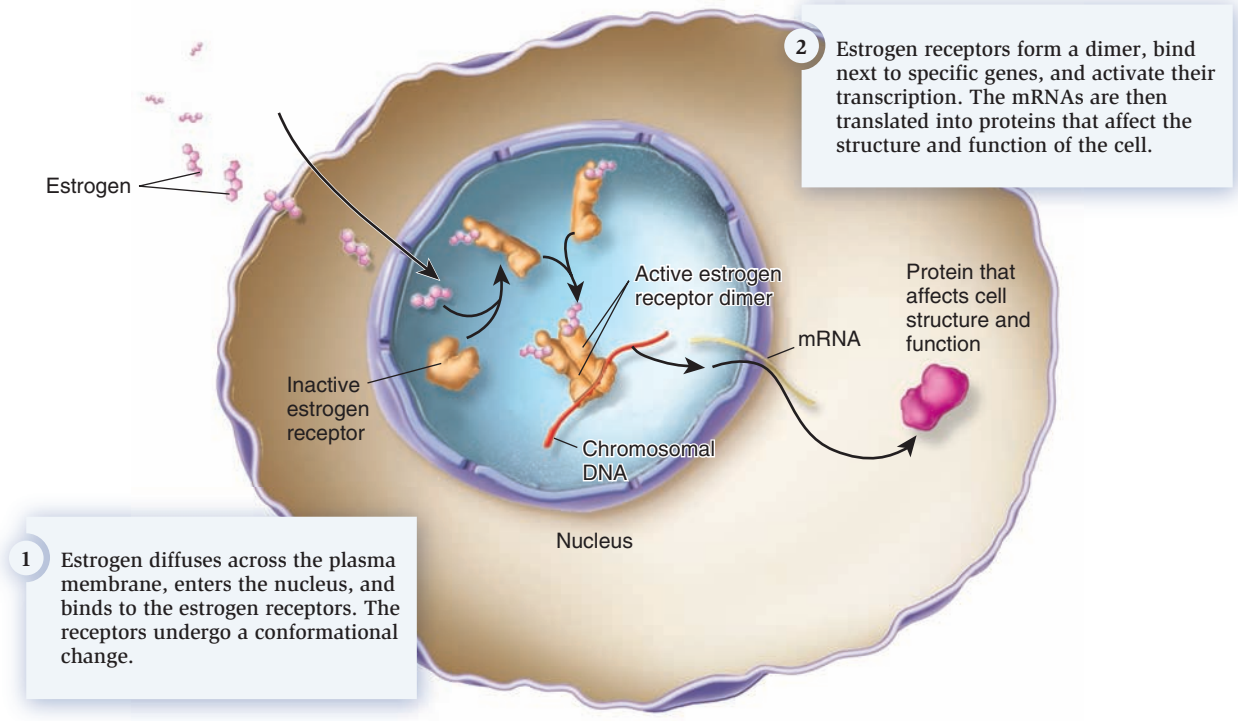

Figure 9.9 Estrogen receptor in mammalian cells. This is an example of an intracellular receptor.

In vertebrates, receptors for steroid hormones are intracellular. As discussed in Chapter 51, steroid hormones, such as estrogens and androgens, are secreted into the bloodstream from cells of endocrine glands. The behavior of estrogen is typical of many steroid hormones (**Figure 9.9**). Because estrogen is hydrophobic, it can diffuse through the plasma membrane of a target cell and bind to a receptor inside the cell. Some steroids bind to receptors in the cytosol, which then travel into the nucleus. Other steroid hormones, such as estrogen, bind to receptors in the nucleus. After binding, the estrogen•receptor complex undergoes a conformational change that enables it to form a dimer with another estrogen•receptor complex. The dimer then binds to the DNA and activates the transcription of specific genes. The estrogen receptor is an example of a transcription factor—a protein that regulates the transcription of genes. The expression of specific genes changes cell structure and function in a way that results in a cellular response.

9.3 Signal Transduction and the Cellular Response

Learning Outcomes:

1. For signaling molecules that bind to receptor tyrosine kinases or G-protein-coupled receptors, describe the signal transduction pathways and how those pathways lead to a cellular response.
2. Relate the function of second messengers to signal transduction pathways.
3. List examples of second messengers, and explain how they exert their effects.

We now turn our attention to the intracellular events that enable a cell to respond to a signaling molecule that binds to a cell surface receptor: signal transduction and a cellular response. In most cases, the binding of a signaling molecule to its receptor stimulates a signal transduction pathway. We begin by examining a pathway that is controlled by an enzyme-linked receptor. We will then examine pathways and cellular responses that are controlled by G-protein-coupled receptors. As you will learn, these pathways sometimes involve the production of intracellular signals called second messengers.

Receptor Tyrosine Kinases Activate Signal Transduction Pathways Involving a Protein Kinase Cascade That Alters Gene Transcription

Receptor tyrosine kinases are a category of enzyme-linked receptors that are found in all animals and also in choanoflagellates, which are the protists that are most closely related to animals (see Chapter 32). However, they are not found in bacteria, archaea, or other eukaryotic species. (Bacteria do have receptor histidine kinases, and all eukaryotes have receptor serine/threonine kinases.) The human genome contains about 60 different genes that encode receptor tyrosine kinases that recognize various types of signaling molecules such as hormones.

Figure 9.10 describes a simplified signal transduction pathway for epidermal growth factor (EGF). A **growth factor** is a signaling molecule that promotes cell division. Multicellular organisms, such as plants and animals, produce a variety of different growth factors to coordinate cell division throughout the body. In vertebrate animals, EGF is secreted from endocrine cells, travels through the bloodstream, and binds to a receptor tyrosine kinase, which is located on target cells and called the EGF receptor. EGF is responsible for stimulating epidermal cells, such as skin cells, to divide. Following receptor activation, the three general parts of the signal transduction pathway are (1) relay proteins activate a protein kinase cascade; (2) the protein kinase cascade phosphorylates proteins in the cell

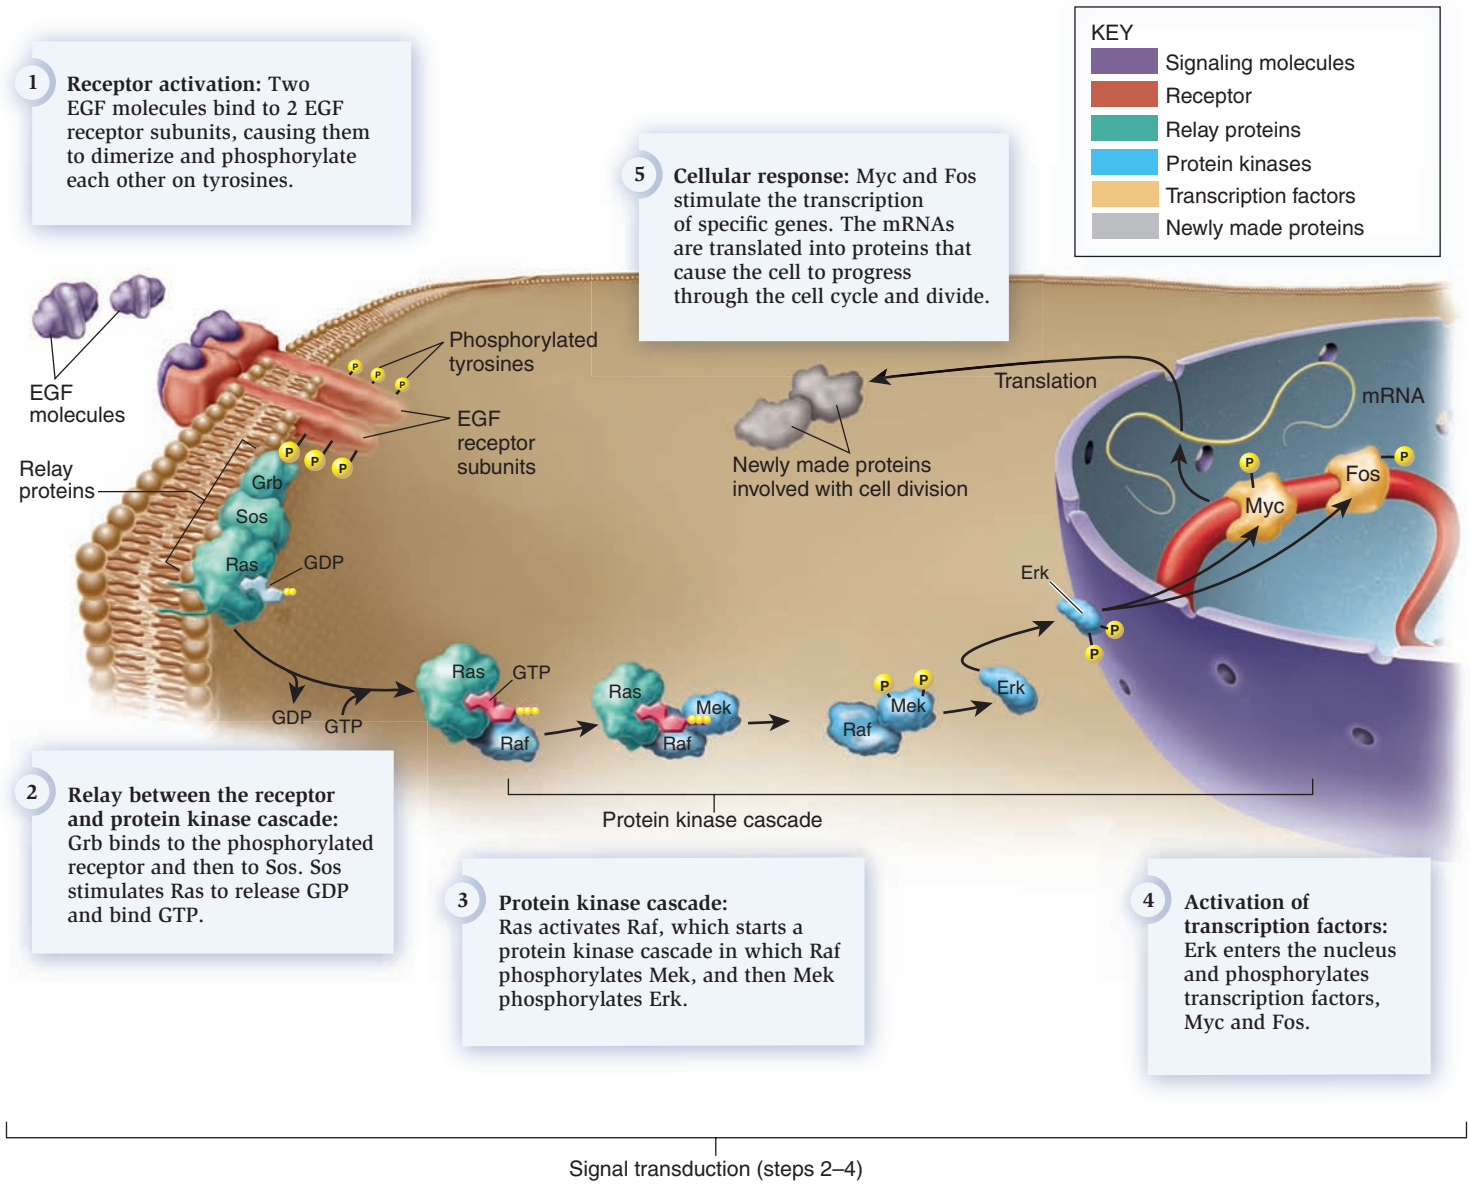

Figure 9.10 **The epidermal growth factor (EGF) pathway that promotes cell division.**

BioConnections: *Look ahead to Figures 14.11 and, in particular, 14.12. Certain mutations alter the structure of the Ras protein so it does not hydrolyze GTP. Such mutations cause cancer. Explain why.*

such as transcription factors; and (3) the phosphorylated transcription factors stimulate gene transcription. Next, we will consider the details of this pathway.

EGF Receptor Activation For receptor activation to occur, two EGF receptor subunits each bind a molecule of EGF. The binding of EGF causes the subunits to dimerize and phosphorylate each other on tyrosines within the receptors, which is why they are named receptor tyrosine kinases. Next comes the signal transduction pathway.

Relay Proteins The phosphorylated form of the EGF receptor is first recognized by a relay protein of the signal transduction pathway called Grb. This interaction changes the conformation of Grb, causing it to bind another relay protein in the signal transduction pathway termed Sos, thereby changing the conformation of Sos. The activation of Sos causes a third relay protein called Ras to release GDP and bind GTP. The GTP form of Ras is the active form.

Protein Kinase Cascade The function of the relay proteins is to activate a **protein kinase cascade**. This cascade involves the sequential activation of three protein kinases. Activated Ras binds to Raf, the first protein kinase in the cascade. Raf then phosphorylates Mek, which becomes active and, in turn, phosphorylates Erk.

Activation of Transcription Factors and the Cellular Response The phosphorylated form of Erk enters the nucleus and phosphorylates

transcription factors such as Myc and Fos. What is the cellular response? Once these transcription factors are phosphorylated, they stimulate the transcription of genes that encode proteins that promote cell division. After these proteins are made, the cell is stimulated to divide.

Growth factors such as EGF cause a rapid increase in the expression of many genes in mammals, perhaps as many as 100. As discussed in Chapter 14, growth factor signaling pathways are often involved in cancer. Mutations that cause proteins in these pathways to become hyperactive result in cells that divide uncontrollably!

BIO TIPS **THE QUESTION** *One of the genes that is activated by the EGF signaling pathway is a gene called HSF1, which encodes a protein that is thought to be important for regulating cell division. Let's suppose that researchers have identified a drug that prevents EGF from activating the HSF1 gene. In the laboratory, this drug seems to prevent the growth of certain types of cancer cells. Propose a hypothesis for how this drug exerts its effect. In other words, which protein in the cell might drug X be binding to, and how does drug X affect that protein's function?*

TOPIC ***What topic in biology does this question address?*** The topic is cell communication. More specifically, the question asks you to propose a hypothesis for how a drug might interfere with the EGF pathway and prevent cancer.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you have learned that the EGF pathway activates the *HSF1* gene, which plays a role in regulating cell division. Drug X prevents EGF from turning on the *HSF1* gene and inhibits the growth of certain kinds of cancer cells. From your understanding of the topic, you may remember that the EGF pathway involves a series of steps, beginning with the binding of EGF to its receptor.

PROBLEM-SOLVING STRATEGY ***Sort out the steps in a complicated process. Propose a hypothesis.*** One strategy to begin to solve this problem is to analyze the steps in the EGF pathway (see Figure 9.10) and identify the proteins involved. Any of these proteins could potentially be the target of drug X. Propose a hypothesis for how drug X could bind to one of these proteins and alter its function in a way that would prevent the expression of the *HSF1* gene and thus prevent cancer cells from dividing.

ANSWER *For drug X to exert its effect, it must be inhibiting one of the steps of the EGF pathway. Here are some possible hypotheses for how drug X works:*

1. *Drug X binds to the EGF receptor and inhibits the ability of EGF to bind to the receptor.*
2. *Drug X binds to the EGF receptor and inhibits its ability to phosphorylate itself.*
3. *Drug X binds to Grb and inhibits its ability to bind to the EGF receptor or to Sos.*
4. *Drug X binds to Sos and inhibits its ability to bind to Grb or to Ras.*
5. *Drug X binds to Ras and inhibits its ability to bind to Sos or Raf.*
6. *Drug X binds to Ras and inhibits its ability to release GDP or to bind GTP.*
7. *Drug X binds to Raf, Mek, or Erk and inhibits those proteins from phosphorylating their target proteins.*
8. *Drug X binds to Myc or Fos and inhibits their ability to activate genes.*

Second Messengers Such as Cyclic AMP Are Key Components of Many Signal Transduction Pathways

Let's now turn to examples of signal transduction pathways and cellular responses that involve G-protein-coupled receptors (GPCRs). Extracellular signaling molecules that bind to cell surface receptors are sometimes referred to as first messengers. After first messengers bind to receptors such as GPCRs, many signal transduction pathways lead to the production of **second messengers**—small molecules or ions that relay signals inside the cell. The signals that result in second messenger production often act quickly, in a matter of seconds or minutes, but their duration is usually short. Therefore, such signaling typically occurs when a cell needs a quick and short cellular response.

Production of cAMP Mammalian and plant cells make several different types of G protein α subunits. One type of α subunit binds to **adenylyl cyclase**, an enzyme in the plasma membrane. This interaction stimulates adenylyl cyclase to synthesize **cyclic adenosine monophosphate (cyclic AMP**, or **cAMP**) from ATP (**Figure 9.11**). cAMP is an example of a second messenger.

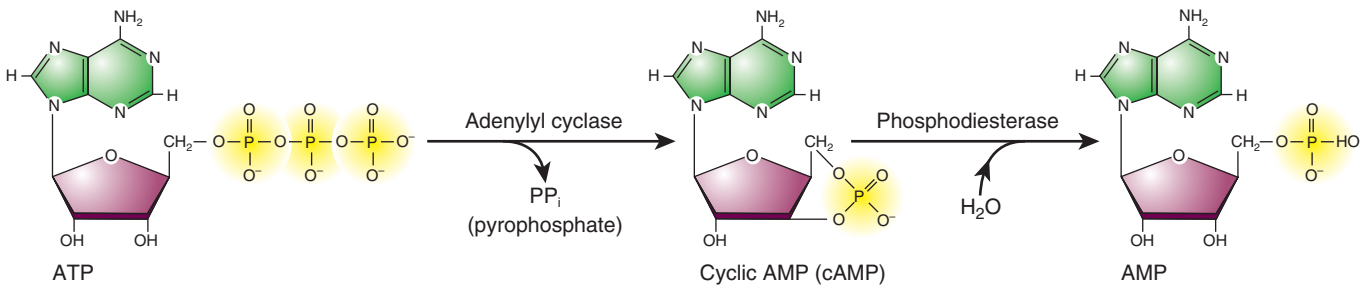

Figure 9.11 **The synthesis and breakdown of cyclic AMP.** Cyclic AMP (cAMP) is a second messenger formed from ATP by adenylyl cyclase, an enzyme in the plasma membrane. cAMP is inactivated by the action of an enzyme called phosphodiesterase, which converts cAMP to AMP.

Signal Transduction Pathway Involving cAMP Let's explore a signal transduction pathway in which the GPCR recognizes the hormone epinephrine (also called adrenaline). This hormone is sometimes called the fight-or-flight hormone. Epinephrine is produced when an individual is confronted with a stressful situation and helps the individual deal with a perceived threat or danger.

First, epinephrine binds to its receptor and activates a G protein (**Figure 9.12**). The α subunit then activates adenylyl cyclase, which catalyzes the production of cAMP from ATP. One effect of cAMP is to activate protein kinase A (PKA), which is composed of four subunits: two catalytic subunits that phosphorylate specific cellular proteins, and two regulatory subunits that inhibit the catalytic subunits when they are bound to each other. cAMP binds to the regulatory subunits of PKA. The binding of cAMP separates the regulatory and catalytic subunits, which allows each catalytic subunit to be active.

Cellular Response via PKA How does PKA activation lead to a cellular response? The catalytic subunit of PKA phosphorylates specific cellular proteins such as enzymes, structural proteins, and transcription factors. The phosphorylation of enzymes and structural proteins influences the structure and function of the cell. Likewise, the phosphorylation of transcription factors leads to the synthesis of new proteins that affect cell structure and function.

As a specific example of a cellular response, **Figure 9.13** shows how a skeletal muscle cell responds to elevated levels of epinephrine. When PKA becomes active, it phosphorylates two enzymes—phosphorylase kinase and glycogen synthase. Both of these enzymes are involved with the metabolism of glycogen, which is a polymer of glucose used to store energy.

- When phosphorylase kinase is phosphorylated, it becomes activated. The function of phosphorylase kinase is to phosphorylate another enzyme in the cell called glycogen phosphorylase, which then becomes activated. This enzyme causes glycogen breakdown by phosphorylating glucose units at the ends of a glycogen polymer, which releases individual glucose-phosphate molecules from glycogen:

$$\text{Glycogen}_n + P_i \xrightarrow{\text{Glycogen phosphorylase}} \text{Glycogen}_{n-1} + \text{Glucose-phosphate}$$

  where n is the number of glucose units in glycogen.

- When PKA phosphorylates glycogen synthase, the function of this enzyme is inhibited rather than activated (see Figure 9.13). The function of glycogen synthase is to make glycogen. Therefore, the effect of cAMP is to prevent glycogen synthesis.

Taken together, the effects of epinephrine in skeletal muscle cells are to stimulate glycogen breakdown and inhibit glycogen synthesis. This provides these cells with more glucose molecules, which they can use for the energy needed for muscle contraction. In this way, the individual is better prepared to fight or flee.

Reversal of the Cellular Response As mentioned, signaling that involves second messengers is typically of short duration. When the signaling molecule is no longer produced and its level falls, a larger percentage of the receptors are not bound by their ligands. When a ligand dissociates from the GPCR, the GPCR becomes deactivated.

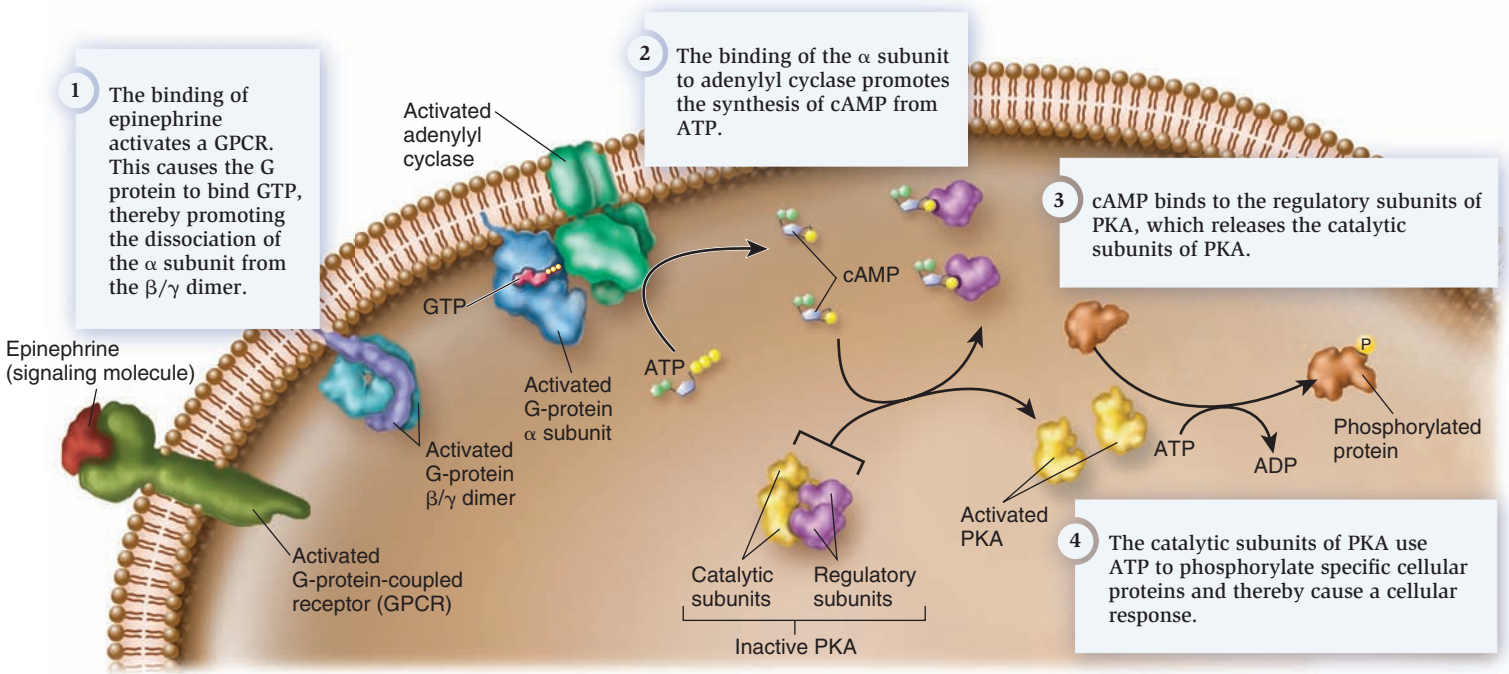

Figure 9.12 A signal transduction pathway involving cAMP. The pathway leading to the formation of cAMP and subsequent activation of protein kinase A (PKA), which is mediated by a G-protein-coupled receptor (GPCR).

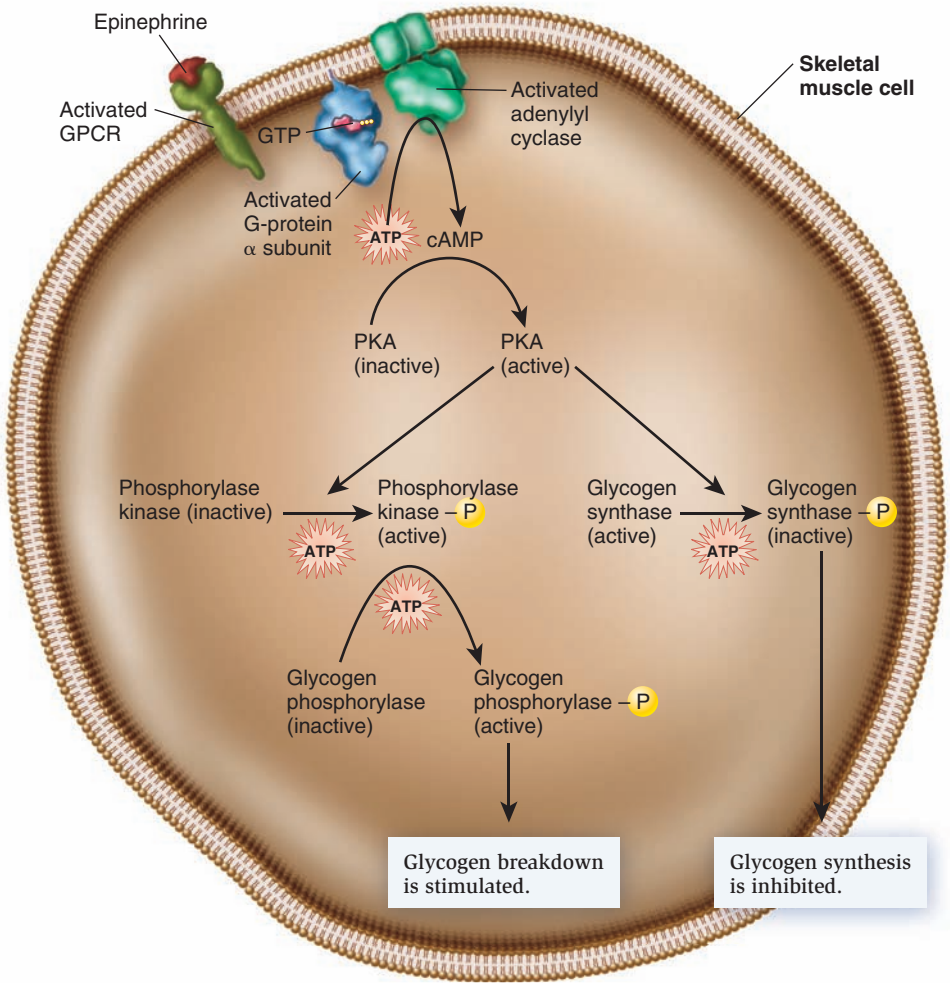
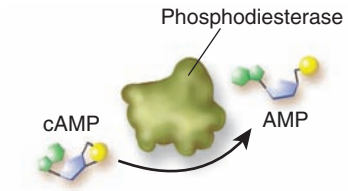
Concept Check: *In this figure, which part is the signal transduction pathway, and which is the cellular response?*





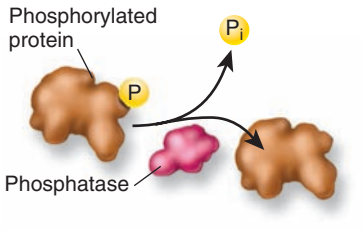


Figure 9.13 **A cellular response of a skeletal muscle cell to epinephrine.**

Concept Check: *Explain whether phosphorylation activates or inhibits enzyme function.*

Intracellularly, the α subunit hydrolyzes its GTP to GDP, and the α subunit and β/γ dimer reassociate to form an inactive G protein (see step 3, Figure 9.7). The level of cAMP decreases due to the action of an enzyme called **phosphodiesterase**, which converts cAMP to AMP:

As the cAMP level falls, the regulatory subunits of PKA release cAMP, and the regulatory and catalytic subunits reassociate, thereby inhibiting PKA. Finally, enzymes called **protein phosphatases** are responsible for removing phosphate groups from proteins, which reverses the effects of PKA:

The Main Advantages of Second Messengers Are Amplification and Speed

In the 1950s, Earl Sutherland determined that many different hormones cause the formation of cAMP in a variety of cell types. This observation, for which he won the Nobel Prize in Physiology or Medicine in 1971, stimulated great interest in the study of signal transduction pathways. Since Sutherland's discovery, the production of second messengers such as cAMP has been found to have two important advantages: amplification and speed.

Signal Amplification Amplification of the signal involves the synthesis of many cAMP molecules, which, in turn, activate many PKA proteins (**Figure 9.14**). Likewise, each PKA protein phosphorylates many target proteins in the cell to promote a cellular response.

Speed A second advantage of second messengers such as cAMP is speed. Because second messengers are relatively small and water-soluble, they can diffuse rapidly through the cytosol. For example, Brian Bacskai and colleagues studied the response of neurons to a signaling molecule called serotonin, which is a neurotransmitter that binds to a GPCR. In humans, low serotonin is believed to play a role in depression, anxiety, and other behavioral disorders. To monitor cAMP levels, neurons grown in a laboratory were injected with a fluorescent protein that changes its fluorescence when cAMP is made. As schematically shown in the right drawing in **Figure 9.15**, such cells made a substantial amount of cAMP within 20 seconds after the addition of serotonin.

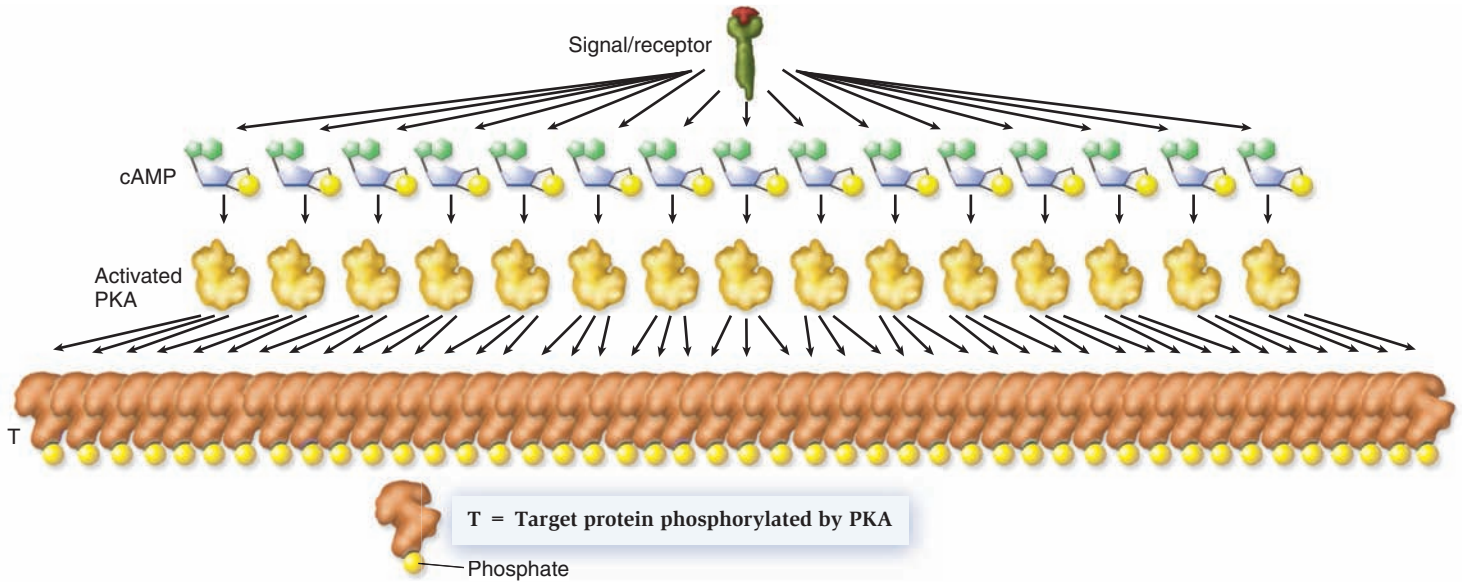

Figure 9.14 Signal amplification. An advantage of a signal transduction pathway is the amplification of a signal. In this case, a single signaling molecule leads to the phosphorylation of many, perhaps hundreds or thousands of, target proteins.

Concept Check: *In the case of signaling pathways involving hormones, why is signal amplification an advantage?*

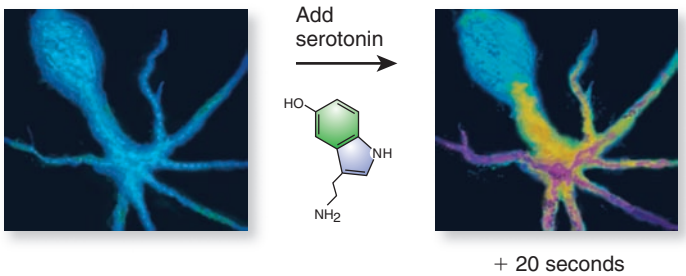

Figure 9.15 The rapid speed of cAMP production. The schematic drawing on the left shows a neuron prior to its exposure to serotonin, a signaling molecule; the drawing on the right shows the same cell 20 seconds after exposure. Blue indicates a low level of cAMP, yellow is an intermediate level, and purple is a high level.

9.4 Hormonal Signaling in Multicellular Organisms

Learning Outcomes:

1. Explain how the cellular response to a particular hormone can vary among different cell types.
2. Describe how a cell's response to a hormone depends on the types of proteins it makes.

Thus far, we have considered how signaling molecules bind to particular types of receptors, thereby activating a signal transduction pathway that leads to a cellular response. In this section, we will consider how hormones in multicellular organisms exert a variety of responses. As you will learn, the type of cellular response that is caused by a given hormone depends on the type of cell. Each cell type responds to a particular hormone in its own unique way. The variation in a cellular response is determined by the types of proteins, such as receptors and signal transduction proteins, that each cell type makes.

The Cellular Response to a Given Hormone Varies Among Different Cell Types

As we have seen, signaling molecules usually exert their effects on cells via signal transduction pathways that control the functions and/or synthesis of specific proteins. In multicellular organisms, one of the amazing effects of hormones is their ability to coordinate cellular activities. One example is epinephrine, which is secreted from endocrine cells. As mentioned, epinephrine is also called the fight-or-flight hormone because it quickly prepares the body for strenuous physical activity in response to a perceived danger. Epinephrine is also secreted into the bloodstream when someone is exercising.

Epinephrine has different effects throughout the body (**Table 9.1**). We have already discussed how it promotes the breakdown of glycogen in skeletal muscle cells (see Figure 9.13). In the lungs, it relaxes

Table 9.1 Effects of Epinephrine in Humans

Organ/Tissue	Effect
Eye	Dilates pupils
Salivary glands	Inhibits the production of saliva
Skeletal muscle	Stimulates cells to break down glycogen and release glucose
Skin	Constricts blood vessels; stimulates sweating
Lungs	Relaxes airways so more oxygen is taken in
Heart	Increases the rate of beating

the airways, allowing a person to take in more oxygen. In the heart, epinephrine stimulates heart muscle cells so the heart beats faster. Interestingly, one of the effects of caffeine can be explained by this mechanism. Caffeine inhibits phosphodiesterase, which converts cAMP to AMP. Phosphodiesterase functions to remove cAMP once a signaling molecule, such as epinephrine, is no longer present. When phosphodiesterase is inhibited by caffeine, cAMP persists for a longer period of time and prolongs the effects of signaling molecules like epinephrine. Therefore, even low levels of epinephrine have a greater effect. This is one of the reasons why drinks containing caffeine, including coffee and many energy drinks, provide a feeling of vitality and energy.

Genomes & Proteomes Connection

A Cell's Response to Hormones and Other Signaling Molecules Depends on the Proteins It Makes

As Table 9.1 shows, a hormone such as epinephrine produces diverse responses throughout the body. How do we explain the observation that various cell types respond so differently to the same hormone? As a multicellular organism develops from a fertilized egg, the cells of the body become differentiated into particular types, such as heart and lung cells. The mechanisms that underlie this differentiation process are described in Chapter 19. Although different cell types, such as heart and lung cells, contain the same set of genes—the same genome—those genes are not expressed in the same pattern in all cells. Certain genes that are turned off in heart cells are turned on in lung cells, whereas some genes that are turned on in heart cells are turned off in lung cells. This phenomenon, which is called **differential gene regulation**, causes each cell type to have its own distinct proteome. The set of proteins made in any given cell type is critical to a cell's ability to respond to signaling molecules. The following are examples of how differential gene regulation affects the cellular response:

1. *A cell may or may not express a receptor for a particular signaling molecule*. For example, not all cells of the human body express a receptor for epinephrine. Cells without such a receptor are not affected when epinephrine is released into the bloodstream.
2. *Different cell types have different cell surface receptors that recognize the same signaling molecule*. In humans, for example, a signaling molecule called acetylcholine has two different types of receptors. One acetylcholine receptor is a ligand-gated ion channel that is expressed in skeletal muscle cells. Another acetylcholine receptor is a G-protein-coupled receptor (GPCR) that is expressed in heart muscle cells. Because of this, acetylcholine activates different signal transduction pathways in skeletal and heart muscle cells. Therefore, these cells respond differently to acetylcholine.
3. *Two (or more) receptors may work the same way in different cell types but have different affinities for the same signaling molecule*. For example, two different GPCRs may recognize the same hormone, but the receptor expressed in liver cells may have a higher affinity (that is, a lower K_d) for the hormone than does the receptor expressed in muscle cells. In this case, liver cells respond to a lower hormone concentration than muscle cells do.
4. *The expression of proteins involved in intracellular signal transduction pathways may vary in different cell types*. For example, one cell type may express the proteins that are needed to activate PKA, but another cell type may not.
5. *The expression of proteins that are controlled by signal transduction pathways may vary in different cell types*. For example, the presence of epinephrine in skeletal muscle cells leads to the activation of glycogen phosphorylase, an enzyme involved in glycogen breakdown. However, this enzyme is not expressed in all cells of the body. Glycogen breakdown is only stimulated by epinephrine if glycogen phosphorylase is expressed in that cell.

9.5 Apoptosis: Programmed Cell Death

Learning Outcomes:

1. Define and describe apoptosis.
2. **SciSKILLS »** Analyze the results of experiments indicating that certain hormones control apoptosis.
3. Outline the extrinsic pathway of apoptosis.

We will end our discussion of cell communication by considering one of the most dramatic responses that eukaryotic cells exhibit—**apoptosis**, or programmed cell death. During this process, a cell orchestrates its own destruction! The cell first shrinks and forms a rounder shape due to the internal destruction of its nucleus and cytoskeleton (**Figure 9.16**). The plasma membrane then forms irregular extensions that eventually become blebs—small cell fragments that break away from the cell as it destroys itself (also see chapter opening photo).

Cell biologists have discovered that apoptosis plays many important roles.

- During embryonic development in animals, it is needed to sculpt the tissues and organs. For example, the fingers on a human hand are initially webbed, but become separated during embryonic development when the cells between the fingers undergo apoptosis (see Chapter 19, Figure 19.4).
- Apoptosis is also necessary in adult organisms to maintain the proper cell number in tissues and organs.
- Programmed cell death also eliminates cells that have become worn out or infected by viruses, or have the potential to cause cancer.

During the past few decades, clinical research has revealed that many human diseases are associated with irregularities in apoptosis. **Table 9.2** describes a few examples. In this section, we will examine the pioneering work that led to the discovery of apoptosis and explore its molecular mechanism.

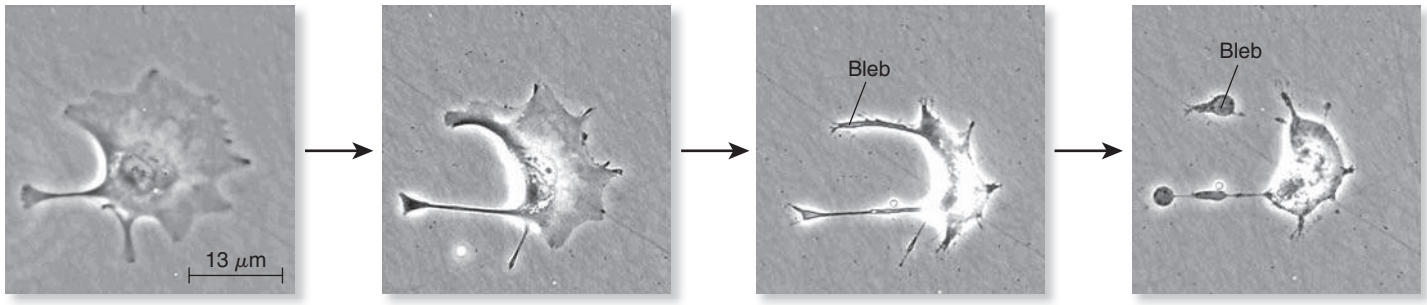

Figure 9.16 **Stages of apoptosis.**

Table 9.2 **Relationship Between Certain Diseases and Abnormal Levels of Apoptosis**

Disease	Description/Examples
Diminished levels of apoptosis	
Cancer	Cancer cells proliferate in an uncontrolled manner. In some forms of cancer, a decrease in the normal rate of apoptosis contributes to the faster proliferation rate. Examples include particular types of prostate and ovarian cancers.
Elevated levels of apoptosis	
Viral diseases	Certain viral diseases are associated with elevated levels of apoptosis. For example, infection by human immunodeficiency virus (HIV) results in an increased rate of apoptosis of helper T cells.
Neurodegenerative diseases	Some neurodegenerative diseases occur because specific neurons undergo an unusually high rate of apoptosis. An example is Parkinson's disease, which arises from a loss of dopaminergic neurons.

Feature Investigation | Kerr, Wyllie, and Currie Found That Hormones May Control Apoptosis

How was apoptosis discovered? One line of evidence involved the microscopic examination of tissues in mammals. In the 1960s, British pathologist John Kerr microscopically examined liver tissue that was deprived of oxygen. Within hours of oxygen deprivation, he observed that some cells underwent a process that involved cell shrinkage. Around this time, similar results had been noted by other researchers, such as Scottish pathologists Andrew Wyllie and Alastair Currie, who had studied cell death in the adrenal glands. In 1973, Kerr, Wyllie, and Currie joined forces to study this process further.

Prior to their collaboration, other researchers had already established that certain hormones affect the growth of the adrenal glands, which sit atop the kidneys. Adrenocorticotropic hormone (ACTH) was known to increase the number of cells in the adrenal cortex, which is the outer layer of the adrenal glands. By contrast, the drug prednisolone was shown to suppress the synthesis of ACTH and cause a decrease in the number of cells in the cortex. In the experiment described in **Figure 9.17**, Kerr, Wyllie, and Currie wanted to understand how ACTH and prednisolone exert their effects. They subjected rats to four types of treatments. The control rats were injected with saline (salt water). Other rats were injected with prednisolone alone, prednisolone plus ACTH, or ACTH alone. After 2 days, samples of adrenal cortex were obtained from the rats and observed by light microscopy. Even in control samples, the researchers occasionally observed cell death via apoptosis (see micrograph under The Data). However, in prednisolone-treated rats, the cells in the adrenal cortex were found to undergo a dramatically higher rate of apoptosis. Multiple cells undergoing apoptosis were found in 9 out of every 10 samples observed under the light microscope. Such a high level of apoptosis was not observed in control samples or in samples obtained from rats treated with both prednisolone and ACTH or ACTH alone. Therefore, ACTH appears to prevent apoptosis.

The results of Kerr, Wyllie, and Currie are important for two reasons. First, their results indicated that tissues decrease their cell number via a mechanism that involves cell shrinkage and eventually blebbing. Second, they showed that cell death followed a program that, in this case, was induced by the presence of prednisolone (which decreases ACTH). They coined the term apoptosis to describe this process.

As you may know, prednisone is an anti-inflammatory and immunosuppressive drug that is used to treat a wide variety of disorders, including asthma and rheumatoid arthritis. When taken into the body, it is converted to prednisolone by the liver. In recent years, prednisone has been used in conjunction with other therapies to treat certain forms of cancer, such as leukemia, which is cancer of white blood cells. Prednisone is thought to exert its effect by promoting apoptosis in the cancer cells.

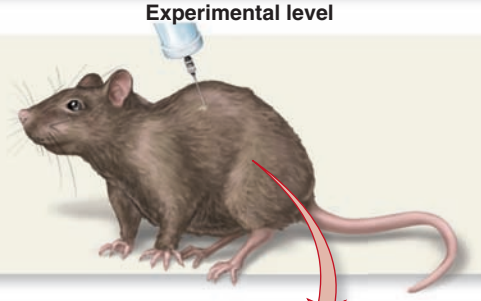

Figure 9.17 Discovery of apoptosis in the adrenal cortex by Kerr, Wyllie, and Currie.

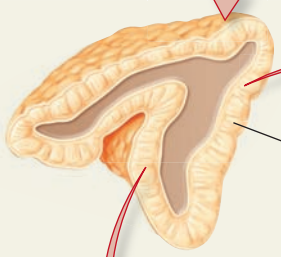
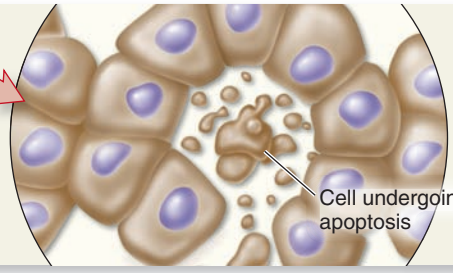
HYPOTHESIS Hormones may affect cell number in the adrenal gland by controlling the rate of apoptosis.

KEY MATERIALS Laboratory rats, prednisolone, and ACTH.



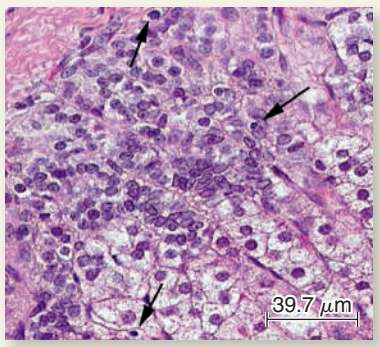
Experimental level | **Conceptual level**



1 Inject 5 rats with saline (control).
Inject 5 rats with prednisolone alone.
Inject 5 rats with prednisolone + ACTH.
Inject 5 rats with ACTH alone.

Previous studies indicated that prednisolone alone may promote apoptosis by lowering ACTH levels.

2 After 2 days, obtain samples of adrenal tissue from all 20 rats.



3 Observe the samples via light microscopy, described in Chapter 4.

4 THE DATA

Micrograph of adrenal tissue showing occasional cells undergoing apoptosis (see arrows)

Treatment	Number of animals	Glands with enhanced apoptosis*/ Total number of animals
Saline	5	0/10
Prednisolone	5	9/10
Prednisolone + ACTH	5	0/10
ACTH	5	0/10

*Samples from two adrenal glands were removed from each animal. Enhanced apoptosis means that cells undergoing apoptosis were observed in every sample under the light microscope.

5 CONCLUSION Prednisolone alone, which lowers ACTH levels, causes some cells to undergo apoptosis. During this process, the cells shrink and form blebs as they kill themselves. Apoptosis is controlled by hormones.

Experimental Questions

1. **SciSKILLS »** In the experiment of Figure 9.17, explain the effects on apoptosis in the control rats (saline injected) versus those injected with prednisolone alone, predinisolone + ACTH, or ACTH alone.
2. Prednisolone inhibits the production of ACTH in rats. Do you think it inhibited the ability of rats to make their own ACTH when they were injected with both prednisolone and ACTH? Explain.
3. **SciSKILLS »** Of the four groups—control, prednisolone alone, prednisolone + ACTH, and ACTH alone—which would you expect to have the lowest level of apoptosis? Explain.

Signal Transduction Pathways Lead to Apoptosis

Apoptosis involves the activation of cell-signaling pathways. One pathway, called the **extrinsic pathway**, begins with the activation of **death receptors** on the cell surface. When death receptors bind to extracellular signaling molecules, a pathway is stimulated that leads to apoptosis. **Figure 9.18** shows a simplified pathway for this process. In this example, the signaling molecule is a protein composed of three identical subunits—a trimeric protein. Such trimeric signaling molecules are typically produced by cells of the immune system that recognize abnormal cells and target them for destruction. For example, when a cell is infected with a virus, cells of the immune system may

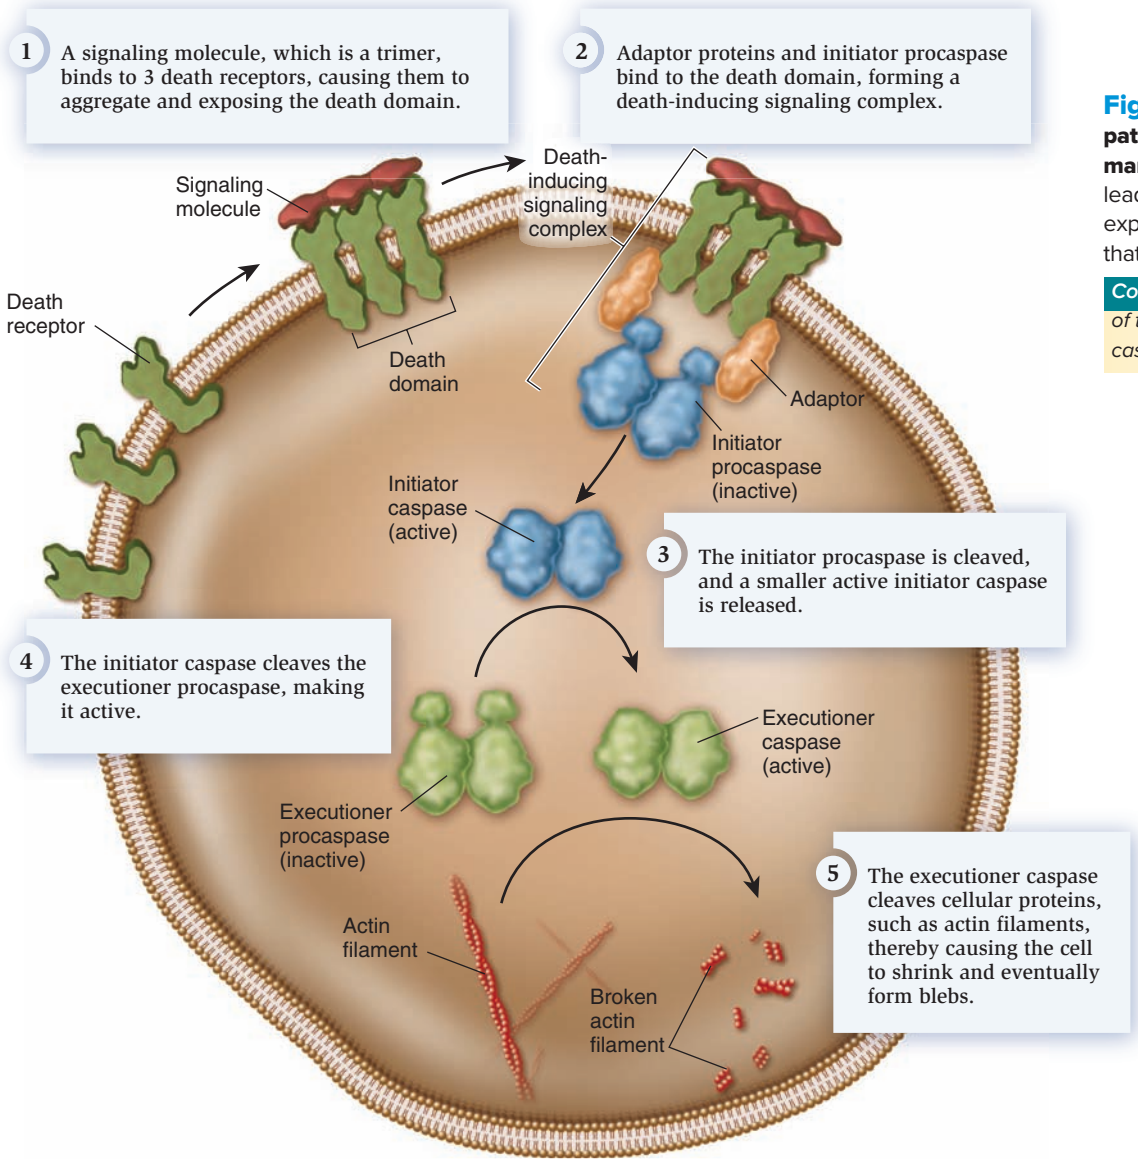

Figure 9.18 The extrinsic pathway for apoptosis in mammals. This simplified pathway leads to apoptosis when cells are exposed to an extracellular signal that causes cell death.

Concept Check: How are the roles of the initiator and the executioner caspases different in this process?

target the infected cell for apoptosis. The signaling molecule binds to three death receptors, which causes them to aggregate into a trimer. This results in a conformational change that exposes a domain on the death receptors called the death domain. Once the death domain is exposed, it binds to adaptors, which then bind to an initiator procaspase. The complex between the death receptors, adaptors, and initiator procaspase is called the death-inducing signaling complex (DISC).

Once the initiator procaspase, which is inactive, is part of the death-inducing signaling complex, it is converted by proteolytic cleavage to an initiator caspase, which is active. An active **caspase** functions as a protease—an enzyme that digests other proteins. After it is activated, the initiator caspase is then released from the DISC. This caspase is called an initiator caspase because it initiates the activation of many other caspases in the cell. These other caspases are called executioner, or effector, caspases because they are directly responsible for digesting intracellular proteins and causing the cell to die. The executioner caspases digest a variety of intracellular proteins, including the proteins that constitute the cytoskeleton and nuclear lamina as well as proteins involved with DNA replication and repair. In this way, the executioner caspases cause the cellular changes described in Figure 9.16. The caspases also activate an enzyme called DNase that chops the DNA in the cell into small fragments. This event may be particularly important for eliminating virally infected cells because it also destroys viral genomes that are composed of DNA.

Alternatively, another pathway of apoptosis, called the **intrinsic** or **mitochondrial pathway**, is stimulated by DNA damage that could cause cancer. Mitochondria release cytochrome *c* (a small mitochondrial protein) into the cytosol, which forms a complex with other proteins called an **apoptosome**. The apoptosome then initiates the activation of caspases.

Summary of Key Concepts

9.1 General Features of Cell Communication

- A signal is an agent that can influence the properties of cells. A signal binds to a receptor to elicit a cellular response. Cell signaling enables cells to sense and respond to environmental changes and to communicate with each other (Figures 9.1, 9.2).
- Cell-to-cell communication varies in the mechanism and distance that a signal travels. Signals are relayed between cells in five common ways: direct intercellular, contact-dependent, autocrine, paracrine, and endocrine signaling (Figure 9.3).
- Cell communication is usually a three-stage process involving receptor activation, signal transduction, and a cellular response. A signal transduction pathway is a group of proteins that convert an initial signal to a different signal inside the cell (Figure 9.4).

9.2 Cellular Receptors and Their Activation

- A signaling molecule, also called a ligand, binds to a receptor with an affinity that is measured as a dissociation constant, or K_d value. The binding of a ligand to a receptor is usually very specific and alters the conformation of the receptor (Figure 9.5).
- Enzyme-linked receptors have some type of catalytic function. Many of them are protein kinases that phosphorylate proteins (Figure 9.6).
- G-protein-coupled receptors (GPCRs) interact with G proteins to initiate a cellular response (Figure 9.7).
- Ligand-gated ion channels are receptors that allow the flow of ions across cellular membranes (Figure 9.8).
- Although most receptors involved in cell signaling are found on the cell surface, some receptors, such as the estrogen receptor, are intracellular receptors (Figure 9.9).

9.3 Signal Transduction and the Cellular Response

- Signaling pathways influence whether or not a cell divides. An example is the pathway that is stimulated by epidermal growth factor, which binds to a receptor tyrosine kinase (Figure 9.10).
- Second messengers, such as cAMP, play a key role in signal transduction pathways, such as those that occur via GPCRs. These pathways are reversible once the signal is degraded (Figures 9.11, 9.12).
- An example of a pathway that uses cAMP is found in skeletal muscle cells responding to elevated levels of epinephrine, the fight-or-flight hormone. Epinephrine enhances the function of enzymes that increase glycogen breakdown and inhibits enzymes that cause glycogen synthesis (Figure 9.13).
- Second messenger pathways amplify the signal and proceed with great speed (Figures 9.14, 9.15).

9.4 Hormonal Signaling in Multicellular Organisms

- Hormones such as epinephrine exert different effects throughout the body (Table 9.1).
- The way in which any particular cell type responds to a signaling molecule depends on the set of proteins it makes. The amounts of these proteins are controlled by differential gene regulation.

9.5 Apoptosis: Programmed Cell Death

- Apoptosis is the process of programmed cell death in which the nucleus and cytoskeleton break down and eventually the cell breaks apart into blebs. Irregularities in apoptosis are associated with some diseases (Table 9.2, Figure 9.16).
- Microscopy studies of Kerr, Wyllie, and Currie, in which they studied the effects of ACTH on the adrenal cortex, were instrumental in the identification of apoptosis (Figure 9.17).
- Apoptosis occurs via extrinsic or intrinsic pathways. The extrinsic pathway is stimulated when an extracellular signaling molecule binds to death receptors (Figure 9.18).

Assess and Discuss

Test Yourself

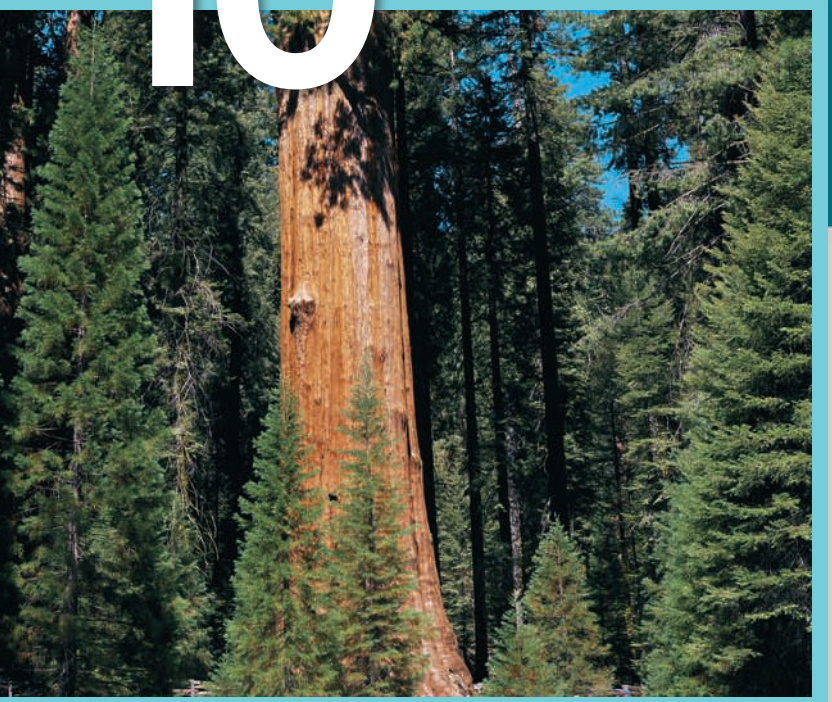
1. An agent that allows a cell to respond to changes in its environment is termed
   a. a cell surface receptor.
   b. an intracellular receptor.
   c. a structural protein.
   d. a signal.
   e. apoptosis.

2. When a cell secretes a signaling molecule that binds to receptors on neighboring cells as well as the cell itself, this is called _____ signaling.
   a. direct intercellular
   b. contact-dependent
   c. autocrine
   d. paracrine
   e. endocrine
3. Which of the following does *not* describe a typical cellular response to signaling molecules?
   a. activation of enzymes within the cell
   b. change in the function of structural proteins, which determine cell shape
   c. alteration of levels of certain proteins in the cell by changing the level of gene expression
   d. change in a gene sequence that encodes a particular protein
   e. All of the above are examples of cellular responses.
4. A receptor has a K_d for its ligand of 50 nM. This receptor
   a. has a higher affinity for its ligand than does a receptor with a K_d of 100 nM.
   b. has a higher affinity for its ligand than does a receptor with a K_d of 10 nM.
   c. is mostly bound by its ligand when the ligand concentration is 100 nM.
   d. must be an intracellular receptor.
   e. Both a and c are true of this ligand.
5. _____ binds to receptors inside cells.
   a. Estrogen
   b. Epinephrine
   c. Epidermal growth factor
   d. All of the above bind to such receptors.
   e. None of the above binds to such receptors.
6. The relay protein Ras is part of the EGF pathway that promotes cell division (see Figure 9.10). The active form of Ras has GTP bound to it, whereas the inactive form has GDP. GTP is hydrolyzed to GDP and P_i to switch Ras from the active to the inactive form. Researchers have discovered that certain forms of cancer involve mutations in the gene that encodes the Ras protein. Which of the following types of mutations would you expect to promote cell division and thereby lead to cancer?
   a. a mutation that prevents the synthesis of Ras
   b. a mutation that causes Ras to bind GDP more tightly
   c. a mutation that prevents the GTP bound to Ras from being hydrolyzed
   d. a mutation that prevents Ras from binding to Raf
   e. both b and c
7. The benefit of second messengers in signal transduction pathways is
   a. an increase in the speed of a cellular response.
   b. duplication of the ligands in the system.
   c. amplification of the signal.
   d. all of the above.
   e. a and c only.
8. All cells of a multicellular organism may not respond in the same way to a particular ligand (signaling molecule) that binds to a cell surface receptor. The difference in response may be due to
   a. the type of receptor for the ligand that the cell expresses.
   b the affinity of the ligand for the receptor in a given cell type.
   c. the type of signal transduction pathways that the cell expresses.
   d. the type of target proteins that the cell expresses.
   e. all of the above.
9. Apoptosis is the process of
   a. cell migration.
   b. cell signaling.
   c. signal transduction.
   d. signal amplification.
   e. programmed cell death.
10. Which statement best describes the extrinsic pathway for apoptosis?
    a. Caspases recognize an environmental signal and expose their death domain.
    b. Death receptors recognize an environmental signal, which then leads to the activation of caspases.
    c. Initiator caspases digest the nuclear lamina and cytoskeleton.
    d. Executioner caspases are part of the death-inducing signaling complex (DISC).
    e. All of the above are true of the extrinsic pathway.

Conceptual Questions

1. What are the two general reasons that cells need to communicate?
2. What are the three stages of cell signaling? What stage does *not* occur when the estrogen receptor is activated?
3.  A principle of biology is that *living organisms interact with their environment*. Discuss how cell signaling helps organisms to interact with their environment.

Collaborative Questions



1. Discuss and compare several different types of cell-to-cell communication. What are some advantages and disadvantages of each type?
2. How does differential gene regulation enable various cell types to respond differently to the same signaling molecule? Why is this useful to multicellular organisms?

Multicellularity

CHAPTER OUTLINE

10.1 Extracellular Matrix and Cell Walls
10.2 Cell Junctions
10.3 Tissues
Summary of Key Concepts
Assess and Discuss

The General Sherman tree in Sequoia National Park, a striking example of the size that multicellular organisms can reach. This tree is thought to be the largest organism (by mass) in the world.

BIOLOGY PRINCIPLE Living organisms grow and develop. In multicellular organisms, growth involves the production of many new cells.

What is the largest living organism on Earth? The size of an organism can be defined by its volume, mass, height, length, or the area it occupies. A giant fungus (*Armillaria ostoyae*), growing in the soil in the Malheur National Forest in Oregon, spans 8.9 km^2, or 2,200 acres, which makes it the largest known organism by area. Most of the organism lies below ground, so it is not visible from the surface. In the Mediterranean Sea, marine biologists discovered a giant aquatic plant (*Posidonia oceanica*) that is 8 km, or 4.3 miles, in length, making it the world's longest known organism. With regard to mass, the largest organism is probably a tree named the General Sherman tree, which is 83.8 meters tall (275 feet), nearly the length of a football field (see chapter opening photo). This giant sequoia tree (*Sequoiadendron giganteum*) is estimated to weigh nearly 2 million kg (over 2,000 tons)—equivalent to a herd of 400 elephants!

An organism composed of more than one cell is said to be **multicellular**. The preceding examples illustrate the amazing sizes that certain multicellular organisms have attained. As we will discuss in Chapter 22, multicellular organisms came into being approximately 1 billion years ago. Some species of protists are multicellular, as are most species of fungi. In this chapter, we will focus on plants and animals, which are always multicellular organisms.

The main benefit of multicellularity arises from the division of labor between different types of cells in an organism. For example, the intestinal cells of animals and the root cells of plants have become specialized for nutrient uptake. Other types of cells in a multicellular organism perform different roles, such as reproduction. In animals, most of the cells of the body—somatic cells—are devoted to the growth, development, and survival of the organism, whereas specialized cells—gametes—function in sexual reproduction.

Multicellular species usually have much larger genomes than unicellular species. The increase in genome size is associated with an increase in proteome size—multicellular organisms produce a larger array of proteins than do unicellular species. The additional proteins play a role in three general phenomena.

- First, in a multicellular organism, cell communication is vital for the proper organization and functioning of cells. Many more proteins involved in cell communication are made in multicellular species.
- Second, both the arrangement of cells within the body and the attachment of cells to each other require a greater variety of proteins in multicellular species than in unicellular species.
- Finally, additional proteins play a role in cell specialization because proteins that are needed for the structure and function of one cell type may not be needed in a different cell type, and vice versa. Likewise, additional proteins are needed to regulate the expression of genes so these proteins are expressed in the proper cell types.

In this chapter, we will consider the cellular characteristics that are specific to multicellular organisms. We begin by exploring the material that is produced by animal and plant cells to form

an extracellular matrix or cell wall, respectively. This material plays many important roles in the structure, organization, and functioning of cells within multicellular organisms. We will then turn our attention to cell junctions, specialized structures that enable cells to make physical contact with one another. Cells within multicellular organisms form junctions that help to make a cohesive and well-organized body. Finally, we will examine the organization and function of tissues, groups of cells that have a similar structure and function. In this chapter, we will survey the general features of tissues from a cellular perspective. Units VI and VII will explore the characteristics of particular plant and animal tissues in greater detail.

10.1 Extracellular Matrix and Cell Walls

Learning Outcomes:

1. Explain the functional roles of the extracellular matrix in animals.
2. Outline the major structural components of the ECM of animals.
3. Describe the structure and function of plant cell walls.

Organisms are not composed solely of cells. A large portion of an animal or plant consists of a network of material that is secreted from cells and forms a complex meshwork outside of cells. In animals, this is called the **extracellular matrix (ECM)**, whereas plant cells are surrounded by a **cell wall**. The ECM and cell walls are a major component of certain parts of animals and plants, respectively. For example, bones and cartilage in animals are composed largely of ECM, and the woody portions of plants are composed mostly of cell walls. Although the cells within wood eventually die, the cell walls they have produced provide a rigid structure that supports the plant for years or even centuries.

In this section, we begin by examining the structure and role of the ECM in animals, focusing on the functions of the major ECM components: proteins and polysaccharides. We will then explore the structure and functions of the cell wall of plant cells.

The Extracellular Matrix in Animals Supports and Organizes Cells and Plays a Role in Cell Signaling

Unlike the cells of bacteria, archaea, fungi, and plants, the cells of animals are not surrounded by a rigid cell wall that provides structure and support. However, animal cells secrete materials that form an ECM that provides support and helps to organize cells. Certain animal cells are completely embedded within an extensive ECM, whereas other cells may adhere to the ECM on only one side. **Figure 10.1** illustrates the general features of the ECM and its relationship to cells. The major macromolecules of the ECM are proteins and polysaccharides. The most abundant proteins are those that form large fibers. The polysaccharides give the ECM a gel-like character.

As we will see, the ECM found in animals performs many important roles, including strength, structural support, organization, and cell signaling.

- **Strength:** The ECM is the "tough stuff" of animals' bodies. In the skin of mammals, the strength of the ECM prevents tearing. The ECM found in cartilage resists compression and provides protection to the joints. Similarly, the ECM protects the soft parts of the body, such as the internal organs.
- **Structural support:** The bones of many animals are composed primarily of ECM. Skeletons not only provide structural support but also facilitate movement via the functioning of attached muscles.
- **Organization:** The attachment of cells to the ECM plays a key role in the proper arrangement of cells throughout the body. In addition, the ECM binds many body parts together, such as tendons to bones.

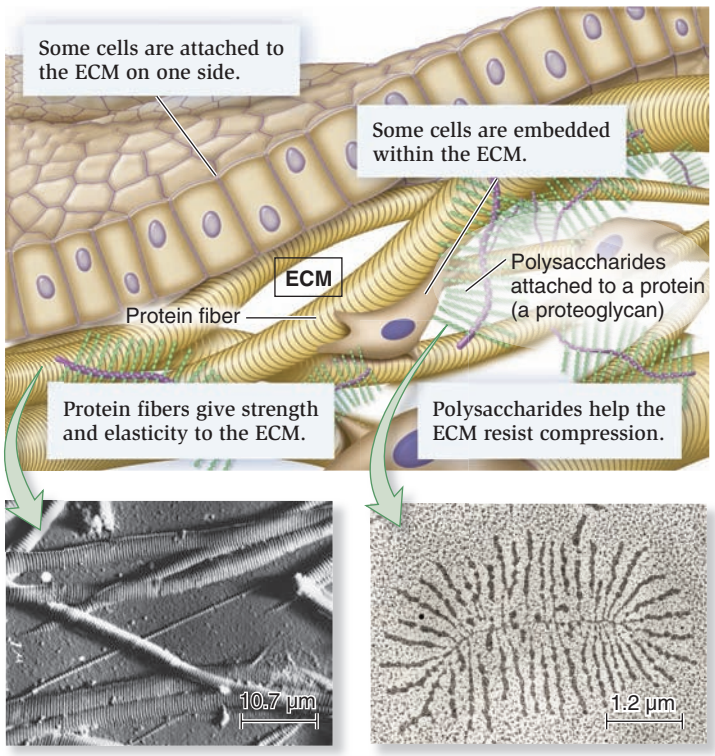

Figure 10.1 The extracellular matrix (ECM) of animal cells. The micrograph (SEM) at the bottom left shows collagen fibers, a type of protein fiber found in the ECM. The micrograph (TEM) at the bottom right shows a proteoglycan, which consists of polysaccharides attached to a protein.

Concept Check: *What are the four functions of the ECM in animals?*

- **Cell signaling:** A less obvious role of the ECM is cell signaling. One way that cells in multicellular organisms sense their environment is via changes in the ECM.

Let's now consider the synthesis and structure of ECM components found in animals.

Adhesive and Structural Proteins Are Major Components of the ECM of Animals

In the 1850s, German biologist Rudolf Virchow suggested that all extracellular materials are made and secreted by cells. Around the same time, biologists realized that gelatin and glue, which are produced by the boiling of animal tissues, contain a common fibrous substance. This substance was named **collagen** (from the Greek, meaning glue-producing). Since that time, experimental techniques in chemistry, microscopy, and biophysics have enabled scientists to probe the structure of the ECM. We now understand that the ECM contains a mixture of several different components, including proteins such as collagen, which form fibers.

The proteins found in the ECM are grouped into adhesive proteins, such as fibronectin and laminin, and structural proteins, such as collagen and elastin (**Table 10.1**). How do adhesive proteins work? Fibronectin and laminin have multiple binding sites that bind to other components in the ECM, such as protein fibers and polysaccharides. These same proteins also have binding sites for receptors on the surfaces of cells. Therefore, adhesive proteins are so named because they adhere ECM components together and to the cell surface. They provide organization to the ECM and facilitate the attachment of cells to the ECM.

Structural proteins, such as collagen and elastin, form large fibers that give the ECM its strength and elasticity. A key function of collagen is to impart tensile strength, which is a measure of how much stretching force a material can bear without tearing apart. Collagen provides high tensile strength to many parts of an animal's body. It is the main protein found in bones, cartilage, tendons, skin, and the lining of blood vessels and internal organs. In the bodies of mammals, more than 25% of the total protein mass consists of collagen, much more than any other protein. Approximately 75% of the protein in mammalian skin is composed of collagen. Leather is largely a pickled and tanned form of collagen.

As described in Chapter 4 (see Figure 4.28), proteins, such as collagen, that are secreted from eukaryotic cells are first directed from the cytosol to the endoplasmic reticulum (ER), then to the Golgi apparatus, and subsequently are secreted from the cell via vesicles that fuse with the plasma membrane. **Figure 10.2** depicts the synthesis and assembly of collagen. Individual procollagen polypeptides (called α chains) are synthesized into the lumen of the ER. Three procollagen polypeptides then associate with each other to form a procollagen triple helix. The amino acid sequences at both ends of the polypeptides, termed extension sequences, promote the formation of procollagen and prevent the formation of a larger fiber. After procollagen is secreted from the cell, extracellular enzymes remove the extension sequences. Once this occurs, the protein, now called

Table 10.1 Proteins in the ECM of Animals

General type	Example	Function
Adhesive	Fibronectin	Connects cells to the ECM and helps to organize components in the ECM.
	Laminin	Connects cells to the ECM and helps to organize components in the basal lamina, a specialized ECM found next to epithelial cells (described in Section 10.3).
Structural	Collagen	Forms large fibers and interconnected fibrous networks in the ECM. Provides tensile strength.
	Elastin	Forms elastic fibers in the ECM that can stretch and recoil.

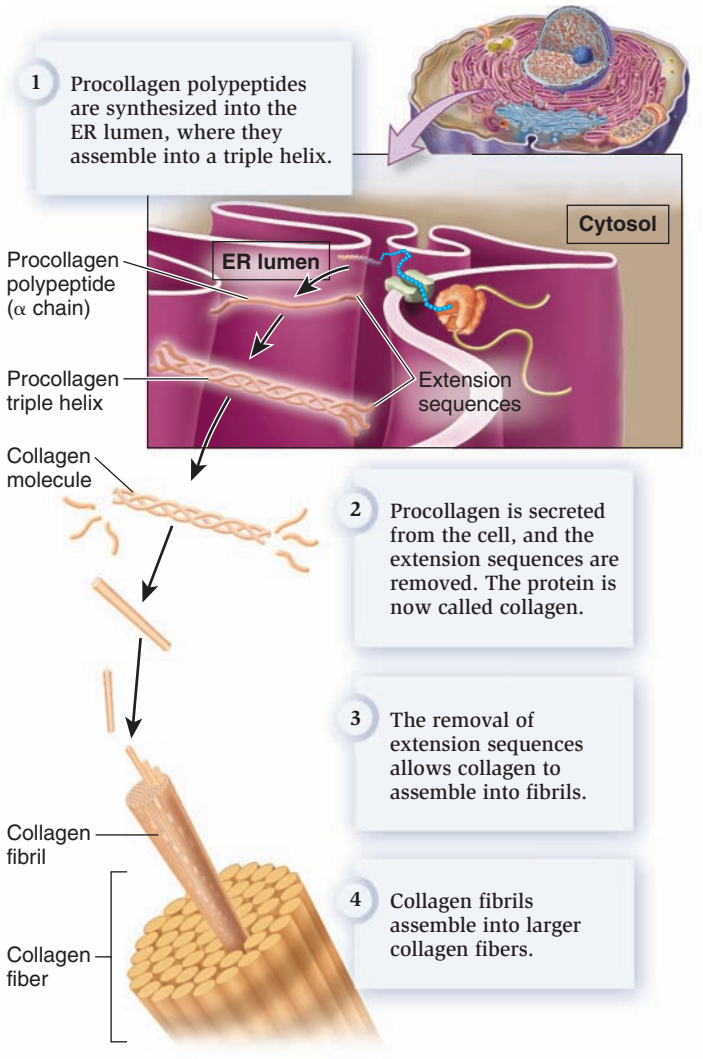

Figure 10.2 Formation of collagen fibers. Collagen is one type of structural protein found in the ECM of animal cells.

Concept Check: What prevents large collagen fibers from forming intracellularly?

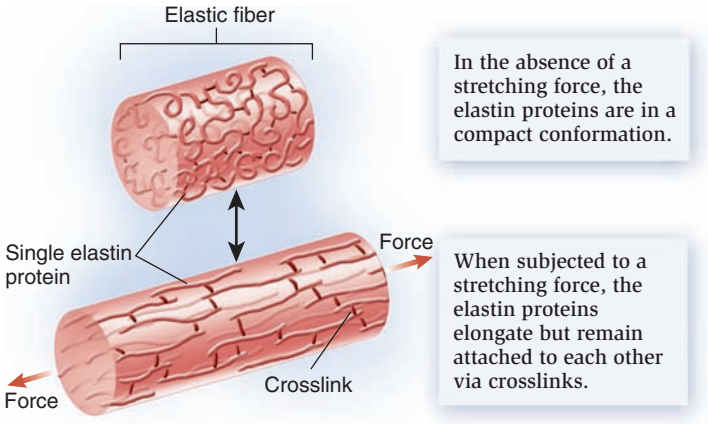

Figure 10.3 Structure and function of elastic fibers. Elastic fibers are made of elastin, one type of structural protein found in the ECM surrounding animal cells.

BIOLOGY PRINCIPLE Structure determines function. Two structural features—the tendency of the elastin protein to adopt a compact conformation and the covalent crosslinking of multiple elastin proteins—provide elastin fibers with the function of elasticity.

Concept Check: Suppose you started with an unstretched elastic fiber and treated it with a chemical that breaks the crosslinks between adjacent elastin proteins. What would happen when the fiber is stretched?

collagen, can form larger structures. Collagen proteins assemble in a staggered way to form relatively thin collagen fibrils, which then align and produce large collagen fibers. The many layers of these proteins give collagen fibers their tensile strength.

In addition to tensile strength, elasticity is needed in regions of the body such as the lungs and blood vessels, which regularly expand and return to their original shape. In these places, the ECM contains elastic fibers composed primarily of the protein **elastin** (Figure 10.3). Elastin proteins form many covalent crosslinks to make a fiber with remarkable elastic properties. In the absence of a stretching force, each protein tends to adopt a compact conformation. When subjected to a stretching force, however, the compact proteins become more linear, with the covalent crosslinks holding the fiber together. When the stretching force has ended, the proteins naturally return to their compact conformation. In this way, elastic fibers behave much like a rubber band, stretching under tension and snapping back when the tension is released.

BIO TIPS

THE QUESTION *Two structural proteins found in the ECM of animals are collagen and elastin. How are the structures of these proteins related to their functions?*

TOPIC ***What topic in biology does this question address?*** The topic is structural proteins in the ECM. More specifically, the question asks you to relate the structures and functions of collagen and elastin.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** In the question, you are reminded that collagen and elastin are structural proteins found in the ECM of animals. From your understanding of the topic, you may remember that collagen is composed of long, thick fibers, and its role is to provide tensile strength. Elastin is a more compact protein that forms crosslinked elastic fibers, which provide elasticity.

PROBLEM-SOLVING STRATEGY ***Relate structure and function.*** Take a closer look at the structures of these proteins, and consider how the structures determine the proteins' functions.

ANSWER *Collagen: A collagen fiber is composed of many smaller fibrils. Three procollagen polypeptides associate with each other to form a protein with a triple helix structure. These collagen proteins then assemble in a staggered way to form relatively thin collagen fibrils. The fibrils, in turn, align with each other and produce larger collagen fibers. The many layers of protein fibrils give collagen fibers their tensile strength.*

Elastin: Elastin has a very different structure from collagen. It is a fairly compact protein that forms elastic fibers with many covalent crosslinks between them. In the absence of a stretching force, the elastin proteins remain in the compact conformation. However, when subjected to a stretching force, they become more linear. The covalent crosslinks keep the proteins within the elactic fiber from coming apart. When the stretching force ends, the proteins naturally return to their compact conformation.

Genomes & Proteomes Connection

Collagens Are a Family of Proteins That Give the ECM of Animals a Variety of Properties

Researchers have determined that animals make many different types of collagen fibers. These are designated as type I, type II, and so on. At least 27 different types of collagens have been identified in humans. To make different types of collagens, the human genome, as well as the genomes of other animals, has many different genes that encode procollagen polypeptides. Some inherited human diseases are caused by mutations in genes that encode collagen proteins. For example, Ehlers-Danlos syndrome is caused by mutations in one of several different collagen genes. Characteristic symptoms are very stretchable skin and hyperflexible joints.

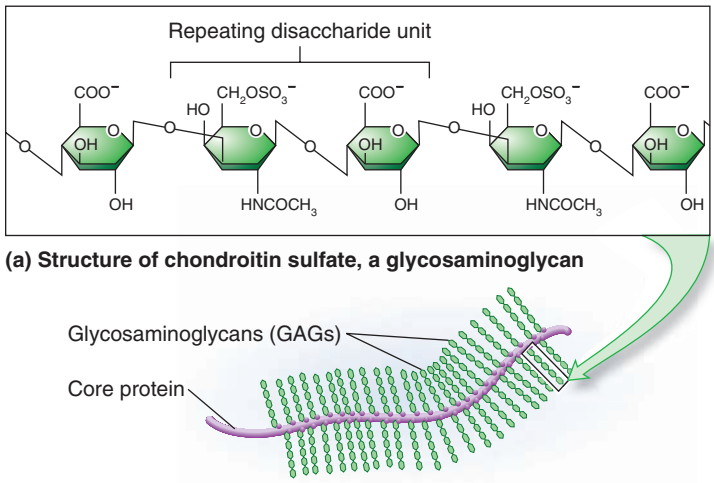
Why are different collagens made? Each of the many different types of collagen polypeptides has a similar yet distinctive amino acid sequence that affects the structure of not only individual collagen proteins but also the resulting collagen fibers. For example, the amino acid sequence may cause the α chains within each collagen protein to bind to each other very tightly, thereby creating rigid proteins that form a relatively stiff fiber. Such collagen fibers are found in bone and cartilage.

The amino acid sequence of the α chains also influences the interactions between the collagen proteins within a fiber. For example, the amino acid sequences of certain α chains promote a looser interaction that produces a more bendable or thinner fiber.

Table 10.2 Examples of Collagen Types in Humans

Type	Sites of synthesis*	Structure and function
I	Tendons, ligaments, bones, and skin	Forms a relatively rigid and thick fiber. Very abundant, provides most of the tensile strength to the ECM.
II	Cartilage, discs between vertebrae	Forms a fairly rigid and thick fiber but is more flexible than type I. Permits smooth movements of joints.
III	Arteries, skin, internal organs, and around muscles	Forms thin fibers, often arranged in a meshwork pattern. Allows for greater elasticity in tissues.
IV	Skin, intestine, and kidneys; also found around capillaries	Does not form long fibers. Instead, the proteins are arranged in a meshwork pattern that provides organization and support to cell layers. Functions as a filter around capillaries.

* The sites of synthesis denote where a large amount of the collagen type is made.



More flexible collagen fibers support the lining of your lungs and intestines. In addition, domains within the collagen polypeptide affect the spatial arrangement of collagen proteins. The collagen shown in Figure 10.2 forms fibers in which collagen proteins align themselves in parallel arrays. However, not all collagen proteins form long fibers. For example, type IV collagen proteins interact with each other in a meshwork pattern. This meshwork acts as a filter around capillaries.

Gene regulation controls which types of collagens are made throughout the body and in what amounts they are made. Of the 27 types of collagens identified in humans, **Table 10.2** considers types I to IV, each of which varies as to where it is primarily synthesized and its structure and function. In skin cells, for example, the genes that encode the polypeptides that make up collagen types I, III, and IV are turned on, but the synthesis of type II collagen is minimal.

The regulation of collagen synthesis has received a great deal of attention due to the phenomenon of wrinkling. As we age, the amount of collagen that is synthesized in our skin significantly decreases. The underlying network of collagen fibers, which provides scaffolding for the surface of our skin, loosens and unravels. This is one factor that causes the skin of older people to sink, sag, and form wrinkles. Various therapeutic and cosmetic agents have been developed to prevent or reverse the appearance of wrinkles, most with limited benefits. For example, many face and skin creams contain collagen as an ingredient. Another approach is collagen injections, in which small amounts of collagen (from cows) are injected into areas where the body's collagen has weakened, filling the depressions to the level of the surrounding skin. Because collagen is naturally broken down in the skin, the injections are not permanent and last only about 3 to 6 months.

Animal Cells Also Secrete Polysaccharides into the ECM

Polysaccharides are the second major component of the ECM of animals. As discussed in Chapter 3, polysaccharides are polymers of sugars. Among vertebrates, the most abundant types of polysaccharides in the ECM are **glycosaminoglycans (GAGs)**. These macromolecules are long, unbranched polysaccharides containing a repeating disaccharide unit (**Figure 10.4a**). GAGs are highly

(a) Structure of chondroitin sulfate, a glycosaminoglycan

(b) General structure of a proteoglycan

Figure 10.4 Structures of glycosaminoglycans and proteoglycans. These macromolecules are found in the ECM, which is located outside of animal cells. **(a)** Glycosaminoglycans (GAGs) are composed of repeating disaccharide units. They range in length from several dozen to 25,000 disaccharide units. The GAG shown here is chondroitin sulfate, which is a component of cartilage. **(b)** Proteoglycans are composed of a long, linear core protein with many GAGs attached. Note that each GAG is typically 80 disaccharide units long but only a short chain of sugars is shown in this illustration.

Concept Check: *What structural feature of GAGs and proteoglycans give them a gel-like character?*

negatively charged molecules that tend to attract positively charged ions and water. The majority of GAGs in the ECM are linked to core proteins, forming **proteoglycans** (**Figure 10.4b**).

Providing resistance to compression is the primary function of GAGs and proteoglycans. Once secreted from cells, these macromolecules form a gel-like component in the ECM. How is this gel-like property important? Due to its high water content, the ECM is difficult to compress and thereby serves to protect cells. GAGs and proteoglycans are found abundantly in regions of the body that are subjected to harsh mechanical forces, such as the joints of the human body. Two examples of GAGs are chondroitin sulfate, which is a major component of cartilage, and hyaluronic acid, which is found in the skin, eyes, and joint fluid. Purified hyaluronic acid is also used to treat wrinkles and give skin fullness.

Among many invertebrates, an important ECM component is **chitin**, a nitrogen-containing polysaccharide. Chitin forms the hard protective outer covering (called an exoskeleton) of insects, such as crickets and grasshoppers, and crustaceans, such as lobsters and shrimp. As these animals grow, they periodically shed this rigid outer layer and secrete a new, larger one—a process called molting (look ahead to Figure 32.12).

The Cell Wall of Plants Provides Strength and Resistance to Compression

Let's now turn our attention to the cell walls of plants. Plant cells are surrounded by a cell wall, a protective layer that forms outside of the plasma membrane. Like animal cells, the cells of plants are

surrounded by material that provides tensile strength and resistance to compression. The cell walls of plants, however, are usually thicker, stronger, and more rigid than the ECM found in animals. Plant cell walls provide rigidity for mechanical support and also play a role in the maintenance of cell shape and the direction of cell growth. As we learned in Chapter 5, the cell wall also prevents expansion when water enters the cell, thereby preventing osmotic lysis.

The main macromolecule of the plant cell wall is **cellulose**, a polysaccharide made of repeating molecules of glucose attached end to end. These glucose polymers associate with each other via hydrogen bonding to form microfibrils that provide great tensile strength (**Figure 10.5**).

Cellulose was discovered in 1838 by French chemist Anselme Payen, who was the first scientist to attempt to separate wood into its component parts. After treating different types of wood with nitric acid, Payen obtained a fibrous substance that was also found in cotton and other plants. His chemical analysis revealed that the fibers were made of the carbohydrate glucose. Payen called this substance cellulose (from the Latin, meaning consisting of cells). Cellulose is probably the single most abundant organic molecule on Earth. Wood consists mostly of cellulose, and cotton and paper are almost pure cellulose. The mechanism of cellulose synthesis is described in Chapter 35.

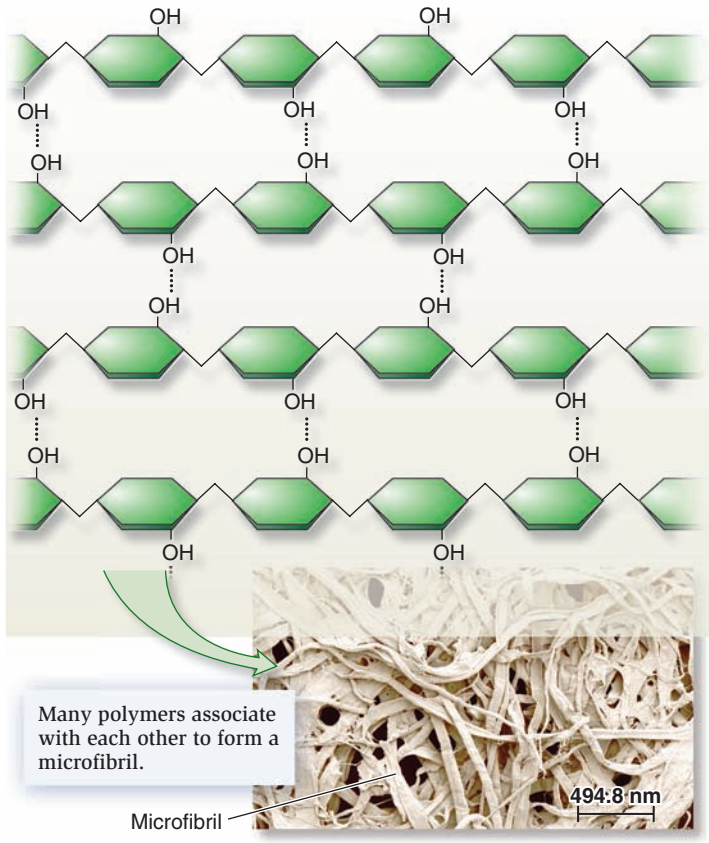


Figure 10.5 Structure of cellulose, the main macromolecule of the primary cell wall. Cellulose is made of repeating glucose units linked end to end that hydrogen-bond to each other to form microfibrils (SEM).

Plant Cell Walls Consist of Primary and Secondary Walls

The cell walls of plants are composed of a primary cell wall and a secondary cell wall (**Figure 10.6**). These walls are named based on the timing of their synthesis—the primary cell wall is made before the secondary cell wall.

Primary Cell Wall During cell division, the primary cell wall develops between two newly formed daughter cells. It is usually very flexible and allows the new cells to increase in size. The main constituent of the primary cell wall is cellulose.

In addition to cellulose, other components found in the primary cell wall include hemicellulose, glycans, and pectins (see Figure 10.6). Hemicellulose is another linear polysaccharide, with a structure similar to that of cellulose, but it contains sugars other than glucose in its structure and usually forms thinner microfibrils. Glycans, polysaccharides with branching structures, are also important in cell wall structure. The crosslinking glycans bind to cellulose and provide organization to the

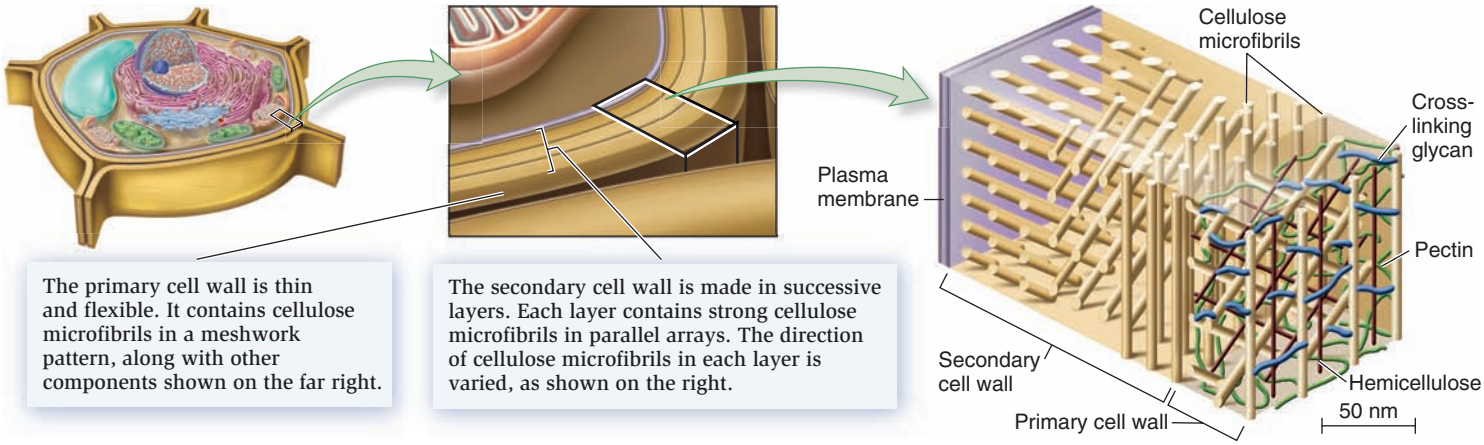

Figure 10.6 Structure of the cell wall of plant cells. The primary cell wall is relatively thin and flexible. It contains cellulose (tan), hemicellulose (red), crosslinking glycans (blue), and pectin (green). The secondary cell wall, which is produced only by certain plant cells, is made after the primary cell wall and is synthesized in successive layers.

Concept Check: *With regard to cell growth, what would happen if the secondary cell wall was made too soon?*

cellulose microfibrils. Pectins, which are highly negatively charged polysaccharides, attract water and have a gel-like character that provides the cell wall with the ability to resist compression.

Secondary Cell Wall The **secondary cell wall** is synthesized and deposited between the plasma membrane and the primary cell wall (see Figure 10.6) after a plant cell matures and has stopped increasing in size. It is made in layers by the successive deposition of cellulose microfibrils and other components. Whereas the primary wall structure is relatively similar in nearly all cell types and species, the structure of the secondary cell wall is more variable. Some plant cells have no secondary cell wall; for example, leaf cells that are involved in photosynthesis lack a secondary wall, allowing light to enter the cells more readily. The secondary cell wall often contains components in addition to those found in the primary cell wall. For example, phenolic compounds called lignins, which are found in the woody parts of plants, are very hard and impart considerable strength to the secondary wall structure.

10.2 Cell Junctions

Learning Outcomes:

1. Compare and contrast the structure and function of anchoring junctions, tight junctions, and gap junctions found between animal cells.
2. **SciSKILLS** » Analyze the results of experiments that determined the size of gap junction channels.
3. Describe the structure and function of the middle lamella and plasmodesmata that connect adjacent plant cells.

Thus far, we have learned that the cells of animals and plants produce an ECM or cell wall that provides strength, support, and organization. To become a multicellular organism, cells within the body must also be linked to each other. In animals and plants, this is accomplished by specialized structures called **cell junctions** (**Table 10.3**).

Animal cells, which lack the structural support provided by the cell wall, have a more varied group of cell junctions than plant cells. In animals, three types of junctions are found between cells: anchoring junctions play a role in anchoring cells to each other or to the ECM; tight junctions seal cells together to prevent small molecules from leaking across a layer of cells; and gap junctions allow the passage of materials between adjacent cells.

In plants, cellular organization is somewhat different because plant cells are surrounded by a rigid cell wall. Plant cells are connected to each other by a component called the middle lamella, which cements their cell walls together. They also have junctions termed plasmodesmata that allow the passage of materials between adjacent cells. In this section, we will examine these various types of junctions found between the cells of animals and plants.

Table 10.3 Common Types of Cell Junctions

Type	Description
Animals	
Anchoring junctions	Cell junctions that hold adjacent cells together or attach cells to the ECM. Anchoring junctions are mechanically strong.
Tight junctions	Junctions between adjacent cells in a layer that prevent the leakage of material between cells.
Gap junctions	A collection of channels that permit the direct exchange of ions and small molecules between the cytosol of adjacent cells.
Plants	
Middle lamella	A polysaccharide layer that cements together the cell walls of adjacent cells.
Plasmodesmata	Passageways between the cell walls of adjacent cells that can be opened or closed. When open, they permit the direct diffusion of ions and molecules between the cytosol of cells.

Anchoring Junctions Link Animal Cells to Each Other and to the ECM

Electron microscopy allows researchers to explore the types of junctions that occur between cells and within the ECM. In the 1960s, Marilyn Farquhar, George Palade, and colleagues conducted several studies showing that various types of cell junctions connect cells to each other. Collectively called **anchoring junctions**, these junctions attach cells to each other and to the ECM. Anchoring junctions are common in parts of the body where the cells are tightly connected and form linings. An example is the layer of cells that line the small intestine. Anchoring junctions keep these intestinal cells tightly adhered to one another, thereby forming a strong barrier between the lumen of the intestine and the blood. A key component of anchoring junctions that form the actual connections are integral membrane proteins called **cell adhesion molecules (CAMs)**. Two types of CAMs are cadherins and integrins.

Anchoring junctions are grouped into four main categories, according to their functional roles and their connections to cellular components. **Figure 10.7** shows these junctions between cells of the mammalian small intestine.

1. **Adherens junctions** connect cells to each other via cadherins. In many cases, these junctions are organized into bands around cells. In the cytosol, adherens junctions bind to cytoskeletal filaments called actin filaments.
2. **Desmosomes** also connect cells to each other via cadherins. They are spotlike points of intercellular contact that rivet cells together. Desmosomes are connected to cytoskeletal filaments called intermediate filaments.
3. **Hemidesmosomes** connect cells to the extracellular matrix via integrins. Like desmosomes, they interact with intermediate filaments.
4. **Focal adhesions** also connect cells to the ECM via integrins. In the cytosol, focal adhesions bind to actin filaments.

Cell Adhesion Molecules (CAMs) Form Links Between Cells and to the ECM

Let's now consider the molecular components of anchoring junctions.

Cadherins As mentioned, **cadherins** are CAMs that create cell-to-cell junctions (**Figure 10.8a**). The extracellular domains of two cadherin proteins, each in adjacent cells, bind to each other to promote cell-to-cell adhesion. This binding requires the presence of calcium ions (Ca^{2+}), which change the conformation of

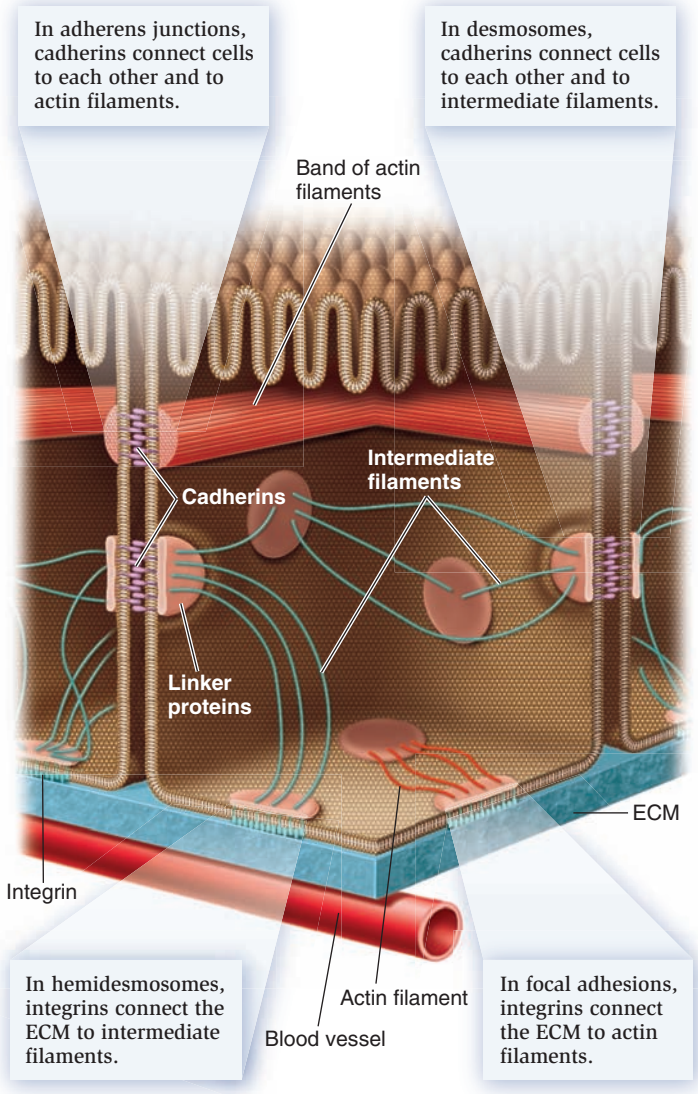

Figure 10.7 Types of anchoring junctions. This figure shows these junctions in three adjacent intestinal cells. The tops of these cells face the lumen of the intestine, whereas the bottoms are adjacent to the ECM and a blood vessel.

Concept Check: *Which junctions are cell-to-cell junctions and which are cell-to-ECM junctions?*

the cadherin protein such that cadherins in adjacent cells bind to each other. (This calcium dependence is where cadherin gets its name—Ca^{2+}-dependent adhering molecule.) On the interior of the cell, linker proteins connect cadherins to actin or intermediate filaments of the cytoskeleton. This promotes a more stable interaction between two cells because their strong cytoskeletons are connected to each other.

The genomes of vertebrates and invertebrates contain multiple cadherin genes, which encode slightly different cadherin proteins. The expression of cadherins in particular cell types allows cells to recognize each other. Dimer formation follows a homophilic, or like-to-like, binding mechanism. To understand the concept of homophilic binding, let's consider an example. One type of cadherin is called E-cadherin, and another is N-cadherin. E-cadherin in one cell binds to E-cadherin in an adjacent cell to form a homodimer. However, E-cadherin in one cell does not bind to N-cadherin in an adjacent cell to form a heterodimer. Similarly, N-cadherin binds to N-cadherin but not to E-cadherin in an adjacent cell. Why is such homophilic binding important? By expressing only certain types of cadherins, each cell binds only to other cells that express the same cadherin types. This phenomenon plays a key role in the proper arrangement of cells throughout the body, particularly during embryonic development.

Integrins Another type of CAMs are proteins called **integrins**, which form connections between cells and the ECM. Integrins do not require Ca^{2+} to function. Each integrin protein is composed of two nonidentical subunits. In the example shown in **Figure 10.8b**, an integrin is bound to fibronectin, an adhesive protein in the ECM that binds to other ECM components such as collagen fibers. Like cadherins, integrins also bind to actin or intermediate filaments in the cytosol of the cell, via linker proteins, to promote a strong association between the cytoskeleton and the ECM. Thus, integrins have an extracellular domain for the binding of ECM components and an intracellular domain for the binding of cytosolic proteins.

When CAMs were first discovered, researchers imagined that cadherins and integrins played only a mechanical role. In other words, their functions were described as holding cells together or to the ECM. More recently, however, experiments have shown that cadherins and integrins are important in cell communication. The formation or breaking of cell-to-cell and cell-to-ECM anchoring junctions affects signal transduction pathways within the cell. Similarly, intracellular signal transduction pathways affect cadherins and integrins in ways that alter intercellular junctions and the binding of cells to ECM components.

Abnormalities in CAMs such as integrins are associated with the ability of cancer cells to metastasize, that is, to move to other parts of the body. CAMs are critical for keeping cells in their correct locations. When they become defective due to cancer-causing mutations, cells lose their proper connections with the ECM and adjacent cells and may move to other parts of the body.

Tight Junctions Prevent the Leakage of Materials Across Animal Cell Layers

In animals, **tight junctions** are a second type of junction, one that forms a tight seal between adjacent cells, thereby preventing material from leaking between cells. As an example, let's consider the intestine. The cells that line the intestine form a sheet that is one cell thick. One side of each cell faces the intestinal lumen, and the other faces the ECM and a blood vessel (**Figure 10.9**). Tight junctions are formed between these cells.

Tight junctions are made by membrane proteins, called occludin and claudin, that form interlaced strands in the plasma membrane (see inset in Figure 10.9). These strands of proteins, each in adjacent cells, bind to each other, thereby forming a tight seal between cells. Tight junctions are not mechanically strong like anchoring junctions, because they do not have strong connections with the cytoskeleton. Therefore, adjacent cells that have tight junctions also have anchoring junctions to hold the cells in place.

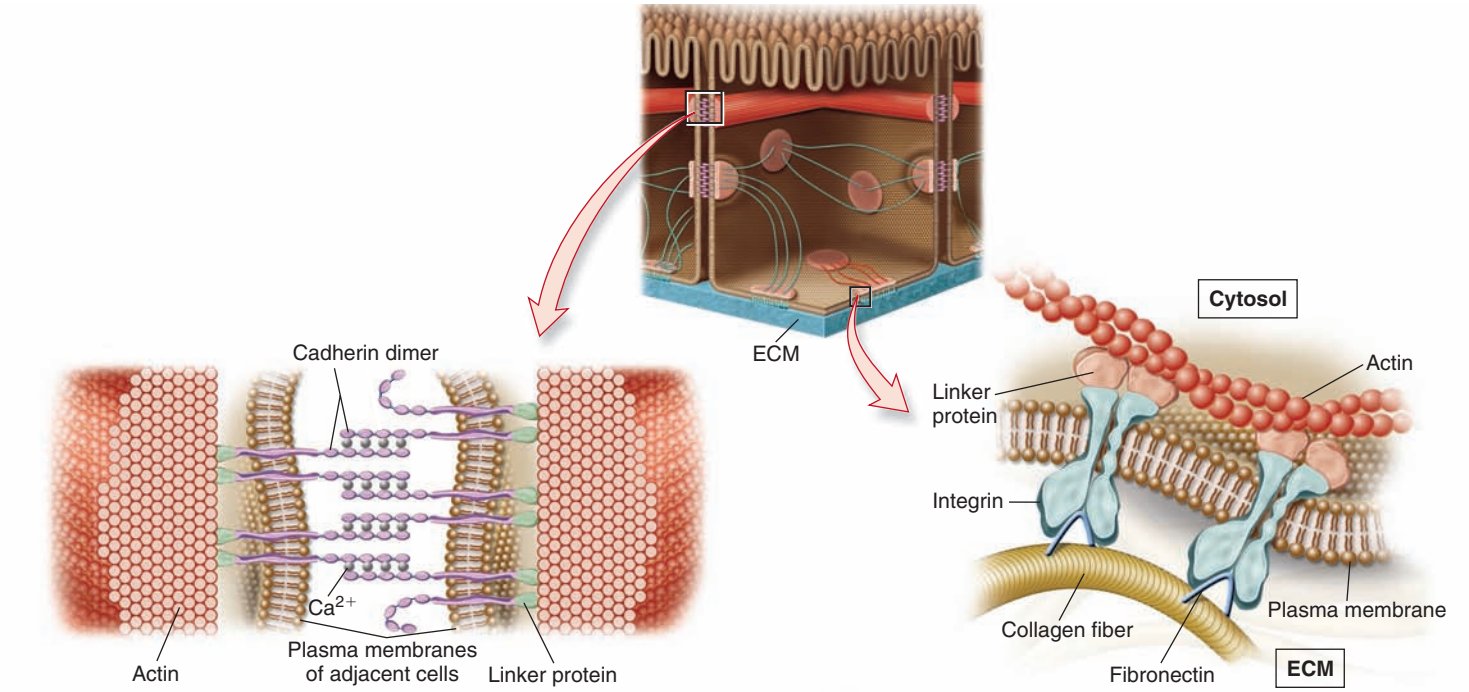

Figure 10.8 Types of cell adhesion molecules (CAMs). Cadherins and integrins are CAMs that form connections in anchoring junctions. **(a)** A cadherin in one cell binds to a cadherin of an identical type in an adjacent cell. This binding requires Ca^{2+}. In the cytosol, cadherins bind to actin or intermediate filaments of the cytoskeleton via linker proteins. **(b)** Integrins link cells to the ECM and form intracellular connections to actin or intermediate filaments. Each integrin protein is composed of two nonidentical subunits, a heterodimer.

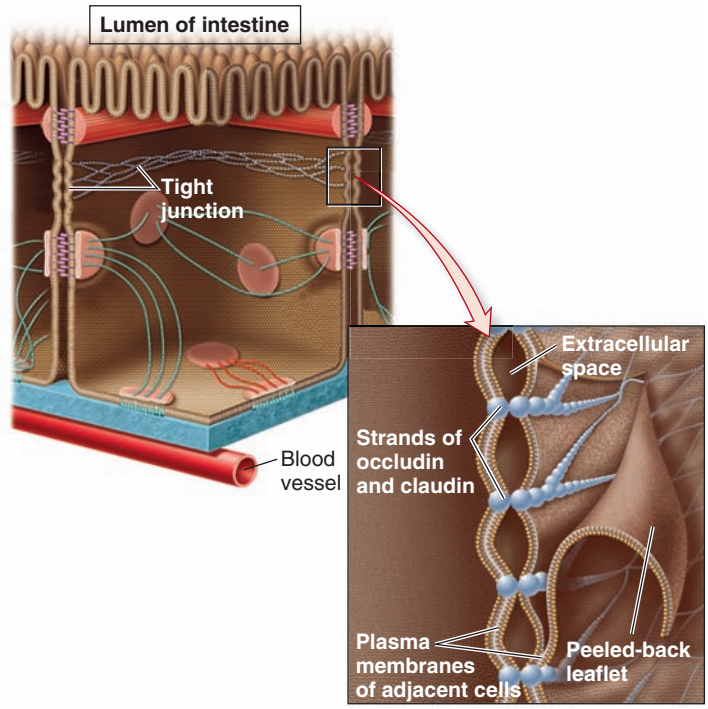

Figure 10.9 Tight junctions between adjacent intestinal cells. In this example, tight junctions form a seal between cells of the intestinal lining. The inset shows the interconnected network of occludin and claudin that forms the tight junction.

Concept Check: *What do you think is the role of tight junctions in the epidermal layers of your skin?*

BioConnections: *Look ahead to Figure 45.8. What problems might arise if tight junctions did not connect the cells that line your small intestine?*

Tight junctions perform several important roles. Let's consider a few examples.

- Tight junctions between intestinal cells prevent leakage of materials between the lumen of the intestine and the blood.
- Tight junctions help maintain the polarity of intestinal cells by preventing the lateral diffusion of integral membrane proteins between the apical side (which faces the lumen of the intestine) and the basolateral side (which faces a blood vessel). For example, proteins involved with receptor-mediated endocytosis are restricted to the apical side, and proteins involved with exocytosis are located at the basolateral side. Thus, intestinal cells are able to take up nutrients from the intestinal lumen and export them into the bloodstream, a phenomenon called **transepithelial transport**.
- Tight junctions prevent microbes from entering the body. In mammals, the skin on the exterior of the body and the lining of the digestive tract are formed from interconnected cells that have tight junctions. Some pathogenic microorganisms, such as those that cause certain forms of diarrhea, are able to cause infection by disrupting tight junctions.

The amazing ability of tight junctions to prevent the leakage of material across cell layers has been demonstrated by dye-injection studies. In 1972, Daniel Friend and Norton Gilula injected lanthanum into the bloodstream of a rat. Lanthanum is an electron-dense element that can be visualized using electron microscopy. A few minutes later, a sample of a cell layer in the digestive tract was removed and observed under an electron microscope. As seen in

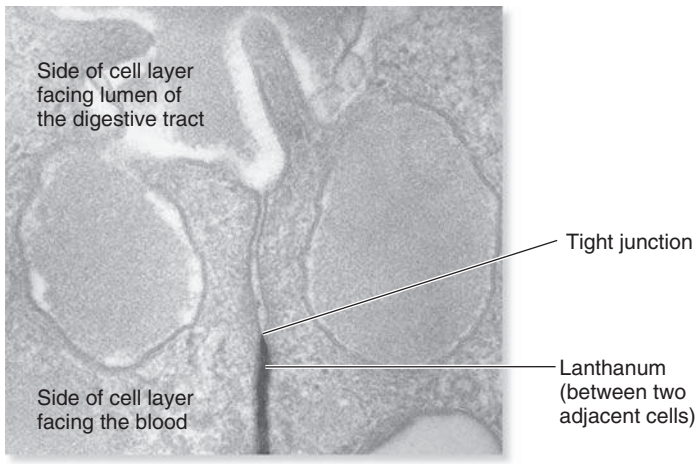

Figure 10.10 An experiment demonstrating the function of a tight junction. When lanthanum was injected into the bloodstream of a rat, it diffused between the cells in the region up to a tight junction but could not diffuse past the junction to the other side of the cell layer.

Concept Check: What results would you expect if a rat was fed lanthanum and then a sample of intestinal cells was observed under an electron microscope?

the micrograph in **Figure 10.10**, lanthanum diffused into the region between the cells that faces the blood, but it could not move past the tight junction to the side of the cell layer facing the lumen of the digestive tract.

Gap Junctions Between Animal Cells Provide Passageways for Intercellular Transport

A third type of junction found between animal cells is called a **gap junction**, because a small gap occurs between the plasma membranes of cells connected by these junctions (**Figure 10.11**). Gap junctions are abundant in tissues and organs where the cells need to communicate with each other. For example, cardiac muscle cells, which cause your heart to beat, are interconnected by many gap junctions. Because gap junctions allow the passage of ions, electrical changes in one cardiac muscle cell are easily transmitted to an adjacent cell that is connected via gap junctions. This is needed for the coordinated contraction of cardiac muscle cells.

In vertebrates, gap junctions are composed of an integral membrane protein called connexin. Invertebrates have a structurally similar protein called innexin. Six connexin proteins in one vertebrate cell form a channel called a **connexon**. A connexon in one cell aligns with a connexon in an adjacent cell to form an intercellular channel (see middle drawing in Figure 10.11). The term gap junction refers to a cluster of many connexons that are close to each other in the plasma membrane and form many intercellular channels.

Connexons allow the passage of ions and small molecules, including amino acids, sugars, and signaling molecules such as Ca^{2+} and cAMP, between cells. In this way, gap junctions allow adjacent cells to share metabolites and directly signal each other. However, gap junction channels are too small to allow the passage of RNA, proteins, or polysaccharides. Therefore, cells that communicate via gap junctions still maintain their own distinctive sets of macromolecules.

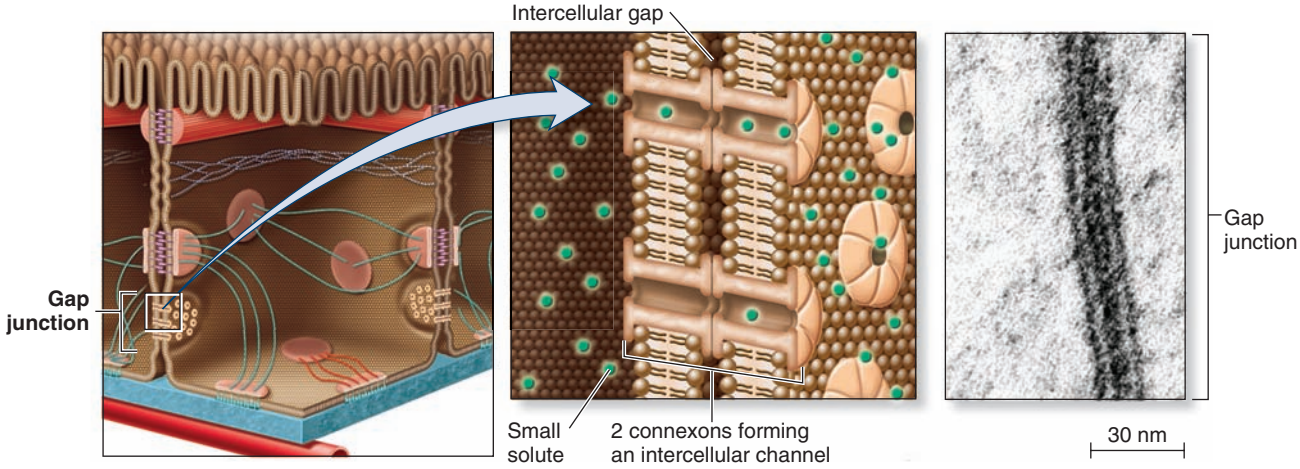

Figure 10.11 Gap junctions between adjacent cells. Gap junctions form intercellular channels that allow the passage of small solutes with masses less than 1,000 Da. A connexon consists of six proteins called connexins. Two connexons align to form an intercellular channel. The micrograph shows a gap junction, which is composed of many connexons, between intestinal cells.

Feature Investigation | Loewenstein and Colleagues Followed the Transfer of Fluorescent Dyes to Determine the Size of Gap-Junction Channels

As mentioned, gap junctions allow the passage of ions and small molecules, those with a mass up to about 1,000 Da. This property of gap junctions was determined in experiments involving the transfer of fluorescent dyes. In 1964, Werner Loewenstein and colleagues observed that a fluorescent dye could move from one cell to an adjacent cell, which prompted them to investigate this phenomenon further.

In the experiment shown in **Figure 10.12**, Loewenstein and colleagues grew rat liver cells in the laboratory, where they formed a single layer. The adjacent cells formed gap junctions. Single cells

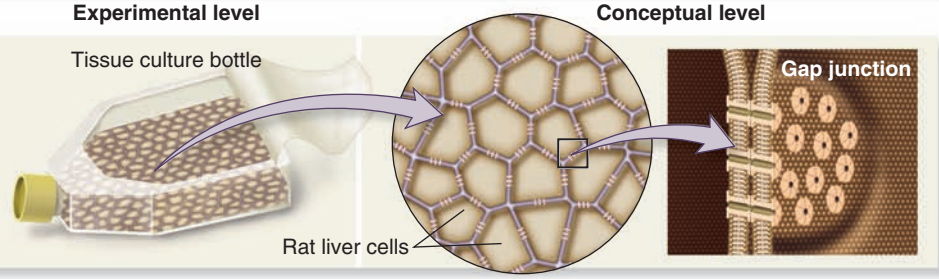

Figure 10.12 Use of fluorescent molecules by Loewenstein and colleagues to determine the size of gap-junction channels.

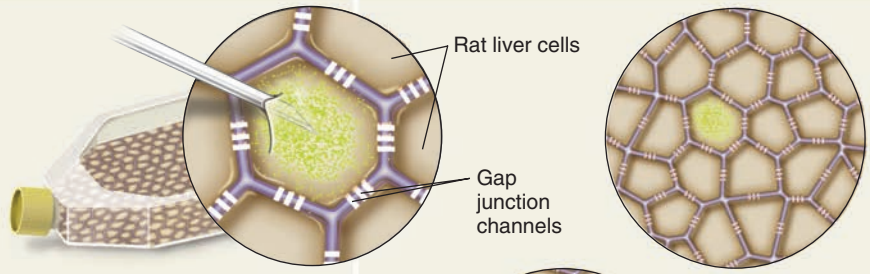
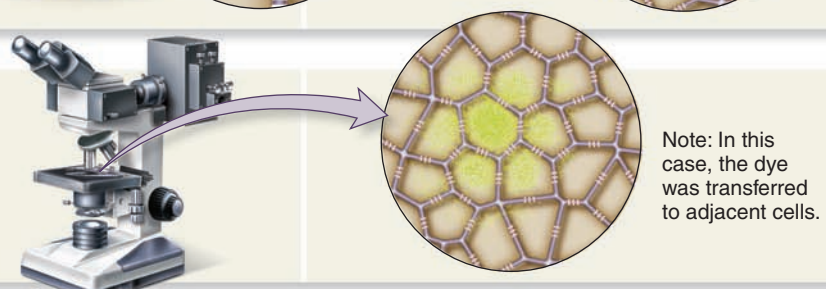
HYPOTHESIS Gap-junction channels allow the passage of ions and molecules, but there is a limit to how large the molecules can be.



KEY MATERIALS Rat liver cells grown in the laboratory, a collection of fluorescent dyes.

Experimental level **Conceptual level**



1 Grow rat liver cells in a laboratory on solid growth medium until they become a single layer. At this point, adjacent cells have formed gap junctions.

2 Inject 1 cell in the layer with fluorescently labeled amino acids or peptides. Note: Several dyes with different molecular masses were tested.

3 Incubate for various lengths of time (for example, 40–45 minutes). Observe cell layer under the fluorescence microscope to determine if the dye has moved to adjacent cells.

4 **THE DATA**

Mass of dye (in daltons)	Transfer to adjacent cells*	Mass of dye	Transfer to adjacent cells*
376	++++	851**	–
464	++++	901	+++
536	+++	946	–
559	++++	1004	–
665	+	1158	–
688	++++	1678	–
817	+++	1830	–

*The number of pluses indicates the relative speed of transfer. Four pluses denotes fast transfer, whereas one plus is slow transfer. A minus indicates that transfer between cells did not occur. **In some cases, molecules with less mass did not pass between cells compared with molecules with a higher mass. This may be due to differences in their structures (for example, charges) that influence whether or not they can easily penetrate the channel.

5 **CONCLUSION** Gap junctions allow the intercellular movement of molecules that have a mass of approximately 900 Da or less.

6 **SOURCE** Flagg-Newton, J., Simpson, I., and Loewenstein, W.R. 1979. Permeability of the Cell-to-Cell Membrane Channels in Mammalian Cell Junction. *Science* 205:404–407.

were injected with various dyes composed of fluorescently labeled amino acids or peptide molecules with different masses, and then the cell layers were observed via fluorescence microscopy. As the data in Figure 10.12 show, dyes with a molecular mass up to 901 Da passed from cell to cell. Dyes with a larger mass, however, did not move intercellularly. Loewenstein and other researchers subsequently investigated dye transfer in other cell types and species. Though some variation is found when comparing different cell types and species, the researchers generally observed that molecules with a mass greater than 1,000 Da do not pass through gap junctions.

Experimental Questions

1. What was the purpose of the study conducted by Loewenstein and colleagues?
2. **SciSKILLS »** Explain the experimental procedure used by Loewenstein to determine the size of molecules that can pass through gap-junction channels.
3. **SciSKILLS »** What do the results of the experiment in Figure 10.12 indicate about the size of gap-junction channels?

The Middle Lamella Cements Adjacent Plant Cell Walls Together

In animals, cell-to-cell contact via anchoring junctions, tight junctions, and gap junctions involves interactions between membrane proteins in adjacent cells. In plants, cell junctions are biochemically different. Rather than using membrane proteins to form cell-to-cell connections, plant cells make an additional component called the **middle lamella** (plural, lamellae), which is found between most adjacent plant cells (**Figure 10.13**). When plant cells are dividing, the middle lamella is the first layer formed. The primary cell wall is then made. The middle lamella is rich in pectins, negatively charged polysaccharides that are also found in the primary cell wall (see Figure 10.6). Pectins attract water and make a hydrated gel. Ca^{2+} and Mg^{2+} interact with the negative charges in the pectins and cement the cell walls of adjacent cells together.

The process of fruit ripening illustrates the importance of pectins in holding plant cells together. An unripened fruit, such as a green tomato, is very firm because the rigid cell walls of adjacent cells are firmly attached to each other. During ripening, the cells secrete a group of enzymes called pectinases, which digest pectins in the middle lamella as well as those in the primary cell wall. As this process continues, the attachments between cells are broken, and the cell walls become less rigid. For this reason, a red ripe tomato is much less firm than an unripe tomato.

Plasmodesmata Are Channels Connecting the Cytoplasm of Adjacent Plant Cells

In 1879, Eduard Tangl, a Russian botanist, observed intercellular connections in the seeds of the strychnine tree and hypothesized that the cytoplasm of adjacent cells is connected by ducts in the cell walls. He was the first to propose that direct cell-to-cell communication integrates the functioning of plant cells. The ducts or intercellular channels that Tangl observed are now known as **plasmodesmata** (singular, plasmodesma).

Plasmodesmata are functionally similar to gap junctions in animal cells because they are open pores that allow the passage of ions and molecules between the cytosol of adjacent plant cells. However, the structure of plasmodesmata is quite different from that of gap junctions. As shown in **Figure 10.14**, the plasma membrane of one cell is continuous with the plasma membrane of the adjacent cell, which permits the diffusion of molecules from the cytosol of one cell to the cytosol of the other. In addition to a cytosolic connection, plasmodesmata also have a central tubule, called a desmotubule, connecting the smooth ER membranes of adjacent cells.

Plasmodesmata can change the size of their opening among closed, open, and dilated states. In the open state, they allow the passage of ions and small molecules, such as sugars and cAMP. In this state, plasmodesmata play a similar role to gap junctions between animal cells. Plasmodesmata tend to close when a large pressure difference occurs between adjacent cells. Why does this happen? One reason is related to cell damage. When a plant is wounded, damaged cells lose their turgor pressure. (Turgor pressure is described in Chapter 38, Figure 38.4.) The closure of plasmodesmata between adjacent cells helps to prevent the loss of water and nutrients from the wound site.

Unlike gap junctions between animal cells, plasmodesmata can dilate to also allow the passage of macromolecules and even viruses between adjacent plant cells. Though the mechanism of dilation is not

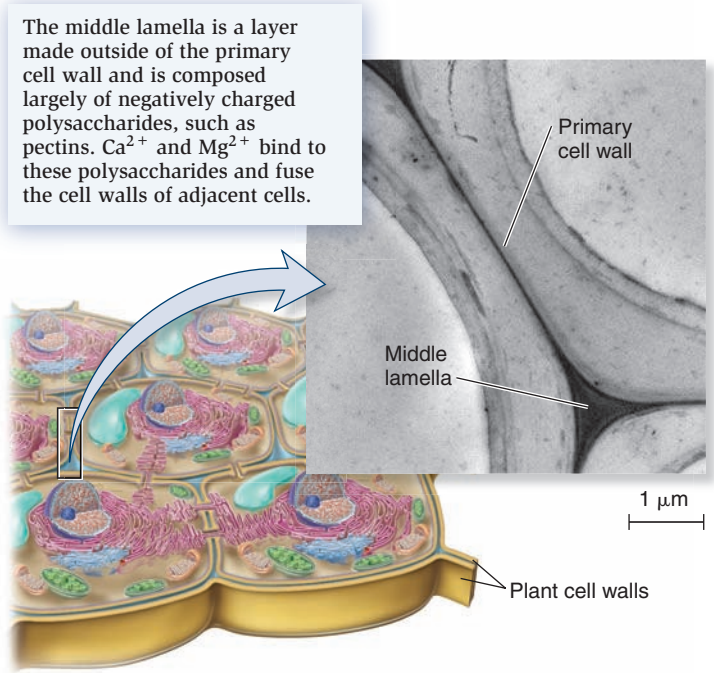


Figure 10.13 Plant cell-to-cell junctions known as middle lamellae.

Concept Check: *How are middle lamellae similar to the anchoring junctions and desmosomes found between animal cells? How are they different?*

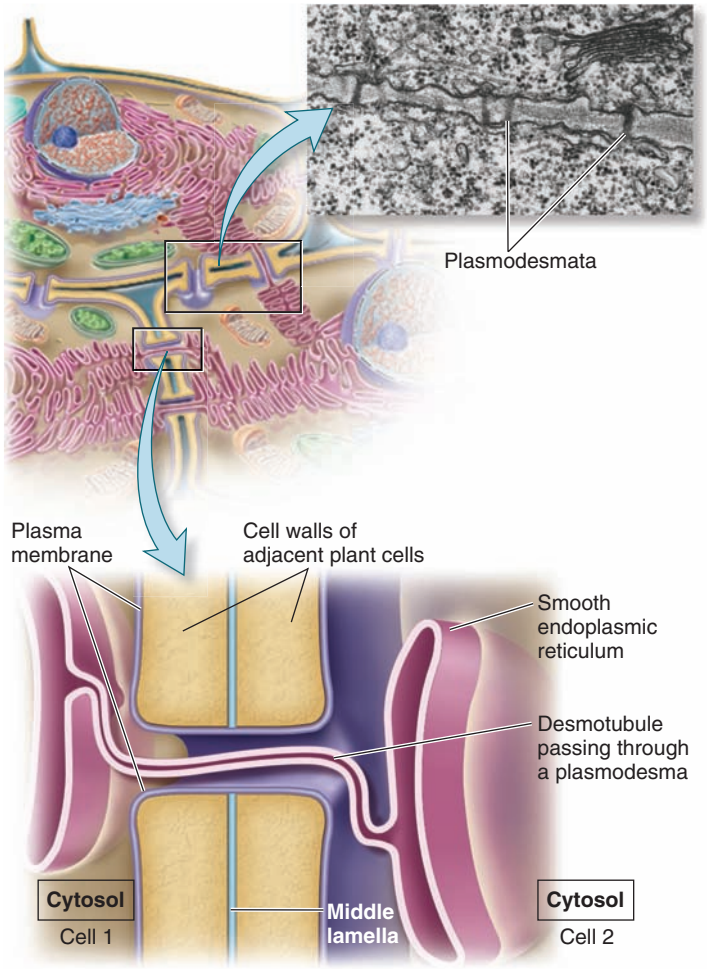

Figure 10.14 Structure of plasmodesmata. Plasmodesmata are cell junctions connecting the cytosol of adjacent plant cells, allowing water, ions, and molecules to pass from cell to cell. At these pores, the plasma membrane of one cell is continuous with the plasma membrane of an adjacent cell. In addition, the smooth ER from one cell is connected to that of the adjacent cell via a desmotubule.

BioConnections: Look ahead to Figure 38.8. How do plasmodesmata play a role in the movement of nutrients through a plant root?

well understood, the wider opening of plasmodesmata is important for the passage of proteins and mRNA during plant development. It also provides a key mechanism whereby viruses can move from cell to cell.

10.3 Tissues

Learning Outcomes:

1. List the six basic cell processes that produce tissues and organs.
2. Outline the structures and functions of the four types of animal tissues: epithelial, connective, nervous, and muscle tissues.
3. Summarize the structures and functions of the three types of plant tissues: dermal, ground, and vascular tissues.

A **tissue** is a part of an animal or plant consisting of a group of cells having a similar structure and function. In this section, we will view tissues from the perspective of cell biology. Animals and plants contain many different types of cells. Humans, for example, have over 200 different cell types, each with a specific structure and function. Even so, these cells can be grouped into a few general categories. For example, muscle cells found in your heart (cardiac muscle cells), in your biceps (skeletal muscle cells), and around your arteries (smooth muscle cells) look somewhat different under the microscope and have unique roles in the body. Yet due to structural and functional similarities, all three types are categorized as muscle tissue. In this section, we begin by surveying the basic processes that cells undergo to make tissues. Then, we will examine the main categories of animal and plant tissues.

Six Different Cell Processes Produce Tissues and Organs

A multicellular organism, such as a plant or animal, contains many cells. For example, an adult human has somewhere between 10 and 100 trillion cells in her or his body. Cells are organized into tissues, and tissues are organized into organs. An **organ** is a collection of two or more tissues that performs a specific function or set of functions. The heart is an organ found in the bodies of complex animals, and a leaf is an organ found in plants. We will examine the structures and functions of organs in Units VI and VII.

How are tissues and organs formed? To form tissues and organs, cells undergo six different processes that influence their morphology, arrangement, and number: cell division, cell growth, differentiation, migration, apoptosis, and the formation of cell connections.

1. *Cell division:* As discussed in Chapter 15, eukaryotic cells progress through a cell cycle that leads to cell division.
2. *Cell growth:* Following cell division, cells take up nutrients and usually expand in volume. Cell division and cell growth are the primary mechanisms for increasing the size of tissues, organs, and organisms.
3. *Differentiation:* Due to gene regulation, cells differentiate into specialized types of cells. Cell differentiation is described in Chapter 19.
4. *Migration:* During embryonic development in animals, cells migrate to their appropriate positions within the body. Also, adults have cells that can move into regions that have become damaged. Cell migration does not occur during plant development.
5. *Apoptosis:* Programmed cell death, also known as apoptosis (discussed in Chapter 9), is necessary to produce certain morphological features of the body. For example, during development in mammals, the formation of individual fingers and toes requires the removal, by apoptosis, of the skin cells between them.
6. *Cell connections:* In the first section of this chapter, we learned that cells produce an extracellular matrix or cell wall that provides strength and support. In animals, the ECM serves to organize cells within tissues and organs. In plants, the connections and structures of cell walls are largely responsible for the shapes of plant tissues. Different types of cell junctions in both animal and plant cells enable cells to make physical contact and communicate with one another.

Animals Are Composed of Epithelial, Connective, Nervous, and Muscle Tissues

The body of an animal contains four general types of tissue—epithelial, connective, nervous, and muscle—that serve very different purposes (**Figure 10.15**).

Epithelial Tissue **Epithelial tissue** is composed of cells that are joined together via tight junctions and form continuous sheets. (Epithelial cells are shown in Figure 10.9.) Epithelial tissue covers or forms the lining of all internal and external body surfaces. For example, epithelial tissue lines organs such as the lungs and digestive tract. In addition, epithelial tissue forms the outer layer of the skin, a protective surface that shields the body from the outside environment.

Connective Tissue Most **connective tissue** provides support to the body and/or helps to connect different tissues to each other. Connective tissue is rich in ECM. Examples of connective tissue include cartilage, tendons, bone, fat tissue, and the inner layers of the skin. Blood is also considered a form of connective tissue because it provides liquid connections to various regions of the body.

Figure 10.16 shows a micrograph of cartilage, a connective tissue found in joints such as your knees. The cells that synthesize cartilage, known as chondrocytes, actually represent a small proportion of the total volume of cartilage. As shown in Figure 10.16, the chondrocytes are found in small cavities within the cartilage called lacunae (singular, lacuna). In some types of cartilage, the chondrocytes represent only 1–2% of the total volume of the tissue! Chondrocytes are the only cells found in cartilage. They are solely responsible for the synthesis of protein fibers, such as collagen, as well as the glycosaminoglycans and proteoglycans that are found in cartilage.

Nervous Tissue **Nervous tissue** receives, generates, and conducts electrical signals throughout the body. In vertebrates, these electrical signals are integrated by nervous tissue in the brain and transmitted down the spinal cord to the rest of the body. Chapter 41 considers the cellular basis of nerve signals, and Chapters 42 and 43 examine the organization of nervous systems in animals.

Muscle Tissue **Muscle tissue** generates a force that facilitates movement. Muscle contraction is needed for bodily movements, such as walking and running, and also plays a role in the movement of materials throughout the body. For example, contraction of heart muscle propels blood through your body, and smooth muscle contractions move food through the digestive system. The properties of muscle tissue in animals are examined in Chapter 44.

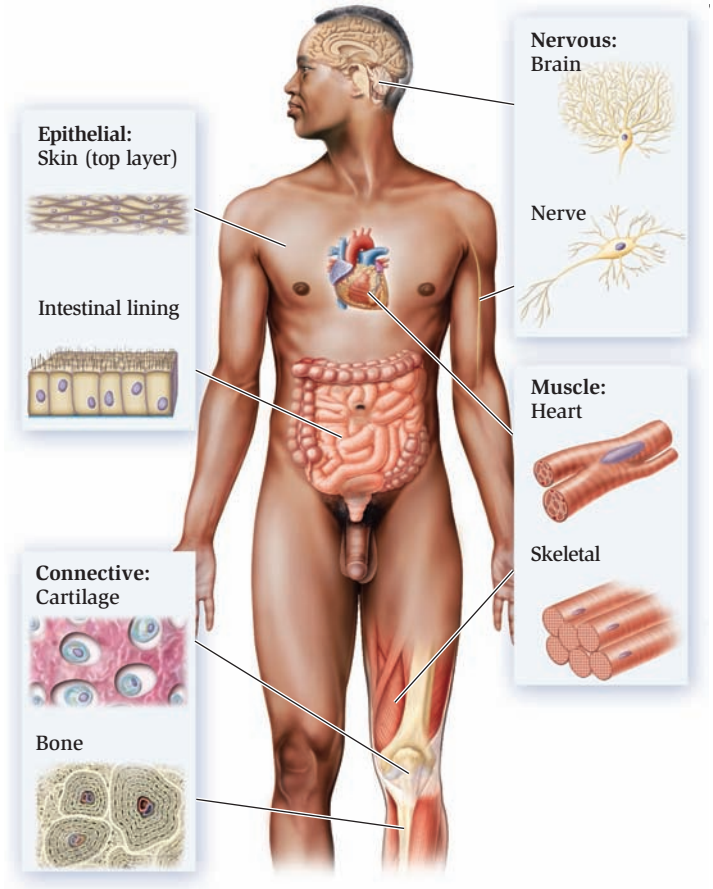

Figure 10.15 **Examples of the four general types of tissues—epithelial, connective, nervous, and muscle—found in animals.**

Concept Check: *Which of these four types of tissues has the most extensive ECM?*

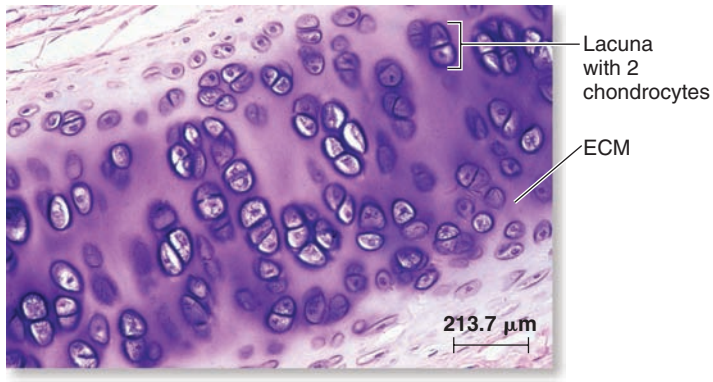

Figure 10.16 **An example of connective tissue in animals that is rich in extracellular matrix.** This micrograph of cartilage shows chondrocytes in the ECM. The chondrocytes, which are responsible for making the components of cartilage, are found in cavities called lacunae.

Plants Contain Dermal, Ground, and Vascular Tissues

Plant biologists classify tissues as simple or complex. Simple tissues are composed of one or possibly two cell types. Complex tissues are composed of two or more cell types but lack an organization that would qualify them as organs. The bodies of most plants contain three general types of simple or complex tissues—dermal, ground, and vascular—each with a different structure suited to its functions (**Figure 10.17**).

Dermal Tissue **Dermal tissue** is a complex tissue that forms a covering on various parts of the plant. The term **epidermis** refers to the newly made dermal tissue on the surfaces of leaves, stems, and roots. Plant epidermal cells have a thick primary cell wall and are tightly interlocked by their middle lamellae. As a consequence, these cells are held closely together, much like epithelial cell layers in animals.

The epidermal cells of leaves usually secrete a waxy cuticle to prevent water loss. In addition, leaf epidermis often has hairs, or trichomes, which are specialized types of epidermal cells. Trichomes

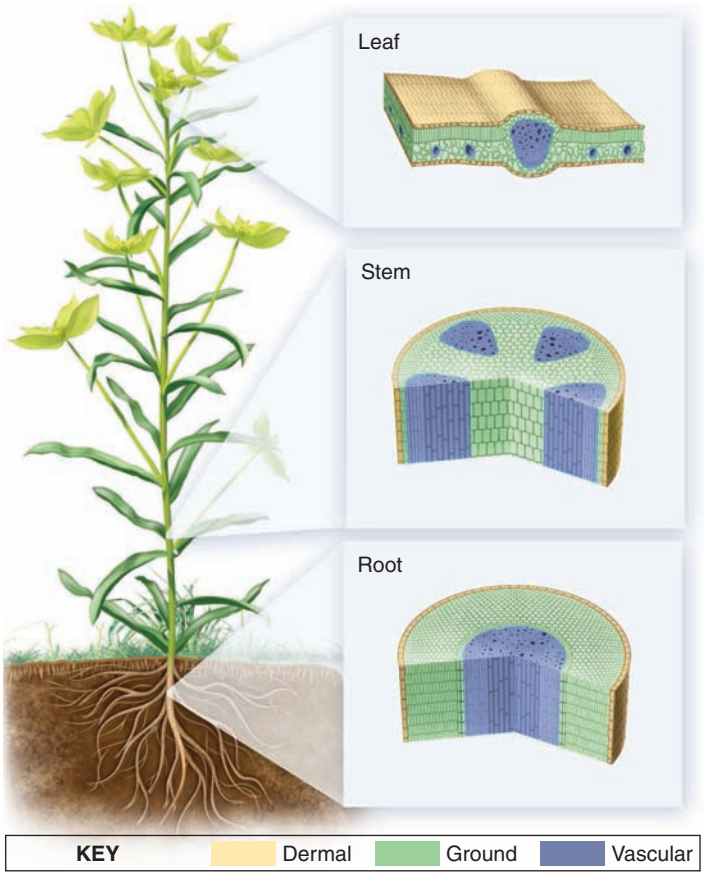

Figure 10.17 Locations of the three general types of tissues—dermal, ground, and vascular—found in plants.

Concept Check: Which of these three types of tissues is found on the surfaces of leaves, stems, and roots?

have diverse functions, including the secretion of oils and leaf protection. In leaves, epidermal cells called guard cells form pores known as stomata, which permit gas exchange. The function of the root epidermis is the absorption of water and nutrients. The root epidermis does not have a waxy cuticle because such a cuticle would inhibit water and nutrient absorption.

Ground Tissue Most of a plant's body is made of **ground tissue**, which has a variety of functions, including photosynthesis, storage of carbohydrates, and support. Ground tissue is subdivided into three types of simple tissues: parenchyma, collenchyma, and sclerenchyma. Let's look briefly at each of these types of ground tissue (also see Figure 35.7).

1. Parenchyma is very active metabolically. The mesophyll, the central part of the leaf that carries out the bulk of photosynthesis, is composed of parenchyma. Parenchyma also functions in the storage of carbohydrates. The cells of parenchyma usually lack a secondary cell wall.
2. Collenchyma provides structural support to the plant body, particularly to growing regions such as the periphery of the stems and leaves. Collenchyma cells tend to have thick, secondary cell walls but do not contain much lignin. Therefore, they provide support but are also able to stretch.
3. Sclerenchyma also provides structural support to the plant body, particularly to those parts that are no longer growing, such as the dense, woody parts of stems. The secondary cell walls of sclerenchyma cells tend to have large amounts of lignin, which provides rigid support. In many cases, sclerenchyma cells are dead at maturity, but their cell walls continue to provide structural support during the life of the plant.

Vascular Tissue Some types of modern plants, such as mosses, are nonvascular plants that lack conducting vessels. These plants tend to be small and live in damp, shady places. Most plants living today, however, are vascular plants. In these species, which include ferns and seed plants, the **vascular tissue** is a complex tissue composed of cells that are interconnected and form conducting vessels for water and nutrients. As described in greater detail in Chapter 38, the two types of vascular tissue are called xylem and phloem. The xylem transports water and mineral ions from the root to the rest of the plant, and the phloem distributes the products of photosynthesis and a variety of other nutrients throughout the plant.

Summary of Key Concepts

10.1 Extracellular Matrix and Cell Walls

- The extracellular matrix (ECM) is a network of material that forms a complex meshwork outside of animal cells; the cell wall is a similar component of plant cells.
- Proteins and polysaccharides are the major constituents of the ECM in animals. These materials are involved in strength, structural support, organization, and cell signaling (Figure 10.1).
- Adhesive proteins, such as fibronectin and laminin, help adhere cells to the ECM. Structural proteins include collagen fibers, which provide tensile strength, and elastic fibers, which allow regions of the body to stretch (Table 10.1, Figures 10.2, 10.3).
- Animals make many different types of collagen fibers, and gene regulation controls the place in the body where they are made (Table 10.2).
- Glycosaminoglycans (GAGs) are polysaccharides of repeating disaccharide units that give a gel-like character to the ECM of animals. Proteoglycans consist of a long, linear core protein with attached GAGs (Figure 10.4).
- Plant cells are surrounded by a cell wall composed largely of cellulose. The primary cell wall is made first and tends to be thin and flexible. The secondary cell wall is made after the primary cell wall and is often thick and rigid (Figures 10.5, 10.6).

10.2 Cell Junctions

- The three common types of cell junctions found in animals are anchoring, tight, and gap junctions (Table 10.3).
- Key components of anchoring junctions are cell adhesion molecules (CAMs), which bind cells to each other or to the ECM. The four types of anchoring junctions are adherens junctions, desmosomes, hemidesmosomes, and focal adhesions (Figure 10.7).
- Cadherins and integrins are two types of CAMs. Cadherins link cells to each other, whereas integrins link cells to the ECM. In the cytosol, CAMs bind to actin or intermediate filaments (Figure 10.8).
- Tight junctions between cells, composed of occludin and claudin, prevent the leakage of materials across a layer of cells (Figures 10.9, 10.10).

- Gap junctions consist of many channels called connexons, which permit the direct passage of ions and small molecules between adjacent cells (Figure 10.11).
- Experiments of Loewenstein and colleagues showed that gap junctions permit the passage of substances with a molecular mass of less than about 1,000 Da (Figure 10.12).
- The cell walls of adjacent plant cells are cemented together via middle lamellae, which are rich in pectins—negatively charged polysaccharides (Figure 10.13).
- The plasma membranes and endoplasmic reticula of adjacent plant cells are connected via plasmodesmata that allow the passage of ions and molecules between the cytosol of adjacent cells (Figure 10.14).

10.3 Tissues

- Cells are organized into tissues, and tissues are organized into organs. A tissue is a group of cells that have a similar structure and function, and an organ is composed of two or more tissues that carry out a particular function or set of functions.
- Six processes—cell division, cell growth, differentiation, migration, apoptosis, and the formation of cell connections—produce tissues and organs.
- The four general kinds of tissues found in animals are epithelial, connective, nervous, and muscle tissues (Figures 10.15, 10.16).
- The three general kinds of tissues found in plants are dermal, ground, and vascular tissues (Figure 10.17).

Assess and Discuss

Test Yourself

1. The function of the extracellular matrix (ECM) in animals is
   a. to provide strength.
   b. to provide structural support.
   c. to organize cells and other body parts.
   d. cell signaling.
   e. all of the above.
2. The protein found in the ECM of animals that provides strength and resistance to tearing when stretched is
   a. elastin.
   b. cellulose.
   c. collagen.
   d. laminin.
   e. fibronectin.
3. The polysaccharide that forms the hard outer covering of many invertebrates is
   a. collagen.
   b. chitin.
   c. chondroitin sulfate.
   d. pectin.
   e. cellulose.
4. The extension sequence found in procollagen polypeptides
   a. causes procollagen to be synthesized into the ER lumen.
   b. causes procollagen to form a triple helix.
   c. prevents procollagen from forming large collagen fibers.
   d. causes procollagen to be secreted from the cell.
   e. Both b and c are correct.
5. The dilated state of plasmodesmata allows the passage of
   a. water.
   b. ions.
   c. small molecules.
   d. macromolecules and viruses.
   e. all of the above.
6. The gap junctions of animal cells differ from the plasmodesmata of plant cells in that
   a. gap junctions serve as communicating junctions and plasmodesmata serve as anchoring junctions.
   b. gap junctions prevent extracellular material from moving between adjacent cells but plasmodesmata do not.
   c. gap junctions allow for direct exchange of cellular material between cells but plasmodesmata cannot allow the same type of exchange.
   d. gap junctions are formed by specialized proteins that form channels through the membranes of adjacent cells but plasmodesmata are formed by connecting the plasma membranes of adjacent cells.
   e. All of the above are correct.
7. Which of the following is (are) involved in the process of tissue and organ formation in multicellular organisms?
   a. cell division
   b. cell growth
   c. cell differentiation
   d. cell connections
   e. all of the above
8. The tissue type common to animals that functions in the conduction of electrical signals is
   a. epithelial.
   b. dermal.
   c. muscle.
   d. nervous.
   e. ground.
9. A type of tissue that is rich in ECM or has cells with a thick cell wall is
   a. dermal tissue in plants.
   b. ground tissue in plants.
   c. nervous tissue in animals.
   d. connective tissue in animals.
   e. both b and d.
10. Which of the following is *not* a correct statement when comparing plant tissues and animal tissues?
    a. Nervous tissue of animals plays the same role as vascular tissue in plants.
    b. The dermal tissue of plants is similar to epithelial tissue of animals in that both provide a covering for the organism.
    c. The epithelial tissue of animals and the dermal tissue of plants have special characteristics that limit the movement of material between cell layers.
    d. The ground tissue of plants and the connective tissue of animals provide structural support for the organism.
    e. The ground tissue of plants and the connective tissue of animals have large amounts of extracellular material (that is, thick cell walls in plants and lots of ECM in animals).

Conceptual Questions

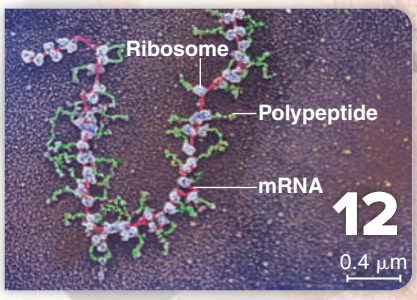
1. What are key differences between the primary cell wall and the secondary cell wall of plant cells?
2. What are similarities and differences in the structures and functions of cadherins and integrins found in animal cells?
3.  A principle of biology is that *organisms grow and develop*. Discuss how cell junctions play a key role in this process.

Collaborative Questions

1. Discuss the similarities and differences between the ECM of animals and the cell walls of plants.
2. Cell junctions in animals are important in preventing cancer cells from metastasizing—moving to other parts of the body. Certain drugs bind to CAMs and influence their structure and function. Some of these drugs may help to prevent the spread of cancer cells. What would you hypothesize to be the mechanism by which such drugs work? What might be some harmful side effects?

UNIT III

GENETICS



Genetics is the branch of biology that deals with **inheritance**—the transmission of characteristics from parents to offspring. We begin this unit by examining the structure of the genetic material, namely DNA, at the molecular and cellular levels. We will explore the structure and replication of DNA and learn how it is packaged into chromosomes (Chapter 11). We will then consider how segments of DNA are organized into units called genes and explore how genes are used to make products such as RNA and proteins (Chapters 12 and 13). The expression of genes is largely responsible for the characteristics of living organisms. We will also examine how mutations alter the properties of genes and even lead to diseases such as cancer (Chapter 14).

In Chapter 15, we turn our attention to the mechanisms of how genes are transmitted from parent to offspring. This topic begins with a discussion of how chromosomes are sorted and transmitted during cell division. Chapters 16 and 17 explore the relationships between the transmission of genes and the outcome of an offspring's traits. We will look at genetic patterns called Mendelian inheritance and more complex patterns that could not have been predicted from Mendel's work.

The remaining chapters explore additional topics that are of interest to biologists. In Chapter 18, we will examine some of the unique genetic properties of bacteria and viruses. Chapter 19 considers how genes play a central role in the development of animals and plants from a fertilized egg to an adult. We end this unit by exploring genetic technologies that are used by researchers, clinicians, and biotechnologists to unlock the mysteries of genes and provide tools and applications that benefit humans (Chapters 20 and 21).

The following biology principles will be emphasized in this unit:

- ***The genetic material provides a blueprint for reproduction:*** *Throughout this unit, we will see how the genetic material carries the information to sustain life.*
- ***Structure determines function:*** *In Chapters 11 through 15, we will examine how the structures of DNA, RNA, genes, and chromosomes underlie their functions.*
- ***Living organisms interact with their environment:*** *In Chapters 16 and 17, we will explore the interactions between an organism's genes and its environment.*
- ***Living organisms grow and develop:*** *In Chapter 19, we will consider how a genetic program is involved in the developmental stages of animals and plants.*
- ***Biology affects our society:*** *In Chapters 20 and 21, we will examine genetic technologies that have many applications in our society.*
- ***Biology is an experimental science:*** *Every chapter in this unit has a Feature Investigation that describes a pivotal experiment that provided insights into our understanding of genetics.*

CHAPTER OUTLINE

11.1 Biochemical Identification of the Genetic Material

11.2 Nucleic Acid Structure

11.3 Overview of DNA Replication

11.4 Molecular Mechanism of DNA Replication

11.5 Molecular Structure of Eukaryotic Chromosomes

Summary of Key Concepts

Assess and Discuss

Nucleic Acid Structure, DNA Replication, and Chromosome Structure

11

A molecular model for the structure of a DNA double helix.

On October 17, 2001, Mario K. was set free after serving 16 years in prison. He had been convicted of a sexual assault and murder that occurred in 1985. The charges were dropped because investigators discovered that another person, Edwin M., had actually committed the crime. How was Edwin M. identified as the real murderer? In 2001, he committed another crime, and his DNA was entered into a computer database. Edwin's DNA matched the DNA that had been collected from the victim in 1985, and other evidence was then gathered indicating that Edwin M. was the true murderer. Like Mario K., over 200 inmates have been exonerated when DNA tests have shown that a different person was responsible for the crime.

Deoxyribonucleic acid, or **DNA**, is the genetic material that provides the blueprint to produce an individual's traits. Each person's DNA is distinct and unique. Even identical twins show minor differences in their DNA sequences. We begin our survey of genetics by examining DNA at the molecular level. Once we understand how DNA works at this level, it becomes easier to see how the function of DNA controls the properties of cells and ultimately the characteristics of unicellular and multicellular organisms. The past several decades have seen exciting advances in techniques and approaches for investigating and even altering the genetic material. These advances have greatly expanded our understanding of molecular genetics, and the techniques are widely used in related disciplines, including biochemistry, cell biology, and microbiology. Likewise, genetic techniques have many important applications in biotechnology and are used in criminal justice, such as forensics, to provide evidence of guilt or innocence.

To a large extent, our understanding of genetics comes from our knowledge of the molecular structure of DNA. In this chapter, we begin by considering some classic experiments that provided evidence that DNA is the genetic material. We will then survey the molecular features of DNA, which will allow us to appreciate how DNA can store information and be accurately copied. We will also consider the components of ribonucleic acid (RNA), which show striking similarities to DNA. Lastly, we will examine the molecular composition of chromosomes where the DNA is found.

11.1 Biochemical Identification of the Genetic Material

Learning Outcomes:

1. List the four key criteria that the genetic material must fulfill.
2. **SciSKILLS** » Analyze the results of experiments that identified DNA as the genetic material.

DNA carries the genetic instructions for the characteristics of living organisms. In the case of multicellular organisms such as plants and animals, the information stored in the genetic material enables a fertilized egg to develop into an embryo and eventually into an adult organism. In addition, the genetic material allows organisms to survive in their native environments. For example, an individual's DNA provides the blueprint to produce enzymes that are needed to metabolize nutrients in food. To fulfill its role, the genetic material must meet the following key criteria:

1. **Information:** The genetic material must contain the information necessary to construct an entire organism.
2. **Replication:** The genetic material must be accurately copied.
3. **Transmission:** After it is replicated, the genetic material can be passed from parent to offspring. It also must be passed from cell to cell during the process of cell division.
4. **Variation:** Differences in the genetic material must account for the known variation within each species and among different species.

How was the genetic material discovered? The quest to identify the genetic material began in the late 19th century, when a few scientists postulated that living organisms possess a blueprint that has a biochemical basis. In 1883, German biologist August Weismann and his Swiss colleague Karl Nägeli championed the idea that a chemical substance exists within living cells that is responsible for the transmission of traits from parents to offspring. During the next 30 years, experimentation along these lines centered on the behavior of **chromosomes**, the cellular structures that we now know contain the genetic material. Taken literally, chromosome is from the Greek words *chromo* and *soma*, meaning colored body, which refers to the observation of early microscopists that chromosomes are easily stained by colored dyes. By studying the transmission patterns of chromosomes from cell to cell and from parent to offspring, researchers were convinced that chromosomes carry the determinants that control the outcome of traits.

Ironically, the study of chromosomes initially misled researchers regarding the biochemical identity of the genetic material. Chromosomes contain two classes of macromolecules: proteins and DNA. Scientists of this era viewed proteins as being more biochemically complex because they are made from 20 different amino acids. Furthermore, biochemists already knew that proteins perform an amazingly wide range of functions, and complexity seemed an important prerequisite for the blueprint of an organism. By comparison, DNA seemed less complex, because it contains only four types of repeating units, called nucleotides, which will be described later in this chapter. In addition, the functional role of DNA in the nucleus had not been extensively investigated prior to the 1920s. Therefore, from the 1920s to the 1940s, most scientists were expecting research studies to reveal that proteins are the genetic material. Contrary to this expectation, however, the experiments described in this section were pivotal in showing that DNA carries out this critical role.

Griffith's Bacterial Transformation Experiments Indicated the Existence of a Genetic Material

Studies in microbiology were important in developing an experimental strategy for identifying the genetic material. In the late 1920s, an English microbiologist, Frederick Griffith, studied a type of bacterium known then as pneumococci and now classified as *Streptococcus pneumoniae*. Some strains of *S. pneumoniae* secrete a polysaccharide capsule, but other strains do not. When streaked on petri plates containing solid growth media, capsule-secreting strains have a smooth colony morphology. Those strains unable to secrete a capsule have a colony morphology that looks rough. In mammals, smooth strains of *S. pneumoniae* may cause pneumonia and other symptoms. In mice, such infections are usually fatal.

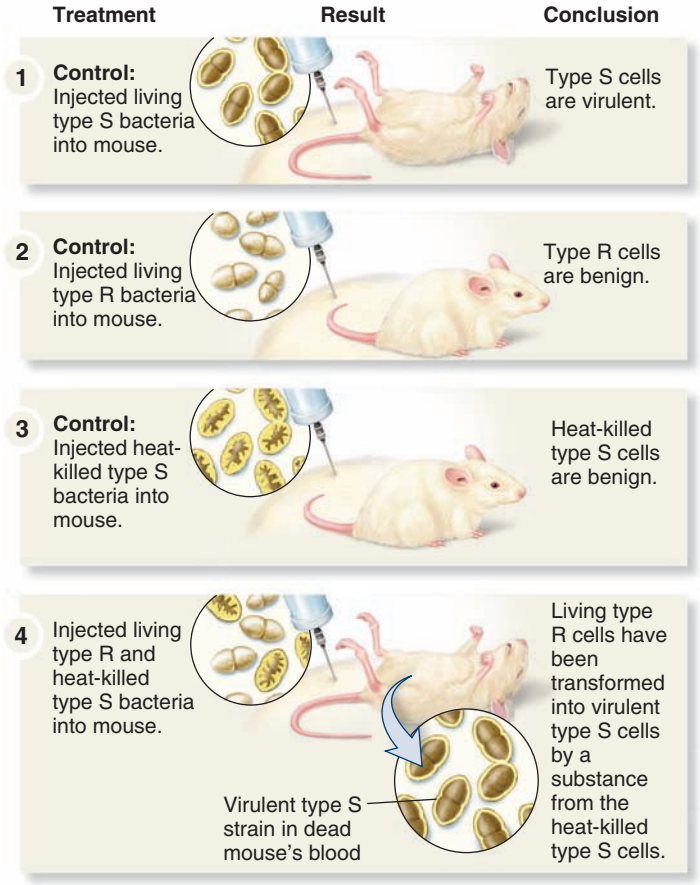


Figure 11.1 Griffith's experiments showing that genetic material can be transferred from one bacterium to another. Note: To determine if a mouse's blood contained live bacteria, a sample of blood was applied to solid growth media to determine if smooth or rough bacterial colonies would form.

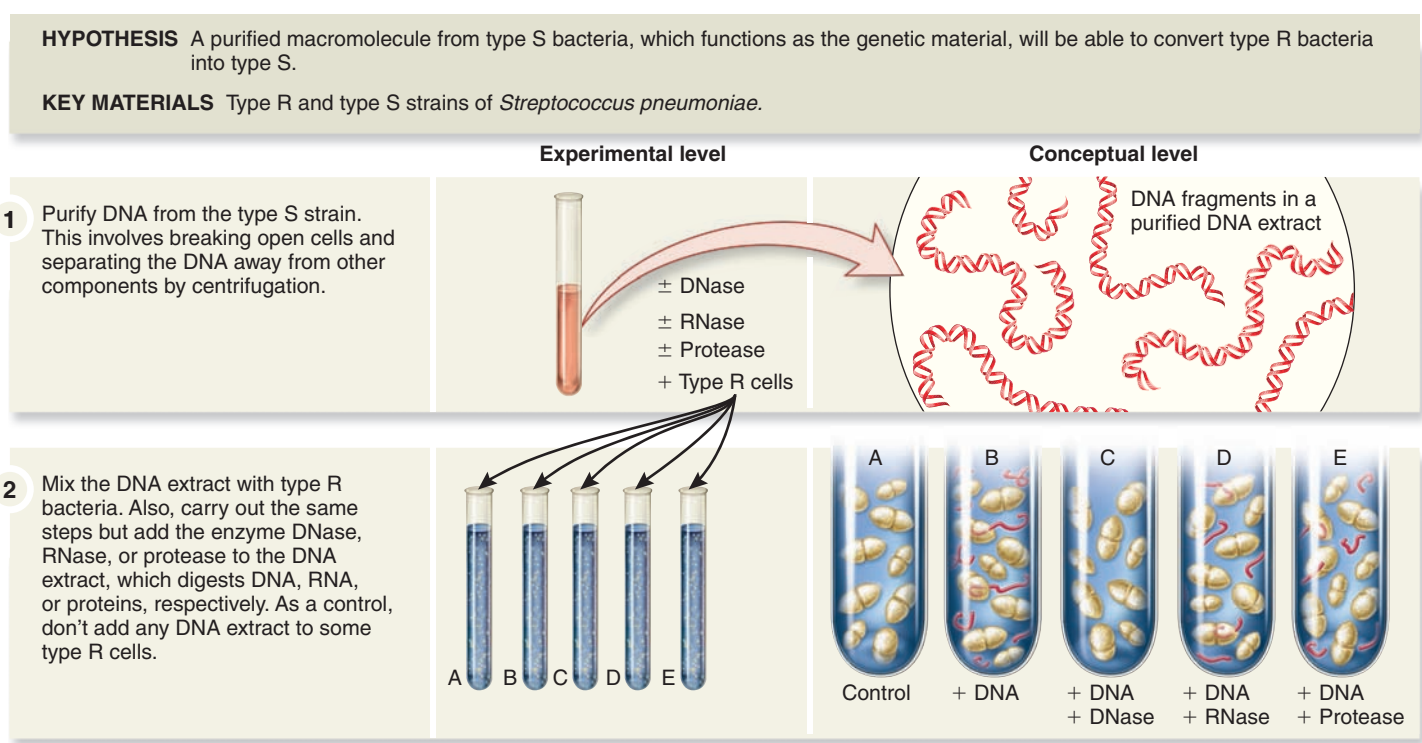
BioConnections: Look ahead to Figure 18.17. How does bacterial transformation play a role in the transfer of genes, such as antibiotic resistance genes, from one bacterial species to another?

As shown in **Figure 11.1**, Griffith injected live and/or heat-killed bacteria into mice and then observed whether or not the bacteria caused them to die. He investigated the effects of two strains of *S. pneumoniae*: type S for smooth and type R for rough.

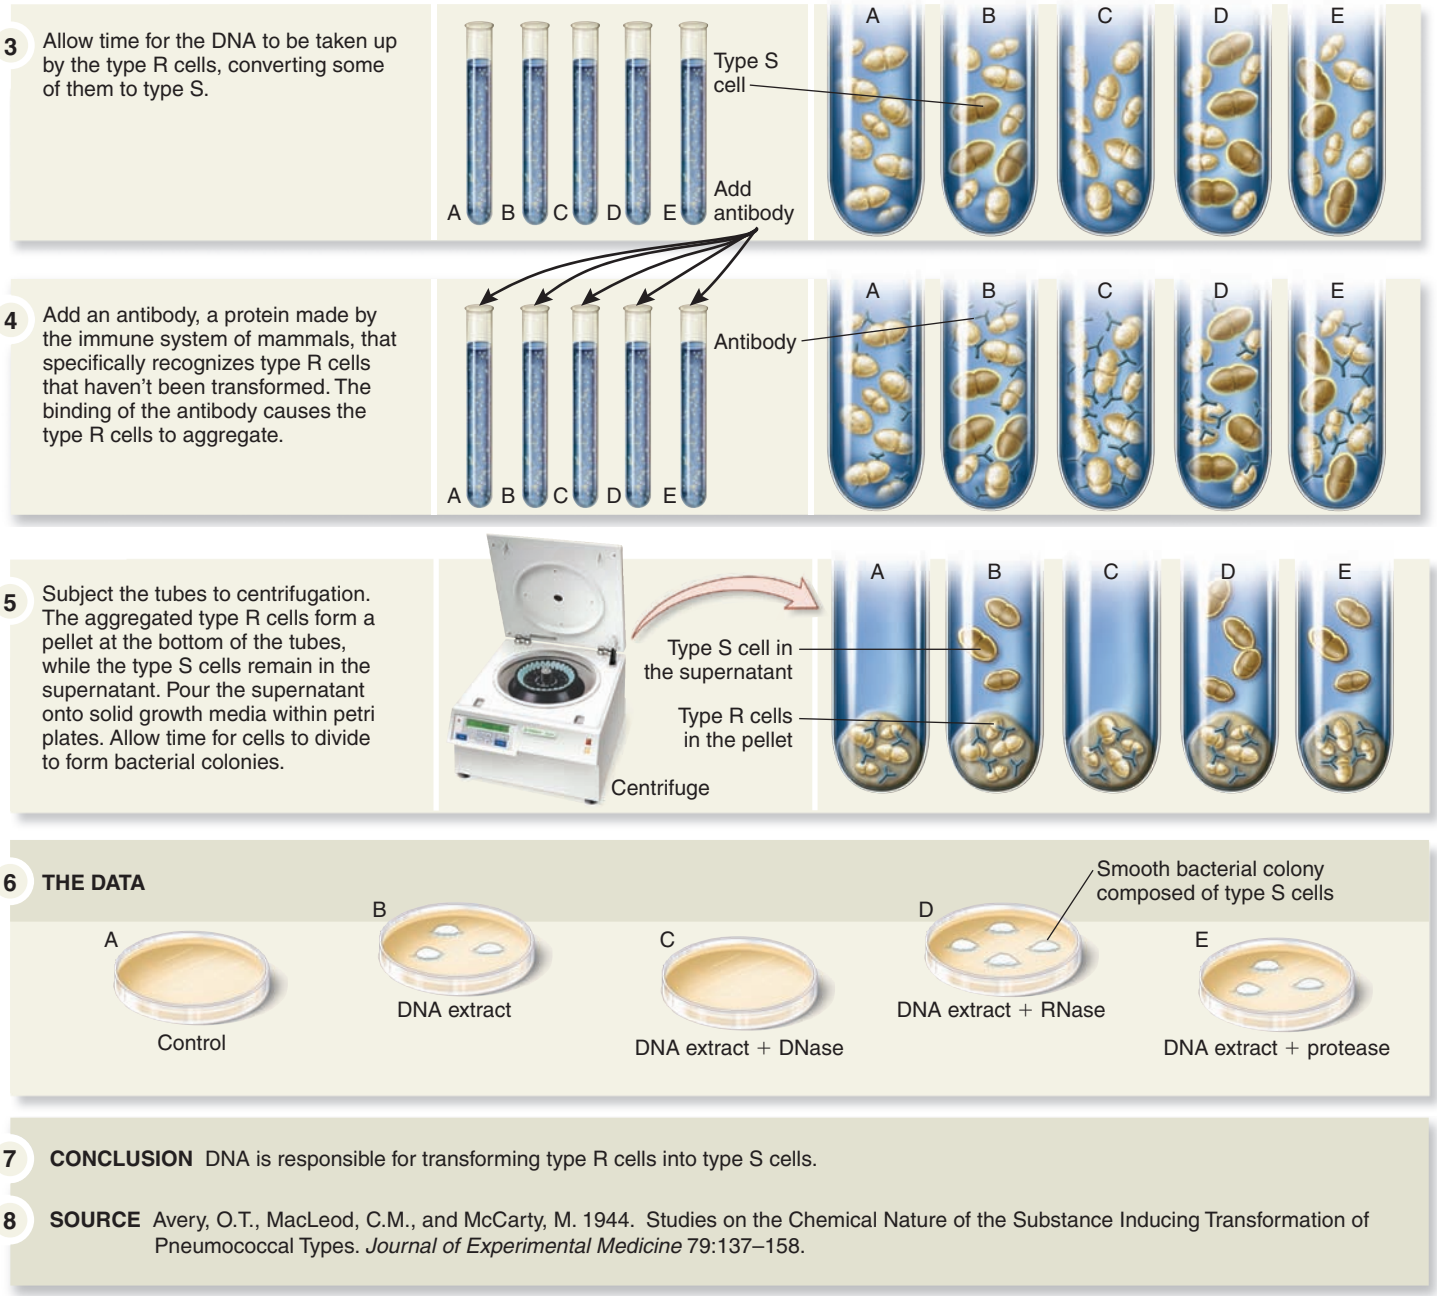
1. When injected into a live mouse, the type S strain killed the mouse (Figure 11.1, step 1). The capsule made by type S strains prevents the mouse's immune system from killing the bacterial cells. Following the death of the mouse, many type S bacteria were found in the mouse's blood.
2. When type R bacteria were injected into a mouse, the mouse survived, and after several days, living bacteria were not found in the live mouse's blood (Figure 11.1, step 2).
3. Griffith also heat-killed the smooth bacteria and then injected them into a mouse. As expected, the mouse survived (Figure 11.1, step 3).
4. A surprising result occurred when Griffith mixed live type R bacteria with heat-killed type S bacteria and then injected them into a mouse—the mouse died (Figure 11.1, step 4). The blood from the dead mouse contained living type S bacteria! How did

Griffith explain these results? He postulated that a substance from dead type S bacteria transformed the type R bacteria into type S bacteria. Griffith called this process **transformation**, and he termed the unidentified material responsible for this phenomenon the "transformation principle."

Let's consider what these observations mean with regard to the four criteria of the genetic material: information, replication, transmission, and variation. According to Griffith's results, the transformed bacteria had acquired the information (criterion 1) to make a capsule from the heat-killed cells. For the transformed bacteria to proliferate and thereby kill the mouse, the substance conferring the ability to make a capsule must be replicated (criterion 2) and then transmitted (criterion 3) from mother to daughter cells during cell division. Finally, Griffith already knew that variation (criterion 4) existed in the ability of his strains to produce a capsule (S strain) or not produce a capsule (R strain). Taken together, these observations are consistent with the idea that the formation of a capsule is governed by genetic material. The experiment of Figure 11.1, step 4, was consistent with the idea that some genetic material from the heat-killed type S bacteria had been transferred to the living type R bacteria and provided those bacteria with a new trait. At the time of his studies, however, Griffith could not determine the biochemical composition of the transforming substance.



Feature Investigation | Avery, MacLeod, and McCarty Used Purification Methods to Reveal That DNA Is the Genetic Material



Exciting discoveries sometimes occur when researchers recognize that another scientist's experimental approach may be modified and then used to dig deeper into a scientific question. In the 1940s, American physician Oswald Avery and American biologists Colin MacLeod and Maclyn McCarty were also interested in the process of bacterial transformation. During the course of their studies, they realized that Griffith's observations could be used as part of an experimental strategy to biochemically identify the genetic material. They asked the question, "What substance is being transferred from the dead type S bacteria to the live type R bacteria?"

To answer this question, Avery, MacLeod, and McCarty needed to purify the general categories of substances found in living cells. They used established biochemical procedures to purify classes of macromolecules, such as proteins, DNA, and RNA, from the type S streptococcal strain. Initially, they discovered that only the purified DNA could convert type R bacteria into type S. To further verify that DNA is the genetic material, they performed the investigation outlined in **Figure 11.2**. They purified DNA from the type S bacteria and mixed it with type R bacteria. After allowing time for DNA uptake into the type R bacteria, they added an antibody that aggregated any nontransformed type R bacteria, which were then removed by centrifugation. The remaining bacteria were incubated overnight on petri plates.

As a control, if no DNA extract was added, no type S bacterial colonies were observed on the petri plates (see plate A in step 6).

Figure 11.2 The Avery, MacLeod, and McCarty experiments that identified DNA as Griffith's transformation principle—the genetic material.

When the researchers mixed their S strain DNA extract with type R bacteria, some of the bacteria were converted to type S bacteria (see plate B in step 6 of Figure 11.2). This result was consistent with the idea that DNA is the genetic material.

Even so, a careful biochemist could argue that the DNA extract might not have been 100% pure. For this reason, the researchers realized that a small amount of contaminating material in the DNA extract could actually be the genetic material. The most likely contaminating substances in this case would be RNA or protein.

To address this possibility, Avery, MacLeod, and McCarty treated the DNA extract with an enzyme that digests either DNA (called **DNase**), RNA **(RNase)**, or protein **(protease)** (see step 2). When the DNA extracts were treated with RNase or protease, the type R bacteria were still converted into type S bacteria, suggesting that contaminating RNA or protein in the extract was not acting as the genetic material (see step 6, plates D and E). Moreover, when the extract was treated with DNase, it lost the ability to convert type R bacteria into type S bacteria (see plate C). Taken together, these results were consistent with the idea that DNA is the genetic material.

Experimental Questions

1. **SciSKILLS »** Avery, MacLeod, and McCarty worked with two strains of *Streptococcus pneumoniae* to determine the biochemical identity of the genetic material. Explain the characteristics of the *S. pneumoniae* strains that made them particularly well suited for such an experiment.
2. What is a DNA extract?
3. **SciSKILLS »** In the experiment of Avery, MacLeod, and McCarty, what was the purpose of using the protease, RNase, and DNase if only the DNA extract caused transformation?

11.2 Nucleic Acid Structure

Learning Outcomes:

1. Outline the structural features of DNA at five levels of complexity.
2. Describe the structure of nucleotides, a DNA strand, and the DNA double helix.
3. **SciSKILLS** » Discuss and interpret the work of Franklin; Chargaff; and Watson and Crick.

A unifying principle in biology is that structure determines function. When biologists want to understand the function of a material at the molecular and cellular level, they focus some of their efforts on determining its biochemical structure. In this regard, an understanding of DNA's structure has proven to be particularly exciting because the structure makes it easier for us to understand how DNA can store information, how it is replicated and then transmitted from cell to cell, and how variation in its structure can occur.

DNA and its molecular cousin, RNA, are known as **nucleic acids**, polymers consisting of nucleotides, which are responsible for the storage, expression, and transmission of genetic information. This term is derived from the discovery of DNA by Swiss physician Friedrich Miescher in 1869. He identified a novel phosphorus-containing substance from the nuclei of white blood cells found in waste surgical bandages. He named this substance nuclein. As the structure of DNA and RNA became better understood, they were found to be acidic molecules, which means they release hydrogen ions (H^+) in solution and have a net negative charge at neutral pH. Thus, the name nucleic acid was coined.

DNA is a very large macromolecule composed of smaller building blocks. We can consider the structural features of DNA at different levels of complexity (**Figure 11.3**):

1. **Nucleotides** are the building blocks of DNA.
2. A **strand** of DNA is formed by the covalent linkage of nucleotides in a linear manner.
3. Two strands of DNA hydrogen-bond with each other to form a **double helix**. In a DNA double helix, two DNA strands are twisted together to form a structure that resembles a spiral staircase.
4. In living cells, DNA is associated with an array of different proteins to form chromosomes. The association of proteins with DNA organizes the long double helix into a compact structure.
5. A **genome** is the complete complement of an organism's genetic material. For example, the genome of most bacteria is a single circular chromosome, whereas eukaryotic cells have DNA in their nucleus, mitochondria, and chloroplasts.

The first three levels of complexity will be the focus of this section. Level 4 will be discussed in Section 11.5, and level 5 is examined in Chapter 21.

Nucleotides Contain a Phosphate, a Sugar, and a Base

A nucleotide has three components: a phosphate group, a pentose (five-carbon) sugar, and a nitrogenous base. The nucleotides in DNA and RNA contain different sugars. Deoxyribose is found in DNA, and ribose is found in RNA. The base and phosphate group are attached to the sugar molecule at different sites (**Figure 11.4**).

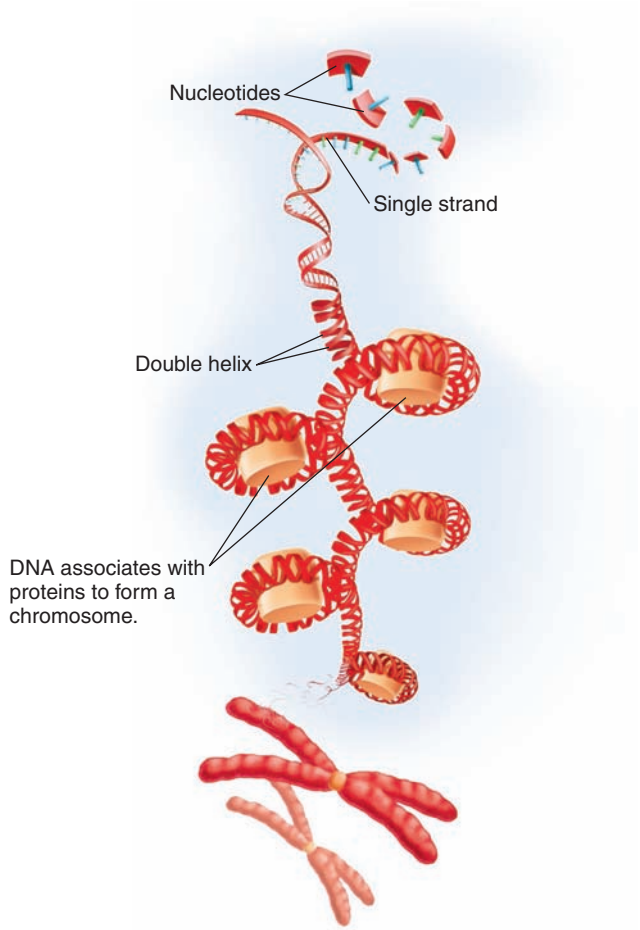


Figure 11.3 **Levels of DNA structure to create a chromosome.**

Five different bases are found in nucleotides, although any given nucleotide contains only one base. The five bases are subdivided into two categories, the **purines** and the **pyrimidines**, due to differences in their structures (see Figure 11.4). The purine bases, **adenine (A)** and **guanine (G)**, have a double-ring structure, whereas the pyrimidine bases, **thymine (T)**, **cytosine (C)**, and **uracil (U)**, have a single-ring structure. Adenine, guanine, and cytosine are found in both DNA and RNA. Thymine is found only in DNA, whereas uracil is found only in RNA.

A conventional numbering system describes the locations of carbon and nitrogen atoms in the sugars and bases (**Figure 11.5**). The prime symbol (′) is used to distinguish the numbering of carbons in the sugar. The atoms in the ring structures of the bases are not given the prime designation. The sugar carbons are designated 1′ (that is, one prime), 2′, 3′, 4′, and 5′, with the carbon atoms numbered in a clockwise direction starting with the carbon atom to the right of the ring oxygen atom. The fifth carbon is outside the ring. A base is attached to the 1′ carbon atom, and a phosphate group is attached at the 5′ position. Compared with ribose (see Figure 11.4), deoxyribose lacks a single oxygen atom at the 2′ position; the prefix deoxy- (meaning without oxygen) refers to this missing atom.

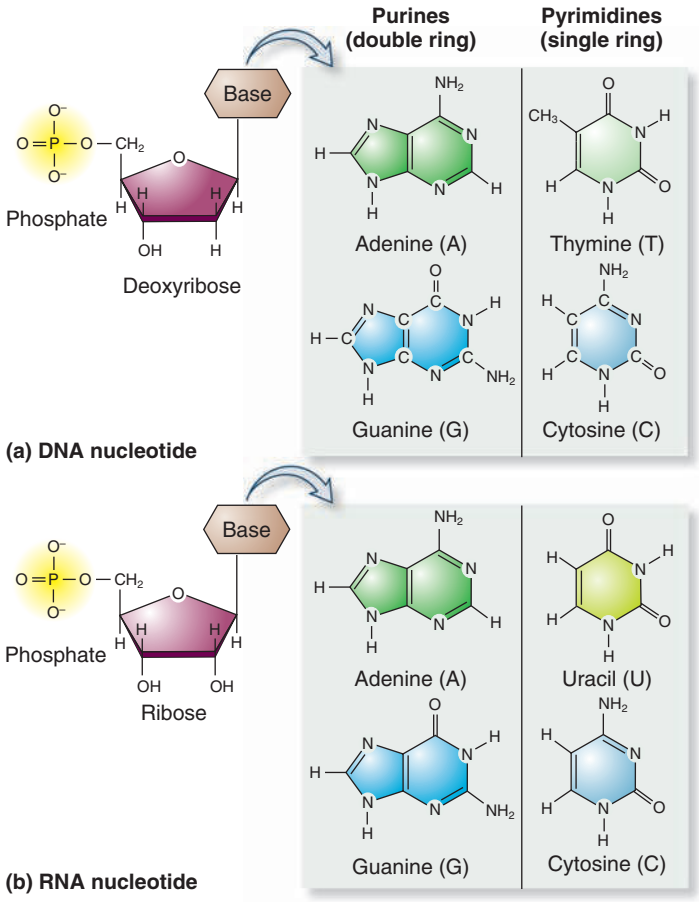

Figure 11.4 Nucleotides and their components. For simplicity, the carbon atoms in the ring structures are not shown.

Concept Check: *Which pyrimidine(s) is (are) found in both DNA and RNA?*

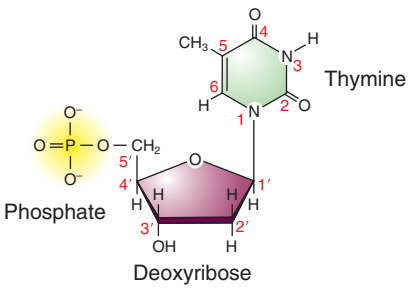

Figure 11.5 Conventional numbering in a DNA nucleotide. The carbons in the sugar are given a prime designation, whereas those in the base are not.

Concept Check: *What is the numbering designation of the carbon atom to which the phosphate is attached?*

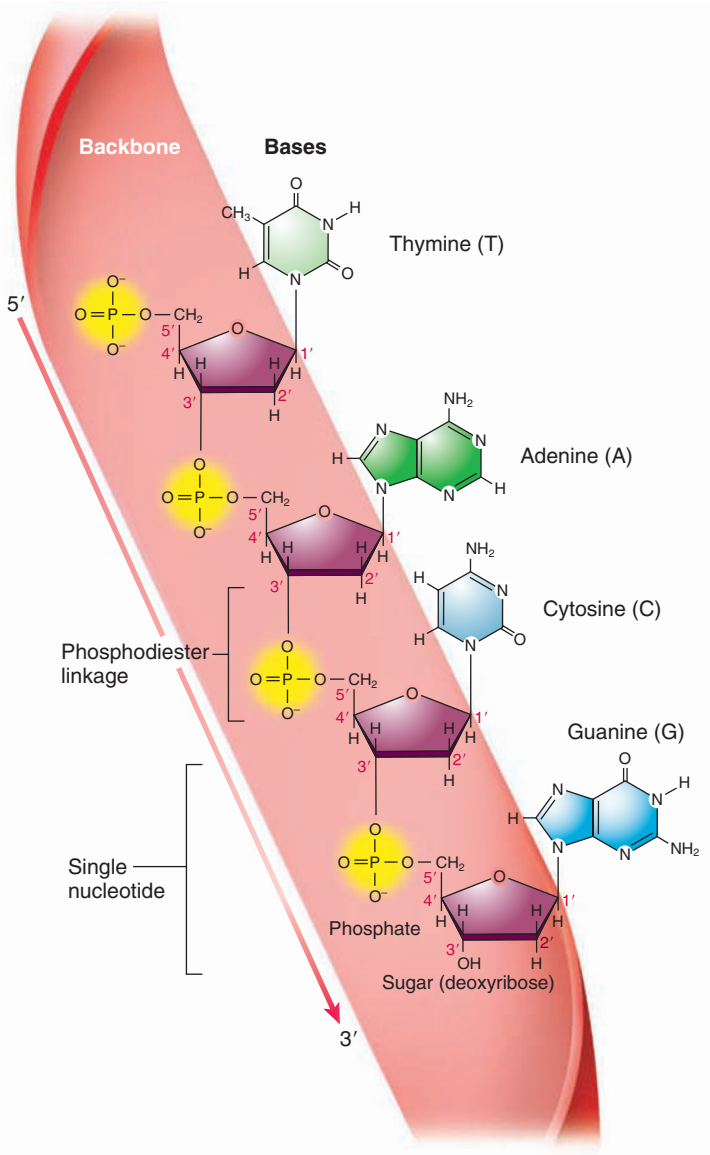

Figure 11.6 The structure of a DNA strand. Nucleotides are covalently bonded to each other in a linear manner. Notice the directionality of the strand and that it carries a particular sequence of bases. An RNA strand has a very similar structure, except the sugar is ribose rather than deoxyribose, and uracil is substituted for thymine.

BIOLOGY PRINCIPLE The genetic material provides a blueprint for reproduction. The covalent linkage of a sequence of bases allows DNA to store information.

Concept Check: *What is the difference between a phosphoester bond and a phosphodiester linkage?*

A Strand Is a Linear Linkage of Nucleotides with Directionality

The next level of nucleotide structure is the formation of a strand of DNA or RNA in which nucleotides are covalently attached to each other in a linear fashion. **Figure 11.6** depicts a short strand of DNA with four nucleotides. The linkage is a phosphoester bond (a covalent bond between phosphorus and oxygen) involving a sugar molecule in one nucleotide and a phosphate group in the next nucleotide. Another way of viewing this linkage is to notice that a phosphate group connects two sugar molecules. From this perspective, the linkage in DNA and RNA strands is called a **phosphodiester linkage**, which has two phosphoester bonds. The phosphates and sugar molecules form the **backbone** of a DNA or RNA strand, and the bases project from the backbone. The backbone is negatively charged due to the negative charges of the phosphate groups.

