Each stromatolite is a rocklike structure, typically 1 m in diameter. **(a)** Section of a fossilized stromatolite. The layers are mats of mineralized cyanobacteria, one layer on top of the other. The existence of fossil stromatolites provides evidence of early autotrophic organisms. **(b)** Modern stromatolites that have formed in western Australia.

Genomes & Proteomes Connection

The Origin of Eukaryotic Cells Involved a Union Between Bacterial and Archaeal Cells

Eukaryotic cells arose during the Proterozoic eon, which began 2.5 bya and ended 543 mya (see Figure 22.9). The manner in which the first eukaryotic cell originated is not entirely understood. In modern eukaryotic cells, genetic material is found in three distinct organelles. All eukaryotic cells contain DNA in the nucleus and mitochondria, and plant and algal cells also have DNA in their chloroplasts. To address the issue of the origin of eukaryotic species, scientists have examined the DNA sequences found in these three organelles. They have concluded that the nuclear, mitochondrial, and chloroplast genomes appear to be derived from once-separate cells that came together.

Nuclear Genome Both bacteria and archaea contributed substantially to the nuclear genome of eukaryotic cells. Eukaryotic nuclear genes encoding proteins involved in metabolic pathways and lipid biosynthesis appear to be derived from ancient bacteria, whereas genes involved with transcription and translation appear to be derived from an archaeal ancestor. To explain the origin of the nuclear genome, several hypotheses have been proposed. The most widely accepted involves an association between ancient bacteria and archaea, which is hypothesized to have been endosymbiotic. In an **endosymbiotic** relationship, a smaller organism (the endosymbiont) lives inside a larger organism (the host).

Researchers have suggested that an archaeal species evolved the ability to invaginate its plasma membrane, which could have two results (**Figure 22.12**). First, it could eventually lead to the formation of an extensive internal membrane system and enclose the genetic material in a nuclear envelope. Second, the ability to invaginate the plasma membrane would provide a mechanism for taking up materials from the environment via endocytosis, which is described in Chapter 5. Along these lines, the closest modern relative to eukaryotes is thought to be a phylum of archaea called Lokiarchaeota, which carries many genes that are hypothesized to play a role in membrane remodeling. In the scenario described in Figure 22.12, an ancient archaeon engulfed a bacterium via endocytosis, maintaining the bacterium in its cytoplasm as an endosymbiont. Over time, some genes from the bacterium were transferred to the archaeal host cell, and the resulting genetic material eventually became the nuclear genome.

Mitochondrial and Chloroplast Genomes As discussed in Chapter 4, the analyses of genes from mitochondria, chloroplasts, and bacteria are consistent with the endosymbiosis theory, which proposes that mitochondria and chloroplasts originated from bacteria that took up residence within a primordial eukaryotic cell (refer back to Figure 4.27). Mitochondria found in eukaryotic cells are likely derived from a bacterial species that resembled modern α-proteobacteria, a diverse group of bacteria that carry out oxidative phosphorylation to make ATP. One possibility is that an endosymbiotic event involving an ancestor of this bacterial species produced the first eukaryotic cell and that the mitochondrion is a remnant of that event. Alternatively, endosymbiosis may have produced the first eukaryotic cell, and then a subsequent endosymbiosis resulted in mitochondria (see Figure 22.12). DNA-sequencing data indicate that chloroplasts were derived from a separate endosymbiotic relationship between a primitive eukaryotic cell and a cyanobacterium. As discussed in Chapter 28, plastids, such as chloroplasts, have arisen on several independent occasions via primary, secondary, and tertiary endosymbiosis (see Figure 28.13).

Interestingly, an endosymbiotic relationship involving two different proteobacteria was reported in 2001. In mealybugs, bacteria survive within the cytoplasm of large host cells of a specialized organ called a bacteriome. Recent analysis has shown that different species of bacteria inside the host cells share their own endosymbiotic relationship. In particular, γ-proteobacteria live endosymbiotically inside β-proteobacteria. Such an observation demonstrates that an endosymbiotic relationship can occur between two prokaryotic cells.

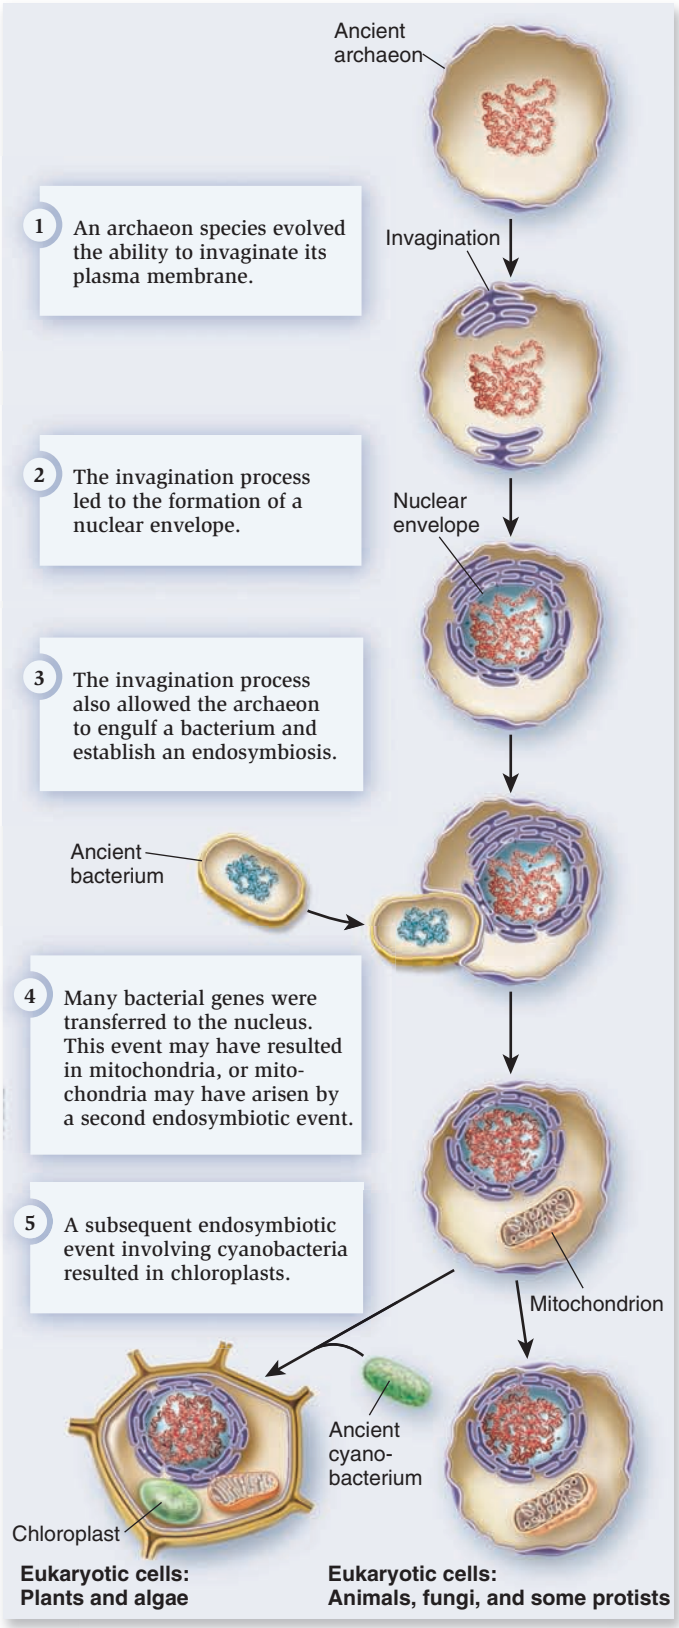

Figure 22.12 **Possible endosymbiotic relationships that gave rise to the first eukaryotic cells.**

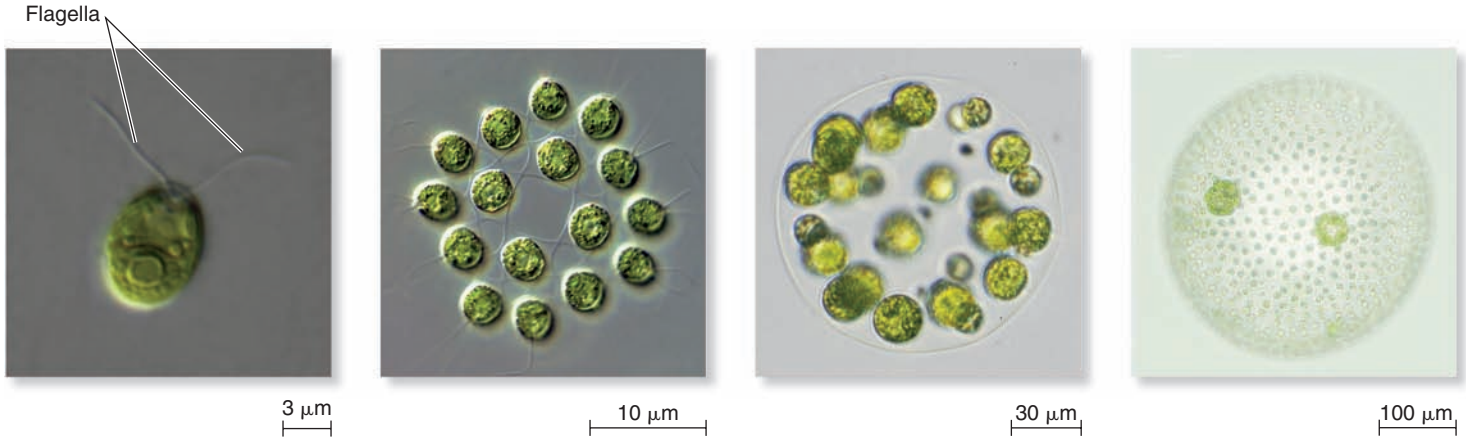
BioConnections: *Look back at Figure 5.24. Explain how endocytosis played a role in endosymbiosis.*

Multicellular Eukaryotes and the Earliest Animals Arose During the Proterozoic Eon

The first multicellular eukaryotes are thought to have emerged about 1.5 bya, in the middle of the Proterozoic eon. The oldest fossil evidence for multicellular eukaryotes was an organism that resembled modern red algae; this fossil was dated at approximately 1.2 billion years old.

Simple multicellular organisms are believed to have originated in one of two different ways. One possibility is that several individual cells found each other and aggregated to form a colony. Cellular slime molds, discussed in Chapter 28, are examples of modern organisms in which groups of single-celled organisms can come together to form a small multicellular organism. According to the fossil record, such organisms have remained very simple for hundreds of millions of years.



Alternatively, another way that multicellularity can occur is when a single cell divides and the resulting cells stick together. This pattern occurs in many simple multicellular organisms, such as algae and fungi, as well as in species with more complex body plans, such as plants and animals. Biologists cannot be certain whether the first multicellular eukaryotes arose by an aggregation process or by cell division and adhesion. However, the development of complex, multicellular organisms now occurs by cell division and adhesion.

An interesting example showing changes in the level of complexity from unicellular eukaryotes to more complex multicellular organisms is found among evolutionarily related species of volvocine green algae. These algae exist as unicellular species, as small clumps of cells of the same cell type, or as larger groups of cells with two distinct cell types. **Figure 22.13** compares four species of volvocine algae. *Chlamydomonas reinhardtii* is a unicellular alga (Figure 22.13a). It is called a biflagellate because each cell has two flagella. *Gonium pectorale* is a multicellular organism composed of 16 cells (Figure 22.13b). This simple multicellular organism is formed from a single cell by cell division and adhesion. All of the cells in this species are biflagellate. Other volvocine algae have evolved into larger and more complex organisms. *Pleodorina californica* has 64–128 cells (Figure 22.13c), and *Volvox aureus* has about 1,000–2,000 cells (Figure 22.13d). A feature of these more complex organisms is they have two cell types: somatic and reproductive cells. The somatic cells are biflagellate cells, but the reproductive cells are not. *V. aureus* has a higher percentage of somatic cells than *P. californica*.

Overall, an analysis of these four species of algae illustrates three important principles found among complex multicellular species:

1. Multicellular organisms arise from a single cell that divides to produce daughter cells that adhere to one another.
2. The daughter cells can follow different fates, thereby producing multicellular organisms with different cell types.
3. As organisms get larger, a greater percentage of their cells tend to be somatic cells. The somatic cells carry out the activities required for the survival of the multicellular organism, whereas the reproductive cells are specialized for the sole purpose of producing offspring.

Toward the end of the Proterozoic eon, multicellular animals emerged. The first animals were invertebrates—animals without a backbone. Most animals, except for organisms such as sponges and jellyfish, exhibit bilateral symmetry—a two-sided body plan with a

(a) *Chlamydomonas reinhardtii*, a unicellular alga

(b) *Gonium pectorale*, composed of 16 identical cells

(c) *Pleodorina californica*, composed of 64–128 cells, has 2 cell types, somatic and reproductive

(d) *Volvox aureus*, composed of about 1,000–2,000 cells, has 2 cell types, somatic and reproductive

Figure 22.13 Variation in the level of multicellularity among volvocine algae.

BIOLOGY PRINCIPLE New properties of life emerge from complex interactions. The formation of different cell types is an emergent property of multicellularity.

right and left side that are mirror images. Because each side of the body has appendages such as legs, one advantage of bilateral symmetry is that it facilitates locomotion. Bilateral animals also have anterior and posterior ends, with the mouth at the anterior end, as noted in Chapter 19. In southern China in 2004, Chinese paleontologist Jun-Yuan Chen, American paleobiologist David Bottjer, and their colleagues discovered a fossil, which they described as the earliest known ancestor of animals with bilateral symmetry. This minute creature, called *Vernanimalcula guizhouena*, has a shape like a flattened helmet and is barely visible to the naked eye (**Figure 22.14**). The fossil is approximately 580–600 million years old. However, the interpretation that *Vernanimalcula guizhouena* was the earliest ancestor of animals with bilateral symmetry remains controversial and is under active investigation.

Phanerozoic Eon: The Paleozoic Era Saw the Diversification of Invertebrates and the Colonization of Land by Plants and Animals

The proliferation of multicellular eukaryotic life has been extensive during the Phanerozoic eon, which started 543 mya and extends to the present day. Phanerozoic means well-displayed life, referring to the abundance of fossils of plants and animals that have been identified from this eon. As described in Figure 22.9, the Phanerozoic eon is subdivided into three eras: the Paleozoic, Mesozoic, and Cenozoic. Because they are relatively recent and we have many fossils from these eras, each of them is further subdivided into periods. We will consider each era with its associated conditions and prevalent forms of life separately.

The term Paleozoic means ancient animal life. The Paleozoic era covers approximately 300 million years, from 543 to 248 mya, and is subdivided into six periods: Cambrian, Ordovician, Silurian, Devonian, Carboniferous, and Permian. Periods are usually named after regions where rocks and fossils of that age were first discovered.

Cambrian Period (543–490 mya) The climate in the Cambrian period was generally warm and wet, with no evidence of ice at the poles. During this time, the diversity of animal species increased rapidly, an event called the **Cambrian explosion**. However, recent evidence suggests that many types of animal groups present during the Cambrian period actually arose prior to this period.

Many fossils from the Cambrian period were found in the Canadian Rockies in a rock bed called the Burgess Shale, which was discovered by American paleontologist Charles Walcott in 1909. At this

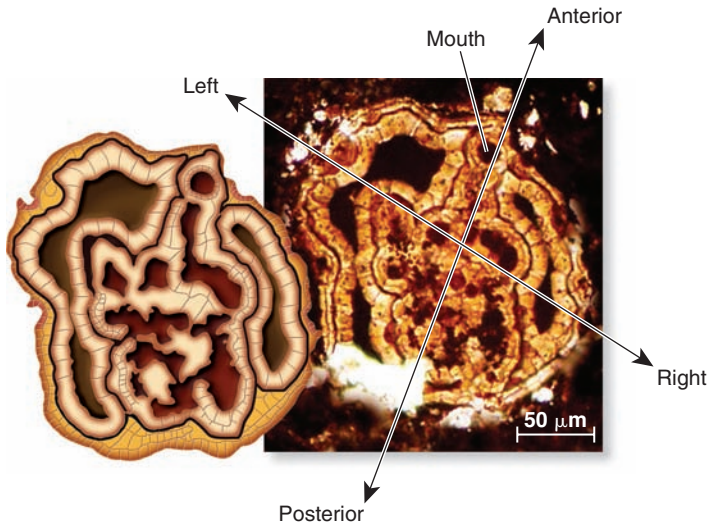


Figure 22.14 Fossil of an early invertebrate animal showing bilateral symmetry. This fossil of an early animal, *Vernanimalcula guizhouena*, dates from 580 to 600 mya.

Concept Check: Name three other species that exhibit bilateral symmetry.

(a) The Burgess Shale **(b) A fossilized arthropod, *Marrella***

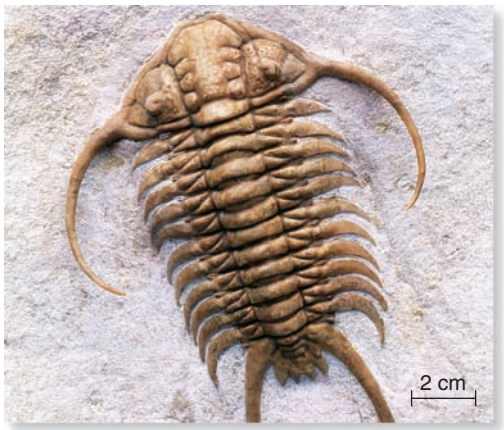
Figure 22.15 The Cambrian explosion and the Burgess Shale. **(a)** This photograph shows the original site in the Canadian Rockies discovered by Charles Walcott. Since its discovery, this site has been made into a quarry for the collection of fossils. **(b)** A fossil of an extinct arthropod, *Marrella*, which was found at this site.

site, both soft- and hard-bodied (shelled) invertebrates were buried in an underwater mudslide and preserved in water that was so deep and oxygen-free that decomposition was minimal (**Figure 22.15a**). The excellent preservation of the softer tissues is what makes this deposit unique (**Figure 22.15b**).

By the middle of the Cambrian period, all of the major types of invertebrates that exist today were present, plus many others that no longer exist. These include over 100 major animal groups with significantly different body plans. Examples that still exist include echinoderms (sea urchins and starfish), arthropods (insects, spiders, and crustaceans), mollusks (clams and snails), chordates (organisms with a dorsal nerve chord), and vertebrates (animals with backbones). Interestingly, although many new species of animals have arisen since this time, these later species have not shown a major reorganization of body plan, but instead exhibit variations on themes that were established during or prior to the Cambrian explosion.

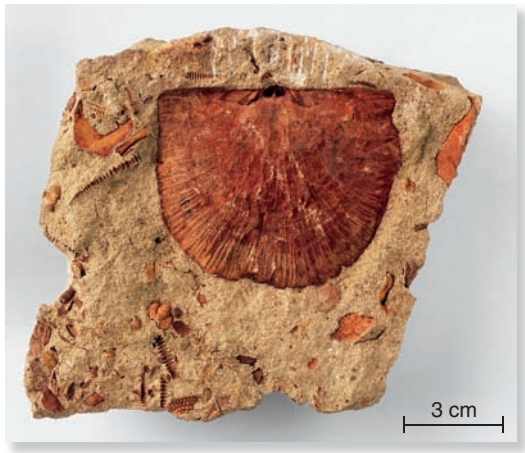
Three possible causes of the Cambrian explosion are the following.

- Because it occurred shortly after marine animals evolved shells, some scientists have speculated that the changes observed in animal species may have allowed them to exploit new environments.
- Alternatively, others have suggested that the increase in diversity may be related to atmospheric oxygen levels. During this period, oxygen levels were increasing, and perhaps more complex body plans became possible only after the atmospheric oxygen surpassed a certain threshold. In addition, as atmospheric oxygen reached its present levels, an ozone (O_3) layer was produced that screens out harmful ultraviolet radiation, thereby allowing complex life to live in shallow water and eventually on land.
- Another possible contributor to the Cambrian explosion was an "evolutionary arms race" between interacting species. The ability of predators to capture prey and the ability of prey to avoid predators may have been a major factor that resulted in a diversification of animals into many different species.



Ordovician Period (490–443 mya) As in the Cambrian period, the climate of the early and middle parts of the Ordovician period was warm, and the atmosphere was moist. During this period, a diverse group of hard-shelled marine invertebrates, including trilobites and brachiopods, appeared in the fossil record (**Figure 22.16**). Marine communities consisted of invertebrates, algae, early jawless fishes (a type of early vertebrate), mollusks, and corals. Fossil evidence also suggests that early land plants and arthropods may have first invaded the land during this period.

Toward the end of the Ordovician period, the climate changed rather dramatically. Large glaciers formed, which drained the relatively shallow oceans, causing the water levels to drop. This resulted in a mass extinction in which as much as 60% of the existing marine invertebrates became extinct.



Silurian Period (443–417 mya) In contrast to the dramatic climate changes observed during the Ordovician period, the climate during the Silurian period was relatively stable. The glaciers largely melted, which caused the ocean levels to rise. No new major types of invertebrate animals appeared during this period, but significant changes were observed among existing vertebrate and plant species. Many new types of fishes appeared in the fossil record. In addition, coral reefs made their first appearance during this period.

The Silurian marked a major colonization of land by terrestrial plants and animals. For this to occur, certain species evolved adaptations that prevented them from drying out, such as an external cuticle. Ancestral relatives of spiders and centipedes became prevalent. The earliest fossils of vascular plants, which have tissues that are specialized for the transport of water, sugar, and salts throughout the plant body, were observed in this period.

Devonian Period (417–354 mya) In the Devonian period, generally dry conditions occurred across much of the northern landmasses. However, the southern landmasses were mostly covered by cool, temperate oceans.

(a) Trilobite

(b) Brachiopod

Figure 22.16 Shelled, invertebrate fossils of the Ordovician period. Trilobites existed for millions of years before becoming extinct about 250 mya. Many species of brachiopods exist today.

The Devonian saw a major increase in the number of terrestrial species. At first, the vegetation consisted primarily of small plants, only a meter tall or less. Later, ferns, horsetails, and seed plants, such as gymnosperms, also emerged. By the end of the Devonian, the first trees and forests were formed. A major expansion of terrestrial animals also occurred. Insects first appeared in the fossil record, and other invertebrates became plentiful. In addition, the first tetrapods—vertebrates with four legs—are believed to have arisen in the Devonian. Early tetrapods included amphibians, which lived on land but required water in which to lay their eggs.

In the oceans, many types of invertebrates flourished, including brachiopods, echinoderms, and corals. This period is sometimes called the Age of Fishes, as many new types of fishes emerged. During a period of approximately 20 million years near the end of the Devonian period, a prolonged series of extinctions eliminated many marine species. The cause of this mass extinction is not well understood.

Carboniferous Period (354–290 mya) The term Carboniferous refers to the deposits of coal, a sedimentary rock primarily composed of carbon, that were formed during this period. The Carboniferous period had the ideal conditions for the subsequent formation of coal. It was a cooler period, and much of the land was covered by forest swamps. Coal was formed over many millions of years from compressed layers of rotting vegetation.

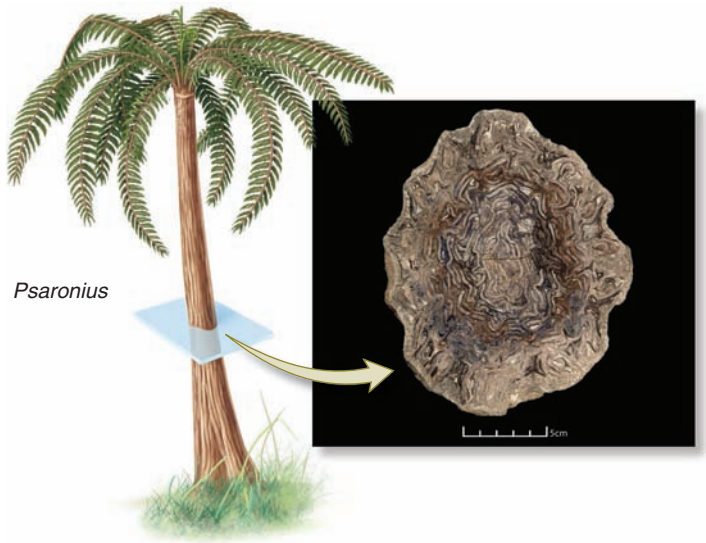


Figure 22.17 A giant tree fern, *Psaronius*, from the Carboniferous period. This genus became extinct during the Permian. The illustration is a re-creation based on fossil evidence. The inset shows a fossilized section of the trunk, also known as petrified wood.

Plants and animals further diversified during the Carboniferous period. Very large plants and trees became prevalent. For example, tree ferns such as *Psaronius* grew to a height of 15 meters or more (**Figure 22.17**). The first flying insects emerged. Giant dragonflies with a wingspan of over 2 feet inhabited the forest swamps. Terrestrial vertebrates also became more diverse. Amphibians were very prevalent. One innovation that seemed particularly beneficial was the amniotic egg. In reptiles, the amniotic egg was covered with a leathery or hard shell, which prevented the desiccation of the embryo inside. This innovation was critical for the emergence of reptiles during this period.

Permian Period (290–248 mya) At the beginning of the Permian, continental drift had brought much of the total land together into a supercontinent known as Pangaea (see Figure 22.10). The interior regions of Pangaea were dry, with great seasonal fluctuations. The forests of fernlike plants were replaced with gymnosperms. Species resembling modern conifers first appeared in the fossil record. Amphibians were prevalent, but reptiles became the dominant vertebrate species.

At the end of the Permian period, the largest known mass extinction in the history of life on Earth occurred; 90–95% of marine species and a large proportion of terrestrial species were eliminated. The cause of the Permian extinction is the subject of much research and controversy. One possibility is that glaciation destroyed the habitats of terrestrial species and lowered ocean levels, which would have caused greater competition among marine species. Another hypothesis is that enormous volcanic eruptions in Siberia produced large ash clouds that abruptly changed the climate on Earth.

Phanerozoic Eon: The Mesozoic Era Saw the Rise and Fall of the Dinosaurs

The Permian extinction marks the division between the Paleozoic and Mesozoic eras. Mesozoic means middle animals. It was a time that saw great changes in animal and plant species. This era is sometimes called the Age of Dinosaurs, because those animals flourished during this time. The climate during the Mesozoic era was consistently hot, and terrestrial environments were relatively dry. Little if any ice was found at either pole. The Mesozoic is divided into three periods: the Triassic, Jurassic, and Cretaceous.

Triassic Period (248–206 mya) Reptiles were plentiful in this period, including new groups such as crocodiles and turtles. The first dinosaurs emerged during the middle of the Triassic. Dinosaurs were reptiles that shared certain anatomical features, such as an erect posture. The first mammals also emerged, such as the small *Megazostrodon* (**Figure 22.18**). Gymnosperms were the dominant land plant. Volcanic eruptions near the end of the Triassic are thought to have caused global warming, resulting in mass extinctions that eliminated many marine and terrestrial species.

Jurassic Period (206–144 mya) Gymnosperms, such as conifers, continued to be the dominant vegetation. Mammals were not prevalent. Reptiles continued to be the dominant land vertebrate. Some dinosaurs attained enormous sizes, including the massive *Brachiosaurus*, which reached a length of 25 m (80 ft) and weighed up to 100 tons! Modern birds are descendents of a dinosaur lineage called theropod (meaning beast-footed) dinosaurs. *Tyrannosaurus rex* is one of the best known theropod dinosaurs. An early birdlike animal, *Archaeopteryx* (**Figure 22.19**), emerged in the Jurassic period. However, paleontologists are debating whether or not *Archaeopteryx* is a true ancestor of modern birds.

Figure 22.18 ***Megazostrodon*, the first known mammal of the Triassic period.** The illustration is a re-creation based on fossilized skeletons. The *Megazostrodon* was 10 to 12 cm long.

BioConnections: Look ahead to Table 34.1. What are the common characteristics of mammals?

Figure 22.19 **A fossil of an early birdlike animal, *Archaeopteryx*, which emerged in the Jurassic period.**

Cretaceous Period (144–65 mya) On land, dinosaurs continued to be the dominant animals in the Cretaceous period. The earliest flowering plants, called angiosperms, which form seeds within a protective chamber, emerged and began to diversify.

The end of the Cretaceous witnessed another mass extinction, which brought an end to many previously successful groups of organisms. Except for the lineage that gave rise to birds, dinosaurs abruptly died out, as did many other species. As with the Permian extinction, the cause or causes of this mass extinction are still debated. One plausible hypothesis suggests that a large meteorite hit the region that is now the Yucatan Peninsula of Mexico, lifting massive amounts of debris into the air and thereby blocking the sunlight from reaching the Earth's surface. Such a dense haze could have cooled the Earth's surface by 11–15°C (20–30°F). Evidence also points to strong volcanic eruptions as a contributing factor for this mass extinction.

Phanerozoic Eon: Mammals and Flowering Plants Diversified During the Cenozoic Era

The Cenozoic era spans the most recent 65 million years. It is divided into two periods: Tertiary and Quaternary. In many parts of the world, tropical conditions were replaced by a colder, drier climate. During this time, mammals became the largest terrestrial animals, which is why the Cenozoic is sometimes called the Age of Mammals. However, the Cenozoic era also saw an amazing diversification of many types of organisms, including birds, fishes, insects, and flowering plants.

Tertiary Period (65–1.8 mya) On land, the mammals that survived from the Cretaceous began to diversify rapidly during the early part of the Tertiary period. Angiosperms became the dominant land plant, and insects became important for their pollination. Fishes also diversified, and sharks became abundant.

Toward the end of the Tertiary period, about 7 mya, hominoids came into existence. **Hominoids** include humans, chimpanzees, gorillas, orangutans, and gibbons, plus all of their recent ancestors. The subset of hominoids called hominins includes modern humans, extinct human species (for example, of the *Homo* genus), and our immediate ancestors. In 2002, a fossil of the earliest known hominin,

Sahelanthropus tchadensis, was discovered in Central Africa. This fossil was dated at between 6 and 7 million years old. Another early hominin genus, called *Australopithecus*, first emerged in Africa about 4 mya. Australopithecines walked upright and had a protruding jaw, prominent eyebrow ridges, and a small braincase.

Quaternary Period (1.8 mya–present) Periodic Ice Ages have been prevalent during the last 1.8 million years, covering much of Europe and North America. This period has witnessed the widespread extinction of many species of mammals, particularly larger ones. Certain species of hominins became increasingly more like living humans. Fossils of *Homo habilis*, or handy man, so called because stone tools were found with the fossil remains, have been dated to close to the beginning of the Quaternary period. *Homo sapiens*—modern humans—first appeared about 170,000 years ago. The evolution of hominins is discussed in more detail in Chapter 34.

Summary of Key Concepts

- Life began on Earth from nonliving material between 3.5 and 4.0 bya (Figure 22.1).

22.1 Origin of Life on Earth

- Life on Earth is hypothesized to have arisen in four overlapping stages. The first stage involved the synthesis of organic molecules to form a prebiotic soup. Possible scenarios as to how this occurred are the reducing atmosphere, extraterrestrial, and deep-sea vent hypotheses (Figures 22.2, 22.3).
- The second stage was the formation of polymers from simple organic molecules. This may have occurred on the surface of clay.
- The third stage involved the emergence of protobionts, which were aggregates of polymers with a boundary that separated them from the external environment (Figure 22.4).
- In the fourth stage, polymers enclosed in membranes acquired properties of cells, such as self-replication and catalytic functions (Figure 22.5).
- During the hypothetical period called the RNA world, the first living cells used RNA for both information storage and catalytic functions.
- Bartel and Szostak demonstrated experimentally that chemical selection for RNA molecules that can catalyze covalent bond formation is possible (Figure 22.6).
- The RNA world was eventually superseded by the modern DNA/RNA/protein world.

22.2 The Fossil Record

- Fossils, which are preserved remnants of past life-forms, are formed in sedimentary rock (Figure 22.7).
- Radiometric dating is one way of estimating the age of a fossil. Fossils provide an extensive record of the history of life on Earth, though the record is incomplete (Figure 22.8, Table 22.1).

22.3 History of Life on Earth

- The geological timescale, which is divided into four eons and many eras and periods, charts the major events that occurred during the history of life on Earth (Figure 22.9).
- Both the emergence of new species and mass extinctions are correlated with changes in temperature, amount of O_2 in the atmosphere, landmass locations, floods and glaciation, volcanic eruptions, and meteorite impacts (Figure 22.10).
- During the Archaean eon, bacteria and archaea arose. The proliferation of cyanobacteria led to a gradual rise in O_2 levels (Figure 22.11).
- Eukaryotic cells arose during the Proterozoic eon. This origin involved a union between bacterial and archaeal cells that is hypothesized to have been endosymbiotic. The origin of mitochondria and chloroplasts was also the result of endosymbiosis (Figure 22.12).
- Multicellular eukaryotes arose about 1.5 bya during the Proterozoic eon. Multicellularity now occurs via cell division and the adherence of the resulting cells to each other. A multicellular organism can have multiple cell types (Figure 22.13).
- The first animal showing bilateral symmetry emerged toward the end of the Proterozoic eon (Figure 22.14).
- The Phanerozoic eon is subdivided into the Paleozoic, Mesozoic, and Cenozoic eras. During the Paleozoic era, invertebrates greatly diversified, particularly during the Cambrian explosion, and the land became colonized by plants and animals. Terrestrial vertebrates, including tetrapods, became more diverse (Figures 22.15, 22.16, 22.17).
- Dinosaurs were prevalent during the Mesozoic era, particularly during the Jurassic period. Mammals and birds also emerged (Figures 22.18, 22.19).
- During the Cenozoic era, mammals diversified, and flowering plants became the dominant plant species. The first hominoids emerged approximately 7 mya. *Homo sapiens*, our species, first appeared about 170,000 years ago.

Assess and Discuss

Test Yourself

1. The prebiotic soup was
   a. the assemblage of unicellular prokaryotes that existed in the oceans of early Earth.
   b. the accumulation of organic molecules in the oceans of early Earth.
   c. the mixture of organic molecules found in the cytoplasm of the earliest cells on Earth.
   d. a pool of nucleic acids that contained the genetic information for the earliest organisms.
   e. none of the above.
2. Which of the following is *not* a characteristic of protobionts necessary for the evolution of living cells?
   a. a membrane-like boundary separating the external environment from an internal environment
   b. polymers capable of functioning in information storage
   c. polymers capable of catalytic activity
   d. self-replication
   e. compartmentalization of metabolic activity
3. RNA is believed to be the first functional macromolecule in protobionts because it
   a. is easier to synthesize than other macromolecules.
   b. has the ability to store information, self-replicate, and perform catalytic activity.
   c. is the simplest of the macromolecules commonly found in living cells.
   d. All of the above are correct.
   e. Only a and c are correct.

4. The movement of landmasses that have changed their positions, shapes, and association with other landmasses is called
   a. glaciation.
   b. Pangaea.
   c. continental drift.
   d. biogeography.
   e. geological scale.
5. Paleontologists estimate the dates of fossils by
   a. the layer of rock in which the fossils are found.
   b. analysis of radioisotopes found in nearby igneous rock.
   c. the complexity of the body plan of the organism.
   d. all of the above.
   e. a and b only.
6. The fossil record does not give us a complete picture of the history of life because
   a. not all past organisms have become fossilized.
   b. only organisms with hard skeletons can become fossilized.
   c. fossils of very small organisms have not been found.
   d. fossils of early organisms are located too deep in the crust of the Earth to be found.
   e. All of the above are true.
7. The endosymbiosis hypothesis explaining the evolution of eukaryotic cells is supported by
   a. DNA-sequencing analysis comparing bacterial genomes, mitochondrial genomes, and eukaryotic nuclear genomes.
   b. naturally occurring examples of endosymbiotic relationships between bacterial cells and eukaryotic cells.
   c. the presence of DNA in mitochondria and chloroplasts.
   d. all of the above.
   e. a and b only.
8. Which of the following explanations of multicellularity in eukaryotes is seen in the development of complex, multicellular organisms today?
   a. endosymbiosis
   b. aggregation of cells to form a colony
   c. division of cells with the resulting cells adhering together
   d. multiple cell types aggregating to form a complex organism
   e. None of the above phenomena are evident today.
9. The earliest fossils of vascular plants were formed during the _____ period.
   a. Ordovician
   b. Silurian
   c. Devonian
   d. Triassic
   e. Jurassic
10. The appearance of the first hominoids dates to the _____ period.
   a. Triassic
   b. Jurassic
   c. Cretaceous
   d. Tertiary
   e. Quaternary

Conceptual Questions

1. What are the four stages that led to the origin of living cells?
2. How are the ages of fossils determined? In your answer, you should discuss which types of rocks are analyzed and explain the concepts of radiometric dating and half-life.
3.  Two principles of biology are (1) *living organisms interact with their environment* and (2) *populations of organisms evolve from one generation to the next.* Describe two examples in which changes in the global climate affected the evolution of species.

Collaborative Questions

1. Discuss possible hypotheses of how organic molecules were first formed.
2. Discuss the key features of a protobiont. What distinguishes a protobiont from a living cell?

An Introduction to Evolution

23

Selective breeding. The horses in this race have been bred for a particular trait, in this case, speed. Such a practice, called selective breeding, can dramatically change the traits of organisms over several generations.

Organic life beneath the shoreless waves
Was born and nurs'd in Ocean's pearly caves
First forms minute, unseen by spheric glass,
Move on the mud, or pierce the watery mass;
These, as successive generations bloom,
New powers acquire, and larger limbs assume;
Whence countless groups of vegetation spring,
And breathing realms of fin, and feet, and wing.

By Erasmus Darwin, grandfather of Charles Darwin.
Published posthumously in 1803.

The term **evolution** is used to describe a heritable change in one or more characteristics of a population from one generation to the next. Evolution can be viewed on a small scale (**microevolution**) as it relates to changes in a single gene or allele frequencies in a population over time, or it can be viewed on a larger scale (**macroevolution**) as it relates to the formation of a new species or groups of related species.

It is helpful to begin our discussion of evolution with a working definition of a species. Biologists often define a **species** as a group of related organisms that share a distinctive form. Among species that reproduce sexually, such as plants and animals, members of the same species are capable of interbreeding in nature to produce viable and fertile offspring. The term **population** refers to all members of a species that live in the same area at the same time and have the opportunity to interbreed. As we will see in Chapter 25, some of the emphasis in the study of evolution is on understanding how populations change over the course of many generations to produce new species.

In the first part of this chapter, we will examine the development of evolutionary thought and some of the basic tenets of evolution, particularly those proposed by the British naturalist Charles Darwin in the mid-1800s. The theory of evolution has been refined over the past 150 years or so, but the fundamental principle of evolution remains unchanged and has provided a cornerstone for our understanding of biology. Ukrainian-born American geneticist Theodosius Dobzhansky, an influential evolutionary scientist of the 1900s, once said, "Nothing in biology makes sense except in the light of evolution." The extraordinarily diverse and often seemingly bizarre array of species on our planet can be explained within the context of evolution. As is the case with all scientific theories, evolution is called a theory because it is supported by a substantial body of evidence and because it explains a wide range of observations. The theory of evolution provides answers to many questions related to the diversity of life. In biology, theories such as this are viewed as scientific knowledge.

In the second part of this chapter, we will survey the extensive data that illustrate the processes by which evolution occurs. These data not only support the theory of evolution but also allow us to understand the interrelatedness of different species, whose similarities are often due to descent from a common ancestor. Much of the early evidence supporting evolution came from direct observations and comparisons of living and extinct species. More recently, advances in molecular genetics, particularly those related to DNA sequencing and genomics, have revolutionized the study of evolution. Scientists now have information that allows us to understand how evolution involves changes in the DNA sequences of a given species. These changes affect both a species' genes and the proteins they encode. **Molecular evolution** refers to the process of evolution at the level of genes

and proteins. Comparisons of gene or protein sequences in different organisms can reveal evolutionary relationships that cannot be seen in morphology. A major focus of this textbook, namely genomes and proteomes, is rooted in an understanding of these changes. In the last section of this chapter, we consider some of the exciting new ways of exploring evolutionary change at the molecular level. In the following chapters of this unit, we will examine how such changes are acted upon by evolutionary factors in ways that alter the traits of a given species and may eventually lead to the formation of new species.

23.1 Overview of Evolution

Learning Outcomes:

1. Define evolution.
2. Describe the factors that led Darwin to the theory of evolution.
3. Explain the process of natural selection.

Undoubtedly, the question "Where did we come from?" has been asked and debated by people for thousands of years. Many of the early ideas regarding the existence of living organisms were strongly influenced by religion and philosophy. Some of these ideas suggested that all forms of life have remained the same since their creation. In the 1600s, however, scholars in Europe began a revolution that created the basis of empirical and scientific thought. **Empirical thought** relies on observation to form an idea or hypothesis rather than trying to understand life from a nonphysical or spiritual point of view. As described in this section, the shift toward empirical thought encouraged scholars to look for the basic rationale behind a given process or phenomenon. This perspective played a key role in the development of the theory of evolution.

The Work of Several Scientists Set the Stage for Darwin's Ideas

In the mid- to late-1600s, the first scientist to carry out a thorough study of the living world was an English naturalist named John Ray, who developed an early classification system for plants and animals based on anatomy and physiology. He established the modern concept of a species, noting that organisms of one species do not interbreed with members of another, and used it as the basic unit of his classification system. Ray's ideas on classification were later expanded by the Swedish naturalist Carolus Linnaeus. How did their work contribute to the development of evolutionary theory? Neither Ray nor Linnaeus proposed that evolutionary change promotes the formation of new species. However, their systematic classification of plants and animals helped scholars of this period perceive the similarities and differences among living organisms.

Late in the 1700s, a small number of European scientists began to quietly suggest that life-forms are not fixed and unchanging. A French zoologist, Georges Buffon, actually proposed that populations of living things change through time. However, Buffon was careful to hide his views in a 44-volume series of books on natural history. Around the same time, a French naturalist named Jean-Baptiste Lamarck suggested an intimate relationship between variation and evolution. By examining fossils, he realized that some species had remained the same over the millennia and others had changed. Lamarck hypothesized that species change over the course of many generations by adapting to new environments. He believed that living things evolved in a continuously upward direction, from dead matter, through simple to more complex forms, toward "human perfection." According to Lamarck, organisms altered their behavior in response to environmental change. He thought that behavioral changes could modify traits and hypothesized that these modified traits were inherited by offspring. He called this idea the **inheritance of acquired characteristics**. For example, according to Lamarck's hypothesis, giraffes developed their elongated necks and front legs by feeding on the leaves at the top of trees. The exercise of stretching up to the leaves altered the neck and legs, and Lamarck presumed that these acquired characteristics were transmitted to offspring. However, further research has rejected Lamarck's idea that acquired traits can be inherited. Even so, Lamarck's work was important in promoting the idea of evolutionary change.

Interestingly, Erasmus Darwin, the grandfather of Charles Darwin, was a contemporary of Buffon and Lamarck and an early advocate of evolutionary change. He was a physician, a plant biologist, and also a poet (see poem at the beginning of the chapter). He was aware that modern species were different from similar types of fossilized organisms and also noted how plant and animal breeders used breeding practices to change the traits of domesticated species (see chapter opening photo). He knew that offspring inherited features from their parents and went so far as to say that life on Earth could have descended from a common ancestor.

Darwin Suggested That Existing Species Are Derived from Pre-existing Species

Charles Darwin played a central role in developing the theory that existing species have evolved from pre-existing ones. Darwin's unique perspective and his ability to formulate evolutionary theory were shaped by several different fields of study, including ideas of his time about geology and population growth, as well as his own biological observations.

Hypotheses about Geology Two main hypotheses about geological processes predominated in the early 19th century. Catastrophism was first proposed by French zoologist and paleontologist Georges Cuvier to explain the age of the Earth. Cuvier suggested that the Earth was just 6,000 years old and that only catastrophic events had changed its geological structure. This idea fit well with certain religious teachings. Alternatively, uniformitarianism, proposed by Scottish geologist James Hutton and popularized by another Scottish geologist, Charles Lyell, suggested that changes in the Earth are directly caused by recurring events. For example, they suggested that geological processes

such as erosion existed in the past and happened at the same gradual rate as they do now. For such slow geological processes to eventually lead to substantial changes in the Earth's characteristics, a great deal of time was required. Hutton and Lyell were the first to propose that the age of the Earth is well beyond 6,000 years. The ideas of Hutton and Lyell helped to shape Darwin's view of the world.

Population Growth Darwin's thinking was also influenced by a paper published in 1798 called *An Essay on the Principle of Population* by Thomas Malthus, an English economist. Malthus asserted that the population size of humans can, at best, increase linearly due to increased land usage and improvements in agriculture, whereas our reproductive potential is exponential (for example, doubling with each generation). He argued that famine, war, and disease, especially among the poor, keep population growth within existing resources. The relevant message from Malthus's work was that not all members of any population will survive and reproduce.

Voyage of the Beagle Darwin's ideas, however, were most influenced by his own experiences and observations. His work as a young man aboard the HMS *Beagle*, a survey ship, lasted from 1831 to 1836 and involved a careful examination of many different species (**Figure 23.1**). The main mission of the *Beagle* was to map the coastline of southern South America and take oceanographic measurements. As the ship's naturalist, Darwin's job was to record information about the weather, geological features, plants, animals, fossils, rocks, minerals, and indigenous people.

Though Darwin made many interesting observations on his journey, he was particularly struck by the distinctive traits of island species. For example, Darwin observed several species of finches found on the Galápagos Islands, a group of volcanic islands 600 miles from the coast of Ecuador. Though it is often assumed that Darwin's personal observations of these finches directly inspired his theory of evolution, this is not the case. Initially, Darwin thought the birds were various species of blackbirds, grosbeaks, and finches. Later, however, the bird specimens from the islands were given to the British ornithologist John Gould, who identified them as several new finch species. Gould's observations helped Darwin in the later formulation of his theory.

As seen in **Table 23.1**, the finches differed widely in the size and shape of their beaks and in their feeding habits. Darwin clearly saw the similarities among these species, yet he noted the differences that provided them with specialized feeding strategies. It is now known these finches all evolved from a single species similar to the dull-colored grassquit finch (*Tiaris obscura*), commonly found along the Pacific Coast of South America. Once they arrived on the Galápagos Islands, the finches' ability to obtain particular types of food in their new habitat depended, in part, on the relative sizes and shapes of their beaks, which, in turn, influenced their abilities to survive and reproduce.

With an understanding of geology and population growth, and his observations from his voyage on the *Beagle*, Darwin had formulated his theory of evolution by the mid-1840s. He had also catalogued and described all of the species he had collected on his *Beagle* voyage except for one type of barnacle. Some have speculated that Darwin may have felt that he should establish himself as an expert on one species before making generalizations about all of them. Therefore, he spent several additional years studying barnacles. During this time, the geologist Charles Lyell, who had greatly influenced Darwin's thinking, strongly encouraged Darwin to publish his theory

Table 23.1 A Comparison of Beak Type and Diet Among the Galápagos Finches That Darwin Studied

Type of finch/diet	Species		Type of beak
Ground finches			
Ground finches have beaks shaped to crush various sizes of seeds; large beaks can crush large seeds, whereas smaller beaks are better for crushing small seeds.	Large ground finch (*Geospiza magnirostris*)		Crushing
	Medium ground finch (*G. fortis*)		
	Small ground finch (*G. fuliginosa*)		
	Sharp-billed ground finch (*G. difficilis*)		
Vegetarian finch			
Vegetarian finches have crushing beaks to pull buds from branches.	Vegetarian finch (*Platyspiza crassirostris*)		Crushing
Tree finches			
Tree finches have grasping beaks to pick insects from trees. Those with heavier beaks can also break apart wood in search of insects.	Large tree finch (*Camarhynchus psittacula*)		Grasping
	Medium tree finch (*Camarhynchus pauper*)		
	Small tree finch (*Camarhynchus parvulus*)		
Tree and warbler finches			
These finches have probing beaks to search for insects in crevices and then pick them up. The woodpecker finch can also use a cactus spine for probing.	Mangrove finch (*Cactospiza heliobates*)		Probing
	Woodpecker finch (*Camarhynchus pallidus*)		
	Warbler finch (*Certhidea olivacea*)		
Cactus finches			
Cactus finches have probing beaks to open cactus fruits and take out seeds.	Large cactus finch (*G. conirostris*)		Probing
	Cactus finch (*G. scandens*)		

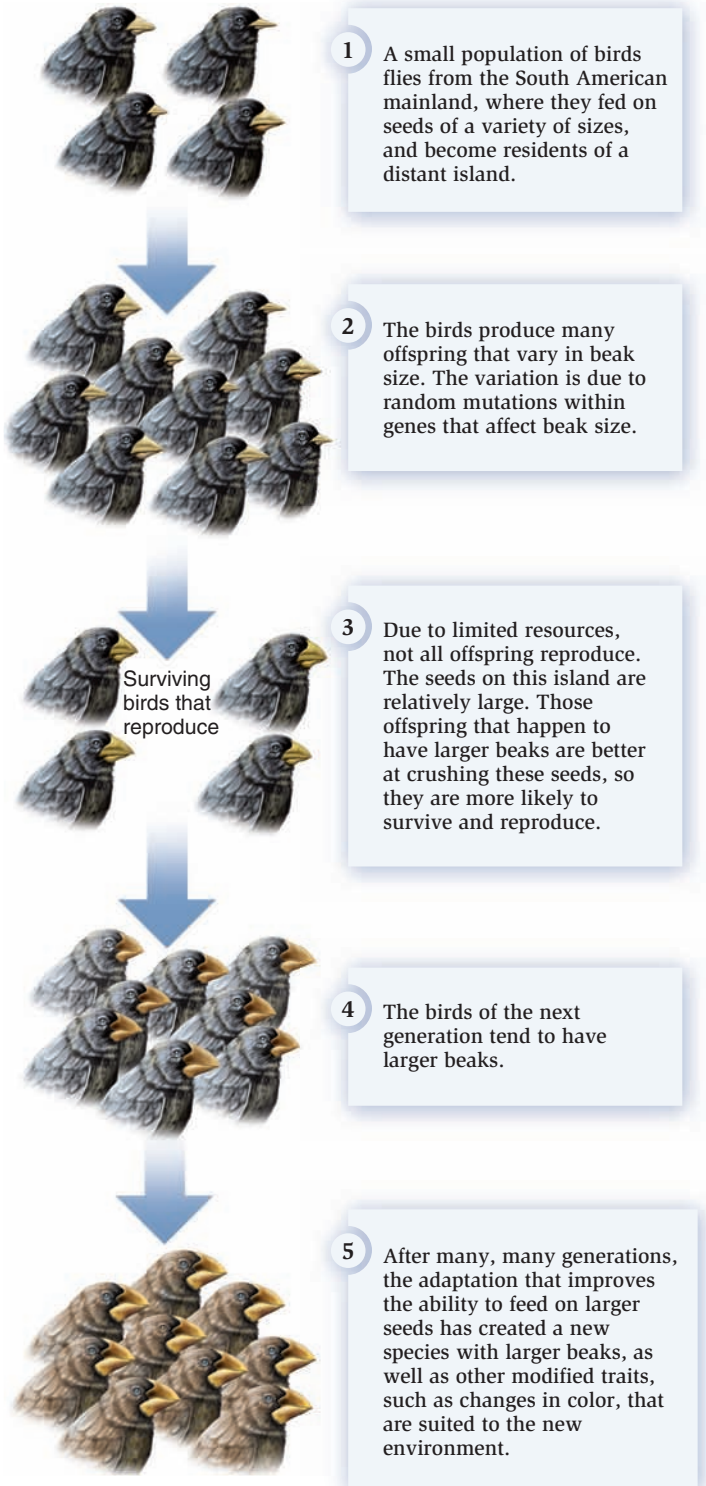

Figure 23.2 Evolutionary adaptation to a new environment via natural selection. The example shown here involves a species of finch adapting to a new environment on a distant island. According to Darwin's theory of evolution, the process of adaptation can lead to the formation of a new species with traits that are better suited to the new environment.

Concept Check: *The phrase "an organism evolves" is incorrect. Explain why.*

BioConnections: *Look back at Figure 22.5. How is natural selection similar to chemical selection? How are they different?*

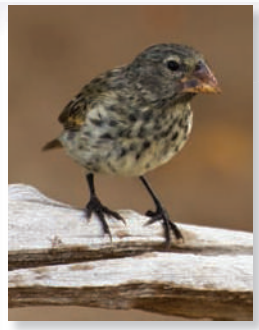
of evolution. In 1856, Darwin began to write a long book to explain his ideas. In 1858, however, Alfred Wallace, a British naturalist working in the East Indies, sent Darwin an unpublished manuscript to read prior to its publication. In it, Wallace proposed the same ideas concerning evolution. In response to this, Darwin decided to use some of his own writings on this subject, and two papers, one by Darwin and one by Wallace, were published in the *Proceedings of the Linnaean Society of London*. These papers were not widely recognized. A year later, however, Darwin finished his book *On the Origin of Species* (1859), which described his ideas in greater detail and included observational support. Although some of his ideas were incomplete because the genetic basis of traits was not understood at that time, Darwin's work remains a foundation of our understanding of biology.

Natural Selection Changes Populations from Generation to Generation

Darwin hypothesized that existing life-forms on our planet result from the modification of pre-existing life-forms. He expressed this concept of evolution as "the theory of descent with modification through variation and natural selection." The term evolution refers to change. What factors bring about evolutionary change? According to Darwin's ideas, evolution occurs from generation to generation due to two interacting factors, genetic variation and natural selection:

1. Variation in traits may occur among individuals of a given species. The heritable traits are then passed from parents to offspring. The genetic basis for variation within a species was not understood at the time Darwin proposed his theory of evolution. We now know that such variation is due to different types of genetic changes such as random mutations in genes. Even though Darwin did not fully appreciate the genetic basis of variation, he and many other people before him observed that offspring resemble their parents more than they do unrelated individuals. Therefore, he assumed that some traits are passed from parent to offspring.
2. In each generation, many more offspring are usually produced than will survive and reproduce. Often, resources in the environment are limiting for an organism's survival. During the process of **natural selection**, individuals with heritable traits that make them better suited to their native environment tend to flourish and reproduce, whereas other individuals are less likely to survive and reproduce. As a result of natural selection, certain traits that favor reproductive success become more prevalent in a population over time.

As an example, we can consider a population of finches that migrates from the South American mainland to a distant island (**Figure 23.2**). Variation exists in the beak sizes among the migrating birds. Let's suppose the seeds produced on the distant island are larger than those produced on the mainland. Those birds with larger beaks would be better able to feed on these larger seeds and therefore would be more likely to survive and pass that trait to their offspring. What are the consequences of this selection process? In succeeding generations, the population tends to have a greater proportion of finches with larger beaks. Alternatively, if a trait happens to be detrimental to an individual's ability to survive and reproduce, natural selection is likely to eliminate this type of variation. For example, if a finch in the same environment had a small beak, this bird would be less likely to acquire enough food, which would decrease its ability to survive and pass this trait to its offspring. Natural selection may ultimately result in a new species with a combination of multiple traits that are quite different from those of the original species, such as finches with larger beaks and changes in coloration. In other words, the newer species has evolved from a pre-existing one.



Feature Investigation | The Grants Observed Natural Selection in Galápagos Finches

Since 1973, British evolutionary biologists Peter Grant, Rosemary Grant, and their colleagues have studied natural selection in finches found on the Galápagos Islands. For over 40 years, the Grants have focused much of their work on one of the Galápagos Islands known as Daphne Major (**Figure 23.3a**). This small island (0.34 km^2) has a moderate degree of isolation (it is 8 km from the nearest island), an undisturbed habitat, and a resident population of *Geospiza fortis*, the medium ground finch (**Figure 23.3b**).

To study natural selection, the Grants observed various traits in finches over the course of many years. One trait they observed is beak size. The medium ground finch has a relatively small crushing beak, allowing it to more easily feed on small, tender seeds (see Table 23.1). The Grants quantified beak size among the medium ground finches of Daphne Major by carefully measuring beak depth—a measurement of the beak from top to bottom (**Figure 23.4**). The small size of the island made it possible for them to measure a large percentage of birds and their offspring. During the course of their studies, they compared the beak depths of parents and offspring by examining many broods over several

Figure 23.3 The Grants' investigation of natural selection in finches. (a) Daphne Major, one of the Galápagos Islands. **(b)** One of the medium ground finches (*Geospiza fortis*) that populate this island.

BIOLOGY PRINCIPLE Populations of organisms evolve from one generation to the next. This study was aimed at analyzing how beak size may change from one generation to the next.

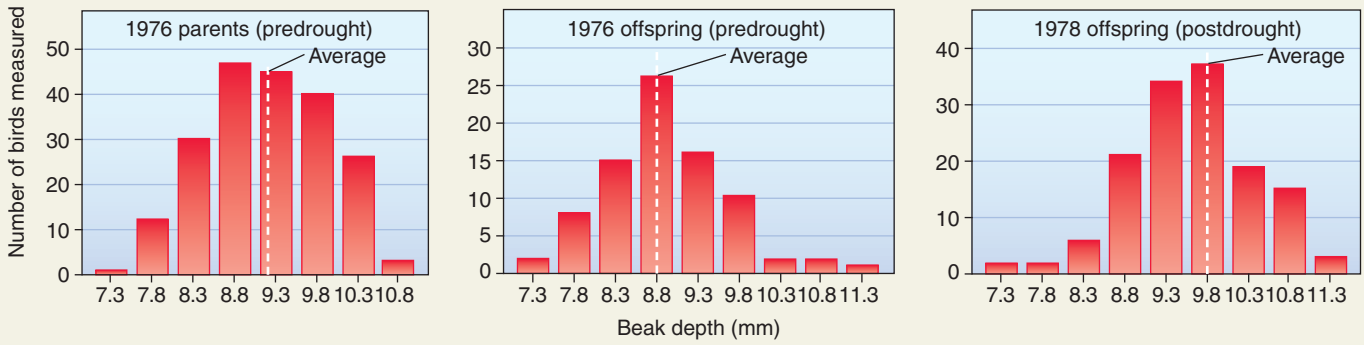

Figure 23.4 The Grants and natural selection of beak size in the medium ground finch.

HYPOTHESIS Dry conditions produce larger seeds and may result in more birds with larger beaks in succeeding generations of *Geospiza fortis* due to natural selection.

KEY MATERIALS A population of *G. fortis* on the Galápagos Island called Daphne Major.

	Experimental level		Conceptual level
1 In 1976, measure beak depth in parents and offspring of the species *G. fortis*.	Capture birds and measure beak depth.		This is a way to measure a trait that may be subject to natural selection.
2 Repeat the procedure on offspring that were born in 1978 and had reached mature size. A drought had occurred in 1977 that caused plants on the island to produce mostly large dry seeds and relatively few small seeds.	Capture birds and measure beak depth.		This is a way to measure a trait that may be subject to natural selection.

3 THE DATA

4 CONCLUSION Because a drought produced larger seeds, birds with larger beaks were more likely to survive and reproduce. The process of natural selection produced postdrought offspring that had larger beaks compared to predrought offspring.

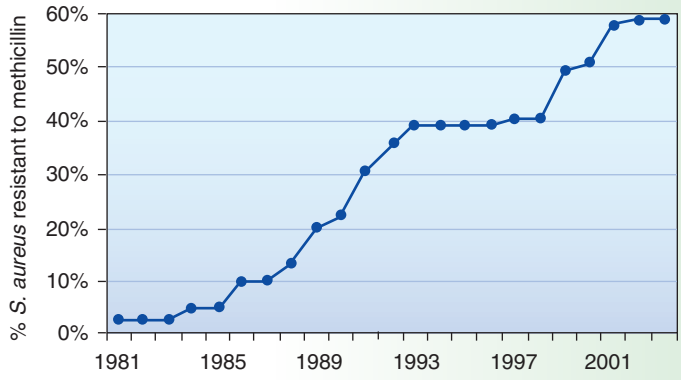
5 SOURCE Grant, B. R., and Grant, P. R. 2003. What Darwin's Finches Can Teach Us about the Evolutionary Origin and Regulation of Biodiversity. *Bioscience* 53:965–975.

years and found that the depth of the beak was transmitted from parents to offspring, regardless of environmental conditions, indicating that differences in beak depths are due to genetic differences in the population. In other words, they found that beak depth was a heritable trait.

By measuring many birds every year, the Grants were able to assemble a detailed portrait of natural selection in action. In the study shown in Figure 23.4, they measured beak depth from 1976 to 1978. In the wet year of 1976, the plants of Daphne Major produced an abundance of the small, tender seeds that these finches could easily eat. However, a severe drought occurred in 1977. During this year, the plants on Daphne Major tended to produce few of the smaller seeds, which the finches rapidly consumed. Therefore, the finches resorted to eating larger, drier seeds, which are harder to crush. As a result, birds with larger beaks were more likely to survive and reproduce because they were better at breaking open the large seeds. As shown in the data, the average beak depth of birds in the population increased substantially, from 8.8 mm in predrought offspring to 9.8 mm in postdrought offspring.

How do we explain these results? According to evolutionary theory, birds with larger beaks were more likely to survive and pass this trait to their offspring. Overall, these results illustrate the power of natural selection to alter the features of a trait—in this case, beak depth—in a given population from one generation to the next.

Experimental Questions



1. What features of Daphne Major made it a suitable field site for studying the effects of natural selection?
2. **SciSKILLS »** Why is beak depth in finches a good trait for a study of natural selection? What environmental conditions were important to allowing the Grants to collect information concerning natural selection?
3. **SciSKILLS »** Analyze the results of the Grants' study, and explain what they mean with regard to natural selection and evolution.

BIO TIPS

THE QUESTION *Antibiotics are medicines used to treat various types of bacterial infections. Examples include streptomycin, tetracycline, and amoxicillin. These drugs inhibit bacterial growth by interfering with processes such as the synthesis of the cell wall, bacterial translation, or vital metabolic pathways. When a strain of bacteria that was originally sensitive to an antibiotic is no longer sensitive, such a strain is said to be antibiotic resistant. Resistant to antibiotics can arise in two common ways:*

- *A new mutation in a bacterium may render the antibiotic ineffective. For example, suppose an antibiotic blocks bacterial growth by binding to a protein that is needed for cell wall synthesis and inhibiting its function. A mutation could occur in the bacterial gene that encodes this protein, altering the protein's structure in a way that prevents the antibiotic from binding.*
- *A bacterium may acquire a gene that confers antibiotic resistance via horizontal gene transfer, which is discussed later in this chapter. For example, a bacterium may acquire a gene that encodes an enzyme that breaks down the antibiotic, thereby rendering it ineffective.*

The bacterium Staphylococcus aureus causes skin infections commonly called staph infections. One antibiotic that has been used to treat staph infections is methicillin. However, resistance to this antibiotic has become a widespread problem. The graph below shows the percentage of S. aureus strains that have become resistant to methicillin over a 20-year period in the United States. As you may have heard, methicillin-resistant S. aureus strains are called MRSA (pronounced "mersa"). Explain these data. Is evolution occurring? If so, propose a hypothesis to explain why S. aureus populations are evolving with regard to antibiotic resistance.

TOPIC ***What topic in biology does this question address?*** The topic is antibiotic resistance. More specifically, the question asks you to analyze data regarding resistance to methicillin exhibited by *S. aureus*.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you have learned what antibiotics are and how antibiotic resistance can arise. You are also given data regarding methicillin resistance in *S. aureus* over a 20-year period. From your understanding of the topic, you may remember that evolution involves heritable changes in a population that are passed from one generation to the next. Natural selection can facilitate evolution.

PROBLEM-SOLVING STRATEGY ***Interpret data. Propose a hypothesis.*** To solve this problem, you can start by observing the trend in the data over time. As you can see in the graph, the level of methicillin resistance has dramatically increased over a 20-year period. The trait that is measured by these data is the ability of *S. aureus* to survive when exposed to methicillin. The population in 2001 has a much higher percentage of bacteria that survive and reproduce when exposed to methicillin compared to the population in 1981.

ANSWER *Evolution is occurring. The U.S. population of S. aureus has changed over a 20-year period such that more of these bacteria are resistant to methicillin compared to the original population. One hypothesis to explain these data is natural selection. In the original population in 1981, relatively few bacteria were resistant. However, a very small percentage of them may have been resistant due to a new mutation or horizontal gene transfer. The use of methicillin to treat staph infections may have selected for the survival of these MRSA strains. Therefore, over the course of many bacterial generations, MRSA strains have become more common.*

23.2 Evidence of Evolutionary Change

Learning Outcomes:

1. Summarize the different types of evidence for evolutionary change, including studies of natural selection, the fossil record, biogeography, convergent traits, selective breeding, and homologies.
2. Provide examples of three types of homologies.

Table 23.2 Evidence of Biological Evolution

Type of evidence	Description
Studies of natural selection	By following the characteristics of populations over time, researchers have observed how natural selection alters populations in response to environmental changes (see Figure 23.4).
Fossil record	When fossils are compared according to their age, from oldest to youngest, successive evolutionary change becomes apparent.
Biogeography	Unique species found on islands and other remote areas have arisen because the species in these locations have evolved in isolation from the rest of the world.
Convergent evolution	Two different species from different lineages sometimes become anatomically similar because they occupy similar environments. This indicates that natural selection results in adaptation to a given environment.
Selective breeding	The traits in domesticated species have been profoundly modified by selective breeding (also called artificial selection) in which breeders choose the parents that have desirable traits.
Homologies	
Anatomical	Homologous structures are structures that are anatomically similar to each other because they evolved from a structure in a common ancestor. In some cases, such structures have lost their original function and become vestigial.
Developmental	An analysis of embryonic development often reveals similar features that point to past evolutionary relationships.
Molecular	At the molecular level, certain characteristics are found in all living cells, suggesting that all living species are derived from an interrelated group of common ancestors. In addition, species that are closely related evolutionarily have DNA sequences that are more similar to each other than they are to the DNA sequences of distantly related organisms.

Evidence that supports the theory of evolution has been gleaned from many sources (**Table 23.2**). As we have already seen, the Grants were able to observe changes in a finch population as a result of a drought. Historically, the first evidence of biological evolution came from studies of the fossil record, the distribution of related species on our planet, selective breeding experiments, and the comparison of similar anatomical features in different species. More recently, additional evidence that illustrates the process of evolution has been found at the molecular level. By comparing DNA sequences from many different species, evolutionary biologists have gained great insight into the relationship between the evolution of species and the associated changes in the genetic material. In this section, we will survey the various types of evidence that show the process of evolutionary change.

Fossils Show Successive Evolutionary Change

As discussed in Chapter 22, the fossil record has provided biologists with evidence of the history of life on Earth. Today, scientists have access to a far more extensive fossil record than was available to Darwin and other scientists of his time. Even though the fossil record is still incomplete, the many fossils that have been discovered provide detailed information regarding evolutionary change in a series of related organisms. When fossils are compared according to their age, from oldest to youngest, successive evolutionary change becomes apparent. Let's consider a couple of examples in which paleontologists have observed evolutionary change.

Evolution of Terrestrial Tetrapods from Fish In 2005, fossils of *Tiktaalik roseae*, nicknamed fishapod, were discovered by paleontologists Ted Daeschler, Neil Shubin, and Farish Jenkins. The discovery of fishapod illuminates one of several steps that led to the evolution of tetrapods, which are animals with four legs. *T. roseae* is called a **transitional form** because it displays an intermediate state between an ancestral form and the form of its descendants (**Figure 23.5**). In this case, the fishapod is a transitional form between fishes, which have fins for locomotion, and tetrapods, which are four-limbed animals. Unlike a true fish, *T. roseae* had a broad skull, a flexible neck, and eyes mounted on the top of its head like a crocodile. Its interlocking rib cage suggests it had primitive lungs. Perhaps the most surprising discovery was that its pectoral fins

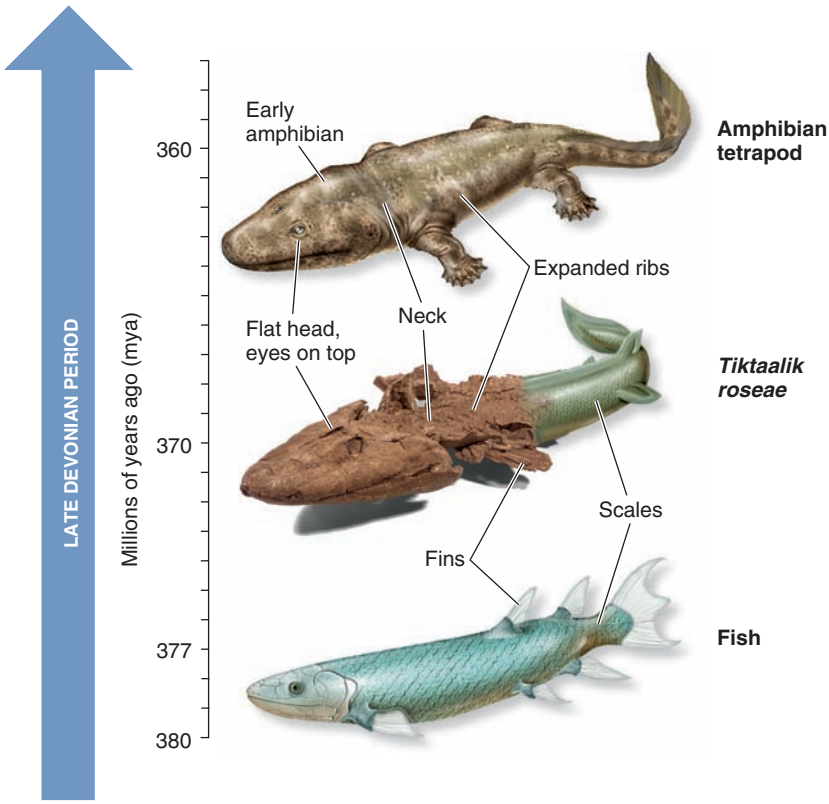


Figure 23.5 A transitional form in the tetrapod lineage. This figure shows two early tetrapod ancestors, a Devonian fish and the transitional form *Tiktaalik roseae*, as well as one of their descendants, an early amphibian. An analysis of the fossils shows that *T. roseae*, also known as a fishapod, had both fish and amphibian characteristics, so it was likely able to survive brief periods out of the water.

(those on the side of the body) revealed the beginnings of a primitive wrist and five finger-like bones. These appendages would have allowed *T. roseae* to support its body on shallow river bottoms and lift its head above the water to search for prey and perhaps even move out of the water for short periods. During the Devonian period (417–354 mya), this could have been an important advantage in the marshy floodplains of large rivers.

The early tetrapods gave rise to three main groups of modern tetrapods:

- Amphibians
- Birds and modern reptiles
- Mammals

Most tetrapods occupy a terrestrial environment. However, some, such as frogs and hippopotamuses, are semi-aquatic, spending a large amount of time in the water. Interestingly, tetrapod evolution has produced new species that are aquatic and no longer have hindlimbs. For example, whales evolved from terrestrial mammals, as described next.

Evolution of Whales from Terrestrial Mammals Cetacea is an order of aquatic animals that includes whales, dolphins, and porpoises. The closest living relatives of cetaceans are the hippos. **Figure 23.6** presents a hypothesis for the evolution of whales based on the fossil record.

- The genus *Pakicetus* comprised the earliest known whales. However, these animals did not bear a striking resemblance to modern whales. They were wolflike meat eaters that spent some of their time in fresh water and ate fish. Their skull had a long shape like that of modern whales. The eyes were positioned close together and high on the skull, which is characteristic of aquatic animals that peer out of the water. A particularly striking trait was a thick, bony wall around the middle ear, which is found in modern whales but not in other mammals.
- The genus *Ambulocetus* consisted of semi-aquatic whales of brackish (slightly salty) waters. They were roughly the size of a male sea lion and had short and powerful legs. The tail vertebrae were particularly large, suggesting that the tail was very muscular and possibly used for swimming. The eyes were more toward the sides but still high on the skull.
- The members of the genus *Remingtonocetus* were similar to those of *Ambulocetus* but with a longer snout and a fat pad in the jaw that aided in underwater hearing. They lived in saltwater habitats.
- In members of the genus *Rodhocetus*, the eyes were on the side of the head, and the nasal opening was beginning to shift away from the tip of the snout. The forelimbs had five fingers, and the hindlimbs had only four toes, suggesting the degeneration of the hindlimbs.
- The genus *Dorudon* was composed of whales that were completely aquatic animals. The nasal opening was shifted back toward the eyes to form a blowhole. The forelimbs became flippers, and the hindlimbs were very tiny. The tail was modified at the end to form a fluke.
- Odontoceti and Mysticeti are suborders of the order Cetacea, which includes many extinct species as well as all modern species of whales, dolphins, and porpoises. These animals show a complete loss of the hindlimbs in the adult. The nasal opening is the blowhole seen in modern whales. In odontocetes, echolocation is used for hunting. In mysticetes, baleen is used for filtering food.

Taken together, the changes observed in the fossil record of whales reveal a progression over the past 50 million years from a terrestrial tetrapod to aquatic animals that lack hindlimbs and have many adaptations that are beneficial in an aquatic environment.

Biogeography Indicates That Species in a Given Area Have Evolved from Pre-existing Species

Biogeography is the study of the geographic distribution of extinct and living species. Patterns of past evolution are often found in the natural geographic distribution of related species. From such studies, scientists have discovered that isolated continents and island groups have evolved their own distinct plant and animal communities.

Islands Islands, which are isolated from other large landmasses, provide numerous examples in which geography has played a key role in the evolution of new species. Islands often have many species of plants and animals that are **endemic**, which means they are naturally found only in a particular location. Most endemic island species have closely related relatives on nearby islands or the mainland.

As an example, let's consider the island fox (*Urocyon littoralis*), which lives on the Channel Islands located off the coast near Santa Barbara in southern California (**Figure 23.7**). This type of fox is found nowhere else in the world. It weighs about 3–6 pounds and feeds largely on insects, mice, and fruits. The island fox evolved from the mainland gray fox (*Urocyon cinereoargenteus*), which is much larger, usually 7–11 pounds. During the last Ice Age, about 16,000–18,000 years ago, the Santa Barbara channel was frozen and narrow enough for ancestors of the mainland gray fox to cross over to the Channel Islands. When the Ice Age ended, the ice melted and sea levels rose, causing the foxes to be cut off from the mainland. Over the last 16,000–18,000 years, the population of foxes on the Channel Islands evolved into the smaller island fox, which is now considered a different species from the larger gray fox. The gray fox is still found on the mainland.

The smaller size of the island fox is an example of island dwarfing, a phenomenon in which the size of large animals on an isolated island shrinks dramatically over many generations. It is the result of natural selection in which a smaller size provides a survival and reproductive advantage, probably because of the limited availability of food and other resources.

Isolated Continents The evolution of major animal groups is also correlated with known changes in the distribution of landmasses on the Earth. The first mammals arose approximately 200 mya, when the area that is now Australia was still connected to the other continents. However, the first placental mammals, which have a long internal gestation and give birth to well-developed offspring, evolved much later, after continental drift had separated Australia from the

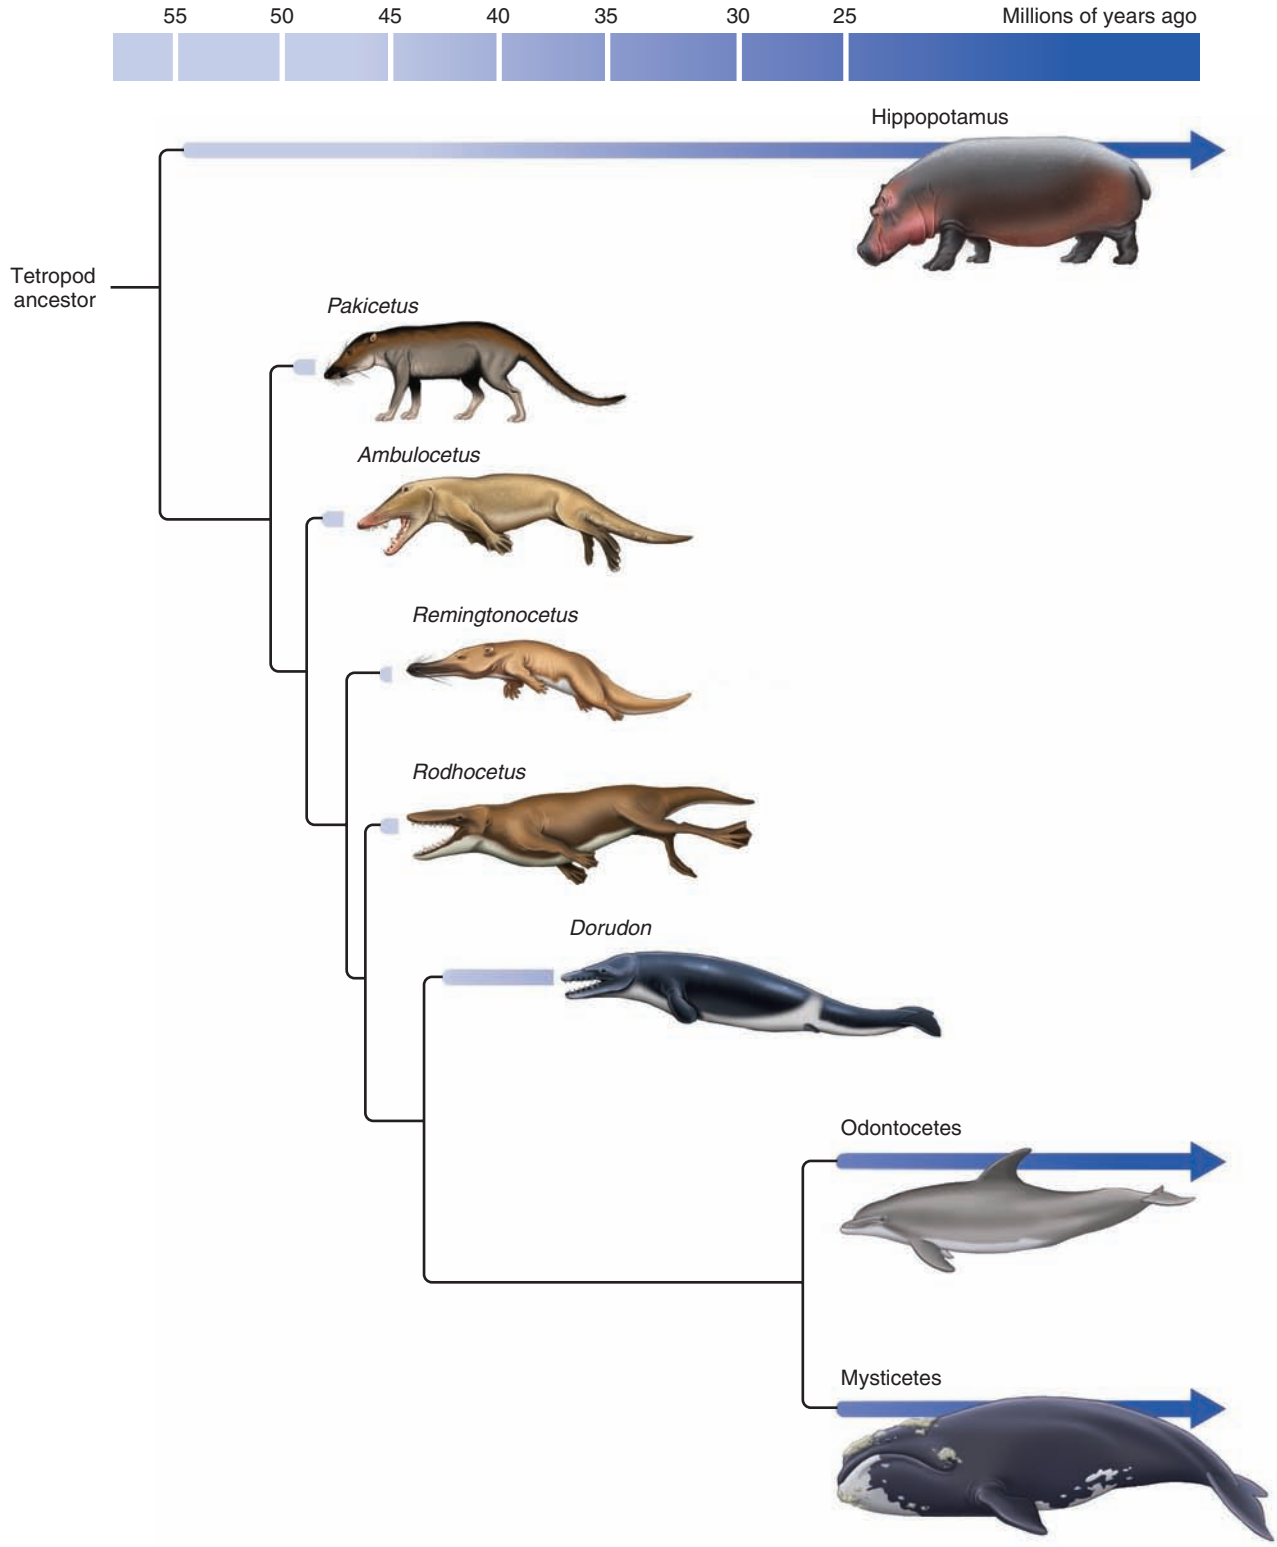

Figure 23.6 **Evolution of whales.** *Pakicetus*, *Ambulocetus*, *Remingtonocetus*, *Rodhocetus*, and *Dorudon* are extinct genera of whales. Odontocetes and Mysticetes are suborders of the order Cetacea, which includes all modern species of whales, dolphins, and porpoises. This simplified representation of whale evolution is a type of diagram called a phylogenetic tree, which is explained in Chapter 26. Note: The genera described in this phylogenetic tree are not depicted as direct ancestors to modern whales, but they all shared common ancestors.

BIOLOGY PRINCIPLE **All species (past and present) are related by an evolutionary history.** This diagram shows the morphological changes that occurred in the evolution of whales.

Figure 23.7 The evolution of an endemic island species from a mainland species. **(a)** The smaller island fox found on the Channel Islands evolved from **(b)** the gray fox found on the California mainland.

Concept Check: *Explain how geography played a key role in the evolution of the island fox.*

other continents (refer back to Figure 22.10). Except for a few species of bats and rodents that have migrated to Australia more recently, Australia lacks any of the larger, terrestrial placental mammals. How do biologists explain this observation? It is consistent with the idea that placental mammals first arose somewhere other than Australia, and that the barrier of a large ocean prevented most terrestrial placental mammals from migrating there.

On the other hand, Australia has more than 100 species of kangaroos, koalas, and other marsupials, most of which are not found on any other continent. Marsupials are a group of mammal species whose young are born in a very immature condition and then develop further in the mother's abdominal pouch, which covers the mammary glands. Evolutionary theory is consistent with the idea that the existence of these unique Australian species is due to their having evolved in isolation from the rest of the world for millions of years.

Convergent Evolution Suggests Adaptation to the Environment

The process of natural selection is also evident in the study of plants and animals that have similar characteristics, even though they are not closely related evolutionarily. This similarity is the result of **convergent evolution**, in which two species from different lineages have independently evolved similar characteristics because they occupy similar environments.

- Both the giant anteater (*Myrmecophaga tridactyla*), found in South America, and the echidna (*Tachyglossus aculeatus*), found in Australia, have a long snout and tongue. Both species independently evolved these adaptations that enable them to feed on ants (**Figure 23.8a**). The giant anteater is a placental mammal, whereas the echidna is an egg-laying mammal known as a monotreme, so they are not closely related evolutionarily.
- Another example of convergent evolution involves aerial rootlets found in vines such as English ivy (*Hedera helix*) and wintercreeper (*Euonymus fortunei*) (**Figure 23.8b**). Based on differences in their structures, these aerial rootlets appear to have developed independently as an effective means of clinging to the support on which a vine attaches itself.
- A third example of convergent evolution is revealed by the molecular analysis of fishes that live in very cold water. Antifreeze proteins enable certain species of fishes to survive the subfreezing temperatures of Arctic and Antarctic waters by inhibiting the formation of ice crystals in body fluids. Researchers have determined that these fishes are an interesting case of convergent evolution (**Figure 23.8c**). Among different species of fishes, one of five different genes has independently evolved to produce antifreeze proteins. For example, in the sea raven (*Hemitripterus americanus*), the antifreeze protein is rich in the amino acid cysteine, and the secondary structure of the protein is in a β pleated sheet conformation. In contrast, the antifreeze protein in the longhorn sculpin (*Trematomus nicolai*) is encoded by an entirely different gene. The antifreeze protein in this species is rich in the amino acid glutamine, and the secondary structure of the protein is largely composed of α helices.

The similar characteristics in the examples shown in Figure 23.8—for example, the snouts of the anteater and the echidna—are called **analogous structures**, or convergent traits. They represent cases in which characteristics have arisen independently, two or more times, because different species have occupied similar types of environments on the Earth.

Selective Breeding Is a Human-Driven Form of Selection

The term **selective breeding** refers to programs and procedures designed to modify traits in domesticated species. This practice, also called **artificial selection**, is related to natural selection. In forming his theory of evolution, Charles Darwin was influenced by his observations of selective breeding by pigeon breeders. The primary difference between natural and artificial selection is how the parents are chosen. Natural selection occurs because of genetic variation in

(a) The long snouts and tongues of the giant anteater (left) and the echidna (right) allow them to feed on ants.

(b) The aerial rootlets of English ivy (left) and wintercreeper (right) enable them to climb up supports.

(c) The sea raven (left) and the longhorn sculpin (right) have antifreeze proteins that enable them to survive in frigid waters.

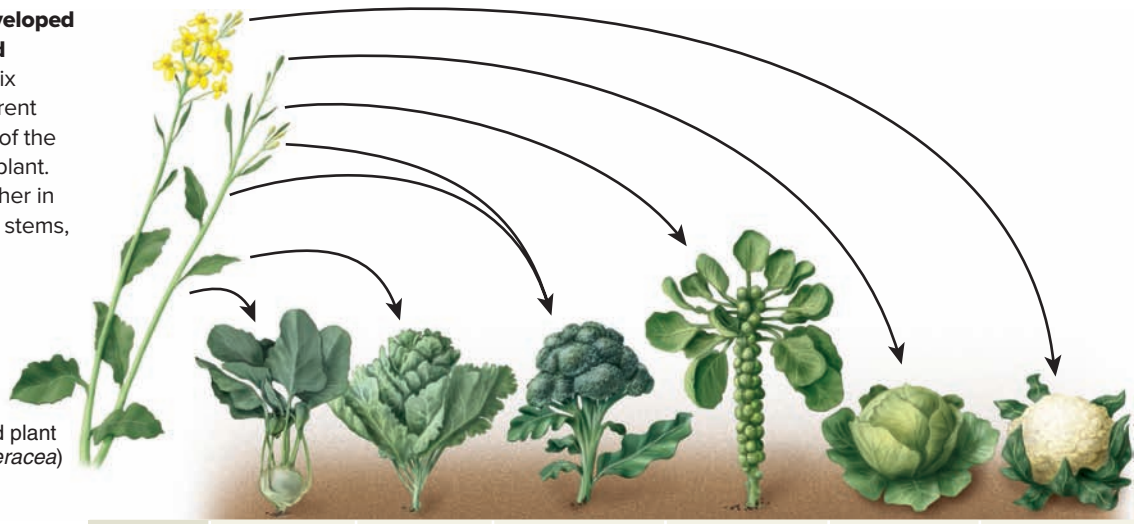
Figure 23.8 Examples of convergent evolution. All three pairs of species shown in this figure are not closely related evolutionarily but occupy similar environments, suggesting that natural selection results in similar adaptations to a particular environment.

Concept Check: *Can you think of another example in which two species that are not closely related have a similar adaptation?*

reproductive success. Organisms that are able to survive and reproduce are more likely to pass their genes to future generations. Environmental factors often determine which individuals will be successful parents. In artificial selection, the breeder chooses as parents those individuals with traits that are desirable from a human perspective.

The underlying phenomenon that makes selective breeding possible is genetic variation. Within a population, variation may exist in a trait of interest. For selective breeding to be successful, the underlying cause of the phenotypic variation is usually related to differences in **alleles**, variant forms of a particular gene, that determine the trait. The breeder chooses parents with desirable phenotypic characteristics. For centuries, humans have employed selective breeding to obtain domesticated species with interesting or agriculturally useful characteristics.

Artificial Selection in Dogs The various breeds of dog are the result of selective breeding strategies (**Figure 23.9**). All dogs are members of the same species, *Canis lupus*, subspecies *familiaris*, so they can interbreed to produce offspring. Selective breeding can dramatically modify the traits in a species. When you compare certain



(a) Bulldog (b) Greyhound (c) Dachshund

Figure 23.9 Common breeds of dogs that have been obtained by selective breeding. By selecting individuals carrying the alleles that influence traits desirable to humans, dog breeders have produced breeds with distinctive features. All the dogs in this figure carry the same kinds of genes (for example, genes that affect their size, shape, and fur color). However, the alleles for many of these genes are different among these dogs, thereby allowing dog breeders to select for or against them and produce breeds with strikingly different phenotypes.

breeds of dogs (for example, a greyhound and a dachshund), they hardly look like members of the same species! Recent work in 2007 by American geneticist Nathan Sutter and colleagues indicates that the size of dogs may be determined by alleles in the *Igf1* gene that encodes a growth hormone called insulin-like growth factor 1. A particular allele of this gene was found to be common to all small breeds of dogs and nearly absent from very large breeds, suggesting that this allele is a major contributor to body size in small breeds of dogs.

Artificial Selection in Agricultural Species Likewise, most of the food we eat—including products such as grains, fruits, vegetables, meat, milk, and juices—is obtained from species that have been profoundly modified by selective breeding strategies. For example, certain characteristics in the wild mustard plant (*Brassica oleracea*) have been modified by selective breeding to produce several varieties of domesticated crops, including broccoli, Brussels sprouts, cabbage, and cauliflower (**Figure 23.10**). The wild mustard plant is native to Europe and Asia, and plant breeders began to modify its traits approximately 4,000 years ago. As seen here, certain traits in the domestic strains differ dramatically from those of the original wild species. These varieties are all members of the same species. They can interbreed to produce viable offspring. For example, in the grocery store you may have seen broccoflower, a vegetable produced from a cross between broccoli and cauliflower.

Figure 23.10 Crop plants developed by selective breeding of the wild mustard plant. Although these six agricultural plants look quite different from each other, they carry many of the same alleles as the wild mustard plant. However, they differ from each other in alleles that affect the formation of stems, leaves, and flowers.

Strain	Kohlrabi	Kale	Broccoli	Brussels sprouts	Cabbage	Cauliflower
Modified trait	Stem	Leaves	Flower buds and stem	Lateral leaf buds	Terminal leaf bud	Flower buds

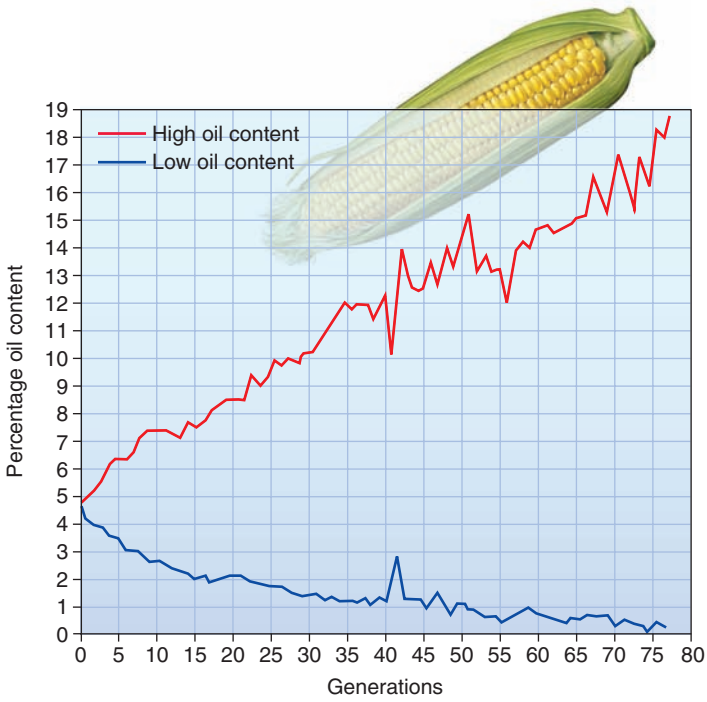


Figure 23.11 Results of selective breeding for oil content in corn plants. In this example, corn plants were selected for breeding based on high or low oil content of the kernels. Over the course of many generations, this had a major influence on the amount of corn oil (an agriculturally important product) made by the two groups of plants.

BIOLOGY PRINCIPLE Populations of organisms evolve from one generation to the next. This study illustrates how a trait in corn, namely oil content, may change over time due to human intervention.

Concept Check: When comparing Figures 23.9, 23.10, and 23.11, what general effects of artificial selection do you observe?

As another example, Figure 23.11 shows the results of a selective breeding experiment on corn begun at the University of Illinois Agricultural Experiment Station in 1896, several years before the rediscovery of Mendel's laws. This study began with 163 ears of corn with an oil content ranging from 4% to 6%. In each of 80 succeeding generations, corn plants were divided into two separate groups. In one group, members with the highest oil content in the kernels were chosen as parents of the next generation. In the other group, members with the lowest oil content were chosen. After many generations, the oil content in the first group rose to over 18%. In the other group, it dropped to less than 1%. These results show that selective breeding can modify a trait in a very directed manner.

A Comparison of Homologies Shows Evolution of Related Species from a Common Ancestor

Let's now consider other widespread observations of the process of evolution among living organisms. In biology, the term **homology** refers to a similarity that occurs due to descent from a common ancestor. Two species may have a similar trait because the trait was originally found in a common ancestor. As described next, such homologies may involve anatomical, developmental, or molecular features.

Anatomical Homologies As noted by Theodosius Dobzhansky, many observations regarding the features of living organisms simply cannot be understood in any meaningful scientific way except as a result of evolution. A comparison of vertebrate anatomy is a case in point. An examination of the limbs of modern vertebrate species reveals similarities that indicate the same set of bones has undergone evolutionary changes, becoming modified to perform different functions in different species. As seen in Figure 23.12, the forelimbs of vertebrates have a strikingly similar pattern of bone arrangements. These are termed **homologous structures**—structures that are similar to each other because they are derived from a common ancestor. The forearm has developed different functions among various vertebrates, including grasping, walking, flying, swimming, and climbing. The theory of evolution explains how these animals have descended from a common ancestor and how natural selection has resulted in modifications to the structure of the original set of bones in ways that ultimately allowed them to be used for several different functions.

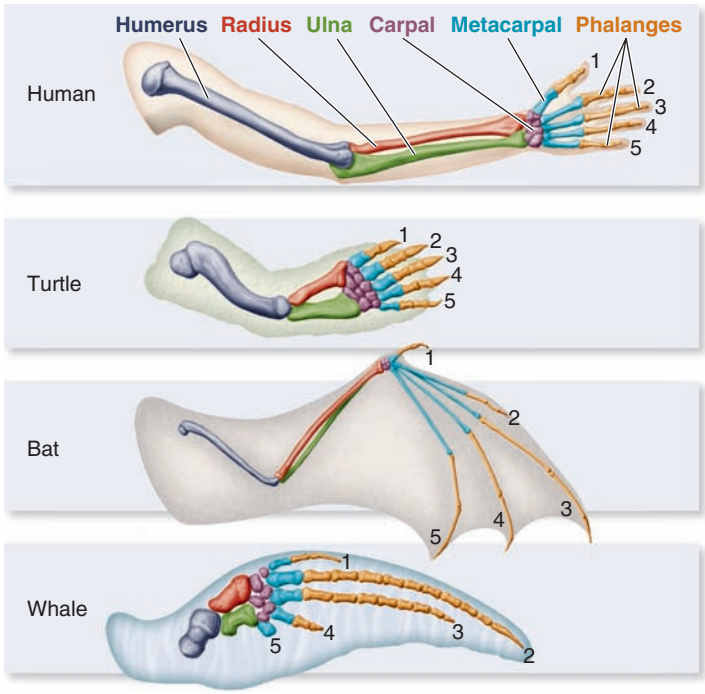

Figure 23.12 An example of anatomical homology: Homologous structures are found in vertebrates. The same set of bones is found in the human arm, turtle arm, bat wing, and whale flipper, although their relative sizes and shapes differ significantly. This homology suggests that all of these animals evolved from a common ancestor.

BIOLOGY PRINCIPLE Structure determines function. These homologous sets of bones have evolved into somewhat different structures due to differences in their functions in humans, turtles, bats, and whales.

Table 23.3 Examples of Vestigial Structures in Animals

Organism	Vestigial structure(s)
Humans	Bony tail in embryo and muscles to wiggle ears in adult
Boa constrictors	Skeletal remnants of hip and hind leg bones
Whales	Skeletal remnants of a pelvis
Manatees	Fingernails on the flippers
Hornbills and cuckoos	Fibrous cords that were derived from the common carotid arteries. In certain families of birds, both of the common carotid arteries are nonfunctional, fibrous cords. Their vascular function has been assumed by other vessels.

Another result of evolution is the phenomenon of **vestigial structures**, anatomical features that have no current function but resemble structures of their presumed ancestors (**Table 23.3**). An interesting case is found in humans. People have a complete set of muscles for moving their ears, even though most people are unable to do so. By comparison, many modern mammals can move their ears, and presumably this was an important trait in a distant human ancestor.

Why would organisms have structures that are no longer useful? Within the context of evolutionary theory, vestigial structures are evolutionary relics. Organisms having vestigial structures share a common ancestry with organisms in which the structure is functional. Natural selection maintains functional structures in a population of individuals. However, if a species changes its lifestyle so the structure loses its purpose, the selection that would normally keep the structure in a functional condition is no longer present. When this occurs, the structure may degenerate over the course of many generations due to the accumulation of mutations that limit its size and shape. Natural selection may eventually eliminate such traits due to the inefficiency and cost of producing unused structures.

Developmental Homologies Another example of homology is the way that animals undergo embryonic development. Species that differ substantially at the adult stage often bear striking similarities during early stages of embryonic development. These temporary similarities are called developmental homologies. In addition, evolutionary history is revealed during development in certain organisms, such as vertebrates. For example, if we consider human development, several features are seen in the embryo that are not present at birth. Human embryos have rudimentary gill ridges like a fish embryo, even though human embryos receive oxygen via the umbilical cord. The presence of gill ridges indicates that humans evolved from an aquatic species that had gill slits. A second observation is that every human embryo has a bony tail. It is difficult to see the advantage of such a structure in utero, but easier to understand its presence assuming that an ancestor of the human lineage possessed a tail. These observations, and many others, illustrate that closely related species share similar developmental pathways.

Molecular Homologies Our last examples of homology due to evolution involve molecular studies. Similarities between organisms at the molecular level due to descent from a common ancestor are called **molecular homologies**. For example, all living species use DNA to store information and rely on the genetic code to translate mRNA into proteins. Furthermore, certain biochemical pathways are found in all or nearly all species, although minor changes in the structure and function of proteins involved in these pathways have occurred. For example, all species that use oxygen, which constitutes the great majority of species on our planet, have similar proteins that together make up an electron transport chain and an ATP synthase (refer back to Figure 7.8). In addition, nearly all living organisms can break down glucose via a metabolic pathway that is described in Chapter 7. How do we explain these types of observations? Taken together, they indicate that such molecular phenomena arose very early in the origin of life and have been passed to all or nearly all modern forms.

Compelling molecular-level evidence indicating that modern life-forms are derived from an interrelated group of common ancestors is revealed by analyzing genetic sequences. The same type of gene is often found in diverse organisms. Furthermore, the degree of similarity between genetic sequences from different species reflects the evolutionary relatedness of those species. As an example, let's consider the *p53* gene, which encodes the p53 protein—a checkpoint protein of the cell cycle (see Chapter 14, Figure 14.15). **Figure 23.13** shows a short amino acid sequence that makes up part of the p53 protein from a variety of species, including five mammals, one bird, and three fish. The top sequence is the human p53 sequence, and the right column gives the percentage of amino acids within each animal's entire sequence that are identical to those in the entire human sequence. Amino acids in the other species that are identical to those in humans are highlighted in orange. The sequences from the two monkeys are the most similar to those in humans, followed by the other two mammalian species (rabbit and dog). The three fish sequences are the least similar to the human sequence, but the fish sequences tend to be similar to each other.

Taken together, the data shown in Figure 23.13 illustrate two critical points about gene evolution. First, specific genes are found in a diverse array of species such as mammals, birds, and fishes. Second, the sequences of closely related species tend to be more similar to each other than they are to the sequences of distantly related species. The mechanisms underlying this second observation are discussed in the next section.

23.3 The Molecular Processes That Underlie Evolution

Learning Outcomes:

1. Explain how paralogs and orthologs are produced.
2. Distinguish between vertical evolution and horizontal gene transfer.

Historically, the study of evolution was based on a comparison of the anatomies of extinct and modern species to identify similarities between related species. However, the advent of molecular approaches for analyzing DNA sequences has revolutionized the field

	Short amino acid sequence within the p53 protein	Percentages of amino acids in the whole p53 protein that are identical to human p53
Human (*Homo sapiens*)	Val Pro Ser Gln Lys Thr Tyr Gln Gly Ser Tyr Gly Phe Arg Leu Gly Phe Leu His Ser Gly Thr	100
Rhesus monkey (*Macaca mulatta*)	Val Pro Ser Gln Lys Thr Tyr His Gly Ser Tyr Gly Phe Arg Leu Gly Phe Leu His Ser Gly Thr	95
Green monkey (*Cercopithecus aethiops*)	Val Pro Ser Gln Lys Thr Tyr His Gly Ser Tyr Gly Phe Arg Leu Gly Phe Leu His Ser Gly Thr	95
Rabbit (*Oryctolagus cuniculus*)	Val Pro Ser Gln Lys Thr Tyr His Gly Asn Tyr Gly Phe Arg Leu Gly Phe Leu His Ser Gly Thr	86
Dog (*Canis lupus familiaris*)	Val Pro Ser Pro Lys Thr Tyr Pro Gly Thr Tyr Gly Phe Arg Leu Gly Phe Leu His Ser Gly Thr	80
Chicken (*Gallus gallus*)	Val Pro Ser Thr Glu Asp Tyr Gly Gly Asp Phe Asp Phe Arg Val Gly Phe Val Glu Ala Gly Thr	53
Channel catfish (*Ictalurus punctatus*)	Val Pro Val Thr Ser Asp Tyr Pro Gly Leu Leu Asn Phe Thr Leu His Phe Gln Glu Ser Ser Gly	48
European flounder (*Platichthys flesus*)	Val Pro Val Val Thr Asp Tyr Pro Gly Glu Tyr Gly Phe Gln Leu Arg Phe Gln Lys Ser Gly Thr	46
Congo puffer fish (*Tetraodon miurus*)	Val Pro Val Thr Thr Asp Tyr Pro Gly Glu Tyr Gly Phe Lys Leu Arg Phe Gln Lys Ser Gly Thr	41

Figure 23.13 An example of genetic homology: a comparison of a short amino acid sequence within the p53 protein from nine different animals. This figure compares a short region of the p53 protein, a tumor suppressor that plays a role in preventing cancer. Amino acids are represented by three-letter abbreviations. The orange-colored amino acids in the sequences are identical to those in the human sequence. The numbers in the right column indicate the percentage of amino acids within the whole p53 protein that is identical with the human p53 protein, which is 393 amino acids in length. For example, 95% of the amino acids, or 373 of 393, are identical between the p53 sequence found in humans and in rhesus monkeys.

Concept Check: *In the sequence shown in this figure, how many amino acid differences occur between the following pairs: rhesus and green monkeys, Congo puffer fish and European flounder, and rhesus monkey and Congo puffer fish? What do these differences tell you about the evolutionary relationships among these four species?*

BioConnections: *Look back at Table 21.5. How are genetic sequences that are retrieved from a database using the BLAST program correlated with the evolutionary relatedness of the species?*

of evolutionary biology. Now researchers can analyze how changes in the genetic material are associated with changes in phenotype. In this section, we will examine some of the molecular changes in the genetic material that reveal evolutionary change.

Homologous Genes Are Derived from a Common Ancestral Gene

Two or more genes derived from the same ancestral gene are called **homologous genes**. The analysis of homologous genes reveals evidence of evolutionary change at the molecular level. How do homologous genes arise? As an example, let's consider a gene in two different species of bacteria that encodes a transport protein involved in the uptake of metal ions into bacterial cells (**Figure 23.14**). Homologous genes that are in different species are termed **orthologs**. Millions of years ago, the two species of bacteria had a common ancestor. Over time, the common ancestor diverged into additional species, eventually evolving into *Escherichia coli*, *Clostridium acetylbutylicum*, and many other species. Since this divergence, the metal transporter gene has accumulated mutations that altered its sequence, though the similarity between the *E. coli* and the *C. acetylbutylicum* genes remains striking. In this case, the two sequences are similar because they were derived from the same ancestral gene, but they are not identical due to the independent accumulation of different random mutations.

Genomes & Proteomes Connection

Gene Duplications Produce Gene Families

Evidence of evolutionary change is also found within a single species. Two or more homologous genes within a single species are termed **paralogs** of each other. Rare gene duplication events produce multiple copies of a gene and ultimately lead to the formation of a **gene family**—a set of paralogs within the genome of a single species. A well-studied example of a gene family is the globin gene family in humans, which is composed of 14 genes that are hypothesized to be derived from a single ancestral globin gene (refer back to Figure 21.8). According to an evolutionary analysis, the ancestral globin gene first duplicated between 500 and 600 mya. Since that time, additional duplication events and chromosomal rearrangements have produced the current number of 14 genes on three different human chromosomes.

What is the advantage of a gene family? Even though all of the globin polypeptides are subunits of proteins that play a role in oxygen binding, the accumulation of changes in the various family members has produced globins that differ in the timing of their expression and in their functional properties. The various globin genes are expressed at different stages of development in humans. The functional differences of the globin proteins correlate with

the oxygen transport needs of humans during the embryonic, fetal, and postpartum stages of life (refer back to Figure 13.3).

What is the evolutionary significance of the globin gene family regarding adaptation? On land, egg cells and small embryos are very susceptible to drying out if they are not protected in some way. Species such as birds and reptiles lay eggs with a protective shell around them. Most mammals, however, have become adapted to a terrestrial environment by evolving internal gestation. The ability to develop young internally has been an important factor in the survival and proliferation of humans and other mammals. The embryonic and fetal forms of hemoglobin allow the embryo and fetus to capture oxygen from the bloodstream of the mother.

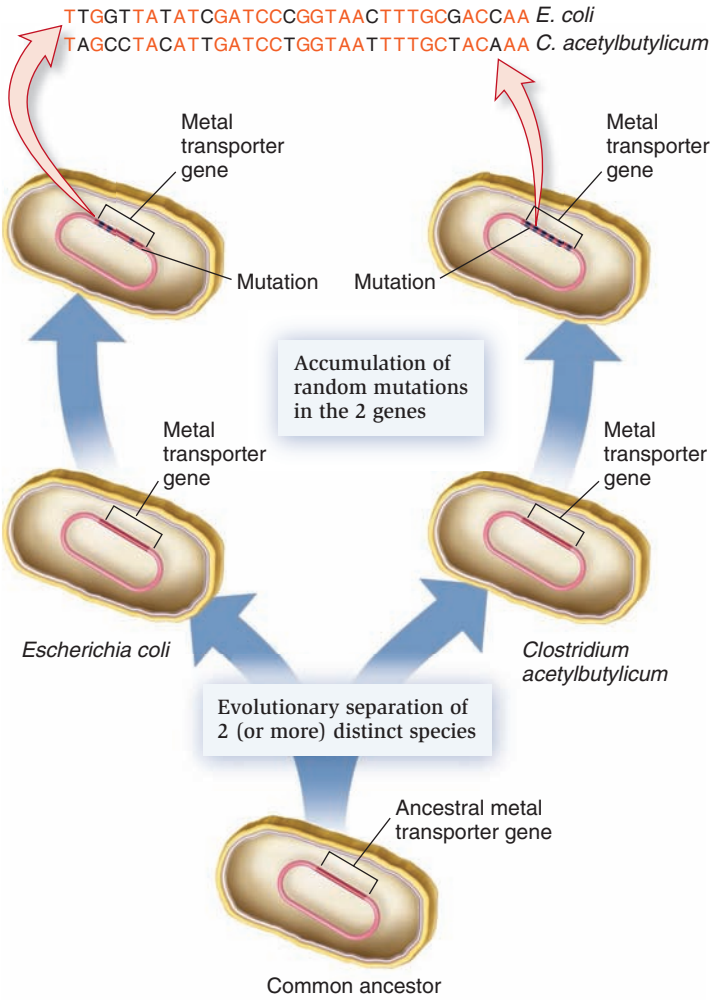

Figure 23.14 The evolution of orthologs, homologous genes from different species. After the two species diverged from each other, the genes accumulated random mutations that resulted in similar, but not identical, gene sequences called orthologs. These orthologs in *E. coli* and *C. acetylbutylicum* encode metal transporters. Only one of the two DNA strands is shown from each gene. Bases that are identical between the two genes are shown in orange.

Concept Check: *Why do these orthologs have similar gene sequences? Why aren't they identical?*

Horizontal Gene Transfer Contributes to the Evolution of Species

At the molecular level, the type of evolutionary change depicted in Figures 23.13 and 23.14 is called **vertical evolution**. In these cases, new species arise from pre-existing species by the accumulation of genetic changes, such as gene mutations and gene duplications. Vertical evolution involves genetic changes in a series of ancestors that form a lineage. In addition to vertical evolution, species accumulate genetic changes by **horizontal gene transfer**—a process in which an organism incorporates genetic material from another organism without being the offspring of that organism. Horizontal gene transfer can involve the exchange of genetic material between members of the same species or different species.

How does horizontal gene transfer occur? **Figure 23.15** illustrates one possible mechanism for horizontal gene transfer. In this example, a paramecium, which is a eukaryotic organism, has engulfed a bacterial cell. During the degradation of the bacterium in a phagocytic vesicle, a bacterial gene escapes to the nucleus of the cell, where it is inserted into one of the chromosomes. In this way, a gene has been transferred from a bacterial species to a eukaryotic species. By analyzing gene sequences among many different species, researchers have discovered that horizontal gene transfer is a common phenomenon. This process can occur from bacteria and archaea to eukaryotes,

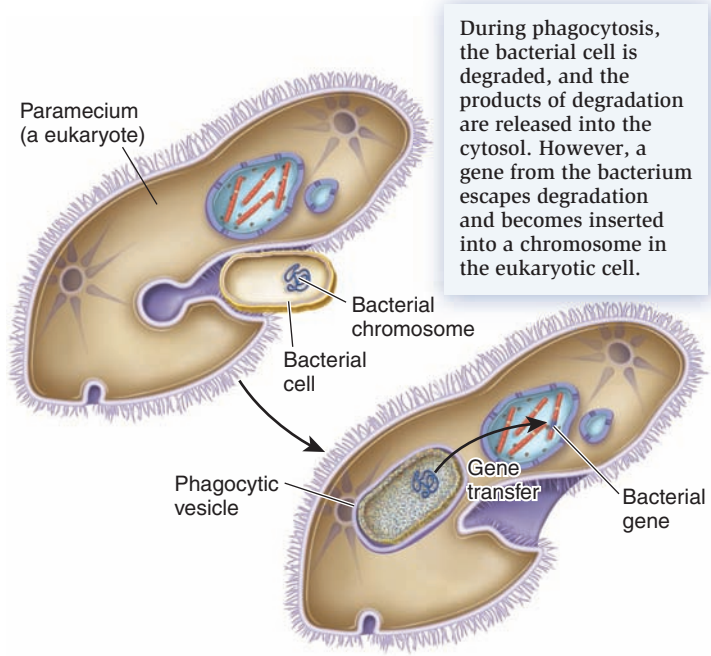

Figure 23.15 Horizontal gene transfer from a bacterium to a eukaryote. In this example, a bacterium is engulfed by a paramecium (a ciliated protist), and a bacterial gene is transferred to one of the paramecium's chromosomes.

BioConnections: *Look back at Table 18.3. What are three mechanisms of gene transfer that could result in horizontal gene transfer between two different bacterial species?*

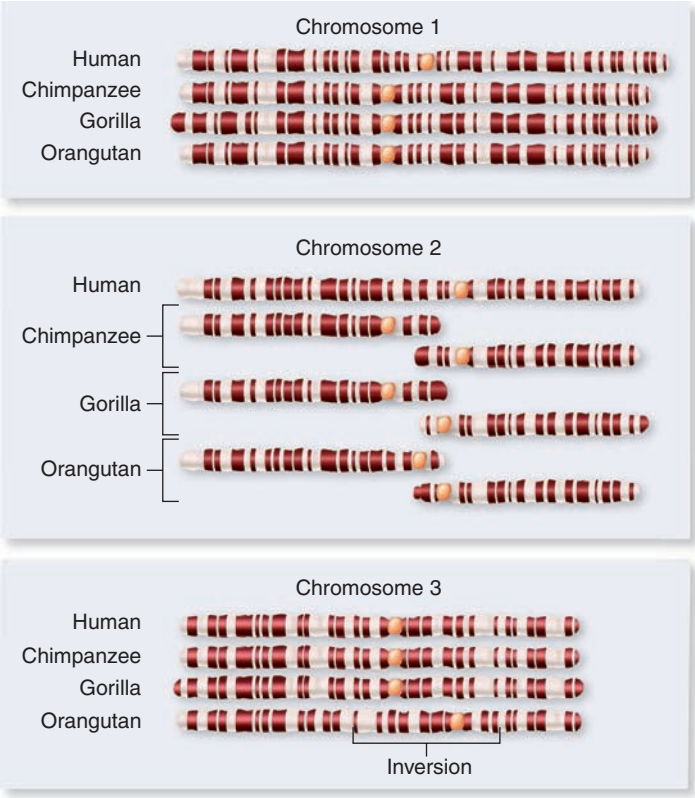

Figure 23.16 Evolutionary changes in chromosome structure and number found in primates. This figure compares the three largest human chromosomes and the corresponding chromosomes in the chimpanzee, gorilla, and orangutan. It is a schematic drawing of Giemsa-stained chromosomes. The differences between these chromosomes illustrate the changes that have occurred during the evolution of these related primate species.

Concept Check: Describe two changes in chromosome structure that have occurred among these chromosomes.

from eukaryotes to bacteria and archaea, between different species of bacteria and archaea, and between different species of eukaryotes. Therefore, when we view evolution, it is not simply a matter of one species evolving into one or more new species via the accumulation of random mutations. It also involves the horizontal transfer of genes among different species, enabling those species to acquire new traits that foster the evolutionary process.

Horizontal gene transfer among bacterial species is relatively widespread. As discussed in Chapter 18, bacterial species may carry out three natural mechanisms of gene transfer known as conjugation, transformation, and transduction. By analyzing the genomes of bacterial species, scientists have determined that many genes within a given bacterial genome are derived from horizontal gene transfer. Genome studies have suggested that as much as 20–30% of the variation in the genetic composition of modern bacterial species can be attributed to this process. The roles of the genes acquired by horizontal gene transfer are quite varied, though they commonly involve functions that are beneficial for survival and reproduction. These include genes that confer antibiotic resistance, the ability to degrade toxic compounds, and pathogenicity (the ability to cause disease).

Evolution at the Genome Level Involves Changes in Chromosome Structure and Number

Thus far, we have considered several ways a species might acquire new genetic variation. These include mutations within pre-existing genes, gene duplications that produce gene families, and horizontal gene transfer. Evolution also involves changes in chromosome structure and number. Comparisons of chromosomes of closely related species have revealed that changes in chromosome structure and/or number are common.

As an example, **Figure 23.16** compares the banding patterns of the three largest chromosomes in humans and the corresponding chromosomes in chimpanzees, gorillas, and orangutans. (Refer back to Figure 15.1 for an example of chromosome banding.) The banding patterns in the chromosomes are strikingly similar because these species are closely related evolutionarily. Chromosome 1 looks very similar in all species. Even so, you can see that some of the other chromosomes show interesting differences. Humans have one large chromosome 2, but this chromosome is divided into two separate chromosomes in the other three species. This explains why human cells have 23 pairs of chromosomes, whereas cells of chimpanzees, gorillas, and orangutans have 24. The fusion of the two smaller chromosomes during the development of the human lineage may have caused this difference in chromosome number. Another interesting change in chromosome structure is seen in chromosome 3. The banding patterns among humans, chimpanzees, and gorillas are very similar, but the orangutan has a large inversion that flips the order of the bands in the centromeric region. As discussed in Chapter 25, changes in chromosome structure and number may affect the ability of two organisms to breed with one another. In this way, such changes have been important in the establishment of new species.

Summary of Key Concepts

23.1 Overview of Evolution

- Evolution is a heritable change in one or more characteristics of a population from one generation to the next.
- Charles Darwin proposed the theory of evolution based on his understanding of geology and population growth and his observations of species in their natural settings. His voyage on the *Beagle*, during which he studied many species, including finches on the Galápagos Islands, was particularly influential in the development of his ideas (Figure 23.1, Table 23.1).
- Darwin expressed his theory of evolution as descent with modification through variation and natural selection. As a result of natural selection, genetic variation changes from generation to generation to produce populations of organisms with traits (adaptations) that favor greater reproductive success (Figure 23.2).
- The Grants' research on finches showed how differences in beak size (a heritable trait) were driven by natural selection (Figures 23.3, 23.4).

23.2 Evidence of Evolutionary Change

- Evidence of evolutionary change is found in studies of natural selection, the fossil record, biogeography, convergent evolution, selective breeding, and homologies (Table 23.2).
- Fossils provide evidence of evolutionary change in a series of related organisms. The fossil record often reveals transitional forms that link past ancestors to modern species (Figures 23.5, 23.6).
- Biogeography provides information on the geographic distribution of related species. When populations become isolated on islands or continents, they often evolve into new species (Figure 23.7).
- In convergent evolution, independent adaptations result in similar characteristics, called analogous structures, because different species occupy similar environments (Figure 23.8).
- Selective breeding, the selecting and breeding of organisms having desired traits, is a human-driven form of selection (Figures 23.9, 23.10, 23.11).
- Homologies are similarities that occur due to descent from a common ancestor. The set of bones in the forearms of vertebrates is an example of an anatomical homology. Homologies can also be seen during embryonic development and at the molecular level (Figures 23.12, 23.13).
- Vestigial structures, structures that were functional in an ancestor but no longer have a useful function in modern species, are evidence of evolutionary change (Table 23.3).

23.3 The Molecular Processes That Underlie Evolution

- Molecular evolution is the process of evolution at the level of genes and proteins. Molecular processes that underlie evolution include the formation of orthologs and paralogs, horizontal gene transfer, and changes in chromosome structure and number.
- Orthologs are homologous genes in different species that have accumulated random mutations over time (Figure 23.14).
- Paralogs are homologous genes in the same species that are produced by gene duplication events. Gene duplication can result in the formation of a gene family such as the globin gene family, which supported the evolutionary adaptation of internal gestation.
- Another mechanism that produces genetic variation is horizontal gene transfer, in which genetic material is transferred from one organism to another organism that is not its offspring. Such genetic changes are subject to natural selection (Figure 23.15).
- Molecular evolution can also involve changes in chromosome structure and number (Figure 23.16).

Assess and Discuss

Test Yourself

1. A change in one or more characteristics of a population that is heritable and occurs from one generation to the next is called
   a. natural selection.
   b. sexual selection.
   c. population genetics.
   d. evolution.
   e. inheritance of acquired characteristics.
2. Lamarck's vision of evolution differed from Darwin's in that Lamarck believed
   a. living things evolve in an upward direction.
   b. behavioral changes modify heritable traits.
   c. genetic differences among individuals in the population allow for evolution.
   d. a and b only.
   e. none of the above.
3. Which of the following scientists influenced Darwin's views on the nature of population growth?
   a. Cuvier c. Lyell e. Wallace
   b. Malthus d. Hutton
4. An evolutionary change in which a population of organisms changes its characteristics over many generations in ways that make it better suited to its environment is
   a. natural selection. d. evolution.
   b. an adaptation. e. both a and c.
   c. an acquired characteristic.
5. Vestigial structures are anatomical structures
   a. that have more than one function.
   b. that were functional in an ancestor but no longer have a useful function.
   c. that look similar in different species but have different functions.
   d. that have the same function in different species but have very different appearances.
   e. of the body wall.
6. Which of the following is an example of a developmental homology seen in human embryonic development and other vertebrate species that are not mammals?
   a. gill ridges c. tail e. all of the above
   b. umbilical cord d. both a and c
7. Two or more homologous genes found within a particular species are called
   a. homozygous. c. paralogs. e. duplicates.
   b. orthologs. d. alleles.
8. As described in Chapter 4 (look back at Table 4.1), actin is a protein that is a component of the cytoskeleton found in eukaryotic cells. If you compared the sequence of an actin gene in bald eagles with that in other species, which of the following species would you expect to have an actin gene sequence most similar to the eagle's?
   a. human c. baker's yeast e. salamander
   b. sea bass d. sparrow
9. Horizontal gene transfer
   a. is a process in which an organism incorporates genetic material from another organism without being the offspring of that organism.
   b. can involve the exchange of genetic material among individuals of the same species.
   c. can involve the exchange of genetic material among individuals of different species.
   d. can be all of the above.
   e. can be a and b only.
10. Genetic variation can occur as a result of
    a. random mutations in genes.
    b. changes in chromosome structure and number.
    c. gene duplication.
    d. horizontal gene transfer.
    e. all of the above.

Conceptual Questions

1. Evolution that results in adaptation is rooted in two phenomena: genetic variation and natural selection. In a very concise way (three sentences or less), describe how genetic variation and natural selection can bring about evolution.
2. What is convergent evolution? How does it support the theory of evolution?
3.  A principle of biology is that *populations of organisms evolve from one generation to the next.* Explain how the homologous forelimbs of vertebrates indicate that populations evolve from one generation to the next.

Collaborative Questions

1. The term natural selection is sometimes confused with the term evolution. Discuss the meanings of these two terms. Explain how the terms are different and how they are related to each other.
2. Make a list of the observations made by biologists that support the theory of evolution. Which of the observations on your list do you find the most convincing and the least convincing?

24.3 Sexual Selection
24.4 Genetic Drift
24.5 Migration and Nonrandom Mating
Summary of Key Concepts
Assess and Discuss

24 Population Genetics

Colorful African cichlids. Color is a factor that influences the choice of mates in populations of cichlids.

Kimbareta, age 19, lives in the Democratic Republic of Congo (formerly Zaire) with his parents, one brother, and two sisters. Kimbareta has sickle cell disease, which causes his red blood cells to occasionally take on a crescent or sickled shape. The sickled cells may block the flow of blood through his vessels. This results in tissue and organ damage along with painful episodes involving his arms, legs, chest, and abdomen. In some people with this disease, stroke may even occur. Sickle cell disease follows a recessive pattern of inheritance. It is caused by a mutation in a gene that encodes β-globin, a subunit of hemoglobin that carries oxygen in the red blood cells.

Many different recessive diseases have been identified by geneticists. Most of them are very rare. However, in the village where Kimbareta lives, sickle cell disease is surprisingly common. Nearly 2% of the inhabitants have the disease—an incidence that is similar to other places in the country. How can we explain such a high occurrence of a serious inherited disease? If natural selection tends to eliminate detrimental genetic variation, as we saw in Chapter 23, why does the sickle cell allele persist in this population? As we will see later, biologists have discovered that the effect of the allele in heterozygotes is the underlying factor. Heterozygotes, who carry one copy of the sickle cell allele and one copy of the more common (non-disease-causing) allele, have an increased resistance to malaria.

Population genetics is the study of genes and genotypes in a population. A **population** is a group of individuals of the same species that occupy the same environment at the same time. For sexually reproducing species, members of a given population can interbreed with one another. The central issue in population genetics is genetic variation—its extent within populations, why it exists, how it is maintained, and how it changes over the course of many generations. Population genetics helps us understand how underlying genetic variation is related to phenotypic variation.

Population genetics emerged as a branch of genetics in the 1920s and 1930s. Its mathematical foundations were developed by theoreticians who extended the principles of Darwin and Mendel by deriving equations to explain the occurrence of genotypes within populations. These foundations can be largely attributed to British evolutionary biologists J. B. S. Haldane and Ronald Fisher, and American geneticist Sewall Wright. As we will see, several researchers who analyzed the genetic composition of natural and experimental populations provided support for the mathematical theories. More recently, population geneticists have used techniques to probe genetic variation at the molecular level. In addition, the staggering improvements in computer technology have aided population geneticists in the analysis of data and the testing of genetic hypotheses.

We will begin this chapter by exploring the extent of genetic variation that occurs in populations and how such variation is subject to change. In many cases, genetic changes are associated with evolutionary adaptations, which are characteristics of a species that have evolved over a long period of time by the process of natural selection. In the second half of the chapter, we will examine the various evolutionary mechanisms that promote genetic change in a population, including natural selection, genetic drift, migration, and nonrandom mating.

24.1 Genes in Populations

Learning Outcomes:

1. Define a gene pool.
2. Distinguish between allele and genotype frequency.
3. **SciSKILLS »** Use the Hardy-Weinberg equation to calculate allele and genotype frequencies of a given population.
4. List the conditions that must be met for a population to be in Hardy-Weinberg equilibrium.
5. Describe the factors that cause microevolution to happen.

Population genetics is an extension of our understanding of Darwin's theory of natural selection, Mendel's laws of inheritance, and newer studies in molecular genetics. All of the alleles for every gene in a given population make up the **gene pool**. Each member of the population receives its genes from its parents. Individuals that reproduce contribute to the gene pool of the next generation. Population geneticists study the genetic variation within the gene pool and how such variation changes from one generation to the next. The emphasis is often on understanding the variation in alleles among members of a population. In this section, we will examine some of the general features of populations and gene pools.

Populations Are Dynamic Units

Recall that a population is a group of individuals of the same species that occupy the same environment at the same time and can interbreed with one another. Certain species occupy a wide geographic range and are divided into discrete populations due to geographic isolation. For example, distinct populations of a given species may be located on different sides of a physical barrier, such as a mountain range.

Populations change from one generation to the next. How might populations become different? Populations may change in size and geographic location. As the size and location of a population change, the genetic composition generally changes as well. Some of the genetic changes involve adaptation, in which a population becomes better suited to its environment, making it more likely to survive and reproduce. For example, a population of mammals may move from a warmer to a colder geographic location. Over the course of many generations, natural selection may change the population such that animals with fur that is thicker and provides better insulation against the colder temperatures become more prevalent.

Genomes & Proteomes Connection

Genes Are Usually Polymorphic

The term **polymorphism** (from the Greek, meaning many forms) refers to the presence of two or more variants or traits for a given character within a population. **Figure 24.1** illustrates a striking example of polymorphism in the elder-flowered orchid (*Dactylorhiza sambucina*). Throughout the range of this species in Europe, both yellow- and red-flowered individuals are prevalent.

Polymorphism in a character is usually due to two or more alleles of a gene that influences the character. Geneticists also use the term polymorphism to describe the variation in the DNA sequence of genes. A gene that commonly exists as two or more alleles in a population is a **polymorphic gene**. To be considered polymorphic, a gene must exist in at least two alleles, and each allele must occur at a frequency that is greater than 1%. By comparison, a **monomorphic gene** exists predominantly as a single allele in a population. When 99% or more of the alleles of a given gene are identical in a population, the gene is considered to be monomorphic.

What types of molecular changes cause genes to be polymorphic? A polymorphism may involve various types of changes, such as a deletion of a significant region of the gene, a duplication of a region, or a change in a single nucleotide. This last type of variation is called a **single-nucleotide polymorphism (SNP)**. SNPs (or "snips") are the smallest type of genetic variation that can occur within a given gene and also the most common. For example, the sickle cell allele discussed at the beginning of the chapter involves a single-nucleotide change in the β-globin gene, which encodes a subunit of the oxygen-carrying protein called hemoglobin. The non-disease-causing allele and sickle cell allele represent a SNP of the β-globin gene:

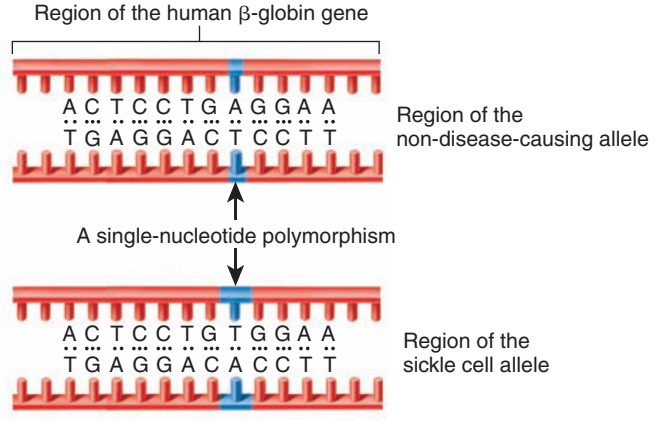

Figure 24.1 An example of polymorphism: the two color variations found in the orchid *Dactylorhiza sambucina*.

Relative to the non-disease-causing allele, this is a single-nucleotide substitution of an A (in the top strand) to a T in the sickle cell allele.

SNPs represent 90% of all variation in human DNA sequences that occurs among different people. In human populations, a gene that is 2,000–3,000 bp in length, on average, contains 10 different SNPs. Likewise, SNPs with a frequency of 1% or more are found very frequently among genes of nearly all species. Polymorphism is the norm for relatively large, healthy populations of nearly all species, as evidenced by the occurrence of SNPs within most genes.

Why do we care about SNPs? One reason is their importance in human health. By analyzing SNPs in human genes, researchers have determined that these small variations in DNA sequences can affect the function of the proteins encoded by the genes. These effects on the proteome, in turn, may influence how humans develop diseases, such as heart disease, diabetes, and sickle cell disease. Variations in SNPs in the human population are also associated with how people respond to viruses, drugs, and vaccines. The analysis of SNPs may be instrumental in the current and future development of **personalized medicine**—a medical practice in which information about a patient's genotype is used to tailor her or his medical care. For example, an analysis of a person's SNPs may be used to select between different types of medication or customize the dosage. In addition, SNP analysis may reveal that a person has a high predisposition to develop a particular disease, such as heart disease. Such information may be used to initiate preventative measures to minimize the chances of developing the disease.

Population Genetics Is Concerned with Allele and Genotype Frequencies

One approach to analyzing genetic variation in populations is to consider the frequency of specific alleles and genotypes in a quantitative way. Two fundamental calculations are central to population genetics: **allele frequency** and **genotype frequency**. Allele and genotype frequency are defined as follows:

$$\text{Allele frequency} = \frac{\text{Number of copies of a specific allele in a population}}{\text{Total number of all alleles for that gene in the population}}$$

$$\text{Genotype frequency} = \frac{\text{Number of individuals with a particular genotype in a population}}{\text{Total number of individuals in the population}}$$

Although allele and genotype frequencies are related, make sure you clearly distinguish between them. As an example, let's consider a population of 100 four-o'clock plants (*Mirabilis jalapa*) with the following genotypes:

49 red-flowered plants with the genotype C^RC^R

42 pink-flowered plants with the genotype C^RC^W

9 white-flowered plants with the genotype C^WC^W

When calculating an allele frequency for a diploid species, remember that homozygous individuals have two copies of a given allele, whereas heterozygotes have only one. For example, in tallying the C^W allele, each of the 42 heterozygotes has one copy of the C^W allele, and each white-flowered plant has two copies. Therefore, the allele frequency for C^W (the white color allele) equals

$$\text{Frequency of } C^W = \frac{(C^RC^W) + 2(C^WC^W)}{2(C^RC^R) + 2(C^RC^W) + 2(C^WC^W)}$$

$$\text{Frequency of } C^W = \frac{42 + (2)(9)}{(2)(49) + (2)(42) + (2)(9)}$$

$$= \frac{60}{200} = 0.3, \text{ or } 30\%$$

This result tells us that the allele frequency of C^W is 0.3. In other words, 30% of the alleles for this gene in the population are the white color (C^W) allele.

Let's now calculate the genotype frequency of C^WC^W homozygotes (white-flowered plants).

$$\text{Frequency of } C^WC^W = \frac{9}{49 + 42 + 9}$$

$$= \frac{9}{100} = 0.09, \text{ or } 9\%$$

We see that 9% of the individuals in this population have the white-flower genotype.

The Hardy-Weinberg Equation Relates Allele and Genotype Frequencies in a Population

In 1908, Godfrey Harold Hardy, an English mathematician, and Wilhelm Weinberg, a German physician, independently derived a simple mathematical expression, now called the Hardy-Weinberg equation, that describes the relationship between allele and genotype frequencies when a population is not evolving. Let's examine the Hardy-Weinberg equation using the population of four-o'clock plants that we just considered. If the allele frequency of C^R is denoted by the symbol p and the allele frequency of C^W by q, then

$$p + q = 1$$

For example, if $p = 0.7$, then q must be 0.3. In other words, if the allele frequency of C^R equals 70%, the remaining 30% of alleles must be C^W, because together they equal 100%.

For a gene that exists in two alleles, the **Hardy-Weinberg equation** states that

$$p^2 + 2pq + q^2 = 1$$

If we apply this equation to our flower color gene, then

p^2 = the genotype frequency of C^RC^R homozygotes

$2pq$ = the genotype frequency of C^RC^W heterozygotes

q^2 = the genotype frequency of C^WC^W homozygotes

If $p = 0.7$ and $q = 0.3$, then

Frequency of $C^RC^R = p^2 = (0.7)^2 = 0.49$

Frequency of $C^RC^W = 2pq = 2(0.7)(0.3) = 0.42$

Frequency of $C^WC^W = q^2 = (0.3)^2 = 0.09$

In other words, if the allele frequency of C^R is 70% and the allele frequency of C^W is 30%, the expected genotype frequency of C^RC^R is 49%, C^RC^W is 42%, and C^WC^W is 9%.

Figure 24.2 uses a Punnett square to illustrate the relationship between allele frequencies and the way that gametes combine to produce genotypes. To be valid, the Hardy-Weinberg equation carries the assumption that two gametes combine randomly with each other to produce offspring. In a population, the frequency of a gamete carrying a particular allele is equal to the allele frequency in that population. For example, if the allele frequency of C^R equals 0.7, the frequency of a gamete carrying the C^R allele also equals 0.7. The probability of producing a C^RC^R homozygote with red flowers is $0.7 \times 0.7 = 0.49$, or 49%. The probability of inheriting both C^W alleles, which produces white flowers, is $0.3 \times 0.3 = 0.09$, or 9%. Two different gamete combinations produce heterozygotes with pink flowers. An offspring could inherit the C^R allele from the pollen and C^W from the egg, or C^R from the egg and C^W from the pollen. Therefore, the frequency of heterozygotes is $pq + pq$, which equals $2pq$. In our example, this is $2(0.7)(0.3) = 0.42$, or 42%. Note that the frequencies for all three genotypes total 100%.

The Hardy-Weinberg equation predicts that allele and genotype frequencies will remain the same, generation after generation, provided that a population is in equilibrium. To be in equilibrium, evolutionary mechanisms that can change allele and genotype frequencies must not be acting on a population. For this to occur, the following conditions must be met:

- No new mutations occur to alter allele frequencies.
- No natural selection occurs; that is, no survival or reproductive advantage exists for any of the genotypes.
- The population is so large that allele frequencies do not change due to random chance.
- No migration occurs between different populations, altering the allele frequencies.
- Random mating occurs; that is, the members of the population mate with each other without regard to their genotypes.

Why is Hardy-Weinberg equilibrium a useful concept? An equilibrium is a null hypothesis, which suggests that evolutionary change is not occurring. In reality, however, populations rarely achieve an equilibrium, though in large natural populations with little migration and negligible natural selection, Hardy-Weinberg equilibrium may be nearly approximated for certain genes. Sometimes, when researchers experimentally examine allele and genotype frequencies for one or more genes in a given species, they discover that the frequencies are not in Hardy-Weinberg equilibrium. In such cases, they assume that one or more of the conditions are being violated—in other words, mechanisms of evolutionary change are affecting the population. Conservation biologists and wildlife managers may wish to determine why such disequilibrium has occurred because it may affect the future survival of the species.

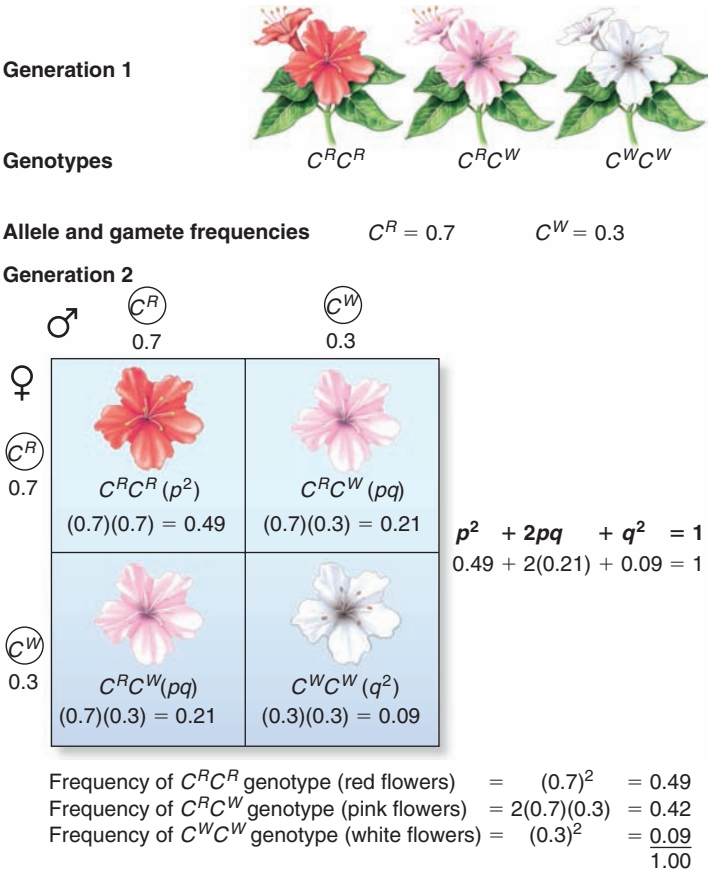

Figure 24.2 Calculating allele and genotype frequencies with the Hardy-Weinberg equation. A population of four-o'clock plants has allele and gamete frequencies of 0.7 for the C^R allele and 0.3 for the C^W allele. Knowing the allele frequencies allows us to calculate the genotype frequencies in the population.

Concept Check: *What would be the frequency of pink flowers in a population in which the allele frequency of C^R is 0.4 and the population is in Hardy-Weinberg equilibrium? Assume that C^R and C^W are the only two alleles.*

BIO TIPS

THE QUESTION *In human populations, the phenotype frequency of the inability to taste the bitter substance phenylthiocarbamide (PTC) is approximately 0.3. This inability is due to a recessive allele. Assuming that there are only two alleles in a population (namely, tasters, T, and nontasters, t) and that the population is in Hardy-Weinberg equilibrium, calculate the frequencies of these two alleles.*

TOPIC ***What topic in biology does this question address?*** The topic is about predicting the allele frequencies in a population. More specifically, the question is about predicting the frequency of alleles that affect the tasting of PTC.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you know the frequency of homozygotes who are nontasters. From your understanding of the topic, you may realize that you can use the Hardy-Weinberg equation to determine allele frequencies if you know the genotype frequencies.

PROBLEM-SOLVING STRATEGY ***Make a calculation.*** One strategy to solve this problem is to use the components of the Hardy-Weinberg equation to determine the allele frequencies. If q represents the allele frequency of the recessive allele (t) that confers nontasting, then q^2 is the genotype frequency of homozygous nontasters:

$$q^2 = 0.3$$

We take the square root to determine q:

$$q = \sqrt{0.3}$$
$$q = 0.55$$

If p represents the frequency of the taster allele (T), then

$$p = 1 - q$$
$$p = 1 - 0.55 = 0.45$$

ANSWER *The frequency of the nontaster allele is 0.55, or 55%, and that of the taster allele is 0.45, or 45%.*

Microevolution Involves Changes in Allele Frequencies from One Generation to the Next

The term **microevolution** is used to describe changes in a population's gene pool, such as changes in allele frequencies, from generation to generation. What causes microevolution to happen? Such change is rooted in two related phenomena (**Table 24.1**). First, the introduction of new genetic variation into a population is one essential aspect of microevolution. New alleles of pre-existing genes arise by random mutation, and, as discussed in Chapter 23, new genes can be introduced into a population by gene duplication, and horizontal gene transfer. Such mutations, albeit rare, provide a continuous source of new variation to populations. In 1926, the Russian geneticist Sergei Chetverikov was the first to suggest that random mutations are the raw material for evolution. However, due to their low rate of occurrence, mutations by themselves do not play a major role in changing allele frequencies in a population over time. They do not significantly disrupt a Hardy-Weinberg equilibrium.

The second phenomenon that is required for evolution to occur is one or more mechanisms that alter the prevalence of a given allele or genotype in a population. These mechanisms are natural selection, genetic drift, migration, and nonrandom mating (see Table 24.1). Over the course of many generations, these mechanisms may promote widespread genetic changes in a population. In the remainder of this chapter, we will examine how natural selection, genetic drift, migration, and nonrandom mating affect the type of genetic variation that occurs when a gene exists as two alleles in a population.

Table 24.1 Factors That Govern Microevolution

*Sources of new genetic variation**	
New mutations within genes that produce new alleles	Random mutations within pre-existing genes introduce new alleles into populations, but at a very low rate. New mutations may be neutral, deleterious, or beneficial. Because mutations are rare, the change from one generation to the next is very small. For alleles to rise to a significant percentage in a population, evolutionary mechanisms, such as natural selection, genetic drift, and migration, must operate on them.
Gene duplication†	Abnormal crossover events and transposable elements may increase the number of copies of a gene. Over time, the additional copies accumulate random mutations and constitute a gene family.
Horizontal gene‡ transfer	Genes from one species may be introduced into another species. The transferred gene may be acted on by evolutionary mechanisms.
Evolutionary mechanisms that alter the frequencies of existing genetic variation	
Natural selection	The process by which individuals that possess certain traits are more likely to survive and reproduce than individuals without those traits. Over the course of many generations, beneficial traits that are heritable become more common and detrimental traits become less common.
Genetic drift	A change in genetic variation from generation to generation due to random chance. Allele frequencies may change as a matter of chance from one generation to the next. Genetic drift has a greater influence in a small population.
Migration	Migration can occur between two populations that have different allele frequencies. The introduction of migrants into a recipient population may change the allele frequencies of that population.
Nonrandom mating	The phenomenon in which individuals select mates based on their genotypes or phenotypes. This alters the relative proportion of homozygotes and heterozygotes that is predicted by the Hardy-Weinberg equation, but it does not change allele frequencies.

* These are examples that affect single genes. Other events, such as crossing over, independent assortment, and changes in chromosome structure and number, may alter the genetic variation among many genes.
† Described in Chapter 21. See Figures 21.7 and 21.8.
‡ Described in Chapter 23. See Figure 23.15.

24.2 Natural Selection

Learning Outcomes:

1. Explain how natural selection can result in a population that is better adapted to its environment and more successful at reproduction.
2. **SciSKILLS** » Calculate the fitness values of given genotypes.
3. List and distinguish the four different types of natural selection.

Recall from Chapter 23 that **natural selection** is the process by which individuals with certain heritable traits tend to survive and reproduce at higher rates than those without those traits. As a result, favorable heritable traits become more common, while detrimental heritable traits become less common. Keep in mind that natural selection itself is not evolution. Rather it is a key mechanism that causes evolution to happen. Over time, natural selection results in **adaptations**—changes in populations of living organisms that increase their ability to survive and reproduce in a particular environment. In this section, we will examine various ways that natural selection produces such adaptations.

Natural Selection Favors Individuals with Greater Reproductive Success

Reproductive success is the likelihood of an individual contributing fertile offspring to the next generation. Natural selection occurs because some individuals in a population have greater reproductive success compared to other individuals. Those individuals having heritable traits that favor reproductive success are more likely to pass those traits to their offspring. Reproductive success is commonly attributed to two categories of traits:

1. Certain characteristics make organisms better adapted to their environment and therefore more likely to survive to reproductive age. Therefore, natural selection favors individuals with characteristics that provide a survival advantage.
2. Reproductive success may involve traits that are directly associated with reproduction, such as the abilities to find a mate and produce viable gametes and offspring. Traits that enhance the ability of individuals to reproduce, such as brightly colored plumage in male birds, are often subject to natural selection.

As discussed in Chapter 23, Charles Darwin and Alfred Wallace independently proposed the theory of evolution by natural selection. A modern description of the principles of natural selection can relate our knowledge of molecular genetics to the process of evolution:

1. Within a population, allelic variation arises from random mutations that cause differences in DNA sequences. A mutation that creates a new allele may alter the amino acid sequence of the encoded protein. This, in turn, may alter the function of the protein.
2. Some alleles encode proteins that enhance an individual's survival or reproductive capability over that of other members of the population. For example, an allele may produce a protein that is more efficient at a higher temperature, conferring on the individual a greater probability of survival in a hot climate.
3. Individuals with beneficial alleles are more likely to survive and contribute their alleles to the gene pool of the next generation.
4. Over the course of many generations, allele frequencies of many different genes may change through natural selection, thereby significantly altering the characteristics of a population. The net result of natural selection is a population that is better adapted to its environment and more successful at reproduction.

Fitness Is a Quantitative Measure of Reproductive Success

As mentioned earlier, Haldane, Fisher, and Wright developed mathematical relationships to explain the phenomenon of natural selection. To begin our quantitative discussion of natural selection, we need to consider the concept of **fitness**, which is the relative likelihood that one genotype will contribute to the gene pool of the next generation compared with other genotypes. Although this property often correlates with physical fitness, the two ideas should not be confused. Fitness is a measure of reproductive success. An extremely fertile individual may have a higher fitness than a less fertile individual that appears more physically fit.

To examine fitness, let's consider an example of a hypothetical gene existing in *A* and *a* alleles. We can assign fitness values to each of the three possible genotypes according to their relative reproductive success. For example, let's suppose the average reproductive successes of the three genotypes are

AA produces 5 offspring
Aa produces 4 offspring
aa produces 1 offspring

By convention, the genotype with the highest reproductive success is given a fitness value of 1.0. Fitness values are denoted by the variable *w*. The fitness values of the other genotypes are assigned values relative to this 1.0 value.

Fitness of *AA*: $w_{AA} = 1.0$

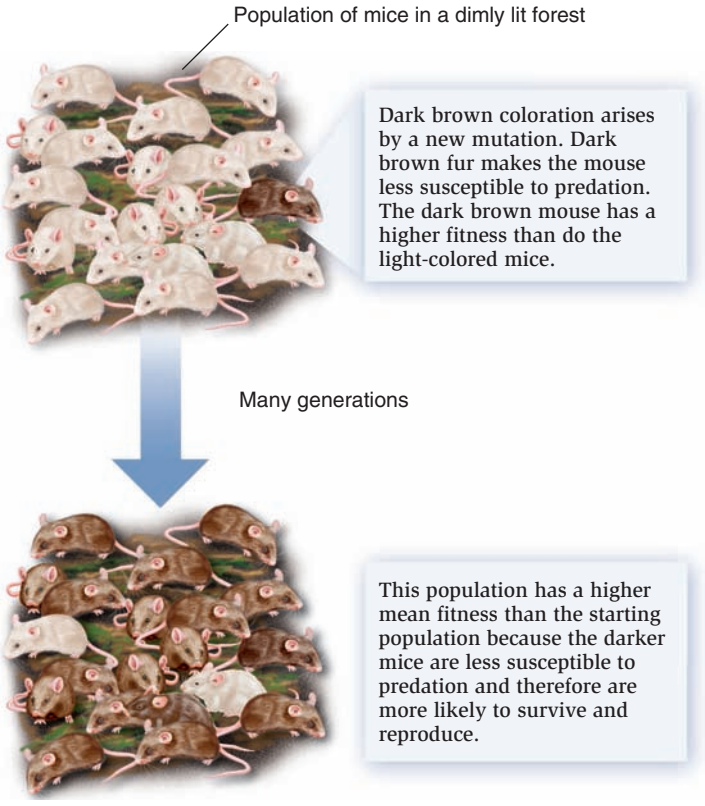
Fitness of *Aa*: $w_{Aa} = 4/5 = 0.8$

Fitness of *aa*: $w_{aa} = 1/5 = 0.2$

Variation in fitness occurs because certain genotypes result in individuals that have a greater reproductive success than other genotypes.

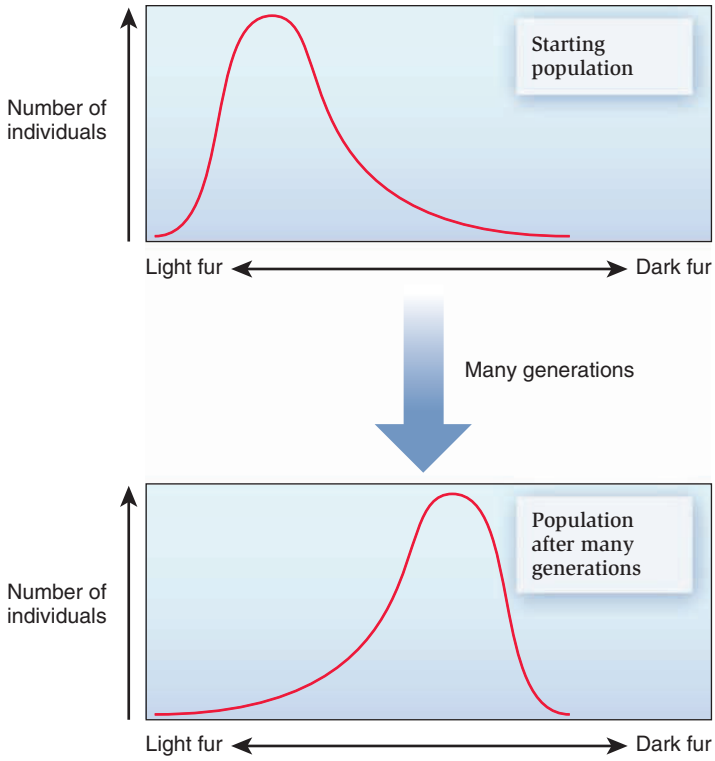
Likewise, the effects of natural selection can be viewed at the level of a population. The average reproductive success of members of a population is called the **mean fitness of the population**. Over many generations, as individuals with higher fitness values become more prevalent, natural selection also increases the mean fitness of the population. In this way, the process of natural selection results in a population of organisms that is well adapted to its native environment and more likely to be successful at reproduction.

Natural Selection Follows Different Patterns



By studying species in their native environments, population geneticists have discovered that natural selection can occur in several ways. In most of the examples described next, natural selection leads to adaptations that make certain members of a species more likely to survive to reproductive age.

Directional Selection During **directional selection**, individuals at one extreme of a phenotypic range have greater reproductive success in a particular environment. Different phenomena may initiate the process of directional selection. A common reason for directional selection is that a population may be exposed to a prolonged change in its living environment. Under the new environmental



conditions, the relative fitness values may change to favor one genotype, which will promote the elimination of other genotypes. As an example, let's suppose a population of finches on a mainland already has genetic variation that affects beak size (refer back to Figure 23.2). A small number of birds migrate to an island where the seeds are generally larger than on the mainland. In this new environment, birds with larger beaks have a higher fitness because they are better able to crack open the larger seeds and thereby survive to reproduce. Over the course of many generations, directional selection would produce a population of birds carrying alleles that promote larger beak size.

Another way that directional selection may arise is that a new allele may be introduced into a population by mutation, and the new allele may confer a higher fitness in individuals that carry it (**Figure 24.3**). What are the long-term effects of such directional selection? If the homozygote carrying the favored allele has the highest fitness value, directional selection may cause this favored allele to eventually predominate in the population, perhaps even leading to a monomorphic gene.

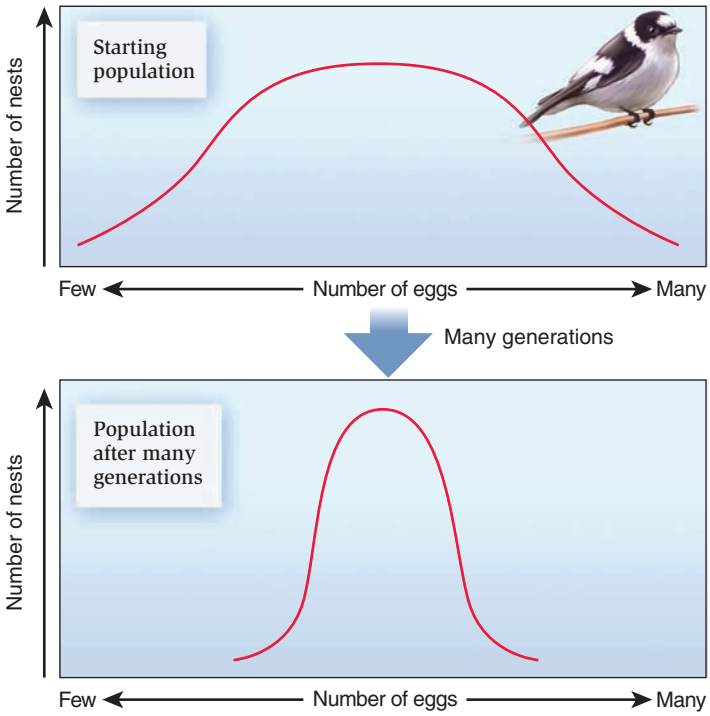
Stabilizing Selection A type of natural selection called **stabilizing selection** favors the survival of individuals with intermediate phenotypes and selects against those with extreme phenotypes. Stabilizing selection tends to decrease genetic diversity. An example of stabilizing selection involves clutch size (number of eggs laid) in birds, which was first studied by British biologist David Lack in 1947. Under stabilizing selection, birds that lay too many or too few eggs per nest have lower fitness values than do those that lay an intermediate number. When a bird lays too many eggs, many offspring die due to inadequate parental care and food. In addition, the strain on the parents themselves may decrease their likelihood of survival and consequently their ability to produce more offspring. Having too few offspring, however, does not contribute many individuals to the next generation. Therefore, the most successful parents are those that produce an intermediate clutch size. In the 1980s, Swedish evolutionary biologist Lars Gustafsson and his colleagues examined the phenomenon of stabilizing selection in the collared flycatcher (*Ficedula albicollis*) on the Swedish island of Gotland. They discovered that Lack's hypothesis concerning an optimal clutch size appears to be true for this species (**Figure 24.4**).

(a) An example of directional selection

(b) Graphical representation of directional selection

Figure 24.3 Directional selection. This pattern of natural selection selects for one extreme of a phenotype that confers the highest fitness in the population's environment. **(a)** In this example, a mutation causing darker fur arises in a population of mice. This new genotype confers higher fitness, because mice with darker fur can better evade predators and are more likely to survive and reproduce. Over many generations, directional selection favors the prevalence of individuals with darker fur. **(b)** These graphs show the change in fur color phenotypes before and after directional selection.

Concept Check: Let's suppose the climate on an island abruptly changed such that the average temperature was 10°C higher. The climate change is permanent. How would directional selection affect the genetic diversity in a population of mice on the island (1) over the short run and (2) over the long run?



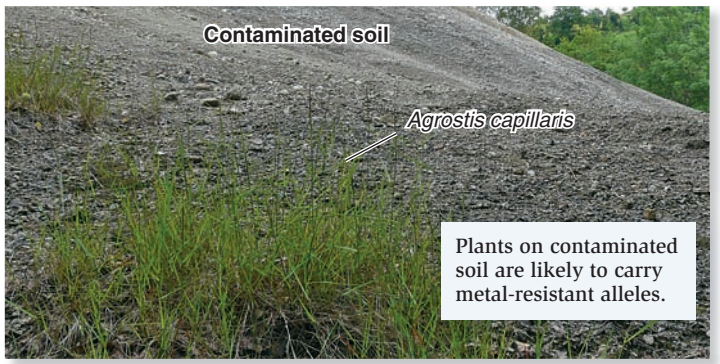


Figure 24.4 Stabilizing selection. In this pattern of natural selection, the extremes of a phenotypic distribution are selected against. Those individuals with intermediate traits have the highest fitness. These graphs show the results of stabilizing selection on clutch size in a population of collared flycatchers (*Ficedula albicollis*). This process results in a population with less diversity and more uniform traits.

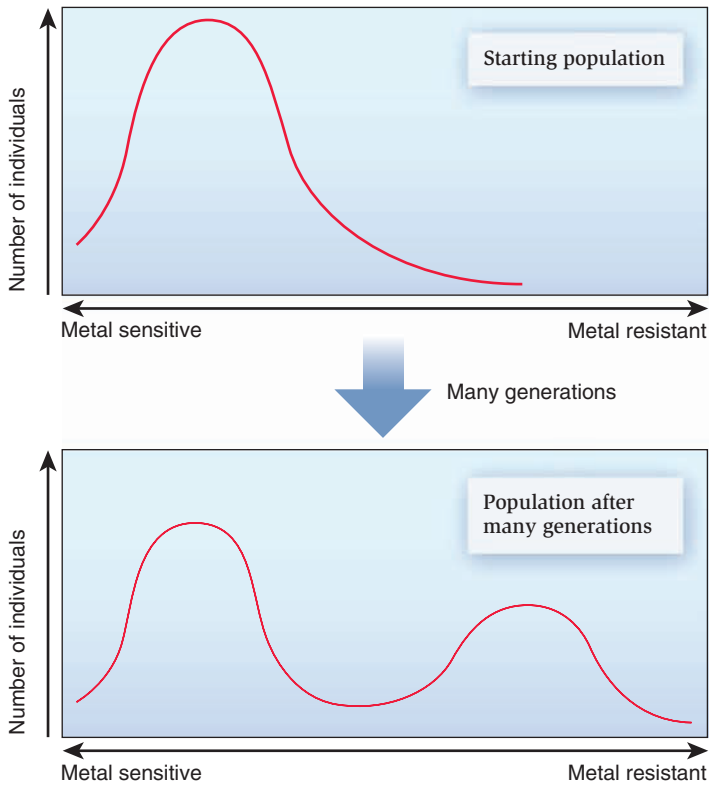

Concept Check: Why does stabilizing selection decrease genetic diversity?

Diversifying Selection **Diversifying selection** (also known as disruptive selection) favors the survival of two or more different genotypes that produce different phenotypes. In diversifying selection, the fitness values of a particular genotype are higher in one environment and lower in a different one, whereas the fitness values of the second genotype vary in an opposite manner. Diversifying selection is likely to occur in populations that occupy heterogeneous environments, so some members of the species are more likely to survive in each type of environmental condition.

An example of diversifying selection involves colonial bentgrass (*Agrostis capillaris*) (**Figure 24.5**). In certain locations where this grass is found, such as South Wales, isolated places occur

(a) Growth of *Agrostis capillaris* on contaminated soil

(b) Graphical representation of disruptive selection

Figure 24.5 Diversifying selection. This pattern of natural selection selects for two different phenotypes, each of which is most fit in a particular environment. **(a)** In this example, random mutations have resulted in metal-resistant alleles in colonial bentgrass (*Agrostis capillaris*) that allow it to grow on contaminated soil. In uncontaminated soils, the grass does not show metal tolerance. The existence of both metal-resistant and metal-sensitive alleles in the population is an example of diversifying selection due to heterogeneous environments. **(b)** Graphs showing the change in phenotypes in this bentgrass population before and after diversifying selection.

BIOLOGY PRINCIPLE **Populations of organisms evolve from one generation to the next.** In this example, the frequencies of metal-resistant alleles become more prevalent when populations of *A. capillaris* are exposed to toxic metals in the soil.

where the soil is contaminated with high levels of heavy metals due to mining. The relatively recent metal contamination has selected for the proliferation of mutant strains of *A. capillaris* that are tolerant of the heavy metals (Figure 24.5a). Such genetic changes enable these mutant strains to grow on contaminated soil but tend to inhibit their growth on normal, noncontaminated soil. These metal-resistant plants often grow on contaminated sites that are close to plants that grow on uncontaminated land and do not show metal tolerance.

Balancing Selection Contrary to a popular misconception, natural selection does not always cause the elimination of "weaker" or less-fit alleles. **Balancing selection** is a type of natural selection that maintains genetic diversity in a population. Over many generations, balancing selection results in a **balanced polymorphism**, in which two or more alleles are kept in balance and therefore are maintained in a population over many generations.

How does balancing selection maintain a polymorphism? Population geneticists have identified two common ways that balancing selection occurs. First, for genetic variation involving a single gene, balancing selection can favor the heterozygote over either corresponding homozygote. This situation is called **heterozygote advantage**. Heterozygote advantage sometimes explains the persistence of alleles that are deleterious in a homozygous condition.

A classic example of heterozygote advantage involves the H^S allele of the human β-globin gene. A homozygous H^SH^S individual, such as Kimbareta, discussed at the beginning of the chapter, has sickle cell disease. This disease causes the red blood cells to form a sickle shape. Sickle-shaped cells deliver less oxygen to the body's tissues and can block the flow of blood through the vessels. The H^SH^S homozygote has a lower fitness than a homozygote with two copies of the more common β-globin allele, H^AH^A. Heterozygotes, H^AH^S, do not typically show symptoms of the disease, but they have an increased resistance to malaria. Compared with H^AH^A homozygotes, heterozygotes have the highest fitness because they have a 10–15% better chance of surviving if infected by the malarial parasite *Plasmodium falciparum*. Therefore, the H^S allele is maintained in populations where malaria is prevalent, such as the Democratic Republic of Congo, even though the allele is detrimental in the homozygous state (**Figure 24.6**). This balanced polymorphism results in a higher mean fitness of the population. In areas where malaria is endemic, a population composed of all H^AH^A individuals would have a lower mean fitness.

Negative frequency-dependent selection is a second way that natural selection produces a balanced polymorphism. In this pattern of natural selection, the fitness of a genotype decreases when its frequency becomes higher. In other words, common individuals have a lower fitness, and rare individuals have a higher fitness. Therefore, common individuals are less likely to reproduce, whereas rare individuals are more likely to reproduce, thereby producing a balanced polymorphism in which no genotype becomes too rare or too common.

Negative frequency-dependent selection is thought to maintain polymorphisms among species that are preyed upon by predators. Research has shown that certain predators form a mental search image for their prey, which is usually based on the common type of prey in an area. A prey that exhibits a rare polymorphism that affects its appearance is less likely to be recognized by the predator. For example, a prey that is a different color from most other members of its species may not be readily recognized by the predator. Such relatively rare organisms are subject to a lower rate of predation. This type of selection maintains polymorphism among certain prey populations.

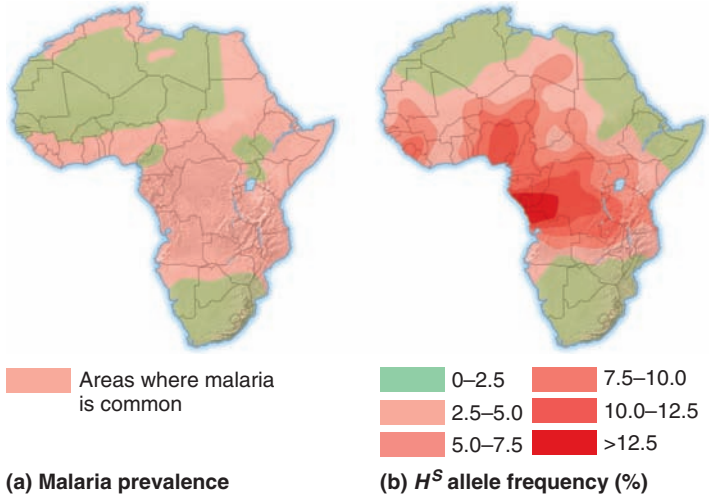

Figure 24.6 Balancing selection and heterozygote advantage. **(a)** The geographic prevalence of malaria in Africa. **(b)** The frequency of the H^S allele of the β-globin gene in the same area. In the homozygous condition, the H^S allele causes sickle cell disease. This allele is maintained in human populations in areas where malaria is prevalent, because the heterozygote (H^AH^S) has a higher fitness than either of the corresponding homozygotes (H^AH^A or H^SH^S).

Concept Check: *If malaria was eradicated, what would you expect to happen to the frequencies of the H^A and H^S alleles over the long run?*

24.3 Sexual Selection

Learning Outcomes:

1. Define sexual selection.
2. Distinguish between intrasexual and intersexual selection.
3. **SciSKILLS** » Analyze the results of Seehausen and van Alphen and explain how they relate to sexual selection.

Thus far, we have largely focused on examples of natural selection that produce adaptations for survival in particular environments. Now let's turn our attention to a form of natural selection, called **sexual selection**, in which individuals with certain traits are more likely to engage in successful reproduction than other individuals. Darwin originally described sexual selection as "the advantage that certain individuals have over others of the same sex and species solely with respect to reproduction." In this section, we will explore how sexual selection alters traits that play a key role in reproduction.

Sexual Selection Is a Type of Natural Selection Pertaining to Traits That Are Directly Involved with Reproduction

In many species of animals, sexual selection affects the characteristics of males more intensely than those of females. Unlike females, which tend to be fairly uniform in their reproductive success, male success tends to be more variable, with some males mating with many females and others not mating at all. Sexual selection results in the prevalence of traits, called secondary sex characteristics, that favor reproductive success. The process can result in **sexual dimorphism**—a significant difference between the appearances of the two sexes within a species.

Sexual selection operates in one of two ways. In **intrasexual selection**, members of one sex, usually males, directly compete for the opportunity to mate with individuals of the opposite sex. Examples of traits that result from intrasexual selection in animals include horns in male sheep, antlers in male moose, and the enlarged claw of male fiddler crabs (**Figure 24.7a**). In fiddler crabs (*Uca paradussumieri*), males enter the burrows of females that are ready to mate. If another male attempts to enter the burrow, the male already inside stands in the burrow shaft and blocks the entrance with his enlarged claw. Males with the largest claws are more likely to be successful at driving off their rivals and being able to mate, and therefore more likely to pass on their genes to future generations.

In **intersexual selection**, also called mate choice, members of one sex, usually females, choose their mates from individuals of the other sex on the basis of certain desirable characteristics. This type of sexual selection often results in showy characteristics in males. **Figure 24.7b** shows a classic example of such a result—the Indian peafowl (*Pavo cristatus*), the national bird of India. Male peacocks have long and brightly colored tail feathers, which they fan out as a mating behavior. Female peahens select among males based on feather color and pattern as well as the physical prowess of the display.

A less obvious type of intersexual selection is cryptic female choice, in which the female reproductive system influences the relative success of sperm. For example, the female genital tract of certain animals selects for sperm that tend to be genetically unrelated to the female. Sperm from males closely related to the female, such as brothers or cousins, are less successful than are sperm from genetically unrelated males. The selection for sperm may occur over the journey through the reproductive tract. The egg itself may even have mechanisms to prevent fertilization by genetically related sperm. Cryptic female choice occurs in species in which females may mate with more than one male, such as many species of reptiles and ducks. A similar mechanism is found in many plant species in which pollen from genetically related plants, perhaps from the same flower, is unsuccessful at fertilization, whereas pollen from unrelated plants is successful. One possible advantage of cryptic female choice is that it inhibits inbreeding (described later in this chapter). At the population level, cryptic female choice may promote genetic diversity by favoring interbreeding among genetically unrelated individuals.

Sexual selection is sometimes a combination of both intrasexual and intersexual selection. During breeding season, male elk (*Cervus*

(a) Intrasexual selection

(b) Intersexual selection

(c) Sexual selection balanced by predation

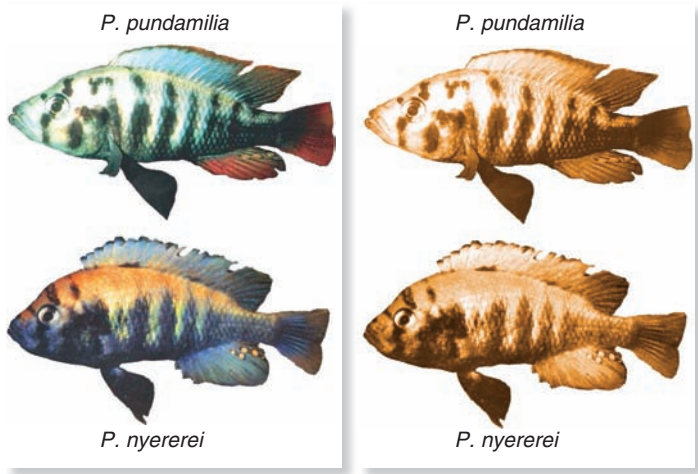
Figure 24.7 Examples of the results of sexual selection, a type of natural selection. **(a)** An example of intrasexual selection. The enlarged claw of the male fiddler crab is used in direct male-to-male competition. In this photograph, a male inside a burrow is extending its claw out of the burrow to prevent another male from entering and mating with the female. **(b)** An example of intersexual selection. Female peahens choose male peacocks based on the males' colorful and long tail feathers and the robustness of their display. **(c)** Male guppies (on the right) are brightly colored to attract a female (on the left), but brightly colored males are less common where predation is high. Note: These photos also illustrate the concept of sexual dimorphism.

Concept Check: *Male birds of many species have loud and elaborate courtship songs. Is this likely to be the result of intersexual or intrasexual selection? Explain.*

elaphus) become aggressive and bugle loudly to challenge other male elk. Males spar with their antlers, which usually turns into a pushing match to determine which elk is stronger. Female elk then choose the strongest bulls as their mates.

Sexual selection can explain the existence of traits that could decrease an individual's chances of survival but increase their chances of reproducing. For example, the male guppy (*Poecilia reticulata*) is brightly colored compared with the female (**Figure 24.7c**). In nature, females prefer brightly colored males. However, brightly colored males are more likely to be seen and eaten by predators. In places with few predators, the males tend to be brightly colored. In contrast, where predators are abundant, brightly colored males are less plentiful because they are subject to predation. In this case, the relative abundance of brightly and dully colored males depends on the balance between sexual selection, which favors bright coloring, and escape from predation, which favors dull coloring.

Many animals have secondary sexual characteristics, and evolutionary biologists generally agree that sexual selection is responsible for such traits. But why should males compete, and why should females be choosy? Researchers have proposed various hypotheses to explain the underlying mechanisms. One possible reason is related to the different roles that males and females play in the nurturing of offspring. In some animal species, the female is the primary caregiver, whereas the male plays a minor role. In such species, mating behavior may influence the fitness of both males and females. Males increase their fitness by mating with multiple females. This increases their likelihood of passing their genes on to the next generation. By comparison, females may produce relatively fewer offspring, and their reproductive success may not be limited by the number of available males. In these circumstances, females will have higher fitness if they choose males that are good defenders of their territory and have alleles that confer a survival advantage to their offspring. One measure of alleles that confer higher fitness is age. Males that live to an older age are more likely to carry beneficial alleles. Many research studies involving female choice have shown that females tend to select traits that are more likely to be well developed in older males than in immature ones. For example, in certain species of birds, females tend to choose males with a larger repertoire of songs, which is more likely to occur in older males.



Sexual selection is governed by the same processes involved in the evolution of traits that are not directly related to sex. Sexual selection can occur by directional, stabilizing, diversifying, or balancing selection. For example, the evolution of the large and brightly colored tail of the male peacock reflects directional selection.

Feature Investigation | Seeha and van Alphen Found That Male Coloration in African Cichlids Is Subject to Female Choice

In 1998, population geneticists Ole Seehausen and Jacques van Alphen investigated the possible role of sexual selection as it pertains to male coloration of two species of cichlid—a tropical freshwater fish popular among aquarium enthusiasts. The Cichlidae family is composed of more than 3,000 species that vary in body shape, coloration, behavior, and feeding habits, making it one of the largest and most diverse vertebrate families. By far, the greatest diversity of these fish occurs in Lake Victoria, Lake Malawi, and Lake Tanganyika in East Africa, where more than 1,800 species are found.

Cichlids have complex mating behavior, and females play an important role in choosing males with particular characteristics, such as color (see chapter opening photo). In some locations, *Pundamilia pundamilia* and *P. nyererei* do not readily interbreed and behave like two distinct biological species, whereas in other places, they behave like a single interbreeding species with two color morphs. Males of both species have blackish underparts and blackish vertical bars on their sides (**Figure 24.8a**). *P. pundamilia* males are grayish white on top and on the sides, and they have a metallic blue and red dorsal fin—the uppermost fin. *P. nyererei* males are red-orange on top and yellow on their sides.

Seehausen and van Alphen hypothesized that females choose males for mates based, in part, on the males' coloration. The researchers took advantage of the observation that colors are obscured under orange monochromatic light. As seen in **Figure 24.8b**, males of both

(a) Males of two species in normal light **(b) Males of two species in artificial light**

Figure 24.8 Male coloration in African cichlids. **(a)** Two males (*Pundamilia pundamilia*, top, and *Pundamilia nyererei*, bottom) under normal illumination. **(b)** The same species under orange monochromatic light, which obscures their color differences.

Figure 24.9 A study by Seehausen and van Alphen evaluating the effects of male coloration on female choice in African cichlids.

HYPOTHESIS Female African cichlids choose mates based on the males' coloration.

KEY MATERIALS Two species of cichlid, *Pundamilia pundamilia* and *P. nyererei* , were chosen. The males differ with regard to their coloration. A total of 8 males and 8 females (4 males and 4 females from each species) were tested.

Experimental level | **Conceptual level**

1 Place 1 female and 2 males in an aquarium. Each male is within a separate glass enclosure. The enclosures contain 1 male from each species.

This is a method to evaluate sexual selection via female choice in 2 species of cichlid.

2 Observe potential courtship behavior for 1 hour. If a male exhibited lateral display (a courtship invitation) and then the female approached the enclosure that contained the male, this was scored as a positive encounter. This protocol was performed under normal light and under orange monochromatic light.

3 THE DATA

Female	Male	Light condition	Percentage of positive encounters*
P. pundamilia	*P. pundamilia*	Normal	16
P. pundamilia	*P. nyererei*	Normal	2
P. nyererei	*P. nyererei*	Normal	16
P. nyererei	*P. pundamilia*	Normal	5
P. pundamilia	*P. pundamilia*	Monochromatic	20
P. pundamilia	*P. nyererei*	Monochromatic	18
P. nyererei	*P. nyererei*	Monochromatic	13
P. nyererei	*P. pundamilia*	Monochromatic	18

*A positive encounter occurred when a male's lateral display was followed by the female approaching the male.

4 CONCLUSION Under normal light, where colors can be distinguished, *P. pundamilia* females prefer *P. pundamilia* males, and *P. nyererei* females prefer *P. nyererei* males.

SOURCE Seehausen, O., and van Alphen, J.J.M. 1998. The effect of male coloration on female mate choice in closely related Lake Victoria cichlids (*Haplochromis nyererei* complex). *Behav. Ecol. Sociobiol.* 42:1–8.

species look similar under these conditions. In this experiment, a female of one species was placed in an aquarium that contained one male of each species within an enclosure (**Figure 24.9**). The males were within glass enclosures to prevent direct competition with each other, which would have likely affected female choice. The goal of the experiment was to determine which of the two males a female would prefer. Courtship between a male and female begins when a male swims toward a female and exhibits a lateral display (that is, shows the side of his body to the female). If the female is interested, she will approach the male, and then the male will display a quivering motion. Such courtship behavior was examined under normal light and under orange monochromatic light.

As seen in the data, Seehausen and van Alphen found that the females' preference for males was dramatically different depending on the illumination conditions. Under normal light, *P. pundamilia* females preferred *P. pundamilia* males, and *P. nyererei* females

preferred *P. nyererei* males. However, such mating preference was lost when colors were masked by artificial light. If the light conditions in their native habitats are similar to the normal light used in this experiment, female choice would be expected to separate cichlids into two populations, with *P. pundamilia* females mating with *P. pundamilia* males and *P. nyererei* females mating with *P. nyererei* males. In this case, sexual selection appears to have followed a diversifying mechanism in which certain females prefer males with one color pattern, whereas other females prefer males with a different color pattern. A possible outcome of such sexual selection is that it can separate one large population into smaller populations that selectively breed with each other and eventually become distinct species. We will discuss the topic of species formation in more depth in Chapter 25.

Experimental Questions

1. What hypothesis was tested in the Seehausen and van Alphen experiment?
2. **SciSKILLS »** Describe the experimental design for this study, illustrated in Figure 24.9. What was the purpose of conducting the experiment under the two different light conditions?
3. **SciSKILLS »** Analyze the results of the experiment in Figure 24.9, and explain what they mean with regard to sexual selection.

24.4 Genetic Drift

Learning Outcomes:

1. Define genetic drift, and explain its effects on allele frequencies over time.
2. Compare and contrast the bottleneck and founder effects.
3. Explain how neutral mutations can spread through a population.

Thus far, we have focused on natural selection as a mechanism that can promote widespread genetic changes in a population. Let's now turn our attention to a second important way the gene pool of a population can change. In the 1930s, Sewall Wright played a large role in developing the concept of **genetic drift** (also called random genetic drift), which refers to changes in allele frequencies due to random chance. The term genetic drift is derived from the observation that allele frequencies may "drift" randomly from generation to generation as a matter of chance.

Changes in allele frequencies due to genetic drift happen regardless of the fitness of individuals that carry those alleles. For example, an individual with a high fitness value may, by chance, not encounter a member of the opposite sex. Likewise, random chance can influence which alleles happen to be found in the gametes that fuse with each other in a successful fertilization. In this section, we will examine how genetic drift alters allele frequencies in populations.

Genetic Drift Has a Greater Effect in Small Populations

What are the effects of genetic drift? Over the long run, genetic drift favors either the elimination or the fixation of an allele, that is, when its frequency reaches 0% or 100% in a population, respectively. However, the number of generations it takes for an allele to be lost or fixed greatly depends on the population size. **Figure 24.10** illustrates the potential consequences of genetic drift in one large (N = 1,000) and two small (N = 10) populations (N is the number of individuals that each population contains). This simulation involves the frequency of hypothetical B and b alleles of a gene for fur color in a population of mice—B is the black allele, and b is the white allele.

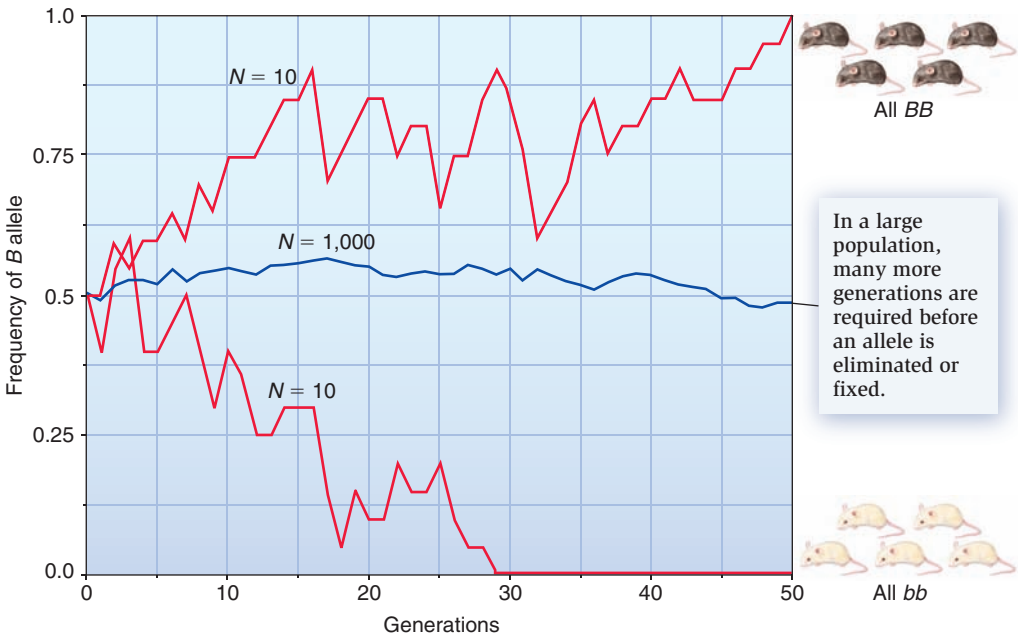


Figure 24.10 Genetic drift and population size. This graph shows three hypothetical simulations of genetic drift and their effects on small and large populations of black (B allele) and white (b allele) mice. In all cases, the starting allele frequencies are B = 0.5 and b = 0.5. The red lines illustrate two populations of mice in which N = 10; the blue line shows a population in which N = 1,000.

At the beginning of this hypothetical simulation, which ran for 50 generations, all three populations had identical allele frequencies: $B = 0.5$ and $b = 0.5$. In the small populations, the allele frequencies fluctuated substantially from generation to generation. Eventually, in one population, the *b* allele was eliminated; in another, it was fixed at 100%. These small populations then consisted of only black mice or white mice, respectively. At this point, the gene became monomorphic, and allele frequencies cannot fluctuate due to genetic drift.

By comparison, the frequencies of *B* and *b* in the large population fluctuated much less. As discussed in Chapter 16, the relative effect of random chance, termed random sampling error, is much smaller when the sample size is large. Nevertheless, genetic drift can eventually lead to allele loss or fixation even in large populations, but this will take many more generations to occur than it does in small populations.

In nature, genetic drift may rapidly alter allele frequencies when the size of a population dramatically decreases. Two examples of this phenomenon are the bottleneck effect and the founder effect, which are described next.

Bottleneck Effect A population can be dramatically reduced in size by events such as earthquakes, floods, drought, and human destruction of habitat. These occurrences may eliminate most members of the population without regard to their genetic composition. The population is said to have passed through a bottleneck. The change in allele frequencies of the resulting population due to genetic drift is called the **bottleneck effect**. Some alleles may be over-represented whereas others may even be eliminated. Such changes may happen for two reasons. First, the surviving population often has allele frequencies that differ from those of the original population that was much larger. Second, as we saw in Figure 24.10, genetic drift acts more quickly to reduce genetic variation when the population size is small. Eventually, a population that has gone through a bottleneck may regain its original size. However, the new population is likely to have less genetic variation than the original one.

A hypothetical example of the bottleneck effect is shown with a population of frogs in **Figure 24.11**. In this example, a starting population of frogs is found in three phenotypes: yellow, dark green, and striped. Due to a bottleneck caused by a drought, the dark green variety is lost from the population.

As a real-life example, the Northern elephant seal (*Mirounga angustirostris*) has lost much of its genetic variation. This was caused by a bottleneck effect in which the population decreased to approximately 20 to 30 surviving members in the 1890s due to hunting. The species has rebounded in numbers to over 100,000, but the bottleneck reduced its genetic variation to very low levels.

Founder Effect Another common phenomenon in which genetic drift may rapidly alter allele frequencies is the **founder effect**. This occurs when a small group of individuals separates from a larger population and establishes a colony in a new location. For example, a few individuals from a large population on a continent may become the founders of an island population. The founder effect differs from a bottleneck in that it occurs in a new location, although both effects are related to a reduction in population size. The founder effect has two important consequences.

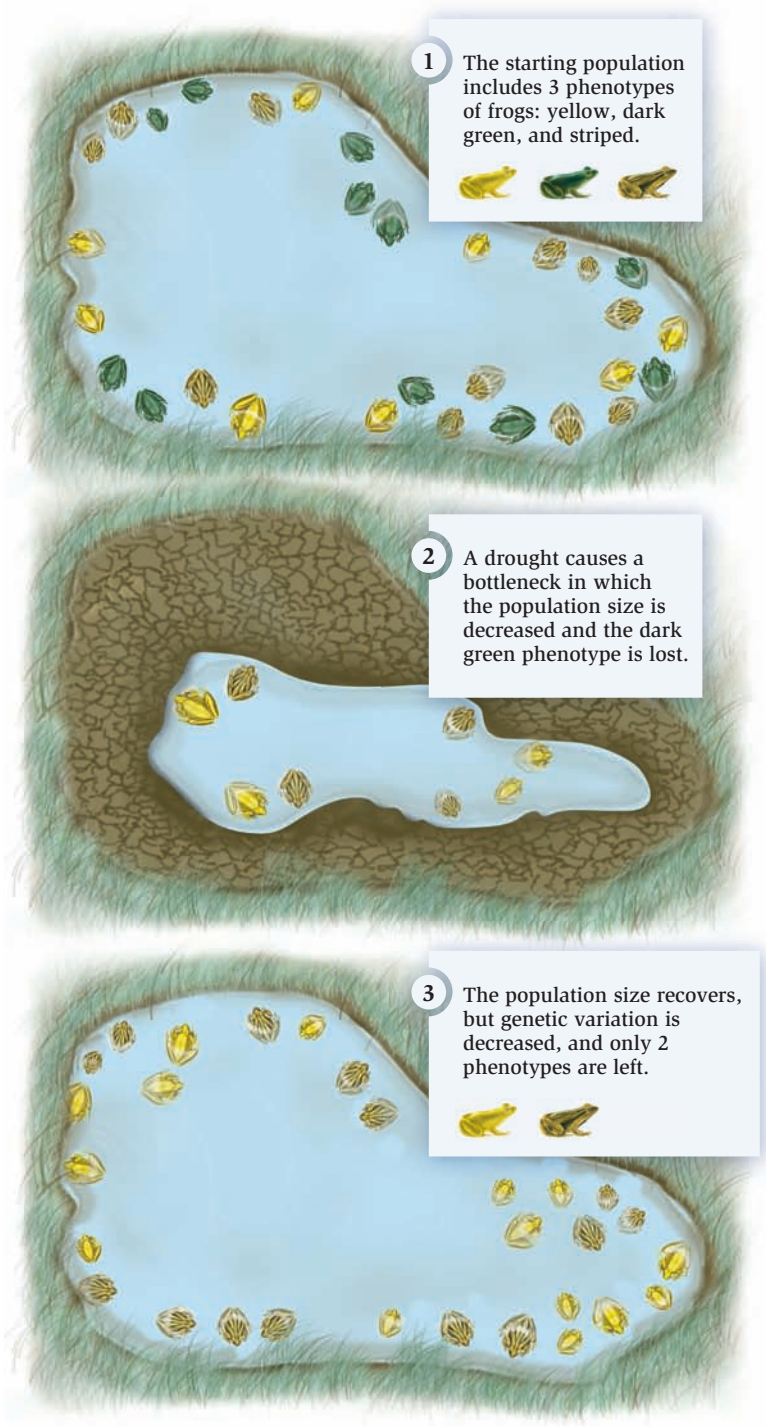

Figure 24.11 A hypothetical example of the bottleneck effect. This example involves a population of frogs in which a drought dramatically reduced population size, resulting in a bottleneck. The bottleneck reduced the genetic diversity in the population.

BIOLOGY PRINCIPLE Populations of organisms evolve from one generation to the next. Genetic drift randomly changes allele frequencies and (in the long run) leads to a loss or fixation of an allele.

Concept Check: How does the bottleneck effect undermine the efforts of conservation biologists who are trying to save species nearing extinction?

- First, the founding population, which is relatively small, is expected to have less genetic variation than the larger original population from which it was derived.
- Second, as a matter of chance, the allele frequencies in the founding population may differ markedly from those of the original population.

Population geneticists have studied many examples in which isolated populations were founded via colonization by members of another population. For example, in the 1960s, American geneticist Victor McKusick studied allele frequencies in the Amish of Lancaster County, Pennsylvania. At that time, this group included about 8,000 people, descended from just three couples that immigrated to the U.S. in 1770. Among this population of 8,000, a genetic disease known as Ellis–van Creveld syndrome (a recessive form of dwarfism) was found at a frequency of 0.07, or 7%. By comparison, this disorder is extremely rare in other human populations, even the population from which the founding members had originated. Evidence suggests that the high frequency in the Lancaster County population can be traced to one couple, one of whom carried the mutated gene that causes the syndrome.

Genetic Drift Plays an Important Role in Promoting Genetic Change

In 1968, Japanese evolutionary biologist Motoo Kimura proposed that much of the DNA sequence variation seen in genes in natural populations is the result of genetic drift rather than natural selection. Genetic drift is a random process that does not preferentially select for any particular allele—it can alter the frequencies of both beneficial and deleterious alleles. Much of the time, genetic drift promotes **neutral variation**—changes in genes and proteins that do not have an effect on reproductive success.

According to Kimura, most variation in DNA sequences is due to the accumulation of neutral mutations that have attained high frequencies in a population via genetic drift. For example, a new mutation within a gene that changes a glycine codon from GGG to GGC would not affect the amino acid sequence of the encoded protein. Both genotypes may be equal in fitness. However, such new mutations can spread throughout a population due to genetic drift (**Figure 24.12**). This phenomenon has been called **non-Darwinian evolution** and also "survival of the luckiest." Kimura agreed with Darwin that natural selection is responsible for adaptive changes in a species during evolution. The long snout of an anteater is the result of natural selection. His main idea is that much of the variation in DNA sequences is explained by neutral variation rather than adaptive variation.

The sequencing of genomes from many species is consistent with Kimura's proposal. When we examine changes of the coding sequence within structural genes, we find that nucleotide substitutions are more prevalent in the third base of a codon than in the first or second base. Mutations in the third base are often neutral; that is, they do not change the amino acid sequence of the protein (refer back to Table 12.1). In contrast, random mutations at the first or second base are more likely to be harmful than beneficial and tend to be eliminated from a population.

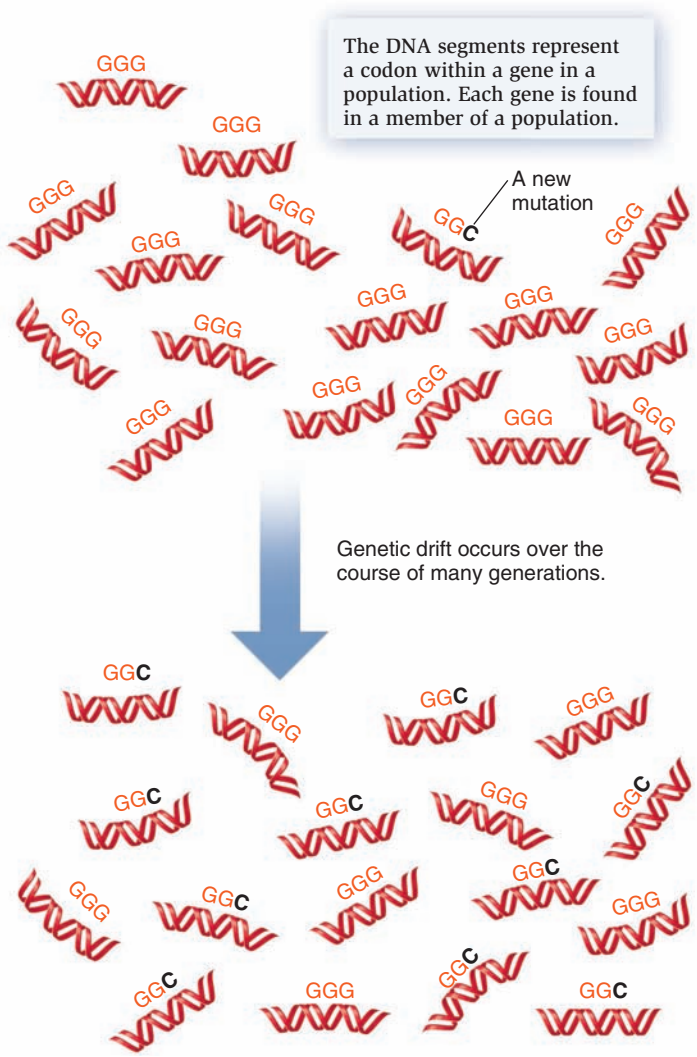

Figure 24.12 Neutral evolution in a population. In this example, a mutation within a gene changes a glycine codon from GGG to GGC, which does not affect the amino acid sequence of the encoded protein. Each gene shown represents a copy of the gene in a member of a population. Over the course of many generations, genetic drift may cause this neutral allele to become prevalent in the population, perhaps even monomorphic.

BioConnections: Look back at the genetic code described in Table 12.1. Describe three different genetic changes that you would expect to be neutral.

24.5 Migration and Nonrandom Mating

Learning Outcomes:

1. Describe how gene flow affects genetic variation in neighboring populations.
2. Define inbreeding, and explain how it may have detrimental consequences.

Thus far, we have considered how natural selection and genetic drift operate as key mechanisms that cause evolution to happen. In addition,

migration between neighboring populations and nonrandom mating may influence genetic variation and the relative proportions of genotypes. In this section, we will explore how these mechanisms work.

Migration Between Two Populations Tends to Increase Genetic Variation

Earlier in this chapter, we considered how migration to a new location by a relatively small group can result in a founding population with an altered genetic composition due to genetic drift. In addition, migration between two different established populations can alter allele frequencies. As an example, let's consider two populations of a particular species of deer that are separated by a mountain range running north and south (**Figure 24.13**). On rare occasions, a few deer from the western population may travel through a narrow pass between the mountains and become members of the eastern population. If the two populations are different with regard to genetic variation, this migration will alter the frequencies of certain alleles in the eastern population. Of course, this migration could occur in the opposite direction as well and would then affect the western population. This transfer of alleles into or out of a population, called **gene flow**, occurs whenever fertile individuals move between populations having different allele frequencies.

What are the consequences of migration? First, migration tends to reduce differences in allele frequencies between neighboring populations. Population geneticists can evaluate the extent of migration between two populations by analyzing the similarities and differences between their allele frequencies. Populations that frequently mix their gene pools via migration tend to have similar allele frequencies, whereas the allele frequencies of isolated populations are more disparate, due to the effects of natural selection and genetic drift. Second, migration tends to increase genetic diversity within populations. As discussed earlier in this chapter, new mutations are relatively rare events. Therefore, a new mutation may arise in only one population, and migration may then introduce this new allele into a neighboring population.

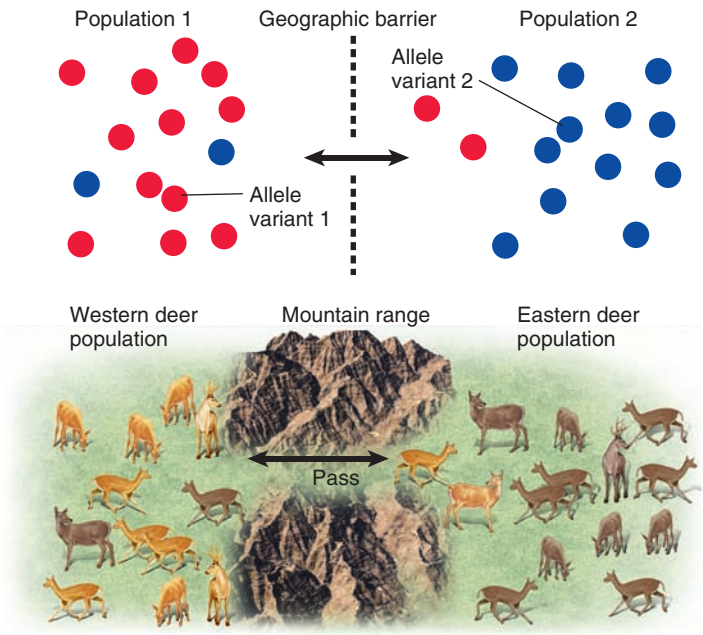

Figure 24.13 **Migration and gene flow.** In this example, two populations of a deer species are separated by a mountain range. On rare occasions, a few deer from one population travel through a narrow pass and become members of the other population. If the two populations differ in regard to genetic variation, this migration will alter the frequencies of alleles in the populations.

Concept Check: *How does migration affect the genetic compositions of populations?*

Nonrandom Mating Affects the Relative Proportion of Homozygotes and Heterozygotes in a Population

As mentioned earlier, one of the conditions required to establish Hardy-Weinberg equilibrium is random mating, which means that members of a population choose their mates irrespective of their genotypes or phenotypes. In many species, including human populations, this condition is violated. Such **nonrandom mating** takes different forms. Assortative mating occurs when individuals with similar phenotypes are more likely to mate. If the similar phenotypes are due to similar genotypes, assortative mating tends to increase the proportion of homozygotes and decrease the proportion of heterozygotes in the population. The opposite situation, where dissimilar phenotypes mate preferentially, causes heterozygosity to increase.

Another form of nonrandom mating involves the choice of mates based on their genetic history rather than their phenotypes. Individuals may choose a mate that is part of the same genetic lineage. The mating of two genetically related individuals, such as cousins, is called **inbreeding**. This sometimes occurs in human societies and is more likely to take place in nature when population size becomes very small.

In the absence of other evolutionary factors, nonrandom mating does not affect allele frequencies in a population. However, it will alter the balance of genotypes predicted by the Hardy-Weinberg equation. As an example, let's consider a human pedigree involving a mating between cousins (**Figure 24.14**). Individuals III-2 and III-3 are cousins and have produced the daughter labeled IV-1. She is said to be inbred, because her parents are genetically related. The parents of an inbred individual have one or more common ancestors. In the pedigree of Figure 24.14, I-2 is the grandfather of both III-2 and III-3.

Inbreeding increases the relative proportions of homozygotes and decreases the likelihood of heterozygotes in a population. Why does this happen? An inbred individual has a higher chance of being homozygous for any given gene because the same allele for that gene could be inherited twice from a common ancestor. For example, individual I-2 is a heterozygote, *Cc*. The *c* allele could pass from I-2 to II-2 to III-2 and finally to IV-1 (see red lines in Figure 24.14). Likewise, the *c* allele could pass from I-2 to II-3 to III-3 and then to IV-1. Therefore, IV-1 has a chance of being homozygous because she inherited both copies of the *c* allele from a common ancestor to both of her parents. Inbreeding does not favor any particular allele—it does not favor *c* over *C*—but it does increase the likelihood that an individual will be homozygous for any given gene.

Although inbreeding by itself does not affect allele frequencies, it may have negative consequences with regard to recessive alleles. Rare recessive alleles that are harmful in the homozygous condition are found in all natural populations. Such alleles do not usually pose a problem because heterozygotes carrying a rare recessive allele are also

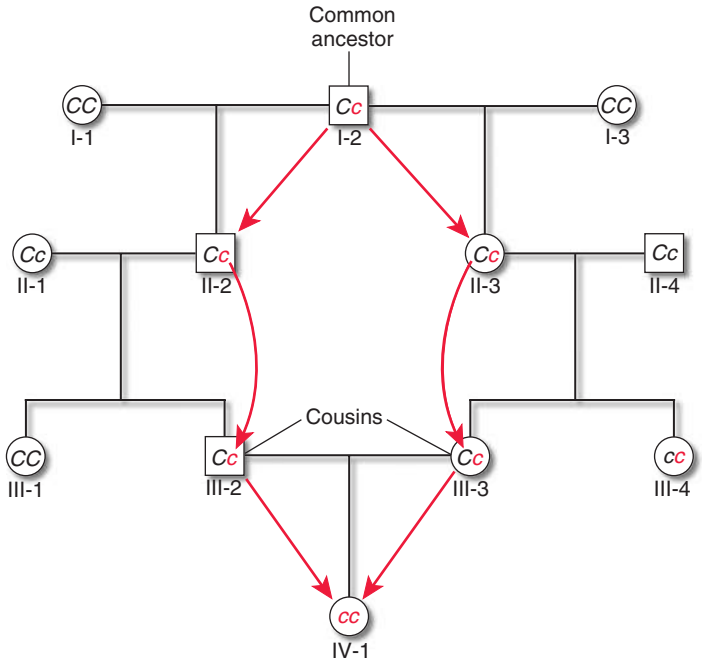

Figure 24.14 A human pedigree containing inbreeding. The parents of individual IV-1 are genetically related (cousins), and, therefore, individual IV-1 is inbred. Inbreeding increases the likelihood that an individual will be homozygous for any given gene. The red arrows show how IV-1 could become homozygous by inheriting the same allele (c) from the common ancestor (I-2) to both of her parents.

BioConnections: Many inherited human diseases show a recessive pattern of inheritance (see Table 16.2). Explain whether inbreeding would increase or decrease the likelihood of such diseases.

rare, making it very unlikely that two such heterozygotes will mate with each other. However, related individuals share some of their genes, including recessive alleles. Therefore, if inbreeding occurs, homozygous offspring are more likely to be produced. For example, rare recessive diseases in humans are more frequent when inbreeding occurs.

In natural populations, inbreeding lowers the mean fitness of the population if homozygous offspring have lower fitness values. This can be a serious problem as natural populations become smaller due to human destruction of habitat. As a population shrinks, inbreeding becomes more likely because individuals have fewer potential mates from which to choose. The inbreeding, in turn, produces homozygotes that are less fit, thereby decreasing the reproductive success of the population. This phenomenon is called **inbreeding depression**. Conservation biologists sometimes try to circumvent this problem by introducing individuals from one population into another. For example, the endangered Florida panther (*Puma concolor coryi*) suffers from inbreeding-related defects, which include poor sperm quality and quantity, and morphological abnormalities. To alleviate these effects, panthers from Texas have been introduced into the Florida population of panthers.

Summary of Key Concepts

24.1 Genes in Populations

- Population genetics is the study of genes and genotypes in a population. A population is a group of individuals of the same species that occupy the same environment and can interbreed. All of the alleles for every gene in a population constitute a gene pool.
- Polymorphism, which is very common in nearly all populations, refers to two or more variants of a character in a population. In contrast, a monomorphic gene exists as a single allele (>99%) in a population (Figure 24.1).
- Allele frequency is the number of copies of a specific allele divided by the total number of all alleles in a population. Genotype frequency is the number of individuals with a given genotype divided by the total number of individuals in a population.
- The Hardy-Weinberg equation ($p^2 + 2pq + q^2 = 1$) predicts that allele and genotype frequencies will remain in equilibrium if no new mutations are formed, no natural selection occurs, the population size is very large, migration does not occur, and mating is random (Figure 24.2).
- Sources of new genetic variation include random gene mutations, gene duplications, and horizontal gene transfer. Natural selection, genetic drift, migration, and nonrandom mating may alter allele and genotype frequencies and cause a population to evolve (Table 24.1).

24.2 Natural Selection

- Natural selection is the process by which individuals with certain heritable traits that favor survival and reproduction tend to become more prevalent in a population. Fitness, the relative likelihood that a genotype will contribute to the gene pool of the next generation, is a measure of reproductive success.
- Directional selection is the process in which one extreme of a phenotypic distribution is favored (Figure 24.3).
- Stabilizing selection is the process in which an intermediate phenotype is favored (Figure 24.4).
- Diversifying selection is the process in which two or more phenotypes are favored. An example is a population that occupies a heterogeneous environment (Figure 24.5).
- Balancing selection maintains genetic polymorphism in a population. Examples include heterozygote advantage and negative frequency-dependent selection (Figure 24.6).

24.3 Sexual Selection

- Sexual selection is a form of natural selection in which individuals with certain traits are more likely than others to breed with another individual. In intrasexual selection, members of one sex compete for the opportunity to mate with individuals of the opposite sex. In intersexual selection, members of one sex choose their mates on the basis of certain desirable characteristics (Figure 24.7).
- Seehausen and van Alphen discovered that female cichlids' choice of mates is influenced by male coloration. This is an example of sexual selection (Figures 24.8, 24.9).

24.4 Genetic Drift

- Genetic drift involves changes in allele frequencies over time due to chance events. It occurs more rapidly in small populations and leads to either the elimination or the fixation of alleles (Figure 24.10).
- In the bottleneck effect, an environmental event dramatically reduces a population size, and the allele frequencies of the resulting population change due to genetic drift (Figure 24.11).

- The founder effect occurs when a small population moves to a new geographic location and genetic drift alters the genetic composition of that population.
- Kimura proposed that genetic drift promotes the accumulation of neutral genetic changes that do not affect reproductive success. Much of the genetic variation in DNA sequences in populations appears to be the result of genetic drift rather than natural selection (Figure 24.12).

24.5 Migration and Nonrandom Mating

- Gene flow occurs when individuals migrate between populations with different allele frequencies. It reduces differences in allele frequencies between populations and enhances genetic diversity (Figure 24.13).
- Inbreeding, a form of nonrandom mating in which genetically related individuals have offspring with each other, tends to increase the proportion of homozygotes relative to heterozygotes. When the resulting homozygotes have lower fitness, this phenomenon is called inbreeding depression (Figure 24.14).

Assess and Discuss

Test Yourself

1. Population geneticists are interested in the genetic variation in populations. The most common type of genetic change that causes polymorphism in a population is
   a. a deletion of a gene sequence.
   b. a duplication of a region of a gene.
   c. a rearrangement of a gene sequence.
   d. a single-nucleotide substitution.
   e. an inversion of a segment of a chromosome.
2. The Hardy-Weinberg equation characterizes the allele and genotype frequencies
   a. of a population that is experiencing selection for mating success.
   b. of a population that is extremely small.
   c. of a population that is very large and not evolving.
   d. of a community of species that is not evolving.
   e. of a community of species that is experiencing selection.
3. In the Hardy-Weinberg equation, what portion represents the frequency of individuals that do not exhibit a recessive disease but are carriers of a recessive allele?
   a. q c. $2pq$ e. both b and d
   b. p^2 d. q^2
4. By itself, which of the following is *not* likely to have a major influence on allele frequencies?
   a. natural selection d. inbreeding
   b. genetic drift e. both c and d
   c. mutation
5. Which of the following statements is correct regarding mutations?
   a. Mutations are not important in evolution.
   b. Mutations provide the source for genetic variation, but other evolutionary factors are more important in determining allele frequencies in a population.
   c. Mutations occur at such a high rate that they promote major changes in the gene pool from one generation to the next.
   d. Mutations are of greater importance in smaller populations than in larger ones.
   e. Mutations are of greater importance in larger populations than in smaller ones.
6. In a population of fish, body coloration varies from a light shade, almost white, to a very dark shade of green. If changes in the environment resulted in decreased predation of individuals with the lightest coloration, this would be an example of _____ selection.
   a. diversifying c. directional e. artificial
   b. stabilizing d. sexual
7. Considering the same population of fish described in question 6, if the stream environment included several areas of sandy, light-colored bottom areas and a lot of dark-colored vegetation, both the light- and dark-colored fish would have selective advantage and increased survival in certain places. This type of scenario could explain the occurrence of
   a. genetic drift. d. stabilizing selection.
   b. diversifying selection. e. sexual selection.
   c. mutation.
8. The microevolutionary factor most sensitive to population size is
   a. mutation. c. selection. e. all of the above.
   b. migration. d. genetic drift.
9. Kimura's proposal regarding neutral mutations differs from Darwinian evolution in that
   a. natural selection does not exist.
   b. most of the genetic variation in a population is due to neutral mutations, which do not affect reproductive success.
   c. neutral variation alters survival and reproductive success.
   d. neutral mutations are not affected by population size.
   e. both b and c.
10. Populations that experience inbreeding may also experience
    a. a decrease in fitness due to an increased frequency of recessive genetic diseases.
    b. an increase in fitness due to increases in heterozygosity.
    c. very little genetic drift.
    d. no apparent change.
    e. increased mutation rates.

Conceptual Questions

1. The percentage of individuals exhibiting a recessive disease in a population is 0.04, which is 4%. Based on the Hardy-Weinberg equation, what percentage of individuals would be expected to be heterozygous carriers?
2. Compare and contrast the four patterns of natural selection that lead to environmental adaptation. You should also discuss sexual selection.
3.  A principle of biology is that *populations of organisms evolve from one generation to the next*. Explain how genetic drift results in evolution.

Collaborative Questions

1. Antibiotics are commonly used to combat bacterial and fungal infections. During the past several decades, however, antibiotic-resistant strains of microorganisms have become alarmingly prevalent. This has undermined the ability of physicians to treat many types of infectious disease. Discuss how the following processes that alter allele frequencies may have contributed to the emergence of antibiotic-resistant strains:
   a. random mutation
   b. genetic drift
   c. natural selection
2. Discuss the similarities and differences among directional, disruptive, balancing, and stabilizing selection.

CHAPTER OUTLINE

25.1 Identification of Species
25.2 Mechanisms of Speciation
25.3 The Pace of Speciation
25.4 Evo-Devo: Evolutionary Developmental Biology
Summary of Key Concepts
Assess and Discuss

Origin of Species and Macroevolution

25

Two different species of zebras. Grevy's zebra (*Equus grevyi*) is shown on the left, and Grant's zebra (*Equus quagga boehmi*), which has fewer and thicker stripes, is shown on the right.

The origin of living organisms has been described by philosophers as the great "mystery of mysteries." Perhaps that is why so many different views have been put forth to explain the existence of living species. At the time of Aristotle (4th century B.C.E.), most people believed that some living organisms came into being by spontaneous generation—the idea that nonliving materials can give rise to living organisms. For example, it was commonly believed that worms and frogs could arise from mud, and mice could come from grain. By comparison, many religious teachings contend that species were divinely made and have remained the same since their creation. In contrast to these ideas, the work of Charles Darwin provided the scientific theory of evolution by descent with modification. Darwin's work, and that of subsequent biologists, helps us to understand the diversity of life, and in particular, it presents a logical explanation for how new species can evolve from pre-existing species.

This chapter provides an exciting way to build on the information that we have considered in previous chapters. In Chapter 22, we examined how the first primitive cells in an RNA world could have evolved into prokaryotic cells and eventually eukaryotes. Chapter 23 surveyed the tenets on which the theory of evolution is built, and in Chapter 24, we viewed microevolution—evolution on a small scale as it relates to allele frequencies in a population. In this chapter, we will consider evolution on a larger scale. **Macroevolution** refers to evolutionary changes that produce new species and groups of species.

To biologists, the concept of a **species** has come to mean a group of related organisms that share a distinctive set of attributes in nature. Members of the same species share an evolutionary history, which makes them more genetically similar to each other than they are to members of a different species. You may already have an intuitive sense of this concept. It is obvious that zebras and mice are different species. However, as we will see in the first section of this chapter, the distinction between different, closely related species is often blurred in natural environments. Two closely related species may look very similar, as the chapter opening photo illustrates. Species identification has several practical uses. For example, it allows biologists to plan for the preservation and conservation of endangered species. In addition, it is often important for a physician to correctly identify the bacterial species that is causing a disease in a patient so the proper medication can be prescribed.

In this chapter, we will also focus on the mechanisms that promote the formation of new species, a phenomenon called **speciation**. Such macroevolution typically occurs by the accumulation of microevolutionary changes, those that occur in single genes (see Chapter 24). We will also consider how macroevolution can happen at a fast or slow pace and explore how variations in the genes that control development play a role in the evolution of new species.

25.1 Identification of Species

Learning Outcomes:

1. Outline the characteristics that biologists use to distinguish different species.
2. Describe different species concepts.
3. Compare and contrast prezygotic and postzygotic isolating mechanisms.

How many different species are on Earth? The number is astounding. A study done by American biologist E. O. Wilson and colleagues in 1990 estimated the known number of species at approximately 1.4 million. Currently, about 1.8 million species have been identified and catalogued. However, a vast number of species have yet to be classified. This is particularly true among bacteria and archaea, which are difficult to categorize into distinct species. Also, new invertebrate and even vertebrate species are still being found in the far reaches of pristine habitats. Common estimates of the total number of species range from 5 to 50 million!

When studying natural populations, evolutionary biologists are often confronted with situations in which some differences between two populations are apparent, but it is difficult to decide whether the two populations truly represent separate species. When two or more geographically restricted groups of the same species display one or more traits that are somewhat different but not enough to warrant their placement into different species, biologists sometimes classify such groups as **subspecies**. Similarly, many bacterial species are subdivided into **ecotypes**. Each ecotype is a genetically distinct population adapted to its local environment. In this section, we will consider the characteristics that biologists examine when deciding if two groups of organisms constitute different species.

Each Species Is Established Using Characteristics and Histories That Distinguish It from Other Species

As mentioned, a species is a group of organisms that share a distinctive set of attributes in nature. In the case of sexually reproducing species, members of one species usually cannot successfully interbreed with members of other species. Members of the same species share an evolutionary history that is distinct from other species. Although this may seem like a reasonable way to characterize a given species, biologists would agree that distinguishing between species is a more difficult undertaking. What criteria do we use to distinguish species? How many differences must exist between two populations to classify them as different species? Such questions are often difficult to answer.

The characteristics that a biologist uses to identify a species depend, in large part, on the species in question. For example, the traits used to distinguish insect species are quite different from those used to identify different bacterial species. The relatively high level of horizontal gene transfer among bacteria presents special challenges in the grouping of bacterial species. Among bacteria, it is sometimes very difficult and perhaps arbitrary to divide closely related organisms into separate species.

The most commonly used characteristics for identifying species are morphological traits, the ability to interbreed, molecular features, ecological factors, and evolutionary relationships. A comparison of these concepts will help you appreciate the various approaches that biologists use to identify the bewildering array of species on our planet.

Morphological Traits One way to establish that a population constitutes a unique species is based on their physical characteristics. Organisms are classified as the same species if their anatomical traits appear to be very similar. Likewise, microorganisms can be classified according to morphological traits at the cellular level. By comparing many different morphological traits, biologists may decide that certain populations constitute unique species.

Although an analysis of morphological traits is a common way for biologists to establish that a particular group constitutes a species, this approach has drawbacks. First, researchers may have difficulty deciding how many traits to consider. In addition, quantitative traits, such as size and weight, that vary in a continuous way among members of the same species are not easy to analyze. Another drawback is that the degree of dissimilarity that distinguishes different species may not show a simple relationship. The members of the same species sometimes look very different, and conversely, members of different species sometimes look remarkably similar to each other. For example, **Figure 25.1a** shows two different frogs of the species

(a) Frogs of the same species

(b) Frogs of different species

Figure 25.1 Difficulties of using morphological traits to identify species. In some cases, members of the same species appear quite different. In other cases, members of different species look very similar. **(a)** Two frogs of the same species, the dyeing poison frog (*Dendrobates tinctorius*). **(b)** Two different species of frog, the northern leopard frog (*Rana pipiens*, left) and the southern leopard frog (*Rana utricularia*, right).

Concept Check: *Can you think of another example of two different species that look very similar?*

Dendrobates tinctorius, commonly called the dyeing poison frog. This species exists in many different-colored morphs, which are individuals of the same species that have noticeably dissimilar appearances. In contrast, **Figure 25.1b** shows two different species of frogs, the northern leopard frog (*Rana pipiens*) and the southern leopard frog (*Rana utricularia*), which look fairly similar.

Reproductive Isolation Why would biologists describe two species, such as the northern leopard frog and southern leopard frog, as being different if they are morphologically similar? One reason is that biologists have discovered that the two types of frogs are unable to breed with each other in nature. Therefore, a second way of identifying a species is by its ability to interbreed. In the late 1920s, geneticist Theodosius Dobzhansky proposed that each species is reproductively isolated from other species. Such **reproductive isolation** prevents one species from successfully interbreeding with other species. In 1942, German evolutionary biologist Ernst Mayr expanded on the ideas of Dobzhansky to provide a definition of a species. According to Mayr, a key feature of sexually reproducing species is that, in nature, the members of one species have the potential to interbreed with one another to produce viable, fertile offspring but cannot successfully interbreed with members of other species. As discussed later in this section, reproductive isolation among species of plants and animals occurs by an amazing variety of different mechanisms.

Reproductive isolation has been used to distinguish many plant and animal species, especially those that look alike but do not interbreed. Even so, this criterion suffers from four main problems.

- First, in nature, it may be difficult to determine if two populations are reproductively isolated, particularly if the populations have nonoverlapping geographic ranges.
- Second, biologists have noted many cases in which two different species can interbreed in nature yet consistently maintain themselves as separate species. For example, different species of yucca plants, such as *Yucca pallida* and *Yucca constricta*, do interbreed in nature yet typically maintain populations with distinct characteristics. For this reason, they are viewed as distinct species.
- A third drawback of reproductive isolation is that it does not apply to asexual species such as bacteria. Likewise, some species of plants and fungi reproduce only asexually.
- Finally, a fourth drawback is that reproductive isolation cannot be applied to extinct species.

For these reasons, reproductive isolation has been primarily used to distinguish closely related species of modern animals and plants that reproduce sexually.

Molecular Features Molecular features are now commonly used to determine if two different populations are different species. Evolutionary biologists often compare DNA sequences of genes, gene order along chromosomes, chromosome structure, and chromosome number in order to identify similarities and differences among different populations. For example, researchers may compare the DNA sequence of the *16S rRNA* gene between different bacterial populations as a way of determining if two populations represent different species. When the sequences are very similar, such populations would probably be judged as the same species. However, it may be difficult to draw the line when separating groups into different species. How much difference must be present for species to be considered separate? Is a 2% difference in their genome sequences sufficient to warrant placement into two different species, or do we need a 5% difference?

Ecological Factors A variety of factors related to an organism's habitat may be used to distinguish one species from another. For example, certain species of warblers are distinguished by the habitat in which they forage for food. Some species search the ground for food, others forage in bushes or small trees, and some species primarily forage in tall trees. Such habitat differences are used to distinguish different species that look morphologically similar.

Many bacterial species have been categorized as distinct based on ecological factors. Bacterial cells of the same species are likely to use the same resources (such as sugars and vitamins) and grow under the same conditions (such as temperature and pH). However, a drawback of this approach is that different groups of bacteria sometimes display very similar growth characteristics, and even the same species may show great variation in the growth conditions it will tolerate.

Evolutionary Relationships In Chapter 26, we will examine the methods that are used to produce evolutionary trees that describe the relationships between ancestral species and modern species. In some cases, such relationships are based on an analysis of the fossil record. For example, in Chapter 26, we will consider how the fossil record was used to construct a tree that shows the ancestors that led to modern horse species. Alternatively, another way of establishing evolutionary relationships is by the analysis of DNA sequences. Researchers obtain samples of cells from different individuals and compare the genes within those cells to see how similar or different they are.

BIO TIPS

THE QUESTION *A biologist has discovered two populations of snakes that live on opposite sides of a large canyon. The snakes look very similar, but those on the western side of the canyon have a red spot on the top of their head, whereas those on the eastern side have an orange spot. How would decide if these two populations represent one species or two species?*

TOPIC ***What topic in biology does this question address?*** The topic is species identification. More specifically, the question is about deciding if two different populations of snakes are the same or different species.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** In the question, you are given information about two populations of snakes that are found on opposite sides of a canyon. From your understanding of the topic, you may remember that biologists analyze five different characteristics to identify species: (1) morphological traits, (2) reproductive isolation (the ability to interbreed), (3) molecular features, (4) ecological factors, and (5) evolutionary relationships.

PROBLEM-SOLVING STRATEGY ***Design an experiment. Interpret data.*** One strategy for solving this problem is to design an experiment based on one of the five characteristics that biologists use to identify species.

ANSWER *Here are two possible experimental designs:*

1. *Reproductive isolation. Move a few snakes from the western side to the eastern side, and vice versa. Observe whether or not the introduced snakes interbreed with the ones already there. If they do readily interbreed, you can probably conclude that they are not separate species. Alternatively, if they don't interbreed, you may conclude that the two populations are reproductively isolated and are different species.*
2. *Molecular features. Obtain samples of cells from several western and eastern snakes, and analyze their genetic material. If the gene sequences are very similar and the chromosomal composition is very similar, you may conclude they are same species. Alternatively, if the gene sequences show significant differences and the chromosomes differ with regard to structure and/or number, you may conclude the two populations are different species.*

Species Concepts Emphasize Particular Features to Define and Distinguish Species

A **species concept** is a way of defining the concept of a species and/or of providing an approach to distinguish one species from another. Since 1942, over 20 different species concepts have been proposed by a variety of evolutionary biologists.

Biological Species Concept Ernst Mayr proposed one of the first species concepts, called the **biological species concept**. According to Mayr's concept, a species is a group of individuals whose members have the potential to interbreed with one another in nature to produce viable, fertile offspring but cannot successfully interbreed with members of other species. The biological species concept emphasizes reproductive isolation as the most important criterion for delimiting species.

Evolutionary Lineage Concept Another example of a species concept is the **evolutionary lineage concept** proposed by American paleontologist George Gaylord Simpson in 1961. A **lineage** is a series of species that forms a line of descent, with each new species the direct result of speciation from an immediate ancestral species. According to Gaylord, species should be defined based on the separate evolution of lineages.

Ecological Species Concept A third example is the **ecological species concept**, described by American evolutionary biologist Leigh Van Valen in 1976. According to this viewpoint, each species occupies an ecological niche, which is the unique set of habitat resources that a species requires, as well as its influence on the environment and other species.

General Lineage Concept Most evolutionary biologists would agree that different methods are needed to distinguish the vast array of species on Earth. Even so, some evolutionary biologists have questioned whether it is valid to have many different species concepts. In 1998, American zoologist Kevin de Queiroz suggested that there is only a single general species concept, which concurs with Simpson's evolutionary lineage concept and includes all previous concepts. According to de Queiroz's **general lineage concept**, each species is a population of an independently evolving lineage. Each species has evolved from a specific series of ancestors and, as a consequence, forms a group of organisms with a particular set of characteristics. Multiple criteria are used to determine if a population is part of an independent evolutionary lineage, and thus a species, which is distinct from others. Typically, researchers use analyses of morphology, reproductive isolation, DNA sequences, and ecology to determine if a population or group of populations is distinct from others. Because of its generality, the general lineage concept has received significant support.

Reproductive Isolating Mechanisms Help to Maintain the Distinctiveness of Each Species

Thus far we have considered various ways of differentiating species. From the discussion, you may have realized that the identification of a species is not always a simple matter. The phenomenon of reproductive isolation has played a major role in the way biologists study plant and animal species, partly because it identifies a possible mechanism for the process of forming new species. For this reason, much research has been done to try to understand **reproductive isolating mechanisms**, the mechanisms that prevent interbreeding between different species. Why do reproductive isolating mechanisms occur? Populations do not intentionally erect these reproductive barriers. Rather, reproductive isolation is a consequence of genetic changes that occur usually because a species becomes adapted to its own particular environment. The view of evolutionary biologists is that reproductive isolation typically evolves as a by-product of genetic divergence. Over time, as a species evolves its own unique characteristics, some of those traits are likely to prevent breeding with other species.

Reproductive isolating mechanisms fall into two categories: **prezygotic isolating mechanisms**, which prevent the formation of a zygote, and **postzygotic isolating mechanisms**, which block the development of a viable and fertile individual after fertilization has taken place. **Figure 25.2** summarizes some of the more common ways that reproductive isolating mechanisms prevent reproduction between different species. When two species do produce offspring, such an offspring is called an **interspecies hybrid**.

Prezygotic Isolating Mechanisms We will consider five types of prezygotic isolating mechanisms.

Habitat Isolation: One obvious way to prevent interbreeding is for members of different species to never come in contact with each other. This phenomenon, called habitat isolation, may involve a geographic barrier to interbreeding. For example, a large body of water may separate two different plant species that live on nearby islands.

Temporal Isolation: In temporal isolation, species happen to reproduce at different times of the day or year. In the northeastern U.S., for example, the two most abundant field crickets, *Gryllus veletis* and *Gryllus pennsylvanicus* (spring and fall field crickets, respectively), do not differ in song or habitat and are morphologically very similar

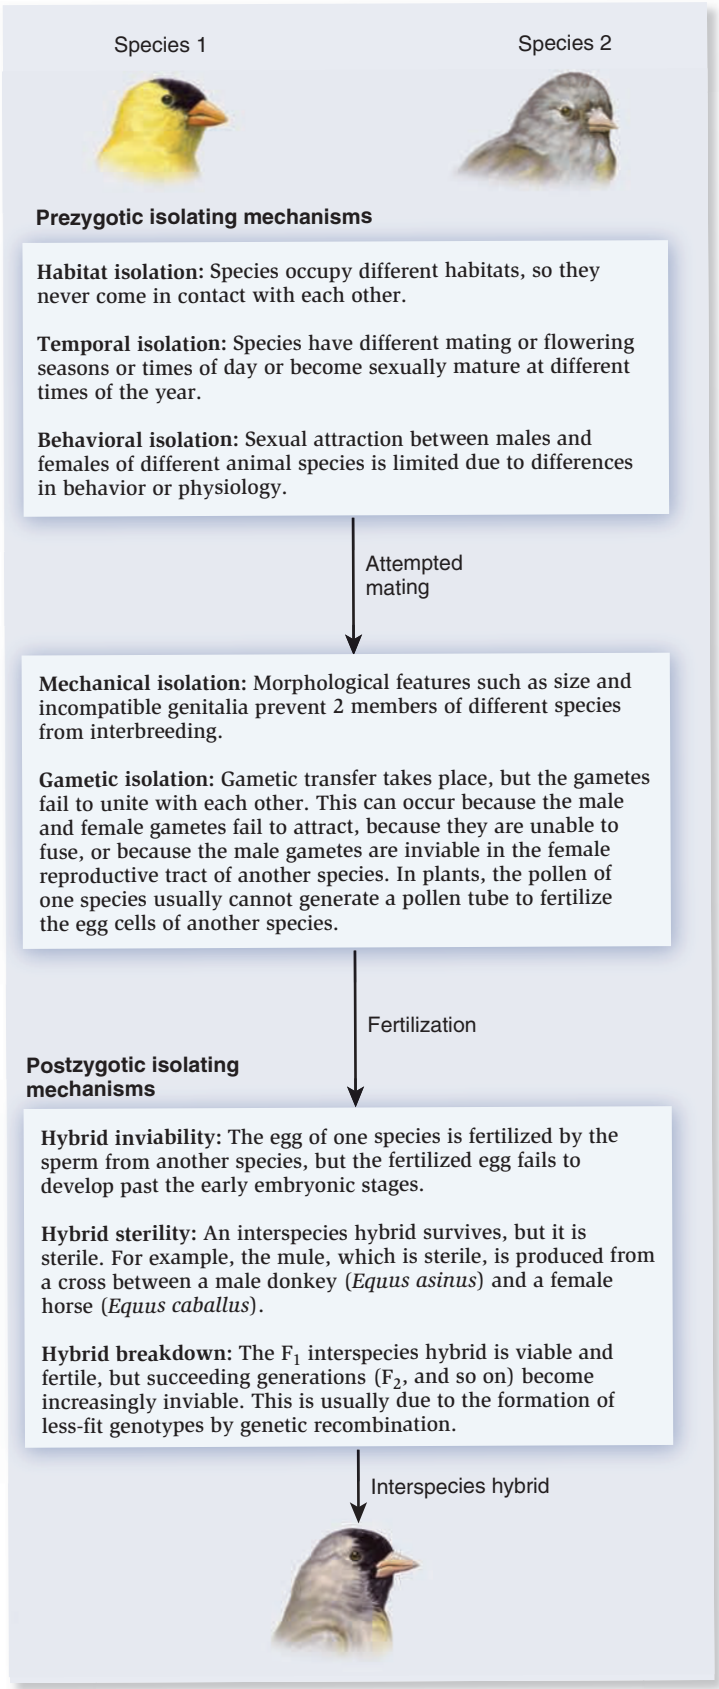

Figure 25.2 Reproductive isolating mechanisms. These mechanisms prevent successful breeding between different species. They can occur prior to fertilization (prezygotic) or after fertilization (postzygotic).

BioConnections: Look back at Figure 24.9. Is female choice an example of a prezygotic or postzygotic isolating mechanism?

(a) Spring field cricket (*Gryllus veletis*) **(b) Fall field cricket (*Gryllus pennsylvanicus*)**

Figure 25.3 Temporal isolation. Interbreeding between these two species of crickets does not usually occur because *Gryllus veletis* matures in the spring, whereas *Gryllus pennsylvanicus* matures in the fall.

Concept Check: Is this an example of a prezygotic or a postzygotic isolating mechanism?

(**Figure 25.3**). How do the two species maintain reproductive isolation? *G. veletis* matures in the spring, whereas *G. pennsylvanicus* matures in the fall. This minimizes interbreeding between the two species.

Behavioral Isolation: In the case of animals, mating behavior and anatomy often play key roles in promoting reproductive isolation. An example of the third type of prezygotic isolation, behavioral isolation, is found between the western meadowlark (*Sturnella neglecta*) and eastern meadowlark (*Sturnella magna*). Both species are nearly identical in shape, coloration, and habitat, and their ranges overlap in the central U.S. (**Figure 25.4**). For many years, they were thought to be the same species. When biologists discovered that the western meadowlark is a separate species, it was given the species name *S. neglecta* to reflect the long delay in its recognition. In the zone of overlap, very little interspecies mating takes place between western and eastern meadowlarks, largely due to differences in their songs. The song of the western meadowlark is a long series of flutelike gurgling notes that go down the scale. By comparison, the eastern meadowlark's song is a simple series of whistles, typically about four or five notes. These differences in songs enable meadowlarks to recognize potential mates as members of their own species.

Mechanical Isolation: A fourth type of prezygotic isolation, called mechanical isolation, occurs when morphological features such as size or incompatible genitalia prevent two species from interbreeding. For example, male dragonflies use a pair of special appendages to grasp females during copulation. When a male tries to mate with a female of a different species, his grasping appendages do not fit her body shape.

Gametic Isolation: A fifth type of prezygotic isolating mechanism occurs when two species attempt to interbreed, but the gametes fail to unite in a successful fertilization event. This phenomenon, called gametic isolation, is widespread among plant and animal species. In aquatic animals that release sperm and egg cells into the water, gametic isolation is important in preventing interspecies hybrids. For example, closely related species of sea urchins may release sperm and eggs into the water at the same time. Researchers have discovered that

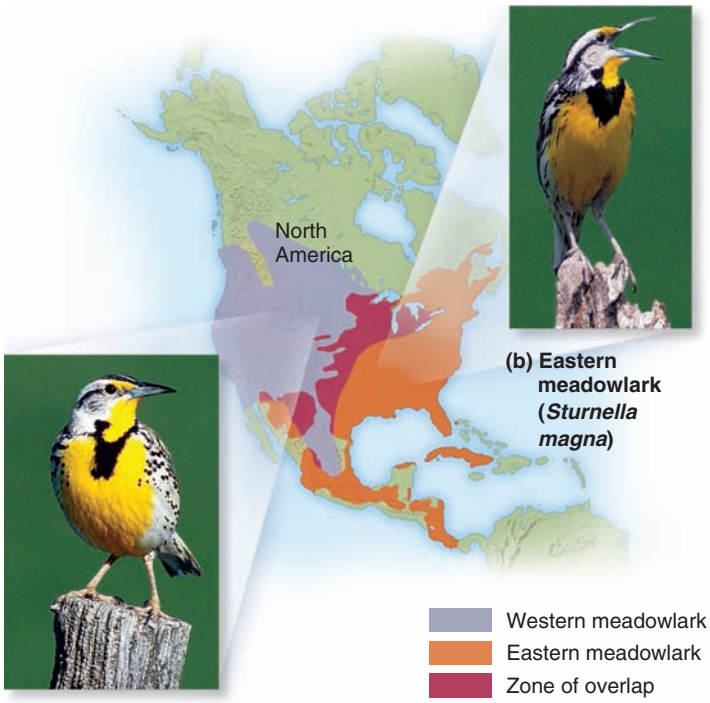

Figure 25.4 Behavioral isolation. **(a)** The western meadowlark (*Sturnella neglecta*) and **(b)** eastern meadowlark (*Sturnella magna*) are very similar in appearance. The red region in this map shows where the two species' ranges overlap. However, very little interspecies mating takes place due to differences in their songs.

BIOLOGY PRINCIPLE Populations of organisms evolve from one generation to the next. For these two species of meadowlarks, one evolutionary change that took place is that their mating songs became different.

sea urchin sperm have a protein on their surface called bindin, which mediates sperm-egg attachment and membrane fusion. The structure of bindin is significantly different among different sea urchin species, thereby ensuring that fertilization occurs only between sperm and egg cells of the same species.

In flowering plants, gametic isolation is commonly associated with pollination. As discussed in Chapter 39, plant fertilization is initiated when a pollen grain lands on the stigma of a flower and sprouts a pollen tube that ultimately reaches an egg cell (look ahead to Figure 39.4). When pollen is released from a plant, it could be transferred to the stigma of many different plant species. In most cases, when a pollen grain lands on the stigma of a different species, it either fails to generate a pollen tube or the tube does not grow properly and reach the egg cell.

Postzygotic Isolating Mechanisms Let's now turn to postzygotic mechanisms of reproductive isolation, of which there are three common types.

Hybrid Inviability: The mechanism of hybrid inviability occurs when an egg of one species is fertilized by a sperm from another species, but the fertilized egg cannot develop past the early embryonic stages.

Hybrid Sterility: A second postzygotic isolating mechanism is hybrid sterility, in which an interspecies hybrid may be viable but sterile. A classic example of hybrid sterility is the mule, which is produced by a mating between a male donkey (*Equus asinus*) and a female horse (*Equus ferus caballus*) (**Figure 25.5**). All male mules and most female mules are sterile. Why are mules usually sterile? Two reasons explain the sterility. Because the horse has 32 chromosomes per set and a donkey has 31, a mule inherits 63 chromosomes (32 + 31). Due to the uneven number, all of the chromosomes cannot pair evenly. Also, the chromosomes of the horse and donkey have structural differences, which either prevent them from pairing correctly or lead to chromosomal abnormalities if crossing over occurs during meiosis. For these reasons, mules usually produce inviable gametes. Note that the mule has no species name because it is not considered a species due to this sterility.

Hybrid Breakdown: Finally, interspecies hybrids may be viable and fertile, but the subsequent generation(s) may harbor genetic abnormalities that are detrimental. This third mechanism, called hybrid breakdown, can be caused by changes in chromosome structure. The chromosomes of closely related species may have structural differences from each other, such as inversions. In hybrids, a crossover may occur in the region that is inverted in one species but not the other. This will produce gametes with too little or too much genetic material. Such hybrids often have offspring with developmental abnormalities.

Postzygotic isolating mechanisms tend to be uncommon in nature compared with prezygotic mechanisms. Why are postzygotic mechanisms rare? One explanation is that they are more costly in terms of

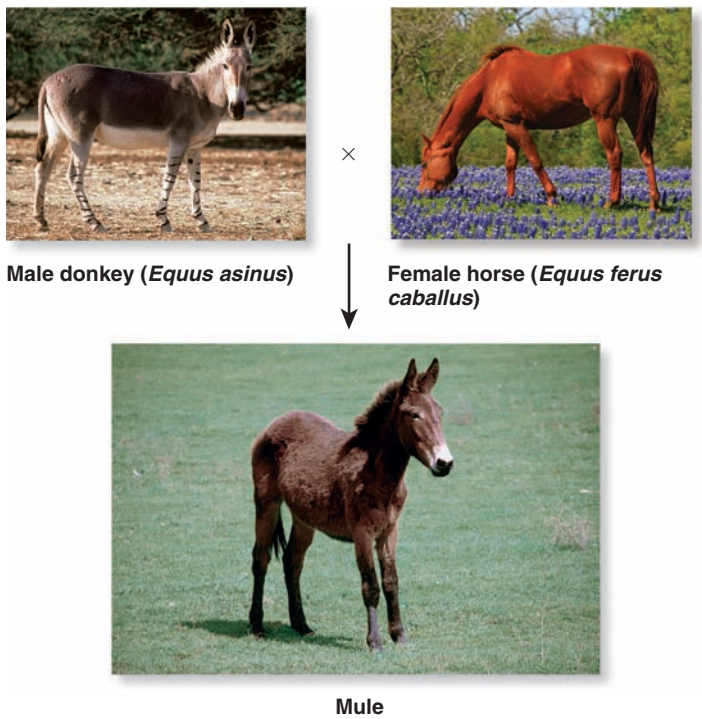

Figure 25.5 Hybrid sterility. When a male donkey (*Equus asinus*) mates with a female horse (*Equus ferus caballus*), their offspring is a mule, which is usually sterile.

Concept Check: Is this an example of a prezygotic or a postzygotic isolating mechanism?

energy and resources used. For example, a female mammal would use a large amount of energy to produce an offspring that is sterile. Evolutionary biologists hypothesize that natural selection has favored prezygotic isolating mechanisms because they do not waste a lot of energy.

25.2 Mechanisms of Speciation

Learning Outcomes:

1. Describe how allopatric speciation can occur and how it can lead to adaptive radiation.
2. Outline three different mechanisms of sympatric speciation.

Speciation, the formation of a new species, is caused by genetic changes in a particular group that make it different from the species from which it was derived. As discussed in Chapter 24, mutations in genes can be acted on by natural selection and other evolutionary mechanisms to alter the genetic composition of a population. New species commonly evolve in this manner. In addition, interspecies matings, changes in chromosome number, and horizontal gene transfer may also contribute to the formation of new species. In all of these cases, the underlying cause of speciation is the accumulation of genetic changes that ultimately promote enough differences that a population can be recognized as a unique species.

Even though genetic changes account for the phenotypic differences observed among living organisms, such changes do not fully explain the existence of many distinct species on our planet. Why does life often diversify into the more or less discrete populations that we recognize as species? Two main explanations have been proposed:

1. In some cases, speciation may occur due to abrupt events, such as changes in chromosome number, that cause reproductive isolation.
2. More commonly, species arise as a consequence of adaptation to different ecological niches. For sexually reproducing organisms, reproductive isolation is typically a by-product of that adaptation.

Depending on the species involved, one or both factors may play a dominant role in the formation of new species. In this section, we will consider how reproductive isolating mechanisms and adaptation to particular environments are critical aspects of the speciation process.

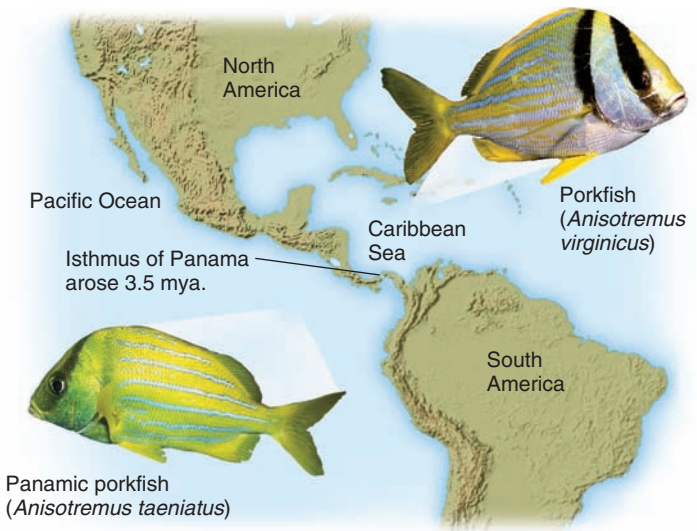
Geographic and Habitat Isolation Can Promote Allopatric Speciation

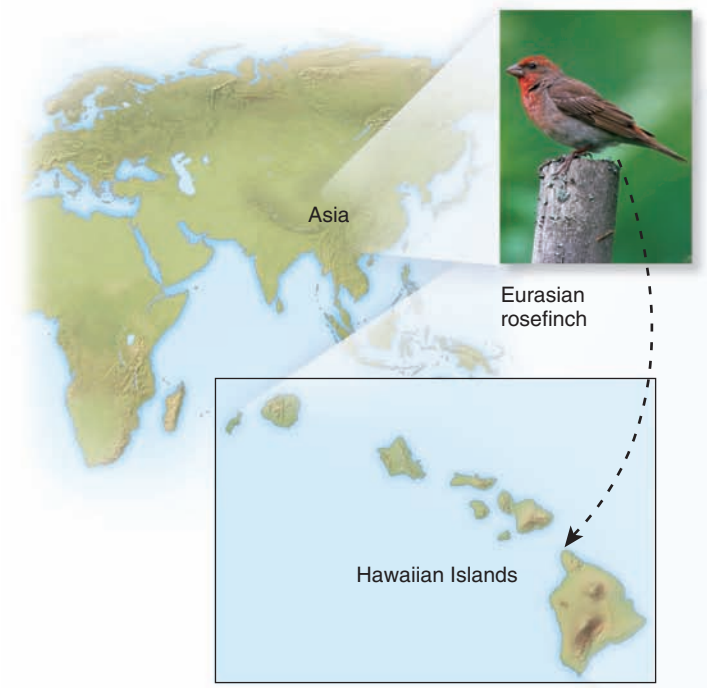
Cladogenesis is the splitting or diverging of one species into two or more species. In the case of sexually reproducing organisms, the process of cladogenesis requires that gene flow becomes interrupted between two or more populations, limiting or eliminating reproduction between members of different populations. **Allopatric speciation** (from the Greek *allos*, meaning other, and the Latin *patria*, meaning homeland) is the most prevalent way for cladogenesis to occur. This form of speciation occurs when a population becomes isolated from other populations and evolves into one or more species. Typically, this isolation may involve a geographic barrier such as a large area of land or body of water.

In some cases, geographic separation may be caused by slow geological events that eventually produce quite large geographic barriers. For example, a mountain range may emerge and split one species that occupies the lowland regions, or a creeping glacier may divide a population. **Figure 25.6** shows an interesting example in which geological separation promoted speciation. A fish called the Panamic porkfish (*Anisotremus taeniatus*) is found in the Pacific Ocean, whereas the porkfish (*Anisotremus virginicus*) is found in the Caribbean Sea. These two species were derived from an ancestral species whose population was split by the formation of the Isthmus of Panama about 3.5 mya. Before that event, the waters of the Pacific Ocean and Caribbean Sea mixed freely. Since the formation of the isthmus, the two populations have been geographically isolated and have evolved into distinct species.

Allopatric speciation can also occur when a small population moves to a new location that is geographically isolated from the main population. For example, a storm may force a small group of birds from a mainland to a distant island. In this case, migration between the island and the mainland population is an infrequent event. In a relatively short period of time, the small founding population on the island may evolve into a new species. How does speciation occur rapidly? Because the environment on the island may differ significantly from the mainland environment, natural selection may rapidly alter the genetic composition of the population, leading to adaptation to the new environment. In addition, as discussed in Chapter 24, a form of genetic drift known as the founder effect can have a larger influence in small founding populations.

The Hawaiian Islands are a showcase of allopatric speciation. The islands' extreme isolation coupled with their phenomenal array of ecological niches has enabled a small number of founding species





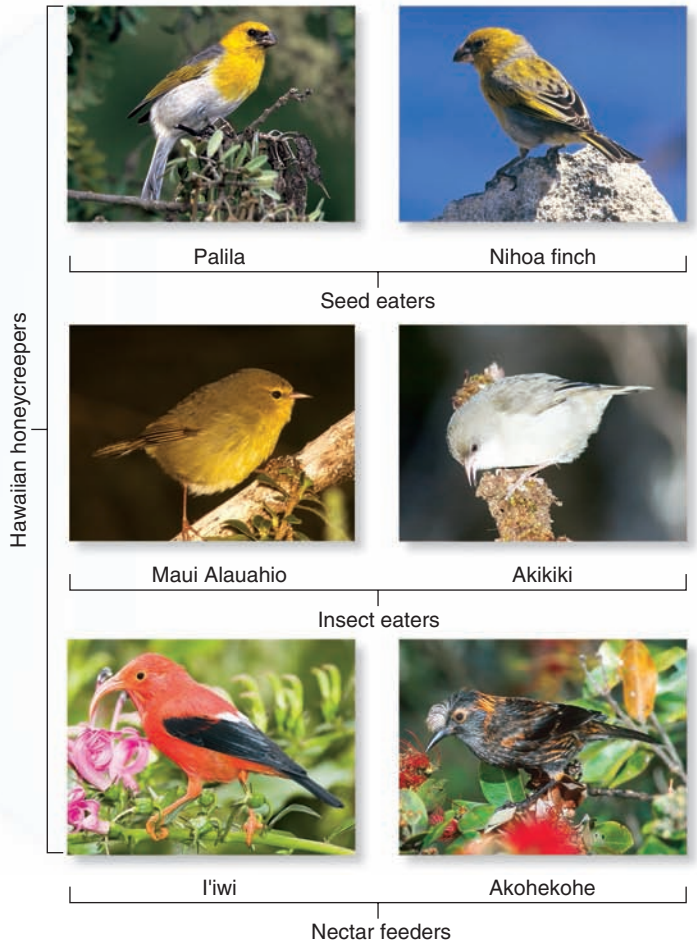


Figure 25.6 Allopatric speciation. An ancestral fish population was split into two by the formation of the Isthmus of Panama about 3.5 mya. Since that time, different genetic changes occurred in the two populations. These changes eventually led to the formation of different species: the Panamic porkfish (*Anisotremus taeniatus*) is found in the Pacific Ocean, and the porkfish (*Anisotremus virginicus*) is found in the Caribbean Sea.

BIOLOGY PRINCIPLE All species (past and present) are related by an evolutionary history. These two species of fish look similar because they share a common ancestor that existed in the fairly recent past.

(a) Migration of ancestor to the Hawaiian Islands

(b) Examples of Hawaiian honeycreepers

Figure 25.7 Adaptive radiation. **(a)** The honeycreepers' ancestor is believed to be related to a Eurasian rosefinch that arrived on the Hawaiian Islands approximately 3–7 mya. Since that time, at least 54 different species of honeycreepers (Drepanidinae) have evolved on the islands. **(b)** Adaptations to feeding have produced honeycreeper species with notable differences in beak morphology.

BioConnections: Look back at Figure 24.5b. Discuss how diversifying selection played a role in the diversity of honeycreepers on the Hawaiian Islands.

to evolve into a vast assortment of different species. Biologists have investigated several examples of **adaptive radiation**, in which a single ancestral species has evolved into a wide array of descendant species that differ in their habitat, form, or behavior. For example, approximately 1,000 species of *Drosophila* are found dispersed throughout the Hawaiian Islands. Evolutionary studies suggest that these evolved from a single colonization by one species of fruit fly! Natural selection resulted in changes in body form and function that produced the amazing diversity of *Drosophila* species that are now found on the islands.

As shown in **Figure 25.7**, an example of adaptive radiation is seen with a family of birds called honeycreepers (Drepanidinae). Researchers estimate that the honeycreepers' ancestor arrived in Hawaii 3–7 mya. This ancestor was a single species of finch, possibly a Eurasian rosefinch (genus *Carpodacus*) or, less likely, the North American house finch (*Carpodacus mexicanus*). At least 54 different species of honeycreepers, many of which are now extinct, evolved from this founding population to fill available niches in the islands' habitats. Natural selection resulted in the formation of many species with different feeding strategies. Seed eaters have stouter, stronger bills capable of cracking tough husks. Insect-eating honeycreepers have thin, warbler-like bills adapted for picking insects from foliage or strong, hooked bills to root out wood-boring insects. The curved bills of nectar-feeding honeycreepers enable them to extract nectar from the flowers of Hawaii's endemic plants.

Before ending our discussion of allopatric speciation, let's consider a common situation in which geographic separation is not complete. The zones where two populations can interbreed are known as **hybrid zones**. **Figure 25.8** shows a hybrid zone along a mountain

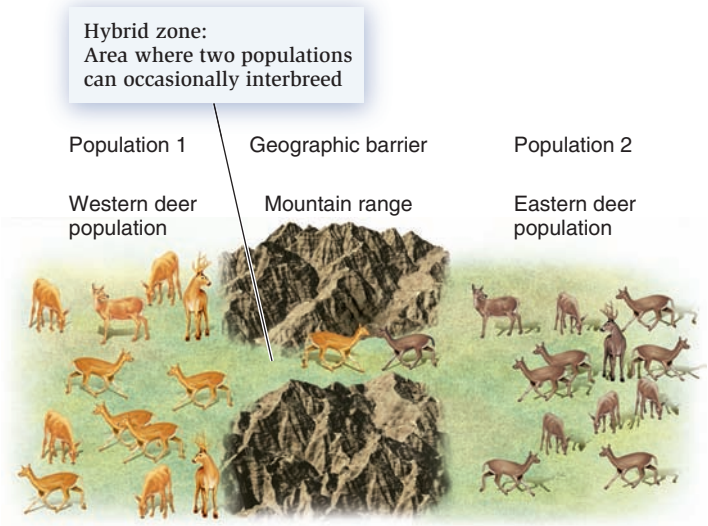

Figure 25.8 Hybrid zones. Two populations of deer are separated by a mountain range. A hybrid zone exists in a mountain pass, where occasional interbreeding may occur.

pass that connects two deer populations. For speciation to occur, the amount of gene flow within hybrid zones must become very limited. How does this happen? As the two populations accumulate different genetic changes, the ability of individuals from different populations to mate with each other in the hybrid zone may decrease. For example, natural selection in the western deer population may favor an increase in body size that is not favored in the eastern population. Over time, as this size difference between members of the two populations becomes greater, breeding in the hybrid zone may decrease. Larger individuals may not interbreed easily with smaller ones due to mechanical isolation. In addition, larger individuals may prefer larger individuals as mates, and smaller individuals may also prefer each other. Once gene flow through the hybrid zone is greatly diminished, the two populations are reproductively isolated. Over the course of many generations, such populations may evolve into distinct species.

Feature Investigation | Podos Found That an Adaptation for Feeding May Have Promoted Reproductive Isolation in Finches

In 2001, American evolutionary biologist Jeffrey Podos analyzed the songs of Darwin's finches on the Galápagos Islands to determine how environmental adaptation may contribute to reproductive isolation. As in honeycreepers, the differences in beak sizes and shapes among the various species of finches are adaptations to different feeding strategies. Podos hypothesized that changes in beak morphology could also affect the songs that the birds produce, thereby having the potential to affect mate choice. The components of the vocal tract of birds, including the trachea, larynx, and beak, work collectively to produce a bird's song. Birds actively modify the shape of their vocal tracts during singing, and beak movements are normally very rapid and precise.

Podos focused on two aspects of a bird's song. The first feature is the frequency range, which is a measure of the minimum and maximum frequencies in a bird's song, measured in kilohertz (kHz). The second feature is the trill rate. A trill is a series of notes or group of notes repeated in succession. **Figure 25.9** shows a graphical depiction of the songs of Darwin's finches. As you can see, the song patterns of these finches are quite different from each other.

To quantitatively study the relationship between beak size and song, Podos first captured male finches on Santa Cruz, one of the Galápagos Islands, and measured their beak sizes (**Figure 25.10**). The birds were banded and then released into the wild. The banding provided a way of identifying the birds whose beaks had already been measured. After release, the songs of the banded birds were recorded on a tape recorder, and their range of frequencies and trill rate were analyzed. Podos then compared the data for the Galápagos finches to a large body of data that had been collected on many other bird species. This comparison was used to evaluate whether beak size, in this case, beak depth—the measurement of the beak from top to bottom, at its base—constrained the frequency range and/or the trill rate of the finches.

The results of this comparison are shown in the data of Figure 25.10. As seen here, the relative constraint on vocal performance became higher as the beak depth became larger. This means that birds with larger beaks had a narrower frequency range and/or a slower trill rate. Podos proposed that as jaws and beaks became adapted for strength to crack open larger, harder seeds, they became less able to perform the rapid movements associated with certain types of songs. In contrast, the finches with smaller beaks adapted to probe for insects or eat smaller seeds had less constraint on their vocal performance. From the perspective of evolution, the changes observed in song patterns for the Galápagos finches could have played an important role in promoting reproductive isolation, because song pattern is an important factor in mate selection in birds. Therefore,

Figure 25.9 Differences in the songs of Galápagos finches. These spectrograms depict the frequency of each bird's song over time, measured in kilohertz (kHz). The songs are produced in a series of trills that have a particular pattern and occur at regular intervals. Notice the differences in frequency and trill rate between different species of birds.

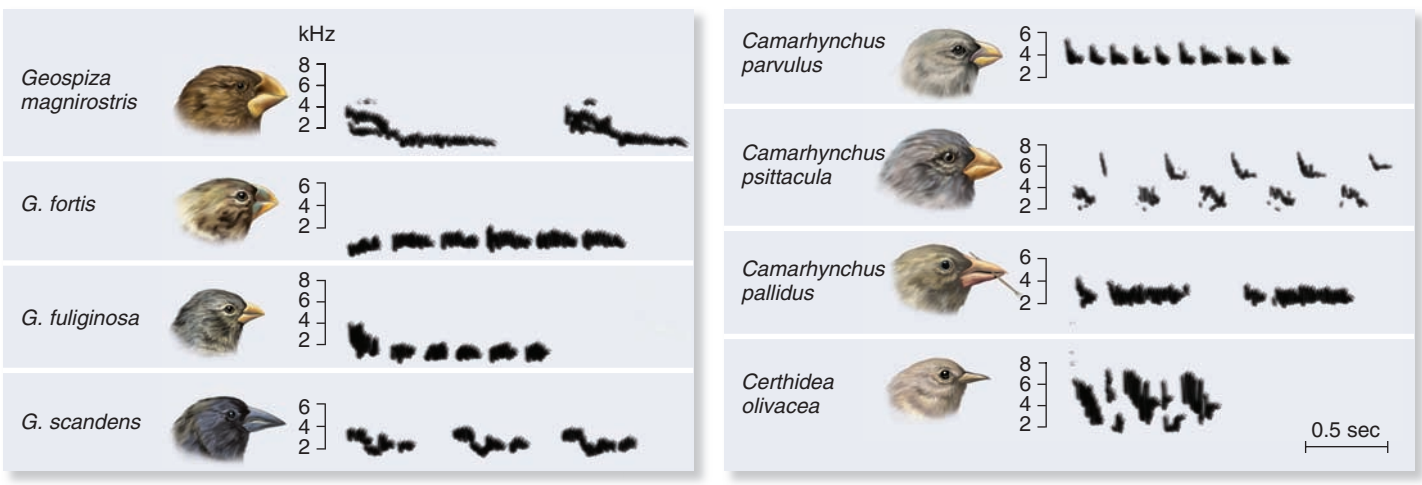

Figure 25.10 **Study by Podos investigating the effects of beak depth on song among different species of Galápagos finches.**

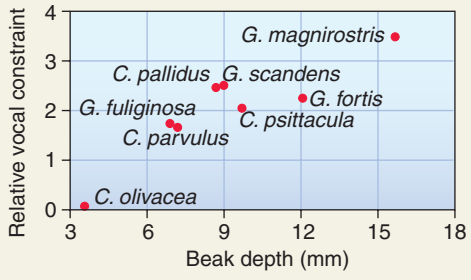


HYPOTHESIS Changes in beak morphology that are an adaptation for feeding may also affect the songs of Galápagos finches and thereby lead to reproductive isolation between species.

KEY MATERIALS This study was conducted on finch populations of the Galápagos Island of Santa Cruz.

	Experimental level	Conceptual level
1 Capture male finches and measure their beak depth. Beak depth is measured at the base of beak, from top to bottom.		This is a measurement of phenotypic variation in beak size.
2 Band the birds and release them back into the wild.		Banding allows identification of birds with known beak depths.
3 Record the bird's songs on a tape recorder.		This is a measurement of phenotypic variation in song.
4 Analyze the songs with regard to frequency range and trill rate.		The frequency range is the value between high and low frequencies. The trill rate is the number of repeats per unit time.

5 THE DATA

The data for the Galápagos finches were compared to a large body of data that had been collected on many other bird species. The relative constraint on vocal performance is higher if a bird has a narrower frequency range and/or a slower trill rate. These constraints were analyzed with regard to each bird's beak depth.

6 CONCLUSION Larger beak size, which is an adaptation to cracking open large, hard seeds, constrains vocal performance. This may affect mating song patterns and thereby promote reproductive isolation and, in turn, speciation.

7 SOURCE Podos, J. 2001. Correlated evolution of morphology and vocal signal structure in Darwin's finches. *Nature* 409:185–188.

a by-product of beak adaptation for feeding is that it also appears to have affected song pattern, possibly promoting reproductive isolation and eventually the formation of distinct species.

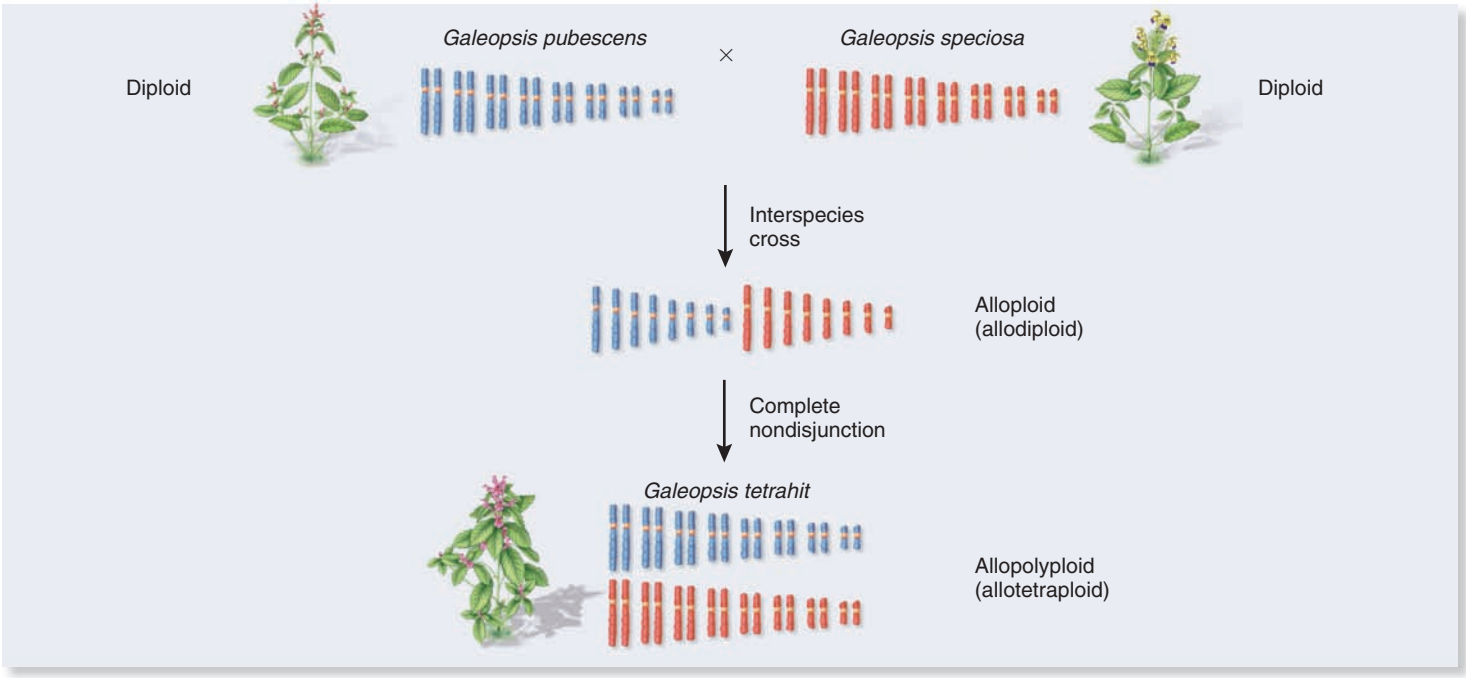
Experimental Questions

1. What did Podos hypothesize regarding the effects of beak size on a bird's song? How could changes in beak size and shape lead to reproductive isolation among the finches?
2. **SciSKILLS** » How did Podos test the hypothesis that beak morphology caused changes in the birds' songs?
3. **SciSKILLS** » Analyze the results of Podos's study, and explain whether they support his original hypothesis. What is meant by by-product of adaptation, and how does it apply to this particular study?

Sympatric Speciation Occurs When Populations Are in Direct Contact

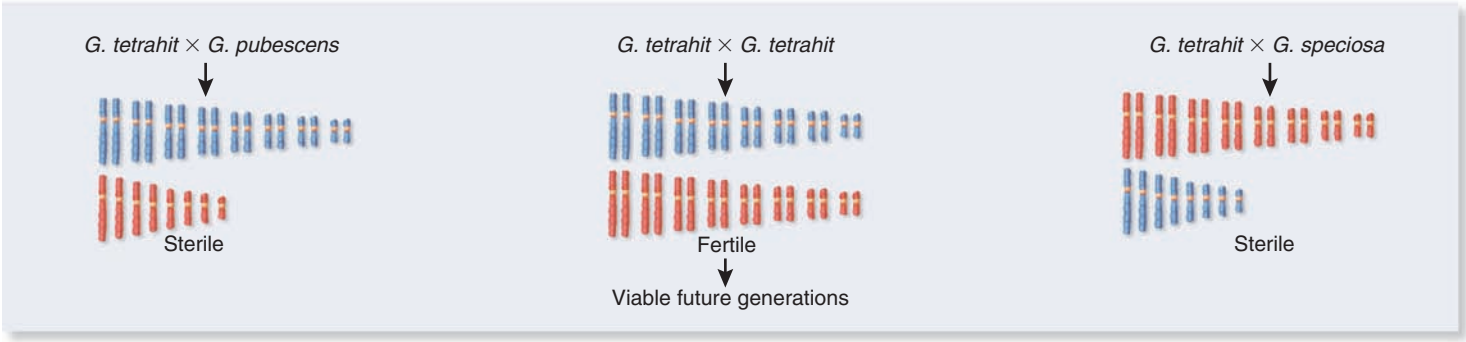
Sympatric speciation (from the Greek *sym*, meaning together) occurs when members of a species that are within the same range diverge into two or more different species even though there are no physical barriers to interbreeding. Although sympatric speciation is believed to be less common than allopatric speciation, particularly in animals, evolutionary biologists have discovered several ways in which it can occur. These include polyploidy, adaptation to local environments, and sexual selection.

Polyploidy A type of genetic change that can cause immediate reproductive isolation is **polyploidy**, in which an organism has more than two sets of chromosomes. Plants tend to be more tolerant of changes in chromosome number than animals. For example, many crops and decorative species of plants are polyploid. How does polyploidy occur? One mechanism is complete nondisjunction of chromosomes, which increases the number of chromosome sets in a given species (autopolyploidy). Such changes can result in an abrupt sympatric speciation. For example, nondisjunction could produce a tetraploid plant with four sets of chromosomes from a species that was diploid with two sets. A cross between a tetraploid and a diploid produces a triploid offspring with three sets of chromosomes. Triploid offspring are usually sterile because an odd number of chromosomes cannot be evenly segregated during meiosis. This hybrid sterility causes reproductive isolation between the tetraploid and diploid species.



Another mechanism that leads to polyploidy is interspecies breeding. An **alloploid** organism contains at least one set of chromosomes from two or more different species. This term refers to the occurrence of chromosome sets (ploidy) from the genomes of different (allo-) species. Interbreeding between two different species may produce an allodiploid, an organism that has only one set of chromosomes from each species. Species that are close evolutionary relatives are most likely to breed and produce allodiploid offspring. For example, closely related species of grasses may interbreed to produce allodiploids. An organism containing two or more complete sets of chromosomes from two or more different species is called an allopolyploid. An allopolyploid can be the result of interspecies breeding between species that are already polyploid, or it can occur as a result of nondisjunction in an allodiploid organism. For example, complete nondisjunction in an allodiploid could produce an allotetraploid, which is an allopolyploid with two complete sets of chromosomes from two species for a total of four sets.

The formation of an allopolyploid can also abruptly lead to reproductive isolation, thereby promoting speciation. As an example, let's consider the origin of a natural species of plant called the common hemp nettle, *Galeopsis tetrahit*. This species is thought to be an allotetraploid derived from two diploid species, *Galeopsis pubescens* and *Galeopsis speciosa* (**Figure 25.11a**). These two diploid species contain 16 chromosomes each ($2n = 16$), whereas *G. tetrahit* contains 32 chromosomes. Though the origin of *G. tetrahit* is not completely certain, research suggests it may have originated from an interspecies cross between *G. pubescens* and *G. speciosa*, which initially produced an allodiploid with 16 chromosomes (one set from each species). The allodiploid then underwent complete nondisjunction to become an allotetraploid carrying four sets of chromosomes—two from each species.



How do these genetic changes cause reproductive isolation? The allotetraploid, *G. tetrahit*, is fertile, because all of its chromosomes occur in homologous pairs that can segregate evenly during meiosis. However, a cross between *G. tetrahit* and a diploid, *G. pubescens* or *G. speciosa*, produces an offspring that is monoploid for one chromosome set and diploid for the other set (**Figure 25.11b**). The chromosomes of the monoploid set cannot be evenly segregated during meiosis. These offspring are expected to be sterile, because they will produce gametes that have incomplete sets of chromosomes. This hybrid sterility causes the allotetraploid to be reproductively isolated from both diploid species. Therefore, this process could have led to the formation of a new species, *G. tetrahit*, by sympatric speciation.

Polyploidy is so frequent in plants that it is a major mechanism of their speciation. In ferns and flowering plants, about 40–70% of the species are polyploid. By comparison, polyploidy can occur in animals, but it is much less common. For example, less than 1% of reptiles and amphibians are polyploids derived from diploid ancestors. The reason why polyploidy is not usually tolerated in animals is not understood.

Adaptation to Local Environments In some cases, populations that occupy different local environments, which are continuous with each other, may diverge into different species. An early example of this type of sympatric speciation was described by American biologists Jeffrey Feder, Guy Bush, and colleagues. They studied the North American apple maggot fly (*Rhagoletis pomenella*). This fly originally fed on native hawthorn trees. However, the introduction of apple trees approximately 200 years ago provided a new local environment for this species. The apple-feeding populations of this species develop more rapidly because apples mature more quickly than hawthorn

(a) Possible formation of *G. tetrahit*

(b) Outcome of breeding among *G. tetrahit*, *G. pubescens*, and *G. speciosa*

Figure 25.11 Polyploidy and sympatric speciation. (a) *Galeopsis tetrahit* may have arisen by an interspecies cross between *Galeopsis pubescens* and *Galeopsis speciosa*, which was followed by a subsequent nondisjunction event. **(b)** Polyploidy may have caused reproductive isolation between these three natural species of hemp nettle. If *G. tetrahit* is mated with either of the other two species, the resulting offspring would be monoploid for one chromosome set and diploid for the other set, making them sterile. Therefore, *G. tetrahit* is reproductively isolated from the diploid species, making it a new species.

Concept Check: *Suppose that G. tetrahit was crossed to G. pubescens to produce an interspecies hybrid as shown at the left side of part (b). If this interspecies hybrid was crossed to G. tetrahit, how many chromosomes do you think an offspring would have? The answer you give should be a range, not a single number.*

fruit. The result is partial temporal isolation, which is an example of a prezygotic isolating mechanism. Although the two populations—those that feed on apple trees and those that feed on hawthorn trees—are considered subspecies, evolutionary biologists speculate they may eventually become distinct species due to reproductive isolation and the accumulation of independent mutations.

American entomologist Sara Via and colleagues have studied the beginnings of sympatric speciation in pea aphids (*Acyrthosiphon pisum*), a small, plant-eating insect. Pea aphids in the same geographic area can be found on both alfalfa (*Medicago sativa*) and red clover (*Trifolium pratenae*) (**Figure 25.12**). Although pea aphids on these two host plants look identical, they show significant genetic differences and are highly ecologically specialized. Pea aphids that are found on alfalfa exhibit a lower fitness when transferred to red clover, whereas pea aphids found on red clover exhibit a lower fitness when transferred to alfalfa. The same traits involved in this host

Figure 25.12 Pea aphids, a possible example of sympatric speciation in progress. Some pea aphids prefer alfalfa, whereas others prefer red clover. These two populations may be in the process of sympatric speciation.

BIOLOGY PRINCIPLE Populations of organisms evolve from one generation to the next. Populations of pea aphids are evolving based on preference for different food sources—alfalfa or red clover. The populations may eventually evolve into separate species.

Concept Check: How may host preference eventually lead to speciation?

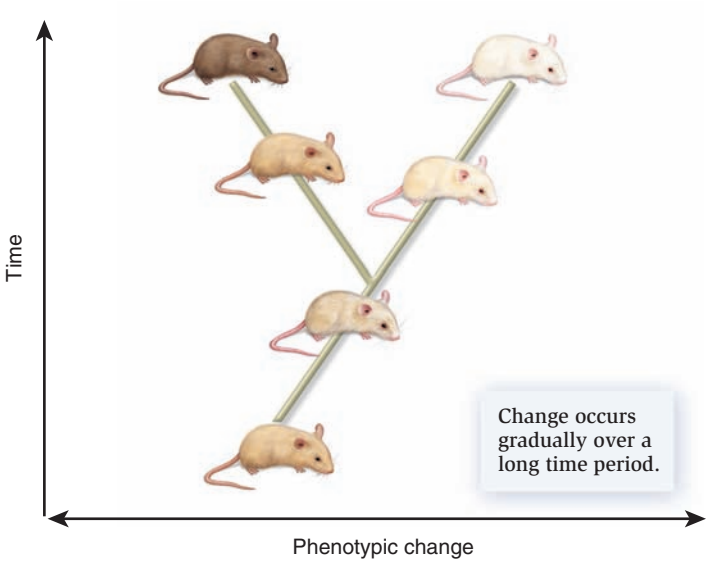
specialization cause these two groups of pea aphids to be substantially reproductively isolated. Taken together, the observations of the North American apple maggot fly, pea aphids, and other insect species suggest that diversifying selection (described in Chapter 24) occurs because some members within the same range evolve to feed on a different host. This may be an important mechanism of sympatric speciation among insects.

Sexual Selection Another mechanism that may promote sympatric speciation is sexual selection. As discussed in Chapter 24, one type of sexual selection is mate choice (refer back to Figures 24.8 and 24.9). Ole Seehausen and Jacques van Alphen found that male coloration in African cichlids is subject to female choice. In this case, sexual selection appears to have followed a diversifying mechanism in which certain females prefer males with one color pattern, and other females prefer males with a different color pattern. A possible outcome of such sexual selection is that it can separate one large sympatric population into smaller populations that eventually become distinct species because they selectively breed among themselves.

25.3 The Pace of Speciation

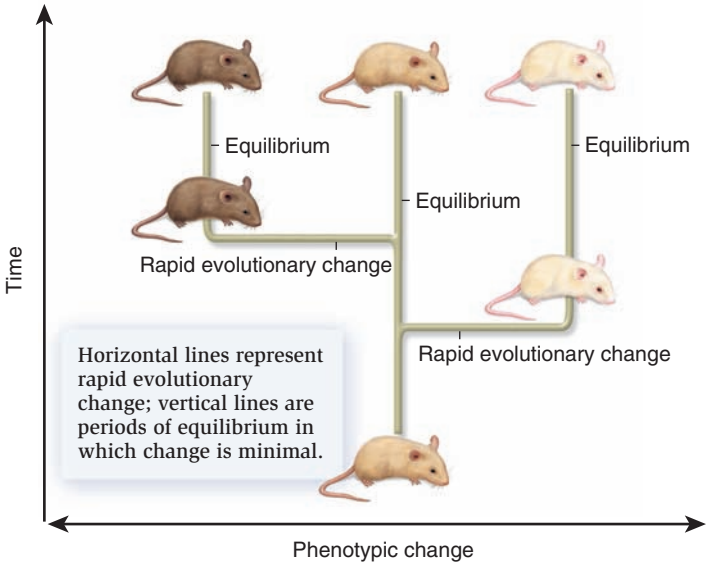
Learning Outcome:

1. Compare and contrast the concepts of gradualism and punctuated equilibrium.



Throughout the history of life on Earth, the rate of evolutionary change and speciation has not been constant. **Figure 25.13** illustrates two contrasting views concerning the rate of evolutionary change. These ideas are not mutually exclusive but represent two different ways to consider the tempo of evolution. The concept of **gradualism** suggests that each new species evolves continuously over long spans of time (Figure 25.13a). The principal idea is that large phenotypic differences that produce new species are due to the gradual accumulation of many small genetic changes.

By comparison, the concept of **punctuated equilibrium**, advocated in the 1970s by American paleontologist Niles Eldredge and American evolutionary biologist Stephen Jay Gould, suggests that the tempo of evolution is more sporadic (Figure 25.13b). According to this hypothesis, species exist relatively unchanged for many generations. During this equilibrium period, genetic changes are likely to accumulate, particularly neutral changes. However, genetic changes that significantly alter phenotype do not substantially change the overall composition of a population. These long periods of equilibria are punctuated by relatively short periods (that is, on a geological timescale) during which the frequencies of certain phenotypes in a population change substantially at a far more rapid rate.



A rapid rate of evolution could commonly occur via allopatric speciation in which a small group migrates away from a larger population to a new environment in which different alleles provide better adaptation to the surroundings. By natural selection, the small population may rapidly evolve into a new species. In addition, events such as polyploidy may abruptly produce individuals with new phenotypic traits. On an evolutionary timescale, these types of events can be rather rapid, because a few genetic changes can have a major influence on phenotype.

In conjunction with genetic changes, species may also be subjected to sudden environmental shifts that quickly drive the gene pool in a particular direction via natural selection. For example, the climate may change or a new predator may infiltrate the geographic range of a species. Natural selection may lead to a rapid evolution of the gene pool by favoring those alleles that allow members of the population to survive the climatic change or to have phenotypic characteristics that allow them to avoid the predator.

Which viewpoint is correct, punctuated equilibrium or gradualism? Both have merit. The occurrence of punctuated equilibrium is often supported by the fossil record. New species seem to arise rather suddenly in a layer of rocks, persist relatively unchanged for a very long period of time, and then become extinct. In such cases, scientists hypothesize that the period during which a previous species evolved into a new species was so short that few, if any, of the transitional forms of the species were preserved as fossils. Even so, these rapid periods of change were probably followed by long periods that likely involved the additional accumulation of many small genetic changes, consistent with gradualism.

(a) Gradualism

(b) Punctuated equilibrium

Figure 25.13 A comparison of gradualism and punctuated equilibrium. **(a)** In gradualism, the phenotypic characteristics of a species gradually change due to the accumulation of small genetic changes. **(b)** In punctuated equilibrium, long periods of equilibrium in which species exist essentially unchanged are punctuated by relatively short periods of evolutionary change during which phenotypic characteristics may change rapidly.

BIOLOGY PRINCIPLE Populations of organisms evolve from one generation to the next. Gradualism and punctuated equilibrium are two different views regarding the pace of evolution.

Finally, another issue associated with the speed of speciation is generation time. Species of large animals with long generation times tend to evolve much more slowly than do microbial species with short generations. Many new species of bacteria will come into existence during our lifetime, whereas new species of large animals tend to arise on a much longer timescale. This is an important consideration because bacteria have great environmental effects. They are decomposers of organic materials and pollutants in the environment, and they play a role in many diseases of plants and animals, including humans.

25.4 Evo-Devo: Evolutionary Developmental Biology

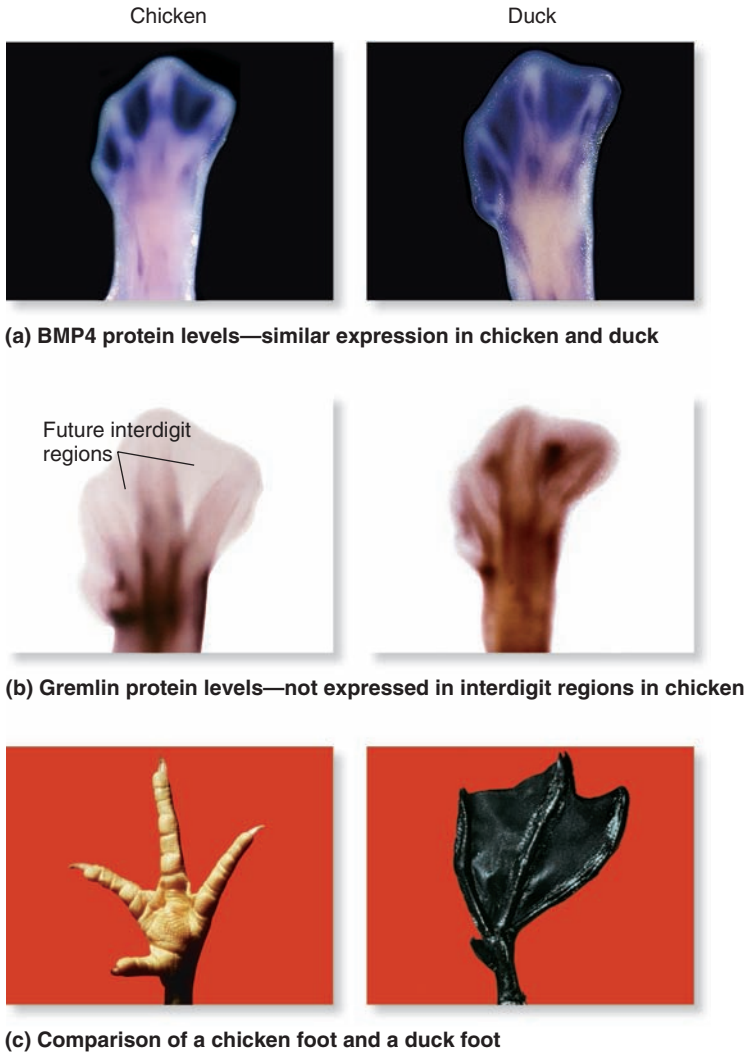
Learning Outcomes:

1. Describe how the spatial expression of genes, such as *BMP4* and *Gremlin*, affects pattern formation.
2. Explain the relationship between the number of *Hox* genes and the body pattern of an animal species.
3. Outline how differences in the growth rates of body parts can change the characteristics of species.
4. Describe how the study of the *Pax6* gene suggests that the eyes of different animal species evolved from a common ancestor.

As we have learned, the origin of new species involves genetic changes that lead to adaptations to environmental niches and/or to reproductive isolating mechanisms that prevent closely related species from interbreeding. These genetic changes result in morphological and physiological differences that distinguish one species from another. In recent years, many evolutionary biologists have begun to investigate how genetic variation produces species and groups of species with novel shapes and forms. The underlying reasons for such changes are often rooted in the developmental pathways that control an organism's morphology.

Evolutionary developmental biology (referred to as **evo-devo**) is an exciting and relatively new field of biology that compares the development of different organisms in an attempt to understand ancestral relationships between organisms and the mechanisms that bring about evolutionary change. During the past few decades, developmental geneticists have gained a better understanding of biological development at the molecular level. Much of this work has involved the discovery of genes that control development in model organisms. As the genomes of more organisms have been analyzed, researchers have become interested in the similarities and differences that occur between closely related and distantly related species. The field of evolutionary developmental biology arose out of this interest.

How do new morphological forms come into being? For example, how does a nonwebbed foot evolve into a webbed foot? How does a new organ, such as an eye, come into existence? As we will learn, such novelty arises through genetic changes, also called genetic innovations. Certain types of genetic innovations have been so advantageous they have resulted in groups of new species. For example, the innovation of wings resulted in the evolution of many different species of birds. In this section, we will see that proteins that control developmental changes, such as cell-signaling proteins and transcription factors, often play a key role in promoting the morphological changes that occur during evolution.



The Spatial Expression of Genes That Affect Development Has a Dramatic Effect on Phenotype

In Chapter 19, we considered the role of genetics in the development of plants and animals. As we learned, genes that play a role in development influence cell division, cell migration, cell differentiation,

and cell death. The interplay among these four processes produces an organism with a specific body pattern, a process called **pattern formation**. As you might imagine, developmental genes are very important to the phenotypes of individuals. They affect traits such as the shape of a bird's beak, the length of a giraffe's neck, and the size of a plant's flower. In recent years, the study of development has revealed that developmental genes are key players in the evolution of many types of traits. Changes in such genes affect traits that can be acted on by natural selection. Furthermore, variation in the expression of these genes may be commonly involved in the acquisition of new traits that promote speciation.

As an example, let's compare the formation of a chicken's foot with that of a duck's foot. Developmental biologists have discovered that the morphological differences between a nonwebbed and a webbed foot are due to the differential expression of two different cell-signaling proteins called bone morphogenetic protein 4 (BMP4) and gremlin. The *BMP4* gene is expressed throughout the developing limb of both the chicken and duck; this is shown in **Figure 25.14a**, in which the BMP4 protein is stained purple. BMP4 causes cells to undergo apoptosis and die. The gremlin protein, which is stained brown in **Figure 25.14b**, inhibits the function of BMP4, thereby allowing cells to survive. In the developing chicken limb, the *Gremlin* gene is expressed throughout the limb, except in the regions between each digit. Therefore, in these regions, the cells die, and a chicken develops a nonwebbed foot (**Figure 25.14c**). By comparison, in the duck, *Gremlin* is expressed throughout the entire limb, including the interdigit regions, and the duck develops a webbed foot. Interestingly, researchers have been able to introduce gremlin protein into the interdigit regions of developing chicken limbs. This produces a chicken with webbed feet!

How are these observations related to evolution? During the evolution of birds, genetic variation arose such that some individuals expressed the *Gremlin* gene in the regions between each digit, but others did not. This variation determined whether or not a bird's feet were webbed. In terrestrial settings, having nonwebbed feet is an advantage because it enables the individual to hold onto perches, run along the ground, and snatch prey. Therefore, natural selection would favor nonwebbed feet in terrestrial environments. This process explains the occurrence of nonwebbed feet in chickens, hawks, crows, and many other terrestrial birds. In aquatic environments, however, webbed feet are an advantage because they act as paddles for swimming, so genetic variation that produced webbed feet in aquatic birds would have been acted on by natural selection. Over time, this gave rise to the webbed feet now found in a wide variety of aquatic birds, including ducks, geese, and penguins.

(a) BMP4 protein levels—similar expression in chicken and duck

(b) Gremlin protein levels—not expressed in interdigit regions in chicken

(c) Comparison of a chicken foot and a duck foot

Figure 25.14 The role of cell-signaling proteins in the morphology of birds' feet. This figure shows how changes in developmental gene expression can affect webbing between the toes. **(a)** Expression of the *BMP4* gene in the developing limbs. BMP4 protein is stained purple here and is expressed throughout the limb. **(b)** Expression of the *Gremlin* gene in the developing limbs. Gremlin protein is stained brown here. Note that *Gremlin* is not expressed in the interdigit regions of the chicken but is expressed in these regions of the duck. Gremlin inhibits the ability of BMP4 to cause programmed cell death. **(c)** Because BMP4 is not inhibited in the interdigit regions in the chicken, the cells in this region die, and the foot is not webbed. By comparison, inhibition of BMP4 in the interdigit regions in the duck results in a webbed foot.

Concept Check: *What would you expect to happen to the morphology of the feet of ducks if the Gremlin gene was underexpressed?*

The *Hox* Genes Have Been Important in the Evolution of a Variety of Body Patterns

The study of developmental genes has revealed interesting trends among large groups of species. *Hox* genes, which are discussed in Chapter 19, are found in nearly all animals, indicating they have originated very early in animal evolution. *Hox* genes are homeotic genes, which specify the fate of a particular segment or region of the body. Developmental biologists have hypothesized that variation in the *Hox* genes has spawned the formation of many new body patterns. As shown in **Figure 25.15**, the number and arrangement of *Hox* genes varies considerably among different types of animals. Sponges, the simplest of animals, have at least one gene that is homologous to *Hox* genes. Insects typically have nine or more *Hox* genes. In most cases, multiple *Hox* genes occur in a cluster in which the genes are close to each other along a chromosome. In mammals, *Hox* gene clusters have been duplicated twice during the course of evolution to form four clusters, all slightly different, containing a total of 39 genes.

Researchers propose that increases in the number of *Hox* genes have been instrumental in the evolution of many animal species with greater complexity in body structure. To understand how, let's first consider *Hox* gene function. All *Hox* genes encode transcription factors that act as master control proteins for directing the formation of particular regions of the body. Each *Hox* gene controls a hierarchy of many regulatory genes that regulate the expression of genes encoding proteins that ultimately affect the morphology of the organism. The evolution of complex body patterns is associated with an increase not only in the number of regulatory genes—as evidenced by the increase in *Hox* gene complexity during evolution—but also in genes that encode proteins that directly affect an organism's form and function.

How would an increase in *Hox* genes enable more complex body patterns to evolve? Part of the answer lies in the spatial expression of the *Hox* genes. Different *Hox* genes are expressed in different regions of the body along the anteroposterior axis (refer back to Figure 19.16). Therefore, an increase in the number of *Hox* genes allows each of these master control genes to become more specialized in the region that it controls. In fruit flies, one segment in the middle of the body can be controlled by a particular *Hox* gene and form wings and legs, whereas a segment in the head region can be controlled by a different *Hox* gene and develop antennae. Therefore, research suggests that one way for new, more complex body patterns to evolve is by increasing the number of *Hox* genes, thereby making it possible to form many specialized parts of the body that are organized along a body axis.

Three lines of evidence support the idea that increases in *Hox* gene number have been instrumental in the evolution and speciation of animals with more complex body patterns.

- As discussed in Chapter 19, *Hox* genes are known to control the fate of regions along the anteroposterior axis.
- As shown in Figure 25.15, a general trend is observed in which animals with a more complex body structure tend to have more *Hox* genes and *Hox* clusters in their genomes than do simpler animals.

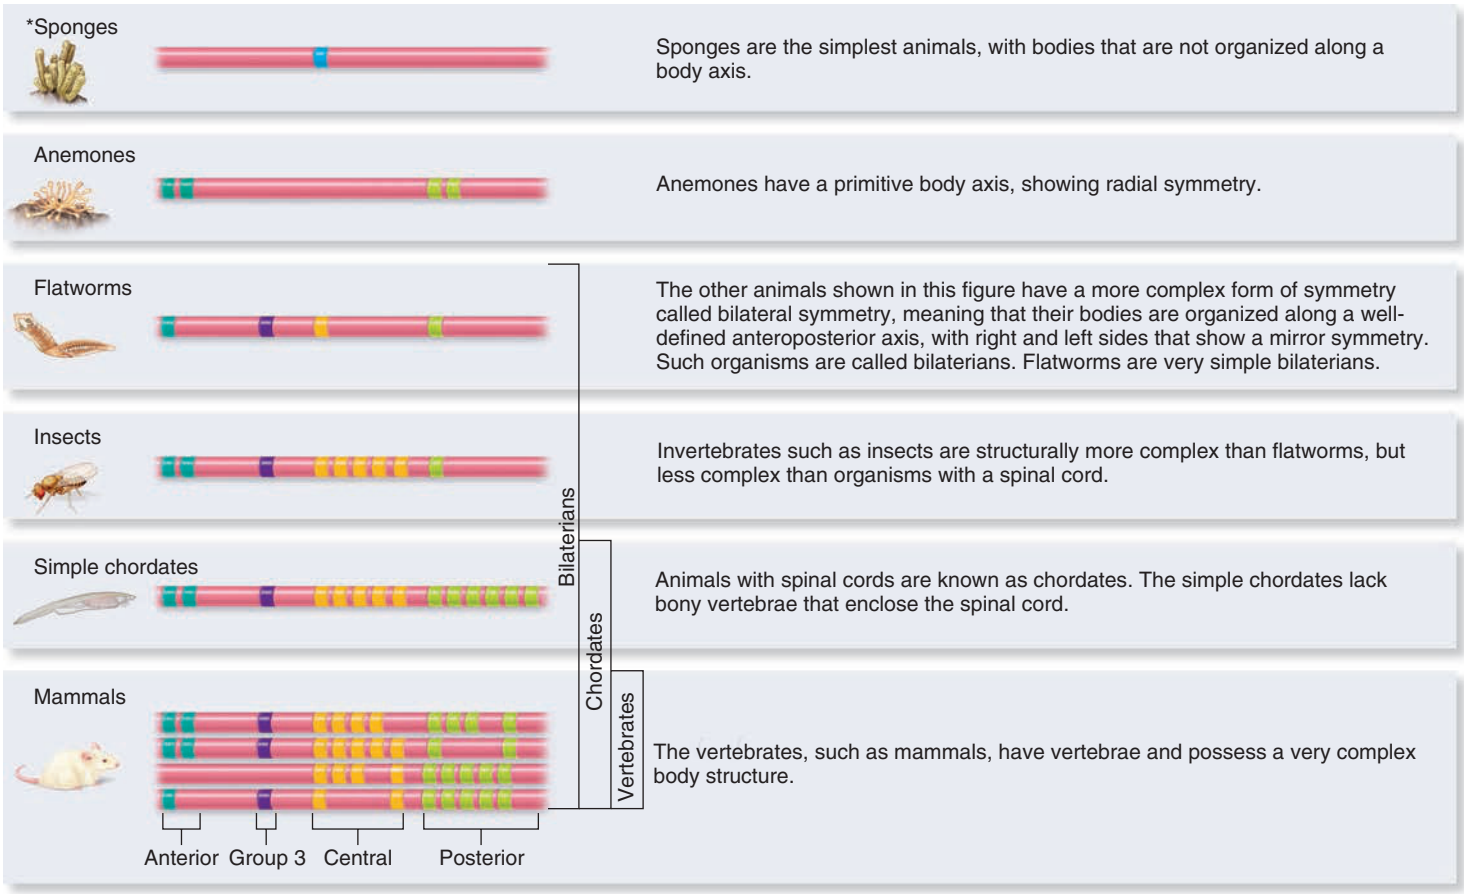


Figure 25.15 ***Hox* gene number and body complexity in different types of animals.** Researchers speculate that the duplication of *Hox* genes and *Hox* gene clusters played a key role in the evolution of more complex body patterns in animals. A correlation is observed between increasing numbers of *Hox* genes and increasing complexity of body structure. The *Hox* genes are divided into four groups, called anterior, group 3, central, and posterior, based on their relative similarities. Each group is represented by a different color in this figure.

*Sponges, which are the simplest animals, with no true tissues, do not have true *Hox* genes, though they have an evolutionarily related gene called an *NK-like* gene. Some species of sponges have more than one copy of this gene.

Concept Check: *What is the relationship between the total number of Hox genes in an animal species and its morphological complexity?*

BioConnections: *Look back at Figures 19.16 and 19.17. How is the expression of Hox genes related to segmentation and the anteroposterior axis?*

- A comparison of *Hox* gene evolution and animal evolution reveals striking parallels. Researchers have analyzed *Hox* gene sequences among modern species and made estimates regarding the timing of past events. Though the date is difficult to precisely pinpoint, the first *Hox* gene arose well over 600 mya. In addition, gene duplications of this primordial gene produced clusters of *Hox* genes in other species. Clusters such as those found in modern insects were likely to be present approximately 600 mya. A duplication of that cluster is estimated to have occurred around 520 mya.

  Estimates of *Hox* gene origins correlate with major diversification events in the history of animals. The Cambrian period, which occurred from 543 to 490 mya, saw a great diversification of animal species. This diversification occurred after the *Hox* cluster was formed and was possibly undergoing its first duplication to produce two *Hox* clusters. Also, approximately 420 mya, a second duplication produced species with four *Hox* clusters. This event preceded the proliferation of tetrapods—vertebrates with four limbs—that occurred during the Devonian period, approximately 417–354 mya. Modern tetrapods have four *Hox* clusters. This second duplication may have been a critical event that led to the evolution of complex terrestrial vertebrates with four limbs, such as amphibians, reptiles, and mammals.

The striking correlation between number of *Hox* genes and body complexity is thought have been instrumental in the evolution of animals. However, research has also shown that body complexity may not be solely dependent on the number of *Hox* genes. For example, the number of *Hox* clusters in most tetrapods is four, whereas some fishes, which do not have more complex bodies than tetrapods, have seven or eight *Hox* clusters. In addition, researchers have discovered that specialized body structures can be formed by influencing the regulation of *Hox* genes and the other genes that are controlled by *Hox* genes. These findings indicate that changes in body complexity do not always have to be related to the total number of *Hox* genes or *Hox* clusters.

Variation in Growth Rates Can Have a Dramatic Effect on Phenotype

Another way that genetic variation can influence morphology is by controlling the relative growth rates of different parts of the body during development. The term **heterochrony** refers to evolutionary changes in the rate or timing of developmental events. The speeding up or slowing down of growth appears to be a common occurrence in evolution and leads to different species with striking morphological differences. With regard to the pace of evolution, such changes may rapidly lead to the formation of new species.

As an example, **Figure 25.16** compares the progressive growth of human and chimpanzee skulls. At the fetal stage, the size and shape of the skulls look fairly similar. However, after this stage, the relative growth rates of certain regions become markedly different, thereby affecting the shape and size of the adult skull. In the chimpanzee, the jaw region grows faster, giving the adult chimpanzee a much larger and longer jaw. In the human, the jaw grows more slowly, and the region of the skull that surrounds the brain—the cranium—grows faster. The result is that adult humans have a smaller jaw but a larger cranium than adult chimpanzees.

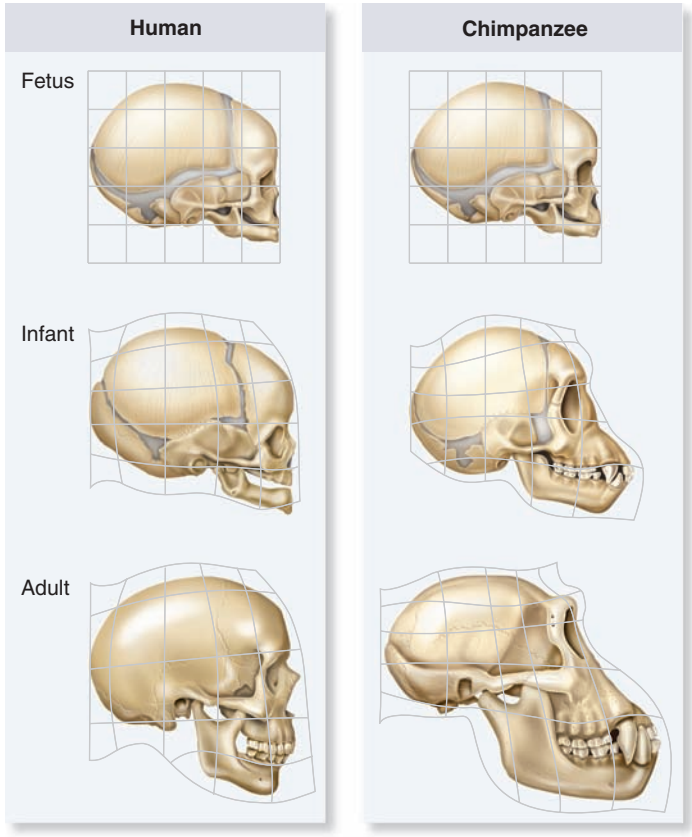

Figure 25.16 Heterochrony. Heterochrony refers to the phenomenon in which one region of the body grows faster than another among different species. The phenomenon explains why the skulls of adult chimpanzees and humans have different shapes even though their fetal skull shapes are quite similar.

Genomes & Proteomes Connection

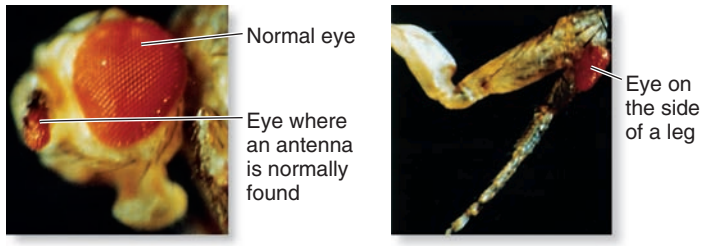
The Study of the *Pax6* Gene Indicates That Different Types of Eyes Evolved from One Simple Form

Thus far in this section, we have focused on the roles of particular genes as they influence the development of species with different body structures. Explaining how a complex organ comes into existence is another major challenge for evolutionary biologists. Although it is relatively easy to comprehend how a limb could undergo evolutionary modifications to become a wing, flipper, or arm, it is more difficult to understand how a body structure, such as a limb, comes into being in the first place. In his book *The Origin of Species*, Darwin addressed this question and admitted that the evolution and development of a complex organ such as the eye was difficult to understand.

As noted by Darwin, the eyes of vertebrate species are exceedingly complex, being able to adjust focus, let in different amounts of light, and detect a spectrum of colors. Darwin speculated that such complex eyes must have evolved from a simpler structure through the process of descent with modification. With amazing

insight, he suggested that a very simple eye would be composed of two cell types, a photoreceptor cell and an adjacent pigment cell. The photoreceptor cell, which is a type of nerve cell, is able to absorb light and respond to it. The function of the pigment cell is to stop the light from reaching one side of the photoreceptor cell. This primitive, two-cell arrangement would allow an organism to sense both light and the direction from which the light comes.

A primitive eye would provide an additional way for an organism to sense its environment, possibly allowing it to avoid predators or locate food. Vision is nearly universal among animals, which indicates a strong selective advantage for eyesight. Over time, eyes could become more complex by enhancing the ability to absorb different amounts and wavelengths of light and also by refinements in structures such as the addition of lenses that focus the incoming light.



Since the time of Darwin, many evolutionary biologists have wrestled with the question of eye evolution. From an anatomical point of view, researchers have discovered many different types of eyes. For example, the eyes of fruit flies, squid, and humans are quite different from each other. This observation led Austrian zoologist Luitfried von Salvini-Plawen and German evolutionary biologist Ernst Mayr to propose that eyes may have independently arisen multiple times during evolution. Based solely on morphology, such a hypothesis seemed reasonable and for many years was accepted by the scientific community.

The situation took a dramatic turn when geneticists began to study eye development. Researchers identified a master control gene, *Pax6*.* The protein encoded by the *Pax6* gene is a transcription factor that controls the expression of many other genes, including those involved in the development of the eye in both rodents and humans. In mice and rats, a mutation in the *Pax6* gene results in small eyes. A mutation in the human *Pax6* gene causes an eye disorder called aniridia, in which the iris and other structures of the eye do not develop properly. Similarly, *Drosophila* has a gene named *eyeless* that also causes a defect in eye development when mutant. *Eyeless* and *Pax6* are homologous genes; they are derived from the same ancestral gene.

In 1995, Swiss geneticist Walter Gehring and his colleagues were able to show experimentally that the expression of the *eyeless* gene in parts of *Drosophila* where it is normally inactive could promote the formation of additional eyes. For example, using genetic engineering techniques, they were able to express the *eyeless* gene in the region where antennae should form. As seen in **Figure 25.17a**, this resulted in the formation of an eye where antennae are normally found! Remarkably, the expression of the mouse *Pax6* gene in *Drosophila* can also cause the formation of eyes in unusual places. For example, **Figure 25.17b** shows the formation of an eye on the leg of *Drosophila*.

Note that when the mouse *Pax6* gene switches on eye formation in *Drosophila*, the eye produced is a *Drosophila* eye, not a mouse eye. Why does this occur? It happens because the *Pax6* gene activates genes from the *Drosophila* genome. In *Drosophila*, the *Pax6* homolog called *eyeless* switches on a cascade involving several hundred genes required for eye morphogenesis.

*Pax is an abbreviation for paired box. The protein encoded by this gene contains a domain called a paired box.

(a) Abnormal expression of the *Drosophila eyeless* gene in the antenna region

(b) Abnormal expression of the mouse *Pax6* gene in a fruit fly leg

Figure 25.17 Formation of additional eyes in *Drosophila* due to the abnormal expression of a master control gene for eye morphogenesis. **(a)** When the *Drosophila eyeless* gene is expressed in the antenna region, eyes are formed where antennae should be located. **(b)** When the mouse *Pax6* gene is expressed in the leg region of *Drosophila*, a small eye is formed there.

Concept Check: What do you think would happen if the Drosophila eyeless gene was expressed at the tip of a mouse's tail?

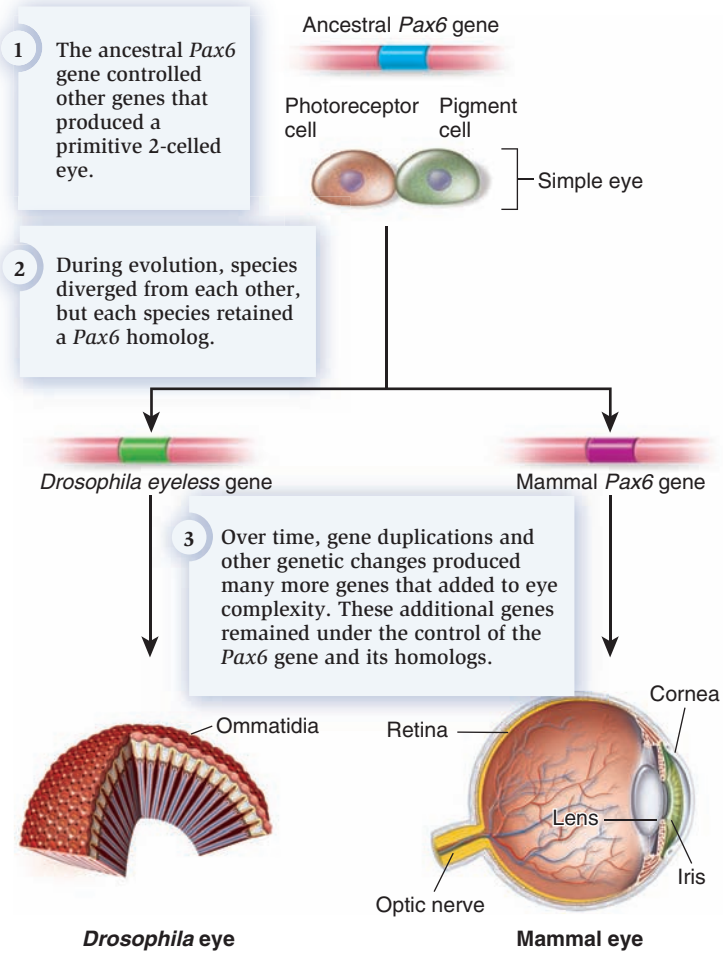


Figure 25.18 Genetic control of eye evolution. In this diagram, genetic changes, under the control of the ancestral *Pax6* gene, led to the evolution of different types of eyes.