An important structural feature of a nucleic acid strand is the orientation of the nucleotides. Each phosphate in a phosphodiester linkage is covalently bonded to the 5′ carbon in one nucleotide and to the 3′ carbon in the other. In a strand, all sugar molecules are oriented in the same direction. For example, in the strand shown in Figure 11.6, all of the 5′ carbons in every sugar molecule are above the 3′ carbons. A strand has a **directionality** based on the orientation of the sugar molecules within that strand. In Figure 11.6, the direction of the strand is said to be 5′ to 3′ when going from top to bottom. The 5′ end of a DNA strand has a phosphate group, whereas the 3′ end has an —OH group.

From the perspective of function, a key feature of DNA and RNA structure is that a strand contains a specific sequence of bases. In Figure 11.6, the sequence of bases is thymine–adenine–cytosine–guanine, or TACG. To indicate its directionality, the strand is abbreviated 5′–TACG–3′. Because the nucleotides within a strand are attached to each other by stable covalent bonds, the sequence of bases in a DNA strand remains the same over time, except in rare cases when mutations occur. The sequence of bases in DNA and RNA is the critical feature that allows them to store and transmit information.

A Few Key Experiments Paved the Way to Solving the Structure of DNA

What experimental approaches were used to analyze DNA structure?

X-ray Diffraction Pattern Produced by Franklin X-ray diffraction was a key experimental tool that led to the discovery of the DNA double helix. When a substance is exposed to X-rays, the atoms in the substance cause the X-rays to be scattered (**Figure 11.7**). If the substance has a repeating structure, the pattern of scattering, known as the diffraction pattern, is related to the structural arrangement of the atoms causing the scattering. The diffraction pattern is analyzed using mathematical theory to provide information regarding the three-dimensional structure of the molecule. British biophysicist Rosalind Franklin, working in the 1950s in the same laboratory as Maurice Wilkins, was a gifted experimentalist who made marked advances in X-ray diffraction techniques involving DNA. The diffraction pattern of DNA fibers produced by Franklin suggested a helical structure with a diameter that is relatively uniform and too wide to be a single-stranded helix. In addition, the pattern provided information regarding the number of nucleotides per turn and was consistent with a 2-nm (nanometers) spacing between the strands in which a purine (A or G) bonds with a pyrimidine (T or C).

Base Composition Determined by Chargaff Another piece of information that proved to be critical for the determination of the double helix structure came from the studies of Austrian-born American biochemist Erwin Chargaff. In 1950, Chargaff analyzed the base composition of DNA that was isolated from many different species. His experiments consistently showed that the amount of adenine in each sample was similar to the amount of thymine, and the amount of cytosine was similar to the amount of guanine (**Table 11.1**).

Model Building by Pauling In the early 1950s, more information was known about the structure of proteins than that of nucleic acids. American biochemist Linus Pauling correctly proposed that some regions of proteins fold into a structure known as an α helix. To determine the structure of the α helix, Pauling built large models by linking together simple ball-and-stick units. In this way, he could see if atoms fit together properly in a complicated three-dimensional structure. This approach is still widely used today, except that now researchers construct three-dimensional models using computers. Use of the ball-and-stick approach was instrumental in solving the structure of the DNA double helix.

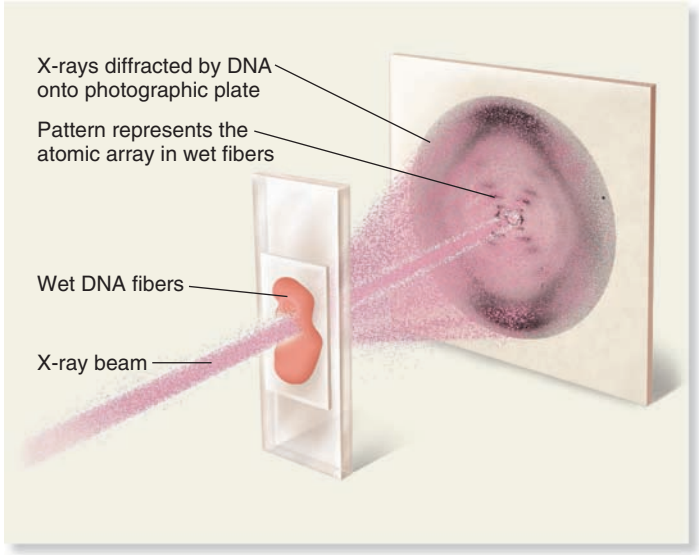

Figure 11.7 Franklin's X-ray diffraction of DNA fibers. The exposure of DNA wet fibers to X-rays causes the X-rays to be scattered and the pattern of scattering is related to the position of the atoms in the DNA fibers.

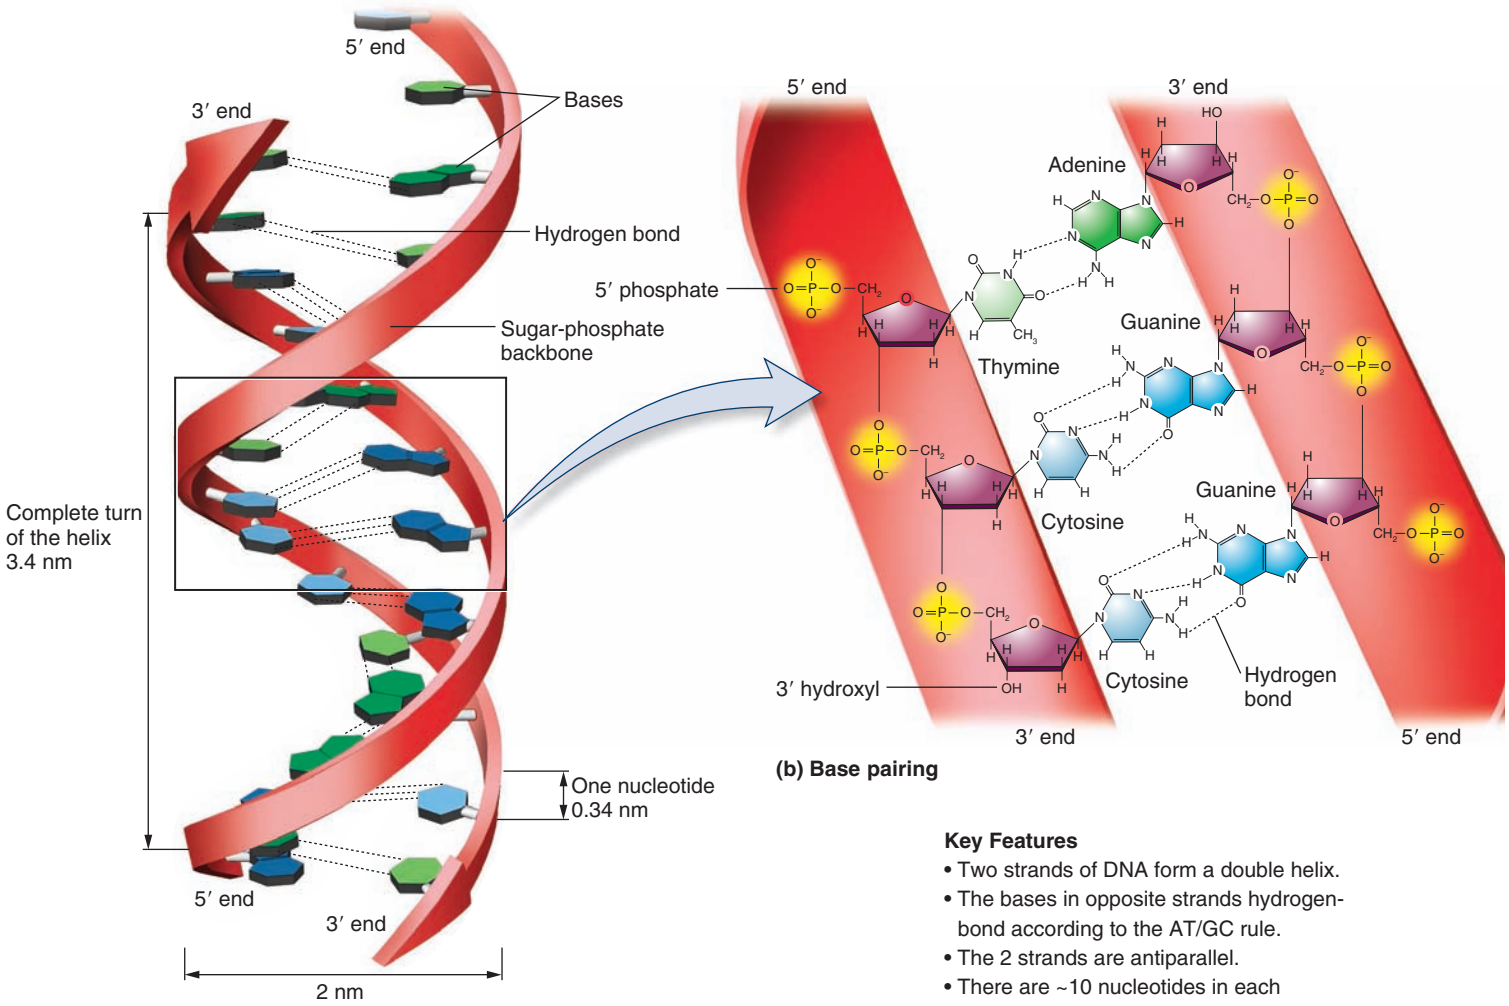
Table 11.1 Base Composition of DNA from a Variety of Organisms as Determined by Chargaff

Percentage of bases (%)				
Organism	Adenine	Thymine	Guanine	Cytosine
Escherichia coli (bacterium)	26.0	23.9	24.9	25.2
Streptococcus pneumoniae (bacterium)	29.8	31.6	20.5	18.0
Saccharomyces cerevisiae (yeast)	31.7	32.6	18.3	17.4
Turtle	28.7	27.9	22.0	21.3
Salmon	29.7	29.1	20.8	20.4
Chicken	28.0	28.4	22.0	21.6
Human	30.3	30.3	19.5	19.9

Watson and Crick Deduced the Double Helix Structure of DNA

Thus far, we have considered the experimental studies that led to the determination of the DNA double helix. American biologist James Watson and English biologist Francis Crick, working together at



Cambridge University, assumed that nucleotides are linked together in a linear fashion and that the chemical linkage between two nucleotides is always the same. In collaboration with Wilkins, they then set out to build ball-and-stick models that incorporated all of the known experimental observations.

Modeling of chemical structures involves trial and error. Watson and Crick initially considered several incorrect models. One model was a double helix in which the bases were on the outside of the helix. In another model, each base formed hydrogen bonds with the identical base in the opposite strand (A to A, T to T, G to G, and C to C). However, model-building revealed that purine-purine pairs were too wide and pyrimidine-pyrimidine pairs were too narrow to fit the uniform diameter of DNA revealed from Franklin's work. Eventually, they realized that the hydrogen bonding of adenine to thymine was structurally similar to that of guanine to cytosine. In both cases, a purine base (A or G) bonds with a pyrimidine base (T or C). With an interaction between A and T and between G and C, the ball-and-stick models showed that the two strands would form a double helix structure in which all atoms would fit together properly.

Watson and Crick proposed the structure of DNA, which was published in the journal *Nature* in 1953. In 1962, Watson, Crick, and Wilkins were awarded the Nobel Prize in Physiology or Medicine. Unfortunately, Rosalind Franklin had died before this time, and the Nobel Prize is awarded only to living recipients.

DNA Has a Repeating, Antiparallel Helical Structure Formed by the Complementary Base Pairing of Nucleotides

The structure that Watson and Crick proposed is a double-stranded, helical structure with the sugar-phosphate backbone on the outside and the bases on the inside (**Figure 11.8a**). This structure is stabilized by hydrogen bonding between the bases in opposite strands to form **base pairs**. A distinguishing feature of base pairing is its

Key Features

- Two strands of DNA form a double helix.
- The bases in opposite strands hydrogen-bond according to the AT/GC rule.
- The 2 strands are antiparallel.
- There are ~10 nucleotides in each strand per complete turn of the helix.

Figure 11.8 **Structure of the DNA double helix.** As seen in part **(a)**, DNA is a helix composed of two antiparallel strands. Part **(b)** shows the AT/GC base pairing that holds the strands together via hydrogen bonds.

Concept Check: *If one DNA strand is 5′–GATTCGTTC–3′, what is the complementary strand?*

specificity. An adenine (A) base in one strand forms two hydrogen bonds with a thymine (T) base in the opposite strand, or a guanine (G) base forms three hydrogen bonds with a cytosine (C) (**Figure 11.8b**). This **AT/GC rule** is consistent with Chargaff's observation that DNA contains approximately equal amounts of A and T, and equal amounts of G and C. According to the AT/GC rule, purines (A and G) always bond with pyrimidines (T and C) (recall that purines have a double-ring structure, whereas pyrimidines have single rings). This keeps the width of the double helix relatively constant. One complete turn of the double helix is 3.4 nm in length and comprises about 10 base pairs.

Due to the AT/GC rule, the base sequences of two DNA strands are **complementary** to each other. That is, you can predict the sequence in one DNA strand if you know the sequence in the opposite strand. For example, if one DNA strand has the sequence of 5′–GCGGATTT–3′, the opposite strand must be 3′–CGCCTAAA–5′. With regard to their 5′ and 3′ directionality, the two strands of a DNA double helix are **antiparallel**. If you look at Figure 11.8, one strand runs in the 5′ to 3′ direction from top to bottom, whereas the other strand is oriented 3′ to 5′ from top to bottom.

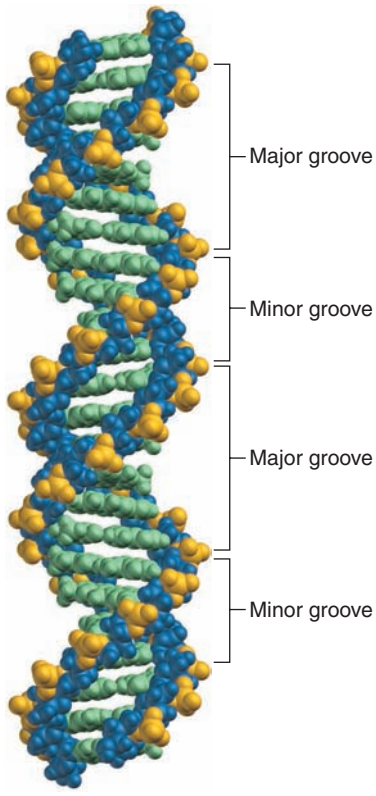


Figure 11.9 A space-filling model of the DNA double helix. In the sugar-phosphate backbone, sugar molecules are shown in blue, and phosphate groups are yellow. The backbone is on the outermost surface of the double helix. The atoms of the bases, shown in green, are more internally located within the double-stranded structure. Notice the major and minor grooves that are formed by this arrangement.

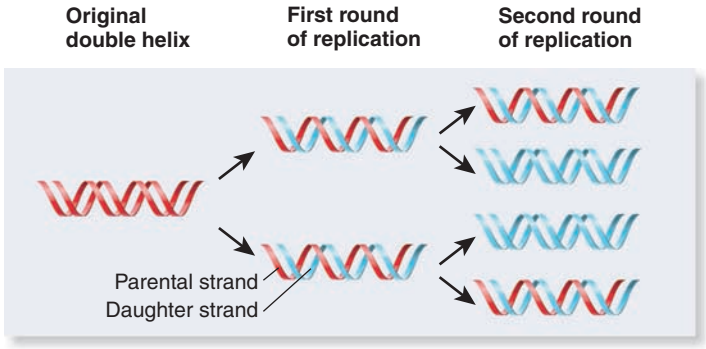
BIOLOGY PRINCIPLE Structure determines function. The major groove provides a binding site for proteins that control the expression of genes.

The DNA model in Figure 11.8a is called a ribbon model, which clearly shows the components of the DNA molecule. However, other models are also used to visualize DNA. The model for the DNA double helix shown in **Figure 11.9** is a space-filling model in which the atoms are depicted as spheres. Why is this model useful? This type of structural model emphasizes the surface of DNA. As you can see in this model, the sugar-phosphate backbone is on the outermost surface of the double helix; the backbone has the most direct contact with water. The atoms of the bases are more internally located within the double-stranded structure. The indentations where the atoms of the bases make contact with the surrounding water are termed grooves. Two grooves, called the **major groove** and the **minor groove**, spiral around the double helix. As discussed in later chapters, the major groove provides a location where a protein can bind to a particular sequence of bases and affect the expression of a gene (for example, look ahead to Figure 13.10).

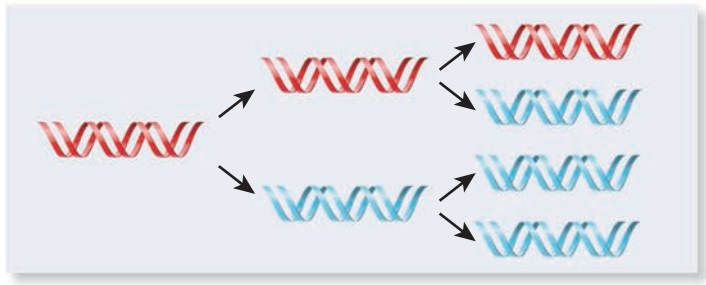
11.3 Overview of DNA Replication

Learning Outcomes:



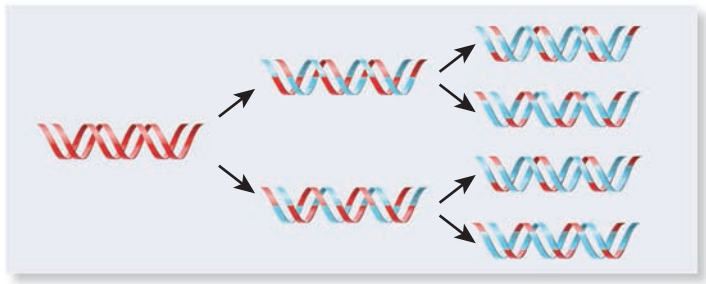
1. **SciSKILLS** » Discuss and interpret the experiments of Meselson and Stahl.
2. Describe the double-stranded structure of DNA, and explain how the AT/GC rule underlies the ability of DNA to be replicated semiconservatively.

The structure of DNA immediately suggested to Watson and Crick a mechanism by which DNA can be copied. They proposed that during this process, known as **DNA replication**, the original DNA strands are used as templates for the synthesis of new DNA strands. In this section, we will look at an early experiment that helped to determine the mechanism of DNA replication and then examine the structural characteristics that enable a double helix to be faithfully copied.



Meselson and Stahl Investigated Three Proposed Mechanisms of DNA Replication

Researchers in the late 1950s considered three different models for the mechanism of DNA replication (**Figure 11.10**). In all of these models, the two newly made strands are called the **daughter strands**, and the original strands are the **parental strands**.



- The first model is a **semiconservative mechanism** (Figure 11.10a). In this model, the double-stranded DNA is half conserved following the replication process so the new double-stranded DNA contains one parental strand and one daughter strand. This model is consistent with the proposal of Watson and Crick.
- According to a second model, called a **conservative mechanism**, both parental strands of DNA remain together following DNA replication (Figure 11.10b). The original arrangement of parental strands is completely conserved, and the two newly made daughter strands are also together following replication.

(a) Semiconservative mechanism. DNA replication produces DNA molecules with 1 parental strand and 1 newly made daughter strand.

(b) Conservative mechanism. DNA replication produces 1 double helix with both parental strands and the other with 2 new daughter strands.

(c) Dispersive mechanism. DNA replication produces DNA strands in which segments of new DNA are interspersed with the parental DNA.

Figure 11.10 Three proposed mechanisms for DNA replication. The strands of the original (parental) double helix are shown in red. Two rounds of replication are illustrated with the daughter strands shown in blue.

- A third possibility, called a **dispersive mechanism**, proposed that segments of parental DNA and newly made DNA are interspersed in both strands following the replication process (Figure 11.10c).

In 1958, American biologists Matthew Meselson and Franklin Stahl devised an experimental approach to distinguish among these three mechanisms. An important feature of their research was the use of isotope labeling. Nitrogen, which is found in DNA, occurs in a common light (^{14}N) form and a rare heavy (^{15}N) form. Meselson and Stahl studied DNA replication in the bacterium *Escherichia coli*.

1. They grew *E. coli* cells for many generations in a medium that contained only the ^{15}N form of nitrogen (**Figure 11.11**). This produced a population of bacterial cells in which all of the DNA was heavy labeled.

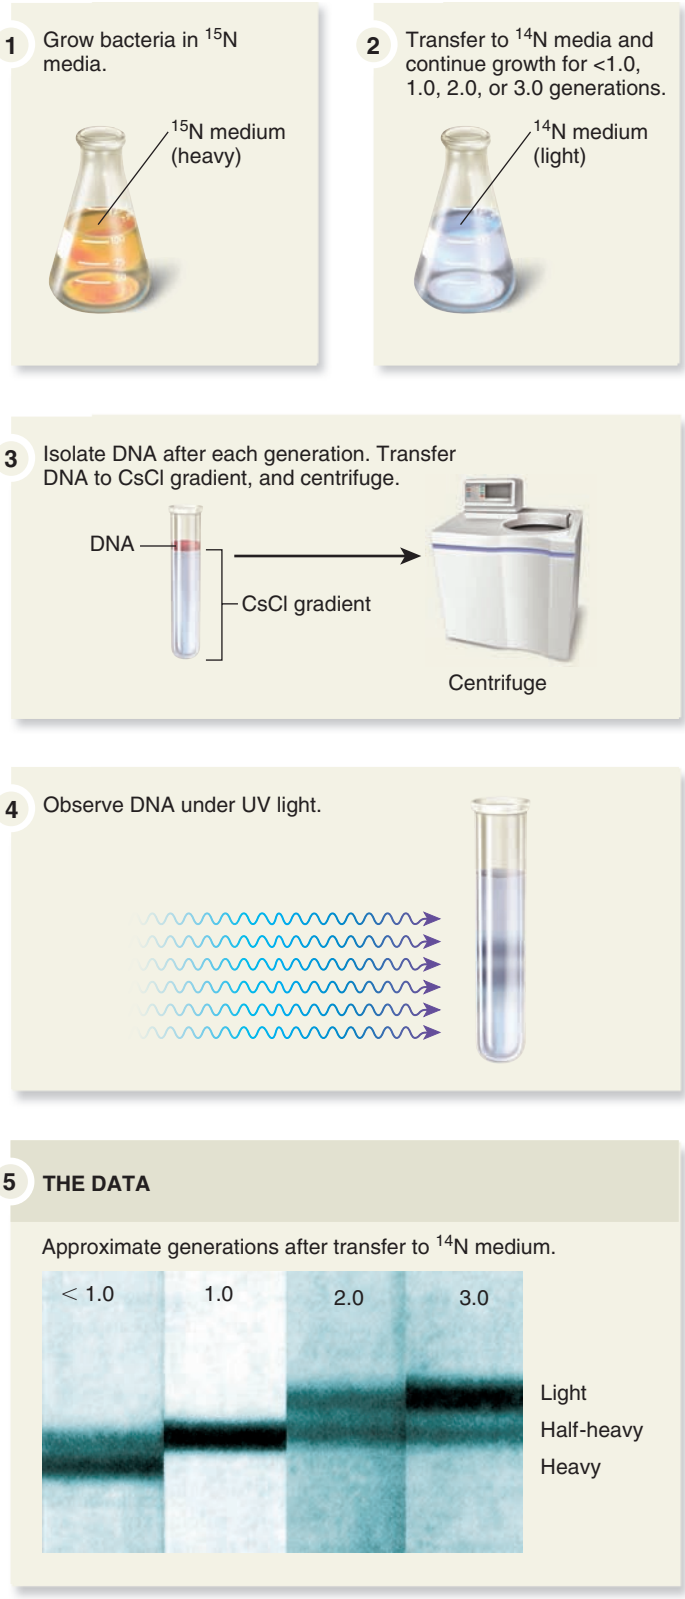


Figure 11.11 The Meselson and Stahl experiment showing that DNA replication is semiconservative.

Concept Check: *If this experiment was conducted for four rounds of DNA replication (that is, four generations), what would be the expected fractions of light DNA and half-heavy DNA according to the semiconservative model?*

2. Then they switched the bacteria to a medium that contained only ^{14}N as its nitrogen source. The cells were allowed to divide, and samples were collected after one generation (that is, one round of DNA replication), two generations, and so on. Because the bacteria were doubling in a medium that contained only ^{14}N, all of the newly made DNA strands were labeled with light nitrogen, but the original strands remained labeled with the heavy form.
3. Meselson and Stahl used centrifugation to separate DNA molecules based on differences in density. Samples were placed on the top of a solution that contained a salt gradient, in this case, cesium chloride (CsCl). A double helix containing all heavy nitrogen has a higher density and therefore travels closer to the bottom of the gradient. By comparison, if both DNA strands contained ^{14}N, the DNA would have a low density and remain closer to the top of the gradient. If one strand contained ^{14}N and the other strand contained ^{15}N, the DNA would be half-heavy and have an intermediate density, ending up near the middle of the gradient.
4. The DNA within the gradient was observed by exposing the gradient to UV light.
5. After one cell doubling (that is, one round of DNA replication), all of the DNA exhibited a density that was half-heavy or intermediate density (Figure 11.11, step 5). These results are consistent with both the semiconservative and dispersive models. In contrast, the conservative mechanism predicts two different DNA bands: one of high density and one of low density. Because the DNA was found in a single half-heavy band after one doubling, the conservative model was disproved.

After two cell doublings, both light DNA and half-heavy DNA bands were observed. This result was also predicted by the semiconservative mechanism of DNA replication, because half of the DNA molecules should contain all light DNA, while the other molecules should be half-heavy (see Figure 11.10a). However, in the dispersive mechanism, all of the DNA strands would have been 1/4 heavy after two generations. This mechanism predicts that the heavy nitrogen would be evenly dispersed among four double helices, each strand containing 1/4 heavy nitrogen and 3/4 light nitrogen (see Figure 11.10c). This prediction did not agree with the data. Taken together, the results of the Meselson and Stahl experiment are consistent only with a semiconservative mechanism for DNA replication.

DNA Replication Proceeds According to the AT/GC Rule

As originally proposed by Watson and Crick, DNA replication relies on the complementarity of DNA strands according to the AT/GC rule. During the replication process, the two complementary strands of DNA separate and serve as **template strands**, also called parental strands, for the synthesis of daughter strands of DNA (**Figure 11.12a**). After the double helix has separated, individual nucleotides have access to the template strands in a region called the replication fork.

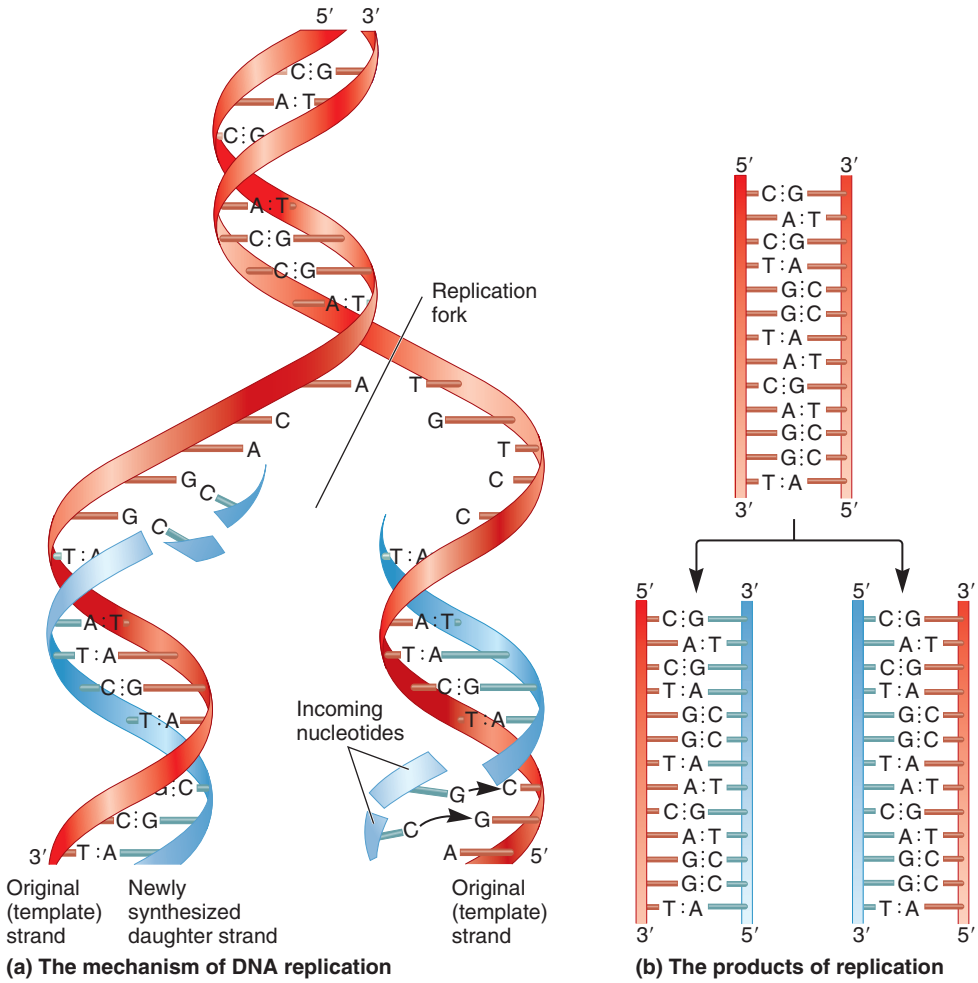

Figure 11.12 DNA replication according to the AT/GC rule. **(a)** The mechanism of DNA replication as originally proposed by Watson and Crick. As we will see in Section 11.4, the synthesis of one newly made strand (the leading strand on the left side) occurs in the direction toward the replication fork, whereas the synthesis of the other newly made strand (the lagging strand on the right side) occurs in small segments away from the fork. **(b)** DNA replication produces two copies of DNA with the same sequence as the original DNA molecule.

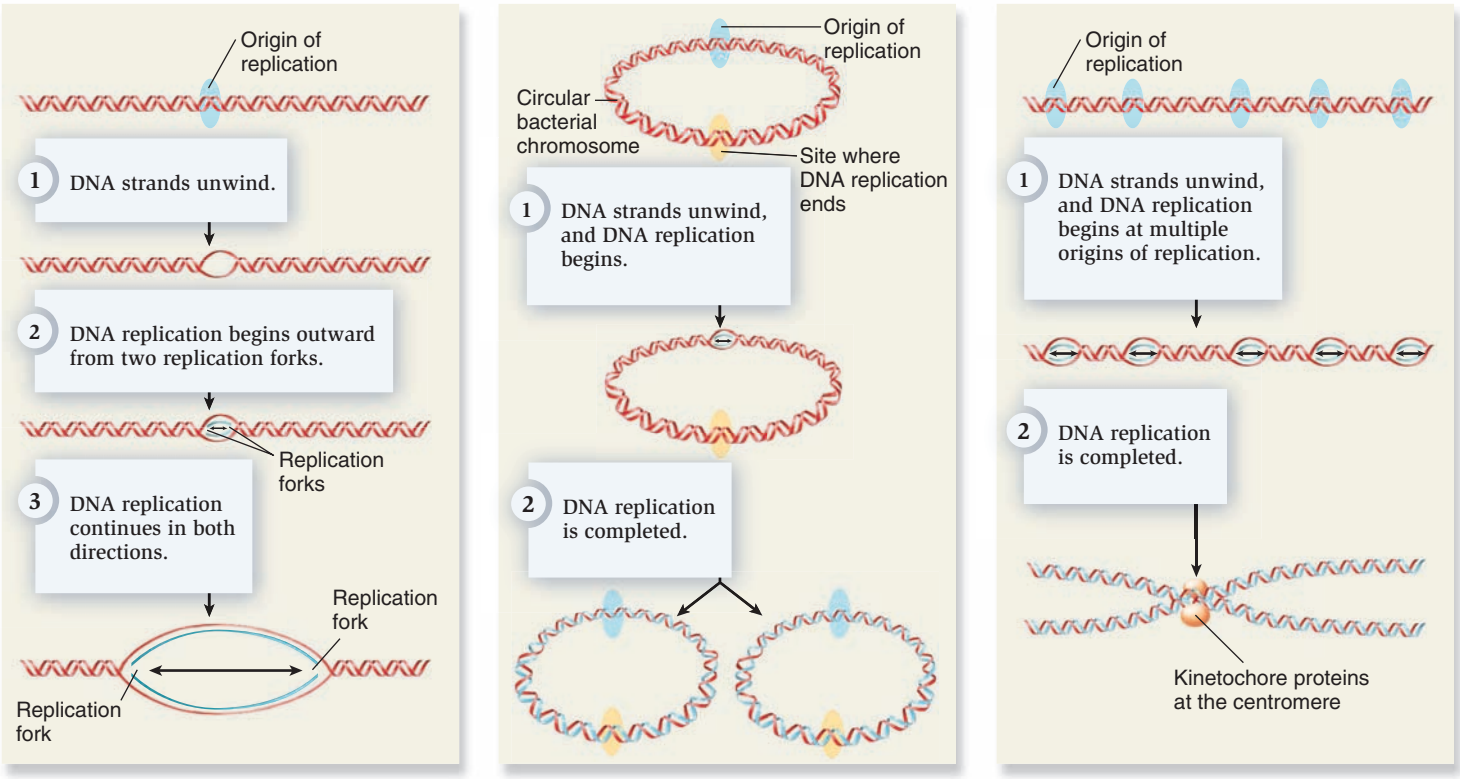
BIOLOGY PRINCIPLE Structure determines function. A double-stranded structure that obeys the AT/GC rule underlies the function of DNA replication.

First, individual nucleotides hydrogen-bond to the template strands according to the AT/GC rule: An adenine (A) base in one strand bonds with a thymine (T) base in the opposite strand, or a guanine (G) base bonds with a cytosine (C). Next, a covalent bond is formed between the phosphate of one nucleotide and the sugar of the previous nucleotide. The end result is that two double helices are made that have the same base sequence as the original DNA molecule (**Figure 11.12b**). This is a critical feature of DNA replication, because it enables the replicated DNA molecules to retain the same information (that is, the same base sequence) as the original molecule. In this way, DNA has the remarkable ability to direct its own duplication.

11.4 Molecular Mechanism of DNA Replication



Learning Outcomes:

1. Describe how the synthesis of new DNA strands begins at an origin of replication.
2. List the functions of helicase, topoisomerase, single-strand binding protein, primase, and DNA polymerase at the replication fork.
3. Outline the key differences between the synthesis of the leading and lagging strands.
4. List three reasons why DNA replication is very accurate.
5. Explain how DNA replication occurs at telomeres in eukaryotic chromosomes.

Thus far, we have examined the general mechanism of DNA replication, known as semiconservative replication, and we've seen how DNA synthesis obeys the AT/GC rule. In this section, we will examine the details of DNA replication as it occurs inside living cells. As you will learn, several different proteins are needed to initiate DNA replication and allow it to proceed quickly and accurately.

DNA Replication Begins at an Origin of Replication

Where does DNA replication begin? An **origin of replication** is a site within a chromosome that serves as a starting point for DNA replication. At the origin, the two DNA strands unwind (**Figure 11.13a**). DNA replication proceeds outward from two **replication forks**, a process termed **bidirectional replication**. The number of origins of replication varies among different organisms. In bacteria, which typically have a small circular chromosome, a single origin of replication is found. Bidirectional replication starts at the origin of replication and proceeds until the new strands meet on the opposite side of the chromosome (**Figure 11.13b**). Eukaryotes have larger chromosomes that are linear. They require multiple origins of replication so the DNA can

(a) Bidirectional replication (b) Single origin of replication in bacteria (c) Multiple origins of replication in eukaryotes

Figure 11.13 The bidirectional replication of DNA. **(a)** DNA replication proceeds in both directions from an origin of replication. **(b)** Bacterial chromosomes have a single origin of replication, whereas **(c)** eukaryotes have multiple origins. Following DNA replication in eukaryotes, the two copies remain attached to each other at the centromere via kinetochore proteins.

be replicated in a reasonable length of time. The newly made strands from each origin eventually make contact with each other to complete the replication process (Figure 11.13c).

DNA Replication Requires the Action of Several Different Proteins

Thus far, we have considered how DNA replication occurs outward from an origin of replication in a region called a DNA replication fork. In all living species, a set of several different proteins is involved in this process. An understanding of the functions of these proteins is critical to explaining the replication process at the molecular level.

Helicase, Topoisomerase, and Single-Strand Binding Proteins: Formation and Movement of the Replication Fork To act as a template for DNA replication, the strands of a double helix must separate, and the resulting fork must move. As mentioned, an origin of replication serves as a site where this separation initially occurs. The strand separation at each fork then moves outward from the origin via the action of an enzyme called **DNA helicase**. At each fork, DNA helicase binds to one of the DNA strands and travels in the 5′ to 3′ direction toward the fork (Figure 11.14). It uses energy from ATP to break hydrogen bonds between base pairs. This separates the DNA strands and keeps the fork moving forward. The action of DNA helicase can cause knots (called supercoils) to form just ahead of the replication fork. These knots are alleviated by another enzyme called **DNA topoisomerase**.

After the two template DNA strands have separated, they must remain that way until the complementary daughter strands have been made. The function of **single-strand binding proteins** is to coat both of the single strands of template DNA and prevent them from re-forming a double helix. In this way, the bases within the template strands are kept exposed so they can act as templates for the synthesis of complementary strands.

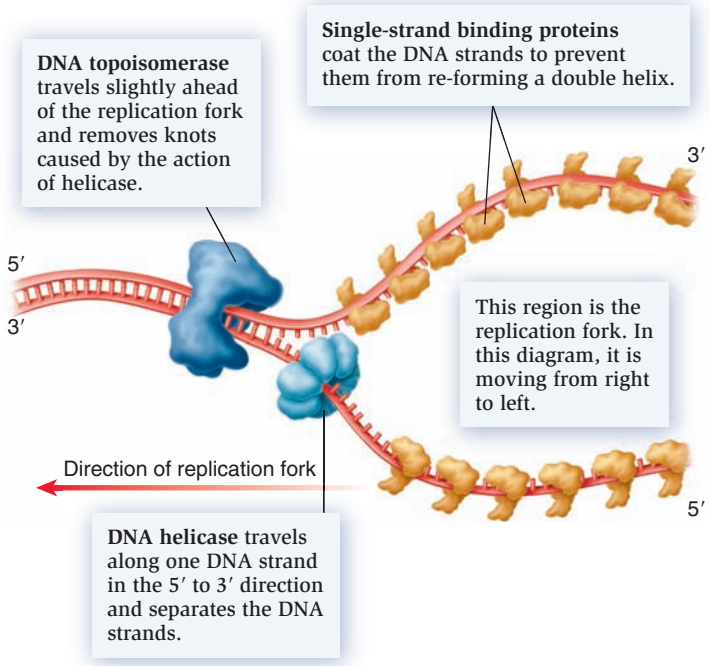


Figure 11.14 Proteins that facilitate the formation and movement of a replication fork.

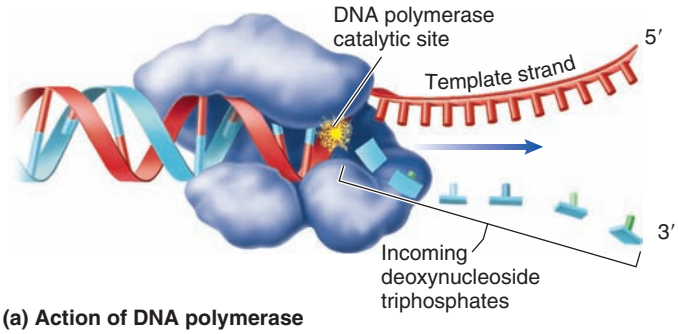
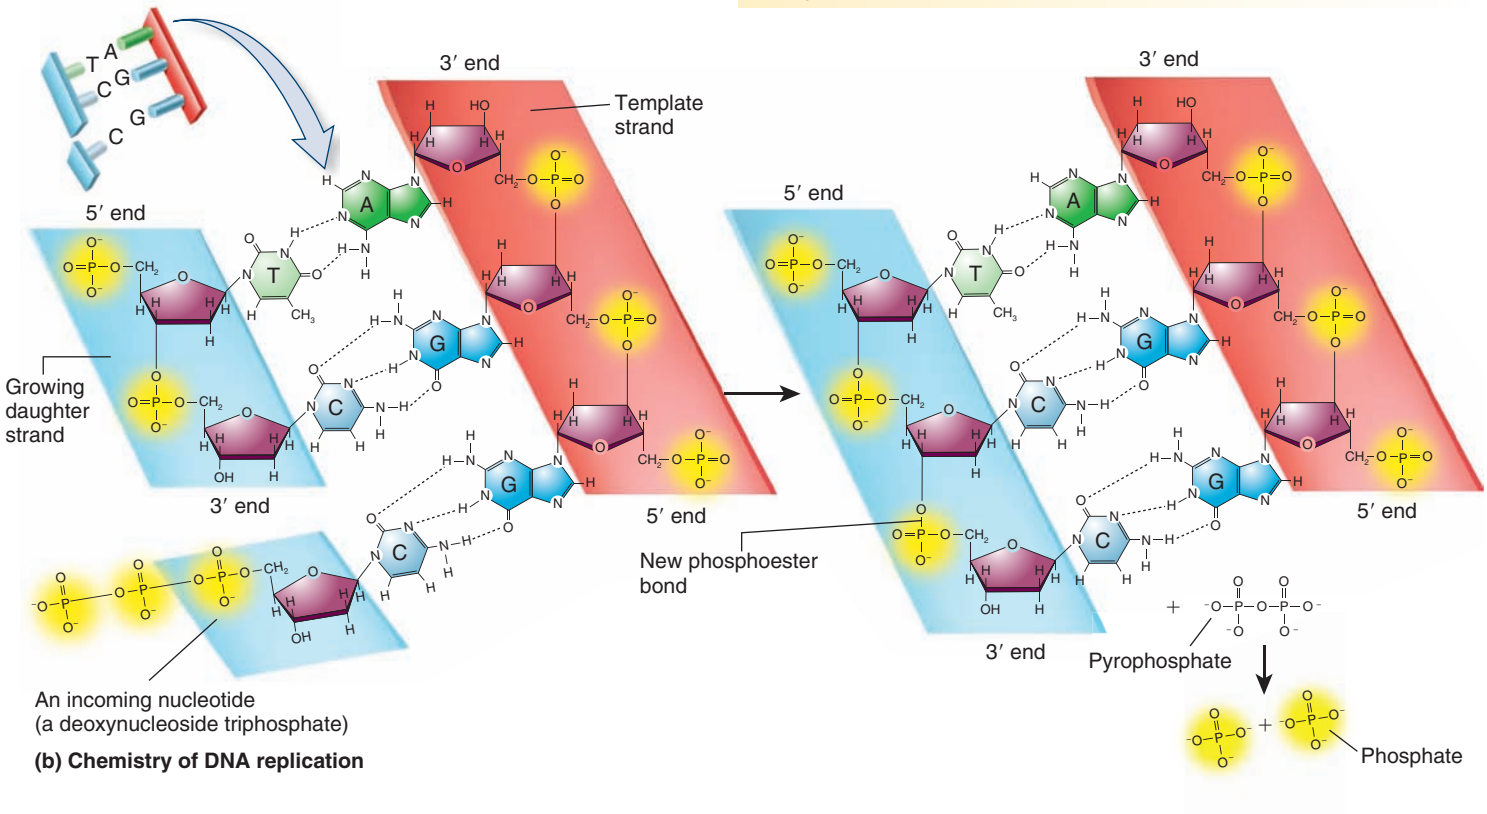


DNA Polymerase and Primase: Synthesis of DNA Strands The enzyme **DNA polymerase** is responsible for covalently linking nucleotides together to form DNA strands. American biochemist Arthur Kornberg discovered this enzyme in the 1950s. The structure of DNA polymerase resembles a human hand with the DNA threaded through it (Figure 11.15a). As DNA polymerase slides along the DNA, individual nucleotides with three phosphate groups, called **deoxynucleoside triphosphates**, hydrogen-bond to the exposed bases in the template strand according to the AT/GC rule. At the catalytic site, DNA polymerase breaks a bond between the first and second phosphate and then attaches the resulting nucleotide with one phosphate group (a deoxynucleoside monophosphate) to the 3′ end of a growing strand via a phosphoester bond. The breakage of the covalent bond releases pyrophosphate, which is an exergonic reaction, and provides the energy to covalently connect adjacent nucleotides (Figure 11.15b). The pyrophosphate is broken down to two phosphates.

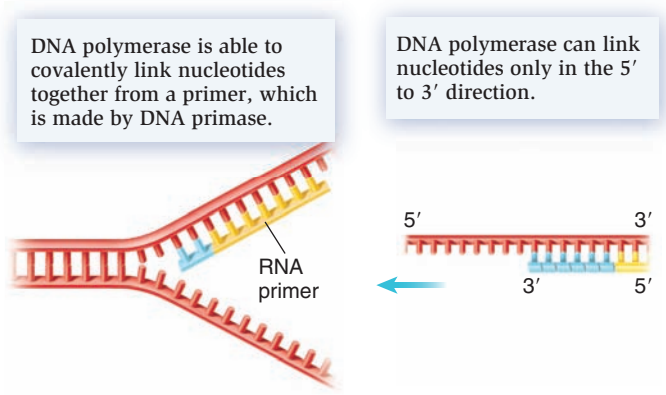
The rate of synthesis is truly remarkable. In bacteria, DNA polymerase synthesizes DNA at a rate of 500 nucleotides per second, whereas eukaryotic species make DNA at a rate of about 50 nucleotides per second.



DNA polymerase has two additional enzymatic features that affect how DNA strands are made. First, if a DNA or RNA strand is already attached to a template strand, DNA polymerase can elongate such a preexisting strand by making DNA. However, DNA polymerase is unable to begin DNA synthesis on a bare template strand. A different enzyme called **DNA primase** is required if the template strand is bare. DNA primase makes a complementary primer that is actually a short segment of RNA, typically 10 to 12 nucleotides in length. These short RNA strands start, or prime, the process of DNA replication (Figure 11.16a). A second feature of DNA polymerase is that once synthesis has begun, it can synthesize new DNA only in a 5′ to 3′ direction (Figure 11.16b).

Leading and Lagging DNA Strands Are Made Differently

Let's now consider how new DNA strands are made at a replication fork. DNA replication occurs near the opening that forms each replication fork (Figure 11.17a, step 1). The synthesis of a strand always begins with an RNA primer (depicted in yellow), and the new DNA is made in the 5′ to 3′ direction. The manner in which the two daughter strands are synthesized is strikingly different. One strand, called the **leading strand**, is made in the same direction that the fork is moving. The leading strand is synthesized as one long continuous molecule. By comparison, the other daughter strand, termed the **lagging strand**, is made as a series of small fragments that are subsequently connected to each other to form a continuous strand. These DNA fragments are known as **Okazaki fragments**, after Japanese biologists Reiji and Tsuneko Okazaki, who initially discovered them in the late 1960s. The synthesis of Okazaki fragments occurs in the opposite direction of the replication fork. For example, the lower fragment seen in Figure 11.17a, steps 2 and 3, is synthesized from left to right. As shown in Figure 11.17a, step 4, the RNA primer is eventually removed, and adjacent Okazaki fragments are connected to each other to form a continuous strand of DNA. Figure 11.17b shows how



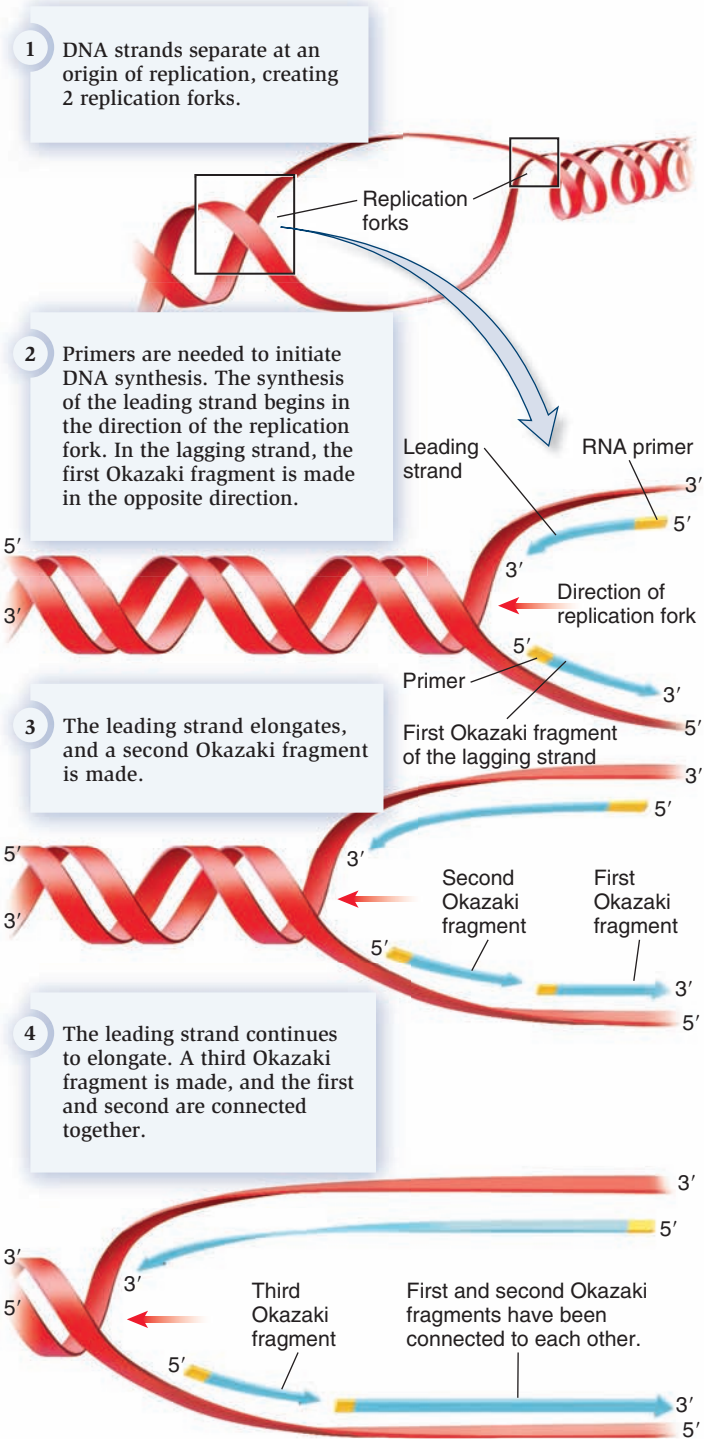
(a) Action of DNA polymerase

(b) Chemistry of DNA replication

Figure 11.15 Enzymatic synthesis of DNA. **(a)** Incoming deoxynucleoside triphosphates first hydrogen-bond to the template strand according to the AT/GC rule. DNA polymerase recognizes these deoxynucleoside triphosphates and attaches a deoxynucleoside monophosphate to the 3′ end of a growing strand. **(b)** DNA polymerase breaks the bond between the first and second phosphate in a deoxynucleoside triphosphate, causing the release of pyrophosphate. This provides the energy to form a covalent bond between the resulting deoxynucleoside monophosphate and the previous nucleotide in the growing strand. The pyrophosphate is broken down to two phosphates.

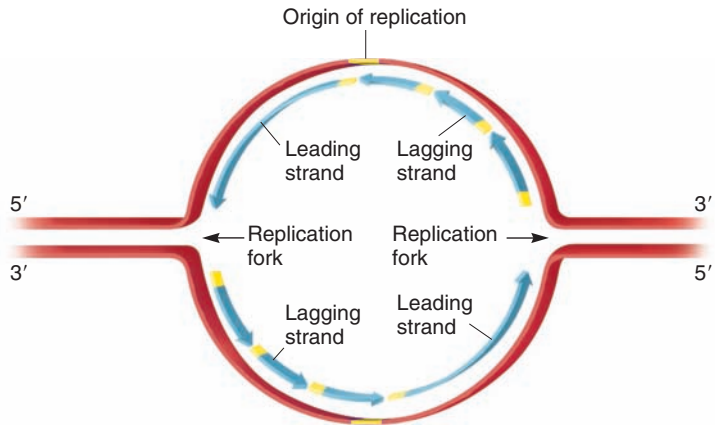
Concept Check: *Does the oxygen in a new phosphoester bond come from the sugar or from the phosphate?*

(a) Need for a primer



(b) 5′ to 3′ direction of DNA synthesis

Figure 11.16 Enzymatic features of DNA polymerase. **(a)** DNA polymerase needs a primer to begin DNA synthesis, and **(b)** it can synthesize DNA only in the 5′ to 3′ direction.



the leading and lagging strands are made during bidirectional DNA replication from a single origin of replication.

As we have seen, Figure 11.17 emphasizes the synthesis of new DNA strands. **Figure 11.18** shows the proteins involved in the synthesis of the leading and lagging strands in *E. coli*. In this bacterium, two different DNA polymerases, called DNA polymerase I and III, are primarily responsible for DNA replication. In the leading strand, DNA primase makes one RNA primer at the origin, and then DNA polymerase III attaches nucleotides in a 5′ to 3′ direction as it slides toward the opening of the replication fork. DNA polymerase III has a subunit called the clamp protein that allows the enzyme to slide along the template strand without falling off, a characteristic called **processivity**.

In the lagging strand, DNA is also synthesized in a 5′ to 3′ direction, but this synthesis occurs in the direction away from the replication fork. In the lagging strand, short segments of DNA are made discontinuously as a series of Okazaki fragments, each of which requires its own primer. DNA polymerase III synthesizes the remainder of the fragment (Figure 11.18, step 2). To complete the synthesis of Okazaki

(a) DNA replication at one replication fork

(b) Replication from an origin

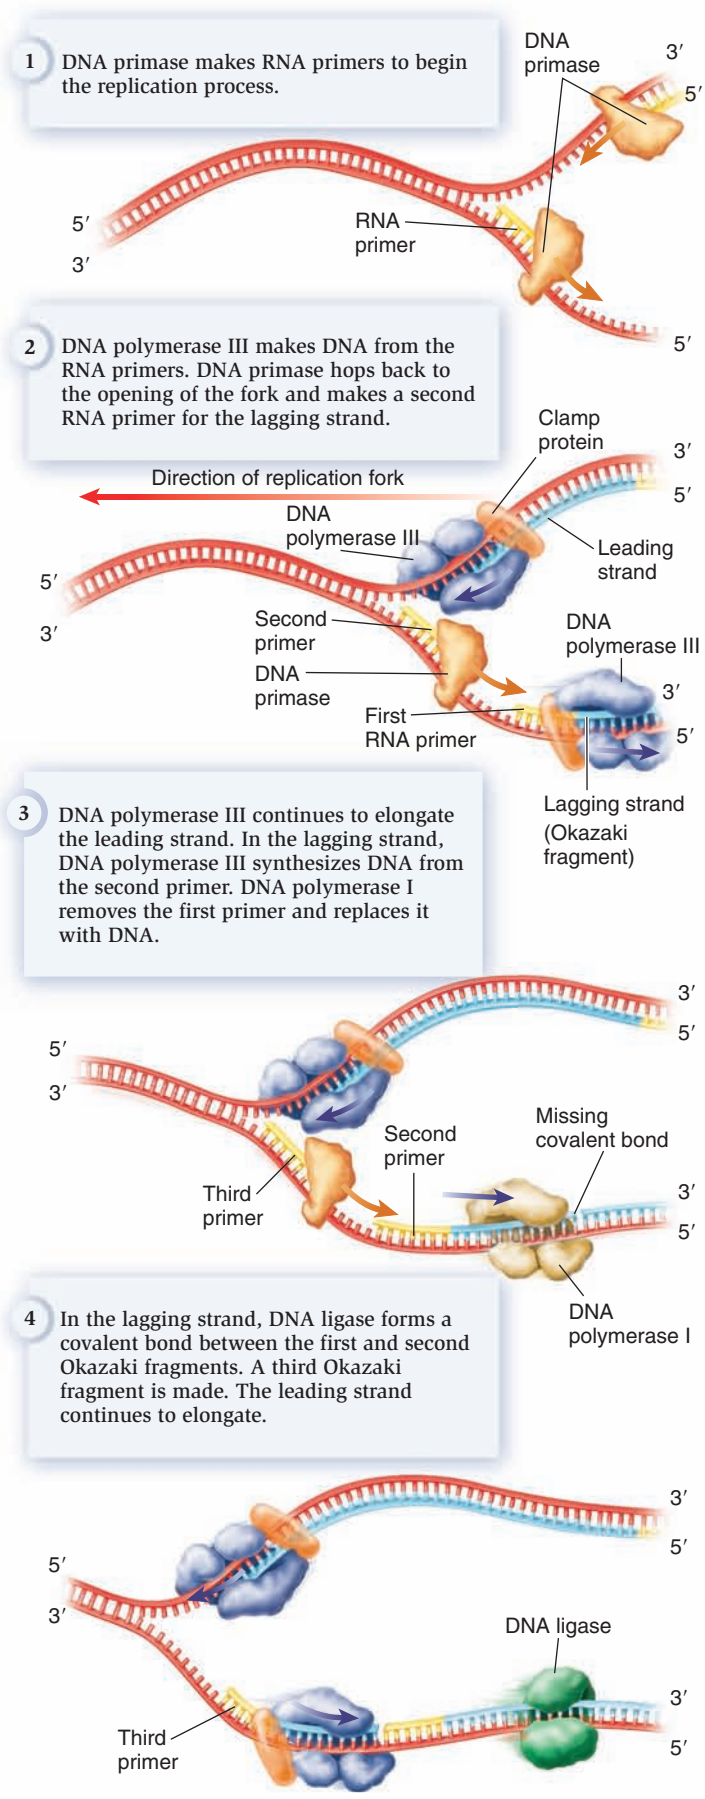
Figure 11.17 Synthesis of new DNA strands. The separation of DNA at the origin of replication produces two replication forks that move in opposite directions. New DNA strands are made near the opening of each fork. **(a)** The leading strand is made continuously in the same direction the fork is moving. The lagging strand is made as small pieces in the opposite direction. Eventually, these small pieces are connected to each other to form a continuous lagging strand. **(b)** This diagram illustrates the locations of the leading and lagging strands that are made during bidirectional DNA replication from one origin of replication.

Concept Check: *Which strand, the leading or lagging strand, is made discontinuously in the direction opposite to the movement of the replication fork?*

Table 11.2 Proteins Involved in DNA Replication

Common name	Function
DNA helicase	Separates double-stranded DNA into single strands
Single-strand binding protein	Binds to single-stranded DNA and prevents it from re-forming a double helix
Topoisomerase	Removes tightened coils ahead of the replication fork
DNA primase	Synthesizes short RNA primers
DNA polymerase	Synthesizes DNA in the leading and lagging strands, removes RNA primers, and fills in gaps
DNA ligase	Covalently attaches adjacent Okazaki fragments in the lagging strand

fragments within the lagging strand, three additional events occur: the removal of the RNA primers, the synthesis of DNA in the area where the primers have been removed, and the covalent joining of adjacent fragments of DNA (Figure 11.18, steps 3 and 4). The RNA primers are removed by DNA polymerase I, which digests the linkages between nucleotides in a 5′ to 3′ direction. After the RNA primer is removed, DNA polymerase I fills in the vacant region with DNA. However, once the DNA has been completely filled in, a covalent bond is missing between the last nucleotide added by DNA polymerase I and the first nucleotide in the adjacent Okazaki fragment. An enzyme known as **DNA ligase** catalyzes the formation of a covalent bond between these two DNA fragments to complete the replication process in the lagging strand (Figure 11.18, step 4). **Table 11.2** provides a summary of the functions of the proteins involved in DNA replication.



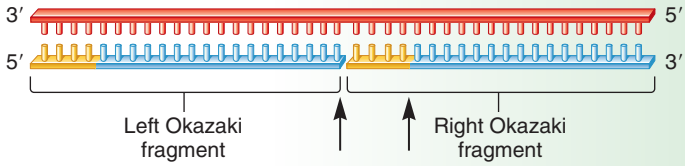


Figure 11.18 Proteins involved with the synthesis of the leading and lagging strands in *E. coli*.

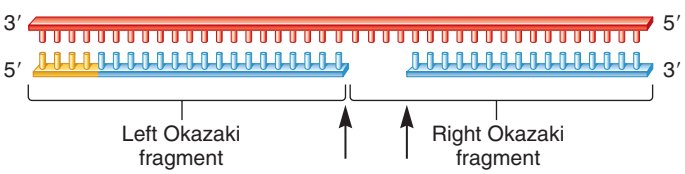
Concept Check: *Briefly describe the movement of primase in the lagging strand in this figure. In which direction does it move when it is making a primer, from left to right or right to left? Describe how it must move after it is done making a primer and has to start making the next primer at a new location. Does it have to hop from left to right or from right to left?*

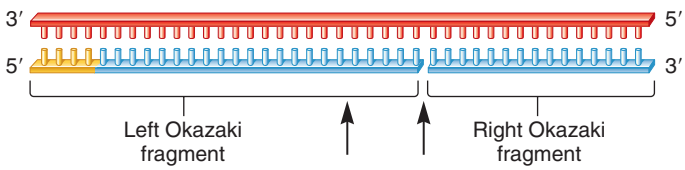
BIO TIPS

THE QUESTION *The drawing below shows the synthesis of the lagging strand of a DNA molecule. The RNA primers are yellow, and the newly made DNA is blue. The top (red) strand is the template strand.*



After DNA polymerase I removes the right RNA primer and fills in the gap with DNA, where will DNA ligase act? See the arrows on either side of the right RNA primer. Is the ligase needed at the left arrow, the right arrow, or both?

TOPIC ***What topic in biology does this question address?*** The topic is DNA replication. More specifically, the question asks you to determine where DNA ligase needs to act for replication of the lagging strand.



INFORMATION ***What information do you know based on the question and your understanding of the topic?*** In the question, you are given the arrangement of two adjacent Okazaki fragments, with arrows pointing to two possible places where DNA ligase may be needed. From your understanding of the topic, you may remember that in *E. coli*, DNA polymerase I removes the RNA primer and fills in the region with DNA; then DNA ligase connects the adjacent Okazaki fragments.

PROBLEM-SOLVING STRATEGY ***Sort out the steps in a complicated process. Make a drawing.*** To solve this problem, it may be helpful to list the steps of the process. Also, you should consider how DNA polymerase I and DNA ligase function.

1. First, DNA polymerase I removes the right RNA primer.

2. Starting at the 3′ end of the left Okazaki fragment, DNA polymerase I then extends the DNA until it fills in the region where the RNA primer was removed. DNA ligase is not needed at the left arrow.

3. As shown above, when DNA polymerase I reaches the (blue) DNA of the right Okazaki fragment, a gap exists between the 3′ end of the left Okazaki fragment and the 5′ end of the DNA of the right Okazaki fragment.

ANSWER *DNA ligase is needed at the right arrow only.*

DNA Replication Is Very Accurate

Although errors can happen during DNA replication, permanent mistakes are extraordinarily rare. For example, during bacterial DNA replication, only 1 mistake per 100 million nucleotides is made. Biologists use the term high fidelity to refer to a process that occurs with relatively few mistakes. How can we explain such a remarkably high fidelity for DNA replication?

- First, hydrogen bonding between A and T or between G and C is more stable than between mismatched pairs.
- Second, the active site of DNA polymerase is unlikely to catalyze bond formation between adjacent nucleotides if a mismatched base pair is formed.
- Third, DNA polymerase can identify a mismatched nucleotide and remove it from the daughter strand. This event, called **proofreading**, occurs when DNA polymerase detects a mismatch and then reverses its direction and digests the linkages between nucleotides at the end of a newly made strand in the 3′ to 5′ direction. Once it passes the mismatched base and removes it, DNA polymerase then changes direction again and continues to synthesize DNA in the 5′ to 3′ direction.

Genomes & Proteomes Connection

DNA Polymerases Are a Family of Enzymes with Specialized Functions

Three important properties of DNA replication are speed, fidelity, and completeness. DNA replication must proceed quickly and with great accuracy, and gaps should not be left in the newly made strands. To ensure that these three requirements are met, living species produce more than one type of DNA polymerase, each of which may differ in the rate and accuracy of DNA replication and/or the ability to prevent the formation of DNA gaps.

The genomes of living species have multiple DNA polymerase genes, which were produced by random gene duplication events. During evolution, mutations have altered each gene to produce a family of DNA polymerase enzymes with more specialized functions.

Natural selection has favored certain mutations that result in DNA polymerase properties that are suited to the organism in which they are found. For comparison, let's consider the families of DNA polymerases found in the bacterium *E. coli* and humans (**Table 11.3**). Why does *E. coli* produce 5 DNA polymerases and humans produce 12 or more? The answer lies in specialization and the functional requirements of each species.

In *E. coli*, DNA polymerase III is responsible for most DNA replication. It synthesizes DNA very rapidly and with high fidelity. By comparison, the role of DNA polymerase I is to remove the RNA primers and fill in the short vacant regions with DNA. DNA polymerases II, IV, and V are involved in repairing DNA and in replicating DNA that has been damaged. DNA polymerases I and III become stalled when they encounter DNA damage and may be unable to make a complementary strand at such a site. By comparison, DNA polymerases II, IV, and V do not stall. Although their rate of synthesis is not as rapid as DNA polymerases I and III, they ensure that DNA replication is complete.

In human cells, DNA polymerase α (alpha) has its own "built-in" primase subunit. It synthesizes RNA primers followed by short DNA regions. Two other DNA polymerases, δ (delta) and ε (epsilon), then extend the DNA at a faster rate. DNA polymerase δ synthesizes the lagging strand, and DNA polymerase ε synthesizes the leading strand. DNA polymerase γ (gamma) functions in the mitochondria to replicate mitochondrial DNA.

When DNA replication occurs, the general DNA polymerases (α, δ, or γ) may be unable to replicate over an abnormality in DNA structure (a lesion). If this happens, lesion-replicating polymerases are attracted to the damaged DNA. These polymerases have special properties that enable them to synthesize a complementary strand over the lesion. Each type of lesion-replicating polymerase may be able to replicate over different kinds of DNA damage, thereby ensuring that DNA replication is complete.

Other human DNA polymerases play an important role in DNA repair. The need for multiple repair enzymes is rooted in the various ways that DNA can be damaged, as described in Chapter 14. Multicellular organisms must be particularly vigilant about repairing DNA, because unrepaired DNA can lead to cancer.

Telomerase Attaches DNA Sequences at the Ends of Eukaryotic Chromosomes

We will end our discussion of DNA replication by considering a specialized form of DNA replication that happens at the ends of eukaryotic chromosomes. This region, called the **telomere**, has a short nucleotide sequence that is repeated a few dozen to several hundred times in a row (**Figure 11.19**). The repeat sequence shown here, 5′–GGGTTA–3′, is the sequence found in human telomeres. A telomere has a region at the 3′ end that is termed a 3′ overhang, because it does not have a complementary strand.

As discussed previously, DNA polymerase synthesizes DNA only in a 5′ to 3′ direction and requires a primer. For these reasons, DNA polymerase cannot copy the tip of a DNA strand with a 3′ end. Therefore, if this replication problem was not overcome, a linear chromosome would become progressively shorter with each round of DNA

Table 11.3 DNA Polymerases in *E. coli* and Humans

Polymerase types*	Functions
E. coli	
III	Replicates most of the DNA during cell division
I	Removes RNA primers and fills in the gaps
II, IV, and V	Repairs damaged DNA and replicates over DNA damage
Humans	
α (alpha)	Makes RNA primers and synthesizes short DNA strands
δ (delta), ε (epsilon)	Displaces DNA polymerase α and then replicates DNA at a rapid rate
γ (gamma)	Replicates the mitochondrial DNA
η (eta), κ (kappa), ι (iota), ζ (zeta)	Replicates over damaged DNA
α, β (beta), δ, ε, σ (sigma), λ (lambda), μ (mu), φ (phi), θ (theta)	Repairs DNA or has other functions

*Certain DNA polymerases have more than one function.

replication. In 1984, American molecular biologist Carol Greider and Australian-born American molecular biologist Elizabeth Blackburn discovered an enzyme called **telomerase** that prevents chromosome shortening by attaching many copies of a DNA repeat sequence to the ends of chromosomes (**Figure 11.20**). Telomerase contains both protein and RNA. The RNA part of telomerase has a sequence that is complementary to the DNA repeat sequence. This allows telomerase to bind to the 3′ overhang region of the telomere. Following binding, the RNA sequence beyond the binding site functions as a template, allowing telomerase to synthesize a 6-nucleotide sequence at the end of the DNA strand. The enzyme then moves to the new end of this DNA strand and attaches another 6 nucleotides to the end. This occurs many times, thereby greatly lengthening the 3′ end of the DNA in the telomere. This lengthening provides an upstream site for an RNA primer to be made. DNA polymerase then synthesizes the complementary DNA strand. In this way, the progressive shortening of eukaryotic chromosomes is prevented.

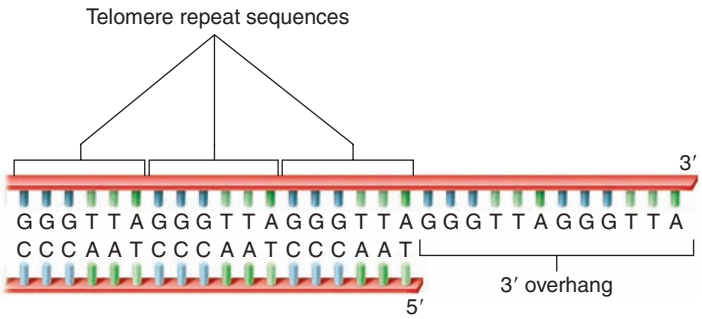


Figure 11.19 Telomere sequences at the end of a human chromosome. The telomere sequence shown here is found in humans and other mammals. The length of the telomere and the 3′ overhang varies among different species and cell types.

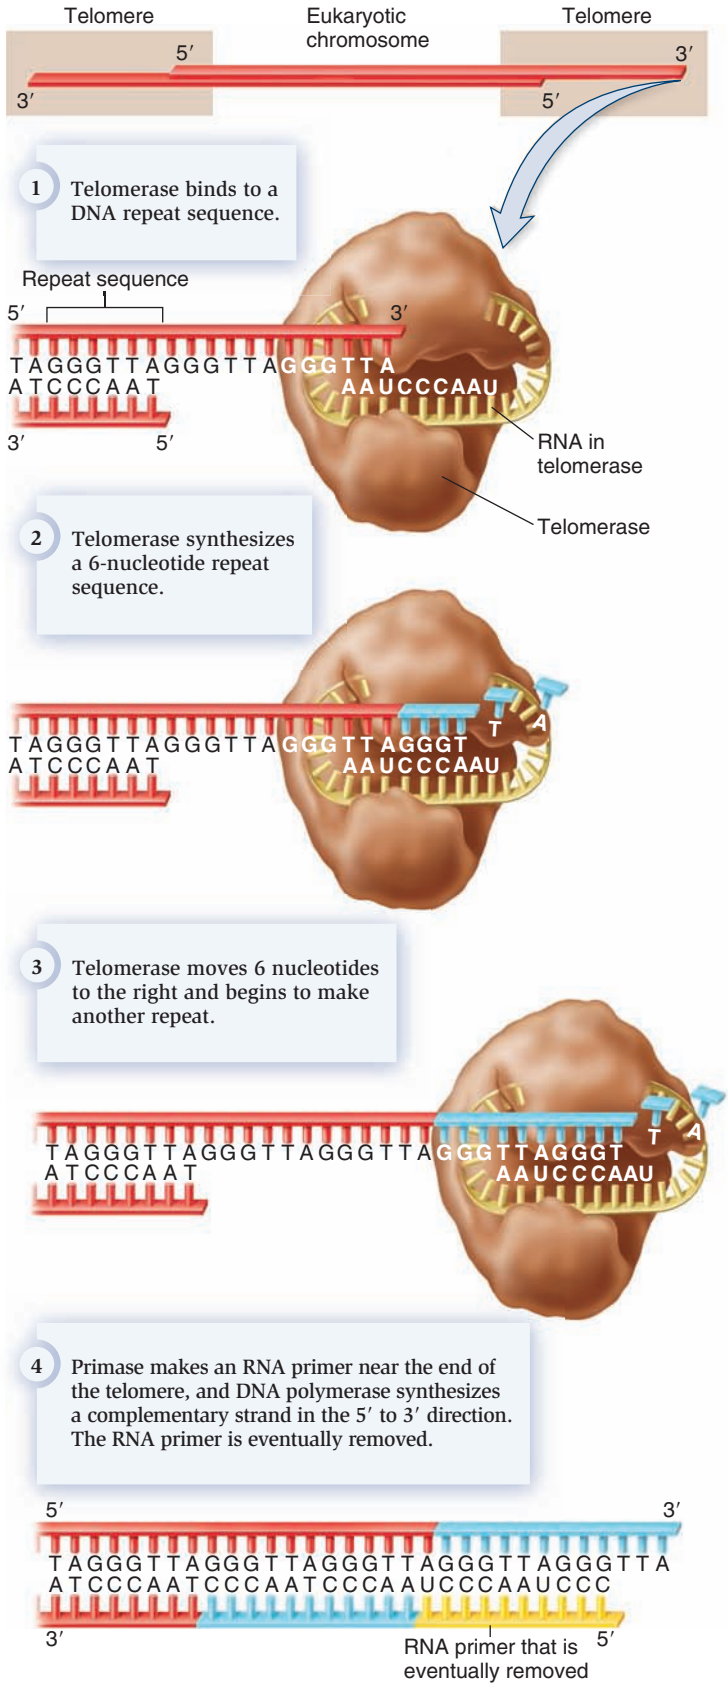

Figure 11.20 Mechanism of DNA replication by telomerase.

Concept Check: *What does telomerase use as a template to make DNA?*

Telomerase function is also associated with cancer. When cells become cancerous, they continue to divide uncontrollably. In 90% of all types of human cancers, telomerase has been found to be present at high levels in the cancer cells. This prevents telomere shortening and may play a role in the continued growth of cancer cells. The mechanism whereby cancer cells are able to increase the function of telomerase is not well understood and is a topic of active research.

Greider and Blackburn shared the 2009 Nobel Prize in Physiology or Medicine with Jack Szostak for their work on telomeres.

11.5 Molecular Structure of Eukaryotic Chromosomes

Learning Outcomes:

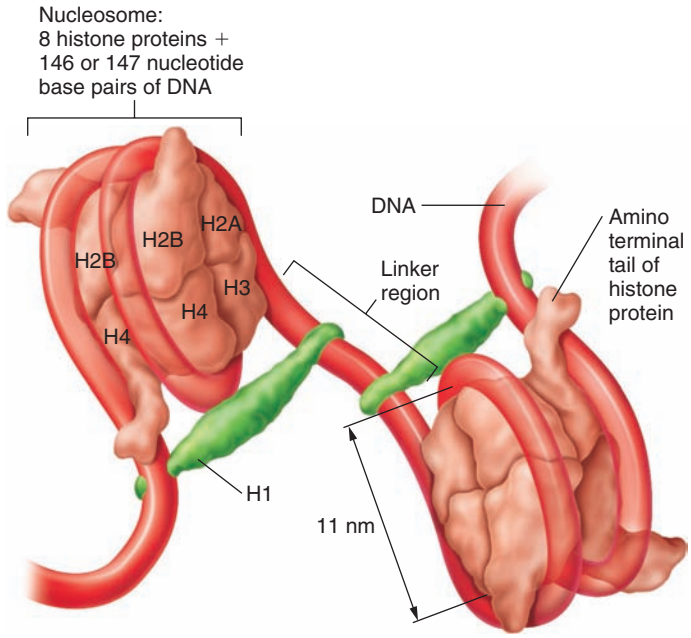
1. Describe the structure of nucleosomes and the 30-nm fiber, and explain how the 30-nm fiber forms radial loop domains.
2. Outline the various levels of compaction that lead to a metaphase chromosome.

We now turn our attention to the structure of eukaryotic chromosomes. A typical eukaryotic chromosome contains a single, linear, double-stranded DNA molecule that may be hundreds of millions of base pairs in length. If the DNA from a single set of human chromosomes was stretched end to end, the length would be over 1 meter! By comparison, most eukaryotic cells are only 10–100 μm (micrometers) in diameter, and the cell nucleus is typically about 2–4 μm in diameter. Therefore, to fit inside the nucleus, the DNA in a eukaryotic cell must be folded and compacted by a staggering amount.

The term chromosome is used to describe a discrete unit of genetic material. For example, a human somatic cell contains 46 chromosomes. By comparison, the term chromatin has a biochemical meaning. **Chromatin** is used to describe the complex of DNA and protein that makes up eukaryotic chromosomes. Chromosomes are very dynamic structures that alternate between tight and loose compaction states. In this section, we will focus on two issues of chromosome structure. First, we will consider how chromosomes are compacted and organized within the cell nucleus. Then, we will examine the additional compaction necessary to produce the highly condensed chromosomes that occur during cell division.

DNA Wraps Around Histone Proteins to Form Nucleosomes

The first way DNA is compacted is by wrapping itself around a group of proteins called **histones**. As shown in **Figure 11.21**, a repeating structural unit of eukaryotic chromatin is the **nucleosome**, which is 11 nm in diameter at its widest point. Each nucleosome is composed of 146 or 147 bp (base pairs) of DNA wrapped around an octamer of histone proteins. An octamer contains two molecules each of four types of histone proteins: H2A, H2B, H3, and H4. Histone proteins are very basic proteins because they contain a large number of the positively charged amino acids lysine and arginine. The negative charges found in the phosphates of DNA are attracted to the positive charges on histone proteins. The amino terminal tail



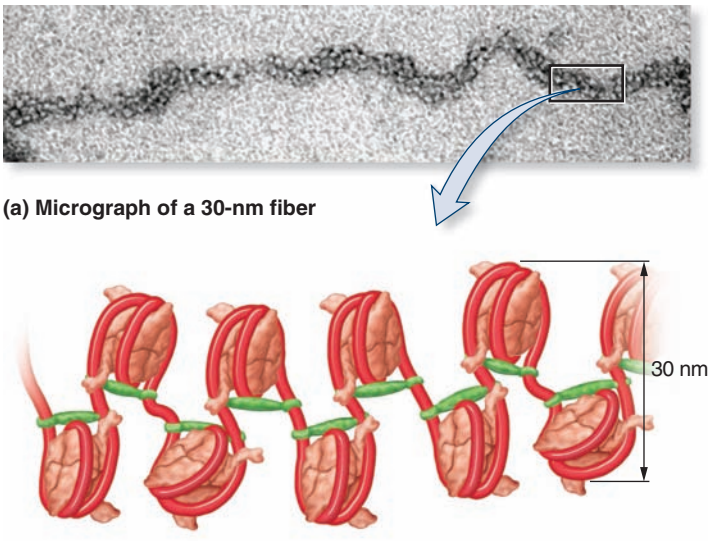


Figure 11.21 Structure of a nucleosome. A nucleosome is composed of double-stranded DNA wrapped around an octamer of histone proteins. A linker region connects two adjacent nucleosomes. Histone H1 is bound to the linker region, as are other proteins not shown in this figure.

of each histone protein protrudes from the histone octamer. As discussed in Chapter 13, these tails can be covalently modified and play a key role in gene regulation.

The nucleosomes are connected by linker regions of DNA that vary in length from 20 to 100 bp, depending on the species and cell type. A particular histone named H1 is bound to the linker region, as are other types of proteins. The overall structure of connected nucleosomes resembles beads on a string. This structure shortens the length of the DNA molecule about sevenfold.

Nucleosomes Form a 30-nm Fiber

Nucleosome units are organized into a more compact structure that is 30 nm in diameter, known as the **30-nm fiber** (**Figure 11.22a**). Histone H1 and other proteins are important in the formation of the 30-nm fiber, which shortens the nucleosome structure another sevenfold. The structure of the 30-nm fiber has proven difficult to determine because the conformation of the DNA may be substantially altered when extracted from living cells. A current model for the 30-nm fiber was proposed by Rachel Horowitz-Scherer and Christopher Woodcock in the 1990s (**Figure 11.22b**). According to their model, linker regions in the 30-nm structure are variably bent and twisted, with little direct contact between nucleosomes. The 30-nm fiber forms an asymmetric, three-dimensional zigzag of nucleosomes. At this level of compaction, the overall picture of chromatin that emerges is an irregular, fluctuating structure with stable nucleosome units connected by bendable linker regions.

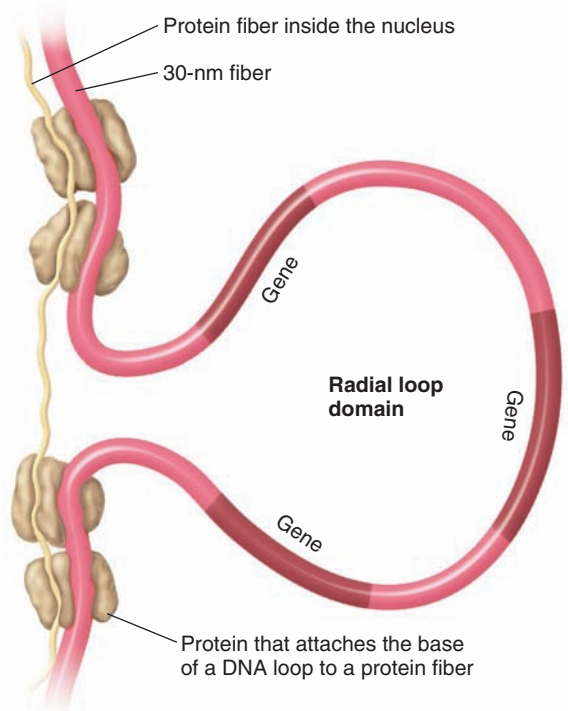

Figure 11.23 Attachment of the 30-nm fiber to a protein fiber to form a radial loop domain.

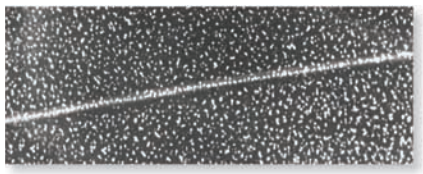
Concept Check: *What holds the bottoms of the loops in place?*

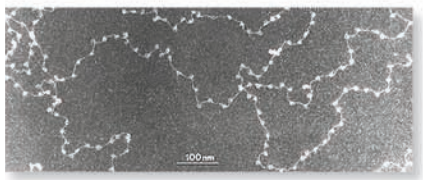
Chromatin Loops Are Anchored to the Nuclear Matrix

Thus far, we have examined two mechanisms that compact eukaryotic DNA: the formation of nucleosomes and their arrangement into a 30-nm fiber. Taken together, these two events shorten the folded DNA about 49-fold. A third level of compaction involves interactions between the 30-nm fibers and a filamentous network of proteins in the nucleus called the **nuclear matrix**. This matrix consists of the **nuclear lamina**, which is composed of protein fibers that line the inner nuclear membrane (refer back to Figure 4.15), and an internal nuclear matrix that is connected to the lamina and fills the interior of the nucleus. The internal nuclear matrix is an intricate network of irregular protein fibers plus many other proteins that bind to these fibers. The nuclear matrix is involved in the compaction of the 30-nm fiber by participating in the formation of **radial loop domains**. These loops, often containing 25,000–200,000 bp, are anchored to the nuclear matrix (**Figure 11.23**).



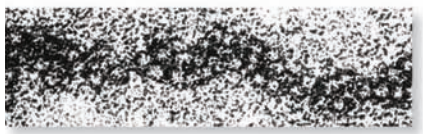
How are chromosomes organized within the cell nucleus? In nondividing cells, each chromosome occupies its own discrete region in the cell nucleus that usually does not overlap with the territory of adjacent chromosomes (refer back to Figure 4.16). In other words, different chromosomes are not substantially intertwined with each other even when they are in a noncompacted condition.

The compaction level of chromosomes in the cell nucleus is not completely uniform. This variability can be seen with a light microscope and was first observed by German cytologist Emil Heitz in 1928. He used the term **heterochromatin** to describe the highly compacted regions of chromosomes. By comparison, the less condensed regions are known as **euchromatin**. Euchromatin is the form of chromatin in which the 30-nm fiber forms radial loop domains. In heterochromatin, these radial loop domains are compacted even further. In nondividing cells, most chromosomal regions are euchromatic, and these are the regions where genes are usually located. By comparison, the centromeric and telomeric regions are often heterochromatic and may not contain genes.



During Cell Division, Chromosomes Undergo Maximum Compaction

When cells prepare to divide, the chromosomes become even more compacted or condensed. Each chromosome becomes entirely compacted into heterochromatin. This aids in their proper alignment during metaphase, which is a stage of eukaryotic cell division described in Chapter 15. **Figure 11.24** illustrates the levels of compaction that contribute to the formation of a metaphase chromosome. DNA in the nucleus is always compacted by forming nucleosomes and condensing into a 30-nm fiber (Figure 11.24a,b,c). In euchromatin, the 30-nm fibers are arranged in radial loop domains that are relatively loose, meaning that a fair amount of space is between the 30-nm fibers (Figure 11.24d). The average width of such loops is about 300 nm.



By comparison, heterochromatin involves a much tighter packing of the loops, so little space is between the 30-nm fibers (Figure 11.24e). Heterochromatic regions tend to be wider, about 700 nm. When cells prepare to divide, all of the euchromatin becomes highly compacted. The compaction of euchromatin greatly shortens the chromosomes. For a metaphase chromosome, which contains two copies of the DNA (Figure 11.24f), the width averages about 1,400 nm, but the length of a metaphase chromosome is much shorter than the same chromosome in the nucleus of a nondividing cell.

Concept Check: *After they have replicated and become compacted in preparation for cell division, chromosomes are often shaped like an X, as in part (f) of this figure. Which proteins are primarily responsible for this X shape?*

BioConnections: *Look ahead to Figure 15.8. Why do you think it is necessary for the chromosomes to become compact in preparation for cell division?*

Summary of Key Concepts

11.1 Biochemical Identification of the Genetic Material

- The genetic material carries information to produce the traits of organisms. It is accurately replicated and transmitted from cell to cell and parent to offspring. The genetic material carries differences that explain the variation among different organisms.
- Griffith's work with type S and type R bacteria indicated the existence of a genetic material, which he called the transformation principle (Figure 11.1).
- Avery, MacLeod, and McCarty used biochemical methods to show that DNA is the genetic material (Figure 11.2).

11.2 Nucleic Acid Structure

- DNA is composed of nucleotides, which are covalently linked to form DNA strands. Two DNA strands are held together by hydrogen bonds between the bases to form a double helix. DNA associates with various proteins to form a chromosome (Figure 11.3).
- Nucleotides are composed of a phosphate, a sugar, and a nitrogenous base. The sugar can be deoxyribose (DNA) or ribose (RNA). The purine bases are adenine and guanine, and the pyrimidine bases are thymine (DNA only), cytosine, and uracil (RNA only). The atoms in a nucleotide are numbered in a conventional way (Figures 11.4, 11.5).
- In a strand of DNA (or RNA), the sugars are connected by covalent bonds in a 5′ to 3′ direction (Figure 11.6).
- The X-ray diffraction data of Franklin, the biochemical data of Chargaff (that is, the amounts of A and T and those of G and C are approximately equal), and the ball-and-stick modeling of Pauling helped reveal the structure of DNA (Figure 11.7, Table 11.1).
- Watson and Crick determined that DNA is a double helix in which the DNA strands are antiparallel and obey the AT/GC rule (Figures 11.8, 11.9).

11.3 Overview of DNA Replication

- Meselson and Stahl used ^{15}N- and ^{14}N-isotope labeling methods to show that DNA is replicated by a semiconservative mechanism in which the product of DNA replication is one original strand and one new strand (Figures 11.10, 11.11).
- During DNA replication, the parental double-stranded DNA separates and each strand serves as a template for the synthesis of daughter strands. Nucleotides hydrogen-bond to the template strands according to the AT/GC rule: An adenine (A) base in one strand bonds with a thymine (T) base in the opposite strand, or a guanine (G) base bonds with a cytosine. The result of DNA replication is two double helices with the same base sequence as the original DNA (Figure 11.12).

11.4 Molecular Mechanism of DNA Replication

- DNA synthesis occurs bidirectionally from an origin of replication. The synthesis of new DNA strands happens near each replication fork (Figure 11.13).
- DNA helicase separates DNA strands, single-strand binding proteins keep them separated, and DNA topoisomerase alleviates coiling ahead of the fork (Figure 11.14).
- Deoxynucleoside triphosphates bind to the template strands according to the AT/GC rule. DNA polymerase recognizes these deoxynucleoside triphosphates and attaches a deoxynucleoside monophosphate to the 3′ end of a growing strand (Figure 11.15).
- DNA polymerase requires a primer and synthesizes new DNA strands only in the 5′ to 3′ direction (Figure 11.16).
- The leading strand is made continuously, in the same direction the fork is moving. The lagging strand is made in the opposite direction as short Okazaki fragments that are synthesized and connected together (Figure 11.17).
- DNA primase makes one RNA primer in the leading strand and multiple RNA primers in the lagging strand. In *E. coli*, DNA polymerase III extends these primers with DNA, and DNA polymerase I removes the primers when they are no longer needed and fills in with DNA. DNA ligase connects adjacent Okazaki fragments in the lagging strand (Figure 11.18, Table 11.2).
- DNA replication is very accurate because (1) hydrogen bonding according to the AT/CG rule is more stable; (2) DNA polymerase is unlikely to catalyze bond formation if a mismatched base pair is formed; and (3) DNA polymerase carries out proofreading.
- Living organisms have several different types of DNA polymerases with specialized functions (Table 11.3).
- The ends of linear, eukaryotic chromosomes have telomeres composed of repeat sequences. Telomerase binds to the telomere repeat sequence and synthesizes a 6-nucleotide repeat. This happens many times in a row to lengthen one DNA strand of the telomere. DNA primase, DNA polymerase, and DNA ligase are needed to synthesize the complementary DNA strand (Figures 11.19, 11.20).

11.5 Molecular Structure of Eukaryotic Chromosomes

- Chromosomes are structures in living cells that carry the genetic material. Chromatin is the name given to the complex of DNA and protein that makes up chromosomes.
- In eukaryotic chromosomes, the DNA is wrapped around histone proteins to form nucleosomes. Nucleosomes are further compacted into 30-nm fibers. The linker regions are variably twisted and bent into a zigzag pattern (Figures 11.21, 11.22).
- A third level of compaction of eukaryotic chromosomes involves the formation of radial loop domains in which the bases of 30-nm fibers are anchored to a network of proteins called the nuclear matrix. This level of compaction is called euchromatin. In heterochromatin, the loops are even more closely packed together (Figure 11.23).
- During cell division, chromosomes become entirely heterochromatic (Figure 11.24).

Assess and Discuss

Test Yourself

1. Why did researchers initially believe the genetic material was protein?
   a. Proteins are more biochemically complex than DNA.
   b. Proteins are found only in the nucleus, but DNA is found in many areas of the cell.
   c. Proteins are much larger molecules and can store more information than DNA.
   d. all of the above
   e. both a and c
2. Considering the components of a nucleotide, what component is always different when comparing nucleotides in a DNA strand and in an RNA strand?
   a. phosphate group
   b. pentose sugar
   c. nitrogenous base
   d. both b and c
   e. a, b, and c
3. Which of the following equations is appropriate when considering DNA base composition?
   a. %A + %T = %G + %C
   b. %A = %G
   c. %A = %G = %T = %C
   d. %A + %G = %T + %C
4. If the sequence of a segment of DNA is 5′–CGCAACTAC–3′, what is the appropriate sequence for the opposite strand?
   a. 5′–GCGTTGATG–3′
   b. 3′–ATACCAGCA–5′
   c. 5′–ATACCAGCA–3′
   d. 3′–GCGTTGATG–5′
5. Of the following statements, which is correct when considering the process of DNA replication?
   a. New DNA molecules are composed of two completely new strands.
   b. New DNA molecules are composed of one strand from the old molecule and one new strand.
   c. New DNA molecules are composed of strands that are a mixture of sections from the old molecule and sections that are new.
   d. none of the above
6. Meselson and Stahl were able to demonstrate semiconservative replication in *E. coli* by
   a. using radioactive isotopes of phosphorus to label the old strand and visually determining the relationship of old and new DNA strands.
   b. using different enzymes to eliminate old strands from DNA.
   c. using isotopes of nitrogen to label the DNA and determining the relationship of old and new DNA strands by density differences of the new molecules.
   d. labeling viral DNA before it was incorporated into a bacterial cell and visually determining the location of the DNA after centrifugation.
7. During replication of a DNA molecule, the daughter strands are not produced in exactly the same manner. One strand, the leading strand, is made toward the replication fork, while the lagging strand is made in fragments in the opposite direction. This difference in the synthesis of the two strands is the result of which of the following?
   a. DNA polymerase is not fast enough to make two leading strands of DNA.
   b. The two template strands are antiparallel, and DNA polymerase makes DNA only in the 5′ to 3′ direction.
   c. The lagging strand is the result of DNA breakage due to UV light.
   d. The cell does not contain enough nucleotides to make two complete strands.
8. In eukaryotic cells, chromosomes consist of
   a. DNA and RNA.
   b. DNA only.
   c. RNA and proteins.
   d. DNA and proteins.
   e. RNA only.
9. A nucleosome is
   a. a dark-staining body composed of RNA and proteins found in the nucleus.
   b. a protein that helps organize the structure of chromosomes.
   c. another word for a chromosome.
   d. a structure composed of DNA wrapped around eight histones.
   e. the short arm of a chromosome.
10. The conversion of euchromatin into heterochromatin involves
    a. the formation of more nucleosomes.
    b. the formation of less nucleosomes.
    c. a greater compaction of loop domains.
    d. a lesser compaction of loop domains.
    e. both a and c.

Conceptual Questions

1. What are the four key criteria that the genetic material must fulfill? What was Griffith's contribution to the study of DNA, and why was it so important?
2. A double-stranded DNA molecule contains 560 nucleotides. How many complete turns occur in this double helix?
3.  A principle of biology is that *structure determines function*. Discuss how the structure of DNA underlies different aspects of its function.

Collaborative Questions

1. **SciSKILLS** » A trait that some bacterial strains exhibit is resistance to killing by antibiotics. For example, certain strains of bacteria are resistant to the drug tetracycline, whereas other strains are sensitive to this antibiotic. Describe an experiment you would carry out to demonstrate that tetracycline resistance is an inherited trait carried in the DNA of the resistant strain.
2. **SciSKILLS** » How might you provide evidence that DNA is the genetic material in mice?

An electron micrograph of many ribosomes in the act of translating an mRNA into polypeptides. This is a colorized electron micrograph of ribosomes attached to a bacterial mRNA and synthesizing polypeptides. Ribosomes are blue, mRNA is red, and emerging polypeptides are green. The complex of one mRNA and many ribosomes is called a polysome.

Mina, age 21, works part-time in an ice-cream shop and particularly enjoys the double-dark chocolate and chocolate fudge brownie flavors on her breaks. She exercises little and spends most of her time studying or watching television. Mina is effortlessly thin. She never worries about what or how much she eats. By comparison, her close friend, Rezzy, has struggled with her weight as long as she can remember. Compared with Mina, she feels like she must constantly deprive herself of food just to maintain her current weight—a weight she would describe as 30 pounds too much.

How do we explain the differences between Mina and Rezzy? Two fundamental factors are involved. Our weight is strongly influenced by the environment, especially our diet, as well as by social and behavioral factors. The amount and types of food we eat are correlated with weight gain. However, there is little doubt that our weight is also influenced by variation in our genes. Obesity, the condition of having too much body fat, runs in families. The degree of obesity is often similar between genetically identical twins who have been raised apart. Why has genetic variation resulted in some genes that cause certain people to gain weight? A popular hypothesis is that some people have inherited "thrifty genes" as hand-me-downs from their ancestors, who periodically faced famines and food scarcity. Such thrifty genes would be advantageous in allowing people to store body fat more easily and to use food resources more efficiently when times are lean. The negative side is that when food is abundant, unwanted weight gain—and associated diseases such as diabetes and heart disease—can constitute a serious health problem.

Why do we care about our genes? Let's consider this question with regard to obesity. Researchers have identified several key genes that influence a person's predisposition to becoming obese. Dozens more are likely to play a minor role. By identifying those genes and studying the proteins specified by them, researchers gain a better understanding of how genetic variation causes certain people to gain weight more easily than others. In addition, this knowledge has led to the development of drugs that are used to combat obesity.

We can broadly define a gene as a unit of heredity. Geneticists view gene function at different biological levels. In Chapter 16, we will examine how genes affect the traits or characteristics of individuals. For example, we will consider how the transmission of genes from parents to offspring affects the color of the offspring's eyes and their likelihood of becoming color blind. In this chapter, we will explore how genes work at the molecular level. You will learn how DNA sequences are organized to form genes and how those genes are used as a template to make RNA copies, ultimately leading to the synthesis of a functional protein. The term **gene expression** can refer to gene function either at the level of traits or at the molecular level. In reality, the two phenomena are intricately woven together. The expression of genes at the molecular level affects the structure and function of cells, which, in turn, determine the traits that an organism expresses.

We begin this chapter by considering how researchers came to realize that most genes store the information to make proteins. We then explore the steps of gene expression as they occur at the molecular level. These steps include the use of a gene as a template to make an RNA molecule, the modification of the RNA into a functional molecule (in eukaryotes), and the use of RNA to direct the formation of a protein.

12.1 Overview of Gene Expression

Learning Outcomes:

1. **SciSKILLS** » Analyze the results of the experiments of Garrod and of Beadle and Tatum.
2. Outline the general steps of gene expression at the molecular level, which together constitute the central dogma.
3. Explain how proteins are largely responsible for determining an organism's characteristics.

Even before DNA was discovered to be the genetic material, scientists had asked, "How does the functioning of genes produce the traits of living organisms?" At the molecular level, a similar question can be asked: "How do genes affect the composition and/or function of molecules found within living cells?" An approach that was successful in answering these questions involved the study of **mutations**, which are changes in the genetic material that can be inherited. Mutations may affect the genetic blueprint by altering gene function. For this reason, research that focused on the effects of mutations proved instrumental in determining the molecular function of genes.

In this section, we will consider two early experiments in which researchers studied the effects of mutations in humans and in a bread mold. Both studies led to the conclusion that the role of some genes is to carry the information to produce enzymes, which are a type of protein. Then we will examine the general features of gene expression at the molecular level.

The Study of Inborn Errors of Metabolism Suggested That Some Genes Carry the Information to Make Enzymes

In 1908, Archibald Garrod, a British physician, proposed a relationship between genes and the production of enzymes. Prior to his work, biochemists had studied many metabolic pathways that consist of a series of conversions of one molecule to another, each step catalyzed by an enzyme. **Figure 12.1** illustrates part of the metabolic pathway for the breakdown of phenylalanine, an amino acid commonly found in human diets. The enzyme phenylalanine hydroxylase catalyzes the conversion of phenylalanine to tyrosine, another amino acid. A different enzyme, tyrosine aminotransferase, converts tyrosine into the next molecule, called *p*-hydroxyphenylpyruvic acid. In each case, a specific enzyme catalyzes a single chemical reaction.

Much of Garrod's early work centered on the inherited disease alkaptonuria, in which the patient's body accumulates abnormal levels of homogentisic acid (also called alkapton). This compound, which is bluish black, results in discoloration of the skin and cartilage and causes the urine to appear black. Garrod hypothesized that the accumulation of homogentisic acid in these patients is due to a defect in an enzyme, namely, homogentisic acid oxidase (see Figure 12.1). Furthermore, he already knew that alkaptonuria is an inherited condition that follows a recessive pattern of inheritance. As discussed in Chapter 16, if a disorder is recessive, an individual with the disease has inherited the mutant (defective) gene that causes the disorder from both parents.

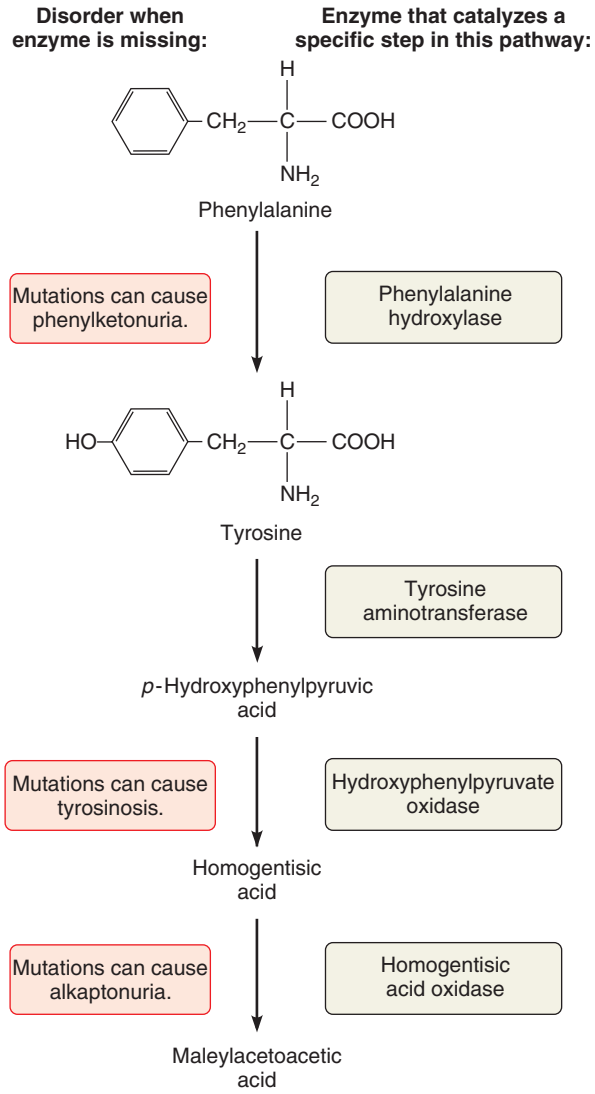

Figure 12.1 The metabolic pathway that breaks down phenylalanine and its relationship to certain genetic diseases. Each step in the pathway is catalyzed by a different enzyme, shown in the boxes on the right. If one of the enzymes is not functioning, the previous compound builds up, causing the disorders named in the boxes on the left.

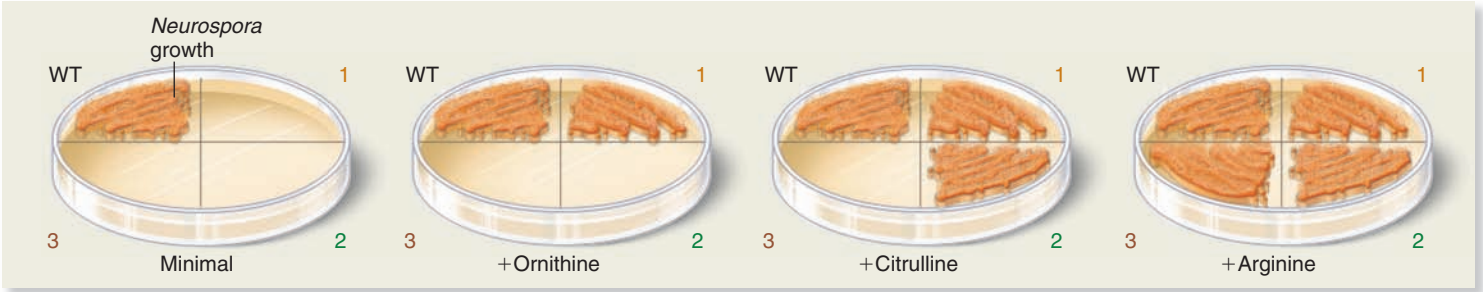
Concept Check: What disease would occur if a person inherited two defective copies of the gene that encodes phenylalanine hydroxylase?

How did Garrod explain these observations? In 1908, he proposed a relationship between the inheritance of a mutant gene and a defect in metabolism. In the case of alkaptonuria, if an individual inherited the mutant gene from both parents, she or he would not produce any normal enzyme and would be unable to metabolize homogentisic acid. Garrod described alkaptonuria as an **inborn error of metabolism**. An inborn error refers to a mutation in a gene that is inherited from

one or both parents. At the turn of the last century, this was a particularly insightful idea because the structure and function of the genetic material were completely unknown.

Beadle and Tatum Proposed the One-Gene/One-Enzyme Hypothesis

In early 1940s, American geneticists George Beadle and Edward Tatum became aware of Garrod's work and were interested in the relationship between genes and enzymes. They focused their studies on *Neurospora crassa*, a common bread mold. *Neurospora* is easily grown in the laboratory and has only a few nutritional requirements: a carbon source (namely, sugar), inorganic salts, and one vitamin known as biotin. Otherwise, *Neurospora* has many different enzymes that synthesize the molecules, such as amino acids and vitamins, which are essential for growth.



Like Garrod, Beadle and Tatum hypothesized that genes carry the information to make specific enzymes. They reasoned that a mutation, or change in a gene, might cause a defect in an enzyme required for the synthesis of an essential molecule, such as a vitamin. A mutant *Neurospora* strain (one that carries such a mutation) would be unable to grow unless the vitamin was supplemented in the growth medium. Strains without a mutation are called wild-type. In their original study of 1941, Beadle and Tatum exposed *Neurospora* cells to X-rays, which caused mutations to occur, and studied the resulting cells. By plating the cells on growth media with or without vitamins, they were able to identify mutant strains that required vitamins for growth. In each case, a single mutation resulted in the requirement for a single type of vitamin in the growth media.

This early study by Beadle and Tatum led them to additional research and further investigations by others to study enzymes involved in the synthesis of other substances, including the amino acid arginine. At that time, the pathway leading to arginine synthesis was known to involve certain precursor molecules, including ornithine and citrulline. A simplified pathway for arginine synthesis is shown in **Figure 12.2a**. Each step is catalyzed by a different enzyme.

Researchers first isolated several different mutants that required arginine for growth. They hypothesized that each mutant strain might be blocked at only a single step in the consecutive series of reactions that lead to arginine synthesis. To test this hypothesis, the mutant strains were examined for their ability to grow in the presence of ornithine, citrulline, or arginine (**Figure 12.2b**). The wild-type strain could grow on minimal growth media that did not contain ornithine, citrulline, or arginine. Based on their growth properties, the mutant strains that had been originally identified as requiring arginine for growth could be placed into three groups, designated 1, 2, and 3. Group 1 mutants were missing enzyme 1, needed for the conversion of a precursor molecule into ornithine. They could grow only if ornithine, citrulline, or arginine was added to the growth medium. Group 2 mutants were missing the second enzyme in this pathway that is needed for the conversion of ornithine into citrulline. The group 2 mutants would not grow if only ornithine was added, but could grow if citrulline or arginine was added. Finally, the group 3 mutants were missing the enzyme needed for the conversion of citrulline into arginine. These mutants could grow only if arginine was added. How were these results interpreted? The researchers were

(a) Simplified pathway for arginine synthesis

(b) Growth of strains on minimal and supplemented growth media

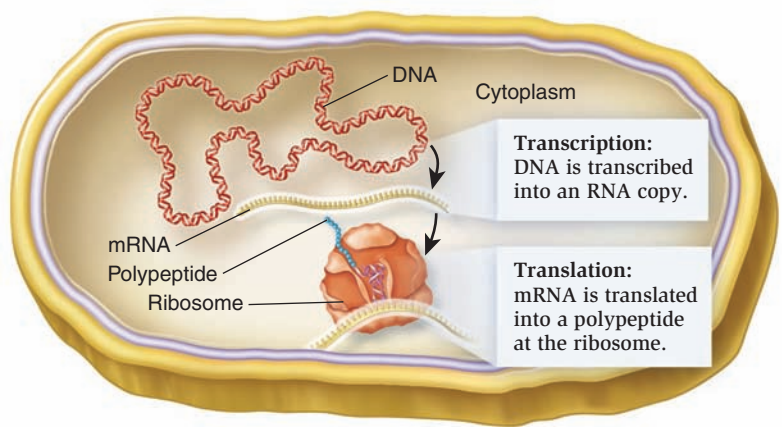
Figure 12.2 An experiment that supported Beadle and Tatum's one-gene/one-enzyme hypothesis. **(a)** This simplified metabolic pathway shows three enzymes that are required for arginine synthesis. **(b)** Growth of wild-type (WT) and mutant *Neurospora* strains (groups 1, 2, and 3) on minimal growth medium or in the presence of ornithine, citrulline, or arginine.

Concept Check: **SciSKILLS** » *What type of enzyme function is missing in group 2 mutants?*

able to order the functions of the genes involved in arginine synthesis in the following way:

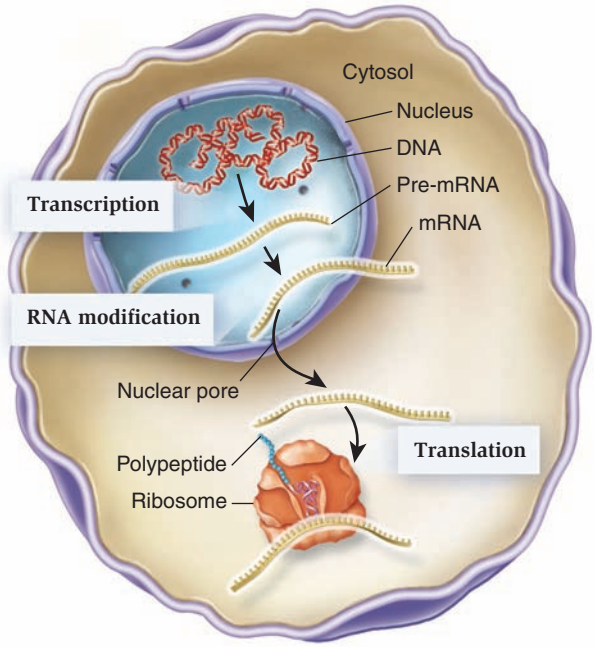
From these results and earlier studies, Beadle and Tatum concluded that a single gene controlled the synthesis of a single enzyme. This was referred to as the **one-gene/one-enzyme hypothesis**. Beadle and Tatum received the 1958 Nobel Prize in Physiology or Medicine for their work on the role of genes in metabolism.

In later decades, this idea was modified in four ways.



1. The information to make all proteins is contained within genes, and many proteins do not function as enzymes.
2. Some proteins are composed of two or more different polypeptides. The term **polypeptide** refers to a linear sequence of amino acids; it denotes structure. Most genes carry the information to make a particular polypeptide. By comparison, the term **protein** denotes function. Some proteins are composed of one polypeptide. In such cases, a single gene does contain the information to make a single protein. In other cases, however, a functional protein is composed of two or more different polypeptides. An example is hemoglobin—the protein that carries oxygen in red blood cells—which is composed of two α-globin and two β-globin polypeptides. In this case, the expression of two genes (that is, the α-globin and β-globin genes) is needed to produce a functional protein.
3. As described in Chapter 13, some mRNAs (messenger RNAs) are spliced in alternative ways so they produce two or more polypeptides. This allows a single gene to encode more than one polypeptide.
4. A fourth modification to the one-gene/one-enzyme hypothesis is that some genes encode RNAs that are not used to make polypeptides. For example, some genes encode RNA molecules that form part of the structure of ribosomes.

Because of these additional complexities, the one-gene/one-enzyme hypothesis was modified as the functions of genes became better understood.



Molecular Gene Expression Involves the Processes of Transcription and Translation

Let's now examine the general steps of gene expression at the molecular level. The first step, known as **transcription**, produces an RNA copy of a gene, also called an RNA transcript (**Figure 12.3**). The term transcription literally means the act of making a copy. Most genes, which are termed **structural genes**,* produce an RNA molecule that contains the information to specify a polypeptide with a particular amino acid sequence. This type of RNA is called **messenger RNA** (abbreviated **mRNA**), because its function is to carry information from the DNA to cellular components called ribosomes. As discussed later, ribosomes play a key role in the synthesis of polypeptides. The process of synthesizing a specific polypeptide on a ribosome is called **translation**. The term translation is used because a nucleotide sequence in mRNA is "translated" into an amino acid sequence of a polypeptide.

Together, the transcription of DNA into mRNA and the translation of mRNA into a polypeptide constitute the **central dogma** of gene expression at the molecular level, which was first proposed by Francis Crick in 1958 (see Figure 12.3). The central dogma applies equally to bacteria, archaea, and eukaryotes. However, in eukaryotes, an additional step occurs between transcription and translation.

(a) Molecular gene expression in bacteria

(b) Molecular gene expression in eukaryotes

Figure 12.3 The central dogma of gene expression at the molecular level. **(a)** In bacteria, transcription and translation occur in the cytoplasm. **(b)** In eukaryotes, transcription and RNA modification occur in the nucleus, whereas translation takes place in the cytosol.

Concept Check: *What is the direction of flow of genetic information?*

*Geneticists commonly use the term structural gene to describe all genes that encode polypeptides, which is how it is used in this textbook. Some geneticists, however, distinguish structural genes from regulatory genes—genes that encode proteins regulating the expression of structural genes.

During **RNA modification**, which is described later in this chapter, the RNA transcript, termed **pre-mRNA**, is modified in ways that make it a functionally active mRNA (Figure 12.3b).

Another difference between bacteria and eukaryotes is the cellular location of transcription and translation. In bacteria, both events occur in the same location, namely, the cytoplasm. In eukaryotes, transcription occurs in the nucleus. The mRNA then exits the nucleus through a nuclear pore, and translation occurs in the cytosol.

Though the direction of information flow, that is, from DNA to RNA to protein, is the most common pathway, exceptions do occur. For example, certain viruses use RNA as a template to synthesize DNA. Such viruses are described in Chapter 18.

The Protein Products of Genes Largely Determine an Organism's Characteristics

The genes that constitute the genetic material provide a blueprint for the characteristics of every organism. They contain the information necessary to produce an organism and allow it to favorably interact with its environment. Each structural gene stores the information for the production of a polypeptide, which then becomes a unit within a functional protein. The activities of proteins determine the structure and function of cells. Furthermore, the characteristics of an organism are rooted in the activities of cellular proteins.

The main purpose of the genetic material is to encode the production of proteins in the correct cell, at the proper time, and in suitable amounts. This is an intricate task, because living cells make thousands of different kinds of proteins. Genetic analyses have shown that a typical bacterium can make a few thousand different proteins, and estimates for eukaryotes range from several thousand in simpler eukaryotes to tens of thousands in more complex eukaryotes like humans.

12.2 Transcription

Learning Outcomes:

1. Give a molecular definition of the term gene.
2. Outline the three stages of transcription and the role of RNA polymerase in this process.
3. Explain how genes within the same chromosome vary in their direction of transcription.
4. Compare and contrast transcription in bacteria and eukaryotes.

DNA is an information storage unit. For genes to be expressed, the information in them must be accessed at the molecular level. Rather than accessing the information directly, however, a working copy of the DNA, composed of RNA, is made. This occurs by the process of transcription, in which a DNA sequence is copied into an RNA sequence. Importantly, transcription does not permanently alter the structure of DNA. Therefore, the same DNA can continue to store information even after an RNA copy has been made. In this section, we will examine the steps necessary for genes to act as transcriptional units. We will also consider some differences in these steps between bacteria and eukaryotes.

At the Molecular Level, a Gene Is Transcribed and Produces a Functional Product

What is a gene? At the molecular level, a **gene** is defined in the following way:

> *A gene is an organized unit of DNA sequences that enables a segment of DNA to be transcribed into RNA and ultimately results in the formation of a functional product.*

When a structural gene is transcribed, an mRNA is made that specifies the amino acid sequence of a polypeptide. After it is made, the polypeptide becomes a functional product. The mRNA is an intermediary in polypeptide synthesis. Among all species, most genes are structural genes. However, for some genes, the functional product is the RNA itself. The RNA from a nonstructural gene is never translated. Two important products of nonstructural genes are transfer RNA and ribosomal RNA. **Transfer RNA (tRNA)** translates the language of mRNA into that of amino acids. **Ribosomal RNA (rRNA)** forms part of ribosomes, which provide the site where translation occurs. We'll learn more about these two types of RNA later in this chapter.

A gene is composed of specific base sequences organized in a way that allows the DNA to be transcribed into RNA. **Figure 12.4** shows the general organization of sequences in a structural gene. The **promoter** is a sequence of DNA that controls when and where transcription will begin. By comparison, the **terminator** specifies the end of transcription. Therefore, transcription occurs between these two boundaries. As shown in Figure 12.4, the DNA is transcribed into mRNA from the end

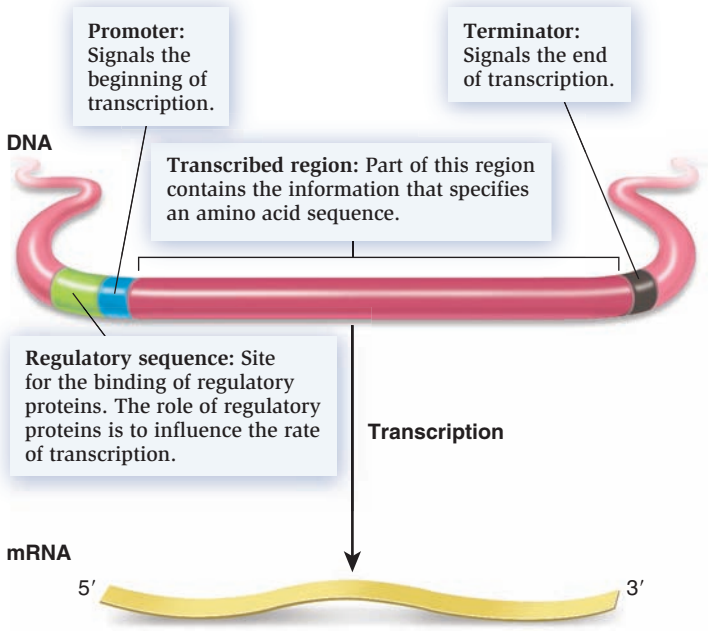


Figure 12.4 A structural gene as a transcriptional unit.

BIOLOGY PRINCIPLE The genetic material provides a blueprint for reproduction. Transcription is the first step in accessing the information that is stored in DNA.

Concept Check: How would removing a terminator from a gene affect transcription? Where would transcription end?

of the promoter through the coding sequence to the terminator. Within this transcribed region is the information that will specify the amino acid sequence of a polypeptide when the mRNA is translated.

Other DNA sequences are involved in the regulation of transcription. These **regulatory sequences** function as sites for the binding of regulatory proteins, which are discussed in Chapter 13. When a regulatory protein binds to a regulatory sequence, the rate of transcription is affected. Some regulatory proteins enhance the rate of transcription, whereas others inhibit it.

During Transcription, RNA Polymerase Uses a DNA Template to Make RNA

Transcription occurs in three stages, called initiation, elongation, and termination, during which various proteins interact with DNA sequences (**Figure 12.5**).

Initiation The stage called **initiation** is a recognition step. In bacteria such as *E. coli*, a protein called **sigma factor** binds to **RNA polymerase**, the enzyme that synthesizes strands of RNA. Sigma factor also recognizes the base sequence of a promoter and binds there. An example of a promoter sequence is described in the legend to Figure 12.5. The role of sigma factor is to cause RNA polymerase to bind to the promoter. The initiation stage is completed when the DNA strands are separated near the promoter to form an **open complex** that is approximately 10–15 bp long.

Elongation During **elongation**, RNA polymerase synthesizes the RNA transcript. For this to occur, sigma factor is released and RNA polymerase slides along the DNA in a way that maintains an open complex as it goes. The DNA strand that is used as a template for RNA synthesis is called the **template strand**. For structural genes, the opposite DNA strand is called the **coding strand**. The coding strand has the same sequence of bases as the resulting mRNA, except that the RNA has uracil instead of the thymine found in the DNA. The coding strand is so named because, like mRNA, it carries the information that codes for a polypeptide.

During the elongation stage of transcription, nucleotides bind to the template strand and are covalently connected in the 5′ to 3′

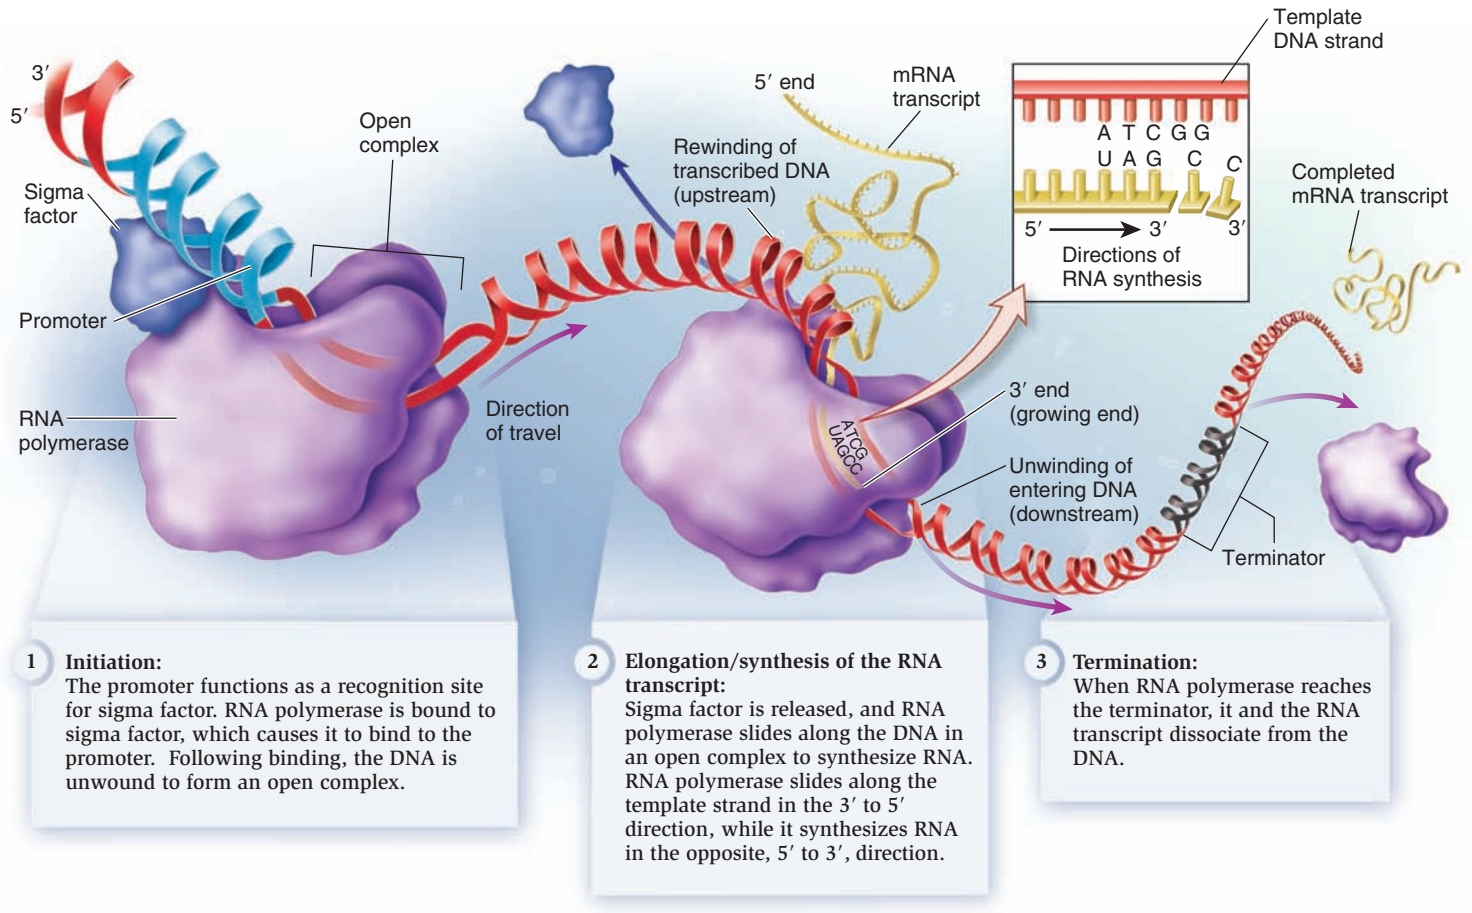

Figure 12.5 Stages of transcription. Transcription can be divided into initiation, elongation, and termination. The inset emphasizes the direction of RNA synthesis and base pairing between the DNA template strand and RNA. An example of a promoter sequence in *E. coli* is:

5′-TTGACATGATAGAAGCACTCTACTATATT-3′

3′-AACTGTACTATCTTCGTGAGATGATATAA-5′

This region is 29 bp long, and it immediately precedes the site where transcription begins. The bases that are specifically recognized by sigma factor are shown in red. The sequences of promoters for different genes are fairly diverse, particularly in eukaryotic species.

BioConnections: Look back at DNA polymerase described in Figure 11.15. What are similarities and differences between the function of DNA polymerase and that of RNA polymerase?

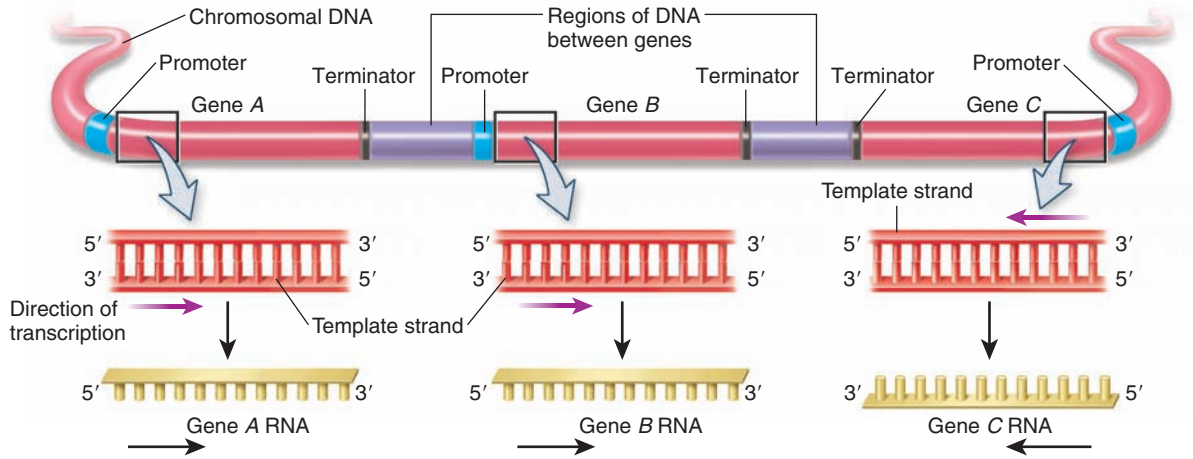

Figure 12.6 The transcription of three different genes found in the same chromosome. RNA polymerase synthesizes each RNA transcript in a 5′ to 3′ direction, sliding along a DNA template strand in a 3′ to 5′ direction. However, the use of the template strand can vary from gene to gene. For example, genes *A* and *B* use the bottom strand, while gene *C* uses the top strand.

direction (see inset of step 2, Figure 12.5). The complementarity rule used in this process is similar to the AT/GC rule of DNA replication, except that uracil (U) in RNA substitutes for thymine (T) in DNA. For example, a DNA template with a sequence of 3′–TACAATGTAGCC–5′ will be transcribed into an RNA sequence reading 5′–AUGUUACAUCGG–3′. In bacteria, the rate of RNA synthesis is about 40 nucleotides per second! Behind the open complex, the DNA rewinds back into a double helix.

Termination Eventually, RNA polymerase reaches a terminator, which causes it and the newly made RNA transcript to dissociate from the DNA. This event constitutes the **termination** of transcription.

When considering the transcription of multiple genes within a chromosome, the DNA strand that is used as the template strand varies among different genes. **Figure 12.6** shows three genes adjacent to each other within a chromosome. Genes *A* and *B* are transcribed from left to right, using the bottom DNA strand as the template strand. By comparison, gene *C* is transcribed from right to left, using the top DNA strand as a template strand. In all three cases, however, the synthesis of the RNA transcript begins at a promoter and always occurs in a 5′ to 3′ direction. The template strand is read in the 3′ to 5′ direction.

Transcription in Eukaryotes Involves More Proteins

The basic features of transcription are similar among all organisms. The genes of all species have promoters, and the transcription process occurs in the stages of initiation, elongation, and termination. However, the transcription of eukaryotic genes tends to involve a greater complexity of protein components than does the transcription of bacterial genes. For example, three forms of RNA polymerase, designated I, II, and III, are found in eukaryotes. RNA polymerase II is responsible for transcribing the mRNA from eukaryotic structural genes, whereas RNA polymerases I and III transcribe nonstructural genes such as the genes that encode tRNAs and rRNAs. By comparison, bacteria have a single type of RNA polymerase that transcribes all genes, though many bacterial species have more than one type of sigma factor that can recognize different promoters.

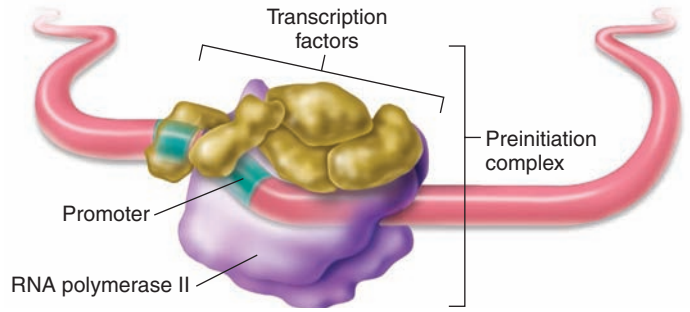

Figure 12.7 The preinitiation complex. Transcription factors and RNA polymerase II assemble into the preinitiation complex at the promoter in eukaryotic structural genes.

The initiation stage of transcription in eukaryotes is also more complex. Recall that in bacteria such as *E. coli*, sigma factor recognizes the promoter of genes. By comparison, RNA polymerase II of eukaryotes always requires five general transcription factors to initiate transcription. **Transcription factors** are proteins that influence the ability of RNA polymerase to transcribe genes. The binding of RNA polymerase II to the promoter is an assembly process in which RNA polymerase II and the five transcripiton factors form a **preinitiation complex** (**Figure 12.7**). The complex then unwinds the DNA to initiate transcription.

12.3 RNA Modification in Eukaryotes

Learning Outcomes:

1. Describe the addition of the 5′ cap and 3′ poly A tail to eukaryotic mRNA.
2. Explain the process of splicing that produces mature eukaryotic mRNA.

As noted previously, eukaryotic mRNA transcripts undergo modifications to produce functional mRNA. Transcription initially produces a longer RNA, called **pre-mRNA**, which undergoes certain

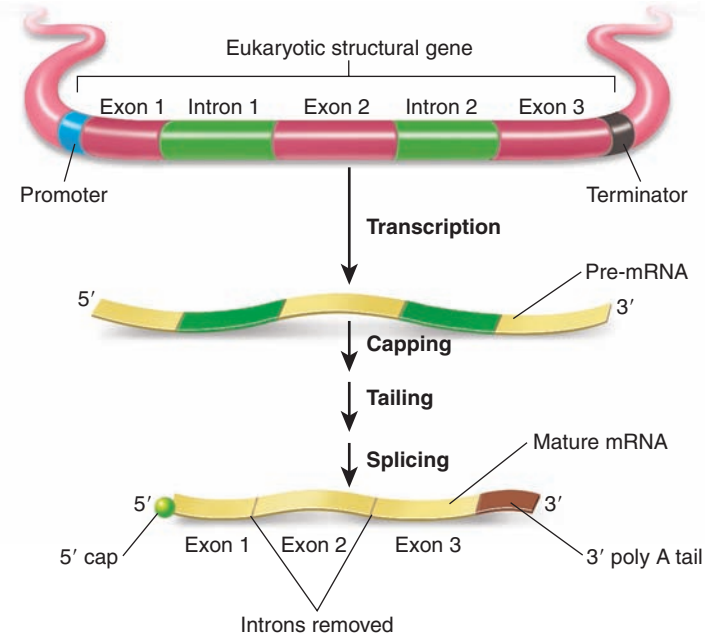

Figure 12.8 Modifications to eukaryotic pre-mRNA that are needed to produce a mature mRNA molecule. Note: Most RNA molecules are spliced after the pre-mRNA is completely synthesized. However, for some of them, splicing may begin before transcription of the pre-mRNA is completed.

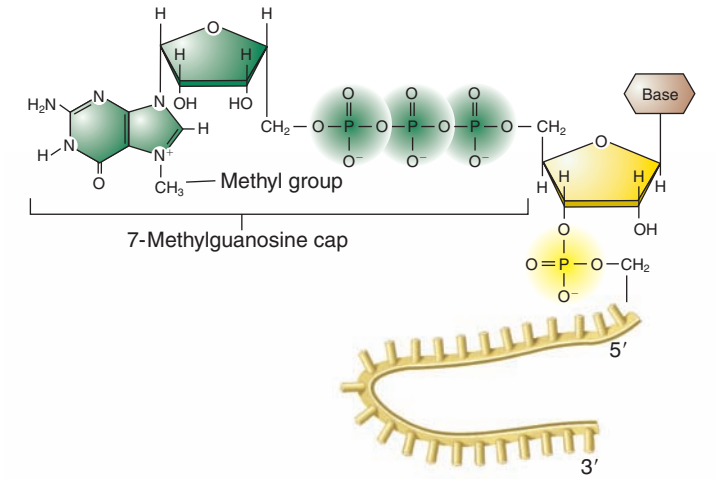
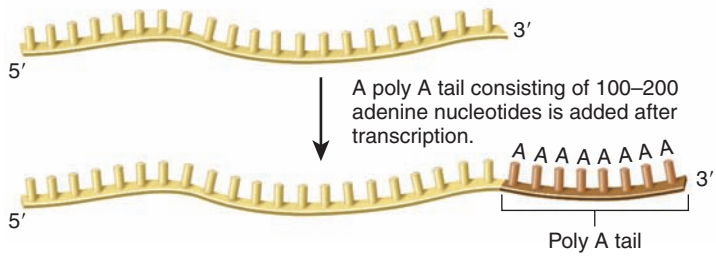


modifications before it exits the nucleus. The final product is called a **mature mRNA**, or simply mRNA (**Figure 12.8**).

In the late 1970s, when the experimental tools became available to study eukaryotic genes at the molecular level, the scientific community was astonished by the discovery that the coding sequences within many eukaryotic structural genes are separated by DNA sequences that are transcribed but not translated into protein. These intervening sequences that are not translated are called **introns**, whereas sequences contained in the mature mRNA are termed **exons**. Exons are expressed regions, whereas introns are intervening regions that are not expressed because they are removed from the pre-mRNA.



To become a functional mRNA, the pre-mRNA undergoes a process known as **RNA splicing**, or simply splicing, in which introns are removed and the remaining exons are connected to each other (see Figure 12.8). In addition to splicing, eukaryotic pre-mRNA transcripts are modified in other ways, including the addition of caps and tails to their ends. After these modifications have been completed, the mRNA leaves the nucleus and enters the cytosol, where translation occurs. In this section, we will examine the molecular mechanisms that account for RNA modifications and consider why they are functionally important.

RNA Modification Involves the Addition of a 5′ Cap and a 3′ Poly A Tail to Eukaryotic mRNAs

Mature mRNAs of eukaryotes have a modified form of guanine covalently attached at the 5′ end, an event known as **capping** (**Figure 12.9a**). Capping occurs while a pre-mRNA is being made by RNA polymerase, usually when the transcript is only 20 to 25 nucleotides in length. What are the functions of the cap?

(a) Cap structure at the 5′ end of eukaryotic mRNA

(b) Addition of a poly A tail at the 3′ end of eukaryotic mRNA

Figure 12.9 Modifications that occur at the ends of mRNA in eukaryotic cells. **(a)** A guanosine cap is attached to the 5′ end. This is a guanine base modified by the attachment of a methyl group. The linkage between the cap and the mRNA is a 5′ to 5′ linkage. **(b)** A poly A tail is added to the 3′ end.

Concept Check: Do the ends of structural genes have a poly T region that provides a template for the synthesis of a poly A tail in mRNA? Explain.

- The 7-methylguanosine structure, called a **5′ cap**, is recognized by cap-binding proteins, which are needed for the proper exit of mRNAs from the nucleus.
- After an mRNA is in the cytosol, the cap structure helps to prevent its degradation and is recognized by other cap-binding proteins that enable the mRNA to bind to a ribosome for translation.

At the 3′ end, most mature eukaryotic mRNAs have a string of adenine nucleotides, typically 100 to 200 nucleotides in length, referred to as a **poly A tail** (**Figure 12.9b**). The poly A tail is not encoded in the gene sequence. Instead, the tail is added enzymatically after a pre-mRNA has been completely transcribed.

- A long poly A tail aids in the export of mRNA from the nucleus.
- It also causes a eukaryotic mRNA to be more stable and thereby exist for a longer period of time in the cytosol.

Interestingly, new research has shown that some bacterial mRNAs also have poly A tails attached to them. However, the poly A tail has an opposite effect in bacteria, where it causes the mRNA to be rapidly degraded. The importance of a poly A tail in bacterial mRNAs is not well understood.

Splicing Involves the Removal of Introns and the Linkage of Exons

Introns are found in many but not all eukaryotic genes. Splicing is less frequent among unicellular eukaryotic species, such as yeast, but is a widespread phenomenon among more complex eukaryotes. In animals and flowering plants, most structural genes have one or more introns. For example, an average human gene has about nine introns. The sizes of introns vary from a few dozen nucleotides to over 100,000! A few bacterial genes have been found to have introns, but they are rare among bacterial and archaeal species.

Introns are precisely removed from eukaryotic pre-mRNA by a large complex called a **spliceosome** that is composed of several different snRNPs (pronounced "snurps"); each snRNP contains small nuclear RNA and a set of proteins. This small nuclear RNA is the product of a nonstructural gene. Intron RNA is defined by a particular sequence within the intron termed the branch site and by two intron-exon boundaries, called the 5′ splice site and the 3′ splice site (**Figure 12.10**). Particular snRNPs bind to specific sequences at these three locations. This binding causes the intron to loop outward, which brings the two exons close together. The 5′ splice site is then cut, and the 5′ end of the intron becomes covalently attached to the branch site. In the final step, the 3′ splice site is cut, and the two exons are covalently attached to each other. The intron is released and eventually degraded.

In some cases, the function of the spliceosome is regulated so the splicing of exons for a given mRNA can occur in two or more ways. This phenomenon, called **alternative splicing**, allows a single gene to encode two or more polypeptides with differences in their amino acid sequences. As described in Chapter 13, alternative splicing allows complex eukaryotic species to use the same gene to make different proteins at different stages of development or in different cell types. This increases the size of the proteome while minimizing the size of the genome.

Although primarily found in mRNAs, introns occasionally occur in rRNA and tRNA molecules of certain species. These introns, however, are not removed by the action of a spliceosome. Instead, such rRNAs and tRNAs are **self-splicing**, which means the RNA itself can catalyze the removal of its own intron. Portions of the RNA act like an enzyme to cleave the covalent bonds at the intron-exon boundaries and connect the exons together. An RNA molecule that catalyzes a chemical reaction is termed a **ribozyme**.

12.4 Translation and the Genetic Code

Learning Outcomes:

1. Explain how the genetic code specifies the relationship between the sequence of codons in mRNA and the amino acid sequence of a polypeptide.
2. **SciSKILLS** » Analyze the experiments of Nirenberg and Leder that led to the deciphering of the genetic code.

In the two previous sections, we considered the first stages of the central dogma—how an RNA transcript is made from DNA and how eukaryotes process that transcript. Recall that this type of RNA is

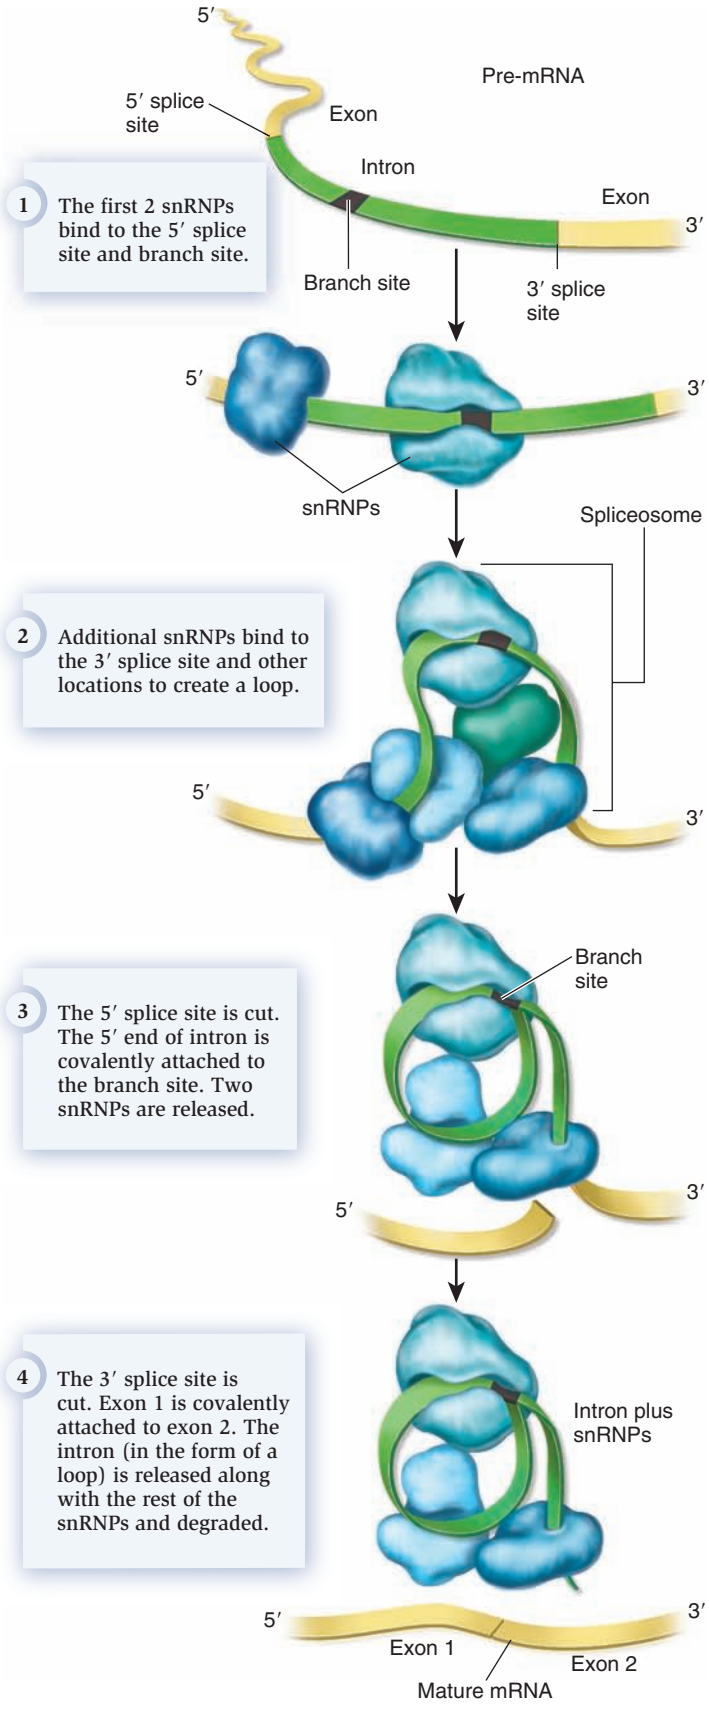


Figure 12.10 **The splicing of a eukaryotic pre-mRNA by a spliceosome.**

	AUA		ACA		AAA	Lys	AGA	Arg	A
	AUG	Met/ start	ACG		AAG		AGG		G
G	GUU	Val	GCU	Ala	GAU	Asp	GGU	Gly	U
	GUC		GCC		GAC		GGC		C
	GUA		GCA		GAA	Glu	GGA		A
	GUG		GCG		GAG		GGG		G

*Exceptions to the genetic code are sporadically found among various species. For example, AUA encodes methionine in yeast and mammalian mitochondria. The three-letter abbreviations for the amino acids are described in Chapter 3 (see Figure 3.13).

called messenger RNA (mRNA), because its function is to transmit information from DNA to cellular components called ribosomes, where polypeptide synthesis occurs. In this section, we will consider the next stage, translation, which is the synthesis of polypeptides using information from the mRNA. To understand the process of translation, we will first examine the **genetic code**, which specifies the relationship between the sequence of nucleotides in the mRNA and the sequence of amino acids in a polypeptide. We will also explore experiments that helped to "crack" the code.

The Genetic Code Specifies the Amino Acids Within a Polypeptide

The ability of mRNA to be translated into an amino acid sequence of a polypeptide relies on the genetic code. The code is read in groups of three nucleotide bases known as **codons**. The genetic code consists of 64 different codons (**Table 12.1**). The sequence of three bases in most codons specifies a particular amino acid. For example, the codon CCC specifies the amino acid proline, whereas the codon GGC encodes the amino acid glycine. From the analysis of many different species, including bacteria, archaea, protists, fungi, plants, and animals, researchers have found that the genetic code is nearly universal. Only a few rare exceptions to the genetic code have been discovered.

Why are there 64 codons, as shown in Table 12.1? Because there are 20 types of amino acids, at least 20 different codons are needed so each amino acid can be specified by a codon. With four types of bases in mRNA (U, C, A, and G), a genetic code containing two bases in a codon would not be sufficient, because only 4^2, or 16, different codons would be possible. A three-base system can specify 4^3, or 64, different codons, which is far more than the number of amino acids. The genetic code is said to be **degenerate** because more than one codon can specify the same amino acid (see Table 12.1). For example, the codons GGU, GGC, GGA, and GGG all code for the amino acid glycine. In most instances, the third base in the codon is the degenerate or variable base.

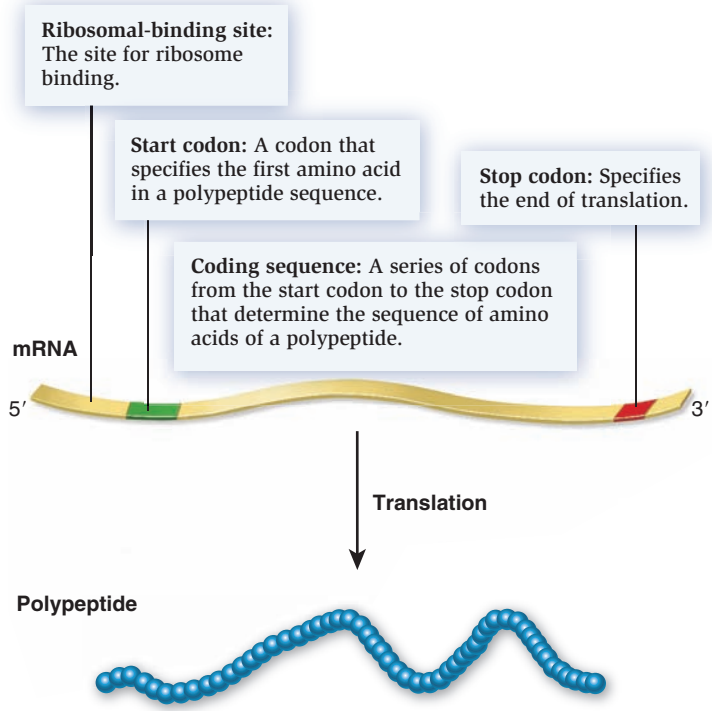

Figure 12.11 The organization of a bacterial mRNA as a translational unit. The string of blue balls represents a sequence of amino acids in a polypeptide. During and following translation, a sequence of amino acids folds into a more compact structure as described in Chapter 3 (see Figure 3.15).

Concept Check: *If a mutation eliminated the start codon from a gene, how would the mutation affect transcription, and how would it affect translation?*

During Translation, mRNA Is Used to Make a Polypeptide with a Specific Amino Acid Sequence

Let's look at the organization of a bacterial mRNA to see how translation occurs (**Figure 12.11**). A ribosomal-binding site is located near the 5′ end of the mRNA. The **start codon**, which specifies the amino acid methionine, is only a few nucleotides from the ribosomal-binding site. Beyond this, a large portion of an mRNA functions as a **coding sequence**—a region that specifies the linear amino acid sequence of a polypeptide. A typical polypeptide is a few hundred amino acids in length. The coding sequence consists of a series of codons. Finally, one of three **stop codons** signals the end of translation. These codons, also known as **termination codons**, are UAA, UAG, and UGA.

The start codon also defines the **reading frame** of an mRNA, which refers to the order in which codons are read during translation. Beginning at the start codon, each adjacent codon is read as a group of three bases, also called a **triplet**, in the 5′ to 3′ direction. For example, look at the following two mRNA sequences and their corresponding amino acid sequences.

	Ribosomal-binding site	Start codon
mRNA	5′–AUAAGGAGGUUACG(AUG)(CAG)(CAG)(GGC)(UUU)(ACC)–3′	
Polypeptide	Met - Gln - Gln - Gly - Phe - Thr	

	Ribosomal-binding site	Start codon
mRNA	5′–AUAAGGAGGUUACG(AUG)(UCA)(GCA)(GGG)(CUU)(UAC)C–3′	
Polypeptide	Met - Ser - Ala - Gly - Leu - Tyr	

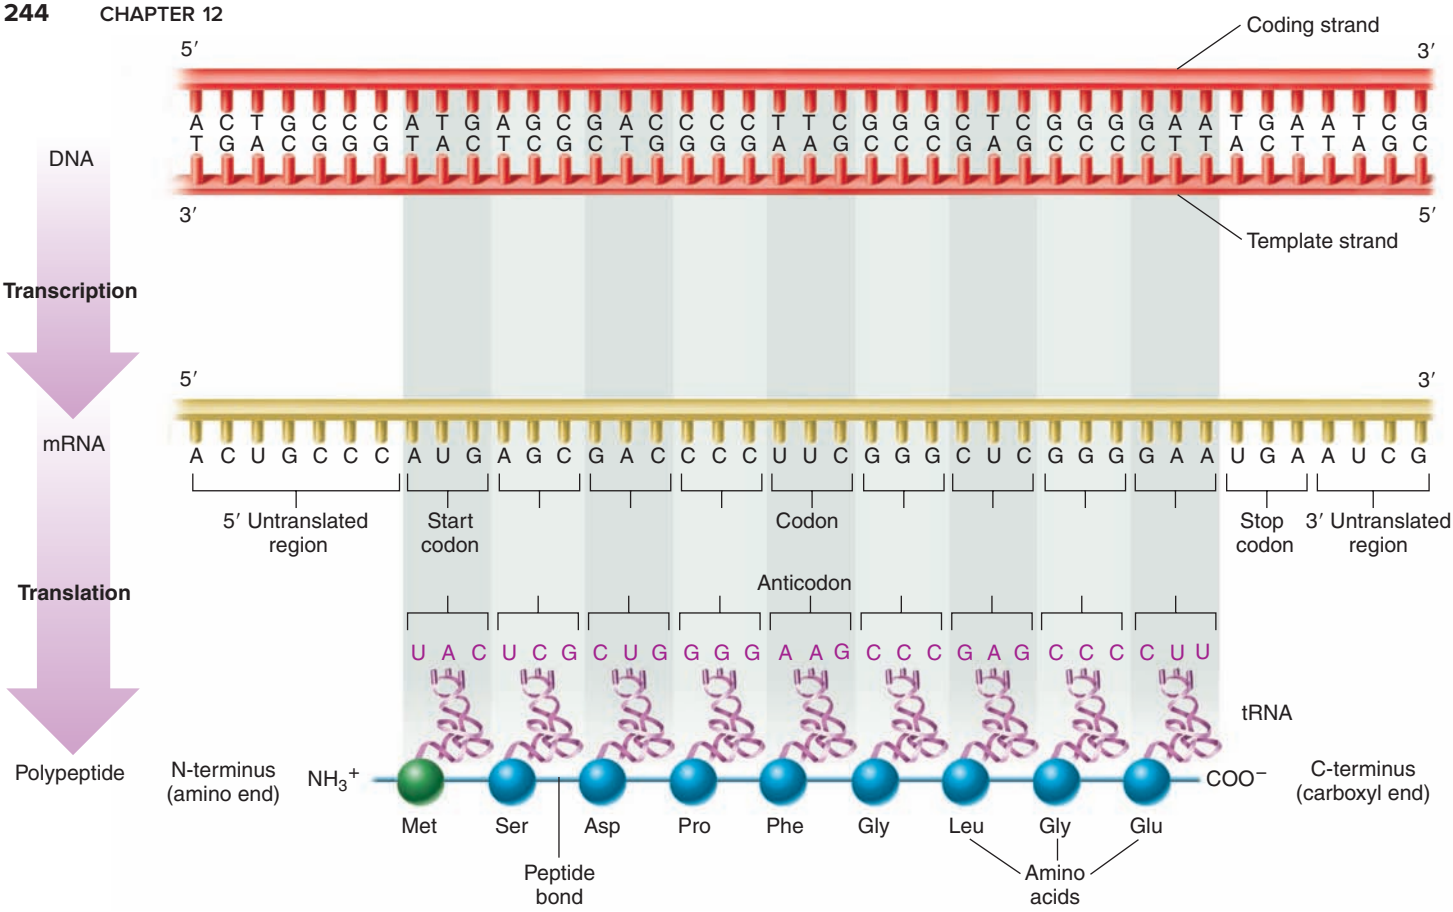

Figure 12.12 **Relationships among the coding sequence of a gene, the codon sequence of an mRNA, the anticodons of tRNA, and the amino acid sequence of a polypeptide.** Note: This gene does not contain any introns.

Concept Check: *If an anticodon in a tRNA molecule has the sequence 3′–ACC–5′, which amino acid does it carry?*

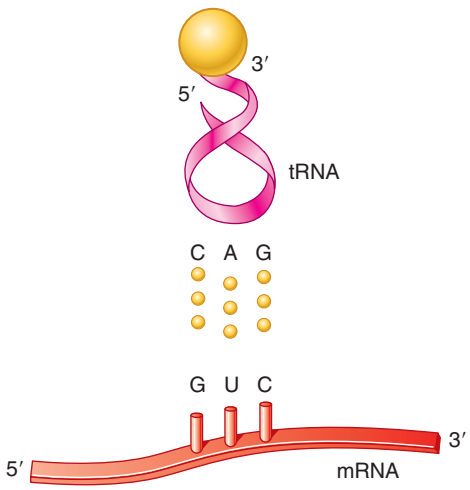
The first sequence shows how the mRNA codons would be correctly translated into amino acids. In the second sequence, an additional U has been added to the same sequence after the start codon. This shifts the reading frame, thereby changing the codons as they occur in the 5′ to 3′ direction. The polypeptide produced from this series of codons has a very different sequence of amino acids. From this comparison, we can also see that the reading frame is not overlapping, which means that each base functions within a single codon.

DNA Stores Information, Whereas mRNA and tRNA Access That Information to Make Polypeptides

The relationships among the DNA sequence of a gene, the mRNA transcribed from the gene, and the polypeptide sequence are shown schematically in **Figure 12.12**. Recall that the template strand is used to make mRNA. The resulting mRNA strand corresponds to the coding strand of DNA, except that U in the mRNA substitutes for T in the DNA. The 5′ end of the mRNA contains an untranslated region (5′ UTR) as does the 3′ end (3′ UTR). The middle portion contains a series of codons that specify the amino acid sequence of a polypeptide.

To translate a nucleotide sequence of mRNA into an amino acid sequence, recognition occurs between mRNA and transfer RNA (tRNA) molecules. Transfer RNA, which is described in Section 12.5, functions as the "translator" or intermediary between an mRNA codon and an amino acid. The **anticodon** is a three-base sequence in a tRNA molecule that is complementary to a codon in mRNA. Due to this complementarity, the anticodon in the tRNA and a codon in an mRNA bind to each other. Furthermore, the anticodon in a tRNA corresponds to the amino acid that it carries. For example, if the anticodon in a tRNA is 3′–AAG–5′, it is complementary to a 5′–UUC–3′ codon. According to the genetic code, a UUC codon specifies phenylalanine (Phe). Therefore, a tRNA with a 3′–AAG–5′ anticodon must carry phenylalanine. As another example, a tRNA with a 3′–GGG–5′ anticodon is complementary to a 5′–CCC–3′ codon, which specifies proline. This tRNA must carry proline (Pro).

As seen at the bottom of Figure 12.12, the direction of polypeptide synthesis parallels the 5′ to 3′ orientation of mRNA. The first amino acid is said to be at the amino end, or **N-terminus**, of the polypeptide. The term N-terminus refers to the presence of a nitrogen atom (N) at this end, whereas amino end indicates the presence of an amino group (NH_2). **Peptide bonds** connect the amino acids together. These covalent bonds form between the carboxyl group (COOH) of the previous amino acid and the amino group of the next amino acid. The last amino acid in a completed polypeptide does not have another amino acid attached to its carboxyl group. This last amino acid is said to be located at the carboxyl end, or **C-terminus**. A carboxyl group is always found at this end of the polypeptide. Note that at neutral pH, the amino group is positively charged (NH_3^+), whereas the carboxyl group is negatively charged (COO^-).



BIO TIPS

THE QUESTION *A tRNA anticodon has the sequence 3′–CAG–5′. What amino acid does this tRNA carry?*

TOPIC ***What topic in biology does this question address?*** The topic is translation. More specifically, the question is about determining the amino acid that a tRNA carries.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you know that a tRNA anticodon is 3′–CAG–5′. From your understanding of the topic, you may remember that the anticodon and codon are complementary and antiparallel. The codon specifies an amino acid according to the genetic code.

PROBLEM-SOLVING STRATEGY ***Make a drawing. Relate structure and function.*** One strategy to begin to solve this problem is to make a drawing of how the given tRNA anticodon binds to a codon in an mRNA.

The basis of anticodon/codon recognition is that they are complementary and antiparallel. The function of the codon is to specify a particular amino acid according to the genetic code.

ANSWER *The anticodon is 3′–CAG–5′, so it is complementary to a codon with the sequence 5′–GUC–3′. According to the genetic code, this codon specifies the amino acid valine. Therefore, this tRNA must carry a valine.*

Synthetic RNA Helped to Decipher the Genetic Code

Now let's look at some early experiments that allowed scientists to decipher the genetic code. During the early 1960s, the genetic code was determined by the collective efforts of several researchers, including American biochemist Marshall Nirenberg, Spanish-American biochemist Severo Ochoa, and American geneticist Philip Leder. Prior to their studies, other scientists had discovered that bacterial cells can be broken open and components from the cytoplasm can synthesize polypeptides. This is termed an in vitro, or cell-free, translation system. Nirenberg and Ochoa made synthetic RNA molecules using an enzyme that covalently connects nucleotides together. Using this synthetic mRNA, they then determined which amino acids were incorporated into polypeptides. For example, if an RNA molecule had only adenine-containing nucleotides (for example, 5′–AAAAAAAAAAAAAAAAAA–3′), a polypeptide was produced that contained only lysine. This result indicated that the AAA codon specifies lysine.

Another method used to decipher the genetic code involved the chemical synthesis of short RNA molecules, as described next in the Feature Investigation.

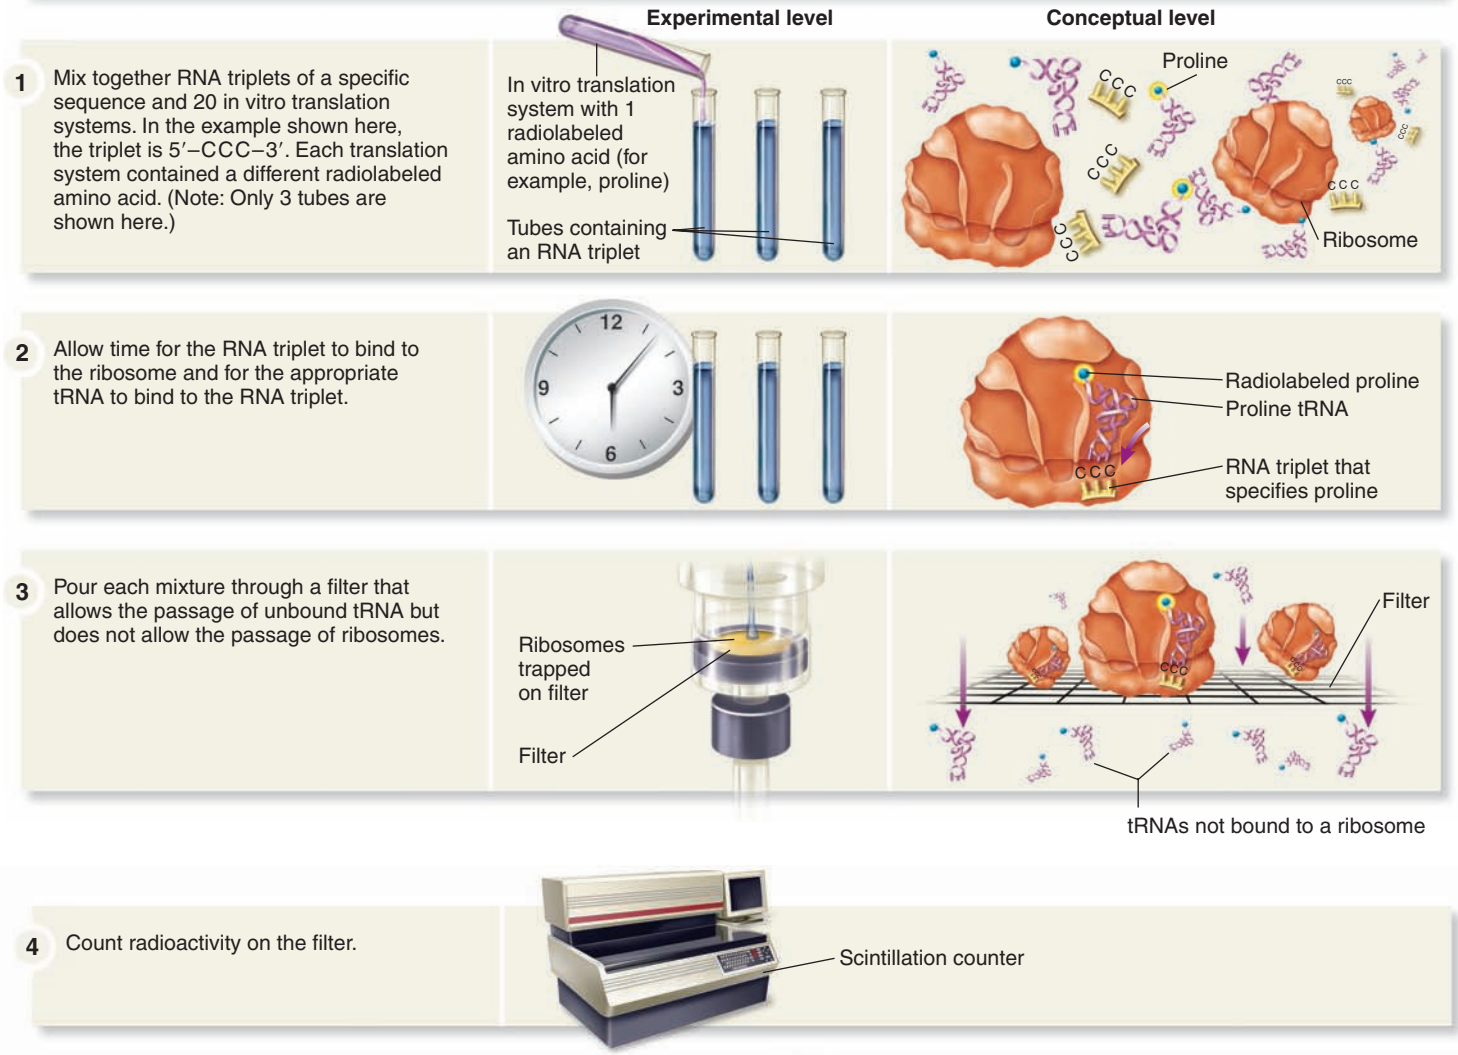
Feature Investigation | Nirenberg and Leder Found That RNA Triplets Can Promote the Binding of tRNA to Ribosomes

In 1964, Nirenberg and Leder discovered that RNA molecules containing three nucleotides (that is, a triplet) can cause a tRNA molecule to bind to a ribosome. In other words, an RNA triplet acts like a codon within an mRNA molecule. To establish the relationship between triplet sequences and specific amino acids, Nirenberg and Leder made triplets with specific base sequences (**Figure 12.13**). For example, in one experiment they studied 5′–CCC–3′ triplets. This particular triplet was added to 20 different tubes. To each tube, they next added an in vitro translation system, which contained ribosomes and tRNAs that already had amino acids attached to them. However, each translation system had only one type of radiolabeled amino acid. One translation system had only proline that was radiolabeled, a second translation system had only serine that was radiolabeled, and so on.

As shown in step 2 of Figure 12.13, the triplets became bound to the ribosomes just like the binding of mRNA to a ribosome. The tRNA with an anticodon that was complementary to the added triplet would bind to the triplet, which was already bound to the ribosome. For example, when the triplet was 5′–CCC–3′, a tRNA with a 3′–GGG–5′ anticodon would bind to the triplet/ribosome complex. This tRNA carries proline.

To determine which tRNA had bound, the contents from each tube were poured through a filter that trapped the large ribosomes but did not trap tRNAs that were not bound to ribosomes (see step 3). If the tRNA carrying the radiolabeled amino acid was bound to the triplet/ribosome complex, radioactivity would be trapped on the filter. Using a scintillation counter, the researchers determined the

amount of radioactivity on each filter. Because only one amino acid was radiolabeled in each in vitro translation system, they could determine which triplet corresponded to which amino acid. In the example shown here, CCC corresponds to proline. Therefore, the in vitro translation system containing radiolabeled proline showed a large amount of radioactivity on the filter. As seen in the data, by studying triplets with different sequences, Nirenberg and Leder identified many codons of the genetic code.



Experimental Questions

1. Briefly explain how a triplet mimics the role of an mRNA molecule. How was this observation useful in the study done by Nirenberg and Leder?
2. **SciSKILLS** » What was the benefit of using radiolabeled amino acids in the Nirenberg and Leder experiment?
3. **SciSKILLS** » Predict the results that Nirenberg and Leder would have found for the following triplets: AUG, UAA, UAG, and UGA.

Figure 12.13 **Nirenberg and Leder's use of triplet binding method to decipher the genetic code.**

HYPOTHESIS An RNA triplet can bind to a ribosome and promote the binding of the tRNA that carries the amino acid that the RNA triplet specifies.

KEY MATERIALS The researchers made 20 in vitro translation systems, which included ribosomes, tRNAs, and 20 amino acids. The 20 translation systems differed with regard to which amino acid was radiolabeled. For example, in 1 translation system, radiolabeled glycine was added, and the other 19 amino acids were unlabeled. In another system, radiolabeled proline was added, and the other 19 amino acids were unlabeled. The in vitro translation systems also contained the enzymes that attach amino acids to tRNAs.

5 THE DATA

Triplet	Radiolabeled amino acid trapped on the filter	Triplet	Radiolabeled amino acid trapped on the filter
5′ – AAA – 3′	Lysine	5′ – GAC – 3′	Aspartic acid
5′ – ACA – 3′	Threonine	5′ – GCC – 3′	Alanine
5′ – ACC – 3′	Threonine	5′ – GGU – 3′	Glycine
5′ – AGA – 3′	Arginine	5′ – GGC – 3′	Glycine
5′ – AUA – 3′	Isoleucine	5′ – GUU – 3′	Valine
5′ – AUU – 3′	Isoleucine	5′ – UAU – 3′	Tyrosine
5′ – CCC – 3′	Proline	5′ – UGU – 3′	Cysteine
5′ – CGC – 3′	Arginine	5′ – UUG – 3′	Leucine
5′ – GAA – 3′	Glutamic acid		

6 CONCLUSION This method enabled the researchers to identify many of the codons of the genetic code.

7 SOURCE Leder, P., and Nirenberg, M. W. 1964. RNA Codewords and Protein Synthesis, III. On the nucleotide sequence of a cysteine and a leucine RNA codeword. *Proceedings of the National Academy of Sciences* 52:1521–1529.

12.5 The Machinery of Translation

Learning Outcomes:

1. Describe the structure and function of tRNA.
2. Explain how aminoacyl-tRNA synthetases attach amino acids to tRNAs.
3. Outline the structural features of bacterial and eukaryotic ribosomes.
4. **SciSKILLS** » Analyze how ribosomal RNA (rRNA) is used to evaluate evolutionary relationships among different species.

Let's now turn our attention to the components in living cells that are needed to use the genetic code and translate mRNA into polypeptides. Earlier in this chapter, we considered transcription, the first step in gene expression. To transcribe an RNA molecule, a pre-existing DNA template strand is used to make a complementary RNA strand. A single enzyme, RNA polymerase, catalyzes this reaction. By comparison, translation requires more components because the sequence of codons in an mRNA molecule must be translated into a sequence of amino acids according to the genetic code. A single protein cannot accomplish such a task. Instead, many different proteins and RNA molecules interact in an intricate series of steps to achieve the synthesis of a polypeptide. A cell must make many different components, including mRNAs, tRNAs, ribosomes, and translation factors, so polypeptides can be made (**Table 12.2**).

Though the estimates vary from cell to cell and from species to species, most cells use a substantial amount of their energy to translate mRNA into polypeptides. In *E. coli*, for example, approximately 90% of the cellular energy is used for this process. This value underscores the complexity and importance of translation in living organisms. In this section, we will focus on the components of the translation machinery. The last section of the chapter will describe the stages of translation as they occur in living cells.

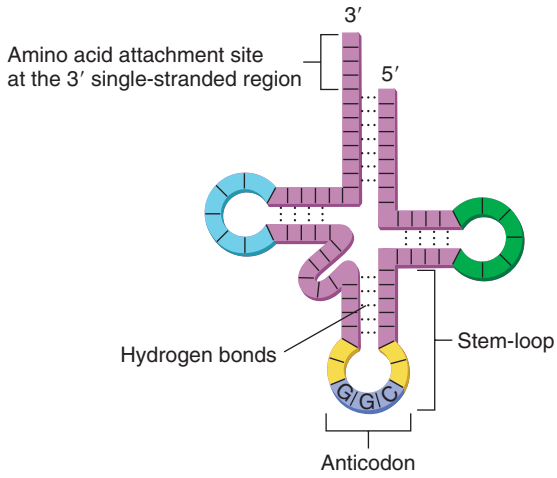
Table 12.2 Components of the Translation Machinery

Component	Function
mRNA	Contains the information for the amino acid sequence of a polypeptide according to the genetic code.
tRNA	A molecule with two functional sites: one site, termed the anticodon, binds to a codon in mRNA, and a second site is where an appropriate amino acid is attached.
Ribosome	Composed of many proteins and rRNA molecules, the ribosome provides a location where mRNA and tRNA molecules can properly interact with each other. The ribosome catalyzes the formation of covalent bonds between adjacent amino acids so a polypeptide can be made.
Translation factors	Proteins needed for the three stages of translation. Initiation factors are required for the assembly of mRNA, the first tRNA, and ribosomal subunits. Elongation factors are needed to synthesize the polypeptide. Release factors are needed to recognize the stop codon and disassemble the translation machinery. Several translation factors use GTP as an energy source to carry out their functions.

Transfer RNAs Share Common Structural Features

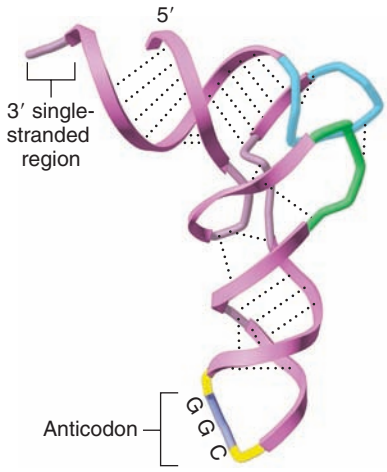
To understand how tRNAs function as carriers of the correct amino acids during translation, researchers have examined their structural characteristics. The tRNAs of bacteria, archaea, and eukaryotes share common features. As originally proposed in 1965 by American biochemist Robert Holley, the two-dimensional structure of a tRNA exhibits a cloverleaf pattern. The structure has three stem-loops and a fourth stem with a 3′ single-stranded region (**Figure 12.14a**). The stem in a stem-loop is a region where the RNA is double-stranded due to complementary base pairing via hydrogen bonding, whereas the loop is a region without base pairing. The anticodon is located in the loop of the middle stem-loop region. The 3′ single-stranded region is the amino acid attachment site. The three-dimensional structure of tRNA molecules involves additional folding of the secondary structure (**Figure 12.14b**).

The cells of every organism make many different tRNA molecules, each encoded by a different gene. A tRNA is named according to the amino acid it carries. For example, $tRNA^{Ser}$ carries a serine. Because the genetic code contains six different serine codons, as shown in Table 12.1, a cell produces more than one type of $tRNA^{Ser}$.



Aminoacyl-tRNA Synthetases Charge tRNAs by Attaching an Appropriate Amino Acid

To perform its role during translation, a tRNA must have the appropriate amino acid attached to its 3′ end. The enzymes that catalyze the attachment of amino acids to tRNA molecules are known as **aminoacyl-tRNA synthetases**. Cells make 20 distinct types of aminoacyl-tRNA synthetase enzymes, with each type recognizing just one of the 20 different amino acids. Each aminoacyl-tRNA synthetase is named for the specific amino acid it attaches to tRNA. For example, alanyl-tRNA synthetase recognizes alanine and attaches this amino acid to all tRNAs with alanine anticodons.



Aminoacyl-tRNA synthetases catalyze chemical reactions involving an amino acid, a tRNA molecule, and ATP (**Figure 12.15**).

1. First, a specific amino acid and ATP bind to the enzyme.
2. Next, the amino acid is activated by the covalent attachment of an AMP (adenosine monophosphate) molecule, and pyrophosphate is released.
3. In a third step, the activated amino acid is covalently attached to the 3′ end of a tRNA molecule, and AMP is released.
4. Finally, the tRNA with its attached amino acid, called a **charged tRNA**, or an **aminoacyl tRNA**, is released from the enzyme.

The ability of each aminoacyl-tRNA synthetase to recognize an appropriate tRNA has been called the second genetic code. A precise recognition process is necessary to maintain the fidelity of genetic information. If the wrong amino acid was attached to a tRNA, the amino acid sequence of the translated polypeptide would be incorrect. However, aminoacyl-tRNA synthetases are amazingly accurate enzymes. The wrong amino acid is attached to a tRNA less than once in 100,000 times! The anticodon region of the tRNA is usually important for recognition by the correct aminoacyl-tRNA synthetase. In addition, the base sequences in other regions may facilitate binding to an aminoacyl-tRNA synthetase.

(a) Two-dimensional structure of tRNA

(b) Three-dimensional structure of tRNA

Figure 12.14 Structure of tRNA. **(a)** The two-dimensional or secondary structure of tRNA is that of a cloverleaf, with the anticodon within the middle stem-loop structure. The 3′ single-stranded region (acceptor stem) is where an amino acid can attach. **(b)** The actual three-dimensional structure folds in on itself.

BIOLOGY PRINCIPLE Structure determines function. The structure of tRNA has two functional sites: a 3′ single-stranded region where an amino acid is attached and an anticodon that binds to a codon on mRNA.

Concept Check: *What is the function of the anticodon?*

Ribosomes Are Assembled from rRNA and Proteins

Let's now turn our attention to the **ribosome**, the site where translation takes place. The ribosome is often described as a molecular machine. Bacterial cells have one type of ribosome, which translates all mRNAs in the cytoplasm. Because eukaryotic cells are compartmentalized into cellular organelles bounded by membranes, biochemically distinct ribosomes are found in different cellular compartments. The most abundant type of eukaryotic ribosome functions in the cytosol. In addition, mitochondria have ribosomes, and plant and algal

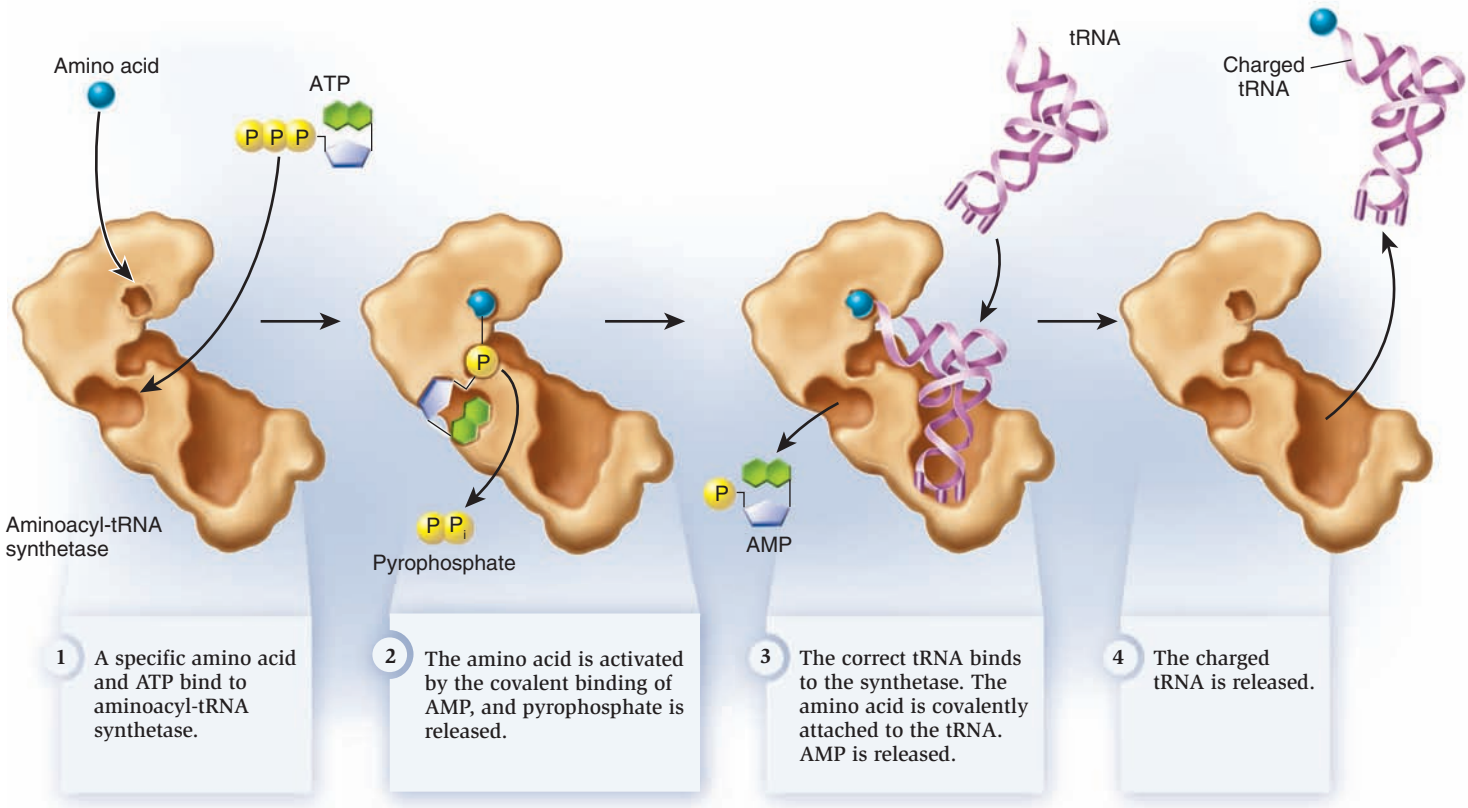


Figure 12.15 **Aminoacyl-tRNA synthetase charging a tRNA.**

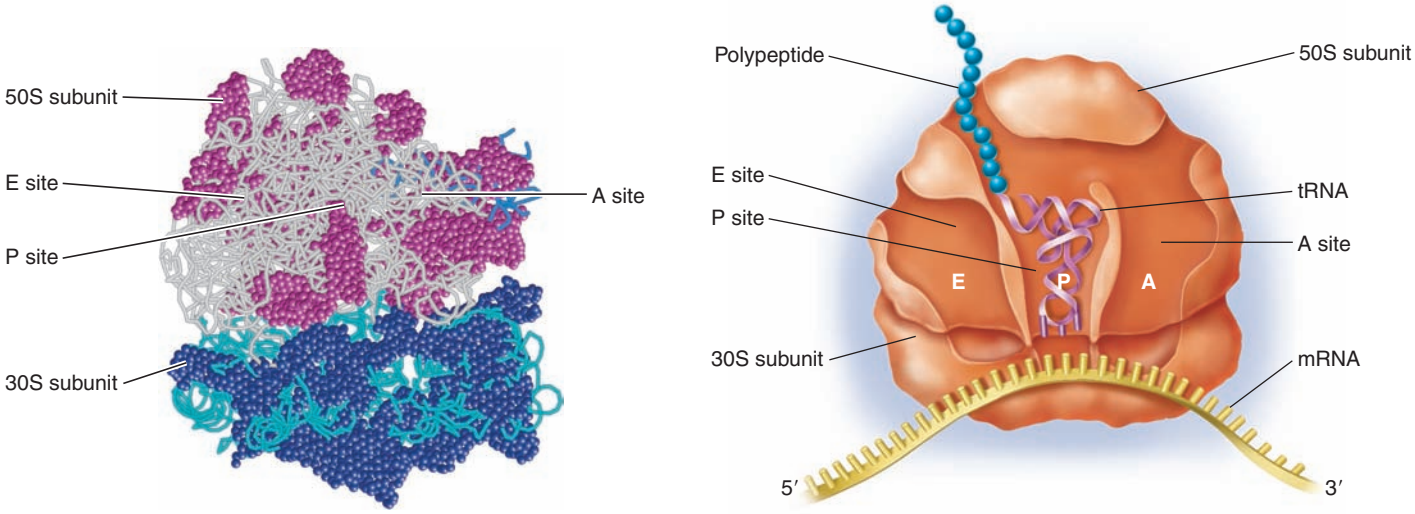
BioConnections: *Look back at Figure 6.3, which describes the hydrolysis of ATP. Why is ATP needed to charge a tRNA?*

cells have ribosomes in their chloroplasts. Unless otherwise noted, the term eukaryotic ribosome refers to ribosomes in the cytosol, not to those found in organelles.



A ribosome is a large complex composed of structures called the large and small subunits. The term subunit is perhaps misleading, because each ribosomal subunit is itself assembled from many different proteins and one or more RNA molecules. In the bacterium *E. coli*, the small ribosomal subunit is called 30S, and the large subunit is 50S (**Table 12.3**). The designations 30S and 50S refer to the rate at which these subunits sediment when subjected to a centrifugal force. This rate is described as a sedimentation coefficient in Svedberg units (S) in honor of Swedish chemist Theodor Svedberg, who invented the ultracentrifuge. The 30S subunit is formed from the assembly of 21 different ribosomal proteins and one 16S rRNA molecule. The 50S subunit contains 34 different proteins and two different rRNA molecules, called 5S and 23S. Together, the 30S and 50S subunits form a 70S ribosome. (Svedberg units don't add up linearly, because the sedimentation coefficient is a function of both size and shape.) In bacteria, ribosomal proteins and rRNA molecules are synthesized in the cytoplasm, and the ribosomal subunits are assembled there as well.

Eukaryotic ribosomes consist of subunits that are slightly larger than their bacterial counterparts (Table 12.3). In eukaryotes, 40S and 60S subunits combine to form an 80S ribosome. The 40S subunit is composed of 33 proteins and an 18S rRNA, and the 60S subunit has 49 proteins and 5S, 5.8S, and 28S rRNAs. The synthesis of eukaryotic

Table 12.3 **Composition of Bacterial and Eukaryotic Ribosomes**

	Small subunit	Large subunit	Assembled ribosome
Bacterial			
Sedimentation coefficient	30S	50S	70S
Number of proteins	21	34	55
rRNA	16S rRNA	5S rRNA, 23S rRNA	16S rRNA, 5S rRNA, 23S rRNA
Eukaryotic			
Sedimentation coefficient	40S	60S	80S
Number of proteins	33	49	82
rRNA	18S rRNA	5S rRNA, 5.8S rRNA, 28S rRNA	18S rRNA, 5S rRNA, 5.8S rRNA, 28S rRNA

(a) Bacterial ribosome model based on X-ray diffraction studies **(b) Schematic model for ribosome structure**

Figure 12.16 Ribosome structure. **(a)** A model for the structure of a bacterial ribosome based on X-ray diffraction studies, showing the large and small subunits and the major binding sites. The rRNA is shown in gray (large subunit) and turquoise (small subunit), whereas the ribosomal proteins are magenta (large subunit) and dark blue (small subunit). **(b)** A schematic model emphasizing functional sites in the ribosome, and showing bound mRNA and tRNA with an attached polypeptide.

rRNA occurs in the nucleolus, a region of the nucleus that is specialized for that purpose. The ribosomal proteins are made in the cytosol and imported into the nucleus. The rRNAs and ribosomal proteins are then assembled within the nucleolus to make the 40S and 60S subunits. The 40S and 60S subunits are exported into the cytosol, where they associate to form an 80S ribosome during translation.

Components of Ribosomal Subunits Form Functional Sites for Translation

To understand the structure and function of the ribosome at the molecular level, researchers have determined the locations and functional roles of individual ribosomal proteins and rRNAs. In recent years, a few research groups have succeeded in purifying ribosomes and causing them to crystallize in a test tube. Using the technique of X-ray diffraction, the crystallized ribosomes provide detailed information about ribosome structure. **Figure 12.16a** shows a model of a bacterial ribosome.

During bacterial translation, the mRNA lies on the surface of the 30S subunit, within a space between the 30S and 50S subunits (**Figure 12.16b**). As a polypeptide is synthesized, it exits through a hole within the 50S subunit. Ribosomes contain discrete sites where tRNAs bind and the polypeptide is synthesized. In 1964, James Watson proposed a two-site model for tRNA binding to the ribosome. These sites are known as the **peptidyl site (P site)** and **aminoacyl site (A site)**. In 1981, German geneticists Knud Nierhaus and Hans-Jörg Rheinberger expanded this to a three-site model (Figure 12.16b). The third site is known as the exit site (E site). In Section 12.6, we will examine the roles of these sites in the synthesis of a polypeptide.

Genomes & Proteomes Connection

Comparisons of Small Subunit rRNAs Among Different Species Provide a Basis for Establishing Evolutionary Relationships

Translation is a fundamental process that is vital for the existence of all living species. Research indicates that the components needed for translation arose very early in the evolution of life on our planet in ancestors that gave rise to all known living species. For this reason, all organisms have translational components that are evolutionarily related to each other. For example, the rRNA found in the small subunit of ribosomes is similar in all forms of life, though it is slightly larger in eukaryotic species (18S) than in bacterial species (16S). In other words, the gene for the small subunit rRNA (SSU rRNA) is found in the genomes of all organisms.

How is this observation useful? One way that geneticists explore evolutionary relationships is to compare the sequences of evolutionarily related genes. At the molecular level, gene evolution involves changes in DNA sequences. After two different species have diverged from each other during evolution, the genes of each species have an opportunity to accumulate changes, or mutations, that alter the sequences of those genes. After many generations, evolutionarily related species contain genes that are similar but not identical to each other, because each species accumulates different mutations. In general, if a very long time has elapsed since two species diverged evolutionarily, their genes tend to be quite different. In contrast, if two species diverged relatively recently on an evolutionary time scale, their genes tend to be more similar.

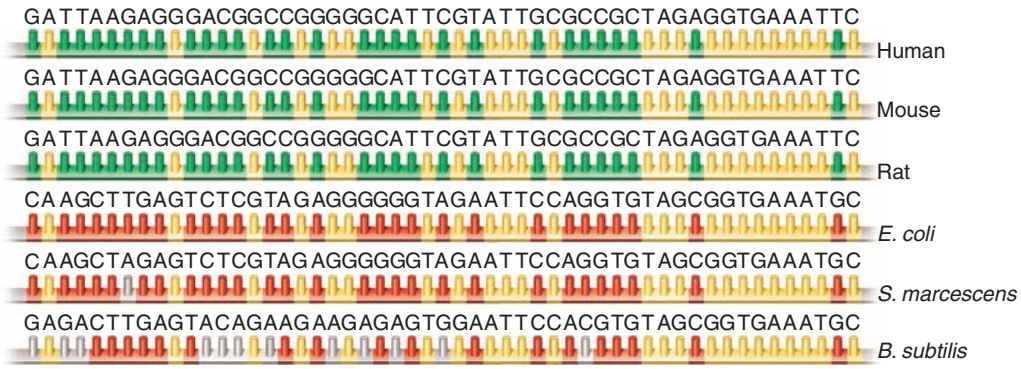


Figure 12.17 Comparison of small subunit rRNA gene sequences from three mammalian and three bacterial species. Note the many similarities (yellow) and differences (green and red) among the sequences. The gray color indicates differences among the three bacterial species.

Concept Check: *Based on the gene sequences shown here, pick two species that are closely related evolutionarily and two that are distantly related.*

Figure 12.17 compares a portion of the sequence of the SSU rRNA gene from three mammalian and three bacterial species. The colors highlight different types of comparisons. The bases shaded in yellow are identical in five or six species. Sequences of bases that are identical or very similar in different species are said to be **evolutionarily conserved**. Presumably, these sequences were found in the primordial gene that gave rise to modern species. Perhaps because these sequences may have some critical function, they have not changed over evolutionary time. Those sequences shaded in green are identical in all three mammals, but differ compared with one or more bacterial species. Actually, if you scan the mammalian species, you may notice that all three sequences are identical in this region. The sequences shaded in red are identical or very similar in the bacterial species, but differ compared with the mammalian SSU rRNA genes. The sequences from *Escherichia coli* and *Serratia marcescens* are more similar to each other than the sequence from *Bacillus subtilis* is to either of them. This observation suggests that *E. coli* and *S. marcescens* are more closely related evolutionarily than either of them is to *B. subtilis*.

12.6 The Stages of Translation

Learning Outcomes:

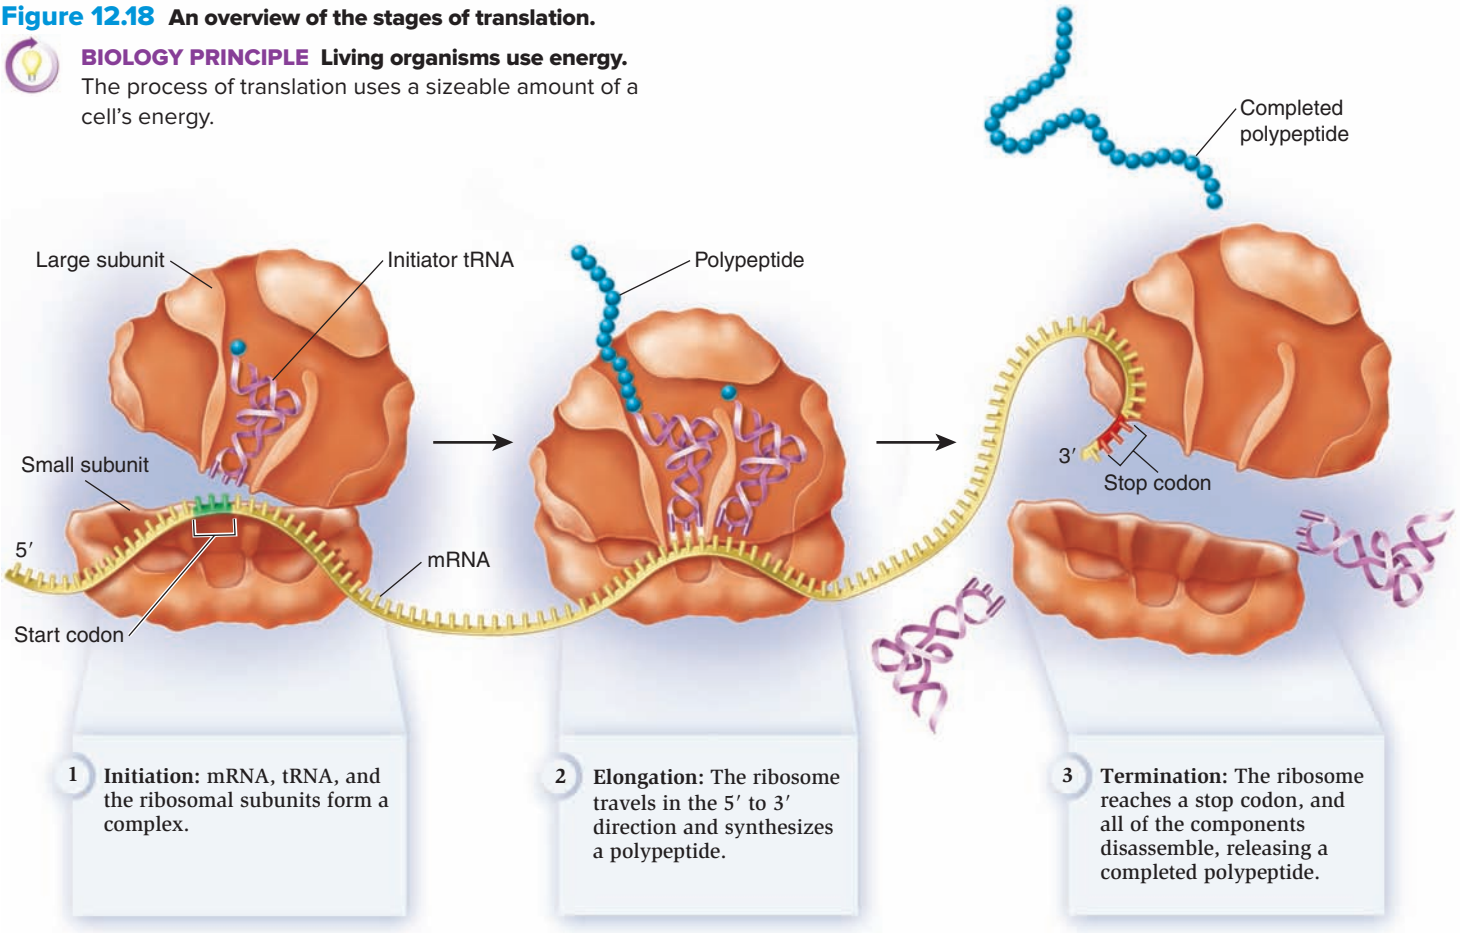
1. Describe the three stages of translation.
2. Summarize the similarities and differences between translation in bacteria and eukaryotes.
3. Explain how some antibiotics inhibit the growth of bacteria by interfering with translation.

Like transcription, the process of translation occurs in three stages called initiation, elongation, and termination. **Figure 12.18** provides an overview of the process. During initiation, an mRNA, the first tRNA, and the ribosomal subunits assemble into a complex. Next, in the elongation stage, the ribosome moves in the 5′ to 3′ direction from the start codon in the mRNA toward the stop codon, synthesizing a polypeptide according to the sequence of codons in the mRNA. Finally, the process is terminated when the ribosome reaches a stop codon and the complex disassembles, releasing the completed polypeptide. In this section, we will examine the steps in this process as they occur in living cells.

Translation Is Initiated with the Assembly of mRNA, tRNA, and the Ribosomal Subunits

During **initiation**, a complex is formed between an mRNA molecule, the first tRNA, and the ribosomal subunits. In all species, the assembly of this complex requires the help of proteins called **initiation factors** that facilitate the interactions between these components (see Table 12.2). The assembly also requires an input of energy. Guanosine triphosphate (GTP) is hydrolyzed by certain initiation factors to provide the necessary energy.

In the absence of translation, the small and large ribosomal subunits exist separately.



1. To begin assembly in bacteria, mRNA binds to the small ribosomal subunit (**Figure 12.19**). The binding of mRNA to this subunit is facilitated by a short ribosomal-binding site near the 5′ end of the mRNA. The ribosomal binding site is a sequence of bases that is complementary to a portion of the 16S rRNA within the small ribosomal subunit. The mRNA becomes bound to the ribosome because the ribosomal-binding site and rRNA hydrogen-bond to each other by base-pairing. The start codon is usually just a few nucleotides downstream (that is, toward the 3′ end) from the ribosomal-binding site.
2. A specific tRNA, which functions as the initiator tRNA, recognizes the start codon in mRNA (AUG) and binds to it. In eukaryotes, this tRNA carries a methionine, whereas in bacteria it carries a methionine that has been modified by the attachment of a formyl group.
3. To complete the initiation stage, the large ribosomal subunit associates with the small subunit. At the end of this stage, the initiator tRNA is located in the P site of the ribosome.

In eukaryotic species, the initiation phase of translation differs in two ways from the process in bacteria.

- First, instead of an RNA sequence that functions as a ribosomal-binding site, eukaryotic mRNAs have a guanosine cap (5′ cap) at their 5′ end. This 5′ cap is recognized by cap-binding proteins that promote the binding of the mRNA to the small ribosomal subunit.
- Also, in bacteria, the start codon is very close to a ribosomal-binding site, but the location of start codons in eukaryotes is more variable.

Figure 12.18 An overview of the stages of translation.

BIOLOGY PRINCIPLE Living organisms use energy. The process of translation uses a sizeable amount of a cell's energy.

In 1978, American biochemist Marilyn Kozak proposed that the small ribosomal subunit identifies a start codon by beginning at the 5′ end and then scanning along the mRNA in the 3′ direction in search of an AUG sequence. In many, but not all, cases the first AUG codon is used as a start codon. By analyzing the sequences of many eukaryotic mRNAs, Kozak and her colleagues discovered that the sequence around an AUG codon is important for it to be recognized as a start codon. The sequence for optimal start codon recognition is shown here:

Upstream of start codon	Start codon	Downstream coding region

. . . G C C (A or G) C C **A U G** G . . . . . .

Aside from an AUG codon itself, a guanine just past the start codon and the sequence of six bases directly upstream from the start codon are important for start codon selection. If the first AUG codon is within a site that deviates markedly from this optimal sequence, the small subunit may skip this codon and instead use another AUG codon farther downstream. Once the small subunit selects a start codon, an initiator tRNA binds to the start codon, and then the large ribosomal subunit associates with the small subunit to complete the assembly process.

Polypeptide Synthesis Occurs During the Elongation Stage

As its name suggests, the stage of translation called **elongation** involves the covalent bonding of amino acids to each other, one at a time, to produce a polypeptide. Even though this process involves several different components, translation occurs at a remarkable rate. Under normal cellular conditions, the translation machinery can elongate a polypeptide at a rate of 15 to 18 amino acids per second in bacteria and 6 amino acids per second in eukaryotes!

tRNA Entry To elongate a polypeptide by one amino acid, a tRNA brings a new amino acid to the ribosome, where it is attached to the end of a growing polypeptide. In step 1 of **Figure 12.20**, translation has already proceeded to a point where a short polypeptide is attached to the tRNA located in the P site of the ribosome. This is called peptidyl tRNA. In the first step of elongation, a charged tRNA carrying a single amino acid binds to the A site. This binding occurs because the anticodon in the tRNA is complementary to the codon in the mRNA. The hydrolysis of GTP by proteins that function as **elongation factors** provides the energy for the binding of the tRNA to the A site (see Table 12.2). At this step in elongation, a peptidyl tRNA is in the P site and a charged tRNA (an aminoacyl tRNA) is in the A site. This is how the P and A sites came to be named.

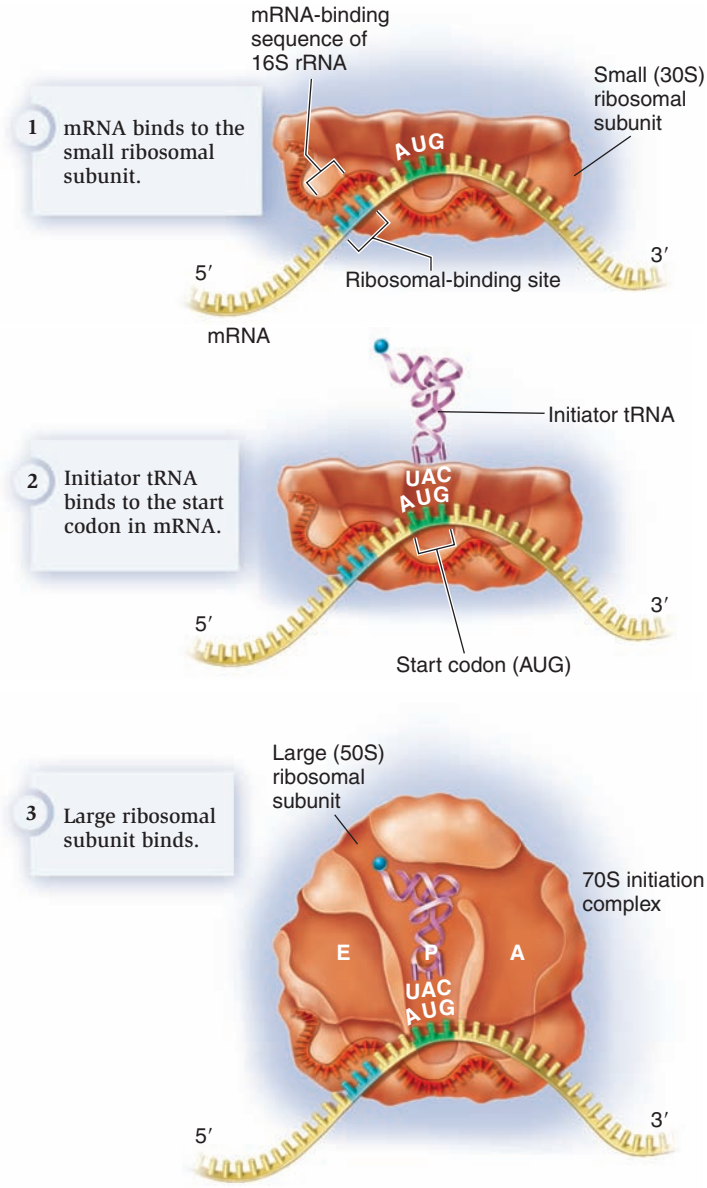


Figure 12.19 **Initiation of translation in bacteria.**

Concept Check: *What promotes the binding between the mRNA and the small ribosomal subunit?*

Peptidyl Transfer Reaction In the second step, a peptide bond is formed between the amino acid at the A site and the growing polypeptide, thereby lengthening the polypeptide by one amino acid. As this occurs, the polypeptide is removed from the tRNA in the P site and transferred to the amino acid at the A site, an event termed a **peptidyl transfer reaction**. This reaction is catalyzed by a region of the 50S subunit known as the peptidyltransferase center, which is composed of several proteins and rRNA. In 2000, American biochemist Thomas Steitz, American biophysicist Peter Moore, and their colleagues proposed that the rRNA is responsible for catalyzing the peptide bond formation between adjacent amino acids. It is now accepted that the ribosome is a ribozyme!

Translocation of the Ribosome and Release of tRNA After the peptidyl transfer reaction is complete, the third step involves the movement or translocation of the ribosome toward the 3′ end

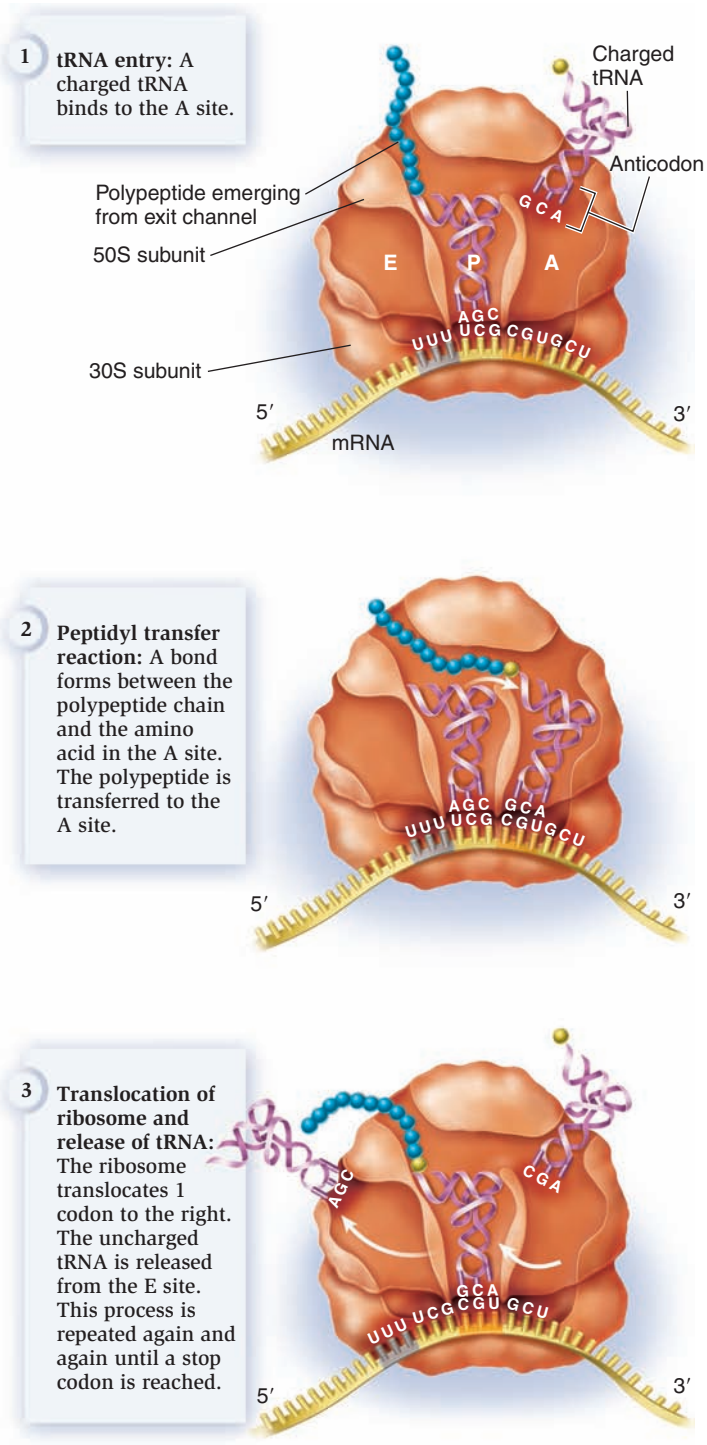

Figure 12.20 **Elongation stage of translation in bacteria.** In this drawing, the amino acids that were already contained within a polypeptide are shown in blue. The amino acids attached to incoming tRNAs in this figure are shown in yellow to distinguish them from the amino acids that were already in the polypeptide.

of the mRNA by exactly one codon. This shifts the tRNAs in the P and A sites to the E and P sites, respectively. The uncharged tRNA exits the E site. Notice that the next codon in the mRNA (GCU in Figure 12.20) is now exposed at the unoccupied A site. At this point, a charged tRNA can enter the A site, and the same series of steps will add the next amino acid to the polypeptide.

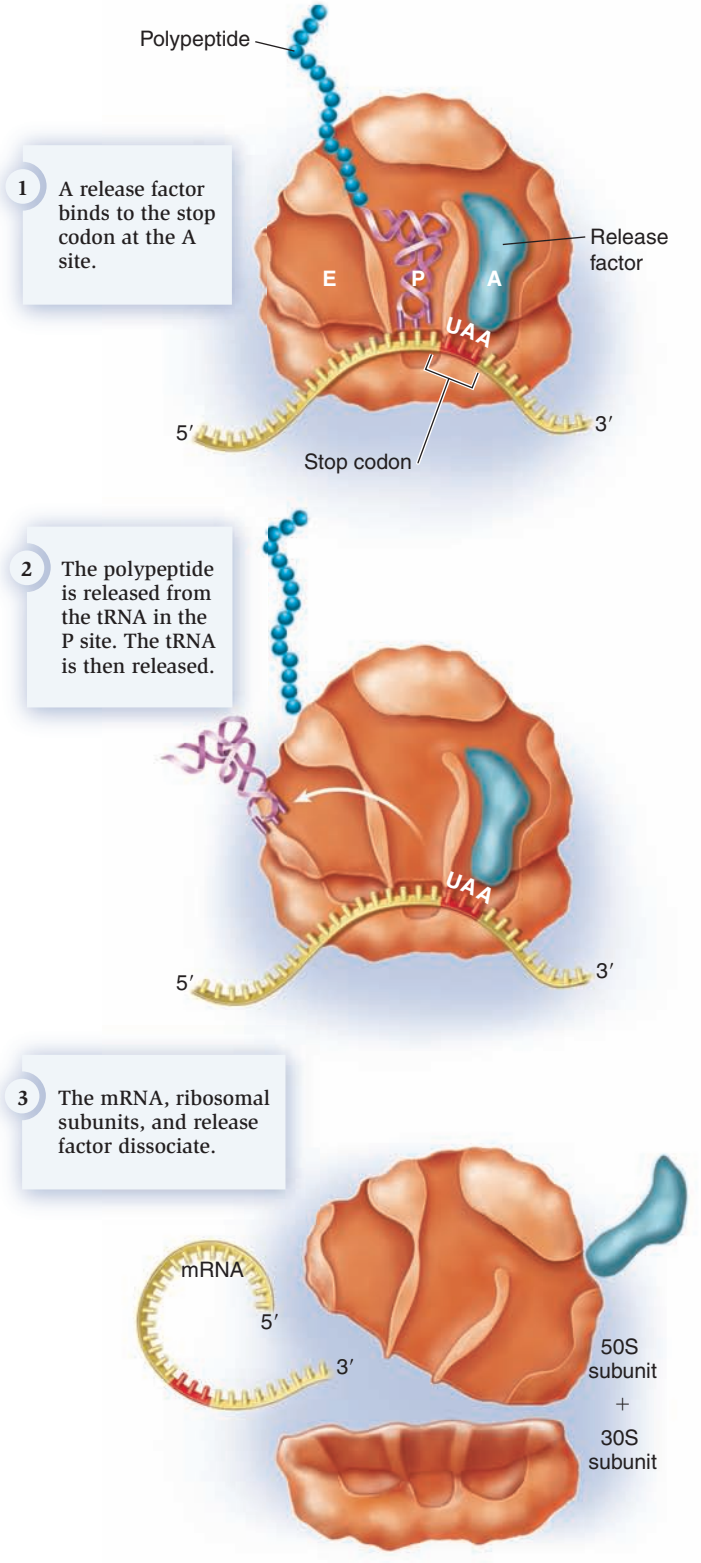

Figure 12.21 **Termination of translation in bacteria.**

Figure 12.20 considers a single ribosome in the act of translating an mRNA. In living cells, it is common for multiple ribosomes to be gliding along the same mRNA and synthesizing polypeptides. The complex of a single mRNA and multiple ribosomes is called a **polysome** (see the chapter opening micrograph).

Termination Occurs When a Stop Codon Is Reached in the mRNA

Elongation continues until a stop codon moves into the A site of a ribosome. The three stop codons, UAA, UAG, and UGA, are recognized by a protein known as a **release factor**. The three-dimensional structure of a release factor protein mimics the structure of tRNAs, which allows it to fit into the A site.

Figure 12.21 illustrates the termination of translation.

1. In step 1 of this figure, a release factor binds to the stop codon at the A site. The completed polypeptide is attached to a tRNA in the P site.
2. In step 2, the bond between the polypeptide and the tRNA is hydrolyzed, causing the polypeptide and tRNA to be released from the ribosome.
3. In step 3, the mRNA, ribosomal subunits, and release factor dissociate.

The termination stage of translation is similar in bacteria and eukaryotes except that bacteria have two different termination factors that recognize stop codons (RF1 and RF2), whereas eukaryotes have only one (eRF). **Table 12.4** compares some of the key differences between bacterial and eukaryotic translation.

Antibiotics That Inhibit Bacterial Translation Are Used to Treat Bacterial Infections

Many diseases that affect people and domesticated animals are caused by pathogenic bacteria. An **antibiotic** is any substance produced by a microorganism that inhibits the growth of other microorganisms, such as pathogenic bacteria. Most antibiotics are small organic molecules, with masses of less than 2,000 Da. In some cases, antibiotics exert their effect because they inhibit or interfere with bacterial translation. Because the components of translation differ somewhat between

Table 12.4 **Comparison of Bacterial and Eukaryotic Translation**

	Bacterial	Eukaryotic
Cellular location	Cytoplasm	Cytosol*
Ribosome composition	70S ribosomes:	80S ribosomes:
	30S subunit: 21 proteins + 1 rRNA	40S subunit: 33 proteins + 1 rRNA
	50S subunit: 34 proteins + 2 rRNAs	60S subunit: 49 proteins + 3 rRNAs
Initiator tRNA	$tRNA^{Formyl\text{-}methionine}$	$tRNA^{Methionine}$
Initial binding of mRNA	Requires a ribosomal-binding site	Requires a 7-methylguanosine cap
Selection of a start codon	Just downstream from the ribosomal-binding site	According to Kozak's sequences
Termination factors	Two factors: RF1 and RF2	One factor: eRF

*The components for eukaryotic translation described in this table refer to those that are used in the cytosol. Different types of ribosomes are used for translation inside mitochondria and chloroplasts.

Table 12.5 Mechanisms of Inhibition of Bacterial Translation by Selected Antibiotics

Antibiotic	Description
Chloraphenical	Blocks elongation by acting as competitive inhibitor of the peptidyltransferase complex.
Erythromycin	Binds to the 23S rRNA and blocks elongation by interfering with the translocation step.
Puromycin	Binds to the A site and causes premature release of the polypeptide. This early termination of translation results in polypeptides that are shorter than normal.
Tetracycline	Blocks elongation by inhibiting the binding of aminoacyl tRNAs to the ribosome.
Streptomycin	Interferes with normal pairing between aminoacyl tRNAs and codons. This causes misreading and thereby produces abnormal proteins.

bacteria and eukaryotes, some antibiotics inhibit bacterial translation without affecting eukaryotic translation. Therefore, they can be used to treat bacterial infections in humans, pets, and livestock. **Table 12.5** describes a few of these antibiotics.

Summary of Key Concepts

12.1 Overview of Gene Expression

- Based on his studies of inborn errors of metabolism, Garrod hypothesized that certain genetic diseases are caused by a defect in a gene encoding an enzyme (Figure 12.1).
- By studying the nutritional requirements of a bread mold, Beadle and Tatum proposed the one-gene/one-enzyme hypothesis in which a single gene controls the synthesis of a single enzyme (Figure 12.2).
- A polypeptide is a unit of structure. A protein, composed of one or more polypeptides, is a unit of function.
- At the molecular level, the central dogma states that most genes are transcribed into mRNA, and then the mRNA is translated into a polypeptide. Eukaryotes modify their RNA transcripts to make them functional (Figure 12.3).
- The molecular expression of genes is an underlying factor that determines an organism's characteristics.

12.2 Transcription

- A site in a gene called a promoter specifies where transcription begins. A terminator specifies where transcription will end (Figure 12.4).
- In bacteria, the initiation of transcription begins when sigma factor binds to RNA polymerase and to a promoter. During elongation, an RNA transcript is synthesized due to base pairing of nucleotides to the template strand of DNA as RNA polymerase slides along the DNA. RNA polymerase and the RNA transcript dissociate from the DNA at the terminator (Figure 12.5).
- The genes along a chromosome are transcribed in different directions using either DNA strand as a template. RNA is always synthesized in a 5′ to 3′ direction (Figure 12.6).
- In eukaryotes, the initiation phase of transcription involves the assembly of RNA polymerase with five transcription factors (Figure 12.7).

12.3 RNA Modification in Eukaryotes

- In eukaryotes, transcription produces a pre-mRNA that is capped, given a poly A tail, and spliced (Figure 12.8).
- The 5′ cap is a methylated guanine base at the 5′ end of the mRNA. The poly A tail is a string of adenine nucleotides that is added to the 3′ end (Figure 12.9).
- During RNA splicing, intervening sequences called introns are removed from eukaryotic pre-mRNA by a spliceosome (Figure 12.10).

12.4 Translation and the Genetic Code

- Based on the genetic code, each of the 64 codons specifies a start codon (methionine), other amino acids, or a stop codon (Table 12.1, Figure 12.11).
- The template strand of DNA is used to make mRNA with a series of codons. Recognition between mRNA and many tRNA molecules determines the amino acid sequence of a polypeptide. A polypeptide has a directionality in which the first amino acid is at the N-terminus, or amino end, whereas the last amino acid is at the C-terminus, or carboxyl end (Figure 12.12).
- Nirenberg and Leder used the ability of RNA triplets to promote the binding of tRNAs to ribosomes as a way to determine many of the codons of the genetic code (Figure 12.13).

12.5 The Machinery of Translation

- Translation requires mRNA, charged tRNAs, ribosomes, and many translation factors (Table 12.2).
- tRNA molecules have a two-dimensional cloverleaf structure. Two important sites are the amino acid attachment site at the 3′ end and the anticodon, which forms base-pairs with a codon in mRNA (Figure 12.14).
- The enzyme aminoacyl-tRNA synthetase attaches the correct amino acid to a tRNA molecule, producing a charged tRNA (Figure 12.15).
- Ribosomes are composed of a small and large subunit, each consisting of rRNA molecules and many proteins. Bacterial and eukaryotic ribosomes differ in their molecular composition (Table 12.3).
- Ribosomes have three sites, termed the A, P, and E sites, which are locations for the binding and release of tRNA molecules (Figure 12.16).
- The gene that encodes the small subunit rRNA (SSU rRNA) has been used to determine evolutionary relationships among different species (Figure 12.17).

12.6 The Stages of Translation

- Translation occurs in three stages called initiation, elongation, and termination (Figure 12.18).
- During initiation of translation, the mRNA assembles with the ribosomal subunits and the initiator tRNA molecule, which carries methionine, the first amino acid (Figure 12.19).

- During elongation, amino acids are added one at a time to a growing polypeptide (Figure 12.20).
- Termination of translation occurs when the binding of a release factor to a stop codon causes the release of the completed polypeptide from the tRNA and the disassembly of the mRNA, ribosomal subunits, and the release factor (Figure 12.21).
- Though translation in bacteria and eukaryotes is strikingly similar, some key differences have been observed (Table 12.4).
- Some antibiotics inhibit bacterial growth by interfering with translation (Table 12.5).

Assess and Discuss

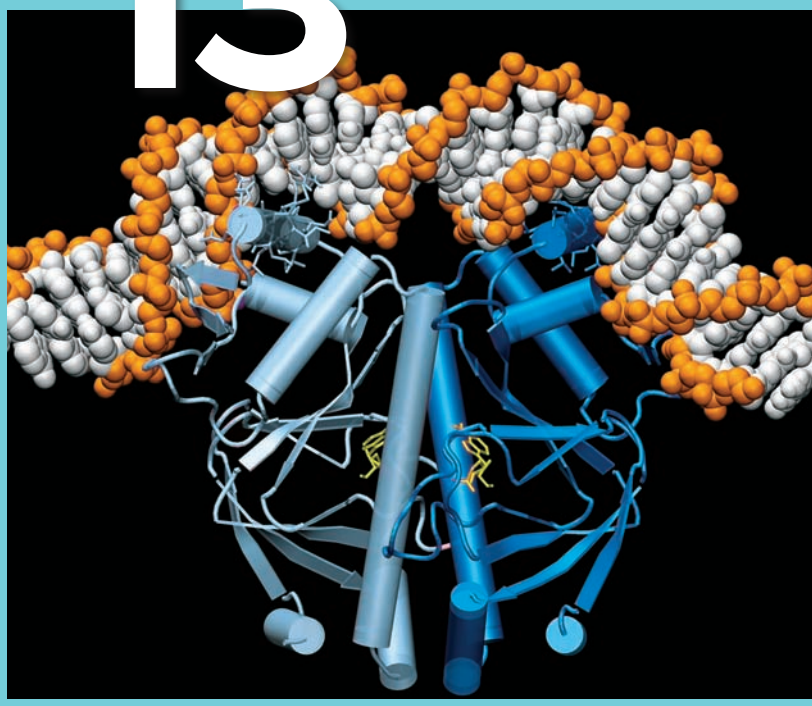
Test Yourself

1. Which of the following best represents the central dogma of gene expression?
   a. During transcription, DNA codes for polypeptides.
   b. During transcription, DNA codes for mRNA, which codes for polypeptides during translation.
   c. During translation, DNA codes for mRNA, which codes for polypeptides during transcription.
   d. none of the above
2. A mutation prevents a gene from being transcribed into an mRNA. The mutation most likely disrupts
   a. the promoter.
   b. the terminator.
   c. the start codon.
   d. the stop codon.
   e. both a and c.
3. The functional product of a structural gene is
   a. tRNA.
   b. mRNA.
   c. rRNA.
   d. a polypeptide.
   e. a, b, and c.
4. Which of the following is *not* a property of the genetic code?
   a. It specifies the amino acids within a polypeptide.
   b. It is composed of codons, which are a specific sequences of three bases.
   c. It has a start codon, which specifies the starting point for polypeptide synthesis.
   d. It has stop codons, which specify the end of polypeptide synthesis.
   e. It determines the rate of transcription.
5. If a eukaryotic mRNA failed to have a cap attached to its 5′ end, what would the negative consequence(s) be?
   a. The mRNA would not properly exit the nucleus.
   b. The mRNA would not properly bind to a ribosome.
   c. The mRNA would not receive a poly A tail.
   d. The mRNA would not use the correct start codon.
   e. Both a and b are correct.
6. The small subunit of a ribosome is composed of
   a. a protein.
   b. an rRNA molecule.
   c. many proteins.
   d. many rRNA molecules.
   e. many proteins and one rRNA molecule.
7. The part of a tRNA that is complementary to a codon in an mRNA is the
   a. acceptor stem.
   b. codon.
   c. peptidyl site.
   d. anticodon.
   e. adaptor loop.
8. During the initiation of translation, the first codon, ____, enters the _____ and associates with the initiator tRNA.
   a. UAG, A site
   b. AUG, A site
   c. UAG, P site
   d. AUG, P site
   e. AUG, E site
9. The movement of the polypeptide from the tRNA in the P site to the tRNA in the A site is referred to as
   a. peptide bonding.
   b. aminoacyl binding.
   c. translation.
   d. the peptidyl transfer reaction.
   e. elongation.
10. During which stage of translation does the synthesis of a polypeptide occur?
    a. initiation
    b. elongation
    c. termination
    d. splicing

Conceptual Questions

1. Describe the one-gene/one-enzyme hypothesis and the more modern modifications of this hypothesis. Briefly explain how studying the pathway that leads to arginine synthesis allowed Beadle and Tatum to conclude that one gene sometimes encodes one enzyme.
2. What is the function of an aminoacyl-tRNA synthetase?
3.  A principle of biology is that *the genetic material provides a blueprint for reproduction.* Explain how the information within the blueprint is accessed at the molecular level.

Collaborative Questions



1. Why do you think some complexes, such as spliceosomes and ribosomes, have both protein and RNA components?
2. Discuss and make a list of the similarities and differences in the events that occur during the initiation, elongation, and termination stages of transcription and translation.

CHAPTER OUTLINE

Gene Regulation

13

A model for a protein that binds to DNA and regulates genes. The catabolite activator protein (CAP), shown in dark and light blue, is binding to the DNA double helix, shown in orange and white. The CAP, shown again in Figure 13.10, activates gene transcription.

Emilio took a weight-lifting class in college and was surprised by the results. Within a few weeks, he was able to lift substantially more weight. He was inspired by his progress and continued lifting weights after the semester-long course ended. A year later, he was not only much stronger, but he could see physical changes in his body. Certain muscles, such as the biceps and triceps in his upper arms, were noticeably larger. How can we explain the increase in mass of Emilio's muscles? Unknowingly, when he was lifting weights, Emilio was affecting the regulation of his genes. Certain genes in his muscle cells were being "turned on" during his workouts, which then led to the synthesis of proteins that increased the mass of Emilio's muscles.

At the molecular level, **gene expression** is the process by which the information within a gene is made into a functional product, such as an RNA molecule or a protein. Most genes in all species are regulated so the proteins they specify are produced at appropriate times and in specific amounts. The term **gene regulation** refers to the ability of cells to control the expression of their genes. By comparison, some genes have relatively constant levels of expression in all conditions over time. These are called **constitutive genes**. In most cases, constitutive genes encode proteins that are constantly required for the survival of an organism, such as certain metabolic enzymes.

The importance of gene regulation is underscored by the number of genes devoted to this process in an organism. For example, in *Arabidopsis thaliana*, a plant that is studied by many plant geneticists, over 5% of the genome is involved with regulating gene transcription. This species has more than 1,500 different genes that encode proteins that regulate the transcription of other genes.

In this chapter, we will begin with an overview that emphasizes the benefits of gene regulation and the general mechanisms that achieve such regulation in bacteria and in eukaryotes. Later sections will describe how bacteria regulate gene expression in the face of environmental change and the more complex nature of gene regulation in eukaryotes.

13.1 Overview of Gene Regulation

Learning Outcomes:

1. Discuss the various ways that organisms benefit from gene regulation.
2. Identify where gene regulation can occur in the pathway of gene expression for bacteria and eukaryotes.

How do living organisms benefit from gene regulation? One reason is that it conserves energy. Proteins that are encoded by genes are produced only when needed. In multicellular organisms, gene regulation also ensures that genes are expressed in the appropriate cell types and at the correct stage of development. In this section, we will examine a few examples that illustrate the important consequences of gene regulation. We will also survey the major points in the gene expression process at which genes are regulated in bacterial and eukaryotic cells.

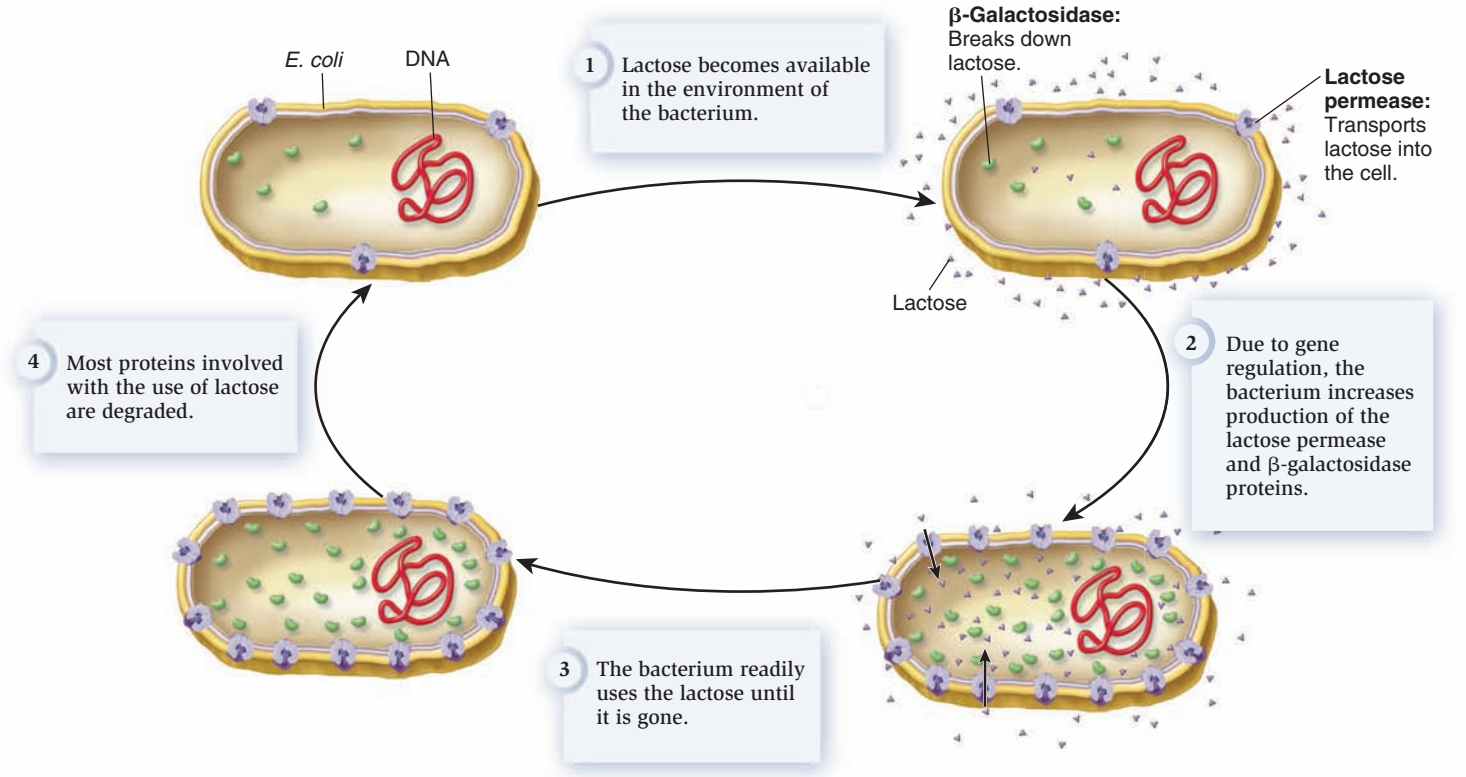

Figure 13.1 **Gene regulation of lactose utilization in *E. coli*.**

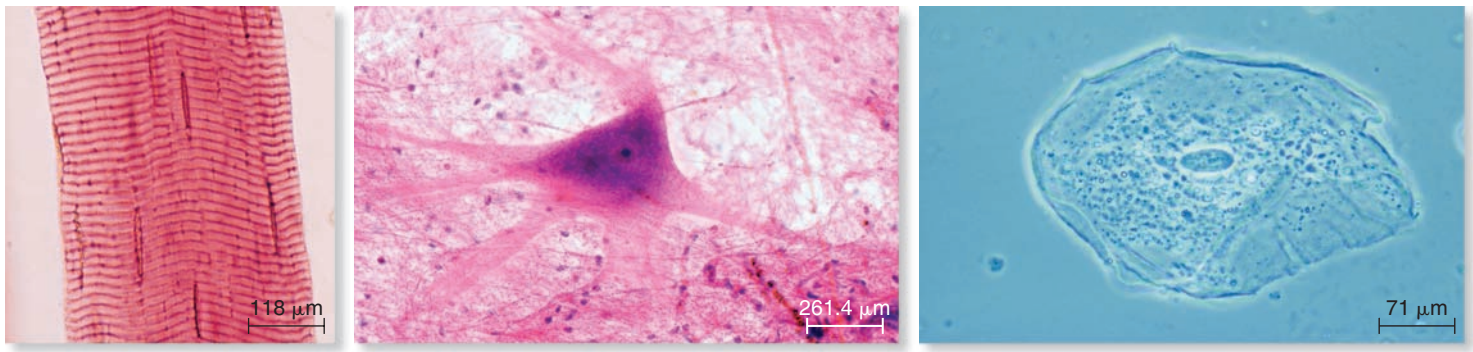
BIOLOGY PRINCIPLE **Living organisms use energy.** Gene regulation provides a way for organisms to avoid wasting energy. They make proteins only when they are needed.

Bacteria Regulate Genes in Response to Changes in Their Environment

The bacterium *Escherichia coli* can use many types of sugars as food sources, thereby increasing its chances of survival. With regard to gene regulation, we will focus on how it uses lactose, which is a sugar found in milk. The genome of *E. coli* carries genes that code for proteins that enable it to take up lactose from the environment and metabolize it.

Figure 13.1 illustrates the effects of lactose on the regulation of those genes. In order to utilize lactose, an *E. coli* cell requires a transporter, called lactose permease, that facilitates the uptake of lactose into the cell, and an enzyme, called β-galactosidase, that catalyzes the breakdown of lactose. When lactose is not present in the environment, an *E. coli* cell makes very little of these proteins. However, when lactose becomes available, the bacterium produces many more copies of these proteins, enabling it to readily use lactose from its environment. Eventually, all of the lactose in the environment is used up. At this point, the genes encoding these proteins will be shut off, and most of the proteins will be degraded. Overall, gene regulation conserves energy because it ensures that the proteins needed for lactose utilization are made only when lactose is present in the environment.



Eukaryotic Gene Regulation Produces Different Cell Types in a Single Organism

One of the most amazing examples of gene regulation is the phenomenon of **cell differentiation**, the process by which cells become specialized into particular types. In humans, for example, cells may differentiate into muscle cells, neurons, skin cells, or other types. **Figure 13.2** shows micrographs of three types of cells found in humans. As seen here, their morphologies are strikingly different. Likewise, their functions within the body are also quite different. Muscle cells are important in body movements, neurons function in cell signaling, and skin cells form a protective outer surface to the body.

Gene regulation is responsible for producing different types of cells within a multicellular organism. The three cell types shown in Figure 13.2 contain the same **genome**, meaning they carry the same set of genes. However, their **proteomes**—the collection of proteins they make—are quite different. Certain proteins are found in particular cell types but not in others. Alternatively, a protein may be present in all three cell types, but the relative amounts of the protein may be different. The amount of a given protein depends on many factors, including how strongly the corresponding gene is turned on and how much protein is synthesized from mRNA. Gene regulation plays a major role in determining the proteome of each cell type.

Eukaryotic Gene Regulation Enables Multicellular Organisms to Proceed Through Developmental Stages

In multicellular organisms that progress through developmental stages, certain genes are expressed at particular stages of development but not others. Let's consider an example of such gene regulation in mammals. Early stages of development occur in the uterus of female mammals. Following fertilization, an embryo develops inside the uterus. In humans, the embryonic stage lasts from fertilization to

(a) Skeletal muscle cell (b) Neuron (c) Skin cell

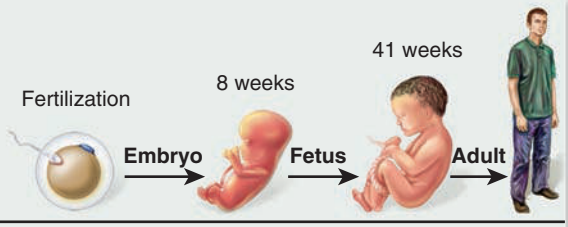


Figure 13.2 Examples of different cell types in humans. These cells have the same genetic composition. Their unique morphologies are due to differences in the proteins they make.

Concept Check: How does gene regulation underlie the different morphologies of these cells?

8 weeks. During this stage, major developmental changes produce the various body parts. The fetal stage occurs from 8 weeks to birth (41 weeks). This stage is characterized by a continued refinement of body parts and a large increase in size.

The oxygen demands of a rapidly growing embryo and fetus are quite different from the needs of the mother. Gene regulation plays a vital role in ensuring that an embryo and fetus get the proper amount of oxygen. Hemoglobin is a protein that delivers oxygen to the cells of a mammal's body. A hemoglobin protein is composed of four globin polypeptides, two encoded by one globin gene and two encoded by another globin gene (**Figure 13.3**). The genomes of mammals carry several genes (designated with Greek letters) that encode slightly different globin polypeptides. During the embryonic stage of development, the ε-globin and ζ-globin (epsilon-globin and zeta-globin) genes are turned on. At the fetal stage, these genes are turned off, and the α-globin and γ-globin (alpha-globin and gamma-globin) genes are turned on. Finally, at birth, the γ-globin gene is turned off, and the beta β-globin (beta-globin) gene is turned on.

How do the embryo and fetus acquire oxygen from their mother's bloodstream? The hemoglobin produced during the embryonic and fetal stages has a higher binding affinity for oxygen than does the hemoglobin produced after birth. Therefore, the embryo and fetus can remove oxygen from the mother's bloodstream and use that oxygen for their own needs. This occurs across the placenta, where the mother's bloodstream is adjacent to the bloodstream of the embryo or fetus. In this way, gene regulation enables mammals to develop internally, even though the embryo and fetus are not breathing on their own. Gene regulation ensures that the correct hemoglobin protein is produced at the right time in development. We'll discuss how gene expression controls the process of development in greater detail in Chapter 19.

	Embryo	Fetus	Adult
Hemoglobin protein	2 ζ-globins 2 ε-globins	2 α-globins 2 γ-globins	2 α-globins 2 β-globins
Oxygen affinity	Highest	High	Moderate
Gene expression			
α-globin gene	Off	On	On
β-globin gene	Off	Off	On
γ-globin gene	Off	On	Off
ζ-globin gene	On	Off	Off
ε-globin gene	On	Off	Off

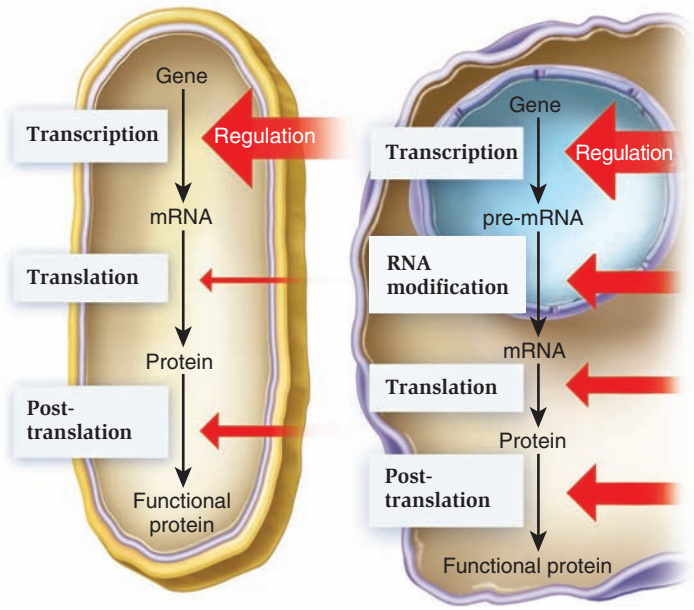

Figure 13.3 Regulation of human globin genes at different stages of development.

BIOLOGY PRINCIPLE Living organisms grow and develop. Gene regulation is an important process that allows organisms to proceed through developmental stages.

Gene Regulation Occurs at Different Points in the Process from DNA to Protein

Thus far, we have learned that gene regulation has a dramatic influence on the ability of organisms to respond to environmental changes, produce different types of cells, and progress through developmental stages. For genes that encode proteins, the regulation of gene expression can occur at any of the steps that are needed to produce a functional protein.

In bacteria, gene regulation most commonly occurs at the level of transcription, which means that bacteria regulate how much mRNA is made from genes (**Figure 13.4a**). When geneticists say a gene is "turned off," they mean that very little or no mRNA is made from that gene, whereas a gene that is "turned on" is transcribed into mRNA. Because transcription is the first step in gene expression, transcriptional regulation is a particularly efficient way to regulate genes because cells avoid wasting energy when the product of the gene is not needed. A second way for bacteria to regulate gene expression is to control the ability of an mRNA to be translated into protein. This form of gene regulation is less common in bacteria. Last, gene expression can be regulated at the protein or post-translational level.

(a) Bacterial gene regulation (b) Eukaryotic gene regulation

Figure 13.4 Overview of gene regulation in (a) bacteria and (b) eukaryotes. The relative width of the red arrows indicates the prominence with which gene regulation is used to control the production of functional proteins.

In eukaryotes, gene regulation occurs at many levels, including transcription, RNA modification, translation, and after translation is completed (**Figure 13.4b**). As in their bacterial counterparts, transcriptional regulation is a prominent form of gene regulation for eukaryotes. As discussed later in this chapter, eukaryotic genes are transcriptionally regulated in several different ways, some of which are not found in bacteria. Regulation of RNA modification (discussed in Chapter 12) and of the rate of translation of mRNAs is also common.

As in bacteria, eukaryotic proteins can be regulated in a variety of ways other than gene regulation, including cellular regulation and biochemical regulation (such as feedback inhibition). These various types of regulation are best understood within the context of cell biology, so they were primarily discussed in Unit II (see Chapter 6 and Figure 6.13). Post-translational modifications are also summarized in Chapter 21 (look ahead to Figure 21.10b).

13.2 Regulation of Transcription in Bacteria

Learning Outcomes:

1. Explain how regulatory transcription factors and small effector molecules are involved in the regulation of transcription.
2. Describe the organization of the *lac* operon and how it is under negative and positive control.
3. **SciSKILLS** » Analyze the results of the experiments of Jacob, Monod, and Pardee.
4. Describe how the *trp* operon is under negative control.

As we have seen, when a bacterium is exposed to a particular nutrient in its environment, such as a sugar, the genes are expressed that encode proteins needed for the uptake and metabolism of that sugar. In addition, bacteria have genes that encode enzymes that synthesize molecules such as particular amino acids. In such cases, the control of gene expression often occurs at the level of transcription. In this section, we will examine the underlying molecular mechanisms that bring about transcriptional regulation in bacteria.

Transcriptional Regulation Involves Regulatory Transcription Factors and Small Effector Molecules

In most cases, regulation of transcription involves the actions of **regulatory transcription factors**—proteins that bind to **regulatory sequences** in the DNA in the vicinity of a promoter and affect the rate of transcription of one or more nearby genes. These transcription factors either decrease or increase the rate of transcription of a gene. **Repressors** are regulatory transcription factors that bind to the DNA and decrease the rate of transcription. This is a form of regulation called **negative control**. **Activators** bind to the DNA and increase the rate of transcription, a form of regulation termed **positive control** (**Figure 13.5a**).

In conjunction with regulatory transcription factors, molecules called **small effector molecules** often play a critical role in transcriptional regulation. A small effector molecule exerts its effects by binding to a regulatory transcription factor and causing a conformational change in the protein. In many cases, the effect of the conformational change determines whether or not the protein can bind to the DNA. **Figure 13.5b** illustrates an example involving a repressor. When the small effector molecule is not present in the cytoplasm, the repressor binds to the DNA and inhibits transcription. However, when the small effector molecule is subsequently found in the cytoplasm, it will bind to the repressor and cause a conformational change that inhibits the ability of the protein to bind to the DNA. Transcription can occur because the repressor is not able to bind to the DNA. Repressors and activators that respond to small effector molecules have two functional regions called domains. One domain is a site where the protein binds to the DNA, whereas the other is the binding site for the small effector molecule.

The *lac* Operon Contains Genes That Encode Proteins Involved in Lactose Metabolism

In bacteria, structural genes are sometimes clustered together and under the transcriptional control of a single promoter. This arrangement is known as an **operon**. The transcription of the genes occurs as a single unit and results in the production of a **polycistronic mRNA**, an mRNA that encodes more than one protein. What advantage does this arrangement provide? An operon organization allows a bacterium to coordinately regulate a group of genes that encode proteins whose functions are used in a common pathway.

The genome of *E. coli* carries an operon, called the ***lac* operon**, that contains the genes for the proteins that allow it to metabolize lactose (see Figure 13.1). **Figure 13.6a** shows the organization of this operon as it is found in the *E. coli* chromosome, as well as

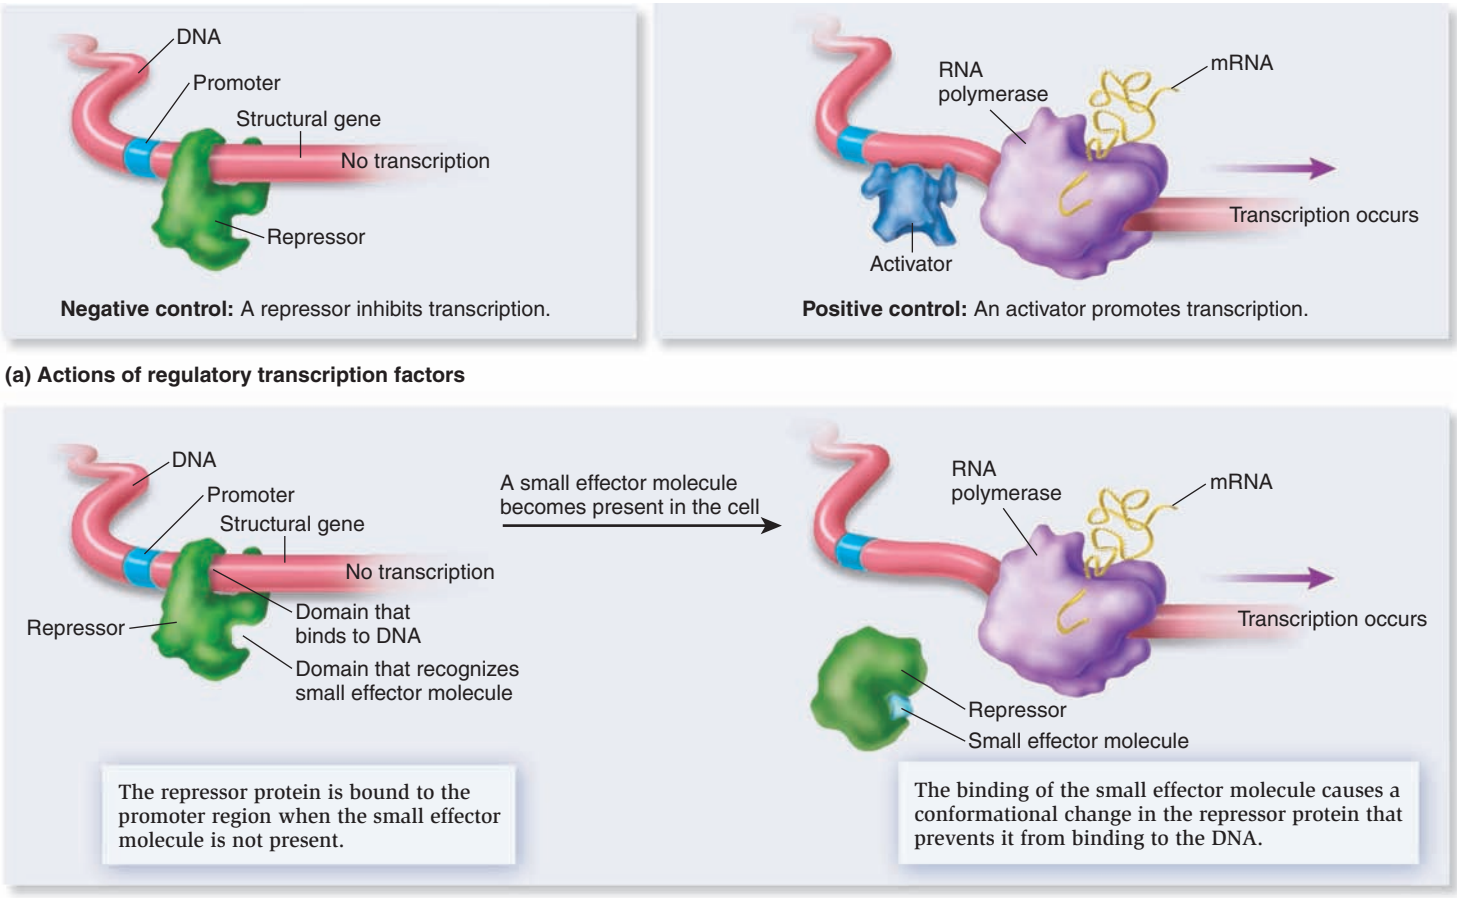

Figure 13.5 Actions of regulatory transcription factors and small effector molecules. **(a)** Regulatory transcription factors are proteins that exert negative or positive control. **(b)** One way that a small effector molecule may exert its effects is by preventing a repressor protein from binding to the DNA.

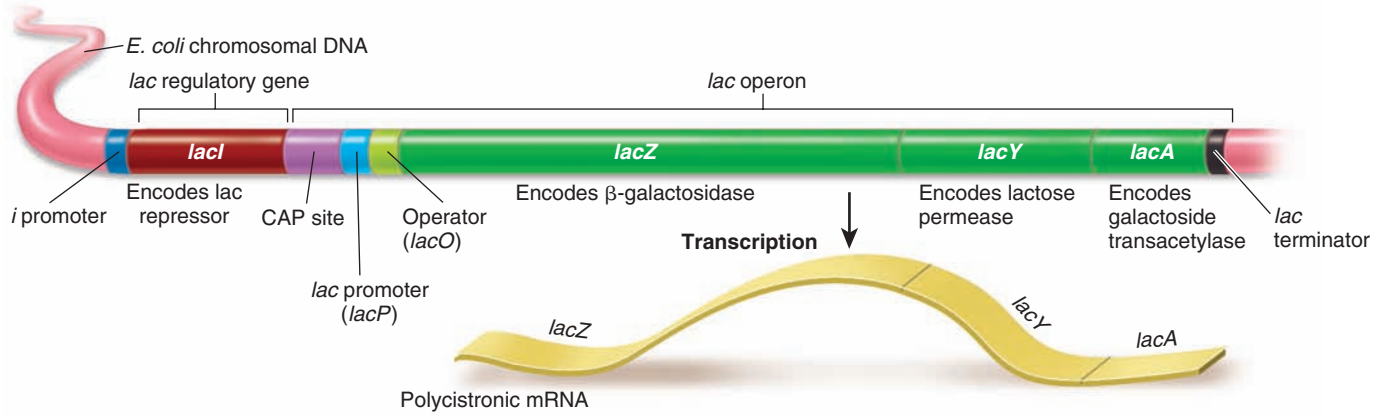
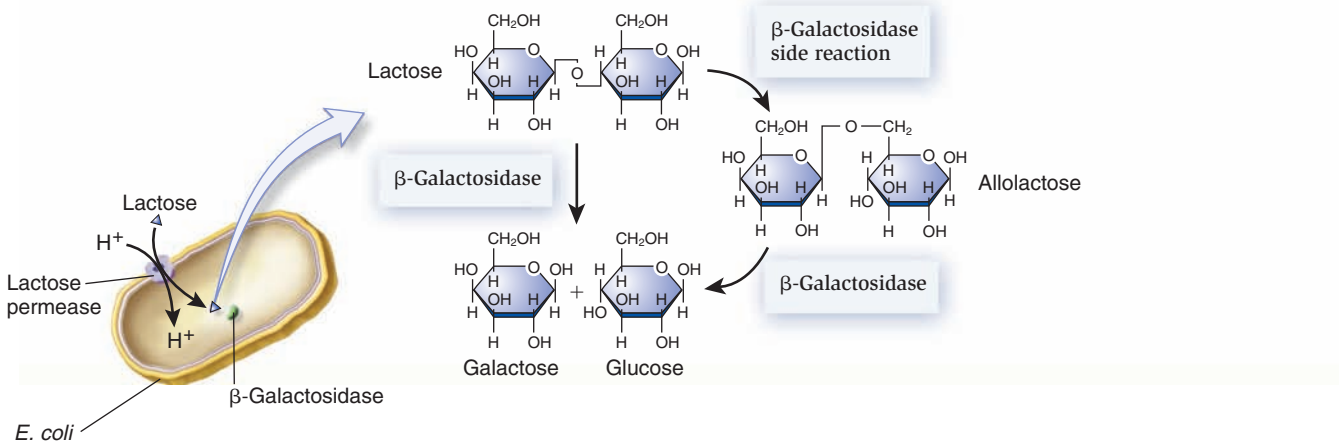
the polycistronic mRNA that is transcribed from it. The *lac* operon contains a promoter, *lacP*, that is used to transcribe three structural genes: *lacZ*, *lacY*, and *lacA*.

- *LacZ* encodes β-galactosidase, which is an enzyme that breaks down lactose (**Figure 13.6b**). As a side reaction, β-galactosidase also converts a small percentage of lactose into allolactose, a structurally similar sugar, or lactose analogue. As described later, allolactose is important in the regulation of the *lac* operon.
- The *lacY* gene encodes lactose permease, which is a membrane protein required for the transport of lactose into the cytoplasm of the bacterium.
- The *lacA* gene encodes galactoside transacetylase, which covalently modifies lactose and lactose analogues by attaching an acetyl group (—$COCH_3$). The attachment of acetyl groups to nonmetabolizable lactose analogues prevents their toxic buildup in the cytoplasm.



Near the *lac* promoter are two regulatory sequences designated the operator and the CAP site (see Figure 13.6a). The **operator (*lacO*)** is a regulatory sequence in the DNA. The sequence of bases at the operator provides a binding site for a repressor protein. The **CAP site** is a regulatory sequence recognized by an activator protein.

Adjacent to the *lac* operon is the *lacI* gene, which encodes the **lac repressor**. This repressor protein is important for the regulation of the *lac* operon. The *lacI* gene, which is constitutively expressed at a fairly low level, has its own promoter called the *i* promoter. The *lacI* gene is not considered a part of the *lac* operon. Let's now take a look at how the *lac* operon is regulated by the lac repressor.



The *lac* Operon Is Under Negative Control by a Repressor Protein

In the late 1950s, the first researchers to investigate gene regulation were French biologists François Jacob and Jacques Monod at the Pasteur Institute in Paris, France. Their focus on gene regulation stemmed from an interest in the phenomenon known as enzyme adaptation, which had been identified early in the 20th century. Enzyme adaptation occurs when a particular enzyme appears within a living cell only after the cell has been exposed to the substrate for that enzyme. Jacob and Monod studied lactose metabolism in *E. coli* to investigate this phenomenon. When they exposed bacteria to lactose, the levels of lactose-using enzymes in the cells increased by 1,000- to 10,000-fold. After lactose was removed, the synthesis of the enzymes abruptly stopped.

The first mechanism of regulation that Jacob and Monod discovered involved the lac repressor, which binds to the sequence of

(a) Organization of DNA sequences in the *lac* region of the *E. coli* chromosome

(b) Functions of lactose permease and β-galactosidase

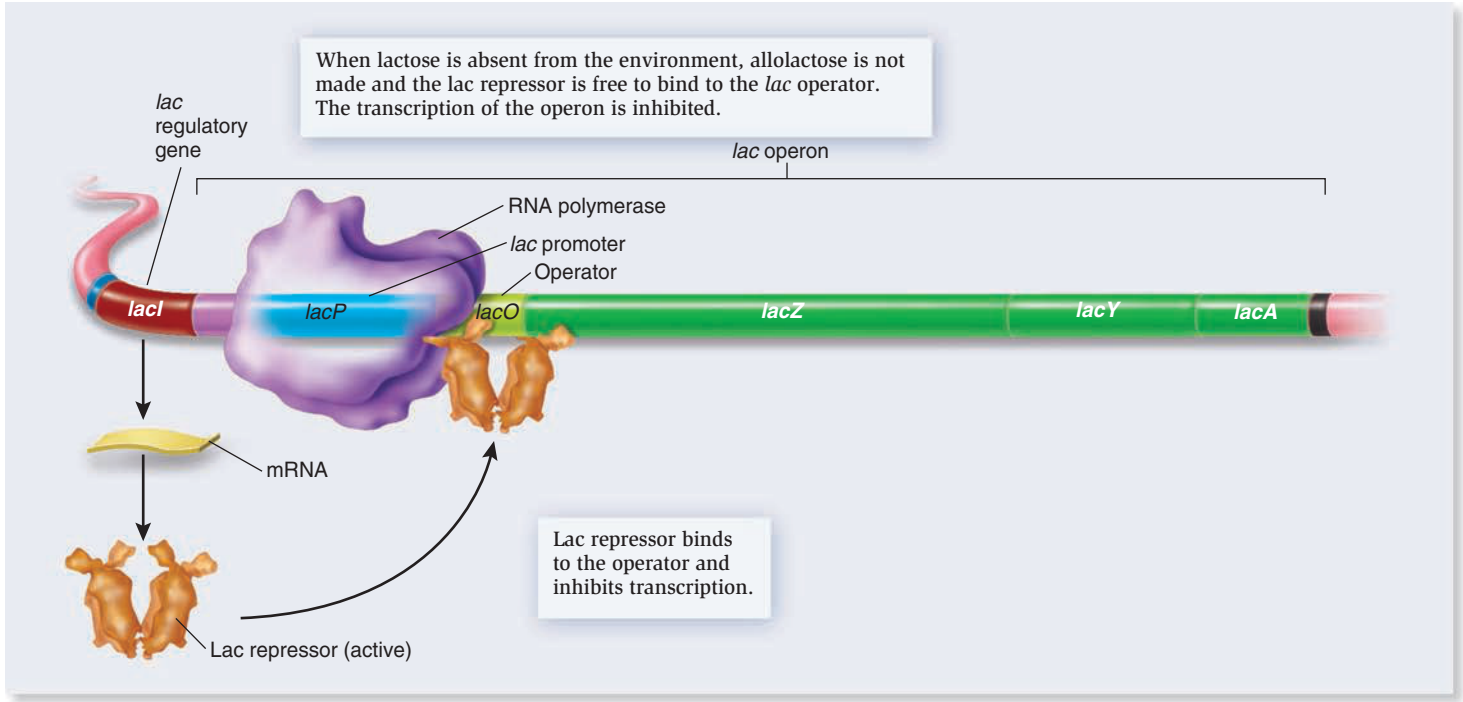


Figure 13.6 The *lac* operon. **(a)** This diagram depicts a region of the *E. coli* chromosome that contains the *lacI* gene and the adjacent *lac* operon, as well as the polycistronic mRNA transcribed from the operon. The mRNA is translated into three proteins: lactose permease, β-galactosidase, and galactoside transacetylase. **(b)** Lactose permease cotransports H^+ with lactose. Bacteria maintain an H^+ gradient across their cytoplasmic membrane that drives the active transport of lactose into the cytoplasm. β-Galactosidase cleaves lactose into galactose and glucose. As a side reaction, it can also convert lactose into allolactose.

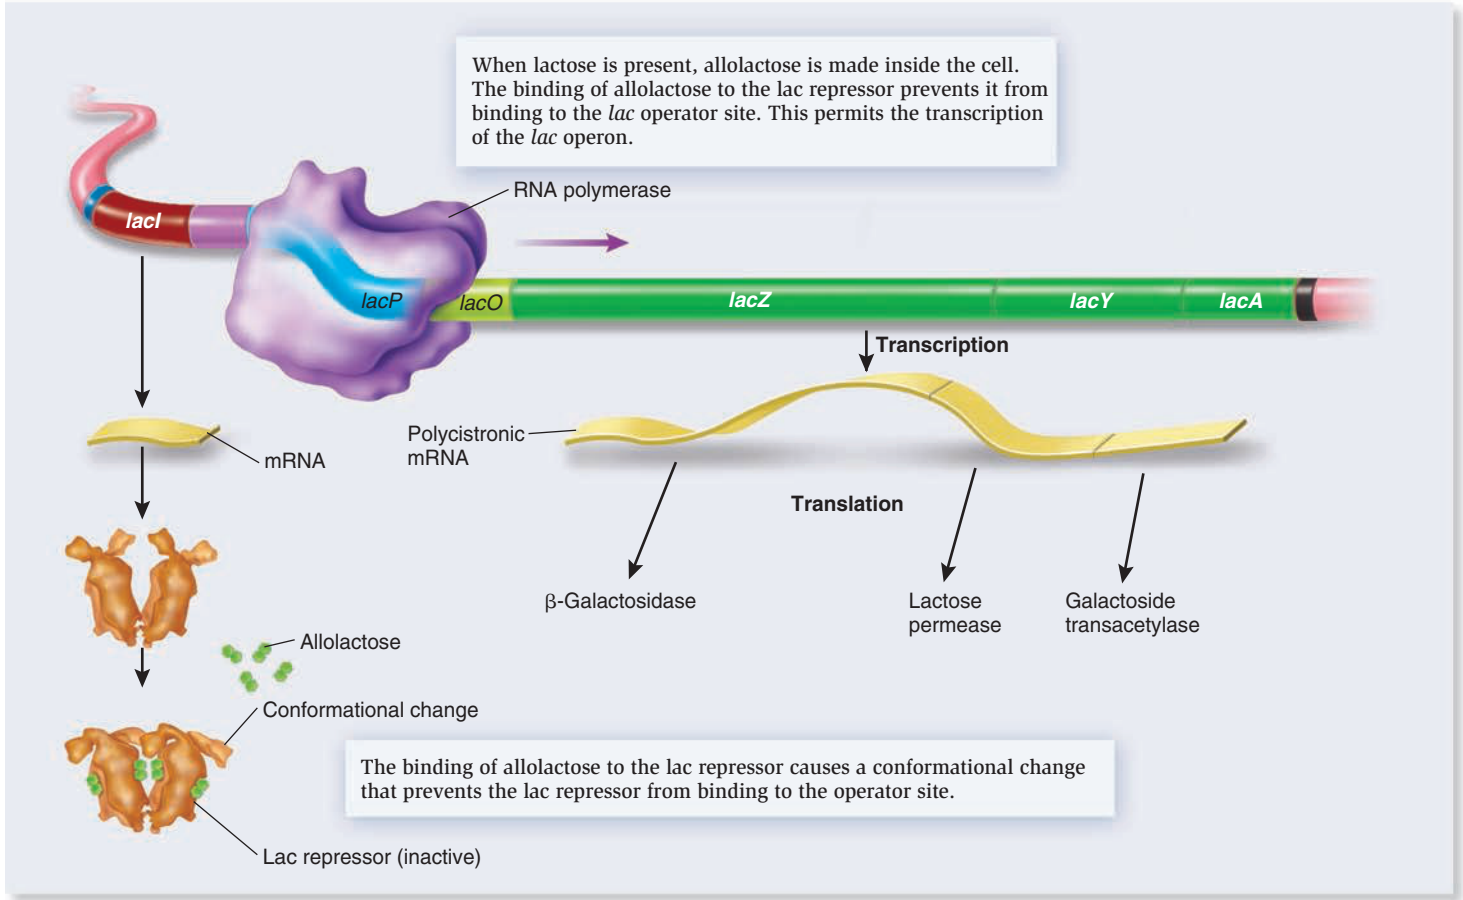
Concept Check: *Which genes are under the control of the lac promoter?*



nucleotides found at the *lac* operator site. Once bound, the lac repressor prevents RNA polymerase from transcribing the *lacZ*, *lacY*, and *lacA* genes (**Figure 13.7a**). RNA polymerase can bind to the promoter when the lac repressor is bound to the operator site, but cannot move past the operator to transcribe the *lacZ*, *lacY*, and *lacA* genes.

Whether or not the lac repressor binds to the operator site depends on allolactose, the previously mentioned side product of the β-galactosidase enzyme (see Figure 13.6b). How does allolactose control the lac repressor? Allolactose is an example of a small effector molecule. The lac repressor protein contains four identical subunits, each one recognizing a single allolactose molecule. When four allolactose molecules bind to the lac repressor, a conformational change occurs that prevents the repressor from binding to the operator. Under these conditions, RNA polymerase is free to transcribe the operon (**Figure 13.7b**).

The regulation of the *lac* operon enables *E. coli* to conserve energy because lactose-utilizing proteins are made only when lactose is present in the environment. Allolactose is an **inducer**, a small effector molecule that increases the rate of transcription, and the *lac* operon is said to be an **inducible operon**. When the bacterium is not exposed to lactose, no allolactose is available to bind to the lac repressor. Therefore, the lac repressor binds to the operator site and inhibits transcription. In reality, the repressor does not completely inhibit transcription, so very small amounts of β-galactosidase, lactose permease, and galactoside transacetylase are made. Even so, the levels are far too low for the bacterium to readily use lactose. When the bacterium is exposed to lactose, a small amount can be transported into the cytoplasm via lactose permease, and β-galactosidase converts some of it to allolactose (see Figure 13.6b). The cytoplasmic level of allolactose gradually rises until allolactose binds to the lac repressor, which induces the *lac* operon and promotes a high rate of transcription of the *lacZ*, *lacY*, and *lacA* genes. Translation of the encoded polypeptides produces the proteins needed for lactose uptake and metabolism as described previously in Figure 13.1.

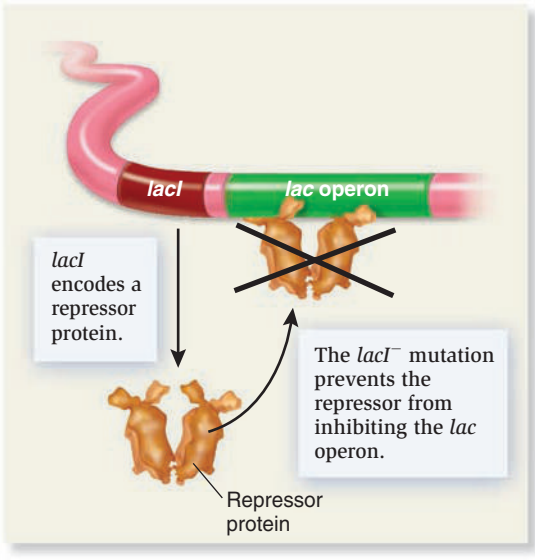
Concept Check: *With regard to regulatory proteins and small effector molecules, explain the meaning of negative control and inducible.*

Feature Investigation | Jacob, Monod, and Pardee Studied a Constitutive Mutant to Determine the Function of the Lac Repressor

Thus far, we have learned that the lac repressor binds to the *lac* operator site to exert its effects. Let's now take a look back at experiments that helped researchers determine the function of the lac repressor. Our understanding of *lac* operon regulation came from studies involving *E. coli* strains that showed abnormalities in the process. In the 1950s, Jacob, Monod, and their colleague, American biochemist Arthur Pardee, had identified a few rare mutant bacteria that expressed the genes of the *lac* operon constitutively, meaning that the *lacZ*, *lacY*, and *lacA* genes were expressed even in the absence of lactose in the environment. The researchers discovered that some mutations that caused this abnormality had occurred in the *lacI* region of the DNA. Such strains were termed $lacI^-$ (*lacI* minus) to indicate that the *lacI* region was not functioning properly. Normal or wild-type *lacI* strains of *E. coli* are called $lacI^+$ (*lacI* plus).

The researchers initially hypothesized that the *lacI* gene encodes an enzyme that degrades an internal inducer of the *lac* operon. The $lacI^-$ mutation was thought to inhibit this enzyme, thereby allowing the internal inducer to always be synthesized. In this way, the $lacI^-$ mutation made it unnecessary for cells to be exposed to lactose for induction. However, over the course of this study and other studies, the researchers eventually arrived at the hypothesis that the *lacI* gene encodes a repressor protein, which proved to be correct (**Figure 13.8**). A mutation in the *lacI* gene that eliminates the synthesis of a functional lac repressor prevents the lac repressor protein from inhibiting transcription. At the time of their work, however, the function of the lac repressor was not yet known.

To understand the nature of the $lacI^-$ mutation, Jacob, Monod, and Pardee applied a genetic approach. Although bacterial conjugation is described in Chapter 18, let's briefly examine this process in order to understand this experiment. The earliest studies of Jacob, Monod, and Pardee in 1959 involved matings between recipient cells, termed F^- (F minus), and donor cells, which were called Hfr strains. Such Hfr strains were able to transfer a portion of the bacterial chromosome to a recipient cell. Later experiments in 1961 involved the transfer of circular segments of DNA known as F factors. We will consider this later type of experiment here. Sometimes an F factor also carries genes that were originally found within the bacterial chromosome. These types of F factors are called F′ factors (F prime factors). A strain of bacteria containing F′ factor genes is called a **merozygote**. The production of merozygotes was instrumental in allowing Jacob, Monod, and Pardee to elucidate the function of the *lacI* gene.



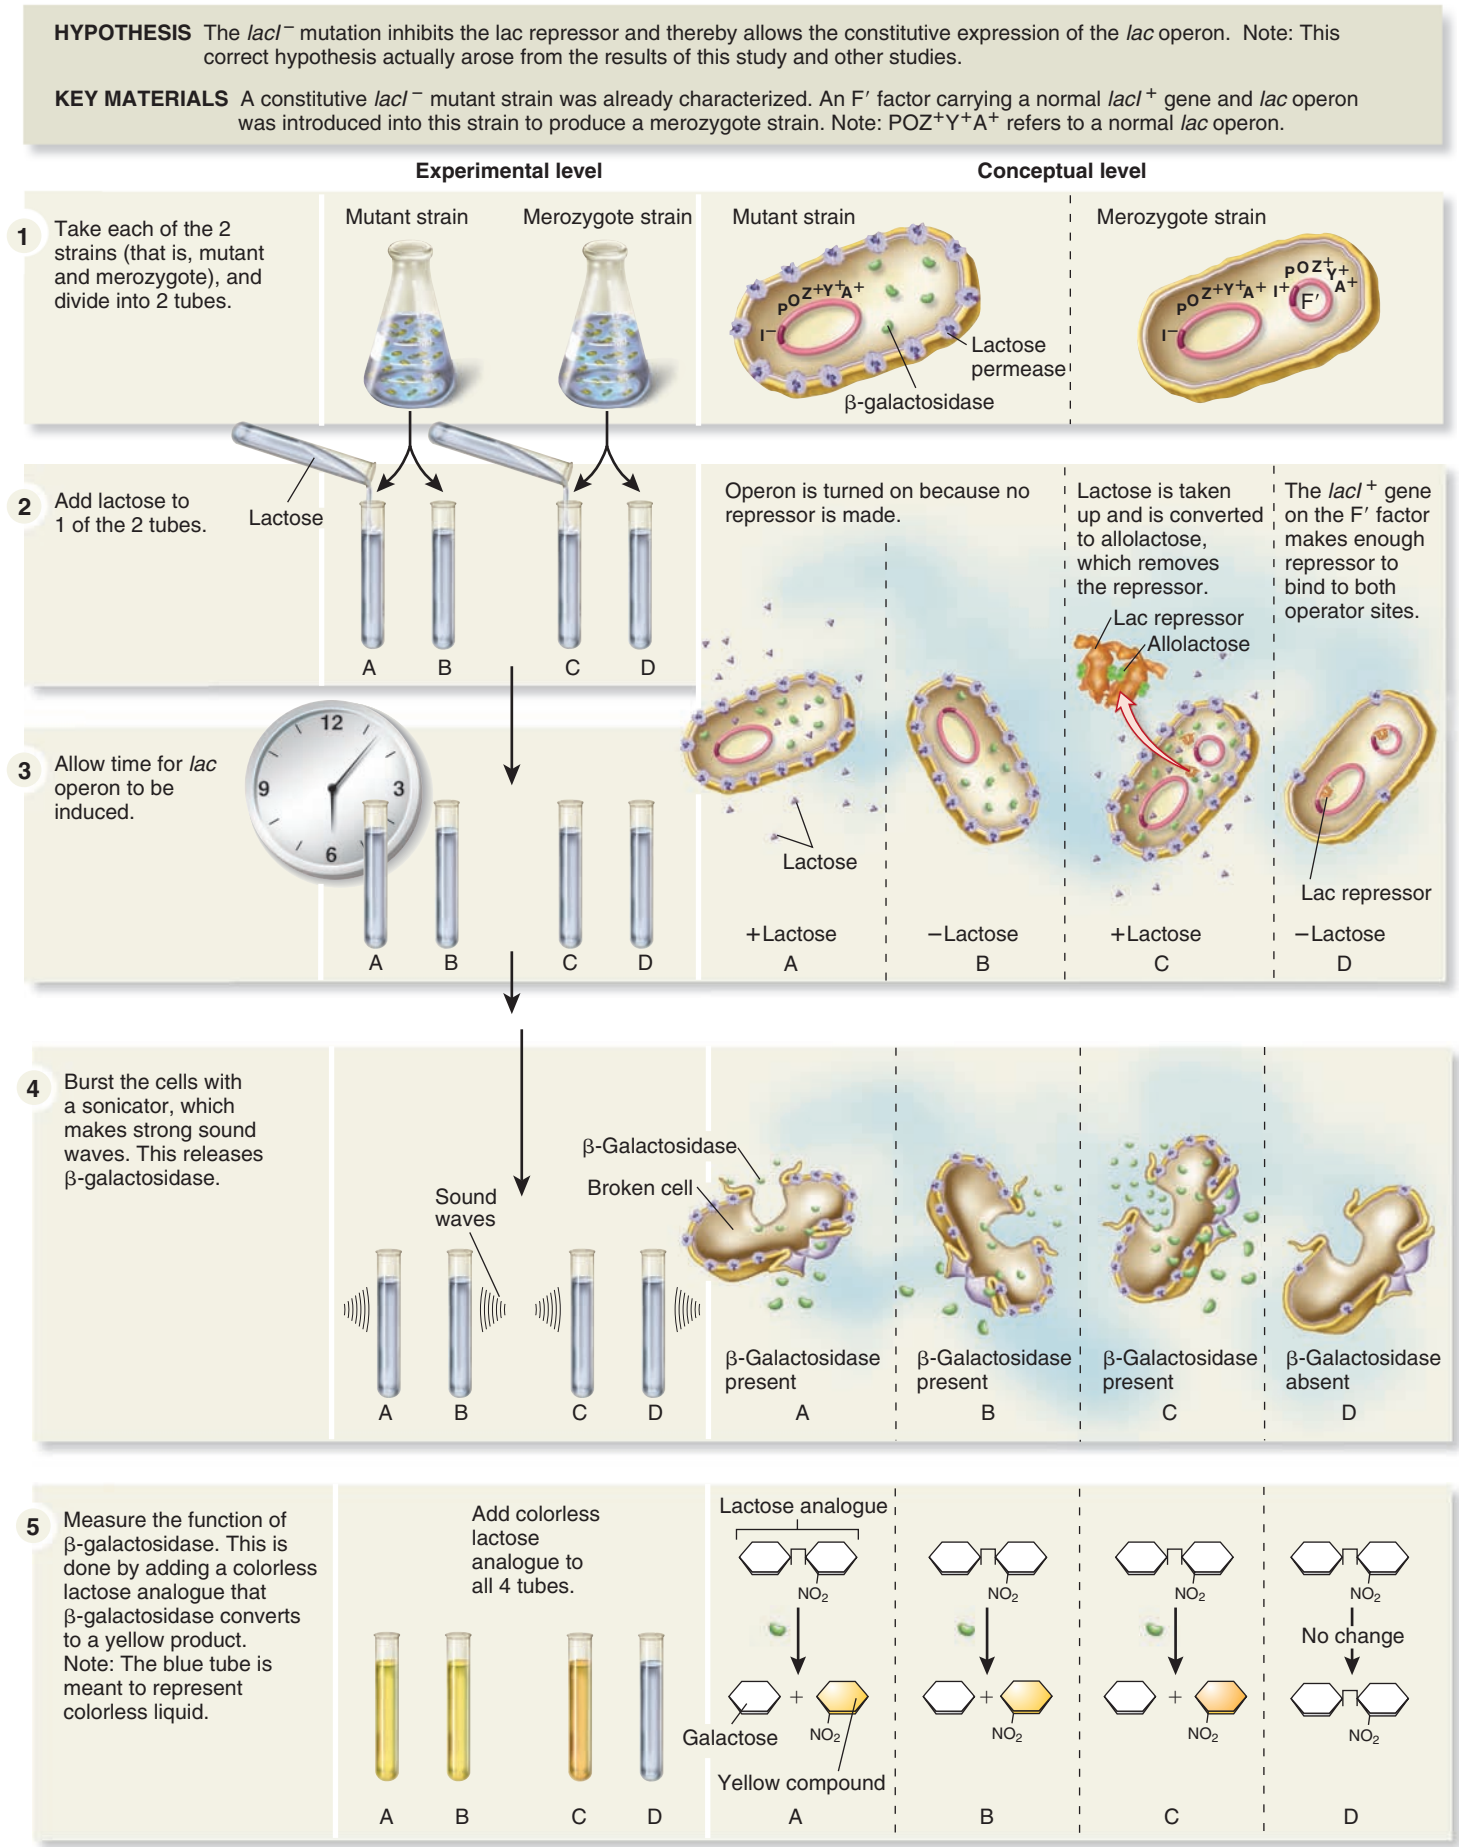


Figure 13.8 **A hypothesis for the function of the *lacI* gene.**

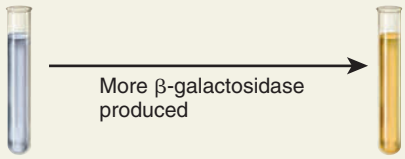
As shown in **Figure 13.9**, these researchers studied the *lac* operon in a bacterial strain carrying a $lacI^-$ mutation that caused constitutive expression of the *lac* operon. In addition, the mutant strain was subjected to mating to produce a merozygote that also carried a normal *lac* operon and a normal $lacI^+$ gene on an F′ factor. The merozygote contained both $lacI^+$ and $lacI^-$ genes. The constitutive mutant and corresponding merozygote were grown separately in liquid media and then divided into two tubes each. In half of the tubes, the cells were incubated with lactose to determine if lactose was needed to induce the expression of the operon. In the other tubes, lactose was omitted. To monitor the expression of the *lac* operon, the cells were broken open and then tested for the amount of β-galactosidase they released by measuring the ability of any β-galactosidase present to convert a colorless compound into a yellow product.

The data table of Figure 13.9 summarizes the effects of this constitutive mutation and its analysis in a merozygote. As Jacob, Monod, and Pardee already knew, the $lacI^-$ mutant strain expressed the *lac* operon constitutively, in both the presence and absence of lactose. However, when a normal *lac* operon and $lacI^+$ gene on an F′ factor were introduced into a cell harboring the mutant $lacI^-$ gene on the chromosome, the normal $lacI^+$ gene could regulate both operons. In the absence of lactose, both operons were shut off. How did Jacob, Monod, and Pardee eventually explain these results? This occurred because a single $lacI^+$ gene on the F′ factor produces enough repressor protein to bind to both operator sites. Furthermore, this protein is diffusible—can spread through the cytoplasm—and binds to *lac* operons that are on the F′ factor and on the bacterial chromosome. Taken together, the data indicated that the normal *lacI* gene encodes a diffusible protein that represses the *lac* operon.



The interactions between regulatory proteins and DNA sequences illustrated in this experiment have led to the definition of three genetic terms. A ***cis*-acting element** is a DNA segment that must be adjacent to the gene(s) that it regulates. The *lac* operator site is an example of a *cis*-acting element. A ***trans*-effect** is a form of gene regulation that can occur even though two DNA segments are not physically adjacent. The action of the lac repressor on the *lac* operon is a *trans*-effect. A ***cis*-effect** is mediated by a *cis*-acting element that binds regulatory proteins, whereas a *trans*-effect is mediated by genes that encode diffusible regulatory proteins.

Figure 13.9 **The experiment performed by Jacob, Monod, and Pardee to study a constitutive *lacI*⁻ mutant.**

6 The amount of yellow color is measured with a spectrophotometer; the deeper the yellow color, the more β-galactosidase was produced.

7 THE DATA

Results from step 6:

	Expression of the *lac* operon	
	With lactose	Without lactose
Mutant strain	100%	100%
Merozygote strain	220%	<1%

8 CONCLUSION The *lacI* gene encodes a diffusible repressor protein.

Experimental Questions

1. What were the key observations made by Jacob, Monod, and Pardee that led to the development of their hypothesis regarding the *lacI* gene and the regulation of the *lac* operon?
2. **SciSKILLS »** What was the eventual hypothesis proposed by the researchers to explain the function of the *lacI* gene and the regulation of the *lac* operon?
3. **SciSKILLS »** How did Jacob, Monod, and Pardee test the hypothesis? What were the results of the experiment? How do these results support the idea that the *lacI* gene produces a repressor protein?

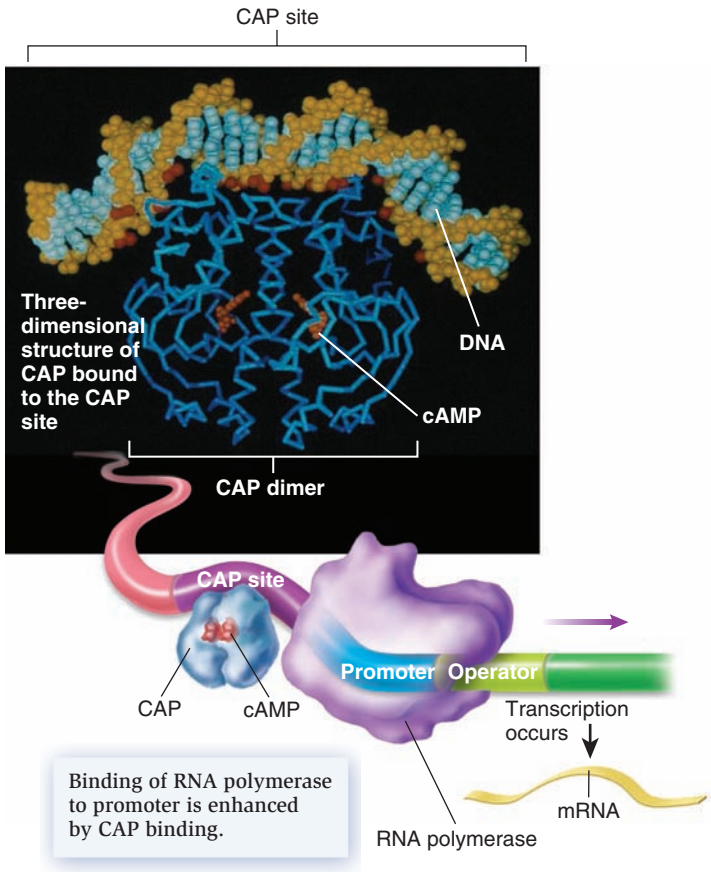
The *lac* Operon Is Also Under Positive Control by an Activator Protein

In addition to negative control by a repressor protein, the *lac* operon is also positively regulated by an activator called the **catabolite activator protein (CAP)**. CAP is controlled by a small effector molecule, **cyclic AMP (cAMP)**, which is produced from ATP via an enzyme known as adenylyl cyclase. Gene regulation involving CAP and cAMP is an example of positive control (**Figure 13.10**). When cAMP binds to CAP, the cAMP-CAP complex binds to the CAP site near the *lac* promoter. This causes a bend in the DNA that enhances the ability of RNA polymerase to bind to the promoter. In this way, the rate of transcription is increased.

The key functional role of CAP is to allow *E. coli* to choose between different sources of sugar. In a process known as **catabolite repression**, the presence of a preferred energy source inhibits the use of other energy sources. In this case, transcription of the *lac* operon is inhibited by the presence of glucose, which is a catabolite (it is broken down—catabolized—inside the cell). This gene regulation allows *E. coli* to preferentially use glucose instead of other sugars, such as lactose. How does this occur? Glucose inhibits the production of cAMP, thereby preventing the binding of CAP to the DNA. In this way, glucose blocks the activation of the *lac* operon by inhibiting transcription. Though it may seem puzzling, the term catabolite repression was coined before the action of the cAMP-CAP complex was understood at the molecular level. Historically, the primary observation of researchers was that glucose (a catabolite) inhibited (repressed) lactose metabolism. Further experimentation revealed that CAP is actually an activator protein.

Figure 13.11 considers the four possible environmental conditions that an *E. coli* bacterium might experience with regard to these two sugars.

- When both lactose and glucose levels are high (Figure 13.11a), the rate of transcription of the *lac* operon is low, because CAP does not activate transcription. Under these conditions, the bacterium primarily uses glucose rather than lactose. Why is this a benefit to the bacterium? The bacterium conserves energy by using one type of sugar at a time.
- If the lactose level is high and the glucose level is low (Figure 13.11b), the transcription rate of the *lac* operon is very high because CAP is bound to the CAP site and the lac repressor is not bound to the operator site. Under these conditions, the bacterium metabolizes lactose.



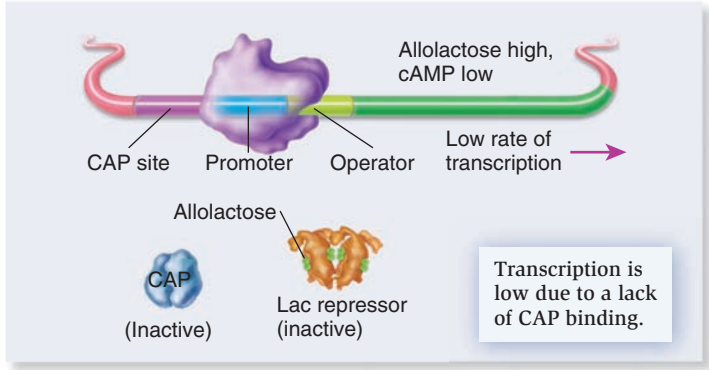


Figure 13.10 Positive control of the *lac* operon by the catabolite activator protein (CAP). When cAMP is bound to CAP, CAP binds to the DNA and causes it to bend. This bend facilitates the binding of RNA polymerase.

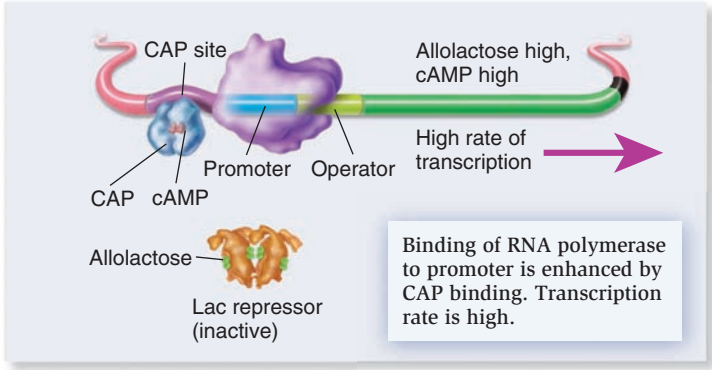
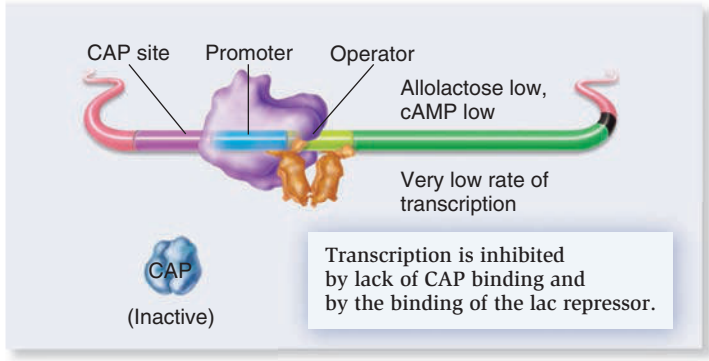
BioConnections: Look back at Figure 9.12. What is the function of cAMP in eukaryotic cells?

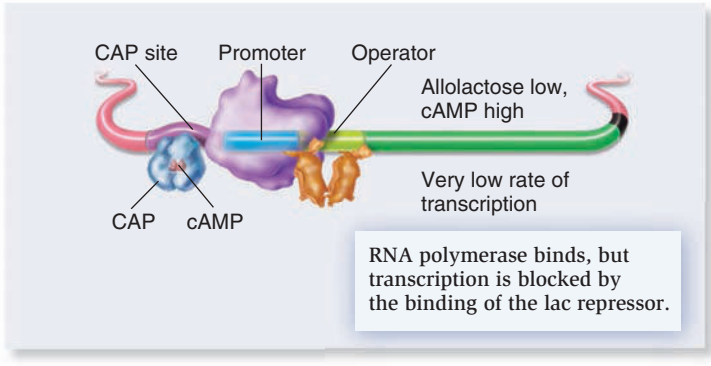


- When the lactose level is low, the lac repressor prevents transcription of the *lac* operon, whether the glucose level is high or low (Figure 13.11c,d).

BIO TIPS **THE QUESTION** *Let's suppose you have isolated a mutant strain of E. coli in which the lac operon is constitutively expressed. In other words, the operon is turned on in the presence or the absence of lactose. One possibility is that the mutation is blocking transcription of the lacI gene, thereby preventing the synthesis of lac repressor. A second possibility is that the mutation altered the sequence of the lac operator site in a way that prevents the lac repressor protein from binding there. How could you distinguish between these two possibilities?*



TOPIC ***What topic in biology does this question address?*** The topic is gene regulation. More specifically, the question asks



(a) Lactose high, glucose high

(b) Lactose high, glucose low

(c) Lactose low, glucose high

(d) Lactose low, glucose low

Figure 13.11 Effects of lactose and glucose on the expression of the *lac* operon.

Concept Check: What are the advantages of having both an activator and a repressor protein?

how you could determine the way a mutation is affecting the expression of the *lac* operon.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you know that the mutation is either inhibiting the expression of *lacI* or has altered *lacO* in a way that prevents the binding of lac repressor. From your understanding of the topic, you may remember that the lac repressor exhibits a *trans*-effect because it is a diffusible protein, whereas *lacO* is a *cis*-acting element.

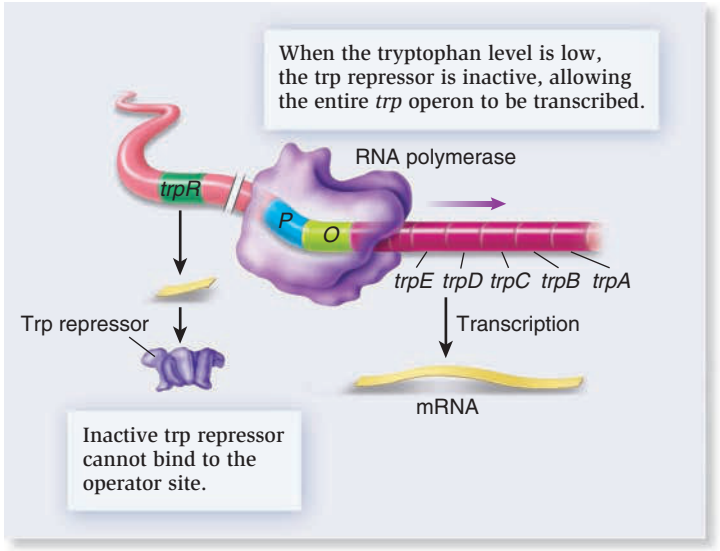
PROBLEM-SOLVING STRATEGY ***Design an experiment. Predict the outcome.*** One strategy to solve this problem is to design an experiment that can distinguish between a mutation that results in a *cis*-effect versus one that produces a *trans*-effect. The use of a merozygote is one way to accomplish that goal.

ANSWER

Key materials: The constitutive strain of E. coli and a merozygote that carries a normal lac operon and a normal lacI gene on an F′ factor (see Figure 13.9).

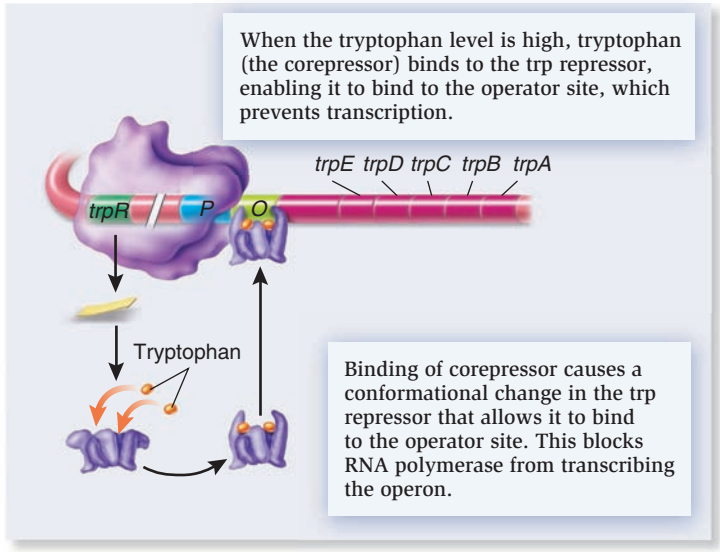
Procedure:

1. *Place each strain into separate tubes with or without lactose.*
2. *Allow induction to occur.*
3. *Burst the cells with a sonicator.*
4. *Add the lactose analogue, and measure yellow color production.*



Expected results: If the mutation is in lacI, the repressor encoded on the F′ factor will inhibit the expression of the lac operon on the chromosome and the one on the F′ factor. There will be very little yellow color in the absence of lactose in the merozygote. (This was the result obtained in Figure 13.9.) Alternatively, if the mutation is in lacO, the lac operon on the chromosome will still be turned on even in the absence of lactose. The merozygote will produce a strong yellow color in the absence of lactose.

The *trp* Operon Is Under Negative Control by a Repressor Protein



So far in this section, we have examined the regulation of the *lac* operon. Let's now consider an example of an operon that encodes enzymes involved in biosynthesis rather than breakdown. Our example is the ***trp* operon** of *E. coli*, which encodes enzymes that are required to make the amino acid tryptophan, a building block of proteins. More specifically, the *trpE*, *trpD*, *trpC*, *trpB*, and *trpA* genes encode enzymes that are involved in a pathway that leads to tryptophan synthesis.

The *trp* operon is regulated by a repressor protein that is encoded by the *trpR* gene. The binding of the repressor to the *trp* operator site inhibits transcription. The ability of the trp repressor to bind to the *trp* operator is controlled by tryptophan, which is the product of the metabolic pathway controlled by the enzymes that are encoded by the operon.

- When the tryptophan level within the cell is very low, the trp repressor cannot bind to the operator site. Under these conditions, RNA polymerase readily transcribes the operon (**Figure 13.12a**). In this way, the cell expresses the genes that encode enzymes that result in the synthesis of tryptophan, which is in short supply.
- When the tryptophan level within the cell is high, tryptophan turns off the *trp* operon. Tryptophan acts as a small effector molecule, or **corepressor**, by binding to the trp repressor protein. This causes a conformational change in the repressor that allows it to bind to the *trp* operator site, inhibiting the ability of RNA polymerase to transcribe the operon (**Figure 13.12b**). Therefore, the bacterium does not waste energy making tryptophan when it is abundant.

(a) Low tryptophan

(b) High tryptophan

Figure 13.12 Negative control of a repressible set of genes: function of the trp repressor and corepressor (tryptophan) in regulating the *trp* operon.

Concept Check: How are the functions of the lac repressor and trp repressor similar to each other, and how are they different?

When comparing the *lac* and *trp* operons, the actions of their small effector molecules are quite different. The lac repressor binds to its operator in the absence of its small effector molecule, whereas the trp repressor binds to its operator only in the presence of its small effector molecule. The *lac* operon is categorized as an inducible operon because allolactose, its small effector molecule, induces transcription. By comparison, the *trp* operon is considered to be a **repressible operon** because its small effector molecule, namely tryptophan, represses transcription.

13.3 Regulation of Transcription in Eukaryotes: Roles of Transcription Factors and Mediator

Learning Outcomes:

1. Explain the concept of combinatorial control.
2. Describe how RNA polymerase and general transcription factors initiate transcription at the core promoter.
3. Compare and contrast how activators, coactivators, repressors, TFIID, and mediator play a role in gene regulation.

Regulation of transcription in eukaryotes follows some of the same principles as those found in bacteria. For example, activator and repressor proteins are involved in regulating genes by influencing the ability of RNA polymerase to initiate transcription. In addition, many eukaryotic genes are regulated by small effector molecules. However, some important differences also occur. In eukaryotic species, genes are almost always organized individually, not in operons. In addition, eukaryotic gene regulation tends to be more intricate, because eukaryotes are faced with complexities that differ from their bacterial counterparts. For example, eukaryotes have more complicated cell structures that contain many more proteins and a variety of cell organelles. Many eukaryotes, such as animals and plants, are multicellular and contain different cell types. As discussed earlier in this chapter, animal cells may differentiate into neurons, muscle cells, and skin cells, and so on. Furthermore, animals and plants progress through developmental stages that require changes in gene expression.

By studying transcriptional regulation, researchers have discovered that most eukaryotic genes, particularly those found in multicellular species, are regulated by many factors. This phenomenon is called **combinatorial control** because the combination of many factors determines the expression of any given gene. At the level of transcription, common factors that contribute to combinatorial control include the following:

1. One or more activators may stimulate the ability of RNA polymerase to initiate transcription.
2. One or more repressors may inhibit the ability of RNA polymerase to initiate transcription.
3. The function of activators and repressors may be modulated in several ways, which include the binding of small effector molecules, protein-protein interactions, and covalent modifications.

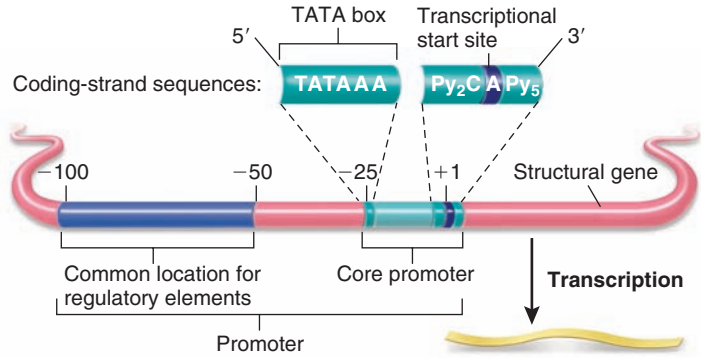


Figure 13.13 A common organization of sequences for the promoter of a eukaryotic structural gene. The core promoter has a TATA box and a transcriptional start site. The TATA box sequence is 5′–TATAAA–3′. However, not all structural genes in eukaryotes have a TATA box. The A highlighted in dark blue is the transcriptional start site. This A marks the site of the first adenine in the RNA transcript. The sequence that flanks the A of the transcriptional start site is two pyrimidines, then C, then five pyrimidines. Py refers to pyrimidine—cytosine or thymine. Regulatory elements, such as enhancers and silencers, are usually found upstream from the core promoter.

4. Activators are necessary to alter chromatin structure in the region where a gene is located, thereby making it easier for the gene to be recognized and transcribed by RNA polymerase.
5. DNA methylation usually inhibits transcription, either by preventing the binding of an activator or by recruiting proteins that inhibit transcription.

All five of these factors may contribute to the regulation of a single gene, or possibly only three or four will play a role. In most cases, transcriptional regulation is aimed at controlling the initiation of transcription at the promoter. In this section and the following section, we will survey these basic types of gene regulation in eukaryotic species.

Eukaryotic Structural Genes Have a Core Promoter and Regulatory Elements

To understand gene regulation in eukaryotes, we first need to consider the DNA sequences that are needed to initiate transcription. For eukaryotic structural genes that encode proteins, three features are common among most promoters: **regulatory elements**, a **TATA box**, and a **transcriptional start site** (Figure 13.13).

The TATA box and transcriptional start site form the **core promoter**. The transcriptional start site is the place in the DNA where transcription actually begins. The TATA box, which is a 5′–TATAAA–3′ sequence, is usually about 25 bp upstream from a transcriptional start site. The TATA box is important in determining the precise starting point for transcription. If it is missing from the core promoter, transcription may start at a variety of different locations. The core promoter, by itself, results in a low level of transcription that is termed **basal transcription**.

Regulatory elements (or regulatory sequences) are DNA segments that regulate eukaryotic genes. As described later, regulatory elements are recognized by regulatory transcription factors that control the ability of RNA polymerase to initiate transcription at the core promoter. Some regulatory elements, known as **enhancers**, play a

role in the ability of RNA polymerase to begin transcription, thereby enhancing the rate of transcription. When enhancers are not functioning, most eukaryotic genes have very low levels of transcription. Other regulatory elements, known as **silencers**, prevent transcription of a given gene when its expression is not needed. When these sequences function, the rate of transcription is decreased.

A common location for regulatory elements is the region that is 50–100 bp upstream from the transcriptional start site (see Figure 13.13). However, the locations of regulatory elements vary greatly among different eukaryotic genes. Regulatory elements can be quite distant from the promoter, even 100,000 bp away, yet exert strong effects on the ability of RNA polymerase to initiate transcription at the core promoter! Regulatory elements were first discovered by Japanese molecular biologist Susumu Tonegawa and coworkers in the 1980s. While studying genes that play a role in immunity, they identified a region that was far away from the core promoter but was needed for high levels of transcription to take place.

RNA Polymerase II, General Transcription Factors, and Mediator Are Needed to Transcribe Eukaryotic Structural Genes

As discussed in Chapter 12, three forms of RNA polymerases, designated I, II, and III, are found in eukaryotes. RNA polymerase II transcribes structural genes that encode proteins. By studying transcription in a variety of eukaryotic species, researchers have identified three types of proteins that play a role in initiating transcription at the core promoter of structural genes. These are RNA polymerase II, five different proteins called **general transcription factors (GTFs)**, and a large protein complex called mediator.

RNA polymerase II and GTFs must come together at the TATA box of the core promoter so transcription can be initiated. A series of interactions occurs between these proteins so RNA polymerase II can bind to the DNA. The completed assembly of RNA polymerase II and GTFs at the TATA box is known as the **preinitiation complex** (**Figure 13.14**).

Another component needed for transcription in eukaryotes is the mediator protein complex. **Mediator** is composed of many proteins that bind to each other to form an elliptically shaped complex that partially wraps around RNA polymerase II and the GTFs. Mediator derives its name from the observation that it mediates interactions between the preinitiation complex and regulatory transcription factors such as activators or repressors that bind to enhancers or silencers. The function of mediator is to control the rate at which RNA polymerase can begin to transcribe RNA at the transcriptional start site.

Activators and Repressors May Influence the Function of GTFs or Mediator

In eukaryotes, regulatory transcription factors called activators and repressors bind to enhancers or silencers, respectively, and regulate the rate of transcription of genes. Activators and repressors commonly regulate the function of RNA polymerase II by binding to GTFs or mediator.

Affecting the Function of GTFs As shown in **Figure 13.15**, some activators bind to an enhancer and then influence the function of

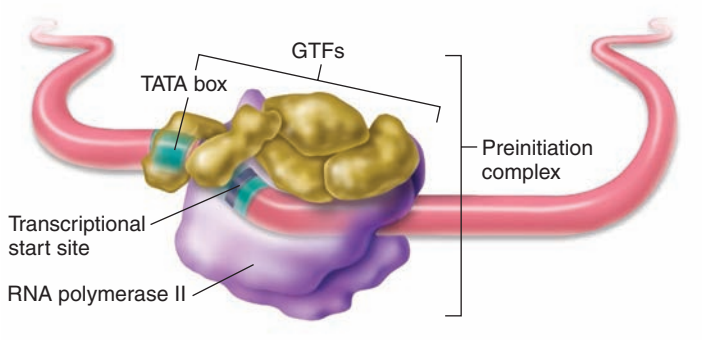

Figure 13.14 The preinitiation complex. General transcription factors (GTFs) and RNA polymerase II assemble into the preinitiation complex at the core promoter in eukaryotic structural genes.

GTFs. For example, an activator may improve the ability of a GTF called transcription factor II D (TFIID) to initiate transcription. The function of TFIID is to recognize the TATA box and begin the assembly process. An activator may recruit TFIID to the TATA box, thereby promoting the assembly of GTFs and RNA polymerase II into the preinitiation complex. In contrast, repressors may bind to a silencer and inhibit the function of TFIID. Certain repressors exert their effects by preventing the binding of TFIID to the TATA box or by inhibiting the ability of TFIID to assemble other GTFs and RNA polymerase II at the core promoter.

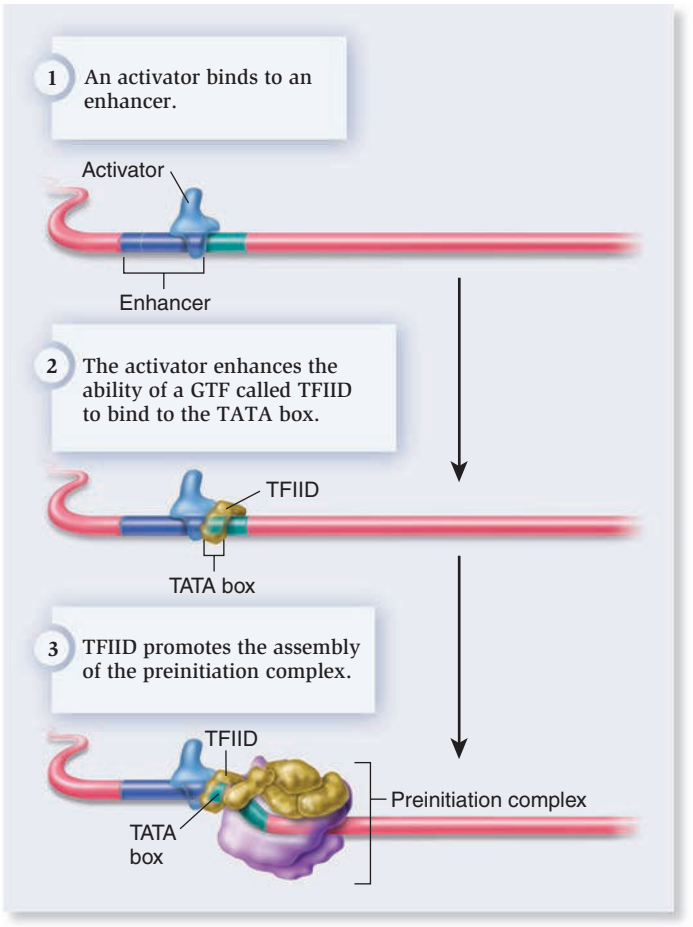

Figure 13.15 Effect of an activator via TFIID, a general transcription factor.

Affecting the Function of Mediator In addition to affecting GTFs, a second way that regulatory transcription factors control RNA polymerase II is via mediator (**Figure 13.16**). In this example, an activator also interacts with a **coactivator**—a protein that increases the rate of transcription but does not directly bind to the DNA itself. The activator-coactivator complex stimulates the function of mediator, thereby causing RNA polymerase II to proceed to the elongation phase of transcription more quickly. Alternatively, repressors have the opposite effect to those seen in Figure 13.16. When a repressor inhibits its mediator, RNA polymerase II cannot progress to the elongation stage.

A third way that regulatory transcription factors influence transcription is by recruiting proteins that affect chromatin structure in the promoter region, as described next.

13.4 Regulation of Transcription in Eukaryotes: Changes in Chromatin Structure and DNA Methylation

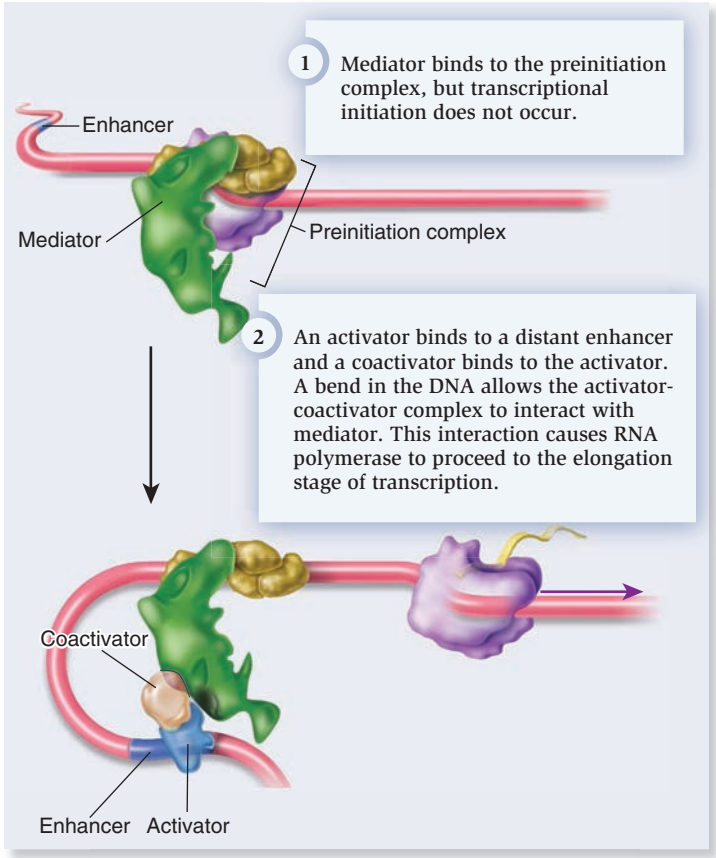
Learning Outcomes:

1. Describe the flanking of eukaryotic genes by nucleosome-free regions, and explain how nucleosomes are altered during gene transcription.
2. Explain how DNA methylation affects transcription.

In eukaryotes, DNA is associated with proteins to form a structure called **chromatin**—the complex of DNA and proteins that makes up eukaryotic chromosomes (see Chapter 11, Figures 11.21 and 11.24). How does the structure of chromatin affect gene transcription? Recall from Chapter 11 that nucleosomes are composed of DNA wrapped around an octamer of histone proteins. Depending on the locations and arrangements of nucleosomes, a region containing a gene may be in a **closed conformation**, and transcription may be difficult or impossible. Transcription requires changes in chromatin structure that allow transcription factors to gain access to and bind to the DNA in the promoter region. Such chromatin, said to be in an **open conformation**, is accessible to GTFs and RNA polymerase II, so transcription can take place. In this section, we will examine how chromatin is converted from a closed to an open conformation. We will also explore how **DNA methylation**—the attachment of methyl groups to the base cytosine—affects chromatin conformation and gene expression.

Transcription Is Controlled by Changes in Chromatin Structure

In recent years, geneticists have been trying to identify the steps that promote the interconversion between the closed and open conformations of chromatin. One way to change chromatin structure is through **ATP-dependent chromatin-remodeling complexes**, which are a group of proteins that alter chromatin structure. Such complexes use energy from ATP hydrolysis to drive a change in the locations and/or compositions of nucleosomes, thereby making the DNA more or less amenable to transcription. Therefore, chromatin remodeling is important for both the activation and repression of transcription.



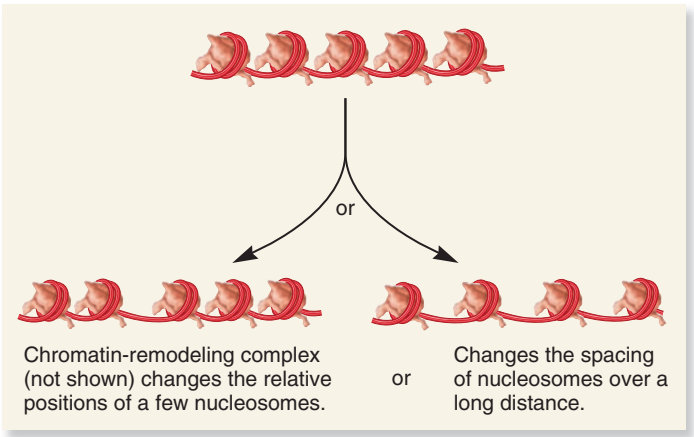


Figure 13.16 **Effect of an activator via mediator.**

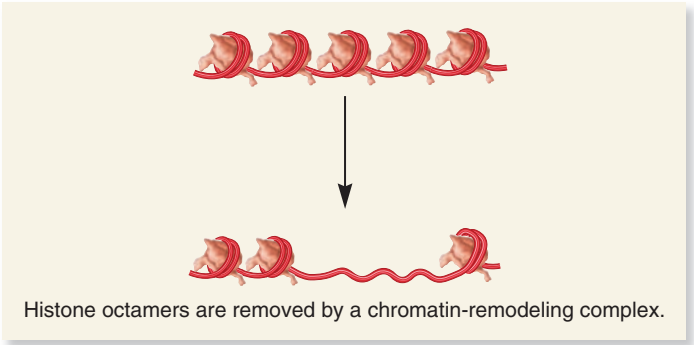
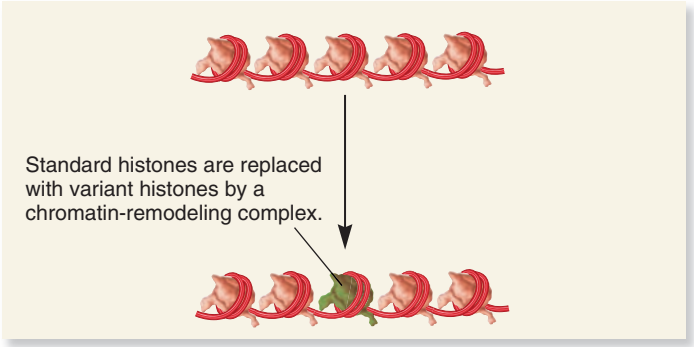


Concept Check: *When an activator interacts with mediator, how does this affect the function of RNA polymerase?*

How do ATP-dependent chromatin-remodeling complexes change chromatin structure? Three effects are possible.



- One result is that these complexes may bind to chromatin and change the locations of nucleosomes (**Figure 13.17a**). This may involve a shift of the relative positions of a few nucleosomes or a change in the relative spacing of nucleosomes over a long stretch of DNA.
- A second effect is that remodeling complexes may evict histone octamers from the DNA, thereby creating gaps where nucleosomes are not found (**Figure 13.17b**).
- A third possibility is that chromatin-remodeling complexes may change the composition of nucleosomes by removing standard histone proteins from an octamer and replacing them with histone variants (**Figure 13.17c**). A **histone variant** is a histone protein that has a slightly different amino acid sequence from the standard histone proteins described in Chapter 11. Some histone variants promote gene transcription, whereas others inhibit it.

(a) Change in nucleosome position

(b) Histone eviction

(c) Replacement with variant histones

Figure 13.17 ATP-dependent chromatin remodeling. Chromatin-remodeling complexes may **(a)** change the locations of nucleosomes, **(b)** remove histones from the DNA, or **(c)** replace standard histones with variant histones. The chromatin-remodeling complex, which is composed of a group of proteins, is not shown in this figure.

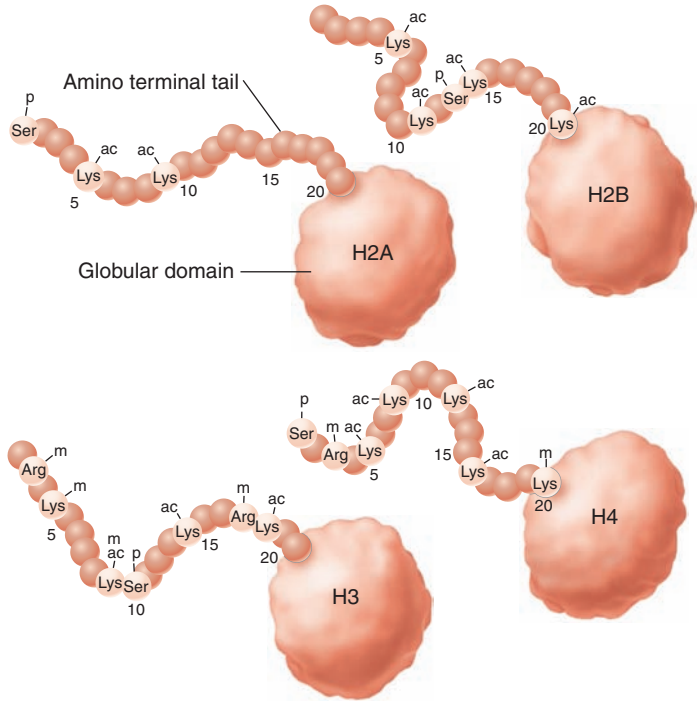


Figure 13.18 Examples of covalent modifications that occur to the amino terminal tails of histone proteins. The amino acids are numbered from the N-terminus, or amino end. The modifications shown here are m for methylation, p for phosphorylation, and ac for acetylation. Many more modifications can occur to the amino terminal tails. These modifications are reversible.

Concept Check: What are the two opposing effects that histone modifications may have with regard to chromatin structure?

Histone Modifications Affect Gene Transcription

In recent years, researchers have learned that the amino terminal tails of histone proteins are subject to several types of covalent modifications. For example, an enzyme called **histone acetyltransferase** attaches acetyl groups (—$COCH_3$) to the amino terminal tails of histone proteins. When acetylated, histone proteins do not bind as tightly to the DNA, which aids in transcription. Over 50 different enzymes have been identified in mammals that selectively modify amino terminal tails. **Figure 13.18** shows an example in the amino terminal tails of histone proteins H2A, H2B, H3, and H4 that can be modified by acetyl, methyl, and phosphate groups.

What are the effects of covalent modifications of histones? First, modifications may directly influence interactions between DNA and histone proteins, and between adjacent nucleosomes. As mentioned, the acetylation of histones loosens their binding to DNA and aids in transcription. Second, histone modifications provide binding sites that are recognized by other proteins. According to the **histone code hypothesis**, proposed by American biologists Brian Strahl and David Allis in 2000, the pattern of histone modification is recognized by proteins much like a language or code. One pattern of histone modification may attract proteins that inhibit transcription. Alternatively, a different combination of histone modifications may attract proteins, such as ATP-dependent chromatin-remodeling complexes, that promote gene transcription. In this way, the histone code plays a key role in accessing the information within the genomes of eukaryotic species.

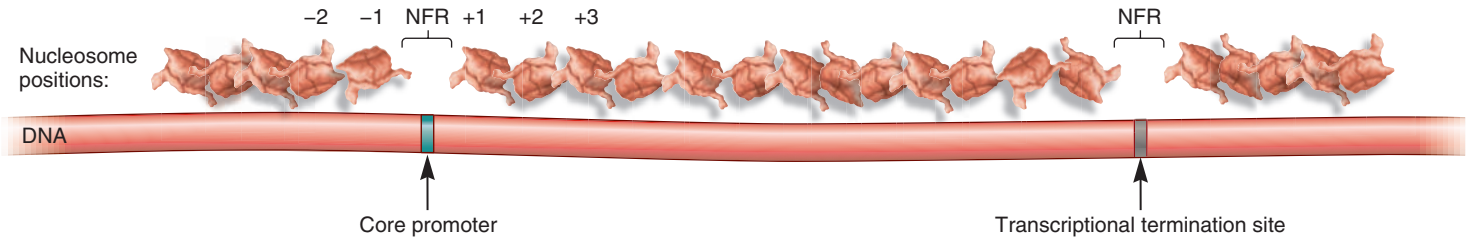

Figure 13.19 **Nucleosome arrangements in the vicinity of a eukaryotic structural gene.**

BioConnections: *Look back at Figure 11.21. What is the composition of a nucleosome?*

Eukaryotic Genes Are Flanked by Nucleosome-Free Regions

Studies over the last 10 years or so have revealed that many eukaryotic genes show a common pattern of nucleosome organization (**Figure 13.19**). For active genes or those genes that can be activated, the core promoter is found at a **nucleosome-free region (NFR)**, which is a site that is missing nucleosomes. The NFR is typically 150 bp in length. Although the NFR may be required for transcription, it is not, by itself, sufficient for gene activation. At any given time in the life of a eukaryotic cell, many genes that contain an NFR are not being actively transcribed. The NFR is flanked by two nucleosomes that are termed the –1 and +1 nucleosomes. These nucleosomes often contain histone variants that promote transcription. The end of many eukaryotic genes is followed by another NFR. This arrangement at the end of genes may be important for transcriptional termination.

Transcriptional Activation Involves Changes in Nucleosome Locations, Composition, and Histone Modifications

A key role of certain activators is to recruit ATP-dependent chromatin-remodeling complexes and histone-modifying enzymes to the promoter region of eukaryotic genes. Though the order of recruitment may differ among specific activators, this appears to be critical for transcriptional initiation and elongation. In the scenario shown in **Figure 13.20**, an activator binds to an enhancer in the NFR. The activator then recruits chromatin-remodeling complexes and histone-modifying enzymes to this region. The chromatin-remodeling complex may shift nucleosomes or temporarily evict nucleosomes from the promoter region. Nucleosomes containing certain histone variants are thought to be more easily removed from the DNA than those containing the standard histones. Histone-modifying enzymes, such as histone acetyltransferase, covalently modify histone proteins and may affect nucleosome contact with the DNA. The actions of chromatin-remodeling complexes and histone-modifying enzymes facilitate the binding of general transcription factors and RNA polymerase II to the core promoter, thereby allowing the formation of a preinitiation complex (see Figure 13.20, step 2).

Further changes in chromatin structure are necessary for elongation to occur. RNA polymerase II cannot transcribe DNA that is tightly wrapped in nucleosomes. For transcription to occur, histones are evicted, partially displaced, or destabilized so RNA polymerase II can pass. Evicted histones are then reassembled by chaperone proteins and placed back on the DNA behind the moving RNA polymerase II (see Figure 13.20). These histones may be deacetylated—have their acetyl groups removed—so they bind more tightly to the DNA.

DNA Methylation Inhibits Gene Transcription

Let's now turn our attention to a mechanism that usually silences gene expression. DNA structure can be modified by the covalent attachment of methyl groups (—CH_3) by an enzyme called **DNA methyltransferase**. This modification, termed DNA methylation, is common in some eukaryotic species but not all. For example, yeast and *Drosophila* have little or no detectable methylation of their DNA, whereas DNA methylation in vertebrates and plants is relatively abundant. In mammals, approximately 5% of the DNA is methylated. Eukaryotic DNA methylation occurs on the cytosine base. The sequence that is methylated is shown here:

$$\begin{array}{l} \quad\quad\quad\

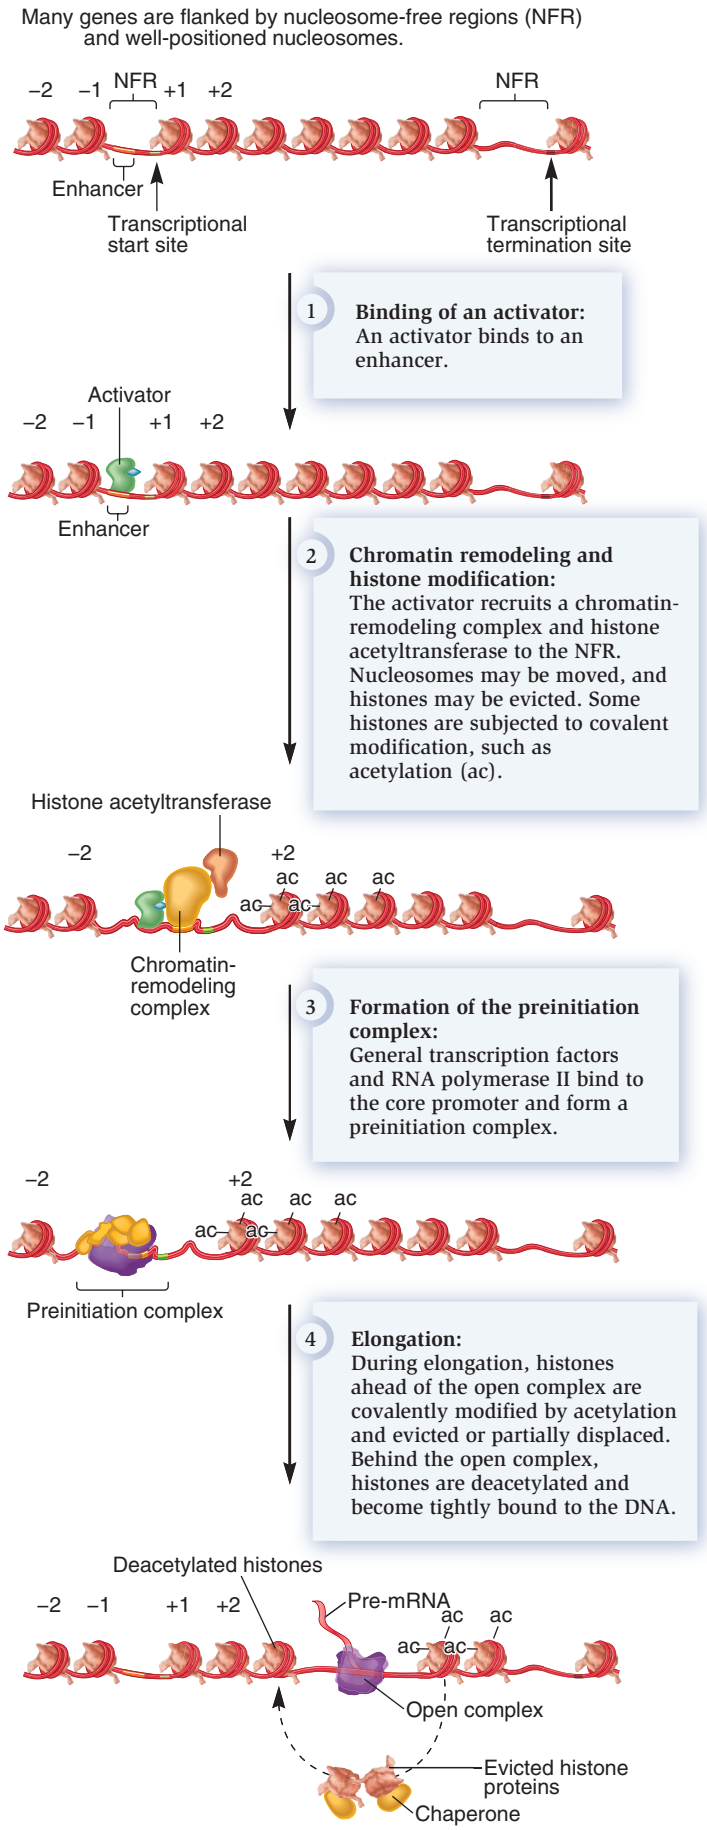

Figure 13.20 **A simplified model for the transcriptional activation of a eukaryotic structural gene.**

13.5 Epigenetic Gene Regulation

Learning Outcomes

1. Define epigenetic gene regulation and epigenetic inheritance.
2. Outline the types of molecular changes that underlie epigenetic gene regulation.
3. Compare and contrast epigenetic changes that are programmed during development versus those that are caused by environmental agents.

The term **epigenetics** was first coined by British biologist Conrad Waddington in 1941. (The prefix epi- means "over.") In the past few decades, researchers have used this term to describe certain types of variation in gene expression that are not based on variation in DNA sequences. How do geneticists distinguish epigenetic events from other types of gene regulation? In epigenetic gene regulation, an initial event causes a change in gene expression. For example, DNA methylation may inhibit transcription. For such a change to be an epigenetic phenomenon, it must be passed from cell to cell and must not involve a change in the DNA sequence. Therefore, a key feature of epigenetic gene regulation is the long-term maintenance of a change in gene expression. However, epigenetic changes are also reversible from one generation to the next. For example, a gene that is silenced in an individual may be active in that individual's offspring. Although researchers are still debating the proper definition, one way to define epigenetic gene regulation is as follows:

> ***Epigenetic gene regulation*** *involves changes in gene expression that can be passed from cell to cell and are reversible, but does not involve a change in the base sequence of DNA.*

Some epigenetic changes are passed from parent to offspring. In multicellular species that reproduce via gametes (sperm and egg cells), the passing of an epigenetic change from parent to offspring is called **epigenetic inheritance**. As discussed in Chapter 17, genomic imprinting is an epigenetic change that is passed from parent to offspring. However, not all epigenetic changes fall into this category. For example, an individual may be exposed to an environmental agent that causes an epigenetic change in a lung cell that is subsequently transmitted from cell to cell and promotes lung cancer. Such a change would not be transmitted to the individual's offspring. In this section, we will begin by examining the molecular changes that cause epigenetic gene regulation. We will then consider how such changes may be programmed into an organism's development or caused by environmental agents.

Different Types of Molecular Changes Underlie Epigenetic Gene Regulation

The molecular mechanisms that promote epigenetic gene regulation in eukaryotes are the subject of a great deal of recent research. The most common types of molecular changes that underlie epigenetic gene regulation are DNA methylation, chromatin remodeling, covalent histone modification, and the localization of histone variants (**Table 13.1**). As we have seen in Section 13.4, these types of changes can also be involved in transient (nonepigenetic) gene regulation. In some cases, epigenetic changes stimulate the transcription of a given gene, and in other cases, they repress gene transcription.

Table 13.1 Molecular Mechanisms That Underlie Epigenetic Gene Regulation

Type of Modification	Description
DNA methylation	Methyl groups may be attached to cytosine bases in DNA. When this methylation occurs near a promoter, transcription is often inhibited.
Chromatin remodeling	Nucleosomes may be moved to new locations or evicted. When such changes occur in the vicinity of a promoter, the level of transcription may be altered. Also, larger-scale changes in chromatin structure may occur, such as those that happen during X-chromosome inactivation in female mammals.
Covalent histone modification	Specific amino acid side chains found in the amino terminal tails of histones can be covalently modified. For example, they can be acetylated or phosphorylated. Such modifications may enhance or inhibit transcription.
Localization of histone variants	Histone variants may become localized to specific locations, such as near a promoter, and affect transcription.

Table 13.2 Factors That Promote Epigenetic Changes

Factor	Examples
Programmed changes during development	
Genomic imprinting	Certain genes, such as *Igf2* described in Chapter 17, undergo different patterns of DNA methylation during oogenesis and spermatogenesis. Such patterns affect whether the maternal or paternal allele is expressed in the offspring.
X-chromosome inactivation	As described in Chapter 17, X-chromosome inactivation occurs during embryogenesis in female mammals.
Cell differentiation	The differentiation of cells into particular cell types involves epigenetic changes such as DNA methylation and covalent histone modification.
Environmental agents	
Temperature	In flowering plants, cold winter temperatures cause specific types of covalent histone modifications that are thought to affect the expression of specific genes the following spring. This process may be necessary for germination and flowering in the spring.
Diet	The differing diet of queen and worker bees alters DNA methylation patterns, which affect the expression of many genes. Such effects may underlie the different traits of queen and worker bees.
Toxins	Cigarette smoke contains a variety of toxins that affect DNA methylation and covalent histone modifications in lung cells. These epigenetic changes may play a role in the development of lung cancer. In addition, heavy metals, such as chromium and cadmium, and certain chemicals found in pesticides and herbicides cause epigenetic changes that can affect gene regulation.

Epigenetic Gene Regulation May Occur as a Programmed Developmental Change

Many epigenetic modifications that regulate gene expression are programmed changes that occur at specific stages of development (**Table 13.2**).

- As discussed in Chapter 17, genomic imprinting of the *Igf2* gene occurs during gametogenesis—the maternal allele is silenced whereas the paternal allele is active.
- X-chromosome inactivation occurs during embryogenesis in female mammals. In early embryonic cells, one of the X chromosomes of a female is inactivated and forms a Barr body, whereas the other remains active. This pattern is maintained as the cells divide and persists in the adult organism.
- Similarly, the differentiation of specific cell types, such as muscle cells and neurons, involves epigenetic modifications. During embryonic development, certain genes undergo epigenetic changes that affect their expression throughout the rest of development. For example, in an embryonic cell that is destined to divide and become a group of muscle cells, a large number of genes that should not be expressed in muscle cells undergo epigenetic modifications that prevent their expression; such changes persist through adulthood.

Epigenetic Gene Regulation May Be Caused by Environmental Agents

As Table 13.2 indicates, an exciting discovery in the field of epigenetics is that a wide range of environmental agents have epigenetic effects. Many recent studies have suggested that environmentally induced changes in an organism's characteristics are sometimes rooted in epigenetic changes that alter gene regulation.

A striking example is found in honeybees (*Apis mellifora*). Female honeybees are of two types: queen bees and worker bees (**Figure 13.21**). Queens are larger, live for years, and produce up to 2,000 eggs each day. By comparison, the smaller worker bees are sterile, typically live a few weeks, and engage in specialized tasks, which include cleaning and constructing comb cells, nurturing larvae, guarding the hive entrance, and foraging for pollen and nectar. The striking differences between queen and worker bees are largely caused by differences in their diet. Certain worker bees, called nurse bees, produce royal jelly in glands in their mouths. All female larvae are initially fed royal jelly, but those that are bathed in royal jelly throughout their entire larval development and feed on it into adulthood become queens. In contrast, female larvae that are switched at an early stage of development to a diet of pollen and nectar become worker bees.

In 2008, a study conducted by Ryszard Maleszka and colleagues indicated that DNA methylation may play a role in controlling the developmental pathways that result in queen and worker bee morphologies. Bee larvae were fed a diet that should produce worker bees. These larvae were injected with a substance that inhibits DNA methyltransferase, the enzyme that methylates DNA. The result was that most of them became queen bees with fully developed ovaries!

Figure 13.21 Epigenetics and the environment. Female honeybees that are fed royal jelly throughout the entire larval stage and into adulthood develop into queen bees. The larger queen bee is marked with a blue disk labeled 68. By comparison, larvae that do not continue to receive this diet become smaller worker bees. These differences in development may be caused by epigenetic changes that affect gene regulation.

Although other factors may contribute to the development of queens, these results are consistent with the hypothesis that royal jelly may contain a substance that inhibits DNA methylation. Such inhibition is thought to allow the expression of genes that contribute to the development of the traits observed in queen bees.

Another topic of great interest to many geneticists is how environmental toxins can cause epigenetic changes. In humans, exposure to tobacco smoke has been shown to alter DNA methylation and the covalent histone modifications of specific genes in lung cells. These alterations are associated with changes in gene regulation that may cause normal cells to become cancerous.

13.6 Regulation of RNA Modification and Translation in Eukaryotes

Learning Outcomes:

1. Outline the process of alternative splicing, and explain how it increases protein diversity.
2. Describe how RNA interference regulates the expression of genes.
3. Explain how RNA-binding proteins regulate the translation of specific mRNAs, using the regulation of iron absorption in mammals as an example.

In the preceding sections of this chapter, we focused on gene regulation at the level of transcription in bacteria and eukaryotes. Eukaryotic gene expression is also commonly regulated at the levels of RNA modification and translation. These added levels of regulation provide important benefits to eukaryotic species. First, by regulating RNA modification, eukaryotes can produce more than one mRNA transcript from a single gene. This allows a gene to encode two or more polypeptides, thereby increasing the complexity of eukaryotic proteomes. A second issue is timing. Regulation of transcription in eukaryotes takes a fair amount of time before its effects are observed at the cellular level. During transcription (1) the chromatin must be converted to an open conformation, (2) the gene must be transcribed, (3) the RNA must be modified and exported from the nucleus, and (4) the protein must be made via translation. All four steps take time, on the order of several minutes. One way to achieve faster regulation is to control steps that occur after an RNA transcript is made. In eukaryotes, regulation of translation provides a faster way to regulate the levels of gene products, namely, proteins. A small RNA molecule or RNA-binding protein can bind to an mRNA and affect the ability of the mRNA to be translated into a polypeptide.

During the past few decades, many critical advances have been made in our knowledge of the regulation of RNA modification and translation. Even so, molecular geneticists are still finding new forms of regulation, making this an exciting area of modern research. In this section, we will survey a few of the known mechanisms of RNA modification and translational regulation.

Alternative Splicing of Pre-mRNAs Increases Protein Diversity

In eukaryotes, a pre-mRNA transcript is modified before it becomes a mature mRNA (refer back to Figure 12.8). When a pre-mRNA has multiple introns and exons, splicing may occur in more than one way, resulting in the production of two or more different polypeptides. Such **alternative splicing** is a form of gene regulation that allows an organism to use the same gene to make different proteins at different stages of development, in different cell types, and/or in response to a change in the environmental conditions. Alternative splicing is an important form of gene regulation in complex eukaryotes such as animals and plants. An advantage of alternative splicing is that two or more different polypeptides can be derived from a single gene, thereby increasing the size of the proteome while minimizing the size of the genome.

Let's consider an example of alternative splicing for a pre-mRNA that encodes a protein known as α-tropomyosin, which functions in the regulation of cell contraction in animals. It is located along the thin filaments found in smooth muscle cells, such as those in the uterus and small intestine, and in striated muscle cells that are found in cardiac and skeletal muscle. α-Tropomyosin is also synthesized in many types of nonmuscle cells but in lower amounts. Within a multicellular organism, different types of cells must regulate their contractibility in subtly different ways. One way this may be accomplished is by the production of different forms of α-tropomyosin.

Figure 13.22 shows the intron-exon structure of the rat α-tropomyosin pre-mRNA and two alternative ways that the pre-mRNA can be spliced. The pre-mRNA contains 14 exons, 6 of which are constitutive exons (shown in red), which are always found in the mature mRNA from all cell types. Presumably, constitutive exons encode polypeptide segments of the α-tropomyosin protein that are necessary for its general structure and function. By

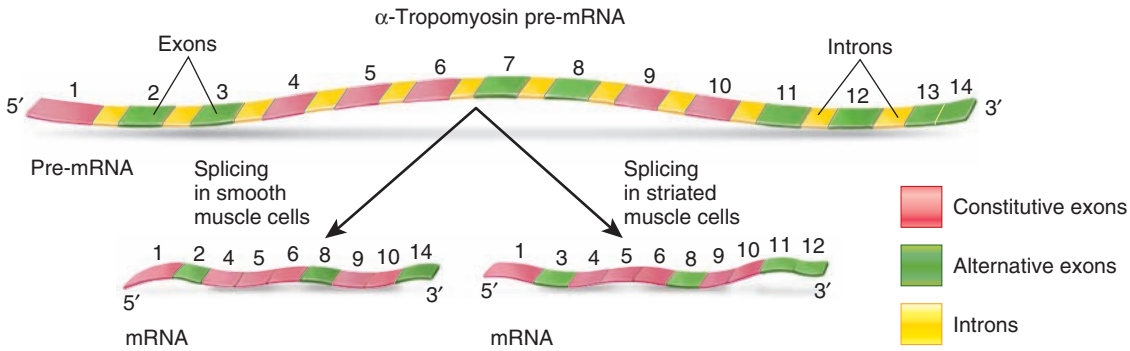

Figure 13.22 Alternative splicing of the rat α-tropomyosin pre-mRNA. The top part of this figure depicts the structure of the rat α-tropomyosin pre-mRNA. Exons are red or green, and introns are yellow. The lower part of the figure describes the final mRNA products in smooth and striated muscle cells after alternative splicing. Note: Exon 8 is found in the final mRNA of smooth and striated muscle cells, but not in the mRNA of some other cell types.

Concept Check: *What is the biological advantage of alternative splicing?*

comparison, alternative exons (shown in green) are not always found in the mRNA after splicing has occurred. The polypeptide sequences encoded by alternative exons may subtly change the function of α-tropomyosin to meet the needs of the cell type in which it is found. For example, Figure 13.22 shows the predominant splicing products found in smooth muscle cells and striated muscle cells. Exon 2 encodes a segment of the α-tropomyosin protein that alters its function to make it suitable for smooth muscle cells. By comparison, the α-tropomyosin mRNA found in striated muscle cells does not include exon 2. Instead, this mRNA contains exon 3, which is more suitable for that cell type.

Genomes & Proteomes Connection

Alternative Splicing Tends to Be More Prevalent in Complex Eukaryotic Species

In the past few decades, many technical advances have improved our ability to analyze the genomes and proteomes of many different species. Researchers have sequenced the DNA from many species and estimated the total number of genes. In addition, scientists can also estimate the number of polypeptides if information is available about the degree of alternative splicing in a given species.

Table 13.3 compares six species: a bacterium (*Escherichia coli*), a eukaryotic single-celled organism (yeast—*Saccharomyces cerevisiae*), a small nematode worm (*Caenorhabditis elegans*), a fruit fly (*Drosophila melanogaster*), a flowering plant (*Arabidopsis thaliana*), and a human (*Homo sapiens*). One general trend is that less complex organisms tend to have fewer genes. For example, unicellular organisms have only a few thousand genes, whereas multicellular species have tens of thousands. However, the trend is by no means a linear one. If we compare *C. elegans* and *D. melanogaster*, the fruit fly actually has fewer genes, even though it is more complex morphologically.

Table 13.3 Genome Size and Biological Complexity

Species	Level of complexity	Genome size (million bp)	Approximate number of genes	Percentage of genes alternatively spliced
Escherichia coli	A unicellular bacterium	4.2	4,300	0
Saccharomyces cerevisiae	A unicellular eukaryote	12	6,300	<1
Caenorhabditis elegans	A tiny worm (about 1,000 cells)	97	20,500	2
Drosophila melanogaster	An insect	137	15,600	7
Arabidopsis thaliana	A flowering plant	142	27,000	11
Homo sapiens	A complex mammal	3,000	22,000	70

A second trend you can see in Table 13.3 concerns alternative splicing. This phenomenon does not occur in bacteria and is rare in *S. cerevisiae*. The frequency of alternative splicing increases from worms to flies to humans. For example, the level of alternative splicing is 10-fold higher in humans than in *Drosophila*. This trend can partially explain the increase in complexity among these species. Even though humans have only about 22,000 different genes, they can make well over 100,000 different polypeptides because most genes are alternatively spliced in multiple ways.

RNA Interference Blocks the Expression of mRNA

Let's now turn our attention to regulatory mechanisms that affect translation. **MicroRNAs (miRNAs)** and **short-interfering RNAs (siRNAs)** are RNA molecules that are processed to a small size,

typically 22 nucleotides in length, and silence the expression of pre-existing mRNAs. The precursors of miRNAs are encoded by genes and usually form a hairpin structure. In most cases, miRNAs are partially complementary to certain cellular mRNAs and inhibit their translation. By comparison, short-interfering RNAs are derived from two RNA molecules that come together to form a double-stranded region. For example, a cellular RNA may bind to an RNA that is transcribed from a viral genome. siRNAs are often a very close match to specific mRNAs and cause those mRNAs to be degraded.

Insight into the mechanism of miRNA inhibition came from the research of American biologists Andrew Fire and Craig Mello, who discovered the mechanism of action of miRNA (**Figure 13.23**). A pre-miRNA is first synthesized as a single-stranded molecule that folds back on itself to form a hairpin structure. (A pre-siRNA, which is not shown in this figure, would be composed of two RNA molecules that come together to form a double-stranded region.) The double-stranded region is trimmed to a 22-bp sequence by an enzyme called dicer. The 22-bp sequence becomes part of a complex called the **RNA-induced silencing complex (RISC)**, which also includes several proteins. One of the RNA strands is then degraded. The miRNA or siRNA in the complex binds to a target mRNA with a complementary sequence.

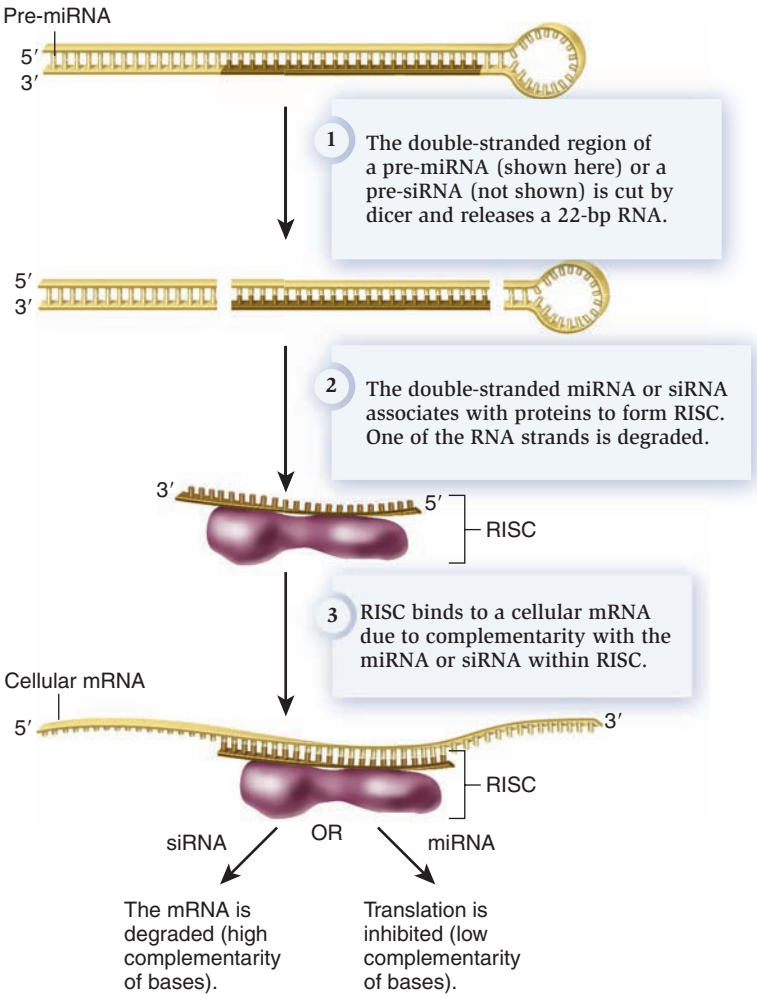

Figure 13.23 Mechanism of action of microRNA (miRNA). Note: Pre-siRNAs are also acted upon by dicer, but siRNAs are derived from two RNA molecules that form a double-stranded region rather than one RNA molecule that forms a hairpin.

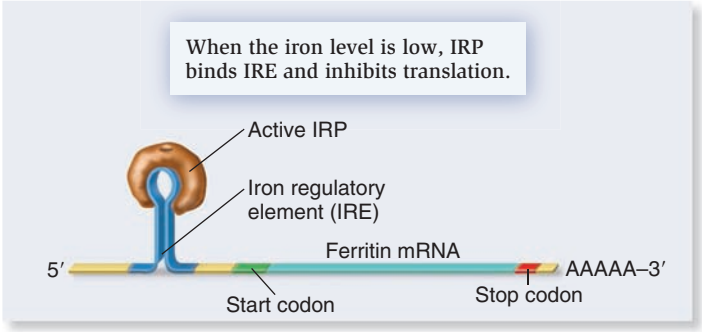
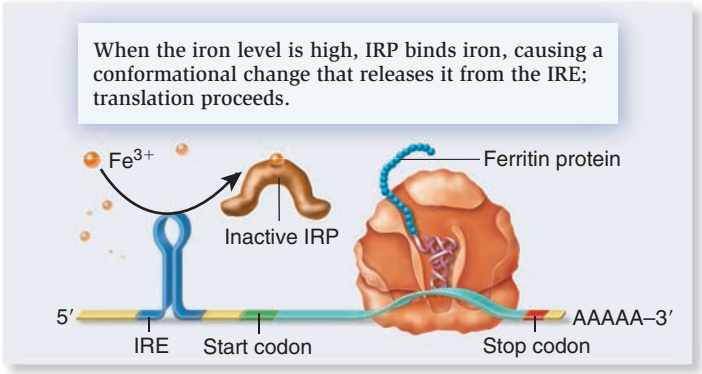
BIOLOGY PRINCIPLE Structure determines function. The structure of an miRNA or siRNA is complementary to an mRNA and inhibits the function of the mRNA or causes its degradation.

Upon binding, two different things may happen. When the miRNA and mRNA are not a perfect match or are only partially complementary, translation is inhibited. Alternatively, when an siRNA and mRNA are a perfect match or highly complementary, the mRNA is cut into pieces and then degraded. Both miRNA and siRNA have the same effect—the expression of the mRNA is silenced. Fire and Mello called this **RNA interference (RNAi)**, because the miRNA interferes with the proper expression of an mRNA.



Since this study, researchers have discovered that genes encoding miRNAs are widely found in animals and plants. In humans, for example, researchers estimate that over 1,000 different genes encode miRNAs. RNAi represents an important mechanism of gene regulation that results in mRNA silencing. In 2006, Fire and Mello were awarded the Nobel Prize in Physiology or Medicine for their studies of RNAi.

The Prevention of Iron Toxicity in Mammals Involves the Regulation of Translation



Another way to regulate translation involves RNA-binding proteins that directly affect the initiation of translation. The regulation of iron absorption provides a well-studied example. Although iron is a vital cofactor for many cellular enzymes, it is toxic at high levels. To prevent toxicity, mammalian cells synthesize a protein called ferritin, which forms a hollow, spherical complex that stores excess iron.

The mRNA that encodes ferritin is controlled by an RNA-binding protein known as the **iron regulatory protein (IRP)**. When the iron level in the cytosol is low and more ferritin is not needed, IRP binds to a regulatory element within the ferritin mRNA known as the **iron regulatory element (IRE)**. The IRE is located between the 5′ cap, where the ribosome binds, and the start codon where translation begins. Due to base pairing, it forms a stem-loop structure. The binding of IRP to the IRE inhibits translation of the ferritin mRNA (**Figure 13.24a**). However, when iron is abundant in the cytosol, the iron binds directly to IRP, which changes its conformation and prevents it from binding to the IRE. Under these conditions, the ferritin mRNA is translated to make more ferritin protein (**Figure 13.24b**).

Why is translational regulation of ferritin mRNA an advantage over transcriptional regulation of the ferritin gene? This mechanism of translational control allows cells to rapidly respond to changes in their environment. When cells are confronted with high levels of iron, they can quickly make more ferritin protein to prevent the toxic buildup of iron. This mechanism is faster than transcriptional regulation, which would require the activation of the ferritin gene and the transcription of ferritin mRNA prior to the synthesis of more ferritin protein.

(a) Low iron level

(b) High iron level

Figure 13.24 Translational regulation of ferritin mRNA by the iron regulatory protein (IRP).

Concept Check: Poisoning may occur when a young child finds a bottle of vitamins, such as those that taste like candy, and eats a large number of them. One of the toxic effects involves the ingestion of too much iron. How does the IRP protect people from the toxic effects of too much iron?

Summary of Key Concepts

13.1 Overview of Gene Regulation

- Most genes are regulated so the level of gene expression can vary under different conditions. By comparison, constitutive genes are expressed at constant levels.
- Gene regulation ensures that gene products are made only when they are needed. An example is the synthesis of the gene products needed for lactose utilization in bacteria (Figure 13.1).
- In eukaryotes, gene regulation leads to the production of different cell types, such as neurons, muscle cells, and skin cells, within an organism (Figure 13.2).
- Eukaryote gene regulation enables gene products to be produced at different developmental stages (Figure 13.3).
- All organisms regulate gene expression at a variety of levels, including transcription, translation, and post-translation. Eukaryotes also regulate RNA modification (Figure 13.4).

13.2 Regulation of Transcription in Bacteria

- Repressors and activators are regulatory transcription factors that bind to the DNA and affect the transcription of genes. Small effector molecules control the ability of regulatory transcription factors to bind to DNA (Figure 13.5).
- An operon is an arrangement of several genes controlled by a single promoter and an operator. The *lac* operon is an example of an inducible operon. The lac repressor exerts negative control by binding to the operator site and preventing RNA polymerase from transcribing the operon. When allolactose binds to the repressor, a conformational change occurs that prevents the repressor from binding to the operator site so transcription can proceed (Figures 13.6, 13.7).
- By constructing a merozygote, Jacob, Monod, and Pardee determined that the *lacI* gene encodes a diffusible protein that represses the *lac* operon (Figures 13.8, 13.9).
- Positive control of the *lac* operon occurs when the catabolite activator protein (CAP) binds to the CAP site in the presence of cAMP. This causes a bend in the DNA, which promotes the binding of RNA polymerase to the promoter (Figure 13.10).
- Glucose inhibits cAMP production, which, in turn, inhibits the expression of the *lac* operon, because CAP cannot bind to the CAP site. This form of regulation provides bacteria with a more efficient utilization of their resources because they use one sugar at a time (Figure 13.11).
- The *trp* operon is an example of a repressible operon. The presence of tryptophan causes the trp repressor to bind to the *trp* operator and stop transcription. This prevents the excessive buildup of tryptophan in the cell, which would be a waste of energy (Figure 13.12).

13.3 Regulation of Transcription in Eukaryotes: Roles of Transcription Factors and Mediator

- Eukaryotic genes exhibit combinatorial control, meaning that many factors control the expression of a single gene. (See list on page 269.)
- Eukaryotic promoters consist of a core promoter (containing a TATA box and transcriptional start site) and regulatory elements, such as enhancers or silencers, that regulate the rate of transcription (Figure 13.13).
- General transcription factors (GTFs) are needed for RNA polymerase II to bind to the core promoter, forming a preinitiation complex (Figure 13.14).
- Activators and repressors regulate RNA polymerase II by affecting the function of TFIID (a GTF) or mediator, a protein complex that wraps around RNA polymerase II (Figures 13.15, 13.16).

13.4 Regulation of Transcription in Eukaryotes: Changes in Chromatin Structure and DNA Methylation

- ATP-dependent chromatin-remodeling complexes change the positions and compositions of nucleosomes (Figure 13.17).
- The pattern of covalent modification of the amino terminal tails of histone proteins, also called the histone code, can inhibit or promote transcription (Figure 13.18).
- Eukaryotic genes are usually flanked by nucleosome-free regions (Figure 13.19).
- For eukaryotic genes, a preinitiation complex forms at a nucleosome-free region. During elongation, nucleosomes are displaced ahead of RNA polymerase and re-form after RNA polymerase has passed (Figure 13.20).

- DNA methylation, which occurs at CpG islands near promoters, usually inhibits transcription by (1) preventing the binding of activator proteins or (2) promoting the binding of proteins that inhibit transcription.

13.5 Epigenetic Gene Regulation

- Epigenetic gene regulation involves changes in gene expression that can be passed from cell to cell and are reversible, but it does not involve a change in the base sequence of DNA.
- Different types of molecular changes underlie epigenetic gene regulation including DNA methylation, chromatin remodeling, covalent histone modification, and localization of histone variants (Table 13.1).
- Epigenetic gene regulation may occur as a programmed developmental change, or it may result from the effects of environmental agents (Figure 13.21, Table 13.2).

13.6 Regulation of RNA Modification and Translation in Eukaryotes

- In alternative splicing, a single type of pre-mRNA can be spliced in more than one way, producing polypeptides with somewhat different sequences. This is a common way for complex eukaryotes to increase the size of their proteomes (Figure 13.22, Table 13.3).
- MicroRNAs (miRNAs) and short-interfering RNAs (siRNAs) inhibit mRNAs by inhibiting translation or by promoting the degradation of mRNAs, respectively (Figure 13.23).
- RNA-binding proteins can regulate the translation of specific mRNAs. An example is the regulation of iron absorption, in which the iron regulatory protein (IRP) regulates the translation of ferritin mRNA (Figure 13.24).

Assess and Discuss

Test Yourself

1. Genes that are expressed at all times at relatively constant levels are known as ____ genes.
   a. inducible
   b. repressible
   c. positive
   d. constitutive
   e. structural
2. Which of the following is *not* a level at which gene regulation occurs in bacteria?
   a. transcription
   b. RNA modification
   c. translation
   d. post-translation
   e. All of the above are levels at which bacteria are able to regulate gene expression.
3. Transcription factors that bind to DNA and stimulate transcription are
   a. repressors.
   b. small effector molecules.
   c. activators.
   d. promoters.
   e. operators.
4. In bacteria, the unit of DNA that contains multiple genes under the control of a single promoter is called ___. The mRNA produced from this unit is referred to as ___ mRNA.
   a. an operator, a polycistronic
   b. a template, a structural
   c. an operon, a polycistronic
   d. an operon, a monocistronic
   e. a template, a monocistronic
5. For the *lac* operon, what would be the expected effects of a mutation in the operator site that prevented the binding of the repressor protein?
   a. The operon would always be turned on.
   b. The operon would always be turned off.
   c. The operon would always be turned on, except when glucose is present.
   d. The operon would be turned on only in the presence of lactose.
   e. The operon would be turned on only in the presence of lactose and the absence of glucose.
6. The presence of _____ in the medium prevents CAP from binding to the DNA, resulting in _____ in transcription of the *lac* operon.
   a. lactose, an increase
   b. glucose, an increase
   c. cAMP, a decrease
   d. glucose, a decrease
   e. lactose, a decrease
7. The *trp* operon is considered _____ operon because the structural genes necessary for tryptophan synthesis are not expressed when the level of tryptophan in the cell is high.
   a. an inducible
   b. a positive
   c. a repressible
   d. a negative
   e. Both c and d are correct.
8. Regulatory elements that function to increase transcription levels in eukaryotes are called
   a. promoters.
   b. silencers.
   c. enhancers.
   d. transcriptional start sites.
   e. activators.
9. Which of the following is *not* an example of epigenetic gene regulation?
   a. genomic imprinting in mammals
   b. X-chromosome inactivation in mammals
   c. cell differentiation in animals and plants
   d. regulation of the *lac* operon in *E. coli* via allolactose
   e. the effects of toxins in cigarette smoke that alter gene expression
10. _____ refers to the phenomenon where a single type of pre-mRNA may give rise to multiple types of mRNAs due to different patterns of intron and exon removal.
    a. Spliceosomes
    b. Variable expression
    c. Alternative splicing
    d. Polycistronic mRNA
    e. Induced silencing

Conceptual Questions

1. What is the difference between inducible and repressible operons? Give an example of each.
2. Transcriptional regulation often involves a regulatory protein that binds to a segment of DNA and a small effector molecule that binds to the regulatory protein. Do each of the following terms apply to a regulatory protein, a segment of DNA, or a small effector molecule?
   a. repressor
   b. inducer
   c. operator
   d. corepressor
   e. activator
3.  A principle of biology is *the genetic material provides a blueprint for reproduction.* Explain how gene regulation is an important mechanism for reproduction and sustaining life.

Collaborative Questions

1. Discuss the advantages and disadvantages of genetic regulation at the different levels described in Figure 13.4.
2. Discuss the advantages and disadvantages of combinatorial control of eukaryotic genes.

CHAPTER OUTLINE

14.1 Consequences of Mutations
14.2 Causes of Mutations
14.3 DNA Repair
14.4 Cancer
Summary of Key Concepts
Assess and Discuss

Mutation, DNA Repair, and Cancer

14

During the past two decades, over 25% of the beluga whales in Canada's St. Lawrence Seaway have died of cancer. Biologists speculate that these deaths are caused by cancer-causing pollutants, such as polycyclic aromatic hydrocarbons (PAHs).

At a summer camp, the children enjoy ice cream, horseback riding, hay rides, swimming, and learning about the habits of owls. Not such an unusual camp, you might be thinking. However, what makes Camp Sundown unique is that the outdoor fun begins at dusk and runs all night. The children at this camp have inherited a disorder called xeroderma pigmentosum (XP), which makes them highly sensitive to sunlight. Their skin will blister or freckle on minimum exposure to sunlight. Of greater concern, however, is skin cancer. Persons with XP may have a 1,000-fold greater risk of developing skin cancer, though such a risk is greatly decreased if exposure to sunlight is minimized.

What explains the symptoms of XP? Individuals with this condition are highly susceptible to **mutation**, which is defined as a heritable change in the genetic material. When a mutation occurs, the order of nucleotide bases in a DNA molecule, its base sequence, is changed permanently, an alteration that can be passed from mother to daughter cells during cell division. Mutations that lead to cancer cause particular genes to be expressed in an abnormal way. For example, a mutation could affect the transcription of a gene, or it could alter the functional properties of the polypeptide that is specified by a gene.

Should we be afraid of mutations? Yes and no. On the positive side, mutations are essential to the long-term continuity of life. Mutations provide the foundation for evolutionary change. They supply the variation that enables species to evolve and become better adapted to their environments. On the negative side, however, new mutations are more likely to be harmful than beneficial to the individual. The genes within modern species are the products of billions of years of evolution and have evolved to work properly. Random mutations are more likely to disrupt genes rather than enhance their function. As we will see in this chapter, mutations can cause cancer. In addition, many inherited disorders, such as XP and cystic fibrosis, are caused by gene mutations. For these and many other reasons, understanding the molecular nature of mutations is a compelling area of research.

All species have evolved several ways to repair damaged DNA. Such DNA repair systems reverse DNA damage before a permanent mutation can occur. DNA repair systems are vital to the survival of all organisms. If these systems did not exist, mutations would be so prevalent that few species, if any, would survive. In this chapter, we will examine how such DNA repair systems operate. But first, let's explore the consequences and causes of mutations.

14.1 Consequences of Mutations

Learning Outcomes:

1. List different ways that mutations can alter the amino acid sequence of a polypeptide.
2. Explain how mutations that occur outside of the coding sequence can affect the expression of a gene.
3. Compare and contrast the effects of mutations in somatic cells versus germ-line cells.

How do mutations affect traits? To answer this question at the molecular level, we must understand how changes in the DNA

sequence of a gene ultimately affect gene function. Most of our understanding of mutation has come from the study of experimental organisms, such as bacteria and *Drosophila*. Researchers can expose these organisms to agents that cause mutations and then study the consequences of the mutations that arise. In addition, because these organisms have a short generation time, researchers can investigate the effects of mutations when they are passed from cell to cell and from parent to offspring.

The structure and amount of genetic material can be altered in a variety of ways. For example, the structure and number of chromosomes can change. We will examine these types of genetic changes in Chapter 15. In this section, we will focus our attention on gene mutations, which are relatively small changes in the sequence of bases in a particular gene. We will also consider how the timing of new mutations during an organism's development has important consequences.

Gene Mutations Alter the DNA Sequence of a Gene

Mutations cause two basic types of changes to a gene: (1) the base sequence within a gene can be changed; and (2) one or more base pairs can be added to or removed from a gene. A **point mutation** affects only a single base pair within the DNA. For example, the DNA sequence shown here has been altered by a **base substitution** in which a T (in the top strand) has been replaced by a G and the corresponding A in the bottom strand is replaced with a C:

```
5′–CCCGCTAGATA–3′   ⟶   5′–CCCGCGAGATA–3′
3′–GGGCGATCTAT–5′       3′–GGGCGCTCTAT–5′
```

A point mutation could also involve the addition or deletion of a single base pair to a DNA sequence. For example, in the following sequence, a single base pair (A-T) has been added to the DNA:

```
5′–GGCGCTAGATC–3′   ⟶   5′–GGCAGCTAGATC–3′
3′–CCGCGATCTAG–5′       3′–CCGTCGATCTAG–5′
```

Though point mutations may seem like small changes to a DNA sequence, they can have important consequences when genes are expressed, as we will see next.

Gene Mutations May Affect the Amino Acid Sequence of a Polypeptide

If a mutation occurs within the region of a structural gene that specifies the amino acid sequence, the mutation may alter that sequence in a variety of ways. **Table 14.1** considers the potential effects of point mutations.

Silent Mutations **Silent mutations** do not alter the amino acid sequence of the polypeptide, even though the nucleotide sequence has changed. As discussed in Chapter 12, the genetic code is degenerate, that is, more than one codon can specify the same amino acid. Silent mutations occur in the third base of many codons without changing the type of amino acid that is encoded.

Missense Mutations A **missense mutation** is a base substitution that changes a single amino acid in a polypeptide sequence. A missense mutation may not alter protein function because it changes only a single amino acid within a polypeptide that is typically hundreds of amino acids in length. A missense mutation that substitutes an amino acid with a chemistry similar to the original amino acid is less likely to alter protein function. For example, a missense mutation that substitutes a glutamic acid for an aspartic acid may not alter protein function because both amino acids are negatively charged and have similar side chain structures.

Alternatively, some missense mutations have a dramatic effect on protein function. A striking example occurs in the human disease known as **sickle cell disease**. This disease involves a missense mutation in the β-globin gene, which encodes one of the polypeptide subunits that make up hemoglobin, the oxygen-carrying protein in red blood cells. In the most common form of this disease, a missense mutation alters the polypeptide sequence such that the sixth amino acid is changed from a glutamic acid to a valine (**Figure 14.1**). Because glutamic acid is hydrophilic but valine is hydrophobic, this single amino acid substitution alters the structure and function of the hemoglobin protein. The mutant hemoglobin subunits tend to stick to one another when the oxygen concentration is low. The aggregated proteins form fiber-like structures within red blood cells, which causes the cells to lose their normal disc-shaped morphology and become sickle-shaped. It is amazing that a single amino acid substitution could have such a profound effect on the structure of cells.

Nonsense Mutations A **nonsense mutation** involves a change from a normal codon to a stop, or termination, codon. This causes translation to be terminated earlier than expected, producing a truncated polypeptide (see Table 14.1). Compared with a normal polypeptide, a shorter polypeptide is much less likely to function properly.

Table 14.1 Consequences of Point Mutations Within the Coding Sequence of a Structural Gene

Mutation in the DNA	Effect on polypeptide	Example*
None	None	ATGGCCGGCCCGAAAGAGACC Met Ala Gly Pro Lys Glu Thr
Base substitution	**Silent**—causes no change	ATGGCCGGCCCCAAAGAGACC Met Ala Gly Pro Lys Glu Thr
Base substitution	**Missense**—changes one amino acid	ATGCCGGCCCGAAAGAGACC Met Pro Gly Pro Lys Glu Thr
Base substitution	**Nonsense**—changes to a stop codon	ATGGCCGGCCCGTAAGAGACC Met Ala Gly Pro STOP
Addition of a single base	**Frameshift**—produces a different amino acid sequence	ATGGCCGGCACCGAAAGAGACC Met Ala Gly Thr Glu Arg Asp

*DNA sequence in the coding strand. This sequence is the same as the mRNA sequence except that RNA contains uracil (U) instead of thymine (T).

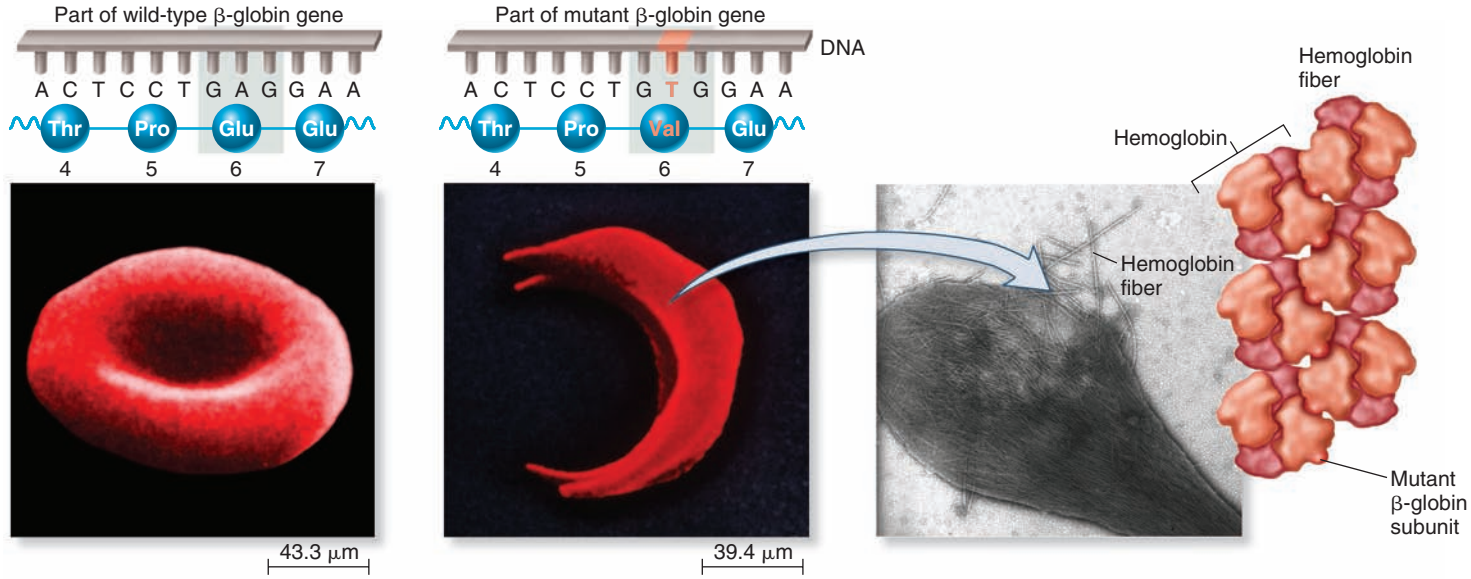


Figure 14.1 A missense mutation that causes red blood cells to sickle in sickle cell disease. Scanning electron micrographs of **(a)** normal red blood cell and **(b)** sickled red blood cell. As shown above the micrographs, a missense mutation in the β-globin gene (which codes for a subunit of hemoglobin) changes the sixth amino acid in the β-globin polypeptide from a glutamic acid (Glu) to a valine (Val). **(c)** This micrograph shows how this alteration to the structure of β-globin causes the formation of abnormal fiber-like structures. In normal cells, hemoglobin proteins do not form fibers.

Concept Check: Based on the fiber-like structures seen in part (c), what aspect of hemoglobin structure does a glutamic acid at the sixth position in normal β-globin prevent? Speculate on how the charge of this amino acid may play a role.

Frameshift Mutations Finally, a **frameshift mutation** involves the addition or deletion of nucleotides that are not in multiples of three nucleotides. For example, a frameshift mutation could involve the addition or deletion of one, two, four, or five nucleotides. Because the codons are read in multiples of three, these types of insertions or deletions shift the reading frame so a completely different amino acid sequence occurs downstream from the mutation (see Table 14.1). Such a large change in polypeptide structure is likely to inhibit protein function.

Changes in protein function may affect the ability of an organism to survive and to reproduce. Except for silent mutations, new mutations are more likely to produce polypeptides that have reduced rather than enhanced function. However, mutations can occasionally produce a polypeptide that has an enhanced function. Such mutations may change in frequency in a population over the course of many generations due to natural selection. This topic is discussed in Chapter 24.

Gene Mutations That Occur Outside of Coding Sequences Can Influence Gene Expression

Thus far, we have focused our attention on mutations in the coding regions of structural genes. In Chapters 12 and 13, we explored the role of DNA sequences in gene expression. A mutation can occur within a noncoding DNA sequence and affect gene expression (**Table 14.2**). For example, a mutation may alter the sequence within the promoter of a gene, thereby affecting the rate of transcription. A mutation that improves the ability of RNA polymerase to bind to the promoter may enhance transcription, whereas other mutations may inhibit transcription.

Mutations in regulatory elements or operator sites can alter the regulation of gene transcription. For example, in Chapter 13, we considered the roles of regulatory elements such as the *lac* operator site in *E. coli*, which is recognized by the lac repressor protein (refer back to Figure 13.7). Mutations in the *lac* operator site can disrupt the proper regulation of the *lac* operon. An operator mutation may change the DNA sequence so the lac repressor protein does not bind to it. This mutation would cause the operon to be constitutively expressed.

Table 14.2 Effects of Mutations Outside of the Coding Sequence of a Gene

Sequence	Effect of mutation
Promoter	May increase or decrease the rate of transcription
Transcriptional regulatory element/operator site	May alter the regulation of transcription
Splice sites	May alter the ability of pre-mRNA to be properly spliced
Translational regulatory element	May alter the ability of mRNA to be translationally regulated
Intergenic region	Not as likely to have an effect on gene expression

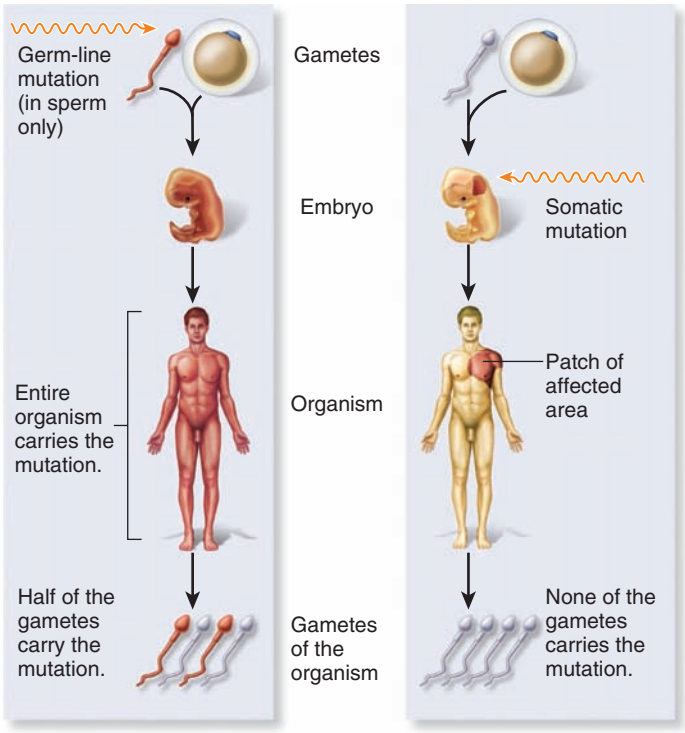

Figure 14.2 The effects of germ-line versus somatic cell mutations. The red color indicates which cells carry the mutation. **(a)** If a mutation is passed via gametes, such germ-line mutations occur in every cell of the body. Because humans have two copies of most genes, a germ-line mutation in one of those two copies is transmitted to only half of the gametes. **(b)** Somatic mutations affect a limited area of the body and are not transmitted to offspring.

BIOLOGY PRINCIPLE Living organisms grow and develop. As a multicellular organism grows and develops, a germ-line mutation is transmitted to all cells of the body, whereas a somatic mutation is found only in a particular region.

Concept Check: Why are somatic mutations unable to be transmitted to offspring?

Mutations Can Occur in Germ-Line or Somatic Cells

Let's now consider how the timing of a mutation may have important consequences for its potential effects. Multicellular organisms typically begin their lives as a single fertilized egg cell that divides many times to produce all the cells of an adult organism. A mutation can occur in any cell of the body, either very early in life, such as in a gamete (egg or sperm) or a fertilized egg, or later in life, such as in the embryonic or adult stages. The number and location of cells with a mutation are critical both to the severity of the genetic effect and to whether the mutation can be passed on to offspring.