Since the discovery of the *Pax6* and *eyeless* genes, homologs of this gene have been discovered in many different species. In all cases where it has been tested, the homologous gene is involved with eye development. Gehring and colleagues have hypothesized that the eyes of many different species have evolved from a common ancestral form consisting of, as proposed by Darwin, one photoreceptor cell and one pigment cell (**Figure 25.18**). As mentioned, such a very simple eye can accomplish a rudimentary form of vision by detecting light and its direction. Eyes such as these are still found in modern species, such as the larvae of certain types of mollusks. Over time, simple eyes evolved into more complex types of eyes by modifications that resulted in the addition of more types of cells, such as lens cells and nerve cells. Alternatively, other researchers propose that *Pax6* may control only certain features of eye development and that different types of eyes may have evolved independently. Future research will be needed to resolve this controversy.

Summary of Key Concepts

25.1 Identification of Species

- A species is a group of related organisms that shares a distinctive set of attributes in nature. Speciation is the process by which new species are formed. Macroevolution refers to evolutionary changes that produce new species and groups of species.
- Different characteristics, including morphological traits, reproductive isolation, molecular features, ecological factors, and evolutionary relationships, are used to identify species (Figure 25.1).
- Reproductive isolating mechanisms prevent two different species from breeding with each other (Figure 25.2).
- Prezygotic isolating mechanisms include habitat isolation, temporal isolation, behavioral isolation, mechanical isolation, and gametic isolation (Figures 25.3, 25.4).
- Postzygotic isolating mechanisms include hybrid inviability, hybrid sterility, and hybrid breakdown (Figure 25.5).

25.2 Mechanisms of Speciation

- Allopatric speciation occurs when a population becomes isolated from other populations and evolves into one or more new species. When speciation from a single ancestral species occurs multiple times, the process is called adaptive radiation. If two populations are incompletely separated, interbreeding may occur in hybrid zones (Figures 25.6, 25.7, 27.8).
- Podos hypothesized that changes in beak depth, associated with adaptation for feeding, promoted reproductive isolation by altering the song pattern of finches (Figures 25.9, 25.10).
- Sympatric speciation involves the formation of different species in populations that are not geographically isolated from one another. Polyploidy, adaptation to local environments, and sexual selection are mechanisms that promote sympatric speciation (Figures 25.11, 25.12).

25.3 The Pace of Speciation

- The pace of evolution may seem relatively constant or it may vary. Gradualism involves steady evolution due to many small genetic changes, whereas punctuated equilibrium is a pattern of evolution in which new species arise more rapidly and then remain unchanged for long periods of time (Figure 25.13).

25.4 Evo-Devo: Evolutionary Developmental Biology

- Evolutionary developmental biology (evo-devo) compares the development of different species in order to understand ancestral relationships and the mechanisms that bring about evolutionary change. These changes often involve variation in the expression of cell-signaling proteins and transcription factors.
- The spatial expression of genes that affect development can affect phenotypes dramatically, as shown by the expression of the *BMP4* and *Gremlin* genes in birds with nonwebbed or webbed feet (Figure 25.14).
- An increase in the number of *Hox* genes played an important role in the evolution of more complex body patterns in animals (Figure 25.15).
- A difference in the relative growth rates of body parts among different species is called heterochrony (Figure 25.16).
- The *Pax6* gene and its homologs control eye development in many species of animals (Figures 25.17, 25.18).

Assess and Discuss

Test Yourself

1. Macroevolution refers to evolutionary changes that
   a. occur in multicellular organisms.
   b. produce new species and groups of species.
   c. occur over long periods of time.
   d. cause changes in allele frequencies.
   e. occur in large mammals.
2. The biological species concept classifies a species based on
   a. morphological characteristics.
   b. reproductive isolation.
   c. the niche the organism occupies in the environment.
   d. genetic relationships between an organism and its ancestors.
   e. both a and b.
3. Which of the following is considered an example of a postzygotic isolating mechanism?
   a. incompatible genitalia
   b. different mating seasons
   c. incompatible gametes
   d. mountain range separating two populations
   e. failure of fertilized eggs to develop normally
4. Hybrid breakdown occurs when species hybrids
   a. do not develop past the early embryonic stages.
   b. have a reduced life span.
   c. are infertile.
   d. are fertile but produce offspring with reduced viability and fertility.
   e. produce offspring that express the traits of only one of the original species.

5. The evolution of one species into two or more species is called
   a. gradualism.
   b. punctuated equilibrium.
   c. cladogenesis.
   d. horizontal gene transfer.
   e. microevolution.
6. The large number of honeycreeper species on the Hawaiian Islands is an example of
   a. adaptive radiation.
   b. genetic drift.
   c. stabilizing selection.
   d. horizontal gene transfer.
   e. microevolution.
7. A major mechanism of speciation in plants but not in animals is
   a. adaptation to new environments.
   b. polyploidy.
   c. hybrid breakdown.
   d. genetic changes that alter the organism's niche.
   e. both a and d.
8. The concept of punctuated equilibrium suggests that
   a. the rate of evolution is constant, with short time periods of no evolutionary change.
   b. evolution occurs gradually over time.
   c. small genetic changes accumulate over time to allow for phenotypic change and speciation.
   d. long periods of little evolutionary change are interrupted by short periods of major evolutionary change.
   e. both b and c.
9. Researchers suggest that an increase in the number of *Hox* genes
   a. leads to reproductive isolation in all cases.
   b. could explain the evolution of color vision.
   c. allows for the evolution of more complex body patterns in animals.
   d. results in the decrease in the number of body segments in insects.
   e. does all of the above.
10. The observation that the mammalian *Pax6* gene and the *Drosophila eyeless* gene are homologous genes that promote the formation of different types of eyes suggests that
    a. *Drosophila* eyes are more complex.
    b. mammalian eyes are more complex.
    c. eyes arose once during evolution.
    d. eyes arose at least twice during evolution.
    e. eye development is a simple process.

Conceptual Questions

1. What is the key difference between prezygotic and postzygotic isolating mechanisms? Give an example of each type. Which type is more costly from the perspective of energy?
2. What are the key differences between gradualism and punctuated equilibrium? How are genetic changes related to these two models?
3.  A principle of biology is that *populations of organisms evolve from one generation to the next.* Describe one example in which genes that control development played an important role in the evolution of different species.

Collaborative Questions

1. What is a species? Discuss how geographic isolation can lead to speciation, and explain how reproductive isolation plays a role.
2. Discuss the type of speciation (allopatric or sympatric) that is most likely to occur under each of the following conditions:
   a. A pregnant female rat is transported by an ocean liner to a new continent.
   b. A meadow containing several species of grasses is exposed to a pesticide that promotes nondisjunction.
   c. In a very large lake containing several species of fishes, the water level gradually falls over the course of several years. Eventually, the large lake becomes subdivided into smaller lakes, some of which are connected by narrow streams.

Taxonomy and Systematics

26

The African forest elephant, *Loxodonta cyclotis*. In 2001, biologists decided that this is a unique species of elephant.

Until recently, biologists classified elephants into only two species—the African savanna elephant (*Loxodonta africana*) and the Asian elephant (*Elephas maximus*). However, by analyzing the DNA of African elephants, researchers have revised this classification, and proposed a third species, called the African forest elephant (*Loxodonta cyclotis*) (shown in the chapter opening photo). How was this new species identified? This surprising finding was made somewhat by accident in 2001. Elephants in Africa are being killed for their tusks at a high rate, despite the 1989 international ban on ivory sales. Scientists set up a DNA identification system to trace tusks to the region in Africa where the elephants were likely killed, which could give law enforcement officials the leverage they need to target poachers in those areas. By studying the DNA from captured tusks, researchers decided that Africa has two distinctly different *Loxodonta* species. The African forest elephant is found in the forests of central and western Africa. The African savanna elephant, which is larger and has longer tusks, lives on open, dry grasslands. One consequence of this discovery is its effect on conservation efforts, which had previously been based on a single species of African elephants.

The rules for the classification of newly described species, such as the African forest elephant, are governed by the discipline of taxonomy (from the Greek *taxis*, meaning order, and *nomos*, meaning law). **Taxonomy** is the science of describing, naming, and classifying **extant** species, those that still exist today, as well as **extinct** species, those that have died out. Taxonomy results in the ordered division of species into groups based on similarities and dissimilarities in their characteristics. This task has been ongoing for over 300 years. As discussed in Chapter 23, the naturalist John Ray made the first attempt to broadly classify all known forms of life. Ray's ideas were later extended by naturalist Carolus Linnaeus in the mid-1700s, which is considered by some as the official birth of taxonomy.

Systematics is the study of biological diversity and the evolutionary relationships among species, both extant and extinct. In the 1950s, German entomologist Willi Hennig began classifying species in a new way. Hennig proposed that evolutionary relationships should be inferred from features shared by descendants of a common ancestor. Since that time, biologists have applied systematics to the field of taxonomy. Researchers now try to place new species into taxonomic groups based on evolutionary relationships with other species. In addition, previously established taxonomic groups are revised as new data shed light on evolutionary relationships. Like any other scientific discipline, taxonomy should be viewed as a work in progress.

In this chapter, we will begin with a discussion of taxonomy and the concept of taxonomic groups. We will then examine how biologists use systematics to determine evolutionary relationships among species, looking in particular at how these relationships are portrayed in diagrams called phylogenetic trees. We will then explore how analyses of morphological data and molecular genetic data are used to understand the evolutionary history of life on Earth.

26.1 Taxonomy

Learning Outcomes:

1. Identify the three domains of life.
2. Explain the hierarchy of groupings in taxonomy.
3. Describe how species are named using binomial nomenclature.

A hierarchy is a system of organization that involves successive levels. In biological taxonomy, every species is placed into several different nested groups within a hierarchy. For example, a leopard and a fruit fly are both classified as animals, though they differ in many characteristics. By comparison, leopards and lions are placed together into a group with a smaller number of species called felines (formally named Felidae), which are predatory cats. The felines are a subset of the animal group, which has species that share many similar features. The species that are placed together into small taxonomic groups are likely to share many of the same characteristics. In this section, we will consider how biologists use a hierarchy to group similar species.

Species Are Subdivided into Three Domains of Life

Modern taxonomy places species into progressively smaller hierarchical groups. Each group at any level is called a **taxon** (plural, taxa). The taxon called the **kingdom** was originally the highest and most inclusive. Linnaeus had classified all life into two kingdoms, plants and animals. In 1969, American ecologist Robert Whittaker proposed a five-kingdom system in which all life was classified into the kingdoms Monera, Protista, Fungi, Plantae, and Animalia. However, as biologists began to learn more about the evolutionary relationships among these groups, they found that this classification did not correctly reflect the relationships among them.

In the late 1970s, based on information in the sequences of genes, American biologist Carl Woese proposed the idea of creating a category called a **domain**. In the taxonomy hierarchy, a domain is above a kingdom. Under this system, all forms of life are grouped within three domains: **Bacteria**, **Archaea**, and **Eukarya** (Figure 26.1). The terms Bacteria and Archaea are capitalized when referring to the domains, but are not capitalized when referring to individual species. A single bacterial cell is called a bacterium, and a single archaeal cell is an archaeon.

The domain Eukarya formerly consisted of four kingdoms called **Protista**, **Fungi**, **Plantae**, and **Animalia**. However, researchers later discovered that protists do not constitute a separate kingdom but instead are a very broad collection of species. Taxonomists now place most eukaryotes into seven groups called supergroups. In the taxonomy of eukaryotes, a **supergroup** lies between a domain and a kingdom (see Figure 26.1). As discussed in Chapter 28, all seven supergroups contain a distinctive group of protists. In addition, kingdoms Fungi and Animalia are within the supergroup Opisthokonta, because they are closely related to the protists in this supergroup. Kingdom Plantae is within the supergroup called Land plants and relatives. Plants are closely related to green algae, which are protists in this supergroup. Table 26.1 compares a variety of molecular and cellular characteristics among the domains Bacteria, Archaea, and Eukarya.

Every Species Is Placed into a Taxonomic Hierarchy

Why is it useful to categorize species into groups? The three domains of life contain millions of different species. Subdividing them into progressively smaller taxonomic groups makes it easier for biologists to appreciate the relationships among such a large number of species.

Below the domain and the supergroup is the kingdom, which is divided into **phyla** (singular, phylum). Each phylum is divided into **classes**, then **orders**, **families**, **genera** (singular, genus), and **species**. As noted in Chapter 25, species may be divided into subspecies, often based on geographical distribution. Each of these taxa contains progressively fewer species that are more similar to each other than

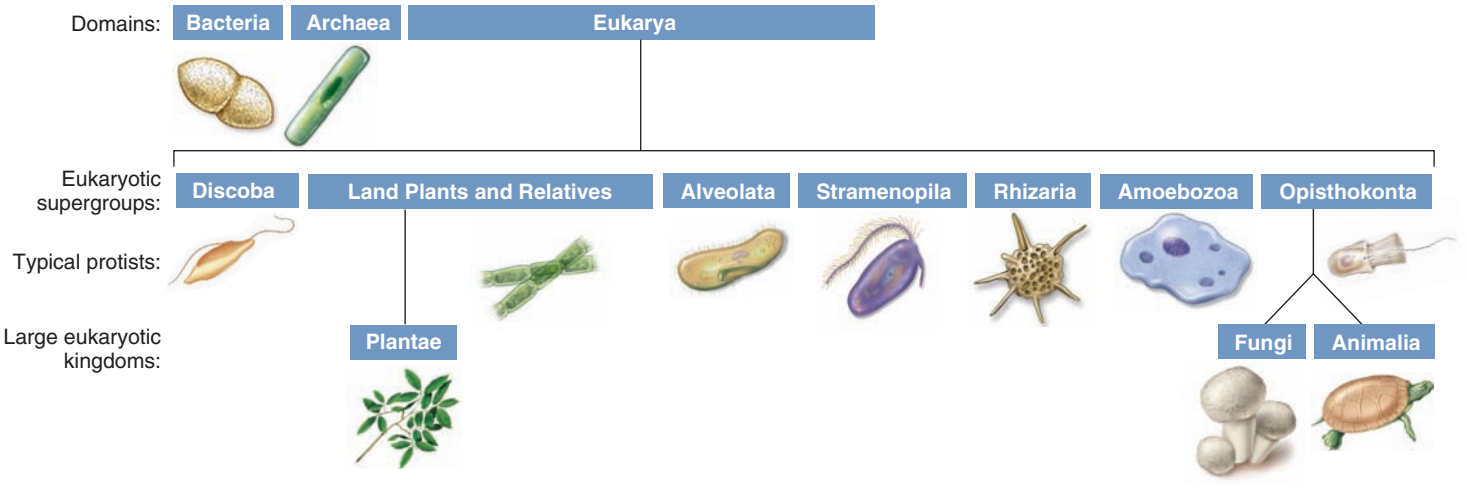

Figure 26.1 A classification system for living and extinct organisms. All organisms are grouped into three domains: Bacteria, Archaea, and Eukarya. Eukaryotes are divided into seven supergroups. These seven supergroups encompass most eukaryotes. However, several small eukaryotic lineages are classified outside of the seven supergroups.

BioConnections: Look back at Figure 4.4. Which of the three domains contain(s) organisms with prokaryotic cells?

Table 26.1 Distinguishing Cellular and Molecular Features of Domains Bacteria, Archaea, and Eukarya*

Characteristic	Bacteria	Archaea	Eukarya
Chromosomes	Usually circular	Circular	Usually linear
Nucleosome structure	No	No	Yes
Chromosome segregation/cell division	Binary fission	Binary fission	Mitosis/meiosis
Introns in genes	Rarely	Rarely	Commonly
Ribosomes	70S	70S	80S
Initiator tRNA	Formylmethionine	Methionine	Methionine
Operons	Yes	Yes	No
Capping of mRNA	No	No	Yes
RNA polymerases	One	Several	Three
Promoters of structural genes	–35 and –10 sequences	TATA box	TATA box
Cell compartmentalization	No	No	Yes
Membrane lipids	Ester-linked	Ether-linked	Ester-linked

*The descriptions in this table represent the general features of most species in each domain. Some exceptions are observed. For example, certain bacterial species have linear chromosomes, and operons occasionally are found in eukaryotes, such as the nematode worm *Caenorhabditis elegans*.

they are to the members of the taxa above them in the hierarchy. For example, the taxon Animalia, which is at the kingdom level, has a larger number of fairly diverse species than does the class Mammalia, which contains fewer species that are relatively similar to each other.

To further understand taxonomy, let's consider the classification of the gray wolf (*Canis lupus*) (**Figure 26.2**). The gray wolf is placed in the domain Eukarya, the supergroup Opisthokonta, and then within the kingdom Animalia. This kingdom contains all animals and has over 1 million species. Next, the gray wolf is classified in the phylum Chordata. The 50,000 species of animals in this phylum all have four common features at some stage of their development. These are a notochord (a cartilaginous rod that runs along the back of all chordates at some point in their life cycle), a tubular nerve or spinal cord located above the notochord, gill slits or arches, and a postanal tail. Examples of animals in the phylum Chordata include fishes, reptiles, and mammals.

The gray wolf is in the class Mammalia, which includes 5,513 species of mammals. Two distinguishing features of animals in this class are hair, which helps the body maintain a warm, constant body temperature, and mammary glands, which produce milk to nourish the young. There are 26 orders of mammals; the order that includes the gray wolf is called Carnivora and has 282 species that are meat-eating animals with prominent canine teeth. The gray wolf is placed in the family Canidae, which is a relatively small family of 34 species, including different species of wolves, jackals, foxes, wild dogs,

Taxonomic group	Gray wolf found in	Number of current species
Domain	Eukarya	~4–10 million
Supergroup	Opisthokonta	>1 million
Kingdom	Animalia	>1 million
Phylum	Chordata	~50,000
Class	Mammalia	5,513
Order	Carnivora	282
Family	Canidae	34
Genus	*Canis*	7
Species	*lupus*	1

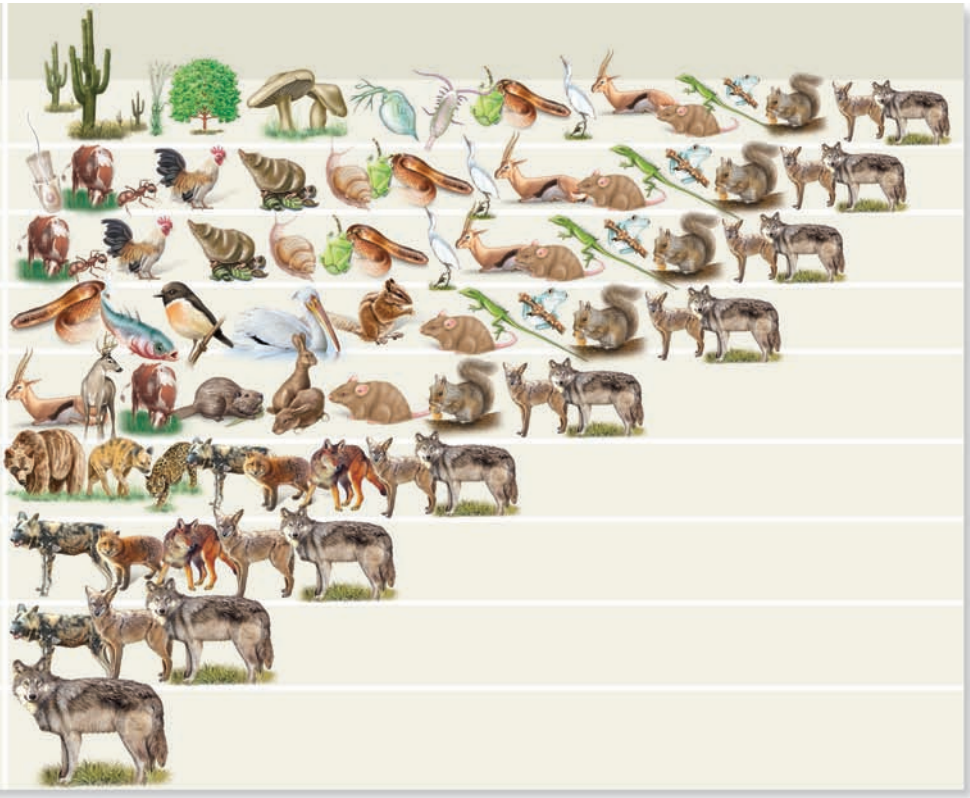

Figure 26.2 A taxonomic classification of the gray wolf (*Canis lupus*).

BIOLOGY PRINCIPLE All species (past and present) are connected by an evolutionary history. A goal of taxonomy is to relate the diversity of species according to their evolutionary relationships. Note: The numbers in this figure will change as new species are discovered and some species become extinct.

Concept Check: *Which group is broader, a phylum or a family?*

and the coyote and domestic dog. All species in the family Canidae are doglike animals. The smallest grouping that contains the gray wolf is the genus *Canis*, which has four species of jackals, the coyote, and two types of wolves. The species *Canis lupus* encompasses several subspecies, including the domestic dog (*Canis lupus familiaris*).

Binomial Nomenclature Is Used to Name Species

As originally advocated by Linnaeus, **binomial nomenclature** is the standard method for naming species. The scientific name of every species has two names, its genus name and its unique specific epithet. For the gray wolf, the genus is *Canis* and the species epithet is *lupus*. The genus name is always capitalized, but the specific epithet is not. Both names are italicized. After the first mention, the genus name is abbreviated to a single letter. For example, we write that *Canis lupus* is the gray wolf, and in subsequent sentences, the species is referred to as *C. lupus*.

When naming a new species, genus names are always nouns or treated as nouns, whereas species epithets may be either nouns or adjectives. The names often have a Latin or Greek origin and refer to characteristics of the species or to features of its habitat. For example, the genus name of the newly discovered African forest elephant, *Loxodonta*, is from the Greek *loxo*, meaning slanting, and *odonta*, meaning tooth. The species epithet *cyclotis* refers to the observation that the ears of this species are rounder than those of *L. africana*.

The rules for naming animal species, such as *Canis lupus* and *Loxodonta africana*, were established by the International Commission on Zoological Nomenclature (ICZN). The ICZN provides and regulates a uniform system of nomenclature to ensure that every animal has a unique and universally accepted scientific name. Who is allowed to identify and name a new species? As long as ICZN rules are followed, new animal species can be named by anyone, not only scientists. The rules for naming plants are described in the International Code of Botanical Nomenclature (ICBN), and the naming of bacteria and archaea is overseen by the International Committee on Systematics of Prokaryotes (ICSP).

26.2 Phylogenetic Trees

Learning Outcomes:

1. Define phylogeny, and explain how it is depicted in phylogenetic trees.
2. Compare and contrast cladogenesis and anagenesis as patterns of speciation.
3. Describe how homology is used to construct phylogenetic trees.

Systematics is the study of biological diversity and evolutionary relationships. By studying the similarities and differences among species, biologists can construct a **phylogeny**, which is the evolutionary history of a species or group of species. To propose a phylogeny, biologists use the tools of systematics. For example, the classification of the gray wolf in Figure 26.2 is based on systematics. Therefore, one use of systematics is to place species into taxa and to understand the evolutionary relationships among different taxa.

In this section, we will consider the features of diagrams or trees that describe the evolutionary relationships among various species, both extant and extinct. As you will learn, such trees are usually based on morphological or genetic data.

A Phylogenetic Tree Depicts Evolutionary Relationships Among Species

A **phylogenetic tree** is a diagram that describes the evolutionary relationships among various species, based on the information available to and gathered by systematists. Phylogenetic trees should be viewed as hypotheses that are proposed, tested, and later refined as additional data become available. Let's look at what information a phylogenetic tree contains and the form in which it is presented. **Figure 26.3** shows a hypothetical phylogenetic tree of the relationships among various flowering plant species, in which the species are labeled A through K. The vertical axis represents time, with the oldest species at the bottom.

New species can be formed by **anagenesis**, in which a single species evolves into a different species, or much more commonly by **cladogenesis**, in which a species diverges into two or more species. The branch points in a phylogenetic tree, also called **nodes**, indicate times when cladogenesis has occurred. For example, approximately 12 mya, species A diverged into species A and species B. Figure 26.3 also shows anagenesis in which species C evolved into species G. The tips of branches represent species that became extinct in the past, such as species B and E, or living species, such as F, I, G, J, H, and K, which are at the top of the tree. Species A and D are also extinct but gave rise to species that are still in existence.

The branch points of a phylogenetic tree group species according to common ancestry. A **clade** consists of a common ancestral species and all of its descendant species. For example, the group highlighted in light green in Figure 26.3 is a clade derived from the common ancestral species labeled D. Likewise, the entire tree forms a clade, with species A as a common ancestor. Therefore, smaller and more recent clades are nested within larger clades that have older common ancestors.

Systematics Constructs Taxonomic Groups Based on Evolutionary Relationships

A key goal of modern systematics is to create taxonomic groups that reflect evolutionary relationships. Systematics attempts to organize species into clades, which means that each group includes an ancestral species and all of its descendants. A **monophyletic group** is a taxon that is a clade. Ideally, every taxon, whether it is a domain, supergroup, kingdom, phylum, class, order, family, or genus, should be a monophyletic group.

What is the relationship between a phylogenetic tree and taxonomy? The relationship depends on how far back we go to identify a common ancestor. For broader taxa, such as a kingdom, the common ancestor existed a very long time ago, on the order of hundreds of millions or even billions of years ago. For smaller taxa, such as a family or genus, the common ancestor occurred much more recently, on the order of millions or tens of millions of years ago. This concept is shown in a schematic way in **Figure 26.4**. This small, hypothetical kingdom is a clade that contains 64 living species. (Actual kingdoms

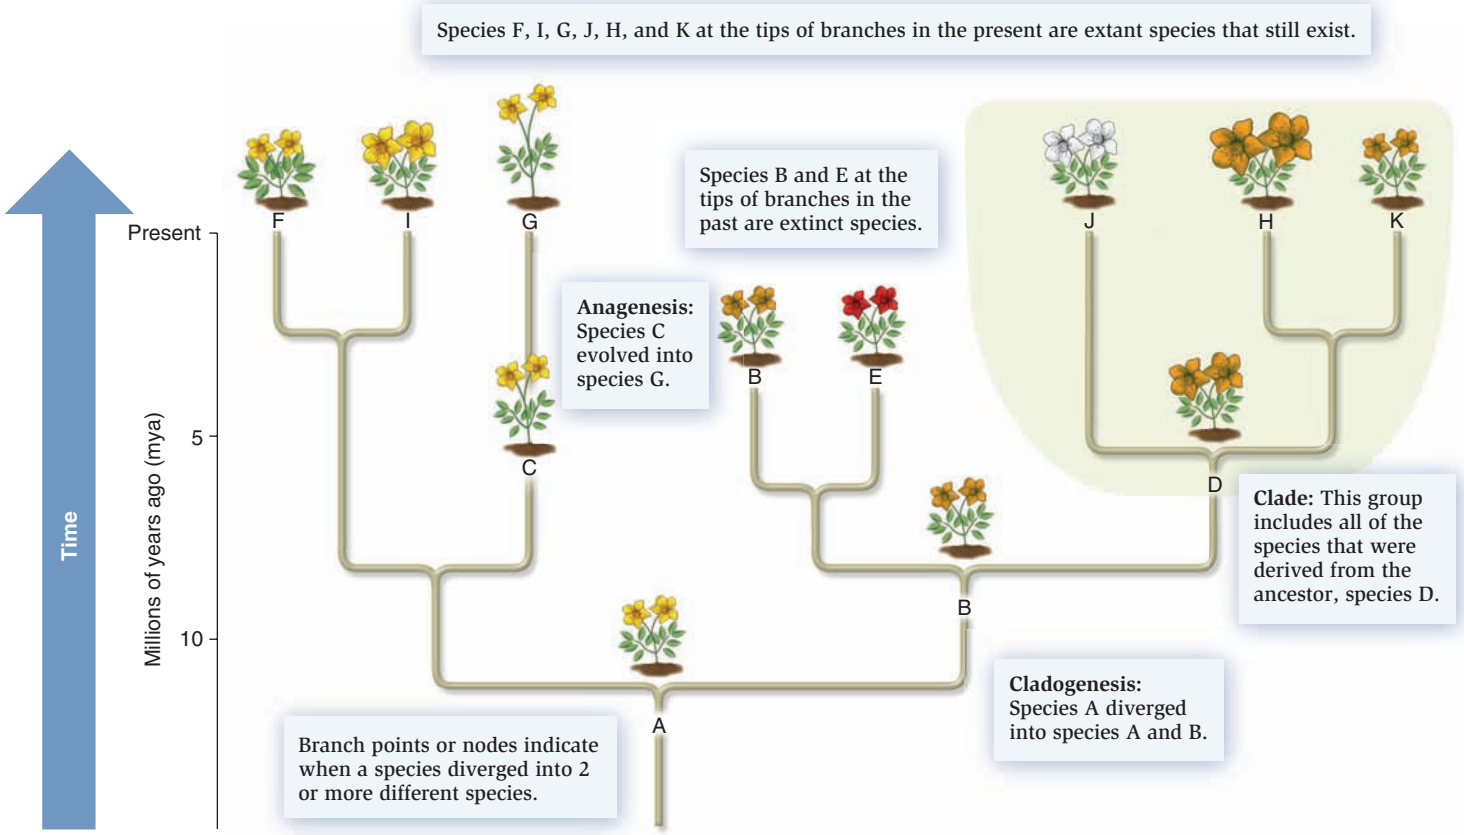

Figure 26.3 **How to read a phylogenetic tree.** This hypothetical tree shows the proposed relationships between various flowering plant species. Species are placed into clades, groups of organisms containing an ancestral organism and all of its descendants.

Concept Check: *Can two different species have more than one common ancestor?*

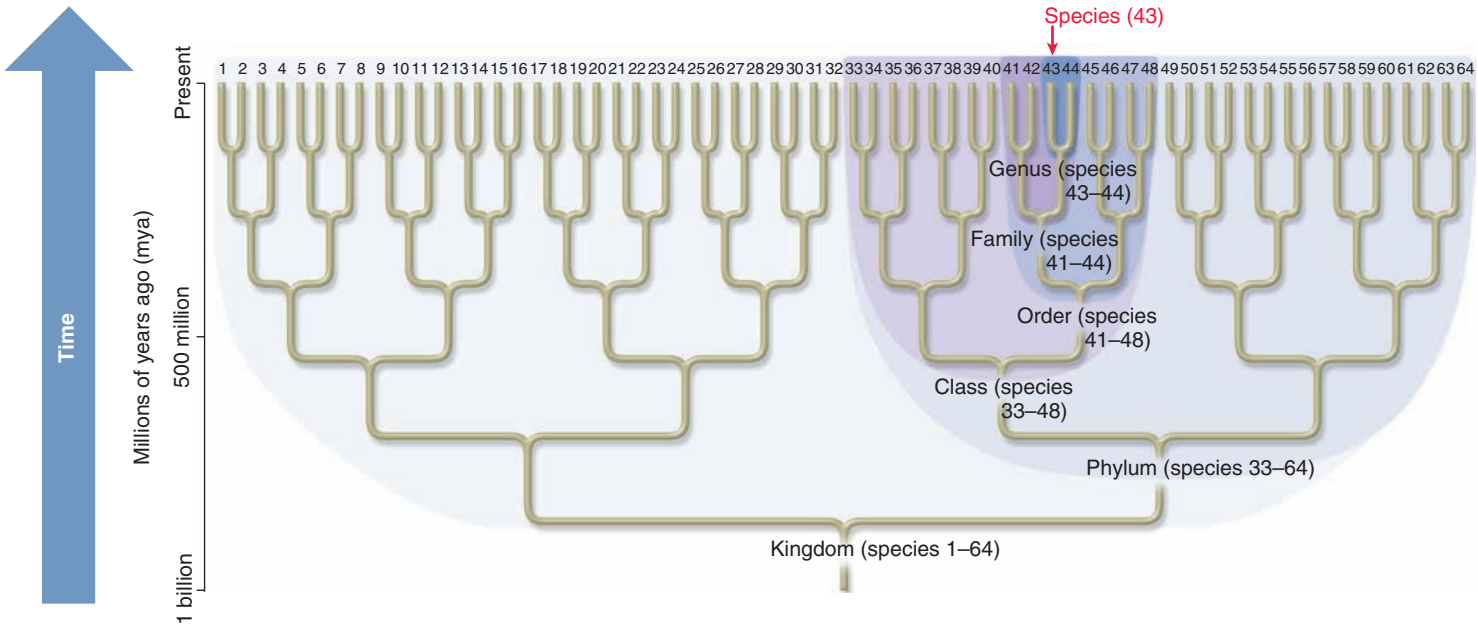

Figure 26.4 **Schematic relationship between a phylogenetic tree and taxonomy, when taxonomy is correctly based on evolutionary relationships.** The shaded areas highlight the kingdom, phylum, class, order, family, and genus for species number 43. All of the taxa are clades. Broader taxa, such as phyla and classes, are derived from more ancient common ancestors. Smaller taxa, such as families and genera, are derived from more recent common ancestors. These smaller taxa are subsets of the broader taxa.

Concept Check: *Which taxon would have a more recent common ancestor, a phylum or an order?*

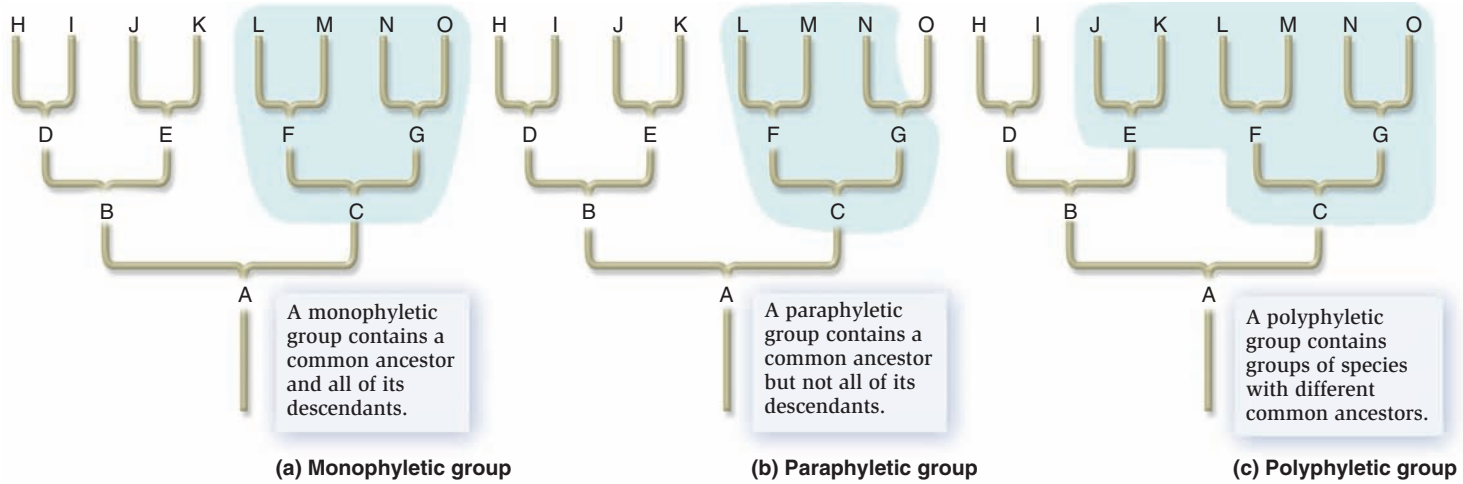

Figure 26.5 **A comparison of monophyletic, paraphyletic, and polyphyletic taxonomic groups.**

are obviously larger and exceedingly more complex.) The diagram emphasizes the taxa that contain the species designated number 43. The common ancestor that gave rise to this kingdom existed approximately 1 billion years ago. Over time, more recent species arose that subsequently became the common ancestors to the phylum, class, order, family, and genus that contain species number 43.

How does research in systematics affect taxonomy? As researchers gather new information, they sometimes discover that some of the current taxonomic groups are not monophyletic. **Figure 26.5** compares a monophyletic group with taxonomic groups that are not. A **paraphyletic group** contains a common ancestor and some, but not all, of its descendants (Figure 26.5b). In contrast, a **polyphyletic group** consists of members of several evolutionary lines and does not include the most recent common ancestor of the included lineages (Figure 26.5c).

As scientists learn more about evolutionary relationships, taxonomic groups are reorganized to recognize only monophyletic groups. For example, traditional classification schemes once separated birds and reptiles into separate classes (**Figure 26.6a**). In this scheme, the reptile class (officially named Reptilia) contained orders that included turtles, lizards and snakes, and crocodiles, with birds constituting a different class. Research indicated that the reptile taxon was paraphyletic, because birds were excluded from the group. This group can be made monophyletic by including birds as a class within the reptile clade and elevating the other groups to a class status (**Figure 26.6b**).

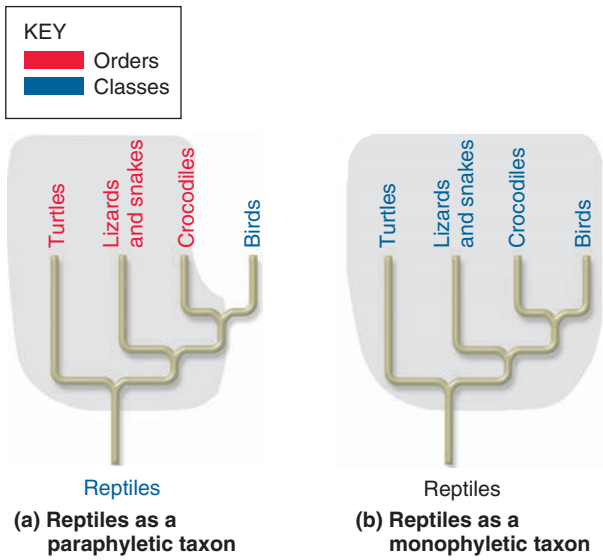

Figure 26.6 **An example of a taxon that is not monophyletic.** **(a)** The class of reptiles as a paraphyletic taxon. **(b)** The group can be made monophyletic if birds and the other orders are classified as classes within the reptile clade.

The Study of Systematics Is Usually Based on Morphological or Genetic Homology

As discussed in Chapter 23, the term **homology** refers to a similarity that occurs due to descent from a common ancestor. Such features are said to be homologous. For example, the arm of a human, the wing of a bat, and the flipper of a whale are homologous structures (refer back to Figure 23.12). Similarly, genes found in different species are homologous if they have been derived from the same ancestral gene (refer back to Figure 23.13).

In systematics, researchers identify homologous features that are shared by some species but not by others, which allows them to group species based on shared similarities. Researchers usually study homology by examining morphological features or genetic data. In addition, the data they gather are viewed in light of geographic data. Many organisms do not migrate extremely long distances. Species that are closely related evolutionarily are relatively likely to inhabit neighboring or overlapping geographic regions, though many exceptions are known to occur.

Morphological Analysis The first studies in systematics focused on morphological features of extinct and living species. Morphological traits continue to be widely used in systematic studies, particularly in those studies pertaining to extinct species and those involving groups that have not been extensively studied at the molecular level. To establish evolutionary relationships based on morphological homology, many traits have to be analyzed to identify similarities and differences.

By studying morphological features of extinct species in the fossil record, paleontologists can propose phylogenetic trees that chart the evolutionary lineages of species, including those that still exist. In this approach, the trees are based on morphological features that change over the course of many generations. As an example, **Figure 26.7** depicts a current hypothesis of the evolutionary changes that led to the development of the modern horse. This figure shows representative species from various genera. Many morphological features were used to propose this tree. Because hard parts of the body are more commonly preserved in the fossil record, this tree is largely based on the analysis of skeletal changes in foot structure, lengths and shapes of various leg bones, skull shape and size, and jaw and tooth morphology. Over an evolutionary timescale, the accumulation of many genetic changes has had a dramatic effect on species' characteristics. In the genera depicted in this figure, a variety of morphological changes occurred, such as an increase in size, a reduction in the number of toes, and modifications in the jaw and teeth consistent with a dietary shift from tender leaves to more abrasive grasses.

How do evolutionary biologists explain these changes in horses' traits? The changes can be attributed to natural selection, which acted on existing variation and resulted in adaptations to changes in climate. Over North America, where much of horse evolution occurred, changes in climate caused large areas of dense forests to be replaced with grasslands. The increase in size and changes in foot structure enabled horses to escape predators more easily and travel greater distances in search of food. The changes seen in horses' teeth are consistent with a shift from eating the tender leaves of bushes and trees to eating grasses and other more abrasive types of vegetation that require more chewing.

Molecular Systematics The field of **molecular systematics** involves the analysis of genetic data, such as DNA sequences or amino acid sequences, to identify and study genetic homologies and

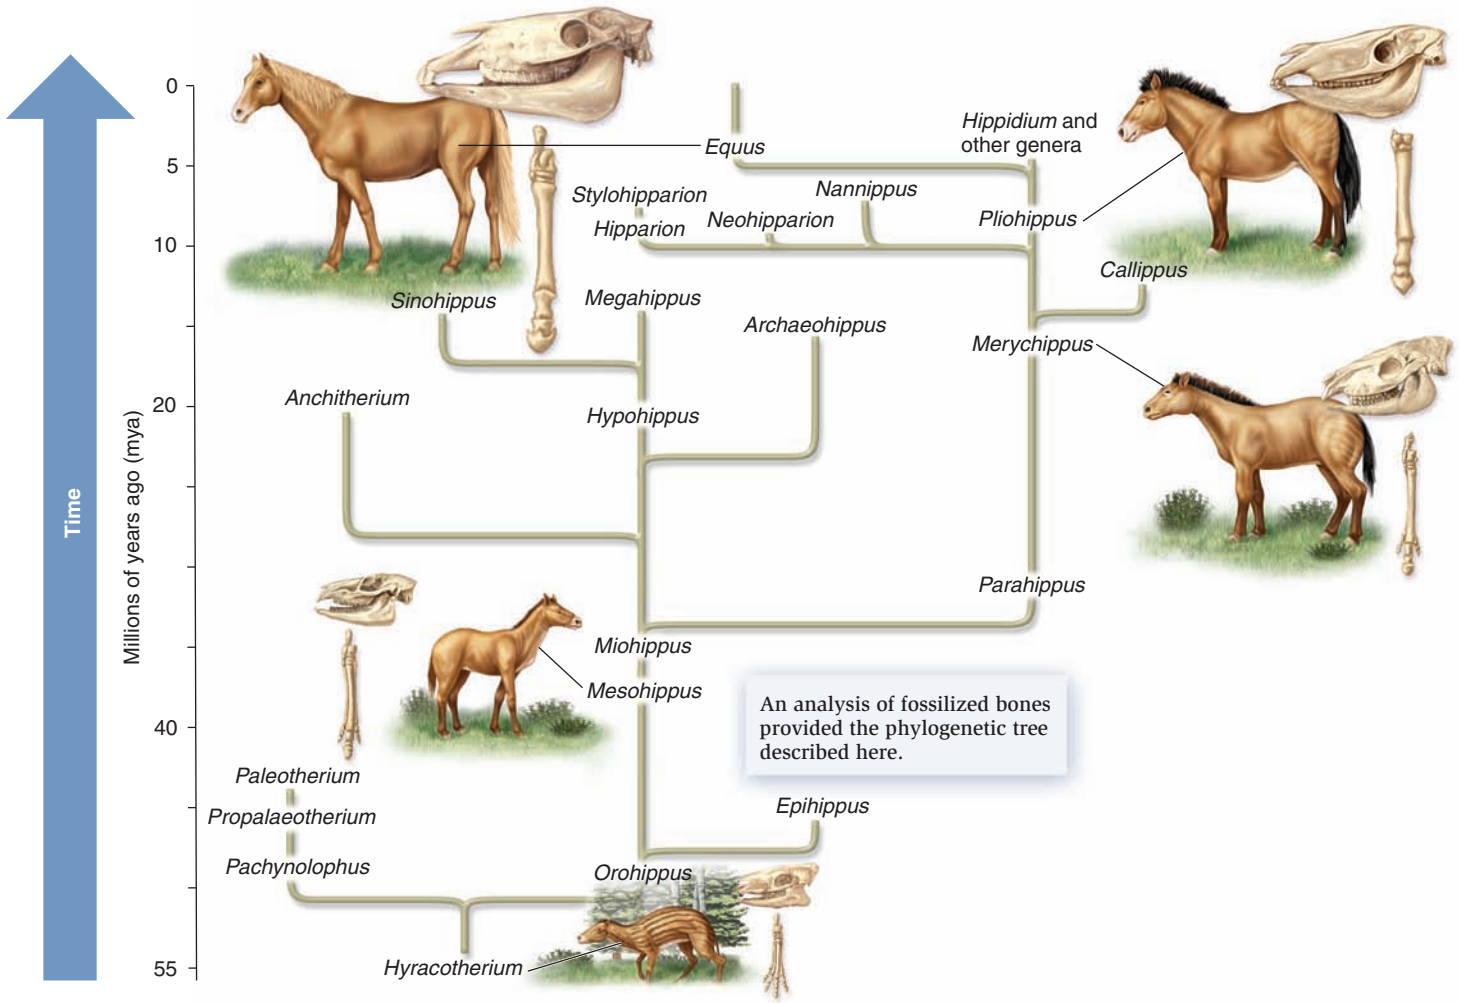

Figure 26.7 Evolution of the horse. An analysis of morphological traits was used to produce this phylogenetic tree, which shows the evolutionary history of the modern horse. As shown next to some of the genera, three important morphological changes were larger size, fewer toes, and a shift toward teeth suited for grazing.

BIOLOGY PRINCIPLE Structure determines function. The changes in structural features during horse evolution are related to changes in functional needs. During this time, horse populations shifted from feeding on leaves in forested regions to feeding on grasses in more open spaces.

propose phylogenetic trees. In 1963, Austrian biologist Emile Zuckerkandl and American chemist Linus Pauling were the first to suggest that molecular data could be used to establish evolutionary relationships. How can a comparison of genetic sequences help to establish evolutionary relationships? As discussed later in this chapter, DNA sequences change over the course of many generations due to the accumulation of mutations. Therefore, when comparing homologous sequences in different species, DNA sequences from closely related species are more similar to each other than they are to sequences from distantly related species.

26.3 Cladistics

Learning Outcomes:

1. Distinguish between shared primitive characters and shared derived characters.
2. Outline the steps involved in using a cladistics approach to construct a phylogenetic tree, and explain how the principle of parsimony is used to choose among phylogenetic trees.
3. Describe how maximum likelihood is also used to discriminate among phylogenetic trees.
4. **SciSKILLS** » Explain how DNA can be analyzed to explore relationships among extant and extinct species.

Cladistics is the classification of species based on evolutionary relationships. A cladistic approach produces phylogenetic trees by considering the possible pathways of evolutionary change that involve characteristics that are shared or not shared among various species. Such trees are known as **cladograms**. In this section, we will consider how biologists produce phylogenetic trees.

Species Differ with Regard to Primitive and Derived Characters

A cladistic approach compares homologous features, also called **characters**, which may exist in two or more **character states**. For example, among different species, a front limb, which is a character, may exist in different character states such as a wing, an arm, or a flipper. The various character states are either shared or not shared by different species.

To understand the cladistic approach, let's take a look at a simplified phylogeny (**Figure 26.8**). We can place the species that currently exist into two groups: D and E, and F and G. The most recent common ancestor to D and E is B, whereas species C is the most recent common ancestor to F and G. With these ideas in mind, let's focus on the front limbs (flippers versus legs) and eyes.

A character that is shared by two or more different taxa and inherited from ancestors older than their last common ancestor is called a **shared primitive character**, or **symplesiomorphy**. Such characters are viewed as being older—ones that occurred earlier in evolution. With regard to species D, E, F, and G, having two eyes is a shared primitive character. It originated prior to species B and C.

By comparison, a **shared derived character**, or **synapomorphy**, is a character that is shared by two or more species or taxa and has originated in their most recent common ancestor. With regard to species D and E, having two front flippers is a shared derived character

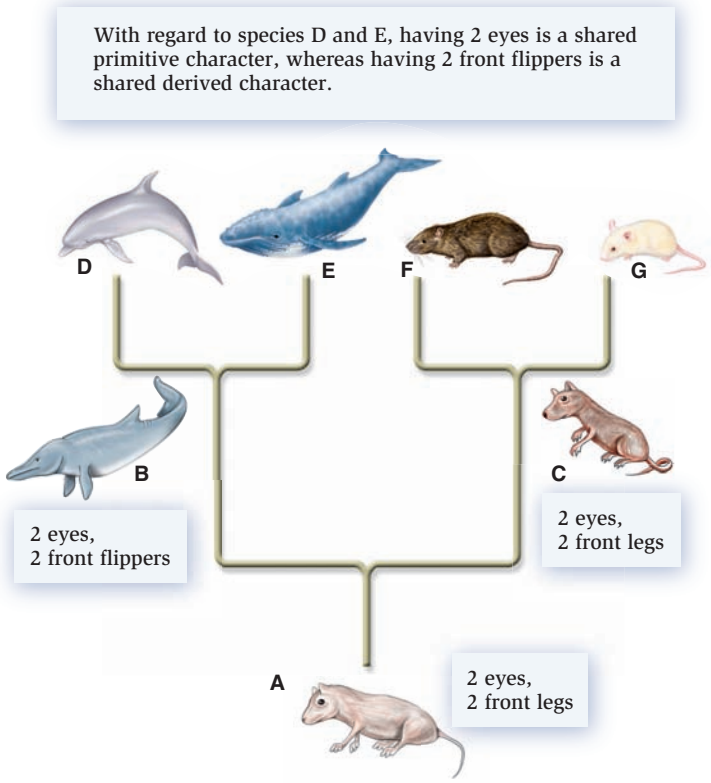

Figure 26.8 A comparison of shared primitive characters and shared derived characters.

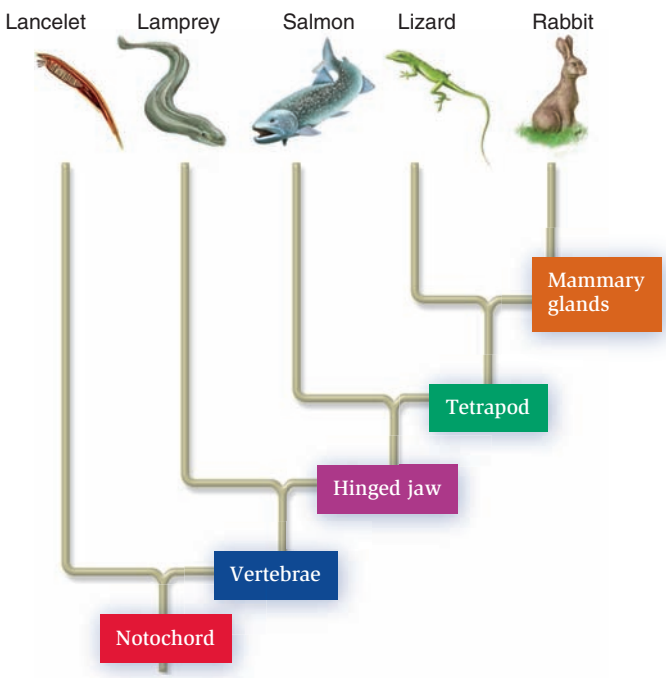
that originated in species B, their most recent common ancestor (see Figure 26.8). Compared with shared primitive characters, shared derived characters are more recent traits on an evolutionary timescale. For example, among mammals, only some species, such as whales and dolphins, have flippers. In this case, flippers were derived from the two front limbs of an ancestral species. The word derived indicates that evolution involves the modification of traits in pre-existing species. In other words, populations of organisms with new traits are derived from changes in pre-existing populations. The basis of the cladistic approach is to analyze many shared derived characters among groups of species to deduce the pathway that gave rise to those species.

Note that the terms primitive and derived do not indicate the complexity of a character. For example, the flippers of a dolphin do not appear more complex than the front limbs of ancestral species A (see Figure 26.8), which were limbs with individual toes. Derived characters can be similar in complexity, less complex, or more complex than primitive characters.

A Cladistic Approach Produces a Cladogram Based on Shared Derived Characters



To show how shared derived characters are used to propose a phylogenetic tree, **Figure 26.9a** compares several traits among five species of animals. The proposed cladogram in **Figure 26.9b** is consistent with the distribution of shared derived characters among these species. A branch point is where two species differ in a character. The oldest common ancestor, which is now extinct, had a notochord and was an ancestor to all five species. Vertebrae are a shared derived character of the

lamprey, salmon, lizard, and rabbit, but not the lancelet, which is an invertebrate. By comparison, a hinged jaw is a shared derived character of the salmon, lizard, and rabbit, but not of the lamprey or lancelet.

In a cladogram, an **ingroup** is the group whose evolutionary relationships we wish to understand. By comparison, an **outgroup** is a species or group of species that is assumed to have diverged before the species in the ingroup. An outgroup lacks one or more shared derived characters that are found in the ingroup. A designated outgroup can be closely related or more distantly related to the ingroup. In the tree shown in Figure 26.9, if the salmon, lizard, and rabbit are an ingroup, the lamprey is an outgroup. The lamprey has a notochord and vertebrae but lacks a character shared by the ingroup, namely, a hinged jaw. Thus, for the ingroup, the notochord and vertebrae are shared primitive characters, whereas the hinged jaw is a shared derived character not found in the outgroup.

	Lancelet	Lamprey	Salmon	Lizard	Rabbit
Notochord	Yes	Yes	Yes	Yes	Yes
Vertebrae	No	Yes	Yes	Yes	Yes
Hinged jaw	No	No	Yes	Yes	Yes
Tetrapod	No	No	No	Yes	Yes
Mammary glands	No	No	No	No	Yes

(a) Characters among species

(b) Cladogram based on morphological traits

Figure 26.9 Using shared primitive characters and shared derived characters to propose a phylogenetic tree. **(a)** A comparison of characters among these species. **(b)** This phylogenetic tree illustrates both shared primitive and shared derived characters in a cladogram of five animal species.

Concept Check: What shared derived character is common to the salmon, lizard, and rabbit, but not the lamprey?

Likewise, the concept of shared derived characters can apply to molecular data, such as a gene sequence. Let's consider an example to illustrate this idea. Our example involves molecular data obtained from seven different hypothetical plant species called A–G. In these species, a homologous region of DNA was sequenced as shown here:

```
   12345678910
A: GATAGTACCC
B: GATAGTTCCC
C: GATAGTTCCG
D: GGTATTACCC
E: GGTATAACCC
F: GGTAGTACCA
G: GGTAGTACCC
```

The cladogram of **Figure 26.10** is a hypothesis of how these DNA sequences arose. A mutation that changes the sequence of nucleotides is comparable to a modification of a character. For example, let's designate species D as an outgroup and species A, B, C, F, and G as the ingroup. In this case, a G (guanine) at the fifth position is a shared derived character. The genetic sequence carrying this G is derived from an older primitive sequence.

Now that we have an understanding of shared primitive and derived characters, let's consider the steps a researcher would follow to propose a cladogram using a cladistics approach.

1. **Choose the species whose evolutionary relationships are of interest.** In a simple cladogram, such as those described in this chapter, individual species are compared with each other. In more complex cladograms, species may be grouped into larger taxa (for example, families) and compared with each other. If such grouping is done, the results are not reliable if the groups are not clades.
2. **Choose characters for comparing the species selected in step 1.** As mentioned, a character is a general feature of an organism and may come in different versions called character states. For example, a front limb is a character in mammals, which could exist in different character states such as a wing, an arm, or a flipper.
3. **Determine the polarity of character states.** In other words, determine if a character state came first and is primitive or came later and is a derived character. This information may be available by examining the fossil record, for example, but is usually done by comparing the ingroup with the outgroup. For a character with two character states, an assumption is made that a character state shared by the outgroup and ingroup is primitive. A character state shared only by members of the ingroup is derived.
4. **Analyze cladograms based on the following principles:**
   - All species (or higher taxa) are placed on tips in a phylogenetic tree, not at branch points.
   - Each cladogram branch point should have a list of one or more shared derived characters that are common to all species above the branch point unless the character is later modified.
   - All shared derived characters appear together only once in a cladogram unless they arose independently during evolution more than once.

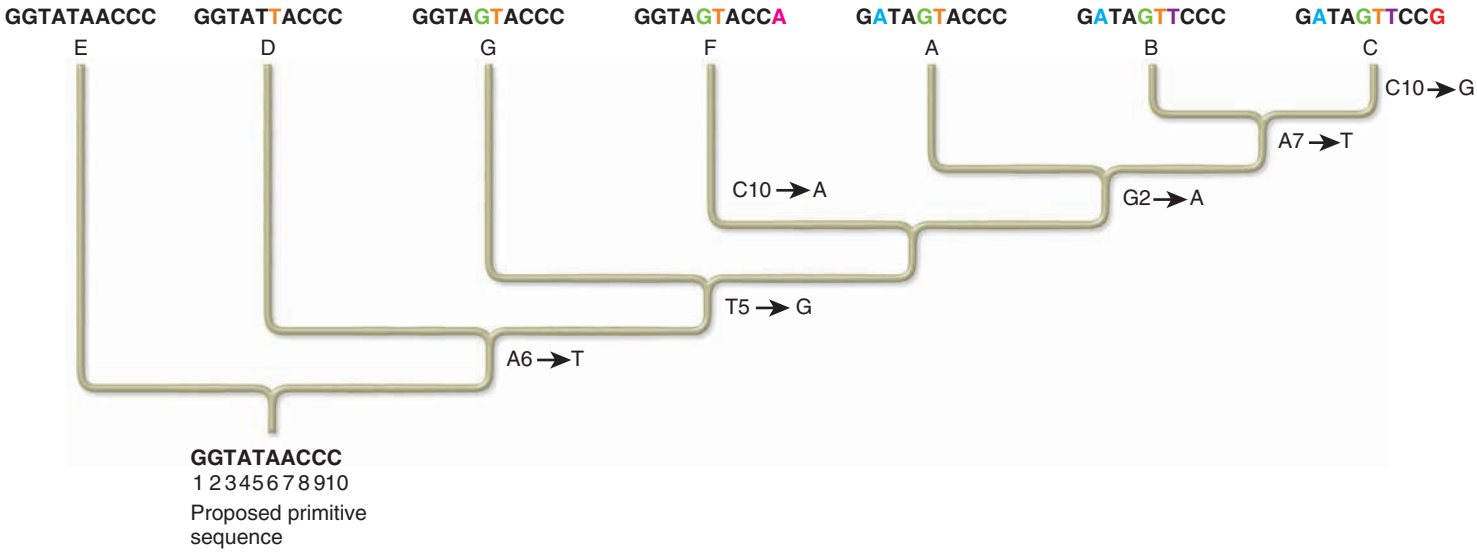


Figure 26.10 The use of shared derived characters applied to molecular data. This phylogenetic tree illustrates a cladogram involving homologous gene sequences found in seven hypothetical plant species. Mutations that alter a primitive DNA sequence are shared among certain species but not others. Note: A, T, G, and C refer to nucleotide bases, and the numbers refer to the position of the base in the nucleotide sequences. For example, A6 refers to an adenine at the sixth position.

Concept Check: What nucleotide change is a shared derived character for species A, B, and C, but not for species G?

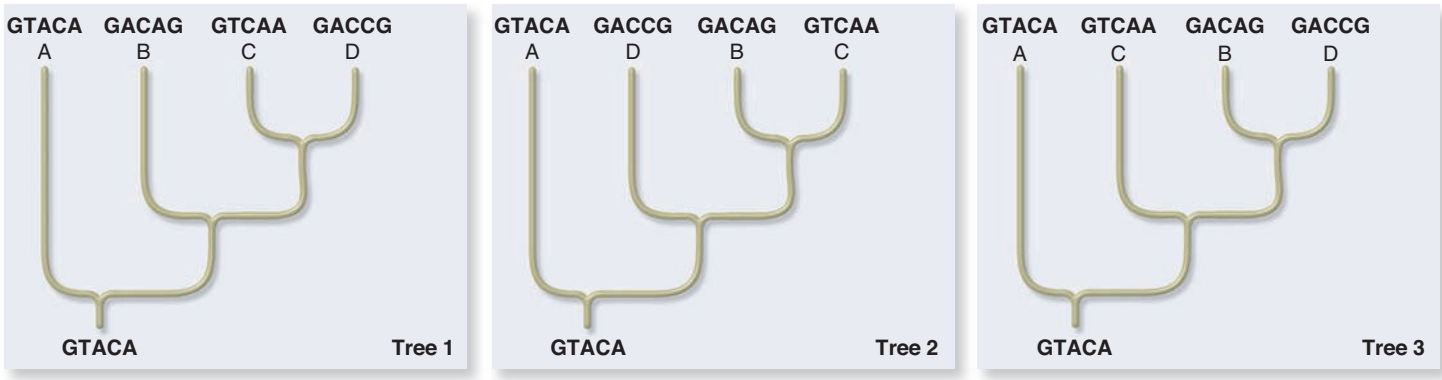
5. **Among many possible options, choose the cladogram that provides the simplest explanation for the data.** A common approach is to use a computer program that generates many possible cladograms. Analyzing the data and choosing among the possibilities are key aspects of this process. As described later, different theoretical approaches, such as the principle of parsimony, can be used to choose among possible phylogenies.
6. **Provide a root to the phylogenetic tree by choosing a noncontroversial outgroup.** In this textbook, most phylogenetic trees are rooted, which means that a single node at the bottom of the tree corresponds to a common ancestor for all of the species or groups of species in the tree. A method for rooting trees is the use of a noncontroversial outgroup. Such an outgroup typically shares morphological traits and/or DNA sequence similarities with the members of the ingroup, to allow a comparison between the ingroup and outgroup. Even so, the outgroup must be noncontroversial in that it has enough distinctive differences with the ingroup to be considered a clear outgroup. For example, if the ingroup was a group of mammalian species, an outgroup could be a reptile.

The Principle of Parsimony Is Used to Choose from Among Possible Cladograms

One approach for choosing among possible cladograms is to assume that the best hypothesis is the one that requires the fewest number of evolutionary changes. This concept, called the **principle of parsimony**, states that the preferred hypothesis is the one that is the simplest for all the characters and their states. For example, if two species possess a tail, we would initially assume that a tail arose once during evolution and that both species have descended from a common ancestor with a tail. Such a hypothesis is simpler, and more likely to be correct, than assuming that tails arose twice during evolution and that the tails in the two species are not due to descent from a common ancestor.

Maximum Likelihood Is Also Used to Discriminate Among Possible Phylogenetic Trees

In addition to the principle of parsimony, evolutionary biologists also apply other approaches to the evaluation of phylogenetic trees. These methods involve the use of an evolutionary model—a set of assumptions about how evolution is likely to happen. For example, mutations affecting the third base in a codon are often neutral because they don't affect the amino acid sequence of the encoded protein and therefore don't affect the fitness of an organism. As discussed in Chapter 24, such neutral mutations are more likely to become prevalent in a population than are mutations in the first or second base. Therefore, one possible assumption of an evolutionary model is that neutral mutations are more likely than nonneutral mutations.



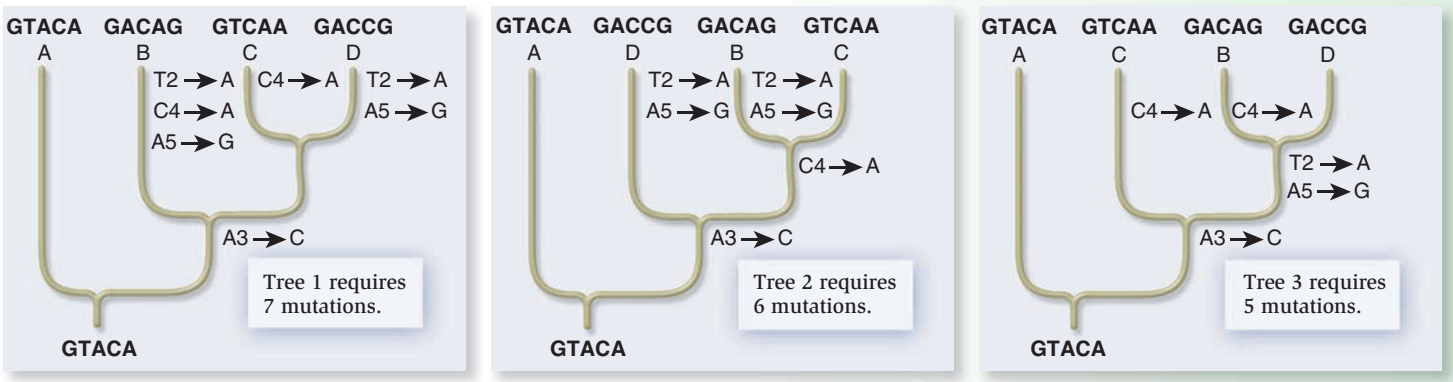
According to an approach called **maximum likelihood**, researchers may ask, "What is the probability that an evolutionary model and a proposed phylogenetic tree would give rise to observed molecular data?" To answer this question, they must devise rules about how DNA sequences change over time. For example, one rule may be that neutral mutations are more likely to occur than nonneutral mutations. A second rule might be that the rate of change of DNA sequences is relatively constant from one generation to the next in a particular lineage. With a set of probability rules, researchers can analyze different possible trees and predict the relative probabilities for each of them. The phylogenetic tree that gives the highest probability of producing the observed data is preferred to any trees that give a lower probability.

BIO TIPS

THE QUESTION *The principle of parsimony can be applied to the analysis of data on gene sequences. In this case, the most likely hypothesis is the one requiring the fewest base changes. Let's consider a hypothetical example involving molecular data from four taxa (A–D), where A is presumed to be the outgroup.*

```
     12345
A:   GTACA  (outgroup)
B:   GACAG
C:   GTCAA
D:   GACCG
```

Given that B, C, and D comprise the ingroup, three possible phylogenetic trees that reflect the given base sequences are shown below.



Based on the principle of parsimony, which of these trees is the most likely to be correct?

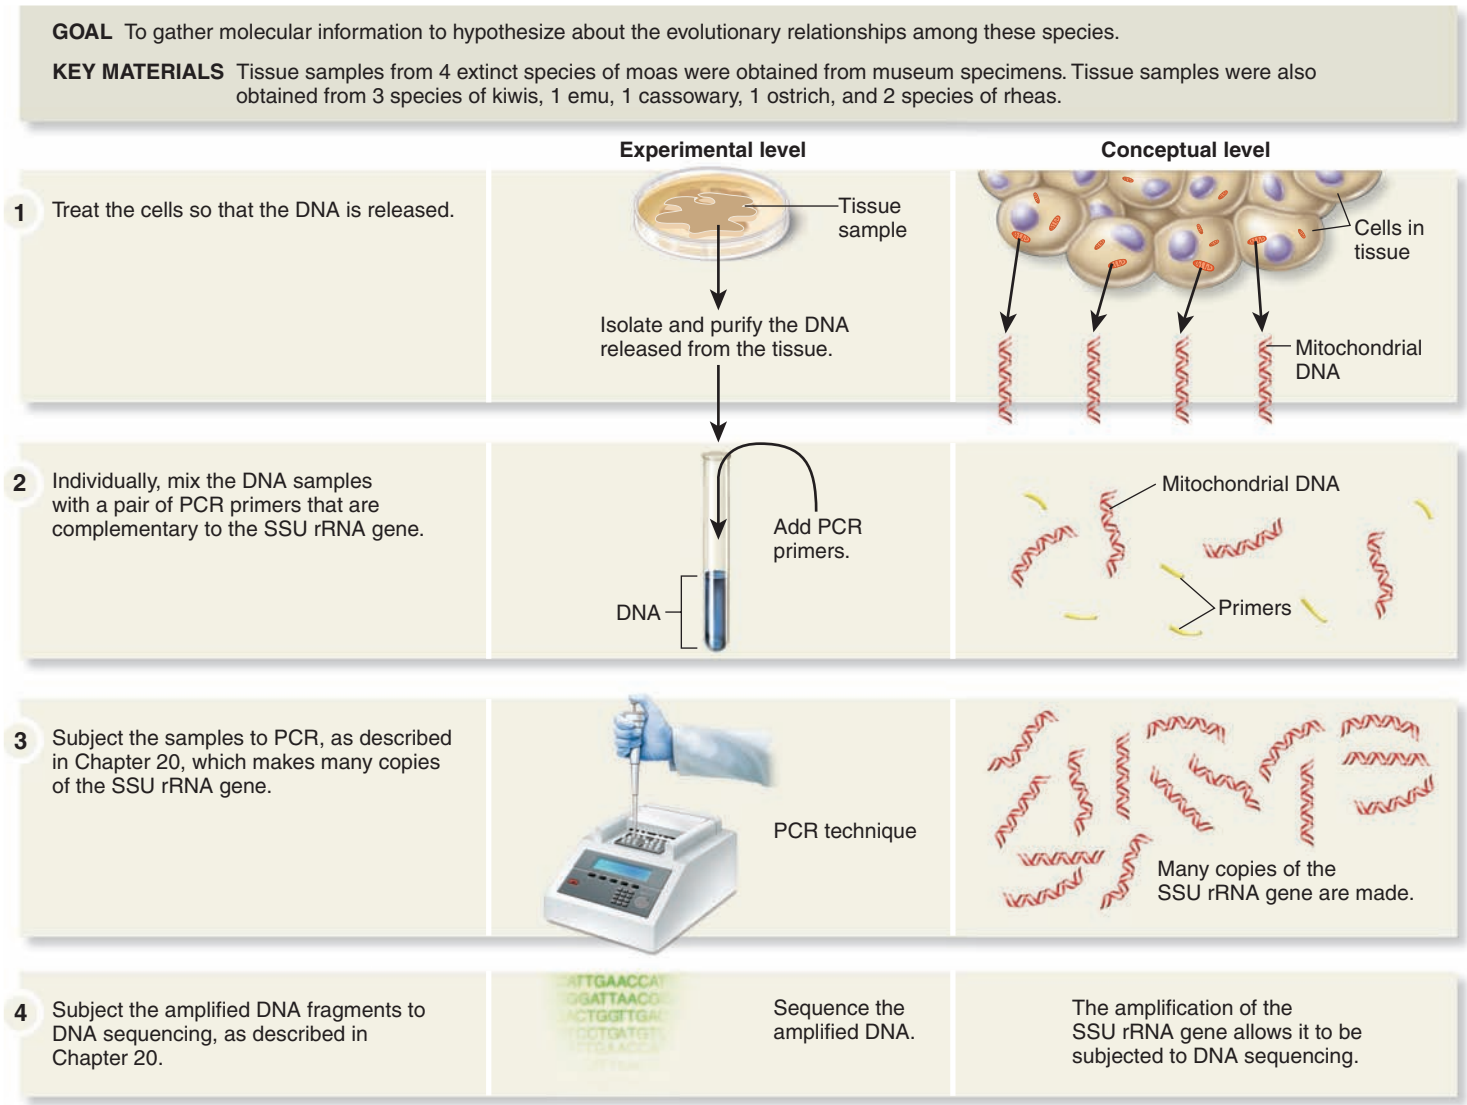
TOPIC ***What topic in biology does this question address?*** The topic is phylogeny. More specifically, the question asks you to compare three phylogenetic trees and decide which one is most likely to be correct based on the principle of parsimony.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** In the question, you have learned that the principle of parsimony can be applied to the analysis of molecular data. You are given four base sequences and three possible phylogenetic trees. From your understanding of the topic, you may remember that the principle of parsimony states that the preferred hypothesis is the one that is the simplest for all the characters and their states.

PROBLEM-SOLVING STRATEGY ***Compare and contrast. Make a calculation.*** One strategy for solving this problem is to compare the base sequence of the outgroup with those of the ingroup and identify the base changes. Then you can calculate which of the three possible phylogenetic trees proposes the fewest number of changes.

ANSWER *The diagrams below show the numbers of base changes in the three trees.*

Tree 1 requires seven mutations, tree 2 requires six, and tree 3 requires only five. Therefore, tree 3 requires the smallest number of mutations and is considered the most parsimonious, and therefore the most likely to be correct. (Note: In practice, researchers usually have multiple base sequences that are much longer than the ones shown here, so computer programs are used to find the most parsimonious tree.)



Feature Investigation | Cooper and Colleagues Compared DNA from Extinct Flightless Birds and Existing Species to Propose a New Phylogenetic Tree

Genetic sequence information is primarily used for studying relationships among existing species. However, in some cases, DNA can be obtained from extinct organisms. Starting with small tissue samples (usually bone, dried muscle, or preserved skin) from extinct species, scientists have discovered that it is occasionally possible to obtain DNA sequence information. This approach is called ancient DNA analysis, or molecular paleontology.

Since the mid-1980s, some researchers have become excited about the information derived from sequencing DNA of extinct specimens. Debate has centered on how long DNA can remain intact after an organism has died. Over time, the structure of DNA is degraded by hydrolysis and the loss of purines. Nevertheless, under certain conditions (such as cold temperature and low oxygen, and so on), DNA samples may be stable for as long as 50,000–100,000 years.

In recent years, this approach has been used to study evolutionary relationships between living and extinct species. As shown in **Figure 26.11**, Alan Cooper, Cécile Mourer-Chauviré, Geoffrey Chambers, Arndt von Haeseler, Allan Wilson, and Svante Pääbo investigated the evolutionary relationships among some extant and

7 CONCLUSION This discovery-based investigation led to a hypothesis regarding the evolutionary relationships among these bird species, which is described in Figure 26.12.

8 SOURCE Cooper, A., et al. 1992. Independent origins of New Zealand moas and kiwis. *Proceedings of the National Academy of Sciences* 89:8741–8744.

extinct species of flightless birds. In this example of discovery-based science, the researchers gathered data with the goal of proposing a hypothesis about the evolutionary relationships among several bird species. The kiwis and moas are two groups of flightless birds that existed in New Zealand during the Pleistocene. Species of kiwis still exist, but the moas are now extinct. Eleven known species of moas formerly existed. In this study, the researchers investigated the phylogenetic relationships among four extinct species of moas, which were available as museum samples; three species of New Zealand kiwis; and living species of other flightless birds, including the emu and the cassowary (both found in Australia and/or New Guinea), the ostrich (found in Africa and formerly Asia), and two rheas (found in South America).

Samples from the various species were subjected to polymerase chain reaction (PCR) to amplify a region of the gene that encodes SSU rRNA (an RNA found in the small subunits of mitochondrial ribosomes of all organisms, as discussed in Chapter 12). This provided enough DNA for sequencing. The data in Figure 26.11 illustrate a comparison of the sequences of a continuous region of the SSU rRNA gene from these species. The first line shows the DNA sequence for one of the four extinct moa species. Below it are the sequences of several of the other species that were analyzed. When

the other sequences are identical to the first sequence, a dot is placed in the corresponding position. When the sequences are different, the changed nucleotide base (A, T, G, or C) is placed there. In a few regions, the genes are different lengths. In these cases, a dash is placed to indicate missing nucleotides.

As you can see from the large number of dots, the gene sequences among these flightless birds are very similar, though some differences occur. If you look carefully at the data, you will notice that the sequence from the kiwi (a New Zealand species) is actually more similar to the sequence from the ostrich (an African species) than it is to that of the moa, which was once found in New Zealand. Likewise, the kiwi is more similar to the emu and cassowary (found in Australia and New Guinea) than to the moa. How were these results interpreted? The researchers concluded that the kiwis are more closely related to African and Australian flightless birds than they are to the moas. From these results, they concluded that New Zealand was colonized twice by ancestors of flightless birds. The researchers used a maximum likelihood analysis to propose a new phylogenetic tree that illustrates the revised relationships among these living and extinct species (**Figure 26.12**).

Experimental Questions

1. What is molecular paleontology? What was the purpose of the study conducted by Cooper and colleagues?
2. What birds were examined in the Cooper study, and what are their geographic distributions? Why were the different species selected for this study?
3. **SciSKILLS »** What results did Cooper and colleagues obtain by comparing these DNA sequences? How did the results of this study affect the proposed phylogeny of flightless birds?

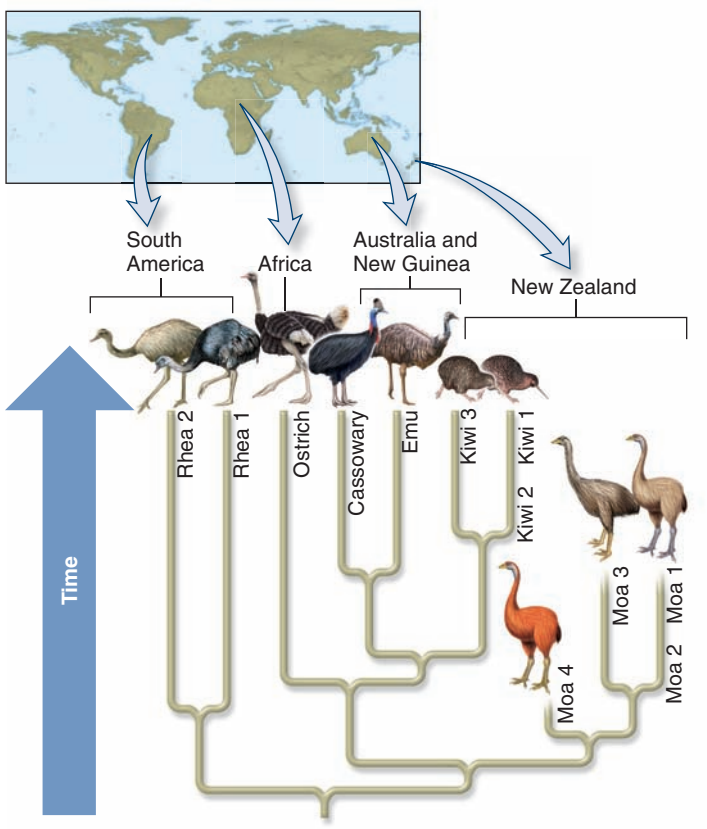

Figure 26.12 A revised phylogenetic tree of flightless birds. This tree is based on a comparison of DNA sequences from extinct and living flightless birds, as described in Figure 26.11.

Concept Check: With regard to geography, why are the results of Cooper and his colleagues surprising?

26.4 Molecular Clocks

Learning Outcomes:

1. Explain how molecular clocks are used in the dating of evolutionary events.
2. **SciSKILLS »** Compare and contrast the use of different genes to produce phylogenetic trees.

As we have seen, researchers employ different methods to choose a phylogeny that describes the evolutionary relationships among various species. Researchers are interested not only in the most likely pathway of evolution (the branches of the trees), but also the timing of evolutionary change (the lengths of the branches). How can researchers determine when different species diverged from each other in the past? As shown earlier in Figure 26.7, the fossil record can sometimes help researchers apply a timescale to a phylogeny.

Another way to infer the timing of past events is by analyzing genetic sequences. The **neutral theory of evolution** proposes that most genetic variation that exists in populations is due to the accumulation of neutral mutations—changes in genes and proteins that are not acted on by natural selection. The reasoning behind this concept is that favorable mutations are likely to be very rare and detrimental mutations are likely to be eliminated from a population by natural selection. A large body of evidence supports the idea that much of the genetic variation observed in living species is due to the accumulation of neutral mutations. From an evolutionary point of view, if neutral mutations occur at a relatively constant rate, they can serve as a **molecular clock** to measure evolutionary time. In this section, we will consider the concept of a molecular clock and its application in phylogenetic trees.

The Timing of Evolutionary Change May Be Inferred from Molecular Clock Data

Figure 26.13 illustrates the concept of a molecular clock. The graph's vertical axis measures the number of base differences in a homologous gene between different pairs of species. The horizontal axis plots the amount of time that has elapsed since each pair of species

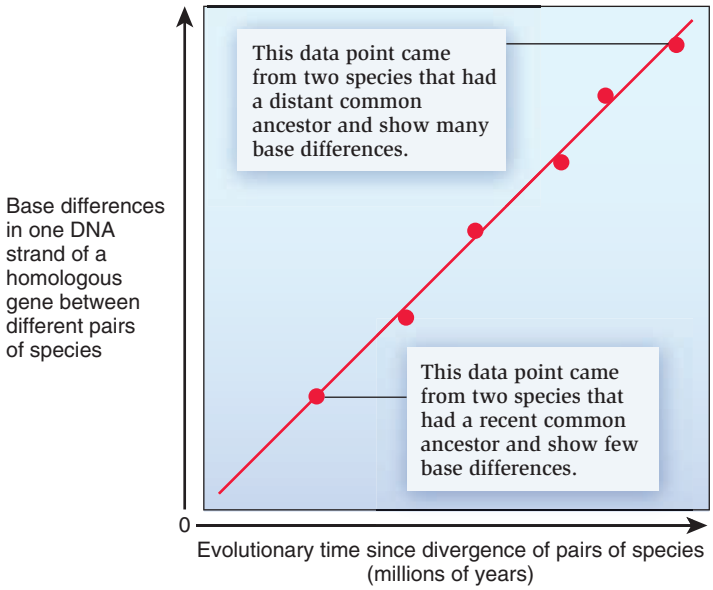

Figure 26.13 A molecular clock. According to the concept of a molecular clock, neutral mutations accumulate at a relatively constant rate over evolutionary time. When comparing the same homologous gene between pairs of different species, those species that diverged more recently tend to have fewer differences than do those whose common ancestor occurred in the distant past.

BioConnections: Look back at Table 12.1, which shows the genetic code. Propose three changes to a codon sequence that you think would be neutral mutations.

shared a common ancestor. As shown in the figure, the number of base differences is lower when two species shared a common ancestor in the more recent past than it is for pairs that shared a more distant common ancestor. The explanation for this phenomenon is that the gene sequences of various species accumulate independent mutations after they have diverged from each other. A longer period of time since their divergence allows for a greater accumulation of mutations, which makes their sequences of bases more different.

Figure 26.13 suggests a linear relationship between the number of base changes and the time of divergence. For example, a linear relationship predicts that a pair of species with, say, 20 base differences in a given gene sequence would have a common ancestor that lived roughly twice as long ago as a pair showing 10 nucleotide differences. Although actual data sometimes show a relatively linear relationship over a defined time period, evolutionary biologists do not think that molecular clocks are perfectly linear over very long periods of time. Several factors can contribute to nonlinearity of molecular clocks. These include differences in the generation times of the species being analyzed and variation in the mutation rates of genes between different species.

To obtain reliable data, researchers must calibrate their molecular clocks. How much time does it take to accumulate a certain percentage of base changes? To perform such a calibration, researchers must have information regarding the date when two species diverged from a common ancestor. Such information could come from the fossil record, for instance. The genetic differences between those species are then divided by the amount of time since their last common ancestor to calculate a rate of evolutionary change.

As an example of clock calibration, let's consider primates. The fossil evidence suggests that humans and chimpanzees diverged from a common ancestor approximately 6 mya. The percentage of base differences between the mitochondrial DNA of humans and chimpanzees is 12%. From these data, the molecular clock for changes in the sequence of bases in mitochondrial DNA of primates is calibrated at roughly 2% base changes per million years. However, molecular dating based on the use of a single fossil as a calibration point can lead to significant inaccuracies in the molecular clock. When possible, researchers advocate using multiple fossils in the calibration process.

Different Genes Are Analyzed to Study Phylogeny and Evaluate the Timing of Evolutionary Change

For evolutionary comparisons, the DNA sequences of many genes have been obtained from a wide range of sources. Many different genes have been studied to propose phylogenetic trees and evaluate the timing of past events. For example, the SSU rRNA gene used by Cooper and colleagues in their research on flightless birds (see Figure 26.11) is commonly used in evolutionary studies. As noted in Chapter 12, the gene for SSU rRNA is found in the genomes of all living organisms. Therefore, its function must have been established at an early stage in the evolution of life on this planet, and its sequence has changed fairly slowly. Furthermore, SSU rRNA is a rather large molecule, so it contains a large amount of sequence information. This gene has been sequenced from thousands of different species (see Figure 12.17). Slowly changing genes such as the gene that encodes SSU rRNA are useful for evaluating distant evolutionary relationships, such as comparing higher taxa. For example, SSU rRNA data can be used to place eukaryotic species into their proper phyla or orders.

Other genes have changed more rapidly during evolution because of a greater tolerance of neutral mutations. For example, the mitochondrial genome and DNA sequences within introns can more easily incur neutral mutations (compared to the coding sequences of genes), and so their sequences change frequently during evolution. More rapidly changing DNA sequences have been used to study recent evolutionary relationships, particularly among eukaryotic species such as species of large animals that have long generation times and therefore tend to evolve more slowly. In these cases, slowly evolving genes may not be very useful for establishing evolutionary relationships because two closely related species may have identical or nearly identical DNA sequences for such genes.

Figure 26.14 shows a simplified phylogeny of closely related species of primates. A molecular clock was used to give a timescale to this phylogenetic tree. The tree was proposed by comparing DNA sequence changes in the gene for cytochrome oxidase subunit II, one of several subunits of cytochrome oxidase, a protein in the mitochondrial inner membrane that is involved in cellular respiration. This

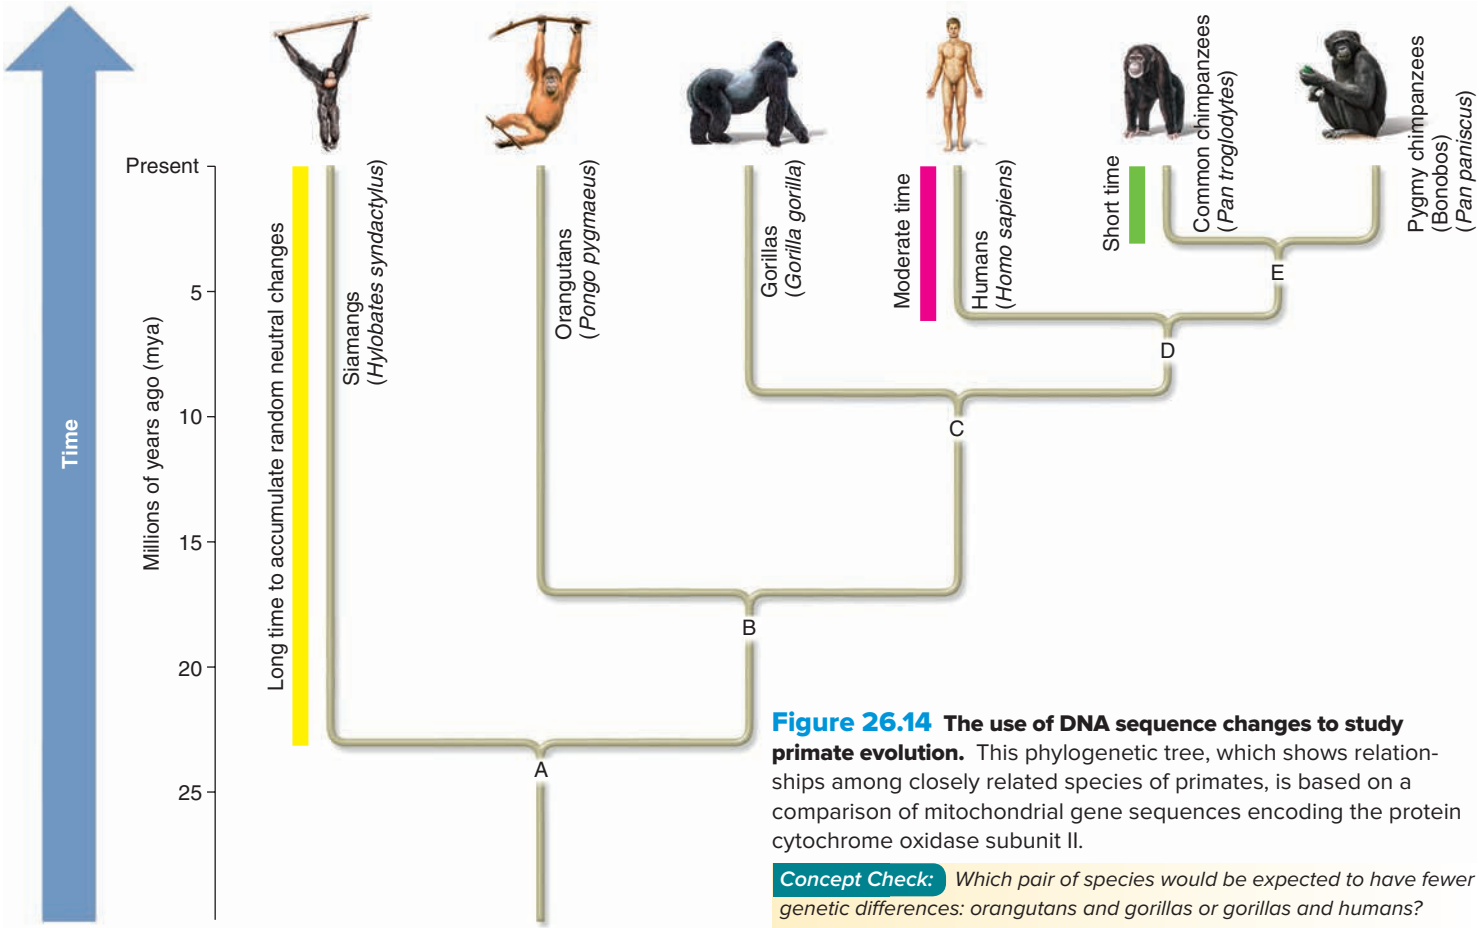

Figure 26.14 The use of DNA sequence changes to study primate evolution. This phylogenetic tree, which shows relationships among closely related species of primates, is based on a comparison of mitochondrial gene sequences encoding the protein cytochrome oxidase subunit II.

Concept Check: *Which pair of species would be expected to have fewer genetic differences: orangutans and gorillas or gorillas and humans?*

gene tends to change fairly rapidly on an evolutionary timescale. The vertical scale on Figure 26.14 represents time, and the branch points labeled with letters represent common ancestors. Let's take a look at three branch points (labeled A, D, and E) and relate them to the accumulation of neutral mutations.

Ancestor A: This ancestor diverged into two species that ultimately gave rise to siamangs and the other five species. Since this divergence, there has been a long time (approximately 23 million years) for the siamang genome to accumulate a relatively high number of random neutral changes that would be different from the random changes that have occurred in the genomes of the other five species (see the yellow bar in Figure 26.14). Therefore, the gene in the siamangs is fairly different from the genes in the other five species.

Ancestor D: This ancestor diverged into two species that eventually gave rise to humans and chimpanzees. This divergence occurred a moderate time ago, approximately 6 mya, as illustrated by the red bar. The differences in gene sequences between humans and chimpanzees are relatively moderate.

Ancestor E: This ancestor diverged into two species of chimpanzees. Since the divergence of species E into two species, approximately 3 mya, the time for the molecular clock to "tick" (that is, accumulate random mutations) is relatively short, as depicted by the green bar in Figure 26.14. Therefore, the two existing species of chimpanzees have fewer differences in their gene sequences compared to other primates.

26.5 Horizontal Gene Transfer

Learning Outcome:

1. Explain how horizontal gene transfer affects evolution and how it affects the relationships among different taxa.

Thus far, we have considered various ways to propose phylogenetic trees, which describe the relationships between ancestors and their descendents. The type of evolution depicted in previous figures, which involves changes in groups of species due to descent from a common ancestor, is sometimes called vertical evolution. Since the time of Darwin, vertical evolution has been the traditional way biologists have viewed the evolutionary process. However, over the past couple of decades, researchers have come to realize that evolution is not so simple. In addition to vertical evolution, horizontal gene transfer has also played a significant role in the phylogeny of living species.

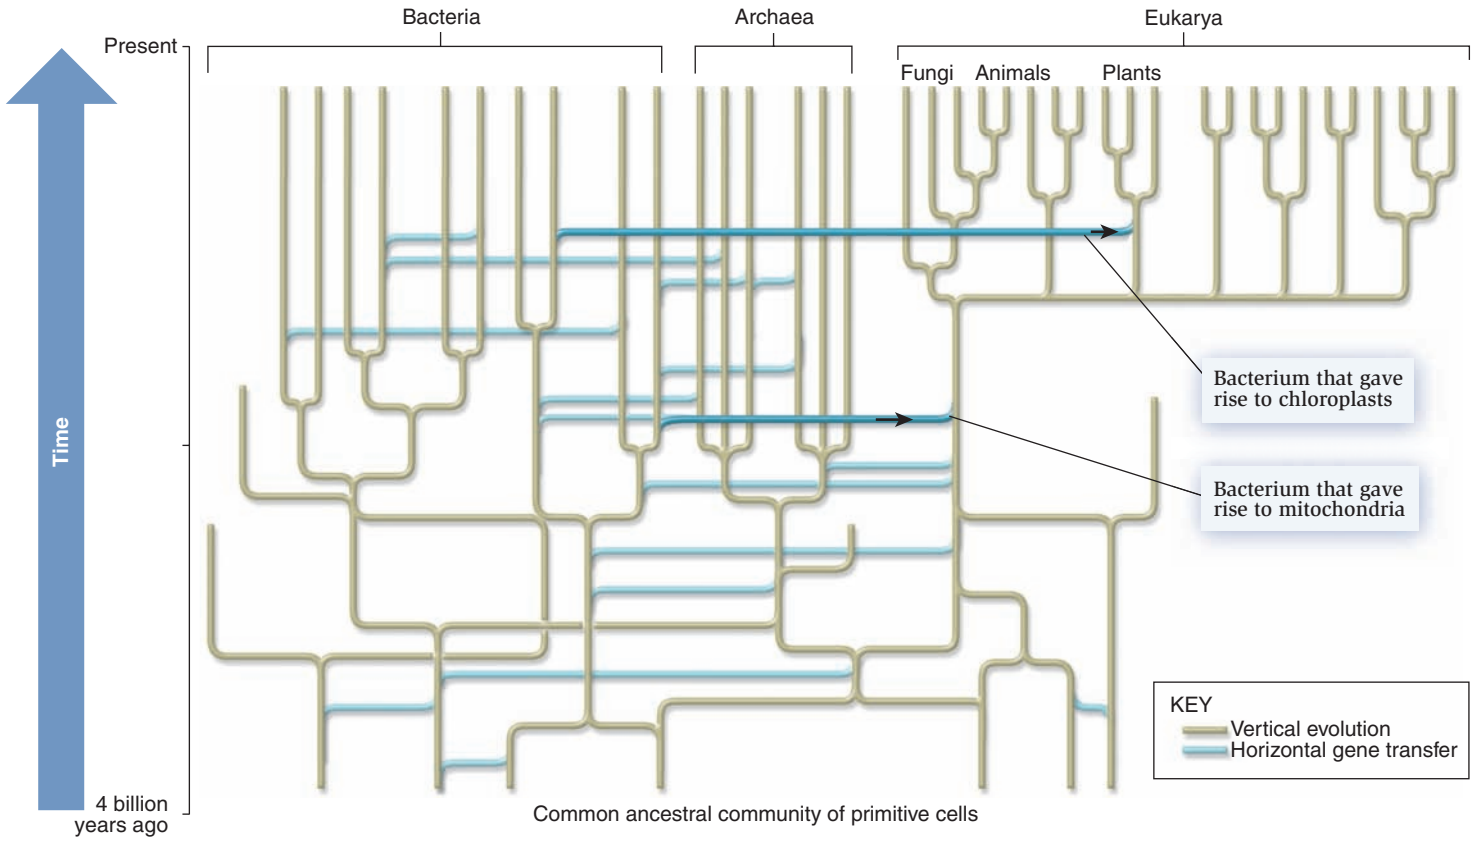

Figure 26.15 **A web of life.** This phylogenetic tree shows not only the vertical evolution of life but also the contribution of horizontal gene transfer. In this scenario, horizontal gene transfer was prevalent during the early stages of evolution, when all organisms were unicellular, and continues to be a prominent factor in the speciation of Bacteria and Archaea. Note: This tree is schematic. Also, although the introduction of chloroplasts into the eukaryotic domain is shown as a single event, such events have occurred multiple times and by different mechanisms.

Concept Check: *How does the phenomenon of horizontal gene transfer muddle the concept of monophyletic groups?*

As discussed in Chapters 1 and 23, **horizontal gene transfer** (also called lateral gene transfer) is used to describe any process in which an organism incorporates genetic material from another organism without being the offspring of that organism. As discussed next, this phenomenon has reshaped the way biologists view the evolution of species.

Genomes & Proteomes Connection

Due to Horizontal Gene Transfer, the "Tree of Life" Is Really a "Web of Life"

Horizontal gene transfer has played a major role in the evolution of many species. As discussed in Chapter 18, bacteria can transfer genes via conjugation, transformation, and transduction. Bacterial gene transfer can occur between strains of the same species or, occasionally, between cells of different bacterial species. The transferred genes may encode proteins that provide a survival advantage, such as resistance to antibiotics or the ability to metabolize an organic molecule in the environment. Horizontal gene transfer is also fairly common among certain unicellular eukaryotes. However, its relative frequency and importance in the evolution of multicellular eukaryotes remains difficult to evaluate.

Scientists have debated the role of horizontal gene transfer in the earliest stages of evolution, prior to the divergence of the bacterial and archaeal domains. The traditional viewpoint was that the three domains of life—Bacteria, Archaea, and Eukarya—arose from a single type of prokaryotic (or pre-prokaryotic) cell called the universal ancestor. However, genomic research has suggested that horizontal gene transfer may have been particularly common during the early stages of evolution on Earth, when all species were unicellular. Horizontal gene transfer may have been so prevalent that the universal ancestor may have actually been an ancestral community of cell lineages that evolved as a whole. If that were the case, the tree of life cannot be traced back to a single ancestor.

Figure 26.15 illustrates a schematic scenario for the evolution of life that includes the roles of both vertical evolution and horizontal gene transfer. This has been described as a "web of life" rather than a "tree of life." In this scenario, instead of a

universal ancestor, a community of primitive cells frequently transferred genetic material in a horizontal fashion. Horizontal gene transfer was also prevalent during the early evolution of bacteria and archaea, and when eukaryotes first emerged as unicellular species. In living bacteria and archaea, it remains a prominent way to foster evolutionary change. By comparison, the region of the diagram that contains most eukaryotic species has a more treelike structure. Researchers have speculated that multicellularity and sexual reproduction have presented barriers to horizontal gene transfer in most eukaryotes. For a gene to be transmitted to eukaryotic offspring, it would have to be transferred into a eukaryotic cell that is a gamete or a cell that gives rise to gametes. Horizontal gene transfer has become less common in eukaryotes, particularly among multicellular species, though it does occur occasionally.

Summary of Key Concepts

26.1 Taxonomy

- Taxonomy is the field of biology concerned with the describing, naming, and classifying living and extinct organisms. Systematics is the study and classification of evolutionary relationships among organisms through time.
- Taxonomy places all living organisms into progressively smaller hierarchical groups called taxa (singular, taxon). The broadest groups are the three domains, called Bacteria, Archaea, and Eukarya, followed by supergroups, kingdoms, phyla, classes, orders, families, genera, and species (Figures 26.1, 26.2, Table 26.1).
- Binomial nomenclature is a naming convention that provides each species with two names: genus name and species epithet.

26.2 Phylogenetic Trees

- The evolutionary history of a species is its phylogeny. A phylogenetic tree is a diagram that describes the phylogeny of particular species and should be viewed as a hypothesis. (Figure 26.3).
- A central goal of systematics is to construct taxa and phylogenetic trees based on evolutionary relationships. Smaller taxa, such as families and genera, are derived from more recent common ancestors than are broader taxa such as kingdoms and phyla (Figure 26.4).
- Ideally, all taxa should be monophyletic, consisting of the most recent common ancestor and all of its descendants, though previously established taxa sometimes turn out to be paraphyletic or polyphyletic (Figures 26.5, 26.6).
- Both morphological and genetic data are used to propose phylogenetic trees. Molecular systematics, which involves the analysis of genetic sequences, has led to major revisions in taxonomy (Figure 26.7).

26.3 Cladistics

- In the cladistic approach to creating a phylogenetic tree, also called a cladogram, species are grouped together according to shared derived characters (Figure 26.8).
- An ingroup is the group of interest, whereas an outgroup is a species or group of species that lacks one or more shared derived characters (synapomorphies). A comparison of an ingroup and outgroup is used to determine which character states are derived and which are primitive (Figures 26.9, 26.10).
- The cladistic approach produces many possible cladograms. The most likely phylogenetic tree is chosen by a variety of methods, including the analysis of fossils, the principle of parsimony, and maximum likelihood.
- Cooper and colleagues analyzed DNA sequences from extinct and living flightless birds and proposed a new phylogenetic tree showing that New Zealand was colonized twice by ancestors of flightless birds (Figures 26.11, 26.12).

26.4 Molecular Clocks

- The neutral theory of evolution proposes that most genetic variation is due to neutral mutations. Assuming that neutral mutations occur at a relatively constant rate, genetic data can serve as a molecular clock to measure the timing of evolutionary changes (Figure 26.13).
- Slowly changing genes are useful for analyzing distant evolutionary relationships, whereas rapidly changing genes are used to analyze more recent evolutionary relationships, particularly among eukaryotes that have long generation times and evolve more slowly (Figure 26.14).

26.5 Horizontal Gene Transfer

- Horizontal gene transfer is the phenomenon in which an organism incorporates genetic material from another organism without being the offspring of that organism. Due to horizontal gene transfer, the tree of life may more accurately be described as a web of life (Figure 26.15).

Assess and Discuss

Test Yourself

1. The study of biological diversity based on evolutionary relationships is
   a. paleontology. c. systematics. e. both a and b.
   b. evolution. d. phylogeny.
2. Which of the following is the correct order of the taxa used to classify organisms?
   a. kingdom, domain, phylum, class, order, family, genus, species
   b. domain, kingdom, class, phylum, order, family, genus, species
   c. domain, kingdom, phylum, class, family, order, genus, species
   d. domain, kingdom, phylum, class, order, family, genus, species
   e. kingdom, domain, phylum, order, class, family, species, genus
3. Which type of taxon consists of organisms with the greatest similarity?
   a. kingdom c. order e. genus
   b. class d. family
4. Which of the following characteristics is not shared by bacteria, archaea, and eukaryotes?
   a. DNA is the genetic material.
   b. Messenger RNA encodes the information to produce proteins.
   c. All cells are surrounded by a plasma membrane.
   d. The cytoplasm is compartmentalized into organelles.
   e. both a and d

5. Which of the following occur at branch points, or nodes, in a phylogenetic tree?
   a. anagenesis
   b. cladogenesis
   c. horizontal gene transfer
   d. a and b
   e. b and c

6. The evolutionary history of a species is its
   a. systematics.
   b. taxonomy.
   c. evolution.
   d. phylogeny.
   e. embryology.

7. A taxon composed of all species derived from a common ancestor is referred to as
   a. a phylum.
   b. a monophyletic group or clade.
   c. a genus.
   d. an outgroup.
   e. all of the above.

8. A goal of modern taxonomy is to
   a. classify all organisms based on morphological similarities.
   b. classify all organisms into monophyletic groups.
   c. classify all organisms based solely on genetic similarities.
   d. determine the evolutionary relationships only between similar species.
   e. None of the above is a goal of modern taxonomy.

9. The concept that the preferred hypothesis is the one that is the simplest is
   a. phenetics.
   b. cladistics.
   c. the principle of parsimony.
   d. maximum likelihood.
   e. both b and d.

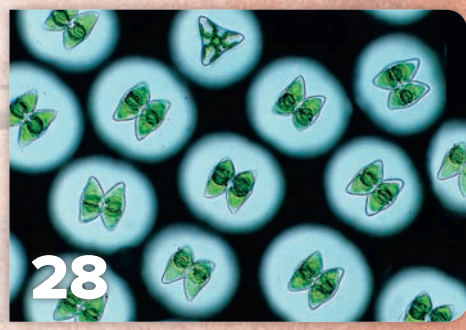
10. Research indicates that horizontal gene transfer is less prevalent in eukaryotes because of
    a. the presence of organelles.
    b. multicellularity.
    c. sexual reproduction.
    d. all of the above.
    e. b and c only.

Conceptual Questions

1. Explain how species' names follow a binomial nomenclature. Give an example.
2. What is a molecular clock? How is it used in depicting phylogenetic trees?
3.  A principle of biology is that *populations of organisms evolve from one generation to the next.* What are some advantages and potential pitfalls of using changes in morphology to construct phylogenetic trees?

Collaborative Questions

1. Discuss how taxonomy is useful. Make a list of some practical applications that are derived from taxonomy.
2. Discuss how systematics is used to propose a phylogenetic tree. Discuss the rationale behind using the principle of parsimony.



UNIT V

DIVERSITY

Biological diversity encompasses the variety of living things that exist now, as well as all the life-forms that lived in the past. Knowing about species that lived in the past and how they are related to modern microorganisms, plants, and animals aids our comprehension of evolution, which is the source of organismal variation. Knowing about the many different kinds of modern organisms also helps us to understand how life-forms are structured in ways that allow them to function differently in nature (described in Units VI and VII) and how species interact with each other and with their environments (described in Unit VIII—Ecology).

Unit V begins with bacteria and archaea, the oldest, simplest, and most numerous of Earth's life-forms, whose prominent ecological roles are described in Chapter 27. In Chapter 28, we survey the surprisingly diverse protists, which affect humans and other organisms in many important ways. Chapter 29 explores the evolutionary origin of the first plants, a process that explains the features and functions of the seed plants that are vital sources of human food, fiber, and medicine, as described in Chapter 30. The mysteries of the fungi, essential to the brewing and baking industries as well as ecological stability, are revealed in Chapter 31. An overview of the diversity and evolutionary history of the animals in Chapter 32 provides the basis for exploring the simplest animals, the invertebrates, in Chapter 33. More complex animals, including humans and their closest relatives, are the focus of Chapter 34, which reveals how our species arose.

The following biology principles will be emphasized in this unit:

- ***Cells are the simplest units of life:*** *Many of Earth's present and past species have bodies consisting of only one or a few cells, whereas other species display more complex bodies composed of many cells.*
- ***Living organisms interact with their environment:*** *Chapters 27 and 29, for example, explain how ancient microorganisms and plants dramatically changed the composition of Earth's atmosphere, and how their modern descendants continue to influence today's atmosphere and climate.*
- ***All species (past and present) are related by an evolutionary history:*** *This concept is emphasized throughout the unit.*

Archaea and Bacteria

27

Cyanobacterial bloom. A visible cyanobacterial bloom gives a blue-green coloration to this lake water.

BIOLOGY PRINCIPLE **Biology affects our society.** Cyanobacterial blooms affect society by poisoning humans and organisms that people value but also have a more positive impact by generating nitrogen-containing molecules that serve as fertilizer.

One late-summer afternoon, a veterinarian was about to close the clinic at the end of a busy day when an emergency case arrived. A very sick dog had collapsed after taking a lakeside walk with its owner. Responding to the vet's questions, the owner reported that the thirsty dog had consumed lake water thick with blue-green material. The vet deduced that the blue-green substance represented a large population of toxin-producing bacteria and that drinking the lake water had poisoned the dog—a conclusion that aided treatment.

Bacteria and archaea are examples of microorganisms, organisms so small they can usually be seen only with the use of a microscope. However, in phosphorus-rich bodies of water, some species of photosynthetic bacteria known as cyanobacteria grow rapidly into large, visible populations that color the water blue-green or cyan (see the chapter opening photo). The individual cells release small amounts of toxins that help to keep small aquatic animals from eating them; when large populations, known as blooms, occur, toxins can rise to levels that poison humans, pets, livestock, and wildlife. Consequently, public health authorities often warn that people should not swim in waters with visible blue-green blooms, and should not allow pets and livestock to drink such water. People can prevent the formation of harmful cyanobacterial blooms by reducing the flow of phosphorus-rich fertilizers, manure, and sewage into bodies of water.

Despite the harmful effects of some species, cyanobacteria provide important benefits to humans and other organisms, such as producing atmospheric oxygen. Many cyanobacteria also have the ability to convert abundant but inert atmospheric nitrogen gas into ammonia, which algae and plants can use to synthesize amino acids and proteins. This process enriches nutrient-poor soils, particularly wet paddy fields where rice is grown in many regions of the world, thereby helping to provide food for billions of people. In this chapter, we will survey the diversity, structure, reproduction, metabolism, and ecology of archaea and bacteria. We will see how bacteria and archaea were important to the evolution of eukaryotic cells and other ancient events in Earth's history. Some bacterial phyla important to everyday human life will illustrate the important concept that relatively few bacterial species are harmful, and many benefit us. We will also learn how horizontal gene transfer increases the diversity of microbial genomes and how this process affects humanity. Our survey will reveal additional surprising ways in which these microorganisms affect the lives of humans and the world we inhabit.

27.1 Diversity and Evolution

Learning Outcomes:

1. **SciSKILLS** » Make a drawing that shows the evolutionary relationship among the domains Archaea, Bacteria, and Eukarya.
2. Describe how many species of archaea are able to grow in extreme habitats.
3. Discuss the medical, environmental, and evolutionary importance of cyanobacteria and proteobacteria.
4. List common mechanisms for horizontal gene transfer.

Life on Earth is classified into three domains. Members of the domain Eukarya—animals, plants, fungi, and protists—have cells with a eukaryotic structure. In contrast, **Archaea** (often referred to as simply archaea) and **Bacteria** (often referred to as simply bacteria) are domains of microorganisms whose cells have a prokaryotic structure. Archaeal and bacterial cells lack nuclei with porous envelopes and other cellular features typical of eukaryotes (see Chapter 4).

Although archaea and bacteria are sometimes collectively termed prokaryotes, such an aggregation is not a monophyletic group, but rather a paraphyletic group—one that does not include all of the descendants of a single common ancestor. That's because domain Archaea is more closely related to domain Eukarya than either is to domain Bacteria (**Figure 27.1**). Even so, archaea and bacteria display some common features in addition to a prokaryotic cell structure.

Archaea and bacteria include the smallest known cells and are the most abundant organisms on Earth. About half of Earth's total biomass consists of an estimated 10^{30} individual bacteria or archaea. Just a pinch of garden soil can contain 2 billion prokaryotic cells, and about a million occur in 1 mL of seawater. Archaea and bacteria live in nearly every conceivable habitat, including extremely hot or salty waters that support no other life, and they are also Earth's most ancient organisms, having originated more than 3 bya. Their long evolutionary history and varied habitats have resulted in extraordinarily high metabolic diversity.

Today, the many millions of species of archaea and bacteria collectively display more diverse metabolic processes than occur in any other group of organisms. Many of these metabolic processes are important on a global scale, influencing Earth's climate, atmosphere, soils, and water quality, as well as human health and technology. In the past, microbiologists studied diversity by isolating these

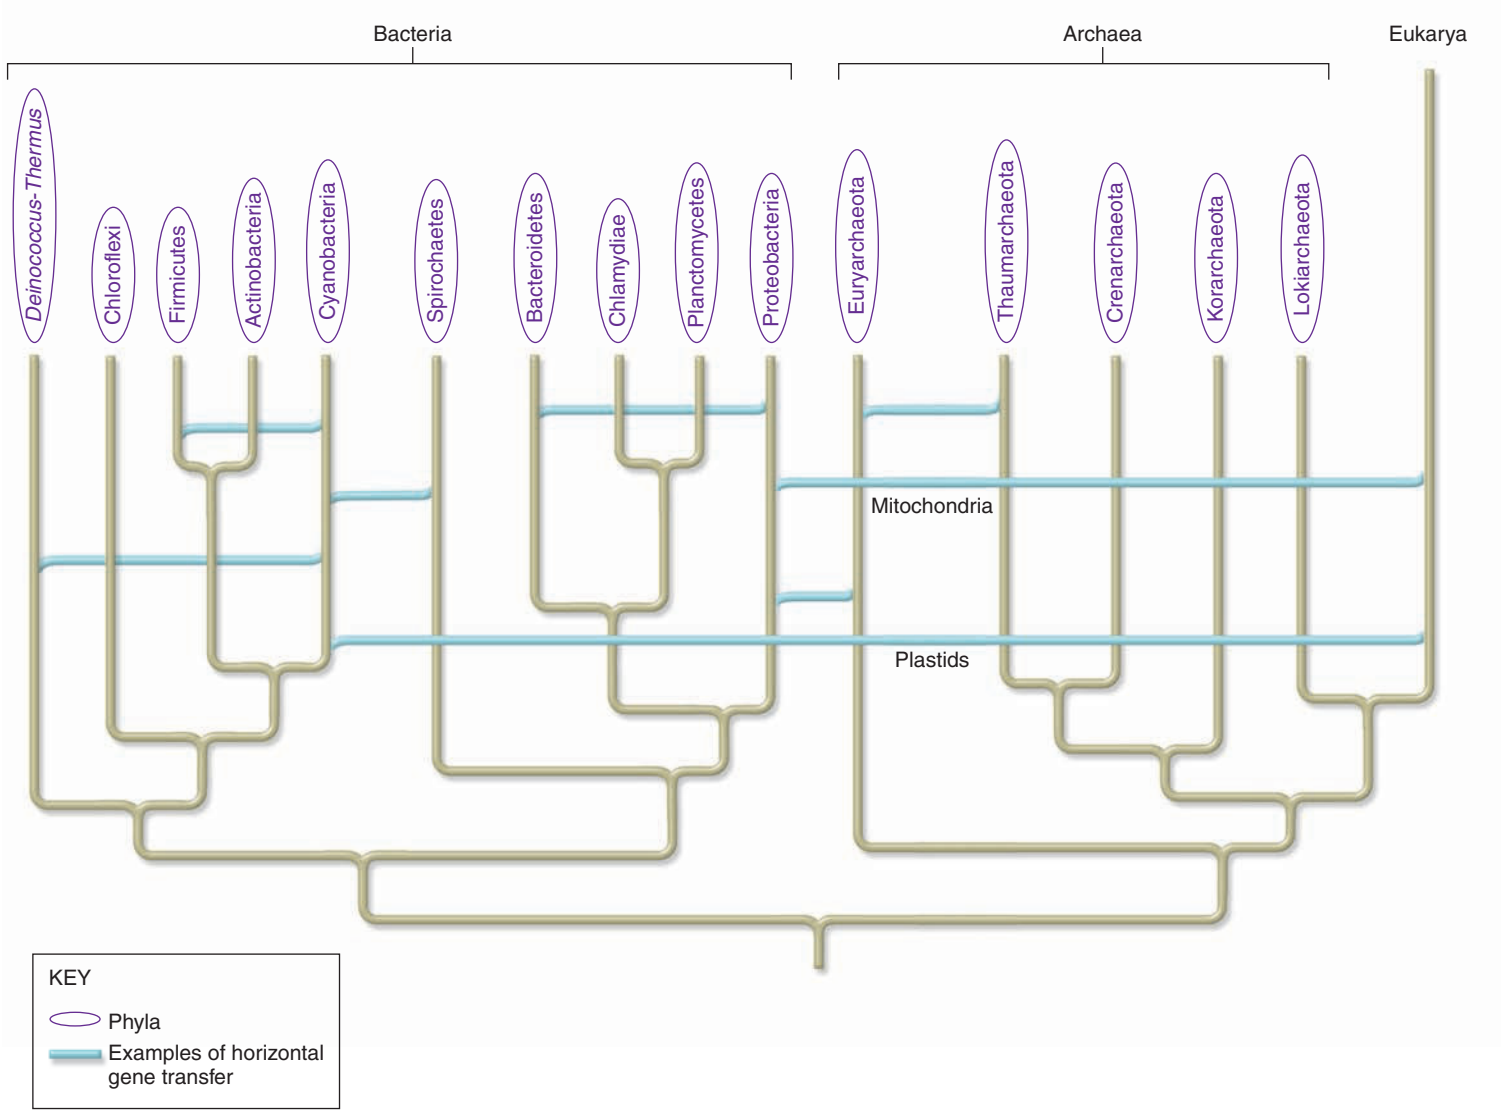

Figure 27.1 Examples of horizontal gene transfer among the domains Bacteria, Archaea, and Eukarya. Bacteria and Archaea are the two domains featuring prokaryotic cells. Eukarya is the domain consisting of organisms whose cells are eukaryotic. Archaea, and particularly the phylum Lokiarchaeota, is more closely related to Eukarya than is Bacteria. Each domain has diversified into multiple phyla, not all shown here, for simplicity. Many cases of horizontal gene transfer among phyla and domains are known. These cases include the acquisition of mitochondria and chloroplasts by eukaryotes.

organisms from nature and growing cultures in the laboratory to observe variation in cell structure and metabolism. Today, biologists also use molecular techniques to assess archaeal and bacterial diversity and infer metabolic functions. Such molecular studies reveal that archaea and bacteria are vastly more diverse than previously realized.

In this section, we will first survey the major kingdoms and phyla of the domains Archaea and Bacteria and then explore how horizontal gene transfer—the transfer of genes between different species—has influenced their evolution.

Domain Archaea Was Ancestral to Domain Eukarya

Organisms classified in the domain Archaea, referred to as archaea, share a number of features with those classified in Eukarya, suggesting common ancestry. For example, histone proteins are typically associated with the DNA of both archaea and eukaryotes, but they are absent from most bacteria. Archaea and eukaryotes share more than 30 ribosomal proteins that are not present in bacteria, and archaeal RNA polymerases are closely related to their eukaryotic counterparts. Even so, archaea possess distinctive membrane phospholipids, which are formed with ether bonds; in contrast, ester bonds characterize the membrane phospholipids of bacteria and eukaryotes (**Figure 27.2**). Ether-bonded membranes are resistant to damage by heat and other extreme conditions, which helps explain why many archaea are able to grow in extremely harsh environments. Also note that archaea use isoprene chains instead of fatty-acid chains in their membranes.

Though many archaea occur in soils and surface ocean waters of moderate conditions, diverse archaea occupy habitats with very high salt content, acidity, methane levels, or temperatures that would kill most bacteria and eukaryotes. Organisms that occur primarily in extreme habitats are known as **extremophiles**. One example is the methane producer *Methanopyrus*, which grows best at deep-sea thermal vent sites where the temperature is 98°C. At this temperature, the proteins of most organisms would denature, but those of *Methanopyrus* are resistant to such damage. *Methanopyrus* is so adapted to its extremely hot environment that it cannot grow when the temperature is less than 84°C. Such archaea are known as **hyperthermophiles**. Some archaea prefer habitats having both high temperatures and extremely low pH. For example, the archaeal genus *Sulfolobus* was discovered in samples taken from sulfur hot springs having a pH of 3 or lower. Archaea help biologists better understand the origin of life, the origin of eukaryotes, how life on Earth has evolved in extreme environments, and what kinds of extraterrestrial life might exist.

The domain Archaea includes several phyla, including Lokiarchaeota, Korarchaeota, Thaumarchaeota, Crenarchaeota, and Euryarchaeota (see Figure 27.1). Lokiarchaeota, identified from deep ocean samples, are particularly closely related to eukaryotes (Eukarya). Korarchaeota are primarily known from DNA sequences found in samples from hot springs. Thaumarchaeota are widespread in terrestrial and aquatic environments, and species that oxidize ammonia are important in global nitrogen cycling. Crenarchaeota includes organisms that live in extremely hot or cold habitats and also some that are widespread in aquatic and terrestrial habitats. Early-diverging Euryarchaeota include some hyperthermophiles, diverse methane producers, and extreme halophiles—species able to grow in higher than usual salt concentrations.

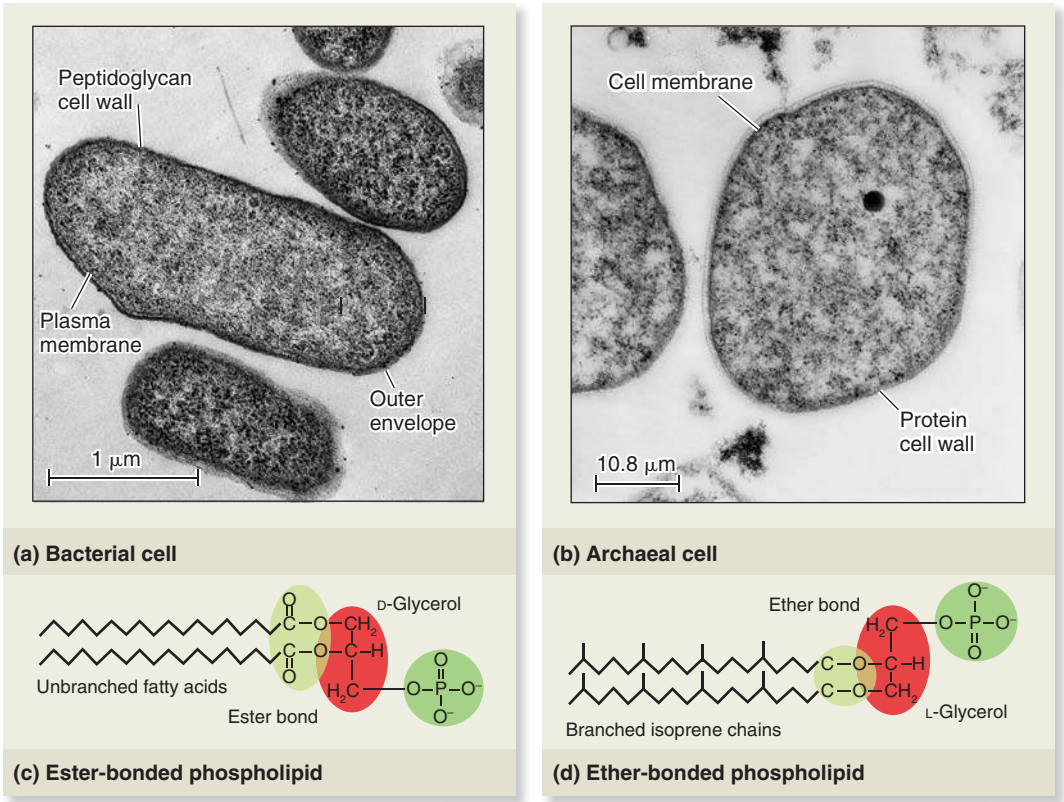

Figure 27.2 Bacteria and Archaea. **(a)** Bacteria and **(b)** archaea both have prokaryotic cell structure, but **(c)** bacterial membrane lipids are formed with ester linkages, whereas **(d)** archaeal membrane lipids feature ether linkages, which are thought to be more stable under extreme environmental conditions. As shown in the transmission electron microscopic (TEM) images in (a) and (b), most bacteria feature a cell wall made of a material known as peptidoglycan and often enclosed by an outer envelope, whereas archaea lack these features. Most archaea have outer coverings made of protein.

Domain Bacteria Includes Cyanobacteria, Proteobacteria, and Many Other Phyla

Domain Bacteria is considerably more diverse than Archaea. Molecular studies suggest the existence of 50 or more bacterial phyla, though many are poorly characterized. Though some members of domain Bacteria live in extreme environments, most favor moderate conditions. Many bacteria form symbiotic associations with eukaryotes and are thus of concern in medicine and agriculture. The characteristics of 10 prominent bacterial phyla are briefly summarized in **Table 27.1**. Among these, Cyanobacteria and Proteobacteria are particularly diverse and relevant to eukaryotic cell evolution, global ecology, and human affairs.

Cyanobacteria The phylum Cyanobacteria contains photosynthetic bacteria that are abundant in fresh waters, oceans, and wetlands and on the surfaces of arid soils. Cyanobacteria are named for the typical blue-green (cyan) coloration of their cells. Blue-green pigmentation results from the presence of photosynthetic pigments called phycobilins that help chlorophyll absorb light energy. Cyanobacteria are the only bacteria known to generate oxygen as a product of photosynthesis. Ancient cyanobacteria produced Earth's first oxygen-rich atmosphere, which allowed the eventual rise of eukaryotes. The chloroplasts of eukaryotic algae and plants were derived from cyanobacteria.

Cyanobacteria display the greatest body diversity found among bacterial phyla (**Figure 27.3**). Some occur as single cells called unicells (Figure 27.3a); others form colonies of cells held together by a thick gluey substance called mucilage (Figure 27.3b), and many cyanobacteria form filaments of cells that are attached end-to-end (Figure 27.3c), including filaments that branch (Figure 27.3d). Some of the filamentous cyanobacteria display hallmarks of multicellularity: cellular attachment, specialized cells, intercellular chemical communication, and programmed cell death.

Proteobacteria Though Proteobacteria share molecular and cell-wall features, this phylum displays amazing diversity of form and metabolism. Genera of this phylum are classified into five major subgroups: alpha (α), beta (β), gamma (γ), delta (δ), and epsilon (ε). As we saw in Chapter 22 (Figure 22.12), the ancestry of mitochondria can be traced to the α-proteobacteria, which also include several genera noted for mutually beneficial relationships with animals and plants. For example, *Rhizobium* and related genera of α-proteobacteria form nutritionally beneficial associations with the roots of legume plants such as beans and peas and are thus agriculturally important (see Figure 38.16). Another α-proteobacterium,

Table 27.1 Representative Bacterial Phyla

Phyla	Characteristics
Firmicutes	Diverse Gram-positive bacteria, some of which produce endospores. The disease-causing *Clostridium difficile* is an example.
Bacteroidetes	Includes representatives of diverse metabolism types; some are common in the human intestinal tract, and others are primarily aquatic.
Chlamydiae	Notably tiny, obligate intracellular parasites. Some cause eye disease in newborns or sexually transmitted diseases.
Planctomycetes	Reproduce by budding rather than binary fission; cell walls lack peptidoglycan; cytoplasm may contain nucleus-like bodies, and endocytosis may occur.
Spirochaetes	Motile bacteria having distinctive corkscrew shapes, with flagella held close to the body. They include the pathogens *Treponema pallidum*, the agent of syphilis, and *Borrelia burgdorferi*, which causes Lyme disease.
Actinobacteria	Gram-positive bacteria producing branched filaments; many form spores. *Mycobacterium tuberculosis*, the agent of tuberculosis in humans, is an example. Actinobacteria are notable antibiotic producers; over 500 different antibiotics are known from this group. Some fix nitrogen in association with plants.
Chloroflexi	Known as the green nonsulfur bacteria; conduct photosynthesis without releasing oxygen (anoxygenic photosynthesis).
Deinococcus and *Thermus*	Extremophiles. The genus *Deinococcus* is known for high resistance to ionizing radiation, and the genus *Thermus* inhabits hot springs. *Thermus aquaticus* has been used in commercial production of *Taq* polymerase enzyme used in the polymerase chain reaction (PCR), an important procedure in molecular biology laboratories.
Cyanobacteria	The oxygen-producing photosynthetic bacteria (some are also capable of anoxygenic photosynthesis). Photosynthetic pigments include chlorophyll *a* and phycobilins, which often give cells a blue-green pigmentation. Occur as unicells, colonies, unbranched filaments, and branched filaments. Many of the filamentous species produce specialized cells: dormant akinetes and heterocytes in which nitrogen fixation occurs. In waters having excess nutrients, cyanobacteria produce blooms and may release toxins harmful to the health of humans and wild and domesticated animals.
Proteobacteria	A very large group of Gram-negative bacteria, collectively having high metabolic diversity. Includes many species important in medicine, agriculture, and industry such as *Agrobacterium tumifaciens*, *Escherichia coli*, and *Haemophilus influenzae*. *Myxococcus xanthus* is a Gram-negative bacterium that is able to glide across surfaces, forming swarms of thousands of cells. This behavior aids feeding by concentrating digestive enzymes secreted by the bacteria. When food is scarce, the swarms form tiny tree-shaped structures from which tough spores disperse. By this means, cells move to new, food-rich places.

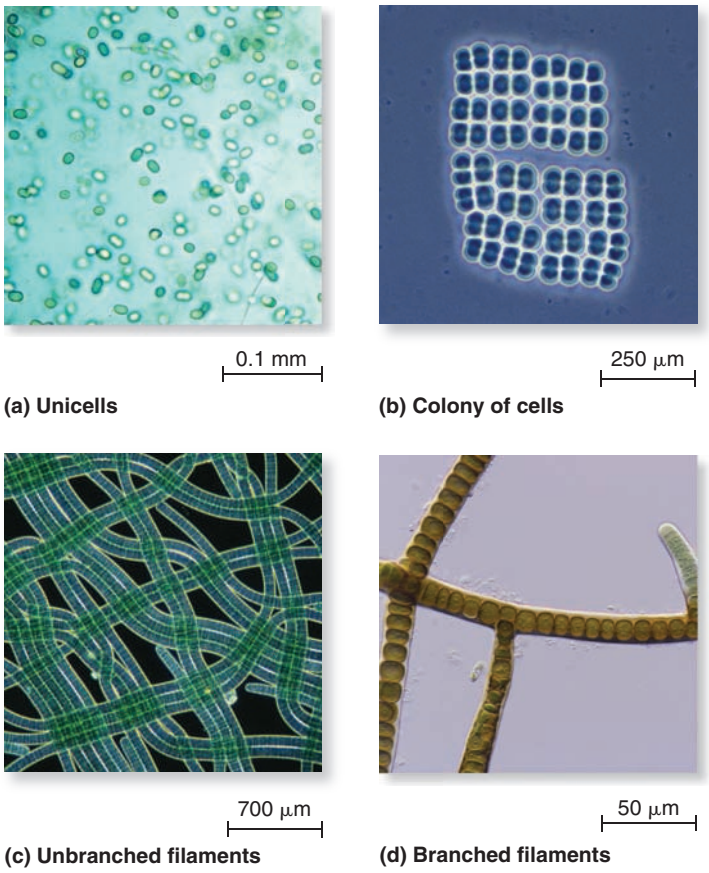

Figure 27.3 Major body types found in the phylum Cyanobacteria. **(a)** The genus *Chroococcus* occurs as unicells. **(b)** The genus *Merismopedia* is a flat colony of cells held together by mucilage. **(c)** The genus *Oscillatoria* forms an unbranched filament. **(d)** The genus *Stigonema* forms a branched filament having a mucilage sheath; sunscreen compounds that protect the cells from damage by ultraviolet (UV) radiation cause the brown color of the sheath.

BioConnections: Look ahead to Figure 28.3d and Figure 31.2. What eukaryotic microbes also display branched filamentous bodies?

Agrobacterium tumifaciens, causes destructive cancer-like tumors called galls to develop on susceptible plants, including grapes and ornamental crops (**Figure 27.4**). *A. tumifaciens* induces gall formation by injecting DNA into plant cells, a property that has led to the use of the bacterium in the production of transgenic plants.

The genus *Nitrosomonas*, a soil inhabitant important in the global nitrogen cycle, represents the β-proteobacteria. *Neisseria gonorrhoeae*, the agent of the sexually transmitted disease gonorrhea, is one of the γ-proteobacteria. *Vibrio cholerae*, another γ-proteobacterium, causes cholera epidemics when drinking water becomes contaminated with animal waste during floods and other natural disasters. The γ-proteobacteria *Salmonella enterica* and *Escherichia coli* strain O157:H7 also cause human disease, so food and water are widely tested for their presence. The δ-proteobacteria include the colony-forming myxobacteria and predatory bdellovibrios, which drill through the cell walls of other bacteria in order to consume them. *Helicobacter pylori*, which causes stomach ulcers, belongs to the ε-proteobacteria.

Figure 27.4 *Agrobacterium tumifaciens* infection. This proteobacterium causes cancer-like tumors to grow on plants.

Additional bacterial phyla mentioned in this chapter because of their medical, ecological, or evolutionary significance include Firmicutes, Bacteroidetes, Chlamydiae, Planctomycetes, Spirochaetes, Actinobacteria, Chloroflexi, and Deinococcus-Thermus (see Table 21.1). Now that we have learned something about the diversity of Archaea and Bacteria, let's consider the evolutionary effects of gene exchanges within and between the domains of life.

Horizontal Gene Transfer Influences the Evolution of Archaea and Bacteria

Horizontal gene transfer is the process in which an organism receives genetic material from another organism without being the offspring of that organism. This process contrasts with vertical evolution, in which gene transfer occurs from parent to progeny, but it is increasingly recognized as an important evolutionary mechanism. Horizontal gene transfer occurs most frequently between species that are closely related or that live in close proximity, and it affects the evolutionary process by increasing genetic diversity.

Horizontal gene transfer is common among archaea and bacteria, and it can result in large genetic changes that confer new metabolic capacities. For example, at least 17% of the genes present in the common human gut inhabitant *E. coli* came from other bacteria. Studies of nearly 200 genomes have revealed that about 80% of prokaryotic genes have been involved in horizontal transfer at some point in their history. Genes also move among the bacterial, archaeal, and eukaryotic domains. For example, salt-tolerant (halophytic) archaea originated after an ancient horizontal transfer of more than a thousand genes from bacteria.

Horizontal gene transfer can occur between different bacterial species via transduction, transformation, and conjugation, as discussed in Chapter 18. In addition, horizontal gene transfer also occurs

by means of endosymbiosis, the process in which one species—the endosymbiont—lives in the body or cells of another species—the host. For example, certain γ-proteobacteria occupy the cells of β-proteobacterial hosts, which themselves live within insect cells. Such close proximity increases the odds for gene exchange between distantly related species. Endosymbiosis theory proposes that the mitochondria and chloroplasts of eukaryotic cells originated from α-proteobacteria and cyanobacteria, respectively, by endosymbiosis (see Chapter 22). In these cases, endosymbiosis resulted in the horizontal transfer of many genes from bacterial genomes to eukaryotic nuclei. In this process, so many genes were lost from the ancestral bacterial genomes that mitochondria and chloroplasts cannot reproduce outside the host eukaryotic cells.

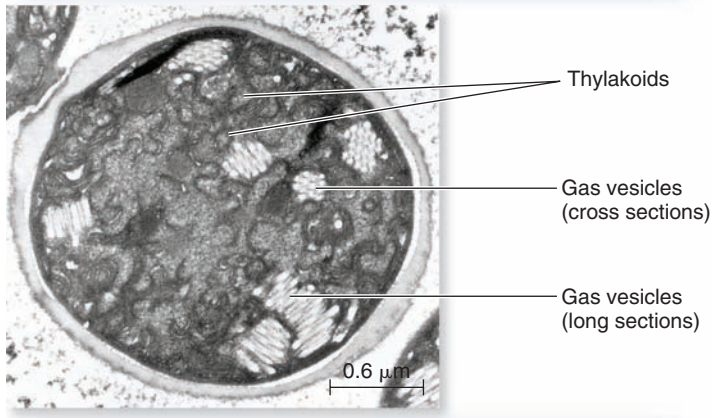
As we have seen, archaea and bacteria share features of prokaryotic cell organization, small size, high environmental populations, and high metabolic diversity, and they exchange genes. Even so, bacteria more frequently interact with other organisms. For example, bacteria play more important roles in animal and plant disease than do archaea. In the next sections, we will focus on the structure, movement, reproduction, ecology, and biotechnological applications of bacteria and archaea.

27.2 Structure and Movement

Learning Outcomes:

1. Discuss structural adaptations that have increased the complexity of prokaryotic cells.
2. Explain how mucilage influences the behavior of bacterial cells.
3. **SciSKILLS** » Make a drawing that shows the structural differences between Gram-positive and Gram-negative bacterial cells, and predict how these features might influence disease treatments.
4. List the different means by which prokaryotic cells can move.

Bulbnose unicorn fish (*Naso tonganus*) living in Australian coastal ocean waters contain cigar-shaped bacterial symbionts (*Epulopiscium*) whose cells are more than 600 μm long, larger than most eukaryotic cells (whose largest dimension is between 10 and 100 μm). Spherical cells of the bacterial species *Thiomargarita namibiensis*, which lives in African coastal regions, likewise reach record-setting sizes, some being 800 μm in diameter and large enough to be seen without a microscope. However, most bacteria (and archaea) are much smaller: 1–5 μm in diameter. Small cell size limits the amount of materials that can be stored within cells but allows much faster cell division. When nutrients are sufficient, many bacteria can divide many times within a single day. This explains how bacteria can spoil food rapidly and why bacterial infections can spread quickly within the human body. Despite their generally small size, bacteria can display a high level of variation in cell structure and shape, surface and cell-wall features, and movement.



Prokaryotic Cells Display a Surprising Degree of Complexity

Bacteria, like archaea, have a much simpler cellular organization than do eukaryotes. Even so, many prokaryotic cells display cellular structural adaptations that increase their complexity. Features of prokaryotic cellular complexity illustrate the biological principle that structure determines function, partly explain why prokaryotic organisms have such high metabolic diversity, and help us understand how the first eukaryotes arose.

Cyanobacteria and other photosynthetic bacteria, for example, are able to use light energy to produce organic compounds because their cells contain large numbers of thylakoids, flattened tubular membranes that grow inward from the plasma membrane (**Figure 27.5**). The extensive membrane surface of the thylakoids bears large amounts of chlorophyll and other components that are needed for photosynthesis. This explains why thylakoids are also abundant in plant chloroplasts, which descended from cyanobacterial ancestors. Thylakoids enable photosynthetic bacteria and chloroplasts to take maximum advantage of light energy in their environments. Aquatic photosynthetic bacteria also commonly contain many gas vesicles. These protein-walled structures increase cell buoyancy and thus help the organisms float within well-illuminated surface waters (see Figure 27.5).

In other bacteria, plasma membrane ingrowth has generated additional intriguing adaptations—magnetosomes and nucleus-like bodies—that are sometimes described as bacterial organelles. Magnetosomes are tiny crystals of an iron mineral known as magnetite,

Thylakoids provide a greater surface area for chlorophyll and other molecules involved in photosynthesis.

The gas vesicles buoy this photosynthetic organism to the lighted water surface, where it often forms conspicuous scums.

Figure 27.5 Photosynthetic thylakoid membranes and numerous gas vesicles in a cell of an aquatic cyanobacterium.

BIOLOGY PRINCIPLE Structure determines function. Thylakoids, which contain chlorophyll and other components that are needed for photosynthesis, are the locations of the light harvesting reactions.

Concept Check: Do you think this cell would tend to float or sink in water?

BioConnections: Look back to Figure 4.25 to see thykaloid membranes in a plant chloroplast, and look ahead to Figure 28.12 to see thylakoids in an algal plastid. What similarities to Figure 27.5 help to demonstrate that plastids evolved from endosymbiotic cyanobacteria?

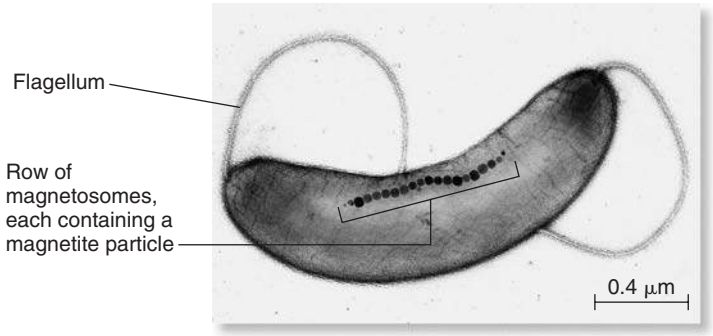


Figure 27.6 Magnetosomes found in *Magnetospirillum magnetotacticum*. An internal row of iron-rich magnetite crystals, each enclosed by a membrane derived from the plasma membrane, functions like a compass needle, allowing this bacterium to detect the Earth's magnetic field. This feature allows *M. magnetotacticum* to orient itself in space and thereby locate its preferred habitat, low-oxygen subsurface waters. These and other bacterial cells use flagella to move to more favorable locations.

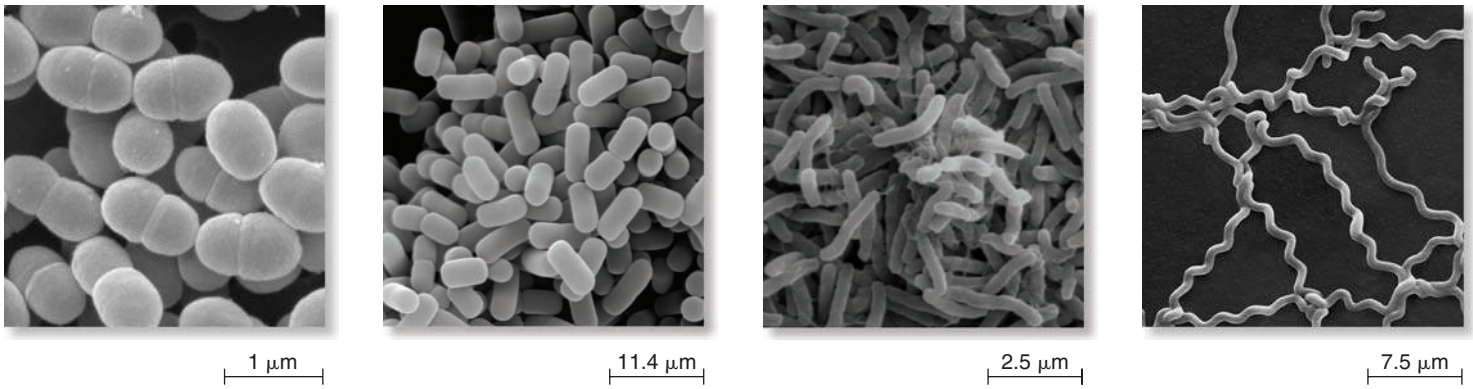
BioConnections: Look ahead to Section 43.4, which describes electromagnetic sensing by animals. What animals are like M. magnetotacticum in being able to sense and respond to magnetic fields?

each surrounded by a membrane. These structures occur in the bacterium *Magnetospirillum* and related genera (**Figure 27.6**). In each cell, about 15 to 20 magnetosomes occur in a row, together acting as a compass needle that responds to the Earth's magnetic field. Magnetosomes help the bacteria to orient themselves in space and thereby locate the submerged, low-oxygen habitats they prefer. Magnetosome development begins with invagination of the plasma membrane to form a row of spherical vesicles. If *Magnetospirillum* cells are grown in media having low iron levels, the vesicles remain empty. But if iron is available, a magnetite crystal forms within each vesicle. Fibrils of an actin-like protein keep the magnetosomes aligned in a row. (Recall from Chapter 4 that actin is a major cytoskeletal protein of eukaryotes.) Mutant bacteria lacking a functional form of this protein produce magnetosomes, but they do not remain aligned in a row. Instead, magnetosomes scatter around mutant cells, disrupting their ability to detect a magnetic field.



Plasma membrane invaginations produce nucleus-like bodies in *Gemmata obscuriglobus* and other members of the bacterial phylum Planctomycetes. In *G. obscuriglobus*, an envelope composed of a double membrane encloses all cellular DNA and some ribosomes. Although this bacterial envelope lacks the nuclear pores characteristic of the eukaryotic nuclear envelope, it likely plays a similar adaptive role in isolating DNA from other cellular influences. *G. obscuriglobus* and related bacterial species are also known to accomplish endocytosis by means of membrane coat proteins similar to those present in eukaryotic cells. The cellular diversity and surprising complexity of bacterial cell structure help us to understand not only how bacteria function in nature, but also how important features of eukaryotic cells first evolved.

Prokaryotic Cells Vary in Shape

Although prokaryotic cells occur in multiple forms, they have five common shapes (**Figure 27.7**): spheres (**cocci**), elongate rods (**bacilli**), comma-shaped cells (**vibrios**), and spiral-shaped cells that are either flexible (**spirochaetes**) or rigid (**spirilli**; see Figure 27.6). Cytoskeletal proteins similar to those present in eukaryotic cells control these cell shapes. For example, helical strands of an actin-like protein are responsible for the rod shape of bacilli; if this protein is not produced, bacilli become spherical in shape. Cellular shape is an important component of bacterial function in nature. Cocci may have a greater surface area/volume ratio, which facilitates exchange of materials with the environment, but bacilli can often store more nutrients.

Slimy Mucilage Often Coats Cellular Surfaces

Many bacteria exude a coat of slimy mucilage, sometimes called a glycocalyx, capsule, or extracellular polymeric substance (EPS). Mucilage, which varies in consistency and thickness, is composed of hydrated polysaccharides and proteins, as well as lipids and nucleic

(a) Sphere-shaped cocci (*Lactococcus lactis*)
(b) Rod-shaped bacilli (*Lactobacillus plantarum*)
(c) Comma-shaped vibrios (*Vibrio cholerae*)
(d) Spiral-shaped spirochaetes (*Leptospira* sp.)

Figure 27.7 Major types of prokaryotic cell shapes. Scanning electron micrographs.

BIOLOGY PRINCIPLE Cells are the simplest units of life. In the case of unicellular bacteria and archaea, a single cell constitutes an entire organism.

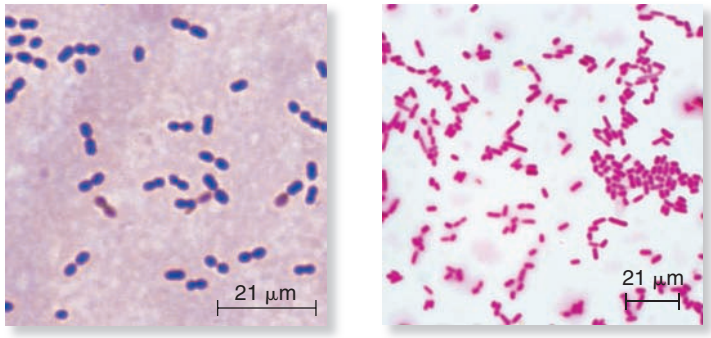
acids. A capsule helps some disease bacteria evade the defense system of their host. You may recall that Frederick Griffith discovered the transfer of genetic material while experimenting with capsule-producing pathogenic strains and capsule-less nonpathogenic strains of the bacterium *Streptococcus pneumoniae* (refer back to Figure 11.1). The immune system cells of mice are able to destroy this bacterium only if it lacks a capsule.

Mucilage plays many additional roles: holding cells together closely enough for chemical communication and DNA exchange to occur, helping aquatic species to float in water, binding mineral nutrients, and repelling attack. Pigmented slime sheaths (see Figure 27.3d) coat some bacterial filaments, helping to prevent UV damage.

Biofilms are aggregations of microorganisms that secrete adhesive mucilage, thereby gluing themselves to surfaces. Formation of a biofilm helps microbes remain in favorable locations for growth; otherwise body or environmental fluids would wash them away. A process known as **quorum sensing** fosters biofilm formation. During quorum sensing, individual microbes secrete small molecules having the potential to influence the behavior of nearby microbes. If enough individuals are present (a quorum), the concentration of signaling molecules builds to a level that causes collective behavior. In the case of biofilms, populations of microbes respond to chemical signals by moving to a common location and producing mucilage.

Biofilms are environmentally and medically important. From a human standpoint, biofilms have both beneficial and harmful consequences. In aquatic and terrestrial environments, they help to stabilize and enrich sand and soil surfaces. Microbial biofilms can also be important in the formation of mineral deposits. Biofilms that form on the surfaces of animal tissues, however, can be harmful. Dental plaque is an example of a harmful biofilm (**Figure 27.8**); if allowed to remain, the bacterial community secretes acids that can damage tooth enamel. Biofilms may also develop in industrial pipelines, where the attached microbes can contribute to corrosion by secreting enzymes that chemically degrade metal surfaces.

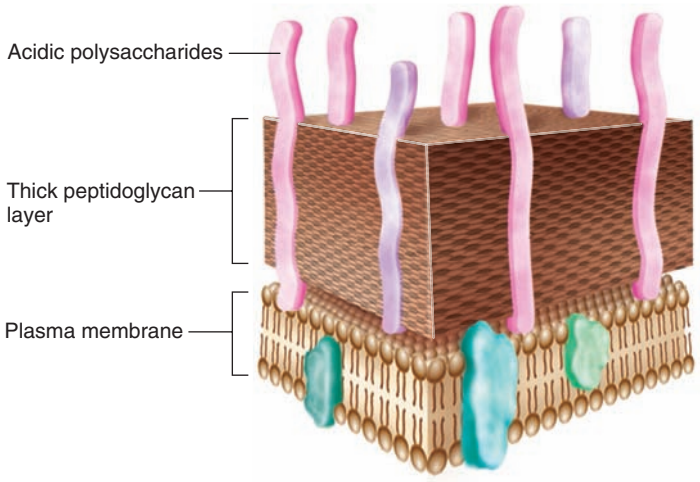
Figure 27.8 A biofilm composed of a community of microorganisms glued by mucilage to a surface. This SEM shows dental plaque, consisting of several types of bacteria—falsely colored purple, green, and blue—attached to a tooth surface by mucilage.



Prokaryotic Cells Vary in Cell-Wall Structure

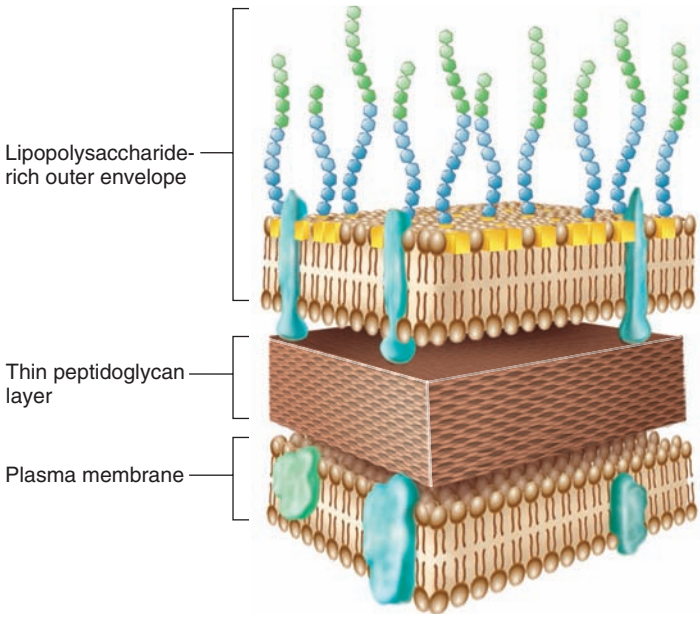
Whether coated with mucilage or not, most prokaryotic cells possess a rigid cell wall outside the plasma membrane. Cell walls maintain cell shape and help protect against attack by viruses or predatory bacteria. Cell walls also help microbes avoid lysing in hypotonic conditions, when the solute concentration is higher inside the cell than outside. The structure and composition of bacterial cell walls are medically important.

Although some archaea lack cell walls, most possess a wall composed of protein. In contrast, the polymer known as **peptidoglycan**, lacking in archaea, is an important component of most bacterial cell walls. Peptidoglycan is composed of carbohydrates that are cross-linked by peptides. Bacterial cell walls occur in two major forms that differ in peptidoglycan thickness, staining properties, and response to antibiotics. Bacteria having these chemically different walls are called Gram-positive or Gram-negative bacteria, after the staining process used to distinguish them (**Figure 27.9**). The stain is named for its inventor, Danish scientist Hans Christian Gram.



Gram-positive bacteria classified in the phyla Firmicutes and Actinobacteria have walls with a relatively thick peptidoglycan layer (**Figure 27.10a**). By contrast, the Gram-negative cell walls of Cyanobacteria, Proteobacteria, and other species have a thinner peptidoglycan layer and are enclosed by a thin, outer envelope whose outer leaflet is rich in **lipopolysaccharides** (**Figure 27.10b**; see also Figure 27.2a). This outer envelope of Gram-negative bacteria is a phospholipid bilayer, but is distinct from the plasma membrane. Peptidoglycan and lipopolysaccharides can affect disease symptoms, the composition of vaccines, and bacterial responses to antibiotics. For example, part of the peptidoglycan covering of the Gram-negative bacterial species *Bordetella pertussis* is responsible for the extensive tissue damage to the respiratory tract associated with whooping cough, and whooping cough vaccines are improved by including antibodies that reduce the ability of the lipopolysaccharide layer to attach to host cells.

The lipopolysaccharide-rich outer envelope of Gram-negative bacteria helps them to resist the entry of some antibiotics. However, this outer envelope also impedes the secretion of proteins from bacterial cells into the environment, a process that normally allows cells to communicate with each other, as in quorum sensing. Gram-negative bacteria have adapted to the presence of an outer envelope



(a) Gram-positive bacteria **(b) Gram-negative bacteria**

Figure 27.9 Gram-positive and Gram-negative bacteria. **(a)** *Streptococcus pneumoniae*, a member of the phylum Firmicutes, stains positive (purple) with the Gram stain. **(b)** *Escherichia coli*, a member of the Proteobacteria, stains negative (pink) when the Gram stain procedure is applied.

(a) Gram-positive: thick peptidoglycan layer, no outer envelope

(b) Gram-negative: thinner peptidoglycan layer, with outer envelope

Figure 27.10 Cell-wall structures of Gram-positive and Gram-negative bacteria. **(a)** The structure of the cell wall of Gram-positive bacteria. **(b)** The structure of the cell wall and lipopolysaccharide-rich envelope typical of Gram-negative bacteria.

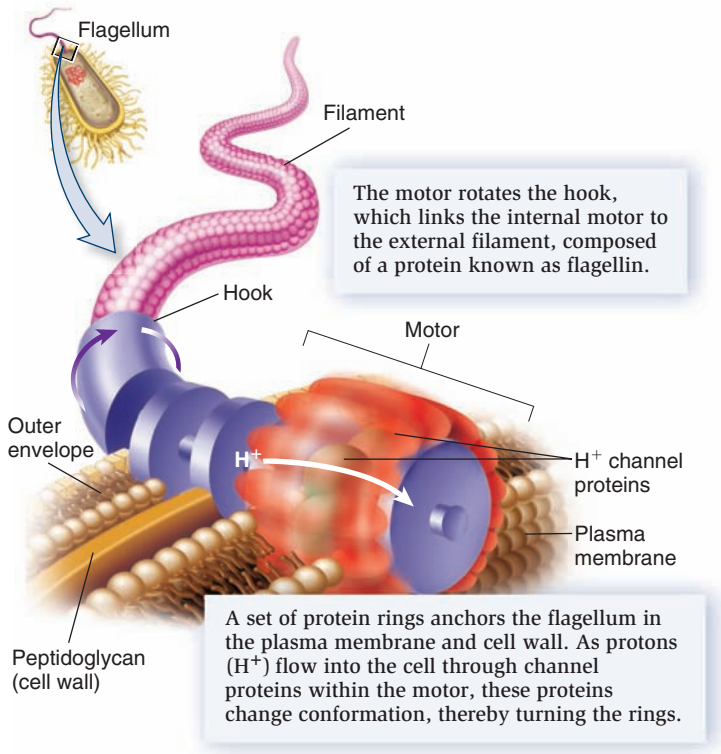
by evolving several types of protein systems that function in secretion. We will later see how some of these secretion systems have been modified in ways that allow disease-causing bacteria to attack eukaryotic cells.

Distinguishing Gram-positive from Gram-negative bacteria is an important factor in choosing the best antibiotics for treating infectious diseases. For example, Gram-positive bacteria are typically more susceptible than Gram-negative bacteria to penicillin and related antibiotics because these antibiotics interfere with synthesis of peptidoglycan, which Gram-positive bacteria require in larger amounts. For this reason, penicillin and related antibiotics such as methicillin are widely used to treat infections caused by Gram-positive bacteria. However, it is of societal concern that some strains of Gram-positive bacteria have become resistant to some antibiotics, an example being methicillin-resistant *Staphylococcus aureus*, or MRSA.

Bacteria and Archaea Display Diverse Types of Movements

Many bacteria and archaea have structures at the cell surface or within that enable them to change position in their environment, a process known as **motility**. Diverse motility adaptations allow microbes to respond to chemical signals emitted from other cells during quorum sensing and mating, and to move to favorable conditions within gradients of light, gases, or nutrients. For example, we have already learned that gas vesicles help cyanobacteria float into well-illuminated waters close to the surface, where photosynthesis can occur (see Figure 27.5). In addition, prokaryotic cells may move by twitching, gliding, or swimming by means of flagella.

Bacterial **flagella** (singular, flagellum) differ from eukaryotic flagella in several ways. Although bacterial flagella are largely built of about 30 types of proteins, they lack a plasma membrane covering, an internal cytoskeleton of microtubules made of the protein tubulin, and the motor protein dynein—all features that characterize eukaryotic flagella (see Chapter 4). Unlike eukaryotic flagella, prokaryotic flagella do not repeatedly bend and straighten. Instead, prokaryotic flagella spin, propelled by molecular machines composed of a filament, hook, and motor that work together somewhat like a boat's outboard motor and propeller (**Figure 27.11**). Lying outside the cell, the



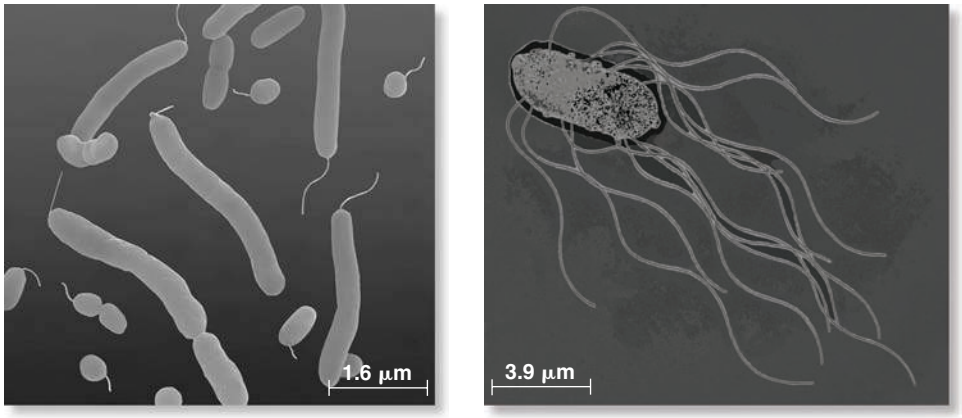


Figure 27.11 Diagram of a prokaryotic flagellum, showing a filament, hook, and motor.

Concept Check: *Does the filament move more like the arms of a human swimmer or the shaft of a boat propeller?*

(a) Bacteria with a single short flagellum (b) Bacterium with multiple long flagella

Figure 27.12 Differences in the number and location of flagella. Depending on the species, microbial cells can produce one or more flagella at the poles or numerous flagella around the periphery. **(a)** *Vibrio parahaemoliticus*, a bacterium that causes seafood poisoning, has a single short flagellum. **(b)** *Salmonella enterica*, another bacterium that causes food poisoning, has many flagella distributed around the cell periphery.

BioConnections: Look ahead to Figure 28.8b. What heterotrophic eukaryote (like V. parahaemoliticus and S. enterica) moves to its food source in the human gut by means of flagella?

long, stiff, curved filament acts as a propeller. The hook links the filament with the motor that contains a set of protein rings at the cell surface. Hydrogen ions (protons), which have been pumped out of the cytoplasm, usually via the electron transport system, diffuse back into the cell through channel proteins within the motor. This proton flow powers the turning of the hook and filament at rates of hundreds of revolutions per second. Archaeal flagella also rotate but are much thinner than bacterial flagella, composed of different proteins, and powered differently (by the hydrolysis of ATP).

Prokaryotic species differ in the number and location of flagella, which may occur singly or in tufts at one pole or may emerge from around the cell (**Figure 27.12**). Differences in flagellar number and location cause microorganisms to exhibit different modes or rates of swimming. For example, spirochaetes' flagella are located outside the peptidoglycan cell wall but within the confines of an outer membrane that holds them close to the cell. Rotation of these flagella causes spirochaetes to display characteristic bending, flexing, and twirling motions. Bacteria are known to swim at rates of more than 150 µm per second.

Some prokaryotic species twitch or glide across surfaces, using threadlike cell surface structures known as **pili** (singular, pilus) (**Figure 27.13**). *Myxococcus xanthus* cells, for example, move by alternately extending and retracting pili from one pole or the other. This process allows directional movement toward food materials. If nutrients are low, cells of these bacteria glide together to form tiny treelike colonies, which are part of a reproductive process. These and other motility adaptations help bacteria and archaea survive in their environments.

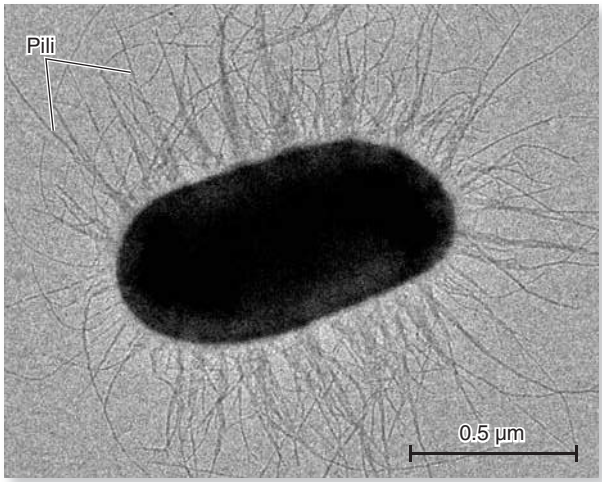

Figure 27.13 Pili extending from the surface of *Escherichia coli*.

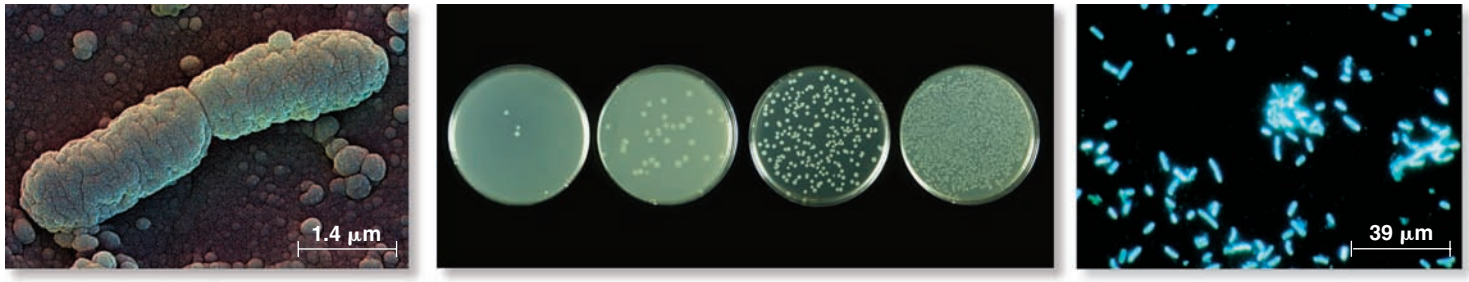
Concept Check: What type of motion does this cell likely use?

27.3 Reproduction



Learning Outcomes:

1. Explain how populations of prokaryotic organisms increase in number.
2. **SciSKILLS** » Describe how bacteria can be counted in medical and environmental samples.
3. Give examples of how some bacteria survive under stressful conditions.

Bacteria and archaea do not engage in sexual reproduction as used by eukaryotes, involving specialized gametes, gamete fusion, and meiosis, though they can exchange some genes by conjugation, transformation, and transduction (described in Chapter 18). Bacteria and archaea commonly reproduce asexually, generally by means of a type of cell division known as binary fission that enlarges populations. In addition, some bacteria produce tough cells that can withstand deleterious conditions for long periods in a dormant condition.

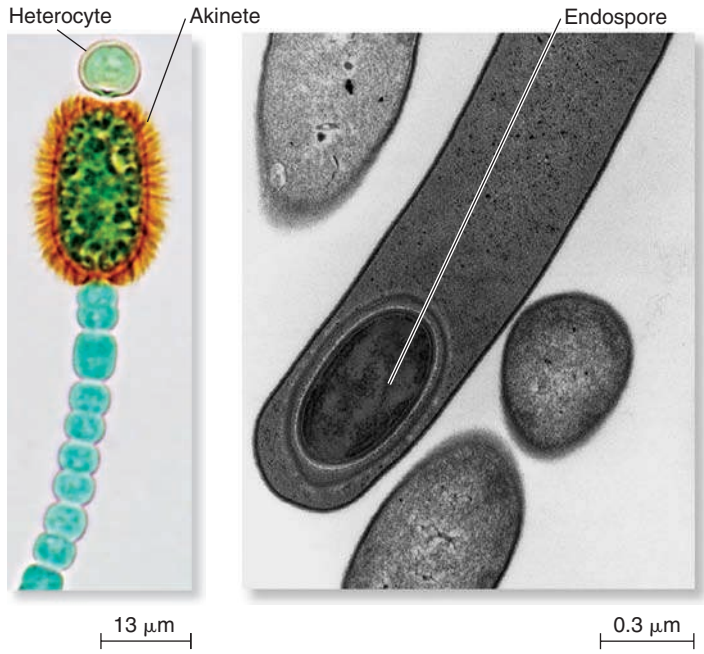
Prokaryotic Cells Generally Divide by Binary Fission

The cells of most bacteria and archaea divide by splitting in two, a process known as **binary fission** (**Figure 27.14a**; refer back to Figure 18.13). Bacterial binary fission generally requires a protein known as FtsZ, which is related to the tubulin that makes up eukaryotic microtubules. FtsZ squeezes dividing cells into two progeny cells; if this protein is not functional, most bacterial cells cannot complete binary fission, and the cells become very long. Some archaea use the FtsZ protein for dividing, but others utilize different mechanisms. When sufficient nutrients are available, an entire population of identical cells can be produced from a single parental cell by repeated binary fission. This growth process allows microbes to become very numerous in water, food, or animal tissues, potentially causing harm.

(a) Bacterium undergoing binary fission (b) Colonies developed from single cells (c) Bacteria stained with fluorescent DNA-binding dye

Figure 27.14 Binary fission and counting microbes. **(a)** Division of a bacterial cell as viewed by scanning electron microscopy. **(b)** When samples are spread onto the surfaces of laboratory dishes containing nutrients, single cells of bacteria or archaea may divide repeatedly to form visible colonies, which can be easily counted. The number of colonies is an estimate of the number of culturable cells in the original sample. **(c)** If a fluorescence microscope is available, cells can be counted directly by applying a fluorescent stain that binds to their DNA. Each cell glows brightly when illuminated with UV light.

Concept Check: *Which procedure would you choose to count bacteria in a sample that is known to include many species that have not as yet been cultured?*



BioConnections: *Look back to Figure 18.13. How many cells result from the binary fission of a single mother cell?*

Binary fission is the basis of a widely used method for detecting and counting bacteria in food, water samples, or patients' body fluids. Microbiologists who study the spread of disease need to quantify bacterial cells in samples taken from the environment. Medical technicians often need to count bacteria in body fluid samples to assess the likelihood of infection. However, because bacterial cells are small and often unpigmented, they are difficult to count directly. One way that microbiologists count bacteria is to place a measured volume of sample into plastic dishes filled with a semisolid nutrient medium. Bacteria in the sample undergo repeated binary fission to form colonies of cells visible to the unaided eye (**Figure 27.14b**). Because each colony represents a single cell that was present in the original sample, the number of colonies in the dish reflects the number of living bacteria in the original sample.

Another way to detect and count prokaryotic cells is to treat samples with a stain that binds bacterial DNA, causing cells to glow brightly when illuminated with UV light. The glowing cells can be viewed and counted by the use of a fluorescence microscope (**Figure 27.14c**). The fluorescence method must be used when the microbes of interest cannot be cultivated in the laboratory. For many bacteria and archaea, the conditions needed to foster population growth in the laboratory are not known.

Some Bacteria Survive Harsh Conditions as Akinetes or Endospores

Some bacteria produce thick-walled cells that are able to survive unfavorable conditions in a dormant state. These specialized cells develop when bacteria have experienced stress, such as low nutrients or unfavorable temperatures. They are able to germinate into metabolically active cells when conditions improve again. For example, aquatic filamentous cyanobacteria often produce **akinetes**, large, food-filled cells, when winter approaches (**Figure 27.15a**). Akinetes are able to survive winter at the bottoms of lakes, and they produce

(a) Cyanobacterial akinete (b) *Clostridium difficile*

Figure 27.15 Specialized cells capable of dormancy. **(a)** Akinetes are thick-walled, food-filled cells produced by some cyanobacteria. They are able to resist stressful conditions and generate new populations when conditions improve. As discussed later, the heterocyte is a specialized cell in which nitrogen fixation occurs. **(b)** An endospore with a resistant wall develops within the cytoplasm of the pathogen *Clostridium difficile*.

Concept Check: *How do endospores influence the ability of some bacteria to cause disease?*

new filaments in spring when they are carried by water currents to the brightly lit surface. Persistence of such akinetes explains how harmful cyanobacterial blooms can develop year after year in overly fertile lakes.

Endospores (Figure 27.15b) are produced inside bacterial cells by the enclosure of DNA and other materials within a tough coat, and then are released when the enclosing cell dies and breaks down. Endospores can remain alive, though in a dormant state, for long periods, then reactivate when conditions are suitable.

The ability to produce endospores allows some Gram-positive bacteria in the phylum Firmicutes to cause serious diseases. For example, *Bacillus anthracis* causes the disease anthrax, a potential agent in bioterrorism and germ warfare. Most cases of human anthrax result when endospores of *B. anthracis* enter breaks in the skin, causing skin infections that are relatively easily cured by antibiotic treatment. But sometimes the endospores are inhaled or consumed in undercooked, contaminated meat, potentially causing more serious illness or death. *Clostridium botulinum* can contaminate improperly canned food that has not been heated to temperatures high enough to destroy its tough endospores. When the endospores germinate and bacterial cells grow in the food, they produce a deadly toxin, as well as NH_3 and CO_2 gases, which cause can lids to bulge. If humans consume the food, the toxin causes botulism, a severe type of food poisoning that can lead to respiratory and muscular paralysis. Interestingly, the botulism toxin is marketed commercially as Botox, which is injected into the skin, where it paralyzes facial muscles, thereby reducing the appearance of wrinkles. *Clostridium tetani* produces a nerve toxin that causes lockjaw, also known as tetanus, when bacterial cells or endospores from soil enter wounds. The ability of the genera *Bacillus* and *Clostridium* to produce resistant endospores helps explain their widespread presence in nature and their effect on humans.

27.4 Nutrition and Metabolism

Learning Outcomes:

1. List the major modes of nutrition used by prokaryotic species.
2. **SciSKILLS** » Compare and contrast the effects of oxygen on the metabolism of different types of prokaryotic species; then predict the outcome when a gas gangrene patient is treated with oxygen.
3. Describe in basic terms the process of biological nitrogen fixation, why it is important, and how oxygen interferes with this process.

All living cells require energy and a source of carbon to build their organic molecules. Bacteria and archaea use a wide variety of strategies to obtain energy and carbon for growth (Table 27.2). These microbes can be classified according to their energy source, carbon source, response to oxygen, and presence of specialized metabolic processes.

Mechanisms of Nutrition and Responses to Oxygen

Cyanobacteria and some other prokaryotic species are **autotrophs** (from the Greek, meaning self-feeders), organisms that are able to produce all or most of their own organic compounds from inorganic sources. Autotrophs fall into two categories: photoautotrophs and chemoautotrophs. **Photoautotrophs**, including cyanobacteria, use light as a source of energy for the synthesis of organic compounds from CO_2 and H_2O or from H_2S. **Chemoautotrophs** such as archaea of the genus *Sulfolobus* use energy obtained by chemical modifications of inorganic compounds to synthesize organic compounds. Such chemical modifications include nitrification (the conversion of ammonia to nitrate) and the oxidation of sulfur, iron, or hydrogen.

Table 27.2 Major Types of Archaea and Bacteria Based on Energy and Carbon Source

Type	Energy source	Carbon source	Example
Autotroph			
Photoautotroph	Light	CO_2	Cyanobacteria
Chemoautotroph	Inorganic compounds	CO_2	*Sulfolobus* (Archaea)
Heterotroph			
Photoheterotroph	Light	Organic compounds	Chloroflexi (Bacteria)
Chemoheterotroph	Organic compounds	Organic compounds	Many

Heterotrophs (from the Greek, meaning other feeders) are organisms that require at least one organic compound, and often more, from their environment. Some microorganisms, including bacteria in the phylum Chloroflexi, are **photoheterotrophs**, meaning that they are able to use light energy to generate ATP, but they must take in organic compounds from their environment as a source of carbon. **Chemoheterotrophs** must obtain organic molecules for both energy and as a carbon source.

Prokaryotic species differ in their need for and responses to oxygen. Like most eukaryotes (including humans), many prokaryotes are **obligate aerobes**, meaning that they require O_2 in order to survive. In contrast to obligate aerobes, obligate anaerobes, such as the Firmicutes genus *Clostridium*, are poisoned by O_2. People suffering from gas gangrene (caused by *Clostridium perfringens* and related species) are usually treated by placement in a chamber having a high oxygen content (called a hyperbaric chamber), which kills the organisms and deactivates the toxins. **Aerotolerant anaerobes** do not use O_2, but they are not poisoned by it either. These organisms obtain their energy by fermentation or anaerobic respiration, which are described in Chapter 7 (see Section 7.8). Anaerobic metabolic processes include denitrification (the conversion of nitrate into N_2 gas) and the reduction of manganese, iron, and sulfate, which are all important in the Earth's cycling of minerals.

Facultative anaerobes can use O_2 via aerobic respiration, obtain energy via anaerobic fermentation, or use inorganic chemical reactions to obtain energy—shifting between modes depending on environmental conditions. One fascinating example of a facultative anaerobe is the earlier-mentioned species *Thiomargarita namibiensis*, a large proteobacterium. This chemoheterotroph obtains its energy in two ways: by oxidizing sulfide with oxygen when this is available or, when oxygen is low or unavailable, by oxidizing sulfide with nitrate. In either case, the cells convert sulfide to elemental sulfur, which is stored within the cells as large globules.

Some Prokaryotic Species Play Important Roles as Nitrogen Fixers

Many cyanobacteria and some other prokaryotic organisms conduct a specialized metabolic process called biological **nitrogen fixation**. The removal of nitrogen from the gaseous phase is called fixation, and microbes that perform this process are known as nitrogen fixers. During nitrogen fixation, the enzyme nitrogenase converts inert atmospheric gas (N_2) into ammonia (NH_3). Plants and algae can use ammonia (though not N_2) to produce proteins and other essential nitrogen-containing molecules. As a result, many plants have developed close relationships with nitrogen fixers, which provide ammonia fertilizer to their plant partners. In addition to the aquatic photosynthetic cyanobacteria mentioned in the chapter opening, many types of heterotrophic soil bacteria also fix nitrogen. Examples include protobacteria of the genus *Rhizobium*, which live within the roots of legume plants (see Chapter 37).

Oxygen can poison nitrogenase, so most nitrogen fixers conduct nitrogen fixation only in low-oxygen conditions. Many cyanobacteria generate low-oxygen conditions in specialized cells known as **heterocytes**, allowing nitrogen fixation to occur in these cells (see Figure 27.15a). Heterocytes display adaptations that reduce nitrogenase exposure to oxygen (including thick walls that reduce inward O_2 diffusion), increase cellular reactions that consume oxygen, and down-regulate the oxygen-producing components of photosynthesis. The latter adaptation, involving reduction in chlorophyll synthesis, explains why heterocytes are paler in color than neighboring photosynthetic cells.

27.5 Ecological Roles and Biotechnology Applications

Learning Outcomes:

1. Discuss the roles of bacteria and archaea in the carbon cycle.
2. List examples of bacterial-eukaryote symbiosis and of pathogenic microbes.
3. Define microbiome, and explain why it is important.
4. List ways in which bacteria contribute to industrial and biotechnology applications.

Bacteria and archaea play many key ecological roles. These include producing and breaking down organic carbon and acting as beneficial symbionts in plants and animals and as disease agents. In this section, we will focus on these diverse ecological roles and also provide examples of ways that humans use the metabolic capabilities of bacteria in biotechnology.

Bacteria and Archaea Play Important Roles in Earth's Carbon Cycle

The Earth's carbon cycle is the sum of all the chemical changes that occur among compounds that contain carbon. (See Chapter 59 for a detailed discussion of the carbon cycle.) One way that bacteria and archaea influence Earth's carbon cycle is by producing and consuming methane. Methane (CH_4)—the major component of natural gas—is a greenhouse gas more powerful than CO_2; CH_4 increases global warming over 20 times more per molecule than does CO_2. In consequence, atmospheric CH_4 has the potential to alter the Earth's climate, and in recent years the level of CH_4 has been increasing in Earth's atmosphere as the result of human activities. Several groups of anaerobic archaea known as **methanogens** convert CO_2, methyl groups, or acetate to CH_4 and release CH_4 from their cells into the atmosphere. Methanogens live in swampy wetlands, in deep-sea habitats, or in the digestive systems of animals including cattle and humans. Marsh gas produced in wetlands is largely composed of CH_4, and large quantities of CH_4 produced long ago are trapped in deep-sea and subsurface Arctic deposits. Certain bacteria known as **methanotrophs** consume CH_4, thereby reducing its concentration in the atmosphere. In the absence of methanotrophs, Earth's atmosphere would be much richer in the greenhouse gas CH_4, which would substantially increase global temperatures.

Bacteria and archaea are also important in producing and degrading complex organic compounds. For example, cyanobacteria and other autotrophic bacteria are important **producers**. Such bacteria, together with algae and plants, use photosynthesis to synthesize the organic compounds used by other organisms for food. **Decomposers**, also known as saprobes, include heterotrophic microorganisms (as well as fungi and animals). These organisms break down dead organisms and organic matter, releasing minerals for uptake by living things. Astonishingly, many bacteria are able to break down antibiotics for use as a source of organic carbon, as discussed next.

Feature Investigation | Dantas and Colleagues Found That Many Bacteria Can Break Down and Consume Antibiotics as a Sole Carbon Source

Many microorganisms naturally secrete antibiotics, chemicals that inhibit the growth of other microorganisms. Antibiotic compounds are evolutionary adaptations that allow bacteria and other microbes to avoid attack or reduce competition for resources. People have taken advantage of high antibiotic production by certain bacteria, particularly species of the phylum Actinomycetes, to make commercial antibiotics in industrial processes.

In nature, many chemoheterotrophic bacteria have taken advantage of widespread natural antibiotic production by utilizing these organic compounds as a source of carbon. In 2008, Gautam Dantas, George Church, and their colleagues reported this conclusion after experimentally testing their hypothesis that soil bacteria might be able to metabolize antibiotics (**Figure 27.16**). The investigators first cultivated bacteria from 11 different soils in the laboratory, finding diverse phylogenetic types. Almost 90% of the cultured bacteria were Gram-negative Proteobacteria, some closely related to human pathogens, while 7% of the cultures were Gram-positive Actinomycetes. These researchers then tested the ability of the bacteria cultured from different soils (isolates) to use various antibiotics as a sole carbon source. The 18 antibiotics tested included penicillin and related compounds,

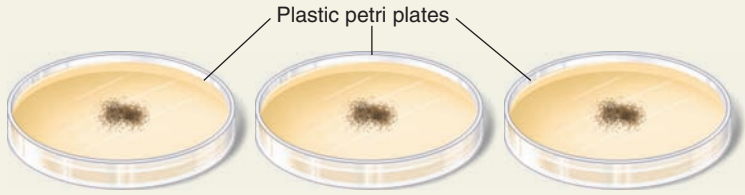


Figure 27.16 Diverse bacteria isolated from different soils are able to grow on many types of antibiotics.

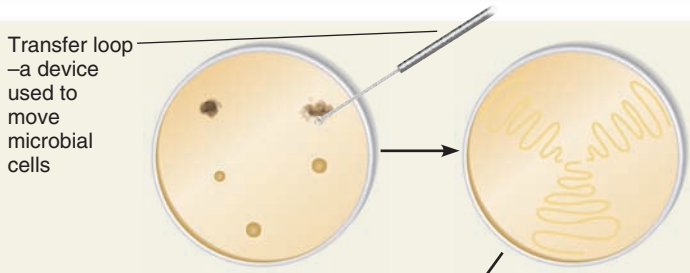
HYPOTHESIS The soil bacterial community contains species that can take up and metabolize antibiotics.

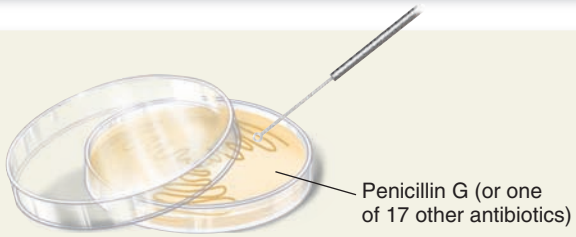


KEY MATERIALS Eleven diverse soil samples; 18 types of antibiotics.

Experimental level | **Conceptual level**

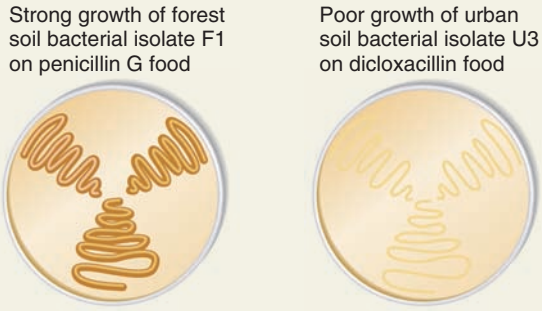
1 Inoculate soil samples onto growth media in culture dishes.

2 Isolate bacterial species that grow from single cells to visible colonies by repeated binary fission.



Different species have distinctive colony characteristics (color, shape, size).

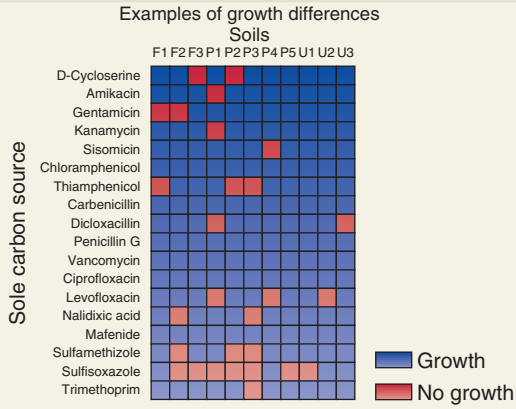
3 Grow isolates into large populations for testing on antibiotics.



Bacterial cells undergo repeated binary fission to quickly form colonies large enough to see with the unaided eye.

4 Inoculate each bacterial isolate onto replicate dishes containing a different antibiotic as the only food source.

Test the ability of each isolate to grow on a range of antibiotics.



5 Allow time for bacterial population growth; compare growth among dishes.

Compare isolate ability to grow on different antibiotics.

6 THE DATA

Most soils tested contained bacterial species that were able to use antibiotics of many types for food and thus were resistant to those antibiotics.

7 CONCLUSION Natural soils contain bacteria that are able to utilize antibiotics produced naturally by other species as food. Soil bacteria are a previously unrecognized source of antibiotic resistance genes that can be transferred to other species.

8 SOURCE Dantas, G., Sommer, M. O. A., Oluwasegun, R. D., and Church, G. M. 2008. Bacteria subsisting on antibiotics. *Science* 320:100–103.

as well as widely prescribed ciprofloxacin (Cipro). Every antibiotic tested supported the growth of bacteria from soil. Importantly, each antibiotic-eating isolate was resistant to several antibiotics at concentrations used in medical treatment of infections.

In today's society, the widespread use of antibiotics in medicine and agriculture is of concern because it is thought to foster increases in antibiotic resistance (see Section 18.5). The experiment by Dantas and associates revealed that natural evolutionary processes—the widespread development by diverse soil bacteria of metabolic processes to utilize many types of antibiotics as food—represent a previously unrecognized source of antibiotic resistance. The study also indicated that natural bacteria are a potential source of antibiotic-resistance genes that could be transferred to disease-causing bacteria.

Experimental Questions

1. What features of soil bacteria attracted the attention of the researchers?
2. **SciSKILLS »** What processes did the researchers use to test their hypothesis that soil bacteria might use antibiotics as a food source?

Many Bacteria Live in Symbiotic Associations

An organism that lives in close association with one or more other organisms is said to occur in **symbiosis** (from the Greek, meaning life together with). If symbiotic association is beneficial to both partners, the interaction is known as a **mutualism**. If one partner benefits at the expense of the other, the association is known as a **parasitism**. Many mutualistic bacteria live in associations of two or a few species that supply each other with essential nutrients. Numerous cases exist of eukaryote associations with mutualistic and parasitic bacteria, but symbioses between eukaryotes and archaea seem rare.

Mutualistic Partnerships Between Bacteria and Eukaryotes Bacteria are involved in many mutually beneficial symbioses in which they provide aquatic or terrestrial eukaryotes with minerals or vitamins or other valuable services. Bioluminescent bacteria, bacteria that have the ability to produce and emit light (**Figure 27.17**), often form symbiotic relationships with squid and other marine animals. In deep-sea thermal vent communities, bacteria live within the tissues of tubeworms and mussels, supplying these animals with carbon compounds used as food. One terrestrial example of mutualism is a complex association involving four partners: ants, fungi that the ants cultivate for food, parasitic fungi that attack the food fungi, and Actinobacteria that produce antibiotics. The antibiotics control the growth of the parasitic fungi, preventing them from destroying the ants' fungal food supply. The ants rear the useful bacteria in cavities on their body surfaces; glands near these cavities supply the bacteria with nutrients.

The Human Microbiome Humans likewise harbor symbiotic microbes. On our skin and in our digestive and reproductive systems exist many types of microbes that are known collectively as the human **microbiome**. An estimated 100 trillion microbes live in or on the typical human body! These microbes provide services using traits that humans do not possess, and the diverse types of metabolism present in the microbiome have coevolved with human metabolism. For this reason, humans and other multicellular organisms, together with

BIO TIPS **THE QUESTION** *The experiment conducted by Dantas and colleagues (Fig. 27.16) revealed that soil bacteria are able to break down and consume many antibiotic compounds commonly used in medicine to treat infections. Bacteria that consume antibiotics are resistant to such compounds. How might bacteria have acquired these abilities and why is this process important to society?*

TOPIC ***What topic in biology does this question address?***
The topic is evolution of the ability of soil bacteria to consume natural antibiotics as a food source. The question also relates to a societal problem, the increasing resistance of disease bacteria to antibiotics used in medicine.

INFORMATION ***What information do you know based on the question and your understanding of the topic?***
This section of the chapter summarizes the major ways in which bacteria acquire organic carbon and energy. Information provided in the Feature Investigation indicates that soil bacteria can obtain carbon from antibiotics. Your knowledge of the evolutionary process allows you to understand how fast-reproducing organisms such as bacteria might quickly acquire the ability to use new types of organic compounds, such as antibiotics, as food and thus become resistant to the antibiotics.

PROBLEM-SOLVING STRATEGY ***Make a drawing.*** Draw a strip of three or four panels, each of which shows the same pattern of soil patches that contain different levels of an antibiotic, from zero to higher levels used to treat infections. You might shade the patches differently. Draw bacterial cells in a homogeneous pattern across all the panels. In the first panel, color a few bacteria that have acquired a mutation allowing them to consume the antibiotic without succumbing to it. Use your knowledge of population adaptation to predict changes in the numbers of colored bacteria in subsequent panels over time.

ANSWER *Your drawing should allow you to understand the process by which populations of soil bacteria that are able to use antibiotics as food might increase over time. These populations of bacteria can quickly become resistant to antibiotics at levels that are used in medical treatments. The larger such populations are, the greater the chances of infections for which antibiotic treatment may not work as expected.*

their microbiomes, are considered to function and evolve as superorganisms. Recent research has revealed that human gut microbiome communities contain hundreds of prokaryotic species, that humans inherited some of their gut microbes from ancestral primates, and that extensive horizontal gene transfer has occurred among gut microbial species. Studies also reveal that gut microbiomes differ among healthy people, and between healthy people and those having different types of medical conditions. The Human Microbiome Project seeks to understand the relationship between human metabolism and microbiome communities at several sites in the human body, with the goal of opening new opportunities to improve human health. Other projects explore the microbiomes of domesticated animals, plants, protists, and other habitats to better understand bacterial communities and how they affect other forms of life.

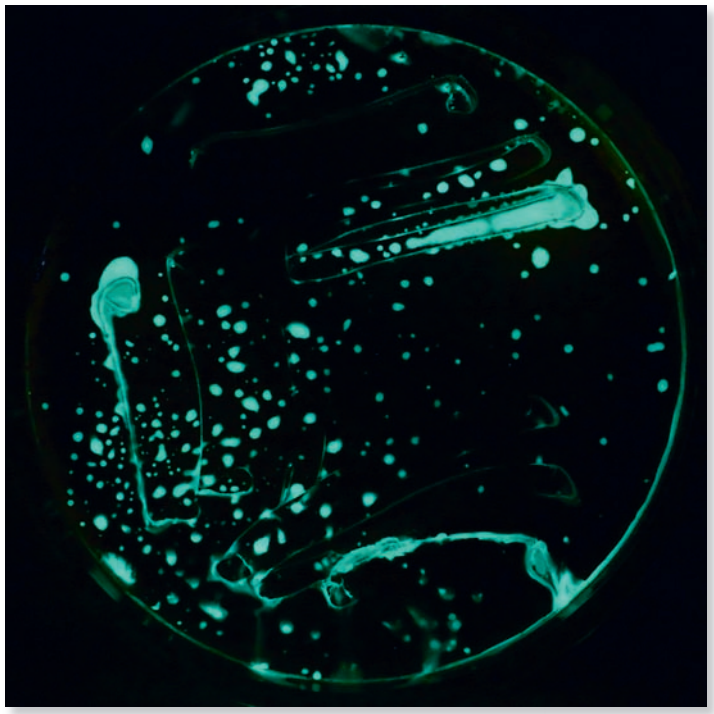


Figure 27.17 **Bioluminescent bacteria.** These blue-green colonies of *Vibrio fischeri* bacteria are growing on nutritive media in a culture plate. The colonies produce so much light that additional light was not needed to make this photo.

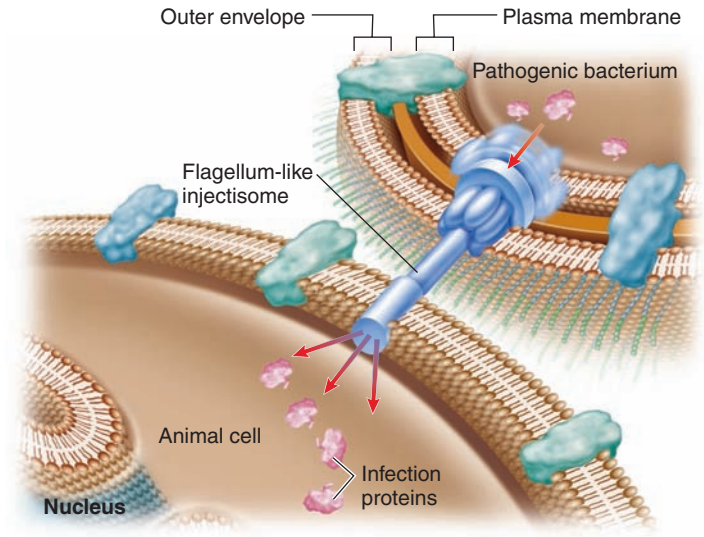
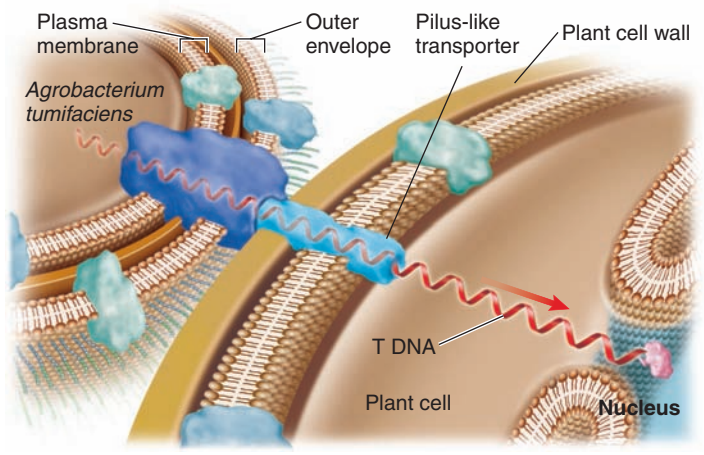


Pathogenic Microbes Microorganisms that cause disease in one or more types of host organism are known as **pathogens**. Cholera, leprosy, tetanus, pneumonia, whooping cough, diphtheria, Lyme disease, scarlet fever, rheumatic fever, typhoid fever, bacterial dysentery, and tooth decay are among the many examples of human diseases caused by bacterial pathogens. Bacteria also cause many plant diseases of importance in agriculture, including blights, soft rots, and wilts. How do microbiologists determine which bacteria cause these diseases? The pioneering research of the Nobel Prize–winning German physician Robert Koch provided the answer.

In the mid- to late 1800s, Koch established a series of four steps to determine whether a particular organism causes a specific disease. First, the presence of the suspected pathogen must correlate with occurrence of symptoms. Second, the pathogen must be isolated from an infected host and grown in pure culture if possible. Third, cells from the pure culture should cause disease when inoculated into a healthy host. Fourth and finally, the same pathogen should be isolatable from the second infected host. Using these steps, known as **Koch's postulates**, Koch discovered the bacterial causes of anthrax, cholera, and tuberculosis. Subsequent investigators have used Koch's postulates to establish the identities of additional bacteria that cause other infectious diseases. Recent studies have also indicated how pathogenic bacteria attack host cells.



How Pathogenic Bacteria Attack Cells Understanding how disease-causing bacteria attack host cells aids in developing strategies

for disease prevention and treatment. Many pathogenic bacteria attack cells by binding to the surface and injecting substances that help them utilize cellular components. During their evolution, some Gram-negative pathogenic bacteria developed needle-like systems, made of components also found in flagella, that inject proteins into animal or plant cells as part of the infection process. Such structures are known as type III secretion systems, also called injectisomes (**Figure 27.18a**). Examples of bacteria whose injectisomes allow them to attack human cells are *Yersinia pestis* (the agent of bubonic plague), *Salmonella enterica* (which causes the food poisoning called salmonellosis), and *Burkholderia pseudomallei* (the cause of melioidosis, a deadly disease of growing concern in some parts of the world). These bacteria also induce the host cell to form a plasma membrane pocket that encloses the bacterial cell, bringing it into the host cell. Once within a host cell, the bacterium uses the cell's resources to reproduce and spread to nearby tissues. More than 20 million people are infected by means of injectisomes every year.

Some other Gram-negative bacterial pathogens use a type IV secretion system to deliver toxins or DNA into cells (**Figure 27.18b**). Examples of such bacteria that cause human disease include *Helicobacter pylori*, *Legionella pneumophila*, and *Bordetella pertussis*. The plant pathogen *Agrobacterium tumifaciens* uses a type IV secretion system to transfer DNA (T DNA) into plant cells. The T DNA encodes an enzyme that affects normal plant growth, with the result that cancer-like tumors called galls develop (see Figure 27.4). The type IV secretion system evolved from pili and other components of bacterial mating. As such, it is an example of descent with modification, the evolutionary process by which organisms acquire new features.

(a) Type III secretion system

(b) Type IV secretion system

Figure 27.18 Attack systems of pathogenic bacteria. **(a)** The type III secretion system functions like a syringe to inject proteins into host cells, in this case an animal cell, thereby initiating the disease process. **(b)** The type IV secretion system forms a channel through which DNA can be transmitted from a pathogen to a host cell, in this case from the bacterium *Agrobacterium tumifaciens* into a plant cell.

Concept Check: *How does the type IV secretion system illustrate the evolutionary concept of descent with modification?*

Genomes & Proteomes Connection

The Evolution of Bacterial Pathogens

Genomic and proteomic studies have illuminated the evolution of bacterial pathogens, providing insight useful in devising new ways to control infectious diseases. Such studies reveal that some pathogens have evolved small, compact genomes encoding specialized metabolic functions, whereas others have acquired large genomes that provide diverse metabolic capabilities. Horizontal gene transfer plays a major role in increasing disease severity.

Mycoplasma pneumoniae, which causes pneumonia in humans, has one of the smallest genomes known to occur among self-replicating organisms. The tiny cells, only 0.3 µm in diameter, possess fewer than 700 protein-coding genes and make only 178 types of protein complexes. The bacterium is a model organism for investigating the minimal cellular machinery required for life. As one way of gaining insight into what forms a minimal proteome, the locations of five types of protein complexes have been mapped in cells by means of specialized microscopic techniques (**Figure 27.19**).

By contrast, *Pseudomonas aeruginosa*—which causes respiratory disease in humans and other animals, and also infects plants—has a larger genome that encodes about 5,000 genes. Diverse strains share a common genome core but also have strain-specific genes acquired by horizontal transfer, which confer a wide variety of metabolic abilities. This genomic flexibility allows *P. aeruginosa* to survive in a wide range of environments. As an example of the wide metabolic capability, an isolate of *P. aeruginosa* obtained from an infected human also possessed the genes and proteins necessary to degrade tough defensive resins produced by trees and use them as a food source!

Escherichia coli strain O157:H7, which causes deadly outbreaks of food-borne illness and is the leading cause of acute kidney failure in children, evolved from harmless strains by the step-wise horizontal gain of toxin genes, a large plasmid that encodes proteins that foster disease (known as virulence factors), and other genetic elements. These genomic features enable this

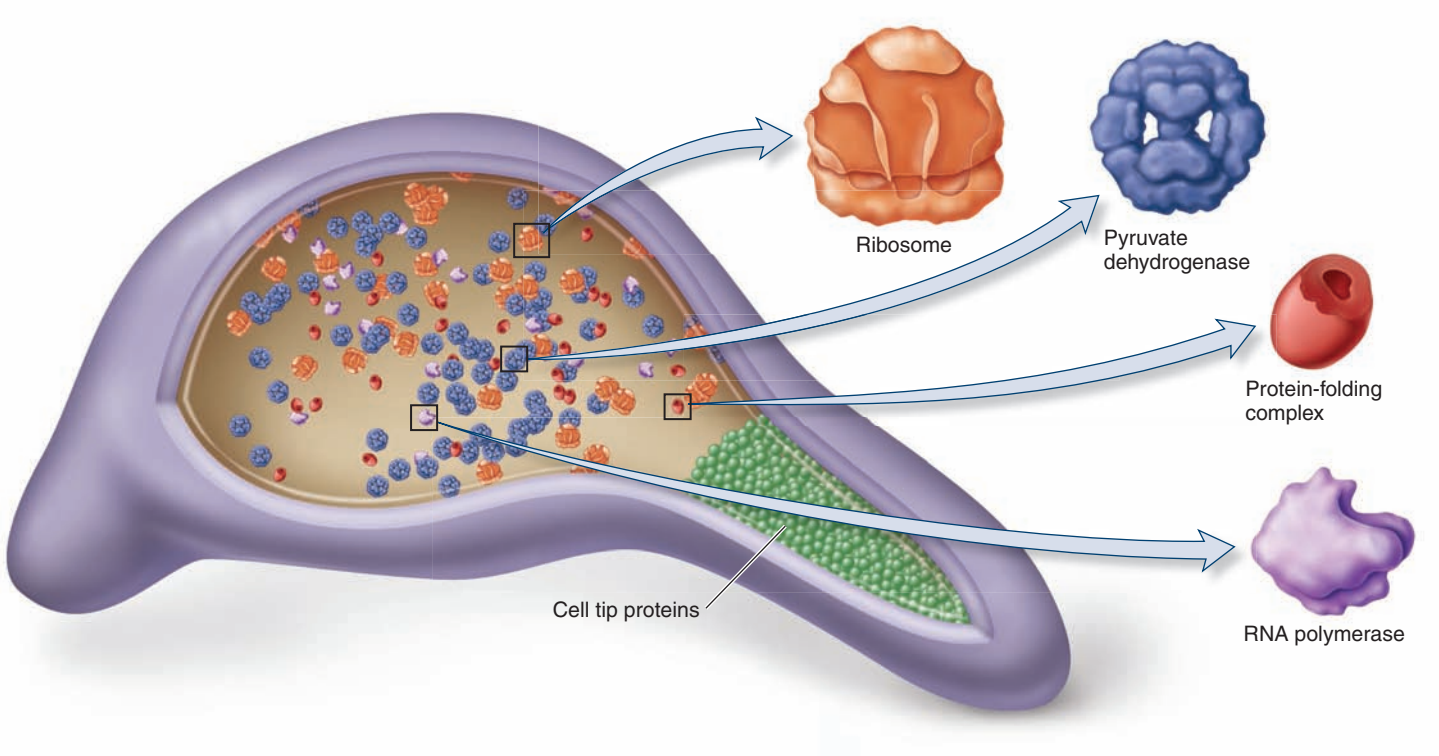


Figure 27.19 Locations of five protein complexes in the tiny pathogen *Mycoplasma pneumoniae*. The cell tip is rich in proteins (colored green) that help these bacteria attach to host epithelial cells. Other mapped protein complexes are pyruvate dehydrogenase (involved in energy metabolism), ribosomes, RNA polymerase, and a protein-folding complex (colored red).

strain to use its flagellar tips to attach to host intestinal epithelium and then attack cells with a type III injectisome. Bacterial toxin produced in the intestine enters the host circulation system and reaches the kidneys, where the toxin inhibits protein synthesis, resulting in severe tissue damage.

Some Bacteria Are Useful in Industrial and Other Applications

Several industries have harnessed the metabolic capabilities of microbes obtained from nature. The food industry uses bacteria to produce chemical changes in food that improve consistency or flavor—for example, to make dairy products, including cheese and yogurt. Cheese makers add pure cultures of certain bacteria to milk. The bacteria consume milk sugar (lactose) and produce lactic acid, which aids in curdling the milk.

The chemical industry produces materials such as enzymes, vinegar, amino acids, vitamins, insulin, vaccines, antibiotics, and other useful pharmaceuticals by growing particular bacteria in giant vats. For example, the hot springs bacterial species *Thermus aquaticus* is a source of a form of DNA polymerase widely used in biology laboratories to amplify DNA in polymerase chain reaction (PCR). Industrially grown bacteria produce the antibiotics streptomycin, tetracycline, kanamycin, gentamycin, bacitracin, polymyxin-B, and neomycin.

The field of synthetic biology utilizes bacteria as chemical factories, by genetically modifying bacterial genomes so that bacteria produce particular useful compounds, such as pharmaceuticals and renewable biofuels. For example, biologists have modified the genome of the bacterium *Caldicellulosiruptor bescii* so it can transform switchgrass into ethanol. The ability of some microorganisms to break down organic compounds or precipitate metals makes them very useful in treating wastewater, industrial discharges, and harmful substances such as explosives, pesticides, and oil spills. This process, known as **bioremediation**, is used to reduce levels of harmful materials in the environment.

Agriculture employs several species of *Bacillus*, particularly *B. thuringiensis* (Bt), which produce toxins that kill the insects that ingest them but are harmless to many noninsect species. Tent caterpillars, potato beetles, gypsy moths, mosquitoes, and black flies are among the pests that can be controlled by the Bt toxin. For this reason, toxin-encoding genes from *B. thuringiensis* have been cloned and introduced into some crop plants, such as corn and cotton, to reduce conventional pesticide use and increase crop yields (refer back to Figure 20.14).

Summary of Key Concepts

27.1 Diversity and Evolution

- Domains of life include Bacteria, Archaea, and Eukarya (whose members are referred to as bacteria, archaea, and eukaryotes). Domain Archaea is more closely related to domain Eukarya than either is to domain Bacteria (Figure 27.1).
- Many representatives of the domain Archaea occur in extremely hot, salty, or acidic habitats. Ether-linked membrane phospholipids are among the features of archaea that enable their survival in extreme habitats (Figure 27.2).

- The domain Bacteria includes 50 or more phyla, including Cyanobacteria and Proteobacteria, which are particularly diverse and of great evolutionary and ecological importance (Table 27.1, Figures 27.3, 27.4).
- Widespread horizontal gene transfer has occurred among bacteria and archaea. Horizontal gene transfer by means of viral transduction, transformation, or conjugation allows microorganisms to evolve rapidly.

27.2 Structure and Movement

- Bacteria and archaea have prokaryotic cells that are smaller and simpler than eukaryotic cells. Structural adaptations that increased the complexity of some types of prokaryotic cells include thylakoids, magnetosomes, and nucleus-like bodies (Figures 27.5, 27.6).
- Major prokaryotic cell shapes are spherical cocci, rod-shaped bacilli, comma-shaped vibrios, and coiled spirochaetes and spirilli. Some cyanobacteria display features of multicellular organisms (Figure 27.7).
- Many microbes secrete a coating of slimy mucilage, which plays a role in diseases and in the development of biofilms. Biofilm development is influenced by quorum sensing, a process in which group activity is coordinated by chemical communication (Figure 27.8).
- Most bacterial cell walls contain peptidoglycan, which is composed of carbohydrates cross-linked by peptides. Gram-positive bacterial cells have thick peptidoglycan walls, whereas Gram-negative cells have less peptidoglycan in their walls and are enclosed by an outer lipopolysaccharide envelope (Figures 27.9, 27.10).
- Motility enables microbes to change positions within their environment, which aids in locating favorable conditions for growth. Some bacteria have gas vesicles, which enable them to float, whereas others swim by means of flagella or twitch or glide by the action of pili (Figures 27.11, 27.12, 27.13).

27.3 Reproduction

- Populations of most bacteria and archaea enlarge by binary fission, a simple type of cell division that provides a means by which culturable microbes can be counted (Figure 27.14).
- Some bacteria are able to survive harsh conditions as dormant akinetes or endospores (Figure 27.15).

27.4 Nutrition and Metabolism

- Bacteria and archaea can be grouped according to mechanism of nutrition, response to oxygen, or presence of distinctive metabolic features. Major nutritional types are photoautotrophs, chemoautotrophs, photoheterotrophs, and chemoheterotrophs (Table 27.2).
- Obligate aerobes require oxygen, whereas obligate anaerobes are poisoned by oxygen. Aerotolerant anaerobes do not use oxygen but are not poisoned by it. Both obligate and aerotolerant anaerobes obtain their energy by anaerobic respiration. Facultative aerobes are able to live with or without oxygen by using different processes for obtaining energy.
- Nitrogen fixation is a distinctive metabolic process displayed only by certain microorganisms.

27.5 Ecological Roles and Biotechnology Applications

- Bacteria and archaea play key roles in Earth's carbon cycle as producers, decomposers, beneficial symbionts, or pathogens. Some bacteria are able to consume antibiotics, a process linked to the evolution of antibiotic resistance (Figure 27.16).
- Methane-producing methanogens and methane-consuming methanotrophs are important in the carbon cycle, and they influence the Earth's climate.
- Pathogenic bacteria obtain organic compounds from living host cells.
- Bacteria attack eukaryotic cells by means of flagella-like type III secretion systems or type IV secretion systems, which evolved from pili (Figure 27.17).
- During their evolution, some pathogenic bacteria have reduced their genomes and proteomes, whereas others have acquired large genomes conferring diverse metabolic capacities; horizontal gene transfer is a major process by which disease severity increases (Figures 27.18, 27.19).
- Many bacteria and archaea are useful in industrial and other applications; others are used to make food products or antibiotics or to clean up polluted environments.

Assess and Discuss

Test Yourself

1. Which of the following features is common to prokaryotic cells?
   a. a nucleus, featuring a nuclear envelope with pores
   b. mitochondria
   c. plasma membranes
   d. mitotic spindle
   e. none of the above
2. The bacterial phylum that typically produces oxygen gas as a product of photosynthesis is
   a. Proteobacteria.
   b. Cyanobacteria.
   c. the Gram-positive bacteria.
   d. all of the above.
   e. none of the above.
3. Gram staining is a procedure that microbiologists use to
   a. determine if a bacterial strain is a pathogen.
   b. determine if a bacterial sample can break down oil.
   c. infer the structure of a bacterial cell wall and the bacterial response to antibiotics.
   d. count bacteria in medical or environmental samples.
   e. do all of the above.
4. Place the following steps in the correct order, according to Koch's postulates:
   I. Determine if pure cultures of bacteria cause disease symptoms when introduced to a healthy host.
   II. Determine if disease symptoms correlate with presence of a suspected pathogen.
   III. Isolate the suspected pathogen and grow it in pure culture, free of other possible pathogens.
   IV. Attempt to isolate pathogen from second-infected hosts.
   a. II, III, IV, I
   b. II, IV, III, I
   c. III, II, I, IV
   d. II, III, I, IV
   e. I, II, III, IV

5. What ecological role do cyanobacteria play?
   a. producers
   b. consumers
   c. decomposers
   d. parasites
   e. none of the above

6. Bacterial structures that are produced by pathogenic bacteria for use in attacking host cells include
   a. type III and IV secretion systems.
   b. magnetosomes.
   c. gas vesicles.
   d. thylakoids.
   e. none of the above.

7. The structures that enable some Gram-positive bacteria to remain dormant for extremely long periods of time are known as
   a. akinetes.
   b. endospores.
   c. biofilms.
   d. lipopolysaccharide envelopes.
   e. pili.

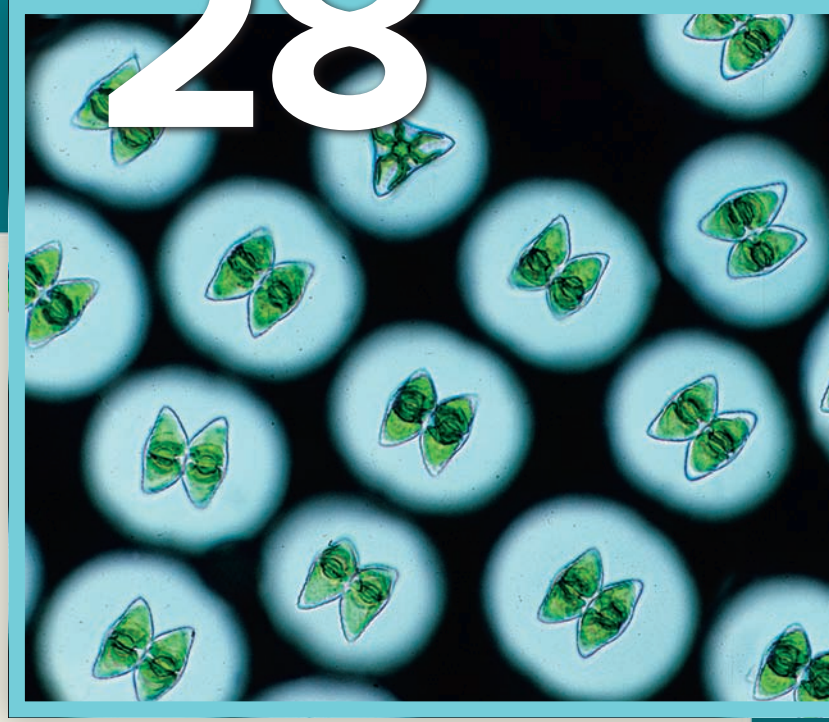
8. By means of what process do populations of bacteria or archaea increase their size?
   a. mitosis
   b. meiosis
   c. conjugation
   d. transduction
   e. none of the above

9. By what means do bacterial cells acquire new DNA?
   a. by conjugation, the mating of two cells of the same bacterial species
   b. by transduction, the injection of viral DNA into bacterial cells
   c. by transformation, the uptake of DNA from the environment
   d. all of the above
   e. none of the above

10. How do various types of bacteria move?
    a. by the use of flagella, composed of a filament, hook, and motor
    b. by means of pili, which help cells twitch or glide along a surface
    c. by using gas vesicles to regulate buoyancy in water bodies
    d. all of the above
    e. none of the above

Conceptual Questions

1. Explain why many microbial populations grow more rapidly than do populations of eukaryotes and how bacterial population growth influences the rate of food spoilage or infection.
2. What processes contribute to antibiotic resistance?
3.  A principle of biology is that *living organisms interact with their environment*. What organisms are responsible for the blue-green blooms that often occur in warm weather on lake surfaces? Think carefully; the answer is not just "cyanobacteria," as you might first guess.



Collaborative Questions

1. How would you go about cataloging the phyla of bacteria and archaea that occur in a particular place?
2. How would you go about developing a bacterial product that could be sold for remediation of a site contaminated with materials that are harmful to humans?

CHAPTER OUTLINE

28.1 An Introduction to Protists
28.2 Evolution and Relationships
28.3 Nutritional and Defensive Adaptations
28.4 Reproductive Adaptations
Summary of Key Concepts
Assess and Discuss

28 Protists

Protists such as these green algal cells and their plant descendants produce much of the Earth's oxygen. Each of the cells in this population is surrounded by a halo of protective mucilage.

Protists are eukaryotes that live in moist habitats and are mostly microscopic in size. Despite their small size, protists have a greater influence on global ecology and human affairs than most people realize. For example, the photosynthetic protists known as algae generate at least half of the oxygen in the Earth's atmosphere and produce organic compounds that feed marine and freshwater animals. The oil that fuels our cars and industry is derived from pressure-cooked algae that accumulated on the ocean floor over millions of years. Today, algae are being engineered into systems for cleaning pollutants from water or air and for producing biofuels.

Protists also include some parasites that cause serious human illnesses. For example, in 1993, the waterborne protist *Cryptosporidium parvum* sickened 400,000 people in Milwaukee, Wisconsin, costing $96 million in medical expenses and lost work time. Species of the related protist *Plasmodium*, which is carried by mosquitoes in many warm regions of the world, cause the disease malaria. Every year, nearly 500 million people become ill with malaria, and more than 2 million die of this disease. As we will see, sequencing the genomes of these and other protist species has suggested new ways of battling such deadly pathogens.

In this chapter, we will survey protist diversity, including structural, nutritional, and ecological variations. We begin by exploring ways of informally labeling protists according to ecological role, habitat, and motility. We will then focus on the defining features, classification, and evolutionary importance of the major protist phyla. Next, the nutritional modes and defensive adaptations of protists are discussed, and we conclude by looking at the reproductive adaptations that allow protists to exploit and thrive in a variety of environments.

28.1 An Introduction to Protists

Learning Outcomes:

1. List three features that define protists.
2. Label protists informally by ecological role, habitat, and type of motility.

The term protist comes from the Greek word *protos*, meaning first, reflecting the observation that protists were Earth's first eukaryotes. Protists are eukaryotes that are not classified in the plant, animal, or fungal kingdoms. Protists display two additional common characteristics: They are most abundant in moist habitats, and most of them are microscopic in size. Protists are often informally labeled according to their ecological roles, habitats, or type of motility.

Protists Can Be Informally Labeled According to Their Diverse Ecological Roles

Protists are often labeled according to their ecological roles, which yields three major types: algae, protozoa, and fungus-like protists. The term **algae** (singular, alga; from the Latin, meaning seaweeds) applies to protists that are generally photoautotrophic, meaning that most can produce organic compounds from inorganic sources by means of photosynthesis. In addition to organic compounds that

can be used as food by heterotrophs—organisms that obtain their food from other organisms—photosynthetic algae produce oxygen, which is also needed by most heterotrophs. Thanks to their photosynthetic abilities, algae are increasingly important sources of renewable biofuels. Despite the general feature of photosynthesis, algae do not form a monophyletic group descended from a single common ancestor.

The term **protozoa** (from the Greek, meaning first life) is commonly used to describe diverse heterotrophic protists. Protozoa feed by absorbing small organic molecules or by ingesting prey. For example, the protozoa known as ciliates consume smaller cells such as the single-celled photosynthetic algae known as diatoms (**Figure 28.1**). Like the algae, the protozoa do not form a monophyletic group.

Several types of heterotrophic **fungus-like protists** have bodies, nutrition, or reproduction mechanisms similar to those of the true fungi. For example, fungus-like protists often have threadlike, filamentous bodies and absorb nutrients from their environment, as do the true fungi (see Chapter 31). However, fungus-like protists are not actually related to fungi; their similar features represent cases of convergent evolution, in which species from different lineages have independently evolved similar characteristics (see Chapter 23). Water molds, some of which cause diseases of fish, and *Phytophthora infestans*, which causes diseases of many crops and wild plants, are examples of fungus-like protists (**Figure 28.2**). Various types of slime molds, some of which can be observed on decaying wood in forests, are also fungus-like, though not closely related to water molds and *Phytophthora*. These examples illustrate that the terms algae, protozoa, and fungus-like protists, although very useful in describing ecological roles, lack taxonomic or evolutionary meaning.

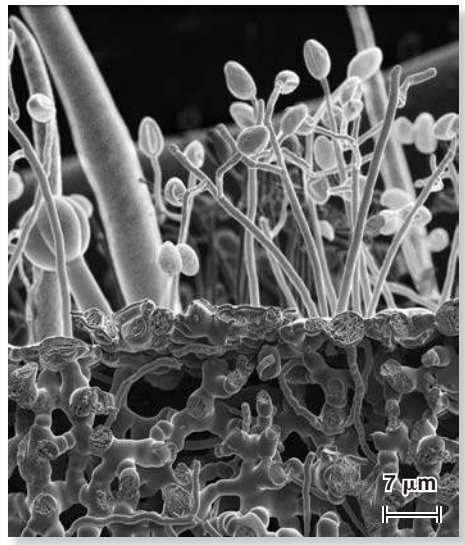


Figure 28.2 A fungus-like protist, *Phytophthora infestans*. This organism causes the disease of potato plants known as late blight, or potato-blight. SEM of protist growing on host leaf.

Figure 28.1 A heterotrophic protozoan feeding on photosynthetic algae. The ciliate shown here has consumed several oil-rich, golden-pigmented, silica-walled algal cells known as diatoms. Diatom cells that have avoided capture glide nearby.

BIOLOGY PRINCIPLE Living organisms use energy. The diatoms were ingested by the process of phagocytosis, and their organic components are digested as food.

Protists Can Be Informally Labeled According to Their Diverse Habitats

Although protists occupy nearly every type of moist habitat, they are particularly common and diverse in oceans, lakes, wetlands, and rivers. Even extreme aquatic environments such as Antarctic ice and acidic hot springs serve as habitats for some protists. In such places, protists may swim or float in open water or live attached to surfaces such as rocks or beach sand. These different habitats influence protist structure and size.

Protists that swim or float in fresh or salt water are members of an informal aggregate of organisms known as plankton, which also includes bacteria, viruses, and small animals. The photosynthetic protists in plankton are called **phytoplankton** (plantlike plankton). Planktonic protists are necessarily quite small in size; otherwise they would readily sink to the bottom. Staying afloat is a particularly important characteristic of phytoplankton, which need light for photosynthesis. For this reason, planktonic protists occur primarily as single cells, colonies of cells held together with mucilage, or short filaments of cells linked end to end (**Figure 28.3a–c**).

Many protists live within **periphyton**—communities of microorganisms attached by mucilage to underwater surfaces such as rocks, sand, and plants. Because sinking is not a problem for attached protists, these often produce multicellular bodies, such as branched filaments (**Figure 28.3d**). Photosynthetic protists large enough to see with the unaided eye are known as **macroalgae**, or seaweeds. Although the bodies of some macroalgae are very large single cells (**Figure 28.3e**), most macroalgae are multicellular, often producing large and complex bodies. Macroalgae usually grow attached to

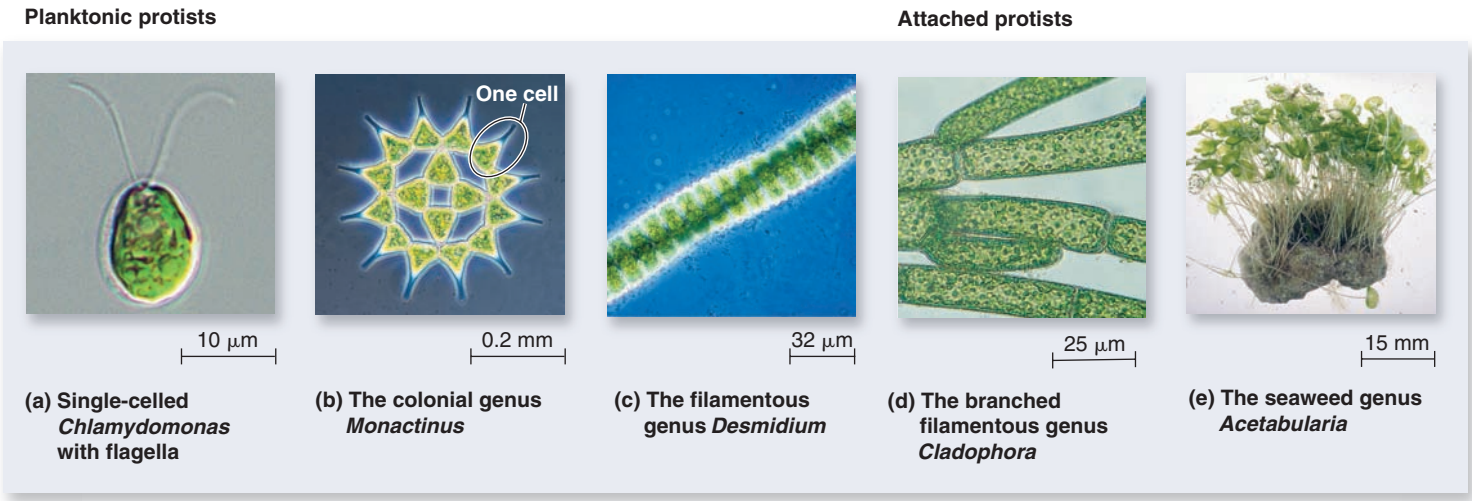

Figure 28.3 The diversity of algal body types reflects their habitats. **(a)** The single-celled flagellate genus *Chlamydomonas* occurs in the phytoplankton of lakes. **(b)** The colonial genus *Monactinus* is composed of several cells arranged in a lacy star shape that helps to keep this alga afloat in water and avoid being consumed by aquatic animals. **(c)** The filamentous genus *Desmidium* occurs as a twisted row of cells. **(d)** The branched filamentous genus *Cladophora* that grows attached to nearshore surfaces is large enough to see with the unaided eye. **(e)** The relatively large seaweed genus *Acetabularia* lives on rocks and coral rubble in shallow tropical oceans. The body of *Acetabularia* is a single very large cell.

underwater surfaces such as rocks, sand, docks, ship hulls, or offshore oil platforms. Seaweeds require sunlight and carbon dioxide for photosynthesis and growth, so most of them grow along coastal shorelines, fairly near the water's surface. Macroalgae serve as refuges for aquatic animals, generate large amounts of organic carbon that enters aquatic food chains, and play additional important ecological roles. Humans harvest some macroalgae for use as food or crop fertilizers or as sources of industrial chemicals to make diverse commercial products.

Protists Can Be Informally Labeled According to Their Type of Motility

Microscopic protists have evolved diverse ways to propel themselves in moist environments. Swimming by means of flagella, cilia, amoeboid movement, and gliding are major types of protist movements.

Many types of photosynthetic and heterotrophic protists are able to swim because they produce one or a few eukaryotic flagella—cellular extensions whose movement is based on interactions between microtubules and the motor protein dynein (refer back to Figure 4.13). Eukaryotic flagella rapidly bend and straighten, thereby pulling or pushing cells through the water. Protists that use flagella to move in water are commonly known as **flagellates** (Figure 28.3a). Flagellates are typically composed of one or only a few cells and are small—usually from 2 to 20 μm long—because flagellar motion is not powerful enough to keep larger bodies from sinking. Some flagellate protists are sedentary, living attached to underwater surfaces. These protists use flagella to collect bacteria and other small particles for food. Macroalgae and other immobile protists often produce small, flagellate reproductive cells that allow these protists to mate and disperse to new habitats.

An alternative type of protist motility relies on cilia, tiny hairlike extensions on the outsides of cells. Cilia are structurally similar to eukaryotic flagella but are shorter and more abundant (**Figure 28.4**). Protists that move by means of cilia are **ciliates**. Having many cilia allows ciliates to achieve larger sizes than flagellates yet still remain buoyant in water.

A third type of motility is amoeboid movement. This kind of motion involves extending cytoplasm into lobes, known as pseudopodia (from the Greek, meaning false feet). Once these pseudopodia move toward a food source or other stimulus, the rest of the cytoplasm flows after them, thereby changing the shape of the entire organism as it creeps along. Protist cells that move by pseudopodia are described as **amoebae** (**Figure 28.5**).

Finally, many diatoms, the malarial parasite genus *Plasmodium*, and some other protists glide along surfaces in a snail-like fashion by secreting protein or carbohydrate slime. With the exception of ciliates, motility classification does not correspond with the phylogenetic classification of protists, our next topic.

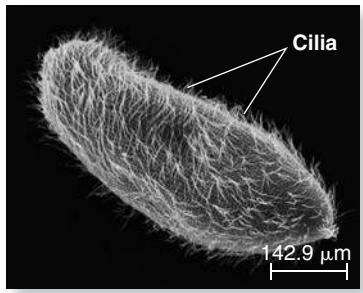

Figure 28.4 A member of the ciliate genus *Paramecium*, showing numerous cilia on the cell surface. SEM view.

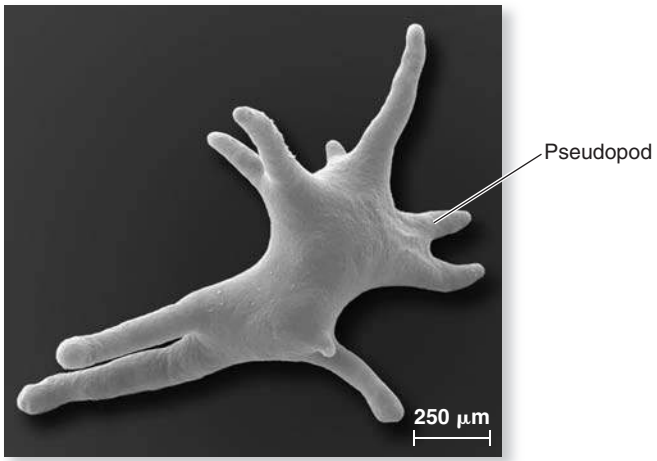

Figure 28.5 A member of the amoebozoan genus *Pelomyxa*, showing pseudopodia. SEM view.

BioConnections: Look ahead to Figure 33.2. What kind of mobile, amoeba-shaped cells carry materials within the bodies of the early-diverging animals known as sponges?

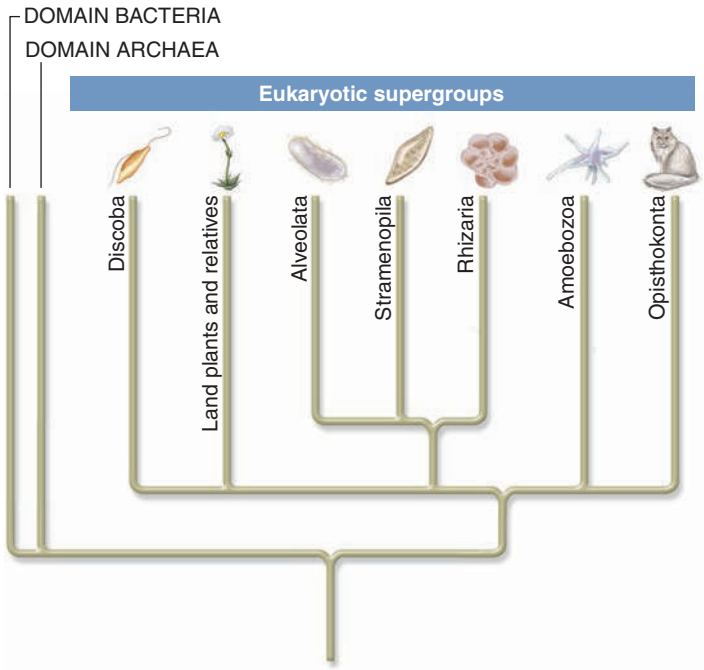

Figure 28.6 A phylogenetic tree showing the major eukaryotic supergroups. Each of the eukaryotic supergroups shown here includes some protist phyla, and most supergroups consist only of protists.

BIOLOGY PRINCIPLE All species (past and present) are related by an evolutionary history. Many more eukaryotic branches exist than are shown in this streamlined diagram.

28.2 Evolution and Relationships

Learning Outcomes:

1. Describe a distinctive structural characteristic for each of seven eukaryotic supergroups.
2. List at least one species of each eukaryotic supergroup that is important to human life.
3. **SciSKILLS »** Draw a diagram showing how the process of endosymbiosis has affected eukaryotic diversity, and predict how this process could continue to affect biodiversity in the future.

At one time, protists were classified into a single kingdom. However, modern phylogenetic analyses based on comparisons of DNA sequences and cellular features reveal that protists do not form a monophyletic group. The relationships of some protists are uncertain or disputed, and new protist species are continually being discovered. As a result, concepts of protist evolution and relationships have been changing as new information becomes available.

Even so, molecular and cellular data reveal that many protist phyla can be classified within several eukaryotic **supergroups** that each display distinctive features (**Figure 28.6**). All of the eukaryotic supergroups include phyla of protists; some, in fact, contain only protist phyla. The supergroup Opisthokonta includes the multicellular animal and fungal kingdoms and related protists, whereas another supergroup includes the multicellular plant kingdom and the protists most closely related to it. The study of such protists helps to reveal how multicellularity originated in animals, fungi, and plants.

In this section, we survey the eukaryotic supergroups, focusing on the defining features and evolutionary importance of the major protist phyla. We will also examine ways in which protists are important ecologically or in human affairs.

Protists Classified in the Discoba Supergroup Feature Disc-Shaped Mitochondrial Cristae

The protist supergroup known as the Discoba originated very early among eukaryotes, so this supergroup is important in understanding the early evolution of eukaryotes. The name Discoba refers to the presence of disc-shaped cristae in the mitochondria of these protists. Many of the Discoba feed by ingesting small particles of food in their aquatic habitats. Once food particles are collected within the feeding groove, they are then taken into cells by a type of endocytosis known as **phagocytosis** (from the Greek, meaning cellular eating; **Figure 28.7**). During phagocytosis, a vesicle of plasma membrane surrounds each food particle and pinches off within the cytoplasm. Enzymes within these food vesicles break the food particles down into small molecules that, upon their release into the cytosol, can be used for energy.

Phagocytosis is also the basis for an important evolutionary process known as **endosymbiosis**, a symbiotic association in which a smaller species known as the endosymbiont lives within the body of a larger species known as the host. Phagocytosis provides a way for protist cells that function as hosts to take in prokaryotic or eukaryotic cells that function as endosymbionts. Such endosymbiotic cells confer valuable traits and are not digested. Endosymbiosis has played a particularly important role in protist evolution. For example, early in protist history, endosymbiotic bacterial cells gave rise to

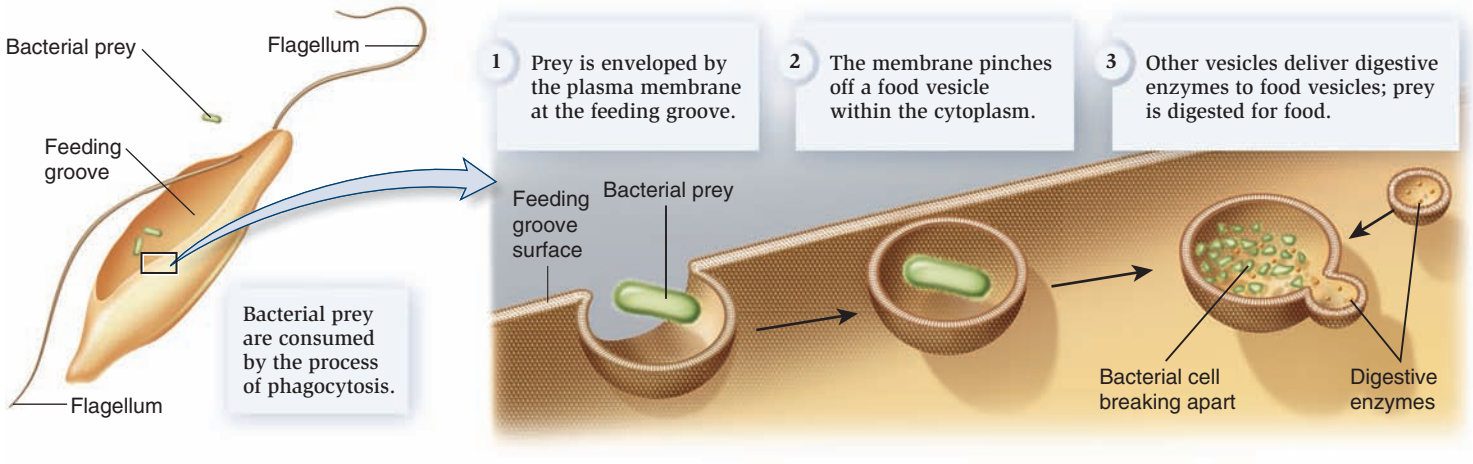

Figure 28.7 Feeding groove and phagocytosis displayed by many species of supergroup Discoba. **(a)** Diagram of *Jakoba libera*, phylum Metamonada, showing flagella emerging from the feeding groove. **(b)** Diagram of phagocytosis, the process by which food particles are consumed at a feeding groove.

Concept Check: *What happens to ingested particles after they enter feeding cells?*

mitochondria, the organelles that are the major site of ATP synthesis in most eukaryotic cells (see Figure 4.27). Consequently, most protists possess mitochondria, though these may be highly modified in some species.

Some members of the Discoba have become parasitic within animals, including human hosts. In addition to feeding by phagocytosis, parasitic species attack host cells and absorb food molecules released from them. For example, *Trichomonas vaginalis* causes a sexually transmitted infection of the human genitourinary tract. In this location, *T. vaginalis* consumes bacteria and host epithelial and red blood cells by phagocytosis, as well as carbohydrates and proteins released from damaged host cells. More than 170 million cases of this infection are estimated to occur each year around the globe, and infections can predispose humans to other diseases. *T. vaginalis* has an undulating membrane and flagella that allow it to move over mucus-coated skin (**Figure 28.8a**).

Giardia intestinalis (previously known as *G. lamblia*), a related protist, contains two active nuclei and produces eight flagella (**Figure 28.8b**). *G. intestinalis* causes giardiasis, an intestinal infection that can result from drinking untreated water or from unsanitary conditions in day-care centers. Nearly 300 million human infections occur every year, and the disease also harms young farm animals, dogs, cats, and wild animals. In the animal body, flagellate cells cause disease and also produce infectious stages known as cysts that are transmitted in feces and can survive several weeks outside a host. When an animal ingests as few as 10 of these cysts, within 15 minutes stomach acids induce the flagellate stage to develop and adhere to cells of the small intestine. *T. vaginalis* and *G. intestinalis* were once thought to lack mitochondria, but they are now known to possess simpler structures that are highly modified mitochondria.

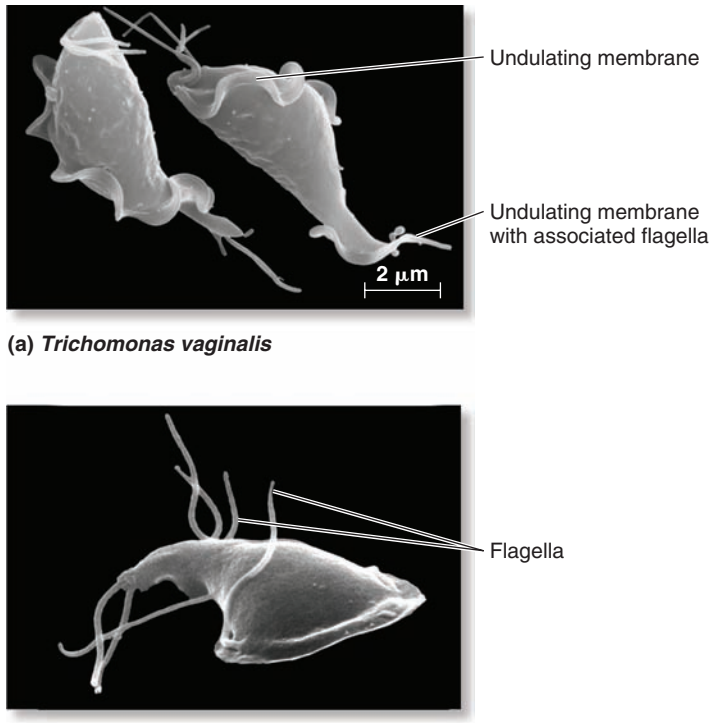

Figure 28.8 Parasitic members of the supergroup Discoba. **(a)** *Trichomonas vaginalis*. **(b)** *Giardia intestinalis*. These specialized heterotrophic flagellates use flagella to disperse across the surfaces of moist host tissues; the flagellates then absorb nutrients from living cells. These images were made with a scanning electron microscope (SEM) that employs electrons rather than visible light, with the result that cellular structures do not appear in color.

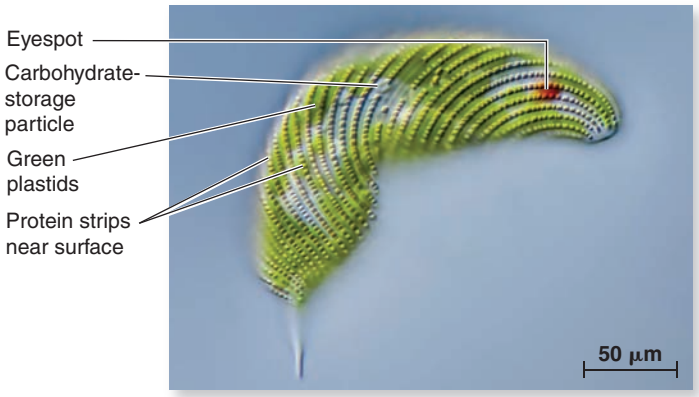
Concept Check: *How do these two parasitic protists differ in the process of transmission from one human host to another?*

Genomes & Proteomes Connection

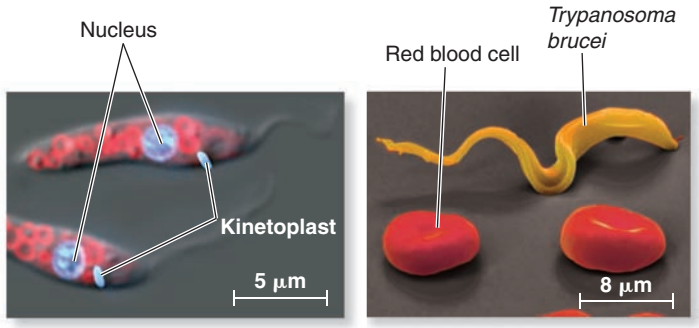
Genome Sequences Reveal the Different Evolutionary Pathways of *Trichomonas vaginalis* and *Giardia intestinalis*

In 2007, genome sequences were reported for *T. vaginalis* and *G. intestinalis*. A comparison of their genomes reveals similarities and differences in the evolution of their parasitic lifestyles. One common feature is that horizontal gene transfer from bacterial or archaeal donors has powerfully affected both genomes. About 100 *G. intestinalis* genes are likely to have originated via horizontal gene transfer. In *T. vaginalis*, more than 150 cases of likely horizontal gene transfer were identified, with most transferred genes encoding metabolic enzymes such as those involved in carbohydrate or protein metabolism. Another similarity between *T. vaginalis* and *G. intestinalis* revealed by comparative genomics is an absence of the cytoskeletal protein myosin, which is present in most eukaryotic cells.



Despite these similarities, the genome sequences of *T. vaginalis* and *G. lamblia* reveal some dramatic differences. The *G. intestinalis* genome is quite compact, with only 11.7 megabase pairs (Mb), and the organism has relatively simple metabolic pathways and machinery for DNA replication, transcription, and RNA processing. In contrast, the *T. vaginalis* genome is a surprisingly large 160 Mb in size. *T. vaginalis* has a core set of about 60,000 protein-encoding genes, one of the greatest coding capacities known among eukaryotes. The additional genes provide an expanded capacity for biochemical degradation. Because most trichomonads inhabit animal intestines, the genomic data suggest that the large genome size of *T. vaginalis* is related to its ecological transition to a new habitat, the urogenital tract.

Euglenoids The members of Discoba known as euglenoids possess unique, interlocking ribbon-like protein strips just beneath their plasma membranes (**Figure 28.9a**). These strips make the surfaces of some euglenoids so flexible that they can crawl through mud. Many euglenoids are colorless and heterotrophic, but *Euglena* and some other genera possess green plastids and are photosynthetic. Plastids are organelles in plant and algal cells that are distinguished by their synthetic abilities and that were acquired via endosymbiosis. Many euglenoids possess a light-sensing system that includes a conspicuous red structure known as an eyespot, or stigma, and light-detecting molecules located in a swollen region at the base of a flagellum. These structures enable green euglenoids to detect light environments that are optimal for photosynthesis. Most euglenoids produce conspicuous carbohydrate-storage particles that occur in the cytoplasm. Euglenoids are particularly abundant and ecologically significant in wetlands, which are rich in the organic materials that many of these protists require.



Kinetoplastids The heterotrophic protists known as kinetoplastids are named for a large mass of DNA known as a kinetoplast that occurs in their single large mitochondrion (**Figure 28.9b**). These protists lack plastids, but they do possess an unusual modified peroxisome in which glycolysis takes place; in most eukaryotes, glycolysis occurs in the cytosol. Some kinetoplastids, including *Leishmania* (see Figure 28.9b), which causes an ulcerative skin disease and can result in organ damage, and *Trypanosoma brucei*, the causative agent of sleeping sickness, are serious pathogens of humans and other animals (**Figure 28.9c**).

Land Plants and Related Algae Share Similar Genetic Features

The supergroup that includes land plants also encompasses several protist phyla (**Figure 28.10**). The land plants, also known as the kingdom Plantae (described more fully in Chapters 29 and 30), evolved from green algal ancestors. Together, plants and some closely related green algae form the clade Streptophyta, informally known as streptophytes, whereas most green algae are classified in the phylum Chlorophyta. The red algae, classified in the phylum Rhodophyta, are also regarded as close relatives of green algae and land plants.

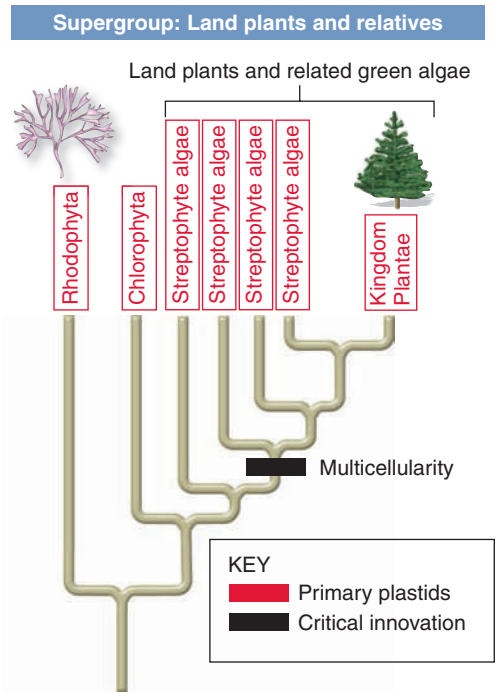

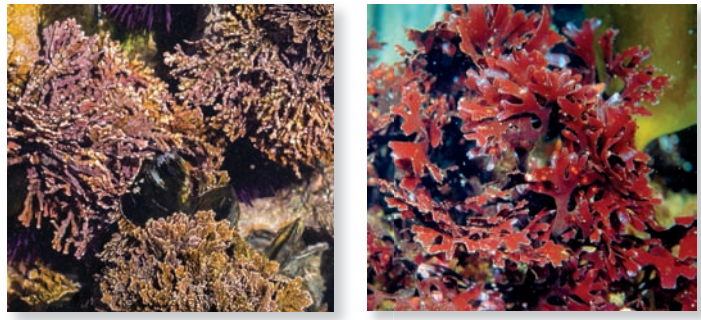

Figure 28.10 A phylogenetic tree of the supergroup that includes land plants and their close protist relatives. Note that plant multicellularity first arose in closely related streptophyte algae. Many chlorophyte and red algae are macroalgae in which multicellularity arose independently.

Green Algae Diverse structural types of green algae (see Figure 28.3) occur in fresh water, the ocean, and on land. Most of the green algae are photosynthetic, and their cells contain the same types of plastids and photosynthetic pigments that are present in land plants. Some green algae are responsible for harmful algal growths, but others are useful as food for aquatic animals, as model organisms, and as sources of renewable oil supplies. Many green algae possess flagella or the ability to produce them during the development of reproductive cells. Green algae are increasingly important in medicine because they produce channelrhodopsins, light-activated ion channels. Green algae use these channel proteins to detect and respond to light, and researchers are studying the proteins in an attempt to understand and possibly treat blindness in animals.

Red Algae Most species of the protists known as red algae are multicellular marine macroalgae (**Figure 28.11**). The red appearance of these algae is caused by the presence of distinctive photosynthetic pigments that are absent from green algae or land plants. Red algae characteristically lack flagella—a feature that has strongly influenced the evolution of this group, resulting in unusually complex life cycles (illustrated in Section 28.4). These life cycles are important to humans because red algae are cultivated in ocean waters for the production of billions of dollars worth of food or industrial and scientific materials yearly. For example, the sushi wrappers called nori are composed of the sheetlike red algal genus *Porphyra*, which is grown in ocean farms. Carrageenan, agar, and agarose are complex polysaccharides that are extracted from red algae and are essential to the food industry and in biology laboratories for cultivating microorganisms and working with DNA.

(a) ***Calliarthron*** **(b)** ***Chondrus crispus***

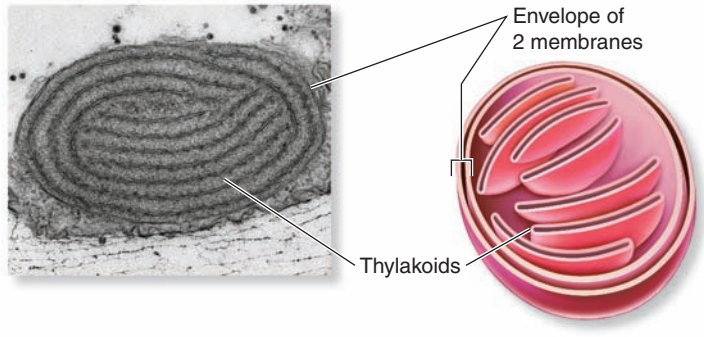
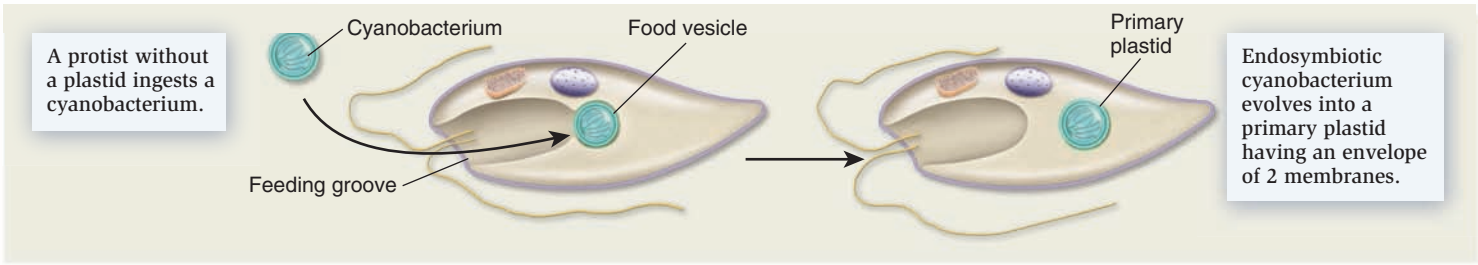
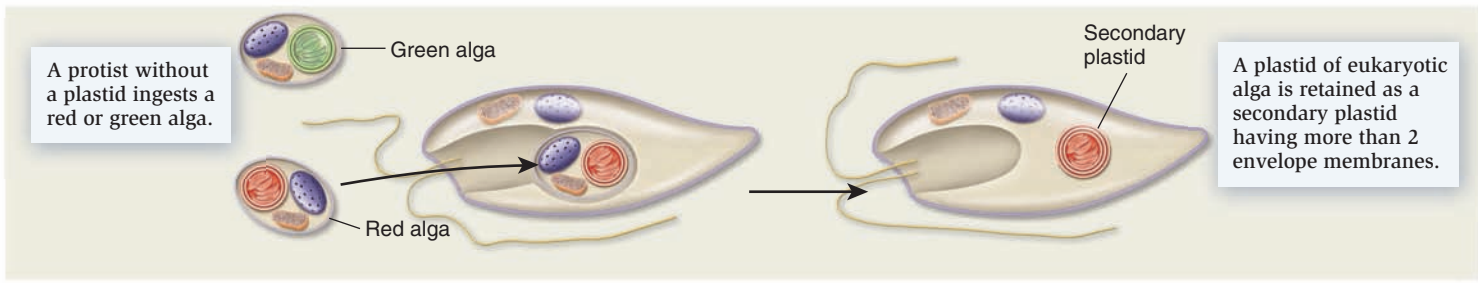
Primary Plastids and Primary Endosymbiosis The plastids of red algae resemble those of green algae and land plants (and differ from those of most other algae) in having an enclosing envelope composed of two membranes (**Figure 28.12**). Such plastids, known as **primary plastids**, are thought to have originated via a process known as **primary endosymbiosis** (**Figure 28.13**). During primary endosymbiosis, heterotrophic host cells captured cyanobacterial cells via phagocytosis but did not digest them. These endosymbiotic cyanobacteria provided host cells with photosynthetic capability and other useful biochemical pathways and eventually evolved into primary plastids (Figure 28.13a).

Endosymbiotic acquisitions of plastids and mitochondria resulted in massive horizontal gene transfer from the endosymbiont to the host nucleus. As a result of such gene transfer, many of the proteins needed by plastids and mitochondria are synthesized in the







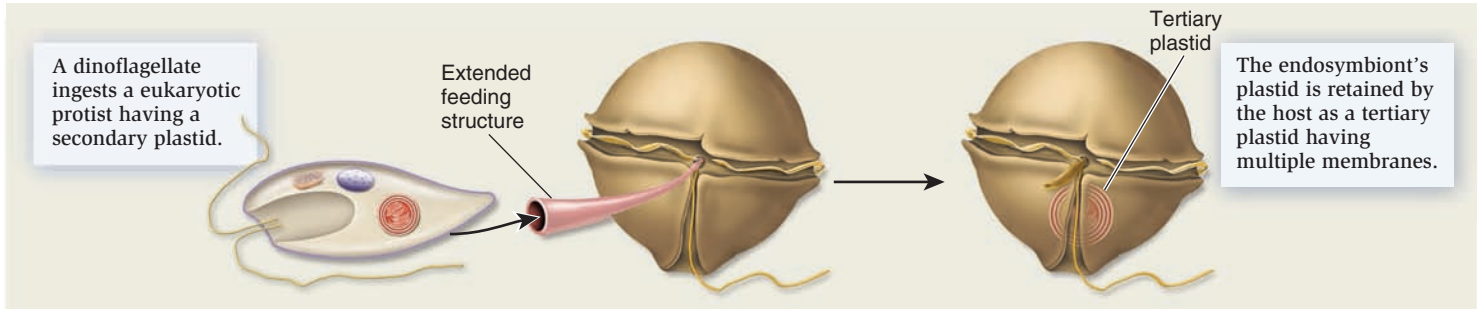


Figure 28.12 A primary plastid, showing an envelope composed of two membranes. The plastid shown here is red, but primary plastids can also be green or blue-green in color.

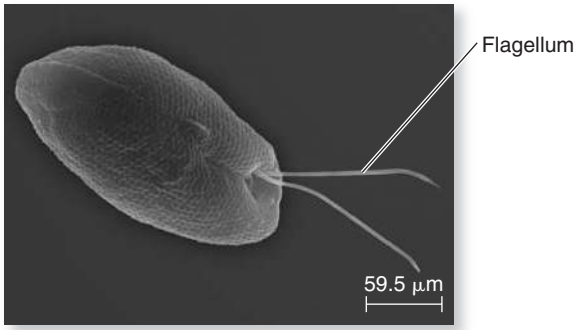
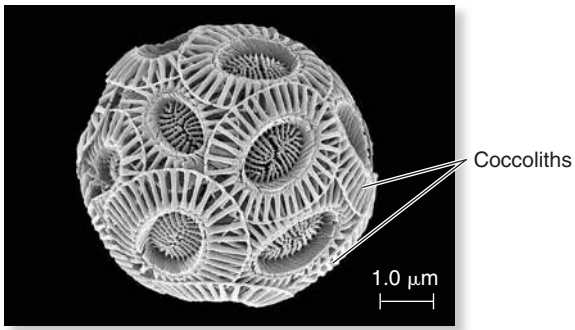
(a) Primary endosymbiosis

(b) Secondary endosymbiosis



(c) Tertiary endosymbiosis

Figure 28.13 Primary, secondary, and tertiary endosymbiosis. **(a)** Primary endosymbiosis involves the acquisition of a cyanobacterial endosymbiont by a host cell without a plastid. During the evolution of a primary plastid, the bacterial cell wall is lost, and most endosymbiont genes are transferred to the host nucleus. **(b)** Secondary endosymbiosis involves the acquisition by a host cell of a eukaryotic endosymbiont that contains one or more primary plastids. During the evolution of a secondary plastid, most components of the endosymbiont cell are lost, but a plastid is often retained within an envelope of endoplasmic reticulum. **(c)** Tertiary endosymbiosis involves the acquisition by a host cell of a eukaryotic endosymbiont that possesses secondary plastids.



host cytosol and then targeted to these organelles. All cells of plants, green algae, and red algae contain one or more plastids, and most of these organisms are photosynthetic. However, some species (or some of the cells within the multicellular bodies of photosynthetic species) are heterotrophic because photosynthetic pigments are not produced in the plastids. In these cases, plastids play other essential metabolic roles, such as producing amino acids and fatty acids.

Secondary Plastids and Secondary Endosymbiosis In contrast to the primary plastids of plants and green and red algae, the plastids of most other photosynthetic protists are derived from a photosynthetic eukaryote. Such plastids are known as **secondary plastids** because they originated by the process of **secondary endosymbiosis** (see Figure 28.13b). Secondary endosymbiosis occurs when a eukaryotic host cell ingests and retains another type of eukaryotic cell that already has one or more primary plastids, such as a red or green alga. Such eukaryotic endosymbionts are often enclosed by the endoplasmic reticulum (ER), explaining why secondary plastids typically have envelopes of more than two membranes. Although most of the endosymbiont's cellular components are digested over time, its plastids are retained, providing the host cell with photosynthetic capacity and other biochemical capabilities.

Cryptomonads (**Figure 28.14a**) and haptophytes are algal phyla that include single-celled flagellates whose plastids originated by secondary endosymbiosis involving the incorporation of plastids derived from a red alga. Occurring in marine and fresh waters, cryptomonads are excellent sources of the fatty-acid-rich food essential to aquatic animals. Haptophytes are primarily unicellular marine photosynthesizers; some have flagella and others do not. Some haptophytes are known as the coccolithophorids because they produce a

(c) Fossil deposit containing coccolithophorids

Figure 28.14 Representative cryptomonads and haptophytes. **(a)** A cryptomonad flagellate. **(b)** A type of haptophyte known as a coccolithophorid, covered with disc-shaped coccoliths made of calcium carbonate. **(c)** Fossil carbonate remains of haptophyte algae and protozoan protists known as foraminifera that were deposited over millions of years formed the white cliffs of Dover in England.

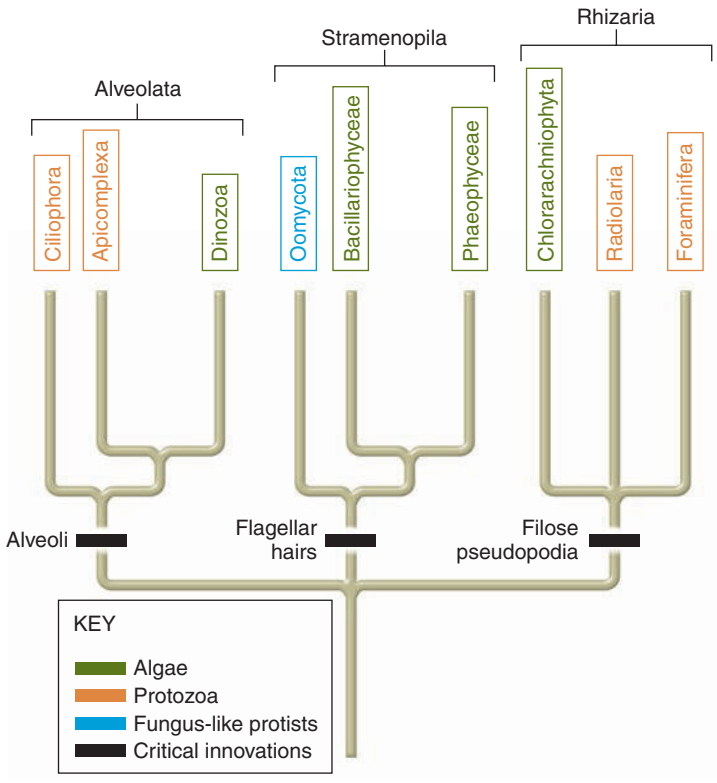
covering of intricate white calcium carbonate discs known as coccoliths (**Figure 28.14b**). Coccolithophorids often form massive ocean growths that are visible from space and play important roles in Earth's climate by reflecting sunlight. In some places, coccoliths produced by huge populations of ancient coccolithophorids accumulated on the ocean floor, together with the calcium carbonate remains of other protists, for millions of years. These deposits were later raised above sea level, forming massive limestone formations or chalk cliffs such as those visible at Dover, on the southern coast of England (**Figure 28.14c**).

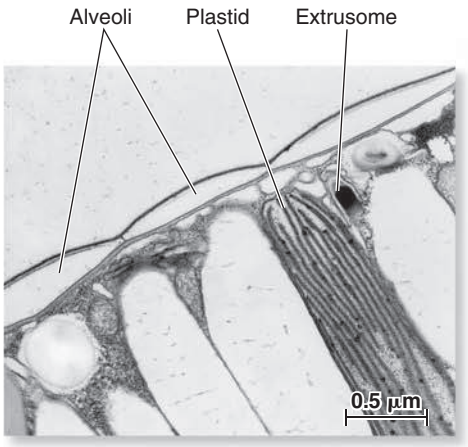
The photosynthetic protists known as alveolates, stramenopiles, and rhizaria have plastids acquired by secondary endosymbiosis or, in some cases, by tertiary endosymbiosis. The three supergroups Alveolata, Stramenopila, and Rhizaria seem to form a cluster in recent phylogenetic studies (**Figure 28.15**).

Membrane Sacs Lie at the Cell Periphery of Alveolata

Turning first to Alveolata, we see that it includes three important phyla: (1) the Ciliophora, or ciliates; (2) the Apicomplexa, a medically important group of parasites; and (3) the Dinozoa, known as dinoflagellates. Apicomplexans include the malarial agent *Plasmodium* (see Section 28.4), the related protist *Cryptosporidium parvum*, whose effects were noted in the chapter opening, and other serious pathogens of humans and other animals. Dinoflagellates are recognized both for their mutualistic relationship with reef-building corals (look ahead to Figure 54.26b) and for the harmful blooms (red tides) that some species produce (see Section 28.3). The supergroup Alveolata is named for saclike membranous vesicles known as alveoli that are present at the cell periphery in all of these phyla (**Figure 28.16a**).

The alveoli of some dinoflagellates seem empty, so the cell surface appears smooth. By contrast, the alveoli of many dinoflagellates contain plates of cellulose, which form an armor-like enclosure (**Figure 28.16b**). These plates are often modified in ways that provide





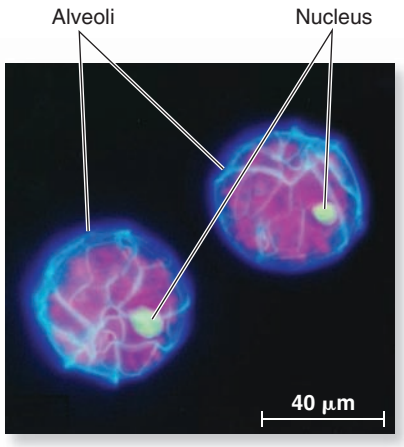


Figure 28.15 A phylogenetic tree illustrating the close relationship among the supergroups Alveolata, Stramenopila, and Rhizaria. Some stramenopiles, such as giant kelps, are multicellular.

Figure 28.16 Dinoflagellates of the supergroup Alveolata and their characteristic alveoli. (a) Sac-shaped membranous vesicles known as alveoli lie beneath the plasma membrane of a dinoflagellate, along with defensive projectiles, called extrusomes, that are ready for discharge. **(b)** Fluorescence microscopy reveals that alveoli of the dinoflagellate *Alexandrium catenella* contain cellulose plates, which glow blue when treated with a cellulose-binding dye. The nucleus appears green because DNA has bound a fluorescent dye, and chlorophyll self-fluoresces red.

an adaptive advantage, such as protection from predators or increased ability to float.

About half of dinoflagellate species are heterotrophic, and half possess photosynthetic plastids of diverse types that originated by secondary or even tertiary endosymbiosis; therefore, these are known as secondary or tertiary plastids. **Tertiary plastids** were obtained by **tertiary endosymbiosis**—the acquisition by hosts of plastids from cells that possessed secondary plastids (see Figure 28.13c). Species having tertiary plastids have received genes by horizontal transfer from diverse genomes.

Flagellar Hairs Distinguish Stramenopila

The supergroup Stramenopila (referred to as the stramenopiles) encompasses a wide range of algae, protozoa, and fungus-like protists that usually produce flagellate cells at some point in their lives (see Figure 28.15). Stramenopila (from the Greek *stramen*, meaning straw, and *pila*, meaning hair) is named for distinctive strawlike hairs that occur on the surfaces of flagella (**Figure 28.17**). These flagellar hairs function something like oars to greatly increase swimming efficiency. Stramenopiles are also known as heterokonts (from the Greek, meaning different flagella), because the two flagella often present on swimming cells have slightly different structures.

Heterotrophic stramenopiles include the fungus-like protist *Phytophthora infestans*, which causes the serious potato disease known as late blight. *P. infestans* is responsible for an estimated $7 billion in crop losses every year. Photosynthetic stramenopiles include diatoms (Bacillariophyceae), whose glasslike silicate cell walls are elaborately ornamented with pores, lines, and other intricate features (**Figure 28.18a**). Vast accumulations of the translucent walls of ancient diatoms, known as diatomite or diatomaceous earth, are mined for use in reflective paint and other industrial products. Recent genome sequencing projects have focused on the processes by which diatoms produce their detailed silicate structures, which may prove useful in industrial microfabrication applications.

Diverse, photosynthetic brown algae (Phaeophyceae) are sources of industrial products such as the polysaccharide emulsifiers known as alginates. Brown algae acquired the ability to produce alginates by means of horizontal transmission of genes from bacteria. The brown algae known as giant kelps are ecologically important because they form extensive forests in cold and temperate coastal

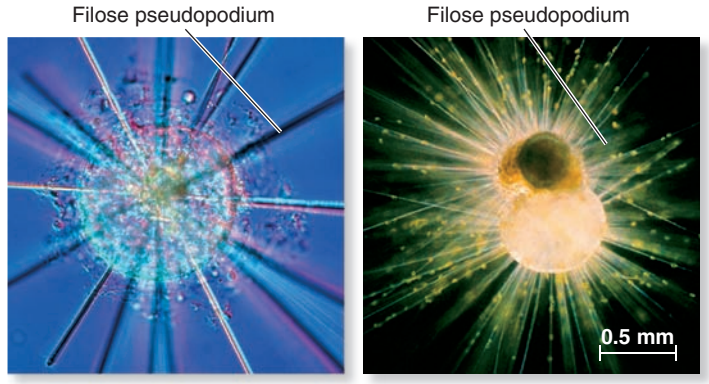
Concept Check: *In what ways are kelp forests economically important?*



oceans (**Figure 28.18b**). Kelp forests are essential nurseries for fish and shellfish. The reproductive processes of diatoms and kelps are described in Section 28.4.

Spiky Cytoplasmic Extensions Are Present on the Cells of Many Protists Classified in Rhizaria

Several groups of flagellates and amoebae that have thin, hairlike extensions of their cytoplasm—known as filose pseudopodia—are classified into the supergroup Rhizaria (from the Greek *rhiza*, meaning root) (see Figure 28.15). Rhizaria includes the phylum Chlorarachniophyta, whose spider-shaped cells possess secondary plastids obtained from endosymbiotic green algae. Other examples of Rhizaria are the Radiolaria (**Figure 28.19a**) and Foraminifera (**Figure 28.19b**)—two phyla of ocean plankton that produce exquisite mineral shells. Fossil shells of foraminiferans are widely used to infer past climatic conditions. Ratios of stable oxygen isotopes contained in the shells can be used to reconstruct past water temperatures.

Amoebozoa Includes Many Types of Amoebae with Pseudopodia

The supergroup Amoebozoa includes many types of amoebae that move by extension of pseudopodia (see Figure 28.5). Several types of protists known as slime molds are classified in this supergroup. One example, *Dictyostelium discoideum*, is widely used as a model organism for understanding movement, communication among cells, and development. During reproduction, in response to starvation, large numbers of *Dictyostelium* amoebae aggregate into a multicellular slug that produces a cellulose-stalked structure containing many single-celled, asexual spores. In favorable conditions,

(a) Radiolarian (b) Foraminiferan

Figure 28.19 Representatives of supergroup Rhizaria. **(a)** A radiolarian, *Acanthoplegma* spp., showing long filose pseudopodia. **(b)** A foraminiferan, showing calcium carbonate shell with long filose pseudopodia extending from pores in the shell.

these spores produce new amoebae, which feed on bacteria. A recent study revealed that some *Dictyostelium* clones carry favored bacterial food through these reproductive stages, showing a simple "farming" behavior.

A Single Flagellum Occurs on Swimming Cells of Opisthokonta

The supergroup Opisthokonta includes the animal and fungal kingdoms and related protists (**Figure 28.20**). This supergroup is named for the presence of a single posterior flagellum on swimming cells.

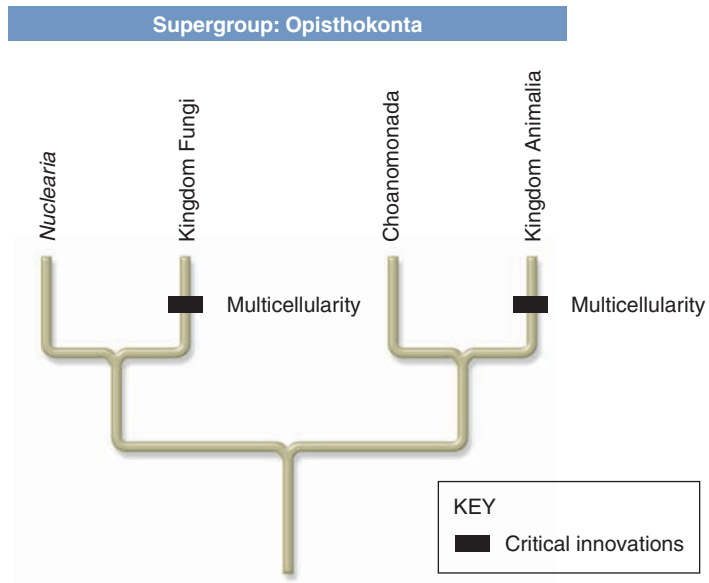


Figure 28.20 A phylogenetic tree of the supergroup Opisthokonta. This supergroup includes protist phyla as well as the kingdoms Fungi and Animalia. Multicellularity arose independently in these kingdoms.

Nuclearia is a protist genus that seems particularly closely related to the kingdom Fungi. The more than 125 species of protists known as choanoflagellates (formally, the Choanomonada) are single-celled or colonial protists featuring a distinctive collar surrounding the single flagellum (**Figure 28.21**). The collar is made of cytoplasmic extensions that filter bacterial food from water currents generated by flagellar motion.

Choanoflagellates are believed to represent the closest living relatives of animals (look ahead to Figure 32.1). Evolutionary biologists interested in the origin of animals study choanoflagellates for molecular clues to this important event in our evolutionary history. Genomic studies have revealed several genes that are present only in choanoflagellates and animals. Some of the shared genes encode cell adhesion and extracellular matrix proteins that help choanoflagellates attach to surfaces and were also essential to the evolution of multicellularity in animals. The choanoflagellate genome also encodes the p53 protein, a regulatory transcription factor that plays essential roles in the animal cell cycle, cancer, and reproduction (refer back to Figure 14.15).

The preceding survey of protist diversity, summarized in **Table 28.1**, illustrates the enormous evolutionary and ecological importance of protists. Next, we consider the diverse ways in which protists have become adapted to their environments.

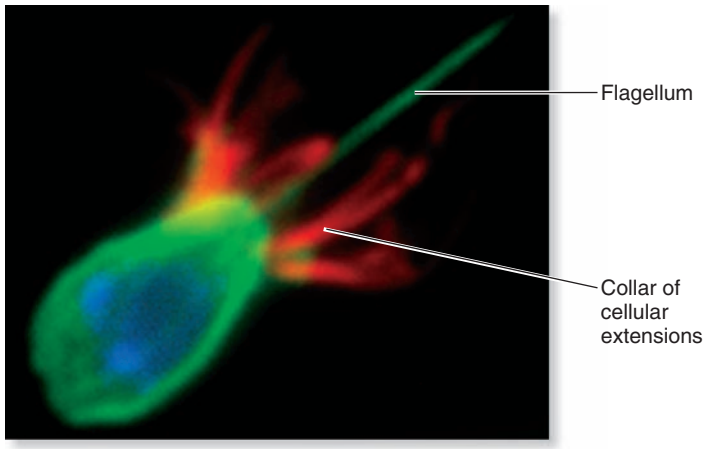

Figure 28.21 A choanoflagellate of the supergroup Opisthokonta. This cell has been stained with fluorescent dyes specific for DNA (blue) and the proteins actin (red) and tubulin (green). The single flagellum is stained green because it is rich in tubulin. A collar of cellular extensions that are rich in actin surrounds the flagellum.

Concept Check: What features of the ancient choanoflagellate ancestors of animals were important in the evolution of multicellularity, and what function do such features serve in modern choanoflagellates?

Table 28.1 Eukaryotic Supergroups and Examples of Constituent Kingdoms, Phyla, Classes, or Species

Supergroup	KINGDOMS, Phyla, classes, or species	Distinguishing features
Discoba	**Metamonada** *Giardia intestinalis* *Trichomonas vaginalis*	Unicellular flagellates, often with feeding groove, characterized by disk-shaped mitochondrial cristae
	Kinetoplastea (kinetoplastids) *Trypanosoma brucei* **Euglenida** (euglenoids)	Secondary plastids (when present) derived from endosymbiotic green algae
Land Plants and Relatives	**Rhodophyta** (red algae) **Chlorophyta** (green algae) KINGDOM PLANTAE and close green algal relatives	Land plants, green algae, and red algae have primary plastids derived from cyanobacteria; such plastids have two envelope membranes.
Alveolata	**Ciliophora** (ciliates) **Apicomplexa** (apicomplexans) *Plasmodium falciparum* *Cryptosporidium parvum* **Dinozoa** (dinoflagellates) *Alexandrium catenella*	Peripheral membrane sacs (alveoli); some ciliates harbor endosymbiotic algal cells or organelles; apicomplexans often have nonphotosynthetic secondary plastids; some dinoflagellates have secondary plastids derived from red algae, some have secondary plastids derived from green algae, and some have tertiary plastids derived from diatoms, haptophytes, or cryptomonads.
Stramenopila	Bacillariophyceae (diatoms) Phaeophyceae (brown algae) *Phytophthora infestans* (fungus-like)	Strawlike flagellar hairs; secondary plastids (when present) derived from red algae; fucoxanthin accessory pigment common in autotrophic forms
Rhizaria	**Chlorarachniophyta** **Radiolaria** **Foraminifera**	Thin, cytoplasmic projections; secondary plastids (when present) derived from endosymbiotic green algae
Amoebozoa	*Entamoeba histolytica* **Dictyostelia** (a slime mold phylum) *Dictyostelium discoideum*	Amoeboid movement by pseudopodia
Opisthokonta	*Nuclearia* spp. KINGDOM FUNGI **Choanomonada** (choanoflagellates) KINGDOM ANIMALIA	Swimming cells possess a single posterior flagellum

28.3 Nutritional and Defensive Adaptations

Learning Outcomes:

1. List four mechanisms of protist nutrition.
2. **SciSKILLS** » Predict how photosynthetic protists might respond to a persistent period of darkness.
3. Give examples of major types of protist defensive adaptations.

Wherever you look in moist places, you will find protists playing diverse and important ecological roles. In this section, we will survey nutritional and defensive adaptations that occur widely among protists, that is, in more than one supergroup. Such adaptations help to explain protists' ecological roles.

Protists Display Four Basic Mechanisms of Nutrition

Protist nutrition occurs by four basic mechanisms: phagotrophy, osmotrophy, photoautotrophy, and mixotrophy. Heterotrophic protists that feed by ingesting particles, or phagocytosis, are known as **phagotrophs** (see Figure 28.7). Protists that rely on osmotrophy—the uptake of small organic molecules across the cell membrane followed by their digestion—are **osmotrophs**. Protists that feed on nonliving organic material function as decomposers, essential in breaking down wastes and releasing minerals for use by other organisms. Protists that feed on the living cells of other organisms are parasites that may cause disease in other organisms. *Trichomonas vaginalis, Giardia intestinalis,* and *Phytophthora infestans* are examples of pathogenic protists. Humans view such protists as pests when they harm us or our agricultural animals and crops, but pathogenic protists also play important roles in nature by controlling the population growth of other organisms.

Photosynthetic protists (algae) are **photoautotrophs**, organisms that can make their own organic nutrients from inorganic sources by harvesting light energy. Because water absorbs much of the red component of sunlight, algae have evolved photosynthetic systems that compensate by capturing more of the blue-green light available underwater. For example, red algae produce the red pigment phycoerythrin, which absorbs blue-green light and transfers energy to chlorophyll *a* (see Figure 28.11). Likewise, blue-green light-absorbing fucoxanthin generates the golden and brown colors of other algae (see Figures 28.1, 28.18b). Carotene (the source of vitamin A) and lutein play similar light-harvesting roles in green algae and were inherited by their land plant descendants, today playing important roles in animal nutrition. Sunlight energy is captured in the bonds of polysaccharide and lipid molecules that function in food storage (see Figure 28.9a), explaining why algae of diverse types are good sources of food for aquatic animals and renewable energy materials.

Mixotrophs are able to use photoautotrophy and phagotrophy or osmotrophy to obtain organic nutrients. The genus *Dinobryon* (**Figure 28.22**), a photosynthetic stramenopile that lives in the phytoplankton of freshwater lakes, is an example of a mixotroph. These protists may switch back and forth between photoautotrophy and heterotrophy, depending on conditions in their environment. If sufficient light, carbon dioxide, and other minerals are available, *Dinobryon* cells produce their own organic food. If a shortage of any of these resources limits photosynthesis or if organic food is especially abundant, *Dinobryon* cells can function as heterotrophs, consuming enormous numbers of bacteria. Mixotrophs thus have remarkable nutritional flexibility, explaining why diverse lineages of photosynthetic eukaryotes seem to have mixotrophic capability.

Figure 28.22 A mixotrophic protist. The genus *Dinobryon* is a colonial flagellate that occurs in the phytoplankton of freshwater lakes. The photosynthetic cells have golden photosynthetic plastids and also capture and consume bacterial cells.

Protists Defend Themselves in Diverse Ways

Protists use a wide variety of defensive adaptations to ward off attack. Major types of defenses are sharp projectiles that can be explosively shot from cells, light flashes, toxic compounds, and cell coverings.

Evolutionarily diverse protist cells contain structures known as extrusomes (extruded bodies) that are ejected when cells are disturbed, forming spear-like defenses (see Figure 28.16a). Some species of ocean dinoflagellates emit flashes of blue light when disturbed, explaining why ocean waters teeming with these protists display bioluminescence. The light flashes may deter herbivores by startling them, but when ingested, the dinoflagellates make the herbivores also glow, revealing them to hungry fishes. Light flashes benefit dinoflagellates by helping to reduce populations of herbivores that consume the algae.

Various protist species produce **toxins**, compounds that inhibit animal physiology and may function to deter small herbivores. Dinoflagellates are probably the most important protist toxin producers; they synthesize several types of toxins that affect humans and other animals. Why does this happen? Under natural conditions, small populations of dinoflagellates produce low amounts of toxin that do not harm large organisms. Dinoflagellate toxins become dangerous to humans when people contaminate natural waters with excess mineral nutrients such as nitrogen and phosphorus from untreated sewage, industrial discharges, or fertilizer that washes off agricultural fields. The excess nutrients fuel the development of harmful algal blooms, which then produce sufficient toxin to affect birds, aquatic mammals, fishes, and humans. Toxins can concentrate in organisms. Humans who ingest shellfish that have accumulated dinoflagellate toxins can suffer poisoning.

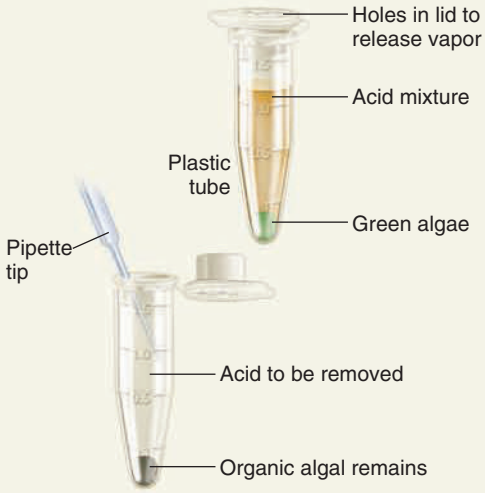
The cell coverings produced by many protists also provide protection. Slimy mucilage (see the chapter opening photo) or spiny cell walls (see Figure 28.3b) provide protection from attack by herbivores or pathogens. Protective cell coverings made of polysaccharide polymers such as cellulose or minerals such as silica help to prevent osmotic damage and may enhance flotation in water. As we have seen, diatoms enclose themselves in glasslike silicate cell walls, haptophytes are covered with calcium carbonate scales, and the cells of brown and green

algae secrete tough, cardboard-like cellulose walls. Cellulose-rich cell walls are also features of plant cells, but algal cellulose can be particularly resistant to chemical and microbial degradation. Algal cell walls made of this tough cellulose explain the occurrence of some fossils, and similar materials may have important industrial applications.

The periphytic, branched green alga *Cladophora* (see Figure 28.3d) is common along marine and freshwater shorelines around the world, where it provides essential habitat for dense populations of diverse microorganisms on its extensive surfaces. Amazingly tough cellulose cell walls allow this alga to harbor extensive microbial diversity without readily decomposing. Acting in this host role, *Cladophora* provides such an important ecological service that it has been called an ecological engineer, a species that strongly affects its habitat. *Cladophora* is known to be resistant to microbial decay, leading to the buildup of organic carbon in aquatic environments, but the basis of this resistance was unknown.

In 2013, American cell biologist Martha Cook and associates reported that the cell walls of *Cladophora* survive harsh chemical treatments well enough to explain why this alga generates so much organic carbon in aquatic systems. The investigation revealed that particularly tough cellulose confers this resistance to degradation. In addition, the results help to explain *Cladophora*-like fossil remains that are about 750 million years old. Such fossils suggest that *Cladophora* may have been functioning as an ecological engineer since that time.

Feature Investigation | Cook and Colleagues Demonstrated That Cellulose Helps Green Algae Avoid Chemical Degradation



A team of investigators performed an experiment to determine whether or not green algae known to resist microbial degradation can also survive extreme chemical treatment in a form similar to that experienced by related algae that are found as 750-million-year-old fossils (**Figure 28.23**).

In the first step of the experiment, the team collected natural growths of the green alga *Cladophora* from lakes and desert streams. In a second step, the investigators treated the algae with concentrated acids at a boiling temperature to mimic harsh chemical and microbial degradation processes. The third step was to examine the

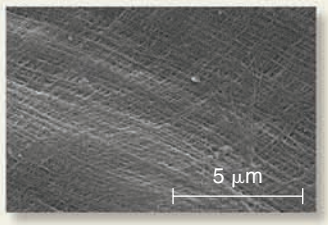
Figure 28.23 Cook and colleagues showed that the green alga *Cladophora* produces tough cellulose walls that survive exposure to strong acids and high temperatures, suggesting potential to leave fossil remains.

GOAL To determine the degree and chemical basis of the resistance to degradation of *Cladophora* for comparison with ancient fossils of related algae.

KEY MATERIALS Samples of *Cladophora* from natural waters; concentrated acids

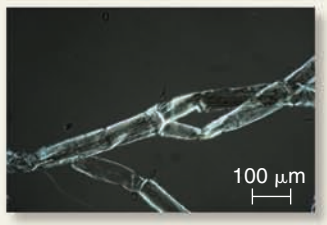
	Experimental level	Conceptual level
1 Collect a green alga *Cladophora*, from its natural aquatic habitat.	*Cladophora* is known to build up in natural waters, but the degree of resistance to chemical degradation or its biochemical basis are unknown.	Natural algae are defensively adapted to cope with microbial attack.
2 Treat the algae with a standard mixture of acids, heated to boiling for 30 minutes, then centrifuge to sediment the algal remains and remove acid.		High-temperature acid treatment, known as acetolysis, is widely used to release plant and algal fossils from rocks. Biochemical materials that survive acetolysis are also likely to have survived microbial degradation long enough to have formed organic fossils.

3 Examine algal remains by means of scanning electron microscopy to determine their structure.



Structure of the algal remains suggests that the biochemical composition includes fibrils made of celluose. Dimensions of microfibrils indicate the degree of chemical resistance: Microfibrils of greater width are known to have greater resistance to degradation.

4 Examine algal remains using a light microscope equipped with crossed polarizers. Compare microscopic appearance of the remains to that of 750-million-year-old fossils.



Crossed polarizers reveal birefringence, a sparkling white appearance typical of highly crystalline cellulose.

5 THE DATA

SEM of *Cladophora* after acetolysis. Microfibrils of cellulose are 100 micrometers in diameter, thicker than those in land plant cell walls, which are only 3.5 nm thick.

Light microscope view of acetolyzed *Cladophora* using crossed-polarizers. The sparkling white appearance is typical of highly crystalline cellulose.

A 750-million-year-old fossil, *Proterocladus*, shows similar dimensions and distinctive branching pattern to modern *Cladophora*, even when the latter has been treated by acetolysis.

6 CONCLUSION Tough cell-wall cellulose resists chemical degradation, allowing *Cladophora*-like algae to form as fossils and explaining modern ecological persistence in aquatic ecosystems.

7 SOURCE Graham, L. E., Cook, M. E., et al. 2013. Resistance of filamentous chlorophycean, ulvophycean, and xanthophycean algae to acetolysis: Testing Proterozoic and Paleozoic microfossil attributions. *International Journal of Plant Sciences* 174:947–957.

algal remains using microscopy to determine their chemical makeup. In a final step, the investigators compared the algal remains to fossils of related algae from deposits about 750 million years old. They found that remains of modern *Cladophora* after chemical degradation closely resembled the ancient fossils, and they inferred that the microbial resistance of modern *Cladophora* derives from the cellulose present in its cell walls.

Experimental Questions

1. Why did the investigators collect the alga *Cladophora* from natural environments?
2. Why was boiling in concentrated acid a reasonable way to infer the presence of biological materials that may resist decay long enough to form fossils?
3. **SciSKILLS** » The dimensions of cellulose microfibrils in algal cell walls are related to resistance to degradation. How much larger in cross section are the cellulose microfibrils of *Cladophora* than those typical of land plants?

BIO TIPS **THE QUESTION** *The experiment by Cook and colleagues revealed that the relatively thick cellulose microfibrils found in the cell walls of common and abundant green algae resist chemical degradation. How much thicker are these algal cellulose microfibrils than the cellulose microfibrils in less-resistant plant cell walls?*

TOPIC ***What topic in biology does this question address?*** The topic is protist defensive structures. More specifically, the question is about the biochemical makeup of the cellulose-rich cell walls of a common green alga.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** You know from Chapter 10 of this textbook that plant cells are typically enclosed by a cell wall that is rich in cellulose, a biochemical material that provides strength and compression resistance. You learned that the strength of cellulose derives from extensive hydrogen bonding between adjacent chains. In this chapter, you learned that protist cells are enclosed by a variety of protective materials, including cellulose that differs in structure (for example, forms microfibrils that are thicker) and is consequently more resistant to degradation than is cellulose present in land plant cell walls. You also learned that the aquatic green alga *Cladophora* is known to host dense populations of hundreds of microbial species on its surfaces, suggesting that it has adapted to resist microbial attack.

PROBLEM-SOLVING STRATEGY ***Interpret data. Compare and contrast.*** The data in Figure 28.23 include an SEM image of *Cladophora* cell-wall cellulose microfibrils, with a scale bar enabling an estimation of their width. The data also provide information as to the width of land plant cellulose microfibrils. Compare the widths of the two types of microfibrils.

ANSWER *The microfibrils of cellulose in Cladophora cell walls are ~100 nm in diameter, whereas those of land plants are ~3.5 nm wide. The Cladophora microfibrils are ~29 times thicker than those of land plants. This greater thickness reduces susceptibility to microbes, which start enzymatic attacks on cellulose at the microfibril surface. Thinner microfibrils have more exposed surface area where microbial attack can start. More extensive hydrogen bonding in the highly crystalline algal cellulose renders it less susceptible to chemical attack.*

28.4 Reproductive Adaptations

Learning Outcomes:

1. Briefly describe asexual reproduction and zygotic, sporic, and gametic sexual life cycles in protists.
2. **SciSKILLS** » Predict the number of chromosome sets (*n* or 2*n*) of an organism, given information about the type of cell that undergoes meiosis.
3. Give examples of how protist life cycles are important to humans.

Diverse reproductive adaptations allow protists to thrive in an amazing variety of environments, including the bodies of hosts in the cases of parasitic protists. These adaptations include specialized asexual reproductive cells, tough-walled dormant cells that allow protists to survive periods of environmental stress, and several types of sexual life cycles.

Protist Populations Increase by Means of Asexual Reproduction

All protists are able to reproduce asexually by mitotic cell divisions of parental cells to produce progeny. When resources are plentiful, repeated mitotic divisions of single-celled protists generate large protist populations. Multicellular protists often generate specialized asexual cells that help disperse the organisms in their environment.

Many protists produce unicellular **cysts** as the result of asexual (and in some cases, sexual) reproduction (**Figure 28.24**). Cysts often have thick, protective walls and can remain dormant through periods of unfavorable climate or low food availability. Dinoflagellates commonly produce cysts that can be transported in the water of a ship's ballast from one port to another, a problem that has caused harmful dinoflagellate blooms to appear in harbors around the world. Ship captains can help to prevent such ecological disasters by heating ballast water before it is discharged from ships.

Many disease-causing protists spread from one host to another via cysts. As noted in the chapter opener, the alveolate pathogen *Cryptosporidium parvum* infects humans via waterborne cysts. The amoebozoan *Entamoeba histolytica* infects people who consume food or water that is contaminated with its cysts. Once inside the human digestive system, *E. histolytica* attacks intestinal cells, causing amoebic dysentery.

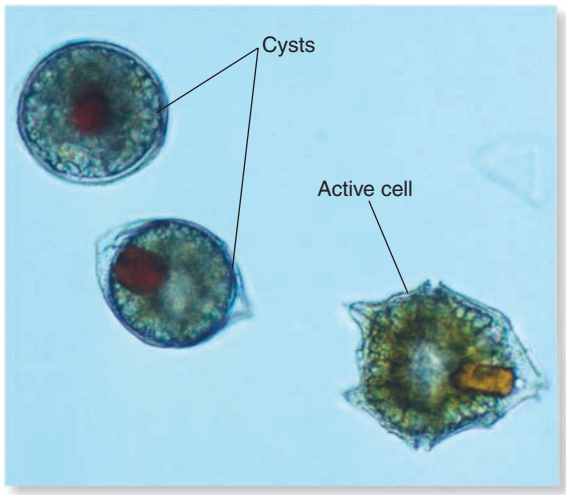


Figure 28.24 **Protistan cysts.** The round cells are dormant, tough-walled cysts of the dinoflagellate *Peridinium limbatum*. The pointed cell is an actively growing cell of the same species. As cysts develop, the outer cellulose plates present on actively growing cells are cast off.

Concept Check: *How are cysts involved in the spread of harmful algae and disease-causing parasitic protists?*

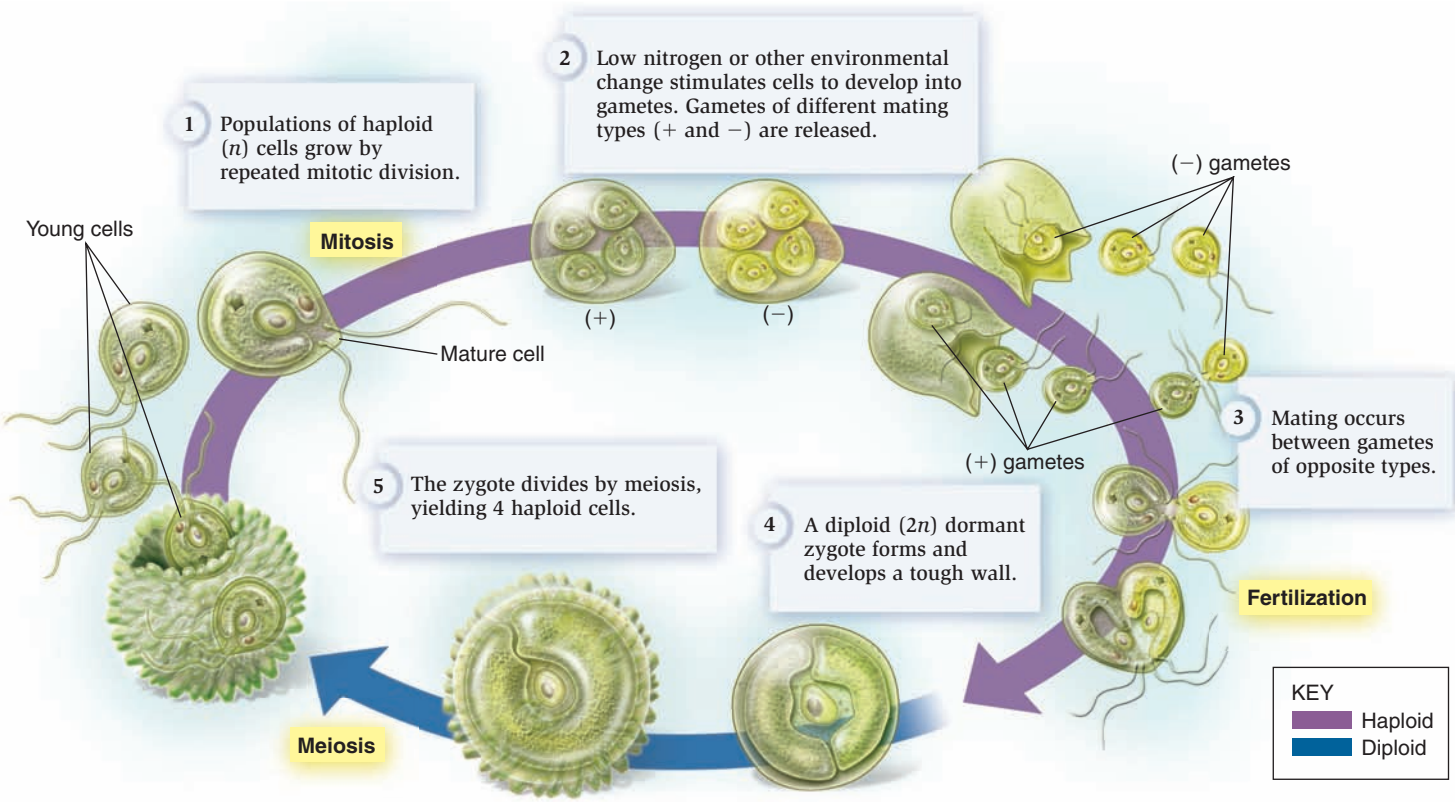
Sexual Reproduction Provides Multiple Benefits to Protists

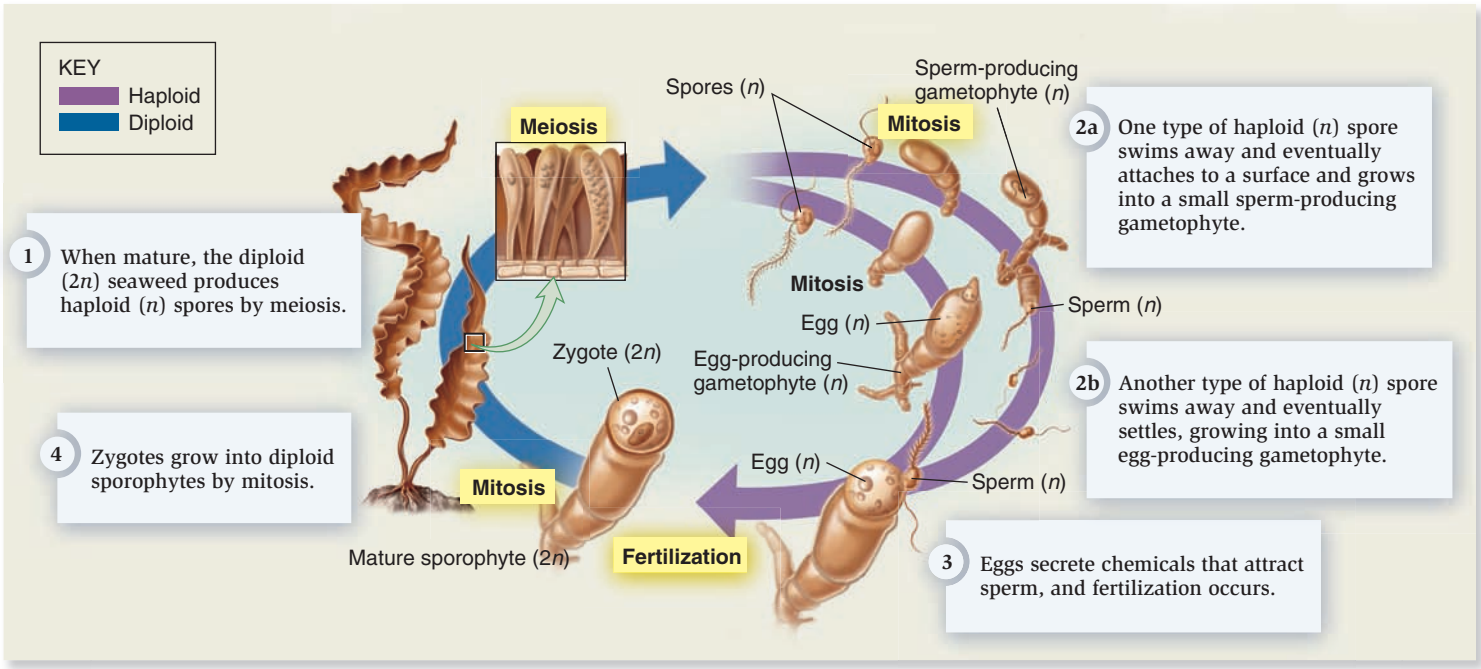
Eukaryotic sexual reproduction, featuring gametes, zygotes, and meiosis, first arose among protists. Sexual reproduction has not been observed in some protist phyla but is common in others. Sexual reproduction is generally adaptive because it produces diverse genotypes, thereby increasing the potential for faster evolutionary response to environmental change. Many protists reap additional ecological benefits from sexual reproduction, illustrated by several types of sexual life cycles.

Zygotic Life Cycles Most unicellular protists that reproduce sexually display what is known as a **zygotic life cycle** (**Figure 28.25**). In this type of life cycle, haploid cells develop into gametes. Some protists produce nonmotile eggs and smaller flagellate sperm. However, many other protists have gametes that look similar to each other structurally but have distinctive biochemical features and hence are known as + and – mating types, as shown in Figure 28.25. Gametes fuse (mate) to produce thick-walled diploid zygotes, which give this type of life cycle its name. Such zygotes often have tough cell walls and can survive stressful conditions, much like cysts. When conditions permit, the zygote divides by meiosis to produce haploid cells that increase in number via mitotic cell divisions.

Sporic Life Cycles Many multicellular green and brown seaweeds display a **sporic life cycle**, which is also known as alternation of generations (**Figure 28.26**). Giant kelps and some other protists having sporic life cycles produce two types of multicellular organisms: a haploid gametophyte generation that produces gametes (sperm or eggs) and a diploid sporophyte generation that produces spores by the process of meiosis (Figure 28.26a). This type of life cycle takes its name from the characteristic production of spores as the result of meiosis. Each of the two types of multicellular organisms can adapt to distinct habitats or seasonal conditions, thus allowing these protists to occupy more types of environments for longer periods.

Many red seaweeds display a variation of the sporic life cycle that involves alternation of three distinct multicellular generations (Figure 28.26b). This unique type of sexual life cycle has evolved as compensation for the lack of flagella on red algal sperm. Because these sperm are unable to swim to eggs, fertilization occurs only when sperm carried by ocean currents happen to drift close to eggs. As a consequence, fertilization can be rare. Many red algae therefore make millions of spores that are produced by two distinct sporophyte generations. A small sporophyte produces diploid spores, and a larger sporophyte produces haploid spores. Diverse economically valuable red algae possess this type of life cycle, an understanding of which is critical to growing seaweed crops.





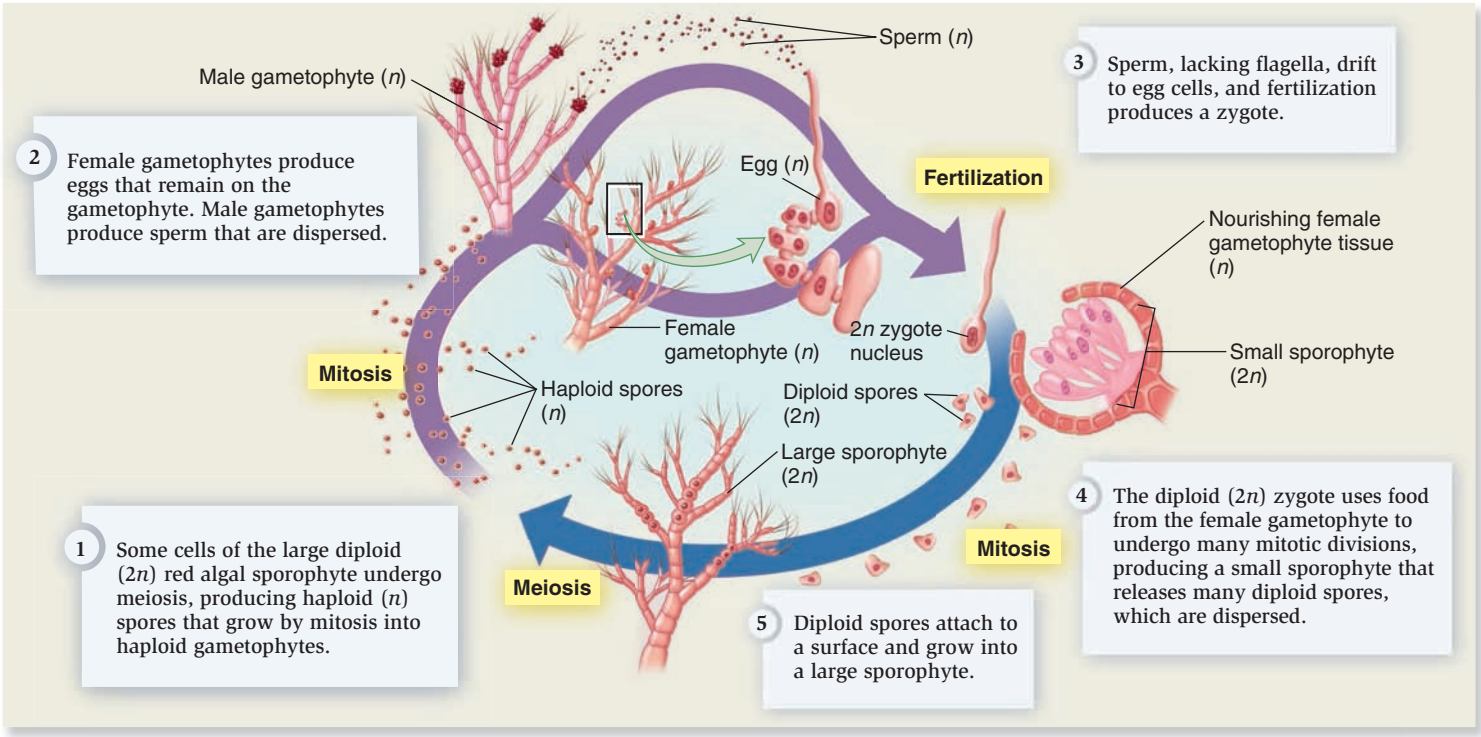


Figure 28.25 Zygotic life cycle, illustrated by the unicellular flagellate genus *Chlamydomonas*. In *Chlamydomonas*, most cells are haploid; only the zygote is diploid.