Geneticists classify the cells of animals into two types: germ-line cells and somatic cells. The term **germ line** refers to cells that give rise to gametes, such as egg and sperm cells. A germ-line mutation can occur directly in an egg or sperm cell, or it can occur in a precursor cell that produces the gamete. If a mutant human gamete participates in fertilization, all the cells of the resulting offspring will contain the mutation, as indicated by the red color in **Figure 14.2a**. Likewise, when such an individual produces gametes, the mutation may be transmitted to future generations of offspring. Because humans carry two copies of most genes, a new mutation in a single gene has a 50% chance of being transmitted from parent to offspring.

The **somatic cells** constitute all cells of the body except for the germ line. Examples include skin cells and muscle cells. Mutations can also occur within somatic cells at early or late stages of development. What are the consequences of a mutation that happens during the embryonic stage? As shown in **Figure 14.2b**, a mutation occurred within a single embryonic cell. This single somatic cell was the precursor for many cells of the adult. Therefore, in the adult, a patch of tissue contains cells that carry the mutation. The size of any patch depends on the timing of a new mutation. In general, the earlier a mutation occurs during development, the larger the patch. An individual with somatic regions that are genetically different from each other is called a **mosaic**.

Figure 14.3 illustrates a child who had a somatic mutation during an early stage of development. In this case, the child has a streak of white hair while the rest of his hair is black. Presumably, a single mutation happened in an embryonic cell that ultimately gave rise to the patch that produced the white hair.

Although a change in hair color is not a harmful consequence, mutations during early stages of life can be quite harmful, especially if they disrupt essential developmental processes. Even though it is sensible to avoid environmental agents that cause mutations at any stage of life, the possibility of somatic mutations is a compelling reason to avoid such agents during the early stages of life such as embryonic and fetal development, infancy, and early childhood.

Figure 14.3 Example of a somatic mutation. This child has a streak of white hair. This is due to a somatic mutation in a single cell during embryonic development. This cell continued to divide to produce a streak of white hair.

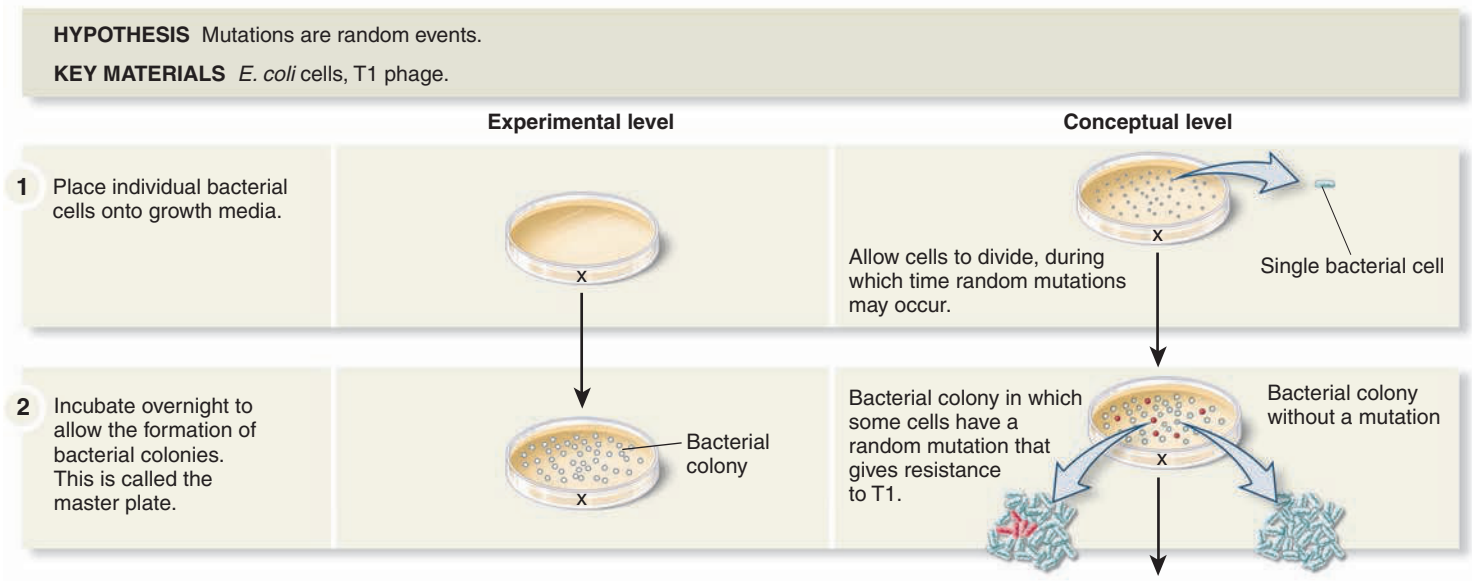
Concept Check: Can this child with a streak of white hair transmit this trait to his future offspring?

14.2 Causes of Mutations

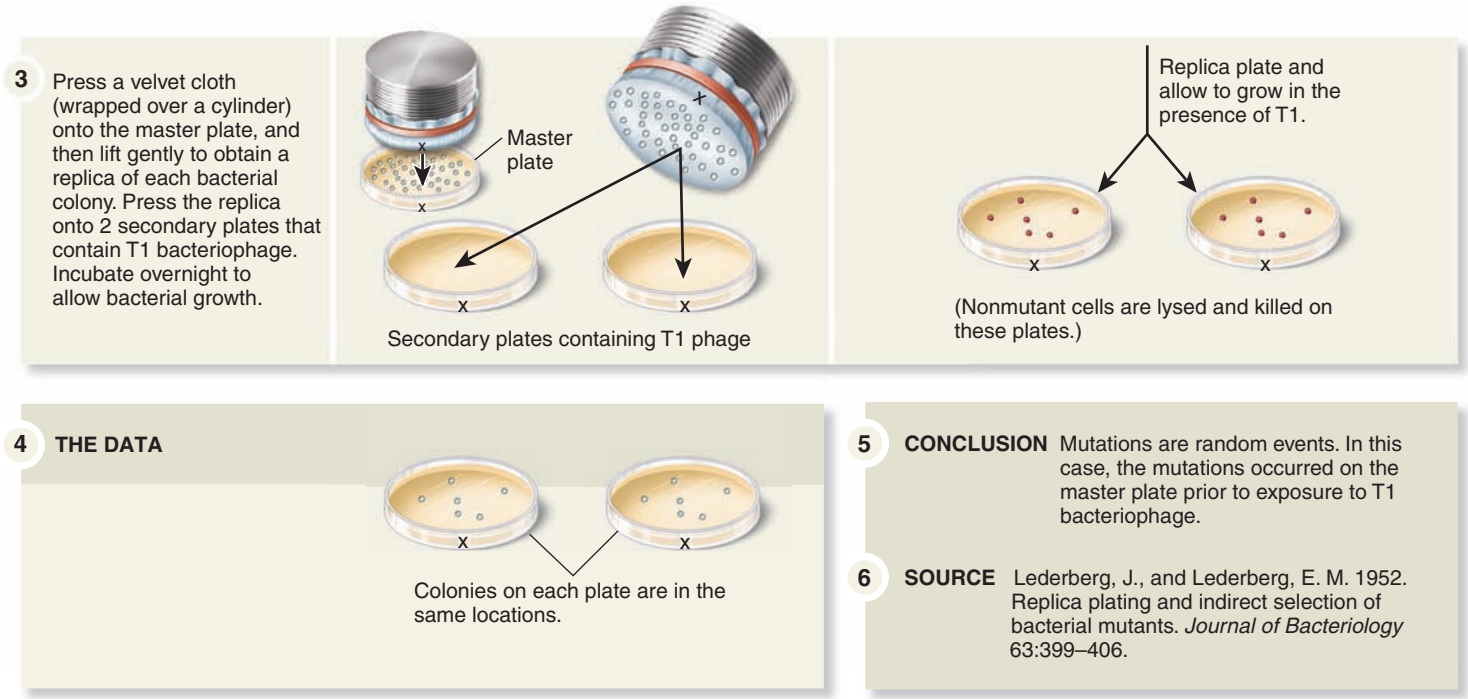
Learning Outcomes

1. **SciSKILLS »** Analyze the replica plating experiments of the Lederbergs.
2. Describe the difference between spontaneous and induced mutations.
3. **SciSKILLS »** Analyze the results of an Ames test for determining if a substance is a mutagen.

As we have seen, mutations affect the expression of genes in a variety of ways, and their timing can have important consequences. Because mutations can have dramatic effects on individuals' traits, a great deal of research has focused on their underlying causes. We begin this section with an experiment showing that mutations are random events. We will then explore how mutations can be either spontaneous (caused by mistakes in natural biological processes) or induced (caused by environmental agents). Finally, we will examine a testing method used to determine if a substance causes mutations.



Feature Investigation | The Lederbergs Used Replica Plating to Show That Mutations Are Random Events



Prior to understanding the causes of mutations at the molecular level, scientists considered the following question: Are mutations that affect the traits of an individual caused by pre-existing circumstances, or are they random events that may happen in any gene of any individual? In the 19th century, French naturalist Jean-Baptiste Lamarck proposed that physiological events (such as use or disuse) determine whether traits are passed along to offspring. For example, his hypothesis suggested that an individual who practiced and became adept at a physical activity, such as the long jump, would pass that quality on to his or her offspring. Alternatively, geneticists in the early 20th century suggested that genetic variation occurs as a matter of chance. According to this view, those individuals whose genes happen to contain beneficial mutations are more likely to survive and pass those genes to their offspring.

These opposing views were tested in bacterial studies in the 1940s and 1950s. One such study, by American microbiologists Joshua and Esther Lederberg, focused on the occurrence of mutations in bacteria (**Figure 14.4**). First, the Lederbergs placed a large number of *E. coli* bacteria onto growth media and incubated them overnight, so each bacterial cell divided many times to form a bacterial colony composed of millions of cells. This is called the master plate. Using a technique known as **replica plating**, a sterile piece of velvet cloth was lightly touched to the master plate to pick up bacterial cells from each colony on the master plate. They then transferred this replica to two secondary plates containing an agent that selected for the growth of bacterial cells with a particular mutation.

In the example shown in Figure 14.4, the secondary plates contained T1 bacteriophages, which are viruses that infect bacteria and cause them to lyse. On these plates, only those rare cells that had acquired a mutation conferring resistance to T1, termed *ton*^{r}, could grow. All other cells were lysed by the proliferation of bacteriophages in the bacteria. Therefore, only a few colonies were observed on the secondary plates. Strikingly, these colonies occupied the same locations on each plate. How did the Lederbergs interpret these results?

Figure 14.4 **The experiment performed by the Lederbergs showing that mutations are random events.**

The data indicated that the *ton*^{r} mutations occurred randomly while the bacterial cells were forming colonies on the nonselective master plate. The presence of T1 bacteriophages in the secondary plates did not cause the mutations to develop. Rather, the T1 bacteriophages simply selected for the growth of *ton*^{r} mutants that were already in the population. These results supported the idea that mutations are random events.

Experimental Questions

1. Explain the opposing views of mutation prior to the Lederbergs' study.
2. **SciSKILLS** » What hypothesis was being tested by the Lederbergs? What were the results of the experiment?
3. **SciSKILLS** » How did the results of the Lederbergs support or falsify the hypothesis?

Mutations May Be Spontaneous or Induced

Biologists categorize the causes of mutation as spontaneous or induced (**Table 14.3**). **Spontaneous mutations** result from abnormalities in biological processes. Spontaneous mutations reflect the observation that biology isn't perfect. Enzymes, for example, can function abnormally. In Chapter 11, we learned that DNA polymerase can make mistakes during DNA replication by putting the wrong base in a newly synthesized daughter strand. Though such errors are rare due to the proofreading function of DNA polymerase, they do occur. In addition, normal metabolic processes within the cell may produce toxic chemicals such as free radicals that can react directly with the DNA and alter its structure. Finally, the structure of nucleotides is not absolutely stable. On occasion, the structure of a base may spontaneously change, and such a change may cause a mutation if it occurs immediately prior to DNA replication.

The rates of spontaneous mutations vary from species to species and from gene to gene. Larger genes are usually more likely to incur a mutation than are smaller ones. A common rate of spontaneous mutation among various species is approximately 1 mutation for every 1 million genes per cell division, which equals 1 in 10^6, or simply 10^{-6}. This is the expected rate of spontaneous mutation, which creates the variation that is the raw material of evolution.

Induced mutations are caused by environmental agents that enter the cell and alter the structure of DNA. They cause the mutation rate to be higher than the spontaneous mutation rate. Agents that cause mutation are called **mutagens**. Mutagenic agents can be categorized as **chemical** or **physical mutagens** (**Table 14.4**). We will consider their effects next.

Mutagens Alter DNA Structure in Different Ways

Researchers have discovered that an enormous array of agents act as mutagens. We often hear in the news media that we should avoid these agents in our foods and living environments. We even use products such as sunscreens that help us avoid the mutagenic effects of ultraviolet (UV) light from the Sun. The public is often concerned about mutagens for two important reasons. First, mutagenic agents are usually involved in the development of human cancers. Second, because new mutations may be deleterious, people want to avoid mutagens to prevent mutations that may have harmful effects in their future offspring.

Table 14.3 Some Common Causes of Gene Mutations

Common causes of mutations	Description
Spontaneous	
Errors in DNA replication	A mistake by DNA polymerase may cause a point mutation.
Toxic metabolic products	The products of normal metabolic processes may be reactive chemicals such as free radicals that can alter the structure of DNA.
Changes in nucleotide structure	On rare occasions, the linkage between a purine and deoxyribose can spontaneously break. Changes in base structure (isomerization) may cause mispairing during DNA replication.
Transposons	As discussed in Chapter 21, transposons are small segments of DNA that can insert at various sites in the genome. If they insert into a gene, they may inactivate the gene.
Induced	
Chemical agents	Chemical substances, such as benzo(*a*)pyrene, a chemical found in cigarette smoke, may cause changes in the structure of DNA.
Physical agents	Physical agents such as UV (ultraviolet) light and X-rays can damage the DNA.

Table 14.4 Examples of Mutagens

Mutagen	Effect(s) on DNA structure
Chemical	
Nitrous acid	Deaminates bases
5-Bromouracil	Acts as a base analogue
2-Aminopurine	Acts as a base analogue
Nitrogen mustard	Alkylates bases
Ethyl methanesulfonate (EMS)	Alkylates bases
Benzo(*a*)pyrene	Inserts between bases in the DNA double helix and causes additions or deletions
Physical	
X-rays	Causes base deletions, single nicks in DNA strands, crosslinking, and chromosomal breaks
UV light	Promotes pyrimidine dimer formation, which involves covalent bonds between adjacent pyrimidines (C or T)

Chemical Mutagens How do mutagens affect DNA structure? Some chemical mutagens act by covalently modifying the structure of nucleotides. For example, nitrous acid (HNO_2) deaminates bases by replacing amino groups with keto groups (—NH_2 to =O). This can change cytosine to uracil. When this altered DNA replicates, the modified base does not pair with the appropriate base in the newly made strand. In this case, uracil pairs with adenine (**Figure 14.5**).

Similarly, 5-bromouracil and 2-aminopurine, which are called base analogues, have structures that are similar to particular bases in DNA and can substitute for them. When incorporated into DNA, they also cause errors in DNA replication. Other chemical mutagens disrupt the appropriate pairing between nucleotides by alkylating bases within the DNA. During alkylation, methyl or ethyl groups are covalently attached to the bases. Examples of alkylating agents include nitrogen mustards (used as a chemical weapon during World War I) and ethyl methanesulfonate (EMS), which is used as a mutagen in laboratory experiments.

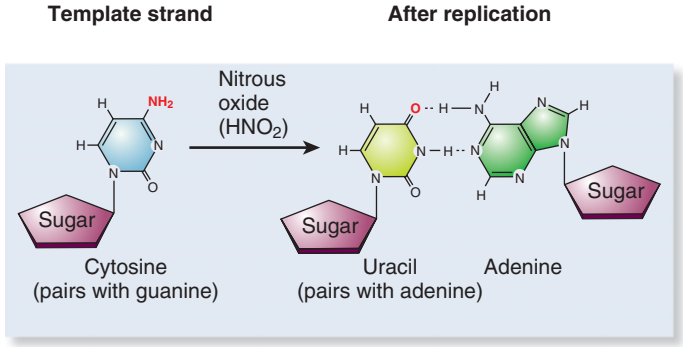


Figure 14.5 Deamination and mispairing of modified bases by a chemical mutagen. Nitrous acid changes cytosine to uracil by replacing NH_2 with an oxygen. During DNA replication, uracil pairs with adenine, thereby creating a mutation in the newly replicated strand.

Some chemical mutagens exert their effects by interfering with DNA replication. For example, benzo(*a*)pyrene, which is found in automobile exhaust, cigarette smoke, and charbroiled food, is metabolized to a compound (benzopyrene diol epoxide) that inserts between the bases of the double helix, thereby distorting the helical structure. When DNA containing such a mutagen is replicated, single-nucleotide additions and deletions may be incorporated into the newly made strands.

Physical Mutagens DNA molecules are also sensitive to physical agents such as radiation. In particular, radiation of short wavelength and high energy, known as ionizing radiation, is known to alter DNA structure. Ionizing radiation includes X-rays and gamma rays. This type of radiation can penetrate deeply into biological materials, where it creates free radicals. These molecules can alter the structure of DNA in a variety of ways. Exposure to high doses of ionizing radiation causes base deletions, breaks in one DNA strand, or even a break in both DNA strands.

Nonionizing radiation, such as UV light, contains less energy, and so it penetrates only the surface of biological materials, such as the skin. Nevertheless, UV light is known to cause mutations. For example, UV light can cause the formation of a **thymine dimer**, which is a site where two adjacent thymine bases become covalently crosslinked to each other (**Figure 14.6**).

Thymine dimers are typically repaired before or during DNA replication. However, if such repair fails to occur, a thymine dimer may cause a mutation when that DNA strand is replicated. When DNA polymerase attempts to replicate over a thymine dimer, proper base pairing does not occur between the template strand and the incoming nucleotides. This mispairing can cause gaps in the newly made strand or the incorporation of incorrect bases. Plants, in particular, must have effective ways to prevent UV damage because they are exposed to sunlight throughout the day.

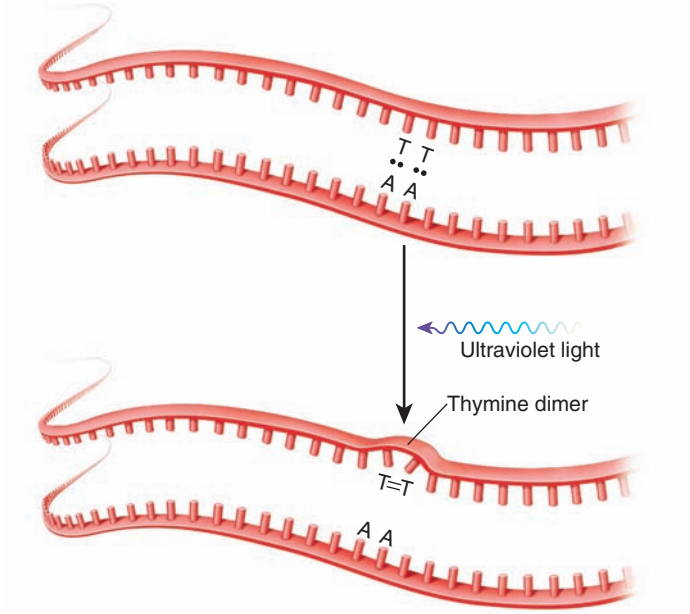

Figure 14.6 **Formation and structure of a thymine dimer.**

Concept Check: *Why is a thymine dimer harmful?*

Testing Methods Determine If an Agent Is a Mutagen

Because mutagens are harmful, researchers have developed testing methods to evaluate the ability of a substance to cause mutation. One commonly used test is the **Ames test**, which was developed by American biochemist Bruce Ames in the 1970s. This test uses a strain of a bacterium, *Salmonella typhimurium*, that cannot synthesize the amino acid histidine. This strain contains a point mutation within a gene that encodes an enzyme required for histidine biosynthesis. The mutation renders the enzyme inactive. The bacteria cannot grow unless histidine has been added to the growth medium. However, a second mutation may correct the first mutation, thereby restoring the ability to synthesize histidine. The Ames test monitors the rate at which this second mutation occurs and thereby indicates whether an agent increases the mutation rate above the spontaneous rate.

Figure 14.7 outlines the steps in the Ames test. The suspected mutagen is mixed with a rat liver extract and the strain of *S. typhimurium* that cannot synthesize histidine. Because some potential mutagens may require activation by cellular enzymes, the rat liver extract provides a mixture of enzymes that may cause such activation. This step improves the ability to identify agents that cause mutations in mammals. As a control, bacteria that have not been exposed to the mutagen are also tested. After an incubation period in which mutations may occur, a large number of bacteria are plated on a growth medium that does not contain histidine. The *S. typhimurium* strain is not expected to grow on these plates. However, if a mutation has occurred that allows a cell to synthesize histidine, the bacterium harboring this second mutation will proliferate during an overnight incubation period to form a visible bacterial colony.

To estimate the mutation rate, the colonies that grow in the absence of histidine are counted and compared with the total number of bacterial cells that were originally placed on the plate for both the suspected-mutagen sample and the control. The control condition is a measure of the spontaneous mutation rate, whereas the other sample measures the rate of mutation in the presence of the suspected

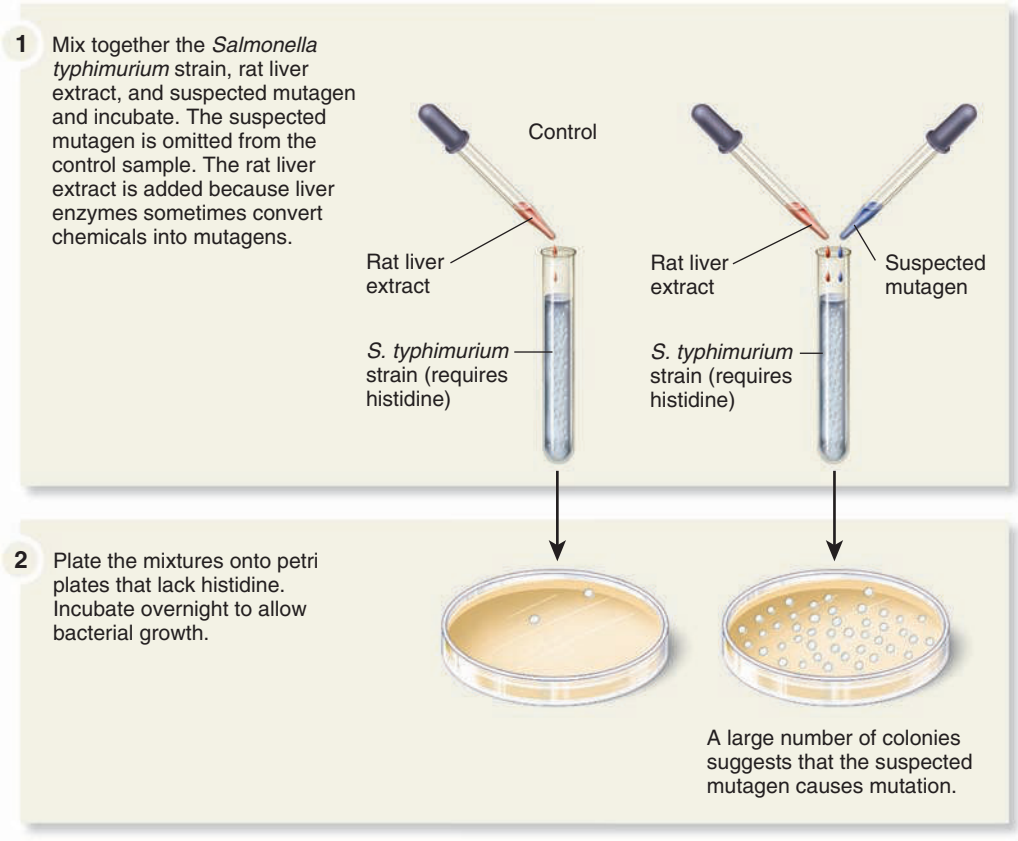

Figure 14.7 **The Ames test for mutagenicity.** In this example, 2 million bacterial cells were placed on plates lacking histidine. Two colonies arose from the control sample, whereas 44 arose from the sample exposed to a suspected mutagen.

BIOLOGY PRINCIPLE
Biology affects our society.
Biologists have developed many methods, including the Ames test, for determining if a substance is a mutagen. The results of these tests have prevented the use of many different chemicals in the production of food and also resulted in warning labels on products such as cigarettes.

Concept Check: *Based on the results seen in this figure, what is the rate of mutation that is caused by the suspected mutagen?*

mutagen. As an example, let's suppose that 2 million bacteria were plated from both the control and the suspected-mutagen tubes. In the control experiment, 2 bacterial colonies were observed. The spontaneous mutation rate is calculated by dividing 2 (the number of mutants) by 2 million (the number of original cells). This equals 1 in 1 million, or 1×10^{-6}. By comparison, 44 colonies arose from the suspected-mutagen sample (see Figure 14.7). In this case, the mutation rate would be 44 divided by 2 million, which equals 2.2×10^{-5}. The mutation rate in the presence of the mutagen is over 20 times higher than the spontaneous mutation rate.

How do we judge if an agent is a mutagen? Researchers compare the mutation rate in the presence and absence of the suspected mutagen. The experimental approach shown in Figure 14.7 is conducted several times. If statistics reveal that the mutation rate in the suspected-mutagen sample is significantly higher than in the control sample, they may tentatively conclude that the agent is a mutagen. Interestingly, many studies have used the Ames test to compare the urine from cigarette smokers with that from nonsmokers. This research has shown that urine from smokers contains much higher levels of mutagens.

BIO TIPS **THE QUESTION** *Let's suppose a researcher studied the effects of a suspected mutagen, mutagen X, using the protocol described in Figure 14.7. The following data were obtained after placing 2 million cells on each plate:*

	Number of colonies	
Trial	Control (no mutagen)	With mutagen X
1	3	62
2	2	77
3	5	46
4	2	55

Calculate the average mutation rate in the presence and absence of mutagen X. Conduct a t-test to determine if suspected mutagen X is significantly affecting the mutation rate.

TOPIC ***What topic in biology does this question address?*** The topic is about testing methods for identifying mutagens. More specifically, the question is about the Ames test.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** In the question, you are given data regarding the outcome of four trials using the Ames test. From your understanding of the topic, you may remember that a higher number of colonies on the experimental plate may indicate that a substance is a mutagen.

PROBLEM-SOLVING STRATEGY ***Make a calculation. Use statistics.*** To begin to solve this problem, you first need to calculate the average mutation rates. To do this, take the average of the four trials and then divide the average number of mutant colonies by the total number of cells applied to each plate (in this case, 2 million). You also need to conduct a *t*-test to determine if the control and experimental data are significantly different. A description of a *t*-test can be found in various statistics textbooks and at http://successinhighered.com/genetics-molecular-biology.

ANSWER *In the control trials, the average mutation rate is 1.5 in 1 million, or 1.5×10^{-6}. In the presence of the suspected mutagen, the average rate is 30 in 1 million, or 30×10^{-6}. From a t-test of these data, $P < 0.01$, so you can reject the null hypothesis that the control and experimental data are not different from each other. Therefore, you can accept the hypothesis that the suspected mutagen is causing a higher mutation rate. Note: This hypothesis is not proven; you are simply able to accept it based on this statistical outcome.*

14.3 DNA Repair

Learning Outcomes:

1. List the general features of DNA repair systems.
2. Describe the steps of nucleotide excision repair.
3. Explain the connection between defects in DNA repair systems and the inherited human disease xeroderma pigmentosum.

In the previous sections, we considered the consequences and causes of mutations. As we have seen, mutations are random events that often have negative consequences. To minimize mutation, all living organisms have the ability to repair changes that occur in the structure of DNA. For example, in Chapter 11, we considered how DNA polymerase has a proofreading function that helps to prevent mutations from happening during DNA replication. In this section, we will examine DNA repair systems that can detect abnormalities in DNA structure and repair them. The importance of these systems becomes evident when they are missing. For example, as discussed at the beginning of this chapter, persons with xeroderma pigmentosum are highly susceptible to the harmful effects of sunlight because they are missing a single DNA repair system.

How do organisms minimize the occurrence of mutations? Cells contain several DNA repair systems that can fix different types of DNA alterations (**Table 14.5**). Each repair system is composed of one or more proteins that play specific roles in the repair mechanism. DNA

Table 14.5 Common Types of DNA Repair Systems*

System	Description
Direct repair	A repair enzyme recognizes an incorrect structure in the DNA and directly converts it back to a correct structure.
Base excision and nucleotide excision repair	An abnormal base or nucleotide is recognized, and a portion of the strand containing the abnormality is removed. The complementary DNA strand is then used as a template to synthesize a normal DNA strand.
Methyl-directed mismatch repair	Similar to excision repair except that the DNA defect is a base pair mismatch in the DNA, not an abnormal nucleotide. The mismatch is recognized, and a strand of DNA in this region is removed. The complementary strand is used to synthesize a normal strand of DNA.

*Other types of repair systems exist; these are common examples.

repair requires two coordinated events. In the first step, one or more proteins in the repair system detect an irregularity in DNA structure. In the second step, the abnormality is repaired. In some cases, the change in DNA structure can be directly repaired. For example, DNA may be modified by the attachment of an alkyl group, such as $—CH_2CH_3$, to a base. In **direct repair**, an enzyme removes this alkyl group, thereby restoring the structure of the original base. More commonly, however, the altered DNA is removed, and a new segment of DNA is synthesized. In this section, we will examine nucleotide excision repair as an example of how such systems operate. This system, which is found in all species, is an important mechanism of DNA repair.

Nucleotide Excision Repair Removes Segments of Damaged DNA

In **nucleotide excision repair (NER)**, a region encompassing several nucleotides in the damaged strand is removed from the DNA, and the intact undamaged strand is used as a template for the resynthesis of a normal complementary strand. NER can fix many different types of DNA damage, including UV-induced damage, chemically modified bases, missing bases, and various types of crosslinks (such as thymine dimers). The system is found in all species, although its molecular mechanism is best understood in bacteria.

In *E. coli*, the NER system is composed of four key proteins: UvrA, UvrB, UvrC, and UvrD. They are named Uvr because they are involved in ultraviolet light repair of thymine dimers, although these proteins are also important in repairing chemically damaged DNA. In addition, DNA polymerase and DNA ligase are required to complete the repair process.

How does the NER system work?

1. Two UvrA proteins and one UvrB protein form a complex that tracks along the DNA (**Figure 14.8**). Damaged DNA will have a distorted double helix, which is sensed by the UvrA-UvrB complex.
2. When the complex identifies a damaged site, the two UvrA proteins are released, and UvrC binds to UvrB at the site.
3. The UvrC protein makes incisions in one DNA strand on both sides of the damaged site.
4. After this incision process, UvrC is released. UvrD binds to UvrB. UvrD then begins to separate the DNA strands, and UvrB is released. The action of UvrD unravels the DNA, which removes a short DNA strand that contains the damaged region. UvrD is released.
5. After the damaged DNA strand is removed, a gap is left in the double helix. DNA polymerase fills in the gap using the undamaged strand as a template. Finally, DNA ligase makes the final covalent connection between the newly made DNA and the original DNA strand.

Human Genetic Diseases Occur When a Component of the NER System Is Missing

Thus far, we have considered the NER system in *E. coli*. In humans, NER systems were discovered by the analysis of genetic diseases that affect DNA repair. These include xeroderma pigmentosum (XP),

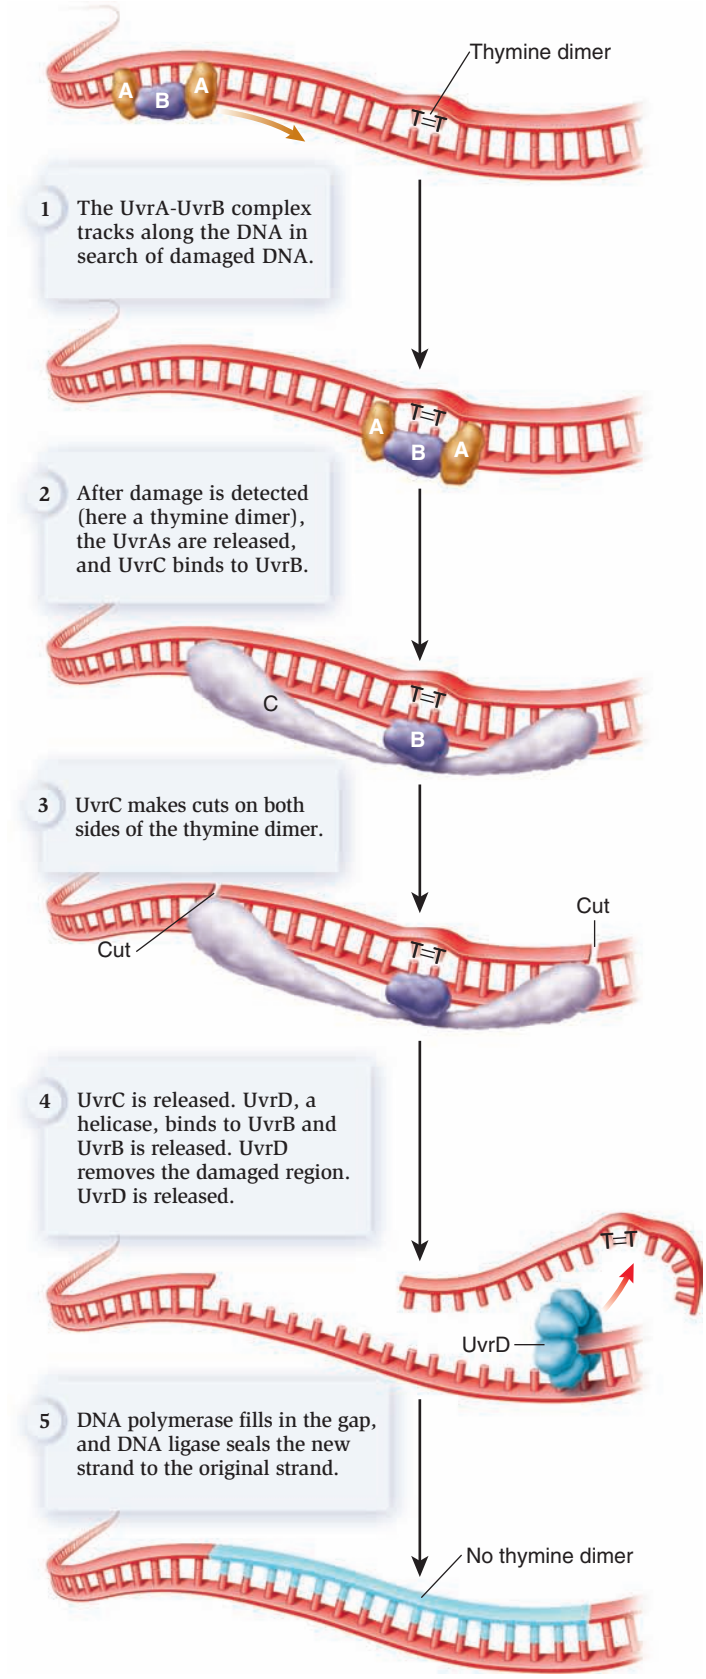

Figure 14.8 Nucleotide excision repair in *E. coli*.

Concept Check: Which components of NER are responsible for removing the damaged DNA?

Figure 14.9 **An individual affected by xeroderma pigmentosum.**

Concept Check: *Why is this person so sensitive to sunlight?*

which was discussed at the beginning of this chapter, and Cockayne syndrome (CS). Photosensitivity is a common characteristic in these syndromes because of an inability to repair UV-induced lesions. Therefore, people with either of these syndromes must avoid prolonged exposure to sunlight, as do the children at Camp Sundown. Figure 14.9 shows a photograph of a child with XP who had some exposure to sunlight. Such individuals may have pigmentation changes, precancerous lesions, and a predisposition to developing skin cancer.

14.4 Cancer

Learning Outcomes:

1. Outline the steps in the development of cancer.
2. Describe the general functions of oncogenes.
3. List the four common types of genetic changes that convert proto-oncogenes into oncogenes.
4. Identify the two general functions of the proteins encoded by tumor-suppressor genes.
5. Describe three common ways that tumor-suppressor genes are silenced.

Cancer is a disease of multicellular organisms characterized by uncontrolled cell division. Worldwide, cancer is the second leading cause of death in humans, exceeded only by heart disease. In the United States, approximately 1.5 million people are diagnosed with cancer each year; over 0.5 million will die from the disease. Overall, about one in four Americans will die from cancer.

In about 10% of cancers, a higher predisposition to develop the disease is an inherited trait. Most cancers, though, perhaps 90%, do not involve genetic changes that are passed from parent to offspring. Rather, cancer is usually an acquired condition that typically occurs later in life. At least 80% of all human cancers are related to exposure to **carcinogens**, agents that increase the likelihood of developing cancer. Most carcinogens, such as UV light and certain chemicals in cigarette smoke, are mutagens that promote genetic changes in somatic cells. These genetic changes can alter gene expression in a way that ultimately affects cell division, leading to cancer. In this section, we will explore such genetic abnormalities.

How does cancer occur? In most cases, the development of cancer is a multistep process (Figure 14.10). Cancers originate from a single cell. This single cell and its lineage of daughter cells undergo a series of mutations and other changes that cause the cells to grow abnormally. At an early stage, the cells form a **tumor**, which is an overgrowth of cells. For most types of cancer, a tumor begins as a precancerous, or **benign**, growth. Such tumors do not invade adjacent tissues and do not spread throughout the body. This may be followed by additional mutations that cause some cells in the tumor to lose their normal growth regulation and become **malignant**. At this stage, the individual has cancer. Cancerous tumors invade healthy tissues and may spread through the bloodstream or surrounding body fluids, a process called **metastasis**. If left untreated, malignant cells will cause the death of the organism.

Over the past few decades, researchers have identified many genes that promote cancer when they are mutant. By comparing the function of each mutant gene with the corresponding nonmutant gene found in healthy cells, these genes have been placed into two categories.

- In some cases, a mutation causes a gene to be overactive—have an abnormally high level of expression. This overactivity contributes to the uncontrolled cell growth that is observed in cancer cells. This type of mutant gene is called an **oncogene**.
- Alternatively, when a **tumor-suppressor gene** is normal (that is, not mutant), it encodes a protein that helps to prevent cancer. However, when a mutation eliminates its function, cancer may occur.

Thus, the two categories of cancer-causing genes are based on the effects of mutations. Oncogenes are the result of mutations that cause overactivity, whereas cancer-causing mutations in tumor-suppressor genes are due to a loss of activity. In this section, we will begin with a discussion of oncogenes and then consider tumor-suppressor genes.

Oncogenes May Result from Mutations That Cause the Overactivity of Proteins Involved with Cell Division

Over the past four decades, researchers have identified many oncogenes. A large number of oncogenes encode proteins that function in signal transduction pathways involved in cell growth. Cell division is regulated, in part, by growth factors. A growth factor binds to a receptor, which results in receptor activation (Figure 14.11). This stimulates an intracellular signal transduction pathway that activates transcription factors. In this way, the transcription of specific genes is activated in response to a growth factor. After they are made, the gene products promote cell division.

Eukaryotic species produce many different growth factors that play a role in cell division. Likewise, cells have several different types of signal transduction pathways, which are composed of proteins that respond to growth factors and promote cell division. Mutations in the genes that encode these signal transduction proteins can change them into oncogenes (Table 14.6).

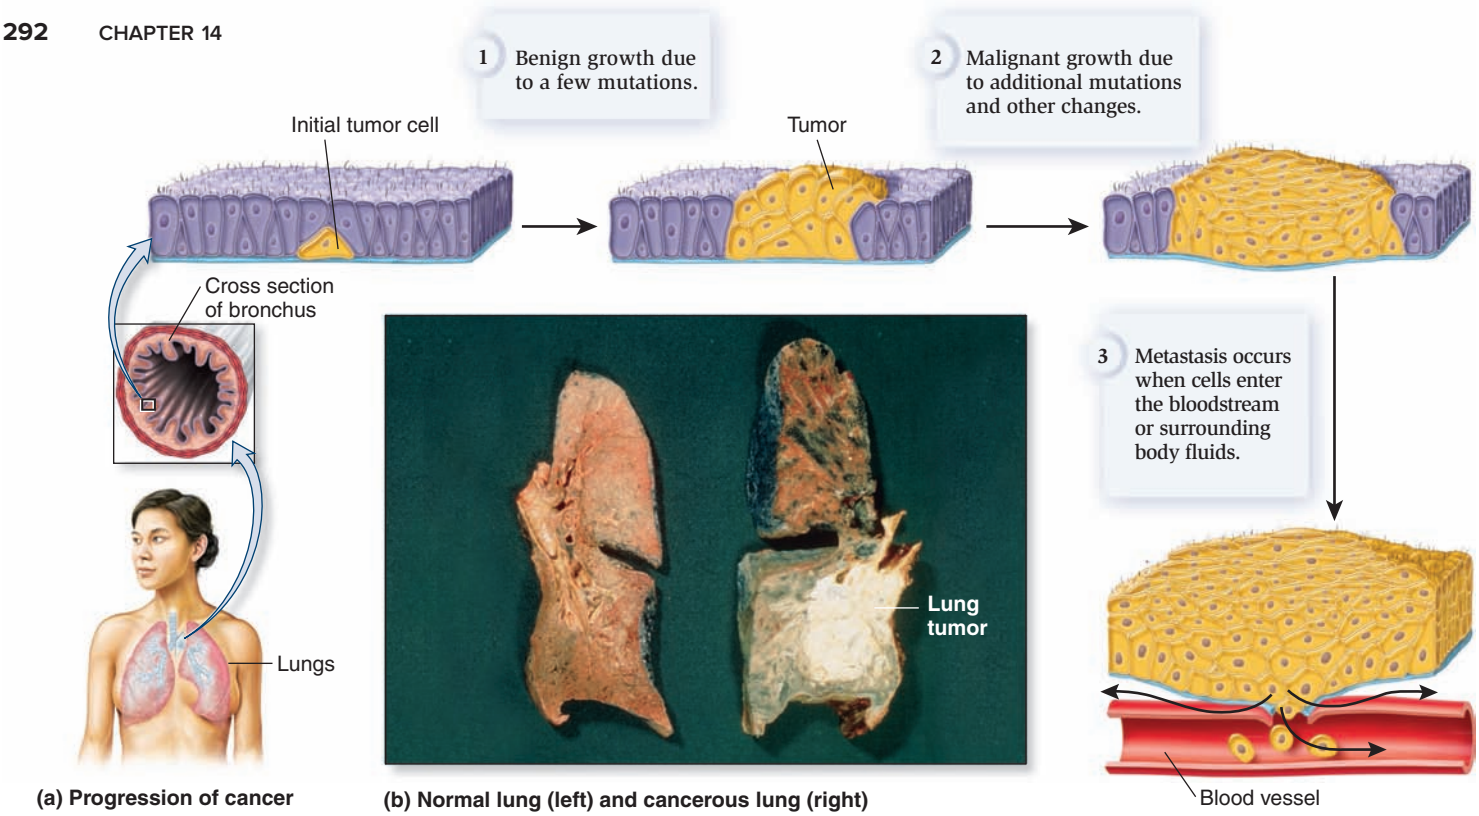

Figure 14.10 **Cancer: Its typical progression and effects.** **(a)** In a healthy individual, a few mutations convert a normal cell into a tumor cell. This cell divides to produce a benign tumor. Additional mutations and other changes in the tumor cells may occur, leading to a malignant tumor. At a later stage in malignancy, the tumor cells invade surrounding tissues, and some malignant cells may metastasize by traveling through the bloodstream to other parts of the body. **(b)** On the left of the photo is a human lung that was obtained from a healthy nonsmoker. The lung shown on the right has been ravaged by lung cancer. This lung was taken from a person who was a heavy smoker.

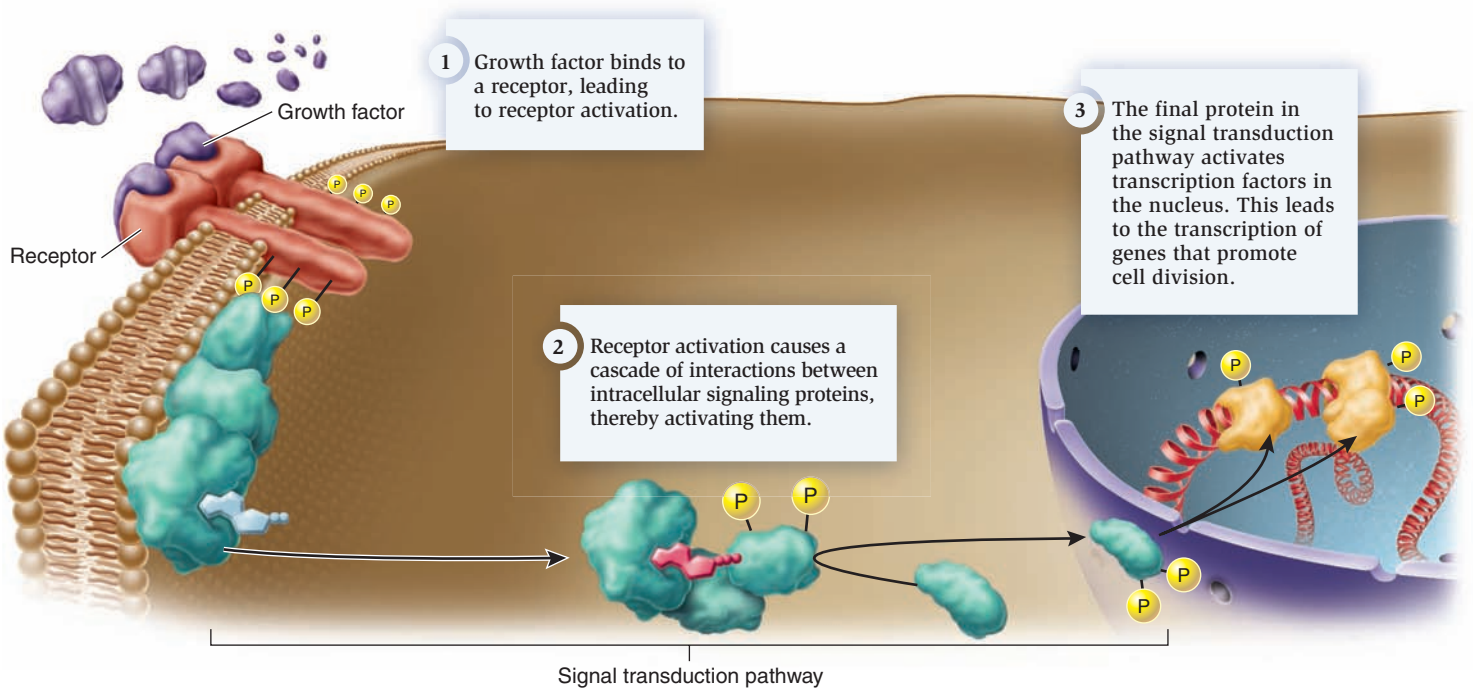

Figure 14.11 **General features of a signal transduction pathway that promotes cell division.** A detailed description of this pathway is found in Chapter 9 (Figure 9.10).

Concept Check: *How does the presence of a growth factor ultimately affect the function of the cell?*

BioConnections: *Look back at Figure 9.10. Could drugs that inhibit protein kinases be used to combat cancer? Explain.*

Table 14.6 Examples of Genes That Encode Signal Transduction Proteins and Can Become Oncogenes

Gene*	Cellular function
erbB	Growth factor receptor for EGF (epidermal growth factor)
ras	Intracellular signaling protein
raf	Intracellular signaling protein
src	Intracellular signaling protein
fos	Transcription factor
jun	Transcription factor

*The genes described in this table are found in humans as well as other vertebrate species. Most of the genes have been given three-letter names that are abbreviations for the type of cancer the oncogene causes or the type of virus in which the gene was first identified.

How does an oncogene promote cancer? In some cases, an oncogene may keep a signal transduction pathway for cell division in a permanent "on" position. One way oncogenes keep cell division turned on is by producing a functionally overactive protein. As a specific example, let's consider how a mutation alters an intracellular signaling protein called Ras (refer back to Figure 9.10). The Ras protein is a GTPase that hydrolyzes GTP to GDP + P_i (**Figure 14.12**). When a signal transduction pathway is activated, the Ras protein releases GDP and binds GTP. When GTP is bound, the activated Ras protein promotes cell division. The Ras protein returns to its inactive state by hydrolyzing its bound GTP, and cell division is inhibited. Mutations that convert the normal *ras* gene into an oncogenic *ras* either decrease the ability of Ras protein to hydrolyze GTP or increase the rate of exchange of bound GDP for GTP. Both of these functional changes result in a greater amount of the active GTP-bound form of the Ras protein. In this way, these mutations keep the signal transduction pathway turned on when it should not be, resulting in uncontrolled cell division.

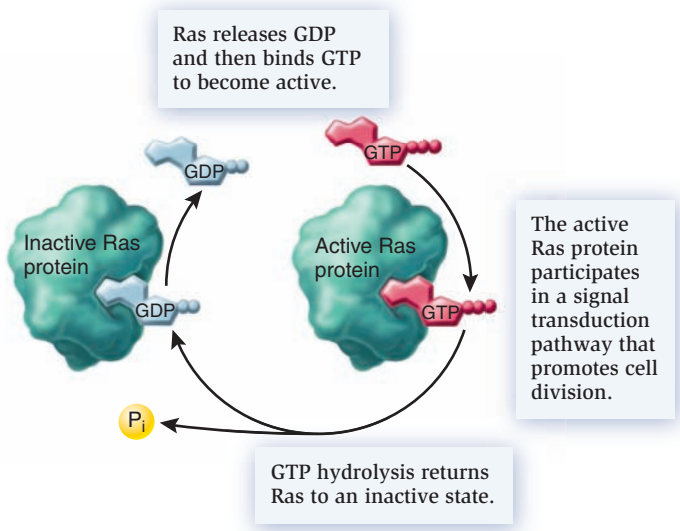

Figure 14.12 The function of Ras, a protein that is part of signal transduction pathways. When GTP is bound, the activated Ras protein promotes cell division. When GTP is hydrolyzed to GDP and P_i, Ras is inactivated, and cell division is inhibited.

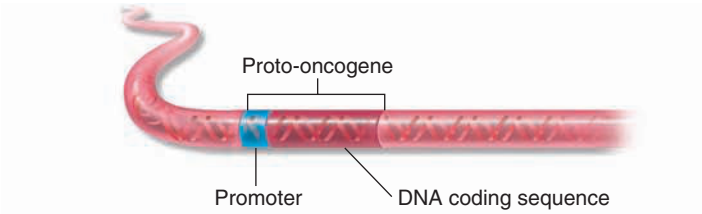
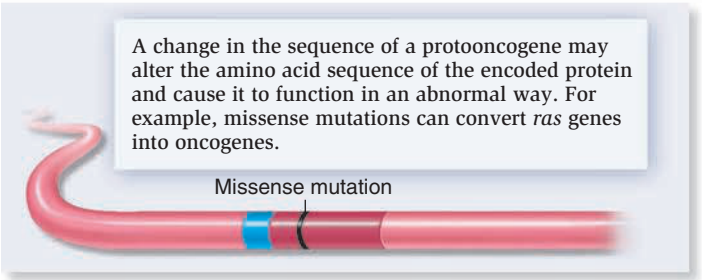
Mutations in Proto-Oncogenes Convert Them to Oncogenes

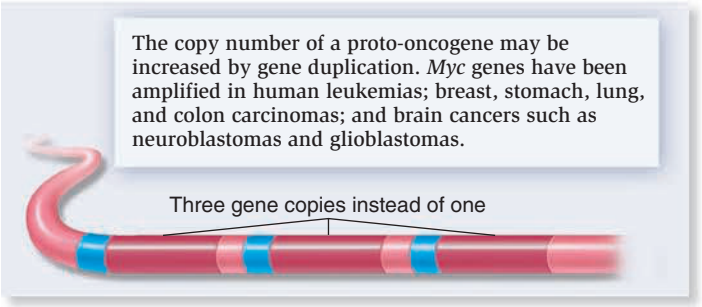


Thus far, we have examined the functions of proteins that cause cancer when they become overactive, resulting in uncontrolled cell division. Let's now consider the common types of genetic changes that create such oncogenes. A **proto-oncogene** is a normal gene that, if mutated, can become an oncogene. An oncogene is a gene that is overexpressed or expressed in the wrong cell type. Several types of genetic changes may convert a proto-oncogene into an oncogene. **Figure 14.13** describes four common types: missense mutations, gene amplifications, chromosomal translocations, and retroviral insertions.



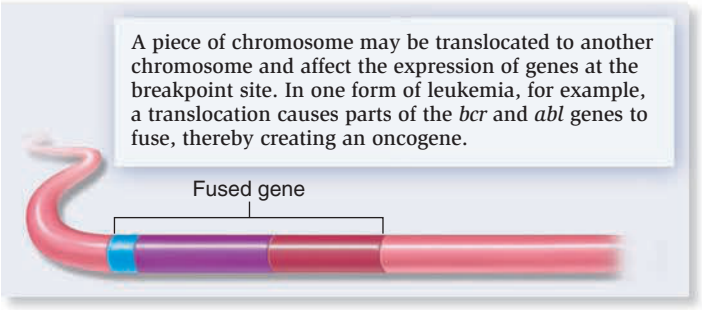
Missense Mutation A missense mutation (Figure 14.13a), which changes a single amino acid in a protein, alters the function of the encoded protein in a way that promotes cancer. This type of mutation is responsible for the conversion of the *ras* gene into an oncogene. An example is a mutation in the *ras* gene that changes a specific glycine to a valine in the Ras protein. This mutation decreases the ability of the Ras protein to hydrolyze GTP, which promotes cell division (see Figure 14.12). Experimentally, chemical mutagens have been shown to cause this missense mutation, thereby leading to cancer.

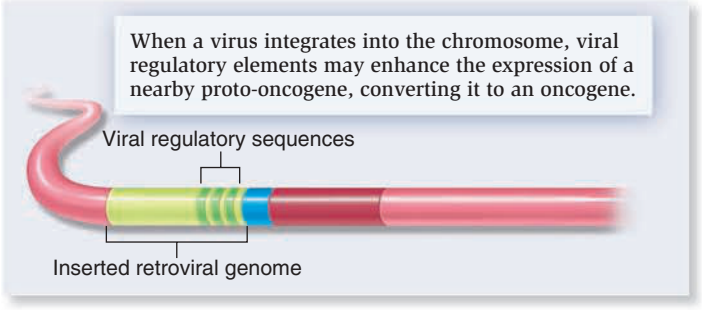
Gene Amplification Another genetic event that occurs in some cancer cells is an increase in the number of copies of a proto-oncogene (Figure 14.13b). An abnormal increase in the number of genes results in too much of the encoded protein. Many human cancers are associated with the amplification of particular proto-oncogenes. In 1982, American molecular biologist Mark Groudine discovered that the *myc* gene, which encodes a transcription factor, was amplified in a human leukemia.



Chromosomal Translocation A third type of genetic alteration that can lead to cancer is a chromosomal translocation (Figure 14.13c). This occurs when one segment of a chromosome becomes attached to a different chromosome. In 1960, American pathologist Peter Nowell discovered that a form of leukemia called chronic myelogenous leukemia (CML)—a type of cancer involving white blood cells—was correlated with the presence of a shortened version of a human chromosome. This shortened chromosome is the result of a chromosome translocation in which two different chromosomes, chromosomes 9 and 22, exchange pieces. This activates a proto-oncogene, *abl*, in an unusual way (**Figure 14.14**). In healthy individuals, the *bcr* gene and the *abl* gene are located on different chromosomes. In CML, these chromosomes break and rejoin in a way that causes the promoter and the first part of *bcr* to fuse with part of *abl*. This abnormal gene acts as an oncogene that encodes a fusion protein whose functional overactivity leads to leukemia.

Retroviral Insertion Certain types of viruses convert proto-oncogenes into oncogenes during the viral replication cycle (see Figure 14.13d). Retroviruses insert their DNA into the chromosomal





(a) Missense mutation

(b) Gene amplification

(c) Chromosomal translocation

(d) Retroviral insertion

Figure 14.13 Common genetic changes that convert proto-oncogenes to oncogenes.

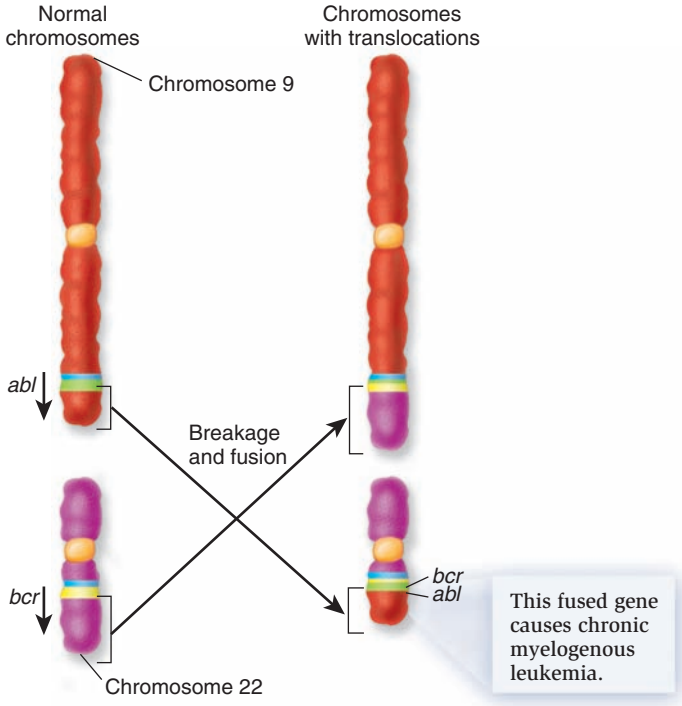


Figure 14.14 The formation of a fused gene found in people with certain forms of leukemia. The fusion of the *bcr* and *abl* genes creates an abnormal gene that encodes a fusion protein, leading to leukemia. The blue regions are the promoters for the *bcr* and *abl* genes.

Concept Check: *The bcr gene is normally expressed in white blood cells. Explain how this observation is related to the type of cancer that the translocation causes.*

DNA of the host cell. The viral genome contains promoter and regulatory elements that cause a high level of expression of viral genes. On occasion, the viral DNA may insert into a host chromosome in such a way that a viral promoter and regulatory elements are next to a proto-oncogene. This may result in the overexpression of the proto-oncogene, thereby promoting cancer. This is one way for a virus to cause cancer. Alternatively, a virus may cause cancer because it carries an oncogene in the viral genome. This phenomenon is described next.

Some Types of Cancer Are Caused by Viruses

The majority of cancers are caused by mutagens or other changes that alter the structure and expression of genes that are found in somatic cells. A few viruses, however, are known to cause cancer in plants and animals, including humans (**Table 14.7**).

In 1911, the first cancer-causing virus to be discovered was isolated from chicken sarcomas by American pathologist Peyton Rous. A **sarcoma** is a tumor of connective tissue such as bone or cartilage. The virus was named the Rous sarcoma virus (RSV). In the 1970s, research involving RSV led to the identification of a viral gene that acts as an oncogene. Researchers investigated RSV by using it to infect chicken cells grown in the laboratory. This causes chicken cells to grow like cancer cells, continuously and in an uncontrolled manner.

Table 14.7 Examples of Viruses That Cause Cancer

Virus	Description
Rous sarcoma virus	Causes sarcomas in chickens
Simian sarcoma virus	Causes sarcomas in monkeys
Abelson leukemia virus	Causes leukemia in mice
Hardy-Zuckerman 4 feline sarcoma virus	Causes sarcomas in cats
Hepatitis B	Causes liver cancer in several species, including humans

Researchers identified mutant RSV strains that infected and proliferated within chicken cells without transforming them into malignant cells. These RSV strains were missing a gene that is found in the form of the virus that does cause cancer. This gene was called the *src* gene because it causes sarcoma.

Americans, biologist Harold Varmus and microbiologist Michael Bishop, in collaboration with molecular biologist Peter Vogt, later discovered that normal (nonviral-infected) chicken cells also contain a copy of the *src* gene in their chromosomes. It is a proto-oncogene. When the *src* gene is incorporated into a viral genome, it is overexpressed because it is transcribed from a very active viral promoter. This ultimately produces too much of the Src protein in infected cells and promotes uncontrolled cell division.

Tumor-Suppressor Genes Prevent Mutation or Cell Proliferation

Thus far, we have examined one category of genes that promote cancer, namely oncogenes. We now turn our attention to the second category, those called tumor-suppressor genes. The functioning of a normal (nonmutant) tumor-suppressor gene prevents cancerous growth. The proteins encoded by tumor-suppressor genes usually have one of two functions: maintenance of genome integrity or negative regulation of cell division (**Table 14.8**).

Maintenance of Genome Integrity Some tumor-suppressor genes encode proteins that maintain the integrity of the genome by monitoring and/or repairing alterations in it. The proteins encoded by these genes are vital for the prevention of abnormalities such as gene mutations, DNA breaks, and improperly segregated chromosomes. Therefore, when these proteins are functioning properly, they minimize the chance that a cancer-causing mutation will occur. In some cases, the proteins encoded by tumor-suppressor genes prevent a cell from progressing through the cell cycle if an abnormality is detected. These are termed **checkpoint proteins** because their role is to check the integrity of the genome and prevent a cell from progressing past a certain point in the cell cycle. Checkpoint proteins are not always required to regulate normal, healthy cell division, but they can stop cell division if an abnormality is detected.

How do checkpoint proteins stop the cell cycle? One way is by controlling proteins called cyclins and cyclin-dependent kinases (cdks), which are responsible for advancing a cell through the four phases of the cell cycle (see Chapter 15). The formation of activated cyclin/cdk complexes can be stopped by checkpoint proteins.

Table 14.8 Functions of Selected Tumor-Suppressor Genes

Gene	
Maintenance of genome integrity	
p53	p53 is a transcription factor that acts as a sensor of DNA damage. It can promote DNA repair, prevent the progression through the cell cycle, and promote apoptosis.
BRCA-1 *BRCA-2*	BRCA-1 and BRCA-2 proteins are both involved in the cellular defense against DNA damage. They play a role in sensing DNA damage and facilitate DNA repair. These genes are mutant in persons with certain inherited forms of breast cancer.
XPD	This represents one of several different genes whose products function in DNA repair. These genes are defective in patients with xeroderma pigmentosum.
Negative regulation of cell division	
Rb	The Rb protein is a negative regulator that represses the transcription of genes required for DNA replication and cell division.
NF1	The NF1 protein stimulates Ras to hydrolyze its GTP to GDP. Loss of NF1 function causes the Ras protein to be overactive, which promotes cell division.
p16	The p16 protein is a negative regulator of cyclin-dependent kinases (cdks).

A specific example of a tumor-suppressor gene that encodes a checkpoint protein is *p53*, discovered in 1979 by American biologist Arnold Levine. Its name refers to the molecular mass of the p53 protein, which is 53 kDa (kilodaltons). About 50% of all human cancers, including malignant tumors of the lung, breast, esophagus, liver, bladder, and brain, as well as leukemias and lymphomas (cancer of the lymphatic system), are associated with mutations in this gene.

As shown in **Figure 14.15**, p53 is a protein that controls the ability of cells to progress from the G_1 stage of the cell cycle to the S phase. The expression of the *p53* gene is induced when DNA is damaged. The p53 protein functions as a regulatory transcription factor that activates several different genes, leading to the synthesis of proteins that stop the cell cycle and other proteins that repair the DNA. If the DNA is eventually repaired, a cell may later proceed through the cell cycle.

Alternatively, if the DNA damage is too severe, the p53 protein will also activate other genes that promote programmed cell death. This process, called **apoptosis**, involves cell shrinkage and DNA degradation. As described in Chapter 9, enzymes known as caspases are activated during apoptosis (refer back to Figure 9.18). They function as proteases that are sometimes called the "executioners" of the cell. Caspases digest selected cellular proteins such as microfilaments, which are components of the cytoskeleton. This causes the cell to break into small vesicles that are eventually phagocytized by cells of the immune system. It is beneficial for a multicellular organism to kill an occasional cell with cancer-causing potential.

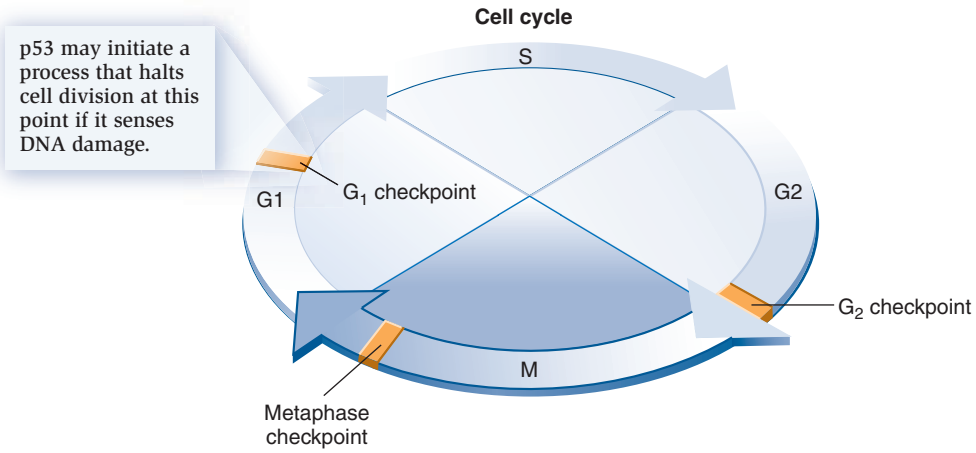

Figure 14.15 The cell cycle and checkpoints. As discussed in Chapter 15, eukaryotic cells progress through a cell cycle composed of G_1, S, G_2, and M phases (look ahead to Figure 15.2). The yellow bars indicate common checkpoints that stop the cell cycle if genetic abnormalities are detected. The p53 protein stops a cell at the G_1 checkpoint if it senses DNA damage.

Concept Check: *Why is it an advantage for an organism to have checkpoints that can stop the cell cycle?*

Negative Regulation of Cell Division A second category of tumor-suppressor genes encodes proteins that are negative regulators or inhibitors of cell division. The function of these genes is necessary to properly halt cell division. If their function is lost, cell division is abnormally accelerated.

An example of such a tumor-suppressor gene is the *Rb* gene. It was the first tumor-suppressor gene to be identified in humans by studying patients with a disease called retinoblastoma, a cancerous tumor that occurs in the retina of the eye. The Rb protein negatively controls a regulatory transcription factor called E2F that activates genes required for cell cycle progression from G_1 to S phase. The binding of the Rb protein to E2F inhibits its activity and prevents cell division (**Figure 14.16**). When a normal cell is supposed to divide, cyclins bind to cyclin-dependent kinases (cdks). This binding activates the kinases, which catalyze the transfer of a phosphate to the Rb protein. The phosphorylated form of the Rb protein is released from E2F, thereby allowing E2F to activate genes needed to progress through the cell cycle. When both copies of Rb are defective due to mutations, the E2F protein is always active. This explains why uncontrolled cell division occurs in retinoblastoma.

Gene Mutations, Chromosome Loss, and DNA Methylation Can Inhibit the Expression of Tumor-Suppressor Genes

Cancer biologists want to understand how tumor-suppressor genes are inactivated, because this knowledge may ultimately help them to prevent or combat cancer. How are tumor-suppressor genes silenced? The function of tumor-suppressor genes is lost in three common ways.

Inactivation of Tumor-Suppressor Genes via Mutation First, a mutation can occur within a tumor-suppressor gene to inactivate its function. For example, a mutation could abolish the function of the promoter for a tumor-suppressor gene or introduce an early stop codon in its coding sequence. Either of these would prevent the expression of a functional protein.

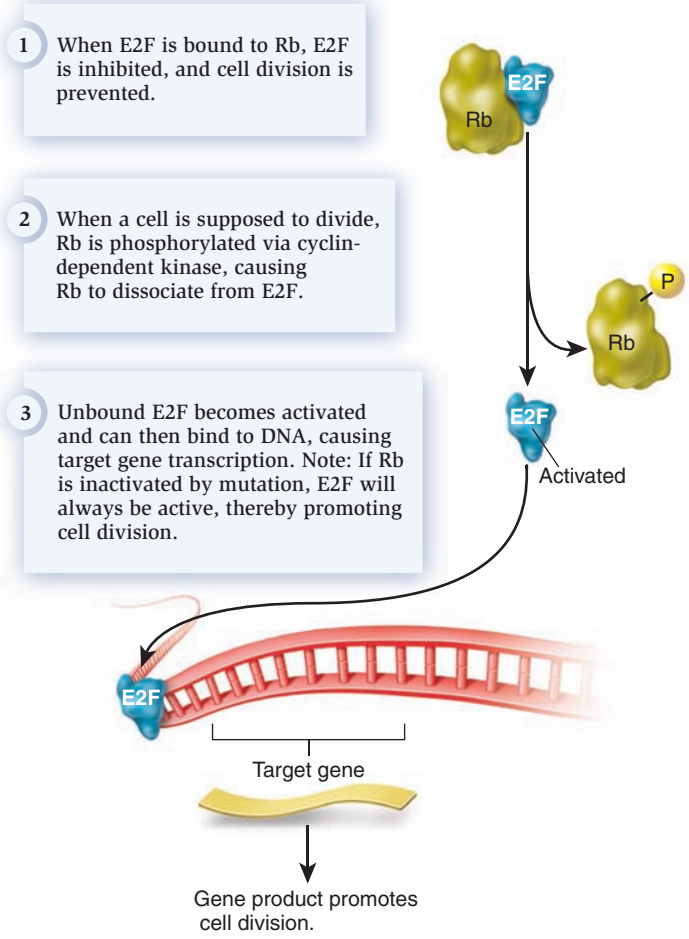

Figure 14.16 Function of the Rb protein. The Rb protein inhibits the function of E2F, which turns on genes that cause a cell to divide. When cells are supposed to divide, Rb is phosphorylated by cyclin-dependent kinase, which allows E2F to function.

Concept Check: *Would cancer occur if both copies of the Rb gene and both copies of the E2F gene were rendered inactive due to mutations?*

Chromosome Loss Chromosome loss is a second way that the function of a tumor-suppressor gene is lost. Chromosome loss may contribute to the progression of cancer if the missing chromosome carries one or more tumor-suppressor genes.

Epigenetic Changes Researchers have discovered a third way that tumor-suppressor genes may be inactivated. Epigenetic changes alter gene expression without altering the base sequence of DNA. For example, tumor-suppressor genes found in cancer cells are sometimes abnormally methylated. As discussed in Chapter 13, transcription is inhibited when CpG islands near a promoter are methylated. Such DNA methylation near the promoters of tumor-suppressor genes has been found in many types of tumors, suggesting that this form of gene inactivation plays an important role in the formation and/or progression of malignancy.

Most Forms of Cancer Are Caused by a Series of Genetic Changes That Progressively Alter the Growth Properties of Cells

The discovery of oncogenes and tumor-suppressor genes has allowed researchers to study the progression of certain forms of cancer at the molecular level. In most cases, multiple genetic changes to the same cell lineage, perhaps in the range of 10 or more, are needed for cancer to occur. Such changes involve the overexpression of oncogenes and the inactivation of tumor-suppression genes. Many cancers begin with a benign genetic alteration that, over time and with additional mutations, leads to malignancy. Furthermore, a malignancy can continue to accumulate genetic changes that make it even more difficult to treat because the cells divide faster or invade surrounding tissues more readily.

As an example, let consider lung cancer, which is diagnosed in approximately 170,000 men and women each year in the United States. More than 1.2 million cases are diagnosed worldwide. Nearly 90% of these cases are caused by tobacco smoking and are thus preventable. Unlike other cancers for which early diagnosis is possible, lung cancer is usually detected only after it has become advanced and is difficult if not impossible to cure. The 5-year survival rate for lung cancer patients is approximately 15%.

What is the cellular basis for lung cancer? Most cancers of the lung are **carcinomas**—cancers of epithelial cells (**Figure 14.17**). (Epithelial cells, which form the lining of all internal and external body surfaces, are described in Chapter 10.) The top images in Figure 14.17 show the normal epithelium found in a healthy lung. The rest of the figure shows the progression of a carcinoma that is due to mutations in basal cells, a type of epithelial cell. Keep in mind that cancer occurs due to the accumulation of mutations in a cell lineage, beginning with an initial mutant cell that then divides multiple times to produce a population of many daughter cells (refer back to Figure 14.10). As mutations accumulate in a lineage of basal cells, their numbers increase dramatically. This causes a thickening of the epithelium, a condition called hyperplasia. The proliferation of such basal cells causes the loss of the ciliated, columnar epithelial cells that normally line the airways and help remove mucus and its trapped particles from the lungs. As additional mutations accumulate in this cell lineage, the basal cells develop more abnormal morphologies,

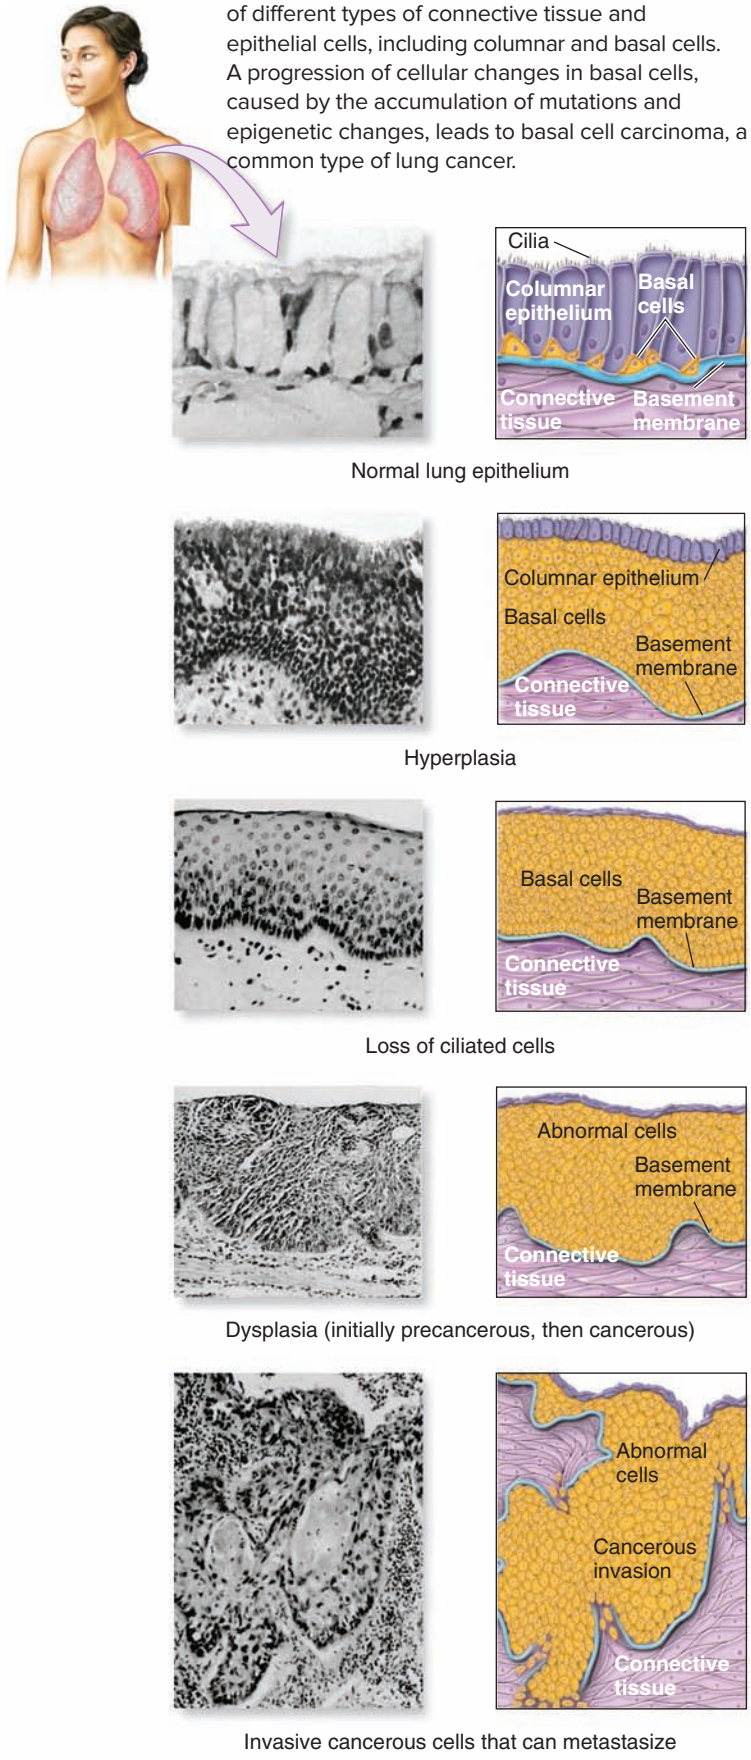

Figure 14.17 Progression of changes leading to lung cancer. Lung tissue is largely composed of different types of connective tissue and epithelial cells, including columnar and basal cells. A progression of cellular changes in basal cells, caused by the accumulation of mutations and epigenetic changes, leads to basal cell carcinoma, a common type of lung cancer.

a condition known as dysplasia. In the early stages of dysplasia, the abnormal basal cells are precancerous. If the source of chronic irritation (usually cigarette smoke) is eliminated, the abnormal cells are likely to disappear. Alternatively, if smoking continues, these abnormal cells may accumulate additional genetic changes and lose the ability to stop dividing. Such cells have become cancerous—the person has basal cell carcinoma.

The basement membrane is a sheetlike layer of extracellular matrix that provides a barrier between the lung cells and the bloodstream. If the cancer cells have not yet penetrated the basement membrane, they will not have metastasized, that is, spread into the blood and to other parts of the body. If the entire tumor is removed at this stage, the patient should be cured. The lower images in Figure 14.17 show a tumor that has broken through the basement membrane. The metastasis of these cells to other parts of the body will likely kill the patient, usually within a year of diagnosis.

The cellular changes that lead to lung cancer are correlated with genetic changes. These include the occurrence of mutations that create oncogenes and inhibit tumor-suppressor genes. The order of mutations is not absolute. It takes time for multiple changes to accumulate, so cancer is usually a disease of older people. Reducing your exposure to mutagens such as cigarette smoke throughout your lifetime helps minimize the risk of mutations to your genes that could promote cancer.

Genomes & Proteomes Connection

Mutations in Approximately 300 Human Genes May Promote Cancer

Researchers have identified a large number of genes that are mutated in cancer cells. Though not all of these mutant genes have been directly shown to affect the growth rate of cells, such mutations are likely to be found in tumors because they provide some type of growth advantage for the cell population from which the cancer developed. For example, certain mutations may affect the functions of proteins that enable cells to metastasize to neighboring locations. These mutations may not affect growth rate, but they provide the growth advantage that cancer cells are not limited to growing in a particular location. They can migrate to new locations.

How many genes can contribute to cancer when they become mutant? Researchers have estimated that about 300 different genes may play a role in the development of human cancer. With an approximate human genome size of 22,000 genes, this observation indicates that over 1% of our genes have the potential to promote cancer if their expression is altered by a mutation or an epigenetic change.

Summary of Key Concepts

14.1 Consequences of Mutations

- A mutation is a heritable change in the genetic material; gene mutations are relatively small changes in the base sequence of a gene.
- Point mutations affect a single base pair and can alter the coding sequence of genes in several ways. These mutations include silent, missense, nonsense, and frameshift mutations (Table 14.1).
- Sickle cell disease is caused by a missense mutation that results in a single amino acid substitution in β-globin (Figure 14.1).
- Gene mutations also alter gene function by changing DNA sequences that are not within the coding region (Table 14.2).
- Germ-line mutations affect gametes, whereas mutations in somatic cells affect only a part of the body and cannot be passed to offspring (Figures 14.2, 14.3).

14.2 Causes of Mutations

- The Lederbergs used replica plating to show that mutations are random events (Figure 14.4).
- Spontaneous mutations are the result of errors in natural biological processes. Induced mutations are caused by agents in the environment that alter DNA structure (Table 14.3).
- Mutagens are chemical or physical agents that lead to mutations in DNA (Table 14.4, Figures 14.5, 14.6).
- The Ames test is a method of testing whether an agent is a mutagen (Figure 14.7).

14.3 DNA Repair

- DNA repair systems consist of proteins that sense DNA damage and repair it before a mutation occurs (Table 14.5).
- In nucleotide excision repair (NER), proteins recognize various types of DNA damage, such as thymine dimers. A region in the damaged strand is excised, and a new strand is synthesized, using the intact strand as a template (Figure 14.8).
- Certain inherited diseases in humans, such as xeroderma pigmentosum (XP), are due to defects in the NER system (Figure 14.9).

14.4 Cancer

- Cancer is due to the accumulation of mutations and epigenetic changes in a lineage of cells that leads to uncontrolled cell growth (Figure 14.10).
- Mutations in proto-oncogenes that result in overactivity produce cancer-causing genes called oncogenes.
- Oncogenes often encode proteins involved in signal transduction pathways that promote cell division (Figures 14.11, 14.12, Table 14.6).
- Four common types of genetic changes, namely, missense mutations, gene amplifications, chromosomal translocations, and retroviral insertions, can change proto-oncogenes into oncogenes (Figures 14.13, 14.14).
- Some types of cancer are caused by viruses (Table 14.7).
- The normal function of tumor-suppressor genes is to prevent cancer. Loss-of-function mutations in such genes promote cancer. Tumor-suppressor genes often encode proteins that maintain the integrity of the genome or function as negative regulators of cell division (Table 14.8).
- Checkpoint proteins such as p53 monitor the integrity of the genome and prevent the cell from progressing through the cell cycle if abnormalities are detected (Figure 14.15).

- The Rb protein is an inhibitor of the cell cycle, because it negatively controls E2F, a transcription factor that promotes cell division (Figure 14.16).
- Tumor-suppressor genes can be inactivated by gene mutations, chromosome loss, and epigenetic changes such as DNA methylation.
- Most forms of cancer, such as lung cancer, involve multiple genetic changes that lead to malignancy (Figure 14.17).
- Over 300 human genes, or over 1% of our genes, are known to be associated with cancer when they become mutant.

Assess and Discuss

Test Yourself

1. A mutation removes a single base pair within the coding sequence of a gene and inactivates the protein encoded by the gene. Such a mutation is
   a. a silent mutation
   b. a missense mutation
   c. a nonsense mutation
   d. a frameshift mutation
   e. both b and c.
2. Some point mutations lead to an mRNA that produces a shorter polypeptide. This type of mutation is known as a ___ mutation.
   a. neutral
   b. silent
   c. missense
   d. nonsense
   e. chromosomal
3. In which location is a mutation least likely to affect gene function?
   a. promoter
   b. coding region
   c. splice junction
   d. intergenic region
   e. regulatory site
4. Mutagens can cause mutations by
   a. chemically altering DNA nucleotides.
   b. disrupting DNA replication.
   c. altering the genetic code of an organism.
   d. all of the above.
   e. a and b only.
5. The mutagenic effect of UV light is
   a. the alteration of cytosine bases to adenine bases.
   b. the formation of adenine dimers that interfere with genetic expression.
   c. the breaking of the sugar-phosphate backbone of the DNA molecule.
   d. the formation of thymine dimers that disrupt DNA replication.
   e. the deletion of thymine bases along the DNA molecule.
6. The Ames test
   a. provides a way to determine if any type of cell has experienced a mutation.
   b. provides a way to determine if an agent is a mutagen.
   c. allows researchers to experimentally disrupt gene activity by causing a mutation in a specific gene.
   d. provides a way to repair mutations in bacterial cells.
   e. does all of the above.
7. Xeroderma pigmentosum
   a. is a genetic disorder that results in uncontrolled cell growth.
   b. is a genetic disorder in which the NER system is not fully functional.
   c. is a genetic disorder that results in the loss of pigment in certain patches of skin.
   d. results from the lack of DNA polymerase proofreading.
   e. Both b and d are true of this disorder.
8. If a mutation eliminated the function of UvrC, which aspect of nucleotide excision repair would not work?
   a. sensing a damaged DNA site
   b. endonuclease cleavage of the damaged strand
   c. removal of the damaged strand
   d. synthesis of a new strand, using the undamaged strand as a template
   e. none of the above
9. Cancer cells are said to be metastatic when they
   a. begin to divide uncontrollably.
   b. invade healthy tissue.
   c. migrate to other parts of the body.
   d. cause mutations in other healthy cells.
   e. do all of the above.
10. Oncogenes can be produced by
    a. missense mutations.
    b. gene amplification.
    c. chromosomal translocation.
    d. retroviral insertion.
    e. all of the above.

Conceptual Questions

1. Is a random mutation more likely to be beneficial or harmful? Explain your answer.
2. Distinguish between spontaneous and induced mutations. Which are more harmful? Which are avoidable?
3. A principle of biology is that the *genetic material provides a blueprint for reproduction*. Explain how mutations may cause alterations to the genetic material that are detrimental for reproduction and sustaining life.

Collaborative Questions

1. Discuss the pros and cons of mutation.
2. A large amount of research is aimed at studying mutation. However, there is not an infinite supply of research funding. Where would you put your money for mutation research?
   a. testing of potential mutagens
   b. investigating molecular effects of mutagens
   c. investigating DNA repair mechanisms
   d. some other area

The Eukaryotic Cell Cycle, Mitosis, and Meiosis

15

A scanning electron micrograph of human chromosomes. These highly compacted chromosomes were found in a dividing cell.

CHAPTER OUTLINE

15.1 The Eukaryotic Cell Cycle
15.2 Mitotic Cell Division
15.3 Meiosis and Sexual Reproduction
15.4 Variation in Chromosome Structure and Number
Summary of Key Concepts
Assess and Discuss

Over 10,000,000,000,000! Researchers estimate that the adult human body contains somewhere between 10 trillion and 50 trillion cells. It is an almost incomprehensible number. Even more amazing is the accuracy of the process that produces these cells. After a human sperm and egg unite, the fertilized egg goes through a long series of cell divisions to produce an adult with over 10 trillion cells. Let's suppose you randomly removed a cell from your arm and compared it with a cell from your foot. If you examined the chromosomes found in both cells under the microscope, they would look identical. Likewise, the DNA sequences along those chromosomes would also be the same, barring rare mutations. Similar comparisons could be made among the trillions of cells in your body. When you consider how many cell divisions are needed to produce an adult human, the precision of cell division is truly remarkable.

What accounts for this high level of accuracy? As we will examine in this chapter, **cell division**, the reproduction of cells, is a highly regulated process that distributes and monitors the integrity of the genetic material. The eukaryotic cell cycle is a series of phases needed for cell division. The cells of eukaryotic species follow one of two different sorting processes so that new daughter cells receive the correct number and types of chromosomes. The first sorting process we will explore, called mitosis, ensures that two daughter cells receive the same amount of genetic material as the mother cell that produced them. We will then examine another sorting process, called meiosis, which is needed for sexual reproduction. In meiosis, cells that have two sets of chromosomes produce daughter cells with a single set of chromosomes. Lastly, we will explore variation in the structure and number of chromosomes. As you will see, certain mechanisms that alter chromosome structure and number have important consequences for the organisms that carry them.

15.1 The Eukaryotic Cell Cycle

Learning Outcomes:

1. **SciSKILLS** » Describe the features of chromosomes, and explain how sets of chromosomes are examined microscopically.
2. Outline the phases of the eukaryotic cell cycle.
3. Explain how cyclins and cdks work together to advance a cell through the eukaryotic cell cycle.

Life is a continuum in which new living cells are formed by the division of pre-existing cells. The Latin axiom *Omnis cellula e cellula*, meaning "Every cell originates from another cell," was first proposed in 1858 by Rudolf Virchow, a German biologist. From an evolutionary perspective, cell division has a very ancient origin. All living organisms, from unicellular bacteria to multicellular plants and animals, have been produced by a series of repeated rounds of cell growth and division extending back to the beginnings of life nearly 4 billion years ago.

A **cell cycle** is a series of events that leads to cell division. In all species, it is a highly regulated process so cell division occurs at the appropriate time. As discussed in Chapter 18, bacterial cells produce more cells via binary fission. The cell cycle in eukaryotes is more complex, in part, because eukaryotic cells have sets

of chromosomes that need to be sorted properly. In this section, we will examine the phases of the eukaryotic cell cycle and see how the cell cycle is controlled by proteins that carefully monitor the division process to ensure its accuracy. But first, we need to consider some general features of chromosomes in eukaryotic species.

Chromosomes Are Inherited in Sets and Occur in Homologous Pairs

To understand the chromosomal composition of cells and the behavior of chromosomes during cell division, scientists observe cells and chromosomes with the use of microscopes. **Cytogenetics** is the field of genetics that involves the microscopic examination of chromosomes. When a cell prepares to divide, the chromosomes become more tightly compacted, a process that decreases their apparent length and increases their diameter. A consequence of this compaction is that distinctive shapes and numbers of chromosomes become visible under a light microscope.

Microscopic Examination of Chromosomes **Figure 15.1** shows the general procedure for preparing and viewing chromosomes from a eukaryotic cell. In this example, the cells were obtained from a sample of human blood. Specifically, the chromosomes within leukocytes (white blood cells) were examined. A sample of the blood cells was treated with drugs that stimulated them to divide. The actively dividing cells were centrifuged to concentrate them into a pellet, which was then mixed with a hypotonic solution that caused the cells to swell. The expansion of the cells caused the chromosomes to spread out from each other, making it easier to see each individual chromosome.

Next, the cells were concentrated by a second centrifugation and treated with a fixative, which chemically fixed them in place so the chromosomes could no longer move around. The cells were then exposed to a chemical dye, such as Giemsa stain, that binds to the chromosomes and stains them. This gives chromosomes a distinctive banding pattern that greatly enhances their contrast and ability to be uniquely identified; in this case, the bands are called G bands.

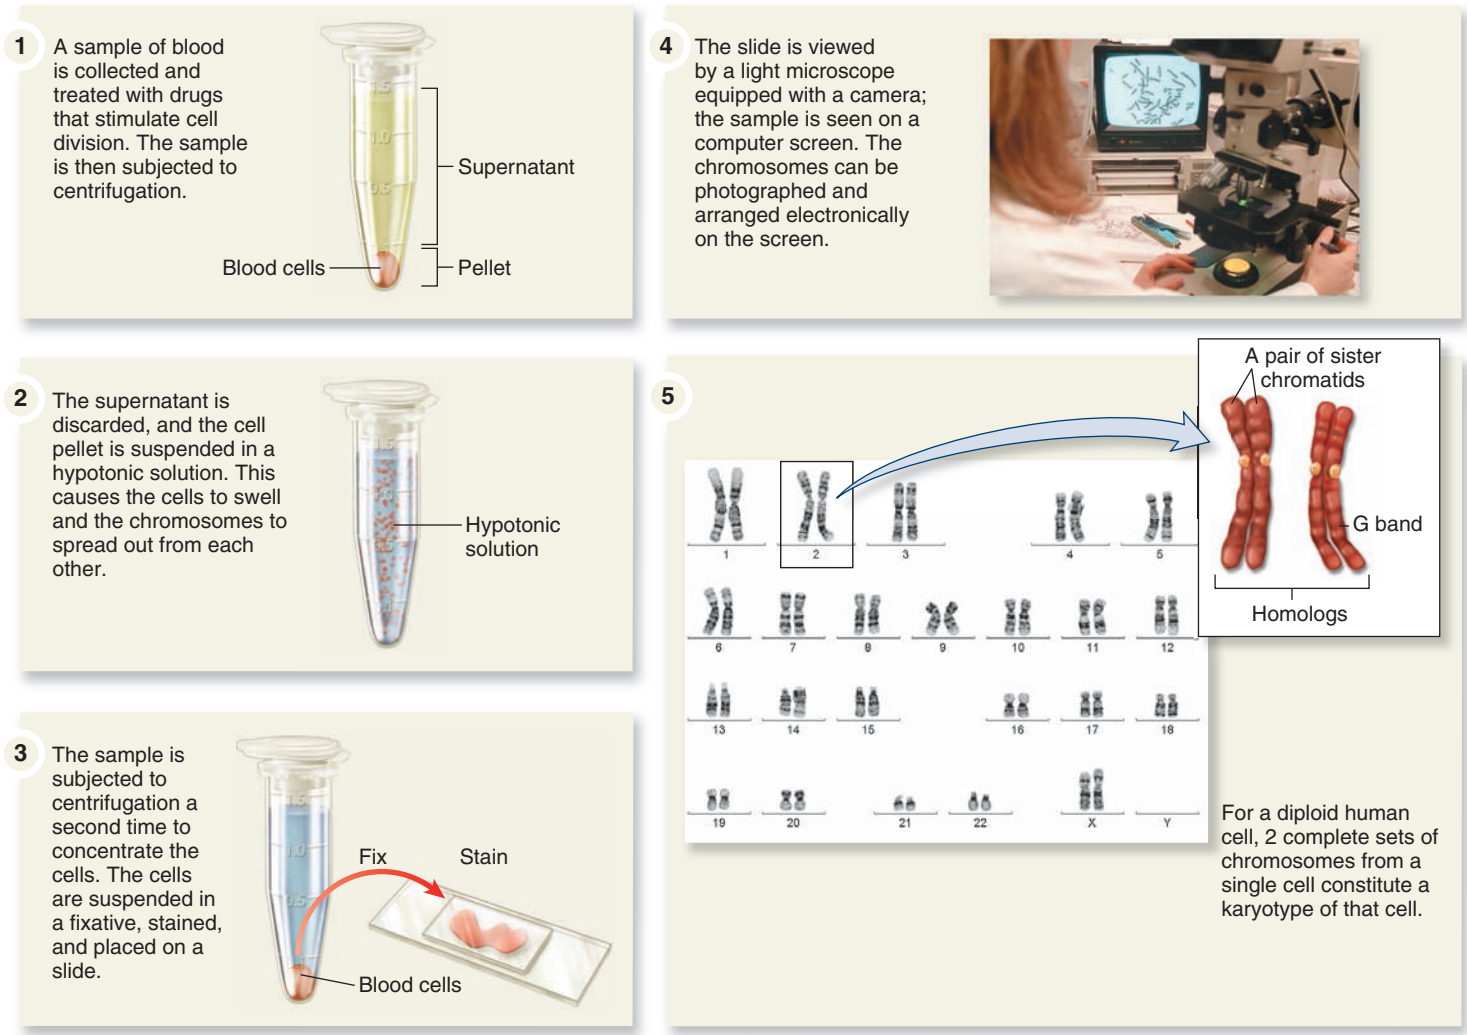

Figure 15.1 **The procedure for making a karyotype.** In this example, the chromosomes were treated with the Giemsa stain, and the resulting bands are called G bands.

Concept Check: *Researchers usually treat cells with drugs that stimulate them to divide prior to the procedure for making a karyotype. Why is this useful?*

The cells were then placed on a slide and viewed with a light microscope. In a cytogenetics laboratory, microscopes are equipped with an electronic camera to photograph the chromosomes. On a computer screen, the chromosomes are organized in a standard way, usually from largest to smallest. A photographic representation of the chromosomes, as in the photo in step 5 of Figure 15.1, is called a **karyotype**. A karyotype reveals the number, size, and form of chromosomes found within an actively dividing cell. It should also be noted that the chromosomes viewed in actively dividing cells have already replicated. The two copies are still joined to each other and referred to as a pair of **sister chromatids** (see inset to Figure 15.1).

Sets of Chromosomes What type of information is learned from a karyotype? By studying the karyotypes of many species, scientists have discovered that eukaryotic chromosomes occur in sets. Each set is composed of several different types of chromosomes. For example, one set of human chromosomes contains 23 different types of chromosomes (see Figure 15.1). By convention, the chromosomes are numbered according to size, with the largest chromosomes having the smallest numbers. For example, human chromosomes 1, 2, and 3 are relatively large, whereas 21 and 22 are the two smallest. This numbering system does not apply to the **sex chromosomes**, which determine the sex of the individual. Sex chromosomes in humans are designated with the letters X and Y; females are XX and males are XY. The chromosomes that are not sex chromosomes are called **autosomes**. Humans have 22 different types of autosomes.

A second feature of many eukaryotic species is that most cells contain two sets of chromosomes. The karyotype shown in Figure 15.1 contains two sets of chromosomes, with 23 different chromosomes in each set. Therefore, this human cell contains a total of 46 chromosomes. Each cell has two sets because the individual inherited one set from the father and one set from the mother. When the cells of an organism carry two sets of chromosomes, that organism is said to be **diploid**. Geneticists use the letter n to represent a set of chromosomes. Diploid organisms are referred to as $2n$, because they have two sets of chromosomes. For example, humans are $2n$, where $n = 23$. Most human cells are diploid. An exception involves **gametes**, the sperm and egg cells. Gametes are **haploid**, or $1n$, which means they contain one set of chromosomes.

Homologous Pairs of Chromosomes When an organism is diploid, the members of a pair of chromosomes are called **homologs** (see inset to Figure 15.1). The term **homology** refers to any similarity that is due to common ancestry. Pairs of homologous chromosomes are evolutionarily derived from the same chromosome. However, homologous chromosomes are not usually identical because over many generations they have accumulated some genetic changes that make them distinct.

How similar are homologous chromosomes to each other? Each of the two chromosomes in a homologous pair is nearly identical in size and contains a very similar composition of genetic material. A particular gene found on one copy of a chromosome is usually found on the homolog. However, because one homolog is received from each parent, the two homologs may vary in the way that a gene affects an organism's traits. As an example, let's consider a gene in humans called *OCA2*, which plays a major role in determining eye color. The *OCA2* gene is found on chromosome 15. One copy of chromosome 15 might carry the form of this eye color gene that confers brown eyes, whereas the gene on the homolog could confer blue eyes. The topic of how genes affect an organism's traits will be considered in Chapter 16.

The DNA sequences on homologous chromosomes are very similar. In most cases, the sequence of bases on one homolog differs by less than 1% from the sequence on the other homolog. For example, the DNA sequence of chromosome 1 that you inherited from your mother is likely to be more than 99% identical to the DNA sequence of chromosome 1 that you inherited from your father. Nevertheless, keep in mind that the sequences are not identical. The slight differences in DNA sequence provide important variation in gene function. Again, if we use the eye color gene *OCA2* as an example, a minor difference in DNA sequence distinguishes two forms of the gene, brown versus blue.

The striking similarity between homologous chromosomes does not apply to the sex chromosomes (for example, X and Y). These chromosomes differ in size and genetic composition. Certain genes found on the X chromosome are not found on the Y chromosome, and vice versa. The X and Y chromosomes are not considered homologous chromosomes, although they do have short regions of homology.

The Cell Cycle Is a Series of Phases That Lead to Cell Division

Eukaryotic cells that are destined to divide progress through the cell cycle, a series of changes that involves growth, replication, and division, and ultimately produces new cells. **Figure 15.2** provides an overview of the cell cycle. In this diagram, the mother cell has three pairs of chromosomes, for a total of six individual chromosomes. Such a cell is diploid ($2n$) and contains three chromosomes per set ($n = 3$). The paternal set is shown in blue, and the homologous maternal set is shown in red.

The phases of the cell cycle are $\mathbf{G_1}$ (first gap), **S** (synthesis of DNA, the genetic material), $\mathbf{G_2}$ (second gap), and **M phase** (mitosis and cytokinesis). The G_1 and G_2 phases were originally described as gap phases to indicate the periods between DNA synthesis and mitosis. In actively dividing cells, the G_1, S, and G_2 phases are collectively known as **interphase**. During interphase, the cell grows and copies its chromosomes in preparation for cell division. Alternatively, cells may exit the cell cycle and remain for long periods of time in a phase called G_0 (G zero). The G_0 phase is an alternative to proceeding through G_1. A cell in the G_0 phase has postponed making a decision to divide or, in the case of terminally differentiated cells (such as muscle cells in an adult animal), will never divide again. G_0 is a nondividing phase.

G_1 Phase The G_1 phase is a period in a cell's life when it may become committed to divide. Depending on the environmental conditions and the presence of signaling molecules, a cell in the G_1 phase may accumulate molecular changes that cause it to progress through the rest of the cell cycle. Cell growth typically occurs during the G_1 phase.

S Phase During the S phase, each chromosome is replicated to form a pair of sister chromatids (see Figure 15.1). When S phase is completed, a cell has twice as many chromatids as the number of chromosomes in the G_1 phase. For example, a human cell in the G_1 phase has 46 distinct chromosomes, whereas the same cell in G_2 would have 46 pairs of sister chromatids, for a total of 92 chromatids.

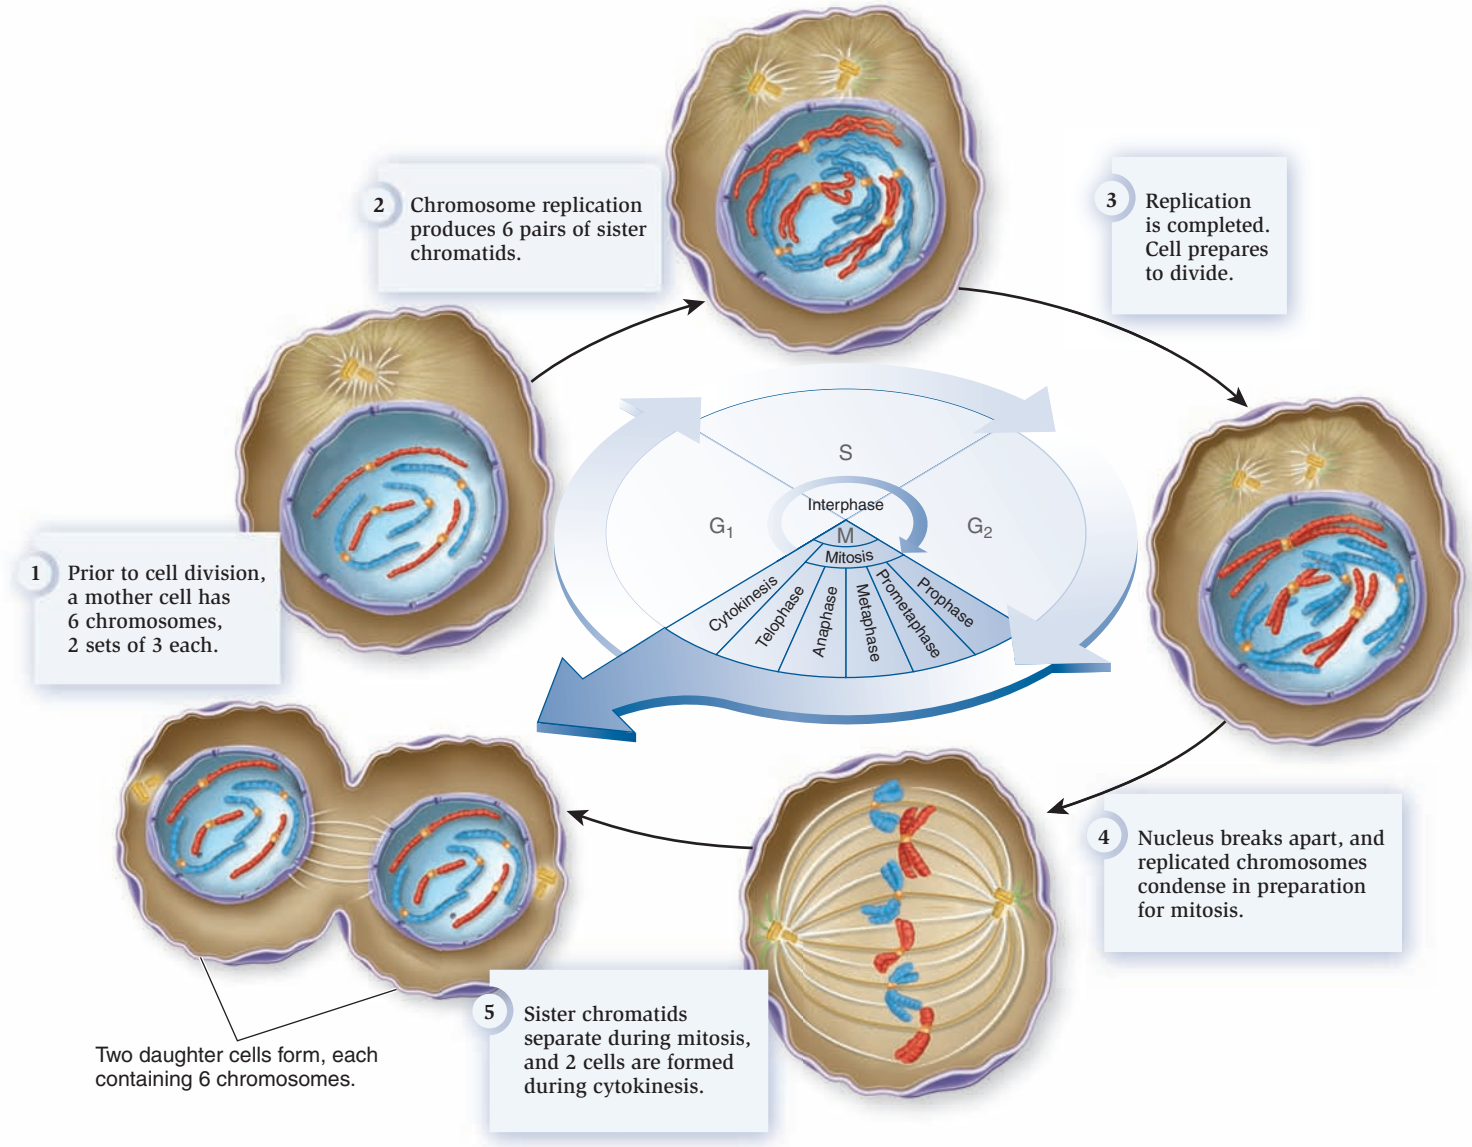

Figure 15.2 The eukaryotic cell cycle. Dividing cells progress through a series of phases denoted G_1, S, G_2, and M. This diagram shows the progression of a cell through the cell cycle to produce two daughter cells. The original diploid cell had three pairs of chromosomes, for a total of six individual chromosomes. During S phase, these have replicated to yield 12 chromatids. After mitosis is complete, two daughter cells each contain six individual chromosomes. The width of the phases shown in this figure is not meant to reflect their actual length. G_1 is typically the longest phase of the cell cycle, whereas M phase is relatively short.

BIOLOGY PRINCIPLE Cells are the simplest units of life. The cells of eukaryotic species are made via cell division during the eukaryotic cell cycle.

Concept Check: Which phases make up interphase?

G_2 Phase During the G_2 phase, a cell synthesizes the proteins necessary for chromosome sorting and cell division. Some cell growth may occur.

M Phase The first part of M phase is **mitosis**. The purpose of mitosis is to divide one cell nucleus into two nuclei, distributing the duplicated chromosomes so each daughter cell receives the same complement of chromosomes. As noted previously, a human cell in the G_2 phase has 92 chromatids, which are found in 46 pairs. During mitosis, these pairs of chromatids are separated and sorted so each daughter cell receives 46 chromosomes. In most cases, mitosis is followed by **cytokinesis**, which is the division of the cytoplasm to produce two distinct daughter cells.

The length of the cell cycle varies considerably among different cell types, ranging from several minutes in quickly growing embryos to several months in slow-growing adult cells. For fast-dividing mammalian cells in adults, such as skin cells, the length of the cycle is often in the range of 10 to 24 hours. The various phases within the cell cycle also vary in length. G_1 is often the longest and also the most variable phase, and M phase is the shortest. For a cell that divides in 24 hours, the following lengths of time for each phase are typical:

- G_1 phase: 11 hours
- S phase: 8 hours
- G_2 phase: 4 hours
- M phase: 1 hour

What factors determine whether or not a cell will divide? First, cell division is controlled by external factors, such as environmental conditions and signaling molecules. The effects of growth factors on cell division are discussed in Chapter 9 (refer back to Figure 9.10). Second, internal factors affect cell division. These include cell cycle control molecules and checkpoints, as we will discuss next.

The Cell Cycle Is Controlled by Checkpoint Proteins

The progression through the cell cycle is a process that is highly regulated to ensure that the genome remains intact and that the conditions are appropriate for a cell to divide. As discussed in Chapter 14, this is necessary to minimize the occurrence of mutations, which could have harmful effects and potentially lead to cancer. Proteins called **cyclins** and **cyclin-dependent kinases (cdks)** are responsible for advancing a cell through the phases of the cell cycle. Cyclins are so named because their amount varies throughout the cell cycle. To be active, the kinases controlling the cell cycle must bind to (are dependent on) cyclins. The number of different types of cyclins and cdks varies from species to species.

Figure 15.3 gives a simplified description of how cyclins and cdks work together to advance a cell through G_1 and mitosis. During G_1, the amount of a particular cyclin termed G_1 cyclin increases in response to sufficient nutrients and growth factors. The G_1 cyclin binds to a cdk to form an activated G_1 cyclin/cdk complex. Once activated, cdk functions as a protein kinase that phosphorylates other proteins needed to advance the cell to the next phase in the cell cycle. For example, certain proteins involved with DNA synthesis are phosphorylated and activated, thereby allowing the cell to replicate its DNA in S phase. After the cell passes into the S phase, G_1 cyclin is degraded. Similar events advance the cell through other phases of the cell cycle. A different cyclin, called mitotic cyclin, accumulates late in G_2. It binds to a cdk to form an activated mitotic cyclin/cdk complex. This complex phosphorylates proteins that are needed to advance the cell into M phase.

Three critical regulatory points called **checkpoints** are found in the cell cycle of eukaryotic cells (see Figure 15.3). At these checkpoints, a variety of proteins, referred to as checkpoint proteins, act as sensors to determine if a cell is in the proper condition to divide. The G_1 checkpoint, also called the **restriction point**, determines if conditions are favorable for cell division. In addition, G_1-checkpoint proteins sense if the DNA has incurred damage. What happens if DNA damage is detected? The checkpoint proteins prevent the formation of active cyclin/cdk complexes, thereby stopping the progression of the cell cycle.

A second checkpoint exists in G_2. This checkpoint also checks the DNA for damage and ensures that all of the DNA has been replicated. In addition, the G_2 checkpoint monitors the levels of proteins that are needed to progress through M phase. A third checkpoint, called the metaphase checkpoint, senses the integrity of the spindle apparatus. As we will see later, the spindle apparatus is involved in chromosome sorting. Metaphase is a step in mitosis during which all of the chromosomes should be attached to the spindle apparatus. If a chromosome is not correctly attached, the metaphase checkpoint will stop the cell cycle. This checkpoint prevents cells from incorrectly sorting their chromosomes during division.

Checkpoint proteins delay the cell cycle until problems are fixed or prevent cell division when problems cannot be fixed. A primary aim of checkpoint proteins is to prevent the division of a cell that has incurred DNA damage or harbors abnormalities in chromosome number. As discussed in Chapter 14, when the functions of checkpoint genes are lost due to mutation, the likelihood increases that undesirable genetic changes will occur that can cause additional mutations and cancerous growth.

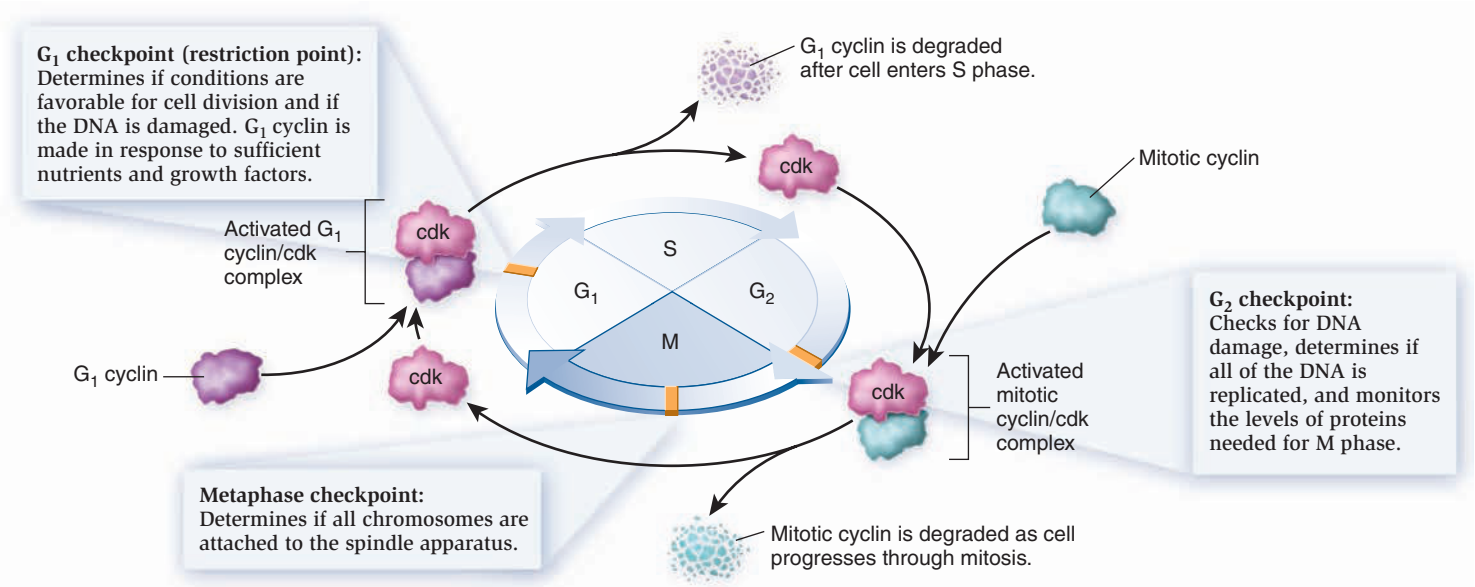

Figure 15.3 Checkpoints in the cell cycle. This is a general diagram of the eukaryotic cell cycle. Progression through the cell cycle requires the formation of activated cyclin/cdk complexes. Cells make different types of cyclin proteins, which are typically degraded after the cell has progressed to the next phase. The formation of activated cyclin/cdk complexes is regulated by checkpoint proteins.

BioConnections: Look back at Figure 14.15. How do checkpoint proteins prevent cancer?

Feature Investigation | Masui and Markert's Study of Oocyte Maturation Led to the Identification of Cyclins and Cyclin-Dependent Kinases

During the 1960s and 1970s, researchers were intensely searching for the factors that promote cell division. In 1971, Japanese zoologist Yoshio Masui and American biologist Clement Markert developed a way to test whether a substance causes a cell to progress from one phase of the cell cycle to the next. They chose to study frog oocytes—cells that mature into egg cells. At the time of their work, researchers had already determined that frog oocytes naturally become dormant in the G_2 phase of the cell cycle for up to 8 months (**Figure 15.4**). During mating season, female frogs produce a hormone called progesterone. After progesterone enters an oocyte and binds to intracellular receptors, the oocyte progresses from G_2 to the beginning of M phase, where the chromosomes condense and become visible under the microscope. This phenomenon is called maturation. When a sperm fertilizes the egg, M phase is completed, and the zygote continues to undergo cellular divisions.

Because progesterone is a signaling molecule, Masui and Markert speculated that this hormone affects the functions and/or amounts of proteins that trigger the oocyte to progress through the cell cycle. To test this hypothesis, they developed the procedure described in **Figure 15.5**, using the oocytes of the leopard frog (*Rana pipiens*). They began by exposing oocytes to progesterone in vitro and then incubated these oocytes for 2 hours or 12 hours. As a control, they also used oocytes that had not been exposed to progesterone. These three types of cells were called the donor oocytes.

Next, they used a micropipette to transfer a small amount of cytosol from the three types of donor oocytes to recipient oocytes that had not been exposed to progesterone. As seen in the data, the recipient oocytes that had been injected with cytosol from the control donor oocytes or from oocytes that had been incubated with progesterone for only 2 hours did not progress to M phase. However, cytosol from donor oocytes that had been incubated with progesterone for 12 hours caused the recipient oocytes to advance to M phase. Masui and Markert concluded that a cytosolic factor, which required more than 2 hours to be synthesized after progesterone treatment, had been transferred to the recipient oocytes and induced maturation. The

HYPOTHESIS Progesterone induces the synthesis of factor(s) that advance(s) frog oocytes through the cell cycle from G_2 to M phase.

KEY MATERIALS Oocytes from *Rana pipiens*.

3 Incubate for several hours, and observe the recipient oocytes under the microscope to determine if the recipient oocytes advance to M phase. Advancement to M phase can be determined by the condensation of the chromosomes.

4 THE DATA

Donor oocytes	Recipient oocytes proceeded to M phase?
Control, no progesterone exposure	No
Progesterone exposure, incubation for 2 hours	No
Progesterone exposure, incubation for 12 hours	Yes

5 CONCLUSION Exposure of oocytes to progesterone for 12 hours results in the synthesis of factor(s) that advance(s) frog oocytes through the cell cycle from G_2 to M phase.

6 SOURCE Masui, Y., and Markert, C.L. 1971. Cytoplasmic control of nuclear behavior during meiotic maturation of frog oocytes. *Journal of Experimental Zoology* 177:129–145.

factor that caused the oocytes to progress (or mature) from G_2 to M phase was originally called the maturation-promoting factor (MPF).

After MPF was discovered in frogs, it was found in all eukaryotic species that researchers studied. MPF is important in the division of all types of cells, not just oocytes. It took another 17 years before Manfred Lohka, Marianne Hayes, and James Maller were able to purify the components that make up MPF. This was a difficult undertaking because these components are found in very small amounts in the cytosol and are easily degraded during purification procedures. We now know that MPF is a complex made of a mitotic cyclin and a cyclin-dependent kinase (cdk), as described in Figure 15.3.

Experimental Questions

1. At the time of Masui and Markert's study shown in Figure 15.5, what was known about the effects of progesterone on oocytes?
2. **SciSKILLS »** What hypothesis did Masui and Markert propose to explain the function of progesterone? Explain the procedure used to test the hypothesis.
3. **SciSKILLS »** How did the researchers explain the difference between the results with 2-hour-exposed donor oocytes versus 12-hour-exposed donor oocytes?

15.2 Mitotic Cell Division

Learning Outcomes:

1. Describe how the replication of eukaryotic chromosomes produces sister chromatids.
2. Explain the structure and function of the mitotic spindle.
3. Outline the key events that occur during the phases of mitosis.

We now turn our attention to a mechanism of cell division and its relationship to chromosome replication and sorting. During the process of **mitotic cell division**, a cell divides to produce two new cells (the daughter cells) that are genetically identical to the original cell (the mother cell). Mitotic cell division involves mitosis—the division of one nucleus into two nuclei—and then cytokinesis in which the mother cell divides into two daughter cells.

Why is mitotic cell division important? One purpose is **asexual reproduction**, a process in which genetically identical offspring are produced from a single parent. Certain unicellular eukaryotic organisms, such as baker's yeast (*Saccharomyces cerevisiae*) and the amoeba, increase their numbers in this manner. A second important reason for mitotic cell division is the production and maintenance of multicellularity. Organisms such as plants, animals, and most fungi are derived from a single cell that subsequently undergoes repeated cellular divisions to become a multicellular organism.

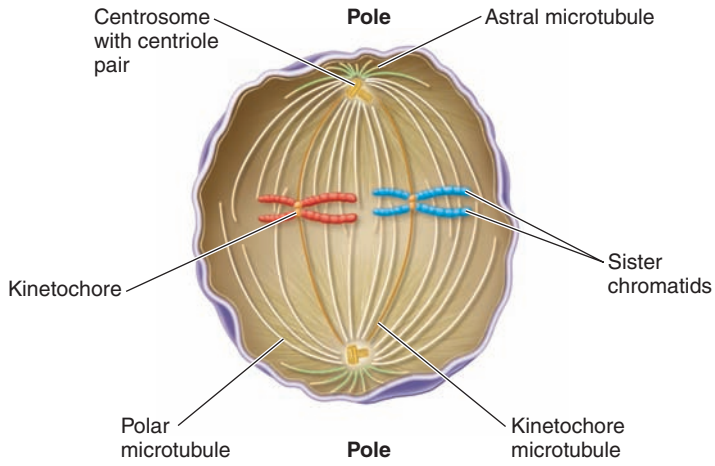
In this section, we will explore the process of mitotic cell division, which requires the replication, organization, and sorting of chromosomes. We will also examine how a single cell is separated into two daughter cells by cytokinesis.

In Preparation for Cell Division, Eukaryotic Chromosomes Are Replicated and Compacted to Produce Pairs Called Sister Chromatids

We now turn our attention to how chromosomes are replicated and sorted during cell division. In Chapter 11, we examined the molecular process of DNA replication. **Figure 15.6** describes the process at the chromosomal level. Prior to DNA replication, the DNA of each eukaryotic chromosome consists of a linear double helix that is found in the nucleus and is not highly compacted. When the DNA is replicated, two identical copies of the original double helix are produced. As discussed earlier, these copies, along with associated proteins, lie side-by-side and are termed sister chromatids. When a cell prepares to divide, the sister chromatids become highly compacted and readily visible under the microscope. As shown in Figure 15.6b, the two sister chromatids are tightly associated at a region called the **centromere**. A protein called cohesin holds the sister chromatids together. In addition, the centromere serves as an attachment site for a group of proteins that form the **kinetochore**, a structure necessary for sorting each chromosome.

The Mitotic Spindle Organizes and Sorts Chromosomes During Cell Division

What structure is responsible for organizing and sorting the chromosomes during cell division? The answer is the **mitotic spindle** (**Figure 15.7**). It is composed of microtubules—protein fibers that are



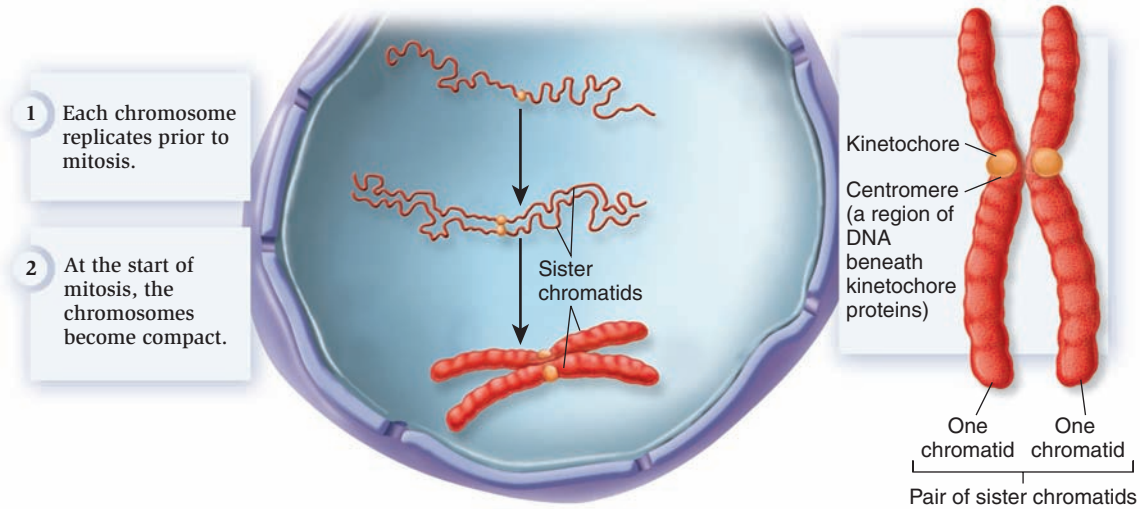


Figure 15.7 The structure of the mitotic spindle. The mitotic spindle in animal cells is formed by the centrosomes, which produce three types of microtubules. The astral microtubules emanate away from the region between the poles. The polar microtubules project into the region between the two poles. The kinetochore microtubules are attached to the kinetochores of sister chromatids. Note: For simplicity, this diagram shows only one pair of homologous chromosomes. Eukaryotic species typically have multiple chromosomes per set.

Concept Check: What are the functions of the three types of microtubules?

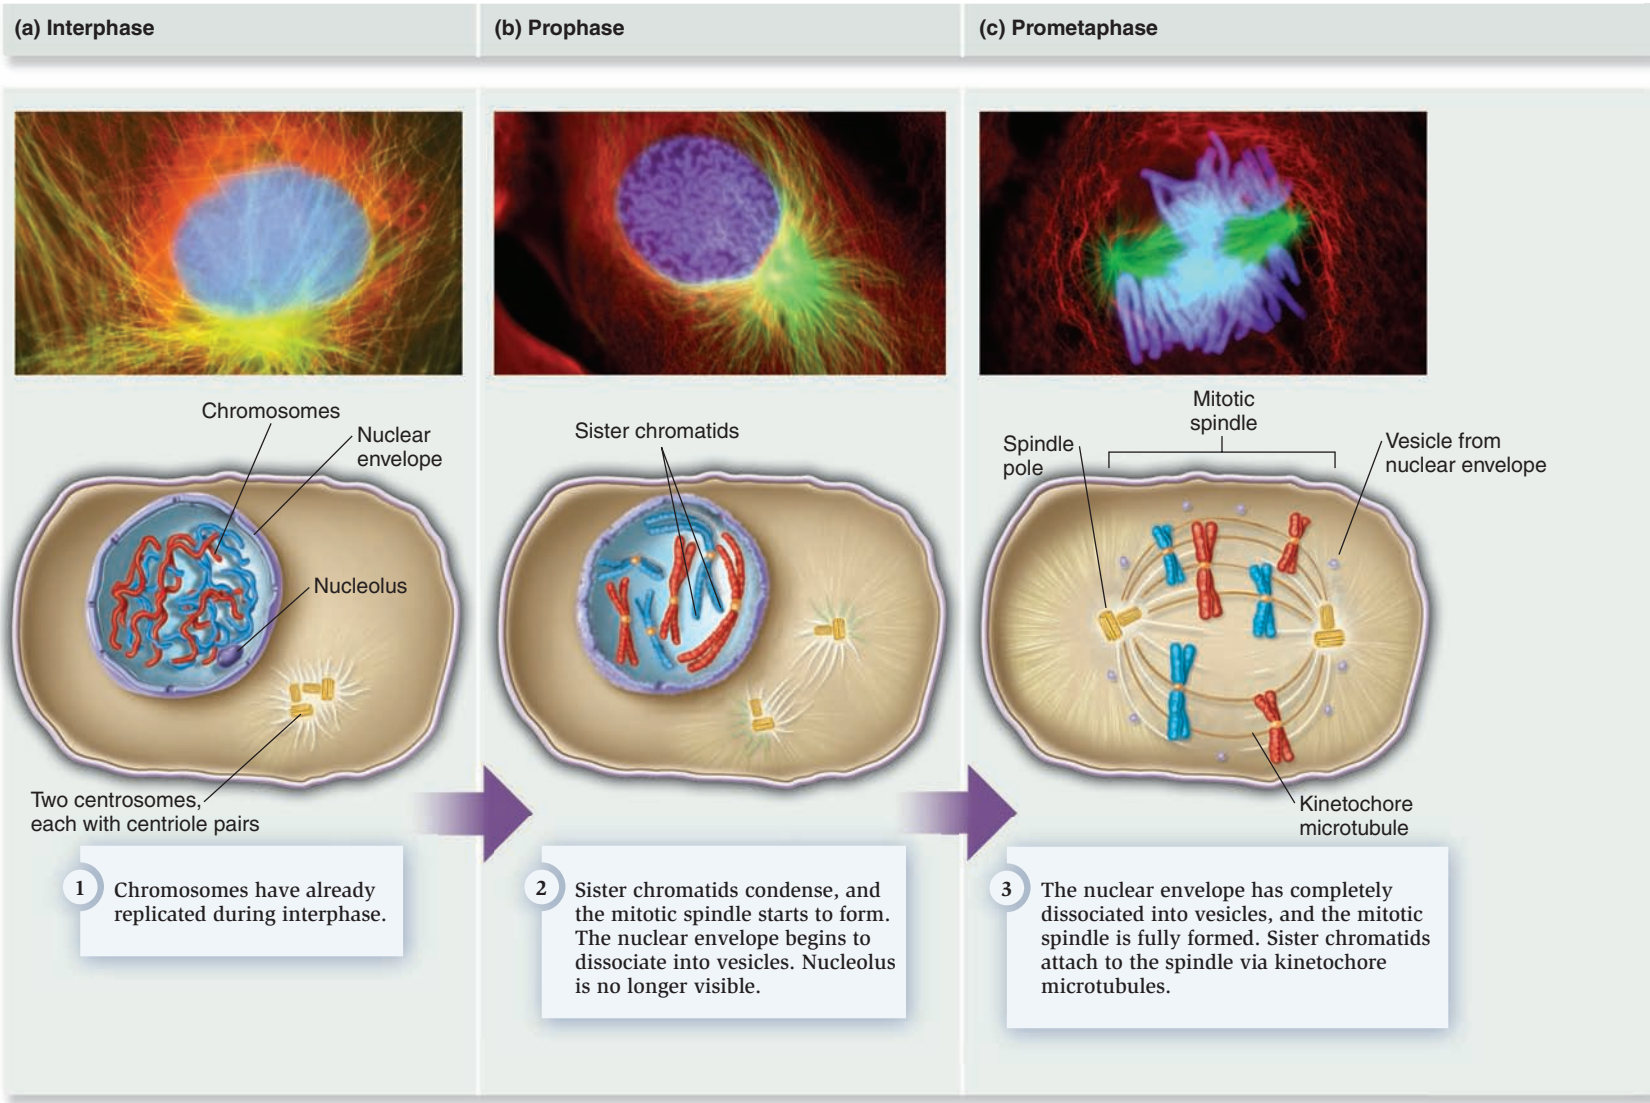
(a) Chromosome replication and compaction

(b) Schematic drawing of a metaphase chromosome

Figure 15.6 Replication and compaction of chromosomes into pairs of sister chromatids. **(a)** Chromosomal replication produces a pair of sister chromatids. While the chromosomes are elongated, they are replicated to produce two copies that are connected and lie parallel to each other. This is a pair of sister chromatids. Later, when the cell is preparing to divide, the sister chromatids condense into more compact structures that are easily seen with a light microscope. **(b)** A schematic drawing of a metaphase chromosome. This structure has two chromatids that lie side-by-side. The two chromatids are held together by cohesin proteins (not shown in this drawing). The kinetochore is a group of proteins that are attached to the centromere and play a role during chromosome sorting.

BIOLOGY PRINCIPLE The genetic material provides a blueprint for reproduction. The process of mitosis ensures that each daughter cell receives a complete copy of the genetic material.

Concept Check: Look back at the karyotype in Figure 15.1. In this micrograph, is each of the 46 objects a pair of sister chromatids?



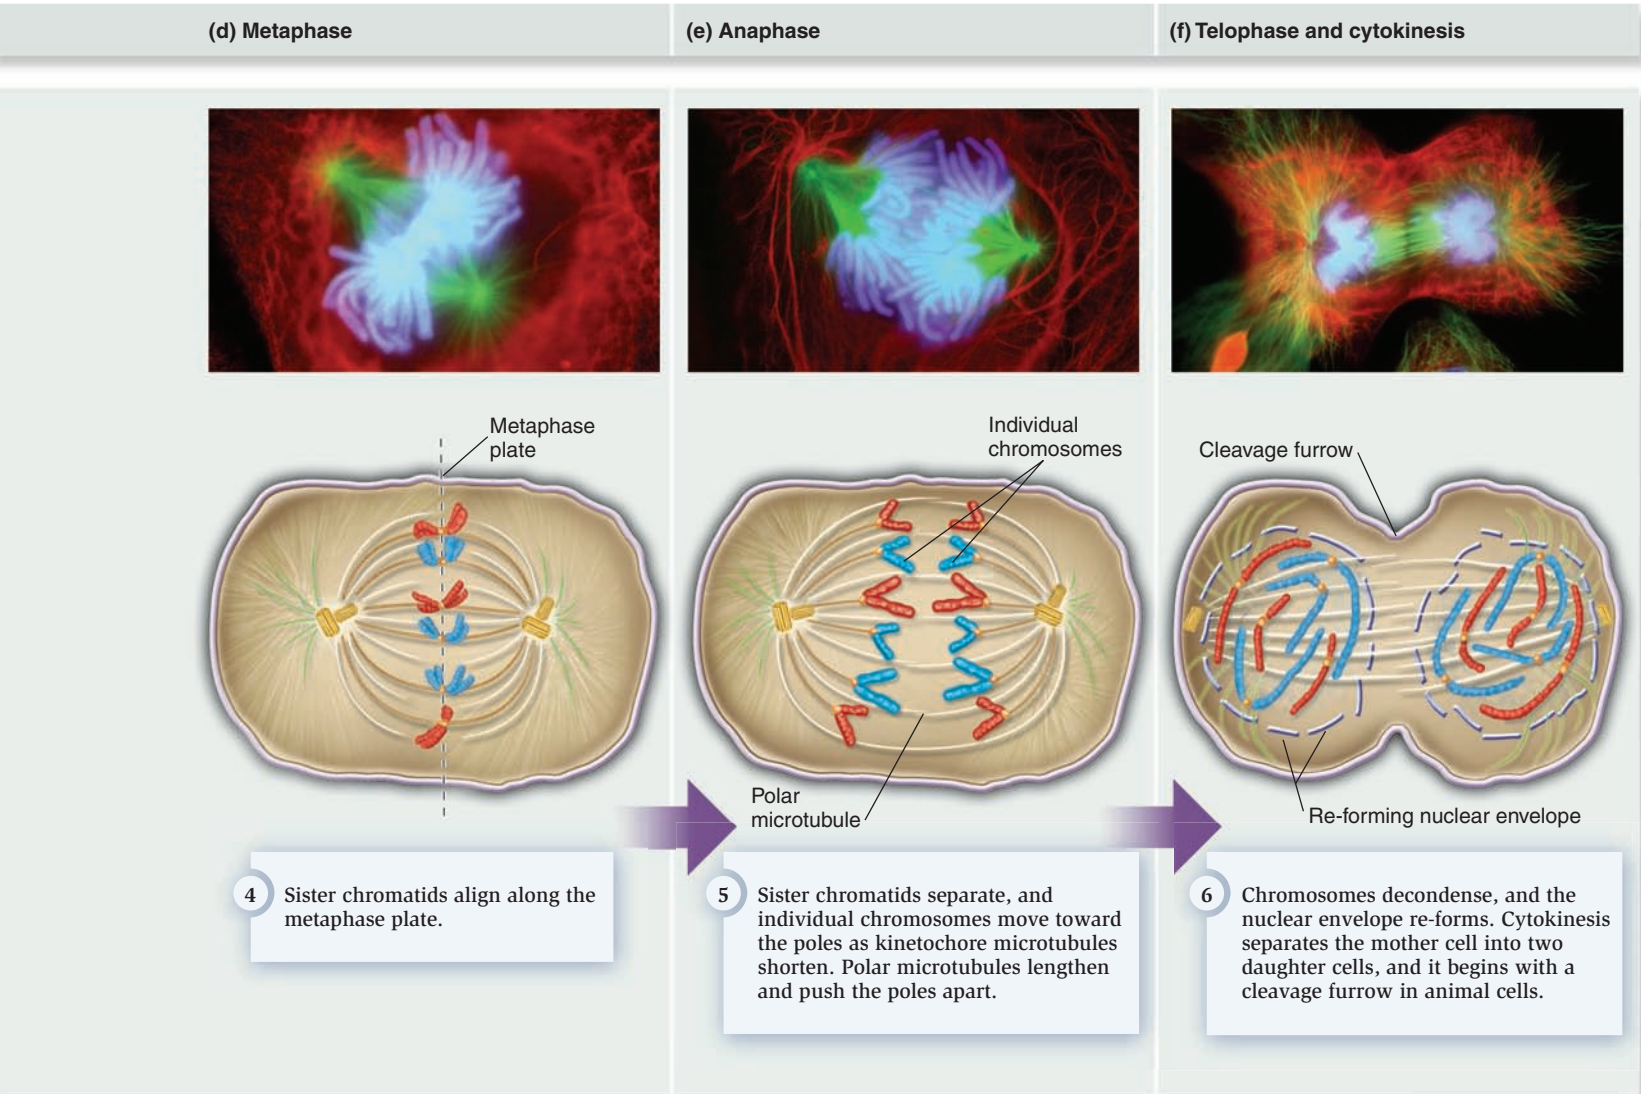
components of the cytoskeleton (refer back to Table 4.1). In animal cells, microtubule growth and organization start at two **centrosomes**, regions that are also referred to as microtubule organizing centers (MTOCs). A single centrosome duplicates during interphase. When the cell enters mitosis, each centrosome defines a **pole** of the spindle apparatus, one within each of the future daughter cells. The centrosome in animal cells has a pair of **centrioles**. Each one is composed of nine sets of triplet microtubules. However, centrioles are not found in many other eukaryotic species, such as plants, and are not required for spindle formation.

Each centrosome organizes the construction of the microtubules by rapidly polymerizing tubulin proteins. The three types of spindle microtubules are termed astral, polar, and kinetochore microtubules (see Figure 15.7).

The Transmission of Chromosomes Requires a Sorting Process Known as Mitosis

Mitosis is the sorting process for dividing one cell nucleus into two nuclei (**Figure 15.8**). The duplicated chromosomes are distributed so each daughter cell receives the same complement of chromosomes. Mitosis was first observed microscopically in the 1870s by a German biologist, Walther Flemming, who coined the term (from the Greek *mitos*, meaning thread). He studied the large, transparent skin cells of salamander larvae as they were dividing and noticed that chromosomes are constructed of "threads" that are doubled in appearance along their length. These double threads divided and moved apart, one going to each of the two daughter nuclei. By this mechanism, Flemming pointed out, the two daughter cells receive

Figure 15.8 The process of mitosis in an animal cell. The top panels are fluorescent micrographs of a newt cell progressing through mitosis. The drawings below emphasize the sorting of the chromosomes, in which the diploid mother cell had six chromosomes (three in each set). At the start of mitosis, these have already replicated into 12 chromatids. The final result is two daughter cells, each containing six chromosomes.



an identical group of threads, the same as the number of threads in the mother cell.

Figure 15.8 depicts the process of mitosis in an animal cell, though the process is quite similar in a plant cell. Mitosis occurs as a continuum of phases known as prophase, prometaphase, metaphase, anaphase, and telophase. In the simplified diagrams shown along the bottom of Figure 15.8, the original cell contains six chromosomes. One set of chromosomes is depicted in red, whereas the homologous set is blue. These different colors represent maternal and paternal chromosomes.

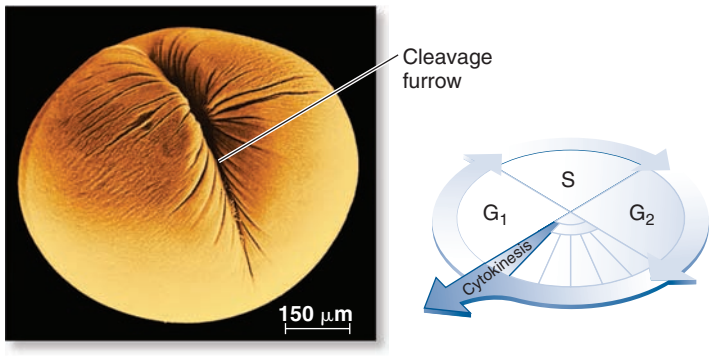
Interphase Prior to mitosis, the cells are in interphase, which consists of the G_1, S, and G_2 phases of the cell cycle. The chromosomes have replicated in S phase and are decondensed and found in the nucleus (Figure 15.8a). The nucleolus, which is the site where the components of ribosomes assemble into ribosomal subunits, is visible during interphase.

Prophase At the start of mitosis, in **prophase**, the chromosomes have already replicated to produce 12 chromatids, joined as six pairs of sister chromatids that have condensed into highly compacted structures readily visible by light microscopy (Figure 15.8b). As prophase proceeds, the nuclear envelope begins to dissociate into small vesicles. The nucleolus is no longer visible.

Prometaphase During **prometaphase**, the nuclear envelope completely fragments into small vesicles, and the mitotic spindle is fully formed (Figure 15.8c). As prometaphase progresses, the centrosomes move apart and demarcate the two poles. Once the nuclear envelope has dissociated, the spindle fibers can interact with the

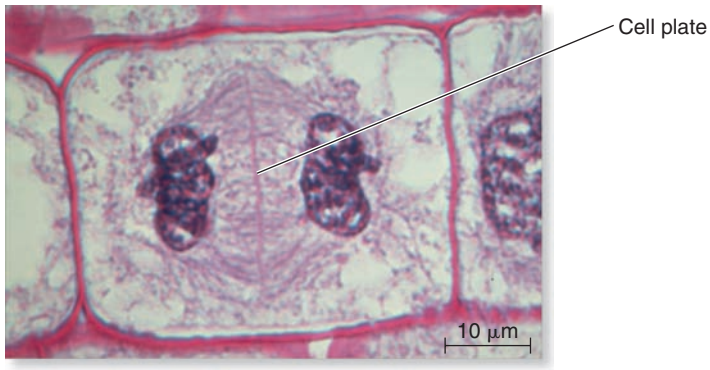
sister chromatids. How do the sister chromatids become attached to the spindle apparatus? Initially, microtubules are rapidly formed and can be seen under a microscope growing out from the two poles. As it grows, if a microtubule happens to make contact with a kinetochore, it is said to be captured and remains firmly attached to the kinetochore. Alternatively, if a microtubule does not collide with a kinetochore, the microtubule eventually depolymerizes and retracts to the centrosome. This random process is how sister chromatids become attached to kinetochore microtubules. As the end of prometaphase nears, the two kinetochores on each pair of sister chromatids are attached to kinetochore microtubules from opposite poles. As these events are occurring, the sister chromatids are seen under the microscope to undergo jerky movements as they are tugged, back and forth, between the two poles by the kinetochore microtubules.

Metaphase Eventually, the pairs of sister chromatids are aligned in a single row along the **metaphase plate**, a plane halfway between the poles. When this alignment is complete, the cell is in **metaphase** of mitosis (Figure 15.8d). The chromatids can then be equally distributed into two daughter cells.



Anaphase During **anaphase**, the connections between the pairs of sister chromatids are broken (Figure 15.8e). Each chromatid, now an individual chromosome, is linked to only one of the two poles by one or more kinetochore microtubules. As anaphase proceeds, the kinetochore microtubules shorten, pulling the chromosomes toward the pole to which they are attached. In addition, the two poles move farther away from each other. This occurs because the overlapping polar microtubules lengthen and push against each other, thereby pushing the poles farther apart.

Telophase During **telophase**, the chromosomes have reached their respective poles and decondense. The nuclear envelope now re-forms to produce two separate nuclei. In Figure 15.8f, two nuclei are being produced that contain six chromosomes each.



Cytokinesis In most cases, mitosis is quickly followed by cytokinesis, in which the two nuclei are segregated into separate daughter cells. Whereas the phases of mitosis are similar between plant and animal cells, the process of cytokinesis is quite different.

- In animal cells, cytokinesis involves the formation of a **cleavage furrow**, which constricts like a drawstring to separate the cells (**Figure 15.9a**).
- In plants, vesicles from the Golgi apparatus move along microtubules to the center of the cell and coalesce to form a **cell plate** (**Figure 15.9b**), which then forms a cell wall between the two daughter cells.

What are the results of mitosis and cytokinesis? These processes ultimately produce two daughter cells with the same number of chromosomes as the mother cell. Barring rare mutations, the two daughter cells are genetically identical to each other and to the mother cell from which they were derived. The critical consequence of this sorting process is ensuring genetic consistency from one cell to the next. The development of multicellularity relies on the repeated process of mitosis and cytokinesis.

Concept Check: What are the similarities and differences between cytokinesis in animal and plant cells?

Genomes & Proteomes Connection

Mitosis in Eukaryotes Evolved from the Binary Fission That Occurs in Prokaryotic Cells

The process of mitosis allows eukaryotic cells to properly sort their chromosomes during cell division. By comparing cell division among prokaryotic cells, simple eukaryotes, and more complex eukaryotes, biologists have pieced together a progression of how mitosis may have evolved.

Binary Fission in Bacterial Cells As described in Chapter 18 (look ahead to Figure 18.13), bacterial cells divide by a relatively simple process known as binary fission (**Figure 15.10a**). After chromosome replication, each copy of the bacterial chromosome becomes anchored to the plasma membrane. A protein called FtsZ forms a ring at the site where the mother cell will divide into two daughter cells.

Dinoflagellates In protists known as dinoflagellates, nuclear division is much simpler than in animal and plant cells (**Figure 15.10b**). After chromosome replication, the chromosomes become attached to the nuclear envelope. The nuclear

envelope does not break apart. Microtubules, which are described in Chapter 4 (see Table 4.1), are formed in the cytosol and pass through tunnels in the nuclear envelope. The nucleus then divides by a process that resembles binary fission.

Diatoms and Some Yeasts In diatoms (a type of protist) and some yeasts (a type of fungus), microtubules form within the cell nucleus (**Figure 15.10c**). Kinetochore microtubules attach to chromosomes and facilitate their sorting, and other microtubules promote the separation of the nucleus into two separate nuclei. As in dinoflagellates, the nuclear envelope does not break apart during this process.

Complex Eukaryotes As we have seen, mitosis in complex eukaryotes, such as animals and plants, involves the breaking apart of the nuclear envelope and the formation of the spindle apparatus (**Figure 15.10d**). After the chromosomes are sorted, the nuclear envelope then re-forms.

Interestingly, the FtsZ protein found in bacteria is evolutionarily related to tubulin, which is the main component of eukaryotic microtubules. Researchers speculate that the first role of FtsZ was to form a ring and promote cell division (Figure 15.10a). In eukaryotic cells, the homologous protein, tubulin, forms linear microtubules and has acquired additional roles in cell division. These include the division of the cell nucleus and the sorting of chromosomes. This is an example of descent with modification.

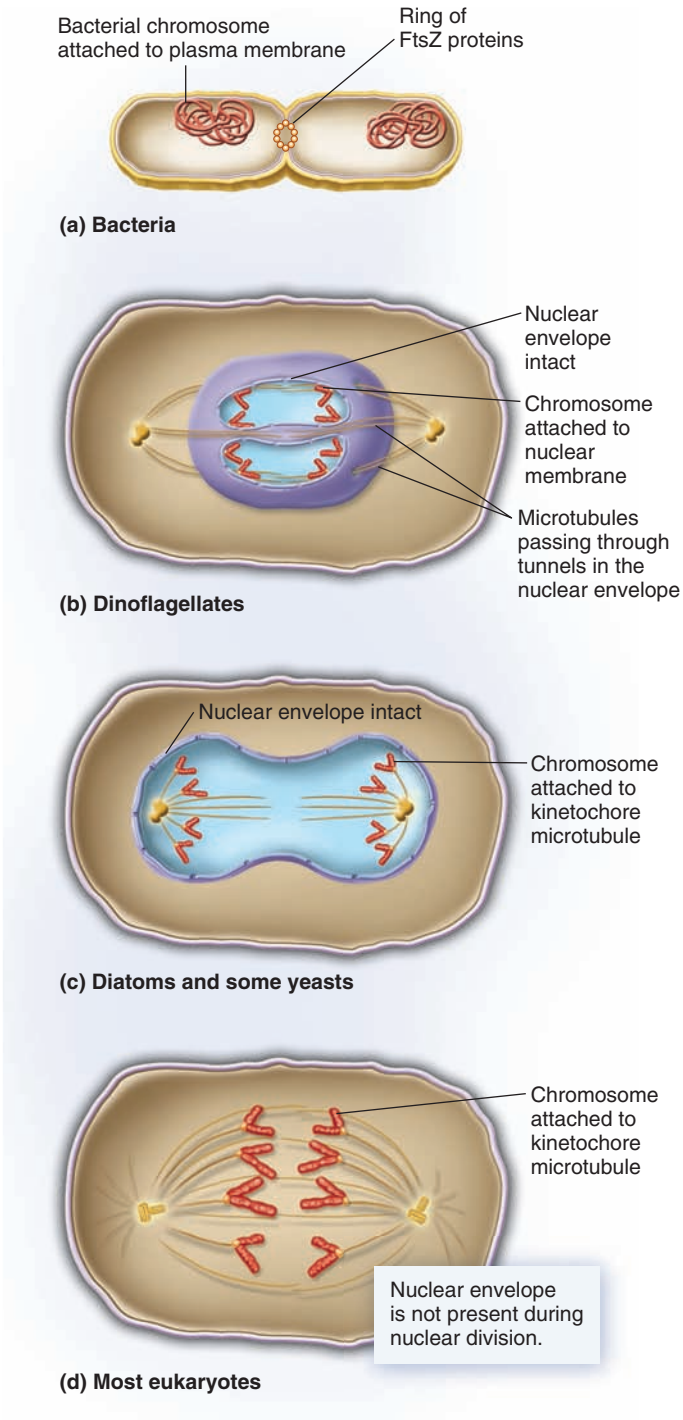

Figure 15.10 A comparison of cell division among bacteria, simple eukaryotes, and more complex eukaryotes.

15.3 Meiosis and Sexual Reproduction

Learning Outcomes:

1. Describe the processes of synapsis and crossing over.
2. Outline the key events that occur during the phases of meiosis.
3. Compare and contrast mitosis and meiosis, focusing on key steps that account for the different outcomes of these two processes.
4. Distinguish between the life cycles of diploid-dominant species, haploid-dominant species, and species that exhibit an alternation of generations.

We now turn our attention to **sexual reproduction**, a process in which two haploid gametes unite to form a diploid cell called a zygote. For multicellular species such as animals and plants, the zygote then grows and divides by mitotic cell divisions into a multicellular organism with many diploid cells.

As discussed earlier, a diploid cell contains two homologous sets of chromosomes, whereas a haploid cell contains a single set. For example, a diploid human cell contains 46 chromosomes, but a human gamete—sperm or egg cell—is a haploid cell that contains only 23 chromosomes. **Meiosis** is the process by which haploid cells are produced from a cell that was originally diploid. The term meiosis, which means to make smaller, refers to the fewer chromosomes found in cells following this process. For this to occur, the chromosomes must be correctly sorted and distributed in a way that reduces the chromosome number to half its original diploid value. In the case of human gametes, for example, each gamete must receive one chromosome from each of the 23 pairs. For this to happen, two rounds of divisions are necessary, termed meiosis I and meiosis II (**Figure 15.11**). When a cell begins meiosis, it contains chromosomes that are found in homologous pairs. When meiosis is completed, a single diploid cell with homologous pairs of chromosomes has produced four haploid cells.

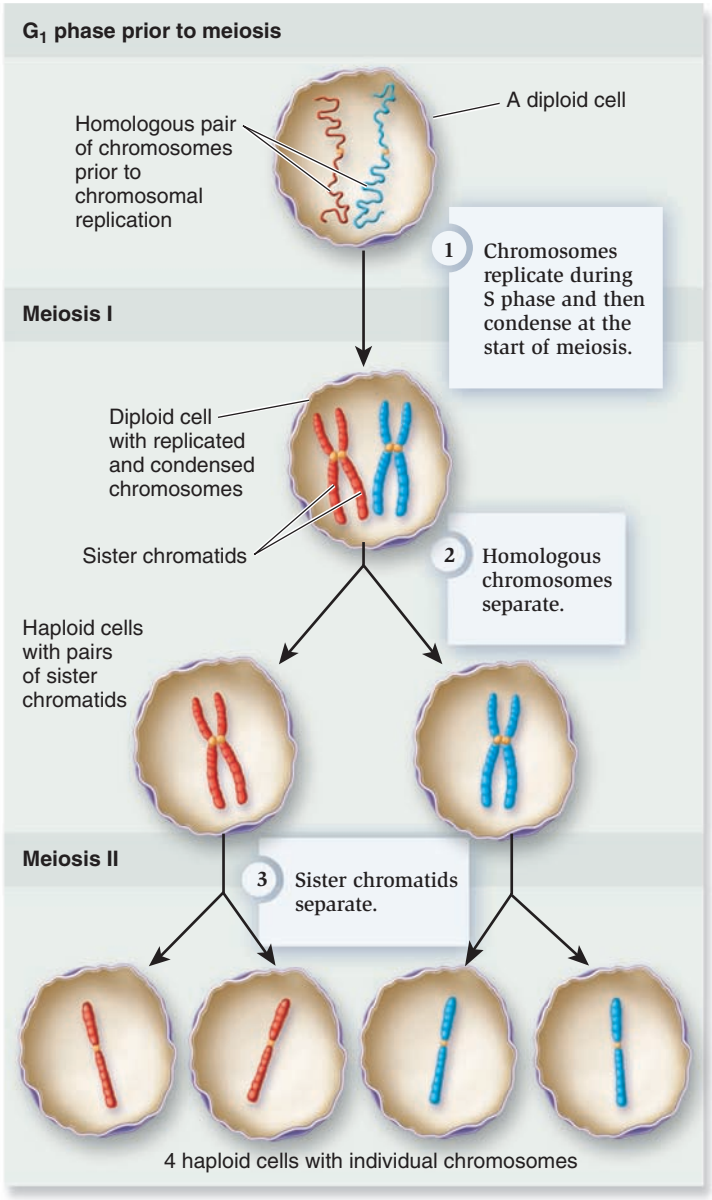

Figure 15.11 How the process of meiosis reduces chromosome number. This simplified diagram emphasizes the reduction in chromosome number as a diploid cell divides by meiosis to produce four haploid cells.

In this section, we will examine the cellular events of meiosis that reduce the chromosome number from diploid to haploid. In addition, we will briefly consider how this process plays a role in the life cycles of animals, plants, fungi, and protists.

Bivalent Formation and Crossing Over Occur at the Beginning of Meiosis

Like mitosis, meiosis begins after a cell has progressed through the G_1, S, and G_2 phases of the cell cycle. However, two key events occur at the beginning of meiosis that do not occur in mitosis. First, homologous pairs of sister chromatids associate with each other, lying side by side to form a **bivalent**, also called a tetrad (**Figure 15.12**). The process of forming a bivalent is termed **synapsis**. In most eukaryotic species, a protein structure called the synaptonemal complex connects homologous chromosomes during a portion of meiosis. However, the synaptonemal complex is not required for the pairing of homologous chromosomes because some species of fungi completely lack such a complex, yet their chromosomes associate with each other correctly. At present, the precise role of the synaptonemal complex is not clearly understood.

The second event that occurs at the beginning of meiosis, but not usually during mitosis, is **crossing over**, which involves a physical exchange between chromosome segments of the bivalent (Figure 15.12). As discussed in Chapter 17, crossing over increases the genetic variation of sexually reproducing species. After crossing over occurs, the arms of the chromosomes tend to separate but remain adhered at a crossover site. This connection is called a chiasma (plural, chiasmata), because the connected chromosomal arms resemble the Greek letter chi, χ. The number of crossovers is carefully controlled by cells and depends on the size of the chromosome and the species. The range of crossovers for eukaryotic chromosomes is typically one or two to a couple dozen. During the formation of sperm in humans, for example, an average chromosome undergoes slightly more than two crossovers, whereas chromosomes in certain plant species may undergo 20 or more.

Meiosis I Separates Homologous Chromosomes

Now that we have an understanding of bivalent formation and crossing over, we are ready to consider the phases of meiosis (**Figure 15.13**). These simplified diagrams depict a diploid cell ($2n$) that contains a total of six chromosomes (as in our look at mitosis in Figure 15.8). Prior to meiosis, the chromosomes are replicated in S phase to produce pairs of sister chromatids. This single replication event is then followed by sequential divisions called meiosis I and II. Like mitosis, each of these is a continuous series of stages called prophase, prometaphase, metaphase, anaphase, and telophase. The sorting that occurs during **meiosis I** separates homologous chromosomes from each other (Figure 15.13a–e).

Prophase I During prophase I, the replicated chromosomes condense, the homologous chromosomes form bivalents, and crossing over occurs. The nuclear envelope then starts to fragment into small vesicles.

Prometaphase I In prometaphase I, the nuclear envelope is completely broken apart into vesicles, and the spindle apparatus is entirely formed. The sister chromatids become attached to kinetochore microtubules. However, a key difference exists between mitosis and meiosis I. In mitosis, each pair of sister chromatids is attached to both poles (see Figure 15.8c). In meiosis I, each pair of sister chromatids is attached to just one pole via kinetochore microtubules (Figure 15.13b).

Metaphase I At metaphase I, the bivalents are organized along the metaphase plate. Notice how this pattern of alignment is strikingly different from that observed during mitosis (see Figure 15.8d). In particular, the sister chromatids are aligned in a double row rather than a single row (as in mitosis). Furthermore, the arrangement of sister chromatids within this double row is random with regard to the (red and blue) homologs. (Remember that these different colors represent maternal and paternal chromosomes.) In Figure 15.13c, one of the

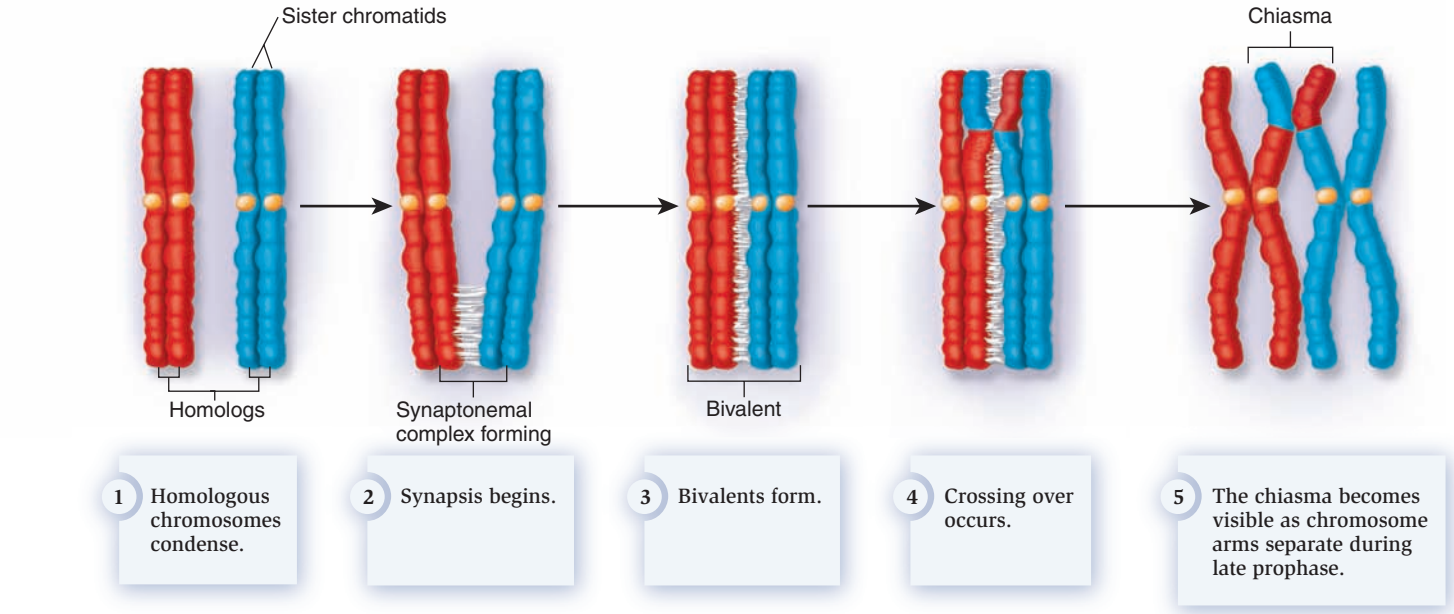

Figure 15.12 Formation of a bivalent and crossing over during meiosis I. At the beginning of meiosis, homologous chromosomes pair with each other to form a bivalent, usually with a synaptonemal complex between them. Crossing over then occurs between homologous chromatids within the bivalent. During this process, homologs exchange segments of chromosomes.

red homologs is to the left of the metaphase plate, and the other two are to the right, whereas two of the blue homologs are to the left of the metaphase plate and the other one is to the right. In other cells, homologs could be arranged differently along the metaphase plate (for example, three blues to the left and none to the right, or none to the left and three to the right).

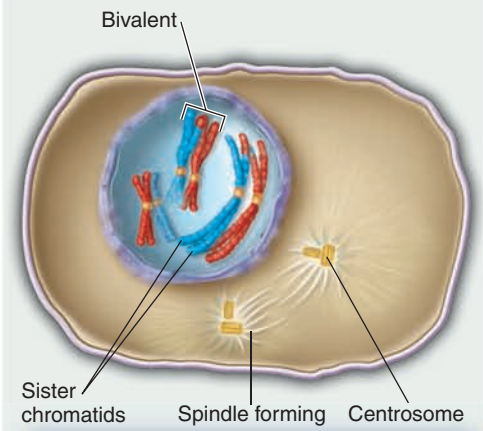
Because eukaryotic species typically have many chromosomes per set, maternal and paternal homologs can be randomly aligned along the metaphase plate in a variety of ways. The possible number of different, random alignments equals 2^n, where n equals the number of chromosomes per set. The reason why the random alignments equals 2^n is because each chromosome is found in a homologous pair and each member of the pair can align on either side of the metaphase plate. It is a matter of chance which daughter cell of meiosis I will get the maternal chromosome of a homologous pair, and which will get the paternal chromosome. In humans, who have 23 chromosomes per set, 2^n equals 2^{23}, or over 8 million possibilities. Because the homologs are genetically similar but not identical, we see from this calculation that the random alignment of homologous chromosomes provides a mechanism to promote a vast amount of genetic diversity among the resulting haploid cells. When meiosis is complete, any two human gametes are extremely unlikely to have the same combination of homologous chromosomes.

Anaphase I The segregation of homologs occurs during anaphase I (Figure 15.13d). The connections between bivalents break, but not the connections that hold sister chromatids together. Each joined pair of chromatids migrates to one pole, and the homologous pair of chromatids moves to the opposite pole, both pulled by kinetochore microtubules.

Telophase I At telophase I, the sister chromatids have reached their respective poles and then decondense. The nuclear envelope now re-forms to produce two separate nuclei.

If we consider the end result of meiosis I, we see that two nuclei are produced, each with three pairs of sister chromatids; this is called a reduction division. The original diploid cell had its chromosomes in homologous pairs, whereas the two cells produced as a result of meiosis I and cytokinesis are considered haploid—they do not have pairs of homologous chromosomes.

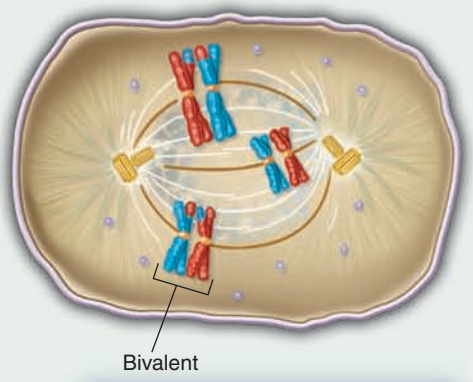
Meiosis II Separates Sister Chromatids



Meiosis I is followed by cytokinesis and then **meiosis II** (see Figure 15.13f–j). DNA replication does not occur between meiosis I and meiosis II. The sorting events of meiosis II are similar to those of mitosis, but the starting point is different. For a diploid cell with six chromosomes, mitosis begins with 12 chromatids that are joined as six pairs of sister chromatids (see Figure 15.8). By comparison, the two cells that begin meiosis II each have six chromatids that are joined as three pairs of sister chromatids. Otherwise, the steps that occur during prophase, prometaphase, metaphase, anaphase, and telophase of meiosis II are analogous to a mitotic division. Sister chromatids are separated during anaphase II.

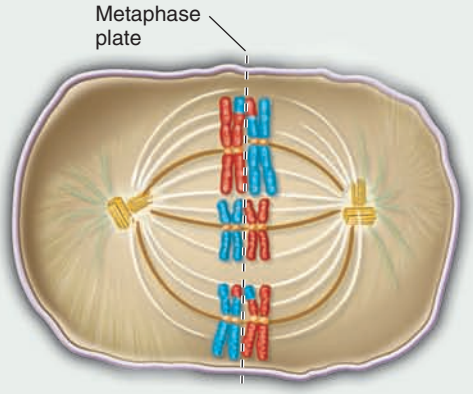
Mitosis and Meiosis Differ in a Few Key Steps

How are the outcomes of mitosis and meiosis different? Mitosis produces two diploid daughter cells that are genetically identical. In our example shown in Figure 15.8, the starting cell had six chromosomes (three homologous pairs of chromosomes), and both daughter cells received copies of the same six chromosomes. By comparison, meiosis reduces the number of sets of chromosomes. In the example shown in Figure 15.13, the starting cell also had six chromosomes, whereas the resulting four daughter cells have only three chromosomes. However, the daughter cells do not contain a random mix of three chromosomes. Each haploid daughter cell contains one



Meiosis I

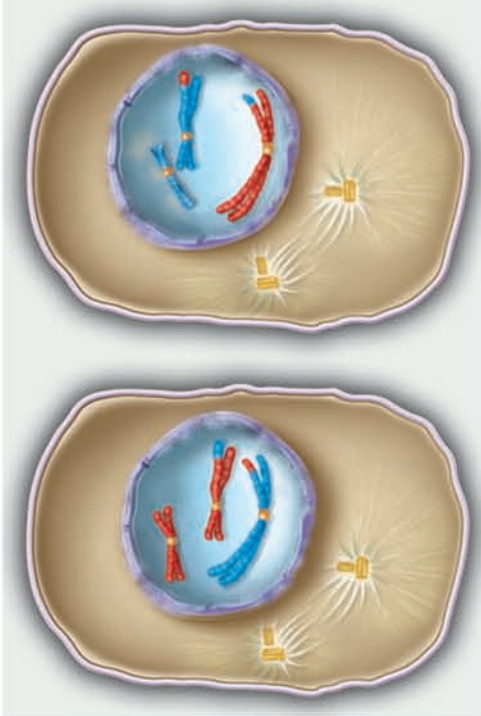
(a) Prophase I



1 Homologous chromosomes synapse to form bivalents, and crossing over occurs. Chromosomes condense, and the nuclear envelope begins to dissociate into vesicles.

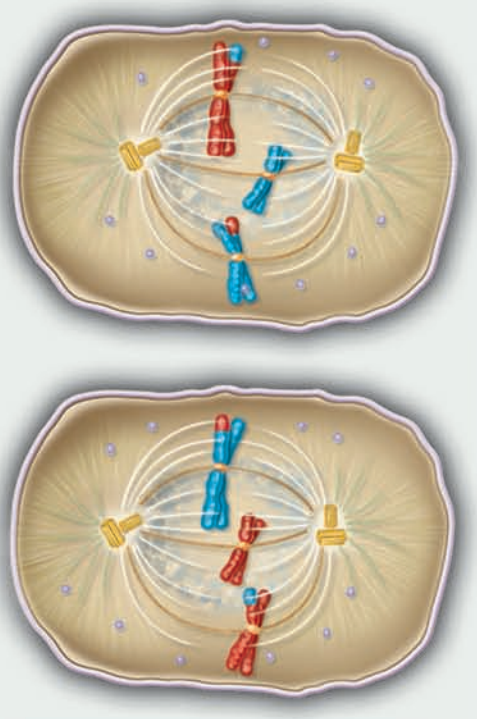
(b) Prometaphase I

2 The nuclear envelope completely dissociates into vesicles, and bivalents become attached to kinetochore microtubules.



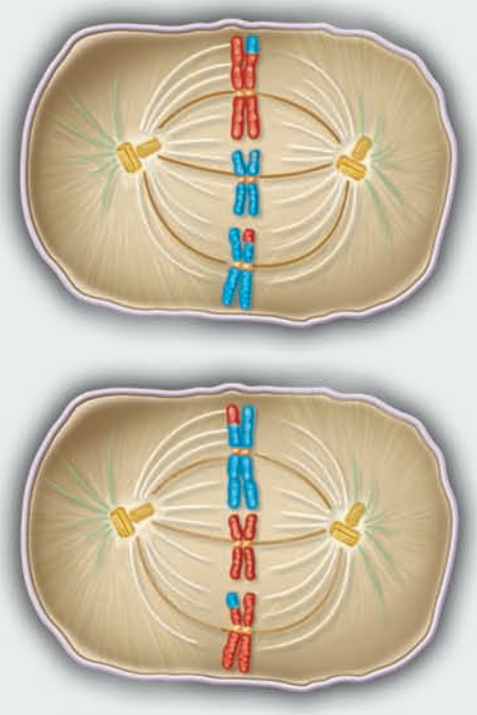
(c) Metaphase I

3 Bivalents randomly align along the metaphase plate. Each pair of sister chromatids is attached to one pole.



Meiosis II

(f) Prophase II



6 Sister chromatids condense, and the spindle starts to form. The nuclear envelope begins to dissociate into vesicles.

(g) Prometaphase II

7 The nuclear envelope completely dissociates into vesicles. Sister chromatids attach to the spindle via kinetochore microtubules.

(h) Metaphase II

8 Sister chromatids align along the metaphase plate. Each pair of sister chromatids is attached to both poles.

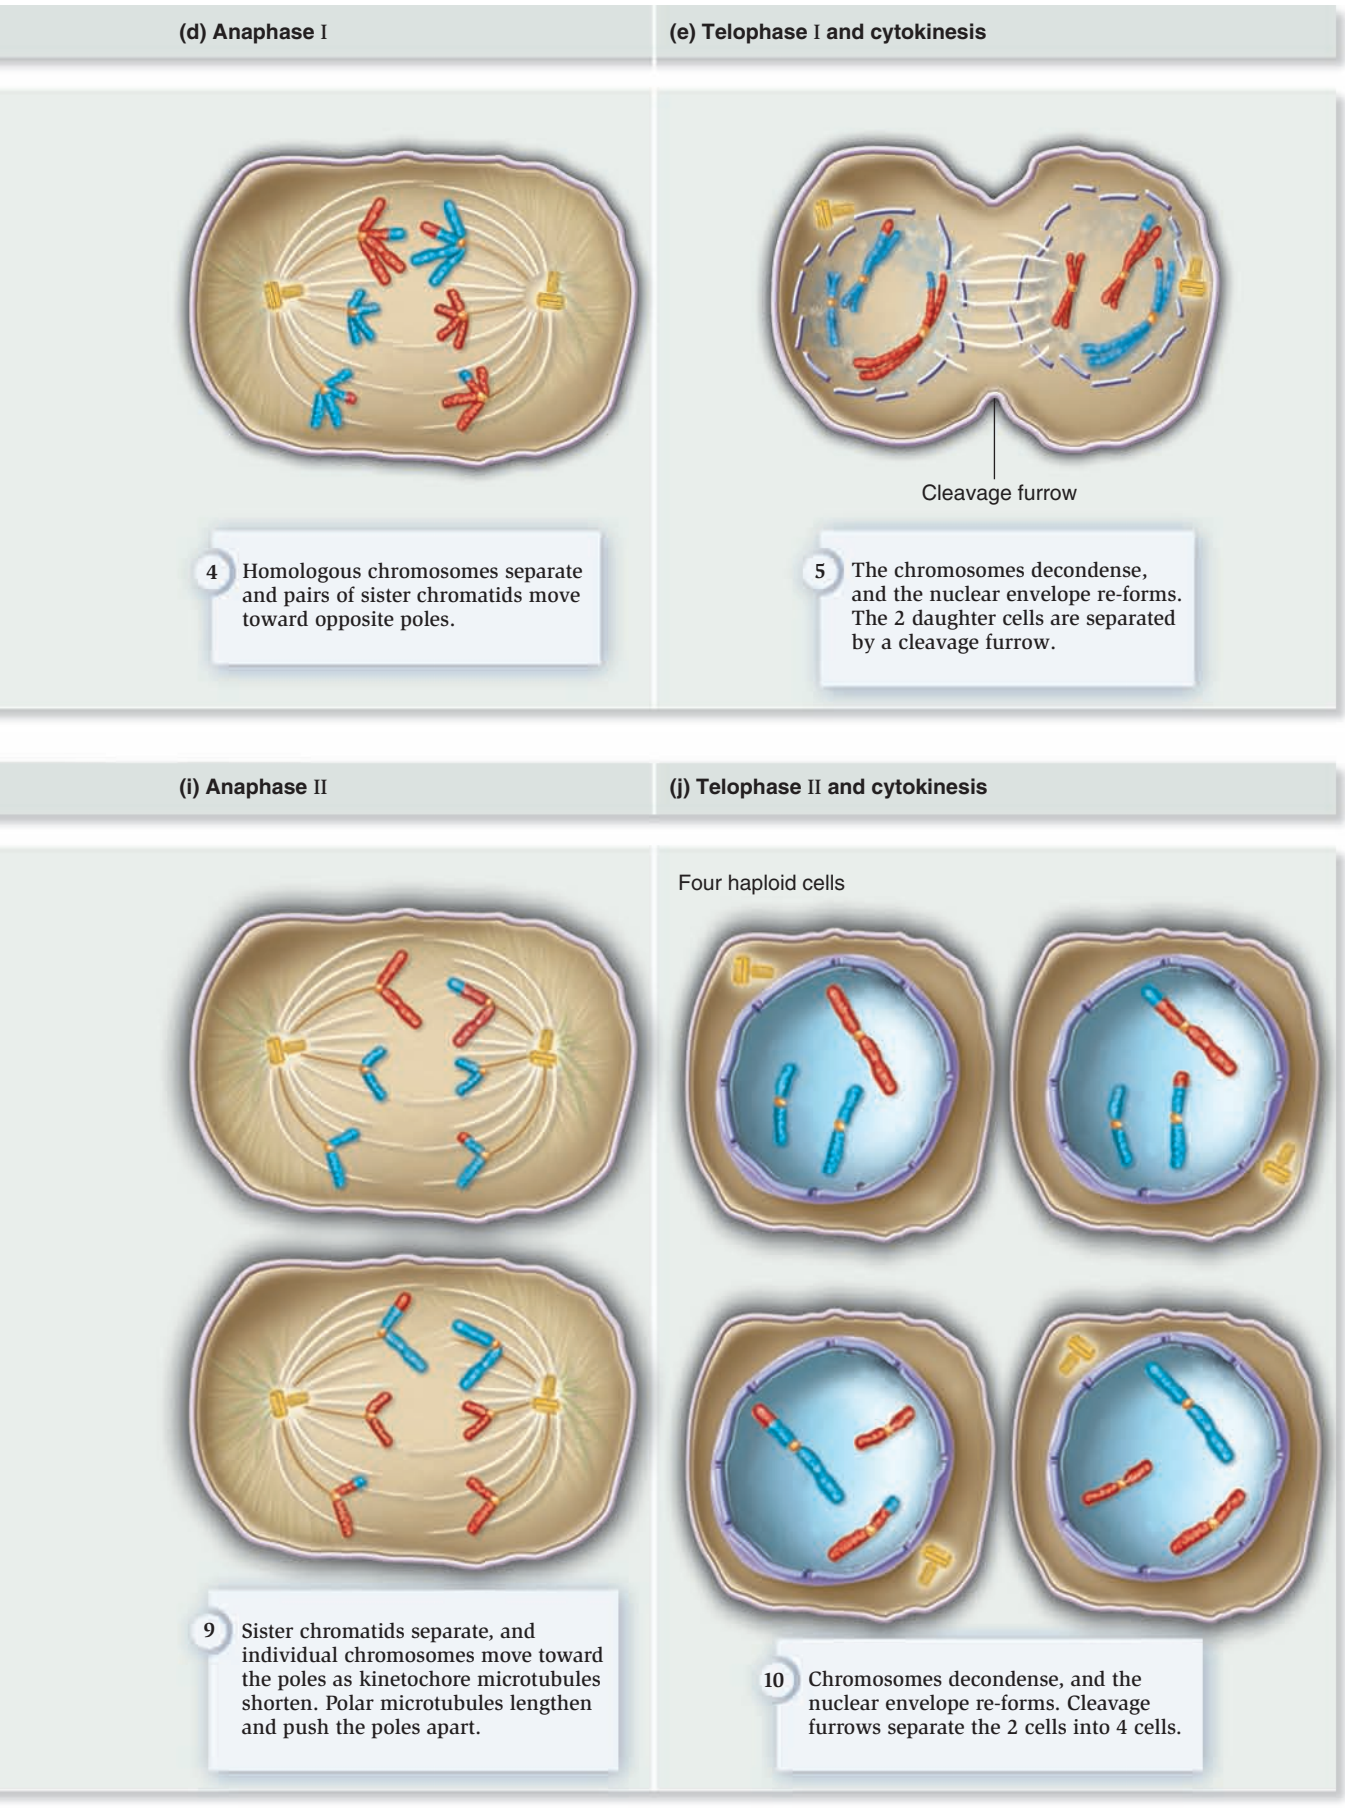


Figure 15.13 The phases of meiosis in an animal cell.

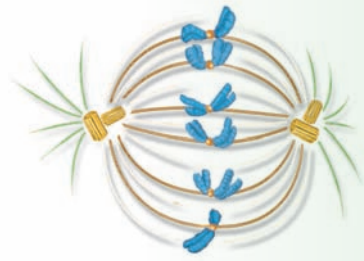
Concept Check: *Relative to the original cell, what is the end result of meiosis?*

Table 15.1 A Comparison of Mitosis, Meiosis I, and Meiosis II



Event	Mitosis	Meiosis I	Meiosis II
DNA replication:	Occurs prior to mitosis	Occurs prior to meiosis I	Does not occur between meiosis I and II
Synapsis during prophase:	No	Yes, bivalents are formed.	No
Crossing over during prophase:	Rarely	Commonly	Rarely
Attachment to poles at prometaphase:	A pair of sister chromatids is attached to kinetochore microtubules from both poles.	A pair of sister chromatids is attached to kinetochore microtubules from just one pole.	A pair of sister chromatids is attached to kinetochore microtubules from both poles.
Alignment along the metaphase plate:	Sister chromatids align.	Bivalents align.	Sister chromatids align.
Type of separation at anaphase:	Sister chromatids separate. A single chromatid, now called a chromosome, moves to each pole.	Homologous chromosomes separate. A pair of sister chromatids moves to each pole.	Sister chromatids separate. A single chromatid, now called a chromosome, moves to each pole.
End result when the mother cell is diploid:	Two daughter cells that are diploid	—	Four daughter cells that are haploid

complete set of chromosomes, whereas the original diploid mother cell had two complete sets.

How do we explain the different outcomes of mitosis and meiosis? **Table 15.1** emphasizes the differences between certain key steps in mitosis and meiosis that account for the different outcomes of these two processes. DNA replication occurs prior to mitosis and meiosis I, but not between meiosis I and II. During prophase of meiosis I, the homologs synapse to form bivalents. This explains why crossing over occurs commonly during meiosis, but rarely during mitosis. During prometaphase of mitosis and meiosis II, pairs of sister chromatids are attached to both poles. In contrast, during meiosis I, each pair of sister chromatids (within a bivalent) is attached to a single pole. Bivalents align along the metaphase plate during metaphase of meiosis I, whereas sister chromatids align along the metaphase plate during metaphase of mitosis and meiosis II. At anaphase of meiosis I, the homologous chromosomes separate, but the sister chromatids remain together. In contrast, sister chromatid separation occurs during anaphase of mitosis and meiosis II. Taken together, the steps of mitosis produce two diploid cells that are genetically identical, whereas the steps of meiosis involve two sequential cell divisions that produce four haploid cells that may not be genetically identical.

BIO TIPS

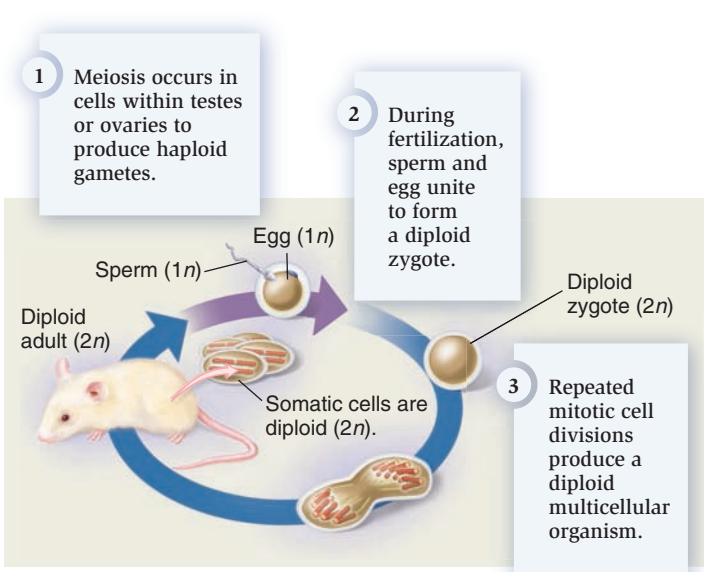
THE QUESTION *A diploid cell has twelve chromosomes, six per set. For the following diagram, in what phase of mitosis, meiosis I or meiosis II, is this cell?*

TOPIC ***What topic in biology does this question address?*** The topic is cell division. More specifically, the question is asking you to be able to look at a drawing and discern which phase of cell division a particular cell is in.

INFORMATION ***What information do you know based on the question and based on your understanding of the topic?*** From the question, you have a diagram of a cell at a particular phase of the cell cycle. This cell is derived from a mother cell with six pairs of chromosomes. From your understanding of the topic, you may remember the various phases of mitosis, meiosis I, and meiosis II, which are described in Figures 15.8 and 15.13. If so, you may initially realize that the cell is in metaphase.

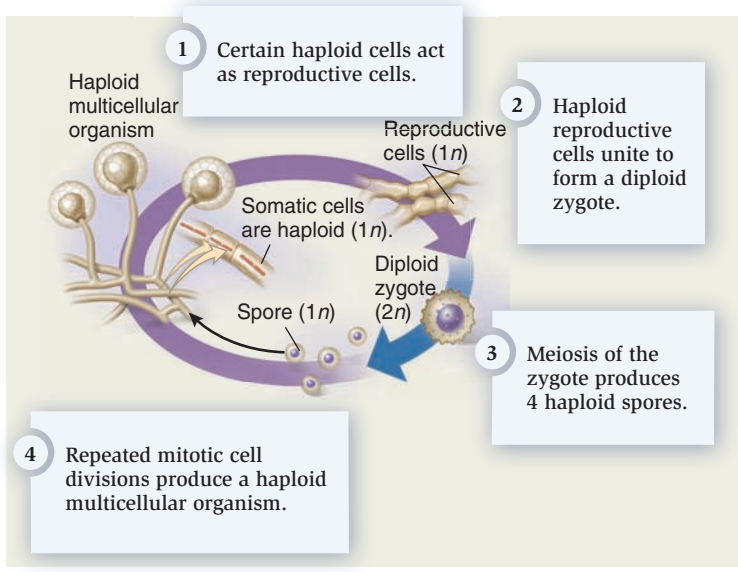
PROBLEM-SOLVING STRATEGY ***Sort out the steps in a complicated process.*** To solve this problem, you may need to describe the steps, starting with a mother cell that has six pairs of chromosomes. Keep in mind that a mother cell with six pairs of chromosomes has twelve chromosomes during G_1, which then replicate to form twelve pairs of sister chromatids during S phase. Therefore, at the beginning of M phase, this mother cell would have twelve pairs of sister chromatids. During mitosis, the mother cell would align twelve pairs of sister chromatids at metaphase. During meiosis I, the mother cell would align six tetrads along the metaphase plate. During meiosis II, two cells would align six pairs of sister chromatids along the metaphase plate.

ANSWER *The cell is in metaphase of meiosis II. You can tell because the chromosomes are lined up in a single row along the metaphase plate, and the cell has only six pairs of sister chromatids. If it were mitosis, the cell would have twelve pairs of sister chromatids. If it were in meiosis I, tetrads would be aligned along the metaphase plate.*



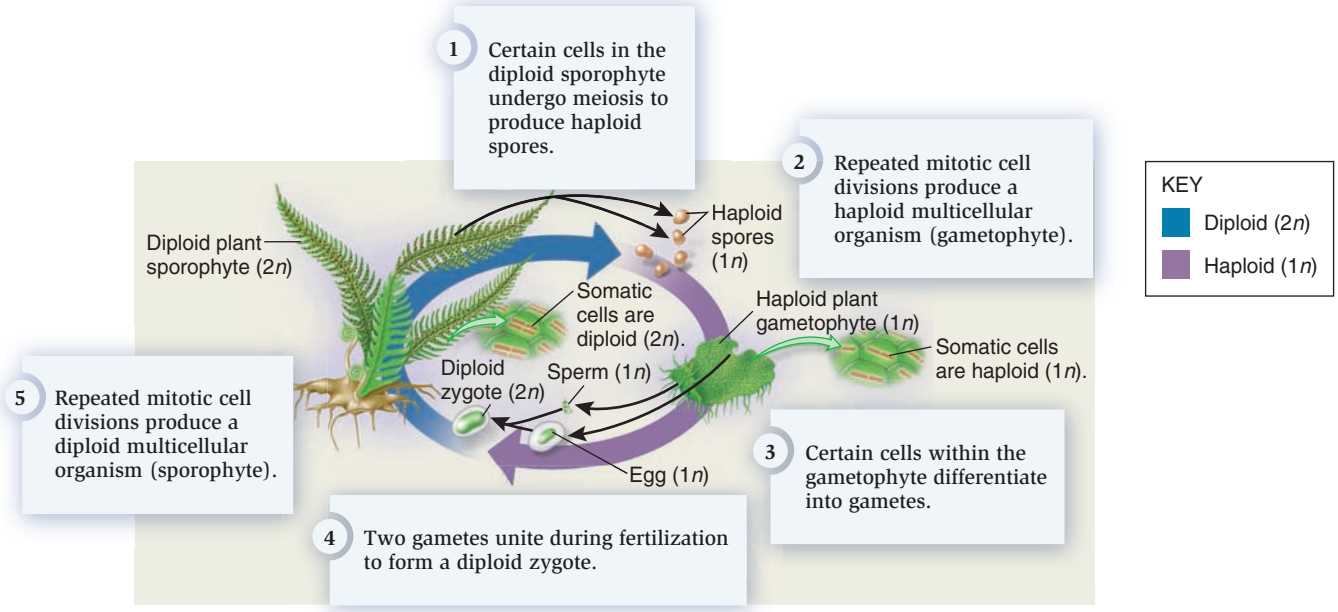
Sexually Reproducing Species Produce Haploid and Diploid Cells at Different Times in Their Life Cycles

Let's now turn our attention to the relationship between mitosis, meiosis, and sexual reproduction in animals, plants, fungi, and protists. For any given species, the sequence of events that produces



another generation of organisms is known as a **life cycle**. For sexually reproducing organisms, this usually involves an alternation between haploid cells or organisms and diploid cells or organisms (**Figure 15.14**).