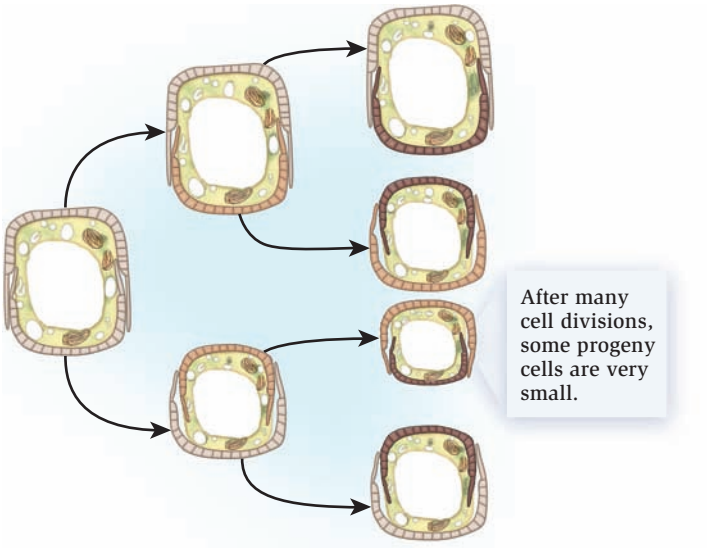
BioConnections: Look back to Figure 19.1, which shows organisms that serve as model systems for the study of plant and animal development. Chlamydomonas is a model system for molecular analyses of flagellar and chloroplast development. What aspects of its life cycle foster such genetic studies?

(a) *Laminaria* life cycle—alternation of 2 generations



(b) *Polysiphonia* life cycle—alternation of 3 generations

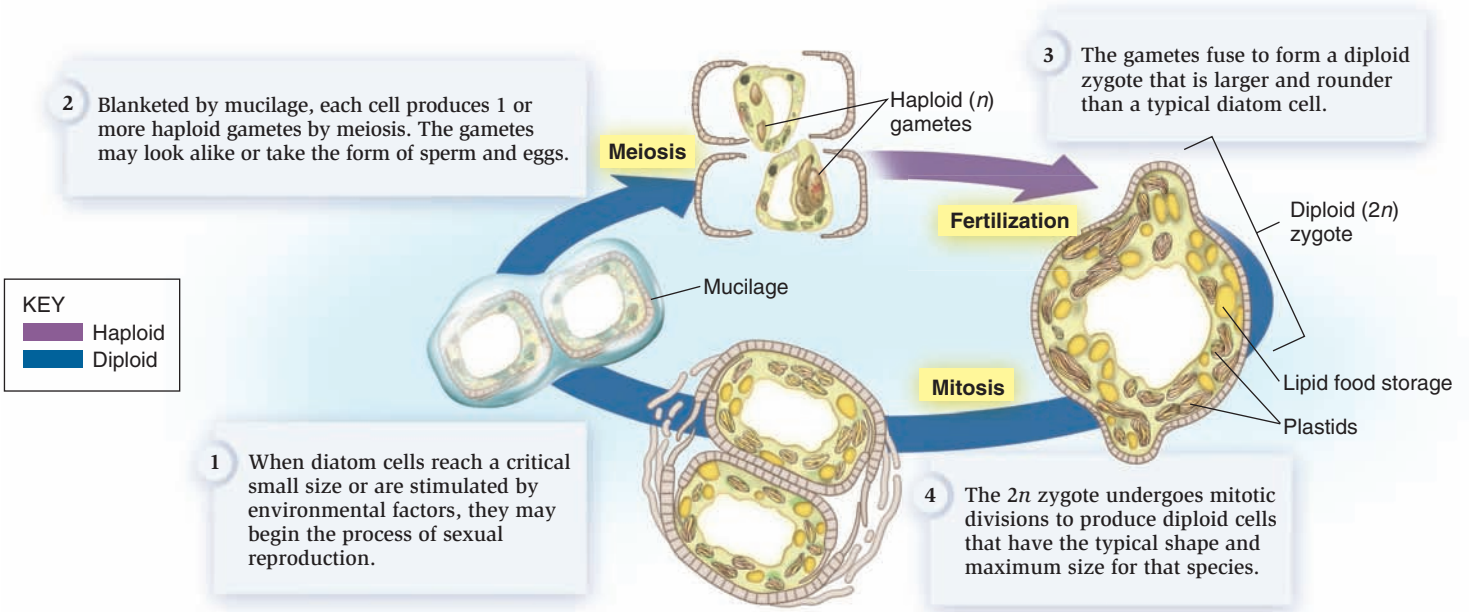


Figure 28.26 Sporic life cycles. **(a)** Sporic life cycle with two alternating generations, illustrated by the brown seaweed *Laminaria*. **(b)** Sporic life cycle involving three alternating generations, illustrated by the common red seaweed *Polysiphonia*.

Gametic Life Cycles Diatoms, which provide food for aquatic animals, are one of the relatively few types of protists known to display a **gametic life cycle** (Figure 28.27), as do animals. In gametic life cycles, all cells except the gametes are diploid, and gametes are produced by meiosis. Sexual reproduction in diatoms not only increases their genetic variability, but also has another major benefit related to cell size.

In many diatoms, one daughter cell arising from asexual reproduction, which involves mitosis, is smaller than the other, and it is also smaller than the parent cell (Figure 28.27a). This happens because diatom cell walls are composed of two overlapping halves, much like two-part round laboratory dishes having lids that overlap the bottoms. After each mitotic division, each daughter cell receives

(a) Asexual reproduction in diatoms

(b) Sexual reproduction in diatoms

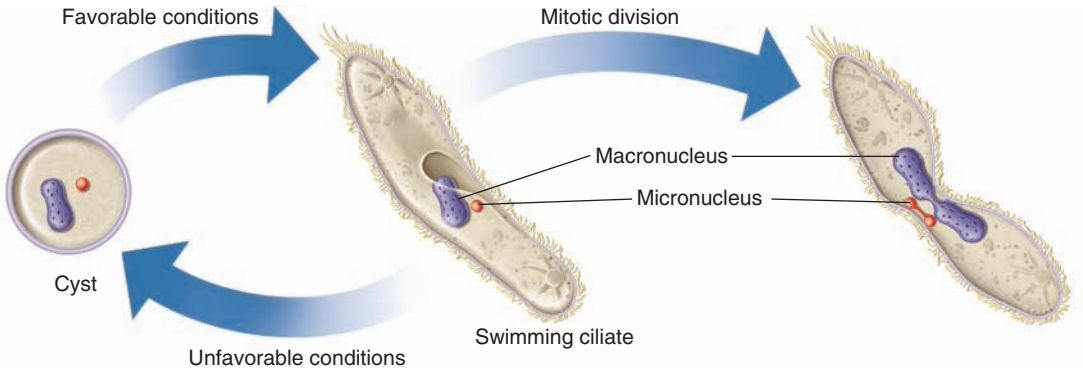

Figure 28.27 Gametic life cycle, as illustrated by diatoms. **(a)** Diatom asexual reproduction involves repeated mitotic division. Because a new bottom cell-wall piece is always synthesized, asexual reproduction may eventually cause the mean cell size to decline in a diatom population. **(b)** Small cell size may trigger sexual reproduction, which regenerates maximal cell size.

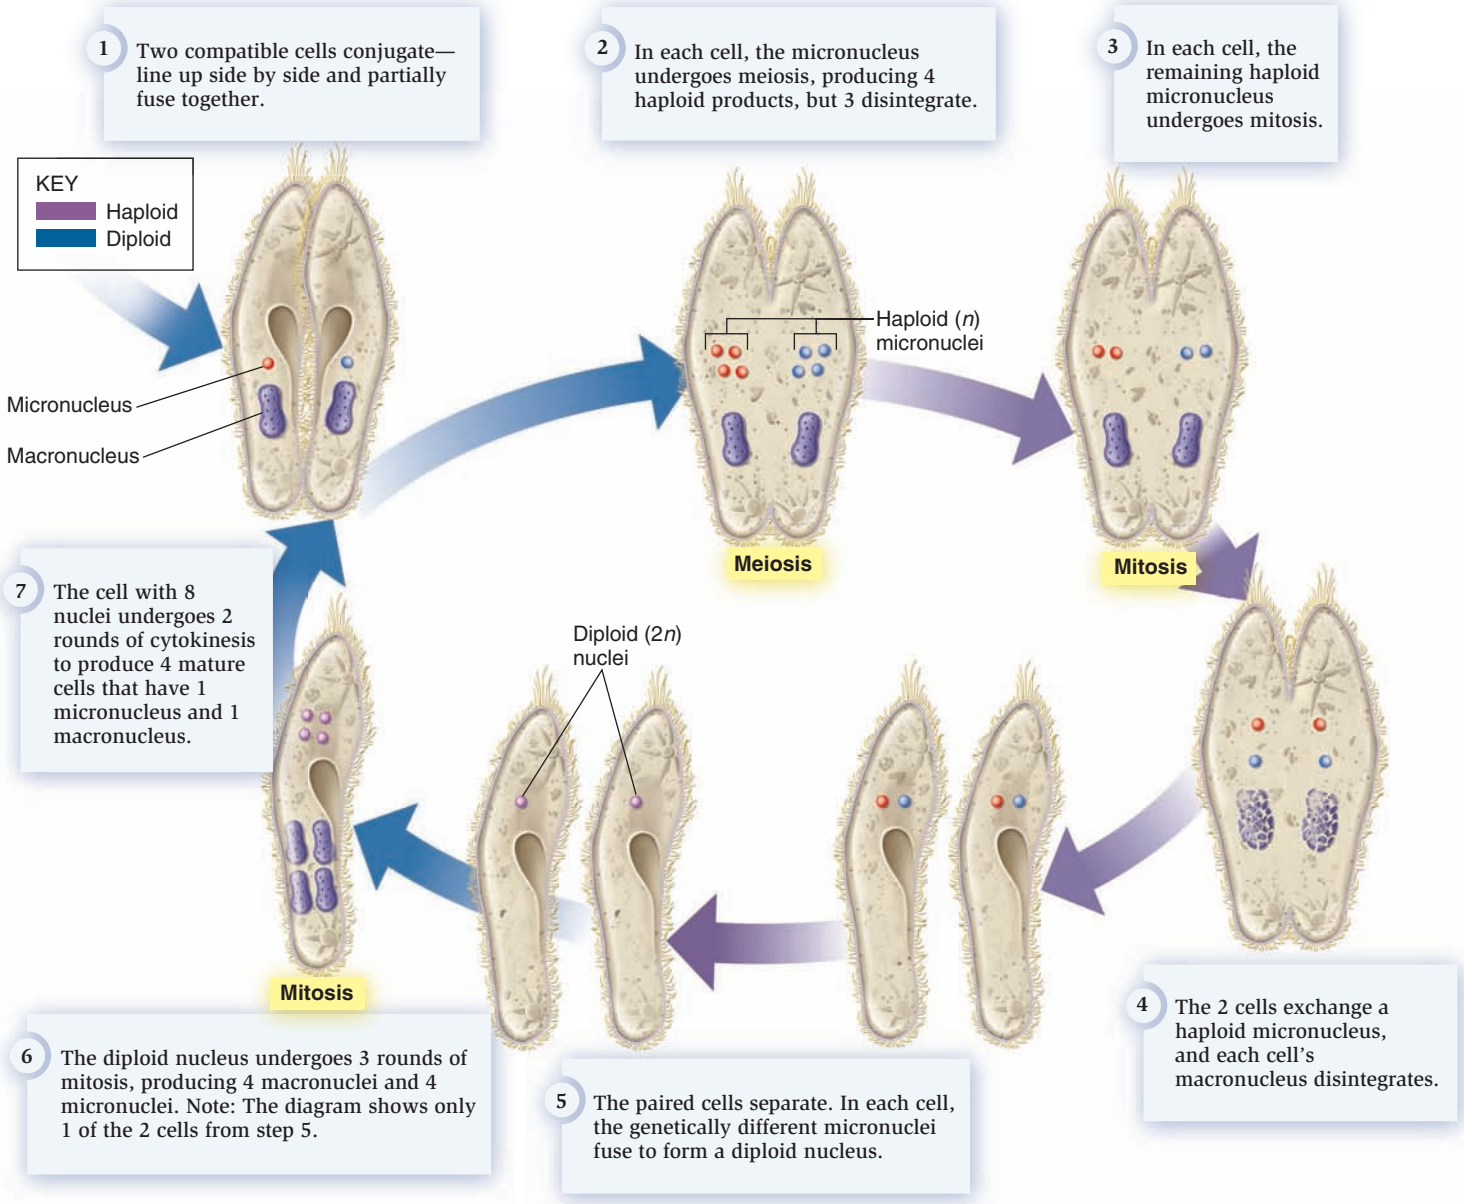
BioConnections: Look back to Figure 15.14, which illustrates the life cycles of animals, fungi, and plants. Which of these life cycles is most similar to that of diatoms?



one-half of the parent cell wall. The daughter cell that inherits a larger, overlapping parental "lid" then produces a new "bottom" that fits inside. This daughter cell will be the same size as its parent. However, the daughter cell that inherits the parental "bottom" uses this as its lid and produces a new, even smaller "bottom." This cell will be smaller than its sibling or parent. Consequently, after many such mitotic divisions, the average cell size of diatom populations often declines over time. If diatom cells become too small, they cannot survive.

Sexual reproduction allows diatom species to attain maximal cell size. Diatom cells mate within a blanket of mucilage, each partner undergoing meiotic divisions to produce gametes. The large, spherical diatom zygotes that result from fertilization (Figure 28.27b) later undergo a series of mitotic divisions to produce new diatom cells having the maximal size for the species. Maintaining a maximal size is important because diatoms provide a large proportion of the organic food at the base of marine and freshwater food chains.

Ciliate Reproduction Ciliates reproduce asexually by mitosis and forming cysts (**Figure 28.28a**). In addition, ciliates can reproduce sexually by a process known as conjugation. Ciliates are unusual in having two types of nuclei: one or more smaller micronuclei and a single large macronucleus. Macronuclei, which contain many copies of the genome, serve as the source of information for cell function. Both macronuclei and micronuclei divide during asexual mitosis. The diploid micronuclei do not undergo gene expression during growth; instead, their role is to transmit the genome to the next generation during sexual reproduction via conjugation. Different species of ciliates vary as to the details of conjugation; the process for *Paramecium caudatum* is shown in **Figure 28.28b**.

(a) Asexual reproduction by mitosis and cysts

(b) Sexual reproduction by conjugation

Figure 28.28 Ciliate reproduction. **(a)** The asexual reproductive process in ciliates. **(b)** The sexual reproductive process, known as conjugation, of the ciliate *Paramecium caudatum*.

Parasitic Protists May Use Alternate Hosts for Different Life Stages

Many parasitic protists are notable for using more than one host organism, in which different life stages occur. The malarial parasite genus *Plasmodium* is a prominent example. About 40% of humans live in tropical regions of the world where malaria occurs, and as noted earlier, millions of infections and human deaths result each year. Malaria is particularly deadly for young children. In addition to humans, the malarial parasite's alternate host is the mosquito in the genus *Anopheles*, which can also transmit malaria to great apes. Though insecticides can be used to control mosquito populations and antimalarial drugs exist, malarial parasites can develop drug resistance. Experts are concerned that cases may double in the next 20 years.

When a mosquito bites a human or a great ape, *Plasmodium* enters the bloodstream in an asexual life stage known as a sporozoite (**Figure 28.29**). Upon reaching a victim's liver, sporozoites enter liver cells where they divide to form an asexual life stage known as merozoites. Hundreds of merozoites are produced within liver cells (see inset of Figure 28.29), which then release into the bloodstream packages of merozoites enclosed by a host-derived cell membrane. This membrane protects merozoites from destruction by host immune cells, which would otherwise engulf the merozoites by phagocytosis

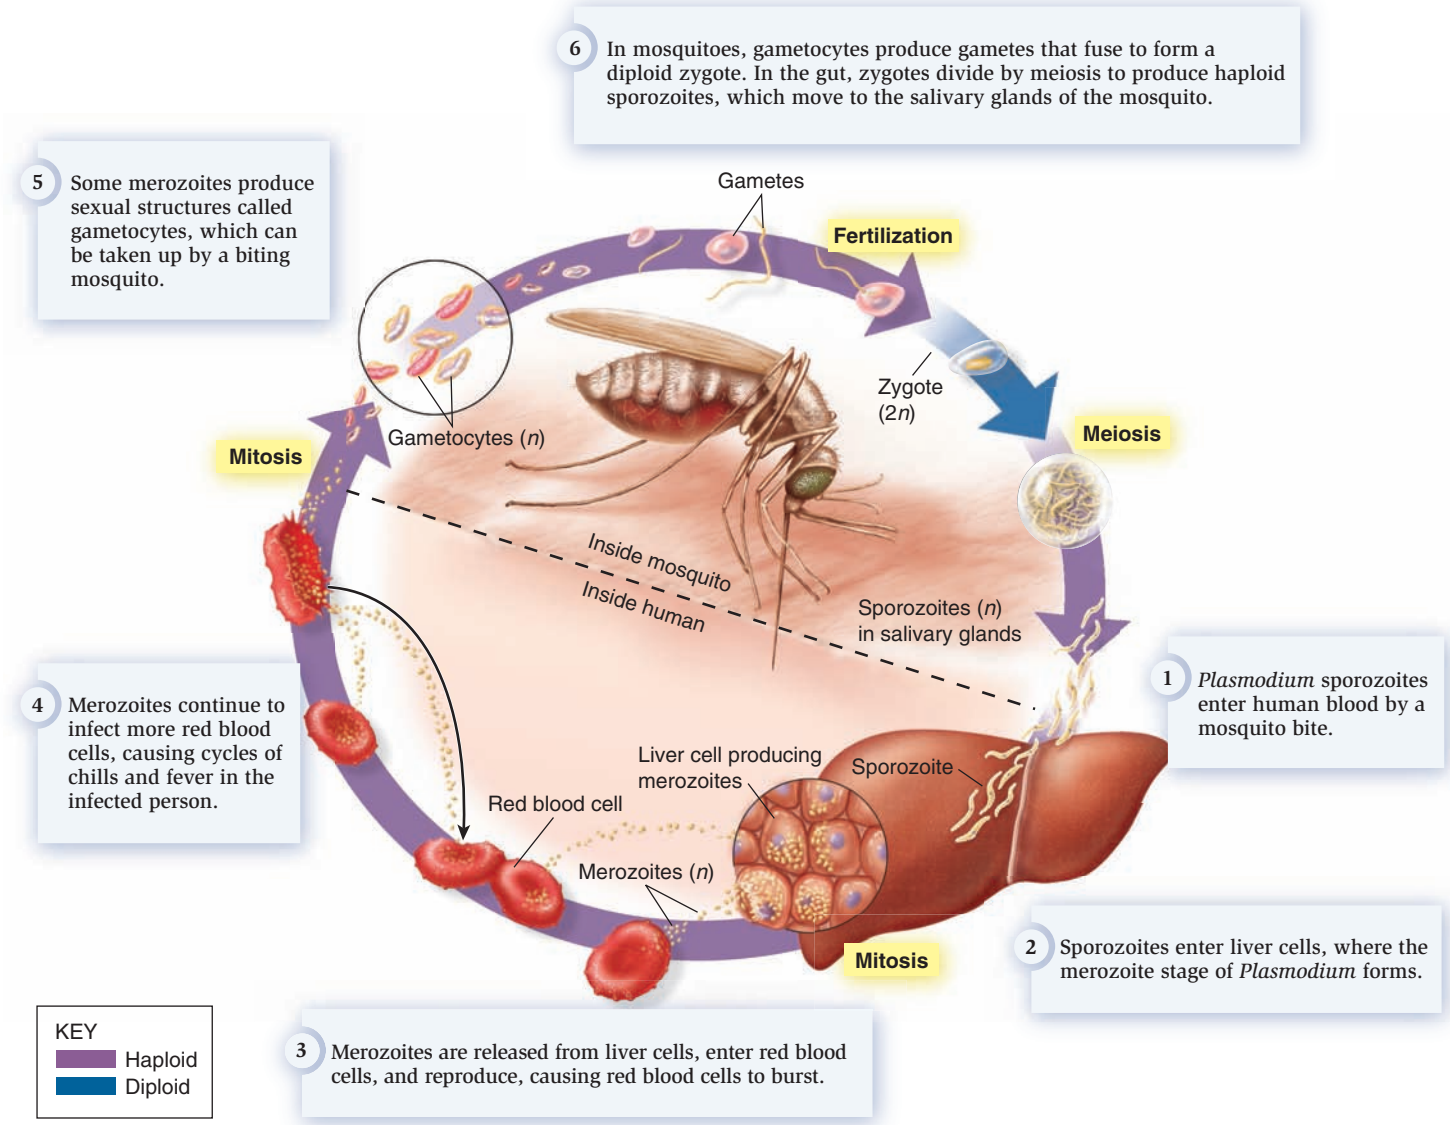


Figure 28.29 Diagram of the life cycle of *Plasmodium falciparum*, a species that causes malaria. This life cycle requires two alternate hosts, humans (or great apes) and *Anopheles* mosquitoes. The inset is a TEM view of an infected human liver cell that contains numerous dark-stained merozoites. Such infected cells bud off groups of merozoites enclosed within a host-produced membrane. This membrane protects merozoites from being engulfed and destroyed by phagocytotic cells of the body's immune system.

Concept Check: *In which of the hosts does sexual mating of P. falciparum gametes occur?*

and then destroy them. In the bloodstream, the protective host membranes disintegrate, releasing merozoites. The merozoites have protein complexes at their front ends, or apices, that allow them to invade human red blood cells. (The presence of these apical complexes gives rise to the phylum name Apicomplexa.) Within red blood cells, merozoites release more than 200 proteins, which enable the parasites to commandeer these cells, causing many changes. For example, infected red blood cells form surface knobs that function like molecular Velcro, attaching cells to capillary linings. This process allows infected red blood cells to avoid being transported to the spleen, where they would be destroyed. The attachment of infected red blood cells to capillary linings disrupts circulation in the brain and kidney, a process that can cause death of the animal host.

While living within red blood cells, merozoites form rings, which can be visualized by staining and the use of a microscope, allowing diagnosis. The merozoites consume the hemoglobin in red blood cells, which gives them fuel to reproduce asexually. Large numbers of new merozoites synchronously break out of red blood cells at intervals of 48 or 72 hours. These merozoite reproduction cycles correspond to cycles of chills and fever that an infected person experiences. Some merozoites produce sexual structures—gametocytes—which, along with blood, are transmitted to a female mosquito as it bites an infected person.

Within the mosquito's body, the gametocytes produce gametes and fertilization occurs, yielding a zygote, the only diploid cell in *Plasmodium*'s life cycle. Thus, *Plasmodium* has a zygotic life cycle (compare with Figure 28.25). Within the mosquito gut, the zygote undergoes meiosis, generating structures filled with many sporozoites, the stage that can be transmitted to a new human host. Sporozoites move to the mosquito's salivary glands, where they remain until they are injected into a human host when the mosquito feeds.

In recent years, genomic information has added to our knowledge of these life stages, thereby helping medical scientists develop new ways to prevent or treat malaria. In the case of *P. falciparum*, genomic data have already highlighted potential new pharmaceutical approaches. About 550 (some 10%) of the parasite's nuclear-encoded proteins are likely imported into a nonphotosynthetic plastid known as an apicoplast, where they are needed for fatty-acid metabolism and other processes. *P. falciparum* and some other apicomplexan possess plastids because they are descended from algal ancestors that had photosynthetic plastids. Because plastids are not present in mammalian cells, enzymes in apicoplast pathways are possible targets for development of drugs that will kill the parasite without harming the host. Mammals also lack calcium-dependent protein kinases (CDPKs), enzymes that are essential to the release of merozoites from red blood cells and the parasite's sexual development, offering another potential drug target.

Summary of Key Concepts

28.1 An Introduction to Protists

- Protists are eukaryotes that are not classified in the plant, animal, or fungal kingdoms; are abundant in moist habitats; and are mostly microscopic in size.
- Protists are often informally labeled according to their ecological roles: Algae are mostly photosynthetic protists; protozoa are heterotrophic protists that are often mobile; and fungus-like protists resemble true fungi in some ways (Figures 28.1, 28.2).
- Protists are particularly diverse in aquatic habitats, occurring as small floating or swimming phytoplankton, attached members of the periphyton, and more complex macroalgae (seaweeds) (Figure 28.3).
- Microscopic protists propel themselves by means of flagella (flagellates), cilia (ciliates), or pseudopodia (amoebae) or by gliding across surfaces (Figures 28.4, 28.5).

28.2 Evolution and Relationships

- Modern phylogenetic analysis has revealed that protists do not form a monophyletic group; instead, many are classified into one of seven major eukaryotic supergroups (Figure 28.6).
- The supergroup Discoba consists of flagellate protists characterized by disc-shaped mitochondrial cristae. Many feed by taking in particles at a feeding groove, including the kinetoplastids and euglenoids, some of which are photosynthetic (Figures 28.7, 28.8, 28.9).
- Land plants are related to green algae and red algae (having primary plastids). Cryptomonads and haptophytes display secondary plastids (Figures 28.10, 28.11, 28.12, 28.13, 28.14).
- The supergroup Alveolata includes the ciliates, apicomplexans, and dinoflagellates, whose cells feature saclike membrane vesicles called alveoli. Many dinoflagellates display secondary plastids, and some feature tertiary plastids (Figures 28.15, 28.16).
- The supergroup Stramenopila includes protists whose flagella have strawlike hairs that aid in swimming. Stramenopiles include diatoms, giant kelps, and other groups of algae, as well as some fungus-like protists (Figures 28.17, 28.18).
- The supergroup Rhizaria consists of flagellates and amoebae with thin hairlike extensions of cytoplasm called filose pseudopodia. Three prominent phyla are Chlorarachniophyta, with secondary green plastids; silicate-shelled Radiolaria; and Foraminifera, with calcium carbonate shells (Figure 28.19).
- The supergroup Amoebozoa is composed of many types of amoebae and includes slime molds such as *Dictyostelium discoideum*.
- The supergroup Opisthokonta includes organisms that produce swimming cells having a single posterior flagellum. It includes the fungal and animal kingdoms and choanoflagellate protists, which are related to the ancestor of animals (Figures 28.20, 28.21, Table 28.1).

28.3 Nutritional and Defensive Adaptations

- Protists display four mechanisms of nutrition: phagotrophs feed by ingesting particles; osmotrophs absorb small organic molecules; photoautotrophs make their own organic food by using light energy; and mixotrophs use both photoautotrophy and heterotrophy to obtain nutrients (Figure 28.22).
- Protists possess defensive adaptations such as sharp projectiles, light flashes, toxic compounds, and protective cell coverings. The green alga *Cladophora* is an example of a protist that produces cellulose-rich cell walls so tough that they help to explain ancient fossils and important modern ecological impacts (Figure 28.23).

28.4 Reproductive Adaptations

- Protist populations grow by means of asexual reproduction involving mitosis, and many persist through unfavorable conditions by producing tough-walled cysts (Figure 28.24).
- Sexual reproduction arose among protists. In the zygotic life cycle, haploid cells develop into gametes, which fuse to produce diploid zygotes. These zygotes often have tough cell walls that enable them to survive unfavorable conditions (Figure 28.25).
- In protists displaying a sporic life cycle (also called alternation of generations), a haploid generation produces gametes and a diploid generation produces spores. Each type can adapt to different environments or conditions, allowing protists to occupy multiple habitats (Figure 28.26).
- In the gametic life cycle, all cells but gametes are diploid. Sexual reproduction in diatoms, which have a gametic life cycle, increases genetic variability and allows species to attain maximal cell size (Figure 28.27).
- Ciliate protists display both asexual reproduction and sexual reproduction by conjugation (Figure 28.28).
- Parasitic protists may have life cycles involving alternate hosts. One example is *Plasmodium*, the agent of malaria, whose alternate hosts are humans (or great apes) and mosquitoes (Figure 28.29).

Assess and Discuss

Test Yourself

1. If you were studying the evolution of animal-specific cell-to-cell signaling systems, from which of the following would you choose representative species to observe?
   a. Rhodophyta
   b. Discoba
   c. Choanomonada
   d. Radiolaria
   e. Chlorophyta
2. If you were studying the origin of land plant traits, which of the following groups would you study?
   a. green algae
   b. radiolarians
   c. choanoflagellates
   d. diatoms
   e. ciliates
3. Which informal ecological group of protists includes photoautotrophs?
   a. protozoa
   b. algae
   c. fungus-like protists
   d. ciliates
   e. all of the above
4. How would you recognize a primary plastid? It would:
   a. have one envelope membrane.
   b. have two envelope membranes.
   c. have more than two envelope membranes.
   d. lack pigments.
   e. be golden brown in color.
5. What organisms have tertiary plastids?
   a. certain stramenopiles
   b. certain euglenoids
   c. certain cryptomonads
   d. certain opisthokonts
   e. certain dinoflagellates
6. What is surprising about mixotrophs?
   a. They have no plastids, but they occur in mixed communities with autotrophs.
   b. They have mixed heterotrophic and autotrophic nutrition.
   c. Their cells contain a mixture of red and green plastids.
   d. Their cells contain a mixture of haploid and diploid nuclei.
   e. They consume a mixed diet of algae.
7. What advantages do diatoms obtain from sexual reproduction?
   a. increased genetic variability
   b. increased ability of populations to respond to environmental change
   c. evolutionary potential
   d. regeneration of maximal cell size for the species
   e. all of the above
8. What are extrusomes?
   a. hairs on flagella
   b. membrane sacs beneath the cell surface
   c. tough-walled asexual cells
   d. spearlike defensive structures shot from cells under attack
   e. special types of survival cysts
9. How do pigments such as phycoerythrin in red algae and fucoxanthin in brown algae benefit these autotrophic protists?
   a. The pigments provide camouflage, so herbivores cannot see the algae.
   b. The pigments absorb blue-green underwater light and transfer the energy to chlorophyll *a* for use in photosynthesis.
   c. The pigments attract aquatic animals that carry gametes between seaweeds.
   d. The pigments absorb UV light that would harm the photosynthetic apparatus.
   e. All of the above are correct.
10. What are the alternate hosts of the malarial parasite *Plasmodium falciparum*?
    a. humans (or great apes) and ticks
    b. ticks and mosquitoes
    c. humans (or great apes) and *Anopheles* mosquitoes
    d. humans (or great apes) and all types of mosquitoes
    e. sporophytes and gametophytes

Conceptual Questions

1. Explain why protists are classified into multiple supergroups, rather than a single kingdom or phylum.
2. Why have molecular biologists sequenced the genomes of several parasitic protists?
3.  A principle of biology is that *biology affects our society*. Why are the cysts of protists important to epidemiologists, the biologists who study the spread of disease?

Collaborative Questions

1. Imagine you are studying an insect species and you discover that the insects are dying of a disease that results in the production of cysts of the type that protists often generate. Thinking that the cysts might have been produced by a parasitic protist that could be used as an insect control agent, how would you go about identifying the disease agent?
2. Imagine you are part of a marine biology team seeking to catalogue the organisms inhabiting a threatened coral reef. The team has found two new types of macroalgae (seaweeds), each of which occurs during a particular time of the year when the water temperature is at a certain point. You suspect that the two macroalgae might be different generations of the same species that have differing optimal temperature conditions. How would you go about testing your hypothesis?

Plants and the Conquest of Land

29

A temperate rain forest containing diverse plant phyla in Olympic National Park in Washington State.

CHAPTER OUTLINE

29.1 Ancestry and Diversity of Modern Plants
29.2 An Evolutionary History of Land Plants
29.3 The Origin and Evolutionary Importance of the Plant Embryo
29.4 The Origin and Evolutionary Importance of Leaves and Seeds
Summary of Key Concepts
Assess and Discuss

When thinking about plants, people envision lush green lawns, shady street trees, garden flowers, or leafy fields of valuable crops. On a broader scale, they might imagine lush rain forests (like that shown in the chapter opening photo), vast grassy plains, or tough desert vegetation. Shopping in the produce section of the local grocery store may remind us that plant photosynthesis is the basic source of our food. Just breathing crisp fresh air might bring to mind the role of plants as oxygen producers—the ultimate air fresheners. Do you start your day with a "wake-up" cup of coffee, tea, or hot chocolate? Then you may appreciate the plants that produce these and many other materials we use in daily life: medicines, cotton, linen, wood, bamboo, cork, and paper.

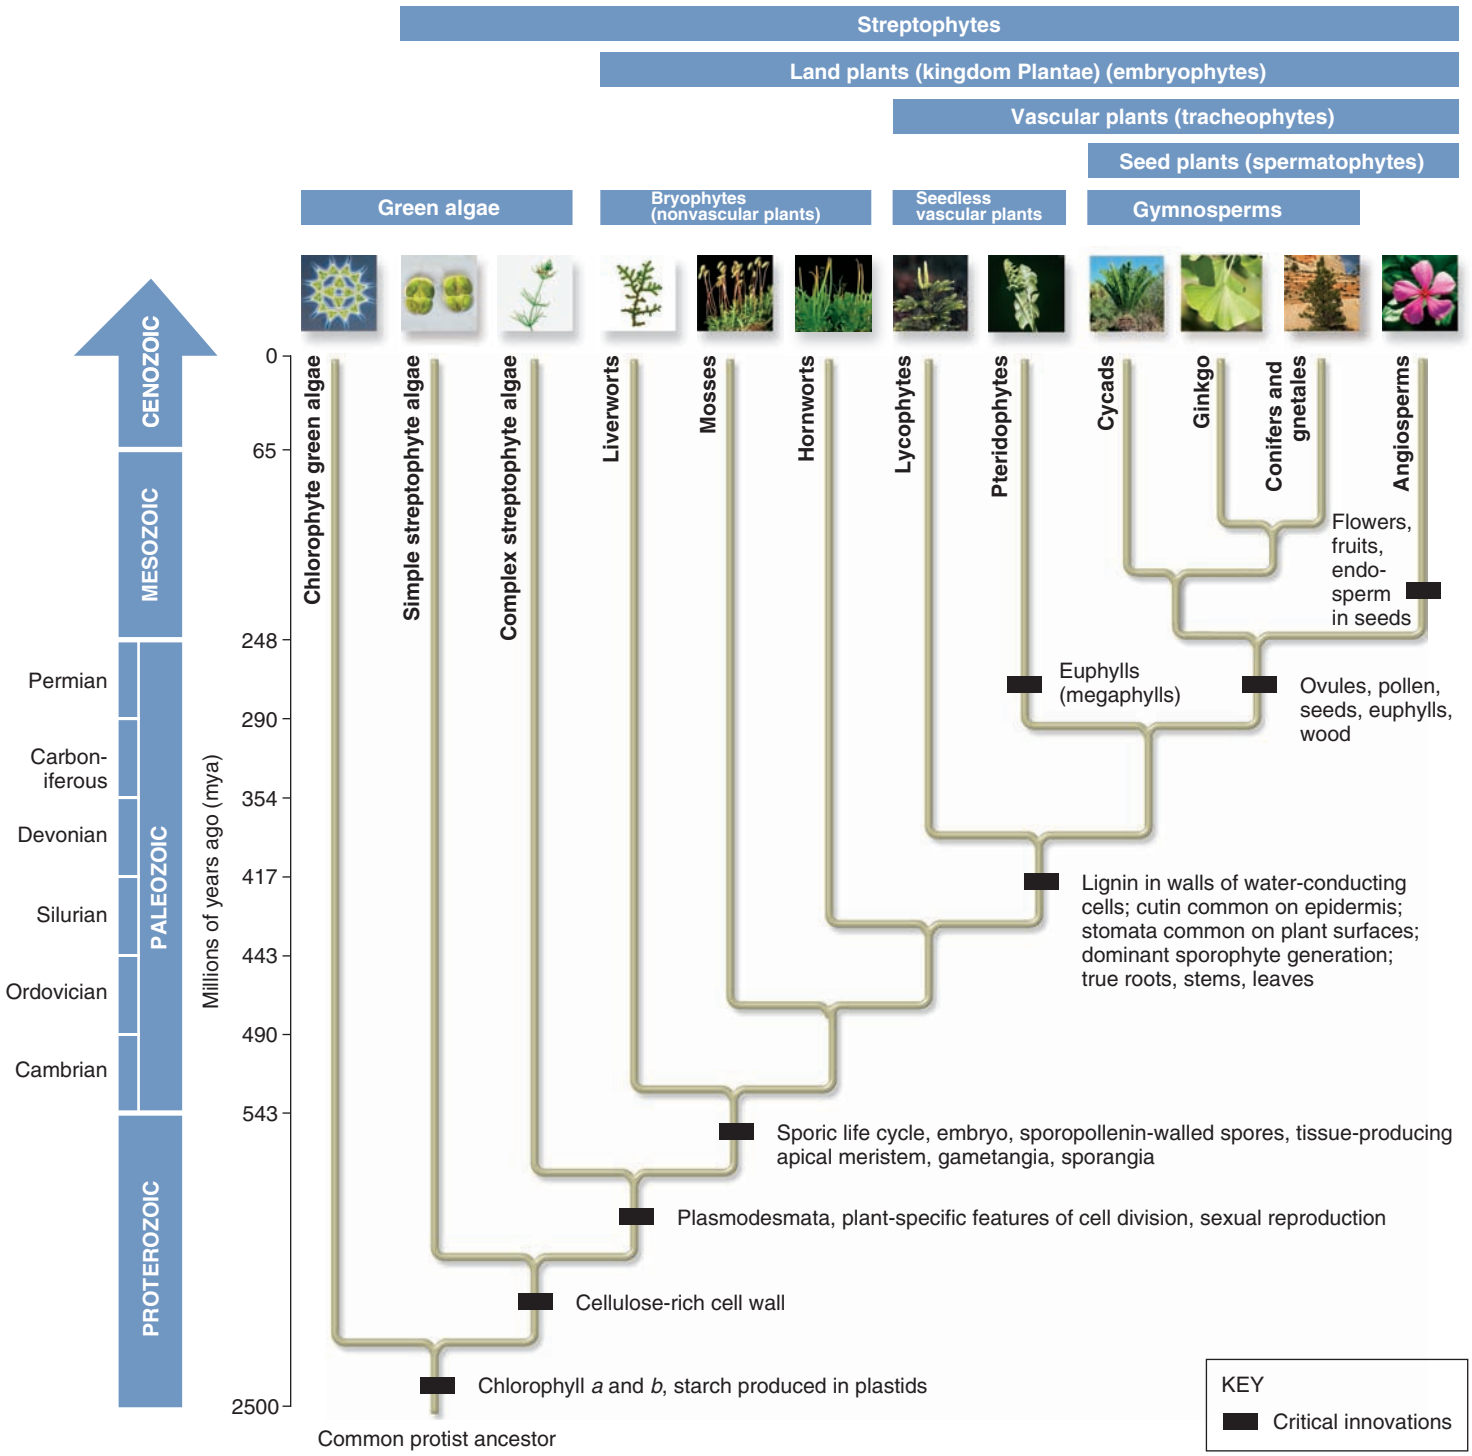
In addition to their importance to humans and modern ecosystems, plants have played dramatic roles in the Earth's past. Throughout their evolutionary history, diverse plants have influenced Earth's atmospheric chemistry, climate, and soils. Plants have also affected the evolution of many other groups of organisms, including humans. In this chapter, we will survey the diversity of modern plant phyla and their distinctive features. This chapter also explains how early plants adapted to land and how plants have continued to adapt to changing terrestrial environments. During this process, we will gain insight into descent with modification and the biological principle that all life is related by an evolutionary history.

29.1 Ancestry and Diversity of Modern Plants

Learning Outcomes:

1. List key derived features that land plants share with their closest algal relatives.
2. Name several characteristics unique to land plants.
3. Compare and contrast the features of vascular and nonvascular plants.
4. **SciSKILLS** » Explain how cuticles, epidermal stomata, and internal conduction systems work together in vascular plants to maintain stable water content.

Several hundred thousand modern species are formally classified into the kingdom Plantae, referred to informally as the plants or land plants (**Figure 29.1**). **Plants** are multicellular eukaryotic organisms composed of cells having plastids, and plants primarily live on land. Molecular and other evidence indicates that the plant kingdom evolved from green algal ancestors that primarily lived in aquatic habitats such as lakes or ponds. Together, plants and their modern green algal relatives are known as **streptophytes**. Plants are distinguished from their algal relatives by the presence of traits that foster survival in terrestrial conditions, which are drier, sunnier, hotter, colder, and less physically supportive than aquatic habitats. In this section, we will examine the modern algae that are most closely related to plants and survey the diverse phyla of living land plants. These comparisons reveal how plants gradually acquired diverse structural, biochemical, and reproductive adaptations that fostered survival on land.



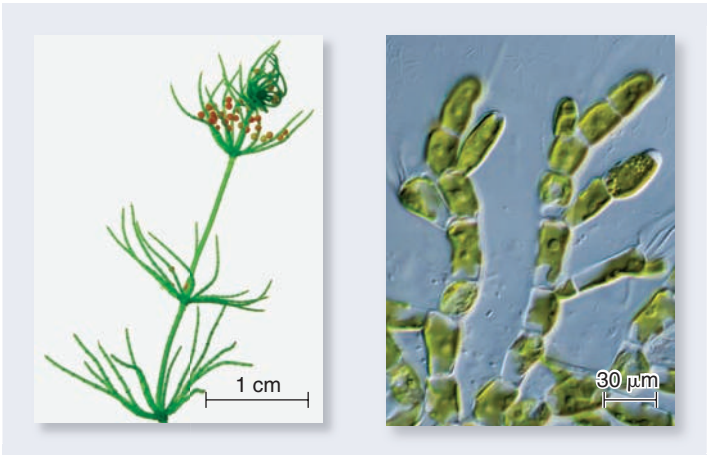


Figure 29.1 **Evolutionary relationships of the modern plant phyla.** Land plants gradually acquired diverse structural, biochemical, and reproductive adaptations, allowing them to better survive in terrestrial habitats. This is a simplified diagram; fewer branches of streptophyte algae are shown here than actually exist.

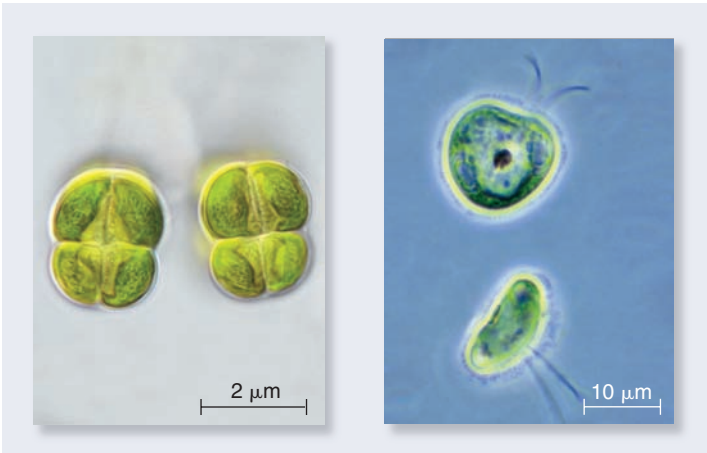
BIOLOGY PRINCIPLE **All species (past and present) are related by an evolutionary history.** This diagram shows maximal evolutionary divergence times indicated by molecular clock and some fossil evidence, suggesting when clades may first have arisen. Other fossil evidence provides minimal divergence times that indicate when clades had become well established; in this case, more numerous and more easily identified fossils were formed.



Modern Green Algae Are Closely Related to the Ancestors of Land Plants

Molecular, biochemical, and structural data indicate that the kingdom Plantae originated from a photosynthetic protist ancestor that, if present today, would be classified among the **streptophyte algae** (**Figure 29.2**). All streptophyte algae have features in common with land plants, but the later-diverging streptophyte algae display several **critical innovations**—derived features shared with land plants that fostered the latter's success on land. Examples of these shared features are a distinctive type of cytokinesis, intercellular connections known as plasmodesmata (see Chapter 10), and sexual reproduction (see Figure 29.1). For this reason, streptophyte algae are good sources of information about the ancestors of land plants.

Streptophyte algae do not form a monophyletic group, but together with land plants, they form a clade—the streptophytes. All other green algae—the chlorophytes—are related to streptophytes (see Figure 29.1). Streptophytes and chlorophytes share distinctive characters such as green, starch-bearing chloroplasts that contain the accessory pigments chlorophyll *b* and β-carotene. Even so, the land plants display several common features that distinguish them from green algae, even their closest algal relatives.

(a) Complex streptophyte algae: *Chara zeylanica* (left) and *Coleochaete pulvinata* (right)

(b) Simple streptophyte algae: *Chlorokybus atmophyticus* (left) and *Mesostigma viridae* (right)

Figure 29.2 Streptophyte green algal relatives of the land plants. Streptophyte algae inhabit freshwater lakes and ponds, and they display structural, reproductive, biochemical, and molecular features in common with land plants.

Distinctive Features of the Land Plants

The features that distinguish land plants represent early adaptations to the land habitat. For example, the bodies of all land plants are primarily composed of three-dimensional tissues, defined as close associations of cells of the same type. Tissues provide land plants with an increased ability to avoid water loss at their surfaces. Water loss is decreased in land plants because bodies composed of tissues have lower surface area/volume ratios than do branched filaments. Land plant tissues arise from one or more actively dividing cells that occur at growing tips. Such localized regions of cell division are known as **apical meristems**. The tissue-producing apical meristems of land plants produce relatively thick, robust bodies able to withstand drought and mechanical stress and produce tissues and organs with specialized functions.

The land plants also have distinctive reproductive features. These include a sporic life cycle involving alternation between two types of multicellular bodies; embryos that depend on maternal tissues during early development; tough-walled reproductive cells known as **spores** that allow dispersal through dry air; and specialized structures that generate, protect, and disperse gametes and spores. The following survey of modern plant phyla and their distinctive features describes how these and other fundamental plant features evolved.

Modern Land Plants Can Be Classified into Nine Phyla

Plant systematists use molecular and structural information from living and fossil plants to classify plants into phyla. In this textbook, nine phyla of living land plants are described: (1) the plants known as **liverworts** (formally called Hepatophyta), (2) **mosses** (Bryophyta), (3) **hornworts** (Anthocerophyta), (4) **lycophytes** (Lycopodiophyta), (5) **pteridophytes** (Pteridophyta), (6) **cycads** (Cycadophyta), (7) **ginkgos** (Ginkgophyta), (8) **conifers** (Coniferophyta), and (9) the **flowering plants**, also known as **angiosperms** (Anthophyta) (see Figure 29.1). Fossils reveal that additional plant phyla once lived but are now extinct.

Phylogenetic information suggests that the modern plant phyla arose in a particular sequence (see Figure 29.1). Although the order in which early land plants diverged is not completely clear, some evidence indicates that liverworts diverged first, mosses diverged next, and then hornworts, which may be closely related to the vascular plants. The vascular plants are distinguished by internal water and nutrient-conducting tissues that also provide structural support. Among modern vascular plants, lycophytes diverged earliest, pteridophytes arose next, and then seed plants. Our survey of these modern plant phyla reveals how plants acquired more adaptations to life on land.

Liverworts, Mosses, and Hornworts Are the Simplest Land Plants

Liverworts, mosses, and hornworts are Earth's simplest land plants (**Figures 29.3, 29.4**, and **29.5**), and each forms a distinct, monophyletic group. There are about 6,500 species of modern liverworts, 12,000 or more species of mosses, and about 100 species of hornworts. Collectively, liverworts, mosses, and hornworts are known informally as the **bryophytes** (from the Greek *bryon*, meaning moss, and *phyton*, meaning plant). The bryophytes may not form a clade, but the term bryophyte is useful for indicating the common structural, reproductive, and ecological features of liverworts, mosses, and hornworts. For example, the bryophytes are all relatively small in stature and are most common and diverse in moist habitats because they lack traits allowing them to grow tall or reproduce in dry places.

Because bryophytes diverged early in the evolutionary history of land plants (see Figure 29.1), they serve as models of the earliest terrestrial plants. Bryophytes display apical meristems that produce specialized tissues and other features that evolved early in the history of land plants, such as the sporic life cycle. A comparison of the life cycle of aquatic algae with that of bryophytes reveals the adaptive value on land of the bryophytes' life cycle.

(a) The common liverwort, *Marchantia polymorpha*

(b) Close-up of liverwort structures

(c) A species of leafy liverwort

Figure 29.3 Liverworts. **(a)** The common liverwort, *Marchantia polymorpha*, has a flat green body that produces raised, umbrella-shaped structures bearing sexually produced sporophytes on the undersides. Mature sporophytes generate spores, then release them. **(b)** A close-up of *M. polymorpha* showing surface cups that contain multicellular, frisbee-shaped asexual structures known as gemmae, which are dispersed by wind and grow into new liverworts. **(c)** A species of liverwort that has leaflike structures and so is known as a leafy liverwort.

Concept Check: *Why do you think liverworts produce their reproductive spores on raised structures?*

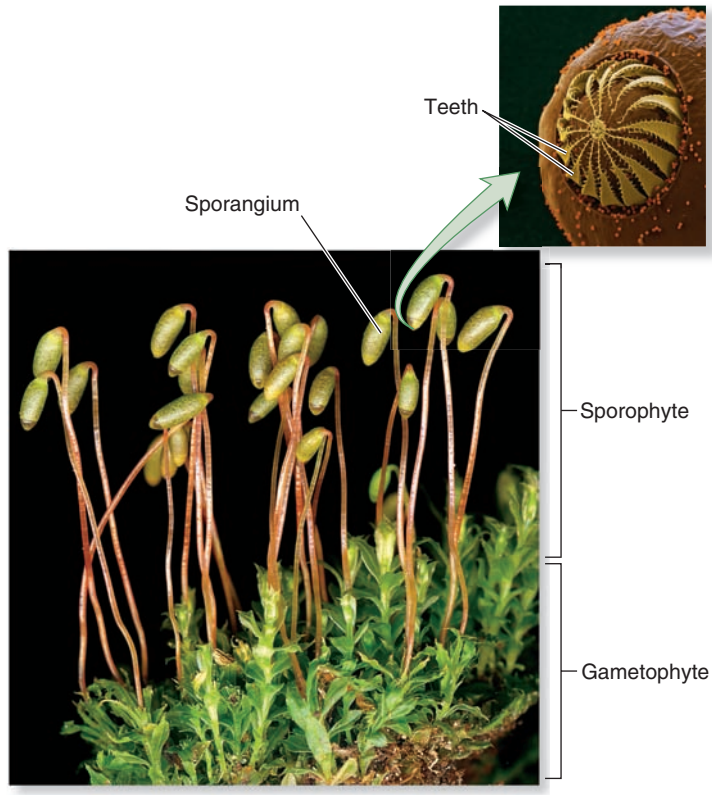


Figure 29.4 Mosses. The common moss genus *Mnium* has a leafy green gametophyte (multicellular body that generates gametes) and an unbranched, dependent sporophyte that bears a spore-producing sporangium at its tip. Inset: This SEM shows that the tips of moss sporangia often have teeth separated by spaces, so spores are sprinkled into the wind and dispersed over time, rather than being released all at once.

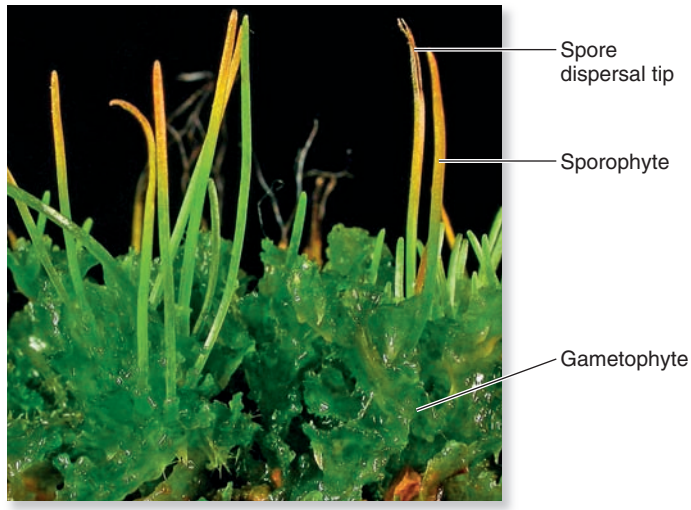
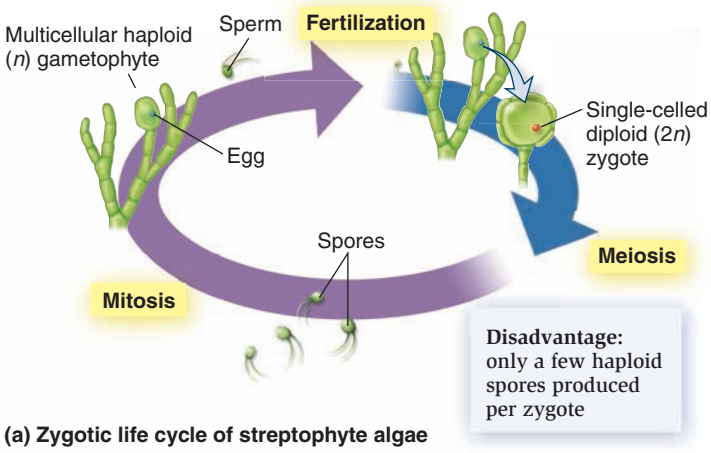
Concept Check: *Why might it be advantageous for a moss sporophyte to release spores gradually?*





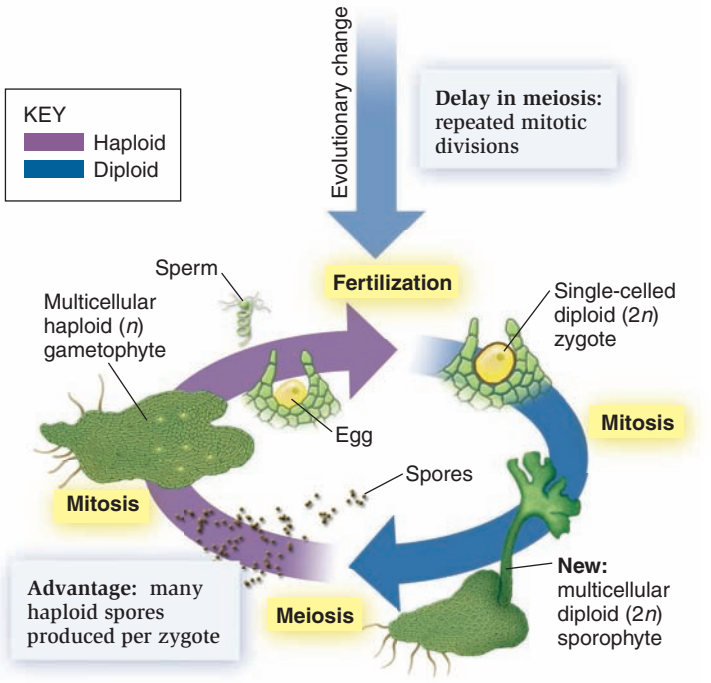


Figure 29.5 Hornworts. Sporophytes of hornworts generally grow up into the air, whereas the gametophytes grow close to the ground. Hornwort sporophytes become mature and open at the top, dispersing spores.

The streptophyte algae display a **zygotic life cycle** in which the diploid generation consists of only one cell, the zygote (**Figure 29.6a**). Zygotic life cycles take their name from the observation that the zygote is the only cell that undergoes meiosis (see Figure 28.25). By contrast, sexual reproduction in bryophytes and all other plants follows what is called a **sporic life cycle**, in which generations alternate (see Figures 15.14c and 28.26a). In the sporic life cycle, meiosis results in the formation of spores, reproductive cells that allow organisms to disperse in the environment (**Figure 29.6b**). **Alternation of generations** means that land plants produce two types of multicellular bodies that alternate in time. These two types of bodies are known as the diploid ($2n$), spore-producing **sporophyte** generation and the haploid (n), gamete-producing **gametophyte** generation. Genomic comparisons indicate that transcription factors encoded by *KNOX* genes were key to the origin of plant sporophytes. These transcription factors suppress gametophyte development, thereby allowing sporophytes to develop from zygotes. For the earliest land plants, having a multicellular diploid generation provided several advantages in coping with terrestrial conditions. What are these advantages? A closer look at the process of sexual reproduction in bryophytes reveals the answer and also highlights ways in which bryophytes differ from other plants.

(a) Zygotic life cycle of streptophyte algae

(b) Sporic life cycle of early plants

Figure 29.6 A comparison of **(a)** the life cycle of primarily aquatic streptophyte algae with **(b)** the derived life cycle of primarily terrestrial bryophytes.

Bryophyte Reproduction Illustrates Early Plant Adaptations to Life on Land

As noted, bryophytes and other land plants display an alternation of generations (**Figure 29.7**). On land, a multicellular diploid sporophyte generation is advantageous because it allows a single plant to disperse widely by using meiosis to produce numerous, genetically variable haploid spores (see Figure 29.6b). Each spore has the potential to grow into a gametophyte. In bryophytes, the gametophyte generation is generally green and photosynthetic, and thus organic food production is one of its major functions. The more spores that sporophytes produce, the greater the numbers of gametophytes, helping bryophytes to spread in their environments, thereby increasing their fitness. We next discuss how gametophytes and sporophytes function together during the life cycle of a bryophyte, starting with gamete production.

Gametophytes From an evolutionary and reproductive viewpoint, the role of plant gametophytes is to produce haploid gametes. Because the gametophyte cells are already haploid, meiosis is not involved in producing the gametes. Instead, plant gametes are produced by mitosis; therefore, all gametes produced from a single gametophyte are genetically identical.

The gametophytes of bryophytes and many other land plants produce gametes in specialized structures known as **gametangia** (from the Greek, meaning gamete containers). Certain cells of gametangia develop into gametes, and other cells form an outer protective jacket of tissue. The gametangial jacket protects the delicate gametes from drying out and from microbial attack while they develop. Flask-shaped gametangia that each enclose a single egg cell are known as **archegonia** (singular, archegonium); spherical or elongate gametangia that each produce many sperm are known as **antheridia** (singular, antheridium) (see Figure 29.7).

When the plant sperm are mature, if moist conditions exist, the sperm are released from antheridia into films of water. Under the influence of sex-attractant molecules secreted from archegonia, the sperm swim toward the eggs, twisting their way down the tubular neck of the archegonium. The sperm then fuse with egg cells (in a process called fertilization) to form diploid zygotes, which grow into embryos. New sporophytes develop from embryos. Although arthropods such as mites and springtails are able to transport moss sperm, likely by carrying the sperm on their surfaces, in general, fertilization cannot occur in bryophytes unless water is present because the sperm are flagellate and need water to reach eggs. Conditions of uncertain moisture, common in land habitats, can thus limit plant reproductive success. As explained, plant embryos and sporophytes are adaptive responses to this environmental challenge.

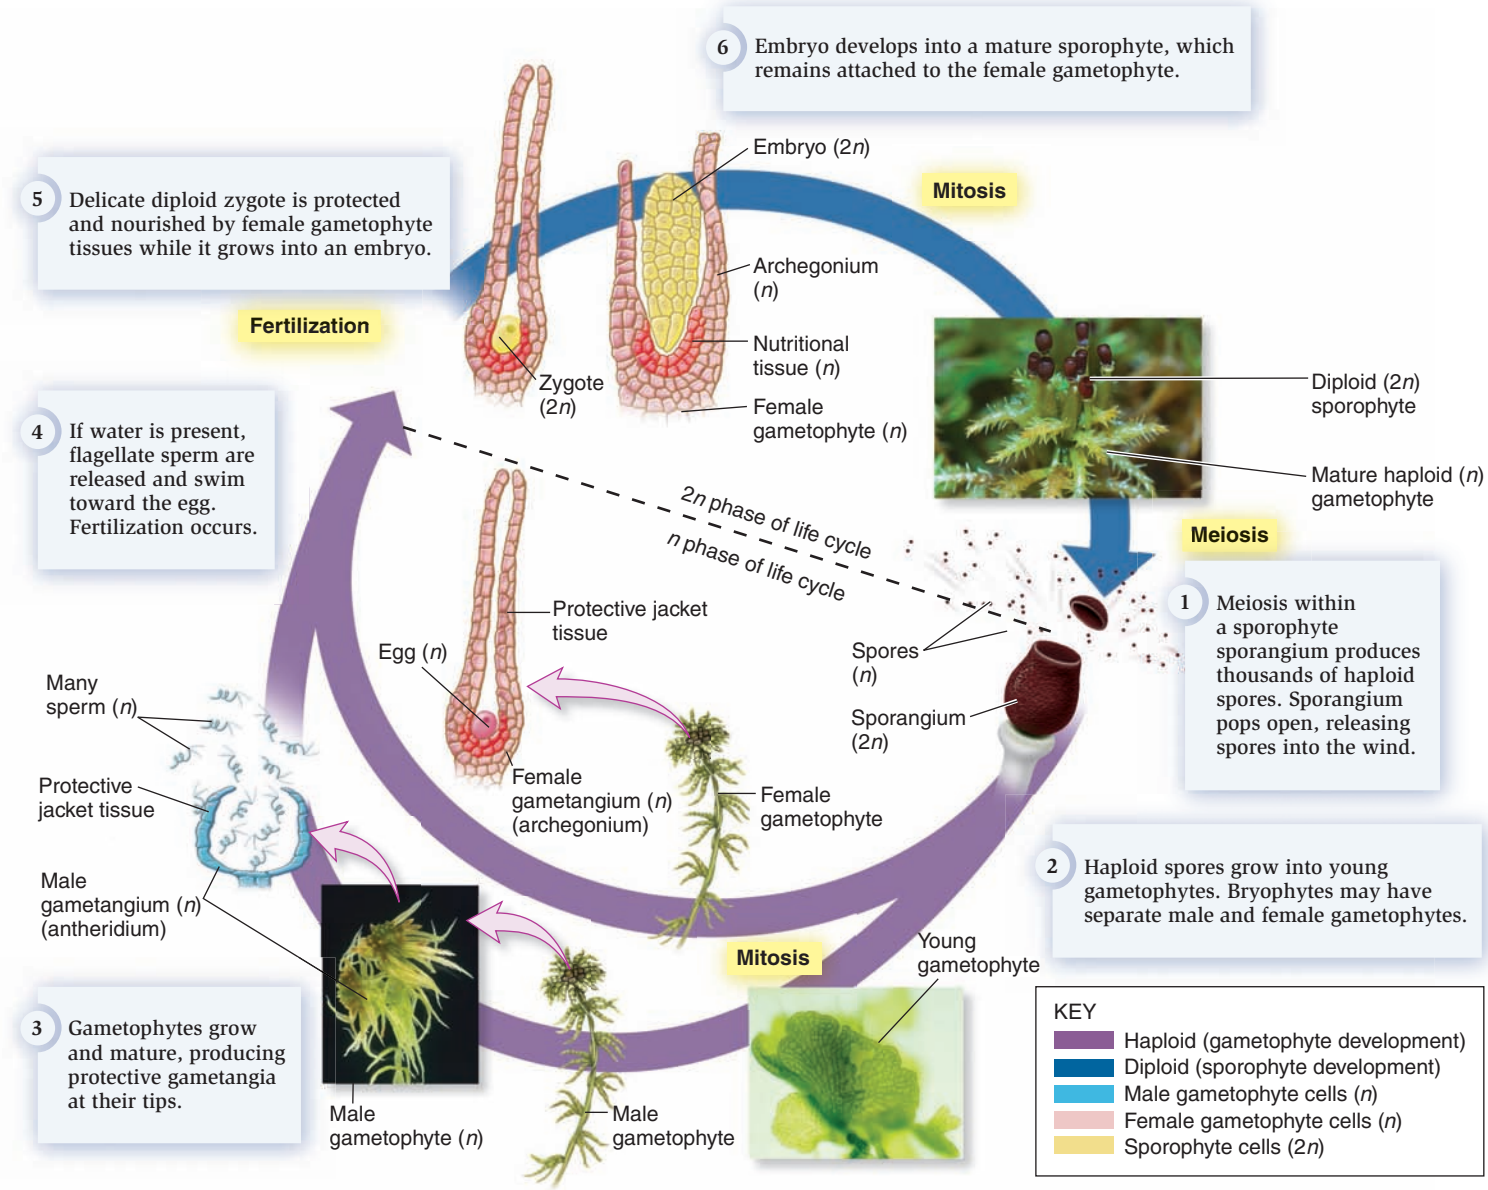

Figure 29.7 The life cycle of the early diverging moss genus *Sphagnum*. The life cycle of this organism illustrates reproductive adaptations that likely helped early plants to reproduce on land. Among modern bryophytes, *Sphagnum* is the single most abundant and ecologically important genus.

Sporophytes One reproductive advantage of the plant life cycle is that zygotes remain enclosed within gametophyte tissues, where they are sheltered and fed (a process described in more detail in Section 29.3). This critical innovation, known as **matrotrophy** (from the Latin, meaning mother, and the Greek, meaning food) gives zygotes a good start while they grow into embryos. Because all groups of land plants possess matrotrophic embryos, they are known as **embryophytes** (see Figure 29.1). Sheltering and feeding embryos is particularly important when embryo production is limited by water availability, as is often the case for bryophytes.

Another reproductive advantage to plants of the sporic life cycle is that, when mature, specialized cells within multicellular sporophytes undergo meiosis to produce many genetically diverse spores. Meiosis occurs within enclosures known as **sporangia** (from the Greek, meaning spore containers), whose tough cell walls protect developing spores from harmful UV radiation and microbial attack. Bryophyte sporangia open in specialized ways that foster dispersal of mature spores into the air, allowing spore transport by wind (see Figures 29.4 and 29.7). Dispersed plant spores have cell walls containing a tough material, known as **sporopollenin,** that helps to prevent cellular damage during transport in air. If spores reach habitats favorable for growth, their cell walls crack open, and new gametophytes develop by mitotic divisions, completing the life cycle.

Spore production is a measure of plant fitness, because plants can better disperse progeny throughout the environment when they produce more spores. The larger the diploid generation, the more spores a plant can produce. As a result, during plant evolution, the sporophyte generation has become larger and more complex (**Figure 29.8**).

Bryophytes Display Several Distinguishing Features

As we have seen, bryophytes share several fundamental adaptive traits: alternation of generations, tissue-producing apical meristems, protective gametangia and sporangia, and sporopollenin-walled spores. These same traits are shared with other land plants. Even so, several features distinguish bryophytes from other land plants. First, bryophyte gametophytes are more common, larger, and longer-lived than bryophyte sporophytes. Green patches of moss that you see in the woods are primarily gametophytes. In order to observe bryophyte sporophytes, you would have to look very closely, because this life stage is quite small and remains attached to gametophytes throughout its short lifetime (see Figures 29.4, 29.5, and 29.7). Plant biologists consider bryophyte gametophytes to be the dominant generation in their life cycle (Figure 29.8a). By contrast, in other plants the sporophyte generation is dominant (Figure 29.8b, c).

Bryophyte sporophytes are small; they remain attached to parental gametophytes, are unable to branch, and have short lifetimes. At their tips, bryophyte sporophytes produce only a single sporangium containing a limited number of spores. By contrast, the sporophytes of other land plants become independent, and because they can branch, they can continue to grow and produce sporangia on lateral branches, often for many years (Figure 29.8c). In all land plants except bryophytes, the sporophyte generation is the dominant generation, meaning that it is larger, more complex, and longer-lived than the gametophyte.

Yet another distinguishing feature of bryophytes is that they lack tissues that both provide structural support and serve in conduction of water and nutrients, known as **vascular tissues**. Although the gametophytes of some bryophytes display simple conducting tissues, these do not provide much structural support; other types of cells provide support. Thus, bryophytes are informally known as **nonvascular plants**. As mentioned, other modern plant phyla are collectively and informally known as **vascular plants** because they produce vascular tissues that function in both conduction and support.

Lycophytes and Pteridophytes Are Vascular Plants That Do Not Produce Seeds

If you take a look outside, most of the plants in view are probably vascular plants. Their dominant sporophyte, presence of vascular tissue, and the ability to branch allow most of these plants to grow much taller than bryophytes and to produce more spores. As a result, vascular plants are more prominent than bryophytes in most modern plant communities.

Vascular plants have been important to Earth's ecology for several hundreds of millions of years. Fossils tell us that the first vascular plants appeared later than the earliest bryophytes (see Section 29.2) and that several early vascular plant lineages became extinct. Molecular data indicate that the lycophytes are the oldest phylum of living vascular plants and that pteridophytes are the next oldest (see Figure 29.1). In the past, lycophytes were very diverse and included tall trees that contributed importantly to coal deposits, but the tree lycophytes became extinct, and now only about 1,000

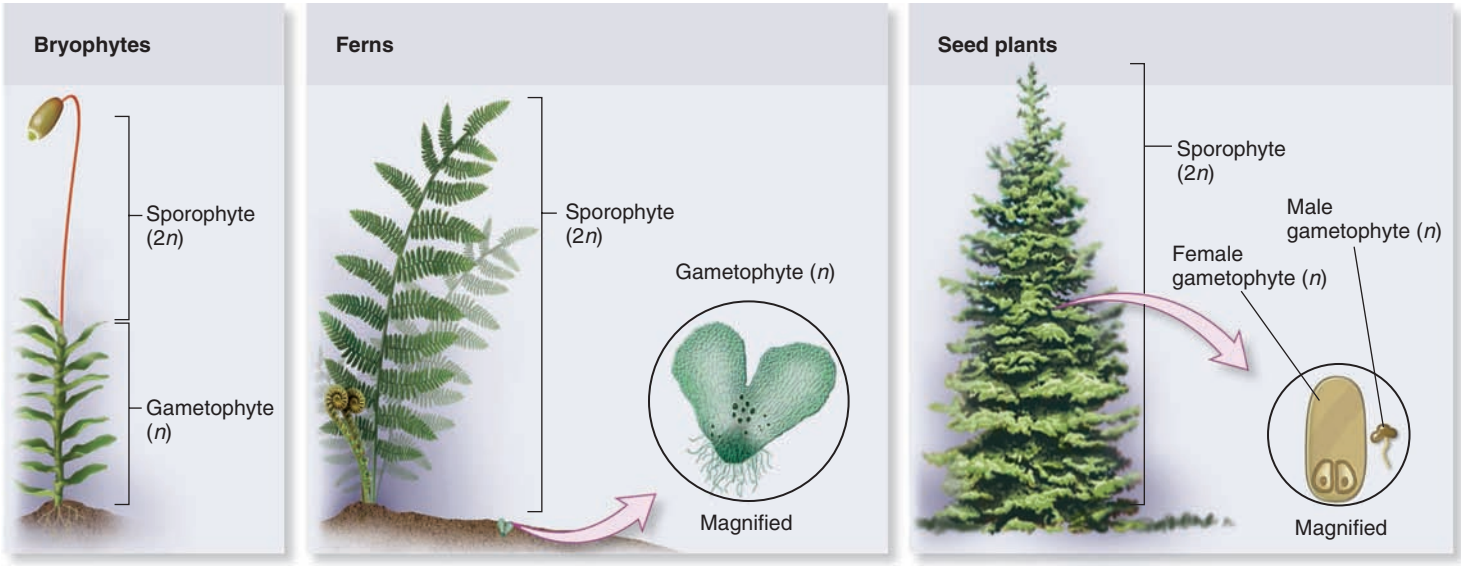

Figure 29.8 **Relative sizes of the sporophyte and gametophyte generations of bryophytes, ferns, and seed plants.**

Concept Check: *What is the advantage to ferns and seed plants of having larger sporophytes relative to those of bryophytes?*

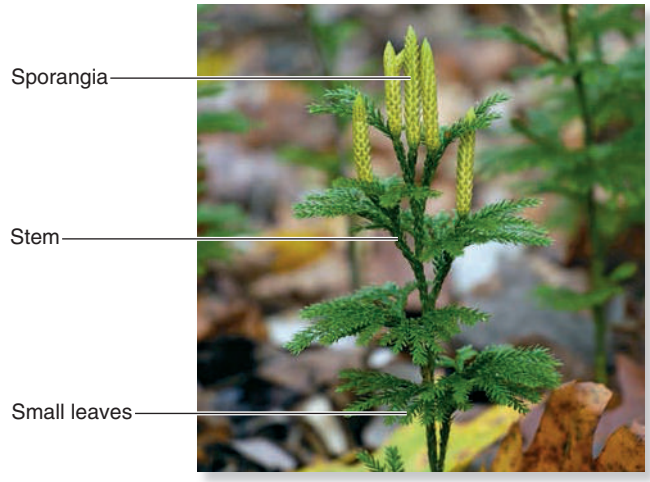

Figure 29.9 An example of a lycophyte (*Lycopodium obscurum*). The sporophyte stems bear many tiny leaves, and sporangia generally occur in club-shaped clusters. For this reason, lycophytes are often referred to as club mosses or spike mosses, though they are not true mosses. The gametophytes of lycophytes are small structures that often occur underground, where they are better protected from drying.

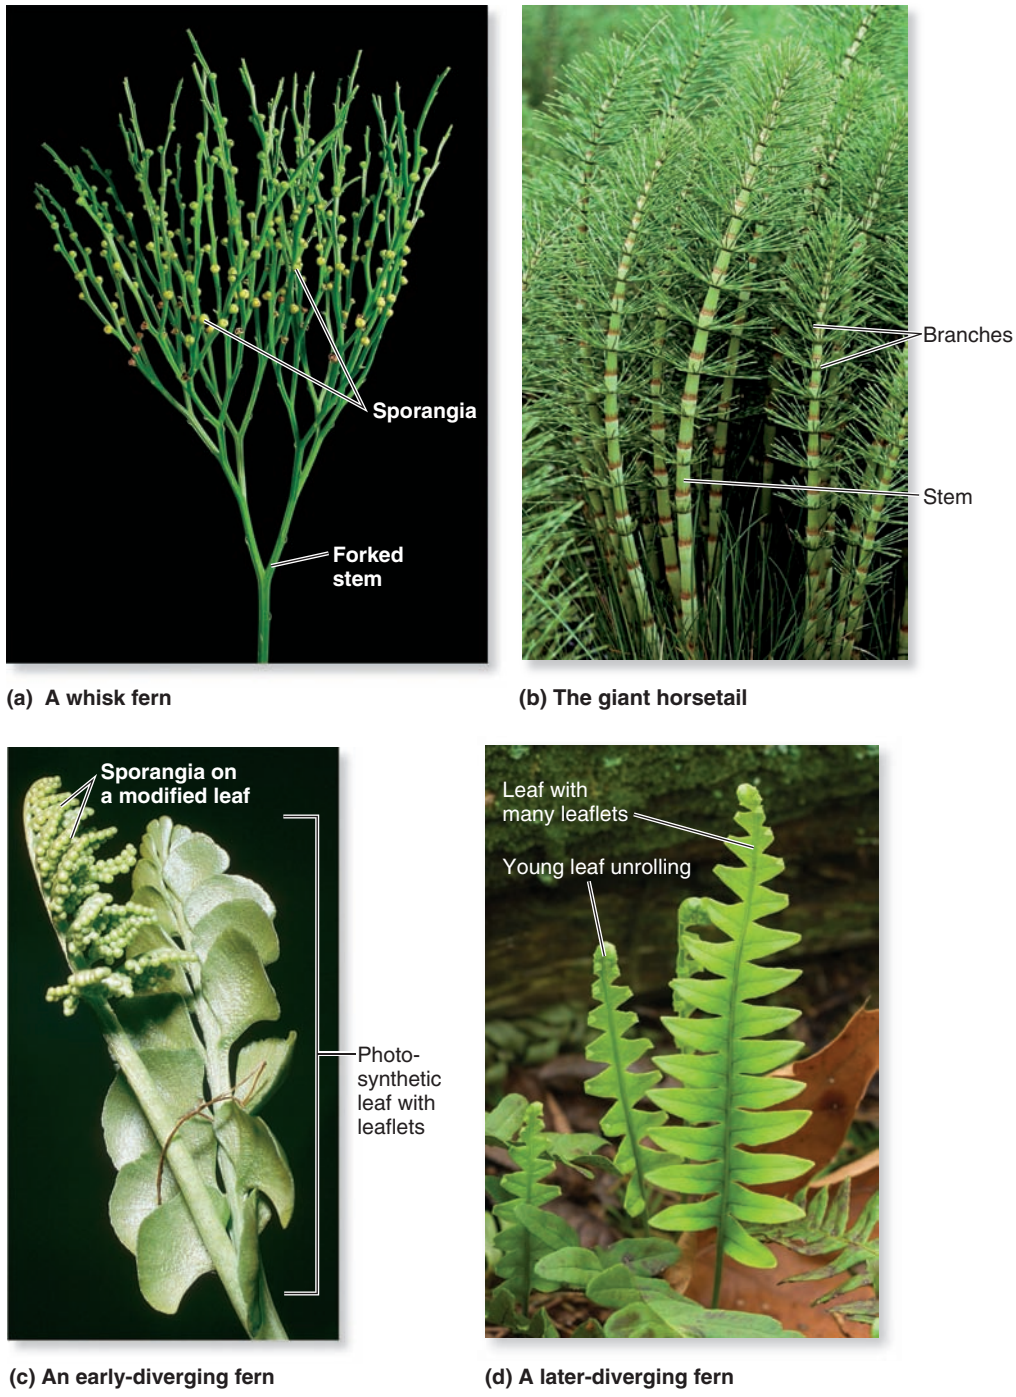
relatively small species exist (**Figure 29.9**). Pteridophytes have diversified more recently, and there are about 12,000 species of modern pteridophytes, including horsetails, whisk ferns, and other ferns (**Figure 29.10**).



Because the lycophytes and pteridophytes diverged prior to the origin of seeds, they are informally known as seedless vascular plants. Together, lycophytes, pteridophytes, and seed-producing plants are known as the **tracheophytes**. The latter term takes its name from **tracheids**, a type of specialized vascular cell that conducts water and minerals and provides structural support. Vascular tissues occur in the major plant organs: stems, roots, and leaves.

Stems, Roots, and Leaves **Stems** are branching structures that contain vascular tissue and produce leaves and sporangia. Stems contain the specialized conducting tissues known as **phloem** and **xylem**, the latter of which contains tracheids. Together, such conducting tissues enable vascular plants to conduct water, minerals, and organic compounds throughout the plant body. The xylem also provides structural support, allowing vascular plants to grow taller than nonvascular plants. This support function relies on the presence of a compression- and decay-resistant waterproof material known as **lignin**, which occurs in the cell walls of tracheids and some other types of plant cells. Most vascular plants also produce **roots**—organs specialized for uptake of water and minerals from the soil—and **leaves**, flattened plant organs that emerge from stems and generally have a photosynthetic function.

Lycophyte roots and leaves differ from those of pteridophytes. For example, lycophyte roots fork at their tips, whereas roots of pteridophytes branch from the inside like the roots of seed plants (see Figure 35.25). Lycophyte leaves are relatively small and possess only one unbranched vein, whereas pteridophyte leaves are larger and have branched veins, as do those of seed plants (compare Figures 29.9 and 29.10d). The evolutionary origins of leaves are discussed in Section 29.4.

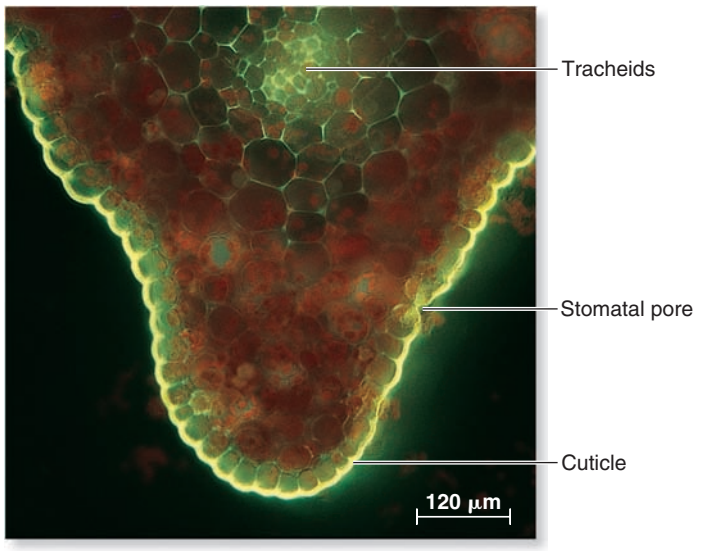
Adaptations That Foster Stable Internal Water Content In relatively dry habitats, lycophytes, pteridophytes, and other vascular plants are able to grow to larger sizes and remain metabolically active for longer periods than bryophytes. Vascular plants have these advantages because they are better able to maintain a stable internal water content by means of several adaptations, including conducting tissues (discussed earlier), a waxy cuticle, and stomata. A protective waxy **cuticle** is present on most surfaces of vascular plant sporophytes (**Figure 29.11a**). The plant cuticle contains a polyester polymer known as cutin, which helps to prevent attack by pathogens, and wax, which helps to prevent desiccation (drying out). The surface tissue of vascular plant stems and leaves contains many **stomata** (singular, stoma or stomate)—pores that are able to open and close (**Figure 29.11b**). Stomata allow plants to take in the carbon dioxide needed for photosynthesis and release oxygen to the air, while conserving water. When the environment is moist, the pores open, allowing gas exchange to occur. When the environment is very dry, the pores close, thereby reducing water loss (more information about stomata can be found in Chapters 35 and 38). Though a cuticle and stomata occur in bryophytes, they are not as common as in vascular plants, and bryophytes easily become dry. In vascular plants, conducting tissues, a waxy cuticle, and stomata function together to maintain moisture homeostasis, allowing tracheophytes to exploit a wider spectrum of land habitats.

Life Cycle Lycophyte and pteridophyte gametophytes are small, delicate, and easily harmed by exposure to heat and drought. This explains why the gametophytes of lycophytes and pteridophytes are restricted to moist places, often existing underground, and why they have short lifetimes. Lycophyte and pteridophyte sperm are released from antheridia into water films, within which they swim to eggs in archegonia (**Figure 29.12**, step 6). For this reason, lycophyte and pteridophyte reproduction is limited by dry conditions, as is the case for bryophytes. However, if fertilization occurs, lycophytes and pteridophytes can produce many more spores, because the spore-producing sporophyte generation grows to a much larger size than do bryophyte sporophytes. This fundamental difference has two consequences. First, vascular plant sporophytes depend on maternal gametophytes for only a short time during early embryo development; they eventually become independent by developing a first leaf and roots able to harvest resources needed for photosynthesis (Figure 29.12, step 8). Second, the stems of vascular plant sporophytes are able to produce branches, forming relatively large adult plants having many leaves. Roots obtain large amounts of soil water and minerals, supporting the ability of leaves to generate abundant organic compounds by photosynthesis. Lycophytes and pteridophytes use such resources to produce large numbers of sporangia that eject multitudes of spores. You might have seen clusters of sporangia as dark brown dots or lines on the undersides of fern leaves. Dispersed by the wind, spores may land

(a) A whisk fern

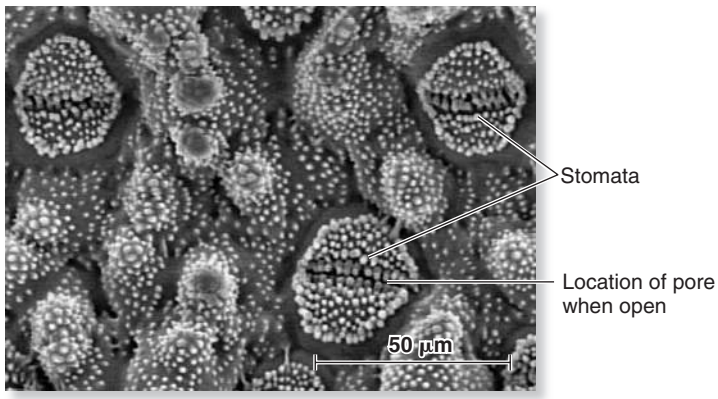
(b) The giant horsetail

(c) An early-diverging fern



(d) A later-diverging fern

Figure 29.10 Pteridophyte diversity. **(a)** The leafless, rootless green stems of the whisk fern (*Psilotum nudum*) branch by forking and bear many clusters of yellow sporangia that disperse spores via wind. The gametophyte of this plant is a tiny pale structure that lives underground in a symbiotic partnership with fungi. **(b)** The giant horsetail (*Equisetum telmateia*) displays branches in whorls around the green stems. The leaves of this plant are tiny, light brown structures that encircle branches at intervals. This plant produces spores in cone-shaped structures, and the wind-dispersed spores grow into small green gametophytes. **(c)** The early-diverging fern *Botrychium lunaria*, showing a green photosynthetic leaf with leaflets and a modified leaf that bears many round sporangia. **(d)** The later-diverging fern *Blechnum capense*, viewed from above, showing a whorl of young leaves that are in the process of unrolling from the bases to the tips. The leaves have many leaflets. The stem of this fern grows parallel to the ground and thus is not shown. Most ferns produce spores in sporangia on the undersides of leaves.



in a suitable place and grow into new gametophytes, completing the life cycle.

Gymnosperms and Angiosperms Are the Modern Seed Plants

Among the vascular plants, the seed plant phyla dominate most modern landscapes. The modern seed plant phyla commonly known as cycads, ginkgos, conifers, and gnetophytes are collectively referred to as gymnosperms (**Figure 29.13** shows an example). **Gymnosperms** reproduce using both spores and seeds, as do the flowering plants, the angiosperms (**Figure 29.14**). For this reason, gymnosperms and angiosperms are known informally as the **seed plants**. **Seeds** are complex structures having specialized tissues that protectively enclose embryos and contain stores of carbohydrate, lipid, and protein. Embryos use such food stores to grow and develop. As discussed in Section 29.4, the ability to produce seeds helps to free seed plants from the reproductive limitations experienced by the seedless plants, revealing why seed plants are the dominant plants on Earth today.

(a) Stem showing tracheophyte adaptations

(b) Close-up of stomata

Figure 29.11 A pteridophyte stem with tracheophyte adaptations for transporting and conserving water. **(a)** A cross section through a stem of the pteridophyte *Psilotum nudum*. When viewed with fluorescence microscopy and illuminated with violet light, an internal core of xylem tracheids glows yellow, as does the surface cuticle. **(b)** Surface pores associated with specialized cells—the complexes known as stomata—allow for gas exchange between plant and atmosphere. This image lacks color because it was made with a scanning electron microscope (SEM), which uses electrons rather than visible light to form magnified images.

BIOLOGY PRINCIPLE Living organisms maintain homeostasis. The structures illustrated in this figure explain how vascular land plants maintain homeostasis in water content.

In addition to the modern seed plant phyla, several additional phyla once existed and left fossils but are now extinct. Collectively, all of the living and fossil seed plant phyla are formally known as **spermatophytes** (the prefix sperm-, from the Greek, means seed) (see Figure 29.1). Many spermatophytes have the capacity to produce wood. Wood is composed of xylem, a tissue whose cellulose-rich cell walls also contain lignin. Functioning something like superglue, lignin cements the microfibrils of cellulose together, making wood exceptionally strong. Wood production enables plants to increase in girth and become tall. Though not all modern seed plants produce wood, many are trees or shrubs that do (described more completely in Chapters 30, 35, and 38).

The angiosperms are distinguished by the presence of flowers, fruits, and a specialized seed tissue known as endosperm. A **flower** is a short stem bearing reproductive organs that are specialized in ways that enhance seed production (see Figure 29.14). **Fruits** are structures that develop from flowers, enclose seeds, and foster seed dispersal in the environment. The term angiosperm comes from the Greek, meaning enclosed seeds, reflecting the observation that the flowering plants produce seeds within fruits. **Endosperm** is a nutritive seed tissue that increases the efficiency with which food is stored in the seeds of flowering plants (explained further in Section 29.4). Flowers, fruits, and endosperm are defining features of the angiosperms, and they are integral components of animal nutrition.

Though gymnosperms produce seeds and many are woody plants, they lack flowers, fruits, and endosperm. The term gymnosperm comes from the Greek, meaning naked seeds, reflecting the observation that gymnosperm seeds are not enclosed within fruits. Despite their lack of flowers, fruits, and seed endosperm, the modern gymnosperms are diverse and abundant in many places (see Chapter 30).

Genomes & Proteomes Connection

Comparison of Plant Genomes Reveals Genetic Changes That Occurred During Plant Evolution

The first complete genome sequence for a seedless vascular plant was reported for the lycophyte *Selaginella moellendorffii* by Jody Banks at Purdue University and coworkers in 2011. This advance allowed plant evolutionary biologists to compare the new sequence with previously sequenced plant genomes, with the goal of identifying genes associated with major evolutionary transitions in plants.

Such genome comparisons revealed that 6,820 gene families, representing a basic set of embryophyte genes, are present in all land plants. The majority of gene families that are involved in flowering plant development were also observed in the lycophyte *Selaginella* and the bryophyte *Physcomitrella*, a moss. A comparison of the genomes of *Selaginella* and *Physcomitrella* indicated that 516 genes were gained and 89 genes were lost during the transition from nonvascular, gametophyte-dominant plants (bryophytes) to vascular, sporophyte-dominant plants (lycophytes). By contrast, 1,350 more genes were gained in the evolution of traits specific to angiosperms. These data indicate that the transition from bryophyte to lycophyte was less genetically complex than was the transition from lycophyte to angiosperm.

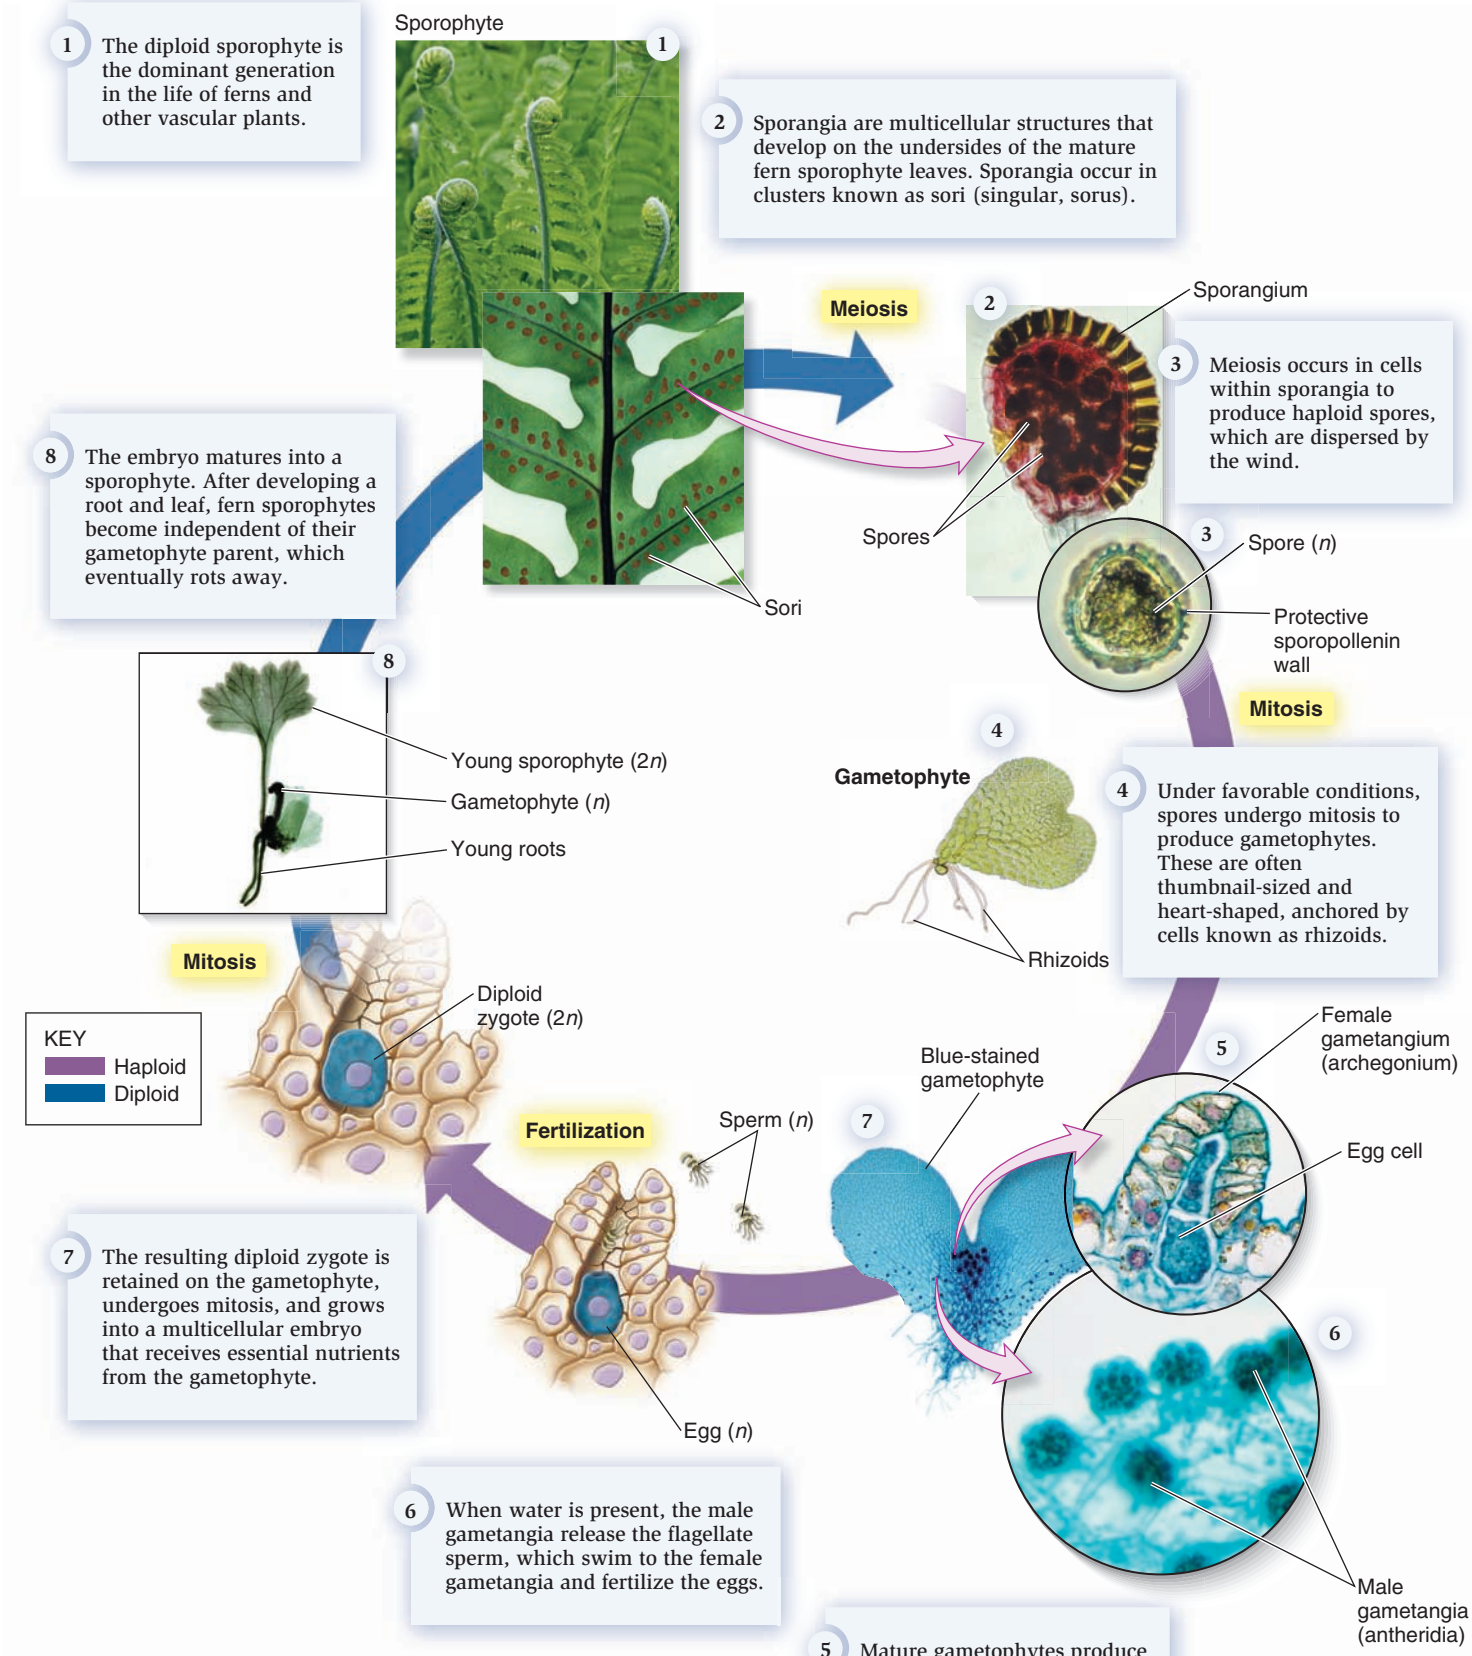


Figure 29.12 The life cycle of a typical fern. The fern life cycle is often used to illustrate plant alternation of generations because both sporophyte and gametophyte are large enough for people to see with the unaided eye.

Figure 29.13 **An example of a gymnosperm, the pine (*Pinus*).**

Concept Check: *What key characteristics of spermatophytes are displayed in this image?*

29.2 An Evolutionary History of Land Plants

Learning Outcome:

1. Describe how two major events in plant history affected other life on Earth.

A billion years ago, Earth's terrestrial surface was comparatively devoid of life. Green or brown crusts of cyanobacteria most likely grew in moist places, but there would have been very little soil, no plants, and no animal life. The origin of the first land plants was essential to development of the first substantial soils, the evolution of modern plant communities, and the ability of animals to colonize land.

How can we know about events such as the origin and diversification of land plants? Some information comes from comparing molecular and other features of modern plants. For example, the genome sequence of the moss *Physcomitrella patens*, first reported in 2007, reveals the presence of genes that aid heat and drought tolerance, which are especially useful in the terrestrial habitat. Plant fossils, the preserved remains of plants that lived in earlier times, provide further information (**Figure 29.15**). The distinctive plant materials sporopollenin, cutin, and lignin do not readily decay and therefore foster the fossilization of plant parts that contain these tough materials.

The study of fossils and the molecular, structural, and functional features of modern plants has revealed an amazing story—how plants gradually acquired adaptations, allowing them to conquer the land. Next we will explore how seedless plants transformed Earth's ecology, and how an ancient cataclysm led to the diversification of modern angiosperm lineages.

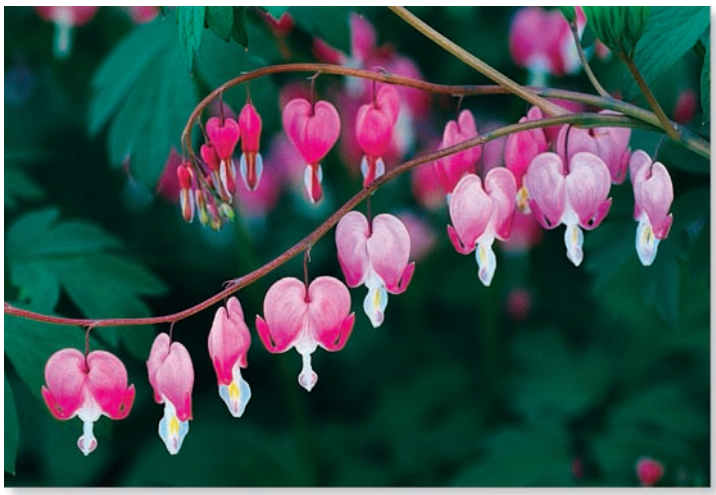

Figure 29.14 **An example of an angiosperm, the bleeding heart plant (genus *Dicentra*).**

Figure 29.15 **Fossil of *Pseudosalix handleyi*, an angiosperm.**

Concept Check: *What biochemical components of plants favor the formation of fossils?*

Seedless Plants Transformed Earth's Ecology

Several types of decay-resistant tissues evolved in early seedless plants, likely in response to attack by soil bacteria and fungi. When the plants died, some of their organic constituents were not completely degraded to carbon dioxide (CO_2), but instead were buried in sediments that were eventually transformed into rock. Such fossil carbon can accumulate and remain buried for very long time periods, with the consequence that the amount of CO_2 in the atmosphere declined. CO_2 is a greenhouse gas, meaning that an increase in its concentration warms the atmosphere, thereby influencing climate. Throughout their evolutionary history, plants have influenced Earth's climate by reducing the concentration of atmospheric CO_2, and they continue to do so today.

Ecological Effects of Ancient and Modern Bryophytes Modern bryophytes play important roles by storing CO_2 as decay-resistant organic compounds, suggesting that ancient relatives likewise played this role. Plants of the modern moss genus *Sphagnum* contain so much decay-resistant body mass that in many places, dead moss has accumulated over thousands of years, forming deep peat deposits. By storing very large amounts of organic carbon for long periods, *Sphagnum* helps to keep Earth's climate steady. Under cooler than normal conditions, *Sphagnum* grows more slowly and thus absorbs less CO_2, allowing atmospheric CO_2 to rise a bit, warming the climate a little. As the climate warms, *Sphagnum* grows faster and sponges up more CO_2, storing it in peat deposits. Such a reduction in atmospheric CO_2 returns the climate to slightly cooler conditions. In this way, ancient and modern peat mosses have helped to keep the world's climate from changing dramatically. Today, experts are concerned that large regions dominated by peat mosses are being affected by changes in land use, harvesting of peat, and other environmental alterations that could reduce the mosses' ability to moderate Earth's climate.

Ecological Effects of Ancient Vascular Plants Fossils tell us that extensive forests dominated by tree-sized lycophytes, pteridophytes, and early seed plants occurred in widespread swampy regions during the warm, moist Carboniferous period (354–290 mya) (**Figure 29.16**). As dead plants fell into the water, low oxygen levels there inhibited microbes that would have caused the plant matter to decay. The dead plants were then buried in sediments that later formed coal. Much of today's coal is derived from the abundant remains of ancient plants, explaining why the Carboniferous is commonly known as the Coal Age. During that period, plants converted huge amounts of the atmospheric CO_2 into decay-resistant organic materials such as lignin. Long-term burial of these materials, compressed into coal, together with chemical interactions between soil and the roots of vascular plants, dramatically changed Earth's atmosphere and climate. The removal of large amounts of the greenhouse gas CO_2 from the atmosphere by plants had a cooling effect on the climate, which also became drier because cold air holds less moisture than warm air.

Mathematical models of ancient atmospheric chemistry, supported by measurements of natural carbon isotopes, led American paleoclimatologist Robert A. Berner to propose that the Carboniferous proliferation of vascular plants was correlated with a dramatic decrease in atmospheric CO_2, which reached the lowest known levels about 290 mya (**Figure 29.17**). During this period of very low CO_2, atmospheric O_2 levels rose to the highest known levels, because less O_2 was being used to convert organic carbon into CO_2. High atmospheric O_2 content has been invoked to explain the occurrence of

Figure 29.16 Reconstruction of a Carboniferous (Coal Age) forest. This ancient forest was dominated by tree-sized lycophytes and pteridophytes, which later contributed to the formation of large coal deposits.

Concept Check: *Why did giant dragonflies occur during the Carboniferous, but not now?*

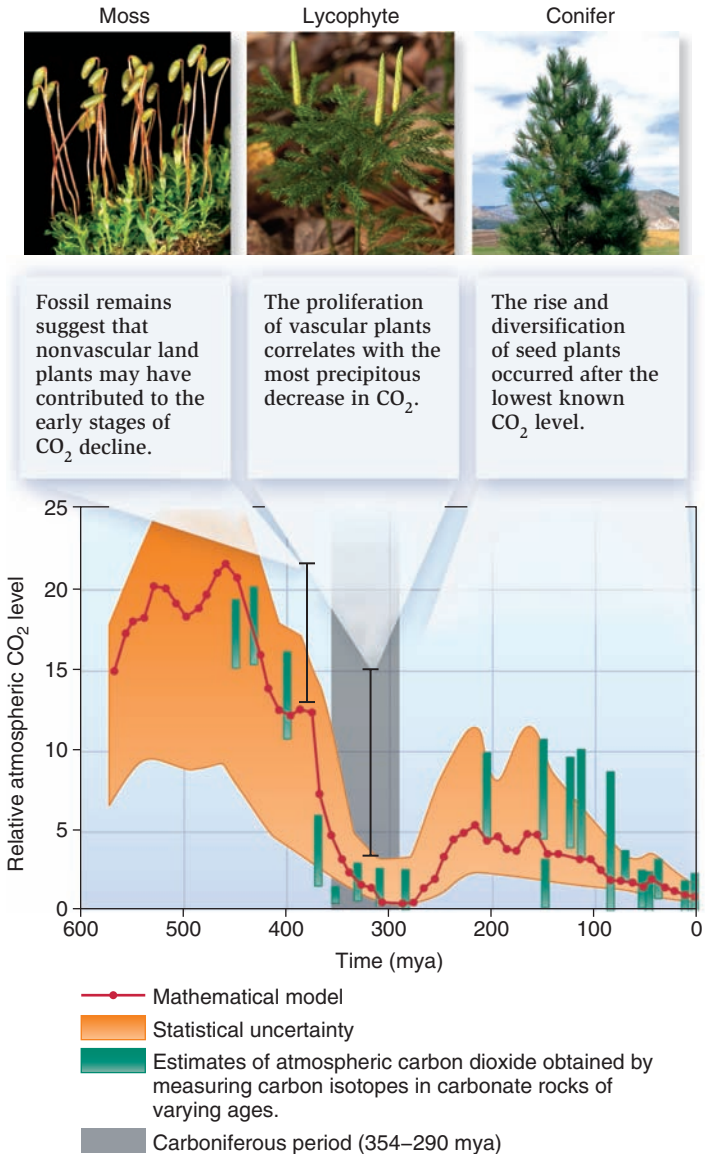

Figure 29.17 Changes in Earth's atmospheric carbon dioxide levels over geological time. Geological evidence indicates that carbon dioxide levels in Earth's atmosphere were once higher than they are now, but that the rise of land plants caused atmospheric CO_2 to reach the lowest known level about 300 mya.

giant Carboniferous dragonflies and other huge insects. The great decline in CO_2 level ultimately caused cool, dry conditions to prevail in the late Carboniferous and early Permian periods. As a result of this relatively abrupt global climate change, many of the tall seedless lycophytes and pteridophytes that had dominated earlier Carboniferous forests became extinct, as did organisms such as the giant dragonflies. Cooler, drier conditions favored extensive diversification of the first seed plants, the gymnosperms. Compared with seedless plants, seed plants were better at reproducing in cooler, drier habitats (as we will see in Section 29.4). As a result, seed plants came to dominate Earth's terrestrial communities, as they continue to do.

An Ancient Cataclysm Marked the Rise of Angiosperms

Diverse phyla of gymnosperms dominated Earth's vegetation through the Mesozoic era (248–65 mya), which is sometimes called the Age of Dinosaurs. In addition, fossils provide evidence that early mammals and flowering plants existed in the Mesozoic. Gymnosperms and early angiosperms were probably sources of food for early mammals as well as for herbivorous dinosaurs. For examples, fossils of an aquatic angiosperm named *Cobbania* have been found with bones of the dinosaur *Ornithomimus* in Dinosaur Park, Alberta, Canada. This dinosaur may have fed on the plant when alive (**Figure 29.18**).

One fateful day about 65 mya, disaster struck from the sky, causing a dramatic change in the types of plants and animals that dominated terrestrial ecosystems. That day, at least one large meteorite crashed into the Earth near the present-day Yucatán Peninsula in Mexico. This episode is known as the **Cretaceous-Paleogene event** (also sometimes referred to as the K/T event). The impact, together with substantial volcanic activity that also occurred at this time, is thought to have produced huge amounts of ash, smoke, and haze that dimmed the Sun's light long enough to kill many of the world's plants. Many types of plants, including *Cobbania*, became extinct, though some survived and their descendants persist to the present time. With a severely reduced food supply, most dinosaurs were also doomed, the exceptions being their descendants, the birds. The demise of the dinosaurs left room for birds and mammals to adapt to many kinds of terrestrial habitats formerly inhabited by dinosaurs.

Figure 29.18 Early angiosperms, sources of food for large herbivorous dinosaurs of the Mesozoic era. In this artist's habitat reconstruction from fossils, the extinct angiosperm *Cobbania corrugata* is shown growing in wetlands that were also inhabited by large dinosaurs such as *Ornithomimus*, whose head is illustrated here.

After the Cretaceous-Paleogene event, ferns dominated long enough to leave huge numbers of fossil spores, and then surviving groups of flowering plants began to diversify into the space opened up by the extinction of earlier plants. The rise of angiosperms fostered the diversification of beetles (see Chapter 33) and other types of insects that associate with modern plants.

Our brief survey of plant evolutionary history reveals some important concepts. Although environment certainly influenced the diversification of plants, plant diversification also changed Earth's environment in ways that affected the evolution of other organisms. In addition, plant evolutionary history serves as essential background for a closer focus on the evolution of critical innovations, new features that foster the diversification of phyla. Among the critical innovations that appeared during the evolutionary history of plants, embryos, leaves, and seeds were particularly important.

29.3 The Origin and Evolutionary Importance of the Plant Embryo

Learning Outcomes:

1. Outline how plant embryos might have evolved, and explain why.
2. **SciSKILLS** » Analyze the results of Browning and Gunning, and explain the role of placental transfer tissues in the movement of nutrients from mother plant to embryo.

The embryo was one of the first critical innovations acquired by land plants (see Figure 29.1). Recall that plant embryos are young sporophytes that develop from zygotes and are enclosed by maternal tissues that provide sustenance. The presence of an embryo is critical to plant reproduction in terrestrial environments. Drought, heat, UV light, and microbial attack could kill delicate plant egg cells, zygotes, and embryos if these were not protected and nourished by enclosing maternal tissues. The first embryo-producing plants diversified into hundreds of thousands of diverse modern species, as well as many species that have become extinct. A closer look at embryos reveals why their origin and evolution are so important to all land plants.

Plant Embryos Grow Protected Within the Maternal Plant Body

A plant embryo has several characteristic features, some of which were previously described. First, plant embryos are multicellular and diploid (see Section 29.1). Plant embryos develop by repeated mitosis from a single-celled zygote resulting from fertilization (see Figure 29.6b). In addition, plant eggs are fertilized while still enclosed by the maternal plant body, and embryos begin their development within the protective confines of maternal tissues (see Figure 29.7). Plant biologists say that plants retain their zygotes and embryos. Third, plant embryo development depends on organic and mineral materials supplied by the mother plant. Nutritive tissues composed of specialized **placental transfer tissues** aid in the transfer of nutrients from mother to embryo. Taking a closer look at placental transfer tissues reveals their valuable role.

Placental transfer tissues function similarly to the placenta present in most mammals, which fosters nutrient movement from the mother's bloodstream to the developing fetus. Plant placental transfer tissues often occur in haploid gametophyte tissues that lie closest to embryos and in the diploid tissues of young embryos themselves. Such transfer tissues contain cells that are specialized in ways that promote the movement of solutes from gametophyte to embryo. For example, the cells of placental transport tissues display complex arrays of finger-like cell-wall ingrowths (**Figure 29.19**). Because the plant plasma membrane lines the plant cell wall, the ingrowths vastly increase the surface area of the plasma membrane. This increase allows for more abundant membrane transport proteins, which move solutes into and out of cells. With more transport proteins present, materials can move at a faster rate from one cell to another. (Similar finger-like structures in animal intestines and placenta likewise foster nutrient flow by increasing cellular surface area.) Classic experiments have revealed that dissolved sugars, amino acids, and minerals first move from maternal plant cells into the intercellular space between maternal tissues and the embryo. Then, transport proteins in the membranes of nearby embryo cells efficiently import the nutrients into the embryo.

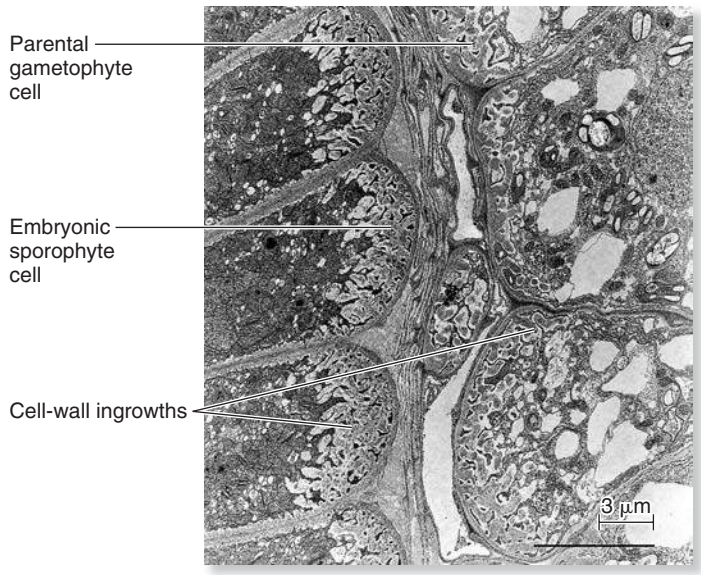

Figure 29.19 Placental transfer tissue from a plant in the liverwort genus *Monoclea*.

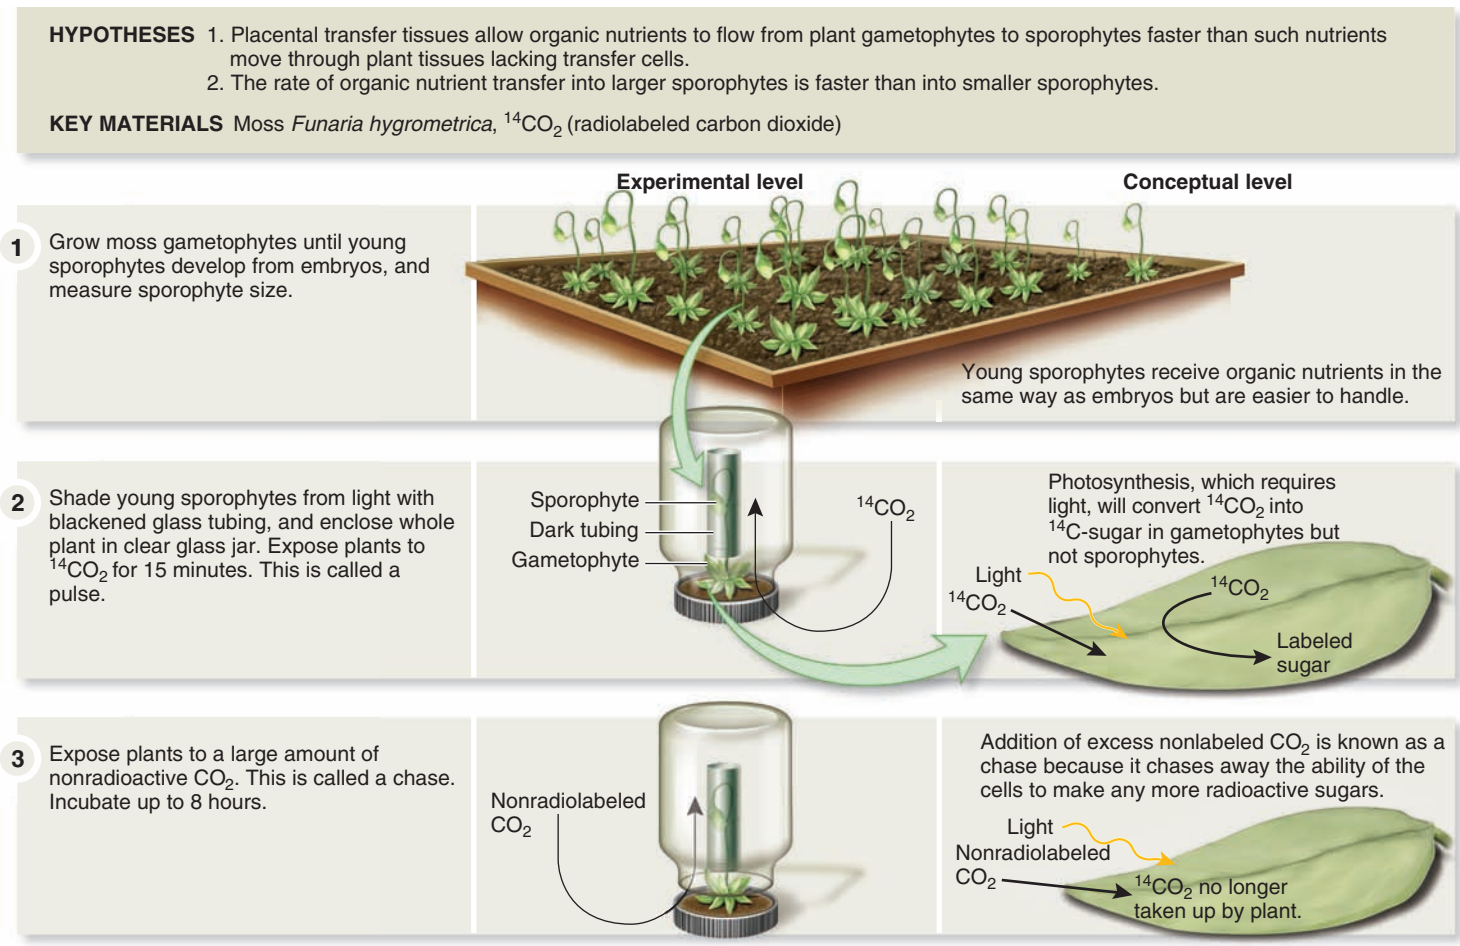
BIOLOGY PRINCIPLE Structure determines function. This TEM shows that placental transfer tissues contain specialized cells having extensive finger-shaped cell-wall ingrowths. Similar cells occur in all plants and help nutrients to move rapidly from parental gametophytes to embryonic sporophytes, a process that fosters plant reproductive success.

BioConnections: Look ahead to Figures 45.6 and 51.10b. How do similar finger-like projections in animal intestines and placenta foster rapid movement of nutrients?

Feature Investigation | Browning and Gunning Demonstrated That Placental Transfer Tissues Facilitate the Movement of Organic Molecules from Gametophytes to Sporophytes



In the 1970s, plant cell biologists Adrian Browning and Brian Gunning explored the function of placental transfer tissues. Using a simple moss experimental system, they investigated the rate at which radiolabeled carbon moves through placental transfer tissues from green gametophytes into young sporophytes. Recall that embryos are very young, few-celled sporophytes and that in mosses and other bryophytes, all stages of sporophyte development are nutritionally dependent on gametophyte tissues. Browning and Gunning investigated nutrient flow into young sporophytes because these slightly older and larger developmental stages were easier to manipulate in the laboratory than were tiny embryos.

In a first step, the investigators grew many gametophytes of the moss *Funaria hygrometrica* in a greenhouse until young sporophytes developed as the result of sexual reproduction (**Figure 29.20**).

In a second step, they placed black glass tubing over young sporophytes as a shade to prevent photosynthesis, enclosed the whole plants—gametophytes and their attached sporophytes—within transparent jars, and supplied the plants with radiolabeled carbon dioxide ($^{14}CO_2$) for measured time periods known as pulses. Because the moss gametophytes were not shaded, their photosynthetic cells were able to convert the $^{14}CO_2$ into labeled organic compounds, such as sugars and amino acids. Shading prevented the young sporophytes, which possess some photosynthetic tissue, from using the $^{14}CO_2$ to produce organic compounds.

In a third step, the researchers added an excess amount of nonradioactive CO_2 to prevent the further uptake of the $^{14}CO_2$ from their experimental system, a process known as a chase. This process stopped the radiolabeling of photosynthetic products because the vast

Figure 29.20 **Browning and Gunning demonstrated that placental transfer tissues increase plant reproductive success.**

4 Pluck young sporophytes of differing sizes from gametophytes. Assay ^{14}C in both sporophytes and gametophytes using a scintillation counter. This was done immediately following the chase, and at 2 or 8 hours after the chase.

Scintillation counter

Determine how much organic carbon flowed into sporophytes during each chase time.

5 THE DATA I

Organic carbon transfer from gametophyte to sporophyte:

Mean ^{14}C content of 5 gametophytes at 0 chase time	Mean ^{14}C lost from gametophytes after 8-hour chase	Mean ^{14}C gained by sporophytes after 8-hour chase
228 units	145 units	51 units

6 THE DATA II

Sporophyte size effect:

Sporophyte size	Mean ^{14}C content of 8 sporophytes after 2-hour chase
5–7 mm	8.47 ± 4.29 units
11–13 mm	9.93 ± 3.94 units
23–25 mm	24.97 ± 5.30 units

7 CONCLUSION Organic carbon moves from photosynthetic gametophytes into developing sporophytes, facilitated by placental transfer tissues. Larger sporophytes absorb more organic carbon than smaller ones.

majority of CO_2 taken up was now unlabeled. (Experiments such as these are known as pulse-chase experiments.) In a final step, Browning and Gunning plucked young sporophytes of different sizes (ages) from the gametophytes and measured the amount of $^{14}CO_2$ present in the separated gametophyte and sporophyte tissues at various times following the chase.

From these data, they were able to calculate the relative amount of organic carbon that had moved from the photosynthetic moss gametophytes to their sporophytes. Browning and Gunning discovered that about 22% of the organic carbon produced by gametophyte photosynthesis was transferred to the young sporophytes during an 8-hour chase period (see data set I in Figure 29.20). They also calculated the rate of nutrient transfer from gametophyte to sporophyte and compared this rate with the rate (determined in other studies) at which organic carbon moves within several other plant tissues that lack specialized transfer cells. Browning and Gunning discovered that organic carbon moved from moss gametophytes to young sporophytes nine times faster than organic carbon moves within these other plant tissues. These investigators inferred that the increased rate of nutrient movement could be attributed to placental transfer cell structure, namely, the fact that cell-wall ingrowths enhanced plasma membrane surface area. By comparing the amount of radioactive carbon accumulated by sporophytes of differing sizes, they also learned that larger sporophytes absorbed $^{14}CO_2$ about three times faster than smaller ones.

These data are consistent with the hypothesis that placental transfer tissues increase plant reproductive success by providing embryos and growing sporophytes with more nutrients than they would otherwise receive. Supplied with the greater amounts of nutrients, sporophytes are able to grow larger than they otherwise would, and eventually they produce more progeny spores.

Experimental Questions

1. What were the goals of the Browning and Gunning investigation?
2. **SciSKILLS »** How did Browning and Gunning prevent photosynthesis from occurring in moss sporophytes during the experiment (shown in Figure 29.20), and why did they do this?
3. **SciSKILLS »** How did the measurements Browning and Gunning made after adding an excess amount of unlabeled CO_2 lead them to their conclusions?

BIO TIPS **THE QUESTION** *The experiment by Browning and Gunning revealed that larger moss sporophytes import more organic carbon from gametophytes than do smaller sporophytes. How much more organic carbon do the larger sporophytes take up, and why do they take up more?*

TOPIC ***What topic in biology does this question address?*** The topic is the function of plant placental tissues in transferring organic carbon into embryonic sporophytes, a feature that increases fitness in all groups of land plants. More specifically, the question concerns the transfer of organic carbon into moss sporophytes of different sizes, which represent stages of developmental maturity.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** You know that all cells require organic compounds for use as food and that photosynthetic cells are able to generate organic compounds from inorganic compounds in the presence of light. Thus, photosynthetic tissues are a potential source of food for plant tissues whose primary function is not photosynthesis, such as sporangia, which carry out spore production. In this chapter, you have learned that most of a moss sporophyte is a sporangium. Moss sporangia use organic carbon to fuel meiosis and spore production. From the Feature Investigation, you know that radiolabeled CO_2 can be used to reveal the movement of organic carbon within a plant.

PROBLEM-SOLVING STRATEGY ***Make a drawing. Interpret data. Use statistics.*** Data set II in Figure 29.20 shows the amounts of ^{14}C taken up by moss sporophytes of differing sizes. From these data, make histograms that include the observed variations. Use these histograms to determine how much more organic carbon is taken up by larger moss sporophytes than smaller ones. Suggest a reason for the difference.

ANSWER *The heights of the histogram bars for the two smaller-sized groups of sporophytes are similar and the variances overlap, indicating a lack of a significant statistical difference. The height of the histogram bar for the largest sporophytes is about twice that for the two groups of smaller sporophytes, and the variance for the largest sporophytes does not overlap those for the smaller sporophytes, suggesting a statistically significant difference. From this difference, you might infer that the metabolic demand for organic carbon becomes twice as large as the sporophyte reaches maturity and produces spores that are ready for dispersal. The cost of producing the tough spore coating, of sporopollenin, would be an additional metabolic demand. These increased metabolic demands as the sporophyte matures parallel those occurring during the course of animal pregnancy.*

29.4 The Origin and Evolutionary Importance of Leaves and Seeds

Learning Outcomes:

1. Describe how the leaves of ferns and seed plants likely evolved from branched-stem systems.
2. Discuss how seeds develop from fertilized ovules.
3. Name several advantages that seeds provide.
4. **SciSKILLS** » Make a drawing that illustrates the hypothetical steps in the evolution of seeds.

Like embryos, leaves and seeds are critical innovations that increased plant fitness and fostered diversification. Unlike the plant embryo, which likely originated just once at the birth of the plant kingdom, leaves and seeds probably evolved several times during plant evolutionary history. Comparative studies of diverse types of leaves and seeds in fossil and living plants suggest how these critical innovations might have originated.

The Large Leaves of Ferns Evolved from Branched-Stem Systems

Leaves are the solar panels of the plant world. Their flat structure provides a large surface area that helps effectively capture sunlight for use in photosynthesis. Among the vascular plants, lycophytes produce the simplest and most ancient type of leaves. Modern lycophytes have tiny leaves, known as **lycophylls** (also known as microphylls), which typically have only a single unbranched vein (**Figure 29.21a**). Some experts think that these small leaves may have evolved from sporangia.

In contrast, the leaves of ferns and seed plants have extensively branched veins. Such leaves are known as **euphylls** (from the Greek, meaning true leaves) (**Figure 29.21b**). The branched veins of euphylls are able to supply relatively large areas of photosynthetic tissue with water and minerals. Thus, euphylls are typically much larger than lycophylls, explaining why euphylls are also known as megaphylls. Euphylls provide considerable photosynthetic advantage to ferns and seed plants, because they provide more surface for solar energy capture than do small leaves. The evolution of relatively large leaves allowed plants to more effectively accomplish photosynthesis, enabling them to grow larger and produce more progeny.

Study of fern fossils indicates that euphylls likely arose from leafless, cylindrical, branched-stem systems by a series of steps (**Figure 29.21c**). First, one branch assumed the role of the main axis, while the other was reduced in size and became flattened in one plane, and then the spaces between the branches of this flattened system became filled with photosynthetic tissue. Such a process would explain why euphylls have branched vascular systems; individual veins apparently originated from the separate branches of an ancestral branched stem. Plant evolutionary biologists suspect that euphylls arose several times by means of similar, parallel processes, and that leaves of ferns and seed plants are not homologous structures.

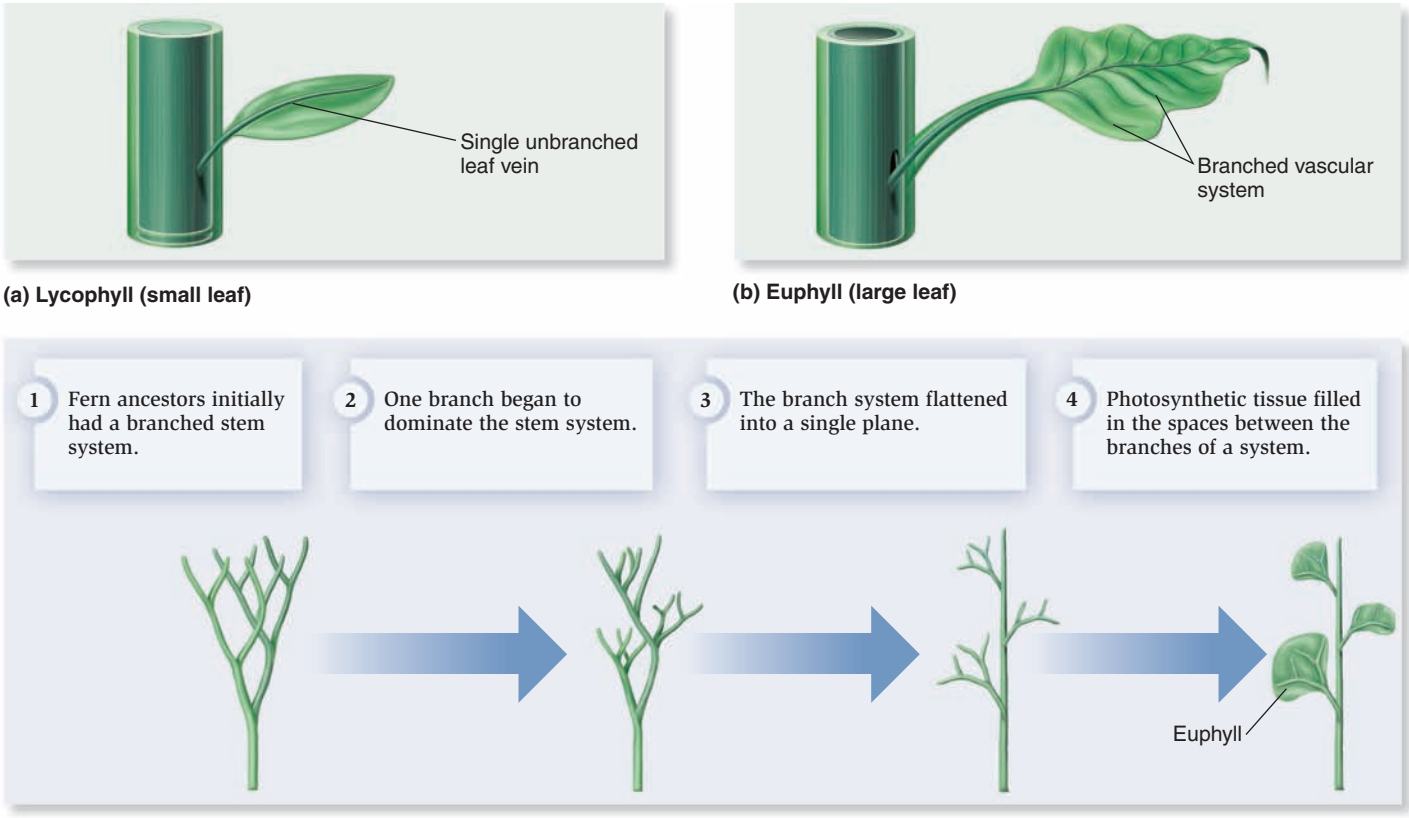

Figure 29.21 **Lycophylls and euphylls.** **(a)** Most lycophylls possess only a single unbranched leaf vein with limited conduction capacity, explaining why lycophylls are generally quite small. **(b)** Euphylls possess branched vascular systems with greater conduction capacity, explaining why many euphylls are relatively large. **(c)** Fossil evidence suggests how pteridophyte euphylls might have evolved from branched-stem systems.

Concept Check: *Imagine that the leaves of some other plant group evolved from stem systems that were more highly branched (that is, there were more branches per unit length of stem) than those of ferns. How do you think the leaves of such plants might differ from those of ferns?*

Seeds Develop from the Interaction of Ovules and Pollen

The seed plants dominate modern ecosystems, suggesting that seeds offer reproductive advantages. Seed plants are also the plants with the greatest importance to humans, as described in Chapter 30. For these reasons, plant biologists are interested in understanding why seeds are so advantageous and how they evolved. To consider these questions, we must first take a closer look at seed structure and development.

We noted earlier that all plants produce spores by meiosis within sporangia, and seed plants are no exception. However, seed plants produce two distinct types of spores in two types of sporangia, a trait known as **heterospory**, meaning different spores. Microsporangia produce small **microspores** that give rise to male gametophytes, which develop into pollen grains. Megasporangia produce larger **megaspores** that give rise to female gametophytes, which develop and produce eggs while enclosed by protective megaspore walls. The female gametophytes are not photosynthetic, so they need help in feeding the embryos that develop from fertilized eggs. Female gametophytes get this help by remaining attached to the previous sporophyte generation, which provides gametophytes with the nutrients needed for embryo development.

Plants produce seeds by reproductive structures known as ovules and pollen that are unique to seed plants. An **ovule** is a sporangium that typically contains only a single spore that develops into a very small egg-producing gametophyte; the entire structure is enclosed by leaflike structures known as **integuments** (**Figure 29.22a**). You can think of an ovule as being like a nesting doll with four increasingly smaller dolls inside. The smallest doll corresponds to an egg cell; intermediate-sized dolls represent the gametophyte, spore wall, and megasporangium; and the largest doll represents the integuments. Fertilization converts such layered ovules into seeds. In seed plants, the sperm needed for fertilization are supplied by **pollen**, tiny male gametophytes enclosed by protective sporopollenin walls.

Embryos develop as the result of fertilization, which cannot occur until after **pollination**, the process by which pollen comes into contact with ovules. Pollination typically occurs by means of wind or animal transport (see Chapter 30). Fertilization occurs in seed plants when a male gametophyte extends a slender pollen tube that carries two sperm toward an egg. The pollen tube enters through an opening in the integument called the micropyle and releases the sperm. The fertilized egg becomes an embryo, and the ovule's integument develops into a protective, often hard and tough **seed coat** (**Figure 29.22b** and **c**).

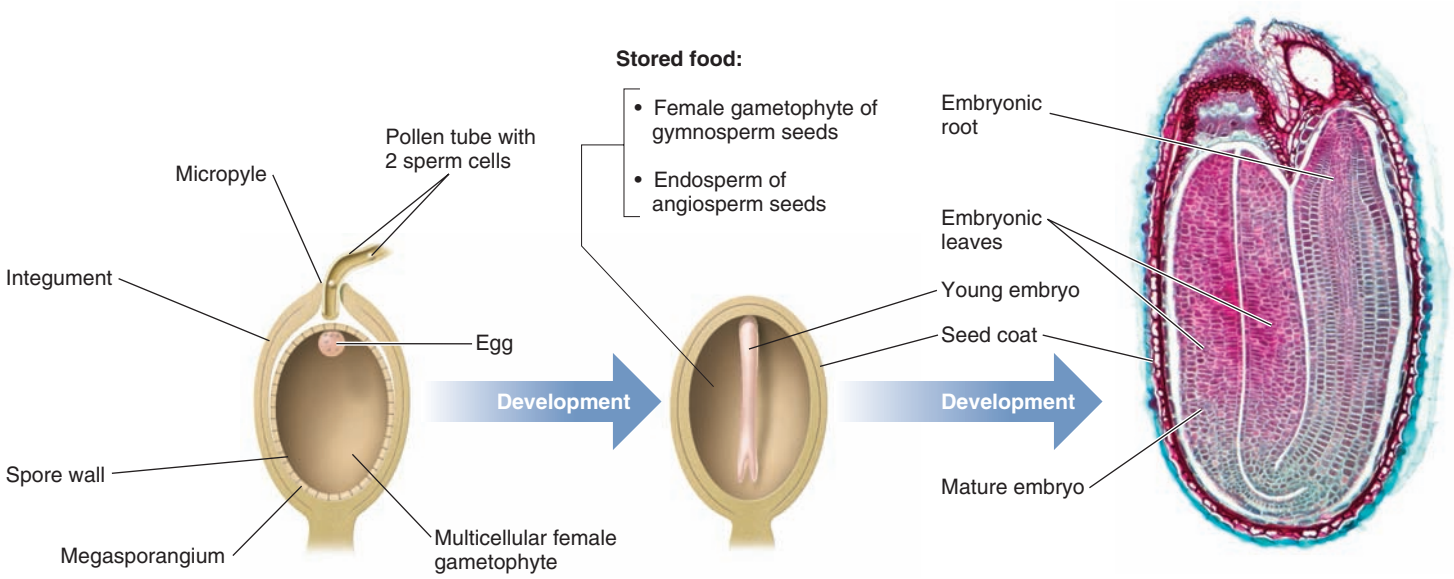

Figure 29.22 **Structure of an ovule developing into a seed.**

Concept Check: *Can you hypothesize why this angiosperm seed with its mature embryo does not show obvious endosperm tissue?*

Gymnosperm seeds contain female gametophyte tissue that has accumulated large amounts of proteins, lipids, and carbohydrates prior to fertilization. These nutrients are used during both embryo development and seed germination to help nurture the growth of the seedling. Angiosperm seeds also contain this useful food supply, but most angiosperm ovules do not store food materials before fertilization. Instead, angiosperm seeds generally store food only after fertilization occurs, ensuring that the food is not wasted if an embryo does not form. How is this accomplished? The answer is a process known as **double fertilization**. This process produces both a zygote and a food storage tissue known as endosperm, a tissue unique to angiosperms. One of the two sperm delivered by each pollen tube fuses with the egg, producing a diploid zygote, as you might expect. The other sperm fuses with different gametophyte nuclei to form an unusual cell that has more than the diploid number of chromosomes; this cell generates the endosperm food tissue. Endosperm will be discussed in more detail in Chapter 39.

Seeds allow embryos access to food supplied by the previous sporophyte generation, an option not available to seedless plants. The layered structure of ovules explains why seeds are also layered, with a protective seed coat enclosing the embryo and stored food. These seed features improve the chances of embryo and seedling survival, thereby increasing seed plant fitness.

Seeds Confer Important Ecological Advantages

Seeds provide plants with numerous ecological advantages. First, many seeds are able to remain dormant in the soil for long periods, until conditions become favorable for germination and seedling growth. Furthermore, seed coats are often adapted in ways that improve dispersal in diverse habitats. For example, many plants produce winged seeds that are effectively dispersed by wind. Other plants produce seeds with fleshy coverings that attract animals, which consume the seeds, digest their fleshy covering, and eliminate them at some distance from the originating plants.

Another advantage of seeds is that they can store considerable amounts of food, which supports embryo growth and helps plant seedlings grow large enough to compete for light, water, and minerals. This is especially important for seeds that must germinate in shady forests. Finally, the sperm of most seed plants can reach eggs without having to swim through water, because pollen tubes deliver sperm directly to ovules. Consequently, seed plant fertilization is not typically limited by lack of water, in contrast to fertilization of seedless plants. Therefore, seed plants are better able to reproduce in arid and seasonally dry habitats. For these reasons, seeds are considered to be a key adaptation to reproduction in a land habitat.

Ovule and Seed Evolution Illustrates Descent with Modification

As we have seen, seed plants reproduce using both spores and seeds, but note that seed plants have not replaced spores with seeds. Rather, seed plants continue to produce spores, and ovules and seeds have evolved from spore-producing structures by descent with modification. Recall that this evolutionary principle involves changes in preexisting structures and processes. Fossils provide some clues about ovule and seed evolution, and other information can be obtained by comparing reproduction in living lycophytes and pteridophytes.

Most modern lycophytes and pteridophytes release one type of spore that develops into one type of gametophyte. Such plants are considered to be homosporous, and their gametophytes live independently and produce both male and female gametangia (see Figure 29.12). However, some lycophytes and pteridophytes produce and release two distinct kinds of spores: relatively small microspores

and larger megaspores, which, respectively, grow into male and female gametophytes. The larger size of megaspores enables them to store food that later supports developing sporophytes. Recall that this reproductive process, known as heterospory, also characterizes all seed plants. The gametophytes produced by heterosporous plants also grow within the confines of microspore and megaspore walls and therefore are known as **endosporic gametophytes**.

An advantage of heterospory is that it mandates cross-fertilization. The eggs and sperm that fuse are derived from different gametophytes and hence from different spores and different meiotic events. This makes it likely that the gametes are of distinct genotypes. Cross-fertilization increases the potential for genetic variation, which aids evolutionary flexibility. Endosporic gametophytes receive protection from environmental damage from the surrounding spore walls. From these observations, we can infer that heterospory and endosporic gametophytes were probably also features of seed plant ancestors and constitute early steps toward seed evolution (**Figure 29.23**). Fossils and modern plants also illustrate subsequent stages in seed evolution, such as retaining megaspores within sporangia, rather than releasing them.

A further step in seed evolution may have been the production of only one megaspore per sporangium rather than multiple spores per sporangium, which is common in seedless plants. Reduction of megaspore numbers (from those present in seedless plants) would have allowed plants to channel more nutrients into each megaspore. A final step might have been the retention of megasporangia on parental sporophytes by the development of integuments (**Figure 29.24**). As we have noted, this adaptation would allow food

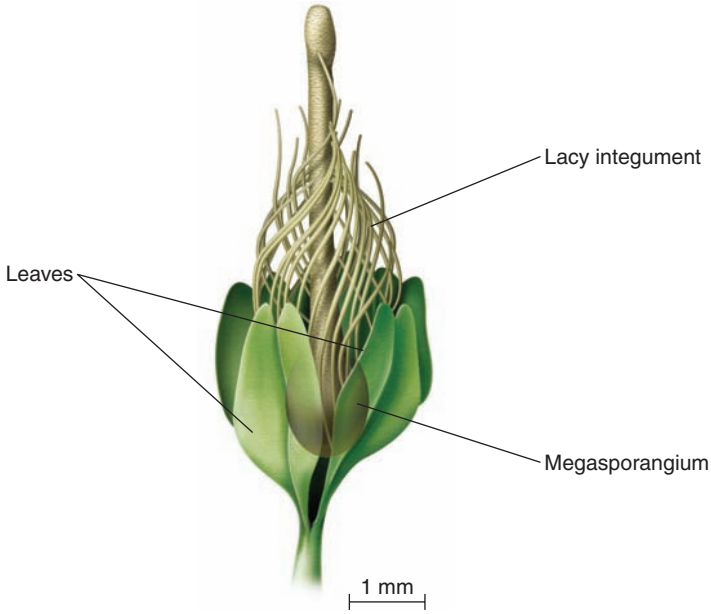

Figure 29.24 The fossil *Runcaria heinzelinii*, a plant with a probable precursor to an ovule or seed.

Concept Check: Based on your knowledge of integument function in modern seed plants, can you hypothesize a function for the lacy integument of Runcaria?

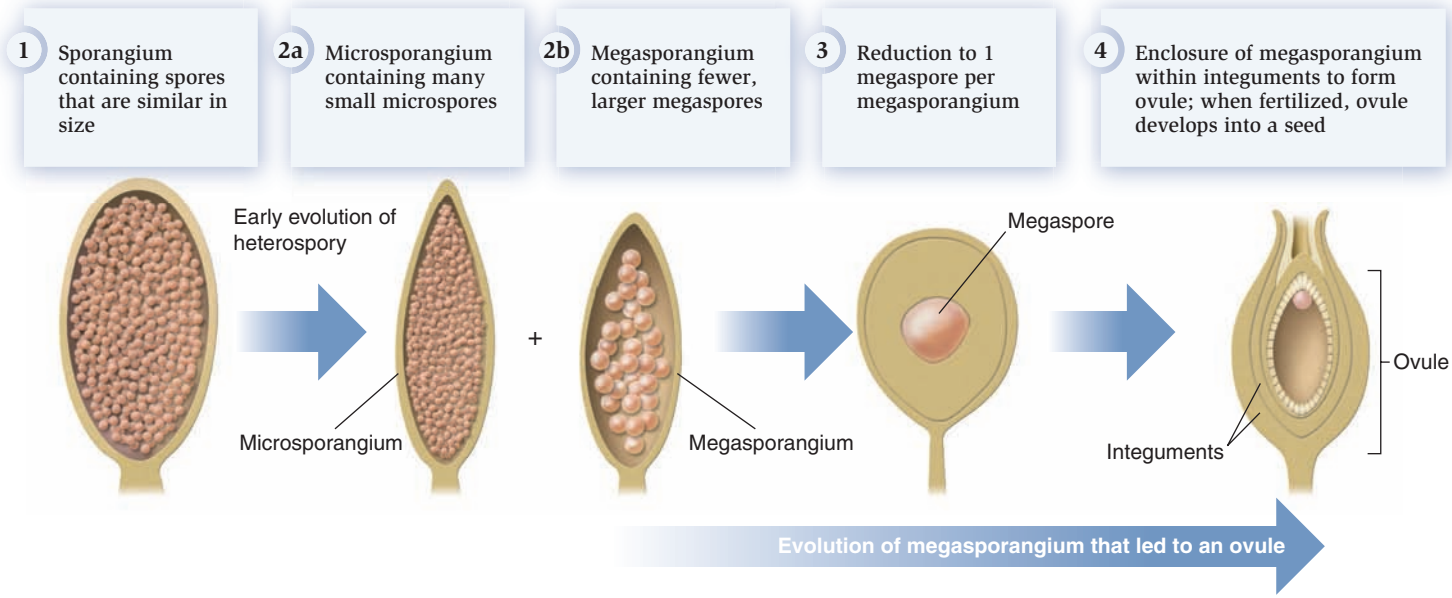

Figure 29.23 Hypothetical stages in the evolution of seeds. The parallel evolution of heterospory and endosporic gametophytes in some lycophytes and pteridophytes as well as the seed plants suggests that these features were acquired early in the evolution of seeds. Later-occurring events in the evolution of seeds included reduction of the number of megaspores to one per megasporangium and enclosure of the megasporangium by protective integuments.

BioConnections: Look ahead to Figure 34.14, which illustrates the amniotic egg produced by many terrestrial animals. How is the plant seed like the amniotic egg?

materials to flow from mature photosynthetic sporophytes to their dependent gametophytes and young embryos. Integuments also help ovules to receive pollen.

Fossils provide information about when and how the process of ovule and seed evolution first occurred. Fossil reproductive structures of an extinct Devonian plant named *Runcaria heinzelinii* may represent a precursor to an ovule or seed (see Figure 29.24). These fossil structures had a lacy integument that did not completely enclose the megasporangium. Very early fossil seeds such as *Elkinsia polymorpha* and *Archaeosperma arnoldii* were present by 365 mya. The evolutionary journey involving the transition from aquatic streptophyte algae to bryophytes, to seedless plants, and finally to seed plants reveals adaptations to a terrestrial environment, as well as ways in which plants themselves have shaped Earth's ecosystems. As a summary of what we have covered in this chapter, **Table 29.1** provides a list of the distinguishing features of land plants and their algal relatives.

Table 29.1 Distinguishing Features of Modern Streptophyte Algae and Land Plants

STREPTOPHYTES

Streptophyte algae: Primarily aquatic habitat; zygotic life cycle; sporangia absent; sporophytes absent

EMBRYOPHYTES: Primarily terrestrial habitat; sporic life cycle consisting of alternation of two multicellular generations (diploid sporophyte and haploid gametophyte); multicellular embryos nutritionally dependent on maternal gametophyte for at least some time during development; spore-producing sporangia; gamete-producing gametangia; sporopollenin-walled spores

Nonvascular plants (Bryophytes) (**liverworts, mosses, hornworts**): Dominant gametophyte generation; supportive, lignin-containing vascular tissue absent; true roots, stems, and leaves absent; sporophytes unbranched and unable to grow independently of gametophytes

VASCULAR PLANTS (TRACHEOPHYTES) (lycophytes, pteridophytes, spermatophytes): Dominant sporophyte generation; lignified water-conducting tissue (xylem); specialized organic food-conducting tissue (phloem); sporophytes branched and eventually becoming independent of gametophytes

LYCOPHYTES: Leaves generally small with a single, unbranched vein (lycophylls); sporangia borne on sides of stems

PTERIDOPHYTES: Leaves relatively large with extensively branched vein system (euphylls or megaphylls); sporangia borne on leaves; seeds absent

SEED PLANTS (SPERMATOPHYTES): Seeds present; leaves are euphylls that evolved independently from those of pteridophytes

GYMNOSPERMS (**cycads, ginkgos, conifers**): Flowers and fruits absent; seed food stored before fertilization in female gametophyte; endosperm absent

ANGIOSPERMS (flowering plants): Flowers and fruit present; seed food stored after fertilization in endosperm formed by double fertilization

*Key: **Phyla**; LARGER MONOPHYLETIC CLADES (synonyms). All other classification terms are not clades.

Summary of Key Concepts

29.1 Ancestry and Diversity of Modern Plants

- Plants are multicellular eukaryotic organisms composed of cells having plastids; they display many adaptations to life on land. The modern plant kingdom consists of several hundred thousand species classified into nine phyla, informally called the liverworts, mosses, hornworts, lycophytes, pteridophytes, cycads, ginkgos, conifers, and angiosperms (Figure 29.1).
- The land plants evolved from ancestors that were probably similar to modern complex streptophyte algae (Figure 29.2).
- The monophyletic liverwort, moss, and hornwort phyla are together referred to as the bryophytes. Bryophytes illustrate early-evolved features of land plants, such as a sporic life cycle involving embryos that develop within protective, nourishing gametophyte tissues (Figures 29.3, 29.4, 29.5, 29.6).
- Bryophytes differ from other plants in having a dominant gametophyte generation and a dependent, nonbranching, short-lived sporophyte generation. Bryophytes also lack supportive vascular tissues, in contrast to other modern plant phyla, which are known as the vascular plants, or tracheophytes (Figures 29.7, 29.8).
- Lycophytes, pteridophytes, and other vascular plants generally possess stems, roots, and leaves having vascular tissues composed of phloem and xylem, cuticle, and stomata (Figures 29.9, 29.10, 29.11).
- The fern life cycle illustrates the dominant sporophyte characteristic of vascular plants (Figure 29.12).
- Cycads, ginkgos, conifers, and gnetophytes are collectively known as gymnosperms. Gymnosperms produce seeds and inherited an ancestral capacity to produce wood. Angiosperms, the flowering plants, produce seeds, and many also produce wood. Flowers, fruits, and seed endosperm are distinctive features of angiosperms (Figures 29.13, 29.14).

29.2 An Evolutionary History of Land Plants

- Paleobiologists and plant evolutionary biologists infer the history of land plants by analyzing the molecular features of modern plants and by comparing the structural features of fossil and modern plants (Figure 29.15).
- Ancient vascular plants transformed Earth's ecology by altering atmospheric chemistry and climate (Figures 29.16, 29.17, 29.18).
- The Cretaceous-Paleogene event, a probable meteorite collision with Earth that occurred 65 mya, helped cause the extinction of previously dominant dinosaurs and many types of gymnosperms, leaving space into which angiosperms, insects, birds, and mammals diversified.

29.3 The Origin and Evolutionary Importance of the Plant Embryo

- The origin of the plant embryo was a critical innovation that fostered diversification of the land plants. Plant embryos are supported by nutrients supplied by female gametophytes with the aid of specialized placental transfer tissues (Figure 29.19).
- In a classic experiment, Browning and Gunning inferred that placental transfer tissues were responsible for an enhanced flow rate of nutrients from parental gametophytes to embryos (Figure 29.20).

29.4 The Origin and Evolutionary Importance of Leaves and Seeds

- Leaves are specialized photosynthetic organs that evolved more than once during plant evolutionary history. The lycophylls of lycophytes are relatively small leaves having a single unbranched vein. The leaves of ferns and seed plants are known as euphylls and are larger, with an extensively branched vascular system. Fossils indicate that fern euphylls evolved from branched-stem systems (Figure 29.21).
- Seeds develop from ovules, integument-enclosed sporangia that typically contain only a single spore that develops into an egg-producing gametophyte. Pollen produces thin cellular tubes that deliver sperm to eggs produced by female gametophytes. Following pollination and fertilization, ovules develop into seeds. Mature seeds contain stored food and an embryonic sporophyte that develops from the zygote (Figure 29.22).
- Seeds confer many reproductive advantages, including dormancy through unfavorable conditions, greater protection for embryos from mechanical and pathogen damage, seed coat modifications that enhance seed dispersal, and reduction of plants' dependence on water for fertilization (Figures 29.23, 29.24).
- The distinctive traits of streptophyte algae and the different phyla of land plants indicate the occurrence of descent with modification (Table 29.1).

Assess and Discuss

Test Yourself

1. The simplest and most ancient phylum of modern land plants is probably
   a. the pteridophytes.
   b. the cycads.
   c. the liverworts.
   d. the angiosperms.
   e. none of the above.
2. An important feature of land plants that originated during the diversification of streptophyte algae is
   a. the sporophyte.
   b. spores, which are dispersed in air and coated with sporopollenin.
   c. tracheids.
   d. plasmodesmata.
   e. fruits.
3. A phylum whose members are also known as bryophytes is commonly known as
   a. liverworts.
   b. hornworts.
   c. mosses.
   d. all of the above.
   e. none of the above.
4. Plants possess a life cycle that involves alternation of two multicellular generations: the gametophyte and
   a. the lycophyte.
   b. the bryophyte.
   c. the pteridophyte.
   d. the lignophyte.
   e. the sporophyte.
5. The seed plants are also known as
   a. bryophytes.
   b. spermatophytes.
   c. pteridophytes.
   d. lycophytes.
   e. none of the above.
6. A waxy cuticle is an adaptation that
   a. helps to prevent water loss from tracheophytes.
   b. helps to prevent water loss from streptophyte algae.
   c. helps to prevent water loss from bryophytes.
   d. aids in water transport within the bodies of vascular plants.
   e. does all of the above.
7. Plant photosynthesis transformed a very large amount of atmospheric carbon dioxide into decay-resistant organic compounds, thereby causing a dramatic decrease in atmospheric carbon dioxide levels during the geological period known as the
   a. Cambrian.
   b. Ordovician.
   c. Carboniferous.
   d. Permian.
   e. Pleistocene.
8. Which of these plant phyla is likely to have the largest leaves?
   a. liverworts
   b. hornworts
   c. mosses
   d. lycophytes
   e. pteridophytes
9. Fern euphylls, also known as megaphylls, probably evolved from
   a. the leaves of mosses.
   b. lycophylls.
   c. branched-stem systems.
   d. modified roots.
   e. none of the above.
10. A seed develops from
    a. a spore.
    b. a fertilized ovule.
    c. a microsporangium covered by integuments.
    d. endosperm.
    e. none of the above.

Conceptual Questions

1. List several common traits that lead evolutionary biologists to infer that land plants evolved from ancestors related to modern streptophyte algae.
2. Why have bryophytes such as mosses been able to diversify into so many species even though they have relatively small, dependent sporophytes?
3. A principle of biology is that *living organisms maintain homeostasis*. Explain how several structural features help vascular plants maintain stable internal water content.

Collaborative Questions

1. Discuss at least one difference in environmental conditions experienced by early land plants and ancestral complex streptophyte algae.
2. Identify and describe as many plant adaptations to land as you can.

The Evolution and Diversity of Modern Gymnosperms and Angiosperms

30

The Madagascar periwinkle (*Catharanthus roseus*), one of the many seed plants on which humans depend.

The seed plants—gymnosperms and angiosperms—are particularly important in our everyday lives because they are the sources of many products, including wood, paper, beverages, food, cosmetics, and medicines. Leukemia, for example, is effectively treated with vincristine, a drug extracted from the beautiful flowering plant known as the Madagascar periwinkle (*Catharanthus roseus*), pictured in the chapter opening photo. Vinblastine—another extract from *C. roseus*—is used to treat lymphatic cancers. Taxol, a compound used in the treatment of breast and ovarian cancers, was first discovered in extracts of the bark of the Pacific yew tree, a gymnosperm known as *Taxus brevifolia*. Vincristine, vinblastine, taxol, and many other plant-derived medicines are examples of plant secondary metabolites, which are distinct from the products of primary metabolism (carbohydrates, lipids, proteins, and nucleic acids). Secondary metabolites play essential roles in protecting plants from disease-causing organisms and plant-eating animals, and they also aid plant growth and reproduction. Though all plants produce secondary metabolites, these natural products are exceptionally diverse in gymnosperms and angiosperms.

In this chapter, we will explore the many important roles that the hundreds of thousands of modern seed plants play in the lives of humans and modern ecosystems. This chapter builds on the introduction to seeds and seed plants provided in Chapter 29. We begin by focusing on the diversity of modern lineages of gymnosperms and angiosperms. Coevolutionary interactions among angiosperms and animals are presented as major factors influencing the diversification of these groups. This chapter concludes by considering human influences on seed plant evolution and the importance of seed plants in modern agriculture.

30.1 The Evolution and Diversity of Modern Gymnosperms

Learning Outcomes:

1. Describe how gymnosperms evolved from woody but seedless ancestors.
2. Identify three gymnosperm phyla, and describe their importance to humans.

Figure 30.1 shows our current understanding of the relationships among modern seed plants, the flowering plants (angiosperms) and three phyla of gymnosperms. Following the early diversification of gymnosperms, an unknown, extinct gymnosperm lineage (not specified in Figure 30.1) gave rise to the angiosperms—the flowering plants. **Table 30.1** provides a summary of the critical innovations of all modern seed plants.

Gymnosperms are plants that produce seeds that are exposed rather than enclosed in fruits, as is the case for angiosperms. The word gymnosperm comes from the Greek *gymnos*, meaning naked (referring to the unclothed state of ancient athletes), and *sperma*,

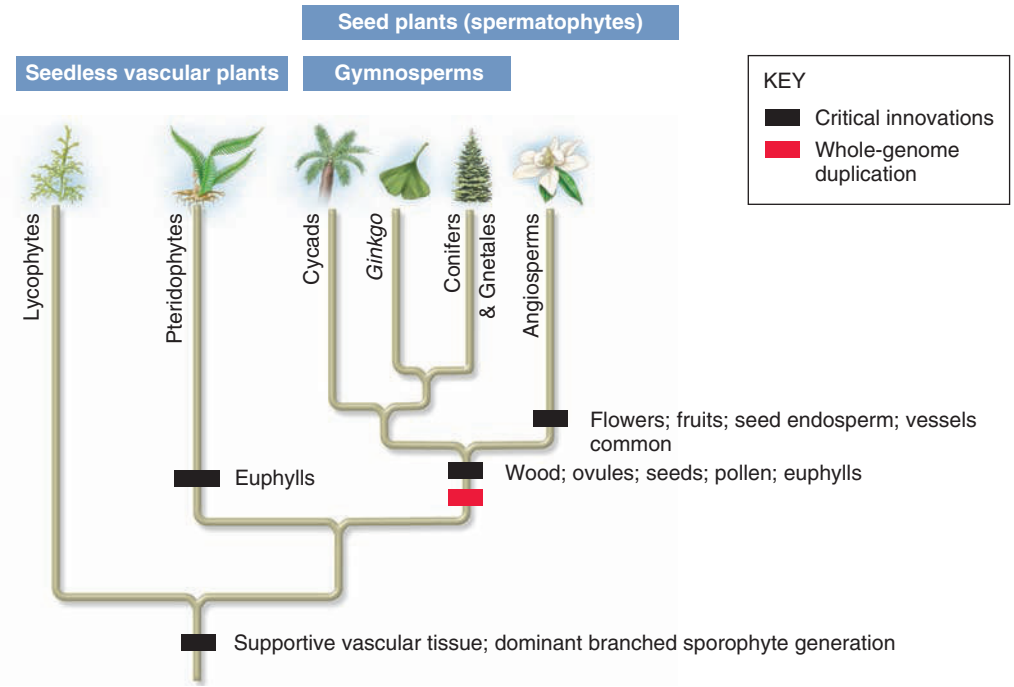

Figure 30.1 **A phylogeny of modern vascular seedless and seed plants.**

Table 30.1 **Critical Innovations of Seed Plant Groups**

Plant group	Innovation	Advantages
All seed plants	Vascular cambium that makes wood and inner bark	Seed plants have the potential to grow tall and produce many branches and reproductive structures.
	Pollen, ovules, seeds	Pollen allows seed plants to disperse male gametophytes. Ovules provide protection and nutrition to female gametophytes and developing embryos. Seeds allow seed plants to reproduce in arid or shady habitats.
Conifers	Tracheid torus	Fosters water flow in arid or cold conditions
	Scales or needle-shaped leaves	Retard water loss from leaf surface
	Conical shape	Sheds snow, preventing damage
	Resin	Protects against pathogens and herbivores
Angiosperms	Flowers	Foster pollen dispersal, ovule protection, pollination, and seed production
	Fruits	Foster seed dispersal
	Endosperm	Efficiently provides food to embryo of developing seed
	Vessels	Relatively wide diameter fosters water flow
	Many secondary compounds	Provide flower colors and fragrances and protect against herbivores

meaning seed. Most modern gymnosperms are woody plants that occur as shrubs or trees. Seeds and wood are critical innovations that allow gymnosperms to cope with global climate changes and to live in relatively cold and dry habitats. In this section, we will first consider some fossil plants that help to explain important gymnosperm traits. Then we will survey the structure, reproduction, ecological roles, and human uses of modern gymnosperm phyla.

Modern Gymnosperms Arose from Woody Ancestors

Modern gymnosperms include the famous giant sequoias (*Sequoiadendron giganteum*) native to the Sierra Nevada mountains of the western U.S. Giant sequoias are among Earth's largest organisms, weighing as much as 6,000 tons and reaching an amazing 100 m in height. The large size of sequoias and other trees is based on the presence of **wood**, a tissue composed of numerous pipelike arrays of empty, water-conducting cells whose walls are strengthened by an exceptionally tough polymer known as lignin. These properties enable woody tissues to transport water upward for great distances and also to provide the structural support needed for trees to grow tall and produce many branches and leaves. In modern seed plants, a special tissue known as the **vascular cambium** produces both thick layers of wood and thinner layers of inner bark. The **inner bark** transports watery solutions of organic compounds. (The structure and function of the vascular cambium, wood, and inner bark are described in more detail in Chapter 35.) Vascular cambium, wood, and inner bark help gymnosperms and woody angiosperms to compete effectively for light and other resources needed for photosynthesis.

Wood first appeared in a group of ancient plants known as the **progymnosperms** (from the Greek, meaning before gymnosperms). Woody progymnosperms, such as the fossil plant *Archaeopteris*, which lived 370 mya, were the first trees that had leafy twigs (**Figure 30.2**). The vascular tissue of progymnosperms was arranged in a ring around a central pith of nonvascular tissue. (The vascular tissue of earlier tracheophytes was arranged differently.) This ring of vascular tissue, known as a **eustele**, contained cells that were able to develop into the vascular cambium as seedlings grew into saplings. The vascular cambium then produced wood, allowing saplings to grow into tall trees. Modern seed plants inherited the eustele, explaining why many gymnosperms and angiosperms are also able to produce vascular cambia and wood. Although progymnosperms were woody plants, fossil evidence indicates that they did not produce seeds. This observation reveals that wood originated before the evolution of seeds, which first appeared more than 300 mya. The evolutionary origin of seeds, discussed in Chapter 29, stimulated the rapid diversification of gymnosperms.

The greatest diversity of gymnosperms occurred during the Mesozoic era, when gymnosperms were the major vegetation present. This period was also known as the Age of Dinosaurs, and gymnosperms are thought to have been the major food for plant-eating dinosaurs during most of their history. Some groups of gymnosperms became extinct before or as a result of the Cretaceous-Paleogene event (K/T event) 65 mya (see Chapter 29). Only a few gymnosperm phyla have survived to modern times: cycads (the Cycadophyta); *Ginkgo biloba*, the only surviving member of a once large phylum termed Ginkgophyta; and conifers and Gnetales, which comprise about 800 species. These phyla display distinctive reproductive features and play important roles in ecology and human affairs.

Figure 30.2 An early forest in which the only trees were the progymnosperm *Archaeopteris*. This illustration was reconstructed from fossil data.

BioConnections: Look ahead to Figure 54.26a–e. In what way did ancient Archaeopteris forests differ from most forests of the present time?

Cycads Are Endangered in the Wild but Are Widely Used as Ornamentals

Cycads are regarded as the earliest diverging modern gymnosperm phylum, originating more than 300 mya. Nearly 300 cycad species occur today, primarily in tropical and subtropical regions. However, many species of cycads are rare, and their tropical forest homes are increasingly threatened by human activities. Many cycads are listed as endangered, and commercial trade in cycads is regulated by CITES (Convention on International Trade in Endangered Species of Wild Fauna and Flora), a voluntary international agreement between governments to protect such species.

The structure of cycads is so interesting and attractive that many species are cultivated for use in outdoor plantings or as houseplants. The nonwoody stems of some cycads emerge from the ground much like tree trunks, some reaching 15 m in height, whereas the stems of other cycads are not conspicuous because they are subterranean (**Figure 30.3**). Cycads display spreading, palmlike leaves (cycad comes from a Greek word meaning palm). Mature leaves of the African cycad *Encephalartos laurentianus* can reach an astounding 8.8 m in length!

(a) Emergent cycad stem **(b) Submergent cycad stem**

Figure 30.3 Cycads. Palmlike foliage and conspicuous seed-producing cones are features of most cycads. **(a)** The stems of some cycads emerge from the ground. **(b)** The stems of other cycads are submerged in the ground, so the leaves emerge at ground level. This image also shows a conspicuous orange cone-like structure that bears seeds.

In addition to underground roots, which provide anchorage and take up water and minerals, many cycads produce coralloid roots. Such roots extend aboveground and have branching shapes resembling corals (**Figure 30.4a**). Coralloid roots harbor light-dependent, photosynthetic cyanobacteria within their tissues. The cyanobacteria, which form a bright blue-green ring beneath the root surfaces (**Figure 30.4b**), convert atmospheric nitrogen (N_2) into ammonia (NH_3), providing their plant hosts with the nitrogen that is crucial to growth (see Chapter 37).

Cycad reproduction is distinctive in several ways. Individual cycad plants produce conspicuous conelike structures that bear either ovules and seeds or pollen (see Figure 30.3). When mature, both types of reproductive structures emit odors that attract beetles. These insects carry pollen to ovules, where the pollen produces tubes that deliver sperm to eggs.

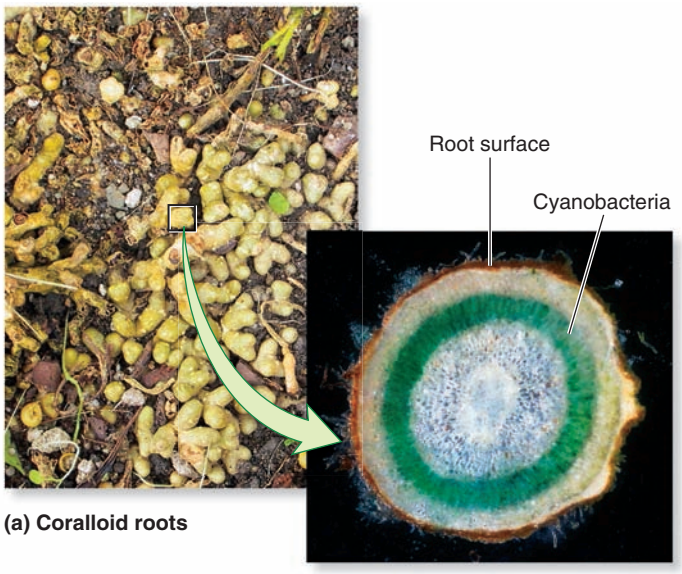

Figure 30.4 Coralloid roots of cycads. **(a)** Many cycads produce aboveground branching roots that resemble branched corals. **(b)** This magnified cross section of a coralloid root shows a ring of symbiotic blue-green cyanobacteria, which provide the plant with a form of nitrogen that can be used to make essential cellular compounds.

Concept Check: *Why do the coralloid roots grow aboveground?*

Ginkgo biloba Is the Last Survivor of a Once Diverse Group

The beautiful tree *Ginkgo biloba* (**Figure 30.5a**) is the single remaining species of a phylum that was much more diverse during the Age of Dinosaurs. *G. biloba* takes its species name from the two-lobed shape of its leaves, which have unusual forked veins (**Figure 30.5b**). Today, *G. biloba* may be nearly extinct in the wild; widely cultivated modern *Ginkgo* trees are descended from seeds produced by a tree found in a remote Japanese temple garden and brought to Europe by 17th-century explorers.

G. biloba trees are widely planted along city streets because they are ornamental and also tolerate cold, heat, and pollution better than many other trees. In addition, these trees are long-lived—individuals can live for more than a thousand years and grow to 30 m in height. Individual trees produce either ovules and seeds or pollen, based on a sex chromosome system much like that of humans. Ovule-producing trees have two X chromosomes; pollen-producing trees have one X and one Y chromosome. Wind disperses pollen to ovules, where pollen grains germinate to produce pollen tubes. These tubes grow through ovule tissues for several months, absorbing nutrients that are used for sperm development. Eventually the pollen tubes burst, delivering flagellate sperm to egg cells. After fertilization, zygotes develop into embryos, and the ovule integument develops into a fleshy, bad-smelling outer seed coat and a hard, inner seed coat (**Figure 30.5c**). For street-side or garden plantings, people usually select the pollen-producing trees to avoid the stinky seeds.

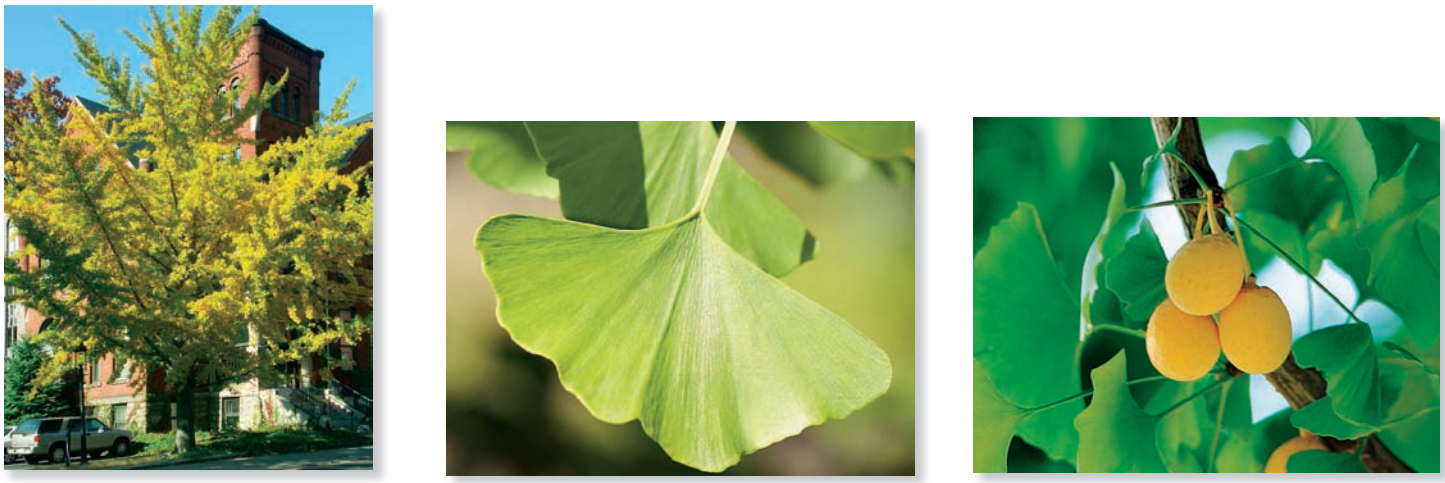

Figure 30.5 *Ginkgo biloba*. **(a)** A *Ginkgo biloba* tree; **(b)** fan-shaped leaves with forked veins; and **(c)** seeds with fleshy, foul-smelling seed coats.

Conifers Are the Most Diverse Modern Gymnosperm Lineage

The conifers (**Figure 30.6**) are a lineage of trees named for their seed cones, of which pinecones are familiar examples. Modern conifer families include more than 50 genera. Conifers are particularly common in mountain and high-latitude forests and are important sources of wood and paper pulp.

Conifers produce simple pollen cones and more complex ovule-bearing cones (**Figure 30.7**). The pollen cones of conifers have many leaflike structures, each bearing a microsporangium in which meiosis occurs and pollen grains develop. The ovule cones, also called seed cones, are composed of many short branch systems that bear ovules. Ovules contain female gametophytes, within which eggs develop.

When conifer pollen is mature, it is released into the wind, which transports it to ovules. When released from pollen tubes, sperm fuse with eggs, generating zygotes that grow into the embryos within seeds. Altogether, it takes nearly 2 years for pines (the genus *Pinus*) to complete the processes of male and female gamete development, fertilization, and seed development (see Figure 30.7). The seeds of pines and some other conifers develop wings that aid in wind dispersal (**Figure 30.8a**). Other conifers, such as yew and juniper, produce seeds or cones with bright-colored, fleshy coatings that are attractive to birds, which help to disperse the seeds (**Figure 30.8b** and **c**).

Conifer wood contains many specialized vascular cells known as tracheids that are adapted for efficient water and mineral conduction even in dry conditions. Like the tracheids of other vascular plants, those of conifers are devoid of cytoplasm and occur in long columns that function like plumbing pipelines (**Figure 30.9a**). Tracheid side and end walls possess many thin-walled, circular **pits** through which water moves both vertically and laterally from one tracheid to another. Conifer pits are unusual in having a porous outer region that lets water flow through and a nonporous, flexible central region called the **torus** (plural, tori) that functions like a valve (**Figure 30.9b**). If conifer tracheids become dry, a common event in arid or cold habitats, they fill with air and are no longer able to conduct water. In this case, the torus presses against the pit opening, sealing it (**Figure 30.9c**). The torus valve thereby prevents air bubbles from spreading to the next tracheid. This conifer adaptation localizes air bubbles, preventing them from stopping water conduction in other tracheids. The presence of tori in their tracheids helps to explain why conifers have been so successful for hundreds of millions of years. Conifer wood (and leaves) may also display conspicuous resin ducts, passageways for the flow of syrup-like resin that helps to prevent attack by pathogens and herbivores. Resin that exudes from tree surfaces may trap insects and other organisms, then harden in the air and fossilize, preserving the inclusions in amber.

Many conifers occur in cold climates and thus display numerous adaptations to such environments. Their conical shapes and flexible branches help conifer trees shed snow, preventing heavy snow accumulations from breaking branches. People who use conifers in landscape plantings also value these traits. Conifer leaf shape and structure are adapted to resist damage from drought that occurs in both summer and winter, when liquid water is scarce. Conifer leaves are often scalelike (**Figure 30.10a**) or needle-shaped (**Figure 30.10b**); these shapes reduce the area of leaf surface from which water can evaporate. In addition, a thick, waxy cuticle coats conifer leaf surfaces (**Figure 30.10c**), retarding water loss and attack by disease organisms.

Many conifers are evergreen; that is, their leaves live for more than 1 year before being shed and are not all shed during the same season. Retaining leaves through winter helps conifers start up photosynthesis earlier than deciduous trees, which in spring must replace leaves lost during the previous autumn. Evergreen leaves thus provide an advantage in the short growth season of alpine or high-latitude environments. However, some conifers do lose all their leaves in the autumn. The bald cypress (*Taxodium distichum*) of southern U.S. floodplains, tamarack (*Larix laricina*) of northern bogs, and dawn

Juniper seeds are used to flavor gin.

BioConnections: *Look forward to Figure 30.21. How are wind-dispersed pine seeds similar to wind-dispersed fruits of the angiosperm maple?*

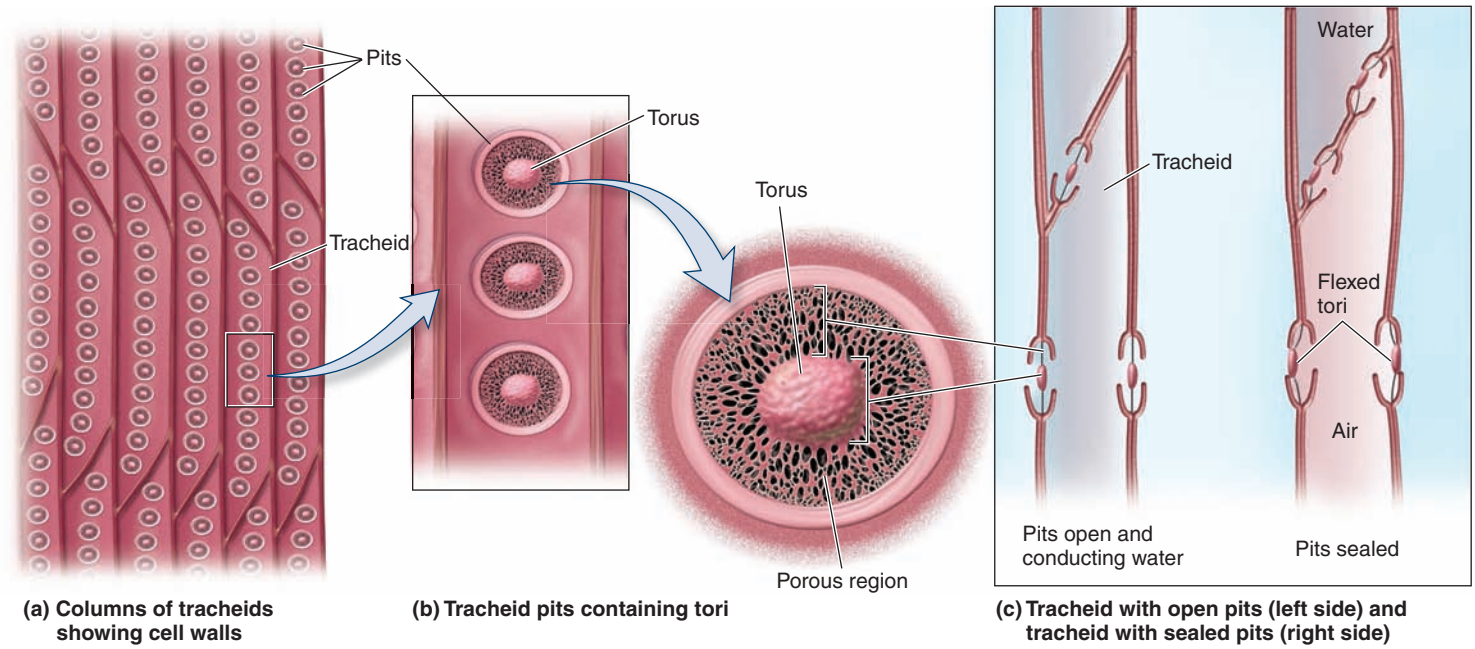

Figure 30.9 Tracheids and tori in conifer wood. **(a)** The lignin-rich cell walls of the water-conducting cells called tracheids. **(b)** Detailed view of a portion of a tracheid that shows the thin-walled areas known as pits, each with a torus. **(c)** A water-filled tracheid with open pits and an air-filled tracheid with pits sealed by the flexed tori.

BIOLOGY PRINCIPLE Structure determines function. This illustration shows how tori in water-conducting cells of conifers aid survival in arid or cold habitats.

redwood (*Metasequoia glyptostroboides*; see Figure 30.6b) are examples of deciduous conifers. Fossils indicate that dawn redwoods once grew abundantly across wide areas of the Northern Hemisphere until a few million years ago and then disappeared. However, in the 1940s, a forester found a living dawn redwood growing in a remote Chinese village, and subsequent expeditions located forests of the conifers. Since then, dawn redwood trees have been widely planted as ornamentals, prized for their attractive foliage and cones. As recently as 1994, botanists found a previously unknown conifer species, *Wollemia nobilis*, in an Australian national park. Like the dawn redwood, *Wollemia* is an attractive tree that is likely to become more widely distributed as the result of human cultivation.

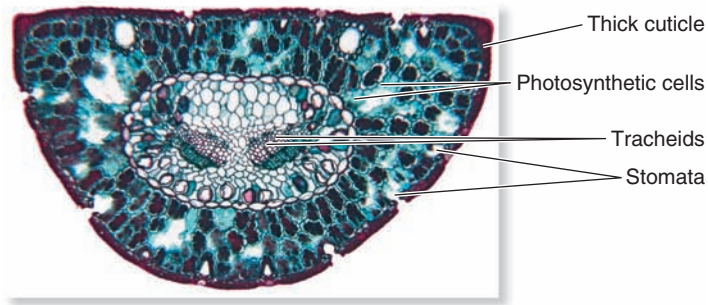
The conifer clade also includes the Gnetales, an order of three genera, *Gnetum*, *Ephedra*, and *Welwitschia*, that feature distinctive adaptations. *Gnetum* is unusual among modern gymnosperms in having broad leaves similar to those of many tropical plants (**Figure 30.11a**). Such leaves maximize light capture in dim forest habitats. More than 30 species of the genus *Gnetum* occur as vines, shrubs, or trees in tropical Africa or Asia. *Ephedra*, native to arid regions of the southwestern U.S., has tiny brown scalelike leaves and green, photosynthetic stems (**Figure 30.11b**). These adaptations help to conserve water by preventing water loss that would otherwise occur from the surfaces of larger leaves. *Ephedra* produces secondary metabolites that aid in plant protection but also affect human physiology. Early settlers of the western U.S. used *Ephedra* to treat colds and other medical conditions. In fact, the modern decongestant drug pseudoephedrine is based on the chemical structure of ephedrine, a substance that was named for and originally obtained from *Ephedra*. Pseudoephedrine sales are now restricted in many places because this compound can be used as a starting point for the synthesis of illegal drugs. Ephedrine has also been used to enhance sports performance, a practice that has elicited medical concern.

Welwitschia has only one living representative species. *Welwitschia mirabilis* is a strange-looking plant that grows in the coastal Namib Desert of southwestern Africa, one of the driest places on Earth (**Figure 30.11c**). A long taproot anchors a stubby stem that barely emerges from the ground. Two very long leaves grow from the stem but are rapidly shredded by the wind into many strips. The plant is thought to obtain most of its water from coastal fog that accumulates on the leaves, explaining how *W. mirabilis* can grow and reproduce in such a dry place.

30.2 The Evolution and Diversity of Modern Angiosperms

Learning Outcomes:

1. List four flower organs and their functions, and explain how each flower part may have first evolved.
2. Describe how diversification of flowers and fruits enhances seed production and dispersal.
3. Name three major types of angiosperm secondary metabolites, and explain how these affect animals.



More than 124 mya, one extinct gymnosperm group, although it's unclear which one, gave rise to the angiosperms—the flowering plants. Charles Darwin famously referred to the origin of the flowering plants as "an abominable mystery," one that has not been fully

(b) Needle-shaped leaves of pine

(c) Stained cross section of pine needle, showing the thick cuticle

Figure 30.10 **Conifer leaves.** The leaves of conifers are typically shaped as small scales or long needles, with similar internal structure.

Concept Check: *In what ways are conifer leaves adapted to resist water loss from their surfaces?*

(a) Genus *Gnetum*

(b) *Ephedra californica*

(c) *Welwitschia mirabilis*

Figure 30.11 **Gnetales.** **(a)** A tropical plant of the genus *Gnetum*, displaying broad leaves and reproductive structures. **(b)** *Ephedra californica* growing in deserts of North America, showing minuscule brown leaves on green, photosynthetic stems and reproductive structures. **(c)** *Welwitschia mirabilis* growing in the Namib Desert of southwestern Africa, showing long, wind-shredded leaves and reproductive structures.

solved even today. Recent geological studies indicate that the rise of angiosperms may be related to a global climate change that brought more humid conditions, arising from the breakup of the supercontinent Pangaea (see Chapter 22). Angiosperms have retained many structural and reproductive features from ancestral seed plants, but have also evolved several traits not found or seldom found among other land plants.

Flowers and fruits are two of the defining features of angiosperms (**Figure 30.12**), because these features do not occur in other modern plants. The term **angiosperm** is from Greek words meaning enclosed seed, which reflects the presence of seeds within fruits. The seed nutritive material known as endosperm is another defining feature of the flowering plants (see Chapters 29 and 39). Flowers, fruits, and seed endosperm are critical innovations that aid reproduction. Flowers foster seed production, fruits favor seed dispersal, and endosperm food helps embryos within seeds grow into seedlings. In addition, most angiosperms possess distinctive water-conducting cells, known as **vessels**, which are wider than tracheids and therefore increase the efficiency of water flow through plants. Although similar conducting cells occur in some seedless plants and certain gymnosperms, the vessels of angiosperms are thought to have evolved independently.

Although humans obtain wood, medicines, and other valuable products from gymnosperms, we depend even more on the angiosperms. Our food, beverages, and spices—flavored by an amazing variety of secondary metabolites—primarily come from flowering plants. People surround themselves with ornamental flowering plants and decorative items displaying flowers or fruit. We also commonly use flowers and fruit in ceremonies. In this section, we will focus on how flowers, fruits, and secondary metabolites played key roles in angiosperm diversification. We will also learn that features of flowers, fruits, and secondary metabolites are used to classify and identify angiosperm species.

Figure 30.12 Angiosperm flowers and fruits. Citrus plants display the critical innovations of flowering plants: the flowers and fruits shown here and seed endosperm (not shown).

Concept Check: *What other trait occurs widely among angiosperms but rarely among other plants?*

Flower Organs Evolved from Leaflike Structures

Flowers are complex reproductive structures that are specialized for the efficient production of pollen and seeds. The sexual reproduction process of angiosperms depends on flowers. As the flowering plants diversified, flowers of varied types evolved as reproductive adaptations to differing environmental conditions. To understand this process, we can start by considering the basic flower parts and their roles in reproduction.

Flower Parts and Their Reproductive Roles Flowers are produced at stem tips, and may contain four types of organs: sepals, petals, pollen-producing stamens, and ovule-producing carpels (**Figure 30.13**). These flower organs are supported by tissue known as a **receptacle**, located at the tip of a flower stalk—a **pedicel**. The functioning of several genes that control flower organ development explains why carpels are the most central flower organs, why stamens surround carpels, and why petals and sepals are the outermost flower organs (refer back to Figure 19.24).

Many flowers produce attractive **petals** that play a role in **pollination**, the transfer of pollen among flowers. **Sepals** of many flowers are green and form the outer layer of flower buds. By contrast, the sepals of other flowers look similar to petals, in which case both sepals and petals are known as **tepals**. All of a flower's sepals and petals are collectively known as the **perianth**. Most flowers produce one or more **stamens**, the structures that produce and disperse pollen. Most flowers also contain a single or multiple **carpels**, structures that produce ovules.

Some flowers lack perianths, stamens, or carpels. Flowers that possess all four types of flower organs are known as **complete flowers**, and flowers lacking one or more organ types are known as **incomplete flowers**. Flowers that contain both stamens and carpels are described as **perfect flowers**, and flowers lacking either stamens or carpels are **imperfect flowers**.

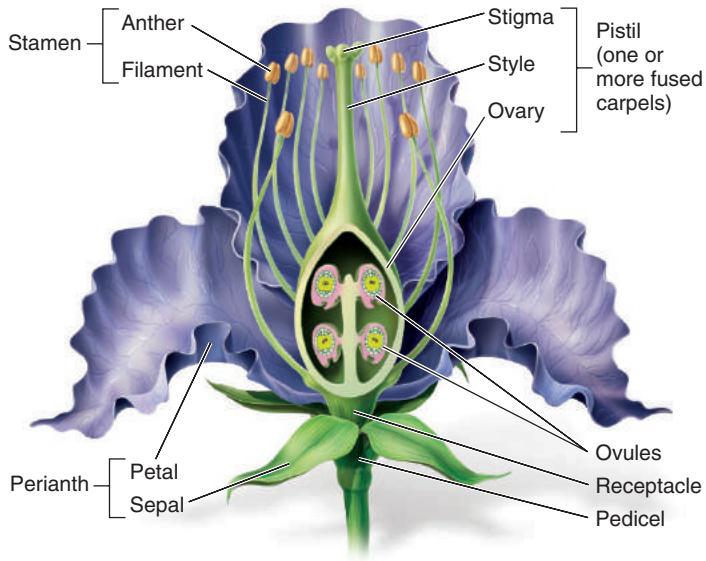

Figure 30.13 Generalized flower structure. Although flowers are diverse in size, shape, and color, they commonly have the parts illustrated here.

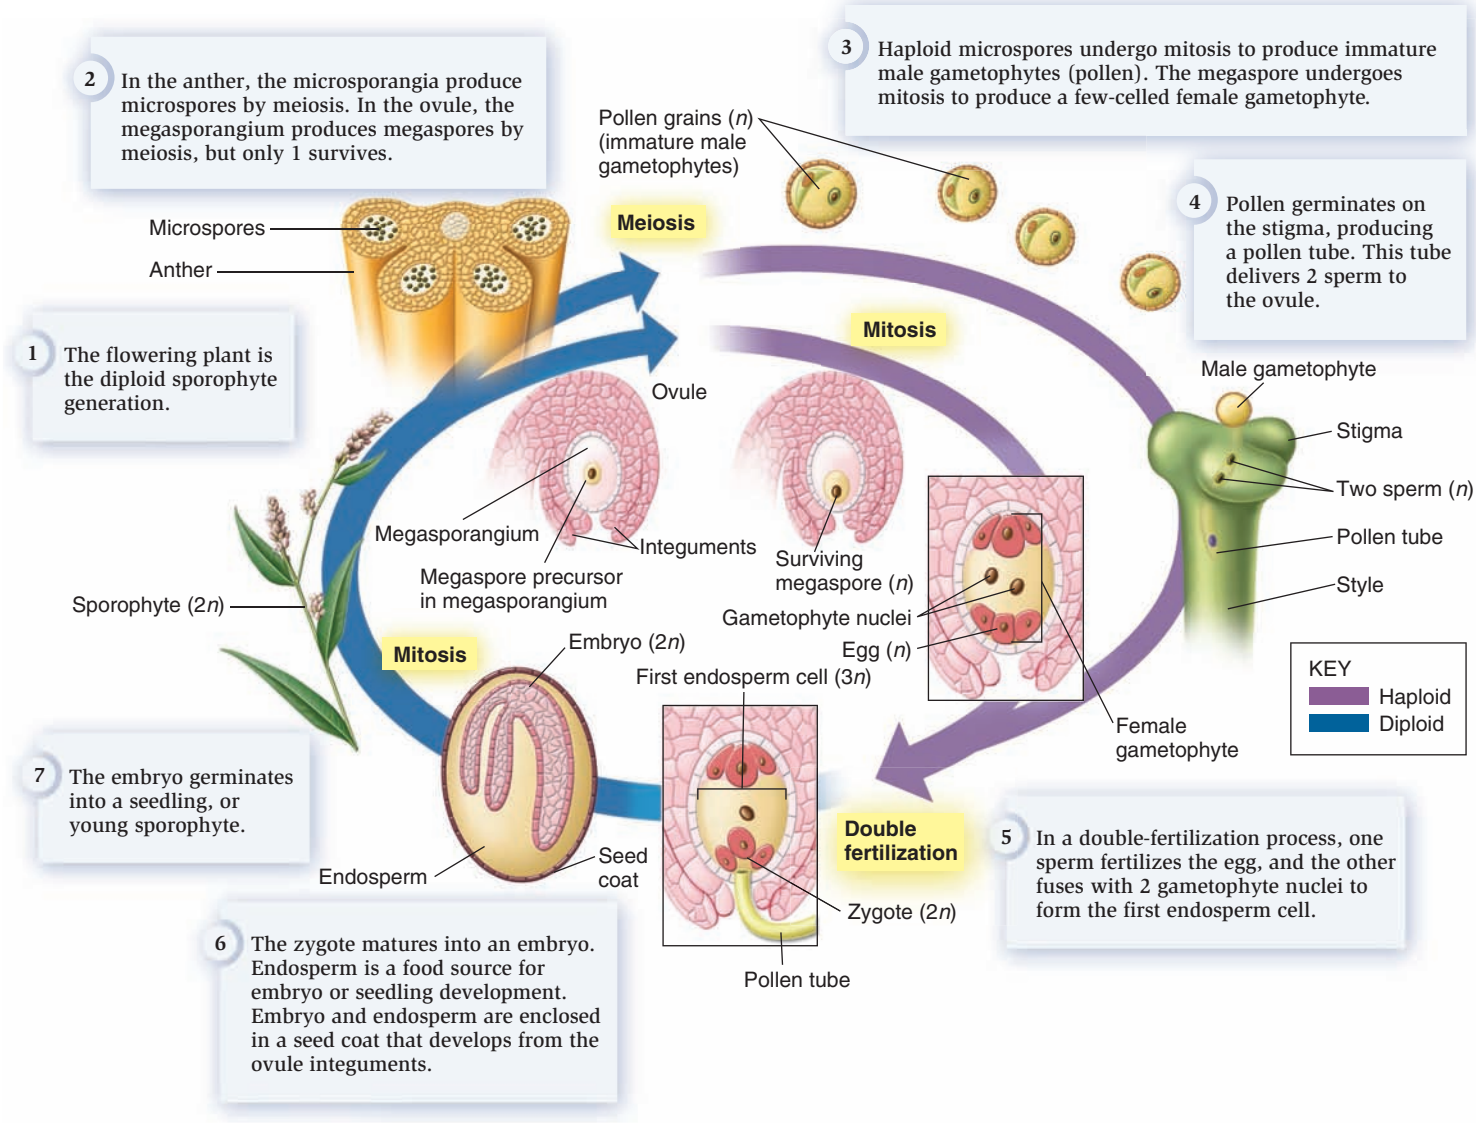
Flowers also differ in the numbers of organs they produce. Some flowers produce only a single carpel, others display several separate carpels, and many possess several carpels that are fused together into a compound structure. Both a single carpel and compound carpels are referred to as a **pistil** (from the Latin *pistillum*, meaning pestle) because it resembles the device people use to grind materials to powder in a mortar (see Figure 30.13). Only one pistil is present in flowers that have only one carpel and in flowers with fused carpels. By contrast, flowers possessing several separate carpels display multiple pistils.

Pistil structure can be divided into three regions having distinct functions. The topmost portion of the pistil, known as the **stigma**, receives and recognizes pollen of the appropriate species or genotype. The elongate middle portion of the pistil is called the **style**. The lowermost portion of the pistil is the **ovary**, which encloses and protects ovules.

During the flowering plant life cycle (**Figure 30.14**), the stigma allows pollen of the appropriate genetic type to germinate, producing a long pollen tube that grows through the style. The pollen tube thereby delivers two sperm cells to ovules. In the distinctive angiosperm process known as **double fertilization**, one sperm fuses with the egg to form a zygote, and the other sperm fuses with other haploid cells of the female gametophyte. The latter is the first step in the development of a characteristic angiosperm nutritive tissue known as endosperm. Fed by the endosperm, the zygote develops into an embryo, and the ovule develops into a seed. Ovaries (and sometimes additional flower parts) develop into fruits.

Early Flowers Fossils of whole plants with recognizable flowers and fruits are known from geological deposits about 124 mya, though molecular data and fossil pollen grains suggest that angiosperms may have originated earlier. Flowers were a critical innovation that led to extensive angiosperm diversification. Comparative studies of the structures of modern and fossil flowers suggest how modern stamens and carpels might have arisen.



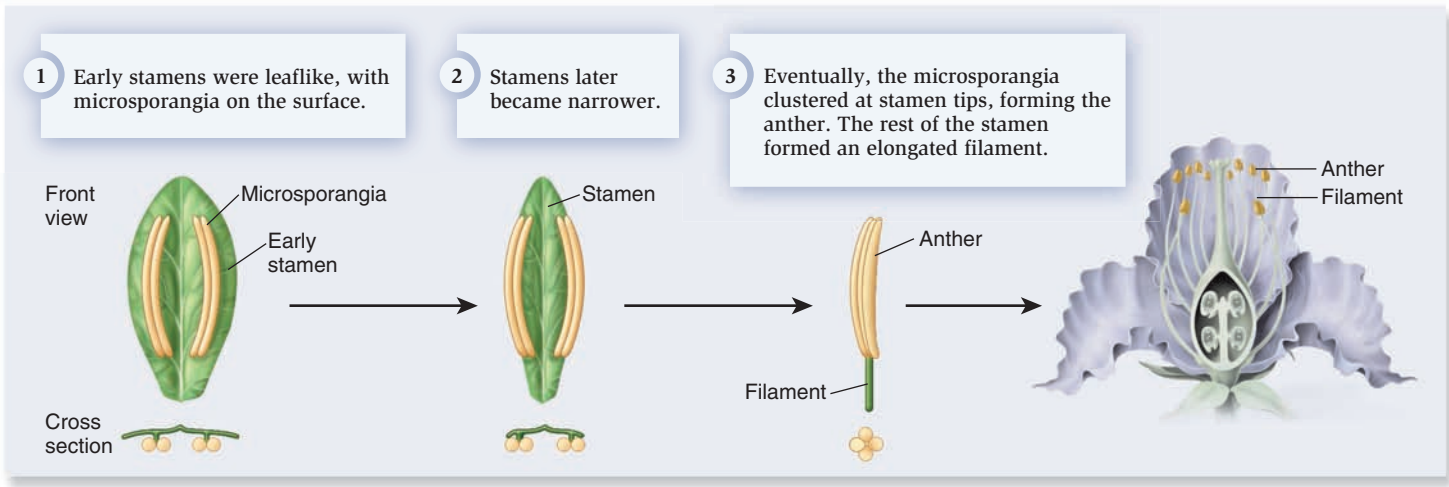


Figure 30.14 The life cycle of a flowering plant, illustrated by the genus *Polygonum*. Flowering plant life cycles differ in length and in the number of cells and nuclei occurring in the female gametophyte, with the seven cells and eight nuclei of *Polygonum* being common.

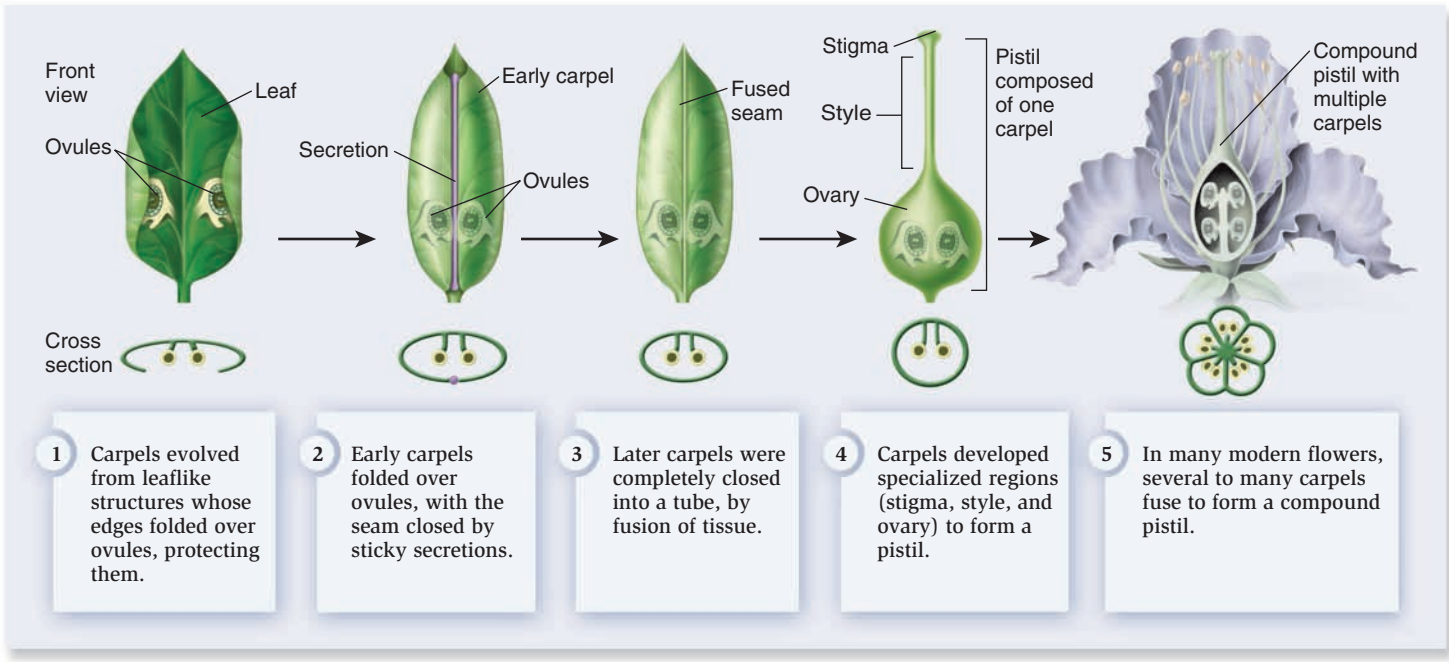

Structural comparisons and molecular data indicate that stamens are homologous to gymnosperm microsporophylls, leaflike structures that produce microspores (young pollen). Early fossil flowers and some modern flowers have broad stamens that are leaf-shaped, with elongated, pollen-producing microsporangia on the stamen surface (**Figure 30.15a**). In contrast, the stamens of most modern plants have narrowed to form **filaments**, or stalks, that elevate **anthers**, clusters of microsporangia that produce pollen and then open to release it (see Figure 30.13). Filaments and anthers are adaptations that foster pollen dispersal.

Plant biologists likewise hypothesize that carpels are homologous to gymnosperm megasporophylls, leaflike structures that bear ovules on their surfaces. In early angiosperms, such leaves folded over ovules, protecting them. In support of this hypothesis is the observation that the carpels of some early-diverging modern plants are leaflike structures that fold over ovules, with the carpel edges stuck together by secretions (**Figure 30.15b**). In contrast, most modern flowers produce carpels whose edges have fused together into a tube whose lower portion (ovary) encloses ovules. Plant biologists hypothesize that such evolutionary change increased ovule protection, which would improve plant fitness.

In contrast, flower sepals and petals have no recognizable homologs in modern gymnosperms. These perianth structures are unique to angiosperms, so plant biologists have long wondered how sepals and

(a) Stamen evolution

(b) Carpel evolution

Figure 30.15 Hypothetical evolutionary origin of stamens, carpels, and pistils. Plant biologists test these models by searching for new fossils or generating additional molecular data.

petals arose. Recent analyses reveal that the gene expression patterns of the pollen cones of gymnosperms (see Figure 30.7) share features with flower stamens, as expected, but also with the flower perianth. These data suggest that perianth parts originated from stamen-like structures, by loss of sporangia. The first flowers arose when early stamens, carpels, and perianth parts aggregated into a single structure.

Flowering Plants Diversified into Several Lineages, Including Monocots and Eudicots

Figure 30.16 presents our current understanding of the relationships among modern angiosperm groups. According to gene-sequencing studies, the earliest-diverging modern angiosperms are represented by a single species called *Amborella trichopoda*, a shrub that lives in cloud forests on the South Pacific island of New Caledonia. The flowers of *A. trichopoda* display hypothesized ancient features. For example, the fairly small flowers have stamens with broad filaments and several separate carpels (**Figure 30.17**). *A. trichopoda* also lacks vessels in the water-conducting tissues. In contrast, typical angiosperm vessels are present in later-diverging groups of angiosperms, including water lilies, the star anise plant, and other close relatives (see Figure 30.16). Magnoliids, represented by the genus *Magnolia*, are the next-diverging group. Magnoliids are closely related to two very large and diverse angiosperm lineages: the **monocots** and the **eudicots**.

Monocots and eudicots are named for differences in the number of embryonic leaves called cotyledons. Monocot embryos possess one cotyledon, whereas eudicots possess two cotyledons. Monocots differ from eudicots in several additional ways (look ahead to Table 35.1). For example, monocots typically have flowers with parts numbering three or some multiple of three (**Figure 30.18a**). In contrast, eudicot flower parts often occur in fours, fives, or a multiple of four or five (**Figure 30.18b**).

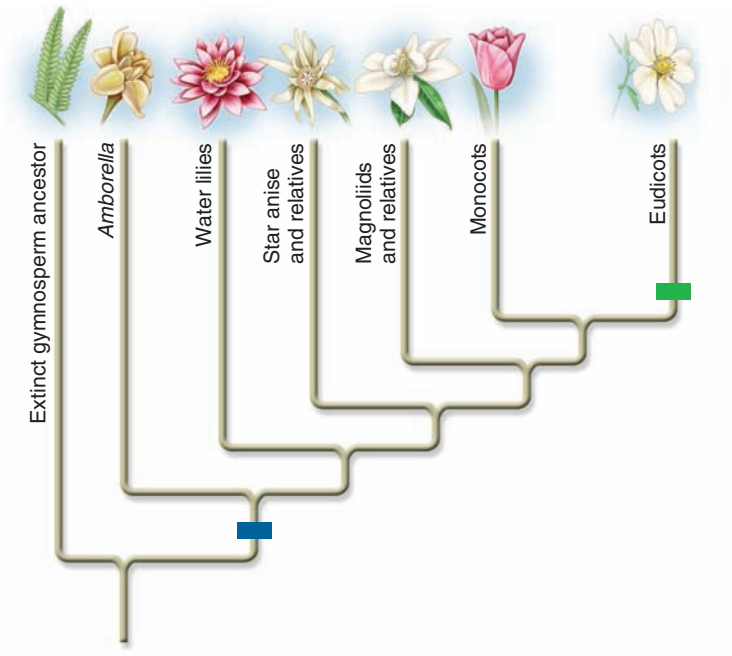

Figure 30.16 A phylogeny showing the major modern angiosperm lineages and examples of whole-genome duplication and triplication events. Molecular data indicate that a whole-genome duplication occurring before the divergence of *Amborella* (blue bar) and a whole-genome triplication during the evolution of eudicots (green bar) strongly influenced the diversification of modern angiosperms.

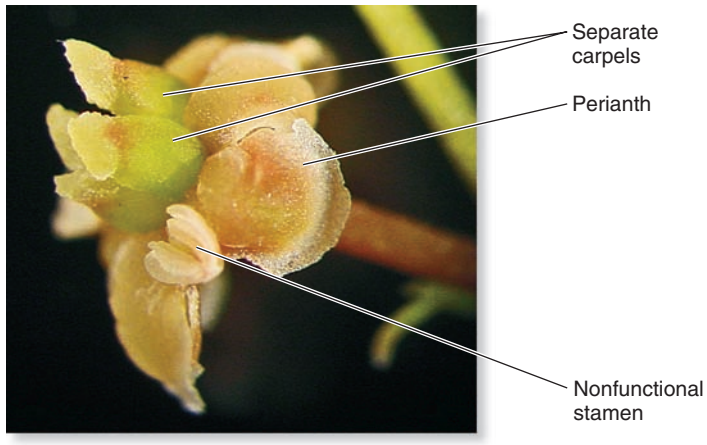

Figure 30.17 *Amborella trichopoda* flower, similar to a hypothesized early flower. This small flower is only about 3–4 mm in diameter. It displays several central, greenish carpels; nonfunctional stamens; and a pink perianth of tepals. This plant species also produces flowers that lack carpels but have many functional stamens.

Genomes & Proteomes Connection

Whole-Genome Duplications Influenced the Evolution of Flowering Plants

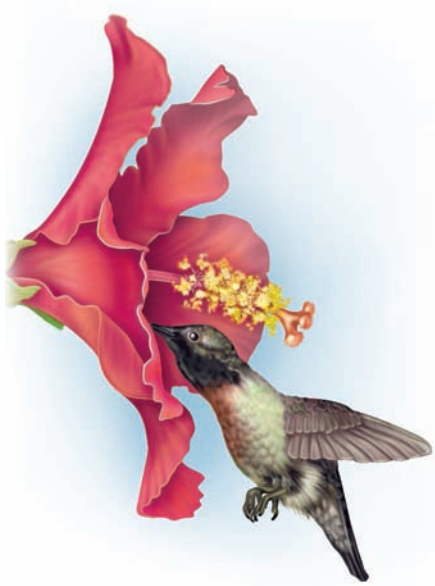
Whole-genome duplication occurs in a wide variety of eukaryotes and has happened during the evolutionary history of plants. For example, a whole-genome duplication event occurred early in the evolution of seed plants (see Figure 30.1). Whole-genome duplications are particularly important in the evolutionary history of flowering plants (Figure 30.16). Recent molecular analyses indicate that the entire plant genome was duplicated before the divergence of *Amborella*. Different patterns of whole-genome duplication occurred in monocots and eudicots after their divergence. After such whole-genome duplications, a plant's genome operates as a diploid system. Although genome sizes vary, the number of genes estimated for plants whose genomes have been studied is about 25,000. Whole-genome duplication has the potential to affect species' evolutionary pathways because it offers the opportunity for many genes to diverge, forming gene families. For example, a whole-genome triplication occurred early in eudicots' evolutionary history. This triplication explains why the recently sequenced coffee genome has exactly three versions of all the chromosome types that are present in the plants that diverged then. A number of whole-genome duplications seem to have occurred in plants near the transition from the Cretaceous period to the Paleogene period. Experts suggest that these whole-genome duplications might have helped plants cope with environmental stresses arising from the Cretaceous-Paleogene event (described in Chapter 29).

(a) A monocot with six tepals

(b) A eudicot with five petals

Figure 30.18 One characteristic difference between monocots and eudicots: flower part number. **(a)** Flowers and buds of a lily (genus *Lilium*), displaying six tepals. **(b)** A flower and buds of apple (genus *Malus*), showing five flower petals. Green sepals are visible around the pink buds.

Flower Diversification Has Fostered Efficient Seed Production



During the diversification of flowering plants, flower evolution has involved several types of changes that foster the transfer of pollen from one plant to another. Effective pollination is essential to efficient seed production because it minimizes the amount of energy plants must expend to accomplish sexual reproduction. Fusion of flower organs, clustering of flowers into groups, and reducing the perianth are some examples of changes leading to effective pollination.

Many flowers have fused petals that form floral tubes. Such tubes tend to accumulate sugar-rich nectar that provides a reward for **pollinators**, animals that transfer pollen among plants. The diameters of floral tubes vary among flowers and are evolutionarily tuned to the feeding structures of diverse animals, which range from the narrow tongues of butterflies to the wider bills of nectar-feeding birds (**Figure 30.19**). Nectar-feeding bats stick their heads into even larger tubular flowers to lap up nectar with their tongues. Orchids provide another example of ways in which flower parts have become fused; stamens and carpels are fused together into a single reproductive column that is surrounded by attractive tepals (**Figure 30.20a**). This arrangement of flower organs fosters orchid pollination by particular insects and is a distinctive feature of the orchid family.

Many plants produce **inflorescences**, groups of flowers tightly clustered together, which occur in several types. The sunflower family features a type of inflorescence in which many small flowers are clustered into a head (**Figure 30.20b**). The flowers at the center of a sunflower head function in reproduction and lack showy petals, but

(a) Zinnia flower and butterfly

(b) Hibiscus flower and hummingbird

(c) Saguaro cactus flower and bat

Figure 30.19 Flowers whose perianths form nectar-containing floral tubes of different widths that accommodate different pollinators. **(a)** This zinnia is composed of an outer rim of showy flowers and a central disc of narrow tubular flowers that produce nectar. Butterflies, but not other pollinators, are able to reach the nectar by means of their narrow tongues. **(b)** The hibiscus flower produces nectar in a floral tube whose diameter corresponds to the dimensions of a hummingbird bill. **(c)** The saguaro cactus (*Carnegiea gigantea*) flower forms a floral tube that is wide enough for nectar-feeding bats to get their heads inside. The cactus flower has been drawn here as if it were transparent, to illustrate bat pollination.

(a) An orchid flower with fused pistil and stamens

(b) A sunflower plant showing inflorescence

(c) Grass flowers lacking showy perianth

Figure 30.20 Evolutionary changes in flower structure. **(a)** An orchid of the genus *Cattleya* has fused stamens and pistil, and six tepals, one of which is specialized to form a lower lip. **(b)** An inflorescence (head) of sunflower (genus *Helianthus*). This inflorescence includes a rim of flowers with conspicuous petals that attract pollinators and an inner disc of flowers that lack attractive perianths. **(c)** Grass flowers of the genus *Triticum* lack a showy perianth.

Concept Check: What advantage does the nonshowy perianth of grass flowers provide?

flowers at the rim have showy petals that attract pollinators. Flower heads allow pollinators to transfer pollen among a large number of flowers at the same time.

The grass family features flowers with few or no perianths, which explains why grass flowers are not showy (**Figure 30.20c**). This adaptation fosters pollination by wind, since petals would only get in the way of such pollen transfer.

Diverse Types of Fruits Function in Seed Dispersal

Fruits are structures that develop from ovary walls in diverse ways that aid the dispersal of enclosed seeds. Seed dispersal helps to prevent seedlings from competing with their larger parents for scarce resources such as water and light. Dispersal of seeds also allows plants to colonize new habitats. Diverse fruit types illustrate the many ways in which plants have become adapted for effective seed dispersal. Like flower types, fruit types are useful in classifying and identifying angiosperms.

Many mature angiosperm fruits, such as cherries, grapes, and lemons, are attractively colored, soft, juicy, and tasty (**Figure 30.21a–c**). Such fruits are adapted to attract animals that consume the fruits, digest the outer portion as food, and eliminate the seeds, thereby dispersing them. Hard seed coats prevent such seeds from being destroyed by the animal's digestive system. Strawberries are aggregate fruits, many fruits that all develop from a single flower having multiple pistils (**Figure 30.21d**). The ovaries of these pistils develop into tiny, single-seeded yellow fruits on a strawberry surface; the fleshy, red, sweet portion of a strawberry develops from a flower receptacle. Aggregate fruits allow a single animal consumer, such as a bird, to disperse many seeds at the same time. Pineapples (**Figure 30.21e**) are juicy multiple fruits that develop when many ovaries of an inflorescence fuse together. Such multiple fruits are larger and attract relatively large animals that have the ability to disperse seeds for long distances.

The plant family informally known as **legumes** is named for its distinctive fruits, dry pods that open down both sides when seeds are mature, thereby releasing them (**Figure 30.21f**). Nuts and grains are additional examples of dry fruits. **Grains** are the characteristic single-seeded fruits of cereal grasses such as rice, corn (maize), barley, and wheat. Coconut fruits are adapted for dispersal in ocean currents and can float for months before being cast ashore (**Figure 30.21g**). Maple trees produce dry and thus lightweight fruits having wings, features that foster effective wind dispersal (**Figure 30.21h**). Other plants produce dry fruits with surface burrs that attach to animal fur. These are just a few examples of the diverse mechanisms that flowering plants use to disperse their seeds.

Angiosperms Produce Diverse Secondary Metabolites That Play Important Roles in Plant Structure, Reproduction, and Protection

Secondary metabolism involves the synthesis of organic compounds that are not essential for cell structure and growth in organisms but aid their survival and reproduction. These molecules, called **secondary metabolites**, are produced by various prokaryotes, protists, fungi, some animals, and all plants, but are most diverse in the angiosperms. About 100,000 different types of secondary metabolites are known, most of which are produced by flowering plants. Because secondary metabolites play essential roles in plant structure, reproduction, and protection, diversification of these compounds has influenced flowering plant evolution. Three major classes of plant secondary metabolites occur: (1) terpenes and terpenoids; (2) phenolics, which include flavonoids and related compounds; and (3) alkaloids (**Figure 30.22**).

(a) A fleshy fruit (cherry)

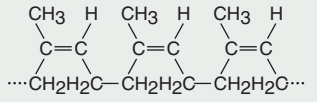
(b) A fleshy berry fruit (grape)

(c) A fleshy fruit (lemon)

(d) An aggregate fruit (strawberry)

(e) A multiple fruit (pineapple)

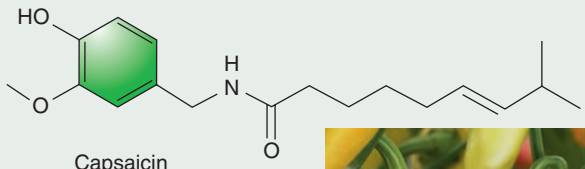
(f) Legumes with dry pods (peas)



(g) Fruit with husk (coconut)

(h) A dry, winged fruit (maple)

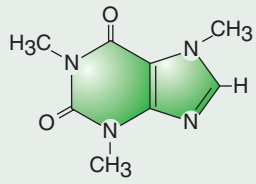
Terpene



Natural rubber (complex terpene)

(a) Natural rubber produced by *Hevea brasiliensis* is an example of a complex terpene.

Phenolic



Capsaicin

(b) Capsaicin extracted from capsicum peppers is an example of a phenolic compound.

Alkaloid

Caffeine

(c) Caffeine produced by *Coffea arabica* is an example of an alkaloid.

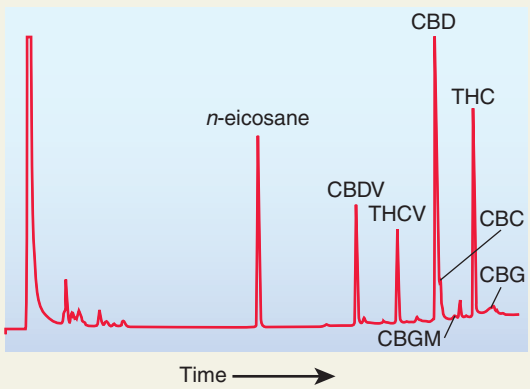
Figure 30.22 Major types of plant secondary metabolites. Note that the chemistry of plant secondary metabolites differs from that of the primary compounds produced by all cells. The production by plants of terpenes, phenolics, and alkaloids helps to explain how plants survive and reproduce and why plants are useful to humans in so many ways.

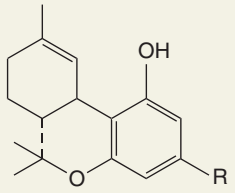
Figure 30.21 Representative fruit types. **(a–c)** The cherry, grape, and lemon are fleshy fruits adapted to attract animals that consume the fruits and excrete the seeds. **(d)** Strawberry is an aggregate fruit, consisting of many tiny, single-seeded fruits produced by a single flower. The fruits are embedded in the surface of a fleshy receptacle that is adapted to attract animal seed-dispersal agents. **(e)** Pineapple is a large multiple fruit formed by the aggregation of smaller fruits, each produced by one of the flowers in an inflorescence. **(f)** Peas produce legumes, fruits that open on two sides to release seeds. **(g)** Coconut fruits possess a fibrous husk that aids dispersal in water. **(h)** Maple trees produce dry fruits with wings adapted for wind dispersal.

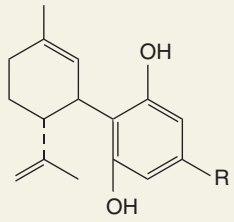
About 25,000 types of plant terpenes and terpenoids are constructed from different arrangements of the simple hydrocarbon gas isoprene. Taxol, previously mentioned for its use in the treatment of cancer, is a terpene, as are citronella and a variety of other compounds that repel insects. Rubber, turpentine, rosin, and amber are complex terpenoids that likewise serve important roles in plant biology as well as having useful human applications.

Phenolic compounds are responsible for some flower and fruit colors as well as the distinctive flavors of cinnamon, nutmeg, ginger, cloves, chilies, and vanilla. Phenolics absorb UV radiation, thereby preventing damage to cellular DNA. They also help to defend plants against insects and disease microbes. Some phenolic compounds found in tea, red wine, grape juice, and blueberries are antioxidants that detoxify free radicals, thereby preventing cellular damage.

Alkaloids are nitrogen-containing secondary metabolites that often have potent effects on the animal nervous system. Plants produce at least 12,000 types of alkaloids, and certain species produce many alkaloids. Caffeine, nicotine, morphine, ephedrine, cocaine, and codeine are examples of alkaloids that influence the physiology and behavior of humans and are thus of societal concern. Like flower and fruit structure, secondary metabolites are useful in distinguishing among Earth's hundreds of thousands of flowering plant species.







Feature Investigation | Hillig and Mahlberg Analyzed Secondary Metabolites to Explore Species Diversification in the Genus *Cannabis*

The genus *Cannabis* has long been a source of hemp fiber used for ropes and fabric. People have also used *Cannabis* (also known as marijuana) in traditional medicine and as a hallucinogenic drug. *Cannabis* produces THC (tetrahydrocannabinol), a type of alkaloid called a cannabinoid. THC and other cannabinoids are produced in glandular hairs that cover most of the *Cannabis* plant's surface but are particularly rich

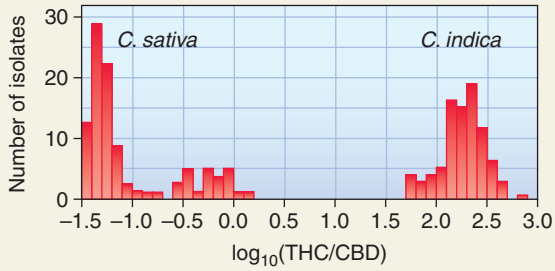


Figure 30.23 **Hillig and Mahlberg's analysis of secondary metabolites in the genus *Cannabis*.**

GOAL To determine if cannabinoids aid in distinguishing *Cannabis* species.

KEY MATERIALS *Cannabis* fruits obtained from nearly 100 different worldwide sources.

	Experimental level	Conceptual level
1 Grow multiple *Cannabis* plants from seeds under standard conditions in a greenhouse.		Eliminates differential environmental effects on cannabinoid content.
2 Extract cannabinoids from leaves surrounding flowers.		Extracts were made from tissues richest in cannabinoids; this reduces the chance that cannabinoids present in lower levels would be missed.
3 Analyze cannabinoids by gas chromatography. Determine ratios of THC (tetrahydrocannabinol) to CBD (cannabidiol) in about 200 *Cannabis* plants.		Previous data suggested that ratios of THC to CBD might be different in separate species.  Tetrahydrocannabinol (THC) ($R = C_5H_{11}$ Δ^9)  Cannabidiol (CBD) ($R = C_5H_{11}$)

4 THE DATA

Cannabis plants isolated from diverse sources worldwide formed 2 groups—those having relatively high THC to CBD ratios and those having lower THC to CBD ratios.

Plants having low THC to CBD ratios, often used as hemp fiber sources, corresponded to the species *C. sativa*.

Plants having high THC to CBD ratios, often used as drug sources, corresponded to the species *C. indica*.

5 CONCLUSION Differing cannabinoid ratios support a concept of 2 *Cannabis* species.

6 SOURCE Hillig, K.W., and Mahlberg, P.G. 2004. A chemotaxonomic analysis of cannabinoid variation in *Cannabis* (Cannabaceae). *American Journal of Botany* 91:966–975.

in leaves located near the flowers. THC mimics compounds known as endocannabinoids, which are naturally produced and act in the animal brain and elsewhere in the body. THC affects humans by binding to receptor proteins in plasma membranes in the same way as natural endocannabinoids do. Cancer patients sometimes choose to use cannabis to reduce nausea and stimulate their appetite, which can decline as a side effect of cancer treatment.

Because humans have subjected cultivated *Cannabis* plants to artificial selection for so long, plant biologists have been uncertain how cultivated *Cannabis* species are related to those in the wild. In the past, plants cultivated for drug production were often identified as *Cannabis indica*, whereas those grown for hemp were typically known as *Cannabis sativa*. However, these species are difficult to distinguish on the basis of structural features, and the relevance of these names to wild cannabis was unknown. At the same time, species identification has become important for biodiversity studies, agriculture, and law enforcement. For these reasons, plant biologists Karl Hillig and Paul Mahlberg hypothesized that ratios of THC to another cannabinoid known as CBD (cannabidiol) might aid in defining *Cannabis* species and identifying plant samples at the species level, as shown in **Figure 30.23**.

To test their hypothesis, the investigators began by collecting *Cannabis* fruits from nearly a hundred diverse locations around the world and then growing these plants from seed under uniform conditions in a greenhouse. The investigators next extracted cannabinoids, analyzed them by means of gas chromatography (a laboratory technique used to identify components of a mixture), and determined the ratios of THC to CBD. The results, published in 2004, suggested that the wild and cultivated *Cannabis* samples evaluated in this study could be classified into two species: *C. sativa*, displaying relatively low THC levels, and *C. indica*, having relatively high THC levels. As a result of this work, ecologists, agricultural scientists, and forensic scientists can reliably use ratios of THC to CBD to classify samples. Similar studies of plant secondary metabolites offer the benefit of uncovering potential new medicinal compounds or other applications of significance to humans.

Experimental Questions

1. **SciSKILLS »** Designing an experiment requires a plan to achieve an adequate number of samples, in order to allow statistical analysis. Hillig and Mahlburg obtained nearly a hundred *Cannabis* fruit samples from around the world. Why were so many samples needed?
2. Why did Hillig and Mahlberg collect samples from the leaves growing nearest the flowers?

BIO TIPS

THE QUESTION *The study by Hillig and Mahlburg revealed that samples of* Cannabis *plants from diverse sources varied in their ratios of alkaloids known as cannabinoids. Why did the investigators grow plants from seeds in a greenhouse before conducting their analyses of cannabinoid content?*

TOPIC ***What topic in biology does this question address?*** The topic is the use of secondary metabolites to differentiate species of plants. More specifically, the question addresses the relative effects of genes and environment on plants' production of secondary metabolites.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** You know from earlier chapters of this textbook that the traits organisms express depend on both genes and environment and that genetically determined traits are used for classifying organisms. In this chapter, you have learned that plants, and flowering plants in particular, produce diverse types of secondary metabolites that play important roles in reproduction and protection. Consequently, you might expect that the ratios of cannabinoids in *Cannabis* plants reflect environmental conditions, genetic composition, or both.

PROBLEM-SOLVING STRATEGY ***Design an experiment.*** Consider how you might design an experiment to determine how cannabinoid ratios differ among individual plants grown from seeds collected from different sources. Because the seeds came from different sources, they may be from different species of *Cannabis*, defined by genetic characteristics. In your experiment, you would have to control for possible environmental effects, so that such effects do not mask any differences due to genetics.

ANSWER *Growing experimental plants from seeds in a greenhouse under the same (standard) conditions is a way to minimize variation caused by environmental effects on cannabinoid ratios. During their development, all of the experimental plants will then experience the same conditions of light, moisture, soil minerals, day length, and other factors that affect plant growth (see Chapters 35–39). Under standardized growth conditions, observed differences in cannabinoid ratios will reflect genetic variation that can be used to classify Cannabis plants into species, as Hillig and Mahlburg were able to do.*

If you wanted to study the effects of environmental variation on cannabinoid ratios in Cannabis plants, you would start by acquiring seeds from plants of the same species, to eliminate genetic effects. Then you would grow replicate plants from these seeds under different conditions of light, moisture, soil minerals, day length, or other factors that affect plant growth.

30.3 The Role of Coevolution in Angiosperm Diversification

Learning Outcomes:

1. Explain the concept of coevolution.
2. List examples of coevolution between plants and animal pollinators.
3. List examples of coevolution between plants and animal seed dispersal agents.

The preceding section described how flowering plants are commonly associated with animals in ways that strongly influence plant evolution. Likewise, plants have influenced animal evolution in a diversity-generating process known as **coevolution**, which is the process by which two or more species of organisms influence each other's evolutionary pathway. During the diversification of flowering plants, coevolution with animals has been a major evolutionary factor. For example, the diversification of bees about 123 million years ago correlates with the diversification of the eudicots, which today make up three-quarters of all angiosperm species. Coevolution is reflected in the diverse forms of most flowers and many fruits and the many ways that plants accomplish effective pollen and seed dispersal. Human attraction to flowers and fruit also is an example of coevolution. This is because human sensory systems are similar to those of various animals that have coevolved with angiosperms.

Pollination Coevolution Influences the Diversification of Flowers and Animals

Animal pollinators transfer pollen from the anthers of one flower to the stigmas of other flowers of the same species. Pollinators thereby foster genetic variability and enhance plant potential for evolutionary change. Insects, birds, bats, and other pollinators learn the characteristics of particular flowers, visiting them preferentially. This animal behavior, known as constancy or fidelity, increases the odds that a flower stigma will receive pollen of the appropriate species. Animal pollinators increase the precision of pollen transfer, which reduces the amount of pollen that plants must produce to achieve pollination. By contrast, wind-pollinated plants must produce much larger amounts of pollen because windblown pollen reaches appropriate flowers by chance.

Flowers attract the most appropriate pollinators by means of attractive colors, odors, shapes, and sizes. Secondary metabolites influence the colors and odors of many flowers. Flavonoids, for example, color many blue, purple, or pink flowers. More than 700 types of chemical compounds contribute to floral odors.

Most flowers reward pollinators with food: sugar-rich nectar, lipid- and protein-rich pollen, or both. In this way, flowering plants provide an important biological service, providing food for many types of animals. However, some flowers "trick" pollinators into visiting or trap pollinators temporarily, thereby achieving pollination without actually rewarding the pollinator. Examples include flowers that look and smell like dead meat, thereby attracting flies, which are fooled but accomplish pollination anyway.

Although many flowers are pollinated by a variety of animals, others have flowers that have become specialized for particular pollinators, and vice versa. These specializations, which have resulted from coevolution, are known as **pollination syndromes** (**Table 30.2**). For example, odorless red flowers, such as those of hibiscus (see Figure 30.19b), are attractive to birds, which can see the color red but have a poor sense of smell. By contrast, bees are not typically attracted to red flowers because bee vision does not extend to the red end of the visible light spectrum. Rather, bees are attracted to blue, purple, yellow, and white flowers having sweet odors. If you are allergic to bee stings or just want to reduce the possibility of being stung, do not dress in bee-attracting flower colors or wear a flowery fragrance when in locales frequented by bees.

Pollination syndromes are also of practical importance in agriculture and in conservation biology. Fruit growers often import colonies of bees to pollinate flowers of fruit crops and so increase crop yields. In recent years, widespread die-offs of bee colonies have become an environmental and agricultural concern. When bee pollinators are not

Table 30.2 Pollination Syndromes

Animal features	Coevolved flower features
Bees	
Color vision includes ultraviolet (UV), not red	Often blue, purple, yellow, white (not red) colors
Good sense of smell	Fragrant
Require nectar and pollen	Nectar and abundant pollen
Butterflies	
Good color vision	Blue, purple, deep pink, orange, red colors
Sense odors with feet	Light floral scent
Need landing place	Landing place
Feed with long, tubular tongue	Nectar in deep, narrow floral tubes
Moths	
Active at night	Open at night; white or bright colors
Good sense of smell	Heavy, musky odors
Feed with long, thin tongue	Nectar in deep, narrow floral tubes
Birds	
Color vision, includes red	Often colored red
Often require perch	Strong, damage-resistant structure
Poor sense of smell	No fragrance
Feed in daytime	Open in daytime
High nectar requirement	Copious nectar in floral tubes
Hover (hummingbirds)	Pendulous (dangling) flowers
Bats	
Color blind	Light, reflective colors
Good sense of smell	Strong odors
Active at night	Open at night
High food requirements	Copious nectar and pollen provided
Navigate by echolocation	Pendulous or borne on tree trunks

available, growers cannot produce some fruit crops. Some plants have become so specialized to particular pollinators that if the pollinator becomes extinct, the plant becomes endangered. An example is the Hawaiian cliff-dwelling *Brighamia insignis* (**Figure 30.24**), whose presumed moth pollinator has become extinct. Humans that hand-pollinate *B. insignis* are all that stand between this plant and extinction.

Seed-Dispersal Coevolution Influences the Characteristics of Fruits and Animals

As in the case of pollination, coevolution between plants and their animal seed-dispersal agents has influenced characteristics of both fruits and the seed-dispersing animals. In addition, flowering plant fruits provide food for animals, an important biological service. For example, many of the plants of temperate forests produce fruits that are attractive to resident birds. Such juicy, sweet fruits have small seeds that readily pass through bird guts. Many plants signal fruit ripeness

Figure 30.24 *Brighamia insignis*, a plant endangered by the loss of its pollinator. The pollinator that coevolved with *B. insignis* has become extinct, with the result that the plant is unable to produce seed unless artificially pollinated by humans.

Concept Check: What kind of animal likely pollinated B. insignis?

by undergoing color changes from unripe green fruits to red, orange, yellow, blue, or black (**Figure 30.25**). Because birds have good color vision, they are able to detect the presence of ripe fruits and consume them before the fruits drop from plants and rot. Apples, strawberries, cherries, blueberries, and blackberries are examples of fruits whose seed dispersal adaptations have made them attractive food for humans as well. By contrast, the lipid-rich fruits of Virginia creeper (*Parthenocissus quinquefolia*) and some other autumn-fruiting plants energize migratory birds but are not tasty to humans. The Virginia creeper's leaves often turn fall colors earlier than surrounding plants, thereby signaling the availability of nutritious, ripe fruit to high-flying birds. Such lipid-rich fruits must be consumed promptly because they rot easily, in which case seed dispersal cannot occur.

Figure 30.25 Fruits attractive to animal seed-dispersal agents. Color and odor signals alert coevolved animal species that fruits are ripe, thus favoring the dispersal of mature seeds.

30.4 Human Influences on Angiosperm Diversification

Learning Outcome:

1. **SciSKILLS »** Use new molecular information about modern crop plants to infer their evolutionary origin by domestication.

By means of the process known as **domestication**, which involves artificial selection for traits desirable to humans, ancient humans transformed wild plant species into new crop species. Cultivated bread wheat (*Triticum aestivum*) was probably among the earliest food crops, having originated more than 8,000 years ago, in what is now southeastern Turkey and northern Syria. Bread wheat originated by a series of steps that included hybridization and whole-genome duplication from wild ancestors (*Triticum boeoticum* and *Triticum dicoccoides*). Among the earliest changes that occurred during wheat domestication was the loss of **shattering**, the process by which ears of wild grain crops break apart and disperse their grains. A mutation probably caused the ears of some wheat plants to remain intact, a trait that is disadvantageous in nature but beneficial to humans. Nonshattering ears would have been easier for humans to harvest than normal ears. Early farmers probably selected seed stock from plants having nonshattering ears and other favorable traits such as larger grains. These ancient artificial selection processes, together with modern breeding efforts, explain why cultivated wheat differs from its wild relatives in shattering and other properties. The accumulation of these trait differences is why cultivated and wild wheat plants are classified as different species.

About 9,000 years ago, people living in what is now Mexico domesticated a native grass known as teosinte (of the genus *Zea*), producing a new species, *Zea mays*, known as corn or maize. The evidence for this pivotal event includes ancient ears that were larger than wild ones and distinctive fossil pollen. Modern ears of corn are much larger than those of teosinte, with many more rows and larger and softer corn grains, and modern corn ears do not shatter, as do those of ancestral teosinte (**Figure 30.26**). These and other trait changes reflect artificial selection accomplished by humans. An analysis of the corn genome, reported in 2005 by Canadian biologist Stephen Wright, American evolutionary biologist Brandon Gaut, and coworkers, suggests that 1,200 corn genes have been affected by artificial selection.

Molecular analyses indicate that domesticated rice (*Oryza sativa*) originated from ancestral wild species of grasses (*Oryza nivara* and/or *Oryza rifipogon*). As in the cases of wheat and corn, domestication of rice involved loss of ear shattering, in this case resulting from a key amino acid substitution. Ancient humans might have unconsciously selected for this mutation while gathering rice from wild populations, because the mutants would not so easily have shed grains during the harvesting process. Eventually, the nonshattering mutant became a widely planted crop throughout Asia, and today it is the food staple for millions of people.

Although humans generated these and other plant species, modern humans have also caused the extinction of plants as the result of habitat destruction and other threats to species. Protecting biodiversity will continue to challenge humans as populations and demands on the Earth's resources increase. Plant biologists are working to identify one or more molecular sequence tools for use in barcoding plants, a process that is widely used to identify and catalog animals (see the Genomes & Proteomes Connection in Chapter 33). The ability to barcode plants, which would enable researchers to quickly analyze the DNA of a species and identify it based on existing barcodes, is important to organizations like CITES and others that monitor international trade in endangered plant species.

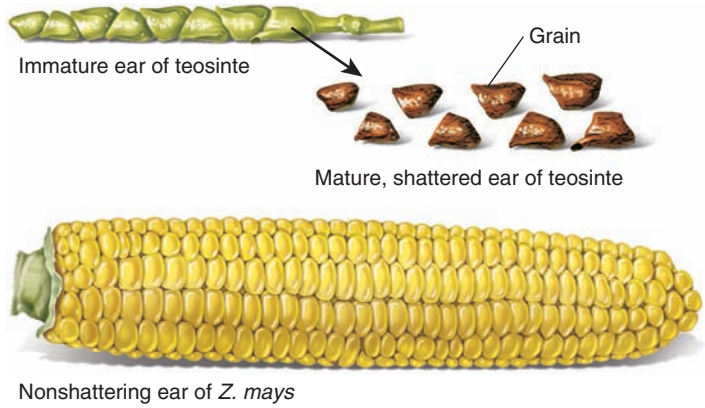

Figure 30.26 Ears and grains of modern corn and its ancestor, teosinte. This illustration shows that domesticated corn ears are much larger than those of the ancestral grass teosinte. In addition, corn fruits are softer and more edible than the grains of teosinte, which are enclosed in a hard casing.

BIOLOGY PRINCIPLE Biology affects our society. The domestication of corn from a wild grass to one of the world's largest production crops is an amazing feat of artificial selection.

Concept Check: In what other way do corn ears differ from those of teosinte?

Summary of Key Concepts

30.1 The Evolution and Diversity of Modern Gymnosperms

- The seed plants (also called spermatophytes) consist of the gymnosperms and the angiosperms (Figure 30.1, Table 30.1).
- Gymnosperms are plants that produce exposed seeds rather than seeds enclosed in fruits. Many gymnosperms produce wood by means of a special tissue called vascular cambium. Several phyla of early gymnosperms have become extinct and are known only from fossils. The greatest diversity of gymnosperms occurred during the Mesozoic era, when gymnosperms were the major vegetation present (Figure 30.2).
- The modern gymnosperms include three phyla: cycads, *Ginkgo biloba*, and the conifers (which include the Gnetales). Nearly 300 species of cycads primarily live in tropical and subtropical regions. Features of cycads include palmlike leaves, nonwoody stems, coralloid roots with cyanobacterial endosymbionts, toxins, and large conelike seed-producing structures (Figures 30.3, 30.4).
- The tree *Ginkgo biloba* is the last surviving species of a phylum that was diverse during the Age of Dinosaurs. Individual trees produce ovules and seeds or pollen, with a sex chromosome system much like that of humans (Figure 30.5).

- Conifers have been widespread and diverse members of plant communities for the past 300 million years and are important sources of wood and paper pulp for humans. Reproduction involves simple pollen cones and complex ovule-producing cones. Many conifers display adaptations that help them to survive in cold climates. Three distinctive genera of Gnetales display distinctive adaptations (Figures 30.6, 30.7, 30.8, 30.9, 30.10, 30.11).

30.2 The Evolution and Diversity of Modern Angiosperms

- Angiosperms inherited seeds and other features from gymnosperm ancestors but display distinctive features not found in other land plants, such as flowers and fruits (Figure 30.12).
- Flowers foster seed production and are adapted in various ways that aid pollination. The major flower organs are sepals and petals (or tepals), stamens, and carpels, which may occur singly or in fused groups. Both single carpels and a group of fused carpels take a distinctive shape known as a pistil, which displays regions of specialized function. The stigma is a receptive surface for pollen, pollen tubes grow through the style, and ovules develop within the ovary. Pollination is the transfer of pollen from a stamen to a pistil, a process distinct from fertilization. Double fertilization, the production of both a zygote and a nutritive tissue known as endosperm, is a critical innovation of angiosperms. If pollen germinates on the stigma and pollen tubes successfully deposit sperm near eggs in ovules, double fertilization may occur. This process allows ovules to develop into seeds containing embryos and endosperm, and ovaries to develop into fruits. Stamens and carpels may have evolved from leaflike structures bearing sporangia (Figures 30.13, 30.14, 30.15).
- The two largest and most diverse lineages of flowering plants are the monocots and eudicots (Figures 30.16, 30.17, 30.18).
- Whole-genome duplications have influenced plant evolution, particularly the diversification of the angiosperms.
- Flower diversification involved evolutionary changes such as fusion of petals, clustering of flowers into inflorescences, and reduced perianth. These changes improve the effectiveness of pollination, which enhances seed production (Figures 30.19, 30.20).
- Fruits are structures that enclose seeds and aid in their dispersal. Fruits occur in many types that foster seed dispersal (Figure 30.21).
- Angiosperms produce three main groups of secondary metabolites: (1) terpenes and terpenoids; (2) phenolics, flavonoids, and related compounds; and (3) alkaloids, which play essential roles in plant structure, reproduction, and defense, respectively (Figure 30.22).
- Hillig and Mahlberg demonstrated the use of particular secondary metabolites in distinguishing species of the genus *Cannabis* (Figure 30.23).

30.3 The Role of Coevolution in Angiosperm Diversification

- Coevolutionary interactions between flowering plants and animals that serve as pollen- and seed-dispersal agents played a powerful role in the diversification of both angiosperms and animals (Table 30.2, Figures 30.24, 30.25).
- Human appreciation of flowers and fruits is based on sensory systems similar to those present in the animals with which angiosperms coevolved.

30.4 Human Influences on Angiosperm Diversification

- Humans have produced new crop species by domesticating wild plants. The process of domestication involved artificial selection for traits such as nonshattering ears of wheat, corn, and rice (Figure 30.26).

Assess and Discuss

Test Yourself

1. What feature must be present for a plant to produce wood?
   a. a type of conducting system in which vascular bundles occur in a ring around pith
   b. a eustele
   c. a vascular cambium
   d. all of the above
   e. none of the above
2. Which sequence of critical innovations reflects the order of their appearance in time?
   a. embryos, vascular tissue, wood, seeds, flowers
   b. vascular tissue, embryos, wood, flowers, seeds
   c. vascular tissue, wood, seeds, embryos, flowers
   d. wood, seeds, embryos, flowers, vascular tissue
   e. seeds, vascular tissue, wood, embryos, flowers
3. How long have ancient and modern groups of gymnosperms been important members of plant communities?
   a. 10,000 years, since the dawn of agriculture
   b. 100,000 years
   c. 300,000 years
   d. 65 million years, since the Cretaceous-Paleogene (K/T) event
   e. 300 million years, since the Coal Age
4. What similar features do gymnosperms and angiosperms possess that differ from other modern vascular plants?
   a. Gymnosperms and angiosperms both produce flagellate sperm.
   b. Gymnosperms and angiosperms both produce flowers.
   c. Gymnosperms and angiosperms both produce tracheids, but not vessels, in their vascular tissues.
   d. Gymnosperms and angiosperms both produce fruits.
   e. none of the above
5. Which part of a flower receives pollen transported by the wind or a pollinating animal?
   a. perianth c. filament e. ovary
   b. stigma d. pedicel
6. The primary function of a fruit is to
   a. provide food for the developing seed.
   b. provide food for the developing seedling.
   c. foster pollen dispersal.
   d. foster seed dispersal.
   e. None of the above identifies the primary function of a fruit.
7. Flowers have diversified with regard to
   a. color.
   b. number of flower parts.
   c. fusion of organs.
   d. aggregation into inflorescences.
   e. all of the above.

8. Plants of the genus *Fuchsia* produce deep pink to red flowers that dangle from plants, produce nectar in floral tubes, and have no scent. Based on these features, which animal is most likely to be a coevolved pollinator of these plants?
   a. bee
   b. bat
   c. hummingbird
   d. butterfly
   e. moth
9. Which type of plant secondary metabolite is best known for the antioxidant properties of human foods such as blueberries, tea, and grape juice?
   a. alkaloids
   b. cannabinoids
   c. carotenoids
   d. phenolics
   e. terpenoids
10. What features of domesticated grain crops might differ from those of wild ancestors?
    a. the degree to which ears shatter, allowing for seed dispersal
    b. grain size
    c. number of grains per ear
    d. softness and edibility of grains
    e. all of the above

Conceptual Questions

1. Make a diagram that shows how plant biologists think flowers arose.
2. Explain why fruits such as apples, strawberries, and cherries are attractive and harmless foods for humans.
3.  A principle of biology is that *structure determines function*. Compare the structures of an apple flower and a sunflower, explaining how they relate to differences in pollination and seed dispersal.

Collaborative Questions

1. Where in the world would you have to travel to find wild plants representing all of the gymnosperm phyla, including the three types of Gnetales?
2. How would you go about trying to solve what Darwin called "an abominable mystery," that is, the identity of the seed plant group that was ancestral to the flowering plants?

CHAPTER OUTLINE

31.1 Evolution and Distinctive Features of Fungi
31.2 Fungal Asexual and Sexual Reproduction
31.3 Diversity of Fungi
31.4 Fungal Ecology and Biotechnology
Summary of Key Concepts
Assess and Discuss

Fungi

31

The aboveground reproductive parts of the fungus *Armillaria ostoyae*. Because of the large extent of its underground components, this fungus may be the largest organism in the world.

You might think that the largest organism in the world is a whale or perhaps a giant redwood tree. Amazingly, giant fungi would also be good candidates. For example, an individual of the fungus *Armillaria ostoyae* weighs hundreds of tons, is more than 2,000 years old, and spreads over 2,200 acres of Oregon forest soil! Scientists discovered the extent of this enormous fungus when they found identical DNA sequences in soil samples taken over this wide area. Other examples of such huge fungi have been found, and mycologists—scientists who study fungi—suspect that they may be fairly common, existing underfoot yet largely unseen.

Regardless of their size, fungi typically occur within soil or other materials, becoming conspicuous only when the reproductive portions such as mushrooms extend above the surface. Even though fungi can be inconspicuous, they play essential roles in the Earth's environment; are associated in diverse ways with other organisms, including humans; and have many applications in biotechnology. In this chapter, we will explore the distinctive features of fungal structure, growth, nutrition, reproduction, and diversity. In the process, we will see how fungi are connected to decomposition, forest growth, food production and food toxins, sick building syndrome, and other topics of great importance to humans.

31.1 Evolution and Distinctive Features of Fungi

Learning Outcomes:

1. **SciSKILLS** » Use information about groups of fungi to draw a diagram showing their evolutionary relationships.
2. Outline the distinctive features of fungi, including how they obtain food.
3. Discuss how fungal feeding is related to fungal growth.

The eukaryotes known as fungi are so distinct from other organisms that they are placed in their own kingdom, the kingdom Fungi (**Figure 31.1**). Together with certain closely related protists, the kingdom Fungi and the kingdom Animalia (also known as Metazoa) form a eukaryotic supergroup known as Opisthokonta (refer back to Figure 28.6). The kingdom Fungi, also known as the true fungi, diverged from Animalia more than a billion years ago, during the Middle Proterozoic Era. Several types of slime molds, disease-causing oomycetes, and other fungus-like protists—though often studied with fungi—are classified with nonopisthokont protists rather than true fungi (see Chapter 28).

The true fungi form a monophyletic group of more than 100,000 species. The earliest fungi originated in aquatic habitats, where they diverged from opisthokont protists and are closely related to the modern genus *Nuclearia*—an amoeba that feeds by ingesting algal and bacterial cells. Feeding on particles such as cells is a process known as phagocytosis (see Figure 31.1). The earliest-diverging modern fungi, informally known as cryptomycota, occur in diverse genetic types in soil and water. Some of the cryptomycota, known as microsporidia, are single-celled fungi that parasitize animal cells, sometimes causing disease. Unlike most fungi, Cryptomycota generally produce flagella and they don't typically produce a cell wall containing **chitin**, a tough polysaccharide polymer that contains nitrogen. Such a cell wall enables most fungi

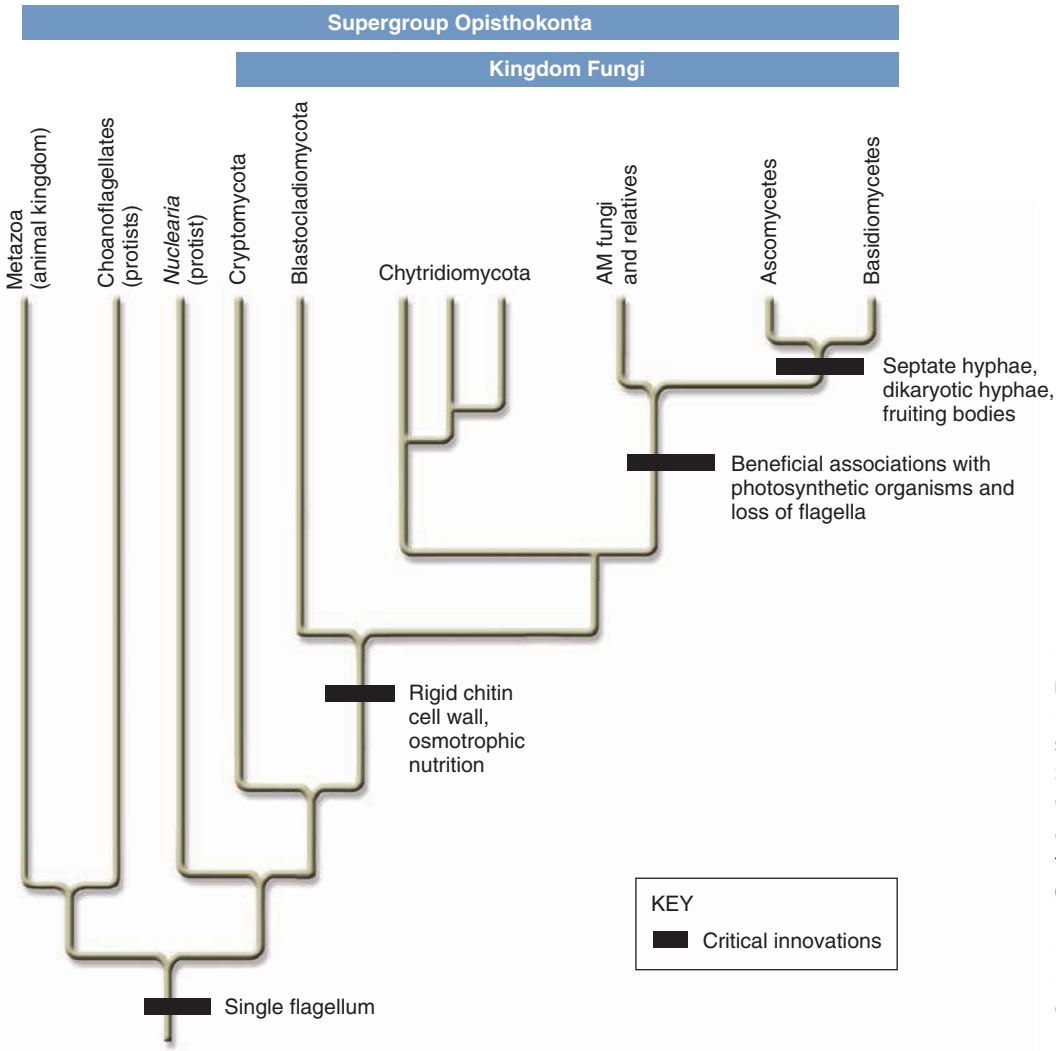

Figure 31.1 Evolutionary relationships of the fungi. The kingdom Fungi arose from a protist ancestor similar to the modern genus *Nuclearia*. Several early-diverging phyla of fungi are Cryptomycota, Blastocladiomycota, and Chytridiomycota. Later-diverging fungal phyla include Glomeromycota (informally, the AM fungi) and close relatives Ascomycota, and Basidiomycota. These three phyla are particularly rich in species and have great environmental significance today.

to resist high osmotic pressure that results when they feed by absorbing small organic molecules, a process known as **osmotrophy**. Fungal cells that possess rigid chitin-rich walls cannot feed by ingesting food particles (phagocytosis; see Figure 28.7). The evolution of this type of wall signals a key evolutionary transition in fungal nutrition from phagocytosis to osmotrophy (see Figure 31.1).

Several aquatic lineages of microscopic species produce flagellate reproductive cells that can move through aquatic environments. Familiar black bread molds are classified together with related fungi that used to be known informally as the zygomycetes. Black bread molds and later-diverging fungi lack flagella, an adaptation to the terrestrial environment. The phylum Glomeromycota, informally referred to as the arbuscular mycorrhizal fungi, abbreviated **AM fungi**, show widespread symbiotic associations with plant roots. The Ascomycota, or **ascomycetes** (also known as the sac fungi), and the Basidiomycota, or **basidiomycetes** (club fungi), are later-diverging fungal phyla that display many adaptations to life on land.

Because fungi are closely related to the animal kingdom, fungi and animals display some common features. For example, both are **heterotrophic**, meaning that they cannot produce their own food but must obtain it from the environment. Fungi use an amazing array of organic compounds as food, which is termed their **substrate**. The substrate can be soil, a rotting log, a piece of bread, a living tissue, or a wide array of other materials. Fungi are also like animals in having **absorptive nutrition**. Both fungi and the cells of animal digestive systems secrete enzymes that break down complex organic materials and absorb the resulting small organic food molecules. In addition, both fungi and animals store surplus food as the carbohydrate glycogen in their cells. Despite these nutritional commonalities, fungal body structure, growth, and reproduction are distinct from those of animals and differ among fungal lineages. Because structure, growth, and reproductive differences are key to understanding fungal diversity, we will focus on these features before exploring fungal diversity in more detail (Section 31.3).

Fungi Have a Unique Body Form

Most fungi have a distinctive body known as a **mycelium** (plural, mycelia), which is composed of individual microscopic, branched filaments known as **hyphae** (singular, hypha) (**Figure 31.2**). Hyphae and mycelia evolved even before fungi made the transition from aquatic to terrestrial habitats. The hyphae of early-diverging fungi are not

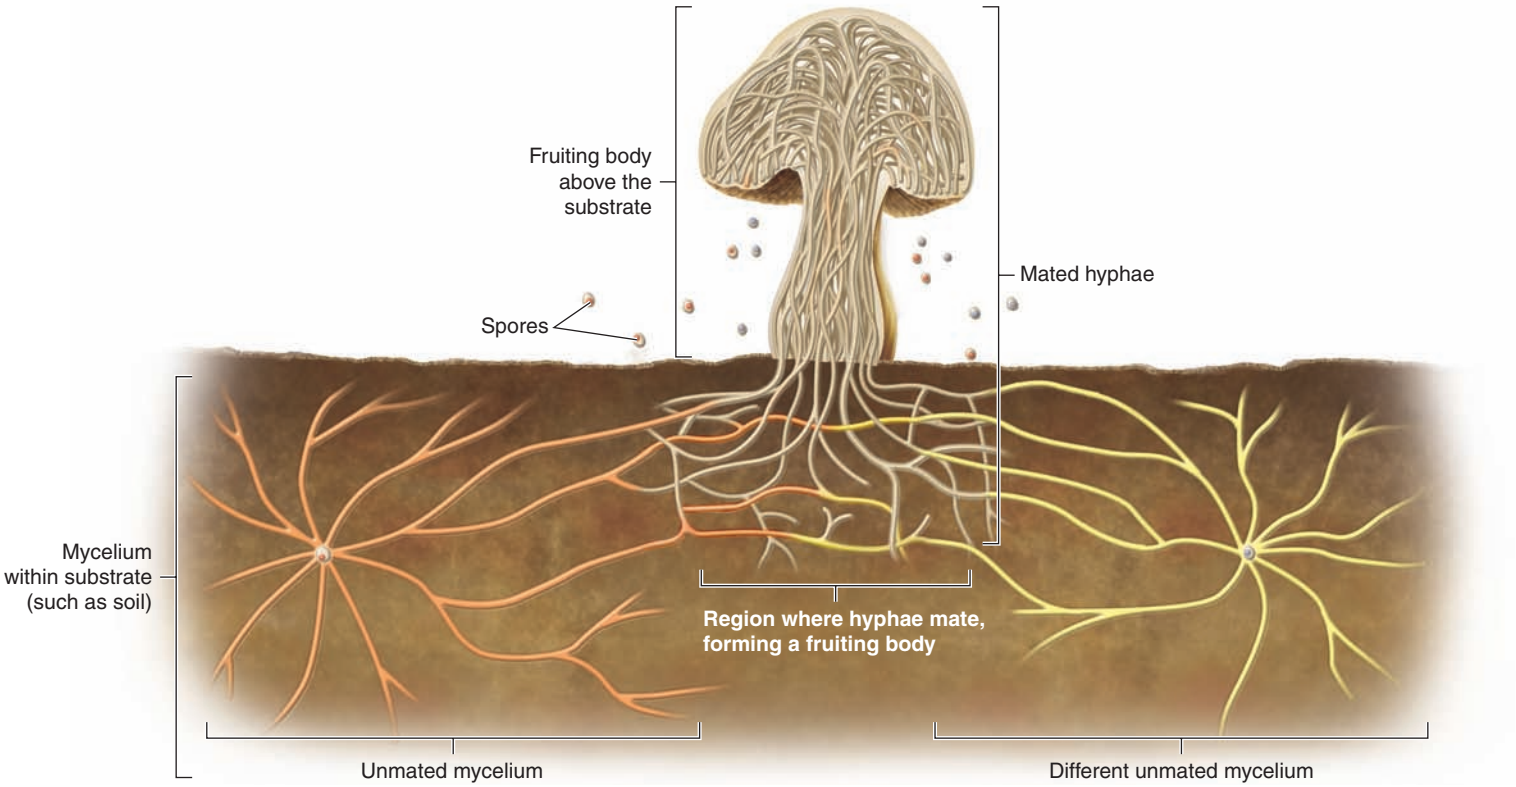

Figure 31.2 **Fungal morphology.** The greater part of a fungus consists of food-gathering hyphae that grow and branch from a central point to form a diffuse mycelium within a food substrate, such as soil.

BIOLOGY PRINCIPLE **Living organisms grow and develop.** After a mating process occurs, mated hyphae may aggregate and grow out of the substrate, forming fruiting bodies that produce and disperse spores. In suitable sites, spores may germinate, producing new mycelia.

partitioned into smaller cells. Rather, these hyphae are **aseptate** and multinucleate (**Figure 31.3a**), a condition that results when nuclei repeatedly divide without intervening cytokinesis. Such aseptate hyphae are described as being coenocytic. By contrast, the hyphae of later-diverging fungi are subdivided into many small cells by cross walls known as **septa** (singular, septum) (**Figure 31.3b**). In such fungi, known as septate fungi, each round of nuclear division is followed by the formation of a septum that is perforated by a small pore. Septate hyphae appeared after the divergence of the AM fungi, but prior to the divergence of ascomycetes from basidiomycetes (see Figure 31.1).

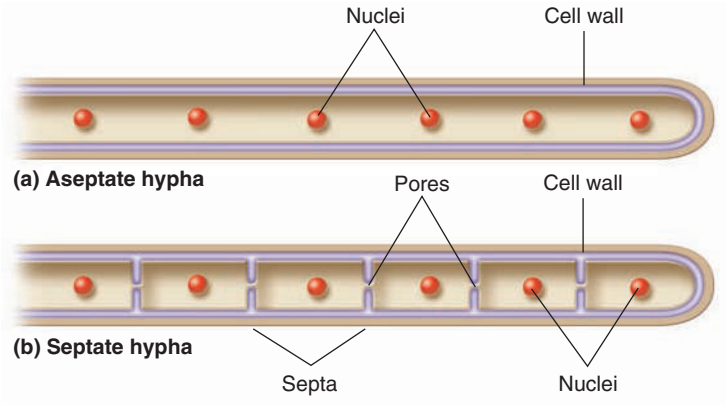
As mentioned, a fungal mycelium may be very extensive, as in the case of *Armillaria ostoyae* (see the chapter opening photo), but is often inconspicuous because the component hyphae are so tiny and spread out in the substrate. The diffuse form of the fungal mycelium makes sense because most hyphae function to absorb organic food from the substrate. By spreading out, hyphae can absorb food from a large volume of substrate. The absorbed food is used for mycelial growth and for reproduction.

Mushrooms are types of fungal reproductive structures called **fruiting bodies** (see Figure 31.2). Fruiting bodies are composed of densely packed hyphae that have undergone a sexual mating process during which unmated hyphae of different, but compatible, mycelia are attracted to each other and fuse. The resulting mated hyphae differ genetically and biochemically from unmated hyphae. Researchers suspect that mating hyphae secrete signaling substances that cause many of them to cluster together and grow out of the substrate and into the air, where reproductive cells can be more easily dispersed. Amazingly diverse in form, color, and odor, mature fruiting bodies are specialized to produce and disperse reproductive cells known as **spores**. Produced by the process of meiosis and protected by tough walls, spores reflect a major adaptation to the terrestrial habitat. When fungal spores settle in places where conditions are favorable for growth, they produce new mycelia. When the new mycelia undergo sexual reproduction, they produce new fruiting bodies.

Fungi Have Distinctive Growth Processes

If you have ever watched bread or fruit become increasingly moldy over the course of several days, you have observed fungal growth. When a food source is plentiful, fungal mycelia can grow rapidly, adding as much as a kilometer of new hyphae per day. The mycelia grow at their edges as the fungal hyphae extend their tips through the undigested substrate. The narrow dimensions and extensive branching of hyphae provide a very high surface area for absorption of organic molecules, water, and minerals.

Hyphal Tip Growth Cytoplasmic streaming and osmosis are important cellular processes in hyphal growth. Osmosis (see Chapter 5) is



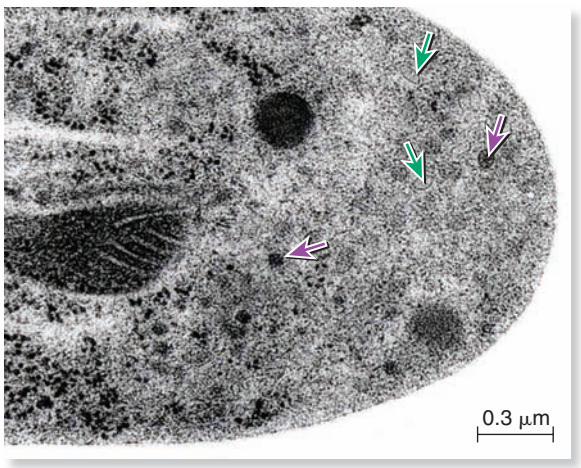


Figure 31.3 Types of fungal hyphae.

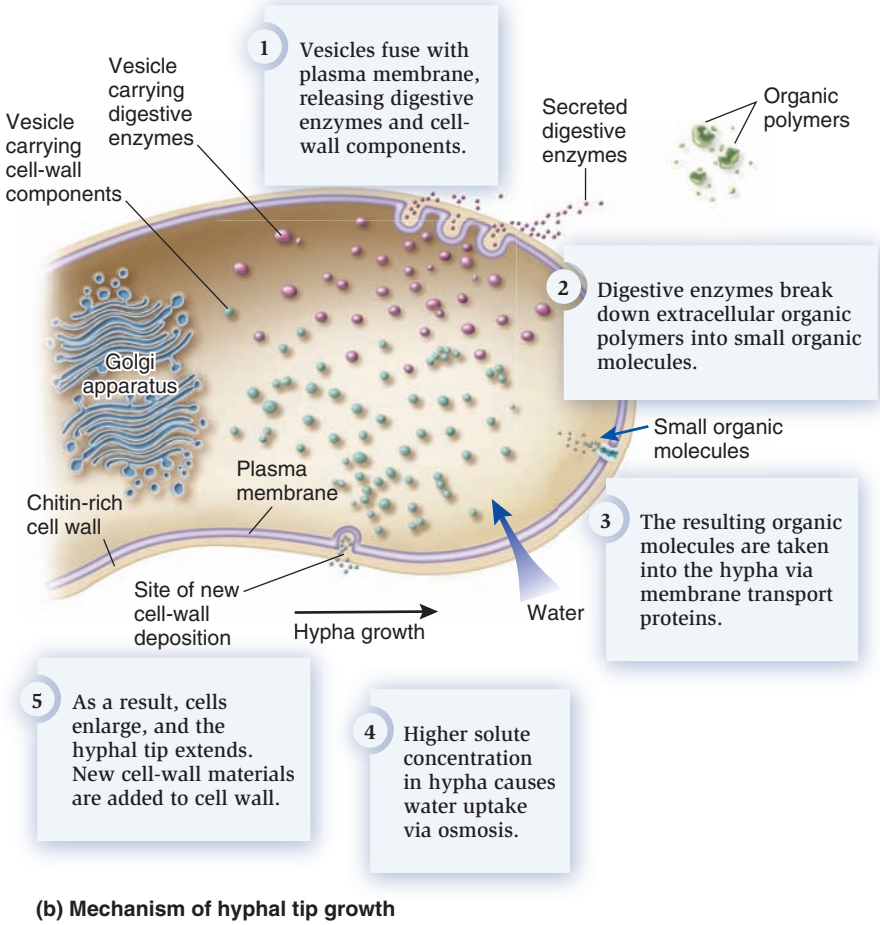
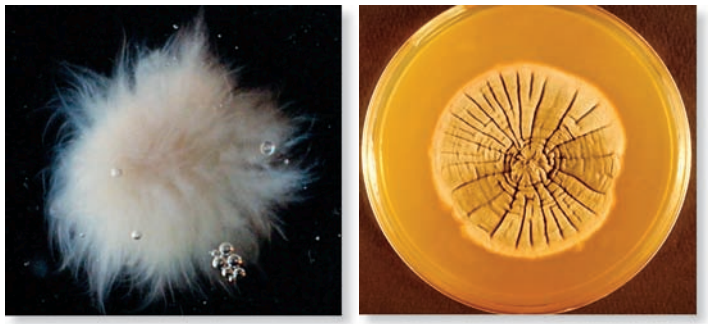


BIOLOGY PRINCIPLE Cells are the simplest units of life. This figure compares **(a)** the multinucleate hypha of an aseptate fungus with **(b)** a hypha of a septate fungus whose cells have a single nucleus.

the diffusion of water through a membrane, from a solution with a lower solute concentration into a solution with a higher solute concentration. Water enters fungal hyphae by means of osmosis because their cytoplasm is rich in sugars, ions, and other solutes. Water entry swells the hyphal tip, producing the force necessary for tip extension. Masses of tiny vesicles carrying enzymes and cell-wall materials made in the Golgi apparatus collect in the hyphal tip (**Figure 31.4**). The vesicles then fuse with the plasma membrane. Some vesicles release enzymes that digest materials in the environment, yielding small organic molecules that are absorbed as food. Other vesicles deliver cell-wall materials to the hyphal tip, allowing it to extend.

Variations in Mycelium Growth Form Fungal hyphae grow rapidly through a substrate from areas where the food has become depleted to food-rich areas. In nature, mycelia may take an irregular shape, depending on the distribution of the food substrate. A fungal mycelium may extend into food-rich areas for great distances, as noted at the beginning of the chapter. In liquid laboratory media,



(a) Electron micrograph of a hyphal tip with numerous vesicles

(b) Mechanism of hyphal tip growth

Figure 31.4 Hyphal tip growth and absorptive nutrition. **(a)** TEM showing the hyphal tip of *Aspergillus nidulans*, an ascomycete commonly used as a genetic model organism. The tip is filled with membrane-bound vesicles that fuse with the plasma membrane. Purple arrowheads show dark-stained vesicles carrying digestive enzymes; green arrowheads point out light-stained vesicles carrying cell-wall materials. **(b)** Diagram of a hyphal tip, with vesicles of the same two types, showing the steps of hyphal tip growth.

Concept Check: *What do you think would happen to fungal hyphae that begin to grow into a substrate with a higher solute concentration? How might your answer be related to food preservation techniques such as drying or salting?*

(a) Mycelium growing in liquid medium

(b) Mycelium growing on flat, solid medium

Figure 31.5 Fungal shape shifting. (a) When a mycelium, such as that of this *Rhizoctonia solani*, is surrounded by food substrate in a liquid medium, it will grow into a spherical form. **(b)** When the food supply is limited to two dimensions, as shown by *Neotestudina rosatii* in a laboratory dish, the mycelium will form a disc. Likewise, distribution of the food substrate determines the mycelium shape in nature.

fungi will grow as a spherical mycelium that resembles a cotton ball floating in water (**Figure 31.5a**). Grown in flat laboratory dishes, the mycelium assumes a more two-dimensional growth form (**Figure 31.5b**).

31.2 Fungal Asexual and Sexual Reproduction

Learning Outcomes:

1. Give examples of fungal asexual reproduction.
2. Identify some of the distinctive sexual reproductive processes in fungi.
3. Explain why humans may safely consume some fungal fruiting bodies, whereas other fungal fruiting bodies are toxic to humans.

Many fungi reproduce either asexually or sexually by means of microscopic spores, each of which can grow into a new mature organism. Asexual reproduction is a natural cloning process; it produces genetically identical organisms. Production of asexual spores allows fungi that are well adapted to a particular environment to disperse to similar, favorable places. Sexual reproduction generates new allele combinations that may allow fungi to colonize new types of habitats.

Fungi Reproduce Asexually by Dispersing Specialized Cells

Asexual reproduction is particularly important to fungi, allowing them to spread rapidly. To reproduce asexually, fungi do not need to find compatible mates or expend resources on fruiting-body formation and meiosis. More than 17,000 fungal species reproduce primarily or exclusively by asexual means. DNA-sequencing studies have revealed that many types of modern fungi that reproduce only asexually have evolved from ancestors that used both sexual and asexual reproduction.

Many fungi produce asexual spores known as **conidia** (from the Greek *konis*, meaning dust) at the tips of their hyphae (**Figure 31.6**). When they land on a favorable substrate, conidia germinate into a new mycelium that produces many more conidia. The green molds that form on citrus fruits are familiar examples of conidial fungi. A single fungus can produce as many as 40 million conidia per hour over a period of 2 days.

Because they can spread so rapidly, asexual fungi are responsible for costly fungal food spoilage, allergies, and diseases. Medically important fungi that reproduce primarily by asexual means include the athlete's foot fungus (*Epidermophyton floccosum*) and the infectious yeast *Candida albicans*. **Yeasts** are unicellular fungi of various lineages. Asexual reproduction in some yeasts occurs by budding (**Figure 31.7**).

Fungi Have Distinctive Sexual Reproductive Processes

As is typical for eukaryotes, the fungal sexual reproductive cycle involves the union of gametes, the formation of zygotes, and the process of meiosis. In contrast to plants, whose life cycle is an alternation of haploid and diploid generations, and diploid-dominant animals, the fungal life cycle is typically haploid-dominant (look back to Figure 15.14). However, some early-diverging fungi are notable for a life cycle involving alternation of two generations, a haploid gametophyte and a diploid sporophyte. Some other aspects of fungal sexual reproduction are unique, including the function of hyphal branches as gametes and the development of fruiting bodies.

Fungal Gametes and Mating Early-diverging fungi that live in the water produce flagellate sperm that swim to nonmotile eggs, as do animals and many protists and plants. By contrast, the gametes of terrestrial fungi are cells of hyphal branches rather than distinguishable male and female gametes. Fungal mycelia occur in multiple mating types that differ biochemically. The compatibility of these mating types is controlled by particular genes. During fungal sexual reproduction, hyphal branches of different, but compatible mycelia are

Figure 31.6 Asexual reproductive cells of fungi. SEM of the asexual spores (conidia) of *Aspergillus versicolor*, which causes skin infections in burn victims and lung infections in AIDS patients. Each of these small cells is able to detach and grow into an individual that is genetically identical to the parent fungus and so is able to grow in similar conditions.

Concept Check: How might you try to protect a burn patient from infection by a conidial fungus?

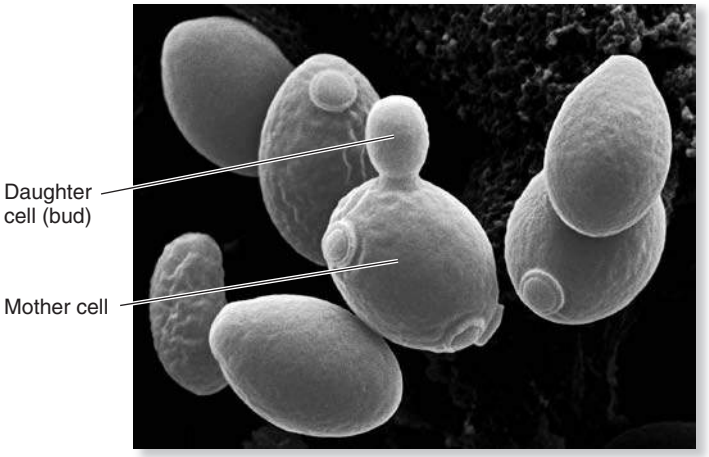


Figure 31.7 The budding yeast *Saccharomyces cerevisiae*. In budding, a small daughter cell is formed on the surface of a larger mother cell, eventually pinching off and forming a new cell.

BioConnections: Look back at Table 13.3, which shows the genome characteristics of some model organisms. How does the genome of S. cerevisiae compare with genomes of other model organisms?

(a) Fruiting bodies adapted for dispersal of spores by wind **(b) Fruiting body adapted for dispersal of spores by insects**

Figure 31.8 Fruiting body adaptations that foster spore dispersal. (a) When disturbed by wind gusts or animal movements, spores puff from fruiting bodies of the puffball fungus (*Lycoperdon perlatum*). **(b)** The fruiting bodies of stinkhorn fungi, such as this *Phallus impudicus*, smell and look like dung or rotting meat. This attracts flies, which come into contact with the sticky fungal spores, thereby dispersing them.

attracted to each other by secreted peptides, and when hyphae have grown sufficiently close, they fuse. This distinctive mating process represents an adaptation to terrestrial life.

Fruiting Bodies Under appropriate environmental conditions, such as seasonal change, a mated mycelium may produce a fleshy fruiting body, such as a mushroom. Fungal fruiting bodies typically emerge from the substrate and produce haploid spores (see Figure 31.2). Each spore acquires a tough chitin wall that protects it from drying out and other stresses. Wind, rain, or animals disperse the mature spores, which grow into haploid mycelia. If a haploid mycelium encounters hyphae of an appropriate mating type, hyphal branches will fuse and start the sexual cycle over again.

Mycelium growth requires organic molecules, minerals, and water provided by the substrate, but in most cases, spores are more easily dispersed if released outside of the substrate. The structures of fruiting bodies vary in ways that reflect different adaptations that foster spore dispersal by wind, rain, or animals. For example, mature puffballs have delicate surfaces upon which just a slight pressure causes the spores to puff out into wind currents (**Figure 31.8a**). Birds' nest fungi form characteristic egg-shaped spore clusters. Raindrops splash on these clusters and disperse the spores. The fruiting bodies of stinkhorn fungi smell and look like rotting meat (**Figure 31.8b**), which attracts carrion flies. The flies land on the fungi to investigate the potential meal and then fly away, in the process dispersing spores that stick to their bodies. The fruiting bodies of fungal truffles are unusual in being produced underground. Truffles have evolved a spore dispersal process that depends on animals that eat fungi. Mature truffles emit an odor that attracts wild pigs and dogs, which break up the fruiting structures while digging for them, thereby dispersing the spores (look ahead to Figure 31.19). Collectors use trained leashed pigs or dogs to locate valuable truffles from forests for the market.

Many fungal fruiting bodies such as truffles and morels are edible, and several species of edible fungi are cultivated for human consumption (**Figure 31.9**). However, the bodies of many other fungi produce toxic substances that may deter animals from consuming them (**Figure 31.10**). For example, several fungi that attack stored grains, fruits, and spices produce **aflatoxins** that cause liver cancer and are a major health concern worldwide. When people consume the forest mushroom *Amanita virosa*, known as the "destroying angel," they ingest a powerful toxin that may cause liver failure so severe that death may ensue unless a liver transplant is performed. Each year, many people in North America are poisoned when they consume similarly toxic mushrooms gathered in the wild. There is no reliable way for nonexperts to distinguish poisonous from nontoxic fungi; it is essential

Figure 31.9 Several types of edible fungi available in the market.

Figure 31.10 Toxic fruiting body of *Amanita muscaria*. Common in conifer forests, *A. muscaria* is both toxic and hallucinogenic. Ancient people used this fungus to induce spiritual visions and to reduce fear during raids. This fungus produces a toxin, amanitin, which specifically inhibits RNA polymerase II of eukaryotes.

BioConnections: Look back at Figure 13.14, which illustrates the cellular role of RNA polymerase II in eukaryotes. What effect would the amanitin toxin have on human cells?

to receive instruction from an expert before foraging for mushrooms in the woods. Therefore, many authorities recommend that it is better to search for mushrooms in the grocery store than in the wild.

Several types of fungal fruiting structures produce hallucinogenic or psychoactive substances. As in the case of fungal toxins, fungal hallucinogens may have evolved as herbivore deterrents, but humans have inadvertently experienced their effects. For example, *Claviceps purpurea*, which causes a disease of rye crops and other grasses known as ergot, produces a psychogenic compound related to LSD (lysergic acid diethylamide) (**Figure 31.11**). Some experts speculate that cases of hysteria, convulsions, infertility, and a burning sensation of the skin that occurred in Europe during the Middle Ages and that were attributed to witchcraft resulted from ergot-contaminated rye used in foods. Another example of a hallucinogenic fungus is the "magic mushroom" (*Psilocybe*), which is used in traditional rituals in some cultures. Like ergot, the magic mushroom produces a compound similar to LSD. Consuming hallucinogenic fungi is risky because the amount used to achieve psychoactive effects is dangerously close to a poisonous dose.

Figure 31.11 Ergot of rye. The fungus *Claviceps purpurea* infects rye and other grasses, producing hard masses of mycelia known as ergots in place of some of the grains (fruits).

BIOLOGY PRINCIPLE Biology affects our society. Ergots such as the one illustrated produce alkaloids related to LSD and thus cause psychotic delusions in humans and animals that consume products made with infected rye.

31.3 Diversity of Fungi

Learning Outcome:

1. Outline the distinguishing features of the fungal phyla Glomeromycota, Ascomycota, and Basidiomycota.

As noted earlier, the kingdom Fungi is a monophyletic group that arose from a protist ancestor, diversifying first in aquatic habitats, then later in terrestrial environments (see Figure 31.1). Here we first mention some features of early diverging fungi such as Cryptomycota, chytrids and bread molds, then describe in more detail the important fungal lineages listed in **Table 31.1**: Glomeromycota, Ascomycota, and Basidiomycota. In this section, we will survey the habitats and characteristics of these groups of fungi, focusing on distinctive ecological, structural, growth, and reproductive features.

Cryptomycota and Chytrids Occur in Water and Soil

Cryptomycota are a recently defined group of genetically diverse, single-celled organisms found in water and soil. Microsporidia have been included in the cryptomycota. An example of a microsporidian is *Nosema ceranae*, a single-celled fungus that parasitizes animals, causing disease (**Figure 31.12**). Polyphyletic chytrids live in aquatic habitats or in moist soil and produce flagellate reproductive cells. A rigid chitin-rich wall is present. Some chytrids occur as single, spherical cells that may produce hyphae (**Figure 31.13**). Most chytrids are decomposers, but some are parasites of protists and pathogens of plants or animals. For example, the chytrid *Batrachochytrium dendrobatidis* has been associated with declining frog populations in Australia and the Americas (look ahead to Figure 54.1).

Other Early-Diverging Fungi Produce Distinctive Zygospores

Other early-diverging fungi feature a mycelium that is mostly composed of aseptate hyphae (those lacking cross walls) and distinctive asexual and sexual reproductive structures. For example, during asexual reproduction, the black bread mold *Rhizopus stolonifer* produces spores in dark-pigmented enclosures known as **sporangia** (singular, sporangium) (**Figure 31.14a**). A sporangium is a structure that produces spores. Bread mold sporangia form at hyphal tips in such large numbers that they make moldy bread appear black. These asexual

Table 31.1 Distinguishing Features of Later-Diverging Fungal Phyla

Phylum	Habitat	Ecological role	Reproduction	Examples cited in this chapter
Glomeromycota	Terrestrial	Form mutually beneficial mycorrhizal associations with plants	Distinctively large, nonflagellate, multinucleate asexual spores	The genus *Glomus*
Ascomycota	Mostly terrestrial	Decomposers; pathogens; many form lichens; some are mycorrhizal	Asexual conidia; nonflagellate sexual spores (ascospores) in sacs (asci) on fruiting bodies (ascocarps)	*Aleuria aurantia*, *Venturia inaequalis*, *Saccharomyces cerevisiae*, *Tuber melanosporum*
Basidiomycota	Terrestrial	Decomposers; many are mycorrhizal; less commonly form lichens	Several types of asexual spores; nonflagellate sexual spores (basidiospores) on club-shaped basidia on fruiting bodies (basidiocarps)	*Coprinus disseminatus*, *Rhizoctonia solani*, *Armillaria mellea*, *Puccinia graminis*, *Ustilago maydis*, *Phanerochaete chrysosporium*, *Laccaria bicolor*, *Amanita muscaria*, *Phallus impudicus*, *Lycoperdon perlatum*

sporangia may each release up to 100,000 spores into the air! The great abundance of such spores means that bread molds easily unless the baker adds retardant chemicals.

The zygospore is a distinctive feature of sexual reproduction in many early-diverging fungi formerly known as zygomycetes (**Figures 31.14b, 31.15**). In the black bread mold, zygospore production begins with the development of **gametangia** (from the Greek, meaning gamete-bearers). In black bread molds, gametangia are hyphal branches whose cytoplasm is isolated from the rest of the mycelium by cross walls. These gametangia enclose gametes that are basically a mass of cytoplasm containing several haploid nuclei. When food supplies run low and if compatible mating strains are present, the gametangia of compatible mating types fuse, as do the gamete cytoplasms. The resulting cell becomes a sporangium that contains many haploid nuclei. Eventually these haploid nuclei fuse in pairs, producing many diploid nuclei (zygote nuclei). For this reason, a zygomycete sporangium produced by sexual reproduction is called a zygosporangium. A single dark-pigmented, thick-walled, multinucleate **zygospore** matures within each zygosporangium. The zygospore is capable of surviving stressful conditions, but when the environment is suitable, the diploid nuclei within the zygospore may undergo meiosis and germinate, dispersing many haploid spores. If the haploid spores land in a suitable place, they germinate to form aseptate hyphae that contain many haploid nuclei produced by mitosis. Most zygospore-producing fungi live on decaying materials in soil, but some are parasites of plants or animals.

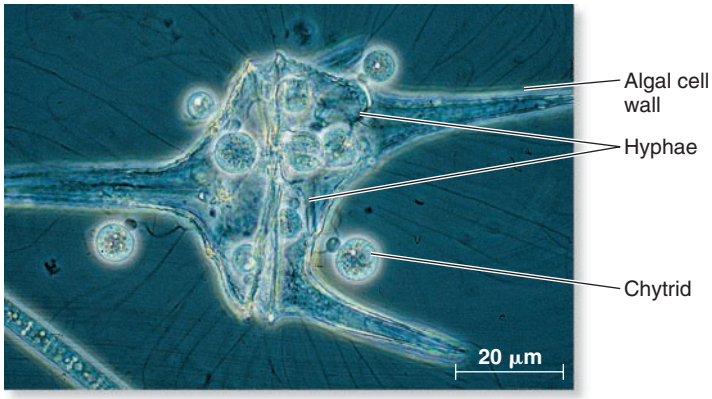

Figure 31.13 Chytrids growing on a freshwater protist. The colorless chytrids produce hyphae that penetrate the cellulose cell walls of the protist *Ceratium hirundinella*, absorbing organic materials. Chytrids use these materials to produce spherical flagellate spores that swim away to attack other algal cells.

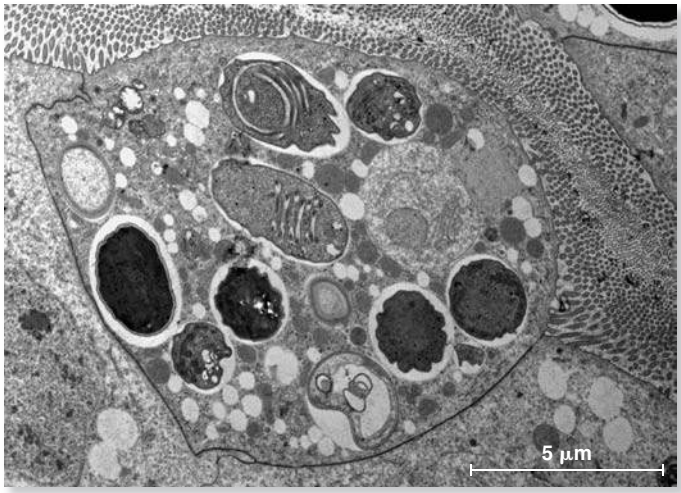

Figure 31.12 The microsporidian fungus *Nosema ceranae*. This fungus, the darker round or oblong structures within a bee cell, is linked with honeybee decline.

Glomeromycota Live with Plant Partners

The microscopic fungi known as Glomeromycota are fully adapted to life on land, and typically occur in mutually beneficial partnerships with the roots of land plants. These partnerships are known as mycorrhizae (from the Greek, meaning fungus roots). Within a plant's root cells, the fungal hyphae often form coils or tree-shaped structures known as arbuscules (from the word arbor, referring to

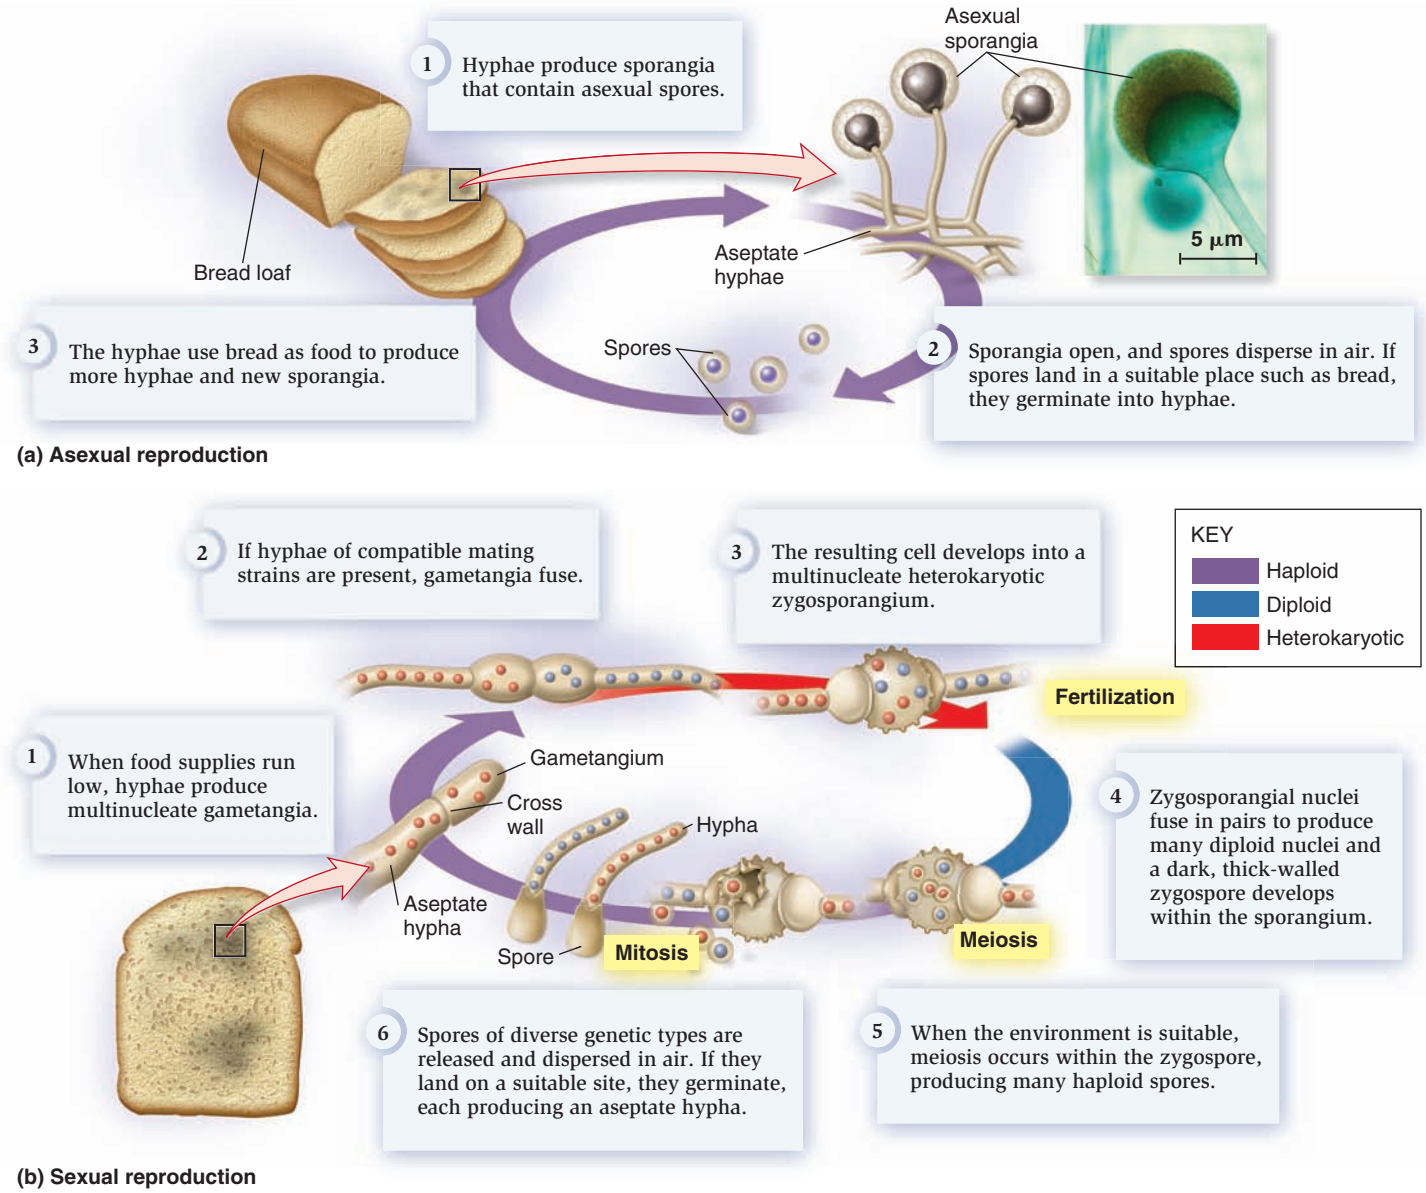

Figure 31.14 **The asexual and sexual life cycles of the black bread mold *Rhizopus stolonifer*.**

the tree shape). For this reason, as noted earlier, the Glomeromycota are informally known as the arbuscular mycorrhizal fungi, or AM fungi.

The AM fungi have hyphae with few septa and reproduce only asexually by means of unusually large spores containing many nuclei (**Figure 31.16**). Many vascular plants depend on AM fungi, and these fungi are not known to grow separately from plants or cyanobacterial partners. Genomic analyses reveal that AM fungi, unlike many other fungi, lack genes that are involved in degrading plant cell walls or in producing toxins. These genetic adaptations reflect the close evolutionary integration of Glomeromycota and plants. The ecological importance of partnerships between the AM fungi and their plant partners are described more completely in Section 31.4.

Molecular evidence suggests that AM fungi originated more than 750 mya. Fossils having aseptate hyphae and large spores similar to those of modern AM fungi are known from the time when land plants first became common and widespread, about 460 mya (see Chapter 29). This and other fossil evidence suggests that the ability of early plants to thrive on land may have depended on help from fungal associates, as is common today.

Ascomycota Produce Sexual Spores in Saclike Asci

Both the Ascomycota and the Basidiomycota (ascomycetes and basidiomycetes) are composed of hyphae subdivided into cells by septa. In ascomycetes, these septa display simpler pores than do the septa of

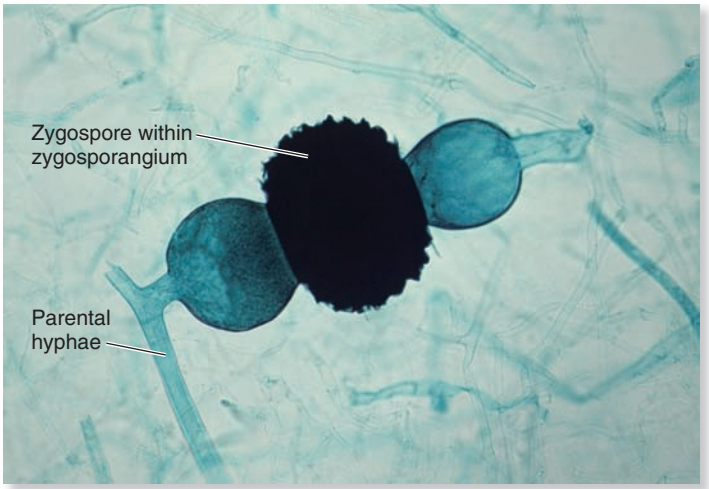

Figure 31.15 Zygospores in zygosporangia. These fungal structures arise from sexual reproduction. They have been stained with a green dye.

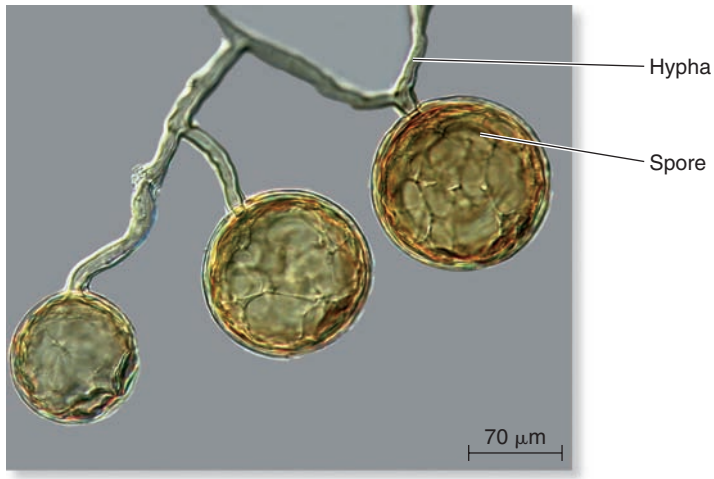

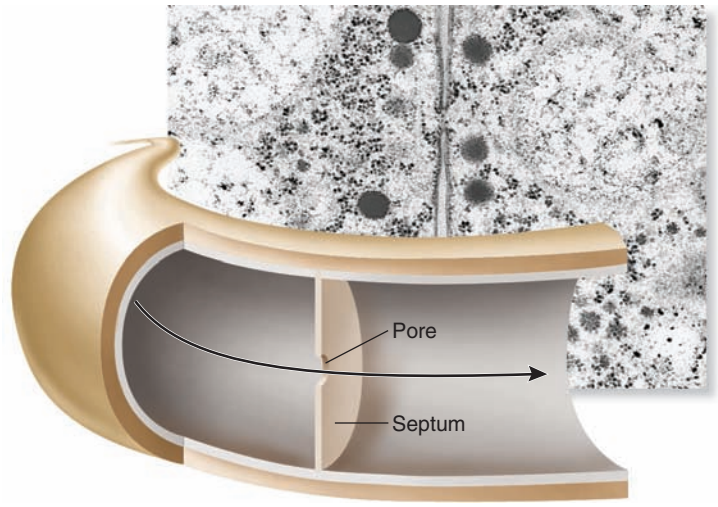

Figure 31.16 The genus *Glomus*, an example of an AM fungus (Glomeromycota). The hyphae of these endomycorrhizal (arbuscular mycorrhizal) fungi are found in roots of many types of plants, helping the plants acquire water and nutrients. AM fungi produce large, multinucleate spores by asexual processes.

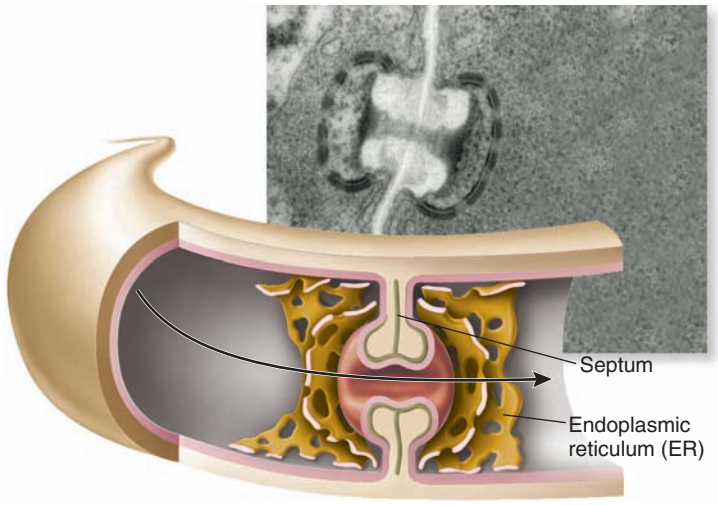

basidiomycetes (**Figure 31.17**). Such pores allow cytoplasmic structures and materials to pass through the hyphae.

The sexual reproductive processes of ascomycetes and basidiomycetes are remarkable in producing a **dikaryotic mycelium**, one whose cells contain two nuclei of differing genetic types (**Figure 31.18**). In most sexual organisms, gametes undergo fusion of their cytoplasms—a process known as **plasmogamy**—and then the nuclei fuse in a process known as **karyogamy**. However, in ascomycete and basidiomycete fungi, after plasmogamy the haploid gamete nuclei generally remain separate for a time, rather than immediately undergoing karyogamy. During this time period, the gamete nuclei both divide at each cell division, producing a mycelium whose cells each possess both parental nuclei. Although the nuclei of dikaryotic mycelia remain haploid, alternative forms of many alleles occur in the separate nuclei. Thus, dikaryotic mycelia are functionally diploid. Eventually, dikaryotic mycelia produce fruiting bodies, the next stage of reproduction.

The name ascomycetes derives from unique sporangia known as **asci** (singular, ascus) from the Greek *asco*, meaning bags or sacs). During sexual reproduction, asci produce spores known as **ascospores** (see Figure 31.18b). The asci are produced on fruiting bodies known as **ascocarps**. Although many ascomycetes have lost the

(a) Simple pore—ascomycetes

(b) Complex pore—basidiomycetes

Figure 31.17 Septal pores of ascomycetes and basidiomycetes. (a) The septa of ascomycetes have simple pores at the centers. **(b)** More complex pores distinguish the septa of most types of basidiomycetes.

ability to reproduce sexually, their hyphal septa with simple pores (see Figure 31.17a) and their DNA sequences can be used to identify them as members of this phylum.

Ascomycetes occur in terrestrial and aquatic environments, and they include many decomposers as well as pathogens. Important ascomycete plant pathogens include powdery mildews, chestnut blight (*Cryphonectria parasitica*), Dutch elm disease (the genus *Ophiostoma*), and apple scab (*Venturia inaequalis*). Cup fungi (see the ascocarp photo in Figure 31.18) are common examples of ascomycetes. Many yeasts are also ascomycetes. Edible truffles (**Figure 31.19**) and morels are the fruiting bodies of particular ascomycetes whose mycelia form partnerships with plant roots, described in Section 31.4. Ascomycetes are the most common fungal components of lichens (see Section 31.4).

Basidiomycota Produce Diverse Fruiting Bodies

DNA-sequencing comparisons indicate that the Basidiomycota (or basidiomycetes) and the ascomycetes are the most recently diverged groups of fungi. The mated dikaryotic mycelia of basidiomycetes can live for hundreds of years and produce many fruiting bodies. The name given to the basidiomycetes derives from **basidia**, the club-shaped cells of fruiting bodies that produce sexual spores known as **basidiospores** (**Figure 31.20**). Basidia are typically located on the undersides of fruiting bodies, which are generally known as **basidiocarps**. Though some basidiomycetes have lost the property of sexual reproduction, they can be identified as members of this phylum by unique hyphal structures known as

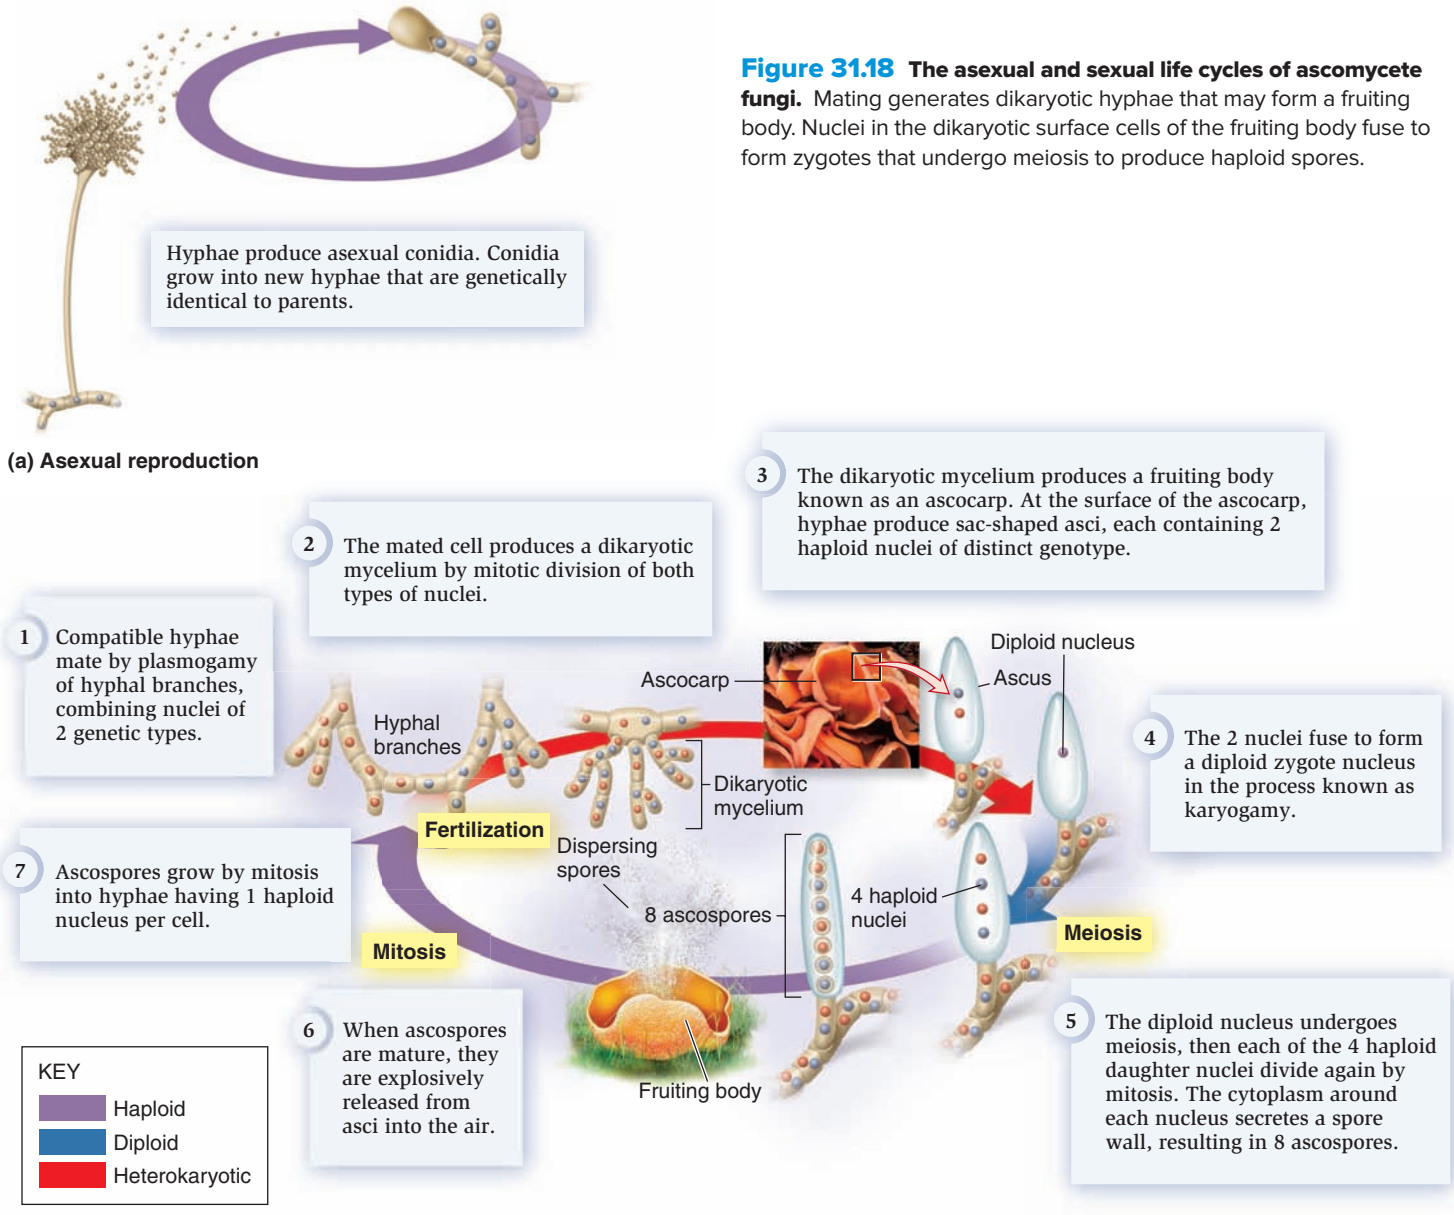

Figure 31.18 The asexual and sexual life cycles of ascomycete fungi. Mating generates dikaryotic hyphae that may form a fruiting body. Nuclei in the dikaryotic surface cells of the fruiting body fuse to form zygotes that undergo meiosis to produce haploid spores.

Figure 31.19 **The black truffle *Tuber melanosporum*, an ascomycete fungus.**

clamp connections that help distribute nuclei during cell division (see Figure 31.20). Basidiomycetes can also be identified by their distinctive septa having complex pores (see Figure 31.17b) and by DNA sequencing. Basidiomycetes reproduce asexually by various types of spores.

An estimated 30,000 modern basidiomycete species are known. Basidiomycetes are very important as decomposers and in symbiotic associations with plants, producing diverse basidiocarps commonly known as mushrooms, puffballs, stinkhorns, shelf fungi, rusts, and smuts (**Figure 31.21**). Basidiocarps are also shown in Figures 31.8, 31.9, and 31.10. The fairy rings of mushrooms that sometimes occur in open, grassy areas are ring- or arc-shaped arrays of basidiomycete fruiting bodies.

31.4 Fungal Ecology and Biotechnology

Learning Outcomes:

1. Identify the ecological roles of decomposer and disease fungi.
2. Give examples of fungal diseases of plants and animals, including humans.
3. Explain how mycorrhizae, endophytes, and lichens form beneficial associations with other organisms.
4. List several uses of fungi in biochemistry, biological studies, and industrial processes.

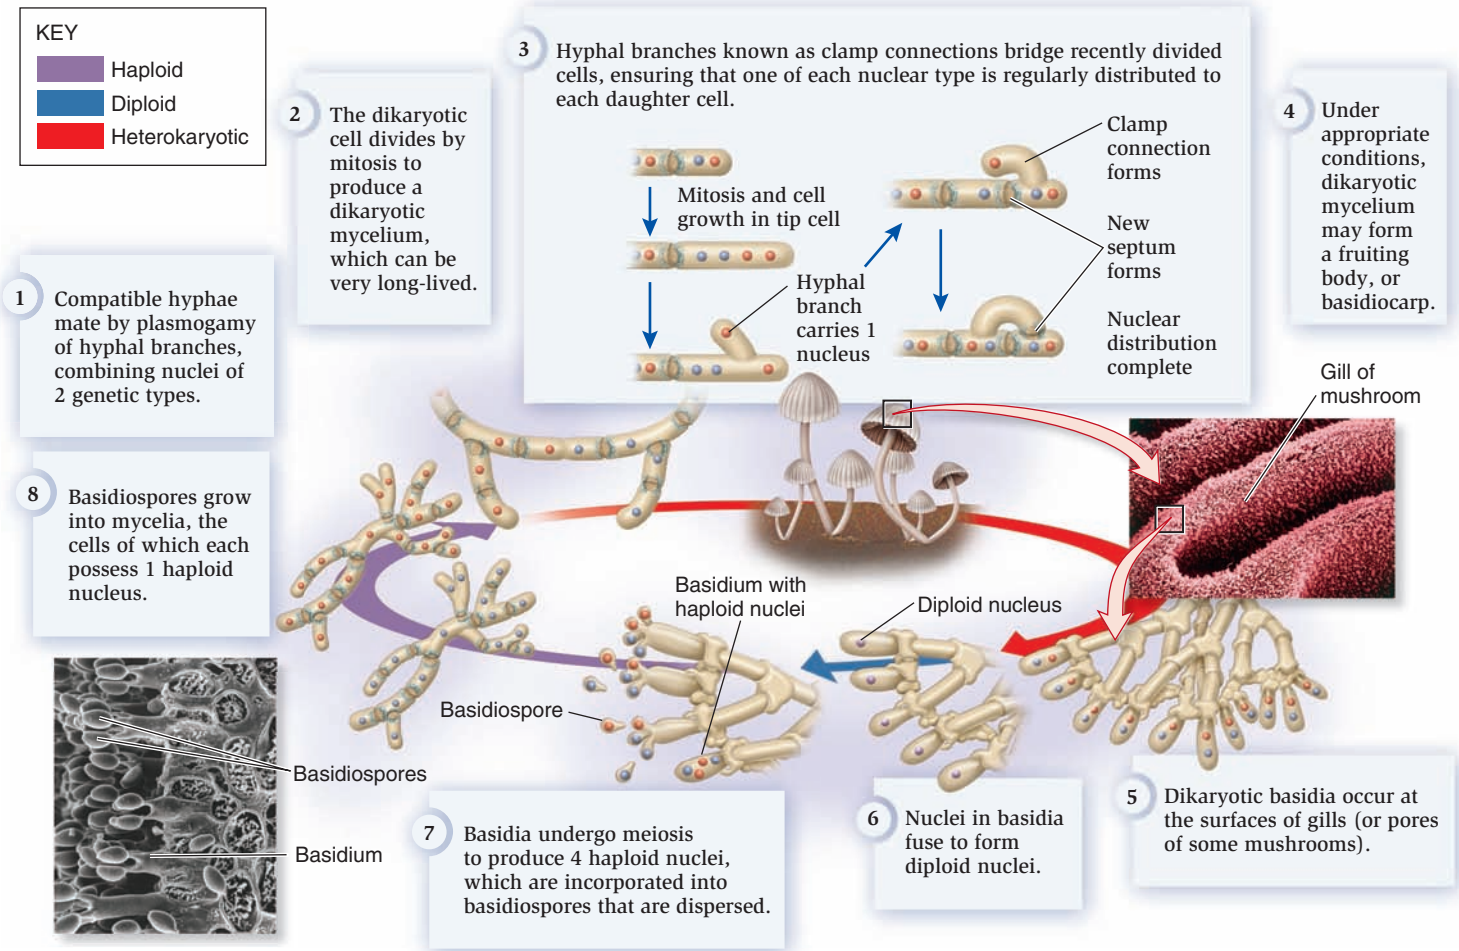

Figure 31.20 **The sexual life cycle of the basidiomycete fungus *Coprinus disseminatus*.**

(a) Corn smut (b) Shelf fungi

Figure 31.21 Fruiting bodies of basidiomycetes. **(a)** Corn smut (*Ustilago maydis*) produces dikaryotic mycelial masses within the kernels (fruits) of infected corn plants. These mycelia produce many dark spores in which karyogamy and meiosis occur. Masses of these dark spores cause the smutty appearance. When the spores germinate, they produce basidiospores that can infect other corn plants. **(b)** Shelf fungi, such as this sulfur shelf fungus (*Laetiporus sulphureus*), are the fruiting bodies of basidiomycete fungi that have infected trees.

Fungi play important ecological roles as decomposers, predators, pathogens, and beneficial symbionts. Such ecological diversity allows humans to utilize fungi in diverse biotechnological applications.

Decomposer and Predatory Fungi Play Important Ecological Roles

Decomposer fungi are essential components of the Earth's ecosystems. Together with bacteria, they decompose dead organisms and wastes, preventing the buildup of organic debris in ecosystems. For example, only certain bacteria and fungi can break down cellulose and lignin, the main components of wood. Decomposer fungi and bacteria are Earth's recycling engineers. They release CO_2 into the air and other minerals into the soil and water, making these essential nutrients available to plants and algae.

More than 200 species of predatory soil fungi use special adhesive or nooselike hyphae to trap tiny soil animals, such as nematodes, and absorb nutrients from their bodies (**Figure 31.22**). Such fungi help to control populations of nematodes, some of which attack plant roots. Other fungi obtain nutrients by attacking insects, and certain of these species have been used as biological control agents to kill black field crickets, red-legged earth mites, and other pests.

Pathogenic Fungi Cause Plant and Animal Diseases

One of the most important ways in which fungi affect humans is by causing diseases of crop plants and animals. Five thousand fungal species are known as plant pathogens because they cause serious crop diseases. Plant pathogenic fungi typically produce specialized balloon-shaped cells known as haustoria, whose increased cell membrane surface area aids the absorption of organic food from plant

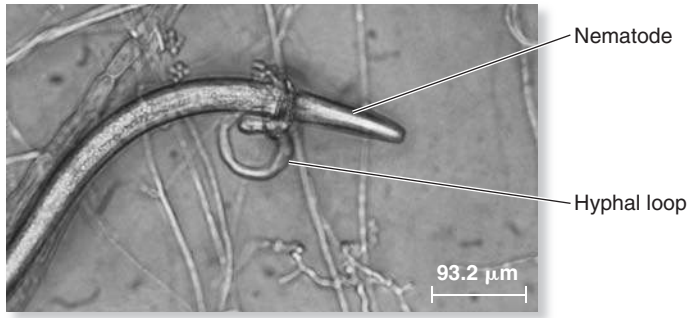

Figure 31.22 A predatory fungus. The fungus *Arthrobotrys anchonia* traps nematode worms in hyphal loops that suddenly swell in response to the animal's presence. Fungal hyphae then grow into the worm's body and digest it.

cells (**Figure 31.23**). Pathogenic fungi use the absorbed organic compounds to grow, attack more plant cells, and produce reproductive spores capable of infecting more plants.

Wheat rust is an example of a common crop disease caused by fungi (**Figure 31.24**). Rusts are named for the reddish spores that emerge from the surfaces of infected plants. Many types of plants can be attacked by rust fungi, but rusts are of particular concern when new strains attack crops. To control the spread of fungal diseases, agricultural experts work to identify effective fungicidal chemicals and develop resistant crop varieties. Agricultural customs inspectors closely monitor the entry of plants, soil, foods, and other materials that might harbor pathogenic fungi.

Fungi cause several types of disease in animals. For example, *Geomyces destructans* is associated with white nose syndrome of bats, which has killed more than 1 million hibernating bats in the U.S. Athlete's foot and ringworm are common human skin diseases caused by several types of fungi that are known as dermatophytes because they colonize the human epidermis. *Pneumocystis jiroveci* and *Cryptococcus neoformans* are fungal pathogens that infect individuals with weakened immune systems, such those with AIDS, sometimes

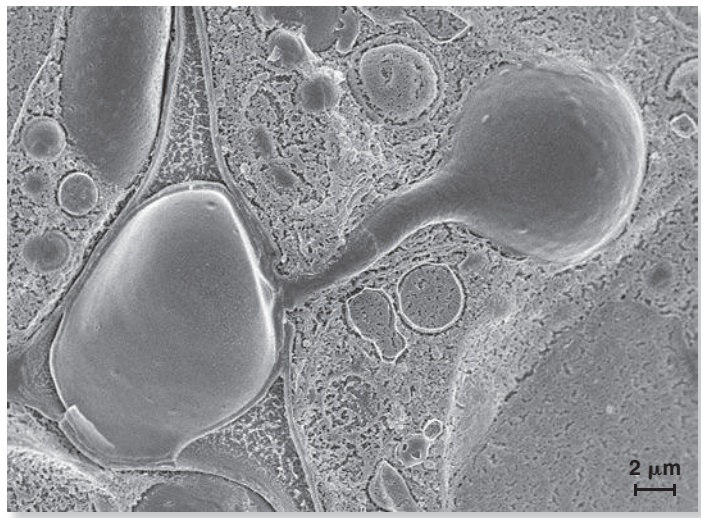

Figure 31.23 Fungal haustoria. Fungi that parasitize plants often produce specialized balloon-shaped cells called haustoria that absorb organic food from plant cells, as shown in this electron micrograph.

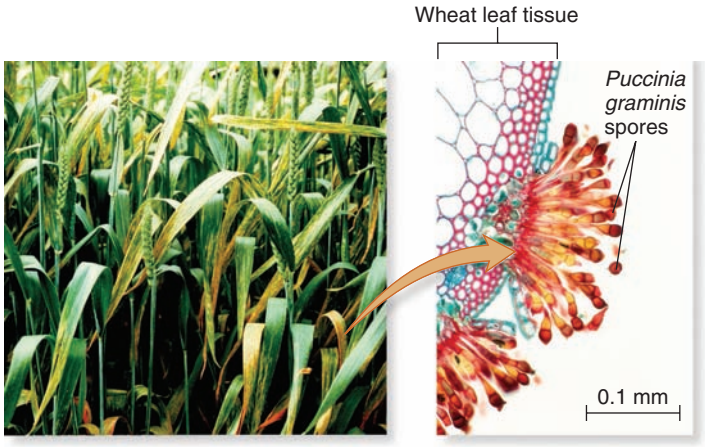

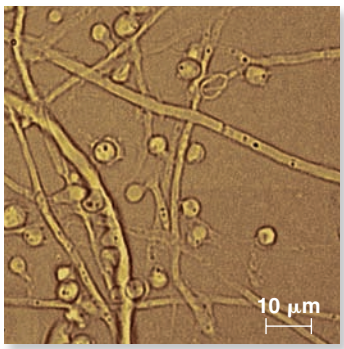

Figure 31.24 Wheat rust. The plant pathogenic fungus *Puccinia graminis* grows within the tissues of wheat plants, using plant nutrients to produce rusty streaks of red spores that erupt at the stem and leaf surface where they can be dispersed. Red spore production is but one stage of a complex life cycle involving several types of spores. Rusts infect many other crops in addition to wheat, causing immense economic damage.

causing death. **Dimorphic fungi** (from the Greek, meaning two forms) live as spore-producing hyphae in the soil but transform into pathogenic yeasts when mammals inhale their wind-dispersed spores (**Figure 31.25**). Dimorphic fungi include *Blastomyces dermatitidis*, which causes the disease blastomycosis; *Coccidioides immitis*, the cause of coccidiomycosis; and *Histoplasma capsulatum*, the agent of histoplasmosis. These fungal diseases affect the lungs and may spread to other parts of the body, causing severe illness. Host body temperature triggers the change from hyphal to yeast form. Instead of producing spores, in the mammalian body, these pathogenic yeasts reproduce by forming buds that more effectively stick to lung cells, spread within lung tissue, and move to other organs. Though fungal diseases that attack humans are of medical concern, in nature, fungal pathogens often help to control populations of other organisms, which is an important ecological role.

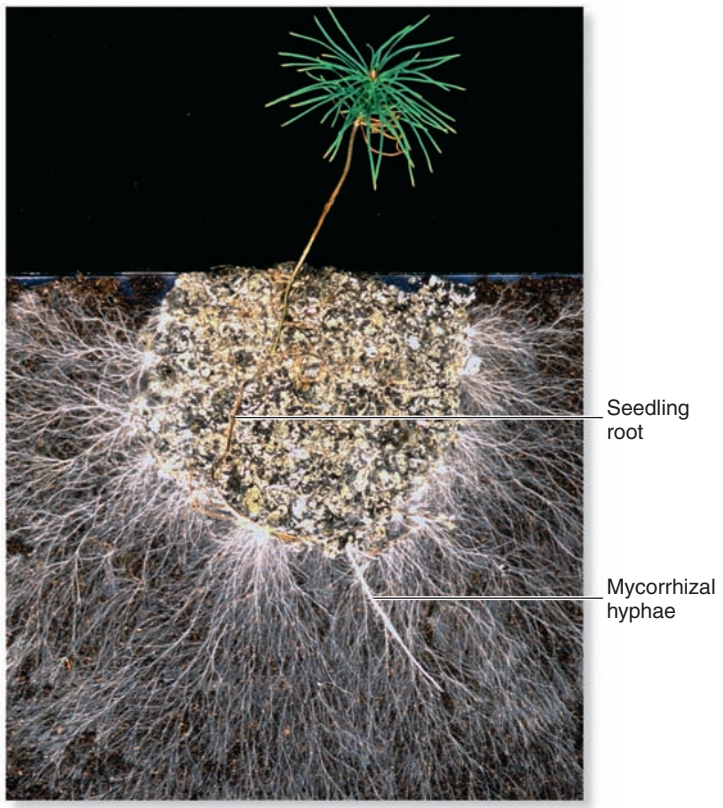
Soil-dwelling hyphal phase

Figure 31.25 Dimorphic fungi. The soil-dwelling hyphal stage reproduces by airborne spores. When a mammal inhales the spores, body heat causes the budding yeast phase to develop and attack host tissues.

Fungi Form Beneficial Associations with Other Species

Symbioses are close associations of one or more other species, and mutualistic symbioses occur when all partners in a close association benefit. Fungi form several types of mutualistic symbiosis with animals, plants, algae, bacteria, and even viruses. For example, leaf-cutting ants, certain termites and beetles, and the salt marsh snail (*Littoraria irrorata*) cultivate particular fungi for food—much as human mushroom growers do. Other fungi obtain organic food molecules from photosynthetic organisms—plants, green algae, or cyanobacteria—that, in turn, receive benefits from the fungi. We focus next on three types of fungi—mycorrhizal fungi, endophytes, and lichen fungi—that are beneficially associated with photosynthetic organisms.

Mycorrhizae Mutualistic symbioses between the hyphae of certain fungi and the roots of most seed plants are known as **mycorrhizae**. Such fungus-root associations are very important in nature and agriculture; more than 80% of terrestrial plants form mycorrhizae. Plants that have mycorrhizal partners receive an increased supply of water and mineral nutrients, primarily phosphate, copper, and zinc. An extensive fungal mycelium is able to absorb minerals from a much larger volume of soil than roots alone are able to do (**Figure 31.26**). Added together, all the branches of a fungal mycelium in 1 m^3 of soil



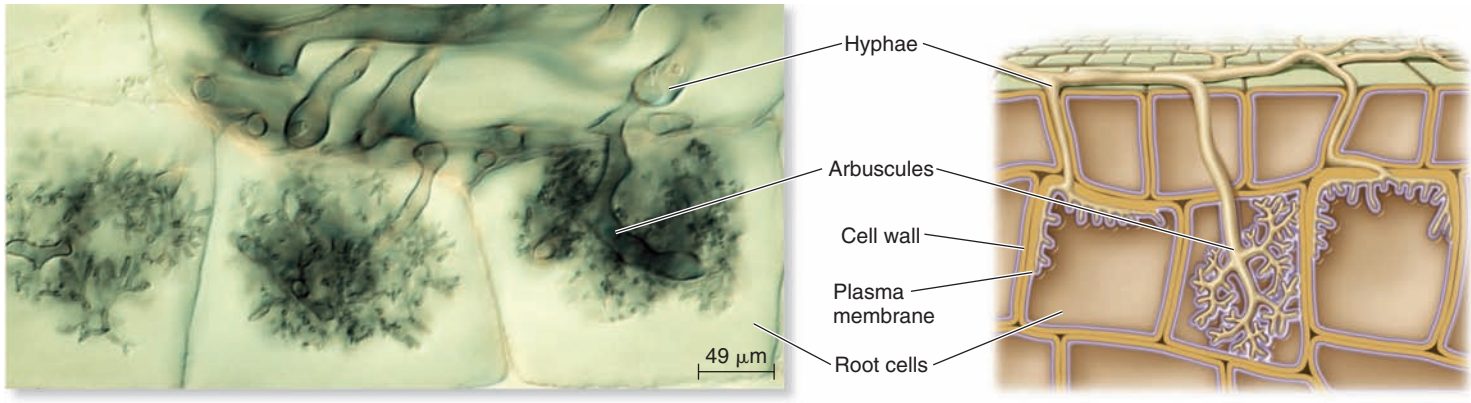


Figure 31.26 Tree seedling with mycorrhizal fungi. Hyphae of a mycorrhizal fungus extend farther into the soil than do plant roots, helping plants to obtain water and mineral nutrients.

(a) Micrograph of arbuscular mycorrhizae

(b) Hyphae growing between cell walls and plasma membranes

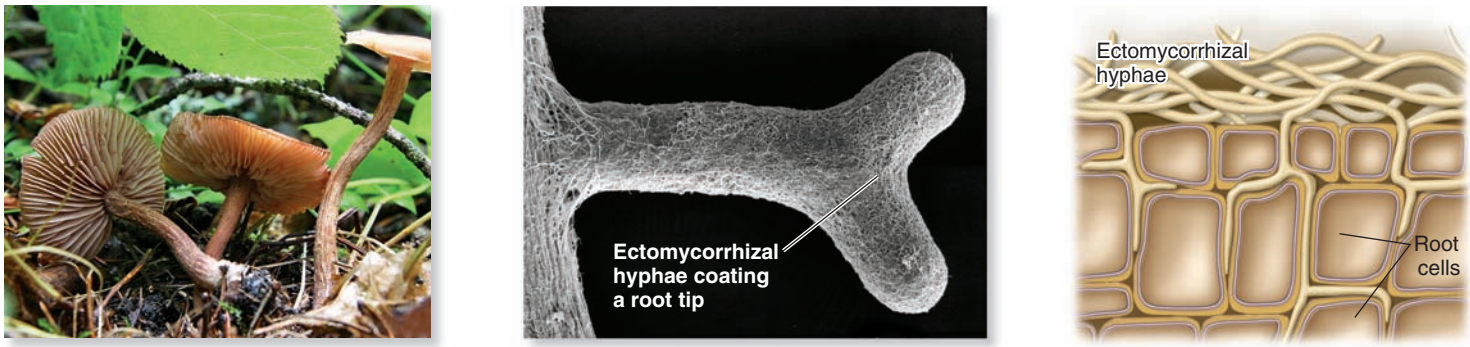

Figure 31.27 **Endomycorrhizae.** **(a)** Light micrograph showing black-stained AM fungi within the roots of the forest herb *Asarum canadensis*. Endomycorrhizal fungal hyphae penetrate plant root cell walls, and then branch into the spaces between cell walls and plasma membranes. **(b)** Diagram showing the position of highly branched arbuscules. The arbuscules are found on the surface of the plasma membrane, which becomes highly invaginated. The result is that both hyphae and plant membranes have very high surface areas.

Concept Check: *What fungal phylum consists entirely of endomycorrhizal fungi that are dependent on plant hosts?*

can reach 20,000 km in total length. Experiments have shown that mycorrhizae greatly enhance the growth of plants, compared to plants lacking fungal partners. In return, plants provide fungi with organic food molecules, sometimes contributing as much as 20% of their photosynthetic products.

The two most common types of mycorrhizae are endomycorrhizae, which occur within root tissues, and ectomycorrhizae, which coat roots. **Endomycorrhizae** (from the Greek *endo*, meaning inside) are partnerships between plants and fungi in which the fungal hyphae penetrate the spaces between root cell walls and plasma membranes and grow along the outer surface of the plasma membrane. In such spaces, endomycorrhizal fungi often form highly branched, bushy arbuscules. As the arbuscules develop, the plasma membrane also expands. Consequently, the arbuscules and the plasma membranes surrounding them have a very high surface area that facilitates rapid and efficient exchange of materials: Minerals flow from fungal hyphae to root cells, while organic food molecules move from root cells to hyphae. These fungus-root associations are known as **arbuscular mycorrhizae**, abbreviated AM (**Figure 31.27**). AM fungi are associated with apple and peach trees, coffee shrubs, and many herbaceous plants, including legumes, grasses, tomatoes, and strawberries.

Ectomycorrhizae (from the Greek *ecto*, meaning outside) are mutualistic symbioses between temperate forest trees and soil fungi. The fungi that engage in such associations are known as ectomycorrhizal fungi (**Figure 31.28a**). The hyphae of ectomycorrhizal fungi coat tree-root surfaces (**Figure 31.28b**) and grow into the spaces between root cells but do not penetrate the cell membrane (**Figure 31.28c**). Some species of oak, beech, pine, and spruce trees will not grow unless their ectomycorrhizal partners are also present. Mycorrhizae are thus essential to the success of commercial nursery tree production and reforestation projects. New genetic information has illuminated how mycorrhizal fungi evolved.

(b) SEM of ectomycorrhizal hyphae

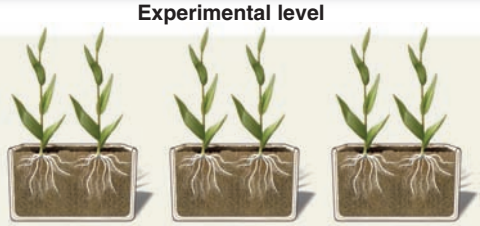
(c) Hyphae invading intercellular spaces

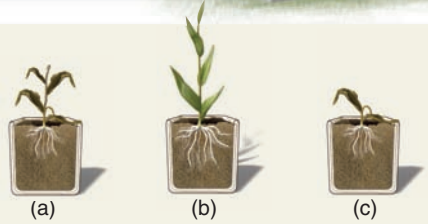
Figure 31.28 **Ectomycorrhizae.** **(a)** The fruiting body of the common forest fungus *Laccaria bicolor*. This is an ectomycorrhizal fungus that is associated with tree roots. **(b)** Ectomycorrhizal fungal hyphae of *L. bicolor* cover the surfaces of young *Pinus resinosa* root tips. **(c)** Diagram showing that the hyphae of ectomycorrhizal fungi do not penetrate root cell walls but grow within intercellular spaces. In this location, fungal hyphae are able to obtain organic food molecules produced by plant photosynthesis.

Concept Check: *What benefits do plants obtain from the association with fungi?*

Fungal Endophytes Other fungi are known as **endophytes** because they live within the leaf and stem tissues of almost all plants, without causing disease. In tropical regions, hundreds of endophytic fungal species can occur within a single tree. The endophytes obtain organic food molecules from plants and, in turn, contribute toxins or antibiotics that deter foraging animals, insect pests, and microbial pathogens. In general, plants that contain nonpathogenic endophytic fungi grow better than plants lacking such fungal partners. Endophytic fungi also help some plants tolerate higher temperatures, as described next.

Feature Investigation | Márquez and Associates Discovered That a Three-Partner Symbiosis Allows Plants to Cope with Heat Stress





The endophytic fungus *Curvularia protuberata* commonly lives within aboveground tissues of the grass *Dichanthelium lanuginosum*, which is unusual in its ability to grow on very hot soils in thermal areas of Yellowstone National Park. When the soil reaches 38°C, *D. lanuginosum* plants and *C. protuberata* fungi both die—unless they live together in a symbiosis. In the symbiotic association, the partners can survive temperatures near 65°C!

In 2007, a team of investigators led by Luis Márquez discovered that a virus is also involved, revealing the occurrence of a three-partner symbiosis (**Figure 31.29**). These biologists were able to isolate the virus from the fungus and named it *Curvularia* thermal tolerance virus (CthTV) to indicate its host and phenotype. The investigators also noticed that some of their fungal cultures contained very little virus, so they were able to use drying and freeze-thaw cycles to cure such cultures of the virus. This procedure allowed them to experimentally determine the relative abilities of virus-infected and virus-free *C. protuberata* fungus to tolerate high temperatures and confer this property to plant partners. They found that plants having viral-infected fungal endophytes tolerated high temperatures much better than plants that lacked fungal endophytes or possessed only virus-free fungal endophytes. Márquez and associates also reintroduced virus

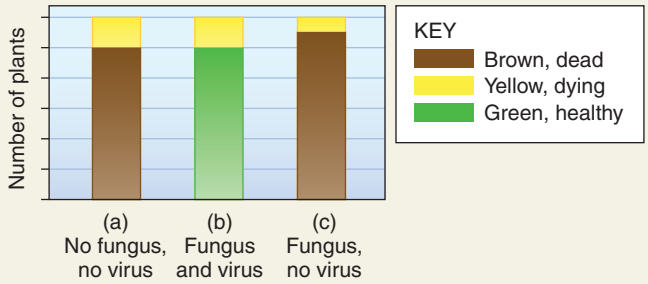


Figure 31.29 Márquez and associates discovered that a three-partner symbiosis allows plants to cope with heat stress.

GOAL To determine if a virus is essential to the protective role of endophytic fungi to host plants under heat stress.

KEY MATERIALS *Curvularia* thermal tolerance virus (CthTV), cultures of the endophytic fungus *Curvularia protuberata* infected with CthTV, *C. protuberata* cultures free of CthTV, and *Dichanthelium lanuginosum* plants.

	Experimental level	Conceptual level
1 Plant 25 replicate containers with *D. lanuginosum* lacking fungal symbionts (a) or having *C. protuberata* endophytes that either did (b) or did not (c) have virus.	 (a) No fungus, no virus (b) Fungus and virus (c) Fungus, no virus	Compare the effects of virus on the ability of the fungus to confer heat stress protection.
2 Expose plants to heat stress treatment (up to 65°C) for 2 weeks in a greenhouse.		Keep environmental conditions constant to reduce experimental error.
3 Count the number of plants that were green (alive), yellow (dying), or brown (dead).	 (a) (b) (c)	Assess plant survival in the presence or absence of fungus and/or virus.

4 THE DATA

5 CONCLUSION A virus enhances the protective role of endophytic fungi in this grass species. The next step will be to try to determine just how the virus changes the fungus so that the fungus is able to protect the plant from heat stress.

6 SOURCE Márquez, L. M., et al. 2007. A virus in a fungus in a plant: three-way symbiosis required for thermal tolerance. *Science* 315:513–515.

to their virus-free fungi and found that such fungi acquired the ability to confer heat tolerance to host plants. Finally, the researchers determined that virus-infected fungi (but not virus-free fungi) could also protect a distantly related crop plant (tomato) from heat stress. These results add to accumulating evidence that multipartner symbioses are more common than previously realized and demonstrated that endophytic fungi may have useful agricultural applications.

Experimental Questions

1. Would you expect plants that grow on unusually hot soils to have endophytic fungi or not?
2. **SciSKILLS »** How did Márquez and associates demonstrate that a virus was important in the heat tolerance of the *Dichanthelium lanuginosum*/*Curvularia protuberata* symbiosis?
3. How might the results of the work by Márquez and associates be usefully applied in agriculture?

BIO TIPS **THE QUESTION** *The data presented in step 4 of Figure 31.29 provide additional information about the relative effects of an endophytic fungus and a virus on heat tolerance in a species of plant. Compare the three bar graphs and explain what these data mean.*

TOPIC ***What topic in biology does this question address?*** The topic is related to species diversity involved in symbiotic interactions. More specifically, the question addresses the relative effects of symbiotic fungal endophytes and viruses on plant heat tolerance.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** Step 4 in Figure 31.29 presents experimental data in the form of a bar graph that shows the relative number of plants in each of three groups that were dead, dying, and healthy at the end of the heat stress experiment. The three groups of plants differed as to whether an endophytic fungus and/or a virus was present in their containers. You have learned in this chapter what endophytic fungi are and how they can affect plants.

PROBLEM-SOLVING STRATEGY ***Compare and Contrast. Interpret data.*** Compare and contrast the bars in the graph, looking for differences in the responses of plants in each group.

ANSWER *First, compare the bars labeled (a) and (b). Notice that the same proportions of dying plants occurred whether the plants had fungal and viral symbionts (b) or had none (a). From these results alone, you might infer that either the fungus or the virus or the combination of the two provided plants with protection from heat, but you could not discriminate among these possibilities. A comparison with the bar labeled (c) reveals that the fungus by itself is not enough to confer protection. Further inspection of the graph reveals that the proportion of dead plants to dying plants in the (c) group (fungus present but no virus) is higher than in the (a) group (no fungus or virus). If this difference is significant (a determination that would require statistical analysis of the basic data), then it suggests that the fungus by itself might speed plant death. You might wonder if the virus is somehow offsetting the negative impact of the fungus on plant health.*

Lichens Multipartner associations are also represented by **lichens**, which are composed of particular fungi, certain photosynthetic green algae and/or cyanobacteria, and nonphotosynthetic bacteria such as actinomycetes. There are at least 25,000 lichen species, but these did not all descend from a common ancestor. DNA-sequencing studies suggest that lichens evolved independently in at least five separate fungal lineages. Molecular analyses also show that some fungi have lost their ancestral ability to form lichen associations.

Lichen bodies take one of three major forms: (1) crustose—flat bodies that are tightly adherent to an underlying surface (**Figure 31.30a**); (2) foliose—flat, leaflike bodies (**Figure 31.30b**); or (3) fruticose—bodies that grow upright (**Figure 31.30c**) or hang

Genomes & Proteomes Connection

Genomic Comparisons of Forest Fungi Reveal Coevolution with Plants

Genome sequences have been obtained for many of the basidiomycete fungi that occur in forests, allowing comparisons that reveal how forest fungi have coevolved with plants. Coevolution, which has strongly influenced the diversification of plants and animals (see Chapter 30), is the process by which two or more species of organisms influence each other's evolutionary pathway. The genome of the forest fungus *Serpula lacrymans*, reported in 2011 by Daniel Eastwood, Sarah Watkinson, and associates, has been key to understanding how fungi have evolved many types of symbiotic associations with plants. Certain forest fungi are parasites, whereas others form mutualistic ectomycorrhizal associations. Other forest fungi decompose cellulose and lignin, major components of wood. Cellulose and lignin are the two most abundant biological polymers on Earth and are relatively resistant to microbial decomposition.

About 6% of forest fungi, including *S. lacrymans*, are known as brown rot fungi because they obtain energy by breaking down the cellulose contained in wood, leaving brown-colored lignin. The lignin that brown rot fungi leave behind contributes a substantial amount of organic carbon to forest soils, thereby influencing soil fertility. Other forest fungi, known as white rot fungi, decompose both the cellulose and lignin present in wood, leaving white-colored remains. White rot fungi, such as *Phanerochaete chrysosporium*, have particularly complex enzymatic pathways, which are needed to break down the many types of chemical bonds present in lignin. Such complex enzymatic pathways are energetically expensive to produce, but allow the fungi ready access to cellulose embedded within a lignin matrix. The appearance of white rot fungi in the Paleozoic era may explain a dramatic decrease in organic carbon burial that occurred near the end of the Carboniferous period (see Figure 29.17). The white rot fungi were able to degrade tough lignin, producing carbon dioxide and thereby changing Earth's atmospheric composition and influencing plant growth.

Genomic comparisons have revealed that brown rot fungi such as *S. lacrymans* evolved from white rot ancestors by loss of protein families involved in lignin degradation. For example, brown rot fungi lack class II peroxidase enzymes that white rot fungi use to help decompose lignin. Consequently, brown rot fungi cannot break down lignin, but they save the energy they would need to expend in this process. Genomic comparisons also suggest that ectomycorrhizal fungi evolved from brown rot ancestors. Patterns of forest fungal divergence match those of forest trees, indicating that forest fungi and plants have coevolved over time.

down from tree branches. The photosynthetic green algae or cyanobacteria typically occur in a distinct layer close to the lichen's surface (**Figure 31.30d**). Lichen structure differs dramatically from that of the fungal component grown separately, demonstrating that the photosynthetic components influence lichen form.

Figure 31.30 Lichen structure. **(a)** An orange-colored crustose lichen grows tightly pressed to the substrate. **(b)** The flattened, leaf-shaped genus *Umbilicaria* is a common foliose lichen. **(c)** The highly branched genus *Cladonia* is a common fruticose lichen. **(d)** A handmade thin slice of *Umbilicaria* viewed with a light microscope reveals that the photosynthetic algae occur in a thin upper layer. Fungal hyphae make up the rest of the lichen.

The photosynthetic partner in a lichen provides the fungal partner with organic food molecules and oxygen, and, in turn, it receives carbon dioxide, water, and minerals from the fungal partner. Lichen fungi also protect their photosynthetic partners from environmental stress. For example, lichens that occupy exposed habitats of high light intensity often produce bright yellow, orange, or red-colored compounds that absorb excess light, thereby helping to prevent damage to the photosynthetic apparatus (see Figure 31.30a). Lichen fungi also produce distinctive organic acids and other compounds that deter animal and microbial attacks.

Many lichens reproduce by both sexual and asexual means, and about one-third of lichen species reproduce only asexually. Asexual reproductive structures include soredia (singular, soredium), small clumps of hyphae surrounding a few algal cells that can disperse in wind currents. Soredia are lichen clones. By forming soredia, lichen fungi can disperse along with their photosynthetic partners.

The fungal partners of many lichens can undergo sexual reproduction, producing fruiting bodies and sexual spores much like those of related fungi that do not form lichens. DNA studies have shown that some lichen fungi can self-fertilize, which is advantageous in harsh environments where potential mates may be lacking.

To produce new lichens, hyphae that grow from sexual spores must acquire new photosynthetic partners, but only particular green algae or cyanobacteria are suitable. However, lichens do not always contain the same algal partners as their parents because lichen fungi may switch algal partners, "trading up" for better algae. Partner switching allows lichens to adjust to changes in their environments.

Lichens often grow on rocks, buildings, tombstones, tree bark, soil, or other surfaces that easily become dry. When water is not available, the lichens are dormant until moisture returns. Thus, lichens may spend much of their time in an inactive state, and for this reason, they often grow very slowly. However, because they can persist for long periods, lichens can be very old; some are estimated to be more than 4,500 years old. Lichens occur in diverse types of habitats, and a number grow in some of the most extreme, forbidding terrestrial sites on Earth—deserts, mountaintops, and the Arctic and Antarctic—places where most plants cannot survive. In these locations, lichens serve as a food source for hardy animals such as reindeer. Though unpalatable, lichens are not toxic to humans and have served as survival foods for indigenous peoples in times of shortages.

Soil building is another important lichen function. Lichen acids help to break up the surfaces of rocks, beginning the process of soil development. Lichens having cyanobacterial partners can also increase soil fertility by adding fixed nitrogen. One study showed that such lichens released 20% of the nitrogen they fixed into the environment, where it is available for uptake by plants.

Lichens are useful as air-quality monitors because they are particularly sensitive to air pollutants such as sulfur dioxide. Air pollutants severely injure the photosynthetic components, causing death of the lichens. The disappearance of lichens serves as an early warning sign of air-pollution levels that are also likely to affect humans. Lichens can also be used to monitor atmospheric radiation levels because they accumulate radioactive substances from the air.

Fungi Have Many Applications in Biotechnology

The ability of fungi to grow on many types of substrates and produce many types of organic compounds reflects their diverse ecological adaptations. Humans have harnessed fungal biochemistry in many types of biotechnology applications. A variety of industrial processes use fungi to convert inexpensive organic compounds into valuable materials such as the citric acid used in the soft-drink industry, glycerol, antibiotics such as penicillin, and cyclosporine, a drug widely used to prevent rejection of organ transplants. Enzymes extracted from fungi are used to break down plant materials for renewable bioenergy production. In the food industry, fungi are used to produce the distinctive flavors of blue cheese and other cheeses. Other fungi secrete enzymes that are used in the manufacture of protein-rich tempeh and other food products from soybeans. The brewing and winemaking industries find yeasts essential, and the baking industry depends on the yeast *Saccharomyces cerevisiae* (see Figure 31.7) for bread production.

S. cerevisiae is also widely used as a model organism for fundamental biological studies. Yeasts are useful in the laboratory because they have short life cycles, they are easy and safe for lab workers to maintain, and their genomes are similar to those of animals. Some 31% of yeast proteins have human homologs, and nearly 50% of human genes that have been implicated in heritable diseases have homologs in yeast.

Summary of Key Concepts

31.1 Evolution and Distinctive Features of Fungi

- Fungi form a monophyletic kingdom of heterotrophs that, together with the animal kingdom and certain protists, form the supergroup Opisthokonta (Figure 31.1).
- Fungal cells typically possess cell walls rich in the polysaccharide chitin. Fungal bodies, known as mycelia, are composed of microscopic branched filaments known as hyphae. Early-diverging fungi have aseptate hyphae that are not subdivided into cells. The hyphae of later-diverging fungi are subdivided into cells by cross walls known as septa (Figures 31.2, 31.3).
- Fungal hyphae feed and grow at their tips (Figure 31.4).
- Mycelial shape depends on the distribution of nutrients in the environment, which determines the direction in which cell division and hyphal growth will occur (Figure 31.5).

31.2 Fungal Asexual and Sexual Reproduction

- Fungi spread rapidly by means of spores produced by asexual or sexual reproduction.
- Asexual reproduction does not involve mating or meiosis, and it occurs by means of asexual spores called conidia or by budding (Figures 31.6, 31.7).
- Fungi display a haploid-dominant sexual life cycle. During sexual reproduction of terrestrial fungi, hyphal branches (gametes) fuse with those of a different mycelium of compatible mating type. Mated hyphae form fruiting bodies in which haploid spores are produced by meiosis. Dispersed spores germinate to produce haploid fungal mycelia.
- Fungi produce diverse types of fruiting bodies that foster spore dispersal by wind, water, or animals. Although many fungal fruiting bodies are edible, many others produce defensive toxins or hallucinogens (Figures 31.8, 31.9, 31.10, 31.11).

31.3 Diversity of Fungi

- The fungi include several early-diverging lineages and the later-diverging phyla Glomeromycota (AM fungi), Ascomycota (ascomycetes), and Basidiomycota (basidiomycetes) (Table 31.1).
- Cryptomycota and chytrids are among the simplest and earliest-diverging fungi. They commonly occur in aquatic habitats and moist soil, where they produce flagellate reproductive cells. Some are parasites of protists, animals, or plants. (Figures 31.12, 31.13).
- Blastocladiomycota occur in water and soil, and some are parasites.
- Other early-diverging fungi produce distinctive, large zygospores as the result of sexual reproduction. Common black bread mold and related fungi reproduce asexually by means of many small spores (Figures 31.14, 31.15).

- The Glomeromycota, also known as the AM fungi, produce distinctive large, multinucleate spores and form beneficial arbuscular mycorrhizal relationships with many types of plants (Figure 31.16).
- Ascomycetes produce sexual ascospores in saclike asci located at the surfaces of fruiting bodies known as ascocarps. Many are lichen symbionts. The septa of hyphae have simple pores (Figures 31.17, 31.18, 31.19).
- Basidiomycetes produce sexual basidiospores on club-shaped basidia located on the surfaces of fruiting bodies known as basidiocarps. Such fruiting bodies take a wide variety of forms, including mushrooms, puffballs, stinkhorns, shelf fungi, rusts, and smuts. The hyphae display complex septal pores and clamp connections. Mating commonly generates a long-lived dikaryotic mycelium that can produce many fruiting bodies (Figures 31.20, 31.21).

31.4 Fungal Ecology and Biotechnology

- Fungi play important roles in nature as decomposers, predators, and pathogens and by forming beneficial associations with other organisms. Pathogenic fungi cause plant and animal diseases (Figures 31.22, 31.23, 31.24, 31.25).
- Mycorrhizae are symbiotic associations between fungi and plant roots. Endomycorrhizae commonly form highly branched arbuscules in the spaces between root cell walls and plasma membranes. Ectomycorrhizae coat root surfaces, extending into root intercellular spaces (Figures 31.26, 31.27, 31.28).
- Endophytic fungi live symbiotically within the tissues of plants (Figure 31.29).
- Genomic comparisons have revealed coevolution of forest fungi and plants.
- Lichens are multispecies partnerships between fungi, photosynthetic green algae and/or cyanobacteria, and other bacteria. Lichens can reproduce asexually or sexually. They occur in diverse habitats, including bare rock surfaces, where they help to build soil (Figure 31.30).
- Fungi are useful in the chemical, food-processing, waste-treatment, and renewable biofuel industries. The yeast *Saccharomyces cerevisiae* is a model organism and also important to the brewing and baking industries.

Assess and Discuss

Test Yourself

1. Fungal cells differ from animal cells in that fungal cells
   a. lack ribosomes, though these are present in animal cells.
   b. lack mitochondria, though these occur in animal cells.
   c. have chitin-rich cell walls, whereas animal cells lack rigid walls.
   d. lack cell walls, whereas animal cells possess walls.
   e. None of the above is true.
2. Conidia are
   a. cells produced by some fungi as the result of sexual reproduction.
   b. fungal asexual reproductive cells produced by the process of mitosis.
   c. structures that occur in septal pores.
   d. the unspecialized gametes of fungi.
   e. none of the above.
3. What are mycorrhizae?
   a. the bodies of fungi, composed of hyphae
   b. fungi that attack plant roots, causing disease
   c. fungal hyphae that are massed together into stringlike structures
   d. fungi that have symbiotic partnerships with algae or cyanobacteria
   e. mutually beneficial associations of particular fungi and plant roots
4. Where could you find diploid nuclei in an ascomycete or basidiomycete fungus?
   a. in spores
   b. in cells at the surfaces of fruiting bodies
   c. in conidia
   d. in soredia
   e. in all of the above
5. Which fungi are examples of hallucinogen producers?
   a. *Claviceps* and *Psilocybe*
   b. *Epidermophyton* and *Candida*
   c. *Pneumocystis jiroveci* and *Histoplasma capsulatum*
   d. *Saccharomyces cerevisiae* and *Phanerochaete chrysosporium*
   e. *Cryphoenectria parasitica* and *Ventura inaequalis*
6. What role do fungal endophytes play in nature?
   a. They are decomposers.
   b. They are human pathogens that cause skin diseases.
   c. They are plant pathogens that cause serious crop diseases.
   d. They live within the tissues of plants, helping to protect them from herbivores, pathogens, and heat stress.
   e. All of the above are correct.
7. What forms do lichens take?
   a. crusts, flat bodies
   b. foliose, leaf-shaped bodies
   c. fruticose, erect or dangling bodies
   d. single cells
   e. a, b, and c
8. Lichens consist of partnerships between fungi and
   a. red algae and brown algae.
   b. green algae, cyanobacteria, and heterotrophic bacteria.
   c. the roots of vascular plants.
   d. choanoflagellates and *Nuclearia*.
   e. none of the above.
9. How can ascomycetes be distinguished from basidiomycetes?
   a. Ascomycete hyphae have simple pores in their septa and lack clamp connections, whereas basidiomycete hyphae display complex septal pores and clamp connections.
   b. Ascomycetes produce sexual spores in sacs, whereas basidiomycetes produce sexual spores on the surfaces of club-shaped structures.
   c. Ascomycetes are commonly found in lichens, whereas basidiomycetes are less commonly partners in lichen associations.
   d. Ascomycetes are not commonly mycorrhizal partners, but basidiomycetes are commonly present in mycorrhizal associations.
   e. All of the above are correct.
10. Which group of organisms is most closely related to the kingdom Fungi?
    a. the animal kingdom
    b. the green algae
    c. the land plants
    d. the bacteria
    e. the archaea

Conceptual Questions

1. Explain three ways in which fungi are like animals and two ways in which fungi resemble plants.
2. Explain why some fungi produce toxic or hallucinogenic compounds.
3.  A principle of biology is that *living organisms interact with their environment*. Explain three ways in which fungi function as beneficial partners with autotrophs, and describe the benefits the fungi receive from the partnerships.

Collaborative Questions

1. Thinking about the natural habitats closest to you, where can you find fungi, and what roles do these fungi play?
2. Imagine that you are helping to restore the natural vegetation on a piece of land that had long been used to grow crops. You are placed in charge of planting pine seedlings (*Pinus resinosa*) and fostering their growth. In what way could you consider using fungi?

An Introduction to Animal Diversity

32

The variety of life forms on Earth is staggering. Naked mole rats, *Heterocephalus glaber*, are long-lived rodents that remain cancer free.

CHAPTER OUTLINE

32.1 Characteristics of Animals
32.2 Animal Classification
32.3 Molecular Views of Animal Diversity
Summary of Key Concepts
Assess and Discuss

Naked mole rats (*Heterocephalus glaber*) are a species of rodents that live in arid areas of the Horn of Africa, including Ethiopia, Somalia, and Kenya. These rats' large protruding teeth are used for digging, and their lips are sealed behind the teeth to keep out soil. As discussed in Chapter 55 on population ecology, naked mole rats have a unique reproductive process in which only one dominant female, the queen, reproduces. But these rats have an even more intriguing claim to fame. Whereas most species of mice and rats live only 4 years on average, naked mole rats can live for 30 years. And they are cancer free! Scientists discovered that the rats produce a super sugar called high-molecular-mass hyaluronan, or HMM-HA. Secretion of HMM-HA in mole rat cells causes contact inhibition, preventing the cells from overcrowding and forming tumors. This ability is lost in cancer cells. When experimenters from the University of Rochester in New York removed HMM-HA from naked mole rat cells, the cells lost their contact inhibition and tumors formed. Naturally, there is much interest in pursuing this line of research to prevent cancer and extend life in humans. The diversity of animal life is so staggering that there are many other examples of species on which increased research could lead to dramatic improvements in human health.

Animals constitute the most species-rich kingdom. About 1.3 million species have been found and described, and an estimated 2–5 million more species await discovery and classification. Beyond being members of this kingdom ourselves, humans depend on animals. Many different kinds of animals and their products are part of our diet. Humans also enjoy animal species as companions and depend on other species to test lifesaving drugs. We share parts of our genome with other organisms such as fruit flies, nematodes, and zebra fish—all of which are used as model organisms for understanding aspects of human molecular and developmental biology.

However, we are also in conflict with animals such as insects that threaten our food supply and transmit deadly diseases. Malaria is transmitted by mosquitoes; sleeping sickness, by tsetse flies; and rabies, by a number of animals, including dogs, raccoons, and bats. With such a huge number and diversity of existing animals and with animals featuring so prominently in our lives, understanding animal diversity is of paramount importance. Therefore, researchers have spent a great deal of effort in determining the unique characteristics of different taxonomic groups and identifying their evolutionary relationships.

Since the time of Carolus Linnaeus in the 1700s, scientists have classified animals based on their morphology, that is, on their physical structure. In the 1990s, animal classifications based on similarities in DNA and rRNA sequences became more common. Quite often, classifications based on morphology and those based on molecular data were similar, but some important differences arose. In this chapter, we will begin by defining the key characteristics of animals and then take a look at the major features of animal body plans that form the basis of classification. We will explore how new molecular data have enabled scientists to revise and refine the animal phylogenetic tree. As more molecular-based evidence becomes available, systematists will likely continue to redraw the tree of animal life. Thus, as you read this chapter, keep in mind that the classification of animals is now, and will continue to be, a work in progress.

32.1 Characteristics of Animals

Learning Outcomes:

1. List the key characteristics of animals that distinguish them from other organisms.
2. Provide a brief overview of the history of animal life on earth.

The Earth contains a dazzling diversity of animal species, living in environments from the deep sea to the desert and exhibiting an amazing array of characteristics. Most animals move and eat multicellular prey, and therefore, they are loosely differentiated from species in other kingdoms. However, coming up with a firm definition of an animal can be tricky because animals are so diverse that biologists can find exceptions to nearly any given characteristic. Even so, a number of key features can help us broadly characterize the group we call animals (**Table 32.1**).

Animals Are Multicellular Heterotrophs

Animals have several characteristics relating to cell structure, mode of nutrition, movement, and reproduction and development that distinguish them from other organisms.

Cell Structure Like some protists, plants and most fungi, animals are multicellular. However, animal cells lack cell walls and are flexible. This flexibility facilitates movement. Animal cells gain structural support from an extensive extracellular matrix (ECM) that forms strong fibers outside the cell (refer back to Figure 10.1). Additionally, a group of unique cell junctions—anchoring, tight, and gap junctions—play an important role in holding animal cells in place and allowing communication between cells (refer back to Table 10.3).

Table 32.1 Common Characteristics of Animals

Characteristic	Example
Multicellularity	Even relatively simple types of animals such as sponges are multicellular, in contrast to the mostly single-celled eukaryotic microorganisms called protists (see Chapter 28).
Heterotrophs	Animals obtain their food by eating other organisms or their products. This contrasts with plants and algae, most of which are autotrophs and essentially make their own food.
No cell walls	Plant, fungal, and bacterial cells possess a rigid cell wall, but animal cells lack a cell wall and are quite flexible.
Nervous tissue	The presence of a nervous system in most animals enables them to respond rapidly to environmental stimuli.
Movement	Most animals have a muscle system, which, combined with a nervous system, allows them to move in their environment.
Sexual reproduction	Most animals reproduce sexually, with small, mobile sperm uniting with a much larger egg to form a fertilized egg, or zygote.
Extracellular matrix	Proteins such as collagen bind animal cells together to give them added support and strength (see Figure 10.1).
Characteristic cell junctions	Animals have characteristic cell junctions, called anchoring, tight, and gap junctions (see Figures 10.7, 10.9, 10.11).
Special clusters of *Hox* genes	All animals possess *Hox* genes, which function in patterning the body axis (see Figures 19.16, 25.15).
Similar rRNA	Animals have very similar genes that encode for RNA of the small ribosomal subunit (SSU rRNA; see Figure 12.17).

Mode of Nutrition Unlike plants, animals are heterotrophs; that is, they cannot synthesize all their organic molecules from inorganic substances and thus must ingest other organisms or their products to sustain life. Many different modes of feeding exist among animals, including suspension feeding (filtering food out of the surrounding water); bulk feeding (eating large food pieces, as done by carnivores and herbivores); and fluid feeding (sucking plant sap or animal body fluids) (**Figure 32.1**). Although fungi and animals both rely on absorptive nutrition—that is, they secrete enzymes that break down complex materials and absorb the resulting small organic molecules—fungi use external digestion to obtain their nutrients. Animals ingest their food into an internal gut and then break it down using enzymes.

Movement Most animals have muscle cells and nerve cells organized into tissues. Muscle tissue is unique to animals, and most animals are capable of some type of locomotion, the ability to move from place to place, in order to acquire food or escape predators. This ability has led to the development of muscular-skeletal systems, systems of sensory structures, and a nervous system that coordinates movement and prey capture. Sessile species such as barnacles, which stay in one place, use bristled appendages to obtain nearby food. However, in many sessile species, although adults are immobile, the larvae can swim.

Reproduction and Development Nearly all members of the animal kingdom reproduce sexually, although certain insects, fish, and lizard species can reproduce asexually. During sexual reproduction, a small, mobile sperm generally unites with a much larger egg to form a fertilized egg, or zygote. Fertilization can occur internally, which is common in terrestrial species, or externally, which is more common in aquatic species. Similarly, embryos develop inside the mother or outside in the mother's environment. A particularly unusual developmental phenomenon is the occurrence of **metamorphosis**, by which an organism changes from a juvenile to an adult form. Metamorphosis is common in arthropods and is thought to reduce competition for food between juveniles and adults and to help disperse the species over long distances. For example, caterpillars—the larval form of moths and butterflies—generally feed in one spot, whereas adult moths and butterflies can fly long distances in search of food.

Animal Life Began More Than a Half Billion Years Ago

The history of animal life spans over 590 million years, starting at the end of the Proterozoic eon, when multicellular animals emerged (refer back to Figure 22.9). The first animals to evolve were invertebrates, animals without a vertebral column, or backbone. A profusion of animal phyla appeared during the Cambrian explosion, 533–525 million years ago (mya), including sponges, jellyfish, corals, flatworms, mollusks, annelid worms, the first arthropods, and echinoderms, plus many phyla that no longer exist today (**Figure 32.2**).

(a) (b) (c)

Figure 32.1 Modes of animal nutrition. **(a)** Suspension feeders, such as this tube worm, filter food particles from the water column. **(b)** Grizzly bears and other bulk feeders tear off large pieces of their food and chew it or swallow it whole. **(c)** Fluid feeders, such as this aphid, suck fluid from their food source.

The causes of this sudden increase in animal life at that time are not fully understood, but three explanations have been proposed.

- Species proliferation may have been related to a warm favorable environment. At the same time, atmospheric and aquatic oxygen levels were increasing, permitting increased metabolic rates, and an ozone layer had developed, blocking out harmful UV radiation and allowing complex life to thrive in shallow water and eventually on land.
- The evolution of the *Hox* gene complex may have permitted much variation in morphology.
- As new types of predators evolved, prey developed adaptations that enabled them to avoid their predators, leading to counteradaptations by predators, and so on. This evolutionary "arms race" may have resulted in a proliferation of predator and prey types. These hypotheses are not mutually exclusive and may well have operated at the same time.

Figure 32.2 The profusion of animal life in the Cambrian period, about 520 mya. This artist's reconstruction of marine life shows many different phyla, some of which are now extinct.

Around 520 mya, the first vertebrates, fishes, appeared at roughly the same time as the first plants invaded land. The appearance of land plants represented a viable food source for any organisms that could utilize them. However, the realm of land and air presented organisms with many challenges. For colonization of land to occur, certain species evolved adaptations that prevented them from drying out and enabled them to breathe, move, and reproduce in the new environment, in much the same way as the plant embryo, leaves, seeds, and other adaptations permitted plants to colonize terrestrial habitats (see Chapter 29). For animal species, such features included lungs and internal fertilization. The development of the amniotic egg, which features a tough, protective shell to prevent drying out, enabled animals to be terrestrial for their entire life cycle. The amniotic egg appeared during the Carboniferous period, about 300 mya, and was responsible for the success of the reptiles, which appeared during this period. Reptiles were to dominate the Earth for many millions of years during the rise and fall of the dinosaurs. Mammals appeared at the same time as dinosaurs, although they were not prevalent. The number and diversity of mammals exploded only after the dinosaurs abruptly died out at the end of the Cretaceous era, about 65 mya.

32.2 Animal Classification

Learning Outcomes:

1. Discuss why choanoflagellates are believed to be the closest living relatives of animals.
2. Describe each of the major morphological and developmental features of animal body plans that form the basis of the classification of animals.
3. **SciSKILLS** » Draw an animal phylogeny based solely on body plans, and contrast it with the animal phylogeny based on body plans and molecular data.

Although animals constitute an extremely diverse kingdom, most biologists agree that the kingdom is monophyletic, meaning that all taxa have evolved from a single common ancestor. Today, scientists recognize about 35 animal phyla. At first glance, many of these phyla

seem so distantly related to one another (for example, chordates and jellyfish) that making sense of this diversity with a classification scheme seems very challenging. However, over the course of centuries, scientists have come to some basic conclusions about the evolutionary relationships among animals. In this section, we will explore the major features of animal body plans that form the basis of animal phylogeny (**Figure 32.3**).

Animals Evolved from a Choanoflagellate-like Ancestor

With the monophyletic nature of the animal kingdom in mind, scientists have attempted to characterize the organism from which animals most likely evolved. According to research, the closest living relative of animals is believed to be a flagellated protist known as a choanoflagellate. Choanoflagellates are tiny, single-celled organisms, each with a single flagellum surrounded by a collar composed of cytoplasmic tentacles (**Figure 32.4a**; look back at Figure 28.21). A number of species form colonies consisting of many individual organisms on a single stalk. Scientists think that some of these cells may have gradually taken on specialized functions—for example, movement or nutrition—while still maintaining coordination with other cells and cell types.

As shown in **Figure 32.4b**, colonial choanoflagellate cells bear a striking similarity to cell types called choanocytes, which are found in sponges, the simplest animals. As discussed later, evolutionary changes to this simple body plan resulted in critical innovations that led to more complex body plans found in other animals. Molecular data also point to choanoflagellates as the closest living relatives of animals.

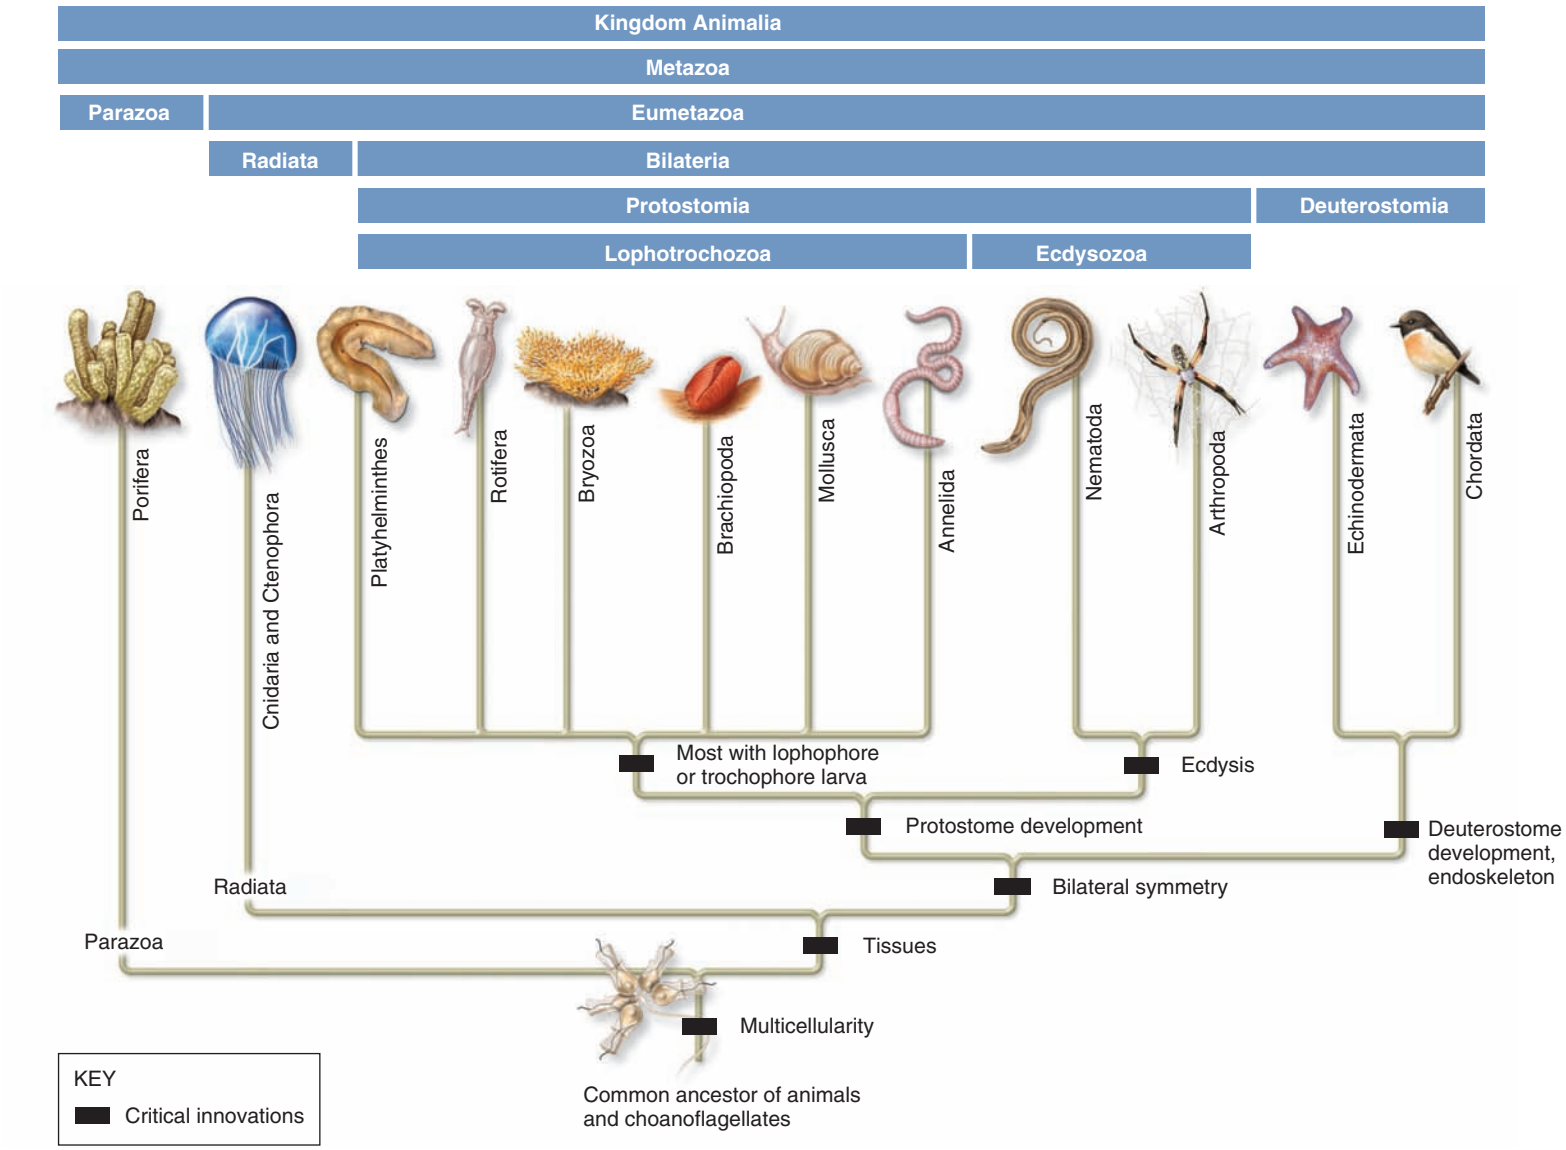

Figure 32.3 An animal phylogeny based on body plans and molecular data. Though there are about 35 different animal phyla, we will focus our discussions here and in the next two chapters on the 12 phyla with the greatest numbers of species.

BIOLOGY PRINCIPLE All species (past and present) are related by an evolutionary history. All animals are believed to be derived from a choanoflagellate-like ancestor.

BioConnections: What shared derived character is common to the Eumetozoa? Look back at Figure 26.9.

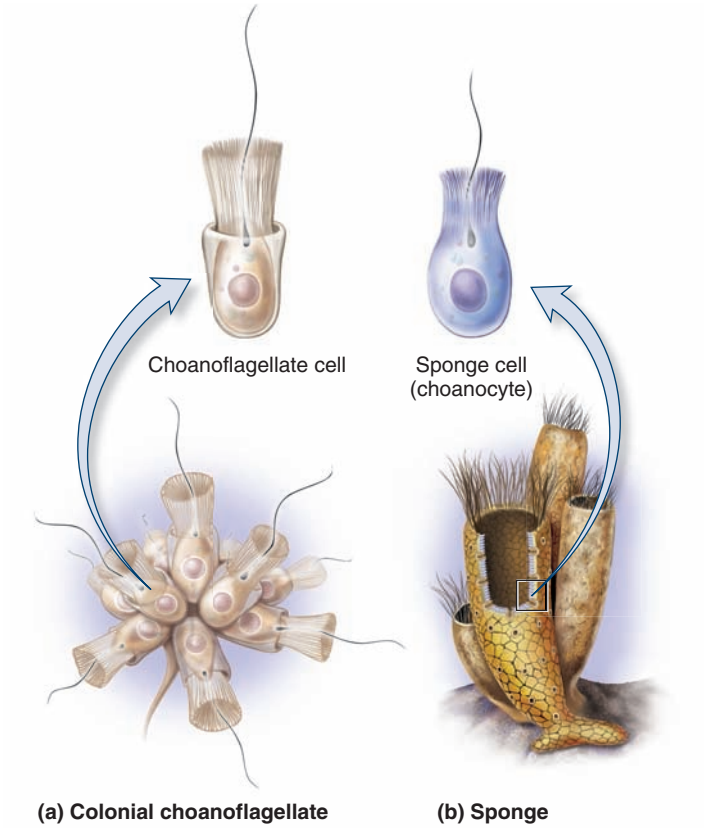

Figure 32.4 Early animal characteristics: a comparison of a colonial choanoflagellate and a sponge. Both types of organisms have very similar types of cells. The structure of sponges and the sponge cell called the choanocyte are described in Chapter 33 (look ahead to Figure 33.2c).

Concept Check: Why are sponges considered animals but simple choanoflagellates are not?

Animal Classification Is Based Mainly on Body Plans

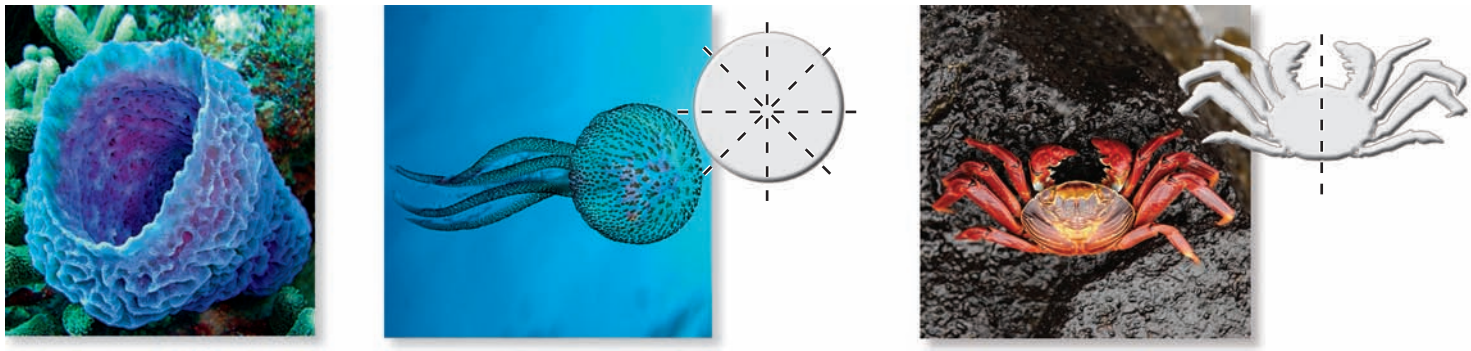
Biologists traditionally classified animal diversity in terms of three main morphological and developmental features of animal body plans:

1. Presence or absence of different tissue types
2. Type of body symmetry
3. Specific features of embryonic development

We will discuss each of these major features of animal body plans next.

Tissues Collectively, animals are known as **Metazoa**. Animals can be divided into two subgroups based on whether or not they have specialized types of tissues, that is, groups of cells that have a similar structure and function. The **Parazoa** (from the Greek, meaning alongside animals) are not generally thought to possess specialized tissue types or organs, although they may have several distinct types of cells. Those cells can change their shape and location, making any associations between them temporary. The Parazoa consist of a single phylum, Porifera (sponges) (**Figure 32.5a**). In contrast, the **Eumetazoa** (from the Greek, meaning true animals) have one or more types of tissue and, for the most part, have different types of organs—a collection of two or more tissues performing a specific function or set of functions.

Symmetry The Eumetazoa are divided according to their type of symmetry. Symmetry refers to the existence of balanced proportions of the body on either side of a median plane. Radially symmetric animals, the **Radiata**, can be divided equally by any longitudinal plane passing through the central axis (**Figure 32.5b**). Such animals are often circular or tubular in shape, with a mouth at one end, and include the animals called cnidarians and ctenophores (jellyfish and related species).



Bilaterally symmetric animals, the **Bilateria**, can be divided along a vertical plane at the midline to create two halves (**Figure 32.5c**). Thus, a bilateral animal has a left side and a right side, which are mirror images, as well as a **dorsal** (upper) and a **ventral** (lower) side, which are not identical, and an **anterior** (head) and a **posterior** (tail) end (refer back to Figure 19.2). Bilateral symmetry is strongly correlated with both the ability to move through the environment and **cephalization**—the localization of sensory structures at the anterior end of the body. Such abilities allow animals to encounter their environment initially with their head, which is best equipped to detect and consume prey and to detect and respond to predators and other dangers. Most animals are bilaterally symmetrical.

Another key difference between the Radiata and Bilateria is that radial animals have two embryonic cell layers, called **germ layers**, whereas bilateral animals have three germ layers. In all animals except the sponges, the growing embryo develops different layers of cells during a process known as **gastrulation** (**Figure 32.6**).

Fertilization of an egg by a sperm creates a diploid zygote. The zygote then undergoes **cleavage**—a succession of rapid cell divisions with no significant growth that produces a hollow sphere of cells called a **blastula**. In gastrulation, an area in the blastula folds inward, or invaginates, creating in the process a structure called a **gastrula**. The inner layer of cells becomes the **endoderm**, which lines the **archenteron**, or primitive digestive tract. The outer layer, or **ectoderm**, covers the surface of the embryo and differentiates into the epidermis and nervous system.

The Bilateria develop a third layer of cells, termed the **mesoderm**, between the ectoderm and endoderm. Mesoderm forms the muscles and most other organs between the digestive tract and the ectoderm (look ahead to Figure 52.7). Because the Bilateria have these three distinct germ layers, they are often referred to as **triploblastic**, whereas the Radiata, which have only ectoderm and endoderm, are termed **diploblastic**.

Specific Features of Embryonic Development The most fundamental feature of embryonic development concerns the development of a mouth and anus (**Figure 32.7a**). In gastrulation, the endoderm forms an indentation, the **blastopore**, which is the opening of the archenteron to the outside. In **protostomes** (from the Greek *protos*, meaning first, and *stoma*, meaning mouth), the blastopore becomes the mouth. If an anus is formed in a protostome, it develops from a secondary opening. In contrast, in **deuterostomes** (from the Greek

(a) Parazoa: no tissue types

(b) Eumetazoa: two tissue types
Radiata: radial symmetry

(c) Eumetazoa: three tissue types
Bilateria: bilateral symmetry

Figure 32.5 Early divisions in the animal phylogeny. Animals can be categorized based on **(a)** the absence of different tissue types (Parazoa; the sponges) or **(b, c)** the presence of tissues (Eumetazoa; all other animals). Further categorization is based on the presence of **(b)** radial symmetry (Radiata; the cnidarians and ctenophores) or **(c)** bilateral symmetry (Bilateria; all other animals).

deuteros, meaning second), the blastopore becomes the anus, and the mouth is formed from the secondary opening.

In addition, protostomes and deuterostomes differ in some other embryonic features. In the early stages of embryonic development, repeated cell divisions occur without cell growth, a process known as cleavage. Protostome development is generally characterized by so-called **determinate cleavage**, in which the fate of each embryonic cell is determined very early (**Figure 32.7b**). If one of the cells is removed from a four-cell protostome embryo, neither the single cell nor the remaining three-cell mass can form viable embryos, and development is halted. In contrast, most deuterostome development is characterized by **indeterminate cleavage**, in which each cell produced by early cleavage retains the ability to develop into a complete embryo. For example, when one cell is excised from a four-cell sea urchin embryo, both the single cell and the remaining three can go on to form viable embryos. Other embryonic cells compensate for the missing cells. In human embryos, if individual embryonic cells separate from one another early in development, identical twins can result.

In the developing zygote, cleavage may occur by two mechanisms (**Figure 32.7c**). In **spiral cleavage**, the planes of cell cleavage are oblique to the vertical axis of the embryo, resulting in an

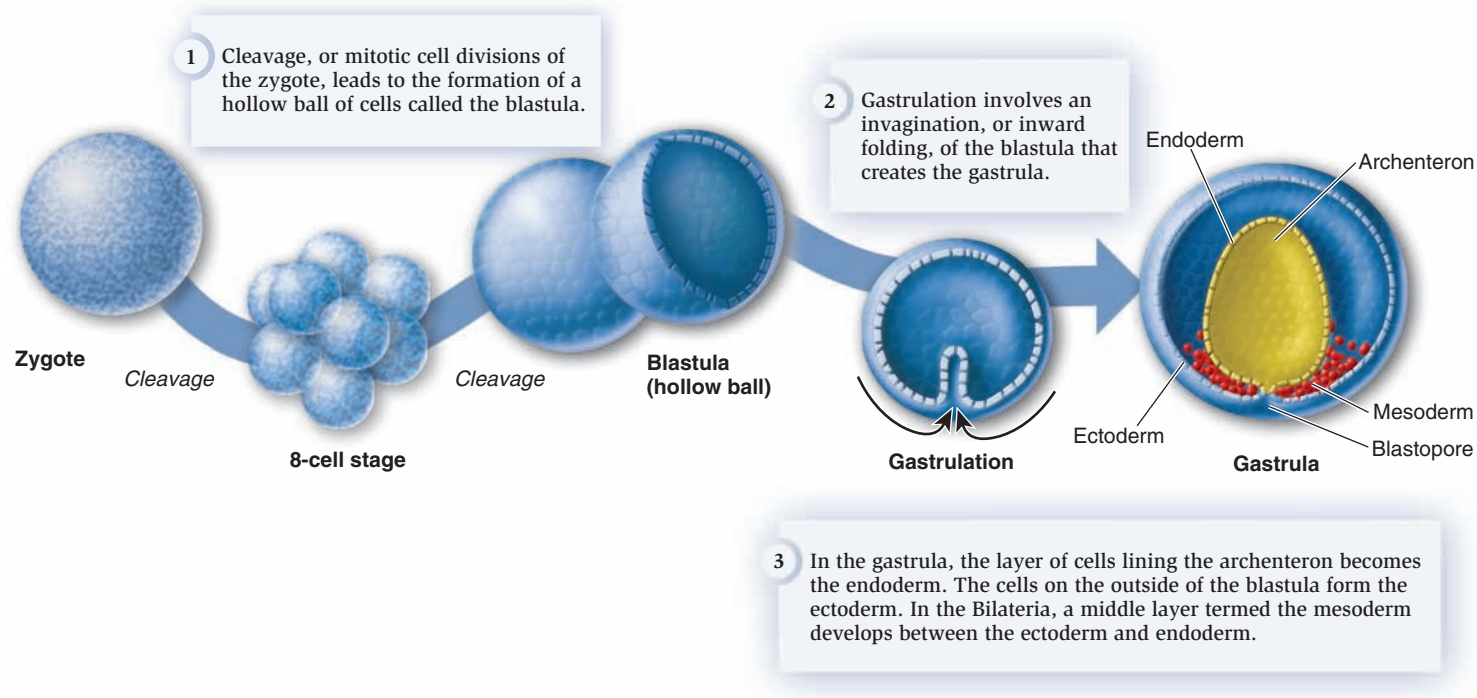


Figure 32.6 Formation of germ layers. Note: Radially symmetric animals (Radiata) do not form mesoderm.

BioConnections: Look back to Figure 26.8. Is the existence of three layers in triploblastic animals a shared primitive character or a shared derived character?

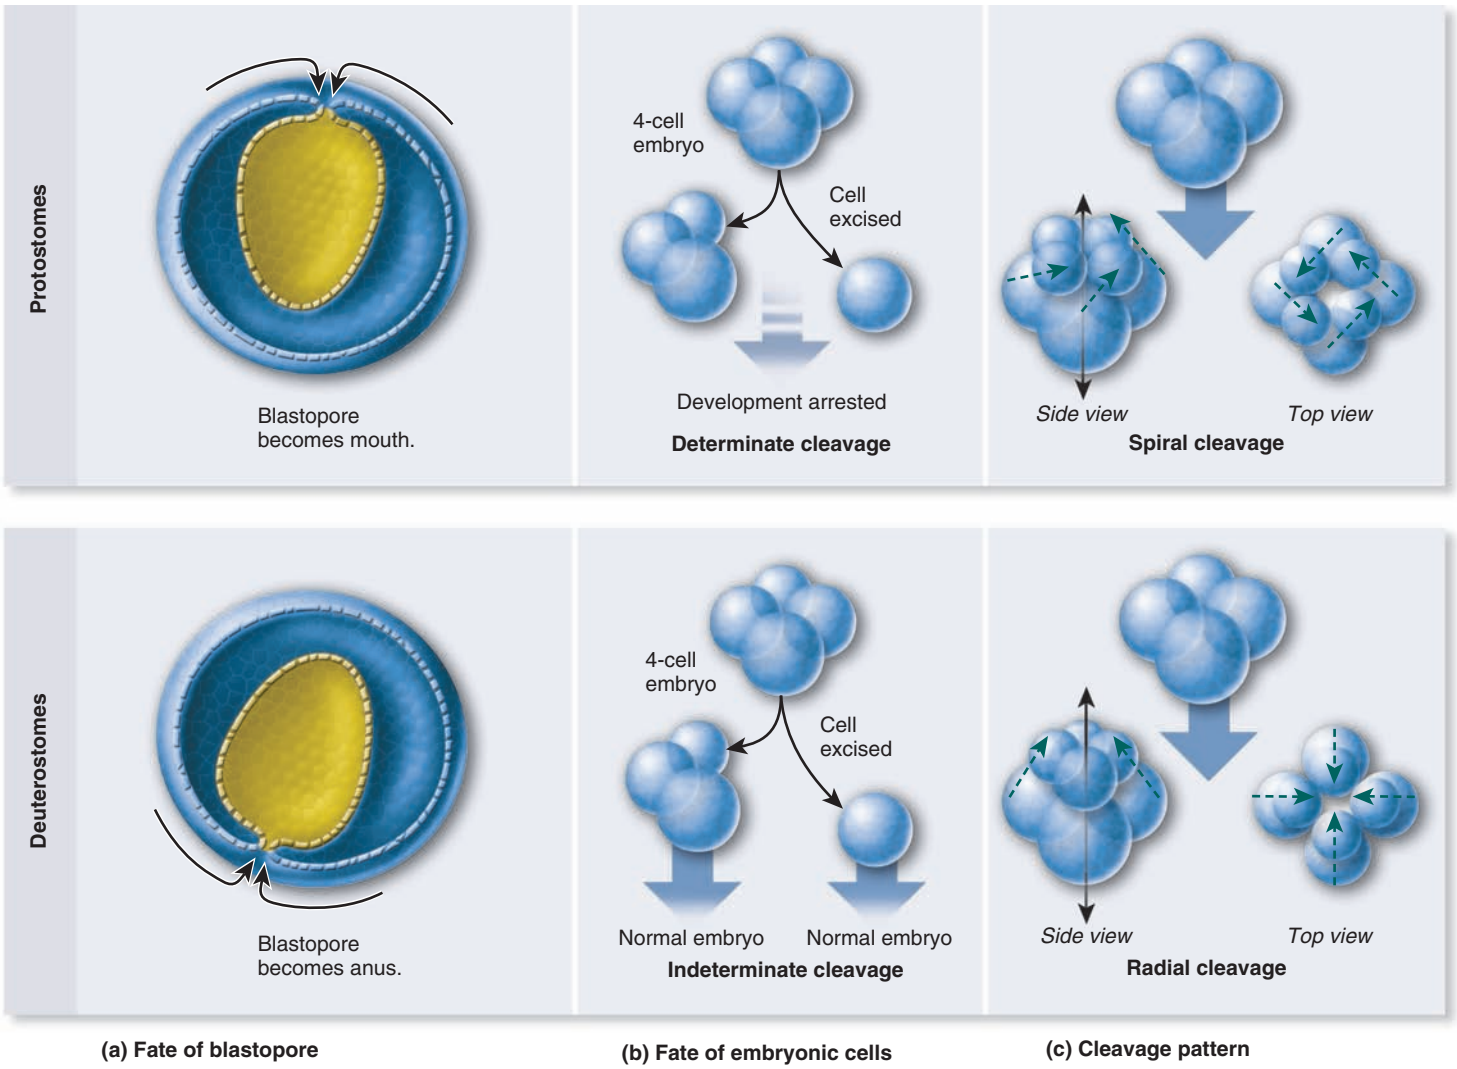

Figure 32.7 Differences in embryonic development between protostomes and deuterostomes. **(a)** In protostomes, the blastopore becomes the mouth. In deuterostomes, the blastopore becomes the anus. **(b)** Protostomes have determinate cleavage, whereas deuterostomes have indeterminate cleavage. **(c)** Many protostomes have spiral cleavage, and most deuterostomes have radial cleavage. The dashed arrows indicate the direction of cleavage.

arrangement in which newly formed upper cells lie centered between the underlying cells. Many protostomes, including mollusks and annelid worms, exhibit spiral cleavage. The coiled shells of some mollusks result from spiral cleavage. Organisms with spiral cleavage are also known as spiralians. In **radial cleavage**, the cleavage planes are either parallel or perpendicular to the vertical axis of the egg. This results in tiers of cells, one directly above the other. All deuterostomes exhibit radial cleavage, as do insects and nematodes, suggesting it may have been an ancestral condition.

Additional Morphological Criteria Are Used to Classify Animals

In older phylogenetic trees of animal life, classification was also based on morphological features, such as the possession of a fluid-filled body cavity called a **coelom** or the presence of body segmentation. More recent molecular data suggest that although these features are helpful in describing differences in animal structure, they are not as useful in shedding light on the evolutionary history of animals as previously believed.

Body Cavity In many animals, the body cavity is completely lined with mesoderm and is called a true coelom. Animals with a true coelom are termed **coelomates** (**Figure 32.8a**). If the fluid-filled cavity is not completely lined by tissue derived from mesoderm, it is known as a pseudocoelom (**Figure 32.8b**). Animals with a pseudocoelom, including rotifers and roundworms, are termed **pseudocoelomates**. Some animals, such as flatworms, lack a fluid-filled body cavity and are termed **acoelomates** (**Figure 32.8c**). Instead of fluid, this region contains mesenchyme, a tissue derived from mesoderm.

A coelom has many important functions, perhaps the most important being that its fluid is relatively incompressible and therefore cushions internal organs such as the heart and intestinal tract, helping to prevent injury from external forces. A coelom also enables internal organs to move and grow independently of the outer body wall. Furthermore, in some soft-bodied invertebrates, such as earthworms, the

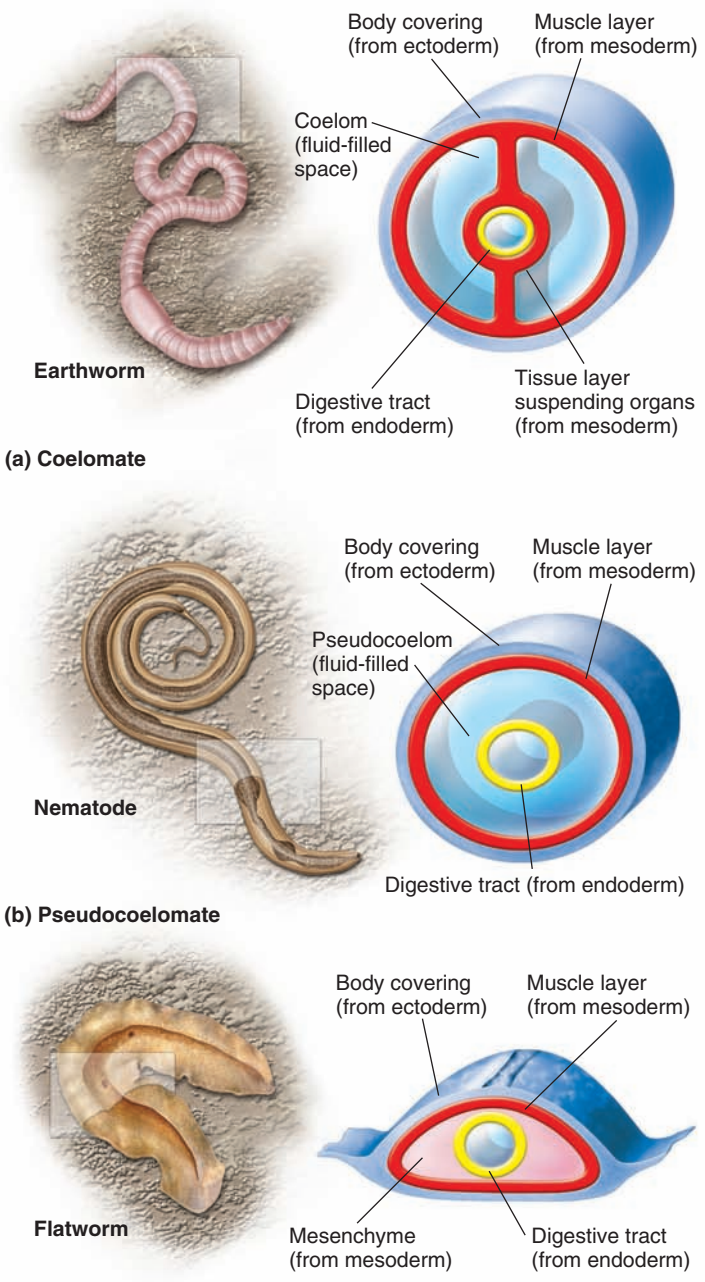

Figure 32.8 The three basic body cavities of bilaterally symmetric animals. Cross sections of each animal are shown on the right.

Concept Check: *What advantages does a coelom confer for movement?*

coelom functions as a **hydrostatic skeleton**—a fluid-filled body cavity surrounded by muscles that gives support and shape to the body of organisms. Muscle contractions at one part of the body push this fluid toward another part of the body. This type of movement can best be observed in an earthworm. Finally, in some organisms, the fluid in the body cavity also acts as a simple circulatory system. At one stage, the presence or absence of a coelom or pseudocoelom was a distinction traditionally used in the construction of animal phylogeny, but scientists now believe this feature may not be useful in classification because animals that once possessed coeloms may have lost them over long periods of evolutionary time, as is true for the ancestors of flatworms. In addition, it is also believed that the coelom may have arisen more than once in animal evolution, once in protostomes and once in deuterostomes.

Segmentation Another well-known feature of the animal body plan is the presence or absence of segmentation. In segmentation, the body is divided into regions called segments. It is most obvious in the annelids, or segmented worms, but it is also evident in arthropods and chordates (**Figure 32.9**). In annelids, each segment contains the same set of blood vessels, nerves, and muscles. Some segments may differ, such as those containing the brain or the sex organs, but many segments are very similar. In chordates, we can see segmentation in the backbone and muscles. The advantage of segmentation is that it allows specialization of body regions. For example, as we will see in Chapter 33, arthropods exhibit a vast degree of specialization of their segments. Many insects have wings and only three pairs of legs, whereas centipedes have no wings and many legs. Crabs, lobsters, and shrimp have highly specialized thoracic appendages that aid in feeding. The presence or absence of segmentation was used in the construction of animal phylogeny, with annelid worms and arthropods thought to be fairly closely related because of their body segmentation. Scientists are beginning to understand the genetic basis for some of these morphological traits. Recent studies have shown that changes in specialization among arthropod body segments can be traced to relatively simple changes in *Hox* genes.

BIO TIPS **THE QUESTION** *Are segmented animals a monophyletic, polyphletic, or paraphyletic group?*

TOPIC ***What topic in biology does this question address?*** The topic is systematics. More specifically, the question is about what constitutes monophyletic, polyphletic, and paraphyletic groups.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you know there are three possible systematic designations for a group of organisms: monophyletic, polyphletic, and paraphyletic. From your understanding of taxonomy and systematics, discussed in Chapter 26, you may remember that a monophyletic group contains a common ancestor and all of its descendants, a paraphyletic group contains a common ancestor but not all of its descendants, and a polyphyletic group contains groups of species with different common ancestors. You should also remember which phyla are segmented.

PROBLEM-SOLVING STRATEGY ***Make a drawing.*** One strategy for solving this problem is to draw a simple version of Figure 32.3 with just the names of the phyla and the branches, and then place a star next to each phylum with segmented animals. Next, look at the comparison of monophyletic, polyphyletic, and paraphyletic taxonomic groups shown in Figure 26.5. Decide which pattern best matches your drawing.

ANSWER *Because segmented animals have different common ancestors, the group is polyphyletic.*

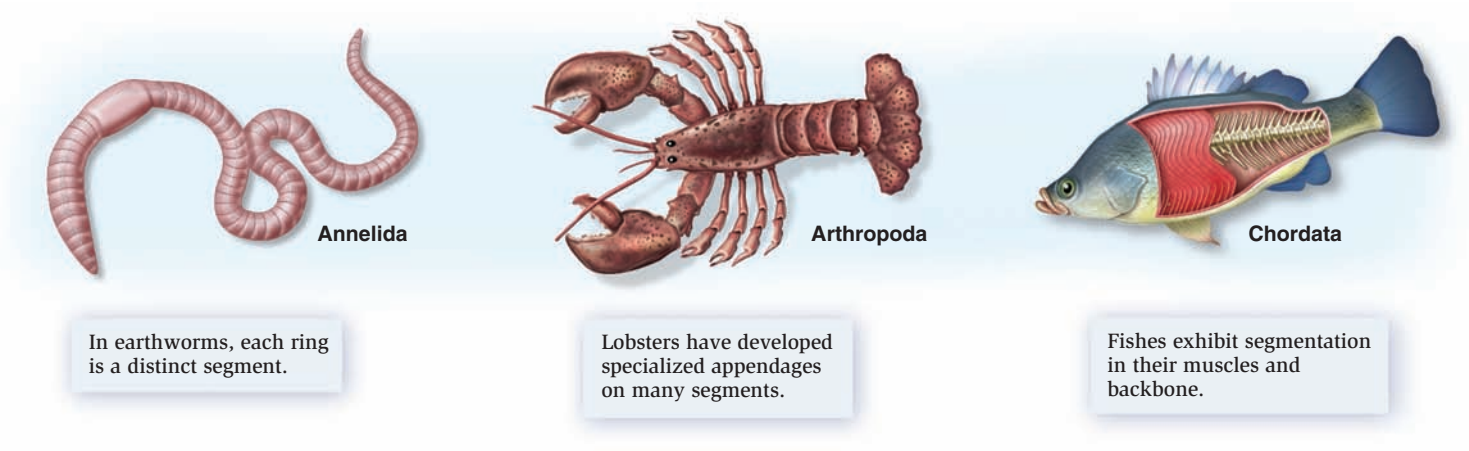

Figure 32.9 Segmentation. Annelids, arthropods, and chordates all exhibit segmentation.

Genomes & Proteomes Connection

Changes in *Hox* Gene Expression Control Body Segment Specialization

***Hox* genes**, which are present in all animals, are involved in determining the spatial patterning of the body and appendages. As described in Chapter 19, animals have several *Hox* genes that are expressed in particular regions of the body. The *Hox* genes are organized into four clusters of 13 genes, each designated with numbers 1 through 13. Some are expressed in anterior segments; others are expressed in posterior segments (refer back to Figure 19.17). In the 1990s, Greek molecular biologist Michalis Averof and coworkers showed how relatively simple shifts in the expression patterns of *Hox* genes along the anteroposterior axis can account for the large variation in arthropod appendage types. More recent work by Averof and colleagues (2010) has shown how specific changes in *Hox* expression could be linked to changes in crustacean maxillipeds—appendages near the mouth that are used for feeding. Maxillipeds arise in the anterior thoracic segments and display a mixture of locomotory and feeding functions. By knocking out *Hox* genes or expressing *Hox* genes in an abnormal position, the researchers could change maxillipeds into leglike appendages or transform leglike appendages into maxillipeds.

Shifts in the patterns of expression of *Hox* genes in the embryo along the anteroposterior axis are similarly prominent in vertebrate evolution. In vertebrates, the transition from one type of vertebra to another, for example, from cervical (neck) to thoracic (chest) vertebrae, is controlled by particular *Hox* genes. The site of the cervicothoracic boundary appears to be influenced by the *HoxC-6* gene (**Figure 32.10**). Differences in its relative position of expression, which occurs prior to vertebrae development, control neck length in vertebrates. In mice, which have a relatively short neck, the expression of *HoxC-6* begins between vertebrae 7 and 8. In chickens and geese, which have longer necks, the expression begins farther back, between vertebrae 14 and 15, or 17 and 18, respectively. The forelimbs also arise at this boundary in all vertebrates. Interestingly, snakes, which essentially have no neck or forelimbs, do not exhibit this boundary, and *HoxC-6* expression occurs immediately behind their heads. This, in effect, means that snakes got longer by losing their neck and lengthening their chest.

American molecular biologist Sean Carroll has remarked that it is very satisfying to find that the evolution of body forms and novel structures in two of the most successful and diverse animal groups, arthropods and vertebrates, is shaped by the shifting of *Hox* genes. It also reminds us of one of the basic principles of biology—that the genetic material provides a blueprint for reproduction. Much of the diversity in animal phyla can be seen as variations on a common theme.

32.3 Molecular Views of Animal Diversity

Learning Outcomes:

1. Discuss the similarities and differences between animal phylogenies based on molecular data and those based on morphological data.
2. List the morphological features of the Ecdysozoa and the Lophotrochozoa.

As discussed in Chapter 26, molecular systematics involves the comparison of genetic data, such as DNA, RNA, and amino acid sequences, from different organisms to estimate their evolutionary relationships based on the degree of similarities between the sequences. More closely related organisms exhibit fewer sequence differences than distantly related organisms. An advantage of the molecular approach over approaches based on morphological data is that genetic sequences among different species are easier to quantify and compare. For example, the DNA sequence contains four easily identified and mutually exclusive characters: the nucleotides A, T, G, and C (RNA has A, U, G, and C). Contrast this with morphological and embryological data, for which characters are scored more subjectively, often based on the qualitative assessment of many traits. Morphological approaches sometimes left us with questions about the evolutionary relationships among animals; biologists now

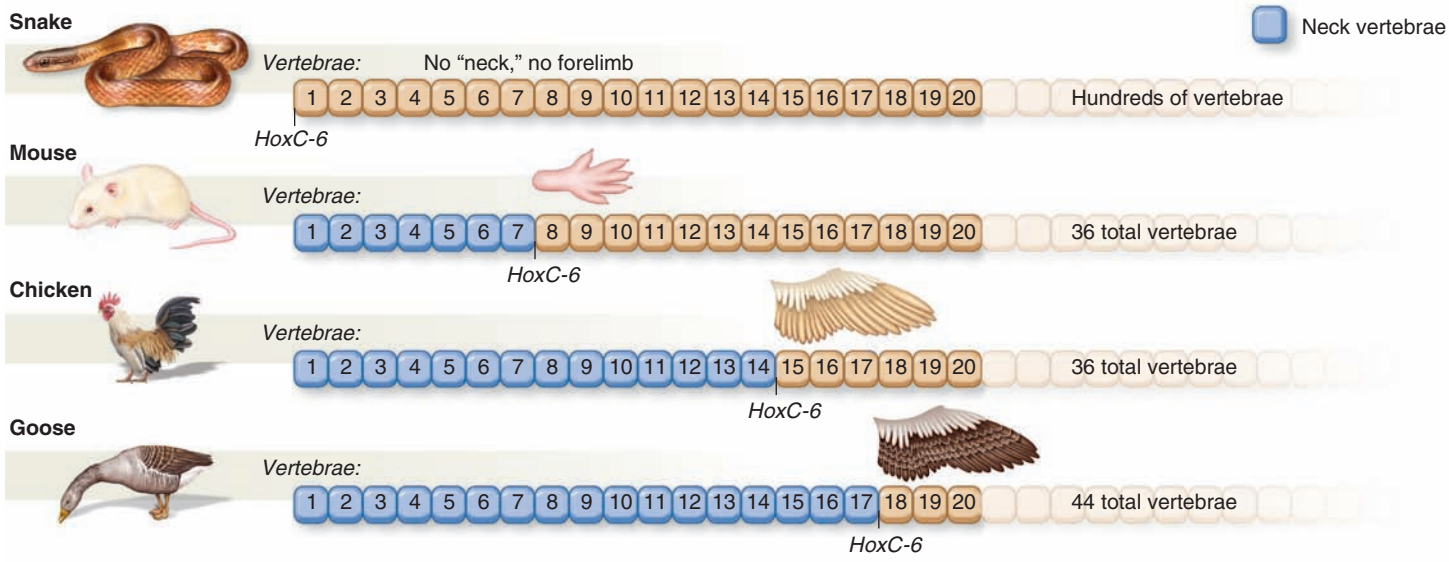

Figure 32.10 **Relationship between *HoxC-6* gene expression and neck length.** In vertebrates, the transition between neck and trunk vertebrae is controlled by the position of the *HoxC-6* gene. In snakes, the expression of this gene is shifted so far forward that a neck does not develop.

use molecular data to clarify questions posed by earlier data and arrive at an interpretation that agrees most closely with the available evidence.

To perform molecular analyses, scientists have often focused on comparing sequences of nucleotides in the gene that encodes RNA of the small ribosomal subunit (SSU rRNA) (see Chapter 12). SSU rRNA is universal in all organisms, and its base sequence has changed very slowly over long periods of time. Researchers have also studied *Hox* genes, which are found in all animals, to study the evolution of body plans (refer back to Figure 25.15). They believe that duplication of *Hox* genes and gene clusters has led to the evolution of more complex animal body forms. Examination of the genes that regulate early developmental differences has provided insight into the evolution of animal development and how, when, and why animal body plans diversified.

Phylogenies based on SSU rRNA and *Hox* genes are similar and, in many cases, agree with the structure of the morphologically based phylogenetic tree. For example, recent analyses of genes have strengthened the view that animals form a single clade—a group of species derived from a single common ancestor. We can appreciate this by comparing a portion of the sequence of the SSU rRNA genes of a sponge, flatworm, seagull, and paramecium (**Figure 32.11**) in much

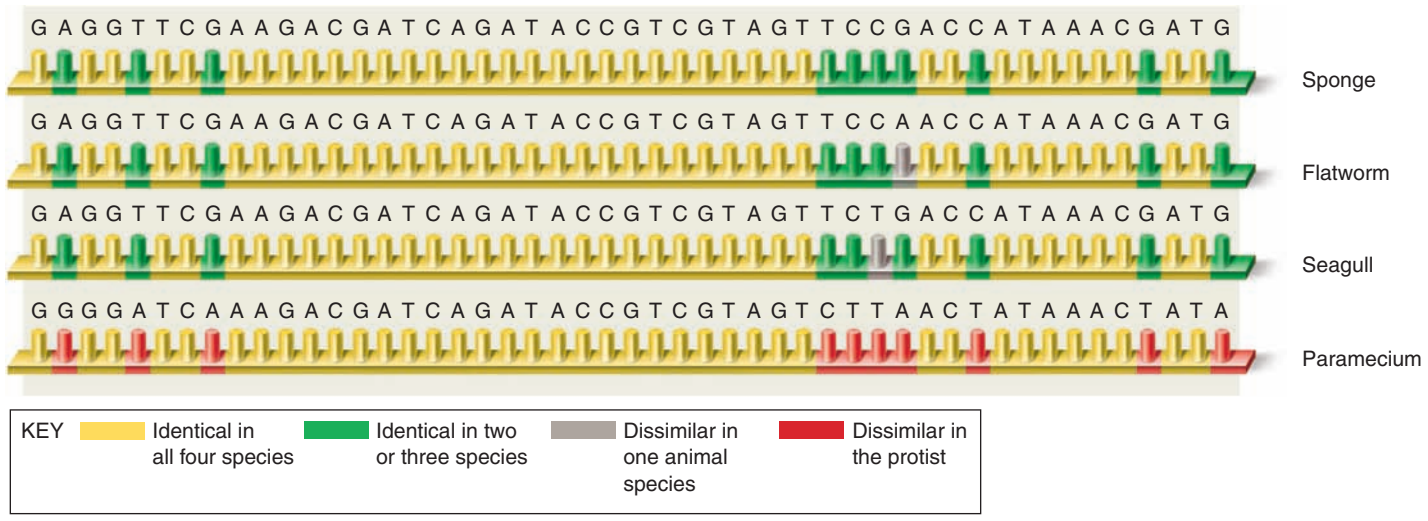

Figure 32.11 **Comparison of small subunit (SSU) rRNA gene sequences from three animals and a protist.** Note the similarities between the animals, even though they are very different species, and the differences with the protist. This and other comparative studies of gene sequences underscore the likelihood that animals share a common ancestor.

BioConnections: *Look back at Figure 12.17. Which color represents sequences of bases that are the most evolutionarily conserved?*

the same way as we did in Chapter 12 (refer back to Figure 12.17). The three animal sequences are very similar compared with that of the paramecium (a protist), indicating that the animals share a common ancestor.

However, phylogenies based on molecular data contain some important differences from those based on assessment of body plans. One of the most influential of the molecular studies was a paper by Anna Marie Aguinaldo and colleagues, which established evidence for a new clade of molting animals, the **Ecdysozoa**, consisting of the nematodes and arthropods. This study (discussed in more detail in the Feature Investigation) represented a scientific breakthrough because it underscored the value of molecular phylogenies. According to molecular evidence, the other major protostome clade is the **Lophotrochozoa**, which encompasses the mollusks, annelids, and several other phyla. When some morphologists reviewed their data given this new information, they found there was also morphological support for these new groupings. Let's look at what morphological features make each of these groups unique.

The Ecdysozoa is so named because all of its members secrete a nonliving cuticle, an external skeleton (exoskeleton); think of the hard shell of a beetle or that of a crab. As these animals grow, the exoskeleton becomes too small, and the animal molts, or breaks out of its old exoskeleton, and secretes a newer, larger one (**Figure 32.12**). This molting process is called ecdysis; hence the name Ecdysozoa. Although this group was named for this morphological characteristic, it was first strongly supported as a separate clade by molecular evidence such as similarities in DNA.

Although the Lophotrochozoa clade was organized primarily through analysis of molecular data, its name stems from two morphological features seen in many organisms of this clade. The "lopho" part is derived from the **lophophore**, a horseshoe-shaped crown of tentacles used for feeding that is present on some phyla in this clade, such as the rotifers, bryozoans, and brachiopods (**Figure 32.13a**). The "trocho" part refers to the **trochophore larva**, a distinct larval stage characterized by a band of cilia around its middle that is used for swimming (**Figure 32.13b**). Trochophore larvae are found in several Lophotrochozoa phyla, such as annelid worms and mollusks, indicating their similar ancestry. Other members of the clade, such as the platyhelminthes, have neither of these morphological features and are classified as lophotrochozoans based strictly on molecular data.

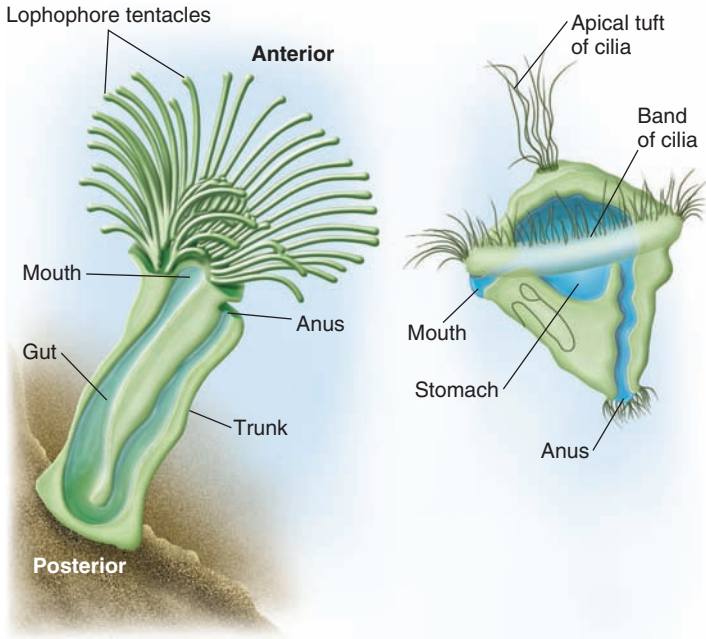

Table 32.2 summarizes the basic characteristics of the major animal phyla. In Chapter 33, we will discuss the diversity of all the phyla in the Parazoa, Radiata, Lophotrochozoa, Ecdysozoa, and Deuterostomia, the latter including the phylum Echinodermata and invertebrate members of the phylum Chordata; these are all the animals without a backbone. In Chapter 34, we will turn our attention to members of the phylum Chordata, including fishes, amphibians, reptiles, and mammals, which possess a backbone.

Figure 32.12 Ecdysis. The dragonfly, shown here emerging from a discarded exoskeleton, is a member of the Ecdysozoa—a clade of animals exhibiting ecdysis, the periodic shedding (molting) and re-formation of the exoskeleton.

BIOLOGY PRINCIPLE Living organisms grow and develop. For animals with exoskeletons, growth and development necessitate molting.

Concept Check: What are the main members of the Ecdysozoa?

(a) Lophophore of a phoronid worm **(b) Trochophore larva**

Figure 32.13 Characteristics of the Lophotrochozoa. **(a)** A lophophore, a crown of ciliated tentacles, generates a current to bring food particles into the mouth. **(b)** The trochophore larval form is found in several animal lineages.

Table 32.2 Summary of the Basic Characteristics of the Major Animal Phyla

Feature	Porifera (sponges)	Cnidaria and Ctenophora (hydra, anemones, jellyfish)	Platyhelminthes (flatworms)	Rotifera (rotifers)	Bryozoa and Brachiopoda (bryozoans and brachiopods)	Mollusca (snails, clams, squids)	Annelida (segmented worms)	Nematoda (roundworms)	Arthropoda (insects, arachnids, crustaceans)	Echinodermata (sea stars, sea urchins)	Chordata (vertebrates and others)

Feature Investigation | Aguinaldo and Colleagues Analyzed SSU rRNA Sequences to Determine the Taxonomic Relationships of Arthropods to Other Taxa

In 1997, American molecular biologists Anna Marie Aguinaldo, James Lake, and colleagues analyzed the relationships of arthropods to other taxa by sequencing the complete gene that encodes SSU rRNA from a variety of representative taxa (**Figure 32.14**). Total genomic DNA was isolated using standard techniques and amplified by polymerase chain reaction (PCR; refer back to Figure 20.6). PCR fragments were then subjected to DNA sequencing, a technique also described in Chapter 20, and the evolutionary relationships among

Figure 32.14 A molecular animal phylogeny based on sequencing of SSU rRNA.

GOAL To determine the evolutionary relationships among many animal species, especially the relationship of arthropods to other species.

KEY MATERIALS Cellular samples from about 50 animals in different taxa.

	Experimental level	Conceptual level
1 Isolate DNA from animals and subject the DNA to polymerase chain reaction (PCR) to obtain enough material for DNA sequencing. PCR is described in Chapter 20.	For more detail, refer back to Figure 20.6. 	The goal of PCR is to amplify a region in the SSU rRNA gene.
2 Sequence the amplified DNA by dideoxy sequencing, also described in Chapter 20.	For more detail, refer back to Figure 20.9. 	Dideoxy sequencing, in which DNA strands are separated according to their lengths by subjecting them to gel electrophoresis, is used to determine the base sequence of DNA.

Figure 32.14 A molecular animal phylogeny based on sequencing of SSU rRNA.

3 Compare the DNA sequences and infer phylogenetic relationships using the cladistic approach described in Chapter 26.

The approach compares traits that are either shared or not shared by different species and creates clades, consisting of a common ancestral species.

4 **THE DATA**

This process resulted in a large group of DNA sequences that were then analyzed with the use of computer programs.

5 **CONCLUSION** The arthropods are most closely related to the nematodes, and both phyla are placed in the clade Ecdysozoa. All other protostomes belong to a new clade called the Lophotrochozoa.

6 **SOURCE** Aguinaldo, A.M., et al. 1997. Evidence for a clade of nematodes, arthropods, and other moulting animals. *Nature* 387 (6632):489–493.

50 species were examined. The resulting data indicated the existence of a monophyletic clade—the Ecdysozoa—containing the nematodes and arthropods.

The hypothesis that nematodes are more closely related to arthropods than previously thought has important ramifications. First, it implies that two well-researched model organisms, *Caenorhabditis elegans* (a nematode) and the fruit fly *Drosophila melanogaster* (an arthropod), are more closely related than had been believed. Second, morphological classification had assumed that arthropods and annelids were closely related to each other based on the presence of segmentation. Molecular data provides no evidence that annelids and arthropods form a clade of segmented animals.

Experimental Questions

1. What was the purpose of the study conducted by Aguinaldo and colleagues?
2. **SciSKILLS »** What was the major finding of this particular study?
3. What impact does the new view of nematode and arthropod phylogeny have on other areas of research?

Summary of Key Concepts

32.1 Characteristics of Animals

- Animals constitute a very species-rich kingdom, with a number of characteristics that distinguish them from other organisms, including multicellularity, an extracellular matrix, and unique cell junctions, in addition to heterotrophic feeding and internal digestion and the possession of nervous and muscle tissues (Table 32.1).
- Many different feeding modes exist among animals, including predation, herbivory, parasitism, filter-feeding, and decomposition (Figure 32.1).
- The history of animal life on earth spans over 540 million years. A profusion of animal phyla appeared in the Cambrian explosion (530–525 mya). Animals evolved adaptations to deal with the colonization of land, about 520 mya, and the number and diversity of mammals exploded after dinosaurs died out at the end of the Cretaceous period, 65 mya (Figure 32.2).

32.2 Animal Classification

- The animal kingdom is monophyletic, meaning that all taxa have evolved from a single common ancestor (Figure 32.3).
- Biologists hypothesize that animals evolved from a colonial choanoflagellate-like ancestor (Figure 32.4).
- Animals can be categorized according to the absence of different types of tissues (the Parazoa, or sponges) and the presence of tissues (Eumetazoa, or all other animals). The Eumetazoa can also be divided according to their type of symmetry, whether radial (Radiata, the cnidarians and ctenophores) or bilateral (Bilateria, all other animals) (Figure 32.5).
- The Radiata have two embryonic cell layers (germ layers): the endoderm and the ectoderm. The Bilateria have a third germ layer termed the mesoderm, which develops between the endoderm and the ectoderm (Figure 32.6).
- Animals are also classified according to patterns of embryonic development. In protostomes, the blastopore becomes the mouth; in deuterostomes, the blastopore becomes the anus. Most protostomes have spiral cleavage, and all deuterostomes have radial cleavage (Figure 32.7).
- Animals with a coelom, a body cavity that is completely lined with mesoderm, are termed coelomates. Animals that possess a coelom that is not completely lined by tissue derived from mesoderm are called pseudocoelomates. Those animals lacking a fluid-filled body cavity are termed acoelomates (Figure 32.8).

- Segmentation, the division of the body into identical subunits called segments, is a key feature of the animal body plan in several phyla (Figure 32.9).
- Shifts in the pattern of expression of *Hox* genes are prominent in evolution. In vertebrates, the transition from one type of vertebra to another is controlled by certain *Hox* genes (Figure 32.10).

32.3 Molecular Views of Animal Diversity

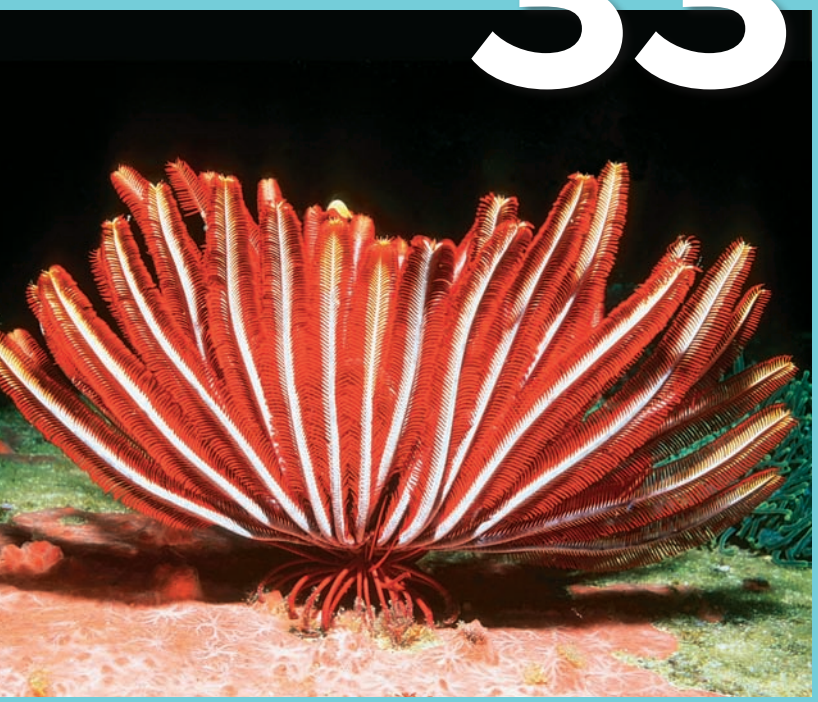
- Molecular techniques that compare similarities in DNA, RNA, and amino acid sequences support the view that all animals share a common ancestor (Figure 32.11).
- Recent molecular studies propose a division of the protostomes into two major clades: the Ecdysozoa and the Lophotrochozoa (Figure 32.14).
- Members of the Ecdysozoa secrete and periodically shed a nonliving cuticle, typically an exoskeleton, or external skeleton (Figure 32.12).
- The Lophotrochozoa are grouped primarily through analysis of molecular data, but some members are distinguished by two morphological features: the lophophore, a crown of tentacles used for feeding, and the trochophore larva, a distinct larval stage (Figure 32.13).
- Each animal phylum shows a distinctive set of general characteristics (Table 32.2).

Assess and Discuss

Test Yourself

1. Which of the following is *not* a distinguishing characteristic of animals?
   a. the capacity to move at some point in the life cycle
   b. possession of cell walls
   c. multicellularity
   d. heterotrophy
   e. All of the above are characteristics of animals.
2. Which is the correct hierarchy of divisions in the animal kingdom, from most inclusive to least inclusive?
   a. Eumetazoa, Metazoa, Protostomia, Ecdysozoa
   b. Parazoa, Radiata, Lophotrochozoa, Deuterostomia
   c. Metazoa, Eumetazoa, Bilateria, Protostomia
   d. Radiata, Eumetazoa, Deuterostomia, Ecdysozoa
   e. none of the above
3. Bilateral symmetry is strongly correlated with
   a. the ability to move through the environment.
   b. cephalization.
   c. the ability to detect prey.
   d. a and b.
   e. a, b, and c.
4. In triploblastic animals, the inner lining of the digestive tract is derived from the
   a. ectoderm.
   b. mesoderm.
   c. endoderm.
   d. pseudocoelom.
   e. coelom.
5. Pseudocoelomates
   a. lack a fluid-filled cavity.
   b. have a fluid-filled cavity that is completely lined with mesoderm.
   c. have a fluid-filled cavity that is partially lined with mesoderm.
   d. have a fluid-filled cavity that is not lined with mesoderm.
   e. have an air-filled cavity that is partially lined with mesoderm.
6. Protostomes and deuterostomes can be classified based on
   a. cleavage pattern.
   b. destiny of the blastopore.
   c. whether the fate of the embryonic cells is fixed early during development.
   d. all of the above.
7. Indeterminate cleavage is found in
   a. annelids.
   b. mollusks.
   c. nematodes.
   d. vertebrates.
   e. all of the above.
8. Naturally occurring identical twins are possible only in animals that
   a. have spiral cleavage.
   b. have determinate cleavage.
   c. are protostomes.
   d. have indeterminate cleavage.
   e. have spiral and determinate cleavage and are protosomes.
9. Genes involved in the patterning of the body axis, that is, in determining characteristics such as neck length and appendage formation, are called
   a. small subunit (SSU) rRNA genes.
   b. *Hox* genes.
   c. metameric genes.
   d. determinate genes.
   e. none of the above.
10. A major finding of recent molecular studies is that
    a. the presence or absence of the mesoderm is not important in phylogeny.
    b. all animals do not share a single common ancestor.
    c. body symmetry, whether radial or bilateral, is not an important determinant in phylogeny.
    d. the echinoderms are not included in the deuterostome clade.
    e. the presence or absence of a coelom is not important for classification.

Conceptual Questions



1. Early morphological phylogenies were based on what three features of animal body plans?
2. Why was the evolution of a coelom important?
3.  A principle of biology is that *all species (past and present) are related by an evolutionary history*. Brachiopods, bryozoans, mollusks and annelids all exhibit a lophophore or trochophore larvae. Are these monophyletic, paraphyletic, or polyphyletic groups? Explain your answer. Refer back to Figure 26.5 to remind yourself about these terms.

Collaborative Questions

1. Discuss the many ways that animals can affect humans, both positively and negatively.
2. Summarize how molecular evidence has enabled scientists to refine their views on animal phylogeny.

The Invertebrates

33

What is this organism, and how does it feed?

If you thought the organism shown in the opening photograph was an underwater plant, complete with long leaflike structures and roots, you'd be wrong. This organism is an animal, a type of echinoderm that is called a feather star and is related to sea stars. Its long arms catch food particles floating in the ocean current, and tiny tube feet pass these particles into special food gutters that run along the center of each arm and empty into the mouth. The number of arms varies from species to species and may reach 200. Feather stars can creep along the ocean floor by means of rootlike projections called cirri. There are about 550 species of feather stars in existence today, but some fossil formations are packed with feather star fragments, showing how successful the group was in the past.

The history of animal life on Earth has evolved over hundreds of millions of years. Some scientists suggest that changing environmental conditions, such as a buildup of dissolved oxygen and minerals in the ocean or an increase in atmospheric oxygen, eventually permitted higher metabolic rates and increased the activity of a wide range of animals. Others suggest that with the development of sophisticated locomotor skills, a wide range of predators and prey evolved, leading to an evolutionary "arms race" in which predators evolved powerful weapons and prey evolved more powerful defenses against them. Such adaptations and counteradaptations would have led to a proliferation of different lifestyles and taxa. Finally, the evolution of *Hox* genes may have permitted an increase in diversity.

Over the next two chapters, we will survey the wondrous diversity of animal life on Earth. In this chapter, we will examine the **invertebrates**, or animals without a backbone, a category that makes up more than 95% of all animal species. We begin by exploring some of the earliest animal lineages, the Parazoa and Radiata. We will then turn to the Lophotrochozoa and Ecdysozoa, the two groups of protostomes introduced in Chapter 32. Finally, we will examine the deuterostomes, focusing here on the echinoderms and the invertebrate members of the phylum Chordata. The animal classification outlined in Chapter 32 (refer back to Figure 32.3) will serve as the basis for our discussion of animal lineages. It is summarized in **Figure 33.1**. Keep in mind, however, that animal phylogeny is a work in progress, and further revisions, refinements, and perhaps surprises lay ahead, as the genomes of more and more species are sequenced and compared.

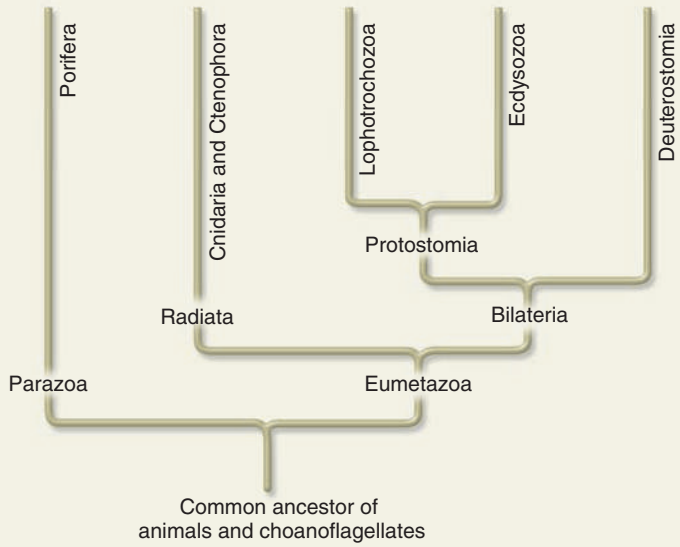


Figure 33.1 An animal phylogeny. This phylogenetic tree summarizes our current understanding about the relationships among animal groups.

CHAPTER OUTLINE

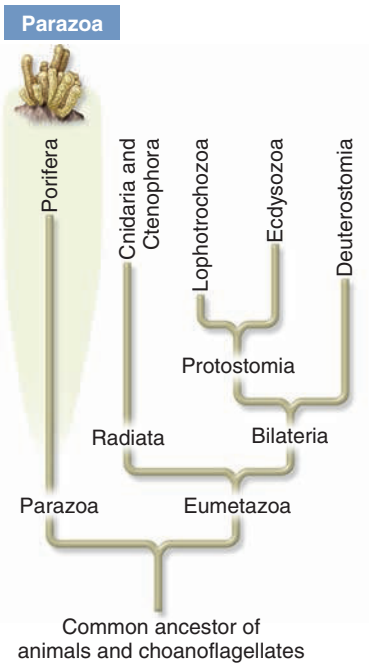
33.1 Parazoa: Sponges, the First Multicellular Animals

33.2 Radiata: Jellyfish and Other Radially Symmetric Animals

33.3 Lophotrochozoa: The Flatworms, Rotifers, Bryozoans, Brachiopods, Mollusks, and Annelids

33.4 Ecdysozoa: The Nematodes and Arthropods

33.5 Deuterostomia: The Echinoderms and Chordates



Summary of Key Concepts

Assess and Discuss

33.1 Parazoa: Sponges, the First Multicellular Animals

Learning Outcomes:

1. Outline the body plan and unique characteristics of sponges.
2. Describe how sponges defend themselves against predators.

The Parazoa consist of one phylum, Porifera (from the Latin, meaning pore bearers), whose members are commonly referred to as sponges. Sponges lack true tissues—groups of cells that have a similar structure and function. However, sponges are multicellular and possess several types of cells that perform different functions. Biologists have identified approximately 8,000 species of sponges, the vast majority of which are marine. Sponges range in size from only a few millimeters across to more than 2 m in diameter. The smaller sponges may be radially symmetrical, but most have no apparent symmetry. Some sponges have a low encrusting growth form, whereas others grow tall and erect (**Figure 33.2a**). Although adult sponges are sessile, that is, anchored in place, the larvae are free-swimming.

Choanocytes Help Circulate Water

The body of a sponge looks similar to a vase pierced with small holes or pores (**Figure 33.2b**). Water is drawn through these pores into a central cavity, the **spongocoel**, and flows out through the large opening at the top, called the osculum. The water enters the pores by the beating action of the flagella of the **choanocytes**, or collar cells, that line the spongocoel (**Figure 33.2c**). In the process, the choanocytes trap and eat small particulate matter and tiny plankton. As noted in Chapter 32, because of striking morphological and molecular similarities between choanocytes and choanoflagellates, a group of modern protists having a single flagellum, scientists believe that sponges originated from a choanoflagellate-like ancestor.

A layer of flattened epithelial cells similar to those making up the outer layer of animals in other phyla protects the sponge body. In between the choanocytes and the epithelial cells lies a gelatinous, protein-rich matrix called the **mesohyl**. Within this matrix are mobile cells called **amoebocytes** that absorb food from choanocytes, digest it, and carry the nutrients to other cells. Thus, considerable cell-to-cell contact and communication exist in sponges. Sponges are unique among the major animal phyla in using intracellular digestion, the uptake of food particles by cells, as a mode of feeding.

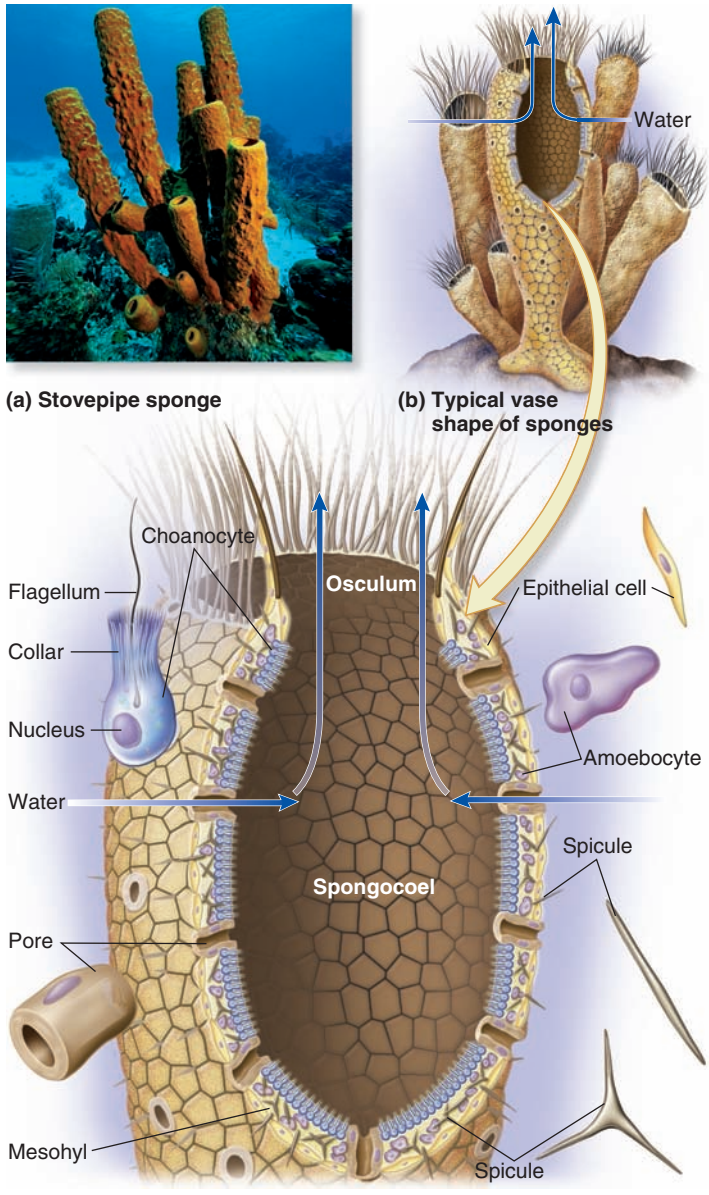


Figure 33.2 Sponge morphology. (a) The stovepipe sponge (*Aplysina archeri*) is a common sponge found on Caribbean reefs. **(b)** Many sponges have a vaselike shape. **(c)** A cross section reveals that sponges are truly multicellular animals, having various cell types but no distinct tissues.

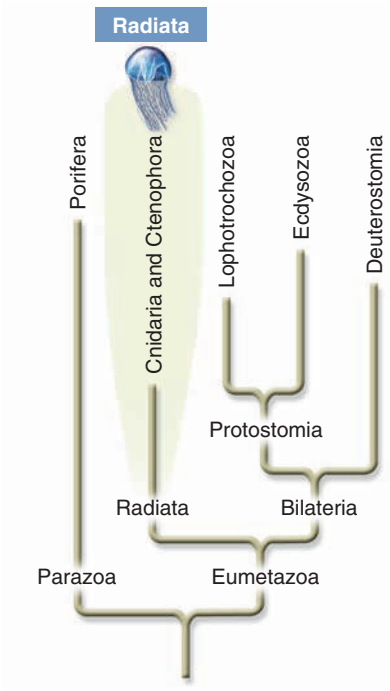
Concept Check: *If sponges are soft and sessile, why aren't they eaten by other organisms?*

Sponges Have Mechanical and Chemical Defenses Against Predators

Some amoebocytes can form tough skeletal fibers that support the sponge's body. In many sponges, this skeleton consists of sharp **spicules** formed of protein, calcium carbonate, or silica. For example, some deep-ocean species, called glass sponges, are distinguished by having needle-like silica spicules that form elaborate lattice-like skeletons. The presence of such tough spicules may help explain why there is not much predation of sponges. Other sponges have fibers of a

tough protein called **spongin** that lend skeletal support. Spongin skeletons are still commercially harvested and sold as bath sponges. Many species produce toxic defensive chemicals, some of which are thought to have possible antibiotic and anti-inflammatory effects in humans.



Sponges Reproduce Sexually and Asexually

Sponges reproduce through both sexual and asexual means. Most sponges are **hermaphrodites** (from the Greek, for the god Hermes and the goddess Aphrodite), individuals that can produce both sperm and eggs. Gametes are derived from amoebocytes or choanocytes. The eggs remain in the mesohyl, and the sperm are released into the water and carried by water currents to fertilize the eggs of neighboring sponges. Zygotes develop into flagellated swimming larvae that eventually settle on a suitable substrate to become sessile adults. In asexual reproduction, a small fragment or bud may detach and form a new sponge.

33.2 Radiata: Jellyfish and Other Radially Symmetrical Animals

Learning Outcomes:

1. Compare and contrast the two body forms of cnidarians.
2. Describe how cnidarians defend themselves.
3. Describe the unique features of ctenophores.

The Radiata consists of two closely related phyla: the Cnidaria (from the Greek *knide*, meaning nettle, and *aria*, meaning related to; pronounced nid-air'-e-ah) and the Ctenophora (from the Greek *ktenos*, meaning comb, and *phora*, meaning bearing; pronounced teen-o-for'-ah). Members of the Radiata phyla, or radiates, are mostly found in marine environments, although a few, such as hydra, are freshwater species. The Cnidaria include hydra, jellyfish, box jellies, sea anemones, and corals, and the Ctenophora consist of the comb jellies. The Radiata have only two embryonic germ layers: the ectoderm and the endoderm, which give rise to the epidermis and the gastrodermis, respectively. A gelatinous substance called the **mesoglea** connects the two layers. In jellyfish, the mesoglea is enlarged and forms a transparent jelly, whereas in coral, the mesoglea is very thin. The Radiata is the first clade with true tissues (refer back to Chapter 32).

Both cnidarians and ctenophores possess a **gastrovascular cavity**, a body cavity with a single opening to the external environment, where extracellular digestion takes place. Extracellular digestion, the breakdown of large molecules, takes place outside of the cell, allows the ingestion of larger food particles, and represents a major increase in complexity over the sponges, which use only intracellular digestion. Most radiates have tentacles around the mouth that aid in food detection and capture. Radiates also have true nerve cells arranged as a **nerve net** consisting of interconnected neurons with no central control organ. In nerve nets, nerve impulses pass in either direction along a given neuron.

Cnidarians Exist in Two Different Body Forms

Most cnidarians exist in one of two different body forms with an associated lifestyle: the sessile **polyp** or the motile **medusa** (Figure 33.3). For example, corals and sea anemones exhibit only the polyp form, and jellyfish exist predominantly in the medusa form.

The polyp form has a tubular body with an opening at the oral (top) end that is surrounded by tentacles and functions as both mouth and anus (see Figure 33.3a). The aboral (bottom) end is attached to the substrate. Polyps exist colonially, as in corals, or alone, as in sea anemones. Corals take dissolved calcium and carbonate ions from seawater and precipitate them as limestone underneath their bodies. With some species, this leads to a buildup of limestone deposits. As each successive generation of polyps dies, the limestone remains in place, and new polyps grow on top. Thus, huge underwater limestone deposits called coral reefs are formed (look ahead to Figure 54.25b). The largest of these is Australia's Great Barrier Reef, which stretches over 2,300 km. Many other extensive coral reefs are known, including the reef system along the Florida Keys. All coral reefs occur in warm water, generally between 20°C and 30°C.

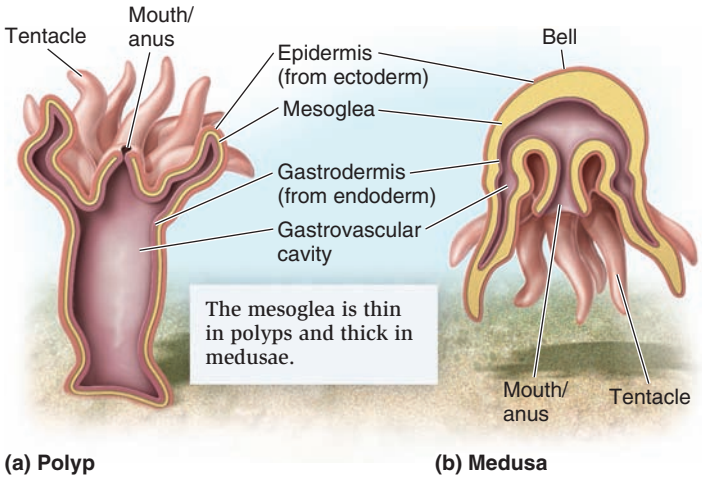


Figure 33.3 Polyp and medusa forms of cnidarians. Both **(a)** polyp and **(b)** medusa forms have two layers of cells, an outer epidermis (from ectoderm) and an inner layer of gastrodermis (from endoderm). In between is a layer of mesoglea, which is thin in polyps, such as corals, and thick in medusae, such as most jellyfish.

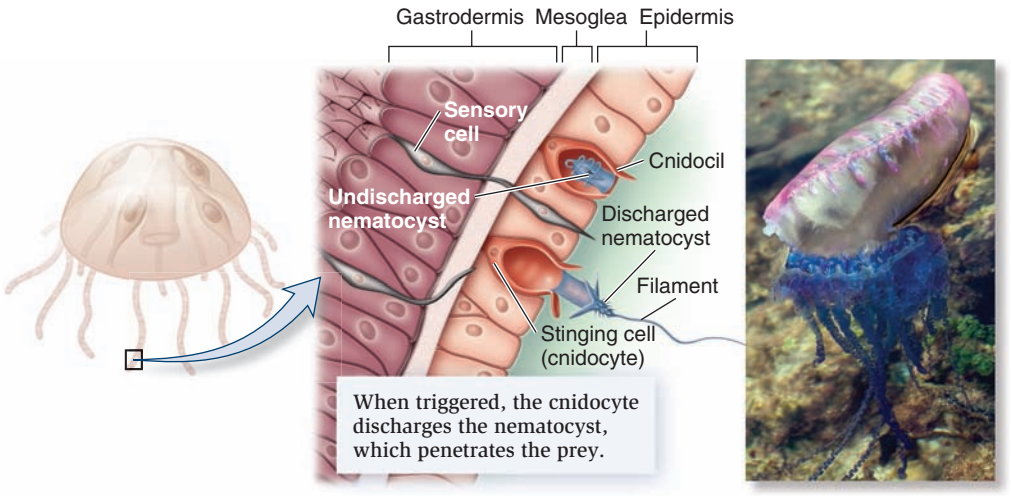
BIOLOGY PRINCIPLE Structure determines function. The inverted, umbrella-shaped medusae are free swimming, whereas the tubular, polyp forms are sedentary.

The free-swimming medusa form has an umbrella-shaped body with an opening that serves as both mouth and anus located on the concave underside and surrounded by tentacles (see Figure 33.3b). More mobile medusae possess simple sense organs near the bell margin, including organs of equilibrium called statocysts and photosensitive organs known as **ocelli**. When one side of the bell tips upward, the statocysts on that side are stimulated, and muscle contraction is initiated to right the medusa. The ocelli allow medusae to position themselves in particular light levels.

Cnidarians Have Specialized Stinging Cells

One of the unique and characteristic features of the cnidarians is the existence of stinging cells called **cnidocytes**, which function in defense or the capture of prey (**Figure 33.4a**). Cnidocytes contain **nematocysts**, powerful capsules with an inverted coiled and barbed thread. Each cnidocyte has a hairlike trigger called a **cnidocil** on its surface. When the cnidocil is touched or a chemical stimulus is detected, the nematocyst is discharged, and its filament penetrates the prey and injects a small amount of toxin. Small prey are immobilized and passed into the mouth by the tentacles. After discharge, the cnidocyte is absorbed, and a new one grows to replace it. The nematocysts of most cnidarians are not harmful to humans, but those on the tentacles of the larger jellyfish and the Portuguese man-of-war (**Figure 33.4b**) can cause extreme pain or even death.

Contractile fibers and nerves exist in their simplest forms in cnidarians. Contractile fibers are found in both the epidermis and gastrodermis. Although not true muscles, which only arise from the mesoderm and therefore do not appear in diploblastic animals, these fibers can contract to change the shape of the animal. For example, in the presence of a predator, an anemone can expel water very quickly through its open mouth and shrink down to a very small body form. The contractile fibers work against the fluid contained in the body, which thus acts as a hydrostatic skeleton. The nerve net that conducts signals from sensory nerves to muscle cells allows coordination of simple movements and shape changes.



The phylum Cnidaria consists of four classes: Hydrozoa (hydroids, including the Portuguese man-of-war), Scyphozoa (jellyfish), Anthozoa (sea anemones and corals), and Cubozoa (box jellies). The distinguishing characteristics of these classes are shown in **Table 33.1**.

Ctenophores Have a Complete Gut

Ctenophores, also known as comb jellies, are a small phylum of fewer than 100 species, all of which are marine and look very much like jellyfish (**Figure 33.5**). They have on their surface eight rows of cilia that resemble combs. The coordinated beating of the cilia, rather than muscular contractions, propels the ctenophores. Averaging about 1–10 cm in length, comb jellies are probably the largest animals to use cilia for locomotion. There are even a few ribbon-like species up to 1 m long.

Comb jellies possess two long tentacles but lack stinging cells. Instead, they have colloblasts, cells on the tentacles that secrete a sticky substance onto which small prey adhere. The tentacles are then drawn over the mouth. As with cnidarians, digestion occurs in a gastrovascular cavity, but waste and water are eliminated through two anal pores. Thus, the comb jellies possess the first complete gut. Prey are generally small and may include tiny crustaceans called copepods and small fishes. Comb jellies are often transported around the world in ships' ballast water. *Mnemiopsis leidyi*, a ctenophore species native to the Atlantic coast of North and South America, was accidentally introduced into the Black and Caspian seas in the 1980s. With a plentiful food supply and a lack of predators, *Mnemiopsis* underwent a population explosion and ultimately devastated the local fishing industries.

All ctenophores are hermaphroditic, possessing both ovaries and testes, and gametes are shed into the water to eventually form free-swimming larvae that grow into adults. There is no polyp stage. Nearly all ctenophores exhibit **bioluminescence**, a phenomenon that results from chemical reactions that give off light rather than heat. Individuals are particularly evident at night, and ctenophores that wash up onshore can make the sand or mud appear luminescent.

(a) Cnidocytes

(b) Portuguese man-of-war

Figure 33.4 Specialized stinging cells of cnidarians, called cnidocytes. **(a)** Cnidocytes, which contain stinging capsules called nematocysts, are situated in the tentacles. **(b)** The Portuguese man-of-war (*Physalia physalis*) employs cnidocytes that can be lethal to humans.

Concept Check: *How are cnidocytes recycled for re-use once they have been fired?*

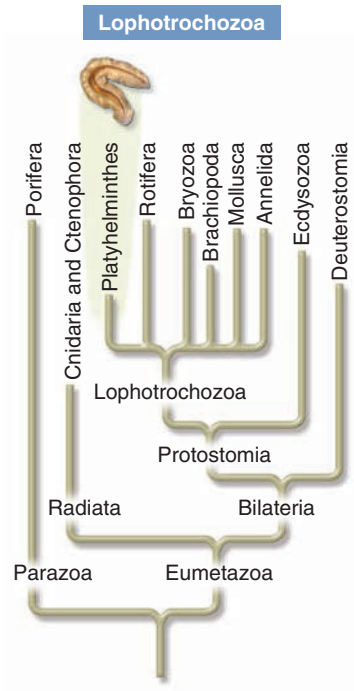
Table 33.1 Main Classes and Characteristics of the Cnidaria

	Class and examples (est. number of species)	Class characteristics
	Hydrozoa: Portuguese man-of-war, *Hydra*, some corals (2,700)	Mostly marine; polyp stage usually dominant and colonial, reduced medusa stage
	Scyphozoa: jellyfish (200)	All marine; medusa stage dominant and large (up to 2 m); reduced polyp stage
	Anthozoa: sea anemones, sea fans, most corals (6,000)	All marine; polyp stage dominant; medusa stage absent; many are colonial
	Cubozoa: box jellies, sea wasps (20)	All marine; medusa stage dominant; box-shaped

Figure 33.5 A ctenophore. Ctenophores are called comb jellies because the eight rows of cilia on their surfaces resemble combs.

33.3 Lophotrochozoa: The Flatworms, Rotifers, Bryozoans, Brachiopods, Mollusks, and Annelids

Learning Outcomes:



1. Describe the unique features of platyhelminthes, rotifers, bryozoans, and brachiopods.
2. Outline the main biological features and list the main classes of the mollusks.
3. List the advantages of segmentation in the annelids.
4. **SciSKILLS** » Analyze the results of Fiorito and Scotto's experiments, and explain how they show that octopuses can learn from one another.

As we explored in Chapter 32 (refer back to Figure 32.3), molecular data suggest that there are three clades of bilateral animals: the Lophotrochozoa and the Ecdysozoa (collectively known as the protostomes) and the Deuterostomia. In this section, we will explore the distinguishing characteristics of the Lophotrochozoa, a diverse group that includes taxa that possess either a lophophore (a crown of ciliated tentacles, seen in Bryozoa and Brachiopoda) or a distinct larval stage called a trochophore (Mollusca and Annelida). Also included in this clade are the Platyhelminthes (some of which have trocophore-like larvae) and the Rotifera (which have a lophophore-like feeding device), both of which share molecular similarities with the other members of the Lophotrochozoa.

The Phylum Platyhelminthes Consists of Flatworms with No Coelom

Platyhelminthes (from the Greek *platy*, meaning flat, and *helminth*, meaning worm), or flatworms, were among the first animals to develop an active predatory lifestyle. Platyhelminthes, and indeed most animals, are bilaterally symmetrical, with a head bearing sensory appendages, a feature called cephalization (**Figure 33.6**).

The Development of Mesoderm The flatworms are also believed to be the first animals to develop three distinctive embryonic germ layers—ectoderm, endoderm, and mesoderm—with mesoderm replacing the simpler gelatinous mesoglea of cnidarians. As such, they are said to be triploblastic. The muscles in flatworms, which are derived from mesoderm, are well developed. The development of mesoderm was therefore a critical evolutionary innovation in animals, leading to the development of more sophisticated organs. Flatworms lack a fluid-filled body cavity in which the gut is suspended, and instead have mesoderm filling the body spaces around the gastrovascular cavity; hence, they are described as acoelomates. Flatworms also lack a specialized respiratory or circulatory system and must respire by diffusion. Thus, no cell can be too far from the surface, making a flattened shape necessary. The digestive system of flatworms is incomplete, with only one opening, which serves as both mouth and anus, as in cnidarians. Most flatworms possess

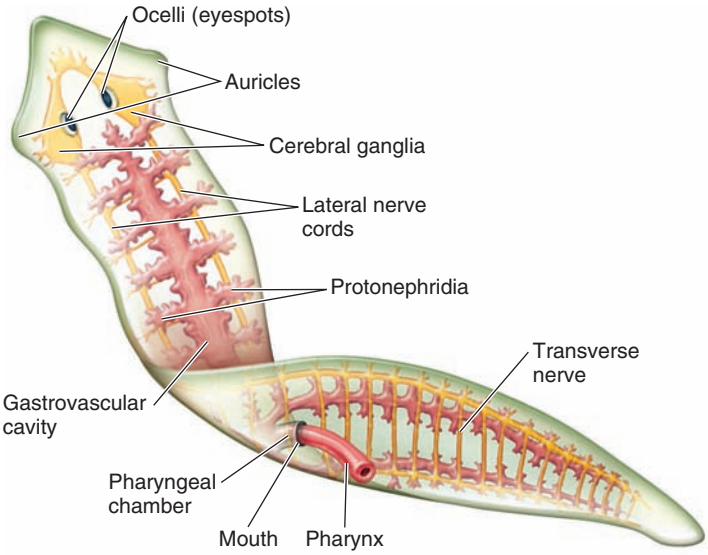


Figure 33.6 Body plan of a flatworm. Flatworm morphology is represented by a planarian, a member of the class Turbellaria.

Concept Check: *How do flatworms breathe?*

Table 33.2 Main Classes and Characteristics of Platyhelminthes

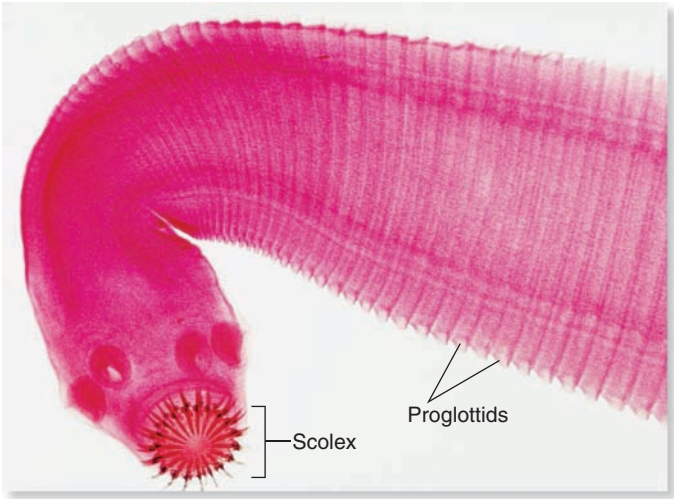
	Class and examples (est. number of species)	Class characteristics
	Turbellaria: planarian (3,000)	Mostly marine; free-living flatworms; predatory or scavengers
	Monogenea: fish flukes (1,000)	Marine and freshwater; usually external parasites of fish; simple life cycle (no intermediate host)
	Cestoda: tapeworms (5,000)	Internal parasites of vertebrates; complex life cycle, usually with one intermediate host; no digestive system; nutrients absorbed across epidermis
	Trematoda: flukes (11,000)	Internal parasites of vertebrates; complex life cycle with several intermediate hosts

a muscular pharynx that may be extended through the mouth. The pharynx opens to a gastrovascular cavity, where food is digested. In large flatworms, the gastrovascular cavity is highly branched to distribute nutrients to all parts of the body. The incomplete digestive system of flatworms prevents continuous feeding. Some flatworms are predators, but many species invade other animals as parasites.

Flatworms have a distinct excretory system, consisting of **protonephridia**, two lateral canals with branches capped by **flame cells**. Protonephridia are dead-end tubules lacking internal openings. The flame cells, which are ciliated and waft water through the lateral canals to the outside (look ahead to Figure 49.7), primarily function in maintaining osmotic balance between the flatworm's body and the surrounding fluids. Simple though this system is, its development was key to permitting the movement of animals into freshwater habitats and even moist terrestrial areas.

Cephalization At the anterior end of some free-living flatworms are light-sensitive eyespots, called ocelli, as well as chemoreceptive and sensory cells that are concentrated in organs called auricles. A pair of **cerebral ganglia**, clusters of nerve cell bodies, receives input from photoreceptors in eyespots and sensory cells. From the ganglia, a pair of lateral nerve cords running the length of the body allow rapid movement of information from anterior to posterior. In addition, transverse nerves form a nerve net on the ventral surface, similar to that of cnidarians. Thus, flatworms retain the cnidarian-style nervous system, while possessing the beginnings of the more centralized type of nervous system seen throughout much of the rest of the animal kingdom.

In Platyhelminthes, reproduction is either sexual or asexual. Most species are hermaphroditic but do not fertilize their own eggs. Flatworms can also reproduce asexually by splitting into two parts, with each half regenerating the missing fragment.



Classes of Flatworms The four classes of flatworms are the Turbellaria, Monogenea, Trematoda (flukes), and Cestoda (tapeworms) (**Table 33.2**). Turbellarians are the only free-living class of flatworms and are widespread in lakes, ponds, and marine environments (**Figure 33.7a**). Monogeneans are relatively simple external parasites with just one host species (a fish). Trematodes and cestodes are internally parasitic in humans and therefore are of great medical and veterinary importance. They possess a variety of organs of attachment, such as hooks and suckers, that enable them to remain embedded within their hosts. For example, cestodes attach to their host by means of an organ at the head end called a scolex (**Figure 33.7b**). They have no mouth or gastrovascular cavity and absorb nutrients across the body surface.

Flatworm life cycles can be complex. Cestodes often require two different vertebrate host species, such as pigs or cattle, to begin their life cycle and another host, such as humans, to complete their development. Behind the scolex in cestodes is a long ribbon of identical segments called proglottids. These are essentially segments of sex organs that develop thousands of eggs. The proglottids are continually shed in the host's feces. Human feces passed out onto the ground are eaten with grass by pigs and cattle. Many tapeworms are ingested by humans who consume undercooked, infected meat—hence the value of thoroughly cooking meat.

The life history of trematodes is even more complex than that of cestodes, involving multiple hosts. The first host, called the intermediate host, is usually a mollusk, and the final host, or definitive host, is usually a vertebrate, but often a second or even a third intermediate host is involved. In the case of the Chinese liver fluke (*Clonorchis sinensis*) (**Figure 33.8**), (1) the adult parasite lives and reproduces in the definitive host, a human. (2) Eggs pass from the host via the feces. (3) An intermediate host, such as a snail, eats the eggs, which transform into sporocysts. (4) The sporocysts asexually produce more sporocysts, which are called rediae. (5) The rediae develop into a free-swimming life stage called cercariae. Cercariae bore their way

(a)

(b)

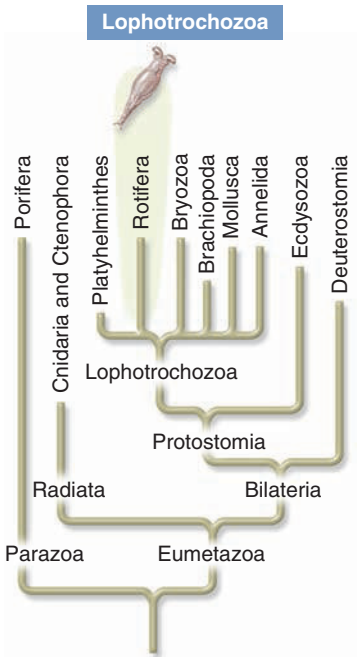


Figure 33.7 Flatworms. **(a)** Many free-living marine turbellarians are brightly colored, such as this racing stripe flatworm, *Pseudoceros bifurcus*, from Bali, Indonesia. **(b)** A tapeworm, *Taenia pisiformis*, a member of the class Cestoda. Note the tiny hooks and suckers that make up the scolex. Each segment is a proglottid, replete with eggs.

BIOLOGY PRINCIPLE Biology affects our society. About 1% of U.S. cattle are infected by beef tapeworms. Consuming beef that is not sufficiently well cooked can lead to infection by these parasites.

out of the snail and (6) infect their second intermediate host, fishes, by entering via the gills. Here, the cercariae develop into juvenile flukes and (7) lodge in fish muscle, which the definitive host will eat, allowing the cycle to continue. From the small intestine of the definitive host, the juvenile flukes travel to the liver and grow into adult flukes, and the life cycle begins anew. The probability of each trematode stage reaching a suitable host is low, so trematodes produce large numbers of offspring to ensure that some survive.

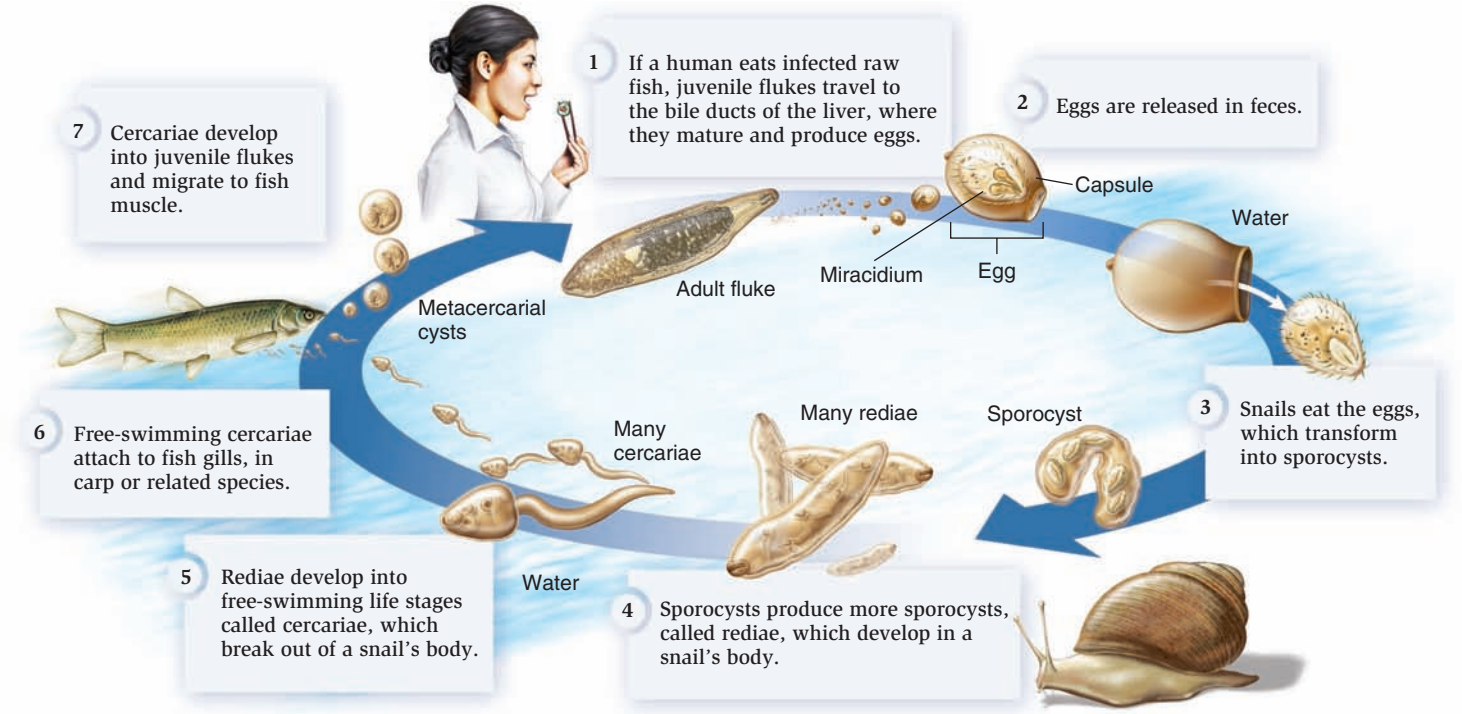
Blood flukes, genus *Schistosoma*, are the most common parasitic trematodes infecting humans; they cause the disease known as schistosomiasis. Over 200 million people worldwide, primarily in tropical Asia, Africa, and South America, are infected with schistosomiasis. The inch-long adult flukes can live for years in human hosts, and the release of eggs may cause chronic inflammation and blockage in many organs. Untreated schistosomiasis can result in severe damage to the liver, intestines, and lungs and can eventually lead to death. Sewage treatment and access to clean water greatly reduce infection rates.

Members of the Phylum Rotifera Have a Pseudocoelom and a Ciliated Crown

Members of the phylum Rotifera (from the Latin *rota*, meaning wheel, and *fera*, meaning to bear) get their name from their ciliated crown, or **corona**, which, when beating, looks similar to a rotating wheel (**Figure 33.9**). Most rotifers are microscopic animals, usually less than 1 mm long, and some have beautiful colors. There are about 2,000 species of rotifers, most of which inhabit fresh water, with a few marine and terrestrial species. Most often they are bottom-dwelling organisms, living on a pond floor or along lakeside vegetation.

Rotifers have an alimentary canal, a digestive tract with a separate mouth and anus, which means they can feed continuously. The corona creates water currents that propel the animal through the water and that waft small planktonic organisms or decomposing organic material toward the mouth. The mouth opens into a circular, muscular pharynx called a **mastax**, which has jaws for grasping and chewing. The mastax, which in some species can protrude through the mouth to seize small prey, is a structure unique to rotifers. The body of the rotifer bears a jointed foot with one to four toes. **Pedal glands** in the foot secrete a sticky substance that aids in attachment to a substrate. The internal organs lie within a pseudocoelom, a fluid-filled body cavity that is not completely lined with mesoderm. The pseudocoelom serves as a hydrostatic skeleton and as a medium for the internal transport of nutrients and wastes. Rotifers also have a pair of protonephridia with flame bulbs that collect excretory and digestive waste and drain into a bladder, which passes waste to the anus. The nervous system consists of nerves that extend from the sensory organs, especially the eyespots and some bristles on the corona, to the brain.

Reproduction in rotifers is unique. In some species, unfertilized diploid eggs that have not undergone meiotic division develop into females through a process known as **parthenogenesis**. In other species, some unfertilized eggs develop into females, whereas others develop into males that live only long enough to produce and release sperm that fertilize the eggs. The resultant fertilized eggs form zygotes, which have a thick shell and can survive for long periods of harsh conditions, such as if a water supply dries up, before developing into new females.



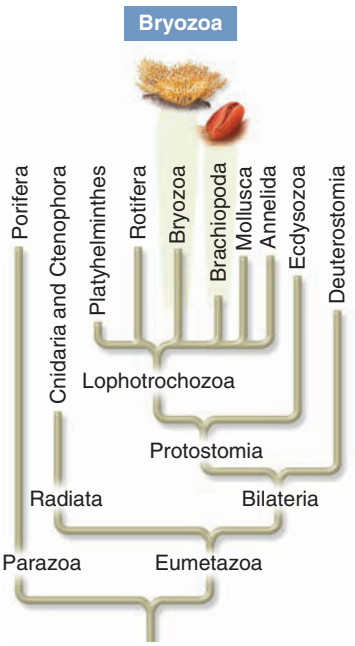


Figure 33.8 The complete life cycle of a trematode. This figure shows the life cycle of the Chinese liver fluke (*Clonorchis sinensis*).

Because the tiny zygotes are easily transported, rotifers show up in the smallest of aquatic environments, such as birdbaths or roof gutters.

Bryozoa and Brachiopoda Have a Lophophore for Feeding and Gas Exchange

The Bryozoa and the Brachiopoda both possess a lophophore, a ciliary feeding device (refer back to Figure 32.13a), and a true coelom (refer back to Figure 32.8a). The lophophore is a circular fold of the body wall bearing tentacles that draw water toward the mouth. Because a thin extension of the coelom penetrates each tentacle, the tentacles also serve as a respiratory organ. Gases diffuse across the tentacles and into or out of the coelomic fluid and are carried throughout the body. Both phyla have a U-shaped alimentary canal, with the anus located near the mouth but outside of the lophophore.

Phylum Bryozoa The bryozoans (from the Greek *bryon*, meaning moss, and *zoon*, meaning animal) are small colonial animals, most of which are less than 0.5 mm long, that can be found encrusted on rocks in shallow aquatic environments. They look very much like plants. There are about 4,500 species, many of which encrust boat hulls and have to be scraped off periodically. Within the colony, each animal secretes and lives inside a nonliving exoskeleton called a zoecium

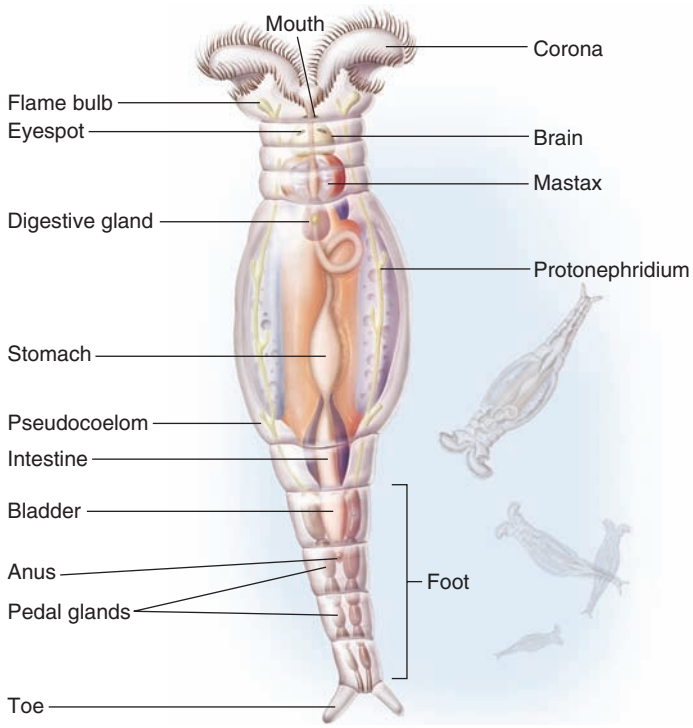

Figure 33.9 Body plan of a common rotifer, *Philodina* genus.

(a) A bryozoan (b) A brachiopod, the northern lamp shell

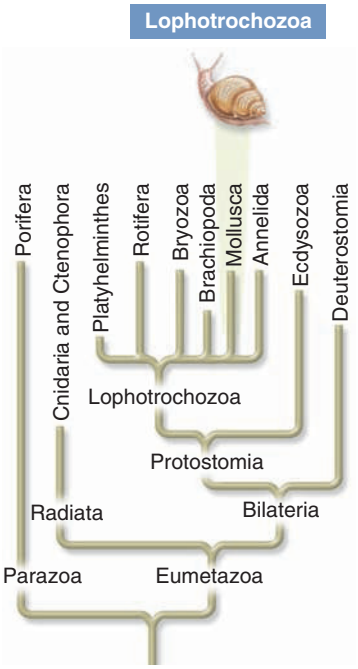

Figure 33.10 Bryozoans and brachiopods.
(a) Bryozoans are colonial animals that reside in a nonliving case called a zoecium. **(b)** Brachiopods, such as this northern lamp shell (*Terebratulina septentrionalis*), have dorsal and ventral shells.

Concept Check: *What are the two main functions of the lophophore?*

that is composed of chitin or calcium carbonate (Figure 33.10a). For this reason, bryozoans have been important reef-builders. Bryozoans date back to the Paleozoic era, and thousands of fossil forms have been discovered and identified.

Phylum Brachiopoda Brachiopods (from the Greek *brachio*, meaning arm, and *podos*, meaning foot) are marine organisms with two shell halves, much like clams (Figure 33.10b). Unlike bivalve mollusks, however, whose shells have a left and right valve (side) with the plane of symmetry lying along the line at which the valves join, brachiopods have a dorsal and ventral valve, with the plane of symmetry perpendicular to the line at which the valves join. In other words, the dorsal and ventral valves of brachiopods are of slightly different sizes and shapes. Brachiopods are bottom-dwelling species that attach to the substrate via a muscular pedicle. Although they are now a relatively small group, with about 300 living species, brachiopods flourished in the Paleozoic and Mesozoic eras—about 30,000 fossil species have been identified. Some of these fossil forms tell of organisms that reached 30 cm in length, although their modern relatives are only 0.5–8.0 cm long.

Mollusca Is a Large Phylum Containing Snails, Slugs, Clams, Oysters, Octopuses, and Squids

Mollusks (from the Latin *mollis*, meaning soft) constitute a very large phylum, with over 100,000 living species, including organisms as diverse as snails, clams, octopuses, and chitons. They are an ancient group, as evidenced by the classification of about 35,000 fossil species. Mollusks have a considerable economic, aesthetic, and ecological importance to humans. Many serve as sources of food, including scallops, oysters, clams, and squids. A significant industry involves the farming of oysters to produce cultured pearls, and rare and beautiful mollusk shells are extremely valuable to collectors. Snails and slugs can damage vegetables and ornamental plants, and boring mollusks can penetrate wooden ships and wharfs. Mollusks are intermediate hosts to many parasites, and several exotic species have become serious pests. For example, populations of the zebra mussel (*Dreissena polymorpha*) appear to have been introduced into North America from Asia via ballast water from transoceanic ships. Since their introduction, they have spread rapidly throughout the Great Lakes and an increasing number of inland waterways, adversely impacting native organisms and clogging water intake valves to municipal water-treatment plants around the lakes.

The Mollusk Body Plan One common feature of the mollusks is their soft body, which exists, in many species, under a protective external shell. Most mollusks are marine, although some have colonized fresh water. Many snails and slugs have moved onto land, but they survive only in humid areas and where the calcium necessary for shell formation is abundant in the soil. The ability to colonize freshwater and terrestrial habitats has led to a diversification of mollusk body plans. Thus, the amazing diversity of mollusks demonstrates how organismal diversity is related to environmental diversity.

Although great variation in morphology occurs between classes, mollusks have a basic body plan consisting of three parts (Figure 33.11). A muscular **foot** is usually used for movement, and a **visceral mass** containing the internal organs rests atop the foot. The **mantle**, a fold of skin draped over the visceral mass, secretes a shell in those species that form shells. The mantle often extends beyond the visceral mass, creating a chamber called the **mantle cavity**, which houses delicate **gills**, filamentous organs that are specialized for gas exchange. A continuous current of water, often induced by cilia present on the gills or by muscular pumping, flushes out the wastes from the mantle cavity and brings in new oxygen-rich water.

Mollusks are coelomate organisms, but the coelom is confined to a small area around the heart. Mollusks have an **open circulatory system** with a heart that pumps body fluid called hemolymph through vessels and into sinuses. Sinuses are open, fluid-filled cavities between the internal organs. The organs and tissues are therefore continually bathed in hemolymph. The sinuses coalesce to form an open cavity known as the hemocoel (blood cavity). From these sinuses, the hemolymph drains into vessels that take it to the gills and then back to the heart.

Excretory organs called **metanephridia** remove nitrogenous and other wastes. Metanephridia have ciliated funnel-like openings inside the coelom that are connected to ducts that lead to the

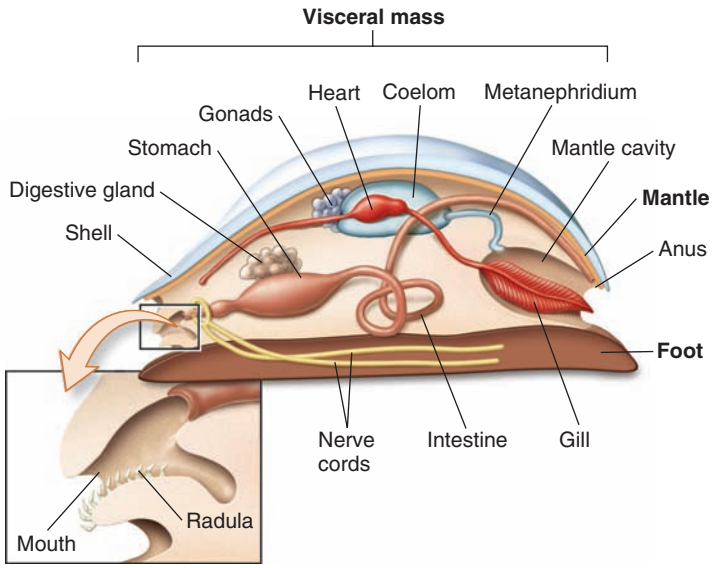

Figure 33.11 The mollusk body plan. The generalized body plan of a mollusk includes the characteristic foot, mantle, and visceral mass.

Concept Check: *Do molluscan hearts pump blood?*

exterior mantle cavity. The pores from the metanephridia discharge wastes into this cavity. The anus also opens into the mantle cavity. The metanephridial ducts may also serve to discharge sperm or eggs from the gonads. The nervous system varies from simple ganglia and nerve chords in most species to much larger brains and sophisticated organs of touch, smell, taste, and vision in octopuses.

The mollusk's mouth may contain a **radula**, a unique, protrusible, tonguelike organ that has many teeth and is used to eat plants, scrape food particles off rocks, or, if the mollusk is predatory, bore into shells of other species and tear flesh. In the cone shells (genus *Conus*), the radula is reduced to a few poison-injecting teeth on the end of a long proboscis that is cast about in search of prey, such as a worm or even a fish. Some Indo-Pacific cone shell species produce a neuromuscular toxin that can kill humans. Other mollusks, particularly bivalves, have lost their radula and are filter feeders that strain water brought in by ciliary currents.

Mollusk Shells Most shells are complex three-layered structures that are secreted by the mantle and continue to grow as the mollusk grows. Shell growth is often seasonal, resulting in distinct growth lines on the shell, much like tree rings (**Figure 33.12a**). Using shell growth patterns, biologists have discovered some bivalves that are over 100 years old. The innermost layer of the shells of oysters, mussels, abalone, and other mollusks is a smooth, iridescent lining called nacre, which is commonly known as mother-of-pearl and is often collected from abalone shells for jewelry. Actual pearl production in mollusks, primarily oysters, occurs when a foreign object, such as a grain of sand, becomes lodged between the shell and the mantle, and layers of nacre are laid down around it to reduce the irritation.

Mollusk Reproduction Most mollusks have separate sexes, although some are hermaphroditic. Gametes are usually released into the water, where they mix and fertilization occurs. In some snails, however, fertilization is internal, with the male inserting sperm directly into the female. Internal fertilization was a key evolutionary development, enabling some snails to colonize land, and can be considered a critical innovation that fostered extensive adaptive radiation. In many species, reproduction involves the production of a trochophore larva that develops into a **veliger**, a free-swimming larva that has a rudimentary foot, shell, and mantle (**Figure 33.13**).

The Major Molluscan Classes Of the eight molluscan classes, the four most common are the Polyplacophora (chitons), Gastropoda (snails and slugs), Bivalvia (clams and mussels), and Cephalopoda (octopuses, squids, and nautiluses) (**Table 33.3**).

- Polyplacophora are marine mollusks with a shell composed of eight separate plates (**Figure 33.12b**). Chitons are common in the intertidal zone, an area above water at low tide and under water at high tide, and they creep along when covered by the tide. Feeding occurs by scraping algae off rock surfaces. When the tide recedes, the muscular foot holds the chiton tight to the rock surface, preventing desiccation.
- The class Gastropoda (from the Greek *gaster*, meaning stomach, and *podos*, meaning foot) is the largest group of mollusks and encompasses about 75,000 living species, including snails, periwinkles, limpets, and other shelled members (**Figure 33.12c**). The class also includes species such as slugs and nudibranchs, whose shells have been greatly reduced or completely lost during their evolution (**Figure 33.12d**). Most gastropods have a one-piece shell, into which the animal can withdraw to escape predators, and are marine or freshwater species, but some species, including snails and slugs, have also colonized land.
- Bivalves are freshwater or marine mollusks whose bodies are enclosed within a hinged shell of two valves or halves. Prominent members include oysters, clams, mussels, and scallops.

The 780 species of Cephalopoda (from the Greek *kephale*, meaning head, and *podos*, meaning foot) are the most morphologically complex of the mollusks and indeed among the most complex of all invertebrates. Most are fast-swimming marine predators that range from organisms just a few centimeters in size to the colossal squid (*Mesonychoteuthis hamiltoni*), which is known to reach over 13 m in length and 495 kg (1,091 lb) in weight. A cephalopod's mouth is surrounded by many long arms commonly armed with suckers. Octopuses have 8 arms with suckers, and squids and cuttlefish have 10 arms—8 with suckers and 2 long tentacles with suckers limited to their ends. Nautiluses have from 60 to 90 tentacles around the mouth. All cephalopods have a beaklike jaw that allows them to bite their prey, and some, such as the blue-ringed octopus (*Hapalochlaena lunulata*), deliver a deadly poison through their saliva (**Figure 33.12e**). Only one group, the nautiluses, has retained its external shell. In octopuses, the shell is not present, and

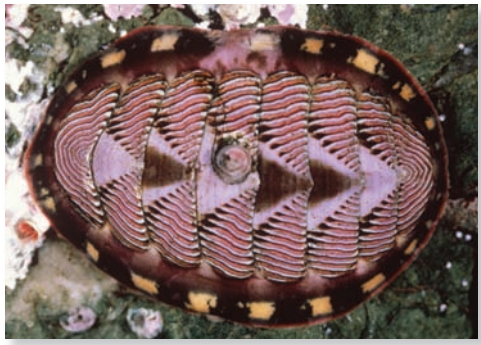

Figure 33.12 Mollusks. **(a)** A bivalve shell, class Bivalvia, with growth rings. Quahog clams (*Mercenaria mercenaria*) can live over 20 years. **(b)** A chiton (*Tonicella lineata*), a polyplacophoran with a shell made up of eight separate plates. **(c)** A gastropod, the tree snail, *Liguus fasciatus*, from the Florida Everglades showing its characteristic coiled shell. **(d)** A nudibranch (*Phyllidia ocellata*). The nudibranchs are a gastropod subclass whose members have lost their shell altogether. **(e)** The highly poisonous blue-ringed octopus (*Hapalochlaena lunulata*), a cephalopod.

Table 33.3 Main Classes and Characteristics of Mollusks

	Class and examples (est. number of species)	Class characteristics
	Polyplacophora: chitons (860)	Marine; eight-plated shell
	Gastropoda: snails, slugs, nudibranchs (75,000)	Marine, freshwater, or terrestrial; most with coiled shell, but shell absent in slugs and nudibranchs; radula present
	Bivalvia: clams, mussels, oysters (30,000)	Marine or freshwater; shell with two halves or valves; primarily filter feeders with siphons
	Cephalopoda: octopuses, squids, nautiluses (780)	Marine; predatory, with tentacles around mouth, often with suckers; shell often absent or reduced; closed circulatory system; jet propulsion via siphon

in squid and cuttlefish, it is greatly reduced and internal. However, the fossil record is full of shelled cephalopods, called ammonites, some of which were as big as truck tires (**Figure 33.14**). They became extinct at the end of the Cretaceous period, although the reasons for this are not well understood.

The foot of some cephalopods has become modified into a muscular siphon. Water drawn into the mantle cavity is quickly expelled through the siphon, propelling the organism forward or backward in a kind of jet propulsion. Such vigorous movement requires powerful muscles and a very efficient circulatory system to deliver oxygen and nutrients to the muscles. Cephalopods are the only mollusks with a **closed circulatory system**, in which blood flows throughout an animal entirely within a series of vessels. One of the advantages of this type of system is that the heart can pump blood through the tissues rapidly, making oxygen more

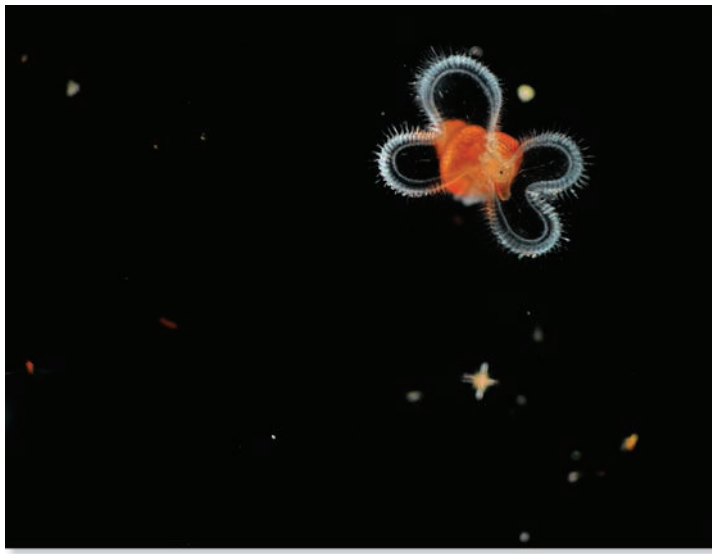

Figure 33.13 A veliger snail. Veligers are free-swimming larval forms of mollusks that look more like adults than the trocophore larvae from which they develop.

readily available. The blood of cephalopods contains the copper-rich protein hemocyanin for transporting oxygen. Less efficient than the iron-rich hemoglobin of vertebrates, hemocyanin gives the blood a blue color.

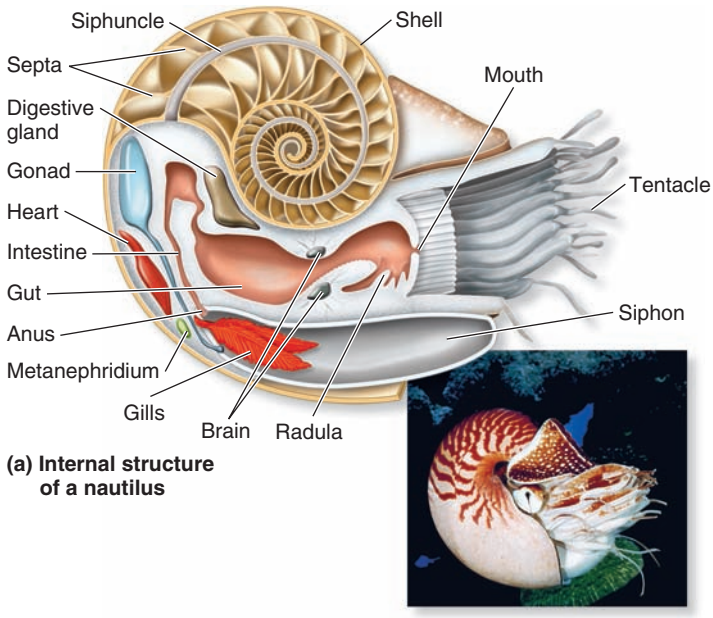

Figure 33.14 A fossil ammonite. These shelled cephalopods were abundant in the Cretaceous period.

BioConnections: In what period did mollusks arise? Look back to Figure 22.9.

The shell of the nautilus is comprised of many individual sealed chambers (**Figure 33.15**). As it grows, the nautilus secretes a new chamber and seals off the old one with a **septum** (plural, septa). The older chambers are gas-filled and act as buoyancy chambers. A thin strip of living tissue called the siphuncle removes liquid from the old chamber and replaces it with gas. The gas pressure within the chambers is only 1 atmosphere, despite the fact that nautiluses may be swimming at 400 m depths at a pressure of about 40 atmospheres. The shell's structure is strong enough to withstand this large pressure differential.

Cephalopods have a well-developed nervous system and brain that support their active lifestyle. Their sense organs, especially their eyes, are also very well developed. Many cephalopods (with the exception of nautiluses) have an ink sac that contains the pigment melanin; the sac can be emptied to provide a "smokescreen" to confuse predators. In many species, melanin is also distributed in special pigment cells in the skin, which allows for color changes. Octopuses often change color when disturbed, and they can change color rapidly to blend in with their background and escape detection. The central nervous system of the octopus is among the most complex in the invertebrate world. Behavioral biologists have demonstrated that octopuses can behave in sophisticated ways, and scientists are currently debating the degree to which they are capable of learning by observation.

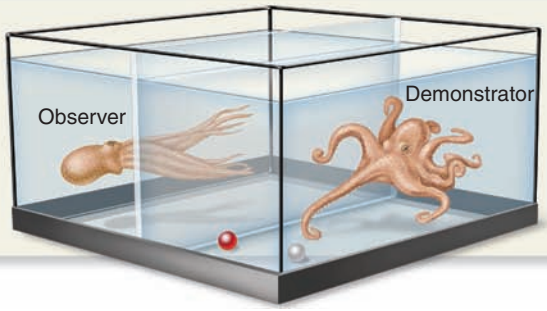
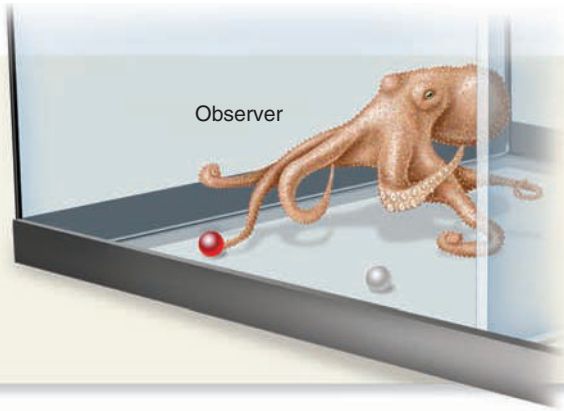
(b) Chambered nautilus

Figure 33.15 The nautilus. **(a)** A longitudinal section of a nautilus, showing the coiled shell with many chambers. The animal secretes a new chamber each year and lives only in the new one. **(b)** The chambered nautilus (*Nautilus pompilius*).

Feature Investigation | Fiorito and Scotto's Experiments Showed That Invertebrates Can Exhibit Sophisticated Observational Learning Behavior





We tend to think of the ability to learn from others as an exclusively vertebrate phenomenon, especially among species that live in social groups. However, in 1992, Italian researchers Graziano Fiorito and Pietro Scotto demonstrated that octopuses can learn by observing the behavior of other octopuses (**Figure 33.16**). This was a surprising finding, in part because *Octopus vulgaris*, the species they studied, lives a solitary existence for most of its life.

In their experiments, they used a system of reward (a small piece of fish placed behind the ball so that the octopus could not see it) and punishment (a small electric shock for choosing the wrong ball) to train octopuses to attack either a red or a white ball. This type of learning is called classical conditioning (see Chapter 55). Because octopuses are color blind, they must distinguish between the relative brightness of the balls. Octopuses were considered to be trained when

Figure 33.16 **Observational learning in octopuses.**

HYPOTHESIS Octopuses can learn by observing another's behavior.

STUDY LOCATION Laboratory setting with *Octopus vulgaris* collected from the Bay of Naples, Italy.

	Experimental level	Conceptual level
1 Train 2 groups of octopuses, one to attack white balls, one to attack red. These are called the demonstrator octopuses.	Reward choice of correct ball (with fish) and punish choice of incorrect ball (with electric shock). Training is complete when octopus makes no "mistakes" in 5 trials. 	Conditions a demonstrator octopus to attack a particular color of ball.
2 In an adjacent tank, allow observer octopus to watch trained demonstrator octopus.		Observer octopus may be learning the correct ball to attack by watching the demonstrator octopus.
3 Drop balls into the tank of the observer octopus. Test the observer octopus to see if it makes the same decisions as the demonstrator octopus.		If the observer octopus is learning from the demonstrator octopus, the observer octopus should attack the ball of the same color as the demonstrator octopus was trained to attack.

4 THE DATA

Participant	Color of ball chosen in 5 trials*	
	Red	White
Observers (watched demonstrator attack red)	4.31	0.31
Observers (watched demonstrator attack white)	0.40	4.10
Untrained (did not watch demonstrations)	2.11	1.94

*Average of 5 trials; data do not always sum to 5, because some trials resulted in no balls being chosen.

5 CONCLUSION Invertebrate animals are capable of learning from watching other individuals behave, in much the same way as vertebrate species learn from watching others.

6 SOURCE Fiorito, G., and Scotto, P. 1992. Observational learning in *Octopus vulgaris. Science* 256:545–547.

they made no mistakes in five trials. Observer octopuses in adjacent tanks were then allowed to watch the trained octopuses attacking the balls. In the third part of the experiment, the observer octopuses were themselves tested. In these cases, observers nearly always attacked the same color ball as they had observed the demonstrators attacking. In addition, learning by observation was achieved more quickly than the original training. This remarkable observational learning behavior is considered by some to be the precursor to more complex forms of learning, including problem solving.

Experimental Questions

1. What was the hypothesis tested by Fiorito and Scotto?
2. **SciSKILLS »** What were the results of the experiment? Did these results support the hypothesis?
3. **SciSKILLS »** Explain the significance of performing the experiment on both trained and untrained octopuses.

BIO TIPS

THE QUESTION *After 5 days, Fiorito and Scotto repeated their experiment to determine how long the learning by the observer octopuses remained stable. In the follow-up trials, the observer octopuses that had watched a demonstrator trained to attack a red ball made the following choices of color: red, 3.88; white, 0.50. The observer octopuses that had watched a demonstrator trained to attack a white ball made the following choices: red, 0.50; white, 3.70. Was the octopuses' learning stable after 5 days?*

TOPIC ***What topic in biology does this question address?*** The topic is animal behavior, more specifically learning in octopuses.

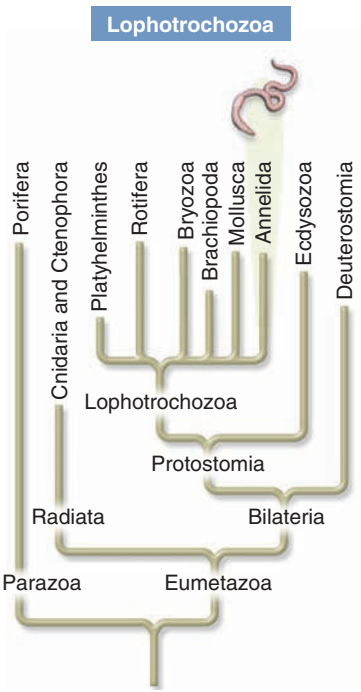
INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the original data in Figure 33.16, you can determine the initial frequency of color choices by the observers. From the question, you know the frequency of color choices made after 5 days.

PROBLEM-SOLVING STRATEGY ***Make a calculation.*** To solve this problem, you determine percentages of "correct" responses, initially (day 1) and after 5 days, for both groups of observer octopuses.

For the octopuses that watched a demonstrator trained to attack red, the percentages are as follows.

$$\text{Day 1: } \left(\frac{4.31}{4.31 + 0.31}\right) \times 100 = 93.3\%$$

$$\text{Day 5: } \left(\frac{3.88}{3.88 + 0.50}\right) \times 100 = 88.6\%$$



For the octopuses that watched a demonstrator trained to attack white, the percentages are as follows.

$$\text{Day 1: } \left(\frac{4.10}{4.10 + 0.40}\right) \times 100 = 91.1\%$$

$$\text{Day 5: } \left(\frac{3.70}{3.70 + 0.50}\right) \times 100 = 88.1\%$$

ANSWER *Learning appeared fairly stable in both groups of observer octopuses because there was a drop in "correct" responses of less than 5% after 5 days.*

The Phylum Annelida Consists of the Segmented Worms

Annelids are a large phylum with about 15,000 described species. Its members include free-ranging marine worms, tube worms, the familiar earthworm, and leeches. They range in size from less than 1 mm to enormous Australian earthworms that can reach a size of 3 m.

The Annelid Body Plan The phylum name Annelida is derived from the Latin *annulus*, meaning little ring. Each ring is a distinct segment of the annelid's body, and each one is separated from the one in front of it and the one behind it by septa (**Figure 33.17**). Segmentation confers at least three major advantages:

- Many components of the body are repeated in each segment, including blood vessels, nerves, and excretory and reproductive organs. If the components in one segment fail, those of another segment will still function.
- Annelids possess a fluid-filled coelom that acts as a hydrostatic skeleton. In unsegmented coelomate animals, muscle contractions can distort the entire body during movement. However, such distortion is minimized in segmented animals, which allows for more effective locomotion over solid surfaces.
- Segmentation permits specialization of some segments, especially at the annelid's anterior end. Therefore, although segments are often similar, they are not identical. In contrast, in tapeworms, most segments are identical. As a rule, as we move from animals with more simple body plans to those with more complex body plans, segments become more specialized.

All annelids except the leeches have chitinous bristles, called **setae**, on each segment. In some, these are situated on fleshy, footlike **parapodia** (from the Greek, meaning almost feet) that are pushed into the substrate to provide traction during movement. In others, the setae are held closer to the body. Many annelid species burrow into soil or into muddy marine sediments and extract nutrients from ingested soil or mud. Some annelids also feed on dead or living vegetation, whereas others are predatory or parasitic.

Annelids have a relatively sophisticated nervous system involving a pair of cerebral ganglia that connect to a subpharyngeal ganglion (Figure 33.17). From there, a large ventral nerve cord runs down the entire length of the body. The ventral nerve cord is unusual because it contains a few very large nerve cells called **giant axons** that facilitate high-speed nerve conduction and rapid responses to stimuli.

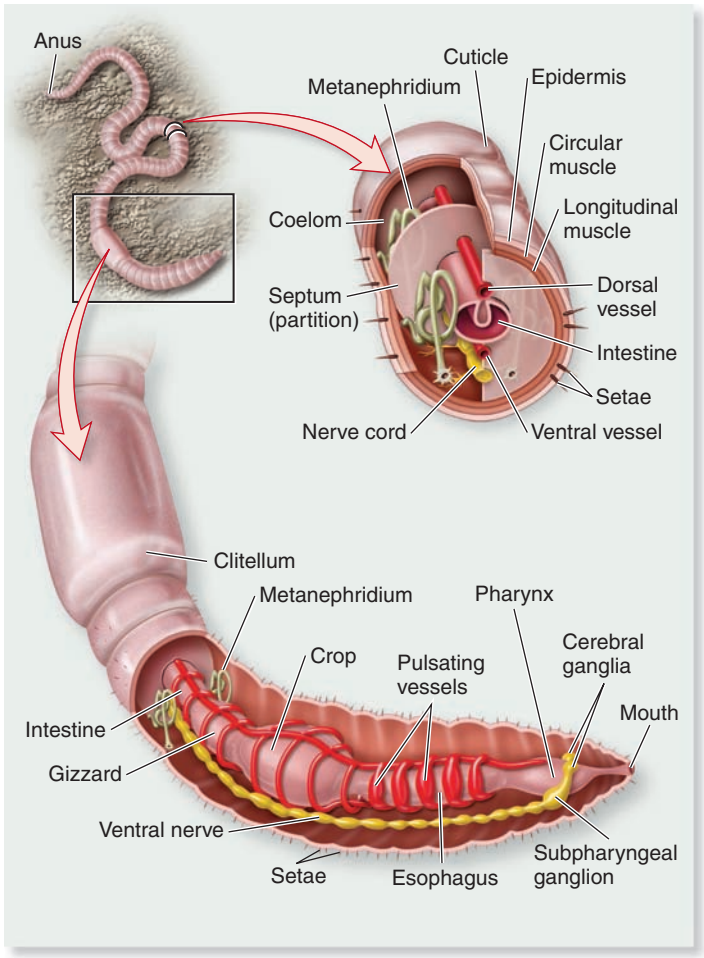


Figure 33.17 The segmented body plan of an annelid, as illustrated by an earthworm. The segmented nature of the worm is apparent internally as well as externally. Individual segments are separated by septa.

Concept Check: *What are some of the advantages of segmentation?*

Annelids have a double transport system. Both the circulatory system and the coelomic fluid carry nutrients, wastes, and respiratory gases. Annelids have a closed circulatory system, with dorsal and ventral vessels connected by pairs of pulsating vessels. The blood of most annelid species contains the respiratory pigment hemoglobin. Respiration occurs directly through the permeable skin surface, which restricts annelids to moist environments. The digestive system is complete and unsegmented, with many specialized regions: mouth, pharynx, esophagus, crop, gizzard, intestine, and anus.

Sexual reproduction involves two individuals, often of separate sexes, but sometimes hermaphrodites, which exchange sperm via internal fertilization. In some species, asexual reproduction by fission occurs, in which the posterior part of the body breaks off and forms a new individual.

The Major Annelidan Groups Evidence published by German evolutionary biologist Torsten Struck and colleagues in 2011 suggests that the phylum Annelida contains two major groups: the Errantia and the Sedentaria.

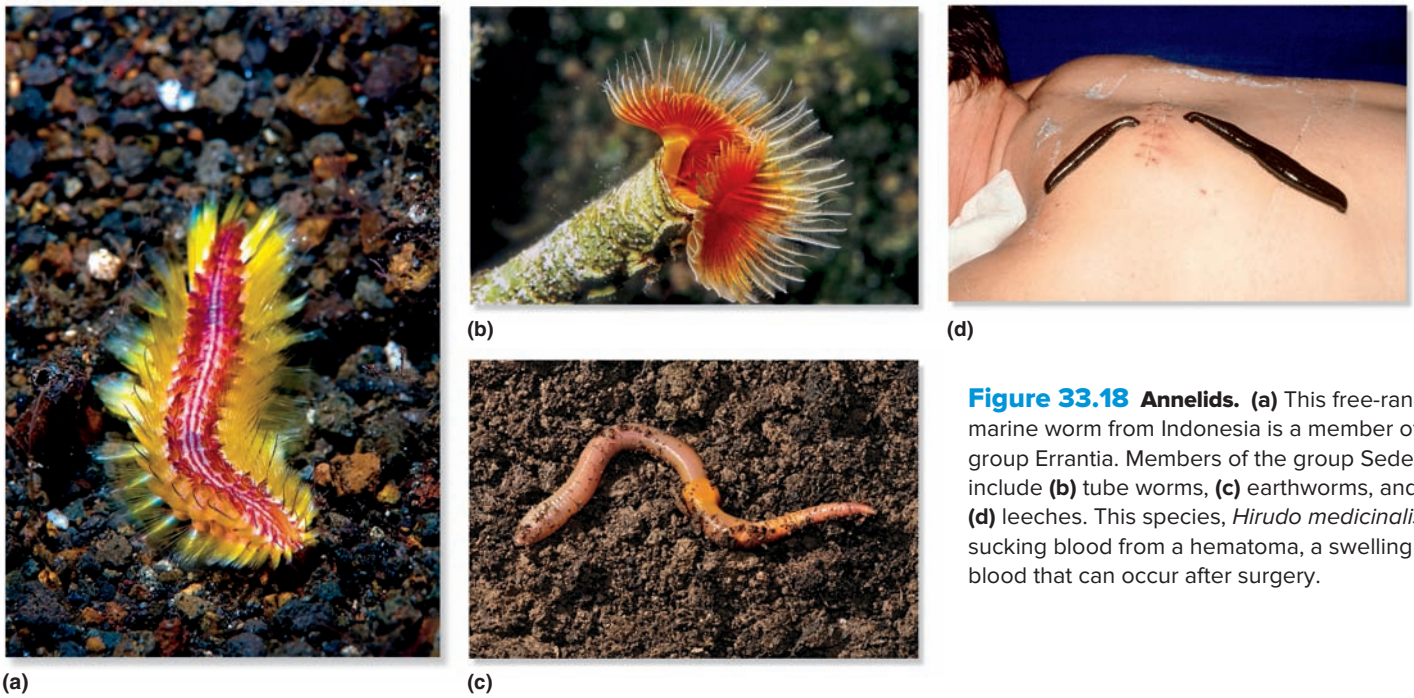

Figure 33.18 Annelids. **(a)** This free-ranging marine worm from Indonesia is a member of the group Errantia. Members of the group Sedentaria include **(b)** tube worms, **(c)** earthworms, and **(d)** leeches. This species, *Hirudo medicinalis*, is sucking blood from a hematoma, a swelling of blood that can occur after surgery.

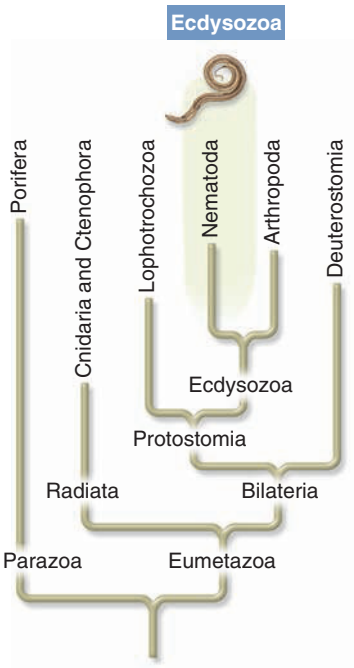
Members of the Errantia have many long setae bristling out of their body and are supported on footlike parapodia (**Figure 33.18a**). Most of them are free-ranging predators with well-developed eyes and powerful jaws. Many are brightly colored. In turn, most species are important prey for fishes and crustaceans.

In the Sedentaria, setae are in close proximity to the body wall, which facilitates better anchorage in tubes and burrows. The more sedentary lifestyle of the Sedentaria is associated with reductions in head appendages. Within this group, three types of lifestyles are apparent: tube worms, earthworms, and leeches. Tube worms are marine sedentarians that exhibit beautiful tentacle crowns for filtering food items, such as plankton, from the water (**Figure 33.18b**). The bulk of these worms remains hidden in a tube deep in the mud or sand.

Earthworms play a unique and beneficial role in conditioning the soil, primarily due to the effects of their burrows and excretion. Earthworms ingest soil and leaf tissue to extract nutrients and in the process create burrows in the Earth. As plant material and soil pass through the earthworm's digestive system, it is finely ground in the gizzard into smaller fragments. Once excreted, this material—called castings—enriches the soil (**Figure 33.18c**). Because a worm can eat its own weight in soil every day, worm castings on the soil surface can be extensive. The biologist Charles Darwin was interested in earthworm activity, and his last work, *The Formation of Vegetable Mould, through the Actions of Worms, with Observations on Their Habits*, was the first detailed study of earthworm ecology. In it, he wrote, "All the fertile areas of this planet have at least once passed through the bodies of earthworms."



Leeches are primarily found in freshwater environments, but there are also some marine species as well as terrestrial species that inhabit warm, moist areas such as tropical forests. Leeches have a fixed number of segments, usually 34, though in most species the septa have disappeared. Most leeches feed as blood-sucking parasites of vertebrates. They have powerful suckers at both ends of the body, and the anterior sucker is equipped with razor-sharp jaws that can bore or slice into the host's tissues. The salivary secretion of leeches (hirudin) acts as an anticoagulant to stop the prey's blood from clotting and an anesthetic to numb the pain. Leeches can suck up to several times their own weight in blood. They were once used in the medical field in the practice of bloodletting, the withdrawal of often considerable quantities of blood from a patient in the erroneous belief that this would prevent or cure illness and disease. Even today, leeches may be used after surgeries (**Figure 33.18d**). In these cases, the blood vessels are not fully reconnected and excess blood accumulates, causing a swelling called a hematoma. The accumulated blood blocks the delivery of new blood and stops the formation of new vessels. The leeches remove the accumulated blood, and new capillaries are more likely to form.

Unlike cestode and trematode flatworms, which are internally parasitic and quite host-specific, leeches are generally external parasites that feed on a broad range of hosts, including fishes, amphibians, and mammals. However, there are always exceptions. *Placobdelloides jaegerskioeldi* is a parasitic leech that lives only in the rectum of hippopotamuses.

33.4 Ecdysozoa: The Nematodes and Arthropods

Learning Outcomes:

1. List the distinguishing characteristics of nematodes.
2. Describe the arthropod body plan and its major features.
3. Give examples of the arthropod subphyla Chelicerata, Myriapoda, Hexapoda, and Crustacea.
4. List the features that help account for the diversity of insect species.
5. **SciSKILLS** » Explain how genetic barcoding can be useful in insect systematics.

The Ecdysozoa is the sister group to the Lophotrochozoa. Although the separation is supported by molecular evidence, the Ecdysozoa is named for a morphological characteristic, the physical phenomenon of **ecdysis**, or the periodic molting of the exoskeleton (refer back to Figure 32.12). All ecdysozoans possess a **cuticle**, a nonliving cover that serves to both support and protect the animal. Once formed, however, the cuticle typically cannot increase in size, which restricts the growth of the animal inside. The solution for growth is the formation of a new, softer cuticle under the old one. The old one then splits open and is sloughed off, allowing the new, soft cuticle to expand to a bigger size before it hardens. Where the cuticle is thick, as in arthropods, it impedes the diffusion of oxygen across the skin. Such species acquire oxygen by lungs, gills, or a set of branching, air-filled tubes called tracheae. The ability to shed the cuticle opened up developmental options for the ecdysozoans. For example, many species undergo a complete metamorphosis, changing from a wormlike larva into a winged adult. Animals with internal skeletons cannot do this because growth occurs only by adding more minerals to the existing skeleton. Another significant adaptation is the development of internal fertilization, which permitted species to live in dry environments. A variety of appendages specialized for locomotion evolved in many species, including legs for walking or swimming and wings for flying.

Because of these innovations, ecdysozoans are an incredibly successful group. Of the eight ecdysozoan phyla, we will consider the two most common: the nematodes and arthropods. The grouping of nematodes and arthropods is a relatively new concept supported by molecular data and implies that the process of molting arose only once in animal evolution. In support of this, certain hormones that stimulate molting have been discovered to exist only in both nematodes and arthropods. Furthermore, in 2007, American geneticist Julie Dunning Hotopp and colleagues demonstrated the existence of lateral gene transfer (the movement of genes between organisms that are not parent and offspring and that may be of different species) between these groups. Elements of the bacterial genome *Wolbachia pipientis* were found in four insect and four nematode species. This both provides a mechanism for the acquisition of new genes by these eukaryotes and further underscores the idea that nematodes and arthropods are closely related.

The Phylum Nematoda Consists of Small Pseudocoelomate Worms Covered by a Tough Cuticle

The nematodes (from the Greek *nematos*, meaning thread), also called roundworms, are small, thin worms that range from less than 1 mm to about 5 cm (**Figure 33.19**), although some parasitic species

Figure 33.19 Scanning electron micrograph of a nematode within a plant leaf.

Concept Check: Both nematodes and annelids are wormlike in appearance. How are they different?

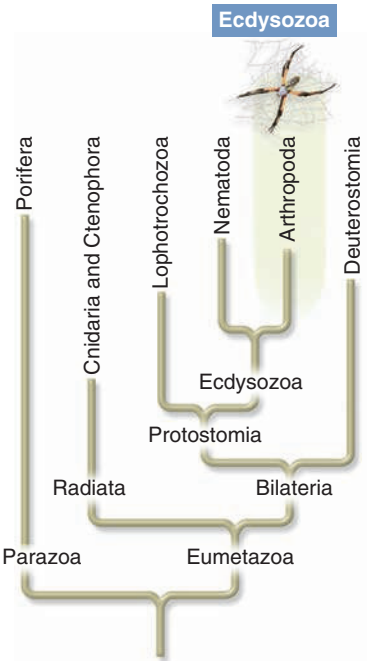
measuring 1 m or more have been found in the placenta of sperm whales. Nematodes are ubiquitous organisms that exist in nearly all habitats, from the poles to the tropics. They are found in the soil, in both freshwater and marine environments, and inside plants and animals as parasites. A shovelful of soil may contain a million nematodes. Over 20,000 species are known, but there are probably at least five times as many undiscovered species.

The Nematode Body Plan Nematodes have several distinguishing characteristics. A tough cuticle covers the body. The cuticle is secreted by the epidermis and is made primarily of **collagen**, a structural protein also present in vertebrates. The cuticle is shed periodically as the nematode grows. Beneath the epidermis are longitudinal muscles but no circular muscles, which means that muscle contraction results in thrashing of the body rather than smoother wormlike movement. The pseudocoelom functions as both a fluid-filled skeleton and a circulatory system. Diffusion of gases occurs through the cuticle. Roundworms have a complete digestive tract composed of a mouth, pharynx, intestine, and anus. The mouth often contains sharp, piercing organs called **stylets**, and the muscular pharynx functions to suck in food. Excretion of metabolic waste occurs via two simple tubules that have no cilia or flame cells.

Nematode Reproduction Nematode reproduction is usually sexual, with separate males and females, and fertilization takes place internally. Females are generally larger than males and can produce prodigious numbers of eggs, in some cases, over 100,000 per day. Development in some nematodes is easily observed because the organism is transparent and the generation time is short. For these reasons, the small, free-living nematode *Caenorhabditis elegans* has become a model organism for researchers to study (refer back to Figure 19.1b and Table 21.2). This nematode has 1,090 somatic cells, but 131 die, leaving exactly 959 cells. In 2002, the Nobel Prize in Medicine or Physiology was shared by South African researcher Sydney Brenner, his American colleague Robert Horvitz, and his British colleague John Sulston for their studies of the genetic regulation of development

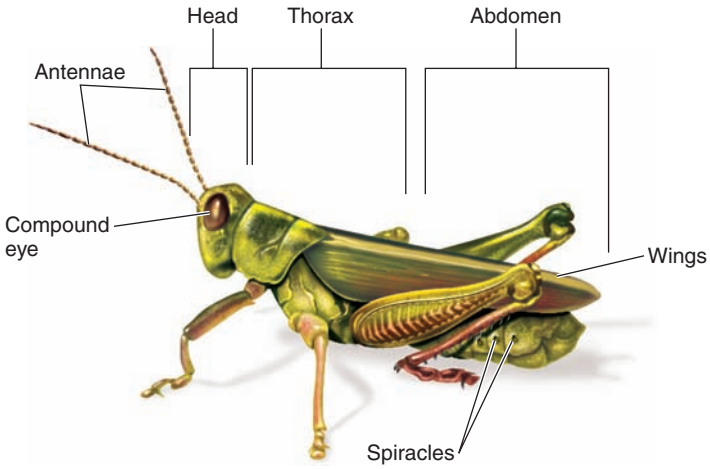
and programmed cell death in *C. elegans*. Many diseases in humans, including acquired immunodeficiency syndrome (AIDS), cause extensive cell death, whereas others, such as cancer and autoimmune diseases, reduce cell death so that cells that should die do not. Researchers are studying the process of programmed cell death in *C. elegans* in the hope of finding treatments for these and other human diseases.

Parasitic Nematodes A large number of nematodes are parasitic in humans and other vertebrates. The large roundworm *Ascaris lumbricoides* is a parasite of the small intestine that can reach up to 30 cm in length. Over a billion people worldwide carry this parasite. Although infections are most prevalent in tropical or developing countries, the prevalence of *A. lumbricoides* is relatively high in rural areas of the southeastern U.S. Eggs pass out in feces and can remain viable in the soil for years, although they require ingestion before hatching into an infective stage. Hookworms (*Necator americanus*), so named because their anterior end curves dorsally like a hook, are also parasites of the human intestine. The eggs pass out in feces, and recently hatched hookworms can penetrate the skin of a host's foot to establish a new infection. In areas with modern plumbing, these diseases are uncommon.



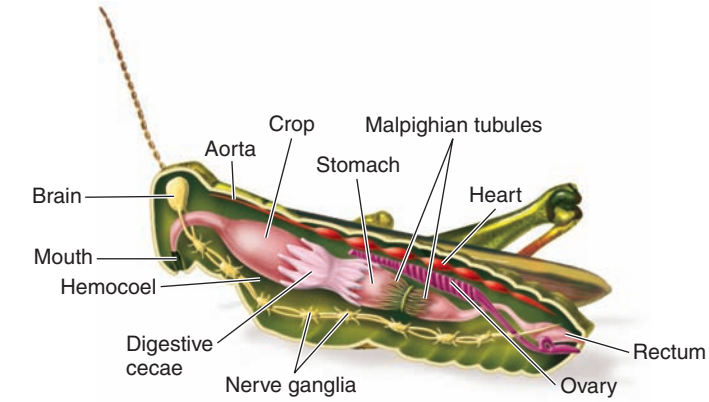
Pinworms (*Enterobius vermicularis*), although a nuisance, have relatively benign effects on their hosts. The rate of infection in the U.S., however, is staggering: 30% of children and 16% of adults are believed to be hosts. Adult pinworms live in the large intestine and migrate to the anal region at night to lay their eggs, which causes intense itching. The resultant scratching can spread the eggs from the hand to the mouth. In the tropics, some 250 million people are infected with *Wuchereria bancrofti*, a fairly large (100 mm) worm that lives in the lymphatic system, blocking the flow of lymph, and, in extreme cases, causing elephantiasis, an extreme swelling of the legs and other body parts (**Figure 33.20**). Females release tiny, live young called microfilariae, which are transmitted to new hosts via mosquitoes.

Figure 33.20 Elephantiasis in a human leg. The disease is caused by the nematode parasite *Wuchereria bancrofti*, which lives in the lymphatic system and blocks the flow of lymph.



The Phylum Arthropoda Contains the Spiders, Millipedes and Centipedes, Insects, and Crustaceans—Species with Jointed Appendages

The arthropods (from the Greek *arthron*, meaning joint, and *podos*, meaning foot) constitute perhaps the most successful phylum on Earth. About three-quarters of all described living species present on Earth are arthropods, and scientists have estimated they are also numerically common, with an estimated 10^{18} (a billion billion) individual organisms. The huge success of the arthropods, in terms of their sheer numbers and diversity, is related to features that permit these animals to live in all the major biomes on Earth, from the poles to the tropics and from marine and freshwater habitats to dry land. Such features include an exoskeleton, segmentation, and jointed appendages.



The Arthropod Body Plan The body of a typical arthropod is covered by a hard cuticle, an **exoskeleton** (external skeleton), made of layers of chitin and protein. The cuticle can be extremely tough in some parts, as in the shells of crabs, lobsters, and even beetles, yet be soft and flexible in other parts, between body segments and segments of appendages, to allow for movement. In the class of arthropods called crustaceans, the exoskeleton is reinforced with calcium carbonate to make it extra hard. The exoskeleton provides protection and also a point of attachment for muscles, all of which are internal. It is also relatively impermeable to water, a feature that may have enabled many arthropods to conserve water and colonize land, in much the same way as a tough seed coat allowed plants to colonize land (see Chapter 29). From this point of view, the development of a hard cuticle was a critical innovation. It also reminds us that the ability to adapt to diverse environmental conditions can itself lead to increased organismal diversity.

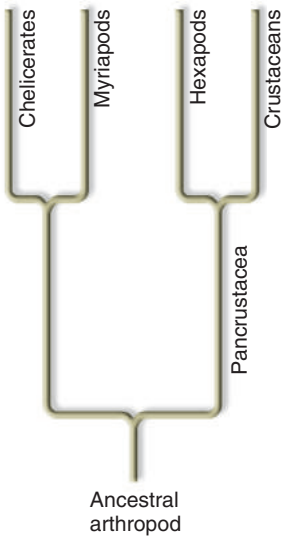
Arthropods are segmented, and many of the segments bear jointed appendages. Jointed appendages permit complex movements and functions such as walking, swimming, sensing, breathing, food handling, or reproduction. These appendages are operated by muscles within each segment. In many orders, the body segments have become fused into functional units, or **tagmata**, such as the head, thorax, and abdomen of an insect (**Figure 33.21**). Cephalization is extensive, and arthropods have well-developed sensory organs, including organs of sight, touch, smell, hearing, and balance. Arthropods have compound eyes composed of many independent visual units called **ommatidia** (singular, ommatidium) (look ahead to Figure 43.13). Together, these lenses render a mosaic-like image of the environment. Some species, particularly some insects, possess additional simple eyes,

(a) External anatomy

(b) Internal anatomy

Figure 33.21 Body plan of an arthropod, as represented by a grasshopper.

BioConnections: Look forward to Figure 49.9. Why did the Malpighian tubule system play a key role in the colonization of land by insects and other arthropods?



or ocelli, that are probably only capable of distinguishing light from dark.

The arthropod brain consists of two or three cerebral ganglia connected to several smaller ventral nerve ganglia. Like most mollusks, arthropods have an open circulatory system (look ahead to Figure 47.1), in which hemolymph is pumped from a tubelike heart into the aorta or short arteries and then into the open sinuses that coalesce to form a cavity called the hemocoel. From the hemocoel, gases and nutrients from the hemolymph diffuse into tissues. The hemolymph flows back into the heart via pores, called ostia, that are equipped with valves.

Because the cuticle impedes the diffusion of gases through the body surface, arthropods possess special organs that permit gas exchange. In aquatic arthropods, these consist of feathery gills that have an extensive surface area in contact with the surrounding water. Terrestrial species have a highly developed **tracheal system** (look ahead to Figure 48.7). On the body surface, pores called **spiracles** provide openings to a series of finely branched air tubes within the body called trachea. The tracheal system delivers oxygen directly to tissues and cells, and the circulatory system does not play a role in gas exchange.

The digestive system is complex and often includes a mouth, crop, stomach, intestine, and rectum. The stomach has glands called digestive cecae that secrete digestive enzymes. Excretion is accomplished by specialized metanephridia or, in insects and some other taxa, by **Malpighian tubules**, extensive tubes that extend from the digestive tract into body cavity, where they are surrounded by hemolymph (look ahead to Figure 49.9). Nitrogenous wastes are absorbed by the tubules and emptied into the gut, where the intestine and rectum reabsorb water and salts and the waste is excreted through the anus. This excretory system, allowing the retention of water, was another critical innovation that permitted the colonization of land by arthropods.

Arthropod Diversity The history of arthropod classification is extensive and active. Although many classifications have been proposed, a 1995 study of the mitochondrial DNA of arthropod species by American geneticist Jeffrey Boore and colleagues suggests a phylogeny with five main subphyla: one now-extinct subphyla, Trilobita (trilobites), and four living subphyla: Chelicerata (spiders and scorpions), Myriapoda (millipedes and centipedes), Hexapoda (insects and relatives), and Crustacea (crabs and relatives) (**Table 33.4**). Boore's research showed that the Trilobita were among the earliest-diverging arthropods. The lineage then split into two groups. One, often referred to as the Pancrustacea, contains the insects and crustaceans. The other, with no overarching name, contains the myriapods and chelicerates. Molecular evidence thus suggests insects are more closely related to crustaceans than they are to spiders or millipedes and centipedes.

Subphylum Trilobita: Extinct Early Arthropods The trilobites were among the earliest arthropods, flourishing in shallow seas of the Paleozoic era, some 500 mya, and dying out about 250 mya. Most trilobites were bottom feeders and were generally 3–10 cm in size, although some reached almost 1 m in length (**Figure 33.22**). They had three main tagmata: the head, thorax, and tail. Trilobites also had two dorsal grooves that divided the body longitudinally into three lobes—an axial lobe and two pleural lobes—a structural characteristic giving the class its name. Most of the body segments showed little specialization. In contrast, later-diverging arthropods developed specialized appendages on many segments, including appendages for grasping, walking, and swimming.

Subphylum Chelicerata: The Spiders, Scorpions, Mites, and Ticks The Chelicerata consists mainly of the class Arachnida, which contains predatory spiders and scorpions as well as the ticks and mites,

Table 33.4 Main Subphyla and Characteristics of Arthropods

	Subphyla and examples (est. number of species)	Class characteristics
	Chelicerata: spiders, scorpions, mites, ticks, horseshoe crabs, and sea spiders (74,000)	Body usually with cephalothorax and abdomen only; six pairs of appendages, including four pairs of legs, one pair of fangs, and one pair of pedipalps; terrestrial; predatory or parasitic
	Myriapoda: millipedes and centipedes (13,000)	Body with head and highly segmented trunk. In millipedes, each segment with two pairs of walking legs; terrestrial; herbivorous. In centipedes, each segment with one pair of walking legs; terrestrial; predatory, poison jaws
	Hexapoda: insects such as beetles, butterflies, flies, fleas, grasshoppers, ants, bees, wasps, termites, and springtails (>1 million)	Body with head, thorax, and abdomen; mouthparts modified for biting, chewing, sucking, or lapping; usually with two pairs of wings and three pairs of legs; mostly terrestrial, some freshwater; herbivorous, parasitic, or predatory
	Crustacea: crabs, lobsters, shrimp (45,000)	Body of two to three parts; three or more pairs of legs; chewing mouthparts; usually marine

some of which are blood-sucking parasites that feed on vertebrates. The two other living classes are the Merostomata, the horseshoe crabs (four species), and the Pycnogonida, the sea spiders (1,000 species), both of which are marine, reflecting the group's marine ancestry. All species have a body consisting of two tagmata: a fused head and thorax, called a cephalothorax, and an abdomen. All species also possess six pairs of appendages: the chelicerae, or fangs; a pair of pedipalps, which have various sensory, predatory, or reproductive functions; and four pairs of walking legs.

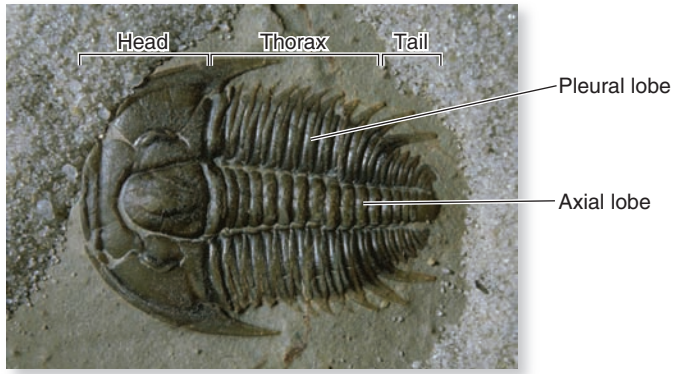


Figure 33.22 A fossil trilobite. About 4,000 fossil species of these early arthropods, including *Modocia centralis* shown here, at about 20 cm long, have been described.

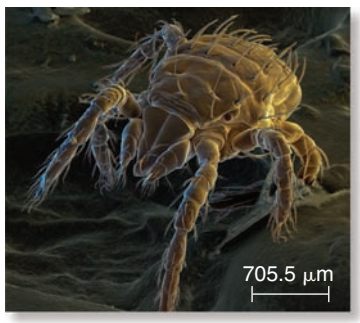
Spider fangs are supplied with venom from poison glands. Most spider bites are harmless to humans, although they are very effective in immobilizing and/or killing their insect prey. Venom from some species, including the black widow (*Latrodectus mactans*; **Figure 33.23a**) and the brown recluse (*Loxosceles reclusa*), are potentially, although rarely, fatal to humans. The toxin of the black widow is a neurotoxin, which interferes with the functioning of the nervous system, whereas that of the brown recluse is hemolytic, meaning it destroys red blood cells around the bite. After the spider has subdued its prey, it pumps digestive fluid into the tissues via the fangs and sucks out the partially digested meal.



Spiders have abdominal silk glands, called spinnerets, and many spin webs to catch prey (**Figure 33.24a**). The silk is a protein that stiffens after extrusion from the body because the mechanical shearing causes a change in the organization of the amino acids. Silk is stronger than steel of the same diameter and is more elastic than Kevlar, the material used in bulletproof vests. Each spider family constructs a characteristic size and style of web and can do it perfectly on its first attempt, indicating that web spinning is an innate (instinctual) behavior (see Chapter 55). Spiders also use silk to wrap up prey and to

Figure 33.23 Common arachnids. **(a)** Female black widow spider (*Latrodectus mactans*). **(b)** The Central American black scorpion (*Centruroides gracilis*) is highly venomous and carries its white young on its back. **(c)** SEM of a chigger mite (*Trombicula alfreddugesi*) that can cause irritation to human skin and spread disease. **(d)** These South African bont ticks (*Amblyomma hebraeum*) are feeding on a white rhinoceros.

Concept Check: *What is one of the main characteristics distinguishing arachnids from insects?*

(a) Normal web

(b) Web spun by spider fed with prey containing caffeine

(c) Web spun by spider fed with prey containing marijuana

Figure 33.24 Spider-web construction by normal and drugged spiders.

BIOLOGY PRINCIPLE Biology is an experimental science. Some scientists have suggested using web-spinning spiders to test substances for the presence of drugs or even to indicate environmental contamination.

construct egg sacs. Interestingly, spiders that are fed drugged prey spin their webs differently than undrugged spiders (**Figure 33.24b** and **c**). Some scientists have suggested that web-spinning spiders be used to test substances for the presence of drugs or even to indicate environmental contamination.

Scorpions (order Scorpionida) are generally tropical or subtropical animals that feed primarily on insects, though they may eat spiders and other arthropods as well as smaller reptiles and mice. Their pedipalps are modified into large claws, and their abdomen tapers into a stinger, which is used to inject venom. Although the venom of most North American species is generally not fatal to humans, that of the *Centruroides* genus from deserts in the U.S. Southwest and Mexico can be deadly. Fatal species are also found in India, Africa, and other countries. Unlike spiders, which lay eggs, scorpions bear live young that the mother then carries around on her back until they have their first molt (**Figure 33.23b**).

In mites and ticks (order Acari), the two main body segments (cephalothorax and abdomen) are fused and appear as one large segment. Many mite species are free-living scavengers that feed on dead plant or animal material. Other mites are serious pests on crops, and some, like chiggers (*Trombicula alfreddugesi*), are parasites of humans that can spread diseases such as typhus (**Figure 33.23c**). Chiggers are parasites only in their larval stage. Chiggers do not bore into the skin; their bite and salivary secretions cause skin irritation. *Demodex brevis* is a hair-follicle mite that is common in animals and humans. The mite is estimated to be present in over 90% of adult humans. Although the mite causes no irritation in most humans, *Demodex canis* causes the skin disease known as mange in domestic animals, particularly dogs.

Ticks are larger organisms than mites, and all are ectoparasitic, feeding on the body surface, on vertebrates. Their life cycle includes attachment to a host, sucking blood until they are replete, and dropping off the host to molt (**Figure 33.23d**). Ticks can carry a huge variety of viral and bacterial diseases, including Lyme disease, a bacterial disease so named because it was first found in the town of Lyme, Connecticut, in the 1970s.

Subphylum Myriapoda: The Millipedes and Centipedes Myriapods have one pair of antennae on the head and three pairs of appendages that are modified as mouthparts, including mandibles that act like jaws. The millipedes and centipedes, both wormlike arthropods with legs, are among the earliest terrestrial animal phyla known. Millipedes (class Diplopoda) have two pairs of legs per segment, as their class name denotes (from the Latin *diplo*, meaning two, and *podos*, meaning feet), not 1,000 legs, as their common name suggests (**Figure 33.25a**). They are slow-moving herbivorous creatures that eat decaying leaves and other plant material. When threatened, the millipede's response is to roll up into a protective coil. Many millipede species also have glands on their underside that can eject a variety of toxic, repellent secretions. Some millipedes are brightly colored, warning potential predators that they can protect themselves.

Class Chilopoda (from the Latin *chilo*, meaning lip, and *podos*, meaning feet), or centipedes, are fast-moving carnivores that have

(a) Two millipedes

(b) A centipede

Figure 33.25 Millipedes and centipedes. (a) Millipedes have two pairs of legs per segment. **(b)** The venom of the giant centipede (*Scolopendra heros*) is known to produce significant swelling and pain in humans.

one pair of walking legs per segment (**Figure 33.25b**). The head has many sensory appendages, including a pair of antennae and three pairs of appendages modified as mouthparts, including powerful claws connected to poison glands. The toxin from venom of some of the larger species, such as *Scolopendra heros*, is powerful enough to cause pain in humans. Most species do not have a waxy waterproofing layer on their cuticle and so are restricted to moist environments under leaf litter or in decaying logs, usually coming out at night to actively hunt their prey.

Subphylum Hexapoda: Insects and Relatives Hexapods are six-legged arthropods. Most are insects, but there are a few earlier-diverging noninsect hexapods, including soil-dwelling groups such as collembolans, that molecular studies have shown represent a separate but related lineage. Insects are in a class by themselves (Insecta), literally and figuratively. There are more species of insects than all other species of animal life combined. One million species of insects have been described, and, according to best estimates, 2–5 million more species await description. At least 90,000 species of insects have been identified in the U.S. and Canada alone. DNA barcoding, which is discussed later in this chapter, can help resolve many taxonomic dilemmas between closely related species.

Insects are the subject of an entire field of scientific study, **entomology**. They are studied in large part because of their significance as pests of the world's agricultural crops and carriers of some of the world's most deadly diseases. Insects live in all terrestrial habitats, and virtually all species of plants are fed upon by at least one, usually tens, and sometimes, in the case of large trees, hundreds of insect species. Because approximately one-quarter of the world's crops are lost annually to insects, researchers are constantly trying to find ways to reduce pest densities. Insect pest reduction often involves chemical control (the use of pesticides) or biological control (the use of living organisms). Many species of insects are also important pests or parasites of humans and livestock, both by their own actions and as vectors of diseases such as malaria and sleeping sickness.

In contrast, insects also provide us with many types of essential biological services. We depend on insects such as honeybees, butterflies, and moths to pollinate our crops. Bees also produce honey, and silkworms are the source of silk fiber. Despite the revulsion they provoke in us, fly larvae (maggots) are important in the decomposition process of both dead plants and animals. In addition, we use insects in the biological control of other insects.

The Insect Body Plan Of paramount importance to the success of insects was the evolution of wings, a feature possessed by no other arthropod and indeed no other living animal except birds and bats. Unlike vertebrate wings, however, insect wings are actually outgrowths of the body wall cuticle and are not true segmental appendages. This means that insects still have all their walking legs. Insects are thus like the mythological horse Pegasus, which sprouted wings out of its back while retaining all four legs. In contrast, birds and bats have one pair of appendages (arms) modified for flight, which leaves them considerably less agile on the ground.

Insects in different orders have also evolved a variety of mouthparts in which the constituent parts, the mandibles and maxillae, are modified for different functions (**Figure 33.26**). Many of these mouthparts are modified walking appendages and are bilaterally paired. As a result, the jaws of many insects, such as grasshoppers, move in a side-to-side motion, rather than up and down as human jaws do.

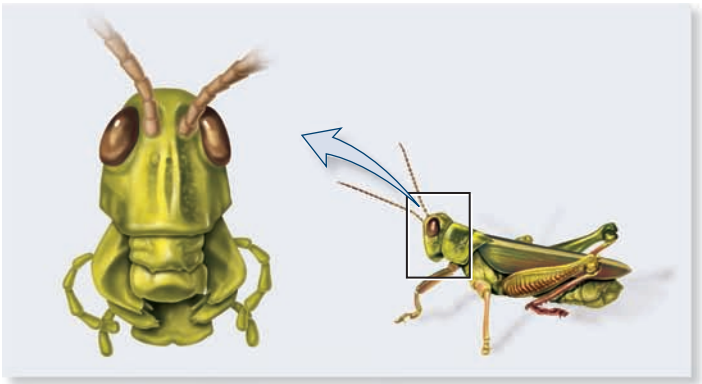
- Grasshoppers, beetles, dragonflies, and many others have mouthparts adapted for chewing.
- Mosquitoes and many plant pests have mouthparts adapted for piercing and sucking.
- Butterflies and moths have a coiled tongue **(proboscis)** that can be uncoiled, enabling them to drink nectar from flowers.
- Some flies have lapping, spongelike mouthparts that sop up liquid food.

Their varied mouthparts are adaptations that allow insects to specialize their feeding on virtually anything: plant matter, decaying organic matter, and other living animals. The biological diversity of insects is therefore related to environmental diversity, in this case, the variety of foods that insects eat. Parasitic insects attach themselves to other species, and there are even some insect parasites (called hyperparasites) that feed on other parasites, as noted in a verse sometimes attributed to the 18th-century English poet and satirist Jonathan Swift:

> Big fleas have little fleas
>
> upon their backs to bite 'em;
>
> and little fleas have lesser fleas
>
> and so, ad infinitum.

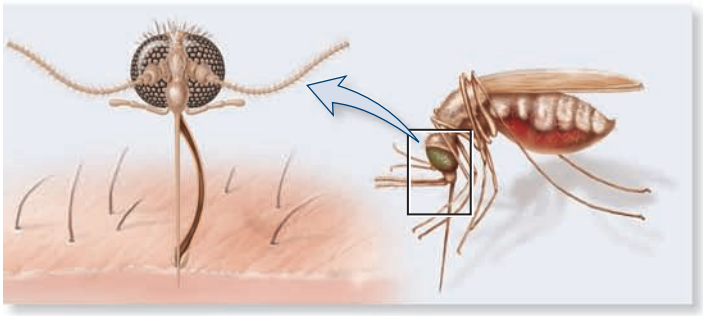
Insect Diversity The great diversity of insects is indicated by the fact that there are 35 orders, some of which have over 100,000 species. The most common orders are covered in **Table 33.5**. Although all insects have six legs, different orders have slightly different wing structures, and many of the orders are based on wing type (their names often include the root *pter-*, from the Greek *pteron*, meaning wing).

- In beetles (Coleoptera), only the back pair of wings is functional; the front wings have become protective shell-like coverings under which the back pair folds when not in use.
- Wasps and bees (Hymenoptera) have two pairs of wings that are hooked together and move as one wing.
- Flies (Diptera) possess only one pair of wings (the front pair); the back pair has been modified into a small pair of balancing organs, called halteres, that act like miniature gyroscopes.
- Butterflies (Lepidoptera) have wings that are covered in scales (from the Greek *lepido*, meaning scale); other insects generally have clear, membranous wings.
- In ant and termite colonies, the queen and the drones (males) retain their wings, whereas female individuals called workers have lost theirs. Other orders, such as fleas and lice, are completely wingless.



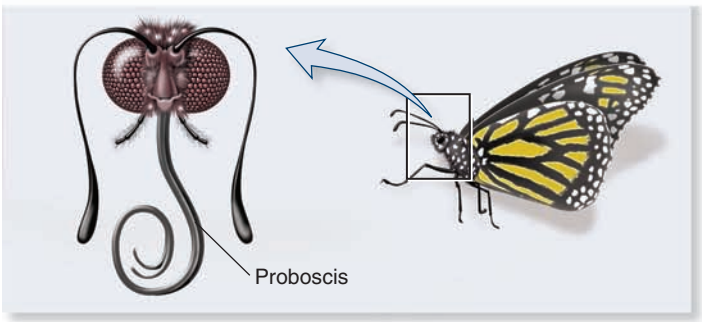
Insect Reproduction and Development All insects have separate sexes, and fertilization is internal. During development, the majority (approximately 85%) of insects undergo a change in body form

Table 33.5 Main Orders and Characteristics of Insects

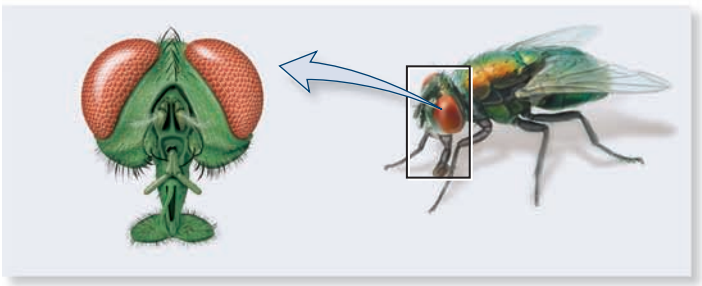


Order and examples (est. number of species)		Order characteristics
Coleoptera: beetles, weevils (500,000)		Two pairs of wings (front pair thick and leathery, acting as wing cases, back pair membranous); armored exoskeleton; biting and chewing mouthparts; complete metamorphosis; largest order of insects
Hymenoptera: ants, bees, wasps (190,000)		Two pairs of membranous wings; chewing or sucking mouthparts; many have posterior stinging organ on females; complete metamorphosis; many species social; important pollinators
Diptera: flies, mosquitoes (190,000)		One pair of wings with hind wings modified into halteres (balancing organs); sucking, piercing, or lapping mouthparts; complete metamorphosis; larvae are grublike maggots in various food sources; some adults are disease vectors
Lepidoptera: butterflies, moths (180,000)		Two pairs of colorful wings covered with tiny scales; long tubelike tongue for sucking; complete metamorphosis; larvae are plant-feeding caterpillars; adults are important pollinators
Hemiptera: true bugs; assassin bug, bedbug, chinch bug, cicada (100,000)		Two pairs of membranous wings; piercing or sucking mouthparts; incomplete metamorphosis; many plant feeders; some predatory or blood feeders; vectors of plant diseases
Orthoptera: crickets, grasshoppers (30,000)		Two pairs of wings (front pair leathery, back pair membranous); chewing mouthparts; mostly herbivorous; incomplete metamorphosis; powerful hind legs for jumping
Odonata: damselflies, dragonflies (6,500)		Two pairs of long, membranous wings; chewing mouthparts; large eyes; predatory on other insects; incomplete metamorphosis; nymphs aquatic; considered early-diverging insects
Siphonaptera: fleas (2,600)		Wingless, laterally flattened; piercing and sucking mouthparts; adults are bloodsuckers on birds and mammals; jumping legs; complete metamorphosis; vectors of plague
Phthiraptera: sucking lice (2,400)		Wingless ectoparasites; sucking mouthparts; flattened body; reduced eyes; legs with clawlike tarsi for clinging to skin; incomplete metamorphosis; very host specific; vectors of typhus
Isoptera: termites (2,000)		Two pairs of membranous wings when present; some stages wingless; chewing mouthparts; social species; incomplete metamorphosis

known as **complete metamorphosis** (from the Greek *meta*, meaning change, and *morph*, meaning form) (**Figure 33.27a**). Animals that undergo complete metamorphosis have four types of stages: egg, larva, pupa, and adult. The dramatic body transformation from larva to adult occurs in the pupa stage. The larval stage is often spent in an entirely different habitat from that of the adult, and larval and adult forms use different food sources. Consequently, they do not compete directly for the same resources. Furthermore, metamorphosis permits existence of a dispersive stage, usually a winged adult, and a feeding stage, often a sac-like caterpillar or larva.



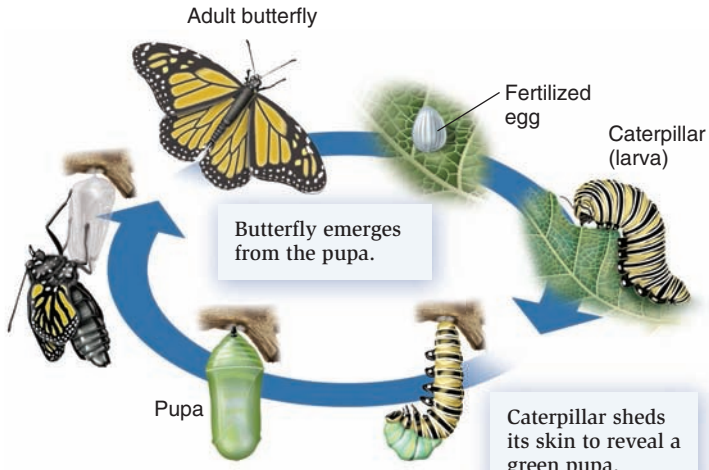
The remaining insects undergo **incomplete metamorphosis**, in which change is more gradual (**Figure 33.27b**). Incomplete



(a) Chewing (grasshopper)

(b) Piercing and blood sucking (mosquito)

(c) Nectar sucking (butterfly)



(d) Sponging liquid (housefly)

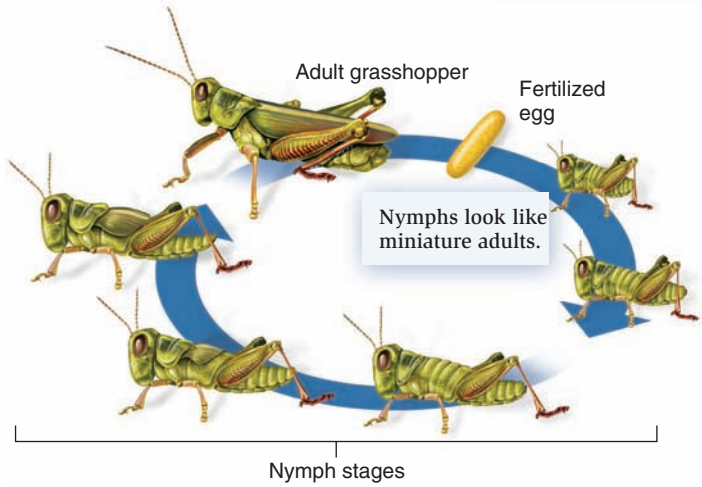


Figure 33.26 A variety of insect mouthparts. Insect mouthparts have become modified in ways that allow insects to feed by a variety of methods, including **(a)** chewing (Orthoptera, Coleoptera, and others), **(b)** piercing and blood sucking (Diptera), **(c)** nectar sucking (Lepidoptera), and **(d)** sponging up liquid (Diptera).

Concept Check: *Insects have a variety of mouthparts. Name two other key insect adaptations.*

BioConnections: *Look forward to Figure 43.23. Some insects do not taste their food with their mouths, so how do they taste?*

(a) Complete metamorphosis

(b) Incomplete metamorphosis

Figure 33.27 Metamorphosis. **(a)** Complete metamorphosis, as illustrated by the life cycle of a monarch butterfly. The adult butterfly has a completely different appearance than the larval caterpillar. **(b)** Incomplete metamorphosis, as illustrated by the life cycle of a grasshopper. The eggs hatch into nymphs, essentially miniature versions of the adult.

metamorphosis has only three types of stages: egg, nymph, and adult. Young insects, called nymphs, look like miniature adults when they hatch from their eggs, but usually don't have wings. As they grow and feed, they shed their exoskeleton and replace it with a larger one several times, each time entering a new instar, or stage of growth. When the insects reach their adult size, they have also grown wings.

Some insects, such as bees, wasps, ants, and termites, have developed complex social behavior and live cooperatively in underground or aboveground nests. Such colonies exhibit a division of labor, in that some individuals forage for food and care for the brood (workers), others protect the nest (soldiers), and some only reproduce (the queen and drones) (**Figure 33.28**).

(a) Worker and soldier ants

(b) Queen ant

Figure 33.28 The division of labor in insect societies. Individuals from the same insect colony may appear very different. Among these army ants (*Eciton burchelli*) from Paraguay, there are **(a)** workers that forage for the colony, soldiers (with large mandibles) that protect the colony from predators, and **(b)** the queen, which reproduces and lays eggs.

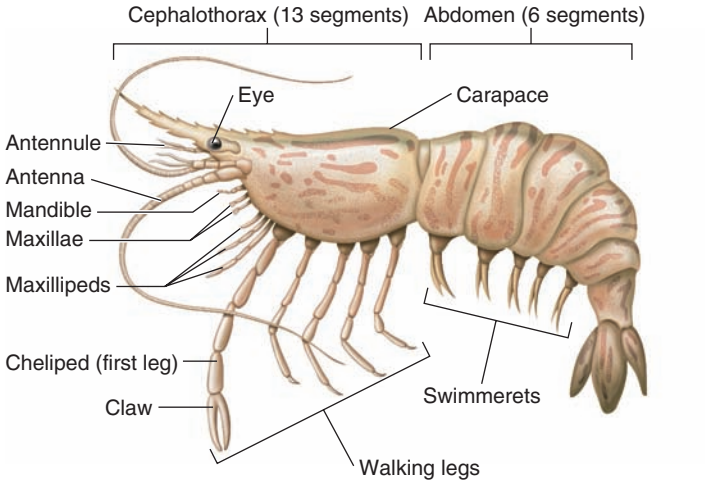

Figure 33.29 Body plan of a crustacean, as represented by a shrimp.

BioConnections: *Look ahead to Figure 43.9. Where are a crustacean's organs of balance located?*

Subphylum Crustacea: Crabs, Lobsters, Barnacles, and Shrimp

The crustaceans are common inhabitants of marine environments, although some species live in fresh water and a few are terrestrial. Many species, including crabs, lobsters, crayfish, and shrimp, are economically important food items for humans; smaller species are important food sources for other predators.

The Crustacean Body Plan The crustaceans are unique among the arthropods in that they possess two pairs of antennae at the anterior end of the body—the antennule (first pair) and antenna (second pair) (**Figure 33.29**). In addition, they have three or more sensory and feeding appendages that are modified mouthparts: the mandibles, maxillae, and maxillipeds. These are followed by walking legs and, often, additional abdominal appendages, called swimmerets, and a powerful tail. In some orders, the first pair of walking legs, or chelipeds, is modified to form powerful claws. The head and thorax are often fused together, forming the cephalothorax. In many species, the cuticle covering the head extends over most of the cephalothorax, forming a hard protective fold called the **carapace**. For growth to occur, a crustacean must shed the entire exoskeleton.

Many crustaceans are predators, but others are scavengers, and some, such as barnacles, are filter feeders. Gas exchange typically occurs via gills, and crustaceans, like other arthropods, have an open circulatory system. Crustaceans possess two excretory organs: antennal glands and maxillary glands, both modified metanephridia, which open at the bases of the antennae and maxillae, respectively. Reproduction usually involves separate sexes, and fertilization is internal. Most species carry their eggs in brood pouches under the female's body. Eggs of most species produce larvae that must go through many different molts prior to assuming adult form. The first of these larval stages, called a **nauplius**, is very different in appearance from the adult crustacean (**Figure 33.30**).

Crustacean Diversity Crustacean clades are numerous, but most are small and obscure, although many orders contain important prey items for other marine organisms. For example, copepods are tiny and abundant planktonic crustaceans, which are a food source for filter-feeding organisms and small fish. The clade Cirripedia is composed of the barnacles, crustaceans whose carapace forms calcified plates that cover most of the body (**Figure 33.31a**). Their legs are modified into feathery filter-feeding structures.

Malacostracans are divided into many orders. Euphausiacea are shrimplike krill that grow to about 3 cm and provide a large part of the diet of many whales, seals, penguins, fish, and squid. The order Isopoda contains many small species that are parasitic on marine fishes. Terrestrial isopods, better known as pill bugs, or wood lice, retain a strong connection to water and need to live in moist environments such as leaf litter or decaying logs (**Figure 33.31b**). When threatened, they curl up into a tight ball, making it difficult for predators to get a grip on them.

Figure 33.30 Crustacean larva. The nauplius is a distinct larval type possessed by most crustaceans, which molts several times before reaching maturity. Many are less than one hundredth of a millimeter long.

(a) Goose barnacles—order Cirripedia

(b) Pill bug—order Isopoda

(c) Coral crab—order Decapoda

Figure 33.31 Common crustaceans. **(a)** Goose barnacles (*Lepas anatifera*). **(b)** Pill bug, or wood louse (*Armadillium vulgare*). **(c)** Coral crab (*Carpilius maculates*).

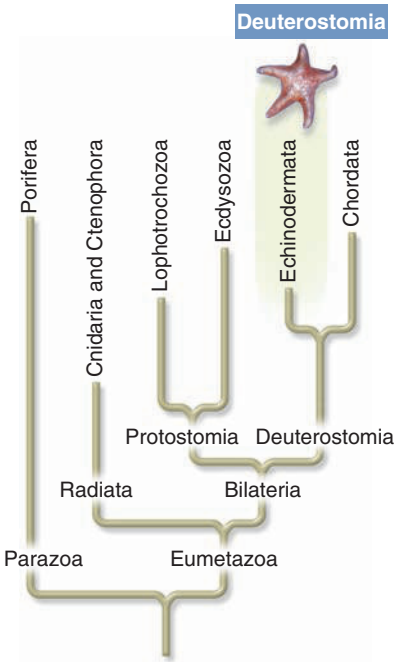
The most famous Malacostracan order is the Decapoda, which includes the crabs and lobsters, the largest crustacean species (**Figure 33.31c**). As their name suggests, these decapods have 10 walking legs (five pairs), although the first pair is invariably modified to support large claws. Most decapods are marine, but many are freshwater species, such as crayfish, and in hot, moist tropical areas, even some terrestrial species called land crabs.

Genomes & Proteomes Connection

DNA Barcoding: A New Tool for Classification

The International Barcoding of Life (IBOL) project, developed in 2003 by Canadian biologist Dr. Paul Hebert of the University of Guelph, is a broad initiative that seeks to create a digital identification system for all life-forms. Hebert made the analogy that the large diversity of products in a grocery store can each be distinguished with a relatively small barcode. Though the diversity of the world's animal species is considerably larger, he reasoned that all species could be distinguished using their DNA. The complete genome would be too large to analyze rapidly, so Hebert suggested analyzing a small piece of DNA of all species. The DNA sequence he proposed is the first 648 base pairs of a gene called *CO1*, for cytochrome oxidase, an enzyme in the electron transport chain of mitochondria (refer back to Figure 7.8). All animals have this gene, and it occurs in the mitochondria. A key element is that although this part of the *CO1* gene varies widely between species, it hardly varies at all between individuals of the same species—only 2%.

Insects are a very species-rich taxon. For example, there are at least 3,500 species of mosquitoes, many of them hard to tell apart. Some mosquitoes transmit deadly diseases such as malaria and yellow fever and are subject to stringent control measures in many countries. Other mosquito species are relatively benign. Distinguishing mosquito species in the field is not easy. The Mosquito Barcoding Initiative aims to catalog each mosquito species by using analysis of its mtDNA (mitochondrial DNA) and thus build up a DNA barcode database. Field researchers will be able to quickly analyze the DNA of a particular species and identify it based on existing barcodes. Appropriate control measures can then be instigated against the species if it is a disease carrier.



For blood-feeding insects, scientists can also barcode their blood meals, target their feeding preferences, and optimize control measures accordingly. For example, tsetse flies transmit tryptosomiasis, a parasitic disease that causes sleeping sickness in humans, and African animal trypanosomiasis, a disease that leads to serious economic losses of livestock. Tsetse flies are hard to track in nature because of their solitary habits and secretive nature, hiding in bushes and waiting for prey to pass by. Capturing individuals and DNA barcoding their blood meals avoids the necessity of costly and difficult field behavioral studies. If cattle are found to be the source of most blood, spraying them with insecticides is an effective control strategy. If wildlife such as buffalo, giraffe, elephants, and warthogs are the source, then trapping devices are used.

Dr. Hebert foresees the day when all species can be identified by their DNA barcode. A huge advantage is that only a small piece of tissue is necessary. The specimen can come from an adult or immature individual, a great help considering much insect taxonomy is based solely on adults. Many scientists anticipate the day when handheld field barcoding identification devices appear. At the moment, barcoding involves a laboratory analysis taking about an hour and costing $2.00 per sample. As of 2014, over 192,000 insect species have been barcoded.

33.5 Deuterostomia: The Echinoderms and Chordates

Learning Outcomes:

1. Identify the distinguishing characteristics of echinoderms.
2. List the four critical innovations in the body plan of chordates.
3. Describe the two invertebrate subphylum of the phylum Chordata and their relationship to the vertebrates.

As discussed in Chapter 32, the deuterostomes are grouped together because they share similarities in patterns of development (refer back to Figure 32.7). Molecular evidence also supports a deuterostome clade. All animals in the phylum Chordata (from the Greek *chorde*, meaning string, referring to the spinal cord), which includes the vertebrates, are deuterostomes. Interestingly, so is one invertebrate group, the phylum Echinodermata, which includes the sea stars, sea urchins, and sea cucumbers. Although there are far fewer phyla and species of deuterostomes than protostomes, the deuterostomes are generally much more familiar to us. After all, humans are deuterostomes.

We will conclude our discussion of invertebrate biology by turning our attention to the invertebrate deuterostomes. In this section, we will explore the phylum Echinodermata and then introduce the phylum Chordata, looking in particular at its distinguishing characteristics and at its two invertebrate subphyla: the cephalochordates, commonly referred to as the lancelets, and the urochordates, also known as the tunicates. We will discuss the subphylum Vertebrata in Chapter 34.

The Phylum Echinodermata Includes Sea Stars and Sea Urchins—Species with a Water Vascular System

The phylum Echinodermata (from the Greek *echinos*, meaning spiny, and *derma*, meaning skin) consists of a unique grouping of deuterostomes. A striking feature of all echinoderms is their modified radial symmetry. The body of most species can be divided into five parts pointing out from the center. As a consequence, cephalization is absent in most classes. There is no brain and only a simple nervous system consisting of a central nerve ring from which arise radial branches to each limb. The radial symmetry of echinoderms is secondary, present only in adults. The free-swimming larvae have bilateral symmetry and metamorphose into the radially symmetrical adult form.

The Echinoderm Body Plan Most echinoderms have an **endoskeleton**, an internal hard skeleton composed of calcareous plates overlaid by a thin skin (**Figure 33.32**). The skeleton is covered with spines and jawlike pincers called pedicellariae, the primary purpose of which is to deter settling of animals such as barnacles. These structures can also have poison glands.

Echinoderms possess a true coelom, and a portion of the coelom has been adapted to serve as a unique **water vascular system**, a network of canals that branch into tiny **tube feet** that function in movement, gas exchange, feeding, and excretion (see inset to Figure 33.32). The water vascular system uses hydraulic power (water pressure generated by the contraction of muscles), which enables the tube feet to extend and contract, allowing echinoderms to move only very slowly.

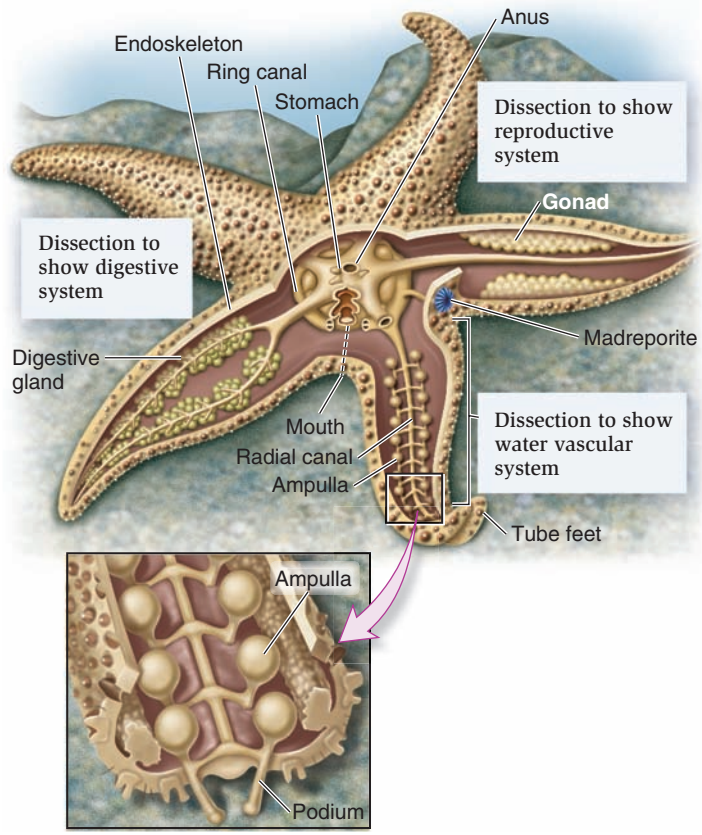


Figure 33.32 Body plan of an echinoderm, as represented by a sea star. The arms of this sea star have been dissected to different degrees to show the echinoderm's various organs. The inset shows a close-up view of the tube feet, part of the water vascular system characteristic of echinoderms.

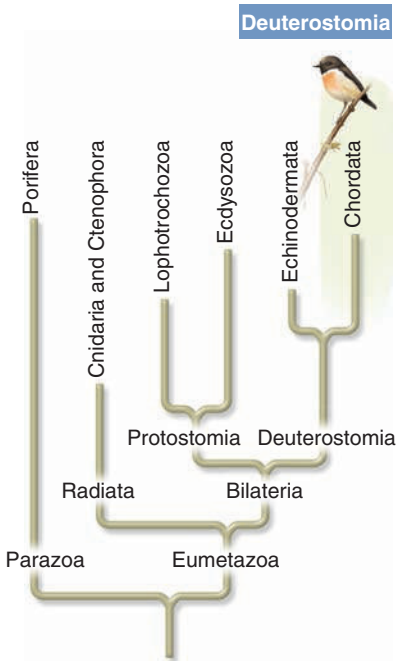
Concept Check: *Echinoderms and chordates are both deuterostomes. What are three defining features of deuterostomes?*

Water enters the water vascular system through the **madreporite**, a sievelike plate on the animal's surface. From there it flows into a **ring canal** in the central disc, into five radial canals, and into the tube feet. At the base of each tube foot is a muscular sac called an **ampulla**, which stores water. Contractions of the ampullae force water into the tube feet, causing them to straighten and extend. When the foot contacts a solid surface, muscles in the foot contract, forcing water back into the ampulla. Sea stars also use their tube feet in feeding, where they can exert a constant and strong pressure on bivalves, whose adductor muscles open and close the shell. The adductor muscles eventually tire, allowing the shell to open slightly. At this stage, the sea star everts its stomach and inserts it into the opening. It then digests its prey, using juices secreted from extensive digestive glands. Sea stars also feed on sea urchins, brittle stars, and sand dollars, prey that cannot easily escape them.

Echinoderms cannot osmoregulate, so no species have entered freshwater environments. No excretory organs are present. For some species, both respiration and excretion of nitrogenous waste take



place by diffusion across their tube feet. Coelomic fluid circulates around the body.

Most echinoderms exhibit **autotomy**, the ability to intentionally detach a body part, such as a limb, that will later regenerate. In some species, a broken limb can even regenerate into a whole animal. Some sea stars regularly reproduce by breaking in two. Most echinoderms reproduce sexually and have separate sexes. Fertilization is usually external, with gametes shed into the water. Fertilized eggs develop into free-swimming larvae, which become sedentary adults.

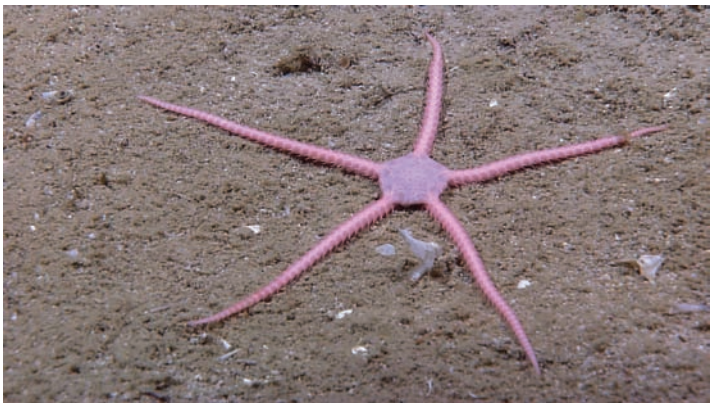
The Major Echinoderm Classes Although over 20 classes of echinoderms have been described from the fossil record, only 5 main classes of echinoderms exist today: the Asteroidea (sea stars), Ophiuroidea (brittle stars), Echinoidea (sea urchins and sand dollars), Crinoidea (sea lilies and feather stars), and Holothuroidea (sea cucumbers). The key features of the echinoderms and their classes are listed in **Table 33.6**, and several members are shown in **Figure 33.33.**

The Phylum Chordata Includes All the Vertebrates and Some Invertebrates

The deuterostomes consist of two major phyla: the echinoderms and the chordates. As deuterostomes, both phyla share similar developmental traits. In addition, both have an endoskeleton, consisting in the echinoderms of calcareous plates and in chordates, for the most part, of bone. However, the echinoderm endoskeleton functions in much the same way as the arthropod exoskeleton, in that an important function is providing protection. The chordate endoskeleton serves a very different purpose. In early-diverging chordates, the endoskeleton is composed of a single flexible rod situated dorsally, deep inside the body. Muscles move this rod, and their contractions cause the back and tail end to move from side to side, permitting a swimming motion in water. The endoskeleton becomes more complex in different lineages that develop limbs, as we will see in Chapter 34, but it is always internal, with muscles attached.

Let's take a look at the four critical innovations in the body plan of chordates that distinguish them from all other animal life (**Figure 33.34**):

1. **Notochord.** Chordates are named for the **notochord**, a single flexible rod that lies between the digestive tract and the nerve cord. Composed of fibrous tissue encasing fluid-filled cells, the notochord is stiff yet flexible and provides skeletal support for all early-diverging chordates. In most chordates, such as vertebrates, a more complex jointed backbone usually replaces the notochord; its remnants exist only as the soft material within the discs between each vertebrae.
2. **Dorsal hollow nerve cord.** Many animals have a long nerve cord, but in nonchordate invertebrates, it is a solid tube that lies ventral to the alimentary canal. In contrast, the nerve cord in chordates is a hollow tube that develops dorsal to the alimentary canal. In vertebrates, the dorsal hollow nerve cord develops into the brain and spinal cord.
3. **Pharyngeal slits.** Chordates, like many animals, have a complete gut, from mouth to anus. However, in chordates, slits develop in the pharyngeal region, close to the mouth, that open to the outside. This permits water to enter through the mouth and exit via the slits, without having to go through the digestive tract. In early-diverging chordates, **pharyngeal slits** function as a filter-feeding device, whereas in later-diverging chordates, they develop into gills for gas exchange. In terrestrial chordates, the slits do not fully form, and they become modified for other purposes.
4. **Postanal tail.** Chordates possess a postanal tail of variable length that extends posterior to the anal opening. In aquatic chordates such as fishes, the tail is used in locomotion. In terrestrial chordates, the tail may be used for a variety of functions. In virtually all other nonchordate phyla, the anus is at the end of the body.



Although few chordates apart from fishes possess all of these characteristics in their adult life, they all exhibit them at some time during development. For example, in adult humans, the notochord

Table 33.6 Main Classes and Characteristics of Echinoderms

	Class and examples (est. number of species)	Class characteristics
	Asteroidea: sea stars (1,600)	Five arms; tube feet; predatory on bivalves and other echinoderms; eversible stomach
	Ophiuroidea: brittle stars (2,000)	Five long, slender arms; tube feet not used for locomotion; no pedicellariae; browse on sea bottom or filter feed
	Echinoidea: sea urchins, sand dollars (1,900)	Spherical (sea urchins) or disc-shaped (sand dollars); no arms; tube feet and moveable spines; pedicellariae present; many feed on seaweeds
	Crinoidea: sea lilies and feather stars (700)	Cup-shaped; often attached to substrate via stalk; arms feathery and used in filter feeding; very abundant in fossil record
	Holothuroidea: sea cucumbers (1,200)	Cucumber-shaped; no arms; spines absent; endoskeleton reduced; tube feet; browse on sea bottom

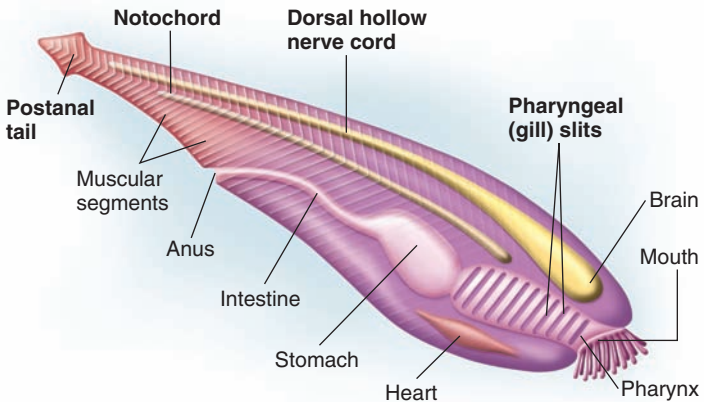

Figure 33.34 Chordate characteristics. The generalized chordate body plan has four main features: notochord, dorsal hollow nerve cord, pharyngeal slits, and postanal tail.

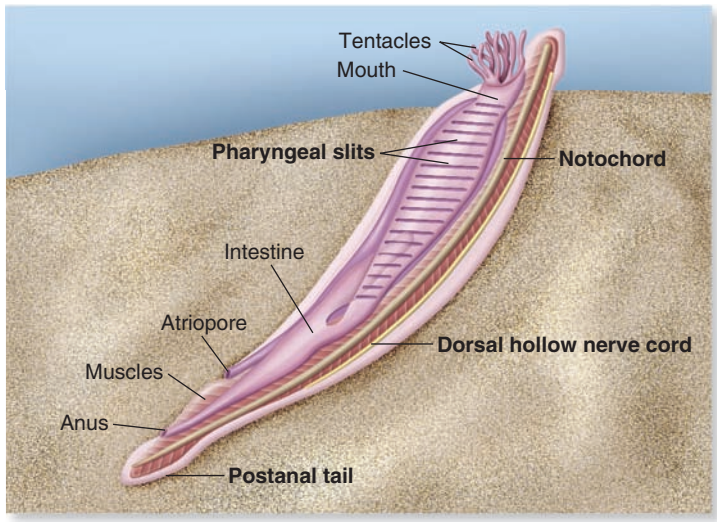
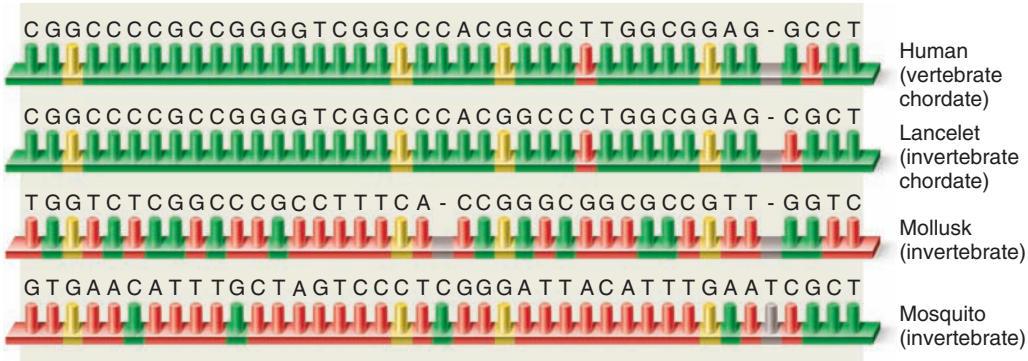


becomes the spinal column, and the dorsal hollow nerve cord becomes the central nervous system. However, humans exhibit pharyngeal slits and a postanal tail only during early embryonic development. All the pharyngeal slits, except one, which forms the auditory (Eustachian) tubes in the ear, are eventually lost, and the postanal tail regresses to form the tailbone (the coccyx).

The phylum Chordata consists of the invertebrate chordates—the subphylum Cephalochordata (lancelets) and the subphylum Urochordata (tunicates)—along with the subphylum Vertebrata. Although the Vertebrata is by far the largest of these subphyla, biologists have focused on the Cephalochordata and Urochordata for clues as to how the chordate phylum may have evolved. Comparisons of gene sequences for the small subunit rRNA (SSU rRNA) show that these two subphyla are our closest invertebrate relatives (**Figure 33.35**).

Subphylum Cephalochordata: The Lancelets The cephalochordates (from the Greek *cephalo*, meaning head) look a lot more chordate-like than do tunicates. They are commonly referred to as lancelets, in reference to their bladelike shape and size, about 5–7 cm in length (**Figure 33.36a**). Lancelets are a small subphylum of 26 species, all marine filter feeders, with 4 species occurring in North American waters. Most of them belong to the genus *Branchiostoma*.

(a) Lancelet in the sand



(b) Body plan of the lancelet

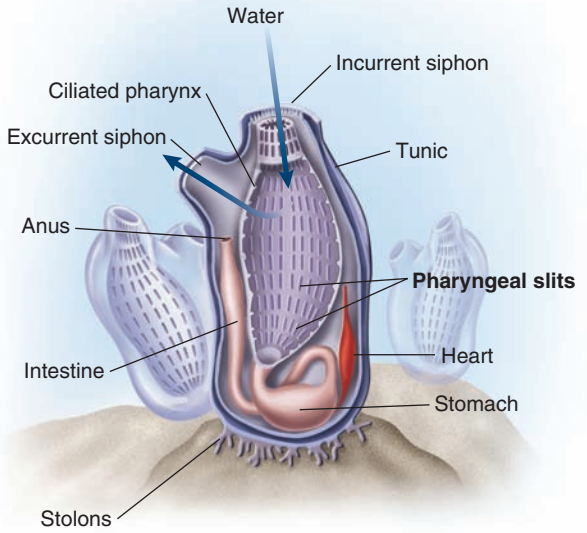


Figure 33.36 Lancelets. **(a)** A bladelike lancelet. **(b)** The body plan of the lancelet clearly displays the four characteristic chordate features.

The lancelets live mostly buried in sand, with only the anterior end protruding into the water. Lancelets have the four distinguishing chordate characteristics: a clearly discernible notochord (extending well into the head), dorsal hollow nerve cord, pharyngeal slits, and postanal tail (**Figure 33.36b**). They are filter feeders, drawing water through the mouth and into the pharynx, where it is filtered through the pharyngeal slits. A mucous net across the pharyngeal

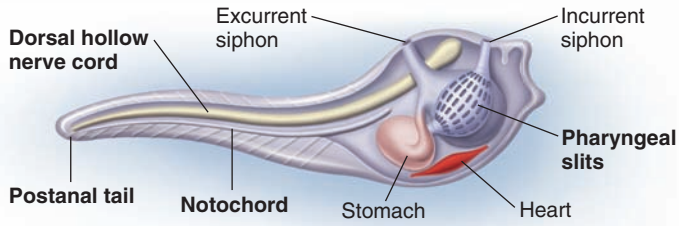

Figure 33.35 Comparison of SSU rRNA gene sequences of chordate and nonchordate species. Note the many similarities (yellow) and differences (green and red) among the sequences.

BIOLOGY PRINCIPLE The genetic material provides a blueprint for sustaining reproduction. The genetic similarities between the invertebrate chordates (represented by the lancelet) and the vertebrates (represented by a human) suggest that the former are indeed our closest invertebrate relatives.

(a) Adult tunicate

(b) The larval form of the tunicate

(c) Typical tunicate

Figure 33.37 Tunicates. **(a)** Body plan of the sessile, filter-feeding adult tunicate. **(b)** The larval form, which shows the four characteristic chordate features, has been proposed as a possible ancestor of modern vertebrates. **(c)** The blue tunicate, *Rhopalaea crassa*.

slits traps food particles, and ciliary action takes the food into the intestine, while water exits via the atriopore. Gas exchange generally takes place across the body surface. Although the lancelet is usually sessile, it can leave its sandy burrow and swim to a new spot, using a sequence of serially arranged muscles that appear like chevrons (<<<<) along its sides. These muscles reflect the segmented nature of the lancelet body and permit a fishlike swimming motion.

Subphylum Urochordata: The Tunicates The urochordates (from the Greek oura, meaning tail) are a group of 3,000 marine species also known as tunicates. Looking at an adult tunicate, you might never guess that it is a relative of modern vertebrates. The only one of the four distinguishing chordate characteristics that it possesses is pharyngeal slits (**Figure 33.37a**). The larval tunicate, in contrast, looks like a tadpole and exhibits all four chordate hallmarks (**Figure 33.37b**). The larval tadpole swims for only a few days, usually without feeding. Larvae settle on and attach to a rock surface via rootlike extensions called stolons. Here the larvae metamorphose into adult tunicates and in the process lose most of their chordate characteristics. In 1928, the English marine biologist Walter Garstang suggested modern vertebrates arose from a larval tunicate form that had somehow acquired the ability to reproduce. Analysis of molecular data in 2006 led French evolutionary biologist Frédéric Delsuc and colleagues to propose that tunicates are the closest living relatives of vertebrates. These researchers group the cephalochordates more closely with the echinoderms. This means the common ancestor of living deuterostomes was a free-living, bilaterally symmetrical animal with pharyngeal slits, a segmented body, and a dorsal hollow nerve cord. This ancestral line split into two groups, the echinoderm–cephalochordate group and the tunicate–vertebrate group. Echinoderms lost most of their ancestral features, but cephalochordates did not. In this view, tunicates lost their segmentation and most became sedentary, whereas vertebrates did not.

Adult tunicates are marine animals, some colonial and others solitary, that superficially resemble sponges or cnidarians. Tunicates are filter feeders that draw in water through an **incurrent siphon**, using a ciliated pharynx, and filter it through extensive pharyngeal slits. The food is trapped on a mucous sheet; passes via ciliary action to the stomach, intestine, and anus; and exits through the excurrent siphon. The whole animal is enclosed in a nonliving **tunic** made of a protein and a cellulose-like material called tunicin. Tunicates are also known as sea squirts for their ability to squirt out water from the excurrent siphon when disturbed. They have a rudimentary circulatory system with a heart and a simple nervous system of relatively few nerves connected to sensory tentacles around the incurrent siphon. The animals are mostly hermaphroditic.

Table 33.7 describes the common body characteristics of the various invertebrate animal phyla that we have considered in this chapter.

Table 33.7 Summary of the Physical Characteristics of the Major Invertebrate Phyla

Feature	Porifera (sponges)	Cnidaria and Ctenophora (hydra, anemones, jellyfish)	Platyhelminthes (flatworms)	Rotifera (rotifers)	Bryozoa and Brachiopoda	Mollusca (snails, clams, squid)	Annelida (segmented worms)	Nematoda (roundworms)	Arthropoda (insects, arachnids, crustaceans)	Echinodermata (sea stars, sea urchins)	Chordata (vertebrates and others)
											
Digestive system	Absent	Gastrovascular cavity; ctenophores have complete gut	Gastrovascular cavity	Complete gut (usually)	Complete gut	Complete gut	Complete gut	Complete gut	Complete gut	Usually complete gut	Complete gut
Circulatory system	Absent	Absent	Absent	Absent	Absent; open; or closed	Open; closed in cephalopods	Closed	Absent	Open	Absent	Closed
Respiratory system	Absent	Absent	Absent	Absent	Absent	Gills	Absent	Absent	Trachae; gills; or book lungs	Tube feet; respiratory tree	Gills; lungs
Excretory system	Absent	Absent	Protonephridia with flame cells	Protonephridia	Metanephridia	Metanephridia	Metanephridia	Excretory tubules	Excretory glands resembling metanephridia	Absent	Kidneys
Nervous system	Absent	Nerve net	Brain; cerebral ganglia; lateral nerve chords; nerve net	Brain; nerve cords	No brain; nerve ring	Ganglia; nerve cords	Brain; ventral nerve cord	Brain; nerve cords	Brain; ventral nerve cord	No brain; nerve ring and radial nerves	Well-developed brain; dorsal hollow nerve cord
Reproduction	Sexual; asexual (budding)	Sexual; asexual (budding)	Sexual (most hermaphroditic); asexual (body splits)	Mostly parthenogenetic; males appear only rarely	Sexual (some hermaphroditic); asexual (budding)	Sexual (some hermaphroditic)	Sexual (some hermaphroditic)	Sexual (some hermaphroditic)	Usually sexual (some hermaphroditic)	Sexual (some hermaphroditic); parthenogenetic; asexual by regeneration (rare)	Sexual; rarely parthenogenetic
Support	Endo-skeleton of spicules and collagen	Mesoglea	Parenchyma	Tissue	Exoskeleton	Hydrostatic skeleton and shell	Hydrostatic skeleton	Fluid skeleton	Exoskeleton	Endoskeleton of plates beneath outer skin	Endoskeleton of cartilage or bone

Summary of Key Concepts

33.1 Parazoa: Sponges, the First Multicellular Animals

- Invertebrates, or animals without a backbone, make up more than 95% of all animal species. An early lineage—the Parazoa—consists of one phylum, the Porifera, or sponges. Although sponges lack true tissues, they are multicellular animals possessing several types of cells (Figures 33.1, 33.2).

33.2 Radiata: Jellyfish and Other Radially Symmetrical Animals

- The Radiata consists of two phyla: the Cnidaria (hydra, jellyfish, box jellies, sea anemones, and corals) and the Ctenophora (comb jellies). Radiata have only two embryonic germ layers: the ectoderm and the endoderm, with a gelatinous substance (mesoglea) connecting the two layers.
- Cnidarians exist in one of two forms: polyp or medusa. A characteristic feature of cnidarians is their stinging cells, or cnidocytes, which function in defense and prey capture. Ctenophores possess the first complete gut, and nearly all exhibit bioluminescence (Figures 33.3, 33.4, 33.5, Table 33.1).

33.3 Lophotrochozoa: The Flatworms, Rotifers, Bryozoans, Brachiopods, Mollusks, and Annelids

- Most Lophotrochozoa possess either a lophophore or trochophore larva. Platyhelminthes, or flatworms, are regarded as the first animals to have the organ-system level of organization (Figure 33.6, Table 33.2).
- The four classes of flatworms are the Turbellaria, Monogenea, Trematoda (flukes), and Cestoda (tapeworms). Flukes and tapeworms are internally parasitic, with complex life cycles (Figures 33.7, 33.8).
- Rotifers are microscopic animals that have a complete digestive tract with separate mouth and anus; the mastax, a muscular pharynx, is a structure unique to the rotifers (Figure 33.9).
- The bryozoa and brachiopods both possess a lophophore, a ciliary feeding structure (Figure 33.10).

- The mollusks, which constitute a large phylum with over 100,000 diverse living species, have a basic body plan with three parts—a foot, a visceral mass, and a mantle—and an open circulatory system (Figures 33.11, 33.12, 33.13).
- The four most common mollusk classes are the polyplacophora (chitons), gastropoda (snails and slugs), bivalvia (clams and mussels), and cephalopoda (octopuses, squids, and nautiluses) (Table 33.3).
- Cephalopods are among the most complex of all invertebrates. They are the only mollusks with a closed circulatory system; they have a well-developed nervous system and brain and are believed to exhibit learning by observation (Figures 33.14, 33.15, 33.16).
- Segmentation, in which the body is divided into compartments, is a critical evolutionary innovation in the annelids, although specialization of segments is only minimally present at the anterior end (Figure 33.17).
- Annelids are a large phylum with two main groups: Errantia, which includes free-ranging marine worms, and Sedentaria, which includes tube worms, earthworms, and leeches (Figure 33.18).

33.4 Ecdysozoa: The Nematodes and Arthropods

- The ecdysozoans are so named for their ability to shed their cuticle, a nonliving cover providing support and protection. The two most common ecdysozoan phyla are the nematodes and the arthropods.
- Nematodes, which exist in nearly all habitats, have a cuticle made of collagen, a structural protein. The small, free-living nematode *Caenorhabditis elegans* is a model organism. Many nematodes are parasitic in humans (Figures 33.19, 33.20).
- Arthropods are perhaps the most successful phylum on Earth. The arthropod body is covered by a cuticle made of layers of chitin and protein, and it is segmented, with segments fused into functional units called tagmata (Figure 33.21).
- The five main subphyla of arthropods are Trilobita (trilobites; now extinct), Chelicerata (spiders, scorpions, and relatives), Myriapoda (millipedes and centipedes), Hexapoda (insects), and Crustacea (crabs and relatives) (Table 33.4, Figures 33.22, 33.23, 33.24, 33.25).
- More insect species are known than all other animal species combined. The development of a variety of wing structures and mouthparts was a key to the success of insects (Figure 33.26, Table 33.5).
- Insects undergo a change in body form during development, either complete metamorphosis or incomplete metamorphosis, and have developed complex social behaviors (Figures 33.27, 33.28).
- Most crustacean orders are small and feature prominently in marine food chains. The most well-known order of crustaceans is the Decapoda, which includes the crabs, lobsters, and shrimp (Figures 33.29, 33.30, 33.31).

33.5 Deuterostomia: The Echinoderms and Chordates

- The Deuterostomia include the phyla Echinodermata and Chordata. A striking feature of the echinoderms is their radial symmetry, which is secondary; the free-swimming larvae are bilaterally symmetrical. Echinoderms possess a unique water vascular system (Figure 33.32).
- Five main classes of echinoderms exist today: the Asteroidea (sea stars), Ophiuroidea (brittle stars), Echinoidea (sea urchins and sand dollars), Crinoidea (sea lilies and feather stars), and Holothuroidea (sea cucumbers) (Table 33.6, Figure 33.33).
- The phylum Chordata is distinguished by four critical innovations: the notochord, dorsal hollow nerve chord, pharyngeal slits, and postanal tail (Figure 33.34).
- The subphylum Cephalochordata (lancelets) and subphylum Urochordata (tunicates) are invertebrate chordates. Genetic studies have shown that tunicates are the closest invertebrate relatives of the vertebrate chordates (subphylum Vertebrata) (Figures 33.35, 33.36, 33.37, Table 33.7).

Assess and Discuss

Test Yourself

1. Choanocytes are
   a. a group of protists that are believed to have given rise to animals.
   b. specialized cells of sponges that function to trap and eat small particles.
   c. cells that make up the gelatinous layer in sponges.
   d. cells of sponges that function to transfer nutrients to other cells.
   e. cells that form spicules in sponges.
2. Why aren't sponges eaten more by predators?
   a. They are protected by silica spicules.
   b. They are protected by toxic defensive chemicals.
   c. They are eaten; it's just that the leftover cells reaggregate into new, smaller sponges.
   d. a and b are correct.
   e. a, b, and c are correct.
3. Which of the following organisms can produce female offspring through parthenogenesis?
   a. cnidarians c. choanocytes e. annelids
   b. flukes d. rotifers
4. What organisms can survive without a mouth, digestive system, or anus?
   a. cnidarians c. echinoderms e. nematodes
   b. rotifers d. cestodes
5. Which phylum does not have at least some members with a closed circulatory system?
   a. Lophophorata
   b. Arthopoda
   c. Annelida
   d. Mollusca
   e. All of the above phyla have some members with a closed circulatory system.

6. A defining feature of the Ecdysozoa is a
   a. segmented body.
   b. closed circulatory system.
   c. cuticle.
   d. complete gut.
   e. lophophore.
7. In arthropods, the tracheal system is
   a. a unique set of structures that function in ingestion and digestion of food.
   b. a series of branching tubes extending into the body that allow for gas exchange.
   c. a series of tubules that allow waste products in the blood to be released into the digestive tract.
   d. the series of ommatidia that form the compound eye.
   e. none of the above.
8. Characteristics of the class Arachnida include
   a. two tagmata.
   b. six walking legs.
   c. an aquatic lifestyle.
   d. a lobed body.
   e. both b and d.
9. Incomplete metamorphosis
   a. is characterized by distinct larval and adult stages that do not compete for resources.
   b. is typically seen in arachnids.
   c. involves gradual changes in life stages where young resemble the adult stage.
   d. is characteristic of the majority of insects.
   e. always includes a pupal stage.
10. Which clade does not include echinoderms?
    a. protostomia
    b. bilateria
    c. eumetazoa
    d. metazoa
    e. Echinoderms are a member of all the above clades.

Conceptual Questions

1. Compare and contrast the five main feeding types discussed in the chapter.
2. Why is external fertilization common in aquatic invertebrates but rare in terrestrial species?
3.  A principle of biology is that *living organisms grow and develop*. Explain the difference between complete metamorphosis and incomplete metamorphosis.

Collaborative Questions

1. Revisit the animal phylogeny outlined in Figure 33.1 and discuss the critical innovations that led to the separation of each of the clades shown.
2. Why are there more species of insects than any other taxa?

The Vertebrates

34

The star-nosed mole (*Condylura cristata*). This species is a vertebrate, a fascinating group of animals that includes human beings.

CHAPTER OUTLINE

34.1 Vertebrates: Chordates with a Backbone

34.2 Gnathostomes: Jawed Vertebrates

34.3 Tetrapods: Gnathostomes with Four Limbs

34.4 Amniotes: Tetrapods with a Desiccation-Resistant Egg

34.5 Mammals: Milk-Producing Amniotes

Summary of Key Concepts

Assess and Discuss

The star-nosed mole, *Condylura cristata,* lives in tunnels in wet areas of eastern Canada and the northeastern United States. It is one of the most distinctive mammals anywhere on Earth. The mole lives for the most part in complete darkness and is virtually blind. It feels its way around by means of 22 fleshy appendages, which consist of more than 25,000 minute and highly sensitive sensory receptors called Eimer's organs that allow it to find prey without using sight. The mole has a voracious appetite and needs to eat frequently. In fact, the star-nosed mole has been identified as the world's fastest eating mammal, averaging less than a quarter of a second to identify and consume a food item. Its astoundingly acute sensory abilities more than make up for its poor eyesight. The moles can swim under water in search of food and smell their prey by exhaling air bubbles then inhaling them to detect scent.

The star-nosed mole is a **vertebrate** (from the Latin *vertebratus*, meaning joint of the spine), an animal with a backbone. Vertebrates range in size from tiny fishes weighing 0.1 g to huge whales of over 100,000 kg. They occupy nearly all of Earth's habitats, from the deepest depths of the oceans to mountaintops and the sky beyond. Throughout history, humans have depended on many vertebrate species for their welfare, domesticating species such as horses, cattle, pigs, sheep, and chickens; using skin and fur for clothes, and keeping countless species, including cats and dogs, as pets. Many vertebrate species are the subjects of conservation efforts, as we will see in Chapter 60.

In Chapter 33, we discussed two chordate subphyla: the cephalochordates (lancelets) and urochordates (tunicates). The third subphylum of chordates, the Vertebrata, with about 53,000 species, is by far the largest and most dominant group of chordates. In this chapter, we will explore the characteristics of vertebrates and the evolutionary development of the major vertebrate clades, including fishes, amphibians, reptiles, and mammals.

Our current understanding of the relationships between the vertebrate groups is shown in **Figure 34.1**. Nested within the vertebrates are various clades based on morphological characteristics. For example, most vertebrates have jaws and are collectively known as gnathostomes. Many gnathostomes have four limbs for movement and are known as tetrapods. Next, we explain these sequential divisions in the vertebrate lineage.

34.1 Vertebrates: Chordates with a Backbone

Learning Outcomes:

1. List the main distinguishing characteristics of vertebrates.
2. Identify the two classes of existing jawless vertebrates.

The vertebrates retain all chordate characteristics outlined in Chapter 33, as well as possessing several additional traits, including the following:

1. **Vertebral column.** During development in vertebrates, the notochord is replaced by a bony or cartilaginous column

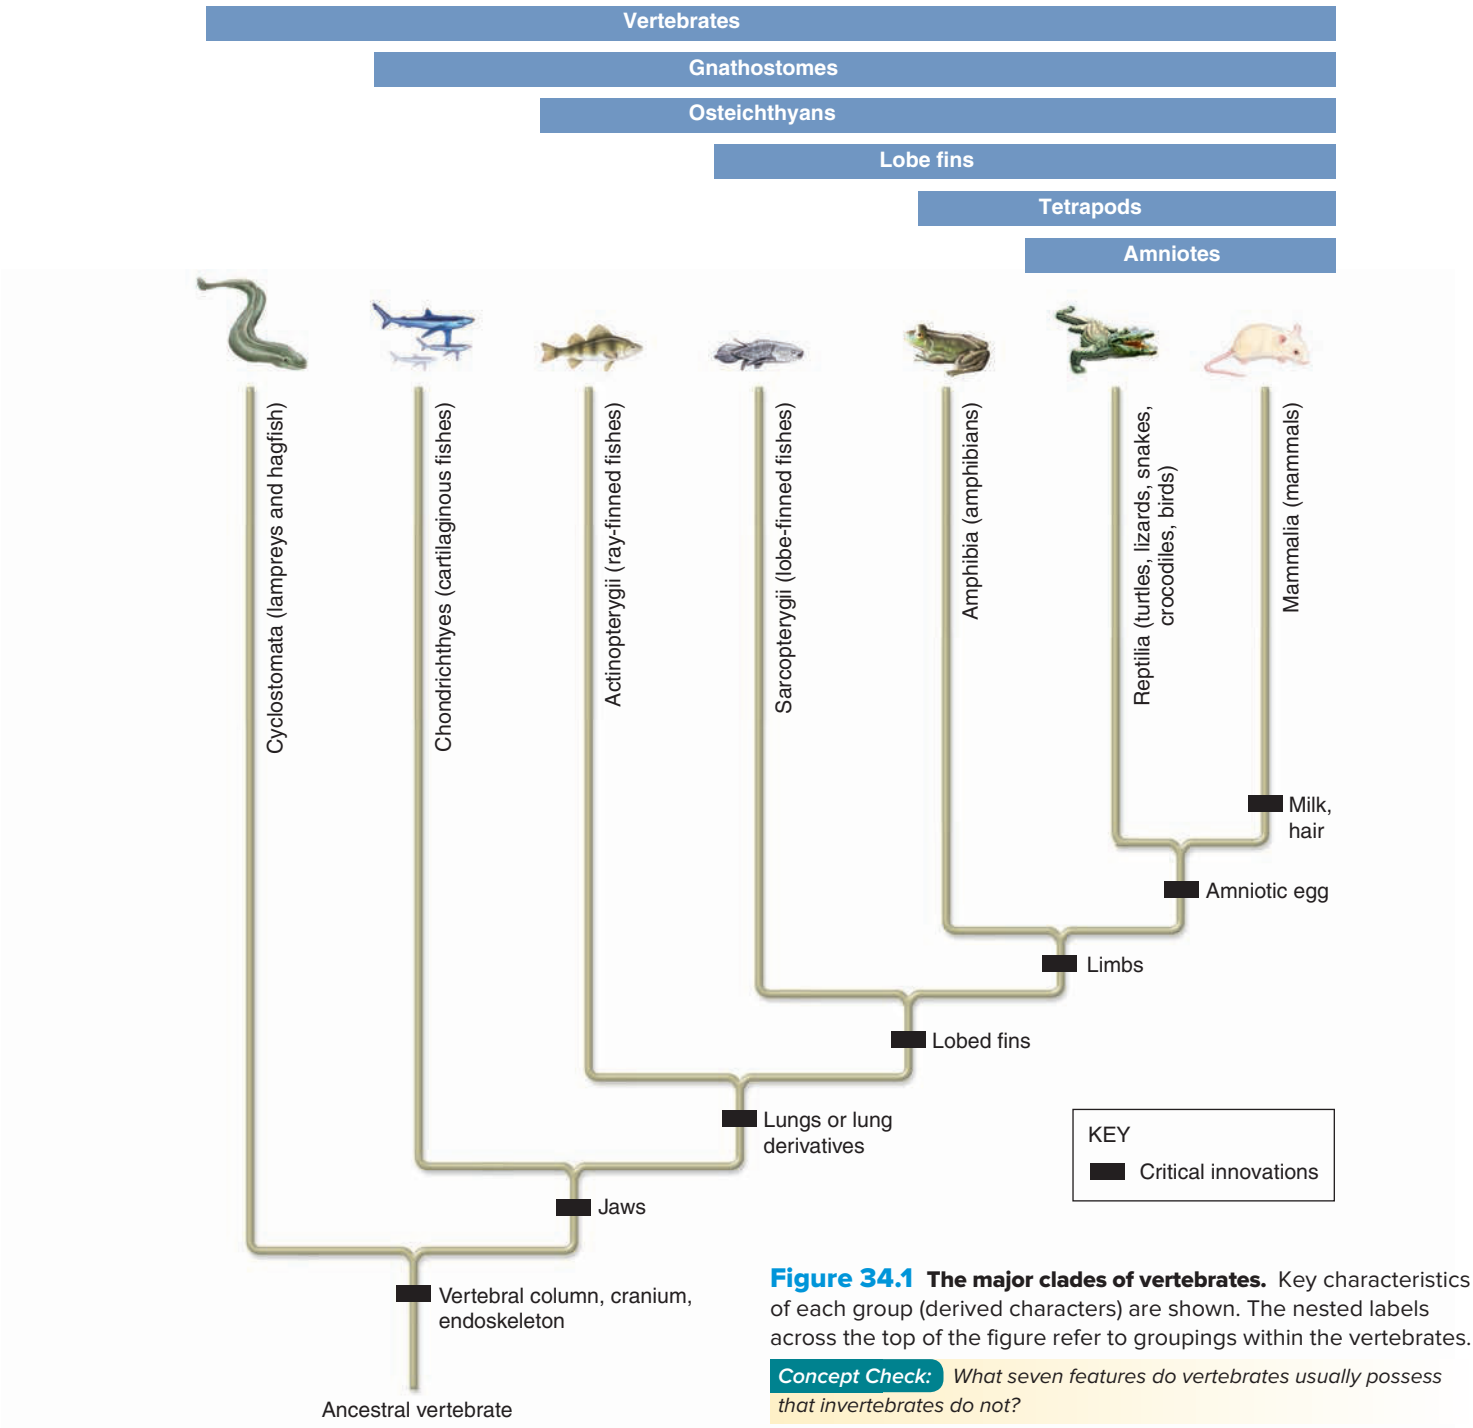

Figure 34.1 **The major clades of vertebrates.** Key characteristics of each group (derived characters) are shown. The nested labels across the top of the figure refer to groupings within the vertebrates.

Concept Check: *What seven features do vertebrates usually possess that invertebrates do not?*

of interlocking **vertebrae** that provides support and also protects the nerve cord, which lies within its tubelike structure.

2. **Cranium.** The anterior end of the nerve cord elaborates to form a more developed brain that is encased in a protective bony or cartilaginous housing called the **cranium**. This continues the trend of cephalization—the development of the head end in animals.
3. **Endoskeleton of cartilage or bone.** The cranium and vertebral column are parts of the endoskeleton, the living skeleton of vertebrates that forms within the animal's body. Most vertebrates also have two pairs of appendages, such as fins, legs, or arms. The endoskeleton is composed of either bone or cartilage, materials that are very strong yet more flexible than the chitin found in insects and other arthropods.

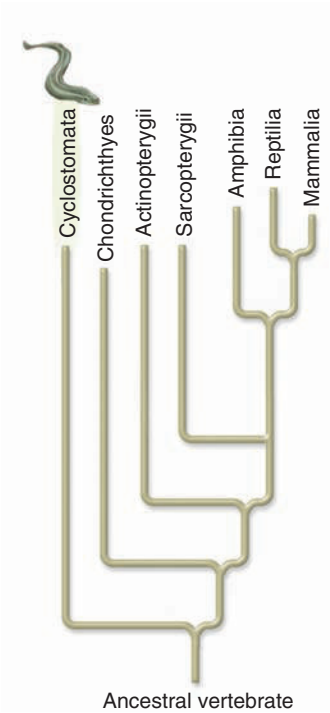
BIO TIPS

THE QUESTION *What derived characters are common to reptiles, amphibians, and lobe-finned fish, but not sharks?*

TOPIC ***What topic in biology does this question address?*** The topic is systematics. More specifically, the question concerns the use of a phylogenetic tree to determine derived characters that are shared between taxa.

INFORMATION ***What information do you know based on the question and you runderstanding of the topic?*** From the question, you know you are comparing ostichythians, tetrapods, and amniotes to chondrichthyans. From your understanding of systematics, which is described in Chapter 26, you may remember the definition of shared derived characters.

PROBLEM-SOLVING STRATEGY ***Make a drawing.*** Look back at Figure 26.9. Draw a table with the derived characters listed on the left side and the major clades across the top. Fill in the table with "Yes" or "No" as in Figure 26.9a, according to whether a clade does or does not possess a derived character.



ANSWER *Reptiles, amphibians, and lobe-finned fish all possess lungs or lung derivatives and lobe fins, but sharks do not.*

Although these are the main distinguishing characteristics of vertebrates, there are others. For example, vertebrates have multiple clusters of *Hox* genes, compared with the single cluster of *Hox* genes in tunicates and lancelets. These additional gene clusters are believed to have permitted increasingly complex morphologies beyond those possessed by invertebrate chordates. Vertebrates also possess a great diversity of internal organs, including a liver, kidneys, endocrine glands, and a heart with at least two chambers. The liver is unique to vertebrates, and the vertebrate kidneys, endocrine system, and heart are more complex than are analogous structures in invertebrate taxa.

Although these features are exhibited in all vertebrate classes, some classes evolved critical innovations that helped them succeed in specific environments such as on land or in the air. For example, birds developed feathers and wings, structures that enable most species to fly. In fact, each of the vertebrate clades is distinctly different from one another, as outlined in **Table 34.1**. One of the earliest innovations was the development of jaws. All vertebrates except some early-diverging fishes possessed jaws. Today, the only jawless vertebrates are hagfish and lampreys, together known as the Cyclostomata. Cyclostomes, or "circle mouths," are eel-like animals that do not possess jaws. In addition, hagfish and lampreys share a very distinct type of immune system. Sequencing of RNA libraries in 2010, together with genomic surveys, yields strong support that the Cyclostomata is monophyletic.

The Hagfish Are the Simplest Living Cyclostomes

The hagfish are entirely marine cyclostomes that lack eyes, jaws, and fins and even vertebrae (**Figure 34.2**). The hagfish skeleton

consists largely of a notochord and a cartilaginous skull that encloses the brain. The lack of a vertebral column leads to extensive flexibility. So how can hagfish be vertebrates without a vertebral column? The strong molecular support for a cyclostome clade suggests that hagfish anatomy has degenerated to a remarkable degree and only the cranium and diversity of organs provide evidence of vertebrate ancestry. Hagfish live in the cold waters of northern oceans, close to the muddy bottom, feeding on marine worms and other invertebrates. Essentially blind, hagfish have a very keen sense of smell and are attracted to dead and dying fish, which they attach themselves to via toothed plates on the mouth. The powerful tongue then rasps off pieces of tissue. Though the hagfish cannot see approaching predators, they have special glands that produce copious amounts of slime. When provoked, the hagfish increases its slime production dramatically, enough to potentially distract predators or coat their gills and interfere with breathing. Hagfish can sneeze to free their nostrils of their own slime.

The Lampreys Are Eel-like Animals That Lack Jaws

Lampreys are similar to hagfish because they lack both a hinged jaw and true appendages. However, lampreys do possess a notochord surrounded by a cartilaginous rod that represents a rudimentary vertebral column. Lampreys can be found in both marine and freshwater environments. Marine lampreys are parasitic as adults. They grasp other fish with their circular mouth (**Figure 34.3a**) and rasp a hole in the fish's side, sucking blood, tissue, and fluids until they are replete (**Figure 34.3b**). Reproduction of all species, whether they live in marine or freshwater environments, is similar. Males and females spawn in freshwater streams, and the resultant larval lampreys bury into the sand or mud, much like lancelets (refer back to Figure 33.36a), emerging to feed on small invertebrates or detritus at night. This stage can last for 3–7 years, at which time the larvae metamorphose into adults. In most freshwater species, the adults do not feed at all but quickly mate and die. Marine species migrate from fresh water back to the ocean, until they return to fresh water to spawn and then die. Although many other species of jawless fishes would evolve and thrive for over 300 million years, they all became extinct by the end of the Devonian period. Jawed fishes, which had appeared in the mid-Ordovician period (about 470 mya), radiated in both fresh and salt water.

Table 34.1 The Main Clades and Characteristics of Living Vertebrates

Clade		Examples (approx. number of species)	Main characteristics
Cyclostomata		Lampreys and hagfish (100)	Jawless fishes, no appendages
Chondrichthyes		Sharks, skates, rays (970)	Fishes with cartilaginous skeleton; teeth not fused to jaw; no swim bladder; well-developed fins; internal fertilization; single blood circulation
Actinopterygii		Ray-finned fishes, most bony fish (27,000)	Fishes with ossified skeleton; single gill opening covered by operculum; fins supported by rays, fin muscles within body; swim bladder often present; mucous glands in skin
Sarcopterygii		Lobe-finned fishes, of which coelacanths (2) and lungfishes (6) are the only living members	Fishes with ossified skeleton; bony extensions, together with muscles, project into pectoral and pelvic fins
Amphibia		Frogs, toads, salamanders (6,346)	Adults able to live on land; fresh water needed for reproduction; development usually involving metamorphosis from tadpoles; adults with lungs and double blood circulation; moist skin; shell-less eggs
Testudines		Turtles (310)	Body encased in hard shell; no teeth; head and neck retractable into shell; eggs laid on land
Squamata		Lizards, snakes (7,900)	Lower jaw not attached to skull; skin covered in scales
Crocodilia		Crocodiles, alligators (23)	Four-chambered heart; large aquatic predators; parental care of young
Aves		Birds (10,000)	Feathers; hollow bones; air sacs; reduced internal organs; endothermic; four-chambered heart
Mammalia		Mammals (5,500)	Mammary glands; hair; specialized teeth; enlarged skull; external ears; endothermic; four-chambered heart; highly developed brains; diversity of body forms

Figure 34.2 **The hagfish.**

34.2 Gnathostomes: Jawed Vertebrates

Learning Outcomes:

1. Describe how jaws evolved.
2. Discuss the distinguishing features of sharks.
3. List the three features that distinguish bony fishes from cartilaginous fishes.
4. Outline the differences between the ray-finned fish and the lobe-finned fish.