Diploid-Dominant Species Most species of animals are diploid, and their haploid gametes are considered to be a specialized type of cell. For this reason, animals are viewed as **diploid-dominant species** (Figure 15.14a). Certain diploid cells in the testes or ovaries undergo meiosis to produce haploid sperm or eggs, respectively. During fertilization, sperm and egg unite to form a diploid zygote, which then undergoes repeated mitotic cell divisions to produce a diploid multicellular organism.



Haploid-Dominant Species By comparison, most fungi and some protists are just the opposite; they are **haploid-dominant species** (Figure 15.14b). In fungi, the multicellular organism is haploid ($1n$); only the zygote is diploid. Haploid fungal cells are most commonly produced by mitosis. During sexual reproduction, haploid cells unite to form a diploid zygote, which then immediately proceeds through meiosis to produce four haploid cells called spores. Each spore goes through mitotic cellular divisions to produce a haploid multicellular organism.

(a) Animal life cycle—diploid dominant

(b) Fungal life cycle—haploid dominant

(c) Plant life cycle—alternation of generations

Figure 15.14 A comparison of three types of sexual life cycles.

Concept Check: *What is the main reason for meiosis in animals? What is the main reason for mitosis in animals?*

Alternation of Generations Plants and some algae have life cycles that are intermediate between diploid or haploid dominance. Such species exhibit an **alternation of generations** (Figure 15.14c). The species alternate between diploid multicellular organisms called **sporophytes**, and haploid multicellular organisms called **gametophytes**. Meiosis in certain cells within the sporophyte produces haploid spores, which divide by mitosis to produce the gametophyte. Particular cells within the gametophyte differentiate into haploid gametes. Fertilization occurs between two gametes, producing a diploid zygote that then undergoes repeated mitotic cell divisions to produce a sporophyte.

Among different plant species, the relative sizes of the haploid and diploid organisms vary greatly. In mosses, the haploid gametophyte is a visible multicellular organism, whereas the diploid sporophyte is smaller and remains attached to the haploid organism. In other plants, such as ferns (Figure 15.14c), both the diploid sporophyte and haploid gametophyte grow independently. The sporophyte is considerably larger and is the organism we commonly think of as a fern. In seed-bearing plants, such as roses and oak trees, the diploid sporophyte is the large multicellular plant, whereas the gametophyte is composed of only a few cells and is formed within the sporophyte.

When comparing animals, plants, and fungi, it's interesting to consider how gametes are made. Animals produce gametes by meiosis. In contrast, plants and fungi produce reproductive cells by mitosis. The gametophyte of plants is a haploid multicellular organism that is created by mitotic cellular divisions of a haploid spore. Within the multicellular gametophyte, certain cells become specialized as gametes.

15.4 Variation in Chromosome Structure and Number

Learning Outcomes:

1. Describe how chromosomes can vary in size, centromere location, and number.
2. Identify the four ways that the structure of a chromosome can be changed via mutation.
3. Compare and contrast changes in the number of sets of chromosomes and changes in the number of individual chromosomes.
4. Give examples of how changes in chromosome number affect the characteristics of animals and plants.

In the previous sections of this chapter, we examined two important features of chromosomes: They occur in sets, and two sorting processes determine the chromosome number following cell division. In this section, we will examine how the structures and numbers of chromosomes may vary between different species and within the same species.

Why is the study of chromosomal variation important? First, geneticists have discovered that variations in chromosome structure and number can have major effects on the characteristics of an organism. We now know that several human genetic diseases are caused by such changes. In addition, changes in chromosome structure and number have been an important factor in the evolution of new species, which is a topic we will consider in Chapter 25.

Chromosome variation can be viewed in two ways. The structure and number of chromosomes among different species tend to vary greatly. There is also considerable variety in the size and shape of the chromosomes of a given species. On relatively rare occasions, however, the structure or number of chromosomes changes so that an individual is different from most other members of the same species. This is generally viewed as an abnormality. In this section, we will examine both normal and abnormal types of chromosome variation.

Natural Variation Exists in Chromosome Structure and Number

Before we begin to examine chromosome variation, we need to have a reference point for a normal set of chromosomes. To determine what the normal chromosomes of a species look like, a cytogeneticist microscopically examines the chromosomes from several members of the species. Chromosome composition within a given species tends to remain relatively constant. In most cases, individuals of the same species have the same number and types of chromosomes. For example, as mentioned previously, the usual chromosome composition of human cells is two sets of 23 chromosomes, for a total of 46. Other diploid species may have different numbers of chromosomes. The dog has 78 chromosomes (39 per set), the fruit fly has 8 chromosomes (4 per set), and the tomato has 24 chromosomes (12 per set). When comparing distantly related species, such as humans and fruit flies, major differences in chromosomal composition are observed.

The chromosomes of a given species also vary considerably in size and shape. Cytogeneticists have various ways to classify and identify chromosomes in their metaphase form. The three most commonly used features are size, location of the centromere, and banding patterns, which are revealed when the chromosomes are treated with stains. Based on centromere location, each chromosome is classified as **metacentric** (near the middle), **submetacentric** (off center), **acrocentric** (near one end), or **telocentric** (at the end) (**Figure 15.15**). Because the centromere is not exactly in the center of a chromosome, each chromosome has a short arm and a long arm. The short arm is designated with the letter p (for the French *petite*), and the long arm is designated with the letter q. In the case of telocentric chromosomes, the short arm may be nearly nonexistent. When preparing a karyotype (see Figure 15.1), the chromosomes are aligned with the short arms on top and the long arms on the bottom.

Because different chromosomes often have similar sizes and centromeric locations, cytogeneticists must use additional methods to accurately identify each type of chromosome within a karyotype. For detailed identification, chromosomes are treated with stains to produce characteristic banding patterns. Cytogeneticists use several different staining procedures to identify specific chromosomes. An example is Giemsa stain, which produces G bands (see Figure 15.1). The alternating pattern of G bands is unique for each type of chromosome.

The banding pattern of eukaryotic chromosomes is useful in two ways. First, individual chromosomes can be distinguished from each other, even if they have similar sizes and centromeric locations. As described next, banding patterns are used to detect changes in chromosome structure that occur as a result of mutation.

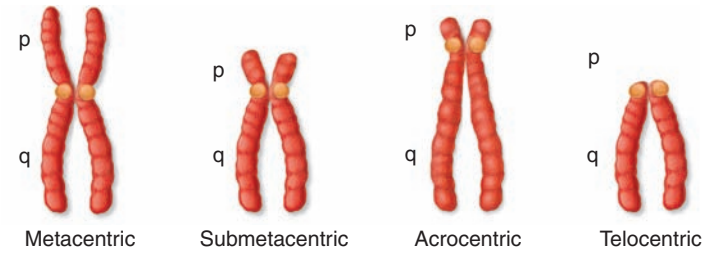


Figure 15.15 **A comparison of centromeric locations among metaphase chromosomes.**

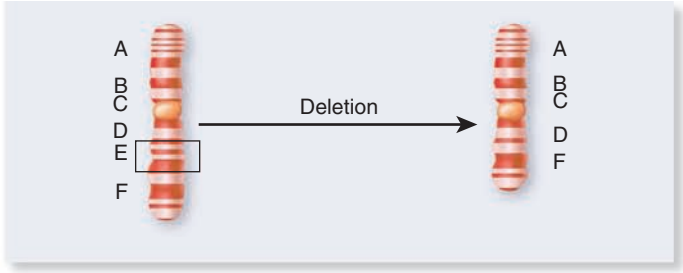
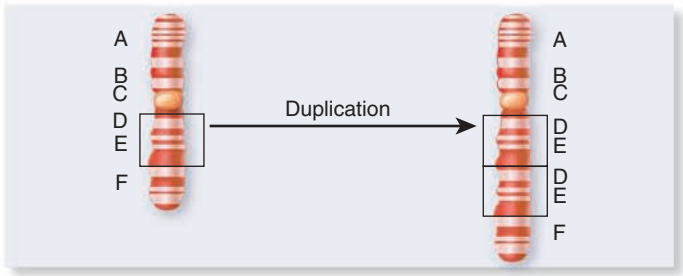
Mutations Can Alter Chromosome Structure

Let's now consider how the structures of chromosomes can be modified by a mutation, a heritable change in the genetic material. Chromosomal mutations, which involve the breaking and rejoining of chromosomes, are categorized as deletions, duplications, inversions, and translocations (**Figure 15.16**).



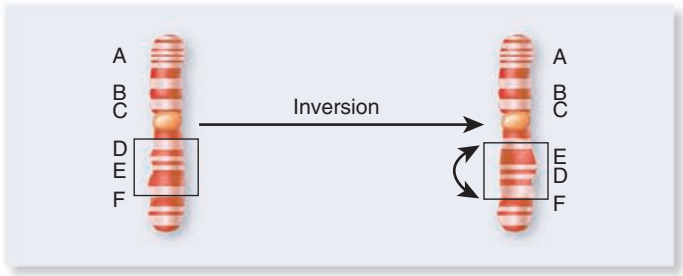
Changes in the Total Amount of Genetic Material Deletions and duplications are changes in the total amount of genetic material in a single chromosome. When a **deletion** occurs, a segment of chromosomal material is removed (Figure 15.16a). The affected chromosome becomes deficient in a significant amount of genetic material. In a **duplication**, a section of a chromosome occurs two times in a row (Figure 15.16b).

What are the consequences of a deletion or duplication? The possible effects depend on the size of the segment affected and whether it includes genes or portions of genes that are vital to the development of the organism. When a deletion or duplication has an effect, it is usually detrimental. Larger changes in the amount of genetic material tend to be more harmful because more genes are missing or duplicated.

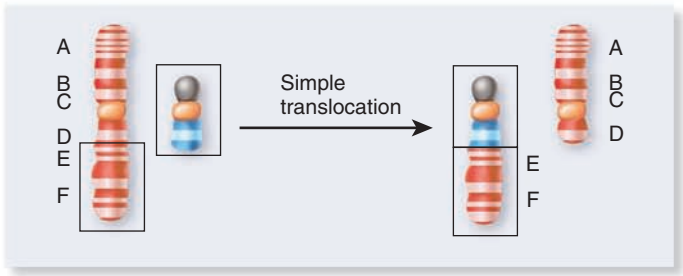


Chromosomal Rearrangements Inversions and translocations are chromosomal rearrangements. An **inversion** is a change in the direction of the genetic material along a single chromosome. When a segment of one chromosome has been inverted, the order of G bands is opposite to that of a normal chromosome (Figure 15.16c). A **translocation** occurs when one segment of a chromosome becomes attached to a different chromosome. In a **simple translocation**, a single piece of chromosome is attached to another chromosome (Figure 15.16d). In a **reciprocal translocation**, two different types of chromosomes exchange pieces, thereby producing two abnormal chromosomes carrying translocations (Figure 15.16e).

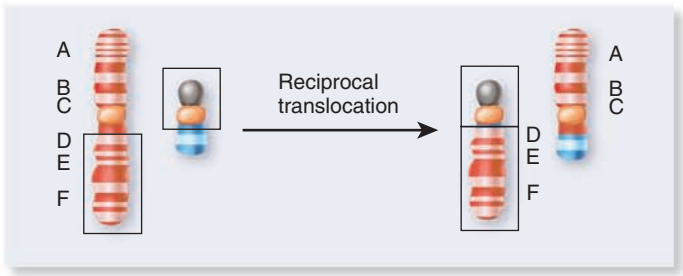
Variation Occurs in the Number of Chromosome Sets and the Number of Individual Chromosomes



Variations in chromosome number can be categorized in two ways: variation in the number of sets of chromosomes and variation in the number of particular chromosomes within a set. The suffix -ploid or -ploidy refers to a complete set of chromosomes. Organisms that are **euploid** (the prefix eu- means true) have chromosomes that occur in one or more complete sets. For example, in a species that is diploid, a euploid organism would have two sets of chromosomes in its somatic cells. In *Drosophila melanogaster*, for example, a normal



(a) Deletion: Removes a segment of chromosome.



(b) Duplication: Doubles a particular region.

(c) Inversion: Flips a region to the opposite orientation.

(d) Simple translocation: Moves a segment of 1 chromosome to another chromosome.

(e) Reciprocal translocation: Exchanges pieces between 2 different chromosomes.

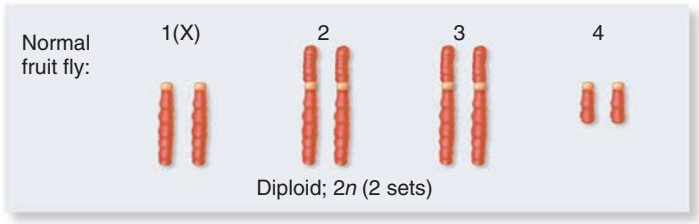


Figure 15.16 **Types of changes in chromosome structure.** The letters alongside the chromosomes are placed there as frames of reference.

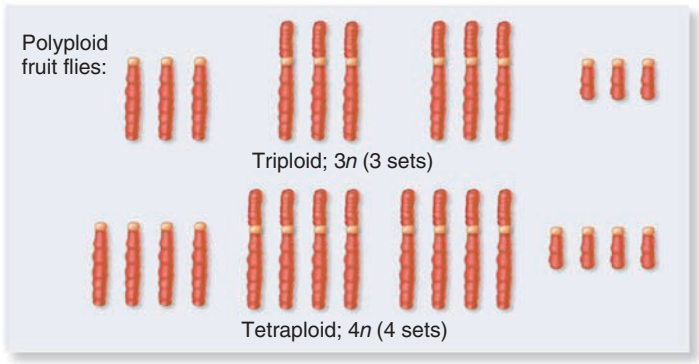
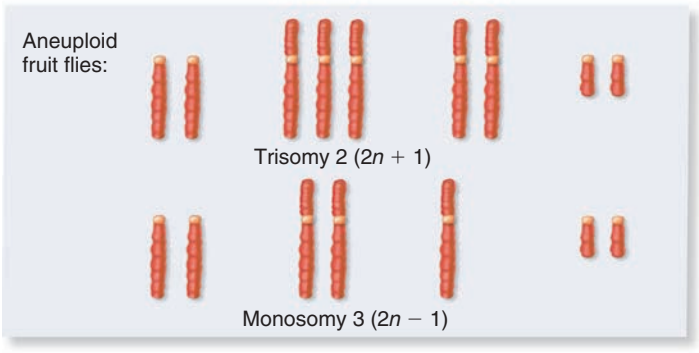
Concept Check: *Which types of changes shown here do not affect the total amount of genetic material?*



individual has eight chromosomes. The species is diploid, having two sets of four chromosomes each (**Figure 15.17a**).

Variation in the Number of Sets of Chromosomes Organisms can vary in the number of sets of chromosomes they have. For example, on rare occasions, an abnormal fruit fly can be produced with 12 chromosomes, containing three sets of 4 chromosomes each (**Figure 15.17b**). Organisms with three or more sets of chromosomes are called **polyploid**. A diploid organism is referred to as $2n$, a **triploid** organism as $3n$, a **tetraploid** organism as $4n$, and so forth. All such organisms are euploid because they have complete sets of chromosomes.



Aneuploidy A second way that chromosome number can vary is called **aneuploidy**. This refers to an alteration in the number of particular chromosomes, so the total number of chromosomes is not an exact multiple of a set. For example, an abnormal fruit fly could contain nine chromosomes instead of eight because it had three copies of chromosome 2 instead of the normal two copies (**Figure 15.17c**). Instead of being perfectly diploid, a trisomic animal is $2n + 1$. Such an animal is said to have **trisomy** 2. By comparison, a fruit fly could be lacking a single chromosome, such as chromosome 3, and contain a total of seven chromosomes ($2n - 1$). This animal is said to be monosomic and would be described as having **monosomy** 3.

(a) Normal fruit fly chromosome composition

(b) Polyploidy

(c) Aneuploidy

Figure 15.17 Types of variation in chromosome number.
(a) The normal diploid number of chromosomes in *Drosophila*. The X chromosome is also called chromosome 1. Examples of chromosomes of **(b)** polyploid flies and **(c)** aneuploid flies.

Variations in chromosome number are fairly widespread and have a significant effect on the characteristics of plants and animals. For these reasons, researchers want to understand the mechanisms that cause these variations. In some cases, a change in chromosome number is the result of the abnormal sorting of chromosomes during cell division. The term **nondisjunction** refers to an event in which the chromosomes do not separate properly during cell division. Nondisjunction can occur during meiosis I or meiosis II and produces haploid cells that have too many or too few chromosomes. **Figure 15.18** illustrates the consequences of nondisjunction during meiosis I. In this case, one pair of homologs moved into the cell on the left instead of separating from each other. This results in the production of aneuploid cells, with either too many or too few chromosomes. If such a cell becomes a gamete that fuses with another gamete during fertilization, the zygote and the resulting organism will have an abnormal number of chromosomes in all of its cells.

Changes in Chromosome Number Have Important Consequences

How do changes in chromosome number affect the characteristics of animals and plants? Let's consider a few examples.

Changes in Chromosome Number in Animals In many cases, animals do not tolerate deviations from diploidy well. For example, polyploidy in mammals is generally a lethal condition. However, a few cases of naturally occurring variations from diploidy do occur in animals. Male bees, which are produced from unfertilized eggs, contain a single set of chromosomes and are therefore haploid organisms. By comparison, fertilized eggs become female bees, which are diploid. A few examples of vertebrate polyploid animals have been discovered. Interestingly, on rare occasions, animals that are morphologically very similar to each other can be found as a diploid species as well as a separate polyploid species. This situation occurs among certain amphibians and reptiles. **Figure 15.19** shows photographs of a diploid and a tetraploid frog. As you can see, they look very similar.

One important reason that geneticists are so interested in aneuploidy is its relationship to certain inherited disorders in humans. Even though most people are born with 46 chromosomes, alterations in chromosome number occur at a surprising frequency during gamete formation. About 5% to 10% of all fertilized human eggs result in an embryo with an abnormality in chromosome number. In most cases, these abnormal embryos do not develop properly and result in a spontaneous abortion very early in pregnancy. Approximately 50% of all spontaneous abortions are due to alterations in chromosome number.

In some cases, an abnormality in chromosome number produces an offspring that can survive. Several human disorders are the result of abnormalities in chromosome number. The most common are trisomies of chromosomes 21, 18, or 13, or abnormalities

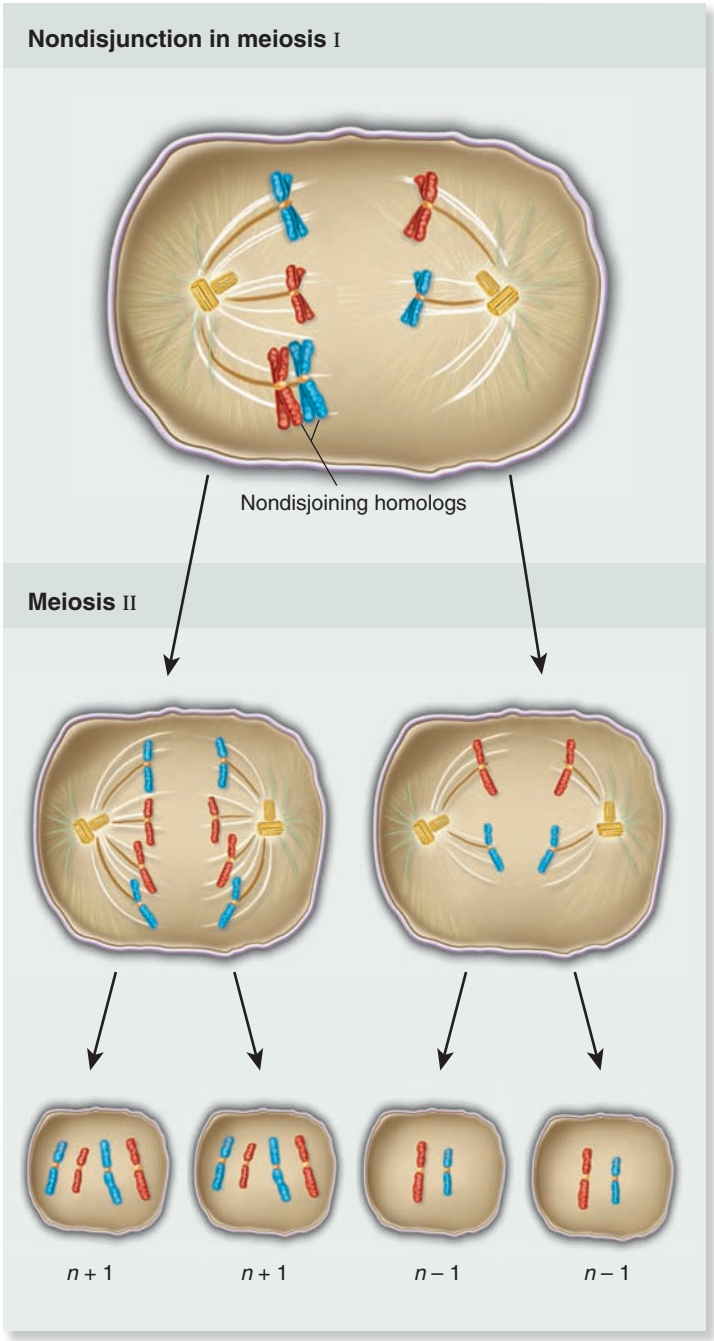


Figure 15.18 Nondisjunction during meiosis I. For simplicity, this cell shows only three pairs of homologous chromosomes. One of the three pairs does not disjoin properly, and both homologs have moved into the cell on the left. The resulting haploid cells shown at the bottom are all aneuploid, resulting in gametes with four chromosomes and two chromosomes, instead of three.

in the number of the sex chromosomes (**Table 15.2**). These syndromes are most likely due to nondisjunction. For example, Turner syndrome (XO) may occur when a gamete that is lacking a sex chromosome due to nondisjunction has fused with a gamete carrying an X chromosome. By comparison, triple X syndrome (XXX) occurs when a gamete carrying two X chromosomes fuses with a gamete carrying a single X chromosome.

(a) *Hyla chrysoscelis* (diploid)

(b) *Hyla versicolor* (tetraploid)

Figure 15.19 Differences in chromosome number in two closely related frog species. The frog in **(a)** is diploid, whereas the frog in **(b)** is tetraploid. These frogs are in the act of performing their mating calls, which is why the skin under their mouths is protruding as a large bubble.

Most of the known trisomies involve chromosomes that are relatively small, so they carry fewer genes. Trisomies of the other human chromosomes and most monosomies are presumed to be lethal and have been found in spontaneously aborted embryos and fetuses.

Human abnormalities in chromosome number are influenced by the age of the parents. Older parents are more likely to produce children with abnormalities in chromosome number, possibly because meiotic nondisjunction is more likely to occur in older cells. **Down syndrome**, which was first described by the English physician John Langdon Down in 1866, provides an example. This disorder is caused by the inheritance of three copies of chromosome 21 (see Table 15.2). The incidence of Down syndrome rises with the age of either parent. In males, however, the rise occurs relatively late in life, usually past the age when most men have children. By comparison, the likelihood of having a child with Down syndrome rises dramatically during the later reproductive ages of women.

Changes in Chromosome Number in Plants In contrast to animals, plants commonly exhibit polyploidy. Polyploidy is also important in agriculture. In many instances, polyploid strains of plants display characteristics that are helpful to humans. They are often larger in size and more robust. These traits are clearly advantageous in the production of food. For example, the species

Table 15.2 Aneuploid Conditions in Humans

Condition	Frequency (per number of live births)	Syndrome	Characteristics
Autosomal			
Trisomy 21	1/800	Down	Mental impairment, abnormal pattern of palm creases, slanted eyes, flattened face, short stature
Trisomy 18	1/6,000	Edward	Mental and physical impairment, facial abnormalities, extreme muscle tone, early death
Trisomy 13	1/15,000	Patau	Mental and physical impairment, wide variety of defects in organs, large triangular nose, early death
Sex chromosomal			
XXY	1/1,000 (males)	Klinefelter	Sexual immaturity (no sperm), breast swelling (males)
XYY	1/1,000 (males)	Jacobs	Tall
XXX	1/1,500 (females)	Triple X	Tall and thin, menstrual irregularity
XO	1/5,000 (females)	Turner	Short stature, webbed neck, sexually undeveloped

of wheat that we use to make bread, *Triticum aestivum*, is a hexaploid (containing six sets of chromosomes) that arose from the union of diploid genomes from three closely related species (**Figure 15.20**). During the course of its cultivation, two diploid species must have interbred to produce a tetraploid, and then a third species interbred with the tetraploid to produce a hexaploid. Plant polyploids tend to exhibit a greater adaptability, which allows them to withstand harsher environmental conditions. Polyploid ornamental plants commonly produce larger flowers than their diploid counterparts.

Although polyploidy is often beneficial in plants, aneuploidy in all eukaryotic species usually has detrimental consequences for the characteristics of an organism. Why is aneuploidy usually detrimental? To answer this question, we need to consider the relationship between gene expression and chromosome number. For many, but not all genes, the level of gene expression is correlated with the number of genes per cell. For example, if a gene is carried on a chromosome that is present in a cell as three copies instead of two, approximately 150% of the normal amount of gene product is usually made. Alternatively, if only one copy of that gene is present due to a missing chromosome, only 50% of the gene product is typically made. For some genes, producing too much or too little of the gene product may not have adverse effects. However, for other genes, over- or underexpression may interfere with the proper functioning of cells.

Figure 15.20 Example of a polyploid plant Cultivated wheat, *Triticum aestivum*, is a hexaploid. It was derived from three different diploid species of grasses that originally were found in the Middle East and were cultivated by ancient farmers in that region. Modern varieties of wheat have been produced from this hexaploid species.

Summary of Key Concepts

15.1 The Eukaryotic Cell Cycle

- Cytogeneticists examine cells microscopically to determine their chromosome composition. A micrograph that shows the alignment of chromosomes from a given cell is called a karyotype. Eukaryotic chromosomes are inherited in sets. A diploid cell has two sets of chromosomes. The members of each pair are called homologs (Figure 15.1).
- The eukaryotic cell cycle consists of four phases called G_1 (first gap), S (synthesis of DNA), G_2 (second gap), and M (mitosis and cytokinesis). The G_1, S, and G_2 phases are collectively known as interphase (Figure 15.2).
- An interaction between cyclin and cyclin-dependent kinase (cdk) is necessary for cells to progress through the cell cycle. Checkpoint proteins sense the environmental conditions and the integrity of the genome and control whether or not the cell progresses through the cell cycle (Figure 15.3).
- Masui and Markert studied the maturation of frog oocytes to identify a substance necessary for oocytes to progress through the cell cycle. This substance was initially called maturation promoting factor (MPF) and was later identified as a complex of mitotic cyclin and cyclin-dependent kinase (Figures 15.4, 15.5).

15.2 Mitotic Cell Division

- In the process of mitotic cell division, a cell divides to produce two new cells (the daughter cells) that are genetically identical to the original cell.

- During S phase, eukaryotic chromosomes are replicated to produce a pair of identical sister chromatids that remain attached to each other (Figure 15.6).
- The mitotic spindle is a network of microtubules that plays a central role in chromosome sorting during cell division (Figure 15.7).
- Mitosis occurs in five phases called prophase, prometaphase, metaphase, anaphase, and telophase. During prophase, the chromosomes condense, and the nuclear envelope begins to dissociate. The spindle apparatus is completely formed by the end of prometaphase. At metaphase, the chromosomes are aligned in a single row along the metaphase plate of the spindle. During anaphase, the sister chromatids separate from each other and move to opposite poles; the poles themselves also move farther apart. During telophase, the chromosomes decondense, and the nuclear envelope re-forms (Figure 15.8).
- Cytokinesis, which occurs after mitosis, is the division of the cytoplasm to produce two distinct daughter cells. In animal cells, cytokinesis involves the formation of a cleavage furrow. In plant cells, two separate cells are produced by the formation of a cell plate (Figure 15.9).
- The analysis of cell division in prokaryotic cells and in simple and complex eukaryotes has revealed an evolutionary progression in which the protein FtsZ plays a role in bacterial cell division and microtubules gain new functions in eukaryotes, such as sorting chromosomes and promoting nuclear division (Figure 15.10).

15.3 Meiosis and Sexual Reproduction

- The process of meiosis begins with a diploid cell and produces four haploid cells with one set of chromosomes each (Figure 15.11).
- During prophase of meiosis, homologous pairs of sister chromosomes synapse, and crossing over occurs. After crossing over, chiasmata—the sites where crossing over occurs—become visible (Figure 15.12).
- Meiosis consists of two divisions—meiosis I and II—each composed of prophase, prometaphase, metaphase, anaphase, and telophase. During meiosis I, the homologs are separated into two different cells, and during meiosis II, the sister chromatids are separated into four different cells (Figure 15.13, Table 15.1).
- Animals are diploid-dominant species, whereas most fungi and some protists are haploid-dominant. Plants alternate between diploid and haploid forms (Figure 15.14).

15.4 Variation in Chromosome Structure and Number

- Chromosomes are classified as metacentric, submetacentric, acrocentric, and telocentric, based on their centromere location. Each type of chromosome can be uniquely identified by its banding pattern after staining (Figure 15.15).
- Deletions, duplications, inversions, and translocations are different ways in which mutations alter chromosome structure (Figure 15.16).
- A euploid organism has chromosomes that occur in complete sets. A polyploid organism has three or more sets of chromosomes. An organism that has one too many (trisomy) or one too few (monosomy) chromosomes is termed aneuploid. Aneuploidy can be caused by nondisjunction, an event in which the chromosomes do not separate properly during cell division (Figures 15.17, 15.18).
- Aneuploidy in humans is responsible for several types of inherited disorders, including Down syndrome (Table 15.2).
- Polyploid animals are relatively rare, but polyploid plants are common and tend to be larger and more robust than their diploid counterparts (Figures 15.19, 15.20).

Assess and Discuss

Test Yourself

1. In which phase of the cell cycle are chromosomes replicated?
   a. G_1 phase
   b. S phase
   c. M phase
   d. G_2 phase
   e. none of the above
2. If two chromosomes are homologous, they
   a. look similar under the microscope.
   b. have very similar DNA sequences.
   c. carry the same types of genes.
   d. may carry different versions of the same gene.
   e. are all of the above.
3. Checkpoints during the cell cycle are important because they
   a. allow the organelle activity to catch up to cellular demands.
   b. ensure the integrity of the cell's DNA.
   c. allow the cell to generate sufficient ATP for cellular division.
   d. are the only time DNA replication can occur.
   e. do all of the above.
4. Which of the following is a reason for mitotic cell division?
   a. asexual reproduction
   b. gamete formation in animals
   c. multicellularity
   d. all of the above
   e. both a and c
5. A replicated chromosome is composed of
   a. two homologous chromosomes held together at the centromere.
   b. four sister chromatids held together at the centromere.
   c. two sister chromatids held together at the centromere.
   d. four homologous chromosomes held together at the centromere.
   e. one chromosome with a centromere.
6. Which of the following is *not* an event of anaphase of mitosis?
   a. The nuclear envelope breaks apart.
   b. Sister chromatids separate.
   c. Kinetochore microtubules shorten, pulling the chromosomes to the poles.
   d. Polar microtubules push against each other, moving the poles farther apart.
   e. All of the above occur during anaphase.
7. A student is looking at cells under the microscope. The cells are from an organism that has a diploid number of 14. In one particular case, the cell has seven replicated chromosomes (sister chromatids) aligned at the metaphase plate of the cell. Which of the following statements accurately describes this particular cell?
   a. The cell is in metaphase of mitosis.
   b. The cell is in metaphase of meiosis I.
   c. The cell is in metaphase of meiosis II.
   d. All of the above are correct.
   e. Both b and c are correct.

8. Which of the following statements accurately describes a difference between mitosis and meiosis?
   a. Mitosis may produce diploid cells, whereas meiosis produces haploid cells.
   b. Homologous chromosomes synapse during meiosis but do not synapse during mitosis.
   c. Crossing over commonly occurs during meiosis, but it does not commonly occur during mitosis.
   d. All of the above are correct.
   e. Both a and c are correct.
9. During crossing over in meiosis I,
   a. homologous chromosomes are not altered.
   b. homologous chromosomes exchange genetic material.
   c. chromosomal damage occurs.
   d. genetic information is lost.
   e. cytokinesis occurs.
10. Aneuploidy may be the result of
   a. duplication of a region of a chromosome.
   b. inversion of a region of a chromosome.
   c. nondisjunction during meiosis.
   d. interspecies breeding.
   e. all of the above.

Conceptual Questions

1. Distinguish between homologous chromosomes and sister chromatids.
2. The *OCA2* gene, which influences eye color in humans, is found on chromosome 15. How many copies of this gene are found in the karyotype of Figure 15.1? Is it one, two, or four?
3.  A principle of biology is that *cells are the simplest unit of life*. Explain why mitosis is a key process in the formation of new cells.

Collaborative Questions

1. Why is it necessary for chromosomes to condense during mitosis and meiosis? What do you think might happen if chromosomes did not condense?
2. A diploid eukaryotic cell has 10 chromosomes (5 per set). As a group, take turns having one student draw the cell as it would look during a phase of mitosis, meiosis I, or meiosis II; then have the other students guess which phase it is.

Simple Patterns of Inheritance

16

An African girl with albinism. This condition results in very light skin and hair color.

Ntombi knew she looked different as long as she can remember. Born in Nigeria in 1997, she has accepted her appearance, though she still finds the occasional stare from strangers to be disturbing. Ntombi has albinism, a condition characterized by a total or a partial lack of pigmentation of the skin, hair, and eyes. As a result, she has very fair skin, blond hair, and blue eyes.* In contrast, her parents and three brothers have dark skin, black hair, and brown eyes, as do most of her relatives and most of the people in the city where she lives. Ntombi is very close to her aunt, who also has albinism.

Cases like Ntombi's have intrigued people for many centuries. How do we explain the traits that are found in people, plants, and other organisms? Can we predict what types of offspring two parents will produce? To answer such questions, researchers have studied the characteristics among related individuals and tried to make some sense of the data. Their goal is to understand **inheritance**—the acquisition of traits by their transmission from parent to offspring.

The first systematic attempt to understand inheritance was carried out by German plant breeder Joseph Kolreuter between 1761 and 1766. In crosses between two strains of tobacco plants, Kolreuter found that the offspring were usually intermediate in appearance between the two parents. He concluded that parents make equal genetic contributions to their offspring and that their genetic material blends together as it is passed to the next generation. This interpretation was consistent with the concept known as blending inheritance, which was incorrect but widely accepted at that time. In the late 1700s, Jean-Baptiste Lamarck, a French naturalist, hypothesized that physiological events (such as use or disuse) could modify traits and such modified traits would be inherited by offspring. For example, an individual who became adept at archery would pass that skill to his or her offspring. Overall, the prevailing view prior to the 1800s was that hereditary traits were rather malleable and could change and blend over the course of one or two generations.

In contrast, microscopic observations of chromosome transmission during mitosis and meiosis in the second half of the 19th century provided compelling evidence for **particulate inheritance**—the idea that the determinants of hereditary traits are transmitted in discrete units or particles from one generation to the next. Remarkably, this idea was first put forward in the 1860s by a researcher who knew nothing about chromosomes. Gregor Mendel used statistical analysis of carefully designed plant breeding experiments to arrive at the concept of a gene, which is broadly defined as a unit of heredity. Forty years later, through the convergence of Mendel's work and that of cell biologists, this concept became the foundation of the modern science of genetics.

In this chapter, we will consider inheritance patterns and how the transmission of genes is related to the transmission of chromosomes. We will first consider the fundamental genetic patterns known as Mendelian inheritance and the relationship of these patterns to the behavior of chromosomes during meiosis. We will then examine the distinctive inheritance patterns of genes located on the X chromosome, paying special attention to the work of Thomas Hunt Morgan, whose investigation of these patterns confirmed that genes are on chromosomes. Finally, we will explore the molecular basis of Mendelian inheritance and its variations and consider how probability calculations can be used to predict the outcome of crosses.

*In contrast to popular belief, most people with albinism have blue eyes, not pink eyes. This is particularly the case among Africans with albinism.

16.1 Mendel's Laws of Inheritance

Learning Outcomes:

1. List the advantages of using the garden pea to study inheritance.
2. Describe the difference between dominant and recessive traits.
3. Distinguish between genotype and phenotype.
4. **SciSKILLS »** Predict the outcome of genetic crosses using a Punnett square.
5. State Mendel's law of segregation and law of independent assortment.

Gregor Johann Mendel (**Figure 16.1**) grew up on a small farm in northern Moravia, then a part of the Austrian Empire and now in the Czech Republic. At the age of 21, he entered the Augustinian monastery of St. Thomas in Brno, and was ordained a priest in 1847. Mendel then worked for a short time as a substitute teacher, but to continue teaching he needed a license. Surprisingly, he failed the licensing exam due to poor answers in physics and natural history, so he enrolled at the University of Vienna to expand his knowledge in these two areas. Mendel's training in physics and mathematics taught him to perceive the world as an orderly place, governed by natural laws that could be stated as simple mathematical relationships.

In 1856, Mendel began his historic studies on pea plants. For 8 years, he analyzed thousands of pea plants that he grew on a small plot in his monastery garden. In 1866, he published the results of his work in a paper entitled "Experiments on Plant Hybrids." This paper was largely ignored by scientists at that time, partly because of its title. Also, Mendel was clearly ahead of his time. During this period, biology had not yet become a quantitative, experimental science. In addition, the behavior of chromosomes during mitosis and meiosis, which provides a framework for understanding inheritance patterns, had yet to be studied. Prior to his death in 1884, Mendel reflected, "My scientific work has brought me a great deal of satisfaction and I am convinced it will be appreciated before long by the whole world." Sixteen years later, in 1900, Mendel's work was independently rediscovered by three biologists with an interest in plant genetics: Hugo de Vries of Holland, Carl Correns of Germany, and Erich von Tschermak of Austria. Within a few years, the influence of Mendel's landmark studies was felt around the world.

In this section, we will examine Mendel's experiments and how they led to the formulation of basic genetic principles known as Mendel's laws. We will see that these principles apply not only to the pea plants Mendel studied, but also to a wide variety of sexually reproducing organisms, including humans.

Mendel Chose the Garden Pea to Study Inheritance

When two individuals of the same species with different characteristics are bred or crossed to each other, this is called **hybridization**, and the offspring are referred to as hybrids. For example, a hybridization experiment could involve breeding a purple-flowered plant to a white-flowered plant. Mendel was particularly intrigued by the consistency with which offspring of such crosses showed characteristics of one or the other parent in successive generations. His intellectual foundation in physics and the natural sciences led him to consider that this regularity might be rooted in natural laws that could be expressed mathematically. To uncover these laws, he carried out quantitative experiments in which he carefully analyzed the numbers of offspring carrying specific traits.

Figure 16.1 **Gregor Johann Mendel.**

Mendel chose the garden pea, *Pisum sativum*, to investigate the natural laws that govern inheritance. Why did he choose this species? Several properties of the garden pea were particularly advantageous for studying inheritance. First, it was available in many varieties that differed in characteristics, such as the appearance of seeds, pods, flowers, and stems. Such general features of an organism are called **characters**. **Figure 16.2** illustrates the seven characters that Mendel eventually chose to follow in his breeding experiments. Each of these characters was found in two discrete variants. For example, one character he followed was height, which had the variants known as tall and dwarf. Another was seed color, which had the variants yellow and green. A **trait** is an identifiable characteristic of an organism. The term trait usually refers to a variant for a character.* For example, seed color is a character, and green and yellow seed colors are traits.

A second important feature of garden peas is they are normally self-fertilizing. In **self-fertilization**, a female gamete is fertilized by a male gamete from the same plant. Like many flowering plants, peas have male and female sex organs in the same flower (**Figure 16.3**). Male gametes (sperm cells) are produced within pollen grains, which are formed in structures called stamens. Female gametes (egg cells) are produced in structures called ovules, which form within an organ called an ovary. For fertilization to occur, a pollen grain must land on the receptacle called a stigma, enabling a sperm to migrate to an ovule and fuse with an egg cell. In peas, the stamens and the ovaries are enclosed by a modified petal, an arrangement that greatly favors self-fertilization. Self-fertilization makes it easy to produce plants that breed true for a given trait, meaning the trait does not vary from generation to generation. For example, if a pea plant with yellow seeds breeds true for seed color, all the plants that grow from these seeds will also produce yellow seeds. A variety that continues to exhibit the same trait after several generations of self-fertilization is called a **true-breeding line**. Prior to conducting the studies described in this chapter, Mendel had already established that the seven characters he chose to study were true-breeding in the strains of pea plants he had obtained.

*Geneticists may also use the term trait to refer to a character.

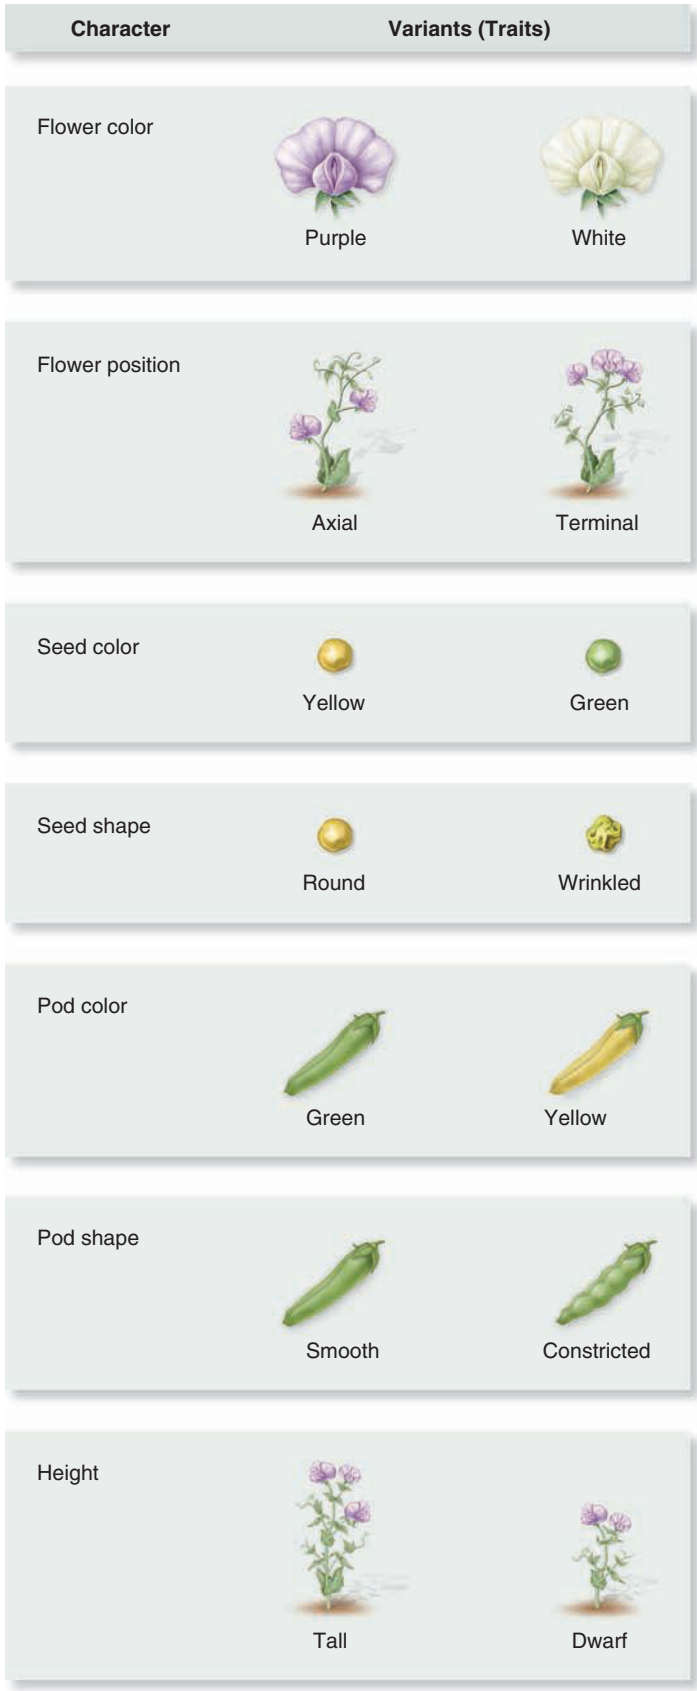

Figure 16.2 **The seven characters that Mendel studied.**

BIOLOGY PRINCIPLE **The genetic material provides a blueprint for reproduction.** The traits that Mendel studied in pea plants are governed by the genetic material of this species.

Concept Check: *Is having blue eyes a character, a variant, or both?*

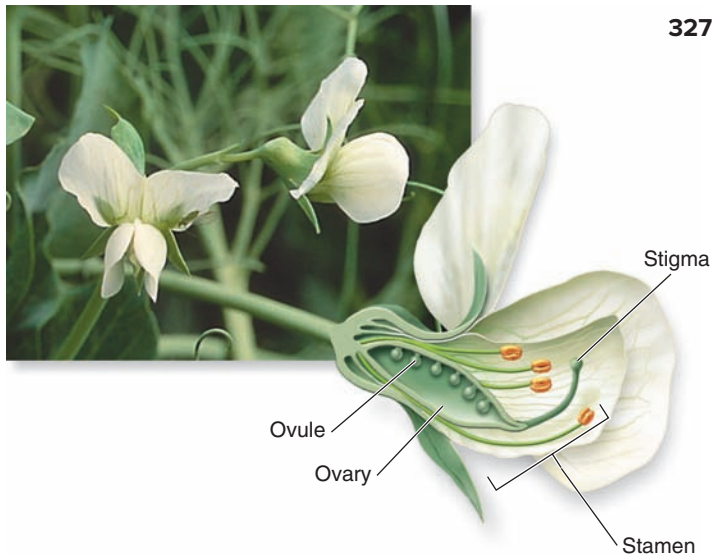

Figure 16.3 **Flower structure in pea plants.** The pea flower produces both male and female gametes. Sperm form in the pollen produced within the stamens; egg cells form in ovules within the ovary. A modified petal encloses the stamens and stigma, encouraging self-fertilization.

A third reason for using garden peas in hybridization experiments is the ease of making crosses: The flowers are fairly large and easy to manipulate. In some cases, Mendel wanted his pea plants to self-fertilize, but in others, he wanted to cross plants that differed with respect to some character, a process called hybridization, or **cross-fertilization**. In garden peas, cross-fertilization requires placing pollen from one plant onto the stigma of a flower on a different plant (**Figure 16.4**). Mendel would pry open an immature flower and remove the stamens before they produced pollen, so the flower could not self-fertilize. He then used a paintbrush to transfer pollen from another plant to the stigma of the flower that had its stamens removed. In this way, Mendel was able to cross-fertilize any two of his true-breeding pea plants and obtain any type of hybrid he wanted.

By Following the Inheritance Pattern of Single Traits, Mendel's Work Revealed the Law of Segregation

Mendel began his investigations by studying the inheritance patterns of pea plants that differed in a single character. A cross in which an experimenter follows the variants of only one character is called a **single-factor cross**. As an example, we will consider a single-factor cross in which Mendel followed the tall and dwarf variants for height (**Figure 16.5**). The left side of Figure 16.5a shows his experimental approach. The true-breeding parents are termed the **P generation** (parental generation), and their offspring constitute the **F_1 generation** (first filial generation, from the Latin *filius*, meaning son). When the true-breeding parents differ in a single character, their F_1 offspring are called single-trait hybrids, or **monohybrids**. When Mendel crossed true-breeding tall and dwarf plants, he observed that all plants of the F_1 generation were tall.

Next, Mendel followed the transmission of this character for a second generation. To do so, he allowed the F_1 monohybrids to self-fertilize, producing a generation called the **F_2 generation** (second filial generation). The dwarf trait reappeared in the F_2 offspring:

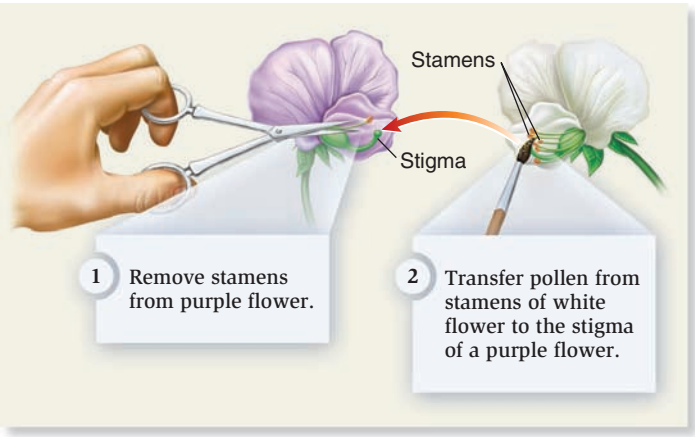

Figure 16.4 **A procedure for cross-fertilizing pea plants.**

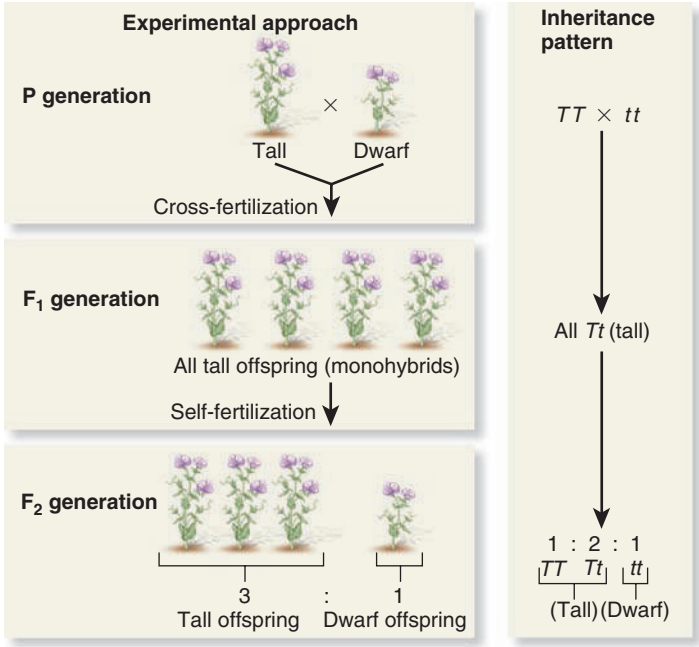

Concept Check: *Why are the stamens removed from the purple flower?*

Three-fourths of the plants were tall and one-fourth were dwarf. Mendel obtained similar results for each of the seven characters he studied, as shown in the data of Figure 16.5b. A quantitative analysis of his data allowed Mendel to postulate three important ideas about the properties of traits and their transmission from parents to offspring:

1. Traits may exist in two forms, dominant and recessive.
2. An individual carries two genes for a given character, and genes have variant forms (now called **alleles**).
3. The two alleles of a gene separate during the process that gives rise to haploid cells and gametes, so each sperm and egg receives only one allele.

Dominant and Recessive Traits Perhaps the most surprising outcome of Mendel's work was that the data argued strongly against the prevailing notion of blending inheritance. In each of the seven cases, the F_1 generation displayed a trait distinctly like one of the two parents rather than an intermediate trait. Using genetic terms that Mendel originated, we describe the alternative traits as dominant and recessive. The term **dominant** describes the displayed trait, whereas the term **recessive** describes a trait that is masked by the presence of a dominant trait. Tall stems and purple flowers are examples of dominant traits; dwarf stems and white flowers are examples of recessive traits. In this case, we say that tall is dominant over dwarf, and purple is dominant over white.

Genes and Alleles Mendel's results were consistent with particulate inheritance, in which the determinants of traits are inherited as unchanging, discrete units. In all seven cases, the recessive trait reappeared in the F_2 generation: Most F_2 plants displayed the dominant trait, whereas a smaller proportion showed the recessive trait. This observation led Mendel to conclude that the genetic determinants of traits are "unit factors" that are passed intact from generation to generation. These unit factors are what we now call **genes** (from the Greek *genos*, meaning birth), a term coined by the Danish botanist Wilhelm Johannsen in 1909. Mendel postulated that every individual carries two genes for a given character and that the gene for each character in his pea plants exists in two variant forms, which we now call alleles. For example, the gene controlling height in Mendel's pea plants occurs in two variants, called the tall allele and the dwarf allele. The right side of Figure 16.5a shows Mendel's conclusions, using genetic symbols (italic letters) that were adopted later. The letters *T* and *t* represent the alleles of the gene for plant height. By convention, the uppercase letter represents the dominant allele (in this case, tall), and the same letter in lowercase represents the recessive allele (dwarf).

(a) Mendel's protocol for making single-factor crosses

THE DATA

P cross	F_1 generation	F_2 generation	Ratio
Purple × white flowers	All purple	705 purple, 224 white	3.15:1
Axial × terminal flowers	All axial	651 axial, 207 terminal	3.14:1
Yellow × green seeds	All yellow	6,022 yellow, 2,001 green	3.01:1
Round × wrinkled seeds	All round	5,474 round, 1,850 wrinkled	2.96:1
Green × yellow pods	All green	428 green, 152 yellow	2.82:1
Smooth × constricted pods	All smooth	882 smooth, 299 constricted	2.95:1
Tall × dwarf stem	All tall	787 tall, 277 dwarf	2.84:1
Total	**All dominant**	**14,949 dominant, 5,010 recessive**	**2.98:1**

(b) Mendel's observed data for all 7 traits

Figure 16.5 **Mendel's analyses of single-factor crosses.**

Concept Check: *Why do offspring of the F_1 generation exhibit only one variant of each character?*

Segregation of Alleles When Mendel compared the numbers of F_2 offspring exhibiting dominant and recessive traits, he noticed a recurring pattern. Although some experimental variation occurred, he always observed a 3:1 ratio between the dominant and the recessive trait (Figure 16.5b). How did Mendel interpret this ratio? He concluded that each F_1 plant carried two versions (alleles) of a gene affecting height (or another character) and that the two alleles carried by an F_1 plant separate, or segregate, from each other during

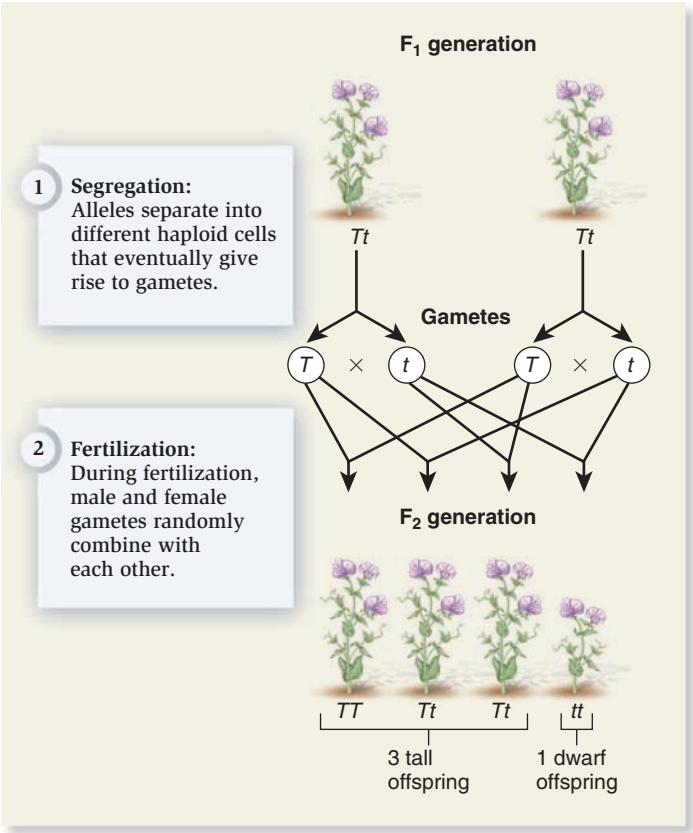

Figure 16.6 How the law of segregation explains Mendel's observed ratios. The segregation of alleles in the F_1 generation gives rise to gametes that carry just one of the two alleles. These gametes combine randomly during fertilization, producing the allele combinations *TT, Tt*, and *tt* in the F_2 offspring. The combination *Tt* occurs twice as often as either of the other two combinations because it can be produced in two different ways. The *TT* and *Tt* offspring are tall, whereas the *tt* offspring are dwarf.

Concept Check: *What is ratio of the T allele to the t allele in the F_2 generation? Does this ratio differ from the 3:1 phenotype ratio? If so, explain why.*

the process that gives rise to gametes. Therefore, each sperm or egg carried only one allele. The diagram in **Figure 16.6** shows that the segregation of the F_1 alleles should result in equal numbers of gametes carrying the dominant allele (*T*) and the recessive allele (*t*). If these gametes combine with one another randomly at fertilization, as shown in the figure, this would account for the 3:1 ratio of the F_2 generation. Note that a *Tt* individual can be produced by two different combinations of alleles—the *T* allele can come from the male gamete and the *t* allele from the female gamete, or vice versa. This accounts for the observation that *Tt* offspring are produced twice as often as either *TT* or *tt*. The results of the study of traits in pea plants gave rise to **Mendel's law of segregation**, which can be stated as follows:

> *The two alleles of a gene separate (segregate) from each other during the process that gives rise to gametes, so every gamete receives only one allele.*

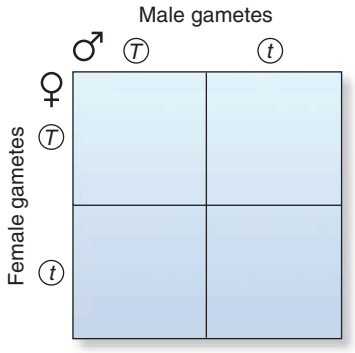
Genotype Describes an Organism's Genetic Makeup, Whereas Phenotype Describes Its Characteristics

To continue our discussion of Mendel's results, we need to introduce a few more genetic terms. The term **genotype** refers to the genetic composition of an individual. In the example shown in Figure 16.5a, *TT* and *tt* are the genotypes of the P generation, and *Tt* is the genotype of the F_1 generation. In the P generation, both parents are true-breeding plants, which means that each has identical copies of the allele of the gene for height. An individual with two identical alleles of a gene is said to be **homozygous** with respect to that gene. In the specific cross we are considering, the tall plant (*TT*) is homozygous for *T*, and the dwarf plant (*tt*) is homozygous for *t*. In contrast, a **heterozygous** individual carries two different alleles of a gene. Plants of the F_1 generation are heterozygous, with the genotype *Tt*, because every individual carries one copy of the tall allele (*T*) and one copy of the dwarf allele (*t*). The F_2 generation includes both homozygous individuals (homozygotes) and heterozygous individuals (heterozygotes).

The term **phenotype** refers to the characteristics of an organism that are the result of the expression of its genes. In the example in Figure 16.5a, one of the parent plants is phenotypically tall, and the other is phenotypically dwarf. Although the F_1 offspring are heterozygous (*Tt*), they are phenotypically tall because each of them has a copy of the dominant tall allele. In contrast, the F_2 plants display both phenotypes in a ratio of 3:1.

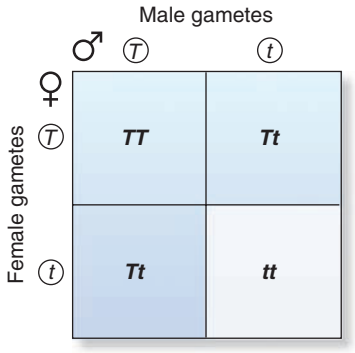
A Punnett Square Is Used to Predict the Outcome of Crosses

A common way to predict the outcome of simple genetic crosses is to make a **Punnett square**, a method originally proposed by the British geneticist Reginald Punnett. To construct a Punnett square, you must know the genotypes of the parents. What follows is a step-by-step description of the Punnett-square approach, using a cross of heterozygous tall plants.



Step 1. *Write down the genotypes of both parents.* In this example, a heterozygous tall plant is crossed to another heterozygous tall plant. The plant providing the pollen is considered the male parent and the plant providing the eggs, the female parent. (In self-pollination, a single individual produces both types of gametes.)

Male parent: *Tt*
Female parent: *Tt*



Step 2. *Write down the possible gametes that each parent can make.* Remember the law of segregation tells us that a gamete contains only one copy of each allele.

Male gametes: *T* or *t*
Female gametes: *T* or *t*

Step 3. *Create an empty Punnett square.* The number of columns equals the number of male gametes, and the number of rows equals the number of female gametes. Our example has two rows and two columns. Place the male gametes across the top of the Punnett square and the female gametes along the side.

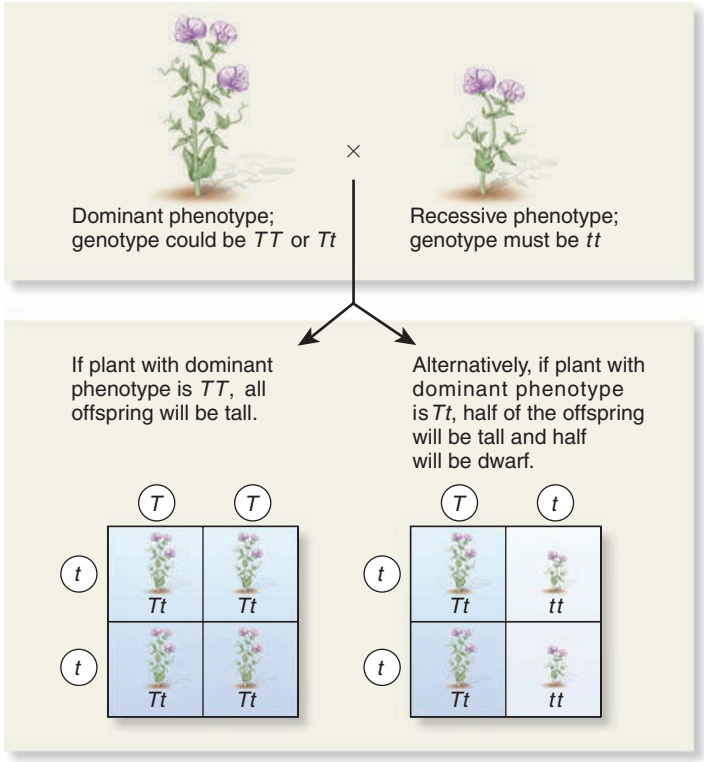
Step 4. *Fill in the possible genotypes of the offspring by combining the alleles of the gametes in the empty boxes.*

Step 5. *Determine the relative proportions of genotypes and phenotypes of the offspring.* The genotypes are obtained directly from the Punnett square. In this example, the genotype ratio is 1*TT* : 2*Tt* : 1*tt*. To determine the phenotypes, you must know which allele is dominant. For plant height, *T* (tall) is dominant to *t* (dwarf). The genotypes *TT* and *Tt* are tall, whereas the genotype *tt* is dwarf. Therefore, our Punnett square shows us that the phenotype ratio is expected to be 3 tall : 1 dwarf.

A Testcross Is Used to Determine an Individual's Genotype

When a character has two variants, one of which is dominant over the other, we know that an individual with a recessive phenotype is homozygous for the recessive allele. A dwarf pea plant, for example, must have the genotype *tt*. But an individual with a dominant phenotype may be either homozygous or heterozygous—a tall pea plant may have the genotype *TT* or *Tt*. How can we distinguish between these two possibilities? Mendel devised a method called a **testcross** to address this question. In a testcross, the researcher crosses the individual of interest to a homozygous recessive individual and observes the phenotypes of the offspring.

Figure 16.7 shows how this procedure can be used to determine the genotype of a tall pea plant. If the testcross produces some dwarf offspring, as shown in the Punnett square on the right side, these offspring must have two copies of the recessive allele, one inherited from each parent. Therefore, the tall parent must be a heterozygote, with the genotype *Tt*. Alternatively, if all of the offspring are tall, as shown in the Punnett square on the left, the tall parent is likely to be a homozygote, with the genotype *TT*.



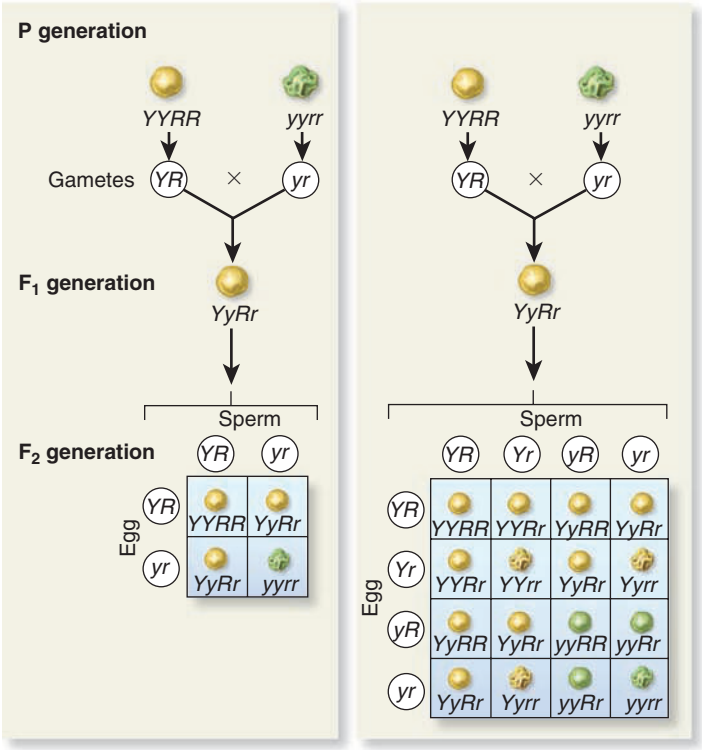


Figure 16.7 A testcross. The purpose of this experiment is to determine if the organism with the dominant phenotype, in this case a tall pea plant, is a homozygote (*TT*) or a heterozygote (*Tt*).

Concept Check: Let's suppose you had a plant with purple flowers and unknown genotype and conducted a testcross to determine its genotype. You obtained 41 offspring plants: 20 with white flowers and 21 with purple flowers. What was the genotype of the original purple-flowered plant?

Analyzing the Inheritance Pattern of Two Characters Demonstrated the Law of Independent Assortment

Mendel's analysis of single-factor crosses suggested that traits are inherited as discrete units and that the alleles for a given gene segregate during the formation of haploid cells. To obtain additional insights into how genes are transmitted from parents to offspring, Mendel conducted crosses in which he simultaneously followed the inheritance of two different characters. A cross of this type is called a **two-factor cross**. We will examine a two-factor cross in which Mendel simultaneously followed the inheritance of seed color and seed shape (**Figure 16.8**). He began by crossing strains of pea plants that bred true for both characters. The plants of one strain had yellow, round seeds, and plants of the other strain had green, wrinkled seeds. He then allowed the F_1 offspring to self-fertilize and observed the phenotypes of the F_2 generation.

What are the possible patterns of inheritance for two characters? One possibility is that the two genes are linked in some way, so variants that occur together in the parents are always inherited as a unit. In our example, the allele for yellow seeds (*Y*) would always be inherited with the allele for round seeds (*R*), and the alleles for green seeds (*y*) would always be inherited with the allele for wrinkled seeds (*r*), as shown in Figure 16.8a. A second possibility is that the two genes are independent of one another, so their alleles are randomly distributed into gametes (Figure 16.8b). By following the transmission pattern of

(a) Hypothesis: linked assortment

(b) Hypothesis: independent assortment

P cross	F_1 generation	F_2 generation
Yellow, round seeds × Green, wrinkled seeds	Yellow, round seeds	315 yellow, round seeds 101 yellow, wrinkled seeds 108 green, round seeds 32 green, wrinkled seeds

(c) The data observed by Mendel

Figure 16.8 Two hypotheses for the assortment of two different genes. In a cross between two true-breeding pea plants, one with yellow, round seeds and one with green, wrinkled seeds, all of the F_1 offspring have yellow, round seeds. When the F_1 offspring self-fertilize, the two hypotheses predict different ratios of phenotypes in the F_2 generation. **(a)** Linked assortment, in which parental alleles stay associated with each other, or **(b)** independent assortment, in which each allele assorts independently. **(c)** Mendel's data supported the independent assortment hypothesis.

Concept Check: What ratio of offspring phenotypes would have occurred if the linked assortment hypothesis had been correct?

two characters simultaneously, Mendel could determine whether the genes that determine seed shape and seed color assort (are distributed) together as a unit or independently of each other.

What experimental results could Mendel predict for each of these two models? The two homozygous plants of the P generation can produce only two kinds of gametes, *YR* and *yr*, so in either case the F_1 offspring would be heterozygous for both genes; that is, they would have the genotype *YyRr*. Because Mendel knew from his earlier experiments that yellow was dominant over green and round over wrinkled, he could predict that all the F_1 plants would have yellow, round seeds. In contrast, as shown in Figure 16.8, the ratios he obtained in the F_2 generation would depend on whether the alleles of both genes assort together or independently.

If the parental genes are linked, as in Figure 16.8a, the F_1 plants could produce gametes that are only *YR* or *yr*. These gametes would combine to produce offspring with the genotypes *YYRR* (yellow, round), *YyRr* (yellow, round), and *yyrr* (green, wrinkled). The ratio of phenotypes would be 3 yellow, round to 1 green, wrinkled. Every F_2 plant would be phenotypically like one P-generation plant or the other. None would display a new combination of the parental traits. However, if the alleles assorted independently, the F_2 generation would have a wider range of genotypes and phenotypes, as shown by the Punnett square in Figure 16.8b. In this case, each F_1 parent produces four kinds of gametes—*YR, Yr*, *yR*, and *yr*—instead of two, so the square is constructed with four rows on each side and shows 16 possible genotypes. The F_2 generation includes plants with yellow, round seeds; yellow, wrinkled seeds; green, round seeds; and green, wrinkled seeds, in a ratio of 9:3:3:1.

The actual results of this two-factor cross are shown in Figure 16.8c. Crossing the true-breeding parents produced **dihybrid** offspring—offspring that are hybrids with respect to both traits. These F_1 dihybrids all had yellow, round seeds, confirming that yellow and round are dominant traits. This result was consistent with either hypothesis. However, the data for the F_2 generation were consistent only with the independent assortment hypothesis. The F_2 offspring showed four different phenotypes in a ratio that was reasonably close to 9:3:3:1.

In his original studies, Mendel reported that he had obtained similar results for every pair of characters he analyzed. This work gave rise to **Mendel's law of independent assortment**, which can be stated as follows:

> *The alleles of different genes assort independently of each other during the process that gives rise to gametes.*

Independent assortment means that a specific allele for one gene may be found in a gamete regardless of which allele for a different gene is found in the same gamete. In our example, the yellow and green alleles assort independently of the round and wrinkled alleles. The union of gametes from F_1 plants carrying these alleles produces the F_2 genotype and phenotype ratios shown in Figure 16.8b.

As we will see in Chapter 17, not all two-factor crosses exhibit independent assortment. In some cases, the alleles of two genes that are physically located near each other on the same chromosome do not assort independently.

16.2 The Chromosome Theory of Inheritance

Learning Outcomes:

1. Outline the principles of the chromosome theory of inheritance.
2. Relate the behavior of chromosomes during meiosis to Mendel's laws of inheritance.

Mendel's studies with pea plants eventually led to the concept of a gene, which is the foundation for our understanding of inheritance. However, at the time of Mendel's work, the physical nature and location of genes were a complete mystery. The idea that inheritance has a physical basis was not even addressed until 1883, when German

biologist August Weismann and Swiss botanist Karl Nägeli championed the idea that a substance in living cells is responsible for the transmission of hereditary traits. This idea challenged other researchers to identify the genetic material. Several scientists, including the German biologists Eduard Strasburger and Walther Flemming, observed dividing cells under the microscope and suggested that the chromosomes are the carriers of the genetic material. As we now know, the genetic material is the DNA within chromosomes.

In the early 1900s, the idea that chromosomes carry the genetic material dramatically unfolded as researchers continued to study the processes of mitosis, meiosis, and fertilization. It became increasingly clear that the characteristics of organisms are rooted in the continuity of cells during the life of an organism and from one generation to the next. Several scientists noted striking parallels between the segregation and assortment of traits noted by Mendel and the behavior of chromosomes during meiosis. Among these scientists were German biologist Theodor Boveri and American biologist Walter Sutton, who independently proposed the chromosome theory of inheritance. According to this theory, the inheritance patterns of traits can be explained by the transmission of chromosomes during meiosis and fertilization.

A modern view of the **chromosome theory of inheritance** consists of a few fundamental principles:

1. Chromosomes contain DNA, which is the genetic material. Genes are found within the chromosomes.
2. Chromosomes are replicated and passed from parent to offspring. They are also passed from cell to cell during the development of a multicellular organism.
3. The nucleus of a diploid cell contains two sets of chromosomes, which are found in homologous pairs. The maternal and paternal sets of homologous chromosomes are functionally equivalent; each set carries a full complement of genes.
4. At meiosis, one member of each chromosome pair segregates into one daughter nucleus, and its homolog segregates into the other daughter nucleus. During the formation of haploid cells, the members of different chromosome pairs segregate independently of each other.
5. Gametes are haploid cells that combine to form a diploid cell during fertilization, with each gamete transmitting one set of chromosomes to the offspring.

In this section, we will relate the chromosome theory of inheritance to Mendel's laws of inheritance.

Mendel's Law of Segregation Is Explained by the Segregation of Homologous Chromosomes During Meiosis

Now that you have an understanding of the basic tenets of the chromosome theory of inheritance, let's relate these ideas to Mendel's laws of inheritance. To do so, it will be helpful to introduce another genetic term. The physical location of a gene on a chromosome is called the gene's **locus** (plural, loci). As shown in **Figure 16.9**, each member of a homologous chromosome pair carries an allele of the same gene at the same locus. The individual in this example is heterozygous (*Tt*), so each homolog has a different allele.

How can we relate the chromosome theory of inheritance to Mendel's law of segregation? **Figure 16.10** follows a pair of homologous

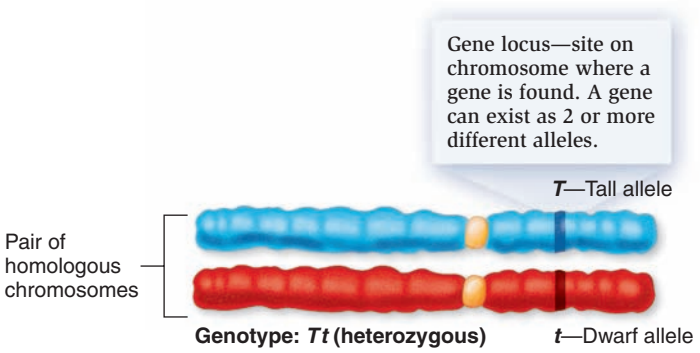

Figure 16.9 A gene locus. The locus (location) of a gene is the same for each member of a homologous pair, whether the individual is homozygous or heterozygous for that gene. This individual is heterozygous (*Tt*) for a gene for plant height.

BioConnections: Look back at Section 15.3. Explain the relationship between sexual reproduction and homologous chromosomes.

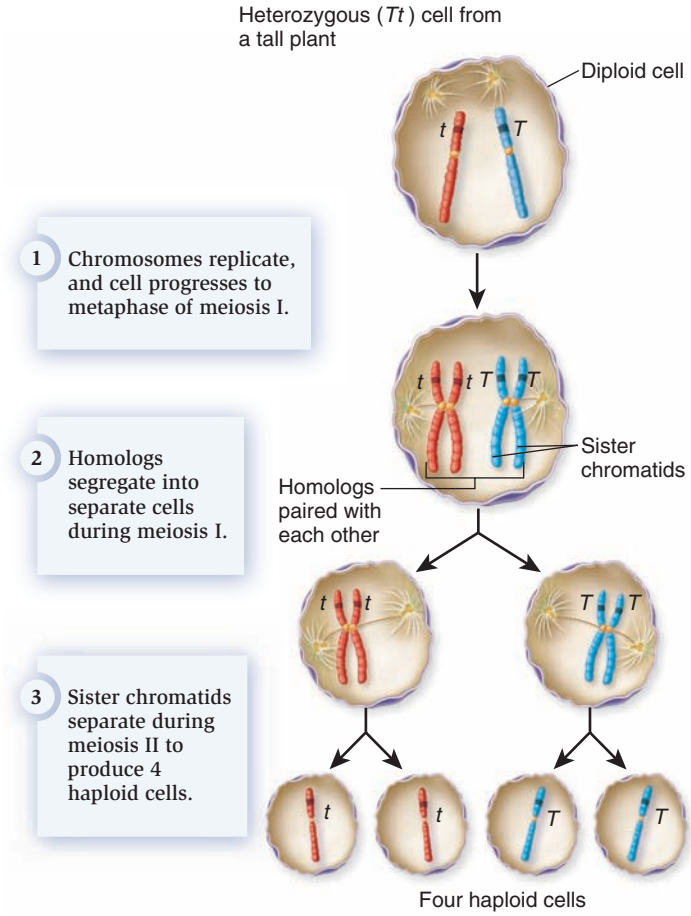

Figure 16.10 The chromosomal basis of allele segregation. This example shows a pair of homologous chromosomes in a cell of a pea plant. The blue chromosome was inherited from the male parent, and the red chromosome was inherited from the female parent. This individual is heterozygous (*Tt*) for a height gene. The two homologs segregate from each other during meiosis, leading to segregation of the tall allele (*T*) and the dwarf allele (*t*) into different haploid cells. Note: For simplicity, this diagram shows a single pair of homologous chromosomes, though eukaryotic cells typically have several different pairs of homologous chromosomes.

BioConnections: When we say that alleles segregate, what does the word segregate mean? How is this related to meiosis, shown in Figure 15.13?

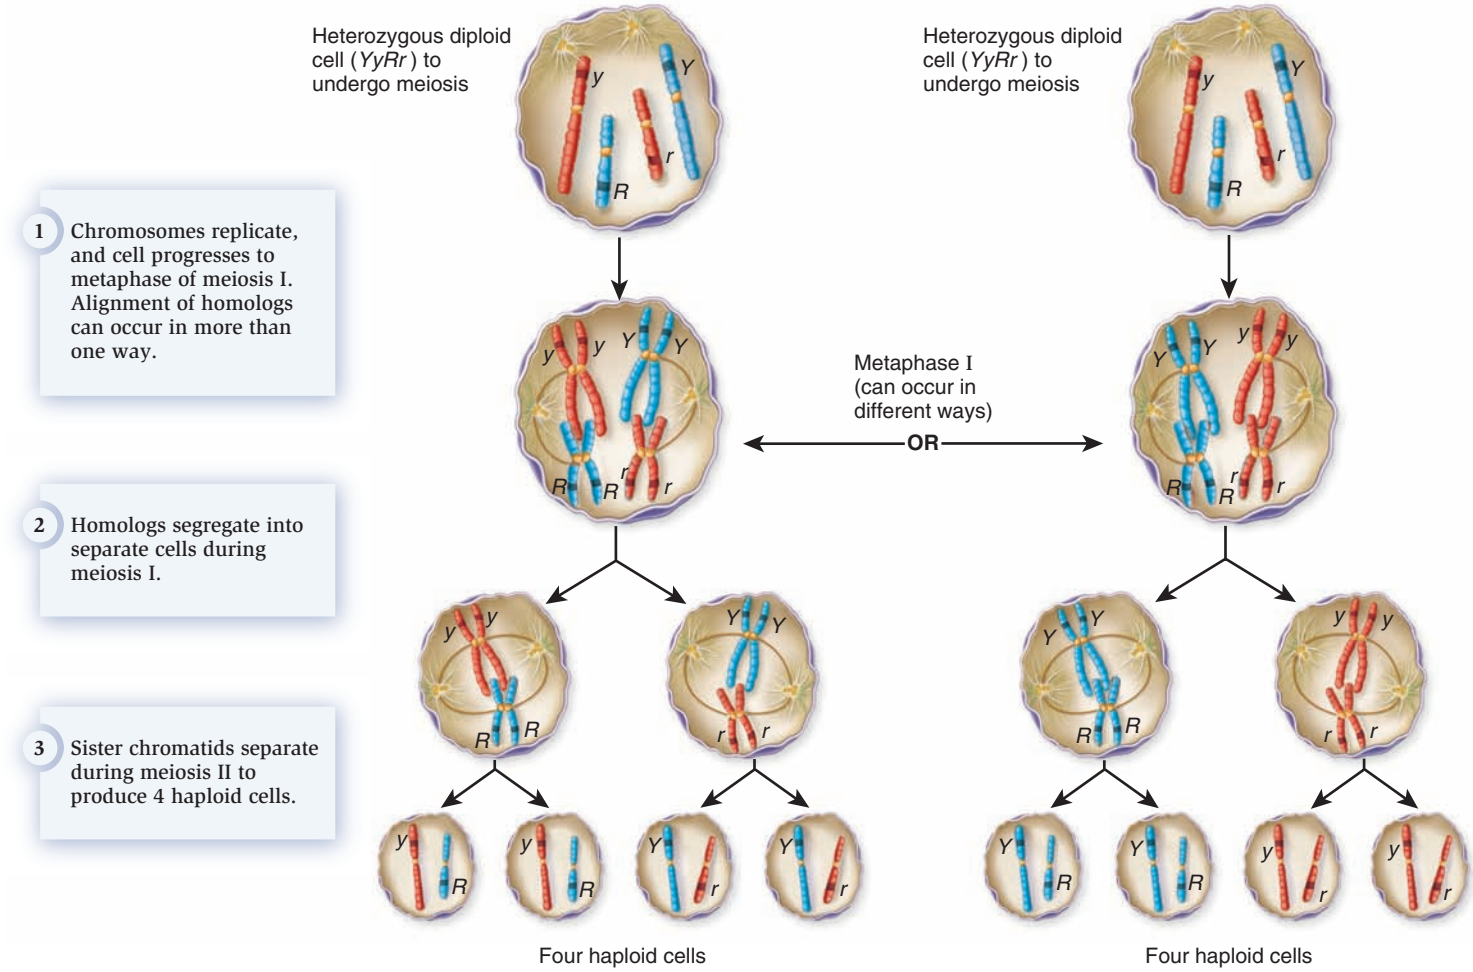

Figure 16.11 The chromosomal basis of independent assortment. The alleles for seed color (*Y* or *y*) and seed shape (*R* or *r*) in peas are on different chromosomes. During metaphase of meiosis I, different arrangements of the two chromosome pairs lead to different combinations of the alleles in the resulting haploid cells. On the left, the chromosome carrying the recessive *y* allele has segregated with the chromosome carrying the dominant *R* allele. On the right, the two chromosomes carrying the dominant alleles (*Y* and *R*) have segregated together. Note: For simplicity, this diagram shows only two pairs of homologous chromosomes, though eukaryotic cells typically have several different pairs of homologous chromosomes.

Concept Check: *Let's suppose that a cell is heterozygous for three different genes (Aa, Bb, and Cc) and that each gene is on a different chromosome. How many different ways can these three pairs of homologous chromosomes align themselves during metaphase I, and how many different types of gametes can be produced?*

chromosomes through the events of meiosis. This example involves a pea plant, heterozygous for height, *Tt*. The top of Figure 16.10 shows the two homologous chromosomes prior to DNA replication. When a cell prepares to divide, the homologs replicate to produce pairs of sister chromatids. Each chromatid carries a copy of the allele found on the original homolog, either *T* or *t*. During meiosis I, the homologs, each consisting of two sister chromatids, pair up and then segregate into two daughter cells. One of these cells has two copies of the *T* allele, and the other has two copies of the *t* allele. The sister chromatids separate during meiosis II, which produces four haploid cells. The end result of meiosis is that each haploid cell has a copy of just one of the two original homologs. Two of the cells have a chromosome carrying the *T* allele, and the other two have a chromosome carrying the *t* allele at the same locus. If the haploid cells shown at the bottom of Figure 16.10 give rise to gametes that combine randomly during fertilization, they produce diploid offspring with the genotype and phenotype ratios shown earlier in Figure 16.6.

Mendel's Law of Independent Assortment Is Explained by the Independent Alignment of Different Chromosomes During Meiosis

How can we relate the chromosome theory of inheritance to Mendel's law of independent assortment? **Figure 16.11** shows the alignment and segregation of two pairs of chromosomes in a pea plant. One pair carries the gene for seed color: The yellow allele (*Y*) is on one chromosome, and the green allele (*y*) is on its homolog. The other pair of chromosomes carries the gene for seed shape: One member of the pair has the round allele (*R*), whereas its homolog carries the wrinkled allele (*r*). Therefore, this individual is heterozygous for both genes, with the genotype *YyRr*.

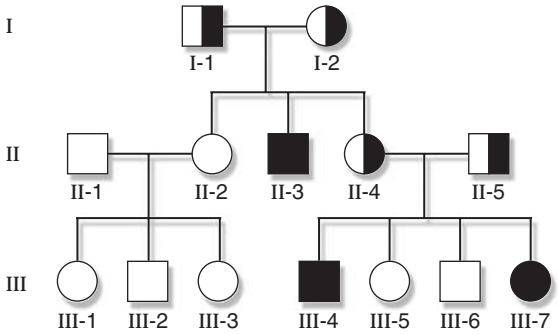
When meiosis begins, the DNA in each chromosome has already replicated, producing two sister chromatids. At metaphase I of meiosis, the two pairs of chromosomes randomly align themselves along the metaphase plate. This alignment can occur in two equally

probable ways, shown on the two sides of the figure. On the left, the chromosome carrying the *y* allele is aligned on the same side of the metaphase plate as the chromosome carrying the *R* allele; *Y* is aligned with *r*. On the right, the opposite has occurred: *Y* is aligned with *R*, and *y* is with *r*. In each case, the chromosomes that aligned on the same side of the metaphase plate segregate into the same daughter cell. In this way, the random alignment of chromosome pairs during meiosis I leads to the independent assortment of alleles found on different chromosomes. For two genes found on different chromosomes, each with two variant alleles, meiosis produces four allele combinations in equal numbers (*yR*, *Yr*, *YR*, and *yr*), as seen at the bottom of the figure.

If a *YyRr* (dihybrid) plant undergoes self-fertilization, any two gametes can combine randomly during fertilization. Because four kinds of gametes are made, 4^2 or 16 possible allele combinations are possible in the offspring. These genotypes, in turn, produce four phenotypes in a 9:3:3:1 ratio, as seen earlier in Figure 16.8. This ratio is the expected outcome when a heterozygote for two genes on different chromosomes undergoes self-fertilization.

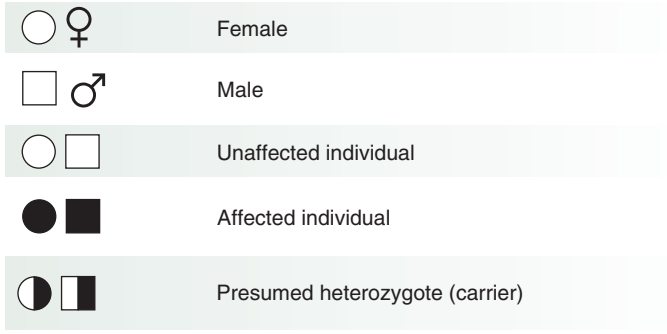
But what if two different genes are located on the same chromosome? In this case, the transmission pattern may not conform to the law of independent assortment. We will discuss this phenomenon, known as linkage, in Chapter 17.

16.3 Pedigree Analysis of Human Traits



Learning Outcomes:

1. **SciSKILLS »** Apply pedigree analysis to deduce inheritance patterns in humans.
2. Distinguish between recessively inherited disorders and dominantly inherited disorders.



As we have seen, Mendel conducted experiments by making selective crosses of pea plants and analyzing large numbers of offspring. Later geneticists also relied on crosses of experimental organisms, especially fruit flies (*Drosophila melanogaster*). However, geneticists studying human traits cannot use this approach, for ethical and practical reasons. Instead, human geneticists must rely on information from family trees, or pedigrees. In this approach, called **pedigree analysis**, an inherited trait is analyzed over the course of a few generations in one family. The results of this method may be less definitive than the results of breeding experiments because the small size of human families may lead to large sampling errors. Nevertheless, a pedigree analysis often provides important clues concerning human inheritance.

Pedigree analysis has been used to understand the inheritance of human genetic diseases that follow simple Mendelian patterns. Many genes that play a role in disease exist in two forms: the common allele and a rare allele that has arisen by mutation. The disease symptoms are associated with the mutant allele. Pedigree analysis allows us to determine whether the mutant allele is dominant or recessive and to predict the likelihood of an individual being affected.

Let's consider a recessive condition to illustrate pedigree analysis. The pedigree in **Figure 16.12** concerns a human genetic disease known as cystic fibrosis (CF), which involves a mutation in a gene

(a) Human pedigree showing cystic fibrosis

(b) Symbols used in a human pedigree

Figure 16.12 A family pedigree for a recessive trait. Some members of the family in this pedigree are affected with cystic fibrosis. Individuals I-1, I-2, II-4, and II-5 do not have cystic fibrosis, but they are presumed to be heterozygotes (carriers) because they have produced affected offspring.

Concept Check: *Let's suppose a genetic disease is caused by a mutant allele. If two affected parents produce an unaffected offspring, can the mutant allele be recessive?*

that encodes the cystic fibrosis transmembrane regulator (the *CFTR* gene, also see Figure 1.16). Approximately 3% of Americans of European descent are heterozygous carriers of the recessive *CFTR* allele. Individuals who are homozygous for the *CFTR* allele exhibit the disease symptoms, which include abnormalities of the lungs, pancreas, intestine, and sweat glands. A human pedigree, like the one in Figure 16.12, shows the oldest generation (designated by the Roman numeral I) at the top, with later generations (II and III) below it. A male (represented by a square) and a female (represented by a circle) who produce offspring are connected by a horizontal line; a vertical line connects parents with their offspring. Siblings (brothers and sisters) are denoted by downward projections from a single horizontal line, from left to right in the order of their birth. For example, individuals I-1 and I-2 are the parents of individuals II-2, II-3, and II-4, who are all siblings. Individuals affected by the disease, such as individual II-3, are depicted by filled symbols.

Why does this pedigree indicate a recessive pattern of inheritance for CF? The answer is that two unaffected individuals can produce an affected offspring. Such individuals are presumed to be heterozygotes (designated by a half-filled symbol). However, the same unaffected parents can also produce unaffected offspring (depicted by an unfilled symbol), because an individual must inherit two copies of the mutant allele to exhibit the disease. A recessive mode of inheritance

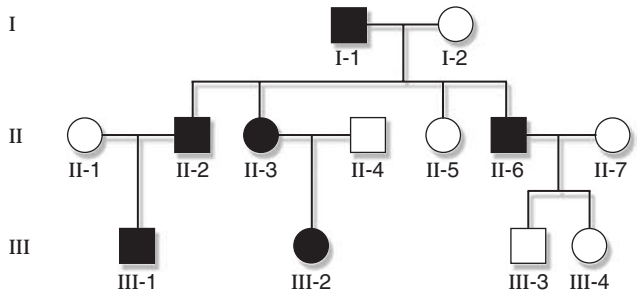


Figure 16.13 A family pedigree for a dominant trait. Huntington disease is caused by a dominant allele.

Concept Check: What observation in a pedigree suggests a dominant pattern of inheritance?

is also characterized by the observation that all of the offspring of two affected individuals are affected themselves. However, for genetic diseases that limit survival or fertility, there are rarely if ever cases where two affected individuals produce offspring.

Although many of the alleles causing human genetic diseases are recessive, some are known to be dominant. Let's consider Huntington disease, a condition that causes the degeneration of brain cells involved in emotions, intellect, and movement. The symptoms of Huntington disease, which usually begin to appear when people are 30 to 50 years old, include uncontrollable jerking movements of the limbs, trunk, and face; progressive loss of mental abilities; and the development of psychiatric problems. If you examine the pedigree shown in **Figure 16.13**, you will see that every affected individual has one affected parent. This pattern is characteristic of most dominant disorders. However, affected parents do not always produce affected offspring. For example, II-6 is a heterozygote that has passed the nondisease-causing allele to his offspring, thereby producing unaffected offspring (III-3 and III-4).

Most human genes are found on the paired chromosomes known as **autosomes**, which are the same in both sexes. Mendelian inheritance patterns involving these autosomal genes are described as autosomal inheritance patterns. Huntington disease is an example of a trait with an autosomal dominant inheritance pattern, whereas cystic fibrosis displays an autosomal recessive pattern. However, some human genes are located on sex chromosomes, which are different in males and females. These genes have their own characteristic inheritance patterns, which we will consider next.

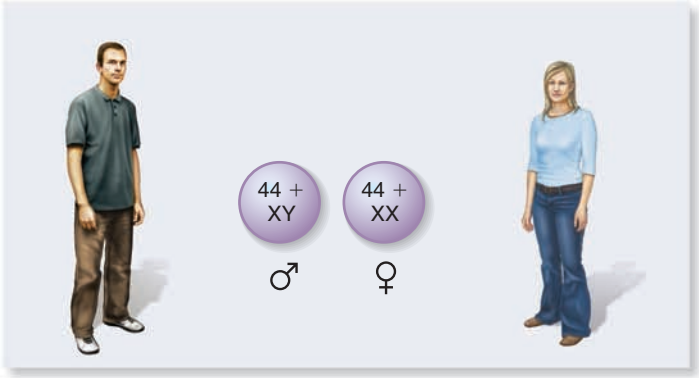
16.4 Sex Chromosomes and X-Linked Inheritance Patterns

Learning Outcomes:

1. Describe different systems of sex determination in animals and plants.
2. **SciSKILLS** » Predict the outcome of crosses when genes are located on sex chromosomes.
3. Explain why X-linked recessive traits are more likely to occur in males.

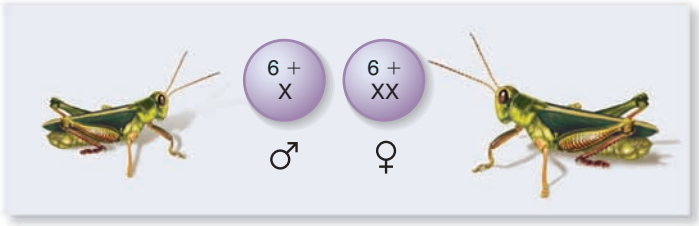
Earlier in this chapter, we discussed Mendel's experiments that established the basis for understanding how traits are transmitted from parents to offspring. We also examined the chromosome theory of inheritance, which provided a framework for explaining Mendel's observations. Mendelian patterns of gene transmission are observed for most genes located on autosomes in a wide variety of eukaryotic species.

We will now turn our attention to genes located on **sex chromosomes**. As you learned in Chapter 15, this term refers to a distinctive pair of chromosomes that are different in males and females and that determine the sex of the individuals. Sex chromosomes are found in many but not all species with two sexes. The study of sex chromosomes proved pivotal in confirming the chromosome theory of inheritance. The distinctive transmission patterns of genes on sex chromosomes helped early geneticists show that particular genes are located on particular chromosomes. Later, other researchers became interested in these genes because some of them were found to cause inherited disorders in humans.



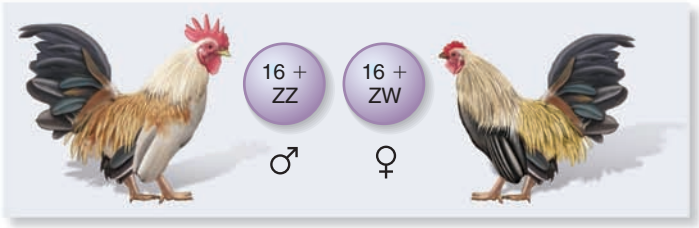
In this section, we will consider a few mechanisms by which sex chromosomes in various species determine an individual's sex. We will then explore the inheritance patterns of genes on sex chromosomes and see that recessive alleles are expressed more frequently in males than in females. Last, we will examine some of the early research involving sex chromosomes that provided convincing evidence for the chromosome theory of inheritance.

In Many Species, Sex Differences Are Due to the Presence of Sex Chromosomes



Some early evidence supporting the chromosome theory of inheritance involved a consideration of sex determination. In 1901, American biologist C. E. McClung suggested that the inheritance of particular chromosomes is responsible for determining sex in fruit flies. Following McClung's initial observations, several mechanisms of sex determination were found in different species of animals. Some examples are described in **Figure 16.14**. All of these mechanisms involve chromosomal differences between the sexes, and most involve a difference in a single pair of sex chromosomes.

X-Y System In the X-Y system of sex determination, which operates in mammals, the somatic cells of males have one X and one Y chromosome, whereas female somatic cells contain two X chromosomes (Figure 16.14a). For example, the 46 chromosomes carried by human cells consist of 22 pairs of autosomes and one pair of sex chromosomes (either XY or XX). Which chromosome, the X or Y, determines sex? In mammals, the presence of the Y chromosome causes maleness. This is known from the analysis of rare individuals who carry chromosomal abnormalities. For example, mistakes that occasionally occur during meiosis may produce an individual who carries two X chromosomes and one Y chromosome. Such an individual develops into a male. A gene called the *SRY* gene located on the Y chromosome of mammals plays a key role in the developmental pathway that leads to maleness.



X-O System The X-O system operates in many insects (Figure 16.14b). Unlike the X-Y system in mammals, the presence of the Y chromosome in the X-O system does not determine maleness. Females in this system have a pair of sex chromosomes and are designated XX. In some insect species that follow the X-O system, the male has only one sex chromosome, the X. In other X-O insect species, such

Figure 16.14 Different mechanisms of sex determination in animals. The numbers shown in the circles indicate the numbers of autosomes.

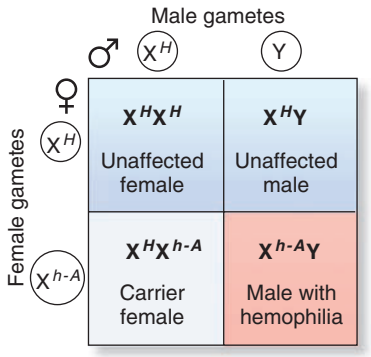
Concept Check: If a person is born with only one X chromosome and no Y chromosome, would you expect that person to be a male or a female? Explain your answer.

as *Drosophila melanogaster*, the male has both an X chromosome and a Y chromosome. In all cases, an insect's sex is determined by the ratio between its X chromosomes and its sets of autosomes. If a fly has one X chromosome and is diploid for the autosomes ($2n$), this ratio is 1/2, or 0.5. This fly will become a male whether or not it receives a Y chromosome. On the other hand, if a diploid fly receives two X chromosomes, the ratio is 2/2, or 1.0, and the fly becomes a female.

Z-W System Thus far, we have considered examples where females have two similar copies of a sex chromosome, the X. However, in some animal species, such as birds and some fish, the male carries two similar chromosomes (Figure 16.14c). This is called the Z-W system to distinguish it from the X-Y system found in mammals. The male is ZZ, and the female is ZW.

Haplodiploid System Not all chromosomal mechanisms of sex determination involve a special pair of sex chromosomes. An interesting mechanism known as the haplodiploid system is found in bees (Figure 16.14d). The male bee, or drone, is produced from an unfertilized haploid egg. Therefore, male bees are haploid individuals. Females, both worker bees and queen bees, are produced from fertilized eggs and are diploid.

Environmental Sex Determination Although sex in many species of animals is determined by chromosomes, other mechanisms are also known. In certain reptiles and fish, sex is controlled by environmental factors such as temperature. For example, in the American alligator (*Alligator mississippiensis*), temperature controls sex development. When eggs of this alligator are incubated at 33°C, nearly all of them produce male individuals. When the eggs are incubated at a temperature significantly below 33°C, they produce nearly all females, whereas increasing percentages of females are produced above 34°C.



Sex Determination in Plants Most species of flowering plants, including pea plants, have a single type of diploid plant, or sporophyte, that makes both male and female gametophytes. However, the sporophytes of some species have two sexually distinct types of individuals, one with flowers that produce male gametophytes, and the other with flowers that produce female gametophytes. Examples include hollies, willows, poplars, and date palms. Sex chromosomes, designated X and Y, are responsible for sex determination in many such species. The male plant is XY, whereas the female plant is XX. However, in some plant species with separate sexes, microscopic examination of the chromosomes does not reveal distinct types of sex chromosomes.

In Humans, Recessive X-Linked Traits Are More Likely to Occur in Males

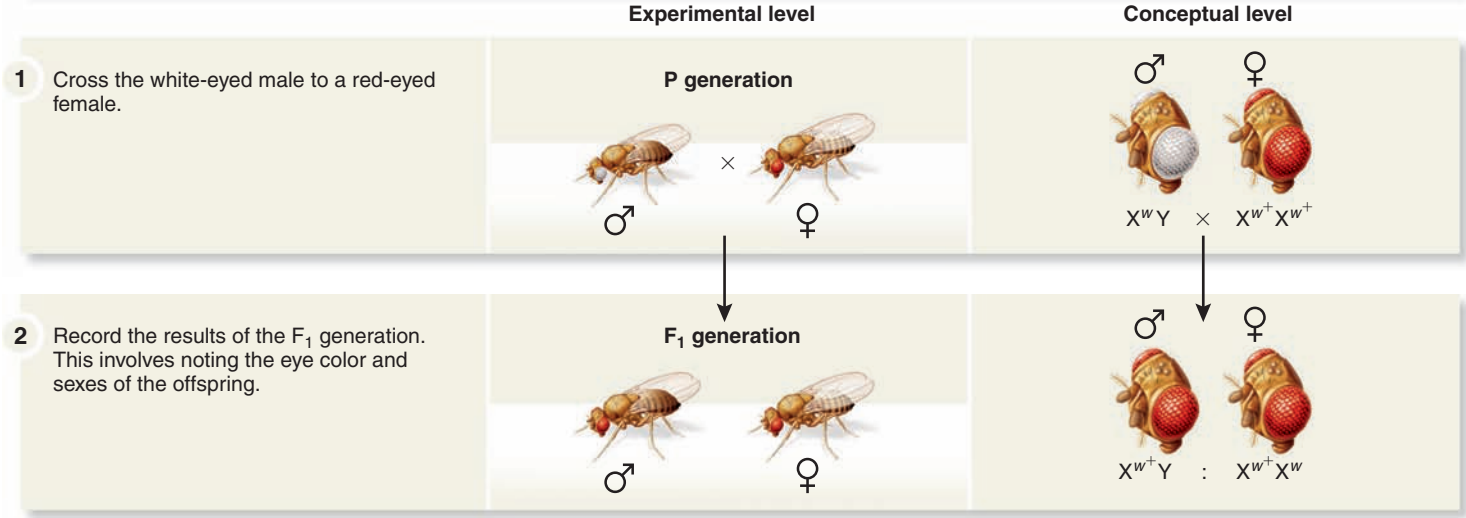
In humans, the X chromosome is rather large and carries over 1,000 genes, whereas the Y chromosome is quite small and has less than 100 genes. Therefore, many genes are found on the X chromosome but not on the Y; these are known as **X-linked genes**. By comparison, fewer genes are known to be Y-linked, meaning they are found on the Y chromosome but not on the X. **Sex-linked genes** are found on one sex chromosome but not on the other. Because fewer genes are found on the Y chromosome, the term usually refers to X-linked genes. In mammals, a male cannot be described as being homozygous or heterozygous for an X-linked gene, because these terms apply to genes that are present in two copies. Instead, the term **hemizygous** is used to describe an individual with only one copy of a particular gene. A male mammal is said to be hemizygous for an X-linked gene.

Many recessive X-linked alleles cause diseases in humans, and these diseases occur more frequently in males than in females. As an example, let's consider the X-linked recessive disorder called classical hemophilia (hemophilia A). In individuals with hemophilia, blood does not clot properly, and a minor cut may bleed for a long time. Common accidental injuries that are minor in most people pose a threat of severe internal or external bleeding for hemophiliacs.

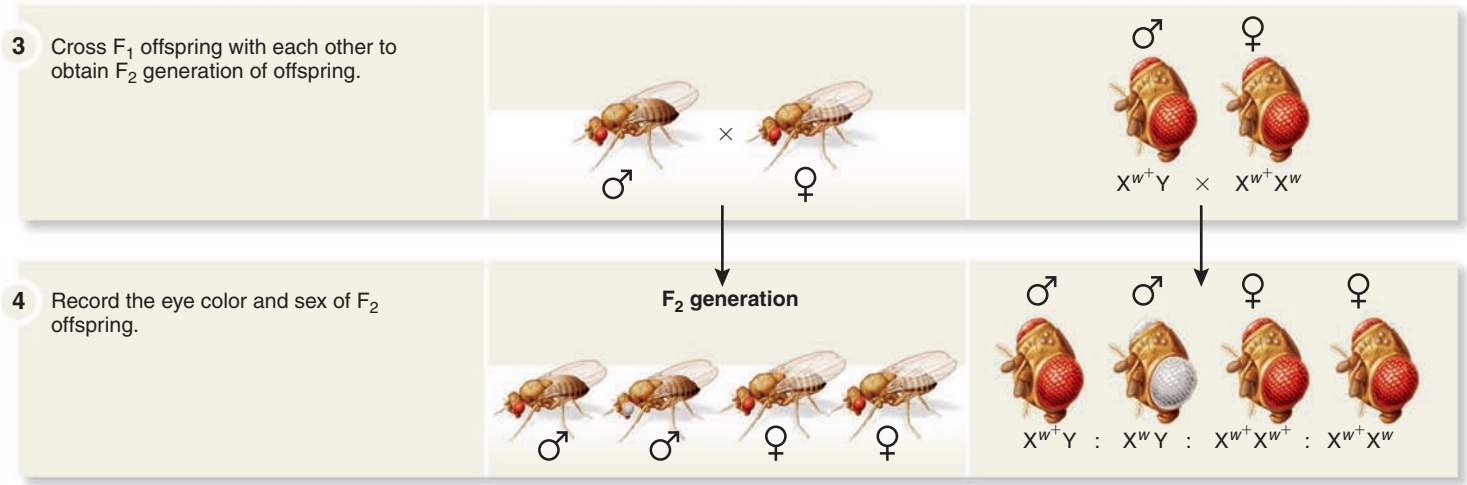
Hemophilia A is caused by a recessive X-linked allele that encodes a defective form of a clotting protein. If a mother is a heterozygous carrier of hemophilia A, each of her children has a 50% chance of inheriting the recessive allele. The following Punnett square shows a cross between an unaffected father and a heterozygous mother. X^H designates an X chromosome carrying the dominant functional allele, and $X^{h\text{-}A}$ is the X chromosome that carries the recessive nonfunctional allele for hemophilia A.

Although each child has a 50% chance of inheriting the hemophilia allele from their mother, only 1/2 of the sons will exhibit the disorder. Because a son inherits only one X chromosome, a son who inherits the recessive (disease-causing) allele from his mother will have hemophilia. However, a daughter inherits an X chromosome from both her mother and her father. In this example, a daughter who inherits the recessive allele from her mother also inherits a dominant allele from her father. This daughter will not have hemophilia, but if she passes the recessive allele to a son, he will have hemophilia.

Feature Investigation | Morgan's Experiments Showed a Correlation Between a Genetic Trait and the Inheritance of a Sex Chromosome in *Drosophila*



The distinctive inheritance pattern of X-linked alleles provides a way of demonstrating that a specific gene is on an X chromosome. An X-linked gene was the first gene to be located on a specific chromosome. In 1910, American geneticist Thomas Hunt Morgan began work on a project in which he reared large populations of fruit flies, *Drosophila melanogaster*, in the dark to determine if their eyes would atrophy from disuse and disappear in future generations. Even after many consecutive generations, the flies showed no noticeable changes. After 2 years of looking at many flies, Morgan happened to discover a male fly with white eyes rather than red, which is the common (wild-type) color. The white-eye trait must have arisen from a new mutation that converted a red-eye allele into a white-eye allele.



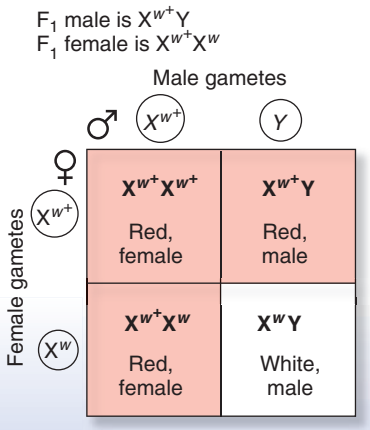
To study the inheritance of the white-eye trait, Morgan followed an approach similar to Mendel's in which he made crosses and quantitatively analyzed their outcome. In the experiment described in **Figure 16.15**, Morgan crossed his white-eyed male to a red-eyed female. All of the F_1 offspring had red eyes, indicating that red is dominant to white. The F_1 offspring were then mated to each other to obtain an F_2 generation. As seen in the data table, this cross produced 1,011 red-eyed males, 782 white-eyed males, and

Figure 16.15 Morgan's crosses of red-eyed and white-eyed *Drosophila*.

GOAL A quantitative analysis of genetic crosses may reveal the pattern of inheritance of a particular gene.

KEY MATERIALS A true-breeding line of red-eyed fruit flies plus one white-eyed male fly that was discovered in the population.

5 THE DATA



Cross	Results
Original white-eyed male to a red-eyed female	F_1 generation All red-eyed flies
F_1 males to F_1 females	F_2 generation 1,011 red-eyed males 782 white-eyed males 2,459 red-eyed females 0 white-eyed females

6 CONCLUSION The data are consistent with an inheritance pattern in which an eye-color gene is located on the X chromosome.

7 SOURCE Morgan, T. H. 1910. Sex limited inheritance in *Drosophila*. *Science* 32:120–122.

2,459 red-eyed females. Surprisingly, no white-eyed females were observed in the F_2 generation.

How did Morgan interpret these results? The results suggested a connection between the alleles for eye color and the sex of the offspring. As shown in the conceptual column of Figure 16.15 and in the following Punnett square, his data were consistent with the idea that the eye-color alleles in *Drosophila* are located on the X chromosome. X^{w+} is the chromosome carrying the common allele for red eyes, and X^{w} is the chromosome with the mutant allele for white eyes.

The Punnett square predicts that the F_2 generation will not have any white-eyed females. This prediction was confirmed by Morgan's experimental data. However, it should also be pointed out that the experimental ratio of red eyes to white eyes in the F_2 generation is (2,459 + 1,011) : 782, which equals 4.4 : 1. This ratio deviates significantly from the ratio of 3:1 predicted in the Punnett square. The lower than expected number of white-eyed flies is explained by a decreased survival of white-eyed flies.

Following this initial discovery, Morgan carried out many experimental crosses that located specific genes on the *Drosophila* X chromosome. This research provided some of the most persuasive evidence for Mendel's laws and the chromosome theory of inheritance, which are the foundations of modern genetics. In 1933, Morgan became the first geneticist to receive a Nobel Prize (Physiology or Medicine).

Experimental Questions

1. Prior to the work described here, what was the original purpose of Morgan's experiments with *Drosophila*?
2. **SciSKILLS** » What results led Morgan to conclude that eye color is associated with the sex of the individual?
3. **SciSKILLS** » What crosses between fruit flies could yield female offspring with white eyes?

16.5 Variations in Inheritance Patterns and Their Molecular Basis

Learning Outcomes:

1. Relate dominant and recessive traits to protein function.
2. Define pleiotropy, and explain why it occurs.
3. **SciSKILLS** » Predict the outcome of crosses that exhibit incomplete dominance and codominance.
4. Discuss how the environment plays a critical role in determining the outcome of traits.

The term **Mendelian inheritance** describes the inheritance patterns of genes that segregate and assort independently. In the first section of this chapter, we considered the inheritance pattern of traits affected by a single gene that is found in two variants, one of which is dominant over the other. This pattern is called **simple Mendelian inheritance**, because the phenotype ratios in the offspring clearly demonstrate Mendel's laws. In this section, we will discuss the molecular basis of dominant and recessive traits and see how the molecular expression of a gene can have widespread effects on an organism's phenotype. In addition, we will examine the inheritance patterns of genes that segregate and assort independently but do not display a simple dominant/recessive relationship. The transmission of these genes from parents to offspring does not usually produce the ratios of phenotypes we would expect on the basis of Mendel's observations. This does not mean that Mendel was wrong. Rather, the inheritance patterns of many traits are different from the simple patterns he chose to study. As summarized in **Table 16.1**, our understanding of gene function at the molecular level explains both simple Mendelian inheritance and other, more complex inheritance patterns that conform to Mendel's laws. This modern knowledge also sheds light on the role of the environment in producing an organism's phenotype, which we will discuss at the end of the section.

Protein Function Explains the Phenomenon of Dominance

As we discussed at the beginning of this chapter, Mendel studied seven characters that were found in two variants each (see Figure 16.2). The dominant variants are caused by the common alleles for these traits in pea plants. For any given gene, geneticists refer to a prevalent allele in a population as a **wild-type allele**. In most cases, a wild-type allele encodes a protein that is made in the proper amount and functions properly. By comparison, alleles that have been altered by mutation are called **mutant alleles**; these tend to be rare in natural populations. In the case of Mendel's seven characters in pea plants, the recessive alleles are due to rare mutations.

How do we explain why one allele is dominant and another allele is recessive? By studying genes and their gene products at the molecular level, researchers have discovered that a recessive allele is often defective in its ability to express a functional protein. In other words, mutations that produce recessive alleles are likely to decrease or eliminate the synthesis or functional activity of a protein. These are called loss-of-function alleles. To understand why many loss-of-function alleles are recessive, we need to take a quantitative look at protein function.

In a simple dominant/recessive relationship, the recessive allele does not affect the phenotype of the heterozygote. In this type of relationship, a single copy of the dominant (wild-type) allele is sufficient to mask the effects of the recessive allele. How do we explain the dominant phenotype of the heterozygote? **Figure 16.16** considers the example of flower color in a pea plant. The gene encodes an enzyme (protein P) that is needed to convert a colorless molecule into a purple pigment. The *P* allele is dominant because one *P* allele encodes enough of the functional protein—50% of the amount found in a *PP* homozygote—to provide a purple phenotype. Therefore, the *PP* homozygote and the *Pp* heterozygote both make enough of the purple pigment to yield purple flowers. The *pp* homozygote cannot make any of the functional protein required for pigment synthesis, so its flowers are white.

Table 16.1 Different Types of Mendelian Inheritance Patterns and Their Molecular Basis

Type	Description
Simple Mendelian inheritance	**Inheritance pattern:** Pattern of traits determined by a pair of alleles that display a dominant/recessive relationship and are located on an autosome. The presence of the dominant allele masks the presence of the recessive allele.
	Molecular basis: In many cases, the recessive allele is nonfunctional. Though a heterozygote may produce 50% of the functional protein compared with a dominant homozygote, this is sufficient to produce the dominant trait.
X-linked inheritance	**Inheritance pattern:** Pattern of traits determined by genes that display a dominant/recessive relationship and are located on the X chromosome. In mammals and fruit flies, males are hemizygous for X-linked genes. In these species, X-linked recessive traits occur more frequently in males than in females.
	Molecular basis: In a female with one recessive X-linked allele (a heterozygote), the protein encoded by the dominant allele is sufficient to produce the dominant trait. A male with a recessive X-linked allele does not have a dominant allele and does not make any of the functional protein.
Incomplete dominance	**Inheritance pattern:** Pattern that occurs when the heterozygote has a phenotype intermediate to the phenotypes of the homozygotes, as when a cross between red-flowered and white-flowered plants produces pink-flowered offspring.
	Molecular basis: Fifty percent of the protein encoded by the functional (wild-type) allele results in an intermediate phenotype.
Codominance	**Inheritance pattern:** Pattern that occurs when the heterozygote expresses both alleles simultaneously. For example, a human carrying the A and B alleles for the ABO antigens of red blood cells produces both the A and the B antigens (has an AB blood type).
	Molecular basis: The codominant alleles encode proteins that function somewhat differently from each other. In a heterozygote, the function of each protein affects the phenotype uniquely.

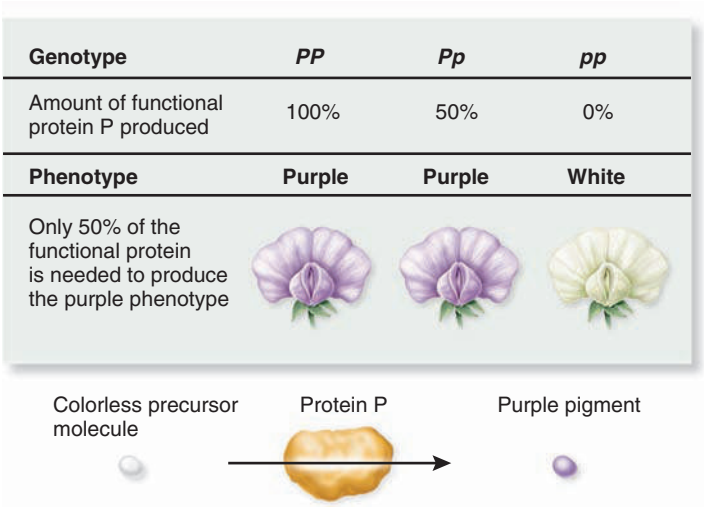


Figure 16.16 How genes give rise to traits during simple Mendelian inheritance. In the heterozygote, the amount of protein encoded by a single dominant allele is sufficient to produce the dominant phenotype. In this example, the gene encodes an enzyme that is needed to produce a purple pigment. A plant with one or two copies of the dominant allele makes enough pigment to produce purple flowers. In a *pp* homozygote, the complete lack of the functional protein (enzyme) results in white flowers.

This explanation—that 50% of the functional protein is enough—is true for many dominant alleles. In such cases, the homozygote with two dominant alleles is making much more of the protein than necessary, so if the amount is reduced to 50%, as it is in the heterozygote, the individual still has plenty of this protein to accomplish whatever cellular function it performs. In other cases, however, an allele may be dominant because the heterozygote actually produces more than 50% of the functional protein. This increased production is due to the phenomenon of gene regulation. The dominant allele is up-regulated in the heterozygote to compensate for the lack of function of the recessive allele.

Genomes & Proteomes Connection

Recessive Alleles That Cause Diseases May Have Multiple Effects on Phenotype

The idea that recessive alleles usually cause a substantial decrease in the expression of a functional protein is supported by analyses of many human genetic diseases. Keep in mind that many genetic diseases are caused by rare mutant alleles. **Table 16.2** lists a few examples of human genetic diseases in which a recessive allele fails to produce a specific cellular protein in its active form. Over 9,000 human disorders are caused by mutations in single genes; most of these are recessive alleles. With a human genome size of about 22,000 genes, roughly one-third of our genes are known to cause some kind of abnormality when mutations alter the expression or functionality of their gene product.

Single-gene disorders often illustrate the phenomenon of **pleiotropy**, which means that a mutation in a single gene can have multiple effects on an individual's phenotype. Pleiotropy occurs for several reasons, including the following:

1. The expression of a single gene can affect cell function in more than one way. For example, a defect in a microtubule protein may affect cell division and cell movement.
2. A gene may be expressed in different cell types in a multicellular organism.
3. A gene may be expressed at different stages of development.

In this genetics unit, we tend to discuss genes as they affect a single trait. This educational approach allows us to appreciate how genes function and how they are transmitted from parents to offspring. However, this focus may also obscure how amazing genes really are. In all or nearly all cases, the expression of a gene is pleiotropic with regard to the characteristics of an organism. The expression of any given gene influences the expression of many other genes in the genome, and vice versa. Pleiotropy is revealed when researchers study the effects of gene mutations.

As an example of a pleiotropic effect, let's consider cystic fibrosis (CF), which we discussed earlier as an example of a recessive human disorder (see Figure 16.12). In the late 1980s, the gene for CF was identified. The gene encodes a protein called the cystic fibrosis transmembrane conductance regulator (CFTR), which regulates ion balance by allowing the transport of chloride ions (Cl^-) across epithelial cell membranes. The mutation that causes CF diminishes the function of this Cl^- transporter, affecting several parts of the body in different ways. Because the movement of Cl^- affects water transport across membranes, the most

Table 16.2 Examples of Recessive Human Genetic Diseases

Disease	Protein encoded by the gene*	Description
Phenylketonuria	Phenylalanine hydroxylase	Inability to metabolize phenylalanine. Can lead to severe mental impairment and physical degeneration. The disease can be prevented by following a phenylalanine-free diet beginning early in life.
Cystic fibrosis	A chloride-ion transporter	Inability to regulate ion balance in epithelial cells. Leads to a variety of symptoms, including production of thick lung mucus and chronic lung infections.
Tay-Sachs disease	Hexosaminidase A	Inability to metabolize certain lipids. Leads to paralysis, blindness, and early death.
Hemophilia A	Coagulation factor VIII	A defect in blood clotting due to a missing clotting factor. An accident may cause excessive bleeding or internal hemorrhaging.

*Individuals who exhibit the disease are homozygous (or hemizygous) for a recessive allele that results in a defect in the amount or function of the protein.

severe symptom of CF is the production of thick mucus in the lungs, which occurs because of a water imbalance. Similarly, thick mucus can also block the tubes that carry digestive enzymes from the pancreas to the small intestine. Without these enzymes, certain nutrients are not properly absorbed into the body. As a result, persons with CF may show poor weight gain. Another effect is seen in the sweat glands. The Cl^- transporter has the function of recycling salt out of the glands and back into the skin before it can be lost to the outside world. Persons with CF have excessively salty sweat due to their inability to recycle salt back into their skin cells. A common test for CF is the measurement of salt on the skin. Taken together, we can see that a defect in CFTR has multiple effects throughout the body.

Incomplete Dominance Results in an Intermediate Phenotype

We will now turn our attention to examples in which the alleles for a given gene do not show a simple dominant/recessive relationship. In some cases, a heterozygote that carries two different alleles exhibits a phenotype that is intermediate between the corresponding homozygous individuals. This phenomenon is known as **incomplete dominance**.

In 1905, Carl Correns discovered this pattern of inheritance for alleles affecting flower color in the four-o'clock plant (*Mirabilis jalapa*). **Figure 16.17** shows a cross between two four-o'clock plants: a red-flowered homozygote and a white-flowered homozygote. The allele for red flower color is designated C^R, and the white allele is C^W. These alleles are designated with superscripts rather than upper- and lowercase letters because neither allele is dominant. The offspring of this cross have pink flowers—they are C^RC^W heterozygotes with an intermediate phenotype. If these F_1 offspring are allowed to self-fertilize, the F_2 generation has 1/4 red-flowered plants, 1/2 pink-flowered plants, and 1/4 white-flowered plants. This is a 1:2:1 phenotype ratio rather than the 3:1 ratio observed for simple Mendelian inheritance. What is the molecular explanation for this ratio? In this case, the red allele encodes a functional protein needed to produce a red pigment, whereas the white allele is a mutant allele that is nonfunctional. In the C^RC^W heterozygote, 50% of the protein encoded by the C^R allele is not sufficient to produce the red-flower phenotype, but it does provide enough pigment to give pink flowers.

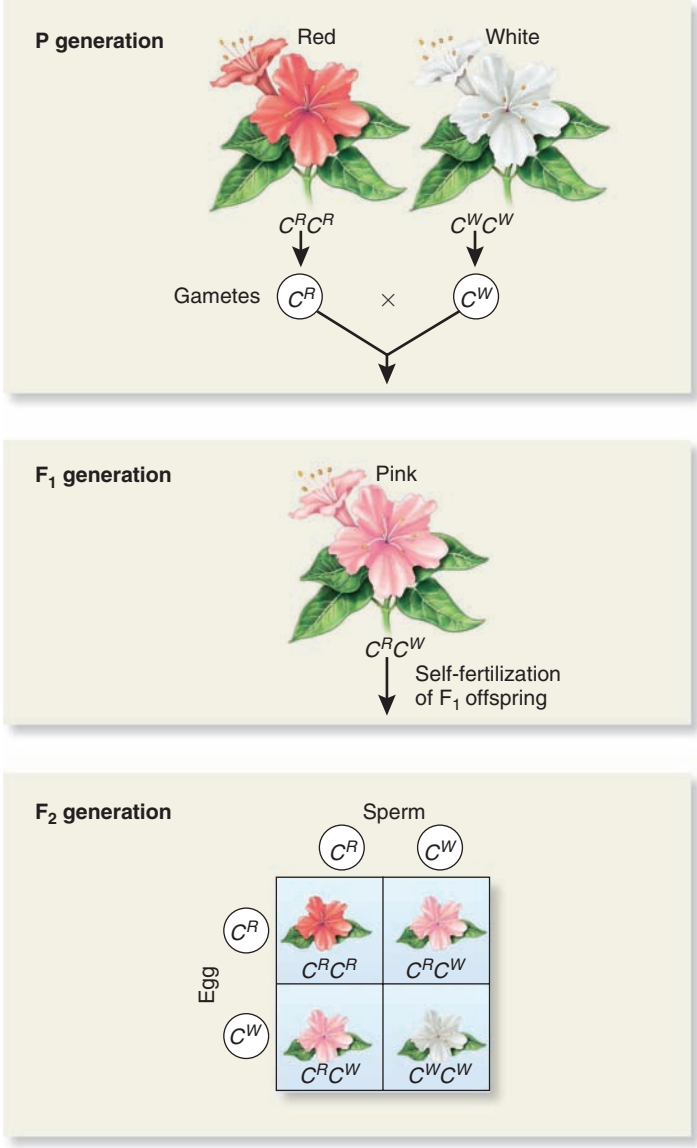

Figure 16.17 Incomplete dominance in the four-o'clock plant. When red-flowered and white-flowered homozygotes (C^RC^R and C^WC^W) are crossed, the resulting heterozygote (C^RC^W) has an intermediate phenotype of pink flowers.

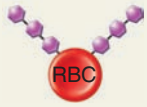

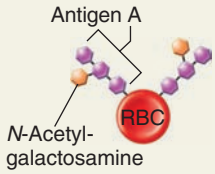

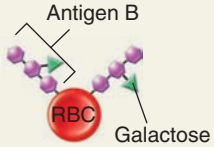

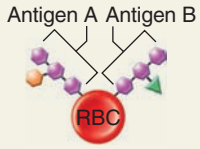

ABO Blood Types Provide an Example of Multiple Alleles and Codominance

Although diploid individuals have only two copies of most genes, the majority of genes have three or more variants in natural populations. We describe such genes as occurring in **multiple alleles**. Particular phenotypes depend on which two alleles each individual inherits. ABO blood types in humans are an example of phenotypes produced by multiple alleles.

As shown in **Table 16.3**, human red blood cells have structures on their plasma membrane known as surface antigens, which are constructed from several sugar molecules that are connected to form a carbohydrate tree. The carbohydrate tree is attached to lipids or membrane proteins to form glycolipids or glycoproteins, respectively. As noted in Chapter 5, glycolipids and glycoproteins often play a role in cell surface recognition.

Antigens are substances (in this case, carbohydrates) that may be recognized as foreign material when introduced into the body of an animal. Let's consider two types of surface antigens, known as A and B, which may be found on red blood cells. The synthesis of these antigens is determined by enzymes that are encoded by a gene that exists in three alleles, designated I^A, I^B, and i, respectively. The i allele is recessive to both I^A and I^B. A person who is ii homozygous does not produce surface antigen A or B and has blood type O. The red blood cells of an I^AI^A homozygous or I^Ai heterozygous individual have surface antigen A (blood type A). Similarly, a homozygous I^BI^B or heterozygous I^Bi individual produces surface antigen B (blood type B).

Table 16.3 The ABO Blood Group

				
Blood type:	O	A	B	AB
Genotype:	*ii*	I^AI^A or I^Ai	I^BI^B or I^Bi	I^AI^B
Surface antigen:	Neither A nor B	A	B	A and B
Antibodies:	Against A and B	Against B	Against A	Neither

A person who is I^AI^B heterozygous makes both antigens, A and B, on every red blood cell (blood type AB). The phenomenon in which a single individual expresses two alleles is called **codominance**.

What is the molecular explanation for codominance? Biochemists have analyzed the carbohydrate tree produced in people of differing blood types. The differences are shown schematically in Table 16.3. In type O, the carbohydrate tree is smaller than in type A or type B because a sugar has not been attached to a specific site on the tree. People with blood type O have a loss-of-function mutation in the gene that encodes the enzyme that attaches a sugar at this site. This enzyme, called a glycosyl transferase, is inactive in type O individuals. In contrast, the type A and type B antigens have sugars attached to this site, but each of them has a different sugar. This difference occurs because the enzymes encoded by the I^A allele and the I^B allele have slightly different active sites. As a result, the enzyme encoded by the I^A allele attaches a sugar called *N*-acetylgalactosamine to the carbohydrate tree, whereas the enzyme encoded by the I^B allele attaches galactose. *N*-Acetylgalactosamine is represented by an orange hexagon in Table 16.3, and galactose by a green triangle. The importance of surface antigens and blood type for safe blood transfusions is discussed in Chapter 53.

The Environment Plays a Vital Role in the Making of a Phenotype

In this chapter, we have been mainly concerned with the effects of genes on phenotypes. In addition, phenotypes are shaped by an organism's environment. An organism cannot exist without its genes or without an environment in which to live. Both are indispensable for life. An organism's genotype provides the plan to create a phenotype, and the environment provides nutrients and energy so that plan can be executed.

The **norm of reaction** is the phenotype range that individuals with a particular genotype exhibit under differing environmental conditions. To evaluate the norm of reaction, researchers study members of true-breeding strains that have the same genotypes and subject them to different environmental conditions. For example, **Figure 16.18** shows the norm of reaction for genetically identical plants raised at different temperatures. As shown in the figure, these plants attain a maximal height when raised at 75°F. At 50°F and 85°F, the plants are substantially shorter. Growth cannot occur below 40°F or above 95°F.

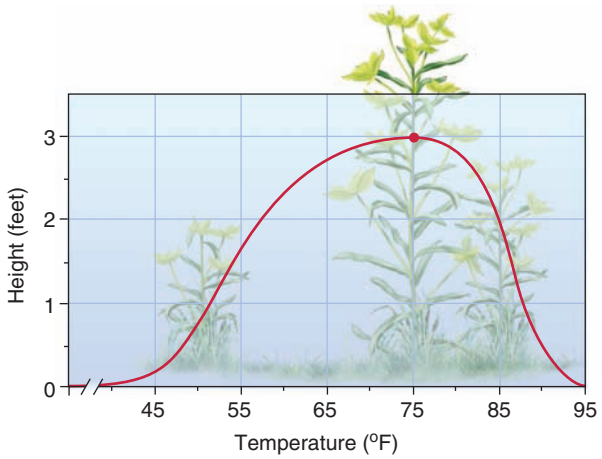

Figure 16.18 The norm of reaction. The norm of reaction is the range of phenotypes that a population of organisms with a particular genotype exhibit under different environmental conditions. In this example, genetically identical plants were grown at different temperatures in a greenhouse and then measured for height.

BIOLOGY PRINCIPLE Living organisms interact with their environment. As seen in this figure, the environment plays a key role in the outcome of traits.

Concept Check: Could you study the norm of reaction in a wild population of squirrels?

The norm of reaction can be quite dramatic when we consider environmental influences on certain inherited diseases. A striking example is the human genetic disease phenylketonuria (PKU). This disorder is caused by a rare mutation in the gene that encodes the enzyme phenylalanine hydroxylase, which is needed to metabolize the amino acid phenylalanine. People with one or two functional copies of the gene can eat foods containing the amino acid phenylalanine and metabolize it properly. However, individuals with two copies of the mutant gene cannot metabolize phenylalanine. When these individuals eat a standard diet containing phenylalanine, this amino acid accumulates within their bodies and becomes highly toxic. Under these conditions, PKU

Figure 16.19 PKU and the environment. This child has PKU, but she has followed a phenylalanine-free diet and has developed properly.

BIOLOGY PRINCIPLE Biology affects our society. The study of genetic diseases has sometimes led to treatment options that prevent the harmful consequences of certain mutations, such as the one associated with PKU.

homozygotes manifest a variety of detrimental symptoms, including mental impairment, underdeveloped teeth, and foul-smelling urine. In contrast, when these individuals are identified at birth and given a restricted diet that is free of phenylalanine, they develop properly (Figure 16.19). This is a dramatic example of how genes and the environment interact to determine an individual's phenotype. In the United States, most newborns are tested for PKU, which occurs in about 1 in 10,000 babies. A newborn who is found to have this disorder can be raised on a phenylalanine-free diet and avoid the harmful symptoms.

16.6 Genetics and Probability

Learning Outcomes:

1. Explain the concept of probability.
2. **SciSKILLS** » Apply the product rule to problems involving genetic crosses.

As we have seen throughout this chapter, Mendel's laws of inheritance can be used to predict the outcome of genetic crosses. How is this useful? In agriculture, plant and animal breeders use predictions about the types and relative numbers of offspring their crosses will produce in order to develop commercially important crops and livestock. Also, people are often interested in the potential characteristics of their future children. This has particular importance to individuals who may carry alleles that cause inherited diseases. Of course, no one can see into the future and definitively predict what will happen. Nevertheless, genetic counselors can help couples predict the likelihood of having an affected child. This probability is one factor that may influence a couple's decision about whether to have children.

Earlier in this chapter, we considered how a Punnett square can be used to predict the outcome of simple genetic crosses. In addition to Punnett squares, we can apply the tools of mathematics and probability to solve more complex genetic problems. In this section, we will examine a couple of ways to calculate the outcomes of genetic crosses using these tools.

Genetic Predictions Are Based on the Rules of Probability

The chance that an event will have a particular outcome is called the **probability** of that outcome. The probability of a given outcome depends on the number of possible outcomes. For example, if you draw a card at random from a 52-card deck, the probability that you will get the jack of diamonds is 1 in 52, because 52 outcomes are possible. In contrast, only two outcomes are possible when you flip a coin, so the probability is one in two (1/2, or 0.5, or 50%) that the heads side will be showing when the coin lands. The general formula for the probability (P) that an event will have a specific outcome is

$$P = \frac{\text{Number of times an event occurs}}{\text{Total number of possible outcomes}}$$

For a single coin toss, the chance of getting heads is

$$P_{\text{heads}} = \frac{1 \text{ heads}}{(1 \text{ heads} + 1 \text{ tails})} = \frac{1}{2}$$

Earlier in this chapter, we used Punnett squares to predict the fractions of offspring with a given genotype or phenotype. In a cross between two pea plants that were heterozygous for the height gene (Tt), our Punnett square predicted that one-fourth of the offspring would be dwarf. We can make the same prediction by using a probability calculation.

$$P_{\text{dwarf}} = \frac{1\ tt}{(1\ TT + 2\ Tt + 1\ tt)} = \frac{1}{4} = 0.25, \text{ or } 25\%$$

A probability calculation allows us to predict the likelihood that a future event will have a specific outcome. However, the accuracy of this prediction depends to a great extent on the number of events we observe—in other words, on the size of our sample. For example, if we toss a coin six times, the calculation we just presented for P_{heads} suggests we should get heads three times and tails three times. However, each coin toss is an independent event, meaning that every time we toss the coin there is an equal chance that it will come up heads or tails, regardless of the outcome of the previous toss. With only six tosses, we would not be too surprised if we got four heads and two tails instead of the expected three heads and three tails. The deviation between the observed and expected outcomes is called the **random sampling error**. With a small sample, the random sampling error may cause the observed data to be quite different from the expected outcome. By comparison, if we flipped a coin 1,000 times, the percentage of heads would be fairly close to the predicted 50%. With a larger sample, we expect the sampling error to be smaller.

The Product Rule Is Used to Predict the Outcome of Independent Events

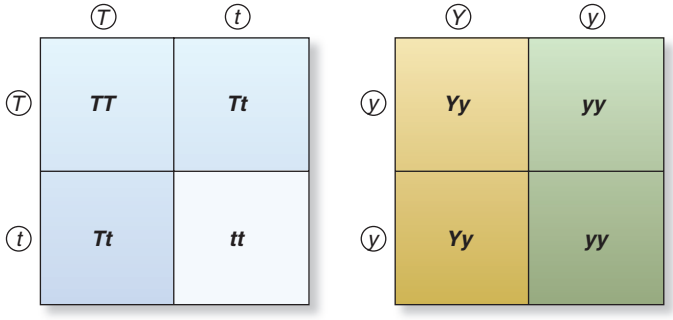
Punnett squares allow us to predict the likelihood that a genetic cross will produce an offspring with a particular genotype or phenotype. To predict the likelihood of producing multiple offspring with

particular genotypes or phenotypes, we can use the **product rule**, which states:

> *The probability that two or more independent events will occur is equal to the product of their individual probabilities.*

As we have already discussed, events are independent if the outcome of one event does not affect the outcome of another. In our previous coin-toss example, each toss is an independent event—if one toss comes up heads, another toss still has an equal chance of coming up either heads or tails. If we toss a coin twice, what is the probability that we will get heads both times? The product rule says that it is equal to the probability of getting heads on the first toss (1/2) times the probability of getting heads on the second toss (1/2), or one in four ($1/2 \times 1/2 = 1/4$).

To see how the product rule can be applied to a genetics problem, let's consider a rare recessive human trait known as congenital analgesia. (Congenital refers to a condition present at birth; analgesia means insensitivity to pain.) People with this trait can distinguish between sensations such as sharp and dull, or hot and cold, but they do not perceive extremes of sensation as painful. The first known case of congenital analgesia, described in 1932, was a man who made his living entertaining the public as a "human pincushion." For a couple, each heterozygous for the recessive allele causing congenital analgesia, we can ask, "What is the probability that their first three offspring will have the disorder?" To answer this question, we must first determine the probability of a single offspring having the disorder. By using a Punnett square, we would find that the probability of an individual offspring being homozygous recessive is 1/4. Thus, each of this couple's children has a one in four chance of having congenital analgesia.



We can now use the product rule to calculate the probability of this couple having three affected offspring in a row. The phenotypes of the first, second, and third offspring are independent events; that is, the phenotype of the first offspring does not affect the phenotype of the second or third offspring. The product rule tells us that the probability of all three children having the disorder is

$$\frac{1}{4} \times \frac{1}{4} \times \frac{1}{4} = \frac{1}{64} = 0.016, \text{ or } 1.6\%$$

The probability of the first three offspring having the disorder is 0.016, or 1.6%. In other words, we can say that this couple's chance of having three children in a row with congenital analgesia is very small—only 1.6 out of 100.

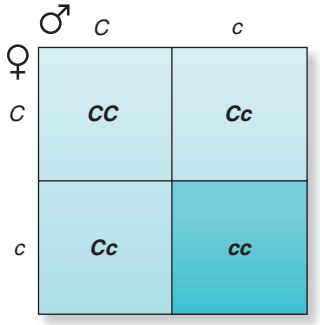
The product rule can also be used to predict the outcome of a cross involving two or more genes. Let's suppose a pea plant with the genotype *TtYy* was crossed with a plant with the genotype *Ttyy*. We could ask, "What is the probability that an offspring will have the genotype *ttYy*?" If the two genes independently assort, the probability of inheriting alleles for one gene is independent of the probability for other gene. Therefore, we can separately calculate the probability of the desired outcome for each gene. By constructing two small Punnett squares, we can determine the probability of genotypes for each gene individually, as shown in the following Punnett squares.

Cross: *TtYy* × *Ttyy*

Probability that an offspring will be *tt* is 1/4, or 0.25.

Probability that an offspring will be *Yy* is 1/2, or 0.5.

We can now use the product rule to determine the probability that an offspring will be *ttYy*:



$$P = (0.25)(0.5) = 0.125, \text{ or } 12.5\%$$

BIO TIPS **THE QUESTION** *As described earlier in this chapter, the human disease known as cystic fibrosis (CF) is inherited via a recessive allele. Two individuals, who do not have disease symptoms, have a first child who has CF. What is the probability that their next two children will not have the disease?*

TOPIC ***What topic in biology does this question address?*** The topic is Mendelian inheritance. More specifically, the question is about a single-factor cross involving cystic fibrosis.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you know that both parents are unaffected, but they produced an affected offspring, who must be homozgyous for the recessive allele. Therefore, both parents must be heterozygotes. If *C* is the dominant allele and *c* is the recessive, disease-causing allele, the genotype of each parent must be *Cc*. From your understanding of the topic, you may remember that alleles segregate during the process that yields gametes and parents pass one allele to their offspring, when gametes combine at fertilization.

PROBLEM-SOLVING STRATEGY ***Predict the outcome. Make a calculation.*** One strategy to predict the outcome is to use a Punnett square, as shown below.

C = dominant allele
c = recessive, disease-causing allele

To calculate the probability, you need to consider two things. First, you need to know the probability of having an unaffected offspring. This probability can be deduced from the Punnett square. Once this is known, you can use the product rule to calculate the likelihood of having two unaffected offspring in a row, because these are independent outcomes.

ANSWER *The genotype ratio for the offspring is 1 CC : 2 Cc : 1 cc. The ratio of the phenotypes is 3 unaffected with CF : 1 affected with CF.*

The probability of these parents having a single unaffected offspring is

$$P_{\text{unaffected}} = \frac{3}{(3+1)} = \frac{3}{4}$$

To obtain the probability that they will have two unaffected offspring in a row, you need to apply the product rule.

$$\frac{3}{4} \times \frac{3}{4} = \frac{9}{16} = 0.56, \text{ or } 56\%$$

The chance that their next two children will not have CF is 56%.

Summary of Key Concepts

16.1 Mendel's Laws of Inheritance

- Mendel studied seven characters found in garden peas that existed in two variants each (Figures 16.1, 16.2).
- Mendel allowed his peas to self-fertilize, or he carried out cross-fertilization, also known as hybridization (Figures 16.3, 16.4).
- By following the inheritance pattern of a single character (a single-factor cross) for two generations, Mendel determined the law of segregation, which states that two alleles of a gene segregate during the process that gives rise to gametes, so every gamete receives only one allele (Figures 16.5, 16.6).
- The genotype is the genetic makeup of an organism. Alleles are alternative versions of the same gene. Phenotype is a description of the traits that an organism displays.
- A Punnett square is constructed to predict the outcome of crosses.
- A testcross is conducted to determine if an individual displaying a dominant trait is a homozygote or a heterozygote (Figure 16.7).
- By conducting a two-factor cross, Mendel determined the law of independent assortment, which states that the alleles of different genes assort independently of each other during the process that gives rise to gametes. In a two-factor cross, this yields a 9:3:3:1 ratio in the F_2 generation (Figure 16.8).

16.2 The Chromosome Theory of Inheritance

- The chromosome theory of inheritance explains how the behavior of chromosomes during meiosis accounts for Mendel's laws of inheritance. Each gene is located at a particular site, or locus, on a chromosome (Figures 16.9, 16.10, 16.11).

16.3 Pedigree Analysis of Human Traits

- The inheritance patterns in humans are determined from a pedigree analysis (Figures 16.12, 16.13).

16.4 Sex Chromosomes and X-Linked Inheritance Patterns

- Many species of animals and some species of plants have separate male and female sexes. In many cases, sex is determined by differences in sex chromosomes (Figure 16.14).
- X-linked genes are found on the X chromosome but not the Y chromosome. Recessive X-linked alleles in humans can cause disorders such as hemophilia, which are more likely to occur in males.
- Morgan's experiments showed that an eye-color gene in *Drosophila* is located on the X chromosome (Figure 16.15).

16.5 Variations in Inheritance Patterns and Their Molecular Basis

- Several inheritance patterns have been discovered that obey Mendel's laws but yield differing ratios of offspring compared with Mendel's crosses (Table 16.1).
- Recessive inheritance is often due to a loss-of-function mutation. In many simple dominant/recessive relationships, the heterozygote has a dominant phenotype because 50% of the functional protein is sufficient to produce that phenotype (Figure 16.16).
- Mutant genes are responsible for many inherited disorders in humans. In many cases, the effects of a mutant gene are pleiotropic, meaning the gene affects several different aspects of bodily structure and function (Table 16.2).
- Incomplete dominance occurs when a heterozygote has a phenotype that is intermediate between either homozygote. This occurs because 50% of the functional protein is not enough to produce the same phenotype as a homozygote (Figure 16.17).
- ABO blood types are produced by the expression of a gene that exists in multiple alleles in humans. The I^A and I^B alleles show codominance, a phenomenon in which both alleles are expressed in a heterozygous individual (Table 16.3).
- Genes and the environment interact to determine an individual's phenotype. The norm of reaction is a description of how a phenotype may change under different environmental conditions (Figures 16.18, 16.19).

16.6 Genetics and Probability

- Probability is the likelihood that an event will occur in the future. Random sampling error is the deviation between observed and expected values.
- The product rule states that the probability of two or more independent events occurring is equal to the product of their individual probabilities.

Assess and Discuss

Test Yourself

1. Based on Mendel's experimental crosses, what is the expected F_2 phenotype ratio of a single-factor cross?
   a. 1:2:1
   b. 2:1
   c. 3:1
   d. 9:3:3:1
   e. 4:1

2. During which phase of nuclear division does Mendel's law of segregation physically occur?
   a. mitosis
   b. meiosis I
   c. meiosis II
   d. all of the above
   e. b and c only
3. An individual that has two different alleles of a particular gene is said to be
   a. dihybrid.
   b. recessive.
   c. homozygous.
   d. heterozygous.
   e. hemizygous.
4. Which of Mendel's laws cannot be observed in a single-factor cross?
   a. segregation
   b. dominance/recessiveness
   c. independent assortment
   d. codominance
   e. All of the above can be observed in a single-factor cross.
5. During a ____ cross, an individual with the dominant phenotype and unknown genotype is crossed with a ___ individual to determine the unknown genotype.
   a. single-factor, homozygous recessive
   b. two-factor, heterozygous
   c. test, homozygous dominant
   d. single-factor, homozygous dominant
   e. test, homozygous recessive
6. A woman is heterozygous for an X-linked disorder, hemophilia A. If she has a child with a man without hemophilia A, what is the probability that the child will be a male with hemophilia A? (Note: The child could be a male or female.)
   a. 100%
   b. 75%
   c. 50%
   d. 25%
   e. 0%
7. A gene that affects more than one trait is said to be
   a. dominant.
   b. wild-type.
   c. dihybrid.
   d. pleiotropic.
   e. heterozygous.
8. A hypothetical flowering plant species produces blue, light blue, and white flowers. To determine the inheritance pattern, the following crosses were conducted with the results indicated:

   blue × blue → all blue

   white × white → all white

   blue × white → all light blue

   What type of inheritance pattern does this represent?
   a. simple Mendelian
   b. X-linked
   c. codominance
   d. incomplete dominance
   e. pleiotropy
9. Genes located on a sex chromosome are said to be
   a. X-linked.
   b. dominant.
   c. hemizygous.
   d. sex-linked.
   e. autosomal.
10. A man and woman are both heterozygous for the recessive allele that causes cystic fibrosis. What is the probability that their first two offspring will have the disorder?
    a. 1
    b. 1/4
    c. 1/16
    d. 1/32
    e. 0

Conceptual Questions

1. Describe one observation in a human pedigree that rules out a recessive pattern of inheritance. Describe an observation that rules out a dominant pattern.
2. A cross is made between individuals having the following genotypes: *AaBbCCDd* and *AabbCcdd*. What is the probability that an offspring will be *AAbbCCDd*? Hint: Don't waste your time making a really large Punnett square. Make four small Punnett squares instead and use the product rule.
3.  A principle of biology is that *living organisms interact with their environment.* Discuss how the environment plays a key role in determining the outcome of an individual's traits.

Collaborative Questions

1. Discuss the principles of the chromosome theory of inheritance. Which principles do you think were deduced via light microscopy, and which were deduced from crosses? What modern techniques could be used to support the chromosome theory of inheritance?
2. When examining a human pedigree, what patterns do you look for to distinguish between X-linked recessive inheritance and autosomal recessive inheritance? How would you distinguish X-linked dominant inheritance from autosomal dominant inheritance from an analysis of a human pedigree?

Complex Patterns of Inheritance

17

A calico cat. The inheritance of variegated coat colors in the calico cat can't be predicted by Mendel's laws.

As shown in the chapter opening photo, calico cats have patches of orange and black fur with a white underside. Calico refers to the pattern of orange and black patches, not to a particular breed of cat. Many different cat breeds, including Persian, British shorthair, Manx, and Japanese bobtail, occur in calico varieties. An interesting feature of this trait is that it is found only in female cats. It is caused by changes in the X chromosome that occur in female mammals. The calico pattern is an example of a complex pattern of inheritance, one that could not have been predicted from Mendel's laws.

In this chapter, we will explore inheritance patterns that would be difficult if not impossible to predict based solely on Mendel's laws of inheritance, which we discussed in Chapter 16. Some of them even violate the law of segregation or the law of independent assortment. Studies of complex inheritance patterns have helped us appreciate more fully how genes influence phenotypes. Such research has revealed an astounding variety of ways that inheritance occurs. The picture that emerges is of a wonderful web of diverse mechanisms by which genes give rise to phenotypes. **Table 17.1** provides a summary of Mendelian inheritance and the types of inheritance patterns we will consider in this chapter.

Table 17.1 Different Types of Inheritance Patterns

Type	Description
Mendelian	Inheritance patterns in which a single gene affects a single trait and the alleles obey the law of segregation. These patterns include simple Mendelian inheritance, X-linked inheritance, incomplete dominance, and codominance (refer back to Table 16.1).
Epistasis	A type of gene interaction in which the alleles of one gene mask the effects of an allele of another gene.
Continuous variation	Inheritance pattern in which the offspring display a continuous range of phenotypes. This pattern is produced by the additive interactions of several genes, along with environmental influences.
Linkage	Inheritance pattern involving two or more genes that are close together on the same chromosome. Linked genes do not assort independently.
Extranuclear inheritance	Inheritance pattern of genes found in the genomes of mitochondria or chloroplasts. Usually these genes are inherited from the mother.
X-chromosome inactivation	Phenomenon of female mammals in which one X chromosome is inactivated in every somatic cell, producing a mosaic phenotype.
Genomic imprinting	Inheritance pattern in which an allele from one parent is silenced in the somatic cells of the offspring, but the allele from the other parent is expressed.

17.1 Gene Interaction

Learning Outcomes:

1. Describe how the alleles of one gene can mask or be epistatic to the alleles of a different gene.
2. Explain why polygenic traits usually show a continuum of phenotype variation.

The study of single genes was pivotal in establishing the science of genetics. This focus allowed Mendel to formulate the basic laws of inheritance for traits with a simple dominant/recessive inheritance pattern. Likewise, this approach helped later researchers understand inheritance patterns involving incomplete dominance and codominance, as well as traits that are influenced by an individual's sex. However, all or nearly all traits are influenced by many genes. For example, in both plants and animals, height is affected by genes that encode proteins involved in the production of growth hormones, cell division, the uptake of nutrients, metabolism, and many other functions. Variation in any of the genes involved in these processes is likely to influence an individual's height.

If height is controlled by many genes, how was Mendel able to study the effects of a single gene that produced tall or dwarf pea plants? The answer lies in the genotypes of his strains. Although many genes affect the height of pea plants, Mendel chose true-breeding strains that differed with regard to only one of those genes. As a hypothetical example, let's suppose that pea plants have 10 genes affecting height, which we will call *K*, *L*, *M*, *N*, *O*, *P*, *Q*, *R*, *S*, and *T*. The genotypes of two hypothetical strains of pea plants may be:

Tall strain: *KK LL MM NN OO PP QQ RR SS TT*

Dwarf strain: *KK LL MM NN OO PP QQ RR SS tt*

In this example, the tall and dwarf strains differ at only a single gene. One strain is *TT* and the other is *tt*, and this accounts for the difference in their height. If we make crosses of tall and dwarf plants, the genotypes of the F_2 offspring will differ with regard to only one gene; the other nine genes will be identical in all of them. This approach allows a researcher to study the effects of a single gene even though many genes may affect a single character.

In this section, we will examine situations in which a single character is controlled by two or more different genes, each of which has two or more alleles. This phenomenon is called **gene interaction**. As you will see, allelic variation at two or more genes may affect the outcome of traits in different ways. First, we will look at a gene interaction in which an allele of one gene prevents the phenotypic expression of an allele of a different gene. Then we will discuss an interaction in which multiple genes have additive effects on a single character. These additive effects, together with environmental influences, account for the continuous phenotypic variation that we see in most traits.

In an Epistatic Gene Interaction, the Alleles of One Gene Mask the Phenotypic Effects of a Different Gene

In some gene interactions, the alleles of one gene mask the expression of the alleles of another gene. This phenomenon is called **epistasis** (from the Greek *ephistanai*, meaning stopping). An example is the unexpected gene interaction discovered by English geneticists William Bateson and Reginald Punnett in the early 1900s, when they were studying crosses involving the sweet pea, *Lathyrus odoratus*. A cross between a true-breeding purple-flowered plant and a true-breeding white-flowered plant produced an F_1 generation with all purple-flowered plants and an F_2 generation with a 3:1 ratio of purple- to white-flowered plants. Mendel's laws predicted this result. The surprise came when the researchers crossed two different true-breeding varieties of white-flowered sweet peas (**Figure 17.1**). All of the F_1 generation plants had purple flowers! When these plants were

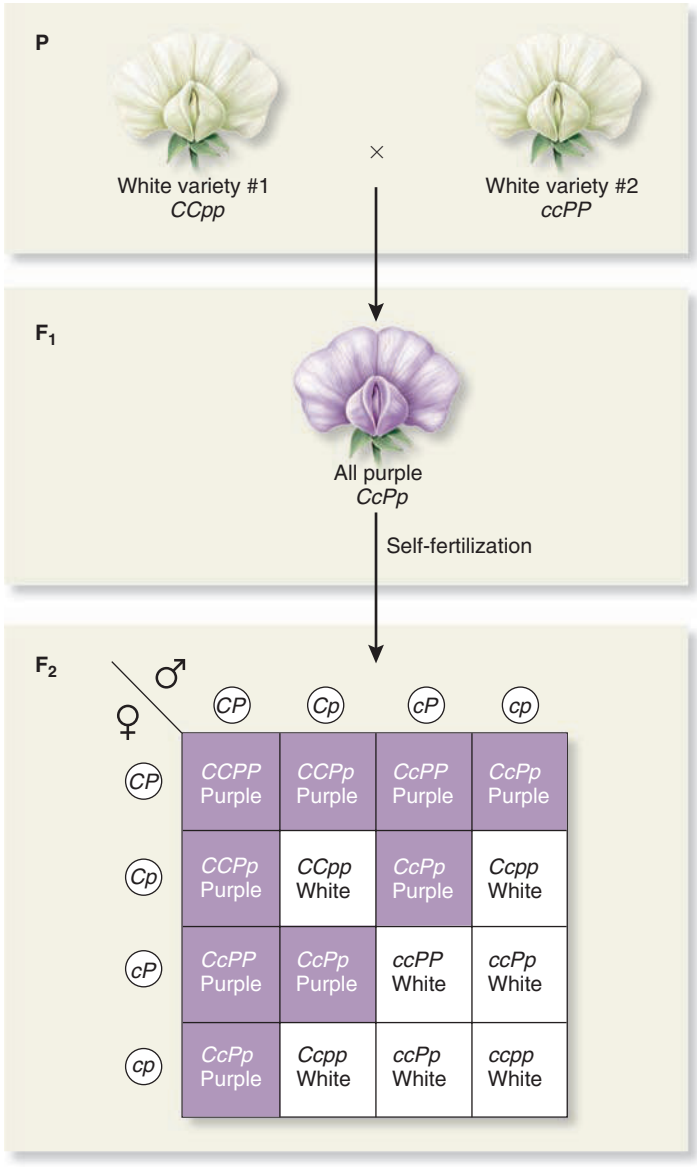

Figure 17.1 Epistasis in the sweet pea. The color of the sweet pea flower is controlled by two genes, each with a dominant and a recessive allele. Each of the dominant alleles (*C* and *P*) encodes an enzyme required for the synthesis of purple pigment. A plant that is homozygous recessive for either gene (*cc* or *pp*) cannot synthesize the pigment and has white flowers.

Concept Check: In a Ccpp individual, which functional enzyme is missing? Is it the enzyme encoded by the C or P gene?

allowed to self-fertilize, the F_2 generation had purple-flowered and white-flowered plants in a 9:7 ratio. From these results, Bateson and Punnett deduced that two different genes were involved. To have purple flowers, a plant must have one or two dominant alleles for each of these genes. The relationships among the alleles are as follows:

C (one allele for purple) is dominant to *c* (white)

P (an allele of a different gene for purple) is dominant to *p* (white)

cc masks *P*, or *pp* masks *C*, in either case producing white flowers

A plant that is homozygous for either *c* or *p* has white flowers even if it has a dominant purple-producing allele for the other gene.

How do we explain these results at the molecular and cellular level? Epistatic interactions often arise because two or more different proteins are involved in a single cellular function. For example, two or more proteins may be part of a metabolic pathway leading to the formation of a single product. This is the case for the formation of a purple pigment in the sweet pea strains we have been discussing:

Colorless precursor $\xrightarrow{\text{Enzyme C}}$ Colorless intermediate $\xrightarrow{\text{Enzyme P}}$ **Purple pigment**

In this example, a colorless precursor molecule must be acted on by two different enzymes to produce the purple pigment. Gene *C* encodes a functional protein called enzyme C, which converts the colorless precursor into a colorless intermediate. The recessive *c* allele results in a lack of production of enzyme C in the homozygote. Gene *P* encodes the functional enzyme P, which converts the colorless intermediate into the purple pigment. Like the *c* allele, the *p* allele results in an inability to produce a functional enzyme. A plant homozygous for either of the recessive alleles does not make any functional enzyme C or enzyme P. When either of these enzymes is missing, the plant cannot make the purple pigment and has white flowers. Note that the results observed in Figure 17.1 do not conflict with Mendel's laws of segregation or independent assortment. Mendel investigated the effects of only a single gene on a given character. The 9:7 ratio is due to a gene interaction in which two genes affect a single character.

Polygenic Inheritance and Environmental Influences Produce Continuous Phenotypic Variation

Until now, we have discussed the inheritance of characters with clearly defined phenotypic variants, such as red or white eyes in fruit flies or round or wrinkled seed shape in garden peas. These are known as **discrete traits**, because the phenotypes do not overlap. For most traits, however, the phenotypes cannot be sorted into discrete categories. Traits that show continuous variation over a range of phenotypes are called **quantitative traits**. In humans, quantitative traits include height, weight, skin color, metabolic rate, and heart size. In the case of domestic animals and plant crops, many of the traits that people consider desirable are quantitative in nature, such as the number of eggs a chicken lays, the amount of milk a cow produces, and the number of apples on an apple tree. Consequently, much of our modern understanding of quantitative traits comes from agricultural research.

Quantitative traits are usually **polygenic**, which means that multiple genes contribute to the outcome of the trait. For many polygenic traits, genes contribute to the phenotype in an additive way. As a hypothetical example, let's suppose that three different genes (*W1*, *W2*, and *W3*) affect weight in turkeys; each gene can occur in heavy (*W*) and light (*w*) alleles. A heavy allele contributes an extra pound to an individual's weight compared with the effect of a light allele. A turkey homozygous for all the heavy alleles (*W1W1 W2W2 W3W3*) would weigh 6 pounds more than an individual homozygous for all the light alleles (*w1w1 w2w2 w3w3*). A turkey heterozygous for all three genes (*W1w1 W2w2 W3w3*) would have an intermediate weight that would be 3 pounds lighter than the homozygous turkey carrying all of the heavy alleles, because the heterozygote carries three light alleles.

An individual's environment is another important factor affecting the expression of quantitative traits. As we learned in Chapter 16, the environment plays a vital role in the phenotypic expression of genes. Environmental factors often have a major effect on quantitative traits. For example, an animal's diet affects its weight, and the amounts of rain and sunlight that fall on an apple tree affect how many apples it produces.

Because quantitative traits are polygenic and greatly influenced by environmental conditions, the phenotypes among different individuals may vary substantially in any given population. As an example, let's consider skin pigmentation in humans. This character is influenced by several genes that tend to interact in an additive way. As a simplified example, let's consider a population in which skin pigmentation in people is controlled by three genes, which we will designate *A*, *B*, and *C*. Each gene may exist as a dark allele, designated A^D, B^D, or C^D, or a light allele, designated A^L, B^L, or C^L, respectively. All of the alleles encode enzymes that cause the synthesis of skin pigment, but the enzymes encoded by dark alleles cause more pigment synthesis than the enzymes encoded by light alleles.

Figure 17.2 considers a hypothetical case in which people who were heterozygous for all three genes produced a large population of offspring. The bar graph shows the genotypes of the offspring, grouped according to the total number of light and dark alleles. As shown by the shading of the figure, skin pigmentation increases as the number of dark alleles increases. Offspring who have all light alleles or who have all dark alleles—that is, those who are homozygous for all three genes—are fewer in number than those with some combination of light and dark alleles. As seen in the bell-shaped curve above the bar graph, the phenotypes of the offspring fall along a continuum. This continuous phenotypic variation, which is typical of quantitative traits, is produced by genotypic differences together with environmental effects. A second bell-shaped curve (the dashed line) depicts the expected phenotypic range if the same population of offspring had been raised in a sunnier environment, which increases pigment production. This curve illustrates how the environment can also have a significant influence on the range of phenotypes.

In our discussion of genetics, we tend to focus on discrete traits because this makes it easier to relate a specific genotype with a phenotype. This is usually not possible for continuous traits. For example, as depicted in the middle bar of Figure 17.2, seven different genotypes can produce individuals with a medium amount of pigmentation. It is important to emphasize that the majority of traits in all organisms are continuous, not discrete. Most traits are influenced by multiple genes, and the environment has an important influence on the phenotypic outcome.

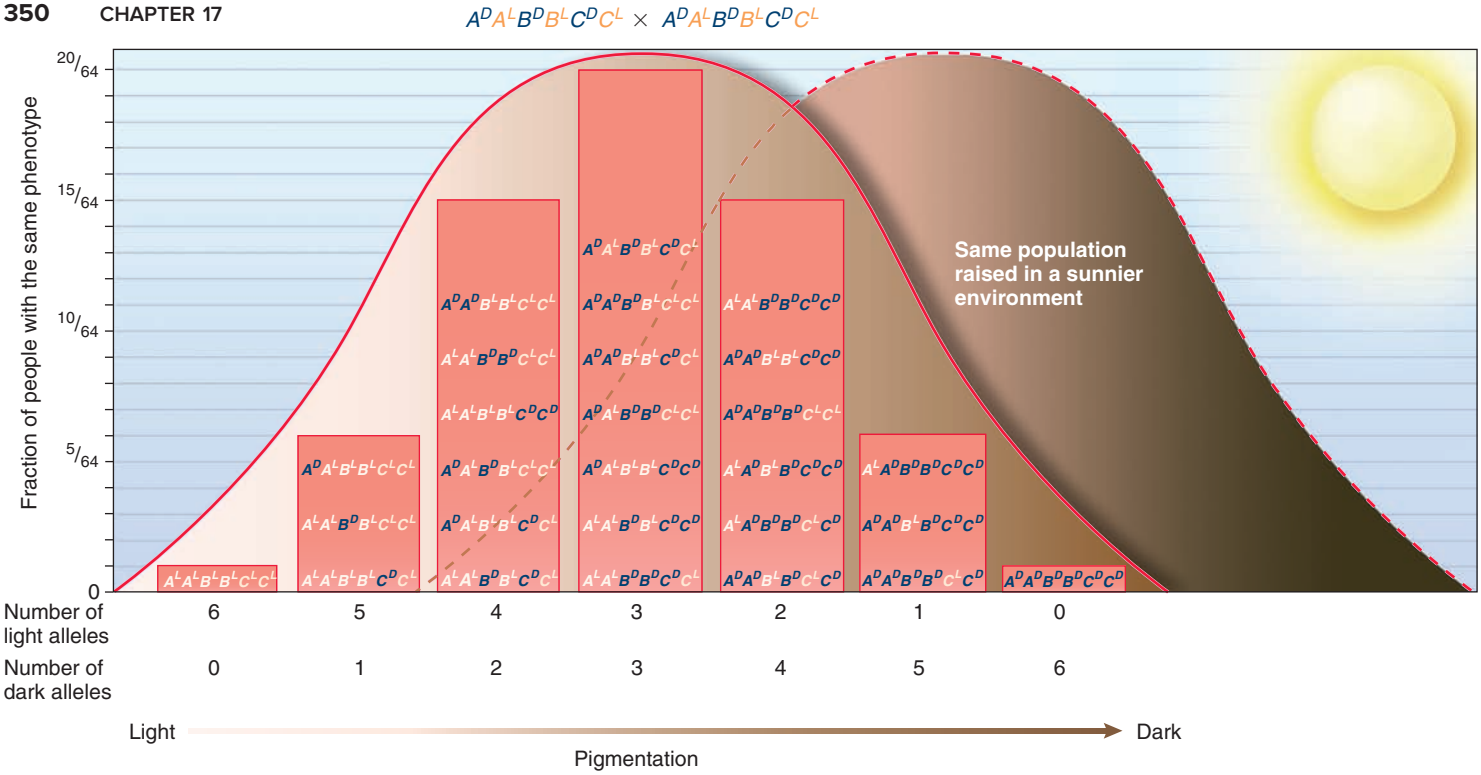

Figure 17.2 Continuous variation in a polygenic trait. Skin color is a polygenic character that displays a continuum of phenotypes. The bell curve on the left (solid line) shows the range of skin pigmentation in a hypothetical human population. The bar graph below this curve shows the additive effects of three genes that affect pigment production in this population; each bar shows the fraction of people with a particular number of dark alleles (A^D, B^D, and C^D) and light alleles (A^L, B^L, and C^L). The bell curve on the right (dashed line) represents the expected range of phenotypes if the same population was raised in a sunnier environment.

BIOLOGY PRINCIPLE The genetic material provides the blueprint for reproduction. The genetic blueprint usually involves the expression of several different genes that affect the same trait. In many cases, this results in continuous variation.

17.2 Genes on the Same Chromosome: Linkage, Recombination, and Mapping

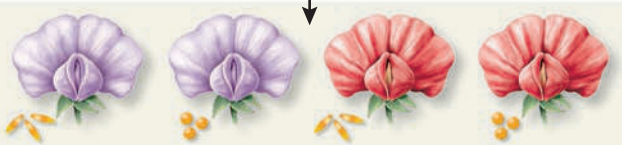
Learning Outcomes:

1. Describe how linkage violates the law of independent assortment.
2. Explain how experimental crosses can demonstrate linkage.
3. **SciSKILLS»** Calculate the distance between genes that are linked on the same chromosome.

In Chapter 16, we learned that the independent assortment of alleles is due to the random alignment of homologous chromosomes during meiosis (refer back to Figure 16.11). But what happens when the alleles of different genes are on the same chromosome and do not independently assort? A typical chromosome contains many hundreds or even a few thousand different genes. When two genes are close together on the same chromosome, they tend to be transmitted as a unit, a phenomenon known as **linkage**. A group of genes that usually stay together during meiosis is called a **linkage group**, and the genes in the group are said to be linked. In a two-factor cross, linked genes that are close together on the same chromosome do not follow the law of independent assortment.

In this section, we begin by examining the first experimental cross that demonstrated linkage. This pattern was subsequently explained by Thomas Hunt Morgan, who proposed that different genes located close to each other on the same chromosome tend to be inherited together. We will also see how crossing over between such genes provided the first method of mapping genes along chromosomes.

Feature Investigation | Bateson and Punnett's Cross of Sweet Peas Showed That Genes Do Not Always Assort Independently



The first study showing linkage between two different genes was a cross of sweet peas carried out by William Bateson and Reginald Punnett in 1911. A surprising result occurred when they conducted a two-factor cross involving flower color and pollen shape (**Figure 17.3**). One of the parent plants had purple flowers (*PP*) and long pollen (*LL*); the other had red flowers (*pp*) and round pollen (*ll*). As Bateson and Punnett expected, the F_1 plants all had purple flowers and long pollen (*PpLl*). The unexpected result came in the F_2 generation.

Although the F_2 offspring displayed the four phenotypes predicted by Mendel's laws, the observed numbers of offspring did not conform

Figure 17.3 **A cross of sweet peas showing that independent assortment does not always occur.**

HYPOTHESIS The alleles of different genes assort independently of each other.

KEY MATERIALS True-breeding sweet pea strains that differ with regard to flower color and pollen shape.

	Experimental level	Conceptual level
1 Cross a plant with purple flowers and long pollen to a plant with red flowers and round pollen.	 Purple flowers, long pollen × Red flowers, round pollen	*PPLL* × *ppll*
2 Observe the phenotypes of the F_1 offspring.	 Purple flowers, long pollen	*PpLl*
3 Allow the F_1 offspring to self-fertilize.	 Purple flowers, long pollen × Purple flowers, long pollen	Meiosis *PL* and *pl* gametes — more frequent *Pl* and *pL* gametes — less frequent
4 Observe the phenotypes of the F_2 offspring.	 Purple flowers, long pollen 15.6 : Purple flowers, round pollen 1.0 : Red flowers, long pollen 1.4 : Red flowers, round pollen 4.5	Fertilization F_2 offspring having phenotypes of purple flowers with long pollen or red flowers with round pollen occurred more frequently than expected from Mendel's law of independent assortment.

5 THE DATA

Phenotypes of F_2 offspring	Observed number	Observed ratio	Expected number	Expected ratio
Purple flowers, long pollen	296	15.6	240	9
Purple flowers, round pollen	19	1.0	80	3
Red flowers, long pollen	27	1.4	80	3
Red flowers, round pollen	85	4.5	27	1

6 CONCLUSION The data are not consistent with the law of independent assortment.

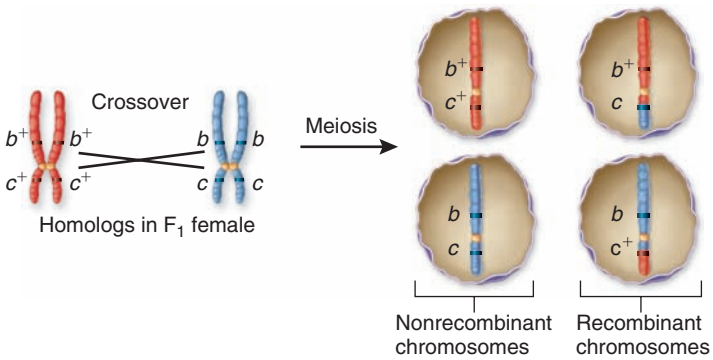
7 SOURCE Bateson, W., and Punnett, R. C. 1911. On the inter-relations of genetic factors. *Proceedings of the Royal Society of London, Series B*, 84:3–8.

to the predicted 9:3:3:1 ratio (refer back to Figure 16.8). Rather, as seen in the data in Figure 17.3, the F_2 generation had a much higher proportion of the two phenotypes found in the parental generation: purple flowers with long pollen, and red flowers with round pollen. How did Bateson and Punnett explain these results? They suggested that the transmission of flower color and pollen shape was somehow coupled, so these traits did not always assort independently. Although the law of independent assortment applies to many other genes, in this example, the hypothesis of independent assortment was rejected.

Experimental Questions

1. What hypothesis was Bateson and Punnett testing when conducting the crosses in the sweet pea?
2. **SciSKILLS** » What were the expected results of Bateson and Punnett's cross?
3. **SciSKILLS** » How did the observed results differ from the expected results?

Linkage and Crossing Over Produce Parental and Recombinant Types



Bateson and Punnett realized their results did not conform to Mendel's law of independent assortment. However, they did not know why the genes were not assorting independently. A few years later, Thomas Hunt Morgan obtained similar ratios in crosses of fruit flies while studying the transmission pattern of genes in *Drosophila*. Like Bateson and Punnett, Morgan observed many more F_2 offspring with the combination of traits found in the parental generation than predicted on the basis of independent assortment. To explain his data, Morgan proposed three ideas:

1. When different genes are located on the same chromosome, the traits determined by those genes are more likely to be inherited together. This violates the law of independent assortment.
2. Due to crossing over during meiosis, homologous chromosomes can exchange pieces of chromosomes and create new combinations of alleles.
3. The likelihood of a crossover occurring in the region between two genes depends on the distance between the two genes. Crossovers between homologous chromosomes are much more likely to occur between two genes farther apart along a chromosome compared to two genes that are closer together.

To illustrate the first two ideas, **Figure 17.4** considers a series of crosses involving two genes linked on the same chromosome in *Drosophila*. The two genes are located on an autosome, not on a sex chromosome. The P generation cross is between flies that are homozygous for alleles that affect body color and wing shape. The female is homozygous for the dominant wild-type alleles that produce gray body color (b^+b^+) and straight wings (c^+c^+); the male is homozygous for recessive mutant alleles that produce black body color (bb) and curved wings (cc). The symbols for the genes are based on the names of the mutant phenotypes; the dominant wild-type allele is indicated by a superscript plus sign ($^+$). The chromosomes next to the flies in Figure 17.4 show the arrangement of these alleles. If the two genes are on the same chromosome, we know the arrangement of alleles in the P generation flies because these flies are homozygous for both genes ($b^+b^+c^+c^+$ for one parent and $bbcc$ for the other parent). In the P generation female, on the left, b^+ and c^+ are linked, whereas b and c are linked in the male, on the right.

Let's now look at the outcome of the crosses in Figure 17.4. As expected, the F_1 offspring (b^+bc^+c) all had gray bodies and straight wings, confirming that these are the dominant traits. In the next cross, F_1 females were mated to males that were homozygous for both recessive alleles ($bbcc$). Recall from Chapter 16 that a testcross is conducted to determine if an individual with a dominant phenotype is a homozygote or a heterozygote. However, in the crosses we are discussing here, the purpose of the testcross is to determine if the genes for body color and wing shape are linked. If the genes are on different chromosomes and assort independently, this testcross will produce F_2 offspring with the four possible phenotypes in a 1:1:1:1 ratio. The observed numbers clearly conflict with this prediction. The two most abundant phenotypes are those with the combinations of characteristics in the P generation: gray bodies and straight wings or black bodies and curved wings. These offspring are termed **nonrecombinants**. The smaller number of offspring that have a combination of traits not found in the parental generation—gray bodies and curved wings or black bodies and straight wings—are called **recombinants**.

How do we explain the occurrence of recombinants when genes are linked on the same chromosome? As shown beside the flies of the F_2 generation in Figure 17.4, each recombinant individual has a chromosome that is the product of a crossover. The crossover occurred during the process of egg formation in the F_1 female fly. As shown below, four different egg cells are possible:

Due to crossing over, two of the four egg cells produced by meiosis have recombinant chromosomes. What happens when eggs containing such chromosomes are fertilized in the testcross? Each of the male fly's sperm cells carries a chromosome with the two recessive alleles. If the egg contains the recombinant chromosome carrying the b^+ and c alleles, the testcross will produce an F_2 offspring with a gray body and curved wings. If the egg contains the recombinant chromosome carrying the b and c^+ alleles, F_2 offspring will have a black body and straight wings. Therefore, crossing over in the F_1 female can explain the occurrence of both types of F_2 recombinant offspring.

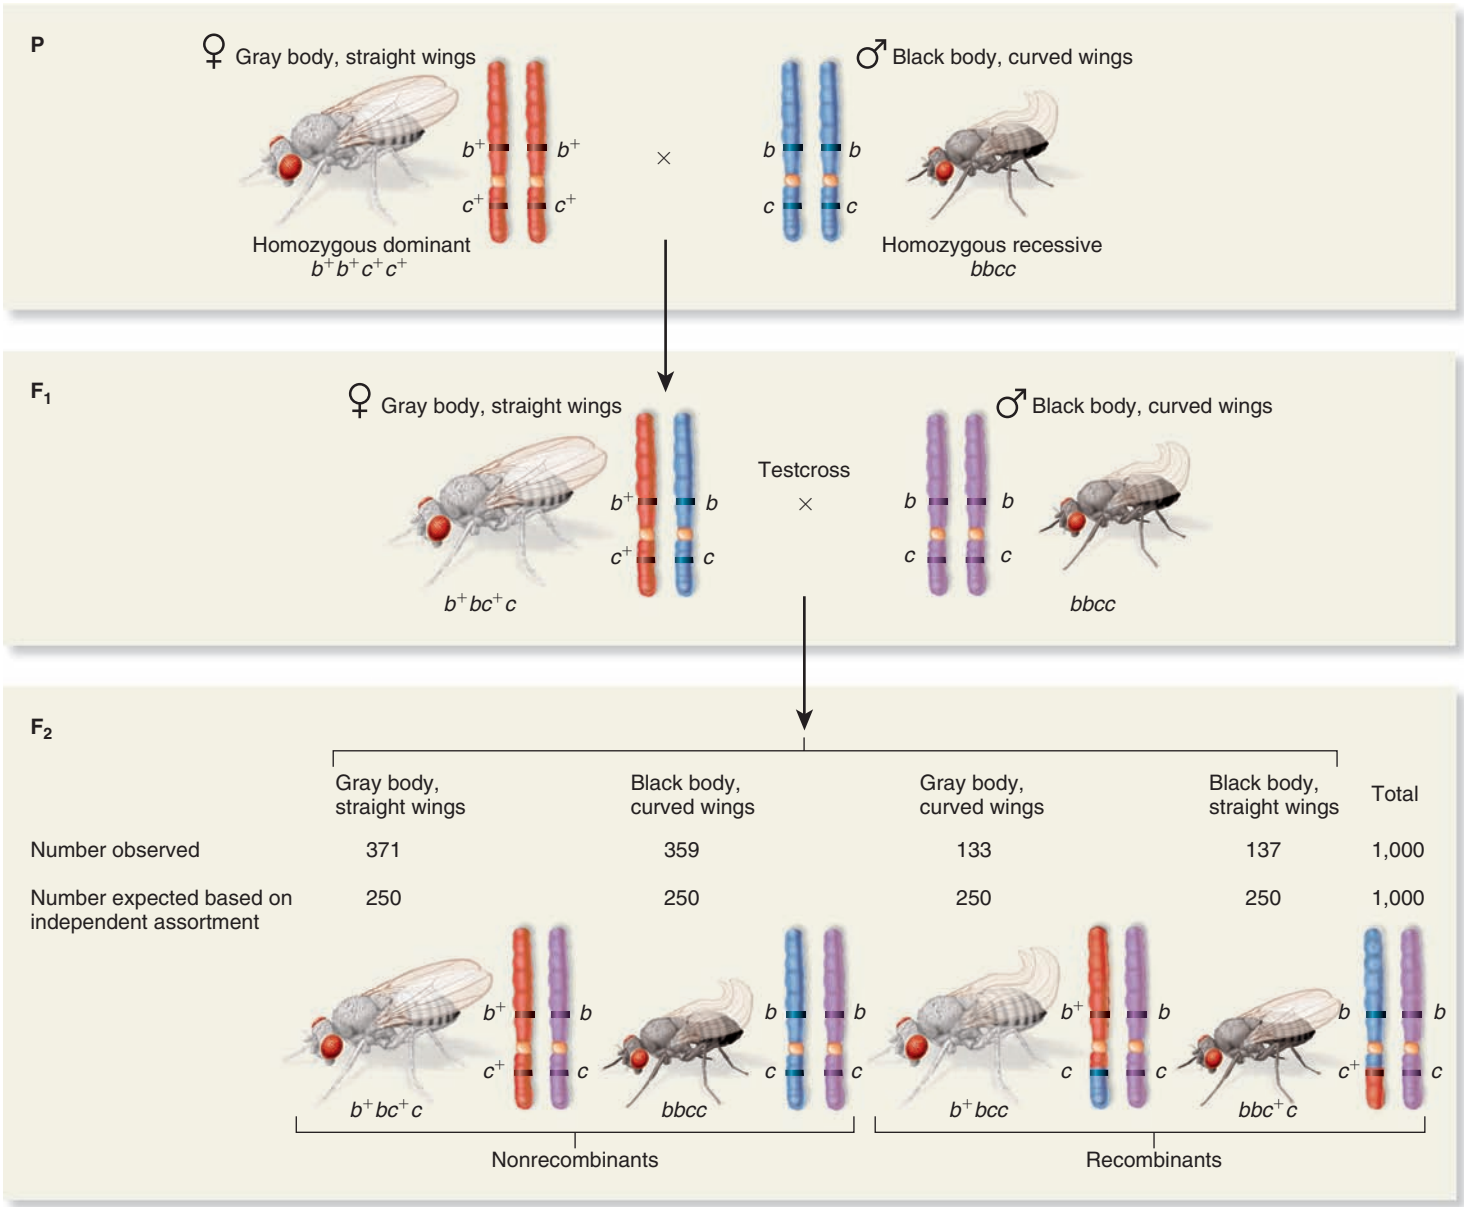


Figure 17.4 **Linkage and recombination of alleles.** An experimenter crossed $b^+b^+c^+c^+$ and *bbcc* flies to produce F_1 heterozygotes. F_1 females were then testcrossed to *bbcc* males. The large number of nonrecombinant phenotypes in the F_2 generation suggests that the two genes are linked on the same chromosome. F_2 recombinant phenotypes occur because the alleles can be rearranged by crossing over. Note: The b^+ and c^+ alleles are dominant, and the *b* and *c* alleles are recessive.

Concept Check: *In which fly or flies did crossing over occur to produce the recombinant offspring of the F_2 generation?*

BioConnections: *Look back at Figure 15.13. When does crossing over occur?*

Morgan's third idea regarding linkage was that the frequency of crossing over between linked genes depends on the distance between them. This suggested a method for determining the relative positions of genes on a chromosome, as we will discuss next.

Recombination Frequencies Provide a Method for Mapping Genes Along Chromosomes

The study of the arrangement of genes in a species' genome is called **genetic mapping**. As depicted in **Figure 17.5**, the linear order of genes along a chromosome is shown in a chart known as a **genetic map**. Each gene has its own physical location, or locus, on a chromosome. For example, the gene for black body color (*b*) discussed earlier is located near the middle of the chromosome, whereas the gene for curved wings (*c*) is closer to one end. The first genetic map, showing five genes on the *Drosophila* X chromosome, was constructed in 1911 by American geneticist Alfred Sturtevant, when he was an undergraduate student in Morgan's laboratory.

Genetic mapping allows us to estimate the relative distances between linked genes based on the likelihood that a crossover will occur between them. This likelihood is proportional to the distance between the genes, as Morgan first proposed. If the genes are very

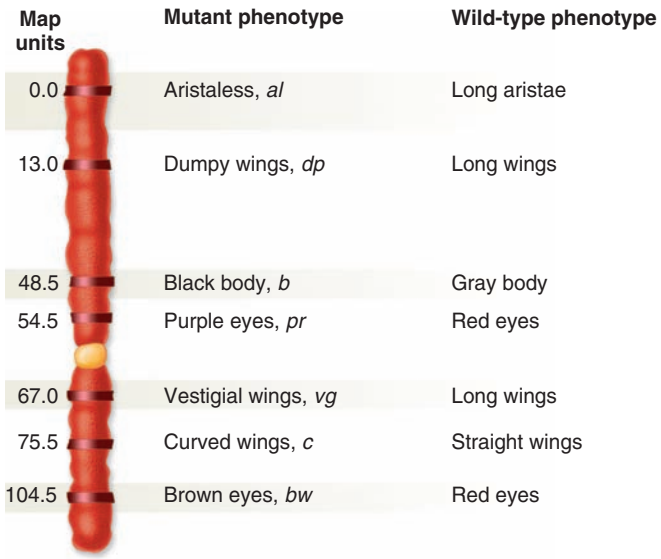

Figure 17.5 A simplified genetic map. This map shows the relative locations of a few genes along chromosome number 2 in *Drosophila melanogaster*. The name of each gene is based on the mutant phenotype. The numbers on the left are map units (mu). The distance between two genes, in map units, corresponds to their recombination frequency in testcrosses.

Concept Check: How would you set up a testcross to determine the distance between the al and dp genes? What would be the genotypes of the P, F_1, and F_2 generations?

close together, a crossover is unlikely to occur in the region between them. However, if the genes are very far apart, a crossover is more likely to be initiated in the region between the genes and thereby recombine the alleles. Therefore, in a testcross involving two genes on the same chromosome, the percentage of recombinant offspring is correlated with the distance between the genes. If a two-factor testcross produces many recombinants, the experimenter concludes that the two genes are far apart. If very few recombinants are observed, the two genes must be close together.

To find the distance between two genes, the experimenter must determine the frequency of crossing over between them, called their **recombination frequency**. This is accomplished by conducting a testcross. As an example, let's refer back to the *Drosophila* testcross described in Figure 17.4. As we discussed, the genes for body color and wing shape are on the same chromosome. The recombinants are the result of crossing over during egg formation in the F_1 female. We can use the data from the testcross shown in Figure 17.4 to estimate the distance between these two genes. The **map distance** between two genes is defined as the number of recombinants divided by the total number of offspring times 100.

$$\text{Map distance} = \frac{\text{Number of recombinants}}{\text{Total number of offspring}} \times 100$$

$$= \frac{133 + 137}{371 + 359 + 133 + 137} \times 100$$

$$= 27.0 \text{ map units}$$

The units of map distance are called **map units (mu)**. One map unit is equivalent to a 1% recombination frequency. In this example, 270 out of 1,000 offspring are recombinants, so the recombination frequency is 27%, and the two genes are 27.0 mu apart.