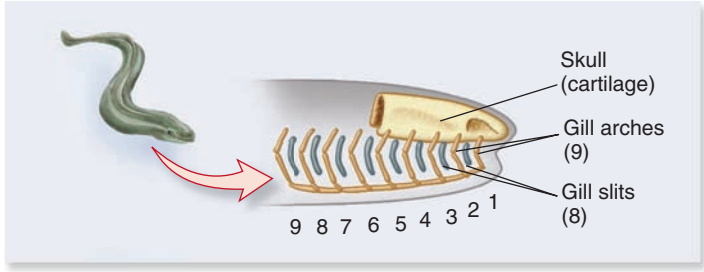
All vertebrate species that possess jaws are called **gnathostomes** (from the Greek, meaning jaw mouth) (see Figure 34.1). Gnathostomes are a diverse clade of vertebrates that include fishes, amphibians, reptiles, and mammals. The earliest-diverging gnathostomes were fishes. Biologists have identified about 28,000 species of living fishes, more than

(a) Jawless mouth of a sea lamprey

(b) A sea lamprey feeding

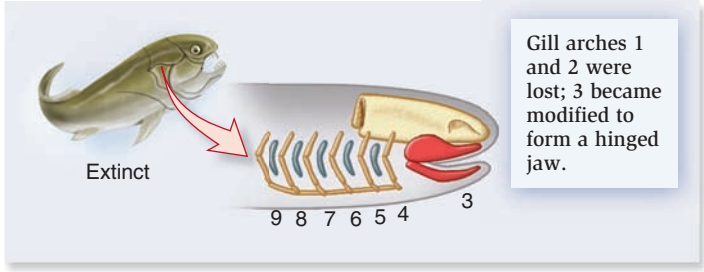
Figure 34.3 The lamprey, a modern jawless fish. **(a)** The sea lamprey (*Petromyzon marinus*) has a circular, jawless mouth. **(b)** A sea lamprey feeding on a fish.

any other clade of vertebrates. Most are aquatic, gill-breathing species that usually possess fins and a scaly skin. There are three separate clades of jawed fishes, each of which has distinguishing characteristics (see Table 34.1): the Chondrichthyes (cartilaginous fishes), Actinopterygii (ray-finned fishes), and Sarcopterygii (coelacanths and lungfishes).



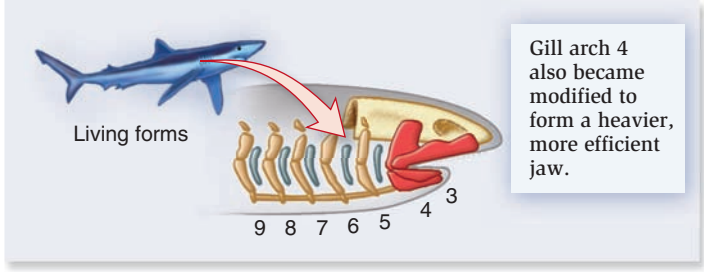
The jawed mouth was a significant evolutionary development. It enabled an animal to grip its prey more firmly, which may have increased its rate of capture, and to attack larger prey species, thus increasing its potential food supply. Accompanying the jawed mouth was the development of more sophisticated head and body structures, including two pairs of appendages called fins. Gnathostomes also possess two *Hox* gene clusters more than do the cyclostomes (bringing their total to four), which led to increased morphological complexity.

The hinged jaw developed from the gill arches, cartilaginous or bony rods that help to support gills. Similarities between cells that make up jaws and gill arches support this view. Primitive jawless fishes had nine gill arches surrounding the eight gill slits (**Figure 34.4a**). During the late Silurian period (about 417 mya), some of these gill arches became modified. The first and second gill arches were lost, and the third and fourth pairs evolved to form the jaws (**Figure 34.4b** and **c**). This is how evolution typically works; body features do not appear de novo, but instead, existing features become modified to serve other functions.



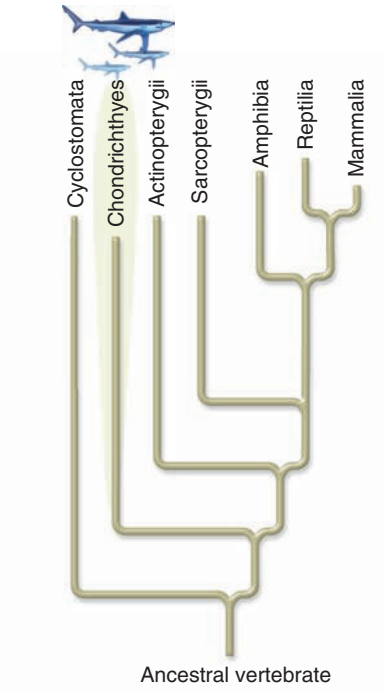
By the mid-Devonian period, two classes of jawed fishes, the Acanthodii (spiny fishes) and Placodermi (armored fishes) were common. Some of the placoderms were huge individuals, over 9 m long. Both classes died out by the end of the Devonian as part of one of several mass extinctions that occurred in the Earth's geological and biological history. The reasons for this extinction are not well understood, but other types of jawed fishes present at the same time—the cartilaginous and bony fishes—did not go extinct and in fact flourished in the aftermath of the extinction.

Chondrichthyans Are Fishes with Cartilaginous Skeletons



Members of the clade Chondrichthyes (the **chondrichthyans**)—sharks, skates, and rays—are also called cartilaginous fishes because their skeleton is composed of flexible cartilage rather than bone. The cartilaginous skeleton is not considered an ancestral character but rather a derived character. This means that the ancestors of the

(a) Primitive jawless fishes

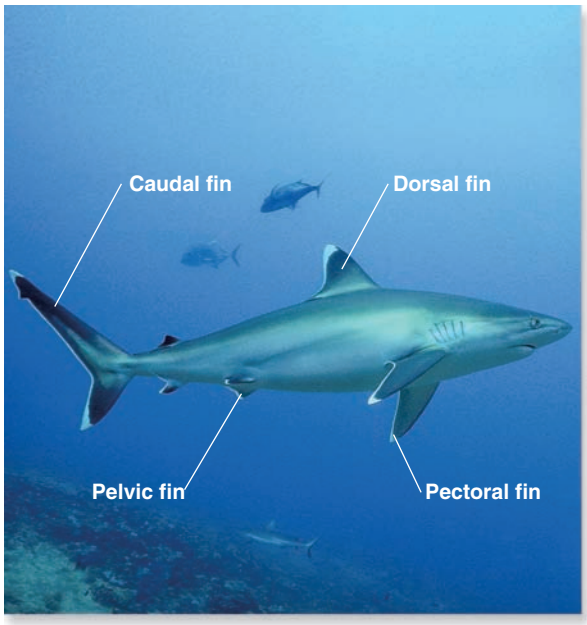


(b) Early jawed fishes (placoderms)

(c) Modern jawed fishes (cartilaginous and bony fishes)

Figure 34.4 The evolution of the vertebrate jaw. **(a)** Primitive fishes and extant jawless fishes such as lampreys have nine cartilaginous gill arches that support eight gill slits. **(b)** In early jawed fishes such as the placoderms, the first two pairs of gill arches were lost, and the third pair became modified to form a hinged jaw. This left six gill arches (4–9) to support the remaining five gill slits, which were still used in breathing. **(c)** In modern jawed fishes, the fourth gill arch also contributes to jaw support, allowing more powerful bites to be delivered.

BIOLOGY PRINCIPLE Structure determines function. The development of a jaw increased the predatory capabilities of gnathostomes.



chondrichthyans had bony skeletons, but that members of this class subsequently lost this feature. This hypothesis is reinforced by the observation that during development, the skeleton of most vertebrates is cartilaginous, and then it becomes bony (ossified) as a hard calcium-phosphate matrix replaces the softer cartilage. A change in the developmental sequence of the cartilaginous fishes is believed to prevent the ossification process.

Chondrichthyan Body Plan

All chondrichthyans are denser than water, which theoretically means that they would sink if they stopped swimming. Many sharks never stop swimming and maintain buoyancy via the use of their fins and a large oil-filled liver. Perhaps the most important fin for propulsion is the large and powerful caudal fin, or tail fin, which, when swept from side to side, thrusts the fish forward at great speed (**Figure 34.5a**). For example, great white sharks (*Carcharodon carcharias*) can swim at over 40 km per hour, and Mako sharks (*Isurus oxyrinchus*) have been clocked at nearly 50 km per hour. The paired pelvic fins (at the back) and pectoral fins (at the front) act like flaps on airplane wings, allowing the shark to dive deeper or rise to the surface. They also aid in steering. In addition, the dorsal fin (on the shark's back) acts as a stabilizer to prevent the shark from rolling in the water as the tail fin pushes it forward. Skates and rays are essentially flattened sharks that cruise along the ocean floor, using hugely expanded pectoral fins. In addition, their thin, whiplike tails are often equipped with a venomous barb used in defense (**Figure 34.5b**). Most of the 475 or so species of skates and rays feed on bottom-dwelling crustaceans and mollusks.

During swimming, water continually enters the mouth and is forced over the gills, allowing sharks to extract oxygen and breathe. How then do skates and rays breathe when they rest on the ocean floor? These species, and a few sharks such as the nurse shark, use a muscular pharynx and jaw muscles to pump water over the gills. In these and indeed in all species of fishes, the heart consists of two chambers, an atrium and a ventricle, that contract in sequence. They employ what is known as a single circulation, in which blood is pumped from the heart to capillaries in the gills to collect oxygen, and then it flows through arteries to the tissues of the body, before returning to the heart (look ahead to Figure 47.3a).

Sharks were among the earliest fishes to develop teeth. Shark teeth evolved from rough scales on the skin that contained dentin and enamel. Although shark's teeth are very sharp and hard, they are not set into the jaw, as are human teeth, so they break off easily. Teeth are

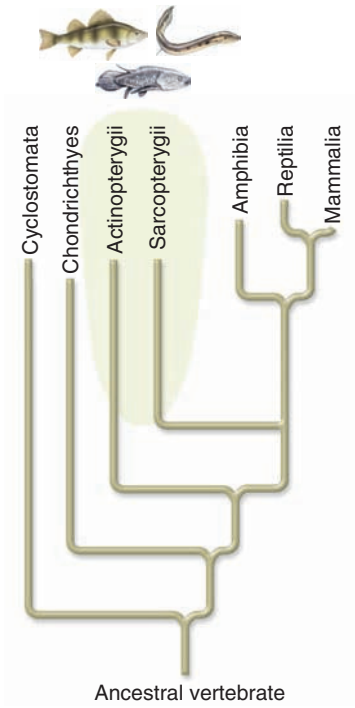
BioConnections: *Are "fish" a monophyletic group?*

continually replaced, row by row (**Figure 34.5c**). Sharks may have 20 rows of teeth, with the front pair in active use and the ones behind ready to grow in as replacements when needed.



Chondrichthyan Senses Sharks have a powerful sense of smell, facilitated by sense organs in the nostrils (sharks and other fishes do not use nostrils for breathing). They can see well but cannot distinguish colors. Although sharks have no eardrum, they can detect pressure waves generated by moving objects. All jawed fishes have a row of microscopic organs in the skin, arranged in a line that runs laterally down each side of the body, that can sense movements in the surrounding water. This system of sense organs, known as the **lateral line**, senses pressure waves and sends nervous signals to the inner ear and then on to the brain. Sharks have an extra sense that helps them find and track prey. The ampullae of Lorenzini, vesicles and pores found around the shark's head, are sensory organs that detect electromagnetic fields produced by other organisms.

The Chondrichthyan Life Cycle Fertilization is internal in chondrichthyans, with the male transferring sperm to the female via a pair of **claspers**, modifications of the pelvic fins. Some shark species are **oviparous**; that is, they lay eggs, often inside a protective pouch called a mermaid's purse (**Figure 34.5d**). In **ovoviparous** species, the eggs are retained within the female's body, but there is no placenta to nourish the young. A few species are **viviparous**; the eggs develop within the uterus, receiving nourishment from the mother via a placenta. Both ovoviparous and viviparous sharks give birth to live young.

Osteichthyans Are Fishes with Bony Skeletons

Unlike the cartilaginous fishes, all other gnathostomes have a bony skeleton and belong to the clade known as osteichthyes. This term means "bony fish" and was originally proposed for just that group. With the advent of modern phylogenetic systematics, the term **osteichthyans** expanded to include all vertebrates with a bony skeleton, including tetrapods (refer back to Figure 34.1).

Bony fishes are the most numerous of all types of fishes, with more individuals and more species (about 27,000) than any other.

Most authorities now recognize two living clades: the Actinopterygii (ray-finned fishes) and the Sarcopterygii (lobe-finned fishes).

Osteichthyan Body Plan Fishes in both clades possess a bony skeleton and scale-covered skin. The skin of bony fishes, unlike the rough skin of sharks, is covered by a thin epidermal layer containing glands that produce mucus, an adaptation that reduces drag during swimming. Just as in the cartilaginous fishes, water is drawn over the gills for breathing, but in bony fishes, a protective flap called an **operculum** covers the gills (**Figure 34.6**). Muscle contractions around the gills and operculum draw water across the gills so that bony fishes do not need to swim continuously to breathe. Some early bony fishes lived in shallow, oxygen-poor waters and developed lungs as an embryological offshoot of the pharynx. These fish could rise to the water surface and gulp air. As we will see, modern lungfishes operate in much the same fashion. Many other fishes, known as bimodal breathers, can breathe through their gills and by gulping air, absorbing oxygen through their digestive tracts or accessory organs. For example, Siamese fighting fish (*Betta splendens*, known as betta), a popular freshwater aquarium fish, is a bimodal breather that is relatively easy to care for, since it can survive without an air pump in its aquarium. In most bony fishes, the lungs evolved into a **swim bladder**, a gas-filled, balloon-like structure that helps the fish remain buoyant in the water even when it is completely stationary. In early-diverging bony fishes, the gut and swim bladder are connected

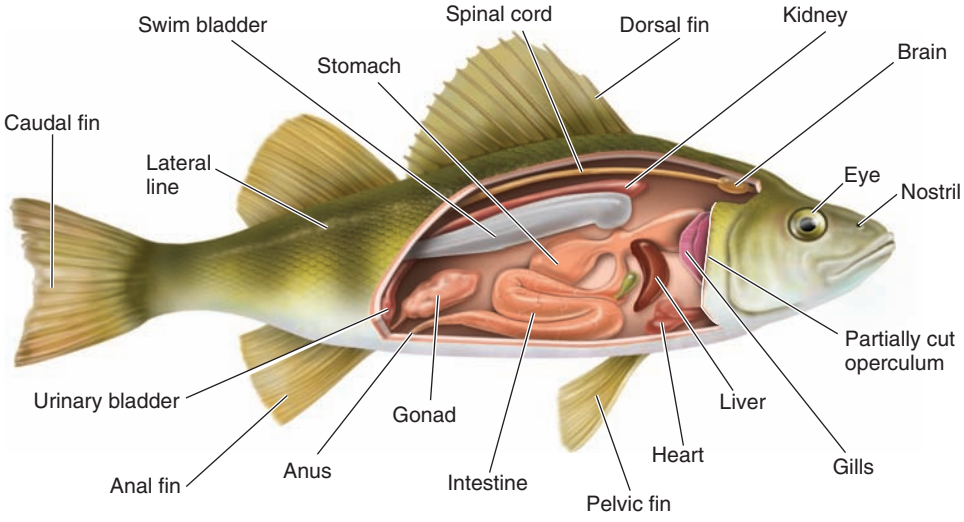


Figure 34.6 Generalized body plan of a bony fish. Bony fish possess a swim bladder and an operculum that covers the gills.

Concept Check: *What features distinguish ray-finned fishes from sharks?*

via a duct, and the fishes can fill their swim bladder by gulping air. In later-diverging species, the swim bladder is connected to the circulatory system, and gases are transported in and out of the blood, allowing the fishes to change the volume of the swim bladder and so to rise and sink. Therefore, unlike the sharks, many bony fishes can remain motionless and use a "sit-and-wait" ambush style. These three features—bony skeleton, operculum, and swim bladder—distinguish bony fishes from cartilaginous fishes.

Osteichthyan Reproduction and Diversity Reproductive strategies of bony fishes vary tremendously, but most species reproduce via external fertilization, with the female shedding her eggs and the male depositing sperm on top of them. Although adult bony fishes can maintain their buoyancy, their eggs tend to sink. This is why many species spawn in shallow, more oxygen- and food-rich waters and why coastal areas are important fish nurseries.

Bony fishes have colonized nearly all aquatic habitats. Following the cooling of the newly formed Earth, water condensed into rain and over a vast period of time filled what are now the oceans. Later, as water evaporated from the oceans and sodium, potassium, and calcium were added via runoff from the land, the oceans became salty. Therefore, most fishes probably evolved in freshwater habitats and secondarily became adapted to marine environments. This, of course, required the development of physiological adaptations to the different osmotic problems seawater presents compared with fresh water (look ahead to Figure 49.2).

Actinopterygii, the Ray-Finned Fish The most species-rich clade of bony fishes is the Actinopterygii, or **ray-finned fishes**, which includes all bony fishes except the coelacanths and lungfishes. In Actinopterygii, the fins are supported by thin, bony, flexible rays and are moved by muscles on the interior of the body. The clade has a diversity of forms, from lionfish and large predatory moray eels to delicate sea dragons (**Figure 34.7**). Whole fisheries are built around the harvest of species such as cod, anchovies, and salmon.

Sarcopterygii, the Lobe-Finned Fish The Actinistia (coelacanths) and Dipnoi (lungfishes) are both considered Sarcopterygii, or **lobe-finned fishes**. The name Sarcopterygii used to refer solely to the lobe-finned fishes, but since it has become clear that terrestrial vertebrates (tetrapods) evolved from such fishes, the definition of the group has been expanded to include both lobe-finned fishes and tetrapods (see Figure 34.1). In the lobe-finned fishes, the fins are supported by skeletal extensions of the pectoral and pelvic areas that are moved by muscles within the fins.

The fossil record revealed that the Actinistia, or coelacanths, were a very successful group in the Devonian period, but all fishes of the class were believed to have died off at the end of the Mesozoic era (some 65 mya). You can therefore imagine the scientific excitement when in 1938, a modern coelacanth was discovered as part of the catch of a boat fishing near the Chalumna River in South Africa (**Figure 34.8a**). Intensive searches in the area revealed that coelacanths were living in deep waters off the southern African coast and especially off a group of islands near the coast of Madagascar called the Comoros Islands. Another species was found more recently in Indonesian waters.

Early-diverging lobe-finned fishes probably evolved in fresh water and had lungs, but the coelacanth lost lungs and returned to the sea. One distinctive feature of this group is a special joint in the skull that allows the jaws to open extremely wide and gives the coelacanth a powerful bite. As further evidence of the coelacanth's unusual body plan, its swim bladder is filled with oil rather than gas, although it serves a similar purpose—to increase buoyancy.

The Dipnoi, or **lungfishes**, like the coelacanths, are also not currently a very species-rich group, having just three genera and six species (**Figure 34.8b**). Lungfishes live in oxygen-poor freshwater swamps and ponds. They have both gills and lungs, the latter of which enable them to come to the surface and gulp air. In fact, lungfish will drown if they are unable to breathe air. When ponds dry out, some species of lungfish can dig a burrow and survive in it until the next rain. Because they also have muscular lobe fins, they are often able to successfully traverse quite long distances over shallow-bottomed lakes that may be drying out.

The morphological features of coelacanths, lungfishes, and primitive terrestrial vertebrates, together with the similarity of their nuclear genes, suggest to many scientists that lobe-fin ancestors gave

Figure 34.8 The Sarcopterygii (lobe-finned fish). (a) An actinisian, the coelacanth (*Latimeria chalumnae*). **(b)** A dipnoi, the Australian lungfish (*Neoceratodus forsteri*).

Concept Check: How are lungfishes similar to coelacanths?

rise to three lineages: the coelacanths, the lungfishes, and the tetrapods. In the next section, we will examine the biology of tetrapods in more detail.

34.3 Tetrapods: Gnathostomes with Four Limbs

Learning Outcomes:

1. List adaptations that the transition to life on land required.
2. List the amphibian orders, and describe the features that differentiate them.
3. **SciSKILLS** » Explain how relatively simple experiments with mice showed that mutations in just two genes can cause large changes in limb development.

During the Devonian period (from about 417 to 354 mya), a diversity of plants and animals colonized the land. The plants served as both a source of oxygen and a potential food source for animals that ventured out of the aquatic environment. Terrestrial arthropods appeared during the Devonian, as did the first land-living vertebrates.

The transition to life on land involved a large number of adaptations. Paramount among these were adaptations preventing desiccation and making locomotion and reproduction on land possible. We have seen that some fish evolved the ability to breathe air. In this section, we begin by outlining the development of the **tetrapods**, vertebrate animals having four legs or leglike appendages. We will discuss the first terrestrial vertebrates and their immediate descendants, the amphibians. We will then explore the characteristic features and diversity of modern amphibians.

The Origin of Tetrapods Involved the Development of Four Limbs

Over the Devonian period, the fossil records demonstrate the evolution of sturdy lobe-finned fishes to fishes with four limbs. The abundance of light and nutrients in shallow waters encouraged a profusion of plant life and the invertebrates that fed on them. The development of lungs enabled lungfishes to colonize these productive yet often oxygen-poor waters. Here, the ability to move in shallow water clogged with plants and debris was more vital than the ability to swim swiftly through open water and may have favored the progressive development of sturdy limbs. As an animal's weight began to be borne more by the limbs, the vertebral column strengthened, and hip bones and shoulder bones were braced against the backbone for added strength. Such modifications are the result of changes in the expression of genes, especially *Hox* genes (see the Feature Investigation). In particular, *Hox* genes 9–13 work together to specify limb formation from proximal to distal, meaning from close to the point of attachment to the body to the terminal end of the limb (**Figure 34.9**; see also Figure 19.17).

Early Transitional Amphibians One of the transitional forms between fish and tetrapods was *Tiktaalik roseae*, nicknamed fishapod (refer back to Figure 23.5). Fishapods had broad skulls with eyes mounted on the top; lungs; and pectoral fins with five fingerlike bones. This is an important species, for it represents a transitional form, displaying an intermediate state between an ancestral form and the form of its descendants. Eventually, species more like modern amphibians evolved, species that were still tied to water for reproduction but increasingly lived on land. In these species, the vertebral column, hip bones, and shoulder bones grew sturdier. Such

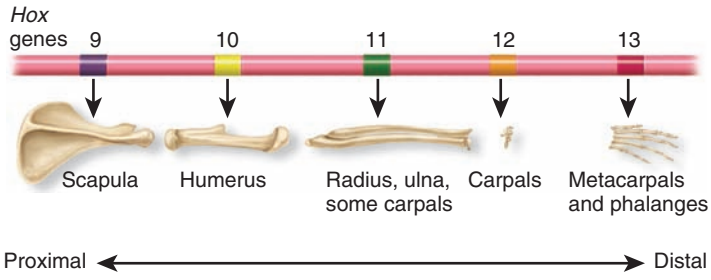

Figure 34.9 The roles of *Hox* genes 9–13 in specifying limb formation from proximal to distal. The axis of limb development in mice is shown, together with the associated genes.

changes were needed as the animal's weight was no longer supported by water but was borne entirely on the limbs.

By the middle of the Carboniferous period (about 320 mya), species similar to modern amphibians had become common in the terrestrial environment. For example, *Cacops* was a large amphibian, as big as a pony (**Figure 34.10**). Its skin was heavy and tough, an adaptation that helped prevent water loss; its breathing was accomplished more by lungs than by skin; and it possessed **pentadactyl limbs** (limbs ending in five digits). With a bonanza of terrestrial arthropods to feast on, the amphibians became very numerous and species rich, and the mid-Permian period (some 260 mya) is sometimes known as the Age of Amphibians. However, most of the large amphibians became extinct at the end of the Permian period. This was the largest known mass extinction in Earth's history, with the extinction of 90–95% of marine species and a large proportion of terrestrial species. Most surviving amphibians were smaller organisms resembling modern species.

Figure 34.10 A primitive tetrapod. *Cacops* was a large, early amphibian of the Permian period.

Concept Check: *What were the advantages to animals of moving onto land?*

Feature Investigation | Davis and Colleagues Provided a Genetic-Developmental Explanation for Limb Length in Tetrapods

The development of limbs in tetrapods was a vital step that allowed animals to colonize land. The diversity of vertebrate limb types is amazing, from fins in fish and marine mammals to different wing types in bats and birds to legs and arms in primates. Early in vertebrate evolution, an ancestral gene complex was duplicated twice to give rise to four groups of genes, called *HoxA*, *B*, *C*, and *D*, which control limb development. In 1995, Allen Davis, Mario Capecchi, and colleagues analyzed the effects of mutations in specific *Hox* genes that are responsible for determining limb formation in mice. The vertebrate forelimb is divided into three zones: humerus (upper arm); radius and ulna (forearm); and carpals, metacarpals, and phalanges (digits). The researchers had no specific hypothesis in mind; their goal was to understand the role of *Hox* genes in limb formation. As described in **Figure 34.11**, they began with strains of mice carrying loss-of-function mutations in *HoxA-11* or *HoxD-11* that, on their own, did not cause dramatic changes in limb formation. They bred the mice and obtained offspring carrying one, two, three, or four loss-of-function mutations. Double mutants exhibited dramatically different phenotypes not seen in mice homozygous for the individual mutations. The radius and ulna were almost entirely eliminated.

As seen in the data, the mutations affected the formation of limbs. For example, the wrist contains seven bones: three proximal carpals—called navicular lunate (NL), triangular (T), and pisiform (P)—and four distal carpals (d1–d4). In mice with the genotypes *aaDD* and *AAdd*, the proximal carpal bones are usually fused together. Individuals having one recessive allele (*AADd* and *AaDD*) do not show this defect, but individuals having two recessive alleles (*AaDd*) often do. Therefore, any two mutant alleles (either from both *HoxA-11* and *HoxD-11* or one from each locus) cause carpal fusions. Deformities became even more severe with three mutant alleles (*Aadd* or *aaDd*) or four mutant alleles (*aadd*) (data not shown in the figure). Thus, the researchers showed that relatively simple mutations can control relatively large changes in limb development.

Figure 34.11 Relatively simple changes in *Hox* genes control limb formation in tetrapods.

GOAL To determine the role of *Hox* genes in limb development in mice.

KEY MATERIALS Mice with individual mutations in *HoxA-11* and *HoxD-11* genes.

	Experimental level	Conceptual level
1 Breed mice with individual mutations in *HoxA-11* and *HoxD-11* genes. (The *A* and *D* refer to wild-type alleles; *a* and *d* are mutant alleles.)	 *AaDd* mice The mice bred were heterozygous for both genes (*AaDd*).	Based on previous studies, researchers expect mutant mice to produce viable offspring, perhaps with altered limb morphologies.

2 Using molecular techniques described in Chapter 20, obtain DNA from the tail and determine the genotypes of offspring.

The resulting genotypes occur in Mendelian ratios, generating mice with different combinations of wild-type and mutant alleles.

	(AD)	(Ad)	(aD)	(ad)
(AD)	*AADD*	*AADd*	*AaDD*	*AaDd*
(Ad)	*AADd*	*AAdd*	*AaDd*	*Aadd*
(aD)	*AaDD*	*AaDd*	*aaDD*	*aaDd*
(ad)	*AaDd*	*Aadd*	*aaDd*	*aadd* ← Double mutant

9:3:3:1 phenotypic ratio expected a two-factor cross

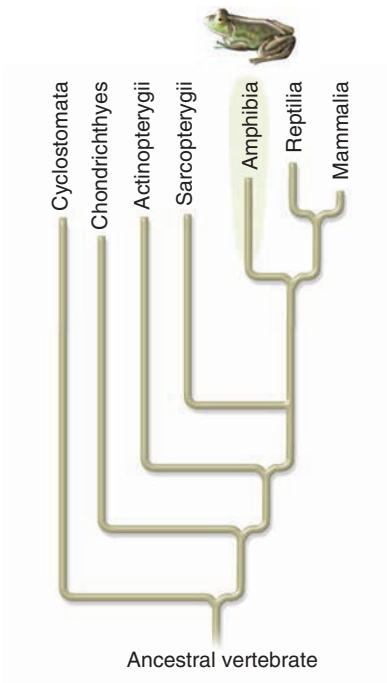
3 Stain the skeletons and compare the limb characteristics of the wild-type mice (*AADD*) to those of strains carrying mutant alleles in one or both genes.

Mutant mice may have altered bone morphologies.

4 THE DATA

Genotype	Carpal bone fusions (% of mice showing the fusion)			
	Normal (none fused)	NL fused to T	T fused to P	NL fused to T and P
AADD	100	0	0	0
AaDD	100	0	0	0
aaDD	33	17	50	0
AADd	100	0	0	0
AAdd	0	17	17	67
AaDd	17	17	33	33

5 CONCLUSION Relatively simple mutations involving two genes can cause large changes in limb development.



6 SOURCE Davis, A.P. et al. 1995. Absence of radius and ulna in mice lacking *Hoxa-11* and *Hoxd-11*. *Nature* 375:791–795.

Experimental Questions

1. What was the purpose of the study conducted by Davis and colleagues?
2. **SciSKILLS »** Explain how the researchers were able to study the effects of individual genes.
3. **SciSKILLS »** Summarize the results of the experiment, and explain how they relate to limb development in vertebrates.

Amphibian Lungs Are an Adaptation to a Semiterrestrial Lifestyle

Amphibians (from the Greek *amphibios*, meaning both ways of life) live in two worlds: They have successfully invaded the land, but most must return to the water to reproduce. One of the first challenges terrestrial animals had to overcome was breathing air when on land. Amphibians use the same technique as lungfishes: They open their mouths to let in air. Alternatively, they may take in air through their nostrils. They then close and raise the floor of the mouth, creating a positive pressure that pumps air into the lungs. This method of breathing is called **buccal pumping**. In addition, the skin of amphibians is much thinner than that of fishes, and amphibians absorb oxygen from the air directly through their outer moist skin or through the skin lining of the inside of the mouth or pharynx.

Amphibians have a three-chambered heart, with two atria and one ventricle. One atrium receives blood from the body, and the other receives blood from the lungs. Both atria pump blood into the single ventricle, which pumps some blood to the lungs and some to the rest of the body (look ahead to Figure 47.3b). This form of circulation allows the tissues to receive well-oxygenated blood at a higher pressure than is possible via single circulation, because some of the blood that returns to the heart is directly pumped to the tissues without being slowed down by passage through the lung capillaries. Oxygenated and deoxygenated bloods are kept somewhat separate, which enhances the delivery of nutrients and oxygen to the tissues.

Amphibian Reproduction Because the skin of amphibians is so thin, these animals face the problem of desiccation, or drying out. As a consequence, even amphibian adults are more abundant in damp habitats, such as swamps or rain forests, than in dry areas. Also, most amphibians cannot venture too far from water because their larval stages are aquatic. In frogs and toads, fertilization is generally external, with males shedding sperm over the gelatinous egg masses laid by the females in water (**Figure 34.12a**). The fertilized eggs lack a shell and would quickly dry out if exposed to the air. They soon hatch into tadpoles (**Figure 34.12b**), small fishlike animals that lack limbs and breathe through gills. As the tadpole nears the adult stage, the tail and gills are resorbed, and limbs and lungs appear (**Figure 34.12c**). Such a dramatic change in body form, from juvenile to adult, is known as **metamorphosis**. A few species of amphibians do not require water to reproduce. These species are ovoviparous or viviparous—retaining the eggs in the reproductive tract and giving birth to live young.

Modern Amphibians Include a Variety of Frogs, Toads, Salamanders, and Caecilians

Approximately 6,300 living amphibian species are known, and the vast majority of these, some 5,600 species, are frogs and toads of the order **Anura** (from the Greek, meaning tail-less ones) (**Figure 34.13a**). The other two orders are the **Apoda** (from the Greek, meaning legless ones), the wormlike caecilians; and the **Urodela** (from the Latin, meaning tailed ones), the salamanders. Global warming is currently threatening many anurans with extinction.

Adult anurans are carnivores, eating a variety of invertebrates by catching them on a long, sticky tongue. In contrast, the aquatic larvae (tadpoles) are primarily herbivores. Frogs generally have smooth, moist skin and long hind legs, making them excellent jumpers and swimmers. In addition to secreting mucus, which keeps their skin moist, some frogs can also secrete poisonous chemicals that deter would-be predators. Some amphibians advertise the poisonous nature of their skin with warning coloration (look ahead to Figure 57.9b). Others use camouflage as a way of avoiding detection by predators. Toads have a drier, bumpier skin and shorter legs than frogs. They are less impressive leapers than frogs, but toads can better tolerate drier conditions.

(b) Tadpole

(c) Tadpole undergoing metamorphosis

Figure 34.12 **Amphibian development in the wood frog (*Rana sylvatica*).** **(a)** Amphibian eggs are laid in gelatinous masses in water. **(b)** The eggs develop into tadpoles, aquatic herbivores with a fishlike tail that breathe through gills. **(c)** During metamorphosis, the tadpole loses its gills and tail and develops limbs and lungs.

BioConnections: *Look ahead to Figure 48.3. Do frogs breathe through their skin while they are underwater?*

(a) Tree frog

(b) A caecilian

(c) Mud salamander

Figure 34.13 Amphibians. **(a)** Most amphibians are frogs and toads of the order Anura, including this red-eyed tree frog (*Agalychnis callidryas*). **(b)** The order Apoda includes wormlike caecilians such as this species from Ecuador, *Siphonops annulatus*. **(c)** The order Urodela includes species such as this mud salamander (*Pseudotriton montanus*).

Concept Check: *Do all amphibians produce tadpoles?*

Caecilians (order Apoda) are a small order of about 170 species of legless, nearly blind amphibians (**Figure 34.13b**). Most are tropical and burrow in forest soils, but a few live in ponds and streams. They are secondarily legless, which means they evolved from legged ancestors. Caecilians have tiny jaws equipped with teeth and eat worms and other soil invertebrates. In this order, fertilization is internal, and females usually bear live young. The young are nourished inside the mother's body by a thick, creamy secretion known as uterine milk. In most caecilian species, the young grow into adults about 30 cm long, though species up to 1.3 m in length are known.

The salamanders (order Urodela, about 570 species) possess a tail and have a more elongate body than anurans (**Figure 34.13c**). During locomotion, they seem to sway from side to side, perhaps reminiscent of how the earliest tetrapods may have walked. Like frogs, salamanders often have colorful skin patterns that advertise their distastefulness to predators. Salamanders retain their moist skin by living in damp areas under leaves or logs or beneath lush vegetation. They generally range in size from 10 to 30 cm. Fertilization is usually internal, with females using their cloaca, a common opening for the digestive and urogenital tracts, to pick up sperm packets deposited by males. A very few salamander species do not undergo metamorphosis, and the newly hatched young resemble tiny adults. However, some species, such as Cope's giant salamander (*Dicamptodon copei*), retain the gills and tail fins characteristic of the larval stage into adulthood, and mature sexually in the larval stage, a phenomenon known as paedomorphosis.

34.4 Amniotes: Tetrapods with a Desiccation-Resistant Egg

Learning Outcomes:

1. Diagram the structure of the amniotic egg.
2. Identify the critical innovations of the amniotes.
3. Describe the distinguishing features of the major amniote classes.
4. List the features that allowed birds to fly.

Although amphibians live successfully in a terrestrial environment, they must lay their eggs in water or in a very moist place, so the shell-less eggs do not dry out on exposure to air. Thus, a critical innovation in animal evolution was the development of a shelled egg that sheltered the embryo from desiccating conditions on land. A shelled egg containing fluids was like a personal enclosed pond for each developing individual. Such an egg evolved in the common ancestor of turtles, lizards, snakes, crocodiles, birds, and mammals—a group of tetrapods collectively known as the **amniotes**. The amniotic egg permitted animals to lay their eggs in a dry place so that reproduction was no longer tied to water. It was truly a critical innovation, untethering animals from water in much the same way as the development of seeds liberated plants from water (see Chapter 29).

In time, the amniotes became very diverse in species and morphology. Mammals are considered amniotes, too, because even though most of them do not lay eggs, they retain other features of amniotic reproduction. In this section, we begin by discussing in detail the morphology of the amniotic egg and other adaptations that permitted animal species to become fully terrestrial. We will then discuss the biology of the reptiles, the first group of vertebrates to fully exploit land.

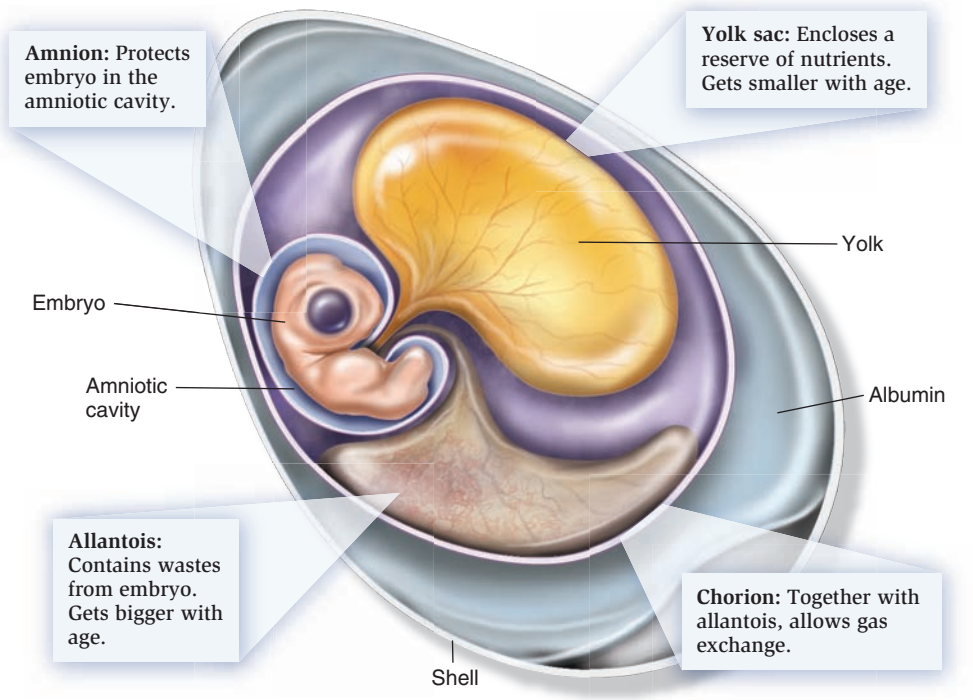
The Amniotic Egg and Other Innovations Permitted Life on Land

The **amniotic egg** (**Figure 34.14**) contains the developing embryo and the four separate extraembryonic membranes that it produces:

1. The innermost membrane is the **amnion**, which protects the developing embryo in a fluid-filled sac called the amniotic cavity.
2. The **yolk sac** encloses a stockpile of nutrients, in the form of yolk, for the developing embryo.
3. The **allantois** functions as a disposal sac for metabolic wastes.
4. The **chorion**, along with the allantois, provides gas exchange between the embryo and the surrounding air.

Surrounding the chorion is the albumin, or egg white, which also stores nutrients. The **shell** provides a tough, protective covering that is not very permeable to water and prevents the embryo from drying out. However, the shell remains permeable to oxygen and carbon dioxide, so the embryo can breathe. In birds, this shell is hard and calcareous, whereas in reptiles and early-diverging mammals such as the platypus and echidna, it is soft and leathery. In most mammals, however, the embryos embed into the wall of the uterus and receive their nutrients directly from the mother.

Along with the amniotic egg, other critical innovations that enabled animals' conquest of land include the following:



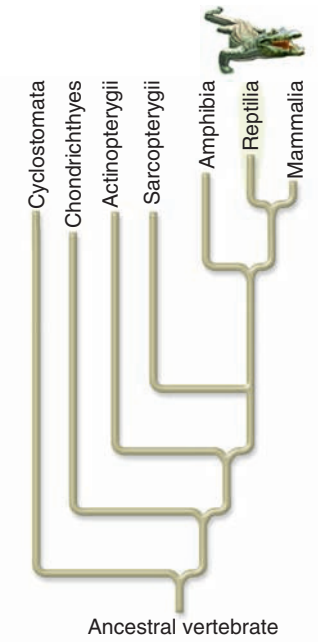


Figure 34.14 **The amniotic egg.**

Concept Check: *What are the other critical innovations of amniotes?*

- **Desiccation-resistant skin.** Whereas the skin of amphibians is moist and aids in respiration, the skin of amniotes is thicker and water resistant and contains keratin, a tough protein. As a result, most gas exchange takes place through the lungs.
- **Thoracic breathing.** Amphibians use buccal pumping to breathe, contracting the mouth to force air into the lungs. In contrast, amniotes use thoracic breathing, in which coordinated contractions of muscles expand the rib cage, creating a negative pressure to suck air in and then forcing it out later. This results in a greater volume of air being displaced with each breath than with buccal pumping.
- **Water-conserving kidneys.** The ability to concentrate wastes prior to elimination and thus conserve water is an important role of the amniotic kidneys.
- **Internal fertilization.** Because sperm cannot penetrate a shelled egg, fertilization occurs internally, within the female's body before the shell is secreted. In this process, the male of the species often uses a copulatory organ (penis) to transfer sperm into the female reproductive tract. However, birds usually transfer sperm from cloaca to cloaca.

Reptiles Include Turtles, Lizards, Snakes, Crocodilians, Dinosaurs, and Birds

Early amniote ancestors gave rise to all modern amniotes that exist today, from lizards and snakes to birds and mammals. The traditional view of amniotes identified three living classes: the reptiles (turtles, lizards, snakes, and crocodilians), birds, and mammals. As we will see later in the chapter, modern systematists have argued that enough similarities exist between birds and the classic reptiles that birds should be considered part of the reptilian lineage. This is the classification scheme that we will follow in this chapter. The fossil record includes other reptilian clades, all of which are extinct, including two clades of dinosaurs (ornithischian and saurischian dinosaurs), flying reptiles (pterosaurs), and two clades of ancient aquatic reptiles (icthyosaurs and plesiosaurs).

Testudines: The Turtles Turtles is an umbrella term for terrestrial species, also called tortoises, and aquatic species, sometimes known as terrapins. The turtle lineage is ancient and has remained virtually unchanged for 200 million years. The major distinguishing characteristic of the turtles is a hard protective shell into which the animal can withdraw its head and limbs. In most species, the vertebrae and ribs are fused to form this shell. All turtles lack teeth but have sharp beaks for biting.

Most turtles are aquatic and have webbed feet. The forelimbs of marine species have evolved to become large flippers. All turtles, even the aquatic species, lay their eggs on land, usually in soft sand. The gender of hatchlings is dependent on temperature, with high temperatures producing more females. Marine species often make long migrations to sandy beaches to lay their eggs (**Figure 34.15a**). Most land turtles are quite slow movers, possibly due to a low metabolic rate and

(a) Green turtle

(b) Common collared lizard

(c) Juvenile tree python

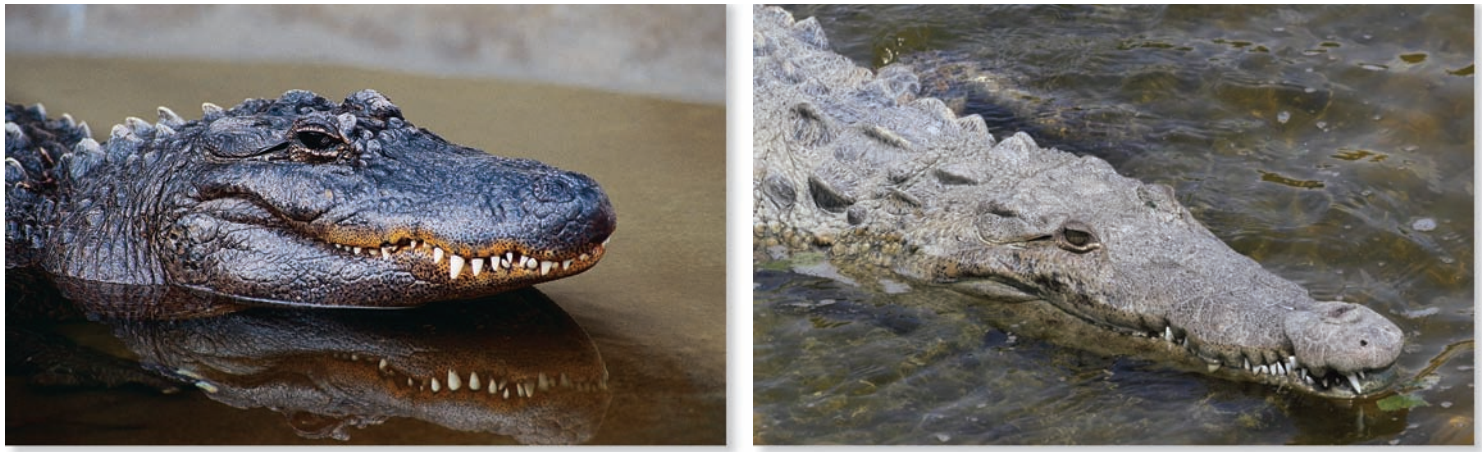
Figure 34.15 A variety of reptiles. **(a)** A green turtle (*Chelonia mydas*) laying eggs in the sand in Malaysia. **(b)** The common collared lizard (*Crotaphytus collarus*). **(c)** The juvenile tree python (*Morelia veridis*).

a heavy shell. However, they are very long-lived species, often surviving for 120 years or more. Furthermore, turtles do not appear to show reproductive senescence or aging, reproducing continually throughout their lifetime. Most organs such as the liver, lungs, and kidneys of a centenarian turtle function as effectively as do organs in young individuals, prompting genetic researchers to examine the turtle genome for longevity genes. Many turtle species are in danger of extinction, due to egg hunting, harvesting for shells or meat, destruction of habitat and nesting sites, and death in fishing nets.

Squamata: Lizards and Snakes The clade **Squamata** is the largest clade within the traditional reptiles, with about 4,900 species of lizards and 3,000 species of snakes. Many species have an elongated body form. One of the defining characteristics of the orders is a **kinetic skull**, in which the joints between various parts of the skull are extremely mobile. The lower jaw does not join directly to the skull but rather is connected by a multijointed hinge, and the upper jaw is hinged and movable from the rest of the head. This allows the jaws to open relatively wider than other vertebrate jaws, with the result that lizards, and especially snakes, can swallow large prey (**Figure 34.16**). Nearly all species are carnivores.

A main difference between lizards and snakes is that lizards generally have limbs, whereas snakes do not (**Figure 34.15b, c**). Legglessness is a derived condition, meaning snake ancestors possessed legs but later lost them. Also, snakes may be venomous, whereas lizards usually are not.

Crocodilia: The Crocodiles and Alligators The Crocodilia is a small clade of large, carnivorous, aquatic animals that have remained essentially unchanged for nearly 200 million years (**Figure 34.17**). Indeed, these animals existed at the same time as the dinosaurs. Most of the 23 recognized species live in tropical or subtropical regions. There are only two extant species of alligators: one living in the southeastern U.S. and one found in China.



Although the group is small, it is evolutionarily very important. Crocodiles have a four-chambered heart, a feature they share with birds and mammals (look ahead to Figure 47.3c). In this regard, crocodiles are more closely related to birds than to any other living reptiles. Their teeth are set in sockets, a feature typical of the dinosaurs and the earliest birds. Similarly, crocodiles care for their young, another trait they have in common with birds. These and other features suggest that crocodiles and birds are more closely related than crocodiles and lizards. As with turtles, the gender of crocodiles' offspring is dependent on nest temperature.

Ornithischia and Saurischia: The Dinosaurs In 1841, the English paleontologist Richard Owen coined the term **dinosaur** (from the Greek, meaning terrible lizard) to describe some of the wondrous fossil animals discovered in the 19th century. About 215 mya, dinosaurs were the dominant tetrapods on Earth and remained so for 150 million years, far longer than any other vertebrate. The two main clades were the ornithischians, or bird-hipped dinosaurs, which were herbivores such as *Stegosaurus*; and the saurischians, or lizard-hipped dinosaurs, which were fast, bipedal carnivores such as *Tyrannosaurus*

Figure 34.16 The kinetic skull. In snakes and lizards, both the upper and lower jaw are movable, thereby permitting large prey to be swallowed. This Horned bush viper (*Atheris ceratophora*) is swallowing a leaf folding frog.

Concept Check: *If snakes are limbless, how can they be considered tetrapods?*

(a) American alligator (b) American crocodile

Figure 34.17 Crocodilians. The Crocodilia is an ancient clade that has existed unchanged for millions of years. **(a)** Alligators, such as this American alligator (*Alligator mississippiensis*), have a broad snout, and the lower jaw teeth close on the inside of the upper jaw (and thus are almost completely hidden when the mouth is closed). **(b)** Crocodiles, including this American crocodile (*Crocodylus acutus*), have a longer, thinner snout, and the lower jaw teeth close on the outside of the upper jaw (and thus are visible when the mouth is closed).

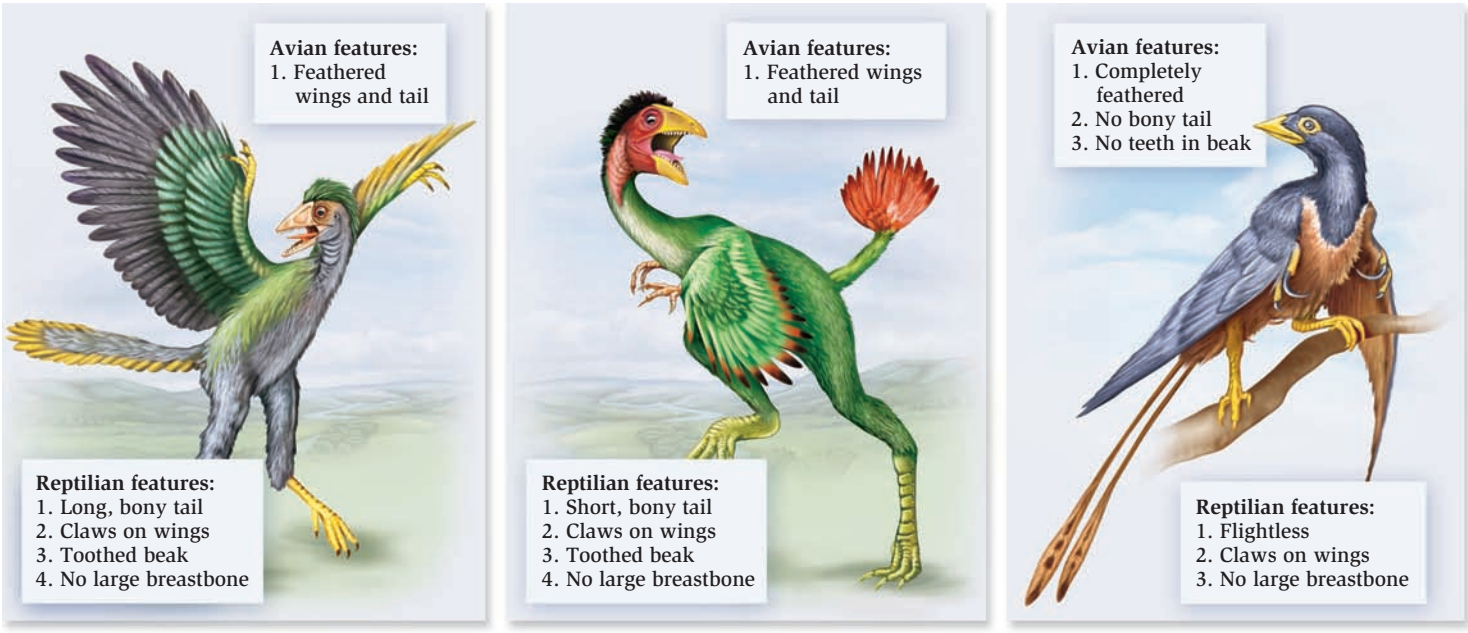
BioConnections: *Look ahead to Figure 47.3c. In what ways are crocodilians similar to birds and mammals?*

(**Figure 34.18**). In contrast to the limbs of lizards, amphibians, and crocodiles, which splay out to the side, the legs of dinosaurs were positioned directly under the body, like pillars, a position that may have helped support their heavy bodies. Because less energy was devoted to lifting the body from the ground, some dinosaurs are believed to have been fast runners. Members of different but closely related clades—the pterosaurs (the first vertebrates to fly) and ichthyosaurs and plesiosaurs (marine reptiles)—were also common at that time.

Dinosaurs were the biggest animals ever to walk on the planet, with some weighing up to 50 tonnes (metric tons) or over 100,000 pounds. The variety of the thousands of dinosaur species found in fossil form around the world is staggering. However, perhaps not surprisingly for such long-extinct species, scientists are still hotly debating many details of their lives. For example, an issue still unresolved is whether some dinosaur species were **endothermic**, capable of generating and retaining body heat through their own metabolism, as birds and mammals are, or whether they were **ectothermic**, dependent on external heat as the main source of their body heat, as most reptiles are. Another issue is whether dinosaurs exhibited parental care of their young.

(a) Ornithischian (*Stegosaurus*) (b) Saurischian (*Tyrannosaurus*)

Figure 34.18 Dinosaurs. **(a)** Herbivorous ornithischians included *Stegosaurus*, and **(b)** carnivorous saurischians included bipedal species such as *Tyrannosaurus rex*.



All nonavian dinosaurs, and many other animals, died out abruptly during a mass extinction at the end of the Cretaceous period (about 65 mya). Although widely attributed to climatic change brought about by the impact of a meteorite, scientists continue to debate the cause or causes of this mass extinction. We do not yet know why dinosaurs died out, while many other animals, including birds and small mammals, survived.

Aves: The Birds The defining characteristics of birds (Aves, plural of the Latin *avis*, meaning bird) are that they have feathers and nearly all species can fly. As we will see, the ability to fly has shaped nearly every feature of the bird body. The other vertebrates that have evolved the ability to fly, the bats and the now-extinct pterosaurs, used skin stretched tight over elongated limbs to fly. Such a surface can be irreparably damaged, though some holes may heal remarkably quickly. In contrast, birds use feathers, epidermal outgrowths that can be replaced if damaged. Recent research shows that feathers evolved in dinosaurs before the appearance of birds.

In the rest of this section, we will discuss the likely evolution of birds from dinosaur ancestors, outline the key characteristics of birds, and provide a brief overview of the various bird orders.

Modern Birds Evolved from Small, Feather-Covered Dinosaurs

To trace the evolution of birds, it is necessary to look at transitional forms, the earliest animals that had feathers. One of the first known fossils exhibiting the faint impression of feathers was *Archaeopteryx lithographica* (from the Greek, meaning ancient wings and stone

(a) ***Archaeopteryx lithographica*** **(b)** ***Caudipteryx zoui*** **(c)** ***Confuciusornis sanctus***

Figure 34.19 Transitional forms between dinosaurs and birds. **(a)** *Archaeopteryx lithographica* was a Jurassic animal with dinosaur-like features as well as wings and feathers. **(b)** *Caudipteryx zoui* was a dinosaur with feathers on its tail and wings. **(c)** *Confuciusornis sanctus* was a birdlike animal with a horny, toothless beak.

picture), found in a limestone quarry in Germany in 1861. The fossil was dated at 150 million years old, which places it during the Jurassic period. Except for the presence of feathers, *Archaeopteryx* appears to have had features similar to those of dinosaurs (**Figure 34.19a**; see also Figure 22.19). First, the fossil had an impression of a long tail with many vertebrae, a dinosaur feature. Some modern birds have long tails, but they are made of feathers, with the actual tailbone being much reduced. Second, the wings had claws halfway down the leading edge, another dinosaur-like character. Among modern birds, only the hoatzin, a South American swamp-inhabiting bird, has claws on its wings, which enable the chicks to climb back into the nest if they fall out. A third dinosaur-like feature is *Archaeopteryx*'s toothed beak. Fourth, the fossils show that *Archaeopteryx* lacked an enlarged breastbone, a feature that modern birds possess to anchor their large flight muscles, so it likely could not fly.

Structural similarities of the skull, feet, and hind leg bones have led scientists to conclude that *Archaeopteryx* is closely related to **theropods**, a group of bipedal saurischian dinosaurs. The wings and feathers of *Archaeopteryx* may have enabled it to glide from tree to tree, helped to keep it warm, or cut out the glare when folded over its head when hunting, in much the same way as some herons fold their wings over their heads when they are fishing. Later, the wings and feathers may have taken on functions of flight.

In China in the mid-1990s, paleontologists unearthed fossils of about the same age as *Archaeopteryx* that similarly suggest a close kinship between dinosaurs and modern birds. *Caudipteryx zoui* was a dinosaur-like animal with feathers on its wings and tail and a toothed beak (**Figure 34.19b**). *Confuciusornis sanctus* was a small, flightless but completely feathered dinosaur lacking the long, bony tail and toothed jaw found in other theropod dinosaurs. Its large tail feathers may have functioned in courtship displays (**Figure 34.19c**).

These three species—*Archaeopteryx, Caudipteryx,* and *Confuciusornis*—help trace a lineage from dinosaurs to birds. By the early Cretaceous period, and only a relatively short period after *Archaeopteryx* evolved, the fossil record shows the existence of a huge array of bird types resembling modern species. These were to share the skies with pterosaurs for 70 million years, before eventually having the airways to themselves.

Birds Have Feathers, a Lightweight Skeleton, Air Sacs, and Reduced Organs

Modern birds possess many characteristics, including scales on their feet and legs and shelled eggs, that reveal their reptilian ancestry. In addition, however, birds have four features that are unique among living animals and that are all associated with flight.

1. **Feathers.** Feathers are modified scales that keep birds warm and enable flight (**Figure 34.20a**). Soft, downy feathers, which are close to the body, maintain heat, whereas stiffer contour feathers, supported on a modified forelimb, give the wing the airfoil shape it needs to generate lift. Each contour feather develops from a follicle, a tiny pit in the skin. If a feather is lost, a new one can be regrown. The contour feathers consist of many paired barbs, each of which supports barbules that contain hooks that interlock with barbules from neighboring barbs to give the feather its shape (**Figure 34.20b**).
2. **Air sacs.** Flight requires a great deal of energy generated by an active metabolism that requires abundant oxygen. Birds have nine air sacs—large, hollow sacs that may extend into

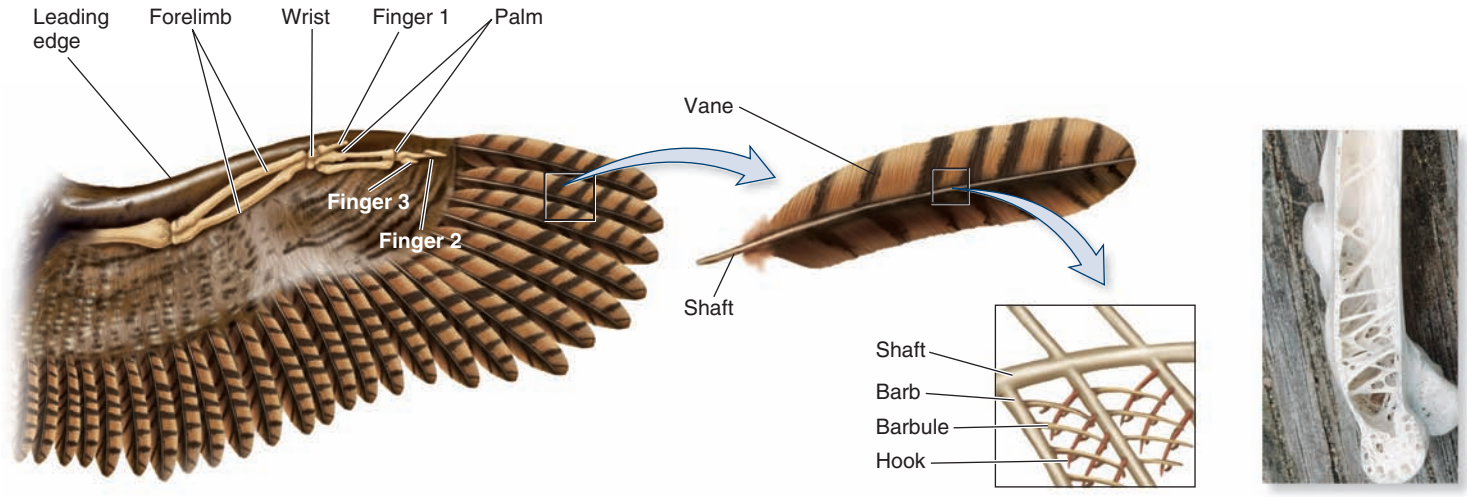


Figure 34.20 **Features of the bird wing and feather.** **(a)** The wing is supported by an elongated and modified forelimb with three extended fingers. **(b)** Each feather has a hollow shaft that supports many barbs, which, in turn, support barbules that interlock with hooks to give the feather its form. **(c)** The bones of a pelican (*Pelicanus occidentalis*) are hollow but crisscrossed with a honeycomb structure that provides added strength.

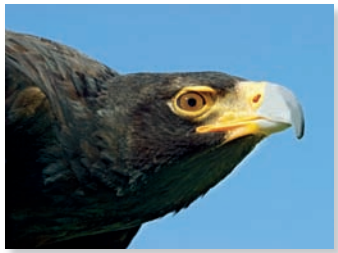
Concept Check: *What adaptations in birds help reduce their body weight to enable flight?*

the bones—that expand and contract when a bird inhales and exhales, while the lungs remain stationary. Air is therefore being constantly moved across the lungs during inhalation and exhalation. Although making bird breathing very efficient, this process also makes birds especially susceptible to airborne toxins (hence, the utility of the canary in the coal mine; the bird's death signaled the presence of harmful carbon dioxide or methane gas that was otherwise unnoticed by miners).

3. **Reduction of organs.** Some organs are reduced in size or are lacking altogether in birds, which reduces the total mass that the bird carries. For example, birds have only one ovary and can carry relatively few eggs. As a result, they lay fewer eggs than most other reptile species. In fact, the gonads of both males and females are reduced, except during the breeding season, when they increase in size. Most birds also lack a urinary bladder. In addition, the loss of teeth reduces weight at the head end.
4. **Lightweight bones.** Most bird bones are thin and hollow and are crisscrossed internally by tiny pieces of bone to give them a honeycomb structure (**Figure 34.20c**). An enlarged breastbone, or **sternum**, provides an anchor on which a bird's powerful flight muscles attach. These muscles may contribute up to 30% of the bird's body weight.

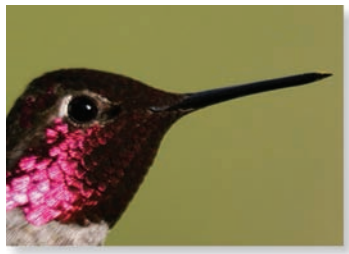
Birds also have other distinct features, though mammals also possess some of these. For example, birds are endotherms, which ensures rapid metabolism and the quick production of adenosine triphosphate (ATP), which these active organisms need to fuel flight and other activities. Birds' body temperatures are generally 40–42°C, considerably warmer than the human body's average of 37°C. Birds have a double circulation and a four-chambered heart that ensures rapid blood circulation. Rapid flight requires good vision, and bird vision is the best in the vertebrate world. Birds generally have high energy needs, and most birds are carnivores, eating insects or other invertebrates. However, some birds, such as parrots, eat just nutrient-rich fruits and seeds. The keratin of bird beaks is tough and malleable, and a wide assortment of beaks has evolved, with the form dependent on the function (**Figure 34.21**). Bird eggs also need be kept warm for successful development, which entails brooding by an adult bird. Often, the males and females take turns brooding so that each parent can feed and maintain its strength. Picking successful partners is therefore an important task, and birds often engage in complex courtship rituals (look ahead to Figure 55.23).

Birds Are Placed into Many Different Orders, All with the Same Body Plan

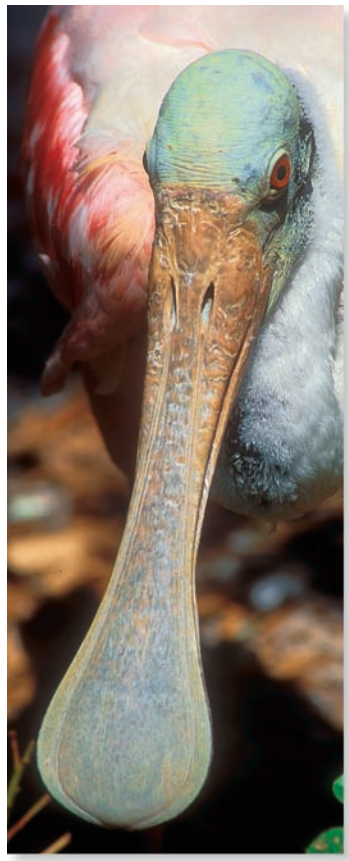


Birds are the most species-rich clade of terrestrial vertebrates, with 28 orders, 166 families, and about 10,000 species (**Table 34.2**). Despite this diversity, birds lack the variety of body shapes that exist in the mammals, some of which can swim, others fly, others walk on four legs, and yet others walk only on two legs. Most birds fly, and therefore, most have the same general body shape. The biggest departures from this body shape are the flightless birds, including the cassowaries, emus, and ostriches. These birds have smaller wing bones, and the keel on the breastbone is greatly reduced or absent. Penguins are also flightless birds whose upper limbs are modified as flippers used in swimming.

(a) Cracking beak



(b) Scooping beak



(c) Tearing beak

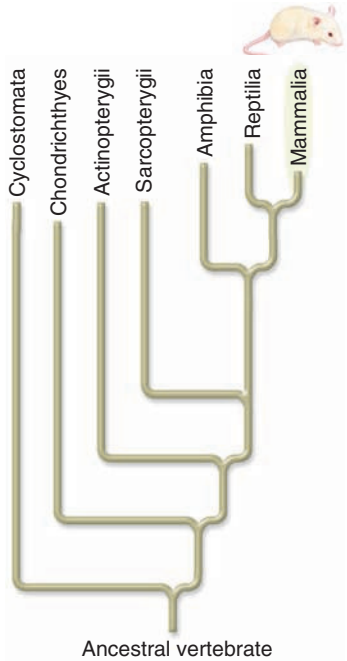
(d) Probing beak

(e) Nectar-feeding beak

(f) Sieving beak

Figure 34.21 A variety of bird beaks. Birds have evolved a variety of beak shapes used in different types of food gathering. **(a)** Hyacinth macaw (*Anodorhynchus hyacinthinus*)—cracking. **(b)** White pelican (*Pelecanus onocrotalus*)—scooping. **(c)** Verreaux's eagle (*Aquila verreauxii*)—tearing. **(d)** American avocet (*Recurvirostra americana*)—probing. **(e)** Anna's hummingbird (*Calypte anna*)—nectar feeding. **(f)** Roseate spoonbill (*Platalea ajaja*)—sieving.

BIOLOGY PRINCIPLE Structure determines function. Each of these beak shapes permits a different method of feeding.



34.5 Mammals: Milk-Producing Amniotes

Learning Outcomes:

1. Identify the four features that separate mammals from other vertebrate clades.
2. List the defining characteristics of primates.
3. **SciSKILLS »** Contrast the out-of-Africa and multiregional hypotheses concerning human evolution.

Mammals evolved from amniote ancestors earlier than birds. About 225 mya, the first mammals appeared in the mid-Triassic period (refer back to Figure 22.18). They evolved from small mammal-like reptiles that went extinct about 170 mya. Mammals survived, and until recently, most were believed to have been small, insect-eating species that lived in the shadows of dinosaurs. However, in 2005, the discovery of two fossils of a 130-million-year-old mammalian genus called *Repenomamus* challenged the notion of mammals as small insect eaters. One fossil was of an animal estimated to weigh about 13 kg (30 pounds), about the size of a small dog, which is larger than some dinosaurs living in the same region at the time. The other fossil had the remains of a baby dinosaur in its stomach area.

The extinction of the dinosaurs in the Cretaceous period, some 65 mya, paved the way for mammals to increase in size. Today, biologists have identified about 5,500 species of mammals with a diverse array of lifestyles, from fishlike dolphins to birdlike bats, and from small insectivores such as shrews to large herbivores such as giraffes and elephants. The range of sizes and body forms of mammals is unmatched by any other vertebrate group, and mammals are prime illustrations of the concept that organismal diversity is related to environmental diversity. In this section, we will outline the features that distinguish mammals from other taxa. We will also examine the diversity of mammals that exists on Earth and will end by turning our attention to the evolution of primates and, in particular, humans.

Mammals Have Mammary Glands, Hair, Specialized Teeth, and an Enlarged Skull

Four characteristics distinguish mammals: the possession of mammary glands, hair, specialized teeth, and an enlarged skull.

Table 34.2 The Main Orders of Birds, in Order of Species Richness

Order	Examples (approx. number of species)	Main characteristics
Passeriformes 	Robins, starlings, sparrows, warblers (5,400)	Perching birds with perching feet; songbirds
Apodiformes 	Hummingbirds, swifts (430)	Fast fliers with rapidly beating wings; small bodies
Piciformes 	Woodpeckers, toucans (380)	Large with specialized beaks; two toes pointing forward and two backward
Psittaciformes 	Parrots, cockatoos (360)	Large, powerful beaks
Chadradriiformes 	Seagulls, wading birds (330)	Shorebirds
Columbiformes 	Doves, pigeons (330)	Round bodies; short legs
Galliformes 	Chickens, pheasants, quail (270)	Often large birds; weak flyers; ground nesters
Accipitriformes 	Eagles, hawks, vultures (240)	Large diurnal carnivores; birds of prey; powerful talons; strong beaks
Coraciiformes 	Hornbills, kingfishers (200)	Large beaks; cavity nesters
Strigiformes 	Owls (170)	Nocturnal carnivores; powerful talons; strong beaks
Anseriformes 	Ducks, swans, geese (160)	Able to swim; webbed feet; broad bills
Pelecaniformes 	Pelicans, ibises, herons (100)	Large, water inhabiting
Sphenisciformes 	Penguins (17)	Flightless; wings modified into flippers for swimming; marine; Southern Hemisphere

- **Mammary glands.** Mammals, or the clade Mammalia (from the Latin *mamma*, meaning breast), are named after the female's distinctive mammary glands, which secrete milk. Milk is a fluid rich in fat, sugar, protein, and vital minerals, especially calcium. Newborn mammals suckle this fluid, which helps promote rapid growth.
- **Hair.** All mammals have hair, although some have more than others. Whales have hair in utero, but adults are hairless or retain only a few hairs on their snout. Compared with many mammals, humans are relatively hairless. In some animals, the hair is dense and is referred to as fur. In some aquatic species such as beavers, the fur is so dense it cannot be thoroughly wetted, so the hair underneath remains dry. Mammals are endothermic, and their fur is an efficient insulator. Hair can also take on functions other than insulation. Many mammals, including cats, dogs, walruses, and whales, have sensory hairs called vibrissae (**Figure 34.22a**). Hair can be of many colors, to allow the mammals to blend into their background (**Figure 34.22b**). In some cases, as in porcupines and hedgehogs, the hairs become long, stiffened, and sharp (quills) and serve as a defense mechanism (**Figure 34.22c**).
- **Specialized teeth.** Mammals are the only vertebrates with highly differentiated teeth—incisors, canines, premolars, and molars—that are adapted for different types of diets (**Figure 34.23**). Although teeth are generally present in all species, different teeth are larger, smaller, lost, or reduced, depending on diet. Of particular importance to carnivores such as wolves are the piercing canine teeth, whereas herbivorous species such as deer depend on their chisel-like incisors to snip off vegetation and their many molars to grind plant material. Only mammals chew their food in this fashion. Rodent incisors grow continuously throughout life, and species such as beavers wear them down by gnawing tough plant material such as wood. Mammals that have different types of teeth are

(a) Sensory hairs

(b) Camouflaged coat

(c) Defensive quills

Figure 34.22 **Mammalian hair.** **(a)** The sensory hairs (vibrissae) of the walrus (*Odobenus rosmarus*). **(b)** The camouflaged coat of a bobcat (*Lynx rufus*). **(c)** The defensive quills of the crested porcupine (*Hystrix africaeaustralis*).

called heterodonts; others, such as dolphins, whose teeth are of uniform size and shape, are called homodonts.

- **Enlarged skull.** The mammalian skull differs from other amniote skulls in several ways. First, the brain is enlarged and is contained within a relatively large skull. Second, mammals have a single lower jawbone, unlike reptiles, whose lower jaw is composed of multiple bones. Third, mammals have three bones in the middle ear, as opposed to reptiles, which have one bone in the middle ear. Fourth, most mammals, except some seals, have external ears.

In addition to those uniquely mammalian characteristics, some, but not all, mammals possess these additional features:

- **The ability to digest plants.** Apart from tortoises and marine iguanas, certain species of mammals are the only large vertebrates alive today that can exist on a steady diet of grasses or tree leaves; indeed, most large mammals are herbivores. Though mammals cannot digest cellulose, the principal constituent of the cell wall of many plants, some species have a large four-chambered stomach containing cellulose-digesting bacteria. These bacteria can break down the cellulose and make the plant cell contents available to the animal. Others have an extensive cecum or large intestine where digestion occurs.
- **Horns and antlers.** Mammals are the only living class of vertebrates to possess horns or antlers. Many mammals, especially antelopes, cattle, and sheep, have horns, typically consisting of a bony core that is a permanent outgrowth of the skull surrounded by a hairlike keratin sheath, as shown in the large antelope called a kudu (**Figure 34.24a**). Hooves, also made of keratin, protect an animal's toes from the force

(a) Biting teeth

(b) Grinding teeth

(c) Gnawing teeth

(d) Tusks

(e) Grasping teeth

Figure 34.23 **Mammalian teeth.** Mammals have different types of teeth, according to their diet. **(a)** The wolf has long canine teeth that bite its prey. **(b)** The deer has a long row of molars that grind plant material. **(c)** The beaver, a rodent, has long, continually growing incisors used to gnaw wood. **(d)** The elephant's incisors are modified into tusks. **(e)** Dolphins and other fishes or plankton feeders have numerous small teeth used to grasp prey.

(a) Skull outgrowths (b) Epidermal outgrowths (c) Bony antlers

Figure 34.24 Horns and antlers in mammals. Mammals have a variety of outgrowths that are used for defense or by males as weapons in contests over females. **(a)** The horns of this male kudu (*Tragelaphus strepsiceros*) are bony outgrowths of the skull covered in a keratin sheath. **(b)** The horns of the black rhinoceros (*Diceros bicornis*) are outgrowths of the epidermis, made of tightly matted hair. **(c)** The antlers of the caribou (*Rangifer tarandus*), also known as reindeer, are made entirely of bone and are grown and shed each year.

of impact of its feet against the ground. Rhinoceros horns are outgrowths of the epidermis, consisting of very tightly matted hair (**Figure 34.24b**). In contrast, deer antlers are made entirely of bone (**Figure 34.24c**). Deer grow a new set of antlers each year and shed them after the mating season.

Mammals Are Morphologically Diverse and Occupy a Wide Range of Environments

Modern mammals are incredibly diverse in morphology and life styles (**Table 34.3**). They vary in size from tiny insect-eating bats,

Table 34.3 The Main Orders of Mammals, in Order of Species Richness

Order	Examples (approx. number of species)	Main characteristics
Rodentia	Mice, rats, squirrels, beavers, porcupines (2,277)	Plant eating; gnawing habit, with two pairs of continually growing incisor teeth
Chiroptera	Bats (1,116)	Insect or fruit eating; small; have ability to fly; navigate by sonar; nocturnal
Eulipotyphla	Shrews, moles, hedgehogs (452)	Insect eaters; primitive placental mammals
Primates	Monkeys, apes, humans (404)	Opposable thumb; binocular vision; large brains
Carnivora	Cats, dogs, weasels, bears, seals, sea lions (286)	Flesh-eating mammals; canine teeth
Artiodactyla	Deer, antelopes, cattle, sheep, goats, camels, pigs (240)	Herbivorous hoofed mammals, usually with two toes, hippopotamus and others with four toes; many with horns or antlers
Diprotodontia	Kangaroos, koalas, opossums, wombats (143)	Pouched mammals mainly found in Australia
Lagomorpha	Rabbits, hares (92)	Powerful hind legs; rodent-like teeth
Cetacea	Whales, dolphins (84)	Marine fishes or plankton feeders; front limbs modified into flippers; no hind limbs; little hair except on snout
Perissodactyla	Horses, zebras, tapirs, rhinoceroses (18)	Hoofed herbivorous mammals with odd number of toes, one (horses) or three (rhinoceroses)
Monotremata	Duck-billed platypuses, echidna (5)	Egg-laying mammals found only in Australia and New Guinea
Proboscidea	Elephants (3)	Long trunk; large, upper incisors modified as tusks

weighing in at only 2 g, to leviathans such as the blue whale, the largest animal ever known, which tips the scales at 100 tonnes (over 200,000 pounds). Mammalian orders are divided into two distinct subclasses (**Figure 34.25**). The subclass Prototheria contains only the order Monotremata, or **monotremes**, which are found in Australia and New Guinea. There are only five species: the duck-billed platypus (**Figure 34.26a**) and four species of echidna, a spiny animal resembling a hedgehog. Monotremes are early-diverging mammals that lay eggs rather than bear live young, lack a placenta, and have mammary glands with poorly developed nipples. The mothers incubate the eggs, and upon hatching, the young simply lap up the milk as it oozes onto the fur.

The subclass Theria contains all remaining live-bearing mammals. The Theria are divided into two clades, the Metatheria and the Eutheria. The clade Metatheria, or the **marsupials**, is a group of seven orders, with about 280 species, including the swamp wallaby pictured in **Figure 34.26b**. Once widespread, members of this order are now largely confined to Australia, although some marsupials exist in South America, and one species—the opossum—is found in North America. Fertilization is internal, and reproduction is viviparous in marsupials. Marsupials have a placenta that nourishes the embryo. Unlike other mammals, however, marsupials are extremely small when they are born (often only 1–2 cm) and make their way to a ventral pouch called a marsupium for further development.

All the other mammalian orders are members of the clade Eutheria and are considered **eutherians**, or placental mammals, such as the

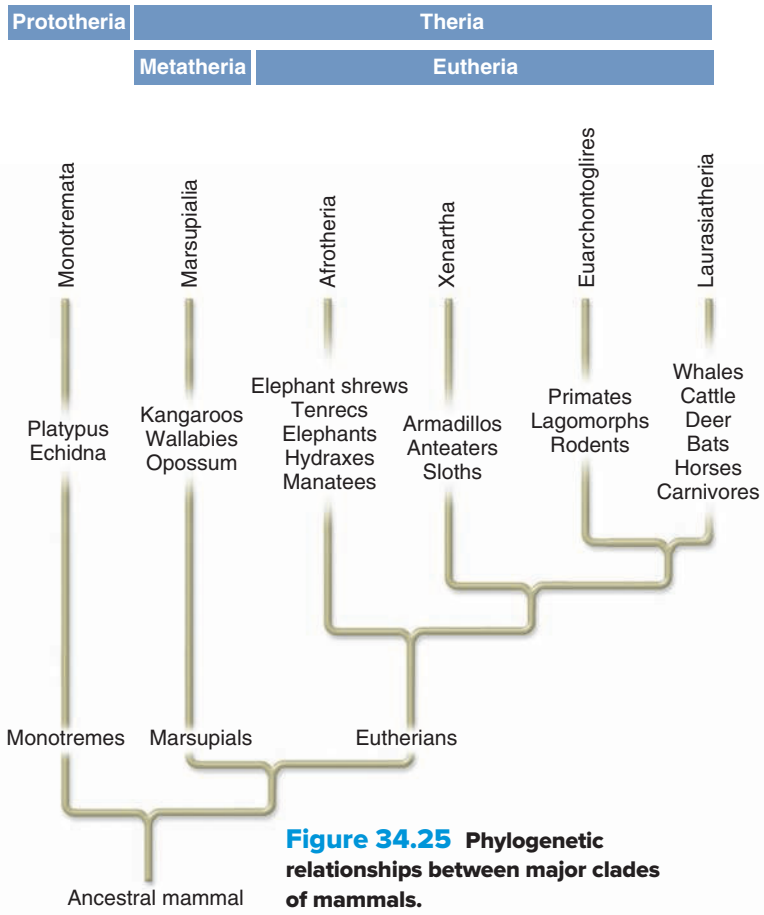


Figure 34.25 Phylogenetic relationships between major clades of mammals.

(a) Prototherian (duck-billed platypus)

(b) Metatherian (swamp wallaby)

(c) Eutherian (gray langur)

Figure 34.26 Diversity among mammals. **(a)** Prototherians, such as this duck-billed platypus (*Ornithorhynchus anatinus*), lay eggs, lack a placenta, and possess mammary glands with poorly developed nipples. **(b)** Metatherians, or marsupials, such as this swamp wallaby (*Wallabia bicolor*), feed and carry their developing young, or "joeys," in a ventral pouch. **(c)** Gestation lasts longer in eutherians, and their young are more developed at birth, as illustrated by this young langur monkey (*Presbytis entellus*).

BioConnections: Look ahead to Figure 51.10. The placenta serves as the provisional lungs, intestine, and kidneys of the developing fetus. How much mixing is there of maternal and fetal blood?

langur monkeys shown in **Figure 34.26c**. Eutherians have a long-lived and complex placenta, compared with that of marsupials. In eutherians, fertilization is internal, and reproduction is viviparous, but the developmental period, or gestation, of the young is prolonged. Molecular studies suggest four clades of placental mammals that diverged in the Cretaceous. The earliest diverging clade was the Afrotheria, which evolved in the African landmass starting about 110–100 mya. This clade includes the elephant shrews, tenrecs, golden moles, manatees and dugongs, hyraxes, aardvark, and elephants. Shortly thereafter, about 100–95 mya, the Xenartha evolved in South America, where the armadillos, anteaters, and sloths appeared. The other two clades, the Euarchontoglires, containing the primates, lagomorphs, and rodents, and the Laurasiatheria, containing the whales, artiodactyla, bats, horses, and carnivores, both evolved in the northern continent of Laurasia and became separate about 95–85 mya. Later, following continental drift, Africa and Arabia collided with Laurasia, and the Isthmus of Panama joined North and South America. These new land bridges facilitated animal movement between once separated continents.

The diversity of mammals is often threatened by human activities such as habitat destruction. In addition, many species are hunted for food. Others, such as wild cats and whales, are hunted for their products (fur and oil, respectively), and still others, such as the oryx, have simply been shot for sport.

Primates Are Mammals with Opposable Thumbs and a Large Brain

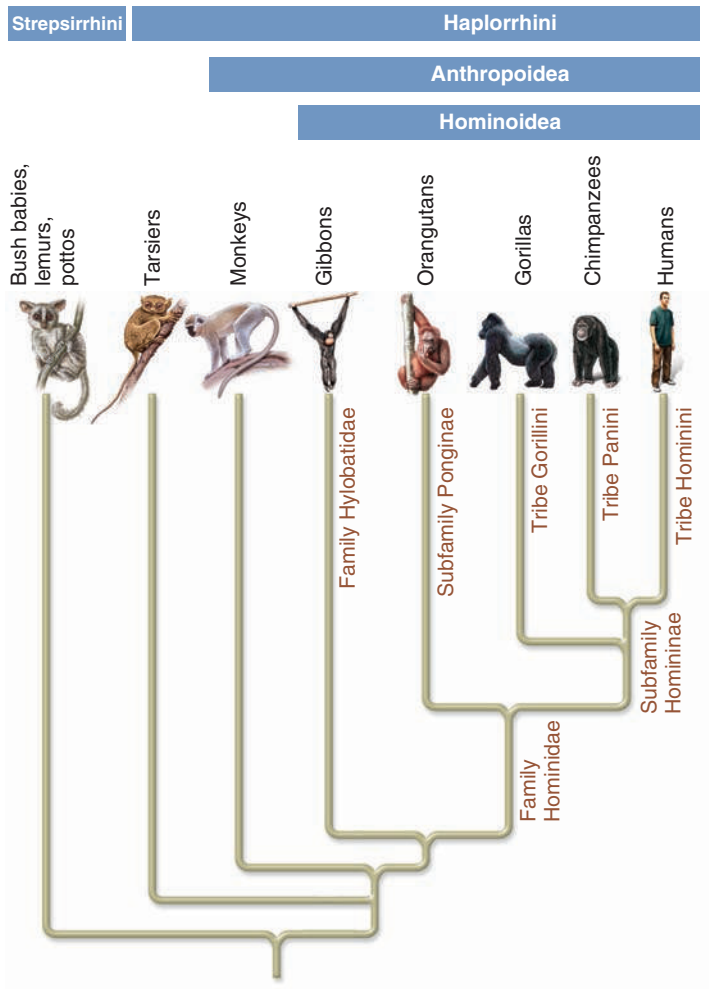
The primates, and specifically humans, have had a huge impact on the world. Primates are primarily tree-dwelling species that are believed to have evolved from a group of small, arboreal insect-eating mammals about 85 mya, before dinosaurs went extinct. Primates have several defining characteristics, mostly relating to their tree-dwelling nature:

- **Grasping hands.** All primates have grasping hands, a characteristic that enables them to hold onto branches (see Figure 34.28a and b). Most primate species also possess an opposable thumb, a thumb that can be placed opposite the fingers of the same hand, which gives them a precision grip and enables the manipulation of small objects. All primates except humans also have an opposable big toe.
- **Large brain.** Acute vision and other senses enhancing the ability to move quickly through the trees require the efficient processing of large amounts of information. As a result, the primate brain is large and well developed. In turn, this has facilitated complex social behaviors.
- **At least some digits with flat nails instead of claws.** This feature is believed to aid in the manipulation of objects.
- **Binocular vision.** Primates have forward-facing eyes that are positioned close together on a flattened face, though some other mammals share this characteristic. Jumping from branch to branch requires accurate judgment of distances. This is facilitated by binocular vision in which the field of vision for both eyes overlaps, producing a single image.
- **Complex social behavior and well-developed parental care.** Primates have a tendency toward complex social behavior and increased parental care.

Some of these characteristics are possessed by other animals. For example, binocular vision occurs in owls and some other birds, grasping hands are found in raccoons, and relatively large brains occur in marine mammals. Primates are defined by possessing the whole suite of these characteristics together.

Primates may be classified in several ways. Taxonomists often divide them into two groups: the strepsirrhini and the haplorrhini (**Figure 34.27**). The **strepsirrhini** contain the smaller species such as bush babies, lemurs, and pottos. These are generally nocturnal and smaller-brained primates with eyes positioned a little more toward the side of their heads (**Figure 34.28a**). The strepsirrhini are named for their wet noses with no fur at the tip. The **haplorrhini** have dry noses with a fully furred nose tip and fully forward-facing eyes. This group consists of the tarsiers and the larger-brained and diurnal **anthropoidea**: the apes and monkeys (**Figure 34.28b and c**). Within the anthropoidea are the **hominoidea** (gibbons, orangutans, gorillas, chimpanzees, and humans) and the monkeys.

What differentiates monkeys from hominoids? Most monkeys have tails, but hominoids do not. In addition, apes have more mobile shoulder joints, broader rib cages, and a shorter spine. These features aid in brachiation, a swinging movement in trees. Apes also possess relatively long limbs and short legs and, with the exception of gibbons,



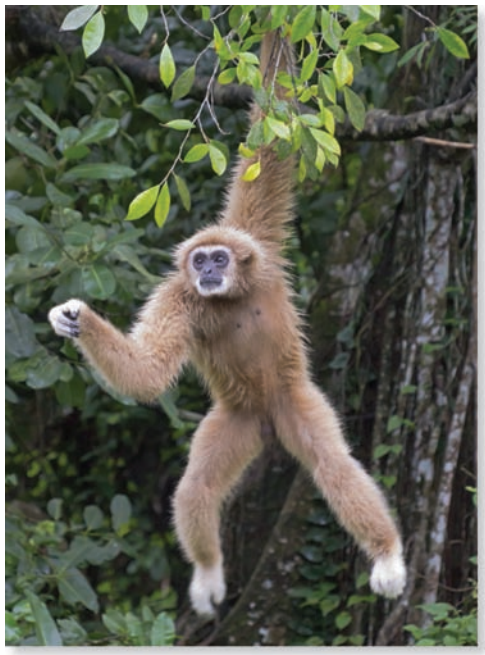


Figure 34.27 **Evolutionary tree of the primates.**

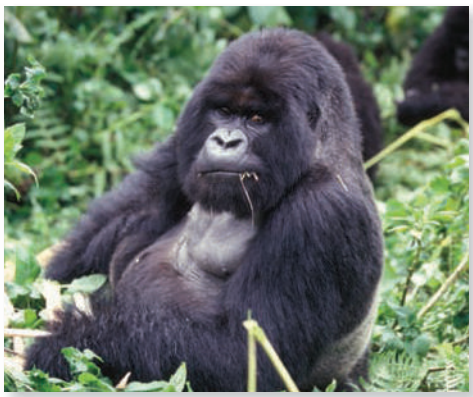
(a) Strepsirrhini (lesser bush baby)

(b) Anthropoidea (capuchin monkey)



(c) Hominoidea (white-handed gibbon)

Figure 34.28 Primate classification. Many authorities divide the primates into two groups: **(a)** the strepsirrhini (smaller, nocturnal species such as this bush baby), and the haplorrhini (larlarger diurnal species). Haplorrhini comprise **(b)** the monkeys and tarsiers, such as this capuchin monkey (*Cebus capucinus*), and **(c)** the hominoids, species such as this white-handed gibbon (*Hylobates lar*).

Concept Check: *What are the defining features of primates?*

are much larger than monkeys. The 20 species of hominoids are split into two groups: the lesser apes (family Hylobatidae), or the gibbons; and the greater apes (family Hominidae), or the orangutans, gorillas, chimpanzees, and humans (**Figure 34.29**). The lesser apes are strictly arboreal, whereas the greater apes often descend to the ground to feed.

Although humans are closely related to chimpanzees and gorillas, they did not evolve directly from them. Rather, all hominoid species shared a common ancestor. Recent molecular studies show that gorillas, chimpanzees, and humans are more closely related to one another than they are to gibbons and orangutans, so scientists have split the family Hominidae into groups, including the subfamily Ponginae (orangutans) and the subfamily Homininae (gorillas, chimpanzees, and humans and their ancestors). In turn, the Homininae are split into three tribes: the Gorillini (gorillas), the Panini (chimpanzees), and the Hominini (humans and their ancestors). The sequencing of the chimpanzee genome by the Chimpanzee Sequencing and Analysis Consortium in 2005 allowed detailed comparisons to be made with the human genome.

(a) Gorilla (*Gorilla gorilla*)

(b) Chimpanzee (*Pan troglodytes*)

(c) Human (*Homo sapiens*)

Figure 34.29 Members of the family Hominidae. **(a)** Gorillas, the largest of the living primates, are ground-dwelling herbivores that inhabit the forests of Africa. **(b)** Chimpanzees are smaller, omnivorous primates that also live in Africa. The chimpanzees are close living relatives of modern humans. **(c)** Humans are also members of the family Hominidae. The orangutan is also a member of this group.

Genomes & Proteomes Connection

Comparing the Human and Chimpanzee Genetic Codes

A male chimp called Clint who lived at a primate research center in Atlanta provided the DNA used to sequence the chimp genome. In 2005, the Chimpanzee Sequencing and Analysis Consortium published an initial sequence of the chimpanzee genome. The draft sequence followed the 2003 publication of the human genome (see Chapter 21) and allowed scientists to make detailed comparisons between the two species. These comparisons revealed that the sequences of base pairs making up both species' genomes differ by only 1.23%, 10 times less than the difference between the mouse and rat genomes. Comparisons of human and chimpanzee proteomes revealed that 29% of all proteins are identical, with most others differing by one or two amino acid substitutions.

Many of the genetic differences between chimps and humans result from chromosome inversions and duplications. Geneticists have found over 1,500 inversions between the chimp and human genomes. Although many inversions occur in the noncoding regions of the genome, the DNA in these regions may regulate the expression of the genes in the coding regions. Duplications and deletions are also common. For example, one gene that codes for a subunit of a protein found in areas of the brain occurs in multiple copies in a wide range of primates, but humans have the most copies. However, humans appear to have lost a gene called *caspase-12*, which in other primates may protect against Alzheimer's disease.

Some interesting genetic differences were apparent between chimps and humans even before their entire genomes were sequenced. In 1998, Indian physician-geneticist Ajit Varki and colleagues investigated a molecule called sialic acid that occurs on cell surfaces and acts as a locking site for pathogens such as malaria and influenza. They found an altered form of the molecule in humans, coded for by a single damaged gene, which may explain why humans are more susceptible to these diseases than are chimpanzees. In 2002, Swedish molecular geneticist Svante Pääbo discovered differences between humans and chimps in a gene called *FOXP2*, which plays a role in speech development. Proteins encoded by this gene differ in just two amino acids of a 715-amino-acid sequence. Researchers propose that the mutations in this gene have been crucial for the development of human speech.

More recently, a team led by American geneticist David Reich discovered in 2006 that the human X chromosome diverged from the chimpanzee X chromosome about 1.2 million years more recently than the other chromosomes. This indicated to the researchers that the human and chimp lineages split apart, then began interbreeding before diverging again. This would explain why many fossils appear to exhibit traits of both humans and chimps, because they may actually have been human-chimpanzee hybrids.

Humans Evolved from Ancestral Primates

About 6 mya in Africa, a lineage that led to humans began to separate from other primate lineages. The evolution of humans should not be viewed as a neat, stepwise progression from one species to another. Rather, human evolution, like the evolution of most species, can be visualized more like a tree, with one or two **hominin** species—members of the Hominini tribe—likely coexisting at the same point in time, with some eventually going extinct and some giving rise to other species (**Figure 34.30**).

The key characteristic differentiating hominins from other apes is that hominins walk on two feet; that is, they are **bipedal**. At about the time when hominins diverged from other ape lineages, the Earth's

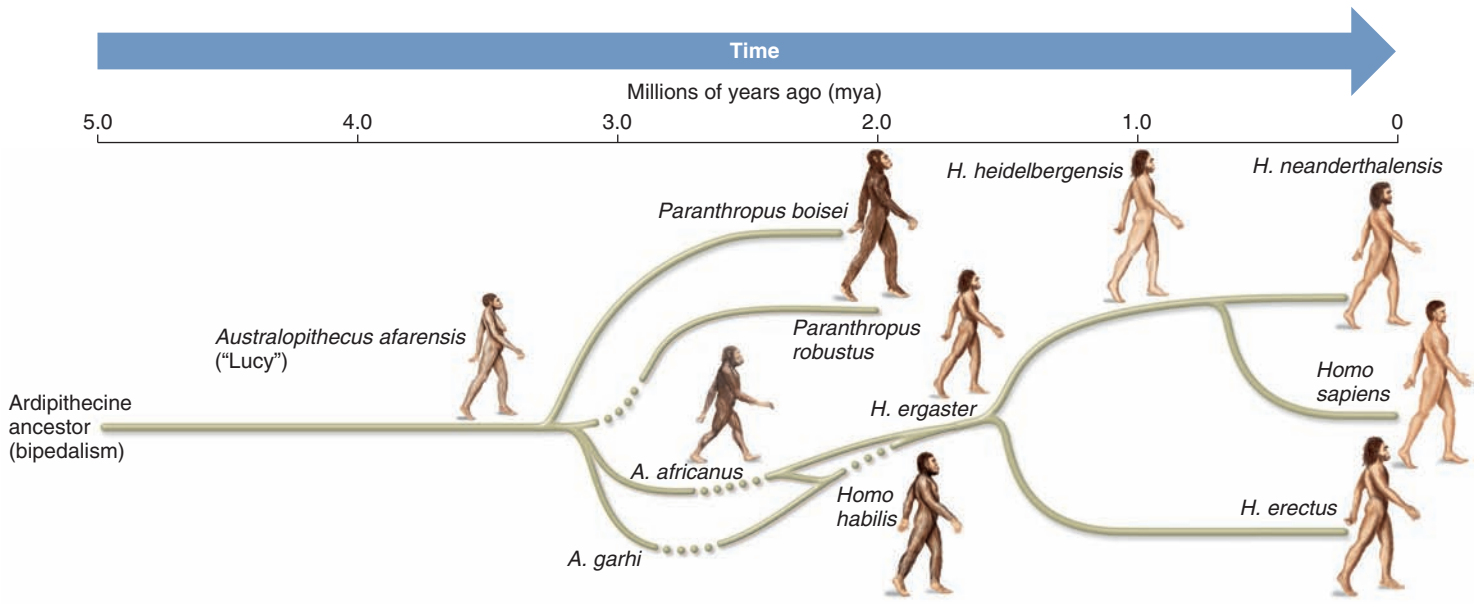


Figure 34.30 A possible scenario for human evolution. In this human family tree (based on the ongoing work of Donald Johanson), several hominin species lived contemporaneously with one another, but only one lineage gave rise to modern humans (*Homo sapiens*).

climate had cooled, and the forests of Africa had given way to grassy savannas. A bipedal method of locomotion and upright stance may have been advantageous in allowing hominins to peer over the tall grass of the savanna to see predators or even prey.

Bipedalism is correlated with many anatomical changes in hominins. First, the opening of the skull where the spinal cord enters shifted forward, allowing the spine to be more directly underneath the head. Second, the hominin pelvis became broader to support the additional weight. And third, the lower limbs, used for walking, became relatively larger than those in other apes. These are the types of anatomical changes paleontologists look for in the fossil record to help determine whether fossil remains are hominin. The earliest known hominin, *Sahelanthropus tchadensis*, was discovered in Central Africa in 2002. Another early group of hominins included several species of a smaller-brained genus, *Australopithecus*, which first emerged in Africa about 4 mya. *Australopithecus afarensis* is generally regarded as the common ancestor of most of these species. From there, the evolution of different species becomes somewhat hazy. It is generally agreed that two genera evolved from *Australopithecus*: the robust *Paranthropus* and the more slender *Homo*. The early stages of the evolution of *Homo* species, and their differentiation from at least two possible *Australopithecus* species, have not yet been determined with any certainty. However, the later divergence of various *Homo* species is a little better understood.

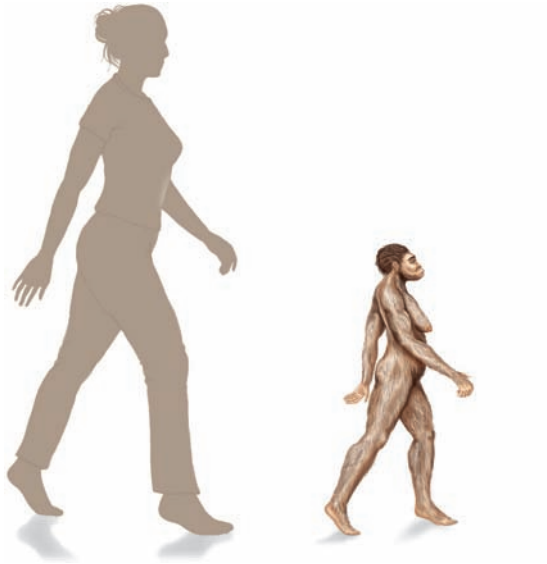

Figure 34.31 A modern woman compared to an australopithecine. Compared with modern humans, Australopithecines, as illustrated by this reconstruction of the famous fossil Lucy, were much smaller and lighter.

Australopithecines Since 1924, when the first fossil australopithecine (from the Latin *austral*, meaning southern, and the Greek *pithecus*, meaning ape) was found in South Africa, hundreds of fossils of this group have been unearthed all over southern and eastern Africa, the areas where fossil deposits are best exposed to paleontologists. This was a widespread group, with at least six species. In 1974, American paleontologist Donald Johanson unearthed the skeleton of a female *A. afarensis* in the Afar region of Ethiopia and dubbed her Lucy. (The Beatles' song "Lucy in the Sky with Diamonds" was playing in the camp the night when Johanson was sorting the unearthed bones.) Over 40% of the skeleton had been preserved, enough to provide a good idea of the physical appearance of australopithecines. Compared with modern humans, all were relatively small, about 1–1.5 m in height and around 18 kg in weight (**Figure 34.31**). Females were much smaller than males, a condition known as sexual dimorphism. Examination of the bones revealed that *A. afarensis* walked on two legs. They possessed a facial structure and brain size (about 500 cubic centimeters [cm^3]) similar to those of a chimp.

In the 1930s, the remains of bigger-boned hominids were found. Two of the larger species now considered to be a separate genus, *Paranthropus*, weighed about 40 kg and lived contemporaneously with australopithecines and members of *Homo* species. *Paranthropus* were vegetarians with enormous jaws used for grinding up tough roots and tubers. Both *Paranthropus* species died out rather suddenly about 1.5–2.0 mya. Although *Australopithecus africanus* was thought to have evolved slightly later than *A. afarensis*, its bones had been found much earlier than those of *A. afarensis.* In the 1920s, Australian anthropologist Raymond Dart described *A. africanus* from infant bones discovered in a cave in Taung, South Africa. The type specimen was called Taung child. The well-preserved skull was small but was well rounded, unlike the skulls of chimpanzees and gorillas. Also, the positioning of the head on the vertebral column suggested bipedalism. These facts suggested to Dart that he had found a transitional form between apes and humans. However, it would take another 20 years and the discovery of more fossils to convince the scientific world to support Dart's view. In 1996, remains of another species, *Australopithecus garhi*, were also found in the Afar region. They were somewhat of a surprise in that the dentition suggested similarities with *Paranthropus boisei.* "Garhi" means surprise in the local Afar language. The position of both *A. garhi* and *A. africanus* as ancestors of modern humans has been the subject of much debate, and they have been viewed as dead-end cousins or the ancestors of the first members of the genus *Homo.*

The Genus Homo and Modern Humans In the 1960s, British paleontologist Louis Leakey found hominin fossils estimated to be about 2 million years old in Olduvai Gorge, Tanzania. Two particularly interesting observations about these fossils stand out. First, reconstruction of the skull showed a brain size of about 680 cm^3, larger than that of *Australopithecus.* Second, the fossils were found with a wealth of stone tools. As a result, Leakey assigned the fossils to a new species, *Homo habilis*, from the Latin, meaning handy man. The discovery of several more *Homo* fossils followed, but there have been no extensive finds, as there were with Lucy. This makes it difficult to determine which *Australopithecus* lineage gave rise to the *Homo* lineage (see Figure 34.30), and scientists remain divided on this point.

Homo habilis lived alongside *Paranthropus* in East Africa but had much smaller jaws and teeth, indicating that it probably ate large quantities of meat. The smaller jaw provided more space in the skull for brain development. *Homo habilis* probably scavenged most of its meat from the kills of large predators. A meatier diet is easier to digest and is rich in nutrients and calories. The human brain uses a lot of energy, 20% of the body's total energy production. The meat-eating habit thus helped propel the evolution of increasing brain size in humans. Cut

marks on animal bones of the period reveal that early humans used stone tools to smash open bones and extract the protein-rich bone marrow—a food source that other organisms were unable to obtain.

Although we are not clear exactly how, researchers believe that *H. habilis* probably gave rise to one of the most important species of *Homo*, *Homo ergaster. Homo ergaster* was a hominin that evolved in Africa; it had a human-looking face and skull, with downward-facing nostrils. *Homo ergaster* was also a tool user, and the tools, such as hand axes, were larger and more sophisticated. *Homo ergaster* evolved in a period of global cooling and drying that reduced tropical forests even more and promoted savanna conditions. Hairlessness and the regulation of body temperature through sweating may also have evolved at this time as adaptations to the sunny environment. A leaner body shape was evident. We know this from so-called Turkana boy, a fossil teenage boy found in Kenya in 1984. Though only 13 years old, scientists predict he would have been about 185 cm (6 ft 1 in.) when adult, much the same height as the Masai tribesman that inhabit the area today. A dark skin probably protected *H. ergaster* from the sun's rays. The pelvis had narrowed, promoting efficiencies in walking upright, and the size of the brain and hence the skull increased, which may have produced more difficulty in childbirth. Mothers had to push increasingly large-brained infants through a narrowed pelvis. Researchers think that as a result, the human gestation period was shortened. Earlier birth leads to prolonged care of human infants compared with that in other apes. Prolonged child care required well-nourished mothers, who would have benefited from the support of their male partner and other members of a social group. Some anthropologists have suggested this was the beginning of the family.

H. ergaster is thought to have given rise to many species, including *Homo erectus*, *Homo heidelbergensis*, *Homo neanderthalensis*, and *Homo sapiens.* A possible timeline and geographic locations for these species are shown in **Figure 34.32**. *Homo ergaster* probably was the first type of human to leave Africa, as similar bones have been found in the Eurasian country of Georgia. *H. ergaster* is believed to be a direct ancestor of modern humans, with *Homo heidelbergensis* viewed as an intermediary step. Living contemporaneously with *H. heidelbergensis* was another descendent of *H. ergaster*, *H. erectus.*

H. erectus was a large hominin, as large as a modern human but with heavier bones and a smaller brain capacity of between 750 and 1,225 cm^3 (modern brain size is about 1,350 cm^3). Fossil evidence shows that *H. erectus* was a social species that used tools, hunted animals, and cooked over fires. The meat-eating habit may have sparked the migration of *H. erectus*, because carnivores had larger ranges than similar-sized herbivores, their prey being scarcer per unit area. *H. erectus* spread out of Africa soon after the species appeared, over a million years ago, and fossils have been found as far away as China and Indonesia. The first fossil was found by Dutch physician Eugene Dubois in 1891 on the Indonesian island of Java. Stone tools are rarely found in these Asian sites, suggesting *H. erectus* based their technology on other materials, such as bamboo, which was abundant at that time. Bamboo is strong yet lightweight and could have been used to make spears. These people may even have used rafts to take to the seas. *H. erectus* went extinct about 100,000 years ago, for reasons that are unclear but may be related to the spread of *H. sapiens* into its range.

Homo heidelbergensis was similar in body form to modern humans. Large caches of this species' bones were found in Spain, at

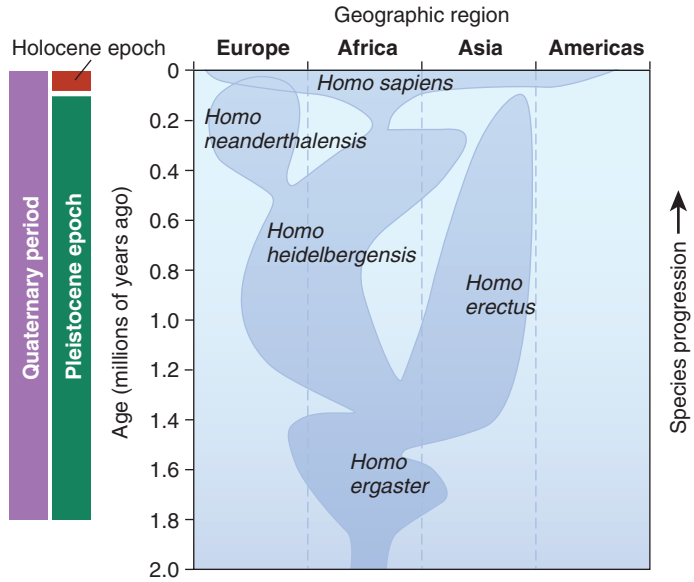

Figure 34.32 One view of the temporal and geographic evolution of hominid populations. The Holocene epoch is a geological time period beginning at the end of the Pleistocene and continuing to the present.

the bottom of a 14 m (45 ft) shaft known as La Sima de Los Huesos (the pit of bones). Similar remains were also found at Boxgrove in England. Shinbones recovered from Boxgrove suggest males stood around 180 cm (6 ft) and weighed 88 kg (196 pounds). Skulls were large, with brain volumes from 1,100 to 1,400 cm^3, similar to modern humans. Animal bones from these sites showed cut marks from stone blades beneath tooth marks from carnivores. This indicated that humans were killing large prey before scavengers arrived. Horses, giant deer, and rhinoceroses were common prey and would have required much skill and cooperation to hunt.

Homo heidelbergensis gave rise to two species, *H. neanderthalensis* and *H. sapiens. H. neanderthalensis* was named for the Neander Valley of Germany, where the first fossils of its type were found. In the Pleistocene epoch (see Figure 34.32), glaciers were locked in a cycle of advance and retreat, and the European landscape was often covered with snow. The more slender body form of *H. heidelbergensis* evolved into a shorter, stockier build that was better equipped to conserve heat; we now call this type of human Neanderthal. Neanderthals also possessed a more massive skull and larger brain size than modern humans, about 1,450 cm^3, perhaps associated with their bulk. Males were about 168 cm (5 ft 6 in.) in height and would have been very strong by modern standards. They had a large face with a prominent bridge over the eyebrows, a large nose, and no chin. They lived predominantly in Europe, with a range extending to the Middle East. Their muscular physique was well suited to the rigors of cold climates and hunting prey. Paleontologists have found a high rate of head and neck injuries in Neanderthal bones, similar to that seen in present-day rodeo riders. This suggests that close encounters with large prey often resulted in blows that knocked the hunters off their feet. The hyoid bone, which holds the larynx (voice box) in place, was well developed, suggesting speech was used. However, about 30,000 years ago, this species disappeared, replaced by another hominin species, *H. sapiens* (from the

Latin, meaning wise man), our own species. *H. sapiens* was a taller, lighter-weight species with a slightly smaller brain capacity than that of the Neanderthals. Researchers posit a variety of reasons for why *H. sapiens* thrived while the Neanderthals disappeared, including possessing a more efficient body type with lower energy needs, increased longevity, and differences in social structure and cultural adaptations.

Paleontologists remain divided as to whether *H. sapiens* evolved in Africa and spread from there to other areas of the world, or whether premodern humans such as *H. ergaster* that migrated from Africa evolved to become modern humans in different parts of the world. The first model, the out-of-Africa hypothesis, suggests that after the evolution of hominins in Africa, they migrated to other continents three times, once for *H. ergaster*, once for *H. erectus*, and once for *H. sapiens*. Then *H. sapiens* would have gradually replaced species such as *H. erectus* and *H. neanderthalensis* in other parts of the world. Some scientists find this difficult to accept, however, and suggest that human groups have evolved from *H. ergaster* populations in a number of different parts of the world, a model known as the multiregional hypothesis. According to this hypothesis, gene flow between neighboring populations prevented the formation of several different species.

Studies of human mitochondrial DNA (mtDNA), which occurs only in the cellular organelles called mitochondria, and which is passed from mother to offspring, show that all modern people share a common ancestor, dubbed "mitochondrial Eve," dating to about 170,000 years ago. This evidence is consistent with the out-of-Africa hypothesis, because the common ancestor would have to be much older than that to support the multiregional hypothesis. Furthermore, 2006 analyses of DNA from Neanderthal bones show it to be distinct from the DNA of *H. sapiens*, even though Neanderthals and humans share 99.5% of their genome. This also suggests that there was relatively little interbreeding between Neanderthals and the *H. sapiens* who migrated into Europe.

Evidence overall appears to support the out-of-Africa hypothesis. In this scenario, *H. ergaster* evolved in Africa and spread to Asia and Europe. Later, *H. erectus* evolved in Africa and spread into Asia, and *H. neanderthalensis* evolved in Europe. Both of these species shared the same fate, extinction at the hands of the later-evolving *H. sapiens*. *Homo sapiens* evolved in Africa about 170,000 years ago from *H. heidelbergensis*. The mtDNA data suggest a migration of *H. sapiens* from eastern Africa to other parts of the globe beginning 170,000–150,000 years ago (**Figure 34.33**). Modern humans spread first into the Middle East and Asia, then later into Europe and Australia, finally crossing the Bering Strait to the Americas.

Much remains to be resolved in human evolution, and new data constantly forces paleontologists to revise their hypotheses. For example, in 2004, the remains of a small human on the Indonesian island of Flores were discovered and were given the name *Homo florensiensis*, nicknamed "hobbits" by the media. Many species—for example, deer and elephants—develop into small forms in insular situations, so hobbit humans seemed plausible. Since then, many researchers have suggested these people were modern humans who were suffering from a genetic disorder. Even modern humans on Flores are pygmies. Pathological dwarfism would have made these people even smaller. Only *H. sapiens* tools have been found at the area where the bones occur, suggesting these individuals were indeed dwarf forms of modern humans.

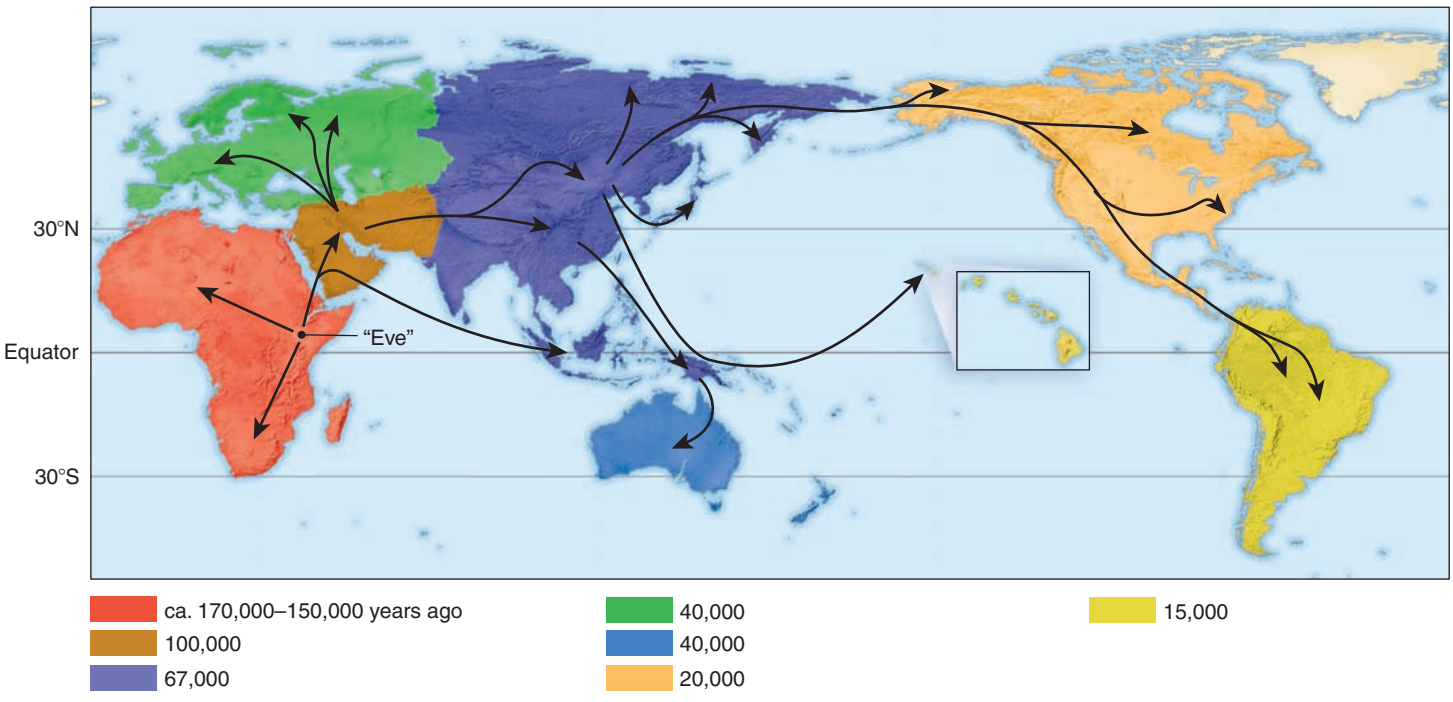

Figure 34.33 The probable origin and spread of *Homo sapiens* throughout the world. This map, based on differences of mtDNA throughout current members of the world's population, suggests *Homo sapiens* originated from "mitochondrial Eve" in east Africa. About 100,000 years ago, the species spread into the Middle East and from there to Europe, Asia, Australia, and the Americas.

Summary of Key Concepts

34.1 Vertebrates: Chordates with a Backbone

- Vertebrates have several characteristic features, including a vertebral column, cranium, and an endoskeleton of cartilage or bone (Figure 34.1, Table 34.1).
- Early-diverging vertebrates lacked jaws. Today, the only jawless vertebrates are the hagfish and lampreys (Figures 34.2, 34.3).

34.2 Gnathostomes: Jawed Vertebrates

- A critical innovation in vertebrate evolution is the hinged jaw, which first developed in fishes. Gnathostomes are vertebrate species that possess a hinged jaw (Figure 34.4).
- The chondrichthyans (sharks, skates, and rays) have a skeleton composed of flexible cartilage and powerful appendages called fins. They are active predators with acute senses and were among the earliest fishes to develop teeth (Figure 34.5).
- Bony fishes consist of the Actinopterygii (ray-finned fishes, the most species-rich clade), and the Sarcopterygii (lobe-finned fishes). In Actinopterygii, the fins are supported by thin, flexible rays and moved by muscles inside the body (Figures 34.6, 34.7).
- The Sarcopterygii comprise the lobe-finned fishes (Actinistia and Dipnoi) and the tetrapods. In the lobe-finned fishes, the fins are supported by extensions of the pectoral and pelvic areas and are moved by their own muscles (Figure 34.8).

34.3 Tetrapods: Gnathostomes with Four Limbs

- The fossil record reveals the evolution of lobe-finned fishes to fishes with four limbs. Recent research has shown that relatively simple mutations control large changes in limb development (Figures 34.9, 34.10, 34.11).
- Amphibians live on land but return to the water to reproduce. The larval stage undergoes metamorphosis, losing gills and tail and gaining lungs and limbs (Figure 34.12).
- The majority of amphibians belong to the order Anura (frogs and toads). Other orders are the Apoda (caecilians) and Urodela (salamanders) (Figure 34.13).

34.4 Amniotes: Tetrapods with a Desiccation-Resistant Egg

- The amniotic egg permitted animals to become fully terrestrial. Other critical innovations included desiccation-resistant skin, thoracic breathing, water-conserving kidneys, and internal fertilization (Figure 34.14).
- Living reptilian clades include the Testudines (turtles), Squamata (lizards and snakes), Crocodilia (crocodiles), and Aves (birds). The Ornithischia and Saurischia are two extinct clades of dinosaurs (Figures 34.15, 34.16, 34.17, 34.18).
- Three species—*Archaeopteryx*, *Caudipteryx*, and *Confuciusornis*—help trace a lineage from dinosaurs to birds (Figure 34.19).
- The four key characteristics of birds are feathers, air sacs, reduced organs, and a lightweight skeleton. Birds are the most species-rich clade of terrestrial vertebrates. The diversity of bird beaks reflects the varied methods they use for feeding (Figures 34.20, 34.21, Table 34.2).

34.5 Mammals: Milk-Producing Amniotes

- The distinguishing characteristics of mammals are mammary glands, hair, specialized teeth, and an enlarged skull. Other distinguishing characteristics of some mammals are the ability to digest plants and horns or antlers. Mammal tooth shape varies according to diet (Figures 34.22, 34.23, 34.24).
- Two subclasses of mammals exist: the Prototheria (monotremes) and the Theria (the live-bearing mammals). The live-bearing mammals are, in turn, divided into the Metatheria (marsupials) and Eutheria (placental mammals). The Eutheria have been divided into four different clades (Table 34.3, Figures 34.25, 34.26).
- Many defining characteristics of primates relate to their tree-dwelling nature and include grasping hands, large brain, nails instead of claws, and binocular vision (Figures 34.27, 34.28, 34.29).
- About 6 mya in Africa, a lineage that led to humans began to separate from other primate lineages. A key characteristic of hominins (extinct and modern humans) is bipedalism. Human evolution can be visualized like a tree, with a few hominin species coexisting at the same point in time, some eventually going extinct, and some giving rise to other species (Figures 34.30, 34.31).
- The out-of-Africa hypothesis suggests that the migration of hominins from Africa happened at least three times, with *Homo sapiens* gradually replacing other hominin species in other parts of the world (Figure 34.32). The multiregional hypothesis proposes that human groups evolved in a number of different parts of the world. Most scientists believe the out-of-Africa hypothesis is better supported by the data.
- Data from human mitochondrial DNA suggest all humans derive from a "mitochondrial Eve" that originated in east Africa. From there, *H. sapiens* spread to Asia and then to all other parts of the globe (Figure 34.33).

Assess and Discuss

Test Yourself

1. Which of the following is *not* a defining characteristic of vertebrates?
   a. cranium
   b. hinged jaw
   c. vertebral column
   d. endoskeleton
2. The presence of a bony skeleton, an operculum, and a swim bladder are all defining characteristics of
   a. Myxini.
   b. lampreys.
   c. Chondrichthyes.
   d. bony fishes.
   e. amphibians.
3. Organisms that lay eggs are said to be
   a. oviparous.
   b. ovoviparous.
   c. viviparous.
   d. placental.
   e. none of the above.
4. Which clade does not include frogs?
   a. vertebrates
   b. gnathostomes
   c. tetrapods
   d. amniotes
   e. lobe fins

5. In some amphibians, the adult retains certain larval characteristics, which is known as
   a. metamorphosis.
   b. parthenogenesis.
   c. cephalization.
   d. paedomorphosis.
   e. hermaphrodism.
6. The membrane of the amniotic egg that serves as a site for waste storage is
   a. the amnion.
   b. the yolk sac.
   c. the allantois.
   d. the chorion.
   e. the albumin.
7. Which characteristic qualifies lizards as gnathostomes?
   a. a cranium
   b. a skeleton of bone or cartilage
   c. a hinged jaw
   d. the possession of limbs
   e. amniotic eggs
8. Which of the following is *not* a distinguishing characteristic of birds?
   a. amniotic egg
   b. feathers
   c. air sacs
   d. lack of certain organs
   e. lightweight skeletons
9. What is *not* a derived trait of primates?
   a. opposable thumb
   b. grasping hands
   c. prehensile tail
   d. flat nails
   e. large brain
10. Despite their small size and nocturnal habits, tarsiers are classed with much larger monkeys and apes as Haplorrhini. On which of the following characteristics is this classification based?
    a. dry fully furred noses
    b. forward-facing eyes
    c. DNA similarities
    d. a and b
    e. a, b, and c

Conceptual Questions

1. How is vertebrate movement similar to arthropod movement, and how is it different?
2. Why aren't all reptiles endothermic if both birds and mammals are?
3.  A principle of biology is that *all species (past and present) are related by an evolutionary history.* Are birds living dinosaurs?

Collaborative Questions

1. By what means can vertebrates move?
2. Why are amphibians considered good indicator species, which are species whose status provides information on the overall health of an ecosystem?

UNIT VI

FLOWERING PLANTS

Flowering plants, also known as the angiosperms, are essential to the lives of humans and most other organisms on Earth. Flowering plants provide most of our food, either directly in the form of vegetables and grains and other fruits or indirectly as animal fodder. Cotton, linen, and other fibers that we use for clothing and wood that we use for construction and fuel, as well as powerful cancer drugs and many other medicines, come from flowering plants. Unit VI reveals molecular, biochemical, structural, evolutionary, and ecological features of the hundreds of thousands of flowering plants that support Earth's life.

Unit VI begins with Chapter 35, which provides an overview of flowering plant structure and function, focusing on the seed-to-seed life cycle. By comparing plant bodies with those of animals, we will discover how plants are constructed and how they grow. Building on this background, Chapter 36 explains the genetic and physiological bases of plant behavior—plant responses to external stimuli such as day length that are mediated by internally produced hormones. In this chapter, we will see that like animals, plants have evolved sophisticated sensory systems that monitor environmental conditions and allow plants to respond in predictable ways. Chapter 37 explains the nutritional requirements of plants, a deep understanding of which is critical to human agriculture and our ability to feed increasing populations of humans. In Chapter 38, we see how plant water transport influences global climate and how plants import organic food into nonphotosynthetic organs and tissues. This chapter will explain how plant fruits become so sweet. Chapter 39 focuses on the molecular and cellular bases of plant reproduction, the process that generates seeds and fruits. This chapter ties together key concepts presented throughout Unit VI: the seed-to-seed life cycle of plants and their distinctively structured bodies, plant development and growth in response to environmental and hormonal influences, and plant acquisition and transport of materials that support growth and reproduction.

The following biology principles will be emphasized in this unit:

- ***Living organisms use energy:*** *Though sunlight is the major source of energy for photosynthetic plants, hundreds of flowering plant species as well as diverse tissues occurring in all flowering plants are heterotrophic and thus require a supply of organic food as a source of energy.*
- ***Living organisms interact with their environment:*** *Some of the ways in which plants detect and respond to light and other environmental factors are similar to those operating in microbes or animals, but others are distinctive.*
- ***Living organisms maintain homeostasis:*** *As is the case for animals, it is essential for flowering plants to maintain body water content and energy balance within tolerance limits, or they will die.*
- ***Living organisms grow and develop:*** *Some of the cellular and molecular bases of plant growth and development are also features of microbes and animals, but plants display some unique growth and development modes.*
- ***Structure determines function:*** *Have you ever wondered why and how trees become so tall? The unique features of plant bodies as well as variations occurring among plants explain how flowering plants function in nature and in human agriculture.*

An Introduction to Flowering Plant Form and Function

35

CHAPTER OUTLINE

35.1 From Seed to Seed—the Life of a Flowering Plant

35.2 How Plants Grow and Develop

35.3 The Shoot System: Stem and Leaf Adaptations

35.4 Root System Adaptations

Summary of Key Concepts

Assess and Discuss

Diverse types of seeds produced by flowering plants. Seeds, each containing a plant embryo along with stored food and protected by a tough seed coat, are key resources for modern agriculture and ecological restoration projects.

Anyone who seeks to improve human life by reducing the effects of disease, producing more food, or improving our environment needs to know something about plant form and function. That's because humans depend on flowering plants not only for nutritious food, fibers such as cotton and linen, wood and paper, medicines, and biofuels, but also for plentiful fresh air and clean water. Knowledge of basic plant form and function, including how plants develop from and produce seeds, is essential to understanding these useful plant features.

Seeds, such as those in the chapter opening photo, are key to human ability to produce crops to support ever-increasing populations and to restore degraded environments. For this reason, people store seeds of diverse plant species in seed banks, from which plant geneticists and restoration biologists can make withdrawals. Plant geneticists use seeds obtained from seed banks to breed new crop varieties that are resistant to pests and diseases, or that will help farmers cope with changing environmental conditions. Restoration biologists need large amounts of seeds of diverse natural species for replanting degraded or destroyed lands. For example, the Kew Botanical Garden in the U.K. stores 1.8 billion seeds of 30,000 plant species in temperature-controlled vaults. The U.S. and other nations also maintain valuable seed banks to help biologists of the future understand how plants evolve in response to environmental change.

This chapter provides an introduction to the seed-producing flowering plants, focusing on fundamental principles of body form and function—anatomy and physiology. These principles are basic to human efforts to use genetic methods to improve crops in ways that enhance human health. Just as medical scientists seek to understand how mutations influence human anatomy and physiology, plant geneticists need to know how genes affect the plant body and its health. The principles of plant form and function are equally important to evolutionary biologists who seek to understand how and why variations in plant body structure arise, as well as to ecologists who want to know how plants, animals, and microbes function together in nature.

We will begin by considering the life of a flowering plant, from seed germination to the production of a new generation, analogous to the life of an animal from birth to reproductive adulthood. Next, an overview of how plants grow and develop reveals fascinating similarities to animals, but also intriguing differences. Finally, centering our attention on the adult plant body reveals how adaptation to different environments has generated diverse species whose form and function vary dramatically. This background supports subsequent chapters in this unit that provide more information about flowering plant behavior, nutrition, transport, and reproduction and development.

35.1 From Seed to Seed—the Life of a Flowering Plant

Learning Outcomes:

1. List ways in which seed plant reproduction and growth resemble or differ from those of animals.
2. Describe how the two major types of flowering plants—monocots and eudicots—differ in form.

3. **SciSKILLS** » Distinguish among annual, biennial, and perennial plants, and understand how their differences influence human uses of plants as food.

Several major events punctuate the lives of flowering plants, also known as the **angiosperms**. When seeds germinate, dormant embryos wake to metabolic activity and begin the process of seedling development. Seedlings grow and develop into mature plants capable of reproduction. Finally, flowers produce fruits that disperse the next generation of seeds. In this section, we will briefly survey the life of flowering plants, focusing on the basic structural features of each life stage.

Seedlings Develop from Embryos in Seeds

Seeds are reproductive structures produced by flowering plants and other seed plants, usually as the result of sexual reproduction. Seeds contain embryos that develop into young plants—seedlings—when seeds germinate. As in animals, the embryo is an essential stage in the sexual cycle of plants. The plant sexual cycle explains how embryos typically arise (**Figure 35.1**; see also Figure 30.14).

Unlike animals, sexual reproduction in plants requires two multicellular stages: a gamete-producing **gametophyte** and a spore-producing **sporophyte** (refer back to Figure 30.14). In the life cycle of plants, these two life stages alternate with one another in a process called **alternation of generations**. Flowering plants produce relatively large sporophytes and microscopic gametophytes that grow and develop within flowers. Diploid sporophytes produce haploid spores by the process of meiosis. These spores grow into gametophytes that produce plant gametes—eggs and sperm. Fusion of egg and sperm in the process of fertilization generates a diploid zygote, which undergoes repeated mitotic divisions to form the plant **embryo**.

The plant embryo is a very young sporophyte that lies dormant within a seed, accompanied by a supply of stored food and enclosed by a tough, protective seed coat (**Figure 35.2a**), much like the animal amniotic egg. Like an eggshell, the seed coat protects the delicate plant embryo during the dispersal of seeds from parent plants into the environment. Dispersed seeds may remain dormant in the soil—sometimes for long periods—but germinate when temperature, moisture, and light conditions are favorable. Such conditions activate embryo metabolism, in which stored food is respired for energy needed for cell division and growth. As is the case for animals, **growth** is an increase in weight or size, and **development** is a series of changes in the state of a cell, tissue, organ, or organism. Enlarging plant embryos break the seed coat and grow into seedlings (**Figure 35.2b**). If sufficient resources such as water and minerals are available, seedlings develop into mature plants (**Figure 35.2c**).

The angiosperm plant body is simpler in form than most animal bodies and is composed of only three types of organs: stems, leaves, and roots. **Stems** produce leaves and branches and bear the reproductive structures of mature plants. **Leaves** are flattened structures that emerge from stems and are often specialized in ways that enable photosynthesis. Stems and leaves together make up the plant **shoot** (see Figure 35.2b). Mature plants often possess multiple stems bearing many leaves, which together form the **shoot system**. **Roots** provide anchorage in the soil and also foster efficient uptake of water and minerals. The aggregate of a plant's roots make up the **root system** (see Figure 35.2c).

As in animals, the process of body and organ development in plants involves the differentiation of specialized cells having distinctive structure and function. But unlike animals, plant seedlings and mature plants produce new tissues in specific areas called meristems. A **meristem** (from the Greek *merizein*, meaning to divide) is a region of undifferentiated cells that produces new tissues by cell division. A dormant meristem occurs at the shoot and root tips of seed embryos, and these meristems become active in seedlings (see Figure 35.2a and b). In mature plants, active meristems occur at each stem and root tip. Such meristems are known as shoot and root **apical meristems** because they occur at shoot and root tips, also known as apices.

Mature Sporophytes Develop from Seedlings

As seedlings develop into mature sporophytes, the aboveground shoot typically becomes green and photosynthetic and thus able to produce organic food. Photosynthesis powers the transformation of seedlings into mature plants. The development of mature plants encompasses

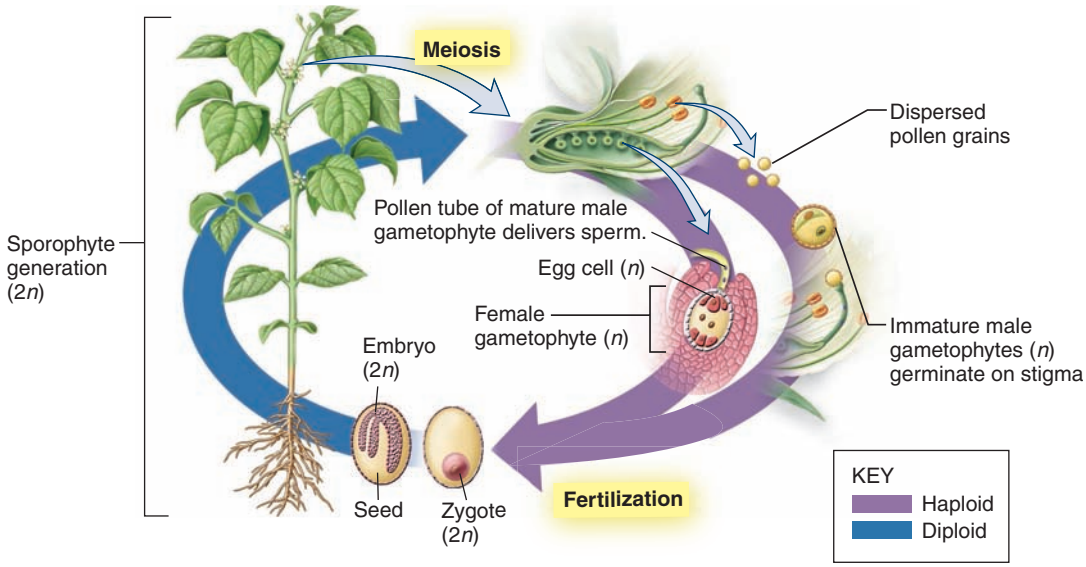

Figure 35.1 The plant sexual cycle. The sexual cycle of flowering plants involves alternation of sporophyte and gametophyte generations. In flowering plants, the sporophyte is the dominant, conspicuous generation, whereas the tiny gametophytes are mostly hidden within flowers. The bean plant shown here produces both male and female gametophytes. Embryos form when eggs produced by female gametophytes are fertilized by sperm produced by male gametophytes. Embryos, which are the young sporophytes of the next generation, are dispersed from plants within seeds.

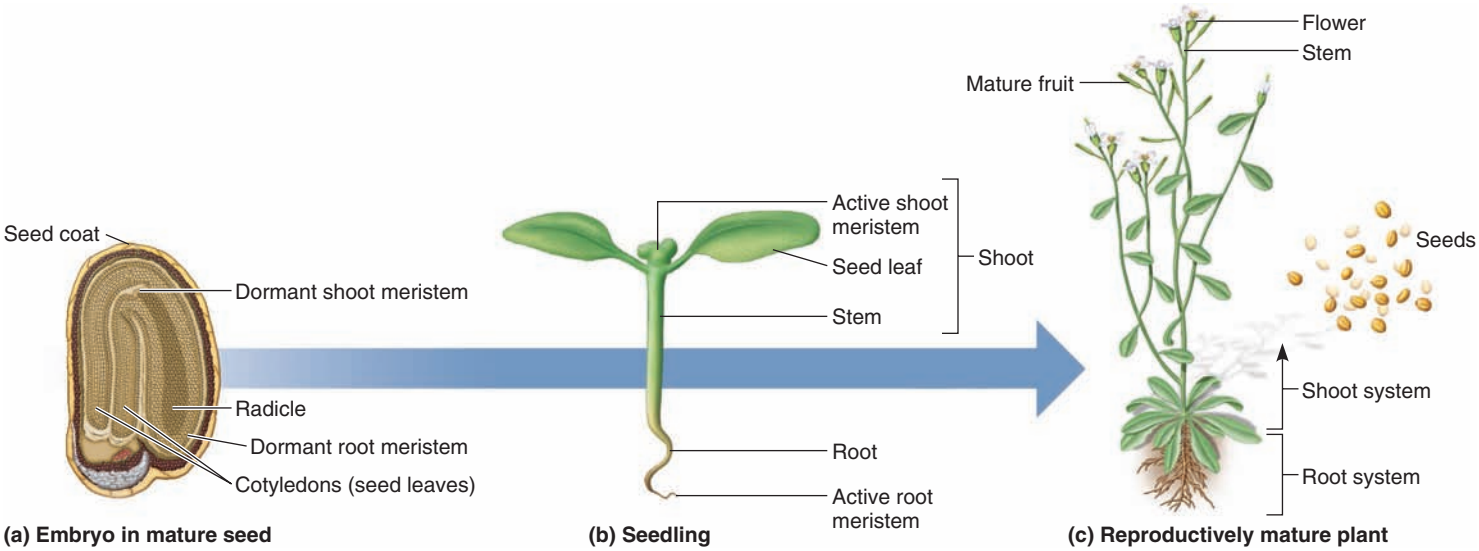

Figure 35.2 The seed-to-seed life cycle of flowering plants. **(a)** Seed embryos possess embryonic leaves, known as cotyledons; a dormant shoot meristem; an embryonic root, known as a radicle; and a dormant root meristem. **(b)** When seeds germinate, the shoot and root meristems become active. Meristem activity allows the radicle to produce the seedling root and the young shoot of the seedling to grow and produce leaves. **(c)** Reproductively mature plants have branched shoot and root systems and bear flowers and fruits that disperse seeds.

BIOLOGY PRINCIPLE **Living organisms grow and develop.** The plant *Arabidopsis thaliana* is widely used as a model organism for understanding the genetics of plant structure and development.

both **vegetative growth**, a process that increases the size of the shoot and root systems, and reproductive development. Vegetative growth and reproductive development involve **organ systems**, structures that are composed of more than one organ. Branches, buds, flowers, seeds, and fruits are organ systems, analogous to organ systems such as the circulatory, skeletal, and reproductive systems in the animal body. The hierarchy of structure in a mature plant, ranging from specialized cells, tissues, organs, and organ systems to root and shoot systems, is shown in **Figure 35.3**.

Vegetative Growth During their growth, plant shoots produce **buds**—miniature shoots each having a dormant shoot apical meristem. Scaly modified leaves protect the bud contents. Under favorable conditions, the bud scales fall off, and the vegetative buds open. Newly opened buds display young leaves on a short shoot. The shoot apical meristem then becomes active, producing new stem tissue and leaves. In this way, buds generate leafy branches. A bud is an example of an organ system because it contains more than one organ.

Vegetative shoots often display **indeterminate growth**, meaning that apical meristems continuously produce new stem tissues and leaves as long as conditions remain favorable. This process explains how very large plants, such as trees, can develop from seedlings (**Figure 35.4a**). However, plant size is also under genetic control, so some plants remain small even when they are mature. The tiny floating plants of *Lemna* species, commonly known as duckweeds, which sometimes cover the surfaces of ponds in summer, are examples of plants whose small size is genetically determined (**Figure 35.4b**). Indeterminate growth allows plants to adapt their vegetative body structure to environmental conditions. By contrast, animal bodies and flowers display **determinate growth**, which is growth of limited duration.

Development Under favorable conditions, mature plants produce reproductive structures: flowers, seeds, and fruits. **Flowers** and floral buds are reproductive shoots that develop when shoot apical meristems produce flower parts instead of new stem tissues and leaves. Flower development occurs under the control of several genes whose roles are well understood (refer back to Figure 19.24). In contrast to shoots, which often show indeterminate growth, flowers are produced by determinate growth. A floral shoot no longer produces new stem growth or leaves. Therefore, vegetative growth and reproductive development are alternative processes. In order to flower, a plant must give up some of its potential to continue vegetative growth.

Flower tissues enclose and protect tiny male and female gametophytes during their growth and development (see Figure 35.1). Female gametophytes produce eggs within structures known as ovules, produced in the ovary of a flower pistil. Male gametophytes begin their development within pollen grains produced in the anthers of a flower stamen. Pollen is dispersed to the flower pistil, where the pollen grains may germinate, producing a tube that delivers sperm to eggs. Fertilization generates zygotes, which develop into embryos, and also triggers the process by which ovules develop into seeds and flower parts develop into fruits. **Fruits** thus enclose seeds and function in seed dispersal. Flower buds, flowers, fruits, and seeds are organ systems because they consist of more than one organ. For example, flowers typically contain several leafy organs, including sepals and petals, as well as stamens and pistils, that evolved from leaves (refer back to Figure 30.15).

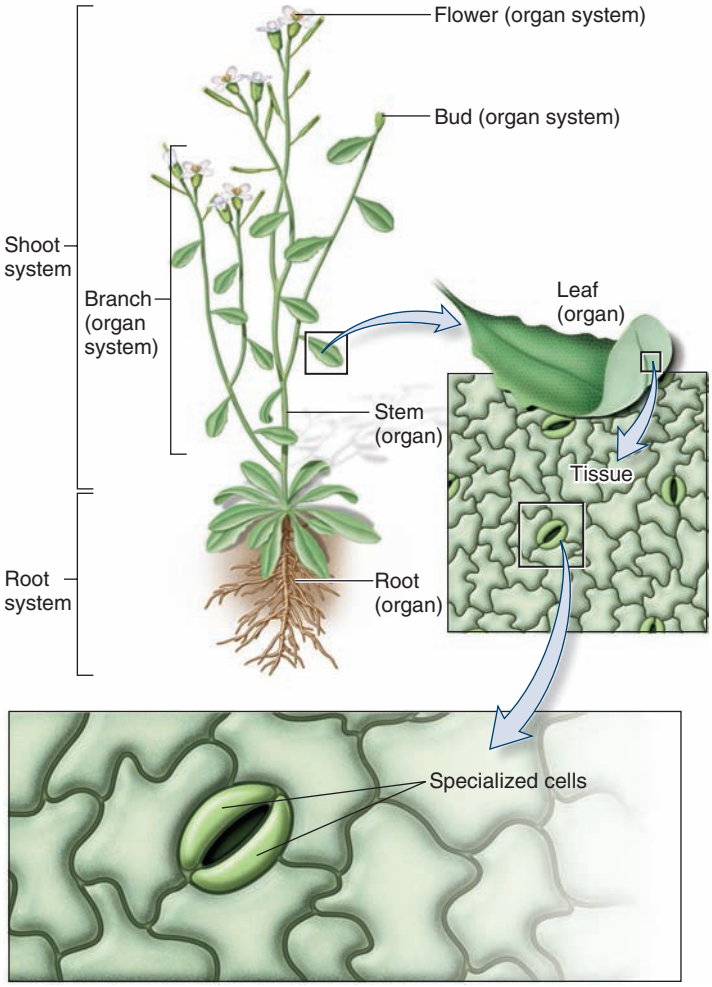

Figure 35.3 Levels of biological organization in a plant. Flowering plant sporophyte bodies consist of a root system and a shoot system. Shoot systems produce organ systems such as buds, flowers, fruits, and seeds, which are composed of organs, tissues, and specialized cells. Root systems are likewise composed of organs, tissues, and specialized cells.

Flowering Plants Vary in the Structure of Organs and Organ Systems

With some exceptions, flowering plants occur in two groups, informally known as the **eudicots** and the **monocots** (refer back to Figure 30.18). These groups take their names from the number of seed leaves (cotyledons) that are present on seed embryos. For example, bean plants and relatives, which possess two (*di*) seed leaves, are examples of eudicots. Most woody trees, shrubs, and vines are also eudicots. Corn, which has only one (*mono*) seed leaf, is an example of a monocot, as is tiny duckweed (see Figure 35.4b). Eudicots and monocots also vary in the structure of other organs and organ systems. For example, eudicot flowers typically have petals and other parts numbering four, five, or a multiple of those numbers, whereas monocot flower parts usually occur in threes or a multiple of three. Stems, roots, leaves, and pollen of eudicots and monocots also vary in distinctive ways, as shown in **Table 35.1**.

(a) *Brachychiton*, a tree native to Australia

(b) *Lemna* (common duckweed)

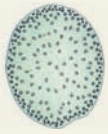

Figure 35.4 Plants display indeterminate growth, but vary in size. A large woody angiosperm **(a)** has the same indeterminate growth pattern as a tiny duckweed plant **(b)**.

Flowering Plants Vary in Seed-to-Seed Lifetime

The lifetime of a flowering plant can vary from a few weeks to many years. Plants that die after producing seed during their first year of life are known as **annuals**. Corn and the common bean are examples of annual crops whose nutrient-rich seeds are harvested within a few months after planting and must be replanted at the beginning of each new growing season. Plants that do not reproduce during the first year of life but may reproduce within the following year are known as **biennials**. Such plants often store food in fleshy roots during the first year of growth, and this food fuels reproduction during the second or later year of life. Humans use some of these fleshy roots for food, including carrots, parsnips, and sugar beets. Trees are examples of **perennials**, plants that live for more than 2 years, often producing seed each year after they reach reproductive maturity.

Many flowering plants use environmental signals to time flowering in ways that enhance seed production. Temperature and day length are examples of environmental factors that determine flowering time. Plant seed-to-seed lifetimes are also influenced by the longevity of their seeds. Seeds of some plants are able to germinate after more than a thousand years of dormancy, whereas other plant seeds are unable to remain alive for long periods.

Table 35.1 Distinguishing Features of Eudicots and Monocots, Two Major Groups of Flowering Plants

Feature	Eudicots	Monocots
Number of seed leaves (cotyledons)	Two 	One 
Number of flower parts	Usually four, five, or multiples of these 	Usually three or multiple of three 
Stem vascular bundles	Arranged in a ring 	Scattered 
Root system	Branched taproot 	Fibrous; adventitious 
Leaf venation	Netted or branched 	Often parallel 
Pollen	Three pores or slits 	One pore or slit 

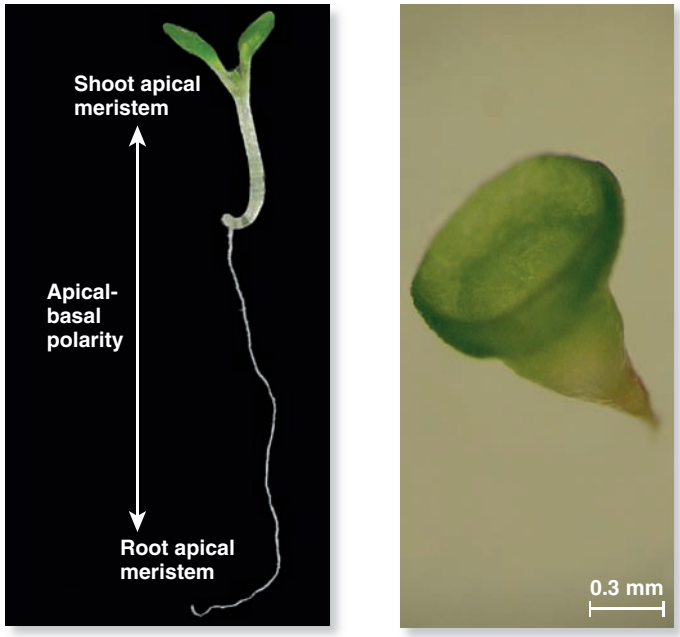
35.2 How Plants Grow and Develop

Learning Outcomes:

1. **SciSKILLS »** Compare and contrast plant body architecture and development with those of animals.
2. Explain how the shoot system differs from the root system.

As plants grow from seedlings, their development depends on four processes that are also essential to animal growth and development: cell division, growth, cell specialization, and programmed cell death. Additional and distinctive aspects of plant growth and development include (1) development and maintenance of a plant-specific architecture throughout life, (2) an increase in length by the activity of apical meristems, (3) maintenance of a population of youthful stem cells in meristems, and (4) expansion of cells in controlled directions, by water uptake.

Plants Display a Distinctive Architecture



In plant biology, the term apical has two distinct meanings. As we have seen, apical refers to the tips or apices of shoots and roots, as in shoot apical meristems or root apical meristems. A second meaning for apical is the part of a plant that typically projects upward, which is the top of the shoot. By contrast, the bottom of a root is termed the basal region. So the shoot apical meristem occurs at the apical pole, and the root apical meristem occurs at the basal pole. This property, known as **apical-basal polarity**, explains why plants produce shoots at their tops and roots at their lower regions. Apical-basal polarity originates during embryo development. As seedlings and maturing plants grow in length by the activity of shoot and root meristems, apical-basal polarity is maintained (**Figure 35.5a**). Animals likewise have anterior and posterior ends, whose development is influenced by *Hox* genes (refer back to Chapter 32). In contrast, plant apical-basal polarity is under the control of genes such as *GNOM*; mutations in these genes result in plant embryos that are cone-shaped or spherical and thus lack normal apical-basal architecture (**Figure 35.5b**).

A second architectural feature of the typical plant body is **radial symmetry**. Plant embryos normally display a cylindrical shape, also known as an axis, which is retained in the stems and roots of seedlings and mature plants. A thin slice or cross section of an embryo, stem, or root is typically circular in shape. Most plants produce new leaves or flower parts in circular whorls, or spirals, around shoot tips (**Figure 35.6**). Buds and branches likewise emerge from stems in radial patterns, as do lateral roots from a central root axis. Together, apical-basal polarity and radial symmetry explain why diverse plant species have a fundamentally similar architecture. Although radial symmetry also characterizes early-diverging animals, most animals exhibit bilateral symmetry (look back at Figure 32.5).

Primary Meristems Increase Plant Length and Produce Plant Organs

We previously discussed how plant embryos grow into seedlings by adding new cells from distinctive growth points, the **shoot apical meristem (SAM)** and the **root apical meristem (RAM)**. During plant development, the SAM and RAM of the embryo give rise to many apical meristems located in the buds of shoots and at the tips of roots.

A SAM produces tissues that increase plant length and generate new organs. Such meristems are known as the **primary meristems**, and in a process known as **primary growth**, they ultimately produce primary tissues and organs of diverse types (**Table 35.2**). Tissues differ in their cellular complexity. Simple primary tissues are those composed of only one or two cell types; complex primary tissues are

(a) Normal seedling

(b) Abnormal *GNOM* mutants

Figure 35.5 **Plant apical-basal polarity.** **(a)** Normal plants exhibit apical-basal polarity, as shown by this seedling. Such growth occurs at two meristems, one at the shoot (SAM) and one at the root (RAM). **(b)** *GNOM* mutants of *Arabidopsis thaliana* lack apical-basal polarity and thus produce abnormal embryos and seedlings.

BioConnections: *Look back to Figure 19.17 to see the relationship between Hox gene expression and body organization in the mouse, as a model animal. How is animal body polarity similar to that of plants?*

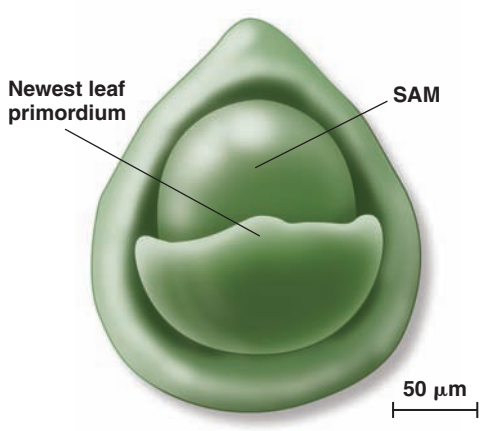


Figure 35.6 **Plant radial symmetry.** This top-down view of a shoot apical meristem (SAM) reveals the radial symmetry of the shoot, indicated by its cylindrical shape. Leaf primordia are produced in circles or spirals around the shoot axis.

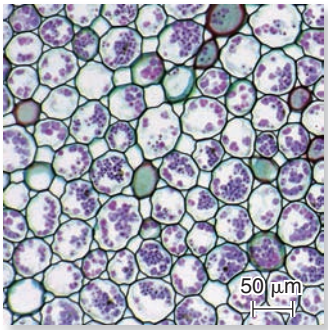
Concept Check: *How could you determine that roots have radial symmetry?*

made of more cell types. As described in Section 35.3, the primary meristems of woody plants also give rise to secondary or lateral meristems. In a process known as **secondary growth**, the secondary meristems increase the girth of woody plant stems and roots by producing secondary tissues (Table 35.2).



Plant biologists have discovered that plant cell specialization and tissue development do not depend on the lineage (the parentage) of a cell or tissue. Chemical influences such as hormones, proteins known as transcription factors, and microRNAs that move through plants are much more important in determining the type of specialized tissue produced by unspecialized plant cells. Examples of such chemical influences are provided in the rest of this chapter.

Primary Stem Structure and Development New primary stem tissues arise via cell divisions in shoot apical meristems. A layer of outermost tissue known as the **epidermis** develops at the stem surface. The epidermis produces a waxy surface coating known as the **cuticle**, which helps to reduce water loss from the plant surface and to protect plants from damage by ultraviolet (UV) light, animals, and disease-causing microorganisms (refer back to Figure 29.11a).

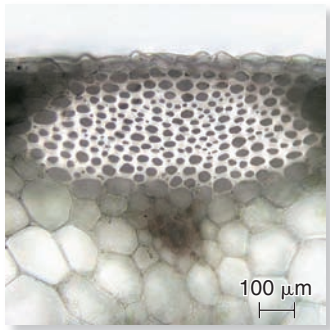


Table 35.2 **Examples of Tissues and Specialized Cells Found in Flowering Plants***

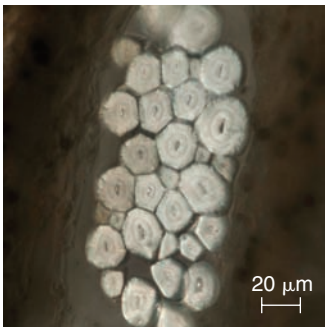
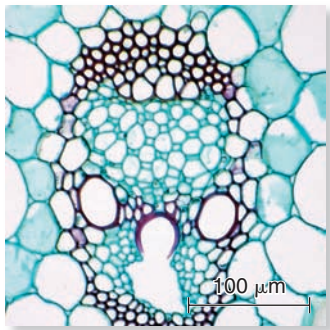
Primary Growth	
Simple primary tissues (composed of one or two cell types)	**Plant cell types found in those tissues**
Parenchyma	Parenchyma cells
Collenchyma	Collenchyma cells
Sclerenchyma	Fibers and sclereids
Root endodermis	Endodermal cells
Root pericycle	Pericycle cells
Complex primary tissues (composed of at least two cell types)	**Plant cell types found in those tissues**
Leaf or stem epidermis	Flattened epidermal cells, trichomes, stomatal guard cells
Root epidermis	Flattened epidermal cells, root hairs
Leaf mesophyll	Spongy parenchyma cells, palisade parenchyma cells
Leaf, stem, or root xylem	Tracheids, vessel elements, fibers, parenchyma cells
Leaf, stem, or root phloem	Sieve-tube elements, companion cells, fibers, parenchyma cells
Secondary Growth	
Simple and complex secondary tissues	**Plant cell types found in those tissues**
Secondary xylem (wood)	Tracheids, vessel elements, fibers, parenchyma
Secondary phloem (inner bark)	Sieve-tube elements, companion cells, fibers, parenchyma
Outer bark	Cork cells



*This list does not include all of the tissues and cell types found in flowering plants. Some of these examples will be described later in this chapter.



(a) Parenchyma

(b) Collenchyma

(c) Sclerenchyma

(d) Vascular bundle

Figure 35.7 Examples of tissues produced by primary shoot meristems. **(a)** Parenchyma, **(b)** collenchyma, **(c)** sclerenchyma, and **(d)** a vascular bundle composed of complex xylem and phloem tissues. The purple-stained particles in parenchyma cells are stored starch. The walls of sclerenchyma cells are notably thick. The darker-stained, thickened walls of the water-conducting cells of xylem contrast with the lighter-stained, thinner-walled food-conducting cells of phloem.

Beneath the epidermis lies the stem **cortex**, which is largely composed of a type of tissue called **parenchyma** (Figure 35.7a). This tissue is composed of only one cell type, thin-walled cells known as **parenchyma cells**. These cells often store starch in plastids and therefore serve as an organic food reserve. Stem parenchyma also has the ability to undergo cell division (meristematic capacity), which aids wound healing when stems are damaged. The cell division capability of stem parenchyma also explains how people are able to grow new plants from stem cuttings. Stems also contain **collenchyma** (Figure 35.7b), tissue composed of flexible **collenchyma cells**, and rigid **sclerenchyma** (Figure 35.7c), tissue composed of two types of tough-walled sclerenchyma cells termed **fibers** and **sclereids**. These tough cells provide strength and protection to the plant stem.

New water- and food-conducting tissues develop at the core of a young shoot. These conducting tissues are known as **primary vascular tissues** because they develop from new cells produced by the SAM. Vascular tissues occur in two forms—**xylem** and **phloem**—which are composed of several types of specialized tissues and cells (see Section 35.3 and Table 35.2). Newly formed stem xylem and phloem connect with older conducting tissues that extend throughout the stem system. Stem xylem and phloem link to vascular tissues of the root system, forming a continuous route for conduction of water, minerals, and organic compounds through the plant. However, in contrast to the circulatory system of most animals, the plant conduction system is not closed, but instead is open to the environment (plant transport is described more completely in Chapter 38). Primary vascular tissues are typically arranged in elongate clusters known as **vascular bundles** that appear round or oval when cross-cut (Figure 35.7d). In the primary stems of beans and other eudicots, the vascular bundles are arranged in a ring, which is easily seen in thin slices made across a stem (see Table 35.1). By contrast, in the stems of corn and other monocots, the vascular bundles are scattered.

Leaf Structure and Development Young leaves are produced at the sides of a SAM as small bumps known as **leaf primordia** (see Figure 35.5). As young leaves develop, they acquire vascular tissue that is connected to the stem xylem and phloem (Figure 35.8a) and become flattened, a process that expands the area of leaf surface available for light collection during photosynthesis. For some leaves, thinness is an adaptation that helps them to release excess heat. Leaves also become bilaterally symmetrical, meaning that they can be divided into two equal halves in only one direction, from the leaf tip to its base (Figure 35.8b).

Upper and lower leaf tissues develop differently in several ways that foster photosynthesis (Figure 35.8c). For example, the more shaded lower epidermis of a leaf usually displays larger numbers of pores, known as **stomata** (from the Greek word *stoma*, meaning mouth), than the sunnier upper surface (refer back to Figure 29.11b). When open, stomata allow CO_2 to enter and water vapor and O_2 to escape leaf tissues. Closure of stomata helps to prevent excess water loss from plant surfaces. **Palisade parenchyma** consists of closely packed, elongated cells of the inner leaf that are adapted to absorb sunlight efficiently. **Spongy parenchyma**, located closer to the lower leaf surface, contains rounder cells separated by abundant air spaces. These air spaces foster CO_2 absorption and O_2 release by leaves. Together, the palisade and spongy parenchyma are known as the leaf **mesophyll**.

Leaf veins composed of vascular tissue commonly occur at the junction of palisade and spongy parenchyma, or within the spongy parenchyma (see Figure 35.8c). Palisade parenchyma and spongy parenchyma are typically green and active in photosynthesis, a process that requires water, carbon dioxide, and dissolved minerals. Parenchyma cells can only take up carbon dioxide that has first dissolved into water, a feature inherited from ancient aquatic algal ancestors. Therefore, to perform photosynthesis, leaf parenchyma cells must be bathed in water. The xylem tissues of veins conduct water and minerals throughout leaf tissues, fostering photosynthesis. Phloem tissues of leaf veins carry the sugar products of photosynthesis from leaf cells to stem vascular tissues. In this way, sugar produced in leaves can be exported to other parts of the plant. The density of veins in angiosperm leaves is about four times that of other vascular plants. This allows plants to conduct materials more efficiently, which helps to explain why flowering plants are the dominant type of vegetation in most habitats today.

Root System Structure and Development In beans and most other eudicots, a main root develops from the embryonic root and then produces branch roots, also known as lateral roots. Such a root system of eudicots is known as a **taproot system**, which has one main root with many branch roots (see Table 35.1). In contrast, the embryonic root of most monocots dies soon after seed germination, and it is replaced by a **fibrous root system** consisting of multiple roots that grow from the stem base (see Table 35.1). Fibrous roots are examples of **adventitious roots**, structures that are produced on the surfaces of

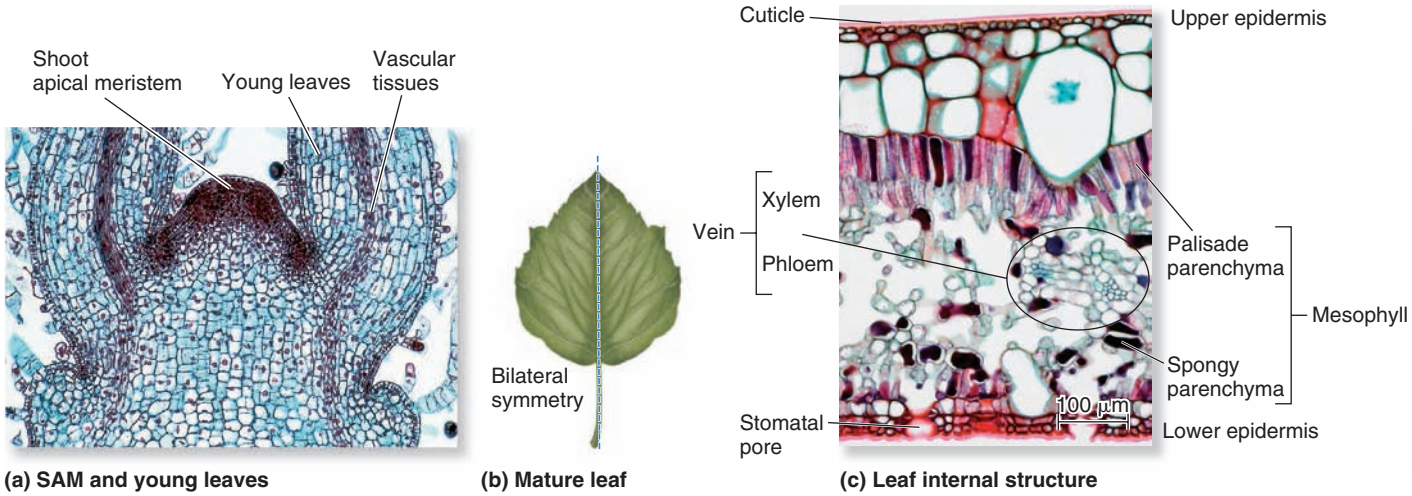


Figure 35.8 Leaf development and structure. **(a)** Young leaves develop at the sides of SAMs, as shown in this thinly sliced, stained shoot tip. Note that the darkly stained vascular tissues of young leaves are connected to those of the stem. **(b)** Mature leaves are typically thin and flat and show bilateral symmetry. **(c)** An internal view of a thinly sliced and stained leaf reveals tissue differentiation from the upper to the lower surface. A layer of palisade parenchyma lies just beneath the upper epidermis, which is capped with a waxy cuticle. Veins of conducting tissue (xylem and phloem) are embedded in the photosynthetic mesophyll. Spongy parenchyma lies above the lower epidermis, which displays stomata. These structural features of mature foliage leaves facilitate photosynthesis.

Concept Check: *What advantage do plant leaves obtain by having stomata on the lower epidermal surface?*

stems (and sometimes leaves) of both monocots and eudicots. Roots that develop at the bases of stem cuttings are also adventitious.

As noted earlier, the tips of roots and their branches each possess an apical meristem that adds new cells. Expansion of these new cells allows roots to grow into the soil. As they lengthen, roots produce branches but not from buds, as is the case for stems. Instead, branch roots develop from meristematic tissues located within the root (see Section 35.4). The root system both anchors the plant in the soil and plays an essential role in harvesting water and mineral nutrients. Root tissues are usually not green and photosynthetic. They must rely on organic compounds transported from the shoot. A plant's root system and shoot system therefore depend on each other.

Plant Meristems Contain Youthful Stem Cells

Plant meristems include undifferentiated cells referred to as **stem cells**. In the late 19th century, the Russian-born American biologist Alexander Maximow coined the term *Stammzelle*, which is derived from the German words *stamm*, meaning stem, such as a plant stem, and *zelle*, meaning cell. Maximow used the term stem cell to describe animal cells that remain undifferentiated but are able to generate specialized tissues. Animal stem cells are often in the news because of their potential for use in the treatment of human diseases that cause cell or tissue damage. The term stem cell is also widely used for cells located within the plant meristem that likewise remain undifferentiated but can divide and produce cells that generate new tissues. In the context of plant development, the term does not mean any cell located in a plant stem, only the undifferentiated cells located within the meristems of the shoot and root.

When plant stem cells divide, they produce two cells: one that remains young and unspecialized and divides relatively rarely, plus another cell. This second cell may differentiate into various types of specialized cells, but it often continues to divide, thereby adding new cells to shoot and root tips. The indeterminate growth typical of plant shoots and roots is based on the localization of stem cells in the SAM and RAM. By contrast, animal stem cells are located differently, which helps to explain the determinate growth of animal bodies. In the SAM of plants, a transcription factor (a type of protein) called WUS maintains stem cells. In the RAM, a different transcription factor, WOX, maintains stem cells. Maintaining a cache of stem cells that divide relatively rarely helps plants avoid accumulating mutations. Cells that divide frequently tend to acquire mutations. Such mutations arise because a polymerase that copies the lagging strand of DNA is error-prone.

Plant Cells Expand in a Controlled Way by Absorbing Water

As we have observed, meristem production of new cells is an important component of plant growth. In addition, plant growth involves cell expansion, which is a much less important component of animal growth. The diameters of newly formed stem and root cells are usually equal in all dimensions, but many soon begin to extend lengthwise, thereby helping shoots and roots to grow longer. Recall that plant cells typically possess a relatively large central vacuole (refer back to Figure 4.20a). Cell extension occurs when water enters the central vacuole by osmosis (**Figure 35.9**). As the central vacuole expands, the cell wall also expands and increases the cell's volume. By taking up water, plant cells can enlarge quickly, allowing rapid plant growth. Bamboo, for instance, can grow taller by 2 m within a week and can grow up to 30 m in less than 3 months! The importance of water uptake in cell expansion helps to explain why plant growth is so dependent on water supply.

Plant cell walls contain cellulose microfibrils that are held together by crosslinking polysaccharides. When plant cells and their vacuoles absorb water, pressure builds on cell walls. In response to this pressure and under acidic conditions, proteins unique to plants—known

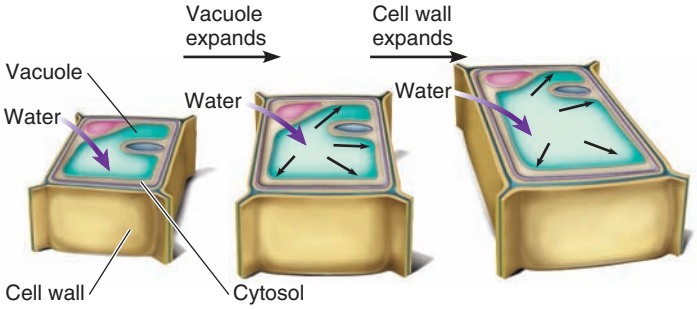

Figure 35.9 Plant cells expand by taking up water into their vacuoles.

BioConnections: Look back to Figure 4.20a to see an electron micrograph of a plant vacuole and Figure 4.9, which compares generalized animal and plant cells. How do plant cells differ from animal cells in terms of vacuoles?

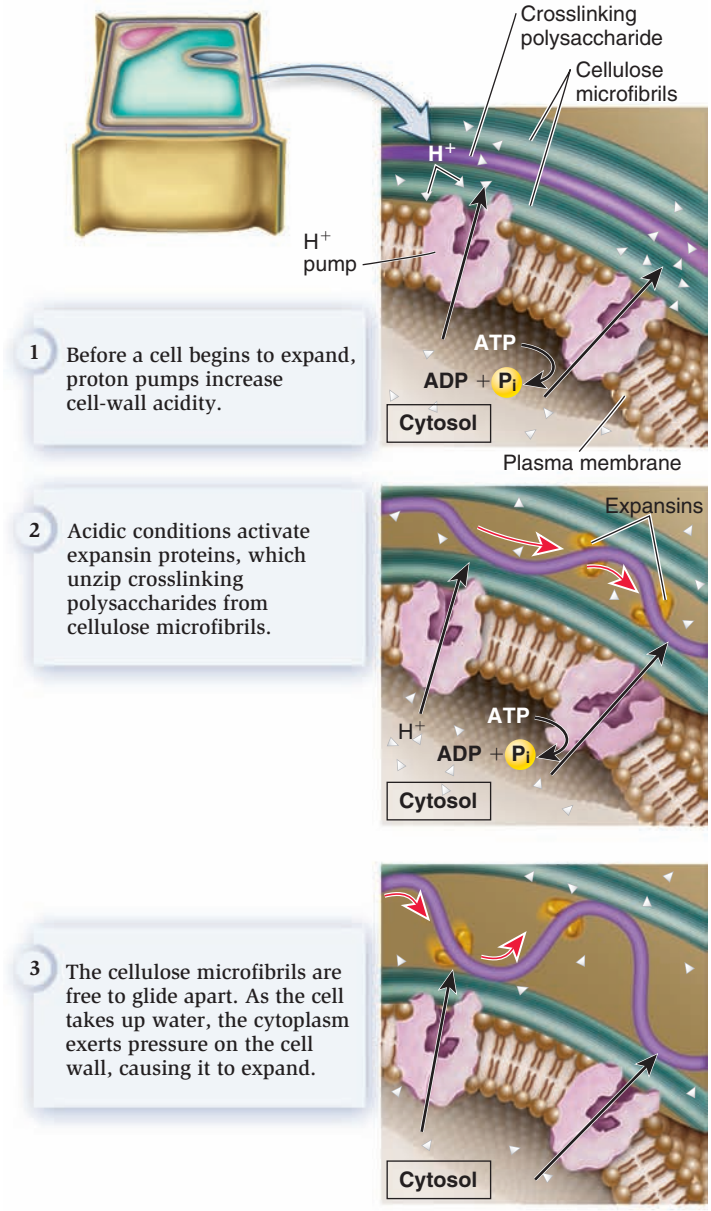

Figure 35.10 A hypothetical model of the process of cell-wall expansion.

as expansins—are produced. **Expansins** unzip crosslinking cell-wall polysaccharides from cellulose microfibrils so that the cell wall can stretch (**Figure 35.10**). As a result, cells enlarge, often by elongating in a particular direction, which is important to plant form. Some plant cells are able to elongate up to 20 times their original length.

The direction in which a plant cell expands depends on the arrangement of cellulose microfibrils in its cell wall, which is in turn determined by the orientation of cytoplasmic microtubules. These microtubules are thought to influence the positions of cellulose-synthesizing protein complexes located in the plant plasma membrane. The protein complexes connect sugars to form cellulose polymers, spinning cellulose microfibrils onto the cell surface to form the cell wall. As a result, cell-wall cellulose microfibrils encircle cells in the same orientation as underlying cytoplasmic microtubules (**Figure 35.11**). Because cellulose microfibrils do not extend lengthwise, plant cell walls expand more easily in a direction perpendicular to the microfibrils. To visualize this process, imagine encircling a spherical balloon with several parallel bands of tape before it has been completely inflated. The tape bands, which do not extend lengthwise, represent encircling cellulose microfibrils. As you add more air, the balloon tends to extend in the direction perpendicular to the bands of tape.

Microtubules control not only the direction of cell expansion but also the plane of cell division, which is also critical to plant form. Mutation of the *FASS* gene in the model plant *Arabidopsis* illustrates the importance of microtubule orientation to plant structure. In cells of the mutant plants, microtubules are randomly arranged, causing cells to divide and grow abnormally, and producing plants with stubby organs.

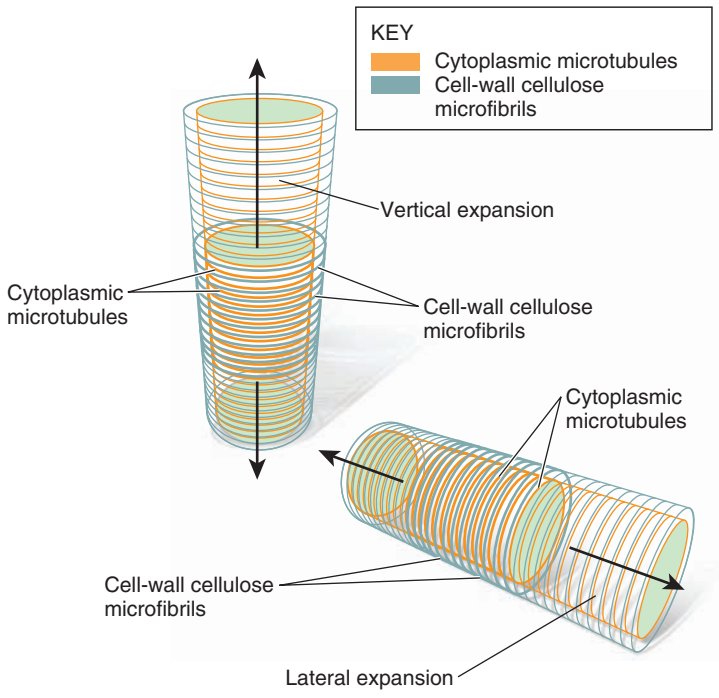

Figure 35.11 Control of the direction of plant cell expansion by microfibrils and microtubules. Plant cells enlarge in the direction perpendicular to encircling cell-wall cellulose microfibrils, which run parallel to the orientation of underlying cytoplasmic microtubules.

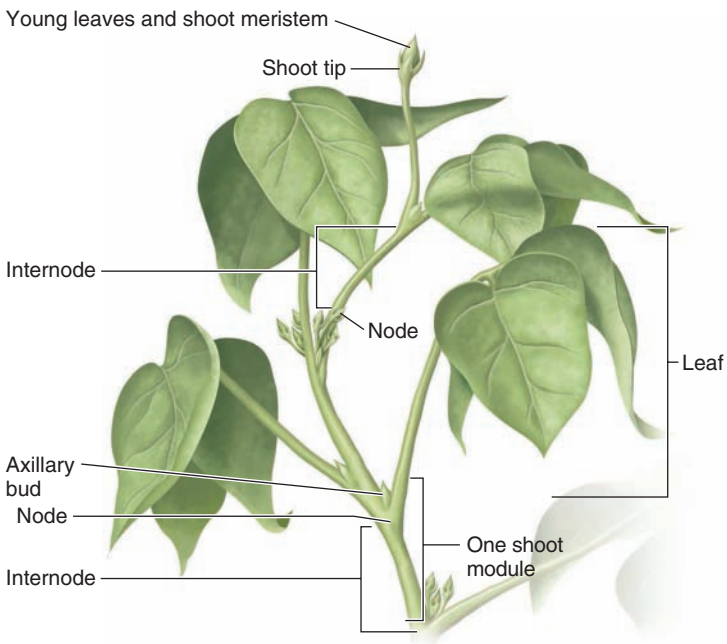
BioConnections: Look back to Table 4.1 to see an image of microtubules. How are plant and animal microtubules different?

35.3 The Shoot System: Stem and Leaf Adaptations

Learning Outcomes:

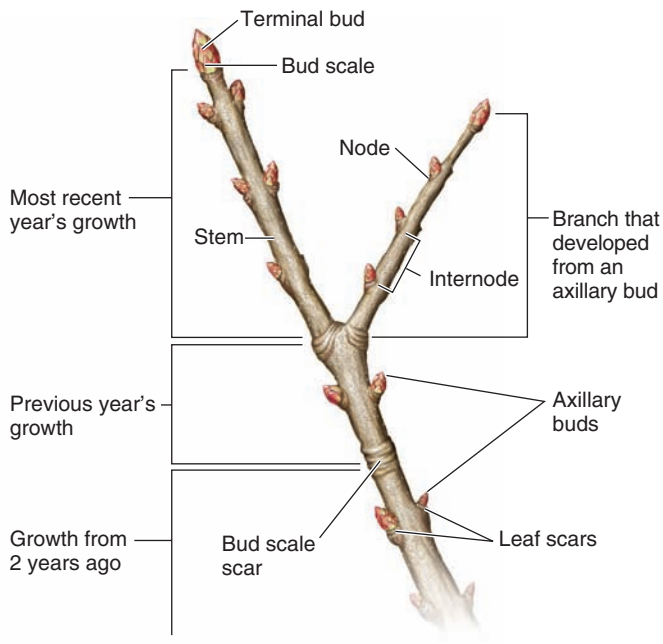
1. Discuss why plant shoots are said to have a modular structure.
2. Explain why leaves having different shapes and vein patterns exist in nature.
3. Compare the structure and function of the conducting tissues xylem and phloem.
4. **SciSKILLS** » Create a drawing showing how bark and wood originate in woody plants.

As we have seen, the shoot system includes all of a plant's stems, branches, leaves, and buds. The shoot system also produces flowers and fruits when the plant has reached reproductive maturity. Thus, the shoot system is essential to plant growth, photosynthesis, and reproduction. Features of stems and leaves vary among plants in ways that explain plant ecological function and are useful in distinguishing plant species.



Shoot Systems Have a Modular Structure

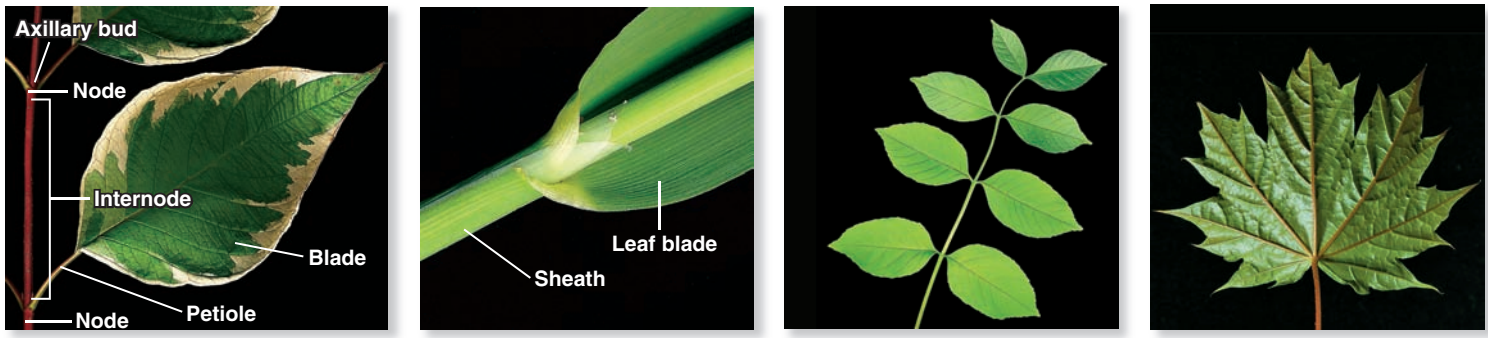
More than 200 years ago, the German author, politician, and scientist Johann Wolfgang von Goethe realized that plants are modular organisms, composed of repeated units. Shoots are notably modular (**Figure 35.12**). Each shoot module consists of four parts: a stem node, an internode, a leaf, and an axillary meristem or bud. A **node** is the stem region from which one or more leaves emerge. An **internode** is the region of stem between adjacent nodes. Differences in numbers and lengths of internodes help to explain why plants differ in height (look back to Figure 35.4). Each time a young leaf is produced at the SAM, a new meristem develops in the upper angle formed where the leaf emerges from the stem. This angle is known as an axil (from the Greek *axilla*, meaning armpit), and the meristem formed there is called an **axillary meristem**. Such axillary meristems generate **axillary buds**, which can produce flowers or branches known as lateral shoots. Such new branches bear a SAM at their tips. SAMs located at the apices of both main and lateral shoots produce new leaves. What causes new leaves to arise? The answer involves chemical messengers known as hormones.



Hormones Influence Leaf Development

As we have noted, leaf primordia are surface bumps of tissue that develop at the sides of a SAM (see Figure 35.5). Production of leaf primordia is under the control of a hormone known as **auxin**. In general, **hormones** are signaling molecules that exert their effects at a site distant from the place where they are produced. Plant hormones are important in coordinating both plant development and plant responses to environmental conditions and are discussed in more detail in Chapter 36.

The outermost epidermal layer of cells at shoot tips produces auxin, which moves from cell to cell by means of specific membrane transport proteins. Auxin accumulates in particular locations because cells of the shoot apex differ in their ability to import and export auxin. When auxin accumulates in a particular apical region, the hormone causes increased expression of the gene that encodes expansin. When expansin loosens their cell walls (see Figure 35.10), cells expand by taking up water, thereby forming a tissue bulge—a



(a) Modular structure of herbaceous shoot

(b) Modular structure of woody shoot in winter

Figure 35.12 The modular organization of plant shoots. **(a)** The top end of an herbaceous stem showing the shoot modules. Each module consists of a node with its associated leaf and axillary meristem or bud and an internode. **(b)** The modular organization shown by a woody stem as it appears during winter. Axillary buds lie above the scars left by leaf fall. Regions between successive sets of bud scale scars mark each year's growth.

Concept Check: *If a twig has five sets of bud scale scars, how old is the twig likely to be?*

(a) Eudicot stem with simple leaf and pinnate venation

(b) Monocot stem and leaf

(c) A compound leaf

(d) A simple leaf and palmate venation

Figure 35.13 **Examples of variation in leaf form.** **(a)** A simple eudicot leaf, showing blade, petiole, and axillary bud. This leaf has a pinnate venation pattern. **(b)** The leaf of a monocot, showing parallel veins. The base of the leaf encircles the stem. **(c)** A compound leaf divided into leaflets. **(d)** A simple leaf having palmate venation.

leaf primordium. The development of leaf primordia depletes auxin from nearby tissue, with the result that the next leaf primordium will develop in a different place on the shoot apex, where the auxin level is higher. Such changes in auxin concentration on the surface of the shoot explain why leaf (and flower) primordia develop in spiral or whorled patterns around the shoot tip. The youngest leaf primordia occur closest to the shoot tip, and successively older leaf primordia occur on the sides of the shoot tip (see Figure 35.5). Leaf primordia produce a plant hormone known as **gibberellic acid**. This hormone stimulates both cell division and cell enlargement, causing young leaves to grow.

Leaf Shape and Surface Features Reflect Adaptation to Environmental Stress

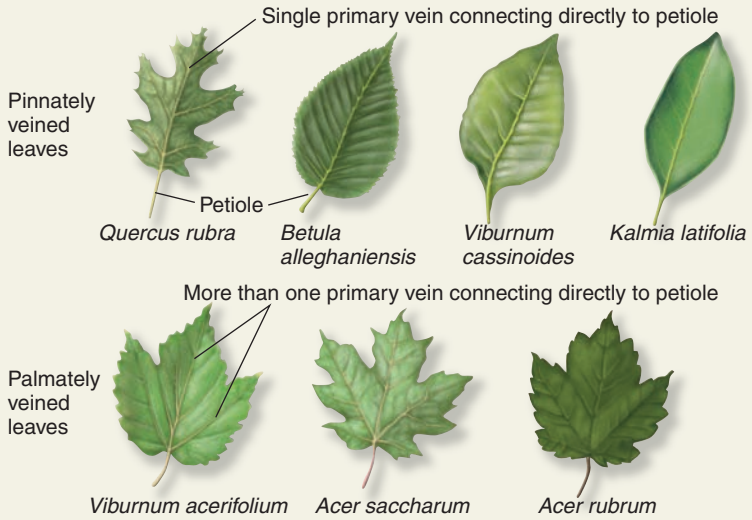
As discussed earlier, leaf flatness facilitates solar energy collection, and thinness helps leaves to avoid overheating. Leaf shape and surface features also reflect adaptation to stressful environmental conditions.

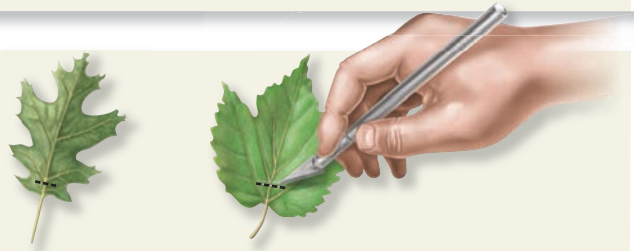
Leaf Form The flattened portion of a leaf is known as the leaf **blade**. In beans and most other eudicots, blades are attached to the stem by means of a stalk known as a **petiole**, and an axillary bud occurs at the junction of stem and petiole (**Figure 35.13a**). In contrast, corn and other monocots have leaf blades that grow directly from the stem, encircling it to form a leaf sheath (**Figure 35.13b**).

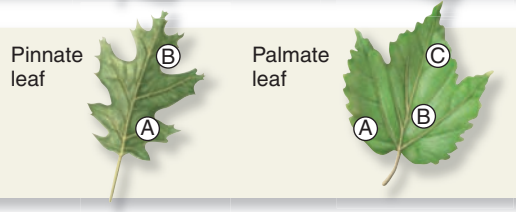
Leaf shape can be simple or compound, each having particular advantages. Simple leaves have only one blade, though the edges may be smooth, toothed, or lobed. Simple leaves are advantageous in shady environments because they provide maximal light absorption surface, but they can overheat in sunny environments. As an evolutionary response to heating stress, the blades of some leaves have become highly dissected into leaflets. Such leaves are known as compound leaves (**Figure 35.13c**). Leaflets can be distinguished from leaves because leaflets lack axillary buds at their bases. Compound leaves are common in hot environments because leaflets foster heat dissipation. During the development of at least some compound leaves, the transcription factor KNOX becomes active shortly after the leaf primordia form, causing these primordia to produce multiple growth points that generate the leaflets. In contrast, during simple leaf development, KNOX is not active, because the presence of other proteins suppresses *KNOX* gene expression.

Leaf Vein Patterns Leaf vein patterns are known as **venation**. Eudicot leaves occur in two major venation forms. They may have a single main vein from which smaller lateral veins diverge in a feather-like pattern known as **pinnate** venation (Figure 35.13a). Alternatively, several main veins may spread from a common point on the petiole like the fingers of your hand, a pattern known as **palmate** venation (**Figure 35.13d**). In eudicot leaves, small veins connect in a netted pattern, but most monocot leaves have a distinctive parallel venation (Figure 35.13b and Table 35.1).

Feature Investigation | Sack and Colleagues Showed That Palmate Venation Confers Tolerance of Leaf Vein Breakage







In 2008, Lawren Sack and colleagues studied the adaptive value of leaf venation patterns by comparing water conduction after injury in pinnately and palmately veined leaves (**Figure 35.14**). Leaves with palmate venation have several main veins, whereas leaves with pinnate venation have just one main vein. The investigators hypothesized that the multiple main veins of palmate leaves could confer greater tolerance of vein breakage of the type that would occur during mechanical injury or insect damage; if one main vein were damaged, water flow could continue through the other main veins. To test the hypothesis, the investigators experimentally cut a

main vein in the leaves of several plants belonging to seven different plant species: four having pinnately veined leaves and three having palmately veined leaves. They conducted the experiments in vivo, that is, in living trees. After the wounds had healed, the investigators measured the extent of water flow within the leaves at two or three places on each leaf. They found that across all species examined,

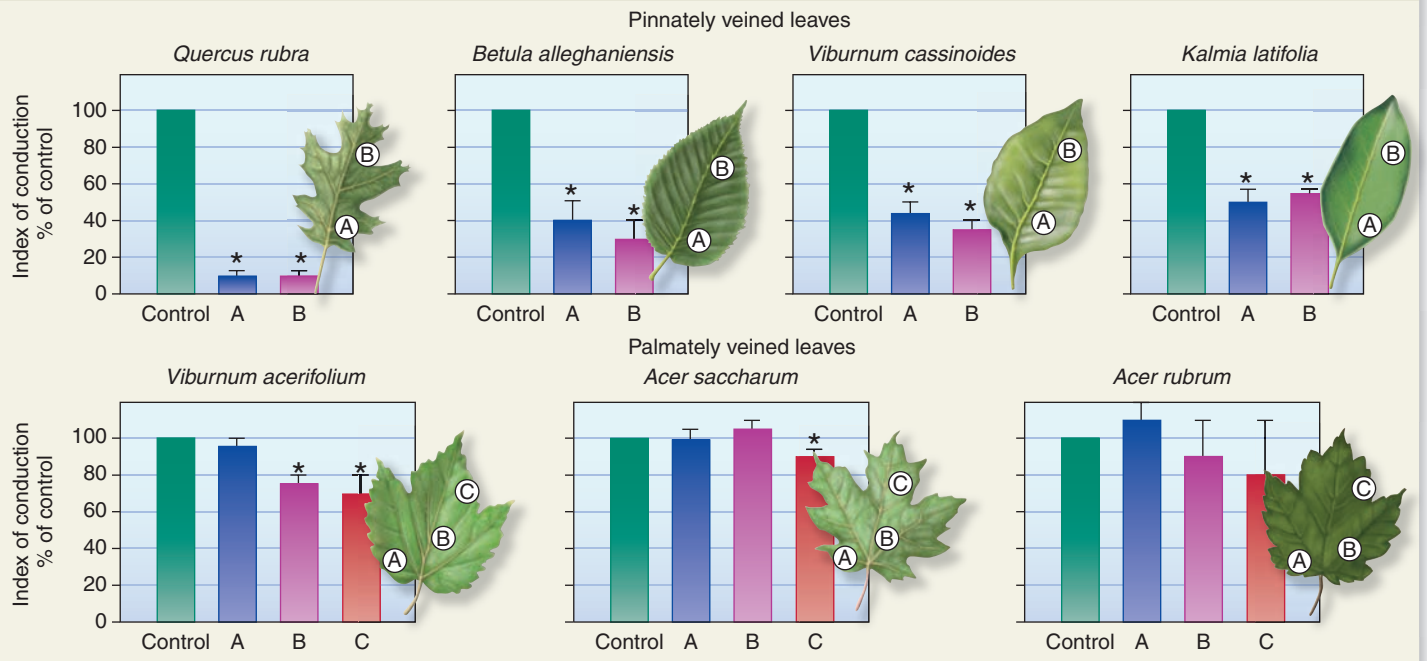


Figure 35.14 **Sack and colleagues investigated the function of palmate venation.**

HYPOTHESIS Palmate venation provides vascular redundancy, which allows leaves to tolerate vein breakage.

KEY MATERIALS Seven species of trees or shrubs at Harvard Forest, Petersham, MA.

	Experimental level	Conceptual level
1 Identify 7 species, 4 with pinnately veined leaves and 3 with palmately veined leaves. For each species, the researchers analyzed 10 leaves on 3 different plants.		Locate pinnate and palmate leaves for comparison.
2 With the leaf still attached to the plant, use a scalpel to cut across 1 primary vein in 5 experimental leaves but not 5 control leaves.		This procedure initially cuts off water supply via 1 primary vein.
3 Cover the cuts with medical tape on both top and bottom of leaves. Tape same area of uncut control leaves.		The tape prevents infection. Controls: Tape is applied to controls for experimental consistency.
4 Fold cardboard over base of cut leaves, forming a splint. Splint the same area of uncut control leaves.		The cardboard prevents leaf collapse. Controls: Cardboard is applied to controls for experimental consistency.
5 Measure water conduction 2–9 weeks after treatment, in 2 regions (A, B) of each pinnate leaf and in 3 regions (A, B, C) of each palmate leaf.		After 2–9 weeks, the cuts had healed. Measurement of water conduction will determine the effect of the vein cut.

6 THE DATA

7 CONCLUSION Palmately veined leaves did not suffer as much conduction loss from a primary vein cut as did pinnately veined leaves.

8 SOURCE Sack, L., et al. 2008. Leaf palmate venation and vascular redundancy confer tolerance of hydraulic disruption. *Proceedings of the National Academy of Sciences of the U.S.* 105:1567–1572.

palmately veined leaves tolerated the disruption in water flow better than pinnately veined leaves. Although palmate venation provides redundancy in case a main vein becomes damaged, it is more costly in terms of materials needed to construct the additional main veins. Hence, leaves with pinnate venation are less costly to produce and work well when the potential for vein damage is low.

Experimental Questions

1. Why did Sack and colleagues conduct their studies of palmate venation on plants growing in a forest rather than in a greenhouse?
2. **SciSKILLS** » Why did Sack and colleagues splint leaves having cut veins as well as controls?
3. **SciSKILLS** » Why did Sack and colleagues measure leaf water conduction at two or more places on each leaf?

Leaf Surface Features Leaf surfaces also show adaptive features. As we have previously discussed, a layer of epidermal tissue occurs at upper and lower leaf surfaces (see Figure 35.8c). These epidermal cells secrete a cuticle composed of protective wax and polyester compounds. The cuticle helps plants to avoid drying in the same way that enclosure in waxed paper keeps food moist. Plants that grow in very arid climates often have thick cuticles, whereas plants native to moist habitats typically have thinner cuticles.

Some leaf epidermal cells may differentiate into spiky or hairlike projections known as **trichomes** (**Figure 35.15**). Blankets of trichomes offer protection from excessive light, UV radiation, extreme air temperature, excess water loss, or attack by herbivores—animals that consume plant tissues. Broken trichomes of the stinging nettle, for example, release a caustic substance that irritates animals' skin, causing them to avoid these plants. Leaf epidermal cells include pairs of specialized guard cells located on either side of stomata (see Figure 35.15). These

guard cells allow stomata to be open during moist conditions and to close when conditions are dry, thereby preventing plants from losing too much water. The genetic basis of guard-cell development is becoming increasingly well understood.

BIO TIPS

THE QUESTION *Which species of tree or shrub tested by Sack and colleagues showed the greatest tolerance to damaged primary veins?*

TOPIC ***What topic in biology does this question address?*** The topic is variation in leaf venation, which many people first encounter as young children making leaf collections for school projects. More specifically, the question is about the functional role of the palmate pattern of leaf venation.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** You have learned in this chapter that leaf veins are vascular bundles composed of xylem and phloem tissues. You also know that xylem conducts water, minerals, and other dissolved materials and that leaf mesophyll cells require water and minerals to perform photosynthesis. Disruption of the flow of water to mesophyll cells occurs when veins are damaged, which prevents normal leaf function. Sack and colleagues hypothesized that leaves having palmate venation might be more resistant to disruption of water flow than leaves with pinnate venation, because the former have more main veins.

PROBLEM-SOLVING STRATEGY ***Interpret data.*** The data in step 6 of Figure 35.14 are presented in the form of histogram bars, showing differences in water conduction among the species studied when leaf veins were cut. Look for the species that displays the least difference between control leaves and experimentally cut leaves. Pay particular attention to the indicator of statistical significance (the asterisk). In displays of numerical data, asterisks are commonly used to indicate significant differences in outcomes between experimentally manipulated organisms and unmanipulated controls.

ANSWER *Bars indicating results for leaves of pinnately veined species that were experimentally cut are all noticeably shorter than the bars for control leaves, and all are marked with an asterisk, indicating statistical significance. Among the palmately veined species, the histogram bars for experimentally cut leaves of Viburnum acerifolium are taller than those for pinnately veined species, but shorter than those for the other palmately veined species studied. For the Acer species, the heights of the histogram bars for the Acer saccharum leaves that were experimentally cut are approximately the same as the height of the control bar, except for the bar for leaves cut at point C, which shows a significant difference from the control. By contrast, the heights of the histogram bars for all manipulations of the palmately veined Acer rubrum are similar, and no bars display an asterisk indicating a significant difference from the control. These results indicate that, of the species examined, Acer rubrum showed the greatest tolerance to the experimental leaf cuts.*

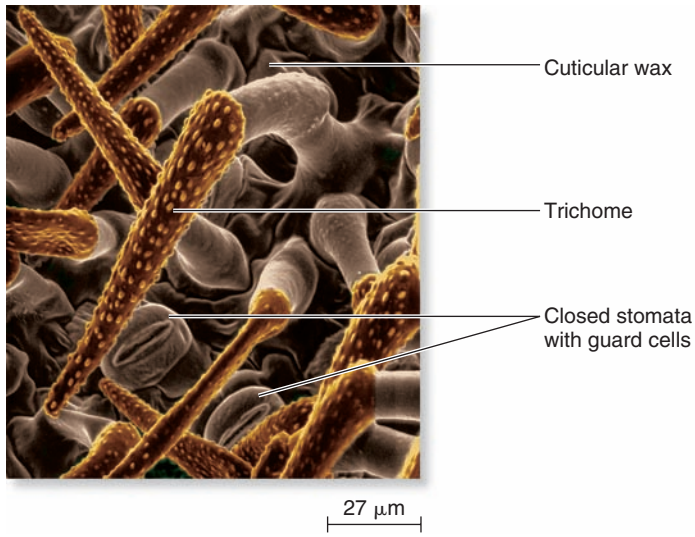

Figure 35.15 **Leaf surface features.** The features shown in this artificially colored SEM are cuticular wax, trichomes, and stomatal pores with guard cells.

Genomes & Proteomes Connection

Genetic Control of Guard-Cell Development

The flowering plant *Arabidopsis thaliana* is a model organism that is widely used to explore the genetic basis for plant structure and development. Several features increase *A. thaliana*'s utility for such studies: It is small in size, it has a fast seed-to-seed life cycle, it produces a relatively large number of seeds, and the genome has been sequenced. Mutants of this plant have been used to identify the genes controlling many aspects of plant structure and development, including the development of specialized stomatal guard cells.

Guard-cell development begins with an unspecialized protodermal cell that divides unequally (**Figure 35.16**). Unequal cell division is controlled by the protein RBR, which is related to the animal tumor suppressor Rb (Retinoblastoma). Plant cells having mutations in the gene that encodes RBR fail to differentiate normally. The larger of the two leaf cells arising from unequal division becomes a flat, puzzle piece–shaped epidermal cell, and the smaller is called a meristemoid because it functions as a stem cell. Meristemoids undergo one or more unequal cell divisions, producing more puzzle piece–shaped epidermal cells before finally dividing equally to produce a pair of guard cells. Genetic studies of *A. thaliana* have revealed that the meristemoid secretes a protein that inhibits division by adjacent cells but does not affect cells farther away. This process distributes stomata evenly and prevents too many of them from forming, which could increase the loss of water from plant surfaces.

In 2007, two teams, led by Lynn Pillitteri and Cora MacAlister, respectively, independently reported experiments with *A. thaliana* showing how three closely related genes control guard-cell

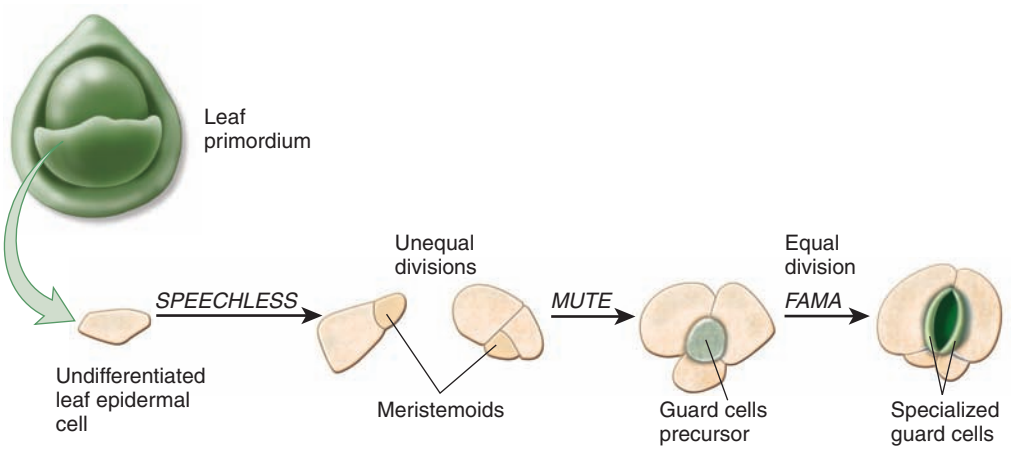

Figure 35.16 The development of stomatal guard cells, controlled by three genes.

BIOLOGY PRINCIPLE The genetic material provides a blueprint for reproduction. This sequence shows the gene actions necessary to generate stomata.

development at three consecutive steps. A gene called *SPEECHLESS* starts the process by establishing the first unequal cell divisions of meristemoids. A protein encoded by the *MUTE* gene then causes meristemoids to stop dividing unequally and produces the cell that will eventually divide to produce guard cells (guard cell precursor) (see Figure 35.16). Disabling mutations of these two genes cause the plant epidermis to completely lack stomatal pores (and so lack epidermal "mouths" and be speechless or mute). Finally, the gene *FAMA* directs the production of guard cells and their specialization. The proteins encoded by these plant genes are members of a type known as basic helix-loop-helix (bHLH) proteins. Similar bHLH proteins control the development of muscle and nerve cells in animals (refer back to Figure 19.21).

Modified Leaves Perform Diverse Functions

Though most leaves function primarily as photosynthetic organs, some plants produce leaves that are modified in ways that allow them to play other roles. For example, threadlike tendrils that help some plants attach to a supporting structure are modified leaves or leaflets (**Figure 35.17a**). The tough scales that protect buds on plants such as the sycamore from winter damage are modified leaves (**Figure 35.17b**). Poinsettia "petals" are actually modified leaves known as bracts, which are larger and more brightly colored than the flowers they surround and help attract pollinators (**Figure 35.17c**). Cactus spines are actually modified leaves that have taken on a defensive role, leaving photosynthesis to the cactus stem (**Figure 35.17d**).

Stems May Contain Primary and Secondary Vascular Systems

Stems, leaves, roots, buds, flowers, and fruits all contain vascular systems composed of xylem and phloem tissues that conduct water, minerals, and organic compounds. **Herbaceous plants** such as corn and bean produce mostly primary vascular tissues. In contrast, **woody plants** produce both primary and secondary vascular tissues. A comparison of primary and secondary vascular tissues will aid in understanding their roles.

Primary Vascular Tissues **Primary vascular tissues** are composed of primary xylem and phloem. Primary xylem is a complex tissue containing several cell types (see Table 35.2). These include unspecialized parenchyma cells; stiff fibers that provide structural support; and two types of cells that facilitate water transport: narrower tracheids and wider vessel elements (see Figures 38.11 and 38.12). Arranged in pipeline-like arrays, **tracheids** and **vessel elements** conduct water, along with dissolved minerals, hormones, and some other organic substances. These materials pass from one tracheid or vessel element to another through thin areas in the cell walls known as pits (**Figure 35.18**). Mature tracheids and vessel elements are no longer living cells, and the absence of cytoplasm facilitates water flow. During development, these cells lose their cytoplasm by the process of programmed cell death, a process that resembles apoptosis in animals. However, the cell walls of tracheids and vessel elements don't easily break down or collapse because they are impregnated with a tough polymer known as lignin, except at pits. The rigid cell walls of tracheids and vessel elements not only foster water conduction but also help support the plant body. Like the tough plastic used in plumbing pipes, lignin provides the hydrophobic surface needed for water movement, as well as the strength to support trees weighing more than 2,000 metric tons.

In contrast to the conducting cells of xylem, mature conducting cells of phloem are alive. Phloem tissue transports organic compounds such as sugars, amino acids and proteins, hormones, RNA, and certain minerals in a watery solution. Phloem tissue includes **sieve-tube elements**, thin-walled living cells that are arranged end to end to form pipelines (**Figure 35.19**). Pores in the end walls of sieve-tube elements allow the watery solution to move from one cell to another. Phloem tissue also includes companion cells that aid sieve-tube element metabolism, supportive fibers, and parenchyma cells (see Table 35.2). Phloem fibers are tough-walled sclerenchyma cells that are surprisingly long, 20–50 mm, and valued for their high strength. The phloem fibers of hemp (*Cannabis sativa*), flax (*Linum usitatissimum*), jute (*Corchorus capsularis*), kenaf (*Hibiscus cannabinus*), and ramie (*Boehmeria nivea*) are commercially important in the production of rope, textiles, and paper.

Secondary Vascular Tissues Woody plants begin life as herbaceous seedlings that possess only primary vascular systems. But

(a) Tendrils (b) Bud scales (c) Bracts (d) Spines

Figure 35.17 Examples of modified leaves. **(a)** The tendrils of an American vetch plant are modified leaves that help the plant attach to a trellis. **(b)** Bud scales, such as those on this sycamore bud, are modified leaves that protect buds from winter damage. **(c)** The attractive red bracts of poinsettia are modified leaves that function like flower petals to attract pollinator insects to the small flowers. **(d)** Cactus spines, such as these on this giant saguaro, are modified leaves that function in defense.

Concept Check: *Cactus leaves are so highly modified for defense that they cannot effectively accomplish photosynthesis, so how do cacti obtain organic compounds?*

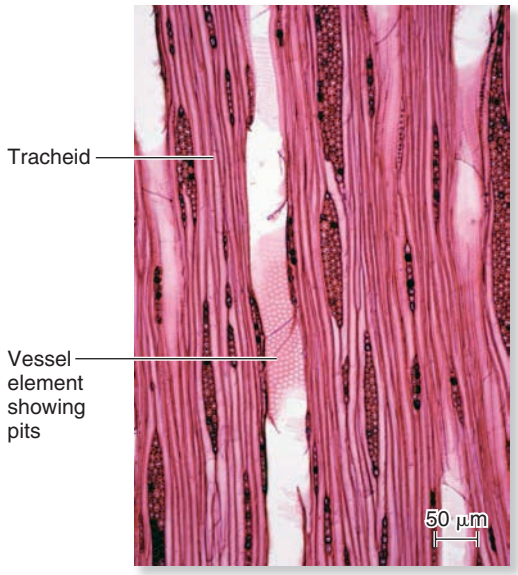

Figure 35.18 Water-conducting cells of the xylem. In this thinly sliced portion of a stem, the stained, lignin-impregnated walls of narrow tracheids and wider vessel elements can be distinguished.

BIOLOGY PRINCIPLE Structure determines function. Because lignin strengthens these cells, they do not collapse as large volumes of water move through them.

as these plants mature, they produce secondary vascular tissues and bark. Secondary vascular tissues are composed of secondary xylem and secondary phloem. **Secondary xylem** is also known as **wood**, a component of plants that plays many important roles in human life. Wood is composed of about 25% lignin, 45% cellulose, and 25% other polysaccharides that are together known as hemicelluloses.

Secondary phloem is the **inner bark**. **Outer bark** is protective layers of mostly dead cork cells that cover the outside of woody stems and roots. Therefore, bark includes both inner bark (secondary phloem) and outer bark (cork). Woody plants produce secondary vascular tissues by means of **secondary meristems**, also known as **lateral meristems**, which form rings of actively dividing cells that encircle the stem. The two types of secondary meristems are vascular cambium and cork cambium, which are derived from primary meristems.

The secondary meristem known as **vascular cambium** is a ring of dividing cells that produces secondary xylem to its interior and secondary phloem to its exterior (**Figure 35.20**). Secondary xylem conducts most of a woody plant's water and minerals. Cell divisions that occur in secondary meristems increase the girth of woody stems. During each new growing season, the vascular cambium produces new cylinders of secondary xylem and secondary phloem. In temperate trees, each year's addition of new secondary xylem forms growth rings that can be observed on the cut stem surfaces (**Figure 35.21**). The growth rings of secondary xylem surround the remains of the primary xylem and a central cylinder of parenchyma cells known as the pith. If environmental conditions favor plant growth, the growth rings formed at that time will be wider than those formed during stressful conditions. Climatologists use growth ring widths in samples of old wood to deduce past climatic conditions, and archeologists use growth ring data to determine the age of wood constructions and artifacts left by ancient cultures.

Secondary xylem may transport water for several years, but usually only the current year's production of secondary phloem is active in food transport. This is because thin-walled sieve elements typically live for only a year. Thus, only a thin layer of phloem,

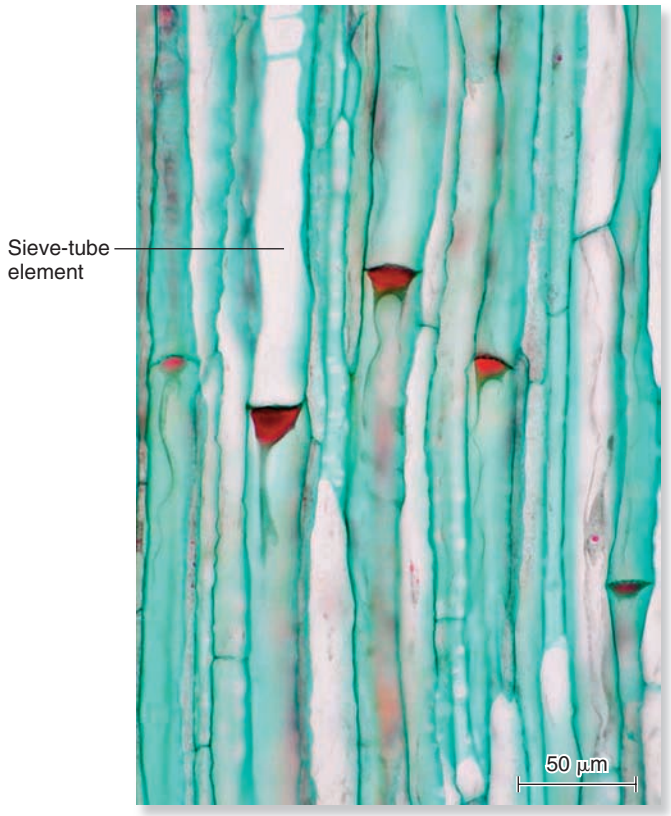

Figure 35.19 Food-conducting cells of the phloem. This thinly sliced portion of a stem shows stained, thin-walled sieve-tube elements that conduct a watery solution known as phloem sap. This solution contains sugars and other organic compounds, including amino acids and proteins, hormones, and RNA. When sieve-tube elements are damaged, which occurred when this thin slice was cut, protein plugs form. These plugs, stained red in this image, reduce loss of phloem sap, in much the same way that clotting reduces blood loss in animals.

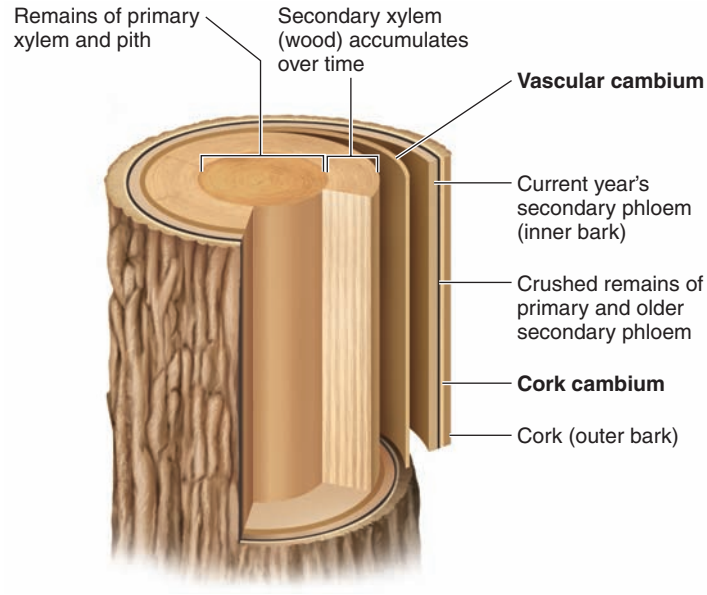

Figure 35.20 Formation of wood and bark by secondary (lateral) meristems. The vascular cambium is a thin cylinder of tissue that produces a thick cylinder of wood (secondary xylem) toward the inside of the stem and a thinner cylinder of inner bark (secondary phloem) toward the outside of the stem. The cork cambium forms an outer coating of protective cork (outer bark).

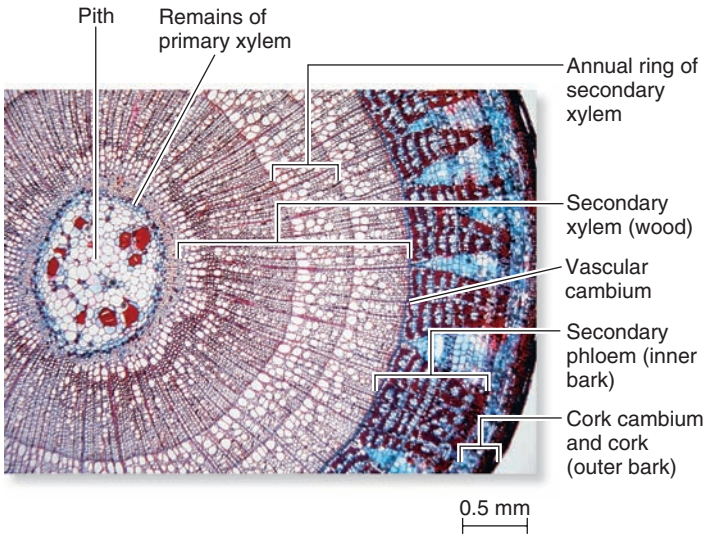

Figure 35.21 The anatomy of a tree trunk. Each year, a new cylinder of wood is produced; this yearly wood production appears as annual rings on the cut surface of a woody stem.

Concept Check: Why do tree trunks have a thicker layer of wood (secondary xylem) than of inner bark (secondary phloem)?

the inner bark, is responsible for most of the sugar transport in a large tree. Deep abrasion of tree bark may damage this thin phloem layer, disrupting a tree's food transport. If a groove is cut all the way around a tree trunk—a practice known as girdling—the tree will die because all of its functional phloem transport routes will have been interrupted.

As a young woody stem begins to increase in diameter, its thin epidermis eventually ruptures and is replaced by outer bark, which is composed of protective cork tissues. Cork is produced by a secondary meristem called the **cork cambium**, another ring of actively dividing cells. The cork cambium surrounds the secondary phloem (see Figures 35.20 and 35.21). Together, the cork cambium, layers of cork tissue produced by the cambium, and associated parenchyma cells are known as a **periderm**. The outer bark becomes thicker as woody stems accumulate multiple periderm layers. The outer bark surface is often interrupted by passages known as **lenticels** that allow inner stem tissues to accomplish gas exchange.

Cork cells are dead when mature, and their walls are layered with suberin, a material that helps to prevent both attack by microbial pathogens and water loss from the stem surface. Cork tissues also produce tannins, compounds that protect against pathogens by inactivating their proteins. The cracked surfaces of tree trunks are dead cork tissues of the outer bark. Commercial cork is sustainably harvested from the cork oak tree (*Quercus suber*) for production of flooring material, bottle stoppers, and other items. Additional information about the structure and function of primary and secondary xylem and phloem can be found in Chapter 38.

Modified Stems Display Diverse Forms and Functions

Stems mostly grow upright because light is required for photosynthesis. But some stems, known as rhizomes, occur underground and grow horizontally. For example, potato tubers are the swollen, food-storing tips of rhizomes. Grass stems also grow horizontally, as either rhizomes just beneath the soil surface or stolons, which grow along the soil surface. The leaves and reproductive shoots of grasses grow upward from the point where they are attached to these horizontal stems. Grass blades continue to elongate from their bases even if you cut their tips off, explaining why lawns must be mowed repeatedly during the growing season. The horizontal stems of grasses are adaptations that help to protect vulnerable shoot apical meristems against natural hazards such as fire and grazing animals.

35.4 Root System Adaptations

Learning Outcomes:

1. List ways that root structure has been modified in different plants in response to different habitats.
2. **SciSKILLS** » Create a drawing that shows how root systems and branch roots develop.
3. Discuss how mobile proteins influence root development.

Roots play the essential roles of absorbing water and minerals, anchoring plants in soil, and storing nutrients. The external form of roots varies among flowering plants, reflecting adaptation to particular life spans or habitats. In contrast, root internal structure is more uniform. In this section, we first consider variation in root external structure and then focus on root internal structure and development.

Modified Roots Display Diverse External Forms and Functions

As we have observed, the common bean and other eudicots display an underground taproot system, whereas corn and other monocots have a fibrous root system (see Table 35.1). Plants produce several other types of roots that provide adaptive advantages in response to different habitats. For example, corn and many other plants produce supportive prop roots from the lower portions of their stems. Many tropical trees grow in such thin soils that the trees are vulnerable to being blown down in windstorms. Such trees often produce dramatic aboveground buttress roots that help keep trees upright (**Figure 35.22a**). Many mangrove trees that grow along tropical coasts produce pneumatophores (Greek meaning breath bearers), roots that grow upward into the air (**Figure 35.22b**). Functioning like snorkels, pneumatophores absorb oxygen-rich air, which diffuses to submerged roots growing in oxygen-poor sediments. This is necessary because, like animals, roots require a supply of oxygen in order to produce ATP. Roots use this ATP to power their growth and the uptake of mineral nutrients (see Chapter 37).

Root Internal Growth and Tissue Specialization Occur in Distinct Zones

Studies of gene expression in *Arabidopsis* roots reveal that roots are amazingly complex in their internal structure, having at least 15 distinct cell types. For our purposes, a simpler microscopic examination of root internal structure reveals three major zones: (1) a root apical meristem (RAM) protected by a root cap, (2) a zone of root elongation, and (3) a zone of maturation in which specialized cells can be observed (**Figure 35.23**).

(a) Buttress roots

(b) Pneumatophores

Figure 35.22 Modified aboveground roots. **(a)** Buttress roots help to keep tropical trees such as this *Pterocarpus hayesii* from toppling in windstorms. **(b)** Pneumatophores produced by mangroves are roots that extend upward into the air. These roots take up air and then transmit it to underwater roots that grow in oxygen-poor sediments.

Root Apical Meristem and Root Cap As discussed earlier, an apical meristem occurs at the tips of roots and their branches. Like the SAM, the RAM contains stem cells, but these are organized differently in root apices. Root stem cells surround a tiny region of cells that rarely divide, known as the quiescent center. Signals emanating from the quiescent center keep nearby stem cells in an undifferentiated state. Root stem cells farther away from the quiescent center produce new cells in multiple directions. Toward the root tip, stem cells produce columella cells that sense gravity and touch, which helps roots extend downward into the soil and around obstacles such as rocks. At the sides of the quiescent center, stem cells produce a protective root cap and epidermal cells. Root tip epidermal cells secrete a sticky substance called mucigel that lubricates root growth through the soil. Toward the shoot, stem cells generate cells that become internal root tissues.

Zones of Elongation and Maturation Above the RAM lies the **zone of elongation**, in which cells extend by water uptake, thereby dramatically increasing root length (see Figure 35.23). The root elongation zone illustrates the general principle that cell expansion in plants is not necessarily linked directly to cell division. (By contrast, animal cell expansion is more closely linked to cell division.)

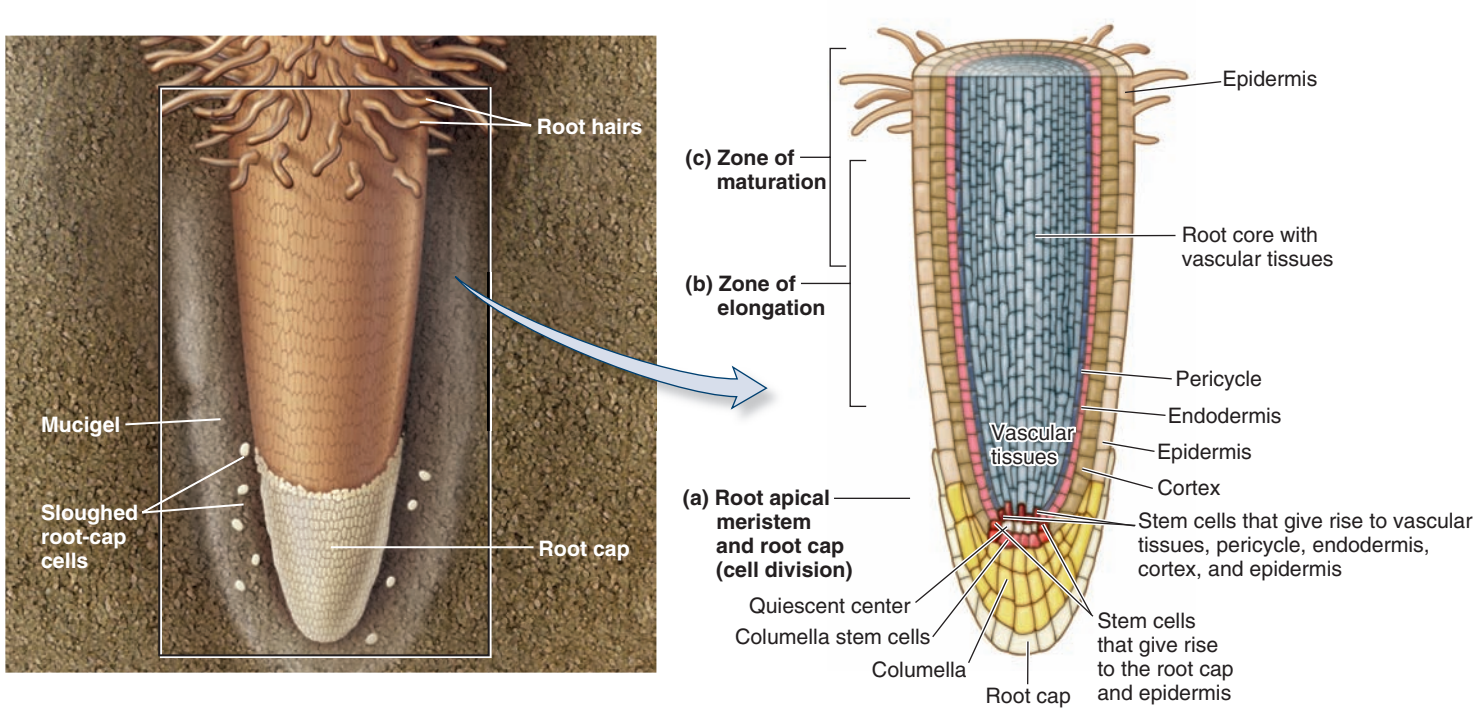

Figure 35.23 **Three zones of root growth.** A longitudinal view of a typical root reveals three major zones: **(a)** a root apical meristem region that includes stem cells, a quiescent zone, columella, and a root cap; **(b)** a zone of elongation; and **(c)** a zone of maturation, characterized by specialized cells and tissues including epidermal root hairs, cylinders of endodermis and pericycle tissue, and a core of vascular tissue.

Above and overlapping with the root zone of elongation is the **zone of maturation**, where most root cell differentiation and tissue specialization occur. Specialized root tissues include mature vascular tissues at the root core, an enclosing cylinder of cells known as the pericycle, another cell cylinder called the endodermis (meaning inside skin), and epidermal cells at the root surface. Relatively unspecialized parenchyma cells form a cortex that lies between the endodermis and the epidermis. Starting with the epidermis and moving inward, we will take a closer look at these root tissues and factors that control their development.

The zone of maturation can be identified by the presence of numerous microscopic hairs that emerge from the root epidermis. **Root hairs** are specialized epidermal cells that can be as long as 1.3 cm, about the width of your little finger, but are only 10 μm in diameter, less than the width of a finger cell. Their small diameter allows root hairs to obtain water and minerals from soil pores that are too narrow for even the smallest roots to enter. Root hair plasma membranes are rich in transport proteins that use ATP to selectively absorb materials from the soil (look ahead to Figure 38.3).

The production of hairs from root epidermal cells is controlled by the activity of transcription factors that move between cells and also by cell position (**Figure 35.24**). A root hair will develop from epidermal cells lying over the junction of two cortical cells, whereas no hair will develop if an epidermal cell lies over only one cortical cell. Root hairs are so delicate that they are easily damaged by abrasion as roots grow through the soil, and they live for only 4 or 5 days. As a result, root hairs are absent from older regions above the zone of maturation. To compensate, roots must continually produce new root hairs. The average rate of root hair production has been estimated at more than 100 million per day for some plants. One reason that gardeners use care when transplanting seedlings is to prevent extensive damage to the root hair zone.

The epidermis of mature roots encloses a cylinder of parenchyma known as the root cortex (**Figure 35.25**). Much like the stem cortex, root cortex cells are often rich in starch and therefore serve as a food storage site for plants. The root cortex of some plants contains intercellular air spaces that arise from programmed cell death and provide routes for oxygen diffusion within the root. Water and dissolved minerals also diffuse from the environment into roots through

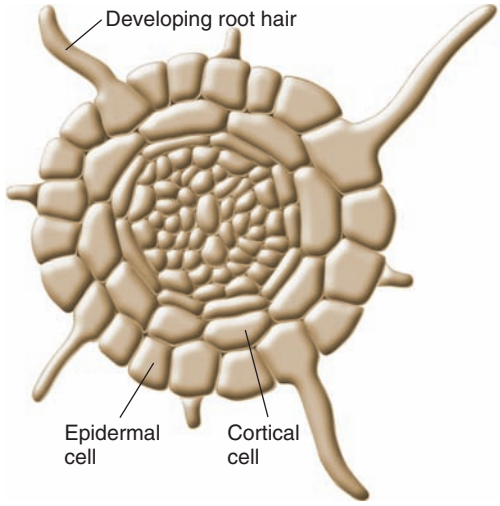

Figure 35.24 **A cross section of a root showing positional influence on root-hair development.**

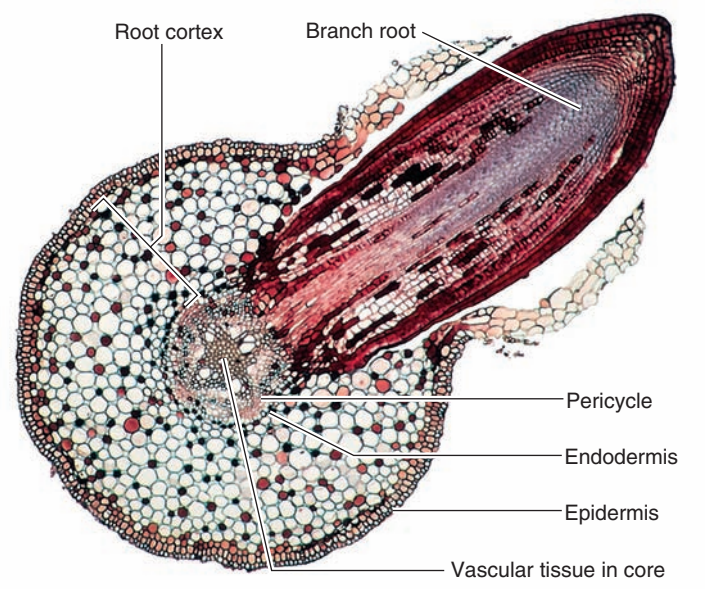

Figure 35.25 **Cross section of a mature root.** This stained light micrograph shows the epidermis and cortex of a root surrounding a central core of vascular tissue. An inner cortex layer is the endodermis, which surrounds a cylinder of meristematic pericycle tissue. The pericycle has produced a young branch (lateral) root that has grown through the cortex and the epidermis.

Concept Check: *Why must lateral roots be produced in this way?*

spaces between cortex cells, stopping only when they reach a one-cell-thick cylinder of specialized tissue known as **endodermis** (inside skin). This endodermal cell layer is an important component of the mechanism by which roots absorb selected minerals (described further in Chapter 37). Endodermal cells specialize in response to a transcription factor (called SHORT ROOT) that is synthesized in cells of the root core, then transported outward.

A cylinder of tissue having cell division (meristematic) capacity, known as the **pericycle**, encloses the root vascular tissue (see Figure 35.25). In response to the hormone auxin, the pericycle produces lateral branch roots that force their way through the cortex to the surface. This process differs from the way that stems produce branches by means of buds. In some roots, the pericycle generates a vascular cambium that produces wood—secondary xylem. Such woody roots also possess a cork cambium that makes a protective covering of suberin-coated cork tissue. Like woody stems, woody roots produce primary vascular tissues in their youth and secondary vascular tissues at maturity. The woody roots of trees are sometimes visible aboveground.

Summary of Key Concepts

35.1 From Seed to Seed—the Life of a Flowering Plant

- Seed embryos, seedlings, and mature plants are components of the sporophyte generation in the plant sexual cycle; tiny gametophytes develop and grow within flowers (Figure 35.1).
- Plant organs are composed of tissues that contain specialized cells. The basic plant organs are roots, stems, and leaves. Shoot systems include stems and stem branches, and stems produce leaves, buds, flowers, and fruits. Root systems include one or more main roots with branches. Buds, flowers, fruits, and seeds are organ systems, composed of more than one organ (Figures 35.2, 35.3).
- The two major groups of flowering plants—eudicots and monocots—differ in the structure of their seed embryos, flowers, stems, roots, leaves, and pollen (Figure 35.4, Table 35.1).

35.2 How Plants Grow and Develop

- The principles of plant growth and development include the presence of a fundamental architecture featuring apical-basal polarity and radial symmetry throughout the life of a plant (Figures 35.5, 35.6).
- Plants grow by producing new cells at meristems and by controlled cell enlargement involving water uptake.
- Shoot apical meristems produce primary meristems that increase plant length and produce organs (Table 35.2).
- The simple plant tissues, containing one or two cell types, include parenchyma, collenchyma, and sclerenchyma. Complex plant tissues include the vascular tissues known as xylem and phloem, and the primary vascular tissues occur in vascular bundles (Figure 35.7).
- Leaves develop from primordia at shoot apices. Foliage leaves have internal and external structure that is adapted for photosynthetic functions (Figure 35.8).
- Meristems include stem cells that divide relatively rarely, thereby reducing the accumulation of harmful mutations. Cells that arise from stem cells may divide more frequently, producing new tissue.
- Plant cells are able to expand under conditions that result in loosening of cell-wall components, and by water uptake into vacuoles. The direction in which plant cells expand is determined by the arrangement of cellulose microfibrils in the cell wall, which is influenced by the orientation of microtubules in the nearby cytosol (Figures 35.9, 35.10, 35.11).

35.3 The Shoot System: Stem and Leaf Adaptations

- Shoots are modular systems; each module includes a node, internode, leaf, and axillary meristem or bud. An axillary bud develops in leaf axils; such buds may grow into new branches (Figure 35.12).
- Variations in leaf structure reflect adaptations that aid photosynthesis or protect against stress. For example, Sack and colleagues demonstrated that palmate leaves provide conducting system redundancy that is useful in coping with vein damage (Figures 35.13, 35.14, 35.15).
- Stomatal guard-cell differentiation is controlled by several genes (Figure 35.16).
- Leaves not only function in photosynthesis but also play other roles, including attachment, attraction, and protection (Figure 35.17).
- Herbaceous plants are those whose stems produce little or no wood and are mostly composed of primary vascular tissues. The primary vascular tissues are primary xylem and primary phloem (Figures 35.18, 35.19).
- In addition to primary tissues, woody plants such as trees and shrubs possess secondary meristems that produce wood and bark. The vascular cambium produces secondary xylem (wood) and secondary phloem (inner bark). The cork cambium produces cork tissues that form outer bark (Figures 35.20, 35.21).

- Stems occur in diverse forms that reflect adaptation to environmental conditions. Examples include grass rhizomes, which grow horizontally underground and are therefore better protected from fire and grazing animals (as well as lawnmowers).

35.4 Root System Adaptations

- Roots occur in multiple forms that reflect adaptation to environmental conditions. Examples of aboveground roots include prop roots, buttress roots, and pneumatophores (Figure 35.22).
- The internal organization of roots is comparatively uniform, and three major zones can be recognized with the use of a microscope: the root apical meristem and root cap, a zone of cell and root elongation, and a zone of tissue maturation. Features of the mature root include epidermal root hairs that aid nutrient uptake, a food-storing cortex, an endodermis that functions in mineral selection, a pericycle that produces lateral (branch) roots (and vascular cambium in the case of woody roots), and an inner core of vascular tissue (Figures 35.23, 35.24, 35.25).

Assess and Discuss

Test Yourself

1. Where would you look to find the gametophyte generation of a flowering plant?
   a. at the shoot apical meristem
   b. at the root apical meristem
   c. in seeds
   d. in flower parts
   e. Flowering plants lack a gametophyte generation.
2. What is a radicle?
   a. an embryonic leaf
   b. an embryonic stem
   c. an embryonic root
   d. a mature root system of a monocot
   e. an organism that has extreme political views
3. Which type of plant is most likely to have food-rich roots that are useful as human food?
   a. an annual
   b. a biennial
   c. a perennial
   d. a centennial
   e. plants that grow along coastal shorelines
4. Which of the following terms best describes the distinctive architecture of plants?
   a. radial symmetry and apical-basal polarity
   b. bilateral symmetry and apical-basal polarity
   c. radial symmetry and absence of apical-basal polarity
   d. bilateral symmetry and absence of apical-basal polarity
   e. absence of symmetry and absence of apical-basal polarity
5. Which is the most accurate description of how plants grow?
   a. by the addition of new cells at meristems that include stem cells
   b. by cell enlargement as the result of water uptake
   c. by both the addition of new cells and cell expansion
   d. by addition of fat cells
   e. by all of the above
6. Where would you look for leaf primordia?
   a. at a vegetative shoot tip
   b. at the root apical meristem
   c. at the vascular cambium
   d. at the cork cambium
   e. in a floral bud
7. Which leaf tissues display the greatest amount of air space?
   a. the upper epidermis
   b. the lower epidermis
   c. the palisade parenchyma
   d. the spongy parenchyma
   e. the vascular tissues
8. What are adventitious roots?
   a. roots that develop on plant cuttings that have been placed in water
   b. buttress roots that grow from tree trunks
   c. the only kinds of roots produced by monocots, because their embryonic root dies soon after seed germination
   d. any root that is produced by stem (or sometimes leaf) tissue, rather than developing directly from the embryonic root
   e. All of the above are true of adventitious roots.
9. During its development, a tracheid elongates in a direction parallel to the shoot or root axis. Based on this information, what can you say about the orientation of cell-wall cellulose microfibrils and cytoplasmic microtubules in the developing tracheid?
   a. The microfibrils will be oriented perpendicularly (at right angles) to the long axis of the developing tracheid, encircling it, but the cytoplasmic microtubules will be oriented parallel to the direction in which the tracheid is elongating.
   b. Microfibrils and microtubules will both be oriented perpendicularly (at right angles) to the elongating axis of the tracheid.
   c. Microfibrils and microtubules will both be oriented parallel to the direction of tracheid elongation.
   d. Microfibrils will be oriented parallel to the direction of tracheid elongation, but microtubules will be perpendicular (at right angles) to both the microfibrils and the elongating tracheid.
   e. None of the above is correct.
10. What are examples of woody plants?
    a. trees
    b. shrubs
    c. herbaceous plants
    d. all of the above
    e. only a and b

Conceptual Questions

1. What would be the consequences if overall plant architecture were bilaterally symmetric?
2. What would be the consequences if leaves were radially symmetric (shaped like spheres or cylinders)?
3. A principle of biology is that *structure determines function.* Why are most tall plants woody, rather than herbaceous?

Collaborative Questions

1. Find a tree stump or a large limb that has recently been cut from a tree (or imagine doing so). Which of the following features could you locate with the unaided eye: the outer bark, the inner bark, the secondary xylem, the vascular cambium, annual rings?
2. Which physical factors would you expect to influence shoot growth most strongly? Which physical factors would you expect to influence underground root growth most strongly?

CHAPTER OUTLINE

36.1 Overview of Plant Behavioral Responses
36.2 Plant Hormones
36.3 Plant Responses to Environmental Stimuli
Summary of Key Concepts
Assess and Discuss

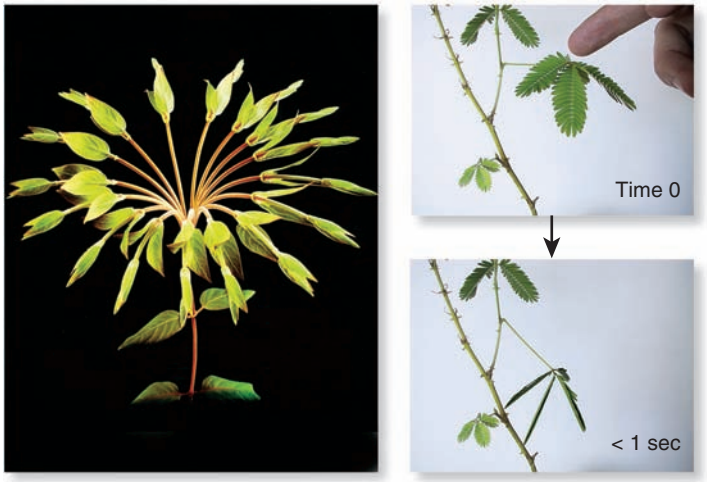
Flowering Plants: Behavior

36

Behavior of the snow buttercup. The snow buttercup (***Ranunculus adoneus***) holds its flowers above the surface of the snow. The flowers move so they always face the Sun during the day, a behavior known as sun tracking.

The snow buttercup (*Ranunculus adoneus*) grows in deep snowbanks in the high Rocky Mountains, with flower stems protruding above the snow surface toward the Sun, as shown in the chapter opening photo. Amazingly, snow buttercup flowers change their position so they face the Sun throughout the day, a process known as sun tracking. Experiments have demonstrated that sun tracking warms snow buttercup flowers, thereby favoring pollen development and germination. These processes foster fertilization, which leads to more effective seed production. In this way, sun tracking can be understood as an adaptation that increases snow buttercup reproductive fitness. Like sun-tracking solar panels, the leaves of alfalfa, lupine, soybean, common bean, cotton, and other wild and agricultural plants also track the Sun, a process that aids energy storage via photosynthesis.

Sun tracking is but one example of the many ways in which plants display behavior—that is, responses to stimuli. Plants respond not only to changes in Sun position, but also to day length, which is the period of daily illumination. In addition to light, plants respond to gravity, wind, attack by animals and disease-causing microorganisms, and other environmental stimuli. This chapter provides examples of ways in which understanding plant behavior has been key to increasing agricultural productivity and protecting natural ecosystems for the benefit of humans.



We begin with a survey of the diverse types of stimuli that induce plant behavior and review how cells perceive and respond to stimuli by means of signal transduction pathways. Next, we will focus on plant hormones and other major types of mobile internal molecules that influence plant behavior. Finally, we will consider how responses to environmental stimuli foster plant survival and reproduction.

36.1 Overview of Plant Behavioral Responses

Learning Outcomes:

1. List examples of plant responses to internal and environmental stimuli.
2. Describe the three stages of cell signaling.

Behavior is defined as a response of organisms to an internal or external stimulus. Examples of plant behavior include plant movements, some types of which were described in 1880 by Charles Darwin and his son Francis in their book *The Power of Movement in Plants*. Modern time-lapse photography, which makes plant behavior more obvious to humans, reveals that most plants are constantly in motion, bending, twisting, or rotating in dancelike movements known as nutation (**Figure 36.1a**). Some plants display relatively rapid movements, illustrated by the sensitive plant (*Mimosa pudica*), whose leaves quickly fold when touched then open more slowly (**Figure 36.1b**). Plant shoots typically grow toward light and against the pull of gravity, and most roots grow toward water and in the same direction as the gravitational force. Seeds germinate when they detect the presence of sufficient light and moisture for successful seedling growth. Producing flowers, fruit, and seeds only at the season most favorable for reproductive success is likewise a behavioral response to environmental change. Plants also take protective actions when they sense attack by disease-causing microbes or hungry animals,

(a) Nutation movements (b) Leaf folding

Figure 36.1 Examples of plant movements. **(a)** Sixteen superimposed photographs of a shoot of the honeysuckle vine *Lonicera japonica*, taken over a period of 2 hours, reveal the circular movement known as nutation. **(b)** Photographs of the sensitive plant (*Mimosa pudica*) made before and shortly after a touch reveal the rapid process of leaf folding. Even if only one leaflet is touched, electrical signals travel throughout the complex leaf, causing the entire organ to fold. The leaves will eventually unfold.

thereby preventing excessive damage to their own bodies or those of neighboring plants. To gain a more complete understanding of plant behavior, we will begin by surveying the types of stimuli that cause plant responses.

Plant Behavior Involves Responses to Internal and External Stimuli

Most people are aware that both internal chemical signals and environmental factors influence animal behavior. Bird nesting behavior in spring, for example, involves hormonal changes triggered by seasonal conditions. Plants likewise respond to internal and environmental stimuli (**Figure 36.2**).

Internal Stimuli Plants respond to two types of internal stimuli: internal biological clocks and mobile chemical signals. Internal biological clocks, known as **circadian rhythms**, occur not only in plants, but also in animals and other organisms. The word circadian comes from the Latin words meaning about and day. Circadian rhythms evolved under the influence of Earth's rotation, which causes the regular alternation of night and day. Leaf movements, flower opening, fragrance emission, and many other behaviors result from the operation of circadian rhythms in plants. Circadian clocks are thought to influence the timing of about 30% of gene activity in plants.

Like animals, plants also respond to internal chemical signals that are produced within the body and move from one location to another, acting at very low concentrations. In plants, these chemical signals may move short distances from cell to cell via plasmodesmata or by cell membrane transporter systems, or long distances within the vascular system. Plant chemical signals include transcription factors and other proteins, as well as chemically different compounds known as **hormones**. Some plant hormones are similar to particular animal hormones. One example is the plant hormone jasmonic acid, which is much like prostaglandins produced by animals. The gaseous hormone nitric oxide (NO) functions in both animals and plants. Other hormones are distinctive to plants. Even so, as in the case of animal hormones, plant hormones often interact with each other and with external stimuli to maintain a stable internal environment (homeostasis) and enable progress through life stages.

Environmental Stimuli Plants sense and respond to many types of physical and biological environmental stimuli (see Figure 36.2). Physical stimuli in natural plant environments include light, atmospheric gases such as CO_2 and water vapor, temperature, touch, wind, gravity, soil water, rocks and other barriers to root growth, and soil minerals. Biological stimuli include herbivores (animals that consume plant parts), airborne pathogens (disease-causing microbes), organic chemicals emitted from neighboring plants, and beneficial or harmful soil microorganisms. Crop plants also respond to applications of agricultural chemicals, which may include hormones. That plants have evolved such a broad array of sensory capacity is not

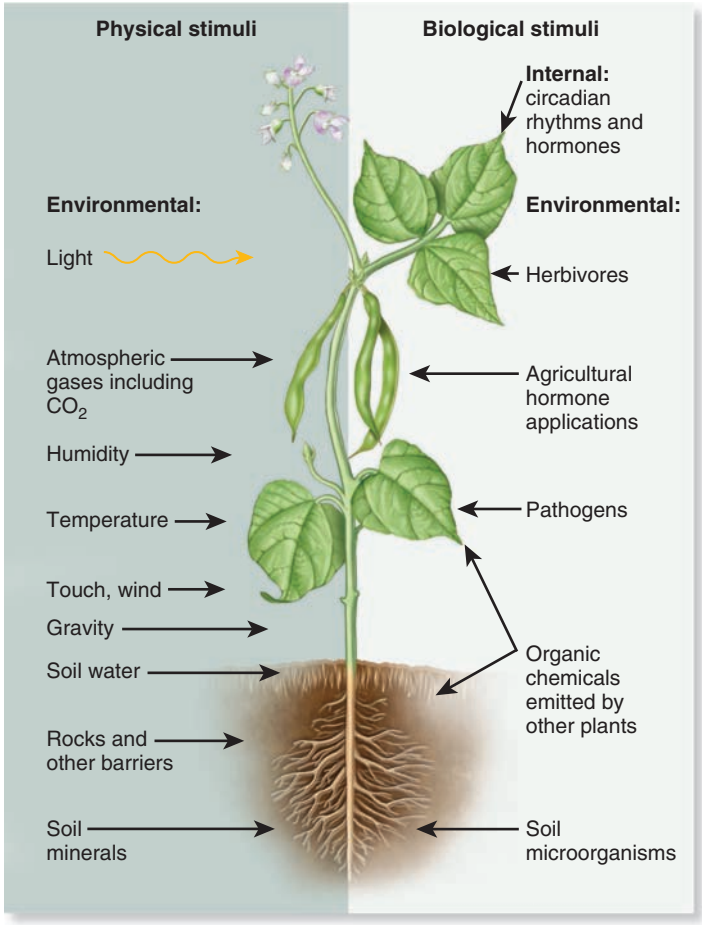


Figure 36.2 Types of plant stimuli. Plants respond to both physical and biological stimuli. Stimuli may be internal to the plant or come from the environment.

surprising, because all of the listed environmental influences affect plant survival and reproduction.

Plant Responses to Environmental Stimuli Though plants lack the specialized sense organs typical of animals, receptor molecules located in plant cells sense stimuli and cause responses. When many cells of a tissue receive and respond to the same biological or physical stimuli, entire organs or plant bodies display behavior. For example, houseplants tend to grow toward a light source such as a window. This process, known as positive **phototropism**, involves both a cellular perception of light and a growth response of stem tissue to an internal chemical signal. In general, a **tropism** is a growth response that depends on a stimulus that occurs in a particular direction. In the case of phototropism, the plant senses the direction of light and responds by changing the location of a plant hormone known as auxin. As a result, the stem bends toward light. We will next review how plant cells more generally receive signals and transmit them intracellularly, a process known as cell signaling that occurs in all cells (refer back to Chapter 9).

Plant Cell Signaling Involves Receptors, Second Messengers, and Effectors

Cell signaling is the process in which a cell receives a physical or chemical signal, thereby switching on an intracellular pathway that leads to a cellular response (**Figure 36.3**). The process of cell signaling often involves three types of molecules: receptors that may become activated, second messengers that transmit signals, and effectors that cause a cellular response (refer back to Figure 9.4).

Receptors (also known as sensors) are proteins that become activated when they receive a specific type of signal (see Figure 36.3). Receptors occur in diverse cellular locations. Whereas some plant defense receptors are located within the plasma membrane, light receptors may occur in the cytosol and auxin receptors in the nucleus. Some activated receptors directly generate a response, such as an increased flow of ions across a membrane. In contrast, many activated receptors first bind to signaling molecules that initiate an intracellular signaling pathway. For example, the binding of certain defense hormones to plasma membrane receptors results in the intracellular production of second messenger molecules that transmit the signal.

Second messengers transmit messages from many types of activated receptors. Cyclic AMP (cAMP), inositol trisphosphate (IP_3), and calcium ions (Ca^{2+}) are major second messengers in animal and plant cells. Ca^{2+} is a particularly common second messenger in plant cells. Touch and various other stimuli cause Ca^{2+} to flow from storage sites in the lumen of the endoplasmic reticulum (ER) into the cytosol. Calmodulin or other calcium-binding proteins then bind the Ca^{2+}. Calcium binding alters the structure of such proteins, causing them to interact with other cell proteins or to alter enzymatic function.

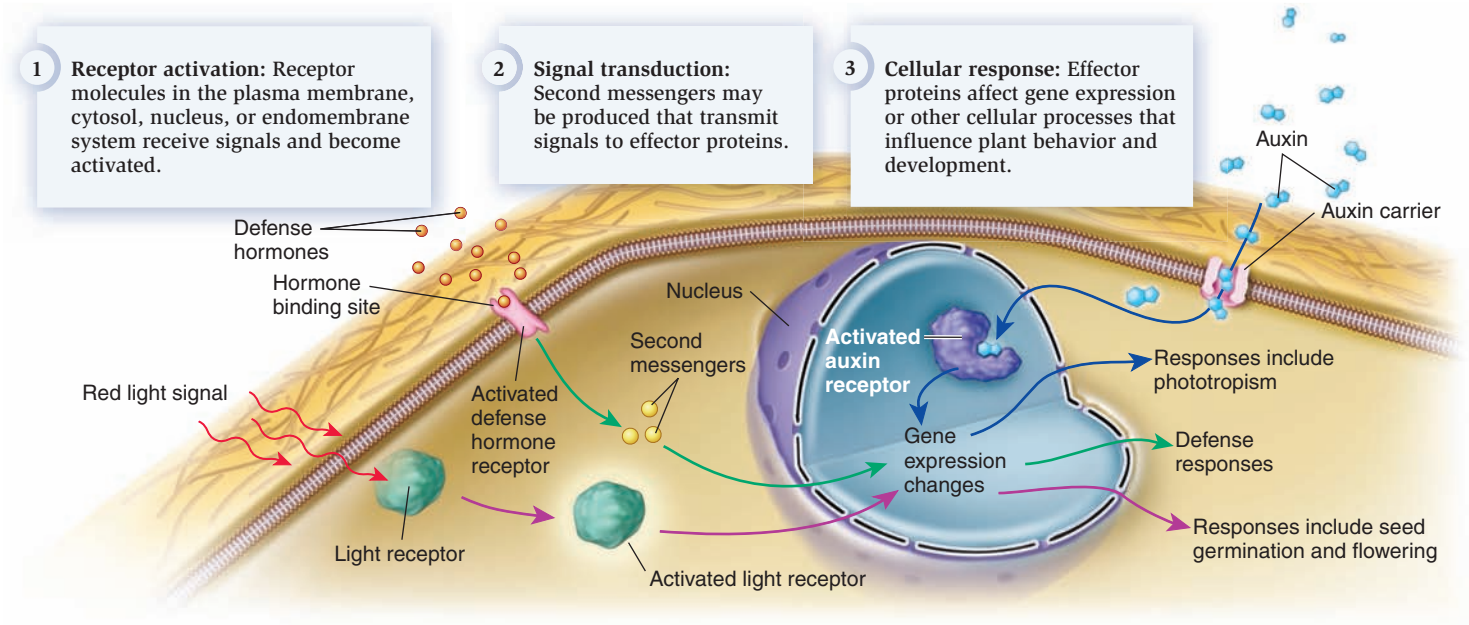

Figure 36.3 An overview of plant cell signaling. Plant cells respond to hormonal signals produced within the plant body, as well as to environmental stimuli. Three different signal transduction processes are shown here: one started by light, one started by a defense hormone having a plasma membrane receptor, and another started by an auxin having a receptor located in the nucleus.

BIOLOGY PRINCIPLE **Cells are the simplest units of life.** Internal and environmental stimuli are received and elicit responses at the cellular level.

BioConnections: *Look back to Figure 9.4, which shows an example of a cell-signaling process in an animal cell. Which of the processes shown above is most similar to that process?*

Effectors are molecules that directly influence cellular responses. In plants, calcium-dependent protein kinases (CDPKs) are particularly important effector molecules. Cell signaling ends when an effector causes a cellular response, such as opening or closing an ion channel or switching the transcription of particular genes on or off. A single activated receptor can dispatch many second-messenger molecules, which, in turn, can activate scores of effectors, leading to many molecular responses within a single cell.

36.2 Plant Hormones

Learning Outcomes:

1. List some examples of plant hormones.
2. Explain how auxin functions in phototropism.
3. Explain how cytokinins, gibberellins, and ethylene are relevant to agriculture.
4. Discuss how abscisic acid and brassinosteroids help plants cope with environmental stress.

Along with proteins and RNA molecules, plant hormones are chemical signals transported within the plant body; when taken up by target cells, the signals elicit responses. Here, we focus on plant hormones, about a dozen types of small molecules that are synthesized in metabolic pathways that also make amino acids, nucleotides, sterols, or secondary metabolites. Auxins, cytokinins, gibberellins, ethylene, abscisic acid, and brassinosteroids are examples of plant hormones (**Table 36.1**).

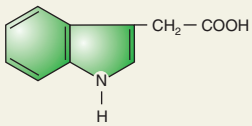
Individual plant hormones often have multiple effects, and different concentrations or combinations of hormones can produce distinct growth or developmental responses. Several plant hormones are known to act by causing the removal of gene repressors, thereby allowing gene expression to occur. This general mechanism allows hormones to cause relatively rapid responses. A closer look at the major types of plant hormones reveals their multifaceted roles.

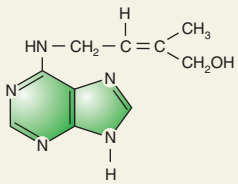
Auxins Are the Master Plant Hormones

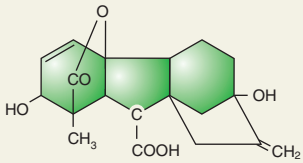
Plants produce several types of **auxins**, which are considered to be the master plant hormones because they influence plant structure, development, and behavior in many ways, often working with other hormones. Indoleacetic acid (IAA) is one plant auxin (see Table 36.1), but other natural and artificial compounds have similar structures and effects. In this section, we will refer to this family of related compounds simply as auxin.

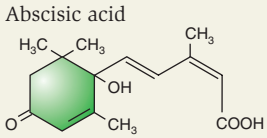
Auxin exerts so many effects because it promotes the expression of thousands of genes known as **auxin-response genes**. Under low auxin conditions, proteins called Aux/IAA repressors prevent plant cells from expressing these genes. The repressor proteins prevent gene expression by binding to activator proteins at gene promoters. When the auxin concentration is high enough, auxin molecules glue repressors onto a protein complex called TIR1, which causes the breakdown of the repressors. Free of the repressors, the activator proteins enhance the expression of auxin-response genes.

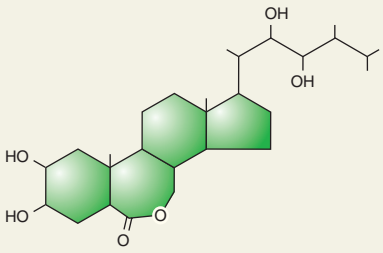
Auxin Transport The way in which auxin is transported into and out of cells is integral to its effects in plants. Auxin is produced in apical shoot tips and young leaves, and it is directionally transported from one living parenchyma cell to another. Auxin in an uncharged form (IAAH) may enter cells from intercellular spaces by means of diffusion; however, the negatively charged form (IAA^-) requires the aid of a plasma membrane protein known as the **auxin influx carrier (AUX1/LAX)**. Several types of proteins, called PIN proteins, transport auxin out of cells. They are named for the pin-shaped shoot apices of plants having mutations in *PIN* genes. Because they transport auxin out of cells, PIN proteins are called **auxin efflux carriers**. They are necessary because in the cytoplasm, auxin occurs as a charged ion that does not readily diffuse out of cells.











In shoots, AUX1/LAX is located at the apical ends of cells, whereas PIN proteins often occur at the basal ends (**Figure 36.4a**). This polar distribution of auxin carriers explains why auxin primarily flows downward in shoots and into roots, a process called **polar transport** (**Figure 36.4b**). However, the locations of auxin carriers can also change within cell plasma membranes, allowing lateral or upward transport of auxin. Differences in the presence and positions of auxin carrier proteins explain variations in auxin concentration within plants. The local auxin concentration allows plant cells to determine their position within the plant body and to respond by dividing, expanding, or specializing.

Auxin Effects In nature, auxin influences plants throughout their lifetimes. Auxin establishes the apical-basal polarity of seed embryos, induces vascular tissue to differentiate, mediates phototropism, promotes formation of adventitious roots, and stimulates fruit development. Many of auxin's effects are also of practical importance to humans. Auxin is used to produce some types of seedless fruit, retard premature fruit drop in orchards, and stimulate root development on stem cuttings. Although there is still much to learn about auxin function, auxin's role in phototropism has been elucidated by a series of experiments, described next.

The Role of Auxin in Phototropism In the 1880s, Charles Darwin and his son Francis were the first to publish results of experiments on plant phototropism. The Darwins performed their experiments on cereal seedlings, whose tips are protected by a sheath of tissue called a coleoptile. In a simple but elegant experiment, the Darwins covered either the tips or lower portions of coleoptiles with shading materials such as blackened glass tubes, left other seedlings uncovered, and removed the tips of some seedlings. They then compared how those seedlings responded to illumination from the side. The seedlings whose tips were left uncovered grew toward the light, whereas seedlings whose tips were covered or removed did not. The Darwins concluded that seedling tips transmit some "influence" to lower portions, causing them to bend toward the light. You can probably guess what this influence was, but technology available at the time did not allow the Darwins to determine this.

Three decades later, in the 1910s, Danish botanist Peter Boysen-Jensen confirmed the Darwins' results and demonstrated that the influence was a chemical substance that diffused from the tips of the seedlings to other parts. To do this, Boysen-Jensen cut off the tips of oat seedlings and placed either a porous layer of gelatin or a nonporous material such as a sheet of the mineral mica on the cut surface. Then he replaced the tips. Oat seedlings layered with porous gelatin displayed a normal phototropic response, bending

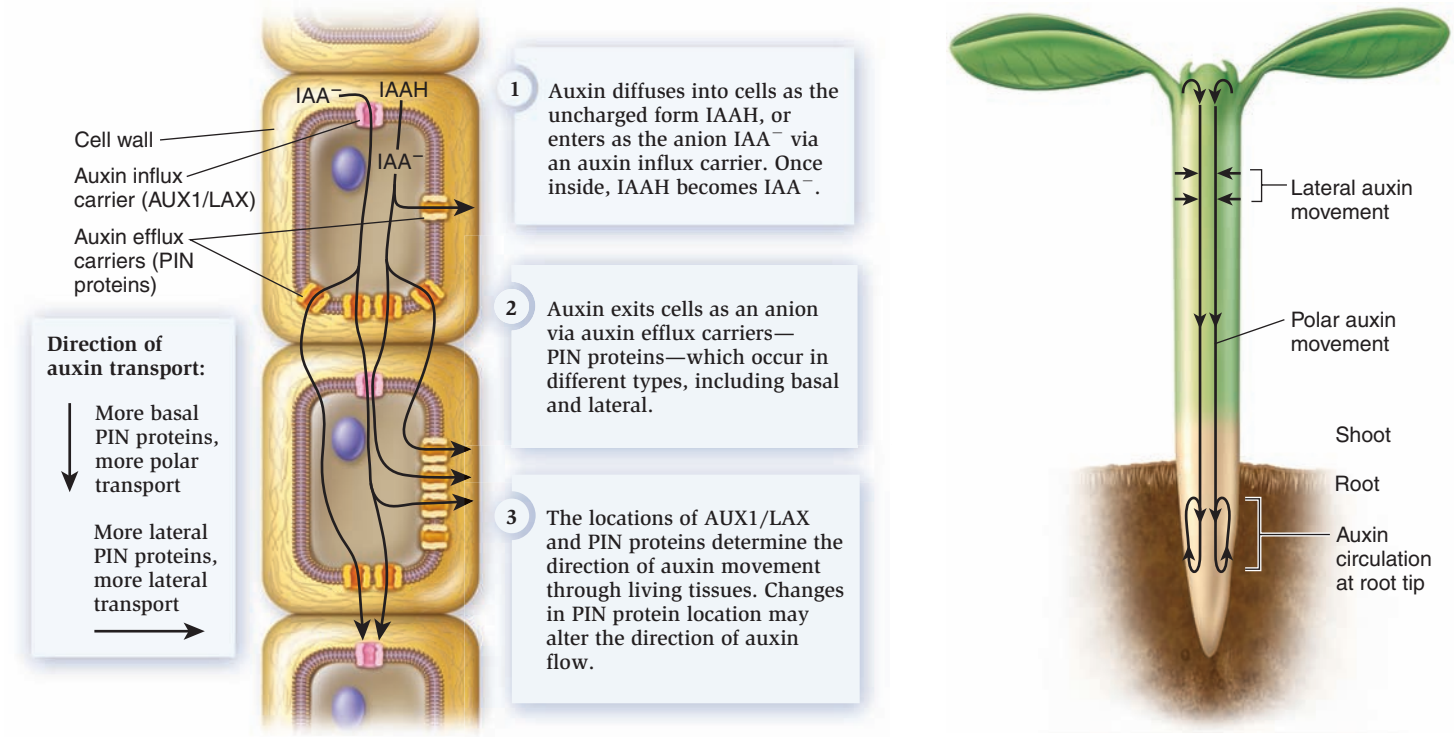


Table 36.1 Examples of Plant Hormones

Type of plant hormone	Chemical structure of an example	Functions*
Auxins	Indoleacetic acid (IAA) 	Establish apical-basal polarity, induce vascular tissue development, mediate phototropism, promote formation of adventitious roots, inhibit leaf and fruit drop, and stimulate fruit development
Cytokinins	Zeatin 	Promote cell division, influence cell specialization and plant aging, activate secondary meristem development, promote adventitious root growth, and promote shoot development on callus
Gibberellins	Gibberellic acid 	Stimulate cell division and cell elongation, stimulate stem elongation and flowering, and promote seed germination
Ethylene	Ethylene 	Promotes seedling growth, induces fruit ripening, plays a role in leaf and petal aging and drop, coordinates defenses against osmotic stress and pathogen attack
Abscisic acid	Abscisic acid 	Slows or stops metabolism during environmental stress, induces bud and seed dormancy, prevents seed germination in unfavorable conditions, and promotes stomatal closing
Brassinosteroids	Brassinolide 	Promote cell expansion, stimulate shoot elongation, retard leaf drop, stimulate xylem development, and promote stress responses

*The lists of functions are only partial lists.

toward the light, but those layered with nonporous mica did not. Boysen-Jensen's experiment demonstrated that the phototropic substance was a diffusible chemical, but exactly which one, and how it worked, remained unknown. A series of additional experiments provided some answers.

In the 1920s, Dutch plant physiologist Frits Went named the substance discovered by Boysen-Jensen auxin (from the Greek word *auxein*, meaning to increase). Although the chemical structure of auxin was not determined until 1934, Went performed experiments that helped explain how auxin works. In a first step, Went cut the tips off oat seedlings and placed these tips onto agar blocks. Agar, a complex polysaccharide derived from red algae, forms a mesh capable of holding considerable water and dissolved compounds. Agar's permeability to auxin is similar to that of the protein gelatin used by Boysen-Jensen, but agar is much more stable at room temperature and more resistant to microbial breakdown and therefore is easier to use in laboratory experiments. In Went's experiment, the auxin diffused from cut seedling tips into these agar blocks. In the next steps, he treated decapitated seedlings in one of four ways: (1) placed auxin-laden agar blocks off-center on some, (2) placed auxin-laden blocks evenly on others, (3) placed plain agar blocks off-center on some, and (4) left some uncapped. All seedlings were then kept in the dark throughout the experiment. Only seedlings that were capped off-center with an auxin-laden block grew in the direction away from the agar block. This experiment demonstrated that auxin application could substitute for the directional light stimulus

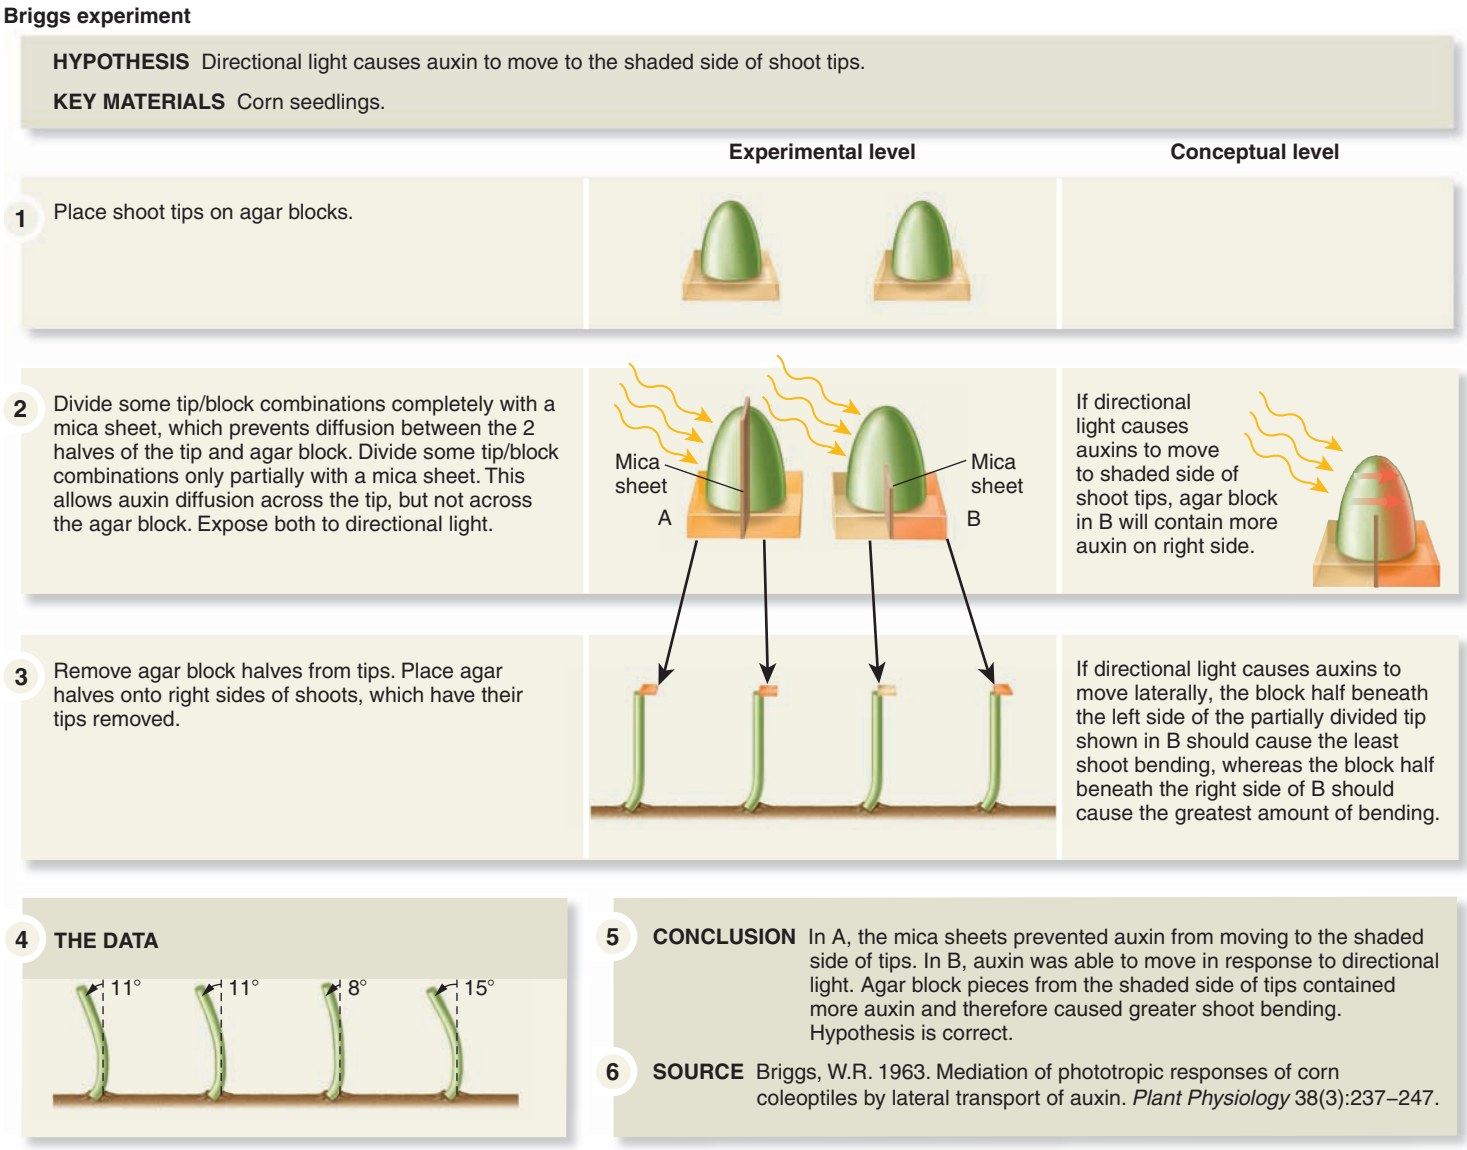
(a) Cellular mechanism of auxin transport

(b) Auxin transport throughout a plant

Figure 36.4 Auxin transport. **(a)** Polar and lateral auxin transport is controlled by the distribution of auxin efflux carriers located in the plasma membrane. When efflux carriers primarily occur at the basal ends of cells, auxin will flow downward. Auxin may flow laterally when auxin efflux carriers occur at the sides of cells. **(b)** In a whole plant, auxin primarily flows downward from shoot tips to root tips, where it then flows upward for a short distance.

Concept Check: *How could auxin carriers be organized to allow auxin to move upward in roots?*

and suggested that asymmetric auxin distribution is the mechanism by which light causes plants to bend.



Subsequently, Went and N. O. Cholodny independently proposed that light causes auxin to move to the unlit side of seedling tips, causing cells on that side to elongate more, which results in bending. But other scientists argued that bending could result if light destroys auxin on the illuminated side of a seedling. In the 1950s, American plant biologist Winslow Briggs designed two experiments to test these alternate hypotheses.

In his first experiment, which tested the hypothesis that auxin might be destroyed by light, Briggs first grew corn seedlings in the dark. Then he cut off their tips, put the tips on agar blocks, and exposed some to darkness and others to directional light. During this process, auxin from tips diffused evenly into the agar blocks. If auxin were destroyed by light, agar blocks under lighted tips should receive less auxin than blocks under tips kept in the dark. The auxin-destruction hypothesis also predicts that when agar blocks from lighted tips are placed on one side of decapitated seedlings, they should cause less bending than will blocks from tips kept in the dark. However, Briggs discovered that both types of agar blocks caused the same amount of shoot bending. This result is not consistent with the hypothesis that light destroys auxin.

Feature Investigation | An Experiment Performed by Briggs Revealed the Role of Auxin in Phototropism

In a second experiment, Briggs tested the hypothesis that light causes auxin to move to the shaded side of seedlings (**Figure 36.5**). Briggs set shoot tips onto agar blocks (step 1) and then used a mica sheet (which is impervious to auxin) to completely divide some tips and blocks into halves (step 2A). In other cases, he divided blocks completely but left tips incompletely divided, allowing auxin to diffuse across tips but not the block halves (step 2B). Then Briggs exposed all sets of tips and blocks to directional light. He predicted that auxin would not be able to move across tips having complete mica barriers but that auxin would be able to move across tips that had been only partially divided. Auxin diffused from tips into blocks, but it could not diffuse evenly across blocks divided by mica

Figure 36.5 Briggs demonstrated the relationship between directional light and auxin function.

sheets. When Briggs later placed the agar block halves on decapitated shoots (step 3), those receiving auxin from completely divided tips were bent by the same amount. By contrast, agar block halves from the lit side of partially divided tips induced less bending, whereas halves from the unlit side of partially divided tips caused the most bending (see the data in step 4 of Figure 36.5). These experimental results support the hypothesis that unidirectional light causes auxin to accumulate on the shaded side. Modern plant scientists would explain such auxin movement as the result of lateral transport involving PIN proteins.

How might auxin accumulation cause phototropic bending? One widely held hypothesis is that auxin accumulation on the shaded side of a plant shoot causes plasma membrane proton pumps located there to work at a faster rate. In response, the cell wall becomes more acidic, which activates expansins—proteins that break crosslinks between cellulose microfibrils and allow cells to elongate (refer back to Figure 35.10). This process might explain how auxin accumulation in cells located on the shaded side of shoot tips causes them to elongate more than do cells on the sunny side, causing the tip to bend toward the light.

Experimental Questions

1. What is the current hypothesized mechanism by which auxin accumulation causes shoot bending in response to directional light?
2. **SciSKILLS** » Figure 36.5 illustrates experiments performed with four seedling tips. Would this number really be enough to allow conclusions to be made about how such seedling tips would generally respond?

BIO TIPS **THE QUESTION** *Show how Briggs tested the auxin-destruction hypothesis: that coleoptile bending in response to directional light occurs because light destroys auxin.*

TOPIC ***What topic in biology does this question address?*** The topic is how plants sense and respond to directional light. More specifically, the question asks you to show the procedure Briggs used to investigate the possibility that bending toward the light occurs because light destroys auxin.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** You learned earlier in this chapter that phototropism in plants is initiated by directional light and followed by a growth response of stem tissue to an internal chemical signal. The signal was discovered to be the asymmetric distribution of the plant hormone auxin. Because the mechanism by which auxin changed location within the plant tissue was not known before Briggs's experiment, destruction of some auxin by directional light was a possibility that required investigation. Briggs tested this auxin-destruction hypothesis using corn seedlings (coleoptiles), directional light, and agar blocks.

PROBLEM-SOLVING STRATEGY ***Make a drawing.*** Drawing a diagram of a process is an excellent way to achieve understanding and communicate that understanding to others. Use the text description of Briggs's experiment to draw diagrams that show how he proceeded.

ANSWER *Start by drawing two cut coleoptile tips placed onto agar blocks. Add arrows on one of the drawings that indicate how auxin is expected to flow into the agar block if the coleoptile tip is evenly illuminated. Add arrows to the other drawing to indicate how auxin is expected to flow into the agar block if directional light destroys auxin. These contrasting drawings illustrate the beginning hypothesis. Now draw diagrams that show how coleoptiles whose tips have been removed respond when agar blocks are placed on one side of them. This is the experimental test. Finally, draw these coleoptiles after they have responded by bending, which is the experimental result. Lack of a difference in bending of the experimental coleoptiles is evidence that directional light does not cause phototropism by destroying auxin.*

Cytokinins Stimulate Cell Division

Like auxins, the plant hormones known as **cytokinins** play varied and important roles throughout the lives of plants. The name of these hormones reflects their major effect—an increase in the rate of plant cytokinesis, or cell division. Root tips are major sites of cytokinin production, but shoots and seeds also make this plant hormone. Transported in the xylem to meristems and other plant parts, cytokinins bind to receptors thought to be located in the plasma membrane. At shoot and root tips, cytokinins influence meristem size, stem cell activity, and vascular tissue development. Cytokinins are also involved in root and shoot growth and branching, the production of flowers and seeds, and leaf aging.

Plant Tissue Culture In the laboratory, cytokinin and auxin are essential to cloning plants. This involves a process, known as **plant tissue culture**, which is used commercially to produce thousands of identical plants having the same desirable characteristics. Plant tissue culture begins with pieces of stem, leaf, or root that have been removed from a plant, and have had their surfaces sterilized to prevent growth of microbes (**Figure 36.6**, step 1). The cleaned plant pieces are then placed into dishes containing nutrients (minerals, vitamins, and sugar) and various proportions of auxin and cytokinin. If the proportions of auxin and cytokinin are about the same (1:1), plant cells undergo division, forming a mass of white tissue known as a callus (step 2). If the callus is then transferred to a new dish containing the same nutrients, with auxin-to-cytokinin proportions greater than 10:1, the callus will form roots (step 3). Auxin-to-cytokinin proportions of less than 10:1 cause the callus to develop green shoots (step 4). Thus, by altering the ratios of auxin and cytokinin, entire plants can be regenerated from a callus. A single callus can be divided into many pieces and each piece treated with these hormones, thereby producing many hundreds of identical new plants.

Gibberellins Stimulate Cell Division and Elongation

The **gibberellins** (such as gibberellic acid, or GA; see Table 36.1) are another group of plant hormones. Gibberellins are produced in apical buds, roots, young leaves, and seed embryos. In addition to promoting shoot development on laboratory calluses, gibberellins interact with light and other hormones to foster seed germination and enhance stem elongation and flowering in nature. Gibberellins also retard leaf and fruit aging. These multiple effects largely arise from the hormones' stimulatory effects on cell division and elongation.

More than a hundred different forms of gibberellin have been found. Many kinds of dwarf plants are short because they produce less gibberellin than taller varieties of the same species. The dwarf strain of pea plants Mendel used in some of his breeding experiments is an example. When dwarf varieties of plants are experimentally sprayed with gibberellin, their stems grow to normal heights. However, dwarf wheat and rice crops are valued in agriculture because they can be more productive and less vulnerable to storm damage than taller varieties. Since the discovery of gibberellin, plant scientists have discovered how this plant hormone works at the molecular level and how gibberellin regulation of plant growth evolved, discussed next.

Genomes & Proteomes Connection

Gibberellin Function Arose in a Series of Stages During Plant Evolution

In flowering plants, gibberellin works by helping to liberate repressed transcription factors. In the absence of gibberellin, DELLA proteins bind particular transcription factors needed for the expression of gibberellin-responsive genes (**Figure 36.7a**). In this way, DELLAs function as brakes that restrain cell division and expansion. When sufficient gibberellin is present, it binds receptor proteins called GID1 (**Figure 36.7b**).

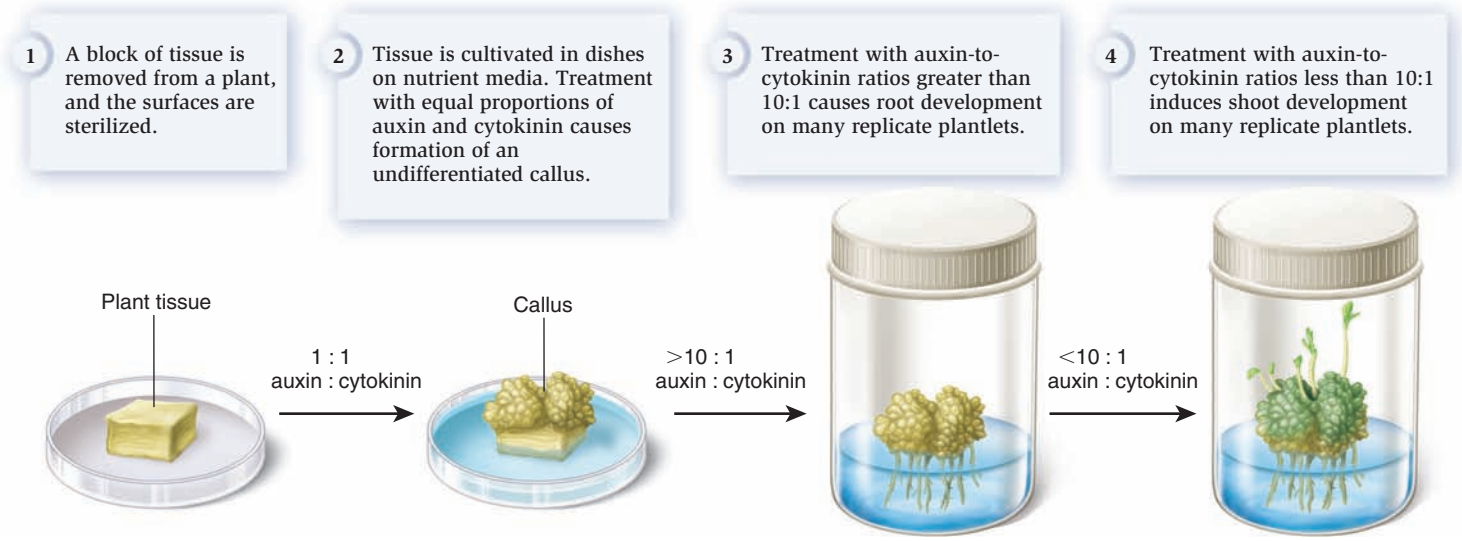


Figure 36.6 The process of plant tissue culture. Plant tissue culture illustrates the effect of different proportions of auxin and cytokinin on plant organ development.

Concept Check: *How do commercial growers use this process to produce many identical plants?*

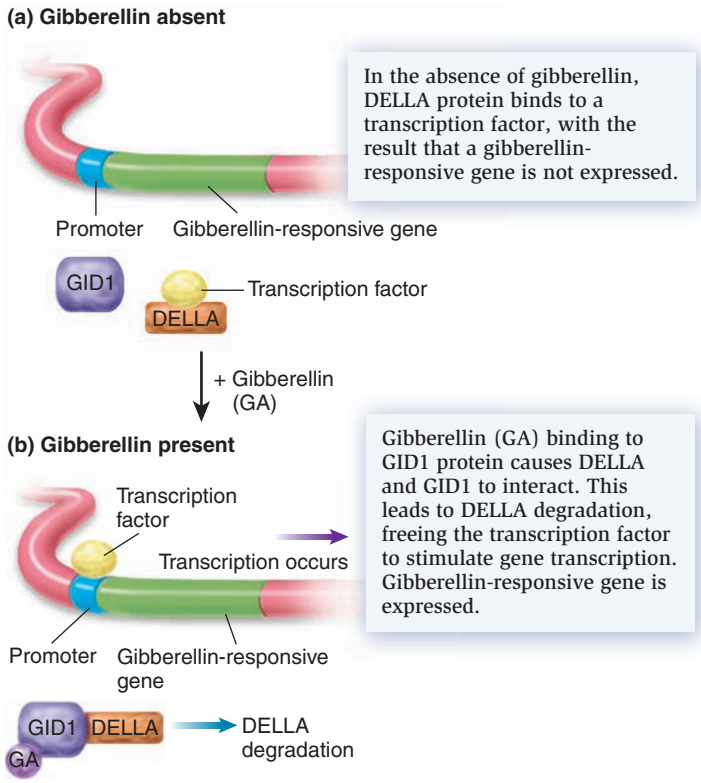

Figure 36.7 Gibberellin works by releasing trapped transcription factors. (a) In the absence of gibberellin, DELLA binds transcription factors, and so gibberellin-response genes are not expressed. **(b)** When gibberellin binds to the protein GID1, GID1 can bind DELLA proteins, which causes DELLA proteins to be degraded. As a result, transcription factors that had been bound to DELLA proteins are released and can bind to gene promoters, thereby inducing gene expression.

Gibberellin-binding increases the ability of GID1 proteins to interact with DELLA proteins, starting a process that leads to the destruction of DELLAs. In the absence of DELLA proteins, transcription factors are able to bind to the promoter regions of gibberellin-responsive genes, allowing their expression. As a result, cell division and expansion occur, leading to growth.

In 2007, Yuki Yasumura, Nicholas Harberd, and their colleagues reported that the gibberellin-DELLA mechanism for regulating the growth of flowering plants arose in a step-wise fashion. They discovered this by comparing the DELLA and GID1 proteins of flowering plants with homologous proteins of a moss and a lycophyte. The seedless lycophytes, the oldest living phylum of vascular plants, first appeared millions of years before the first flowering plants, and the seedless, nonvascular mosses arose millions of years before the first vascular plants (refer back to Figure 29.1). The investigators studied the interactions of DELLA proteins with GID1 and evaluated the extent to which gibberellin enhanced DELLA-GID1 binding and growth in these different groups of plants.

The results indicated that the moss possesses DELLA and GID1 proteins, but these proteins don't interact, and moss DELLA does not repress growth. In contrast, differences in the protein structure of lycophyte DELLAs enable them to interact with GID1 and gibberellin, but without detectably influencing growth. Neither the moss nor the lycophyte showed detectable growth responses to gibberellin, though their DELLAs were able to repress growth when expressed in a flowering plant. This pattern led the biologists to propose that DELLA-mediated repression of plant growth evolved after the divergence of lycophytes but prior to the appearance of the first flowering plants (**Figure 36.8**). Though the necessary components (DELLAs and GID1 proteins) were present earlier, they did not assemble into a growth regulation system until later in plant evolutionary history.

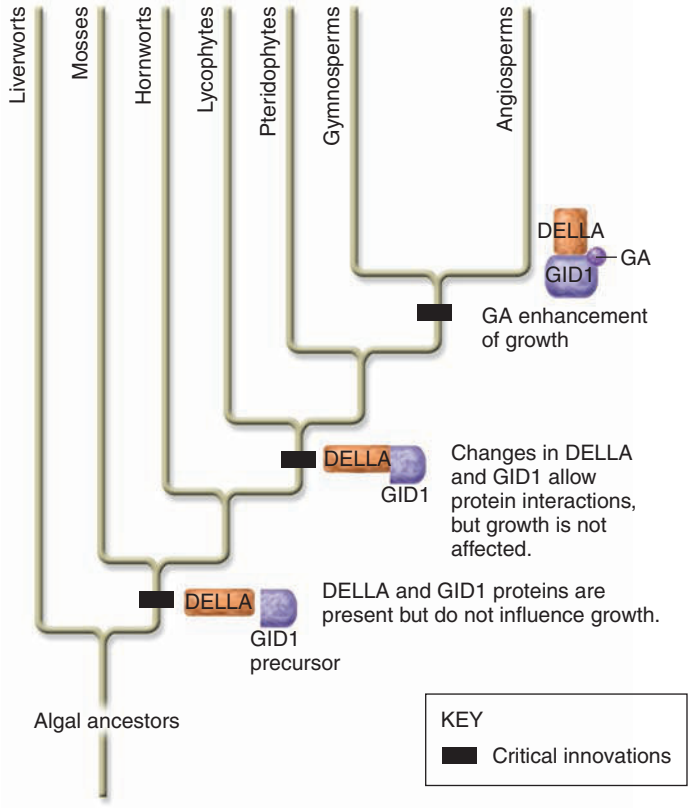

Figure 36.8 Evolution of the gibberellin-DELLA system. Although DELLA and GID1 proteins are present in a moss, they do not interact, nor does gibberellin bind to GID1. In lycophytes, GID1 interacts with DELLA, but the system does not influence growth. The growth responses of gibberellin apparently evolved after the divergence of lycophytes.

BIOLOGY PRINCIPLE All species (past and present) are related by an evolutionary history. The gibberellin-DELLA system that controls growth of flowering plants evolved in a step-by-step fashion.

Ethylene's Effects Include Cell Expansion

The plant hormone **ethylene** is particularly important in coordinating plant developmental and stress responses. Ethylene is a simple hydrocarbon gas produced during seedling growth, flower development, and fruit ripening (see Table 36.1). In the root tip, ethylene determines how many stem cells remain inactive in the quiescent center and how many cells undergo divisions. This hormone also plays important roles in defense against osmotic stress and pathogen attack, and leaf and petal aging and drop. As a gas, ethylene is able to diffuse through the plasma membrane and cytosol to bind to ethylene receptors localized in the endoplasmic reticulum. When activated by ethylene binding, these receptors inactivate a protein kinase known as CTR1. This action ultimately enables transcription factors to induce the transcription of various genes.

People first noticed the effects of ethylene gas on plants in the 1800s when they observed that street-side trees exposed to leaking street lanterns unexpectedly lost their leaves. A 17-year-old student in St. Petersburg, Russia, Dimitry Neljubov, performed the first experiments to explore the effects of illumination gas on plants. He exposed pea seedlings grown in the laboratory to illumination gas and noticed that the pea seedlings grew sideways rather than upward. Then he tested the individual chemical components of illumination gas for the same effect. After conducting many experiments, in 1901, Neljubov reported that ethylene was the only component of illumination gas that caused the seedlings to grow horizontally and that ethylene was effective in very low concentrations (as low as 0.06 parts per million in air). Later, scientists established that ethylene influences cell expansion, often in association with auxin. Ethylene does this by increasing the disorder of microtubules within cells, thereby causing random orientation of cell-wall microfibrils. As a result, cells exposed to ethylene tend to expand in all directions rather than elongating.

Ethylene's effects on cell expansion explain this hormone's important role in dicot seedling growth. The tender apical meristems of seedlings could be easily damaged during their growth through crusty soil. Ethylene helps seedlings avoid such damage by inducing what is known as the triple response (**Figure 36.9**). First, ethylene prevents the seedling stem and root from elongating. Second, the hormone induces the stem and root to swell radially, thereby increasing in thickness. Together, these responses strengthen the seedling stem and root. Third, the seedling stem bends so that embryonic leaves and the delicate meristem grow horizontally rather than vertically; this is the sideways growth response that Neljubov first observed. The bent portion of the stem, known as a hook, then pushes up through the soil.

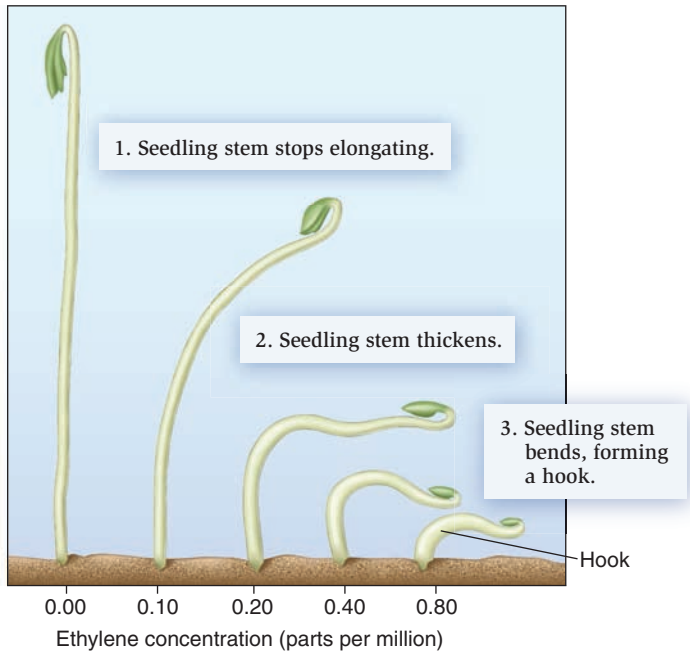

Figure 36.9 Seedling growth showing the triple response to ethylene. When applied at levels above a particular concentration (0.80 ppm), ethylene causes seedlings to cease elongation, swell radially, and bend to form a hook that can push upward through the soil. Ethylene produced naturally within seedlings causes the same response.

Concept Check: What adaptive advantage does this seedling behavior provide?

The hook forms as the result of an imbalance of auxin across the stem axis, which causes cells on one side of the stem to elongate faster than cells on the other side. Ethylene drives this auxin imbalance.

Knowledge of the effects of ethylene on fruit has been very useful commercially. Ripe fruit can be easily damaged during transit, but tomatoes and apples can be picked before they ripen for transport with minimal damage. At their destination, such fruit can be ripened by treatment with ethylene. However, fruit that becomes overripe may exude ethylene, which hastens ripening in nearby, unripe fruit. For this reason, fruit that must be stored for extended periods is kept in ethylene-free environments.

Several Hormones Help Plants Cope with Environmental Stresses

Several plant hormones share the property of helping plants respond to environmental stresses such as flooding, drought, high salinity, cold, heat, and attack by disease-causing microorganisms and animal herbivores. These protective hormones include the major plant hormones known as **abscisic acid** and **brassinosteroids** (see Table 36.1).

Abscisic Acid Abscisic acid (ABA) was named at a time when plant biologists thought that it played a role in leaf or fruit drop, also known as abscission. Later, they discovered that ethylene actually causes leaf and fruit abscission, whereas abscisic acid slows or stops plant metabolism when growing conditions are poor. For example, ABA may induce bud and seed dormancy. Dormant buds and seeds resume growth only when specific environmental signals reveal the onset of conditions suitable for survival. In preparation for winter, ABA stimulates the formation of tough, protective scales around the buds of perennial plants. Seed coats of apple, cherry, and other plants also accumulate ABA, which prevents seeds from germinating unless temperature and moisture conditions are favorable for seedling growth. Water-stressed roots also produce ABA, which is then transported to shoots, where (together with ABA produced by water-stressed leaf mesophyll) it helps to prevent water loss from leaf surfaces by inducing leaf pores (stomata) to close. ABA receptors are soluble proteins. The binding of ABA to receptors promotes the transcription of ABA-responsive genes.

Brassinosteroids Brassinosteroids are named after the cruciferous plant genus *Brassica* (which includes cabbage and broccoli), from which they were first identified. However, seeds, fruit, shoots, leaves, and flower buds of all types of plants contain brassinosteroids. These plant hormones induce water uptake by vacuoles and influence enzymes that alter cell-wall carbohydrates, thereby fostering cell expansion. Mutations that affect brassinosteroid synthesis cause plants to exhibit dwarfism. Such plants have small, dark green cells because their tissues are unable to expand. Brassinosteroids also impede leaf drop, help grass leaves to unroll, and stimulate xylem development. They can be applied to crops to help protect plants from heat, cold, high salinity, and herbicide injury.

Brassinosteroids are chemically related to animal steroid hormones, such as human sex hormones. However, unlike animal steroid hormones, which bind to receptors in the nucleus or cytosol, brassinosteroids bind to receptors in the plasma membrane. When they bind brassinosteroids, the membrane receptors initiate a signal transduction pathway that activates transcription factors for brassinosteroid-responsive genes.

36.3 Plant Responses to Environmental Stimuli

Learning Outcomes:

1. Describe how photoreceptors allow plants to respond to light, including day length.
2. Discuss how plant roots respond to gravity and touch.
3. Give examples of how plants respond to flood and drought.
4. Outline how plants protect themselves against pathogenic attack.

Plants encounter many types of environmental challenges and behave accordingly. For example, if buried seeds were to germinate beneath soil layers too deep for light to penetrate, or beneath a cover of established plants, seedlings would not be able to obtain sufficient light for photosynthesis and would die in the ground. A related reproductive challenge for plants is to flower at times of the year that are most beneficial for achieving pollination or seed dispersal. How do plants determine if there is enough light for seeds to germinate and for seedlings to grow? How do plants determine when to flower?

The answer is that plants possess cellular systems for measuring light and determining the seasonal time of year. Using these systems, plant seeds germinate only when there is sufficient light for seedling growth, and flowering occurs during the most advantageous season. Therefore, plants can sense and respond to their light environments. Plants are also able to respond to other physical and biological external stimuli. In this section, we survey plant responses to these stimuli, beginning with light.

Plants Detect Light and Measure Day Length

A plant's ability to measure and respond to the amount of light and day length, a process called **photoperiodism**, is based on the presence of light receptors within cells. Such light sensors are known as **photoreceptors**, of which there are several types. Some types of plant photoreceptors also occur in animals, whereas others are particular to plants. Each type of photoreceptor has a light-absorbing component as well as other regions that respond to light absorption by switching on signal transduction pathways. Responses by many cells in a tissue or organ cumulatively result in behaviors such as sun tracking, phototropism, flowering, and seed germination.

Blue-Light Receptors Cryptochromes and phototropins are two types of blue-light receptors—molecules that absorb and respond to blue light. Experiments suggest that receptors called **cryptochromes** help young seedlings determine if their light environment is bright enough to allow photosynthesis. If not, seedlings continue to elongate through the soil, toward the light. Cryptochromes also function as light sensors in animals.

Phototropin is the main blue-light sensor involved in plant phototropism. The light-activated form of this sensor has two components: a protein that has a kinase domain and a flavin pigment that

can absorb blue light. In the dark, the flavin is not covalently bound to the protein. However, when the flavin absorbs blue light, it changes conformation and becomes able to covalently bind to the protein. Flavin binding, in turn, changes the conformation of the phototropin protein, allowing it to phosphorylate itself by means of the protein kinase domain. When a plant organ is exposed to directional blue light, phototropin becomes phosphorylated. In this way, a light signal is converted into a chemical signal that influences auxin movement.

Phytochrome, the Red- and Far-Red-Light Receptor Many plant growth and developmental processes are influenced by **phytochrome**, a red- and far-red-light receptor. Phytochrome operates much like a light switch, flipping back and forth between two conformations: P_r absorbs red light, and P_{fr} absorbs only far-red light (light having a wavelength longer than that of red light) (**Figure 36.10**). When red light is abundant, as in full sunlight, P_r absorbs red light and changes to P_{fr}, which activates cellular responses such as seed germination. When left in the dark for a long period, P_{fr} slowly transforms into P_r.

The role of phytochrome as a plant "light switch" has been shown experimentally in studies of lettuce-seed germination. Researchers have found that water-soaked lettuce seeds will not germinate in darkness, but they will germinate if exposed to as little as 1 minute of red light (**Figure 36.11**). This amount of light exposure is sufficient to transform a critical amount of P_r to the active P_{fr} conformation, which stimulates germination. However, if this brief red-light treatment is followed by a few minutes of treatment with far-red light, the lettuce seeds will not germinate. This short period of far-red illumination is enough to convert seed P_{fr} back to the inactive P_r conformation.

The most recent light exposure determines whether the phytochrome occurs in the active or inactive conformation. In nature, if seeds are close enough to the surface that their phytochrome is switched on by red light, the seeds will germinate. But if seeds are buried too deeply for red light to penetrate, they will not germinate. In this way, seeds can sense if they are close enough to the surface to begin the germination process.

Most of our understanding of phytochrome's effect on gene expression comes from the study of the model plant *Arabidopsis thaliana.* This plant has five phytochrome genes (*PHYA* through *PHYE*). Each of the five types of phytochrome is composed of two proteins, each having a light-sensitive nonprotein pigment called a chromophore (see Figure 36.10). In the dark, phytochrome molecules in the P_r state reside in the cytosol. After exposure to red light, activated phytochrome (P_{fr}) molecules typically move from the cytosol to the nucleus. Within the nucleus, P_{fr} interacts with a transcription factor protein known as PIF3 (phytochrome-interacting factor 3). PIF3 binds to the regulatory elements of several phytochrome-responsive genes, functioning as a positive regulator of some of the genes and as a negative regulator of others.

Photoperiodism Phytochromes also play a critical role in photoperiodism, the response to relative lengths of darkness that influence the timing of dormancy and flowering. Flowering plants can be classified as long-day, short-day, or day-neutral plants. When scientists named these groups, they thought that plants measured the amount of daylight. Researchers later discovered that plants actually measure night length.

Lettuce, spinach, radish, beet, clover, gladiolus, and iris are examples of **long-day plants** because they flower in spring or early summer, when the night period is shorter (and thus the day length is longer) than a defined length (**Figure 36.12**). In contrast, asters, strawberries, dahlias, poinsettias, potatoes, soybeans, and goldenrods are examples of **short-day plants** because they flower only when the night length is longer than a defined period. Such night lengths occur in late summer, fall, or winter, when days are short. As shown

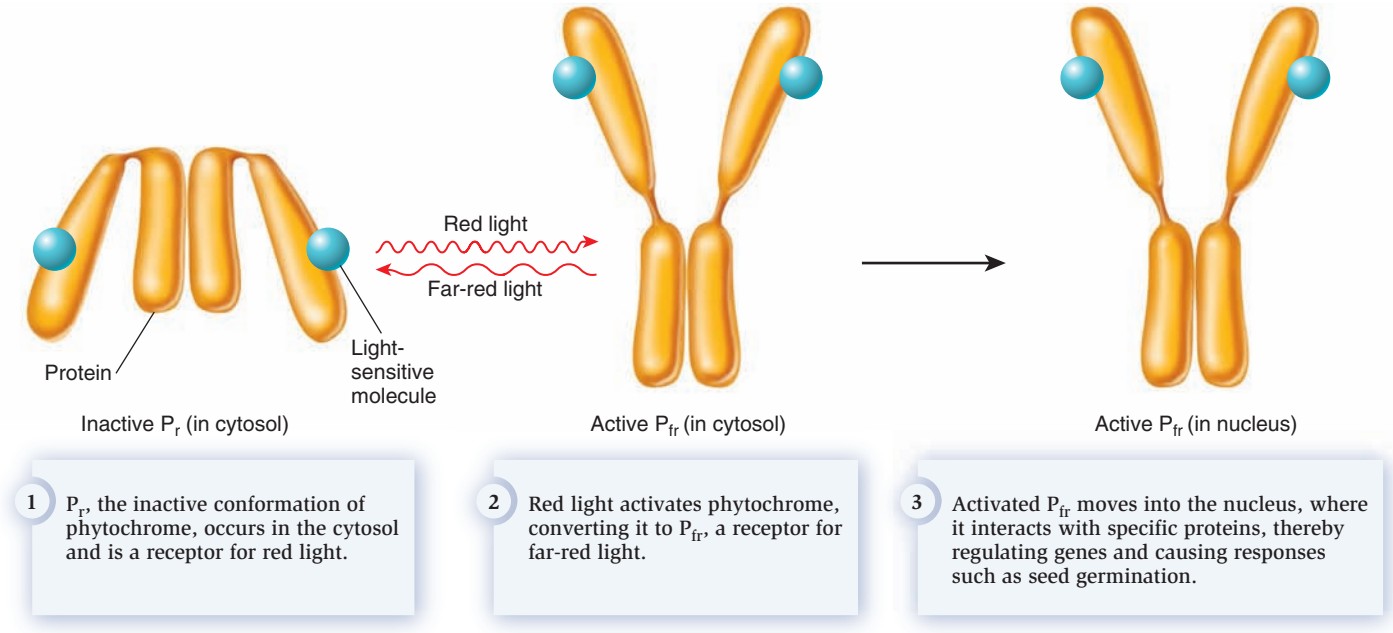

Figure 36.10 How phytochrome acts as a molecular light switch.

Concept Check: *What kind of light does the active conformation of phytochrome absorb, and what kind of change does such absorption cause?*

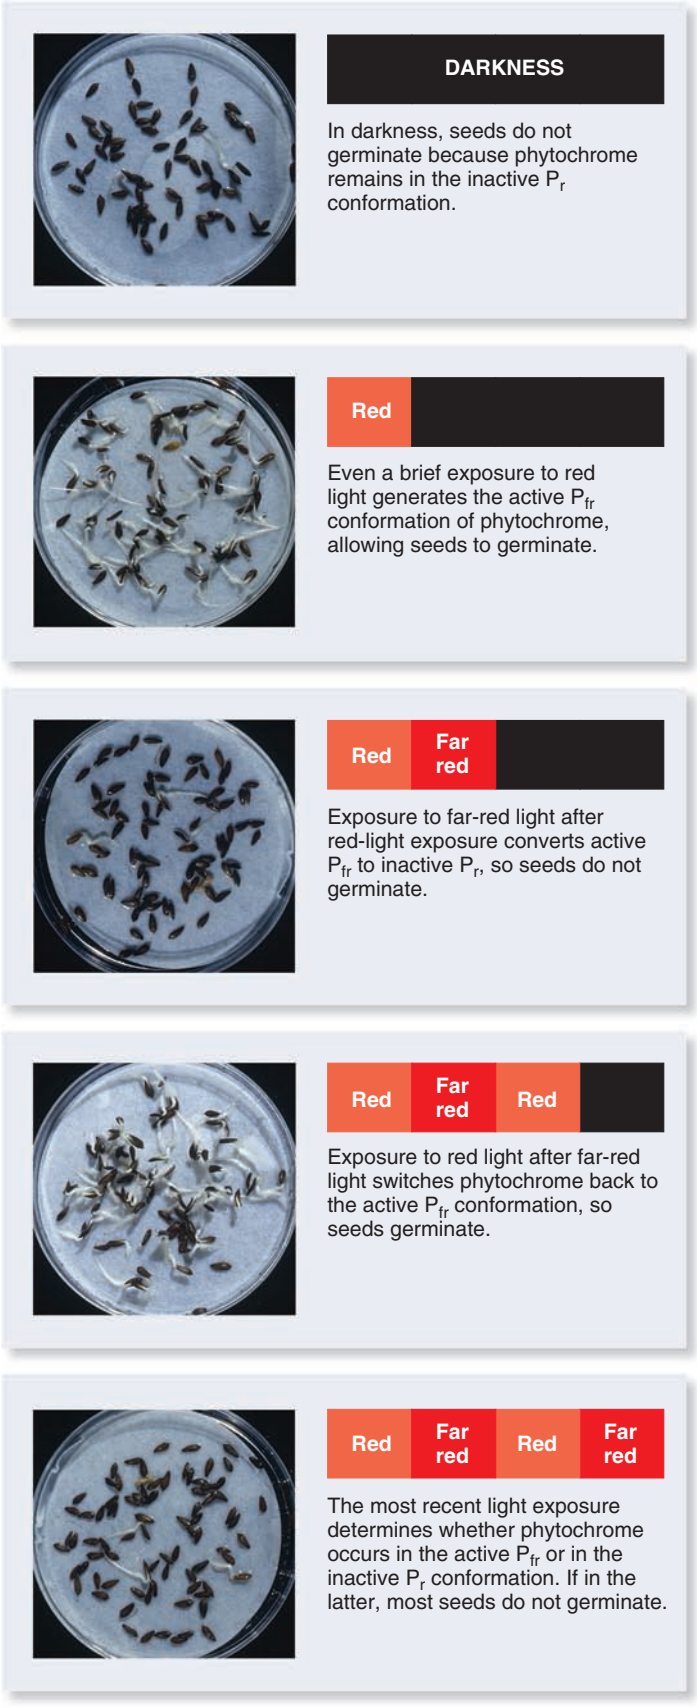

Figure 36.11 How phytochrome influences seed germination.

Concept Check: Describe the change in phytochrome that would occur if a deeply buried seed were uncovered enough to receive sunlight.

in Figure 36.12, when plants are given an experimental light flash in the middle of a long dark period, the long-day plants flower but the short-day plants do not. These results indicate that both types of plants measure night length. Roses, snapdragons, cotton, carnations, dandelions, sunflowers, tomatoes, and cucumbers flower regardless of the night length, as long as day length meets the minimal requirements for plant growth, and are thus known as **day-neutral plants**.

Ornamental plant growers manipulate night length to produce flowers for market during seasons when they are not naturally available. For example, chrysanthemums are short-day plants that usually flower in the fall, but growers use light-blocking shades to increase night length in order to produce flowering plants at any season.

Shading Responses Phytochrome also mediates plant responses to shading. These responses include the extension of leaves from shady portions of a dense tree canopy into the light, and growth that allows plants to avoid being shaded by neighboring plants. These growth responses occur by the elongation of branch internodes. Leaves detect shade as an increased proportion of far-red light to red light. This means that more of the phytochrome in shaded leaves is in the inactive (P_r) conformation than is the case for leaves in the sun. Activated phytochrome (P_{fr}) inhibits the growth of shoot internodes, but phytochrome in the inactivated state does not, so branches bearing shaded leaves extend toward sunlight.

Plants Respond to Gravity and Touch

Have you ever wondered what causes plant stems to generally grow upward and roots downward? The upward growth of shoots and the downward growth of roots are behaviors known as **gravitropism**, growth in response to the force of gravity. Shoots are said to be negatively gravitropic because they often grow in the direction opposite to gravitational force. If a potted plant is turned over on its side, the shoot will eventually bend and begin to grow vertically again (**Figure 36.13**). Most roots are said to be positively gravitropic because they grow in the same direction as the gravitational force.

Both roots and shoots detect gravity by means of starch-heavy plastids known as **statoliths**, which are located in specialized gravity-sensing cells called statocytes. In shoots, statocytes are located in a tissue known as the endodermis, which forms a sheath around vascular tissues. In roots, gravity-sensing cells primarily occur in the center of the root cap.

Gravity causes the relatively heavy statoliths to sink, which causes changes in calcium ion second messengers that affect the direction of auxin transport. This process induces changes in the direction of shoot or root growth. For example, in a root that becomes oriented horizontally, the statoliths are pulled by gravity to the lower sides of statocytes (**Figure 36.14**). The change in statolith position causes auxin to move to cells on the lower sides of roots. In roots, auxin inhibits cell elongation (in contrast to its action in shoots). Therefore, root growth slows on the lower side, while cell elongation continues normally on the upper side. This process causes the root to bend, so that it eventually grows downward again.

Recent studies suggest that gravity responses are related to touch responses, known as **thigmotropism** (from the Greek *thigma*,

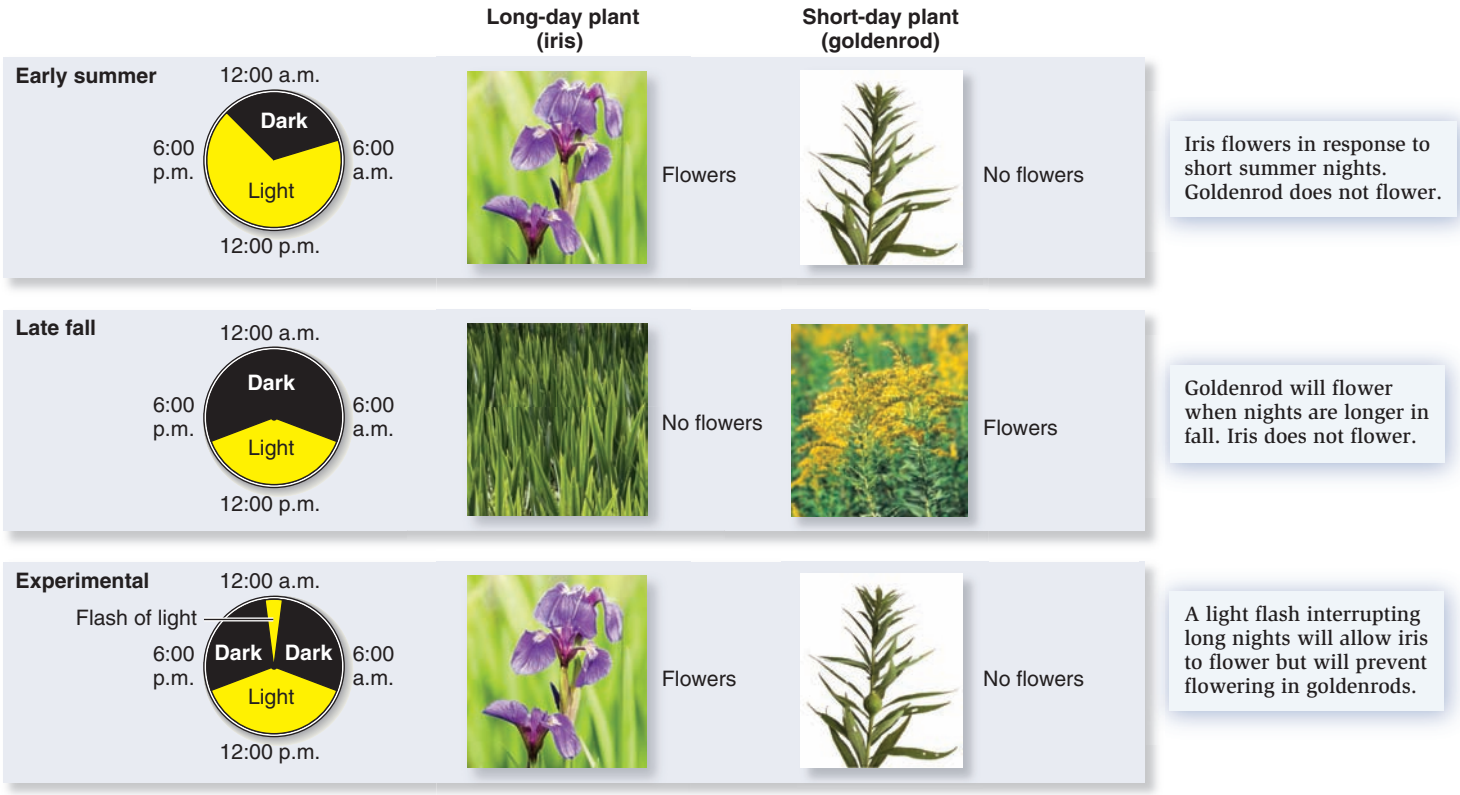

Figure 36.12 Flowering and photoperiodism. Iris is a long-day plant that flowers in response to the short nights of late spring and early summer, whereas goldenrod is a short-day plant that flowers in response to the longer nights of autumn. The length of night is the critical factor, as shown by the effects of light flashes.

Concept Check: *What would happen if you gave these plants a brief exposure to darkness in the middle of the daytime?*

Figure 36.13 Negative gravitropism in a shoot. This tomato shoot system has resumed upward growth after being placed on its side. Upward growth started about 4 hours after the plant was turned sideways; this photo was taken 20 hours later. Shoots sense gravity by means of starchy statoliths present in stem tissue near the central vascular tissue.

meaning touch). For example, when roots encounter rocks or other barriers to their downward growth in the soil, they display a touch response that temporarily supersedes their response to gravity. Such roots grow horizontally until they get around the barrier, whereupon downward growth in response to gravity resumes. Plant shoots also respond to touch; examples include vines with tendrils that wind around or clasp supporting structures. Wind also induces touch responses. In very windy places, trees tend to be shorter than normal, giving them the advantage of being less likely to blow over than taller trees. In the laboratory, plant scientists have simulated natural touch responses by rubbing plant stems and found that this treatment can result in shorter plants. Touch causes the release of calcium ion second messengers that influence gene expression.

More rapid responses to touch, such as leaf folding by the sensitive plant (see Figure 36.1b), are based on changes in the water content of cells within a structure known as a pulvinus (plural, pulvini), a swelling located at the base of attachment of each pair of leaflets in complex leaves. A pulvinus consists of a thick layer of parenchyma cells that surrounds a core of vascular tissue (**Figure 36.15**). When the leaflet of a sensitive plant is touched, an electrical signal called an action potential opens ion channels in parenchyma cells near the lower surfaces of the pulvini. These cells expel potassium and chloride ions, causing water to flow out and the cells to become flattened. This bends the leaflets together, starting the leaflet-folding process. The action potential generated at the touch site also flows through the leaflet, causing many or all of the leaflets to also bend, with the result that the entire leaf folds. Reversal of this process allows the leaf to unfold.

The action of pulvini also explains some plant movements that are unrelated to touch, including sleep movements and sun tracking. Sleep movements are changes in leaf position that occur in response

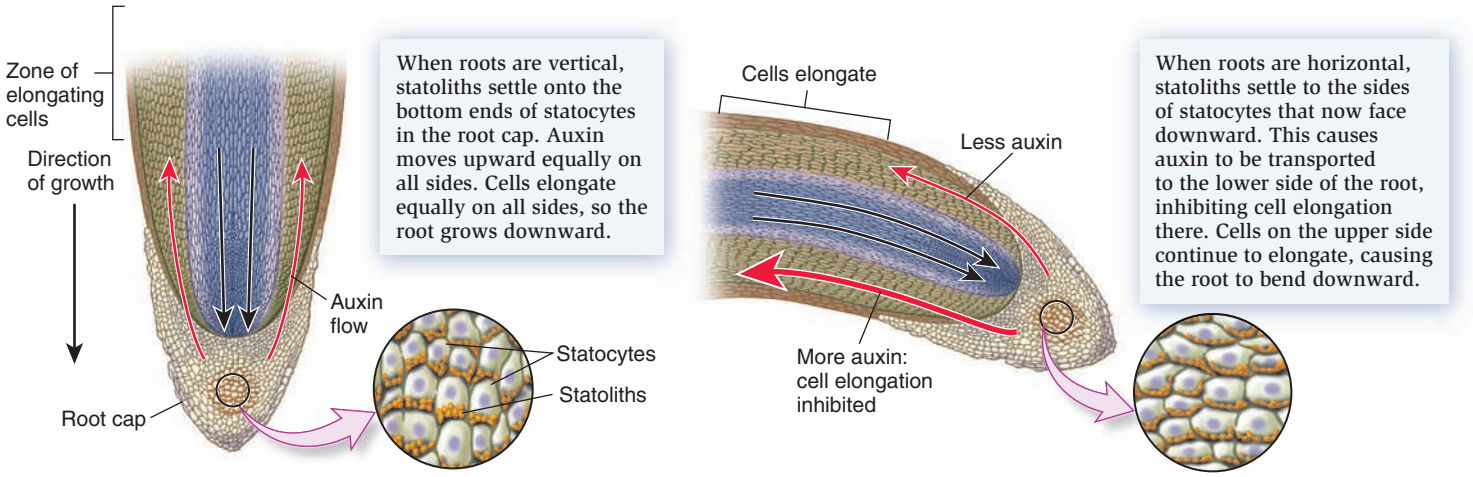

Figure 36.14 **Positive gravitropism in a root.** Root-tip cells sense gravity by means of starchy statoliths present in cells at the center of the root cap.

Concept Check: *Is there any other environmental signal that roots could use to achieve downward growth?*

to day-night cycles. Sun tracking, as mentioned at the beginning of this chapter, is the movement of leaves or flowers in response to the Sun's position.

Plants Respond to Physical Stresses Such as Flooding and Drought

Plants display many types of adaptations that help them cope with unfavorable growth conditions, such as flooding and drought. These responses are often mediated by hormones.

The major harmful effect of flooding is that too much water makes roots unable to obtain sufficient oxygen to fuel respiratory processes. Without oxygen from the air, roots cannot produce the ATP needed to absorb minerals from soil. Many plants reduce the effects of flooding by producing **aerenchyma**, a tissue containing large, snorkel-like air channels that allow more oxygen to flow from shoots to the submerged roots (**Figure 36.16**). In some plants, aerenchyma formation is developmentally programmed, and in others, it is a response to change in environmental conditions. For example, aerenchyma develops in the roots of many plants native to wetland habitats even when the soil is not wet. Aerenchyma can also form in the roots of plants such as corn as a response to flooding. Aerenchyma formation is regulated by the action of ethylene, which leads to programmed cell death, followed by cell collapse.

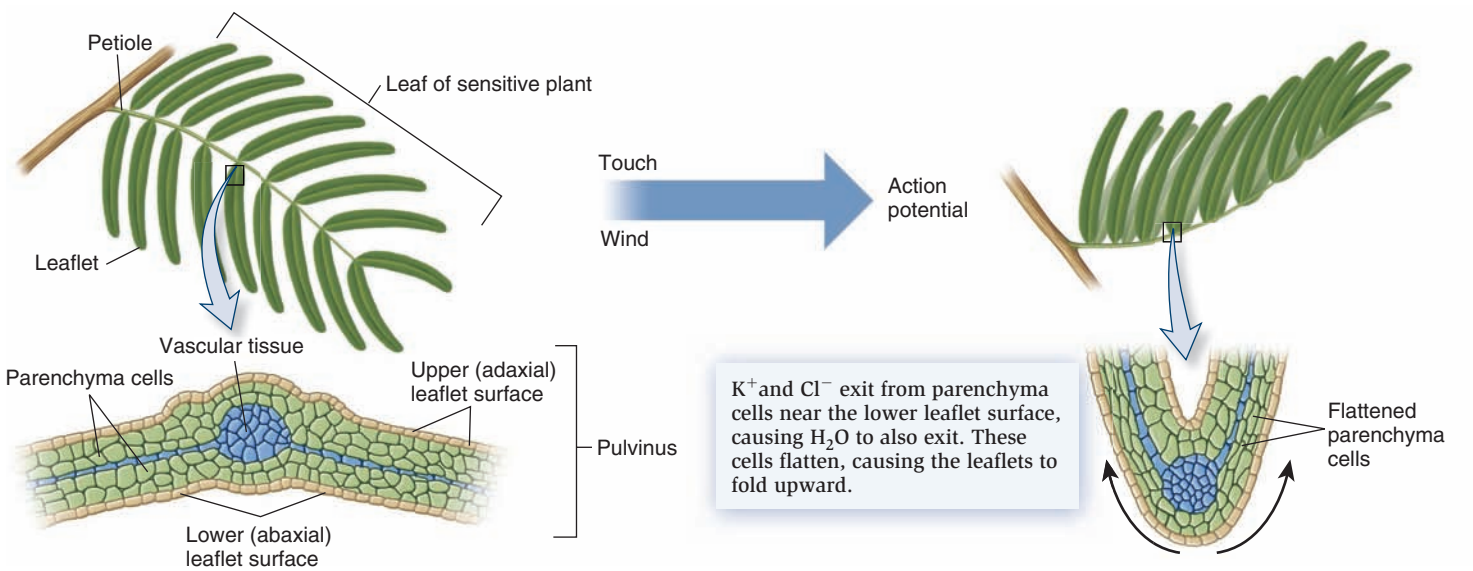

Figure 36.15 **Leaf folding in the sensitive plant: how pulvini change the positions of leaflets.** The electrical signals known as action potentials result from the rapid flow of ions through membrane ion channels. Electrical signals spread from one cell to another through plasmodesmata. Cells near the lower surface of the pulvinus respond to ion flow by losing water, causing them to flatten.

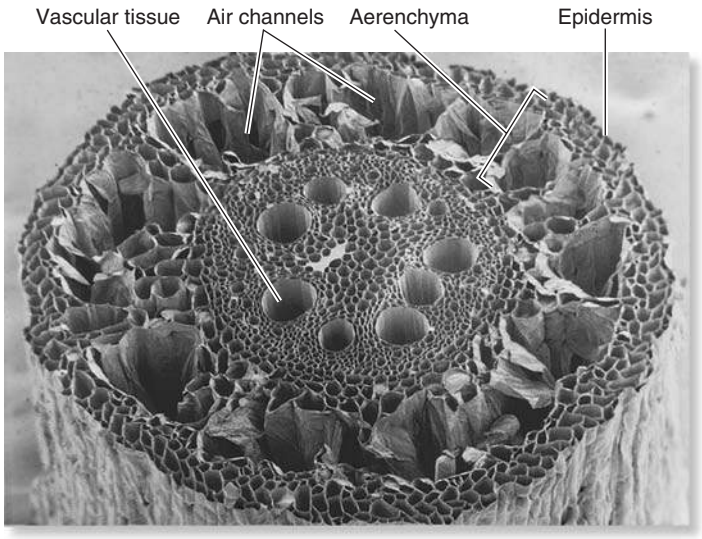

Figure 36.16 **A plant response to flooding.** This image of a slice of a root shows air channels within aerenchyma.

BIOLOGY PRINCIPLE **Structure determines function.** Air channels within aerenchyma allow air to flow from shoots to roots even when the plant is partially submerged.

Concept Check: *What are two ways in which aerenchyma is formed?*

Drought is related to several other environmental stresses—high salinity, heat, and cold—all of which reduce the amount of liquid water present in plant cells. Most plants that lose half or more of their water are unable to recover. Thus, plants possess diverse adaptations that reduce water loss, and the hormone abscisic acid often triggers these responses.

Plants Respond to Biological Stresses Such as Herbivore and Pathogen Attack

Plants are vulnerable to attack by animal herbivores and pathogens—disease-causing microorganisms. Structural barriers such as cuticles, epidermal trichomes, and outer bark, described in Chapter 35, help to reduce infection and herbivore attack. These barriers, together with chemical defense compounds, explain why remarkably little natural vegetation is lost to herbivore or pathogen attack. However, agricultural crops can be more vulnerable to attack than their wild counterparts. This is because some protective adaptations have been lost during crop domestication as the result of genetic changes that increase edibility. For this reason, crop scientists are particularly interested in understanding plant defense, with the goal of being able to breed or genetically engineer crop plants that are better protected from pests.

Plant Responses to Herbivores Herbivore defense compounds include diverse secondary metabolites—terpenes and terpenoids, phenolics, and alkaloids (refer back to Figure 30.22)—but also poisonous hydrogen cyanide and other molecules. Some of these substances act directly on herbivores, making plants taste bad so that herbivores learn to avoid them. Other chemical compounds function indirectly. For example, when attacked by insect caterpillars, cruciferous plants release terpenoids that attract the bodyguard wasp (*Cotesia rubecula*), which attacks the caterpillars.

Wounded plants can communicate with nearby plants, helping them to resist attack by herbivores (**Figure 36.17**). For example, when cutworms wound tomato plants, damaged cells release a volatile alcohol, hexenol. Nearby plants convert the hexenol into a compound that reduces the cutworms' ability to attack them.

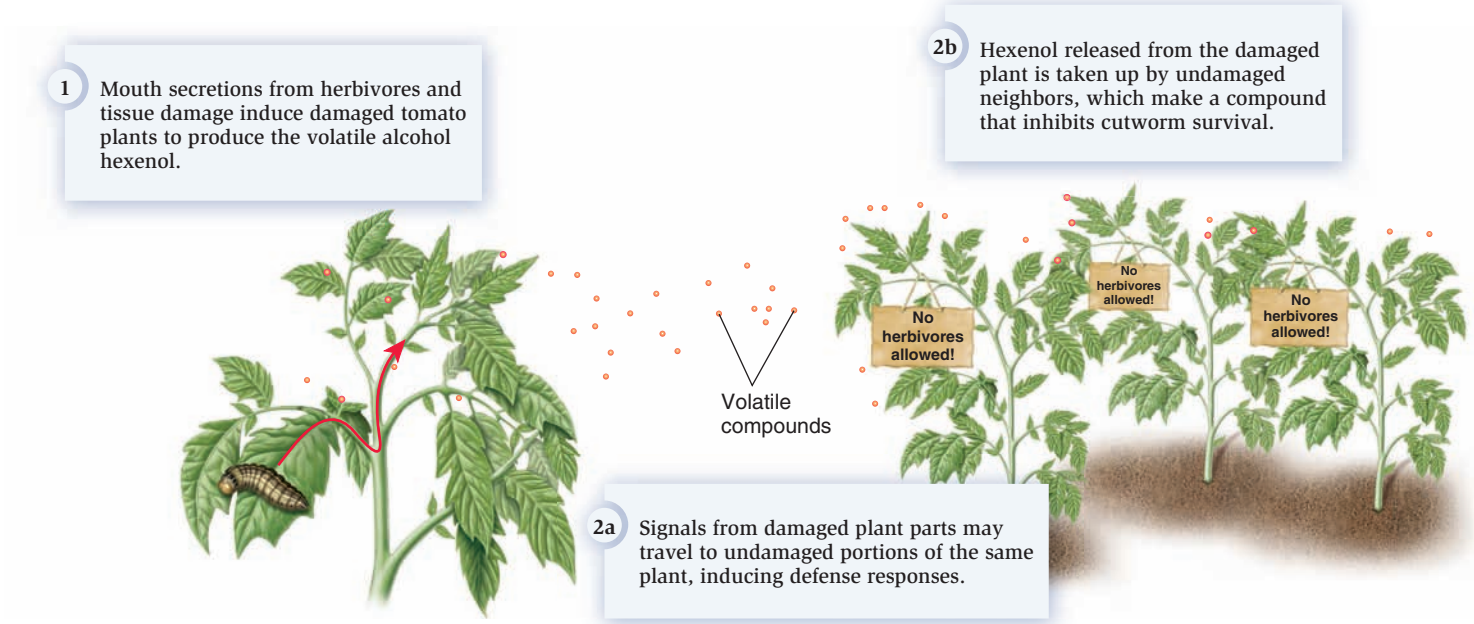

Figure 36.17 **Plant responses to herbivore attack.** **(1)** Leaf damage induces defensive responses such as release of volatile compounds. **(2a)** These compounds foster the development of defenses in undamaged parts of the same plant. **(2b)** Such volatile compounds may also induce defenses in neighboring plants, which then become less vulnerable to herbivores.

Plant Responses to Pathogen Attack Every year, about 15% of crop production is lost to disease caused by certain bacteria, fungi, protists, or viruses. During their evolution, plants have evolved mechanisms for detecting and responding to such microbes, but microbes can rapidly evolve new disease processes. Agricultural scientists aim to understand how pathogenic microbes attack plants and how plants are able to prevent disease, in order to develop disease-resistant crop varieties.

Plant pathogens produce compounds known as **elicitors**. Such elicitors promote **virulence**, the infection of plant cells and tissues. **Avirulence genes (*Avr* genes)** are microbial genes that encode virulence-enhancing elicitors (**Figure 36.18**, step 1). Some bacteria inject elicitors into plant cells by means of syringe-like systems (see Figure 27.18). Fungal pathogens often deliver elicitors into plant cells and absorb nutrients from them by means of penetration structures known as haustoria (from a Latin word, meaning to drink; see Figure 31.23). In response to elicitors, plant cells have evolved first and second lines of defense. The first line of defense consists of plasma membrane receptors that specifically bind microbe-associated molecules, such as bacterial lipopolysaccharides, the flagellar protein flagellin, or the fungal cell wall compound chitin. These plasma membrane receptors, which are typically protein kinases, allow plant cells to sense disease-causing microbes. Animal cells use similar receptor molecules to sense and respond to pathogens.

A second line of defense occurs in the cytosol. Here, miRNAs help to destroy the nucleic acids of invading viruses, in processes similar to those present in animal cells. In addition, receptors that occur in the cytosol allow plant cells to recognize injected elictors. The binding of receptors with elicitors triggers the production of chemical defense signals: hydrogen peroxide (H_2O_2), the gas nitrous oxide (NO), and mobile hormones. Defense responses include deposition of polymers that strengthen plant cell walls at the site of attack, programmed death of infected cells as a way of limiting the spread of infection, and production of compounds that kill pathogens (see Figure 36.18).

Many types of **resistance genes (*R* genes)** in plants encode disease receptor proteins. If a plant is genetically unable to produce a receptor that can recognize a pathogen's presence or elicitor, disease may result. By contrast, plants successfully resist disease when the product of a dominant *R* gene (a receptor) recognizes a pathogen's presence by characteristic compounds or its dominant *Avr* gene product (an elicitor). Diverse alleles of *R* genes occur in plant populations, providing plants with a large capacity to cope with different types of pathogens. These receptors, together with plant responses—the hypersensitive response and systemic acquired resistance—represent the plant immune system.

The Hypersensitive Response to Pathogen Attack The plant **hypersensitive response (HR)** is a local reaction to pathogen attack that limits the progression of disease (see Figure 36.18, steps 3 and 4). H_2O_2 can kill pathogens and also helps strengthen the cell wall by deposition of cross-binding polymers. The gaseous hormone NO

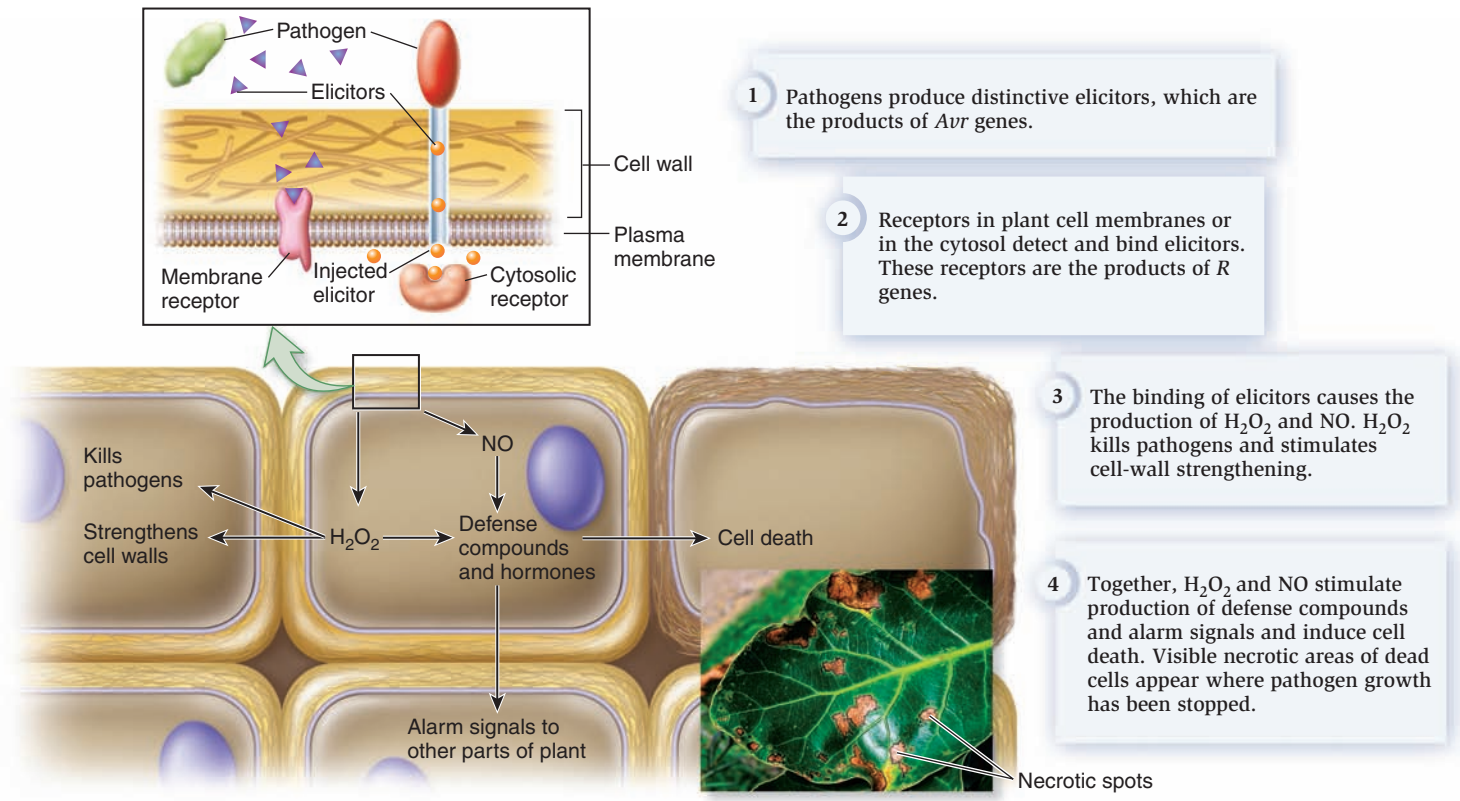

Figure 36.18 **Pathogen/plant interactions and the hypersensitive response to pathogen attack.**

Concept Check: *In what way is systemic acquired resistance to pathogens similar to the immune systems of animals?*

works with H_2O_2 to stimulate the synthesis of hydrolytic enzymes, defensive secondary metabolites, defense hormones, and tough lignin in the cell walls of nearby tissues. NO also induces programmed cell death, which deprives pathogens of food, helping to limit the spread of disease. Necrotic spots are brown patches on plant organs that reveal where pathogens have attacked plants and where plant tissues have battled back. Defense hormones send alarm signals to other parts of the plant, which respond by preparing defenses.

Systemic Acquired Resistance Whereas the HR is a local reaction, **systemic acquired resistance (SAR)** is an immune response of the whole plant induced by a pathogen attack (**Figure 36.19**). SAR immunizes the plant not only from the inducing pathogen, but also many others for weeks to months. Plant SAR is somewhat similar to the immune systems present in animals. At or near a wound, defense hormones are produced and then travel throughout the plant.

Summary of Key Concepts

36.1 Overview of Plant Behavioral Responses

- Plants sense and respond to diverse internal stimuli and external signals and thus display behavior (Figures 36.1, 36.2).
- During the process of cell signaling, cellular receptors respond to environmental stimuli as well as to internal hormonal signals. The process involves receptor activation, signal transduction by second messengers, and a cellular response (Figure 36.3).
- Cellular responses include changes in gene expression and ion channels that influence plant growth, development, reproduction, chemistry, and movements such as sun tracking and leaf folding.

36.2 Plant Hormones

- Plant hormones interact with environmental stimuli to control plant development, growth, and behavior (Table 36.1).
- Auxin plays an important role in many aspects of plant behavior, including phototropism, as demonstrated by the classic experiments of the Darwins, Went, Briggs, and others. Auxin can be transported downward or upward (polar transport) and sideways (lateral transport) in the plant. The positioning of auxin influx and efflux carriers determines the direction of auxin transport (Figures 36.4, 36.5).
- The major effect of cytokinins is to increase the rate of cell division. Auxin and cytokinin are used in laboratory and commercial plant tissue culture (Figure 36.6).
- Gibberellin function illustrates the general principle that plant hormones often act to release cellular brakes on gene expression. The components of a system by which gibberellin and cell proteins interact to influence plant growth evolved in a step-by-step fashion (Figures 36.7, 36.8).
- The gaseous hormone ethylene plays an important role in seed germination (Figure 36.9).
- Abscisic acid (ABA) and brassinosteroids help plants to respond to environmental stress.

36.3 Plant Responses to Environmental Stimuli

- Light-sensitive pigments such as cryptochrome, phototropin, and phytochrome allow plants to respond to light stimuli and influence sun tracking, seed germination, and photoperiodic control of flowering (Figures 36.10, 36.11, 36.12).
- Plant shoots and roots respond to gravity (in the process of gravitropism) by means of starch-heavy statoliths located within statocytes. Rapid touch responses (thigmotropism), such as leaf folding in the sensitive plant, depend on changes in the water content of cells in structures known as pulvini (Figures 36.13, 36.14, 36.15).
- Many plants cope with flooding through the production of special tissue (aerenchyma), which is regulated by ethylene (Figure 36.16).
- Plants cope with biological stresses such as herbivore and pathogen attack by means of structural and chemical adaptations. Injured plant parts produce volatile hormones that signal other parts of the same plant and nearby plants to produce defensive responses. Plant pathogens begin their attack by producing elicitor compounds encoded by avirulence (*Avr*) genes. If an attacked plant can produce a compound that interferes with that elicitor, encoded by an *R* (resistance) gene, then the plant can resist infection by that pathogen. The hypersensitive response (HR) is a local defensive response to pathogen attack, whereas systemic acquired resistance (SAR) is a whole-plant immune response (Figures 36.17, 36.18, 36.19).

Assess and Discuss

Test Yourself

1. Examples of plant hormones include
   a. cyclic AMP, IP_3, and calcium ions.
   b. calcium, CDPKs, and DELLA proteins.
   c. auxin, cytokinin, and gibberellin.
   d. cryptochrome, phototropin, and phytochrome.
   e. statoliths, pulvini, and aerenchyma.
2. Phototropism is the
   a. production of flowers in response to a particular day length.
   b. production of flowers in response to a particular night length.
   c. growth response of a plant, organ system, or organ to directional light.
   d. growth response of a plant, organ system, or organ to gravity.
   e. growth response of a plant, organ system, or organ to touch.
3. What is the most accurate order of events during signal transduction?
   a. first, receptor activation; then, messenger signaling; and last, an effector response
   b. first, an effector response; then, messenger signaling; and last, receptor activation
   c. first, messenger signaling; then, receptor activation; and last, an effector response
   d. first, an effector response; then, receptor activation; and last, messenger signaling
   e. none of the above
4. Which of the plant hormones is known as the master plant hormone and why?
   a. cytokinin, because many plant functions require cell division
   b. gibberellins, because growth is essential to many plant responses
   c. abscisic acid, because it is necessary for leaf and fruit drop
   d. brassinosteroids, because water uptake is so fundamental to plant growth
   e. auxin, because there are many different auxin-response genes
5. Gaseous hormones are able to enter cells without requiring special membrane transporter. Which of the major plant hormones is a diffusible gas?
   a. auxin
   b. gibberellin
   c. cytokinin
   d. ethylene
   e. abscisic acid
6. Photoreceptor molecules allow plant cells to detect light of particular wavelengths. Which of these molecules is considered to be a plant photoreceptor?
   a. cryptochrome
   b. phototropin
   c. phytochrome
   d. a, b, and c
   e. none of the above
7. Thigmotropism is a plant response to
   a. light.
   b. cold.
   c. touch.
   d. gravity.
   e. drought.
8. Which response is an adaptation to flooding?
   a. geotropism
   b. stomatal closure
   c. photoperiodism
   d. production of aerenchyma
   e. opening aquaporins
9. What are avirulence genes?
   a. plant genes that encode proteins that prevent infection (virulence)
   b. plant genes that cause infection when the proteins they encode bind to pathogen elicitors
   c. pathogen genes that prevent the pathogens from causing plant disease
   d. pathogen genes that encode elicitors that foster disease in plants
   e. None of the above correctly describes avirulence genes.
10. How do plants defend themselves against pathogens?
    a. Plants produce resistance molecules (usually proteins) that bind pathogen elicitors, thereby preventing disease.
    b. Plants display a hypersensitive response that limits the ability of pathogens to survive and spread.
    c. Plants display systemic acquired resistance, whereby an infection induces immunity to diverse pathogens in other parts of a plant.
    d. All of the above are correct.
    e. None of the above is correct.

Conceptual Questions

1. Why can plants be said to display behavior?
2. Why do plants produce so many types of resistance (*R*) genes?
3. A principle of biology is that *living organisms interact with their environment.* Because diverse plants exude volatile compounds in response to herbivore or pathogen attack, some experts have written about "talking plants." Is there any such thing?

Collaborative Questions

1. Why are most wild plants distasteful, and some even poisonous, to people?
2. How could you increase the resistance of a crop plant species to particular types of herbivores?

Flowering Plants: Nutrition

37

CHAPTER OUTLINE

37.1 Plant Nutritional Requirements
37.2 The Role of Soil in Plant Nutrition
37.3 Biological Sources of Plant Nutrients
Summary of Key Concepts
Assess and Discuss

The tentacled leaves of the sundews (*Drosera rotundifolia and D. intermedia*), shown with a trapped fly, are a plant adaptation for the acquisition of nutrients.

Many types of fascinating carnivorous (meat-eating) plants grow abundantly in wetlands around the world, even though the soils in these places are infertile. How is this possible? Like most plants, carnivorous plants are photosynthetic and thus produce their own organic food from carbon dioxide and water, using sunlight as an energy source. These resources are abundant in wetlands, but wetland soils are low in other nutrients, such as nitrogen, that are needed for plant growth. Carnivorous plants, such as the sundews pictured in the chapter opening photo, have adapted by obtaining nutrients from the bodies of trapped insects and other small animals. Carnivorous plants lure animals with enticing fragrances, brightly colored leaves, or glistening sugar-rich drops of nectar. The unsuspecting prey fall into deep, water-filled pitchers; become ensnared by glue-like mucilage; or are trapped within the walls of leafy jails whose doors suddenly snap shut. Decomposition of the animal bodies releases nutrients that plant leaves quickly absorb. Other wild and cultivated plants face similar nutritional challenges and likewise display adaptations that help them acquire sufficient resources for growth and reproduction.

This chapter focuses on plant nutrition, the processes by which plants obtain essential resources. We will begin by describing the resources needed by plants for completion of their seed-to-seed life cycle in good health. Next, we will explore the role of soil as an essential resource for plants. Last, we will examine the biological sources of plant nutrients, focusing on nutritional associations between plants and microorganisms, sources of nutrients for carnivorous plants, and how some plants obtain nutrients from other plants. An understanding of these topics is crucial for those who seek ways to grow more plant-derived food or biofuels for humans without causing environmental harm. Plant nutritional information is also useful to people who tend gardens or houseplants, and those who seek to restore degraded habitats.

37.1 Plant Nutritional Requirements

Learning Outcomes:

1. List the major nutritional resources that most plants need for healthy growth.
2. Describe how some plants have adapted to light limitation in shady habitats.
3. **SciSKILLS** » Distinguish between plant macronutrients and micronutrients, using quantitative comparisons.

The case of carnivorous plants illustrates the concept that all plants—like all animals—have nutritional requirements. A **nutrient** is a substance that is metabolized by or incorporated into an organism. Photosynthetic plants require carbon dioxide (CO_2), water (H_2O), and more than a dozen elements, such as potassium (as K^+), nitrogen (in the form of NH_4^+ or NO_3^-), and calcium (as Ca^{2+}) to produce organic food by means of photosynthesis. CO_2 is primarily absorbed from air, whereas H_2O and elements are primarily taken up from soil in the form of dissolved ions (**Figure 37.1**). As is the case for animals, deficiency symptoms develop in plants that

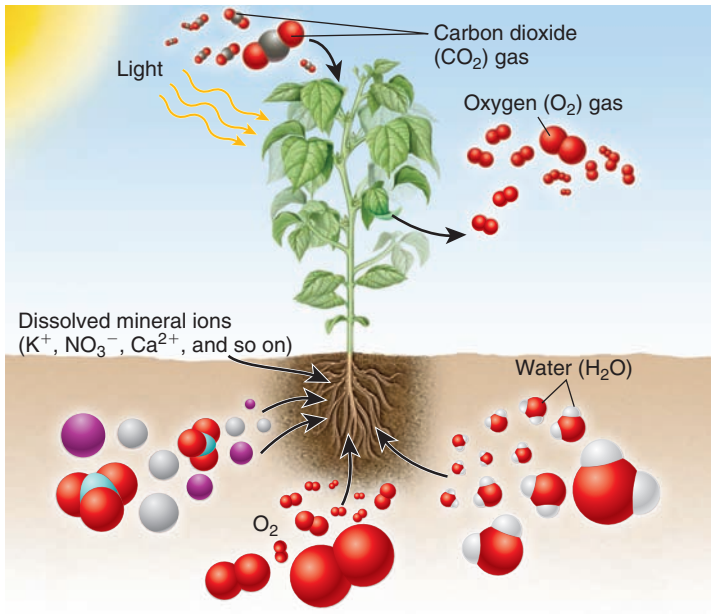

Figure 37.1 The major types of plant nutrients and their sources. Elements that are required in relatively large amounts are known as macronutrients, whereas elements required in smaller amounts are known as micronutrients. A mineral is a naturally occurring inorganic compound. Many minerals dissolve in water to form ions.

receive too little of these substances. The environmental scarcity of nutrients selects for adaptations that help plants to acquire them, illustrated by the existence of carnivorous plants.

Essential elements are chemical elements that are required by plants and play many roles in plant metabolism, often functioning as enzyme cofactors (**Table 37.1**). Elements that are generally required in amounts of at least 1 g/kg of plant dry mass are known as **macronutrients**. In contrast, elements that are needed in amounts at or less than 0.1 g/kg of plant dry mass are known as **micronutrients**, or trace elements. Because insufficient amounts of light, carbon dioxide, water, and other mineral nutrients can limit the extent of green plant growth, these resources are known as **limiting factors**. If you were in charge of a garden, greenhouse, farm, or forest used to generate products such as wood or paper, or if you were overseeing an environmental restoration project, you would want to understand the conditions that foster or limit plant growth. In this section, we will focus on plant resource requirements, starting with light.

Light Is an Essential Resource for the Growth of Green Plants

All photosynthetic plants require light energy for the formation of the covalent bonds of organic compounds that make up the plant body. Green plants' use of light energy as an essential resource parallels animals' nutritional requirements for organic food as a source of chemical energy. For the several hundred species of heterotrophic plants that have lost their photosynthetic capacity, such as the Indian pipe (*Monotropa uniflora*), essential nutrients include absorbed organic compounds that replace light as a source of energy (**Figure 37.2**).

Table 37.1 Plant Essential Nutrients

Element (chemical symbol)	Percent of plant dry mass	Major source	Form taken up by plants	Function(s)
Macronutrients				
Carbon (C)	45	Air	CO_2	Component of all organic molecules
Oxygen (O)	45	Air, soil, water	CO_2, O_2, H_2O	Component of organic molecules
Hydrogen (H)	6	Water	H_2O	Component of all organic molecules; protons used in chemiosmosis and cotransport
Nitrogen (N)	1.5	Soil	NO_3^-, NH_4^+	Component of proteins, nucleic acids, chlorophyll, coenzymes, and alkaloids
Potassium (K)	1.0	Soil	K^+	Has essential role in cell ionic balance
Calcium (Ca)	0.5	Soil	Ca^{2+}	Component of cell walls; messenger in signal transduction
Magnesium (Mg)	0.2	Soil	Mg^{2+}	Component of chlorophyll; activates some enzymes
Phosphorus (P)	0.2	Soil	HPO_4^{2-}	Component of nucleic acids, ATP, phospholipids, and some coenzymes
Sulfur (S)	0.1	Soil	SO_4^{2-}	Component of proteins, some coenzymes, and defense compounds
Micronutrients				
Chlorine (Cl)	0.01	Soil	Cl^-	Required for water splitting in photosystem; cell ion balance
Iron (Fe)	0.01	Soil	Fe^{3+}, Fe^{2+}	Enzyme cofactor; component of cytochromes
Manganese (Mn)	0.005	Soil	Mn^{2+}	Enzyme cofactor
Boron (B)	0.002	Soil	$B(OH)_3$	Enzyme cofactor; component of cell walls
Zinc (Zn)	0.002	Soil	Zn^{2+}	Enzyme cofactor
Sodium (Na)	0.001	Soil	Na^+	Required to generate PEP in C_4 and CAM plants*
Copper (Cu)	0.0006	Soil	Cu^+, Cu^{2+}	Enzyme cofactor
Molybdenum (Mo)	0.00001	Soil	MoO_4^{2-}	Enzyme cofactor
Nickel (Ni)	0.000005	Soil	Ni^{2+}	Enzyme cofactor

*PEP stands for phosphoenolpyruvate; CAM stands for crassulacean acid metabolism.

Figure 37.2 The heterotrophic flowering plant, Indian pipe (*Monotropa uniflora*).

BIOLOGY PRINCIPLE Living organisms use energy. This nongreen heterotrophic plant lacks photosynthetic capacity and therefore must absorb organic compounds for use as an energy source. In contrast, nearby autotrophic green plants use sunlight as a source of energy.

BioConnections: Look back at Figure 31.5a to see the white body of a fungus, known as a mycelium. How is the nutrition of this (and all fungi) similar to that of the flowering plant Monotropa uniflora?

In nature, plants must adapt to environments with varying amounts of light and shade. For example, in forests, light availability limits the growth of tree seedlings and other small plants that are shaded by the leafy tree canopy overhead. Conversely, plants growing in deserts or on mountains often experience light so intense that it can damage the photosynthetic components. Plants have evolved adaptations that help them cope with environments that have too little or too much light.

Adaptations to Shade Plants can adapt to shading by producing thin leaves that allow some light to pass through to other leaves, producing more chlorophyll, or producing distinctive sun and shade leaves (**Figure 37.3**). Sun leaves have a thicker layer of chlorophyll-containing mesophyll and are able to harvest more of the bright sunlight that penetrates deeply into the leaf. In contrast, shade leaves have a thinner mesophyll layer, with more air spaces than do sun leaves. The arrangement of leaves on plants and stem-branching patterns also reflect adaptations that reduce shading. For example, many tropical forest trees that must compete for light with closely crowded neighbors are extremely tall, and they produce branches and leaves only at their very tops. Shorter plants native to the shady interiors of tropical rain forests are so well adapted to these moist but dim conditions that they make excellent houseplants (**Figure 37.4**).

Adaptations to Excessive Light Too much light can damage plant chloroplasts by destroying an essential photosynthetic protein, called the D1 protein. Specific carotenoid pigments in the chloroplast absorb some of the excess light energy and dissipate it as harmless heat. Other adaptations prevent ultraviolet (UV) damage. Harmful amounts of UV

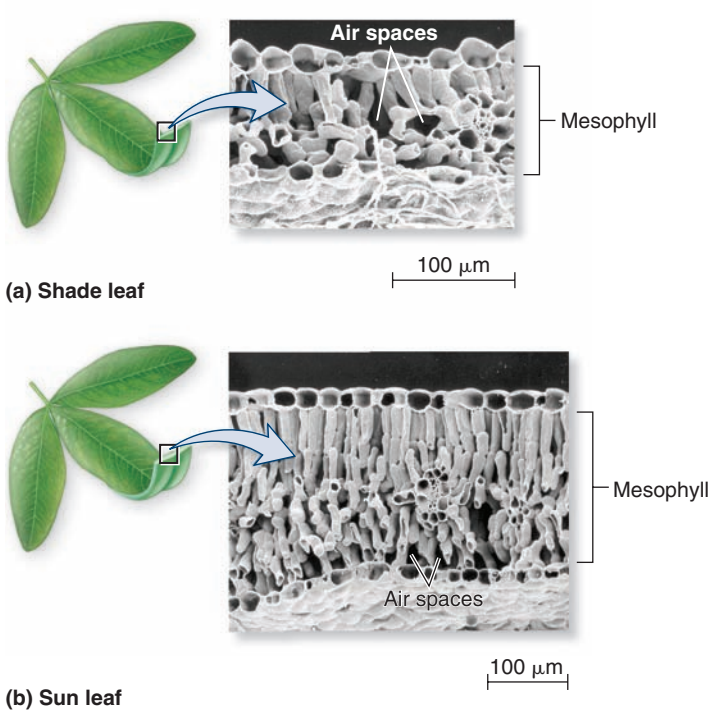

Figure 37.3 Shade and sun leaves.

BIOLOGY PRINCIPLE Structure determines function. These scanning electron micrographs of cut leaves reveal the thinner mesophyll and greater number of air spaces in **(a)** shade leaves as compared with **(b)** sun leaves.

Figure 37.4 The tropical houseplant *Monstera deliciosa*.
M. deliciosa makes an attractive houseplant because its large, deep green leaves are adapted to the moist and shady conditions present in the interiors of tropical forests.

radiation are absorbed by the plant's surface cuticle, as well as by carotenoid and flavonoid compounds located within leaf cells. These protective compounds are often brightly colored and, when present in large amounts, explain the attractive red or purple colors of some leaves.

Carbon Dioxide Concentration Influences Plant Growth

Although light provides the energy for plant photosynthesis, most plant dry mass originates from carbon dioxide (CO_2). Most plants obtain CO_2 gas from the atmosphere, by absorption through stomata, pores that occur in the plant epidermis. Under experimental conditions, plant photosynthetic rates increase with CO_2 concentration until the Calvin cycle enzyme rubisco has become fully supplied, that is, saturated with CO_2. (To review leaf structure, see Figure 35.8c; to review the role of rubisco and the Calvin cycle in photosynthesis, see Figure 8.13.)

CO_2 Limitation In nature, plants are often unable to obtain enough CO_2 for maximal photosynthesis. As a result, CO_2 limits agricultural crop productivity. This is partly because the modern atmospheric concentration of CO_2 is only 390 µL/L (a small fraction of atmospheric content), whereas considerably more CO_2 would be required to saturate photosynthesis in most plants. Evidence that plant photosynthesis can be limited by CO_2 availability is provided by studies of crops grown in greenhouses, where atmospheric gas content can be controlled. When supplied with air enriched with CO_2, tomatoes, cucumbers, leafy vegetables, and some other crops can double their growth rate. In nature, plants that experience hot, dry conditions are particularly vulnerable to low CO_2 levels when their stomata close to conserve water. When stomata are closed, plants cannot absorb CO_2, which limits photosynthesis. Many plants possess structural and biochemical adaptations that help them cope with CO_2 limitation by improving CO_2 absorption.

CO_2-Absorption Adaptations Many plants that live in arid or hot environments display an adaptation known as C_4 photosynthesis, which improves productivity by aiding CO_2 absorption (refer back to Figure 8.17). About 30,000 plant species utilize C_4 photosynthesis, which is thought to have evolved from ancestral C_3 photosynthesis on more than 40 separate occasions. Today, C_4 plants dominate extensive warm grassland habitats of the world, contributing about 25% of the total terrestrial photosynthesis.

C_4 photosynthesis relies on specializations in the internal structure of leaves. In C_4 plants, the leaf mesophyll harvests light, but does not contain Calvin-cycle enzymes that bind CO_2 to form sugar. Instead, C_4 leaf mesophyll produces the enzyme phosphoenolpyruvate (PEP) carboxylase, which binds CO_2 more readily than does rubisco. PEP carboxylase adds CO_2 to PEP, a three-carbon molecule, to produce the four-carbon compound oxaloacetate. The leaves of C_4 plants also have increased vein density, and specialized bundle-sheath cells surround each vein. In the leaves of most C_4 plants, such as maize (corn), the four-carbon compounds produced in mesophyll move through intracellular connections into the bundle-sheath cells. Within the bundle-sheath cells, enzymes release CO_2 from the C_4 compounds, and the CO_2 is incorporated into organic carbon by Calvin cycle enzymes.

Some plants native to arid regions have evolved a type of C_4 photosynthesis that occurs within a single cell. Photosynthetic cells of these plants have two types of plastids, one type containing PEP carboxylase and the other containing rubisco (**Figure 37.5**). C_4 photosynthesis is particularly valuable to plants that occur in hot, dry environments because it allows plants to absorb sufficient CO_2 without losing too much water.

Water Is an Essential Plant Resource

Water is essential to plants for several reasons. As a nutrient, water is the source of most of the hydrogen atoms and many of the oxygen atoms in organic compounds (see Table 37.1). For example, the oxygen in the abundant plant polymer cellulose derives from water taken up from the soil. Hydrogen is incorporated when CO_2 is reduced during the process of photosynthesis, and oxygen is incorporated during hydrolysis reactions. Water is also the solvent for other mineral nutrients and is the main transport medium in plants, allowing movement of minerals and other solutes throughout the plant body via the vascular tissues. Cytoplasmic and vacuolar water also help to support plants by maintaining hydrostatic pressure on the cell wall.

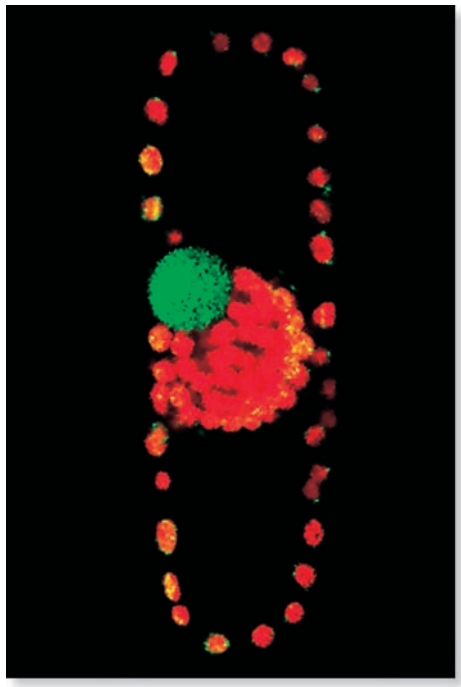

Figure 37.5 A CO_2 absorption adaptation. In contrast to most C_4 plants, *Bienertia cycloptera* is able to conduct C_4 photosynthesis within the confines of a single cell. In this fluorescence photograph of a *B. cycloptera* cell, the red plastids at the cell periphery function like the mesophyll cells of most C_4 plants. In contrast, the red plastids clustered near the green nucleus function much like the bundle-sheath cells of most C_4 plants. The plastids appear red because chlorophyll emits red light when it fluoresces.

Concept Check: *Which plastids should have more of the enzyme rubisco in them, plastids at the cell periphery or those clustered near the nucleus?*

Though plants vary in water content, water typically makes up about 90% of the weight of living plants. Most plants die when their water content falls below half of the amount normal for that particular species. Although many types of desiccation-resistant plants display adaptations that allow them to survive for extended periods in fairly dry conditions, all plants require an adequate supply of water for active metabolism and growth.

Soil Provides Additional Plant Nutrients

In addition to light, CO_2, and water, plants require additional elements that occur naturally in water and soil or that can be added in the form of fertilizers. Plant biologists have quantitatively analyzed the elemental requirements of plants by growing them hydroponically, that is, by bathing plant roots in a water solution to which elements in the form of dissolved minerals are added in various combinations and amounts. Hydroponic studies reveal that when plants lack an adequate supply of an essential elemental nutrient, they display characteristic deficiency symptoms. Such symptoms include failure to reproduce, tissue death, and changes in leaf color. Yellowing of leaves, known as **chlorosis**, is a common mineral deficiency symptom, because many elements are needed for chlorophyll production (**Figure 37.6**). Hydroponic studies reveal the relative amounts and roles of essential elements in plant growth more easily than can be accomplished by growing plants in soil, which supplies most plants with most of the elements they need (see Table 37.1). Soil plays several additional roles in plant growth.

Figure 37.6 Chlorosis as a symptom of mineral deficiency. This camellia plant is suffering from an iron deficiency, as revealed by the yellow leaves, a symptom known as chlorosis.

Concept Check: Does chlorosis always indicate iron deficiency in plants?

37.2 The Role of Soil in Plant Nutrition

Learning Outcomes:

1. List the benefits of soil organic matter for plant growth.
2. Explain why plants require a source of fixed nitrogen and how they obtain it.
3. Discuss various plant adaptations that increase the ability to obtain phosphorus.

Soil is an essential resource for most wild and cultivated plants, providing water and other essential nutrients. For this reason, extensive loss of soil by wind and water erosion is of wide concern. Soils vary greatly in fertility, that is, their ability to support plant growth. Thus, plants of many types have had to adapt to the challenges of obtaining nutrients from poor soils. In this section, we will explore soil structure and chemistry from the perspective of plant growth and examine how plants take up nutrients from the soil.

The Physical Structure of Soils Affects Their Aeration, Water-Holding Capacity, and Fertility

Natural soils display layers, known as soil horizons (**Figure 37.7a**). The remains of plants that have recently died and other organisms form a layer of litter above the **topsoil**; the topsoil is also known as the A horizon. Many of the inorganic minerals and organic materials that enrich high-quality topsoil arise from the activities of microorganisms that decompose the litter. In this way, the minerals contained in living plants are eventually recycled to subsequent generations. Beneath the topsoil lie layers called subsoil and soil base, which are largely composed of mineral materials. Bedrock is the bottom layer that supports the soil horizons. Plant roots play an important role in conveying deep-lying minerals to the surface, thereby helping to enrich the topsoil.

Soil horizons vary in composition and thickness, depending on various factors—including climate, vegetation, bedrock type, and human influences. For example, natural grasslands produce deep, rich topsoil that is used for cropland in many regions of the world (**Figure 37.7b**). In dramatic contrast, tropical rain forests often have only thin layers of topsoil; their low-fertility soils are composed mostly of inorganic materials that are not useful to plants (**Figure 37.7c**). Farmers cope with reduced soil fertility by adding organic or inorganic fertilizers. The proportions of organic to inorganic materials and the sizes of inorganic particles are used to classify soils into different types. Soils also display variation in their amount of aeration, water-holding capacity, pH, and mineral content. All of these soil properties affect plant growth. For this reason, we will take a closer look at soil structure and the role of fertilizers.

Soil Organic Matter Soil organic matter, also known as humus, is largely derived from plant detritus, the dead and decaying remains of plants, although animal wastes and decayed animal bodies also contribute to the organic content of soils. Soil organic matter provides many benefits. Organic-rich soils, containing 8% or so organic matter, are less likely to erode—wash or blow away with water or wind. Soil organic matter also binds mineral nutrients, thereby fostering soil fertility, and gives soil a soft consistency that fosters plant root growth and farmers' ability to cultivate. Gardeners often produce their own organic-matter-rich compost by layering vegetable waste from the

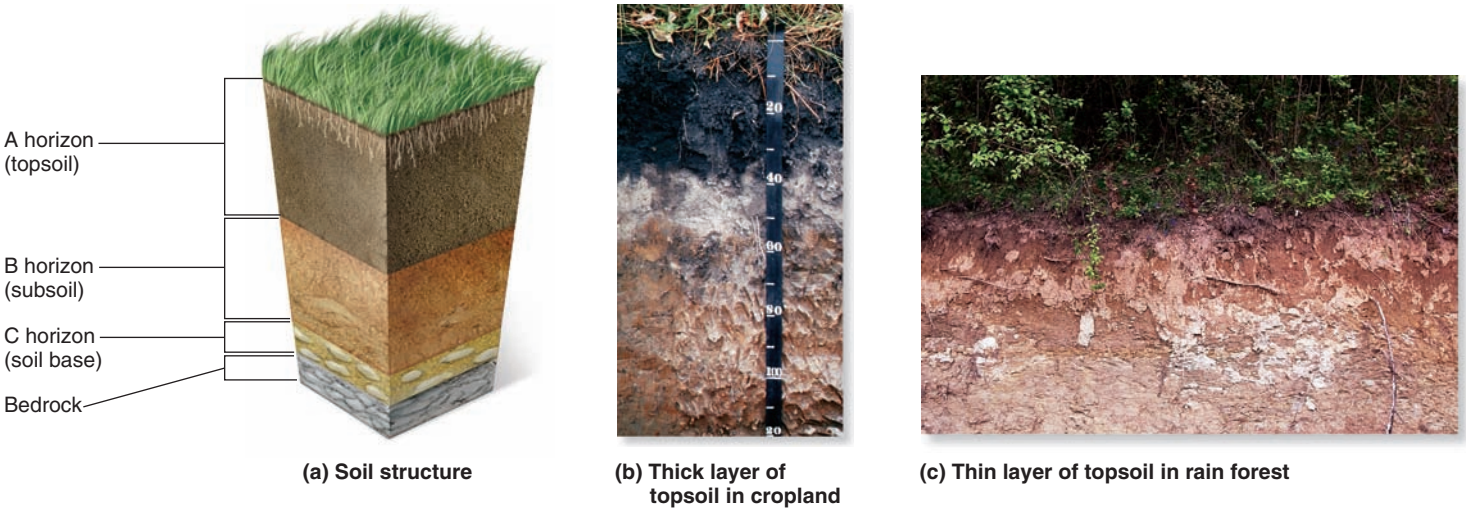

Figure 37.7 Soil horizons, the structural layers of soil. **(a)** Diagram showing general soil structure. **(b)** A vertical view of an agricultural soil, showing a relatively deep layer of dark topsoil. **(c)** A vertical view of a tropical rain forest soil, showing a thin layer of dark topsoil.

BioConnections: Look ahead to Figure 60.17b, which shows a habitat that was seriously degraded by phosphate mining, and whose topsoil had to be replaced. How could damaged land possibly be rehabilitated to support natural vegetation or agriculture, and what are the likely consequences?

kitchen and yard waste with soil, and turning the pile occasionally to introduce the oxygen necessary for decomposition (Figure 37.8). Mature compost is then mixed with garden soil to improve its fertility.

Inorganic Soil Constituents Inorganic materials in soil are derived from the physical and chemical breakdown of rock, a process known as **weathering**. Rock, which is an aggregate of two or more minerals, is physically weathered by changes such as cycles of freezing and thawing. Lichens and plant roots may produce organic acids that contribute to chemical weathering of rocks. During chemical weathering, soluble salts are washed out, and minerals are hydrolyzed or oxidized. **Leaching** is the dissolution and removal of inorganic ions as water percolates through materials. Heavy rainfall can reduce the fertility of soils by leaching large amounts of nutrients from them.

Figure 37.8 Composting. Gardeners produce compost by layering small amounts of soil with vegetable waste from the kitchen and yard waste and periodically turning the pile to introduce the oxygen needed for decomposition. Compost can be used to increase the organic and mineral content of garden soils.

The leached elements often end up in natural bodies of water, where they can foster the growth of cyanobacteria, algae, and aquatic plants.

Inorganic soil materials occur as particles that can be categorized according to their size as sand, silt, or clay (Figure 37.9). Sand grains range from 2 mm to 62.5 μm in diameter. Particles of silt range from 20 to 2 μm in diameter, and clay particles are even smaller. Soils can be classified according to their relative content of coarse and fine materials. For example, soils that contain 45% or more sand and 35% or less clay are classified as sandy soils. The other main types of soil are silt, clay, and loam. **Loam** contains a mixture of sand, silt, and clay and is ideal for the cultivation of most plants.

Because of their size differences, sand, silt, and clay particles confer different properties on soils. The relatively large size and irregular shapes of sand particles allow air and water to move rapidly through sandy soils, which are said to be porous (Figure 37.10). Sandy soils are well aerated, which is favorable to the growth of plant roots, because

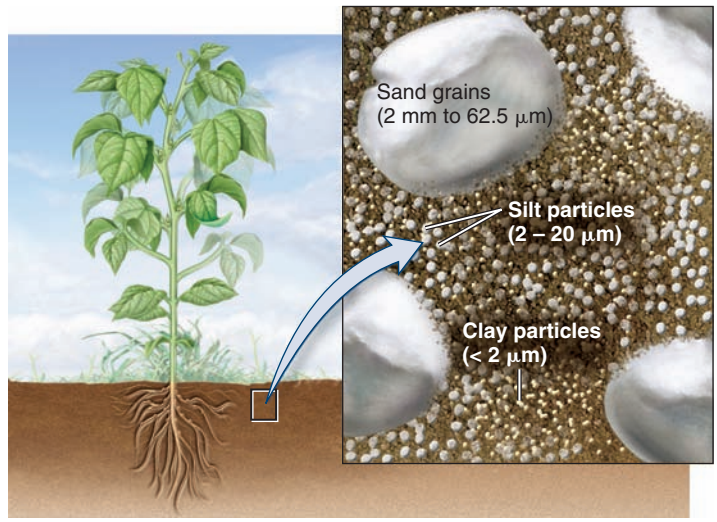

Figure 37.9 The relative sizes of inorganic soil components.

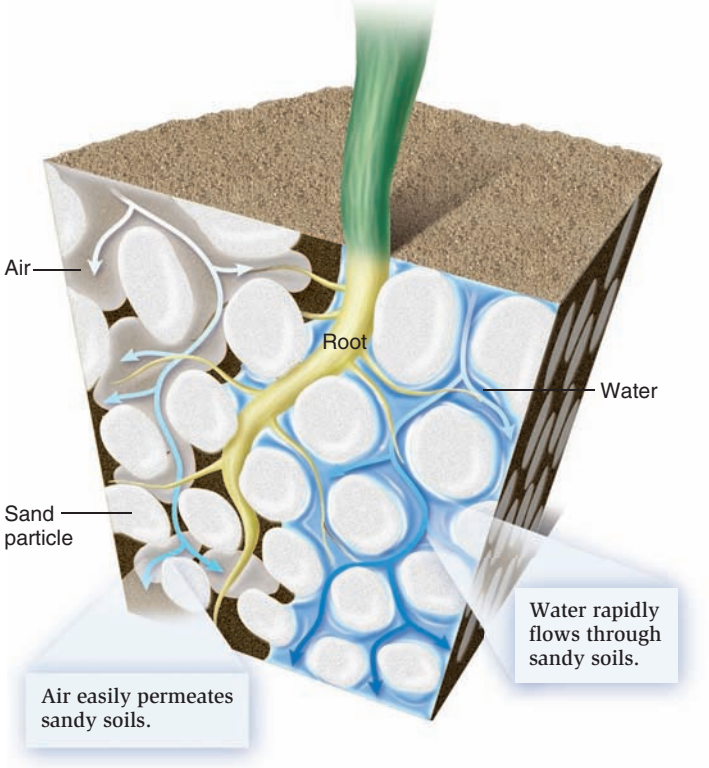

Figure 37.10 **The movement of air and water in sandy soil.**

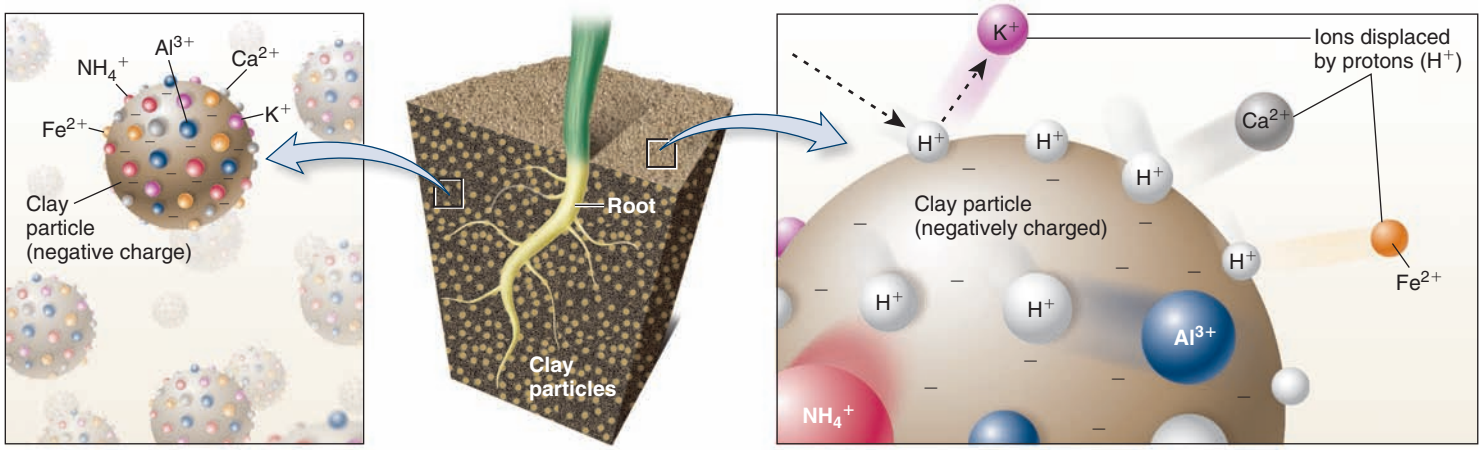

Concept Check: *In which type of soil is nutrient leaching a more common problem, sandy or clay soil?*

they require oxygen for cellular respiration. However, sandy soils hold less water than the same volume of clay, and rapid percolation of water through sandy soils both reduces the amount of water available to the roots and leaches minerals from the soil.

Silt and clay particles fit closely together, so soils containing larger amounts of these materials are less porous than sandy soils. Water percolates less easily through silty and clay soils, which therefore retain more ionic mineral nutrients than do sandy soils. Clay particles have negative charges on their surfaces that electrostatically bind positively charged ions (cations) such as NH_4^+, Ca^{2+}, and Fe^{2+} (**Figure 37.11a**). Cations having higher valence numbers (such as Fe^{2+}) are bound more tightly than ions having lower valence numbers. In order to be available to plants, cations must be detached from clay particles. Hydrogen ions (H^+, protons) are able to replace mineral cations on the surfaces of clay particles in a process known as **cation exchange** (**Figure 37.11b**). Cation exchange releases cations to soil water, making them available for uptake by plant roots. However, free ions are also more easily washed out of soil. If the H^+ concentration becomes too high, large numbers of mineral ions are released and can be leached from soil by heavy rainfall. Such leached minerals may include heavy metals such as aluminum (Al^{3+}) that would otherwise be bound in soil. Cation exchange is the mechanism by which acid rain, which adds H^+ to soil, causes loss of soil fertility and the pollution of streams with toxic substances, such as aluminum, that can harm human health.

Despite their water- and mineral-retention features, silt- and clay-rich soils may be poorly aerated and therefore unfavorable to root growth. Gardeners often mix organic materials and sand into silt or clay-rich soils to improve their aeration properties. Loam is the preferred soil for agriculture because it combines the aeration provided by sand with the mineral and water retention capacity of silt and clay. Even with a good soil mix, fertilizers may be needed to achieve maximum crop production.

The Role of Fertilizers **Fertilizers** are soil additions that enhance plant growth by providing essential elements. The addition of fertilizer to soils can compensate for deficiencies in soil organic matter or mineral content and thus improve soil fertility. Fertilizers occur in organic and inorganic forms. Organic fertilizers are those in which most of the minerals are bound to organic molecules and are thus released relatively slowly. They play an important role in **organic farming**, the production of crops without the use of inorganic fertilizers, growth substances, and pesticides. Manure and compost are examples of organic fertilizers.

(a) Electrostatic attraction between clay particles and mineral ions

(b) Cation exchange

Figure 37.11 **Cation binding and exchange.** **(a)** Clay and organic particles in the soil display negative electrostatic surface charges that bind cations. Bound cations include not only plant mineral nutrients such as ammonium (NH_4^+) but also cations that are not plant nutrients, such as Al^{3+}. **(b)** Cation exchange occurs when protons (H^+) displace other cations, releasing them to soil water. This process makes cations more available for uptake by plant roots, but it also increases the potential for cations to leach away during rains or floods.

In contrast, inorganic fertilizers consist largely of inorganic minerals, which are immediately useful to plants but can more easily leach from soils during heavy rainfall. Nitrogen (N), phosphorus (P), and potassium (K) are the mineral nutrients that most frequently limit crop growth. For this reason, these minerals are the main components of the most common type of commercial inorganic fertilizers. Such fertilizers are available with different ratios of minerals, which are optimal for different types of plants.

Excessive application of fertilizers to fields and lawns is undesirable because minerals not taken up by plant roots are easily washed by rain into waterways, where they can fuel large growths of algae and aquatic plants that can harm other aquatic life-forms. For example, large areas of the Gulf of Mexico and other coastal regions are now known as "dead zones" because microbial decomposition of large algal populations has depleted oxygen from the water, suffocating the animal life. These large populations of algae are fostered by fertilizers that wash from farm soils into rivers, such as the Mississippi River, that drain into coastal oceans. More careful application of fertilizers and planting stream and river edges with vegetation that helps to absorb mineral nutrients can help reduce or prevent dead zones.

Figure 37.12 A soil surface crust that includes nitrogen-fixing, soil-enriching cyanobacteria and lichens. Such crusts are widespread in grasslands and other arid regions.

Concept Check: How might soil crusts influence the ecology and economy of regions in which grazing is important?

Plants Require Fixed Nitrogen

Nitrogen is frequently limiting to plant growth in nature and in crop fields, because large amounts of it are required for plant synthesis of amino acids, nucleotides, and alkaloids, among many other cellular constituents. Nitrogen is the largest component of plants by mass after carbon, oxygen, and hydrogen. Although the Earth's atmosphere is 78% nitrogen gas (N_2), plants cannot utilize nitrogen in this form. To be of use to plants, soil nitrogen must occur in a combined form, such as ammonia (NH_3), ammonium ion (NH_4^+), or nitrate ion (NO_3^-), also known as **fixed nitrogen**. Ammonia and its dissolved form—NH_4^+—can be used directly for amino acid production by plants, explaining why ammonia is often applied as a fertilizer to farm fields in springtime. However, in oxygen-rich soils, microorganisms oxidize much of the NH_4^+ to nitrate, so NO_3^- may be the form in which fixed nitrogen enters most plants. Plants use NH_4^+ and NO_3^- to make a wide range of essential organic compounds, including amino acids, nucleic acids, and chlorophyll.

Much of the fixed nitrogen in soils has been recycled from compounds previously utilized by other organisms. Nitrogen flows through the environment in a nitrogen cycle, discussed in Chapter 59 (look ahead to Figure 59.21). New fixed nitrogen can be added to soils by the action of lightning, fire, and air pollution, as well as biological and industrial nitrogen fixation. **Nitrogen fixation** is the process by which atmospheric N_2 is combined with hydrogen to produce NH_3. Most of the fixed nitrogen in soils is produced by **biological nitrogen fixation**, which is performed in nature only by certain prokaryotic organisms. Nitrogen fertilizers applied to crops are produced by **industrial nitrogen fixation**, a human activity.

Biological Nitrogen Fixation by Bacteria Nitrogen-fixing prokaryotic organisms include many types of cyanobacteria, which are photosynthetic organisms that occur in oceans, lakes, and other aquatic systems, as well as in surface soil crusts (**Figure 37.12**). Various types of nonphotosynthetic bacteria living in water and soil are also able to fix nitrogen. Nitrogen-fixing prokaryotic organisms often excrete a substantial amount of fixed nitrogen, and their death makes still more fixed nitrogen available to plants. Many plants have nitrogen-fixing, prokaryotic symbionts that transfer fixed nitrogen directly to plant cells. Nitrogen-fixation symbioses are so important in nature and in agriculture that they are discussed in more detail in Section 37.3.

All nitrogen-fixing prokaryotic organisms utilize relatively large amounts of ATP and an enzyme known as **nitrogenase** to fix nitrogen (**Figure 37.13**). This process occurs in three steps. In the first step, a molecule of nitrogen gas (N_2) binds to nitrogenase. In the second step, the bound nitrogen is reduced by the addition of two hydrogen atoms (2 H), a reaction powered by the breakdown of ATP. Such a reduction occurs three times, with the addition of a total of three hydrogen atoms to each nitrogen atom. In a third and final step, two molecules of ammonia (NH_3) are released and dissolve in cell water to form NH_4^+. The nitrogenase enzyme is then free to bind more N_2.

Because the O_2 molecule resembles N_2, oxygen can bind to the active site of nitrogenase. Oxygen binding disables nitrogenase, thereby stopping nitrogen fixation. Many of the genes involved in prokaryotic nitrogen fixation are known, and crop scientists are working to genetically engineer nitrogen-fixation capacity into crop plants such as rice and maize (corn). However, the vulnerability of nitrogenase to oxygen means that this enzyme may need to be altered so that it binds oxygen less readily, or plants must be engineered with some mechanism that protects nitrogenase from oxygen.

Industrial Nitrogen Fixation Worldwide, farmers apply more than 80 million metric tons of nitrogen fertilizer per year. The fixed nitrogen found in fertilizer is produced industrially from N_2 by means of a procedure invented by German chemists Fritz Haber and Carl Bosch in 1909. The reduction of N_2 gas to NH_3 is energetically favorable at room temperature, but the activation energy is very high, so the reaction occurs extremely slowly. Using an iron catalyst, temperatures of 400–650°C (752–1,202°F), and high pressures (150–400 atmospheres), the Haber-Bosch process generates NH_3 rapidly. However,

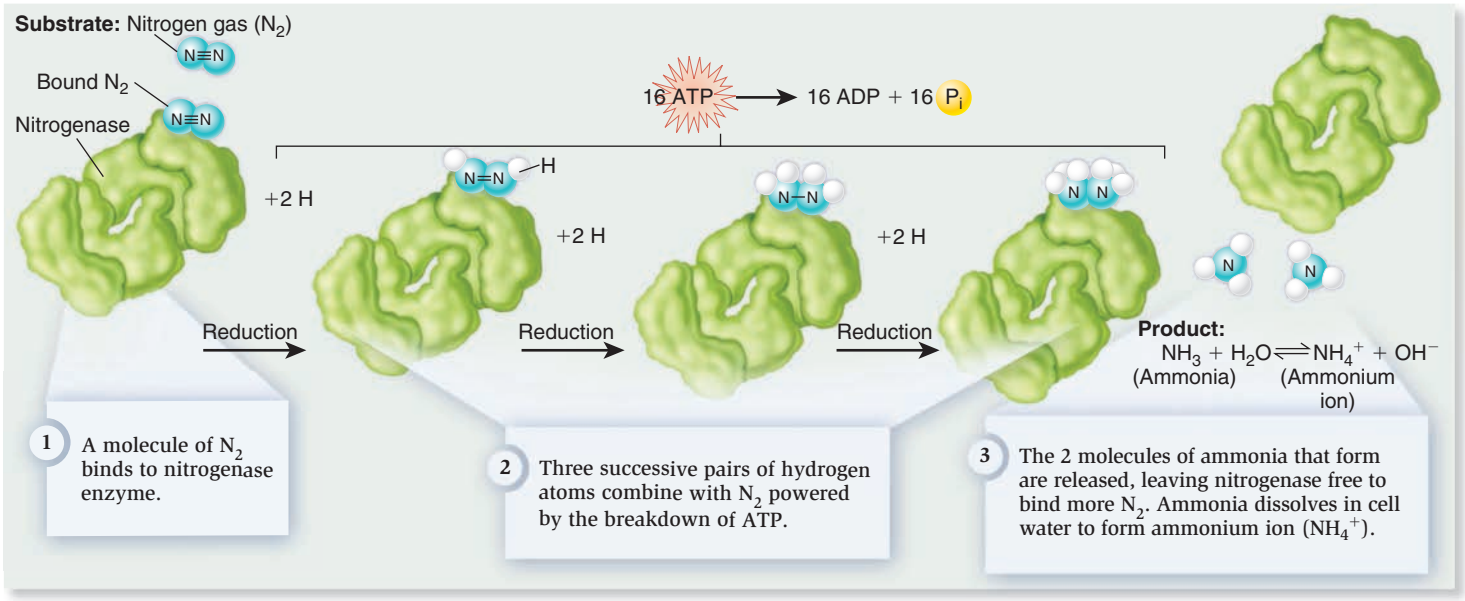

Figure 37.13 **The biological process of nitrogen fixation.**

Concept Check: *What common substance inactivates nitrogenase enzyme by binding to its active site?*

because of its high energy requirements, industrial nitrogen fixation can be costly from the perspective of many of the world's farmers. The high cost of fertilizers helps to explain why agricultural scientists are so interested in the possibility of genetically engineering biological nitrogen fixation into crop plants.

Plants Display Adaptations for Acquiring Phosphorus

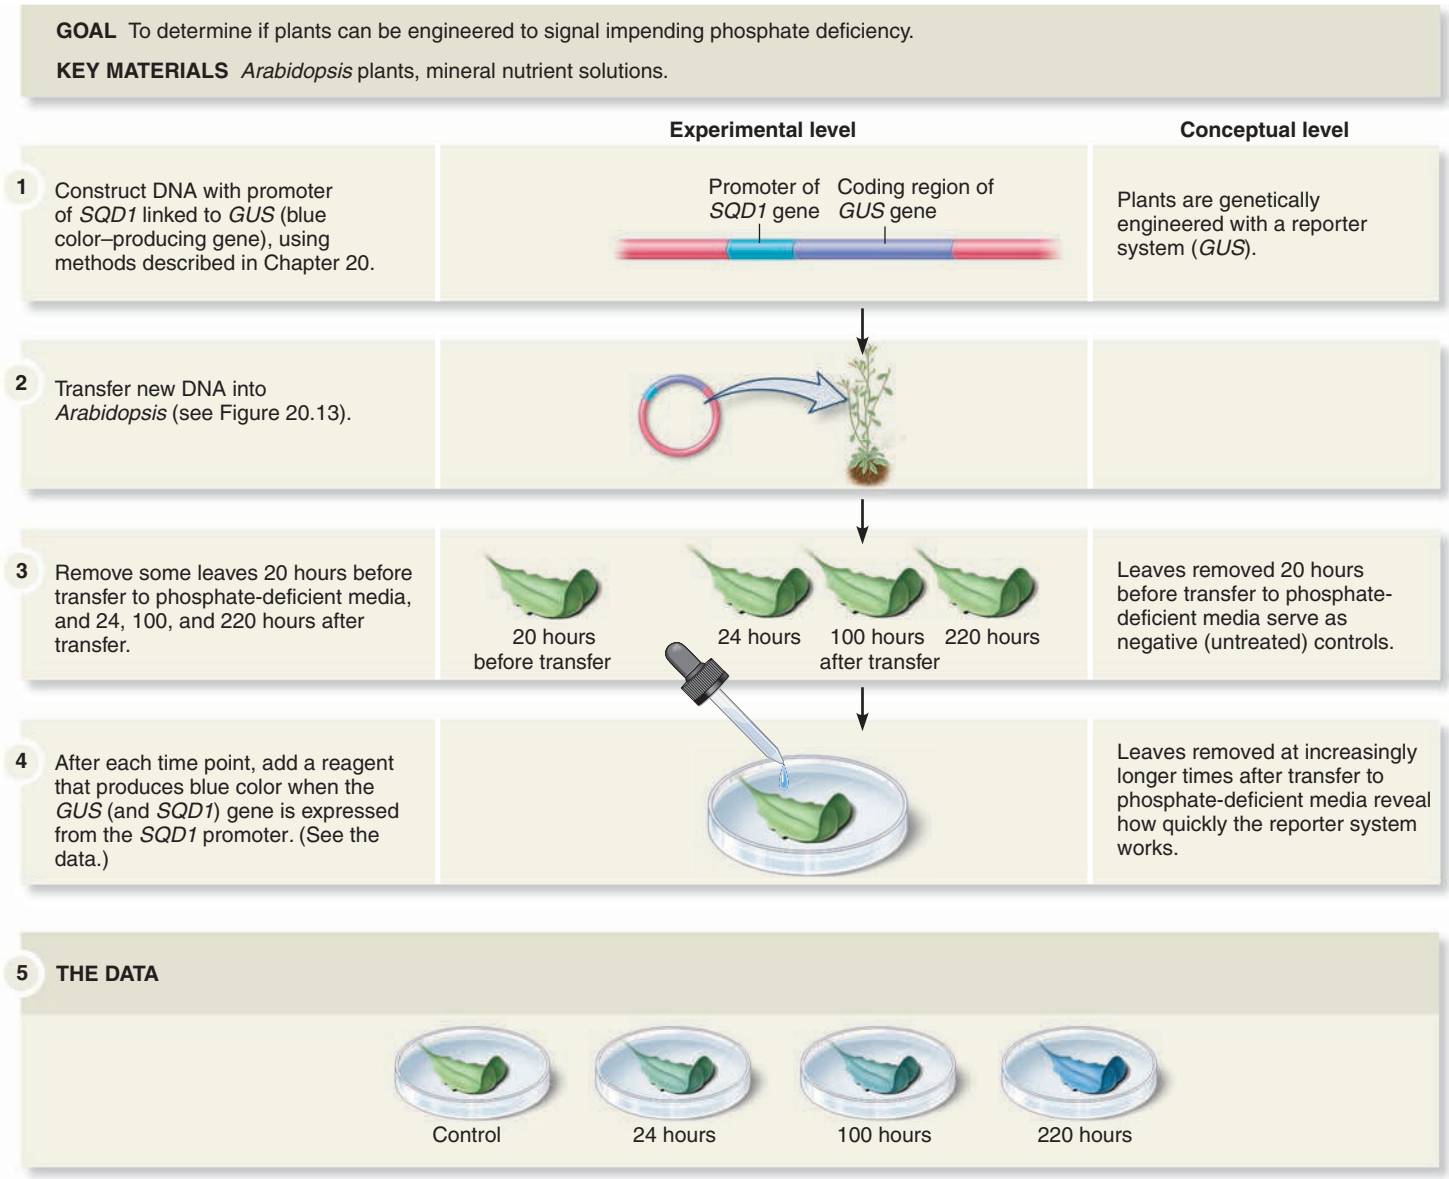
Phosphorus (P) is another soil mineral that often limits plant growth. Plants obtain phosphorus from the ion known as phosphate (PO_4^{3-}), which occurs in the soil in three dissolved forms: H_3PO_4, $H_2PO_4^-$, and HPO_4^{2-}. HPO_4^{2-} (called hydrogen phosphate ion) is the form most commonly absorbed by plants. Phosphate uptake involves ATP-requiring proton cotransport, as is the case for other anions such as nitrate (NO_3^-) and sulfate (SO_4^{2-}). The uptake of these nutrients at the root hair surface is discussed further in Chapter 38.

Although phosphorus can be abundant in soil, it is often unavailable to plants. One reason is that PO_4^{3-} forms tightly bound complexes with clay, iron and aluminum oxides, and calcium carbonate in soils. In addition, soil microbes incorporate PO_4^{3-} into organic compounds that are not taken up by plants.

Because plants need large supplies of phosphorus for a variety of cell processes, they have evolved various adaptations that increase their ability to obtain PO_4^{3-} from soil. A common adaptation for acquiring PO_4^{3-} is the symbiotic association of plant roots with various types of fungi (see Section 37.3). In addition, plants that grow in soils having low phosphorous content may produce more highly branched roots and more and longer root hairs. Plant roots also secrete protons and organic acids such as citrate and malate into the soil, which help release phosphorus from inorganic complexes. For example, the plant *Lupinus alba* releases as much as 25% of its total photosynthetic carbon into the soil as organic acids—a high price to pay but apparently one that is essential for the plant to obtain sufficient phosphorus. Plants may also secrete phosphatase enzymes from roots. These enzymes release phosphorus from organic compounds in the soil. The general process by which P, N, CO_2, and other minerals are released from organic compounds is called **mineralization**.

Farmers and gardeners apply phosphate-rich fertilizers to crop fields and gardens as a way of preventing phosphorous deficiencies, which reduce yields. Phosphorous fertilizers are obtained from phosphate-rich mineral deposits, but experts have warned that inexpensive sources of PO_4^{3-} will be exhausted within the next 90 years. Consequently, there is much interest in devising ways to maximize the efficiency by which plants are able to take up and use phosphorus. Genetic engineering to produce "smart plants" that can sense the levels of nutrients in the soil may offer some options.

Feature Investigation | Hammond and Colleagues Engineered Smart Plants That Can Communicate Their Phosphate Needs



If farmers could apply fertilizer to crops in the precise amounts needed by plants, not only would farmers save money, but also less fertilizer would run off fields into aquatic habitats, where it can lead to harmful ecological effects. Plant biologists have used genetic engineering to produce smart plants that signal impending nutrient deficiency via a visible marker. Such plants could serve

as sentinels, warning farmers of the conditions of an entire field. With this information, farmers could apply just enough mineral nutrients to prevent deficiency, thereby avoiding overapplication of fertilizers.

In 2003, working with the model plant *Arabidopsis*, John Hammond, Philip White, and their associates grew plants hydroponically, which means their roots were in a water solution rather than soil. They identified some of the genes whose expression changes when plants are transferred from nutrient solutions containing sufficient phosphorus to solutions lacking phosphorus. They found that some genes were turned on quickly after phosphorus removal, but other genes took much longer, up to 100 hours or more. This timing is important because genes expressed between 24 and 72 hours after PO_4^{3-} removal are considered useful as phosphorous monitors. During this window of time, plant tissue levels of PO_4^{3-} decreased, but the decrease had not yet affected plant growth. One gene that met this timing criterion was *SQD1*, which is required for the synthesis of sulfur-containing lipids. Expression of *SQD1* allows plants to respond to low phosphorous levels by replacing plastid phospholipids with sulfur-containing lipids, thereby reducing the plants' phosphorous requirement. This evidence suggested that smart plants could be engineered to communicate impending PO_4^{3-} deficiency by expressing *SQD1*.

To make smart plants, the researchers first placed the reporter gene *GUS* under the control of the *SQD1* promoter and transformed this gene into *Arabidopsis* plants (**Figure 37.14**). The researchers then grew these genetically engineered plants for various time periods in hydroponic solutions of differing PO_4^{3-} levels. After different time periods, they removed leaves and chemically treated them with a compound that produces a light blue color when the *GUS* gene is expressed. Some leaves were removed before transfer to the phosphate-deficient solution and served as controls. Because the *GUS*

Figure 37.14 The experiment of Hammond and colleagues showed that plants can be engineered to communicate changes in the level of nutrients.

6 **CONCLUSION** Plants can be genetically engineered to express color signals in time for farmers to apply fertilizer sufficient to prevent nutrient deficiency.

7 **SOURCE** Hammond, J. P., et al. June 2003. Changes in gene expression in *Arabidopsis* shoots during phosphate starvation and the potential for developing smart plants. *Plant Physiology* 132:578–596.

gene was under the control of the *SQD1* promoter, leaves from plants that were developing PO_4^{3-} deficiency turned blue! These smart plants were able to communicate impending phosphorous deficiency in time for a farmer to apply fertilizer.

In a later and more extensive study of gene expression in *Arabidopsis*, other investigators discovered that PO_4^{3-} induces the activity of about 612 genes and represses the activity of about 254 genes. Some of these genes may encode proteins useful in monitoring plant phosphorous status. If smart plant technology can be developed for crop plants, farmers may be able to monitor and fertilize fields with much greater precision.

Experimental Questions

1. What advantage do plants obtain when the *SQD1* gene is expressed?
2. **SciSKILLS »** How were the investigators able to identify potential sentinel plants that were starting to experience phosphorous deficiency?

BIO TIPS

THE QUESTION *Explain why Hammond and colleagues sought to identify plant genes whose expression changed during the period from 24 to 72 hours after the imposition of a phosphorus limitation.*

TOPIC ***What topic in biology does this question address?*** The topic is plant nutrition, or more specifically, plant responses to nutrient limitation and their relevance to developing technological monitoring systems that allow more efficient applications of fertilizer to crops.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** Phosphorus is an element that is essential to living things, including plants. Table 37.1 briefly reviews its role in plant nutrition. This chapter has explained how nutrients affect plant growth, and you have also learned that soil phosphorus is often bound to inorganic and organic materials that reduce its availability to plant roots. Thus, phosphorus is often applied to fields to enhance crop yields. You also know that plants (like other living organisms) respond to environmental change and that such responses include changes in gene expression.

PROBLEM-SOLVING STRATEGY Think about Hammond and colleagues' desire to find genes that would react to phosphorous limitation in a rather short period and whose response could be observed. Realize that a system for monitoring plant nutrient limitation needs to reveal the problem before it causes irreversible effects. Understand that farmers do not want to wait so long to apply fertilizer that crop plants will suffer in the meantime.

ANSWER *Monitoring changes in plant gene expression at different times after the onset of phosphorous limitation allowed the investigators to identify genes that could be used to reveal the point at which the plants started to respond to nutrient limitation but before they incurred serious damage.*

37.3 Biological Sources of Plant Nutrients

Learning Outcomes:

1. Explain the importance of mycorrhizal fungi to plants.
2. List the major types of prokaryotic organisms that occur in symbioses with plants, thereby helping them to acquire nitrogen.
3. Distinguish carnivorous plants from parasitic plants, giving examples.

This section focuses on several fascinating ways in which plants use other organisms as sources of nutrients. Biological sources of plant nutrients include symbiotic fungi or bacteria, the animal prey of carnivorous plants, and green plants that serve as hosts for nonphotosynthetic plant parasites.

Mycorrhizal Associations Help Most Plants Obtain Mineral Nutrients

At least 80% of seed plants have symbiotic associations with fungi that live within the tissues of plant roots or that envelop root surfaces (Figures 31.26–31.28). These associations are termed **mycorrhizae**; the prefix *myco* refers to fungi, and *rhiza* means root, so the term literally means fungus root.

In mycorrhizal associations, soil fungi obtain organic food from the roots of photosynthetic plant hosts, and the fungi supply the plants with water and mineral nutrients. Due to the extensive mycelia that fungi produce within the soil, these fungus root associations provide an exceptionally efficient way for plants to harvest water and minerals, especially phosphate, from a much larger volume of soil than is available to roots by themselves. The presence of lush vegetation on thin, infertile tropical rain forest soils is largely due to the ability of mycorrhizae to rapidly absorb mineral nutrients released by decaying organisms and transmit the nutrients directly to plant roots

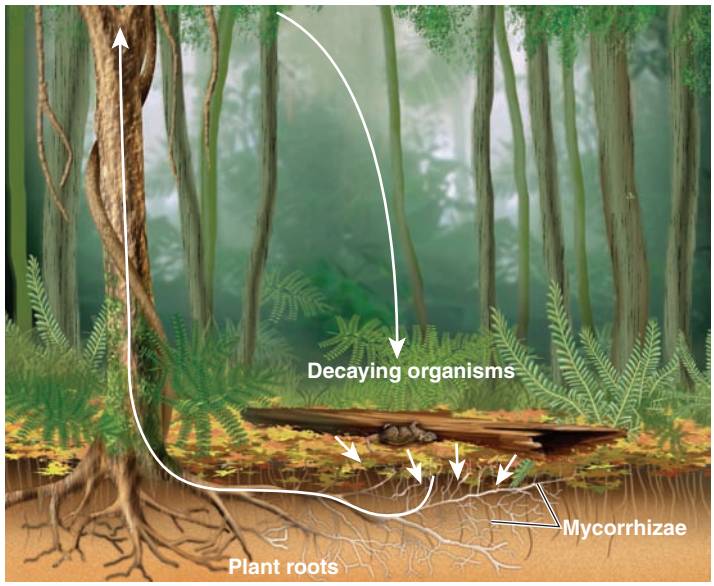


Figure 37.15 Nutrient acquisition via mycorrhizae.

BIOLOGY PRINCIPLE New properties of life emerge from complex interactions. In all forests, but particularly those of tropical regions, mycorrhizal fungi rapidly collect soil minerals released from decaying organisms and transport them directly to plant roots. Such efficient nutrient cycling bypasses the soil, from which mineral ions can be easily leached by heavy rainfall. This process explains how lush forests can grow on thin, infertile soils.

(**Figure 37.15**). In many tropical rain forests, mineral nutrients occur within the bodies of living organisms, rather than accumulating in the soil where they could easily be leached away by heavy, frequent rains.

Various species of ghostly pale plants have lost their photosynthetic pigments (see Figure 37.2) and have thus become dependent on organic compounds supplied by fungi that form mycorrhizal associations with a photosynthetic host, such as a nearby tree. In this process, known as mycoheterotrophy, the fungus serves as an underground conduit for the flow of organic nutrients from a green, photosynthetic plant to a heterotrophic plant. Many plant seedlings that grow in the shade of taller plants also use mycoheterotrophy to survive until they are able to obtain enough light for photosynthesis.

Plant-Bacteria Symbioses Provide Some Plants with Fixed Nitrogen

Soils contain large populations of thousands of bacterial species, many of which aid plant growth. Some soil bacteria produce plant hormones that affect root structure, others help plants to tolerate drought and other stresses, and some provide plants with nutrients, notably fixed nitrogen. In nitrogen-fixation symbioses, the plants provide organic nutrients to the bacteria, and the bacteria supply the plants with a much higher supply of fixed nitrogen than the plants could obtain from most soils. Representatives of three types of nitrogen-fixing bacteria—cyanobacteria, actinobacteria, and proteobacteria—are symbiotically associated with specific types of plants. (For more information about the characteristics of these bacterial groups, see Chapter 27.)

Plant-Cyanobacteria Symbioses Although most cyanobacteria are themselves photosynthetic, organic compounds supplied by plant partners subsidize the high energy costs of nitrogen fixation. This allows the cyanobacteria to fix more nitrogen than they require, secreting the excess to plant partners. Nitrogen-fixing cyanobacteria form symbioses with some bryophytes, ferns, and gymnosperms, as well as the flowering plant *Gunnera*. This plant, commonly known as the giant rhubarb or prickly rhubarb, can produce leaves almost 3 m across (**Figure 37.16**). Nitrogen-fixing symbionts are advantageous to *Gunnera* because this large plant grows in nitrogen-poor habitats, such as volcanic slopes in Hawaii. *Gunnera* harbors cyanobacteria within stems and leaf petioles. In these locations, the cyanobacteria can use cyclic electron flow to transform light energy into ATP, needed to produce fixed nitrogen. The presence of nitrogen-fixing cyanobacteria helps to explain why *Gunnera* can grow to dramatic size on poor soils.

Woody Plant–Actinobacteria Symbioses In contrast to cyanobacteria, actinobacteria are heterotrophic nitrogen-fixing bacteria. Actinobacteria known as *Frankia* occur in nodules formed on the underground roots of certain shrubs or trees, such as alder (*Alnus*) and myrtle (*Myrica*). These plants receive fixed nitrogen from their bacterial partners, which, in turn, obtain organic nutrients. Woody plants, such as *Ceanothus* shrubs, that have *Frankia* symbionts are able to grow abundantly even in places where soil nitrogen is low.

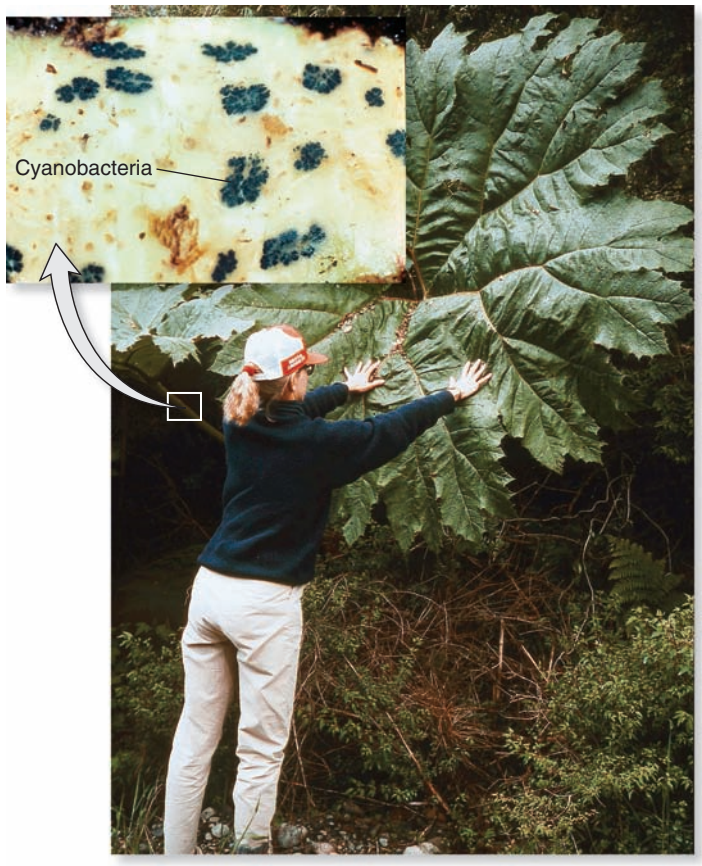

Figure 37.16 *Gunnera* growing on nitrogen-poor soil. Nitrogen-fixing cyanobacteria that live within cavities in this plant's leaf petioles provide the plant with fixed nitrogen, which explains how such a large plant can grow on infertile soils.

This symbiosis helps to explain why *Ceanothus* covers extensive areas in mountainous regions of the western U.S.

Legume-Rhizobia Symbioses The nitrogen-fixation symbioses most important in nature and to agriculture involve certain proteobacteria that are collectively known as **rhizobia** (from the Greek rhiza, meaning root). Rhizobia live within root cells of wild and cultivated legumes, forming legume-rhizobia symbioses. In nature, legume plants are important sources of fixed nitrogen for other plants. When legumes die, they generate soil organic matter that is enriched with fixed nitrogen. Consequently, wild legumes are regarded as particularly valuable members of natural plant communities.

Important legume crops include soybeans, peas, beans, peanuts, clover, and alfalfa. Foods produced from soybeans, peas, beans, and peanuts are valued for their high protein content. Clover and alfalfa are used for animal food and to enrich fields with the fixed nitrogen needed by subsequent food crops. The value of these crops arises from their fixed-nitrogen content. The amount of ammonia produced by legume-rhizobia symbioses nearly equals the world's entire industrial production.

Genomes & Proteomes Connection

Development of Legume-Rhizobia Symbioses

Rhizobia can live independently in the soil, but are also found within lumpy **nodules** that form on legume roots (**Figure 37.17**). Different species of rhizobia preferentially form symbioses with particular plant species. Because of their agricultural importance, these legume-rhizobia symbioses have been extensively studied, and a great deal is now known about the molecular basis of their development. This information is potentially useful in efforts to genetically engineer nitrogen-fixation capacity into nonlegume crops.

Nodule development involves a series of chemical signals sent back and forth between rhizobia and their host plants (**Figure 37.18**). Legumes start this exchange by secreting particular flavonoid compounds from their roots. Recall that flavonoids are phenolic secondary metabolites that play essential roles in plant structure, reproduction, and protection (see Figure 30.22b). These flavonoids bind to receptors in the plasma membranes of compatible soil rhizobia (Figure 37.18, step 1). In response, the rhizobia typically secrete **Nod factors** (nodulation factors). Each rhizobial species produces Nod factors with distinctive structural variations that can be recognized by the preferred host species. These Nod factors function something like keys that unlock doors, allowing bacteria to enter roots via root hairs. The factors bind to receptors in the membranes of root hair cells in the host plant (step 2).

Within minutes after its membrane receptors bind Nod factors, the root hair plasma membrane allows an influx of calcium ions, and a few minutes later, root hair calcium ion concentrations start oscillating rapidly. Root hairs respond to these calcium changes by swelling at their tips and curling around the rhizobia (step 3). The rhizobia then inject infection proteins into root hairs. In response, the cell wall at the root hair tip changes in a way that allows bacterial enzymes to erode a small hole in the wall, allowing bacterial cells to enter. The plasma membrane forms a tubular infection thread through which rhizobia move into the root cortex. The tip of the infection thread fuses with the plasma membrane of a cortex cell, then the rhizobia are released into the cell's cytoplasm, each bacterial cell enclosed by the host membrane (step 4).

Meanwhile, plants produce proteins known as **nodulins** that foster nodule development. Within 18–30 hours after the initial infection, root cortex cells start to divide to form root nodules. Environmental conditions in developing nodules cause rhizobia to undergo changes in their structure and gene expression patterns. These modified rhizobia are known as **bacteroids** (step 5). Bacteroid respiration provides the large amounts of ATP that are necessary for nitrogen fixation.

Legume nodules typically produce **leghemoglobin** (legume hemoglobin), a pink protein that helps to regulate local oxygen concentrations, transporting enough oxygen to bacteroids to support respiration but preventing oxygen from disabling nitrogenase (step 6). Mature nodules also produce vascular tissue that moves nitrogen fixed by bacteroids to the root vascular system for transport throughout the plant. These nodule vascular tissues also supply organic food produced by the legume to their bacteroid partners (step 7). Nearly 5,000 gene expression changes are associated with the legume-rhizobia symbiosis.

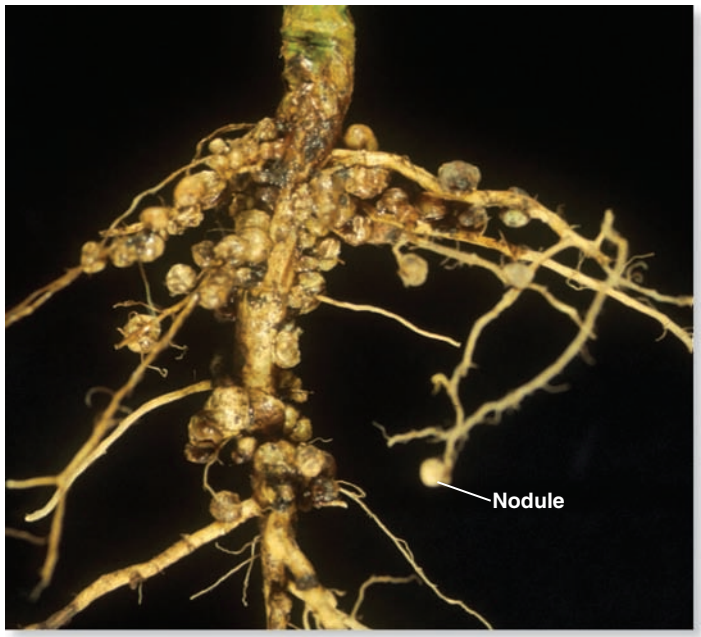

Figure 37.17 Legume root nodules. The cells of nodules on the roots of this soybean plant (*Glycine max*) and other legumes contain nitrogen-fixing bacteria known as rhizobia.

Carnivorous Plants Are Autotrophs That Obtain Mineral Nutrients from Animals

About 600 species of flowering plants have adapted to low-nitrogen environments by evolving mechanisms for trapping and digesting animals and are therefore known as carnivorous plants. Their leaves are

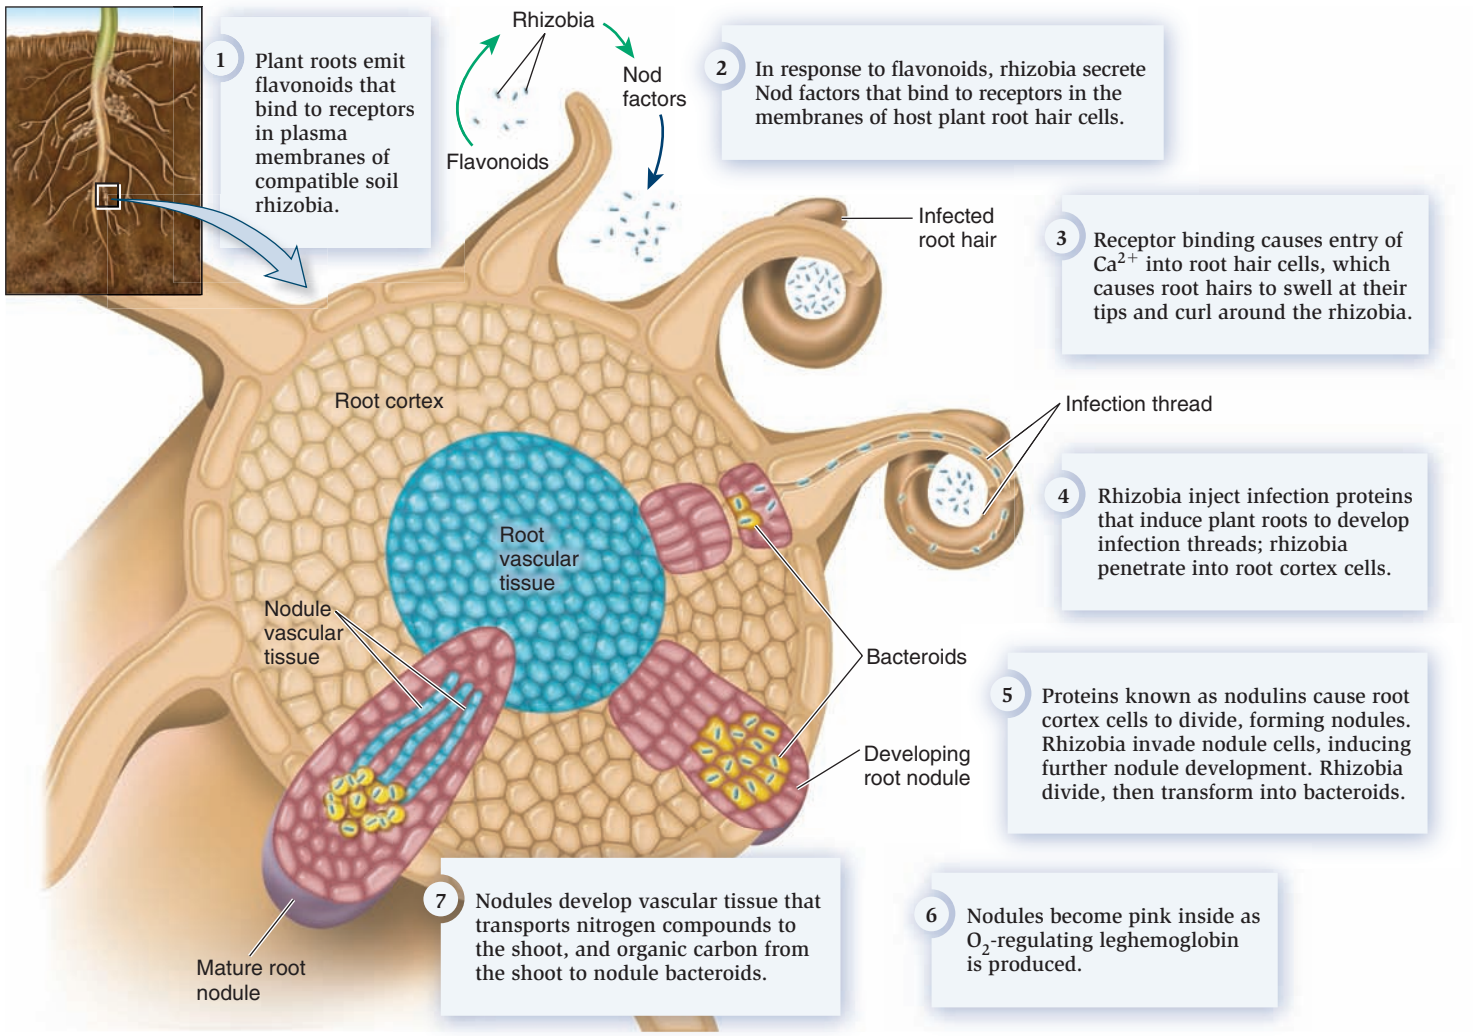

Figure 37.18 Root nodule development. The process of root nodule development involves a chemical conversation between the legume plant and nitrogen-fixing bacteria.

modified in ways that allow them to capture animal prey, primarily insects, though larger animals are sometimes snared as well. Carnivorous plants are photosynthetic autotrophs that supply their own organic compounds; prey animals are primarily sources of nitrogen. The experimental use of radioactively labeled prey insects has revealed that carnivorous plants obtain as much as 87% of their nitrogen from animals.

The trapping mechanisms used by carnivorous plants are classified as passive or active. Plants with passive trapping mechanisms depend on the prey to fall or wander into the trap. For example, tropical pitcher plants (genus *Nepenthes*) have leaves that are folded and partially fused to form tubes that collect rainwater (**Figure 37.19a**). The interior walls of these pitchers are slippery and have downward-pointing hairs. Insects and other small animals such as lizards and frogs that fall into the pitchers are unable to climb out. Eventually, the trapped animals drown and are digested by microbes living within the pitchers.

Plants with active mechanisms, such as Venus flytraps and sundews (see the chapter opening photo), have traps that are stimulated by touch. Charles Darwin, who was fascinated by carnivorous plants, was one of the first to study the trapping mechanisms of Venus flytraps and sundews. The Venus flytrap (*Dionaea muscipula*) has an active trap formed by a two-lobed leaf that is edged with lance-shaped teeth (**Figure 37.19b**). The leaf surface has glands that secrete carbohydrates, which lure prey, as well as glands that secrete digestive enzymes after prey has been trapped. Also present on the leaf surface are modified hairs, usually three per leaf lobe. If a single hair is touched—perhaps by wind or rain, or debris—and another touch does not occur soon thereafter, nothing happens. But when a fly or similar prey lands on the leaf and brushes against the same hair twice, or touches a second hair within 20–40 seconds, the leaf lobes snap shut around it.

Experimental studies indicate that an action potential—much like that occurring during signal transmission in animal nerves—develops in the stimulated hairs. The electrical signal then travels from cell to cell along plasma membranes, via plasmodesmata, at about 10 cm/second. This signal causes leaf cells to take up ions and water so that the leaf enlarges and changes shape, springing the trap. Digestion of the prey is typically finished within 10 days, whereupon the trap may reopen. Trap leaves can go through three or four digestive cycles during their lifetime.

Sundews (such as *Drosera rotundifolia*) have leaves bearing glandular hairs whose sticky tips glisten in the sunlight. Insects that land on

(a) Pitcher plant (genus *Nepenthes*)

(b) Venus flytrap (*Dionaea muscipula*)

Figure 37.19 Carnivorous plants. **(a)** A pitcher plant passively captures animals that accidentally fall into its water-filled pitcher. **(b)** The Venus flytrap has an active trap that is stimulated by the touch of its prey, in this case, a fly.

sundew leaves get mired in the sticky mucilage exuded by these hairs, as shown in the chapter opening photo. As the insects struggle to get away, they become covered with more mucilage and eventually smother as their breathing pores become clogged. Darwin discovered that sundew leaves bend after being touched and that glandular hairs not originally in contact with the insects also bend, folding over the prey as you would fold your fingers over an object in your palm. Later, investigators discovered that this bending involves the plant hormone auxin. In response to touch, auxin accumulates in sundew leaf tips and then flows downward, stimulating the cell expansion that causes the leaf bending. The glandular hairs also produce enzymes that digest the prey.

Parasitic Plants Obtain Nutrients from Photosynthetic Plants

More than 4,500 species of plants live as complete or partial **parasites**, organisms that obtain all or much of their water, minerals, and organic compounds from another organism. Dodder and witchweed are prominent examples of plants that are completely parasitic.

Dodder (*Cuscuta pentagona*) lacks roots and does not grow from the soil. Instead, all of the 150 species of this parasite live aboveground (**Figure 37.20**). These parasites twine their yellow or orange stems around green plant hosts, into which they sink peg-shaped, absorptive structures known as haustoria. These haustoria tap into the host plant's vascular system, gaining water, minerals, and sugar, which the parasite uses for growth and reproduction. The long, flexible stems of dodder often loop from one plant to another, allowing an individual dodder plant to tap into many different host plants at the same time. Dodder reproduces very rapidly by means of broken-off stem fragments and seeds. A single dodder plant can produce more than 16,000 seeds. In consequence, dodder is a widespread agricultural pest that attacks citrus, tomatoes, and many other fruit, vegetable, forage, and flower crops.

Another group of parasitic plants, the witchweeds (genus *Striga*), are serious problems for agriculture worldwide, because these parasites attack major cereal crops: corn, sorghum, rice, and millet. Witchweed seeds lie dormant in soil until secretions from host plant roots stimulate their germination. Genetic engineers are working to find ways to protect crops from the debilitating effects of these crop parasites.

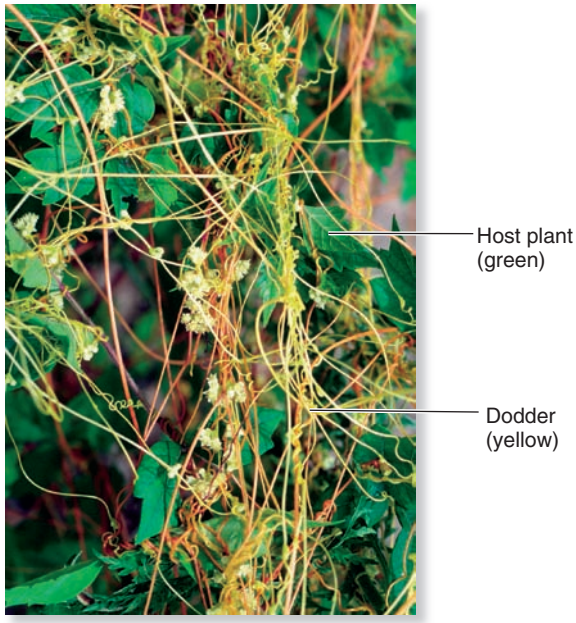

Figure 37.20 A parasitic plant. Dodder (*Cuscuta pentagona*) is an example of a parasitic plant that obtains all of its water, minerals, and organic compounds from one or more green plant hosts.

BioConnections: Look back to Figure 33.7b to see an example of a parasitic animal—a tapeworm—and Table 33.2, which describes characteristics of tapeworms. What is similar about food acquisition in dodder and tapeworms?

Summary of Key Concepts

37.1 Plant Nutritional Requirements

- The nutritional requirements of green plants are light energy, CO_2, H_2O, and several types of elements absorbed from soil or water (Figure 37.1, Table 37.1).
- Like animals and fungi, heterotrophic plants obtain chemical energy by metabolizing organic compounds absorbed from their environment (Figure 37.2).

- Plants display many adaptations that allow them to cope with insufficient or excess amounts of light and inadequate CO_2 (Figures 37.3, 37.4, 37.5).
- Nutrients can limit plant growth and cause nutrient-deficiency symptoms (Figure 37.6).

37.2 The Role of Soil in Plant Nutrition

- Natural soils display layers known as soil horizons. Soils are composed of organic material and inorganic minerals. Soil organic matter is largely derived from plant detritus, animal wastes, and decayed animal bodies (Figures 37.7, 37.8).
- Inorganic soil components occur as particles that can be categorized according to their size as sand, silt, or clay. Cation exchange releases cations to soil water, making cations available for uptake by plant roots (Figures 37.9, 37.10, 37.11).
- Biological or industrial processes can convert atmospheric nitrogen gas into fixed nitrogen that plants can utilize. Biological nitrogen fixation can be performed only by certain prokaryotes (Figures 37.12, 37.13).
- Plants display several types of adaptations to cope with phosphate deficiency. Genetically modified smart plants can signal impending phosphate deficiency (Figure 37.14).

37.3 Biological Sources of Plant Nutrients

- Mycorrhizal fungi, which are associated with the roots of most plants, provide plants with water, phosphorus, and other minerals (Figure 37.15).
- Nitrogen-fixing prokaryotes living within the tissues of some plants provide them with fixed nitrogen. Legume-rhizobia associations are particularly important in nature and in agriculture (Figures 37.16, 37.17, 37.18).
- Carnivorous plants obtain mineral nutrients from the digested bodies of trapped animals. Parasitic plants obtain water, mineral ions, and organic compounds from green plant hosts (Figures 37.19, 37.20).

Assess and Discuss

Test Yourself

1. Which of the following substances can limit plant growth in nature?
   a. sunlight
   b. water
   c. carbon dioxide
   d. fixed nitrogen
   e. all of the above
2. In what form do plants take up most soil minerals?
   a. as ions dissolved in water
   b. as neutral salts
   c. as mineral-clay complexes
   d. linked to particles of organic carbon
   e. None of the above describes how plants take up minerals.
3. Why do plants need sulfur?
   a. for the construction of cell walls
   b. as an essential component of chlorophyll
   c. to produce proteins and some coenzymes
   d. for all of the above
   e. for none of the above
4. Soil organic matter provides the benefit of
   a. allowing water to percolate rapidly through soil.
   b. making soil softer in consistency.
   c. increasing the aluminum content of soil.
   d. causing minerals to be leached more rapidly from soil.
   e. none of the above.
5. Which environments are conducive to heavy leaching of minerals from soils?
   a. those having soils that are composed primarily of sand particles
   b. those having acidic soils
   c. those impacted by acid rain
   d. regions characterized by heavy rainfall
   e. all of the above
6. Which property is *not* characteristic of clay-rich soils?
   a. high mineral nutrient retention
   b. high water retention
   c. high aeration
   d. lower amounts of sand than clay
   e. All of the above characterize clay-rich soils.
7. Which of the plants listed below is most likely to be heterotrophic (to obtain organic food from the environment)?
   a. a green houseplant
   b. a legume plant such as bean
   c. a carnivorous plant such as the sundew
   d. ghostly white *Monotropa*
   e. none of the above
8. What kinds of organisms occur in nitrogen-fixing symbioses with plants?
   a. cyanobacteria
   b. actinobacteria
   c. rhizobia bacteria
   d. all of the above
   e. none of the above
9. How do legume roots attract rhizobia?
   a. They secrete flavonoids.
   b. They secrete carotenoids.
   c. They secrete alkaloids.
   d. They secrete Nod factors.
   e. None of the above is a means of attracting rhizobia.
10. Which plant uses a passive trap to obtain animal prey as a source of mineral nutrients?
    a. the Indian pipe (*Monotropa uniflora*)
    b. the tropical pitcher plant (*Nepenthes* spp.)
    c. the Venus flytrap (*Dionaea muscipula*)
    d. dodder (*Cuscuta* spp.)
    e. all of the above

Conceptual Questions

1. Why are agricultural experts and ecologists concerned about overfertilization of crop fields?
2. Draw a diagram showing how rhizobia and legume roots communicate chemically during nodule formation.

Collaborative Questions

1. Imagine that you have bought a farm and want to start growing a crop to sell at a local market. How could you go about determining if the soil needs to be fertilized and with what mineral nutrients?
2. A principle of biology is that *biology affects our society.* Imagine that you own a large farm with a trout stream running through it. How would you protect the water quality of the stream?

Flowering Plants: Transport

38

CHAPTER OUTLINE

38.1 Overview of Plant Transport
38.2 Uptake and Movement of Materials at the Cellular Level
38.3 Tissue-Level Transport
38.4 Long-Distance Transport
Summary of Key Concepts
Assess and Discuss

A shade tree. The evaporation of water from plant leaves cools them and us, and even affects local and global climate.

On hot days, people naturally gravitate to the cool shade beneath trees, as shown in the chapter opening photo. But most people do not realize that trees are not only sun umbrellas. Plants actually cool the air around them as water evaporates from their surfaces. That's why grass feels cool when you walk barefoot on it, even on a hot day.

Plants benefit from this evaporation process—known as transpiration—because it cools their surfaces and enables the movement of a continuous stream of water from the soil, through roots and stems, to leaves. This evaporation process not only helps to distribute water throughout the plant body, it also aids the movement of dissolved minerals, organic compounds such as sugars and hormones, and other organic materials over long distances within plants. Transport is therefore crucial for the functions of plant growth, behavior, and nutrition, which were described in the preceding three chapters.

In addition, plant transport plays a critical role in Earth's global climate. On a worldwide basis, plant transpiration annually moves 32×10^3 billion tons of water from the soil into the atmosphere as water vapor. Plant transpiration provides important ecological services. For example, plant-produced atmospheric water vapor is the source of 30% of rain, the rest originating by evaporation from the surfaces of oceans and freshwater bodies. Along with other atmospheric gases (including carbon dioxide and methane), water vapor also works as a greenhouse gas that helps to warm Earth's climate by absorbing the Sun's heat. Plant transport processes are also relevant to agriculture, as humans seek to improve crop productivity and the efficiency of water and nutrient use. Conservation biologists understand that plant transport processes are important to the preservation and restoration of natural environments.

To comprehend plant transport more fully, in this chapter, we first survey the materials that move through plants and the general directions of material movements. Next, we will focus more closely on water and solute uptake by plant cells. We will then examine how these materials are moved within plants over short and long distances and explore some of the plant adaptations that allow such transport to be as efficient as possible in a variety of environments. In the process, we will learn why plants are so cool!

38.1 Overview of Plant Transport

Learning Outcomes:

1. Describe how plants transport water and minerals from roots to leaves.
2. Describe how plants transport organic molecules from leaves to nonphotosynthetic parts.

In Chapters 35–37, we surveyed the structure, behavior, and nutrition of flowering plants (the angiosperms) and noted the interdependence of plant root and shoot systems. We have observed that

in most plants, the root system absorbs water and dissolved minerals from the soil and that the shoot system takes up carbon dioxide (CO_2) from the atmosphere via stomata, pores that occur in the surfaces of leaves and other aboveground structures (**Figure 38.1**). Photosynthetic cells use these materials to produce sugar and other organic compounds needed for overall plant growth and reproduction. Nonphotosynthetic plant cells, such as those of roots and flowers, depend on organic food produced by green tissues. Therefore, plants must transport water and minerals upward from roots to shoots and transport organic food from photosynthetic to nonphotosynthetic parts. Since plants can grow to sizeable heights, the tallest trees being over 100 m tall, transport of materials often occurs over long distances.

The long-distance transport of water, dissolved minerals, and sugar throughout the plant body occurs within a continuous system of conducting tissues. Recall that the complex tissues of vascular plants that primarily conduct water and dissolved minerals are known as the xylem, and those that conduct mostly organic substances in a watery sap are termed the phloem. These conducting tissues are key to the ability of vascular plants to thrive in terrestrial habitats, which can sometimes be quite arid. To fully understand how plants accomplish long-distance transport, we will begin by reviewing the processes by which minerals, organic compounds, and water are taken up and move at the cellular level.

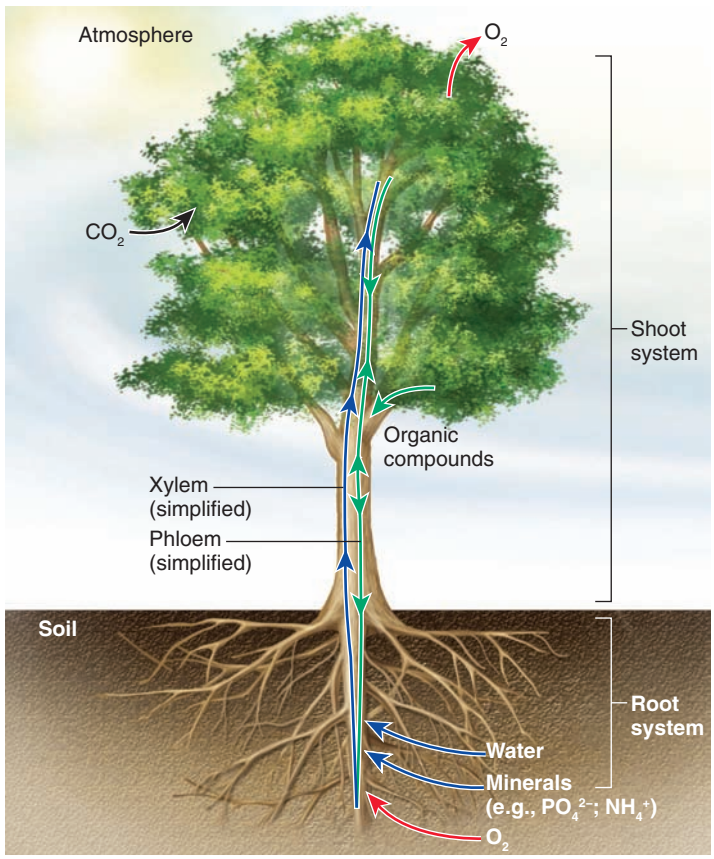

Figure 38.1 **Overview of material uptake and long-distance transport processes in plants.**

38.2 Uptake and Movement of Materials at the Cellular Level

Learning Outcomes:

1. Describe the differences among turgid, flaccid, and plasmolyzed plant cells.
2. **SciSKILLS** » Explain how water potential and relative water content are calculated.
3. List ways in which plants cope with cellular osmotic stress.

Chapter 5 described how all cells use both passive and active processes to import or export materials. Here, we briefly review these processes, illustrating how they work in flowering plants.

Passive Transport Does Not Require the Input of Energy

Recall that water, gases, and certain small, uncharged compounds can diffuse across plasma membranes in the direction of their concentration gradients. **Passive transport** is the movement of materials into or out of cells down a concentration gradient without the expenditure of energy in the form of ATP. Passive transport across plasma membranes occurs in two ways: by simple or facilitated diffusion. **Simple diffusion** into or out of cells is the movement of molecules through a phospholipid bilayer down a concentration gradient. **Facilitated diffusion** is the transport of molecules across a plasma membrane down a concentration gradient with the aid of membrane transport proteins (**Figure 38.2a**).

The two main types of membrane transport proteins that function in facilitated diffusion are channels and transporters. **Channels** are membrane pores formed by proteins that allow movement of ions and molecules across membranes (see Figure 38.2). **Transporters** are proteins that transport molecules by binding them on one side of the membrane and then changing conformation so that the molecule is released to the other side of the membrane (refer back to Figure 5.19). Transporters increase the rate at which specific mineral ions and organic molecules are able to enter or leave plant cells and vacuoles.

Recall that osmosis is the diffusion of water across a selectively permeable membrane in response to differences in solute concentrations. In the case of plants, water moves from a solution that has a lower solute concentration (soil) to one of higher solute concentration (root cells). Osmotic water uptake into living plant cells is essential to photosynthesis, as well as to cell expansion and structural support. However, simple diffusion of water does not occur rapidly enough to supply the water needs of rapidly expanding plant cells. In this case, facilitated diffusion of water occurs through protein channels known as **aquaporins**, which occur widely in living cells. Thirty-five distinct aquaporin genes have been identified in the genome of the model plant *Arabidopsis*. Aquaporins increase the rate at which water flows into expanding plant cells and their vacuoles. Similarly, many other types of plasma membrane protein channels and transporters facilitate the diffusion of specific mineral ions and organic molecules into and out of plant cells and vacuoles.

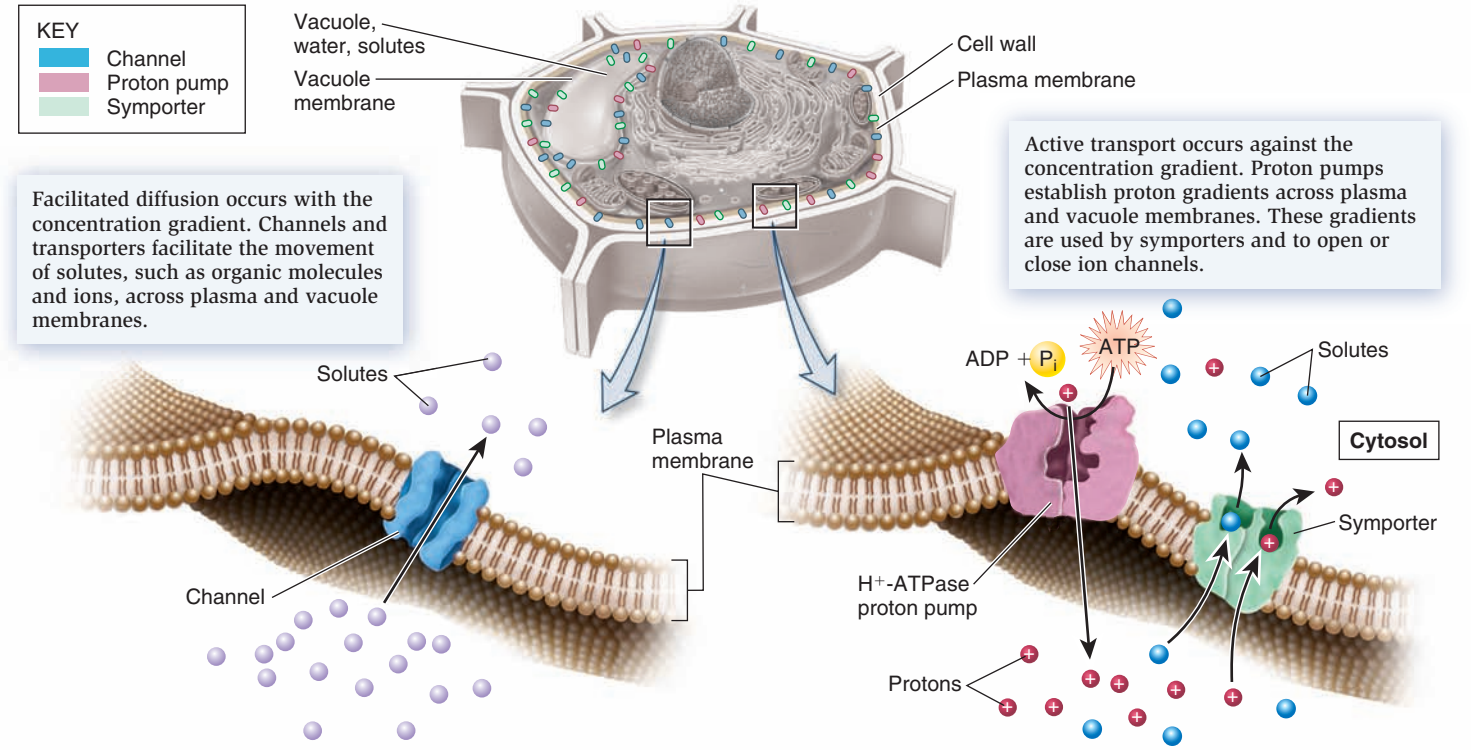

Figure 38.2 **Passive and active transport.**

ATP Hydrolysis Powers Active Transport

If a substance must be transported across a plasma membrane against its concentration gradient, work must be performed, in the process known as active transport. During **active transport**, membrane transport proteins use energy to move substances against their concentration gradients. An example is the H^+-ATPase proton pump, found in the plasma membranes of plant cells, which uses ATP to pump H^+, which are protons, against a gradient (**Figure 38.2b**). This concentration gradient generates an electrical difference across the membrane, which is known as a **membrane potential**. Energy is released when protons pass back across the plasma membrane, in the direction of their proton gradient. This energy can then be used to power other active transport of ions or organic materials. For example, it might be used to open or close ion channels or in the functioning of a proton/solute **symporter**, a protein that transports two substances in the same direction across a membrane. Symporters are needed for the uptake of organic solutes such as sugars, amino acids, and nucleotide bases.

Active transport proteins are particularly abundant in root cell membranes (**Figure 38.3**), allowing root cells to concentrate dissolved mineral nutrients to more than 75 times their abundance in soil. As a result, soil water flows into root cells by osmosis. We next take a closer look at osmotic water movement into and out of plant cells.

Cellular Water Content Is Influenced by Solute Content and Turgor Pressure

The water content of plant cells depends on osmosis, and osmosis depends on two factors: solute content and turgor pressure. **Turgor pressure** is the hydrostatic pressure required to stop the net flow of water across a plasma membrane due to osmosis. Turgor pressure increases as water enters plant cells, because their cell walls restrict the extent to which the cells can swell.

A plant cell whose cytosol is so full of water that the plasma membrane presses right up against the cell wall is said to be **turgid** (**Figure 38.4a**). The pressure relationship between the cytosol and cell wall resembles the way that a soccer ball's leather skin presses inward upon the air within, while at the same time the internal air presses on the ball's cover. If you add more air to a limp ball, the ball will stiffen. In the same way, if a nonturgid cell absorbs more water, it will become more rigid as the water exerts pressure on the cell wall. By contrast, a plasmolyzed cell is one that has lost so much water by osmosis that turgor pressure has also been lost. **Plasmolysis** is the condition in which the plasma membrane no longer presses on the cell wall (**Figure 38.4b**). The concentration of solutes is the same outside and inside a **flaccid cell**, which will have a water content higher than a plasmolyzed cell but lower than a turgid cell (**Figure 38.4c**).

Together, solute concentration and presence of a cell wall influence an important plant cell property known as **water potential**, the potential energy of water. Water moves from a region of higher water potential to a region of lower water potential. A good analogy is a waterfall, in which the water has high gravitational potential energy at the top. Pressure also influences water potential; a waterfall would flow upward if pressure greater than the force of gravity were applied. Solutes and some other factors also affect water potential. Water potential is measured in pressure units known as

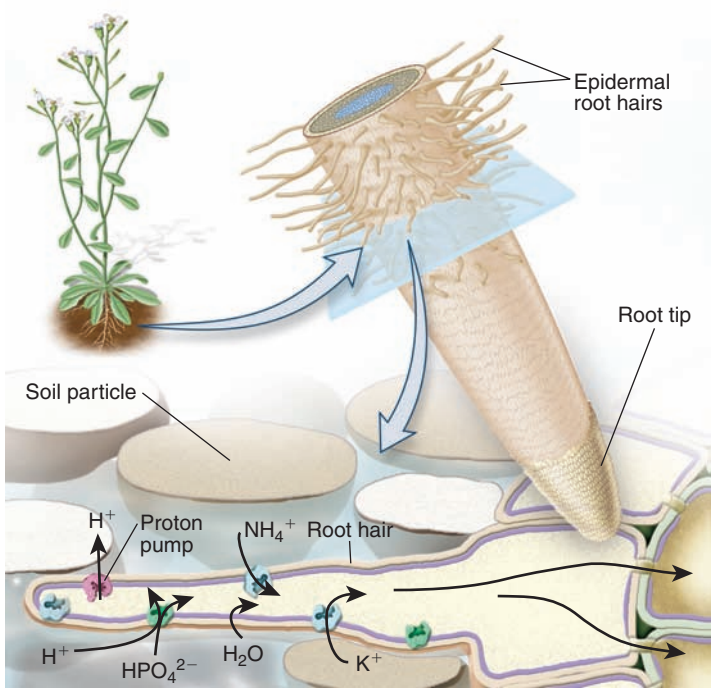

Figure 38.3 Ion uptake at root-hair membranes. The H^+-ATPase proton pump establishes an electrochemical gradient that drives the active uptake of solutes. The resulting increase in intracellular solute concentration also drives the osmotic diffusion of water into the cell.

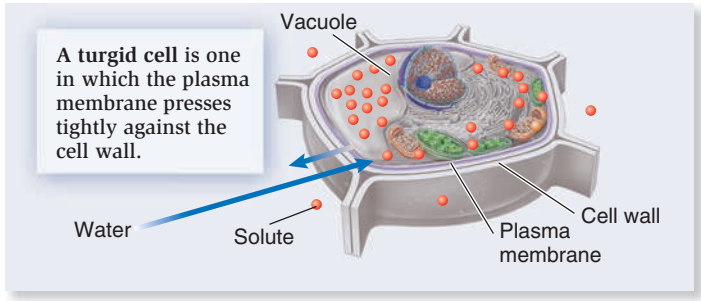
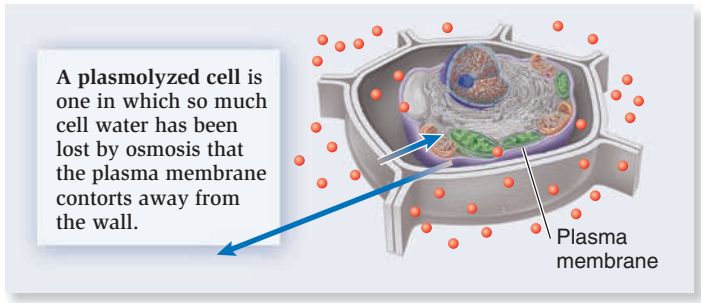
BIOLOGY PRINCIPLE Living organisms use energy. When soil mineral ion concentrations are lower than those within cells, root-hair plasma membranes take up nutrient ions by active transport, which requires energy in the form of ATP.



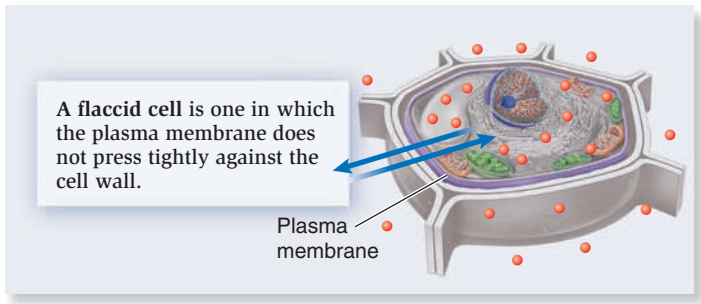
megapascals (MPa) (a pascal is equal to 1 newton per square meter). One MPa is equal to 10 times the average air pressure at sea level, about the same pressure that occurs within an inflated bicycle tire. As another reference point, 1 MPa is several times the pressure in typical home plumbing pipes, which you experience when turning on a water faucet.

In the study of plants, the concept of water potential is used to understand the movement of water into and out of cells (cellular water potential) and between entire plants and their environment. The concept of relative water content is used to gauge the water status of whole plants or organs. We begin by considering the water potential of cells.



Cellular Water Potential A water potential equation can be used to predict the direction of cellular water movement, given information about the solute concentrations inside and outside of plant cells, and a measure of pressure at the cell-wall–membrane interface. In this equation, cellular water potential is symbolized by the Greek letter psi (ψ) with the subscript W for water: ψ_W. In its simplest form, total ψ_W is calculated as:

$$\psi_W = \psi_S + \psi_P$$



where ψ_S is solute potential and ψ_P is pressure potential.

(a) Turgid cell in a hypotonic solution

(b) Plasmolyzed cell in a hypertonic solution

(c) Flaccid cell in an isotonic solution

Figure 38.4 Turgid, plasmolyzed, and flaccid plant cells. **(a)** When the concentration of solutes inside a cell is greater than that outside (the cell is surrounded by a hypotonic solution), more water may enter the cell than will leave it. As a result, the plant cell may become swollen, or turgid. **(b)** When the concentration of solutes outside a cell is greater than within it (the cell is surrounded by a hypertonic solution), more water will leave the cell than will enter it. As a result, a plant cell will become plasmolyzed. **(c)** When a cell is bathed in an isotonic solution, it will be flaccid.

Solute potential (ψ_S) is the component of water potential due to the presence of solute molecules. As you might expect, solute potential is proportional to the concentration of solutes in a solution. The solute potential of pure water open to the air, at sea level and room temperature, is defined as zero. When solutes are added, they interact with water molecules, thereby diluting the water and affecting its disorder. As a result, fewer free water molecules are present, which reduces the potential energy of water. Thus, in the absence of a pressure potential, water that contains solutes always has a negative solute potential. The higher the concentration of dissolved solutes, the lower (more negative) the solute potential.

Pressure potential (ψ_P) is the component of water potential due to hydrostatic pressure. In plant cells, the hydrostatic pressure is determined in part by the resistance provided by the cell wall. Because of this resistance, the value for pressure potential can be either positive or negative. For example, a turgid cell has a positive pressure potential, which typically measures about 1 MPa. This high pressure inside turgid plant cells is a testimony to the strength of their cellulose-rich cell walls. In contrast to turgid cells, both flaccid and plasmolyzed cells have a pressure potential of zero. Plants or plant organs having many cells with low turgor pressure appear wilted. If your houseplants become wilted, watering will enable the cells to increase their pressure potential, restoring cell turgor and normal plant appearance. Therefore, the water content of an entire organ or plant is influenced by the water potential of its component cells (**Figure 38.5**).

Relative Water Content The property known as **relative water content (RWC)** is often used to gauge the water content of a plant organ or entire plant and is easy to measure with common equipment. RWC integrates the water potential of all cells within an organ or plant and is thus a measure of relative turgidity. Measurements of RWC can be used to predict a plant's ability to recover from the wilted condition. An RWC of less than 50% spells death for most plants, but some plants can tolerate lower water content for substantial time periods.

A standard method for determining RWC involves three simple weight measurements: fresh weight, turgid weight, and dry weight. Sample tissue taken from a plant under a given set of conditions is first weighed to obtain the fresh weight. Then it is completely hydrated in water within an enclosed, lighted chamber until constant turgid weight is achieved. Finally, the sample is dried to a constant dry weight. Researchers use these measurements to calculate RWC using the equation

$$\text{RWC} = \frac{(\text{fresh weight} - \text{dry weight})}{(\text{turgid weight} - \text{dry weight})} \times 100$$

RWC measurements have been very useful in ecological studies of natural plant adaptation to cold, drought, or salt stress and in agricultural research for developing drought-tolerant crops. Developing new crops that are better able to withstand water stress requires an understanding of not only water potential but also how plant cells cope with cellular osmotic stress, which leads to water stress.

Plant Adaptations to Cellular Osmotic Stress Plants native to cold, dry, or saline environments have evolved many different adaptations that allow them to cope with low water content. For example, plants often increase the solute concentrations of their cells' cytosol, a process known as **osmotic adjustment**. Increased amounts of the amino acid proline, sugars, or sugar alcohols such as mannitol decrease the cells' water potential, thus drawing water into cells. By increasing the concentration of solutes inside cells, cold-resistant plants prevent water from moving out of their cells when ice crystal formation in intercellular spaces lowers the water potential outside the cells. The additional solutes also lower the freezing point of the cytosol, in the same way that adding antifreeze to a car's radiator in winter keeps the radiator fluid from freezing.

Plants of arid lands often possess adaptations that help them survive water stress. Many can survive in a nearly dry state for as much as 10 months of the year, growing and reproducing only after the rains come. The cytosol of such desiccation-tolerant plants is typically rich in sugars that bind to phospholipids to form a glasslike structure. This helps to stabilize the cellular membranes, preventing them from becoming damaged during plasmolysis (see Figure 38.4b). Plant cells under water stress may also increase the number of plasma membrane aquaporins. These additional protein channels increase the rate of water uptake, allowing cells to recover turgor more quickly when water becomes available.

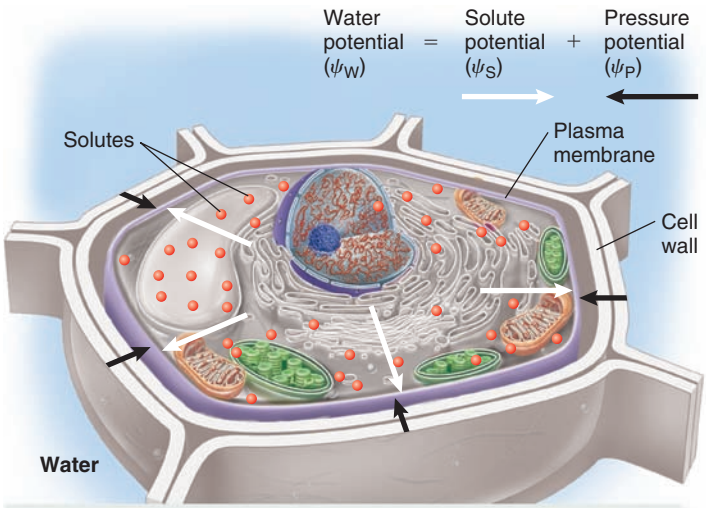


Figure 38.5 Plant-cell water potential. The water potential of a plant cell, which predicts the direction of water movement into or out of the cell, can be simplified as the sum of the solute potential and the pressure potential resulting from pressure exerted by the cell-wall–plasma membrane complex. Examples of water potential calculations are shown for a turgid cell, a plasmolyzed cell, and a flaccid cell.

Concept Check: Make a drawing that shows the direction of water movement when a cell of each of these types is placed into a solution of pure water (whose water potential, ψ_W, is defined as 0 MPa).

38.3 Tissue-Level Transport

Learning Outcomes:

1. Define transmembrane transport, symplastic transport, and apoplastic transport.
2. Explain how the root endodermis functions as a diffusion barrier.

Now that we have reviewed how water, dissolved minerals, and organic compounds enter or leave plant cells, we are prepared to consider short-distance transport within and among nearby tissues. Tissue-level transport occurs in three forms: transmembrane transport, symplastic transport, and apoplastic transport (**Figure 38.6**).

Transmembrane transport involves the export of a material from one cell via membrane proteins, followed by import of the same substance by an adjacent cell (Figure 38.6a). One prominent example of transmembrane transport is the movement of the plant hormone auxin downward in shoots. Auxin travels from one phloem parenchyma cell to another in a linear series with the aid of carrier proteins (refer back to Figure 36.4). This process explains how auxin produced in one part of the plant body can influence more distant tissues.

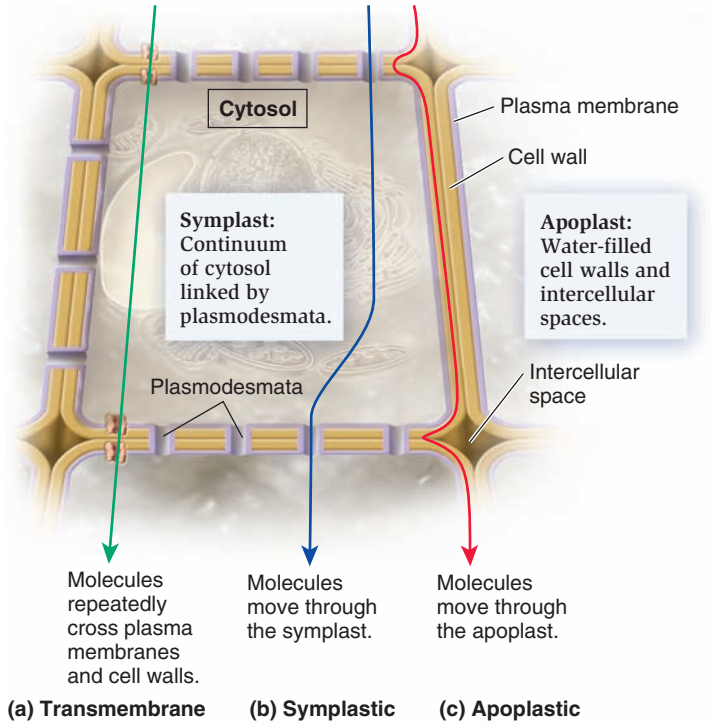

Figure 38.6 **Three routes of tissue-level transport in plants: (a) transmembrane, (b) symplastic, and (c) apoplastic.**

Symplastic transport is the movement of a substance from the cytosol of one cell to the cytosol of an adjacent cell via membrane-lined channels called plasmodesmata (Figure 38.6b). Plasmodesmata are large enough in diameter to allow transport of proteins and nucleic acids, as well as smaller molecules. Together, all of a plant's protoplasts (the cell contents without the cell walls) and plasmodesmata form the **symplast**. Symplastic transport has the potential to move molecules widely among the cells and tissues of the plant body.

The **apoplast** is the continuum of water-filled cell walls and intercellular spaces (Figure 38.6c). **Apoplastic transport** is the movement of solutes along cell walls and the spaces between cells. Water and dissolved minerals often move through plant tissues for short distances by apoplastic transport.

Both symplastic and apoplastic transport play important roles in mineral nutrient transport through the outer tissues of roots (**Figure 38.7**). As we have noted, the plasma membrane of epidermal root hair cells is rich in channels and transporters that selectively absorb essential mineral ions from soil water. Absorbed ions can move symplastically from the cytosol of root hairs, cortex, and endodermis directly to xylem parenchyma cells. Plasmodesmata make such cell-to-cell, tissue-level transport possible.

Apoplastic transport can also move water and dissolved minerals into root epidermal and cortex tissues. However, apoplastic movement of water and minerals stops at the **endodermis**, a term meaning inside skin. In roots, the endodermis is a thin cylinder of tissue whose close-fitting cells and specialized cell walls form a barrier

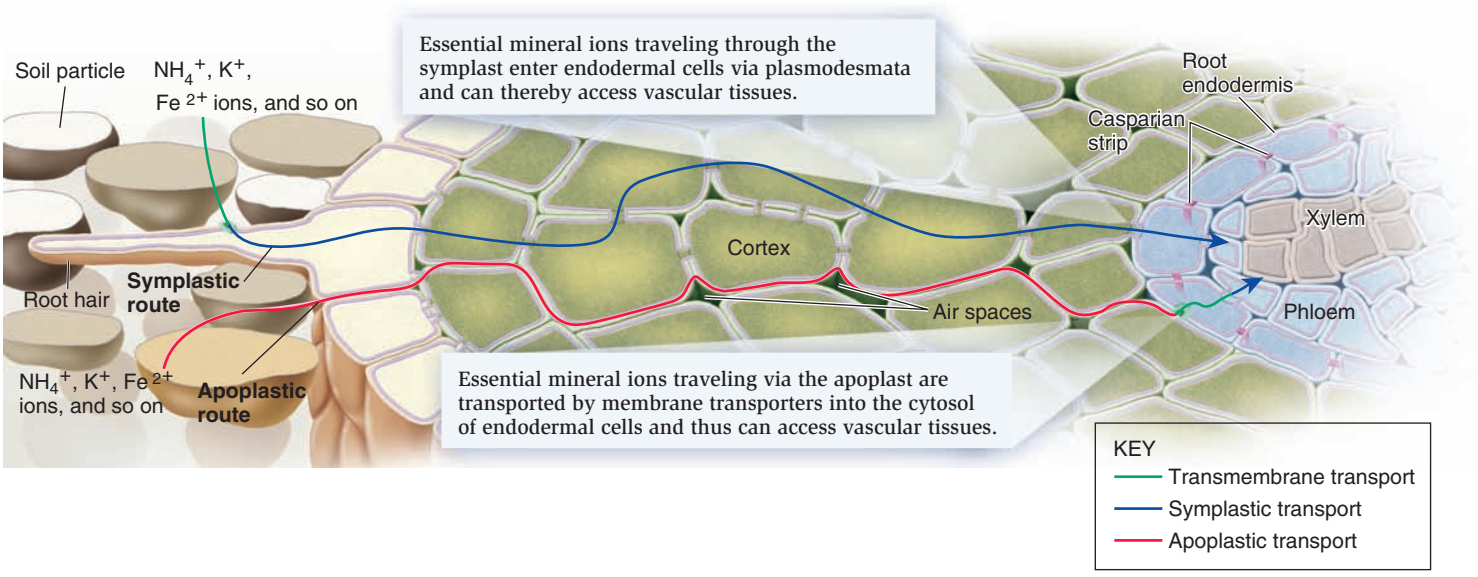

Figure 38.7 **Symplastic and apoplastic transport of mineral ions in roots.**

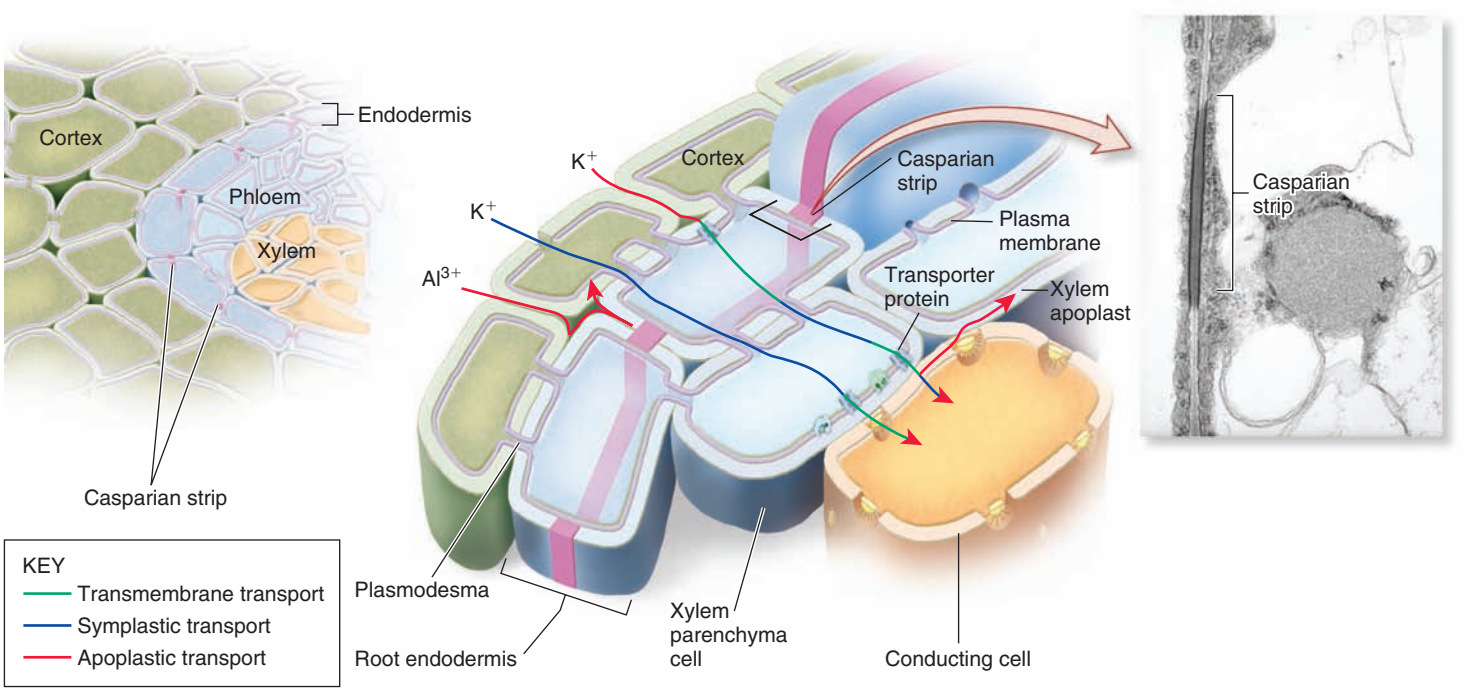

Figure 38.8 **Ion transport pathways across the root endodermis.** Casparian strips in endodermal cell walls prevent apoplastic transport across the root endodermis, limiting entry of harmful soil minerals such as Al^{3+} and exit of useful solutes. Mineral nutrients that are transported into the cytosol of endodermal cells are able to pass through the endodermal barrier to xylem parenchyma cells via plasmodesmata. Once past the endodermis, nutrient ions such as K^+ are moved across plasma membranes to the apoplast of the vascular tissue and are thus able to enter xylem. Inset shows a transmission electron micrograph (TEM) of a Casparian strip in the wall of an endodermal cell.

BioConnections: Look back to Figure 10.9 to see a diagram of tight junctions between adjacent cells of animal intestinal epithelium. How is the root endodermis similar in structure and function?

to diffusion between the cortex and the central core of vascular tissue. The plant endodermis is functionally analogous to animal epithelial tissues whose cellular tight junctions likewise form diffusion barriers. Materials in the root apoplast cannot penetrate farther into the root unless endodermal cells transport them into their cytosol, a process that requires specific transporter proteins.

Root endodermal cell walls possess ribbon-like strips of waxy, waterproof suberin and phenolic polymers. These ribbons, known as **Casparian strips**, prevent apoplastic diffusion of water and solutes through endodermal cell walls and into the root vascular tissues (**Figure 38.8**). The root endodermis also prevents harmful solutes (such as toxic metal ions) from moving through the apoplast to vascular tissues and being transported to the shoot. For example, aluminum ions (Al^{3+}) are commonly dissolved in soil water, but they are not plant nutrients and are highly toxic to plants. Aluminum ions can penetrate the root epidermis and cortex by moving through the apoplast, but they stop at the endodermis because they are unable to enter the cytosol of endodermal cells.

Endodermal plasma membranes possess specific channels and transporters for essential mineral nutrients (such as K^+), which are thereby able to enter the cytosol of root endodermal cells. By moving through endodermal cytosol, symplastically transported essential minerals are able to bypass the Casparian strips. Therefore, the root endodermis functions as a molecular filter that allows the passage of beneficial solutes.

Once solutes have moved through endodermal cells, they are transported into the apoplast of the vascular system, which includes conducting cells of the xylem (see Figure 38.8). The endodermis prevents solutes from returning to outer root tissues or the soil, so the solute concentrations of xylem parenchyma cells rise, decreasing their cellular water potential. As a result, water flows into vascular tissues from outer root tissues and the soil. In the next section, we will see how water and solutes are transported for long distances through the plant.

38.4 Long-Distance Transport

Learning Outcomes:

1. Describe how bulk flow occurs in the xylem and phloem of flowering plants.
2. Explain how vessel elements differ from tracheids, and how both function in the xylem of flowering plants.
3. Describe the cohesion-tension theory as an explanation for long-distance water movement in plants.
4. Explain how stomata and leaf abscission help reduce transpirational water loss.
5. Describe how sieve-tube elements and companion cells work together to form a transport system.
6. **SciSKILLS** » Create a diagram showing how and why phloem sap moves from source to sink.

Plants rely on long-distance transport to move water and dissolved materials from roots to shoots and among organs. Tall trees are able to transport water and minerals to astounding heights, more than 110 m in some cases. This is possible because plants possess an extensive, branched, long-distance vascular system composed of xylem and phloem tissues. Watery solutions move through these tissues by **bulk flow**, the mass movement of liquid caused by pressure, gravity, or both. Plant conducting tissues are specialized in ways that foster bulk flow and aid plants in adapting to water stress. In this section, we will take a closer look at bulk flow and the major factors involved in long-distance transport by this process.

Bulk Flow Is Water Movement Under the Influence of Pressure and Gravity

Bulk flow (also known as mass flow) occurs when molecules of liquid all move together from one place to another as the result of differences in pressure and/or gravity. One example of bulk flow is leaching, the movement of water and dissolved minerals downward through soil layers as the result of gravity (Chapter 37). Bulk flow is one way in which mineral ions can move through soil toward plant roots. Likewise, once inside the plant, minerals and other dissolved solutes can move through xylem and phloem conducting tissues via bulk flow, which is much faster than diffusion. For example, phloem sap, which contains sugars and other dissolved solutes, moves by bulk flow up to 1 m per hour. The bulk movement of water and solutes within xylem and phloem results from difference in water pressure. However, such pressure differences arise from the operation of different processes in xylem as compared with phloem.

Water and dissolved materials move by bulk flow through xylem tissues as the result of differences in root and shoot water pressure. When soil water is abundantly available to roots, water pressure will be higher in root xylem than in shoot xylem. Water pressure is higher in shoot xylem located closer to roots than in xylem located in the upper parts of plant shoots, because water diffuses from the plant through stomata into the atmosphere (**Figure 38.9**). The extent to which plants lose water to the atmosphere depends on atmospheric humidity; water will diffuse outward more readily when the humidity is lower than when it is higher.

Pressure differences arise in phloem by a different process. Pressure builds up in the phloem sap of leaves because they produce organic solutes such as sugars as the result of photosynthesis. An increase in sap organic solutes causes water to enter, causing sap pressure to rise. Phloem sap that contains fewer solutes will display lower pressure. Such differences in pressure cause water to flow from regions of higher solute concentration to regions of lower solute concentrations, such as developing fruit. Bulk flow is impeded by obstructions such as cytoplasm. This explains why phloem conducting cells have reduced amounts of cytoplasm and why xylem conducting cells are devoid of cytoplasm altogether.

Although xylem serves as the primary transport system for water and minerals, and phloem for organic compounds dissolved in water, the transport functions of xylem and phloem overlap somewhat. Phloem can aid in the distribution of certain minerals, and xylem sometimes transports organic compounds. For example, in early spring, trees convert starch stored in stem parenchyma cells into sugars that are used during bud expansion and flower development. These sugars are transported in xylem sap. Maple trees produce a copious flow of sugar-rich xylem sap that people have long tapped to make maple syrup (**Figure 38.10**).

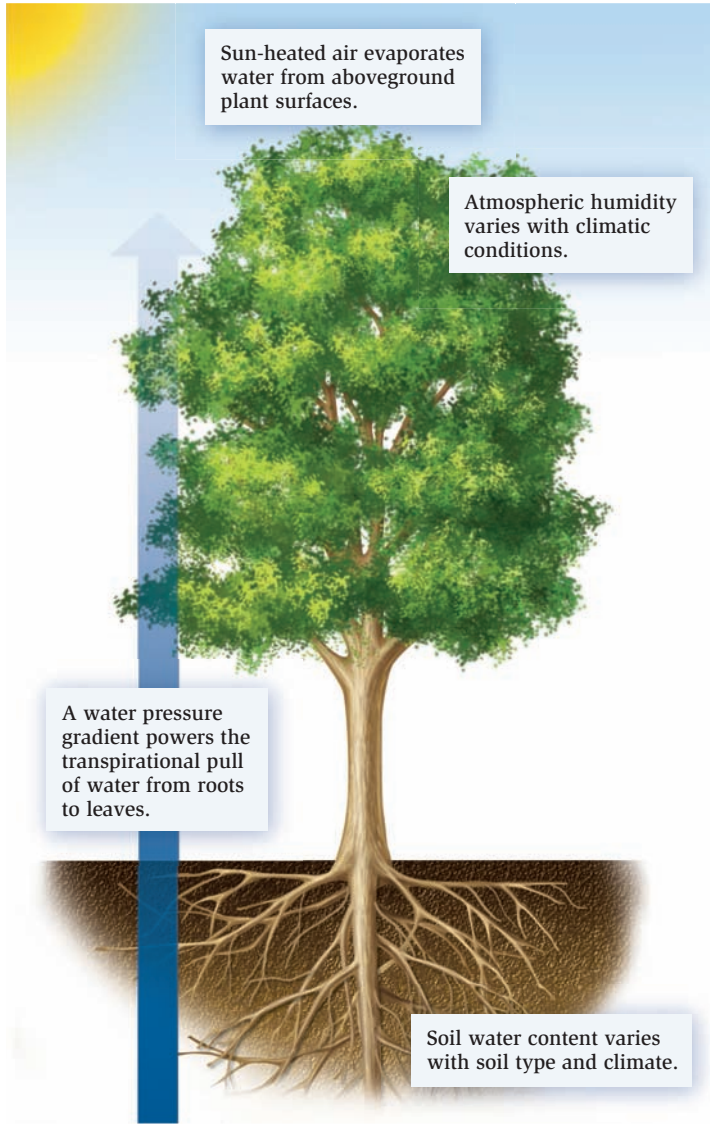

Figure 38.9 Upward transport of water in xylem. Water pressure differences between moist soil and drier air drive the upward movement of water in plants.

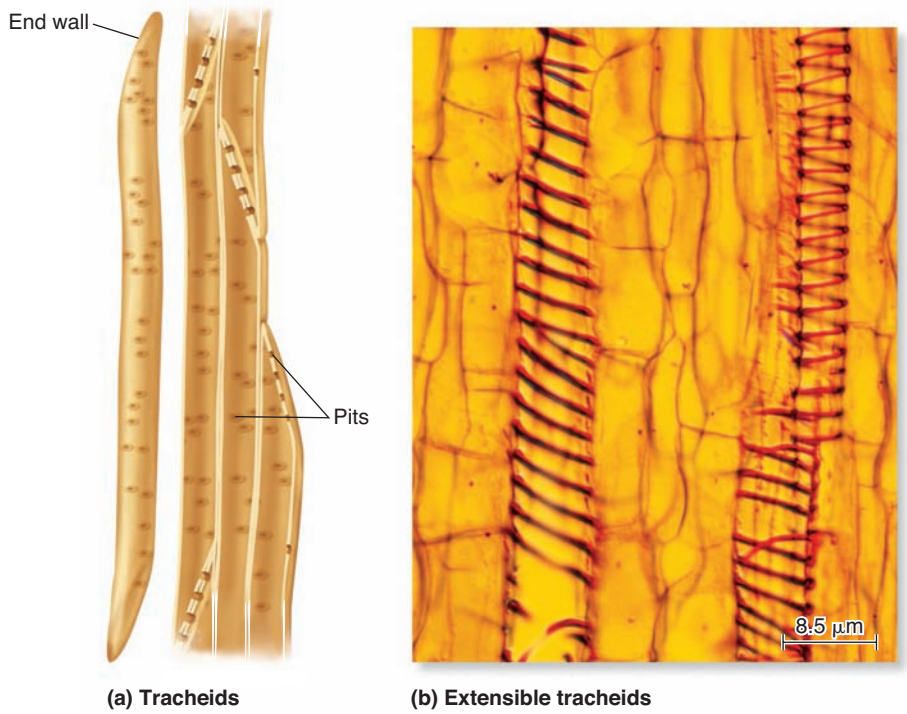
Xylem Is Adapted for Long-Distance Transport of Water and Minerals

Xylem structure plays an essential role in its transport function. The xylem of flowering plants contains several types of specialized cells, some of which remain alive at maturity, and some of which are dead when they are fully functional. Xylem parenchyma cells are alive, but thick-walled supportive fibers may be alive or dead at maturity. Two types of specialized water-conducting cells are always dead and empty of cytosol when mature: tracheids and vessel elements.

Together, tracheids and vessel elements are known as **tracheary elements**. During the development of tracheary elements,

Figure 38.10 Sugar-maple tapping. In early spring, xylem transports sugar from storage sites to the shoot buds of woody plants such as this sugar maple (*Acer saccharum*).

BIOLOGY PRINCIPLE Biology affects our society. People tap sugar maples by boring holes into the tree trunks and collecting the xylem sap (shown here in buckets). The sap is boiled to evaporate some of the water, leaving the concentrated product—maple syrup.



a secondary wall is deposited in patterns on the inside of the primary cell wall. This secondary wall is rich in a plastic-like polymer known as lignin. Because lignin is resistant to compression, microbial decay, and water infiltration, it confers strength, durability, and waterproofing. Like the plumbing pipes of a building, lignin-reinforced tracheary elements do not readily collapse as water moves through them under tension. In contrast, the xylem of lignin-deficient mutant plants is more collapsible. These characteristics explain why tracheary elements contribute to structural support of the plant body as well as transport.

Tracheids Long and narrow in shape, **tracheids** typically have slanted end walls that fit together to form long tubes (**Figure 38.11a**). The end walls of tracheids are not lignified, nor are large areas of the side walls of tracheids that occur in plant tissues that are still growing. Such tracheids are extensible because they have rings or spirals of lignin that allow them to continue elongating (**Figure 38.11b**). In contrast, tracheids that develop in tissues that have already expanded have more lignin, which makes them rigid and unable to elongate any more. Tracheid walls that are extensively lignified display numerous small, lignin-free cell-wall regions known as **pits**. At such pits, the thin primary wall of the tracheid remains readily permeable to water. Water moves from one tracheid to another both vertically and laterally through pits.

Vessels and Vessel Elements Mature **vessel elements** are a second type of water-conducting cell present in xylem tissue. Vessel elements are aligned in pipeline-like files known as **vessels** (**Figure 38.12a**). Flowering plants are distinguished from other plant groups by the abundance of vessels; nonflowering plants primarily rely on tracheids for water conduction. Vessel elements are larger in diameter and longer than tracheids, conferring greater capacity for bulk flow and therefore represent one of the many ways in which flowering plants are particularly well adapted to life on land.

Development of vessel elements resembles that of tracheids in some ways. For example, lignified secondary walls are deposited in spirals or sheets on the inside of the primary cell wall. Vessel elements also have numerous pits in their side walls. In contrast to tracheids, the end walls and some side walls of vessel elements are extensively perforated, meaning that all cell-wall material is removed from some areas (**Figure 38.12b** and **c**). This allows water to flow faster from one vessel element to another than it can flow from one tracheid to another.

Because the perforated end walls and large diameter of vessels allow them to transport more water at a faster rate than tracheids, you might wonder why flowering plants possess two types of water-conducting cells. The answer is that vessels are more vulnerable than tracheids to embolism, meaning blockage by air bubbles. Once an embolism forms in a vessel element, it can extend through the large end-wall perforations into many elements, thereby blocking an entire vessel. Just as air bubbles can cause disruption of blood circulation in people,

(a) Tracheids (b) Extensible tracheids

Figure 38.11 Tracheid cells in xylem tissue. (a) Tracheids are long, tubular cells with slanted end walls. Water and ions move from cell to cell through the pits. **(b)** Light micrograph of extensible tracheids from the xylem of pumpkin.

Concept Check: *If you applied a stain specific for lignin to tracheids present in a longitudinal slice of a plant stem that is still growing in length, then observed the cells with a light microscope, what portions of the tracheids would be stained, and what parts would not be stained?*

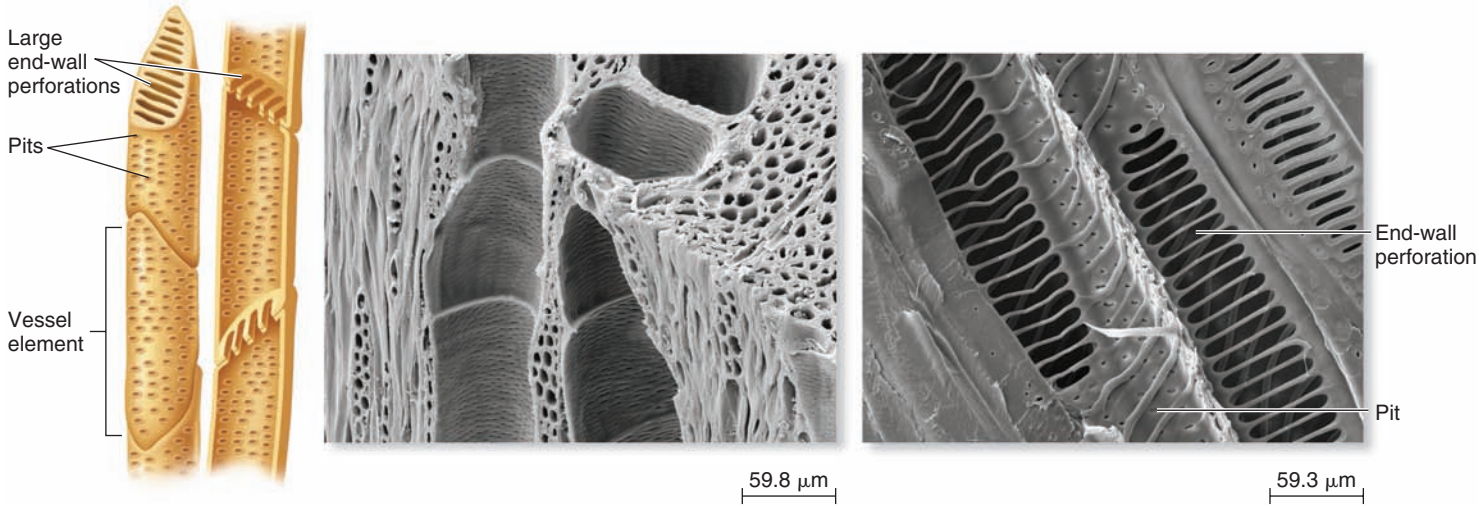


Figure 38.12 Vessels composed of vessel elements in xylem tissue. **(a)** This illustration shows the wide diameter of vessel elements with many pits and end-wall perforations. **(b)** SEM of vessels in the wood of the walnut tree (genus *Juglans*). **(c)** SEM of a perforated vessel element end wall from the tulip tree (*Liriodendron tulipifera*).

Concept Check: Which structural features of vessel elements explain the vulnerability of vessels to embolism, that is, blockage by air bubbles?

sometimes leading to death, such bubbles also disrupt water transport in plants, sometimes severely. An embolism can form within a vessel as the result of physical damage, drought, or repeated cycles of freezing and thawing. Air bubbles form frequently during winter, because air does not dissolve in ice. By the end of a cold winter, the functional vessels of many woody plants have become almost completely blocked by air. Blocked vessels in trees often cease to function in water transport and must be replaced by new growth in the spring. Fortunately, even if vessels become blocked, water conduction can still occur via tracheids. This is because tracheid pits are so small that they do not allow air bubbles to move to other tracheids. Thus, an air bubble is confined to the single tracheid in which it first formed, and water continues to flow through nearby tracheids. Tracheids thereby provide a fail-safe conduction route when vessels have become disabled by embolisms.

Some plants are able to refill embolized vessels by means of a process known as **root pressure**. At night, the xylem of roots may accumulate high concentrations of ions that are not immediately transported upward to shoots. In this case, the root acts much like a cell rich in solutes, with the result that water gushes in so rapidly that it pushes upward to leaves. Evidence of this process can be observed in the early morning as droplets of water at the edges of leaves, a phenomenon known as **guttation** (**Figure 38.13**). As the water rushes upward, it can dislodge air bubbles or dissolve them, thereby reversing an embolism. Root pressure refilling has been observed to occur in nonwoody plants such as corn (*Zea mays*) and in some woody plants, including the sugar maple (*Acer saccharum*).

Cohesion-Tension Theory Explains the Role of Transpiration in Long-Distance Water Transport

In warm, dry air, water evaporates from plant surfaces. This evaporation process is known as **transpiration** (from the French *transpirer*, meaning to perspire) (**Figure 38.14a**). Transpiration is capable of pulling water by bulk flow up to the tops of the tallest trees and is the primary way in which water is transported for long distances in plants. Plants expend no energy to transport water and minerals by transpiration. Rather, the Sun's energy indirectly powers this process by generating a water pressure difference between moist soil and drier air (see Figure 38.9).

How does evaporation at plant surfaces influence long-distance water transport in the xylem? To answer this question, we must consider the unique physical properties of it. Liquid water molecules are linked by hydrogen bonds (see Chapter 2). As a result, liquid water is amazingly cohesive, explaining why it tends to form continuous streams (**Figure 38.14b**). Consequently, when water molecules

Figure 38.13 Guttation, the result of root pressure.

Concept Check: What functions can root pressure serve in plants?

evaporate from plants, water films present in leaves display high surface tension. This tension causes a curved water surface known as a meniscus to form (**Figure 38.14c**); the surface tension pulls on neighboring liquid water molecules and eventually on water in the nearest vein, which is connected to the plant's entire water supply. As the result of water's cohesion and the tension exerted on water at the plant's surface, a continuous stream of water can be pulled up through the plant body from the soil, into roots, through stems, and into leaves. This explanation for long-distance water movement in plants is known as the **cohesion-tension theory**. (Recall from Chapter 1 that a scientific theory is a well-established concept, not just a hypothesis.)

Plant transpiration moves huge amounts of water from the soil to the atmosphere. About 99% of the water that enters plants via roots is generally lost as water vapor during transpiration. Each crop season, a single corn plant (*Zea mays*) loses more than 200 L of water, which is more than 100 times the corn plant's mass. A typical tree loses 400 L of water per day! On a regional and global basis, plant transpiration has enormous climate effects. For example, an estimated one-half to three-quarters of rainfall received by the Amazon tropical rain forest actually originates from plant-transpired water vapor, often visible as mist (**Figure 38.15**). Furthermore, about half of the solar heat received by Amazonian plants is dispersed to the atmosphere during transpiration. This heat dispersal has a cooling effect on regional ground temperature, which would be much higher in the absence of plant transpiration. Such cooling effects result from water's unusually high heat of vaporization, the amount of heat needed to isolate water molecules from the liquid phase and move them to the vapor phase. Most of this energy is needed to break the large numbers of hydrogen bonds that occur in liquid water. The evaporation of large amounts of water from plant surfaces effectively dissipates heat, explaining how plants cool themselves and their environments.

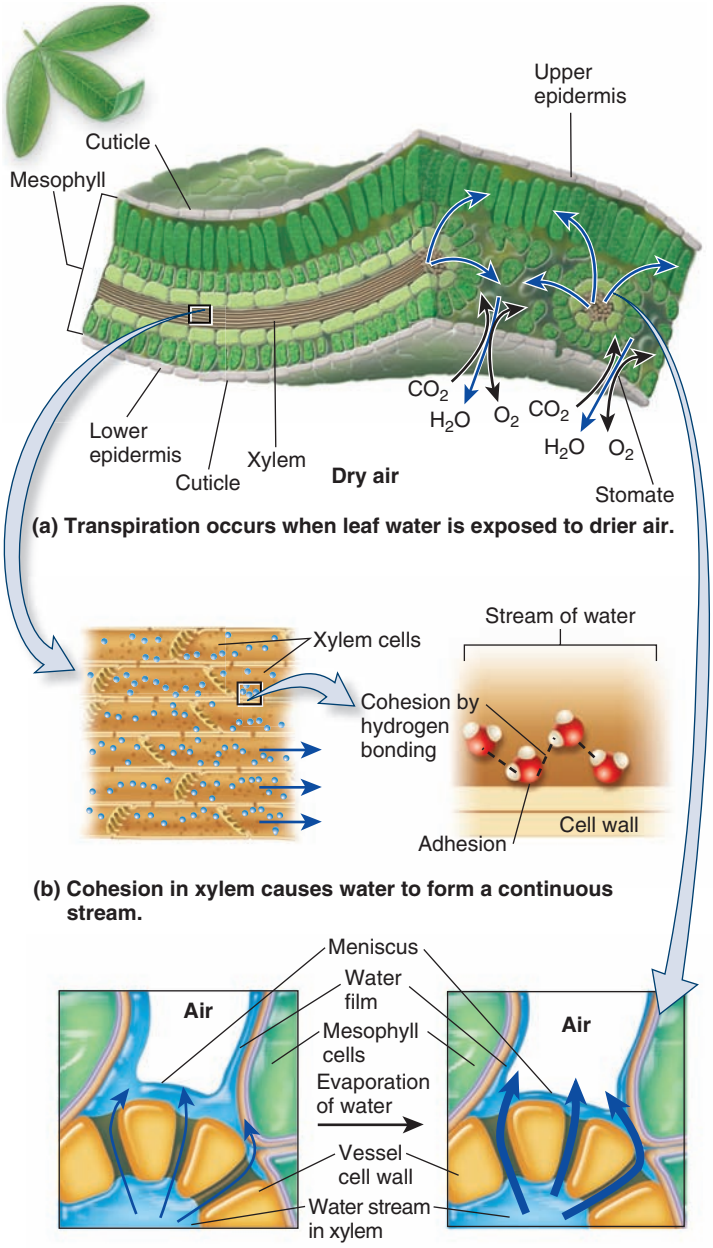

Figure 38.14 **The roles of transpiration, cohesion, adhesion, and tension in long-distance water transport.**

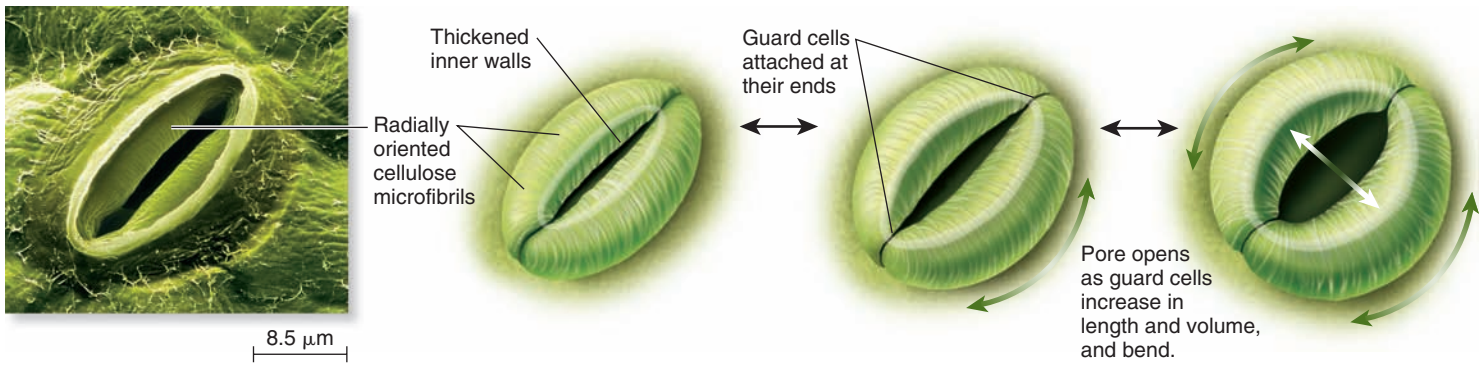
Figure 38.15 **Plant-transpired water vapor rising as mist from a tropical rain forest.** This mist visually illustrates the enormous amount of water that is transpired from the surfaces of plants into the atmosphere. Water vapor derived from plant transpiration is an important source of rainfall, and the process of evaporation cools plant surfaces and affects the local and global climate.

Concept Check: *Why does evaporation of water have such a powerful cooling effect?*



Although evaporation of water from plant surfaces plays an essential role in bulk flow through xylem, if plants lose too much water, they will die. Plant surfaces, including those of leaves, typically produce a cuticle, a wax-containing layer that retards water loss. Only about 5% of water evaporated from plant surfaces emerges through the cuticle, however. More than 90% of the water that evaporates from plants is lost through stomata, surface pores that can be closed to retain water or opened to allow the entry of CO_2 needed for photosynthesis. When the stomata are open, O_2 also exits the plant, as does water vapor when the atmospheric humidity is relatively low. Stomata are often abundantly located on the lower surfaces of leaves. Tobacco leaves, for example, possess an estimated 12,000 stomata per square centimeter of leaf surface! Plants face a constant dilemma: whether to open their stomata for CO_2 intake and suffer the effect of reduced water content or to close stomata to retain water, thereby preventing CO_2 uptake.

Stomata Closing Helps to Reduce Transpirational Water Loss

Under some conditions, almost all plants experience water stress, or water deficit, which is an inadequate amount of water. Water stress is common for plants of the world's arid regions, and their growth is often limited by water availability. Even plants of moist, forested regions of the world experience water stress during drier or colder seasons or under windy conditions. The leaves at the tops of tall trees are generally under considerable water stress because gravity has a substantial effect on their water potential. Earlier, we considered examples of plant cellular adaptations to deal with osmotic stress. Flowering plants have evolved additional ways to prevent excessive loss of water by transpiration. One example is the regulation of stomatal opening and closing. Plant stomata close to conserve water under conditions of water stress and open when the stress has been relieved, allowing air exchange with the leaf's spongy mesophyll. Stomata are bordered by a pair of **guard cells**, which are sausage-shaped chloroplast-containing cells attached to one another at their ends (**Figure 38.16a**). The distinctive structural features of guard cells explain how they are able to open and close a pore. As guard cells become fully turgid, their volume expands by 40–100%. This expansion does not occur evenly, however, because the innermost cell walls of guard cells are thicker and less extensible than are other parts of the cell walls. In addition, the guard cells expand primarily in the lengthwise direction because bands of radially oriented cellulose microfibrils prevent lateral expansion (**Figure 38.16b**). Thus, when guard cells are turgid, a stomatal pore opens between them, allowing air exchange with the leaf's spongy mesophyll. Conversely, when the guard cells lose their turgor, their volume decreases, and the stomatal pore closes.

What causes the change in turgor? In flowering plants, stomata often open early in the morning, in response to sunlight. This response makes sense, given that light, water, and carbon dioxide are all required for photosynthesis. Blue light stimulates H^+-ATPase proton pumps in guard cells, leading to the uptake of ions, especially potassium (K^+), and other solutes. As a result of increases in solute concentrations inside guard cells, osmotic water uptake occurs via plasma membrane aquaporins, resulting in cell expansion and stomatal opening (**Figure 38.17a**).

At night, the reverse process closes flowering plant stomata. Potassium and other solutes are pumped out of guard cells, causing water to exit, deflating the cells and resulting in pore closure. Flowering plants also close stomata during the daytime under conditions of water stress, a process mediated by the stress hormone abscisic acid (ABA). Water stress causes a 50-fold increase in ABA, which is transported in the xylem sap to guard cells. ABA then binds to a receptor, which elicits a Ca^{2+} second messenger, causing the guard cells to lose solutes and deflate (**Figure 38.17b**). An understanding of the process of stomatal closure suggests strategies by which crop plants might be genetically engineered to more effectively withstand drought.

Figure 38.16 The structure of guard cells. When flaccid, guard cells close stomata. Turgid guard cells produce a stomatal opening. **(a)** An SEM of a stomate in a rose leaf, showing the two guard cells bordering a partly open pore. **(b)** Thickened inner cell walls and radial orientation of cellulose microfibrils in the guard cell walls explain why they separate when turgid, forming a pore.

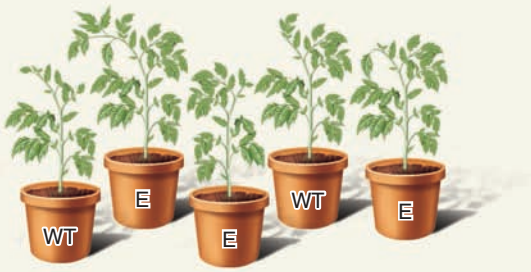
Concept Check: *How could you make a physical model that would illustrate how guard-cell structure affects function?*

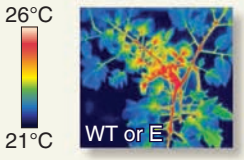
(a) The process of stomate opening

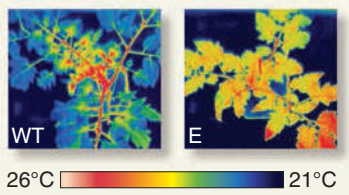
(b) The process of stomate closing

Figure 38.17 How stomata of flowering plants open and close. **(a)** Angiosperm stomata usually open in response to sunlight. **(b)** Angiosperm stomata usually close in response to lack of sunlight. They can also close during the day under conditions of water stress, which induces plants to produce more of the hormone abscisic acid (ABA). Guard-cell plasma membranes possess ABA receptors, which receive the drought signal.

Feature Investigation | The Park Team Genetically Engineered an ABA Receptor Protein to Foster Crop Survival During Droughts







Global climate change has increased the frequency and length of drought episodes that endanger agricultural production of human food. Increasing crop resistance to drought is one way in which plant biologists are trying to improve agricultural productivity. Because the plant hormone abscisic acid (ABA) is key to seed plants' drought response, agricultural biologists have been working to identify methods that farmers could use to stimulate ABA activity in such plants.

Previous crystallographic studies had revealed the three-dimensional structure of the ABA receptor protein in the model plant *Arabidopsis thaliana*, indicating how the protein binds ABA. A team of biochemists led by Sang-Youl Park and Sean Cutler hypothesized that chemicals already approved for use in protecting crops (known as agrochemicals) might be employed to also activate ABA. The team created a collection of *A. thaliana* plants containing different mutations in the ABA receptor gene (known as *PYR1*). The collection included all of the 475 single substitutions that could possibly occur in the 25 amino acids at the ABA binding site. The team then examined the responses of these mutant plants to a set of widely used agrochemicals. This process, which involved more than 7,000 individual tests of the binding of different agrochemicals to the ABA receptor, revealed that some of the mutants responded to

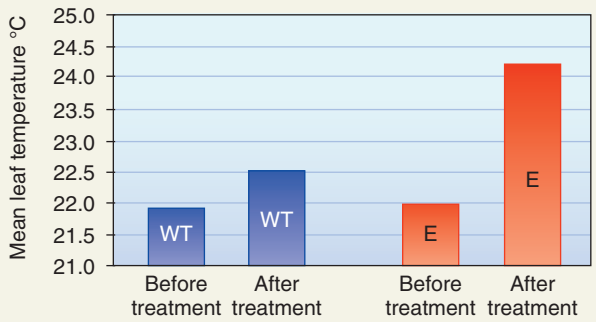


Figure 38.18 **The Park team's experiment with a genetically engineered ABA receptor protein.**

HYPOTHESIS Tomato plants bearing a genetically engineered ABA receptor will close their stomata in response to treatment with an agrochemical.

KEY MATERIALS Genetically engineered tomato plants, wild-type (nonengineered) tomato plants, agrochemical, controlled environment culture chamber, thermal imaging equipment.

	Experimental level	Conceptual level
1 Grow replicate wild-type (WT) and genetically engineered (E) plants of the same age together for 3 weeks.		Replicates provide reproducibility, and controlled growth conditions reduce the effects of environment.
2 Obtain thermal images before experimental treatment.		Plant temperature indicates degree of evaporation through open stomata. Blue indicates open stomata; red indicates closed stomata.
3 Treat all plants with the agrochemical.		WT plants with the agrochemical should not respond to treatment by closing their stomata, but engineered plants should do so.
4 Obtain thermal images after experimental treatment.		Comparison of thermal image reveals differences in surface temperatures resulting from stomata closure.

5 THE DATA

6 CONCLUSION Farmers might be able to use common agrochemicals to foster survival of genetically engineered crops during drought periods.

7 SOURCE Park, S.-Y., Peterson, F. C., Mosquna, A., Yao, J., Volkman, B.F., and Cutler, S.R. 2015. Agrochemical control of plant water use using engineered abscisic acid receptors. *Nature*. 520:545–548.

mandipropamid, an agrochemical widely used to control pathogens called oomycetes. Oomycetes are heterotrophic protists (of the supergroup Stramenopila) that cause diseases in diverse species of natural plants and crops (Chapter 28).

The Park team discovered that, in the responsive mutants, the ability of the agrochemical to fit within the ABA binding site was improved, and hydrophobic interactions and hydrogen bonding occurred between the agrochemical and the receptor. With this fundamental information in hand, the team could next try to show applicability to crops. To do so, the investigators created similar mutant tomato plants (**Figure 38.18**). They then used measurements of leaf temperature to assess the responsiveness of the ABA receptors in these plants to the agrochemical mandipropamid. The selected mutant plants appeared to close their stomata in response to mandipropamid. Thus, genetic engineering can be used to manipulate plants' responses and thus create crop varieties that farmers can treat with agrochemicals to increase the plants' drought resistance.

Experimental Questions

1. Why did the Park team grow replicate wild-type (WT) tomato plants and genetically engineered (E) tomato plants of the same age together for 3 weeks?
2. **SciSKILLS** » Why did the Park team use thermal images to compare the responses of the WT and E plants before and after experimental treatment with the agrochemical?

BIO TIPS **THE QUESTION** *The data in step 5 of Figure 38.18 reveal that genetically engineered (E) tomato plants showed a higher level of response to application of an agrochemical than did wild-type (WT) plants. Did the WT plants also show a response to the experimental treatment, and if so, why might this response have occurred?*

TOPIC ***What topic in biology does this question address?*** The topic is leaf stomatal responses of angiosperms to drought stress. More specifically, the question concerns how fundamental biochemical knowledge regarding leaf stomatal responses can be applied to improve crop productivity.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From this chapter and Chapter 35, you know that stomata are pores that occur on plant surfaces, particularly the undersides of leaves. Stomata in angiosperms open and close in response to changes in the water content of guard cells, and the formation of a pore is determined by differences in the thickness of guard-cell walls as well as the orientation of microtubules (shown in Figure 38.16). From this chapter and Chapter 36, you also know that roots under water stress produce the plant hormone ABA, which is transported via the xylem to shoots, providing an early warning of impending water stress (water deficit). Figure 38.17 illustrates the role of ABA receptor proteins that occur in stomatal guard-cell membranes; when such receptors bind ABA, they stimulate changes in the movement of solutes and the consequent movement of water, due to osmosis. In this way, seed plants use ABA to induce stomatal closure, thereby reducing water loss by transpiration. These observations reveal the key role of ABA in seed plants' responses to water stress. The Park team knew that ABA binds to a specific receptor protein, and they decided to explore whether genetic engineering could be used to improve

the binding of agrochemicals to the ABA receptor protein. Such binding is influenced by protein structure, in which hydrophobic interactions and hydrogen bonding play important roles (refer back to Figure 3.17).

PROBLEM-SOLVING STRATEGY ***Interpret data. Compare and contrast.*** Compare the bar graphs in step 5 of Figure 38.18 and the thermal images collected before and after the experimental treatment (in steps 2 and 4). Think about how WT plants (those not genetically engineered) might respond to treatment with the agrochemical.

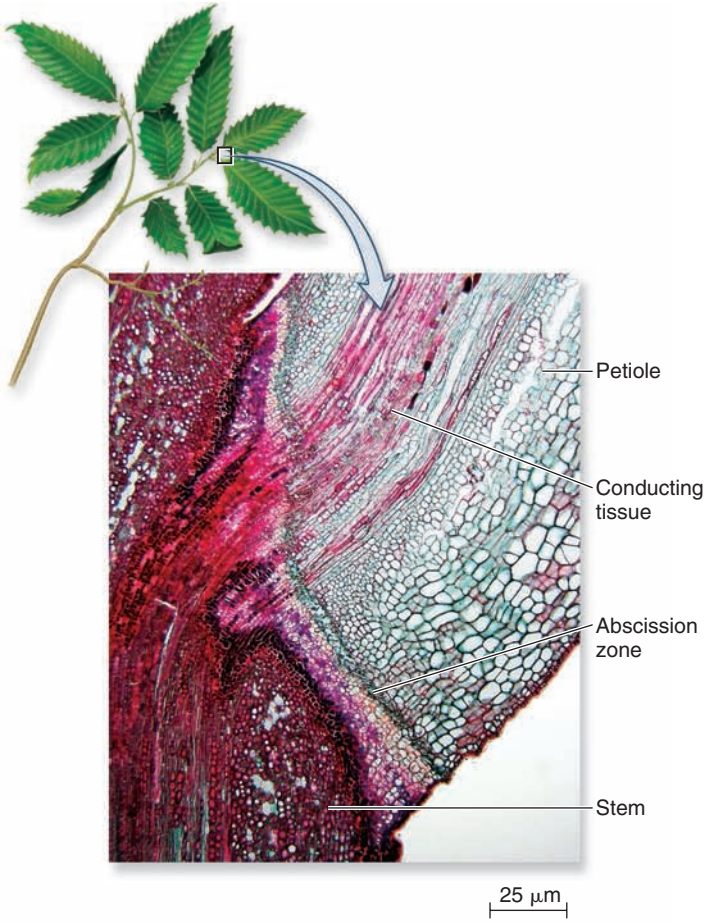
ANSWER *Agrochemical treatment did induce a small response in WT tomato plants. This result may indicate that WT plants close at least some of their stomata in response to agrochemical treatment, though not as many as in the E plants. Genetic engineering improved the ability of a particular agrochemical to fit within the receptor-binding site and also improved the strength of the hydrophobic interactions and hydrogen bonding there. For this reason, the ABA receptors of E plants bind the agrochemical more effectively than do those of WT plants. The study results suggest that even WT plants respond by closing some stomata, but E plants respond more strongly.*

Note: You might have noticed that the bar graphs lack error bars indicating the variation in responses of replicate plants. The use of replicate observations and appropriate statistical analysis would indicate whether the response of WT plants to the agrochemical is significantly different from that of untreated WT plants. Likewise, comparison of responses of E plants would be improved by replicate data and statistical analysis. In this case, the thermal images provide strong evidence that the differences are real.

Leaf Abscission Also Prevents Water Loss

A second way that plants can prevent water loss is by dropping their leaves, a process known as **leaf abscission**. Angiosperm trees and shrubs of seasonally cold habitats experience water stress every winter, when evaporation from plant surfaces occurs, yet soil water is frozen and therefore unavailable for uptake by roots. Desert plants also experience water stress conditions, but at less predictable times and for much of the year. Both types of plants are adapted to cope with water stress by dropping their leaves. This process lets these plants avoid very low leaf water potentials and the consequent danger of xylem embolism. Leaf abscission also reduces the amount of root mass that plants must produce to obtain water under arid conditions. The ocotillo (*Fouquieria splendens*) of North American deserts can produce leaves after sporadic rains and then drop all of its leaves as a direct response to drought as many as six times a year (**Figure 38.19**).

The sugar maple (*Acer saccharum*) is an example of the many types of temperate forest trees or shrubs that drop their leaves each autumn and are thus known as deciduous plants. Deciduous plants contrast with evergreen conifers, whose needle- or scale-shaped leaves are adaptations that reduce the area of leaf surface from which water can evaporate, which helps these gymnosperms cope with water stress during the cold season (refer back to Figure 30.10). The broader, thinner leaves produced by many angiosperms are well adapted for efficient light-capture, but more vulnerable to the stresses caused by cold. During their evolution, temperate zone angiosperm trees and shrubs have acquired the genetic capacity to predict the onset of cold, dry winter conditions and respond with pre-emptive leaf abscission. In contrast to the case of the ocotillo, autumn leaf drop in temperate angiosperms is not directly induced by drought.



Leaf abscission is a highly coordinated developmental process. The hormone ethylene stimulates an abscission zone to develop at the bases of leaf petioles (**Figure 38.20a**). The abscission zone contains two types of tissues: a separation layer of short, thin-walled cells and an underlying protective layer of suberin-impregnated cork cells (**Figure 38.20b**). The walls of the cork cells contain both waterproofing wax and phenolic polymers that retard microbial attack. As the abscission layer develops across the vein linking the petiole with the stem, it eventually cuts off the water supply to the leaf. Chlorophyll in the leaves degrades, revealing colorful orange and yellow carotenoid and xanthophyll pigments that were previously masked by the chlororphyll. In addition, some plants synthesize red and reddish-blue pigments in response to changing environmental conditions. The presence of these pigments explains colorful autumn vegetation in temperate zones. Enzymes eventually break down the cell-wall components of the separation layer, causing the petiole to break off the stem. The underlying protective layer forms a leaf scar that seals the wound, helping to protect the plant stem from water loss and pathogen attack.

BIOLOGY PRINCIPLE Living organisms maintain homeostasis. This is illustrated by leaf drop in response to, or in anticipation of, arid conditions.

Genomes & Proteomes Connection

Stomatal Responses to Abscisic Acid Arose Relatively Late in Plant Evolution

Most studies of leaf stomatal responses have been conducted in angiosperms, the plant group most important to humans as sources of food and other resources. Such studies have revealed that angiosperm stomata open when water flows into guard cells and close when water flows out of guard cells, and that the plant hormone abscisic acid (ABA) controls such water flow by activating solute exchange between guard cells and neighboring leaf epidermal cells (see Figure 38.17). Abscisic acid allows plant roots to transmit information about drying soil conditions through the plant conduction system to leaves, signaling the stomata to close soon enough to prevent excessive water loss. In this way, ABA functions as an early warning system that aids the survival of flowering plants.

Wondering if other types of plants behaved in the same way, Timothy Broadribb and Scott McAdam examined the responses to ABA of leaf stomata in representative gymnosperms, ferns, and lycophytes. Some previous experiments had suggested that the stomata of ferns might respond to environmental signals differently than do those of flowering plants. Comparative analysis of stomatal responses after the addition of ABA into the xylem transpiration stream revealed that the stomata of angiosperm and gymnosperm species responded as expected, but those of lycophytes and ferns did not (**Figure 38.21**). These investigators concluded that the stomata of lycophytes and ferns open or close in response to the water content of surrounding leaf cells. Stomata of these plants close only when the leaf water content has already been compromised. The evolution of an early warning system involving signaling by ABA and movement of solutes and water between neighboring leaf epidermal cells and guard cells apparently occurred after the divergence of ferns and prior to the divergence of seed plants. This critical innovation fostered the rise of seed plants and helps to explain why they are dominant in today's world.

Long-Distance Transport of Organic Molecules Occurs in the Phloem

Phloem plays an essential role in long-distance transport of organic molecules and some minerals in the plant body. Phloem often transports sugars from where they are produced to other sites where they are also used. Recall that primary phloem occurs in the vascular bundles of herbaceous plants and secondary phloem occurs as the inner bark of woody plants (refer back to Figure 35.20). In contrast to xylem, whose transport tissues are dead and empty of cytoplasm at maturity, mature phloem tissues remain alive and retain at least some cytoplasmic components. A closer look at phloem structure and function will help to illuminate these differences.

Phloem Structure Phloem tissues of flowering plants include supporting fibers, parenchyma cells, sieve-tube elements, and adjacent companion cells. **Sieve-tube elements** are arranged end to end to form transport pipes (**Figure 38.22**), analogous to the way that

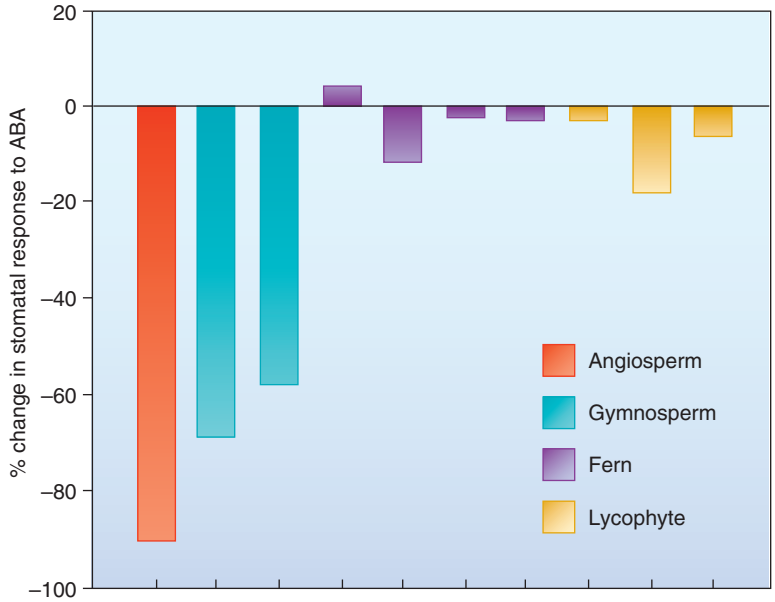

Figure 38.21 **Comparison of stomatal response to ABA among angiosperms, gymnosperms, lycophytes, and ferns.**

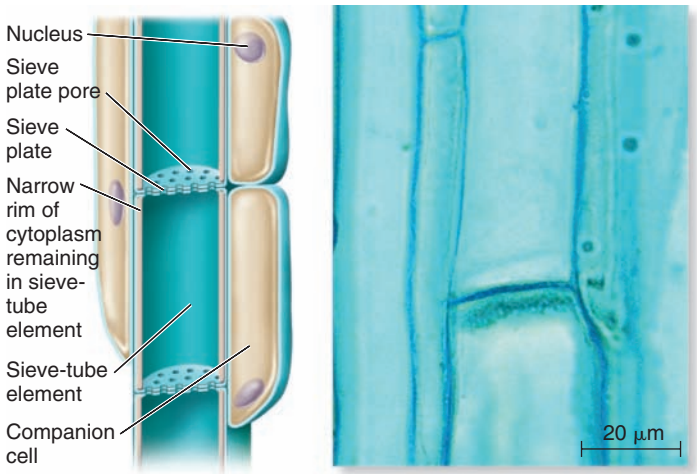

the xylem's vessel elements are aligned to form longitudinal vessels. Together, the sieve-tube elements and companion cells form a system for the transport of soluble organic substances made during photosynthesis. In addition, phloem sap may contain hormones such as auxin and abscisic acid, as well as many types of proteins and RNA.

Each pair, consisting of a sieve-tube element and its companion cell, has a common origin. The two cells are produced by an unequal division of a single precursor cell and are therefore linked by plasmodesmata formed at cytokinesis. The smaller of the two cells develops into a companion cell, whose name reflects its life-support function, and the larger of the two cells develops into a sieve-tube element. The sieve-tube element loses its nucleus and most of its cytoplasm as an adaptation that reduces obstruction to bulk flow. Mature sieve-tube elements retain only a thin film of peripheral cytoplasm that includes some endoplasmic reticulum, plastids, and mitochondria. The end walls of developing sieve-tube elements become perforated by the action of wall-digesting enzymes that enlarge existing plasmodesmata. The perforated end walls of mature sieve-tube elements are known as **sieve plates**, and the numerous perforations are known as **sieve plate pores**. Phloem sap passes through these plates from one sieve-tube element to another.

Mature sieve-tube elements are not dead. However, because they lack a nucleus, they depend on their neighboring companion cell for messenger RNA (mRNA) and proteins, which are supplied via plasmodesmata. For example, when a plant's conducting system is damaged, a short-term wound response occurs that involves a protein known as **P protein** (for phloem protein). Large amounts of this protein accumulate along sieve plates, preventing loss of phloem sap (**Figure 38.23**). This protein accumulation functions much like a clot that helps reduce blood loss from wounded animals. P protein also binds to the cell walls of pathogens, thereby helping to prevent infection at wounds. However, sieve-tube elements cannot produce P protein by themselves. The companion cells provide either P protein mRNA or the protein itself to sieve-tube elements. In a longer term response, plants deposit the carbohydrate callose as a sealant at the wound site.

Phloem Loading Companion cells also play an essential role in moving sugars into sieve-tube elements for long-distance transport, a process known as **phloem loading**. Although glucose and some other monosaccharides can occur in phloem, the disaccharide sucrose is the main form in which most plants transport sugar over long distances. Plant biologists think that sucrose is less vulnerable to metabolic breakdown en route than are monosaccharides.

Two types of phloem loading occur: symplastic and partly apoplastic. Many woody plants transport sucrose from sugar-producing cells of the leaf mesophyll to companion cells and then to sieve-tube

(a) Sieve-tube elements and companion cells

(b) Light micrograph of phloem stained with blue dye, showing sieve-tube elements

Figure 38.22 **Sieve-tube elements and companion cells of phloem.**

BioConnections: *Look back to Figure 35.16, which illustrates the development of guard cells. In what way are guard cell development and companion cell development similar?*

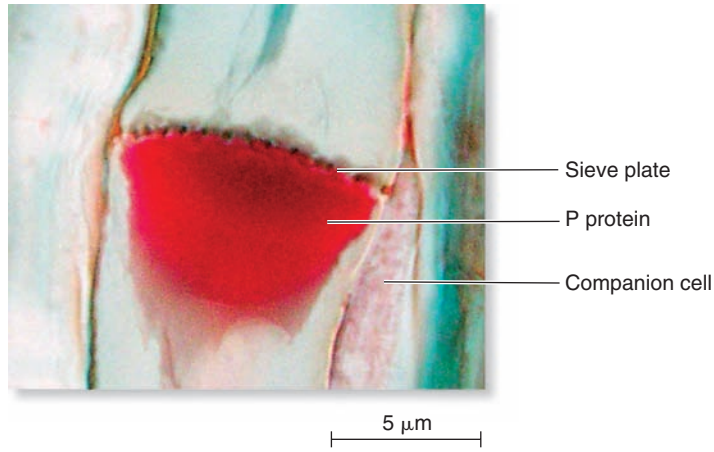

Figure 38.23 **Phloem wound response.** When phloem is damaged, the cytoplasm of a sieve-tube element surges toward the sieve plate, depositing P protein, stained red in this light micrograph. In this location, P protein helps to prevent infection and leakage of solutes.

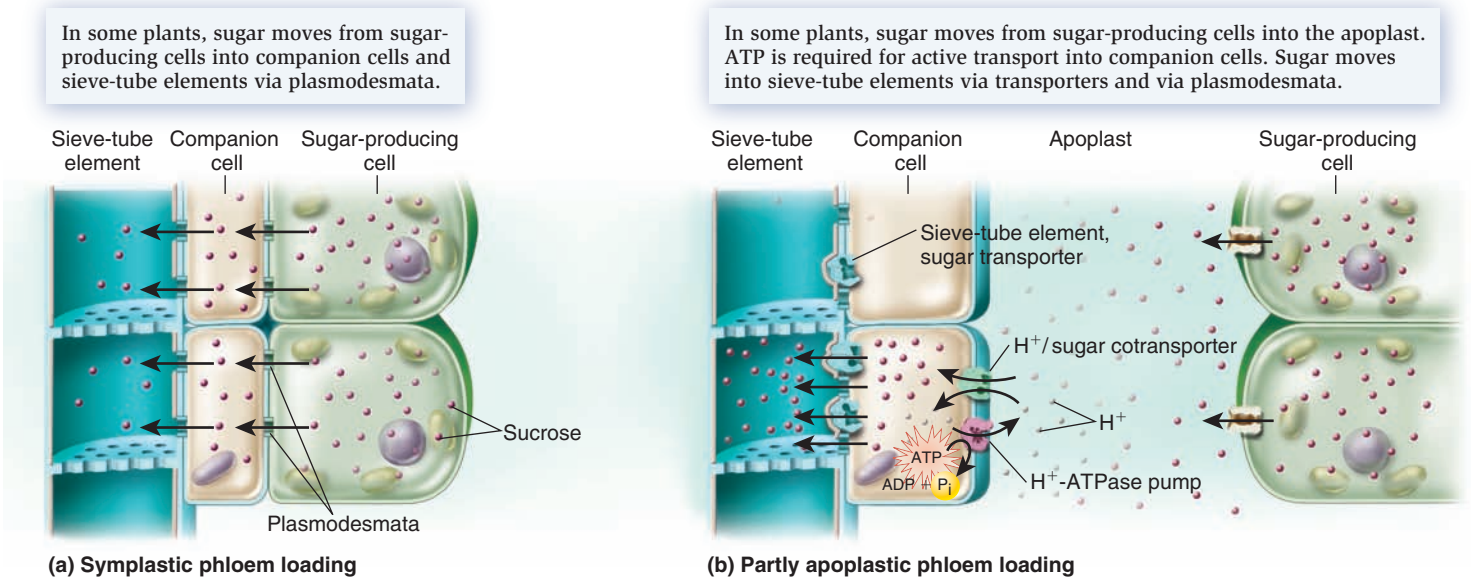

Figure 38.24 **Symplastic and partly apoplastic phloem loading.**

elements via plasmodesmata, a process known as symplastic phloem loading (**Figure 38.24a**). The advantage of symplastic loading is that it does not require ATP; by moving through plasmodesmata, sugar does not have to cross plasma membranes.

In contrast, most herbaceous plants, including important crop plants and the model plant *Arabidopsis,* load sugar into sieve-tube elements or companion cells from intercellular spaces, often against a concentration gradient. ATP must be used to move the sugar across a plasma membrane into a companion cell or sieve-tube element (**Figure 38.24b**). Therefore, this second type of phloem loading is partly apoplastic and partly a transmembrane process.

The Pressure-Flow Hypothesis Helps Explain Transport in Phloem Tissues

We have learned that transpiration, driven by the Sun's energy, moves water in plant xylem by the processes of cohesion and tension. Once sugar has been loaded into phloem sieve-tube elements, how does it move within the plant? The most common explanation is that phloem transport is driven by differences in turgor pressure that occur between cells of a **sugar source**, where sugar is produced, and those of a **sugar sink**, where sugar is not made, but still needed by nonphotosynthetic cells. Photosynthetic leaf mesophyll is the

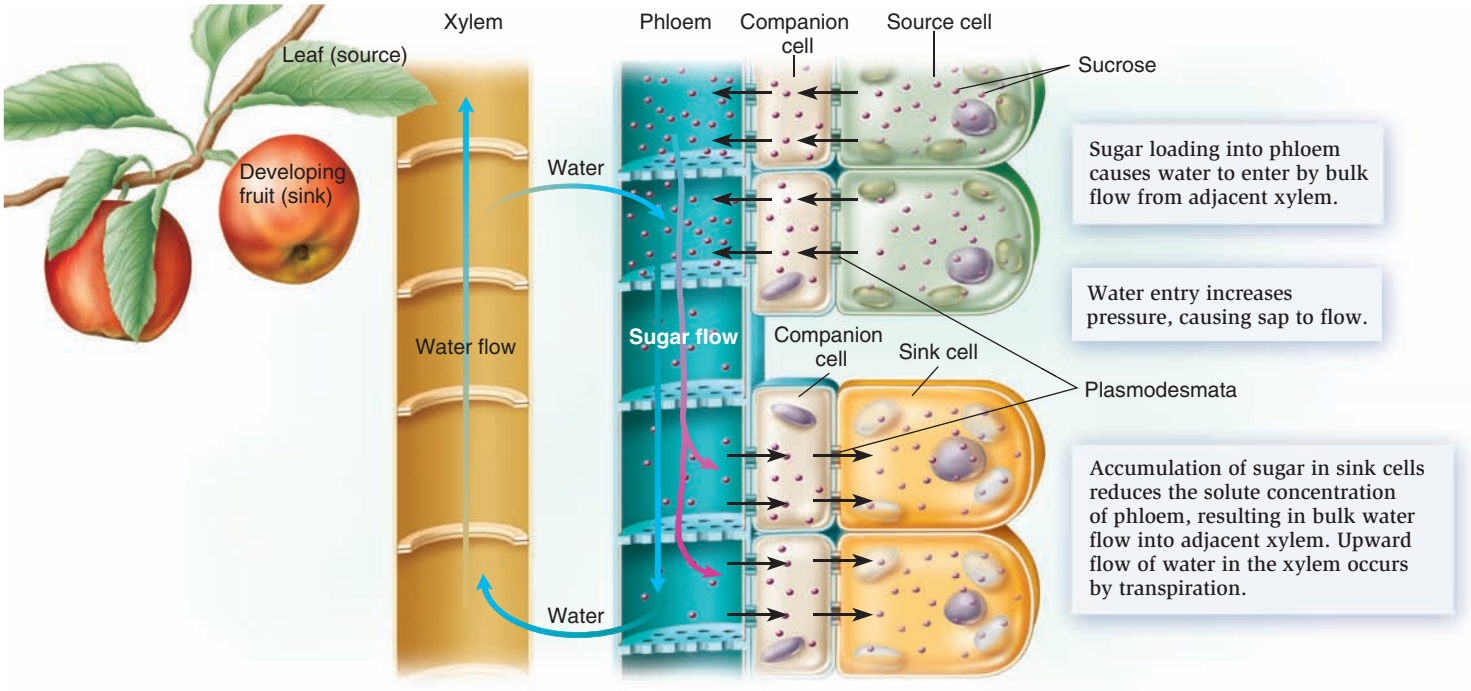

Figure 38.25 **Pressure-flow hypothesis for phloem transport.**

main sugar source. Roots and developing leaves, seeds, and fruits are examples of sugar sinks. In the process known as **translocation**, phloem transports substances from source to sink. The direction of phloem movement can be horizontal as well as vertical, depending on the relative positions of the sources and sinks.

Because sieve-tube elements near source tissues have higher solute contents than surrounding tissues, water tends to rush into them from nearby xylem, thereby building turgor pressure. The production of turgor pressure requires an intact plasma membrane. This explains why mature phloem sieve-tube elements must be alive in order to function.

In contrast to sieve-tube elements near source tissues, sieve-tube elements near sink tissues have lower solute concentration. The resulting water pressure difference drives the bulk flow of phloem sap from source to sink tissues. This explanation for translocation is known as the **pressure-flow hypothesis** (**Figure 38.25**). At sink tissues, sugar is typically unloaded through plasmodesmata (see Figure 38.25). Because plasmodesmata are very narrow in comparison with sieve-tube elements, they slow the flow of phloem sap from sieve-tube elements into sink tissues. This reduction in flow rate helps to equalize the distribution of phloem sap, preventing delivery of too much sap to any single sink. When the solute concentration of phloem sap has been sufficiently reduced, water flows from the phloem back into the xylem, where upward transport occurs. The reliance of phloem bulk flow on water supplied by the xylem explains the close proximity of phloem and xylem tissues in vascular bundles and woody stems.

Summary of Key Concepts

38.1 Overview of Plant Transport

- The plant root system takes up water and minerals, and the shoot system absorbs carbon dioxide from the air. Photosynthetic cells use these materials to produce organic compounds. In the vascular system, xylem transports water and minerals from roots to shoots, and phloem transports organic compounds from photosynthetic to nonphotosynthetic tissues (Figure 38.1).

38.2 Uptake and Movement of Materials at the Cellular Level

- Facilitated diffusion is the transport of molecules across plasma membranes down a concentration gradient with the aid of membrane transport proteins, typically channels and transporters. Active transport—the transport of substances across plasma membranes against concentration gradients—usually requires ATP. Plasma membrane proton pumps use the energy released by ATP hydrolysis to move protons from the cytosol into the intercellular space, generating a membrane potential. Potential energy released by the flow of protons back into the cell can be coupled to the transport of ions and solutes (Figures 38.2, 38.3).
- Turgor pressure increases as water enters plant cells because cell walls restrict the extent to which cells can swell. A cell that is so full of water that the plasma membrane presses closely against the cell wall is turgid. A cell that contains so little water that the plasma membrane pulls away from the cell wall is plasmolyzed. A flaccid cell has a water content between these extremes (Figure 38.4).
- Solute potential and pressure potential arising from the presence of a cell wall are major factors that determine cellular water potential. Water moves from a region of higher water potential to a region of lower water potential (Figure 38.5).
- Plants display a variety of adaptations that help them cope with cellular osmotic stress.

38.3 Tissue-Level Transport

- Tissue-level transport occurs in three forms. Transmembrane transport involves the movement of materials from one cell to another from intercellular spaces, across plasma membranes, and into the cytosol. Symplastic transport allows materials to move from one cell to another through the symplast, the cells' cytosol and plasmodesmata, without crossing plasma membranes. In apoplastic transport, water and solutes move through the apoplast, the water-filled cell walls and intercellular spaces of tissues (Figures 38.6, 38.7).
- In roots, waxy Casparian strips on cell walls of endodermal tissue function as diffusion barriers that reduce both the entry of toxic metal ions into and the exit of useful solutes from the vascular system (Figure 38.8).

38.4 Long-Distance Transport

- Water and solutes move for long distances by bulk flow within the xylem and phloem. Plant vascular tissues are adapted in ways that reduce resistance to bulk flow. Bulk flow of water upward in xylem is powered by the water pressure difference between moist soil and drier air, the latter resulting from solar heating. Xylem is the main conduit for water and dissolved mineral nutrients, but it may also transport certain organic compounds (Figures 38.9, 38.10).
- The water-conducting cells of xylem, tracheids and vessel elements (together known as tracheary elements), are dead and empty of cytoplasm at maturity. Pits in tracheary element walls allow water entry and exit, and narrow or constrict in response to xylem sap solute content. Vessel elements are wider than tracheids but are more vulnerable to blockage by air bubbles, or embolism. Root pressure, the effects of which include the morning water drops on leaf tips known as guttation, helps some plants to refill embolized vessels (Figures 38.11, 38.12, 38.13).
- Transpiration is the evaporative loss of water from plant surfaces. The cohesion-tension theory proposes that as the result of water's cohesion and the tension exerted on water at the plant's surface by evaporation, a continuous stream of water can be pulled up through the plant body from the soil, into roots, through stems, and into leaves, from which water is evaporated into the atmosphere (Figures 38.14, 38.15).
- Regulation of stomata helps plants prevent excessive water loss by transpiration. Expansion of guard cells causes stomata to open, allowing CO_2 intake. Guard-cell deflation causes pores to close, limiting water loss. In seed plants, abscisic acid (ABA) stimulates stomatal closure in response to drought, a process that suggests strategies for genetically engineering crops that have greater drought tolerance. Nonseed plants seem to lack stomatal response to abscisic acid. Plants under existing or predicted water stress often drop their leaves in a process known as abscission, an adaptive response that lets plants avoid very low water potentials and the threat of embolism (Figures 38.16, 38.17, 38.18, 38.19, 38.20, 38.21).
- Organic solutes and minerals are transported in phloem sap as the result of osmosis. Phloem sap moves within sieve-tube elements, which are living when mature, but lack a nucleus and are thus dependent on companion cells. Phloem loading, the movement of sugars into sieve-tube elements for long-distance transport, occurs by symplastic or partly apoplastic transport (Figures 38.22, 38.23, 38.24).
- In the process known as translocation, phloem transports substances from source to sink. The pressure-flow hypothesis helps to explain

translocation as a process driven by differences in turgor pressure that occur between a sugar source (for example, leaves) and a sugar sink (for example, developing fruit) (Figure 38.25).

Assess and Discuss

Test Yourself

1. An aquaporin is
   a. a channel protein that allows the influx of K^+ into cells, causing water to also flow in between the phospholipids of the plasma membrane.
   b. a type of blue-colored pore in the epidermal surfaces of plants.
   c. a protein channel in plasma membranes that facilitates the diffusion of water.
   d. a transport protein, or transporter, in plasma membranes that uses protons to cotransport water.
   e. none of the above.
2. Why is turgor pressure a property of plant cells?
   a. Plant cells possess the necessary chloroplasts.
   b. Plant cells possess a cell wall, necessary for formation of turgor.
   c. Plant cells possess mitochondria, which provide the ATP needed for turgor.
   d. All of the above are true.
   e. None of the above are true.
3. How do plant cells avoid losing too much water in very cold, dry, or saline habitats?
   a. They balance the osmotic condition of their cytosol with that of the environment.
   b. Their epidermal cells are coated with waxy cuticle.
   c. They stabilize their membranes with sugars.
   d. They produce more aquaporin water channels to take maximum advantage of available moisture.
   e. All of the above.
4. What are ways in which plants accomplish tissue-level transport?
   a. transmembrane transport of solutes from one cell to another
   b. symplastic transport of materials from one cell to another via plasmodesmata
   c. apoplastic transport of water and dissolved solutes through cell walls and intercellular spaces
   d. All of the above are used for tissue-level transport.
   e. None of the above are used for tissue-level transport.
5. A root endodermis is
   a. an innermost layer of cortex cells that display characteristic Casparian strips.
   b. a layer of cells just inside the epidermis of a root.
   c. a layer of cells just outside the epidermis of a root.
   d. a group of specialized cells that occur within the root epidermis.
   e. none of the above.
6. Which of the statements listed best explains how water enters root cells from the soil?
   a. Roots accumulate sugars from shoots, thereby increasing root cell ability to absorb water by osmosis.
   b. Roots actively pump water from the soil using the chemical energy of ATP.
   c. Water enters the spongy spaces between cells and within cell walls.
   d. Membrane-level transport of ions from soil into root hair cells increases the osmotic flow of water into them.
   e. Both c and d are correct.
7. What features of water explain how it can be drawn up a tall tree from roots to leaves?
   a. cohesion, the result of extensive hydrogen bonding
   b. adhesion, water's tendency to stick to surfaces such as the inner walls of tracheid and vessels
   c. high surface tension that develops when water evaporates from intercellular leaf spaces
   d. all of the above
   e. none of the above
8. What feature of vascular plants contributes to their ability to maintain relatively stable internal water content?
   a. a waxy surface cuticle
   b. an extensive root system that mines water from soil
   c. specialized water-conducting tracheary elements composed of dead cells
   d. epidermal pores that open and close
   e. All of the above are contributing features.
9. What structural features of guard cells foster their ability to form an open pore in plant epidermal surfaces?
   a. thickened inner cell walls and radially oriented microfibrils
   b. thickened outer cell walls and radially oriented microfibrils
   c. thickened inner cell walls and longitudinal microfibrils
   d. thickened outer cell walls and longitudinal microfibrils
   e. uniform thickness of cell walls and randomly arranged microfibrils
10. What substances plug wounded sieve-tube elements, thereby preventing the leakage of phloem sap?
    a. X protein and callose
    b. C protein and callose
    c. P protein and callose
    d. P protein and sucrose
    e. none of the above

Conceptual Questions

1. Why is it a bad idea to overfertilize your houseplants? If the amount recommended on the package is good, wouldn't more be better?
2. Why is it a bad idea for subsistence farmers (those barely able to grow enough crops to feed themselves) to allow livestock to graze natural vegetation to the point that it disappears?
3.  A principle of biology is that *living organisms interact with their environment.* In the arid southwestern U.S., the ocotillo plant is often used as a landscaping plant, because of its interesting shape and beautiful floral displays. Imagine that you are responsible for property landscaped with ocotillo but find the plants bare of leaves. Can you assume that the plants are dead and need to be replaced?

Collaborative Questions

1. Imagine that you are part of a team assigned to determine what environmental conditions best suit a new crop so that the crop can be recommended to farmers in appropriate climate regions. What features of the crop plants might you investigate?
2. Take a look outside or imagine a forest or grassland. What can you deduce about the availability of soil water from the types of plants that occur?

CHAPTER OUTLINE

39.2 Flower Production, Structure, and Development
39.3 Male and Female Gametophytes and Double Fertilization
39.4 Embryo, Seed, Fruit, and Seedling Development
39.5 Asexual Reproduction in Flowering Plants
Summary of Key Concepts
Assess and Discuss

Flowering Plants: Reproduction

39

The reproductive success of dandelions.

Dandelions sometimes seem to be taking over the world, growing abundantly in open, sunny areas. Bright yellow flower heads, as shown in the chapter opening photo, are one of the secrets of dandelions' success. If you pull a dandelion flower head apart, you can see that it is actually a bouquet of 200 or so small flowers. Each flower produces a tiny, one-seeded fruit equipped with a "parachute" for effective long-distance dispersal by wind. Each dandelion plant can produce up to 5,000 fruits during its lifetime, which explains how dandelions can spread so rapidly across a landscape.

Though most flowering plants produce seeds by means of sexual reproduction, dandelions and some other plants are able to produce seeds by a type of asexual reproduction, a process that does not involve the fusion of gametes. As a result, the traits of asexually reproducing dandelion parents and their progeny are uniform. Asexual reproduction could be very usefully applied in agriculture, because most crops reproduce only sexually. Each year many U.S. farmers buy and plant hybrid seeds that develop into mature plants having uniform and desirable trait combinations. Such farmers typically do not use seed from one year's crop to plant the next, because sexual reproduction mixes genes into diverse combinations present among the resulting seeds. For this reason, plants that grow from sexually produced seeds do not uniformly express the desirable trait combinations present in their hybrid parents. But if hybrid crop plants could be engineered to produce seed asexually, as dandelions do, farmers might be able to use seed from one crop to plant the next and continue to harvest uniformly desirable crops. Because reproduction is so important to agriculture, plant biologists aim to better understand both sexual and asexual reproduction in flowering plants.

Flowers, fruits, and seeds are essential reproductive features of the diverse types of flowering plants found in nature. This chapter begins with an overview of the reproductive cycle of flowering plants that describes how flowers, fruits, and seeds function. This overview provides essential background for a closer look at flower structure and development and some of the genes that control flower production and appearance. We will also examine the sexual reproductive processes by which plants produce gametes and accomplish fertilization, thereby producing zygotes, embryos, seeds, fruits, and seedlings. Finally, we will take a closer look at the ways in which dandelions and some other flowering plants reproduce without using the sexual process.

39.1 An Overview of Flowering Plant Reproduction

Learning Outcomes:

1. Explain how the sexual life cycle of flowering plants differs from that of earlier evolved mosses.
2. List the four organs found in many flowers and the functions of each organ.
3. Describe the phenomenon of double fertilization.
4. Describe the parts of an angiosperm seed, and explain how each part is produced and functions.

Most flowering plants display **sexual reproduction**, the process by which two gametes fuse to produce offspring that have unique combinations of genes. Flowering plants, also known as

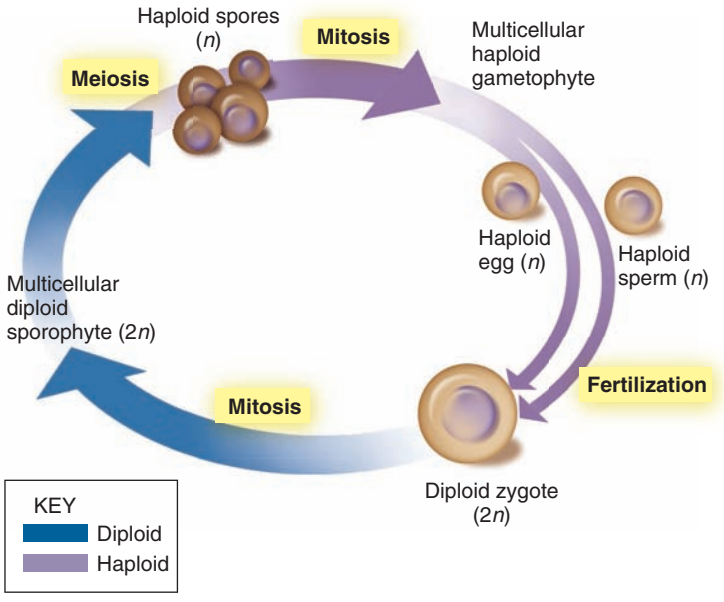
angiosperms, inherited their sexual life cycle, known as alternation of generations, from ancestors extending back to the earliest land plants (see Chapters 29 and 30). Though all plants share the same basic life cycle, flowering plants display unique reproductive features. In this section, we will first review the general features of alternation of generations and then consider more specific features of the angiosperm life cycle.

Flowering Plants Display Alternation of Generations

All groups of land plants produce two multicellular life cycle stages, in essence, two distinct plants. These two life cycle stages are the diploid, spore-producing **sporophyte** and the haploid, gamete-producing **gametophyte**. In all groups of plants, haploid spores are typically produced by diploid sporophytes via meiosis. These spores undergo mitotic cell divisions to produce multicellular gametophytes. Certain cells within the gametophytes differentiate into gametes. Thus, meiosis does not directly generate the gametes of plants. The processes of meiosis and fertilization form the transitions between the sporophyte and gametophyte life stages and link them in a cycle (**Figure 39.1**). The land plant life cycle is known as **alternation of generations** because it involves the cycling between distinct sporophyte and gametophyte generations.

During the evolutionary diversification of land plants, the sporophyte generation has become larger and more complex, while the gametophyte generation has become smaller and less complex. To illustrate this, let's compare the life cycle stages of mosses to those of angiosperms. Mosses diverged early in the history of land plants, whereas angiosperms appeared much later. During the intervening time, the relative sizes and dependence of the sporophyte and gametophyte generations changed dramatically. Moss sporophytes are small structures that always grow attached to larger, photosynthetic gametophytes, because moss sporophytes are incapable of independent life (**Figure 39.2a**). Moss sporophytes depend on gametophytes to supply them with essential nutrients.

In contrast, flowering plant sporophytes are notably larger and more complex than gametophytes. A tall oak tree, for example, is a single sporophyte. Oak gametophytes are few-celled, microscopic structures that develop and grow within flowers (**Figure 39.2b**). In addition, photosynthetic oak seedlings and trees grow independently, but nonphotosynthetic oak gametophytes depend completely on the sporophyte generation for their nutrition. A closer look at flower structure will help us to gain a more complete view of angiosperm gametophyte structure and function.



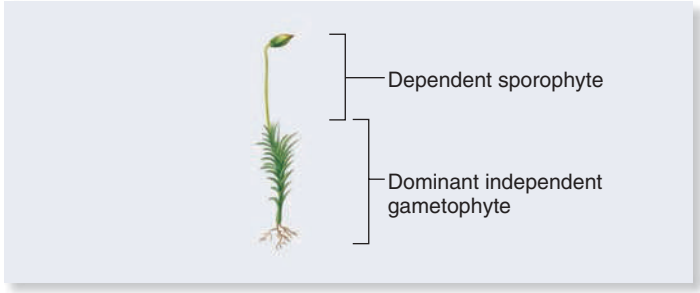


Figure 39.1 Alternation of generations, the plant life cycle.

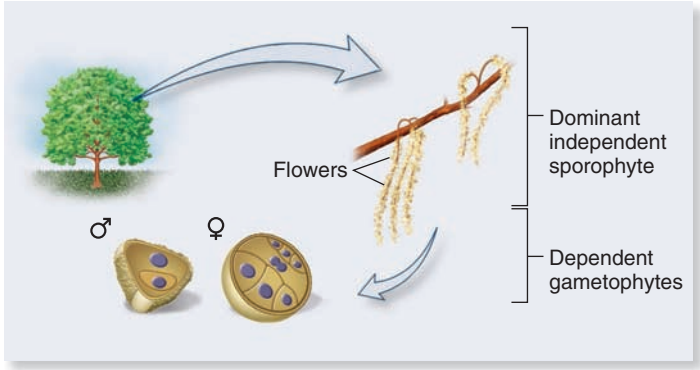
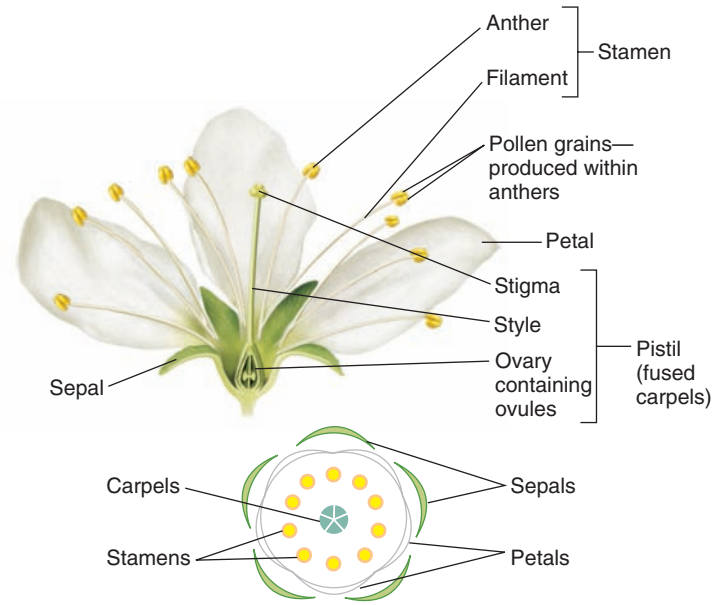


BioConnections: Look back to Figure 30.14 to see a more detailed illustration of the flowering plant life cycle. How can one recognize and where can one find the gametophyte generation of a flowering plant?

Flowers Produce and Nurture Male and Female Gametophytes

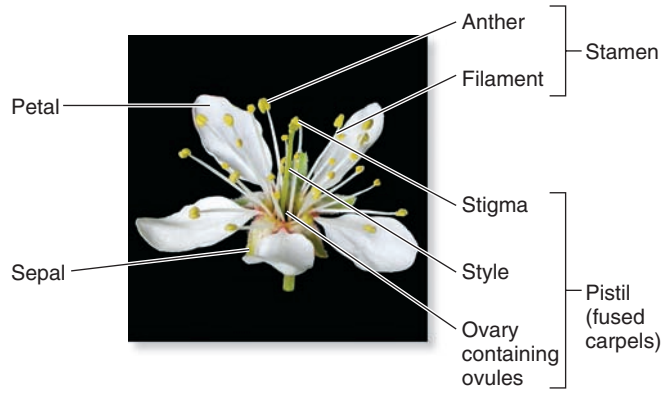
The literary wit Gertrude Stein famously paraphrased Shakespeare ("a rose by any other name would smell as sweet") when she wrote, "A rose is a rose is a rose." Everyone knows that a rose is a flower, but what, exactly, is a flower? A **flower** is defined as a reproductive

(a) Gametophyte-dominant bryophyte (moss)



(b) Sporophyte-dominant flowering plant (oak)

Figure 39.2 Evolutionary shift in life cycle stage dominance in plants. **(a)** In mosses, the gametophyte is the dominant life cycle stage, and the sporophyte depends on the gametophyte for resources. **(b)** In flowering plants such as oak trees, the sporophyte life cycle stage is dominant. Microscopic flowering plant gametophytes develop and grow within sporophytic flower tissues and depend completely on sporophytes.



Concept Check: What advantages do flowering plants obtain by having such small and dependent gametophytes?

shoot, a stem branch that produces reproductive organs instead of leaves. Flowers are organ systems because several different organs typically occur within a flower (see Chapter 35). Flower organs are produced by shoot apical meristems much like those that generate leaves and are thought to have evolved from leaflike structures by descent with modification (refer back to Figure 30.15). Most flowering plants are classified into one of two major groups, eudicots and monocots (Chapter 30).

Most eudicot flowers contain four types of organs: sepals, petals, stamens, and carpels (**Figure 39.3**). **Sepals** often function to protect the unopened flower bud. **Petals** usually serve to attract insects or other animals for pollen transport (refer back to Figures 30.19 and 30.20). Monocot flowers typically have tepals, which are outer flower parts that are not differentiated into petals and sepals. Monocots and eudicots alike produce stamens and/or carpels at the flower's center. **Stamens** and **carpels** each produce distinctive types of spores by the process of meiosis. From these spores, tiny multicellular gametophytes develop, and certain gametophytic cells become specialized gametes.

(a) Flower parts

(b) *Prunus americana* (plum)

Figure 39.3 The structure of a typical eudicot flower.

Concept Check: Do all flowers have all of the structures illustrated here?

Stamens Stamens produce **male gametophytes** and foster their early development. Most stamens display an elongate **filament**, which is topped by an anther (see Figure 39.3). Filaments contain vascular tissue that delivers nutrients from the parental sporophyte to the anthers. Each **anther** is a group of four sporangia, structures in which spores are produced. Within the anther's sporangia, many diploid cells undergo meiosis, each producing four tiny, haploid spores. Because they are so small, generally 25–50 μm in diameter, the spores produced within anthers are known as **microspores**. Immature male gametophytes, known as **pollen grains**, develop from microspores. The term pollen comes from a Latin word meaning fine flour, reflecting the small size of pollen grains. Pollen grains are eventually dispersed through pores or slits in the anthers. At the time of dispersal, the pollen grain is a two- or three-celled immature male gametophyte produced by mitotic division. During a later phase of development, a mature male gametophyte produces **sperm cells**.

Carpels Carpels are vase-shaped structures that produce, enclose, and nurture **female gametophytes**. Carpels contain veins of vascular tissue that deliver nutrients from the parent sporophyte to the developing gametophytes. The term **pistil** (named for its resemblance to the pestle used to grind materials to a powder) refers to a single carpel or several fused carpels (see Figure 39.3). The topmost portion of a pistil, known as a **stigma** (Greek, meaning mark), receives pollen grains. The **style** is the middle portion of the pistil, and an ovary is at the bottom of the pistil. The **ovary** produces and nourishes one or more ovules. An **ovule** of flowering plants consists of a spore-producing structure (a sporangium) and encloses tissues consisting of modified leaves, known as **integuments**. Within an ovule, a diploid cell produces four haploid **megaspores** by meiosis, three of which die. The surviving megaspore generates a female gametophyte by mitosis. The female gametophytes of flowering plants typically consist of seven cells, one of which is the female gamete, the **egg cell**. This basic information about male and female gametophytes helps in understanding how they function to produce a young sporophyte within a seed.

Fertilization Triggers the Development of Embryonic Sporophytes, Seeds, and Fruits

In flowering plants, fertilization leads to the production of a young sporophyte that lies within a seed, completing the life cycle (**Figure 39.4**). Prior to fertilization, pollen grains released from anthers first find their way to the stigma of a compatible flower, a process known as **pollination**. Some plants display **self-pollination**, in which pollen from the anthers of a flower is transferred to the stigma of the same flower or between flowers of the same plant. **Cross-pollination**, which occurs when a stigma receives pollen from a different plant of the same species, is also common. Many flowers are attractive to insects or other animals that transport pollen, whereas oak flowers and those of some other angiosperms are adapted for pollen transport by wind. A few plants move pollen by means of water currents. Flowers are adapted for effective pollination by diverse pollination mechanisms (refer back to Table 30.2).

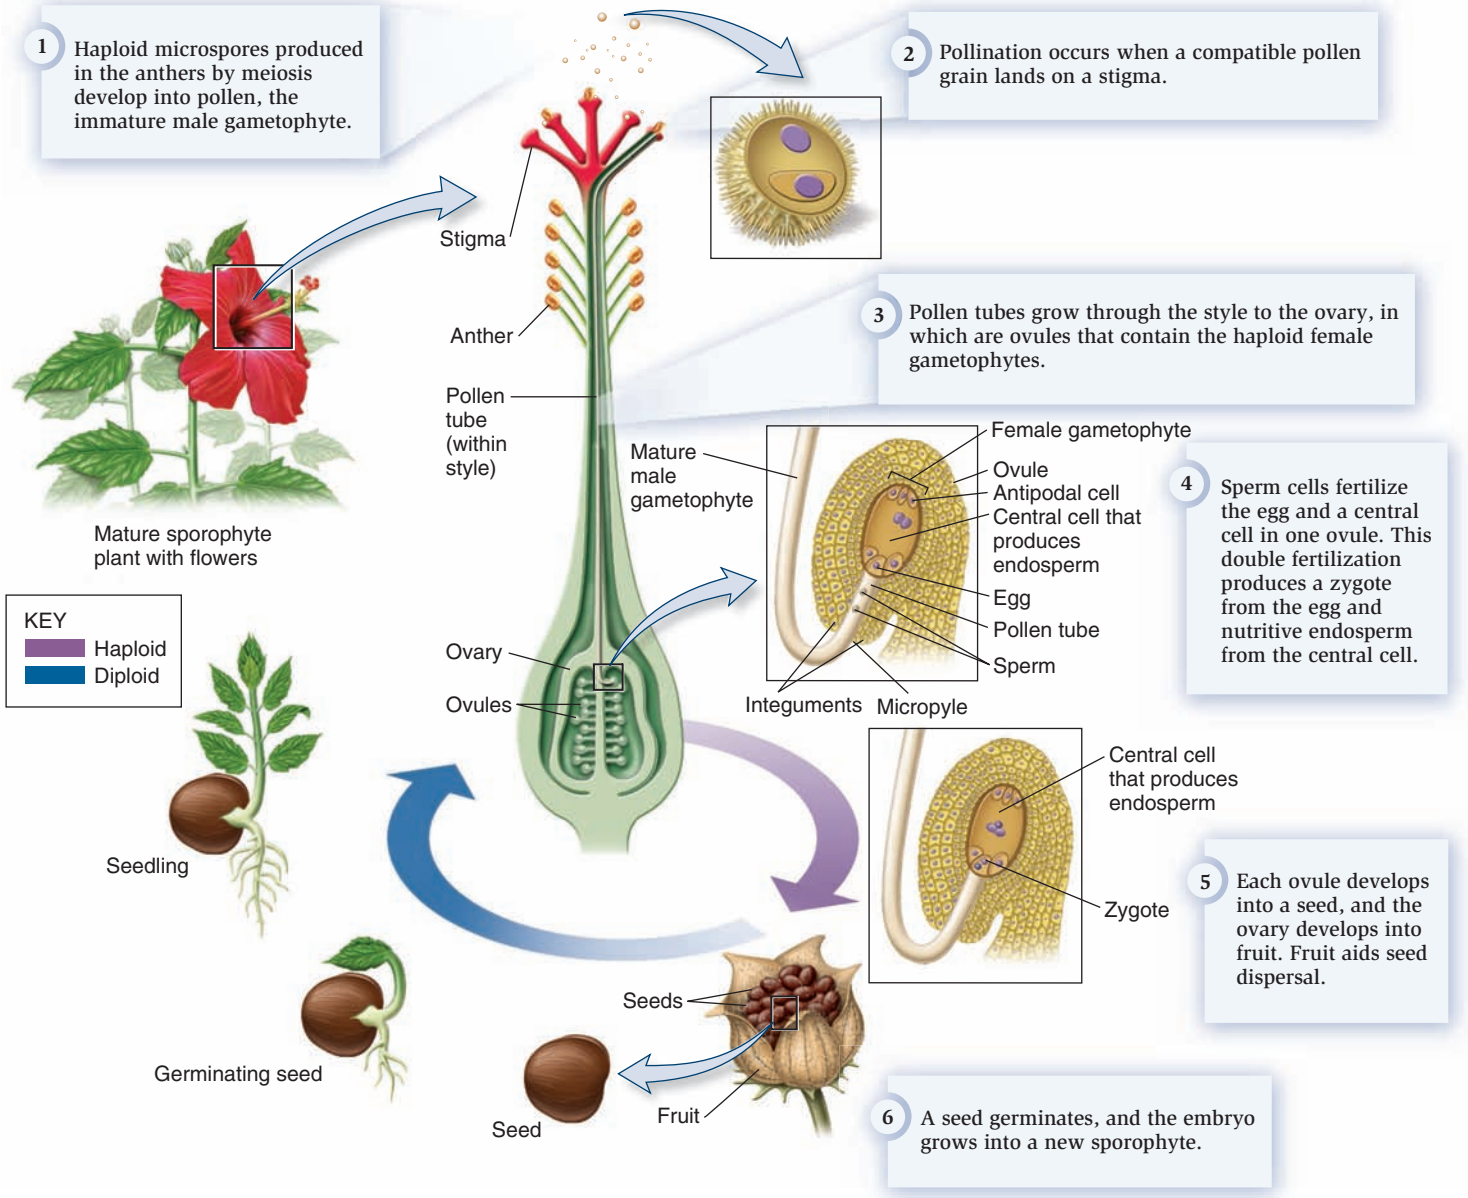


Figure 39.4 **The life cycle of a flowering plant.** The plant reproductive cycle is illustrated here by the eudicot hibiscus.

Concept Check: *What advantage does the hibiscus flower gain by clustering its stamens around the pistil?*

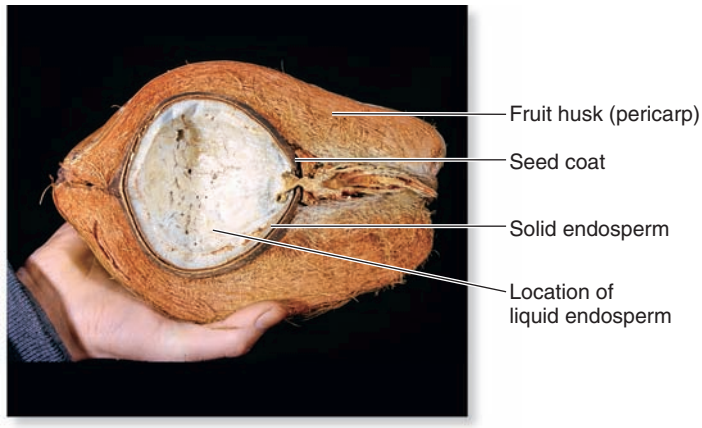
Pollen Germination When pollen grains land on the stigma, the stigma functions as a gatekeeper, allowing only pollen of appropriate genotype to germinate. During germination, a pollen grain produces a long, thin **pollen tube** that contains two sperm cells. The pollen tube grows through the style toward the ovary. Upon reaching the ovules, the pollen tube grows through the **micropyle**, an opening in the ovule, and delivers sperm to the female gametophyte (see Figure 39.4). These sperm unite with haploid cells of the female gametophyte in the process of **fertilization**. Note that pollination and fertilization are distinct processes in flowering plants.

Double Fertilization Angiosperms display a phenomenon known as **double fertilization**. In this process, two different fertilization events occur. One of the two sperm cells delivered by a pollen tube fertilizes the egg cell, thereby forming a diploid **zygote**. This zygote may develop by mitotic division into a young sporophyte, known as an **embryo**. Fertilization thus begins a new cycle of alternation between sporophyte and gametophyte generations. The other sperm delivered by the same pollen tube fuses with two nuclei present in one of the cells of the female gametophyte. The cell formed by this second fertilization undergoes mitosis, eventually producing a nutritive tissue known as the **endosperm**. The embryo and the endosperm are essential parts of maturing angiosperm seeds. Fertilization not only starts the development of zygotes into embryos but also triggers the transformation of ovules into seeds and ovaries into fruits. Embryo, seed, and fruit development occur at the same time.

Embryos and Seeds An embryo is a young, multicellular, diploid sporophyte that develops from a single-celled zygote by mitosis.

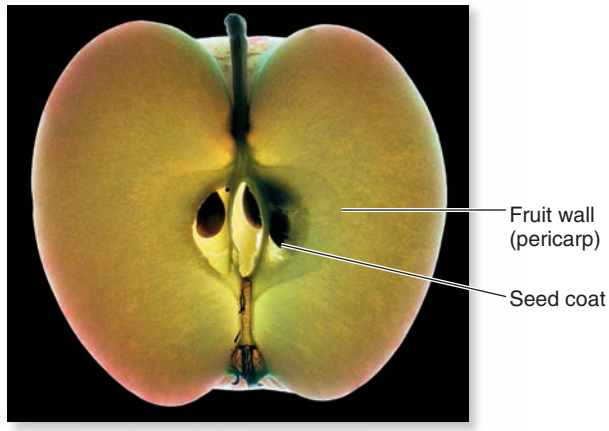
Because they are not yet capable of photosynthesis, embryos depend on sporophytes for organic food and other materials. Therefore, embryo development occurs within developing seeds located in a flower ovary. Seeds develop from fertilized ovules. Each developing seed contains an embryo and nutritive endosperm tissue, enclosed and protected by a **seed coat** that develops from the ovule integuments. When embryos and the seed coat have fully matured, they undergo drying, and the seed enters a phase of metabolic slowdown known as **dormancy**. Fully mature, dormant seeds are ready to be dispersed.

Fruit and Seed Dispersal A **fruit** is a structure that encloses and helps to disperse seeds (see Figure 39.4). Seed dispersal benefits plants by reducing competition for resources among seedlings and parental plants, and it allows plants to colonize new sites.



Fruits develop from the flower's ovary and sometimes include other flower parts. Young fruits bearing immature seeds are typically small and green. During the time that embryos and seeds are developing, the fruit also matures. The ovary wall changes into a fruit wall known as a **pericarp** (from the Greek, meaning surrounding the fruit). Mature fruits vary greatly among plant species in size, shape, color, and water content. These variations represent adaptations for seed dispersal in different ways. For example, single-seeded dandelion fruits are dry and lightweight and bear a fluffy "parachute" derived from the flower's sepals (see the chapter opening photo). These features foster dispersal by wind. In contrast, coconut fruits feature an airy husk (the pericarp) that keeps them afloat in ocean currents so that they can be carried from one tropical shore to another. Inside the coconut fruit is a single, large seed loaded with liquid and solid endosperm, which people consume as coconut milk and coconut meat, respectively (**Figure 39.5a**). These large amounts of endosperm provide nutrients that sustain coconut seedling growth on infertile, sandy shores. Fruit variation is also extremely important to wild animals and in human agriculture. For example, most fruit crops are juicy and sweet, with relatively small seeds (**Figure 39.5b**). In nature, these features foster dispersal by birds and other animals that feed on such fruits.

Seed Germination and Seedlings If a dispersed seed encounters favorable conditions, including sufficient sunlight and water, it will undergo seed **germination**. During seed germination, the embryo absorbs water, becomes metabolically active, and grows out of the seed coat, producing a seedling. If the seedling obtains sufficient nutrients from the environment, it grows into a mature sporophyte capable of producing flowers. In the next section, we will focus on flower production, structure, and development.



39.2 Flower Production, Structure, and Development

Learning Outcomes:

1. List some examples of particular genes that control flower production or shape.
2. Give an example of how gene expression affects flowering time or flower appearance.
3. **SciSKILLS** » Explain recent research findings on how flowers bloom, that is, open up from a closed bud.

(a) Coconut fruit and seed

(b) Apple fruit and seed

Figure 39.5 Fruit adaptations for seed dispersal. **(a)** The coconut fruit's outer wall, called a husk, allows the fruit to float and thus disperse its seed among tropical shores. **(b)** The apple is a juicy, sweet fruit that attracts animals to consume it, thereby helping to disperse its seeds.

Flowers are essential sources of food for many animal pollinators. As the result of coevolutionary relationships with such animals, flowers occur in a spectacular array of colors and forms that attract particular pollinators (refer back to Table 30.2). Flowers also attract humans because we possess sensory systems much like those of animal pollinators. We give bouquets to show love and appreciation; decorate homes, workplaces, and objects with flowers; display flower arrangements on ceremonial occasions; and make perfume from flowers. Consequently, many types of flowers are grown for the florist and perfume industries. Flowers are also necessary for the production of grain and other fruit crops. For these and other reasons, biologists investigate how flower development is controlled by environmental signals and changes in gene expression.

Environmental Signals Interact with Genes to Control Flower Production

You've probably noticed that different plants flower at particular times of the year. How do plants know when to flower? Flowering time is controlled by the integration of environmental information

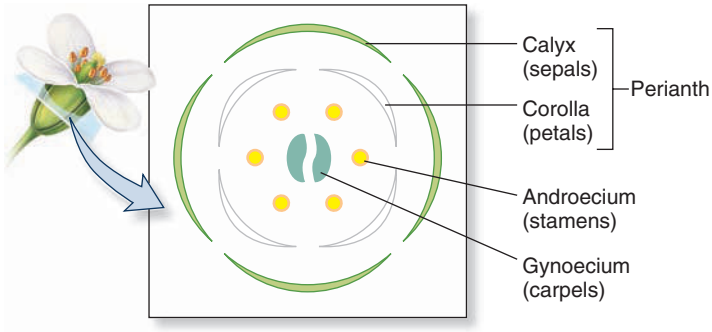
such as temperature and day length (photoperiod) with hormonal influences and circadian rhythms (see Chapter 36). These stimuli are perceived and integrated by leaves, which then use a mobile protein known as FT (for Flowering locus Time) to signal shoot meristems to produce flowers. FT protein travels in the phloem to shoot meristems and interacts with other proteins there, initiating the process by which a leaf-producing apical meristem transforms into a reproductive meristem.

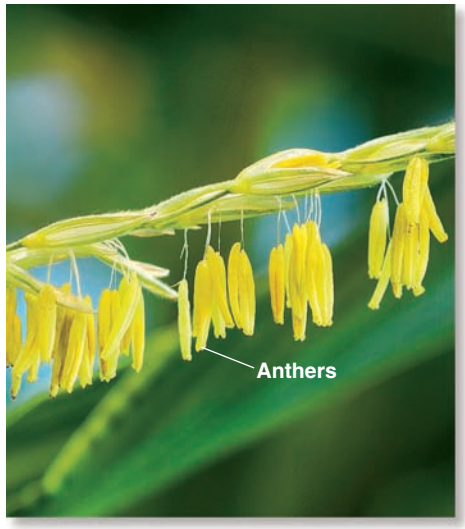
Some plants—such as winter wheat—are planted and sprout in fall, are dormant in winter, and flower in the following spring. In these plants a transcription factor known as FLC (for Flowering Locus C) represses flowering genes, thereby preventing flowers from appearing too soon. Exposure to cold winter conditions causes the production of a small RNA molecule that silences FLC, allowing these plants to flower when the appropriate day length occurs in spring. The process by which cold exposure allows plants to flower in spring is known as vernalization.

Developmental Genes Control Flower Structure

Organ identity genes specify the four basic flower organs that occur in eudicot flowers—sepals, petals, stamens, and carpels. Other genes determine flower shape, color, odor, or grouping into bunches known as inflorescences.

The Genetic Basis of Flower Organ Identity Sepals, petals, stamens, and carpels occur in four concentric rings known as **whorls**. Sepals (collectively known as the calyx) form the outermost whorl, and petals (together known as the corolla) form an adjacent whorl type. Stamens (together, the androecium) create a third type of whorl, and carpels (the gynoecium) form the innermost whorl (**Figure 39.6**). The **perianth** consists of the calyx plus the corolla. In monocot flowers, such as those of lilies, the perianth consists of tepals rather than petals and sepals. You may recall that *A*, *B*, *C*, and *E* genes encode transcription factors that control the production and arrangement of these whorls (refer back to Figure 19.24).





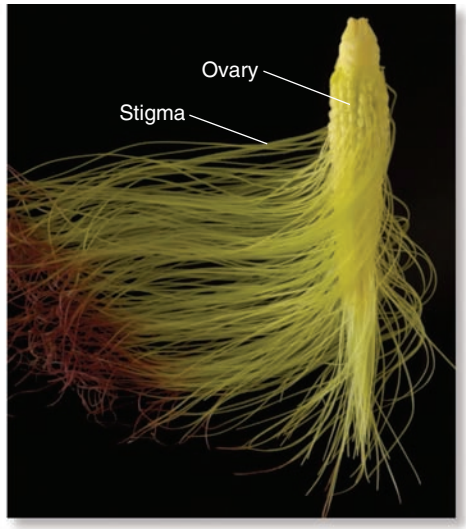


Figure 39.6 The occurrence of eudicot flower parts in concentric whorls.

Variation in Number of Whorls Eudicot flowers that possess all four types of flower whorls—calyx, corolla, androecium (stamens), and gynoecium (one or more carpels)—are known as **complete flowers**. Complete monocot flowers possess tepals, androecium, and gynoecium. In contrast, flowers that lack one or more flower whorls are described as **incomplete flowers**. Flowers having both stamens and carpels are said to be **perfect flowers**, whereas flowers lacking stamens or carpels are described as **imperfect flowers**. An imperfect flower that produces only carpels is known as a carpellate flower (or pistillate flower). Imperfect flowers that produce only stamens are described as staminate flowers.

Corn produces both imperfect staminate and carpellate flowers on an individual plant (**Figure 39.7**). The flowers of corn start to develop as perfect flowers, but in carpellate flowers, the stamens stop developing. After pollination and fertilization, each carpellate flower produces one of the kernels on a cob of corn. In contrast, staminate flowers of corn, which are found in corn tassels, produce the pollen. Corn is termed **monoecious** (meaning one house) because it produces staminate and carpellate flowers on the same plant. Holly and willow also produce staminate and carpellate flowers, though on separate plants, and are examples of plants described as **dioecious** (meaning two houses).

(a) Staminate flowers of *Zea mays* (corn)

(b) Carpellate flowers of *Zea mays* (corn)

Figure 39.7 Imperfect flowers of corn, a monoecious plant. **(a)** Staminate flowers lack carpels, and **(b)** carpellate flowers lack stamens, but both types of flowers occur on a single corn plant. In contrast, dioecious plants produce staminate and carpellate flowers on separate plants. These features foster cross-pollination.

Concept Check: *What inference can you draw from the observation that flowers of corn lack showy petals?*

Variation in Flower Organ Number In addition to variation in whorls, flowers vary in number of organs. Also, in addition to the differences in perianth structure that we have noted, eudicots and monocots commonly differ in number of flower organs (refer back to Table 35.1). Eudicot flower organs usually occur in fours or fives or a multiple of these numbers. By contrast, monocot flower organs typically occur in threes or a multiple of three. Other flowers possess relatively few organs. For example, the minuscule flowers of the tiny aquatic flowering plant *Lemna gibba* produce no perianths and only two stamens.

Many plants sold for use in gardens have been bred so that the flowers produce multiple organs. Garden roses, for example, typically have many more whorls of petals than do wild roses. This change results from a mutation that causes organs that would have become stamens to instead develop into additional petals.

Variation in Flower Color Different flower parts may vary in color. The calyx and corolla of monocot flowers such as tulip and lily are often similar in appearance and attractive function. In contrast, eudicot flowers tend to have green, leaflike sepals (see Figure 39.3) that are quite distinct from petals, which are often colorful and fragrant. Color variations arise from differences in gene action that influence the pathways by which plants synthesize pigments.

In 1990, American plant molecular biologist Rich Jorgensen and colleagues reported one of the first cases of gene silencing in plants. Gene silencing occurs when miRNA and siRNA block gene expression (see Chapter 13). In an attempt to produce flowers of deeper color, the researchers introduced an extra copy of a pigment-producing gene into petunia plants. To their surprise, the extra copy of the gene sometimes produced flowers whose petals had white patches or were completely white (**Figure 39.8**). Adding the extra gene caused the plants to produce short-interfering RNA (siRNA) that not only silenced the expression of the extra gene, but also the natural pigment-producing genes, causing white patches on the petals.

Variation in Flower Fragrance The fragrances of flowers result from secondary metabolites that diffuse into the air from petals and other flower organs. One example is the terpene known as geraniol that gives roses their distinctive fragrance. Diverse fragrances function to attract particular types of animal pollinators. Because humans possess sensory systems similar to those of many pollinators, we are also attracted to many of these fragrances. Genetic variation in the synthesis of different types of secondary metabolites is responsible for the many types of flower scents.

Flower Shape Variation Resulting from Organ Fusion During their development, many flowers undergo genetically controlled fusion of whorls or fusion of the organs within a whorl. For example, pistils are often composed of two or more fused carpels. In addition, stamen filaments often partially fuse with the carpel or form a tube surrounding the pistil, a feature displayed by hibiscus flowers (see Figure 39.4). Each small dandelion flower has five petals that are fused at their sides to form a single strap-shaped structure. Some flowers have petals that are fused together to form a tube that holds nectar consumed by animal pollinators.

Variations in Flower Symmetry and Aggregation Flower shape variation can also result from changes in symmetry. Flowers that possess radial symmetry are described as regular, actinomorphic, or polysymmetric flowers. Flowers having radial symmetry can be divided into two equal parts by more than one plane inserted through the center of the flower. In contrast, flowers that display bilateral symmetry are known as irregular, zygomorphic, or monosymmetric flowers. Flowers having bilateral symmetry can be divided into two equal parts by only a single plane inserted through the center.

Symmetry, like other flower features, is under genetic control. The production of flowers having bilateral symmetry is controlled by transcription factors such as those encoded by the *CYCLOIDEA* gene. For example, snapdragon (*Antirrhinum majus*) flowers are

(a) Normal purple petunia flowers **(b) Petunia flower affected by siRNA**

Figure 39.8 Gene silencing and flower color in petunias. **(a)** Normal purple petunia (*Petunia hybrida*) flowers produced by the expression of all genes involved in flavonoid synthesis. **(b)** Flower of a genetically engineered plant displays petal tissues in which expression of one of the genes needed for production of purple pigment production has been silenced (suppressed) by siRNA.

(a) Normal snapdragon flower

(b) Snapdragon flower with *CYCLOIDEA* mutation

Figure 39.9 Genetic control of flower symmetry. **(a)** Normal snapdragon flowers, with functioning *CYCLOIDEA* genes, are bilaterally symmetric. **(b)** Snapdragon plants carrying mutations in the *CYCLOIDEA* gene produce flowers that have radial symmetry.

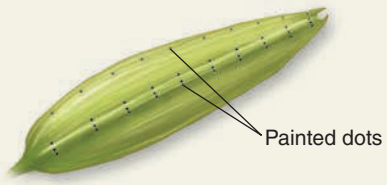
BIOLOGY PRINCIPLE The genetic material provides a blueprint for reproduction. This principle is illustrated by a comparison of normal and mutant snapdragon flowers.

normally bilaterally symmetric, but a loss-of-function mutation in the *CYCLOIDEA* gene causes these flowers to display radial symmetry (**Figure 39.9**). Another interesting example is the cut-flower crop plant *Gerbera hybrida*, whose "flowers" are actually **inflorescences**, groups of flowers clustered together. Although many flowers occur singly, many others occur in inflorescences of diverse types that are adapted to particular pollination circumstances. As in the case of sunflowers (refer back to Figure 30.20b), *Gerbera* flowers occur in more than one structural type having distinctive functions. During inflorescence development, a transcription factor similar to those encoded by the *CYCLOIDEA* gene is expressed more strongly at the margins, so flowers in that position become bilaterally symmetric, whereas the centermost flowers of *Gerbera* are more radially symmetric (**Figure 39.10**). These central flowers produce stamens and therefore function to supply pollen. In contrast, stamens do not develop in the marginal flowers, and their petals fuse to form larger colorful structures that are specialized to attract pollinators.

Figure 39.10 An inflorescence. The clustering of flowers into a type of inflorescence known as a head, displayed here by a *Gerbera* daisy, is an adaptation that fosters pollination by insects.

Concept Check: List several ways in which the flowers at the rim of the Gerbera inflorescence differ from those at the center.

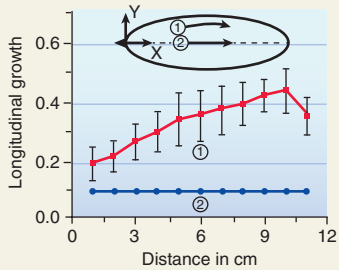
Feature Investigation | Liang and Mahadevan Used Time-Lapse Video and Mathematical Modeling to Explain How Flowers Bloom



Like the curled limbs of a human embryo within the womb, concave and overlapping petals occupy minimal space within a flower bud. But when flowers bloom, petals rapidly become convex, spreading outward from each other. Various hypotheses had been proposed to explain petal movements during the opening of flowers. One was that growth started at the midrib running along the center of each petal; another proposed that the blooming process was driven by differential growth rates of top and bottom petal surfaces. In 2011, Haiyi Liang and Lakshminarayanan Mahadevan reported a new explanation for blooming based on their studies of the Asiatic lily, *Lilium casablanca* (**Figure 39.11**).

The investigators placed cut stems bearing young green buds into water, in an environment of constant humidity, temperature, and light. To evaluate growth during blooming, they first painted small black dots 1 cm apart along the edges and centers of many tepals. (Recall that the flowers of monocot plants such as lily have similarly structured perianth parts known as tepals rather than separate petals and sepals.) By marking many tepals, the researchers repeated, or replicated, the experiment. Replication is key to the experimental process because it helps researchers avoid making erroneous conclusions that might be reached on the basis of just a few observations. Investigators then used time-lapse video to track changes in positions of the black dots during the opening of young green buds, until the flowers had fully bloomed $4^1/_2$ days later. This process allowed investigators to measure and graph growth strain at the petal edge versus the center. Strain is the ratio of the change in length of a material to the initial

Figure 39.11 Liang and Mahadevan used time-lapse video and mathematical modeling to explain how flowers bloom.

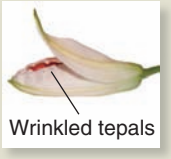


GOAL To better understand flower blooming.

KEY MATERIALS Asiatic lily, *Lilium casablanca*, cut stems with flower buds.

	Experimental level	Conceptual level
1 Paint small black dots at 1 cm intervals along edges and centers of perianth parts on replicate flower buds.		Compare rate of growth at center and edges of tepals.
2 Maintain cut stems at constant temperature, humidity, and light conditions for 4.5 days, until flowers open.		Avoid confounding the results due to environmental changes.
3 Set up an automatic time-lapse video system that records blooming at intervals of 1 minute.		Generates a record of changes in the positions of dots on tepals.
4 Use equations for growth of thin films to model tepal shape changes.		Compare model to video-based observations.

5 THE DATA



(1) The strain of longitudinal growth at tepal edges increases more rapidly than at centers.

(2) Simulation of the blooming process based on mathematical modeling matches observations made with time-lapse video.

6 CONCLUSION Lily blooming is caused by faster growth at the edges than at centers of tepals.

The blooming process suggests new ways to engineer the shapes of plastic sheets.

7 SOURCE Liang, H., and Mahadevan, L. 2011. Growth, geometry, and mechanics of a blooming lily. *Proceedings of the National Academy of Sciences* (USA) 108:5516–5521.

unstressed length. These measurements also enabled them to mathematically model changes in tepal shape, starting with equations that describe changes in the shapes of thin sheets (see Figure 39.11).

The biologists observed that by the end of the fourth day, each bud had absorbed one-fifth of a liter of water, increased in length by 10% and width by 20%, and turned white. The inner three tepals had become wrinkled, especially at the edges, a key clue to the mechanism underlying the blooming process. The wrinkling reflected faster growth at the edges than in the tepal's center. This difference in growth generated strain values large enough to cause the flower to bloom rapidly as individual tepals simultaneously reversed curvature and bent outward, a process predicted by mathematical modeling. The study revealed that flower blooming is based on a different mechanism than previously thought and illustrates the value of applying physics and mathematical models to biological phenomena.

Experimental Questions:

1. Why do you think Liang and Mahadevan used *Lilium casablanca* for their analysis of flower blooming?
2. How did time-lapse video improve data gathering in this study?

BIO TIPS **THE QUESTION** *By employing time-lapse video, Liang and Mahadevan determined that the blooming of lily flowers resulted from faster growth of the tepals at their edges than at their centers. Consider the data from their study in step 5 of Figure 39.11. How much faster was the longitudinal growth at the edges of the tepals than the longitudinal growth at the centers?*

TOPIC ***What topic in biology does this question address?*** The topic is flowering plant reproduction, or, more specifically, how flowers bloom, that is, open fully from the bud stage. Most people have observed flowers in stages of opening, but few have watched the process from start to finish. For this reason, the physical mechanism underlying flower blooming had not been clear until this experiment was performed.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** You know from this chapter that monocots such as lilies produce flowers whose perianth parts are known as tepals because they are not specialized into outer sepals and inner petals, as they are in eudicots. The outermost parts of the lily bud transform into petal-like tepals as the flower blooms. The investigators focused on the longitudinal (lengthwise) growth of the tepals.

PROBLEM-SOLVING STRATEGY ***Interpret data*** The data are presented in the form of line graphs based on video recordings of changes in the positions of black dots marked on the surfaces of lily buds. Compare the red line showing longitudinal growth at the tepal edges to the blue line showing longitudinal growth at the tepal centers.

ANSWER *Longitudinal growth of the tepals always occurred more rapidly at the edges than at the centers, and the maximal difference was more than 4 times (0.45/0.1).*

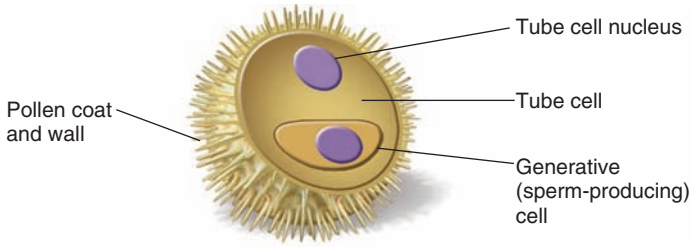
39.3 Male and Female Gametophytes and Double Fertilization

Learning Outcomes:

1. Explain how sperm production in plants differs from that in animals.
2. Discuss how the pistil controls pollen germination.
3. Describe the structure of the female gametophyte.
4. Outline the different fates of the two sperm cells transmitted by each pollen tube.

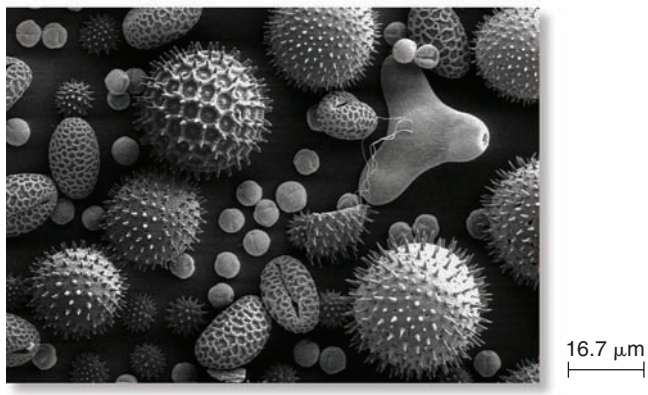
In flowering plants, mature male gametophytes are pollen tubes that deliver sperm cells, the male gametes. Mature female gametophytes are located within ovules and produce egg cells, the female gametes. In this section, we will focus on the structure and function of male and female gametophytes to learn more about how fertilization occurs.

Pollen Grains Are Immature Male Gametophytes



In animals, the cells that will produce gametes—known as the germ line—are set aside from other body cells during early development, but this is not the case for plants. Instead, plants make gamete-producing cells from body cells each time that stamens form, on an "as needed" basis. Plant sperm arise from male gametophytes. Immature male gametophytes, known as pollen grains, are produced within stamens.

Pollen grains develop within sporangia located in the anthers of stamens (see Figure 39.4). Sporangia are structures produced by all plants, within which meiosis generates spores. (Note that in plants, meiosis generates haploid spores, not haploid gametes as in animals.) Inside protective plant sporangia, diploid body cells produce a cluster of four haploid microspores, each having a thin cellulose cell wall. The development of microspores into pollen grains involves two processes that occur at the same time: (1) microspore division to produce a young male gametophyte, and (2) development of a tough pollen wall that protects the gametophyte during pollen



transport. Both of these processes are completed before the anthers release pollen.

Each microspore nucleus undergoes one or two mitotic divisions to form a young male gametophyte. The first division gives rise to two specialized cells: a tube cell and a generative cell suspended within the tube cell (**Figure 39.12a**). The **generative cell** divides to produce two sperm cells, either before or (more commonly) after pollination. The **tube cell** produces the pollen tube, which delivers sperm to the female gametophyte.

A mature pollen grain has a tough wall, and each plant species produces pollen whose wall has a distinctive sculptural shape (**Figure 39.12b**). The pollen wall, which surrounds the plasma membrane of the tube cell, is composed largely of a tough polymer known as sporopollenin. Named for its presence on the surfaces of mature spores and pollen, sporopollenin protects spores and pollen from damage. Development of the pollen wall starts with deposition of a blanket of the carbohydrate callose around each cluster of four microspores after they form by meiosis. The callose blanket seals microspores off from the influences of adjacent sporophyte tissues, thereby aiding pollen differentiation. Callose also provides a surface pattern for sporopollenin deposition and holds microspores together until an anther enzyme degrades the callose, freeing pollen grains from each other. As pollen grains mature, anther cells secrete a pollen coat, a layer of material that covers the sporopollenin-rich pollen wall. Coat materials include additional sporopollenin, pigments that give pollen its typically yellow, orange, or brown coloration, and lipids and proteins that aid in pollen attachment to carpels. Certain of these pollen coat compounds are responsible for allergic reactions in people exposed to particular types of airborne pollen. About 10% of flowering plants are wind-pollinated, and such plants produce copious amounts of pollen. For example, ragweed plants (genus *Ambrosia*), which are commonly associated with allergies, each produce an estimated 1 billion pollen grains during a year.

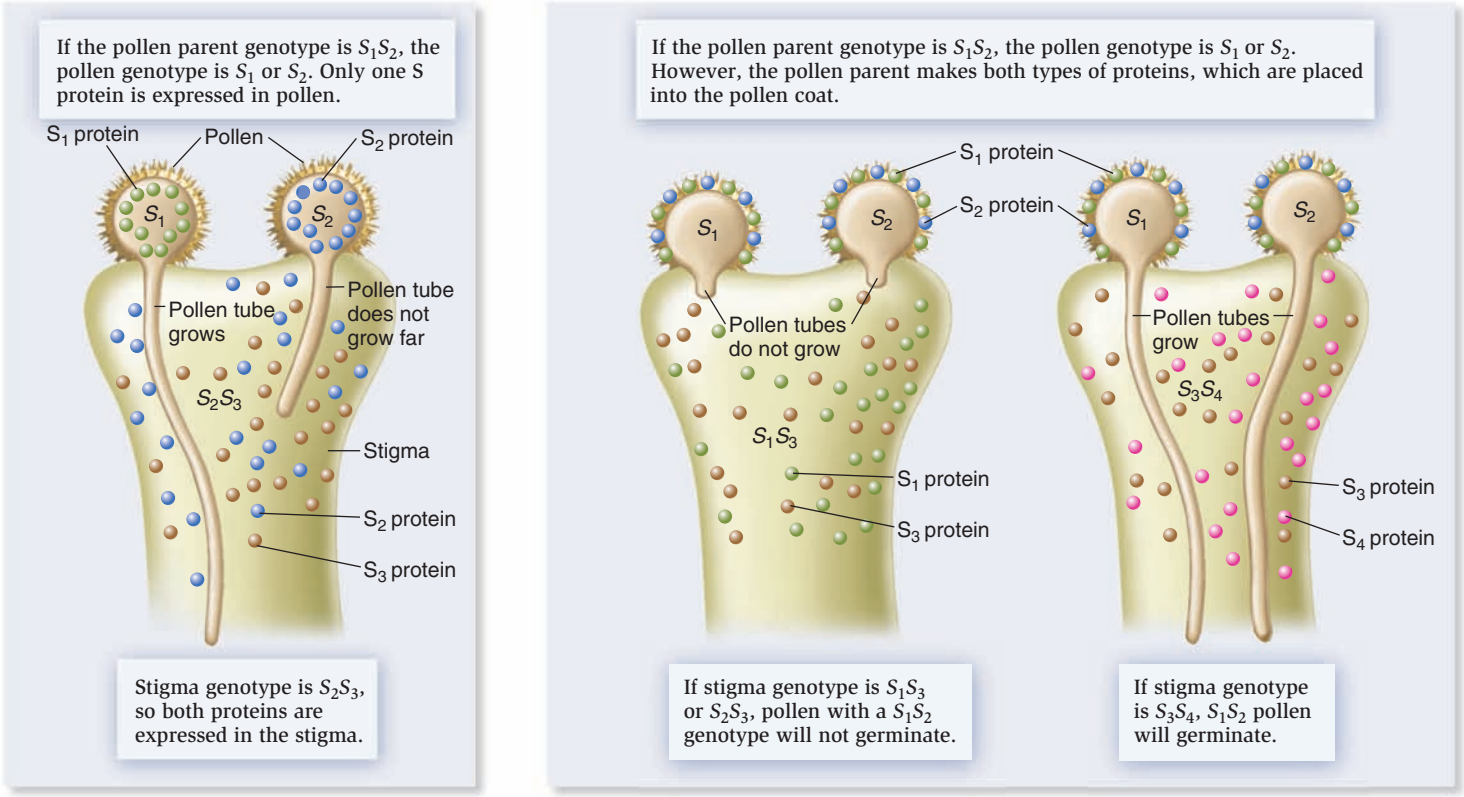
Concept Check: *What is the maximum number of cells in a mature male gametophyte of a flowering plant?*

After Pollination, the Pistil Controls Pollen Germination

Recall that pollination is the process by which pollen is delivered to surfaces of the stigma, the uppermost part of the flower pistil. However, even if a pollen grain reaches the stigma of the right flower species, it may not be able to germinate and produce a sperm-delivery tube. The stigma and the style determine whether or not pollen grains germinate and pollen tubes grow toward ovules. How is this accomplished?



About half of plant species can serve as both mother and father to their progeny, because pollen produced by those plants is able to germinate on pistils of the same plants. Such self-pollinating plants are said to display **self-compatibility (SC)**. By contrast, plants that prevent the germination of pollen that is too genetically similar to the pistil are said to display **self-incompatibility (SI)**. Similar to human cultural practices that prevent mating between close relatives, SI helps to decrease the likelihood of recessive disorders in offspring. In many plants, SI involves the *S* gene locus, which encodes S proteins. Each locus contains genetic sequences that determine pollen compatibility traits and pistil compatibility traits. Multiple *S* alleles for both genes occur in plant populations.

Two major types of SI are known: gametophytic SI and sporophytic SI. Gametophytic SI occurs when one or more *S* genes within pollen determine compatibility by encoding S proteins located in the pollen cytosol. When the gametophyte controls compatibility, tubes may start to grow from incompatible pollen, but S proteins encoded by pistil cells enters the tubes and destroys the pollen tube RNA. This halts tube growth. In contrast, S protein within genetically compatible pollen binds the pistil-produced protein, thereby preventing destruction of pollen tube RNA and allowing tube growth to continue (**Figure 39.13a**).

Sporophytic SI occurs when pollen compatibility is determined by the sporophyte that produces the pollen. This control is exerted when anthers deposit proteins into the pollen coat. When the sporophyte controls compatibility, pollen cannot germinate when S proteins in the plasma membranes of stigma cells recognize (bind) the S proteins of incompatible pollen. In this case, protein binding leads to signal transduction processes that prevent pollen germination. However, pollen can germinate if stigma proteins are unable to bind genetically distinct S proteins in its coat (**Figure 39.13b**).

A Female Gametophyte Develops Within Each Ovule

Each ovule produces a single female gametophyte that often consists of seven cells and eight nuclei (**Figure 39.14**). One of these cells is an egg cell, which lies wedged between two cells known as **synergids**. These synergids help move nutrients from the larger sporophyte to the nonphotosynthetic female gametophyte. Synergids also produce small proteins that attract pollen tubes. As a pollen tube approaches,

(a) Gametophytic SI: If pollen *S* allele does not match either stigma allele, pollen will germinate.

(b) Sporophytic SI: If pollen coat S proteins do not match either stigma S protein, pollen tubes will grow.

Figure 39.13 Self-incompatibility. Self-incompatibility helps plants to avoid the combination of gametes that are too genetically similar. It is controlled by interactions between chemical constituents of pollen and the pistil. **(a)** In gametophytic self-incompatibility, compatibility between pollen and pistil is determined by the haploid genotype of the pollen. In this case, pollen S protein is located in the cytosol. **(b)** In sporophytic self-incompatibility, compatibility between pollen and pistil is determined by the sporophyte that produced the pollen and contributed S proteins to its coat.

synergids use molecular communication processes to detect the tube and help prepare the egg cell to be fertilized. The other four cells of the angiosperm female gametophyte consist of three antipodal cells, whose functions are not well understood, and a large **central cell** that contains two nuclei. This central cell and the egg cell are involved in the process of double fertilization.

Pollen Tubes Deliver Sperm Cells That Accomplish Double Fertilization

When pollen grains germinate successfully, they take up water, and the tube cell produces a long pollen tube. Within the tube, the generative cell divides by mitosis to produce two sperm cells. To deliver sperm to female gametophytes, the tube must grow at its tip from the stigma, through the style, to reach the ovule (**Figure 39.15**). Tip growth is controlled by the tube cell nucleus. During tip growth, new cytoplasm and cell-wall material are added to the tip of an elongating cell. Pollen tubes have been observed to grow toward ovules at about 0.5 mm per hour, commonly taking from 1 hour to 2 days to reach their destination. When a pollen tube encounters an ovule, it enters through the micropyle and penetrates a female synergid. The tube then stops growing, and its thin tip wall bursts, releasing the sperm. The bursting process propels the two sperm toward the egg and the central cell. One sperm nucleus fuses with the egg cell to produce

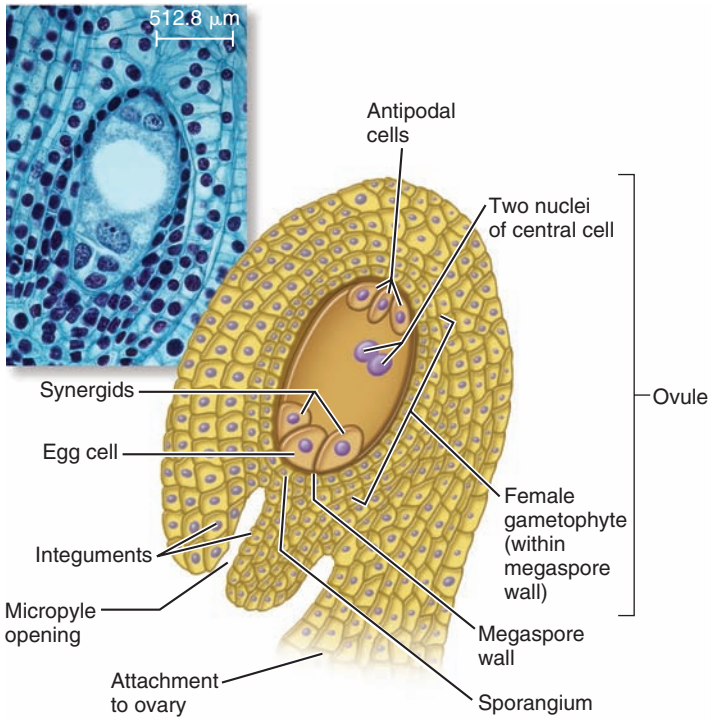


Figure 39.14 Angiosperm female gametophyte within an ovule.

Concept Check: *How do female gametophytes obtain nutrients?*

a zygote, the first cell of a new sporophyte generation (see step 4 in Figure 39.4). The other sperm fuses with the two nuclei of the central cell to form the first endosperm cell (see step 5 in Figure 39.4). The term double fertilization arises from these two processes.

The zygote and fertilized central cell have dramatically different fates. The endosperm absorbs protein, lipid, carbohydrates, vitamins, and minerals from the mother plant and stores these nutrients. The stored nutrients provide material and energy needed by the zygote to develop into an embryo and by the embryo to develop into a seedling. The nutritive role of endosperm explains why a large percentage of human and animal food comes from seed endosperm of grain crops; corn, wheat, rice, and other grain crops generate more than 380 billion pounds of endosperm per year in the U.S. alone. You might wonder why the embryo and endosperm resulting from double fertilization have such different fates despite similar genetic composition. Part of the answer is that during its development, plant endosperm undergoes genomic imprinting by DNA methylation, a process also known to occur in mammals (see Figure 17.12). The imprinting process causes gene expression to occur differently in plant endosperm than it does in the embryo.

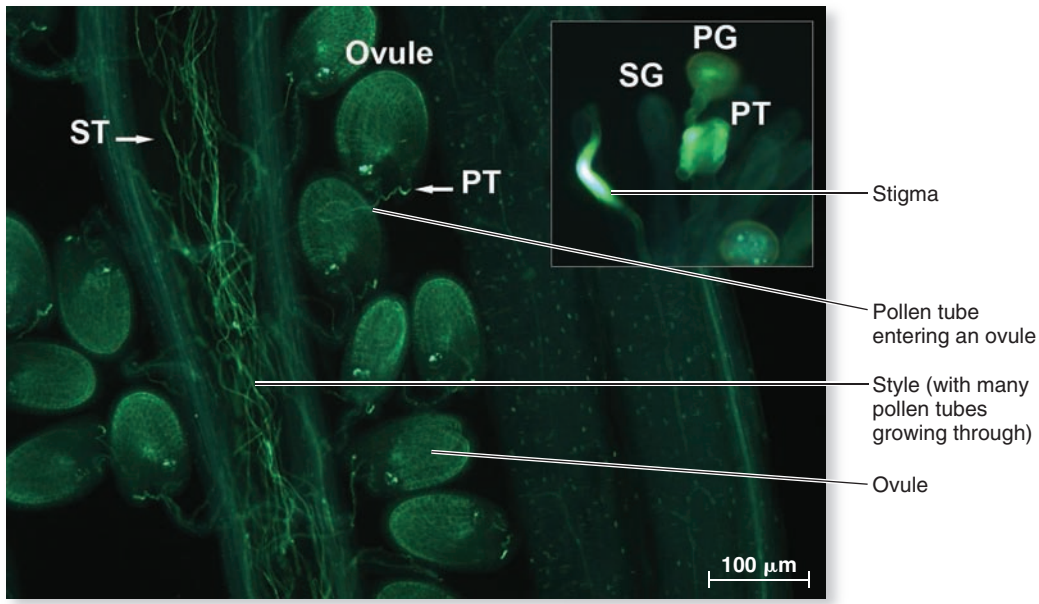

Figure 39.15 Pollen tubes delivering sperm to ovules. This fluorescence microscopic view shows pollen grains (the pale objects) germinating on the stigma surface (SG) and pollen tubes (PT) growing through the style (ST) toward ovules.

BioConnections: Look forward to Figure 51.5, which illustrates the male sexual organ of humans, an adaptation that allows internal fertilization. How is the mature male gametophyte of plants like a human penis?

39.4 Embryo, Seed, Fruit, and Seedling Development

Learning Outcomes:

1. Discuss the major stages in angiosperm embryo development.
2. List examples of environmental and internal factors that influence seed germination.
3. Explain how seed germination varies among plants.

Seeds and fruits are major components of plant reproduction and are essential to the nutrition of animals, including humans. Seeds contain dormant plant embryos that may develop into seedlings under favorable conditions. As noted earlier, fruits aid seed dispersal, which allows plants to colonize new sites. Embryos, seeds, and fruits mature simultaneously, and their development is coordinated by hormonal signals that were introduced in Chapters 35 and 36. Seedling development is also hormonally regulated.

Embryos Develop from Zygotes

Fueled by endosperm nutrients, angiosperm embryos undergo development in a series of stages known as **embryogenesis** (**Figure 39.16**). Sometime within a period of days to several weeks following fertilization, a zygote begins to divide. At this point, a zygote is blanketed with a layer of callose, which helps to seal it off from the environment, thereby fostering embryo-specific gene expression. The zygote's first cell division is unequal, producing a smaller cell and a larger cell (Figure 39.16, step 1). This unequal division helps to establish the apical-basal (top-bottom) polarity of the embryo, which persists through the life of the plant. The smaller cell develops into the embryo, whose radial symmetry is established at this point and continues in adult plants. The larger cell develops into a **suspensor**, a short chain of cells anchored near the micropyle at the ovule entrance (Figure 39.16, step 2). The suspensor channels nutrients and hormones into the young embryo, which absorbs them at its surfaces.

Young eudicot embryos are spherical, but they soon become heart-shaped as the seedling leaves, called **cotyledons**, start to develop. At this point, auxin and a mobile transcription factor are involved in establishing the young shoot and root at the apical and basal poles, respectively. This process is also influenced by the TOPLESS protein, which helps to repress auxin-response genes that would otherwise promote root development at the apical pole. (Mutants that have lost normal *TOPLESS* function have roots at both apical and basal poles, but no shoots, and are thus topless.) Eudicot embryos such as *Arabidopsis* then become torpedo-shaped, and as the cotyledons grow, they often curl to fit within the developing seed (Figure 39.16, step 4). In contrast, mature monocot embryos are cylindrical, with a single cotyledon and a side notch where the apical meristem forms.

Mature Seeds Contain Dormant Embryos

As seeds mature, they undergo changes leading to dormancy, an adaptation that prevents them from germinating when environmental conditions are not suitable for seedling growth. During

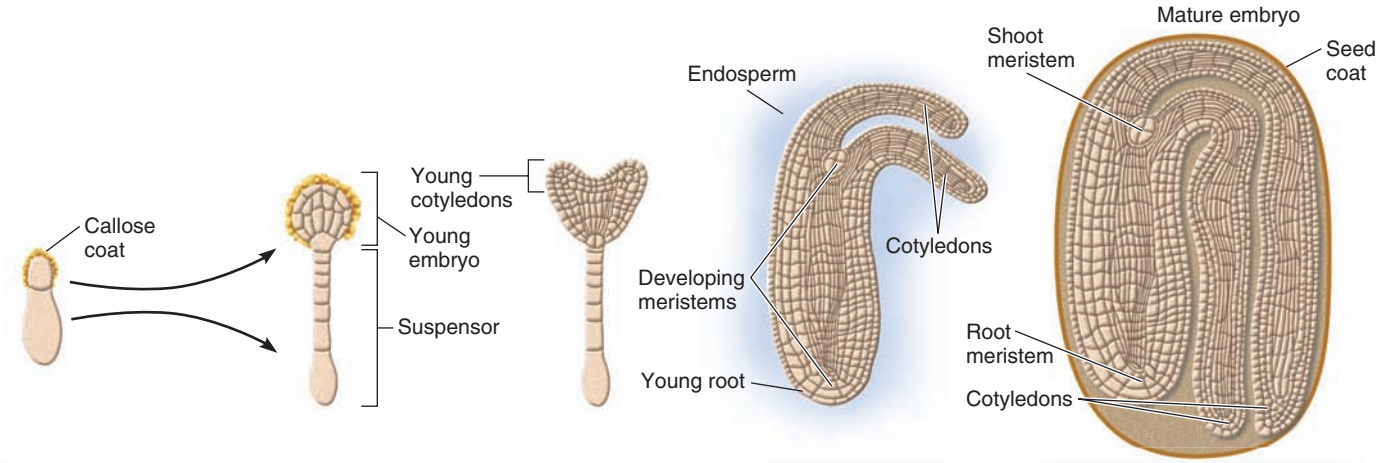

Figure 39.16 **Embryogenesis in the eudicot *Arabidopsis*.**

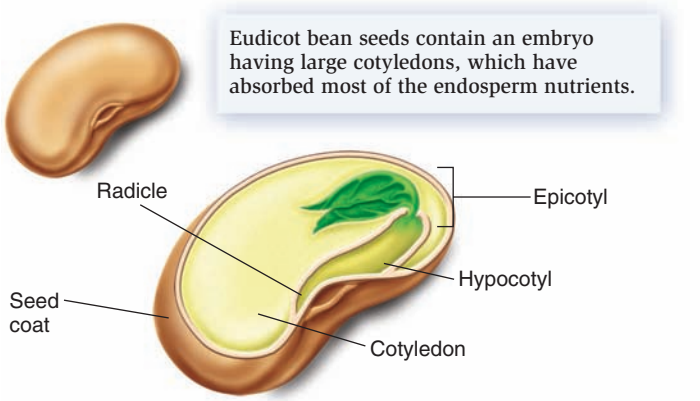
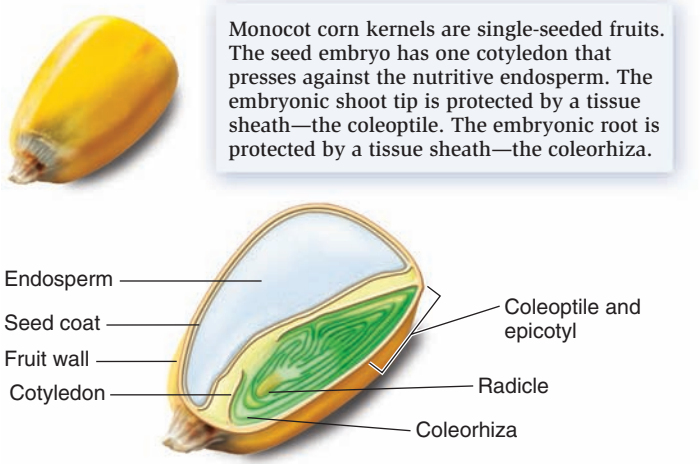
Concept Check: *How would this embryo differ if its TOPLESS gene was nonfunctional?*

this process, embryos become dry and thus able to survive in the absence of water. Seed maturation includes transformation of the ovule's integuments into a tough seed coat (see Figure 39.16, step 5). The seed coat restrains seedlings from growing and prevents the entry of water and oxygen, which maintains low seed metabolism. In addition, the coats of some seeds are darkly colored with pigments that may help to prevent damage by UV radiation or microbial attack.



Another change leading to seed dormancy is gradual, controlled loss of water from the embryo and other seed tissues. As the result, the water content of dispersed seeds is only 5–15%. Abscisic acid (ABA) is a hormone that induces the activity of genes that help embryo tissues to survive the drying process. Some of these desiccation-tolerance genes encode proteins that form loose coils enclosing cell contents, thereby preventing damage as the cytoplasm becomes almost completely dry. When the seeds of flowering plants are dry and ready for dispersal, they are released from the plant while enclosed in a fruit or released when the fruit breaks open.

The structure of mature monocot and eudicot seeds differs. Within eudicot seeds, mature embryos often display an **epicotyl**, the portion of an embryonic stem with two tiny leaves in a first bud that is located above the point of attachment of the cotyledons (**Figure 39.17a**). The **hypocotyl** is the portion of an embryonic stem located below the point of attachment of the cotyledons. An embryonic root, the **radicle**, extends from the hypocotyl. Much of the endosperm has been absorbed into the large cotyledons. In contrast, mature monocot embryos, such as those of corn, feature an epicotyl with a first bud enclosed in a protective sheath known as the **coleoptile**. The young monocot root is enclosed within a protective envelope known as the **coleorhiza** (**Figure 39.17b**).



Fruits Develop from Ovaries and Other Flower Parts

All fruits develop from ovaries and sometimes other flower parts. They occur in diverse forms that aid seed dispersal. Some fruits are dry, whereas others are moist and juicy; some open to release seeds, and others do not. Fruits also display a wide variety of sizes, colors, and fragrances. These variations result from differences in the process of fruit development. Plant hormones, including auxin, gibberellic acid, and cytokinins, control this transformation. ABA stimulates cell expansion, and ethylene influences fruit ripening. For instance, ethylene helps to ripen nuts, a type of dry fruit, by inducing plasma membranes to rupture, causing water loss. Under the influence of plant hormones, the pericarp (ripened ovary wall) of peaches, plums, and related fruits swells and softens, and orange or red chromoplasts replace green chloroplasts. As fruits mature, the outer protective cuticle often becomes very thick, contributing to peel toughness, which helps to prevent microbe attack. In addition, many maturing fruits increase their sugar and acid content, which produces the distinctive tastes of ripe fruit. Many fruits also produce fragrant volatile compounds.

Differences in the shape, color, fragrance, and moisture content of wild fruits reflect evolutionary adaptation for effective seed dispersal. Though many fruits and seeds are dispersed by wind or water or by attaching to animal fur, others are consumed by fruit-eating animals that are attracted by fruit color and fragrance. Blackberries provide a good example of fruits adapted for animal dispersal. Blackberry flowers produce many separate pistils, each containing a single ovule (**Figure 39.18a**). Following pollination and fertilization, the ovary of each pistil develops into a sweet, juicy fruitlet containing a single seed. As the individual fruitlets develop, they fuse together at the sides.

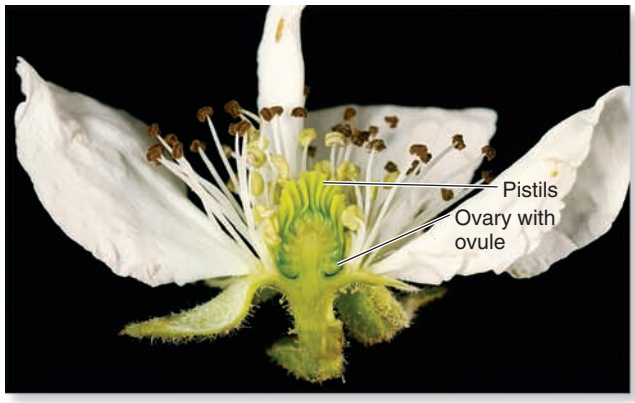
(b) Monocot corn seed, showing an embryo protected by coleoptile and coleorhiza

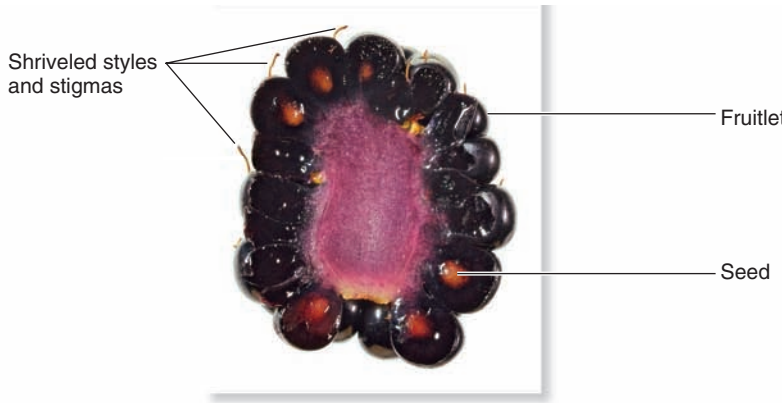
Figure 39.17 Structure of mature seeds and embryos.