Genetic mapping has been useful for analyzing the genes of organisms that are easily crossed and produce many offspring in a short time. It has been used to map the genes of several plant species and of certain species of animals, such as *Drosophila*. However, for most organisms, including humans, genetic mapping via crosses is impractical due to long generation times or the inability to carry out experimental crosses. Fortunately, many alternative methods of gene mapping have been developed in the past few decades that are faster and do not depend on crosses. These newer cytological and molecular approaches, which we will discuss in Chapter 20, are also used to map genes in a wide variety of organisms.

17.3 Extranuclear Inheritance: Organelle Genomes

Learning Outcomes:

1. Describe the general features of mitochondrial and chloroplast genomes.
2. **SciSKILLS »** Predict the outcome of crosses that exhibit maternal inheritance.
3. List human diseases associated with mutations in mitochondrial genes.

In the previous section, we examined the inheritance patterns of linked genes that violate the law of independent assortment. In this section, we will explore inheritance patterns that violate the law of segregation. The segregation of genes is explained by the pairing and segregation of homologous chromosomes during meiosis. However, some genes are not found on the chromosomes in the cell nucleus, and these genes do not segregate in the same way. The transmission of genes located outside the cell nucleus is called **extranuclear inheritance**. Two important types of extranuclear inheritance patterns involve genes found in chloroplasts and mitochondria. Extranuclear inheritance is also called cytoplasmic inheritance because these organelles are in the cytoplasm of the cell. In this section, we will examine the transmission patterns observed for genes found in the chloroplast and mitochondrial genomes and consider how mutations in these genes may affect an individual's traits.

Genomes & Proteomes Connection

Chloroplast and Mitochondrial Genomes Are Relatively Small, but Contain Genes That Encode Important Proteins

As we discussed in Chapter 4, mitochondria and chloroplasts are found in eukaryotic cells because of an ancient endosymbiotic relationship. They contain their own genetic material, called the mitochondrial genome and chloroplast genome, respectively (**Figure 17.6**). Mitochondrial and chloroplast

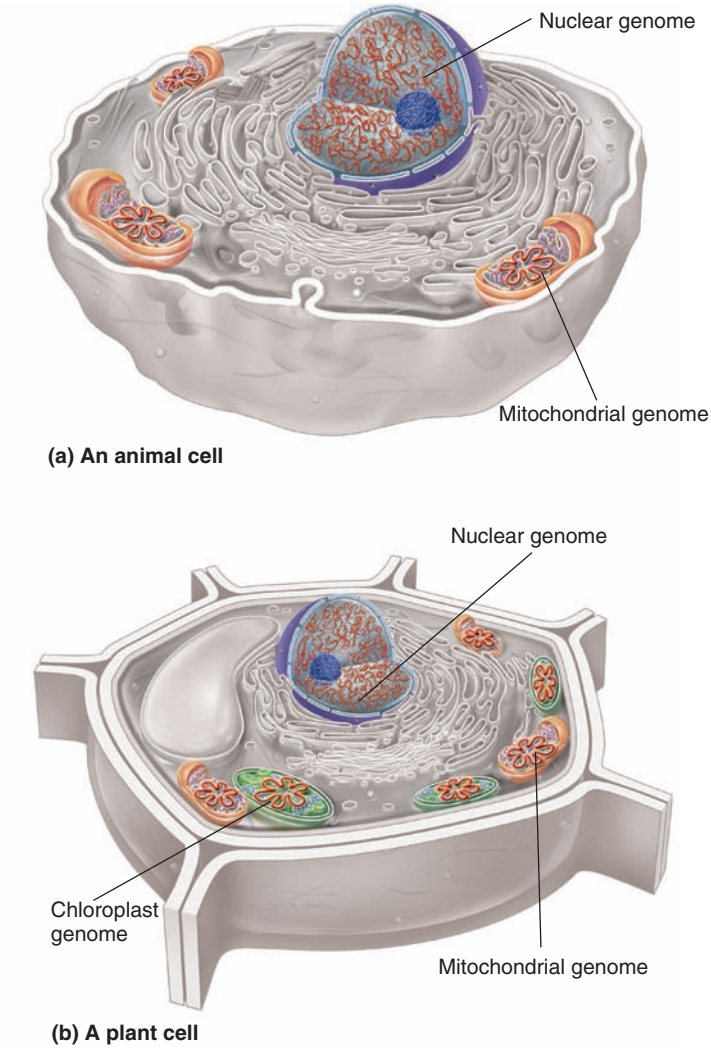

Figure 17.6 The locations of genetic material in animal and plant cells. The chromosomes in the cell nucleus are collectively known as the nuclear genome. Mitochondria and chloroplasts have small circular chromosomes called the mitochondrial and chloroplast genomes, respectively.

BioConnections: *Look back at Figure 4.27. What is the evolutionary origin of mitochondria and chloroplasts in eukaryotic cells?*

genomes are composed of a single, circular DNA molecule. The mitochondrial genome of many mammalian species has been analyzed and usually contains a total of 37 genes. Twenty-four genes encode tRNAs and rRNAs, which are needed for translation inside the mitochondrion, and 13 genes encode proteins that are involved in oxidative phosphorylation. As discussed in Chapter 7, the primary function of the mitochondrion is the synthesis of ATP via oxidative phosphorylation. Among different species of plants, chloroplast genomes typically contain about 110 to 120 genes. Many of these genes encode proteins that are vital to the process of photosynthesis, which we discussed in Chapter 8.

Chloroplast Genomes Are Often Maternally Inherited

One of the first experiments showing an extranuclear inheritance pattern was carried out by German botanist Carl Correns in 1909. Correns discovered that leaf pigmentation in the four-o'clock plant (*Mirabilis jalapa*) follows a pattern of inheritance that does not obey Mendel's law of segregation. Four-o'clock leaves may be green, white, or variegated. Correns observed that the pigmentation of the offspring depended solely on the pigmentation of the female parent, a phenomenon called **maternal inheritance** (**Figure 17.7**). In cross 1, if the female parent providing the eggs had white leaves and the male parent providing the pollen had green leaves, all of the offspring had white leaves like the female parent. Correns also conducted a **reciprocal cross**—a cross in which the sexes and phenotypes are reversed. In the reciprocal cross of cross 1, the female parent had green leaves and the male parent had white leaves. Again, the offspring exhibited a phenotype like the female parent. Similarly, if the female was green, so were all of the offspring. In cross 2, the offspring of a variegated female parent could be green, white, or variegated.

What accounts for maternal inheritance? At the time, Correns did not understand that chloroplasts contain genetic material. Subsequent research identified DNA present in chloroplasts as responsible for the unusual inheritance pattern observed. We now know that the pigmentation of four-o'clock leaves can be explained by the occurrence of genetically different types of chloroplasts in the leaf cells. As discussed in Chapter 8, chloroplasts are the site of photosynthesis, and their green color is due to the presence of the pigment called chlorophyll. Certain genes required for chlorophyll synthesis are found within the chloroplast DNA. The green phenotype is due to the presence of chloroplasts that have functional genes and synthesize the usual quantity of chlorophyll. The white phenotype is caused by a mutation in a gene within the chloroplast DNA that prevents the synthesis of most of the chlorophyll. (Enough chlorophyll is made for the plant to survive.) The variegated phenotype occurs in leaves that have a mixture of the two types of chloroplasts.

Leaf pigmentation follows a maternal inheritance pattern because the chloroplasts in four-o'clocks are transmitted only through the cytoplasm of the egg (**Figure 17.8**). In most species of plants, the egg cell provides most of the zygote's cytoplasm, whereas the much smaller male gamete often provides little more than a nucleus. Therefore, chloroplasts are most often inherited via the egg. Recall from Chapter 4 that chloroplasts are derived from proplastids. In four-o'clocks, the egg cell contains several proplastids that are inherited by the offspring. The sperm cell does not contribute any proplastids. For this reason, the phenotype of a four-o'clock plant reflects the types of proplastids it inherits from the maternal parent.

- If the maternal parent transmits only normal proplastids, all offspring will have green leaves (Figure 17.8a).
- Alternatively, if the maternal parent transmits only mutant proplastids, all offspring will have white leaves (Figure 17.8b).
- Because an egg cell contains several proplastids, an offspring from a variegated maternal parent may inherit only normal

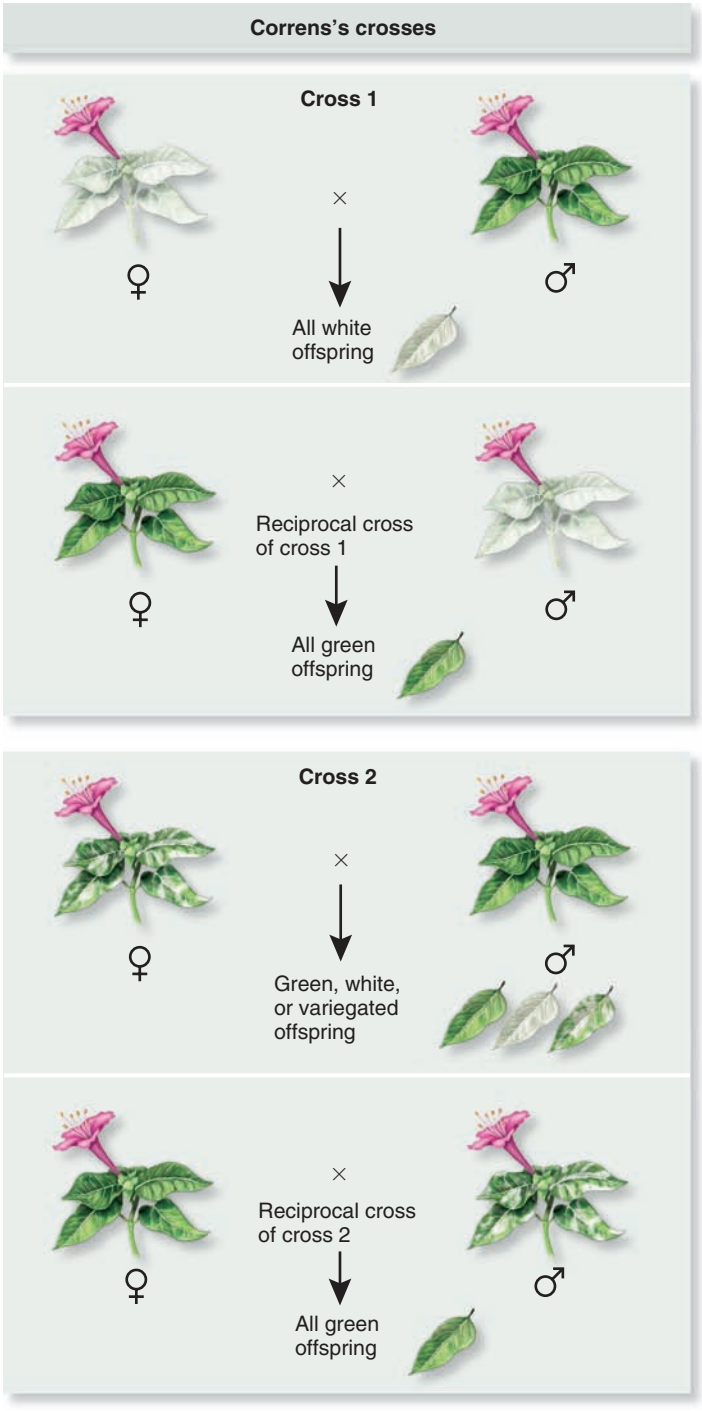

Figure 17.7 Maternal inheritance in the four-o'clock plant. In four-o'clocks, the egg contains all of the proplastids, which develop into chloroplasts, that are inherited by the offspring. The phenotype of the offspring is determined by the maternal parent. The green phenotype is due to the presence of normal chloroplasts. The white phenotype is due to chloroplasts with a mutant allele that greatly reduces green pigment production. The variegated phenotype is due to a mixture of normal and mutant chloroplasts.

Concept Check: In this example, where is the gene located that causes the green color of four-o'clock leaves? How is this gene transmitted from parent to offspring?

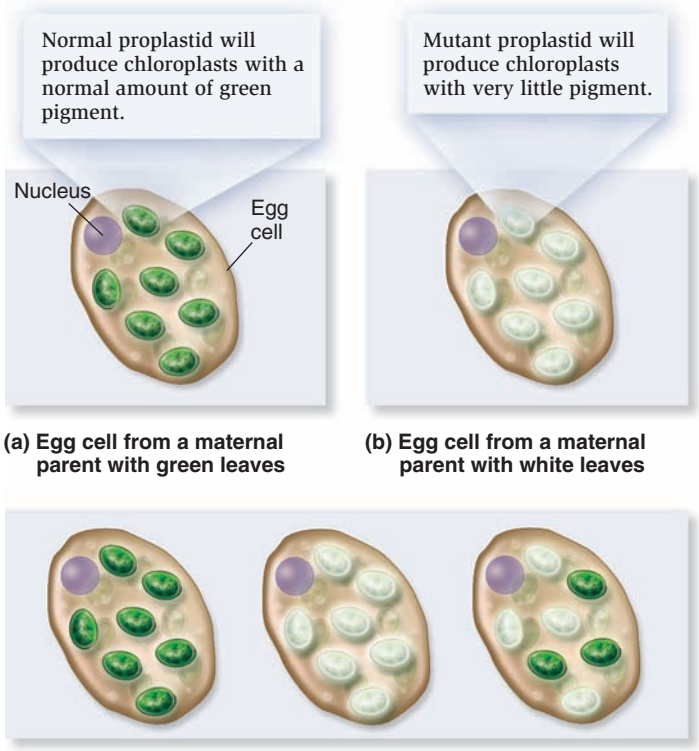

Figure 17.8 Plastid compositions of egg cells from green, white, and variegated four-o'clock plants. In this drawing of four-o'clock egg cells, normal proplastids are represented as green and mutant proplastids as white. (Note: This drawing is schematic. Proplastids do not differentiate into chloroplasts in egg cells, and they are not actually green.) **(a)** A green plant produces eggs carrying normal proplastids. **(b)** A white plant produces eggs carrying mutant proplastids. **(c)** A variegated plant produces eggs that may contain either or both types of proplastids.

proplastids, only mutant proplastids, or a mixture of normal and mutant proplastids. Consequently, the offspring of a variegated maternal parent can be green, white, or variegated individuals (Figure 17.8c).

How do we explain the variegated phenotype at the cellular level? This phenotype is due to events that occur after fertilization. As a zygote containing both types of proplastids grows via cellular division to produce a multicellular plant, some cells may receive mostly those that develop into normal chloroplasts. Further division of these cells gives rise to a patch of green tissue. Alternatively, as a matter of chance, other cells may receive all or mostly mutant chloroplasts that are defective in chlorophyll synthesis. The result is a patch of white tissue.

In seed-bearing plants, maternal inheritance of chloroplasts is the most common transmission pattern. However, certain species exhibit a pattern called **biparental inheritance**, in which both the pollen and the egg contribute chloroplasts to the offspring. Others exhibit **paternal inheritance**, in which only the pollen contributes these organelles. For example, most types of pine trees show paternal inheritance of chloroplasts.

BIO TIPS

THE QUESTION *One strain of periwinkle plants has green leaves, and another strain has variegated leaves. You do not know if the difference in the phenotypes is due to a mutation in a nuclear gene or an organellar gene (one found in the chloroplasts or mitochondria). Using reciprocal crosses of the two strains, the following results were obtained:*

Variegated plant pollinated by green plant	Green plant pollinated by variegated plant
↓	↓
Offspring with green, white, or variegated leaves	All offspring with green leaves

Explain this pattern of inheritance.

TOPIC ***What topic in biology does this question address?*** The topic is inheritance. More specifically, the question is about distinguishing nuclear and extranuclear (organellar) inheritance patterns.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you know there are different strains of periwinkles, including green-leaved and variegated-leaved. You are also given the results of reciprocal crosses. From your understanding of the topic, you may remember that some genes are found in the nucleus, whereas others are found in organelles, chloroplasts or mitochondria.

PROBLEM-SOLVING STRATEGY ***Predict the outcome. Compare and contrast.*** Crosses of these two strains will yield different results depending on the mode of inheritance. For example, if the gene is a nuclear gene and the green-leaved allele is dominant, you would predict that all of the F_1 offspring will be green-leaved. On the other hand, if the gene is in the chloroplasts and follows maternal inheritance, the phenotype of the offspring will depend on which plant contributed the egg.

ANSWER *The results of the reciprocal crosses are consistent with maternal inheritance because the phenotypes of the offspring correlate with inheriting the gene from the plant contributing the egg cells.*

Mitochondrial Genomes Are Maternally Inherited in Humans and Most Other Species

Mitochondria are found in nearly all eukaryotic species. As with the transmission of chloroplasts in plants, maternal inheritance is the most common pattern of mitochondrial transmission in eukaryotes, although some species do exhibit biparental or paternal inheritance.

In humans, mitochondria are maternally inherited. Researchers have discovered that mutations in human mitochondrial genes cause a variety of rare diseases (Table 17.2). These are usually chronic degenerative disorders that affect organs, such as the brain, eyes, heart, muscle, kidneys, and endocrine glands, whose cells require high levels of ATP. For example, Leber's hereditary optic neuropathy (LHON) affects the optic nerve and leads to the progressive loss of vision in one or both eyes. LHON is caused by point mutations in several different mitochondrial genes.

Table 17.2 Examples of Human Mitochondrial Disease

Disease	Causes and symptoms
Leber's hereditary optic neuropathy (LHON)	A mutation in one of several mitochondrial genes that encode electron transport proteins. The main symptom is loss of vision.
Neurogenic muscle weakness	A mutation in a mitochondrial gene that encodes a subunit of mitochondrial ATP synthase, which is required for ATP synthesis. Symptoms involve abnormalities in the nervous system that affect the muscles and eyes.
Maternal myopathy and cardiomyopathy	A mutation in a mitochondrial gene that encodes a tRNA for leucine. The primary symptoms involve muscle abnormalities, most notably in the heart.
Myoclonic epilepsy and ragged-red muscle fibers	A mutation in a mitochondrial gene that encodes a tRNA for lysine. Symptoms include epilepsy, dementia, blindness, deafness, and heart and kidney malfunctions.

17.4 Epigenetic Inheritance

Learning Outcomes:

1. Describe the process of X-chromosome inactivation and its effects on the phenotype of heterozygous females.
2. Explain the molecular basis of genomic imprinting, and predict how it affects inheritance patterns.

We will end our discussion of complex inheritance patterns by considering examples in which the timing and control of gene expression result in inheritance patterns that are determined by the sex of the individual or by the sex of the parents. We will consider two patterns, called X-chromosome inactivation and genomic imprinting, which are types of **epigenetic inheritance**. In epigenetic inheritance, modification of a gene or chromosome occurs during egg formation, sperm formation, or early stages of embryo growth. This modification does not alter the DNA sequence, but it affects gene expression in a way that is fixed during an individual's lifetime. Such epigenetic changes affect the phenotype of the individual, but they are not permanent over the course of two or more generations. For example, a gene may undergo an epigenetic change that inactivates the gene for an individual's entire life, so it is never expressed in that individual. However, when the same individual produces gametes, the gene may become activated and remain active during the lifetime of an offspring that inherits it.

In Female Mammals, One X Chromosome Is Inactivated in Each Somatic Cell

In 1961, British geneticist Mary Lyon proposed the epigenetic phenomenon of **X-chromosome inactivation**, in which one of the two copies of the X chromosome in the somatic cells of female

mammals is inactivated, meaning that its genes are not expressed. X-chromosome inactivation is based on two lines of evidence. The first came from microscopic studies of mammalian cells. In 1949, Canadian physicians Murray Barr and Ewart Bertram identified a highly condensed structure in the cells of female cats that was not found in the cells of male cats. This structure was named a **Barr body** after one of its discoverers (**Figure 17.9**). In 1960, Asian-American geneticist Susumu Ohno correctly proposed that a Barr body is a highly condensed X chromosome. Lyon's second line of evidence was the inheritance pattern of variegated coat colors in certain female mammals. A classic case is the calico cat, which has randomly distributed patches of black and orange fur (see chapter opening photo).

How do we explain this patchwork phenotype? According to Lyon's hypothesis, the calico pattern is due to the permanent inactivation of one X chromosome in each cell that forms a patch of the cat's skin, as shown in **Figure 17.10**. The gene involved is an X-linked gene that occurs as an orange allele, X^O, and a black allele, X^B. A female cat heterozygous for this gene will be calico. (The cat's white underside is due to a dominant allele of a different autosomal gene.) At an early stage of embryonic development, one of the two X chromosomes is randomly inactivated in each of the cat's somatic cells, including those that will give rise to the hair-producing skin cells. As the embryo grows and matures, the pattern of X-chromosome inactivation is maintained during subsequent cell divisions. Skin cells derived from a single embryonic cell in which the X^B-carrying chromosome has been inactivated produce a patch of orange fur, because they express only the X^O allele that is carried on the active chromosome. Alternatively, a group of skin cells in which the chromosome carrying X^O has been inactivated express only the X^B allele, producing a patch of black fur. If female mammals are heterozygous for X-linked genes, approximately half of their somatic cells express one allele, whereas the rest of their somatic cells express the other allele. The result is an animal with randomly distributed patches of black and orange fur. These heterozygotes are called **mosaics** because they are composed of two types of cells.

For many X-linked traits in humans, females who are heterozygous for recessive X-linked alleles usually show the dominant trait because the expression of the dominant allele in 50% of their cells is sufficient to produce the dominant phenotype. For example, let's

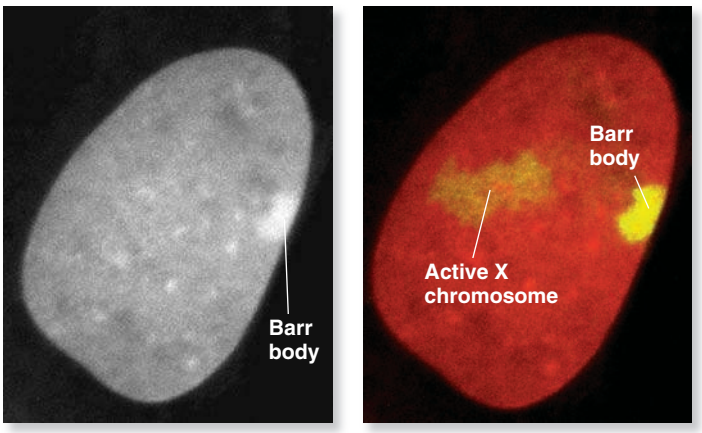

Figure 17.9 X-chromosome inactivation in female mammals. **(a)** A Barr body is seen on the periphery of a human nucleus (during interphase) after staining with a DNA-specific dye. Because it is compact, the Barr body is the most brightly stained. **(b)** The same nucleus was labeled using a yellow fluorescent probe that recognizes the X chromosome. The Barr body is more compact than the active X chromosome, which is to the left of the Barr body.

Concept Check: *How is the Barr body different from the other X chromosome in this cell?*

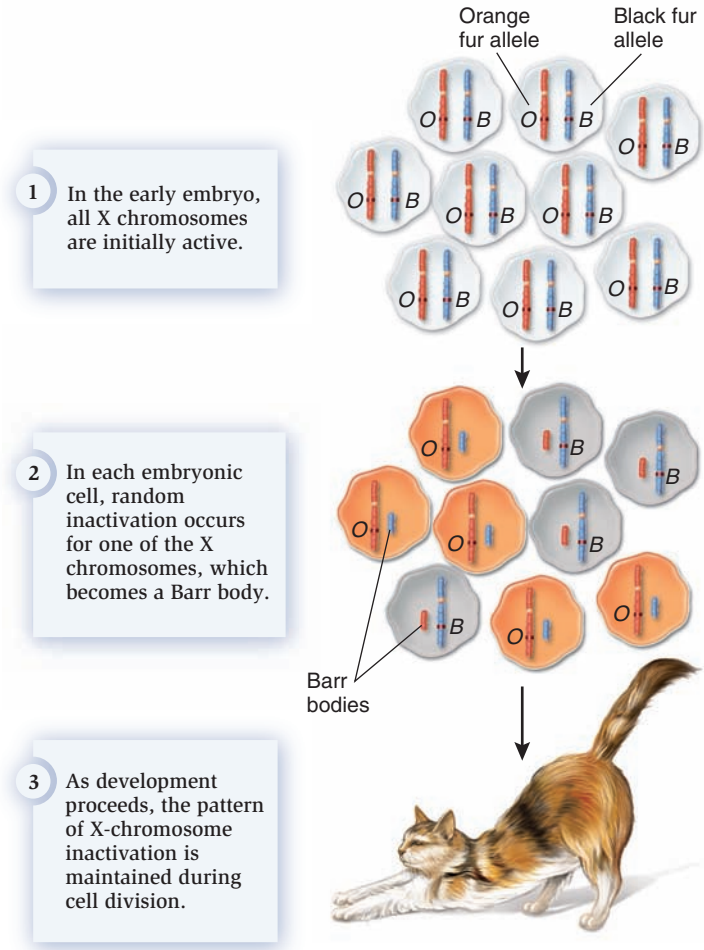

Figure 17.10 X-chromosome inactivation in a calico cat. The calico pattern is due to random X-chromosome inactivation in a female that is heterozygous for an X-linked gene with black and orange alleles. The cells at the top of this figure represent a small mass of cells making up the very early embryo. In these cells, both X chromosomes are active. At an early stage of embryonic development, one X chromosome is randomly inactivated in each cell. The initial inactivation pattern is maintained in the descendents of each cell as the embryo matures into an adult. The pattern of orange and black fur in the adult cat reflects the pattern of X-chromosome inactivation in the embryo.

BIOLOGY PRINCIPLE The genetic material provides a blueprint for reproduction. In this example, the process of X-chromosome inactivation produces a variegated pattern of fur color.

consider the recessive X-linked form of hemophilia that we discussed in Chapter 16 (hemophilia A). This type of hemophilia is caused by a defect in a gene that encodes a blood-clotting protein, called factor VIII, which is made by cells in the liver and secreted into the bloodstream. In a heterozygous female, approximately half of her liver cells make and secrete this clotting factor, which is sufficient to prevent hemophilia. Therefore, she exhibits the dominant trait of proper blood clotting.

On rare occasions, a female who is heterozygous may show mild or even severe disease symptoms. How is this possible? X-chromosome inactivation in humans occurs when an embryo is 10 days old. At this stage, the liver contains only about a dozen cells. In most females who are heterozygous for the dominant and recessive (hemophilia-causing) alleles, roughly half of their liver cells express the dominant allele. However, on rare occasions, all or most of the dozen embryonic liver cells may inactivate the X chromosome carrying the dominant functional allele. Following growth and development, such a female will have a very low level of factor VIII and as a result will show symptoms of hemophilia.

Why does X-chromosome inactivation occur? Researchers have proposed that X-chromosome inactivation achieves **dosage compensation**, a process that equalizes the expression of X-linked genes in male and female mammals. The inactivation of one X chromosome in the female reduces the number of expressed copies (doses) of X-linked genes from two to one. As a result, the expression of X-linked genes in females and males is roughly equal.

The X Chromosome Has an X Inactivation Center That Controls Compaction into a Barr Body

After Lyon's hypothesis was confirmed, researchers became interested in the genetic control of X-chromosome inactivation. The cells of humans and other mammals have the ability to count their X chromosomes and allow only one of them to remain active. Additional X chromosomes are converted to Barr bodies. In females, two X chromosomes are counted and one is inactivated. In males, one X chromosome is counted and none inactivated.

On rare occasions, people are born with abnormalities in the number of their sex chromosomes (refer back to Table 15.2). In the disorders known as Turner syndrome, triple X syndrome, and Klinefelter syndrome, the cells inactivate the number of X chromosomes necessary to leave a single active chromosome (**Table 17.3**). For example, in triple X syndrome, in which an extra X chromosome is found in each cell, two X chromosomes are converted to Barr bodies. In spite of X-chromosome inactivation, people with these three syndromes do exhibit some phenotypic abnormalities. The symptoms associated with these disorders may be due to effects that occur prior to X-chromosome inactivation or may arise because not all of the genes on the Barr body are completely silenced.

Although the genetic control of inactivation is not entirely understood at the molecular level, a short region on the X chromosome called the **X inactivation center (Xic)** is known to play a critical role. Finnish-born American geneticist Eeva Therman and German-born American geneticist Klaus Patau determined that X-chromosome inactivation is accomplished by counting the number of Xics and inactivating all X chromosomes except for one. In cells with two X chromosomes, if one of them is missing its Xic due to a chromosome mutation, neither X chromosome will be inactivated, because only one Xic is counted. Having two active X chromosomes is a lethal condition for a human female embryo.

Table 17.3 Relationship Between X-Chromosome Inactivation and the Number of X Chromosomes

Phenotype	Chromosome composition	Number of Barr bodies	Number of active X chromosomes
Female	XX	1	1
Male	XY	0	1
Turner syndrome (female)	XO	0	1
Triple X syndrome (female)	XXX	2	1
Klinefelter syndrome (male)	XXY	1	1

The expression of a specific gene within the Xic is required for compaction of the X chromosome into a Barr body. This gene, discovered in 1991, is named *Xist* (for X inactive specific transcript). The *Xist* gene product is a long RNA molecule that does not encode a protein. Instead, the role of *Xist* RNA is to coat one of the two X chromosomes during the process of X-chromosome inactivation. After coating, proteins associate with the *Xist* RNA and promote compaction of the chromosome into a Barr body. The *Xist* gene on the Barr body continues to be expressed after other genes on this chromosome have been silenced. The expression of the *Xist* gene also maintains a chromosome as a Barr body during cell division. Whenever a somatic cell divides in a female mammal, the Barr body is replicated to produce two Barr bodies.

For Imprinted Genes, the Gene from Only One Parent Is Expressed

As we have seen, X-chromosome inactivation is a type of epigenetic inheritance in which a chromosome is modified in the early embryo, permanently altering gene expression in that individual. Other types of epigenetic inheritance occur when genes or chromosomes are modified in the gametes of a parent, permanently altering gene expression in the offspring. **Genomic imprinting**, which was discovered in the early 1980s, refers to an inheritance pattern in which a segment of DNA is imprinted or marked so that gene expression occurs only from the genetic material inherited from one parent. It occurs in numerous species, including insects, plants, and mammals.

Genomic imprinting may involve a single gene, a part of a chromosome, an entire chromosome, or even all of the chromosomes inherited from one parent. It is permanent in the somatic cells of a

given individual, but the marking of the DNA is altered from generation to generation. Imprinted genes do not follow a Mendelian pattern of inheritance because imprinting causes the offspring to distinguish between maternally and paternally inherited alleles. Depending on how a particular gene is marked by each parent, the offspring expresses either the maternal or the paternal allele, but not both.

One of the first imprinted genes to be identified is a gene called *Igf2* that is found in mice and other mammals. This gene encodes a growth hormone called insulin-like growth factor 2 (Igf2) that is needed for proper growth. If a functional copy of this gene is not expressed, a mouse will be dwarf. The *Igf2* gene is known to be located on an autosome, not on a sex chromosome. Because mice are diploid, they have two copies of this gene, one from each parent.

Researchers have discovered mutations in the *Igf2* gene that block the function of the Igf2 hormone. This allele is designated *Igf2*$^{-}$. When a homozygous *Igf2 Igf2* mouse and a homozygous *Igf2*$^{-}$ *Igf2*$^{-}$ mouse are crossed, the results are surprising (**Figure 17.11**). If the male parent is homozygous for the functional allele and the female is homozygous for the mutant allele (left), all of the offspring grow to a normal size. In contrast, if the male is homozygous for the mutant allele and the female is homozygous for the functional allele (right), all of the offspring are dwarf. The reason this result is so surprising is that the normal-size and dwarf offspring have the same genotype (*Igf2 Igf2*$^{-}$) but different phenotypes! In mice, the *Igf2* gene is imprinted in such a way that only the paternal allele is expressed, which means it is transcribed into mRNA. The maternal allele is not transcribed. The baby mice shown on the left side of the photograph of Figure 17.11 are normal size, because they express a functional paternal allele. In contrast, the baby mice on the right are dwarf because the paternal gene is a mutant allele that results in a nonfunctional hormone.

The Transcription of an Imprinted Gene Depends on Methylation

Why is the maternal gene encoding Igf2 not transcribed into mRNA? To answer this question we need to consider the regulation of gene transcription in eukaryotes. As discussed in Chapter 13, DNA methylation, which is the attachment of methyl (—CH_3) groups to bases of DNA, can alter gene transcription. Researchers have discovered that DNA methylation is the marking process that occurs during the imprinting of certain genes, including the *Igf2* gene. For most genes, DNA methylation silences gene expression by inhibiting the initiation of transcription or by causing the chromatin in a region to become more compact. In contrast, for a few imprinted genes, DNA methylation may enhance gene expression by attracting activator proteins to the promoter or by preventing the binding of repressor proteins.

Figure 17.12 shows the imprinting process in which a maternal gene is methylated. The left side of the figure follows the marking process during the life of a female individual; the right side follows the same process in a male. Both individuals received a methylated

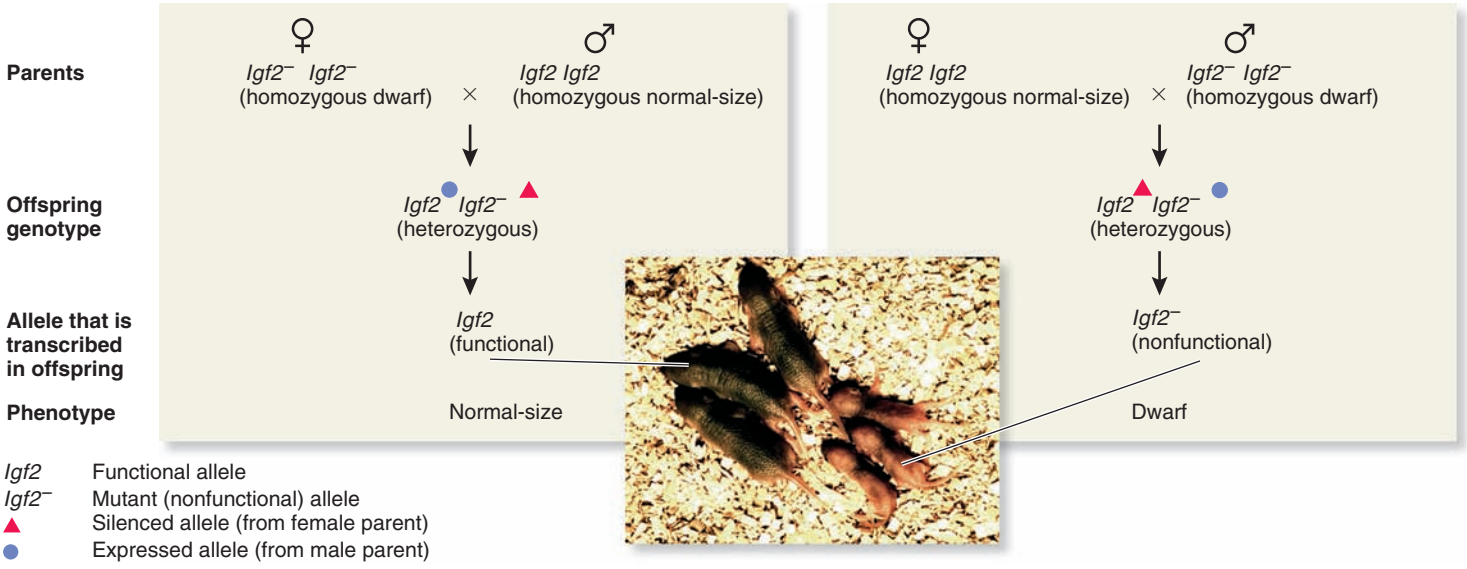

Figure 17.11 An example of genomic imprinting in the mouse. In the cross on the left, a homozygous male with the functional *Igf2* allele was crossed to a homozygous female carrying the mutant allele, *Igf2*$^{-}$. Offspring are normal size, because the paternal allele is expressed. In the cross on the right, a homozygous male carrying the mutant allele was crossed to a homozygous *Igf2 Igf2* female. In this case, offspring are dwarf because the paternal allele is defective and the maternal allele is not expressed. The photograph shows normal-size (left) and dwarf littermates (right) derived from a cross between a wild-type female (*Igf2 Igf2*) and a heterozygous male carrying a loss-of-function allele (*Igf2 Igf2*$^{-}$) (courtesy of A. Efstratiadis). The loss-of-function allele was made using methods described in Chapter 20.

Concept Check: *If you cross an Igf2 Igf2*$^{-}$ *male mouse to an Igf2 Igf2 female mouse, what would be the expected results?*

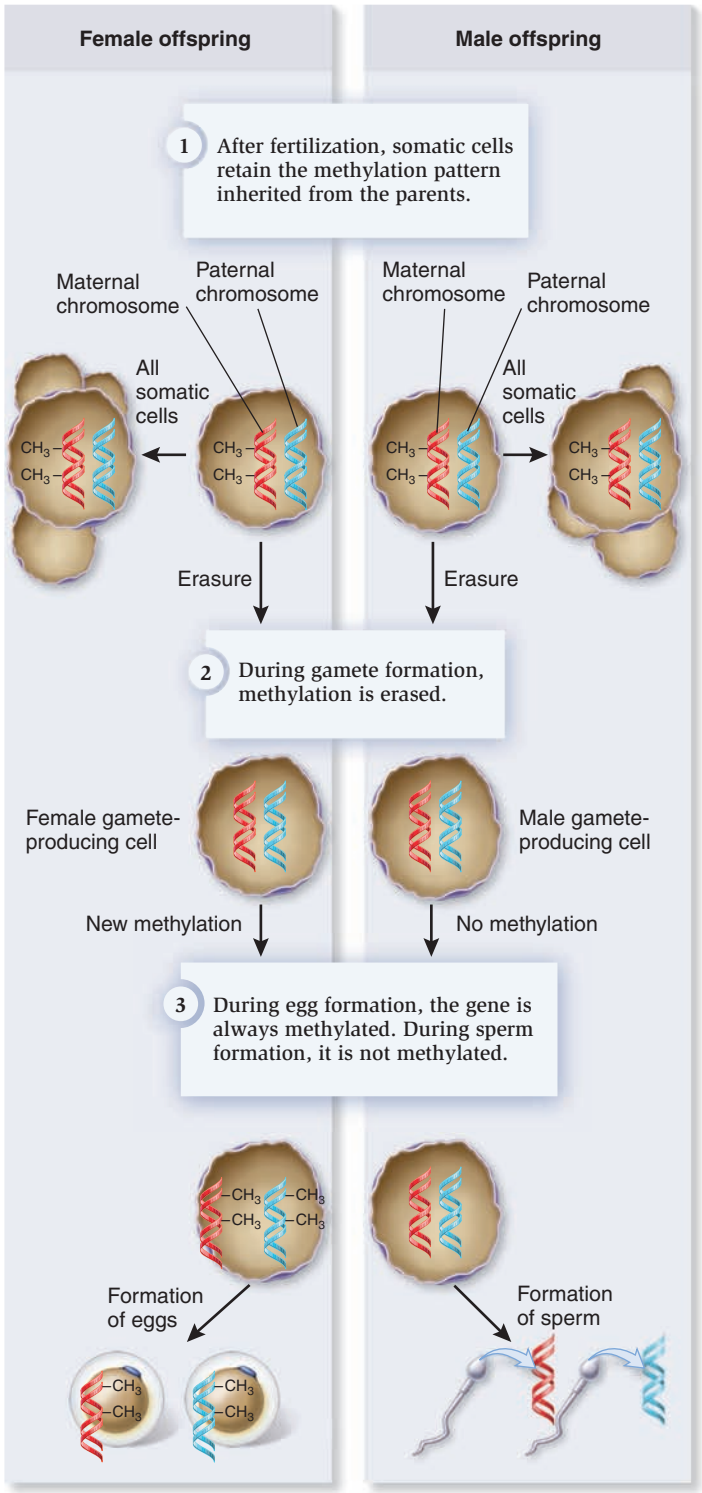

Figure 17.12 Genomic imprinting via DNA methylation. The cells at the top of this figure have a methylated gene inherited from the mother and a nonmethylated version of the same gene inherited from the father. This pattern of methylation is the same in male and female offspring and is maintained in their somatic cells. The methylation is erased during gamete formation, but in females, the gene is methylated again at a later stage in the formation of eggs. Therefore, females always transmit a methylated, transcriptionally silent copy of this gene, whereas males transmit a nonmethylated, transcriptionally active copy.

gene from their mother and a nonmethylated copy of the same gene from their father. Via cell division, the zygote develops into a multicellular organism. Each time a somatic cell divides, enzymes in the cell maintain the methylation of the maternal gene, but the paternal gene remains unmethylated. If methylation inhibits transcription of this gene, only the paternal copy will be expressed in the somatic cells of both the male and female offspring.

The methylation state of an imprinted gene may be altered when individuals make gametes. First, the methylation is erased (Figure 17.12, step 2). Next, the gene may be methylated again, but that depends on whether the individual is a female or male. In females making eggs, both copies of the gene are methylated; in males making sperm, neither copy is methylated. When we consider the effects of methylation over the course of two or more generations, we can see how this phenomenon results in an epigenetic transmission pattern. The male in Figure 17.12 has inherited a methylated gene from his mother that is transcriptionally silenced in his somatic cells. Although he does not express this gene during his lifetime, he can pass on an active, nonmethylated copy of this exact same gene to his offspring.

Genomic imprinting is a recently discovered phenomenon that has been shown to occur for a few genes in mammals. For some genes, such as *Igf2*, the maternal allele is silenced, but for other genes, the paternal allele is silenced. Although several hypotheses have been advanced, biologists are still trying to understand the reason for this curious marking process.

Summary of Key Concepts

- A variety of inheritance patterns are now known, and some of them do not obey one or both of Mendel's laws of inheritance (Table 17.1).

17.1 Gene Interaction

- Epistasis is a gene interaction that occurs when the alleles of one gene mask the effects of the alleles of a different gene (Figure 17.1).
- Quantitative traits such as height and weight are polygenic, which means that multiple genes govern the trait. Often, the alleles of such genes contribute in an additive way to the phenotype and are greatly affected by the environment. This produces continuous variation in the trait, which is graphed as a bell-shaped curve (Figure 17.2).

17.2 Genes on the Same Chromosome: Linkage, Recombination, and Mapping

- When two different genes are on the same chromosome, they are said to be linked. Linked genes tend to be inherited as a unit, unless crossing over separates them (Figures 17.3, 17.4).
- Genetic mapping allows us to determine the order of genes along a chromosome and the relative distances between them, based on the frequency of crossing over observed in testcrosses (Figure 17.5).

17.3 Extranuclear Inheritance: Organelle Genomes

- Mitochondria and chloroplasts carry a small number of genes. The inheritance of such genes is called extranuclear inheritance (Figure 17.6).
- Chloroplasts in the four-o'clock plant are transmitted via the egg, a pattern called maternal inheritance (Figures 17.7, 17.8).
- Several human diseases are known to be caused by mutations in mitochondrial genes, which follow a maternal inheritance pattern (Table 17.2).

17.4 Epigenetic Inheritance

- Epigenetic inheritance refers to a modification of a gene or chromosome that affects the expression of one or more genes but does not alter the DNA sequence. Such changes may remain through the life of an organism, but are not permanent over the course of two or more generations.
- X-chromosome inactivation in female mammals occurs when one X chromosome in every somatic cell is randomly inactivated. If the female is heterozygous for an X-linked gene, this can lead to a mosaic phenotype, with some of the somatic cells expressing one allele and some expressing the other (Figures 17.9, 17.10, Table 17.3).
- In genomic imprinting, offspring express either a maternal or paternal allele, depending on how a particular gene is marked, or imprinted. During gamete formation, DNA methylation of an allele from one parent is a mechanism to achieve imprinting (Figures 17.11, 17.12).

Assess and Discuss

Test Yourself

1. When two genes are located on the same chromosome they are said to be
   a. homologous.
   b. allelic.
   c. epistatic.
   d. linked.
   e. polygenic.
2. Based on the ideas proposed by Morgan, which of the following statements concerning linkage is *not* true?
   a. Traits determined by genes located on the same chromosome are likely to be inherited together.
   b. Crossing over between homologous chromosomes can create new allele combinations.
   c. A crossover is more likely to occur in a region between two genes that are close together than in a region between two genes that are farther apart.
   d. The probability of crossing over depends on the distance between the genes.
   e. Genes that tend to be transmitted together are physically located on the same chromosome.
3. In genetic mapping, 1 map unit is equivalent to
   a. 100 base pairs.
   b. 1 base pair.
   c. 10% recombination frequency.
   d. 1% recombination frequency.
   e. 1% of the length of the chromosome.
4. Extranuclear inheritance occurs because
   a. certain genes are found on the X chromosome.
   b. chromosomes in the nucleus may be transferred to the cytoplasm.
   c. some organelles contain DNA.
   d. the nuclear membrane breaks apart during cell division.
   e. both a and c.
5. In many organisms, organelles such as the mitochondria are transmitted only by the egg. This phenomenon is known as
   a. biparental inheritance.
   b. paternal inheritance.
   c. X-linked inheritance.
   d. maternal inheritance.
   e. both c and d.
6. Modification of a gene during gamete formation or early development that alters the way the gene is expressed during the individual's lifetime but is not permanent over two or more generations is called
   a. maternal inheritance.
   b. epigenetic inheritance.
   c. epistasis.
   d. multiple allelism.
   e. alternative splicing.
7. A male mouse that is homozygous for the functional allele of the *Igf2* gene is mated to a female that is heterozygous, carrying one functional copy and one mutant (nonfunctional) copy of the gene. What would be the expected outcome of this cross?
   a. all normal-size offspring
   b. 1/2 normal-size and 1/2 dwarf
   c. all dwarf
   d. 3/4 normal-size and 1/4 dwarf
   e. none of the above
8. When a gene is inactivated during gamete formation and that gene is maintained in an inactivated state in the somatic cells of offspring, such an inheritance pattern is called
   a. linkage.
   b. X-chromosome inactivation.
   c. epistasis.
   d. genomic imprinting.
   e. polygenic inheritance.
9. Calico coat pattern in cats is the result of
   a. X-chromosome inactivation.
   b. epistasis.
   c. organelle heredity.
   d. genomic imprinting.
   e. maternal inheritance.
10. Genomic imprinting can be explained by
    a. DNA methylation of genes during gamete formation.
    b. epistasis.
    c. the spreading of X-chromosome inactivation from the Xic locus.
    d. the inheritance of alleles that contribute additively to a trait.
    e. none of the above.

Conceptual Questions

1. Two genes (called gene *A* and gene *B*) are located on the same chromosome and are 12 mu apart. An *AABB* individual was crossed to an *aabb* individual. The F_1 (*AaBb*) offspring were crossed to *aabb* individuals. What percentage of the F_2 offspring would you expect to be *Aabb*?
2. Certain forms of human color blindness are inherited as X-linked recessive traits. Heterozygous females are not usually color blind, but on rare occasions, a female may exhibit partial color blindness or may be color blind in just one eye. Explain how this could happen.
3.  A principle of biology is that *biology is as an experimental science.* Describe how the phenomenon of linkage enables biologists to conduct experiments that are aimed at the mapping of genes along a chromosome.

Collaborative Questions

1. As discussed in Chapter 16, Mendel studied seven characters in pea plants, and the garden pea happens to have seven different chromosomes. It has been pointed out that Mendel was very lucky not to have conducted crosses involving two traits that are closely linked on the same chromosome because the results would have confounded his theory of independent assortment. It has even been suggested that Mendel may not have published data involving traits that were linked. An article by S. Blixt ("Why Didn't Gregor Mendel Find Linkage?" *Nature* 256:206[1975]) considers this issue. Look up this article and discuss why Mendel did not find linkage.
2. Discuss the similarities and differences between X-chromosome inactivation and genomic imprinting.

Genetics of Viruses and Bacteria

CHAPTER OUTLINE

18.1 Genetic Properties of Viruses
18.2 Viral Reproductive Cycles
18.3 Viroids and Prions
18.4 Genetic Properties of Bacteria
18.5 Gene Transfer Between Bacteria
Summary of Key Concepts
Assess and Discuss

A colorized micrograph of *Haemophilus influenzae*, type b. This bacterium is a common cause of meningitis—a serious infection of the fluid in the spinal cord and the fluid that surrounds the brain.

While studying for his calculus test, Jason was having trouble concentrating due to a severe headache and fever. He thought he must be coming down with a cold. Though he had taken some aspirin, it didn't seem to be working. As he was eating some potato chips, one dropped in his lap. When he tried to look down to see where the chip had fallen, he realized that his neck was extremely stiff; he could barely move his head to look downward. Also, the brightness of his desk light seemed freakishly painful to his eyes. Over the course of that evening, Jason became confused and lethargic, and his roommate urged him to see a doctor. Fortunately, Jason took his advice and went to the college clinic. The diagnosis was bacterial meningitis—an inflammation of the protective membranes that cover the brain and spinal cord, collectively called the meninges. Although a relatively rare disease, bacterial meningitis is up to six times more common among people living in close quarters, such as college dormitories. Because Jason sought help early enough, his disease was successfully treated with antibiotics. Had he not gotten help, the disease could have progressed to the point of causing severe brain damage and even death.

Jason's story highlights a primary reason why biologists are so interested in viruses and bacteria. Infectious diseases caused by viruses and bacteria are a leading cause of human suffering and death, accounting for one-quarter to one-third of deaths worldwide. The spread of infectious diseases results from human behavior, and in recent times, it has been accelerated by changes in land-use patterns, increased trade and travel, and the inappropriate use of antibiotic drugs. Although the incidence of fatal infectious diseases in the U.S. is low compared to the worldwide average, an alarming increase in more deadly strains of viruses and bacteria has occurred over the past few decades. Since 1980, the number of deaths in the U.S. due to infectious diseases has approximately doubled.

In this chapter, we turn our attention to the genetic analyses of viruses and bacteria. We will begin by examining viruses and other nonliving particles that infect living cells. All organisms are thought to be susceptible to infection by one or more types of viruses, which use the host's cellular machinery to replicate. Once a cell is infected, the genetic material of a virus orchestrates a series of events that ultimately leads to the production of new virus particles. We will consider the biological complexity of viruses and explore viral reproductive cycles. We will also examine some of the simplest and smallest infectious agents, called viroids and prions.

In the remaining sections of this chapter, we will examine the bacterial genome and the methods used in its investigation. Like their eukaryotic counterparts, bacteria have genetic differences that affect their cellular traits, and techniques of modern microbiology make many of these differences, such as sensitivity to antibiotics and differences in nutritional requirements, easy to study. Although bacteria reproduce asexually by cell division, their genetic variety is enhanced by the phenomenon called gene transfer, in which genes are passed from one bacterial cell to another. Like sexual reproduction in eukaryotes, gene transfer enhances the genetic diversity observed among bacterial species. In this chapter, we will explore three interesting ways that bacteria transfer genetic material.

18.1 Genetic Properties of Viruses

Learning Outcome:

1. Compare and contrast how viruses differ with regard to their host range, structure, and genomes.

Viruses are nonliving particles with nucleic acid genomes. Why are viruses considered nonliving? The answer is that they do not exhibit all of the properties associated with living organisms (refer back to Figure 1.4). Viruses are not composed of cells, and by themselves, they do not use energy or carry out metabolism, maintain homeostasis, or even reproduce. A virus or its genetic material must be taken up by a living cell to replicate.

The first virus to be discovered was tobacco mosaic virus (TMV). This virus infects many species of plants and causes mosaic-like patterns in which normal-colored patches are interspersed with light green or yellowish patches on the leaves (**Figure 18.1**). TMV damages leaves, flowers, and fruit but almost never kills the plant. In 1883, German chemist Adolf Mayer determined that this disease could be spread by spraying the sap from one plant onto another. By subjecting this sap to filtration, Russian scientist Dmitri Ivanovski demonstrated that the disease-causing agent was not a bacterium. Sap that had been passed through filters with pores small enough to prevent the passage of bacterial cells was still able to spread the disease. At first, some researchers suggested the agent was a chemical toxin. However, Dutch botanist Martinus Beijerinck ruled out this possibility by showing that sap continued to transmit the disease after many plant generations. A toxin would have been diluted after many generations, but Beijerinck's results indicated the disease agent was multiplying in the plant. Around the same time, animal viruses were discovered in connection with a disease of cattle called foot-and-mouth disease. In 1900, the first human virus, the virus that causes yellow fever, was identified.

Since these early studies, microbiologists, geneticists, and molecular biologists have taken a great interest in the structure, genetic composition, and replication of viruses. In this section, we will discuss their general properties.

Figure 18.1 **A plant infected with tobacco mosaic virus.**

Viruses Are Remarkably Varied, Despite Their Simple Structure

A **virus** is a small infectious particle that consists of nucleic acid enclosed in a protein coat. Researchers have identified and studied over 4,000 different types of viruses. Although all viruses share some similarities, such as small size and the reliance on a living cell for replication, they vary greatly in their characteristics, including their host range, structure, and genome composition. Some of the major differences are described next, and characteristics of selected viruses are shown in **Table 18.1**.

Differences in Host Range A cell that is infected by a virus is called a **host cell**, and a species that can be infected by a specific virus is called a host species for that virus. Viruses differ greatly in their **host range**—the number of species and cell types they can infect. Table 18.1 lists a few examples of viruses with widely different ranges of host species. Tobacco mosaic virus, which we discussed earlier, has a broad host range. TMV is known to infect over 150 different species of plants. By comparison, other viruses have a narrow host range, with some infecting only a single species. Furthermore, a virus may infect only a specific cell type in a host species. **Figure 18.2** shows some viruses that infect particular human cells and cause disease.

Structural Differences Viruses cannot be resolved by even the best light microscope. Although the existence of viruses was postulated in the 1890s, viruses were not observed until the 1930s when the electron microscope was invented. Viruses range in size from 20 to 400 nm in diameter (1 nm [nanometer] = 10^{-9} meter). For comparison, a typical bacterium is 1,000 nm in diameter, and the diameter of most eukaryotic cells is 10 to 1,000 times that of a bacterium. Adenoviruses, which cause infections of the respiratory and gastrointestinal tracts, have an average diameter of 75 nm. Over 50 million adenoviruses could fit into an average-sized human cell.

What are the common structural features of all viruses? As shown in **Figure 18.3**, all viruses have a protein coat called a **capsid**, which encloses a genome consisting of one or more molecules of nucleic acid (DNA or RNA). Capsids are composed of one or several different protein subunits called capsomers. Capsids have a variety of shapes, including helical and polyhedral. Figure 18.3a shows the structure of TMV, which has a helical capsid made of identical capsomers. Figure 18.3b shows an adenovirus, which has a polyhedral capsid. Protein fibers with a terminal knob are located at the corners of the polyhedral capsid. Many viruses that infect animal cells, such as the influenza virus shown in Figure 18.3c, have a **viral envelope** enclosing the capsid. The envelope consists of a lipid bilayer that is derived from the plasma membrane of the host cell and is embedded with virally encoded spike glycoproteins.

In addition to encasing and protecting the genetic material, the capsid and envelope enable viruses to infect their hosts. Many viruses have protein fibers with a knob (Figure 18.3b) or spike glycoproteins (Figure 18.3c) that help them bind to the surface of a host cell. Viruses that infect bacteria, called **bacteriophages**, or simply **phages**, may have more complex protein coats, with accessory structures used for anchoring the virus to a host cell and injecting the viral

Table 18.1 Hosts and Characteristics of Selected Viruses

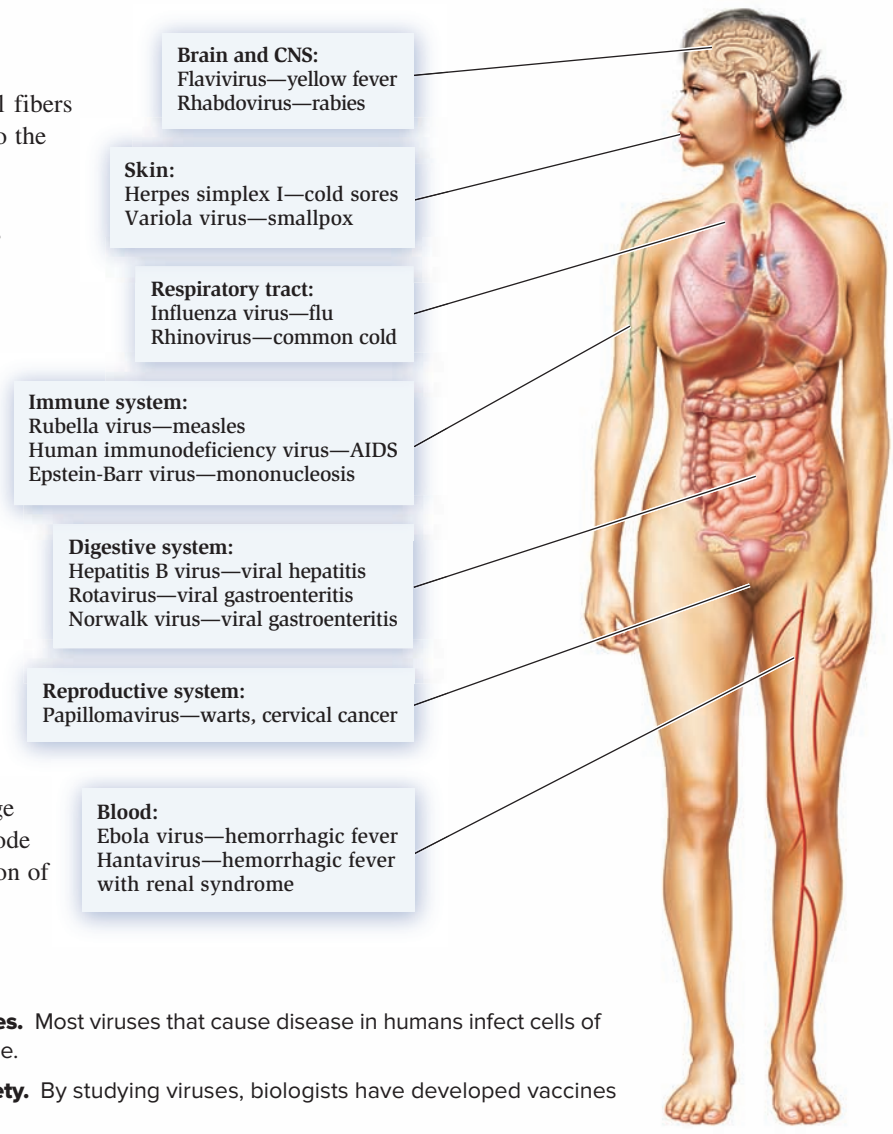
Virus or group of viruses	Host	Effect on host	Nucleic acid*	Genome size (kb)†	Number of genes†
Phage fd	*E. coli*	Slows growth	ssDNA	6.4	10
Phage λ	*E. coli*	Can exist harmlessly in the host cell or cause lysis	dsDNA	48.5	36
Phage T4	*E. coli*	Causes lysis	dsDNA	169	288
Tobacco mosaic virus (TMV)	Many plants	Causes mottling and necrosis of leaves and other plant parts	ssRNA	6.4	6
Baculoviruses	Insects	Most baculoviruses are species specific; they usually kill the insect	dsDNA	133.9	154
Parvovirus	Mammals	Causes respiratory, flulike symptoms	ssDNA	5.0	5
Influenza virus	Mammals	Causes classical "flu," with fever, cough, sore throat, and headache	ssRNA	13.5	11
Epstein-Barr virus	Humans	Causes mononucleosis, with fever, sore throat, and fatigue	dsDNA	172	80
Adenovirus	Humans	Causes respiratory symptoms and diarrhea	dsDNA	34	35
Herpes simplex type II	Humans	Causes blistering sores around the genital region	dsDNA	158.4	77
HIV (type I)	Humans	Causes AIDS, an immunodeficiency syndrome eventually leading to death	ssRNA	9.7	9

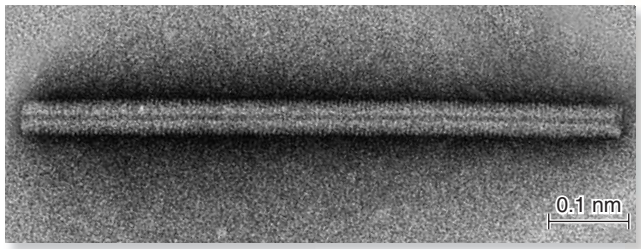
*The abbreviations ss and ds refer to single stranded and double stranded, respectively.
†Several of the viruses listed in this table are found in different strains that vary with regard to genome size and number of genes. The numbers reported in this table are typical values. The abbreviation kb means kilobase, which equals 1,000 bases.

nucleic acid (Figure 18.3d). As discussed later, the tail fibers of such bacteriophages are needed to attach the virus to the bacterial cell wall.

Genome Differences The genetic material in a virus is called a **viral genome**. The composition of viral genomes varies markedly among different types of viruses, as suggested by the examples in Table 18.1. The nucleic acid of some viruses is DNA, whereas in others it is RNA. These are referred to as DNA viruses and RNA viruses, respectively. It is striking that some viruses use RNA for their genome, whereas all living organisms use DNA. In some viruses, the nucleic acid is single stranded, whereas in others, it is double stranded. The genome can be linear or circular, depending on the type of virus. Some kinds of viruses have more than one copy of the genome.

Viral genomes also vary considerably in size, ranging from a few thousand to more than a hundred thousand nucleotides in length (see Table 18.1). For example, the genome of TMV is only 6,400 base pairs in length and contains only six genes. Other viruses, particularly those with a complex structure, such as phage T4, contain many more genes. These extra genes encode many different proteins that are involved in the formation of the elaborate structure shown in Figure 18.3d.





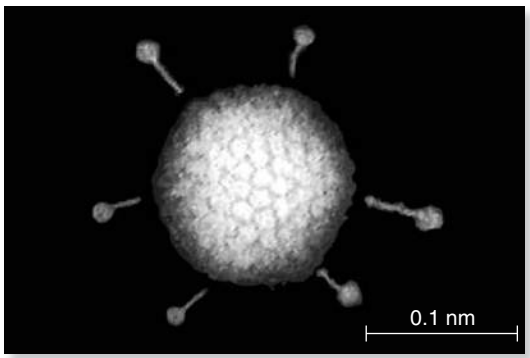


Figure 18.2 Some viruses that cause human diseases. Most viruses that cause disease in humans infect cells of specific tissues, as illustrated by the examples in this figure.

BIOLOGY PRINCIPLE Biology affects our society. By studying viruses, biologists have developed vaccines and drugs to help prevent their spread.

(a) Tobacco mosaic virus, a nonenveloped virus with a helical capsid

(b) Adenovirus, a nonenveloped virus with a polyhedral capsid and protein fibers with a knob

(c) Influenza virus, an enveloped virus with spikes

(d) T4, a bacteriophage

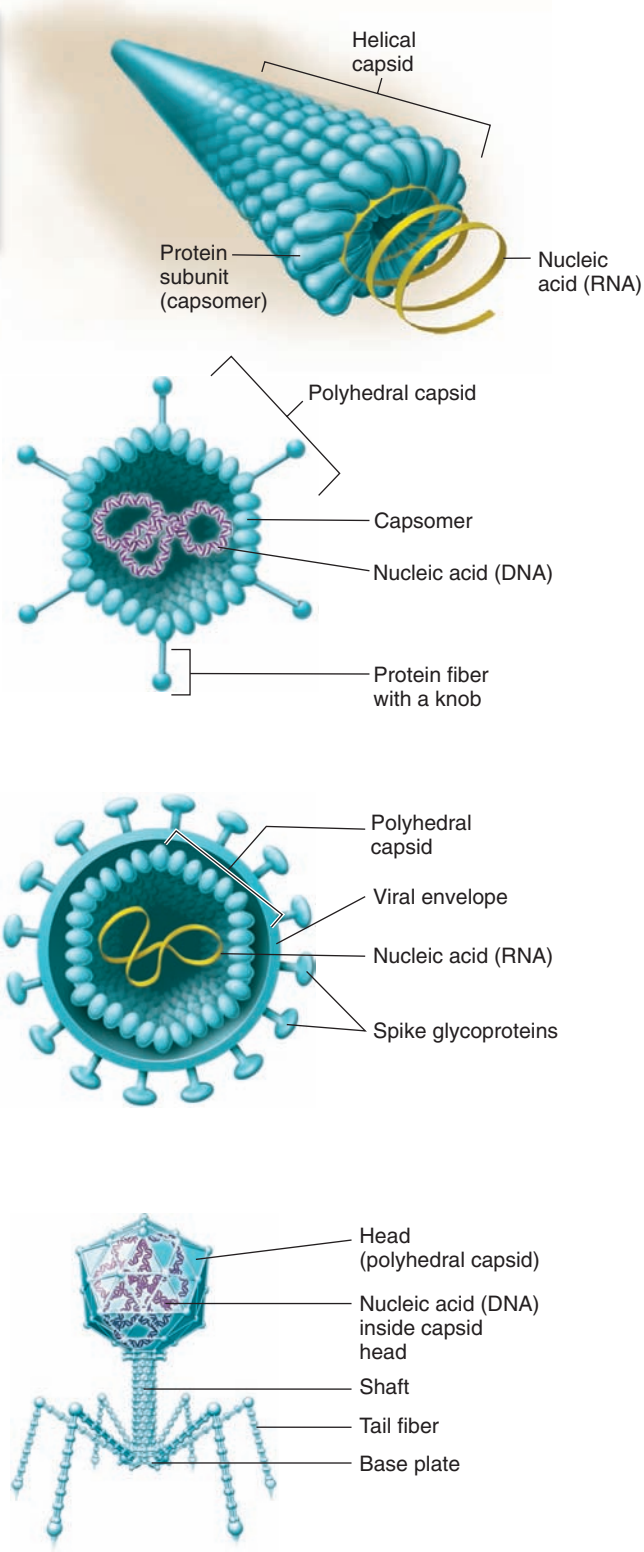

Figure 18.3 Variations in the structure of viruses, as shown by transmission electron micrographs (left side) and schematic diagrams (right side). All viruses contain nucleic acid (DNA or RNA) surrounded by a protein capsid. They may or may not have an outer envelope surrounding the capsid. **(a)** Tobacco mosaic virus (TMV) has a capsid made of 2,130 identical protein subunits, helically arranged around a strand of RNA. **(b)** Adenoviruses have polyhedral capsids containing protein fibers with a knob. **(c)** Many animal viruses, including influenza virus, have an envelope composed of a lipid bilayer and spike glycoproteins. The lipid bilayer is obtained from the host cell when the virus buds from the plasma membrane. **(d)** Some bacteriophages, such as T4, have protein coats with accessory structures such as tail fibers that facilitate invasion of a bacterial cell.

Concept Check: *What features vary among different types of viruses?*

18.2 Viral Reproductive Cycles

Learning Outcomes:

1. List the steps in a viral reproductive cycle, and distinguish between the lysogenic and lytic cycles.
2. Describe how emerging viruses such as HIV arise and spread through a population.
3. Explain how an understanding of viral structure and reproduction can aid in the development of drugs to combat viruses.
4. Outline two hypotheses regarding the origin of viruses.

When a virus infects a host cell, the expression of viral genes leads to a series of steps, called a **viral reproductive cycle**, which results in the production of new viruses. The details of the steps differ among various types of viruses, and a given type of virus may follow alternative cycles. Even so, by studying hundreds of different viruses, researchers have determined that the viral reproductive cycle consists of five or six common steps. In this section, we will examine viral reproductive cycles in detail, paying particular attention to human immunodeficiency virus (HIV), which causes acquired immunodeficiency syndrome (AIDS) in humans.

Viral Reproductive Cycles Consist of a Few Common Steps

To illustrate the general features of viral reproductive cycles, **Figure 18.4** considers these steps for two types of viruses. Figure 18.4a shows the cycle of phage λ (lambda), a bacteriophage with double-stranded DNA as its genome, and Figure 18.4b depicts the cycle of HIV, an enveloped animal virus containing single-stranded RNA. The descriptions that follow compare the reproductive cycles of these two very different viruses.

Step 1: Attachment In the first step of a viral reproductive cycle, the virus attaches to the surface of a host cell. This attachment is usually specific for one or just a few types of cells because proteins in the virus recognize and bind to specific molecules on the cell surface. In the case of phage λ, the tail fibers bind to proteins in the outer bacterial cell membrane of *E. coli* cells. In the case of HIV, spike glycoproteins in the viral envelope bind to protein receptors in the plasma membrane of human white blood cells called helper T cells.

Step 2: Entry After attachment, the viral genome enters the host cell. Attachment of phage λ stimulates a conformational change in its coat proteins, so the shaft contracts, and the phage injects its DNA into the bacterial cytoplasm. In contrast, the envelope of HIV fuses with the plasma membrane of the host cell, so both the capsid and its contents are released into the cytosol. Some of the HIV capsid proteins are then removed by host cell enzymes, a process called uncoating. This releases two copies of the viral RNA and molecules of two enzymes called reverse transcriptase and integrase into the cytosol. As discussed shortly, these enzymes are needed for step 3.

Once a viral genome has entered the cell, one or a few viral genes are expressed immediately due to the action of host cell enzymes and ribosomes. Expression of these early genes leads quickly to either step 3 or step 4 of the reproductive cycle, depending on the specific virus. The genome of some viruses, including both phage λ and HIV, can integrate into a chromosome of the host cell. For such viruses, the cycle may proceed from step 2 to step 3 as described next, delaying the production of new viruses. Alternatively, the cycle may proceed directly from step 2 to step 4 and quickly lead to the production of new viruses.

Step 3: Integration Viruses capable of integration carry a gene that encodes an enzyme called **integrase**, which cuts the host's chromosomal DNA and inserts the viral genome into the chromosome. In the case of phage λ, the double-stranded DNA that entered the cell can be directly integrated into the double-stranded DNA of the chromosome. Once integrated, the phage DNA in a bacterium is called a **prophage**. When a bacterial cell divides, the prophage DNA is copied and transmitted to daughter cells along with the bacterial chromosomal DNA. When a prophage is integrated into a bacterial chromosome, this type of viral reproductive cycle is called the **lysogenic cycle**. As discussed later, new phages are not made during the lysogenic cycle, and the host cell is not destroyed. On occasion, a prophage can be excised from the bacterial chromosome and proceed to step 4.

How can an RNA virus integrate its genome into the host cell's DNA? For this to occur, the viral genome must be copied into DNA. HIV accomplishes this by means of a viral enzyme called **reverse transcriptase**, which is carried within the capsid and released into the host cell along with the viral RNA. Reverse transcriptase uses the viral RNA strand to make a complementary copy of DNA. The complementary DNA is then used as a template to make double-stranded viral DNA. This process is called reverse transcription because it is the reverse of the usual transcription process, in which a DNA strand is used to make a complementary strand of RNA. The viral double-stranded DNA enters the host cell nucleus and is inserted into a host chromosome via integrase. Like reverse transcriptase, integrase is carried within the HIV capsid and released into the host cell during uncoating. Once integrated, the viral DNA in a eukaryotic cell is called a **provirus**. Viruses that follow this mechanism are called **retroviruses**.

Step 4: Synthesis of Viral Components The production of new viruses by a host cell involves the replication of the viral genome and the synthesis of viral proteins that make up the protein coat. A prophage must be excised as described in step 3 before the synthesis of new viral components can occur. An enzyme called excisionase is required for this process. Following excision, host cell enzymes make many copies of the phage DNA and transcribe the genes within these copies into mRNA. Host cell ribosomes translate this viral mRNA into viral proteins. The expression of phage genes also leads to the degradation of the host chromosomal DNA.

In the case of HIV, the provirus DNA is not excised from the host chromosome. Instead, it is transcribed in the nucleus to produce many copies of viral RNA. These viral RNA molecules enter the cytosol, where they are used to make viral proteins and serve as the genome for new viral particles.

Step 5: Viral Assembly After all of the necessary components have been synthesized, they must be assembled into new viruses. Some viruses with a simple structure self-assemble—viral components

spontaneously bind to each other to form a complete virus particle. An example of a self-assembling virus is TMV, which we examined earlier (see Figure 18.3a). TMV capsid proteins assemble around a TMV RNA molecule, which becomes trapped inside the hollow capsid.

Other viruses, including the two shown in Figure 18.4, do not self-assemble. The assembly of phage λ requires the help of noncapsid proteins not found in the completed phage particle. Some of these noncapsid proteins function as enzymes that modify capsid proteins, whereas others serve as scaffolding for the assembly of the capsid.

The assembly of HIV occurs in two stages. First, capsid proteins assemble around two molecules of viral RNA and molecules of reverse transcriptase and integrase. Next, the newly formed capsid acquires its outer envelope in a budding process. This second phase of assembly occurs during step 6, as the virus is released from the cell.

Step 6: Release The last step of a viral reproductive cycle is the release of new viruses from the host cell. The release of bacteriophages is a dramatic event. Because bacteria are surrounded by a rigid cell wall, the phages must burst, or lyse, their host cell to escape. After the phages have been assembled, a phage-encoded enzyme called lysozyme digests the bacterial cell wall, causing the cell to burst. Lysis releases many new phages into the environment, where they can infect other bacteria and begin the cycle again. Collectively, steps 1, 2, 4, 5, and 6 are called the **lytic cycle** because they lead to cell lysis.

The release of enveloped viruses from an animal cell is far less dramatic. This type of virus escapes by a mechanism called budding that does not lyse the cell. In the case of HIV, a newly assembled virus particle associates with a portion of the plasma membrane containing HIV spike glycoproteins. The membrane enfolds the viral capsid and eventually buds from the surface of the cell. This is how the virus acquires its envelope, which is a piece of host cell membrane studded with viral glycoproteins.

Latency in Bacteriophages As we saw in step 3, viruses can integrate their genomes into a host chromosome. In some cases, the prophage or provirus may remain inactive, or **latent**, for a long time. Most of the viral genes are silent during latency, and the viral reproductive cycle does not progress to step 4.

Latency in bacteriophages is also called lysogeny. When this occurs, both the prophage and its host cell are said to be lysogenic. When a lysogenic bacterium prepares to divide, it copies the prophage DNA along with its own DNA, so each daughter cell inherits a copy of the prophage. A prophage can be replicated repeatedly in this way without killing the host cell or producing new phage particles. As mentioned earlier, this is called the lysogenic cycle.

Bacteriophages that can follow both lysogenic and lytic cycles are called **temperate phages** (**Figure 18.5**). Phage λ is an example of a temperate phage. Upon infection, it can either enter the lysogenic cycle or proceed directly to the lytic cycle. Other phages, called **virulent phages**, have only lytic cycles. The genome of a virulent phage is not capable of integration into a host chromosome. Phage T4 is a virulent phage that infects *E. coli* (see Figure 18.3d). Unlike phage λ, which may coexist harmlessly with *E. coli*, T4 always lyses the infected cell.

For temperate phages such as λ, environmental conditions influence whether or not viral DNA is integrated into a host chromosome and how long the virus remains in the lysogenic cycle. If nutrients are readily available, phage λ usually proceeds directly to the lytic cycle after its DNA enters the cell. Alternatively, if nutrients are in short supply, the lysogenic cycle is favored because sufficient material may not be available to make new viruses. If more nutrients become available later, the prophage may become activated. At this point, the viral reproductive cycle switches to the lytic cycle, and new viruses are made and released.

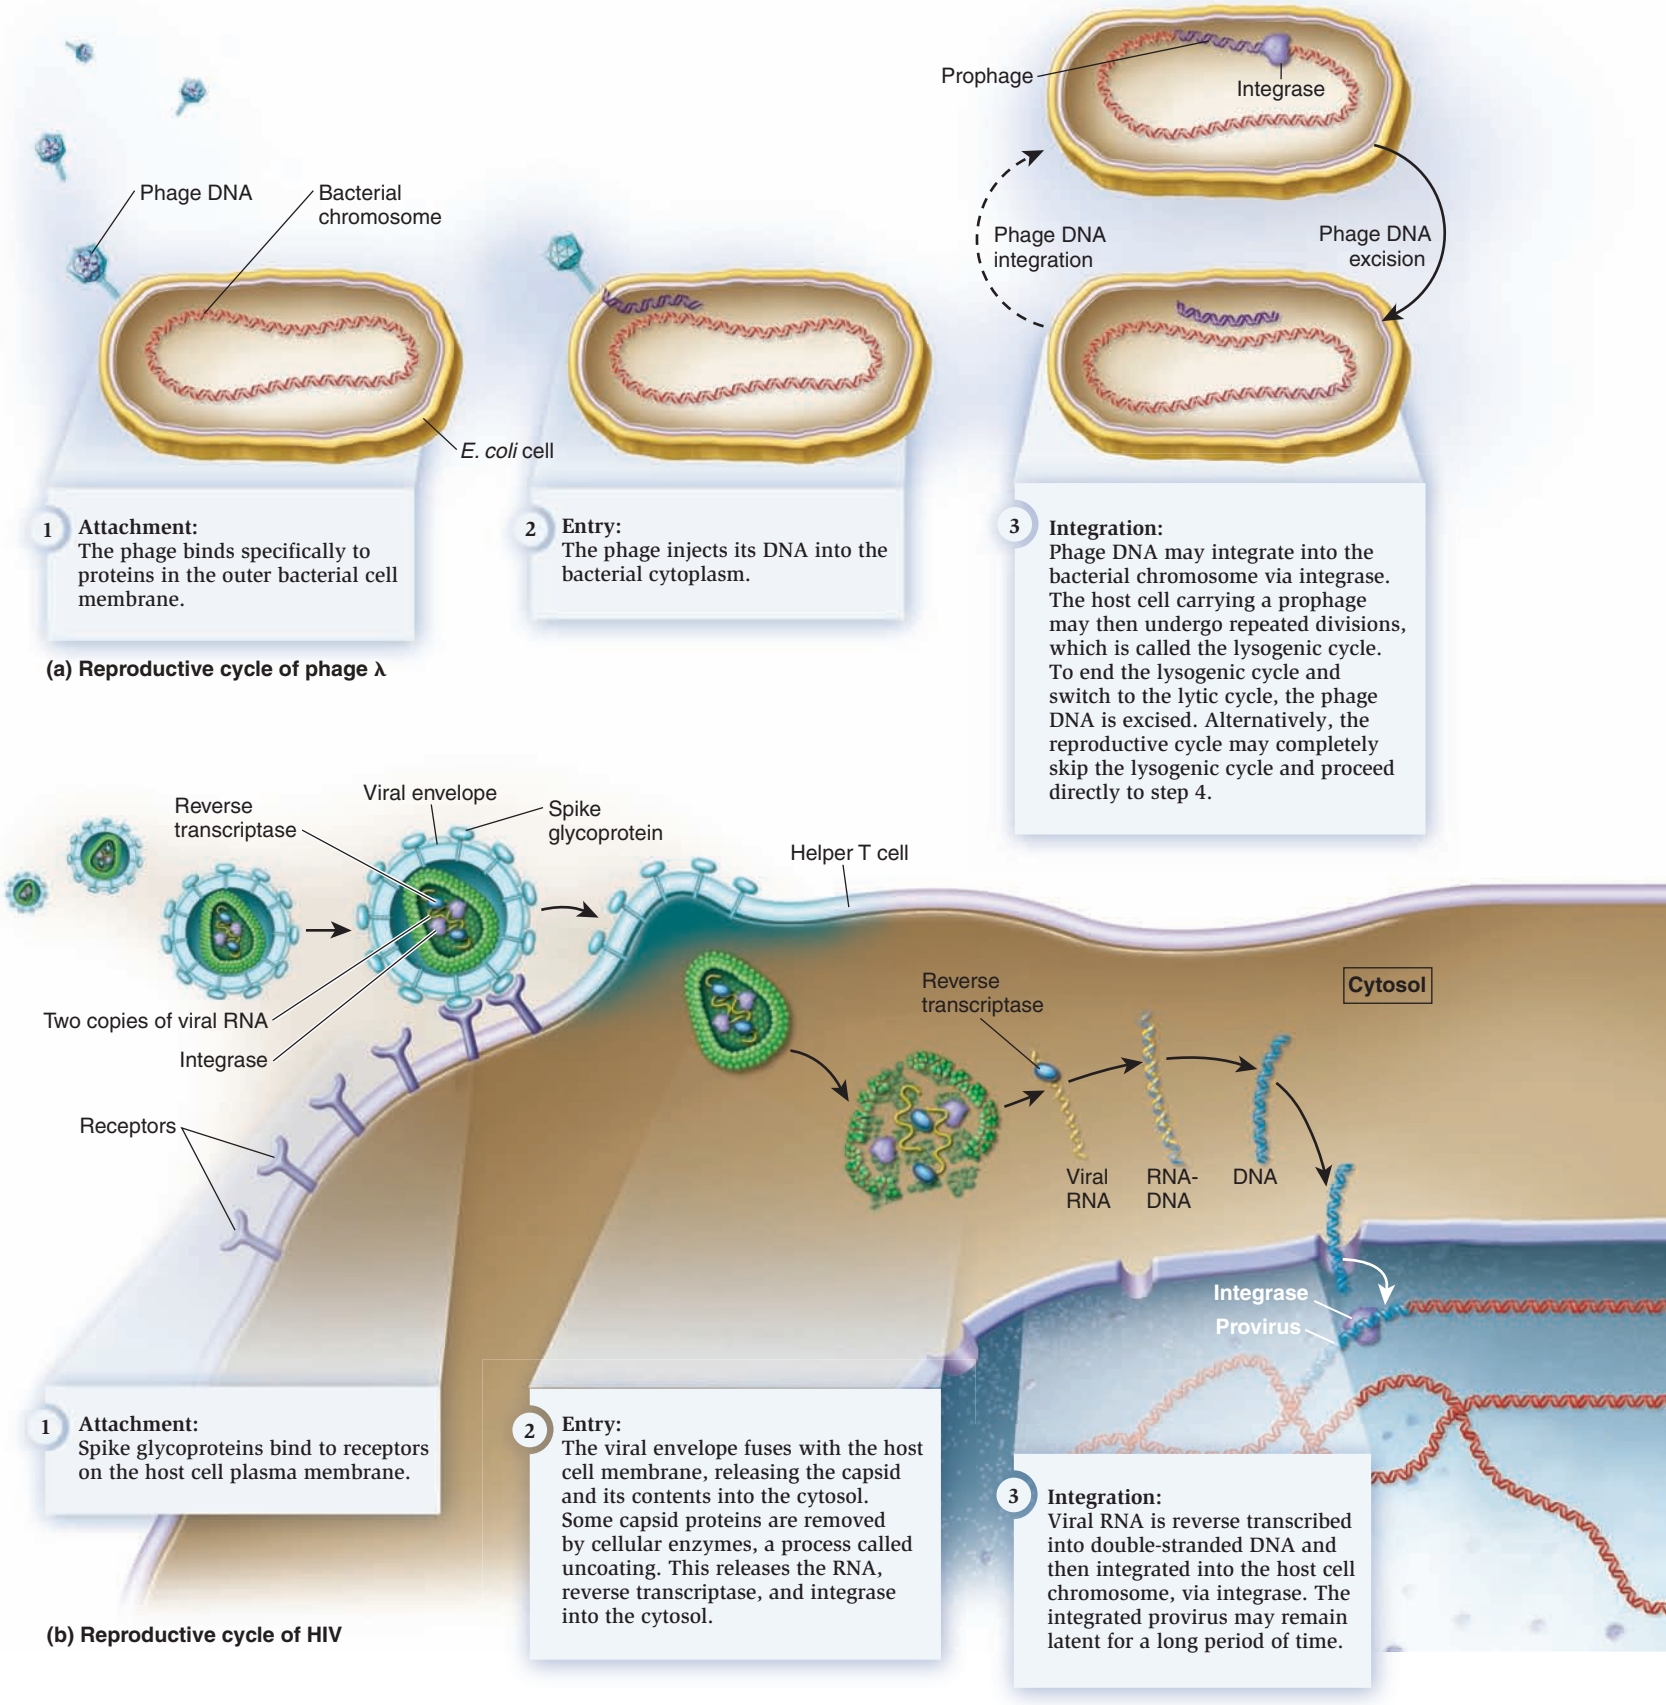
Latency in Human Viruses Latency among human viruses can occur in two different ways. For HIV, latency occurs because the virus has integrated into the host genome and may remain dormant for a long time. In addition, the genome of some other viruses can exist as an **episome**—a genetic element that replicates independently of the chromosomal DNA but also can occasionally integrate into chromosomal DNA. Examples of viral genomes that exist as episomes include different types of herpesviruses that cause cold sores (usually herpes simplex type I), genital herpes (usually herpes simplex type II), and chickenpox (varicella-zoster). A person infected with a given type of herpesvirus may have periodic outbreaks of disease symptoms when the virus switches from the latent, episomal form to the active form that produces new virus particles.

As an example, let's consider the herpesvirus called varicella-zoster. The initial infection by this virus causes chickenpox, after which the virus may remain latent for many years as an episome. The disease called shingles occurs when varicella-zoster switches from the latent state and starts making new virus particles. Shingles begins as a painful rash that eventually erupts into blisters. The blisters follow the path of the neurons that carry the latent varicella-zoster virus. The blisters often form a ring around the back of the patient's body. The name shingles is derived from a Latin word meaning girdle, referring to the observation that the blisters girdle a part of the body.

Emerging Viruses, Such as HIV, May Spread Rapidly Through a Population

A key reason researchers have been interested in viral reproductive cycles is the ability of many viruses to cause diseases in humans and other hosts. **Emerging viruses** are ones that have arisen recently or have recently shown a greater probability of causing infection. Because the base sequences of many viruses are already known, researchers have determined that emerging viruses typically result from mutations in pre-existing viruses. They may lead to a significant loss of human life and often cause public alarm. New strains of influenza virus arise fairly regularly due to mutations. An example is the strain H1N1, also called swine flu. In the U.S., despite attempts to minimize deaths by vaccination, over 30,000 people die annually from influenza.

During the past few decades, the most devastating example of an emerging virus is **human immunodeficiency virus (HIV)**, the causative agent of acquired immune deficiency syndrome (AIDS). HIV is primarily spread by sexual contact between infected and uninfected individuals, but it can also be spread by the transfusion of HIV-infected blood, by the sharing of needles among drug users, and from infected mother to unborn child. Since AIDS was first recognized in 1981, the total number of AIDS deaths is over 30 million, making it one of the most deadly diseases in human history. More than 0.5 million of these deaths have occurred in the U.S.



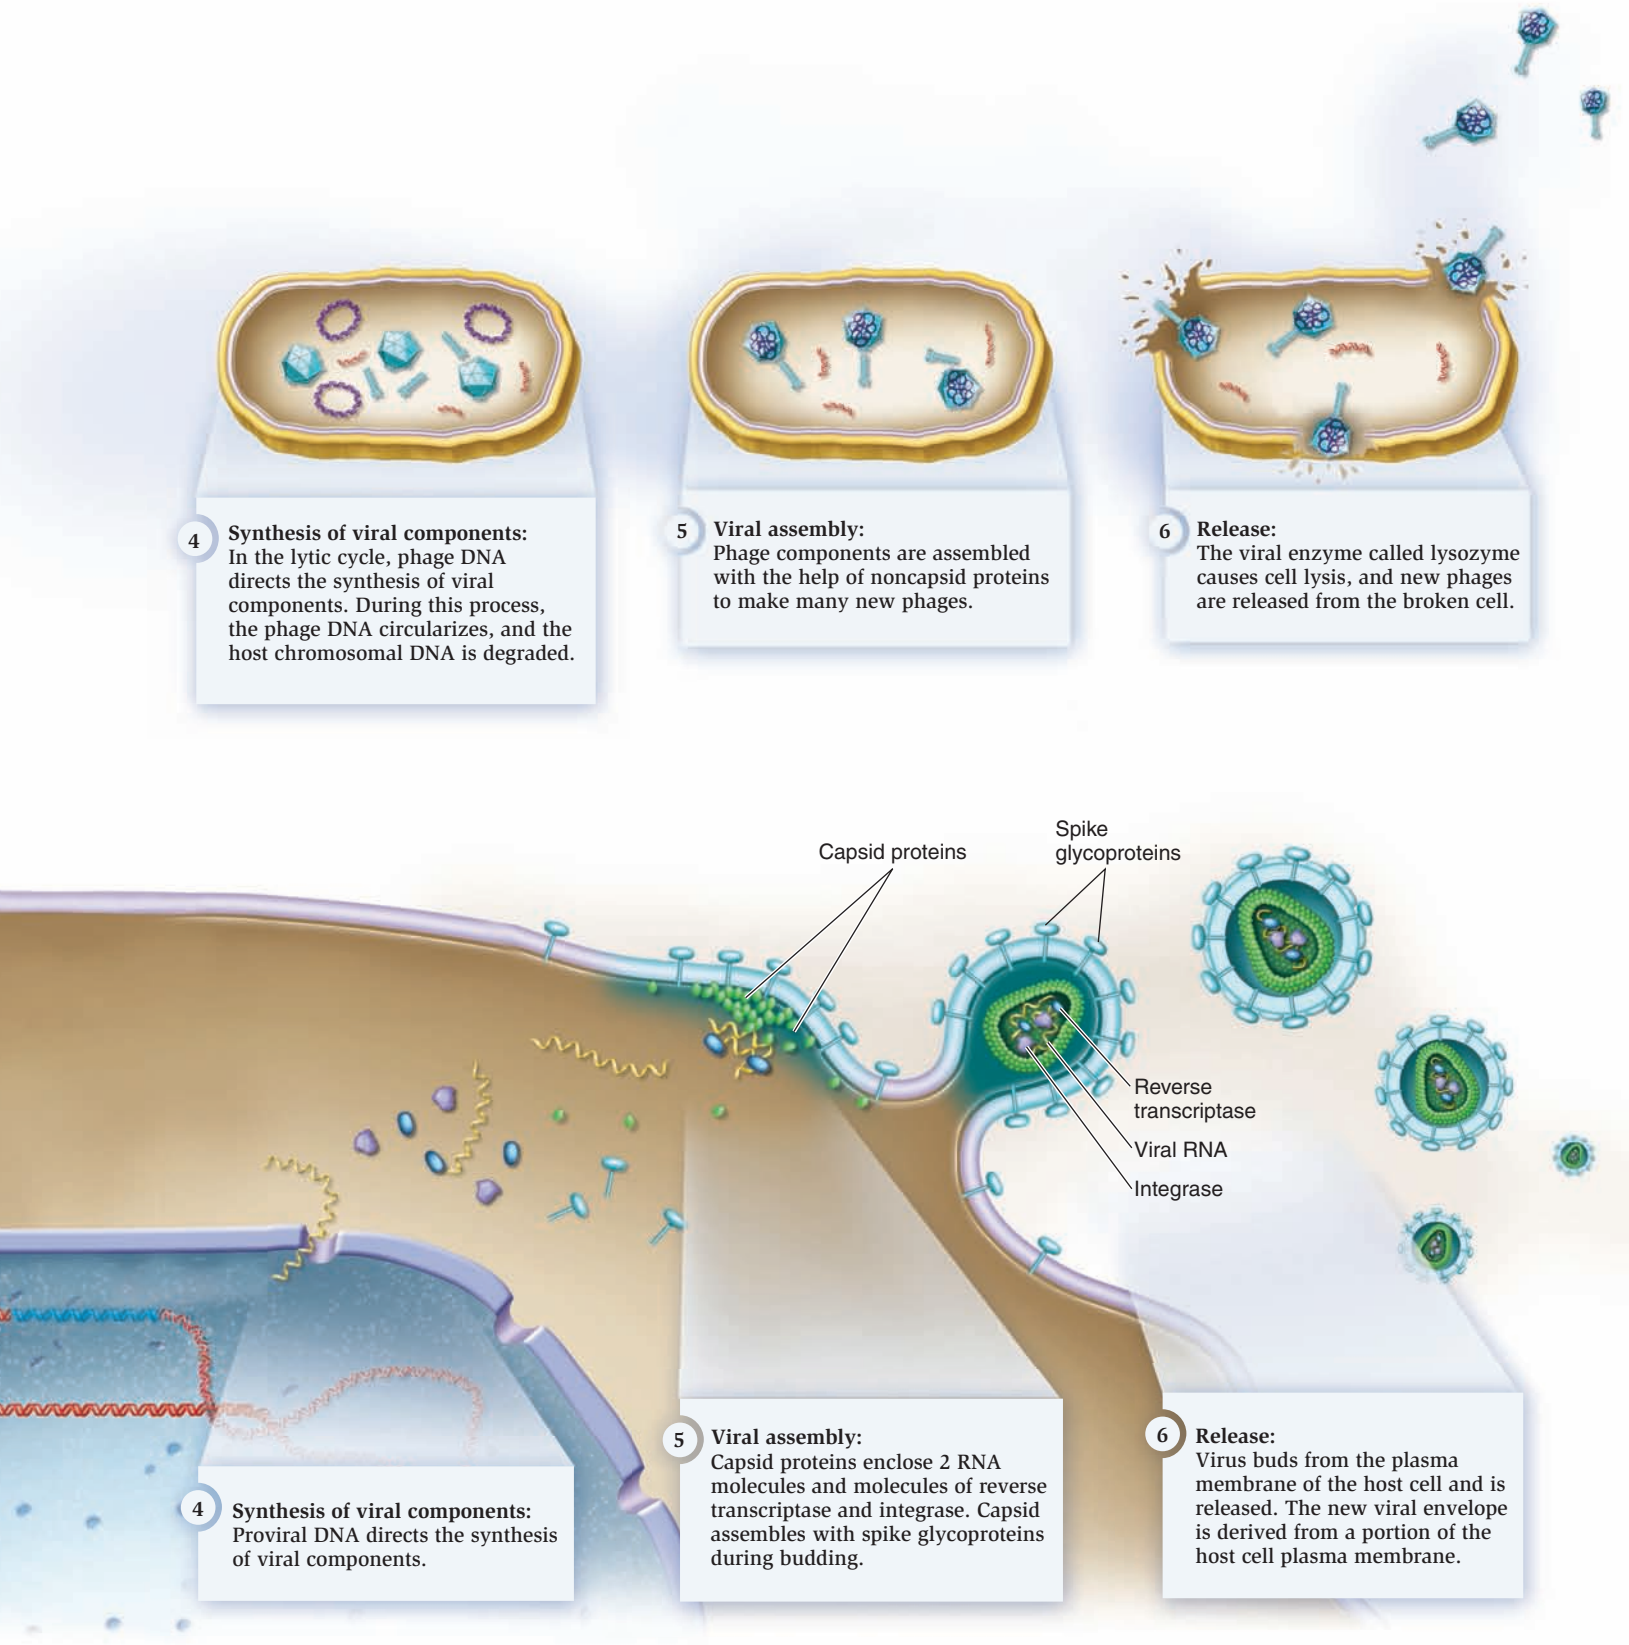


Figure 18.4 Comparison of the steps of two viral reproductive cycles. **(a)** The reproductive cycle of phage λ, a bacteriophage with a double-stranded DNA genome. **(b)** The reproductive cycle of HIV, an enveloped animal virus with a single-stranded RNA genome.

BioConnections: *Look back at Figure 5.23. How does the release of HIV resemble exocytosis?*

4 **Synthesis of viral components:** In the lytic cycle, phage DNA directs the synthesis of viral components. During this process, the phage DNA circularizes, and the host chromosomal DNA is degraded.

5 **Viral assembly:** Phage components are assembled with the help of noncapsid proteins to make many new phages.

6 **Release:** The viral enzyme called lysozyme causes cell lysis, and new phages are released from the broken cell.

4 **Synthesis of viral components:** Proviral DNA directs the synthesis of viral components.

5 **Viral assembly:** Capsid proteins enclose 2 RNA molecules and molecules of reverse transcriptase and integrase. Capsid assembles with spike glycoproteins during budding.

6 **Release:** Virus buds from the plasma membrane of the host cell and is released. The new viral envelope is derived from a portion of the host cell plasma membrane.

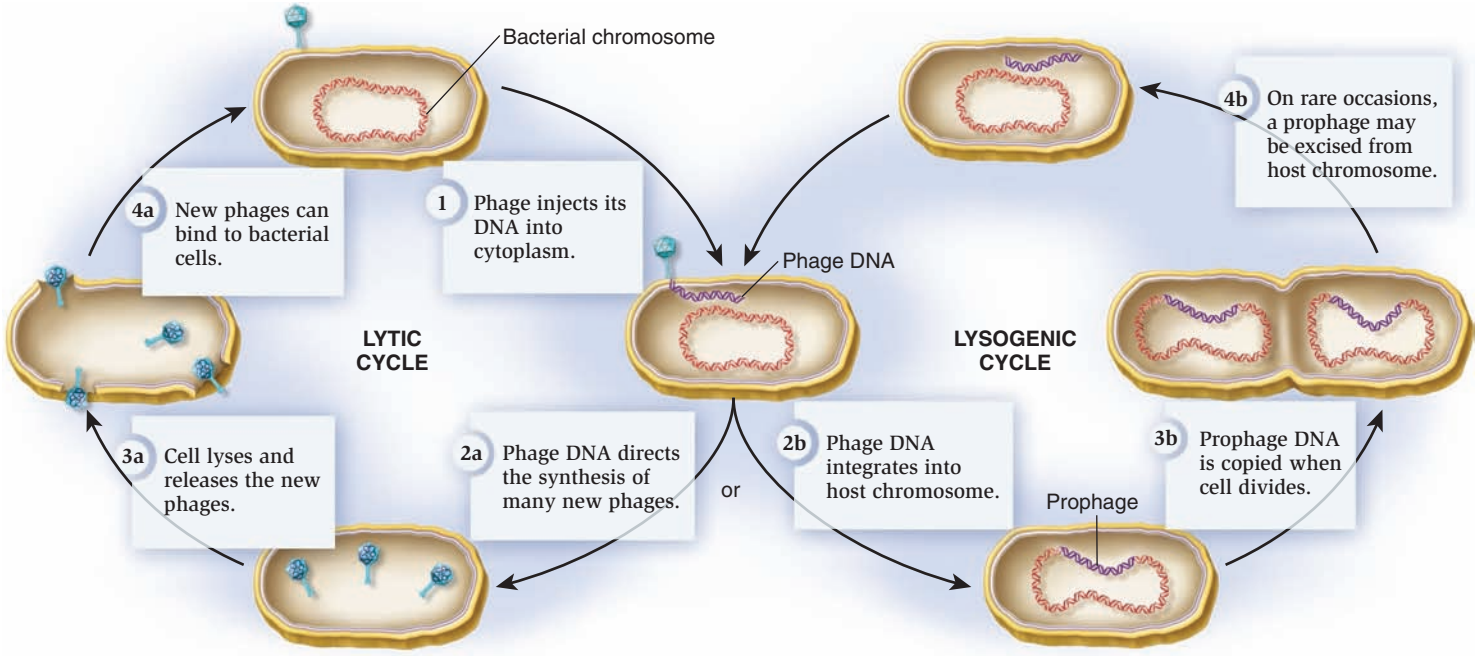

Figure 18.5 Lytic and lysogenic cycles of bacteriophages. Some phages, such as phage λ, may follow either a lytic or a lysogenic reproductive cycle. During the lytic cycle, new phages are made, and the bacterial cell lyses. During the lysogenic cycle, the integrated phage DNA, or prophage, is replicated along with the DNA of the host cell. Environmental conditions influence how long the phage remains in the lysogenic cycle.

Concept Check: *From the perspective of the virus, what are the primary advantages of the lytic and lysogenic cycles?*

In 2014, about 34 million people were living with HIV; approximately 3 million of them were infected that year. In that same year, nearly 2 million died from AIDS. Worldwide, nearly 1 in every 100 adults between ages 15 and 49 is infected. In the U.S., about 55,000 new HIV infections occur each year, 70% of which are in men and 30% in women.

The devastating effects of AIDS result from viral destruction of helper T cells, a type of white blood cell that plays an essential role in the immune system of mammals. **Figure 18.6** shows HIV virus particles invading a helper T cell. As described in Chapter 53, helper T cells interact with other cells of the immune system to facilitate the production of antibodies and other molecules that target and kill foreign invaders of the body. When large numbers of helper T cells are destroyed by HIV, the function of the immune system is seriously compromised, and the individual becomes susceptible to infectious diseases called opportunistic infections that would not normally occur in a healthy person. For example, *Pneumocystis jiroveci*, a fungus that causes a type of pneumonia, is easily destroyed by a healthy immune system. However, in people with AIDS, *Pneumocystis jiroveci* pneumonia can be fatal.

An insidious feature of HIV replication, described earlier in Figure 18.4b, is that reverse transcriptase, the enzyme that copies the RNA genome into DNA, lacks a proofreading function. In Chapter 11, we learned that DNA polymerase can identify and remove mismatched nucleotides in newly synthesized DNA. Because reverse transcriptase lacks this function, it makes more errors and thereby tends to create mutant strains of HIV. This undermines the ability of the body to combat HIV because mutant strains may be resistant to the body's defenses.

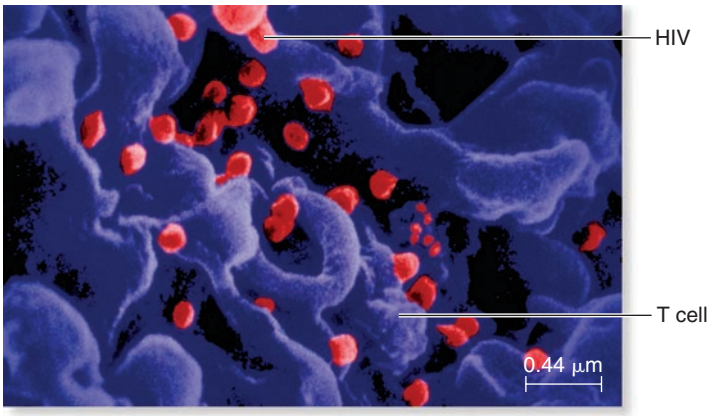

Figure 18.6 Micrograph of HIV invading a human helper T cell. This is a colorized scanning electron micrograph. The surface of the T cell is purple, and HIV particles are red.

BIO TIPS **THE QUESTION** *Propose an experiment to explain how an emerging virus could arise.*

TOPIC ***What topic in biology does this question address?*** The topic is about emerging viruses. More specifically, it is about proposing an experiment whose results could explain how they come into existence.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From your understanding of the topic, you may remember that emerging viruses typically arise via mutations in pre-existing viruses.

PROBLEM-SOLVING STRATEGY ***Design an experiment. Compare and contrast.*** To design an experiment that may explain how an emerging virus could arise, you want to keep in mind that new forms of viruses typically result from the genetic alteration of pre-existing viruses. Another important point to keep in mind is that the base sequences of many viruses have already been determined.

ANSWER *The rationale behind the design of this experiment is based on the premise that emerging viruses arise from genetic alterations in pre-existing viruses. Here is a suggested procedure:*

1. *Determine the base sequence of the emerging virus that you are interested in. (Note: The topic of DNA sequencing is described in Chapter 20.)*
2. *Compare its base sequence with those of other viruses. The expectation is that the emerging virus will be closely related to some other virus that is already known.*
3. *Analyze the differences in DNA sequences between the emerging virus and its closest relative. You may identify differences in particular genes in the emerging virus that may have altered the infectivity of the virus. For example, a mutation may have altered a viral protein in a way that allows the virus to bind more easily to host cells and enter them.*

Drugs Have Been Developed to Combat the Proliferation of HIV

A compelling reason to understand the reproductive cycle of HIV and other disease-causing viruses is that such knowledge may be used to develop drugs that stop viral proliferation. For example, in the U.S., the highest rate of AIDS-related deaths was approximately 17 per year per 100,000 people in 1994 and 1995. The current rate is about 4 to 5 deaths per year per 100,000 people, owing in part to the use of new antiviral drugs. These drugs inhibit viral proliferation, though they cannot eliminate the virus from the body.

One approach to the design of antiviral treatments is to develop drugs that specifically bind to proteins encoded by the viral genome. For example, azidothymidine (AZT) mimics the structure of a normal nucleotide and binds to the enzyme reverse transcriptase. In this way, AZT inhibits reverse transcription, thereby inhibiting viral replication. Another way to combat HIV involves the use of antiviral drugs that inhibit proteases, enzymes that are needed during the assembly of the HIV capsid. Certain HIV proteases cut capsid proteins, which makes them smaller and able to assemble into a capsid structure. If the proteases do not function, the capsid will not assemble, and new HIV particles will not be made. Several drugs known as protease inhibitors have been developed that bind to HIV proteases and inhibit their function.

A major challenge in AIDS research is to discover drugs that inhibit viral proteins without also binding to host cell proteins and inhibiting normal cellular functions. A second challenge is to develop drugs to which mutant strains will not become resistant. As mentioned, HIV readily accumulates mutations during viral replication. A current strategy is to treat HIV patients with a "cocktail" of three or more HIV drugs, making it less likely that any mutant strain will overcome all of the inhibitory effects.

Several Hypotheses Have Been Proposed to Explain the Origin of Viruses

Because viruses are such small particles, no fossil record is available to provide evidence about their evolution. Researchers must rely on analyses of modern viruses to develop hypotheses about their origin. Viral genomes follow the same rules of gene expression as the genomes of their host cells. Viral genes have promoter sequences similar to those of their host cells, and the translation of viral proteins relies on the genetic code. Viruses depend entirely on host cells for their proliferation. No known virus makes its own ribosomes or generates the energy it requires to make new viruses. Therefore, many biologists have argued that cells must have evolved before viruses.

How did viruses come into existence?

Progressive Evolution from Genetic Elements Within Cells A common hypothesis for the origin of viruses is that they evolved from macromolecules inside living cells. The precursors of the first viruses may have been RNA molecules or they may have been plasmids—small, circular DNA molecules that exist independently of chromosomal DNA. (Plasmids are described later in this chapter.) Biologists have hypothesized that such RNA or DNA molecules may have become more complex by acquiring genes that code for proteins that facilitate their own replication.

Regressive Evolution from Cells Though many biologists favor the idea that viruses originated from primitive plasmids or other chromosomal elements, some have suggested they are an example of regressive evolution—the reduction of a trait or traits over time. This hypothesis proposes that viruses are degenerate cells that have retained the minimal genetic information essential for reproduction. For example, some viruses may have originated as small cells that infected larger cells. Over time, genes not required for their independent existence were lost.

Parallel Evolution with Cells A new and interesting hypothesis is that viruses did not evolve from living cells but instead evolved in parallel with cellular organisms. As discussed in Chapter 22, the precursors of cellular DNA genomes may have been RNA molecules that could replicate independently of cells. This stage of evolution, termed the RNA world, could have involved the parallel evolution of both viruses and cellular organisms.

18.3 Viroids and Prions

Learning Outcomes:

1. Distinguish between a viroid and a virus.
2. Describe the structure of prions, and explain how they cause disease.

Some nonliving infectious agents are simpler than viruses. Viroids are composed solely of RNA, and prions are composed solely of protein. In this section, we begin by examining viroids, infectious agents

that cause diseases in plants. Next, we will discuss infectious proteins known as prions, which cause devastating neurological diseases in humans and other mammals.

Viroids Are RNA Molecules That Infect Plant Cells

In 1971, Swiss-born American plant pathologist Theodor Diener discovered that the agent of potato spindle tuber disease is a small RNA molecule devoid of any protein. He coined the term **viroid** for this newly discovered infectious particle. Viroids are composed solely of a single-stranded circular RNA molecule that is a few hundred nucleotides in length.

Viroids infect plant cells, where they depend entirely on host enzymes for their replication. Some viroids are replicated in the host cell nucleus, others in the chloroplast. In contrast to viral genomes, the RNA genomes of viroids do not code for any proteins. How do viroids affect plant cells? The RNA of some viroids has ribozyme activity, and some researchers think this activity may damage plants by interfering with the function of host cell molecules. However, the mechanism by which viroids induce disease is not well understood.

Since Diener's initial discovery, many more viroids have been characterized as the agents of diseases affecting many economically important plants, including potato, tomato, cucumber, orange, coconut, grape, avocado, peach, apple, pear, and plum. Some viroids have devastating effects, as illustrated by the case of the coconut cadang-cadang viroid, which has killed more than 20 million coconut trees in Southeast Asia and New Guinea (**Figure 18.7**). Other viroids produce less severe damage, causing necrosis on leaves, shortening of stems, bark cracking, and delays in foliation, flowering, and fruit ripening. A few viroids induce mild symptoms or no symptoms at all.

Figure 18.7 Effects of a viroid. This palm tree (left foreground) in Papua, New Guinea, has been infected with the coconut cadang-cadang viroid and shows symptoms of stunting and yellowing.

Prions Are Infectious Proteins That Cause Neurodegenerative Diseases

Before we end our discussion of nonliving, infectious particles, let's consider an unusual infectious agent that causes a group of rare, fatal brain diseases affecting humans and other mammals. Until the 1980s, biologists thought that any infectious agent, whether living or nonliving, must have genetic material. It seemed logical that genetic material is needed to store the information to produce new infectious particles.

In the 1960s, British researchers Tikvah Alper and John Stanley Griffith discovered that preparations from animals with certain neurodegenerative diseases remained infectious even after exposure to radiation that would destroy any DNA or RNA. They suggested that the infectious agent was a protein. In the early 1970s, American neurologist Stanley Prusiner, moved by the death of a patient from such a neurodegenerative disease, began to search for the causative agent. In 1982, Prusiner isolated a disease-causing particle composed entirely of protein, which he called a **prion**. The term was based on his characterization of the particle as a proteinaceous infectious agent. In 1997, Prusiner was awarded the Nobel Prize in Physiology or Medicine for his work on prions.

Prion diseases arise from the ability of the prion to induce abnormal folding in normal protein molecules (**Figure 18.8**). The prion exists in a disease-causing conformation designated PrP^{Sc}. The superscript Sc refers to scrapie, an example of a prion disease. A normal conformation of this same protein, which does not cause disease, is termed PrP^{C}. The superscript C stands for cellular. The normal protein is encoded by an individual's genome, and it is expressed at low levels in certain types of neurons.

How does someone contract a prion disease? A healthy person may become "infected" with the abnormal protein by eating meat of an animal with the disease. Unlike most other proteins in the diet, the prion escapes digestion in the stomach and small intestine and is absorbed into the bloodstream. After being taken up by neurons, the prion gradually converts the cell's normal proteins to the abnormal conformation. As a prion disease progresses, the PrP^{Sc} proteins are deposited as dense aggregates that form tough fibrils in the cells of the brain and peripheral nervous tissues, causing the disease symptoms. Some of the abnormal proteins are also secreted from infected cells, where they travel through the bloodstream. In this way, a prion disease spreads through the body like many viral diseases.

Prions cause several types of fatal neurodegenerative diseases affecting humans, livestock, and wildlife (**Table 18.2**). Prion diseases are termed transmissible spongiform encephalopathies (TSEs). The postmortem examination of the brains of affected individuals reveals a substantial destruction of brain tissue. The brain has a spongy appearance. Most prion diseases progress fairly slowly. Over the course of a few years, symptoms proceed from a loss of motor control to dementia,

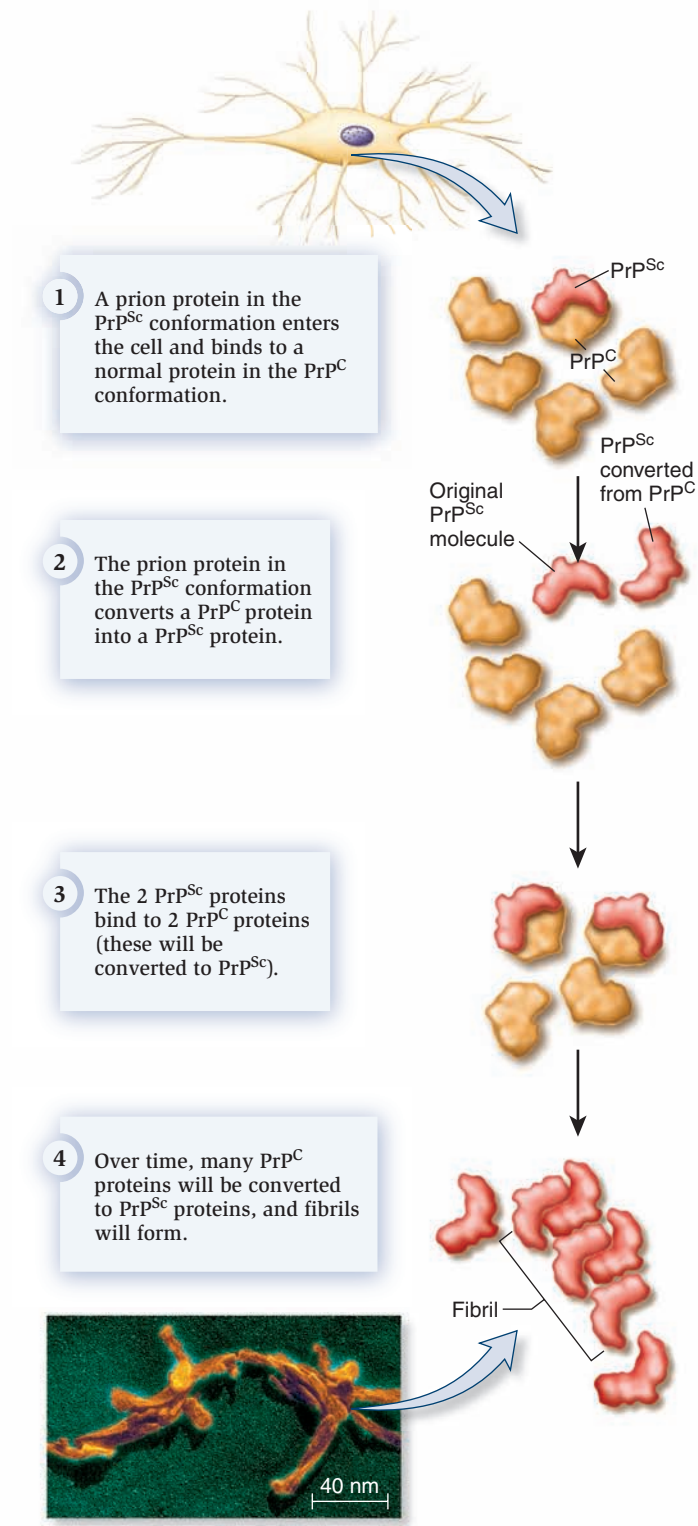

Figure 18.8 A proposed molecular mechanism of prion diseases. A healthy neuron contains only the PrP^C conformation of the protein. The abnormal PrP^{Sc} conformation catalyzes the conversion of PrP^C proteins into PrP^{Sc} proteins, thereby causing the symptoms of the prion disease.

BIOLOGY PRINCIPLE Structure determines function. The two protein conformations have different structures. The abnormal conformation of the prion has the functional ability to convert normal proteins to the abnormal conformation.

Table 18.2 Examples of Neurodegenerative Diseases Caused by Infectious Prions

Disease	Description
Scrapie	A disease of sheep and pigs characterized by intense itching. The animals tend to scrape themselves against trees or other objects, followed by neurodegeneration.
Mad cow disease	Begins with changes in posture and temperament, followed by loss of coordination and neurodegeneration.
Chronic wasting disease	A disease of deer (genus *Odocoileus*) and Rocky Mountain elk (*Cervus elaphus*). A consistent symptom is weight loss over time. The disease is progressive and fatal.

paralysis, wasting, and eventually death. These symptoms are correlated with an increase in the level of prion proteins in the neurons of infected individuals. No current treatment can halt the progression of any of the TSEs. For this reason, great public alarm occurs when an outbreak of a TSE is reported. For example, in 2003, a report of a single cow in the U.S. with a TSE commonly known as mad cow disease prompted several countries to restrict the import of American beef.

18.4 Genetic Properties of Bacteria

Learning Outcomes:

1. Outline the key features of a bacterial chromosome.
2. Explain the two processes that compact the bacterial chromosome.
3. Outline the structure and functions of plasmids.
4. Diagram the process of cell division in bacteria.

Many bacteria exist as unicellular organisms. However, some of them may remain associated with each other after cell division, forming pairs, chains, or clumps. Bacteria are widespread on Earth, and numerous species are known to cause various types of infectious diseases. We begin this section by exploring the structure and replication of the bacterial genome and the organization of DNA sequences along a bacterial chromosome. We then examine how the chromosome is compacted to fit inside a bacterium and how it is transmitted during asexual reproduction.

Bacteria Typically Have Circular Chromosomes That Carry a Few Thousand Genes

The genes of bacteria are within structures known as bacterial chromosomes.

- Although a bacterial cell usually has a single type of chromosome, it may have more than one copy of that chromosome. The number of copies depends on the bacterial species and on growth conditions, but a bacterium typically has one to four identical chromosomes.
- Each bacterial chromosome is tightly packed within a distinct **nucleoid** of the cell (**Figure 18.9**). Unlike the eukaryotic

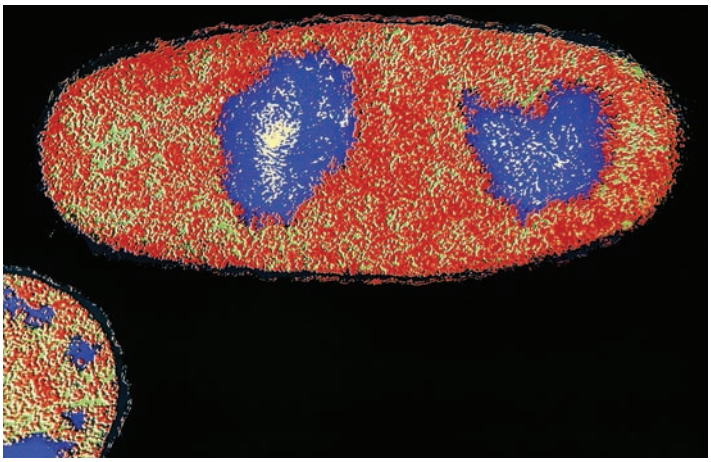

Figure 18.9 Nucleoids within the bacterium *Bacillus subtilis*. In this light micrograph, the nucleoids are fluorescently labeled and seen as purple, oval-shaped areas within the bacterial cytoplasm. Two or more nucleoids are usually found within each cell.

Concept Check: *How many nucleoids are in the bacterial cell at the top?*

BioConnections: *Look back at Figures 4.4 and 4.5. How is a nucleoid different from a nucleus found in a eukaryotic cell?*

nucleus, the bacterial nucleoid is not a separate cellular compartment bounded by a membrane. The DNA in a nucleoid is in direct contact with the cytoplasm of the cell.

- Bacterial chromosomes contain molecules of double-stranded DNA along with many different proteins. They are usually circular and are typically a few million base pairs (bp) long. For example, the chromosome of *Escherichia coli* has approximately 4.6 million bp, and the *Haemophilus influenzae* chromosome has roughly 1.8 million bp. By comparison, an average human chromosome is over 100 million bp in length. The genomes of bacteria, archaea, and eukaryotes are compared in Chapter 21.
- A typical bacterial chromosome contains a few thousand unique genes that are found throughout the chromosome. Gene sequences, primarily those that encode proteins, account for the largest part of bacterial DNA.
- Other nucleotide sequences in the chromosome play a role in DNA replication, gene expression, and chromosome structure. One of these sequences is the origin of replication, which is a few hundred base pairs long. Bacterial chromosomes have a single origin of replication that functions as an initiation site for the assembly of several proteins that are required for DNA replication (refer back to Figure 11.13b).

The Formation of Chromosomal Loops and DNA Supercoiling Make the Bacterial Chromosome Compact

Bacterial cells are much smaller than most eukaryotic cells (refer back to Figure 4.1). *E. coli* cells, for example, are approximately 1 μm wide and 2 μm long. To fit within a bacterial cell, the DNA of a typical bacterial chromosome must be compacted about 1,000-fold. How does this occur? The compaction of a bacterial chromosome, shown in **Figure 18.10**, occurs by two processes: the formation of loops and DNA supercoiling.

Unlike eukaryotic DNA, bacterial DNA is not wound around histone proteins to form nucleosomes. However, the binding of proteins to bacterial DNA is important in the formation of **loop domains**—chromosomal segments that are folded into loops. As seen in Figure 18.10, DNA-binding proteins anchor the bases of the loops in place. The number of loops varies according to the size of a bacterial chromosome and the species. The *E. coli* chromosome has 50 to 100 loop domains, each with about 40,000 to 80,000 bp. This looping compacts the circular chromosome about 10-fold. A similar process of loop-domain formation occurs in eukaryotic chromatin compaction, which is described in Chapter 11 (Figure 11.23).

DNA supercoiling is a second important way to compact the bacterial chromosome. Because DNA is a long, thin molecule, twisting can dramatically change its conformation. This process of compaction is similar to what happens to a rubber band if you twist it in one direction. Because the two strands of DNA already coil around each other, the formation of additional coils due to twisting is referred to as supercoiling. Bacterial enzymes called topoisomerases twist the DNA and control the degree of DNA supercoiling.

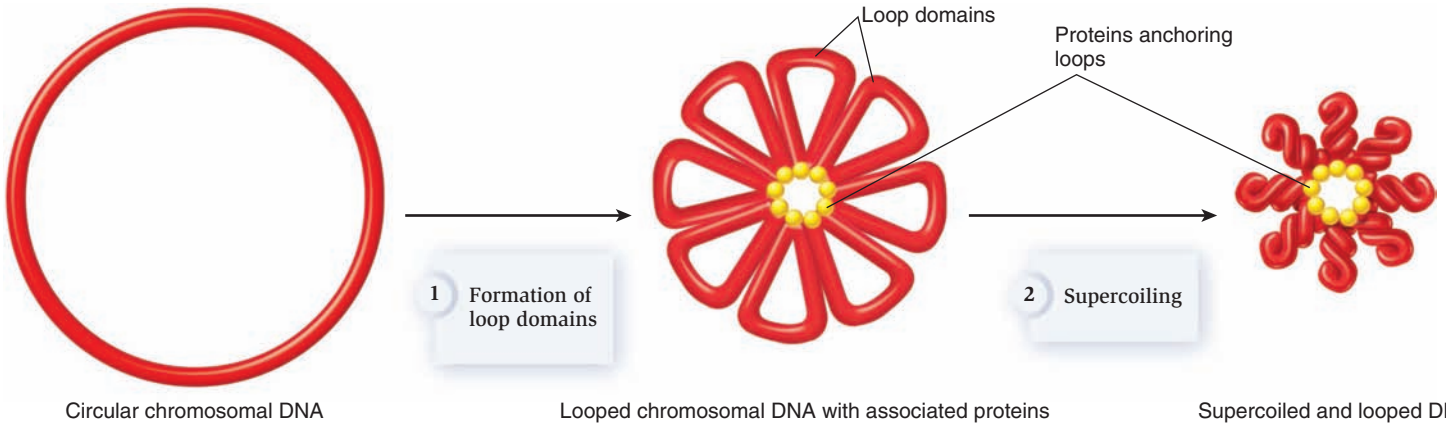

Figure 18.10 The compaction of a bacterial chromosome. As a way to compact the large, circular chromosome, segments are organized into smaller loop domains by binding to proteins at the bases of the loops. These loops are made more compact by DNA supercoiling. Note: This is a simplified drawing; bacterial chromosomes typically have 50–100 loop domains.

Concept Check: *Describe how the loop domains are held in place.*

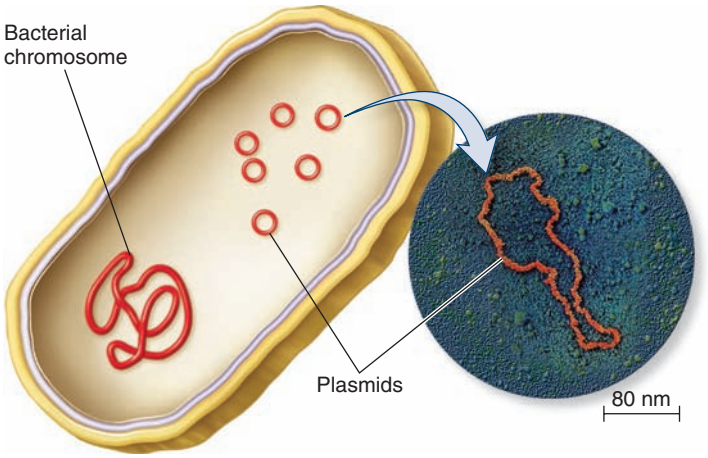

Figure 18.11 **Plasmids in a bacterial cell.** Plasmids are small, circular DNA molecules that exist independently of the bacterial chromosome.

Concept Check: *Describe the similarities and differences between a bacterial chromosome and a plasmid.*

Plasmids Are Small, Circular Pieces of Extrachromosomal DNA

In addition to chromosomal DNA, bacterial cells commonly contain **plasmids**, small, circular pieces of DNA that exist separately from the bacterial chromosome (**Figure 18.11**). Plasmids occur naturally in many strains of bacteria and in a few types of eukaryotic cells, such as yeast. The smallest plasmids consist of just a few thousand base pairs and carry only a gene or two. The largest are in the range of 100,000 to 500,000 bp and carry several dozen or even hundreds of genes. A plasmid has its own origin of replication that allows it to be replicated independently of the bacterial chromosome. The DNA sequence of the origin of replication influences how many copies of the plasmid are found within a cell. Some origins are said to be very strong because they result in many copies of the plasmid, perhaps as many as 100 per cell. Other origins of replication have sequences that are much weaker, so the number of copies is relatively low, such as one or two per cell.

Why do bacteria have plasmids? Certain genes within a plasmid usually provide some type of growth advantage to the cell or may aid in survival under certain conditions. By studying plasmids in many different species, researchers have discovered that most plasmids fall into five different categories:

1. Resistance plasmids, also known as R factors, contain genes that confer resistance against antibiotics and other types of toxins.
2. Degradative plasmids carry genes that enable the bacterium to digest and utilize an unusual substance. For example, a degradative plasmid may carry genes that allow a bacterium to digest an organic solvent such as toluene.
3. Col-plasmids contain genes that encode colicins, which are proteins that kill other bacteria.
4. Virulence plasmids carry genes that turn a bacterium into a pathogenic strain.
5. Fertility plasmids, also known as F factors, allow bacteria to transfer genes to each other, a topic described later in this chapter.

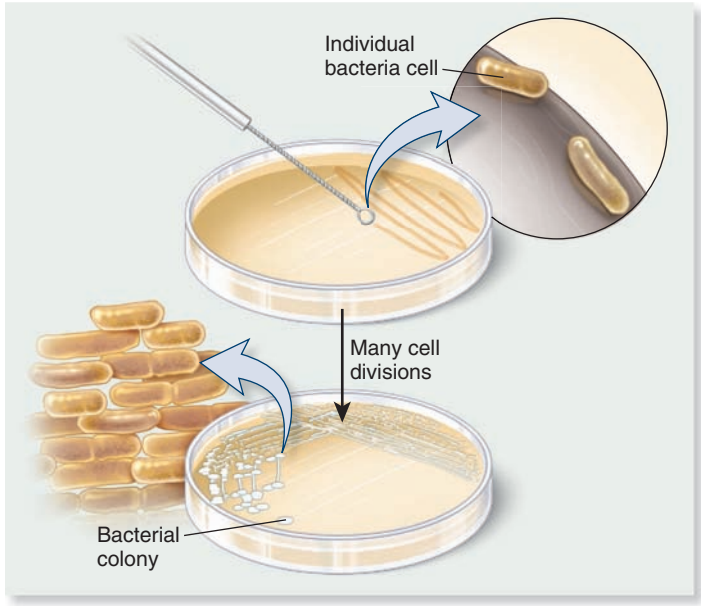

Figure 18.12 **Growth of a bacterial colony.** Through successive cell divisions, a single bacterial cell of *E. coli* forms a genetically identical group of cells called a bacterial colony.

Concept Check: *Let's suppose a bacterial strain divides every 30 minutes. If a single cell is placed on a plate, how many cells will be in the colony after 16 hours?*

On occasion, a plasmid may integrate into the bacterial chromosome. Such plasmids, which can integrate or remain independent of the chromosome, are also termed episomes.

Most Bacteria Reproduce by Binary Fission

Thus far, we have considered the genetic material of bacteria and how the bacterial chromosome is compacted to fit inside the cell. Let's now turn our attention to the process of cell division. The capacity of bacteria to divide is really quite astounding. The cells of some species, such as *E. coli*, can divide every 20–30 minutes. When placed on a solid growth medium in a petri dish, an *E. coli* cell and its daughter cells undergo repeated cellular divisions and form a clone of genetically identical cells called a **bacterial colony** (**Figure 18.12**). Starting

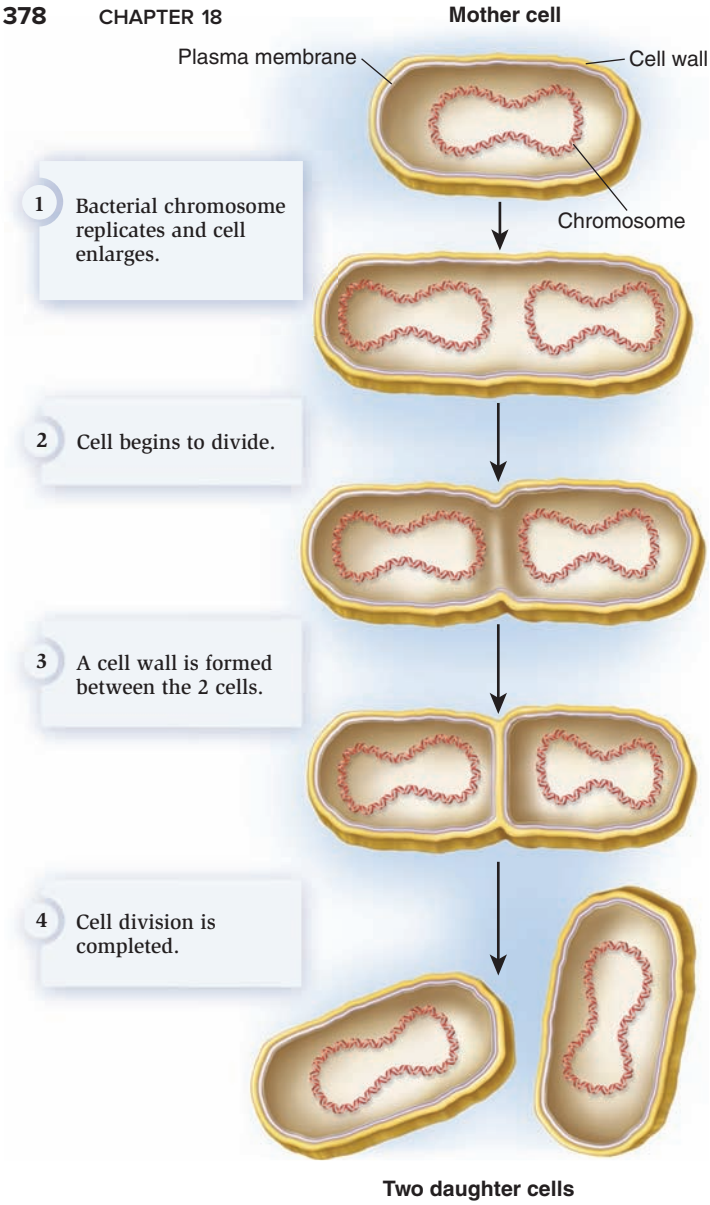

Figure 18.13 Bacterial cell division. Bacteria reproduce by binary fission. Before a bacterium divides, the bacterial chromosome is replicated to produce two identical copies. These two copies segregate from each other, with one copy going to each daughter cell.

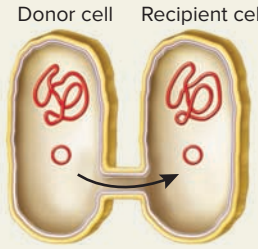
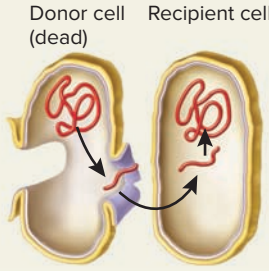
BIOLOGY PRINCIPLE Living organisms grow and develop. After cell division, a bacterial cell increases in size.

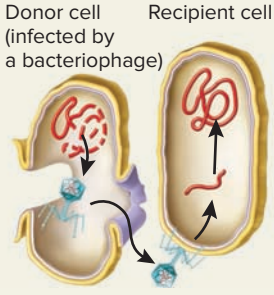
with a single cell that is invisible to the naked eye, a visible bacterial colony containing 10–100 million cells forms in less than a day!

Cell division of most bacterial species occurs by a process called **binary fission**, during which a cell divides into two daughter cells. Figure 18.13 shows this process for a cell with a single chromosome. Before it divides, the cell replicates its DNA. This produces two identical copies of the chromosome. Next, the cell's plasma membrane is drawn inward and deposits new cell-wall material, separating the two daughter cells. Each daughter cell receives one of the copies of the original chromosome. Therefore, except when a mutation occurs, each daughter cell contains an identical copy of the mother cell's genetic material.

Plasmids replicate independently of the bacterial chromosome. During binary fission, the plasmids are distributed to daughter cells so each daughter cell usually receives one or more copies of the plasmid.







18.5 Gene Transfer Between Bacteria

Learning Outcomes:

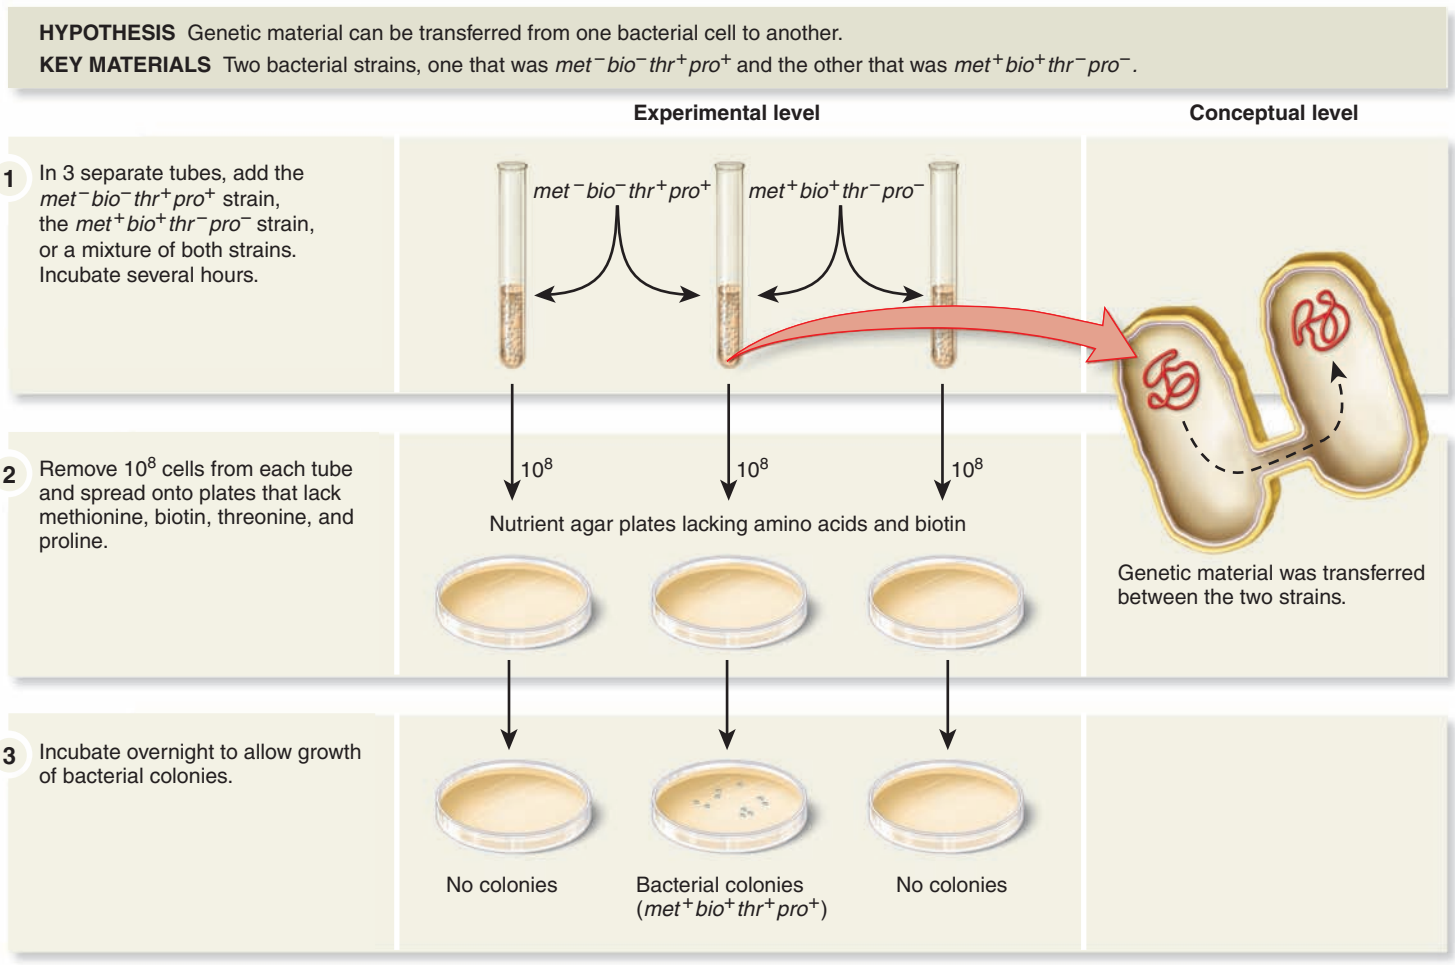
1. Compare and contrast the three forms of gene transfer—conjugation, transformation, and transduction—in bacteria.
2. **SciSKILLS** » Analyze the results of Lederberg and Tatum, and explain how they led to the discovery of conjugation.
3. Describe the process of horizontal gene transfer.

Even though bacteria reproduce asexually, they exhibit a great deal of genetic diversity. Within a given bacterial species, the term **strain** refers to a lineage that has genetic differences compared to another strain. For example, one strain of *E. coli* may be resistant to an antibiotic, whereas another strain may be sensitive to the same antibiotic. How does genetic diversity arise in an asexual species? It comes primarily from two sources. First, mutations occur that alter the bacterial genome and affect the traits of bacterial cells. Second, diversity

Table 18.3 Mechanisms of Gene Transfer Between Bacterial Cells

Mechanism	Description
Conjugation: 	Requires direct contact between a donor cell and a recipient cell. The donor cell transfers a strand of DNA to the recipient. In the example shown here, DNA from a plasmid is transferred to the recipient cell. The end result is that both donor and recipient cells have a plasmid.
Transformation: 	A fragment of DNA from a donor cell is released into the environment. This may happen when a bacterial cell dies. This DNA fragment is taken up by a recipient cell, which incorporates the DNA into its chromosome.
Transduction: 	When a bacteriophage infects a donor cell, it causes the bacterial chromosome of the donor cell to break up into fragments. A fragment of bacterial chromosomal DNA is incorporated into a newly made bacteriophage. The bacteriophage then transfers this fragment of DNA to a recipient cell.

arises by **gene transfer**, in which genetic material is transferred from one bacterial cell to another. Through gene transfer, genetic variation that arises in one bacterium can be spread to other strains and even to other species. For example, an antibiotic-resistance gene may be transferred from a resistant strain to a sensitive strain.



Gene transfer occurs in three different ways, termed conjugation, transformation, and transduction (**Table 18.3**). The process known as **conjugation** involves a direct physical interaction between two bacterial cells. During conjugation, one bacterium acts as a donor and transfers DNA to a recipient cell. In the process of **transformation**, DNA is released into the environment and taken up by another bacterial cell. **Transduction** occurs when a virus infects a bacterial cell and then transfers some of that cell's DNA to another bacterium. These three types of gene transfer have been extensively investigated in research laboratories, and their molecular pathways continue to be studied with great interest. In this section, we will examine these mechanisms in greater detail and consider the experiments that led to their discovery.

Feature Investigation | Lederberg and Tatum's Work with *E. coli* Demonstrated Gene Transfer Between Bacteria and Led to the Discovery of Conjugation

In 1946 and 1947, Joshua Lederberg and Edward Tatum carried out the first experiments that showed gene transfer from one bacterial cell to another (**Figure 18.14**). The researchers studied strains of *E. coli* that had different nutritional requirements for growth. They designated one strain $met^-bio^-thr^+pro^+$ because its growth required the amino acid methionine (met) and the vitamin biotin (bio) in the growth medium. This strain did not require the amino acids threonine (thr) or proline (pro) for growth. Another strain, designated $met^+bio^+thr^-pro^-$, had just the opposite requirement. It needed threonine and proline, but not methionine or biotin. These differences in nutritional requirements correspond to allelic differences between the two strains. The $met^-bio^-thr^+pro^+$ strain had defective genes encoding enzymes necessary for methionine and biotin synthesis, whereas the $met^+bio^+thr^-pro^-$ strain had defective genes for the enzymes required to make threonine and proline.

Figure 18.14 compares the results of mixing the two *E. coli* strains with the results when they were not mixed. The tube on the left contained only $met^-bio^-thr^+pro^+$ cells, and the tube on the right had only $met^+bio^+thr^-pro^-$ cells. The middle tube contained a mixture of the two kinds of cells. In each case, the researchers applied about 100 million (10^8) cells to plates containing a growth medium

Figure 18.14 Experiment of Lederberg and Tatum demonstrating gene transfer between *E. coli* cells.

4 THE DATA

Strain	Number of colonies after overnight growth
$met^-bio^-thr^+pro^+$	0
$met^+bio^+thr^-pro^-$	0
Both strains together	~10

5 CONCLUSION Gene transfer has occurred from one bacterial cell to another.

6 SOURCES Lederberg, J., and Tatum, E. L. 1946. Novel genotypes in mixed cultures of biochemical mutants of bacteria. *Cold Spring Harbor Symposia on Quantitative Biology* 11:113–114.

Tatum, E. L., and Lederberg, J. 1947. Genetic recombination in the bacterium *Escherichia coli*. *Journal of Bacteriology* 53:673–684.

lacking amino acids and the vitamin biotin. When the unmixed strains were applied to these plates, no colonies were observed to grow. This result was expected because the plates did not contain the methionine and biotin that the $met^-bio^-thr^+pro^+$ cells needed for growth or the threonine and proline that the $met^+bio^+thr^-pro^-$ cells required. The striking result occurred when the researchers plated 10^8 cells from the tube containing the mixture of the two strains. In this case, approximately 10 cells multiplied and formed visible bacterial colonies on the plates. Because these cells multiplied without supplemental amino acids or vitamins, their genotype must have been $met^+bio^+thr^+pro^+$. Mutations cannot account for the occurrence of this new genotype because colonies were not observed on the other two plates, which had the same number of cells and also could have incurred mutations.

To explain the results of their experiment, Lederberg and Tatum hypothesized that some genetic material had been transferred between the two strains when they were mixed. This transfer could have occurred in two ways. One possibility is that the genes providing the ability to synthesize threonine and proline (thr^+pro^+) were transferred to the $met^+bio^+thr^-pro^-$ strain. Alternatively, the genes providing the ability to synthesize methionine and biotin (met^+bio^+) may have been transferred to the $met^-bio^-thr^+pro^+$ cells. The experimental results cannot distinguish between these two possibilities, but they provide compelling evidence that at least one of them occurred.

How did the bacteria in Lederberg and Tatum's experiment transfer genes between strains? Two mechanisms seemed plausible. Either genetic material was released from cells of one and taken up by cells of the other, or cells of the two different strains made contact with each other and directly transferred genetic material. To distinguish these two scenarios, American microbiologist Bernard Davis conducted experiments using the same two strains of *E. coli*. The apparatus he used, known as a U-tube, is shown in **Figure 18.15**. The tube had a filter with pores big enough for pieces of DNA to pass through, but too small to permit the passage of bacteria. After filling the tube with a liquid medium, Davis added $met^-bio^-thr^+pro^+$ bacteria on one side of the filter and $met^+bio^+thr^-pro^-$ bacteria on the other. The application of pressure or suction promoted the movement of liquid through the pores. Although the two kinds of bacteria could not mix, any genetic material released by one of them would be available to the other.

After allowing the bacteria to incubate in the U-tube, Davis placed cells from each side of the tube on growth media lacking methionine, biotin, threonine, and proline. No bacterial colonies grew on the media. How did Davis interpret these results? He proposed that without physical contact, the two *E. coli* strains could not transfer genetic material from one cell to the other. The conceptual level of Figure 18.14, step 1, shows the physical connection that explains Lederberg and Tatum's results. Conjugation is the process of gene transfer that requires direct cell-to-cell contact. It has been subsequently observed in other species of bacteria. Many, but not all, species of bacteria can conjugate.

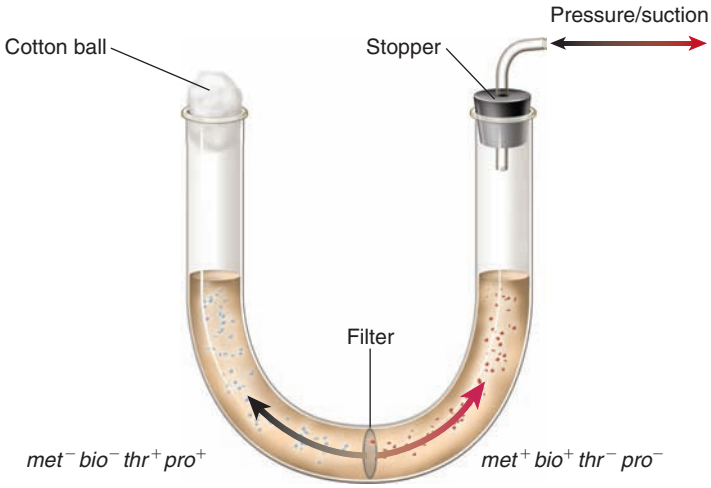


Figure 18.15 A U-tube apparatus like the one used by Davis. Bacteria of two different strains were suspended in the liquid in the tube and separated by a filter. The liquid was forced through the filter by alternating suction and pressure. The pores in the filter were too small for the passage of bacteria, but they allowed the passage of DNA.

BIOLOGY PRINCIPLE Biology is an experimental science. The U-tube apparatus allowed Davis to determine if direct cell-to-cell contact was needed for gene transfer.

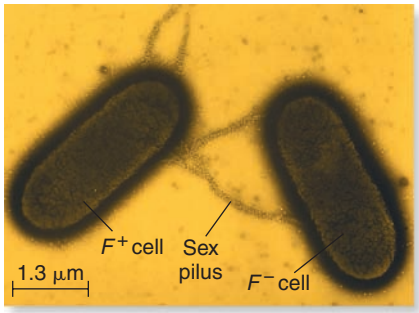
Concept Check: Would the results have been different if the pore size was larger and allowed the passage of bacterial cells?

Experimental Questions

1. What hypothesis did Lederberg and Tatum test?
2. **SciSKILLS »** During the Lederberg and Tatum experiment, the researchers compared the growth of mutant strains under two scenarios: mixed strains or unmixed strains. When the unmixed strains were plated on the experimental growth medium, why were no colonies observed to grow? When the mixed strains were plated on the experimental growth medium, 10 colonies were observed. What was the significance of these colonies?
3. **SciSKILLS »** The gene transfer seen in the Lederberg and Tatum experiment could have occurred in one of two ways: taking up DNA released into the environment or contact between two bacterial cells allowing for direct transfer. Davis conducted an experiment to determine the correct process. Explain how his results indicated the correct gene transfer process.

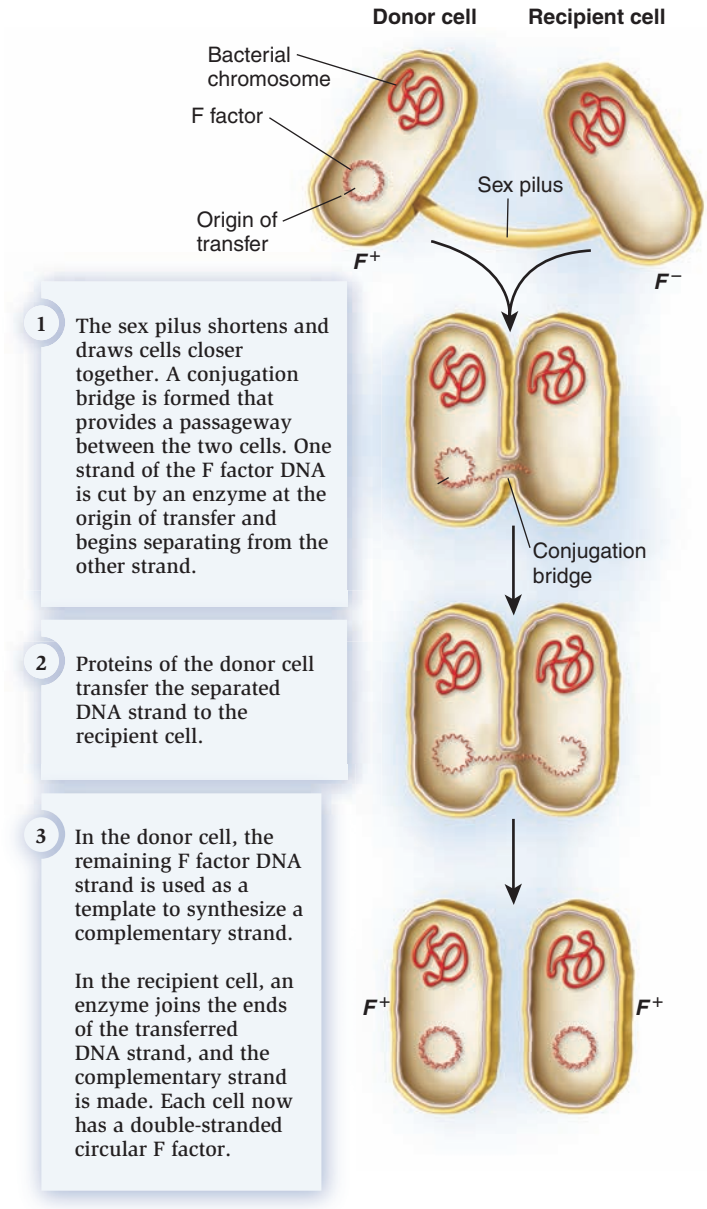
During Conjugation, DNA Is Transferred from a Donor Cell to a Recipient Cell

In the early 1950s, Americans Joshua and Esther Lederberg, Irish physician William Hayes, and Italian geneticist Luca Cavalli-Sforza independently discovered that only certain bacterial strains can donate genetic material during conjugation. For example, only about 5% of *E. coli* strains found in nature act as donor strains. Further research showed that a strain that is incapable of acting as a donor can acquire this ability after being mixed with a donor strain. Hayes correctly proposed that donor strains contain a type of plasmid called a fertility factor, or **F factor**, that can be transferred to recipient strains. Also, other donor *E. coli* strains were later identified that transfer portions of the bacterial chromosome at high frequencies. After a segment of the chromosome is transferred, it then inserts, or recombines, into the chromosome of the recipient cell. Such donor strains were named *Hfr* (for High frequency of recombination). In our discussion, we will focus on donor strains that carry F factors.



The micrograph in **Figure 18.16a** shows two conjugating *E. coli* cells. The cell on the left is designated F^+, meaning that it has an F factor. This donor cell is transferring genetic material to the recipient cell on the right, which lacks an F factor and is designated F^-. F factors carry several genes that are required for conjugation and also may carry genes that confer a growth advantage for the bacterium.

Figure 18.16b describes the events that occur during conjugation in *E. coli*. **Sex pili** (singular, pilus) are made by F^+ cells that bind specifically to F^- cells. They are so named because conjugation has been called bacterial mating. However, this term is a bit misleading because the process does not involve equal genetic contributions from two gametes and it does not produce offspring. Donor strains have genes responsible for the formation of sex pili. In F^+ strains, the genes are located on the F factor. In *E. coli* and some other species, F^+ cells make very long pili that attempt to make contact with nearby F^- cells. Once contact is made, the pili shorten, drawing the donor and recipient cells closer together.



After the pili have shortened, contact between donor and recipient cell stimulates the donor cell to begin the transfer process. First, a conjugation bridge is formed that provides a direct passageway for DNA transfer. One strand of F factor DNA is cut at the origin of transfer and then travels through the conjugation bridge into the recipient cell. The other strand remains in the donor cell, and the complementary strand is synthesized, thereby restoring the F factor DNA to its original double-stranded condition. In the recipient cell, the two ends of the newly acquired F factor DNA strand are joined to form a circular molecule, and its complementary strand is synthesized to produce a double-stranded F factor. If conjugation is successful, the end result is that the recipient cell has acquired an F factor, converting it from an F^- to an F^+ cell. The genetic composition of the donor strain has not been changed.

In Transformation, Bacteria Take Up DNA from the Environment

In contrast to conjugation, the process of gene transfer known as bacterial transformation does not require direct contact between bacterial cells. Frederick Griffith first discovered this process in 1928 while working with strains of *Streptococcus pneumoniae*. We discussed early experiments involving transformation in Chapter 11 (refer back to Figures 11.1 and 11.2).

(a) Micrograph of conjugating cells

(b) Transfer of an F factor

Figure 18.16 Bacterial conjugation. **(a)** A micrograph of two *E. coli* cells that are conjugating. The cell on the left, designated F^+, is the donor; the cell on the right, designated F^-, is the recipient. The two cells make contact via sex pili made by the F^+ cell. **(b)** The transfer of an F factor during conjugation. At the end of conjugation, both the donor cell and the recipient cell are F^+.

Concept Check: *If a donor cell has only one F factor, explain how the donor and recipient cell both contain one F factor following the transfer of an F factor during conjugation.*

How does a bacterial cell become transformed? First, it imports a strand of DNA from the environment. This DNA strand, which is typically derived from a dead bacterial cell, may then insert or recombine into the bacterial chromosome. The live bacterium then carries genes from the dead bacterium—the live bacterium has been transformed.

Not all bacterial strains have the ability to take up DNA. Those that do have this ability are described as naturally **competent**, and they have genes that encode proteins called competence factors. Competence factors facilitate the binding of DNA fragments to the bacterial cell surface, the uptake of DNA into the cytoplasm, and the incorporation of the imported DNA into the bacterial chromosome. Temperature, ionic conditions, and the availability of nutrients affect whether or not a bacterium will be competent to take up genetic material.

In recent years, biologists have unraveled some of the steps that occur when competent bacterial cells are transformed by taking up genetic material from the environment. In the example shown in **Figure 18.17**, the DNA released from a dead bacterium carries a gene, tet^R, that confers resistance to the antibiotic tetracycline. First, a large fragment of the DNA binds to a cell surface receptor on the outside of a bacterial cell that is sensitive to tetracycline. Enzymes secreted by the bacterium cut this large fragment into fragments small enough to enter the cell. In our example, one of the two strands of a fragment of DNA containing the tet^R gene is degraded. The other strand enters the bacterial cytoplasm via a DNA uptake system that transports the DNA across the plasma membrane. Finally, the imported DNA strand is incorporated into the bacterial chromosome, and the complementary strand is synthesized. Following transformation, the recipient cell has been transformed from a tetracycline-sensitive cell to a tetracycline-resistant cell.

In Transduction, Viruses Transfer Genetic Material from One Bacterium to Another

A third mechanism of gene transfer is transduction, in which bacteriophages transfer bacterial genes from one bacterium to another. As discussed earlier in this chapter, a bacteriophage (or simply phage) is a virus that uses the cellular machinery of a bacterium for its own replication. The new viral particles made in this way usually contain only viral genes. On rare occasions, however, a phage may pick up a piece of DNA from the bacterial chromosome. When a phage carrying a segment of bacterial DNA infects another bacterium, it transfers this segment into the chromosome of its new bacterial host.

Transduction is actually an error in a phage lytic cycle, as shown in **Figure 18.18**. In this example, a phage called P1 infects an *E. coli* cell that has a gene (his^+) for histidine synthesis. Phage P1 causes the host cell chromosome to be degraded into small pieces. New phage DNA and proteins are synthesized. When new phages are assembled, coat proteins may accidentally enclose a piece of host DNA that carries this gene. This produces a phage carrying bacterial chromosomal DNA. In the example shown in Figure 18.18, this transducing phage is released and binds to an *E. coli* cell that lacks the his^+ gene. It inserts the bacterial DNA fragment into the recipient cell, which then integrates this fragment into its own chromosome. In this case, gene transfer by transduction converts a his^- strain of *E. coli* to a his^+ strain.

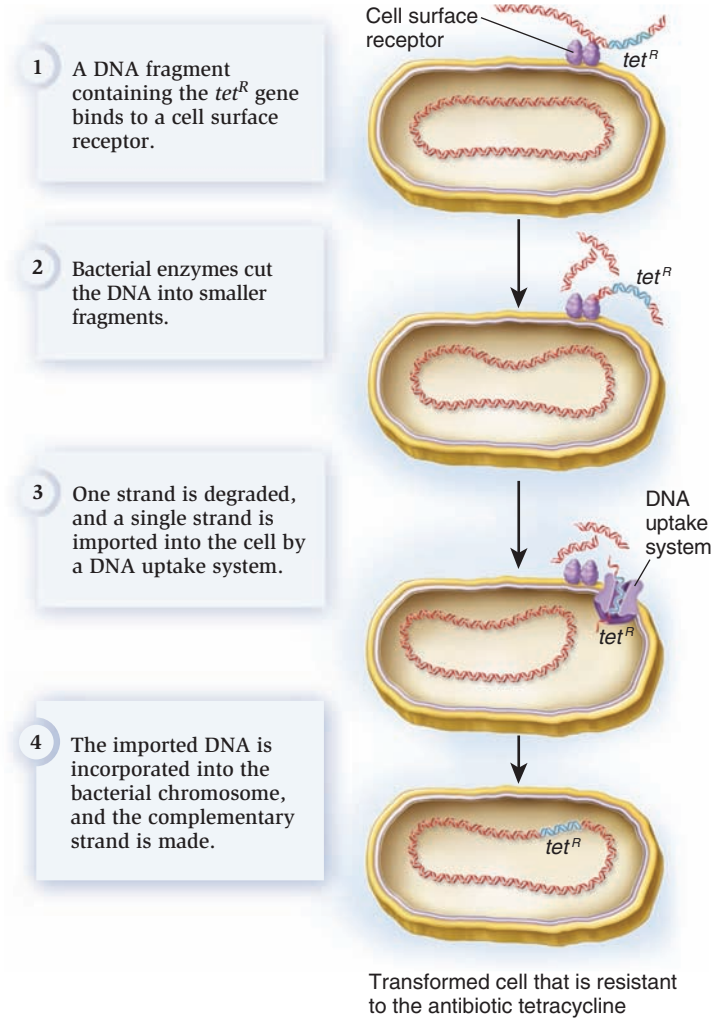


Figure 18.17 Bacterial transformation. This process has transformed a bacterium that was sensitive to the antibiotic tetracycline into one that is resistant to this antibiotic.

BioConnections: Look back at Figures 11.1 and 11.2. How did the phenomenon of transformation allow researchers to demonstrate that DNA is the genetic material?

Genomes & Proteomes Connection

Horizontal Gene Transfer Can Occur Within a Species or Between Different Species

The term **horizontal gene transfer** refers to a process in which an organism incorporates genetic material from another organism without being the offspring of that organism. Conjugation, transformation, and transduction are examples of horizontal gene transfer. In contrast, vertical gene transfer occurs when genes are passed from one generation to the next—from parents to offspring and from mother cells to daughter cells.

Conjugation, transformation, and transduction occasionally occur between cells of different bacterial species. In recent years,

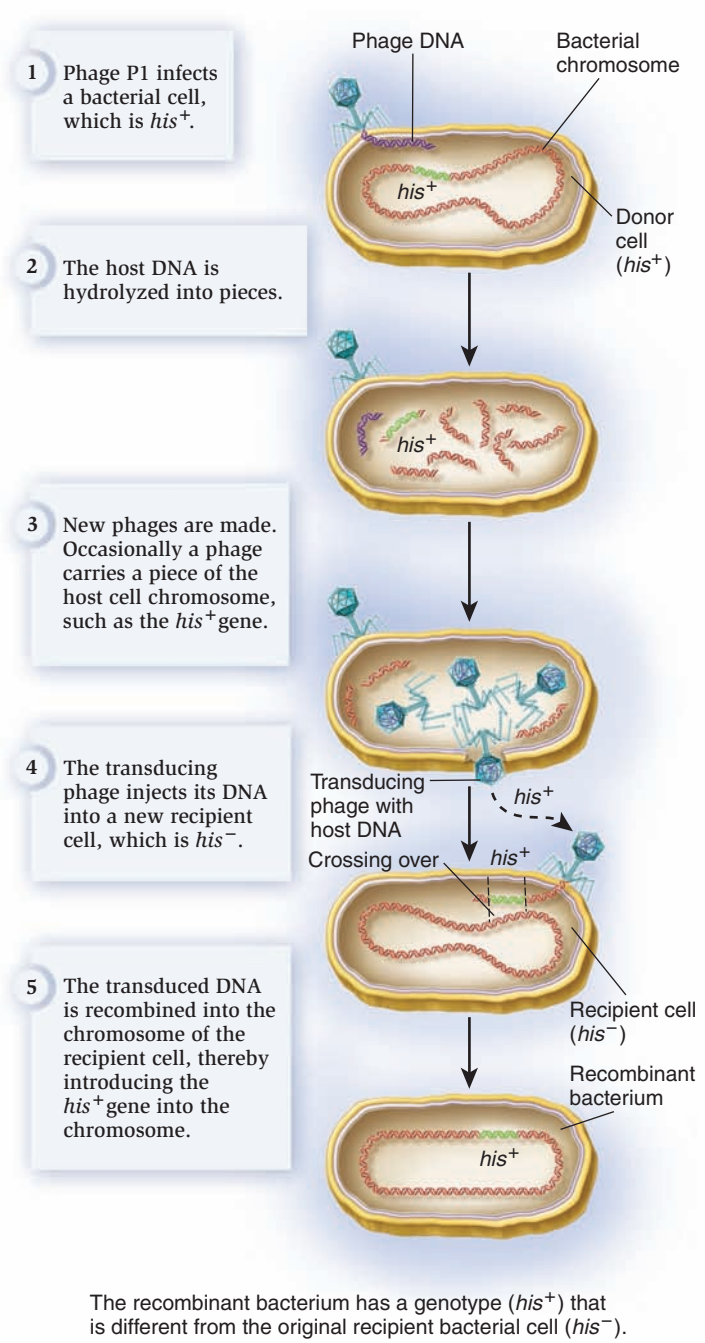

Figure 18.18 **Bacterial transduction by phage P1.**

Concept Check: *Is transduction a normal part of the phage life cycle? Explain.*

analyses of bacterial genomes have shown that a sizeable percentage of bacterial genes are derived from horizontal gene transfer. For example, roughly 17% of the genes of *E. coli* and of *Salmonella typhimurium* have been acquired from other species by horizontal gene transfer during the past 100 million years. Many of these acquired genes affect traits that give cells a selective advantage, including genes that confer antibiotic resistance, the ability to degrade toxic compounds, and the ability to withstand extreme environments. Some horizontally transferred genes confer pathogenicity, turning a harmless bacterial strain into one that can cause disease. Geneticists have suggested that horizontal gene transfer has played a major role in the evolution of different bacterial species. In many cases, the acquisition of new genes allows a bacterium to survive in a new type of environment and can eventually lead to the formation of a new species.

A second reason why horizontal gene transfer is important is its medical relevance. Let's consider the topic of antibiotic resistance. Antibiotics are widely prescribed to treat bacterial infections in humans. They are also used in agriculture to control bacterial diseases. Unfortunately, the widespread use of antibiotics has greatly increased the prevalence of antibiotic-resistant strains of bacteria, strains that have a selective advantage over those that are susceptible to antibiotics. Resistant strains carry genes that counteract the action of antibiotics in various ways. A resistance gene may encode a protein that breaks down the antibiotic, pumps it out of the cell, or prevents it from inhibiting cellular processes.

The term **acquired antibiotic resistance** refers to the common phenomenon of a previously susceptible strain becoming resistant to a specific antibiotic. This change may result from genetic alterations in the bacteria's own genome, but it is often due to the horizontal transfer of resistance genes from a resistant strain. As often mentioned in the news media, antibiotic resistance has increased dramatically worldwide over the past few decades, with resistant strains reported in almost all pathogenic strains of bacteria. As an example, some *Staphylococcus aureus* strains have developed resistance to methicillin and all penicillins. Evidence suggests that these so-called methicillin-resistant strains of *Staphlococcus aureus* (MRSA) acquired the methicillin-resistance gene by horizontal gene transfer, possibly from a strain of *Enterococcus faecalis*. MRSA strains cause skin infections that are more difficult to treat than ordinary "staph" infections caused by nonresistant strains of *S. aureus*.

Summary of Key Concepts

18.1 Genetic Properties of Viruses

- Viruses are nonliving particles that do not exhibit all of the properties associated with living organisms. A virus or its genetic material must be taken up by a living cell to replicate. Tobacco mosaic virus (TMV) was the first virus to be discovered (Figure 18.1).
- Viruses vary with regard to their host range, structure, and genome composition (Table 18.1, Figures 18.2, 18.3).

18.2 Viral Reproductive Cycles

- The viral reproductive cycle consists of a series of steps, including attachment, entry, integration, synthesis, assembly, and release (Figure 18.4).

- Some bacteriophages can follow two different reproductive cycles: the lytic cycle and lysogenic cycle (Figure 18.5).
- Emerging viruses, such as human immunodeficiency virus (HIV), can cause significant loss of human life. HIV, the causative agent of the disease AIDS, is a retrovirus whose reproductive cycle involves the integration of the viral genome into a chromosome in the host cell (Figure 18.6).
- Drugs to combat viral proliferation are often developed to specifically inhibit viral proteins.

18.3 Viroids and Prions

- Viroids are RNA molecules that infect plant cells (Figure 18.7).
- Prions are proteins that induce abnormal folding in normal proteins. They cause several fatal neurodegenerative diseases in humans (Figure 18.8, Table 18.2).

18.4 Genetic Properties of Bacteria

- Bacteria typically have a single type of circular chromosome found in the nucleoid region of the cell. The chromosome contains many genes and one origin of replication (Figure 18.9).
- The bacterial chromosome is made more compact by the formation of loop domains and by DNA supercoiling (Figure 18.10).
- Plasmids are small, circular DNA molecules that exist independently of the bacterial chromosome (Figure 18.11).
- When placed on solid growth media, a single bacterial cell will divide many times to produce a colony composed of many cells (Figure 18.12).
- Bacterial cells reproduce by asexual reproduction in a process called binary fission, during which a cell divides to form two daughter cells (Figure 18.13).

18.5 Gene Transfer Between Bacteria

- Three common modes of gene transfer among bacteria are conjugation, transformation, and transduction (Table 18.3).
- Lederberg and Tatum's work demonstrated the transfer of bacterial genes between different strains of *E. coli* by conjugation. Davis showed that direct contact was needed for this type of gene transfer (Figures 18.14, 18.15).
- During conjugation, a strand of DNA from an F factor is transferred from a donor to a recipient cell by physical contact (Figure 18.16).
- Transformation is the process in which a segment of DNA from the environment is taken up by a naturally competent bacterial cell and incorporated into the bacterial chromosome (Figure 18.17).
- Bacterial transduction is a form of gene transfer in which a bacteriophage transfers a segment of bacterial chromosomal DNA from one bacterial cell to another (Figure 18.18).
- Horizontal gene transfer is a process in which an organism incorporates genetic material from another organism without being the offspring of that organism. It has played an important role in the evolution of bacterial species.

Assess and Discuss

Test Yourself

1. The _____ is the protein coat of a virus that surrounds the genetic material.
   a. host
   b. prion
   c. capsid
   d. viroid
   e. capsule
2. The characteristics of viral genomes show many variations. Which of the following does *not* describe a typical characteristic of viral genomes?
   a. The genetic material may be DNA or RNA.
   b. The nucleic acid may be single stranded or double stranded.
   c. The genome may carry just a few genes or several dozen.
   d. The number of copies of the genome may vary.
   e. All of the above describe typical variation in viral genomes.
3. During viral infection, attachment is usually specific to a particular cell type because
   a. the virus is attracted to the appropriate host cells by proteins secreted into the extracellular fluid.
   b. the virus recognizes and binds to specific molecules in the cytoplasm of the host cell.
   c. the virus recognizes and binds to specific molecules on the surface of the host cell.
   d. the host cell produces channel proteins that provide passageways for viruses to enter the cytoplasm.
   e. the virus releases specific proteins that make holes in the membrane large enough for the virus to enter.
4. HIV, a retrovirus, has a high mutation rate because
   a. the DNA of its genome is less stable than other viral genomes.
   b. the viral enzyme reverse transcriptase has a high likelihood of making replication errors.
   c. the viral genome is altered every time it is incorporated into the host genome.
   d. antibodies produced by the host cell mutate the viral genome when infection occurs.
   e. all of the above.
5. A ___ is an infectious agent composed solely of RNA, whereas a ___ is an infectious agent composed solely of protein.
   a. retrovirus, bacteriophage
   b. viroid, virus
   c. prion, virus
   d. retrovirus, prion
   e. viroid, prion
6. Genetic diversity is maintained in bacterial populations by all of the following except
   a. binary fission.
   b. mutation.
   c. transformation.
   d. transduction.
   e. conjugation.
7. Bacterial cells divide by a process known as
   a. mitosis.
   b. cytokinesis.
   c. meiosis.
   d. binary fission.
   e. glycolysis.

8. Gene transfer in which a bacterial cell takes up bacterial DNA from the environment is called
   a. conjugation.
   b. binary fission.
   c. asexual reproduction.
   d. transformation.
   e. transduction.
9. A bacterial cell can donate DNA during conjugation when it
   a. produces competence factors.
   b. contains an F factor.
   c. is virulent.
   d. has been infected by a bacteriophage.
   e. All of the above allow a bacterial cell to donate DNA during conjugation.
10. A bacterial species that becomes resistant to certain antibiotics may have acquired the resistance genes from another bacterial species. The phenomenon of acquiring genes from another organism without being the offspring of that organism is known as
    a. hybridization.
    b. integration.
    c. horizontal gene transfer.
    d. vertical gene transfer.
    e. competence.

Conceptual Questions

1. How are viruses similar to living cells, and how are they different?
2. Describe the three mechanisms of gene transfer in bacteria.
3.  A principle of biology is *the genetic material provides the blueprint for reproduction*. Discuss how horizontal gene transfer alters the blueprint.

Collaborative Questions

1. Discuss the possible origin of viruses. Which idea(s) do you think is (are) the most likely?
2. Conjugation is sometimes called "bacterial mating." Discuss how conjugation is similar to sexual reproduction in eukaryotes and how it is different.

Developmental Genetics

19

CHAPTER OUTLINE

19.1 General Themes in Development
19.2 Development in Animals
19.3 Development in Plants
Summary of Key Concepts
Assess and Discuss

A child with aniridia. The *Pax6* gene plays an important role in eye development. A mutation in this gene causes aniridia, which results in an absence of the iris.

Take a close look at the child in the chapter opening photo. Do you notice anything unusual? Though it may not be immediately apparent, this child has a disorder called aniridia, in which the iris in each eye does not develop properly. The iris is the part of the eye, usually blue, green, or brown, that regulates the amount of light entering the eye. In aniridia, some or all of the iris is missing, giving the appearance of very large pupils. People with aniridia cannot adjust the amount of light entering their eyes, which results in a decreased quality of vision and leads to eye diseases such as glaucoma and cataracts. In addition, other structures within the eye, such as the retina and optic nerve, may not develop correctly. What is the underlying cause of aniridia? It is due to a mutation in a gene called *Pax6*, which is responsible for the development of the eye. People with aniridia are heterozygotes, having one functional copy of the *Pax6* gene and one mutant copy; it is a dominant disorder. The proper development of the eye requires two functional copies of the *Pax6* gene. This disorder illustrates how genes play a key role in the development of our bodies.

In biology, the term **development** refers to a series of changes in the state of a cell, tissue, organ, or organism. Development is the underlying process that gives rise to the structures and functions of living organisms. The structure or form of an organism is called its **morphology**. As we have learned throughout this textbook, an important principle of biology is that structure (morphology) determines function.

How do developmental changes occur? Since the 1940s, the genetic makeup of an organism has emerged as the fundamental factor behind development. The science of **developmental genetics** is concerned with understanding how gene expression controls the process of development.

In this chapter, we will examine how the sequential actions of genes provide a program for the development of an organism from a fertilized egg to an adult. Utilizing a few organisms such as the fruit fly, a nematode worm, the mouse, and the plant *Arabidopsis*, scientists are working to identify and characterize the genes required to run developmental programs and are exploring how proteins encoded by these genes control the course of development. In this chapter, we begin with an overview that emphasizes the general principles of development. We will then examine specific examples of development in animals and plants, focusing on the role of genes in embryonic development. Chapters 39 and 52 also consider plant and animal development, respectively, with an emphasis on structure and function.

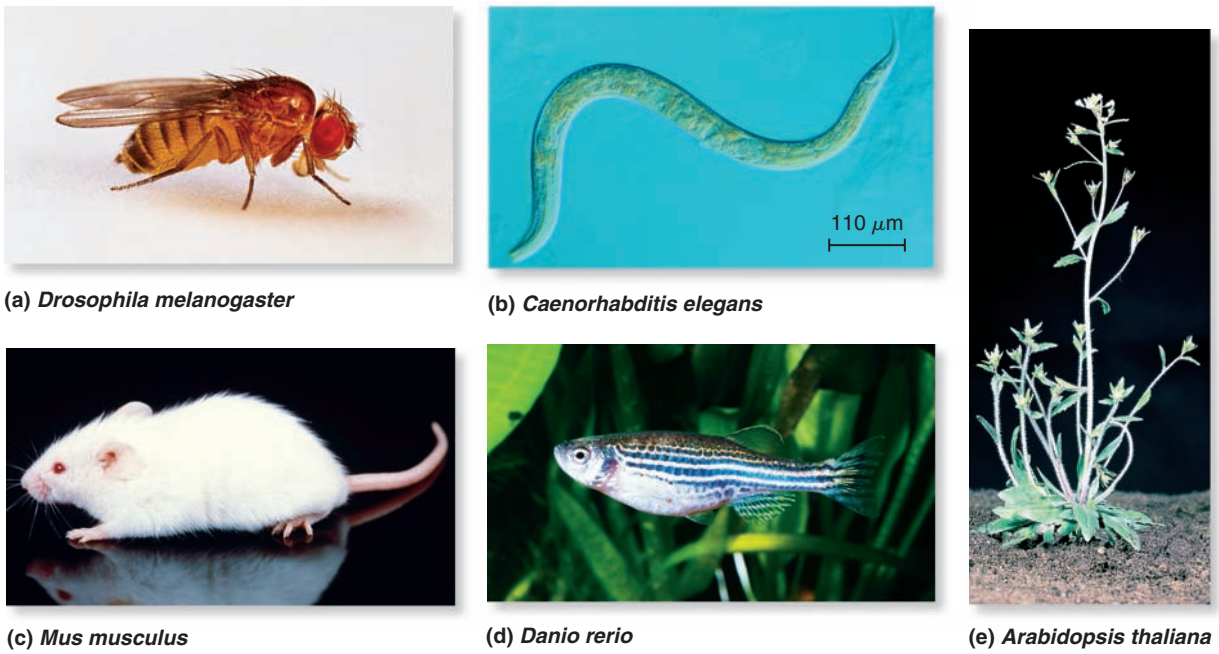
19.1 General Themes in Development

Learning Outcomes:

1. List several invertebrate, vertebrate, and plant model organisms, and describe the reasons why biologists study them.
2. Outline the process of pattern formation in plants and animals.
3. Describe the four ways that cells respond to positional information.
4. Explain how morphogens and cell-to-cell contacts convey positional information.
5. Outline four phases of pattern formation in animals, and describe how they are controlled by transcription factors.

Animals and plants begin to develop when a sperm and an egg unite to produce a **zygote**, a diploid cell that divides and develops into a multicellular **embryo**, and eventually into an adult organism. During the early stages of development, cells divide and begin to arrange themselves into ordered units. As this occurs, each cell also becomes **determined**, which means it is committed to become a particular cell type, such as a muscle or intestinal cell. The commitment to become a specific cell type occurs long before a cell differentiates. During the process of **cell differentiation**, a cell's morphology and function have changed, usually permanently, into a highly specialized cell type. In an adult, each cell type plays its own particular role. In animals, for example, muscle cells enable an organism to move, and intestinal cells facilitate the absorption of nutrients. This division of labor among various cells of an organism works collectively to promote its survival.

The genomes of living organisms contain a set of genes that constitute a program of development. In unicellular species, the program controls the structure and function of the cell. In multicellular species such as animals and plants, the program not only controls cell morphology but also determines the arrangement of cells. In this section, we will examine some of the general concepts associated with the development of multicellular species.



Developmental Biologists Use Model Organisms to Study Development

The development of even a simple multicellular organism involves many types of changes in form and function. For this reason, the research community has focused its efforts on only a few **model organisms**—organisms studied by many different researchers so they can compare their results and determine scientific principles that apply more broadly to other species.

With regard to animal development, the two organisms that have been the most extensively investigated are two invertebrate species: the fruit fly (*Drosophila melanogaster*) and the nematode worm (*Caenorhabditis elegans*) (**Figure 19.1a,b**). Why have these two organisms been chosen as models to investigate development? *Drosophila* has been studied for a variety of reasons. First, researchers have exposed this organism to mutagens and identified many mutant strains with altered developmental pathways. Second, in all of its life stages, *Drosophila* has distinct morphological features and is large enough to easily identify the effects of mutations. *C. elegans* is used by developmental geneticists because of its simplicity. The adult organism is a small transparent worm about 1 mm in length and composed of only about 1,000 somatic cells. Starting with a fertilized egg, the pattern of cell division and the fate of each cell within the embryo are completely known. This pattern is essentially identical from one worm to another, which allows researchers to predict the fate of cells in this organism.

Embryologists have also studied the morphological features of development in vertebrate species. Historically, amphibians and birds have been studied extensively, because their eggs are rather large and easy to manipulate. From a morphological point of view, the developmental stages of the chicken (*Gallus gallus*) and the African clawed frog (*Xenopus laevis*) have been described in great detail. More recently, a few vertebrate species have been the subject of genetic studies of development. These include the house mouse (*Mus musculus*) and the small aquarium zebrafish (*Danio rerio*) (**Figure 19.1c,d**).

In the study of plant development, the model organism for genetic analysis is a small flowering plant known as thale cress (*Arabidopsis thaliana*), which is typically called *Arabidopsis* by researchers (**Figure 19.1e**). *Arabidopsis* is an annual (a plant that lives out its entire life cycle during a single growing season) belonging to the wild mustard family. It occurs naturally throughout temperate regions of

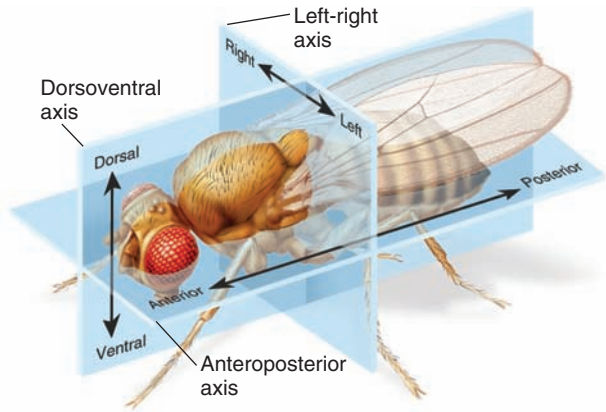
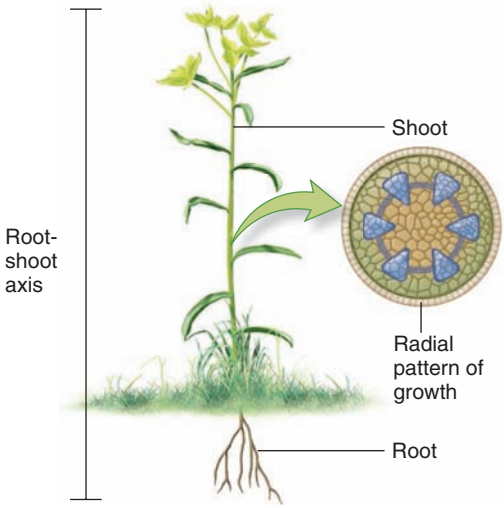
Figure 19.1 **Model organisms used to study developmental genetics.**



BIOLOGY PRINCIPLE **Biology is an experimental science.** Biologists often focus their attention on model organisms with the expectation that the results will apply more broadly to many species.

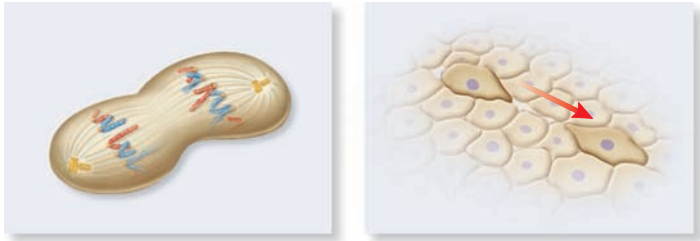
the world. *Arabidopsis* has a short generation time of about 6 weeks and a small genome size of 12×10^7 bp, which is similar to the genome sizes of *Drosophila* and *C. elegans*. A flowering *Arabidopsis* plant is small enough to be grown in the laboratory and produces a large number of seeds.



Both Animals and Plants Develop by Pattern Formation

Development in animals and plants produces a body plan, or pattern. At the cellular level, the body pattern is due to the arrangement of cells and their differentiation. The process, called **pattern formation**, gives rise to the formation of a body with a particular morphology. Pattern formation in most animals is organized along three axes: the **dorsoventral axis**, the **anteroposterior axis**, and the **left-right axis** (**Figure 19.2a**). In addition, many animal bodies are then segmented into separate sections containing specific body parts such as wings or legs.

Pattern formation in plants is quite different, being organized along a **root-shoot axis** and in a **radial pattern**, in which the cells found in roots and shoots form concentric rings of tissues (**Figure 19.2b**). The root-shoot axis is determined at the first division of the fertilized egg. As we'll see later, the identification of mutant alleles that disrupt development has permitted great insight into the genes controlling pattern formation.



(a) Body plan found in many animals

(a) Cell division (b) Cell migration

(c) Cell differentiation

(d) Cell death (apoptosis)

Figure 19.3 **Four types of cellular responses to positional information in animals.**

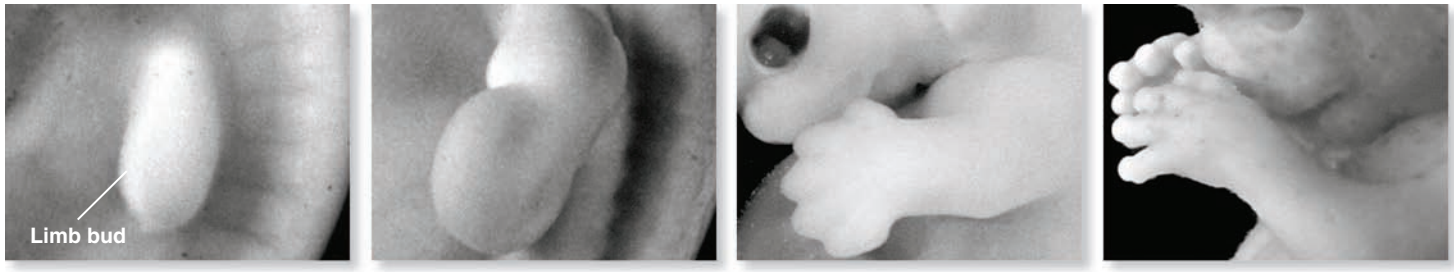
Concept Check: *Which of these four responses do you expect to be more prevalent in the early stages of development, and which would become more prevalent in later stages?*

BioConnections: *Look back at Figure 9.16. What are the stages of apoptosis?*

Pattern Formation Depends on Positional Information

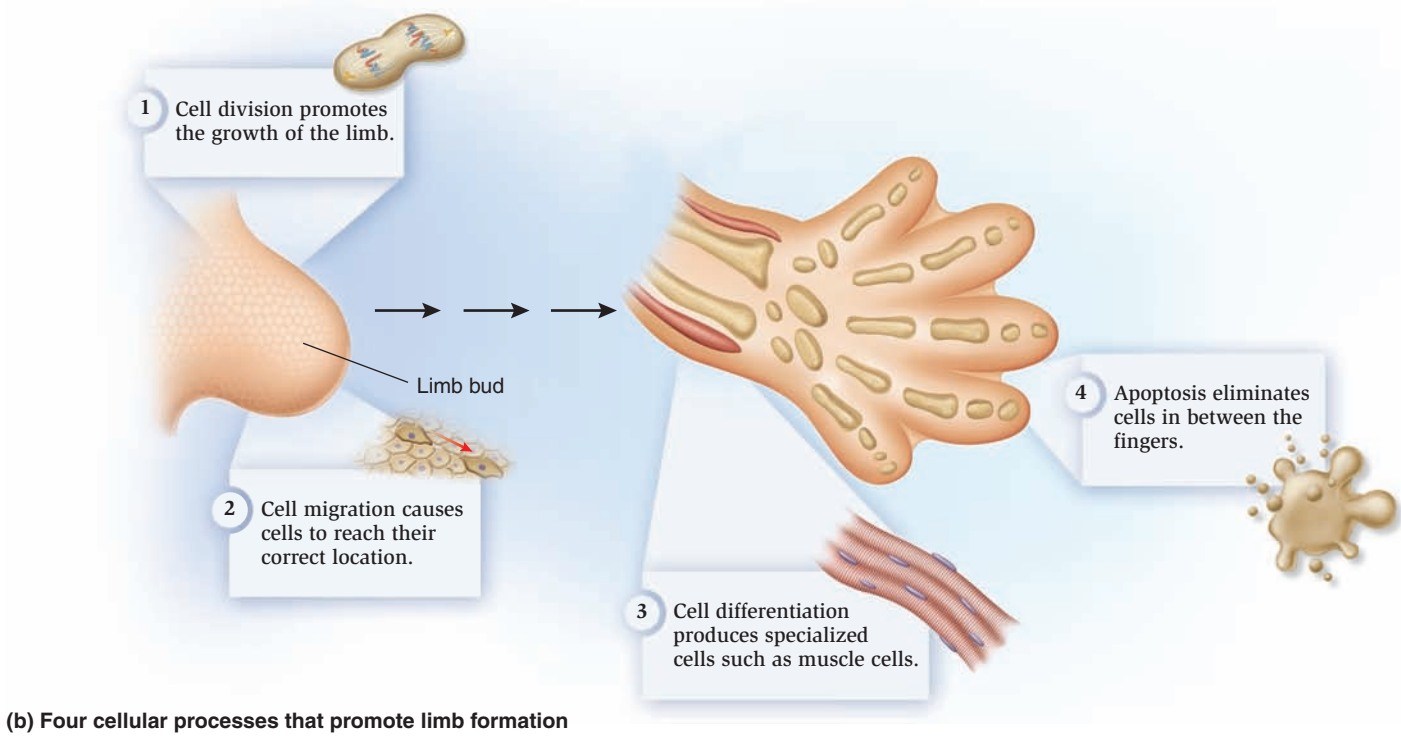
For an organism to develop the correct morphological features or pattern, each cell of the body must become the appropriate cell type based on its position relative to other cells. How does this occur? At appropriate times during development, cells receive **positional information**—molecules that provide a cell with information regarding its location relative to other cells of the body. Later in this chapter, we will examine how the expression of genes at the correct times provides this information.