Concept Check: Why do mature seeds of eudicots lack extensive amounts of endosperm?



Consequently, the many fruitlets produced by a single blackberry flower are dispersed together (**Figure 39.18b**). Attracted by the color, birds consume the whole aggregate and excrete the seeds, thereby dispersing many at a time. Many other types of fruits occur and these likewise represent adaptations that foster seed dispersal (refer back to Figure 30.21). Although a fruit is usually defined as a mature ovary containing seeds, seedless fruits such as watermelon are produced commercially by genetic modification or treatment with artificial auxin.

Environmental and Internal Factors Influence Seed Germination



Seeds vary greatly in their ability to germinate after dispersal. Small seeds such as those of dandelions and lettuces germinate quickly if light is available. Other seeds require a period of dormancy before germination occurs. Some seeds can remain dormant for amazingly long time periods. For example, a lotus (*Nelumbo nucifera*) seed collected from a lake bed in China germinated at the age of 1,300 years, as determined by radiocarbon dating. In 2005, plant scientists germinated a 2,000-year-old date seed found in Israel.

Water is generally required to rehydrate seeds so that embryos can resume their metabolic activity. Water absorption also swells seeds, helping to break the seed coat and allowing embryonic organs to emerge. In some cases, rainfall of sufficient duration to leach germination-inhibiting compounds out of seeds is required. The optimal temperature for germination of most seeds lies between 25°C and 30.25°C (77°F and 86.25°F). This explains why gardeners wait until the soil is warm before planting seeds outdoors in spring. However, some seeds need a period of cold treatment or seed coat abrasion before they will germinate. Such physical stimuli induce the activity of more than 2,000 genes associated with seed germination.

When grass seeds rehydrate, the young shoot secretes the hormone gibberellic acid from the seed cotyledon into the outermost endosperm layer, known as the aleurone. In response, the aleurone secretes digestive enzymes into the central endosperm, releasing sugars from stored starch (**Figure 39.19**). The seedling uses these sugars

(a) *Rubus allegheniensis* (common blackberry) flower

(b) Blackberry fruit

Figure 39.18 Blackberry flower and fruit. **(a)** Each of the many separate pistils in a blackberry flower is able to produce a single one-seed fruit (called a fruitlet) if fertilization occurs. **(b)** Together, the individual fruitlets of the blackberry compose an aggregate fruit that allows many seeds to be efficiently dispersed at the same time by the same animal agent.

BIOLOGY PRINCIPLE Living organisms interact with their environment. This principle is illustrated by the dispersal by birds of many blackberry seeds at the same time.

for growth. This highly coordinated process allows grass seeds to quickly germinate when it rains, an advantage in arid grassland habitats. Humans also use this basic process of germination to make beer. In the process known as malting, beer brewers apply gibberellic acid to barley seeds to induce them to germinate simultaneously. The barley seeds are then baked at a high temperature to stop germination, a process that produces malt. Brewers then treat malt with water and heat, add the dried flowers of the hop plant (the genus *Humulus*), and add yeasts to ferment the plant sugars to alcohol.

Once seeds have germinated, plants vary in the process by which the embryonic shoot emerges. When bean and onion seeds germinate, the hypocotyl forms a hook that first breaches the soil surface and then straightens, thereby pulling the rest of the seedling and cotyledons aboveground (**Figure 39.20a** and **b**). In contrast, when pea seeds germinate, the epicotyl forms a hook that pulls the shoot tip out of the ground, leaving the cotyledons beneath the soil surface (**Figure 39.20c**). In both cases, the tough hook cells bear the brunt of passage through hard surface soil crusts, thereby protecting the delicate shoot tips. The plant hormone ethylene controls seedling hook formation, as described in Chapter 36 (refer back to Figure 36.9). However, not all seedlings form hooks. For example, as they grow through the soil, the shoot tips of corn seedlings and those of other grasses are protected by the coleoptile, a protective sheath that encloses the first foliage leaves (**Figure 39.20d**).

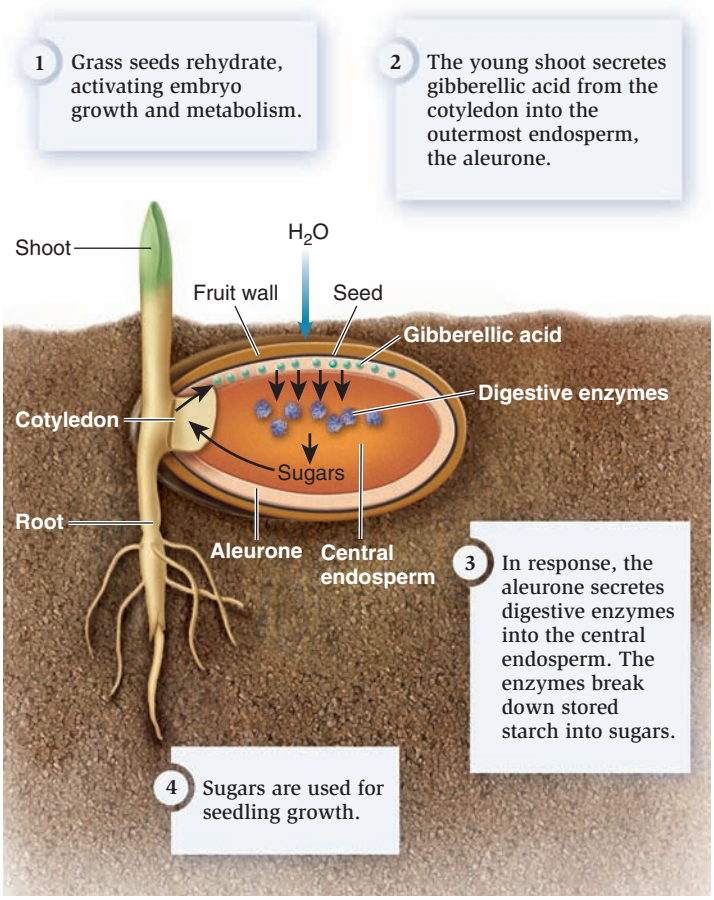


Figure 39.19 **Germination of grass seeds.**

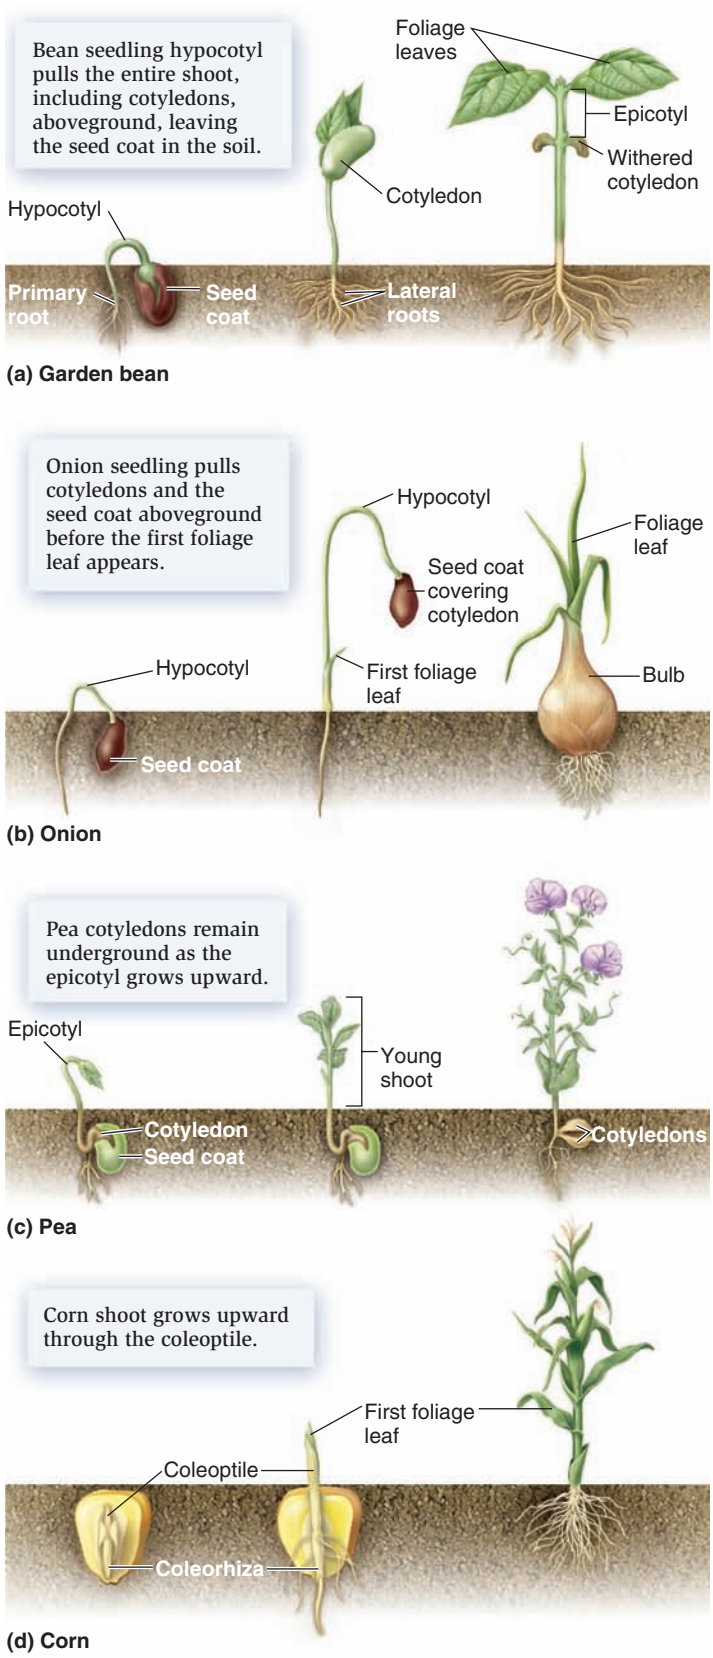

Figure 39.20 **Variations in seed germination and seedling growth patterns.**

39.5 Asexual Reproduction in Flowering Plants

Learning Outcomes:

1. Explain the benefits of asexual reproduction in flowering plants.
2. List several examples of ways in which plant asexual reproduction is important to agriculture.

Many plants rely on sexual reproduction. However, a wide variety of angiosperms reproduce primarily by asexual means, and other plants commonly utilize both sexual and asexual reproduction. **Asexual reproduction** is the production of new individuals from a single parent without the occurrence of fertilization. Although sexual reproduction provides beneficial genetic variation, asexual reproduction can be advantageous in other ways. For example, asexual reproduction maintains favorable gene combinations that allow faster population growth in stable environments. Asexual reproduction is also advantageous in stressful habitats where pollinators or mates can be rare, because it allows a single individual to start a new population. Finally, asexual reproduction allows some plants to persist for very long periods of time. Among the oldest known plants are creosote bushes that are asexual clones of a parent that grew from a seed about 12,000 years ago!

The artificial vegetative propagation of plants from cuttings is a form of asexual reproduction that is widely used commercially and by home gardeners. In this section, we will explore the three main mechanisms of plant asexual reproduction: specialized reproductive structures, somatic embryogenesis, and apomixis.

Vegetative Asexual Reproduction Generates Plant Clones from Organs

Roots, stems, and leaves are vegetative plant organs that can function as asexual reproductive structures. For example, root sprouts, such as those produced by aspens, can generate entire groves of genetically identical trees. Sucker shoots, such as those appearing at the bases of banana plants and date palms, and the pieces of tuber with "eyes" (which are buds) that develop into potato plants are examples of vegetative plant organs that have agricultural importance. Attractive horticultural varieties of African violets and other plants can be propagated from leaf cuttings. Such asexual offspring grow into adult plants that have the same valued properties as their parent plant. In contrast, seeds from these plants would produce diverse progeny, not all of which would have economically prized properties.

Somatic embryogenesis is the production of plant embryos from body (somatic) cells. Embryos can develop from many types of plant cells. Somatic embryos develop normally to the torpedo stage but do not dehydrate and become dormant, as is normal for zygotic embryos. Rather, somatic embryos produce root and shoot systems and develop into mature plants. Somatic embryogenesis occurs naturally in citrus, mango, onion, and tobacco plants, but agricultural scientists have made use of it as well.

In the 1950s, British plant biologist F. C. Steward and associates were the first researchers to successfully clone a complex organism, the carrot plant, by means of somatic embryogenesis. They used differentiated cells from carrot roots, grew the cells in conditions that caused some cells to lose their specialized properties and develop into embryos, and then cultivated each embryo in conditions that favored development into a mature carrot plant. Many types of plants are now cloned by somatic embryogenesis, which allows commercial growers to produce large numbers of genetically identical individuals.

The common houseplant *Kalanchoë daigremontiana* has leaves bearing many tiny plantlets at their edges. When these detach, they are able to take root and grow into new individuals (**Figure 39.21**). Recent molecular studies have revealed that embryogenesis genes are involved in this process and its evolution.

Genomes & Proteomes Connection

The Evolution of Plantlet Production in *Kalanchoë*

Kalanchoë daigremontiana is informally known as mother of thousands because it produces many plantlets at the edges of leaves. Helena Garces, Neelima Sinha, and their colleagues investigated the evolution of this type of asexual reproduction by studying genes that are involved in the development of organs and embryos in four species of *Kalanchoë*. In addition to *K. daigremontiana*, they investigated *K. marmorata*, which does not produce plantlets; *K. pinnata*, which produces plantlets only under certain stressful conditions; and *K. gastonis-bonnieri*, which produces plantlets both normally and when stressed. In leaves of these species, the biologists looked for expression of the gene *STM*, which encodes a key regulator of leaf production at the shoot meristem. They found that *STM* is expressed in cells at the leaf margins of all *Kalanchoë* species that produce leaf plantlets, but not the species that do not produce plantlets. Then the investigators checked for the expression in leaves of two genes that are involved in embryo development (*LEC1* and *FUS3*). They discovered that these embryo-linked genes were expressed only in the leaf margins of species that normally form plantlets, not the species in which plantlet formation is induced by stress.

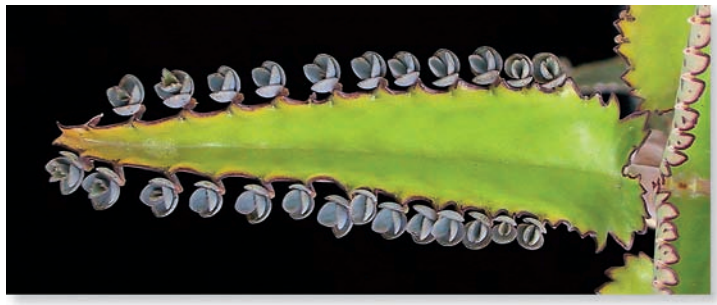

Figure 39.21 Asexual reproduction via somatic embryogenesis. The leaves of this *Kalanchoë* plant bear small plantlets around the edges. When mature, these plantlets drop off and, under the right conditions, grow into new plants.

In a survey of a larger number of species, these investigators also discovered that *Kalanchoë* species that normally produce plantlets have an altered LEC1 protein. The normal form of LEC1 protein is essential to the process by which embryos become dry and thus tolerant of arid conditions. LEC1 is therefore necessary for the production of viable seeds, those able to germinate. *Kalanchoë* species that produce plantlets only under stressful conditions and those that do not produce plantlets at all were able to produce viable seeds. By contrast, the seeds of plantlet-producing species were not viable.

Together, these data allowed the investigators to infer that the evolution of plantlet formation began when certain leaf cells of some species gained the ability to function like a shoot meristem, thereby producing structures resembling small shoots. In some of the descendents of these species, normal LEC1 function in seeds was lost, as was the ability to produce viable seeds. Some species adapted by expressing the embryo-development process in leaf margin cells, a process that allowed them to produce plantlets. Such plantlets are not affected by loss of LEC1 function because, unlike seeds, they do not undergo a drying process during development.

Apomixis Is Seed Production Without Fertilization

Apomixis (from the Greek, meaning away from mixing, that is, genetic mixing) is a natural asexual reproductive process in which fruits and seeds are produced in the absence of fertilization. More than 300 species of flowering plants, including hawkweeds, dandelions, and some types of citrus, are able to reproduce asexually by apomixis. Dandelions and some other apomictic plants require pollination to stimulate seed development, but others do not. Agricultural scientists are interested in apomixis as a potential method for producing genetically uniform seeds, propagating hybrids, and removing the need for fertilization in crop plants.

Most studies of apomixis have been carried out with dandelions, because they are widespread and populations are composed mainly of individuals that reproduce by apomixis. In these plants, meiosis produces microspores, but most pollen grains have abnormal chromosomes. Such grains produce pollen tubes but not sperm cells, so that fertilization does not follow pollination. However, female gametophytes and the eggs they produce are diploid. This condition arises because during the preceding meiotic divisions that generate megaspores, homologous chromosomes do not pair and meiosis II does not occur. The diploid eggs of apomictic dandelions develop into normal embryos without fertilization and an endosperm develops from the unfertilized central cell. This explains why apomictic dandelions can produce their single-seeded fruits despite the absence of gamete fusion.

Summary of Key Concepts

39.1 An Overview of Flowering Plant Reproduction

- Flowering plants display a sexual life cycle known as alternation of generations. The gamete-producing male and female gametophytes of flowering plants are very small and depend entirely on nurturing sporophytic tissues. Plant gametes arise by the process of mitosis (Figures 39.1, 39.2).
- Flowers are reproductive shoots that develop from a shoot apical meristem. The role of flowers is to promote seed production. A flower shoot generally produces four types of organs: sepals and petals (or tepals in the case of monocots), stamens, and carpels. Stamens produce pollen grains, which are immature male gametophytes. Carpels produce, enclose, and nurture female gametophytes (Figure 39.3).
- Mature male gametophytes, or pollen tubes, each produce two sperm and deliver them to ovules within the ovary. Flowering plants display double fertilization: One of the two sperm released from a pollen tube combines with an egg cell to form a zygote, and the other fuses with two nuclei located in a central cell of the female gametophyte, producing the first cell of endosperm tissue. Endosperm is a nutritive tissue that supports development of an embryonic sporophyte (Figure 39.4).
- Seeds are reproductive structures that contain a dormant embryo enclosed by a protective seed coat that develops from ovule integuments. Fruits are structures that contain seeds and foster seed dispersal. Like flowers and endosperm, fruits are unique features of flowering plants (Figure 39.5).

39.2 Flower Production, Structure, and Development

- Plants flower in response to environmental stimuli, such as temperature and day length, by the conversion of a leaf-producing shoot into a flowering shoot.
- Flowers vary in the type of whorls present, the number of flower organs, color, fragrance, organ fusion, symmetry, and arrangement (whether single or in inflorescences). These variations are related to pollination mechanisms and are genetically controlled (Figures 39.6, 39.7, 39.8, 39.9, 39.10).
- Flower blooming involves dramatic changes in petal shape caused by faster growth at petal edges than at their centers (Figure 39.11).

39.3 Male and Female Gametophytes and Double Fertilization

- Pollen grains are immature male gametophytes protected by a tough sporopollenin wall. Female gametophyte development occurs within an ovule. Mature female gametophytes include an egg and two synergids, a central cell with two nuclei, and three antipodal cells (Figures 39.12, 39.13).
- After pollination, interactions between proteins of pistil cells and those of pollen determine pollen germination (Figure 39.14).
- Germinated pollen delivers two sperm to female gametophytes by means of a long pollen tube. The style plays a role in the guidance, nutrition, and fate of the pollen tube. One sperm nucleus fuses with the egg to produce a zygote, the first cell of a new sporophyte generation; the other sperm nucleus fuses with the two nuclei of the central cell, generating the first cell of the nutritive endosperm tissue (Figure 39.15).

39.4 Embryo, Seed, Fruit, and Seedling Development

- Unequal division of a zygote leads to development of a nutritive suspensor and an embryo. Young eudicot embryos are heart-shaped as two embryonic leaves (cotyledons) develop, and the embryo assumes a torpedo shape as the embryonic root forms. Monocot

embryos have only a single cotyledon; the embryonic shoot tip is protected by the coleoptile, and the embryonic root is protected by the coleorhiza (Figures 39.16, 39.17).

- Mature seeds contain embryos that become dry and are protected by desiccation-resistance proteins and a tough seed coat. These adaptations enable seeds to withstand long periods of dormancy, germinating only when conditions are favorable for seedling survival. Mature fruits develop from ovaries and aid in seed dispersal (Figure 39.18).
- Seed germination is influenced by environmental and internal factors. The embryonic root (radicle) is the first organ to emerge, an adaptation that allows rapid water uptake, essential for seedling development (Figures 39.19, 39.20).

39.5 Asexual Reproduction in Flowering Plants

- Asexual reproduction is the production of new individuals from a single parent without the occurrence of fertilization. Vegetative reproduction is the development of whole plants from nonreproductive organs. Somatic embryogenesis is the production of embryos from individual body cells. Apomixis is a mechanism by which some plants produce seeds from flowers without fertilization (Figure 39.21).

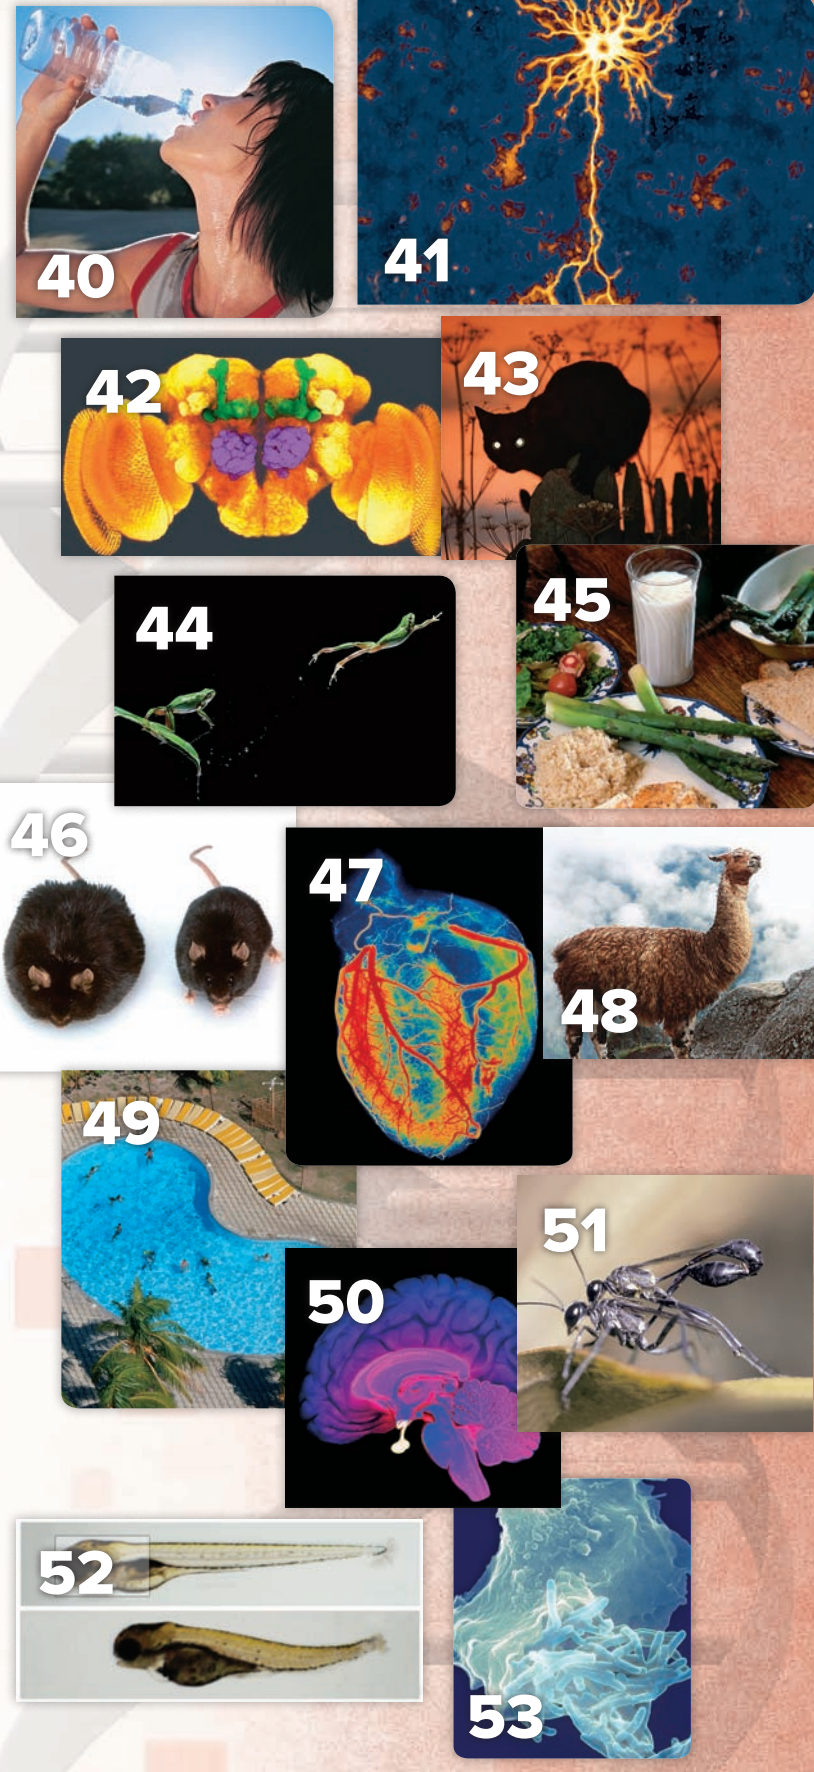
Assess and Discuss

Test Yourself

1. Where do the pollen grains of flowering plants develop?
   a. in the anthers of a flower
   b. in the carpels of a flower
   c. while being dispersed by wind, water, or animals
   d. within ovules
   e. within pistils
2. Where do mature male gametophytes of flowering plants primarily develop?
   a. in the anthers of a flower
   b. in the carpels of a flower
   c. while being dispersed by wind, water, or animals
   d. within ovules
   e. on the surfaces of leaves
3. Where would you find female gametophytes of a flowering plant?
   a. in the anthers of a flower
   b. at the stigma of a pistil
   c. in the style
   d. within ovules in a flower's ovary
   e. in structures that are dispersed by wind, water, or animals
4. How does double fertilization occur in flowering plants?
   a. The two sperm in a pollen tube fertilize the two egg cells present in each female gametophyte.
   b. One of the two sperm in a pollen tube fertilizes the single egg in a female gametophyte, and the other fuses with the two nuclei present in the central cell.
   c. Two sperm, one contributed by each of two different pollen tubes, fertilize the two egg cells in a single female gametophyte.
   d. Two sperm contributed by separate pollen tubes enter a single female gametophyte; one of the sperm fertilizes the egg cell, and the other fertilizes the central cell.
   e. None of the above is correct.
5. A seed is
   a. an embryo produced by the fertilization of an egg, which is protected by a seed coat.
   b. a structure that germinates to form a seedling under the right conditions.
   c. an embryo produced by parthenogenesis that is enclosed by a seed coat.
   d. all of the above.
   e. none of the above.
6. What is the chemical stimulus of flowering that is produced by leaves and transported to the shoot apical meristem?
   a. the hormone auxin
   b. the protein STM
   c. the carbohydrate callose
   d. the mineral ion K^+
   e. None of the above is correct.
7. How many whorls of organs occur in complete flowers?
   a. two
   b. four
   c. six
   d. eight
   e. ten
8. If an ovary contains eight ovules, how many seeds could potentially result if pollen tubes reach all eight ovules?
   a. one
   b. four
   c. eight
   d. more than 20
   e. None of the above is correct.
9. What function(s) does the carbohydrate callose have in the reproduction of flowering plants?
   a. Callose forms a coat that isolates young embryos during their early development.
   b. Callose forms a coat that isolates groups of four microspores during their early development into pollen grains.
   c. Callose helps to form the patterns on the sporopollenin walls of pollen grains.
   d. all of the above
   e. none of the above
10. From what structure does a fruit pericarp primarily develop?
    a. the style
    b. a stamen filament
    c. the ovary wall
    d. a group of fused sepals
    e. the stigma

Conceptual Questions

1. Why are pollen grain walls composed of sporopollenin?
2. Why are seed coats often tough?
3. A principle of biology is that *all species (past and present) are related by an evolutionary history.* Modern flowering plants likely possessed a single common ancestor. Why, then, do flowers occur in such a diversity of shapes and colors?



Collaborative Questions

1. Observe or view images of orchid flowers. Are these flowers bilaterally symmetric or radially symmetric? Are these flowers more likely to be wind-pollinated or pollinated by animals? What gene might be involved in the production of orchid flower shape?
2. How do plants prevent the production of many offspring expressing deleterious recessive traits?

UNIT VII

ANIMALS

Despite the amazing diversity of animal life, fundamental similarities link the millions of animal species. We will explore many of these similarities in this unit. The basic features of animal bodies and the maintenance of homeostasis will be introduced in Chapter 40. Chapters 41–43 will describe major principles of nervous systems. The ability of animals to move through their environments will be covered in Chapter 44. How food is obtained, processed, and utilized in animals is the subject of Chapters 45 and 46. Circulatory, respiratory, urinary, and endocrine systems are then covered in Chapters 47–50. The unit concludes with Chapters 51–53, which cover animal reproduction, development, and immune systems, respectively.

The following biology principles will be emphasized in this unit:

- ***Living organisms maintain homeostasis.*** *This is one of the fundamental principles of biology and is key to understanding virtually all aspects of animal biology; it is introduced in Chapter 40.*
- ***Living organisms use energy.*** *We will see how many of the processes required to achieve and maintain homeostasis require energy; for example, it takes energy to maintain blood flow (Chapter 47) and a stable concentration of sodium ions in an animal's body fluids (Chapter 49).*
- ***Living organisms grow and develop.*** *In Chapter 52, we will explore the genetic and environmental factors that regulate how an embryo develops into a mature animal.*
- ***Living organisms interact with their environment.*** *How animals sense changes in their external environment will be covered in Chapter 43.*
- ***Structure determines function.*** *The relationship between structure and function in animals will be evident at multiple levels: cells, tissues, organs, and whole bodies.*
- ***All species (past and present) are related by an evolutionary history.*** *This principle will be explored in Genomes & Proteomes Connections throughout the unit. As an example, the importance of an ancient family of proteins found in most animals in providing immune defenses will be covered in Chapter 53.*
- ***Biology affects our society.*** *At the end of each chapter in this unit is a section entitled "Impact on Public Health." These sections relate what you've learned in the chapter to several important facets of human health and disease.*
- ***Biology is an experimental science.*** *Every chapter has a Feature Investigation that describes a classic or recent experiment notable not only for its innovation and creativity, but also for moving the field of animal biology forward in a significant way.*

CHAPTER OUTLINE

40.1 Organization of Animal Bodies
40.2 The Relationship Between Structure and Function
40.3 Homeostasis
Summary of Key Concepts
Assess and Discuss

Animal Bodies and Homeostasis

40

Perspiring and drinking water are both mechanisms that help achieve homeostasis—a stable internal body environment.

Look at the young woman in the chapter opening photo. What is happening at that moment? Obviously it is a hot day, and the woman is perspiring and thirsty; it appears that she has just been exercising outdoors. To accomplish this seemingly ordinary feat, however, several important things must occur. First, her body must prevent an excessive buildup of heat, because high body temperature can destroy enzymes and damage cellular membranes. One way some animals, including humans, can eliminate heat from the body is to perspire; recall from Chapter 2 that water has a high heat of vaporization, and therefore the evaporation of water from the body surface helps eliminate body heat. This comes with a cost, however, because perspiration depletes some of the body's water, potentially leading to changes in body fluid ion concentrations, blood pressure, and other critical physiological variables. Consequently, structures in the brain and other organs that are sensitive to the body's fluid levels and ion concentrations trigger the sensation of thirst, and the woman drinks water to replenish what was lost through perspiration. The process through which the different aspects of an animal's internal environment (in this case, temperature and body fluids) are maintained within normal limits, even in the face of changing circumstances or external challenges, is known as **homeostasis**.

Maintenance of homeostasis is one of the fundamental principles of virtually all aspects of animal biology. Before we can fully appreciate what homeostasis means to animals and how it is achieved, however, we first need to understand some basic features of animal bodies. We begin this chapter with a discussion of how cells are organized into tissues, and tissues into organs, and how fluids exist in different body compartments. Chapter 10 considered the organization of cells into tissues from the perspective of cell biology; here, we look at tissues and organs from the perspective of the whole animal, examining how the properties of life arise from the complex interactions of its components. Next, we will discuss a principle of biology that also helps us understand homeostasis, the concept that structure (form) determines function. We then link these principles together with a detailed look at what homeostasis means for different animals, how it may be challenged, and how it is restored or maintained.

40.1 Organization of Animal Bodies

Learning Outcomes:

1. List the different categories of animal tissue, providing general functions and specific examples of each.
2. Name the various organ systems found in many animals, list the components of each, and describe their general functions.
3. Describe how the bodies of animals are organized into fluid compartments.
4. **SciSKILLS** » Predict how water will move between body fluid compartments if solute concentrations differ between the compartments.

All animal cells share similarities in the ways in which they exchange materials with their surroundings, obtain energy from organic nutrients, synthesize complex molecules, reproduce themselves, and detect and respond to signals in their immediate environment. Animals typically begin life as a single cell—most commonly a fertilized egg—which divides to create two cells, each of which divides in turn, resulting in four cells, and

so on. If cell multiplication were the only event occurring, the end result would be a spherical mass of identical cells. As we will see in Chapter 52, however, cells become specialized during development to perform a particular function (that is, they differentiate). Examples of differentiated cells are muscle and blood cells. Cells also migrate to new locations within the developing organism and form clusters with other cells. In this way, the cells of an animal's body are arranged in various combinations to form organized, multicellular structures (**Figure 40.1**). Cells with similar properties group together to form tissues (for example, muscle tissue), which combine with other types of tissues to form organs (a urinary bladder). Organs are anatomically or functionally linked to form organ systems (the urinary system).

Specialized Cells Are Organized into Tissues

A **tissue** is an association of many cells that have a similar structure and function. The tissues in a typical animal's body can be classified into four categories, according to their locations and the types of functions they perform: muscle, nervous, epithelial, and connective tissues. Within each of these functional categories, subtypes of tissues perform variations of that function, as illustrated by the three types of muscle tissue.

Muscle Tissues **Muscle tissues** consist of cells specialized to shorten, or contract, generating the mechanical forces that may produce body movement, decrease the diameter of a tube, or exert pressure on a fluid-filled cavity. Three types of muscle tissue may be found in animals: skeletal, smooth, and cardiac (**Figure 40.2**). **Skeletal muscles** are generally linked to bones in vertebrates, via bundles of collagen fibers called tendons, and to the exoskeleton of invertebrates. When skeletal muscles are stimulated by signals from the nervous system, they generate force that leads to the contraction of the muscle (see Chapter 44). Contraction of these muscles may be under voluntary control and can produce the types of movements required for locomotion, such as extending limbs or flapping wings. **Smooth muscles** surround hollow tubes and cavities inside the body's organs, so their contraction can move the contents of those organs. For example, the contraction of smooth muscle in the stomach wall propels partially digested food into the intestines, where it can be digested fully. Smooth muscle also surrounds and forms part of small blood vessels and airway tubes (bronchioles). Contraction in those regions reduces blood flow or movement of air, respectively. Contraction of all smooth muscle is involuntary—that is, it occurs automatically without conscious control. In the third type, **cardiac muscle**, physical and electrical connections between individual cells enable many cells to contract almost simultaneously. Like smooth muscle, cardiac muscle contracts involuntarily. It is found only in the heart, where it provides the force that generates pressure sufficient to pump blood through an animal's body.

Nervous Tissues **Nervous tissues** are complex networks of cells called **neurons** that are specialized to initiate and conduct electrical signals from one part of an animal's body to another part (**Figure 40.3**). Depending on where it is generated in an animal's body, an electrical signal produced in one neuron may stimulate or inhibit other neurons to initiate new electrical signals, stimulate

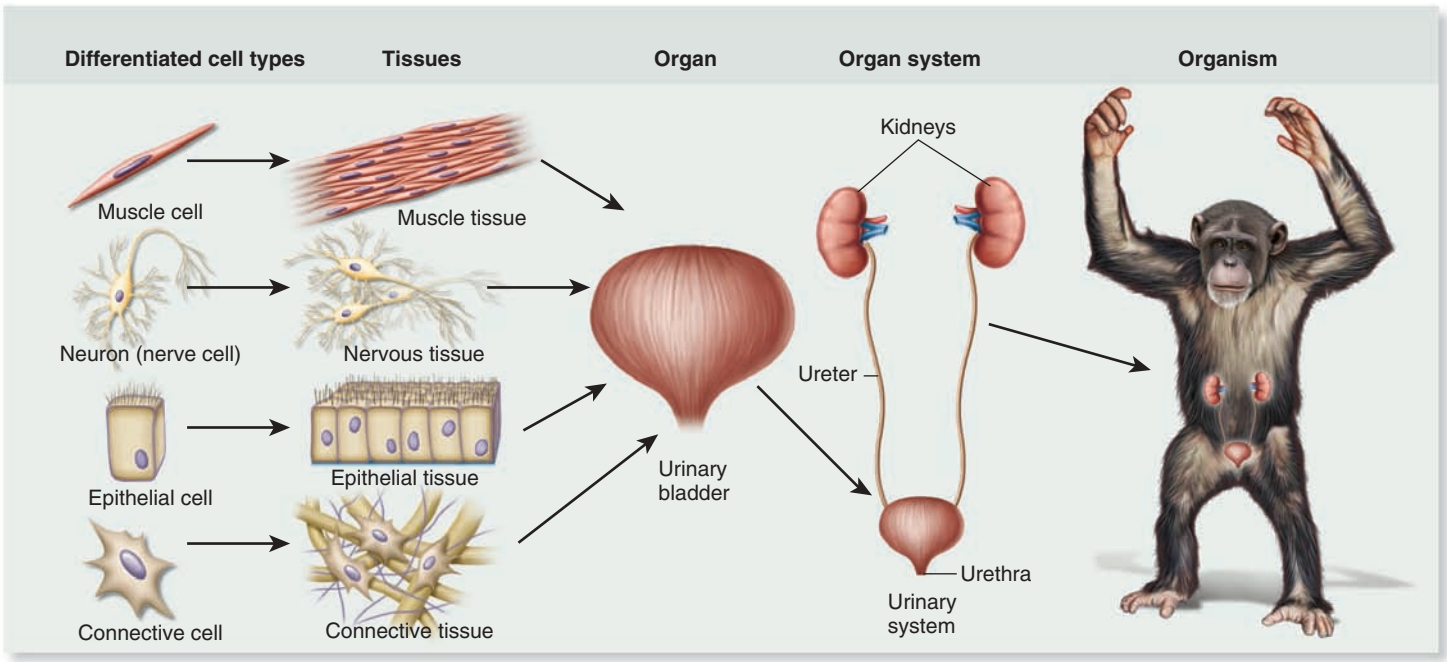


Figure 40.1 The internal organization of cells, tissues, organs, and organ systems in a mammal. Most animals share the same four tissue types.

BIOLOGY PRINCIPLE **New properties of life emerge from complex interactions.** By themselves, none of the four tissues that constitutes a bladder or kidney could perform the functions of those organs, but when combined in precise ways, the result is a functional organ system capable of purifying the fluids of an animal's body.

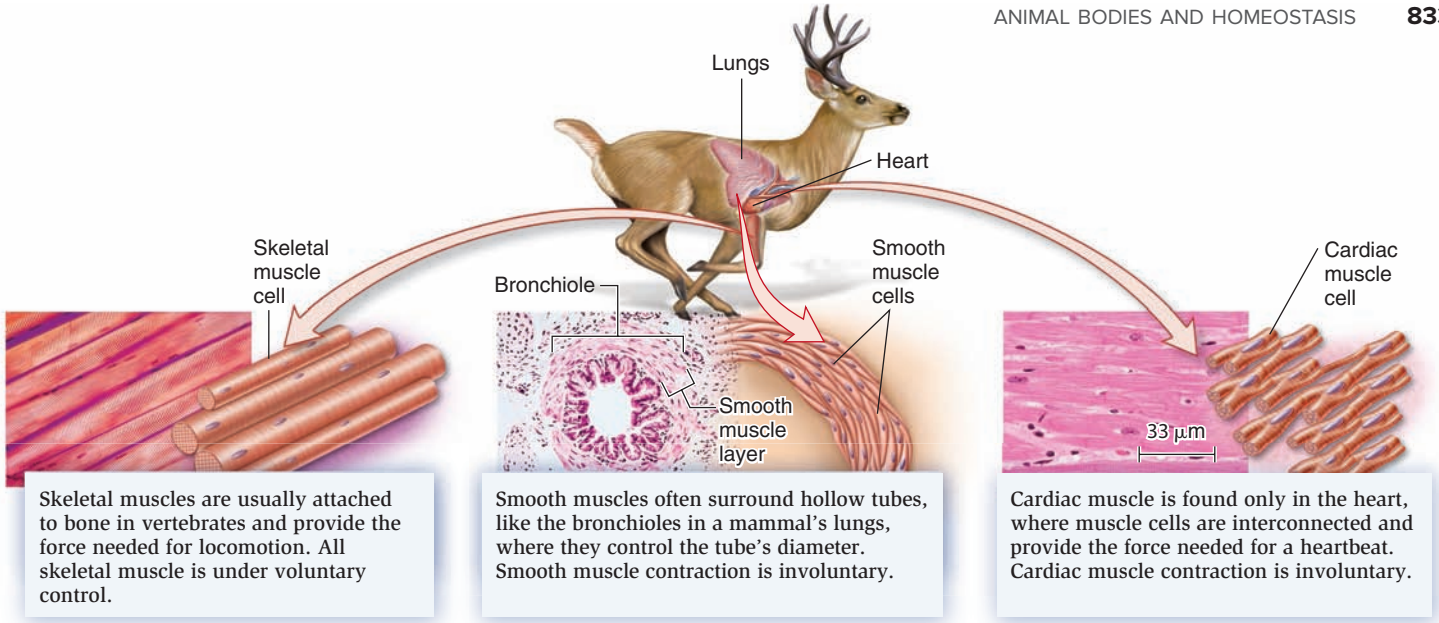

Figure 40.2 Three types of muscle tissue: skeletal, smooth, and cardiac. All three types produce force, but they differ in their appearance and in their locations within animals' bodies. (Right inset: © Dr. Richard Kessel/Visuals Unlimited)

Concept Check: *All muscles produce movement, but only skeletal muscle produces locomotion. What is meant by this statement?*

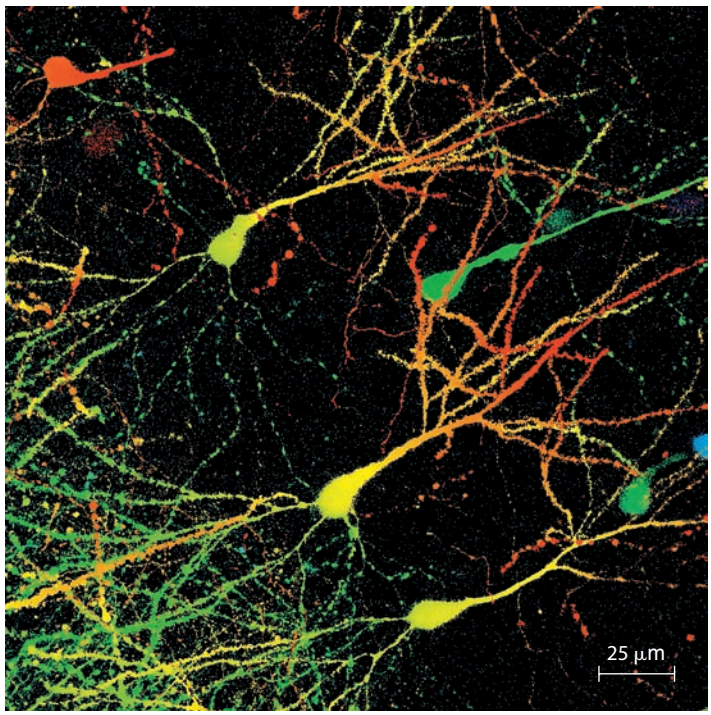

Figure 40.3 Nervous tissue in the brain of a vertebrate. Nervous tissue consists of neurons with extensive cell-cell contacts, as shown in this confocal micrograph of a section from a human brain. The cells are labeled with fluorescent markers; different colors signify different depths in the section.

BIOLOGY PRINCIPLE Living organisms interact with their environment. Animals interact with their environment in many ways; this interaction largely depends on the use of nervous tissue, which allows animals to sense and respond to changes in the environment.

muscle cells to contract, or stimulate glandular cells to release chemicals into an animal's body fluids. Thus, nervous tissue provides a critical means of controlling diverse activities of the body's cells.

Epithelial Tissues **Epithelial tissues** are sheets of densely packed cells that cover the body or individual organs or line the walls of various cavities inside the body. Epithelial cells are specialized to protect structures and to secrete and absorb ions and organic molecules (see Chapter 10). For example, epithelial tissue can invaginate (fold inward) to form sweat glands that secrete water and ions onto the surface of an animal's skin. Epithelial cells come in a variety of shapes, such as cuboidal (cube-shaped), squamous (flattened), and columnar (elongated). They are arranged in various ways to form different types of epithelial tissues: simple (one layer of cells), stratified (multiple layers), pseudostratified (one layer, but with nuclei located in such a way that it appears stratified), or, in certain cases such as the urinary system, transitional (multiple layers with the ability to expand and contract) (**Figure 40.4**).

Regardless of their shape, organization into tissues, or location, all epithelial cells are asymmetric, or polarized. This means that one side of such a cell is anchored to an extracellular matrix (ECM) called the basal lamina, or basement membrane (see Figure 10.1); this side is called the basal or basolateral membrane. The other side, called the apical membrane, faces the internal or external environment of the animal. Thus, epithelial cells form boundaries between different body compartments, as discussed later in this chapter. In this way, epithelial tissues can function as selective barriers that regulate the exchange of molecules between compartments. For example, epithelial tissues in an animal's skin help to form a barrier that prevents most substances in the external environment from entering the body.

Connective Tissues As their name implies, **connective tissues** connect, surround, anchor, and support the structures of an animal's

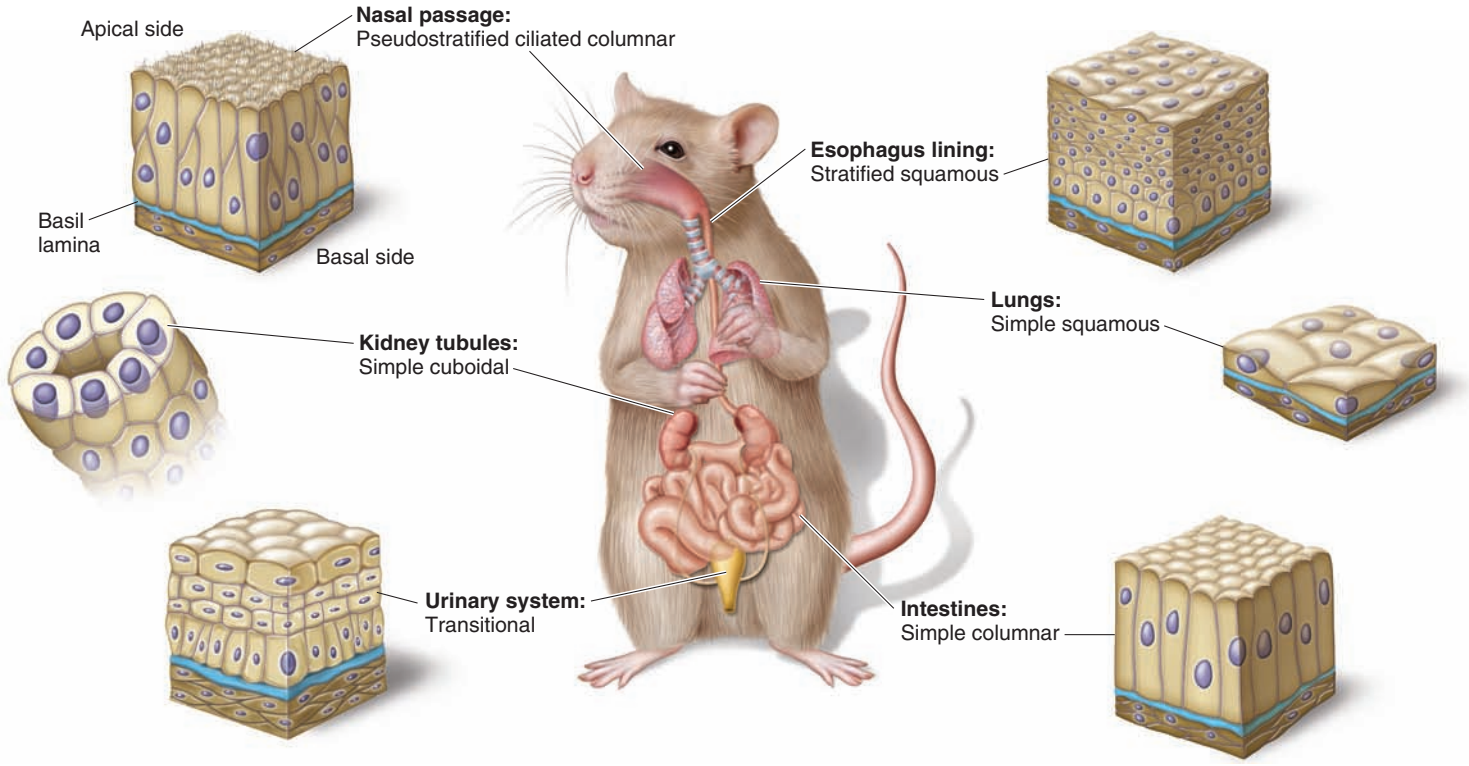

Figure 40.4 Examples of epithelial tissue. There are several types of epithelial tissue, distinguished by their appearance. Epithelial tissue is used to construct body coverings and the protective sheets that line and cover hollow tubes and cavities. The epithelial cells that make up epithelial tissues have an apical and basal (or basolateral) membrane; the apical side typically faces the exterior of the body or the lumen of a structure such as the intestines.

BIOLOGY PRINCIPLE Structure determines function. Note in this illustration how different types of epithelial cells arranged in different ways form tissues with different functions. For example, simple cuboidal cells arranged as tubules in the kidney permit the passage of filtered body fluids, and pseudostratified ciliated columnar cells lining the nasal passage act as filters of airborne particles and debris.

body. Connective tissues include blood, adipose (fat-storing) tissue, bone, cartilage, loose connective tissue, and dense connective tissue (**Figure 40.5**).

An important function of some types of connective tissue cells is to form part of the ECM around cells by secreting a mixture of fibrous proteins and carbohydrates, such as glycosaminoglycans. These carbohydrates may covalently attach to proteins to form proteoglycans (refer back to Figure 10.4). In some cases, the ECM is rich in minerals. The final characteristics of any type of connective tissue are determined in part by the relative proportions and types of proteins, proteoglycans, and minerals secreted into the ECM. The ECM serves several general functions, which include (1) providing a scaffold to which cells attach and organize themselves into more complex structures, (2) protecting and cushioning parts of the body, (3) providing mechanical strength, and (4) cell signaling—transmitting information to the cells that helps regulate their activity, migration, growth, and differentiation.

The proteins of the ECM of a tissue consist mainly of two types. The first type is insoluble fiber-like proteins such as **collagen** and the rubber-band-like protein **elastin**; these proteins are often referred to as fibers. A second category is adhesive proteins (fibronectin and laminin) that serve to organize the protein and carbohydrate components of the ECM (refer back to Table 10.1).

Different Tissue Types Combine to Form Organs and Organ Systems

An **organ** is composed of two or more kinds of tissues arranged in various proportions and patterns, such as sheets, tubes, layers, bundles, or strips. For example, the vertebrate stomach (**Figure 40.6**) consists of the following layers (from outermost to innermost):

- an outer covering of simple squamous epithelial tissue;
- connective tissue layers covering and cementing the organ together;
- layers of smooth muscle tissue, the contractions of which mechanically break up food and propel it through the stomach and into the small intestine;
- nervous tissue that comes in close contact with the smooth muscle tissues and helps regulate their activity;
- an inner lining of simple columnar epithelial tissue that secretes enzymes and acid (important in the digestive process) and protective mucus into the cavity, or lumen, of the stomach.

In an **organ system**, different organs function together to perform an overall function. In the example just described, the stomach is part

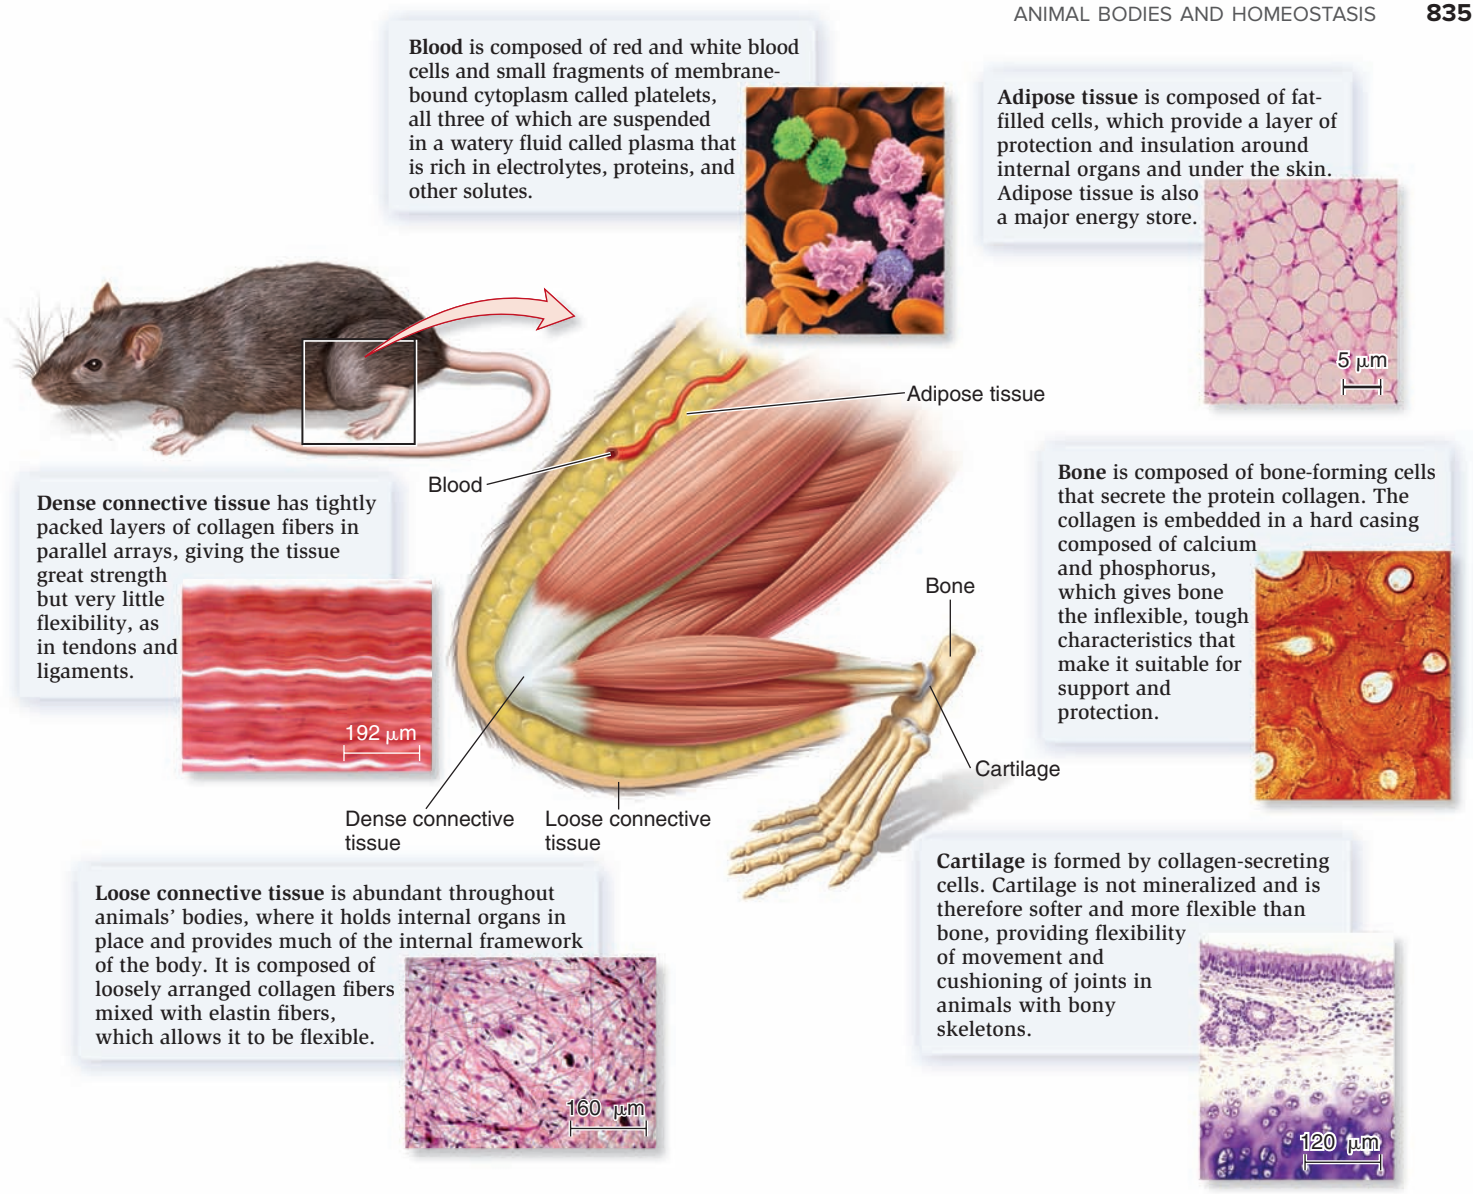

Figure 40.5 Examples of connective tissue in mammals. Connective tissue connects, surrounds, anchors, and supports other tissues and may exist as isolated cells (blood), clumps of cells (fat), or tough, rigid material (bone and cartilage). The samples have been stained or the micrographs have been colorized to reveal connective tissue.

of the digestive system, along with other structures, such as the mouth, esophagus, small and large intestines, and anus. In another familiar example, the kidneys, the urinary bladder, the tubes leading from the kidneys to the bladder, and the tube leading from the bladder to the exterior of the body constitute the urinary system in mammals (see Figure 40.1). This system helps regulate the composition of body fluids and removes waste products from the blood, which are then excreted in the urine. The organ systems found in animals are listed in **Table 40.1**.

Organ systems should not be considered as functioning in isolation. Instead, they frequently influence each other and depend on each other in many ways. For example, signals from the nervous, circulatory, and endocrine systems strongly influence how much water the mammalian kidney retains as it forms urine, an adaptation that can be lifesaving under certain circumstances.

The spatial arrangement of organs into organ systems is part of the overall body plan of animals. Organ systems develop at specific times and locations within the body and along the anteroposterior body axis, as do other structures, such as limbs, tentacles, antennae, and other animal appendages. Scientists have long wondered how the layout of animal bodies is determined during the period when an embryo is developing. Remarkably, organ development in animals appears to be under the control of a highly conserved family of body-plan genes with homologs in all animals, as described next.

Genomes & Proteomes Connection

Organ Development and Function Are Controlled by *Hox* Genes

In previous chapters, you have learned about a family of genes called *Hox* genes that are found in all animals. *Hox* genes

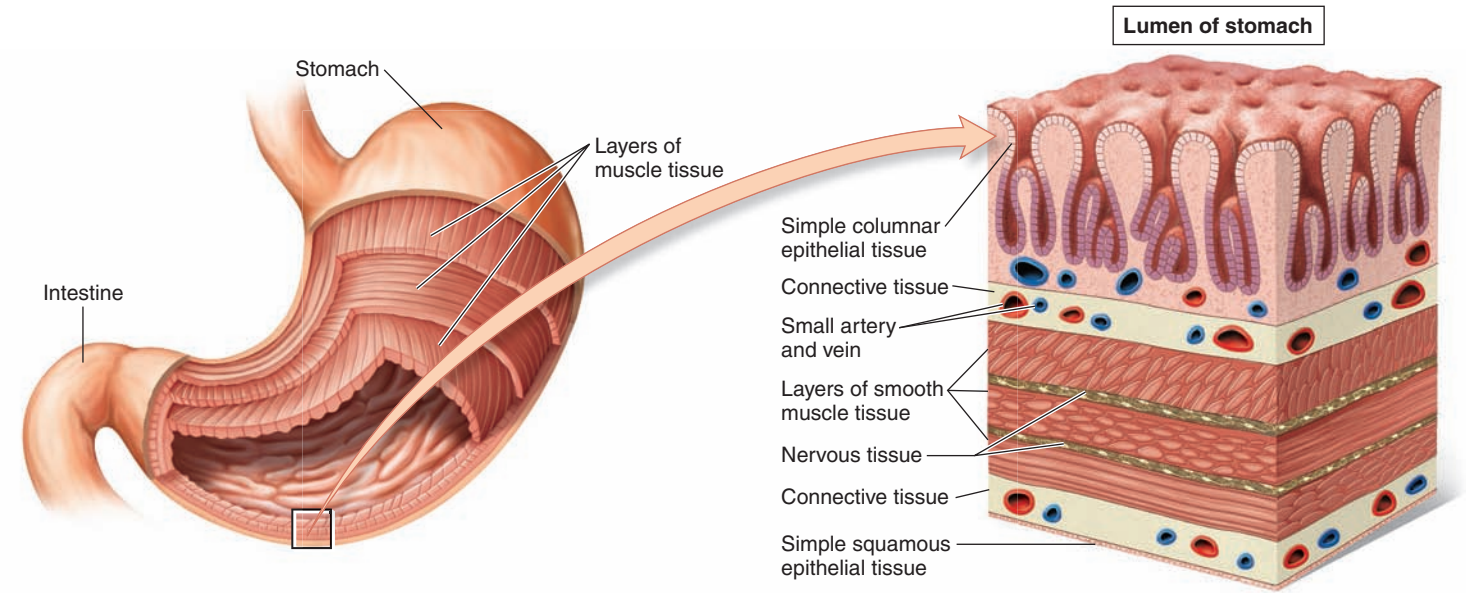

Figure 40.6 **The vertebrate stomach as an example of an organ composed of all four tissue types.** In this illustration, the thickness and appearance of the layers of nervous tissue have been considerably exaggerated for visual clarity.

Concept Check: *Do all animal organs contain all four tissue types? Can you think of an example that does not?*

BioConnections: *Look ahead to Figure 45.6 and compare the structure of the small intestine in that figure with the structure of the stomach shown in this figure. What can you conclude about common functions of the stomach and intestine from this comparison?*

Table 40.1 **Organ Systems Found in Animals**

Organ system	Major components*	Major functions
Circulatory	Contractile element (heart or vessel); distribution network (blood vessels); blood or hemolymph	Distributes solutes (nutrients, gases, wastes, and so on) to all parts of an animal's body
Digestive	Ingestion structures (mouth, mouthparts); storage structures (crop, stomach); digestive and absorptive structures (stomach, intestines); elimination structures (rectum, anus); accessory structures (pancreas, gallbladder)	Breaks complex foods into absorbable units; absorbs organic nutrients, ions, and water; eliminates solid wastes
Endocrine	All glands, organs, or tissues that secrete hormones	Regulates and coordinates growth, development, metabolism, mineral balance, water balance, blood pressure, behavior, and reproduction
Excretory	Filtration system (kidneys or comparable structures); storage sites for soluble wastes (bladder); tubes connecting kidneys and bladder and bladder to external environment	Eliminates soluble metabolic wastes; regulates body fluid volume and solute concentrations
Immune and lymphatic	Circulating white blood cells; lymph vessels and nodes	Defends against pathogens
Integumentary	Body surfaces (skin)	Protects from dehydration and injury; defends against pathogens; in some animals, plays a role in regulation of body temperature
Muscular-skeletal	Force-producing structures (muscles); support structures (bones, cartilage, exoskeleton); connective structures (tendons, ligaments)	Produces locomotion; generates force; propels materials through body organs; supports body
Nervous	Processing (brain); signal delivery (spinal cord, peripheral nerves and ganglia, sense organs)	Regulates and coordinates movement, sensation, organ functions, and learning
Reproductive	Gonads and associated structures	Produces gametes (sperm and egg); in some animals, provides nutritive environment for embryo and fetus
Respiratory	Gas-exchange sites (gills, skin, trachea, lungs)	Exchanges oxygen and carbon dioxide with environment; regulates blood pH

*Selected examples only; these do not necessarily pertain to all animals.

determine the timing and spatial patterning of the anteroposterior body axis during development. For example, we saw in Chapter 19 how these genes determine the number and position of legs and wings in *Drosophila*. *Hox* genes play a similar role in determining the spatial patterning of the vertebrate body and appendages. Recently, scientists have begun exploring the role of *Hox* genes in the development and spatial patterning of the organs that make up animals' organ systems.

By generating mutant mice that fail to express one or more *Hox* genes (the genes are said to have been knocked out; see Chapter 20), researchers have discovered the important function these genes have in determining where within the vertebrate body particular organs form. Recall from Chapter 19 (refer back to Figures 19.16 and 19.17) that mouse *Hox* genes are arranged in four clusters, designated A–D, with multiple genes per cluster. Because these homologous genes (for example, *HoxA-3*, *HoxB-3*, and *HoxD-3*) are found within a single species, they are considered paralogous genes. Such paralogous genes typically act in concert to regulate similar developmental processes. For example, *HoxA-3* is important for development of anterior parts of the body, including the neck. When this gene is knocked out, mouse embryos show defects in neck structure. Notably, the organs within the neck—including the thymus, thyroid, and parathyroid glands—do not develop normally. When two or more paralogs of this group are knocked out, certain neck organs fail to form at all. Experimental deletion of *Hox* genes associated with other body segments does not affect the development and function of neck glands and organs. Likewise, investigators have uncovered vital roles of different *Hox* genes in lung development within the thorax and the proper positioning and development of the vertebrate kidneys in the abdomen.

Of particular interest is the discovery that *Hox* genes are important not only for spatial patterning of organs but also for their growth, development, and function. Genes in the *Hox* 1 and 3 groups, for instance, help determine the final branching patterns of the airways of the lungs, the final size of the lungs, and the ability of the lungs to produce secretions that are important for breathing air after birth. Other *Hox* genes have been shown to control cell proliferation, shape changes, apoptosis, cell migration, and cell-cell adhesion within various organs. This is also true in invertebrates, such as the leech, where *Hox* genes are first expressed during organ formation, and in *Drosophila*, where the final shape and size of the heart are partly controlled by *Hox* genes.

Body Fluids Are Distributed into Compartments

All animal bodies are composed primarily of water. Most of the water in an animal's body is contained inside its cells and therefore is called **intracellular fluid** (from the Latin *intra*, meaning inside of). The rest of the water in the body exists outside of the cells and is therefore called **extracellular fluid** (from the Latin *extra*, meaning outside of). Extracellular fluid is composed of the fluid part of blood, called **plasma**, and the fluid-filled spaces that surround cells, called **interstitial fluid** (from the Latin *inter*, meaning between) (**Figure 40.7**). In vertebrates and some invertebrates, plasma and interstitial fluid are kept separate within a closed circulatory system. In many invertebrates with open circulatory systems (see Chapter 47), however, plasma and interstitial fluid are intermingled in a single fluid called hemolymph.

The fluids depicted in Figure 40.7 are said to be enclosed in compartments. In a typical vertebrate, the total water volume in the three compartments (intracellular fluid, plasma, and interstitial fluid) accounts for about two-thirds of body weight, with solids comprising the rest. Of the total body water, up to two-thirds is intracellular and one-third extracellular, the majority of which is located in the interstitial compartment.

Plasma membranes separate the intracellular fluid from the extracellular fluid. The two components of extracellular fluid in vertebrates and some invertebrates—the interstitial fluid and the plasma—are separated by the walls of the blood vessels (arteries, capillaries, and veins).

The solute composition of the extracellular fluid is very different from that of the intracellular fluid. Maintaining differences in solute composition across the plasma membrane is an important way in which animal cells regulate their own activity. For example, many different proteins that are important in regulating cellular events such as mitosis, cytokinesis, and metabolism are confined to the intracellular fluid.

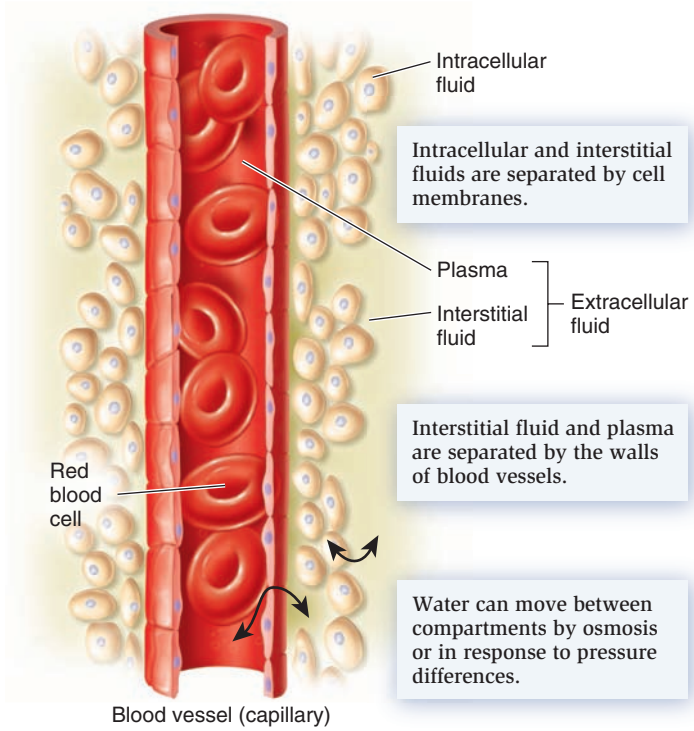

Figure 40.7 Fluid compartments in a typical vertebrate. Most of the fluid within an animal's body exists within cells (intracellular fluid). Extracellular fluid is that portion of the body's fluid that lies outside cells (interstitial fluid) and within blood vessels (plasma), such as the capillary shown here. Arrows indicate directions of water movement between adjacent compartments.

Concept Check: *What would happen to the distribution of water in the fluid compartments of an animal's body if a blood vessel was damaged and leaked its contents internally?*

Movement of Solutes Between Compartments Solutes must move between body fluid compartments in order for cells in an animal's body to maintain concentrations of ions, nutrients, and gases such as oxygen within their normal ranges. Barriers separating adjacent fluid compartments determine which solutes can move between them. Solute movement, in turn, accounts for the differences in composition of the different compartments. We discussed the mechanisms by which solutes move in Chapter 5. Let's summarize those mechanisms, which apply to all animal cells.

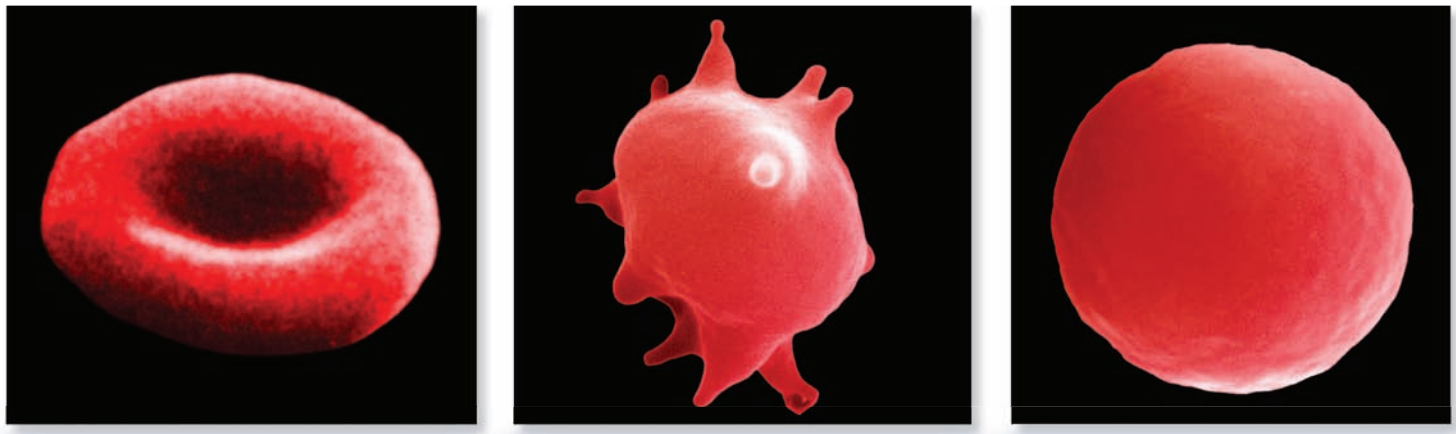
Simple diffusion is the net movement of a solute down its concentration gradient without the aid of a transport protein or hydrolysis of ATP. Simple diffusion is one way in which cells gain and lose solutes. Molecules that can cross phospholipid bilayers are able to passively diffuse into or out of a cell. Examples include nonpolar solutes such as lipids and CO_2, and some very small polar solutes such as ethyl alcohol. Most polar molecules and ions, however, can diffuse through a plasma membrane only if the membrane has channels or transporters of some type that permit the molecule to pass through the bilayer. The rate of diffusion of any solute depends on several factors, notably the concentration gradient of the solute and the area across which it is diffusing. The rate of diffusion of a solute across a membrane of given thickness can be calculated using a modified form of Fick's first law of diffusion adapted for movement across a membrane:

$$J = KA(C_1 - C_2)$$

where J is the rate of diffusion, K is a constant that includes temperature, A is the cross-sectional area of the barrier across which diffusion is occurring, and C_1 and C_2 are the concentrations of the solute at two locations (for example, inside and outside a cell). This equation makes it possible to determine how changes in solute concentrations, temperature, or area can influence the rate at which a substance moves across a plasma membrane. For example, breathing a gas mixture that is enriched in oxygen from a tank will increase the amount of oxygen entering the blood in a mountain climber at high altitude, where oxygen is limited. According to Fick's first law, the difference between C_1 (oxygen in the inhaled gas mixture) and C_2 (oxygen in the blood) will be increased by breathing from the tank. Therefore, we can predict that J, the rate of diffusion of oxygen into the blood, will also be increased, an important survival mechanism at very high altitudes.

In contrast to simple diffusion, the movement of most solutes between compartments or across plasma membranes is mediated by transport proteins via facilitated diffusion or active transport (see Chapter 5). Each of these processes is critical to regulation of intracellular and extracellular fluid composition in animal cells. In Chapter 45, we will discuss one example, the mechanism by which cells obtain their most important energy source, glucose. Because glucose is a moderately sized polar molecule, it cannot diffuse through phospholipid bilayers. Instead, it is transported from the interstitial fluid into cells by membrane-bound proteins.

Movement of Water Between Compartments Water can readily move between adjacent compartments in an animal's body, because barriers such as plasma membranes tend to be highly permeable to water due to the presence of water channels called aquaporins (see Figure 5.18). This movement depends on pressure differences in the fluids of each compartment and on osmosis (see Chapter 5), in which water moves from a region of lower solute concentration to one of higher solute concentration. For cells to function properly, they require a relatively stable internal composition, including ion and protein concentrations, cellular volume, and pH. A decrease in solute concentration outside a cell, for example, will cause water to move by osmosis from outside the cell to inside. In this case, osmosis redistributes fluid from the interstitial to the intracellular compartment. This will cause a cell to become deformed as it swells due to the influx of water. In contrast, an increase in extracellular solute concentration will lead to osmosis of water from inside the cell to outside, causing the cell to shrink. In either case, a swollen or shrunken animal cell generally is more fragile than a normal cell and will die if its membrane ruptures. **Figure 40.8** shows examples of mammalian red blood cells in which intracellular fluid levels have been altered. This could occur, for example, if the blood cells were exposed to extracellular fluids that were either more dilute or more concentrated than the fluid inside the blood cell. When red blood cells swell, they may burst, a phenomenon called hemolysis; shrinkage of red blood cells is called crenation and is also potentially destructive (Figure 40.8, middle panel).



40.2 The Relationship Between Structure and Function

Learning Outcomes:

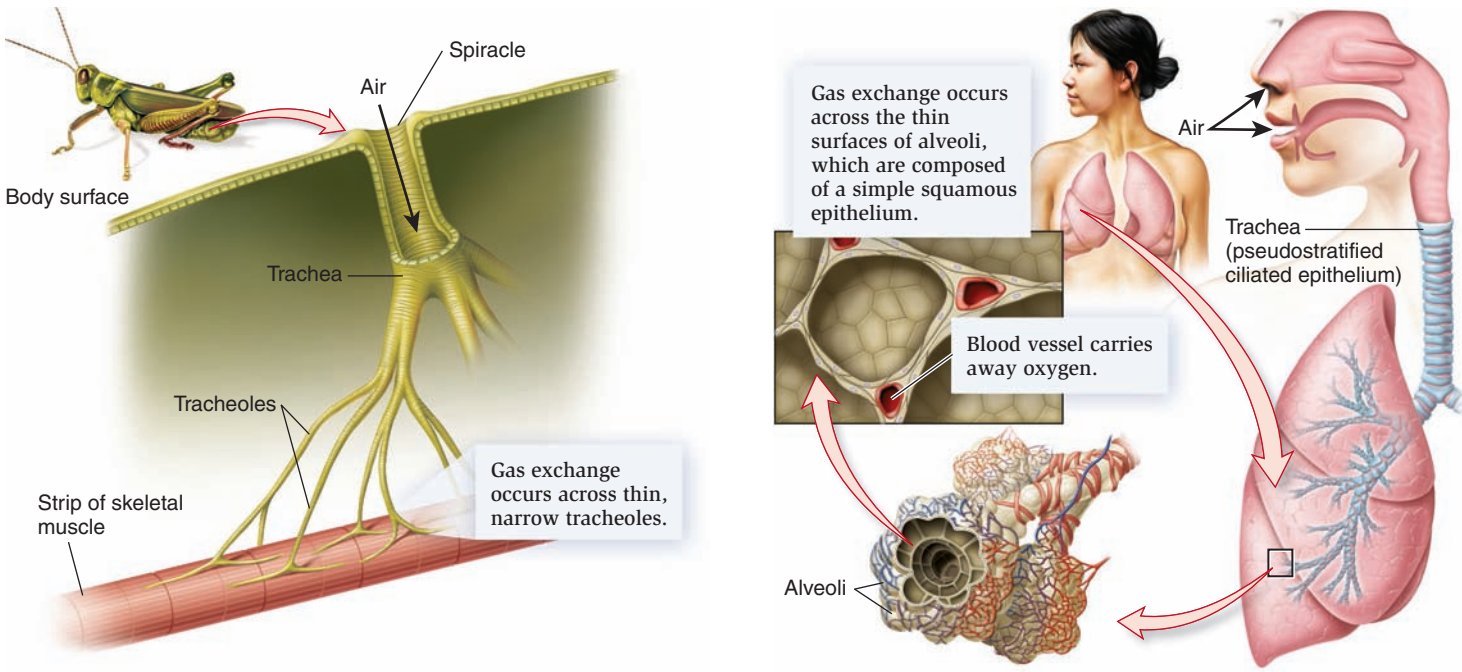
1. Provide an example of how the structure of an animal's tissues or organs can help predict their function.
2. **SciSKILLS** » Explain the importance of the surface area/volume (SA/V) ratio to animal form and function.

A key principle of biology emphasized throughout this unit is that form (structure) and function are closely related. The appearance or structure of an animal's tissues and organs can often help us predict the function. For example, let's compare the respiratory systems of an insect and a mammal (**Figure 40.9**). The respiratory systems of animals exchange oxygen from the environment with carbon dioxide generated by the body. Although many important differences exist between the respiratory systems of insects and mammals, notably the absence of lungs in insects, certain structural similarities suggest that both systems serve similar functions. In both cases, for example, a series of internal branching tubes composed of epithelial and connective tissues arises from one or more openings that connect with the outside environment (the mouth and nose in the mammal, and the pores called spiracles in the insect). These tubes become smaller and smaller as they continue to branch, eventually terminating in narrow structures that are only one cell thick.

Without knowing anything else about the respiratory systems of these two animals, we can surmise that in both cases these branching tubes serve as conduits for air to flow back and forth between the environment and the internal spaces of the animal. In the insect, the ends of the branching tubes called tracheoles are where oxygen diffuses from the air to the fluid around individual cells (and from there to intracellular fluid) (Figure 40.9a). In the mammal, the ends of the tubes form saclike structures called alveoli across which oxygen diffuses into the bloodstream.

Red blood cell in a solution of normal solute concentration

Red blood cell that has lost intracellular fluid when placed in a solution of higher than normal solute concentration



Red blood cell that has gained intracellular fluid when placed in a solution of lower than normal solute concentration

Figure 40.8 Changes in cell shape due to alterations in intracellular fluid volume. Alterations in intracellular fluid volume can have drastic effects on cell shape, as shown by these scanning electron micrographs of red blood cells. Each cell is approximately 5-8 µm in diameter. Dramatic changes in shape like those in the middle and right are usually lethal for cells.

Concept Check: *What effect would changes in intracellular fluid volume have on intracellular solute concentration?*

If we examine the mammalian lung in greater detail (Figure 40.9b), we see that the alveoli are composed of extremely thin, squamous epithelial cells. The shape of the cells provides a clue to their function. Their flat, thin structure permits rapid diffusion of gases across the cells. Imagine the resistance to oxygen diffusion if the cells were thick or scaly, like the cells of the body surface of many animals, for example. Therefore, both the gross and microscopic anatomy of the gas-exchange surfaces of respiratory systems facilitates their functions.

An additional structural similarity found in essentially all respiratory surfaces, including gills, is an extensive surface area. In fact, this structural similarity applies to all cells, tissues, and organs that mediate diffusion or absorption of a solute from one compartment to another, or which require extensive cell-to-cell contacts. Consider, for instance, the finger-like projections of the small intestine of a human, the skin folds of some high-altitude frogs, the cellular extensions on the surface of neurons of a mouse, and the feathery antennae of a moth

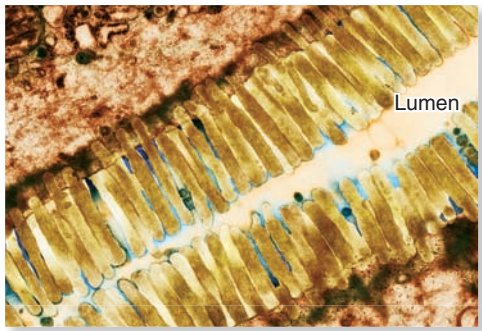
(a) Insect respiratory system

(b) Human respiratory system

Figure 40.9 Comparison of the branching air tubes in (a) an insect and (b) a mammal. Note the similar features of highly branching, internalized hollow tubules that connect to the outside air, suggesting that these systems perform similar functions.

(**Figure 40.10**). What do these structures have in common? They all have a large surface area, which maximizes their ability to absorb solutes (intestine), obtain oxygen by diffusion from the environment (frog skin), communicate with other cells (neurons), or detect airborne molecules (moth antennae). Increasing surface area of a structure, however, comes at the expense of greatly increasing volume if the shape of the structure is not changed (refer back to Figure 4.8). This is because as an object enlarges, its volume grows relatively more than its surface area; as an object enlarges, its surface area increases by a power of 2, and its volume increases by a power of 3. For example, if an animal's height, length, and width are increased by a factor of 10, its surface area is increased 100 times, but its volume is increased 1,000 times. This relationship is also true for an animal's organs and other structures, and could create certain disadvantages. For example, the ability to obtain sufficient oxygen from water requires a great amount of surface area within the fine structure of a fish's gills. Were the gills to increase their volume in the expected proportion just described, they would become far too unwieldy to allow the normal behaviors required for survival of a fish. The challenge of packaging an extensive surface area into a confined space is overcome by changes in shape (see, for example, the way the inner surface of the intestines in Figure 40.10a folds inward to form finger-like extensions). In a fish gill, numerous thin, flat, platelike structures are packed together, one on another, forming a dense array of surfaces available for oxygen diffusion.

The ratio between a structure's surface area and the volume in which the structure is contained is called the **surface area/volume (SA/V) ratio** (see Figure 4.8). A high SA/V ratio is ideal for exchange of heat, solutes, and water across a surface without contributing greatly to the mass of an animal or body part. This concept will appear throughout this unit as we explore the ways in which animals obtain energy, regulate their metabolism and body temperature, obtain oxygen, and eliminate wastes.

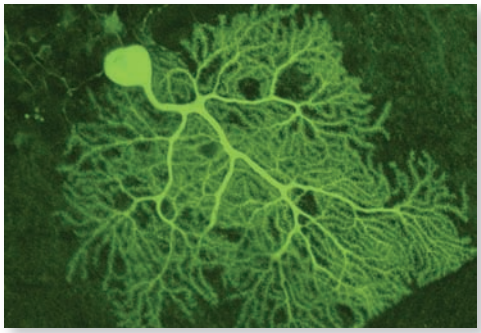


When all of an animal's organ systems function properly and body fluid levels and solute composition are maintained within normal ranges, the animal is generally considered to be in a healthy condition. In the rest of this chapter, we will examine the process of achieving and maintaining this condition, which is known as homeostasis.

40.3 Homeostasis

Learning Outcomes:

1. Discuss the concept of homeostasis as it applies to the internal environment of animals.
2. Distinguish between conforming and regulating as strategies to maintain homeostasis.
3. List several variables that are regulated within a homeostatic range in vertebrate animals.
4. Name the four components of a homeostatic control system, and describe the importance of each to the regulation of an animal's internal environment.
5. **SciSKILLS** » Define negative feedback, positive feedback, and feedforward regulation, and explain how they contribute to the maintenance of homeostasis in animals.
6. Explain the importance of paracrine and hormonal signaling to homeostasis, and provide examples of each.



The environmental conditions in which animals live are rarely, if ever, constant. Animals are exposed to fluctuations in air and water temperatures, nutrient and water supplies, pH, and, in some cases,

(a) Human intestine

(b) Frog skin

(c) Mouse brain neuron stained with a fluorescent marker

(d) Moth antennae

Figure 40.10 Examples of structures in which extensive surface area is important for function. A large surface area allows **(a)** high rates of transport of solutes across the intestine of a human, **(b)** increased diffusion of oxygen across the folds of skin of a frog living at high altitude, where O_2 is less available, **(c)** extensive communication between neurons in a mouse's brain, and **(d)** detection of airborne chemicals by moth antennae.

Concept Check: *Is an extensive surface area important only for animals, or could it also provide advantages to other living organisms?*

oxygen availability. Any one of these environmental changes could be harmful or even fatal if an animal is unable to respond appropriately. However, as you might expect from the incredible diversity of environments in which they exist, animals can adjust in many ways to their surroundings and thrive.

The process of maintaining a relatively stable internal environment despite changes in the external surroundings is known as homeostasis (from the Greek *homoios*, meaning similar, and *stasis*, meaning to stand still). The term was coined in the 20th century by the American physiologist Walter Cannon, but the concept itself originated in the 19th century with the French physiologist Claude Bernard, who postulated that a constant *milieu interieur* (internal environment) was a prerequisite for good health.

Some Animals Conform to External Environments; Others Regulate Their Internal Environments

Generally speaking, animals maintain homeostasis in one of two ways: conforming and regulating. Some animals conform to their environments so that some feature of their internal body composition matches their external surroundings. A marine crab, for example, has about the same solute concentration in its body fluids as is found in seawater. Likewise, the body temperatures of many fishes and aquatic invertebrates match the temperatures of the surrounding waters. Energetically speaking, conforming is a cheap strategy for survival. It would take a great deal of energy for a small fish to maintain its body temperature at, say, 37°C when swimming in the waters near Antarctica. However, because they do not actively adjust their internal body composition, conformers are often restricted to living in environments that are relatively unchanging.

Other animals regulate the composition of their fluids and solutes at levels or concentrations that are different from those of the external environment. Regulating the internal environment requires considerable energy in the form of ATP, which may be used, for example, to actively transport solutes between fluid compartments or to generate heat in cold environments. For this reason, homeostasis for regulators comes with a high energy price tag. However, the price paid by regulators makes it possible for them to exploit environments that fluctuate significantly, something that is difficult for conformers.

Vertebrates Maintain Most Physiological Variables Within a Narrow Range

In vertebrates, the common physiological variables—concentrations of blood-borne solutes such as minerals, glucose, and oxygen, for example—are usually maintained within a certain range despite fluctuating external environmental conditions (**Table 40.2**). At first glance, homeostasis may appear to be a state of stable balance of physiological variables. However, this simple idea cannot capture the scope of homeostasis. For example, no physiological function is

Table 40.2 Selected Examples of Homeostatic Variables in Animals

Variable	Factors that influence homeostasis	Examples of functions
Minerals	Eating food; excreting wastes	
Na^+ and K^+		Establish resting membrane potentials across plasma membranes in all cells and transmit electrical signals in excitable tissues (muscles and nervous tissue)
Ca^{2+}		Important for muscle contraction; neuron function; skeleton and shell formation
Fe^{2+}		Binds and transports oxygen in blood or body fluids (some invertebrates use copper instead of iron)
Energy sources	Eating food; expending energy	
Glucose		Broken down to provide energy for use by all cells, especially brain cells
Fat		Provides an alternate source of energy, particularly for cells not in the nervous system; major component of plasma membranes
ATP		Provides energy to drive most chemical reactions and body functions; modifies function of many proteins by transferring its terminal phosphate group to proteins
Body temperature	Rate of energy expenditure; environmental temperature; behavioral mechanisms (look ahead to Chapter 46)	Determines the rate of chemical reactions in an animal's body
pH of body fluids	Hydrogen ion pumps in cells; buffers in body fluids; rates of energy expenditure; breathing rate	Affects enzymatic activity in all cells
Other variables		
Oxygen and carbon dioxide	Movement of air or water across respiratory surfaces (for example, lungs and gills); rate of metabolism	Oxygen circulates in body fluids and enters cells, where it is used during the production of ATP; carbon dioxide is a waste product that is eliminated to the environment, but it is also a key factor that regulates the rate of breathing air or water.
Water	Drinking, eating, excretion of wastes, perspiration, osmosis across body surface (skin or gills)	Numerous biological functions including participating in chemical reactions; helping to regulate body temperature; acting as a solvent for biologically important molecules (refer back to Chapter 2)

constant for very long, which is why we call them variables. Some variables may fluctuate around an average value during the course of a single day yet still be considered in balance. Homeostasis is a dynamic process, not a static one.

Consider an example in your own body. Normally, blood sugar (glucose) remains at fairly steady and predictable concentrations in any healthy individual. After a meal, however, the concentration of glucose in your blood can increase quickly, especially if you have just eaten something sweet. Conversely, if you skip a few meals, your blood glucose concentration may decrease slightly (**Figure 40.11**). Such fluctuations above and below the normal value might suggest that blood glucose concentrations are not homeostatic, but this is incorrect. Once blood glucose increases or decreases, homeostatic mechanisms restore the concentration back toward normal. In the case of glucose, the nervous and endocrine systems are primarily responsible for this quick adjustment, but in other examples, a wide variety of control systems may be initiated. In later chapters, we will see how every organ and tissue of an animal's body contributes to homeostasis, sometimes in multiple ways, and usually in concert with each other.

Homeostasis, then, does not imply that a given physiological function or variable is rigidly constant. Instead, homeostasis means that a variable fluctuates within a certain normal range and that once it deviates from that range, compensatory mechanisms restore the variable toward normal.

Homeostatic Control Systems Maintain the Internal Environment

The activities of cells, tissues, and organs must be regulated and coordinated with each other so that any change in the extracellular fluid—the internal environment—initiates a response to correct the change. These compensating regulatory responses are performed by homeostatic control systems. A **homeostatic control system** must have several components, including:

- a **set point**—the normal value for a controlled variable;
- a **sensor**, which monitors the level or activity of a particular variable;
- an **integrator**, which compares signals from the sensor with the set point; and
- an **effector**, which compensates for any deviation between the actual value and the set point.

Figure 40.12 shows an example of a homeostatic control system that regulates body temperature in mammals. This system is somewhat analogous to the heating system of a home. In that case, a sensor and integrator within the thermostat compare the actual room temperature with the set point temperature that was determined by setting the thermostat to a given temperature. If the room temperature becomes cooler than the thermostat setting, the effector (furnace) is activated and adds heat to the room. In a mammal, the sensors are temperature-sensitive neurons in the skin and brain, whereas the integrator is within the brain. Signals from the brain are sent along nerves to the effectors, which include skeletal muscles. If body temperature decreases, the muscles contract vigorously in response to these signals, resulting in shivering—a key way in which mammals' bodies generate heat. We will discuss other heat-conserving and heat-generating mechanisms that contribute to this homeostatic control system in Chapter 46.

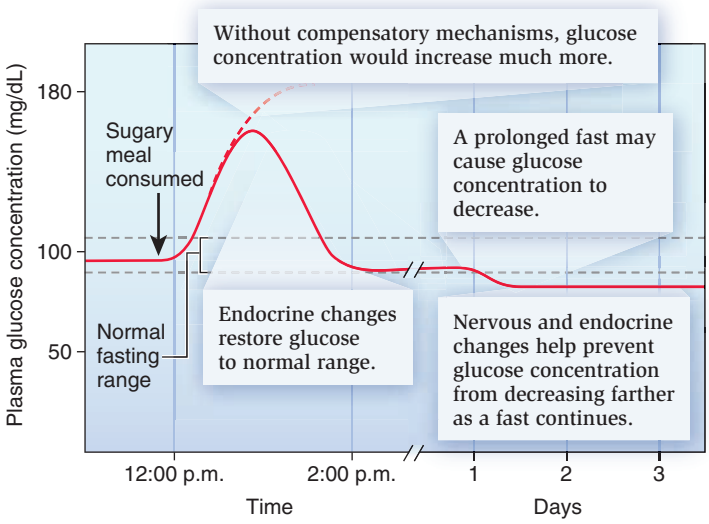


Figure 40.11 An example of a homeostatically controlled variable, glucose concentration in human blood. Note that glucose concentration in the plasma may increase or decrease, depending on whether an animal has recently eaten. However, even after a sugary meal or a prolonged fast, homeostatic mechanisms either return glucose concentration to normal or enable it to remain within the range required for survival. Traditional units for glucose used in the U.S. are used on the vertical axis; as a reference, a value of 100 mg/dL is equal to 5.5 mM.

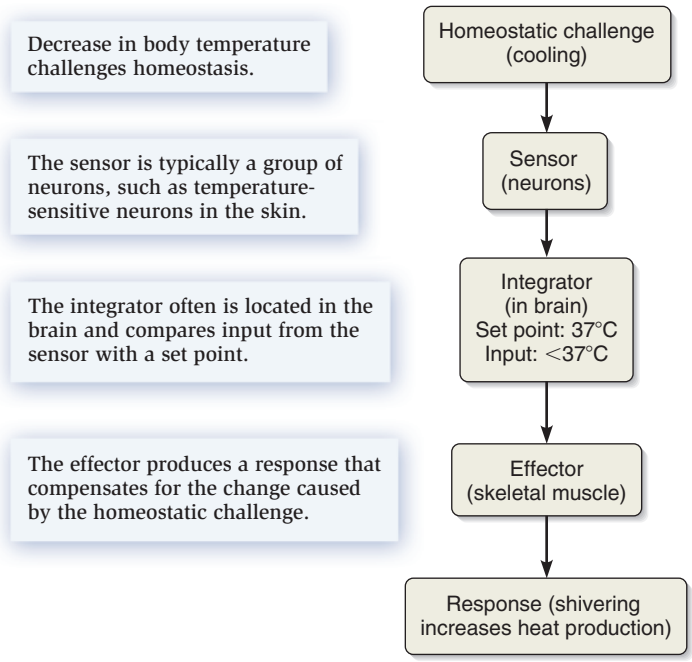

Figure 40.12 An example of a homeostatic control system. The sensor and effector for responding to a decrease in body temperature are shown. Different homeostatic control systems have different sensors and effectors.

Concept Check: Would you expect all animals to have similar set points for a given homeostatic variable?

BIO TIPS **THE QUESTION** *A mouse emerges from its burrow on a cold day to forage for food. Its body temperature quickly decreases, but then does not increase back to normal. Looking at Figure 40.12, how might you account for this failure to respond?*

TOPIC ***What topic in biology does this question address?*** The topic is homeostatic control systems. Specifically, the question addresses how such a system might fail.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you know that the mouse had a homeostatic challenge and failed to respond to it. From your understanding of the topic, you know that there are several components to any homeostatic control system.

PROBLEM-SOLVING STRATEGY ***Sort out the steps in a complicated process.*** Figure 40.12 indicates that in a homeostatic control system that regulates body temperature in a mammal, several responses must occur in sequence for the body temperature to be maintained when the mammal is in a cold environment. These include: (1) sensing the change in the variable (body temperature), (2) comparing it to a set point in the brain, and (3) inducing a compensatory change in temperature by activating effectors (skeletal muscles). To answer the question, consider which, if any, of these responses could have failed to occur in the mouse.

ANSWER *In the mouse, any of these three responses could have failed to function properly. Perhaps the temperature-sensitive neurons were not functioning, or the brain cells responsible for comparing the input to a set point were diseased or not functioning. Finally, the output to the effectors or the effectors themselves may not have been functioning normally. Without further data, none of these possibilities can be ruled out.*

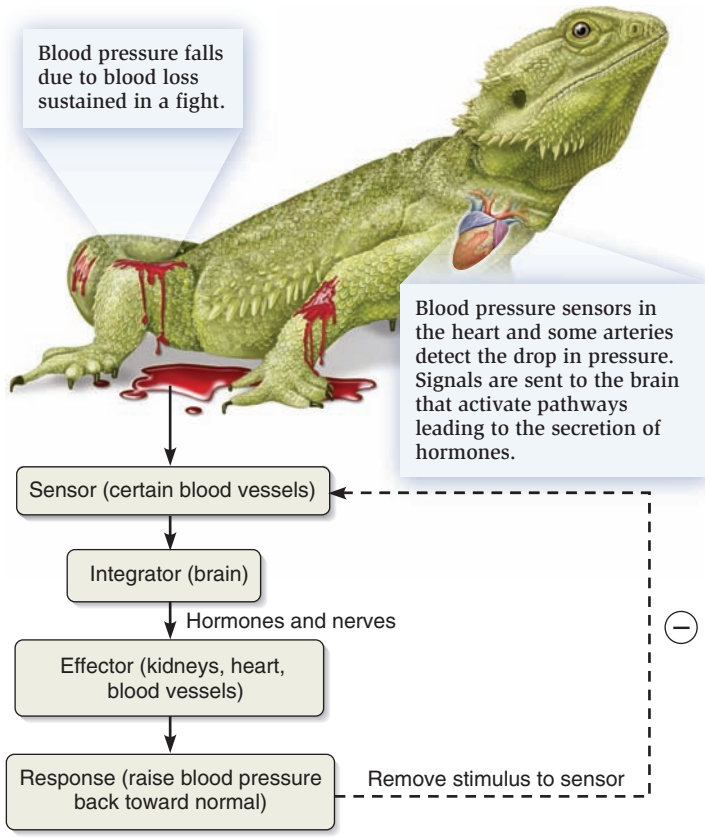

Figure 40.13 **Negative feedback as a mechanism by which homeostatic control systems operate.** In this example, loss of blood results in a decrease in blood pressure, which could be life-threatening if not corrected. Effectors such as the kidneys, heart, and blood vessels help restore blood pressure toward normal. They do not increase blood pressure above normal, however, because of negative feedback (as denoted by the minus sign).

BioConnections: *Can negative feedback occur at levels other than the organ system level shown in this figure? Refer back to Figure 6.13 for help.*

When a homeostatic control system functions normally, changes in a physiological variable are minimized. These changes are further limited by the process of feedback, as we will now see.

Negative Feedback Is a Key Feature of Homeostasis

The temperature regulation system just described is an example of a **negative feedback loop**, in which a change in the variable being regulated brings about responses that move the variable in the opposite direction. Thus, a decrease in body temperature leads to responses that increase body temperature—that is, move it back toward its original value.

Negative feedback also prevents homeostatic responses from overcompensating. When the blood pressure of a bleeding animal decreases as more and more blood is lost, for example, pressure sensors in the heart and certain blood vessels detect the change in pressure and send the information to the integrator—the brain (**Figure 40.13**). In the brain, the signal is compared with the normal set point for blood pressure. The brain responds to this sharp deviation from the blood pressure set point in two ways. First, signals are sent along nerves to the effectors—in this case, the kidneys, heart, and blood vessels. Second, the brain stimulates the release of certain hormones into the blood; these hormones act with the nervous system on the effectors. The result is that the heart beats more rapidly and forcefully, the kidneys produce less urine and thereby retain more body fluid, and the blood vessels preferentially direct blood to the most vital organs such as the brain. These responses raise the animal's blood pressure back toward the set point. Restoring the blood pressure removes the stimulus from the sensor, and this, in turn, shuts off further production of the hormonal and neural responses (negative feedback). If feedback inhibition did not occur, the blood pressure would not only rebound back to the set point but might continue to increase to abnormally high and possibly dangerous levels.

Negative feedback may occur at the organ, cellular, or molecular level. For instance, feedback mechanisms regulate many enzymatic processes. In one example, ATP regulates the rate of its own formation

in cells by inhibiting certain intracellular enzymes that catalyze the breakdown of glucose molecules, a key event in the production of ATP.

Not all forms of feedback contribute to homeostasis. In some cases, a **positive feedback loop** may accelerate a process (think of an avalanche that begins with a small snowball rolling down a steep hill). This is contrary to the principle of homeostasis, in which large fluctuations in a variable are minimized and reversed. Not surprisingly, perhaps, positive feedback is far less common than negative feedback in animals. Nonetheless, positive feedback is crucial to some processes in animal biology. One example is the process of birth in mammals (**Figure 40.14**). Birth is triggered by a positive feedback loop between nerve signals arising from smooth muscle cells of the cervix (the lower narrower part of the uterus) and the mother's brain and pituitary gland (a component of the endocrine system). As the uterus pushes the baby's head against the cervix in late pregnancy, nerve signals from the cervix send information to the brain, which triggers the pituitary gland to release certain hormones. These hormones stimulate the uterus to contract with more force, which in turn sends additional nerve signals to the brain, and so on. Eventually, the uterus contracts strongly enough to deliver the baby—an event that stops the signals from the cervix to the brain and allows the uterus to gradually relax.

Feedforward Regulation Prepares for an Upcoming Challenge to Homeostasis

Built into the homeostatic mechanisms of many animals, particularly those with well-developed nervous systems, is another important feature that minimizes large swings in physiological variables. In **feedforward regulation**, an animal's body begins preparing for a change in some variable (for example, blood glucose concentration) before it even occurs. Consider the anticipatory changes that occur when a hungry dog smells or sees food; indeed, the same phenomenon happens in humans. First, the animal starts to salivate, and its stomach begins to churn. Salivation and movements of the stomach are important components of the digestive process, yet at this stage, the animal has not actually eaten any food. Instead, its digestive system is already preparing for the arrival of food in order to maximize digestive efficiency, speed the flow of nutrients into the blood, and minimize the time required for active cells to replenish energy stores. Therefore, feedforward regulation speeds up the body's homeostatic responses and minimizes fluctuations in the variable being regulated—that is, it reduces the amount of deviation from the set point.

In the preceding example, feedforward control uses sensory detectors that recognize odors and sights. Many examples of feedforward control, however, result from, or are modified by, the phenomenon called learning. The result of this process is that the nervous system learns to anticipate a homeostatic challenge. Familiar examples are the increased heart rate and breathing rate that occur just before an athletic competition—for example, in trained racehorses before the start of a race (**Figure 40.15**). The process of training, in which the horses' bodies learn to prepare for the exertion of the race, prevents a delay between the start of exercise and the flow of blood and nutrients to skeletal muscle. The most famous example of feedforward control was first demonstrated in the early 20th century by Russian physiologist Ivan Pavlov, as described next.

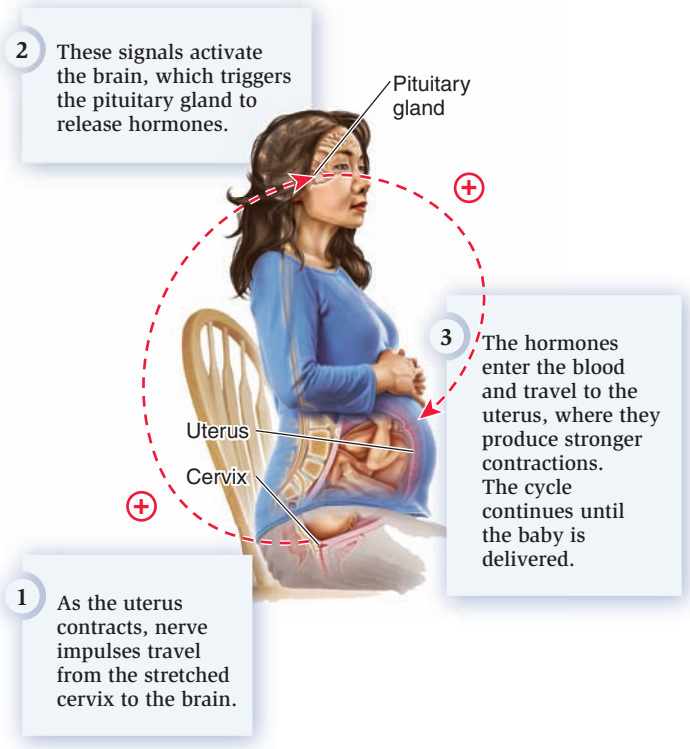

Figure 40.14 The human birth process as an example of positive feedback.

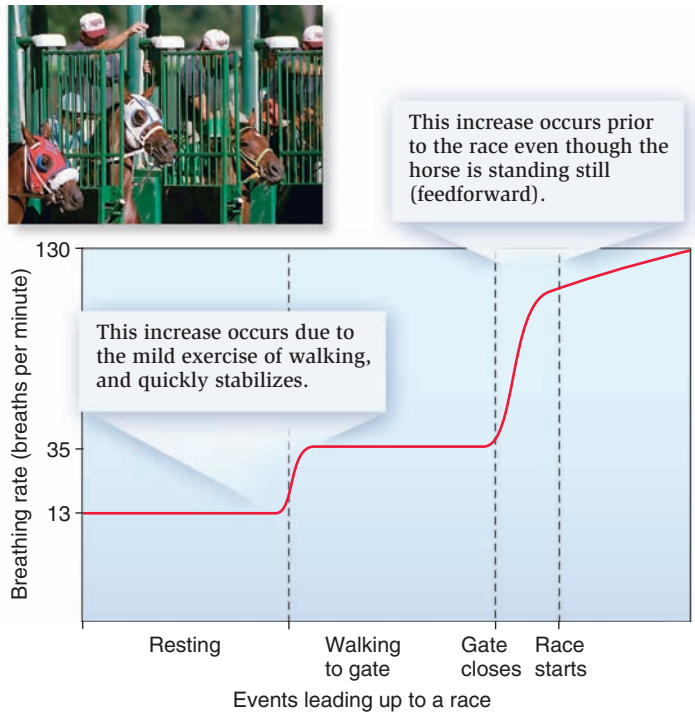

Figure 40.15 Feedforward control of breathing rate in an animal trained for athletic exercise. Feedforward processes prepare the body for an ensuing challenge or event, such as the race shown here.

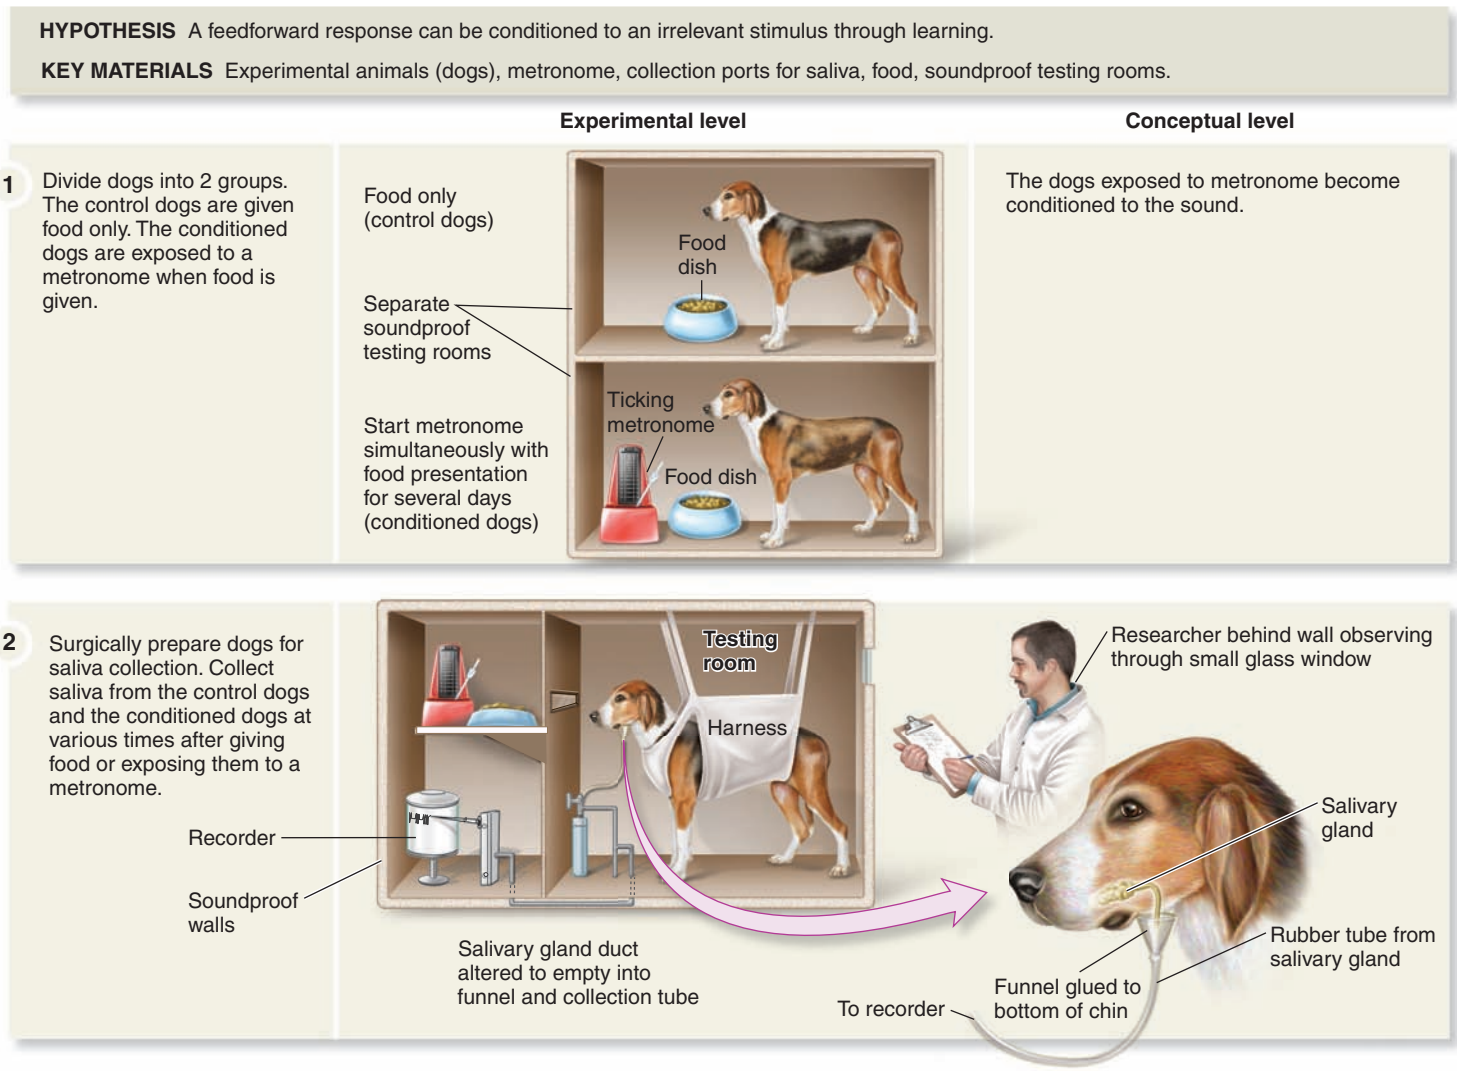
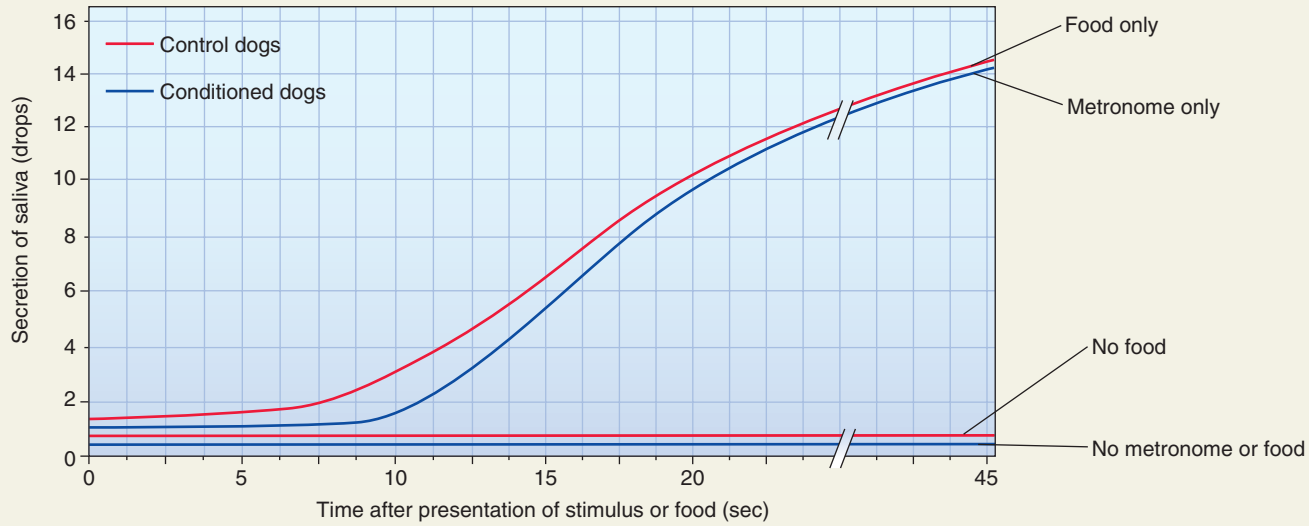
Concept Check: What kind of similar feedforward response might occur in nature?

Feature Investigation | Pavlov Demonstrated the Relationship Between Learning and Feedforward Processes



The Russian physiologist Ivan Pavlov made numerous contributions to our understanding of digestive processes in mammals, for which he earned a Nobel Prize in Physiology or Medicine in 1904. Today, however, Pavlov is best remembered for work he did later in his career, when he demonstrated that feedforward processes associated with digestion could be conditioned to an irrelevant stimulus, that is, one that normally is not associated with digestive processes.

Pavlov was interested in the factors that increase production of saliva in a hungry animal. Saliva is a secretion made by glands in the mouth. It is important because among other things it aids in swallowing and contains enzymes that kill pathogens that may have been ingested with food. Pavlov discovered that dogs accustomed to being fed by the same researcher each day would begin to salivate any time they saw the researcher approaching, even without receiving, seeing, or smelling any food. In other words, the dogs had become conditioned to associate the researcher with food. This did not happen in dogs that were not yet accustomed to the regular feeding schedule of the laboratory. Pavlov hypothesized that any stimulus could elicit the feedforward process of salivation, even one that is not normally associated with feeding, so long as that stimulus was somehow paired with feeding.



To test this hypothesis, Pavlov presented two groups of dogs with either food (the control group) or food plus the ticking of a metronome (the experimental group) (**Figure 40.16**). Each dog was isolated in a room so it could not see, hear, or smell the researcher or sense any other cues that might interfere with the experiment. Pavlov reasoned that after some period of time, the experimental dogs would become conditioned to the sound of the metronome and would learn to associate it with the arrival of food. If this was correct, the metronome by itself should eventually be sufficient to elicit the feedforward process of salivation.

To measure salivary production rates, Pavlov surgically altered the ducts leading from the salivary glands located under the dogs' tongues such that the ducts opened up outside the dog's chin. A glass funnel was then secured beneath the chin. In Pavlov's initial experiments, the

Figure 40.16 **Pavlov's experiments showed that feedforward responses can be conditioned by learning.**

3 THE DATA

4 CONCLUSION The feedforward response of salivation can be modulated by experience and learning, demonstrating the adaptability of animals' physiological responses.

5 SOURCE These idealized data were compiled from several of the original published experiments performed by Pavlov and coworkers. The original experiments were reported in Pawlow, J. 1903. Sur la sécrétion psychique des glandes salivaires. *Archives Internationales Physiologie* 1:119–135. (Note the alternate spelling of Pavlov's name.)

amount of saliva was quantified simply by counting the number of drops coming from a tube leading from the funnel. This was achieved by allowing the saliva to settle onto a mechanical device attached to a rocker arm that caused a deflection on a rotating electrical recorder. Each time a drop was collected, the arm moved and registered a hatch mark on the recorder. The number of hatch marks was equal to the total number of drops of saliva collected in any given period. Pavlov's hypothesis was confirmed when, after a conditioning period of several days, the conditioned stimulus by itself (the metronome) elicited increased salivation in the conditioned dogs in under 10 seconds. The control dogs responded slightly sooner to the appearance of food than the conditioned dogs did to the metronome, but the amount of saliva produced was roughly comparable in both groups of dogs.

In later experiments, Pavlov's data indicated that the response to a conditioned stimulus was not permanent. If a dog that was already conditioned to the sound of a metronome was then repeatedly exposed to that sound without the simultaneous presentation of food, the salivary response to the sound would eventually cease. These experiments demonstrated that certain feedforward processes can be modulated by experience and learning, and they suggested that animals have a much greater ability to recognize and adapt to changes in their environment than previously thought.

Experimental Questions

1. How is feedforward regulation beneficial to animals? Can you think of a situation in which a feedforward process like the one described in Pavlov's experiment might not be beneficial?
2. How did Pavlov control for the possibility that other stimuli, such as the smell of the investigator, were somehow causing the feedforward response?
3. **SciSKILLS »** Analyze the results of Pavlov's experiment, and draw a conclusion about whether or not his hypothesis was supported by the data.

Local and Long-Distance Chemical Signals Coordinate Homeostatic Responses

A common thread that links all homeostatic processes together is communication between cells, whether cells are close to each other or in different parts of an animal's body. Some homeostatic responses are highly localized, occurring only in the area of a disturbance. For example, damage to an area of skin causes cells in the injured area to release molecules that help contain the injury, prevent infections, and promote

tissue repair in the immediate vicinity (see Chapter 53). Local responses provide areas of the body with mechanisms for local self-regulation. It is no benefit to an animal to promote tissue repair in regions of the body that are not injured. This type of cellular communication—in which molecules are released into the interstitial fluid and act on nearby cells—is called **paracrine signaling** (refer back to Figure 9.3d).

Another example of extremely localized signaling occurs between neurons. Most neurons communicate through the release of **neurotransmitters**, small signaling molecules that are synthesized and stored in neurons. When a neuron releases these neurotransmitters, they diffuse to combine with receptor proteins on a single, adjacent neuron (or in some cases a muscle or gland cell), altering the activity of that cell. This type of cell-to-cell communication is typically very rapid, finishing within milliseconds. Consequently, neurotransmitter responses can make immediate homeostatic adjustments, like those associated with reflexes. These are just two of the many types of localized signaling that occur in animals' bodies and that will be described in subsequent chapters in this unit.

In addition to paracrine and neurotransmitter signaling, cells can communicate over long distances by releasing chemical messenger molecules into the blood. This type of signaling is mediated by **hormones**—chemical messengers produced by the endocrine system of animals. A hormone released in response to a homeostatic disturbance, such as the decrease in blood pressure described earlier, can influence the activities of many different cells, tissues, and organs simultaneously because the hormone is carried throughout the entire blood circulation. Some hormones act quickly—within seconds—whereas others take minutes or even hours for their effects to occur. In subsequent chapters, we will see that hormones are a key part of the regulatory processes that govern the functions of every organ system in a vertebrate's body, and they play key roles in growth, development, and reproduction in invertebrates.

Summary of Key Concepts

40.1 Organization of Animal Bodies

- In an animal's body, differentiated cells with similar properties group to form tissues, which combine with other types of tissues to form organs. Organs are functionally linked to form organ systems (Figure 40.1).
- Muscle tissues consist of cells specialized to contract. The three categories of muscle tissue are skeletal, smooth, and cardiac. Nervous tissues initiate and conduct electrical signals from one part of an animal's body to another part. Epithelial tissues are specialized to protect structures and to secrete and absorb ions and organic molecules. Connective tissues connect, surround, anchor, and support the structures of an animal's body (Figures 40.2, 40.3, 40.4, 40.5).
- An organ is composed of two or more kinds of tissues. In an organ system, different organs work together to perform an overall function (Figure 40.6, Table 40.1).
- The development, spatial positioning, and function of many body organs are under the control of *Hox* genes in vertebrates.
- An animal's body fluids are distributed into three compartments (intracellular fluid, plasma, and interstitial fluid). Alterations in intracellular fluid volume can have drastic effects on cell shape (Figures 40.7, 40.8).

40.2 The Relationship Between Structure and Function

- The structure of an animal's tissues and organs are related to the function of those structures (Figure 40.9).
- Extensive surface area maximizes the ability of a tissue or organ to absorb solutes, exchange oxygen and carbon dioxide with the environment, communicate with other cells, and receive sensory information from the environment. The ratio between a structure's surface area and the volume in which the structure is contained is called the surface area/volume (SA/V) ratio (Figure 40.10).

40.3 Homeostasis

- Homeostasis is the process of maintaining a relatively stable internal environment despite changes in the external environment. Some animals conform to their environment, and others regulate internal processes in response to their environment.
- Vertebrates maintain most physiological variables within a certain range despite variations in external environmental conditions (Table 40.2, Figure 40.11).
- Homeostatic control systems regulate the activities of cells, tissues, and organs. Negative feedback loops minimize changes in a variable and prevent homeostatic responses from overcompensating (Figures 40.12, 40.13).
- Positive feedback loops accelerate a process and may not contribute to homeostasis. Feedforward regulation prepares an animal's body for an upcoming challenge to homeostasis (Figures 40.14, 40.15).
- Pavlov's experiments with dogs demonstrated that feedforward responses can be conditioned by experience and learning (Figure 40.16).
- Chemical communication between cells is essential to homeostasis. Local and long-distance chemical signals coordinate homeostatic processes.

Assess and Discuss

Test Yourself

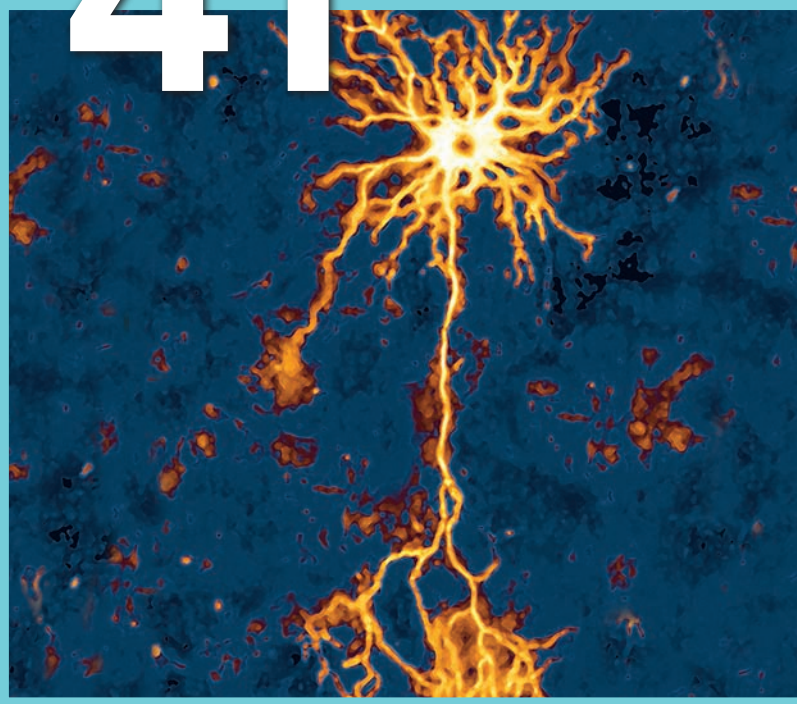
1. Tissue that is specialized to conduct electrical signals from one structure in the body to another structure is _____ tissue.
   a. epithelial
   b. connective
   c. nervous
   d. muscle
2. Structures composed of two or more tissue types arranged in various proportions and patterns are
   a. cells.
   b. tissues.
   c. organs.
   d. organ systems.
   e. organisms.
3. The extracellular matrix (ECM) of connective tissue
   a. contains different proteins that provide structural support to cells.
   b. provides a scaffolding for the cells of the tissue.
   c. plays a role in cellular communication.
   d. does all of the above.
   e. does a and b only.

4. From an examination of the structure of many animal organs,
   a. it is apparent that an organ's surface area increases more than its volume as an organ enlarges.
   b. a general function can sometimes be predicted based on the structural adaptations.
   c. it can be seen that different tissues do not come into contact with each other within an organ.
   d. all four tissues are equally represented in all organs.
   e. None of the above is correct.
5. Most of the water in an animal's body
   a. lacks any type of dissolved ions or other solutes.
   b. is found in the spaces between cells.
   c. is contained inside the cells.
   d. is located in the extracellular fluid.
   e. is unable to move between body compartments.
6. The folds, convolutions, or extensions found in many animal structures result in
   a. decreased level of activity in that particular structure.
   b. interruption in the normal functioning of the structure.
   c. increased surface area for absorption, communication, or exchange.
   d. increased volume without a change in surface area.
   e. none of the above.
7. Adapting to changes in the external environment and maintaining internal variables within physiological ranges is
   a. equilibrium.
   b. a conditioned response.
   c. positive feedback.
   d. homeostasis.
   e. both c and d.
8. Which of the following statements regarding negative feedback is *false*?
   a. It helps regulate variables such as body temperature and blood pressure.
   b. It is the mechanism by which birth occurs in mammals.
   c. It is a major feature of homeostatic control systems.
   d. It prevents homeostatic responses from overcompensating.
   e. It may occur at the organ, cellular, or molecular level.
9. The ability of an animal's body to prepare for a change in some variable before the change occurs is called
   a. positive feedback.
   b. negative feedback.
   c. homeostasis.
   d. feedforward regulation.
   e. autoregulation.
10. A hormone differs from a neurotransmitter in that
    a. hormones act extracellularly, whereas neurotransmitters act within the cell that synthesized them.
    b. hormones are released only by neurons, whereas neurotransmitters are released by many different types of cells.
    c. hormones cause only fast responses (seconds or less) to stimuli, whereas neurotransmitters cause slow responses (minutes to hours) to stimuli.
    d. hormones affect only epithelial cells, whereas neurotransmitters affect only muscle cells.
    e. hormones are released into the bloodstream and can activate many cells in many parts of the body, whereas neurotransmitters are released by neurons and affect adjacent cells.

Conceptual Questions

1. Describe the relationship between structure and function in animals, and explain how surface area and volume are related.
2. Define homeostasis, and give examples of homeostatic variables in animals.
3.  Two principles of biology are *living organisms use energy* and *living organisms maintain homeostasis.* How are energy use and the maintenance of homeostasis related?

Collaborative Questions



1. Define the terms negative feedback loop and positive feedback loop, and describe how they differ.
2. Discuss the organization of animal bodies from the cellular to the organ system level. Given that organ systems interact extensively with each other, should each system really be considered distinct, or is it possible to think of an animal's body as being composed of one large, integrated "system"?

CHAPTER OUTLINE

41.1 Cellular Components of Nervous Systems
41.2 Electrical Properties of Neurons and the Resting Membrane Potential
41.3 Generation and Transmission of Electrical Signals Along Neurons
41.4 Neurons Communicate Electrically or Chemically at Synapses
41.5 Impact on Public Health
Summary of Key Concepts
Assess and Discuss

Neuroscience I: Cells of the Nervous System

41

A fluorescently stained human neuron. These types of cells are responsible for sending signals throughout the nervous systems of animals.

As you begin reading, stop and think. Can you describe everything you are doing right now? Your eyes are sensing light reflected off this page, and your brain is interpreting the meanings of the words you are reading. You may be hearing sounds and, in some cases, choosing to ignore them as you concentrate on reading. Your digestive system may be sending signals about hunger, or perhaps if you've just eaten, you feel full and are digesting what you ate. You are breathing, perspiring, feeling the chair on which you're sitting, and your heart is beating. All of these processes and many others are under the control of the **nervous system**, coordinated circuits of cells that sense internal and environmental changes and transmit signals that enable you to respond in an appropriate way. Our nervous system helps us exert control over our bodies. It also allows us, like other animals, to sense what is going on in the outside world, initiate actions that influence events and respond to demands, and regulate internal processes—all while maintaining homeostasis (see Chapter 40 for a discussion of homeostasis). You are conscious of some of these functions, such as reading this text or feeling hungry. Many others, however, such as maintaining your body temperature and controlling your heart rate, occur without your awareness.

Neuroscience is the scientific study of nervous systems. Neuroscientists are interested in topics such as the structure and function of the brain and the biological basis of consciousness, memory, learning, and behavior. Neuroscience is an interdisciplinary field that interfaces with other disciplines such as cell and molecular biology, chemistry, physics, psychology, and linguistics. It is experiencing an unprecedented level of new discoveries and rapid growth.

In this chapter, our focus on neuroscience will be at the cellular level. Nervous systems are composed of circuits of **neurons**, highly specialized cells that communicate with each other and with other types of cells by electrical or chemical signals (see the chapter opening photo). In many animals, such as ourselves, neurons become organized into a central processing area of the nervous system called a **brain**. The brain sends commands to and receives signals from various parts of the body through **nerves**—bundles of neuronal cell extensions encased in connective tissue and projecting to and from various tissues and organs.

We begin by investigating the special features of neurons that make them suited for rapid communication between cells. We will look at electrical and chemical gradients across the neuronal plasma membrane and how these gradients produce a way for neurons to convey signals. Next, we will explore how neurons send and receive signals. We will consider general features of the main classes of signaling molecules called neurotransmitters and end by examining the various effects of therapeutic, recreational, and illicit drugs on neurotransmitter action. Chapters 42 and 43 will explore how nervous systems evolved and are organized, how the brain functions, and how animals use their nervous systems to sense the world around them.

41.1 Cellular Components of Nervous Systems

Learning Outcomes:

1. Explain the difference between the central nervous system (CNS) and the peripheral nervous system (PNS).
2. List the cellular components of the nervous system, and describe the function of each cell type.
3. **SciSKILLS »** Identify the different parts of a typical neuron, and explain how the structure of each relates to its function.
4. Describe the functional relationships among sensory neurons, motor neurons, and interneurons.
5. **SciSKILLS »** Explain what a reflex is, and propose reasons why reflexes are important in animals.

The organization of the nervous system permits extremely rapid responses to changes in an animal's external or internal environment. In many animals, the **central nervous system (CNS)** consists of a brain and a nerve cord, which in vertebrates extends from the brain through the vertebral column and is called the **spinal cord**. The **peripheral nervous system (PNS)** consists of all neurons and projections of their plasma membranes that are outside of but connect with the CNS, such as projections that end on muscle and gland cells. In certain invertebrates with simple nervous systems, the distinction between the CNS and PNS is less clear or not present.

The evolution of nervous systems has allowed animals to receive information about the environment via their PNS, transmit that information along nerves to a CNS, where that information is interpreted, and, if necessary, initiate a behavioral response via their PNS (**Figure 41.1**). For example, if a hungry hyena receives stimuli such as the smell and taste of food, odor-sensing cells in the nose and taste-sensing cells in the tongue act as receptors for the stimuli and then send signals along nerves to the brain. There, the signals are interpreted and recognized. The brain then sends a signal via nerves that stimulate gland cells in the mouth, which respond by producing saliva in preparation for the arrival and swallowing of food. In this section, we will survey the general properties of the cells of the central and peripheral nervous system.

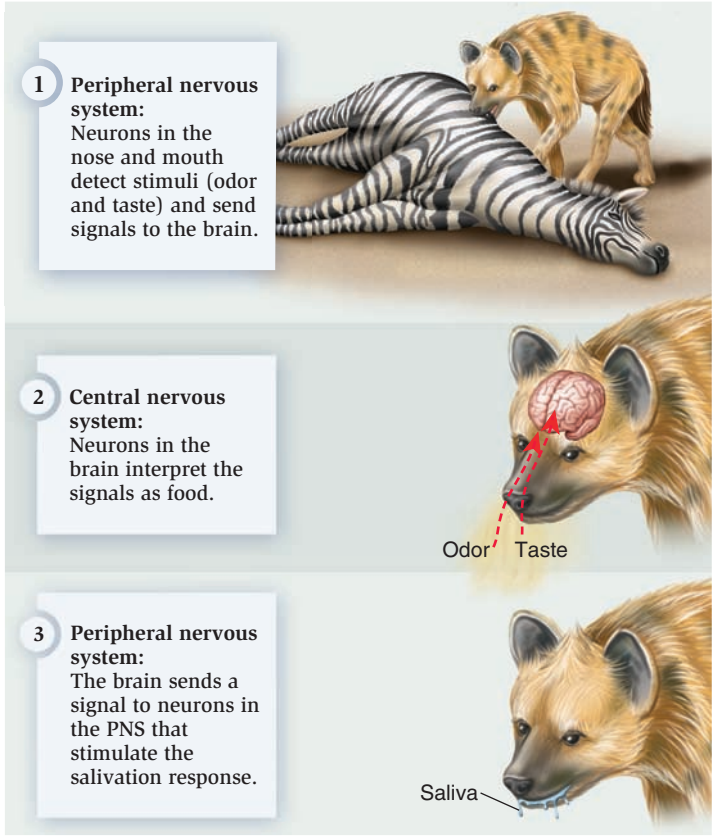


Figure 41.1 Functional relation between the central and peripheral nervous systems. In this example, a hungry hyena senses a smell and taste, which the brain interprets as a potential food source. This initiates a biological response (salivation) that prepares the hyena for eating.

BIOLOGY PRINCIPLE Living organisms interact with their environment. Throughout this and the following two chapters, you will see many examples of how the nervous system of an animal is key to fulfilling this principle. In this example, a hungry animal uses both divisions of its nervous system to interact with its environment.

BioConnections: Look back at Figures 40.15 and 40.16. What type of response is demonstrated by the production of saliva in this figure? Note that saliva is being produced before the animal has consumed any food.

Cells of the Nervous System Are Specialized to Receive and Send Signals

Nervous systems transfer signals from one part of the body to another and direct the activities of cells, tissues, organs, and glands. Although these are complex tasks, nervous systems have only two unique classes of cells: neurons and glia.

Neurons All animals except sponges have neurons, cells that send and receive electrical and chemical signals to and from each other and other cells throughout the body. The number of neurons in the nervous systems of different species varies widely, partly as a function of the size of an animal's head and brain, but also as a function of the complexity of its behavior. As a comparison, the tiny, short-lived nematode *Caenorhabditis elegans* has 302 neurons in its nervous system, compared with several thousand in a wasp, several hundred thousand in a salamander, 300 million in an octopus, and over 100 billion in a human!

Regardless of their total number, neurons in one animal species look and function much like neurons from any other species. A neuron is composed of a **cell body** (sometimes called the soma), which contains the cell nucleus and other organelles (**Figure 41.2a** and **b**). There are two types of extensions or projections that arise from the cell body: dendrites and the axon. **Dendrites** (from the Greek word *dendron*, meaning tree) may be single projections of the cell body but more commonly are elaborate treelike structures with numerous branching extensions that provide a large surface area for contacts with other neurons. Electrical and chemical messages from other neurons are received by the dendrites, and electrical signals move toward the cell body (**Figure 41.2c**). The cell body processes these signals, as well as others that it receives directly, and produces an outgoing signal to a structure called an axon.

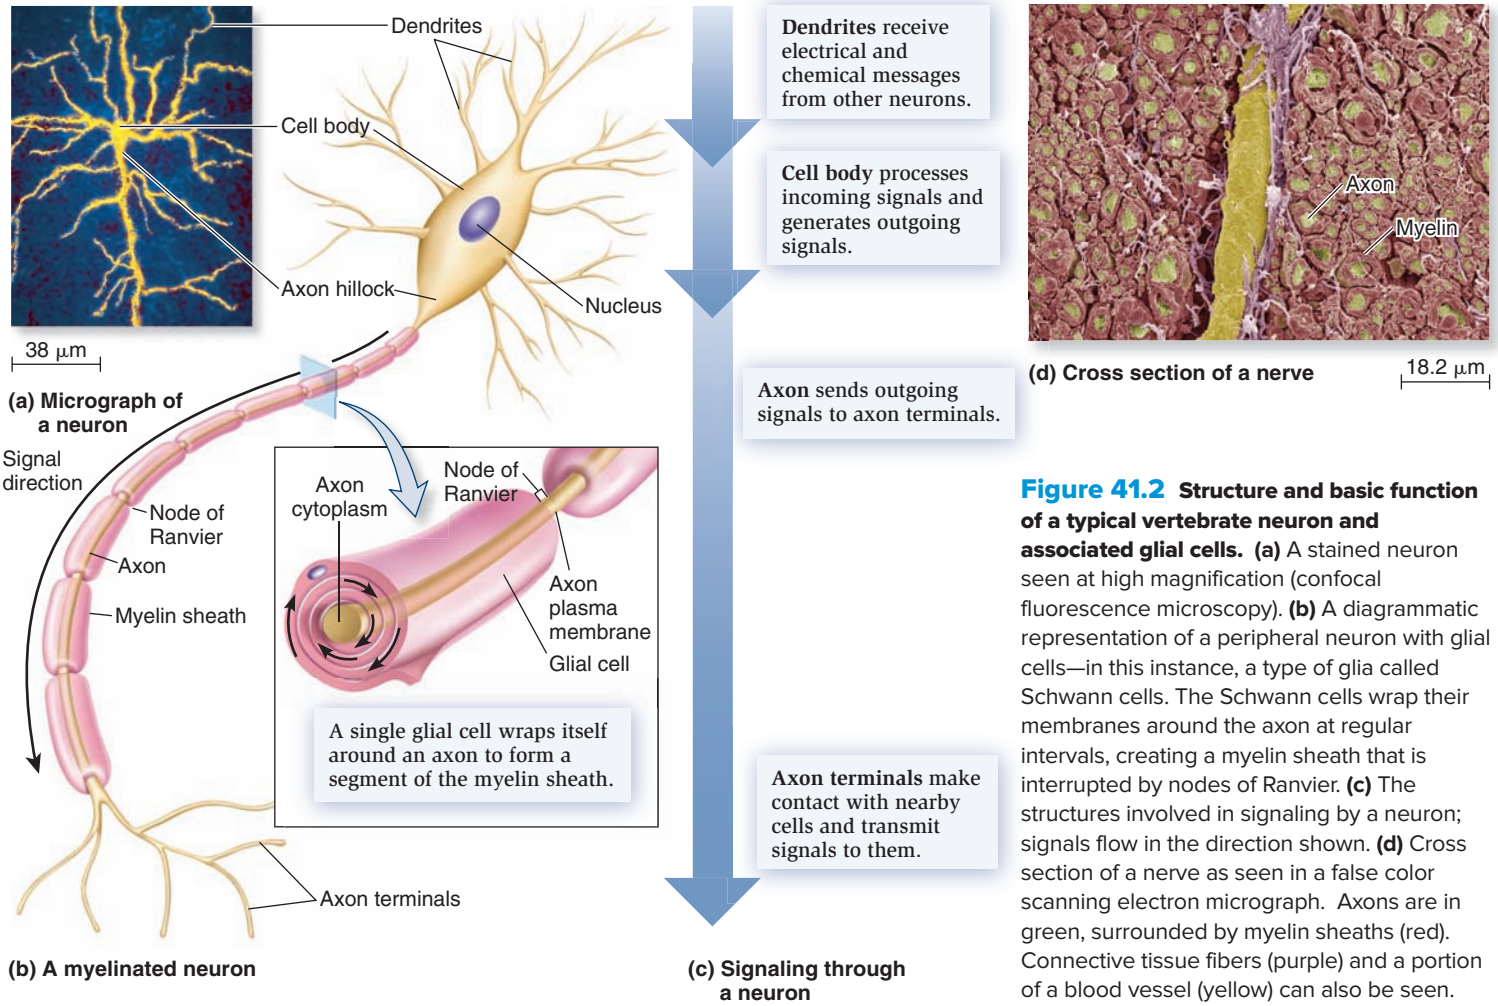

Figure 41.2 Structure and basic function of a typical vertebrate neuron and associated glial cells. **(a)** A stained neuron seen at high magnification (confocal fluorescence microscopy). **(b)** A diagrammatic representation of a peripheral neuron with glial cells—in this instance, a type of glia called Schwann cells. The Schwann cells wrap their membranes around the axon at regular intervals, creating a myelin sheath that is interrupted by nodes of Ranvier. **(c)** The structures involved in signaling by a neuron; signals flow in the direction shown. **(d)** Cross section of a nerve as seen in a false color scanning electron micrograph. Axons are in green, surrounded by myelin sheaths (red). Connective tissue fibers (purple) and a portion of a blood vessel (yellow) can also be seen.

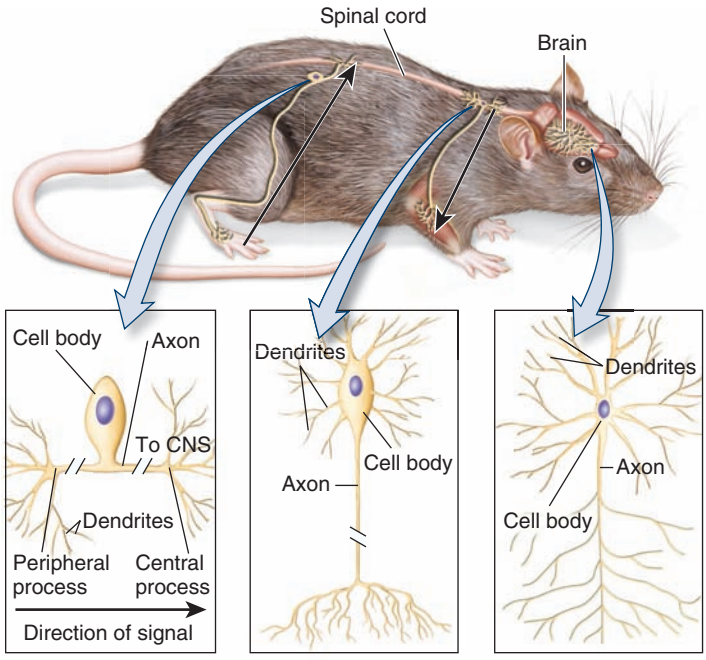
An **axon** is an extension of the cell body that transmits signals along its length and eventually to neighboring cells. An axon may be only a few micrometers long or as long as 2 m, such as those in very large or long-limbed animals. A typical neuron has a single axon, which may have branches and which may be wrapped in an insulating layer of tissue called myelin (described shortly). The part of the axon closest to the cell body is named the **axon hillock**. As we will see later, the axon hillock is important in the generation of the electrical signals that travel along an axon. At the other end of the axon are one or more **axon terminals**, which convey electrical or chemical messages to other cells, such as other neurons or muscle cells.

Within an animal's body, many axons tend to run in parallel bundles to form nerves, within and around which are protective layers of connective tissue (**Figure 41.2d**). Nerves enter and leave the CNS and transmit signals between the PNS and the CNS. Along the way, the axon terminals communicate with particular cells of the body.

Glia **Glia** (from the Greek, meaning glue) are cells that surround neurons and perform numerous roles. One type of glia, called astrocytes, provide metabolic support for neurons and are also involved in forming the blood-brain barrier, which is a physical barrier between blood vessels and most parts of the CNS. This barrier prevents the passage of toxins and other damaging chemicals from the blood into the extracellular fluid around neurons in the CNS. Astrocytes also help to maintain a stable concentration of ions in the extracellular fluid. Other glia, called microglia, participate in immune functions and remove cellular debris produced by damaged or dying cells.



In vertebrates, specialized glial cells wrap around the axons at regular intervals to form an insulating layer called a **myelin sheath** (see Figure 41.2b and d). The sheath is periodically interrupted by noninsulated gaps called **nodes of Ranvier**. In the vertebrate brain and spinal cord, the myelin-producing glial cells are called **oligodendrocytes**. **Schwann cells** are the glial cells that form myelin on axons that travel outside the brain and spinal cord. As we will see later, myelin and the nodes of Ranvier increase the speed with which electrical signals pass down the axon.

Sensory and Motor Neurons Along with Interneurons Form Pathways in a Nervous System

Neurons can be categorized into three main types: sensory neurons, motor neurons, and interneurons. The structures of each type reflect their specialized functions.

Sensory Neurons As their name suggests, **sensory neurons** detect or sense information from the outside world, such as light, odors, touch, or heat. In addition, sensory neurons detect internal body conditions such as blood pressure or body temperature. Sensory neurons are also called afferent (from the Latin, meaning to bring toward) neurons because they transmit information from the periphery to the CNS. Many sensory neurons have a long, single axon that branches into a peripheral process and a central process, with the cell body in between (**Figure 41.3a**). This arrangement allows for the rapid transmission of a sensory signal to the CNS.

Motor Neurons **Motor neurons** transmit signals away from the CNS and elicit some type of response that depends on the type of cell receiving the signal. Motor neurons are so named because one type of response they cause is movement. In addition, motor neurons may cause other effects such as the secretion of hormones from endocrine glands. Because they send signals away from the CNS, motor neurons are also called efferent (from the Latin, meaning to carry from) neurons. Like sensory neurons, motor neurons tend to have long axons (**Figure 41.3b**), but these do not branch into two main processes.

(a) Sensory neuron **(b) Motor neuron** **(c) Interneuron**

Figure 41.3 Types of neurons. **(a)** Vertebrate sensory neurons are afferent neurons with an axon that bypasses the cell body and projects to the CNS. **(b)** Motor neurons are efferent neurons that transmit signals away from the CNS and usually have long axons that enable them to act on distant cells. **(c)** Interneurons are usually short neurons that connect two or more other neurons within the CNS. Although short, the axons and dendrites may have extensive branches, allowing them to receive many inputs and transmit signals to many neurons.

BIOLOGY PRINCIPLE **Cells are the simplest units of life.** Cells are the simplest units of any organ system, including the nervous system. However, the variety and complexity of cells within an organ system can be great, as seen here.

Interneurons A third type of neuron, called the **interneuron**, forms interconnections between other neurons in the CNS. The signals sent between interneurons are critical in the interpretation of information that the CNS receives, as well as the response that it may elicit. Interneurons tend to have many dendrites, and their axons are typically short and highly branched (**Figure 41.3c**). This arrangement allows interneurons to form complex connections with many other cells.

Reflex Arcs As a way to understand the interplay between sensory neurons, interneurons, and motor neurons, let's consider a simple example in which these types of neurons form interconnections with each other. Neurons transmit signals to each other through a series of connections that form a circuit. An example of a simple circuit is a **reflex arc**, which allows an organism to respond rapidly to inputs from sensory neurons and consists of only a few neurons (**Figure 41.4**). The stimulus from sensory neurons is sent to the CNS, but there is little or no interpretation of the signal; typically there are very few, if any, interneurons involved, as in the example shown in Figure 41.4. The signal is then transmitted to motor neurons, which elicit a response, such as a knee jerk. Such a response is very quick and automatic.

Reflexes are among the evolutionarily oldest and most important features of nervous systems, because they allow animals to respond quickly to potentially dangerous events. For instance, many vertebrates will immediately cringe, jump, leap, or take flight in response to a loud noise, which could represent sudden danger. Some animals that live in the water will reflexively dive deeper in response to a shadow overhead, which could represent a passing shark or other predator. Many infant primates have strong grasping reflexes that help them hold onto their mother as she moves about. Countless examples of useful reflexes are found in animals, and their importance is evident from the observation that they arose early in evolution and exist in nearly all animals.

41.2 Electrical Properties of Neurons and the Resting Membrane Potential

Learning Outcomes:

1. Explain what a membrane potential is.
2. Describe how the resting membrane potential is established and maintained.
3. Describe how an electrochemical gradient determines the direction in which an ion will move.
4. **SciSKILLS** » State the Nernst equation, and use it to predict the direction in which different ions move across a plasma membrane.

In the late 18th century, Italian scientists Luigi Galvani and Alessandro Volta experimented with ways to stimulate the contraction of frog leg muscles that had been dissected and placed in saline (NaCl) solutions. The saline solutions approximated the ion concentrations in plasma, kept the muscles alive, and also conducted electricity. The two scientists discovered that the stimulation of the nerve to the muscle or the stimulation of the muscle itself with any source of electric current caused the muscle to contract. Eventually, Galvani postulated

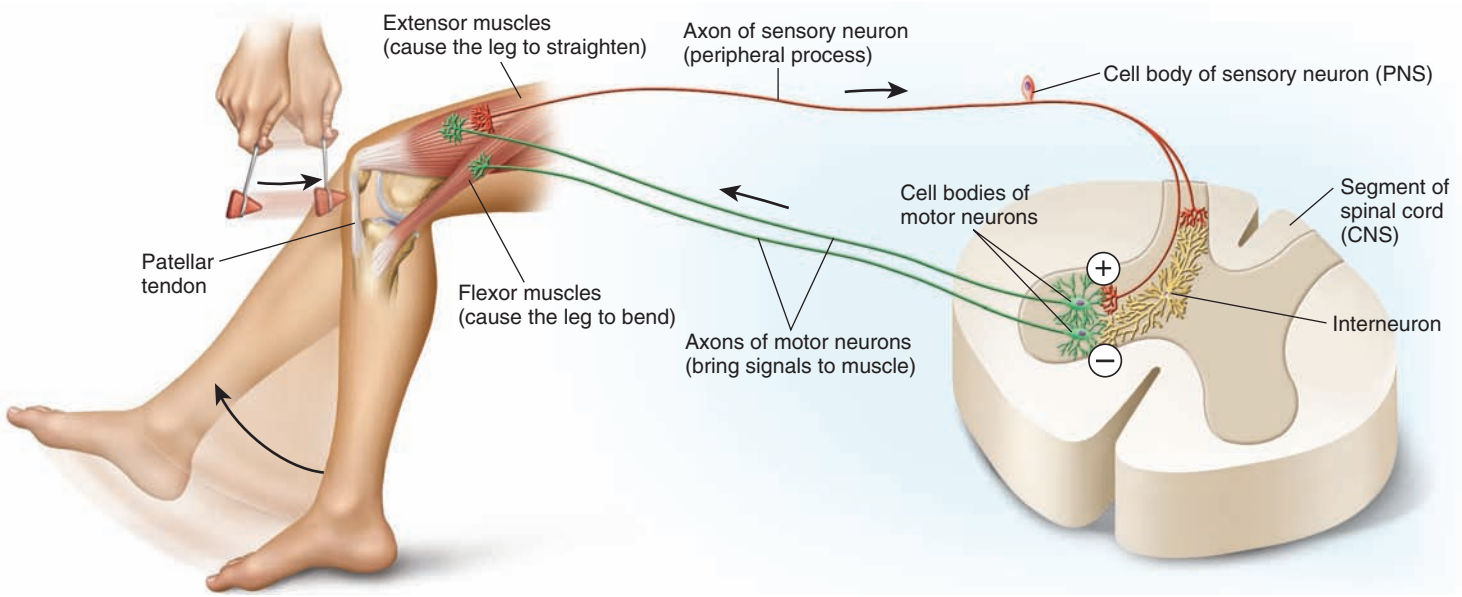


Figure 41.4 A reflex arc. The knee-jerk response is an example of a reflex arc. A tap below the kneecap (also known as the patella) stretches the patellar tendon, which acts as a stimulus for a sensory neuron. This stimulus initiates a reflex arc that activates (+) a motor neuron that causes the extensor muscle on top of the thigh to contract. At the same time, an interneuron inhibits (–) the motor neuron of the flexor muscle, causing it to relax.

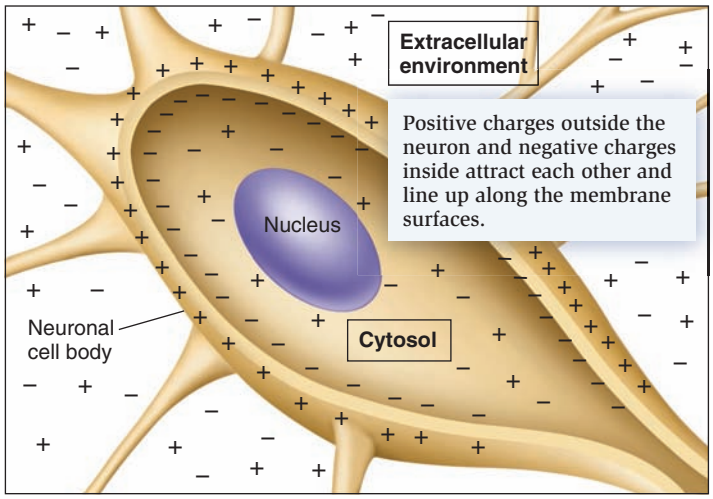
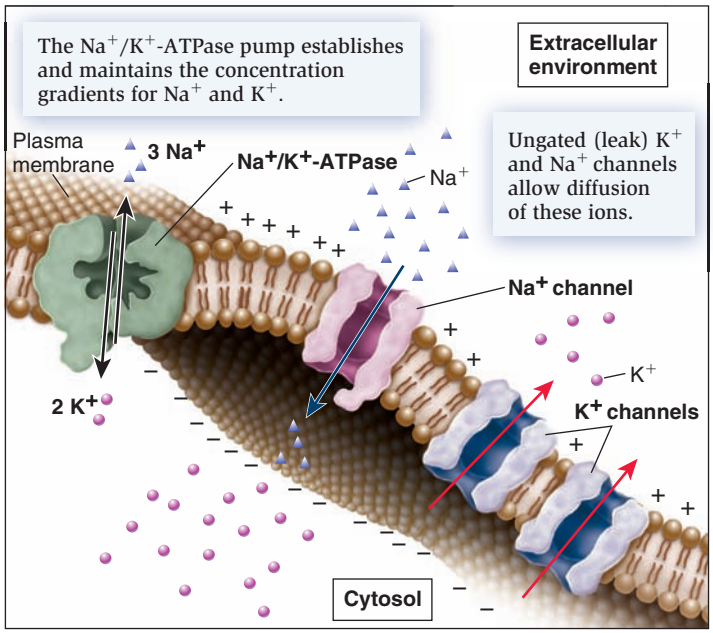
Concept Check: Animals have many types of reflexes. Once initiated, must all reflexes occur to completion, or do you think that in some cases they may be overridden or partially suppressed?

that electric current could somehow be generated by the tissue itself, something he called "animal electricity."



Today, we know that Galvani's animal electricity comes from neurons, which use electrical signals to communicate with other neurons, muscle cells, or gland cells. These signals, often called nerve impulses but properly called action potentials, involve changes in the amount of electric charge across a neuron's plasma membrane. In this section, we will first examine the electrical and chemical gradients across the plasma membrane of neurons. Later, we will explore how such gradients provide a way for neurons to conduct signals.

Neurons Establish Differences in Ion Concentration and Electric Charge Across Their Membranes



Like all cell membranes, the plasma membrane of a neuron acts as a barrier that separates charges. Ion concentrations differ between the interior and exterior of the cell. Such differences in charge act as an electrical force measured in **volts** (V), named after Alessandro Volta. Analogous to a battery, neurons have negative and positive poles, but these are the inside and outside surfaces of the plasma membrane. For this reason, a neuron is said to be electrically polarized. The difference between the electric charges along the inside and outside surfaces of a cell membrane is called a potential difference, or **membrane potential**. The **resting membrane potential** refers to the membrane potential of an unstimulated cell that is not sending action potentials.

Let's begin our discussion of electrical signaling by examining how the resting membrane potential is established and maintained. The plasma membrane is not very permeable to cations and anions, so it separates charge by keeping different ions largely inside or outside the cell. When investigators first measured the resting membrane potential of neurons, they registered a voltage that read about −70 millivolts (mV) inside the cell with respect to the outside. This means that the interior of the cell had a more negative charge than the exterior, which turns out to be typical of animal cells in their resting state. For comparison, a resting potential of −70 mV is tiny compared with the voltages used to provide electric current in a home (approximately 120 V), or even that of a small 1.5 V battery. Nonetheless, this tiny difference in charge across the membrane of a neuron is sufficient to provide the means for generating an action potential that can travel from one end of a neuron to the other, as we will see later in this chapter.

The resting membrane potential is determined by the ions located along the inner and outer surfaces of the plasma membrane (**Figure 41.5a**). Ions of opposite charges align on either side of the membrane because they are attracted to each other due to electrical forces. Negative ions within the cell are drawn to the positive ions arrayed on the outer surface of the plasma membrane. Although there are more positive charges along the outside surface of a neuron and more negative charges inside, the actual number of ions that contribute to the resting membrane potential is extremely small compared with the total number of ions inside and outside the cell. **Table 41.1** lists the ions that are important in maintaining the resting potential and their typical intracellular and extracellular concentrations in mammals and many other vertebrates. The ions that are most critical for establishing the resting membrane potential are Na^+ and K^+ and, to a lesser extent, Cl^-.

(a) Distribution of charges across the neuronal plasma membrane

(b) Two major factors that influence the resting membrane potential

Figure 41.5 The resting membrane potential. The slight excess of negative charges inside the cell is shown in part **(a)**. In part **(b)**, the two major factors that contribute to this charge distribution are shown: the Na^+/K^+-ATPase pump that establishes ion concentration gradients, and ungated ion channels that permit diffusion of Na^+ and especially K^+ across the membrane.

BIOLOGY PRINCIPLE Living organisms use energy. The Na^+/K^+-ATPase pump uses the energy stored in ATP to transport ions across the neuronal plasma membrane. Consequently, establishing and maintaining resting membrane potentials accounts for a significant fraction of the energy consumed per day in an animal, including a human.

Two factors are primarily responsible for the resting membrane potential (Figure 41.5b).

1. **Establishment of ion concentration gradients:** The Na^+/K^+-ATPase pump within the plasma membrane continually moves Na^+ out of the cell and K^+ into the cytosol (refer back to Figure 5.22). The Na^+/K^+-ATPase pump uses the energy of ATP to transport three Na^+ out of the cell for every two K^+ it moves into the cell. Consequently, the pump contributes modestly to a charge difference across the plasma membrane. More importantly, however, it establishes concentration gradients for Na^+ and K^+ by continually transporting them across the membrane in opposite directions. These concentration gradients will determine the directions in which the ions will move by diffusion either into or out of the cell.
2. **Membrane permeability to different ions:** The plasma membrane contains ion-specific channels that affect the permeability of Na^+ and K^+ across the membrane. Ungated channels that are specific for Na^+ or K^+ influence the resting potential by allowing the passive movement of these ions. An ungated channel, sometimes referred to as a leak channel, is one that is open at rest and that does not require stimuli such as ligand binding to open. In most neurons, there are anywhere from 10 to 100 times more ungated K^+ channels than ungated Na^+ channels, so at rest, the membrane is more permeable to K^+ than to Na^+. As you will learn shortly, Na^+ tends to diffuse into cells and K^+ diffuses out of cells when the cell is at rest. The greater number of leak channels for K^+, therefore, means that diffusion of K^+ makes a more significant contribution to resting membrane potential than does diffusion of Na^+, and excess positive charges exit the cell.

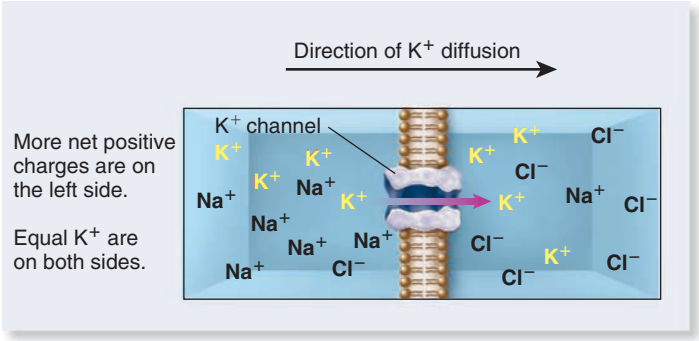


Table 41.1 Extracellular and Intracellular Concentrations of Ions for a Typical Mammalian Neuron

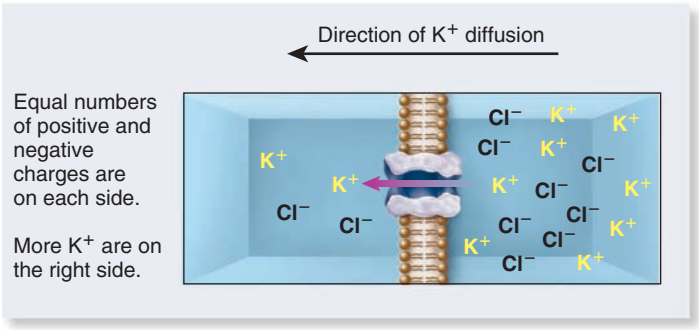
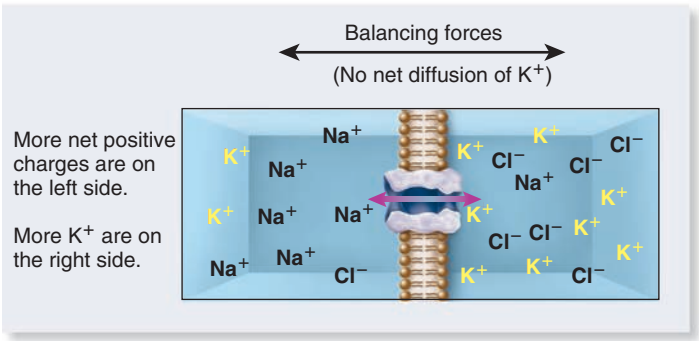
	Concentration (mM)	
Ion	Extracellular	Intracellular
Na^+	145	15
K^+	5	150
Cl^-	110	7



Now let's see how this movement of ions occurs, and its consequences.

An Electrochemical Gradient Governs the Movement of Ions Across a Membrane



The direction that an ion moves depends on the **electrochemical gradient** for that ion, which is the combined effect of both an electrical and a chemical (concentration) gradient. Figure 41.6 considers the concept of an electrochemical gradient for K^+, using two compartments separated by a semipermeable membrane that permits the diffusion of only K^+. Figure 41.6a illustrates an electrical gradient. In this case, the concentration of K^+ is equal on both sides of the membrane, but the concentrations of other ions (Na^+ and Cl^-) are unequal on both sides of the membrane and thereby produce an electrical gradient. Because K^+ is positively charged, it is attracted to the side of the membrane with more negative charge. Figure 41.6b shows a concentration gradient in which K^+ concentration is higher on one side than the other. In this scenario, K^+ diffuses from a region of high to low concentration. Finally, Figure 41.6c

(a) Electrical gradient, no concentration gradient for K^+

(b) Concentration gradient for K^+, no electrical gradient

(c) Electrochemical equilibrium

Figure 41.6 Electrical and chemical (concentration) gradients. This hypothetical example depicts two compartments separated by a membrane that is permeable only to K^+. **(a)** In this example, the compartments initially contain equal concentrations of K^+, but an electrical gradient exists due to an unequal distribution of Na^+ and Cl^-. Potassium ions are attracted to the higher amount of negative charge on the right side of the membrane. **(b)** In this case, there is initially no electrical gradient across the membrane, and the left compartment contains a lower concentration of K^+ than in the right compartment. Under these conditions, K^+ diffuses down its chemical concentration gradient from right to left. **(c)** This example illustrates opposing electrical and concentration gradients. The right compartment contains a higher concentration of K^+, and the left side has a higher net amount of positive charge. These gradients balance each other, so no net movement of K^+ occurs and a state of electrochemical equilibrium is reached.

Concept Check: *In part (b), does the diffusion of K^+ down its concentration gradient result in an electrical gradient? What will eventually stop the net diffusion of K^+?*

BioConnections: *What are some biological functions of electrochemical ion gradients in living organisms? Look back at Table 5.3 for help.*

shows a balance of forces creating an electrochemical equilibrium. The electrical gradient would favor the movement of K^+ from left to right, but the concentration gradient would favor movement from right to left. These opposing forces create an electrochemical equilibrium in which there is no net diffusion of K^+ in either direction. In living cells, the membrane potential at which this occurs for a particular ion at a given concentration gradient is referred to as that ion's **equilibrium potential**.

With two different forces—electrical and concentration gradients—acting on a given ion, is it possible to predict the direction that ion will move across a membrane at any concentration gradient? In other words, can we compare the relative strengths of the electrical and chemical gradients and predict their net effect? By measuring the membrane potential of isolated neurons in the presence of changing concentrations of extracellular ions, scientists have deduced a mathematical formula that relates electrical and concentration gradients to each other. This formula, named the **Nernst equation** after the German chemist and Nobel laureate Walther Nernst, gives the equilibrium potential for an ion at any given concentration gradient. For monovalent cations such as Na^+ and K^+ at 37°C, the Nernst equation can be expressed as

$$E = 60 \text{ mV} \log_{10} ([X_{\text{extracellular}}]/[X_{\text{intracellular}}])$$

where E is the equilibrium potential; $[X]$ is the concentration of an ion, outside or inside the cell; and 60 mV is a value that depends on temperature, valence of the ion, and other factors. (For anions, the value would be −60 mV.)

The Nernst equation allows researchers to predict when an ion is or is not in electrochemical equilibrium. To understand the usefulness of this equation, consider two examples. First, let's suppose the membrane potential is −88.6 mV and the K^+ concentration is 5 mM outside and 150 mM inside a neuron. If we enter these concentrations into the Nernst equation, we obtain

$$E = 60 \text{ mV} \log_{10} (5/150) = 60 \text{ mV} (-1.48)$$
$$= -88.6 \text{ mV}$$

Under these conditions, where the calculated K^+ equilibrium potential equals the actual resting membrane potential, K^+ is in electrochemical equilibrium, and no net diffusion of K^+ occurs, even when many K^+ channels are open.

As a second example, let's suppose that the membrane potential is at a typical resting value of −70 mV and the Na^+ concentration is 100 mM outside and 10 mM inside. If we enter these concentrations into the Nernst equation, we get

$$E = 60 \text{ mV} \log_{10} (100/10) = 60 \text{ mV} (1)$$
$$= 60 \text{ mV}$$

At a resting membrane potential of −70 mV, the value of +60 mV tells us that Na^+ is not in electrochemical equilibrium. When the equilibrium potential for a given ion—calculated by the Nernst equation—and the resting membrane potential do not match, there will be a driving force for that ion to diffuse across the membrane. In this example, Na^+ will diffuse into the cell, because both the electrical and concentration gradients favor an inward flow. However, if the membrane potential was +60 mV instead of −70 mV, Na^+ would be in electrochemical equilibrium at these concentrations, and therefore, there would be no net diffusion of Na^+ in any direction.

By establishing electrochemical gradients and maintaining them with the Na^+/K^+-ATPase pump, neurons have the ability to suddenly allow ions to move across the plasma membrane by opening additional (gated) channels that were previously closed. The movement of a charged ion down its electrochemical gradient results in an electric current (a current is any flow of electric charge). This small current provides the necessary electrical signal that neurons use to communicate with one another, as we will see next.

41.3 Generation and Transmission of Electrical Signals Along Neurons

Learning Outcomes:

1. Distinguish between ligand-gated and voltage-gated ion channels.
2. Compare and contrast graded potentials and action potentials.
3. **SciSKILLS »** Describe the steps involved in the generation of an action potential, beginning with the spread of excitation to the axon hillock.
4. Describe the events in the propagation of an action potential.
5. Discuss how myelination influences the speed of an action potential.

Communication between neurons begins when one cell receives a stimulus and sends an electrical signal along its plasma membrane via currents generated by ion movements. This signal then influences the next neuron in a circuit. Each signal is brief (only a few milliseconds), but a neuron may receive and transmit millions of signals in its lifetime. In this section, we will survey the amazing ability of neurons to send and receive rapid, brief, and repeated signals.

Signaling by a Neuron Occurs Through Changes in the Membrane Potential

Recall that a cell is polarized because of the separation of charge across its membrane. At rest, the inside of the membrane is more negative than outside. Changes in the membrane potential, therefore, are changes in the degree of polarization. **Depolarization** occurs when the cell membrane becomes less polarized, that is, less negative inside the cell relative to the surrounding fluid. As described later, when a neuron is stimulated by an electrical or chemical stimulus, one or more types of gated membrane channels open, and Na^+ ions diffuse into the cell, bringing with them their positive charge. This makes the new membrane potential somewhat less negative than the resting membrane potential. Consequently, the membrane is said to be depolarized. In contrast, **hyperpolarization** occurs when the cell membrane becomes more polarized, that is, more negative on the inside relative to the extracellular fluid. For example, increased diffusion of K^+ out of the cell would make the charge along the inside of the cell membrane more negative than it normally is while at the resting membrane potential.

Whereas all cells in an animal's body have a membrane potential, neurons (and muscle cells) are called excitable cells because they can generate electrical signals. For a cell to communicate using electrical signals, it must be able to change its membrane potential very rapidly. This is accomplished by gated ion channels, so called because they open and close in a manner analogous to a gate in a fence (**Figure 41.7**). **Voltage-gated ion channels** open and close in response to changes in voltage across the membrane. **Ligand-gated ion channels** open or close when ligands, molecules such as neurotransmitters, bind to them. The opening and closing of ligand-gated and voltage-gated ion channels are responsible for two types of changes in a neuron's membrane potential: graded potentials and action potentials.

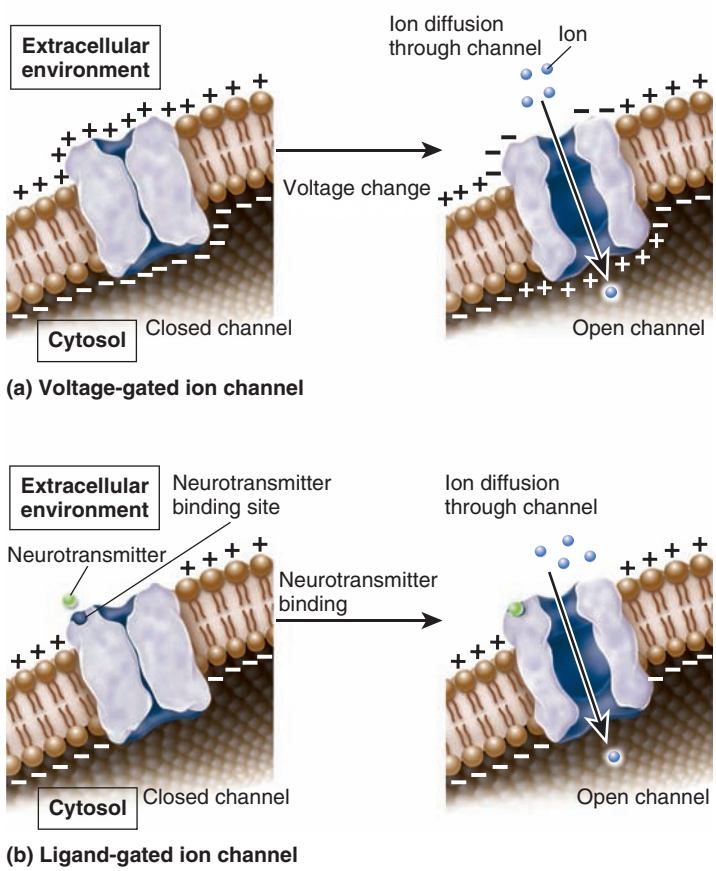


Figure 41.7 Examples of gated ion channels. **(a)** A voltage-gated ion channel allows ions to diffuse into the cell. These channels open or close depending on changes in charge (voltage) across the membrane. **(b)** A ligand-gated ion channel opens or closes in response to ligand binding. In the example here, the binding of a neurotransmitter opens the channel.

BioConnections: Are ions the only things that can move through channels in plasma membranes? Look back at Figure 5.18 to recall an important molecule that diffuses through membranes via channels.

Graded Potentials Vary in Size Depending on the Strength of a Stimulus

A **graded potential** is any depolarization or hyperpolarization that varies depending on the strength of the stimulus. A large change in membrane potential occurs when a strong stimulus opens many channels, whereas a weak stimulus causes a small change because only a few channels open (**Figure 41.8**).

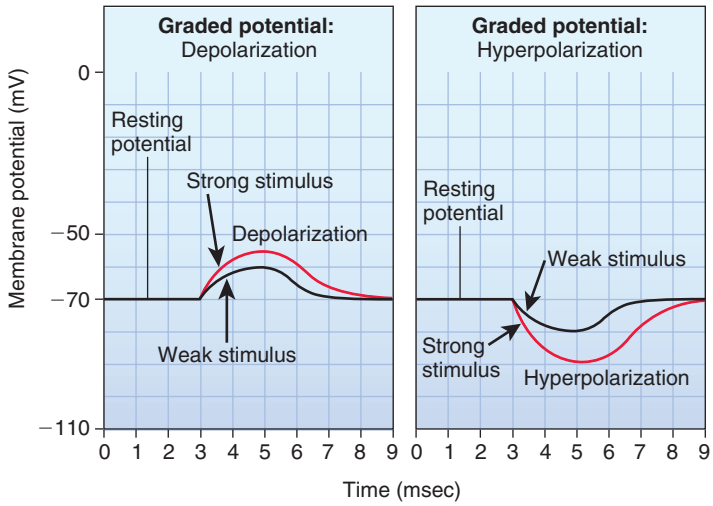

Figure 41.8 Graded membrane potentials. Within a limited range, the change in the membrane potential occurs in proportion to the intensity of the stimulus. If the membrane potential becomes less negative following a stimulus, the resulting change is called a depolarization. If the membrane potential becomes more negative, it is called hyperpolarization.

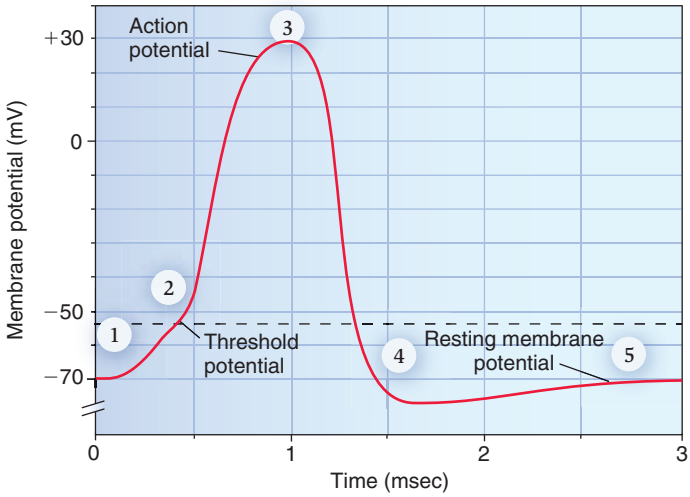
Graded potentials occur locally on a particular area of the plasma membrane, such as on dendrites or the cell body, where an electrical or chemical stimulus opens ion channels. From this area, a graded potential spreads a small distance across a region of the plasma membrane. In a short time, the membrane potential returns to the resting potential because ion pumps restore the ion concentration gradients, and the ion channels close again.

Graded potentials occur on all neurons and are particularly important for the function of sensory neurons, which must distinguish between strong and weak stimuli reaching the organism from the environment. In addition, though, graded potentials can act as triggers for the long distance type of electrical signal, the action potential.

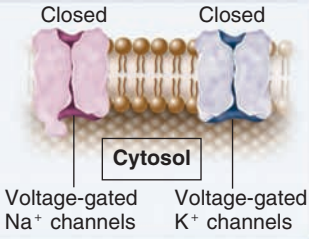
Action Potentials Occur in an All-or-None Fashion

Action potentials are the electrical events that carry a signal along an axon. In contrast to a graded potential, an action potential is always a large depolarization; all action potentials in a given neuron have very similar amplitudes, which is the degree to which an action potential changes the membrane potential away from its resting state. Once an action potential has been triggered, it occurs in an all-or-none fashion. In other words, it cannot be graded. Unlike a graded potential, an action potential is actively propagated along the axon, regenerating itself as it travels. Action potentials travel rapidly down the axon to the axon terminals, where they initiate a response at the junction with the next cell.



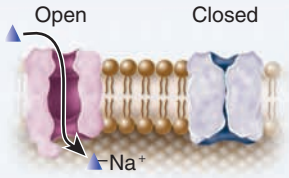
Depolarization Phase of an Action Potential **Figure 41.9** shows the electrical changes that happen in a localized region of an axon when an action potential is occurring. Voltage-gated Na^+ and K^+ channels are both present in very high numbers from the axon hillock to the axon terminals. An action potential begins when a graded potential is large enough to spread to the axon hillock and depolarizes the membrane to a value called the threshold potential (step 2 in Figure 41.9). The **threshold potential** is the membrane potential, typically around −55 to −50 mV, that is sufficient to open large numbers of voltage-gated Na^+ channels and trigger an action potential.

Voltage-gated Na^+ channels open rapidly when the membrane potential changes from the resting membrane potential (for example, around −70 mV) to the threshold potential. The opening of Na^+ channels involves a change in the conformation of the membrane-spanning region of the channel (see Figure 41.9). When the protein changes shape, the central pore opens, and Na^+ rapidly diffuses into the cell down its electrochemical gradient (recall that a typical equilibrium potential for Na^+ is around +60 mV). This influx of charges further depolarizes the cell, causing even more voltage-gated Na^+ channels to open, resulting in the spike in membrane potential that characterizes the action potential. This positive feedback process is so rapid that the membrane potential reaches its peak positive value in less than 1 millisecond (msec)!

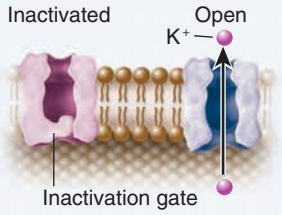


Repolarization Phase of an Action Potential The action potential approaches but does not reach the equilibrium potential for Na^+. When the membrane potential becomes sufficiently positively polarized, a second conformational change in the Na^+ channel blocks the continued flow of Na^+ into the cell. The conformational change involves the **inactivation gate**, a string of amino acids that juts out from the channel protein into the cytosol (step 3 in Figure 41.9). The inactivation gate swings into the channel, thereby preventing any further movement of Na^+ through the channel into the cell. Under these conditions, the Na^+ channel is said to be inactivated. The inactivation gate does not swing out of the channel until the membrane potential returns to a value that is close to the resting potential.

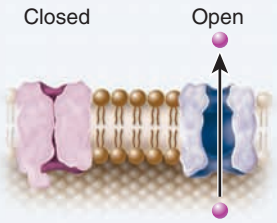
Once Na^+ channels are inactivated, the continued action of the Na^+/K^+-ATPase pump begins the process of repolarization by transporting 3 Na^+ out of the cell for every 2 K^+ pumped in. Of greater importance, however, is a change that occurs in membrane permeability to K^+. Voltage-gated K^+ channels are also triggered to open by the change in voltage to the threshold potential, but they open about 1 msec later than Na^+ channels. When K^+ channels open, some K^+ leaves the cell down its electrochemical gradient, and the membrane potential becomes more negative again. The membrane shows a brief period of hyperpolarization because the K^+ channels remain open for a short time and the membrane potential approaches the equilibrium potential for K^+, which is more negative than the resting potential (step 4 in Figure 41.9). As repolarization proceeds, the voltage-gated K^+ channels eventually close. The membrane then returns to the resting potential as the Na^+/K^+-ATPase pump restores the original concentration gradients (step 5 in Figure 41.9). At this stage, both the Na^+ and K^+ voltage-gated channels are closed, but they have the ability to reopen if the resting potential increases again to the threshold potential.



The evolution of K^+ channels with a slightly slower opening time than Na^+ channels was a key event that led to the formation of nervous systems. Imagine what would happen if the voltage-gated Na^+ and K^+ channels opened simultaneously: As Na^+ entered the cell down its electrochemical gradient, K^+ would leave the cell down its electrochemical gradient, and they would negate each other's effects on membrane potential.



1 **Resting membrane potential:** The membrane is at the resting potential, occasionally generating graded potentials.



2 **Depolarization to threshold:** An action potential is triggered when the threshold potential of about −55 to −50 mV is reached. Voltage-gated Na^+ channels open. Na^+ diffuses into the cell and depolarizes the membrane.

3 **Peak of action potential:** At about +30 mV, voltage-gated Na^+ channels are inactivated, and voltage-gated K^+ channels open. K^+ exits the cell and repolarizes the membrane. At this time, the membrane is in its absolute refractory period.

4 **Repolarization:** Voltage-gated Na^+ channels change from inactivated to closed. Voltage-gated K^+ channels remain open, causing a hyperpolarization of the membrane. The membrane is now in its relative refractory period.

5 **Restoration of resting membrane potential:** Voltage-gated K^+ channels close, and the resting potential of the membrane is restored by the Na^+/K^+-ATPase pump.

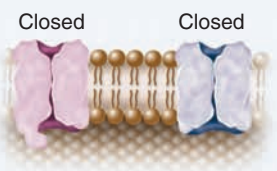


Figure 41.9 Changes that occur during an action potential. The electrical gradient across the plasma membrane of an axon first depolarizes and then repolarizes the cell. The values given for membrane potential are representative and not necessarily the same in all neurons. These changes in the membrane potential are caused by the opening and closing of voltage-gated Na^+ and K^+ channels.

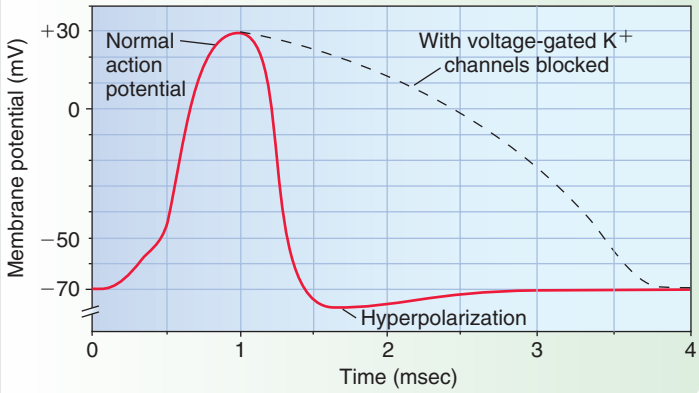
Concept Check: How would the action potential be affected if the Na^+ channels were missing their inactivation gate?

Refractory Periods During the times when the voltage-gated Na^+ channels are inactivated, the membrane is in its **absolute refractory period** (see Figure 41.9), during which time that portion of membrane is unresponsive to another stimulus. A change in voltage cannot open the Na^+ channels while they are inactivated. As the cell repolarizes, however, the inactivation gate is released and the voltage-gated Na^+ channels revert to the closed state. While the voltage-gated K^+ channels are still open, however, the membrane enters a brief **relative refractory period** (see Figure 41.9). During this time, when the membrane is hyperpolarized, a new action potential may be generated but only in response to an unusually large stimulus that can counteract the continued efflux of K^+. Therefore, the refractory periods place limits on the frequency with which a neuron can generate and transmit action potentials. As we will see, the refractory periods also ensure that the action potential does not "retrace its steps" by moving backward toward the cell body.



BIO TIPS **THE QUESTION** *Imagine that just before the repolarization phase of an action potential begins, the voltage-gated K^+ channels become blocked and are unable to open. How might such an action potential look on a graph like that in Figure 41.9?*

TOPIC ***What topic in biology does this question address?*** The topic is an action potential. Specifically, the question addresses how voltage-gated K^+ channels can affect the shape of a graph of an action potential.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you know that an action potential has begun, but the voltage-gated K^+ channels cannot open. From your understanding of the topic and from Figure 41.9, you know that voltage-gated K^+ channels normally open at the peak of an action potential; the movement of K^+ through these channels out of the cell is what causes repolarization of the cell. You also know that the Na^+/K^+-ATPase pump contributes to repolarization.

PROBLEM-SOLVING STRATEGY ***Make a drawing.*** Referring to Figure 41.9 as a guide, draw a similar graph of an action potential and imagine how the second half of it—that is, the portion beginning at point 3 in the figure—would appear if K^+ ions were not able to leave the cell through their voltage-gated channels.

ANSWER *The action potential would be prolonged because repolarization would be slower. Repolarization would still occur, however, because the Na^+/K^+-ATPase pump would eventually restore the ion concentration gradients. Without the rapid and large efflux of K^+ out of the cell through the voltage-gated channels, however, repolarization would take much longer. Note that there would be no hyperpolarization, because this normally occurs as K^+ leaves the cell through voltage-gated channels that temporarily remain open while Na^+ channels are closed.*

Action Potentials Are Propagated Along the Axon to the Axon Terminals

Thus far, we have considered the electrical changes that happen when an action potential is initiated. We will now consider how such potentials are conducted down an axon from the axon hillock to the axon terminals (**Figure 41.10**). Let's begin at the axon hillock. When the neuron receives stimuli from other cells, this causes a graded potential that reaches the axon hillock. If the change in membrane potential is sufficient to reach threshold, an action potential will be triggered. The action potential starts with the abrupt opening of several voltage-gated Na^+ channels just beyond the axon hillock, where many voltage-gated Na^+ channels are found. This action potential, in turn, triggers the opening of nearby Na^+ channels farther along the axon, which allows even more Na^+ to flow into the neuron and depolarize a region closer to the axon terminals, leading to another action potential. In this way, the sequential opening of Na^+ channels along the axon membrane conducts a wave of depolarization from the axon hillock to the axon terminals.

Direction of Propagation Why doesn't the action potential move backward from the terminals to the hillock? Experimentally, if an axon is stimulated in its middle, action potentials can travel in both directions, toward the cell body and the terminals. The key reason why this doesn't ordinarily happen is the inactivation state of the Na^+ channel, which contributes to the absolute refractory period. Again, let's begin at the hillock. When these voltage-gated Na^+ channels open for 1 millisecond, they allow Na^+ to rapidly enter the cell, and then they become inactivated. This inactivation prevents the action potential from moving backward (see Figure 41.10). Although the Na^+ channels are inactivated, K^+ channels open, and the resting potential is restored. At the resting potential, the Na^+ channels switch

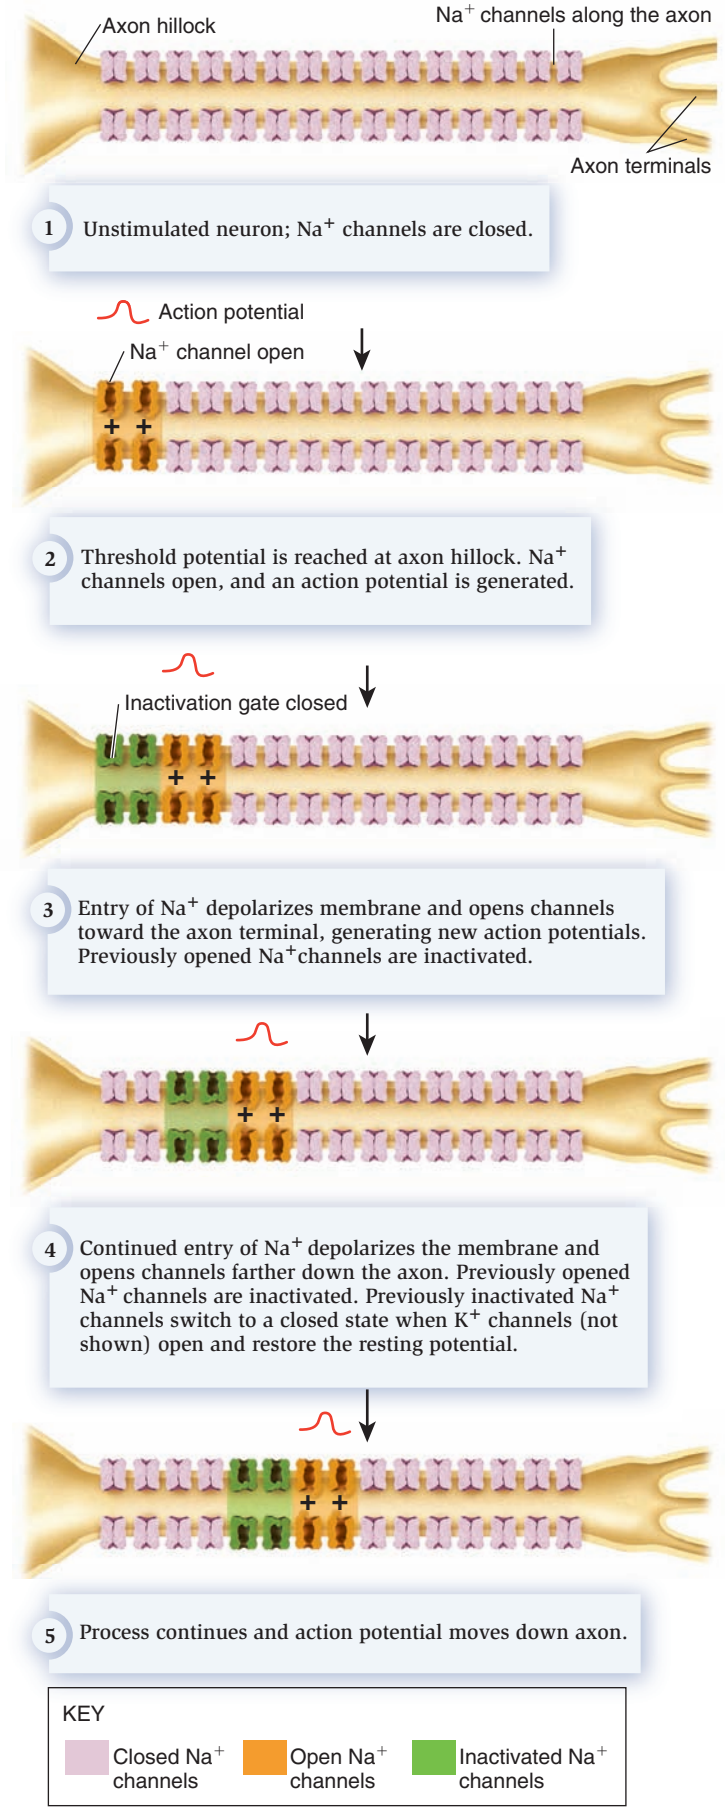


Figure 41.10 Conduction of the action potential along an axon. All Na^+ channels shown are voltage-gated channels.

from the inactivated to the closed state, in which they are once again capable of being opened by a change in voltage. The opening of K^+ channels also travels from the axon hillock to the axon terminals, but it causes a wave of hyperpolarization that helps to reestablish the resting potential.

Speed of Propagation An action potential can be conducted down the axon as fast as 100 m/second or as slow as a centimeter or two per second. The speed is determined by two factors: the axon diameter and the presence or absence of myelin.

The axon diameter influences the rate at which incoming ions can spread along the inner surface of the plasma membrane. The flow of ions meets less resistance in a wide axon than it does in a thin axon, just as water moves more easily through a wide hose than a narrow one. Therefore, in a wider axon, the action potential moves faster. The very large axons of motor neurons of squids and lobsters, for example, conduct action potentials very rapidly, allowing the animals to move quickly when threatened.

Myelination also influences the speed at which action potentials travel along an axon. Myelinated axons conduct action potentials at a faster rate than do unmyelinated axons. Invertebrate neurons generally lack myelination, whereas vertebrate neurons may be myelinated or unmyelinated. Recall that certain glial cells (oligodendrocytes and Schwann cells) wrap around vertebrate axons to form an insulating sheath of membrane. The insulating layer of myelin reduces charge leakage across the membrane of the axon. However, this myelin sheath is not continuous (**Figure 41.11**). As described earlier (see Figure 41.2), the axons of myelinated neurons have exposed areas known as the nodes of Ranvier; these nonmyelinated regions are characterized by having many voltage-gated Na^+ channels. The nodes of Ranvier are the only areas of myelinated axons that have enough voltage-gated Na^+ channels to elicit an action potential. When Na^+ ions diffuse into the cell at one node, the charge spreads through the cytosol and causes the opening of Na^+ channels at the next node, where an action potential is regenerated. This type of conduction is called **saltatory conduction** (from the Latin *saltare*, meaning to leap) because the action potential seems to "jump" from one node to the next. In reality, action potentials do not jump from place to place; saltatory conduction speeds up the conduction process because it takes less time for changes in membrane potential to travel from node to node, eliciting new action potentials only at the nodes, than it would if each tiny strip of membrane generated action potentials all along the length of the axon.

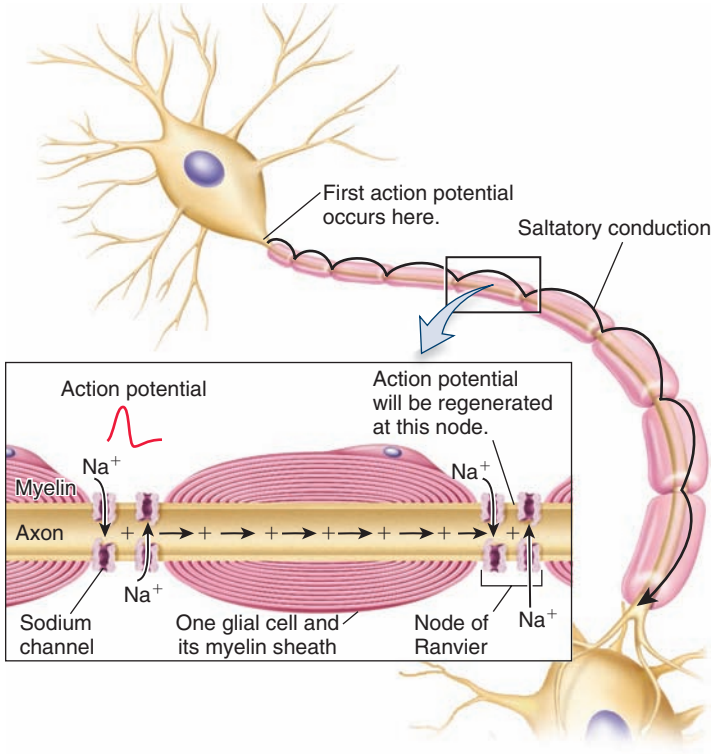

Figure 41.11 Saltatory conduction along a myelinated axon. Action potentials are generated only at the nodes of Ranvier, which lack a surrounding sheath of myelin.

Concept Check: *What is a major advantage of saltatory conduction?*

41.4 Neurons Communicate Electrically or Chemically at Synapses

Learning Outcomes:

1. Describe the structural features of a synapse.
2. Distinguish between two types of potentials produced in postsynaptic cells: excitatory postsynaptic potentials (EPSPs) and inhibitory postsynaptic potentials (IPSPs).
3. **SciSKILLS** » Describe the difference between spatial summation and temporal summation, and make predictions about postsynaptic potentials in a cell receiving multiple inputs from other cells.
4. List the classes of neurotransmitters, and provide brief descriptions of their generalized functions.
5. Describe the two general types of postsynaptic membrane receptors.

Neurons communicate with other cells at a **synapse**, which is a junction where an axon terminal meets another neuron, muscle cell, or gland cell. At a synapse, an electrical or chemical signal passes from an axon terminal to the next cell. A synapse includes the axon terminal of the neuron that is sending the message, the nearby plasma membrane of the receiving cell, and in certain cases the **synaptic cleft**, or extracellular space between the two cells. The **presynaptic cell** sends the signal, and the **postsynaptic cell** receives it. A given cell may be presynaptic to one cell, and postsynaptic to another (**Figure 41.12**).

Synapses May Be Electrical or Chemical

By studying neurons from both invertebrates and vertebrates, researchers have identified two types of synapses: electrical and chemical. The first type, the **electrical synapse**, directly passes electric current from the presynaptic to the postsynaptic cell. The electrical signal passes through this type of synapse extremely rapidly, because the plasma membranes of adjacent cells are connected by gap junctions (see Chapter 10) that can move electric charge freely from one cell to the other. Recent research indicates that electrical synapses are more widespread among taxa than originally thought,

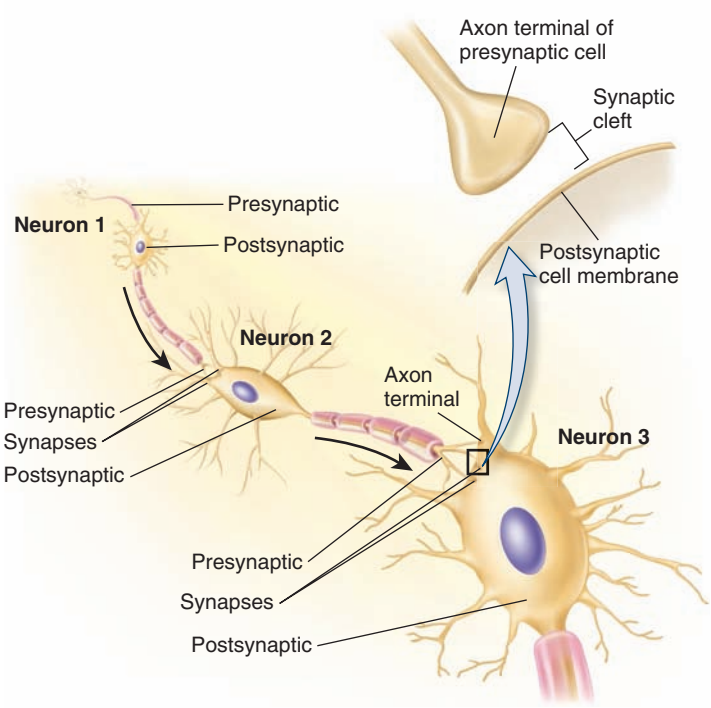

Figure 41.12 Presynaptic and postsynaptic cells. The arrows show the direction of signal transmission from one neuron to the next. Note that neuron 2 is postsynaptic with respect to neuron 1 and presynaptic with respect to neuron 3.

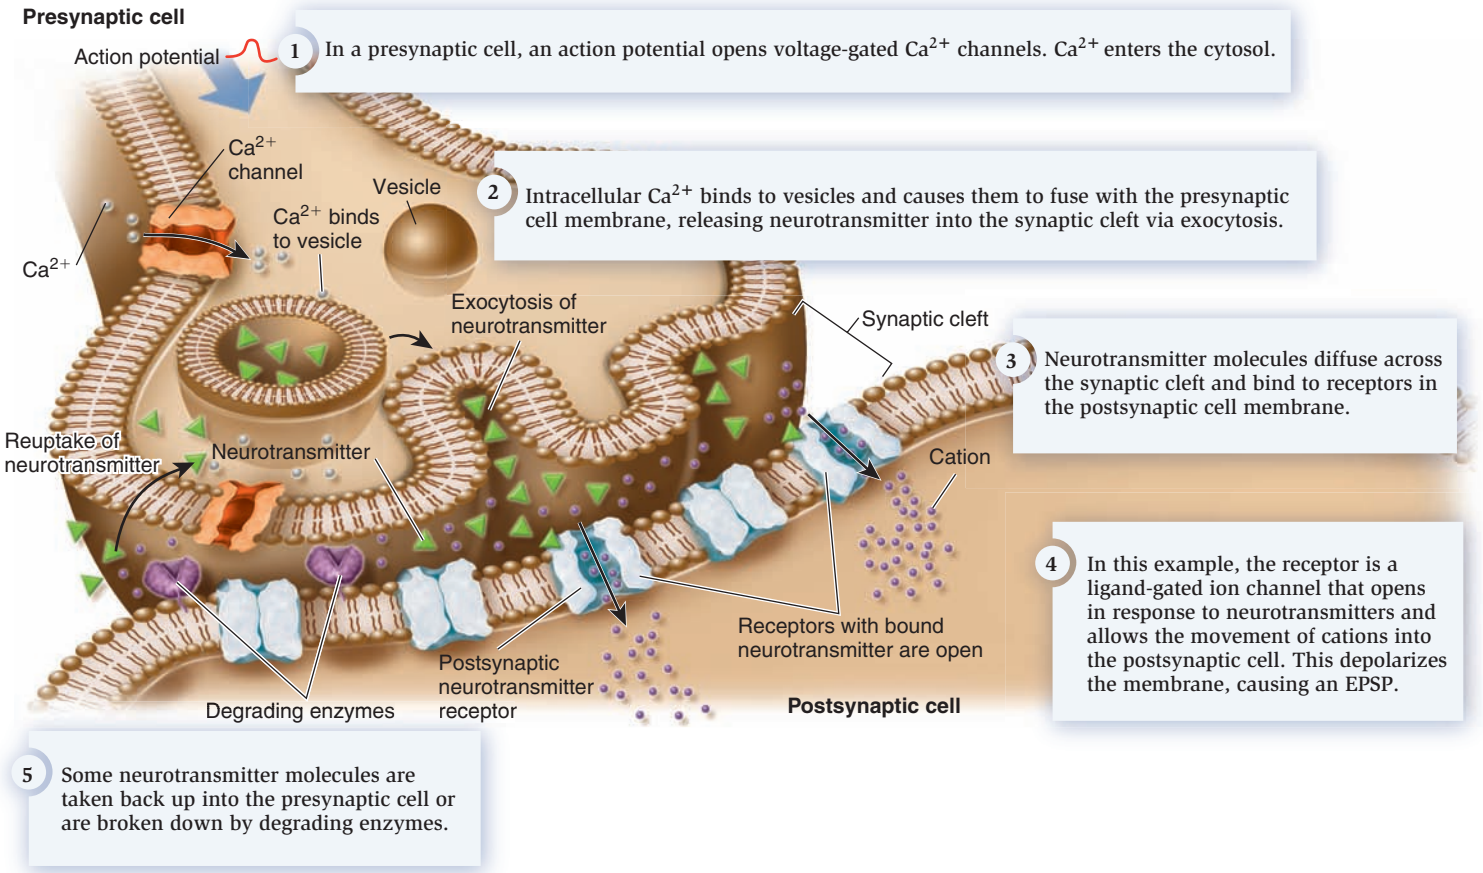
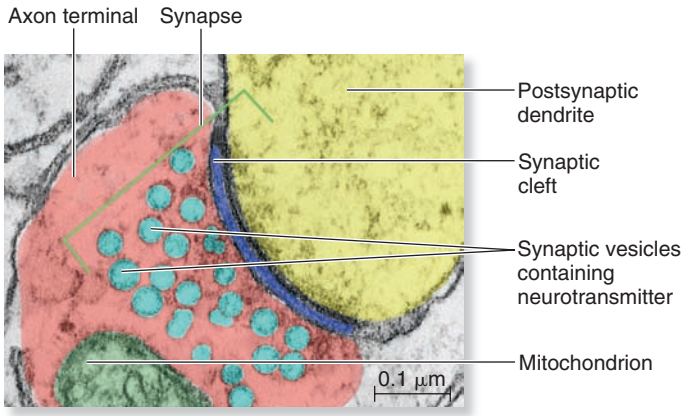
including vertebrates. The most well-studied examples, however, occur in some aquatic invertebrates such as leeches. In those animals, electrical synapses occur where a group of neurons must fire rapidly and synchronously, such as when an animal must coordinate a number of muscles to swim or escape danger.

The second type of synapse is a **chemical synapse**, in which a chemical called a neurotransmitter is released from the axon terminal and acts as a signal from the presynaptic to the postsynaptic cell. Chemical synapses are more common, particularly in vertebrates. Some neurons release only one type of neurotransmitter, and some neurons can release two or more different ones. Chemical synapses are slower than electrical synapses. However, unlike electrical synapses, a major advantage of these synapses is that they allow for complex modulation of the response of the postsynaptic cell, as we will see next.



At Chemical Synapses, Neurotransmitters Elicit Excitatory or Inhibitory Signals in Postsynaptic Cells

Figure 41.13 describes the steps that occur when two cells communicate via a chemical synapse. The axon terminal of a presynaptic cell contains vesicles—small, membrane-enclosed packets, each containing thousands of molecules of neurotransmitter. The membranes of axon terminals contain voltage-gated Ca^{2+} channels. When an action potential arrives at an axon terminal, these channels open, allowing Ca^{2+} ions to diffuse down their electrochemical gradient into the cell. Calcium binds to a protein associated with the vesicle membrane. This triggers exocytosis, in which the vesicle fuses with the presynaptic membrane, thereby releasing its neurotransmitter molecules into the synaptic cleft. The neurotransmitter molecules diffuse across the 10- to 20-nm-wide synaptic cleft and bind to ligand-gated ion channels or other receptor proteins in the postsynaptic cell membrane.



The binding of neurotransmitter molecules opens or closes ligand-gated ion channels, thereby changing the membrane potential of the postsynaptic cell. In some cases, neurotransmitters directly bind to ion channels and cause the channels to open or close. In other cases, neurotransmitters bind to receptor proteins on the postsynaptic cell membrane and induce the formation of second messengers in the cell (see Chapter 9). These messengers, in turn, open or close ion channels by any of several mechanisms. Some neurotransmitters are called excitatory, because they depolarize the postsynaptic membrane; the response is an **excitatory postsynaptic potential (EPSP)**. The response they cause is called excitatory because the depolarization of the postsynaptic cell membrane brings the membrane potential closer to the threshold potential that would trigger an action potential. An EPSP can be caused by the opening of Na^+ channels in a neuronal membrane or by the closing of K^+ channels. In both cases, positive charges accumulate inside the cell. Conversely, an inhibitory neurotransmitter usually hyperpolarizes the postsynaptic membrane, producing an **inhibitory postsynaptic potential (IPSP)**, which reduces the likelihood of an action potential. An IPSP can be caused by, for example, the opening of Cl^- channels. The equilibrium potential for Cl^- is typically close to or more negative than the resting membrane potential. Therefore, when Cl^- channels are opened, Cl^- moves into cells, bringing them closer to the equilibrium potential for Cl^-. Hyperpolarization is the major way in which neurons are inhibited; see, for example, the motor neuron that innervates a flexor muscle depicted in the reflex arc in Figure 41.4.

To end the synaptic signal, neurotransmitter molecules in the synaptic cleft are broken down by enzymes or transported back into the terminal of the presynaptic cell and repackaged into vesicles for reuse. The latter event, called reuptake, is an efficient mechanism for recapturing unused neurotransmitters that were released into the synaptic cleft. As we will see at the end of this chapter, drugs that block the reuptake process can sometimes be used to treat people with disorders of neurotransmission, including depression.

We can appreciate the power of neurotransmitters when we consider the effects of toxins that are known to affect neurotransmitter release. For example, the venom of black widow spiders (genus *Latrodectus*), α-latrotoxin, acts on presynaptic proteins involved in exocytosis to cause massive release of neurotransmitter from motor neurons that stimulate contraction of skeletal muscle. Correspondingly, the symptoms of black widow spider bites in humans are painful muscle cramping and rigidity due to overstimulation of the muscle. Researchers have also determined the function of several proteins involved in vesicle membrane fusion and exocytosis by experimenting with certain toxins that decrease neurotransmitter release. For instance, the toxin secreted by the bacterium *Clostridium botulinum* prevents exocytosis of motor neuron vesicles and release of their neurotransmitter. If ingested in food, the toxin causes botulism, a sometimes fatal form of food poisoning characterized by weak muscles, trouble focusing the eyes, and difficulty swallowing. Researchers have discovered

(a) Events occurring at a chemical synapse

(b) False-colored electron micrograph of a chemical synapse

Figure 41.13 Structure and function of a chemical synapse.
(a) In response to an action potential, Ca^{2+} enters the presynaptic neuron axon terminal. This results in fusion of the vesicle with the plasma membrane, which releases neurotransmitter molecules into the synaptic cleft. The neurotransmitter molecules then bind to receptors in the plasma membrane of the postsynaptic cell. This causes ion channels to open (as in this example) or close, which, in turn, changes the membrane potential of the postsynaptic cell. **(b)** Transmission electron micrograph of a chemical synapse from a rat brain.

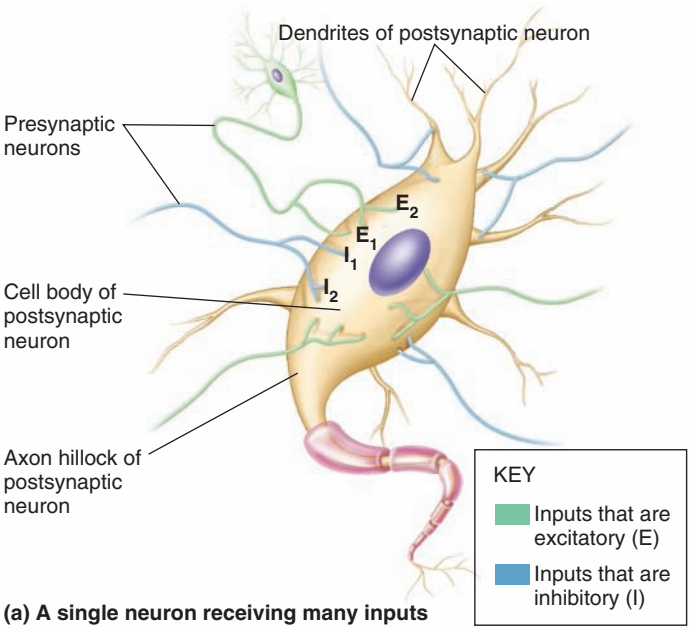
Concept Check: What is the benefit of having synaptic enzymes break down neurotransmitter molecules?

several cosmetic and medical uses for this toxin, however. For example, when injected into a chronically stimulated muscle, it blocks contraction of the muscle by preventing the motor neurons from releasing neurotransmitter, resulting in muscle relaxation. Clinicians may also administer a synthetic form of the toxin (the generic name of which is onabotulinumtoxinA, but is more commonly known as Botox) to patients who wish to reduce facial wrinkles. The effect is to reduce the contractions of the facial muscles that cause frown lines. The procedure is not without risk, however, as the toxin may diffuse from the site of the injection and affect other targets.

Neurons Respond to Multiple Synaptic Inputs

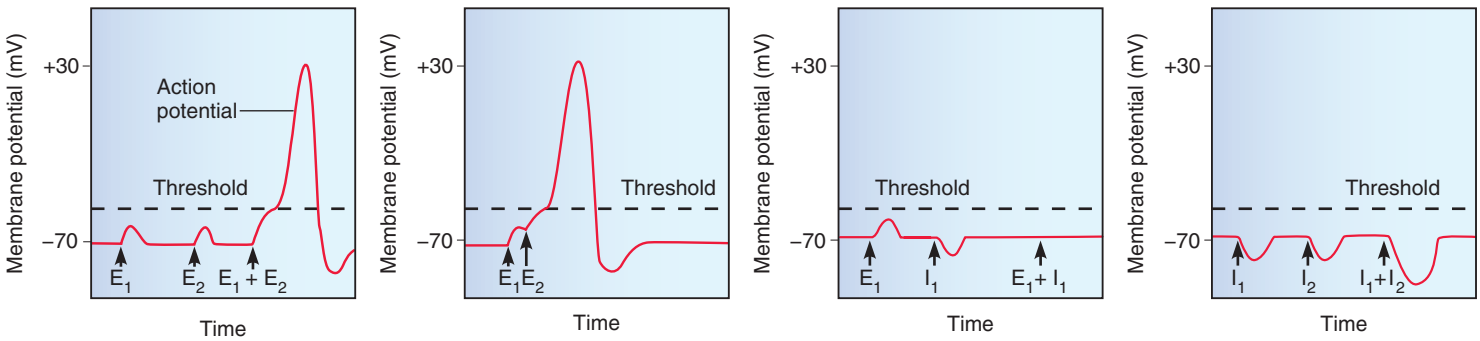
A neuron may receive inputs from many synapses occurring on its dendrites or cell body (**Figure 41.14a**), and some of these synapses may release their neurotransmitter onto the neuron at the same or nearly the same time. Certain neurotransmitters are excitatory, and others are inhibitory. When do these different inputs lead to an action potential? The effect of a single synapse is usually far too weak to elicit an action potential in the postsynaptic neuron. However, when

two or more EPSPs are generated at one time along different regions of the dendrites and cell body, their depolarizations sum together. The resulting larger depolarization may bring the membrane potential at the axon hillock to the threshold potential, initiating an action potential. This is called **spatial summation** (Figure 41.14b). In another example of summation, two or more EPSPs may arrive at the same location in quick succession, such that the first EPSP has not yet decayed away when the next EPSP arrives. In that case, the depolarizations sum and may reach threshold upon arrival at the axon hillock. This is called **temporal summation** (Figure 41.14c). Finally, if EPSPs and IPSPs arrive together at a postsynaptic cell, the two types of signals may cancel each other out, and no action potential is elicited (Figure 41.14d). From this discussion, you might deduce that when two or more IPSPs arrive together, their hyperpolarizations might sum, too. That is exactly what happens. In that case, the membrane potential of the cell receiving multiple IPSPs moves farther away from threshold (Figure 41.14e).



In addition to the number of synapses that stimulate the postsynaptic membrane, the location of the synapses is also important. Synapses initially cause a graded potential in the postsynaptic membrane that spreads only a short distance. If two excitatory synapses are close together and activated at the same time, the resulting depolarization will be larger and will spread farther. This spread increases the chances that the depolarization will reach the axon hillock, where the high concentration of Na^+ channels can trigger an action potential. Synapses that occur far from the axon hillock are less effective than synapses on the cell body nearer the axon hillock.

Neurotransmitters Can Be Categorized According to Size or Structure



Neuroscientists have identified more than 100 different neurotransmitters in animals. Generally, neurotransmitters are categorized by size or structure (Table 41.2). The changing balance between excitatory and inhibitory neurotransmission controls the state of nervous system circuits at any one time. To understand how neurotransmitters work, imagine driving a car with one foot on the accelerator and one foot on the brake. To speed up, you could press down on the accelerator, ease up on the brake, or both, whereas to slow down, you could do the opposite. All nervous systems operate in this way, with combined excitatory and inhibitory actions of neurotransmitters.

Next, we consider major features of the different chemical classes of neurotransmitters found in animals, which include acetylcholine, biogenic amines, amino acids, neuropeptides, and gaseous neurotransmitters. With the exception of acetylcholine, all of these classes contain several different neurotransmitters that are similar in chemical structure but may have different functions in nervous systems.

Acetylcholine Acetylcholine (ACh), one of the most widespread neurotransmitters in animals, is released at the synapses of **neuromuscular junctions** in vertebrates, where a neuron contacts a skeletal or cardiac muscle cell. It is also released at synapses within the brain and elsewhere. Acetylcholine acts as an excitatory neurotransmitter in the brain and on skeletal muscle cells, but it is inhibitory when released from neurons that control cardiac muscle

(a) A single neuron receiving many inputs

(b) Spatial summation of EPSPs (c) Temporal summation of EPSPs (d) Cancellation of EPSP and IPSP (e) Spatial summation of IPSPs

Figure 41.14 Integration of synaptic inputs. Membrane potential changes in a postsynaptic membrane are shown under several different circumstances. When multiple excitatory (E) or inhibitory (I) inputs arrive simultaneously or nearly so, the subsequent EPSPs and IPSPs may add (summate) or cancel each other out, depending on the situation.

Table 41.2 Classes of Neurotransmitters and Some Representative Examples and Functions

Transmitter	Some major functions
Acetylcholine	CNS: Stimulates the brain; important in memory, motor control, and many other functions
	PNS: Stimulates skeletal muscle at neuromuscular junctions; inhibits cardiac muscle; promotes digestion
Biogenic amines	
Catecholamines: dopamine, norepinephrine, epinephrine	CNS: Regulate mood, attention, learning, behavior
Serotonin	PNS: Stimulates cardiac muscle; improves lung function; helps animals respond to stressful situations
Histamine	CNS: Helps to maintain awake state
Amino acids	
Excitatory amino acids: glutamate, aspartate	CNS: Widespread mediators of activity in all areas of CNS; the major "on" signal of the CNS
Inhibitory amino acids: γ-aminobutyric acid (GABA), glycine	CNS: Hyperpolarize neurons; act as a "brake" on the nervous system
Neuropeptides	
Opiate peptides: endorphin	CNS: Modulate postsynaptic cell response to neurotransmitters; play a role in mood, behavior, appetite, pain perception, and many other areas
Gases	
Nitric oxide, carbon monoxide	CNS: Possible role in memory and odor sensation
	PNS: Relax smooth muscle, especially in blood vessels

Note: CNS stands for central nervous system; PNS stands for peripheral nervous system.

contraction. Therefore, it stimulates skeletal muscle but inhibits cardiac muscle. As we will see later, a single type of neurotransmitter can exert both excitatory and inhibitory effects, often because it has more than one type of receptor to which it binds on different cells.

Biogenic Amines The biogenic amines are compounds containing amine groups that are formed from amino acids. Common biogenic amines include the catecholamines—dopamine, norepinephrine, and epinephrine—and serotonin and histamine. The catecholamines are formed from the amino acid tyrosine, serotonin is formed from tryptophan, and histamine from histidine.

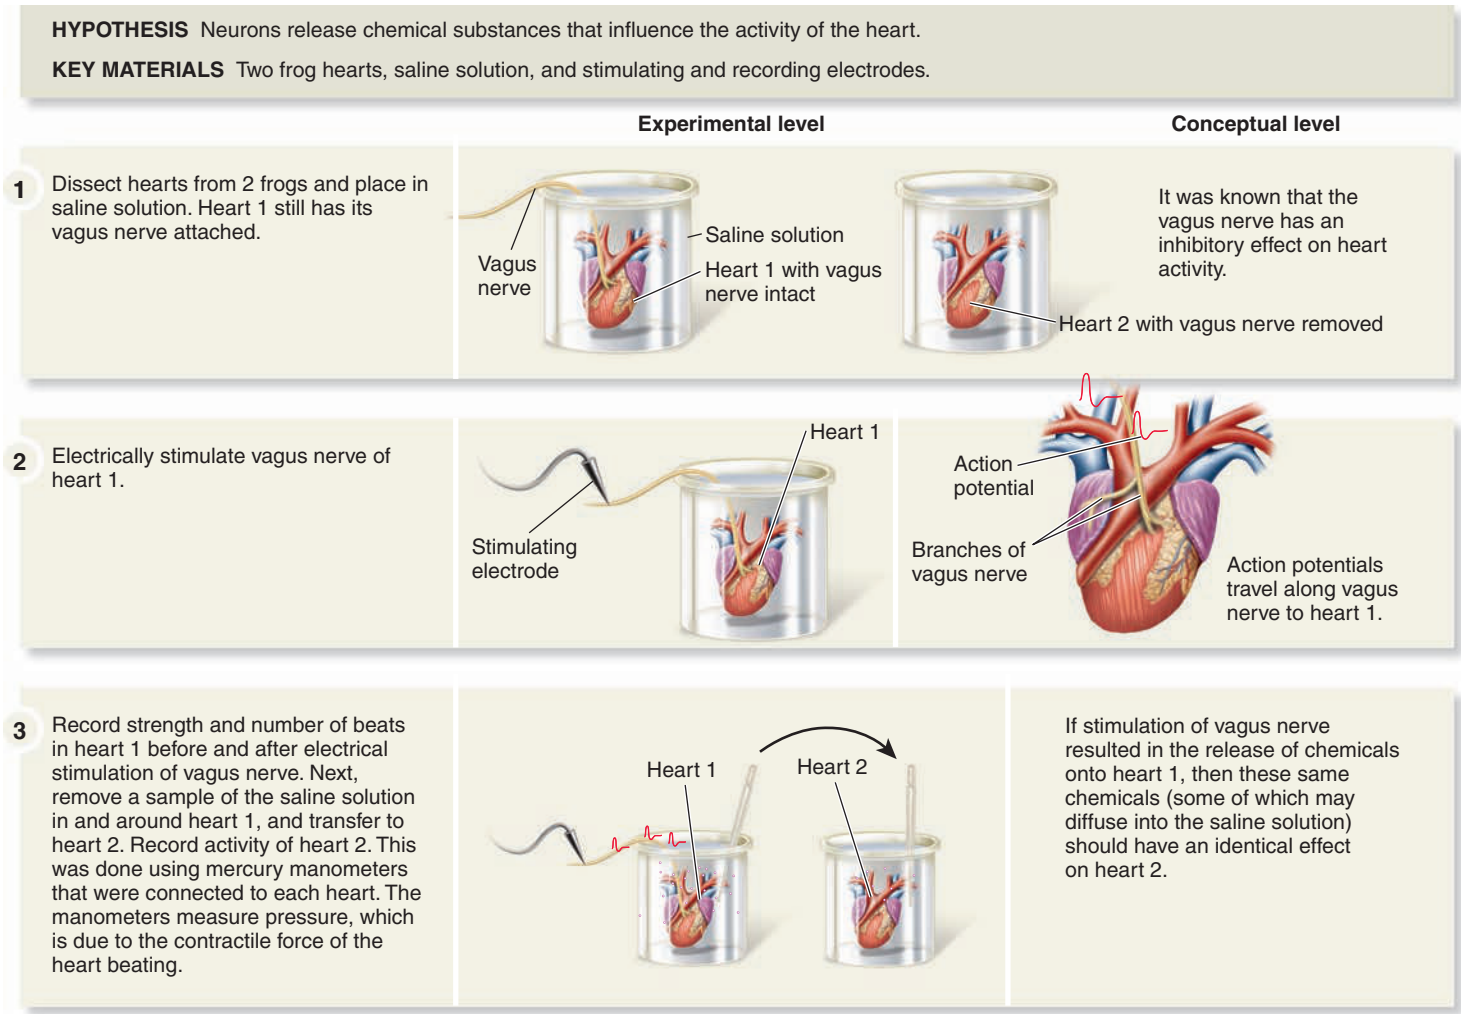
In addition to widespread physiological effects such as control of heart and lung function, catecholamines and serotonin are psychoactive; that is, they affect mood, attention, behavior, and learning. In humans, for example, abnormally high or low levels of catecholamines and serotonin have been associated with a variety of mental illnesses, including schizophrenia, attention-deficit disorder, and depression. Histamine is well known as a component of allergic reactions in people, but this is not related to its neurotransmitter functions. In the brain, neurons that produce histamine are important in modulating sleep; they are most active during waking and are nearly inactive during sleep. This explains why certain antihistamines (drugs that block the ability of histamine to bind to its receptor, thereby inhibiting its action) used to treat colds and allergies also induce drowsiness.

Amino Acids The amino acids glutamate, aspartate, glycine, and γ-aminobutyric acid (GABA) function as neurotransmitters. Glutamate is the most widespread excitatory neurotransmitter found in animal nervous systems, whereas GABA is the most common inhibitory neurotransmitter. GABA hyperpolarizes the postsynaptic membrane by opening chloride channels, allowing negatively charged Cl^- to diffuse into the cell (see Table 41.1); in this way, GABA brings neurons further away from the threshold potential required to generate an action potential, and thus it acts as the major "brake" on the CNS.

Neuropeptides Neuropeptides are short polypeptides containing from 2 to about 15 amino acids. Like the other neurotransmitters discussed, neuropeptides can be excitatory or inhibitory. Neuropeptides are often called **neuromodulators**, because they can alter or modulate the response of the postsynaptic neuron to other neurotransmitters. For example, a neuropeptide may stimulate synthesis of receptors for another neurotransmitter, which makes a cell more responsive to that neurotransmitter. One group of neuropeptides is called the opiate peptides because opium-like drugs, such as morphine, bind to their receptors. Opiate peptides include the endorphins, a group of peptides that decrease pain and cause natural feelings of euphoria (extreme happiness and sense of invulnerability).

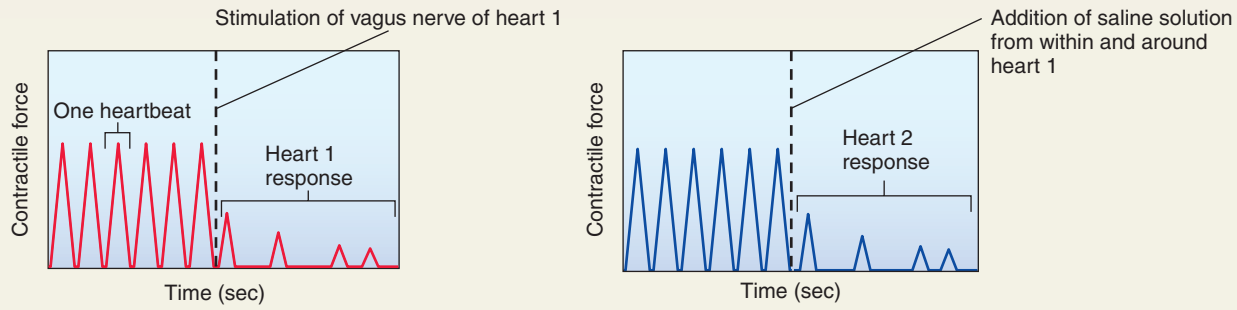
Gaseous Neurotransmitters Certain gases such as nitric oxide (NO) and carbon monoxide (CO) act locally in many tissues and sometimes function as neurotransmitters. Unlike other neurotransmitters, these molecules are not sequestered into vesicles and are produced locally as required. Gaseous neurotransmitters are short-acting and influence other cells by diffusion. In humans, NO is responsible for relaxing the smooth muscle surrounding blood vessels, including those in the penis. When a male becomes sexually aroused, NO levels increase in this tissue, dilating the vessels and increasing blood flow into the penis, producing an erection. Several drugs used to treat male sexual dysfunction enhance erections by increasing or mimicking the action of NO on smooth muscle. The functions of CO are still uncertain, but scientists think it may act as a neurotransmitter in the sense of smell in some animals, such as the terrestrial mollusk *Limax maximus.*

The discovery that the actions of neurons are mediated in large part by neurotransmitters was one of the most significant discoveries in the history of neuroscience. That discovery laid the foundation for our understanding of the nervous system and of many human diseases. Amazingly, the existence of neurotransmitters was demonstrated in a remarkably simple experiment that arose from a dream, as we see next.



Feature Investigation | Otto Loewi Discovered Acetylcholine

German physiologist Otto Loewi was interested in how neurons communicate with skeletal muscle. He knew from the work of other researchers that the electrical stimulation of a nerve in a frog's leg would result in contraction of the muscle associated with that nerve, so it appeared that neurons communicated with the muscle by electrical signals. In 1921, he turned his studies to another type of muscle, the heart. As we will see in Chapter 47, all vertebrate and some invertebrate hearts receive both excitatory and inhibitory signals from different nerves that regulate the rhythm and intensity of the heartbeat. Loewi hypothesized that because different nerves produced opposite effects on the heart, the effects of the nerves could not be a direct electrical action on heart muscle, because there would be no way for the heart muscle to discern between the same type of signal (that is, electricity) from two different nerves. Instead, perhaps the neurons in each nerve released different chemicals of some type, and it was these chemicals that exerted opposite actions on the heart.



As shown in **Figure 41.15**, Loewi removed the hearts from two frogs and placed the hearts in baths containing a solution of ions and other substances that helped keep the tissue alive. When a frog's heart is maintained in this solution, it will continue to beat for several hours before eventually dying.

Initially, Loewi began by examining the major inhibitory nerve of the vertebrate heart, called the vagus nerve. When Loewi dissected the hearts from the two frogs, he left the vagus nerve intact in one heart, but removed it from the second heart. Next, Loewi used an electrode to electrically stimulate the vagus nerve attached to the first frog's heart. As schematically depicted in panel 4 of Figure 41.15, this resulted in a decrease in the rate at which the first heart contracted. He then removed some of the saline solution from within and around the first heart and transferred it to the solution that was bathing the second (unstimulated) heart. The rate and force of beating of the second heart quickly decreased, even though it had no vagus nerve and was not exposed to any electrical stimulation. Loewi concluded that a

Figure 41.15 **Loewi's experimental discovery of chemical neurotransmission.**

4 THE DATA

5 CONCLUSION Electrical stimulation causes the vagus nerve to secrete chemicals that decrease heart contractions.

6 SOURCE Loewi, O. 1921. On humoral transmission of the action of heart nerves. Pflügers archives. *European Journal of Physiology* 189:239–242.

chemical substance was released from the nerve of the first heart into the surrounding fluid and that when this chemical was added to the second heart, it reproduced the effects of electrical stimulation that were observed on the first heart.

Loewi initially named this substance *vagusstoff* (vagus substance), after the vagus nerve he stimulated. It was later renamed acetylcholine when its chemical nature (acetic acid bonded to choline) was determined. Acetylcholine was the first neurotransmitter discovered. Loewi's research opened the door for what we now know about chemical transmission at synapses, and the enormous pharmaceutical industry, which builds on this knowledge to treat neurological disorders (diseases of the nervous system).

Interestingly, as Loewi described later, the idea for his experiment, which would be largely responsible for his earning a share of the 1936 Nobel Prize in Physiology or Medicine, came to him in a dream. He woke in the middle of the night, scribbled down his idea, and returned to sleep. The next morning, he despaired to find that he couldn't read his sleepy scribbling! Incredibly, he had the dream again the following night and, not taking any chances, got up and went directly to his laboratory.

Experimental Questions

1. What key prior observation led Loewi to develop his hypothesis of how nerves stimulate or inhibit heart muscle contractions?
2. **SciSKILLS** » What were the results of Loewi's experiment? Did the results support his hypothesis? Can you think of an alternative hypothesis based on Loewi's results?
3. **SciSKILLS** » After you finish reading the rest of this chapter, design an experiment to test the hypothesis that acetylcholine is Loewi's proposed *vagusstoff*, using a heart (without its vagus nerve), some acetylcholine, and an acetylcholine receptor blocker.

Postsynaptic Membrane Receptors Determine the Type of Response to Neurotransmitters

As was mentioned earlier, in some cases the same neurotransmitter can have both excitatory and inhibitory effects. The response of the postsynaptic cell depends on the type of receptor present in the postsynaptic membrane. The two major types of postsynaptic membrane receptors are ionotropic and metabotropic, and many neurotransmitters, such as acetylcholine, act on both (**Figure 41.16**). Neurotransmitter molecules bind to the extracellular portion of these receptors.

Ionotropic receptors are ligand-gated ion channels that open in response to neurotransmitter binding (Figure 41.16a). When neurotransmitter molecules bind to these receptors, ions flow through the channels to cause an EPSP or IPSP. Acetylcholine and amino acids bind to ionotropic receptors. Ionotropic receptors are composed of multiple subunits that associate in a ring to form the receptor's channel.

Metabotropic receptors are G-protein-coupled receptors (GPCRs) (refer back to Figure 9.7). They do not form a channel but instead are coupled to an intracellular signaling pathway that initiates changes in the postsynaptic cell (Figure 41.16b). A common type of response is the phosphorylation of ion channels for sodium, potassium, or calcium ions, which are present in the plasma membrane. In Chapter 43, we will see that metabotropic receptors are important in activating sensory cells that respond to visual and other stimuli.

Not only do many neurotransmitters bind to more than one type of receptor, but receptors that are composed of subunits may exist in multiple forms made up of different combinations of subunits. What benefit is there to an organism to express such a variety of receptor

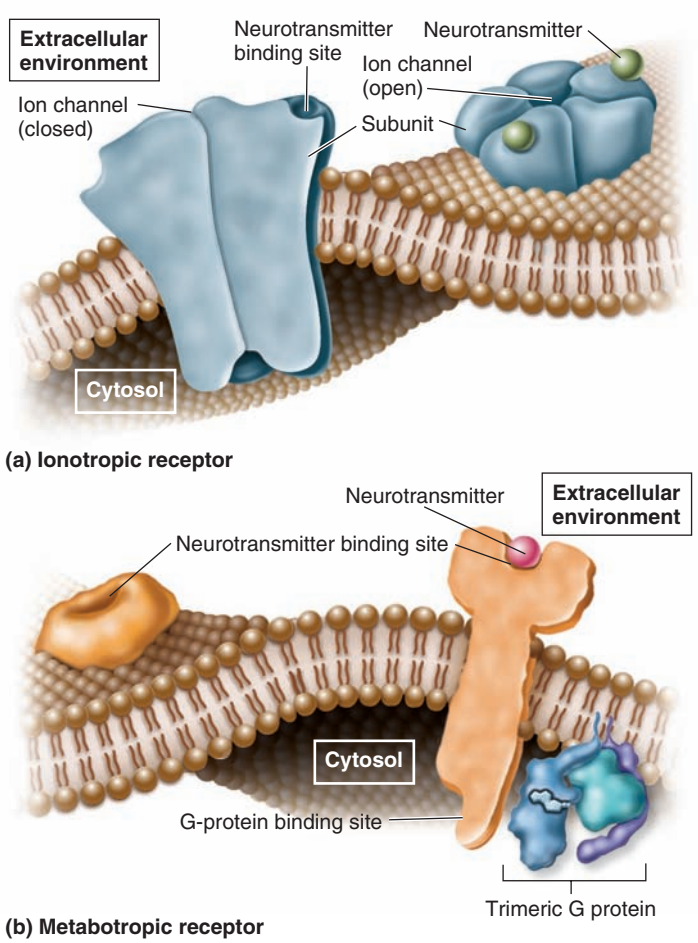


Figure 41.16 The two major types of postsynaptic receptors. **(a)** Ionotropic receptors have several subunits. Neurotransmitters bind to ionotropic receptors and directly open ion channels in the membrane. **(b)** Metabotropic receptors are G-protein-coupled receptors, which are discussed in Chapter 9. Neurotransmitters bind to metabotropic receptors and initiate a signaling pathway that typically opens or closes ion channels.

types for a given neurotransmitter? One helpful way to understand this diversity and its importance is to consider the amazing complexity of one well-studied receptor family, that of the widespread amino acid neurotransmitter GABA.

Genomes & Proteomes Connection

Varied Subunit Compositions of Neurotransmitter Receptors Allow Precise Control of Neuronal Regulation

As mentioned earlier, γ-aminobutyric acid (GABA) is an inhibitory neurotransmitter that opens Cl^- channels. Though cells can possess different types of GABA receptors, we will focus here on one type called the GABA-A receptor, which functions as a ligand-gated ion channel. The binding of GABA to this ionotropic receptor opens the channel. This event allows Cl^- to diffuse into the cell, causing a hyperpolarization of the plasma membrane and shifting the membrane potential toward the equilibrium potential for Cl^- (usually between about −70 to −90 mV) (**Figure 41.17**). In this way, the binding of GABA to this receptor decreases the likelihood that a neuron will generate an action potential.

The GABA-A receptor is a good example of how receptor subunits can influence a postsynaptic response to a neurotransmitter. GABA-A receptors are usually composed of five polypeptide subunits (designated α, β, γ, and so on). All animals with a nervous system possess some form of GABA-A receptor. Recent evidence points to an ancestral gene pair for two of these polypeptide subunits in bilaterally symmetric animals. The genomes of humans and other mammals have a group of homologous genes that encode at least 19 different GABA-A receptor subunits. In addition, subunit variation can be further increased by alternative splicing (refer back to Figure 13.22). This amazing variety in subunits allows cells to potentially express dozens of different kinds of GABA-A receptors.

What are the survival advantages of having evolved such a variety of different GABA-A receptor subunits? Though the answer is not entirely understood, each type of subunit has its own unique properties that can fine-tune the function of the GABA-A receptor so that it works optimally in the neuron in which it is expressed.

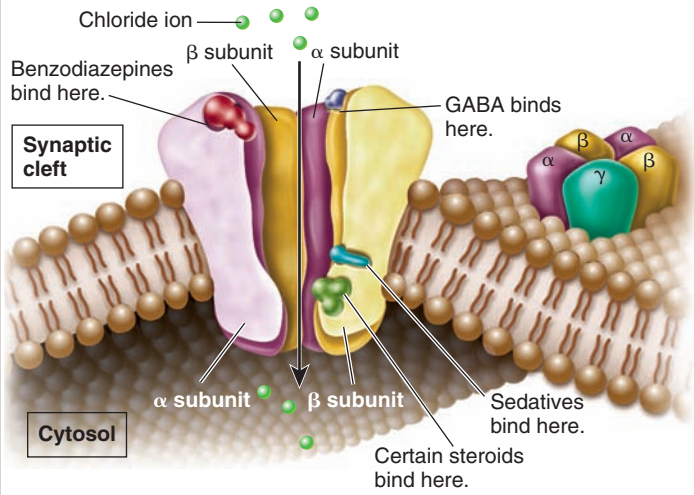

Figure 41.17 The structure and function of the GABA-A receptor. Each type of GABA-A receptor has five subunits that form an ion channel allowing the passage of chloride ions. When GABA binds to the receptor, chloride ions move through the open channel and hyperpolarize the cell. Various other molecules bind to different sites on the receptor. These include molecules that naturally occur in animals' bodies, such as certain steroid hormones, and drugs, such as sedatives and benzodiazepines, used to treat anxiety and other disorders.

BIOLOGY PRINCIPLE Structure determines function. Neurotransmitter receptors are excellent examples of this biological principle at the molecular level. The three-dimensional structure of the receptor determines its ability to bind a particular neurotransmitter and, as shown in this figure, various other ligands that can modulate the receptor's activity.

For example, the various subunits may differ in their affinity for GABA and the rate of Cl^- movement through the channel.

In addition, neuroscientists have been particularly interested in whether the various subunits differ in their ability to recognize molecules other than GABA (see Figure 41.17). This work has shown that the subunits of the GABA receptor bind a variety of other molecules, including naturally occurring ones such as certain steroid hormones. The binding of these molecules enhances or reduces the effectiveness of GABA in activating the receptor. This knowledge has proven beneficial in understanding how certain drugs exert their actions. For example, ethanol—found in alcoholic drinks—binds to one of the GABA-A receptor subunits expressed in brain and motor neurons and enhances the actions of GABA. This may explain in part why alcohol depresses the activity of the brain and impairs motor coordination, among other effects. Other subunits of the GABA-A receptor bind drugs including benzodiazepines such as alprazolam (Xanax), which are used to treat chronic or severe anxiety. Apparently, the inhibitory effects of GABA are part of the mechanism for achieving a balance between anxiety and calmness. The ability of the receptor to bind numerous ligands and the many different combinations of subunits in the receptor provide an enormous degree of control over precisely how this neurotransmitter system regulates the activity of the brain.

41.5 Impact on Public Health

Learning Outcomes:

1. Describe how disorders of neurotransmission can affect human health.
2. List several "recreational" and illicit drugs, and describe the effects these drugs have on the nervous system.
3. Give examples of disorders of neural conduction, and describe how they arise.

When neurons fail to develop properly or their function is impaired, the consequences can be devastating, affecting mood, behavior, and even the ability to think or move. Over 100 neurological disorders have been identified in humans, and therapeutic drugs to treat them are among the most widely prescribed medicines today (**Table 41.3**). All so-called recreational drugs, including alcohol and tobacco, as well as illicit drugs such as marijuana, cocaine, heroin, LSD, and methamphetamine, exert their effects by altering neurotransmission. The use of these drugs, therefore, can result in symptoms similar to those of neurological disorders. Note in Table 41.3 that certain therapeutic drugs used to treat neurological disorders also exert many of their actions on neurotransmission.

Disorders of Neurotransmission Can Affect Mood

Several neurological disorders result from disrupted neurotransmission between cells. Genetic processes involved in the production of neurotransmitters or malfunction of synaptic events can increase or decrease activity at synapses, which, in turn, affects emotions and behavior. The most common mood disorder is **major depressive disorder,** or, simply, depression. This illness results in prolonged periods of sadness, despair, and lack of interest in daily activities without alternating episodes of euphoria. Depression affects 5–12% of men and 10–25% of women at some time during their lives. This condition is thought to result from decreased activity of synapses that release biogenic amines, such as serotonin, which changes neuronal activity within specific areas in the brain involved in processing emotion. Drugs used to treat major depression include the **selective serotonin reuptake inhibitors (SSRIs)**, such as Prozac, Zoloft, and Paxil, which reduce the reuptake of serotonin into the presynaptic terminal after it is released. This allows serotonin to accumulate in the synaptic cleft, counteracting the deficit that causes the alteration in mood.

In many respects, the use of such drugs to treat depression reflects a profound change in the public's attitude toward mental illness. Historical attitudes toward mood disorders held that individuals who were depressed lacked the ability to cope with stressful events in their lives. Only relatively recently has it become accepted that mood disorders are typically caused by changes in the balance of neurotransmitters in the brain. Drugs can be very effective in treating these disorders. Patients taking SSRIs often report decreased sadness, increased energy, and a greater interest in daily activities.

Many Illicit Drugs Disrupt Normal Neurotransmission

Many illicit drugs work at the synapse to either enhance or interfere with the normal mechanisms of neurotransmission (see Table 41.3). At the presynaptic terminal, such drugs can decrease neurotransmitter release by reducing Ca^{2+} entry into the cell or by preventing the exocytosis of vesicles containing stored neurotransmitters. In the synaptic cleft, drugs can slow the rate at which the neurotransmitter is broken down into an inactive form or taken back up into the presynaptic neuron, thereby prolonging the action of the neurotransmitter in the synaptic cleft. Some substances act on the postsynaptic membrane by either preventing the neurotransmitter from binding to its receptor or by acting as a substitute for the neurotransmitter by stimulating the receptor.

In effect, these drugs produce changes or imbalances in neurotransmission similar to those observed in some neurological disorders. These substances can induce euphoria, increase activity, alter mood, and produce hallucinations. They can also have potentially life-threatening effects and may be highly addictive.

Some drugs, such as cocaine, block the removal of dopamine and norepinephrine from the synaptic cleft by preventing their reuptake into the presynaptic terminal. Morphine and marijuana mimic the actions of biological substances already in the brain, binding to receptors on the postsynaptic membrane. With these drugs, the resulting effects are much stronger than are the effects of natural neurotransmitters. It is no surprise that many of these drugs are mind-altering. They do, after all, change the ways in which neurons communicate with each other.

Table 41.3 Representative Effects of Common Therapeutic, Illicit, or Recreational Drugs on Neurotransmitter Action and Mood

Name of drug	Actions on neurotransmission	Effects on mood	Effects of abuse or overdose
*Illicit or Recreational**			
Alcohol (ethanol)	Enhances inhibitory GABA transmission; increases dopamine transmission; inhibits glutamate transmission	Relaxation; euphoria; sleepiness	Liver damage; brain damage
Amphetamines ("uppers," "crystal meth," "pep pills")	Stimulate the release of dopamine and norepinephrine	Euphoria; increased activity	High blood pressure; psychosis
Cocaine	Blocks norepinephrine and dopamine reuptake	Intense euphoria followed by depression	Convulsions; hallucinations; death from overdose
LSD (lysergic acid diethylamide)	Binds to serotonin receptors	Hallucinations; sensory distortions	Unpredictable and irrational behavior
Marijuana (tetrahydrocannabinol)	Binds to receptors for natural cannabinoids	Increased sense of well-being; decreased short-term memory; decreased goal-directed behavior; increased appetite	Delusions; paranoia; confusion
Narcotics: heroin, morphine, meperidine (Demerol), codeine	Bind to opiate receptors	Pain relief; euphoria; sedation	Slowed breathing; death from overdose
Nicotine	Initially stimulates but then depresses activity in adrenal medulla and neurons in the peripheral nervous system; increases dopamine in brain	Increased attention; decreased irritability	Heart disease and lung disease
PCP (phencyclidine or "angel dust")	Blocks channel for excitatory amino acid neurotransmitters; increases dopamine activity	Violent behavior; feelings of power; numbness; disorganized thoughts	Psychosis; convulsions; coma; death
Therapeutic			
Tricyclic antidepressants (for example, Elavil, Anafranil)	Block the reuptake of norepinephrine from synapses	Relieve depression and obsessive-compulsive disorder	Drowsiness; confusion
Selective serotonin reuptake inhibitors (SSRIs) (for example, Prozac, Zoloft, Paxil, Lexapro)	Block the reuptake of serotonin from synapses	Relieve depression and obsessive-compulsive disorder	Insomnia; anxiety; headache
Monoamine oxidase inhibitors (for example, Parnate, Nardil)	Block the breakdown of biogenic amine neurotransmitters	Relieve depression	Liver damage; hyperexcitability
Antianxiety drugs: benzodiazepines [for example, Xanax, Valium, Librium, Rohypnol ("date rape drug," "roofies")]	Bind to GABA receptors and increase inhibitory neurotransmission	Relieve anxiety; cause sleepiness and in some cases amnesia	Drowsiness; memory loss in some cases
Antipsychotic drugs: phenothiazines (for example, Thorazine, Mellaril, Stelazine) and atypical antipsychotics (Abilify, Risperdal)	Block dopamine receptors	Ease schizophrenic symptoms	Decreased control of movement

*Some of these illicit or recreational drugs have some therapeutic value under certain conditions.

Disorders of Conduction May Result in Motor Problems and Abnormal Neuronal Development

Some human diseases are caused by the inability of certain axons to properly conduct an action potential. This occurs most commonly because an axon fails to become myelinated or because a myelinated axon becomes demyelinated.

In **congenital hypothyroidism**, axons fail to become wrapped with myelin during fetal development, which leads to slow conduction speeds and abnormal connections between brain neurons. This results in profound mental defects that cannot be reversed unless treatment begins immediately after birth. Congenital hypothyroidism is caused by a deficiency of thyroid hormone in the fetus. Among its many actions, thyroid hormone stimulates the formation of myelin during fetal development. However, thyroid hormone cannot be synthesized without the element iodine, which is part of its structure. The iodine in the fetus comes from the mother's diet. If a mother's dietary intake of iodine is too low, the fetus will not have enough iodine to make its own thyroid hormone, and therefore will not be able to make normal amounts of myelin. Congenital hypothyroidism is rare in the U.S. and many other countries since the advent of iodized table salt; however, it is not uncommon in many parts of the world.

Unlike congenital hypothyroidism, **multiple sclerosis (MS)** usually begins between the ages of 20 and 50 in individuals with apparently healthy nervous systems. With MS, a person's own immune system, for reasons unknown, attacks and destroys myelin as if it were a foreign substance. Eventually, these repeated attacks leave multiple scarred (sclerotic) areas of tissue in the nervous system

Figure 41.18 MRI scan of a brain from a person with multiple sclerosis. The arrows point to a few of numerous regions of damaged nervous tissue (white patches).

(**Figure 41.18**) and impair the function of myelinated neurons that control movement, speech, memory, and emotion. Multiple sclerosis is a serious and unpredictable disease, characterized by flare-ups followed by periods of remission in which symptoms are reduced or absent. No cure is currently available, but certain drugs may slow its progression and reduce the severity of symptoms. This disease affects roughly 2.5 million people worldwide, about 75% of them women.

Summary of Key Concepts

41.1 Cellular Components of Nervous Systems

- The central nervous system (CNS) is composed of a brain and a nerve cord. The peripheral nervous system (PNS) consists of all neurons and their projections that are outside of and connect with the CNS. Nerves transmit signals between the PNS and CNS (Figure 41.1).
- The two major classes of cells in nervous systems are neurons and glia. In neurons, signals flow from dendrites to the cell body and then to the axon and axon terminal. Types of neurons include sensory neurons, motor neurons, and interneurons. A neuron's structure is a reflection of its function (Figures 41.2, 41.3).
- The most basic circuit is a reflex arc, which acts rapidly in response to inputs from sensory neurons and consists of only one or a few afferent and efferent cells (Figure 41.4).

41.2 Electrical Properties of Neurons and the Resting Membrane Potential

- Neuronal membranes are electrically polarized. The membrane potential is determined by the differential distribution and differential permeability of ions across the plasma membrane. The resting membrane potential is the membrane potential of a cell that is not sending electrical signals. Neurons use electrical signals to communicate with other neurons, muscle cells, or gland cells. These signals involve changes in the amount of electric charge on either side of a cell's plasma membrane (Figure 41.5, Table 41.1).
- Diffusion of ions through membrane channels occurs as a result of the concentration gradient of an ion across the membrane and the electric charge across the membrane. Ions move in response to an electrochemical gradient (Figure 41.6).
- The Nernst equation gives the equilibrium potential for an ion at any given concentration gradient.

41.3 Generation and Transmission of Electrical Signals Along Neurons

- Gated ion channels enable a cell to communicate by changing its membrane potential rapidly. The opening and closing of voltage-gated and ligand-gated ion channels cause two types of changes in the neuron's membrane potential—graded potentials and action potentials (Figures 41.7, 41.8).
- Graded potentials can trigger an action potential, an event that carries an electrical signal along an axon, from the axon hillock to the axon terminal. Axon diameter and myelination influence the speed of an action potential (Figures 41.9, 41.10, 41.11).

41.4 Neurons Communicate Electrically or Chemically at Synapses

- In an electrical synapse, an electrical current is conducted from one cell to another via gap junctions. In a chemical synapse, a neurotransmitter carries the signal from the presynaptic to the postsynaptic cell. Many excitatory postsynaptic potentials (EPSPs) generated at one time can sum together and bring the membrane potential to the threshold potential, initiating an action potential (Figures 41.12, 41.13, 41.14).
- Chemical classes of neurotransmitters found in animals include acetylcholine, biogenic amines, amino acids, neuropeptides, and gaseous neurotransmitters. The discovery that the actions of neurons are mediated in large part by neurotransmitters was one of the most significant discoveries in the history of neuroscience (Table 41.2, Figure 41.15).
- The receptors of the postsynaptic neuron determine the types of signals that pass from one neuron to the other. The two major types of postsynaptic receptors are ionotropic and metabotropic (Figures 41.16, 41.17).

41.5 Impact on Public Health

- Most neurological conditions can be classified as disorders of either neurotransmission or conduction. Mood disorders caused by disrupted neurotransmission include major depressive disorder. Drugs used in the treatment of neurological disorders and many recreational and illicit drugs usually alter neurotransmission (Table 41.3).
- Some neurological conditions are caused by the inability of the axon to conduct an action potential. This occurs most commonly because axons fail to become myelinated (congenital hypothyroidism) or because myelinated axons become demyelinated (multiple sclerosis) (Figure 41.18).

Assess and Discuss

Test Yourself

1. In vertebrates, the brain and the spinal cord constitute
   a. the peripheral nervous system.
   b. the efferent division of the nervous system.
   c. the central nervous system.
   d. the autonomic nervous system.
   e. the central and peripheral nervous systems.
2. The structures of a neuron that function mainly in receiving signals from other neurons are the
   a. myelin sheaths.
   b. axons.
   c. axon terminals.
   d. dendrites.
   e. K^+ channels.
3. The myelin sheath
   a. is produced by neurons in the peripheral nervous system.
   b. is formed only around neurons in the brain.
   c. is present on all neurons.
   d. is generally present around long axons in either the CNS or the PNS.
   e. significantly slows transmission along neurons.
4. Neurons that function mainly in connecting other neurons in the central nervous system are
   a. sensory neurons.
   b. efferent neurons.
   c. motor neurons.
   d. afferent neurons.
   e. interneurons.
5. The difference in charges across the plasma membrane of an unstimulated neuron is called
   a. an EPSP.
   b. the resting membrane potential.
   c. an IPSP.
   d. the graded potential.
   e. the action potential.
6. Which of the following contribute(s) to the resting membrane potential?
   a. the relative leakiness of the membrane to Na^+ and K^+
   b. active transport of ions across the membrane
   c. concentration of Na^+ and K^+ inside and outside of the cell
   d. all of the above
   e. b and c only
7. A neuron has reached a threshold potential when it has depolarized to the point where
   a. the voltage-gated Na^+ channels have become inactivated.
   b. sufficient numbers of voltage-gated Na^+ channels open to initiate a positive feedback cycle, contributing to further depolarization.
   c. voltage-gated K^+ channels close.
   d. voltage-gated Na^+ channels close.
   e. both b and c occur.
8. The speed of transmission of an action potential along an axon is influenced by
   a. the presence of myelin.
   b. an increased concentration of Ca^{2+}.
   c. the diameter of the axon.
   d. all of the above.
   e. a and c only.
9. Gap junctions are characteristic of
   a. electrical synapses.
   b. chemical synapses.
   c. acetylcholine synapses.
   d. GABA synapses.
   e. synapses between motor neurons and muscle cells.
10. The response of the postsynaptic cell is determined by
    a. the type of neurotransmitter released at the synapse.
    b. the type of receptors the postsynaptic cell has.
    c. the number of Na^+ channels in the postsynaptic membrane.
    d. the number of K^+ channels in the postsynaptic membrane.
    e. all of the above.

Conceptual Questions

1. Describe the difference between graded and action potentials.
2. In certain diseases, such as kidney failure, the Na^+ concentration in the body's extracellular fluid can become altered. What effect might a high extracellular Na^+ concentration have on neurons?
3. A principle of biology is that *structure determines function*. How can this be applied to neurons?

Collaborative Questions

1. Describe the difference between an electrical synapse and a chemical synapse. What advantage is provided by chemical synapses?
2. Name the parts of a neuron, and give a brief description of their major characteristics.

Neuroscience II: Evolution, Structure, and Function of the Nervous System

42

Three-dimensional reconstruction of the brain of a fruit fly. The brains of animals are organized into anatomical structures with specialized functions. For example, the green structures in this image are important for learning and memory, the purple structures for olfaction, and the large orange structures on either side process visual information.

CHAPTER OUTLINE

42.1 The Evolution and Development of Nervous Systems

42.2 Structure and Function of the Nervous Systems of Humans and Other Vertebrates

42.3 Cellular Basis of Learning and Memory

42.4 Impact on Public Health

Summary of Key Concepts

Assess and Discuss

It will take you approximately 2–3 seconds to read this sentence. During that time, many of the 100 billion or so neurons of your brain will have fired off millions of action potentials. Some of those signals will help process the visual information reaching your eyes as you scan the page. Others will activate centers of learning and memory to allow you to understand the meanings of the words you've read. Still other signals will help filter out extraneous inputs—such as background noise—that might distract you from your task. The complexity of the seemingly simple task of reading a single sentence emphasizes the enormous level of activity that goes on continually in the brain, even at rest.

The wonder of the brain lies in its incredible complexity. The human brain, for example, has several thousand miles of interconnected neurons and hundreds of trillions of synapses, resulting in a total surface area that if spread out, would cover more than four soccer fields. The brain allows us to move, think, and experience sensation and emotion. Groups of neurons also coordinate homeostatic functions such as breathing, blood circulation, and body temperature. When we examine the way that groups of neurons communicate, we begin to understand the complex mental functions of nervous systems, including learning, memory, and motivation.

Neuroscience—the study of nervous systems—is an area of intense research activity worldwide. In 2013, the administration of President Barack Obama announced the formation of the BRAIN Initiative (Brain Research through Advancing Innovative Neurotechnologies), a 10-year, federally funded effort to map the location, structure, and function of all the 100 billion or so neurons in the human brain. This initiative has the potential to revolutionize our understanding of how the human brain functions in both health and disease, and it launches a thrilling new era of neuroscience research.

In this chapter, we will first survey a variety of nervous systems, which allow animals to sense and respond to environmental changes. We will then examine the nervous system of humans. However, keep in mind that we still have much to learn about the organization, connectivity, and functions of nervous system structures. Our own nervous system is fascinating and mysterious, and the study of how it functions will ultimately tell us much about what makes us human.

42.1 The Evolution and Development of Nervous Systems

Learning Outcomes:

1. List the different types of nervous systems found in animals.
2. Describe the general anatomical organization of the brain in vertebrates.
3. Relate the structural changes in brain complexity that accompanied the evolution of mammals to brain function.

Animal nervous systems are the products of hundreds of millions of years of evolution. They provide advantages to animals that promote reproductive success. For example, nervous systems allow animals to sense their environment and respond to changes in an appropriate way. In addition, nervous systems form connections with muscles and facilitate movement, which has allowed animals to travel distances to obtain food. Likewise, nervous systems help animals to avoid predation and other environmental dangers; form social bonds that enhance the chances of survival for both the individual and the group; and even perform the complex tasks of thinking, learning, remembering, and planning.

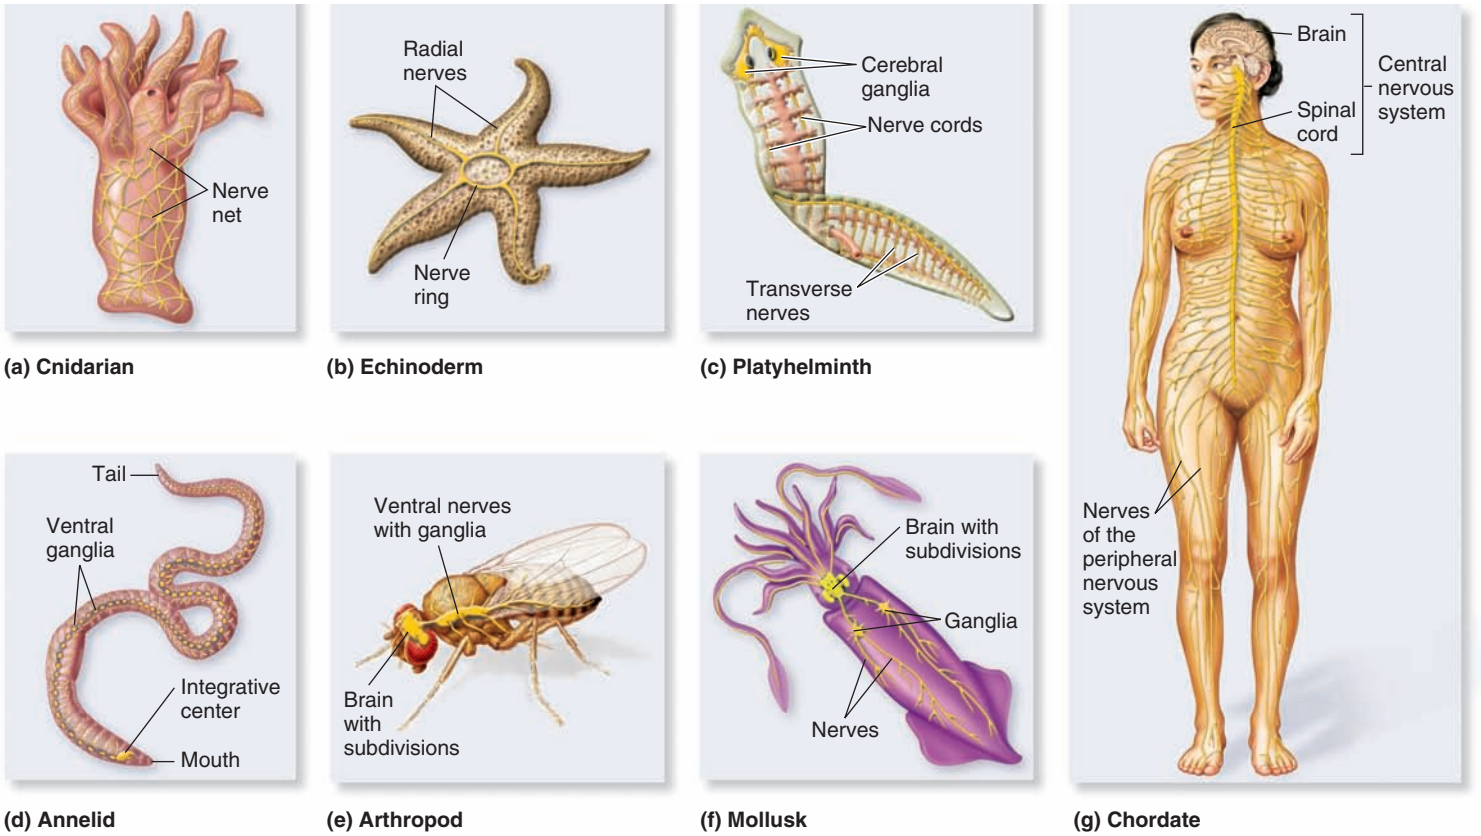
Studying the evolution and development of nervous systems helps us understand how particular nervous systems are adapted to different functions. At the structural level, the organization of nervous systems ranges from a relatively simple network of a few cells to the complexity of the human brain. The characteristics of an animal's nervous system determine the behaviors that it displays. In this section, we will survey some comparative features of the nervous systems of invertebrates and vertebrates.

Nervous Systems Evolved to Sense and Respond to Changes in the Environment

Precisely when nervous systems first arose and whether or not the nervous systems of most or all animals can be traced back to a common ancestor are questions of active investigation by neuroscientists. For example, recent genetic studies have uncovered remarkable similarities in the expression and activation of genes coding for proteins that regulate neuronal development across taxa in bilaterally symmetric animals. Those studies suggest that the patterning of nervous system development in these bilaterians may be traced to a common ancestor that lived more than 500 mya!

Today, all animals except sponges have a nervous system. Interestingly, though, researchers have recently discovered that sponges express dozens of genes that are similar to genes expressed in human neurons, particularly those that code for proteins that regulate synaptic function. The functions of the sponge genes are uncertain, but the proteins coded for by the genes interact in ways that are reminiscent of human synaptic proteins. Thus, the origin of nervous systems almost certainly can be traced to genes of evolutionarily ancient organisms; as animals evolved, these genes were modified and formed the basis of all future nervous systems.

The simplest nervous system is the **nerve net** of the radially symmetric cnidarians (jellyfish, hydras, and anemones) (**Figure 42.1a**). The neurons are arranged in a network of connections between the inner and outer body layers of the animals. A characteristic feature of nerve nets is that activation of neurons in any one region leads to activation of most or all other neurons, with the excitation spreading in all directions at once. Many of these neurons stimulate contractile cells to contract. This allows the organism to move large areas of its body simultaneously, thereby coordinating simple movements such as swimming. Recent research has identified regions of specialized function in the nerve nets of some cnidarians, such as local sensory neurons in the outer body wall; these findings push the origin of specialized nervous system structures and function further back in evolutionary time than previously thought. Some cnidarians, such as the jellyfish, have two nerve nets: one for moving tentacles and one for swimming.



Sea stars and other echinoderms also have a simple nervous system, but it is structurally slightly more complex than that of cnidarians. A nerve ring surrounds the mouth and is connected to larger radial nerves extending into the arms (**Figure 42.1b**). This arrangement allows the mouth and arms to operate independently.

In Platyhelminthes such as *Planaria*, collections of neurons in the animal's head form **cerebral ganglia** (singular, ganglion). These are groups of neuronal cell bodies that perform the basic functions of integrating inputs from sense organs, such as the eyes, and controlling motor outputs, such as those involved in swimming (**Figure 42.1c**). Two lateral nerve cords extend along the ventral surface of the animal from the anterior end to the posterior end and are connected to each other by transverse nerves. In annelids (segmented worms), the basic structure is similar, except that more neurons are present and a single ventral nerve cord has ganglia located in each body segment (**Figure 42.1d**). In the head, cerebral ganglia form an integrative center, which functions as a rudimentary brain to control body movements. The other ventral ganglia along the nerve cord receive sensory information from a particular body segment and control local movements. In the simpler types of mollusks, such as the snail, the nervous system is very similar to that of the annelids. The head contains a pair of anterior ganglia; paired nerve cords extend from these ganglia to the eyes, muscular foot, and digestive system.

During the evolution of animals, more complex body types have been associated with **cephalization** (from the Greek *cephalo*, meaning head). This term refers to the concentration of sense organs at the anterior end of the body, forming an increasingly complex **brain** that controls sensory and motor functions of the entire body. Within the brain, neuronal pathways provide the integrative functions necessary for an animal to make more sophisticated responses to its environment. Brains are found in all vertebrates and most invertebrates, and they are usually composed of more than one anatomical and functional region. For instance, in *Drosophila* (**Figure 42.1e** and the chapter opening photo), the brain has several subdivisions with separate functions, such as a region devoted to learning and memory. Some mollusks, such as the squid and octopus, have brains with well-developed subdivisions that allow these animals to coordinate the complex visual sensing and motor behaviors necessary for their predatory lifestyle (**Figure 42.1f**). In chordates, the brain is connected to a dorsally located **spinal cord**. The brain and spinal cord constitute the **central nervous system (CNS)** (**Figure 42.1g**). Nerves from the **peripheral nervous system (PNS)** route information into and out of the CNS at separate regions along the spinal cord.

Brains of Vertebrates Have Three Basic Divisions

Development of the vertebrate brain begins with the formation of a central fold in the embryo called the neural tube. This hollow tube is the structure from which the entire nervous system develops (you can look ahead to Figure 52.11 for additional details). Increased cell proliferation leads to bending and folding of the neural tube during embryonic development, resulting in bulges that become separate divisions of the nervous system. The anterior end develops into the brain, while the posterior portion becomes the spinal cord.

Figure 42.1 Representative nervous systems throughout the animal kingdom.

BioConnections: Nervous systems are one of the defining features of animals. In Chapter 32, you learned that several other features define animals and distinguish them from other living organisms. What are some of these features?

In vertebrates, the brain has three major anatomic divisions, the **hindbrain**, **midbrain**, and **forebrain** (**Figure 42.2**). Fossils of jawless fishes that lived 400 mya show that their brains were already organized into the three basic divisions that have been retained in all modern vertebrates.

Let's look at the development of the human brain. At 4 weeks, the human embryo exhibits just the hindbrain, midbrain, and forebrain (Figure 42.2a). Just a week later, the hindbrain and forebrain have each formed two separate subdivisions (Figure 42.2b). The hindbrain subdivides into the metencephalon and the myelencephalon. The forebrain subdivides into the telencephalon and the diencephalon. The midbrain, by contrast, does not subdivide and is termed the mesencephalon. By the time the human brain is fully developed, some of these structures have further divided and specialized (Figure 42.2c; the functions of each of these structures will be described later). The development of brain subdivisions increases the capacity of the brain to perform complex, distinct functions.

Evolution of Increased Brain Complexity Involved a Larger, Highly Folded Forebrain

As evolution resulted in animals with more complex nervous systems, the size of the forebrain and its major subdivision, the **cerebrum**, also increased, making up a greater proportion of the brain. Many of the important functions of the forebrain are carried out by neurons in the outer surface of the cerebrum called the cerebral cortex (described later). Therefore, increased complexity of the brain is also correlated with an increased surface area of the cerebral cortex (see Figure 42.2). During the evolution of mammals, this increase in surface area occurred more rapidly than an expansion in the size of the skull. How could this occur? The answer is that the external surface of the forebrain in animals with increasingly complex brains is highly convoluted, forming many folds called gyri (singular, gyrus), separated by grooves called sulci (singular, sulcus). Compare the relatively smooth-looking surface of the brain of a rat with the highly folded one of a dolphin or primate in **Figure 42.3**.

As body size increases across the animal kingdom, you might expect that brain mass would increase proportionately—that the brain of an elephant would be proportionately larger than that of a bat, for instance. That is generally the case, with a few important exceptions (**Figure 42.4**). In particular, the masses of the human and dolphin brains are considerably greater than would be expected on the basis of body mass (note the logarithmic scale on the vertical axis).

Brain mass and the amount of folding of forebrain structures are correlated with more complex behaviors. Why is this so? As we will see in the next section, the outer surface of the brain, the cerebral cortex, plays a key role in conscious thought, reasoning, and learning. Greater size and folding provide a larger number of neurons and synapses and more surface area, which allows greater processing and interpretation of information. Even so, evidence does not suggest

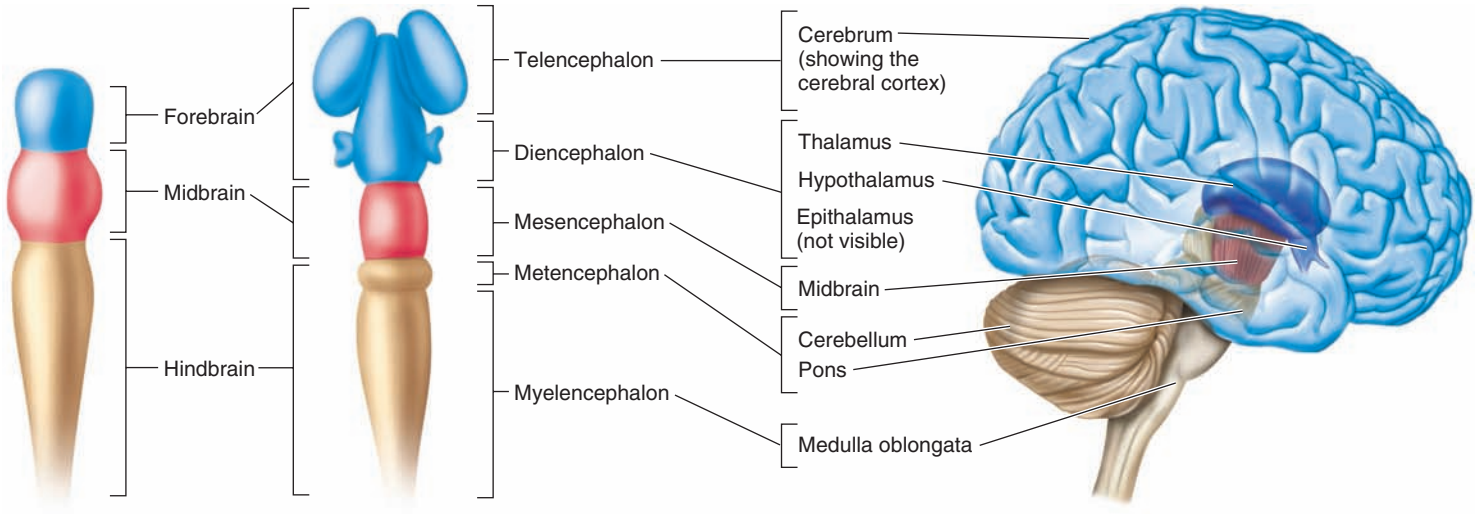

Figure 42.2 Development of the human brain. The structures shown here that occur during embryonic development at **(a)** 4 weeks and **(b)** 5 weeks are compared with **(c)** how they appear in the adult. Some forebrain structures beneath the cerebrum are not shown. The functions of all of these structures will be described in Section 42.2.

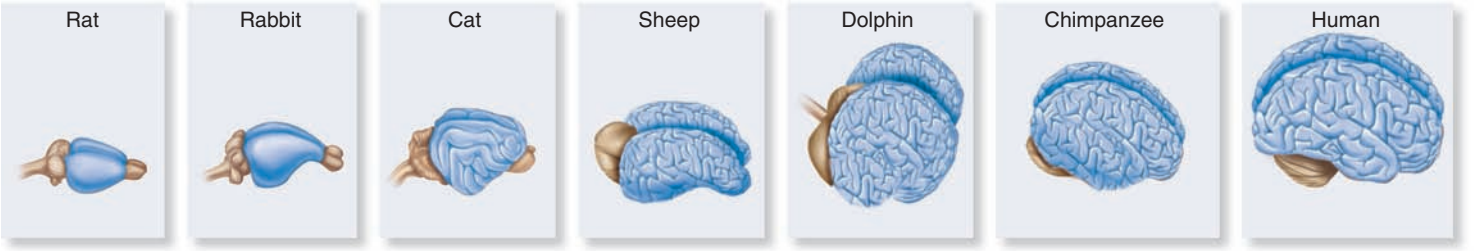

Figure 42.3 The degree of cerebral cortex folding in different mammalian species. The brains are not shown to scale.

BIOLOGY PRINCIPLE Structure determines function. The increased folding of the cerebral cortex of certain mammals increases the surface area of this part of the brain, allowing for more neuronal connections and complex behaviors.

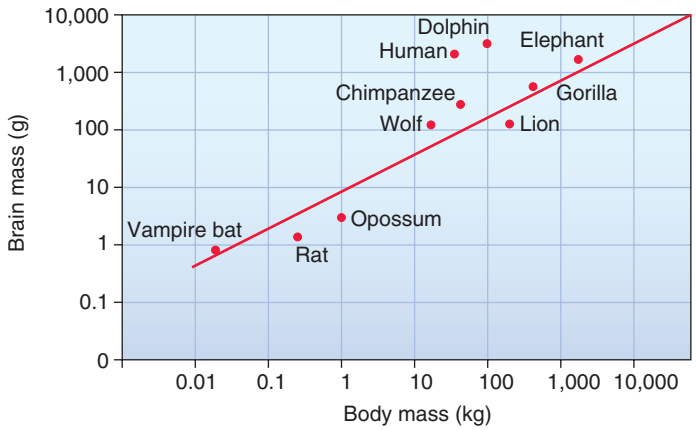

Figure 42.4 Brain mass as a function of body mass in mammals. For most mammals, brain weight is in proportion to body mass. However, humans and dolphins have a much higher brain mass relative to their body mass than do other mammals.

Concept Check: Scientists have determined that the brain mass of Homo neanderthalensis (Neanderthals) was greater than that of our own. Does this mean that Neanderthals were more intelligent and capable of more complex behaviors than we are?

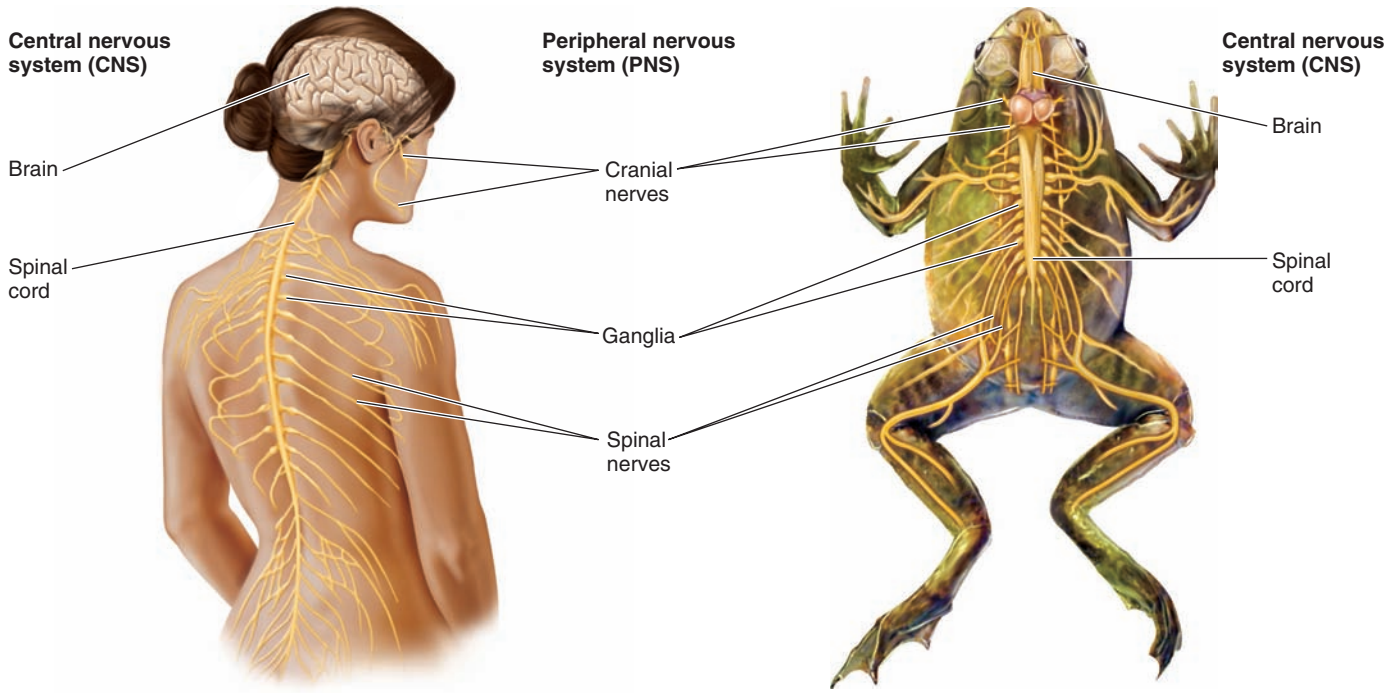
that people with small differences in brain size differ in intelligence. Also, it would be wrong to assume that an animal with a small brain is profoundly limited in its behavioral repertoire. A bat with a 0.9-g brain and an elephant with a 2,500-g brain can both perform a great variety of interesting and complex behaviors, such as navigating across great distances and interacting with fellow members of their species.

42.2 Structure and Function of the Nervous Systems of Humans and Other Vertebrates

Learning Outcomes:

1. Outline the anatomical organization of the human nervous system.
2. Describe the organization of the peripheral nervous system.
3. Identify the differences between the somatic and autonomic nervous systems.
4. Briefly describe the major structures and functions of the human hindbrain, midbrain, and forebrain.

The nervous system of the human is amazingly complex—the brain alone has over 100 billion neurons and as many as a few hundred billion glia cells. Moreover, complexity is defined by more than just numbers of cells. Within the human brain, for example, are enormous numbers of connections between neurons—a single neuron in the cerebellum may have as many as 100,000 or more synapses with other cells! In this section, we will examine the human nervous system, with an emphasis on the functions of the major parts of the brain and spinal cord.



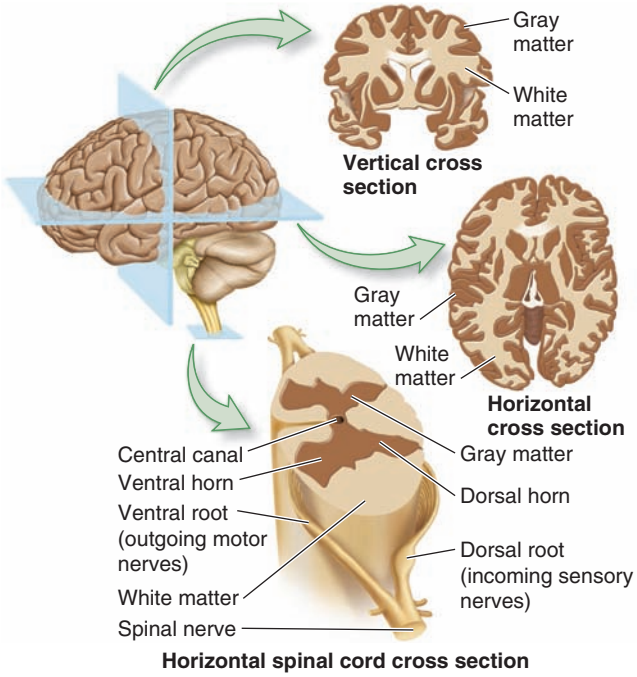
Information is Conveyed Throughout the Vertebrate Nervous System by Nerves and Tracts

In vertebrates, the CNS and PNS are anatomically and functionally connected (**Figure 42.5**). The CNS receives information about the internal or external environment from the PNS. The CNS interprets that information and may initiate a response that is then carried out by the PNS. For example, suppose you accidentally lean against a newly painted fence. Neuronal endings in your skin, which are part of the PNS, would transmit tactile (touch) information through axons that bring information directly into the spinal cord. From there, the information travels to your brain, where the sensation is analyzed and identified as something sticky. Signals are sent from your brain, down your spinal cord, and through the neurons of the PNS to your muscles, causing you to move away.

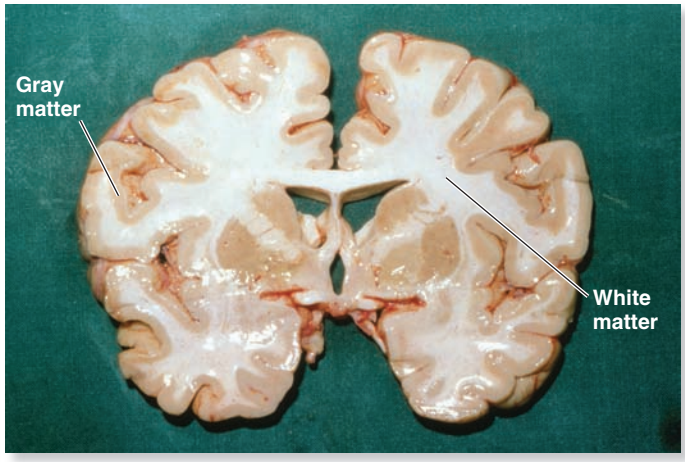
Within the nervous system, groups of neurons may associate with each other and perform a particular function. In the CNS, the cell bodies of neurons that are involved in a similar function may be grouped into a structure called a **nucleus** (plural, nuclei), which may include thousands of cell bodies. For instance, neuronal cell bodies that regulate body temperature and those that recognize visual information are located in separate nuclei in the brain. In the context of the vertebrate nervous system, the term **ganglion** is used to refer to a group of neuronal cell bodies located in the PNS (see Figure 42.5).

Within the vertebrate nervous system, many myelinated axons may run in parallel bundles. (Myelination is described in Chapter 41; see Figure 41.2.) Such a structure is called a **tract** when it is found in the CNS. Tracts convey information from region to region within the brain and between the brain and the spinal cord. Bundles of myelinated axons also form outside the CNS, in the PNS, in which case they are called **nerves** (refer back to Figure 41.2d). The cell bodies that give rise to the axons of nerves may be within the PNS or the CNS; in other words, a given nerve may carry information from outside the CNS into the CNS, from the CNS to structures outside the CNS, or, as occurs commonly, in both directions. Connections between the PNS and the CNS occur at the brain or spinal cord. **Cranial nerves** are directly connected to the brain, primarily to sites within the hindbrain and midbrain. By comparison, **spinal nerves** are connections between the PNS and spinal cord (see Figure 42.5).

One of the most obvious characteristics of the CNS is that some parts look white, and others appear gray (**Figure 42.6**). The **white matter** gets its color from myelin; it consists of myelinated axons bundled together in large numbers to form tracts. The **gray matter** is



(a) The human nervous system



(b) The amphibian nervous system

Figure 42.5 Organization of the vertebrate nervous system. The CNS consists of the brain and spinal cord, both of which are encased in bone (not shown). The PNS includes cranial nerves, ganglia, and spinal nerves, which carry information to and from the CNS, and many other neurons throughout the body. Note the similarities between two widely divergent vertebrates, **(a)** humans and **(b)** frogs.

BIOLOGY PRINCIPLE **All species (past and present) are related by an evolutionary history.** The similarities between the nervous systems of these two very different-looking animals point to a common ancestor.

(a) Gray and white matter in the brain and spinal cord

(b) Photograph of a vertical cross section of the human brain

Figure 42.6 Gray matter and white matter in the CNS. **(a)** The gray matter is composed of groups of cell bodies, dendrites, and unmyelinated axons. The white matter consists of tracts of myelinated axons. **(b)** Photograph of a vertical cross section through an adult human brain. In these images, gray matter is darkened for better visibility.

Concept Check: *Is a spinal nerve composed of axons from afferent or efferent neurons, or both?*

darker in appearance and consists of neuronal cell bodies, dendrites, and some unmyelinated axons. The cerebral cortex is composed of gray matter that sits on top of a large collection of white matter pathways. In the spinal cord, the gray matter is located in the center and forms two dorsal horns and two ventral horns (Figure 42.6a). Each dorsal horn connects to a dorsal root, which is part of a spinal nerve. Dorsal roots receive incoming information from sensory (afferent) nerves of the PNS. The ventral horn connects to the ventral root, which is also part of a spinal nerve that transmits outgoing information to motor (efferent) nerves. A central canal runs through the spinal cord, carrying a nutritive and protective fluid, as described shortly.

The CNS is Encased in Protective Membranes

Unlike the PNS, the CNS is encased in protective structures including bone (the skull and backbone) and three layers of sheathlike membranes called **meninges** (Figure 42.7). The outermost membrane, the dura mater (from the Latin, meaning hard mother), is a thick protective layer that lies just inside the skull and vertebrae. The middle membrane is called the arachnoid mater (from the Latin, meaning spidery mother) because it has numerous weblike tissue connections to the innermost membrane, the pia mater (from the Latin, meaning thin mother). The pia mater is a very thin membrane that lies on the surface of the brain and spinal cord, folding with the brain's surface.

Between the arachnoid mater and pia mater is the subarachnoid space. This space is filled with **cerebrospinal fluid**, which surrounds the exterior of the brain and spinal cord and absorbs physical shocks to the brain that result from sudden movements or blows to the head. The cerebrospinal fluid contains nutrients, hormones, and other substances that are taken up by cells of the brain. The fluid is also a reservoir for metabolic waste products that are then carried away by the circulatory system. In addition to the subarachnoid space, the cerebrospinal fluid also fills a series of connected cavities called the ventricles that lie deep within the brain and connect to the central canal that extends the length of the spinal cord (see Figure 42.6). These fluid-filled structures provide a cushion of support and protection for the CNS.

The PNS Consists of the Somatic and Autonomic Nervous Systems

The PNS of vertebrates is subdivided into two major functional and anatomical components: the somatic nervous system and the autonomic nervous system. Both divisions have sensory (afferent) nerves and motor (efferent) nerves.

Somatic Nervous System The major functions of the **somatic nervous system** are to sense the external environment and control skeletal muscles. The sensory neurons of the somatic nervous system receive stimuli, such as heat, light, odors, chemicals (in food), sounds, and touch, and transmit signals to the CNS. The motor neurons of the somatic nervous system control skeletal muscles. The cell bodies of these motor neurons are located within the CNS. The axons from these cells leave the spinal cord and project directly onto skeletal muscle without any intermediary synapses along the way.

Many of the responses of the somatic nervous system can be controlled consciously. For example, we use our somatic nervous system to walk and hold a pencil. However, not all responses are voluntary. An example is a reflex arc, such as the knee-jerk response, which is automatic (refer back to Figure 41.4).

Autonomic Nervous System The **autonomic nervous system** regulates homeostasis and organ function. For example, it is involved in regulating heart rate, blood pressure, glucose homeostasis, and the amount of stomach acid secreted in response to a meal. Though the

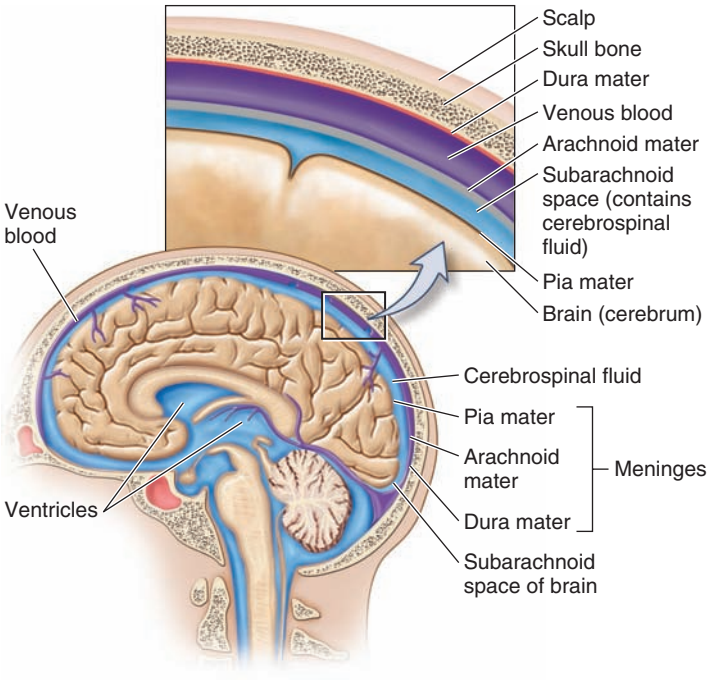


Figure 42.7 The meninges and ventricles of the CNS. The thickness of the meninges are exaggerated for illustration purposes. Note that the cerebrospinal fluid encases the entire CNS and also fills the ventricles.

Concept Check: In a procedure known as a lumbar puncture (commonly referred to as a spinal tap), physicians use a needle to withdraw a small amount of cerebrospinal fluid from the bottom of the spine to help diagnose specific illnesses. What effects might this procedure have on a patient?

autonomic nervous system is predominantly composed of motor neurons, it also has sensory neurons that detect internal body conditions. For example, baroreceptors are sensory neurons located in the heart and certain blood vessels that detect changes in blood pressure. For the most part, the autonomic nervous system is not subject to voluntary control. We usually cannot consciously change our heart rate or blood pressure.

The efferent pathways of the autonomic nervous system involve sets of two motor neurons. The cell body of the first neuron is within the CNS and synapses on a second neuron in ganglia outside the spinal cord; these ganglia, therefore, are part of the PNS. This second neuron sends its axon to an effector cell, where it alters that cell's function. These neurons control smooth muscles, cardiac muscle, and glands.

The efferent nerves of the autonomic system are subdivided into the sympathetic and parasympathetic divisions (**Figure 42.8**). Both divisions of the autonomic system act on the same organs and usually have opposing actions. The **sympathetic division** is responsible for rapidly activating systems that prepare the body for danger or stress. Imagine, for example, the physiological responses that would occur if a person was hiking and came upon a grizzly bear. This is the **fight-or-flight response**, which is characterized by increased heart rate, stronger pumping action of the heart, relaxed (opened) airways and faster breathing, inhibition of digestive activity, increased blood flow to skeletal muscles, and increased secretion of energy-supplying substances such as glucose and fats into the blood by the liver and adipose tissue. These features prepare us to confront (fight) or avoid (flight) a perceived or real threat.

The **parasympathetic division** of the autonomic nervous system is involved in maintaining and restoring body functions. It is particularly active during restful periods or after a meal, which is why it is sometimes said to mediate the **rest-or-digest response**. Neurons of the parasympathetic division promote digestion and absorption of food from the gut, slow the heart rate, and decrease the amount of fuel supplied to the blood from the liver and adipose tissue. A summary of these and other major functions of the two divisions of the autonomic nervous system can be found in Figure 42.8.

The Human Hindbrain Is Important for Homeostasis and Essential Bodily Functions

Let's now turn our attention to the structure and function of the human brain (**Figure 42.9**). We will begin with the evolutionarily oldest structures of the brain, some of which are located in the hindbrain and control the basic processes that sustain life.

Cerebellum The **cerebellum**, a large structure that sits dorsal to the rest of the hindbrain, receives sensory inputs from the cerebral cortex and the auditory and visual areas of the brain. It also receives inputs from the spinal cord and inner ears that convey information about the position of the head and limbs and thereby helps maintain balance and coordinate hand-eye movements. In addition, the cerebellum helps control the use of multiple muscles at one time and synchronizes fine motor activities such as texting, making a jump shot in basketball, or touching the fingers to the tip of the nose with your eyes closed. When the cerebellum is damaged or injured, such as in an accident, a person may find it difficult to maintain balance and fine-tune motor functions. Although historically scientists have thought that the cerebellum does not play a role in learning, memory, and conscious thought, recent evidence has strongly suggested that the cerebellum may indeed have significant cognitive functions, the full extent of which remains to be discovered.

Pons The **pons** sits anterior to the medulla oblongata and beneath the cerebellum. Major tracts involved in motor function pass through the pons into and out of the cerebellum, so the pons serves as a relay between the cerebellum and other areas of the brain. In addition to this integrative motor function, the pons contains nuclei that play a very important role in regulating the rate and depth of breathing. The pons is also the origin of some cranial nerves.

Medulla Oblongata The **medulla oblongata** is located between the pons and the anterior part of the spinal cord. It coordinates many processes that maintain homeostasis. It is involved in the control of heart rate, breathing, blood pressure, digestion, swallowing, and vomiting, and it is the origin of several cranial nerves.

The Human Midbrain Processes Sensory Inputs and Maintains Alertness

The midbrain lies anterior to the pons. It processes several types of sensory inputs, including vision, olfaction, and audition. It has tracts that pass this information to other parts of the brain for further processing

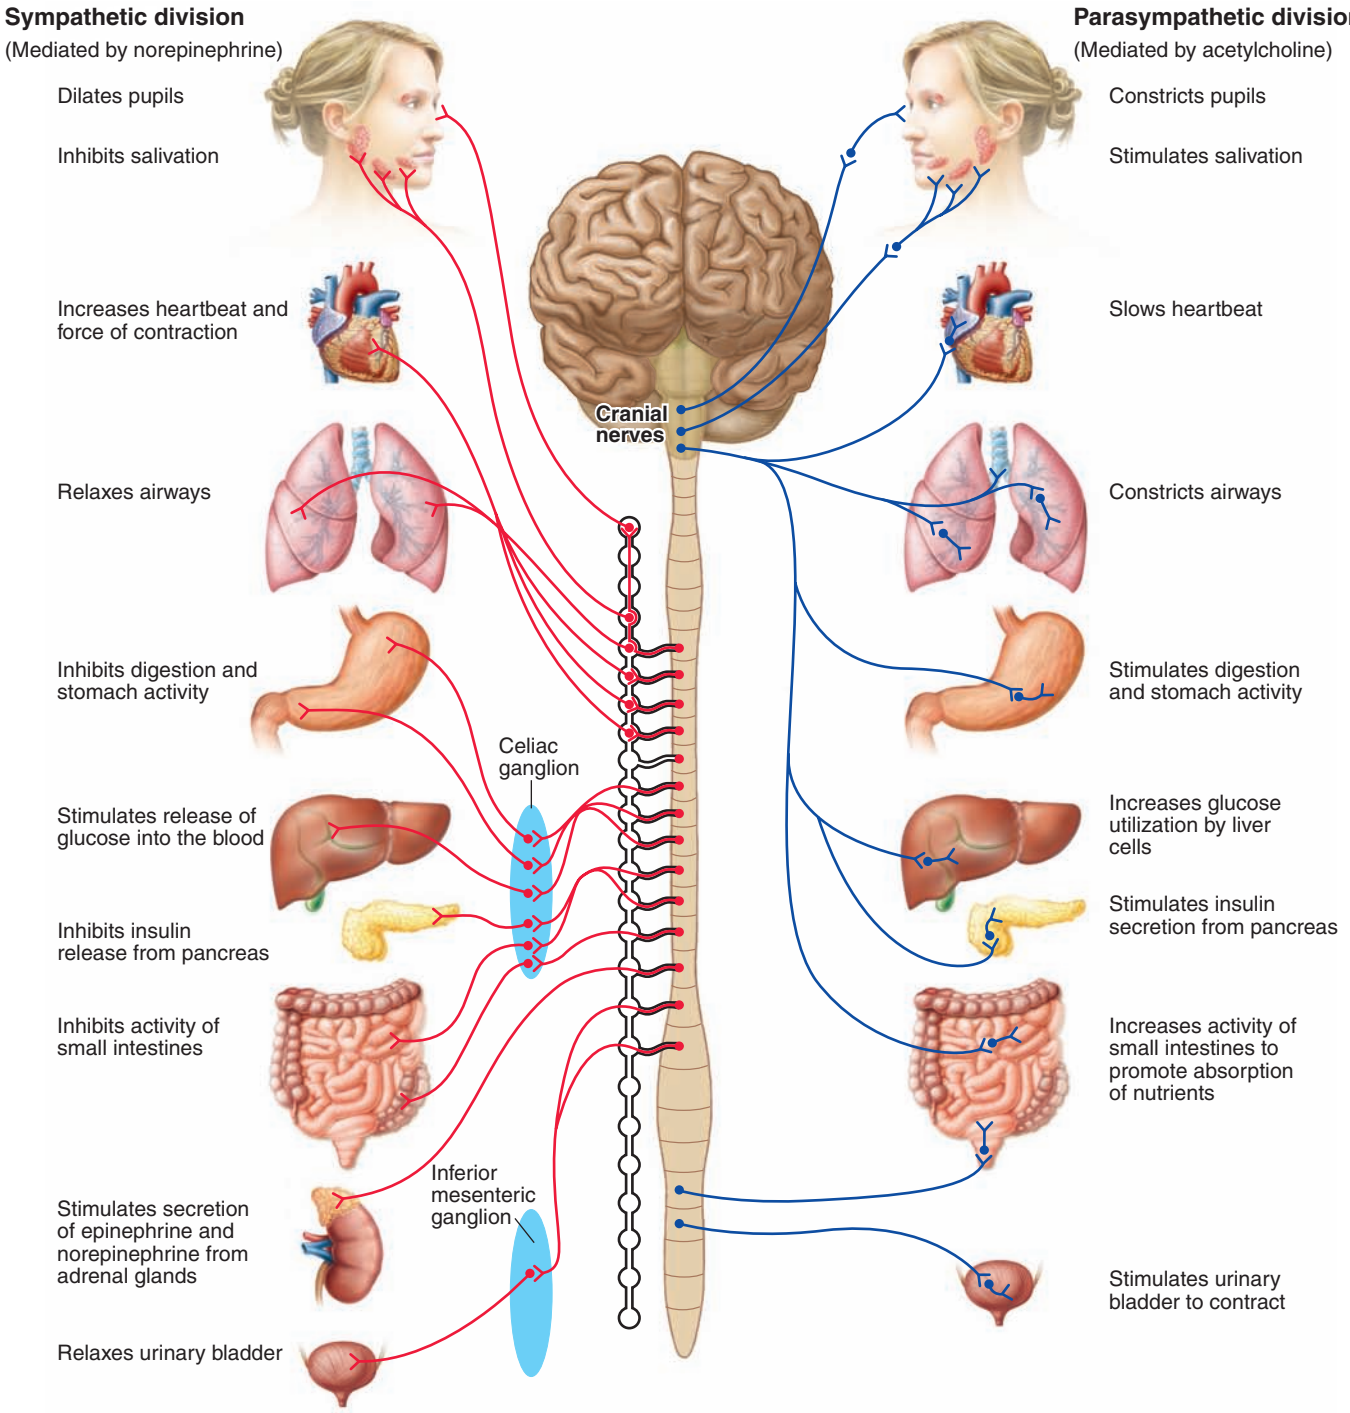

Figure 42.8 **Sympathetic and parasympathetic divisions of the autonomic nervous system.** For simplicity, only some of the major functions of each division are shown in this figure. The sympathetic and parasympathetic systems tend to have opposite effects, and most parts of the body receive inputs from both divisions. Nerves from the sympathetic division make connections with a chain of ganglia, most, but not all, of which are alongside the spinal cord. Nerves from the parasympathetic division make connections in ganglia near or in their targets (for clarity, the ganglia are only shown near the targets).

BIOLOGY PRINCIPLE **Living organisms maintain homeostasis.** The autonomic nervous system is an excellent illustration of one way in which homeostasis is maintained; many organs and other structures in the body are controlled in opposite ways by the two divisions of this branch of the nervous system. Therefore, the function of these structures can be modulated in two directions; for example, heart rate can be accelerated or slowed to match an animal's immediate metabolic requirements.

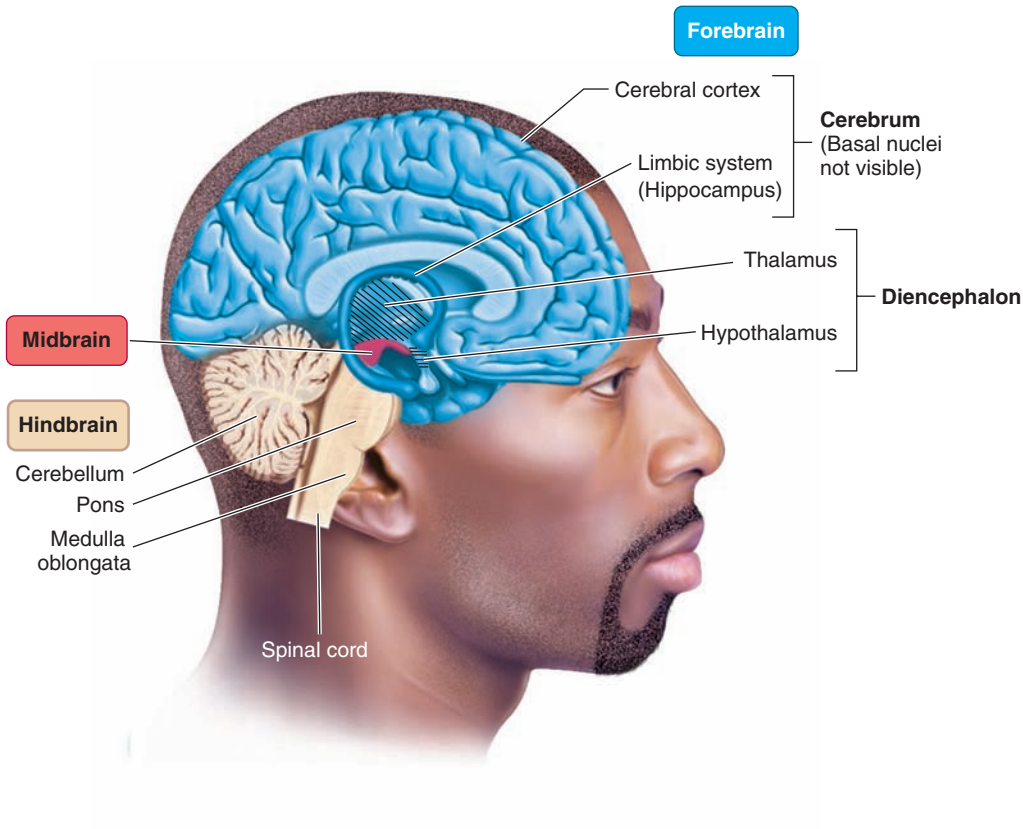

Figure 42.9 Major structures of the human brain. An overview of the brain, showing several internal structures (not all structures are visible in this plane, such as the basal nuclei). The limbic system consists of the olfactory bulbs, amygdala, and hippocampus, all of which are part of the cerebrum (many neuroscientists consider parts of the thalamus and hypothalamus as part of the limbic system). The midbrain, pons, and medulla oblongata collectively comprise the brainstem.

Concept Check: *How would an injury to the cerebellum affect a person's behavior?*

and interpretation. As one example, the midbrain is responsible for activating neural pathways that change the diameter of the pupil of the eye in response to a change in the amount of ambient light. If the midbrain is damaged, this pupillary reflex is impaired or destroyed.

The medulla oblongata, the pons, and the midbrain collectively constitute the **brainstem**. In addition to the functions just described, all three major parts of the brainstem contain additional nuclei that together form the **reticular formation**. This is a network of nuclei and tracts that extends throughout much of the brainstem and sends signals to many other brain regions. The reticular formation maintains and controls consciousness, alertness, and sleep, plus essential functions such as regulation of the respiratory and circulatory systems. Because of the importance of the brainstem's functions, damage to it is catastrophic and may result in coma or death.

The Human Forebrain Is Responsible for Motor, Sensory, and Higher Functions

The forebrain comprises the diencephalon and cerebrum (**Figure 42.10**). The diencephalon is made up of the thalamus, hypothalamus, and epithalamus. The cerebrum consists of the cerebral cortex, basal nuclei, and limbic system.

Diencephalon (Thalamus, Hypothalamus, and Epithalamus)

In vertebrates, the **thalamus** plays a major role in relaying sensory information to appropriate parts of the cerebrum and, in turn, sending outputs from the cerebrum to other parts of the brain. It receives input from all sensory systems except olfaction. One type of processing performed by neurons in the thalamus is filtering out sensory information in a way that allows us to pay attention to important cues while temporarily ignoring less important ones. This filtering mechanism begins in the reticular formation, which relays information about sensory inputs to the thalamus. Together, these brain regions permit selective attention to certain stimuli. A good example of this is a new parent's ability to sleep through a thunderstorm but awaken immediately to the cry of a baby in the next room. The thalamus also directs feedback about motor activities that it receives from the cerebellum and other structures to the cerebral cortex, which can then adjust its outgoing motor signals if necessary. Last, the thalamus is involved in the perception of pain and the degree of mental arousal in the cerebral cortex.

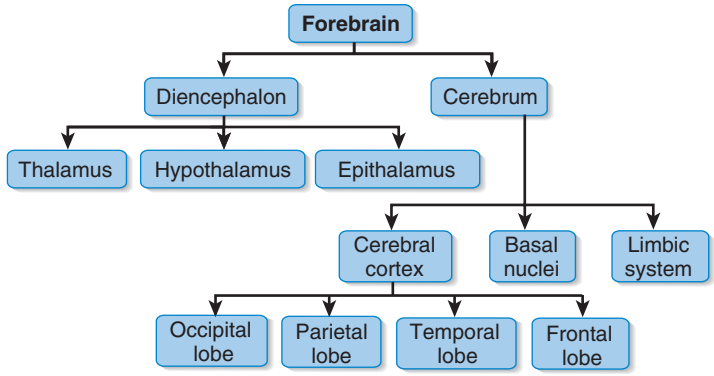

Figure 42.10 Relationships among structures that make up the human forebrain.

The **hypothalamus**, located below the thalamus at the floor of the forebrain, controls functions of the digestive and reproductive systems, body temperature (thermoregulation), and many basic behaviors such as eating and drinking. This area has great importance for homeostasis of the body and the control of behavior. Though small in size, it is composed of many nuclei, each with its own vital functions. A major role of the hypothalamus is the production of hormones, which travel to the pituitary gland located just beneath the brain. The pituitary gland, in turn, regulates hormone secretion from other glands in the body, including the thyroid, gonads, and adrenal glands. In addition to producing hormones, the hypothalamus is sensitive to the actions of other hormones. For example, certain hormones produced by cells in the stomach, intestine, adipose tissue, gonads, and elsewhere act within the hypothalamus to facilitate the expression of feeding, drinking, sexual, and aggressive behaviors. Finally, a small pair of hypothalamic nuclei called the suprachiasmatic nuclei acts as the "master clock" of the CNS, establishing circadian rhythms, which control the expression of behavioral, physiological, and hormonal rhythms over the 24-hour day.

The **epithalamus** is a collection of structures that have varied roles in the control of food and water intake, the integration of olfactory and visceral inputs with emotion and memory centers of the brain, and in some vertebrates rhythmic and seasonal behaviors. One of these structures, the pineal gland, is located in the center of the brain and secretes a hormone called melatonin into the blood. Production of melatonin is regulated by the length of the light period in each day. Although the function of melatonin in humans is still debated, it has been suggested to function in daily cycles such as our sleep/wake rhythm.

Cerebrum: Hemispheres As mentioned, the cerebrum consists of the cerebral cortex, basal nuclei, and limbic system. One of the most recognizable features of the cerebrum, however, is its division into two halves, or **hemispheres**. Each hemisphere is connected to the other by a major tract called the **corpus callosum** (**Figure 42.11a**). In the 1950s, American neuroscientists Roger Sperry and Ronald Meyers examined the separate functions of the hemispheres in laboratory animals by performing split-brain surgeries in which they severed the corpus callosum. The animals that underwent such surgery maintained their overall health and functioning; therefore, the surgery was considered safe for humans. This became important in 1961, when the procedure was used for the first time to treat patients with severe epilepsy, a disorder characterized by uncontrolled electrical activity that begins in one place in the brain and can spread via the corpus callosum to the other side. Cutting the connection between the hemispheres reduced the severity of epileptic seizures.

As it turned out, split-brain surgery also provided an opportunity for the researchers to make critical observations about the importance of communication between the two hemispheres. Split-brain humans generally show normal behavior and intellectual function, because both hemispheres can function fairly independently. However, psychological tests revealed that the two sides of the brain process different types of information. One study demonstrated that the left hemisphere produces a descriptive word for an object but does not identify certain characteristics of that object, such as its shape and texture (**Figure 42.11b**). The right hemisphere, in contrast, cannot use words to name the object but can identify other qualities. Sperry, Meyers, and other neuroscientists have concluded that the left hemisphere is involved in understanding language and producing speech in most people. Therefore, the left hemisphere is said to be dominant for those functions. The right hemisphere is dominant for nonverbal memories, recognizing faces, and interpreting emotions. In 1981, Sperry received the Nobel Prize in Physiology or Medicine for his insight regarding specialization in each hemisphere of the brain.

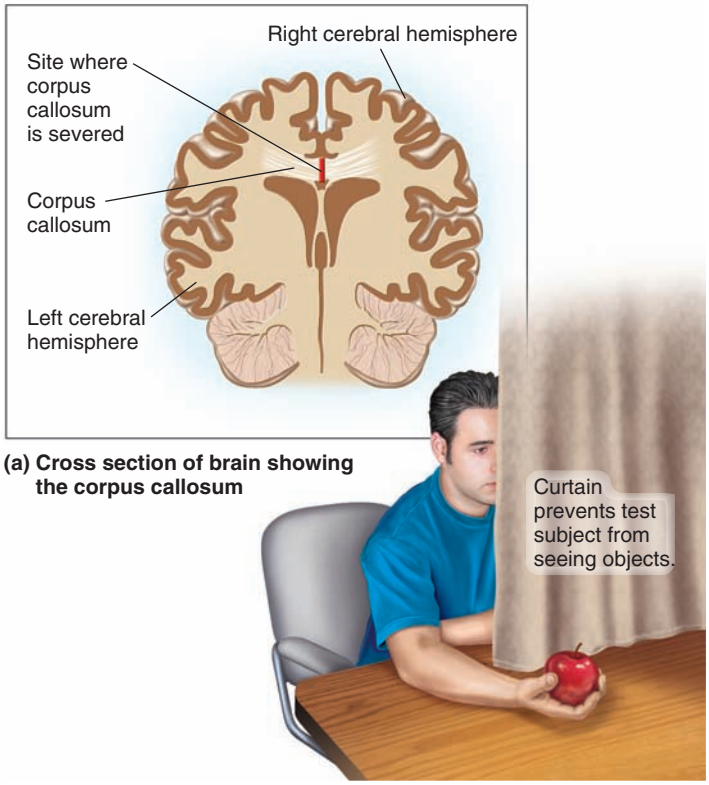

Figure 42.11 The hemispheres of the human brain. **(a)** The cerebral hemispheres and their connection by the corpus callosum. (Note: The left hemisphere controls the right side of the body, and the right hemisphere controls the left side.) **(b)** Split-brain patient being tested for hemispheric dominance. By using this apparatus, Roger Sperry and his collaborators showed that the left and right cerebral hemispheres have different capabilities. When a split-brain patient held an object in his right hand but could not see it or touch it with his left hand, he could give it a name (for example, an apple). When he held another object in his left hand, he could describe it (for example, smooth), but could not name it.

Concept Check: *With her eyes closed, a split-brain patient was given a rock to hold, and she described it as a rock. Which hand was it in?*

Cerebrum: Cerebral Cortex The **cerebral cortex** is the surface layer of gray matter that covers the cerebrum (see the darkly shaded outer rim of the brain hemispheres in Figure 42.11a). Within the cortex are identifiable regions whose neurons play roles in sensory, motor, or other functions. Although the cerebral cortex is only a few millimeters thick, it contains about 10% of all the neurons in the human brain. The cerebral cortex is functionally divided into four

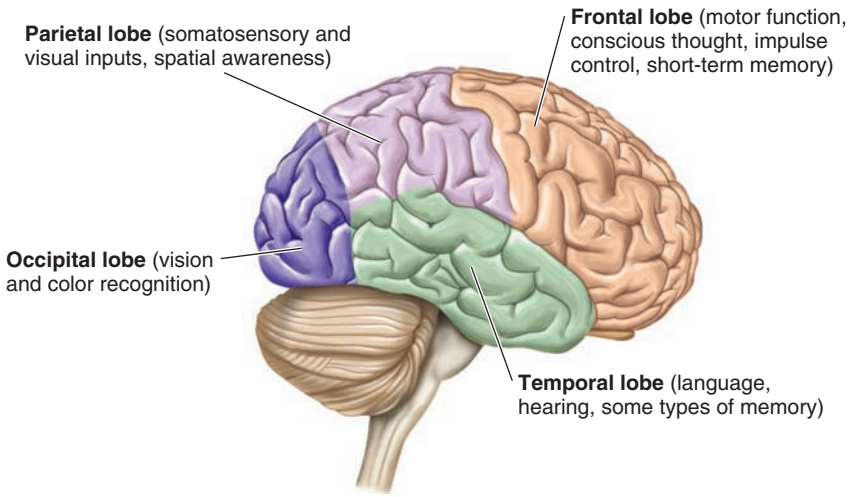

Figure 42.12 The four lobes of the cerebral cortex as seen on the right hemisphere, and some major functions they control.

lobes in each hemisphere of the brain: the frontal, parietal, occipital, and temporal lobes (Figure 42.12). Each lobe has a number of functions, many of which are still being actively investigated by researchers. Among other things, the **frontal lobe** is important for voluntary initiation of movement, decision making, controlling impulses, making plans, exhibiting judgment, short-term memory, and conscious thought and social awareness. The primary motor cortex, where commands for movement originate, is located at the posterior part of the frontal lobes running in a band roughly from ear to ear (see the red highlighted area in Figure 42.13). Slightly posterior to the motor cortex and at the beginning of the **parietal lobe** is the region known as the somatosensory cortex (blue highlighted region in Figure 42.13). The somatosensory cortex and parietal lobe receive and interpret sensory input from somatic pathways, including touch from the surface of the body. In addition, the parietal lobe plays an important role in spatial awareness, that is, our ability to use visual cues to orient ourselves in space. The **occipital lobe** controls many aspects of visual perception and color recognition. The **temporal lobe** is necessary for language, hearing, and some types of memory.

An amazing finding is that sensory inputs enter and motor outputs exit the cerebral cortex in a pattern that forms a map of the body (see Figure 42.13). The regions of the body are represented in proportion to the amount of cortical area devoted to them. For instance, a larger part of the cerebral cortex is devoted to sensory inputs from the lips than from other areas of the face. The lips have more nerve endings and are more sensitive to touch than these other areas. Other cortical functions are also mapped in this way; for example, a map that reflects different sound frequencies (the pitch of sound) exists in the temporal lobes. The organization of the cerebral cortex may not be permanent, however, because the map may change depending on the amount of use or disuse of a given part of the body, as discussed in the Feature Investigation later in this chapter. Some of the major functions of the hindbrain, midbrain, and forebrain are summarized in Table 42.1.

Cerebrum: The Basal Nuclei The **basal nuclei** (or, less accurately, basal ganglia) are a group of nuclei that surround the thalamus and lie beneath the cerebral cortex. Like the cerebellum, the basal nuclei are involved in planning, learning, and fine-tuning movements. They also function via a complex circuitry to initiate or inhibit movements.

Parkinson's disease is a relatively common neurological disorder that affects the basal nuclei. People with Parkinson's disease have trouble initiating movement, such as beginning to move their legs when they wish to walk. They are capable of walking once movement has begun, but they move slowly with muscle tremors and a shuffling, jerky gait. These symptoms result from the gradual deterioration of dopamine-releasing neurons in an area of the midbrain called the substantia nigra, the neurons of which send axons to the basal nuclei. People in the early stages of Parkinson's disease can be treated with L-dopa, a substance that enters the blood and travels to the basal nuclei. There, axon terminals from remaining healthy cells originating in the substantia nigra take up the L-dopa and convert it into dopamine, which is then released onto cells of the basal nuclei. L-Dopa, therefore, increases the amount of dopamine in the basal nuclei and reduces the symptoms of Parkinson's disease.

Cerebrum: The Limbic System The **limbic system** refers to a collection of evolutionarily older structures that form an inner layer at the base of the forebrain. These include structures such as the **olfactory bulbs** (which process information about smells), **amygdala**, and **hippocampus**. Many neuroscientists also consider parts of the diencephalon as part of the limbic system, because of the extensive connections between these regions. The limbic system is primarily involved in the formation and expression of emotions, and it plays an important role in learning, long-term memory, and the perception and recognition of smells. The expression of emotions occurs early in childhood before the more advanced functions of the cerebral cortex are evident. Thus, even very young babies can express fear, distress, and anger as well as bond emotionally with their parents.

Deep within the brain, the amygdala is one of the limbic areas critical for understanding and remembering emotional situations. This area also is involved in the ability to recognize emotional expression in others. Emotions are not unique to humans, however, and some are clearly present in other primates and mammals. Being able to express and detect emotions imparts a selective advantage by enabling animals to establish and maintain relationships. Emotions such as fear help an animal defend itself against danger by avoiding conflict. Likewise, anger is associated with aggression, a key behavior by which many animals defend themselves or their territories.

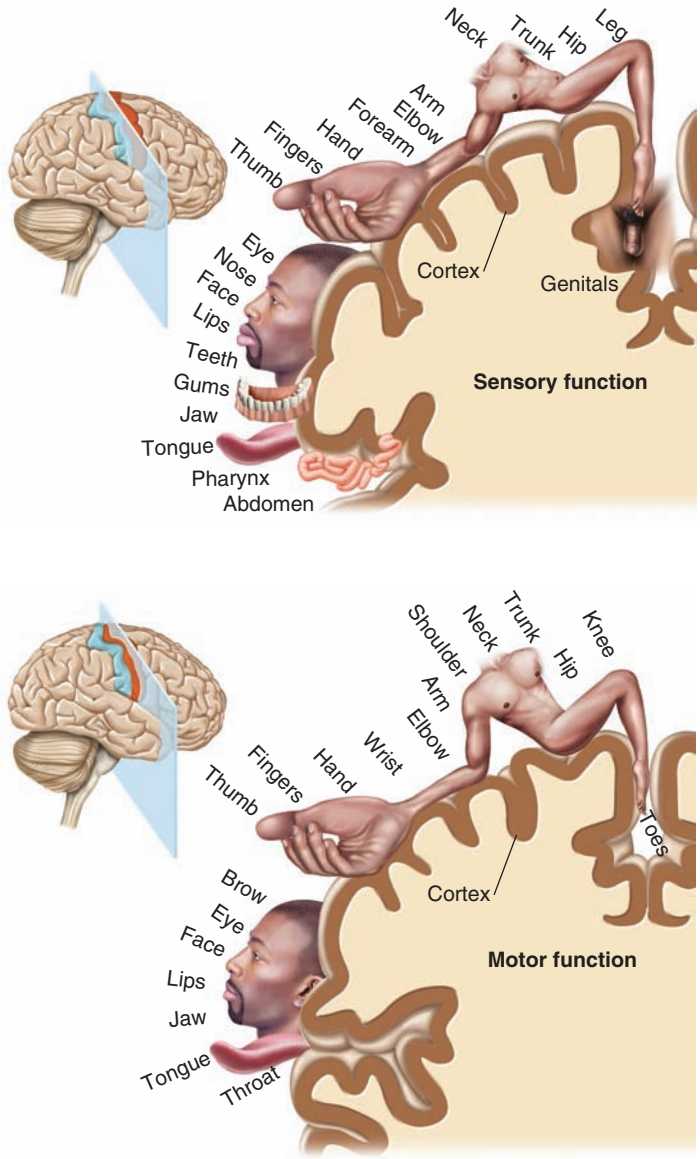

Figure 42.13 Maps of human body parts along the cerebral cortex. These maps represent how the cortex interprets sensory information from these body parts and controls body movements of these parts (motor function). The relative sizes of body parts reflect the relative amount of cortex devoted to them. The blue highlighted region is the somatosensory cortex; the red region is the primary motor cortex.

Table 42.1 Major Functions of Brain Regions in Humans

Region		Major Functions
Hindbrain		
	Medulla oblongata and pons	Coordinate homeostatic functions such as breathing, heart rate, digestion; form part of reticular formation that controls sleep and alertness; origins of cranial nerves
	Cerebellum	Fine-tuning of complex body movements; maintenance of balance
Midbrain		Processes visual, auditory, and olfactory sensory inputs; forms part of reticular formation
Forebrain		
Diencephalon		
	Thalamus	Routes sensory information (except olfaction) to discrete parts of cerebrum; filters irrelevant sensory information; directs outgoing motor information from cerebral cortex to spinal cord; involved in pain perception and mental arousal
	Hypothalamus	Regulates activities of gastrointestinal and reproductive systems; controls function of pituitary gland; regulates body temperature, appetite, thirst, aggressive behavior, sexual behavior, and body rhythms
	Epithalamus	Produces cerebrospinal fluid; plays a role in food and water intake; contains the pineal gland, which may regulate sleep/wake cycle and body rhythms
Cerebrum		
	Cerebral cortex	Voluntary motor control; perception of sensory inputs; attention; integration of sensory and motor information; generation of speech; decision making; impulse control; judgment; planning; conscious thought; learning; memory; and emotion
	Basal nuclei	Planning, fine-tuning, initiating, inhibiting and learning movements
	Limbic system	Formation and expression of emotions; perception of odors; learning and memory

Adjacent to the amygdala and forming a loop within the medial regions within the brain, the hippocampus is composed of several layers of cells that are connected in a circuit. Its main function appears to be establishing memories for spatial locations, facts, and sequences of events. Damage to certain parts of the hippocampus in humans results in an inability to form new memories, a devastating condition that prevents recognition of other people or even an awareness of daily events. Experiments with laboratory animals have also demonstrated the importance of the hippocampus for memory and learning in other mammals. In a particularly well-studied example, rats are placed into a pool of milky water containing a hidden platform. The animals swim until they find the platform, on which they can safely stand. The time it takes to find the platform in subsequent trials is shorter as they learn and remember its whereabouts. This type of spatial learning depends on activity in the hippocampus. Rats with parts of their hippocampus destroyed fail to improve their times with repeated trials. The hippocampus also receives extensive inputs from the olfactory bulbs, which may explain why smells are such potent triggers of memory in humans and why many animals use their sense of smell as a major way to learn and remember aspects of their environments.

BIO TIPS **THE QUESTION** *Animal brains have numerous anatomical and functional structures. Many of these structures consist of smaller structures, which in turn contain even smaller structures. Name the progressively larger structures of the human brain that contain the region responsible for visual perception and color recognition.*

TOPIC ***What topic in biology does this question address?*** The topic is the structure of animal brains. More specifically, the question asks you to identify a hierarchy of structure in a region of the human brain.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you know that the human brain contains numerous structures that contain smaller structures within them. The question also indicates that the region of the brain responsible for visual perception and color vision is part of progressively larger structures. From your understanding of the topic, you know that the three major divisions of the brain are the forebrain, midbrain, and hindbrain, and that sensory processing (such as vision) occurs within the forebrain. You need to recall which part of the forebrain is responsible for visual processing.

PROBLEM-SOLVING STRATEGY ***Make a drawing.*** Draw the major divisions of the forebrain in a hierarchy, with the forebrain at the top, and continuing down to the region responsible for visual processing. Refer to Figures 42.9 and 42.10 for help.

ANSWER *Visual processing occurs in the occipital lobe of the cerebral cortex, which is part of the cerebrum, which in turn is one of the two largest divisions of the forebrain; lastly, the forebrain is one of the three major divisions of the brain.*

Genomes & Proteomes Connection

Many Genes Have Been Important in the Evolution and Development of the Cerebral Cortex

Although the cerebral cortex is not unique to humans, its extensive development is one of the defining features of the human brain, responsible for much of what we call our individual personalities. Researchers are now beginning to understand the molecular mechanisms by which this important brain structure evolved and how it develops.

A number of genes are now known to be involved in the evolution and development of the cerebral cortex. Some have been identified by examining genetic mutations in developmentally disabled individuals; others, by comparing human genes with genes known to be involved in brain development in other species such as *Drosophila*. Researchers have also compared these genes in many species that show notable differences in cerebral structure. This last approach can determine whether a relationship exists between the expression of a particular gene and the organization of the cerebral cortex.

One inherited disorder that involves abnormal development of the cerebral cortex is polymicrogyria (from the Greek, meaning many small folds). Recall that the surface of the cerebrum normally has many folds called gyri. In people with polymicrogyria, the cerebral cortex is characterized by multiple and unusually small surface folds. The symptoms associated with polymicrogyria include mental impairment as well as disrupted gait and language production. One type of polymicrogyria is a recessively inherited condition for which eight different mutations of a single gene are known. This gene, called *GPR56*, encodes a G-protein-coupled receptor (described in Chapter 9), which has large extracellular loops. All eight mutations that produce polymicrogyria alter these extracellular loops of the receptor, and scientists think that this alters the ability of the G-protein-coupled receptor to bind its ligand. Recent studies using transgenic mice have clearly demonstrated that preventing expression of the *GPR56* gene results in decreased neurogenesis during embryonic life, whereas overexpression of the gene has the opposite effect, resulting in increased proliferation of neurons.

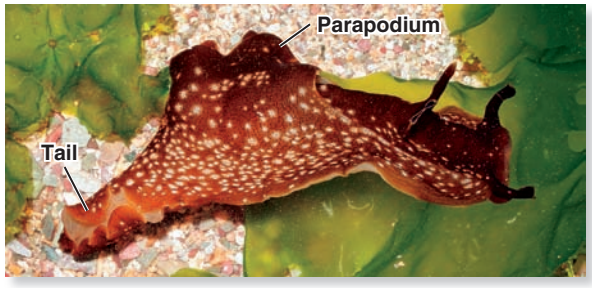
Several other genes, including *microcephalin* (*MCPH1*) (from the Greek, meaning small head) and *ASPM* (*abnormal spindle-like microcephaly-associated gene*), have been shown to be determinants of brain size. For example, mutations of these genes in the human population produce individuals with much smaller frontal lobes. Interestingly, the sequences of these genes in several primates, including humans, as well as in other mammals such as dogs and sheep, have shown that the proteins produced by the normal *MCPH1* and *ASPM* genes have undergone greater changes in humans and great apes than in other species. Therefore, these genes may have been under greater selection pressure in animals with larger cerebral cortexes, suggesting that the genes have played a key role in the evolution of the cerebral cortex.

42.3 Cellular Basis of Learning and Memory

Learning Outcomes:

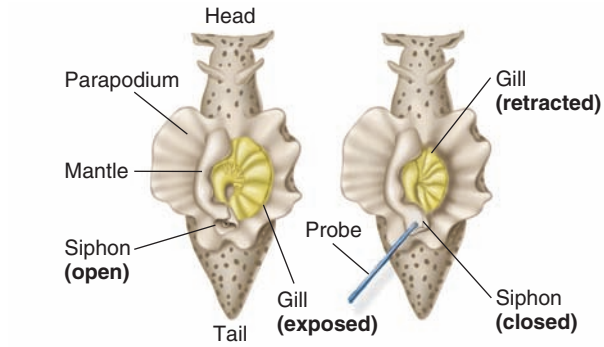
1. Define the terms learning and memory, and describe their relationship to one another.
2. Discuss how memory is related to changes in the strength of connections between neurons.
3. **SciSKILLS »** Describe the evidence that shows that the brain is capable of neurogenesis, and predict how neurogenesis might be important for human learning and memory.
4. Discuss the similarities and differences in the technologies of CT, MRI, and fMRI.

In the past few decades, an exciting advance in neuroscience has occurred—researchers have begun to understand complex behaviors, such as learning and memory, at the cellular level. Though it is



difficult to separate the two concepts, **learning** can be defined as the process by which new information is acquired. Learning is an evolutionary adaptation that allows past experiences to affect ongoing and future behavior. **Memory** is the ability to retain, retrieve, and use information that was previously learned. Memory connects an animal's experiences throughout life. Our own behavior is largely controlled by what we have learned and remember from past experiences. Neuroscientists want to understand how the brain learns and how it captures memories. In this section, we will examine some current ideas about how this may be achieved at the cellular level and consider experimental approaches that researchers employ when investigating such complicated phenomena.

Learning and Memory Occur via Changes Within Neurons and Their Connections with Each Other

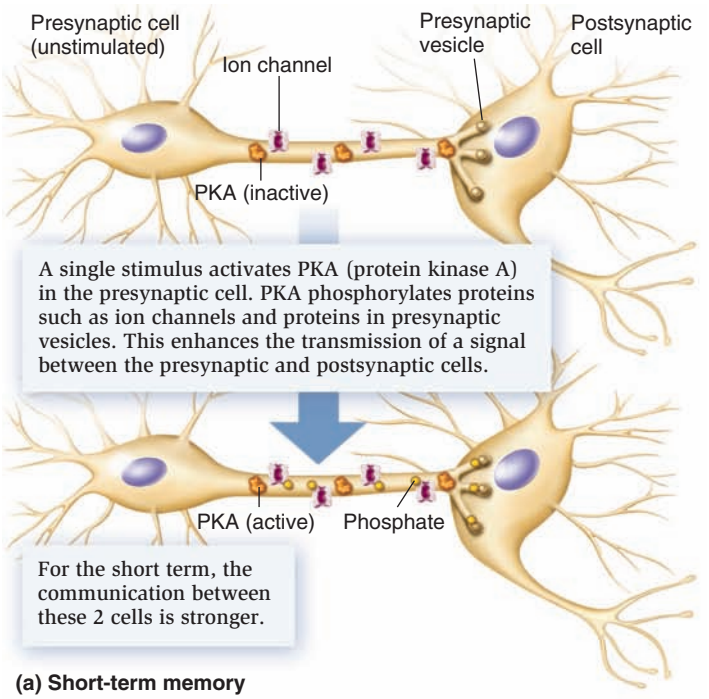


Beginning in the 1960s, research along two fronts led to key insights regarding the cellular basis of memory. Norwegian neuroscientist Terje Lømo and British researcher Timothy Bliss focused their efforts on the hippocampus. As described earlier, this is a key region of the brain involved with learning and memory. Lømo and Bliss conducted experiments on anesthetized rabbits in which they monitored signal transmission across particular regions of the hippocampus. Their key discovery involved the effects of multiple stimuli. Experimentally, a series of short, electrical stimulations to a neuron was shown to strengthen, or potentiate, its communication at a synapse with an adjacent cell for minutes or hours. Such multiple stimuli caused neurons to communicate more readily; responses were stronger and more prolonged. This phenomenon was termed **long-term potentiation (LTP)**. LTP is the long-lasting strengthening of the connection between neurons. Later work showed that LTP occurs naturally in the hippocampus and can last from hours to days, and even years.

Austrian-born American neuroscientist Eric Kandel also was interested in learning and the formation of memory. In the 1960s, however, he took a different approach by studying a simpler organism called the California sea slug or sea hare (*Aplysia californica*). He chose this organism for several key reasons. First, it has only about 20,000 neurons, making it easier to identify pathways that are involved in specific types of behavior. Second, some of the neurons in this organism are extremely large, which facilitated the study of action potentials via microelectrodes. In addition, the large size of the neurons made it technically simpler to inject substances into them and study their effects. Finally, another advantage is that Kandel and colleagues could isolate proteins and mRNA from these large neurons and identify the biochemical and genetic changes that occur when the animal responds to a stimulus.

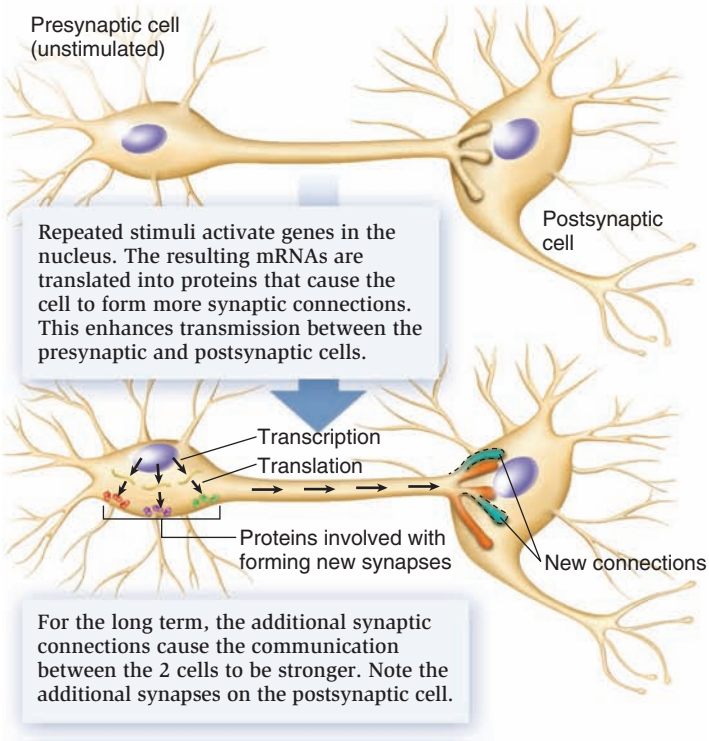
Much of Kandel's work focused on one type of learning involving the gill-withdrawal reflex, a simple protective reflex that is thought to involve less than 100 neurons in the CNS. The gill and siphon are organs involved in respiration, located in the animal's mantle cavity and protected by muscular appendages called parapodia (**Figure 42.14a**). When the siphon is gently touched with a fine probe, the sea slug closes the siphon and retracts its gills into the mantle cavity for protection (**Figure 42.14b**). Though a reflex, this behavior is subject to learning. For example, if the touching of

(a) Sea slug



(b) Gill-withdrawal reflex

Figure 42.14 The gill-withdrawal reflex in the sea slug. **(a)** Photo of *Aplysia punctata* (closely related to *A. californica*) in its natural habitat; note the parapodium and tail. **(b)** When touched with a probe, the siphon closes and the gill retracts. In this drawing, the parapodia are moved apart for a better view of the gill.



BIOLOGY PRINCIPLE Biology is an experimental science. The use of animals such as *Aplysia* as model organisms has revealed numerous fundamentally important properties of the nervous system in all animals. Despite the obvious differences in complexity between a sea slug and a human, much of what is learned in these relatively simple animal models is fully applicable to the function of human neurons and the nervous system.

the siphon is accompanied with a brief electrical shock to the tail, the sea slug can learn to withdraw its gill in response to a subsequent shock without the siphon being touched. Kandel's study of the sea slug is similar in some ways to the famous conditioning experiments of Ivan Pavlov, described in Chapter 40. Interestingly, a single tail shock paired with a touch of the siphon will result in conditioning that lasts for a few minutes. Amazingly, though, multiple trials over several days result in a lasting memory—a shock given 3 weeks later (without siphon touch) still results in the gill-withdrawal reflex!

Over the course of many years, the work of Kandel and colleagues revealed many clues regarding the cellular basis of learning and memory. As in vertebrates, memory in the sea slug occurs in two forms: short-term memory and long-term memory (**Figure 42.15**). Short-term memory lasts for minutes or hours. This type of memory is typically caused by a single stimulus. Kandel found that short-term memory does not require the synthesis of new proteins. Rather, a single stimulus activates intracellular second-messenger pathways that

(a) Short-term memory

(b) Long-term memory

Figure 42.15 Cellular changes associated with short-term and long-term memory in the sea slug.

make it easier for neurons involved in a particular behavior to communicate with each other. For example, as shown in Figure 42.15a, a single stimulus may lead to the activation of protein kinases such as protein kinase A (PKA) in the presynaptic (sensory) cell. PKA, in turn, can phosphorylate proteins such as ion channels, which leads to release of an increased amount of neurotransmitter. These changes enhance the transmission of a signal between the presynaptic and postsynaptic cells.

Kandel and colleagues also discovered that repeated stimuli result in long-term memory, which lasts days or weeks. Such repeated stimuli require the synthesis of new proteins (Figure 42.15b). Long-term memory involves the activation of genes in the presynaptic cell, which leads to the synthesis of mRNA and the translation of the encoded proteins. Once made, such proteins cause the formation of additional synaptic connections. These connections also allow the presynaptic and postsynaptic cells to communicate with each other more readily. Such a change in strength of the connection between two neurons, which occurs as a result of learning, is termed **synaptic plasticity**.

Kandel's work provides a foundation for our ability to understand how learning and memory may occur at the cellular level. Short-term memory may involve changes in pre-existing cellular proteins that make it easier for neurons to communicate. Long-term memory results in protein synthesis that causes physical changes in the synapse itself, also affecting communication. Later studies by Kandel and others showed that such changes also occur in vertebrates such as the mouse. For his work on learning and memory, Kandel shared the Nobel Prize in Physiology or Medicine in 2000.

Recently, researchers have made astonishing progress toward understanding the cellular networks that encode memories in the mammalian brain. For example, using the technique called optogenetics, in which light is used to activate ion channels in genetically altered neurons of the hippocampus of rodents, investigators have for the first time mapped a cellular network that stores a specific memory, in this case, one that is associated with a stimulus that induces fear. They have even been able to induce behaviors associated with that memory by reactivating the network at a later time in response to a nonfearful stimulus! In other words, the investigators have created a "false memory" in mice.

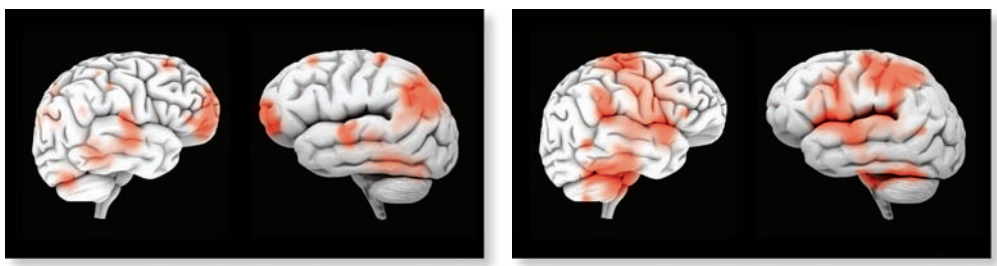
Neurogenesis May Also Contribute to Learning and Memory

Until fairly recently, neuroscientists had thought that the brain of vertebrates did not produce new neurons in adulthood, that is, that the brain was incapable of **neurogenesis**, the production of new neurons by cell division. However, in 1983, a study showing neurogenesis in an adult vertebrate was carried out by Argentinean biologist Fernando Nottebohm and colleagues. Their research revealed that an increase in the number of neurons in certain brain areas of the canary occurred during the mating season. In the late 1990s, evidence also showed that the primate and human CNS, like other parts of the body, contain stem cells, cells with the potential to differentiate into a variety of cells (refer back to Chapter 19). For example, American researchers Elizabeth Gould and Bruce McEwen demonstrated the appearance of new neurons in the hippocampus and olfactory bulbs of adult marmosets and rhesus monkeys. In 1998, American researcher Fred Gage and Swedish physician Peter Eriksson made a key discovery: They found evidence of recent mitotic activity in neurons in the hippocampus of deceased adult cancer patients. Those patients had previously been treated with a drug called bromodeoxyuridine (BrdU)

to combat their cancer. BrdU is taken up by cancerous cells, but also any other cells that are actively dividing. Its presence in cells can be detected with special stains on sections of brain or other tissue. Gage conducted such staining procedures on the brains of the deceased patients and observed the presence of BrdU in the hippocampus, demonstrating recent neurogenesis.

A key question is whether the neurogenesis observed in adult brains is involved in learning and memory. This question is hotly debated and not resolved. However, some evidence suggests that it could play a role. For example, studies have shown that the hippocampus of adult rhesus monkeys grows new neurons when the animals are placed in enriching environments, and the formation of these neurons slows when animals are chronically stressed. Also, other studies of rats suggested that new neurons are retained in the hippocampus in response to training in particular tasks that require hippocampus function.

Imaging Studies Help Scientists Understand the Functions of Brain Regions



Because of the enormous number of neurons and connections between neurons in the vertebrate brain, a key challenge in neuroscience is to understand how such complexity results in sophisticated forms of learning, memory, and responses to environmental conditions. Several imaging techniques allow doctors and researchers to examine the structure and activity level of the human brain without anesthesia or surgery. The earliest technique to be developed was computerized tomography (CT). A **CT scan** involves the use of an X-ray beam and a series of detectors that rotate around the head, producing slices of images that are reconstructed into three-dimensional images based on differences in the density of brain tissue. CT scans can easily visualize the ventricles and differences between white and gray matter, but they cannot examine the brain in great detail.

A more sensitive method, called **magnetic resonance imaging (MRI)**, was developed in the 1980s. The patient is placed in a device that contains a magnet powerful enough to generate a magnetic field many thousands of times greater than that of the Earth. This stabilizes the spinning, or resonance, of atomic nuclei (usually those of hydrogen atoms in water molecules) so that most of the nuclei align with the magnetic field. When body tissue is stimulated with a beam of radio waves, its atoms absorb the energy of the waves and the resonance of their nuclei changes, thereby altering their alignment with the magnetic field. When the radio wave pulse stops, the atoms release their energy, which is recorded by a detector. This information is analyzed by a computer, and an image is produced. MRI images allow detection of structures as small as 0.10 mm. For example, they can provide information about abnormal tissue, such as brain tumors, which respond to magnetic and radio frequency pulses differently than normal tissue. MRIs are widely used in medicine to check for injured tissue, cancers, and other abnormalities throughout the body. In 2003, American chemist Paul Lauterbur and British physicist Peter Mansfield received the Nobel Prize in Physiology or Medicine for their work in developing this method.

With certain modifications, MRI can be used to assess the functional activity of areas within the brain. This technique, which is widely used by neuroscientists, is called **functional MRI (fMRI)**. It takes advantage of the observation that blood flow, and therefore oxygen delivery, increases to areas where neurons are more active. This increase in oxygenation is detected via fMRI. In this way, fMRI determines which neurons in particular areas of the brain are active when an individual performs certain intellectual or motor tasks (**Figure 42.16**). The principle is similar to the standard MRI, except that the increased oxygen use of active tissue alters the resonance of local hydrogen atoms.

The use of fMRI has revealed many fascinating aspects of the activities of different brain regions, notably in people who have suffered brain damage or loss of sensory inputs. For example, individuals who are blind from birth might be predicted to have occipital lobes that are less functional or active than are those in sighted persons (recall that the occipital lobes play the major role in visual processing). However, the work of American researcher Harold Burton and others has revealed with fMRI that the occipital lobes of blind persons are active but have become adapted to other sensory functions such as tactile signals from the fingers, including those arising from Braille reading. Amazingly, this reassignment of occipital function occurs to some extent even in individuals who have lost their vision later in life. Most likely, this does not represent a new function of the occipital lobes, but rather an expansion of an existing function that remains relatively minor in sighted persons.

The plasticity of the brain revealed by the work of Burton and coworkers is not restricted to clinical situations, as just described. MRI and fMRI are also revealing differences in brain structure and function in individuals due to the types of activities in which they regularly engage, as described next.

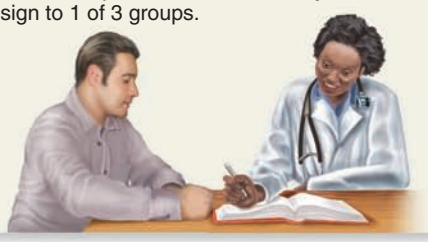
(a) Brain activity of a person thinking about a task that requires finger movements

(b) Brain activity when the same person is performing this task

Figure 42.16 Exploring the functional activity of brain regions using fMRI scans. Red color indicates greater O_2 use; both hemispheres are shown.

Concept Check: What can we conclude from part (a) about the metabolic cost of thinking?

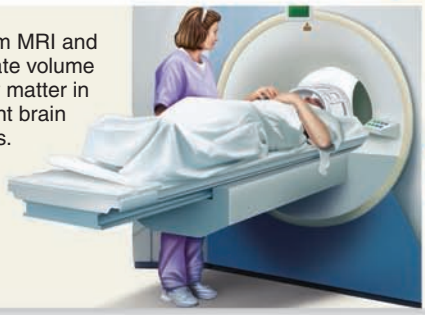
Feature Investigation | Gaser and Schlaug Showed That the Sizes of Certain Brain Structures Differ Between Musicians and Nonmusicians



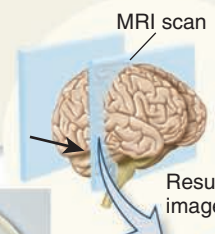
MRI and fMRI have been extremely useful in revealing which brain areas are involved in a particular function. They have also shown that the human brain is surprisingly adaptable. A number of studies have been carried out on musicians, because they practice extensively throughout their lives, enabling researchers to study the effects of repeated use on brain function.

American neuroscientist Christian Gaser and German neuroscientist Gottfried Schlaug used MRI to examine the sizes of brain structures in three groups of people—professional musicians, amateur musicians, and nonmusicians (**Figure 42.17**). Individuals were assigned to each group based on their reported history of musical training: professional musicians with over 2 hours of musical practice time each day, amateur musicians who played a musical instrument regularly but not professionally (practicing about 1 hour/day), and those who never played a musical instrument regularly. The researchers hypothesized that repeated exposure to musical training would increase the size of brain areas associated with visual, motor, and auditory skills, because each of these activities is used to read, make, and interpret music. The results showed that brain areas involved in hearing, moving the fingers, and coordinating movements with vision and hearing were larger in professionals than in amateur musicians, and larger in amateurs than in nonmusicians. The region of the brain that controls finger movements was particularly well developed in the professional musicians, an interesting finding because all of the musicians in this study played keyboard instruments such as the piano.

Figure 42.17 **Gaser and Schlaug's study of the size of visual, motor, and auditory nuclei in the brains of musicians and nonmusicians.**



HYPOTHESIS Musical training is associated with structural differences in the brain.

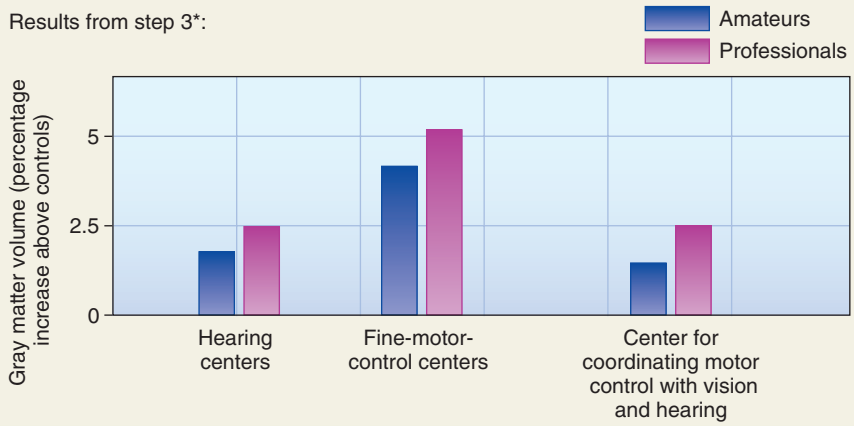


KEY MATERIALS Volunteer subjects with different degrees of musical training.

	Experimental level	Conceptual level
1 Establish 3 groups of subjects with different musical backgrounds.	Interview subjects for musical history and assign to 1 of 3 groups. 	**Controls (nonmusicians)** No musical training. **Amateur musicians** Play an instrument about 1 hr/day and are not employed as musicians. **Professional musicians** Employed as musicians and practice their instrument > 2 hr/day.
2 Control for possible factors that might affect results.	Make group assignments in a way that matches subjects' age and other characteristics.	

	Controls	Amateurs	Professionals
Age (average)	23	26	27
Type of instrument	None	Keyboard	Keyboard
Mental IQ	119	123	118
Sex	Male	Male	Male

3 Perform MRI and calculate volume of gray matter in different brain regions.



4 THE DATA

Results from step 3*:

*Controls are not shown separately because the data are expressed relative to controls.

5 CONCLUSION Musical training is associated with increased volumes of brain regions involved in hearing, fine-motor control, and the coordination of motor and sensory information.

6 SOURCE Gaser, C., and Schlaug, G. 2003. Brain structures differ between musicians and non-musicians. *Journal of Neuroscience* 23:9240–9245.

In subsequent studies, Schlaug and colleagues examined the brains of people of different ages who either did or did not have musical training beginning in childhood. The researchers were able to correlate the degree of training with the sizes of different brain regions. They identified one particular region within the temporal lobe that was highly correlated with the extent of musical training in the course of one's life. This region, called the planum temporale, is believed to be especially important for recognizing and interpreting sound, identifying its source, and translating auditory signals (such as music) into motor processes (such as playing an instrument or humming a melody).

In a related study, American researchers Vincent Schmithorst and Scott Holland used fMRI to determine if musicians' brains were activated differently than nonmusicians' brains when they heard music. They found that one area of the cerebral cortex was selectively activated by melodies only in musicians. This study differed from that of Gaser and Schlaug, because Schmithorst and Holland examined the activity of brain areas as well as their sizes. Their results showed that listening to music activates certain neurons and pathways in the brains of musicians but not in nonmusicians.

The human studies of Gaser, Schlaug, Schmithorst, and Holland have not determined the underlying reason(s) for increased brain size. One possibility is that people with increased brain size in these regions are more likely to become musicians. Alternatively, musical training may actually cause certain regions of the brain to grow larger and alter their neuronal pathways. In other research studies involving experimental animals, groups of animals have been randomly separated into those learning a task versus controls, which do not learn the task. Such experiments have shown increases in the size of brain regions that are associated with learning and memory. The increased size may result from formation of new synapses, growth of blood vessels to the region, and/or production of more glial cells.

Experimental Questions

1. What was the hypothesis proposed by Gaser and Schlaug? How did Gaser and Schlaug test this hypothesis? What were the results of their experiment?
2. **SciSKILLS »** How did the research of Schmithorst and Holland differ from that of Gaser and Schlaug? Were their results generally supportive of Gaser and Schlaug's hypothesis?
3. **SciSKILLS »** Based on the results described here and what you have learned in this chapter, predict general differences that might be found between the brain of a professional athlete, such as a tennis player, and that of a nonathlete. What about the brain of a person who has been deaf from birth compared to that of a person with normal hearing?

42.4 Impact on Public Health

Learning Outcomes:

1. List the broad groups of diseases affecting the human nervous system.
2. Discuss the impact of meningitis and Alzheimer's disease on public health.

Most neurological disorders can be classified into several broad groups (**Table 42.2**). These disorders collectively affect hundreds of millions of people around the world. By far, the most common are headache disorders, which affect nearly half of the world's population at one time or another. We will consider two disorders—meningitis and Alzheimer's disease—that result from very different causes and affect millions of individuals worldwide.

Table 42.2 Categories of Diseases and Disorders Affecting the Human Central Nervous System

Category	Examples
Infectious	Meningitis, encephalitis
Neurodegenerative	Alzheimer's disease
Movement	Parkinson's disease
Seizure	Epilepsy
Sleep	Sleep apnea (brain fails to regulate breathing during sleep)
Tumors	Glioma (a tumor arising from glial cells)
Headache	Migraine (severe recurring headache)
Mood	Major depressive disorder; bipolar disorder (see Chapter 41)
Demyelinating	Multiple sclerosis (see Chapter 41)
Injury-related	Brain and spinal cord injuries due to accidents

Meningitis Is an Infectious Disease That Attacks the Meninges

An essential response to infection is inflammation. This response increases the permeability of blood vessels in infected areas, allowing immune cells to be delivered to the site of an infection. When that infection occurs within the meninges (causing **meningitis**), fluid accumulates in the subarachnoid space. This accumulation compresses the underlying brain tissue and its blood vessels, interrupting oxygen flow to the neurons of the cerebral cortex. If not treated, the resulting loss of oxygen (and nutrients) causes neuronal death and the loss of function of brain regions associated with those neurons.

The initial symptoms of meningitis include severe headaches, fever, or seizures. Many patients with meningitis also develop a stiff neck because the inflammation proceeds down the spinal cord. If the infection progresses untreated, it may lead to unconsciousness and even death within hours.

Several different viruses or bacterial species can cause meningitis. It usually results from an untreated infection in neighboring regions, such as the sinuses behind the eyes, nose, or ears. Meningitis can be confirmed by using a long needle to sample the cerebrospinal fluid in the spinal cord and analyzing the pressure and contents of the fluid. Large numbers of white blood cells, which are the body's infection-fighting cells, indicate infection in the cerebrospinal fluid and meninges. If the infection is the result of bacterial invasion, meningitis can be treated with bacteria-killing agents such as antibiotics. Antibiotics do not kill viruses, but fortunately the viral form of meningitis is usually less serious than the bacterial form and runs its course after several days or weeks.

Meningitis strikes roughly 25,000 people a year in the U.S. and can affect people of any age. Its incidence in children has greatly declined since the widespread use of a vaccine against the bacterium *Haemophilus influenzae* type b (Hib) began in the U.S. in the early 1990s. Despite the vaccine, meningitis is still a dangerous and prevalent disease worldwide, and it tends to occur in individuals living in close quarters, such as military barracks and college dormitories, where infections may spread rapidly. Occasionally, meningitis can become epidemic. For example, 250,000 people in sub-Saharan Africa were infected and 25,000 died in epidemics in 1996, and nearly 75,000 people in Southeast Asia died of meningitis in 2004.

Alzheimer's Disease Impairs Memory, Thought, and Language

Alzheimer's disease (AD) is the leading cause of dementia worldwide. It is characterized by a loss of memory and cognitive function. AD is a progressive incurable disease that begins with small memory lapses, leading in later stages to problems with language and abstract thinking, and finally to loss of normal motor control and eventual death. The disease usually appears after age 65, though some inherited forms can strike people in their 30s and 40s.

Although psychological testing can help to diagnose AD, historically a definitive diagnosis is possible only after death when the brain is examined microscopically. Brains of Alzheimer patients show two major changes: plaques and neurofibrillary tangles (**Figure 42.18**). Plaques are extracellular deposits of a misfolded protein, β-amyloid, that forms large, sticky aggregates. These plaques were first noted in 1906 by German physician Alois Alzheimer, after whom the disease was named. Neurofibrillary tangles are intracellular, twisted accumulations of cytoskeletal fibers. Scientists are unsure how these changes influence intellectual function and memory. AD is also associated with the degeneration and death of neurons, particularly in the hippocampus and parietal lobes, which is why it is considered a neurodegenerative disease.

Researchers have identified variation in a few genes whose products are associated with the likelihood of developing AD later in life, but the underlying changes that result in the expression of these and other possible AD-related genes are still the subject of considerable research. Although genetics undoubtedly plays a role in AD, it is not the only possible cause. For example, when one identical twin develops AD, the other appears to be at increased risk but does not always develop the disease, even if he or she survives to very old age. Moreover, evidence suggests that severe head injuries, metabolic diseases such as diabetes, and heart and blood vessel disease may predispose a person to AD in later life.

Currently, AD cannot be prevented or cured. However, three major clinical approaches to prevent or slow down its progression are currently being tested. These approaches are designed to (1) induce a person's immune system to destroy β-amyloid as soon as it is formed, (2) prevent the formation of β-amyloid with drugs that block its synthesis, or (3) prevent the accumulation of β-amyloid into large aggregates using antiaggregation drugs. Each of these approaches holds great promise but is still unproven. Exciting recent research has demonstrated that neuronal stem cell transplants into the hippocampus of old mice can reverse the learning and memory deficits associated with a mouse model of Alzheimer's disease, providing hope for potential future therapies for humans.

Until a cure for AD is found, its impact on public health remains enormous. Currently, about 4–5 million Americans have AD, and this number is expected to grow to nearly 16 million by 2050. The prevalence of the disease is about 3% for people between the ages of

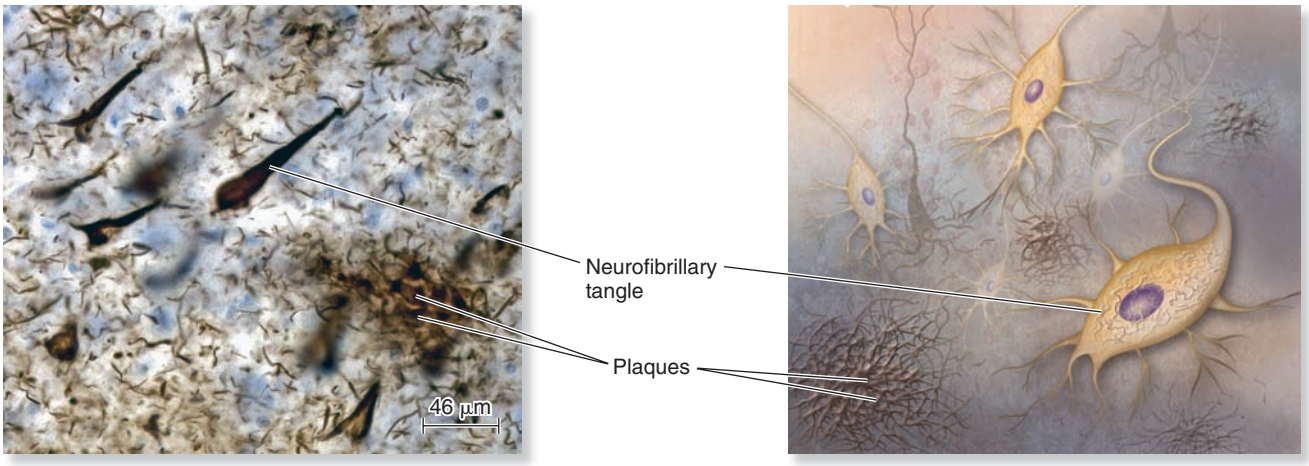


Figure 42.18 Cellular section from the brain of a person who died from Alzheimer's disease. The section has been stained for visualization of proteins found in plaques and neurofibrillary tangles. An illustration of plaques and tangles is shown for comparison.

65 and 74, and 25–50% for people older than 85. Estimated costs associated with providing health care and housing for AD patients (30% of whom live in nursing homes), as well as lost productivity in the workplace, total a staggering $100 billion per year in the U.S. This number will rise substantially now that the oldest members of the population spike known as the baby boom generation are older than 65.

Summary of Key Concepts

42.1 The Evolution and Development of Nervous Systems

- All multicellular animals except sponges have a nervous system. Simpler nervous systems include the nerve net of cnidarians and cerebral ganglia, which integrate inputs from sense organs. As animal bodies become more complex, the integrative center in the head becomes a brain that is larger and capable of more functions (Figure 42.1).
- In all vertebrates, the three major divisions of the brain are the hindbrain, midbrain, and forebrain. Human embryos develop these divisions by 4 weeks (Figure 42.2).
- Additional folding of the brain and increased mass allow for expansion of regions associated with conscious thought, reasoning, and learning (Figures 42.3, 42.4).

42.2 Structure and Function of the Nervous Systems of Humans and Other Vertebrates

- In humans and other vertebrates, the brain and spinal cord are the central nervous system (CNS). The neurons and all axons outside the CNS, including the cranial and spinal nerves, constitute the peripheral nervous system (PNS). The CNS relies on the PNS for sensory input, and the PNS acts on commands from the CNS (Figure 42.5).
- The gray matter of the CNS is composed of dendrites, cell bodies, and unmyelinated axons. The white matter consists of tracts of myelinated axons. The meninges are protective coverings of the CNS. Cerebrospinal fluid fills the subarachnoid space and ventricles (Figures 42.6, 42.7).
- The PNS can be subdivided into the somatic and autonomic nervous systems. The somatic nervous system senses external environmental conditions and controls skeletal muscles and skin. The autonomic nervous system senses internal body conditions and controls homeostasis. The efferent part of the autonomic nervous system is divided into two components: sympathetic (fight or flight) and parasympathetic (rest or digest) (Figure 42.8).
- The evolutionarily oldest structures of the brain, some of which are located in the hindbrain, control the basic processes that sustain life. These structures include the medulla oblongata, cerebellum, and pons (Figure 42.9).
- The midbrain processes several types of sensory inputs, including vision, olfaction, and audition. The medulla oblongata, the pons, and the midbrain collectively constitute the brainstem. Some nuclei of these three structures form the reticular formation, a network of neurons that sends signals to many other brain regions (Figure 42.9).
- The forebrain is made of the thalamus, hypothalamus, epithalamus (diencephalon), and the cerebrum (Figure 42.10). The cerebrum is divided into two hemispheres. Each hemisphere is specialized to perform certain aspects of behavior and can operate independently (Figure 42.11).
- The cerebrum consists of the basal nuclei, limbic system, and cerebral cortex. Each side of the human cerebral cortex is divided into four lobes, each of which has a number of functions (Figures 42.12, 42.13, Table 42.1).

42.3 Cellular Basis of Learning and Memory

- Learning is the process by which new information is acquired; memory involves the retention of that information.
- Repeated stimuli result in long-term potentiation, in which the connections between adjacent neurons become stronger. Studies of the sea slug indicate that short-term memory is caused by a single stimulus that activates second-messenger pathways. Long-term memory is caused by repeated stimuli that activate genes, which

results in more synaptic connections, a phenomenon called synaptic plasticity (Figures 42.14, 42.15).

- Imaging techniques such as CT scans, MRI, and fMRI allow neuroscientists and physicians to examine the structure and activity of the brain (Figures 42.16, 42.17).

42.4 Impact on Public Health

- Disorders of the human central nervous system can be placed into several broad categories (Table 42.2).
- Meningitis is a potentially life-threatening infectious disease in which the meninges become inflamed. Alzheimer's disease is a progressive disorder characterized by the formation of plaques and neurofibrillary tangles in brain tissue. Both are examples of neurological disorders with a large impact on public health (Figure 42.18).

Assess and Discuss

Test Yourself

1. A nerve net consists of
   a. bilateral neurons that extend from the head of the animal to the tail.
   b. a group of neurons that are interconnected and are activated all at once.
   c. a single nerve cord with ganglia in each body segment.
   d. a central nervous system with peripheral nerves associated with different body structures.
   e. none of the above.
2. The division of the vertebrate brain that includes the cerebellum is the
   a. hindbrain.
   b. telencephalon.
   c. midbrain.
   d. forebrain.
   e. diencephalon.
3. In general, the brains of more complex vertebrates
   a. are larger.
   b. have fewer neurons.
   c. have more folds in the cerebral cortex.
   d. use less oxygen.
   e. Both a and c are true.
4. The white matter of the CNS is composed of
   a. dendrites.
   b. unmyelinated axons.
   c. myelinated axons.
   d. cell bodies.
   e. a and b only.
5. The division of the nervous system that controls voluntary muscle movement is the
   a. autonomic nervous system.
   b. sensory division.
   c. somatic nervous system.
   d. parasympathetic division.
   e. sympathetic division.
6. Which of the following is *not* a response to activation of the sympathetic division of the autonomic nervous system?
   a. increased breathing rate
   b. decreased heart rate
   c. increased blood flow to the skeletal muscles
   d. increased blood glucose levels
   e. inhibition of digestion
7. The ___ acts as a relay for the cerebrum.
   a. medulla
   b. pons
   c. hypothalamus
   d. midbrain
   e. thalamus
8. The _____ is a portion of the limbic system that is important for memory formation.
   a. amygdala
   b. hippocampus
   c. pons
   d. epithalamus
   e. mesencephalon
9. In humans, the _____ hemisphere of the cerebrum is dominant in nonverbal processing.
   a. right
   b. left
   c. The hemispheres contribute equally to nonverbal processing.
10. _____ is a progressive disease that causes a loss of memory and intellectual and emotional function.
    a. Meningitis
    b. Parkinson's disease
    c. Amnesia
    d. Alzheimer's disease
    e. Stroke

Conceptual Questions

1. One of the most important and fundamental features of all nervous systems is the reflex. Describe why reflexes are adaptive.
2. Explain the differences between white matter and gray matter.
3. A principle of biology is that *new properties of life emerge from complex interactions*. How is this principle evident in the structure and function of animal nervous systems?

Collaborative Questions

1. Discuss how the two parts of the nervous system of many animals—the central and peripheral nervous systems—interact with each other.
2. List the three major divisions of the brain of vertebrates and briefly describe the function of each in humans.

43.7 Impact on Public Health
Summary of Key Concepts
Assess and Discuss

Neuroscience III: Sensory Systems

43

Vision in the dark. As in many animals that are active at night, a cat's eye contains a layer of reflective tissue called a tapetum lucidum. This tissue increases the cat's ability to see in the dark by bouncing light back into the retina.

What does the world look, sound, smell, and feel like to other animals? We can never know exactly how an animal perceives its environment. Biologists can perform experiments, however, to determine the capabilities of an animal's sensory systems. For instance, researchers have examined the structure of a goldfish's eye, conducted behavioral studies to determine if a goldfish can discriminate between different colors, and measured the electrical responses of neurons in the animal's visual system to different visual stimuli. From such studies, we know that goldfish and probably most animals can discriminate between light of different wavelengths.

Despite the prevalence of such abilities as light, odor, sound, taste, and touch detection across animal taxa, the sensory experience of different animals may differ radically from our own. We do not see the color patterns of flowers produced by the reflection of UV light the way honeybees do, or hear the very low frequency sounds (such as those produced by earthquakes) that elephants, whales, and alligators hear. We cannot detect the presence of chemicals using our entire body surface, the way an earthworm can as it seeks food. We cannot detect the electric field generated by excitable tissues of marine animals, although many elasmobranchs and catfish can. We can see relatively well at night, but would have better night vision if we had light-reflective substances in the back of our eyes like some animals, such as the cat in the chapter opening photo.

Senses allow living organisms to perceive their environments. In neuroscience, a **sense** is broadly defined as a system that consists of specialized cells that detect a specific type of chemical, energy, or physical stimulus (also known as a modality) and send signals to the central nervous system (CNS), where the signals are received and interpreted. The senses allow animals to perceive subtle and complex aspects of their environments. They are the windows through which animals experience the world around them. The nervous systems of most animals also have the ability to sense signals arising from within the body, such as hunger or pain.

In this chapter, we will examine how nervous systems collect incoming sensory information and how membrane potentials of specialized neurons change in response to sensory inputs. We will learn that other structures of the nervous system may modify or enhance this neural activity before sending it to the brain, where it is interpreted. Finally, we will discuss how problems with sensory systems—in particular vision and hearing deficits—can affect human health.

43.1 An Introduction to Sensation

Learning Outcomes:

1. Describe the relationship between sensation and perception.
2. Discuss how sensory receptors pass along the intensity of a stimulus.
3. List the classes of sensory receptors and the stimuli to which they respond.

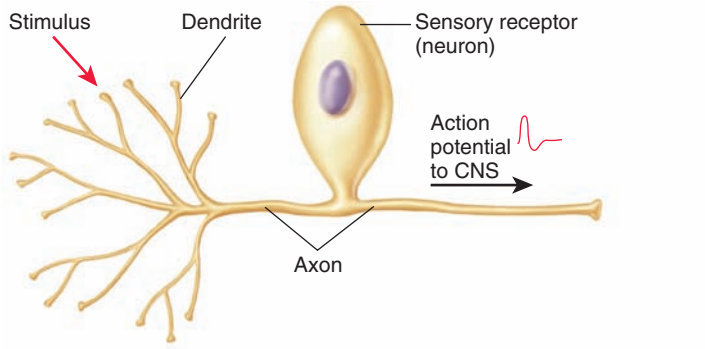
Sensory systems convert chemical or physical stimuli from an animal's body or the external environment into a signal that causes a change in the membrane potential of sensory neurons. **Sensory transduction** is the process by which incoming stimuli are converted into neural (electrical) signals. Sensory transduction

involves cellular changes, such as opening of ion channels, which cause either graded potentials or action potentials in neurons.

Perception is an awareness of sensations that are experienced. For instance, touching a hot object generates a thermal sensation, which initiates a neuronal response, giving us the perception that this stimulus is hot. Not all sensations are consciously perceived by an organism. Most of the time, for example, we are not aware of the touch of our clothing. The brain also processes sensory information in areas that do not generate conscious thought. For instance, certain neurons constantly monitor blood pressure and the concentrations of oxygen, glucose, and other substances in the blood, but we are not aware that this is occurring.

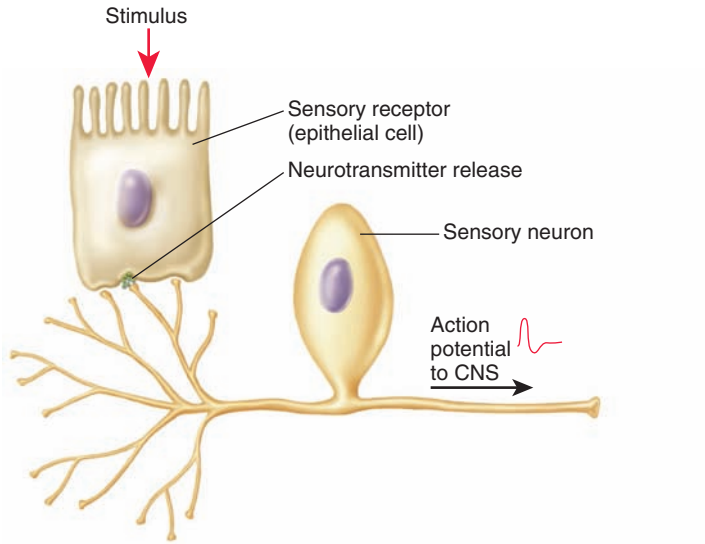
We begin our study of sensory systems by examining the specialized cells that receive sensory inputs. A **sensory receptor** is a neuron or specialized epithelial cell that recognizes an internal or external (environmental) stimulus and initiates sensory transduction by creating graded potentials (described in Chapter 41) in itself or an adjacent cell (**Figure 43.1**). When a response is strong enough, sensory receptors initiate electrical responses to stimuli, such as chemicals, light, heat, and sound, which lead to action potentials that are sent to the CNS.

A Strong Stimulus Generates More Frequent Action Potentials



How do sensory receptors pass along the intensity of a stimulus? Let's consider an example involving weak and strong stimuli to the sense of touch (**Figure 43.2**). Sensory transduction begins when the specialized endings of a sensory receptor respond to a stimulus. Such a stimulus—in this case, the touch of a glass rod—opens ion channels that allow sodium ions (Na^+) to diffuse down their electrochemical gradient into the cell, depolarizing the sensory receptor. The amount of depolarization is directly related to the intensity of the stimulus, because a stronger stimulus opens more ion channels.

The first response of a sensory receptor is usually a graded change in the membrane potential of the cell body that is proportional to the intensity of the stimulus (see Figure 43.2). The membrane potential, known as the **receptor potential** in these cells, becomes less and less negative as the strength of the stimulus increases. When a stimulus is strong enough, it depolarizes the membrane to the threshold potential at the axon hillock and produces an action potential in a sensory neuron (refer back to Figure 41.9).



Recall from Chapter 41 that action potentials proceed in an all-or-none fashion, regardless of the nature or strength of the stimulus that elicits them. How, then, can action potentials provide information about the intensity of a stimulus? The answer is that the strength of the stimulus is determined by the frequency of action potentials generated. A strong stimulus generates many action potentials in a short period of time. As a result, the frequency of action potentials is higher when the stimulus is strong than when it is weak. The action potentials are transmitted into the CNS and carried to the brain for interpretation. The brain interprets a higher frequency of action potentials as a more intense stimulus.

The CNS Processes Each Sense Within Its Own Pathway

Different stimuli produce different sensations because they activate specific neural pathways that are dedicated to processing only that type of stimulus. We know that we are seeing light because the signals

(a) A neuron as a sensory receptor

(b) A specialized epithelial cell as a sensory receptor

Figure 43.1 Sensory receptors. **(a)** Many sensory receptors are neurons that directly sense stimuli. **(b)** Other sensory receptors are specialized epithelial cells that sense stimuli and secrete neurotransmitter that stimulates nearby sensory neurons. In both cases, when stimulated, the neurons send action potentials to the CNS, where the signals are interpreted.

BioConnections: The term receptor is used in more than one way in biology. What is the difference between the sensory receptor described in this chapter and the membrane receptors described in Chapter 9?

generated by visual sensory receptors in the eye are transmitted along a neural pathway that sends action potentials into areas of the brain that are devoted to processing vision. For this reason, the brain interprets such signals as visual stimuli. The brain can separate and identify each sense because each one uses its own dedicated pathway.

Sensory receptors can be divided into general classes based on the type of stimulus, or modality, to which they respond. Each class of receptor uses a different mechanism to detect stimuli and to transmit the information to different regions of the CNS.

- **Mechanoreceptors** transduce mechanical energy such as touch, pressure, stretch, movement, and sound.
- **Thermoreceptors** detect cold and heat.
- **Nociceptors**, or pain receptors, detect extreme heat, cold, and pressure, as well as certain potentially damaging molecules such as acids.

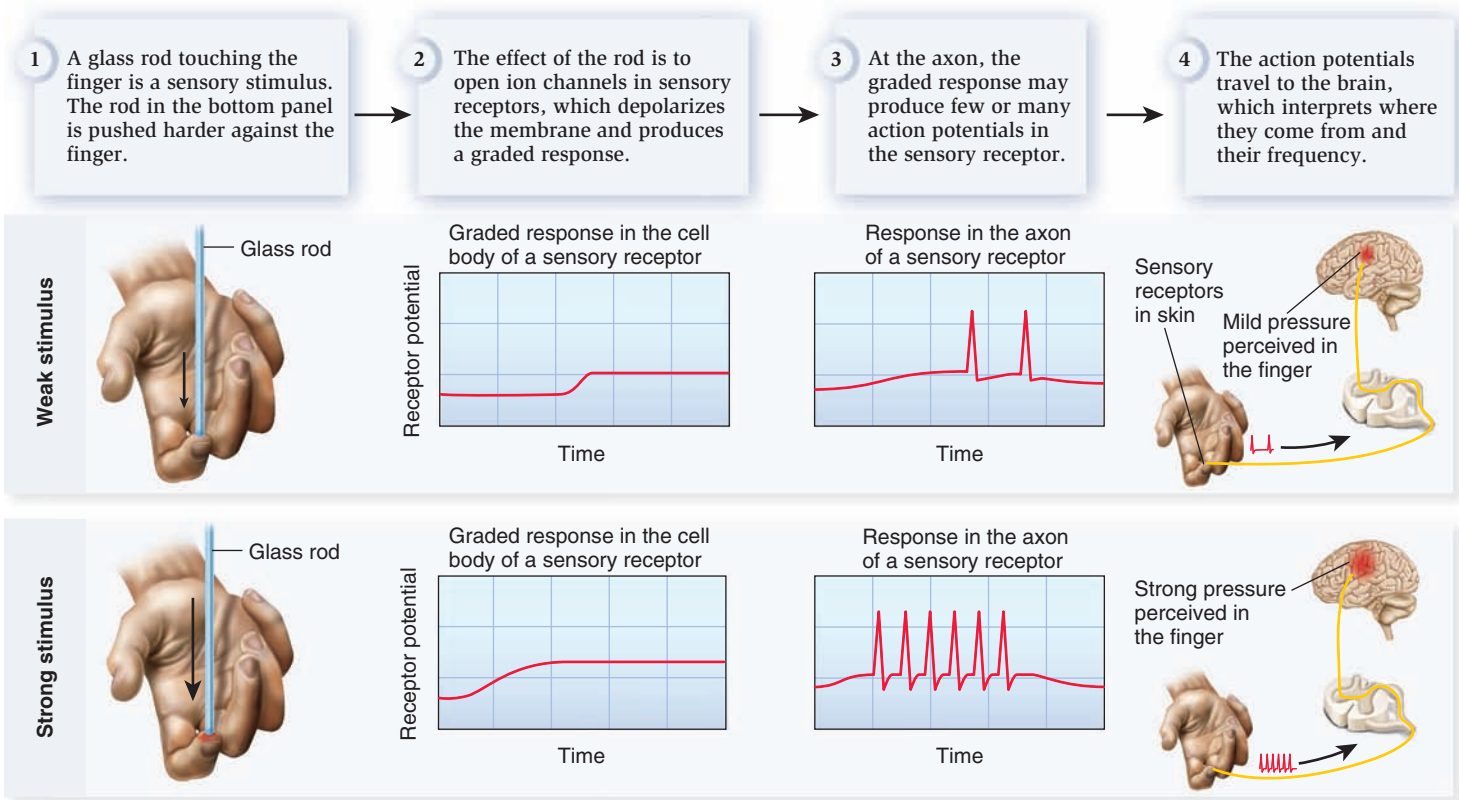


Figure 43.2 Transduction of a sensory stimulus of two different intensities. In this example, the sensory receptor is a neuron. Note the faster and larger graded response following the stronger stimulus.

- **Electromagnetic receptors** sense radiation within a portion of the range of the electromagnetic spectrum, including visible, UV, and infrared light, as well as electrical and magnetic fields in some animals.
- **Photoreceptors** are electromagnetic receptors that detect visible light.
- **Chemoreceptors** recognize specific chemical compounds in the air, water, body fluids, or food.

Most of the remaining sections of this chapter will examine the structures and functions of these types of sensory receptors and the organs in which they are found.

43.2 Mechanoreception

Learning Outcomes:

1. List the types of mechanoreceptors that detect touch, stretch, or movement, and describe how their structures relate to their functions of hearing and balance.
2. Describe the structure of the mammalian ear, and explain how mechanical forces move through it.
3. Give examples of adaptations for hearing in animals that inhabit different environments.
4. Describe how body position and movement are detected by sense organs.

Mechanoreceptors are cells that detect physical stimuli such as touch. Physically touching or deforming a mechanoreceptor cell opens ion channels in its plasma membrane (see Figure 43.2). As discussed in this section, some mechanoreceptors are neurons that send action potentials to the CNS in response to physical stimuli. Other mechanoreceptors are specialized epithelial cells that contain hairlike structures that bend in response to mechanical forces.

Skin Receptors Detect Touch and Pressure

Several types of receptors in the skin of many animals detect touch, deep pressure, or the bending of hairs on the skin. Some of these specialized receptors consist of neuronal dendrites covered in dense connective tissue. In mammals, these receptors are located at different depths below the surface of the skin, which makes them suitable for responding to different types of stimuli (**Figure 43.3**). For example, **Meissner corpuscles** lie just beneath the skin surface and sense touch and light pressure. They are found throughout the skin but are concentrated in areas sensitive to light touch, such as the fingertips, lips, eyelids, and genitals. In contrast, **Pacinian corpuscles** and **Ruffini corpuscles** are located much deeper beneath the surface, particularly in the soles of the feet and the palms of the hands. These corpuscles respond best to deep pressure or vibration. All skin corpuscles contain sensory receptor neurons that generate action potentials when the structure of the corpuscle is deformed. Other skin mechanoreceptors located in the hair follicles respond to movements of hairs and whiskers.

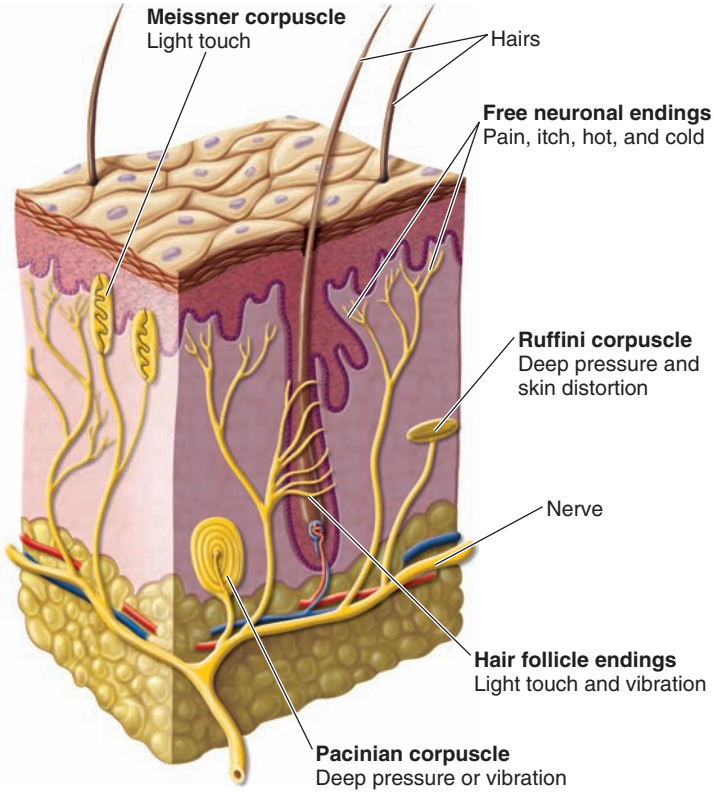

Figure 43.3 Examples of sensory receptors in the skin of mammals.

Concept Check: The several types of touch receptors in the skin respond to different stimuli. What different qualities of touch are you aware of?

Stretch Receptors Detect Expansion

Mechanoreceptors called **stretch receptors** are neuron endings commonly found in the walls of organs that can be distended. They occur in organs such as the stomach and urinary bladder and also in skeletal muscles. Although stretch receptors are probably found throughout the animal kingdom, they have been best studied in crustaceans and mammals. In decapod crustaceans such as crabs and lobsters, for example, stretch receptors in muscles of the tail, abdomen, and thorax relay signals to the brain regarding the position in space of the different body parts. This information allows the animal to perform complex motor functions, such as walking backward or sideways. In another example, when the mammalian stomach stretches after a meal, the stretch receptors in the stomach are deformed, causing them to become depolarized and send action potentials to the brain. The brain interprets the signals as fullness, which inhibits appetite.

Hair Cells Are Mechanoreceptors That Detect Sound and Motion

Thus far, we have considered skin and stretch mechanoreceptors, which are neurons that detect physical stimuli. Other mechanoreceptors are specialized epithelial cells called **hair cells**, which have deformable projections called **stereocilia**. The stereocilia are different from true cilia (see Figure 4.13) because they do not contain motor proteins in their structure, and are displaced by movements of fluid or other physical stimuli (**Figure 43.4**). They allow hair cells to be responsive to movements made by an animal.

Hair cells contain ion channels that open or close when the stereocilia bend and thereby change the cell's membrane potential. When the plasma membrane depolarizes, this opens voltage-gated

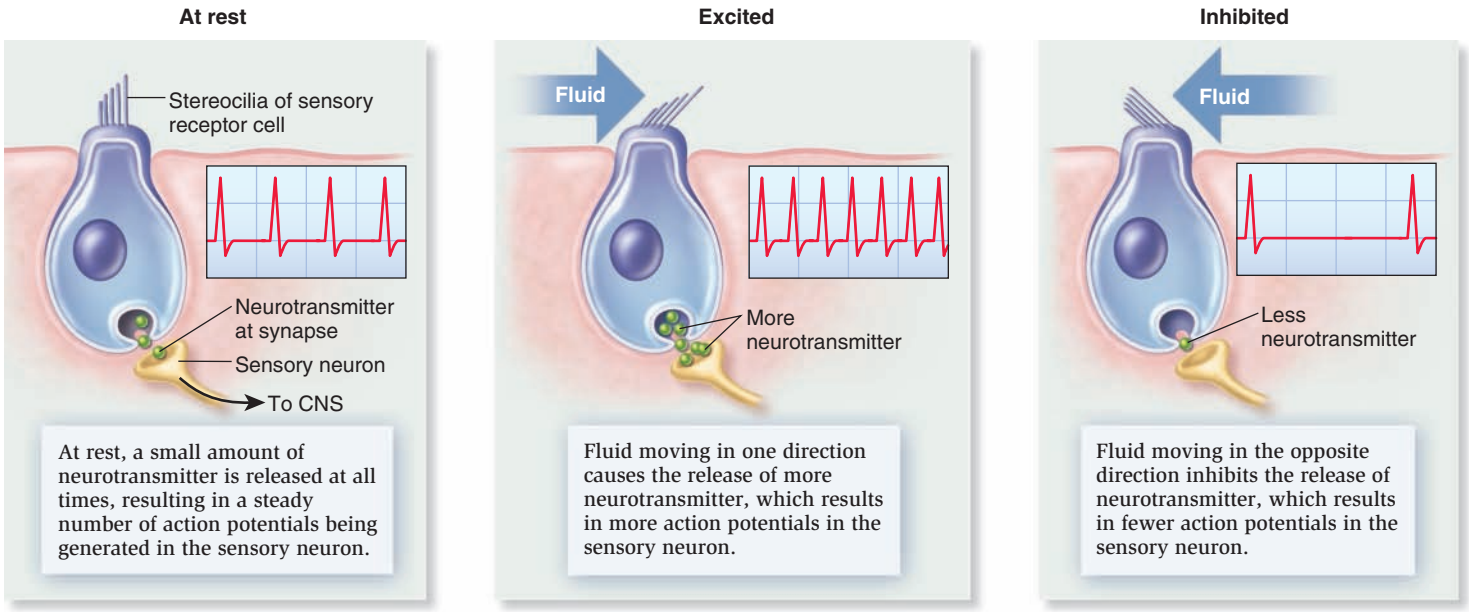

Figure 43.4 The response of hair cells to mechanical stimulation. The stereocilia inside these hair cells are hairlike projections of the plasma membrane that contain actin filaments.

BioConnections: How are stereocilia different from cilia, which are described in Chapter 4?

Ca^{2+} channels and results in the release of neurotransmitter molecules from the hair cells. The neurotransmitter then binds to protein receptors in adjacent sensory neurons and may initiate action potentials being sent to the CNS. Even when unstimulated, hair cells usually release a small amount of neurotransmitter onto nearby sensory neurons, resulting in a resting rate of action potentials in the sensory neurons. In the example shown in Figure 43.4, bending of the stereocilia in one direction in response to fluid movement increases the release of neurotransmitter from the hair cell, exciting the sensory receptors, whereas bending in the other direction decreases the release of the same neurotransmitter, inhibiting the sensory receptors. The result is an increase or decrease, respectively, in the number of action potentials produced in the sensory neurons.

Hair cells provide a rich array of sensory capabilities in many animal species. For example, these cells are found in the hearing and equilibrium (balance) organs of many invertebrates and vertebrates, where they detect sound or changes in head position. They are also found along the body surface of fishes and some amphibians, where they detect external water currents, as described later.

Audition (Hearing) Involves the Reception of Sound Waves

The sense of hearing, called **audition**, is the ability to detect and interpret sound waves. This sense is critical for the survival and reproduction of many types of animals. For example, a mother seal locates her pup by hearing its calls, and a male bird sings an elaborate song to attract a mate. Hearing is also important for detecting the approach of danger—a predator, a thunderstorm, an automobile—and locating its source.

Sound travels through air or water in waves. The distance from the peak of one wave to the peak of the next is a **wavelength**. The number of complete wavelengths that occur in 1 second is called the **frequency** of the sound, which is measured in number of waves per second, or hertz (Hz), after the German physicist and pioneer of radio wave research, Heinrich Hertz. The length and frequency of sound waves impart certain characteristics to the stimulus. Short wavelengths have high frequencies that are perceived as a high pitch, or tone, and long wavelengths have lower frequencies and a lower pitch. The human hearing range is 20–20,000 Hz.

The sense of hearing is present in vertebrates and arthropods, but not in other phyla. Arthropods do not appear to have more than a general sensitivity to sound, although some exceptions exist. For example, some species of moths have sound-sensitive membranes that detect the high frequencies emitted by their chief predators, bats. The sense of hearing, however, is especially well developed in many vertebrates (notably birds and mammals); we turn now to a detailed discussion of the mammalian ear and the mechanism by which it detects sound.

Structure of the Mammalian Ear The mammalian ear has three main compartments: the outer, middle, and inner ears (**Figure 43.5**). The outer ear consists of the external ear, or pinna (plural, pinnae), and the auditory canal. The outer ear is separated from the middle ear by the tympanic membrane (eardrum). The middle ear contains three small bones called ossicles (named the malleus, incus, and stapes) that link movements of the eardrum with the oval window. The oval window is another membrane similar to the eardrum that separates the middle ear from the inner ear. The inner ear is composed of the **cochlea** (from the Latin, meaning snail)—a coiled chamber of bone containing hair cells and the membrane-like round window—and the vestibular system, which plays a role in balance, as described later. These structures in the inner ear generate the signals that travel via the auditory nerve to the auditory cortex of the brain.

Generation of Electrical Signals in the Mammalian Ear To understand how mammals hear, let's first consider how mechanical

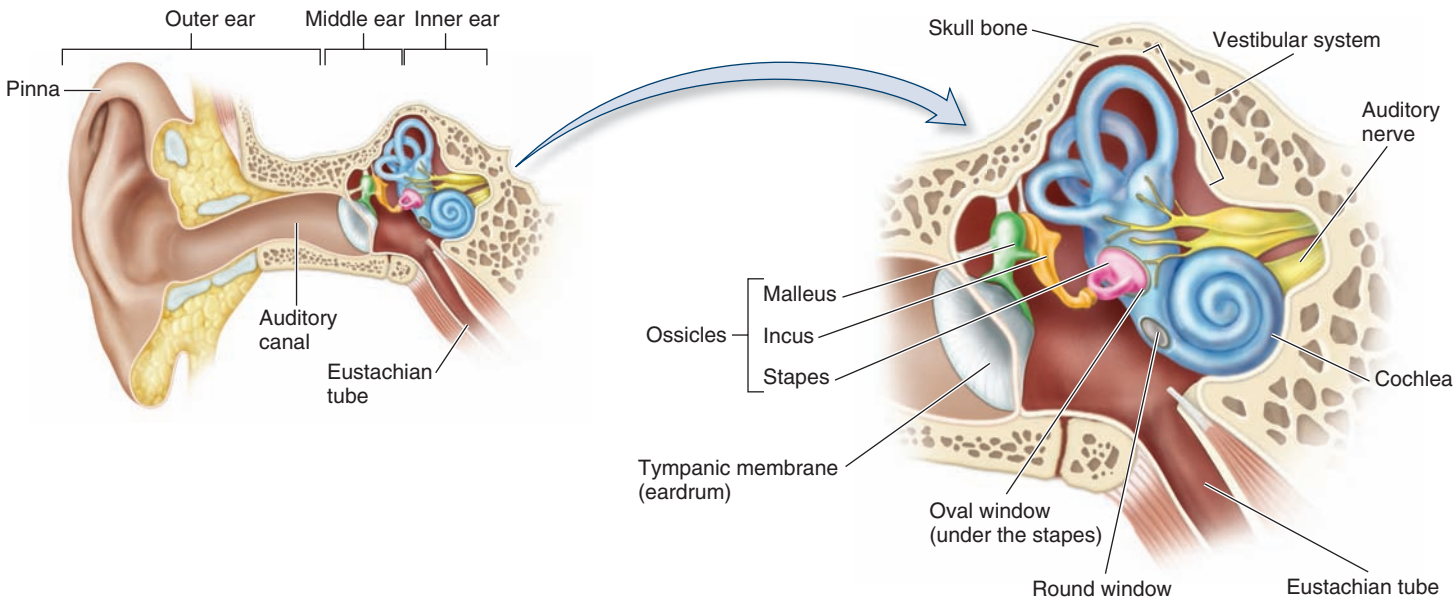

Figure 43.5 The structure of the human ear. The three main compartments are the outer, middle, and inner ear. (The eustachian tube connects the middle ear to the pharynx and helps to equalize air pressures in the ear.)

forces move through the human ear. Sound waves entering the outer ear cause the tympanic membrane to vibrate back and forth (**Figure 43.6**). The malleus, incus, and stapes transfer the vibration of the tympanic membrane to the oval window, causing it to vibrate against the cochlea. This sends pressure waves through a fluid called perilymph. Perilymph is found within two narrow passages in the cochlea called the vestibular and tympanic canals. The waves travel from the vestibular canal to the tympanic canal and eventually strike the round window, where they dissipate. Along the way, the waves cause the vibration of a membrane called the **basilar membrane**, which is formed from elastic fibers tensed across the cochlear duct. Sounds of very low frequency (longer wavelength) create pressure waves that take the complete route through the vestibular and tympanic canals (see the green arrows in Figure 43.6). Sounds of higher frequency (shorter wavelength) produce pressure waves that follow a different route, passing from the vestibular canal through a tube between the canals called the cochlear duct (as shown by the blue arrows in Figure 43.6). They then pass through the basilar membrane, before reaching the tympanic canal.

Within the cochlea, mechanical vibrations are transduced into electrical signals. This happens in a structure called the **organ of Corti** which rests on top of the basilar membrane. To understand how this works, we need to look at a cross section through the cochlea (**Figure 43.7**). The organ of Corti contains supporting cells and rows of hair cells. The stereocilia of the hair cells are embedded in a gelatinous tectorial membrane. The vibration of the basilar membrane bends the stereocilia in one direction and then the other. When bent in one direction, the hair cells depolarize and release neurotransmitter, which activates adjacent sensory neurons that then send action potentials to the CNS via the auditory nerve. When bent in the other direction, the hair cells hyperpolarize and shut off the release of neurotransmitter. In this way, the frequency of action potentials generated by the sensory neurons is determined by the up-and-down vibration of the basilar membrane.

The basilar membrane is lined with protein fibers that span its width. These fibers function much like the strings of a guitar. The fibers near the oval and round windows at the base of the cochlea are short and rigid, and they vibrate in response to high-frequency waves. Longer and more resilient fibers are near the other end of the cochlea and vibrate to lower-frequency waves. For this reason, hair cells closer to the oval and round windows respond to high-pitched sounds, whereas those at the opposite end are triggered by lower-pitched sounds. When we hear a great number of sound frequencies at once, such as at a musical concert, the waves traveling through the cochlea activate hair cells all along the basilar membrane in a physical representation of the music! These cells stimulate sensory neurons, which send multiple action potentials to the auditory areas of the brain for processing. The most incredible feature of this process, however, is that the mammalian ear and brain can "tune in" to all of these frequencies simultaneously.

Adaptations for Hearing Provide Survival Advantages for Animals

Different animals are capable of hearing sounds of different pitches. As noted, humans can hear between 20 and 20,000 Hz (conversation averages 90–300 Hz). Insectivorous bats, toothed whales, and

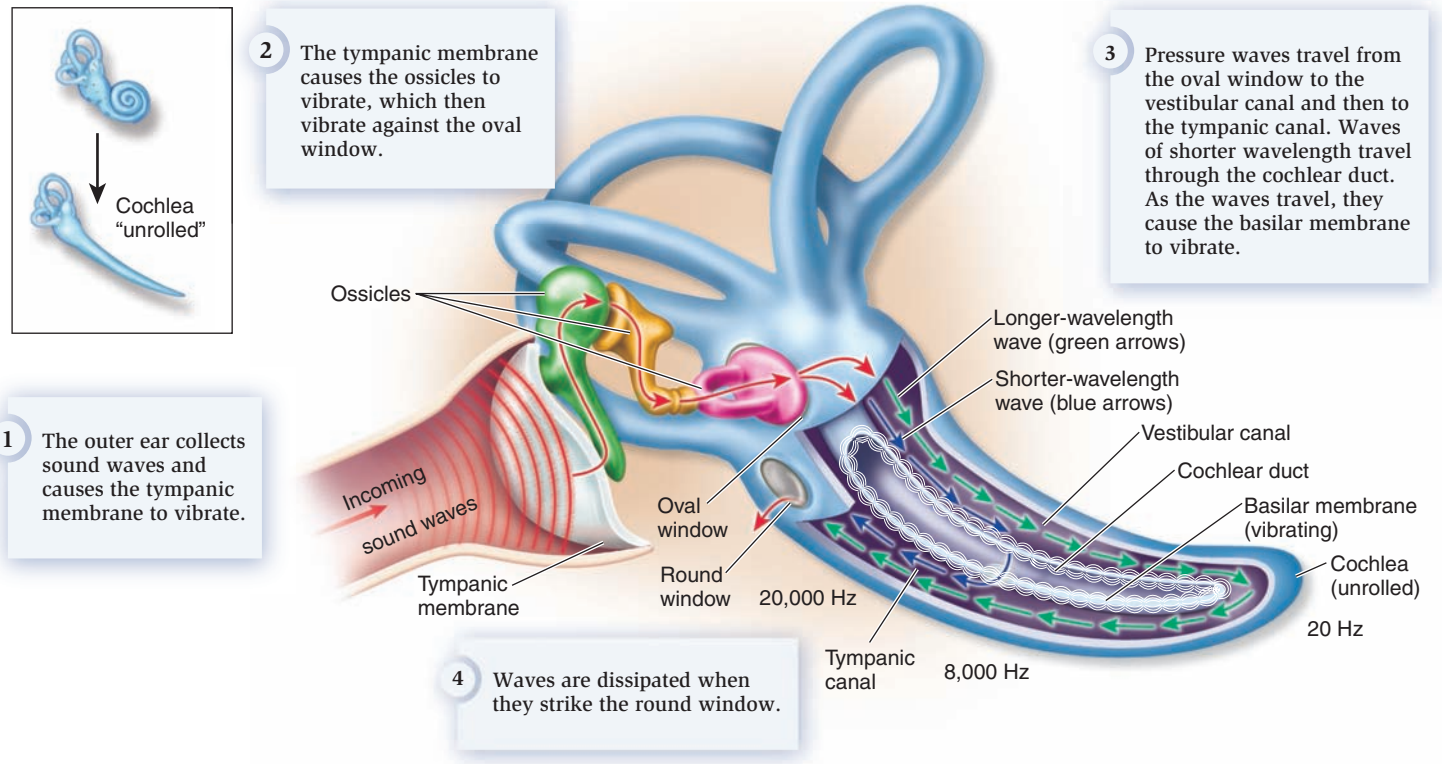

Figure 43.6 **Movement of sound waves through the human ear.**

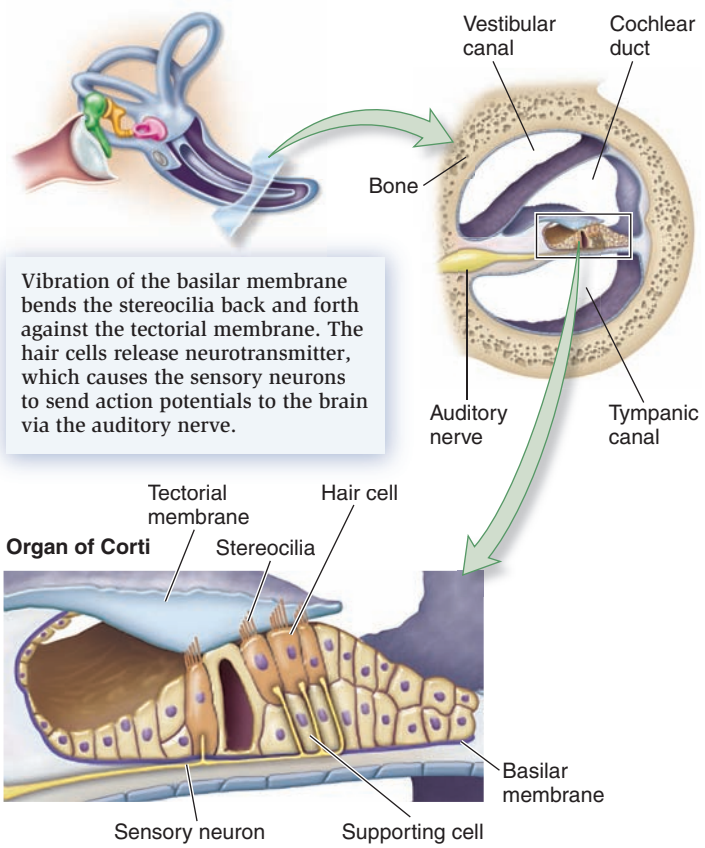

Figure 43.7 Transduction of mechanical vibrations to action potentials in the organ of Corti.

Concept Check: *What causes vibration of the basilar membrane?*

some species of moths may have the highest-frequency sensitivity (100,000–240,000 Hz), and baleen whales and elephants may have the lowest-frequency sensitivity (to nearly 1 Hz). These adaptations increase the animals' ability to communicate and survive. For instance, low-frequency sounds carry great distances through water or air and hearing them is especially useful for animals with large territories.

A vital feature of hearing is the ability to locate the origin of a sound. For example, this ability makes the difference between a successful and an unsuccessful hunter. How does an animal locate a sound? Under most circumstances, sound does not arrive at both ears simultaneously. Sound waves coming from the right, for example, excite the sensory receptors in the right ear first and the left ear some milliseconds later, and therefore the brain receives action potentials from the auditory nerves of each ear at slightly different times. The brain interprets the time difference to determine the direction and origin of the sound.

Animals such as owls that rely on hearing to pinpoint prey tend to be extremely good at identifying the direction of a sound. An interesting experiment demonstrated this by outfitting owls in a dark room with small headphones. Just as in a human hearing test, sounds could be sent to either headphone or to both. If the investigator sent a high-pitched noise (that mimicked the sounds of a mouse) first to the left headphone and then a single millisecond later to the right headphone, the owl turned its head to the left, because the owl's brain perceived the sound to be coming from that direction. If the noises reached both headphones simultaneously, the owl behaved as if the signal was coming from directly in front of its head.

Bats in the air, whales and dolphins in the sea, and shrews in underground tunnels generate high-frequency sound waves to determine the location of an object. In this phenomenon, called **echolocation**, the sound waves bounce off a distant object, like an echo, and return to the animal. The time it takes for the sound to return to each ear indicates the distance and direction of the object. Echolocation is especially useful in situations where vision is limited, such as in the dark.

The Sense of Balance Is Mediated by Statocysts in Invertebrates and the Vestibular System in Vertebrates

Let's now turn our attention to another form of mechanoreception, the sense of balance, also called equilibrium. Balance is part of a broader sense called proprioception, which is the ability to sense the position, orientation, and movement of the body. Being able to sense body position is vital for the survival of animals. This is how a lobster, for example, rights itself when flipped over by a predator or how a bird maintains its balance while flying.

Statocysts Many aquatic invertebrates have sensory organs called **statocysts** that send information to the brain about the position of the animal in space (**Figure 43.8**). Statocysts are small round structures consisting of an outer sphere of hair cells and one or more **statoliths**, which are tiny granules of sand or other dense objects. When the animal

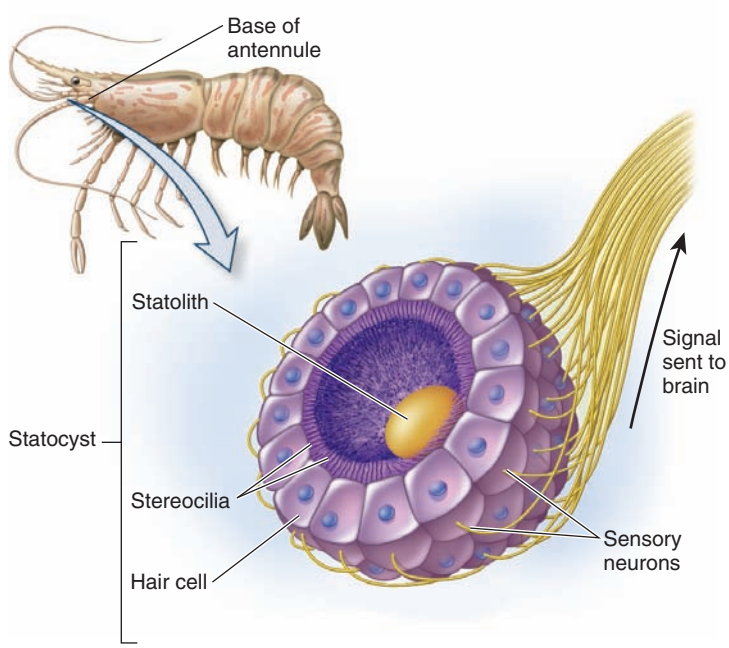

Figure 43.8 Sensing of balance in aquatic invertebrates.
Statocysts located near the antennae consist of a sphere of sensory hair cells surrounding one or more stony statoliths. When the animal moves, gravity shifts the statolith and stimulates the hair cells beneath it.

BioConnections: *Is the use of statoliths unique to animals? Look back to Figure 36.14 for a hint.*

moves, gravity alters the statoliths' position. If the animal turns on its left side, for example, the movement of statoliths stimulates a new set of hair cells to release neurotransmitter, generating action potentials in sensory neurons that inform the brain of the change in body position.

Several experiments have demonstrated the importance of statoliths. In one particularly dramatic example, researchers replaced the statoliths of crayfish with iron filings. Moving a magnet to different positions around the animal displaced the filings, causing the animal to change its position, and even to swim upside-down when the magnet was placed directly above its head.

The Vestibular System The organ of balance in vertebrates, known as the **vestibular system**, is located in the inner ear next to the cochlea (**Figure 43.9**). The vestibular system is composed of a series of fluid-filled sacs and tubules, which provide information about either linear or rotational movements. The utricle and saccule, the two sacs nearest the cochlea, detect linear movements of the head (Figure 43.9a), such as those that occur when an animal runs or jumps or changes its posture. The hair cells within these structures are embedded in a gelatinous substance that contains granules of calcium carbonate called **otoliths** (from the Latin, meaning ear stones), which are analogous to statoliths. When the head moves forward, the heavy otoliths are temporarily "left behind" as they are dragged forward more slowly, and the weight of the otoliths bends the stereocilia of the hair cells in the direction opposite that of the linear movement. This changes the membrane potential of the hair cells and alters the electrical responses of nearby sensory neurons. These signals are sent to the brain, which uses them to interpret how the head has moved.

Three **semicircular canals** connect to the utricle at bulbous regions called the ampullae (singular, ampulla). The function of the semicircular canals is to detect rotational motions of the head (Figure 43.9). The hair cells in the semicircular canals are embedded in the ampullae in a gelatinous cone called the **cupula**. When the head moves, the fluid in the canal shifts in the opposite direction. This movement of fluid pushes on the cupula and bends the stereocilia of the hair cells in the direction of the fluid flow, which is opposite that of the motion. The three canals are oriented at right angles to each other, and each canal is maximally sensitive to motion in its own plane. For example, the canal that is oriented horizontally would respond most to rotations such as shaking the head "no," whereas

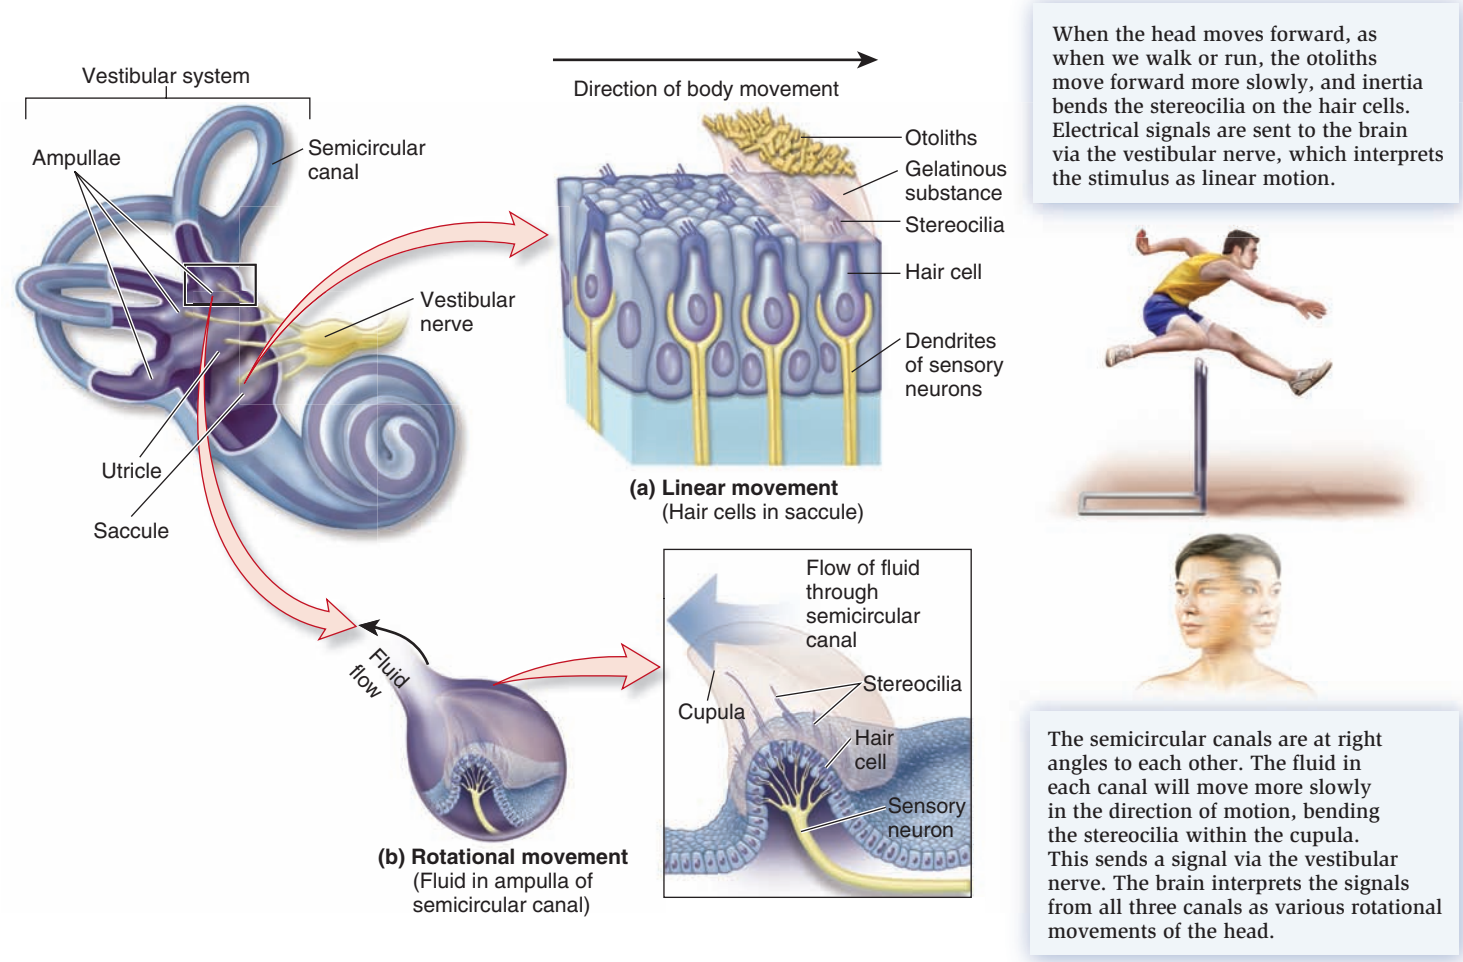

Figure 43.9 **The vertebrate vestibular system.**

Concept Check: *Note the orientation of the three semicircular canals with respect to each other. Why are the canals oriented in three different planes?*

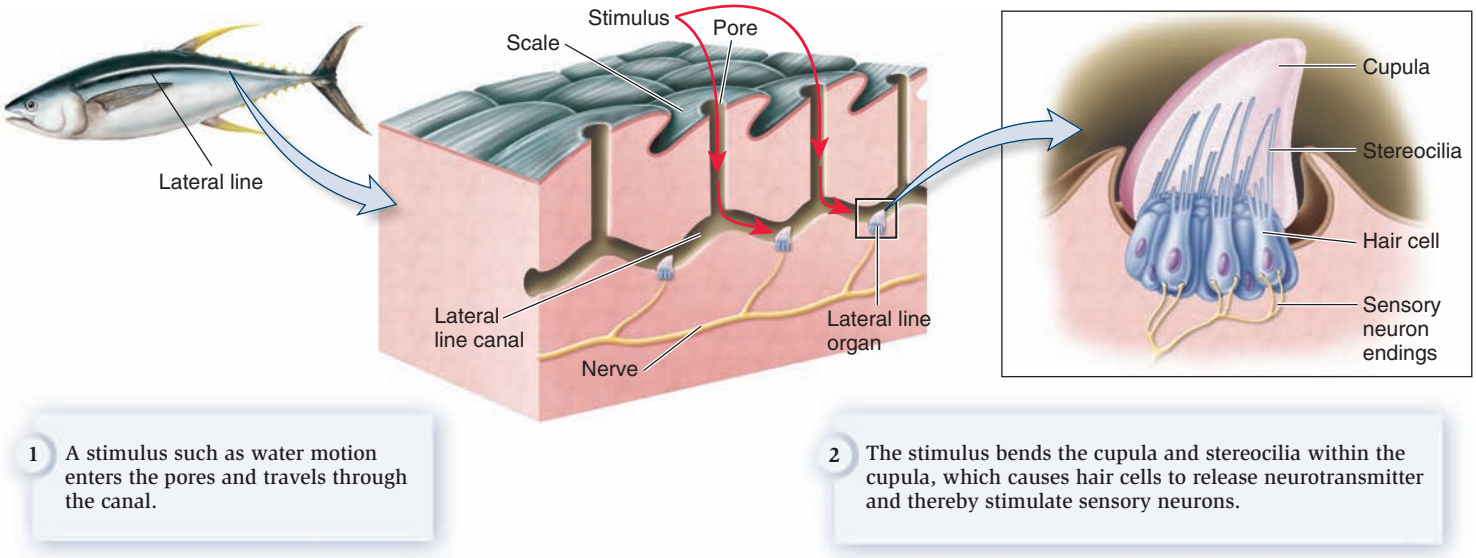

Figure 43.10 **Mechanoreceptors in the lateral line system of fishes that detect changes in water movement.**

the other canals respond to "yes" motions or to tipping the ear to the shoulder. Overall, by comparing the signals from the three canals, the brain can interpret the motion of the head in three dimensions.

The vestibular system of vertebrates provides conscious information about body position and movement. It also supplies unconscious information for reflexes that maintain normal posture, control head and eye movements, and assist in locomotion.

Mechanoreceptors in the Lateral Line System Detect Movements in Water

Fishes and some toads detect changes in their environment through a **lateral line system** (Figure 43.10). This sensory system has hair cells that detect changes in water currents brought about by waves, nearby moving objects, and low-frequency sounds traveling through the water. The lateral line system runs along both sides of the body and the head of the animal. Small pores let water enter into a lateral line canal. The stereocilia of hair cells of each lateral line organ protrude into a gelatinous structure called a cupula (similar to the cupula of the vertebrate vestibular system). When the cupula is moved by the water, the stereocilia bend, causing the release of neurotransmitter from the hair cell. This stimulates a response in sensory neurons at the base of the hair cells. The response provides information to the brain about changes in water movement, such as the approach of a predator.

43.3 Thermoreception and Nociception

Learning Outcome:

1. **SciSKILLS** » Distinguish between thermoreception and nociception, and propose reasons why they are vital to the safety and survival of an animal.

The perception of temperature and pain enables animals to respond effectively to potentially dangerous changes in their environments. As described in this section, these sensory stimuli are related in that their receptors are located in some of the same areas (for example, the skin; see Figure 43.3), share similar physical features, and under certain conditions result in similar perceptions.

Thermoreceptors Detect Temperature

Sensing the outside temperature is important for animals because their body temperature is affected by the external temperature. This is particularly true for ectotherms, animals whose body temperature changes with the environmental temperature. Animals can survive only if their body temperature remains within certain limits, because cell membranes and the proteins in cells function optimally only within a particular temperature range. Thermoreceptors respond to cold or hot temperatures by activating or inhibiting enzymes within their plasma membranes, which alters membrane channels. There are two types of thermoreceptors: those that respond to hot and those that respond to cold. Both of these types of sensory receptors are free neuronal endings. Thermoreceptors are often linked with reflexive behaviors, such as when an animal steps on a hot surface and pulls its foot away.

In addition to skin receptors that sense the outside temperature, thermoreceptors in the brains of some animals also detect changes in core body temperature. Activation of skin or brain thermoreceptors triggers physiological and behavioral adjustments that help maintain homeostasis. These adjustments, described in Chapter 46, include changes in blood flow, shivering, and behaviors such as seeking shade or sunlight.

Nociceptors Warn of Pain

Nociceptors are free neuronal endings in the skin and internal organs (see Figure 43.3). They respond to tissue damage or to stimuli that are about to cause tissue damage. Nociceptors are unusual because they can respond not only to external stimuli, such as extreme temperatures, but also to internal stimuli, such as molecules released into the extracellular space from injured cells. Damaged cells release a number of substances, including acids and small signaling molecules

called prostaglandins, that cause inflammation and make nociceptors more sensitive to painful stimuli. Anti-inflammatory drugs such as aspirin and ibuprofen reduce pain by preventing the production of prostaglandins.

Signals arising from nociceptors travel to the CNS and reach the cerebrum, where the type or cause of the pain is interpreted. The signals are also sent to the limbic system, which holds memories and emotions associated with pain, and to the brainstem reticular formation, which increases alertness and arousal—an important response to a painful stimulus.

Nociception tells an animal whether it has been injured and triggers behavioral responses that protect it from further danger. Although in many cases we cannot know whether or how animals perceive pain, nociceptors have been identified in all classes of vertebrates and in many invertebrates.

43.4 Electromagnetic Reception

Learning Outcome:

1. Identify ways that animals use electromagnetic receptors to sense their environments.

Electromagnetic receptors detect radiation within a wide range of the electromagnetic spectrum, including those wavelengths that correspond to visible light, UV light, and infrared light, as well as electrical and magnetic stimuli. Photoreceptors are specialized electromagnetic receptors that respond to light and are covered in Section 43.5. Here, we will examine the ability of some animals to sense electrical and magnetic fields and also heat in the form of infrared radiation.

The ability to detect the presence of nearby prey or predators can be especially challenging in animals that inhabit low-light environments. The more ways an animal has to detect other animals, the better it can avoid danger or obtain food. Many fishes living in dark waters can detect the weak electric field generated by the activity of excitable tissues such as the muscles and nerves of other fishes. To do this, they use exquisitely sensitive electroreceptors located in pores in the head region. These sensory receptors are as heavily innervated as the eyes of these fishes, suggesting the importance of this sense for their survival. Sharks and rays can even detect the tiny electrical signals generated by the heartbeats of prey hiding beneath a layer of sand on the ocean floor. Similarly, the platypus, which lives in the murky waters of streams and ponds, has receptors on the skin of its bill that can detect very small electrical currents produced by its prey.

Homing pigeons use a type of electromagnetic sensing to return to their starting points from as far away as 1,500 km. This navigational feat is made possible by small particles of magnetite (iron oxide) in their beaks, which indicate direction by acting as a compass. The magnetic particles respond to the Earth's magnetic field and alter the activity of neurons that project to the brain. In one experiment, pigeons were placed individually in large tubes and trained that food was present in only one end of the tube. When the tube was placed in a changeable magnetic field, pigeons readily learned which end contained food based solely on the magnetic polarity of the tube. In another experiment, the pigeons lost this ability when their beaks were anesthetized or cooled down, procedures that block action potentials from being sent to the brain. This finding demonstrates that their magnetic sensing ability is located in the beak and the sensations are communicated by nerves to the brain.

Figure 43.11 Infrared sensing. Sensory pits enable a white-lipped pit viper (*Cryptelytrops albolabris*) to detect the heat given off by its prey.

Concept Check: What advantage is provided by having sensory pits on both sides of a pit viper's head?

Magnetic field sensing is not unique to birds. Magnetite has also been found in the heads of migratory fishes such as rainbow trout. However, this probably does not entirely explain the extraordinary ability of migratory animals to navigate great distances, because other cues, such as smell and visual recognition of landmarks, also appear to play roles in this process.

Venomous snakes known as pit vipers (a group that includes copperheads and rattlesnakes) can localize prey in the dark with detectors that sense the heat emitted from animals as infrared radiation. These detectors are located in pits on each side of the head between the eyes and nostrils (**Figure 43.11**). Within the pit, a thin, nerve-rich, temperature-sensitive membrane becomes activated in response to infrared waves emitted by live animals. When the snake detects the heat of the animal, it localizes its prey by moving its head back and forth until both pits detect the same intensity of radiation. This indicates that the prey is centered in front of the snake.

Electrical, magnetic, and infrared sensing are adaptations for long-distance migration or low-light environments. When light is plentiful, however, photoreception becomes a dominant sensory ability in many animals, as described next.

43.5 Photoreception

Learning Outcomes:

1. Describe the structure of invertebrate visual organs.
2. Describe the structure of the vertebrate (single-lens) eye, and explain how its structure is related to its ability to form images.
3. Compare and contrast the structure and function of rods and cones.
4. Describe the steps involved in the mechanisms by which photoreceptors respond to light in a single-lens eye.
5. Outline the neural pathway by which visual signals travel to reach the brain.

Although it is a form of electromagnetic reception, photoreception is such an important and widespread sense that we will cover it separately here. Visual systems employ specialized neurons called photoreceptors, which detect photons of light arriving from the Sun or other light sources or reflecting off an object. A photon is the fundamental unit of electromagnetic radiation and has the properties of both a particle and a wave. The properties of light are described in Chapter 8. In this section, we will examine the organs found in animals, usually called **eyes**, that detect light and send signals to the brain. The amazing features of these organs reflect the importance of vision in the animal world.

Eyecups and Compound Eyes Are Found in Many Invertebrates

The ability to sense light is an ancient adaptation found even in many unicellular organisms, where it may provide a selection advantage for photosynthesis or protection. Typically, such organisms may have a single eyespot that contains a small number of light-sensitive molecules, but lack the ability to discern the direction of a light source or to interpret a visual image.

Eyecups A slightly more sophisticated visual organ is found in free-living flatworms such as *Planaria*. These animals have two concave structures called **eyecups** (Figure 43.12). Each eyecup contains the endings of photoreceptor cells and a layer of pigment cells that shields the photoreceptors from one side. The left and right eyecups receive light from different directions. This allows the eyecups to detect not only the presence or absence of light, but also its direction. The nervous system compares the amount of light detected by each eyecup, and the flatworm moves toward darkness, a behavior that protects it from predators. However, this type of photoreceptor does not form visual images of the environment.

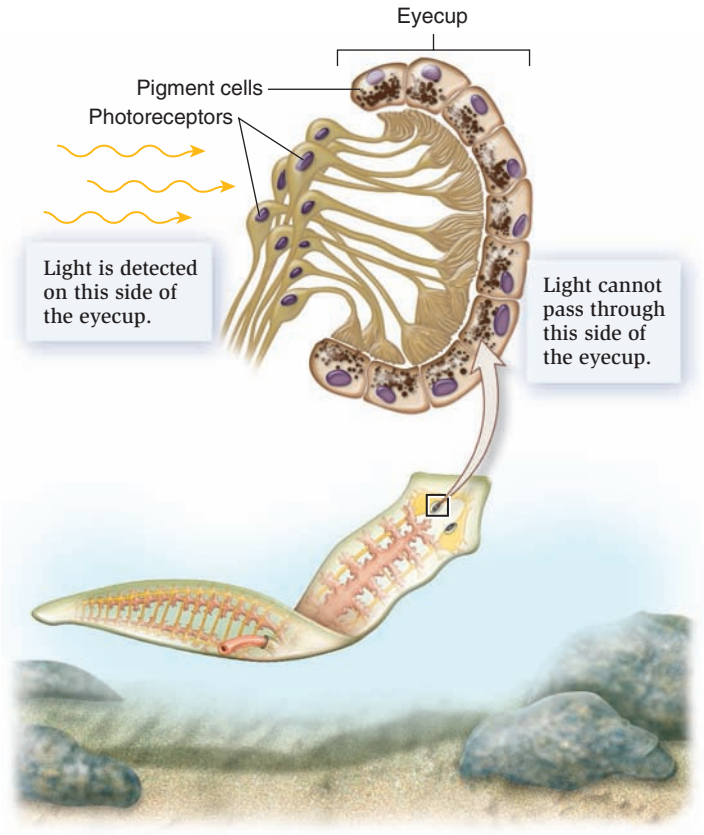

Figure 43.12 The eyecup of a flatworm. The orientation of the eyecup allows light to stimulate photoreceptors from primarily one direction. This type of eye senses the presence or absence of light and its direction, but does not form visual images.

Compound Eyes In contrast, arthropods and some annelids have image-forming **compound eyes** (Figure 43.13a), which consist of several hundred to more than 10,000 light detectors called **ommatidia** (singular, ommatidium) (Figure 43.13b). Each ommatidium makes up one facet of the eye. Within the ommatidium, a **lens**—composed in this case of a cornea and a crystalline cone—focuses light onto a long central structure called a rhabdom (Figure 43.13c). The rhabdom is a column of light-sensitive microvilli that project from the cell membranes of the photoreceptor cells of the ommatidium (Figure 43.13d). The light-sensitive molecules required for vision are located in the microvilli; the extensive surface area imparted by the microvilli provides the animal with increased sensitivity to light. Pigmented cells surrounding the photoreceptor cells absorb excess light and thereby isolate each ommatidium from its neighbors.

Each ommatidium senses the intensity and color of light. Combining the different inputs from neighboring ommatidia, the compound eye forms an image that the brain interprets. Animals such as bees and fruit flies, with large numbers of ommatidia, presumably have sharper vision than those with fewer sensory cells, such as grasshoppers.

As anyone who has tried to swat a fly knows, the compound eye is extremely sensitive to movement and helps flying insects evade birds and other predators. Behavioral studies have shown, however, that the resolving power of even the best compound eye is considerably less than that of the single-lens eye, which we will consider next.

Vertebrates and Some Invertebrates Have a Single-Lens Eye

Structure of the Single-Lens Eye **Single-lens eyes** are found in vertebrates and also in some mollusks, such as squid, octopuses, and some snails, and in some annelids. In such eyes, different patterns of light emitted from or reflected off objects in the animal's field of view are transmitted through a small opening, or **pupil**, through the lens, to a sheetlike layer of photoreceptors called the **retina** at the back of the eye (Figure 43.14a). The light inputs form a visual image of the environment on the retina. The activation of these photoreceptors triggers electrical changes in neurons that pass out of the eye through the **optic nerves**, which carry the signals to the brain. The brain then interprets the visual image that was transmitted.

As illustrated in Figure 43.14a, the vertebrate eye has a strong outer sheath called the **sclera** (the white of the eye). Between the sclera and the retina is a layer of blood vessels called the choroid. At the front of the eye, the sclera is continuous with a thin, clear layer known as the **cornea**. Within the eye are two cavities, the anterior and posterior cavities. The anterior cavity is the part of the eye between the lens and the cornea. It is subdivided into the anterior chamber

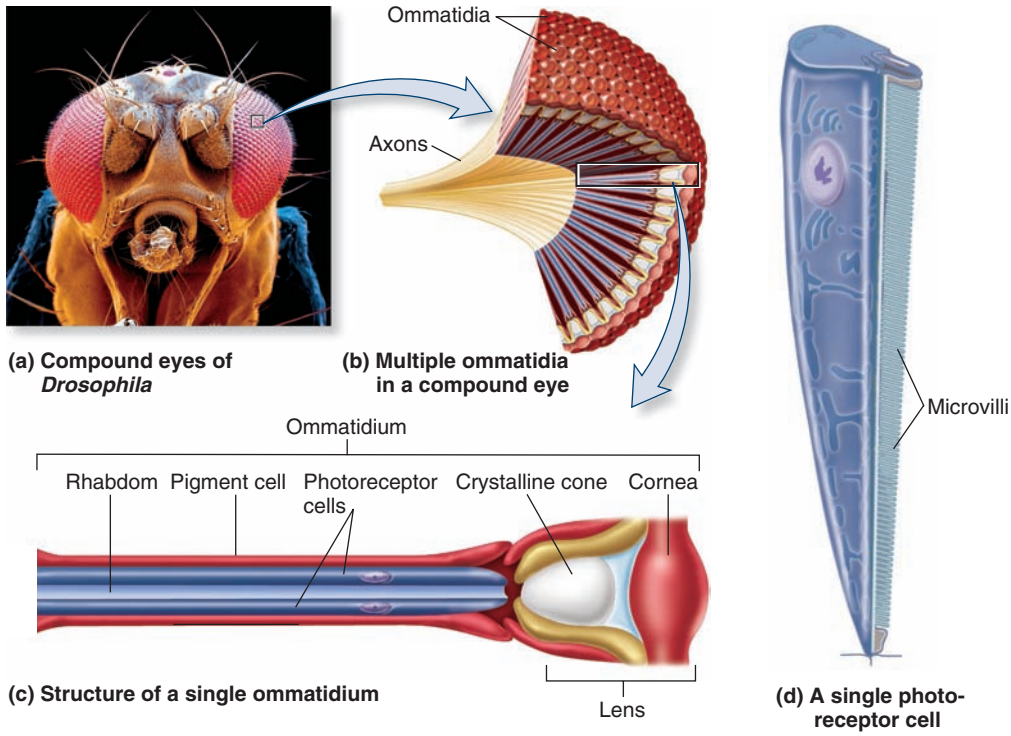

Figure 43.13 The compound eye of insects. **(a)** Close-up of the eyes of a fruit fly (*Drosophila melanogaster*). **(b)** Each eye has approximately 1,000 ommatidia, which form a sheet on the surface of the eye. **(c)** Each ommatidium has a lens that directs light to the photosensitive rhabdom. **(d)** Extending from each photoreceptor cell into the rhabdom are many light-sensitive microvilli.

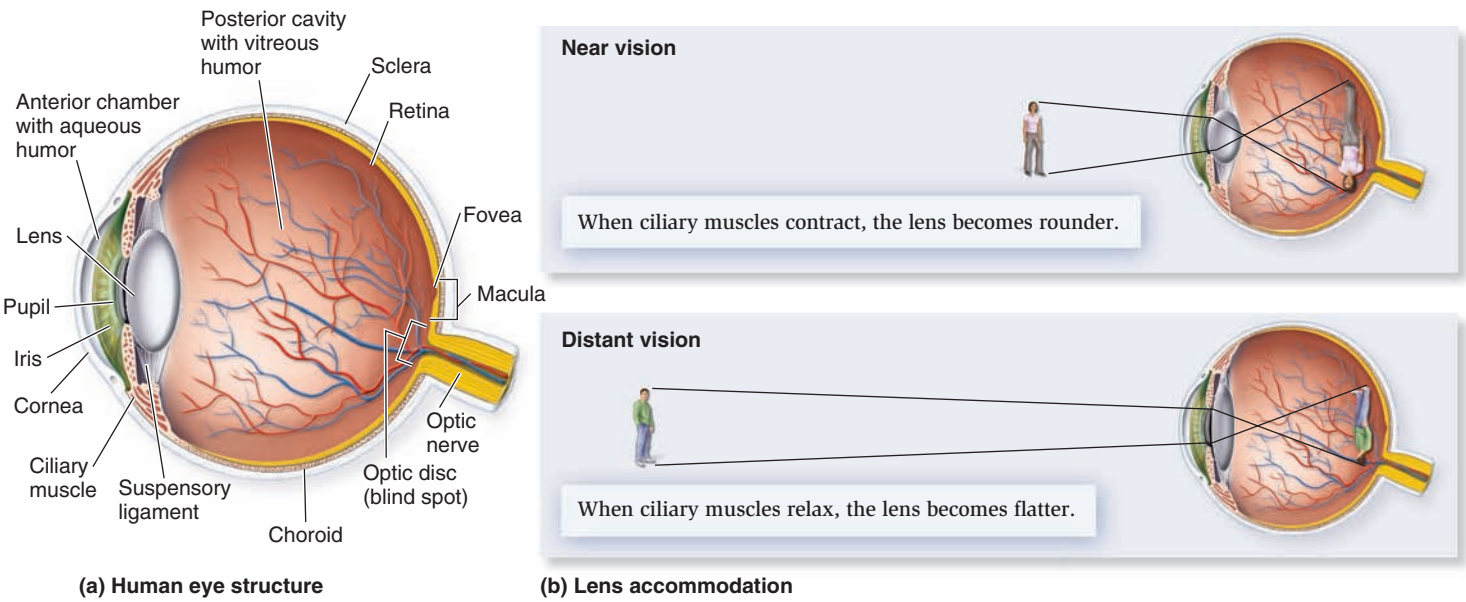

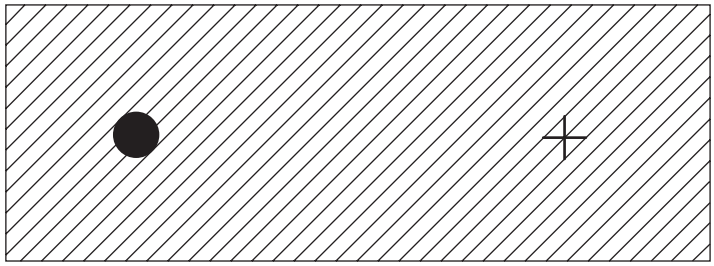

Figure 43.14 The vertebrate single-lens eye. **(a)** The structure of the human eye. **(b)** Changes in lens shape during accommodation. When an object is near, the ciliary muscles contract and the lens becomes rounder, causing light to bend more. When the object is far away, the ciliary muscles relax and the lens flattens. **(c)** Demonstration of the blind spot. First, hold this picture up in front of your face, or place the book on a table and stand over it. Next, close your left eye and stare at the black spot with your right eye while you move the picture toward and away from your face. At some point, light reflecting off the plus (+) sign will fall directly on your optic disc, and it will seem to disappear. It will then reappear as you continue getting closer.

and posterior chamber. The anterior chamber is located between the cornea and the **iris**—the circle of pigmented smooth muscle responsible for eye color. This chamber is filled with a thin liquid called the **aqueous humor**. The posterior chamber is the space between the single lens and the iris. The larger posterior cavity between the lens and the retina contains the thicker **vitreous humor**, which helps maintain the shape of the eye.

The hole in the center of the iris is the pupil. The size of the pupil changes when the muscles of the iris reflexively relax or contract to allow more or less light to enter the eye.

Light Focusing Because light radiates in all directions from a light source, light must be bent (refracted) inward toward the photoreceptors at the back of the eye. This is accomplished by the cornea and the lens. Whenever light passes from one medium to another medium of a different density, light waves will bend (try looking at a pencil in a glass partly filled with water). The cornea, which is at the interface between the air and the aqueous humor, initially refracts the light. The light then passes through the thicker lens, where it is refracted again and focused onto the layer of photoreceptors, the retina, at the back of the posterior chamber. The bending of the incoming light results in an upside-down and laterally inverted image on the retina, but the brain adjusts for this, and the image is perceived correctly.

The lens is adjusted to focus light that comes from different distances. In fishes and amphibians, the lens is moved forward or backward. In the avian and mammalian eye, the lens remains stationary but changes shape to become more or less round. When the lens is stretched, it flattens, and light passing through it bends less than when it is round. Contraction and relaxation of the ciliary muscles adjust the lens according to the angle at which light enters the eye, a process called **accommodation** (Figure 43.14b).

How does the retina form such sharp images? The region on the retina directly in line with the pupil and lens is called the macula. Near the center of the macula is the **fovea**, which contains the highest density of photoreceptors for color. The fovea is responsible for the sharpness with which we and many other animals see in daylight. However, the retina also has limitations in forming images. In the eye, as mentioned, the image initiates signals that travel from the retina to the brain through neurons in the optic nerve that exits the eye. In vertebrates, the point on the retina where the optic nerve leaves the eye is called the **optic disc**. The optic disc does not have any photoreceptors, forming a blind spot where light does not activate a response (Figure 43.14c). Invertebrates with single-lens eyes do not have a blind spot, because the photoreceptors in their eyes are at the front of the retina; consequently, the optic nerve does not pass through the layer of photoreceptors before leaving the eye.

Rods and Cones Are Photoreceptor Cells

Vertebrates have two types of photoreceptors with names that are derived from their shapes: rods and cones (Figure 43.15). **Rods** are very sensitive to low-intensity light and can respond to as little as one photon, but they do not discriminate different colors. Rods are used mostly at night, and they send signals to the brain that generate a black-and-white visual image. **Cones** are less sensitive to low levels of light but, unlike rods, are sensitive to wavelengths of light that allow animals to perceive color.

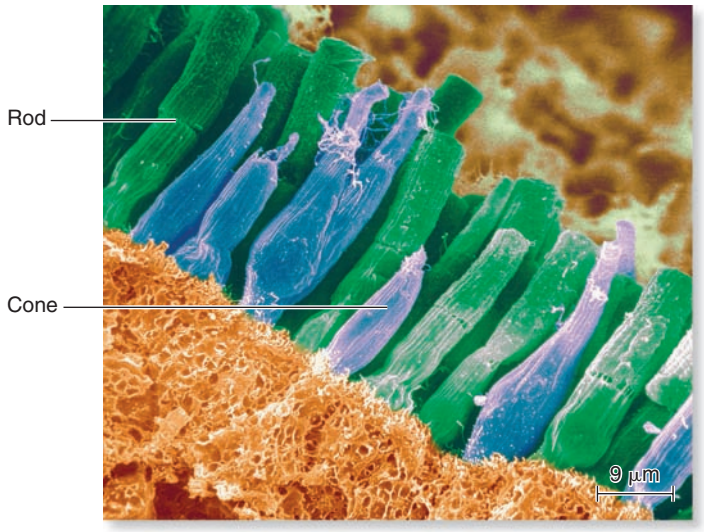

Figure 43.15 Rod and cone photoreceptors. Rods are shown as green and cones as blue in this false-color scanning electron micrograph (SEM).

Rods and cones are cells with three functional parts: the outer segment, inner segment, and synaptic terminal. The **outer segment** of the cell contains folds of membranes that form stacks like discs (Figure 43.16). These discs contain the pigment molecules that absorb light. The **inner segment** of the cell contains the cell nucleus and other cytoplasmic organelles. Rods and cones do not have axons but have synaptic terminals with neurotransmitter-containing vesicles, which synapse with other neurons within the retina.

Nocturnal animals (those active predominantly at night) rely primarily on rod vision, though some have limited color vision, too. In diurnal animals (active predominantly by day) with both rods and cones, such as humans, the rods are located around the periphery of the retina away from the fovea. Therefore, it is easiest to see low-intensity light if it comes into the eye at an angle. You can easily verify this. In early evening, before many stars are visible, look at the sky until you notice a star out of the corner of your eye. Now shift your gaze to where you thought you saw the star. You will probably not be able to locate it anymore. When you look away again so that light from the dim star enters your eye at an angle, it will reappear. This demonstrates that under low-light conditions, your vision is better when the light is directed to the part of the retina that contains only rods.

Cones are used in daylight by most diurnal vertebrate species and by some insects such as the honeybee, which can detect the yellow color of pollen. Compared to rods, the human retina has fewer cones, which are clustered in and around the fovea. Cones provide sharp images because of their density at the fovea. Although they are less sensitive to light than rods, this is less critical in daylight because the amount of light reaching the eyes at this time far exceeds what is needed to stimulate any photoreceptor cell.

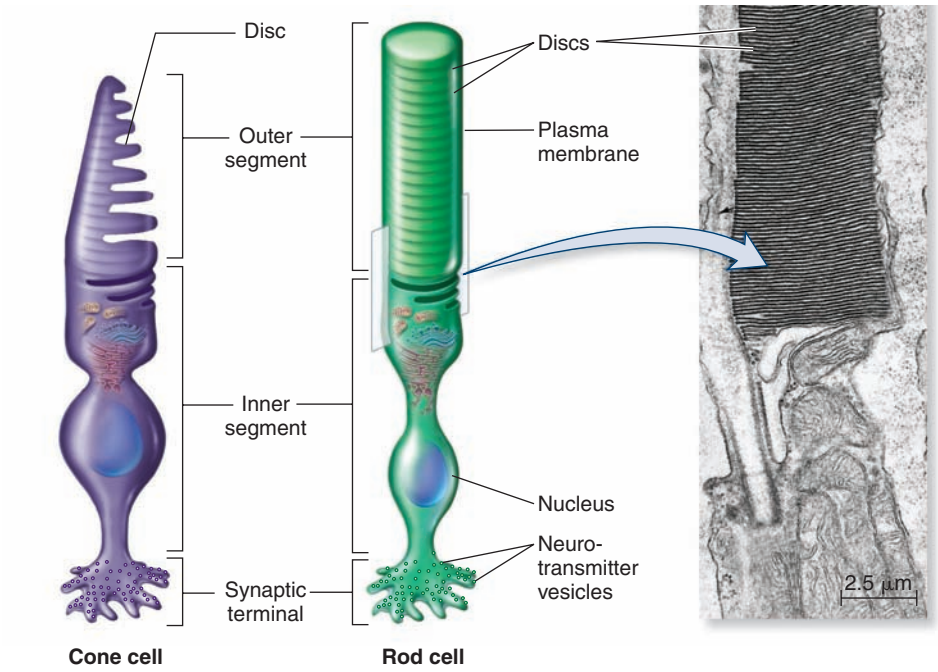

Figure 43.16 Structure of a cone and a rod. The illustration shows the structure of a cone and rod photoreceptor and the appearance of a rod in a transmission electron micrograph (TEM). Note the multiple stacks of membranous discs in the outer segments of the cells.

Rods and Cones Contain Visual Pigments That Absorb Light

Visual pigments are molecules that absorb light; they are found embedded in the disc membranes of the outer segment of rods and cones. In the mid-20th century, American biologist and Nobel Prize winner George Wald discovered that these pigments consist of two components bonded together. The first is **retinal**, a derivative of vitamin A that is capable of absorbing light energy. The discovery of retinal in the visual pigment explains the need for vitamin A in the diet and its importance in vision. The second component of visual pigments is a protein called **opsin**, of which there are several types. Opsins are examples of G-protein-coupled receptors (see Figure 9.7), which trigger a biochemical cascade that changes the permeability of membrane channels to ions.

Rods and cones have visual pigments containing different types of opsin proteins. These pigments are named according to the type of opsin they contain. In rods, the visual pigment is named **rhodopsin** (**Figure 43.17**). Cones contain several types of visual pigments called cone pigments, or **photopsins**. In humans, photopsins are composed of retinal plus one of three possible opsin proteins. Each type of opsin protein determines the wavelength of light that the retinal in a cone can absorb. For example, each cone pigment in humans responds best to red, green, or blue light. Any given cone cell makes only one type of cone pigment. Many different shades of these colors can be perceived, however, because the brain uses information about the proportion of each type of cone that was stimulated to generate all other colors.

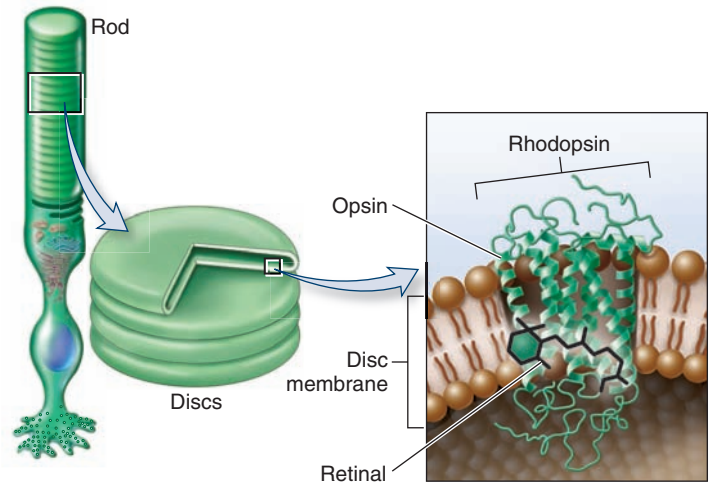

Figure 43.17 A visual pigment. The visual pigment rhodopsin is found within the membrane of the rod photoreceptor discs. It is composed of a transmembrane protein, opsin, that is bonded to a molecule of retinal, a derivative of vitamin A that is capable of absorbing light energy.

BIOLOGY PRINCIPLE Structure determines function. The stacks of discs in the photoreceptor outer segment are an excellent example of a structural adaptation that increases surface area without significantly increasing volume, thereby allowing for greater light-capturing ability and improving the function of the cell as a sensory cell.

Genomes & Proteomes Connection

Color Vision Is an Ancient Adaptation in Animals

Color vision requires the presence of at least two types of opsins with optimal sensitivities to light of different wavelengths. Genome analyses and behavioral and neurophysiological testing of many animals have confirmed that color vision is widespread across invertebrate and vertebrate taxa, and arose early in animal evolution. It appears that the primordial color sensitivity was to short wavelengths in the ultraviolet/blue region of visible light (refer back to Figure 8.4), and from there additional opsins

evolved with sensitivities to medium and longer wavelengths. Humans have three types of color-sensitive photoreceptors; most vertebrates that have been studied, however, have four. It is impossible for us to understand how the world must appear to such an animal, which presumably sees shades of colors we cannot. Some insects, including the butterfly *Papilio xuthus*, appear to have up to six types of light receptors, and certain crustaceans (for example, mantis shrimp) have 12! A well-studied model is the honeybee, which has four color-sensitive photoreceptors that respond to wavelengths ranging from 300 nm to 600 nm (refer back to Figure 8.4); honeybees can see ultraviolet wavelengths that humans can't. A rainbow would appear very differently to a honeybee than it does to us; to the bee, the rainbow would extend past the blue edge and stop short of the red edge.

It is debatable why color vision provided a selective advantage to animals. Some investigators believe that it produced more acute vision due to an overall improved contrast and was not originally related to commonly observed phenomena today, including colorful plumage displays or brightly colored flowers. Coloration in plants may have evolved in response to the color sensitivity in animals, not vice versa, but this is unclear.

An intriguing exception to vertebrates are most mammals and in particular primates. When mammals first evolved, they were most likely entirely nocturnal animals and therefore there would have been no selection pressure to retain sensitive color vision; recall that cones are less sensitive to low levels of light and therefore color vision is limited at night. Most mammals today are dichromatic, that is, they only have two types of opsins and therefore see a more limited color palette than do other vertebrates. Primates, however, are an exception, because a third opsin reappeared in the course of primate evolution, one that was sensitive to middle (green) wavelengths. It has been postulated that this may have imparted an advantage that allowed fruit and leaf-eating primates to better discern orange, red, and yellow fruits against a background of green leaves, but again, this is uncertain.

About 92% of human males and over 99% of females have normal trichromatic color vision. However, problems in color vision may result from defects in the cone pigments arising from mutations in the opsin genes. The most common is red-green color blindness, which occurs predominantly in men (1 in 12 males compared with 1 in 200 females). Individuals with red-green color blindness either lack the red or green cone pigments entirely or, more commonly, have one or both of them in an abnormal form. In one form, for example, an abnormal green pigment responds to red light as well as green, making it difficult to discriminate between the two colors.

Researchers have determined that color blindness results from a recessive mutation in one or more genes encoding the opsins. Genes encoding the red and green opsins are located very close to each other on the X chromosome, but the gene encoding the blue opsin is located on a different chromosome. In males, the presence of only one X chromosome means that a single recessive allele from the mother results in red-green color blindness, even though the mother herself is not color blind (**Figure 43.18**).

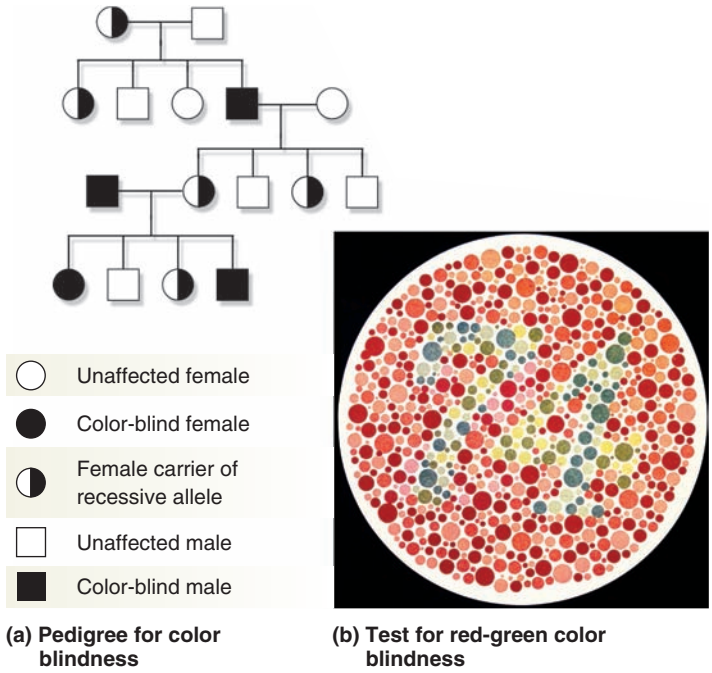

Figure 43.18 Color blindness. **(a)** A pedigree for red-green color blindness showing all possible offspring. **(b)** A standard eye test to screen for red-green color blindness. People with red-green color blindness will not see the number 74 hidden in this pattern.

Concept Check: *Why is red-green color blindness rare in females?*

Photons Change Photoreceptor Activity by Altering the Conformation of Visual Pigments

Photoreceptors differ from other sensory receptor cells because at rest in the dark their membrane potential is slightly depolarized, whereas in response to a light stimulus, it is hyperpolarized rather than depolarized (**Figure 43.19**). In the dark, the cell membranes of the outer segments

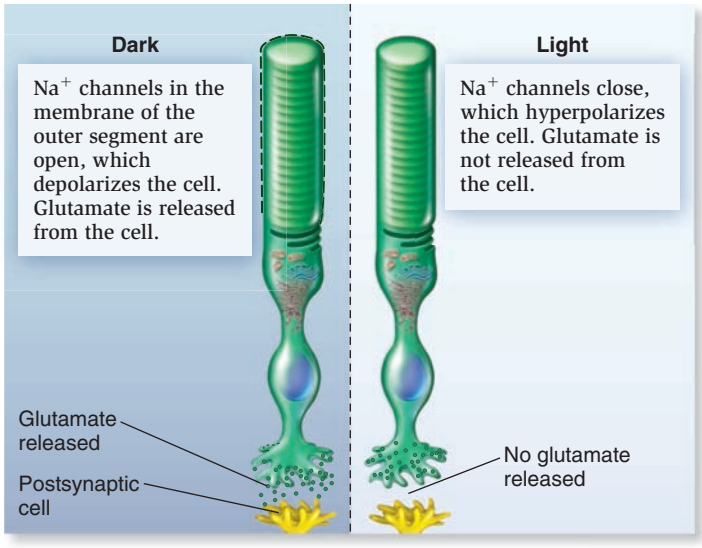

Figure 43.19 Membrane potential response of photoreceptors to dark and light.

of resting cells are highly permeable to Na^+ ions. Sodium ions flow into the cytosol of the cell through open Na^+ channels in the outer segment membrane. The Na^+ channels are gated by intracellular cyclic guanosine monophosphate (cGMP). In the dark, cytosolic concentrations of cGMP are high, keeping Na^+ channels open and depolarizing the cell. This depolarization results in a continuous release of the neurotransmitter glutamate from the synaptic terminal of the photoreceptor. The photoreceptor synapses with a postsynaptic cell that is the next neuron in the visual pathway. This initiates a series of events within the retina that is interpreted by the brain as an absence of light. In contrast, when exposed to light, the Na^+ channels in the outer segment membranes of the photoreceptor close. The resulting decrease in Na^+ concentration leads to a hyperpolarization of the cell. In response, the release of glutamate is stopped. This results in a series of cellular activations within the retina and brain that is interpreted as a visual image.

Let's take a more detailed look at the signal transduction pathway that allows a photoreceptor to respond to light (**Figure 43.20**). When the photoreceptor is exposed to light, the retinal within the visual pigment absorbs a photon. The energy of the photon alters the retinal from *cis*-retinal to *trans*-retinal, an isomer with a slightly different conformation due to a rotation at one of the molecule's double bonds (see Figure 43.20). This change results in retinal briefly dissociating from the opsin protein, causing the opsin to change its three-dimensional shape and activate a G protein called transducin, located in the disc membrane. The activated transducin, in turn, activates another disc protein, the enzyme phosphodiesterase.

The action of phosphodiesterase results in the closure of Na^+ channels in the outer segment membrane. Remember that in the dark, these channels are kept open by intracellular cGMP. However, when phosphodiesterase is activated, it decreases the concentration of cytosolic cGMP by converting it to GMP. This results in the dissociation of cGMP from the channels, so the channels close, and there is no longer any net diffusion of Na^+ into the cell. The membrane potential of the cell becomes less positive than it was in the dark. Therefore, the response of the cell is a hyperpolarization that is proportional to the intensity of the light. The final result is a decrease in glutamate release from the photoreceptor (see Figure 43.19), ultimately leading to a visual image. The sequential activation of enzymes following activation of a single photoreceptor results in an amplification of the original signal (refer back to Figure 9.14). Because of this property, we are able to detect extremely low levels of light.

The Visual Image Is Refined in the Retina

Thus far, we have considered the structure of the vertebrate eye and how photoreceptors transduce light. We will now turn our attention to the neural pathway through which the visual signal travels to reach the brain. To do so, we must consider the cellular organization of the retina. The vertebrate retina has several layers of cells (**Figure 43.21**). The photoreceptors (rods and cones) form the deepest layer, closest to the inside of the sclera. Immediately behind the photoreceptors is a pigmented epithelium that absorbs light that missed the photoreceptors; this prevents scattering of light within the retina, which could degrade the sharpness of vision. Because the photoreceptors are positioned at the back of the retina, light must pass through two transparent layers of cells before it reaches them. The

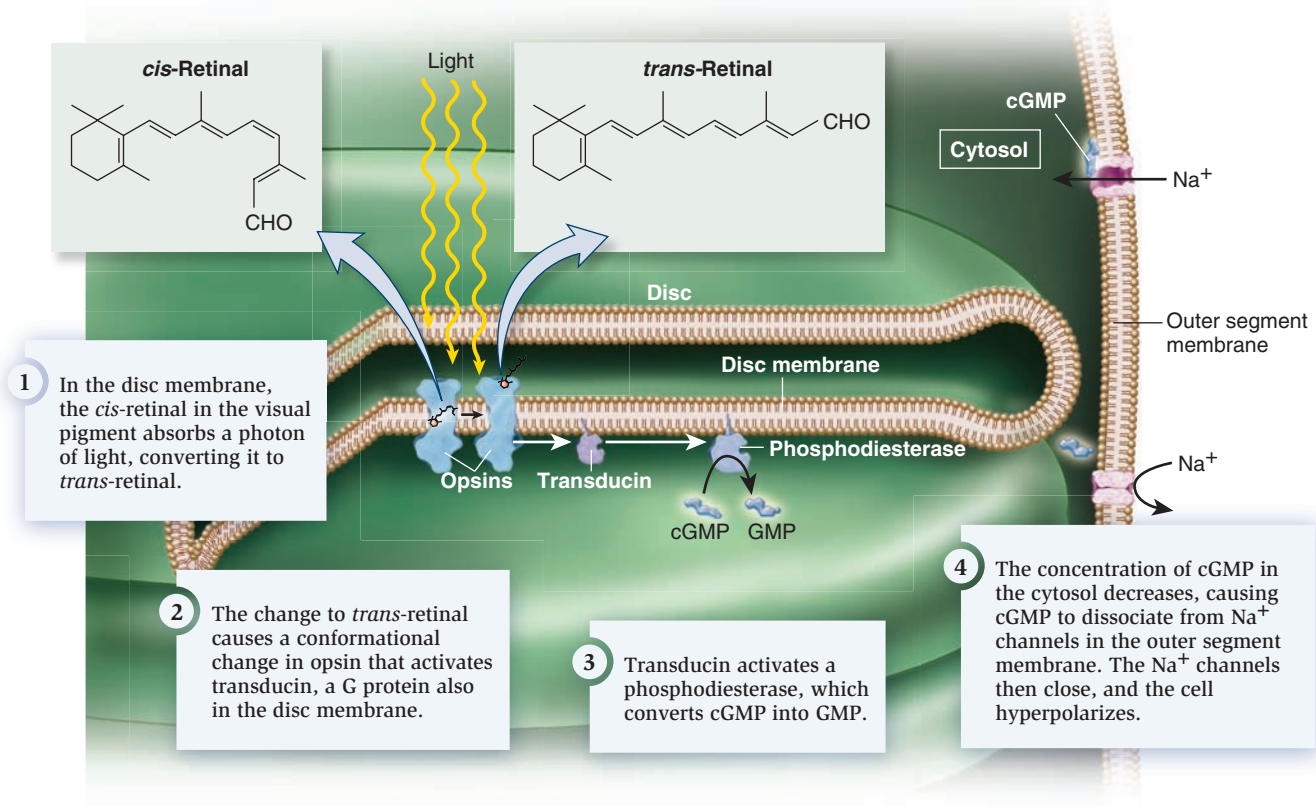

Figure 43.20 **Signal transduction pathway in photoreceptor (rod) cells in response to light.**

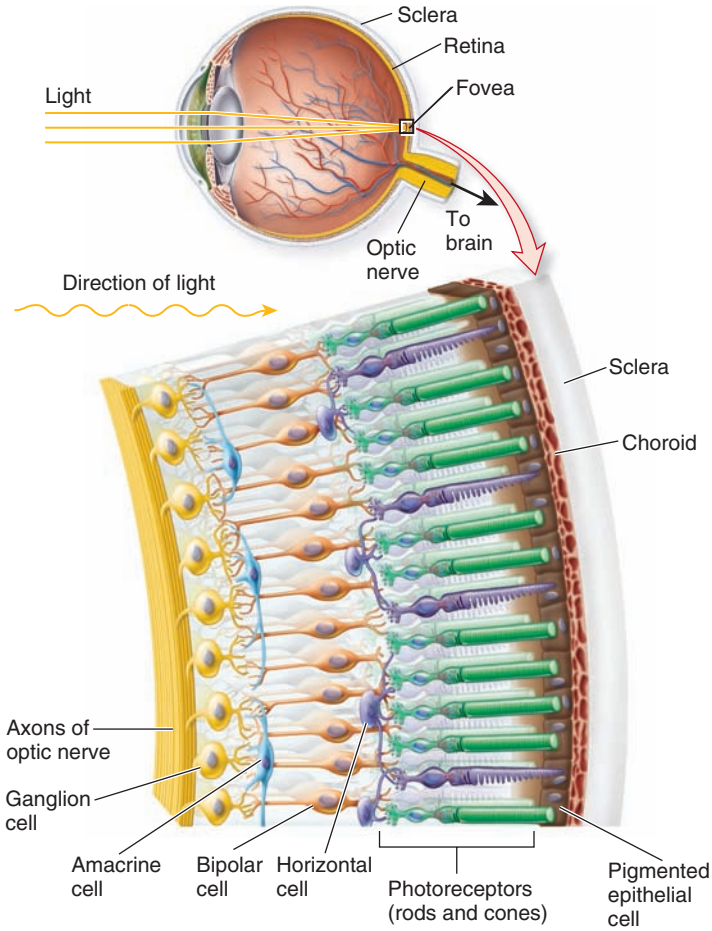

Figure 43.21 The arrangement of cells in the retina. Light passes through two layers of cells before it reaches the photoreceptors. Amacrine and horizontal cells integrate the responses of the bipolar and ganglion cells. The ganglion cells generate action potentials to carry the information to the brain.

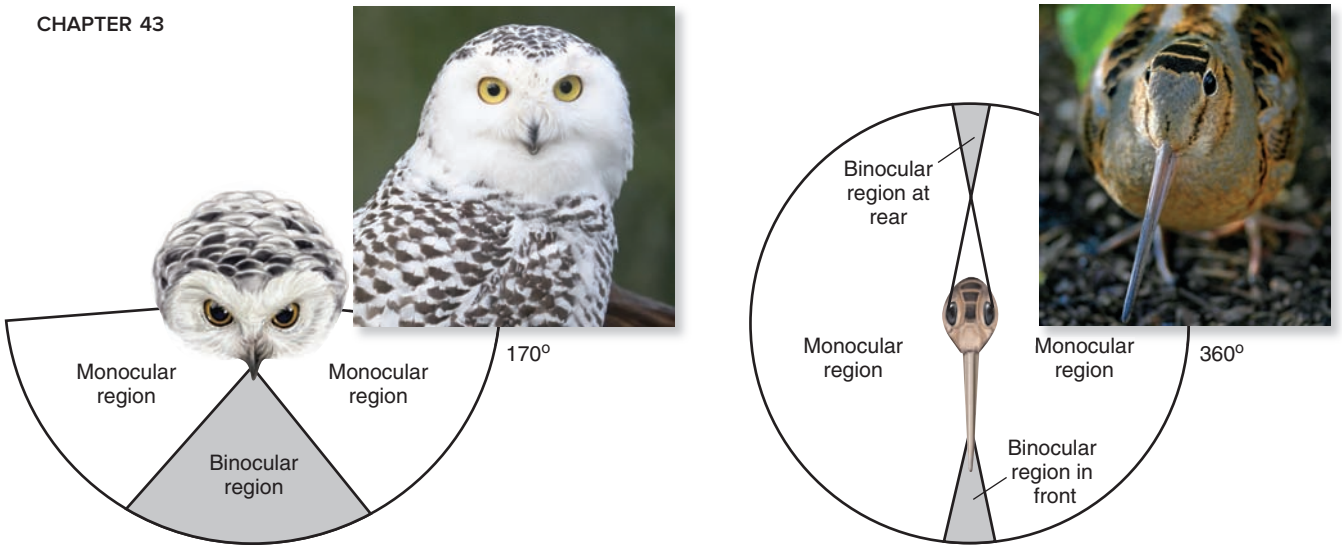
Concept Check: *With what cells do photoreceptors form synapses?*

middle layer contains **bipolar cells**, so named because one end (or "pole") of the cell synapses with the photoreceptors, and the other end relays responses to a top layer of cells, the **ganglion cells**. The ganglion cells send their axons out of the eye into the optic nerve. In addition, two other types of cells, horizontal and amacrine cells, are interspersed across the retina.

The pathway for light reception begins at the rods and cones. These photoreceptor cells release neurotransmitter molecules that affect the membrane potential of bipolar cells. The membrane potential of the bipolar cells determines the amount of neurotransmitter that they release, which, in turn, controls the membrane potential of ganglion cells. When a threshold potential is reached in ganglion cells, action potentials are sent out of the eye via the optic nerve to the brain. These signals travel along pathways that include the thalamus, brainstem, cerebellum, and the cerebral cortex. Visual information is further refined and interpreted within the vision centers of the cortex. The cortex responds to such characteristics of the visual scene as whether something is moving, how far away it is, how one color compares with another, and the nature of the image (for example, a face). The cortex does not form a picture in the brain, but forms a spatial and temporal pattern of electrical activity that is perceived as an image.

Horizontal and amacrine cells modify electrical signals as they pass from the photoreceptors to the ganglion cells. These cells adjust the signals significantly, enhancing an animal's ability to visualize a scene by emphasizing the differences between images. Horizontal cells make connections between photoreceptors and help to define the boundaries of an image. Amacrine cells are important in adjusting the eye to different light intensities and increasing the sensitivity of the eye to moving images. The ability of the retina to refine the image is especially well developed in birds and reptiles. These animals have complex retinas that process the image extensively before it is interpreted in the brain.



Vertebrate Eyes Are Adapted to Environmental Conditions and Life Histories

Many vertebrates show unique modifications of their visual systems that are the result of evolutionary adaptations to environmental conditions. Other adaptations have occurred as a result of behavioral requirements for obtaining food or attracting a mate.

Differences in Eye Placement Except for some of the ray-finned fishes, blunt-headed cetaceans, and most amphibians, vertebrate animals have some degree of **binocular** (or stereoscopic) **vision**. Animals with both eyes located at or near the front of the head, such as primates and raptors, have greater binocular vision, because the overlapping images coming into both eyes are processed together in the brain to form one perception (**Figure 43.22**). Binocular vision provides excellent depth perception because the images come into each eye from slightly different angles. The brain processes those tiny differences to determine where an object is relative to other objects in its environment. Predators benefit from binocular vision because it helps them judge distance and determine the location of their prey. Binocular vision is present in predatory birds such as the snowy owl (Figure 43.22a) and mammals (as well as in predatory insects such as mantids), and also in arboreal animals that must judge distances between tree limbs.

In contrast, animals with eyes on the sides of the head, such as most fishes, blunt-headed cetaceans, amphibians, herbivorous mammals, and insects, have strictly or primarily **monocular vision**. Monocular vision allows an animal to see a wide area at one time, at the cost of reduced depth perception. Many prey species have monocular vision, which may have evolved because it helps them scan for predators across a wide field of vision. The placement of the eyes in the American woodcock (*Scolopax minor*) actually permits a field of vision of 360°, most of which is monocular (Figure 43.22b); in other words, these and similar birds can see directly behind themselves, even when digging in the dirt for earthworms!

Vision in the Deep Sea Fishes and other deep-sea vertebrates have color vision that is limited primarily to the color blue. Light with longer wavelengths that would be seen as red or orange does not usually penetrate more than ~6 m into the water, whereas the higher-energy, shorter-wavelength light, which we perceive as blue, can penetrate to greater depths. Aquatic animals that live in the deep sea are usually capable of seeing only blue, because they generally have only one opsin, which is responsive to blue light. Deep-dwelling fishes tend to be drab-colored, because most wavelengths of light do not penetrate that far and therefore could not reflect off the surface of the fishes;

(a) Visual field of the snowy owl

(b) Visual field of the American woodcock

Figure 43.22 Examples of binocular and monocular fields of vision. Visual fields are shown for **(a)** the snowy owl (*Bubo scandiacus*) and **(b)** the American woodcock (*Scolopax minor*). Monocular regions are white; binocular regions are shaded.

BIOLOGY PRINCIPLE Living organisms interact with their environment. Different animals may interact with their environments in ways that are hard for us to imagine. Not only do different animals have vastly different visual fields, but some see better at night than we do, and some see wavelengths of light that we cannot see.

thus, there was no selection pressure for evolving bright coloration. In those deep-dwelling fishes with more than one type of opsin, the additional visual pigments detect the bioluminescence (self-generated light, like that of a firefly) produced by their own or other species.

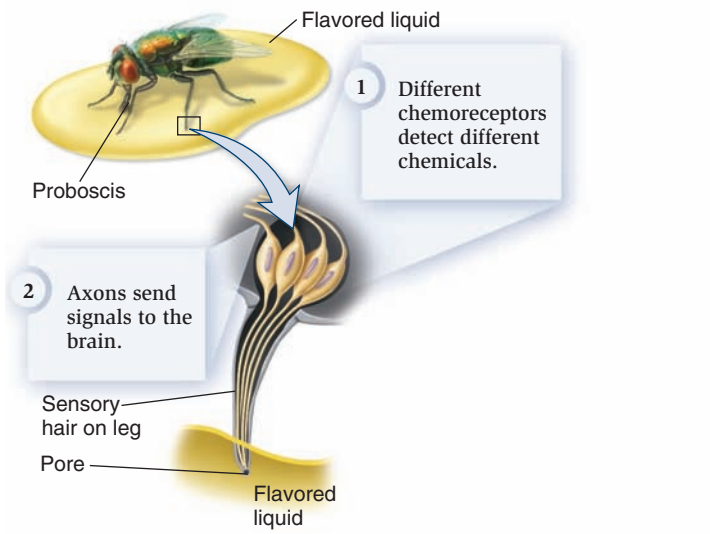
By contrast, fishes that live near the water's surface sometimes have four or five different opsins, giving them excellent color vision. Not surprisingly, shallow water and surface-dwelling fishes are often very colorful, because light of all wavelengths penetrates shallow water. These fishes have adapted by using coloration for protection (camouflage) or for identification.

Vision in the Dark: The Tapetum Lucidum Did you ever wonder why cats' eyes seem to glow in photographs, as in the chapter opening photo? What you see is light being reflected off the tapetum lucidum, a reflective layer of tissue located beneath the photoreceptors at the back of the eye in some animals. When light enters the retina, some of it passes into the layer containing the photoreceptors, but some light also passes through this layer. Normally, the pigmented epithelium at the back of the eye absorbs this light. However, in animals with a tapetum lucidum, the light reflects off this structure and back to the photoreceptors. This gives the photoreceptors a "second chance" to capture light, making it easier to detect low levels of light. Many nocturnal animals, both vertebrate and invertebrate, have a tapetum lucidum, which increases their ability to see in the dark.

43.6 Chemoreception

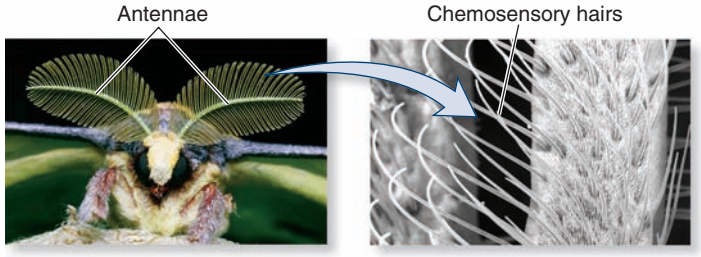
Learning Outcomes:

1. **SciSKILLS »** Describe olfaction and gustation in animals, and propose reasons why these senses are advantageous.
2. Explain how olfactory receptors respond to the binding of odor molecules.
3. Outline how receptor cells within taste buds respond to the binding of food molecules.



Chemoreception includes the senses of smell **(olfaction)** and taste **(gustation)**, both of which involve detecting chemicals in air, water, or food. These chemicals bind to chemoreceptors, which, in turn, initiate electrical responses in other neurons that send signals to the brain. Amazingly, the binding of a single molecule to a receptor cell can sometimes be perceived as an odor! Airborne molecules that bind to olfactory receptors must be small enough to be carried in the air and into the nose. Taste molecules can be heavier because they are conveyed in food and liquid.

Taste and smell are closely related. In fact, the distinction is largely meaningless for aquatic animals, because for them all chemoreception comes through the water. Even in terrestrial animals, about 80% of the perception of taste is actually due to activation of olfactory receptors. (This is why food loses its flavor when the sense of smell is impaired, such as when you have a cold.) In this section, we explore chemoreception in one class each of invertebrates and vertebrates.



Olfaction and Taste in Insects Involve Chemoreceptors in Sensory Hairs

Insects are highly dependent on odor and taste for finding food and mates. In insects, chemoreceptors are neurons that are located on sensory hairs on the proboscis (coiled tongue), legs, feet, and antennae. Each sensory hair on the proboscis and feet has a pore at the tip through which the substance passes. As the example in **Figure 43.23a** shows, a blowfly has four separate chemoreceptors within each hair, and each of these neurons responds to different molecules. Dendrites of the chemoreceptor cells inside the pore bind to the molecules and initiate a sensory transduction pathway that opens ion channels in the membrane. This depolarizes the plasma membrane of the chemoreceptor cell and generates action potentials, which are sent to the brain for interpretation.

In certain moths, males have elaborate antennae that can sense pheromones, extremely potent signaling molecules given off by a female. The female secretes a sex-attractant pheromone into the air

(a) Chemoreception in the blowfly

(b) Chemosensory hairs on antennae of the male moth detect the odor molecules.

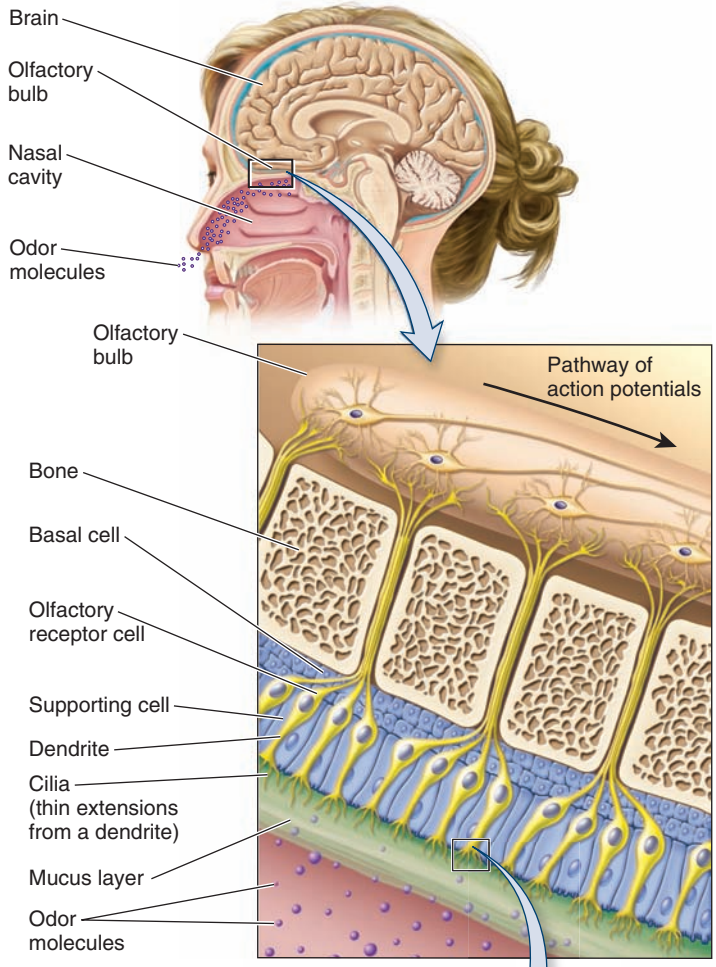


Figure 43.23 Chemoreception in insects. **(a)** Chemosensory cells of the blowfly located on the proboscis, legs, and feet sense different chemicals. **(b)** Chemosensory hairs on a male's antennae bind odor molecules secreted by females.

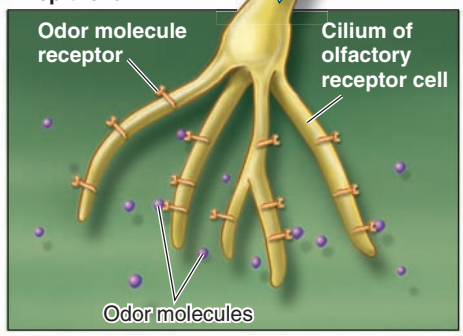
from an abdominal gland and the chemosensory hairs on the male's antennae (**Figure 43.23b**) can detect extremely low concentrations of it from several kilometers away. This highly sensitive detection system enables the male to locate the female in the dark.



Mammalian Olfactory Receptors Respond to the Binding of Odor Molecules

The olfactory sensitivity of mammals varies widely depending on their supply of olfactory receptor cells, which ranges from 5 or 6 million in humans to 100 million in rabbits and 220 million in dogs. Olfactory sensory receptors are neurons that are located in the epithelial tissue at the upper part of the nasal cavity in mammals (**Figure 43.24a**). These cells are surrounded by two additional cell types: supporting cells and basal cells. Supporting cells are located between the receptor cells and provide physical support for the olfactory receptors. The basal cells differentiate into new olfactory receptors every 30–60 days, replacing those that have died after prolonged exposure of their cell endings.

Olfactory sensory receptors have dendrites from which long, thin extensions called cilia extend into a mucous layer that covers

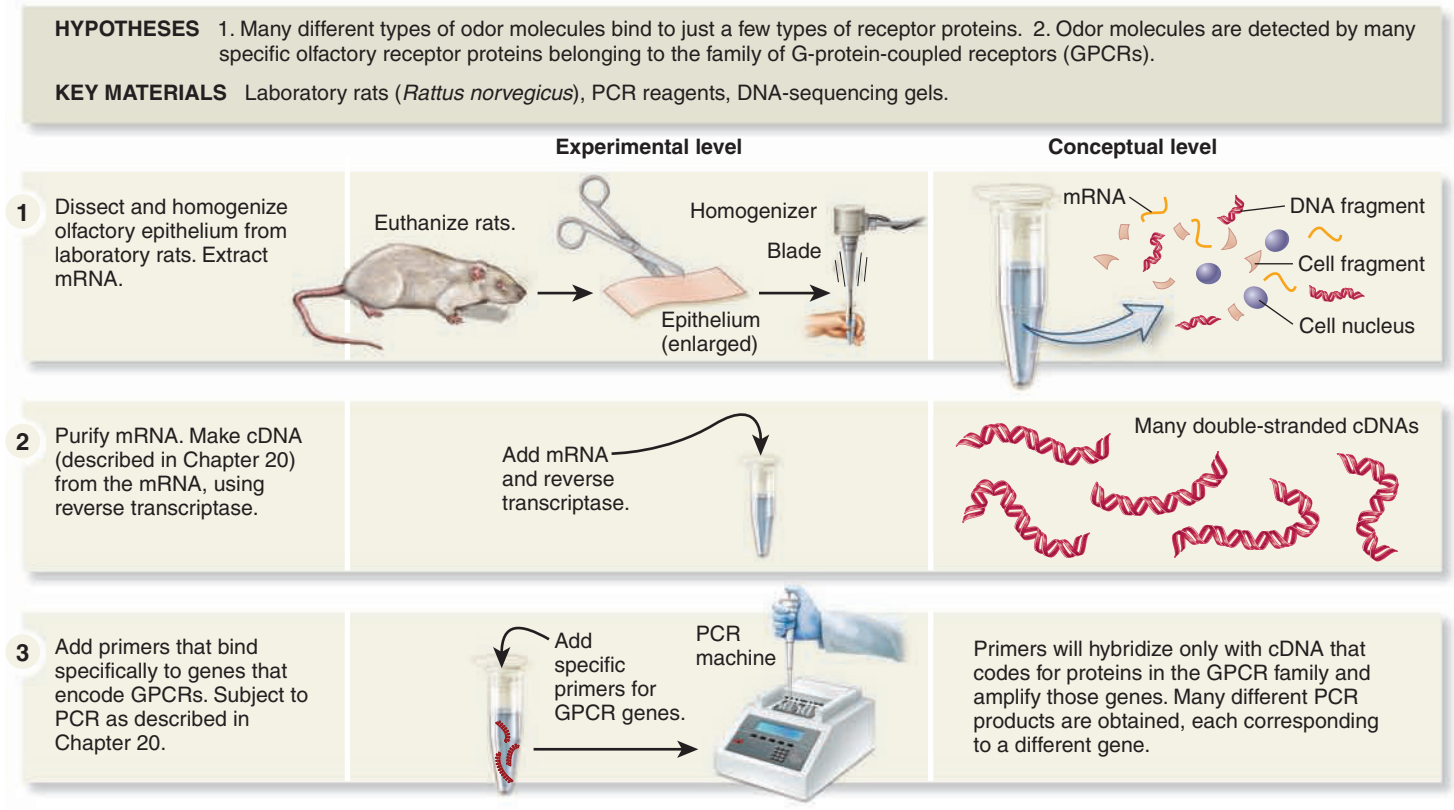
(a) Olfactory receptor cells in olfactory epithelium

(b) Cilia from dendrite with odor molecule receptors

Figure 43.24 Olfactory structures in the human nose. Odor molecules dissolve in a layer of mucus that coats the olfactory receptor cells. The molecules bind to protein receptors in the membrane of cilia that extend from the olfactory receptor cells. Action potentials in the olfactory receptor cells are conducted to cells in the olfactory bulb, and from there to the brain for interpretation. Basal cells periodically differentiate into new olfactory receptor cells, replacing dead or damaged cells.

the epithelium. Despite the superficial similarity in structure, these cells do not function like the mechanoreceptor hair cells of the auditory and vestibular systems; these cilia are different from hair cell stereocilia, which bend. Instead, olfactory receptor cells have receptor

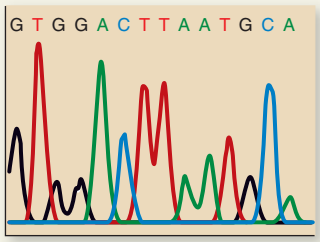
proteins within the plasma membranes of the cilia, which provide an extensive surface area (**Figure 43.24b**). Airborne molecules dissolve in the mucus and bind to these olfactory receptor proteins. When an odor molecule binds to its receptor protein, it initiates a signal transduction pathway that ultimately opens Na^+ channels in the plasma membrane. The subsequent depolarization results in action potentials being transmitted to the next series of cells in the olfactory bulbs of the brain. The olfactory bulbs are a collection of neurons that act as an initial processing center of olfactory information and relay it to the cerebrum for further processing and interpretation.



The relative size of the olfactory bulbs indicates the importance of olfaction to an animal. In humans, the olfactory bulbs make up only about 5% of the weight of the brain, whereas in nocturnal animals like rats and mice, they can comprise as much as 20%. Even with their relatively limited olfactory sensitivity, however, humans have the capacity to detect 10,000 or more different odors. In fact, recent evidence suggests that this number may be as high as 1 trillion! Exactly how this is possible remained a mystery until 1991, when two scientists uncovered the molecular basis of olfaction.

Feature Investigation | Buck and Axel Discovered a Family of Olfactory Receptor Proteins That Bind Specific Odor Molecules

How does the olfactory system discriminate among thousands of different odors? American neuroscientists Linda Buck and Richard Axel set out to answer this question. When they began, two hypotheses were proposed to explain this phenomenon. One possibility was that many different types of odor molecules might bind to one or just a few types of receptor proteins, with the brain responding differently depending on the number or distribution of the activated receptors. The second hypothesis was that olfactory receptor cells can make many different types of receptor proteins, each type binding a particular odor molecule or group of odor molecules.

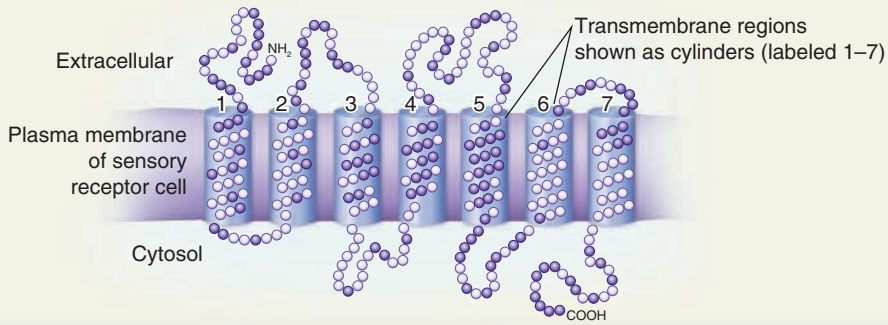


To begin their study, Buck and Axel assumed that olfactory receptor proteins would be highly expressed in the olfactory sensory receptor cells, but not in other parts of the body. Based on previous work, they also postulated that the receptor proteins would be members of the large family of G-protein-coupled receptors (GPCRs). As shown in **Figure 43.25**, they isolated olfactory sensory receptor cells from rats and then used a homogenizer to break open the cells to release the mRNA. The mRNA was purified and then used to make complementary DNA (cDNA) using the enzyme reverse transcriptase. This generated a large pool of cDNAs, representing all of the genes that were expressed in the receptor cells at the time of mRNA collection. To determine if any of these cDNAs encoded GPCRs, they used primers that recognized conserved regions within previously identified genes that encoded GPCRs. A conserved region is a DNA sequence that rarely changes among different members of a gene family. The primers were used in the PCR technique to amplify

Figure 43.25 **Buck and Axel identified olfactory receptor proteins in olfactory receptor cells.**

4 Subject each PCR product to DNA sequencing, also described in Chapter 20.

Output from Automated Sequencing (example)



Different GPCRs will have slightly different DNA sequences.

5 THE DATA

At least 100 different GPCRs were uniquely expressed in olfactory sensory receptor cells. Analysis of their predicted amino acid sequences revealed significant variability in the putative ligand-binding regions (transmembrane domains 3–5).

- Amino acids that were the same in all the olfactory GPCRs.
- Amino acids that were different among the olfactory GPCRs.

6 CONCLUSION Olfactory receptor cells express many different receptor proteins that account for an animal's ability to detect a wide variety of odors.

7 SOURCE Buck, L., and Axel, R. 1991. A novel multigene family may encode odorant receptors: A molecular basis for odor recognition. *Cell* 65:175–187.

cDNAs that encoded GPCRs. This produced many PCR products that were then subjected to DNA sequencing. As shown in the data in step 5 of Figure 43.25, Buck and Axel initially identified at least 100 different genes, each encoding a GPCR with a slightly different amino acid sequence, as predicted from the DNA sequences. Significant variability in the predicted amino acid sequences for the GPCRs was found in the putative ligand-binding region of the molecules (believed to be transmembrane domains 3–5). Further research showed that these genes were expressed in olfactory cells, but not in other parts of the body. These results were consistent with the second hypothesis, namely, that organisms produce a large number of distinct olfactory receptor proteins, each type binding a particular odor molecule or a group of related odor molecules.

Since these studies, researchers have determined that this family of olfactory genes in mammals is surprisingly large. In humans, roughly 400 genes encode olfactory receptor proteins. Each olfactory receptor cell is thought to express only one type of GPCR that recognizes its own specific odor molecule or group of closely related molecules. Most odors that an animal encounters, however, are due to multiple chemicals that activate many different types of odor receptors at the same time. We perceive odors based on the combination of receptors that become activated. This ability to combine different inputs allows animals such as humans to perceive at least thousands of different odors despite expressing only a few hundred different olfactory receptor proteins.

The research of Buck and Axel explained, in part, how animals detect a myriad of odors. In 2004, they received the Nobel Prize in Physiology or Medicine for this pioneering work.

Experimental Questions

1. What were the two major hypotheses to explain how animals discriminate between different odors? How did Buck and Axel test the hypothesis of multiple olfactory receptor proteins?
2. **SciSKILLS** » Of the two hypotheses explaining how animals discriminate between different odors (see question 1), which one was supported by the results of this experiment? With the evidence presented by Buck and Axel, what is the current hypothesis explaining the discrimination of odors in animals?
3. **SciSKILLS** » Predict the survival or reproductive advantages that may be provided to animals by the ability to sense thousands or more different types of odors.

Taste Buds Detect Food Molecules

Chemical senses are present in all animal phyla, although not all animals have taste-sensing organs. Many animals use their taste (gustation) sense to select appropriate foods. For example, butterflies select nectar based on the sugars found in a particular flower, and carnivorous animals detect the taste of different meats based on the combination of amino acids, fats, and sugars that are present. Some freshwater and marine animals, such as catfish and lobsters, have exceptionally sensitive chemoreceptors for specific amino acids that are particularly important as neurotransmitters in the nervous system. Taste can also help an animal seek out necessary nutrients, such as salt, and avoid poisonous chemicals. Toxic substances are often perceived as bitter or distasteful, which may cause an animal to immediately stop eating any such substance.

Taste buds are structures containing chemosensory cells that detect particular molecules in food. The bumps that you see on your tongue are not the taste buds but the papillae, elevated structures on the tongue that collect food molecules in depressions called taste pores. These pores contain many taste buds with sensory receptor cells (**Figure 43.26**). The sensory receptor cells form a complex structure with several supporting cells that is organized like the wedges of an orange. The tips of the sensory receptor cells have microvilli that extend into the taste pore (another example of an anatomical sensory adaptation that increases surface area). Here, molecules in food that have dissolved in saliva bind to receptor proteins. This triggers intracellular signals that alter ion permeability and membrane potentials. The sensory receptor cells then release neurotransmitters onto underlying sensory neurons. Action potentials travel from these neurons to the thalamus and other regions of the forebrain, where the taste is perceived and recognized.

There are a number of different types of taste cells, and they are distributed on the tongue in different areas, but these areas overlap considerably. Each type of cell has a specific transduction mechanism that allows it to detect specific chemicals present in ingested foods and fluids. Their activation results in the perception of sweet, sour, salty, and bitter tastes. In addition, a recently recognized fifth taste perception called umami (after the Japanese word for delicious) is associated with the presence in ingested food of glutamate and other similar amino acids, and is usually described as imparting flavorfulness to food. It may account for the widely recognized effects of monosodium glutamate (MSG) in enhancing the flavor of food.

The senses of taste and smell are enhanced when we are hungry, a phenomenon that most likely occurs in other animals as well. Once we have eaten, we are less aware of the smell and taste of food. The importance of this for survival is clear: A hungry animal needs to eat. An improved sense of smell aids in locating food, and a heightened sense of taste encourages an animal to eat. Afterward, these senses become temporarily dampened so as not to distract an animal from its other needs. The mechanism by which these changes occur is uncertain, but it may involve a temporary alteration in the number of smell and taste receptors, or in their ability to bind ligands.

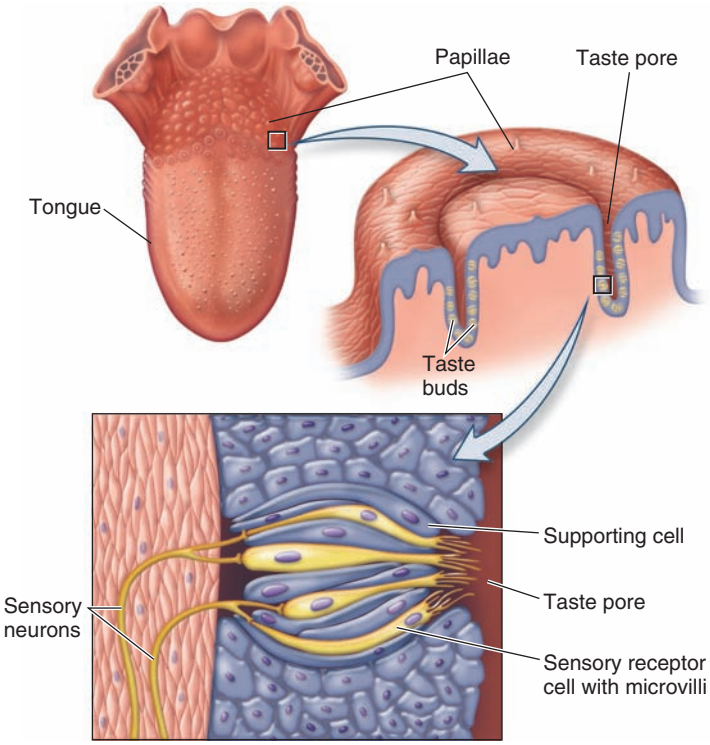


Figure 43.26 Structures involved in the sense of taste. This sense occurs in taste buds, which contain the sensory receptor cells that respond to dissolved food molecules.

Concept Check: *Why have many animals, including humans, evolved the ability to sense salty, sweet, sour, bitter, and umami?*

BIO TIPS **THE QUESTION** *Look at Figures 43.13d, 43.16, 43.23, 43.24, and 43.26. Despite their many differences, the sensory receptor cells depicted in these figures share at least one important similarity in their general structures. Can you identify that structural similarity?*

TOPIC ***What topic in biology does this question address?*** The topic is sensory receptor cells in animals. More specifically, the question asks you to find a structural similarity shared by many of these receptors.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you know that there is at least one important structural feature that is common to these sensory receptor cells: the insect photoreceptor, the vertebrate photoreceptors, the invertebrate chemosensory cell, the vertebrate olfactory receptor cell, and the vertebrate gustatory sensory receptor cell. From your understanding of the topic, you know that sensory receptor cells are highly specialized structures that have evolved to detect and discriminate among particular types of stimuli.

PROBLEM-SOLVING STRATEGY ***Compare and contrast. Relate structure and function.*** To answer this question, look carefully at the structural features of these various sensory receptors, and compare their structural features to identify a similarity they share.

ANSWER *In each of these sensory receptors, structural adaptations are present that greatly increase the total surface area of the cell. These adaptations include microvilli, cilia, and hairs. Despite their differences in overall appearance and in the stimuli to which they respond, many animal sensory receptors have evolved structures with extensive surface areas to optimize their ability to detect environmental signals such as light and chemicals.*

43.7 Impact on Public Health

Learning Outcome:

1. Identify common types of visual and hearing deficits in humans and the causes of each.

Sensory disorders are among the most common neurological problems found in humans and range from mild (needing eyeglasses or a hearing aid) to severe (blindness or deafness). This section presents an overview of a few representative sensory disorders that have a major impact on public health.

Visual Disorders Include Glaucoma, Macular Degeneration, and Cataracts

Visual disorders affect an enormous number of people. In the U.S. alone, more than 10 million people have severe eye problems that cannot be corrected by eyeglasses, and more than 1 million people are blind (42 million worldwide). The costs to the U.S. government associated with blindness and severe visual loss amount to nearly $4 billion yearly. Although vision loss has many causes, three disorders account for over half of all cases: glaucoma, macular degeneration, and cataracts.

Glaucoma Normally, the fluid that makes up the aqueous humor in the eye is produced and reabsorbed (drained) in a circulation that keeps the fluid levels constant. In **glaucoma**, drainage of aqueous humor becomes blocked, and the pressure inside the eye increases as the fluid level rises. If untreated, this eventually damages cells in the retina and leads to irreversible loss of vision (**Figure 43.27a**). The cause of glaucoma is not always known, but in some cases it is due to trauma to the eye, chronic use of certain medicines, or diseases such as diabetes. Some forms of glaucoma may have a genetic component. Glaucoma can be treated with eye drops that reduce fluid production in the eye or with laser surgery to reshape the drainage structures in the eye. The American Foundation for the Blind estimates that 400,000 new cases of glaucoma are diagnosed each year in the U.S., and up to 10 million individuals have elevated eye pressure. Glaucoma accounts for roughly 10% of all cases of blindness in the U.S.

Macular Degeneration In **macular degeneration**, photoreceptor cells in and around the macula (the region that contains the fovea) are lost. Because this is the region where cones are most densely packed, this condition is associated with loss of sharpness and color vision (**Figure 43.27b**). It usually does not occur before age 60, but in some cases it is hereditary and can occur at any age. Risk factors in addition to heredity include smoking, hypertension, elevated blood cholesterol, and obesity. Macular degeneration is the leading cause of blindness in the U.S., accounting for roughly 25% of all cases, but its causes remain obscure.

(a) How the world is seen by a person with glaucoma

(b) How the world is seen by a person with macular degeneration

(c) How the world is seen by a person with cataracts

Figure 43.27 Appearance of the visual field in a person with (a) glaucoma, (b) macular degeneration, and (c) cataracts.

Cataracts **Cataracts**, regions of accumulation of protein in the lens, cloud the lens and cause blurring, poor night vision, and difficulty focusing on nearby objects (**Figure 43.27c**). By age 65, as many as 50% of individuals have one or more cataracts in either eye, and this jumps to 70% by age 75. Many cataracts are small enough not to affect vision. In fact, many people do not even realize they have cataracts until they undergo an eye exam. The causes of cataracts are not all known but include trauma, medicinal drugs, diabetes, and heredity. The treatment, when needed, is usually to have the affected lens surgically removed and replaced with an artificial lens. Nearly 1.4 million such surgeries are performed each year in the U.S. Without the natural lens, which helps protect the retina by absorbing some of the high-energy UV light from the Sun, the retina must be protected during the day by wearing dark sunglasses.

Damaged Hair Cells Within the Cochlea Can Cause Deafness

Deafness (hearing loss) is usually caused by damage to the hair cells within the cochlea, although some cases result from functional problems in brain areas that process sound or in the nerves that carry information from the hair cells to the brain. When the hair cells are damaged, noises have to be louder to be detected, and an affected person may require the use of hearing aids to amplify incoming sounds.

Hearing loss may be mild or severe and may result from many causes, including injury to the ear or head, hereditary defects of the inner ear, and exposure to certain diseases (for example, rubella) or toxins during fetal life. By far, however, the most significant cause of hearing loss is repeated, long-term exposure to loud noise. The amplitude of a sound wave (that is, the distance between the peak and the trough of the wave) determines its loudness; as the amplitude of a sound wave gets larger, the perceived loudness of the sound increases. The loudness of sound is measured in decibels (technically, decibels measure the intensity of the pressure of the sound, which we perceive as loudness). The decibel (dB) scale is logarithmic; an increase of 10 dB represents a 10-fold increase in sound pressure, and thus a louder sound. Normal conversation is about 60 dB, a chainsaw is 108 dB, and a jet plane taking off can reach 150 dB. Estimates of noise-induced hearing loss, which usually results from job-related activities, range from 7% to 21% of all cases of hearing loss worldwide; this makes it the leading occupational disorder in the U.S. It is, therefore, one of the most significant disabilities in the U.S. in terms of numbers of people affected and costs to society. Scientists estimate that nearly 40 million people are exposed daily to dangerous noise levels in the U.S. as a result of their occupation.

Recent research has led to a better understanding of the mechanism by which noise impairs hearing. Chronic exposure to loud sounds appears to produce a state of metabolic exhaustion in the hair cells of the cochlea. As a result, the cells become fatigued and are unable to maintain normal biochemical processes. One consequence of this is a buildup of free radicals. These compounds oxidize lipids in cellular membranes, damaging the membranes in the process. Mitochondrial membranes appear to be particularly susceptible to these free radicals. Once mitochondria are destroyed, a cell's ability to produce the ATP needed to fulfill its energy demands is compromised, and the cell dies. As hair cells die, the ear becomes less sensitive to sound.

Researchers are investigating drugs that might prevent the formation of free radicals in the cells of the ear, but such drugs are not yet available. If a cochlea is severely damaged, it can be surgically replaced with artificial cochlear implants. In response to sound waves, these devices generate electrical signals that can stimulate the auditory nerve, which communicates with the brain. Cochlear implants cannot restore hearing to normal, but they can make it possible to hear conversations.

Summary of Key Concepts

43.1 An Introduction to Sensation

- Sensory transduction is the process by which incoming stimuli are converted to neural signals. Perception is an awareness of the sensations that are experienced. Sensory receptors are either neurons or specialized epithelial cells that respond to stimuli and begin the process of sensory transduction. A sensory receptor often responds to a stimulus by eliciting a graded response proportional to the intensity of the stimulus (Figures 43.1, 43.2).
- Sensory receptors can be divided into the general classes of mechanoreceptors, thermoreceptors, nociceptors, electromagnetic receptors, photoreceptors, and chemoreceptors.

43.2 Mechanoreception

- Mechanoreceptors respond to physical stimuli such as touch, pressure, stretch, movement, and sound. In mammals, several types of receptors in the skin detect stimuli such as touch and pressure, including Meissner corpuscles, Ruffini corpuscles, and Pacinian corpuscles (Figure 43.3).
- Hair cells have projections called stereocilia that respond to movements of fluid or other stimuli and release neurotransmitter that may result in action potentials in an adjacent sensory neuron (Figure 43.4).
- Audition (hearing) is the ability to sense sound waves and is well developed in vertebrates. The mammalian ear has three main compartments: the outer, middle, and inner ear (Figure 43.5).
- Sound waves move through outer ear, tympanic membrane, malleus, incus, and stapes to the cochlea of the ear, where they cause the basilar membrane to vibrate. This causes the stereocilia of overlying hair cells to bend, which results in action potentials being sent to the brain, leading to the perception of sound (Figures 43.6, 43.7).
- Many adaptations for hearing improve an animal's ability to sense sound in diverse environments.
- Statocysts in certain invertebrates allow an animal to sense its body position or equilibrium. The vestibular system in vertebrates allows animals to sense linear and rotational movement (Figures 43.8, 43.9).
- The lateral line system of fishes consists of hair cells that detect water movements (Figure 43.10).

43.3 Thermoreception and Nociception

- Thermoreceptors in the skin and brain allow an animal to sense external and internal temperatures, respectively. Nociceptors in the skin and internal organs sense pain, an important survival adaptation in animals.

43.4 Electromagnetic Reception

- Some animals can detect electrical and magnetic stimuli; in some cases, this ability is used to locate prey (Figure 43.11).

43.5 Photoreception

- The eyecup in flatworms is a simple eye that detects light and its direction but does not form an image. The compound eye found in many invertebrates consists of many ommatidia that focus light (Figures 43.12, 43.13).
- The single-lens eye is found in vertebrates and certain invertebrates. In such an eye, images in the animal's field of view emit patterns of light that are transmitted through the pupil and the lens to a layer of photoreceptors called the retina. This forms a visual image of the environment on the retina. Activation of photoreceptors triggers electrical changes in neurons that pass out of the eye through the optic nerves, carrying the signals to the brain, which then interprets the visual image that was transmitted. Stretching and flattening of the lens aids in focusing on objects at varying distances (Figure 43.14).
- Rods and cones are photoreceptors found in the vertebrate eye. Rods do not discriminate colors; cones can detect color. The visual pigment in rods and cones consists of retinal and a protein called opsin (Figures 43.15, 43.16, 43.17).
- Red-green color blindness is due to a defect in a type of opsin found in cone pigments (Figure 43.18).
- Absorption of photons by retinal triggers a signal transduction pathway that causes hyperpolarization of the cell leading to a visual image (Figures 43.19, 43.20).
- The retina is composed of layers of cells, including photoreceptors, that receive light input and convey electrical signals to the visual centers of the brain via the optic nerve (Figure 43.21).
- The vertebrate eye has several adaptations that aid in proper vision for particular animals (Figure 43.22).

43.6 Chemoreception

- Invertebrates have taste receptors on their proboscis, legs, feet, and antennae. Some insects can detect pheromones (Figure 43.23).
- In mammals, olfactory receptors are neurons located in epithelial tissue at the upper part of the nasal cavity. They contain cilia with protein receptors that bind specific odor molecules. The binding initiates a signal transduction pathway that ultimately depolarizes the plasma membrane and transmits action potentials to the olfactory bulb of the brain. Buck and Axel discovered that olfactory sensory receptors have many different types of protein receptors for odor molecules (Figures 43.24, 43.25).
- Taste buds contain chemosensory cells that detect molecules in food. There are different types of taste cells, the activation of which results in the perception of five tastes: sweet, sour, salty, bitter, and umami (Figure 43.26).

43.7 Impact on Public Health

- Common visual disorders include glaucoma, macular degeneration, and cataracts. Prolonged exposure to intense sound can damage hair cells within the cochlea and lead to deafness (Figure 43.27).

Assess and Discuss

Test Yourself

1. The process whereby incoming sensory stimulation is converted to electrical signals in neurons is called
   a. an action potential.
   b. sensory reception.
   c. perception.
   d. sensory transduction.
   e. perceptual transduction.
2. Vibrations of the _____, located within the _____, bend stereocilia in the mammalian ear and activate sensory neurons.
   a. tympanic membrane, cochlear duct
   b. round window, middle ear
   c. basilar membrane, organ of Corti
   d. ossicle, outer ear
   e. ampulla, semicircular canals
3. _____ sense pain; _____ sense heat or cold; and _____ sense touch.
   a. Mechanoreceptors; thermoreceptors; nociceptors
   b. Nociceptors; thermoreceptors; mechanoreceptors
   c. Nociceptors; thermoreceptors; stretch receptors
   d. Mechanoreceptors; nociceptors; stretch receptors
   e. Nociceptors; photoreceptors; mechanoreceptors
4. Statocysts are sensory organs for
   a. hearing found in many invertebrates.
   b. equilibrium found in mammals.
   c. equilibrium found in many invertebrates.
   d. water current changes found in fish.
   e. hearing found in vertebrates.
5. Which process(es) are hair cells involved in?
   a. balance in vertebrates and invertebrates
   b. hearing in mammals
   c. vision in animals with compound eyes
   d. heat sensing in pit vipers
   e. both a and b
6. Which statement about compound eyes is *true*?
   a. They do not contain a lens or lenslike structure.
   b. They cannot sense color.
   c. They have from 1 to 10 ommatidia.
   d. They are found in insects and also many vertebrates.
   e. They probably have less resolving power than single-lens eyes.
7. In the mammalian eye, light from near or far objects is focused on the retina when
   a. the lens moves forward or backward.
   b. the lens rounds up or flattens.
   c. the eyeball changes shape.
   d. the cornea changes shape.
   e. the retina changes shape.
8. The amount of glutamate release from photoreceptors of the vertebrate eye is highest when
   a. an animal is in full sunlight.
   b. an animal is in a completely dark place.
   c. an animal is in a dimly lit place.
   d. Na^+ channels of the photoreceptors are closed.
   e. Both a and d are true.

9. Cone pigments detect different wavelengths of light due to
   a. their location in the retina.
   b. the amount of light they absorb.
   c. the type of retinal they have.
   d. the type of opsin protein they have.
   e. interactions with bipolar cells.
10. The stimulation for olfaction involves odorant molecules
   a. bending the cilia of olfactory sensory receptor cells.
   b. binding to protein receptors of olfactory sensory receptor cells.
   c. entering the cytoplasm of olfactory sensory receptor cells.
   d. opening K^+ channels of olfactory sensory receptor cells.
   e. binding to cells located in the olfactory bulbs.

Conceptual Questions

1. Distinguish between sensory transduction and perception.
2. Despite the differences in their appearances, can you identify structural and functional similarities in the compound and single-lens eyes found in animals?
3.  A principle of biology is that *living organisms interact with their environment*. This is certainly a fundamental principle of sensory neuroscience. Of the ways in which you use your senses to interact with the environment, which do you think is the least important?

Collaborative Questions

1. Discuss the several types of sensory stimuli that animals can detect, and some general features of the sensory receptors that are adapted for each of these stimuli.
2. Explain how the structures of the mammalian ear are adapted to detect and distinguish different frequencies of sound.

Muscular-Skeletal Systems and Locomotion

44

European tree frog (*Hyla arborea*) using its muscular-skeletal system to leap from a leaf.

In 1991, Olympic athlete Mike Powell established a record long jump of 8.95 m, roughly 5 times the height of a person. A jump of nearly 9 m sounds impressive, and it is for us, but how do humans compare with other animals? Red kangaroos can hop up to 12 m while running at top speed. Some tree frogs, however, like the one shown in the chapter opening photo, can leap distances up to 1.4 m without a running start, yet the frog is only 4.5 cm long and weighs only 8 g! This is a sensational leap for an animal that size, roughly 30 times its body length. The jumping abilities of frogs are related to their relatively large leg muscle mass, the elongation of the bones in their legs and feet, and elastic elements in the connective tissue associated with their muscle and bone. Indeed, the jumping ability of frogs makes them excellent model organisms for the study of muscle function in vertebrates.

Muscles are composed of highly specialized cells that have the ability to contract in response to stimuli. The three types of muscle—skeletal, smooth, and cardiac—were introduced in Chapter 40. This chapter will explore the structure and function of skeletal muscle and how skeletal muscle controls movements such as those required for **locomotion**, the movement of an animal from place to place.

For skeletal muscles to produce locomotion, they must exert a force on an animal's skeleton. We begin the chapter, therefore, with an overview of animal skeletons. Then we will examine the structure and function of skeletal muscle and see how the interaction of two muscle proteins, actin and myosin, produces muscle contraction. Next, we will consider various modes of locomotion in animals. We will conclude with a consideration of important bone and muscle diseases in humans.

44.1 Types of Animal Skeletons

Learning Outcomes:

1. Distinguish between exoskeletons and endoskeletons.
2. **SciSKILLS** » Relate the structure of an exoskeleton to its function, and propose reasons why such a skeleton provides advantages to an animal.
3. List the major functions of the vertebrate skeleton.
4. Describe the composition of vertebrate bone.

When we think of the word skeleton, an image of the vertebrate system of bones usually comes to mind. However, invertebrates possess a skeleton as well, although it is not made of bone. Therefore, a broader definition of a **skeleton** is a structure that serves one or more functions related to support, protection, and locomotion. Using this definition, the two major types of skeletons found in animals are exoskeletons and endoskeletons. A third type of skeleton that broadly fits the definition is called a hydroskeleton (which will not be discussed in this chapter); this type is found in some soft-bodied invertebrates that use water pressure to propel their bodies.

Exoskeletons Are on the Outside of Animal Bodies

Arthropods have an **exoskeleton**, an external skeleton that surrounds and protects most of the body surface (**Figure 44.1a**). Exoskeletons provide support for the body, protection from the environment and predators, and protection for internal organs. The arthropod skeleton is made of a polysaccharide called chitin, and in crustaceans

such as lobsters and shrimp, it is sometimes strengthened with calcium and other minerals. Exoskeletons are often tough, durable, and segmented to allow movement. However, to allow growth, they must be periodically shed, regrown, and strengthened again, a process called ecdysis, or molting. A disadvantage of exoskeletons is that when an animal is molting, its new exoskeleton is temporarily soft, making the animal more vulnerable to predators and the environment.

Exoskeletons vary enormously in their complexity, thickness, and durability. The differences in exoskeletons are usually adaptations that enhance an animal's survival. Think, for example, of the difference between the wing of a butterfly and the body surface of a lobster. A butterfly's exoskeleton must be light enough for the animal to fly, whereas the thick, tough exoskeleton of the lobster provides a very effective defense against predators. Exoskeletons may seem somehow primitive compared with the endoskeletons of vertebrates (discussed next), particularly because of the requirement for molting. Even so, arthropods are among the most successful of all animal phyla living today, having survived for hundreds of millions of years and inhabiting nearly every possible ecological niche on the planet. Clearly, exoskeletons have been sufficient for one of the planet's greatest success stories.

Endoskeletons Are Internal Support Structures

Like exoskeletons, **endoskeletons** provide support and protection. Unlike exoskeletons, however, endoskeletons are internal structures and do not protect the body surface. Some endoskeletons do, however, protect internal organs such as those in the thorax of vertebrates.

Various types of endoskeletons are found in some species of sponges and all echinoderms and vertebrates. Minerals including Ca^{2+}, Mg^{2+}, PO_4^{2-}, and CO_3^{2-} supply the hardening material that gives an endoskeleton its firm structure. The endoskeletons of sponges and echinoderms consist of spiky networks of proteins and minerals, or mineralized platelike structures, respectively. Beneath the body surface of echinoderms, for example, arrays of mineralized plates made largely of $CaCO_3$ extend into the spines and arms that radiate from the main body (**Figure 44.1b**).

Vertebrate endoskeletons, by contrast, are composed of either cartilage (refer back to Figure 40.5), as in cartilaginous fishes (sharks, rays, and skates), or both cartilage and bone, as in bony fishes, amphibians, reptiles, birds, and mammals.

Bone Consists of a Mixture of Organic and Mineral Components

Bone is a living, dynamic tissue with both organic and mineral components. Organic materials include cells that form bone—called osteoblasts and osteocytes—and cells that break it down—called osteoclasts. The organic part of bone is secreted by osteoblasts and osteocytes, and consists of the protein collagen, which has a unique triple helical structure that gives bone both strength and flexibility (refer back to Figure 10.2). The mineral component is composed of a crystalline mixture of primarily Ca^{2+} and PO_4^{2-} and other ions that provide bone its rigidity. These ions must be obtained in an animal's diet, absorbed into the blood, and deposited in bone.

A proper proportion of organic and mineral components is required for normal bone function. Bone lacking sufficient mineral, for example, is easily fractured. Bone is formed at high rates during an animal's growth periods, but even in adulthood bone is continuously formed, broken down, and re-formed. The skeleton is continually changing—the one in your body right now is completely remodeled from the one that was in your body a few years ago. Similarly, the skeleton you will have a few years from now will be different from the one you have today.

The Vertebrate Skeleton Performs Several Important Functions

In the vertebrate skeleton, bones are connected in ways that allow for support, protection of internal structures, and movement. The

(b) Echinoderm (sea star) and (right) SEM of its endoskeleton

Figure 44.1 Types of skeletons. (a) Exoskeleton. An arthropod's skeleton covers and protects its body, but it must be periodically shed and replaced to allow growth of the animal, as shown in this photo. **(b)** Endoskeleton. Echinoderms such as the sea star (starfish) have endoskeletons of bony plates made of calcium carbonate ($CaCO_3$) shown in close-up in the inset. Vertebrate endoskeletons will be described later.

BIOLOGY PRINCIPLE Living organisms grow and develop. Part of the growth and development of animals involves their skeletons, as shown in this figure. For animals with exoskeletons, however, growth may create a brief period when the animal is particularly vulnerable to predation.

Concept Check: Unlike exoskeletons, endoskeletons do not provide protection for the body surface of animals. How can the lack of an external skeleton also be an advantage for animals?

vertebrate skeleton is often considered in two parts: the axial and appendicular skeletons (**Figure 44.2**). The axial skeleton is composed of the bones that form the main longitudinal axis of an animal's body, including the skull, vertebrae, sternum, and ribs. The appendicular skeleton consists of the limb or fin bones and the bones that connect them to the axial skeleton. A **joint** is formed where two or more bones come together. Some joints permit free movement (for example, the shoulders). Figure 44.2 illustrates three types of joints that allow different types of movements: pivot, hinge, and ball-and-socket joints. Other joints do not allow movement (fused joints like those interlocking the skull bones) or allow only limited movement (such as those of the vertebral column).

The skeleton of vertebrates serves several other functions in addition to support, protection, and movement. For example, blood cells and platelets, the latter of which help blood to clot (see Chapter 47), are formed within the marrow of the ilia, vertebrae, the ends of the femurs, and other bones. In addition, Ca^{2+} and PO_4^{2-} homeostasis is achieved in large part through exchanges of these ions between bone and blood. For example, if dietary intake of Ca^{2+} is low, Ca^{2+} is removed from bone and added to the blood, so that all of the vital cellular activities that depend on Ca^{2+}, such as neuron and muscle function, can continue to operate normally. When dietary Ca^{2+} is restored to normal, Ca^{2+} is redeposited in bone. This Ca^{2+} cycling is under the control of hormones such as parathyroid hormone produced by the parathyroid glands (see Chapter 50). About 99% of all the Ca^{2+} in a typical vertebrate's body exists in bone. This represents a huge reservoir of Ca^{2+} for the blood.

Bones cannot move by themselves but instead provide the scaffold on which skeletal muscles cause body movement. We turn now to skeletal muscle and the mechanism by which it generates force.

44.2 Skeletal Muscle Structure and the Mechanism of Force Generation

Learning Outcomes:

1. List the three types of muscle found in vertebrates, and describe where they are found in the body.
2. Describe how antagonistic muscles function at a joint.
3. Identify the structural components of a muscle down to the level of the sarcomere.
4. Explain the sliding filament mechanism of muscle contraction.

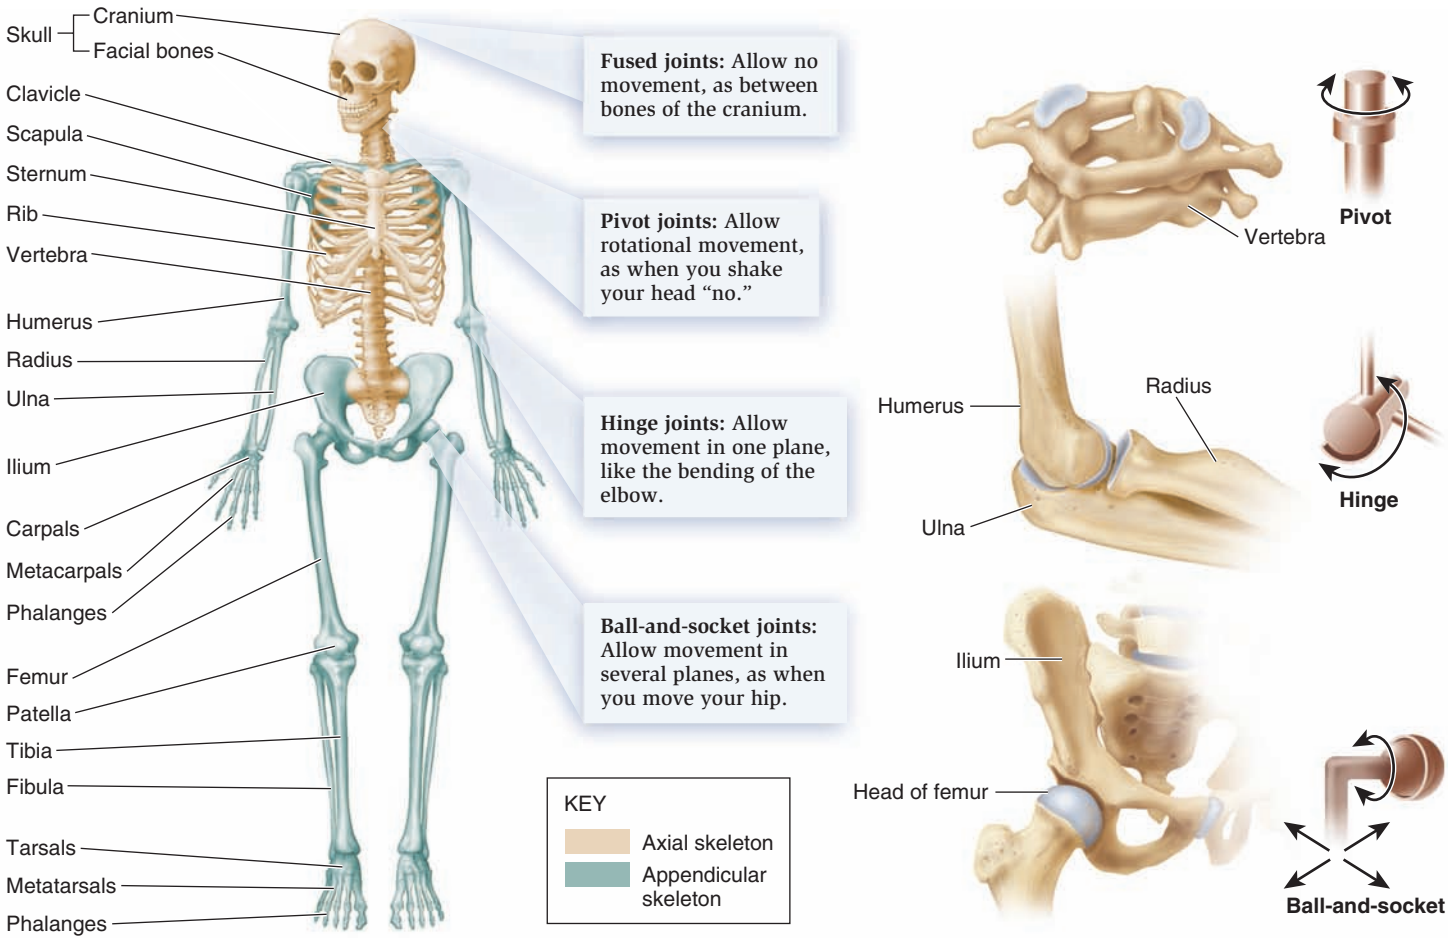

Figure 44.2 The adult human skeleton. This diagram shows the axial (beige) and appendicular (green) parts of the skeleton in an adult human, an animal with an endoskeleton. The adult human skeleton consists of 206 separate bones. Three examples of movable joints—pivot, hinge, and ball-and-socket—are shown.

5. Explain how tropomyosin and troponin help regulate muscle contraction.
6. **SciSKILLS** » Predict how skeletal muscle contraction would be affected by changes in electrical activity in motor neurons.
7. Describe the structural features of a neuromuscular junction and the role of acetylcholine in mediating skeletal muscle excitation.

Vertebrates have three types of muscle that are classified according to their structure, function, and control mechanisms. **Cardiac muscle** is found only in the heart and provides the force required for the heart to pump blood; it will be discussed in Chapter 47. **Smooth muscle** surrounds and forms part of the lining of hollow organs and tubes, including those of the digestive tract, urinary bladder, uterus, blood vessels, and airways. Contraction of the smooth muscle in such organs may propel the contents forward or churn them up, as when the stomach contracts after a meal. In other cases, smooth muscle regulates the flow of substances by changing the tube diameter, as in the widening or narrowing of small blood vessels. Smooth muscle contraction is not under voluntary control. Instead, it is controlled by the autonomic nervous system, hormones, and local chemical signals.

Skeletal muscle is found throughout the body and is directly involved in locomotion. In vertebrates, but not invertebrates, skeletal muscle is electrically excitable—it can generate action potentials in response to a stimulus (invertebrate skeletal muscle cells have graded membrane potentials but do not have action potentials). The action potentials of vertebrate skeletal muscle cells result in an increased concentration of Ca^{2+} in the cytosol, which triggers force generation. Before seeing how this is possible, however, let's begin with an overview of skeletal muscle structure and function.

A Skeletal Muscle Is a Contractile Organ That Supports and Moves Bones

A skeletal muscle is a grouping of cells—called **muscle fibers**—bound together in bundles (called fascicles) by a succession of connective tissue layers (**Figure 44.3**). Skeletal muscles are usually linked to bones by bundles of collagen fibers known as tendons. The transmission of force from contracting muscle to bone can be likened to a number of people pulling on a rope attached to a heavy object. Each person corresponds to a single muscle fiber, the rope corresponds to the tendons, and the bone is the heavy object.

Some tendons are very long, with the site of their attachment to bone far removed from the end of the muscle. For example, some of the muscles that move the fingers are in the forearm. You can wiggle your fingers and feel the movement of the muscles in your lower arm. These muscles are connected to the finger bones by long tendons.

When the force is great enough, a bone moves as the muscle shortens. A contracting muscle exerts only a pulling force, so as the muscle attached to it via tendons shortens, the attached bones are pulled toward or away from each other. Muscles that bend a limb at a joint (that is, reduce the angle between two bones) are called **flexors**, whereas muscles that straighten a limb (increase the angle between two bones) are called **extensors**. Groups of muscles that produce oppositely directed movements at a joint are known as **antagonists**. For example, in **Figure 44.4**, we can see that contraction of the hamstrings flexes the leg at the knee joint, relaxing the quadriceps, whereas contraction of the quadriceps causes the leg to extend and the hamstrings to relax. Both antagonistic muscles exert only a pulling force when they contract.

Muscle Fibers Contain Myofibrils Composed of Arrays of Filaments

Each skeletal muscle fiber arises from several cells that fuse to form a single mature cell with multiple nuclei. Each fiber contains numerous cylindrical bundles known as **myofibrils** (**Figure 44.5**). Myofibrils extend from one end of the fiber to the other and are linked to the tendons at the ends of the fiber. Each myofibril contains numerous functional structures called thick and thin filaments. These filaments are arranged in a repeating pattern running the length of the myofibril. One complete unit of this repeating pattern is known as a **sarcomere**

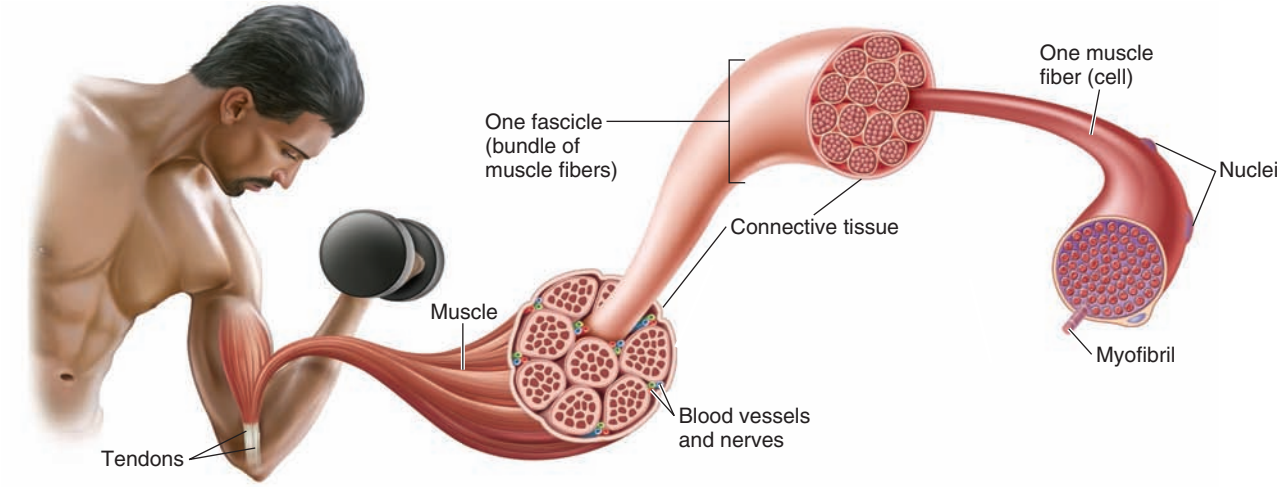

Figure 44.3 Skeletal muscle structure. Skeletal muscles attach to bone by tendons, which are bundles of collagen fibers. Each muscle consists of bundles of muscle fibers (muscle cells) bound together by connective tissue.

Concept Check: What would happen to the ability of a muscle to move a bone if its tendon were torn, for example, due to injury?

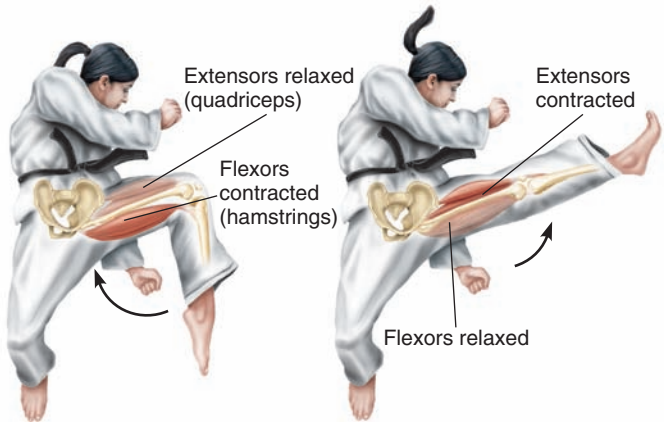

Figure 44.4 Actions of flexors and extensors. The figure shows how skeletal muscles cause flexion or extension of a limb. When the flexor muscle contracts, the extensor relaxes, and vice versa.

(from the Greek sarco, meaning muscle, and mer, meaning part). The **thick filaments** are composed almost entirely of the motor protein **myosin**. The **thin filaments**, which are about half the diameter of the thick filaments, contain the cytoskeletal protein **actin** and associated proteins. Because the arrangement of thick and thin filaments looks like a series of light and dark bands when viewed by a microscope, skeletal muscle is also known as striated muscle.

The components of a sarcomere, shown in Figure 44.5, have the following features:

- The **A band** is formed by the thick filaments located in the middle of each sarcomere, where their orderly parallel arrangement produces a wide, dark band. The thin filaments overlap a portion of the thick filaments.
- The **Z line** is a network of proteins to which thin filaments are attached. Two successive Z lines define the boundaries of one sarcomere.
- The **I band** lies between the A bands of two adjacent sarcomeres. Each I band contains those portions of the thin filaments that do not overlap the thick filaments, and each I band is bisected by a Z line.
- The **H zone** is a narrow region in the center of the A band. It corresponds to the space between the two sets of thin filaments in each sarcomere.
- The **M line** is in the center of the H zone and is composed of proteins that link the central regions of adjacent thick filaments.

The spaces between overlapping thick and thin filaments are bridged by projections known as **cross-bridges**, which are regions of myosin molecules that extend from the surface of the thick filaments toward the thin filaments (see Figure 44.5).

Skeletal Muscle Shortens When Thin Filaments Slide over Thick Filaments

Movement requires shortening of muscles to pull against the attached tendons and bones. However, a muscle can generate force, or contract, without producing movement. Holding a heavy weight at a constant

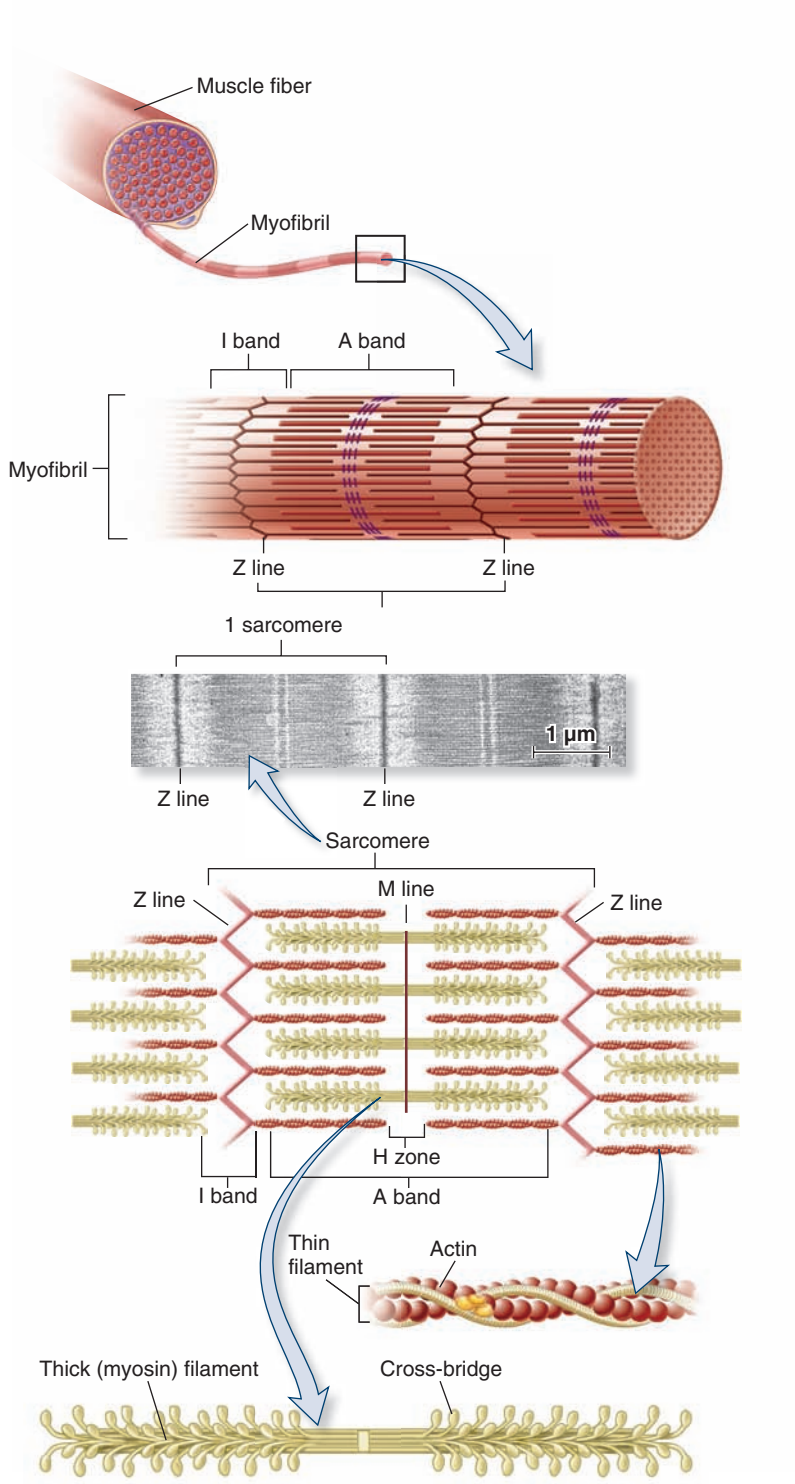

Figure 44.5 Myofibril structure. Each muscle fiber consists of numerous myofibrils containing thick and thin filaments. Their arrangement produces a striated banding pattern seen with microscopy (in the inset). Each repeating unit of the arrayed filaments constitutes a sarcomere.

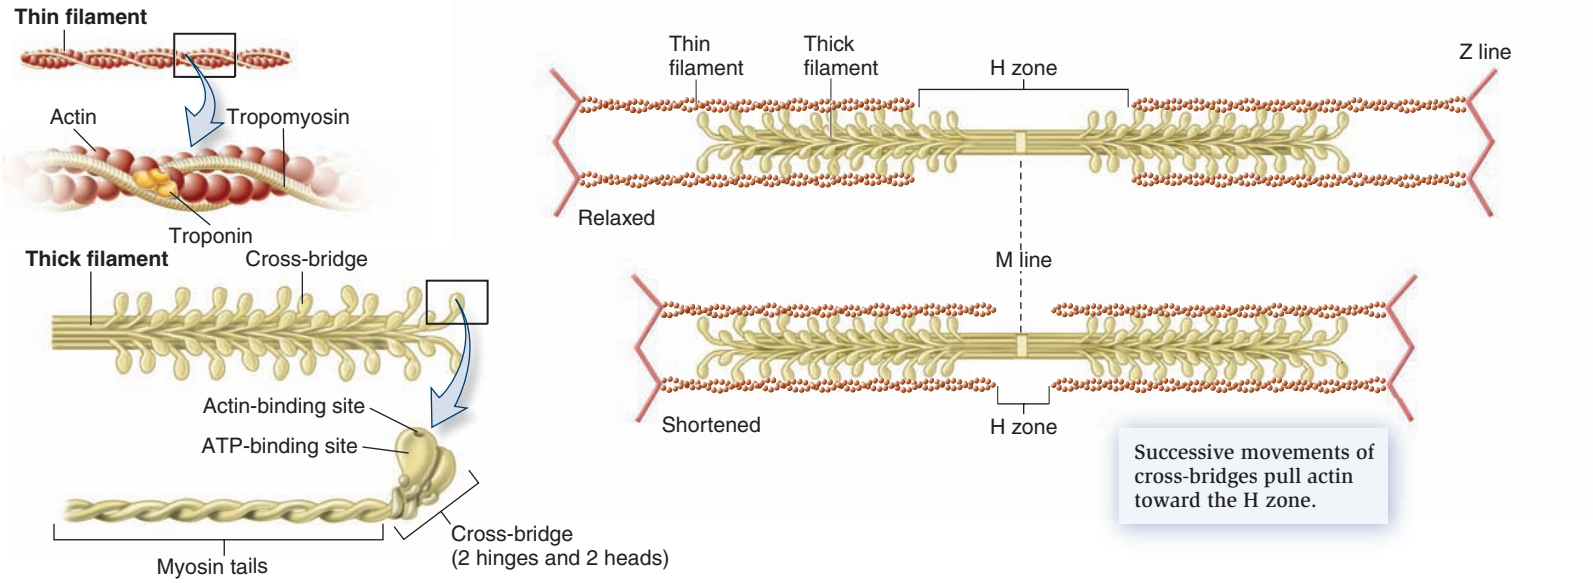
BIOLOGY PRINCIPLE Cells are the simplest units of life. A muscle (an organ) consists of many cells called fibers arranged in a very precise way. As the cells change their shape by shortening, the shape of the entire organ also changes.

position, for example, requires muscle contraction, but not muscle shortening. Therefore, as used in muscle physiology, the term contraction refers to activation of the cross-bridges within muscle fibers, which initiates the generation of force. When these mechanisms are turned off, contractions end, allowing the muscle fiber to relax.

Let's look at how the structure of the thin and thick filaments allows them to move. In thin filaments, actin molecules form polymers that are arranged into two intertwined helical chains. These chains are closely associated with two proteins called tropomyosin and troponin that play important roles in regulating contraction (**Figure 44.6a**). Myosin proteins have a three-domain structure composed of two intertwined tails, two hinges, and two heads. The hinges are flexible regions that connect the heads to the tails. Each filament is made up of many myosin proteins associated in a parallel array, with the hinges and heads extending out to the sides, forming cross-bridges. Each head contains two binding sites—one for actin and one for ATP. The hydrolysis of ATP provides the energy for the cross-bridge to move via a bending motion at the hinge.

How a muscle fiber actually shortens is known as the **sliding filament mechanism** of muscle contraction (**Figure 44.6b**). In this mechanism, the sarcomeres shorten, but neither the thick nor the thin filaments change in length. Instead, the thick filaments remain stationary while the thin filaments slide, pulling on the Z lines and shortening the sarcomere.



The sliding filament movement is propelled by the myosin cross-bridges. During shortening, each cross-bridge attaches to an actin molecule in a thin filament and moves in a motion much like your fist bending at your wrist. Because of the opposing orientation of the thick filaments, the movement of a cross-bridge forces the thin filaments toward the center of the sarcomere (the M line in the H zone), thereby narrowing the H zone and shortening the sarcomere. One stroke of a cross-bridge produces only a very small movement of a thin filament relative to a thick filament. As long as a muscle fiber is stimulated to contract, however, each cross-bridge repeats its motion many times, resulting in continued sliding of the thin filaments. Thus, the ability of a muscle fiber to generate force and movement depends on the amount of interaction of actin and myosin.

The protein myosin was first discovered in extracts of frog leg muscle in the 1860s by the German physiologist Wilhelm Kühne. We now know that eukaryotic genomes encode a family of related myosin proteins, as described next.

Genomes & Proteomes Connection

Did an Ancient Mutation in Myosin Play a Role in the Development of the Human Brain?

Myosins are among the most ancient eukaryotic proteins and are found throughout the animal kingdom. Small differences in the sequences of genes that arose from a single primordial myosin gene have led to tissue-specific expression of various myosin

(a) Structure of thin and thick filaments **(b) Sliding filament mechanism**

Figure 44.6 Structure and function of the thin and thick filaments. **(a)** Thin filaments are composed of two intertwined actin molecules and associated proteins tropomyosin and troponin. Thick filaments are made of the protein myosin, which has two intertwined tails, two hinges, two heads, an actin-binding site, and an ATP-binding site. The end of a myosin molecule that contains the actin-binding site is bent at an angle to form the cross-bridges. **(b)** When the cross-bridges on myosin molecules bind to actin, the thin filaments are pulled toward the H zone, shortening the sarcomere. The sliding of thin filaments past the overlapping thick filaments shortens the sarcomere, but does not change the lengths of the filaments themselves.

BIOLOGY PRINCIPLE **Structure determines function.** It is the precise structural arrangement of the proteins that make up thick and thin filaments that gives them their function. Without this structure, actin and myosin would not produce a coordinated force resulting in the shortening of the skeletal muscle cell.

proteins, each with a characteristic ability to bind actin and hydrolyze ATP. One member of this gene family, called *MYH16*, codes for a heavy chain of a myosin molecule that is expressed mainly in the muscles of the jaw in primates. In 2004, American researcher Hansell Stedman and colleagues discovered that this gene, although present in humans, did not code for a functional protein because of a mutation that deleted two base pairs from it. This mutation was present in 100% of people tested worldwide but was not found in the eight nonhuman primate species tested, which included chimpanzees.

Based on genetic comparisons and estimates of genetic divergence among species, the researchers estimated that the mutation occurred approximately 2.4 mya. Significantly, the genus *Homo*, with its smaller jaw and larger braincase, is also thought to have first appeared about 2.4 mya, leading Stedman to suggest that the loss of the MYH16 protein led to the smaller, less muscular jaws characteristic of humans (**Figure 44.7**). Because jaw muscles are attached to skull bones, massive jaw muscles may have placed a mechanical constraint on skull growth in early hominins (as well as in modern nonhuman primates). Smaller jaw-closing muscles would require less bone formation on the outside of the skull (in particular, the areas of muscle attachment obscuring the sutures or growth plates). This in turn would prevent the early cessation of brain growth seen in the nonhuman primates. This may have eliminated a major constraint on the evolution of the larger brains seen in modern humans.

Stedman's hypothesis is compelling, given that the myosin mutation affects the jaw-closing muscles and is present only in humans. Another research group, using statistical analyses of additional gene sequences made available through the Chimpanzee Sequencing and Analysis Consortium, concluded that the mutation may have arisen earlier—perhaps 4.0–5.4 mya, before small-jawed species of *Homo* appear in the fossil record. Stedman's hypothesis will require confirmation by future research. Scientists are certain that a human-specific mutation in *MYH16* arose at some point in the evolution of hominins. Whether the mutation facilitated expansion of the cranium, which in turn permitted enlargement of the brain, is unknown. The hypothesis, however, does provide an intriguing piece of the puzzle of how modern humans may have evolved.

The Cross-Bridge Cycle Requires ATP and Ca^{2+}

Let's now turn our attention to how actin and myosin interact to promote muscle contraction and shortening. The sequence of events that occurs between the time when a cross-bridge binds to a thin filament and when it is set to repeat the process is known as a **cross-bridge cycle**.

Cross-bridge cycling occurs when the Ca^{2+} concentration exceeds a critical threshold in the cytosol. This usually occurs when neural input results in the release of Ca^{2+} from intracellular storage sites (described in detail shortly). In other words, the contraction of skeletal muscle fibers is under nervous control.

Figure 44.8 illustrates the events that occur during the four steps of the cross-bridge cycle: (1) cross-bridge binding, (2) power stroke (moving), (3) detaching, and (4) resetting. As the cycle begins, the myosin cross-bridges are in an energized state, which is produced by the hydrolysis of their bound ATP to ADP and inorganic phosphate (P_i). The ADP and P_i remain bound to the cross-bridge until step 2. The sequence of storage and release of energy by myosin is analogous to the operation of a mousetrap: Energy is first stored in the trap by cocking the spring (ATP hydrolysis) and is then released by the springing of the trap (head binds to actin and moves in power stroke). Let's look at each step of the process more closely.

Step 1: Ca^{2+} concentration increases, triggering the cross-bridge to bind to actin.
When the Ca^{2+} concentration in the cytosol increases, an energized myosin cross-bridge, along with its associated ADP and P_i, binds to an actin molecule on a thin filament.

Step 2: Release of phosphate (P_i) fuels the power stroke. The cross-bridge and thin filaments move.
The binding of an energized myosin cross-bridge to actin in step 1 triggers the release of P_i. This release causes a conformational change in the hinge domain of the myosin molecule. This causes the cross-bridge to rotate toward the M line in the H zone at the center of the sarcomere, as myosin returns to its lower energy conformation. This process is known as the **power stroke**, which moves the actin filament. At this time, ADP is released from the cross-bridge.

Step 3: ATP binds to myosin, causing the cross-bridge to detach.
During the power stroke, myosin is bound very firmly to actin; this linkage must be broken to allow the cross-bridge to be reenergized and repeat the cycle. The binding of a new molecule of ATP to the myosin cross-bridge breaks the link between actin and myosin. The dissociation of actin and myosin by ATP is an example of allosteric regulation of protein activity. When ATP binds at one site on myosin (called an allosteric site; refer back to Chapter 6), myosin's affinity for actin decreases. ATP is not hydrolyzed in this step. Instead, ATP functions at this stage as an allosteric modulator of the myosin head, weakening the binding of myosin to actin and leading to their dissociation.

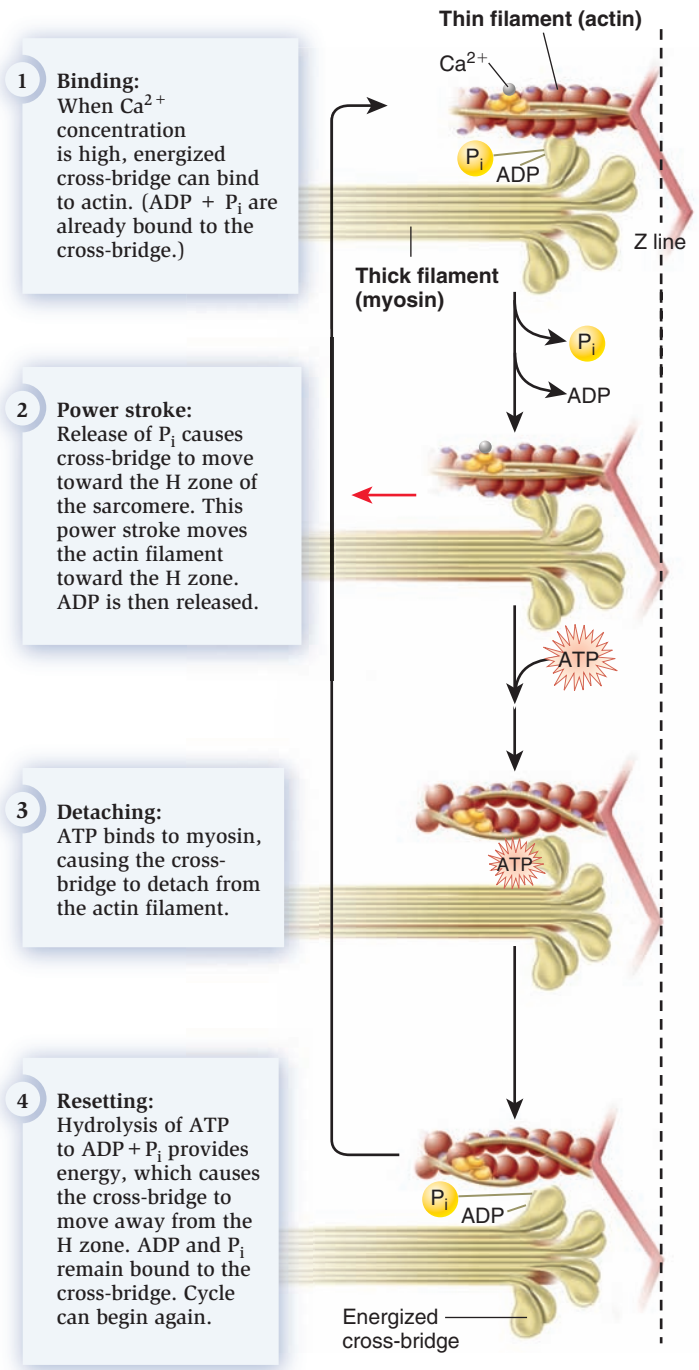

Figure 44.8 The four stages of cross-bridge cycling in skeletal muscle.

Concept Check: Rigor mortis is a condition of contracted skeletal muscle that occurs shortly after death. Why would the muscle remain contracted for a time after death, and why does such contraction eventually stop? (Hint: Think how the concentration of ATP might be expected to change in a dying muscle cell.)

Step 4: ATP hydrolysis reenergizes and resets the cross-bridge.
After actin and myosin dissociate, the ATP bound to myosin is hydrolyzed. This hydrolysis reenergizes myosin, causing it to reset to the position that allows actin binding. If Ca^{2+} is still available at this time, the cross-bridge can reattach to a new actin molecule in the thin filament, and the cross-bridge cycle repeats, causing the muscle fiber to shorten further.

As we have seen, ATP performs two different roles in the cross-bridge cycle. First, the energy released from ATP hydrolysis provides the energy for cross-bridge movement. Second, ATP binding breaks the link formed between actin and myosin during the cycle, allowing a new cycle to start. Although the precise mechanisms may differ slightly between vertebrates and invertebrates, biologists think that all skeletal muscle functions via steps similar to those just described.

The Regulation of Muscle Contraction by Ca^{2+} Is Mediated by Tropomyosin and Troponin

How does the presence of Ca^{2+} in the cytosol of muscle cells regulate the cycling of cross-bridges? The answer requires a closer look at the two additional thin filament proteins briefly mentioned earlier, tropomyosin and troponin.

Tropomyosin is a rod-shaped molecule composed of two intertwined proteins (**Figure 44.9a**). Tropomyosin molecules are arranged end to end along the actin thin filament. In the absence of Ca^{2+}, they partially cover the myosin-binding site on each actin molecule, thereby preventing cross-bridges from making contact with actin. Each tropomyosin molecule is held in this blocking position by **troponin**, a smaller, globular-shaped protein with three subunits that is bound to both tropomyosin and actin. In this way, troponin and tropomyosin block access to myosin-binding sites on actin molecules in the relaxed muscle fiber.

One of the three subunits of troponin is capable of binding Ca^{2+}. The binding of Ca^{2+} produces a change in the shape of troponin, which—through troponin's linkage to tropomyosin—causes tropomyosin to move away from the myosin-binding site on each actin molecule (**Figure 44.9b**). This movement permits cross-bridge cycling to occur. Conversely, release of Ca^{2+} from troponin reverses the process, blocking the myosin-binding site and turning off contractile activity.

Thus, the concentration of cytosolic Ca^{2+} determines whether or not Ca^{2+} is bound to troponin molecules, which, in turn, determines the number of actin sites available for cross-bridge binding. The cytosolic concentration of Ca^{2+}, however, is very low in resting muscle. Let's see how the Ca^{2+} concentration is increased so that contraction can occur.

Ca^{2+} Concentration and Contraction of Skeletal Muscle Are Coupled with Electrical Excitation

Like neurons, vertebrate skeletal muscle cells generate and propagate action potentials in response to an appropriate stimulus. This causes an increase in the concentration of cytosolic Ca^{2+}, which triggers contraction of a muscle fiber. The sequence of events by which an action potential in the plasma membrane of a muscle fiber

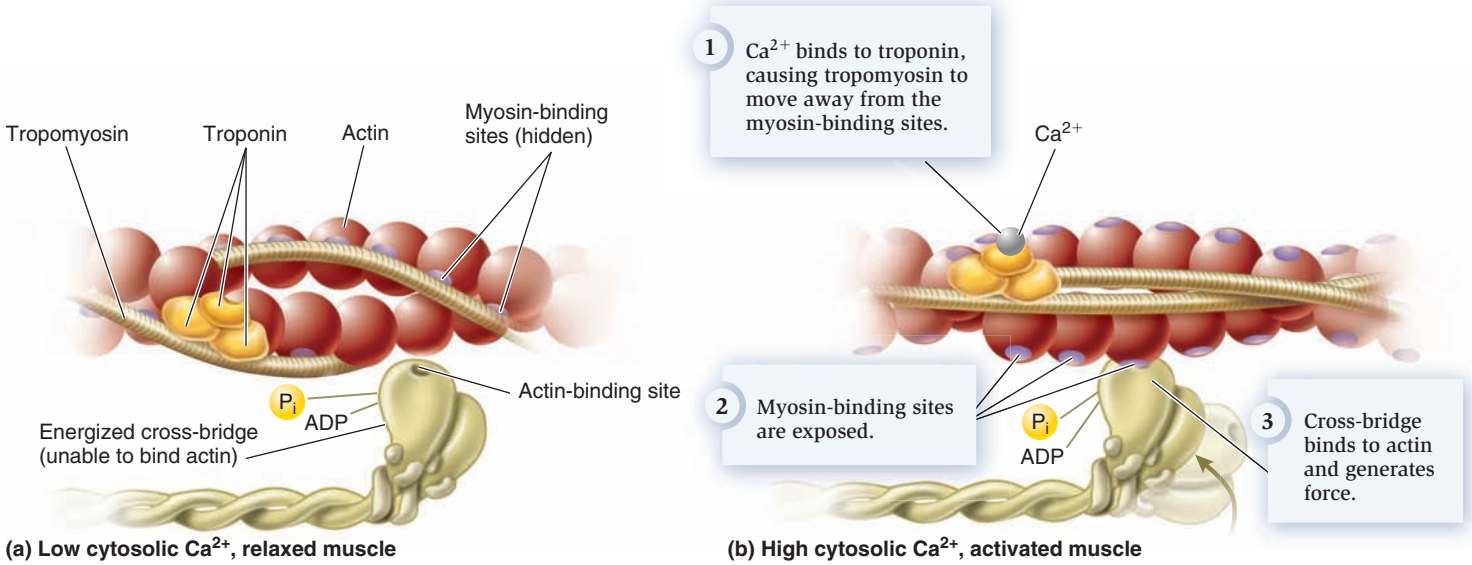

Figure 44.9 Function of Ca^{2+}, tropomyosin, and troponin in cross-bridge cycling. **(a)** When cytosolic Ca^{2+} is low, the myosin-binding sites on actin are blocked by tropomyosin. **(b)** When cytosolic Ca^{2+} increases, Ca^{2+} binds to troponin, which, in turn, causes tropomyosin to move away from the myosin-binding sites on actin.

leads to cross-bridge activity by the mechanisms just described is called **excitation-contraction coupling**. The electrical activity in the plasma membrane does not act directly on the contractile proteins but instead acts as a stimulus to increase cytosolic Ca^{2+} concentration. The increased Ca^{2+} concentration continues to activate the contractile apparatus long after electrical activity in the membrane has ceased.

The source of the increased cytosolic Ca^{2+} that occurs following a muscle action potential is the fiber's **sarcoplasmic reticulum**, which acts as a Ca^{2+} reservoir. The sarcoplasmic reticulum, which is a specialized form of the endoplasmic reticulum found in most cells, is composed of interconnected sleevelike compartments and sacs around each myofibril (**Figure 44.10**). Separate tubular structures, the **transverse tubules (T-tubules)**, are invaginations of the plasma membrane that lie close to the sarcoplasmic reticulum. The T-tubules conduct action potentials from the outer surface of the muscle fiber to the myofibrils. An action potential causes the opening of Ca^{2+} channels in the lateral sacs of the sarcoplasmic reticulum, which allows Ca^{2+} to diffuse into the cytosol and bind to troponin, initiating muscle contraction.

A contraction continues until Ca^{2+} is removed from troponin and the cytosol. This is achieved by ATP-driven Ca^{2+} pumps in the sarcoplasmic reticulum that decrease the Ca^{2+} concentration in the cytosol back to its resting concentration.

Electrical Stimulation of Skeletal Muscle Occurs at the Neuromuscular Junction

We have seen that an action potential in the plasma membrane of a skeletal muscle fiber is the signal that triggers contraction. The mechanism by which action potentials are initiated in a skeletal muscle involves stimulation by a motor neuron. The cell bodies of these neurons are located in the central nervous system (CNS) and transmit signals from the CNS to directly control muscles.

The site where a motor neuron's axon synapses with a muscle fiber is known as a **neuromuscular junction** (**Figure 44.11**). Near the surface of the muscle fiber, the axon divides into several short processes, or terminals, containing synaptic vesicles filled with the neurotransmitter acetylcholine (ACh) (see Chapter 41). The region of the muscle fiber plasma membrane that lies directly under the axon terminal is called the **motor end plate**; it is folded into what are known as junctional folds, which contain many ACh receptors. These folds therefore increase the total surface area available for the membrane to respond to ACh. The extracellular space between the axon terminal and the motor end plate is called the synaptic cleft.

When an action potential in a motor neuron arrives at the axon terminal, it triggers the release of stored ACh, which diffuses across the synaptic cleft and binds to receptors in the junctional folds of the muscle fiber. The ACh receptor is a ligand-gated ion channel (see Chapter 5). The binding of ACh opens the channel and causes an influx of Na^+ into the muscle fiber, which causes the muscle fiber to depolarize, resulting in an action potential that spreads along the membrane of the muscle fiber and through the T-tubules. Most neuromuscular junctions are located near the middle of a muscle fiber, and newly generated muscle action potentials propagate from this region toward the ends of the fiber and throughout the T-tubule network. Overstimulation of a muscle fiber is prevented by the action of **acetylcholinesterase**. This enzyme breaks down excess ACh in the synaptic cleft to inactive forms that cannot bind the ACh receptor.

Now let's explore how skeletal muscle is adapted to meet the varied functional demands of vertebrates.

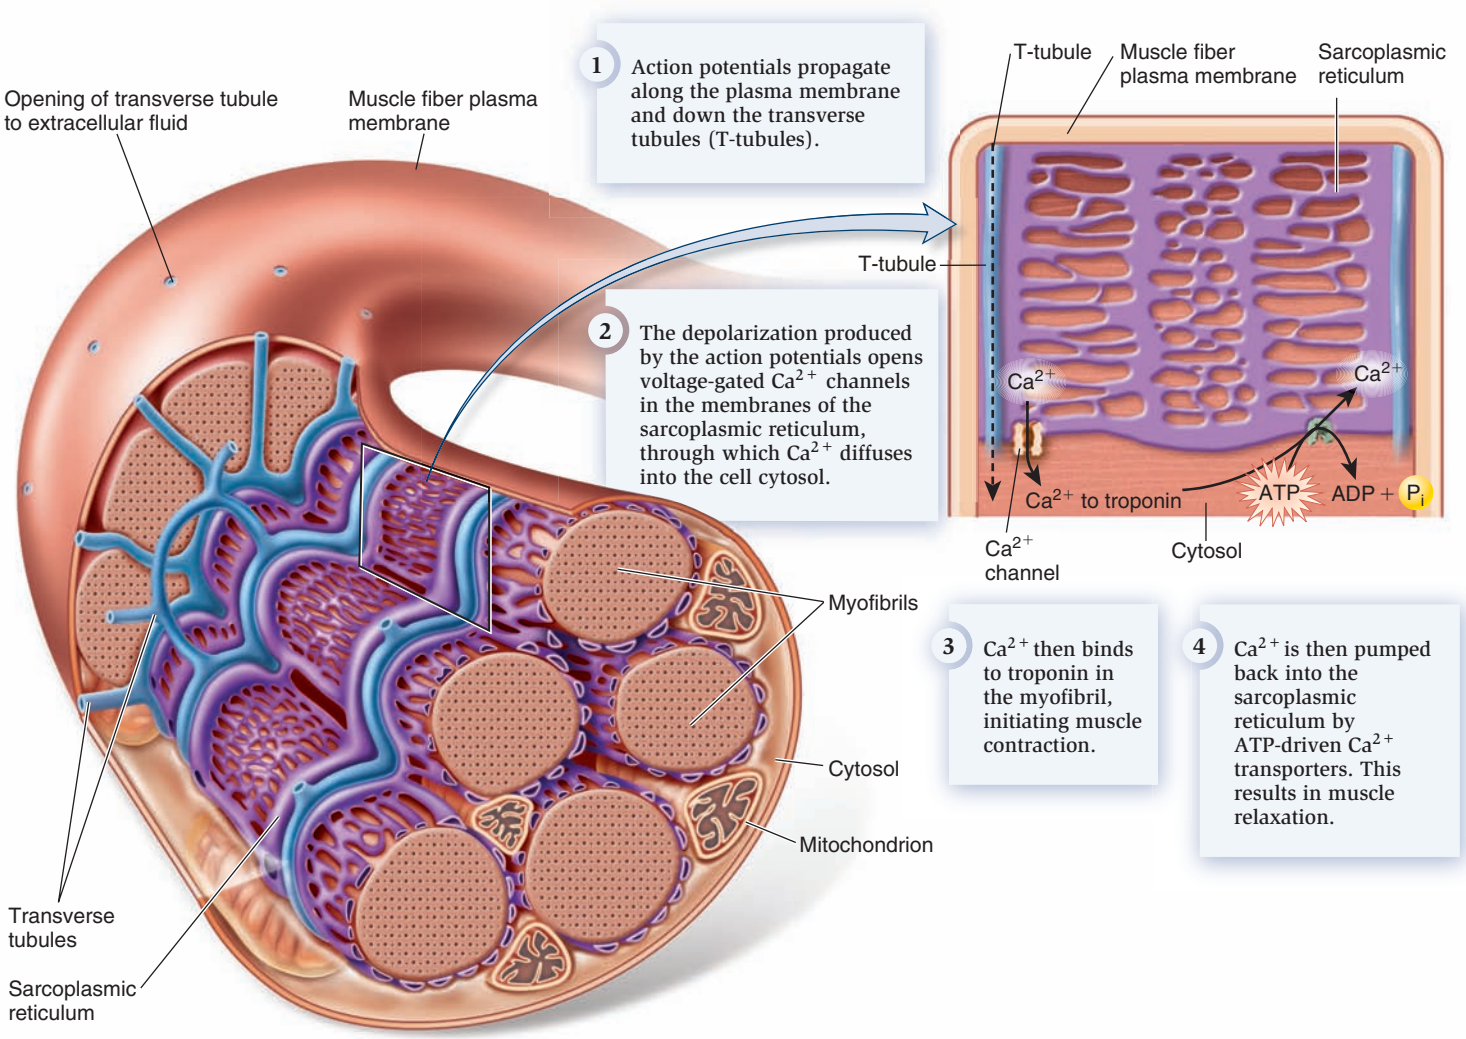

Figure 44.10 **Structure and function of the sarcoplasmic reticulum, transverse tubules (T-tubles), and myofibrils in a skeletal muscle fiber.**

44.3 Types of Skeletal Muscle Fibers and Their Functions

Learning Outcomes:

1. Outline the general characteristics of the three types of skeletal muscle fibers.
2. **SciSKILLS** » Predict how muscles may adapt to exercise.

Animals use skeletal muscle for a wide variety of activities, such as locomotion, stretching, chewing, breathing, and maintaining balance, to name a few. Therefore, it is not surprising that not all skeletal muscle fibers share the same mechanical and metabolic characteristics. In this section, we will consider how different types of fibers can be classified on the basis of their rates of shortening (as either fast or slow) and the way in which they produce the ATP needed for contraction (as oxidative or glycolytic).

Skeletal Muscle Fibers Are Adapted for Different Types of Movement

Different muscle fibers contain forms of myosin that differ in the maximal rates at which they can hydrolyze ATP. This, in turn, determines the maximal rates of cross-bridge cycling and muscle shortening. Fibers containing myosin with low ATPase activity are called **slow fibers**. Those containing myosin with higher ATPase activity are classified as **fast fibers**. Although the rate of cross-bridge cycling is about four times faster in fast fibers than in slow fibers, the maximal force produced by both types of cross-bridges is approximately the same.

The second means of classifying skeletal muscle fibers is based on the type of metabolic pathways available for synthesizing ATP. Fibers that contain numerous mitochondria and have a high capacity for oxidative phosphorylation are classified as **oxidative fibers**. Most of the ATP production by such fibers depends on blood flow delivering oxygen and nutrients to the muscle. Not surprisingly, therefore,

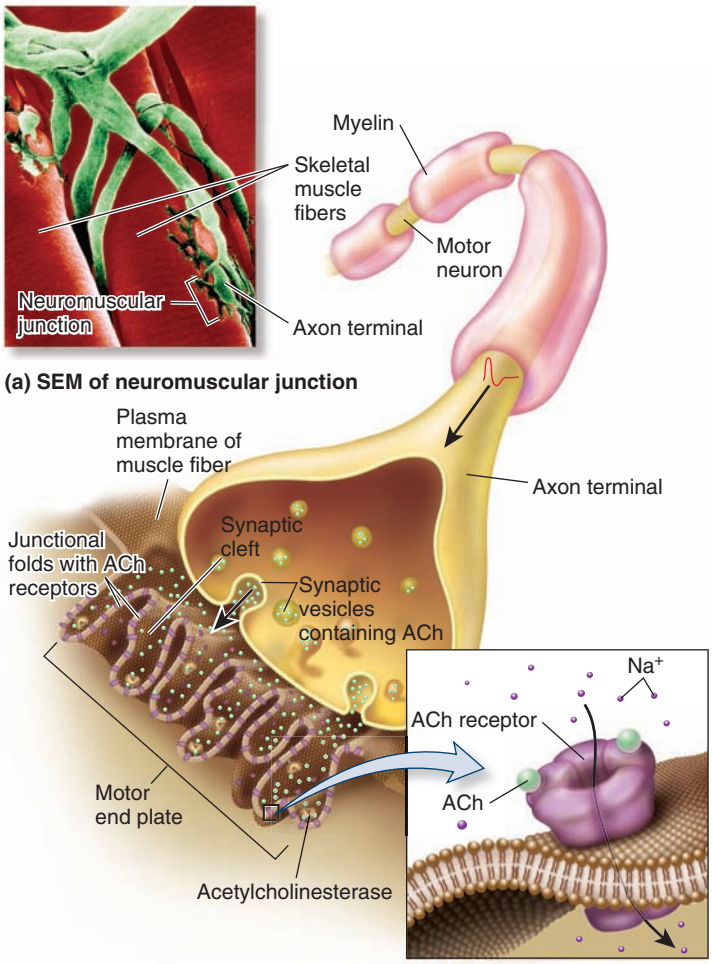

Figure 44.11 The neuromuscular junction. **(a)** The structure of a neuromuscular junction as seen in a colorized scanning electron micrograph. The motor neurons are green and muscle fibers are red. **(b)** Action potentials in the motor neuron cause exocytosis of ACh-containing synaptic vesicles. ACh binds to receptors in the plasma membrane of the junctional folds of the skeletal muscle cell. This initiates Na^+ entry and, consequently, an action potential in the muscle cell. Excess ACh is removed by the enzyme acetylcholinesterase.

Concept Check: *Why does Na^+ diffuse into the muscle cell after the ACh receptor is activated?*

BioConnections: *What is the function of the myelin shown in this figure? Refer back to Figures 41.2 and 41.11 for help.*

these fibers are surrounded by many small blood vessels. They also contain large amounts of **myoglobin**, an oxygen-binding protein that increases the availability of oxygen in the fiber by providing an intracellular reservoir of oxygen. The large amounts of myoglobin present in oxidative fibers give these fibers a dark-red color. For this reason, oxidative fibers are often referred to as red muscle fibers. The benefit of red muscle fibers is they can maintain sustained action over a long period of time without fatigue.

By contrast, **glycolytic fibers** have few mitochondria but possess both a high concentration of the proteins involved in glycolysis (glycolytic enzymes; refer back to Figure 7.3) and large stores of glycogen, the storage form of glucose. Corresponding to their limited use of oxygen, these fibers are surrounded by relatively few blood vessels and contain little myoglobin. The lack of myoglobin is responsible for the pale color of glycolytic fibers and their designation as white muscle fibers.

On the basis of these two characteristics, three major types of skeletal muscle fibers have been distinguished:

1. **Slow-oxidative fibers** have low rates of myosin ATPase activity but have the ability to make large amounts of ATP. These fibers are used for prolonged, regular types of movement, such as long, steady flight, long-distance swimming, or the maintenance of posture. These muscles, for example, are what give the red color to the dark meat of ducks, which use the muscles for flight. Long-distance runners have a high proportion of these fibers in their leg muscles. These types of activities require muscles that do not fatigue easily.
2. **Fast-oxidative fibers** have high myosin ATPase activity and can make large amounts of ATP. Like slow-oxidative fibers, these fibers do not fatigue quickly and can be used for long-term activities. They are also particularly suited for rapid actions, such as the rapid trilling sounds made by the throat muscles in songbirds or the shaking of a rattlesnake's tail that produces a clicking sound.
3. **Fast-glycolytic fibers** have high myosin ATPase activity but cannot make as much ATP as oxidative fibers, because their source of ATP is glycolysis. These fibers are best suited for rapid, intense actions, such as a cheetah's short sprint at maximum speed. Sloths, by contrast, have few or no fast-glycolytic fibers in their leg muscles, which is not surprising given a sloth's very sedentary lifestyle. Fast-glycolytic fibers fatigue more rapidly than fast-oxidative fibers. The breast meat of chickens, for example, appears white because, unlike ducks, chickens do not fly except for very short distances and therefore do not require oxidative pectoral muscles. The fast-glycolytic muscles of chickens, however, are ideal for short flights in the air that help them quickly escape predators. When they land, chickens use slow-oxidative fibers in their leg muscles to run long distances as they continue to elude a predator.

Different muscle groups within an animal's body have different proportions of each fiber type interspersed with one another; many activities require the action of all three types of fibers at once. This is important when you consider the wide range of animal activities related to locomotion alone, including walking, climbing, running, swimming, flying, crawling, crouching, jumping, and maintaining balance and posture. Depending on the needs of an animal at any given moment, the motor nerve inputs can be adjusted to stimulate different ratios of fiber types. When you lift a heavy weight for a brief time, the fast-glycolytic fibers in your arm muscles are activated in large numbers. When a crab uses its pincers to grab prey, fast-glycolytic muscles snap the claws closed quickly, but then slow-oxidative fibers maintain a tight grip for as long as required. The characteristics of the three types of skeletal muscle fibers are summarized in **Table 44.1.**

Muscles Adapt to Exercise

The regularity with which a muscle is used, as well as the duration and intensity of the activity and whether it includes resistance, affects the properties of the muscle. For example, increased amounts of

Table 44.1 Characteristics of the Three Types of Skeletal Muscle Fibers

	Slow-oxidative	Fast-oxidative	Fast-glycolytic
Primary source of ATP production	Oxidative phosphorylation	Oxidative phosphorylation	Glycolysis
Mitochondria	Many	Many	Few
Blood supply	High	High	Moderate
Myoglobin content	High (red)	High (red)	Low (white)
Rate of fatigue	Slow	Intermediate	Fast
Myosin ATPase activity	Low	High	High
Rate of contraction	Slow	Fast	Fast

resistance exercise—such as weight lifting—results in hypertrophy (increase in size) of muscle fibers. Because the number of fibers in a muscle does not normally change significantly throughout adult life, the increases in muscle size that occur with resistance exercise do not result from increases in the number of muscle fibers, but primarily from increases in the size of each fiber. These fibers undergo an increase in diameter due to the increased synthesis of actin and myosin filaments, which form more myofibrils.

Exercise of relatively low intensity but long duration—popularly called aerobic exercise, including running and swimming—increases the number of mitochondria in the fibers that are needed in this type of activity. In addition, the number of blood vessels around these fibers increases to supply the greater energy demands of active muscle. All of these changes increase endurance.

By contrast, short-duration, high-intensity exercise, such as weight lifting, primarily affects fast-glycolytic fibers, which are used during strong contractions. In addition, glycolytic activity is enhanced by increased synthesis of glycolytic enzymes. The results of such high-intensity exercise are the increased strength and bulging muscles of a conditioned weight lifter. Such muscles, although very powerful, have little capacity for endurance and therefore fatigue rapidly.

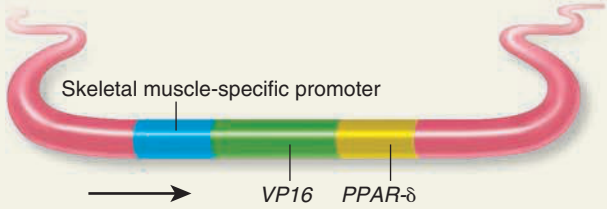
A decline or cessation of muscular activity results in the condition called **atrophy**, a reduction in the size of the muscle. Likewise, if the neurons to a skeletal muscle are destroyed or the neuromuscular junctions become nonfunctional, the denervated muscle fibers will become progressively smaller in diameter. This condition is known as denervation atrophy. Even with an intact nerve supply, a muscle can atrophy if it is not used for a long period of time, as when a broken limb is immobilized in a cast.

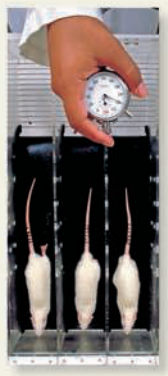
The mechanism by which changes occur in skeletal muscle during exercise is an active area of research, but recent discoveries have provided intriguing clues, an example of which is described next.

Feature Investigation | Evans and Colleagues Activated a Gene to Produce "Marathon Mice"

In the course of investigating possible ways to reverse or prevent obesity in humans, American biologist Ron Evans and his colleagues at the Salk Institute in California discovered one way in which the proportions of oxidative and glycolytic fibers change in skeletal muscle. Evans was interested in a gene that encodes a transcription factor called PPAR-δ. Activation of this protein results in the expression of genes that enable skeletal muscle or other cells to more efficiently burn fat instead of glucose for energy. Evans hypothesized that mice in which PPAR-δ was chronically activated at high concentrations would lose weight due to increased fat burning, as shown in **Figure 44.12**.

To test this hypothesis, Evans created transgenic mice (see Chapter 20) which contained the *PPAR*-δ gene in a modified form. The modified gene had a promoter that caused the gene to be expressed only in skeletal muscle cells. The region of the gene that encoded PPAR-δ was linked to a region of another gene that encoded a viral protein domain called VP16. This domain also facilitates gene activation. The researchers expected the combination of PPAR-δ and VP16 to strongly activate genes that enable cells to more efficiently burn fat instead of glucose for energy.





In the first part of the experiment, Evans monitored the body weights of the transgenic mice after they reached adulthood. The transgenic mice gained significantly less weight than the wild-type mice when fed high-fat diets (which normally cause mice—like humans—to gain weight), confirming Evans's hypothesis. As is sometimes the case in scientific discovery, an unexpected finding arose from this study. When Evans examined several tissues in these mice under the microscope, he observed that the skeletal muscle of the transgenic mice showed a noticeable shift from glycolytic fibers to slow-oxidative fibers. The muscle in transgenic mice appeared redder than it did in wild-type mice. It contained more myoglobin and mitochondria, and had higher concentrations of oxidative enzymes capable of providing the cells with sustained levels of ATP. These changes occurred even though the mice had not been subjected to exercise training.

Based on these observations, Evans also tested the hypothesis that the transgenic mice would have a greater capacity for prolonged exercise than wild-type mice. When the transgenic mice were challenged with an endurance exercise test, Evans discovered that they outperformed age- and weight-matched wild-type mice by a factor of nearly twofold! They could sustain a high level of activity on a miniature treadmill for nearly twice as long as wild-type mice (hence the nickname "marathon mice"). This effect occurred in transgenic mice even without prior exercise training. In other words, simply increasing the ratio of oxidative to glycolytic fibers gave the mice greater ability to sustain aerobic activity.

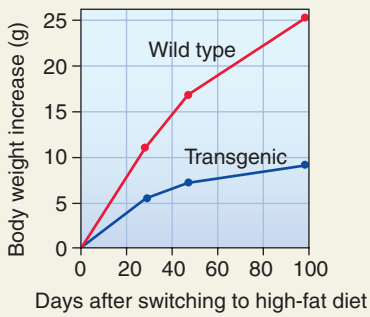


Figure 44.12 **Evans and colleagues' activation of a gene to produce "marathon mice."**

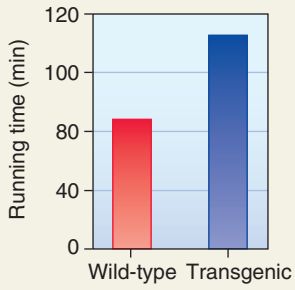
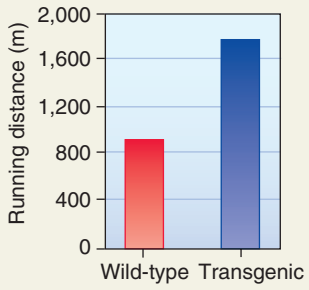
HYPOTHESES 1. Increased expression of genes that lead to increased fat oxidation in skeletal muscle cells will prevent obesity in mice.
2. Transgenic mice have a greater capacity for prolonged exercise than do wild-type mice.

KEY MATERIALS Mice, light and electron microscopes, motorized treadmills.

	Experimental level	Conceptual level
1 Prepare a modified gene containing a skeletal muscle–specific promoter and a coding sequence that links *VP16* and *PPAR*-δ. See Chapter 20 for gene cloning methods.		Skeletal muscle–specific promoter ensures gene is turned on only in skeletal muscle. VP16 domain is a domain that always activates transcription. *PPAR*-δ codes for a transcription factor that specifically activates genes that allow cells to efficiently burn fat.
2 Make transgenic mice expressing the *VP16–PPAR*-δ gene.	 See Chapter 20 for a discussion of gene addition.	All of the cells will carry this gene, but only skeletal muscle cells will express the gene.
3 **Perform the following tests:** (a) Feed wild-type control mice and transgenic mice a normal-fat diet (4%) and then switch to a high-fat diet (35%). Weigh mice weekly. (b) Examine the muscle fibers in the mice. (c) Test their endurance on a treadmill.	 Scale  Microscope  Treadmills	(a) Eating a high-fat diet is known to cause obesity in mice and other mammals. (b) The appearance of skeletal muscle can be examined by light and electron microscopy. (c) The treadmills are motorized to keep mice moving until they become exhausted, at which time the treadmills are stopped.

4 **THE DATA**





(a) Weight gain

Characteristics of skeletal muscle in transgenic mice:

– redder than wild type
– more myoglobin
– more mitochondria
– more slow-oxidative fibers

(b) Difference in skeletal muscle

(c) Muscle endurance

5 **CONCLUSION** PPAR-δ contributes to both weight loss and endurance in mice. The fiber-type switching associated with exercise does not require exercise, because increasing fat oxidation in skeletal muscle cells resulted in more oxidative fibers even without exercise training.

6 **SOURCE** Wang, Y.X., et al. 2004. Gene targeting turns mice into long-distance runners. *Public Library of Science Biology* 2:322.

The results of these experiments indicate that increasing the amount of activated PPAR-δ facilitates an oxidative state in skeletal muscle fibers that somehow signals them to convert to types that are best suited for oxidative metabolism. Therefore, the switch in fiber type that occurs in exercise training may not require exercise per se, and it may be mediated in part by proteins that activate or induce *PPAR*-δ expression. These results may have important implications for enhancing physical endurance in humans, as well as for possible treatments for various muscle diseases and for protection against obesity.

Experimental Questions

1. What is the normal function of the PPAR-δ protein in mice?
2. **SciSKILLS »** What was the hypothesis proposed by Evans in relation to PPAR-δ and obesity? How did Evans and his colleagues test this hypothesis, and what did they observe?
3. **SciSKILLS »** Assume that the mean weight of both groups of mice—wild-type and transgenic—prior to being switched to the high-fat diet was 24 g. Calculate the approximate mean weights of the two groups at the conclusion of the study. How does a diet containing 35% of its calories from fat compare to a typical human diet?

44.4 Animal Locomotion

Learning Outcomes:

1. Explain the mechanisms of animal locomotion in water, on land, and in air.
2. **SciSKILLS »** Compare the quantitative differences in energy costs of swimming, running, and flying.
3. Explain how evolution has shaped the structures used for locomotion.

Locomotion, the movement of an animal from place to place, may take many forms, as described earlier. In all cases, animals experience certain constraints to locomotion. For example, all animals must overcome frictional forces (drag) generated by the air, water, or surface of the Earth. In addition, all forms of locomotion require energy to provide thrust, defined as the forward motion of an animal in any environment, and/or lift, which is movement against gravity.

Although the precise mechanism may differ among animals, locomotion with few exceptions (such as the rhythmic beating of cilia in ctenophores) results from muscular contractions that exert force on one of the types of skeletons discussed at the beginning of this chapter. In this section, we will examine the similarities and differences between locomotion in water, on land, and in air.

Aquatic Animals Must Overcome the Resistance of Water

The greatest challenge to locomotion that aquatic animals face is the density of water, which is much greater than that of air. This is apparent when you compare waving your hand through the air and underwater. Water's resistance to movement increases exponentially as the speed of locomotion increases, which is one reason why many fishes swim at relatively slow speeds. Overcoming this resistance requires considerable muscular effort. Most swimming animals, including fishes, amphibians, reptiles, diving birds, and marine mammals, have evolved streamlined bodies that reduce drag and so make swimming more efficient.

Although the density of water creates challenges to locomotion, it also provides certain benefits. An energetic advantage to swimming is that fishes and other swimmers do not need to provide as much lift to overcome gravity. Because the density of water is similar to that of an animal's body, water provides buoyancy, which helps support the animal's weight.

The mechanism of swimming is similar among many different vertebrates. Most fishes, for example, contract posterior skeletal muscles to move the tail end of the animal from side to side. This pushes water backward and propels the fish forward. Other muscles and fins provide additional thrust and enable changes in direction. Likewise, amphibians and marine reptiles rely predominantly on their hind legs, their tail, or undulations of the posterior parts of the body for propulsion through the water. Cetaceans (whales and dolphins) use up-and-down thrusts of their tail flukes to provide propulsion. Confining most of the swimming muscles to the rear of an animal's body has certain advantages. With the rear end devoted to movement, the front end is free to explore the environment, fight off aggressors, or find food.

Energetically, swimming is the "cheapest" form of locomotion in animals that are adapted to it, due to streamlining, the relatively slow speed of most swimmers, and the buoyancy of water. By contrast, terrestrial animals face considerable energetic costs to locomotion, as we examine next.

Locomotion on Land is Energetically Costly

Locomotion on land is, on average, the most energetically costly means of locomotion (**Figure 44.13**). Whereas gravity is not an important factor for locomotion in swimming animals, terrestrial

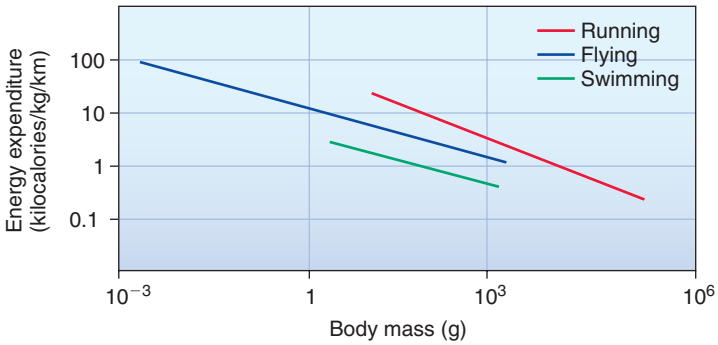


Figure 44.13 Energy costs of locomotion. The energy costs of three different modes of locomotion for animals of different sizes are shown. The vertical axis measures the energy costs as kilocalories expended per kilogram (kg) per kilometer (km). Energy costs are highest for runners compared with similarly sized fliers and swimmers. Note: Only a portion of the full range of body sizes of swimmers is shown.

animals must overcome gravity each time they take a step. Of even greater importance to walking and running animals, though, is the requirement to accelerate and decelerate the limbs with every step. In essence, each step is like starting a movement from scratch, without the luxury of occasionally gliding through water or air as fishes and birds do. This challenge is even greater when an animal moves uphill or over rough terrain.

Apart from terrestrial gastropods, which move along the surface of the Earth on a layer of secreted mucus, and snakes, which undulate along the ground on a portion of their ventral body surface, most terrestrial animals limit the amount of contact with the ground while moving, thereby minimizing the amount of friction they encounter. Tetrapods usually have only two feet on the ground at any time when walking, and for brief moments, an animal such as a horse galloping at full speed has all four feet off the ground.

Having fewer legs touching the ground surface at any one time helps increase speed but can compromise stability. Arthropods, for example, have at least six legs. This apparently provides excellent stability but reduces maximal speed (although cockroaches can attain rapid speeds by running on only two legs). At the other extreme are animals that move by jumping—fleas, certain spiders, click beetles, grasshoppers, frogs, and kangaroos.

Flying Has Evolved in Four Different Lineages

Flying is a highly successful means of locomotion and is hypothesized to have evolved in four different lineages: pterosaurs (extinct reptiles that were the first vertebrates to fly), insects, birds, and mammals (bats). Flying provides numerous advantages: Animals can escape land-based predators, scan their surroundings over great distances, and inhabit environments such as high cliffs that may be inaccessible to nonflying animals. The mechanics of flying, however, require animals to overcome gravity and air resistance, which makes flying more energetically costly than swimming but still less costly than running on land (see Figure 44.13). Many migratory birds can travel hundreds of miles daily for a week or longer. As with swimming, resistance to flight is decreased by streamlined bodies. However, earthbound animals have one advantage over flying animals—they can grow to much larger sizes than animals that fly. The vast majority of flying animals have a mass between about 1 mg and 1 kg. Only a few large birds have masses exceeding 10 kg. Although this represents a wide range, it falls far short of the sizes achieved by earthbound or aquatic animals.

In flying vertebrates, lift and thrust are provided by pectoral and other muscles that move the wings. The pectoral muscles are so powerful and massive that they constitute as much as 15–20% of a bird's total body mass and up to 30% in hummingbirds, which use their wings not only to fly but also to hover. The requirement for large, strong pectoral muscles is one reason why the body mass of flying vertebrates is limited. The extinct pterosaurs would seem to be an exception because some species were known to have had wingspans of nearly 10 m. However, scientists think that these large animals were unable to generate the force required to lift their massive bodies off the Earth and instead glided off trees or cliffs to fly.

In birds and bats, the wings are modifications of the forelimbs. In general, bat wings are far more maneuverable than bird wings, because unlike birds, bats have digits at the end of their forelimbs/wings. This allows bats to precisely alter the shape of their wings and perform rapid, fine-tuned changes in direction, even at high speeds. The largest birds, such as hawks and eagles, are able to glide because of the great surface area of their large wings. By using a bird's momentum to propel it forward, gliding provides a considerable energy savings. Bats and small birds, however, can glide for only very brief moments.

BIO TIPS **THE QUESTION** *Look again at Figure 44.13. Which flying animal expends more total energy over a distance of 1 km: one that weighs 1 g or another that weighs 1 kg?*

TOPIC ***What topic in biology does this question address?*** The topic is animal locomotion. More specifically, the question concerns the relationship of body mass to energy expenditure in flying animals.

INFORMATION ***What information do you know based on the question and your understanding of the topic?*** From the question, you know you need to compare two animals that differ in body mass by a factor of 1,000 (1 g versus 1 kg) with regard to their total energy expenditure while flying an equivalent distance (1 km). From your understanding of the topic, based on Figure 44.13, you know that smaller animals expend more energy than larger ones when energy expenditure is normalized to a standard mass (such as 1 kg).

PROBLEM-SOLVING STRATEGY ***Interpret data. Compare and contrast.*** To answer this question, you must interpret the relationship between body mass and energy expenditure for flying animals (Figure 44.13). First, find the approximate energy values for flying animals with body masses of 1 g and 1 kg (1,000 g), by moving upward from those masses on the horizontal axis to the line for flying animals and then moving left

from there to the vertical axis to get the energy values. Second, consider that the question asks for *total* energy expenditure. The data shown are for energy expenditure per kilogram of body mass. Thus, you must account for the fact that the animals differ in mass by a factor of 1,000.

ANSWER *A 1-g flying animal expends approximately 10 kilocalories/kg/km; because it weighs only 1 g, you must divide this value by 1,000 (there are 1,000 g in 1 kilogram). The result for the 1-g animal is thus 0.01 kilocalories expended over 1 km. By contrast, a 1-kg animal expends approximately 1 kilocalorie/kg/km; since the animal weighs 1 kg, there is no need to normalize the value. Therefore, the answer is that the 1-kg animal expends much more total energy flying a distance of 1 km than does a 1-g animal.*

44.5 Impact on Public Health

Learning Outcomes:

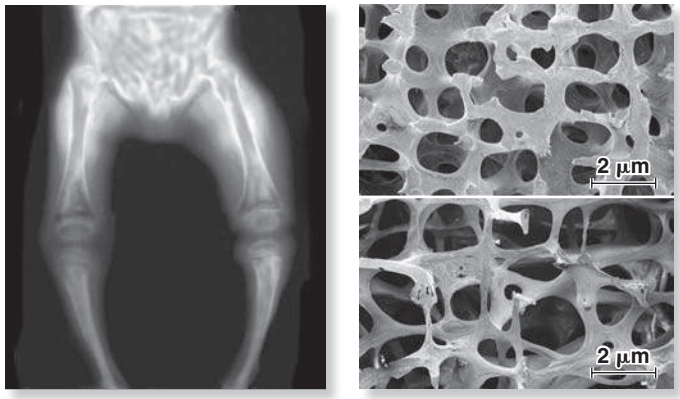
1. Describe the impact of the bone diseases rickets and osteoporosis on public health.
2. Recognize the main symptoms and causes of muscular dystrophy.

In this chapter, we have seen how skeletal muscles and, in vertebrates, bones work together to provide animals with protection and enable them to move around in their environments. A number of diseases affect bone structure and function in humans. Bone disease may involve defects in either the mineral or organic components of bone. Poor bone formation and structure may result from inadequate nutrition, hormonal imbalances, aging, or skeletal muscle atrophy, to name just a few of the common causes.

In addition, many diseases or disorders directly affect the contraction of skeletal muscle. Some of them are temporary and not serious, such as muscle cramps, whereas others are chronic and severe, such as the disease muscular dystrophy. Also, some muscle diseases result from defects in parts of the nervous system that control contraction of the muscle fibers rather than from defects that originate in the fibers themselves. One example is amyotrophic lateral sclerosis, a degenerative disease in which the destruction of motor neurons leads to skeletal muscle atrophy that may result in death from respiratory failure.

Other diseases that affect skeletal muscle function result when normal processes go awry. For example, the immune system that normally protects the body from invaders may turn on itself, or faulty genes may produce an abnormal protein. In this section, we will look at a few of these conditions in more detail.

Rickets and Osteoporosis Affect the Bones of Millions of People



Bone diseases are fairly common, particularly among individuals older than 50. Two major abnormalities can occur in bone. The first is improper mineral deposition in bone, usually due to inadequate dietary calcium intake or inadequate absorption of Ca^{2+} from the small intestine. Without adequate minerals, bone becomes soft and easily deformed, as occurs in the weight-bearing bones of the legs of children with **rickets** (or **osteomalacia**, as it is called in adults) (**Figure 44.14a**). These disorders are best prevented or treated with vitamin D, because this vitamin is the most important factor in promoting absorption of Ca^{2+} from the small intestine.

A second major abnormality is a more common disease called **osteoporosis**, in which both the mineral and organic portions of bone are reduced (**Figure 44.14b**). This disease, which affects four times as many women as men, occurs when the normal balance between bone formation and bone breakdown is disrupted.

One cause of osteoporosis is prolonged disuse of muscles. In ways that are not completely clear, the force produced by active skeletal muscle contractions helps maintain bone mass. When muscles are not or cannot be used—due to paralysis or long-term immobilizing illnesses—bone mass declines.

More commonly, osteoporosis may result from hormonal imbalances. Some hormones—for example, estrogen—stimulate bone formation. When estrogen concentrations decline after menopause (the period of time when a woman's reproductive cycles cease), bone density may decline, increasing the risk of bone fractures. By contrast, some hormones—such as parathyroid hormone (see Chapter 50)—act to demineralize bone, releasing Ca^{2+} as part of the way in which the body normally maintains mineral homeostasis in the blood. If such hormones are present in excess, however, they can cause enough demineralization of bone to result in osteoporosis. This may happen in rare cases when the glands that make these hormones malfunction and overproduce the hormones.

Osteoporosis can be minimized with adequate calcium and vitamin D intake and weight-bearing exercise programs. In some cases, postmenopausal women may be given estrogen to replace what their bodies are no longer producing, but this therapy is controversial due to the potential adverse effects of estrogen on cardiovascular health and possible increased risk of developing breast cancer. Osteoporosis is the most prevalent bone disease in the U.S., affecting up to 15–30 million individuals. It results in annual national expenditures of approximately $15–20 billion in hospital and other medical costs.

Figure 44.14 **Human bone diseases.**

Muscular Dystrophy Is a Rare Genetic Disease That Causes Muscle Degeneration

The group of diseases collectively called muscular dystrophy affects 1 of every 3,500 American males; it is much less common in females. **Muscular dystrophy** is associated with the progressive degeneration of skeletal and cardiac muscle fibers, weakening the muscles and leading ultimately to death from heart failure and other causes. The signs and symptoms become evident at about 2–6 years of age, and most affected individuals do not survive beyond the age of 30.

The most common form of muscular dystrophy, called **Duchenne muscular dystrophy**, is an X-linked recessive disorder resulting from a defective gene on the X chromosome. Since females have two X chromosomes, and males only one (plus one Y), a heterozygote female with one abnormal and one normal allele will not generally develop Duchenne muscular dystrophy. If she passes the abnormal allele to a son, however, he will have the disease. The affected gene encodes a protein known as dystrophin, which is absent in patients with the disease. Dystrophin is a large protein that links cytoskeletal proteins to the plasma membrane. Scientists think it is involved in maintaining the structural integrity of the plasma membrane in muscle fibers. In the absence of dystrophin, the plasma membrane of muscle fibers is disrupted, causing extracellular fluid to enter the cell. Eventually, the cell ruptures and dies.

One focus of interest in attempts to develop a treatment for muscular dystrophy is a protein called myostatin, which is one of a large number of proteins that control muscle growth in mammals. Myostatin functions to prevent overgrowth of skeletal muscle by inhibiting maturation of stem cells into new muscle fibers and by preventing excessive growth of mature fibers. Researchers have identified animals with mutations in the gene that encodes myostatin. The mutations result in the production of an inactive protein, and such animals show astonishing muscle development (**Figure 44.15**). Whether or not targeting the myostatin protein will lead to a treatment that can reverse muscle loss in patients with muscular dystrophy and other diseases remains to be determined.

Figure 44.15 **Example of an animal with a mutation in the myostatin gene, that results in an inactive myostatin protein and resulting overgrowth of skeletal muscle.**

Summary of Key Concepts

44.1 Types of Animal Skeletons

- Skeletons are structures that provide support and protection and also function in locomotion.
- Two types of skeletons are commonly found in animals. In arthropods, exoskeletons are protective external structures that must be shed to accommodate growth of the animal. Endoskeletons—found in some species of sponges and all echinoderms and vertebrates—are internal structures that grow with the animal but do not protect its body surface (Figure 44.1).
- Vertebrate endoskeletons are made up of axial and appendicular skeletons. A joint is formed where two or more bones of a vertebrate endoskeleton come together (Figure 44.2).
- In addition to the functions of support, protection, and locomotion, the vertebrate skeleton produces blood cells and constitutes a reservoir for ions crucial to homeostasis. A proper proportion of organic to mineral components is required for normal bone function.

44.2 Skeletal Muscle Structure and the Mechanism of Force Generation

- A skeletal muscle is a grouping of cells, called muscle fibers, bound together by connective tissue layers. Muscles that bend a limb at a joint are called flexors, whereas muscles that straighten a limb are called extensors. Groups of muscles that produce oppositely directed movements at a joint are known as antagonists (Figures 44.3, 44.4).
- Within each muscle cell are cylindrical bundles known as myofibrils, each of which contains thick filaments of myosin and thin filaments composed of actin and two other proteins, arranged in repeating units called sarcomeres. Regions of the thick filaments that extend from the surface are called cross-bridges (Figure 44.5).
- During muscle contraction, the sarcomeres shorten by a process known as the sliding filament mechanism. In muscle contraction, the thick filaments remain stationary while the thin filaments slide past them propelled by action of the cross-bridges (Figure 44.6).
- Mutations in a myosin gene expressed mainly in the jaw muscle may have allowed the human brain to become larger (Figure 44.7).
- In the cross-bridge cycle, the binding of myosin cross-bridges to actin causes a change in the shape of the myosin molecule. As a result, the two filaments slide past each other, shortening the sarcomere and contracting the muscle fiber. Release of the

cross-bridge from actin and return of myosin to its original conformation require ATP binding and hydrolysis (Figure 44.8).

- Tropomyosin and troponin, the two proteins associated with actin, play a critical role in the regulation of muscle contraction. The binding of Ca^{2+} to troponin allows tropomyosin to move away from the myosin-binding sites, initiating cross-bridge binding (Figure 44.9).
- The concentration of cytosolic Ca^{2+} determines the number of actin sites available for cross-bridge binding. The source of the cytosolic Ca^{2+} involved in a muscle fiber action potential is the muscle fiber's sarcoplasmic reticulum. Transverse tubules (T-tubules) conduct action potentials from the plasma membrane at the outer surface of the muscle fiber to the myofibrils, allowing Ca^{2+} to be released from the sarcoplasmic reticulum to the cytosol (Figure 44.10).
- Electrical stimulation of skeletal muscle occurs at a neuromuscular junction, in which a motor neuron's axon and a muscle fiber are in close proximity (Figure 44.11).

44.3 Types of Skeletal Muscle Fibers and Their Functions

- Three major types of skeletal muscle fibers have been distinguished. Slow-oxidative fibers have low rates of ATP hydrolysis by myosin; they do not fatigue easily and are used for prolonged, regular activities. Fast-oxidative fibers have high myosin ATPase activity, do not fatigue quickly, and are particularly suited for rapid, long-term actions. Fast-glycolytic fibers have high myosin ATPase activity but cannot make as much ATP as oxidative fibers; they are best suited for rapid, short-term actions (Table 44.1).
- Increased expression of *PPAR*-δ in mice results in increased slow-oxidative muscle, greater exercise endurance, and weight loss (Figure 44.12).

44.4 Animal Locomotion

- Locomotion, the movement of an animal from place to place, may take many forms, including swimming, walking, running, crawling, hopping, and flying.
- Due to streamlining, the relatively slow speed of most swimmers, and the buoyancy of water, swimming is energetically the most efficient form of locomotion. Locomotion on land is, on average, the most energetically costly means of locomotion. The energy expenditure required for flight is intermediate between those for swimming and land-based locomotion (Figure 44.13).

44.5 Impact on Public Health

- Several health conditions affect bone or muscle structure and function in humans. Rickets (osteomalacia in adults) is characterized by soft, deformed bones, usually resulting from insufficient dietary intake of calcium or inadequate absorption of Ca^{2+}. In osteoporosis, bone density is reduced when bone formation fails to keep pace with normal bone breakdown. Muscular dystrophy is an ultimately fatal genetic disease associated with the progressive degeneration of skeletal and cardiac muscle fibers (Figures 44.14, 44.15).

Assess and Discuss

Test Yourself

1. A disadvantage of an exoskeleton is that it
   a. cannot protect an animal's internal organs.
   b. must be periodically shed, leaving the animal in a vulnerable state.
   c. does not provide any flexibility for the ease of movement of an animal.
   d. is a soft, easily damaged structure.
   e. cannot protect the outside of the body surface.
2. Which, if any, of the following is *not* a function of the vertebrate skeleton?
   a. structural support
   b. protection of internal organs
   c. Ca^{2+} reserve
   d. blood cell production
   e. All of the above are functions of the vertebrate skeleton.
3. The protein that provides strength and flexibility to bone is
   a. actin. b. myosin. c. myoglobin. d. collagen. e. elastin.
4. Which of the following statements is *true*?
   a. A muscle fiber is a collection of cells embedded in connective tissue.
   b. A sarcomere contains both actin and myosin molecules arranged in a parallel fashion.
   c. The role of Ca^{2+} in contraction is to bind to tropomysin.
   d. Myofibrils are individual muscle cells.
   e. The I band of a sarcomere is the region where thin and thick filaments overlap.
5. The function of ATP during muscle contraction is to
   a. cause an allosteric change in myosin so it detaches from actin.
   b. provide the energy necessary for the movement of the cross-bridge.
   c. expose the myosin-binding sites on the thin filaments.
   d. do all of the above.
   e. do a and b only.
6. The function of Ca^{2+} in skeletal muscle contraction is to
   a. cause an allosteric change in myosin so it detaches from actin.
   b. provide the energy necessary for the movement of the cross-bridge.
   c. expose the myosin-binding sites on the thin filaments.
   d. bind to tropomyosin.
   e. do a and c only.
7. Stimulation of a muscle fiber by a motor neuron occurs at
   a. the neuromuscular junction.
   b. the transverse tubules.
   c. the myofibril.
   d. the sarcoplasmic reticulum.
   e. none of the above.
8. Muscle fibers that have a high number of mitochondria, contain large amounts of myoglobin, and exhibit low rates of ATP hydrolysis are called _____ fibers.
   a. slow-glycolytic
   b. fast-glycolytic
   c. intermediate
   d. fast-oxidative
   e. slow-oxidative

9. Which of the following statements about movement and locomotion is *false*?
   a. Terrestrial animals and flying animals expend energy to provide lift.
   b. Swimming animals expend energy to provide thrust but not lift.
   c. Flexors and extensors are examples of muscles called agonists.
   d. Flexors cause bending at a joint.
   e. Extensors cause straightening of a limb.
10. For animals adapted to it, swimming is energetically the cheapest type of locomotion because of
   a. streamlined body forms in aquatic organisms.
   b. slow speed of movement of some swimmers.
   c. buoyancy of water.
   d. a and c only.
   e. a, b, and c.

Conceptual Questions

1.  Compare the structural and functional features of exoskeletons and endoskeletons and their advantages and disadvantages.
2. List and briefly describe the steps in the cross-bridge cycle.
3. A principle of biology is that *living organisms use energy*. How is that principle illustrated in this chapter, particularly with regard to the mechanism by which skeletal muscle cells contract?

Collaborative Questions

1. Describe as many types of animal locomotion as you can, and discuss the benefits and challenges presented by each in terms of energy usage.
2. Discuss the three types of muscle tissues found in vertebrates, and identify distinguishing functional features of each.

Nutrition and Animal Digestive Systems

45

A balanced meal containing many nutrients, including carbohydrates, lipids, proteins, vitamins, minerals, and water.

CHAPTER OUTLINE

45.1 Animal Nutrition
45.2 General Principles of Digestion and Absorption of Food
45.3 Overview of Vertebrate Digestive Systems
45.4 Mechanisms of Digestion and Absorption in Vertebrates
45.5 Neural and Endocrine Control of Digestion
45.6 Impact on Public Health
Summary of Key Concepts
Assess and Discuss

What would 50,000,000 calories worth of food look like if it were assembled all in one place? (Try to imagine about 170,000 cheeseburgers, or slices of pizza.) That is roughly the amount of calories you will consume in your lifetime (in food labeling, 1 calorie is actually equivalent to 1 kilocalorie, or 1 Calorie with a capital C). All that energy is required for the trillions of body cells to perform varied activities such as synthesizing proteins, making cellular organelles, and maintaining concentration gradients of ions across cellular membranes. These and other activities are necessary for homeostasis and require a lifelong supply of food energy and chemical building blocks. These materials must be consumed by animals in the form of nutrients. A **nutrient** is any organic or inorganic substance that is taken in by an organism and is required for survival, growth, development, tissue repair, or reproduction; the process of consuming and using food and nutrients is called **nutrition**. All organisms require nutrients to survive. Animals receive their nutrients by consuming food, such as the nutritionally balanced meal in the chapter opening photo.

Food processing in animals occurs in four phases: ingestion, digestion, absorption, and egestion (**Figure 45.1**). **Ingestion** is the act of taking food into the body via a structure such as a mouth. From there, the food moves into a digestive cavity, known in most animals as an **alimentary canal**. If the nutrients in food are in a form that cannot be directly used by cells, they must be broken down into smaller molecules, a process known as **digestion**. This is followed by the process of **absorption**, in which ions, water, and small molecules diffuse or are transported from the alimentary canal into an animal's circulatory system or body fluids. **Egestion** (or defecation) is the process by which animals pass undigested material and other wastes out of the body.

In this chapter, we will begin by looking at the types of nutrients that animals require. Next, we will discuss the mechanisms by which animals digest and absorb those nutrients, and consider how these processes are regulated. We will end by considering some of the common ways in which the function of the digestive system may go awry in humans.

45.1 Animal Nutrition

Learning Outcomes:

1. List the major categories of nutrients consumed by animals and some of their general functions.
2. Identify four groups of essential nutrients, listing several examples of each.
3. **SciSKILLS** » Predict some of the consequences of a deficiency of a given nutrient.

Animals require both organic (carbon-containing) and inorganic nutrients. Organic nutrients fall into five categories: carbohydrates, proteins, lipids, nucleic acids, and vitamins. These provide energy and the building blocks of new molecules or serve as coenzymes in many enzymatic reactions. Inorganic nutrients include water and minerals such as calcium, copper, and iron. The importance of water

to life was covered in Chapter 2. Minerals serve many functions, including acting as cofactors in enzymatic reactions.

Because of similarities in the ways their organ systems function, animals share many nutritional requirements. However, the types of foods eaten by animals differ depending on an animal's physiology. The digestive systems of **herbivores**, animals that eat only vegetation, contain microorganisms that assist in the digestion of cellulose, so these animals are well adapted to subsist on plants. By contrast, **carnivores** are primarily adapted to consume animal flesh or fluids, and **omnivores**, such as humans, eat both plant and animal products.

Although broadly useful, the three dietary categories are limited when describing the diversity of animal feeding habits. For example, some animals eat protists, algae, and/or fungi as a major source of food. Also, other animals are almost strictly carnivores at one time of year but herbivores at other times. Many nonmigratory birds, for example, feed on insects and worms during the summer but switch to eating whatever vegetation, buds, or seeds they can find during the winter.

The amount of each type of nutrient required by an animal may also differ, depending on the animal's activity level, or metabolic rate, which we will discuss in Chapter 46. Generally, highly active and energetic animals, such as most birds and mammals, require a proportionally greater amount of nutrients each day than do relatively inactive or sedentary animals, such as nonmotile invertebrates. In this section, we will examine the various organic and inorganic nutrients consumed by animals and some of their major functions.

Animals Require Nutrients for Energy and the Synthesis of New Molecules