A cell may respond to positional information in one of four ways: cell division, cell migration, cell differentiation, and cell death (**Figure 19.3**).



- Positional information may stimulate a cell to divide.
- Positional information in animals may cause the migration of a cell or group of cells in a particular direction from one region of the embryo to another. (Cell migration does not occur during development in plants.)
- Positional information may cause a cell to differentiate into a specific cell type such as a neuron.
- Positional information may promote **apoptosis**, or programmed cell death, which is described in Chapter 9. Apoptosis plays a key role in sculpting the bodies of animals. In vascular plants, certain cells undergo programmed cell death to form tracheids, specialized cells that function in water transport.

As an example of how the coordination of these four processes is required for pattern formation, **Figure 19.4** shows the growth and development of a human arm during the embryonic stage.

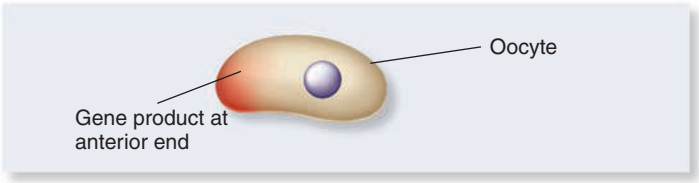


- Cell division with accompanying cell growth increases the size of the limb.
- Cell migration is also important for limb development. For example, embryonic cells that eventually form muscles in the arm and hand must migrate from outside the limb to reach their correct location within the limb.
- As development proceeds, cell differentiation produces the various tissues that will eventually be found in the fully developed limb. Some cells become neurons, others muscle cells, and still others become epidermal cells, forming the outer layer of skin.
- Finally, apoptosis is important in the formation of fingers. If apoptosis did not occur, a human hand would have webbed fingers.

Morphogens and Cell-to-Cell Contacts Convey Positional Information

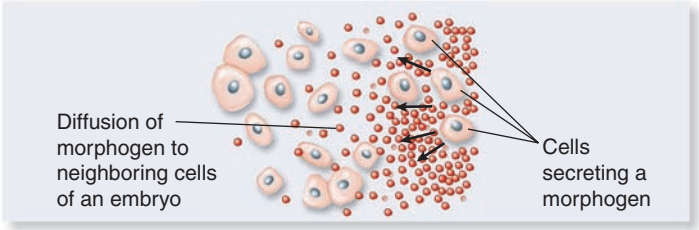
How does positional information lead to the development of a body plan? Though the details of pattern formation vary widely among different species, two main mechanisms are commonly used to communicate positional information. One of these mechanisms involves

(a) Limb development in a human embryo



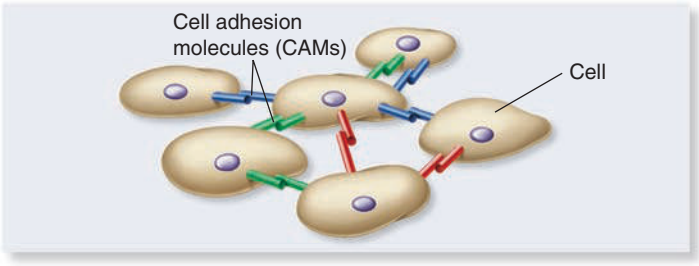
(b) Four cellular processes that promote limb formation

Figure 19.4 Limb development in humans. **(a)** Photographs of limb development in human embryos. The limb begins as a protrusion called a limb bud that eventually forms an arm and hand. **(b)** The development of a human hand from an embryonic limb bud.



Concept Check: *How would finger formation be affected if apoptosis did not occur?*

molecules called morphogens. **Morphogens** impart positional information and promote developmental changes at the cellular level. Many morphogens are proteins, but they can also be small signaling molecules. A morphogen influences the fate of a cell by promoting cell division, cell migration, cell differentiation, or apoptosis. A key feature of morphogens is that they act in a concentration-dependent manner. At a high concentration, a morphogen restricts a cell into a particular developmental pathway, whereas at a lower concentration, it does not. There is often a critical **threshold concentration** above which the morphogen exerts its effects.



Morphogens typically are distributed asymmetrically along a concentration gradient. Morphogen gradients may be established in the **oocyte**, a cell that matures into an egg cell (**Figure 19.5a**). In addition, a morphogen gradient can be established in the embryo by secretion and diffusion (**Figure 19.5b**). A certain cell or group of cells may synthesize and secrete a morphogen at a specific stage of development.

(a) Asymmetric distribution of morphogens in the oocyte

(b) Induction: asymmetric synthesis and extracellular distribution of a morphogen

(c) Cell adhesion: Cell-to-cell contact conveys positional information.

Figure 19.5 Molecular mechanisms that convey positional information. Morphogen gradients may be established in the **(a)** oocyte or **(b)** embryo. **(c)** Positional information may also be conveyed by cell-to-cell contact. The different colored molecules in the plasma membrane represent different CAMs.

Concept Check: Why is positional information important during development?

BioConnections: Look back at Chapter 9. Discuss the role of cell receptors in responding to positional information.

After secretion, the morphogen diffuses to neighboring cells, as in Figure 19.5b, or it may be transported to cells that are distant from the cells that secrete the morphogen. The morphogen may then influence the fate of cells exposed to it. The process by which a cell or group of cells governs the fate of other cells is known as **induction**.

Another mechanism to convey positional information is **cell adhesion** (**Figure 19.5c**). Each animal cell makes its own collection of surface receptors that enable it to adhere to other cells and to the extracellular matrix (ECM). Such receptors, known as **cell adhesion molecules (CAMs)**, are described in Chapter 10 (refer back to Figure 10.8). The positioning of a cell within a multicellular organism is strongly influenced by the combination of contacts it makes with other cells and with the ECM.

The phenomenon of cell adhesion and its role in multicellular development was first recognized by American biologist Henry V. Wilson in 1907. He took multicellular sponges and passed them through a sieve, dissociating them into individual cells. Remarkably, the cells actively migrated until they adhered to one another to form a new sponge, complete with the chambers and canals that characterize a sponge's internal structure! When sponge cells from different species were mixed, they sorted themselves properly, adhering only to cells of the same species. Overall, these results indicate that cells possess specific CAMs, which are critical in cell-to-cell recognition. Cell adhesion plays an important role in governing the position that an animal cell will adopt during development.

Pattern Formation Occurs in Phases That Are Controlled by Transcription Factors

The formation of a body, in both animals and plants, occurs in a series of overlapping organizational phases. As an overview of this process, let's consider four general phases of pattern formation in an animal (**Figure 19.6**). This example involves human development, but research suggests that pattern formation in all complex animals follows a similar plan.

1. The first phase organizes the body along major axes. The anteroposterior axis is organized from head to tail, the dorsoventral axis is organized from back (dorsal) to front/abdomen (ventral), and the left-right axis is organized from side to side (refer back to Figure 19.2a).
2. During the second phase, the body becomes organized into smaller regions, a process called **segmentation**. In insects, these regions form well-defined segments. In mammals, some segmentation of the body is apparent during embryonic development, but defined boundaries are lost as the embryo proceeds to the fetal and adult stages.
3. In the third phase, the cells within the segments organize themselves in ways that will produce particular body parts.
4. Finally, during the fourth phase, the cells change their morphologies and become differentiated. This final phase of development produces an organism with many types of tissues, organs, and other body parts with specialized functions.

It should be noted that the four phases of development are overlapping. For example, cell differentiation begins to occur as the cells are adopting their correct locations.

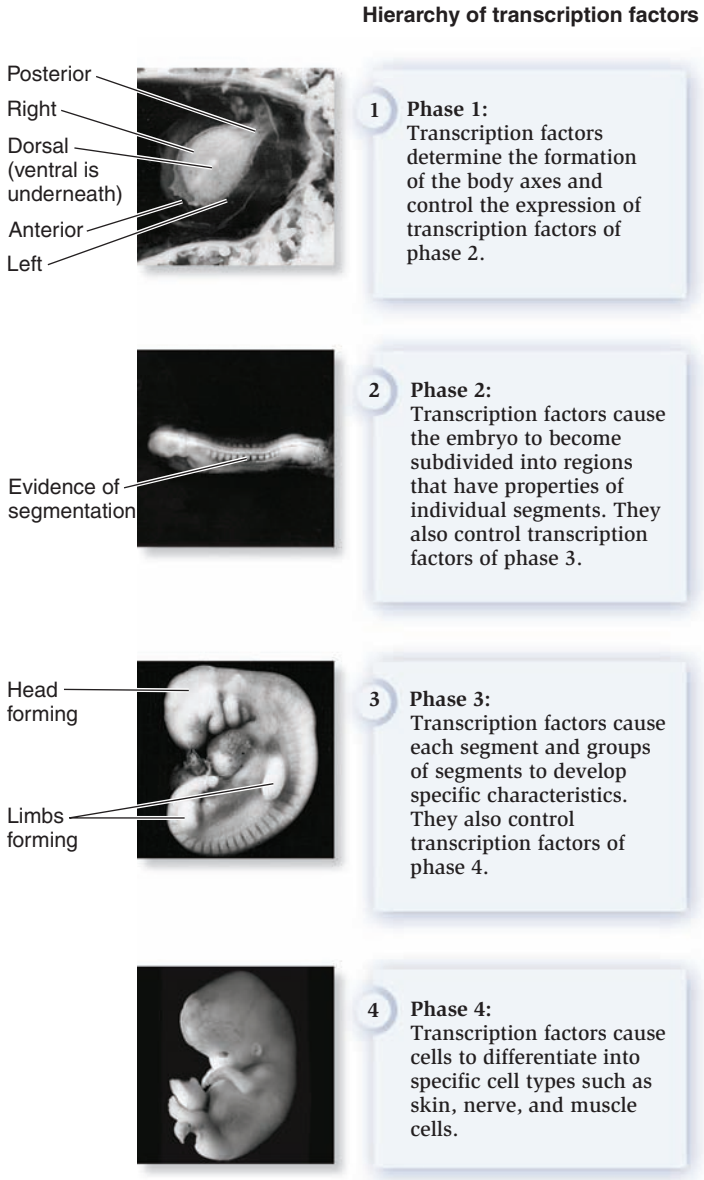


Figure 19.6 Pattern formation in a human embryo. As shown here, pattern formation in animals occurs in four phases controlled by a hierarchy of transcription factors. The ideas in this scenario are based largely on analogies between pattern formation in *Drosophila* and mammals. Many of the transcription factors that control the early phases of pattern formation in mammals have yet to be identified.

Concept Check: *During which of the four phases of pattern formation would you expect cell division and cell migration to be the most prevalent?*

How does genetics underlie the phases of animal development? Geneticists have discovered a parallel between the expression of specific transcription factors, which are described in Chapter 13, and the four major phases of animal development. As noted in Figure 19.6, a hierarchy of transcription factors controls whether or not certain genes are expressed at a specific phase of development in a particular cell type, a phenomenon called **differential gene regulation**. Many morphogens, particularly those that act during early phases of development, function as transcription factors.

19.2 Development in Animals

Learning Outcomes:

1. **SciSKILLS »** Explain how the analysis of mutants has been an important tool in our understanding of development in animals.
2. Distinguish the functions of maternal effect genes, segmentation genes, and homeotic genes in animal development.
3. Define the general properties of stem cells.
4. Describe how transcription factors control cell differentiation.
5. **SciSKILLS »** Analyze the results of experiments that indicated that master transcription factors control cell differentiation.

In this section, we will begin by examining the general stages of *Drosophila* development and then focus our attention on its embryonic stage. During this stage, the overall body plan is determined. We will see how the differential expression of particular genes within the embryo controls pattern formation. Although the roles of genes in the organization of mammalian embryos are not as well understood as they are in *Drosophila*, the analysis of the genomes of mammals and many other species has revealed many interesting parallels in the developmental program of all animals.

This section will end with an examination of cell differentiation. This process is better understood in mammals than in *Drosophila* because researchers have been studying mammalian cells in the laboratory for many decades. To explore cell differentiation, we will consider mammals as our primary example.

Embryonic Development Determines the Pattern of Structures in the Adult

As a way to appreciate the phases of pattern formation in animals, we will largely focus on development in *Drosophila*. However, as described in Chapter 52, animal development is quite varied among different species. **Figure 19.7** illustrates a simplified sequence of events in *Drosophila* development. Let's examine these steps before we consider the differential gene regulation that causes them to happen.

1. The oocyte is critical to establishing the pattern of development that will ultimately produce an adult organism. It is an elongated cell that contains positional information. As shown in Figure 19.7a, the fertilized egg already has anterior and posterior ends that correspond to those found in the adult (compare Figure 19.7a and e).
2. A key process in the embryonic development of *Drosophila* is the formation of a segmented body pattern. The embryo is subdivided into visible segments grouped into three general areas: the head, the thorax, and the abdomen. Figure 19.7b shows the segmented pattern of a *Drosophila* embryo about 10 hours after fertilization.
3. A *Drosophila* embryo then develops into a **larva** (Figure 19.7c), a free-living organism that is morphologically very different from the adult. Many animal species do not have larval stages. *Drosophila* undergoes three successive larval stages.

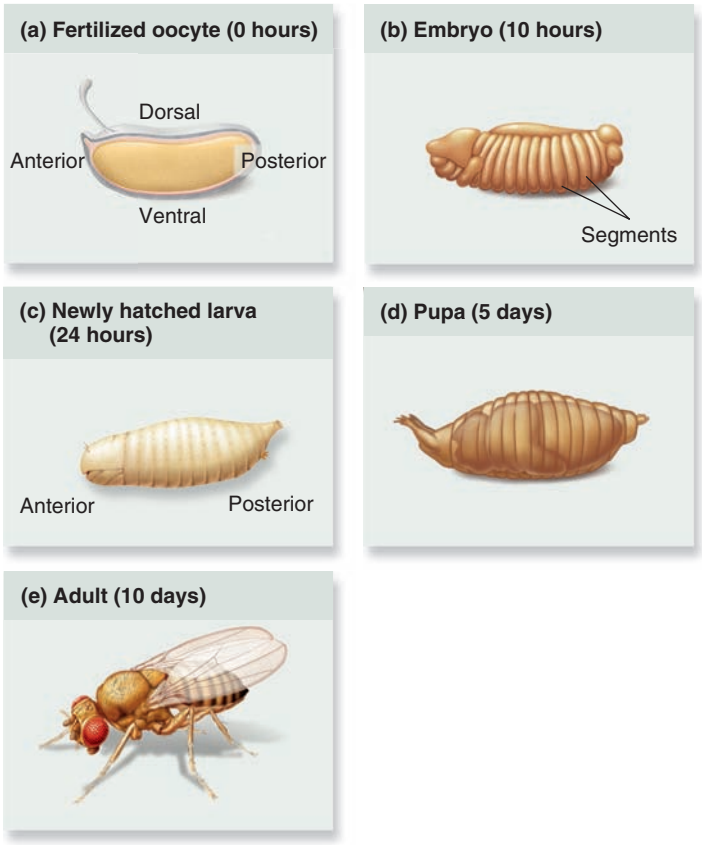

Figure 19.7 **Developmental stages of the fruit fly *Drosophila*.**

4. After the third larval stage, the organism becomes a **pupa** (Figure 19.7d), a transitional stage between the larva and the adult. Through a process known as **metamorphosis**, the larva transforms into a pupa.
5. A pupa then becomes a mature adult that emerges from the pupal case (Figure 19.7e). Each segment in the adult has its own characteristic structures. For example, the wings are on a thoracic segment.

From beginning to end, this process takes about 10 days.

BIO TIPS **THE QUESTION** *One approach to studying development is to isolate mutants that cause abnormal development. This approach helps researchers identify the genes that regulate normal development. However, one problem with this approach is that mutations in genes that control the early stages of development are often lethal because they prevent the embryo from developing properly. To circumvent this problem, developmental biologists may try to isolate temperature-sensitive developmental mutations, or ts alleles. If an embryo carries a ts allele, it will develop correctly if incubated at the permissive temperature (for example, 25°C) but will fail to develop if incubated at the nonpermissive temperature (for example, 30°C). In most cases, ts alleles are mutations that slightly alter the amino acid sequence of a protein, causing a change in its structure that prevents it from working properly at the nonpermissive temperature. Such mutations are useful because they can provide insight regarding the stage of development at which the protein encoded by the gene is necessary. Researchers can take groups of embryos that carry the same ts allele and expose them to the permissive and nonpermissive temperatures at different stages of development. In the experiment described next, embryos carrying a ts allele were divided into five groups and exposed to the permissive or nonpermissive temperature at different times after fertilization. This experiment yielded the following results:*

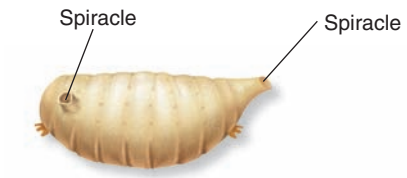
Time after fertilization (hours)	Group				
	1	2	3	4	5
0–1	30°C	25°C	25°C	25°C	25°C
1–2	25°C	30°C	25°C	25°C	25°C
2–3	25°C	25°C	30°C	25°C	25°C
3–4	25°C	25°C	25°C	30°C	25°C
4–5	25°C	25°C	25°C	25°C	30°C
Survival	Yes	Yes	Yes	No	Yes

Explain these results.

TOPIC ***What topic in biology does this question address?*** The topic is about development. More specifically, the question asks you to analyze the effects of a temperature-sensitive mutation that affects development.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you have learned that developmental biologists can isolate *ts* alleles that are lethal only at nonpermissive temperatures. You are also given data about the survival of embryos in an experiment in which the temperature was shifted to the nonpermissive temperature at different times after fertilization.

PROBLEM-SOLVING STRATEGY ***Interpret data. Compare and contrast.*** To solve this problem, you need to interpret data that relate embryo survival to the timing of exposure to the nonpermissive temperature. You want to compare and contrast: When do the embryos survive, and when don't they survive?



ANSWER *The embryos do not survive if they are subjected to the nonpermissive temperature between 3 and 4 hours after fertilization, but they do survive if subjected to the nonpermissive temperature at other times during development. These results indicate that the protein encoded by the ts allele plays a crucial role in development at 3–4 hours after fertilization.*

Phase 1 Pattern Formation: Maternal Effect Genes Promote the Formation of the Body Axes

The first phase in *Drosophila* pattern formation is the establishment of the body axes, which occurs before the embryo becomes segmented. The morphogens necessary to establish these axes are distributed prior to fertilization. In most invertebrates and some vertebrates, certain morphogens, which are important in early developmental stages, are deposited asymmetrically within the egg as it develops (refer back to Figure 19.5a). Later, after the egg has

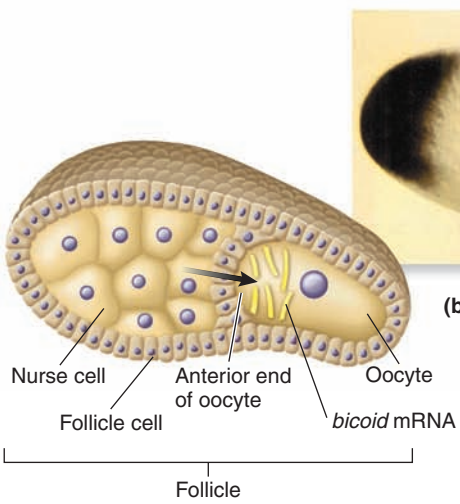
(a) Normal or wild-type (*bicoid*$^{+}$) larva

(b) Mutant (*bicoid*$^{-}$) larva

Figure 19.8 The bicoid mutation in *Drosophila*. **(a)** A normal larva from a *bicoid*$^{+}$ mother. **(b)** An abnormal larva from a *bicoid*$^{-}$ mother, in which both ends of the larva develop posterior structures. For example, both ends develop a spiracle, a small pore that normally is found only at the posterior end.

Concept Check: *What would you expect to be the phenotype of a larva in which the bicoid gene product accumulated in both the anterior region and the posterior region of the oocyte?*

been fertilized and development begins, these morphogens initiate developmental programs that govern the formation of the body axes of the embryo.

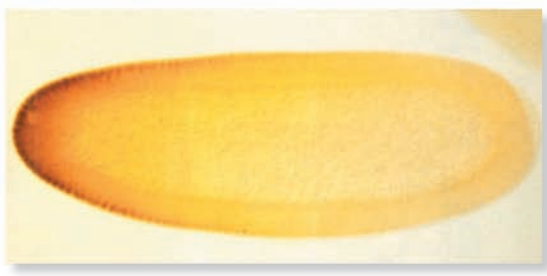


As an example of one morphogen that plays a role in axis formation, let's consider the product of a gene in *Drosophila* called *bicoid*. Its name is derived from the observation that a mutation that inactivates the gene results in a larva with two posterior ends (**Figure 19.8**). It lacks a head and a thorax! During normal oocyte development, the *bicoid* gene product accumulates in the anterior region of the oocyte. This gene product later acts as a morphogen to cause the development of the anterior end of the embryo.

How does the *bicoid* gene product accumulate in the anterior region of the oocyte? The answer involves specialized nurse cells that are found next to the oocyte, which matures in a follicle within the ovary of a female fly. Nurse cells supply oocytes with the products from **maternal effect genes**. They are so named because only the mother's gene product affects the phenotype of the resulting offspring. For example, the *bicoid* gene is a maternal effect gene in *Drosophila* that is transcribed in the nurse cells. The *bicoid* mRNA is then transported from the nurse cells into the anterior end of the oocyte and trapped there (**Figure 19.9a**). Prior to fertilization, the *bicoid* mRNA is highly concentrated near the anterior end of the oocyte (**Figure 19.9b**). After fertilization, the *bicoid* mRNA is translated, and a gradient of Bicoid protein is established across the zygote (**Figure 19.9c**). This gradient starts a progression of developmental events that will provide the positional information that causes the end of the zygote with a high Bicoid protein concentration to become the anterior region of the embryo.

The Bicoid protein is a morphogen that functions as a transcription factor to activate particular genes at specific times. The ability of Bicoid to activate a given gene depends on its concentration. Due to its asymmetric distribution, the Bicoid protein activates genes only in certain regions of the embryo. For example, a high concentration of Bicoid stimulates the expression of a gene called *hunchback* (that also encodes a transcription factor) in the anterior half of the embryo, but its concentration is too low in the posterior half to activate the *hunchback* gene. The ability of Bicoid to activate genes in certain regions but not others plays a role in the second phase of pattern formation—segmentation.

The Study of *Drosophila* Mutants Has Identified Genes That Control the Development of Segments



As shown in Figure 19.7b, the second phase of pattern formation is the development of segments. The *Drosophila* embryo is subdivided into 15 segments: three head segments, three thoracic segments, and nine abdominal segments (**Figure 19.10**). Each segment of the

(a) Transport of maternal effect gene products (*bicoid* mRNA) into the oocyte

(b) Staining of *bicoid* mRNA in an oocyte

(c) Staining of Bicoid protein in an early embryo

Figure 19.9 Asymmetric localization of gene products during egg development in *Drosophila*. **(a)** The nurse cells transport maternal effect gene products such as *bicoid* mRNA into the anterior end of the developing oocyte. **(b)** Staining of *bicoid* mRNA in an oocyte prior to fertilization. The *bicoid* mRNA is trapped at the anterior region. **(c)** Staining of Bicoid protein after fertilization. The Bicoid protein forms a gradient, with its highest concentration near the anterior end.

Concept Check: *What is the function of the Bicoid protein? After fertilization, in which part of the resulting zygote would its function be highest?*

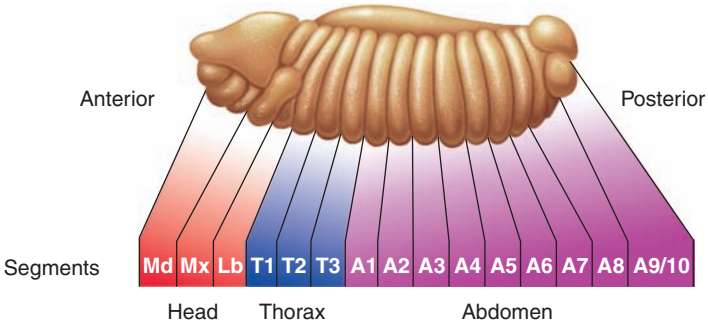


Figure 19.10 The organization of segments in the *Drosophila* embryo. The *Drosophila* embryo is subdivided into 15 segments, each of which gives rise to unique structures in the adult.

embryo gives rise to unique morphological features in the adult. For example, the second thoracic segment (T2) produces a pair of legs and a pair of wings.

In the 1970s, German biologist Christiane Nüsslein-Volhard and American developmental biologist Eric Wieschaus undertook a systematic search for *Drosophila* mutants with disrupted development. They focused their search on **segmentation genes**, genes that alter the segmentation pattern of the *Drosophila* embryo and larva. Based on the characteristics of abnormal larva, they identified three classes of segmentation genes: gap genes, pair-rule genes, and segment-polarity genes. When a mutation inactivates a **gap gene**, several adjacent segments are missing in the larva—a gap occurs. A defect in a **pair-rule gene** causes alternating segments or parts of segments to be absent. Finally, mutations of **segment-polarity genes** cause portions of segments to be missing and cause adjacent regions to become mirror images of each other. The role of these segmentation genes during normal *Drosophila* development is described next.

Phase 2 Pattern Formation: Segmentation Genes Act Sequentially to Divide the *Drosophila* Embryo into Segments

The study of segmentation genes has revealed how segments are formed. To make a segment, particular genes act sequentially to govern the fate of a given region of the body. A simplified scheme of gene expression that leads to a segmented pattern in the *Drosophila* embryo is shown in **Figure 19.11**. Many more genes are actually involved in this process.

In general, the products of maternal effect genes such as *bicoid*, which promote the formation of body axes, activate gap genes. This activation is seen as broad bands of gap proteins in the embryo (Figure 19.11, step 2). Next, products from the gap genes and maternal effect genes function as transcription factors to activate the pair-rule

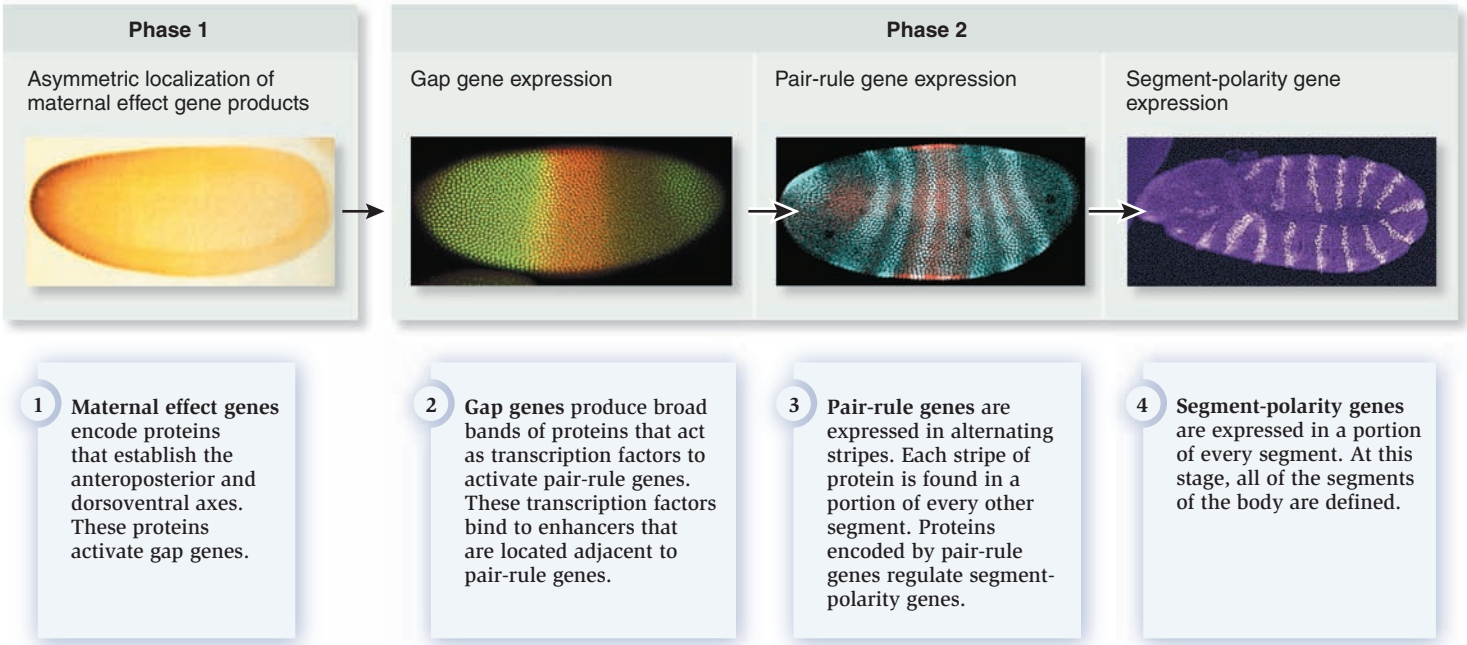

Figure 19.11 Overview of segmentation in *Drosophila*. The micrographs depict the progression of *Drosophila* development during the first few hours following fertilization. The micrographs also show the expression of protein products of a maternal effect gene (step 1) and segmentation genes (steps 2–4). In step 1, the protein is stained brown and is found in the left side of the early embryo, which is the anterior end. In step 2, one protein encoded by a gap gene is stained in green and another is stained in red. The yellow region is where the two different gap proteins overlap. In step 3, a protein encoded by a pair-rule gene is stained in light blue. In step 4, a protein encoded by a segment-polarity gene is stained pink (the rest of the embryo is purple). When comparing steps 3 and 4, note that the embryo has undergone a 180° turn, folding back on itself.

BIOLOGY PRINCIPLE New properties of life emerge from complex interactions. The feature of segmentation is an emergent property that has arisen due to complex interactions among segmentation gene products.

Concept Check: How many pink stripes can you count in the embryo in step 4? How does this number compare with the number of segments in the embryo in Figure 19.10?

(a) Normal fly with two wings

(b) Mutant fly with four wings

Figure 19.12 The bithorax mutation in *Drosophila*. **(a)** A normal fly has two wings on the second thoracic segment, and two halteres on the third thoracic segment. **(b)** This fly carries mutations in a complex of genes called the *bithorax* complex. In this fly, the third thoracic segment has the same characteristics as the second thoracic segment, resulting in four wings instead of two.

genes in alternating stripes in the embryo (Figure 19.11, step 3). Once the pair-rule genes are activated, their gene products then regulate the segment-polarity genes. As you follow the progression from maternal effect genes to segment-polarity genes, notice that a body pattern is emerging in the embryo that matches the segmentation pattern found in the larva and adult animal. As you can see in step 4 of Figure 19.11, the 15 locations where a segment-polarity gene is expressed correspond to portions of segments in the adult fly. To appreciate this phenomenon, notice that the embryo at this stage is curled up and folded back on itself. If you imagine that the embryo was stretched out linearly, the 15 stripes seen in this embryo correspond to portions of the 15 segments of an adult fly.

Phase 3 Pattern Formation: Homeotic Genes Control the Development of Segment Characteristics

Thus far, we have considered how the *Drosophila* embryo becomes organized along axes and then into a segmented body pattern. During the third phase of pattern formation, each segment begins to develop its own unique characteristics (see Figure 19.6, phase 3). Geneticists use the term **fate** to describe the ultimate morphological features that a cell or group of cells adopts. For example, the fate of cells in segment T2 in *Drosophila* is to develop into a thoracic segment containing two legs and two wings. In *Drosophila*, the cells in each segment of the body have their fate determined at a very early stage of embryonic development, long before the morphological features become apparent.

Our understanding of developmental fate has been greatly aided by the identification of mutant genes that alter cell fates. In animals, the first mutant of this type was described by the German entomologist Ernst G. Kraatz in 1876. He observed a sawfly (*Cimbex axillaris*) in which part of an antenna was replaced with a leg. During the late 19th century, the English zoologist William Bateson collected many of these types of observations and published them in a book. He coined the term homeotic to describe changes in which one body part is replaced by another. These abnormalities are caused by mutant alleles of **homeotic genes**—genes that specify the fate of a particular segment or region of the body.

As an example, **Figure 19.12** shows a normal fly and one with mutations in a complex of homeotic genes called the *bithorax* complex. In a normal fly, two wings are found on the second thoracic segment, and two halteres, which together function as a balancing organ that resembles a pair of miniature wings, are found on the third thoracic segment. In this mutant fly, the third thoracic segment has the characteristics of the second, so the fly has no halteres and four wings. The term *bithorax* refers to the duplicated characteristics of the second thoracic segment. Edward Lewis, an American pioneer in the genetic study of development, became interested in the bithorax phenotype and began investigating it in 1946. He discovered that the mutant chromosomal region contains a complex of genes that play a role in the third phase of development.

Drosophila has eight homeotic genes that are found in two clusters called the *Antennapedia* complex and the *bithorax* complex (**Figure 19.13**). Both of these complexes are located on the same chromosome, but a long stretch of DNA separates them. As you can

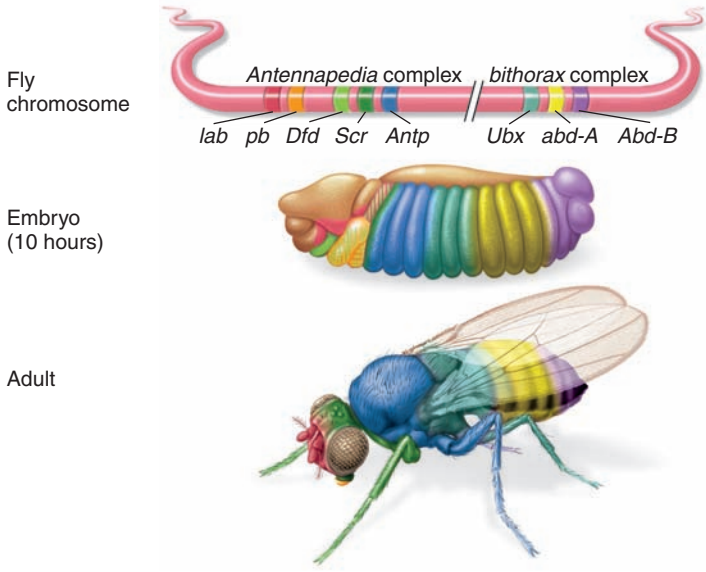

Figure 19.13 Expression pattern of homeotic genes in *Drosophila*. The order of homeotic genes, *labial* (*lab*), *proboscipedia* (*pb*), *Deformed* (*Dfd*), *Sex combs reduced* (*Scr*), *Antennapedia* (*Antp*), *Ultrabithorax* (*Ubx*), *abdominal A* (*abd-A*), and *Abdominal B* (*Abd-B*), correlates with their spatial order of expression in the embryo. (Note: The capitalization of the gene names is not consistent because it is based on the identification of mutations. If the first mutation isolated for a particular homeotic gene was recessive, the gene name is lowercase. If the first mutation discovered was dominant, the gene name begins with a capital letter.)

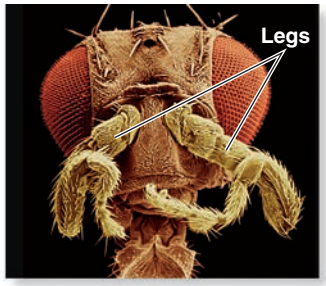
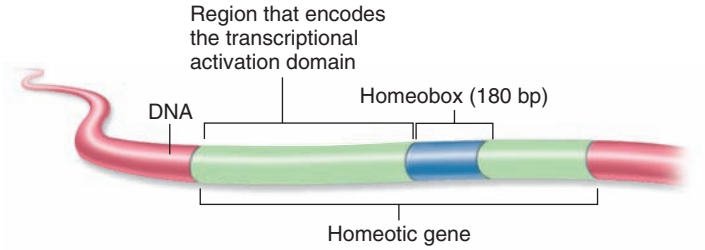
see in Figure 19.13, the order of homeotic genes along the chromosome correlates with their expression along the anteroposterior axis of the body. This phenomenon is called the **colinearity rule**. For example, *lab* (for labial) is expressed in the anterior segment and governs the formation of mouth structures. The *Antp* (for *Antennapedia*) gene is expressed in the thoracic region during embryonic development and controls the formation of thoracic structures such as legs.



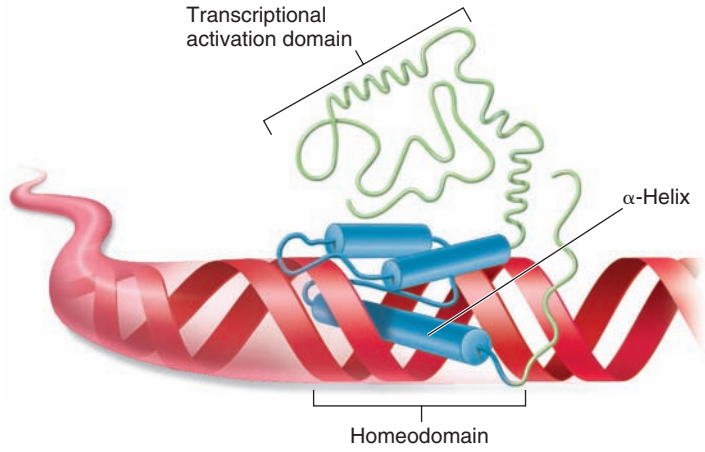
As we have seen in Figure 19.12, the role of homeotic genes in determining the identity of particular segments has been revealed by mutations that alter their function. As a second example, a mutation in the *Antp* gene has been identified in which the gene is incorrectly expressed in an anterior segment (**Figure 19.14**). A fly with this mutation has the bizarre trait in which it develops legs where antennae are normally found!

How do homeotic genes work at the molecular level? Homeotic genes encode homeotic proteins that function as transcription factors. The coding sequence of homeotic genes contains a 180-bp sequence known as a **homeobox** (**Figure 19.15a**). This sequence was first discovered in the *Antp* and *Ubx* genes, and it has since been found in many *Drosophila* homeotic genes. The homeobox is also found in other genes affecting pattern formation. The homeobox encodes a region of the protein called a **homeodomain**, which can bind to DNA (**Figure 19.15b**). The arrangement of α helices in the homeodomain promotes the binding of the protein to the DNA.

The primary function of homeotic proteins is to activate the transcription of specific genes that promote developmental changes in the animal. The homeodomain protein binds to DNA sequences called enhancers, which are described in Chapter 13. These enhancers are found in the vicinity of specific genes that control development. Most homeotic proteins also contain a transcriptional activation domain (see Figure 19.15b). After the homeodomain binds to an enhancer, the transcriptional activation domain of the homeotic protein activates RNA polymerase to begin transcription. Some homeotic proteins also function as repressors of certain genes.



(a) Normal fly



(b) Mutant fly

Figure 19.14 The Antennapedia mutation in *Drosophila*. (a) A normal fly with antennae. **(b)** This fly has a mutation in which the *Antp* gene is expressed in the embryonic segment that normally gives rise to antennae. The abnormal expression of *Antp* causes this region to have legs rather than antennae.

Concept Check: *What phenotype would you expect if the Antp gene was expressed where abd-A is supposed to be expressed?*

(a) Homeotic gene containing homeobox

(b) Homeodomain binding to DNA

Figure 19.15 Molecular features of homeotic genes and proteins. **(a)** A homeotic gene (shown mostly in green) contains a 180-bp sequence called the homeobox (shown in blue). **(b)** Homeotic genes encode proteins that function as transcription factors. The homeobox encodes a region of the protein called a homeodomain, which binds to the DNA at a regulatory site such as an enhancer. The region of the protein called the transcriptional activation domain activates RNA polymerase to begin transcription.

BIOLOGY PRINCIPLE Structure determines function. The structure of a homeotic protein contains one domain (the homeodomain) that allows it to bind to an enhancer and another domain (the transcriptional activation domain) that activates RNA polymerase.

Genomes & Proteomes Connection

A Homologous Group of Homeotic Genes Is Found in Nearly All Animals

Homologous genes are evolutionarily derived from the same ancestral gene and have similar DNA sequences. Researchers have found that homeotic genes in vertebrate species are homologous to genes that control development in simpler invertebrate species such as *Drosophila*. For example, in the mouse and other mammals, including humans, homeotic genes are organized into four clusters, designated *HoxA*, *HoxB*, *HoxC*, and *HoxD*, located on four different chromosomes. These homeotic genes are called ***Hox* genes**, an abbreviation for homeobox-containing genes. Thirty-nine genes

are found in the four clusters, which represent 13 different gene types. As shown in **Figure 19.16**, the *Hox* genes in fruit flies and the mouse and other mammals are evolutionarily related. Among the first six types of *Hox* genes in the mouse, five of them are homologous to genes found in the *Antennapedia* complex of *Drosophila*. Among the last seven (genes numbered 7–13), three are homologous to the genes of the *bithorax* complex.

Like the *Antennapedia* and *bithorax* complexes in *Drosophila*, the arrangement of *Hox* genes along the mouse chromosome follows the colinearity rule, reflecting their pattern of expression from the anterior to the posterior end (**Figure 19.17**). Research has shown that the *Hox* genes play a role in determining the fates of regions along the anteroposterior axis. Nevertheless, additional research is necessary to understand the individual role that each of the *Hox* genes plays during embryonic development.

How widespread are *Hox* genes? Sponges, which are the simplest animals with no true tissues, do not have *Hox* genes, though they have copies of an evolutionarily related gene called an *NK-like* gene. Otherwise, all other types of animals have *Hox* genes, but in different numbers. The role of *Hox* genes in the evolution of animal body plans is discussed in Chapter 25 (look ahead to Figure 25.15).

Phase 4 Pattern Formation: Stem Cells Can Divide and Differentiate into Specialized Cell Types

Thus far we have focused our attention on patterns of gene expression that occur during the early stages of development. These genes control the basic body plan of the organism. During the fourth phase of pattern formation, the emphasis shifts to cell differentiation (see Figure 19.6, phase 4).

Although invertebrates have been instrumental in our understanding of pattern formation in animals, cell differentiation has been studied more extensively in mammals. One reason is because researchers have been able to grow mammalian cells in the laboratory for many decades. The availability of laboratory-grown cells makes it much easier to analyze the process of cell differentiation.

By studying mammalian cells in the laboratory, geneticists have determined that the morphological differences between two different types of differentiated cells, such as muscle cells and neurons, arise through gene regulation. Though muscle cells and neurons in a given organism contain the same set of genes, they regulate the expression of their genes in very different ways. Certain genes that are transcriptionally active in muscle cells are inactive in neurons, and vice versa. Therefore, muscle cells and neurons express different proteins that affect the characteristics of the respective cells in distinct ways. In this manner, differential gene regulation underlies cell differentiation.

General Properties of Stem Cells To understand the process of cell differentiation in a multicellular organism, we need to consider the special properties of **stem cells**, undifferentiated cells that divide and supply the cells that constitute the bodies of all animals and plants. Stem cells have two common characteristics. First, they have the capacity to divide, and second, their daughter cells can differentiate into one or more specialized cell types. The two daughter cells that

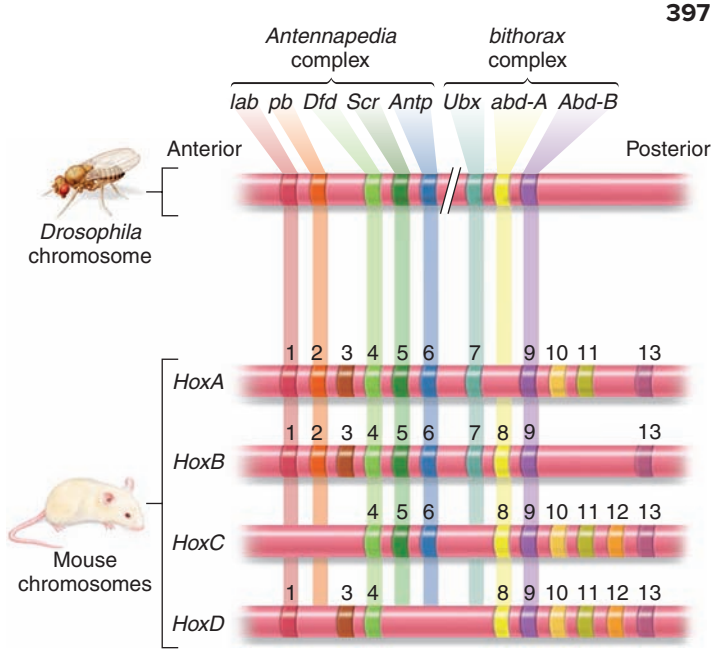


Figure 19.16 A comparison of homeotic genes in *Drosophila* and the mouse. The mouse and other mammals have four gene complexes, *HoxA–D*, that are homologous to certain homeotic genes found in *Drosophila*. Thirteen different types of homeotic genes are found in the mouse, although each *Hox* complex does not contain all 13 genes. In this drawing, homologous genes are aligned in columns. For example, *lab* is the homolog to *HoxA-1*, *HoxB-1*, and *HoxD-1*.

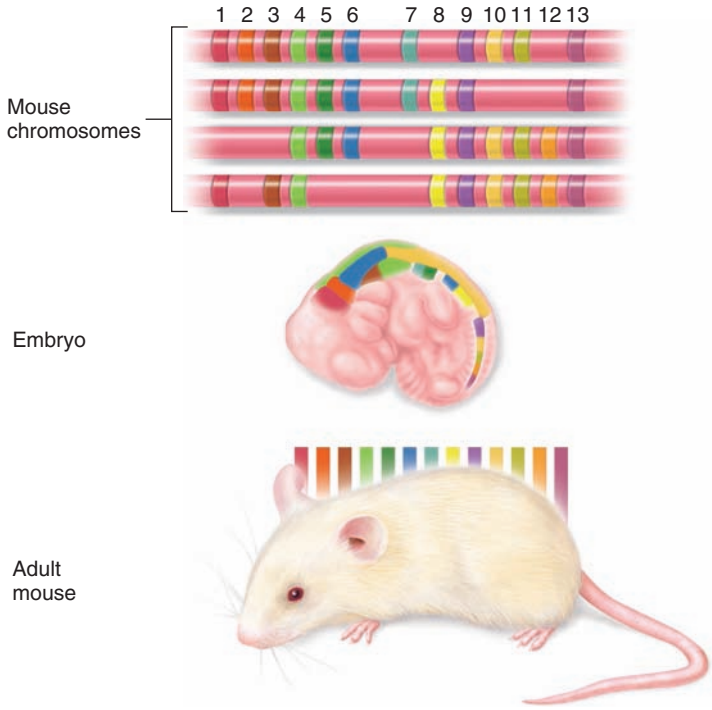

Figure 19.17 Expression pattern of *Hox* genes in the mouse. This schematic illustration shows *Hox* gene expression in the embryo and in the corresponding regions in the adult. The order of *Hox* gene expression, from anterior to posterior, parallels the order of genes along four different chromosomes.

BioConnections: Look ahead to Figure 25.15. How is the number of Hox genes related to the complexity of animal bodies?

are produced from the division of a stem cell can have different fates (**Figure 19.18**). One of the cells may remain an undifferentiated stem cell, and the other daughter cell can differentiate into a specialized cell type. With this asymmetric pattern of division and differentiation, stem cells continue dividing throughout life and generate a population of specialized cells. For example, in mammals, this mechanism is needed to replenish cells that have a finite life span, such as skin cells and red blood cells.

Stem Cells During Development In mammals, stem cells are commonly categorized according to their developmental stage and their ability to differentiate (**Figure 19.19**). The ultimate stem cell is the fertilized egg, which, via multiple cellular divisions, gives rise to an entire organism. A fertilized egg is said to be **totipotent** because it produces all of the cell types in the adult organism. The early embryonic structure called the blastocyst contains **embryonic stem cells (ES cells)**, which are located in the inner cell mass. The inner cell mass is a cluster of cells that give rise to the embryo. Embryonic stem cells are **pluripotent**, which means they can also differentiate into every or nearly every cell type of the body. However, a single embryonic stem cell by itself has lost the ability to produce an entire, intact individual. At an early fetal stage of development, the cells that later give rise to sperm or eggs cells, known as the **embryonic germ cells (EG cells)**, also are pluripotent.

During the embryonic and fetal stages of mammalian development, cells lose their ability to differentiate into a wide variety of cell types. Adults have both multipotent and unipotent stem cells. A **multipotent** stem cell can differentiate into several cell types, but far fewer than a pluripotent embryonic stem cell. For example, hematopoietic stem cells (HSCs) found in the bone marrow give rise to

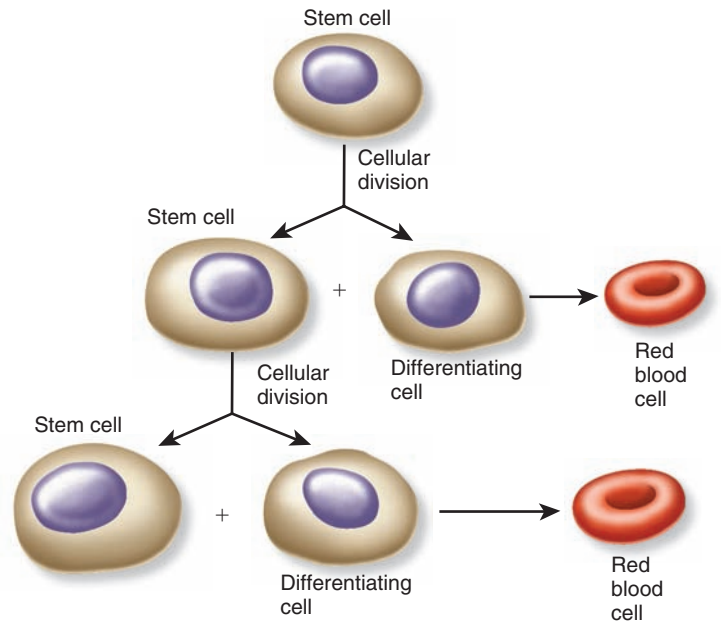

Figure 19.18 Growth pattern of stem cells. When a stem cell divides, one of the two daughter cells may remain a stem cell, while the other cell can differentiate into a specialized cell type, such as the red blood cells shown here.

Concept Check: *What are the two common characteristics of stem cells?*

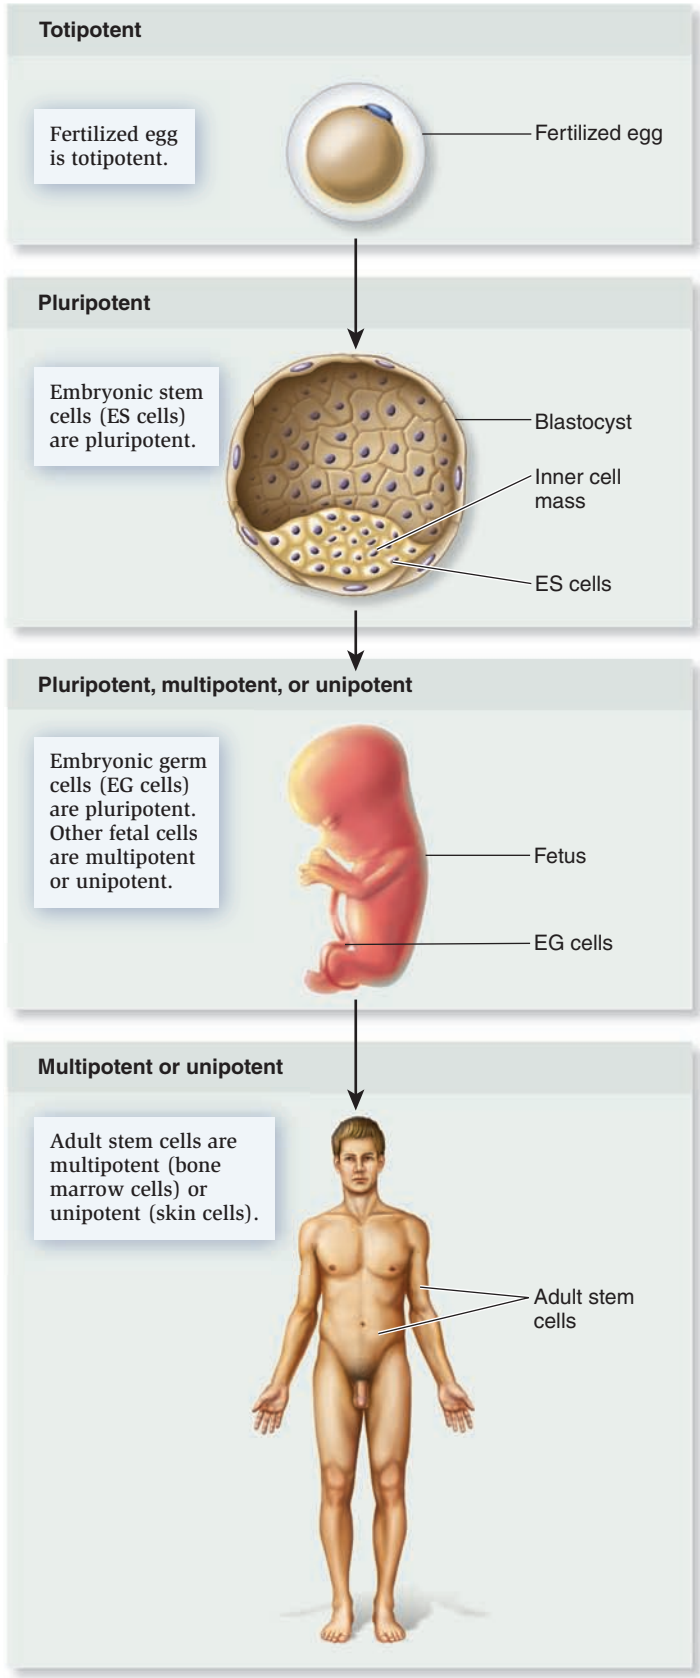

Figure 19.19 Occurrence of stem cells at different stages of mammalian development.

multiple blood cell types (**Figure 19.20**). Multipotent HSCs can follow a pathway in which cell division produces a myeloid cell, which then differentiates into various cells of the blood and immune systems. Alternatively, an HSC follows a path in which it becomes a lymphoid cell that develops into different blood cell types. A **unipotent** stem cell produces daughter cells that differentiate into only one cell type. For example, stem cells in the skin produce daughter cells that develop into skin cells.

Stem Cells in Medicine Why are researchers interested in stem cells? Beyond shedding light on the process of development, stem cells have a potential use in the treatment of human diseases or injuries. This application has already become a reality in certain cases. For example, bone marrow transplants are used to treat patients with certain forms of cancer, such as leukemia. When bone marrow from a healthy person is injected into the body of a patient whose immune system has been wiped out via radiation, the stem cells within the transplanted marrow have the ability to proliferate and differentiate into various types of blood cells within the body of the patient.

Renewed interest in the use of stem cells in the potential treatment of many other diseases has been fostered by studies in 1998 in which researchers obtained ES cells from blastocysts and EG cells from aborted fetuses and successfully propagated them in the laboratory. Because ES and EG cells are pluripotent, they could potentially be used to treat a wide variety of diseases associated with cell and tissue damage (**Table 19.1**). Much progress has been made in testing the use of stem cells in animal models. However, more research is needed before the use of stem cells to treat such diseases in humans is realized.

From an ethical perspective, the primary issue that raises debate is the source of stem cells for research and potential treatments. Most ES cells have been derived from human embryos that were produced from in vitro fertilization, a method of assisted conception in which fertilization occurs outside of the mother's body and a limited number of the resulting embryos are transferred to the uterus. Most EG cells are obtained from aborted fetuses, either those that spontaneously aborted or those in which the decision to abort was not related to donating the fetal tissue to research. Some feel that it is morally wrong to use such tissue in research and/or the treatment of disease. Furthermore, some people fear this technology could lead to intentional abortions for the sole purpose of obtaining fetal tissues for transplantation. Others feel the embryos and fetuses that have been the sources of ES and EG cells were not going to become living individuals, and therefore it is beneficial to study these cells and to use them in a positive

Table 19.1 Some Potential Uses of Stem Cells to Treat Diseases

Cell/tissue type	Disease treatment
Nerve	Implantation of cells into the brain to treat Parkinson disease; treatment of spinal cord injuries
Skin	Treatment of burns and skin disorders
Cardiac	Repair of heart damage associated with heart attacks
Cartilage	Repair of joints damaged by injury or arthritis
Bone	Repair or replacement of damaged bone
Liver	Repair or replacement of liver tissue damaged by injury or disease
Skeletal muscle	Repair or replacement of damaged muscle

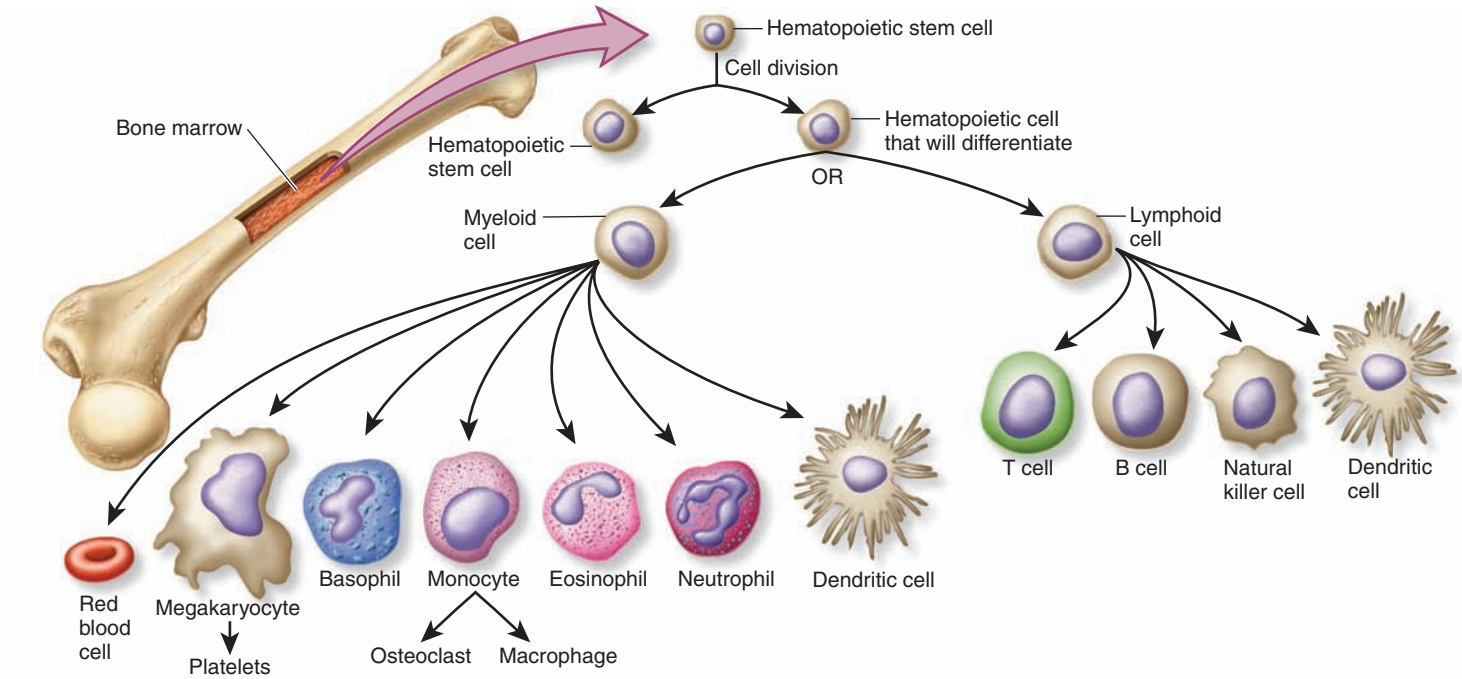

Figure 19.20 Fates of hematopoietic stem cells (HSCs). HSCs can follow two pathways: one in which cell division produces a myeloid cell and one that produces a lymphoid cell. Each develops into different blood cell types.

Concept Check: *Are hematopoietic stem cells totipotent, pluripotent, multipotent, or unipotent?*

way to treat human diseases and injury. It is not clear whether these two opposing viewpoints can reach a common ground.

If stem cells could be obtained from adult cells and induced to become pluripotent cells in the laboratory, an ethical dilemma may be avoided, because most people do not have serious moral objections to current procedures that use adult cells such as bone marrow transplantation. In 2006, work by Japanese physician Shinya Yamanaka and colleagues showed that adult mouse fibroblasts (a type of connective tissue cell) could become pluripotent by the introduction of four different genes that encode transcription factors. In 2007, Yamanaka's laboratory and two other research groups were able to show that such induced pluripotent stem cells can differentiate into all cell types when injected into mouse blastocysts and grown into baby mice. These results indicate that adult cells can be reprogrammed to become embryonic stem cells.

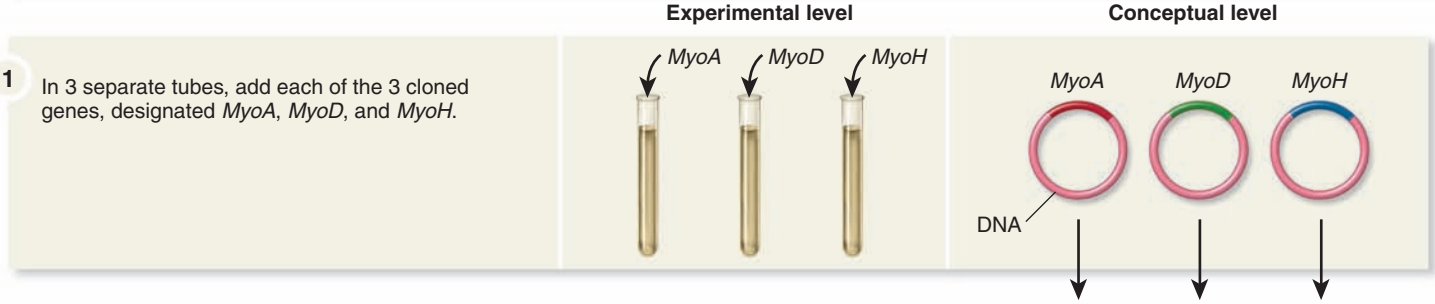
Feature Investigation | Davis, Weintraub, and Lassar Identified Genes That Promote Muscle Cell Differentiation

A key question regarding stem cells is "What causes a stem cell to differentiate into a particular cell type?" Researchers have discovered that certain proteins function as master transcription factors that cause cells to differentiate into specific types of cells. The investigation described here was one of the first studies to reveal this phenomenon.

In 1987, Robert Davis, Harold Weintraub, and Andrew Lassar conducted a study to identify genes that promote skeletal muscle cell differentiation. The initial strategy for their experiments was to identify genes that are expressed only in differentiating skeletal muscle cells, not in nonmuscle cells. Though methods of gene cloning are described in Chapter 20, we will briefly consider these scientists' cloning methods in order to understand their approach. The researchers began with two different laboratory cell lines that could differentiate into muscle cells. From these two cell lines, they cloned and identified about 10,000 different genes that were transcribed into mRNA. Next, they compared the expressed genes in these two muscle cell lines with genes that were expressed in a nonmuscle cell line. Their comparison revealed 26 genes that were expressed only in the two muscle cell lines but not in the nonmuscle cell line. To narrow their search further, they compared these 26 genes with other nonmuscle cell lines they had available. Among the 26, only 3 of them, which the researchers termed *MyoA*, *MyoD*, and *MyoH*, were expressed exclusively in the two muscle cell lines.

In the experiment shown in **Figure 19.21**, the scientists' goal was to determine if any of these three genes could cause nonmuscle cells to differentiate into muscle cells. Using techniques described in Chapter 20, the coding sequence of each gene was placed next to an active promoter that caused a high level of transcription, and then the genes were introduced into fibroblasts, which are a type of cell that normally differentiates into osteoblasts (bone cells), chondrocytes (cartilage cells), adipocytes (fat cells), and smooth muscle cells, but never differentiates into skeletal muscle cells in vivo. The cells were plated on growth media and allowed to grow for 3 to 5 days. When the cloned *MyoD* gene was introduced into fibroblast cells in a laboratory, the fibroblasts differentiated into skeletal muscle cells! These cells contained large amounts of myosin, which is a protein expressed in muscle cells. The other two cloned genes (*MyoA* and *MyoH*) did not cause muscle cell differentiation or promote myosin production.

Since this initial discovery, researchers have found that *MyoD* belongs to a small group of genes that initiate muscle cell development. These myogenic genes encode transcription factors. They are found in all vertebrates and have been identified in several invertebrates, such as *Drosophila* and *C. elegans*. In all cases, myogenic genes are activated during skeletal muscle cell development.



Experimental Questions

1. What was the goal of the research conducted by Davis, Weintraub, and Lassar?
2. **SciSKILLS** » How did Davis, Weintraub, and Lassar's research identify the candidate genes for muscle differentiation?
3. **SciSKILLS** » Once the researchers identified the candidate genes for muscle differentiation, how did they test the effect of each gene on cell differentiation? What were the results of the study?

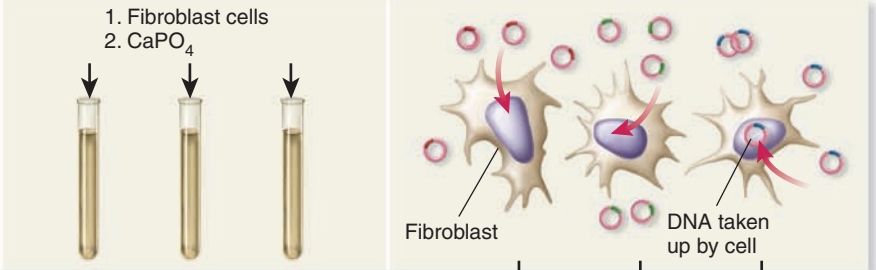


Figure 19.21 Davis, Weintraub, and Lassar and the promotion of skeletal muscle cell differentiation in fibroblasts by the expression of *MyoD*.

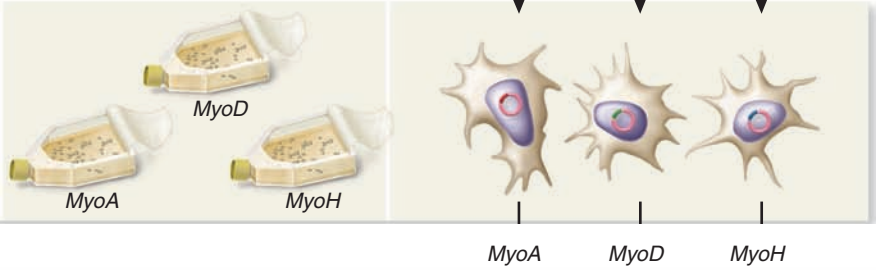
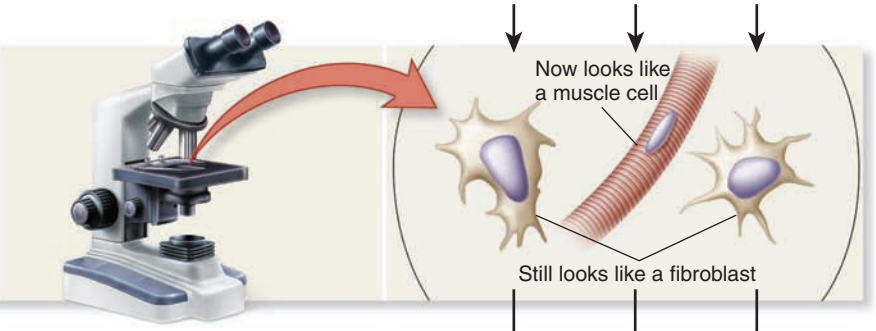
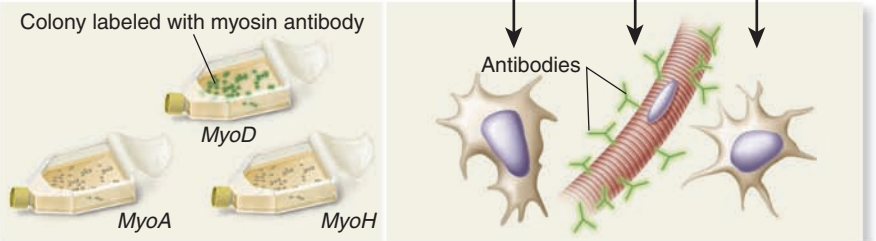
HYPOTHESIS Muscle differentiation is induced by particular genes.



KEY MATERIALS Three cloned genes had been identified that were expressed only in differentiating muscle cell lines. The researchers also had fibroblast cell lines, which do not normally differentiate into muscle cells.



2 Add fibroblast cells to the tubes and incubate in the presence of calcium phosphate ($CaPO_4$), which promotes the uptake of DNA into the cells.



3 Plate the cells on solid growth media. Allow the cells to grow for 3 to 5 days. Cells will express the cloned gene.

4 Examine the cells under a microscope to determine if they have the morphology of muscle cells.

5 Determine if the cells are synthesizing myosin, which is a protein that is abundantly made in muscle cells. This is done by adding a labeled antibody that recognizes myosin and determining the amounts of antibody that bind.

6 THE DATA

Results from step 4:

DNA added	Microscopic morphology of cells
MyoA	Fibroblasts
MyoD	Muscle cells
MyoH	Fibroblasts

Results from step 5:

DNA added	Colonies labeled with antibody that binds to myosin?
MyoA	No
MyoD	Yes
MyoH	No

7 CONCLUSION The *MyoD* gene encodes a protein that causes cells to differentiate into skeletal muscle cells.

19.3 Development in Plants

Learning Outcomes:

1. Outline the stages of pattern formation in plants.
2. **SciSKILLS** » Explain the ABC model for flower development.

Because all eukaryotic organisms share an evolutionary history, animals and plants have many common features, including the types of events that occur during development. However, the general morphology of plants is quite different from animals. Plant morphology exhibits two key features (see Figure 19.2b). The first is the root-shoot axis. Most plant growth occurs via cell division near the tips of the shoots and the bottoms of the roots. Second, this growth occurs in a well-defined radial pattern, which means that growth in the stems and roots occurs in concentric rings of tissues (**Figure 19.22**).

At the cellular level too, plant development shows some differences from animal development. For example, cell migration does not occur during plant development. In addition, the development of a plant does not rely on morphogens that are deposited in the oocyte, as in many animals. In plants, an entirely new individual can be regenerated from many types of somatic cells—cells that do not give rise to gametes. Such somatic cells of plants are totipotent.

In spite of these apparent differences, the underlying molecular mechanisms of pattern formation in plants still share striking similarities with those in animals. Like animals, plants use the mechanism of differential gene regulation to coordinate the development of a body plan. Like their animal counterparts, plants have a developmental program that relies on transcription factors to determine when and how much gene products are made. In this section, we will consider pattern formation in plants and examine how transcription factors play a key role in plant development.

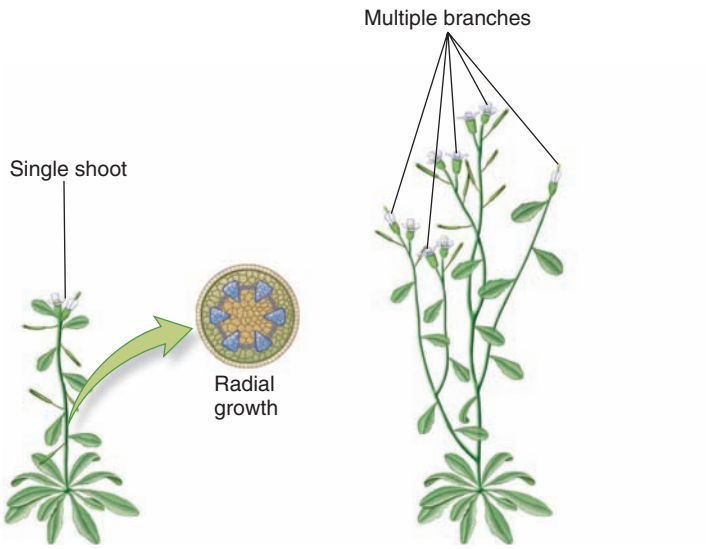

Figure 19.22 Pattern of shoot growth in plants. Early in development, as shown here in *Arabidopsis*, a single shoot promotes the formation of early leaves on the plant. Later, buds will form from this main shoot and grow into branches.

Plant Development Occurs from Meristems That Are Formed in the Embryo

How does pattern formation occur in plants? **Figure 19.23** illustrates a common order of events that takes place in the embryonic development of flowering plants such as *Arabidopsis*. After fertilization, the first cellular division is asymmetrical and produces a smaller apical cell and a larger basal cell (Figure 19.23a). In 2009, Danish geneticist Martin Bayer and colleagues conducted experiments indicating that the sperm carries mRNA molecules that are critical for this asymmetric cell division. The apical cell gives rise to most of the embryo and later develops into the shoot of the plant. In *Arabidopsis*, the basal cell gives rise to the root, along with a structure called the suspensor, which channels nutrients from the parent plant to the young embryo (Figure 19.23b).

At the heart stage, which is composed of only about 100 cells, the basic organization of the plant has been established (Figure 19.23c). Plants have organized groups of actively dividing stem cells called **meristems**. As discussed earlier, stem cells retain the ability both to divide and to differentiate into multiple cell types. The meristem produces offshoots of proliferating and differentiating cells. The **root apical meristem** gives rise only to the root, whereas the **shoot apical meristem** produces all aerial parts of the plant, which include the stem as well as lateral structures such as branches, leaves, and flowers.

The heart stage then progresses to the formation of a seedling that has two cotyledons, which are embryonic leaves that store nutrients for the developing embryo and seedling. In the seedling shown in Figure 19.23d, you can see three main regions. The **apical region** produces the leaves and flowers of the plant. The **central region** creates the stem. Finally, the **basal region** produces the roots. Each of these three regions develops differently, as indicated by their unique cell division patterns and distinct morphologies.

As seen in the inset to Figure 19.23d, the shoot meristem is organized into three areas: the organizing center, the central zone, and the peripheral zone. The **organizing center** ensures the proper organization of the meristem and preserves the correct number of actively dividing stem cells. The **central zone** is an area where undifferentiated stem cells are always maintained. The **peripheral zone** contains dividing cells that eventually differentiate into plant structures. For example, the peripheral zone may form a bud that will produce a leaf or flower.

By analyzing mutations that disrupt the developmental process, researchers have discovered that the apical, central, and basal regions of a growing plant express different sets of genes. A category of genes called **apical-basal-patterning genes** are important in early stages of plant development. A few examples are described in **Table 19.2**. Mutations in apical-basal-patterning genes cause dramatic effects in one of these three regions. For example, the *Aintegumenta* gene is necessary for apical development. When it is defective, the growth of lateral buds is defective.

Plant Homeotic Genes Control Flower Development

Although William Bateson coined the term homeotic to describe mutations in animals in which one body part is replaced by another, the first known homeotic mutations were described in plants. Naturalists in ancient Greece and Rome, for example, recorded their observations

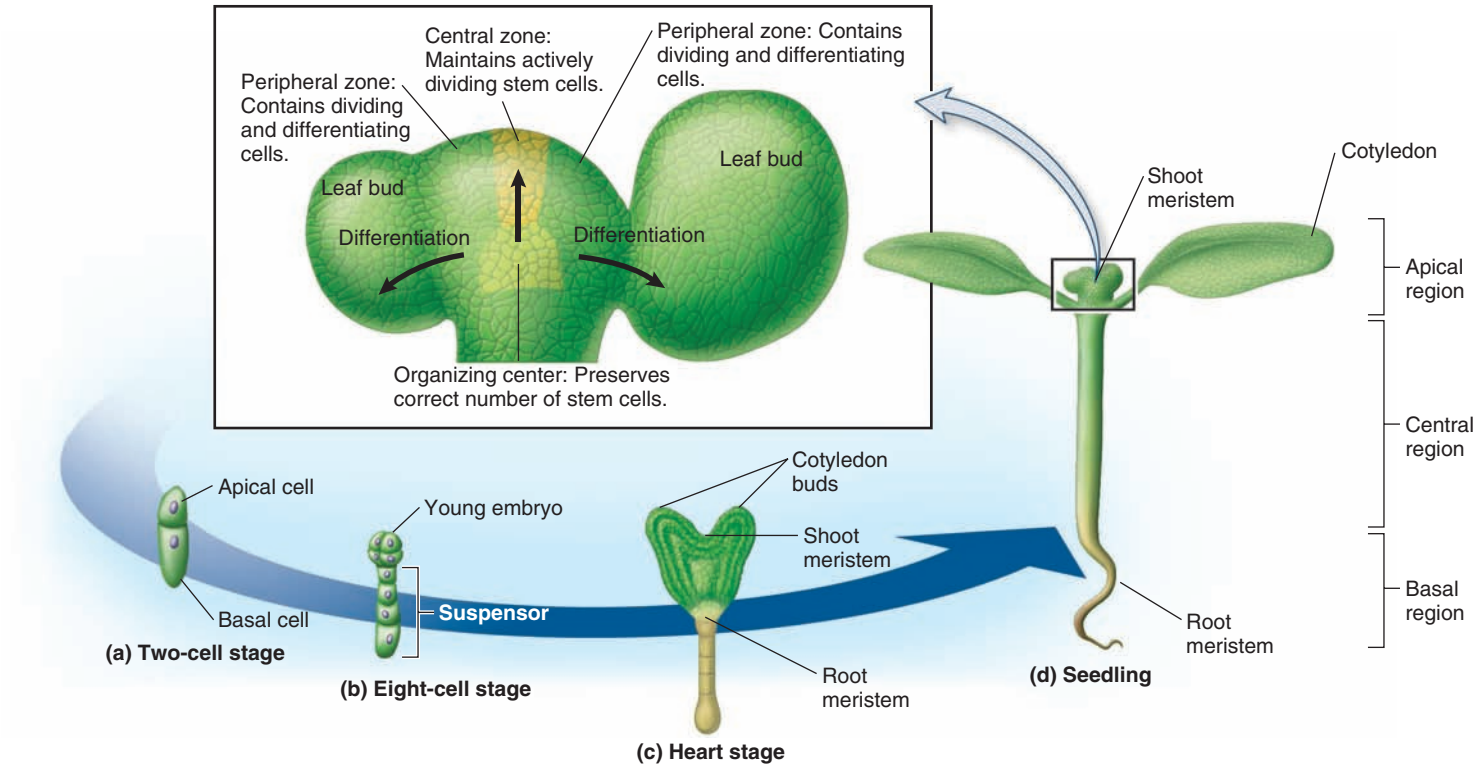

Figure 19.23 **Developmental steps in the formation of a plant embryo.** **(a)** The two-cell stage consists of the apical cell and basal cell. **(b)** The eight-cell stage consists of a young embryo and a suspensor. The suspensor channels nutrients to the young embryo from the parent plant. **(c)** At the heart stage, all of the plant tissues have begun to form. The shoot meristem is located between the future cotyledons, and the root meristem is on the opposite side. **(d)** A seedling showing apical, central, and basal regions. The inset shows the organization of the shoot meristem. Note: The steps shown in parts (a), (b), and (c) occur during seed formation, and the embryo would be enclosed within a seed.

BIOLOGY PRINCIPLE **Living organisms grow and develop.** This diagram depicts how a plant begins as a fertilized egg that grows and develops into a seedling.

Concept Check: *Where are stem cells found in a growing plant?*

of double flowers in which stamens were replaced by petals. In current research, geneticists are studying these types of mutations to better understand developmental pathways in plants. Many homeotic mutations affecting flower development have been identified in *Arabidopsis* and also in the snapdragon (*Antirrhinum majus*).

A normal *Arabidopsis* flower is composed of four concentric whorls of structures (**Figure 19.24a**). The first, outer whorl has four **sepals**, which protect the flower bud before it opens. The second whorl is composed of four **petals**, and the third whorl has six **stamens**, structures that make male gametophytes, pollen. Finally, the fourth, innermost whorl contains two carpels that are fused together. The **carpels** produce, enclose, and nurture the female gametophytes.

By analyzing the effects of many different homeotic mutations in *Arabidopsis*, British plant biologist Enrico Coen and his American colleague, plant geneticist, Elliot Meyerowitz, proposed the **ABC model** for flower development in 1991. In this model, three classes of genes, called *A*, *B*, and *C*, govern the formation of sepals, petals, stamens, and carpels. More recently, a fourth category, called the *E* genes, was found to be required for this process. Figure 19.24a illustrates how these genes affect normal flower development in *Arabidopsis*.

Table 19.2 **Examples of *Arabidopsis* Apical-Basal-Patterning Genes**

Region: *Gene*	Description
Apical:	
Aintegumenta	Encodes a transcription factor that is expressed in the peripheral zone. Its expression maintains the growth of lateral buds.
Central:	
Scarecrow	Encodes a transcription factor that plays a role in the asymmetric division that produces the radial pattern of growth in the stem. The Scarecrow protein also affects cell division patterns in roots and plays a role in sensing gravity.
Basal:	
Monopterous	Encodes a transcription factor. When the *Monopterous* gene is defective, the plant embryo cannot initiate the formation of root structures, although root structures can be formed postembryonically. This gene seems to be required for organizing root formation in the embryo.

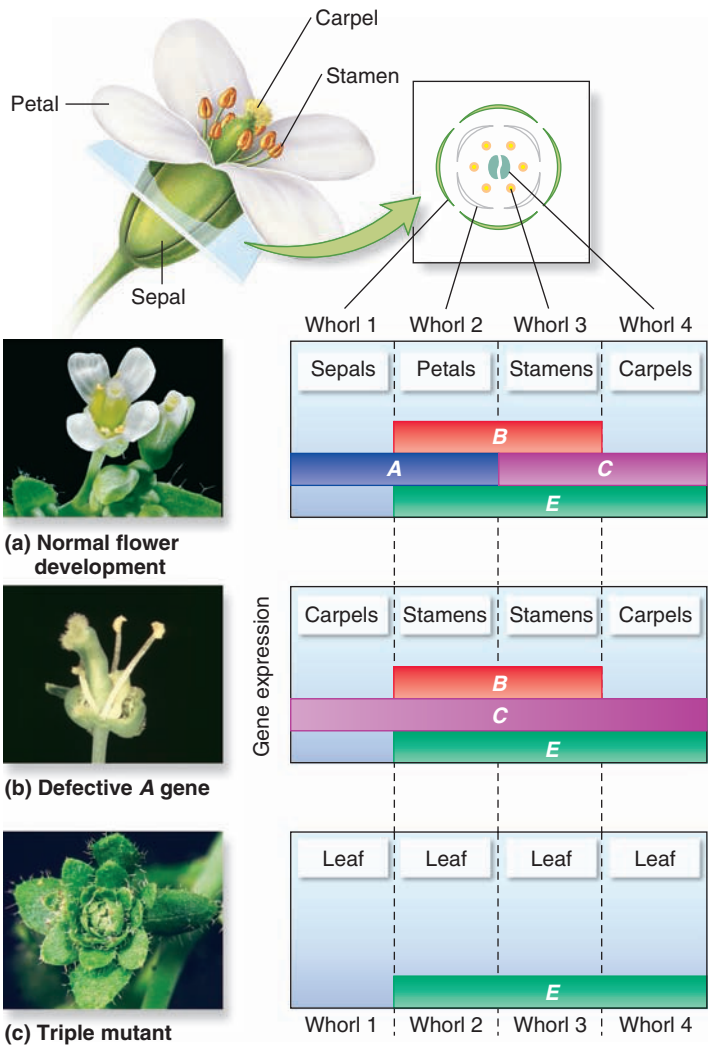

Figure 19.24 Normal and mutant homeotic gene action in *Arabidopsis*. **(a)** A normal flower is composed of four concentric whorls of structures: sepals, petals, stamens, and carpels. To the right is the ABC model of homeotic gene action that has been revised to include *E* genes. **(b)** A homeotic mutant defective in gene *A* in which the sepals have been transformed into carpels and the petals have been transformed into stamens. **(c)** A triple mutant defective in the *A*, *B*, and *C* genes, producing a flower with all leaves.

Concept Check: *What pattern would you expect if the B gene was expressed in whorls 2, 3, and 4?*

In whorl 1, gene *A* product is made. This promotes sepal formation. In whorl 2, *A*, *B*, and *E* gene products are made, which promotes petal formation. In whorl 3, the expression of genes *B*, *C*, and *E* causes stamens to be made. Finally, in whorl 4, the products of *C* and *E* genes promote carpel formation.

What happens in certain homeotic mutants that undergo transformations of particular whorls? According to the original ABC model, genes *A* and *C* repress each other's expression, and gene *B* functions independently. In a mutant defective in gene *A* expression, gene *C* is also expressed in whorls 1 and 2. This produces a carpel-stamen-stamen-carpel arrangement in which the sepals have been transformed into carpels and the petals into stamens (**Figure 19.24b**). When gene *B* is defective, a flower cannot make petals or stamens. Therefore, a gene *B* defect yields a flower with a sepal-sepal-carpel-carpel arrangement. When gene *C* is defective, gene *A* is expressed in all four whorls. This results in a sepal-petal-petal-sepal pattern. If the expression of *E* genes is defective, the flower consists entirely of sepals.

Working together, the genes described in Figure 19.24 promote a pattern of development that leads to sepal, petal, stamen, or carpel structures. But what happens if genes *A*, *B*, and *C* are all defective? This produces a flower composed entirely of leaves (**Figure 19.24c**). These results indicate that the leaf structure is the default pathway and that the *A*, *B*, and *C* genes cause development to deviate from a leaf structure in order to make something else. In this regard, the sepals, petals, stamens, and carpels of plants can be viewed as modified leaves.

Like the *Drosophila* homeotic genes, plant homeotic genes are part of a hierarchy of gene regulation. Most plant homeotic genes belong to a family of genes called MADS box genes, which encode transcription factor proteins that contain a DNA-binding domain called a MADS domain. The *Arabidopsis* homeotic genes do not contain a sequence similar to the homeobox found in animal homeotic genes.

Summary of Key Concepts

- Development refers to a series of changes in the state of a cell, tissue, organ, or organism. Developmental genetics is aimed at understanding how gene expression controls the development process.

19.1 General Themes in Development

- A cell's fate becomes determined before the cell differentiates into a specialized cell type.
- *Drosophila*, *C. elegans*, mice, zebrafish, and *Arabidopsis* are model organisms studied by developmental geneticists (Figure 19.1).
- The process that gives rise to an animal or plant with a particular body structure is called pattern formation (Figure 19.2).
- Pattern formation depends on positional information. Four responses to positional information are cell division, cell migration, cell differentiation, and apoptosis (Figures 19.3, 19.4).
- Positional information is conveyed by morphogens and cell adhesion molecules (CAMs) (Figure 19.5).
- In animals and plants, a hierarchy of transcription factors controls pattern formation. In animals, pattern formation occurs in four general phases (Figure 19.6).

19.2 Development in Animals

- Embryonic development in *Drosophila* occurs in a sequence of stages, from a fertilized egg to an adult. The basic body plan is established in the embryo (Figure 19.7).
- Maternal effect genes control the formation of body axes, the first phase in *Drosophila* pattern formation (Figures 19.8, 19.9).
- In the second phase of pattern formation, the sequential expression of three categories of segmentation genes divides the embryo into segments. Mutations that alter *Drosophila* development have allowed scientists to understand the normal process (Figures 19.10, 19.11).
- During the third phase of pattern formation, each segment begins to develop its own unique characteristics. Homeotic genes control

the development of a particular segment or group of segments (Figures 19.12, 19.13, 19.14, 19.15).

- Invertebrates and vertebrates have a homologous set of homeotic genes. These genes are called *Hox* genes (Figures 19.16, 19.17).
- In the fourth phase of pattern formation, stem cells divide and differentiate into specialized cell types (Figure 19.18).
- Stem cells are categorized according to their developmental stage and their ability to differentiate. In mammals, a fertilized egg is totipotent; certain embryonic and fetal cells are pluripotent; and stem cells in the adult are multipotent or unipotent (Figures 19.19, 19.20).
- Stem cells have the potential to be used to treat a variety of human disorders (Table 19.1).
- The differentiation of cell types within certain tissues or organs are controlled by master transcription factors. An example is *MyoD*, a gene that initiates skeletal muscle cell development (Figure 19.21).

19.3 Development in Plants

- Plants grow along a root-shoot axis and in a well-defined radial pattern. Cell migration does not occur in plants (Figure 19.22).
- Plant stem cells within meristems promote the development of plant structures such as roots, stems, leaves, and flowers (Figure 19.23).
- The apical, central, and basal regions of the growing plant express different sets of pattern formation genes (Table 19.2).
- According to the ABC model, four classes of homeotic genes in plants, *A*, *B*, *C*, and *E*, control flower development (Figure 19.24).

Assess and Discuss

Test Yourself

1. The process whereby a cell's morphology and function have changed is called
   a. determination.
   b. cell fate.
   c. differentiation.
   d. genetic engineering.
   e. both a and c.
2. Pattern formation in plants is along the _____ axis.
   a. dorsoventral
   b. anteroposterior
   c. left-right
   d. root-shoot
   e. All of the above are correct.
3. Positional information is important in determining the fate of a cell in a multicellular organism. Animal cells may respond to positional information by
   a. dividing.
   b. migrating.
   c. differentiating.
   d. undergoing apoptosis.
   e. doing all of the above.
4. Morphogens are
   a. molecules that disrupt normal development.
   b. molecules that convey positional information and promote changes in development.
   c. mutagenic agents that cause apoptosis.
   d. receptors that allow cells to adhere to the extracellular matrix.
   e. both a and c.
5. What group of proteins play a key role in controlling the program of developmental changes?
   a. motor proteins
   b. transporters
   c. transcription factors
   d. restriction endonucleases
   e. cyclins
6. Arrange the following events of animal development in the correct sequence:
   1. Tissues, organs, and other body structures in each segment are formed.
   2. Axes of the entire animal are determined.
   3. Cells become differentiated.
   4. The entire animal is divided into segments.

   a. 2, 3, 4, 1
   b. 1, 2, 4, 3
   c. 2, 4, 3, 1
   d. 3, 2, 4, 1
   e. 2, 4, 1, 3
7. Homeotic genes in *Drosophila*
   a. determine the structural and functional characteristics of different segments of the developing fly.
   b. encode motor proteins that transport morphogens throughout the embryo.
   c. are dispersed randomly throughout the genome.
   d. are expressed in similar levels in all parts of the developing embryo.
   e. Both a and c are correct.
8. Which of the following genes do *not* play a role in the process whereby segments are formed in the fruit fly embryo?
   a. homeotic genes
   b. gap genes
   c. pair-rule genes
   d. segment-polarity genes
   e. All of the above play a role in segmentation.
9. An embryonic stem cell that can give rise to any type of cell of an adult organism but cannot produce an entire, intact individual is called
   a. totipotent.
   b. pluripotent.
   c. multipotent.
   d. unipotent.
   e. antipotent.
10. During plant development, the leaves and the flowers of the plant are derived from
    a. the central region.
    b. the basal region.
    c. the suspensor.
    d. the apical region.
    e. both a and d.

Conceptual Questions

1. If you observed fruit flies with the following developmental abnormalities, would you guess that a mutation had occurred in a segmentation gene or a homeotic gene? Explain your guess.
   a. Three abdominal segments were missing.
   b. One abdominal segment had legs.
2. The *MyoD* gene in mammals plays a role in muscle cell differentiation. The *Hox* genes are homeotic genes that play a role in the differentiation of particular regions of the body. Compare and contrast the functions of these genes.
3. A principle of biology is that *living organisms grow and develop*. Discuss how maternal effect genes, segmentation genes, and homeotic genes control the process of development in animals.

Collaborative Questions

1. It seems that developmental genetics boils down to a complex network of gene regulation. Starting with maternal effect genes and ending with master transcription factors, try to draw/describe how this network is structured for *Drosophila*. How many genes do you think are necessary to specify a complete developmental network for the fruit fly? How many genes do you think are needed for a network to specify one segment?
2. Is it possible for a phenotypically normal female fly to be homozygous for a loss-of-function allele in the *bicoid* gene? What would be the phenotype of the offspring that such a fly would produce if it was mated to a male that was homozygous for the normal *bicoid* allele?

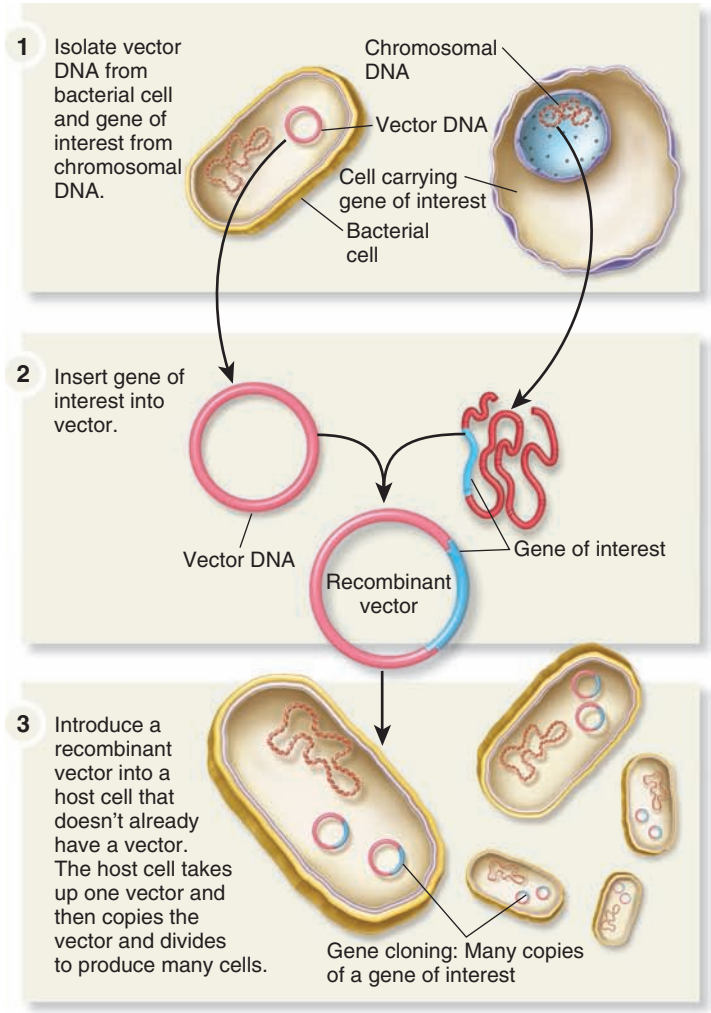
20.3 Biotechnology
Summary of Key Concepts
Assess and Discuss

The first cloned pet. In 2002, the cat shown here called CC (for carbon copy or copy cat) was produced by reproductive cloning, a procedure described later in this chapter.

Jacob was diagnosed with type 1 diabetes, also called insulin-dependent diabetes mellitus, when he was 13 years old. Since then, he's been taking regular injections of insulin, a protein hormone that is normally made by cells in the pancreas. Jacob's pancreas fails to make enough of this hormone. You might be surprised to discover that the injected insulin is not made by human cells. It's actually made by laboratory strains of the bacterium *Escherichia coli* that have been genetically modified to synthesize a hormone that is identical in structure to human insulin. This is just one example of how researchers have been able to apply **recombinant DNA technology**—the use of laboratory techniques to bring together fragments of DNA from multiple sources—to benefit humans. Such technology produces recombinant DNA, which refers to any DNA molecule that has been manipulated so it contains DNA from two or more sources.

In the early 1970s, the first successes in making recombinant DNA molecules were accomplished independently by two groups at Stanford University: David Jackson, Robert Symons, and Paul Berg; and Peter Lobban and A. Dale Kaiser. Both groups were able to isolate and purify pieces of DNA in a test tube and then covalently link two or more DNA fragments. Shortly thereafter, techniques were developed to introduce these recombinant DNA molecules into living cells. Once inside a host cell, the recombinant molecules were replicated to produce many identical copies. The process of making multiple copies of a particular gene is known as **gene cloning**. In the first section of this chapter, we will explore recombinant DNA technology and gene cloning, techniques that have enabled geneticists to probe relationships between gene sequences and phenotypic consequences. Such studies have been fundamental to our understanding of gene structure and function.



In the second section of this chapter, we will consider the topic of **genomics**—the molecular analysis of the entire genome of a species. In recent years, molecular techniques have progressed to the point where researchers can study the structure and function of many genes as large integrated networks. For example, the expression of all genes in a genome can be compared between normal and cancerous cells. This information helps us to understand how changes in gene expression cause uncontrolled cell growth.

In the last section of this chapter, we will explore the topic of **biotechnology**—the use of living organisms or the products of living organisms for human benefit. **Genetic engineering**, the direct manipulation of genes for practical applications, is playing an ever-increasing role in the production of strains of microorganisms, plants, and animals with characteristics that are useful to people. These include bacteria that make hormones such as human insulin, crops that produce their own insecticides, and farm animals that make human medicines.

20.1 Gene Cloning

Learning Outcomes:

1. Outline the steps of gene cloning using vectors.
2. Distinguish between a genomic library and a cDNA library.
3. Explain how gel electrophoresis is used to separate DNA fragments.
4. Describe the steps of gene cloning using polymerase chain reaction (PCR).

Gene cloning is done to achieve one of two main goals:

Producing large amounts of DNA of a specific gene	Expressing the cloned gene to produce the encoded protein
Examples	*Examples*
• Cloned genes provide enough DNA for DNA sequencing. The sequence of a gene can help us understand how a gene works and identify mutations that cause diseases.	• Large amounts of the protein can be purified to study its structure and function.
• Cloned DNA can be used as a probe to identify the same gene or similar genes in other organisms.	• Cloned genes can be introduced into bacteria or livestock to make pharmaceutical products such as insulin.
	• Cloned genes can be introduced into plants and animals to alter their traits.
	• Cloned genes can be used to treat diseases—a clinical approach called gene therapy.

Figure 20.1 Gene cloning. The process of gene cloning is used to produce large amounts of a gene or its protein product.

BIOLOGY PRINCIPLE Biology is an experimental science. The technique of gene cloning allows researchers to study genes and gene products in greater detail.

As mentioned, the term gene cloning refers to the process of making many copies of a particular gene. Why is gene cloning useful? Figure 20.1 provides an overview of the steps and goals of gene cloning. The process is usually done with one of two goals in mind. One goal is that a researcher or clinician wants many copies of the gene, perhaps to study the DNA directly or to use the DNA as a tool. For example, geneticists may want to determine the sequence of a gene from a person with a disease to see if the gene carries a mutation. Alternatively, the goal may be to obtain a large amount of the gene product—mRNA or protein. Along these lines, biochemists use gene cloning to obtain large amounts of proteins to study their structure and function. In recent years, gene cloning has provided the foundation for critical technical advances in a variety of disciplines, including molecular biology, genetics, cell biology, biochemistry, and medicine. In this section, we will examine the procedures that are used in gene cloning.

Step 1: Vector DNA and Chromosomal DNA Are the Starting Materials of Gene Cloning

In the first step of gene cloning, a key material is a type of DNA known as a **vector** (from the Latin, for one who carries) (see Figure 20.1). Vector DNA acts as a carrier of the DNA segment that is to be cloned. In cloning experiments, a vector may carry a small segment of chromosomal DNA, perhaps only a single gene. By comparison, a chromosome carries up to a few thousand genes. When a vector is introduced into a living cell, it can replicate, and so the DNA that it carries is also replicated. This produces many identical copies of the inserted gene.

The vectors commonly used in gene cloning experiments were originally derived from two natural sources: plasmids or viruses. As discussed in Chapter 18, **plasmids** are small, circular pieces of DNA that are found naturally in many strains of bacteria and exist independently of the bacterial chromosome. Plasmids are also found in yeast. Commercially available plasmids have been genetically engineered for effective use in cloning experiments. They contain unique sites into which geneticists can easily insert pieces of DNA. An alternative type of vector used in cloning experiments is a **viral vector**. Viruses can infect living cells and propagate themselves by taking control of the host cell's metabolic machinery. When a chromosomal gene is inserted into a viral vector, the gene is replicated whenever the viral DNA is replicated. Therefore, viruses can be used as vectors to carry other pieces of DNA.

Another material necessary for cloning a gene is the gene itself, which we will call the gene of interest. The source of the gene is the chromosomal DNA that carries the gene. The preparation of chromosomal DNA involves breaking open cells and extracting and purifying the DNA using biochemical separation techniques such as chromatography and centrifugation.

Step 2: Cutting Chromosomal and Vector DNA into Pieces and Linking Them Together Produces Recombinant Vectors

The second step in a gene cloning experiment is the insertion of the gene of interest into the vector (see Figure 20.1). How is this accomplished? DNA molecules are cut and pasted to produce recombinant vectors. To cut DNA, researchers use enzymes known as

Table 20.1 Examples of Restriction Enzymes Used in Gene Cloning

Restriction enzyme*	Bacterial source	Sequence recognized†
*Eco*RI	*Escherichia coli* (strain RY13)	5′–GAATTC–3′ 3′–CTTAAG–5′
*Sac*I	*Streptomyces achromogenes*	5′–GAGCTC–3′ 3′–CTCGAG–5′
*Bam*Hi	*Bacillus amyloliquefaciens* H	5′–GGATCC–3′ 3′–CCTAGG–5′
*Pst*I	*Providencia stuartii*	5′–CTGCAG–3′ 3′–GACGTC–5′

*Restriction enzymes are named according to the species in which they are found. The first three letters are italicized because they indicate the genus and species names. Because a species may produce more than one restriction enzyme, the enzymes are designated I, II, III, etc., to indicate the order in which they were discovered in a given species.

†The arrows show the locations in the upper and lower DNA strands where the restriction enzymes cleave the DNA backbone.

restriction enzymes, or restriction endonucleases. These enzymes, which were discovered by Swiss geneticist Werner Arber and his American colleagues microbiologists Hamilton Smith and Daniel Nathans in the 1960s and 1970s, are made naturally by many different species of bacteria. Restriction enzymes protect bacterial cells from invasion by viruses by degrading the viral DNA into small fragments. Currently, several hundred different restriction enzymes from various bacterial species have been identified and are available commercially to molecular biologists.

The restriction enzymes used in cloning experiments bind to a specific base sequence and then cleave the DNA backbone at two defined locations, one in each strand. Most restriction enzymes recognize sequences that are palindromic, which means the sequence is identical when read in the opposite direction in the complementary strand (**Table 20.1**). For example, the sequence recognized by the restriction enzyme *Eco*RI is 5′–GAATTC–3′ in the top strand. Read in the opposite direction in the bottom strand, this sequence is also 5′–GAATTC–3′. Such restriction enzymes are useful in cloning because they digest DNA into fragments with **sticky ends**. These DNA fragments have single-stranded ends that hydrogen-bond to other DNA fragments that are cut with the same enzyme because the sticky ends have complementary sequences.

Figure 20.2 shows the action of a restriction enzyme and the insertion of a gene into a vector. This vector carries the *amp*^{R} and *lacZ* genes, whose functions will be discussed later. The restriction enzyme binds to specific sequences in both the vector and chromosomal DNA. It then cleaves the DNA backbones, producing DNA fragments with sticky ends (Figure 20.2, step 1). The sticky ends of a piece of chromosomal DNA and the vector DNA can hydrogen-bond with each other (Figure 20.2, step 2). However, this interaction is not stable, because it involves only a few hydrogen bonds between complementary bases. To establish a permanent connection between two DNA fragments, the sugar-phosphate backbones of the DNA strands must be covalently linked. This linkage is catalyzed by DNA ligase (Figure 20.2, step 3). Recall from Chapter 11 that DNA ligase is an enzyme that catalyzes the formation of a covalent bond between adjacent DNA fragments.

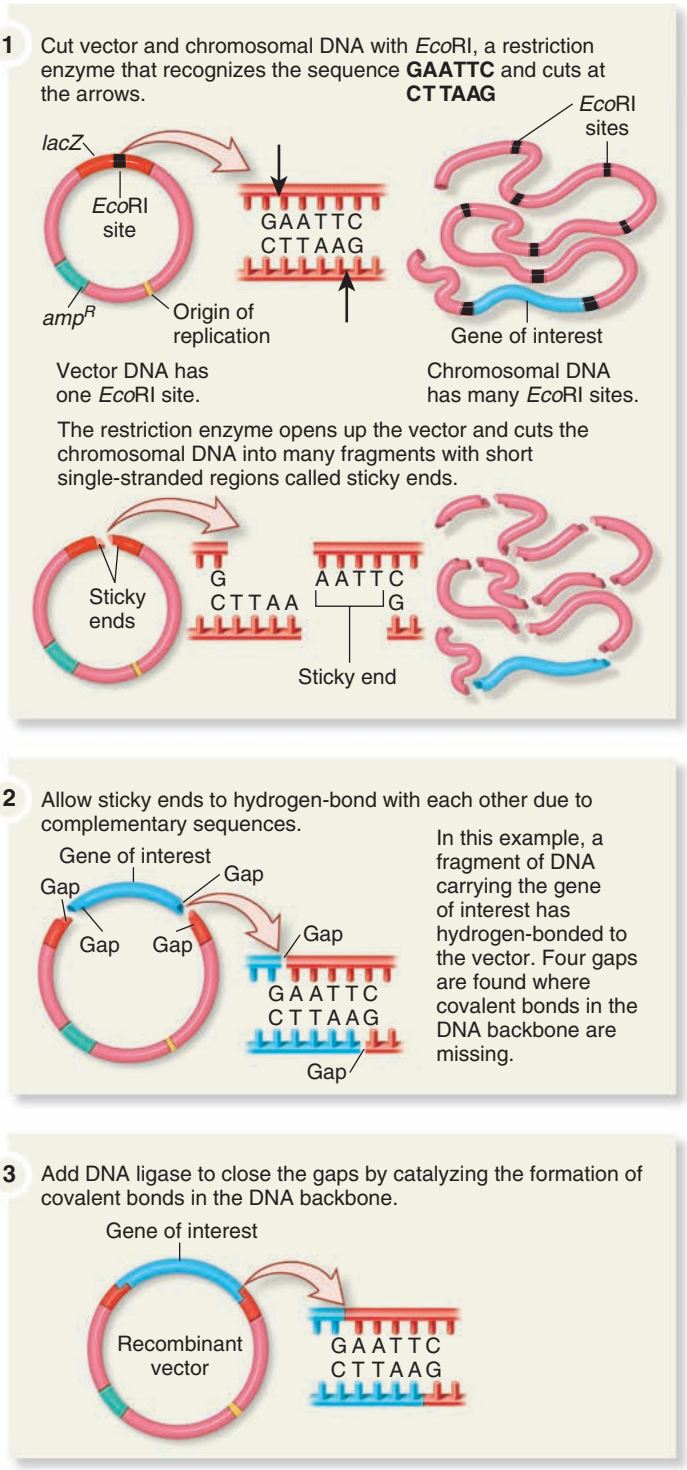


Figure 20.2 Step 2 of gene cloning: The actions of a restriction enzyme and DNA ligase to produce a recombinant vector.

Concept Check: In the procedure shown in this figure, has the gene of interest been cloned?

BioConnections: Look back at Figure 18.11. What are the general properties of plasmids?

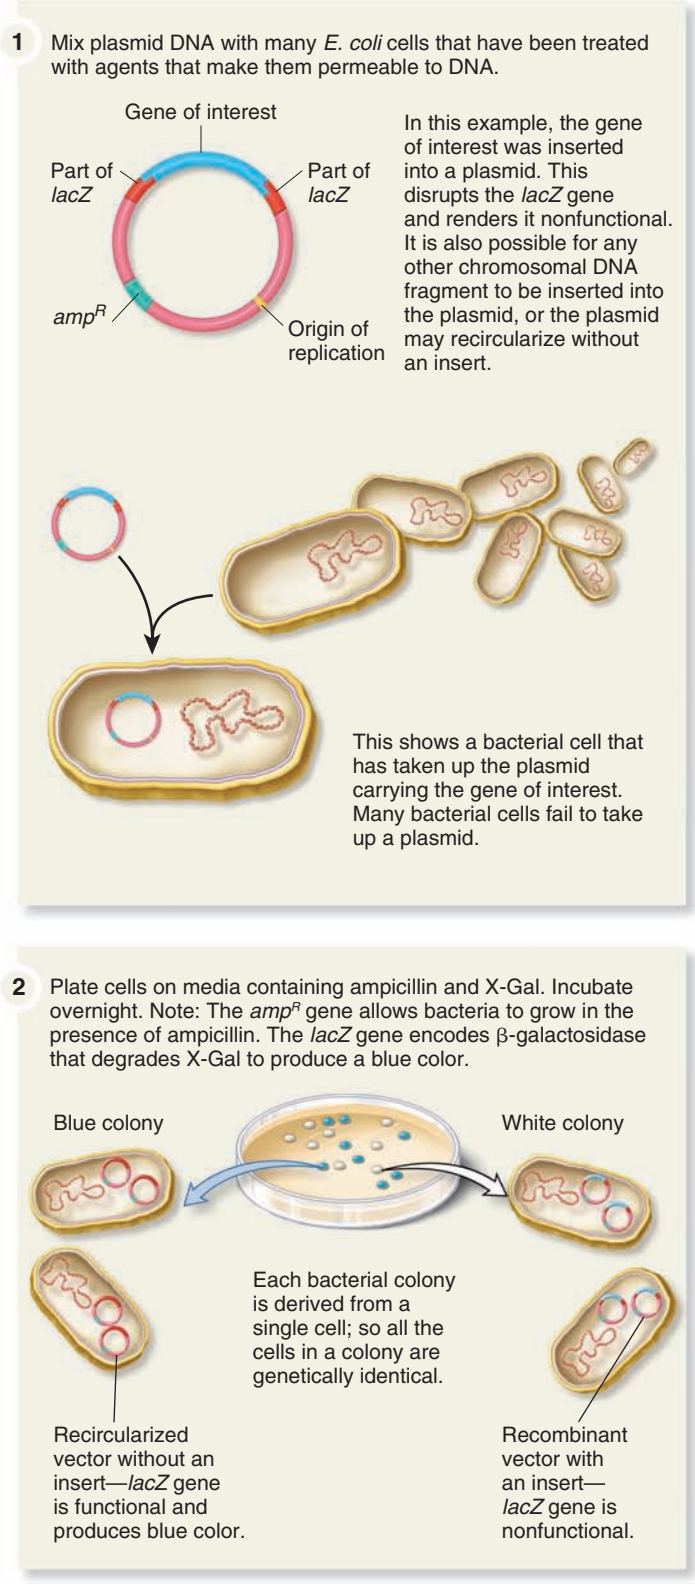

Figure 20.3 Step 3 of gene cloning: Introduction of a recombinant vector into a host cell. For cloning to occur, a recombinant vector is introduced into a host cell, which copies the vector and divides to produce many cells. This produces many copies of the gene of interest.

Concept Check: *In this cloning experiment, what is the purpose of having the lacZ gene in the vector?*

In some cases, the two ends of the vector simply ligate back together, restoring it to its original circular structure; this forms a recircularized vector. In other cases, a fragment of chromosomal DNA may become ligated to both ends of the vector. When this happens, a segment of chromosomal DNA has been inserted into the vector. The result is a vector containing a piece of chromosomal DNA, which is called a **recombinant vector**, or a hybrid vector. Such a vector is ready to be cloned. A recombinant vector may contain the gene of interest, or it may contain a different piece of chromosomal DNA.

Step 3: Putting Recombinant Vectors into Host Cells and Allowing Those Cells to Propagate Achieves Gene Cloning

The third step in gene cloning is the actual cloning of the gene of interest. In this step, the goal is for the recombinant vector carrying the desired gene to be taken up by bacterial cells that have been treated with agents that render them permeable to DNA molecules (**Figure 20.3**). Bacterial cells with the ability to take up DNA are described as **competent**. Some bacterial cells take up a single plasmid, whereas most cells fail to take up a plasmid. The bacteria are then streaked on petri plates containing a bacterial growth medium and ampicillin.

In the experiment shown here, the bacterial cells were originally sensitive to ampicillin. The plasmid already carries an antibiotic-resistance gene, called the *amp*^{R} gene. What is the purpose of this gene in a cloning experiment? Such a gene is called a **selectable marker** because the presence of the antibiotic selects for the growth of cells expressing the *amp*^{R} gene. The *amp*^{R} gene encodes an enzyme that degrades the antibiotic ampicillin, which normally kills bacteria. Bacteria that have not taken up a plasmid are killed by the antibiotic. In contrast, any bacterium that has taken up a plasmid carrying the *amp* ^{R} gene grows and divides many times to form a bacterial colony containing tens of millions of cells. Because each cell in a single colony is derived from the same original cell that took up a single plasmid, all cells within a colony contain the same type of plasmid DNA.

The experimenter also needs a way to distinguish bacterial colonies that contain cells with a recombinant vector from those containing cells with a recircularized vector. In a recombinant vector, a piece of chromosomal DNA has been inserted into a region of the vector that contains the *lacZ* gene, which encodes the enzyme β-galactosidase. The insertion of chromosomal DNA into the vector disrupts the *lacZ* gene, thereby preventing the synthesis of β-galactosidase. By comparison, a recircularized vector has a functional *lacZ* gene. The functionality of *lacZ* can be determined by adding to the growth medium a colorless compound, X-Gal, which is cleaved by β-galactosidase into a blue dye. Bacteria grown in the presence of X-Gal form blue colonies if they produce a functional β-galactosidase enzyme and white colonies if they do not. In this experiment, therefore, bacterial colonies containing recircularized vectors form blue colonies, whereas colonies containing recombinant vectors carrying a segment of chromosomal DNA are white.

After a bacterial cell has taken up a recombinant vector, two subsequent events lead to the production of many copies of that vector. First, when the vector has a highly active origin of replication, the bacterial host cell produces many copies of the recombinant vector per cell. Second, the bacterial cells divide approximately every

20 minutes. Following overnight growth, a population of many millions of bacteria are obtained from a single cell. Each of these bacterial cells contains many copies of the cloned gene. For example, a bacterial colony may comprise 10 million cells, with each cell containing 50 copies of the recombinant vector. Therefore, this bacterial colony has 500 million copies of the cloned gene!

A DNA Library Is a Collection of Many Different DNA Fragments

In a typical cloning experiment, such as the one described in Figures 20.2 and 20.3, the treatment of chromosomal DNA with restriction enzymes actually yields tens of thousands of different DNA fragments. Therefore, after the DNA fragments are ligated individually to vectors, a researcher has a collection of many recombinant vectors, with each vector containing a particular fragment of chromosomal DNA. A collection of recombinant vectors containing DNA fragments from a given organism is known as a **DNA library** (Figure 20.4). Researchers make DNA libraries using the methods shown in Figures 20.2 and 20.3 and then use those libraries to obtain clones of the genes of interest to them.

Two types of DNA libraries are commonly made. The library is called a **genomic library** when the inserts are derived from chromosomal DNA. Alternatively, researchers can isolate mRNA and use the enzyme reverse transcriptase, which is described in Chapter 18, to make DNA molecules using mRNA as a starting material. Such DNA is called **complementary DNA**, or **cDNA**. A **cDNA library** is a collection of recombinant vectors that have cDNA inserts. From a research perspective, an important advantage of cDNA is that it lacks introns—intervening sequences that are not translated into proteins. Because introns can be quite large, it is much simpler for researchers to insert cDNAs into vectors rather than work with chromosomal

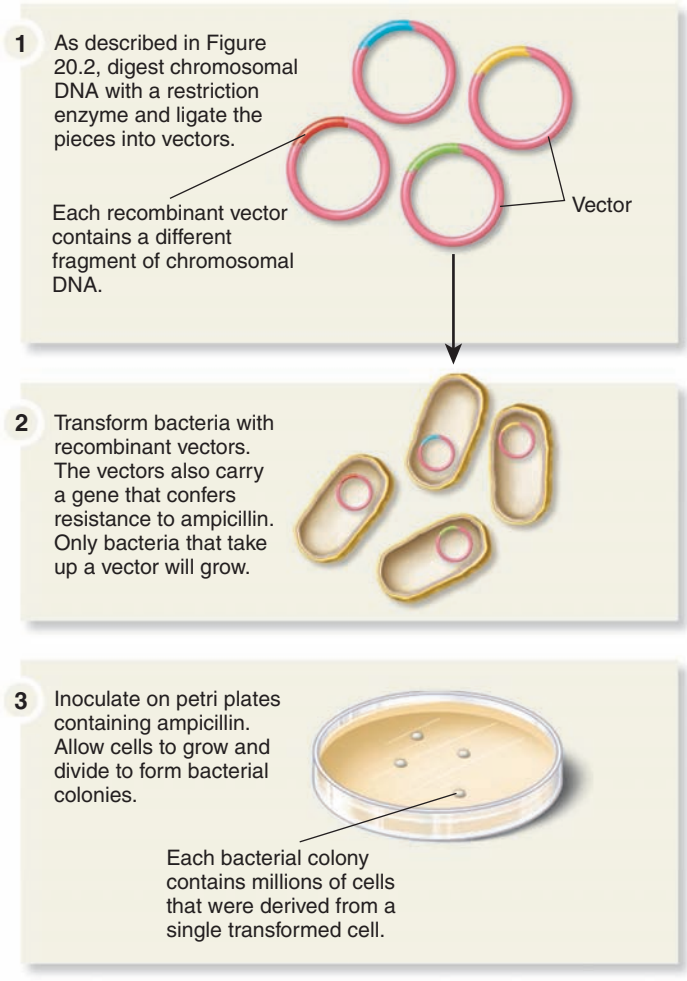

Figure 20.4 A DNA library. Each colony in a DNA library contains a vector with a different piece of chromosomal DNA.

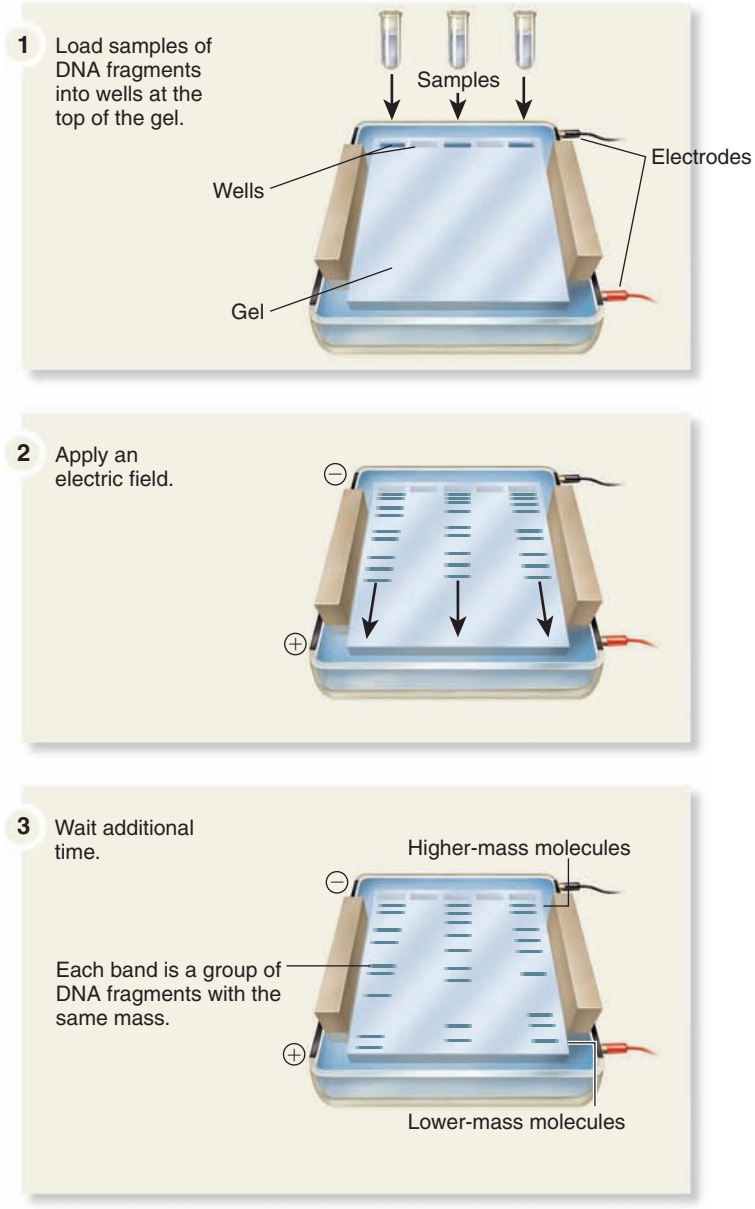

Figure 20.5 Separation of molecules by gel electrophoresis. In this example, samples containing many fragments of DNA are loaded into wells at the top of the gel and then subjected to an electric field that causes the fragments to move toward the bottom of the gel. This separates the fragments according to their masses, with the smaller DNA fragments near the bottom of the gel.

Concept Check: One DNA fragment contains 600 bp and another has 1,300 bp. Following electrophoresis, which would be closer to the bottom of a gel?

DNA if they want to focus their attention on the coding sequence of a gene. In addition, because bacteria do not splice out introns, cDNAs are an advantage if researchers want to express their gene of interest in bacteria.

Gel Electrophoresis Separates Macromolecules, Such as DNA

Gel electrophoresis is a technique for separating macromolecules, such as DNA and proteins, as they migrate through a gel. This method is often used to evaluate the results of a cloning experiment. For example, gel electrophoresis is used to determine the sizes of DNA fragments that have been inserted into recombinant vectors.

Gel electrophoresis can separate molecules based on their charge, size/length, and mass. In the example shown in **Figure 20.5**, gel electrophoresis is used to separate different fragments of chromosomal DNA based on their masses. The flat slab of semisolid gel has depressions at the top called wells where samples are added. A gel made of agarose is usually used to separate relatively large DNA fragments, whereas an acrylamide gel may be used for the precise separation of smaller ones.

An electric field is applied to the gel, which causes charged molecules, either proteins or nucleic acids, to migrate from the top of the gel toward the bottom—a process called electrophoresis. DNA is negatively charged and moves toward the positive end of the gel, which is at the bottom in this figure. Smaller DNA fragments move more quickly through the gel than larger fragments, and therefore are located closer to the bottom of the gel than the larger ones. As the gel runs, the DNA fragments are separated into distinct bands within the gel. The fragments in each band can then be stained with a dye for identification.

Polymerase Chain Reaction (PCR) Is Also Used to Make Many Copies of DNA

As we have seen, one method of cloning involves an approach in which the gene of interest is inserted into a vector, introduced into a host cell, and then propagated. Another technique for copying DNA without the aid of vectors and host cells is a process called **polymerase chain reaction (PCR)**, which was developed by American biochemist Kary Mullis in 1985 (**Figure 20.6**). The goal of PCR is to make many copies of DNA in a defined region, perhaps encompassing a

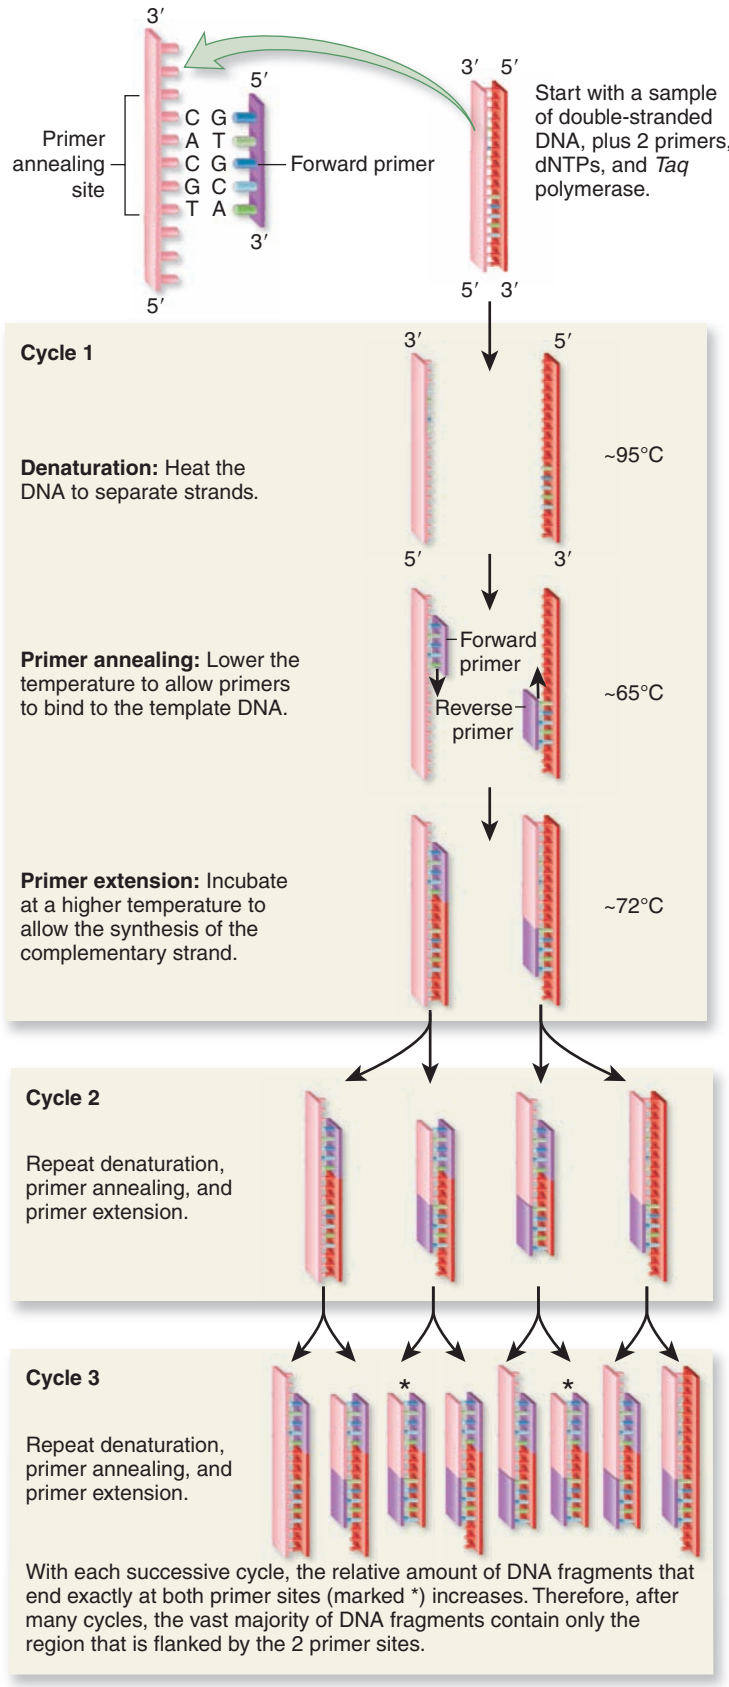

Figure 20.6 Polymerase chain reaction (PCR). During each PCR cycle, the steps of denaturation, primer annealing, and primer extension take place. The net result of PCR is the synthesis of many copies of DNA in the region that is flanked by the two primers. To conduct this type of PCR experiment, researchers must have prior knowledge about the base sequence of the template DNA so they can make primers with base sequences that are complementary to the ends of the template DNA. Note: The temperatures shown in this figure are approximate and may vary depending on the primer sequence and length.

Concept Check: *Why do the PCR primers bind specifically to the primer-annealing sites?*

BioConnections: *Look back at Figure 11.16. Why are primers needed in a PCR experiment?*

gene or part of a gene. Several reagents are required for the synthesis of DNA. First, two different primers are needed that are complementary to sequences at each end of the DNA region to be amplified. These primers are usually about 20 nucleotides long. One primer is called the forward primer, and the other is the reverse primer. PCR also requires all four deoxynucleoside triphosphates (dNTPs) and a heat-stable form of DNA polymerase called *Taq* polymerase. *Taq* polymerase is isolated from the bacterium *Thermus aquaticus*, which lives in hot springs and can tolerate temperatures up to 95°C. A heat-stable form of DNA polymerase is necessary because PCR involves the use of high temperatures that would inactivate most other natural forms of DNA polymerase.

To make copies, a series of three steps is followed (see Figure 20.6):

1. A sample of chromosomal DNA, called the template DNA, is heated to separate (denature) the DNA into single-stranded molecules.
2. Then the primers bind to the DNA as the temperature is lowered. The binding of the primers to the specific sites in the template DNA is called annealing.
3. After the primers have annealed, the temperature is slightly raised and *Taq* polymerase uses dNTPs to catalyze the synthesis of complementary DNA strands, thereby doubling the amount of DNA in the region that is flanked by the primers. This step is called primer extension because the length of the primers is extended by the synthesis of DNA.

The sequential process of denaturation–primer annealing–primer extension is repeated many times in a row. This method is called a chain reaction because the products of each previous step are used as reactants in subsequent steps. A device that controls the temperature and automates the timing of each step, known as a thermocycler, is used to carry out PCR. The PCR technique can amplify the sample of DNA by a staggering amount. After 30 cycles of denaturation, primer annealing, and primer extension, a DNA sample will have increased 2^{30}-fold, approximately a billionfold, in a few hours!

20.2 Genomics: Techniques for Studying Genomes

Learning Outcomes:

1. Distinguish between genomics and functional genomics.
2. Describe the features of BACs and YACs and their use in mapping chromosomes.
3. Outline the steps of DNA sequencing using the dideoxy chain-termination method.
4. Explain what a DNA microarray is and how it is used to identify the genes expressed by an organism.

As discussed throughout Unit III, the genome is the complete genetic composition of a cell, organism, or species. As genetic technology has progressed over the past few decades, researchers have gained an increasing ability to analyze the composition of genomes as a whole unit. The term genomics refers to the use of techniques to study a genome. Segments of chromosomes are cloned and analyzed in progressively smaller pieces, the locations of which are known on the intact chromosomes. This is the mapping phase of genomics. The mapping of a genome ultimately progresses to the determination of the complete DNA sequence, which provides the most detailed description available of an organism's genome at the molecular level. By comparison, **functional genomics** studies the expression of a genome. For example, functional genomics can be used to analyze which genes are turned on or off in normal versus cancer cells. In this section, we will consider a few of the methods that are used in genomics and functional genomics.

BAC Cloning Vectors Are Used to Make Contigs of Chromosomes to Map a Genome

In general, most plasmid and viral vectors can accommodate inserts only a few thousand to perhaps tens of thousands of nucleotides in length. For large eukaryotic genomes, which may contain over 1 billion bp (base pairs), cloning the entire genome is much easier when a cloning vector can accept very large chromosomal DNA inserts. If a plasmid or viral vector has a DNA insert that is too large, it will have difficulty with DNA replication and is likely to suffer deletions in the insert. By comparison, a type of cloning vector known as a **bacterial artificial chromosome (BAC)** can reliably contain much larger inserted DNA fragments. BACs are derived from large plasmids called F factors (see Chapter 18). They can contain inserts up to 500,000 bp. BACs are used in genomic research in the same way as other types of vectors. Similarly, yeast artificial chromosomes (YACs) are used as vectors in yeast. An insert in a YAC can be several hundred thousand to perhaps 2 million bp in length.

The term **mapping** refers to the process of determining the relative locations of genes or other DNA segments along a chromosome. After many large fragments of chromosomal DNA have been inserted into BACs or YACs, the first step of mapping is to determine the relative locations of the cloned pieces as they would occur in an intact chromosome. This is called **physical mapping**. Each vector contains a clone with regions that overlap those of its neighbors (**Figure 20.7**). For example, clones 7 and 8 both carry gene *K*. These overlapping regions allow researchers to identify the order of the clones along the chromosome. To obtain a complete physical map of a chromosome, researchers assemble the clones into a series of contiguous overlapping DNA fragments known as a **contig**.

The Dideoxy Chain-Termination Method Is Used to Determine the Base Sequence of DNA

Another phase of genomic research is **DNA sequencing**, which is a method of determining the base sequence of DNA. Scientists can learn a great deal of information about the function of a gene if its base sequence is known. For example, the investigation of genetic sequences has been vital in our understanding of the genetic basis of human diseases.

A commonly used method for DNA sequencing, developed in 1977 by English biochemist Frederick Sanger and colleagues, is known as the **dideoxy chain-termination method**, or more simply, **dideoxy sequencing**. Dideoxy sequencing is based on our knowledge

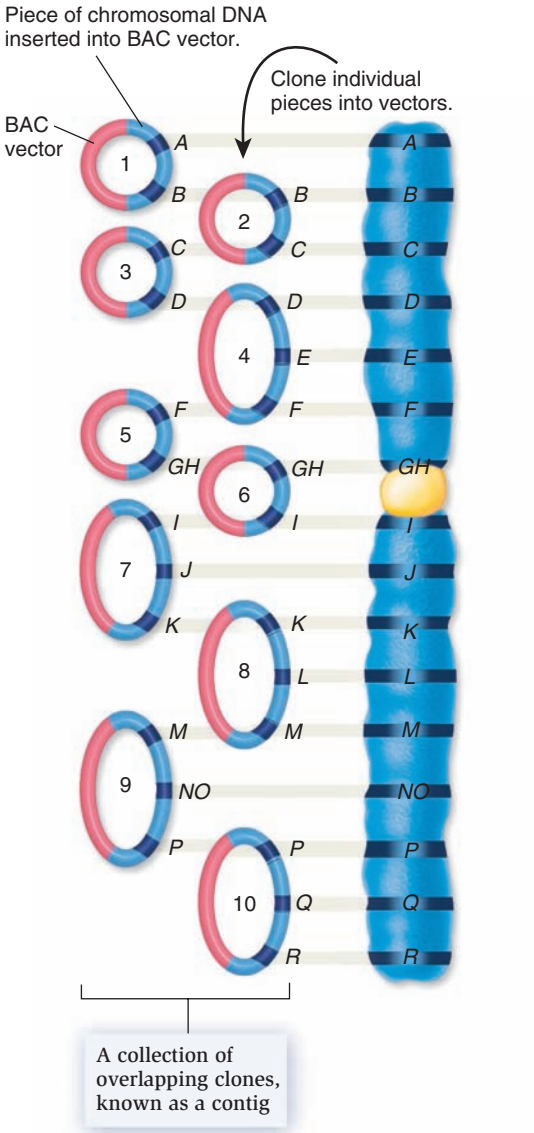

Figure 20.7 A contig. As shown here, a contig is a collection of clones that have overlapping pieces of DNA from a particular chromosome. The numbers denote the order of the members of the contig. The chromosome is labeled with letters that denote the locations of particular genes. The members of the contig have overlapping regions that have the same genes, which allows them to be placed in their proper order.

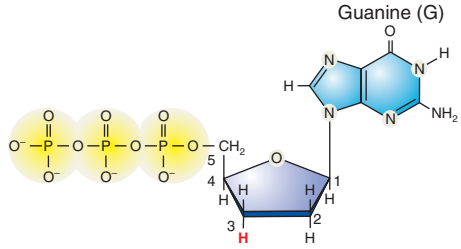
Concept Check: *What does it mean when we say that two members of a contig have overlapping regions?*



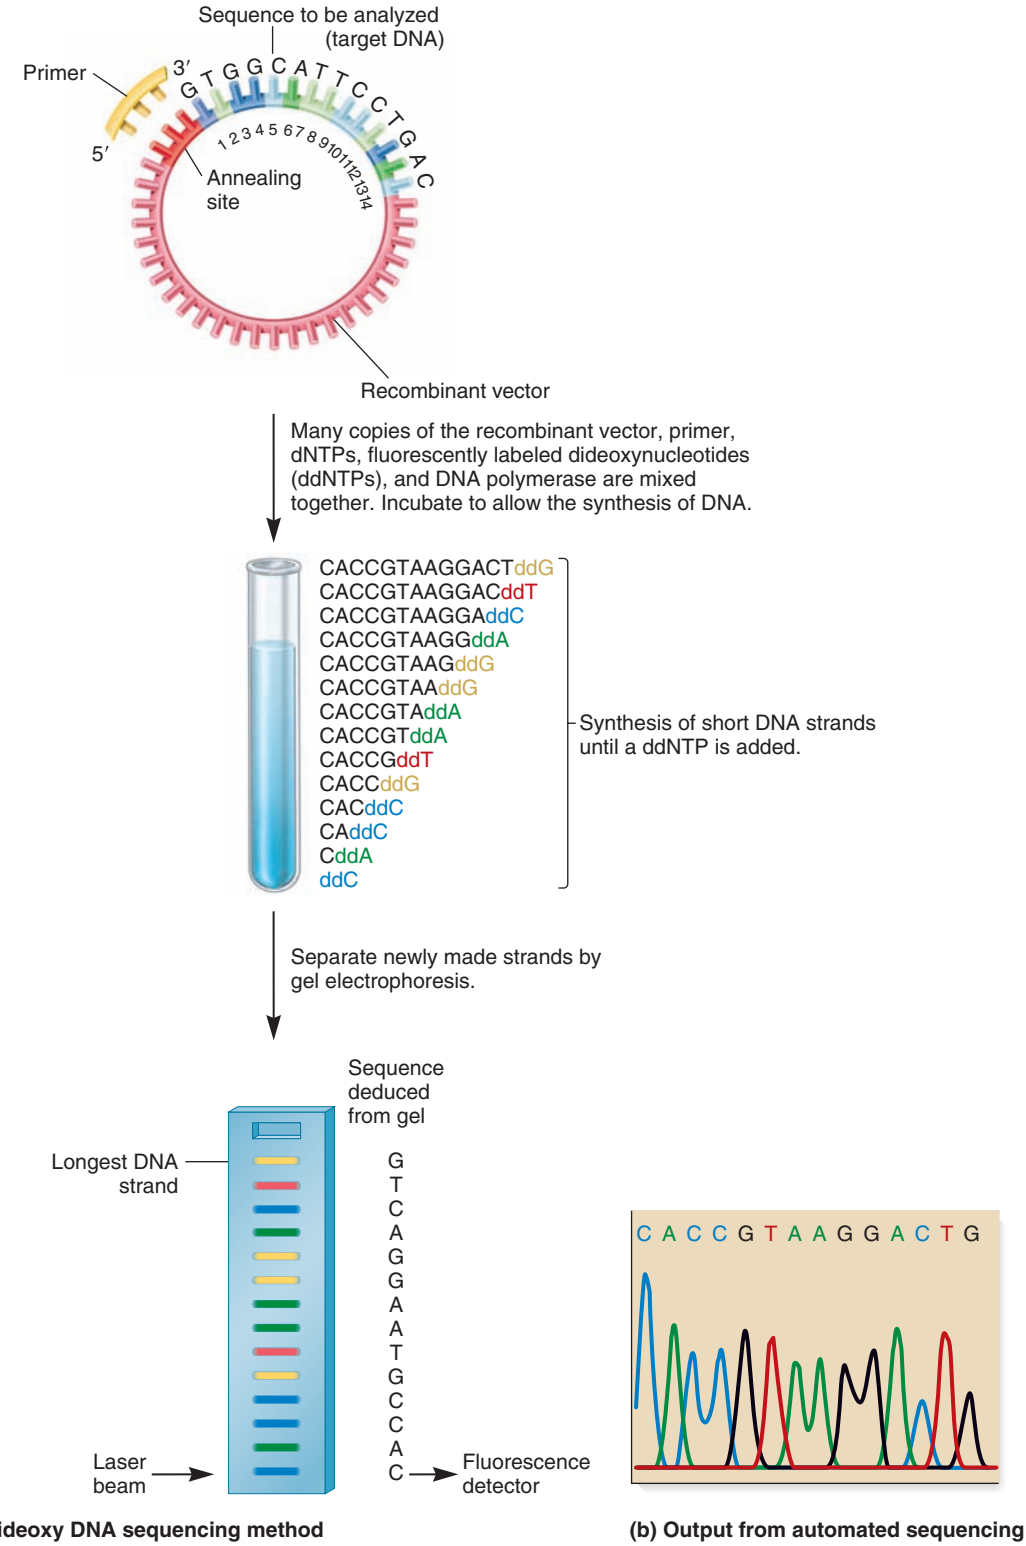


Figure 20.8 Structure of a dideoxynucleotide. This figure shows the structure of dideoxyguanosine triphosphate (ddGTP). It has a hydrogen, shown in red, instead of a hydroxyl group at the 3′ position. The prefix dideoxy- means it has two (di) missing (de) oxygens (oxy) compared with ribose, which has —OH groups at both the 2′ and 3′ positions.

of DNA replication. As described in Chapter 11, DNA polymerase connects adjacent deoxynucleoside triphosphates (dNTPs) by catalyzing a covalent linkage between the phosphate group at the 5′ position on one nucleotide and the —OH group at the 3′ position on the previous nucleotide. Chemists, however, can synthesize nucleotides, called dideoxynucleoside triphosphates (ddNTPs), that are missing the —OH group at the 3′ position (**Figure 20.8**). What happens if a ddNTP is incorporated during DNA replication? If a ddNTP is added to a growing DNA strand, the strand can no longer grow because the 3′ —OH group, the site of attachment for the next nucleotide, is missing. This ending of DNA synthesis is called chain termination.

Before describing the steps of this DNA sequencing protocol, let's first consider the DNA segment that is analyzed in a sequencing experiment. The segment of DNA to be sequenced, the target DNA, must be obtained in large amounts by using the gene cloning techniques that were described earlier in this chapter. In **Figure 20.9a**, the target DNA was inserted into a vector next to a primer-annealing site, the place where a primer will bind. The target DNA is initially double-stranded, but Figure 20.9a shows the DNA after it has been denatured into a single strand by heat treatment.

Let's now examine the steps involved in DNA sequencing. Many copies of this single-stranded template DNA are placed into a tube and mixed with primers that bind to the primer-annealing site. DNA polymerase and all four types of regular dNTPs are also added. In addition, a low concentration of the four possible dideoxynucleoside triphosphates—ddGTP, ddATP, ddTTP, and ddCTP—is added. Each type of ddNTP is tagged with a different colored fluorescent molecule; typically ddA is green, ddT is red, ddG is yellow, and ddC is blue. The tube is then incubated to allow DNA polymerase to synthesize strands that are complementary to the target DNA sequence. However, addition of a ddNTP causes DNA synthesis to terminate early, preventing further elongation of the strand. For example, let's consider ddTTP. Synthesis of new DNA strands stops at the sixth or thirteenth position after the annealing site if a ddTTP, instead of a dTTP, is incorporated into the growing DNA strand (Figure 20.9a). This means the target DNA has a complementary A at the sixth and thirteenth positions. Eventually, a set of fluorescently tagged strands results, with the color of the ddNTP representing the last nucleotide added to the strand.

After the samples have been incubated for several minutes, the newly made DNA strands are separated according to their lengths by subjecting them to gel electrophoresis. This can be done using a slab gel, as shown in Figure 20.9a, or more commonly by running them through a gel-filled capillary tube. The shorter strands move to the bottom of the gel more quickly than the longer ones. Electrophoresis is continued until each band emerges from the bottom of the gel, where a laser excites the fluorescent dye. A fluorescence detector records the amount of fluorescence emission at four wavelengths, corresponding to the four dyes.

(a) Dideoxy DNA sequencing method

(b) Output from automated sequencing

Figure 20.9 **DNA sequencing by the dideoxy method.** **(a)** The procedure of dideoxy sequencing using fluorescently labeled ddNTPs. **(b)** This method uses a fluorescence detector that measures the four kinds of ddNTPs as they emerge from the gel.

Concept Check: *What happens when a ddNTP is incorporated into a growing DNA strand?*

An example of a printout from a fluorescence detector is shown in **Figure 20.9b**. The peaks of fluorescence correspond to the DNA sequence that is complementary to the target DNA. The heights of the fluorescent peaks are not always the same, because ddNTPs get incorporated at some sites more readily than at others. Note that ddG is usually labeled with a yellow dye, but it is converted to black ink on the printout for ease of reading. Though improvements in automated sequencing continue to be made, a typical sequencing run can provide a DNA sequence that is approximately 700–900 bases long, and perhaps even longer.

Researchers are also developing alternative methods to dideoxy chain termination in order to sequence DNA. For example, pyrosequencing is a newer method of DNA sequencing that is based on the detection of released pyrophosphate (PP_i) during DNA synthesis.

Genomes & Proteomes Connection

A Microarray Can Identify Which Genes Are Transcribed by a Cell

Let's now turn our attention to functional genomics. Researchers have developed an exciting new technology, called a **DNA microarray**, that is used to monitor the expression of thousands of genes simultaneously. A DNA microarray is a small silica, glass, or plastic slide that is dotted with many different sequences of single-stranded DNA, each corresponding to a short sequence within a known gene. Each spot contains multiple copies of a known DNA sequence. For example, one spot in a microarray may correspond to a sequence within the β-globin gene; another might correspond to a different gene, such as a gene that encodes a glucose transporter. A single slide contains tens of thousands of different spots in an area the size of a postage stamp. Some microarrays are produced using a technology that "prints" spots of DNA sequences onto a slide, similar to the way that an inkjet printer deposits ink on paper.

What is the purpose of using a DNA microarray? In the experiment shown in **Figure 20.10**, the goal is to determine which genes are transcribed into mRNA from a particular sample of cells. In other words, which genes in the genome are expressed? To conduct this experiment, mRNAs were isolated from the cells and then used to make fluorescently labeled cDNAs. The labeled cDNAs were then incubated with a DNA microarray. Each single-stranded DNA in the microarray corresponds to the coding strand—the strand that has a sequence that is similar to an mRNA. Those cDNAs that are complementary to the DNAs in the microarray hybridize, thereby remaining bound to the microarray. The array is washed and then analyzed using a microscope equipped with a computer that scans each spot and generates an image of the spots' relative fluorescence.

If the fluorescence intensity in a spot is high, a large amount of cDNA was in the sample that hybridized to the DNA at this location. For example, if the β-globin gene was expressed in the cells being tested, a large amount of cDNA for this gene would be

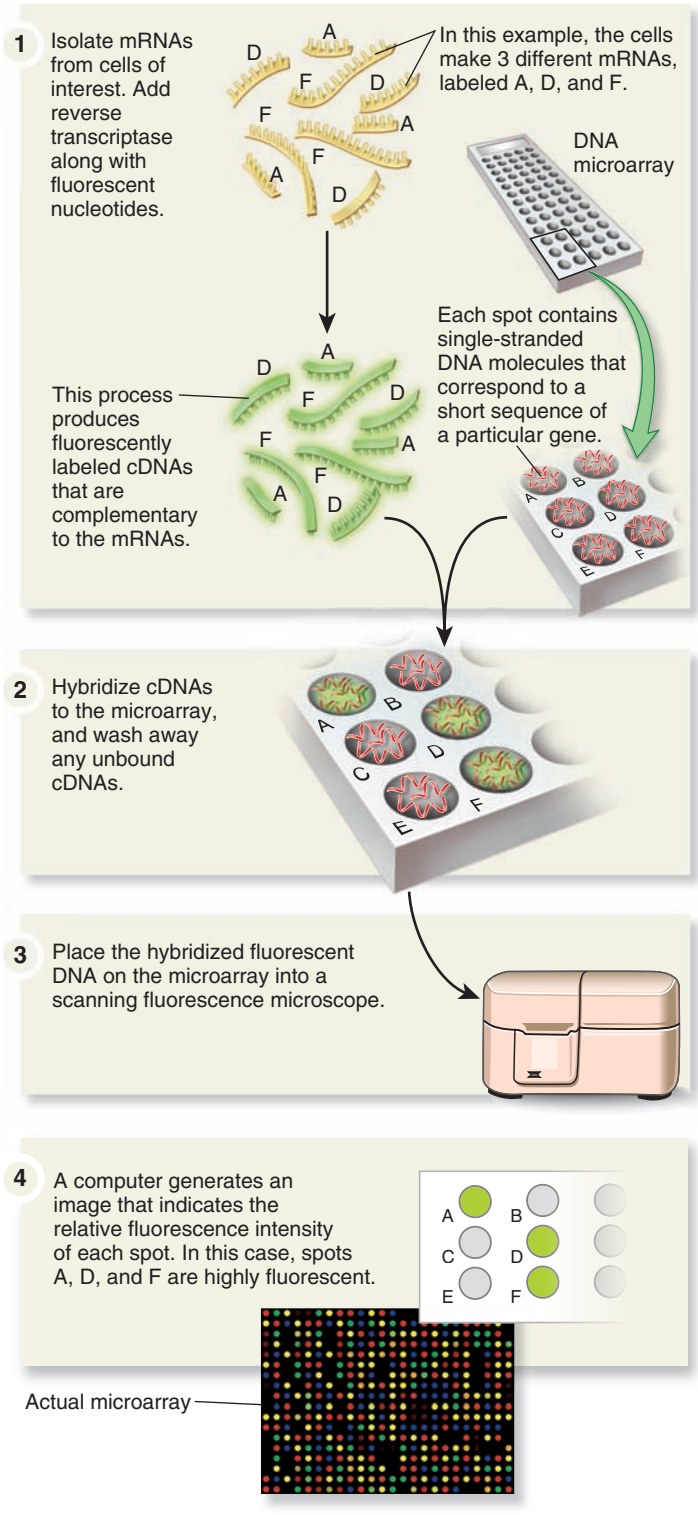

Figure 20.10 Identifying transcribed genes within a DNA microarray. In this simplified example, only three cDNAs specifically hybridize to spots on the microarray. Those genes were expressed in the cells from which the mRNAs were isolated. In an actual experiment, the array typically contains hundreds or thousands of different cDNAs and tens of thousands of different spots.

Concept Check: *If a fluorescent spot appears on a microarray, what information does this provide regarding gene expression?*

made, and the fluorescence intensity for that spot would be high. Because the DNA sequence of each spot is already known, a fluorescent spot identifies cDNAs that are complementary to those DNA sequences. Furthermore, because the cDNAs were generated from mRNAs, this technique identifies genes that have been transcribed in a particular cell type under a given set of conditions. However, the amount of protein encoded by an mRNA may not always correlate with the amount of mRNA, due to variation in the rates of mRNA translation and protein degradation.

Thus far, the most common use of DNA microarrays is to study gene expression patterns. In addition, the technology of DNA microarrays has found several other important uses, as described in **Table 20.2**.

Table 20.2 Applications of DNA Microarrays

Application	Description
Cell-specific gene expression	A comparison of microarray data using cDNAs derived from mRNAs of different cell types can identify genes that are expressed in a cell-specific manner.
Gene regulation	Because environmental conditions play an important role in gene regulation, a comparison of microarray data using cDNAs derived from mRNAs from cells exposed to two different environmental conditions may reveal genes that are induced under one set of conditions and repressed under another set.
Elucidation of metabolic pathways	Genes that encode proteins that participate in a common metabolic pathway are often expressed together and can be revealed from a microarray analysis.
Tumor profiling	Different types of cancer cells exhibit striking differences in their gene expression profiles, which can be revealed by a DNA microarray analysis. This approach is gaining use as a tool to classify tumors that are sometimes morphologically indistinguishable.
Genetic variation	A mutant allele may not hybridize to a spot on a microarray as well as a wild-type allele. Therefore, microarrays are gaining use as a tool for detecting genetic variation. This application has been used to identify disease-causing alleles in humans and to identify mutations that contribute to quantitative traits in plants and other species.
Microbial strain identification	Microarrays can distinguish between closely related bacterial species and subspecies.

20.3 Biotechnology

Learning Outcomes:

1. Define genetically modified organism, and list examples of useful products such organisms can make.
2. Describe how recombinant microorganisms are used to make medicines such as insulin.
3. Distinguish between a gene knockout versus a gene replacement, and describe how both are used in the study of human diseases.
4. Give examples of using transgenic livestock to make medical products.
5. Describe the use of *Agrobacterium tumefaciens* to produce transgenic plants.
6. Outline the steps used to produce Dolly, the first cloned mammal.
7. Explain the technique of DNA fingerprinting, and list its common uses.
8. Describe the technique of gene therapy.

Biotechnology is defined as the use of living organisms, or products from living organisms, as a way to benefit humans. Although the term has become associated with molecular genetics, biotechnology is not a recent development. Its use started about 12,000 years ago, when humans began to domesticate animals and plants for the production of food. Since that time, many species of microorganisms, plants, and animals have become routinely used in agriculture and medicine. Beginning in the 1970s, genetic engineering has provided new ways to make use of living organisms to benefit humans.

In this section, we will consider the applications of biotechnology that involve the genetic engineering of microorganisms, plants, and animals. We will also examine several topics that you often hear about in the news, such as the cloning of mammals, DNA fingerprinting, and gene therapy.

Genetically Modified Organisms Make Products That Are Useful to People

The term **genetically modified organism (GMO)** is used to describe an organism whose genome has been modified using molecular techniques such as gene cloning. **Bioproduction** (also called biomanufacturing) is the production of drugs, vaccines, cell therapies, and other useful products by living organisms or cells from living organisms. Many different microorganisms, plants, and animals have been genetically modified for the purpose of bioproduction. **Table 20.3** presents a few examples. The methods for producing such GMOs are explained later.

When a GMO carries a gene from another species, it is called a **transgenic organism**. Researchers working in the field of biotechnology have produced many GMOs that synthesize products that the unmodified organisms do not make. For example, the components of human insulin are made by genetically modified bacteria. This process is described next.

Important Medicines Are Produced by Genetically Modified Microorganisms

Several important medicines are now produced by genetically modified microorganisms. These include tissue plasminogen activator (TPA), used to dissolve blood clots in heart attack patients; factor VIII, used to treat people with the disease hemophilia; and insulin, used to treat people with diabetes. In 1982, the U.S. Food and Drug Administration approved the sale of human insulin made by recombinant bacteria. In healthy individuals, insulin is produced by the beta cells of the pancreas. Insulin regulates several physiological processes, including the uptake of glucose into muscle cells. Persons

Table 20.3 Examples of Products Made by Genetically Modified Organisms

Product	GMO(s) Used	Description
Insulin	*E. coli*	The method for using bacteria to make insulin is described in Figure 20.11. Insulin is used to treat patients with insulin-dependent (type 1) diabetes.
Factor IX	Sheep	A method for using transgenic animals to make human proteins is described in Figure 20.12. Factor IX is a blood-clotting protein used to treat a certain type of hemophilia.
Biofuels	Algae	Genetically modified algae are used to produce biodiesel, biobutanol, biogasoline, methane, and ethanol.
Vaccines	Bacteria, yeasts, mammalian cells, plants	GMOs that produce proteins normally made by pathogenic organisms are used for vaccine production.

with insulin-dependent diabetes cannot synthesize an adequate amount of insulin due to a defect in their beta cells. Today, people like Jacob, who was introduced at the beginning of the chapter, are usually treated with human insulin that is made by genetically engineered bacteria. Prior to 1982, insulin was isolated from pancreases removed from cattle and pigs. Unfortunately, in some cases, diabetic individuals developed an allergic response to cow and pig insulin. These patients had to use expensive combinations of insulin from human cadavers and other animals. Now, they can use human insulin made by recombinant bacteria.

Insulin is a hormone composed of two polypeptides: the A and B chains, that are held together with disulfide bonds. To produce this hormone, the coding sequence of the A or B chains is inserted into a plasmid vector next to the coding sequence of the *E. coli* protein β-galactosidase (**Figure 20.11**). After such vectors are introduced into bacteria, the cells produce many copies of a fusion protein (β-gal-insulin) comprising β-galactosidase and the A or B chain. Why is this step done? The reason is because the A and B chains are rapidly degraded when expressed in bacterial cells by themselves. The fusion proteins, however, are not. These fusion proteins are then extracted from the bacterial cells and treated with a chemical, cyanogen bromide (CNBr), which cleaves a peptide bond at a methionine (Met) that is found at the end of the β-galactosidase sequence, thereby separating β-galactosidase from the A or B chain. The A and B chains are purified and mixed together under conditions in which they can fold and associate with each other via disulfide bonds to form functional insulin hormone molecules.

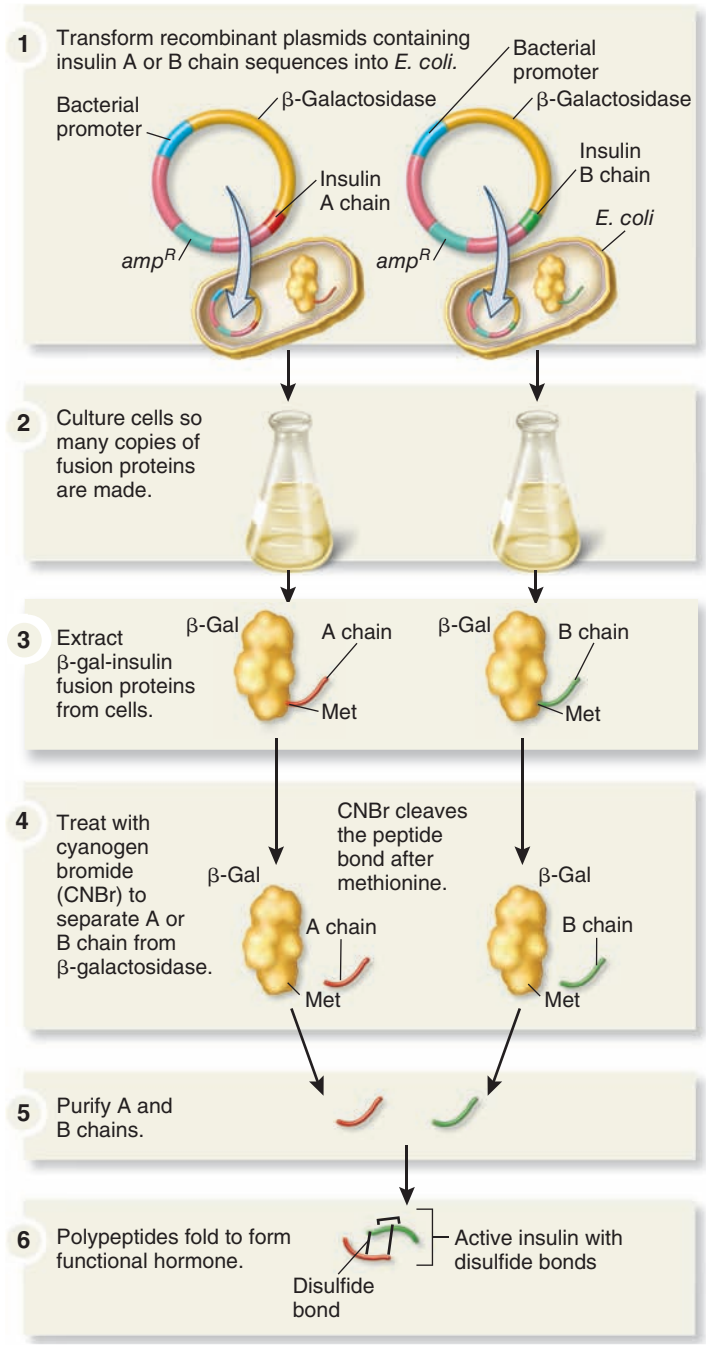

Figure 20.11 The use of bacteria to make human insulin.

BIOLOGY PRINCIPLE Biology affects our society. This method of making insulin, which was developed by researchers, is now used to make insulin for most people suffering from insulin-dependent diabetes.

Concept Check: Why are the A and B chains made as fusion proteins with β-galactosidase?

Gene Replacements and Knockouts Are Used to Understand Gene Function and Human Disease

Let's now turn our attention to the genetic engineering of animals. Researchers can introduce a cloned gene into an oocyte, a fertilized egg, or into embryonic cells to produce animals that carry the cloned gene. Such GMOs are typically made in two ways.

- In some cases, the cloned gene inserts randomly into the genome and results in **gene addition**—the insertion of a cloned gene into the genome.
- Alternatively, a cloned gene may recombine with the normal gene on a chromosome, a phenomenon called **gene replacement**.

For eukaryotic species that are diploid, only one of the two copies is initially replaced. In other words, the initial gene replacement produces a heterozygote carrying one normal copy of the gene and one copy that has been replaced with a cloned gene. Heterozygotes can be crossed to each other to obtain homozygotes, which carry both copies of the cloned gene. If the cloned gene carries a mutation that inactivates the normal gene's function, such a homozygote is said to have undergone a **gene knockout**. The inactive cloned gene has replaced both copies of the normal gene, and the normal gene's function is said to be inoperative, or knocked out. Gene replacements and gene knockouts have become powerful tools for understanding gene function.

A particularly exciting avenue of gene replacement research is its application in the study of human disease. As an example, let's consider the disease cystic fibrosis (CF), which is one of the most common and severe inherited human disorders. In humans, the mutant gene that causes CF has been identified. Likewise, the homologous gene in mice was later identified. Using the technique of gene replacement, researchers have produced mice that are homozygous for the same type of mutation that is found in humans with CF. Such mice exhibit disease symptoms resembling those found in humans, namely, respiratory infections and digestive abnormalities. Why is this approach useful? These mice can be used as model organisms to study this human disease. Furthermore, these mice have been used to test the effects of various therapies for treating the disease.

Biotechnology Holds Promise in Producing Transgenic Livestock

The technology of producing transgenic mice has been extended to other animals, and much research is under way to develop transgenic species of livestock, including fish, sheep, pigs, goats, and cattle. A novel avenue of research involves the production of medically important proteins in the mammary glands of livestock. This approach is sometimes called **molecular pharming**. (The word pharming refers to the use of genetically engineered farm animals or crops to make pharmaceuticals.) Several human proteins have been successfully produced in the milk of domestic livestock such as sheep, goats, and cattle. These include factor IX to treat a certain type of hemophilia, tissue plasminogen activator (TPA) to dissolve blood clots, and α_1-antitrypsin to treat emphysema.

How are human proteins, such as hormones, produced in the milk of livestock? As we learned in Chapter 13, gene regulation may promote the expression of genes in certain cell types. Researchers have identified specific genes that are transcribed only in lactating mammary cells. One example is the gene that encodes β-lactoglobulin, a protein that is found in the milk of sheep and cows. One strategy for producing a human hormone in the milk of livestock is to clone the human hormone gene into a plasmid vector next to the β-lactoglobulin promoter (**Figure 20.12**). The plasmid is then injected into an oocyte, such as a sheep oocyte, where it integrates into the genome. The egg is then fertilized by exposure to sperm and implanted into the uterus of a female sheep. The resulting offspring carries the cloned gene. If the offspring is a female, the protein encoded by the human gene will be expressed within the mammary gland and secreted into the milk. The milk is then obtained from the animal, and the human protein isolated and purified.

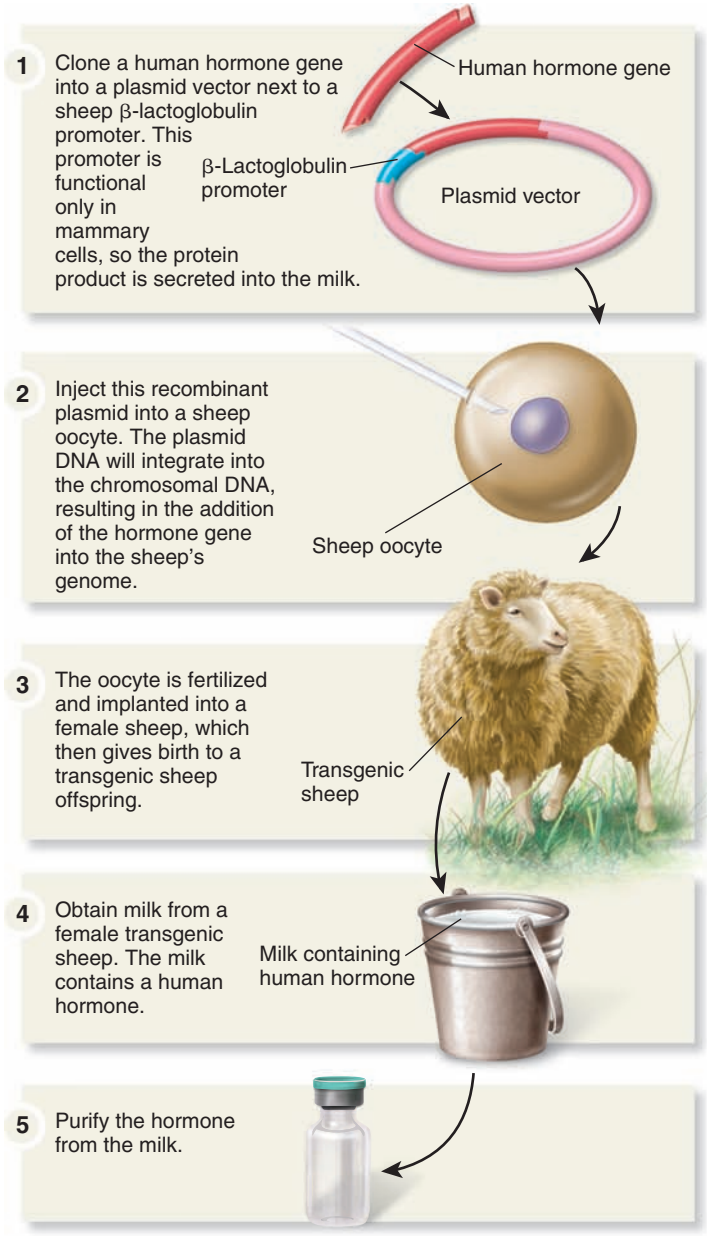

Figure 20.12 **Molecular pharming.**

Compared with the production of proteins in bacteria, one advantage of molecular pharming is that certain proteins are more likely to function properly when expressed in mammals. This may be due to post-translational modifications of proteins that occur in mammals but not in bacteria. In addition, certain proteins may be degraded rapidly or folded improperly when expressed in bacteria. Furthermore, the yield of recombinant proteins in milk can be quite large. Each dairy cow, for example, produces about 10,000 liters of milk per year. In some cases, a transgenic cow can produce approximately 1 g/L of the transgenic protein in its milk.

BIO TIPS **THE QUESTION** *Factor IX is a protein involved in blood clotting. People with a certain type of hemophilia are unable to make this protein, and their blood does not clot properly. Describe the strategy you would follow to make a transgenic sheep that produces factor IX in its milk.*

TOPIC ***What topic in biology does this question address?*** The topic is molecular pharming. More specifically, the question is about producing a human protein in the milk of sheep.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you know that factor IX is a protein involved in blood clotting and that people with a certain type of hemophilia can't produce this protein. From your understanding of the topic, you may remember that creating a transgenic sheep that produces factor IX in its milk involves inserting the human gene into a plasmid vector next to a β-lactoglobulin promoter and then introducing the recombinant plasmid into the oocyte of a sheep.

PROBLEM-SOLVING STRATEGY ***Design an experiment.*** One strategy to solve this problem is to outline the steps involved in producing proteins in the milk of livestock. Remember that milk proteins are encoded by genes whose promoters and regulatory sequences direct the expression of these genes within the cells of the mammary gland.

ANSWER

1. *To get factor IX expressed in the sheep's mammary glands, the first step is to link the promoter and regulatory sequences from the gene that encodes β-lactoglobulin to the coding sequence of the human gene that encodes factor IX.*
2. *This modified gene is then introduced into a sheep oocyte, which is fertilized, and implanted into the uterus of a female sheep.*
3. *The sheep gives birth to a transgenic offspring. If it is a female, the milk may contain the hormone of interest.*
4. *Purify the hormone from the milk.*

Agrobacterium tumefaciens Is Used to Make Transgenic Plants

The production of transgenic plants is somewhat easier than producing transgenic animals because many somatic tissues from plants are totipotent, which means that an entire organism can be regenerated from such tissues. Therefore, a transgenic plant can be made by the introduction of cloned genes into somatic tissue, such as the tissue of a leaf. After the cells of a leaf have become transgenic, an entire plant can be regenerated by treating the leaf with plant growth hormones that cause it to form roots and shoots. The result is an entire plant that is transgenic.

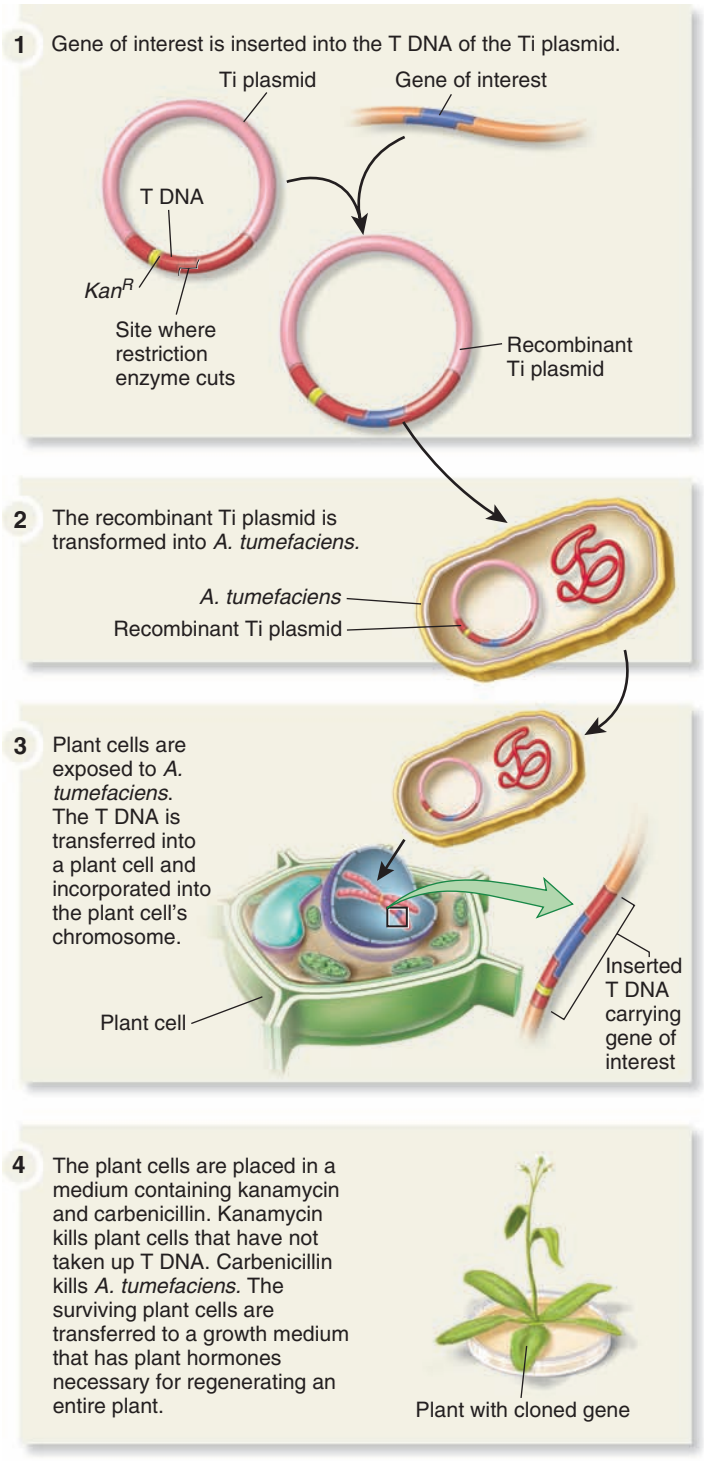
Molecular biologists often use the bacterium *Agrobacterium tumefaciens* to produce transgenic plants. This bacterium contains a plasmid known as the **Ti plasmid**, for tumor-inducing plasmid. The plasmid has a region called T DNA (for transferred DNA) that is transferred from the bacterium to the plant cell and becomes integrated into the plant cell's genome. After this occurs, genes within the T DNA are expressed, causing uncontrolled plant cell growth. This produces a crown gall tumor, a bulbous growth on the plant. Natural strains of *A. tumefaciens* infect many different species of plants, and researchers have developed strains that have an even greater capacity to infect different plant species.

Researchers have modified the Ti plasmid to use it as a vector to introduce a gene of interest into plant cells. In the modified Ti plasmid, the genes that cause a crown gall tumor have been removed or inactivated. In addition, the T DNA carries a selectable marker gene to allow selection of plant cells that have taken up the T DNA. Kan^R, a gene that provides resistance to the antibiotic kanamycin, is commonly used as a selectable marker. Also, the Ti plasmid used in cloning experiments is modified to contain unique restriction sites for the convenient insertion of any gene of interest.

Figure 20.13 shows the general strategy for producing transgenic plants via T DNA–mediated gene transfer. A gene of interest is inserted into the T DNA of a genetically engineered Ti plasmid and then introduced into *A. tumefaciens*. Plant cells are then exposed to *A. tumefaciens* carrying the Ti plasmid. After allowing time for T DNA transfer, the plant cells are grown on a solid medium that contains the antibiotics kanamycin and carbenicillin. Kanamycin kills any plant cells that have not taken up the T DNA, and carbenicillin kills *A. tumefaciens*. Therefore, the only surviving cells are those plant cells that have integrated the T DNA into their genome. Because the T DNA also contains the gene of interest, the selected plant cells are expected to have received this gene as well. The cells are then transferred to a medium that contains the plant growth hormones necessary for the regeneration of entire plants.

Many transgenic plants have been approved for human consumption. Their production has become routine practice for several agriculturally important plant species, including alfalfa, corn, cotton, soybean, tobacco, and tomato. Transgenic plants have been given characteristics that are agriculturally useful, such as those that improve plant quality and insect, disease, or herbicide resistance. In terms of plant quality, gene additions have been made to improve the nutritional value of some plants, such as making the canola grain produce more oil.

Frequently, transgenic research has sought to produce plant strains that are resistant to insects, disease, and herbicides. A successful example of the use of transgenic plants has involved the introduction of genes from *Bacillus thuringiensis* (Bt). This bacterium produces toxins that kill certain types of caterpillars and beetles and has been widely used as an insecticide for several decades. These toxins are proteins that are encoded in the genome of *B. thuringiensis*. Researchers have succeeded in cloning toxin genes from *B. thuringiensis* and transferring those genes into plants. Such Bt varieties of plants produce the toxins themselves and therefore are resistant to many types of caterpillars and beetles. This allows farmers to reduce the use of conventional insecticides and improves yields. Examples of commercialized crops include Bt corn (**Figure 20.14a**) and Bt cotton. Since their introduction in 1996, the commercial use of these two Bt crops has steadily increased (**Figure 20.14b**).



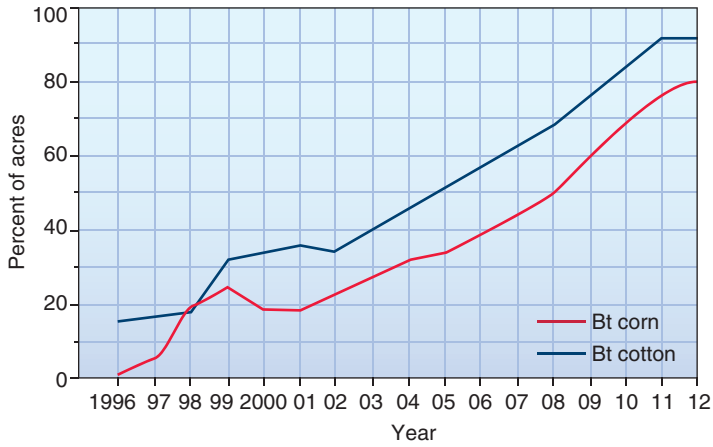


Figure 20.13 Using the Ti plasmid and *Agrobacterium tumefaciens* to produce transgenic plants.

Concept Check: Which region of the Ti plasmid is transferred to the plant cell?

(b) Bt corn and Bt cotton usage since 1996

Figure 20.14 The production of Bt crops. **(a)** A field of Bt corn. These corn plants carry a toxin gene from *Bacillus thuringiensis* that provides them with resistance to insects such as corn borers, which are a major pest of corn plants. **(b)** A graph showing the increase in usage of Bt corn and Bt cotton in the United States since their commercial introduction in 1996.

BIOLOGY PRINCIPLE Biology affects our society. The field of agriculture has been greatly influenced by the development of genetically modified organisms (GMOs) such as Bt corn.

The use of transgenic agricultural plants has been strongly opposed by some people. What are the perceived risks? One potential risk is that transgenic crops could endanger native species. For example, Bt crops may kill pollinators of native species. Another concern is that the planting of transgenic crops could lead to the evolution of resistant insects that would make Bt crops ineffective. To prevent this from happening, researchers are producing transgenic strains that carry more than one toxin gene, which makes it more difficult for insect resistance to arise. A third concern is the potential for transgenic plants to elicit allergic reactions. However, the proteins that are encoded by genes that are introduced into GMOs are tested for their ability to cause an allergic response. Despite these and other concerns, many farmers are embracing transgenic crops, and their use continues to rise.

Researchers Have Succeeded in Cloning Mammals from Somatic Cells

We now turn our attention to cloning as a way of genetically manipulating plants and animals. The term cloning has several different meanings. At the beginning of this chapter we discussed gene cloning,

which involves methods that produce many copies of a gene. The cloning of a multicellular organism, called **reproductive cloning**, is a different matter. By accident, this happens in nature. Identical twins are genetic clones that began from the same fertilized egg. Similarly, researchers can take mammalian embryos at an early stage of development (for example, the two- to eight-cell stage), separate the cells, implant them into the uterus of a female, and obtain multiple births of genetically identical individuals.

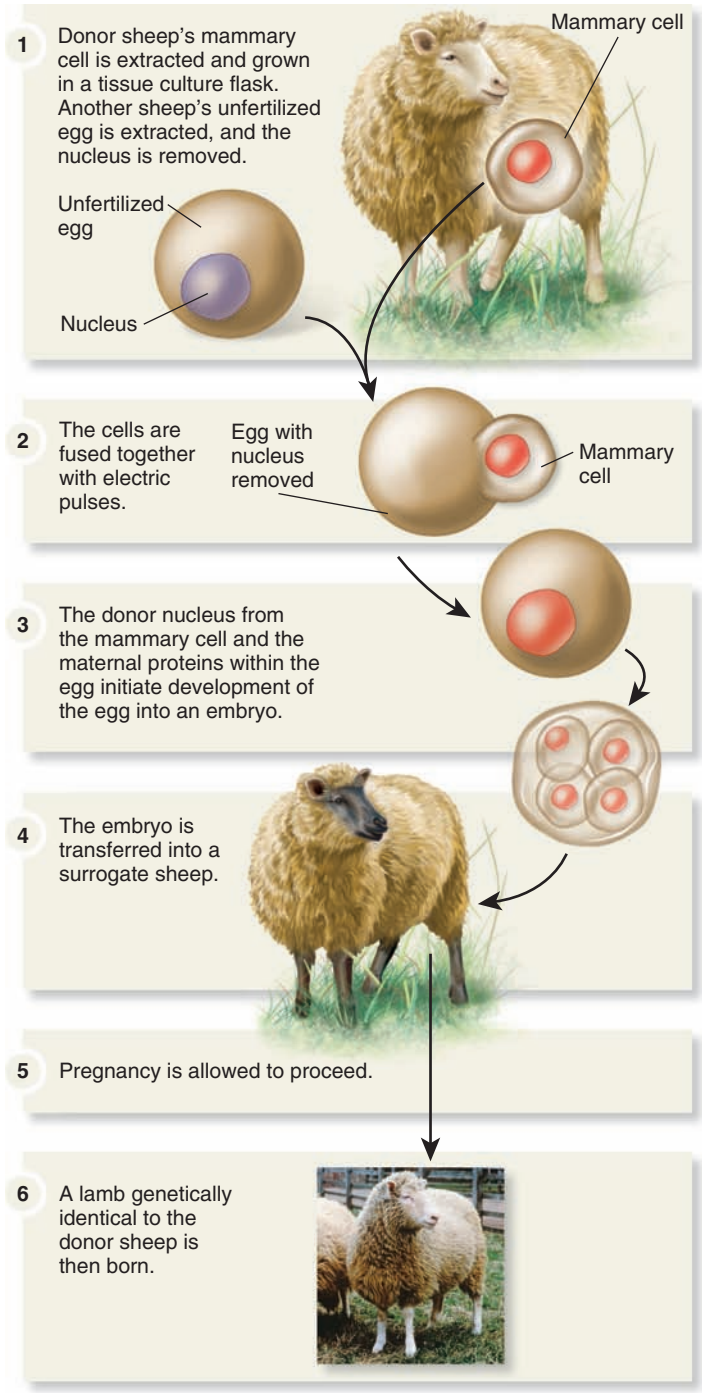
As previously noted, the reproductive cloning of new individuals is relatively easy in the case of plants, which can be cloned from somatic cells. Until recently, this approach had not been possible with mammals. Scientists believed that chromosomes within the somatic cells of mammals had incurred irreversible genetic changes that rendered them unsuitable for reproductive cloning. However, this hypothesis has proven to be incorrect. In 1996, English embryologist Ian Wilmut and his colleagues produced clones of sheep using the genetic material from somatic cells. As you may have heard, they named the first cloned lamb Dolly.

How was Dolly produced? As shown in **Figure 20.15**, the researchers removed mammary cells from an adult female sheep and grew them in the laboratory. They then extracted the nucleus from a sheep oocyte and fused the diploid mammary cell with the enucleated oocyte cell. Fusion was promoted by electric pulses. After fusion, the zygote was implanted into the uterus of an adult sheep. One hundred and forty-eight days later, Dolly was born.

Dolly was (almost) genetically identical to the sheep that donated the mammary cell. Dolly and the donor sheep were (almost) genetically identical in the same way that identical twins are. They carry the same set of genes and look remarkably similar. The reason they may not be completely identical is because Dolly and her somatic cell donor may have some minor genetic differences due to possible differences in their mitochondrial DNA.

Mammalian reproductive cloning is still at an early stage of development. Nevertheless, producing Dolly showed it is technically possible. In recent years, cloning using somatic cells has been achieved in several mammalian species, including sheep, cows, mice, goats, pigs, and cats. In 2002, the first pet was cloned, which was named CC for carbon copy (see chapter opening photo). The cloning of mammals provides the potential for many practical applications. With regard to livestock, cloning would enable farmers to use the somatic cells from their best animals to produce genetically homogeneous herds. This could be advantageous in terms of agricultural yield, although such a genetically homogeneous herd may be more susceptible to certain diseases.

Although reproductive cloning may have practical uses in the field of agriculture, our society has become greatly concerned with the possibility of human cloning. This prospect has raised serious ethical questions. Some people feel it is morally wrong and threatens the basic fabric of parenthood and family. Others feel it is a modern technology that offers a new avenue for reproduction, one that could be offered to infertile couples, for example. Human cloning is a complex subject with many more viewpoints than these two. In the public sector, the sentiment toward human cloning has been generally negative. Many countries have issued a complete ban on human cloning, whereas others permit limited research in this area. In the future, our society will have to wrestle with the legal and ethical aspects of cloning as it applies not only to animals but also to people.



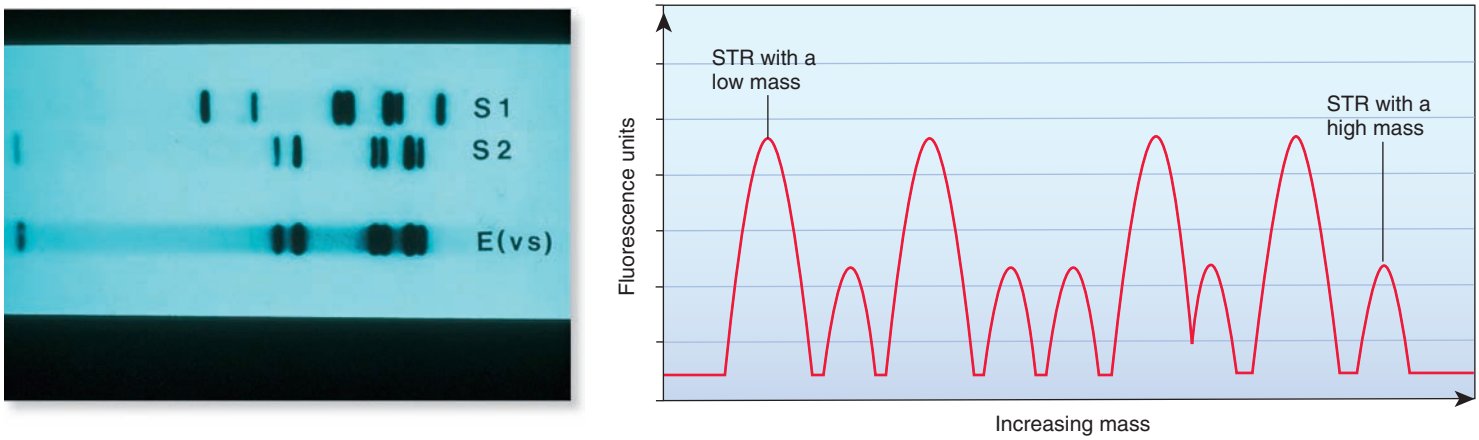


Figure 20.15 **Protocol for the successful cloning of sheep.** In this procedure, the genetic material from a somatic cell was used to make a cloned mammal, in this case, the sheep Dolly.

Concept Check: *Did all of Dolly's DNA come from a mammary cell? Explain.*

DNA Fingerprinting Is Used for Identification and Relationship Testing

DNA fingerprinting is a technology for identifying and distinguishing among individuals based on variations in their DNA. Like the human fingerprint, the DNA of each individual is a distinctive characteristic

(a) Traditional DNA fingerprinting

(b) Automated DNA fingerprinting

Figure 20.16 DNA fingerprinting. **(a)** DNA evidence found at a crime scene (E) was compared with DNA from two different individuals, suspect 1 (S 1) and suspect 2 (S 2), using traditional DNA fingerprinting. Their DNA appears as a series of bands on a gel. **(b)** Automated DNA fingerprinting measures the masses of fluorescently labeled DNA segments called short tandem repeat sequences (STRs) from a selected individual. A printout from the fluorescence detector is shown here. Two individuals are almost always different in the pattern of peaks they exhibit.

Concept Check: *Which suspect's DNA fingerprint (S 1 or S 2) matches the DNA evidence collected at a crime scene?*

that provides a means of identification. When subjected to traditional DNA fingerprinting, selected fragments of chromosomal DNA produce a series of bands on a gel (**Figure 20.16a**). The unique pattern of these bands is usually a distinguishing feature of each individual.

DNA fingerprinting is now done using PCR, which amplifies **short tandem repeat sequences (STRs)**—short DNA sequences that are repeated many times in a row. Such tandem repeat sequences, which are noncoding regions of chromosomal DNA, are found at specific locations in the genomes of all species. The number of repeats at each location tends to vary from one individual to the next. This variation provides a way to distinguish one individual from another. Using primers that are complementary to DNA sequences that flank each STR, the STRs from a sample of DNA are amplified by PCR and then separated by gel electrophoresis according to their molecular masses. As in DNA sequencing, the amplified STR fragments are fluorescently labeled. A laser excites the fluorescent molecule within an STR, and a detector records the amount of fluorescence emission for each STR. The DNA fingerprint yields a series of peaks, each peak having a characteristic molecular mass (**Figure 20.16b**). In this automated approach, the pattern of peaks is an individual's DNA fingerprint.

What are the uses of DNA fingerprinting? First, DNA fingerprinting has gained acceptance as a precise method of identification. In medicine, it is used to identify different species of bacteria and fungi, and it can even distinguish among closely related strains of the same species. This is useful so clinicians can treat patients with the appropriate antibiotic or fungicide.

A second common use is forensics—the use of scientific techniques in the investigation of crimes. DNA fingerprinting can be used as evidence that an individual was at a crime scene. Forensic DNA was first used in the U.S. court system in 1986. When a DNA sample taken from a crime scene matches the DNA fingerprint of an individual, the probability that a match could occur simply by chance can be calculated. Each STR size is given a probability score based on its observed frequency within a reference human population (Caucasian, Asian, and so on). An automated DNA fingerprint contains many peaks, and the probability scores for each peak are multiplied together to arrive at the likelihood that a particular pattern of peaks would be observed. For example, if a DNA fingerprint contains 20 fluorescent peaks, and the probability of an individual having each peak is 1/4, then the likelihood of having that pattern would be $(1/4)^{20}$, or roughly 1 in 1 trillion. Therefore, a match between two samples is rarely a matter of random chance.

Another important use of DNA fingerprinting is to establish paternity and other family relationships. Persons who are related genetically have some peaks in common. The number they share depends on the closeness of their genetic relationship. For example, offspring are expected to receive half of their peaks from one parent and half from the other. Therefore, DNA fingerprinting can be used as evidence in paternity cases.

Feature Investigation | Blaese and Colleagues Performed the First Gene Therapy to Treat ADA Deficiency

Gene therapy is the introduction of cloned genes into living cells in an attempt to cure disease. Many current research efforts in gene therapy are aimed at alleviating human diseases caused by defective genes. Examples include cystic fibrosis, sickle cell disease, phenylketonuria, hemophilia, and severe combined immunodeficiency disease (SCID). Human gene therapy is still at an early stage of development. Relatively few patients have been successfully treated with gene therapy in spite of a large research effort. In addition, experimental gene therapy in humans has been associated with adverse reactions that have raised questions about its safety. In 1999, a patient in a clinical trial died from a reaction to gene therapy treatment.

Adenosine deaminase (ADA) deficiency is an autosomal recessive disorder that results in a lack of the enzyme adenosine deaminase. When present, this enzyme deaminates the nucleoside deoxyadenosine, which is an important step in the proper metabolism of nucleosides. If both copies of the *ADA* gene are defective, however, deoxyadenosine

accumulates within the cells of the individual. At high concentrations, deoxyadenosine is particularly toxic to lymphocytes in the immune system, namely, T cells and B cells. In individuals with ADA deficiency, the destruction of T and B cells leads to SCID. If left untreated, SCID is typically fatal at an early age (generally 1 to 2 years old) because the compromised immune system of these individuals cannot fight infections.

Three approaches are used to treat ADA deficiency. In some cases, a bone marrow transplant is received from a compatible donor. A second method is to treat SCID patients with purified ADA enzyme that is coupled to polyethylene glycol (PEG). This PEG-ADA is taken up by lymphocytes and can correct the ADA deficiency. Unfortunately, these two approaches are not always available and/or successful. A third, more recent approach is to treat ADA patients with gene therapy.

On September 14, 1990, the first human gene therapy was approved for a young girl suffering from ADA deficiency. This work was carried out by a large team of researchers, including American physicians R. Michael Blaese, Kenneth Culver, W. French Anderson, and several collaborators at the National Institutes of Health (NIH). The general aim of this therapy was to remove lymphocytes from the blood of the girl with SCID, introduce the normal *ADA* gene into the cells via a retrovirus, and then return them to her bloodstream.

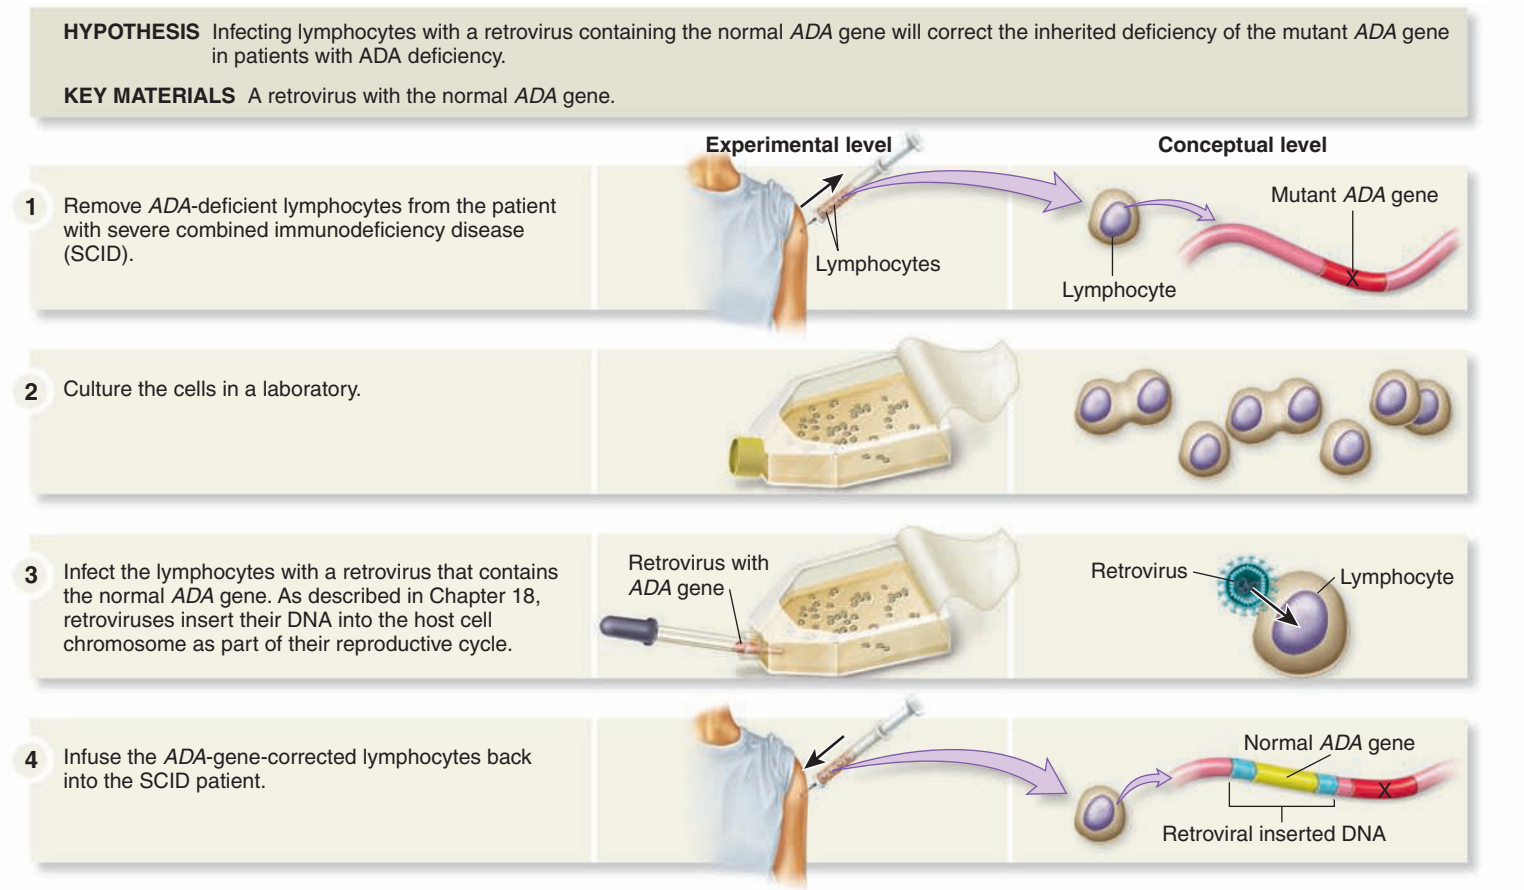

Figure 20.17 outlines the protocol for the experimental treatment. The researchers removed lymphocytes from the girl and cultured them in a laboratory. The lymphocytes were then infected with a recombinant retrovirus that contained the normal *ADA* gene. During the reproductive cycle of the retrovirus, the retroviral genetic material was inserted into the host cell's DNA. Therefore, because this retrovirus contained the normal *ADA* gene, this gene also was inserted into the chromosomal DNA of the girl's lymphocytes, thereby correcting the defect in ADA. After this occurred in the laboratory, the lymphocytes were reintroduced back into the patient.

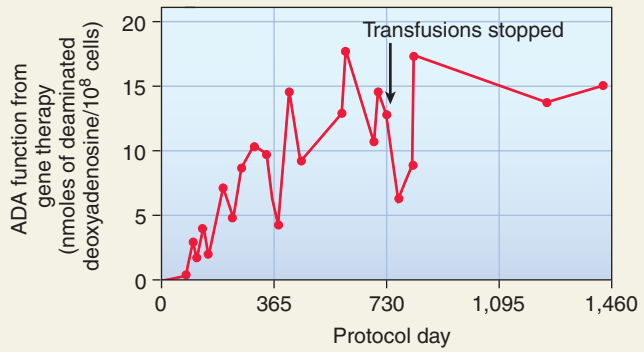
In this clinical trial, two U.S. patients were enrolled, and a third patient was later treated in Japan. The data in Figure 20.17 show the results of this trial for one of the three patients. Over the course of 2 years, this patient was given 11 infusions of lymphocytes that had been corrected with the normal *ADA* gene. Even after 4 years, this patient's lymphocytes were still making ADA. These results suggest that this first gene therapy trial may offer some benefit. However, the patients in this study were also treated with PEG-ADA as an additional therapy to prevent the adverse symptoms of SCID. Therefore, the researchers could not determine whether gene transfer into T cells was of significant clinical benefit.



Another form of SCID, termed SCID-X1, is inherited as an X-linked trait. SCID-X1 is characterized by a block in T-cell growth and differentiation. This block is caused by mutations in the gene encoding the γ_c cytokine receptor, which plays a key role in the recognition of signals that are needed to promote the growth, survival, and differentiation of T cells. A gene therapy trial for SCID-X1 similar to the trial shown in Figure 20.17 was initiated in 2000. A normal

Figure 20.17 The first human gene therapy for adenosine deaminase (ADA) deficiency by Blaese and colleagues.

BioConnections: Look back at Figure 18.4b. How does the genetic material of a retrovirus get incorporated into the host cell's genome?

5 THE DATA

6 CONCLUSION The introduction of a cloned *ADA* gene into lymphocytes via gene therapy resulted in higher ADA function, even after 4 years.

7 SOURCE Blaese, R. M. et al. 1995. T lymphocyte-directed gene therapy for ADA-SCID: Initial trial results after 4 years. *Science* 270:475–480.

γ_c cytokine receptor gene was cloned into a retroviral vector and then introduced into SCID-X1 patients' lymphocytes. The lymphocytes were then reintroduced back into their bodies. At a 10-month follow-up, T cells expressing the normal γ_c cytokine receptor were detected in two patients. Most importantly, the T-cell counts in these two patients had risen to levels that were comparable to those in normal individuals.

This clinical trial was the first clear demonstration that gene therapy can offer clinical benefits, providing in these cases what seemed to be a complete correction of the disease phenotype. However, in a French study involving 10 SCID-X1 patients, an unexpected and serious side effect occurred. Within 3 years of gene therapy treatment, 3 out of the 10 treated children developed leukemia—a form of cancer involving the proliferation of white blood cells. In these cases, the disease occurred because the integration of the retroviral vector into the patients' genome caused a normal gene to become an oncogene, a gene that promotes cancer. The development of leukemia in these patients has prompted researchers to develop alternative methods of introducing genes into human cells for gene therapy.

Experimental Questions

1. What is gene therapy? What is ADA deficiency?
2. **SciSKILLS »** In the investigation of Figure 20.17, how did the researchers treat ADA deficiency?
3. **SciSKILLS »** How successful was the gene therapy for ADA deficiency?

Summary of Key Concepts

- Recombinant DNA technology is the use of laboratory techniques to bring together DNA fragments from two or more sources.

20.1 Gene Cloning

- Gene cloning, the process of making multiple copies of a gene, is used to obtain many copies of a particular gene or large amounts of the protein encoded by the gene (Figure 20.1).
- In the process of gene cloning, both a vector and chromosomal DNA are cut with restriction enzymes. The DNA fragments hydrogen-bond to each other at their sticky ends, and the pieces are covalently linked together via DNA ligase, producing recombinant vectors. When a recombinant vector is introduced into a bacterial cell, the cell replicates the vector and divides to produce many cells (Table 20.1, Figures 20.2, 20.3).
- A collection of recombinant vectors, each with a particular piece of chromosomal DNA, is introduced into bacterial cells to produce a DNA library. If the DNA molecules are derived from mRNA, this creates a cDNA (complementary DNA) library (Figure 20.4).
- Gel electrophoresis is used to separate macromolecules by using an electric field that causes them to move through a gel matrix. Gel electrophoresis typically separates molecules according to their charges, sizes, and masses (Figure 20.5).
- Polymerase chain reaction (PCR) is an alternative technique for making many copies of a gene without the use of vectors and host cells. Primers are used that flank the region of DNA to be amplified (Figure 20.6).

20.2 Genomics: Techniques for Studying Genomes

- Genomics is the study of genomes as whole units; functional genomics studies the expression of a genome.
- For genomics, large fragments of chromosomal DNA are cloned into vectors such as BACs. Researchers may construct a contig, which is a collection of clones that cover a contiguous region of a chromosome. This is a type of mapping—determining the relative locations of genes or other DNA segments along a chromosome (Figure 20.7).
- The dideoxy method of DNA sequencing uses ddNTPs to determine the base sequence of a segment of DNA (Figures 20.8, 20.9).
- A DNA microarray is a small silica, glass, or plastic slide dotted with different sequences of single-stranded DNA, each corresponding to a short sequence within a known gene. It is used to study gene expression patterns (Figure 20.10, Table 20.2).

20.3 Biotechnology

- Biotechnology is the use of living organisms, or the products of living organisms, for human benefit.
- Microorganisms are used to produce human medicines, such as insulin (Figure 20.11).
- Genetically modified organisms (GMOs) are made via gene addition or gene replacement. When they carry a gene from a different species, they are called transgenic organisms. Transgenic livestock have been genetically engineered to produce human hormones in their milk (Table 20.3, Figure 20.12).
- The Ti plasmid in *Agrobacterium tumefaciens* has been used to produce transgenic plants such as Bt corn, which produces its own insecticide (Figures 20.13, 20.14).
- The reproductive cloning of mammals has been achieved by fusing a somatic cell with an egg that has had its nucleus removed (Figure 20.15).
- DNA fingerprinting is a technology for identifying individuals based on the occurrence of segments of DNA called STRs, which are variable in length among different individuals (Figure 20.16).
- Gene therapy is a method to treat human diseases by the introduction of cloned genes into cells. The first gene therapy involved a disease called severe combined immunodeficiency disease (SCID) (Figure 20.17).

Assess and Discuss

Test Yourself

1. Vectors used to clone genes were derived originally from
   a. proteins.
   b. plasmids.
   c. viruses.
   d. all of the above.
   e. b and c only.
2. Restriction enzymes used in most cloning experiments
   a. cut DNA into pieces for gene cloning.
   b. are naturally produced by bacteria cells to prevent viral infection.
   c. produce sticky ends on DNA fragments.
   d. All of the above are correct.
   e. Only a and c are correct.
3. DNA ligase is needed in a cloning experiment
   a. to promote hydrogen bonding between sticky ends.
   b. to catalyze the covalent attachment of the backbone of DNA strands.
   c. to digest the chromosomal DNA into small pieces.
   d. Only a and b are correct.
   e. a, b, and c are correct.
4. Let's suppose you followed the protocols described in Figures 20.2 and 20.3. Which experiment(s) would you conduct to confirm that a white colony really contained a recombinant vector with an inserted fragment of DNA?
   a. Pick a bacterial colony and restreak on plates containing X-Gal to confirm that the cells really form white colonies.
   b. Pick a bacterial colony, isolate plasmid DNA, digest the plasmid DNA with a restriction enzyme, and then perform gel electrophoresis with the DNA.
   c. Pick a bacterial colony and test it to see if β-galactosidase is functional within the bacterial cells.
   d. Pick a bacterial colony and retest it on ampicillin-containing plates to double-check that the cells are really ampicillin resistant.
   e. Both c and d should be conducted.
5. Why is *Taq* polymerase used in PCR rather than other DNA polymerases?
   a. *Taq* polymerase is a synthetic enzyme that produces DNA strands at a faster rate than natural polymerases.
   b. *Taq* polymerase is a heat-stable form of DNA polymerase that can function after exposure to the high temperatures necessary for PCR.
   c. *Taq* polymerase is easier to isolate than other DNA polymerases.
   d. *Taq* polymerase is the DNA polymerase commonly produced by most eukaryotic cells.
   e. All of the above are correct.
6. Let's suppose you want to clone a gene that has never been analyzed before by DNA sequencing. Which of the following statements do you agree with the most?
   a. Do PCR to clone the gene because it is much faster.
   b. Do PCR to clone the gene because it is very specific and gives a high yield.
   c. You can't do PCR because you can't make forward and reverse primers.
   d. Do cloning by insertion into a vector because it will give you a higher yield.
   e. Do cloning by insertion into a vector because it is easier than PCR.
7. The method of determining the base sequence of DNA is termed
   a. PCR.
   b. gene cloning.
   c. DNA fingerprinting.
   d. DNA sequencing.
   e. gene mapping.
8. With regard to dideoxy sequencing, which of the following statements is false?
   a. The dideoxy nucleotides are fluorescently labeled.
   b. The dideoxy nucleotides cannot be incorporated into a growing DNA strand.
   c. When incorporated into a DNA strand, the dideoxynucleotides prevent further growth of the strand.
   d. The dideoxy sequencing method is used to determine the base sequence of DNA.
   e. The dideoxy sequencing method requires the use of primers.
9. Organisms that carry genes that were introduced using molecular techniques are called
   a. transgenics.
   b. recombinant DNA.
   c. mutants.
   d. genetically modified organisms.
   e. both a and d.
10. DNA fingerprinting is used
    a. to precisely identify an organism, such as the identification of specific strains of bacteria.
    b. as a forensics tool to provide evidence in a criminal case.
    c. to determine genetic relationships between individuals.
    d. to determine the identity of an individual.
    e. for all of the above.

Conceptual Questions

1. Explain how using one restriction enzyme to cut both a plasmid and a gene of interest will allow the gene to be inserted into the plasmid.
2. Describe and draw the structural feature of a dideoxyribonucleotide that causes chain termination.
3. A principle of biology is that *biology affects our society*. Describe two examples of how genetic engineering has played an important role in agriculture.

Collaborative Questions

1. Discuss three important advances that have resulted from gene cloning.
2. Discuss the ethical issues associated with genetic engineering and reproductive cloning.

Genomes, Proteomes, and Bioinformatics

21

CHAPTER OUTLINE

21.1 Bacterial and Archaeal Genomes
21.2 Eukaryotic Genomes
21.3 Proteomes
21.4 Bioinformatics
Summary of Key Concepts
Assess and Discuss

Genomes and computer technology. The amount of data derived from analyses of genomes is so staggering in size and complexity that researchers have turned to computers to unravel the amazing information that genomes contain.

Imagine a book that is incredibly long and has taken billions of years to write. Such an analogy applies to the human genome, which is written in only four letters—A, T, G, and C—and is over 3 billion base pairs long. If the entire human genome were typed in a textbook like this, with about 3,000 letters per page, it would be over 1 million pages long! Our genome contains many unsolved mysteries that researchers are trying to unravel, such as: "What are the functions of every gene in the genome? How do gene mutations cause disease? How are humans evolutionarily related to other species?" As you will learn, genomes are full of surprises. For example, did you know that much of your DNA has no known function?

The unifying theme of biology is evolution. The genome of every living species is the product of approximately 4 billion years of evolution. We can understand the unity of modern organisms by realizing that all species evolved from an interrelated group of ancestors. Throughout this textbook, a recurring theme is Genomes & Proteomes Connections—topics that highlight the evolutionary connections among all forms of life and underscore how the genetic material produces the form and function of living organisms. By now, you may feel familiar with the concept of a **genome**, the complete genetic composition of a cell, organism, or species. The genome of each species is critical to its existence in several ways:

- The genome stores information in the form of genes, which provide a genetic blueprint to produce the characteristics of each organism.
- The genome is copied and transmitted from generation to generation.
- The accumulation of genetic changes (mutations) over the course of many generations produces the evolutionary changes that alter species and produce new species.

An extension of genome analysis is the study of proteomes. The term **proteome** refers to the entire complement of proteins that a cell or organism makes. The function of most genes is to encode proteins, which are the key determinants of cell structure and function. Analyzing the proteomes of organisms allows researchers to understand many aspects of biology, including the structure and function of cells, the complexity of multicellular organisms, and the interactions between organisms and their environment.

In the first two sections of this chapter, we will consider genome characteristics of bacteria, archaea, and eukaryotes. We then turn our attention to proteomes and examine the roles of the proteins that a species can make. From a molecular perspective, genomes and proteomes contain extensive and complex information, which is studied using computer technology. In the last section of this chapter, we will consider how the field of bioinformatics, which employs computers and mathematical techniques to analyze biological information, is critical to the study of genomes and proteomes.

21.1 Bacterial and Archaeal Genomes

Learning Outcomes:

1. List the key characteristics of bacterial and archaeal genomes.
2. Describe the method of shotgun DNA sequencing.

The past decade has seen remarkable advances in our overall understanding of the entire genome of many species. As genetic technology has progressed, researchers have gained an increasing ability to analyze the composition of genomes as a whole unit. For many species, we now know the complete DNA sequence, which provides the most detailed description available of an organism's genome at the molecular level. In this section, we will survey the sizes and composition of genomes in selected species of bacteria and archaea.

The Genomes of Bacteria and Archaea Typically Consist of a Circular Chromosome with a Few Thousand Genes

Geneticists have made great progress in the study of bacterial and archaeal genomes. Some of the key features of bacterial chromosomes are described in Chapter 18 (see Section 18.4). Why are researchers interested in the genomes of bacteria and archaea?

- First, bacteria cause many different diseases that affect humans as well as other animals and plants. Studying the genomes of bacteria reveals important clues about the process of bacterial infection, which may also help us find ways to combat it.
- A second reason for studying bacterial and archaeal genomes is that the information we learn about these microscopic organisms often applies to larger and more complex organisms. For example, basic genetic mechanisms, such as DNA replication and gene regulation, were first understood in the bacterium *Escherichia coli*. That knowledge provided a critical foundation to understand how these processes work in humans and other eukaryotic species.
- A third reason is evolution. The origin of the first eukaryotic cell probably involved a union between an archaeal and a bacterial cell, as we will explore in Chapter 22. The study of bacterial and archaeal genomes helps us understand how all living species evolved.
- Finally, another reason to study the genomes of bacteria is because we use them as tools in research and biotechnology, which was discussed in Chapter 20.

The genomes of thousands of bacterial and archaeal species have been completely sequenced and analyzed. The chromosomes of bacteria and archaea are usually a few million base pairs in length. Genomic researchers refer to 1 million base pairs as 1 megabase pair, abbreviated Mb. Most bacteria and archaea contain a single type of chromosome, though multiple copies may be present in a single cell. However, some bacteria are known to have more than one type of chromosome. For example, *Vibrio cholerae*, the bacterium that causes the diarrheal disease known as cholera, has two different chromosomes in each cell, one 2.9 Mb and the other 1.1 Mb.

Table 21.1 Examples of Bacterial and Archaeal Genomes That Have Been Sequenced*

Species	Genome size (Mb)†	Number of genes‡	Description
Methanobacterium thermoautotrophicum	1.7	1,921	An archaeon that produces methane
Haemophilus influenzae	1.8	1,743	One of several different bacterial species that cause respiratory illness and meningitis
Sulfolobus solfataricus	3.0	3,032	An archaeon that metabolizes sulfur-containing compounds
Lactobacillus plantarum	3.3	3,052	A type of lactic acid–producing bacterium used in the production of cheese and yogurt
Mycobacterium tuberculosis	4.4	4,294	The bacterium that causes the respiratory disease tuberculosis
Escherichia coli	4.6	4,377	A naturally occurring intestinal bacterium; certain strains can cause human illness
Bacillus anthracis	5.2	5,439	The bacterium that causes the disease anthrax

*Bacterial and archaeal species often exist in different strains that may differ slightly in their genome size and number of genes. The data are from common strains of the indicated species. The species shown in this table have only one type of chromosome.

†Mb equals 1 million base pairs, or a megabase pair.

‡The number of genes is an estimate based on the analysis of genome sequences.

Bacterial and archaeal chromosomes are usually circular. For example, the two chromosomes in *V. cholerae* are circular, as is the single type of chromosome found in *E. coli*. However, linear chromosomes are found in some species, such as *Borrelia burgdorferi*, the bacterium that causes Lyme disease, the most common tick-borne disease in the U.S. Certain bacterial species may even contain both linear and circular chromosomes. *Agrobacterium tumefaciens*, which infects plants and causes a disease called crown gall, has one linear chromosome (2.1 Mb) and one circular chromosome (3.0 Mb).

Table 21.1 compares the sequenced genomes from several bacterial and archaeal species. They range in size from 1.7 to 5.2 Mb. The total number of genes is correlated with the total genome size. Roughly 1,000 genes are found for every megabase pair of DNA. Compared with eukaryotic genomes, bacterial and archaeal genomes are less complex. Their chromosomes lack centromeres and telomeres and have a single origin of replication. Also, chromosomes of bacteria and archaea have relatively little repetitive DNA, whereas repetitive sequences are usually abundant in eukaryotic genomes.

In addition to one or more chromosomes, bacteria often have plasmids, circular pieces of DNA that exist independently of the bacterial chromosome. Plasmids are typically small, in the range of a few thousand to tens of thousands of base pairs in length, though some can be quite large, even hundreds of thousands of base pairs. The various functions of plasmids are described in Chapter 18, and their use as vectors in gene cloning is discussed in Chapter 20.

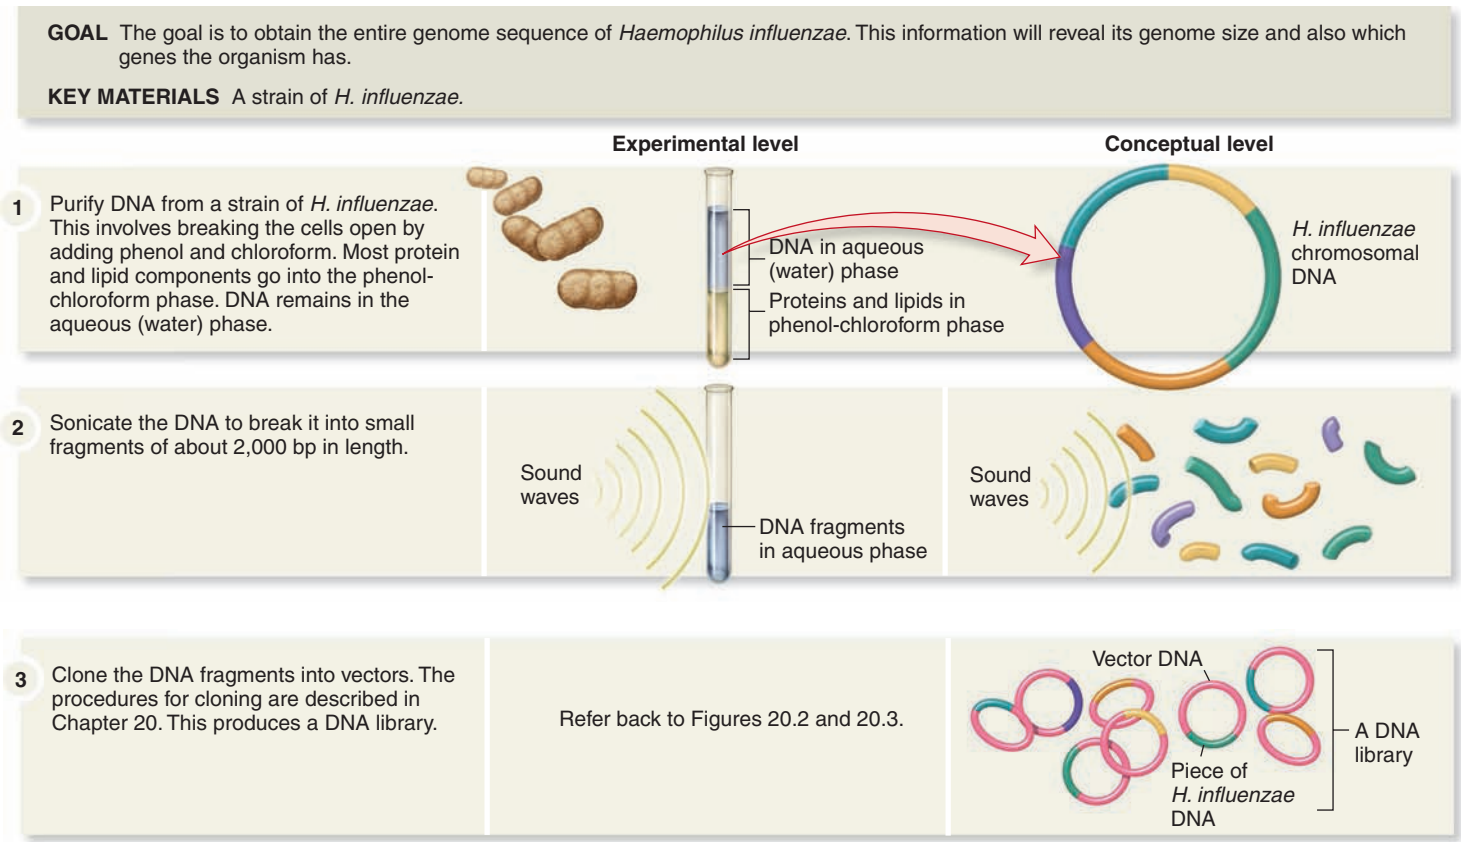
Feature Investigation | Venter, Smith, and Colleagues Sequenced the First Genome in 1995

The first genome to be entirely sequenced was that of the bacterium *Haemophilus influenzae*. This bacterium causes a variety of diseases in humans, including respiratory illnesses and bacterial meningitis. *H. influenzae* has a relatively small genome consisting of approximately 1.8 Mb of DNA in a single circular chromosome.

A common strategy for sequencing an entire genome is called **shotgun DNA sequencing**. In this approach, researchers use a DNA sequencing method, such as the dideoxy chain-termination method (see Figure 20.9), to randomly sequence many DNA fragments from the genome. As a matter of chance, some of the fragments are overlapping—the end of one fragment contains the same DNA region as the beginning of another fragment. Computers are used to align the overlapping regions and assemble the DNA fragments into a contiguous sequence identical to that found in the intact chromosome. The advantage of shotgun DNA sequencing is that it does not require extensive mapping, a process that can be time-consuming. A disadvantage is that researchers may waste time sequencing the same region of DNA more times than necessary in order to assemble the sequence correctly.

To obtain a complete sequence of a genome with the shotgun approach, how do researchers decide how many fragments to sequence? We can calculate the probability that a base will not be sequenced (P) using this equation:

$$P = e^{-m}$$



where e is the base of the natural logarithm ($e = 2.72$), and m is the number of sequenced bases divided by the total genome size. For example, in the case of *H. influenzae*, with a genome size of 1.8 Mb, if researchers sequenced 9.0 Mb, $m = 5$ (that is, 9.0 Mb divided by 1.8 Mb):

$$P = e^{-m} = e^{-5} = 0.0067, \text{ or } 0.67\%.$$

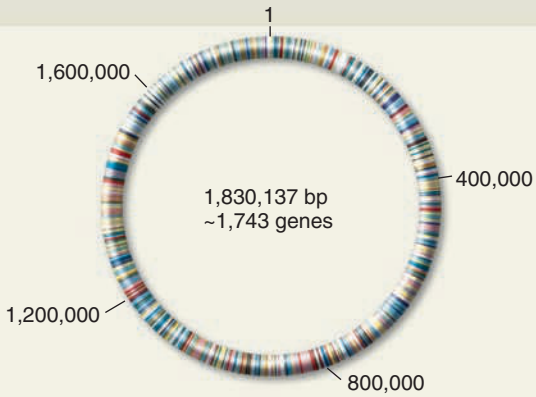
This means that if researchers randomly sequence 9.0 Mb, which is five times the length of a single genome, they are likely to miss only 0.67% of the genome. With a genome size of 1.8 Mb, they would miss about 12,000 nucleotides out of approximately 1.8 million. Such missed sequences are typically on small DNA fragments that, as a matter of random chance, did not happen to be sequenced. The missing links in the genome are identified using mapping methods, which are described in Chapter 20.

In their discovery-based investigation, American biologists Craig Venter and Hamilton Smith and their colleagues used a shotgun DNA sequencing approach (**Figure 21.1**). The researchers isolated chromosomal DNA from *H. influenzae* and used sound waves

Figure 21.1 Determination of the complete genome sequence of *Haemophilus influenzae* by Venter, Smith, and colleagues.

4 Subject many clones to the procedure of dideoxy sequencing, also described in Chapter 20. A total of 10.8 Mb was sequenced.

Refer back to Figure 20.9.



Produces a large number of sequences with overlapping regions.

5 Use tools of bioinformatics, described in the last section of this chapter, to identify various types of genes in the genome.

Explores the genome sequence and identifies and characterizes genes.

6 THE DATA

Functions of Proteins Encoded by Genes

% of genome		% of genome	
6.8	Amino acid biosynthesis	5.3	Metabolism of purines, pyrimidines, nucleosides, and nucleotides
5.4	Biosynthesis of cofactors, prosthetic groups, carriers	6.3	Regulatory functions
8.3	Cell envelope	8.6	Replication
5.3	Cellular processes	12.2	Transport and binding proteins
3.0	Central intermediary metabolism	14.0	Translation
10.4	Energy metabolism	2.7	Transcription
2.5	Fatty acid/phospholipid metabolism	9.2	Other categories

7 CONCLUSION *H. influenzae* has a genome size of 1.83 Mb with approximately 1,743 genes. The functions of many of those genes could be inferred by comparing them to genes in other species.

8 SOURCE Fleischmann et al. 1995. Whole-genome random sequencing and assembly of *Haemophilus influenzae* Rd. *Science* 269:496–512.

to break the DNA into small fragments of approximately 2,000 bp in length. These fragments were randomly inserted into vectors, allowing the DNA to be propagated in *E. coli*. Each *E. coli* clone carried a vector with a different piece of DNA from *H. influenzae*. The complete set of vectors, each containing a different fragment of DNA, is called a **DNA library** (refer back to Figure 20.4). The researchers then subjected many of these clones to the procedure of DNA sequencing. They sequenced a total of approximately 10.8 Mb of DNA.

The outcome of this genome-sequencing project was a very long DNA sequence. In 1995, Venter, Smith, and colleagues published the entire DNA sequence of *H. influenzae*. The researchers then analyzed the genome sequence using a computer to obtain information about the properties of the genome. Questions they asked included "How many genes does the genome contain, and what are the likely functions of those genes?" Later in this chapter, we will examine how scientists can answer such questions with the use of computers. The data in Figure 21.1 summarize these researchers' results. The *H. influenzae* genome is composed of 1,830,137 bp of DNA. The computer analysis predicted 1,743 genes. Based on their similarities to sequences of genes identified in other species, the researchers also predicted the functions of proteins encoded by nearly two-thirds of those genes. The diagram shown in the data of Figure 21.1 places proteins in various categories based on their predicted function. These results gave the first comprehensive "genome picture" of a living organism!

Experimental Questions

1. What was the goal of the experiment conducted by Venter, Smith, and their colleagues?
2. **SciSKILLS »** How does shotgun DNA sequencing differ from procedures that involve mapping? Name an advantage and a disadvantage of the shotgun DNA sequencing approach.
3. **SciSKILLS »** What were the results of the study described in Figure 21.1?

21.2 Eukaryotic Genomes

Learning Outcomes:

1. Describe the key features of eukaryotic genomes.
2. Name the two major types of transposable elements, and describe how they differ.
3. Explain how gene duplications occur and lead to the formation of gene families.
4. Outline the goals and results of the Human Genome Project.

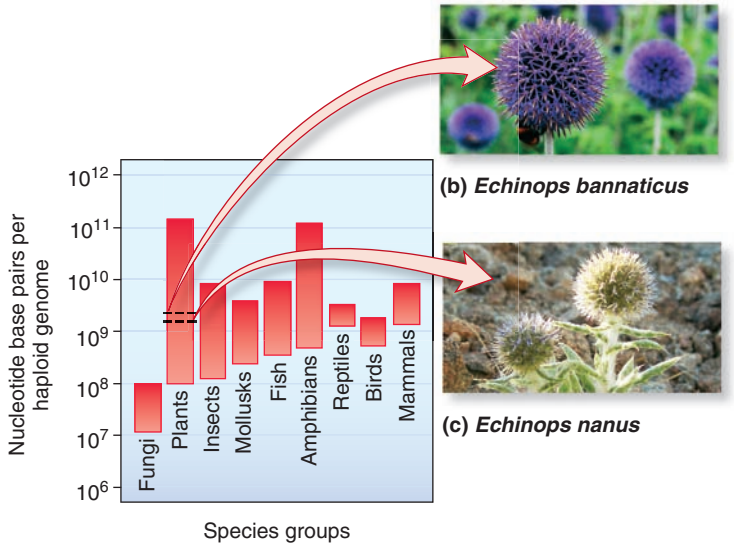
Thus far, we have examined bacterial and archaeal genomes. In this section, we turn to eukaryotes, which include protists, fungi, animals, and plants. As you will learn, their genomes are larger and more complex than their bacterial and archaeal counterparts. In addition to genes, eukaryotic genomes often have abundant amounts of noncoding sequences, whose function is largely unknown. For example, eukaryotic genomes typically have a substantial amount of short repeated sequences called repetitive DNA. We will explore how certain types of repetitive DNA sequences are formed by a process called transposition. We will also examine how the duplication of genes can lead to families of related genes.

The Nuclear Genomes of Eukaryotes Are Sets of Linear Chromosomes That Vary Greatly in Size and Composition Among Different Species

As discussed in Chapter 15, the genome located in the nucleus of eukaryotic species is usually found in sets of linear chromosomes. In humans, for example, one set contains 23 linear chromosomes—22 autosomes and one sex chromosome, X or Y. In addition, certain organelles in eukaryotic cells contain a small amount of DNA. These include the mitochondrion, which plays a role in ATP synthesis, and the chloroplast (found in plants and algae), which carries out photosynthesis. The genetic material in these organelles is referred to as the mitochondrial or the chloroplast genome to distinguish it from the nuclear genome, which is located in the cell nucleus. In this chapter, we will focus on the nuclear genome of eukaryotes.

Sizes of Nuclear Genomes In the past decade or so, the DNA sequence of entire nuclear genomes has been determined for hundreds of eukaryotic species, including several dozen mammalian genomes. Examples are shown in **Table 21.2**.

Motivation to sequence these genomes comes from four main sources.



- First, the availability of genome sequences makes it easier for researchers to identify and characterize the genes of model organisms. This was the impetus for genome projects involving baker's yeast (*Saccharomyces cerevisiae*), the fruit fly (*Drosophila melanogaster*), a nematode worm (*Caenorhabditis elegans*), the plant called thale cress (*Arabidopsis thaliana*), and the mouse (*Mus musculus*).
- A second reason for genome sequencing is to gather more information to identify and treat human diseases, which is an important aim for sequencing the human genome. Knowing the DNA sequence of the human genome will help identify genes in which mutations play a role in disease.
- Third, by sequencing the genomes of agriculturally important species, new strains of livestock and plant species with improved traits can be developed.
- Fourth, biologists are increasingly relying on genome sequences as a way to establish evolutionary relationships.

Table 21.2 Examples of Eukaryotic Nuclear Genomes That Have Been Sequenced

Species	Nuclear genome size (Mb)	Number of genes	Description
Saccharomyces cerevisiae (baker's yeast)	12.1	6,294	One of the simplest eukaryotic species; it has been extensively studied by researchers to understand eukaryotic molecular biology.
Caenorhabditis elegans (nematode worm)	100	~20,000	A model organism used to study animal development.
Drosophila melanogaster (fruit fly)	180	~14,000	A model organism used to study many genetic phenomena, including development.
Arabidopsis thaliana (thale cress)	120	~26,000	A model organism studied by plant biologists.
Oryza sativa (rice)	440	~40,000	A cereal grain with a relatively small genome; it is very important worldwide as a food crop.
Mus musculus (mouse)	2,500	~21,000	A model mammalian organism used to study genetics, cell biology, and development.
Homo sapiens (humans)	3,200	~22,000	Our own genome, the sequencing of which will help to elucidate our understanding of inherited traits and aid in the identification and treatment of diseases.

Note: The genome size refers to the number of megabase (Mb) pairs in one set of chromosomes. For species with sex chromosomes, it would include both sex chromosomes.

Relationship Between Genome Sizes and Repetitive Sequences Eukaryotic genomes are generally larger than bacterial and archaeal genomes, both in terms of the number of genes and genome size. The genomes of simpler eukaryotes, such as yeast, carry several thousand different genes, whereas the genomes of more complex eukaryotes contain tens of thousands of genes (see Table 21.2). Note that the number of genes is not the same as genome size. When we speak of genome size, this means the total amount of DNA, often measured in megabase pairs. The relative sizes of nuclear genomes vary dramatically among different eukaryotic species (**Figure 21.2a**). Surprisingly, major variations in genome sizes are observed among organisms that are similar in form and function. For example, the total amount of DNA found within different species of amphibians varies over 100-fold.

(a) Genome size

Figure 21.2 Genome sizes among selected groups of eukaryotes. **(a)** Genome sizes among various groups of eukaryotes are shown on a log scale. As an example for comparison, two closely related species of globe thistle are pictured. These species have similar characteristics, but *Echinops bannaticus* **(b)** has nearly double the amount of DNA as does *E. nanus* **(c)** due to the accumulation of repetitive DNA sequences.

Concept Check: *What are two reasons why the groups of species shown in part (a) vary in their total amount of DNA?*

The amount of DNA in closely related species can also vary. As an example, let's consider two closely related species of the plant called the globe thistle, *Echinops bannaticus* and *Echinops nanus* (**Figure 21.2b,c**). These species have similar numbers of chromosomes, but *E. bannaticus* has nearly double the amount of DNA compared to *E. nanus*. What is the explanation for the larger genome of *E. bannaticus*? The genome of *E. bannaticus* is not likely to contain twice as many genes. Rather, its genome composition includes many **repetitive sequences**, which are short DNA sequences that are present in many copies throughout the genome. Repetitive sequences are often abundant in eukaryotic species.

Types of Repetitive Sequences Repetitive sequences fall into two broad categories, moderately and highly repetitive. Sequences that are repeated a few hundred to several thousand times are called **moderately repetitive sequences**. In some cases, these sequences are multiple copies of the same gene. For example, the genes that encode ribosomal RNA (rRNA) are found in many copies. The cell needs a large amount of rRNA for its cellular ribosomes. This is accomplished by having and expressing multiple copies of the genes that encode rRNA. In addition, other types of functionally important sequences can be moderately repetitive. For example, multiple copies of origins of replication are found in eukaryotic chromosomes. Other moderately repetitive sequences may play a role in the regulation of gene transcription and translation.

Highly repetitive sequences are those that are repeated tens of thousands to millions of times throughout the genome. Each copy of a highly repetitive sequence is relatively short, ranging from a few nucleotides to several hundred nucleotides in length. Most of these sequences have no known function, and whether or not they benefit the organism is a matter of debate. A widely studied example is the *Alu* family of sequences found in humans and other primates. The *Alu* sequence is approximately 300 bp long. This sequence derives its name from the observation that it contains a site for cleavage by a restriction enzyme known as *Alu*I. It represents about 10% of the total human DNA and occurs (on average) approximately every 5,000–6,000 bp. Evolutionary studies suggest that the *Alu* sequence arose 65 million years ago (mya) from a section of a single ancestral gene known as the 7SL RNA gene. Remarkably, over the course of 65 million years, the *Alu* sequence has been copied and inserted into the human genome so often that it now occurs more than 1 million times! The mechanism for the proliferation of *Alu* sequences will be described later.

Some highly repetitive sequences, like the *Alu* family, are interspersed throughout the genome. However, other highly repetitive sequences are clustered together in a tandem array, in which a very short nucleotide sequence is repeated many times in a row. In *Drosophila*, for example, 19% of the chromosomal DNA is highly repetitive DNA found in tandem arrays. An example is shown here:

```
AATATAATATATAATATAATATAATATAT
TTATATTATATATTATATTATATTATATA
```

In this particular tandem array, two related sequences, AATAT and AATATAT (in the top strand), are repeated multiple times. Highly repetitive sequences, which contain tandem arrays of short sequences, can be quite long, sometimes more than 1 million bp in length!

Figure 21.3 shows the composition of the relative classes of DNA sequences found in the nuclear genome of humans. Surprisingly, exons, the coding regions of structural genes, and the genes that

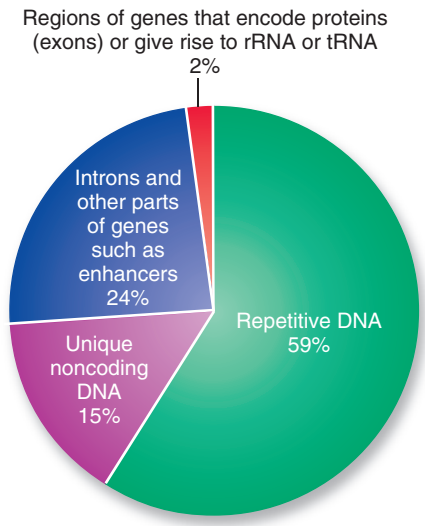


Figure 21.3 The composition of DNA sequences that are found in the nuclear genome of humans. Only about 2% of our genome codes for proteins. Most of our genome is made up of repetitive sequences.

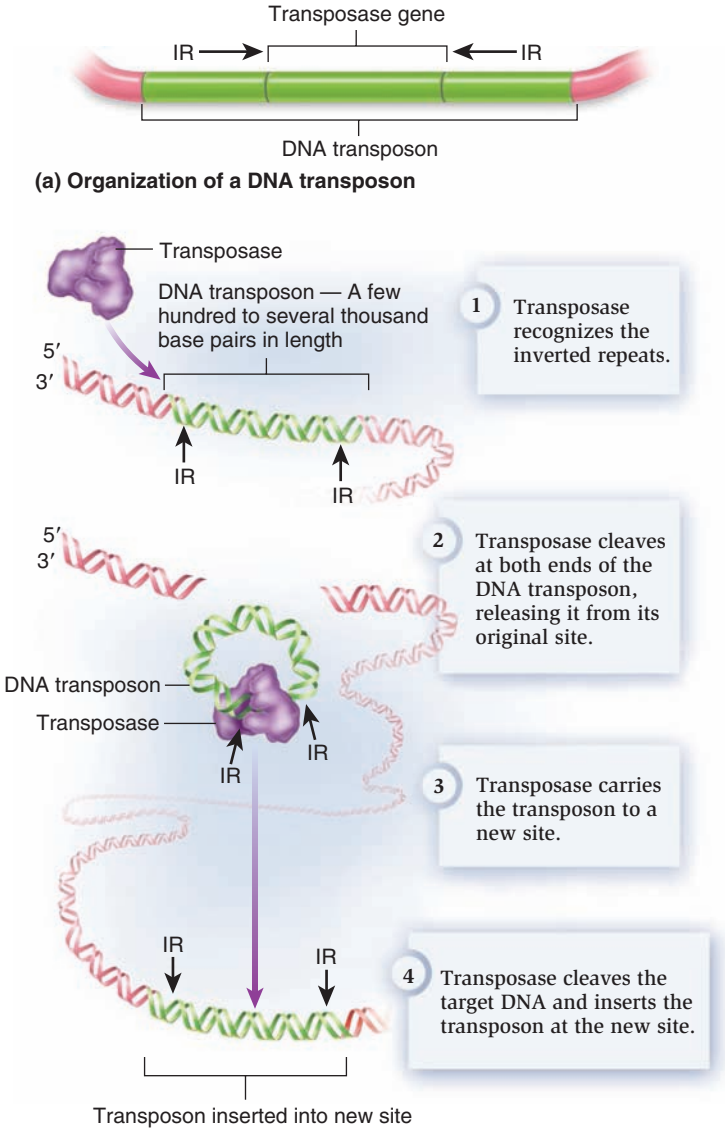
BIOLOGY PRINCIPLE The genetic material provides the blueprint for reproduction. Only a small percentage of the human genome is involved with encoding the proteins that are largely responsible for human traits.

give rise to rRNA and tRNA make up only about 2% of our genome! The other 98% is composed of noncoding sequences. Though we often think of genomes as being the repository of sequences that code for proteins, most eukaryotic genomes are largely composed of other types of sequences. Recent evidence suggests that much of this noncoding DNA plays a role in gene regulation. Intron DNA comprises about 24% of the human genome, and unique noncoding DNA constitutes 15%. Repetitive DNA makes up 59% of the DNA in the genome. Much of the repetitive DNA is derived from transposable elements, stretches of DNA that can move from one location to another, which are described next.

Transposable Elements Move from One Chromosomal Location to Another

During a process called **transposition**, a short segment of DNA moves from its original site to a new site in the genome. Such segments are known as **transposable elements (TEs)**. They range from a few hundred to several thousand base pairs in length. TEs have sometimes been referred to as "jumping genes," because they are inherently mobile. American cytogeneticist Barbara McClintock first identified transposable elements in the late 1940s from her studies with corn plants (**Figure 21.4**). She identified a segment of DNA that could move into and out of a gene that affected the color of corn kernels, producing a speckled appearance. Since that time, biologists have discovered many different types of TEs in nearly all species examined.

Though McClintock identified TEs in corn in the late 1940s, her work was met with great skepticism because many researchers had trouble believing that DNA segments could be mobile. The advent of molecular technology in the 1960s and 1970s allowed scientists to understand more about the characteristics of TEs that enable their movement. Most notably, research involving bacterial TEs eventually progressed to a molecular understanding of the transposition process. In 1983, more than 30 years after her initial discovery, McClintock was awarded the Nobel Prize in Physiology or Medicine.



(a) Barbara McClintock

(b) Speckled corn kernels caused by transposable elements

Figure 21.4 Barbara McClintock, who discovered transposable elements. As shown in part **(b)**, when a transposable element is found within a pigment gene in corn, its frequent movement disrupts the gene, causing the kernel color to be speckled.

(a) Organization of a DNA transposon

(b) Cut-and-paste mechanism of transposition

Figure 21.5 DNA transposons and their mechanism of transposition. **(a)** DNA transposons contain inverted repeat (IR) sequences at each end and may contain a gene that encodes transposase in the middle. **(b)** Transposition occurs by a cut-and-paste mechanism.

Concept Check: *What is the role of the inverted repeats in the mechanism of transposition?*

Researchers have studied TEs from many species, including bacteria, archaea, and eukaryotes. They have discovered that TEs fall into two groups, based on different mechanisms of movement.

DNA Transposons Transposable elements that move via a DNA molecule are called **DNA transposons**. Both ends of DNA transposons have inverted repeats (IRs)—DNA sequences that are identical (or very similar) but run in opposite directions (**Figure 21.5a**), such as the following:

```
5′-CTGACTCTT-3′        5′-AAGAGTCAG-3′
3′-GACTGAGAA-5′  and   3′-TTCTCAGTC-5′
```

Depending on the particular TE, inverted repeats range from 9 to 40 bp in length. In addition, DNA transposons may contain a central region that encodes **transposase**, an enzyme that facilitates transposition.

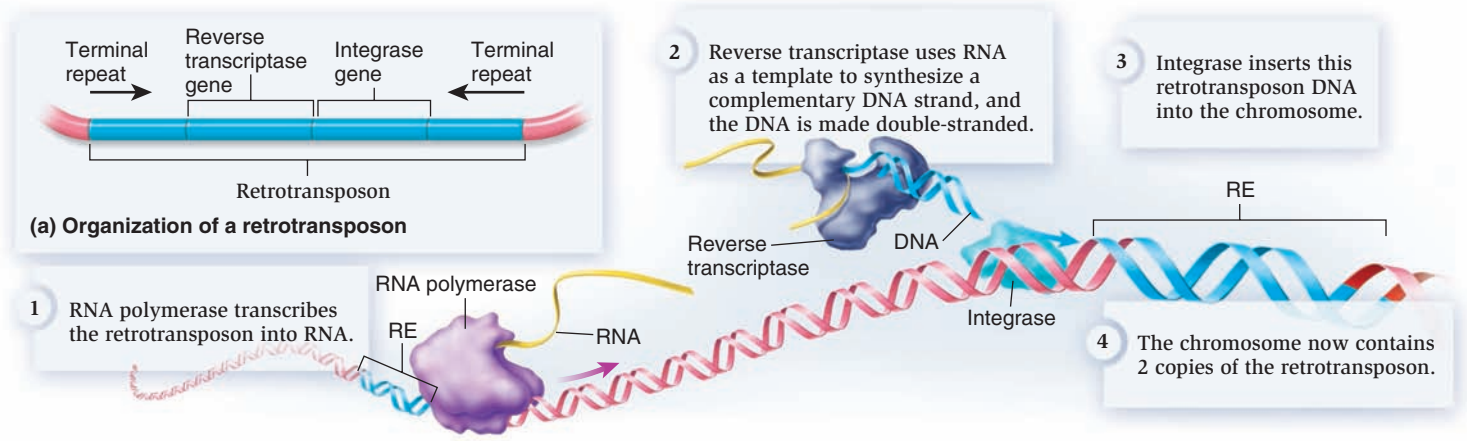


Figure 21.6 Retrotransposons and their mechanism of transposition. Retrotransposons are found only in eukaryotic species. **(a)** Some retrotransposons contain terminal repeats and genes that encode the enzymes reverse transcriptase and integrase, which are needed in the transposition process. **(b)** The process that adds a copy of a retrotransposon into a host chromosome. Note: In addition to using RNA as a template, some forms of reverse transcriptase can also use a DNA template to make a complementary DNA strand. As depicted here, these forms can make double-stranded DNA using a strand of RNA as a starting material. However, some forms of reverse transcriptase can make DNA only using an RNA template. In those cases, reverse transcriptase makes a complementary DNA strand from the RNA template and then the opposite DNA strand is made via a host-cell DNA polymerase.

Concept Check: *Based on their mechanism of movement, which type of TEs do you think would proliferate more rapidly in a genome, DNA transposons (see Figure 21.5b) or retrotransposons?*

As shown in **Figure 21.5b**, transposition of DNA transposons occurs by a cut-and-paste mechanism. Transposase first recognizes the inverted repeats (IR) in the transposon and then removes the DNA transposon from its original site. Next, the transposase/transposon complex moves to a new location, where transposase cleaves the target DNA and inserts the transposon into the site. Transposition may occur when a cell is in the process of DNA replication. If a TE is removed from a site that has already replicated and is inserted into a chromosomal site that has not yet replicated, the transposon will increase in number after DNA replication is complete. This is one way for transposons to become more prevalent in a genome.

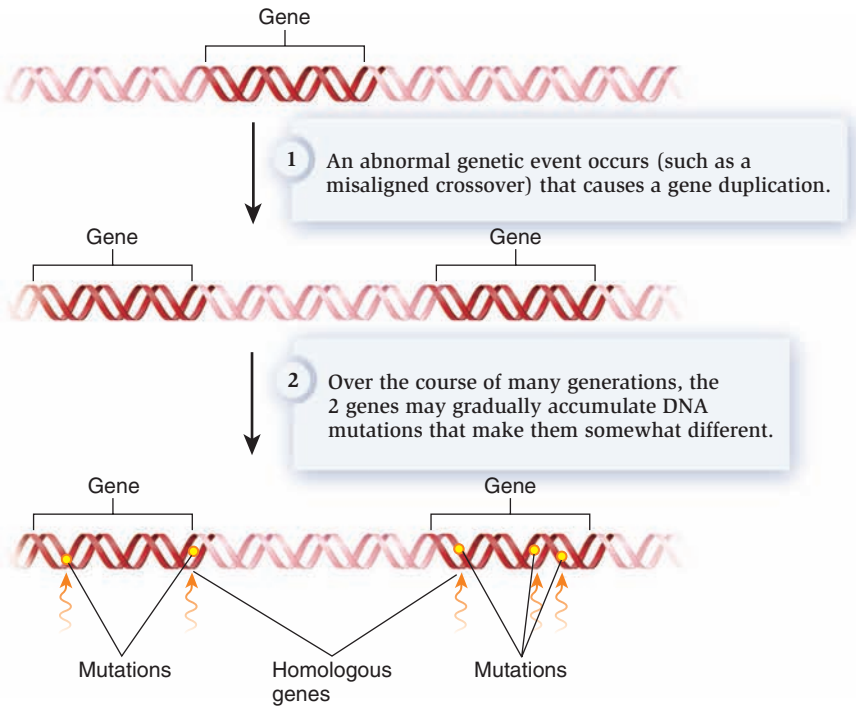
Retrotransposons Another category of TE moves via an RNA intermediate. This form of transposition is very common but is found only in eukaryotic species. These types of elements are known as **retrotransposons**, or **retroelements**. The *Alu* sequence in the human genome is an example of a retrotransposon. Some retrotransposons contain genes that encode the enzymes reverse transcriptase and integrase, which are needed in the transposition process (**Figure 21.6a**). Recall from Chapter 18 that reverse transcriptase uses RNA as a template to synthesize a complementary copy of DNA. Retrotransposons may also contain repeated sequences called terminal repeats at each end that facilitate their recognition.

One mechanism of retrotransposon movement is shown in **Figure 21.6b**. First, the enzyme RNA polymerase transcribes the retrotransposon into RNA. Reverse transcriptase uses this RNA as a template to synthesize a double-stranded DNA molecule. The ends of the double-stranded DNA are then recognized by integrase, which catalyzes the insertion of the DNA into the host chromosomal DNA. The integration of retrotransposons can occur at many locations within the genome. Furthermore, because a single retrotransposon can be copied into many RNA transcripts, retrotransposons may accumulate rapidly within a genome. This explains how the *Alu* sequence in the human genome was able to proliferate and constitute 10% of our genome.

Role of Transposable Elements What is the biological significance of TEs? The question is not resolved. According to the **selfish DNA hypothesis**, TEs exist solely because they have characteristics that allow them to insert themselves into the host cell DNA. In other words, they resemble parasites in that they inhabit the host without offering any advantage. They can proliferate within the host as long as they do not harm the host to the extent that they prevent its survival. However, TEs do not usually proliferate at a fast rate from generation to generation. For example, an *Alu* sequence is inserted into a new site in the human genome in about 1 live birth in 200. Two reasons account for the relatively low rate of movement for most TEs: First, cells possess mechanisms that minimize TE movement. Second, many TEs within a genome may have accumulated mutations that prevent their movement.

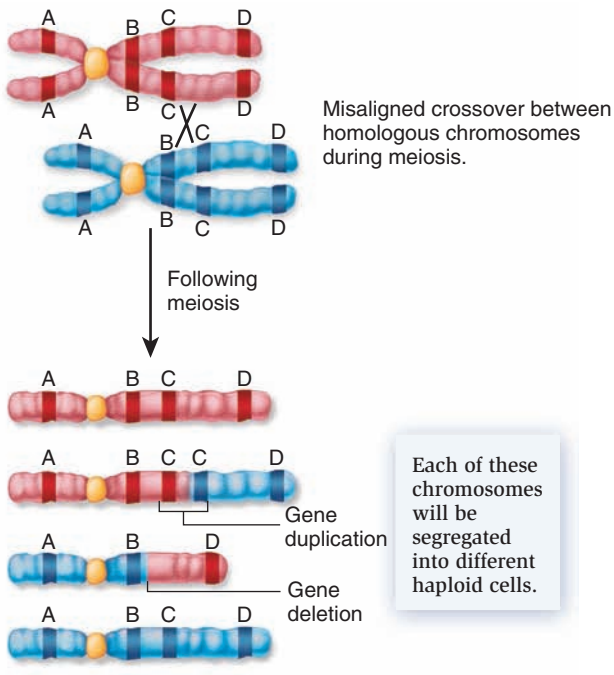
Another hypothesis that has been proposed is that TEs may provide benefits to a given species. For example, bacterial TEs often carry an antibiotic-resistance gene that provides the organism with a survival advantage. In addition, TEs may cause greater genetic diversity by promoting chromosomal rearrangements. As discussed next, such rearrangements can cause a misaligned crossover during meiosis and promote the formation of a gene family.

Gene Duplications Provide Additional Material for Genome Evolution, Sometimes Leading to the Formation of Gene Families



Let's now turn our attention to a way that the number of genes in a genome can increase. These gene duplications are important because they provide raw material for the addition of more genes into a

species' genome. Such duplications can produce **homologous genes**, two or more genes that are derived from the same ancestral gene (**Figure 21.7a**). Over the course of many generations, each version of the gene accumulates different mutations, resulting in genes with similar but not identical DNA sequences.



How do gene duplications occur? One mechanism that produces gene duplications is a misaligned crossover (**Figure 21.7b**). In this example, two homologous chromosomes have paired with each other during meiosis, but the homologs are misaligned. If a crossover occurs, this produces one chromosome with a gene duplication, one with a gene deletion, and two normal chromosomes. Each of these chromosomes is segregated into different haploid cells. If a haploid cell carrying the chromosome with the gene duplication participates in fertilization with another gamete, an offspring with a gene duplication is produced. In this way, gene duplications can form and be transmitted to future generations. The presence of multiple copies of the same transposable element in a chromosome can foster this process. When chromosomes pair up during meiosis, they can misalign with each other if they try to align TEs that are at different locations.

During evolution, gene duplications can occur several times. Two or more homologous genes within a single species are also called paralogous genes, or **paralogs**. Multiple gene duplications followed by the accumulation of mutations in each paralog results in a **gene family**—a group of paralogs that carry out related functions. A well-studied example is the globin gene family found in vertebrate animals. The globin genes encode polypeptides that are subunits of proteins that function in oxygen binding. Hemoglobin, which is made in red blood cells, carries oxygen throughout the body. In humans, the globin gene family is composed of 14 paralogs that were originally derived from a single ancestral globin gene (**Figure 21.8**). According to an evolutionary analysis, the ancestral globin gene duplicated between 500 and 600 mya. Since that time, additional duplication events and chromosomal rearrangements have occurred to produce the current number of 14 genes on three different human chromosomes. Four of these are pseudogenes—genes that have been produced by gene duplication but have accumulated mutations that make them nonfunctional, so they are not transcribed into RNA.

The accumulation of different mutations in the various family members has produced globins that are specialized in their function. For example, myoglobin binds and stores oxygen in muscle cells, whereas the hemoglobins bind and transport oxygen via red blood cells. Also, different globin genes are expressed during different stages of development. The zeta-globin (ζ) and epsilon-globin (ε) genes are expressed very early in embryonic life. During the second trimester of gestation, the alpha-globin (α) and gamma-globin (γ) genes are turned on. Following birth, the γ-globin genes are turned off, and the β-globin gene is turned on. These differences in the

(a) Gene duplication and the formation of homologous genes

(b) Mechanism of gene duplication

Figure 21.7 Gene duplication and the evolution of homologous genes. **(a)** A gene duplication produces two copies of the same gene. Over time, these copies accumulate different random mutations, which results in homologous genes with similar but not identical DNA sequences. **(b)** Mechanism of gene duplication. If two homologous chromosomes misalign during meiosis, a crossover will produce a chromosome with a gene duplication.

BIOLOGY PRINCIPLE **Populations of organisms evolve from one generation to the next.** In this example, evolution involves two different types of genetic changes. First, a gene duplication occurs, and second, each copy of the gene accumulates different mutations.

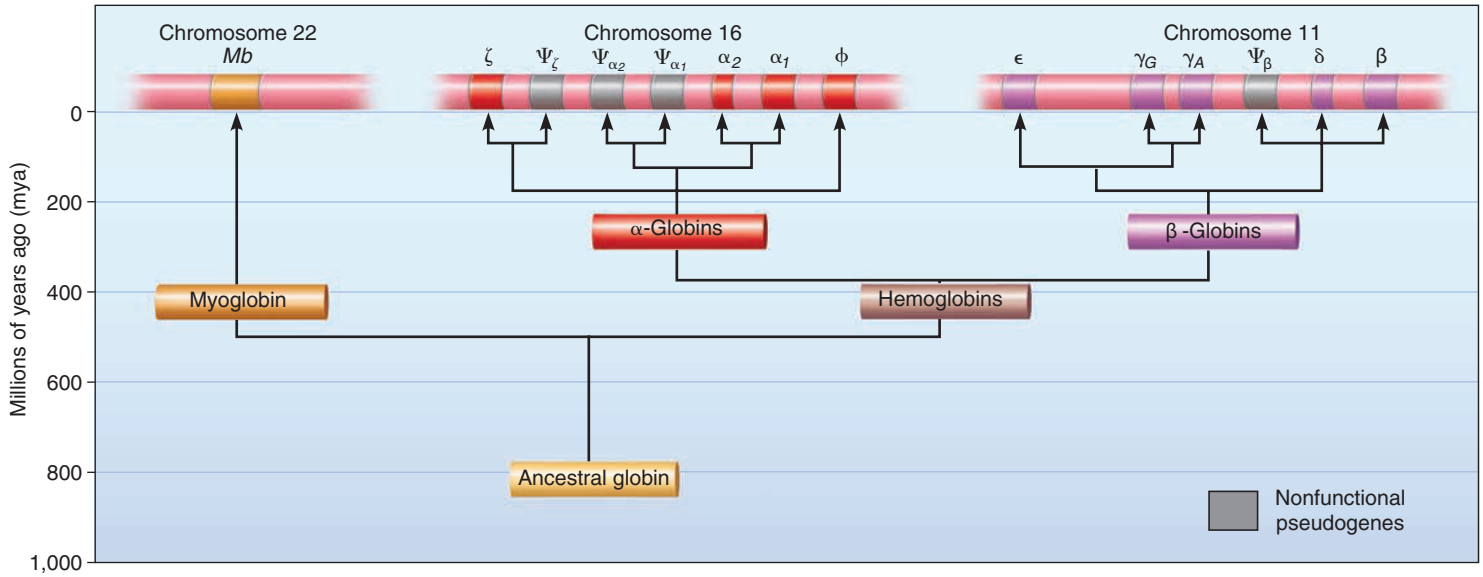


Figure 21.8 The evolution of the globin gene family in humans. The globin gene family evolved from a single ancestral globin gene.

BioConnections: *Look back to Figure 13.3. How do different gene family members vary in their affinity for oxygen?*

expression of the globin genes reflect the differences in the oxygen transport needs of humans during the embryonic, fetal, and postpartum stages of life (refer back to Figure 13.3).

The Human Genome Project Has Stimulated Genomic Research

Before ending our discussion of genomes, let's consider the **Human Genome Project**, a research effort to identify and map all human genes. Scientists had been discussing how to undertake this project since the mid-1980s. In 1988, the National Institutes of Health (NIH) in Bethesda, Maryland, established an Office of Human Genome Research with James Watson as its first director. The Human Genome Project officially began on October 1, 1990, and was largely finished by the end of 2003. It was an international consortium that included research institutions in the U.S., U.K., France, Germany, Japan, and China. From its outset, the Human Genome Project had the following goals:

1. *To identify all human genes*. This involved mapping the locations of genes throughout the entire genome. The data from the Human Genome Project suggest that humans have about 22,000 different genes.
2. *To obtain the DNA sequence of the entire human genome*. The first draft of a nearly completed DNA sequence was published in February 2001, and a second draft was published in 2003. The entire genome is approximately 3.2 billion base pairs in length.
3. *To develop technology for the generation and management of human genome information*. Some of the efforts of the Human Genome Project have involved improvements in molecular genetic technology, such as gene cloning, DNA sequencing, and so forth. The Human Genome Project has also developed computer tools to allow scientists to easily access up-to-date information from the project and analytical tools to interpret genomic information.
4. *To analyze the genomes of model organisms*. These include *E. coli*, *S. cerevisiae*, *D. melanogaster*, *C. elegans*, *A. thaliana*, and *M. musculus*.
5. *To develop programs focused on understanding and addressing the ethical, legal, and social implications of the results obtained from the Human Genome Project*. The Human Genome Project raised many ethical issues regarding genetic information and genetic engineering. Who should have access to genetic information? Should employers, insurance companies, law enforcement agencies, and schools have access to our genetic makeup? Another controversial topic is gene patenting. Should the blueprints of life be considered patentable, like any other invention, or should there be limits to the patenting of genes? The answers to such questions are complex and will require discussion among many groups.

Some current and potential applications of the Human Genome Project include the improved diagnosis and treatment of genetic diseases such as cystic fibrosis, Huntington disease, and Duchenne muscular dystrophy. The project may also enable researchers to identify the genetic basis of common disorders such as cancer, diabetes, and heart disease, which involve alterations in several genes.

21.3 Proteomes

Learning Outcomes:

1. Distinguish between a proteome and a genome.
2. List the major categories of proteins in a proteome.
3. Explain how the number of proteins in an organism's proteome exceeds the number of genes in its genome.

Thus far in this chapter, we have considered the genome characteristics of many different species, including humans. Because most genes encode proteins, a logical next step is to examine the functional roles of the proteins that a species can make. As mentioned, the entire collection of proteins that a cell or organism produces is called a proteome. As we move forward in the 21st century, a key challenge facing molecular biologists is the study of proteomes. Much like the study of genomes, this will require the collective contributions of many scientists, as well as improvements in technologies to investigate the complexities of the proteome. In this section, we will begin by considering the functional categories of proteins and then examine their relative abundance in the proteome. We also will explore the molecular mechanisms that cause an organism's proteome to be much larger than its genome.

A Proteome Is a Diverse Array of Proteins with Many Kinds of Functions

As we have seen, the genomes of simple, unicellular organisms such as bacteria and yeast contain thousands of structural genes, whereas the genomes of complex, multicellular organisms contain tens of thousands. Such genome sizes can produce proteomes with tens of thousands to hundreds of thousands of different proteins. To bring some order to this large amount of complex information, researchers often organize proteins into different categories based on their functions. **Table 21.3** describes some general categories of protein function and provides examples of each type. Many approaches are used to categorize proteins. Table 21.3 shows just one of the more general ways to categorize protein function. Note that the data of Figure 21.1 displays the functions of proteins encoded by genes in a different, more detailed way.

The relative abundance of proteins can be viewed at two levels. First, we can consider abundance in the genome—the numbers of genes in the genome that encode a particular type or category of protein. For example, if an entire genome encodes 10,000 different types of proteins and 1,500 of these are different types of transporters, we would say that 15% of the genome encodes transporters. However, such an analysis ignores the phenomenon that genes are expressed at different levels. In other words, various proteins are made in different amounts. Therefore, a second way to view protein abundance is to consider abundance in the cell—the amount of a given protein or protein category actually made by a living cell. For example, less than 1% of human genes encode proteins, such as collagen, that are found in the extracellular matrix (ECM). Even so, these genes are highly expressed in certain cells, so a large amount of this type of protein is made compared with other types.

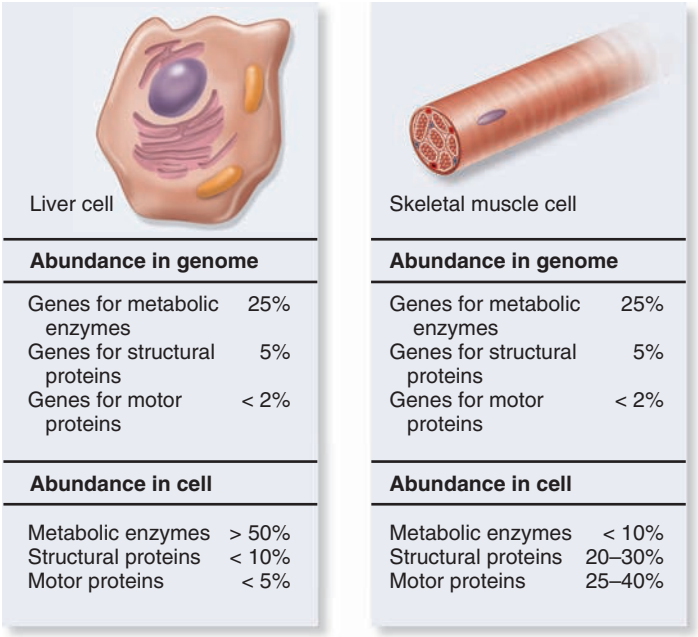

Figure 21.9 is a general comparison of protein abundance in two cell types in humans: liver and muscle cells. Liver cells play a key role in metabolism, whereas muscle cells are involved in bodily movements. Both liver and muscle cells have the same genes. Therefore, at the level of the genome, the percentages of the different protein categories are identical. However, at the cellular level, the relative abundance of certain protein categories is quite different. Liver cells make a large number of different enzymes that play a role in the metabolism of fats, proteins, and carbohydrates. By comparison, their level of structural and motor proteins is relatively small. In contrast, muscle cells have fairly low levels of enzymes but make a high percentage of structural and motor proteins. These differences in protein composition between liver and muscle cells are largely due to differential gene regulation.

Table 21.3 Categories of Proteins Found in the Proteome

Function	Examples
Metabolic enzymes—accelerate chemical reactions in the cell. 	Hexokinase: Phosphorylates glucose during the first step in glycolysis. Glycogen synthetase: Uses glucose to synthesize a large carbohydrate known as glycogen.
Structural proteins—provide shape and protection to cells. 	Tubulin: Forms cytoskeletal structures known as microtubules. Collagen: Forms large fibers in the extracellular matrix (ECM) of animals.
Motor proteins—facilitate intracellular movements and the movements of whole cells. 	Myosin: Involved in muscle cell contraction. Kinesin: Involved in the movement of chromosomes during cell division.
Cell-signaling proteins—allow cells to respond to environmental signals and send signals to each other. 	Insulin: Influences target cell metabolism and growth. Insulin receptor: Recognizes insulin and initiates a cellular response.
Transport proteins—involved in the transport of ions and molecules across membranes and throughout the body. 	Lactose permease: Transports lactose across the bacterial cell membrane. Hemoglobin: Found in red blood cells and transports oxygen throughout the body.
Gene expression and regulatory proteins—involved in transcription, mRNA modification, translation, and gene regulation. 	Transcription factors: Regulate the expression of genes. Ribosomal proteins: Components of ribosomes, which are needed for the synthesis of new proteins.
Defense and protective proteins—help cells and organisms to fight disease and survive environmental stress. 	Antibodies: Fight viral and bacterial infections in vertebrate species. Chaperones such as heat shock proteins: Play a role in protein folding, thereby helping cells cope with stresses such as abrupt increases in temperature.

The Number of Different Polypeptides in a Species' Proteome Is Larger Than the Number of Genes in Its Genome

From the sequencing and analysis of genomes, researchers can identify all or nearly all of the genes of a given species. For example, the human genome is believed to contain about 22,000 different genes

Liver cell

Abundance in genome	
Genes for metabolic enzymes	25%
Genes for structural proteins	5%
Genes for motor proteins	< 2%
Abundance in cell	
Metabolic enzymes	> 50%
Structural proteins	< 10%
Motor proteins	< 5%

Skeletal muscle cell

Abundance in genome	
Genes for metabolic enzymes	25%
Genes for structural proteins	5%
Genes for motor proteins	< 2%
Abundance in cell	
Metabolic enzymes	< 10%
Structural proteins	20–30%
Motor proteins	25–40%

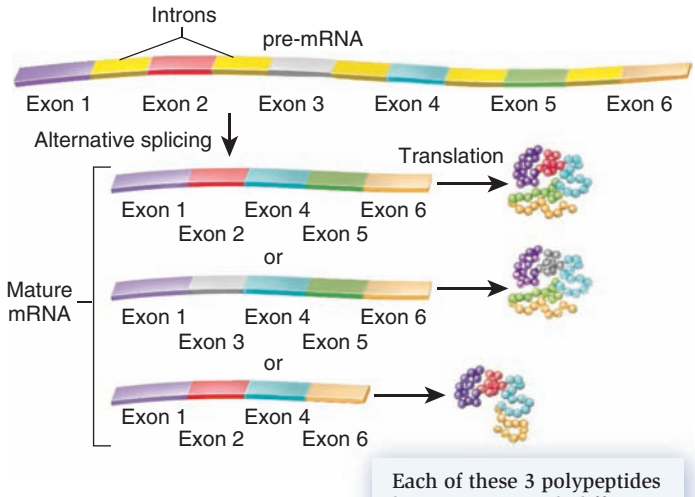

Figure 21.9 A comparison of the proteomes in human liver and skeletal muscle cells. Because all cells of the human body carry the same genome, the percentages of proteins encoded in the genome are the same in each cell type. However, the relative amounts of proteins made in different cell types can be vastly different, as seen here.

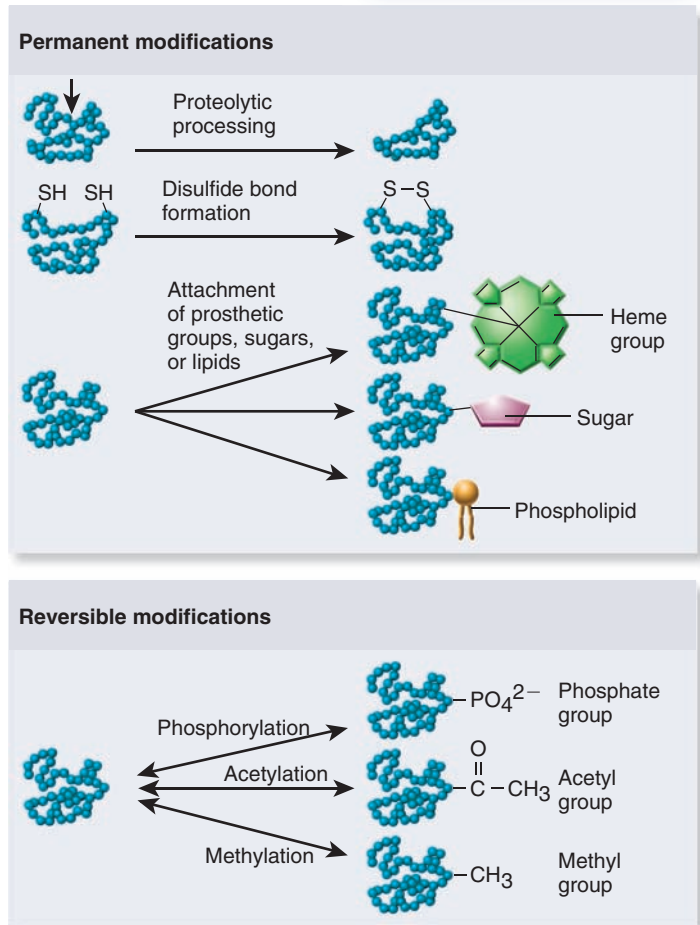
Concept Check: What genetic process explains the differences in protein abundance in liver cells versus muscle cells?

that encode polypeptides. Even so, humans can make many more than 22,000 different types of polypeptides. How is this possible? The larger size of the proteome relative to the genome is primarily due to two types of cellular processes: alternative splicing and post-translational covalent modification, as described next.



Alternative Splicing Due to **alternative splicing**, different mRNA molecules can be produced from the same pre-mRNA transcript (refer back to Figure 13.22). For many genes, a single pre-mRNA can be spliced in more than one way, resulting in the production of two or more polypeptides with different amino acid sequences (**Figure 21.10a**). The splicing is often cell specific or may be related to environmental conditions. Alternative splicing is widespread, particularly among more complex eukaryotes (refer back to Table 13.3). It can lead to the production of several or perhaps dozens of different polypeptides from the same pre-mRNA. This greatly increases the number of proteins in a species' proteome, while minimizing the size of the genome.

Post-translational Covalent Modification A second process that greatly diversifies the composition of a proteome is the phenomenon of **post-translational covalent modification**, the modification of the structure of a protein after translation (**Figure 21.10b**). Such modifications can be permanent or reversible. Permanent modifications are often involved with the assembly and construction of functional proteins. These alterations include proteolytic processing (the cleavage of a polypeptide to a smaller unit), disulfide bond formation, and

Each of these 3 polypeptides has segments with different amino acid sequences.

(a) Alternative splicing

(b) Post-translational covalent modification

Figure 21.10 Cellular mechanisms that increase protein diversity. **(a)** Following alternative splicing, the pattern of exons in the resulting mature mRNA can be different, producing multiple types of polypeptides from the same gene. **(b)** In post-translational covalent modification, after a protein is made, it can be modified in a variety of ways, some of which are permanent and some reversible.

BioConnections: Look back at Figure 9.13. How is reversible phosphorylation used in cell signaling?

the attachment of prosthetic groups (such as heme, a component of hemoglobin), sugars, or lipids. By comparison, reversible modifications, such as phosphorylation, acetylation, and methylation, often transiently affect the function of a protein (see Figure 21.10b). Molecules are covalently attached and later removed by cellular enzymes. Because a given type of protein may be subjected to several different types of modifications, this can greatly increase the forms of a particular protein that are found in a cell at any given time.

21.4 Bioinformatics

Learning Outcomes:

1. Describe how scientists use bioinformatics.
2. Define database.
3. **SciSKILLS** » Explain how the BLAST program works and why it is useful.

In the previous sections, we learned that the number of genes in a genome and the number of proteins made by a given cell type are extremely large. In the 1960s and 1970s, when the tools of molecular biology first became available, researchers tended to focus on the study of just one or a few genes and proteins at a time. Although this is a useful approach, scientists came to realize that certain properties of life emerge from complex interactions involving the expression of many genes and the functioning of many different proteins. The study of such complex interactions is called **systems biology**. This new perspective, coupled with the wealth of data produced by the genomics projects described previously in this chapter, challenged researchers to invent new tools to study many genes and proteins simultaneously.

As a very general definition, **bioinformatics** is the use of computers, mathematical tools, and statistical techniques to record, store, and analyze biological information. Why do we need bioinformatics? Simply put, the main issues are size and speed. Earlier in this chapter, we learned that the human genome has been sequenced and that it is approximately 3.2 billion base pairs long. A single person, or even a group of talented mathematicians, could not, in a reasonable length of time, analyze such an enormous amount of data. Instead, the data are put into computers, and scientists devise computational procedures to study and evaluate it.

In this section, we will consider the branch of bioinformatics that focuses on using molecular information to study biology. This area, also called **computational molecular biology**, uses computers to characterize the molecular components of living things. Molecular genetic data, which come in the forms of DNA, RNA, or protein sequences, are particularly amenable to computer analysis. In this section, we will first survey the fundamental concepts that underlie the analysis of genetic sequences. We will then consider how these methods are used to provide knowledge about how biology works at the molecular level.

Sequence Files Are Stored and Analyzed by Computers

The first steps in bioinformatics are to collect and store data in a computer. As an example, let's consider a gene sequence as a type of data. The gene sequence must first be determined experimentally using the technique of DNA sequencing. After the sequence is obtained, the next step is to put those data into a file on a computer. Typically, genetic sequence data are entered into a computer file by laboratory instruments that can read experimental data—such as data from a DNA-sequencing experiment—and enter the data directly into a computer.

Genetic sequence data in a computer data file can then be investigated in many different ways, corresponding to the many questions a researcher might ask about the data and its functional significance, including the following:

1. Does a sequence contain a gene?
2. Does a gene sequence carry a mutation that might cause a disease?
3. Where are functional sequences, such as promoters, regulatory sites, and splice sites, located within a particular gene?
4. From the sequence of a structural gene, what is the amino acid sequence of the polypeptide encoded by that gene?
5. Is there an evolutionary relationship between two or more genetic sequences?

To answer these and many other questions, computer programs have been written to analyze genetic sequences in particular ways. As an example, let's consider a computer program aimed at translating a DNA sequence into an amino acid sequence. **Figure 21.11** shows a short computer data file of a DNA sequence that is presumed to be part of the coding sequence of a structural gene. In this figure, only the coding strand of DNA is shown. A computer program can analyze this sequence and print out the possible amino acid sequences that this DNA sequence would encode. The program relies on the genetic code (refer back to Table 12.1). In the example shown in Figure 21.11, the computer program shows the results for all three possible reading frames, beginning at nucleotide 1, 2, or 3, respectively. In a newly obtained DNA sequence, a researcher would not know the proper reading frame—the series of codons read in groups of three, which begins with the start codon. Therefore, the computer program provides all three. If you look at the results, reading frames 1 and 2 include several stop codons, whereas reading frame 3 does not. From these results, reading frame 3 is likely to be the correct one. Also, for a new DNA sequence, a researcher may not know which DNA strand is the coding strand. Therefore, the sequence of the other DNA strand, which is not shown in this figure, would also be analyzed by this computer program.

The Scientific Community Has Collected Computer Data Files and Stored Them in Large Databases

Over the past several decades, the amount of genetic information generated by researchers and clinicians has become enormous. With these advances, scientists have realized that another critical use of computers is to store the staggering amount of data produced from genetic research.

A large amount of data that is collected, stored in a single location, and organized for rapid search and retrieval is called a **database**. The files within genetic databases are often annotated, which means they contain a concise description of each gene sequence, the name of the organism from which the sequence was obtained, and the function of the encoded protein, if it is known. The file may also provide a published reference that contains the sequence.

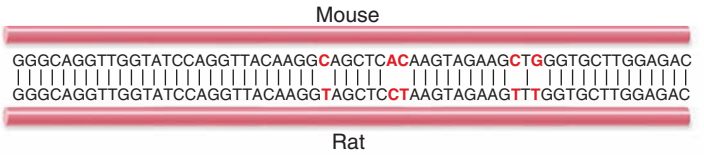
Figure 21.11 The use of a computer program to translate a DNA sequence into an amino acid sequence. The top part of this figure shows the sequence of a segment of the coding strand of a structural gene (divided into groups of 10 bases for ease of reading). A computer program translates the DNA sequence into an amino acid sequence based on the genetic code. The program produces three different amino acid sequences, as shown at the bottom of the figure. In this example, reading frame 3 is likely to be the correct one because it does not contain any stop codons.

Concept Check: Why is it helpful to use a computer program to translate a genetic sequence rather than doing it by hand?

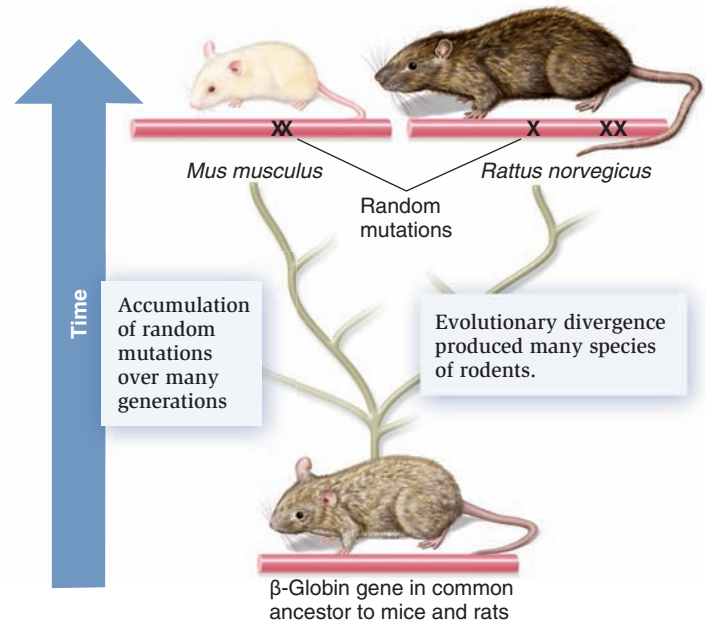
Table 21.4 Examples of Major Genetic Databases

Nucleotide sequences	DNA sequence data are collected into three internationally collaborating databases: GenBank (a U.S. database), EMBL (European Molecular Biology Laboratory Nucleotide Sequence Database), and DDBJ (DNA Data Bank of Japan). These databases receive sequence and sequence annotation data from genome projects, sequencing centers, individual scientists, and patent offices. New and updated entries are exchanged daily.
Amino acid sequences	Protein sequence data are collected into a few international databases, including Swiss-Prot (Swiss protein database), PIR (Protein Information Resource), TrEMBL (translated sequences from the EMBL database), and Genpept (translated peptide sequences from the GenBank database).



The research community has collected genetic information from thousands of research laboratories and created several large databases. **Table 21.4** describes some of the major genetic databases in use worldwide, all of which can be accessed online. These databases enable researchers to access and compare genetic sequences that are obtained by many laboratories. Later in this chapter, we will learn how researchers use databases to analyze genetic sequences.

Many programs are freely available over the Internet to utilize the information within databases. For example, the National Center for Biotechnology Information (NCBI), which is a part of the U.S. National Institutes of Health, manages a website called "Tools for Data Mining," where anyone can run various types of programs that are used to analyze genetic sequences (www.ncbi.nlm.nih.gov/Tools). Like conventional mining, in which a mineral is extracted from a large area of land, **data mining** is the extraction of useful information and often previously unknown relationships from sequence files and large databases.

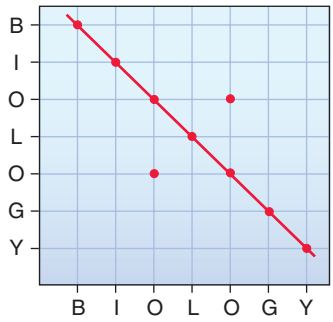


Computer Programs Can Identify Homologous Sequences

Let's now turn our attention to genes that are evolutionarily related. Organisms that are closely related evolutionarily tend to have genes with similar DNA sequences. As an example, let's consider the gene that encodes β-globin. As described earlier in Figure 21.8, β-globin is a polypeptide found in hemoglobin, which carries oxygen in red blood cells. The β-globin gene is found in humans and other vertebrates.

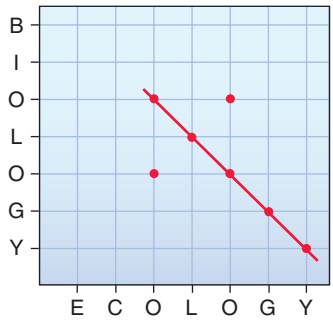
Figure 21.12a compares a short region of the β-globin gene from the laboratory mouse (*Mus musculus*) and from a laboratory rat (*Rattus norvegicus*). As you can see, the gene sequences are similar but not identical. In this 60-nucleotide sequence, five differences are observed. The reason for the sequence similarity is that the genes are derived from the same ancestral gene. This idea is shown schematically in **Figure 21.12b**. An ancestral gene was found in a rodent species that was a common ancestor to both mice and rats. During evolution, this ancestral species diverged into different species, which eventually gave rise to several modern rodent species, including mice and rats. Following divergence, the β-globin genes accumulated distinct mutations that produced somewhat different base sequences

(a) A comparison of one DNA strand of the mouse and rat β-globin genes



(b) The formation of homologous β-globin genes during evolution of mice and rats

Figure 21.12 Structure and formation of the homologous β-globin genes in mice and rats. **(a)** A comparison of a short region of the gene that encodes β-globin in laboratory mice (*Mus musculus*) and rats (*Rattus norvegicus*). Only one DNA strand is shown. Bases that are identical between the two sequences are connected by a vertical line. **(b)** Schematic view of the formation of these homologous β-globin genes during evolution. An ancestral β-globin gene was found in an ancestor common to both mice and rats. This ancestral species later diverged into different species, which gave rise to modern rodent species. During this process, the β-globin genes accumulated different random mutations, resulting in DNA sequences that are slightly different from each other.



Concept Check: *Is it possible for orthologs from two different species to have exactly the same DNA sequence? Explain.*

for this gene. Therefore, in mice and rats, the β-globin genes have homologous sequences—sequences that are similar because they are derived from the same ancestral gene, but not identical because each species has accumulated a few different random mutations. Homologous genes in different species are also called orthologous genes, or **orthologs**. Analyzing orthologs helps biologists understand the evolutionary relationships among modern species, a topic that we will consider in more detail in Units IV and V.

How do researchers, with the aid of computers, determine if two genes are homologous to each other? To evaluate the similarity between two sequences, a matrix can be constructed. **Figure 21.13** illustrates the use of a simplified dot matrix to evaluate two sequences.

(a) Comparison of two identical words

(b) Comparison of two different words

Figure 21.13 The use of a simple dot matrix. In these comparisons, a diagonal line indicates sequence similarity. **(a)** The word BIOLOGY is compared with itself. Dots are placed where the same letter occurs at the two corresponding positions. Notice the diagonal line that is formed. **(b)** Two similar but different sequences, BIOLOGY and ECOLOGY, are compared with each other. Notice that only a partial line is formed by this comparison.

In Figure 21.13a, the word BIOLOGY is compared with itself. Each point in the grid corresponds to one position of each sequence. The matrix allows all such pairs to be compared simultaneously. Dots are placed where the same letter occurs at the two corresponding positions. Sequences that are alike produce a diagonal line on the matrix. Figure 21.13b compares two similar but different sequences: BIOLOGY and ECOLOGY. This comparison produces only a partial diagonal line. Overall, the key observation is that regions of similarity are indicated by many dots along a diagonal line within the matrix. This same concept holds true when base sequences of homologous genes are compared with each other.

To discover whether homology exists between two genes, researchers must compare relatively long DNA sequences. For such long sequences, a dot matrix approach is not adequate. Instead, dynamic computer programming methods are used to identify optimal alignments between genetic sequences. This approach was first proposed by Saul Needleman and Christian Wunsch in 1970. Dynamic programming methods are theoretically similar to the use of a dot matrix, but they involve mathematical operations that are beyond the scope of this textbook. In their original work, Needleman and Wunsch discovered that whale myoglobin and human β-globin genes have similar sequences.

A Database Can Be Searched to Identify Similar Sequences and Thereby Infer Homology and Gene Function

Why is it useful to identify homology between different genes? Because they are derived from the same ancestral gene, homologous genes usually carry out similar or identical functions. In many cases, the first way to identify the function of a newly determined gene sequence is to find a homologous gene whose function is already known. An example is the gene that is altered in cystic fibrosis patients. After this gene was identified in humans, bioinformatic methods revealed that it is homologous to several genes found in other species. A few of the homologous genes were already known

Table 21.5 Results from a BLAST Program Comparing Human Phenylalanine Hydroxylase with Database Sequences

Match	Percentage of identical amino acids*	Species	Function of sequence†
1	100	Human (*Homo sapiens*)	Phenylalanine hydroxylase
2	99	Orangutan (*Pongo pygmaeus*)	Phenylalanine hydroxylase
3	95	Mouse (*Mus musculus*)	Phenylalanine hydroxylase
4	95	Rat (*Rattus norvegicus*)	Phenylalanine hydroxylase
5	89	Chicken (*Gallus gallus*)	Phenylalanine hydroxylase
6	82	Pipid frog (*Xenopus tropicalis*)	Phenylalanine hydroxylase
7	82	Green pufferfish (*Tetraodon nigroviridis*)	Phenylalanine hydroxylase
8	82	Zebrafish (*Danio rerio*)	Phenylalanine hydroxylase
9	80	Japanese pufferfish (*Takifugu rubripes*)	Phenylalanine hydroxylase
10	75	Fruit fly (*Drosophila melanogaster*)	Phenylalanine hydroxylase

*The number indicates the percentage of amino acids that are identical with the amino acid sequence of human phenylalanine hydroxylase. Note: These matches were randomly selected from a long list of matches.

†In some cases, the function of the sequence was determined by biochemical assay. In other cases, the function was inferred due to the high degree of sequence similarity with other species.

to encode proteins that function in the transport of ions and small molecules across the plasma membrane. This observation provided an important clue that cystic fibrosis involves a defect in membrane transport.

The ability of computer programs to identify homology between genetic sequences provides a powerful tool for predicting the function of genetic sequences. In 1990, American mathematician Stephen Altschul, his colleague biologist David Lipman, and their coworkers developed a program called **BLAST** (for Basic Local Alignment Search Tool). The BLAST program has been described by many biologists as the single most important tool in bioinformatics. This computer program starts with a particular genetic sequence—either a nucleotide or an amino acid sequence—and then locates homologous sequences within a large database.

As an example of how the BLAST program works, let's consider the human enzyme phenylalanine hydroxylase, which functions in the metabolism of phenylalanine, an amino acid. Recessive mutations in the gene that encodes this enzyme are responsible for the disease called phenylketonuria (PKU). The computational experiment shown in **Table 21.5** started with the amino acid sequence of this protein and used the BLAST program to search the Swiss-Prot database, which contains millions of different protein sequences. The BLAST program determines which sequences in the Swiss-Prot database are the closest matches to the amino acid sequence of human phenylalanine hydroxylase. Table 21.5 shows some of the results, which includes 10 of the matches to human phenylalanine hydroxylase that were identified by the program. The column to the right of the match number shows the percentage of amino acids that are identical between the species indicated and the human sequence. Because the human phenylalanine hydroxylase sequence is already in the Swiss-Prot database, the closest match of human phenylalanine hydroxylase is to itself. The next nine sequences are in order of similarity. The next most similar sequence is from the orangutan, a primate that is a close relative of humans. This is followed by two other mammals, the mouse and rat, and then five vertebrates that are not mammals. The tenth best match is from *Drosophila*, an invertebrate.

As you may have noticed, the order of the matches follows the evolutionary relatedness of the various species to humans. The similarity between any two sequences is related to the time that has passed since they diverged from a common ancestor. Among the species listed in this table, humans are most closely related to the orangutan, other mammals, other vertebrates, and finally invertebrates.

Overall, Table 21.5 provides a demonstration of the remarkable computational abilities of current computer technology. In less than a minute, the amino acid sequence of human phenylalanine hydroxylase can be compared with millions of different sequences to yield the data shown in this table! The main power of the BLAST program is its use with newly identified sequences, for which a researcher does not know the function of a gene or an encoded protein. When the BLAST program identifies a match to a sequence whose function is already known, it is likely that the newly identified sequence has an identical or similar function.

BIO TIPS

THE QUESTION *A plant biologist interested in genes that play a role in drought resistance identified a gene in rice plants that causes the plants to be drought-resistant when a mutation renders the gene inactive. The sequence of the rice gene was used in a search of a database with the BLAST program. One of the homologs identified by the search was a gene in Arabidopsis thaliana that encodes a protein called aquaporin. What is the likely function of the protein encoded by the rice gene? Propose a hypothesis to explain why rice plants carrying an inactive version of this gene are drought-resistant.*

TOPIC ***What topic in biology does this question address?*** The topic is about homology. More specifically, the question is about understanding the role of a gene in rice plants based on its homology to a gene in *Arabidopsis*.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you know that a gene in rice plants results in drought resistance when it is inactive, and this gene is homologous to a gene in *Arabidopsis* that encodes aquaporin. From your understanding of the topic, you may remember that homologous genes often encode proteins with similar or identical functions.

PROBLEM-SOLVING STRATEGY ***Search the literature. Relate structure and function. Propose a hypothesis.*** To begin to solve this problem, you need to know the function

of aquaporin in *Arabidopsis*. To do so, you can search the scientific literature, using "aquaporin" as a keyword and a search tool such as PubMed (www.ncbi.nlm.nih.gov/pubmed). Because the rice and *Arabidopsis* genes are homologous, they encode proteins with similar structures. Because their structures are similar, these proteins are likely to have similar functions. Determining the likely function of the protein encoded by the rice gene may provide a clue to help you hypothesize the gene's role in drought resistance.

ANSWER *From a literature search, you discover that aquaporin is a membrane-embedded protein that provides a channel for the diffusion of water; it allows water to move more readily across the cell membrane. A reasonable hypothesis is that the rice gene encodes such a channel protein, which could allow water to more easily escape rice plant cells. When this gene is inactivated by a mutation, the rice plants may not lose water as easily and therefore would be more drought-resistant than plants that do not carry this mutation.*

Summary of Key Concepts

21.1 Bacterial and Archaeal Genomes

- The genome is the complete genetic makeup of a cell, organism, or species.
- Bacterial and archaeal genomes are typically a single circular chromosome with a few million base pairs of DNA. Such genomes usually have a few thousand different genes. Bacteria often have plasmids (Table 21.1).
- Venter, Smith, and colleagues used shotgun DNA sequencing to sequence the first genome, that of the bacterium *Haemophilus influenzae* (Figure 21.1).

21.2 Eukaryotic Genomes

- The nuclear genomes of eukaryotic species are composed of sets of linear chromosomes with a total length of several million to billions of base pairs. They typically contain several thousand to tens of thousands of genes (Table 21.2).
- Genome sizes vary among eukaryotic species. In many cases, variation is due to the accumulation of noncoding regions of DNA, particularly repetitive DNA sequences (Figures 21.2, 21.3).
- Much of the repetitive DNA is derived from transposable elements, segments of DNA that can move from one site to another through a process called transposition (Figure 21.4).
- Transposable elements fall into two groups that move by different molecular mechanisms. DNA transposons move by a cut-and-paste mechanism facilitated by the enzyme transposase. Retrotransposons move to new sites in the genome via RNA intermediates (Figures 21.5, 21.6).
- Gene duplication may occur by a misaligned crossover during meiosis. This is one mechanism that can produce a gene family, two or more homologous genes in a species that have related functions (Figures 21.7, 21.8).
- The Human Genome Project, an international effort to map and sequence the entire human genome, was completed by an international consortium in 2003.

21.3 Proteomes

- A proteome is the collection of proteins that a given cell or species makes.
- Proteins can be placed into broad categories based on their functions. These include metabolic enzymes, structural proteins, motor proteins, cell-signaling proteins, transport proteins, proteins involved with gene expression and regulation, and those involved with protection and defense (Table 21.3).
- Protein abundance refers to the number of genes encoding a particular type of protein or the amount of a protein made by a cell (Figure 21.9).
- Protein diversity increases via mechanisms such as alternative splicing and post-translational covalent modification (Figure 21.10).

21.4 Bioinformatics

- Bioinformatics involves the use of computers, mathematical tools, and statistical techniques to record, store, and analyze biological information, particularly genetic data such as DNA and protein sequences.
- Genetic information is stored in large genetics databases that are analyzed using computer programs (Figure 21.11, Table 21.4).
- Homologous genes are derived from the same ancestral gene and have accumulated random mutations that make their sequences slightly different (Figure 21.12).
- Scientists use computer programs to determine if gene sequences are homologous (Figure 21.13).
- Computer programs, such as BLAST, identify homologous sequences that are found in a database (Table 21.5).

Assess and Discuss

Test Yourself

1. The entire collection of proteins produced by a cell or organism is
   a. a genome.
   b. bioinformatics.
   c. a proteome.
   d. a gene family.
   e. a protein family.
2. Important reasons for studying the genomes of bacteria and archaea include all of the following except
   a. it may provide information that helps us understand how bacteria infect other organisms.
   b. it may provide a basic understanding of cellular processes that allow us to determine eukaryotic cellular function.
   c. it may provide the means of understanding evolutionary processes.
   d. it will reveal the approximate number of genes that an organism has in its genome.
   e. All of the above are important reasons.
3. The enzyme that allows short segments of DNA to move from one location in the genome to another is
   a. transposase.
   b. DNA polymerase.
   c. protease.
   d. restriction endonuclease.
   e. DNA ligase.
4. A gene family includes
   a. one specific gene found in several different species.
   b. all of the genes on the same chromosome.
   c. two or more homologous genes found within a single species.
   d. genes that code for structural proteins.
   e. both a and c.

5. Which of the following was *not* a goal of the Human Genome Project?
   a. identify all human genes
   b. sequence the entire human genome
   c. address the legal and ethical implications resulting from the project
   d. develop programs to manage the information gathered from the project
   e. be able to clone a human
6. Bioinformatics is
   a. the analysis of DNA by molecular techniques.
   b. the use of computers to analyze and store biological information.
   c. a collection of gene sequences from a single individual.
   d. cloning.
   e. all of the above.
7. Using bioinformatics, evolutionary relationships among species can be characterized by identifying and analyzing
   a. phenotypes of selected organisms.
   b. homologous DNA sequences from different organisms.
   c. fossils of ancestral species.
   d. all of the above.
   e. a and b only.
8. Repetitive sequences
   a. are short DNA sequences that are found many times throughout the genome.
   b. may be multiple copies of the same gene found in the genome.
   c. are more common in eukaryotes.
   d. all of the above
   e. a and c only
9. The BLAST program is a tool for
   a. inserting many DNA fragments into a cell at the same time.
   b. translating a DNA sequence into an amino acid sequence.
   c. identifying homology between a selected sequence and genetic sequences in databases.
   d. all of the above.
   e. both b and c.
10. Let's suppose you used the BLAST program beginning with a DNA sequence from a *Drosophila* hexokinase gene. (Hexokinase is an enzyme involved with glucose metabolism.) Which of the following choices would you expect to be the closest match?
    a. a *Drosophila* globin gene
    b. a human hexokinase gene
    c. a housefly hexokinase gene
    d. an *Arabidopsis* hexokinase gene
    e. an amoeba hexokinase gene

Conceptual Questions

1. Briefly describe whether or not each of the following could be appropriately described as a genome.
   a. the *E. coli* chromosome
   b. human chromosome 11
   c. a complete set of 10 chromosomes in corn
   d. a copy of the single-stranded RNA packaged into human immunodeficiency virus (HIV)
2. Describe two main reasons why the proteomes of eukaryotes are usually much larger than their genomes.
3.  A principle of biology is that *the genetic material provides a blueprint for reproduction*. Explain the roles of the genome and the proteome with regard to this principle.

Collaborative Questions

1. Compare and contrast the genomes of bacteria, archaea, and eukaryotes.
2. The following is a DNA sequence from one strand of a gene. (The bases are shown in groups of 10 each.) Go to the NCBI website (www.ncbi.nlm.nih.gov/Tools) and select the Basic Local Alignment Search Tool (BLAST) program to determine which gene it is and in which species it is found.

UNIT IV

EVOLUTION

Evolution is a heritable change in one or more characteristics of a population from one generation to the next. This process not only alters the characteristics of populations, it also leads to the formation of new species.

We will begin Unit IV with a discussion of the hypotheses that have been proposed to explain the origin of life on Earth, and then examine a timeline for the evolution of species from 4 billion years ago to the present. In Chapter 23, you will be introduced to the fundamental concepts of evolution, with an emphasis on natural selection. We will examine observations of evolutionary change, which includes (1) the fossil record, (2) a comparison of the characteristics of modern species, and (3) an analysis of molecular data. Chapter 24 continues our discussion of evolution at the molecular level and focuses on how changes in allele and genotype frequencies from one generation to the next are driven by a variety of different factors. By comparison, Chapter 25 shifts the emphasis of evolution to the level of species. We will examine how species are identified and discuss the mechanisms by which new species arise via evolution. Finally, in Chapter 26, we will examine how biologists determine the evolutionary relationships among different species and produce diagrams called evolutionary trees to describe those relationships.

The following biology principles will be emphasized in this unit:

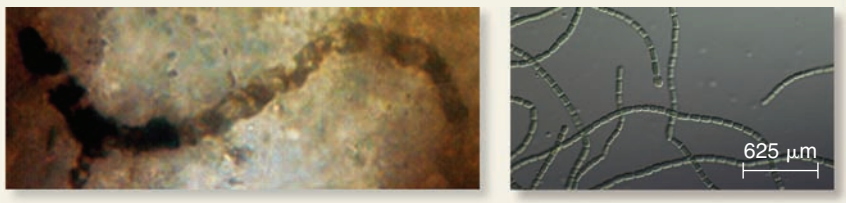
- ***Populations of organisms evolve from one generation to the next.*** *This concept will be emphasized throughout the entire unit.*
- ***Living organisms interact with their environment.*** *As discussed in Chapters 23 and 24, natural selection is a process in which certain individuals have greater reproductive success. This success is often due to their ability to survive in a given environment.*
- ***Structure determines function.*** *Chapters 23 and 24 will also consider how structural features change during the evolution of new species. Such changes are related to changes in function.*
- ***All species (past and present) are related by an evolutionary history.*** *Chapter 26 is devoted to examining how biologists determine evolutionary relationships among different species.*
- ***Biology is an experimental science.*** *Every chapter has a Feature Investigation describing a pivotal experiment that provided insights into our understanding of evolution.*

CHAPTER OUTLINE

22.1 Origin of Life on Earth
22.2 The Fossil Record
22.3 History of Life on Earth
Summary of Key Concepts
Assess and Discuss

The Origin and History of Life on Earth

22



A fossil fish. This 50-million-year-old fossil of a unicorn fish (*Naso rectifrons*) is an example of the many different kinds of organisms that have existed during the history of life on Earth.

The amazing origin of the universe is difficult to comprehend. Astronomers think the universe began with a cosmic explosion called the Big Bang about 13.7 billion years ago (bya), when the first clouds of the elements hydrogen and helium were formed. Over a long time period, gravitational forces collapsed these clouds to create stars that converted hydrogen and helium into heavier elements, including carbon, nitrogen, and oxygen, which are the atomic building blocks of life on Earth. These elements were returned to interstellar space by exploding stars called supernovas, which created clouds in which simple molecules such as water, carbon monoxide, and hydrocarbons formed. The clouds then collapsed to make a new generation of stars and solar systems.

Our solar system began about 4.6 bya after one or more local supernova explosions. According to one widely accepted scenario, hundreds of planetesimals (small celestial bodies like asteroids) occupied the region where Venus, Earth, and Mars are now found. The Earth, which is estimated to be 4.55 billion years old, grew from the aggregation of such planetesimals over a period of 100–200 million years. For the first half billion years or so after its formation, the Earth was too hot to allow liquid water to accumulate on its surface. By 4 bya, the Earth had cooled enough for the outer layers of the planet to solidify and for oceans to begin to form.

The period between 4.0 and 3.5 bya marked the emergence of life on our planet. The first forms of life that we know about produced well-preserved microscopic fossils, such as those found in western Australia. These fossils, estimated to be about 3.5 billion years old, resemble modern cyanobacteria, which are photosynthetic bacteria (**Figure 22.1**).

This chapter, the first in this unit on evolution, emphasizes when particular forms of life arose. Researchers cannot travel back through time and observe how the first life-forms came into being. However, plausible hypotheses regarding how life first arose have emerged from our understanding of modern life. The first section of the chapter surveys a variety of hypotheses regarding (1) the origin of organic molecules on Earth, (2) the formation of complex molecules such as DNA, RNA, and proteins, (3) the formation of primitive cell-like structures, and (4) the process that gave rise to the first living cells. We will then consider fossils, the preserved remains of organisms that existed in the past. Fossils, such as the one shown in the chapter opening photo, have provided biologists with evidence of the history of life on Earth from its earliest beginnings to the present day. The last section provides a broad overview of the geologic time scale and the major events in the history of life on Earth.

(a) Fossil prokaryote **(b) Modern cyanobacteria**

Figure 22.1 Earliest fossils and living cyanobacteria. **(a)** A fossilized prokaryote about 3.5 billion years old that is thought to be an early cyanobacterium. **(b)** A modern cyanobacterium, which has a similar morphology. Cyanobacterial cells are connected to each other to form chains, as shown here.

22.1 Origin of Life on Earth

Learning Outcomes:

1. Outline the four overlapping stages that are hypothesized to have led to the origin of life.
2. List various hypotheses about how complex organic molecules formed.
3. **SciSKILLS »** Analyze the results of Bartel and Szostak that indicated that chemical evolution is possible.
4. Explain the concept of an RNA world, and describe how it could have evolved into a DNA/RNA/protein world.

As we have seen, living cells are complex collections of molecules and macromolecules. DNA stores genetic information, RNA acts as an intermediary in the process of protein synthesis and plays other important roles, and proteins form the foundation for the structure and activities of living cells. Life as we know it requires this interplay between DNA, RNA, and proteins for its existence and perpetuation. On modern Earth, every living cell is made from a pre-existing cell.

But how did life get started? As described in Chapter 1, living organisms have several characteristics that distinguish them from nonliving materials. Because DNA, RNA, and proteins are the central players in the enterprise of life, scientists who are interested in the origin of life have focused much of their attention on the formation of these macromolecules and their building blocks, namely, nucleotides and amino acids. To understand the origin of life, we can view the process as occurring in four overlapping stages:

Stage 1: Nucleotides and amino acids were produced prior to the existence of cells.

Stage 2: Nucleotides became polymerized to form RNA and/or DNA, and amino acids became polymerized to form proteins.

Stage 3: Polymers became enclosed in membranes.

Stage 4: Polymers enclosed in membranes acquired cellular properties.

Researchers have followed a variety of experimental approaches to determine how life may have begun, including the synthesis of organic molecules in the laboratory without the presence of living cells or cellular material. This work has led researchers to propose a variety of hypotheses regarding the origin of life. In this section, we will examine the origin of life at each of these stages and consider a few scientific viewpoints that wrestle with the question "How did life on Earth begin?"

Stage 1: Organic Molecules Formed Prior to the Existence of Cells

Let's begin our inquiry into the first stage of the origin of life by considering how nucleotides and amino acids may have been made prior to the existence of living cells. In the 1920s, the Russian biochemist Alexander Oparin and the Scottish biologist J. B. S. Haldane independently proposed that organic molecules, such as nucleotides and amino acids, arose spontaneously under the conditions that occurred on early Earth. According to this hypothesis, the spontaneous appearance of organic molecules produced what they called a "primordial soup," which eventually gave rise to living cells.

The conditions on early Earth, which were much different from today, may have been more conducive to the spontaneous formation of organic molecules. Current hypotheses suggest that organic molecules, and eventually macromolecules, formed spontaneously. This is termed prebiotic (before life) or abiotic (without life) synthesis. These slowly forming organic molecules accumulated because there was little free oxygen gas, so they were not spontaneously oxidized, and there were as yet no living organisms, so they were also not metabolized. The slow accumulation of these molecules in the early oceans over a long period of time formed what is now called the **prebiotic soup**. The formation of this medium was a key event that preceded the origin of life.

Though most scientists agree that life originated from the assemblage of nonliving matter on early Earth, the mechanism of how and where these molecules originated is widely debated. Many intriguing hypotheses have been proposed, which are not mutually exclusive. A few of the more widely debated ideas are the reducing atmosphere hypothesis, the extraterrestrial hypothesis, and the deep-sea vent hypothesis.

Reducing Atmosphere Hypothesis Based largely on geological data, many scientists in the 1950s proposed that the atmosphere on early Earth was rich in water vapor (H_2O), hydrogen gas (H_2), methane (CH_4), and ammonia (NH_3). These components, along with a lack of atmospheric oxygen (O_2), produce a reducing atmosphere because methane and ammonia readily give up electrons to other molecules, thereby reducing them. Such oxidation-reduction reactions, or redox reactions, are required for the formation of complex organic molecules from simple inorganic molecules.

In 1953, American chemist Stanley Miller, a student in the laboratory of physical chemist Harold Urey, was the first scientist to use experimentation to test whether the prebiotic synthesis of organic molecules is possible. His experimental apparatus was intended to simulate the conditions on early Earth that were postulated in the 1950s (**Figure 22.2**). Water vapor from a flask of boiling water rose into another chamber containing hydrogen gas (H_2), methane (CH_4), and ammonia (NH_3). Miller inserted two electrodes that sent electrical discharges into the chamber to simulate lightning bolts. A condenser jacket cooled some of the gases from the chamber, causing droplets to form that fell into a trap. He then took samples from this trap for chemical analysis. In his first experiments, he observed the formation of hydrogen cyanide (HCN) and formaldehyde (CH_2O). Such molecules are precursors of more complex organic molecules. These precursors also combined to make larger molecules such as the amino acid glycine. At the end of 1 week of operation, 10–15% of the carbon had been incorporated into organic compounds. Later experiments by Miller and others demonstrated the formation of sugars, a few types of amino acids, lipids, and nitrogenous bases found in nucleic acids (for example, adenine).

In a study published in 2011, researchers analyzed samples that Miller had preserved from a 1958 experiment in which he used a mixture of CH_4, NH_3, hydrogen sulfide (H_2S), and carbon dioxide (CO_2). For unknown reasons, Miller had not analyzed what products were made in this experiment. When these preserved samples were analyzed using modern technology, they were found to contain 23 different amino acids and 4 amines (another type of organic molecule), more organic compounds than seen in Miller's classic experiments.

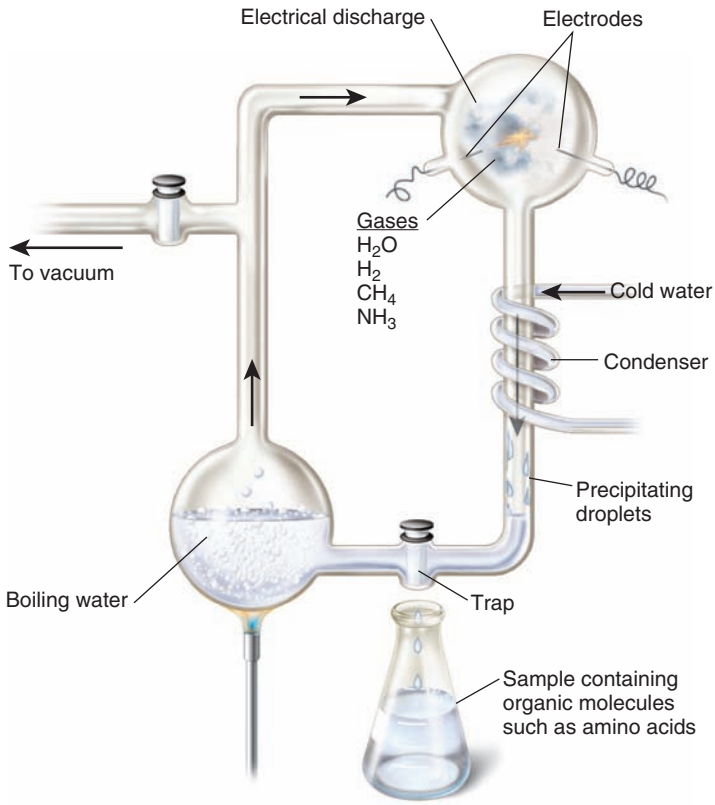


Figure 22.2 Testing the reducing atmosphere hypothesis for the origin of life—the Miller and Urey experiment.

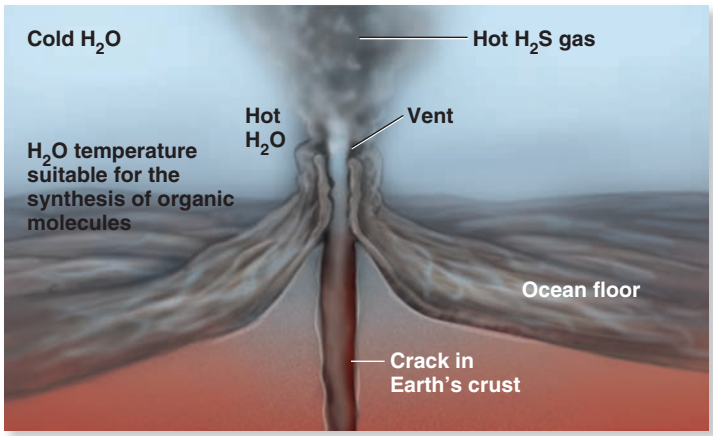
BIOLOGY PRINCIPLE Biology is an experimental science. By conducting experiments, researchers were able to demonstrate the feasibility of the synthesis of organic molecules prior to the emergence of living cells.

Concept Check: With regard to the origin of life, why are biologists interested in the prebiotic synthesis of organic molecules?

Why were these studies important? The work of Miller and Urey was the first attempt to apply scientific experimentation to our quest to understand the origin of life. Their pioneering strategy showed that the prebiotic synthesis of organic molecules is possible, although it could not prove that it really happened that way. In spite of the importance of these studies, critics of the so-called reducing atmosphere hypothesis have argued that Miller and Urey were wrong about the composition of early Earth's environment. More recently, many scientists have suggested that the atmosphere on early Earth was not reducing, but instead was a neutral gaseous mixture consisting mostly of carbon monoxide (CO), carbon dioxide (CO_2), nitrogen (N_2), and H_2O. These newer ideas are derived from studies of volcanic gas, which has much more CO_2 and N_2 than CH_4 and NH_3, and from the observation that ultraviolet (UV) radiation destroys CH_4 and NH_3, so these molecules would have been short-lived on early Earth, which had high levels of UV radiation. Nevertheless, since the experiments of Miller and Urey, many newer investigations have shown that organic molecules can be made under a variety of conditions. For example, organic molecules can be made prebiotically from a neutral gaseous mixture composed primarily of CO, CO_2, N_2, and H_2O.

Extraterrestrial Hypothesis Many scientists have argued that sufficient organic molecules may have been present in the materials from asteroids and comets that reached the surface of early Earth in the form of meteorites. A significant proportion of meteorites belong to a class known as carbonaceous chondrites. Such meteorites may contain a substantial amount of organic carbon, including amino acids and nucleic acid bases. Based on this observation, some scientists have postulated that such meteorites could have transported a significant amount of organic molecules to early Earth.

Opponents of this hypothesis argue that most of this material would have been destroyed by the intense heating that accompanies the passage of large bodies through the atmosphere and their subsequent collision with the surface of the Earth. Though some organic molecules are known to reach the Earth via such meteorites, the degree to which heat would have destroyed many of the organic molecules remains a matter of controversy.



Deep-Sea Vent Hypothesis In 1988, German lawyer and organic chemist Günter Wächtershäuser proposed that key organic molecules may have originated in deep-sea vents, which are cracks in the Earth's surface where superheated water rich in metal ions and hydrogen sulfide (H_2S) mixes abruptly with cold seawater. These vents release hot gaseous substances from the interior of the Earth at temperatures in excess of 300°C (572°F). Supporters of this hypothesis propose that biologically important molecules may have been formed in the temperature gradient between the extremely hot vent water and the cold water that surrounds the vent (**Figure 22.3a**).

Experimentally, the temperatures within this gradient are known to be suitable for the synthesis of molecules that form components of biological molecules. For example, the reaction between iron and H_2S yields pyrites and H_2 and has been shown to provide the energy necessary for the reduction of N_2 to NH_3. Nitrogen is an essential component of both nucleic acids and amino acids—the molecular building blocks of life. But N_2, which is found abundantly on Earth, is chemically inert, so it is unlikely to have given rise to life. The conversion of N_2 to NH_3 at deep-sea vents may have led to the production of amino acids and nucleic acids.

Interestingly, complex biological communities are found in the vicinity of modern deep-sea vents. Various types of fish, worms, clams, crabs, shrimp, and bacteria are found in significant abundance in those areas (**Figure 22.3b**). Unlike most other forms of life on our planet, these organisms receive their energy from chemicals in the vent and not from the Sun. In 2007, American scientist Timothy Kusky and colleagues discovered 1.43-billion-year-old fossils of deep-sea microbes near ancient deep-sea vents. This study provided more evidence that life may have originated on the bottom of the ocean. However, debate continues as to the primary way that organic molecules were made prior to the existence of life on Earth.

Stage 2: Organic Polymers May Have Formed on the Surface of Clay

The preceding three hypotheses provide reasonable mechanisms whereby small organic molecules could have accumulated on early Earth. Scientists hypothesize that the second stage in the origin of

(a) Deep-sea vent hypothesis

(b) A deep-sea vent community

Figure 22.3 The deep-sea vent hypothesis for the origin of life. **(a)** Deep-sea vents are cracks in the Earth's surface that release hot gases such as hydrogen sulfide (H_2S). This heats the water near the vent and results in a gradient between the very hot water adjacent to the vent and the cold water farther from the vent. The synthesis of organic molecules can occur in this gradient. **(b)** Photograph of a biological community near a deep-sea vent, which includes giant tube worms and crabs.

Concept Check: *What properties of deep-sea vents made them suitable for the prebiotic synthesis of molecules?*

life was a period in which simple organic molecules polymerized to form more complex organic polymers such as DNA, RNA, or proteins. Most ideas regarding the origin of life assume that polymers with at least 30–60 monomers are needed to store enough information to make a viable genetic system. Because hydrolysis competes with polymerization, many scientists have speculated that the synthesis of polymers did not occur in a watery prebiotic soup, but instead took place on a solid surface or in evaporating tidal pools.

In 1951, Irish X-ray crystallographer John Bernal first suggested that the prebiotic synthesis of polymers took place on clay. In his book *The Physical Basis of Life*, he wrote that "clays, muds and inorganic crystals are powerful means to concentrate and polymerize organic molecules." Many clay minerals are known to bind organic molecules such as nucleotides and amino acids. Experimentally, many research groups have demonstrated the formation of nucleic acid polymers and polypeptides on the surface of clay, given the presence of monomer building blocks. During the prebiotic synthesis of RNA, the purine bases of the nucleotides could have interacted with the silicate surfaces of the clay. Cations, such as Mg^{2+}, bound the nucleotides to the negative surfaces of the clay, thereby positioning the nucleotides in a way that promoted bond formation between the phosphate of one nucleotide and the ribose sugar of an adjacent nucleotide. In this way, polymers such as RNA may have been formed.

Though the formation of polymers on clay remains a reasonable hypothesis, studies by American chemist Luke Leman and his colleagues English chemist Leslie Orgel and Iranian-American chemist M. Reza Ghadiri indicate that polymers can also form in aqueous solutions, which is contrary to popular belief. Their work in 2004 showed that carbonyl sulfide, a simple gas present in volcanic gases and deep-sea vent emissions, can bring about the formation of peptides from amino acids under mild conditions in water. These results indicate that the synthesis of polymers could have taken place in the prebiotic soup.

Stage 3: Cell-Like Structures May Have Originated When Polymers Were Enclosed by a Boundary

The third stage in the origin of living cells is hypothesized to be the formation of a boundary that separated the polymers such as RNA from the environment. The term **protobiont** is used to describe an aggregate of prebiotically produced molecules and macromolecules that acquired a boundary, such as a lipid bilayer, that allowed it to maintain an internal chemical environment distinct from that of its surroundings. What characteristics make protobionts possible precursors of living cells? Scientists envision the existence of four key features:

1. A boundary, such as a membrane, separated the internal contents of the protobiont from the external environment.
2. Polymers inside the protobiont contained information.
3. Polymers inside the protobiont had catalytic functions.
4. The protobionts eventually developed the capability of self-replication.

Protobionts were not capable of precise self-reproduction like living cells, but could divide to increase in number. Such protobionts are thought to have exhibited basic metabolic pathways in which the structures of organic molecules were changed. In particular, the polymers inside protobionts must have gained the catalytic ability to link organic building blocks to produce new polymers. This would have been a critical step in the process that eventually provided protobionts with the ability to self-replicate. According to this scenario, metabolic pathways became more complex, and the ability of protobionts to self-replicate became more refined over time. Eventually, these structures exhibited the characteristics that we attribute to living cells. As described next, researchers have hypothesized that protobionts may have existed as coacervates or liposomes.

Coacervates In 1924, Alexander Oparin hypothesized that living cells evolved from **coacervates**, droplets that form spontaneously from the association of charged polymers such as proteins,

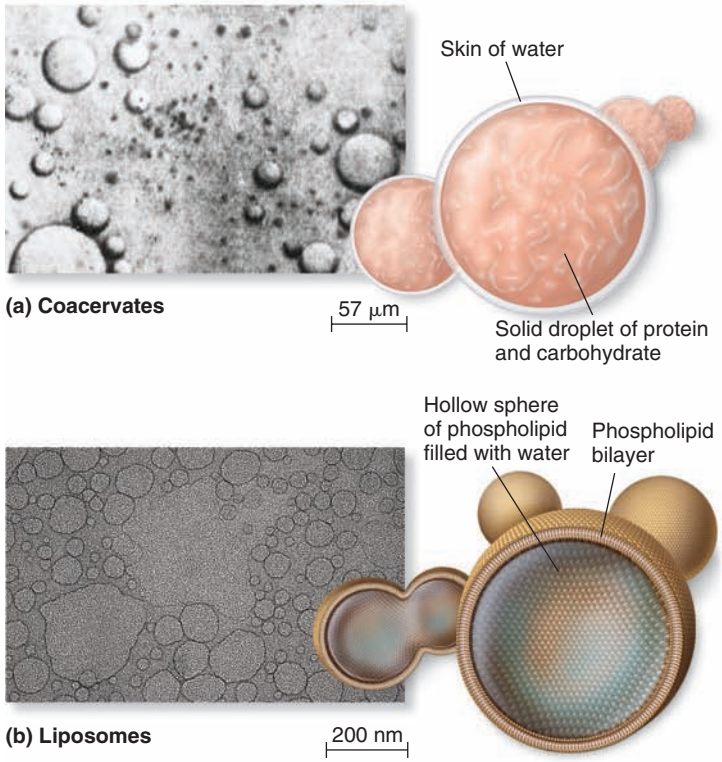


Figure 22.4 Protobionts and their lifelike functions. Primitive cell-like structures such as coacervates or liposomes could have given rise to living cells. **(a)** A micrograph and illustration of coacervates, which are droplets of protein and carbohydrate surrounded by a skin of water molecules. **(b)** An electron micrograph and illustration of liposomes. Each liposome is made of a phospholipid bilayer surrounding an aqueous compartment.

Concept Check: Which protobiont seems most similar to real cells? Explain.

BioConnections: Look back at Figure 3.11. What is the physical/chemical reason why phospholipids tend to form a bilayer?

carbohydrates, or nucleic acids surrounded by water. Their name derives from the Latin *coacervare*, meaning to assemble together or cluster. Coacervates measure 1–100 μm (micrometers) across, are surrounded by a tight skin of water molecules, and possess osmotic properties (**Figure 22.4a**). The skin of water allows the selective absorption of simple molecules from the surrounding medium.

Enzymes trapped within coacervates can perform primitive metabolic functions. For example, researchers have made coacervates containing the enzyme glycogen phosphorylase. When glucose-1-phosphate was made available to these coacervates, it was taken up into them, and starch was produced. The starch merged with the wall of the coacervates, and they increased in size and eventually divided into two. When the enzyme amylase was included, the starch was broken down to maltose, which was released from the coacervates.

Liposomes As a second possibility, protobionts may have resembled **liposomes**—vesicles surrounded by a phospholipid bilayer (**Figure 22.4b**). When certain types of lipids are dissolved in water, they spontaneously form liposomes. As discussed in Chapter 5, phospholipid bilayers are selectively permeable (refer back to Figure 5.11), and some liposomes can even store energy in the form of an electrical gradient. Such liposomes can discharge this energy in a neuron-like fashion, showing rudimentary signs of excitability, which is characteristic of living cells.

In 2003, Danish chemist Martin Hanczyc, American chemist Shelly Fujikawa, and Canadian-American biologist Jack Szostak showed that clay can catalyze the formation of liposomes that grow and divide, a primitive form of self-replication. Furthermore, if RNA was on the surface of the clay, the researchers discovered that liposomes that enclosed RNA were formed. These experiments are compelling because they showed that the formation of membrane vesicles containing RNA molecules is a plausible explanation for the emergence of cell-like structures based on simple physical and chemical properties.

Stage 4: Cellular Characteristics May Have Evolved via Chemical Selection, Beginning with an RNA World

The majority of scientists favor RNA as the first macromolecule that was found in protobionts. Unlike other polymers, RNA exhibits three key functions:

1. RNA has the ability to store information in its nucleotide base sequence.
2. Due to base pairing, its nucleotide sequence has the capacity for self-replication.
3. RNA can perform a variety of catalytic functions. The results of many experiments have shown that some RNA molecules can function as **ribozymes**—RNA molecules that catalyze chemical reactions.

By comparison, DNA and proteins are not as versatile as RNA. DNA has very limited catalytic activity, and proteins are not known to undergo self-replication. RNA can perform functions that are characteristic of proteins and, at the same time, can serve as genetic material with replicative and informational functions.

How did the RNA molecules that were first made prebiotically evolve into more complex molecules that produced cell-like characteristics? Researchers propose that a process called chemical selection was responsible. **Chemical selection** occurs when a chemical within a mixture has special properties or advantages that cause it to increase in number relative to other chemicals in the mixture. (As we will discuss in Chapter 23, natural selection is a similar process except that it describes the changing of a population of living organisms over time due to survival and reproductive advantages.) Chemical selection results in **chemical evolution**—a population of molecules changes over time to become a new population with a different chemical composition.

Scientists speculate that initially the special properties that enabled certain RNA molecules to undergo chemical selection were their ability to self-replicate and to perform other catalytic functions. As a way to understand the concept of chemical selection, let's consider a hypothetical scenario showing two steps of chemical selection. Step 1 of **Figure 22.5** shows a group of protobionts that contain RNA molecules that were made prebiotically. RNA molecules inside these protobionts can be used as templates for the prebiotic synthesis of complementary RNA molecules. Such a process of self-replication, however, would be

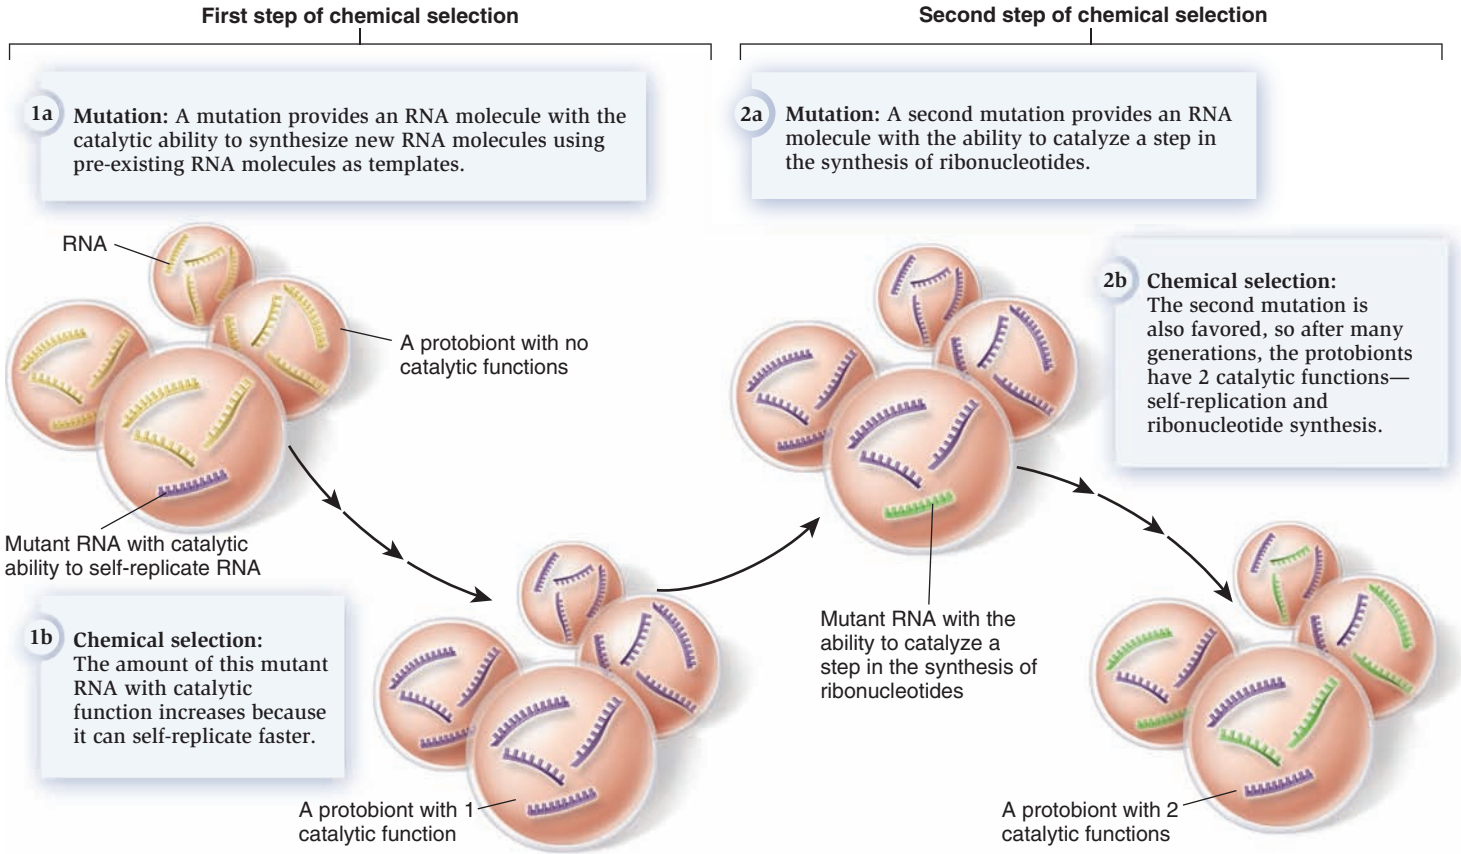

Figure 22.5 A hypothetical scenario illustrating the process of chemical selection. This figure shows a two-step scenario. In the first step, RNAs that can self-replicate are selected, and in the second step, RNAs with the ability to catalyze a step in ribonucleotide synthesis are selected.

Concept Check: *What is meant by the term chemical selection?*

very slow because it would not be catalyzed by enzymes in the protobiont. In a first step of chemical selection, the sequence of one of the RNA molecules has undergone a mutation that gives it the catalytic ability to attach nucleotides together, using other RNA molecules as a template. This protobiont would have an advantage over the others because it would be capable of faster self-replication of its RNA molecules. Over time, due to this enhanced rate of replication, protobionts carrying such RNA molecules would increase in number compared with the others. Eventually, the group of protobionts shown in the figure contains only this type of catalytic RNA.

In the second step of chemical selection (Figure 22.5, right side), a second mutation in an RNA molecule could produce the catalytic function that would help to promote the synthesis of ribonucleotides, the building blocks of RNA. For example, a hypothetical ribozyme may catalyze the attachment of a base to a ribose, thereby catalyzing one of the steps necessary for making a ribonucleotide. This protobiont would not rely solely on the prebiotic synthesis of ribonucleotides, which is a very slow process. Therefore, the protobiont having the ability to both self-replicate and synthesize ribonucleotides would have an advantage over a protobiont that could only self-replicate. Over time, the faster rate of self-replication and ribonucleotide synthesis would cause an increase in the numbers of protobionts with both functions.

The **RNA world** is a hypothetical period on early Earth when both the information needed for life and the catalytic activity of living cells were contained solely in RNA molecules. In this scenario, protobionts containing RNA exhibited the properties of life due to RNA genomes that were copied and maintained through the catalytic function of RNA molecules. Over time, scientists envision that mutations occurred in these RNA molecules, occasionally introducing new functional possibilities. Chemical selection would have eventually produced an increase in complexity in these protobionts, with RNA molecules accruing activities such as the ability to link amino acids together into proteins and other catalytic functions.

But is an RNA world a plausible scenario? As described next in the Feature Investigation, chemical selection of RNA molecules in the laboratory can result in chemical evolution.

Feature Investigation | Bartel and Szostak Demonstrated Chemical Evolution in the Laboratory

Remarkably, scientists have been able to perform experiments in the laboratory that can select for RNA molecules with a particular function. American biologist David Bartel and Jack Szostak conducted the first study of this type in 1993 (**Figure 22.6**). Using molecular techniques, they synthesized a mixture of 10^{15} RNA molecules that we will call the long RNAs. Each long RNA in this mixture contained

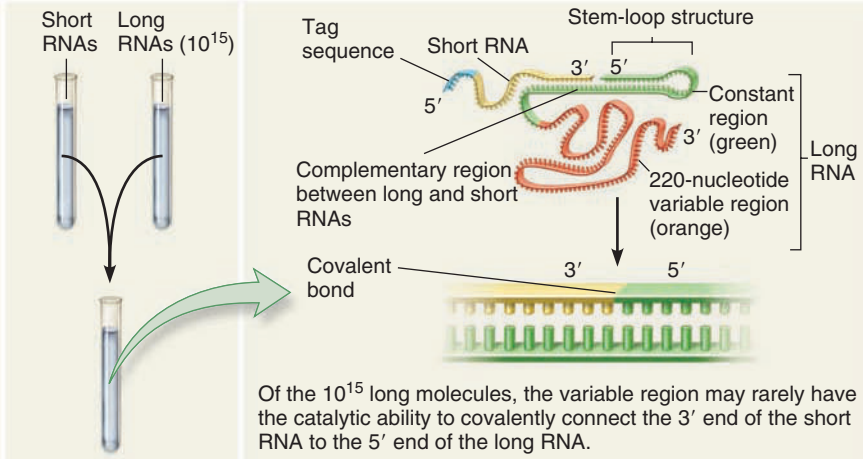

Figure 22.6 Bartel and Szostak demonstrated chemical selection for RNA molecules that catalyze the linkage between nucleotides.

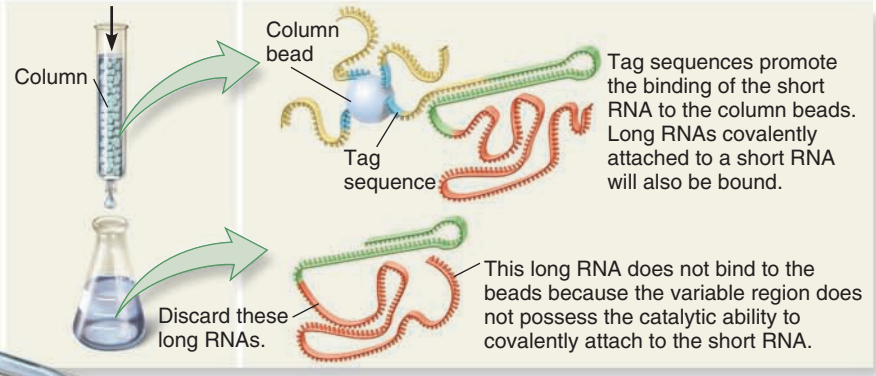
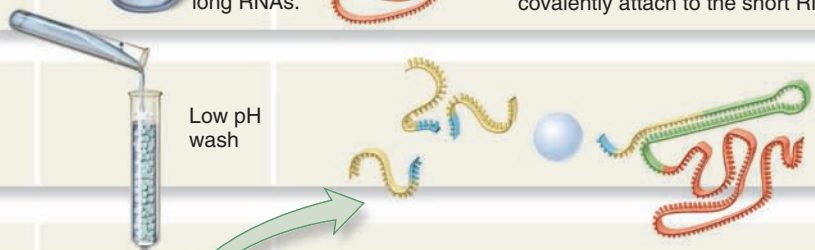
HYPOTHESIS Among a large pool of RNA molecules, some of them may contain the catalytic ability to make a covalent bond between nucleotides; these can be selected for in the laboratory.

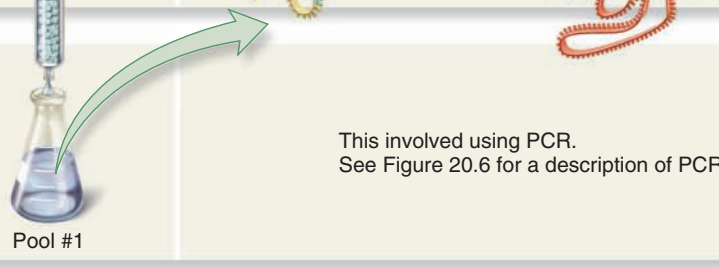


KEY MATERIALS Many copies of short RNA were synthesized that had a tag sequence that binds tightly to column packing material called beads. Also, a population of 10^{15} long RNA molecules was made that contained a constant region with a stem-loop structure and a 220-nucleotide variable region. Note: The variable regions of the long RNAs were made using a PCR step that caused mutations in this region.

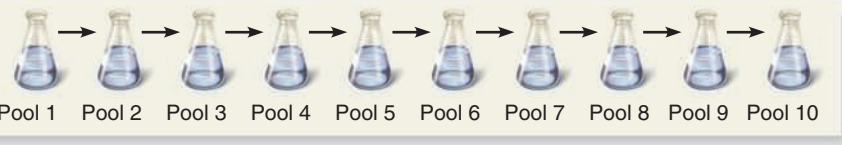
Experimental level **Conceptual level**



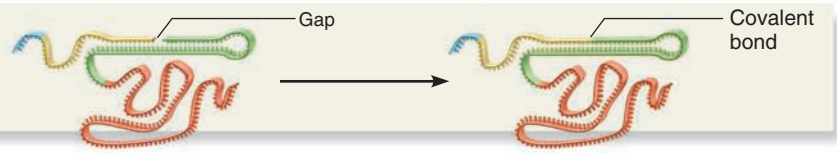
1 Mix together the short RNAs with the 10^{15} variable long RNAs. Allow time for covalent connections to form if the long RNA happens to have the catalytic activity for covalent bond formation.



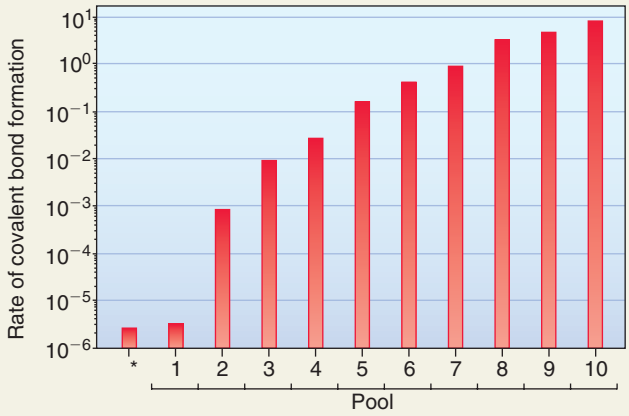
2 Pass the mixture through a column of beads that binds the tag sequence found on the short RNA. Add additional liquid to flush out long RNAs that are not covalently attached to short RNAs.



3 Add a low pH solution to prevent the tag sequence from binding to the beads. This causes the tightly bound RNAs to be flushed out of the column.



4 The flushed-out RNAs are termed pool 1. Use pool 1 to make a second batch of long RNA molecules. This involved a PCR step using reverse transcriptase to make cDNA. The PCR primers recognized the beginning and end of the long RNA sequence and copied only this region. The cDNA was then used as a template to make long RNA via RNA polymerase.



5 Repeat procedure to generate 10 consecutive pools of RNA molecules.

6 Test a sample of the original population and each of the 10 pools for the catalytic ability to make a covalent bond between adjacent nucleotides.

7 THE DATA

*Original 10^{15} molecules

8 CONCLUSION The increase in covalent bond formation from pool 1 to pool 10 indicates that chemical selection can occur.

9 SOURCE Bartel, D. P., and Szostak, J. W. 1993. Isolation of new ribozymes from a large pool of random sequences. *Science* 261:1411–1418.

two regions. The first region at the 5′ end was a constant region that formed a stem-loop. Its sequence was identical among all 10^{15} molecules. The constant region was next to a second region that was 220 nucleotides in length. A key feature of the second region is that its sequence varied among the long RNA molecules. The researchers hypothesized that this variation could occasionally result in a long RNA molecule with the ability to catalyze a covalent bond between two adjacent nucleotides.

They also made another type of RNA molecule, which we will call the short RNAs, with two important properties. First, the short RNAs had a region that was complementary to a site in the constant region of the long RNA molecules. Second, the short RNAs had a tag sequence that caused them to bind tightly to beads in a column. The short RNAs did not have a variable region; they were all the same.

To begin this experiment, the researchers incubated a large number of the long and short RNA molecules together. During this incubation period, long and short RNA molecules hydrogen-bonded to each other due to their complementary regions. Although hydrogen bonding is not permanent, this step allowed the long and short RNAs to connect to each other for a short time. The researchers reasoned that a long RNA with the catalytic ability to form a covalent bond between nucleotides would make this interaction more permanent by catalyzing a bond between the long and short RNA molecules. Following this incubation, the mixture of RNAs was passed through a column with beads that specifically bound the short RNA. The aim of this approach was to select for longer RNA molecules that had covalently bonded to the short RNA molecule (see the conceptual level of step 2).

The vast majority of long RNAs would not have the catalytic ability to form a permanent covalent bond between nucleotides. These would pass out of the column at step 2, because hydrogen bonding between the long and short RNAs is not sufficient to hold them together for very long. Such unbound long RNAs would be discarded. Long RNAs with the ability to catalyze a covalent bond to the short RNA would remain bound to the column beads at step 2. These catalytic RNAs were then flushed out at step 3 to generate a mixture of RNAs termed pool 1. The researchers expected this pool to contain several different long RNA molecules with varying abilities to catalyze a covalent bond between nucleotides.

To further the chemical selection process, the scientists used the first pool of long RNA molecules flushed out at step 3 to make more long RNA molecules. This was accomplished via polymerase chain reaction (PCR), which allowed additional mutations in the variable region. The researchers reasoned that additional mutations in the variable region might occasionally produce an RNA molecule with even better catalytic activity. This second batch of long RNA molecules (pool 2) was subjected to the same steps as the first batch of 10^{15} molecules. In this case, the group of long molecules flushed out at step 3 was termed pool 2. This protocol was followed eight more times to generate 10 consecutive pools of RNA molecules.

The researchers analyzed the original random collection of 10^{15} RNA molecules and each of the 10 pools for the catalytic ability to covalently link RNA molecules. As seen in the data, each successive pool became enriched in molecules with higher catalytic activity.

Pool 10 showed catalytic activity that was approximately 3 million times higher than the original random pool of molecules!

Like the work of Miller and Urey, the experiment by Bartel and Szostak showed the feasibility of another phase of the prebiotic process that led to life. In this case, chemical selection resulted in chemical evolution. The results showed that chemical selection can change the functional characteristics of a group of RNA molecules over time by increasing the proportion of those molecules with enhanced function.

Experimental Questions

1. What is chemical selection? What hypothesis did Bartel and Szostak test?
2. **SciSKILLS »** In conducting the selection experiment among pools of long RNA molecules with various catalytic abilities, what was the purpose of using the short RNA molecules?
3. **SciSKILLS »** What were the results of the experiment conducted by Bartel and Szostak? How did this study influence our understanding of the evolution of life on Earth?

The RNA World Was Superseded by the Modern DNA/RNA/Protein World

Assuming that an RNA world was the origin of life, researchers have asked, "Why and how did the RNA world evolve into the DNA/RNA/protein world we see today?" The RNA world may have been superseded by a DNA/RNA world or an RNA/protein world before the emergence of the modern DNA/RNA/protein world. Let's now consider the advantages of a DNA/RNA/protein world as opposed to the simpler RNA world and explore how this modern biological world might have come into being.

Information Storage RNA can store information in its base sequence. If so, why did DNA take over that function in modern cells? During the RNA world, RNA had to perform two roles: the storage of information and the catalysis of chemical reactions. Scientists have speculated that the incorporation of DNA into cells would have relieved RNA of its storage role, thereby allowing RNA to perform a variety of other functions. For example, if DNA stored the information for the synthesis of RNA molecules, such RNA molecules could bind cofactors, have modified bases, or bind peptides that might enhance their catalytic function. Cells with both DNA and RNA would have had an advantage over those with just RNA, and so they would have been selected. Another advantage of DNA is its stability. Compared with RNA, DNA strands are less likely to spontaneously break.

A second issue is how DNA came into being. Scientists have proposed that an ancestral RNA molecule had the ability to make DNA using RNA as a template. This function, known as reverse transcription, is described in Chapter 18 in the discussion of retroviruses. Interestingly, modern eukaryotic cells can use RNA as a template to make DNA. For example, an RNA sequence in the enzyme telomerase copies the ends of chromosomes, thus preventing progressive shortening of the chromosomes (refer back to Figure 11.20).

Metabolism and Other Cellular Functions Now let's consider the origin of proteins. The emergence of proteins as catalysts may have been a great benefit to early cells. Due to the different chemical properties of the 20 amino acids, proteins have vastly greater catalytic ability than do RNA molecules, again providing a major advantage to cells that had both RNA and proteins. In modern cells, proteins have taken over most, but not all, catalytic functions. In addition, proteins can perform other important tasks. For example, cytoskeletal proteins carry out structural roles, and certain membrane proteins are responsible for the uptake of substances into living cells.

How would proteins have come into being in an RNA world? Chemical selection experiments have shown that RNA molecules can catalyze the formation of peptide bonds and even attach amino acids to primitive tRNA molecules. Similarly, modern protein synthesis still involves a central role for RNA in the synthesis of polypeptides. First, mRNA provides the information for a polypeptide sequence. Second, tRNA molecules act as adaptors for the formation of a polypeptide chain. And finally, ribosomes containing rRNA provide a site for polypeptide synthesis. Furthermore, rRNA within the ribosome acts as a ribozyme to catalyze peptide bond formation. Taken together, the analysis of translation in modern cells is consistent with an evolutionary history in which RNA molecules were instrumental in the emergence and formation of proteins.

22.2 The Fossil Record

Learning Outcomes:

1. Describe how fossils are formed.
2. **SciSKILLS »** Explain how radiometric dating is used to estimate the age of a fossil.
3. List several factors that affect the completeness of the fossil record.

We will now turn our attention to a process that has given us a window into the history of life over the past 3.5 billion years. **Fossils** are the preserved remains of past life on Earth. They can take many forms, including bones, shells, and leaves, and the impression of cells or other evidence, such as footprints or burrows. Scientists who study fossils are called **paleontologists** (from the Greek *palaios*, meaning ancient). Because our understanding of the history of life is derived primarily from the fossil record, it is important to appreciate how fossils are formed and dated and to understand why the fossil record cannot be viewed as complete.

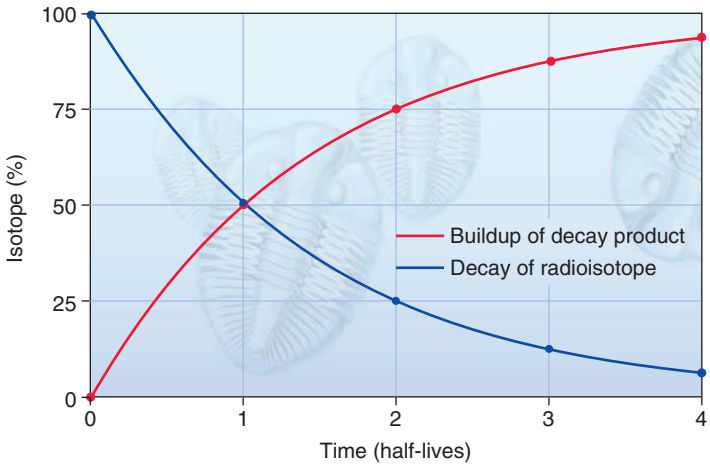
Fossils Are Formed Within Sedimentary Rock

How are fossils usually formed? Many of the rocks observed by paleontologists are sedimentary rocks that were formed from particles of older rocks broken apart by water or wind. These particles, in the form of gravel, sand, or mud, settle and bury living and dead organisms at the bottoms of rivers, lakes, and oceans. Over time, more particles pile up, and sediments at the bottom of the pile eventually become rock. Gravel particles form rock called conglomerate, sand

becomes sandstone, and mud becomes shale. Most fossils are formed when organisms are buried quickly, and then during the process of sedimentary rock formation, their hard parts are gradually replaced over millions of years by minerals, producing a recognizable representation of the original organism (see, for example, the chapter opening photo).

The relative ages of fossils can sometimes be revealed by their locations in sedimentary rock formations. Because sedimentary rocks are formed by small particles settling in layers, the layers are piled one on top of the other. In a sequence of layered rock, the lower layers are usually older than the upper layers. Paleontologists often study changes in life-forms over time by studying the fossils in layers from bottom to top (**Figure 22.7**). The more ancient life-forms are found in the lower layers, and newer species are found in the upper layers. However, such an assumption can occasionally be misleading when geological processes such as folding have flipped the layers.

The Analysis of Radioisotopes Is Used to Date Fossils



A common way to estimate the age of a fossil is by analyzing the decay of radioisotopes within the accompanying rock, a process called **radiometric dating**. As discussed in Chapter 2, many elements occur in multiple forms, called isotopes, that differ in the number of neutrons their atoms contain. A radioisotope is an unstable isotope of an element that decays spontaneously, releasing radiation at a constant rate. The **half-life** is the length of time required for a radioisotope to decay to exactly one-half of its initial quantity. Each radioisotope has its own unique half-life (**Figure 22.8a**). Within a sample of rock, scientists can measure the amount of a given radioisotope as well as the amount of the decay product—the isotope that is produced when the original isotope decays. For dating geological materials, several types of isotope decay patterns are particularly useful: carbon to nitrogen, potassium to argon, rubidium to strontium, and uranium to lead (**Figure 22.8b**).

To determine the age of a rock using radiometric dating, paleontologists need to have a way to set the clock—extrapolate back to a starting point in which a rock did not have any amount of the decay product. Except for fossils less than 50,000 years old, in which carbon-14 (^{14}C) dating can be employed, fossil dating is not usually conducted on the fossil itself or on the sedimentary rock in which the fossil is found. Most commonly, igneous rock—rock formed through the cooling and solidification of lava—in the vicinity of the sedimentary rock is dated. Why is igneous rock chosen? One reason is that igneous rock derived from an ancient lava flow initially contains uranium-235 (^{235}U) but no lead-207 (^{207}Pb). The decay product of ^{235}U is ^{207}Pb. By comparing the relative proportions of ^{235}U and ^{207}Pb in a sample, the age of igneous rock can be accurately determined.

Figure 22.7 An example of layers of sedimentary rock that contain fossils.

Concept Check: Which rock layer in this photo is most likely to be the oldest?

(a) Decay of a radioisotope

Radioisotope	Decay product	Half-life (years)	Useful dating range (years)
Carbon-14	Nitrogen-14	5,730	100–50,000
Potassium-40	Argon-40	1.3 billion	100,000–4.5 billion
Rubidium-87	Strontium-87	47 billion	10 million–4.5 billion
Uranium-235	Lead-207	710 million	10 million–4.5 billion
Uranium-238	Lead-206	4.5 billion	10 million–4.5 billion

(b) Radioisotopes that are useful for geological dating

Figure 22.8 Radiometric dating of fossils. **(a)** A rock can be dated by measuring the relative amounts of a radioisotope and its decay product within the rock. **(b)** These five radioisotopes are particularly useful for the dating of fossils.

Concept Check: If you suspected a fossil is 50 million years old, which pair of radioisotopes would you choose to analyze?

BIO TIPS

THE QUESTION *The process of decay for a radioisotope is represented by the following equation:*

$$N = N_0 e^{-(0.693 t/T_{1/2})}$$

where

N is the number of atoms of a radioisotope after a certain time,
N_0 is the number of atoms of the radioisotope that were originally present (prior to any decay),
e is the natural logarithm,
t is the time during which decay has occurred, and
$T_{1/2}$ is the half-life of the radioisotope.

A paleontologist discovered a fossil of a previously unidentified reptile. A sample of nearby igneous rock contained 0.11 mg of uranium-235 (^{235}U) and 0.035 mg of lead-207 (^{207}Pb). Estimate the age of this fossil.

TOPIC ***What topic in biology does this question address?*** The topic is radiometric dating of fossils. More specifically, the question asks you to calculate an estimated age for a particular fossil.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** In the question, you are given an equation that describes the decay process for a radioisotope. You are also given the relative amounts of uranium-235 and lead-207 in a nearby igneous rock. From your understanding of the topic, you may recall that very old fossils are often dated by analyzing nearby igneous rock because such rock initially contains only uranium-235.

PROBLEM-SOLVING STRATEGY ***Make a calculation.*** You first need to calculate the number of atoms of ^{235}U and ^{207}Pb in the sample of igneous rock. The masses of ^{235}U and ^{207}Pb are approximately 235 g/mol and 207 g/mol, respectively. For ^{235}U, the number of atoms in the sample, which is *N*, is

$$N = \frac{0.11}{235} \times 6.022 \times 10^{23} = 2.82 \times 10^{20}$$

For ^{207}Pb, the number of atoms in the sample is

$$\frac{0.035}{207} \times 6.022 \times 10^{23} = 1.02 \times 10^{20}$$

It is assumed that all of the ^{207}Pb is the decay product of ^{235}U. Therefore, the original number of atoms of ^{235}U, which is N_0, was

$$N_0 = (2.82 \times 10^{20}) + (1.02 \times 10^{20}) = 3.84 \times 10^{20}$$

The half-life ($T_{1/2}$) for ^{235}U is 710 million years (see Figure 22.8). You substitute these values for *N*, N_0, and $T_{1/2}$ into the given equation and solve for *t*.

ANSWER *The fossil is approximately 316 million years old.*

Several Factors Affect the Completeness of the Fossil Record

The fossil record should not be viewed as a complete and balanced representation of the species that existed in the past. Several factors affect the likelihood that extinct organisms have been preserved as fossils and will be identified by paleontologists (**Table 22.1**). First, certain organisms are more likely than others to become fossilized. Organisms with hard shells or bones tend to be over-represented. Factors such as anatomy, size, number, and the environment and time in which they lived also play important roles in determining the likelihood that organisms will be preserved in the fossil record. In addition, geological processes may favor the fossilization of certain types of organisms. Finally, unintentional biases arise that are related to the efforts of paleontologists. For example, scientific interests may favor searching for and analyzing certain species over others. Many paleontologists have been greatly interested in finding the remains of dinosaurs.

Although the fossil record is incomplete, it has provided a wealth of information regarding the history of the types of life that existed on Earth. The rest of this chapter will survey the emergence of life-forms from 3.5 bya to the present.

Table 22.1 Factors That Affect the Fossil Record

Factor	Description
Anatomy	Organisms with hard body parts, such as animals with a skeleton or thick shell, are more likely to be preserved than are organisms composed of soft tissues.
Size	The fossil remains of larger organisms are more likely to be found than those of smaller organisms.
Number	Species that existed in greater numbers or over a larger area are more likely to be preserved within the fossil record than those that existed in smaller numbers or in a smaller area.
Environment	Inland species are less likely to become fossilized than are those that lived in a marine environment or near the edge of water because sedimentary rock is more likely to be formed in or near water.
Time	Species that lived relatively recently or existed for a long time are more likely to be found as fossils than species that lived very long ago or for a relatively short time.
Geological processes	Due to the chemistry of fossilization, certain organisms are more likely to be preserved than are other organisms.
Paleontology	Certain types of fossils may be more interesting to paleontologists. In addition, a significant bias exists with regard to the locations where paleontologists search for fossils. For example, they tend to search in regions where other fossils have already been found.

22.3 History of Life on Earth

Learning Outcomes:

1. List the types of environmental changes that have affected the history of life on Earth.
2. Describe the cell structure and energy utilization of the first living organisms that arose during the Archaean eon.
3. Explain how the origin of eukaryotic cells involved a union between bacterial and archaeal cells.
4. Describe the key features of multicellular organisms, which arose during the Proterozoic eon.
5. Outline the major events and changes in species diversity during the Paleozoic, Mesozoic, and Cenozoic eras.

Thus far, we have considered hypotheses of how the first cells came into existence, and we have also examined the characteristics of fossils. The first known fossils of single-celled organisms were preserved approximately 3.5 bya. In this section, we will begin with a brief description of the geological changes on Earth that have affected the emergence of new forms of life and then examine some of the major changes in life that have occurred since it began.

Many Environmental Changes Have Occurred Since the Origin of the Earth

The **geological timescale** is a timeline of Earth's history and major events from its origin approximately 4.55 bya to the present (**Figure 22.9**). This time line is subdivided into four eons—the Hadean, Archaean, Proterozoic, and Phanerozoic—and then further subdivided into eras. The first three eons are collectively known as the Precambrian because they preceded the Cambrian era, a geological era that saw a rapid increase in the diversity of life. The names of several eons and eras end in -zoic (meaning animal life), because these time intervals have been defined on the basis of animal life. We will examine these time periods later in this chapter.

The changes that occurred in living organisms over the past 4 billion years are the result of two interactive processes. First, as discussed in the next several chapters, genetic changes in organisms can affect their characteristics. Such changes can influence organisms' abilities to survive and reproduce in their native environment. Second, the environment on Earth has undergone dramatic changes that have profoundly influenced the types of organisms that have existed during different periods of time. In some cases, an environmental change has allowed new types of organisms to flourish. Alternatively, environmental changes have resulted in **extinction**—the complete loss of a species or group of species. Major types of environmental changes are described next.

Temperature During the first 2.5 billion years of its existence, the surface of the Earth gradually cooled. However, during the last 2 billion years, the Earth has undergone major fluctuations in temperature, producing Ice Ages that alternate with warmer periods. Furthermore, the temperature on Earth is not uniform, which produces environments where the temperatures are quite different, such as tropical rain forests and the arctic tundra.

Atmosphere The chemical composition of the gases surrounding the Earth has changed substantially over the past 4 billion years. One notable change involves the amount of oxygen. Prior to 2.4 bya, relatively little oxygen gas was in the atmosphere, but at that time, levels of oxygen in the form of O_2 began to rise significantly. The emergence of organisms that are capable of photosynthesis added oxygen to the atmosphere. Our current atmosphere contains about 21% O_2.

Increased levels of oxygen are thought to have a played a key role in various aspects of the history of life, including the following:

- The origin of many animal body plans coincided with a rise in atmospheric O_2.
- The conquest of land by arthropods (about 410 mya) and a second conquest by arthropods and vertebrates (about 350 mya) occurred during periods in which O_2 levels were high or increasing.
- Increases in animal body sizes are associated with higher O_2 levels.

Higher levels of O_2 could have contributed to these events because higher O_2 levels may enhance the ability of animals to carry out aerobic respiration. These events are discussed later in this chapter and in more detail in Unit V.

Landmasses As the Earth cooled, landmasses formed that were surrounded by bodies of water. This produced two different environments: terrestrial and aquatic. Furthermore, over the course of billions of years, the major landmasses, known as the continents, shifted their positions, changed their shapes, and separated from each other. This phenomenon, called **continental drift**, is shown in **Figure 22.10**.

Floods and Glaciations Catastrophic floods have periodically had major effects on the organisms in the flooded regions. Glaciers have moved across continents and altered the composition of species on those landmasses. As an extreme example, in 1992, American geobiologist Joseph Kirschvink proposed the snowball Earth hypothesis, which suggests that the Earth was entirely covered by ice during parts of the period from 790 to 630 mya. This hypothesis was developed to explain various types of geological evidence including sedimentary deposits of glacial origin that are found at tropical latitudes. Although the existence of a completely frozen Earth remains controversial, massive glaciations over our planet have had an important effect on the history of life.

Volcanic Eruptions The eruptions of volcanoes harm organisms in the vicinity of an eruption, sometimes causing extinctions. In addition, volcanic eruptions in the oceans lead to the formation of new islands. Massive eruptions may also spew so much debris into the atmosphere that they affect global temperatures and limit solar radiation, which restricts photosynthetic production.

Meteorite Impacts During its long history, the Earth has been struck by many meteorites. Large meteorites have significantly affected Earth's environment.

The effects of one or more of the changes described above have sometimes caused large numbers of species to go extinct at the same time. Such events are called **mass extinctions**. Five large mass extinctions occurred near the ends of the Ordovician, Devonian, Permian, Triassic, and Cretaceous periods. The boundaries between geological time periods are often based on the occurrences of mass extinctions. A recurring pattern seen in the history of life is the extinction of some species and the emergence of new ones. The rapid extinction of many modern species due to human activities is sometimes referred to as the sixth mass extinction. We will examine mass extinctions and the current biodiversity crisis in more detail in Chapter 60.

Prokaryotic Cells Arose During the Archaean Eon

The Archaean (from the Greek, meaning ancient) was an eon when diverse microbial life flourished in the primordial oceans.

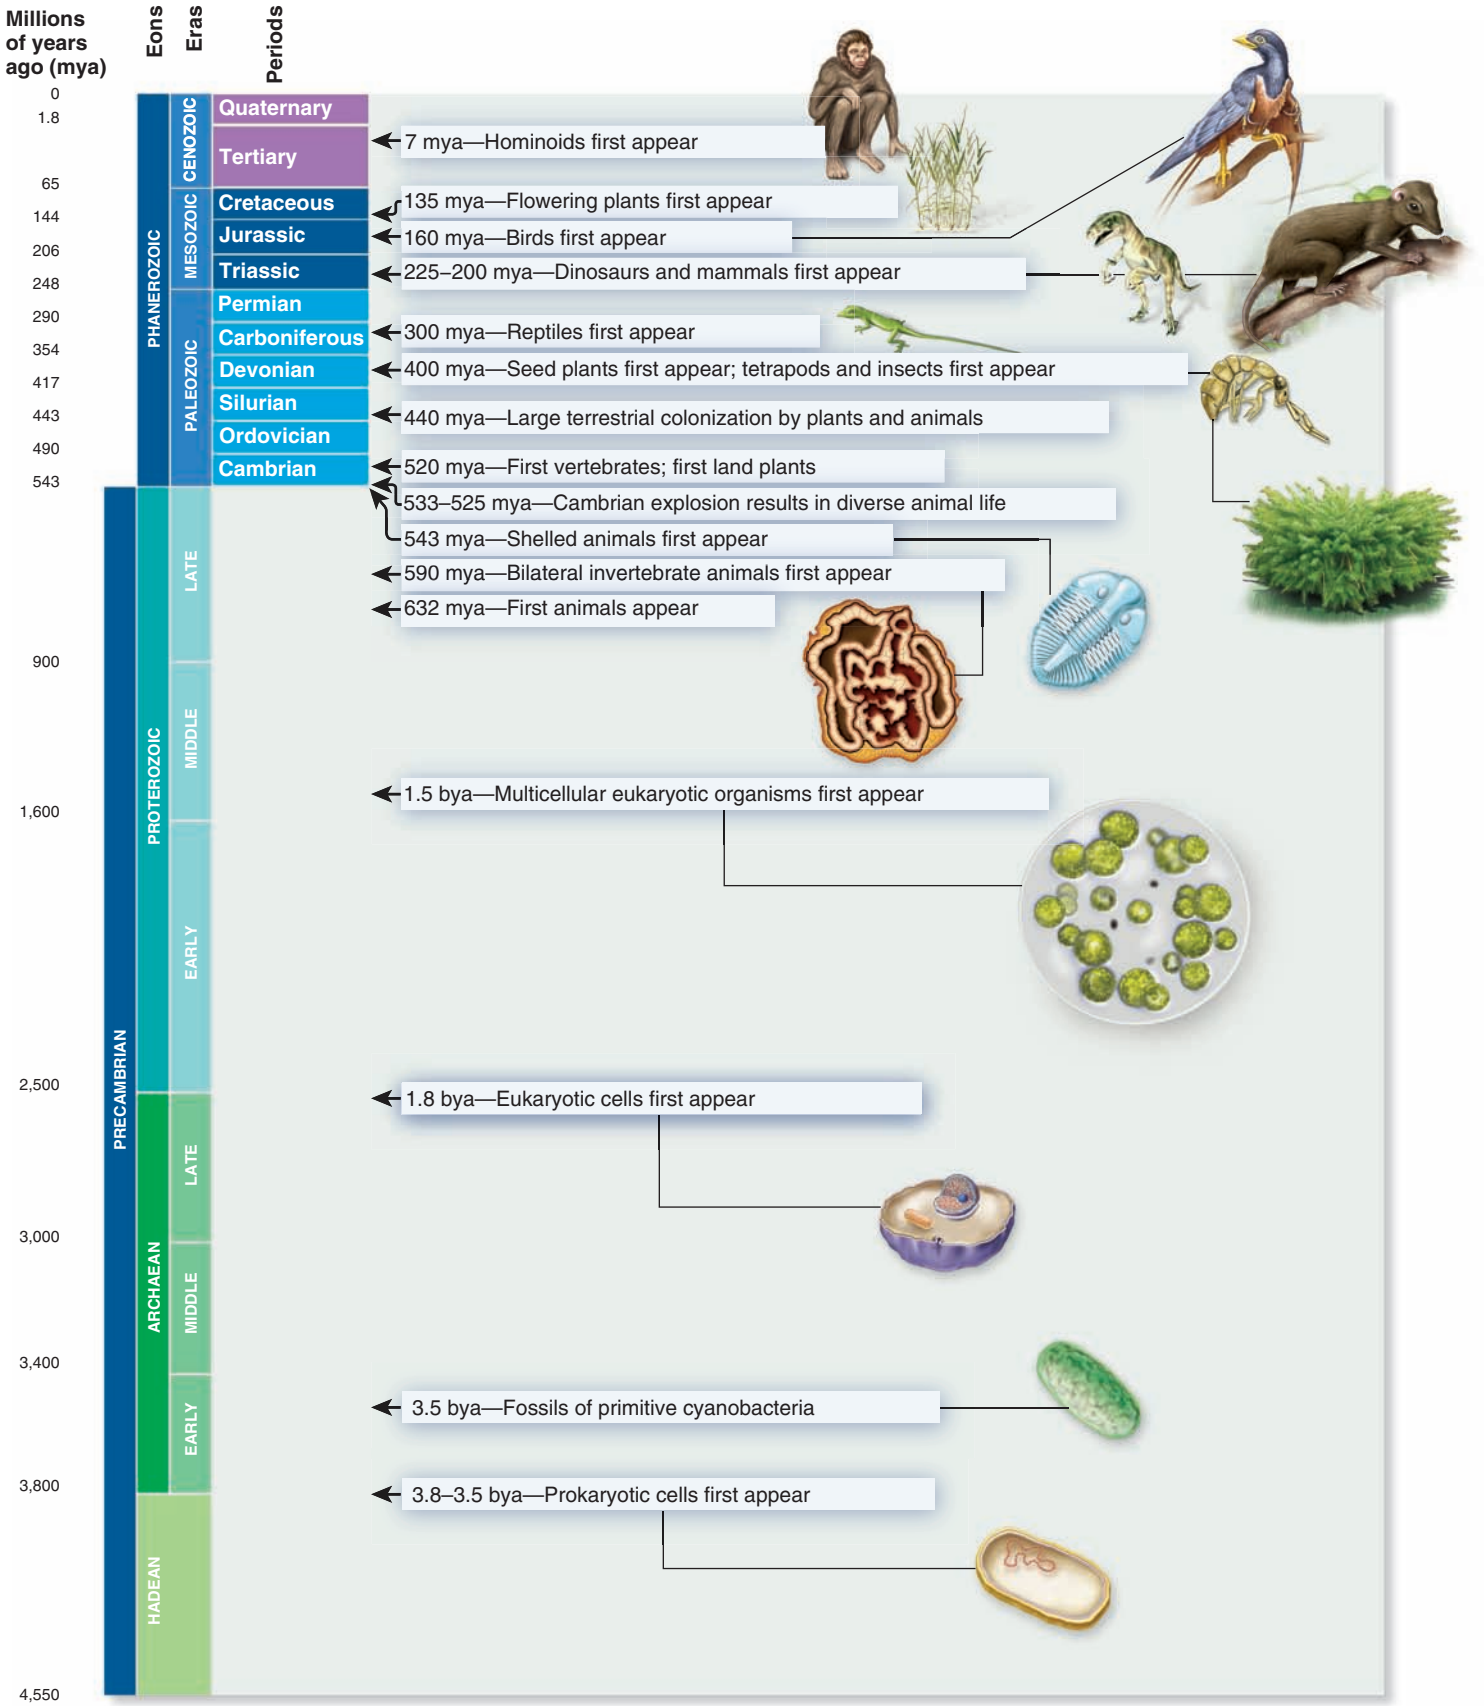


Figure 22.9 **The geological timescale and an overview of the history of life on Earth.**

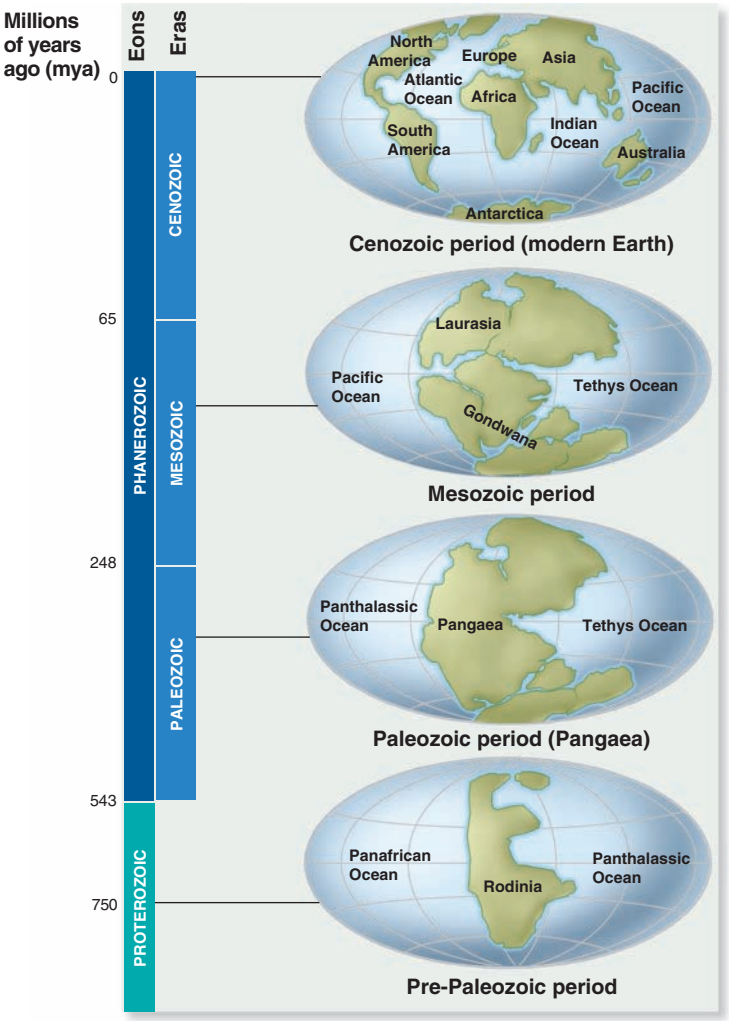

Figure 22.10 Continental drift. The relative locations of the continents on Earth have changed dramatically over time.

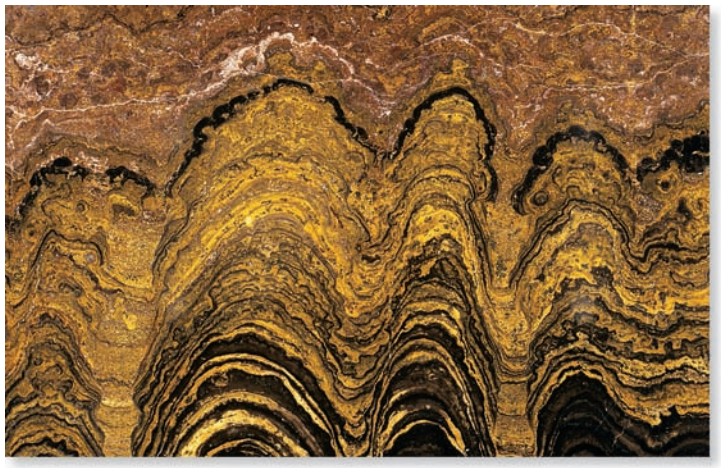
As mentioned previously, the first known fossils of living cells were preserved in rocks that are about 3.5 billion years old (see Figure 22.1), though scientists postulate that cells arose many millions of years prior to this time. Based on the morphology of their fossilized remains, the first cells were prokaryotic. During the more than 1 billion years of the Archaean eon, all life-forms were prokaryotic. Because Earth's atmosphere had very little free O_2, the microorganisms of this eon almost certainly used only anaerobic (without oxygen) respiration.

Organisms with prokaryotic cells are divided into two groups: bacteria and archaea. Bacteria are more prevalent on modern Earth, though many species of archaea have also been identified. Archaea are found in many different environments, with some occupying extreme environments such as hot springs. Bacteria and archaea share fundamental similarities, indicating that they are derived from a common ancestor. Even so, certain differences suggest that these two types of prokaryotes diverged from each other quite early in the history of life. In particular, bacteria and archaea show some interesting differences in metabolism, lipid composition, and genetic pathways (look ahead to Chapter 26, Table 26.1).

Biologists Are Undecided About Whether Heterotrophs or Autotrophs Came First



An important factor that greatly influenced the emergence of new species is the availability of energy. As we learned in Unit II, all organisms require energy to survive and reproduce. Organisms follow two different strategies to obtain energy.

- Some are **heterotrophs**, which means their energy is derived from the chemical bonds within the organic molecules they consume. Because the most common sources of organic molecules today are other organisms, heterotrophs typically consume other organisms or materials from other organisms.
- Alternatively, many organisms are **autotrophs**, which directly harness energy from either inorganic molecules or light. Among modern species, plants are an important example of autotrophs. Plants directly absorb light energy and use it (via photosynthesis) to synthesize organic molecules such as glucose. On modern Earth, heterotrophs ultimately rely on autotrophs for the production of food.

Were the first forms of life heterotrophs or autotrophs? The answer is not resolved. Some biologists have speculated that autotrophs, such as those living near deep-sea vents, may have arisen first. These organisms would have used chemicals that were made near the vents as an energy source to make organic molecules. Alternatively, many scientists have hypothesized that the first living cells were heterotrophs. They reason that it would have been simpler for the first primitive cells to use the organic molecules in the prebiotic soup as a source of energy.

If heterotrophs came first, why were cyanobacteria preserved in the earliest fossils, rather than heterotrophs? One possible reason is related to their manner of growth. Certain cyanobacteria promote the formation of a layered structure called a **stromatolite** (**Figure 22.11**). The aquatic environment where these cyanobacteria survive is rich in minerals such as calcium. The cyanobacteria grow in large mats that form layers. As they grow, they deplete the carbon dioxide (CO_2) in the surrounding water. This causes calcium carbonate in the water to gradually precipitate over the bacterial cells, calcifying the older cells in the lower layers and also trapping grains of sediment. Newer cells produce a layer on top. Over time, many layers of calcified cells and sediment are formed, thereby producing a stromatolite. This process still occurs today in places such as Shark Bay in western Australia, which is renowned for the stromatolites along its beaches (Figure 22.11).

The emergence and proliferation of ancient cyanobacteria had two critical consequences. First, the autotrophic nature of these bacteria enabled them to produce organic molecules from CO_2. This prevented the depletion of organic foodstuffs that would have been exhausted if only heterotrophs existed. Second, cyanobacteria produce O_2 as a waste product of photosynthesis. During the Archaean and Proterozoic eons, the activity of cyanobacteria led to the gradual rise in atmospheric O_2 discussed earlier. The increase in O_2 spelled doom for many anaerobic species, which became restricted to a few anoxic (without oxygen) environments, such as deep within the soil. However, O_2 enabled the emergence of new bacterial and archaeal species that used aerobic (with oxygen) respiration (see Chapter 7). In addition, aerobic respiration is likely to have played a key role in the emergence and eventual explosion of eukaryotic life-forms, which typically have high energy demands. These eukaryotic life-forms are described next.

(a) Fossil stromatolite

(b) Modern stromatolites
